- **Tactile corpuscles**, also called *Meissner corpuscles*, give us sensations of fine touch and pressure and low-frequency vibration. They adapt to stimulation within a second after contact. Tactile corpuscles are fairly large structures, measuring about 100 µm in length and 50 µm in width. These receptors are most abundant in the eyelids, lips, fingertips, nipples, and external genitalia. The dendrites are highly coiled and interwoven, and modified Schwann cells surround them. A fibrous capsule surrounds the entire complex and anchors it within the dermis (Figure 15–4f).

Your sensitivity to tactile sensations may be altered by infection, disease, or damage to sensory neurons or pathways. For this reason, mapping tactile responses can sometimes aid clinical assessment. Sensory losses with clear regional boundaries indicate trauma to spinal nerves. For example, sensory loss within the boundaries of a dermatome can help identify the affected spinal nerve (look back at Figure 13–7). p. 443

Tickle and itch sensations are closely related to the sensations of touch and pain. The receptors involved are free nerve endings. Unmyelinated Type C fibers carry the information. People usually (but not always) describe tickle sensations as pleasurable. A light touch that moves across the skin typically produces a tickle sensation. Psychological factors influence the interpretation of tickle sensations, and tickle sensitivity differs greatly from person to person.

Itching is probably produced by the stimulation of the same receptors, although its precise mechanism is unknown. Specific "itch spots" can be mapped in the skin, the inner surfaces of the eyelids, and the mucous membrane of the nose. Itch sensations are absent from other mucous membranes and from deep tissues and viscera. Itching is very unpleasant, sometimes even more unpleasant than pain, as individuals with extreme itching will scratch even when pain is the result. Itch receptors can be stimulated by the injection of histamine or proteolytic enzymes into the epidermis and superficial dermis.

Baroreceptors

Baroreceptors monitor changes in pressure in an organ. A baroreceptor consists of free nerve endings that branch within the elastic tissues in the wall of a distensible organ, such as a blood vessel or a portion of the respiratory, digestive, or urinary tract. When the pressure changes, the elastic walls of the tract recoil or expand. This movement distorts the dendritic branches and alters the rate of action potential generation. Baroreceptors respond immediately to a change in pressure, but they adapt rapidly, and the output along the afferent fibers gradually returns to normal.

Baroreceptors monitor pressure changes in organs that stretch due to their contents, such as blood, air, or urine. Baroreceptors monitor blood pressure in the walls of major vessels. These vessels include the carotid arteries (at the *carotid sinuses*) and the aorta (at the *aortic sinuses*). The information plays a major role in regulating cardiac function and adjusting blood flow to vital tissues. Baroreceptors in the lungs monitor lung expansion. This information is relayed to the respiratory

rhythmicity centers, which set the pace of respiration. Stretch receptors at various sites in the digestive and urinary tracts trigger a variety of visceral reflexes, including defecation and urination reflexes (Figure 15–5). We describe baroreceptor reflexes in the digestive and urinary system chapters.

Proprioceptors

Proprioception is a somatic sensation—there are no proprioceptors in visceral organs of the thoracic and abdominopelvic cavities. (Therefore, you cannot tell, for example, where your spleen, appendix, or pancreas is at the moment.) Proprioceptors are found in joints, tendons, and muscles, however. These receptors monitor the position of joints, the tension in tendons and ligaments, and the state of muscular contraction.

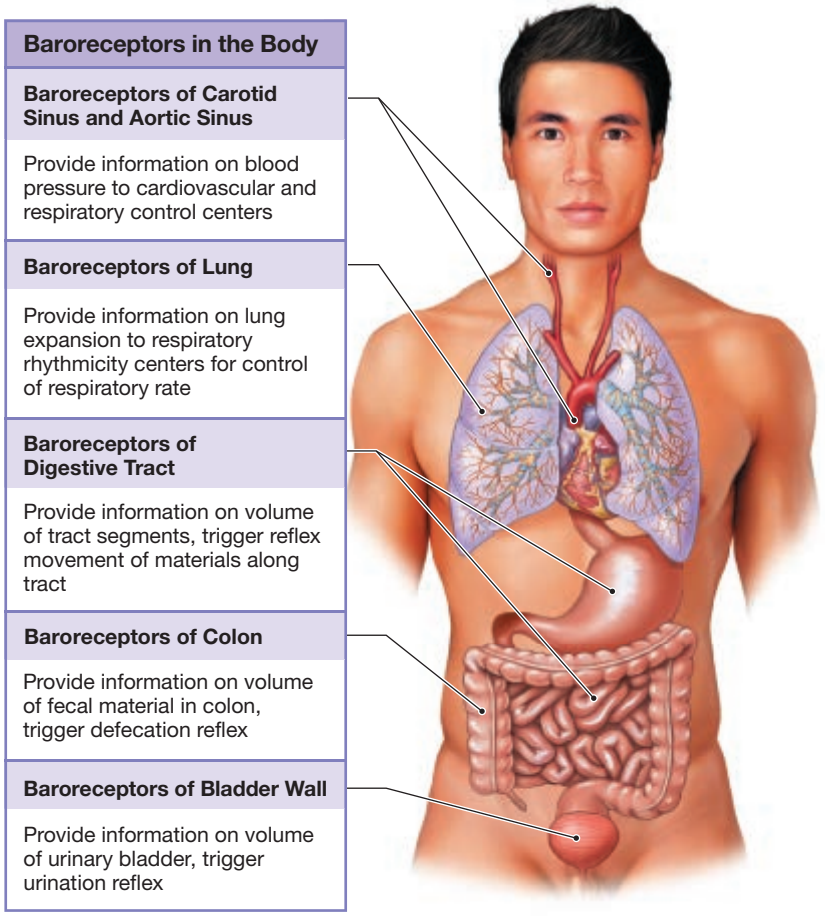
There are three major groups of proprioceptors:

- *Muscle Spindles.* As we discussed in Chapter 13, **muscle spindles** monitor skeletal muscle length and trigger stretch reflexes. p. 457
- *Golgi Tendon Organs.* **Golgi tendon organs** are similar in function to bulbous corpuscles but are located at the junction between a skeletal muscle and its tendon. In a Golgi tendon organ, dendrites branch repeatedly and wind around the densely packed collagen fibers of the tendon. These receptors are stimulated by tension in the tendon. They monitor the external tension developed during muscle contraction.
- *Receptors in Joint Capsules.* Joint capsules are richly innervated by free nerve endings that detect pressure, tension, and movement at the joint.

Your sense of body position results from the integration of information from joint capsule receptors, muscle spindles, Golgi tendon organs, and the receptors of the internal ear.

Proprioceptors do not adapt to constant stimulation, and each receptor continuously sends information to the CNS. Most proprioceptive information is processed at subconscious levels. Only a small proportion of the arriving proprioceptive information reaches your awareness.

Figure 15–5 Baroreceptors and the Regulation of Autonomic Functions.



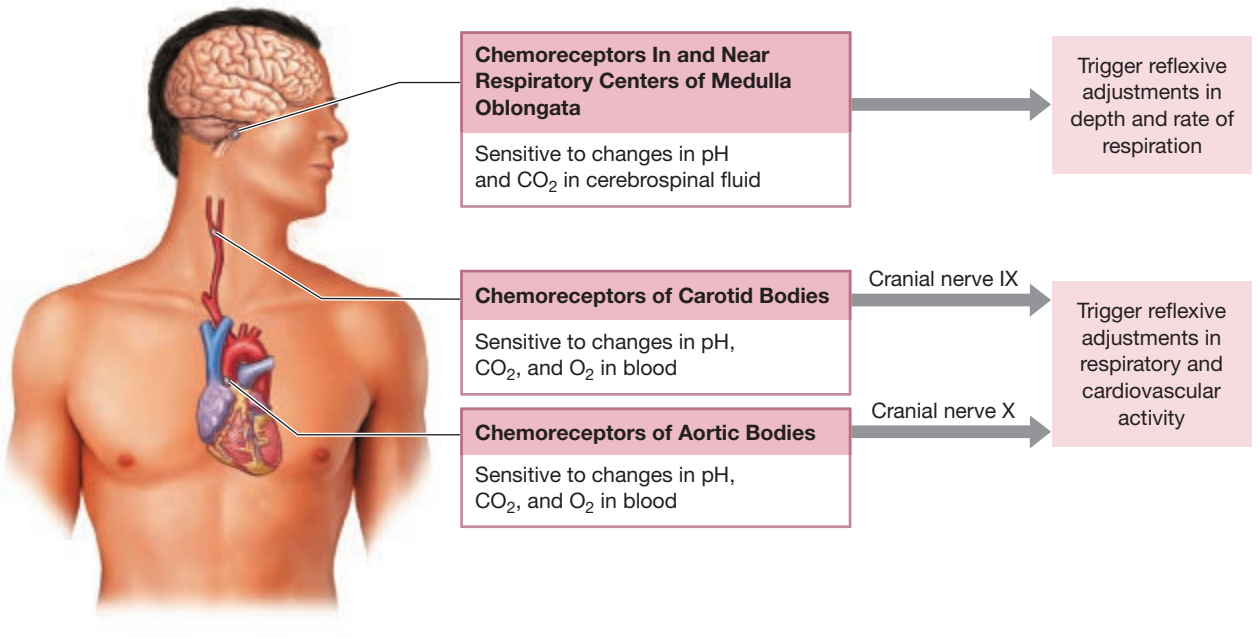
Chemoreceptors

Chemoreceptors (KĒ-mō-rē-sep-terz) are specialized nerve cells that detect small changes in the concentration of specific chemicals or compounds. In general, chemoreceptors respond only to water-soluble and lipid-soluble substances that are dissolved in body fluids [interstitial fluid, blood plasma, and cerebrospinal fluid (CSF)]. These receptors exhibit peripheral adaptation over a period of seconds, although they may also show central adaptation.

The chemoreceptors included in the general senses do not send information to the primary somatosensory cortex, so you are not consciously aware of the sensations they provide. The arriving sensory information is routed to brainstem centers that deal with the autonomic control of respiratory and cardiovascular functions. Neurons in the respiratory centers of the brain respond to the concentrations of hydrogen ions (pH) and carbon dioxide molecules in the CSF.

Chemoreceptors are also located in the **carotid bodies**, near the origin of the internal carotid arteries on each side of the neck, and in the **aortic bodies**, between the major branches of the aortic arch. (The carotid bodies and aortic bodies are small tissue masses of receptors and supporting cells.) These receptors monitor the pH and the carbon dioxide and oxygen levels in arterial blood and play an important role in the reflexive control of breathing and cardiovascular function. The afferent fibers leaving the carotid or aortic bodies reach the respiratory centers by traveling within cranial nerves IX (glossopharyngeal) and X (vagus) (Figure 15–6).

Figure 15–6 Locations and Functions of Chemoreceptors.



15

Checkpoint

5. List the major types of general sensory receptors, and identify the nature of the stimulus that excites each type.
6. Identify the three classes of mechanoreceptors.
7. What would happen to you if the information from proprioceptors in your legs were blocked from reaching the CNS?

See the blue Answers tab at the back of the book.

15-4 The afferent division is made up of separate somatic sensory and visceral sensory pathways that deliver sensory information to the CNS

Learning Outcome Identify the major sensory pathways, and explain how it is possible to distinguish among sensations that originate in different areas of the body.

When a sensory signal is being sent to the CNS along a sensory pathway, it goes through a series of neurons that can be distinguished by their locations. A sensory neuron that delivers sensations directly to the CNS is called a **first-order neuron**. The cell body of a first-order general sensory neuron is located in a spinal ganglion or cranial nerve ganglion. In the CNS, the axon of that sensory neuron synapses (passes signals to) an interneuron known as a **second-order neuron**, which may be located in the spinal cord or brainstem. For us to become aware of the sensation, the second-order neuron in turn must pass on the signal to a **third-order neuron** in the thalamus.

Somewhere along its length, the axon of the second-order neuron crosses over to the opposite side of the CNS in a process called **decussation**. As a result, the right side of the thalamus receives sensory information from the left side of the body, and the left side of the thalamus receives sensory information from the right side. The axon of the third-order neuron then ascends (without crossing back over) and synapses on neurons of the primary somatosensory cortex. Therefore, the right cerebral hemisphere receives sensory information from the left side of the body, and the left cerebral hemisphere receives sensations from the right side.

Our sensory pathways all include first-, second-, and third-order neurons. However, several different pathways bring somatic and visceral sensory information to the CNS. Let's look at some major representatives of each type.

Somatic Sensory Pathways

Somatic sensory pathways carry sensory information from the skin and muscles of the body wall, head, neck, and limbs to the CNS. We will consider three major somatic sensory pathways: (1) the *spinothalamic pathway*, (2) the *posterior column pathway*, and (3) the *spinocerebellar pathway*.

These pathways are made up of pairs of spinal tracts, symmetrically arranged on opposite sides of the spinal cord. All the axons within a tract share a common origin and destination. **Figure 15–7** shows the relative positions of the spinal tracts in each of these somatic sensory pathways.

Note that tract names often give clues to their function. For example, if the name of a tract begins with *spino-*, the tract *starts* in the spinal cord and *ends* in the brain. It must therefore be an ascending tract that carries sensory information. The rest of the name indicates the tract's destination. Thus, a *spinothalamic tract* begins in the spinal cord and carries sensory information to the thalamus.

+ Clinical Note Assessment of Tactile Sensitivities

Regional sensitivity to light touch can be checked by gentle contact with a fingertip or a slender wisp of cotton. The **two-point discrimination test** provides a more detailed sensory map of tactile receptors. Two fine points of a bent paper clip or another object are applied to the skin surface simultaneously. The person then describes the contact. When the points fall within a single receptive field, the person will report only one point of contact. A person usually loses two-point discrimination at 1 mm (0.04 in.) on the surface of the tongue, at 2–3 mm (0.08–0.12 in.) on the lips, at 3–5 mm (0.12–0.20 in.) on the backs of the hands and feet, and at 4–7 cm (1.6–2.75 in.) over the general body surface.

Applying the base of a tuning fork to the skin tests vibration receptors. Damage to an individual spinal nerve produces insensitivity to vibration along the paths of the related sensory nerves. If the sensory loss results from spinal cord damage, the injury site can typically be located by walking the tuning fork down the spinal column, resting its base on the vertebral spinous processes.

Various descriptive terms indicate the degree of sensitivity in an area. *Anesthesia* implies a total loss of sensation. The person cannot perceive touch, pressure, pain, or temperature sensations in that area. *Paresthesia* is the presence of abnormal sensations such as the prickling sensation when an arm or leg "falls asleep" as a result of pressure on a peripheral nerve.

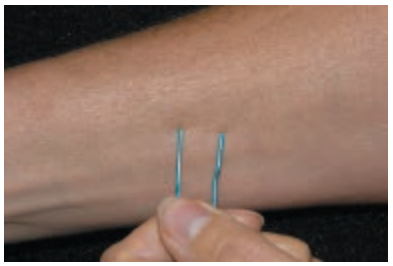


Figure 15–7 Sensory Pathways and Ascending Tracts in the Spinal Cord. A cross-sectional view of the spinal cord showing the locations of the major ascending (sensory) tracts. For information about these tracts, see **Table 15–1**.

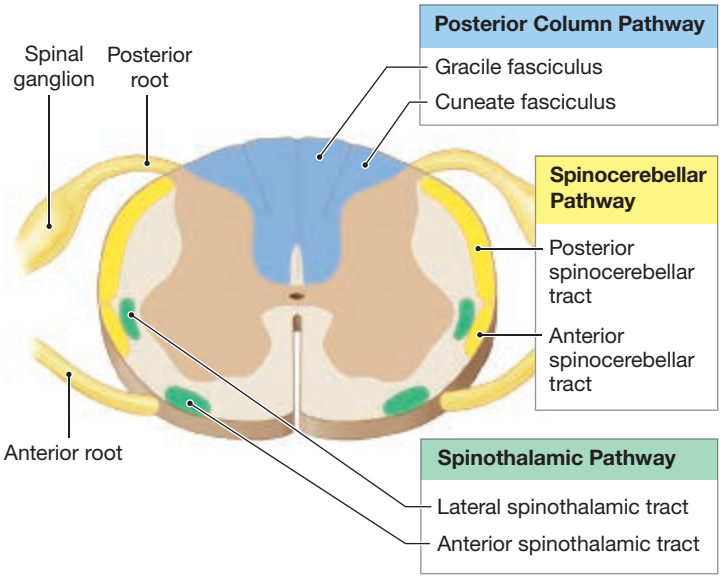


? Which pathway or tract detects sensations of pain and temperature?

The Spinothalamic Pathway

The **spinothalamic pathway** carries sensations of crude touch, pressure, pain, and temperature. This pathway includes larger tracts that carry sensations destined for the cerebral cortex as well as small tracts that deliver sensations to reflex centers in the brainstem. We will ignore the smaller tracts in this discussion.

The larger tracts are the **anterior spinothalamic tract** and the **lateral spinothalamic tract**. Sensations bound for the cerebral cortex ascend within these tracts, which end at third-order neurons in the ventral nuclei of the thalamus. After the sensations have been sorted and processed, they are relayed to the primary somatosensory cortex (**Spotlight Figure 15–8a**).

How we perceive an arriving stimulus, whether as painful, cold, hot, or vibrating, depends on which second-order and third-order neurons are stimulated. The ability to connect that stimulus with a specific location in the body—to *localize* the sensation—depends on the projection of information from the thalamus to an appropriate area of the primary somatosensory cortex.

Any abnormality along the pathway can result in inappropriate sensations or inaccurate localization of the source. Consider these examples:

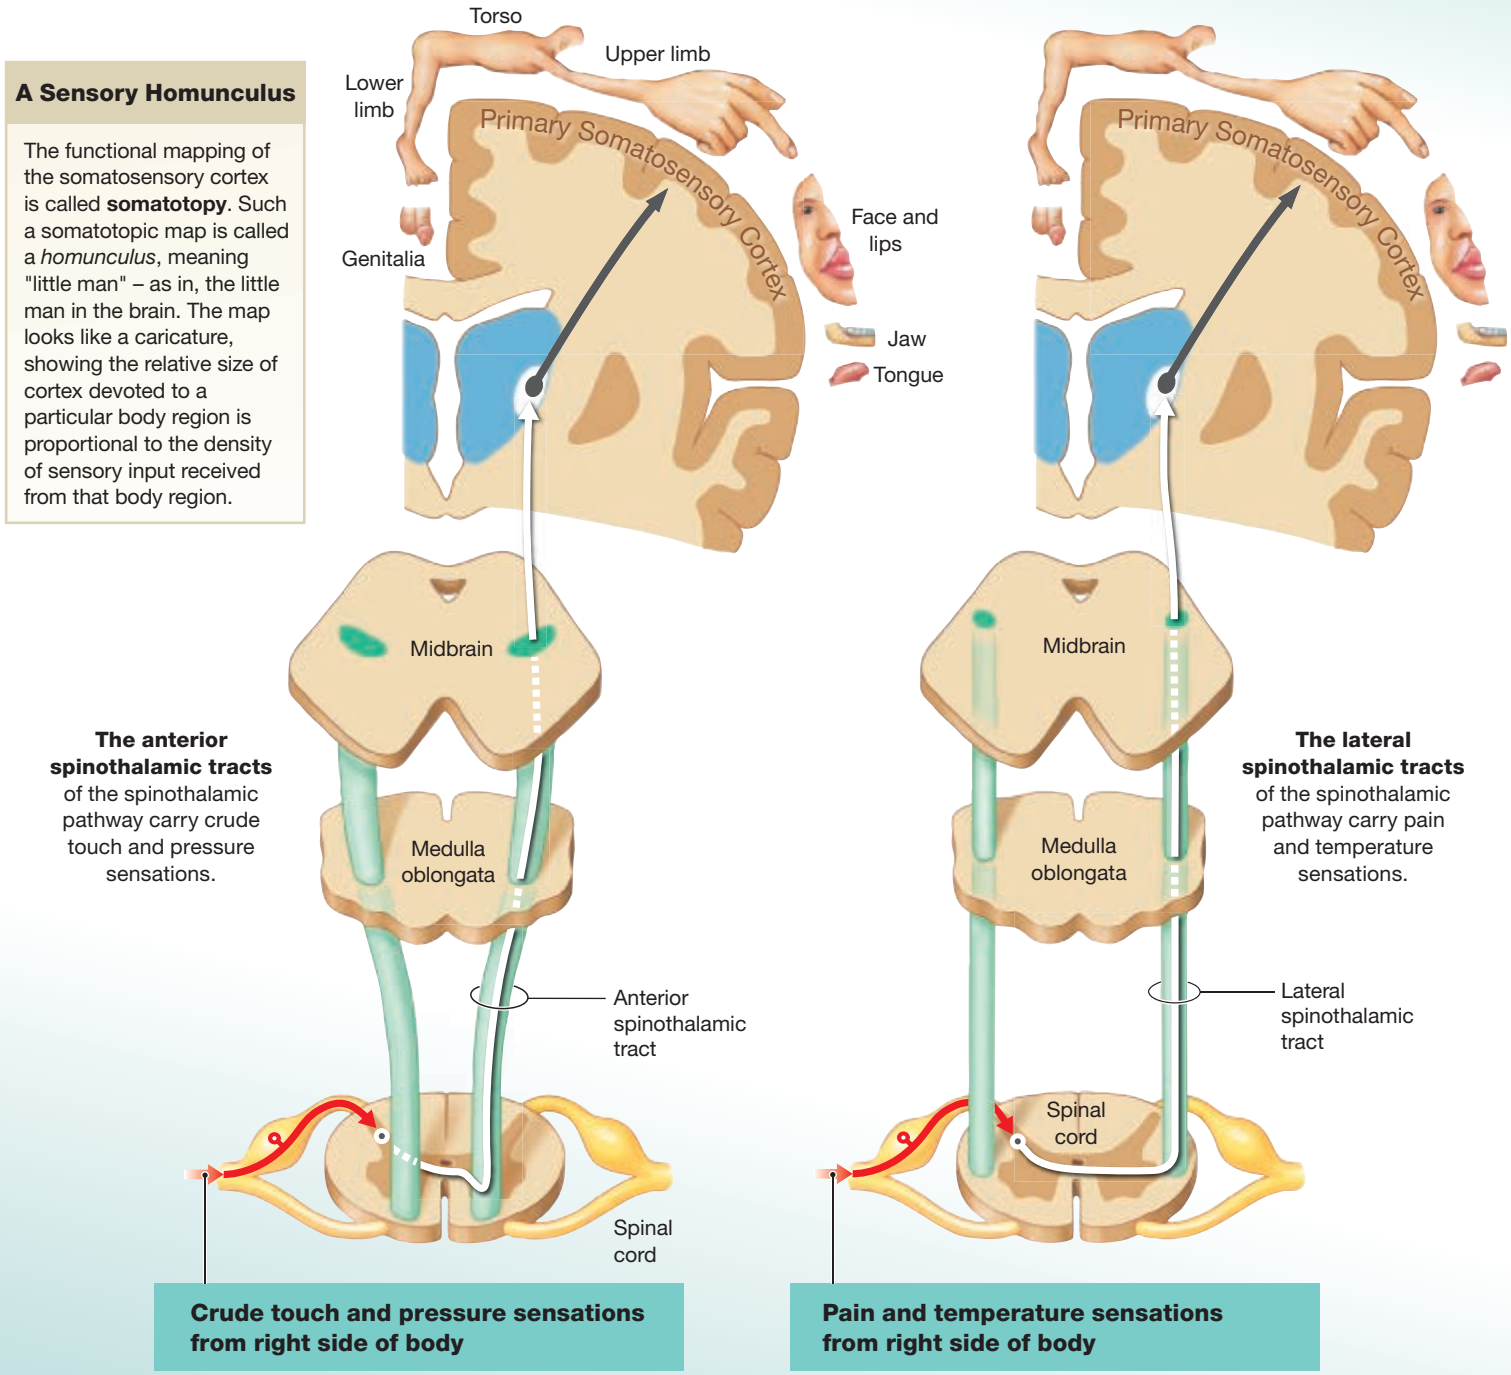
- A person can experience painful sensations that are not produced where they are perceived to originate. For example, a person may continue to experience pain in an amputated limb. This **phantom limb syndrome** is caused by activity in the sensory neurons or interneurons along the spinothalamic pathway. The neurons involved were once part of the labeled line that monitored conditions in the intact limb. These labeled lines and pathways are developmentally programmed. For this reason, even people born without limbs can have phantom limb syndrome.
- A person can feel pain in an uninjured part of the body when the pain actually originates at another location, a phenomenon called **referred pain**. For example, strong visceral pain sensations arriving at a segment of the spinal cord can stimulate interneurons that are part of the spinothalamic pathway. Activity in these interneurons leads to the stimulation of the primary somatosensory cortex, so the individual feels referred

SPOTLIGHT

Figure 15–8
Somatic Sensory Pathways

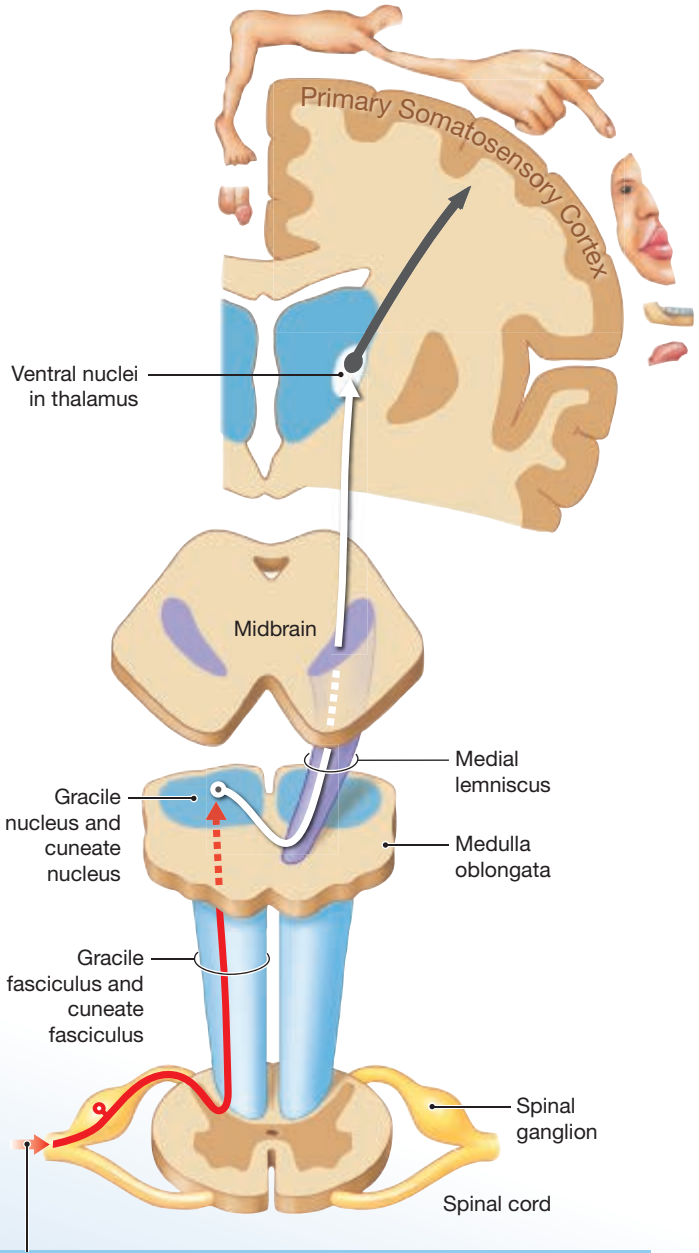
a SPINOTHALAMIC PATHWAY

The **spinothalamic pathway** provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature. In this pathway, the axons of first-order neurons enter the spinal cord and synapse on second-order neurons within the posterior horns. The axons of these interneurons cross to the opposite side of the spinal cord before ascending to the thalamus. The third-order neuron synapses in the primary somatosensory cortex.



b POSTERIOR COLUMN PATHWAY

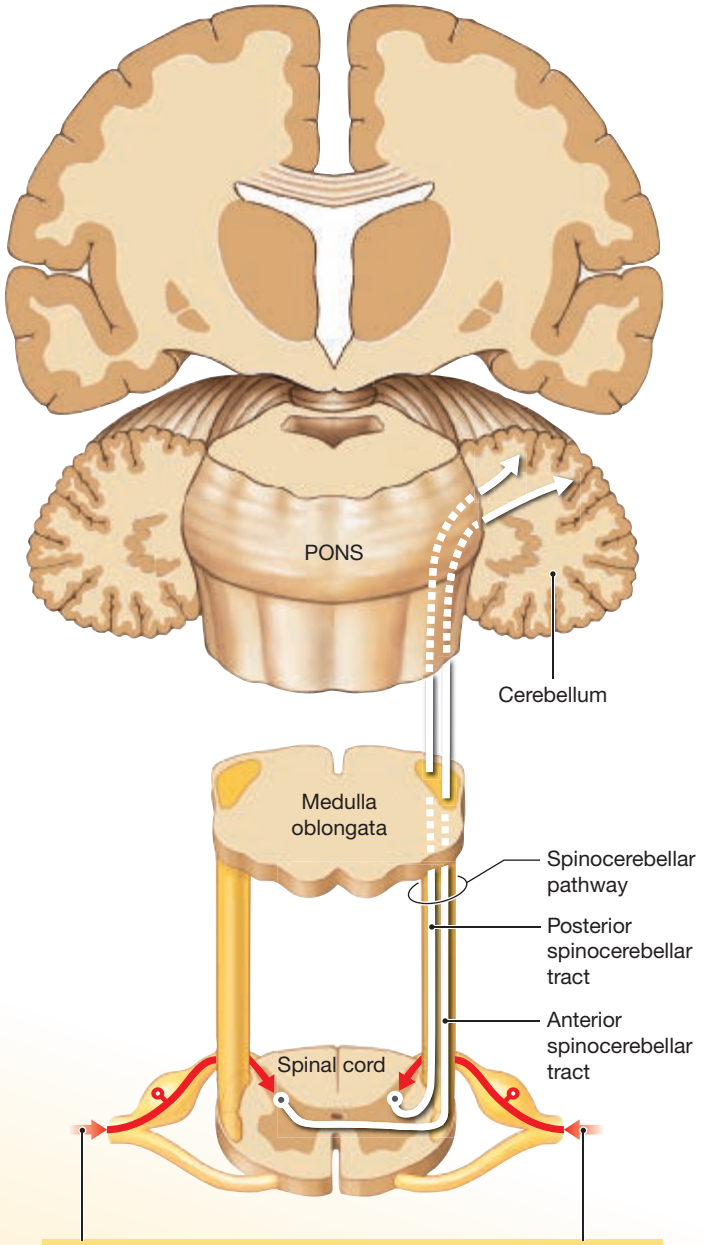
The **posterior column pathway** carries sensations of highly localized ("fine") touch, pressure, vibration, and proprioception. This pathway is also known as the posterior column–medial lemniscus pathway. It begins at a peripheral receptor and ends at the primary somatosensory cortex of the cerebral hemispheres.



Fine touch, vibration, pressure, and proprioception sensations from right side of body

c SPINOCEREBELLAR PATHWAY

The cerebellum receives proprioceptive information about the position of skeletal muscles, tendons, and joints along the **spinocerebellar pathway**. The **posterior spinocerebellar tracts** contain axons that do not cross over to the opposite side of the spinal cord. These axons reach the cerebellar cortex by the inferior cerebellar peduncle of that side. The **anterior spinocerebellar tracts** are dominated by axons that have crossed over to the opposite side of the spinal cord.



Proprioceptive input from Golgi tendon organs, muscle spindles, and joint capsule receptors

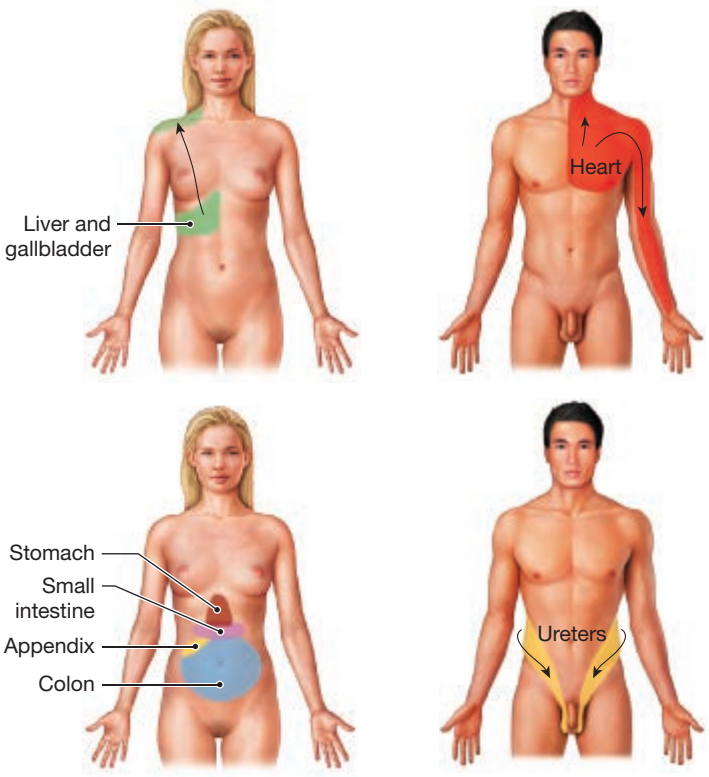
pain in a specific part of the body surface. One familiar example is the pain of a heart attack, which is frequently felt in the left arm. Women are more likely than men to experience shortness of breath, nausea, vomiting, back pain, or jaw pain. Additional examples for both anterior and posterior sides of the body are shown in Figure 15–9.

The Posterior Column Pathway

The **posterior column pathway**, shown in Spotlight Figure 15–8b, carries sensations of fine touch, vibration, pressure, and proprioception. The spinal tracts involved are the left and right **gracile fasciculus** (*gracilis*, slender) and the left and right **cuneate fasciculus** (*cuneus*, wedge shaped). On each side of the posterior median sulcus, the gracile fasciculus is medial to the cuneate fasciculus (see Figure 15–7).

The axons of the first-order neurons reach the CNS within the posterior roots of spinal nerves and the sensory roots of cranial nerves. The axons ascending within the posterior column are organized according to the region innervated. Axons carrying sensations from the inferior half of the body ascend within the gracile fasciculus and synapse in the gracile nucleus of the medulla oblongata. Axons carrying sensations from the superior half of the trunk, upper limbs, and neck ascend in the cuneate fasciculus and synapse in the cuneate nucleus. p. 474

Figure 15–9 Referred Pain. Pain sensations from visceral organs are often perceived as arising from areas distant from the actual origin (arrows). This occurs because the body surface is innervated by the same spinal segments. Each region of perceived pain is labeled according to the organ at which the pain originates.



+ Clinical Note Phantom Limb Syndrome

A soldier in the Afghan War unwittingly steps on a landmine. Although he survives, he loses his leg. During his extended rehabilitation he is at risk for a curious phenomenon called *phantom limb syndrome*. His leg—the one he lost—keeps him up at night with pain. Sometimes the leg burns; other times it feels like pins and needles. He says this leg feels touch, pressure, and vibration. It even itches! Despite the amputation, the sensory pathway for this leg persists and continues to convey messages to the thalamus. If the veteran is fit for a prosthesis (an artificial limb replacement) and wears it early and regularly, the device will ease his phantom limb pain by applying a real physical stimulus to the limb stump.

Axons of the second-order neurons of the gracile nucleus and cuneate nucleus decussate in the brainstem as they ascend toward the thalamus. Once on the opposite side of the brain, the axons enter a tract called the **medial lemniscus** (*lemniskos*, ribbon). The axons in this tract synapse on third-order neurons in one of the ventral nuclei of the thalamus. p. 481 These nuclei sort the arriving information according to (1) the nature of the stimulus and (2) the region of the body involved. Processing in the thalamus determines whether you perceive a given sensation as fine touch, pressure, or vibration.

We then localize the sensation by where it arrives in the primary somatosensory cortex. Sensory information from the toes arrives at the medial end of the primary sensory cortex, and information from the head arrives at the lateral end. When neurons in one portion of your primary somatosensory cortex are stimulated, you become aware of sensations originating at a specific location.

The Sensory Homunculus

The same sensations are reported whether the cortical neurons are activated by axons ascending from the thalamus or by direct electrical stimulation. Researchers have electrically stimulated the primary somatosensory cortex in awake individuals during brain surgery and asked the subjects where they thought the stimulus originated. The results were used to create a functional map of the primary somatosensory cortex known as a *sensory homunculus*.

In a sensory homunculus, the body features are distorted. For example, the face is huge, with enormous lips and tongue, but the back is relatively tiny. These distortions arise because the area of somatosensory cortex devoted to a particular body region is proportional to the density *of sensory neurons* in the region, not to the region's physical size. In other words, many more cortical neurons are required to process sensory information from the tongue, which has tens of thousands of taste and touch receptors, than to process sensations from the back, where touch receptors are few and far between.

The Spinocerebellar Pathway

The **spinocerebellar pathway** conveys information about muscle, tendon, and joint positions from the spine to the cerebellum (Spotlight Figure 15–8c). This information does not reach our awareness. The axons of first-order sensory neurons synapse on interneurons in the posterior horns of the spinal cord. The axons of these second-order neurons ascend in one of the spinocerebellar tracts: the **posterior spinocerebellar tracts** or the **anterior spinocerebellar tracts**.

The sensations carried by the anterior spinocerebellar tracts reach the cerebellar cortex by the superior cerebellar peduncle. Interestingly, many of the axons that cross over and ascend to the cerebellum then cross over again within the cerebellum, synapsing on the same side as the original stimulus. The functional significance of this "double cross" is unknown.

The information carried by the spinocerebellar pathway ultimately arrives at the *Purkinje cells* of the cerebellar cortex. p. 478 Proprioceptive information from each part of the body is relayed to a specific portion of the cerebellar cortex. We will consider the integration of proprioceptive information and the role of the cerebellum in somatic motor control in Section 15-5.

Visceral Sensory Pathways

Visceral sensory information is collected by interoceptors monitoring visceral tissues and organs, primarily within the thoracic and abdominopelvic cavities. These interoceptors include nociceptors, thermoreceptors, tactile receptors, baroreceptors, and chemoreceptors, although none of them is as numerous as they are in somatic tissues.

Sensory information from these interoceptors is carried from the mouth, palate, pharynx, larynx, trachea, esophagus, and associated vessels and glands by cranial nerves V, VII, IX, and X. The posterior roots of spinal nerves T_1–L_2 carry visceral sensory information provided by receptors in organs located between the diaphragm and the pelvic cavity. The posterior roots of spinal nerves S_2–S_4 carry visceral sensory information from organs in the inferior pelvic cavity. These organs include the last segment of the large intestine, the urethra and base of the urinary bladder, and the prostate gland (males) or the cervix of the uterus and portions of the vagina (females).

The axons of first-order neurons that carry visceral sensory information usually travel in company with autonomic motor fibers innervating the same visceral structures. These first-order neurons deliver the sensory information to second-order interneurons whose axons ascend within the spinothalamic pathway. Most of this information is delivered to the **solitary nucleus**, a large nucleus on each side of the medulla oblongata that has extensive connections with the various cardiovascular and respiratory centers as well as with the reticular formation. These connections allow the solitary nuclei to function as major processing and sorting centers for visceral sensory information. Because there is no third-order neuron in this pathway, this sensory information never reaches the primary sensory cortex, and you remain unaware of these sensations.

Table 15–1 summarizes the somatic sensory pathways discussed in this section.

15-5 The somatic nervous system is an efferent division made up of somatic motor pathways that control skeletal muscles

Learning Outcome Describe the components, processes, and functions of the somatic motor pathways, and the levels of information processing involved in motor control.

Let's take a look now at the structure of the **somatic nervous system (SNS)**, which allows us to control skeletal muscles. The SNS is made up of **somatic motor pathways** that consist of motor nuclei, tracts, and nerves. Throughout this discussion we will use the terms *motor neuron* and *motor control* to refer specifically to these somatic motor neurons and pathways.

Somatic motor pathways always involve at least two motor neurons: an **upper motor neuron**, whose cell body lies in a CNS processing center (the premotor and/or primary motor cortexes), and a **lower motor neuron**, whose cell body lies in a nucleus of the brainstem or spinal cord. Only the axon of the lower motor neuron extends outside the CNS. The upper motor neuron synapses on the lower motor neuron, which in turn innervates a single motor unit in a skeletal muscle. p. 315

Activity in the upper motor neuron may facilitate or inhibit the lower motor neuron. Activation of the lower motor neuron triggers a contraction in the innervated muscle. Destruction of or damage to a lower motor neuron eliminates voluntary and reflex control over the innervated motor unit.

Figure 15–10 indicates the positions of the associated motor (descending) tracts in the spinal cord. Conscious and subconscious motor commands control skeletal muscles by traveling over three integrated motor pathways: the *corticospinal pathway*, the *medial pathway*, and the *lateral pathway*. Note that because the name of the corticospinal tract ends in *-spinal*, this indicates that the tract ends in the spinal cord. The first part of the name indicates the nucleus or cortical area of the brain where the tract originates. Therefore, the name of the corticospinal tract tells you that it carries motor commands from the cerebral cortex to the spinal cord.

Table 15–1 Principal Ascending (Sensory) Pathways

Pathway/Tract	Sensation(s)	Location of Neuron Cell Bodies			Location of Neuron Cell Bodies	
		First-Order	Second-Order	Third-Order	Final Destination	Site of Decussation
SPINOTHALAMIC PATHWAY						
Lateral spinothalamic tracts	Pain and temperature	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter lateral spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons at level of entry
Anterior spinothalamic tracts	Crude touch and pressure	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter anterior spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons at level of entry
POSTERIOR COLUMN PATHWAY						
Gracile fasciculus	Proprioception and fine touch, anterior pressure, and vibration from inferior half of body	Spinal ganglia of inferior half of body; axons enter CNS in posterior roots and join gracile fasciculus	Gracile nucleus of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons before entering the medial lemniscus
Cuneate fasciculus	Proprioception and fine touch, anterior pressure, and vibration from superior half of body	Spinal ganglia of superior half of body; axons enter CNS in posterior roots and join cuneate fasciculus	Cuneate nucleus of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second-order neurons before entering the medial lemniscus
SPINOCEREBELLAR PATHWAY						
Posterior spinocerebellar tracts	Proprioception	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in posterior horn; axons enter posterior spinothalamic tract on same side	Not present	Cerebellar cortex on side of stimulus	None
Anterior spinocerebellar tracts	Proprioception	Spinal ganglia; axons enter CNS in posterior roots	Interneurons in same spinal section; axons enter anterior spinocerebellar tract on the same or opposite side	Not present	Cerebellar cortex on side opposite (and side of) stimulus	Axons of most second-order neurons cross over before entering tract; many recross at cerebellum

The basal nuclei and cerebellum monitor and adjust activity within these motor pathways. The output of these centers stimulates or inhibits the activity of either (1) motor nuclei or (2) the primary motor cortex. Let's look at these motor pathways and how they are monitored.

The Corticospinal Pathway

The **corticospinal pathway** (Figure 15–11), sometimes called the *pyramidal system*, provides voluntary control over skeletal muscles. This system begins at the *pyramidal cells* of the primary motor cortex. p. 490 The axons of these upper motor neurons descend into the brainstem and spinal cord to synapse on lower motor neurons that control skeletal muscles. In general, the corticospinal pathway is direct: The upper motor neurons synapse directly on the lower motor neurons. However, the corticospinal pathway also works indirectly, as it innervates centers of the medial and lateral pathways.

The corticospinal pathway contains three pairs of descending tracts: (1) the *corticobulbar tracts*, (2) the *lateral corticospinal tracts*, and (3) the *anterior corticospinal tracts*. These tracts enter the white matter of the internal capsule, descend into the brainstem, and emerge on either side of the midbrain as the *cerebral peduncles*. p. 478

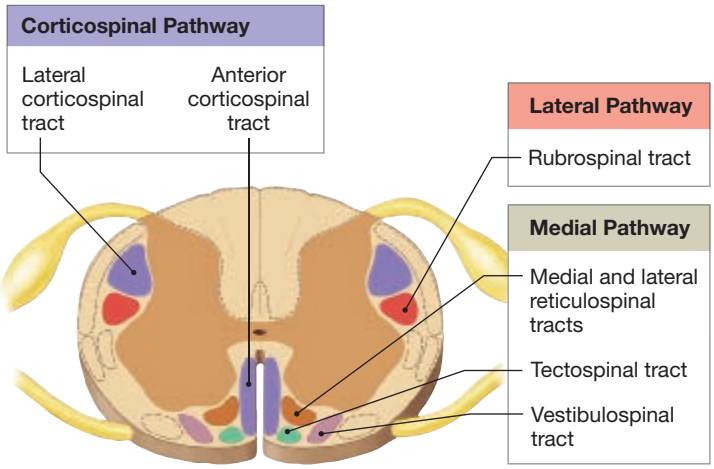
The Corticobulbar Tracts

Axons in the **corticobulbar** (kor-ti-kō-BUL-bar; *bulbar*, brainstem) **tracts** synapse on lower motor neurons in the motor nuclei of cranial nerves III, IV, V, VI, VII, IX, XI, and XII. The corticobulbar tracts provide conscious control over skeletal muscles that move the eyes, jaw, and face, and some muscles of the neck and pharynx. The corticobulbar tracts also innervate the motor centers of the medial and lateral pathways.

The Corticospinal Tracts

Axons in the **corticospinal tracts** synapse on lower motor neurons in the anterior horns of the spinal cord. As they descend, the

Figure 15–10 Descending (Motor) Tracts in the Spinal Cord. A cross-sectional view showing the locations of the major descending (motor) tracts that contain the axons of upper motor neurons. The origins and destinations of these tracts are listed in Table 15–2.



? Identify the descending (motor) tracts in the spinal cord.

corticospinal tracts are visible along the anterior surface of the medulla oblongata as a pair of thick bands, the **pyramids** (which is why these tracts are sometimes called the *pyramidal system*).

Along the length of the pyramids, roughly 85 percent of the axons decussate to enter the descending **lateral corticospinal tracts** on the opposite side of the spinal cord. The other 15 percent continue uncrossed along the spinal cord as the **anterior corticospinal tracts**. Then, at the spinal segment it targets, an axon in the anterior corticospinal tract decussates in the anterior white commissure. The axon synapses on lower motor neurons in the anterior horns.

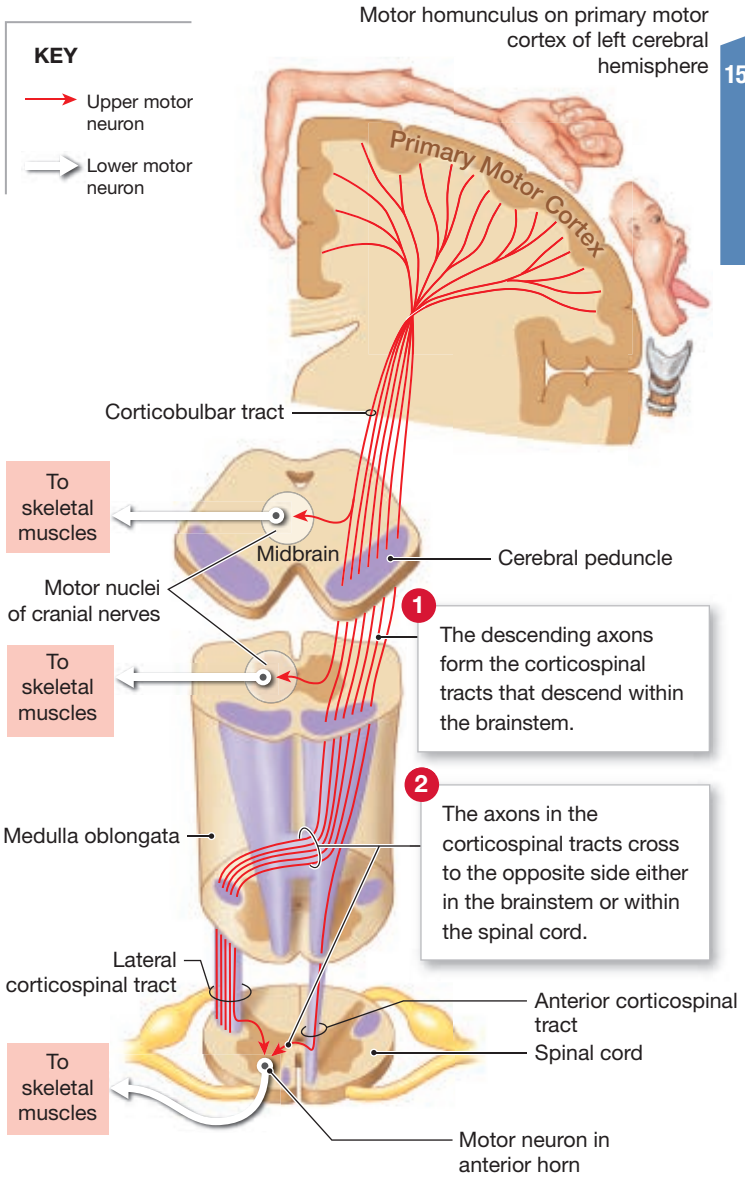
The Motor Homunculus

The activity of pyramidal cells in a specific portion of the primary motor cortex results in the contraction of specific peripheral muscles. Which muscles are stimulated depends on the region of motor cortex that is active. As in the primary somatosensory cortex, the primary motor cortex corresponds point by point with specific regions of the body. The cortical areas have been mapped out in diagrammatic form, creating a **motor homunculus**. Figure 15–11 shows the motor homunculus of the left cerebral hemisphere and the corticospinal pathway controlling skeletal muscles on the right side of the body.

The proportions of the motor homunculus are quite different from those of the actual body, because the area of primary motor cortex devoted to a specific body region is proportional to the density of motor units involved in the region's control, not to the region's physical size. For this reason, the homunculus indicates the degree of fine motor control available. For example, the hands, face, and tongue are all capable of varied and complex movements, so they appear very large. In contrast, the trunk is relatively small. These proportions are similar to those of the sensory homunculus (see Spotlight Figure 15–8).

The sensory and motor homunculi differ, however, with respect to some other areas of the body. For example, some highly sensitive regions, such as the sole of the foot, contain few motor units. Also, some areas with an abundance of motor units, such as the eye muscles, are not particularly sensitive.

Figure 15–11 The Corticospinal Pathway. The corticospinal pathway originates at the primary motor cortex. The corticobulbar tracts end at the motor nuclei of cranial nerves on the opposite side of the brain. Most fibers in this pathway cross over in the medulla oblongata and enter the lateral corticospinal tracts; the rest descend in the anterior corticospinal tracts and cross over after reaching target segments in the spinal cord.



The Medial and Lateral Pathways

Several centers in the cerebrum, diencephalon, and brainstem may issue somatic motor commands as a result of processing performed at a subconscious level. These centers and their associated tracts were long known as the *extrapyramidal system (EPS)* because they were thought to operate independently of, and in parallel with, the corticospinal pathway (pyramidal system). However, this classification scheme is both inaccurate and misleading, because motor control is integrated at all levels through extensive feedback loops and interconnections. We now group these nuclei and tracts in terms of their primary functions: The components of the *medial pathway* help control gross movements of the trunk and proximal limb muscles, and those of the *lateral pathway* help control the distal limb muscles that perform more precise movements.

The medial and lateral pathways can modify or direct skeletal muscle contractions by stimulating, facilitating, or inhibiting lower motor neurons. Note that the axons of upper motor neurons in the medial and lateral pathways synapse on the same lower motor neurons innervated by the corticospinal pathway. This means that the various motor pathways interact not only within the brain, through connections between the primary motor cortex and motor centers in the brainstem, but also at the level of the lower motor neuron, through excitatory or inhibitory interactions.

15

The Medial Pathway

The **medial pathway** is primarily concerned with the control of muscle tone and gross movements of the neck, trunk, and proximal limb muscles. The upper motor neurons of the medial pathway are located in the *vestibular nuclei*, the *superior* and *inferior colliculi*, and the *reticular formation*.

The vestibular nuclei (located at the border of the pons and medulla) receive information over the vestibulocochlear nerve (VIII). This nerve has receptors in the internal ear that monitor the position and movement of the head. These nuclei respond to changes in the orientation of the head, sending motor commands that alter the muscle tone, extension, and position of the neck, eyes, head, and limbs. The primary goal is to maintain posture and balance. The descending fibers in the spinal cord constitute the **vestibulospinal tracts** (see Figure 15–10).

The superior and inferior colliculi are located in the *tectum*, or roof of the midbrain (look back at Figure 14–8, p. 479). The superior colliculi receive visual sensations, and the inferior colliculi receive auditory sensations. Axons of upper motor neurons in the colliculi descend in the **tectospinal tracts**. These axons decussate immediately, before descending to synapse on lower motor neurons in the brainstem or spinal cord. Axons in the tectospinal tracts direct reflexive changes in the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises.

The *reticular formation* is a loosely organized network of neurons that extends throughout the brainstem and has extensive interconnections with the cerebrum, the cerebellum, and brainstem nuclei. ↩ p. 474 Axons of upper motor neurons in the reticular formation of the pons and medulla oblongata descend into the **medial** (pontoreticulospinal) and **lateral** (medullary reticulospinal) **reticulospinal tracts** without crossing to the opposite side. The reticular formation receives input from almost every ascending and descending pathway. The region stimulated determines the effects of reticular formation stimulation. For example, the stimulation of upper motor neurons in one portion of the reticular formation produces eye movements. The stimulation of another portion activates respiratory muscles.

Clinical Note Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive, degenerative disorder that affects motor neurons in the spinal cord, brainstem, and cerebral hemispheres. The degeneration affects both upper and lower motor neurons. A defect in axonal transport is thought to underlie the disease. Because a motor neuron and its dependent muscle fibers are so intimately related, the destruction of CNS neurons causes the associated skeletal muscles to atrophy. ALS is commonly known as Lou Gehrig's disease, named after the famous New York Yankees player who died of the disorder. Noted physicist Stephen Hawking is also afflicted with this condition.

The Lateral Pathway

The **lateral pathway** is primarily concerned with the control of muscle tone and the more precise movements of the distal parts of the limbs. The upper motor neurons of the lateral pathway lie within the red nuclei of the midbrain. ↩ p. 478 Axons of upper motor neurons in the red nuclei decussate in the brain and descend into the spinal cord in the **rubrospinal tracts** (*ruber*, red). In humans, the rubrospinal tracts are small and extend only to the cervical spinal cord. There they provide motor control over distal muscles of the upper limbs. Normally, their role is insignificant as compared with that of the lateral corticospinal tracts. However, the rubrospinal tracts can be important in maintaining motor control and muscle tone in the upper limbs if the lateral corticospinal tracts are damaged.

Table 15–2 summarizes the descending (motor) tracts discussed in this section.

The Monitoring Role of the Basal Nuclei and Cerebellum

The *basal nuclei* and *cerebellum* are responsible for coordination and feedback control over muscle contractions. Those contractions can be consciously or subconsciously directed.

Table 15–2 Principal Descending (Motor) Pathways

Tract	Location of Upper Motor Neurons	Destination	Site of Decussation	Action
CORTICOSPINAL PATHWAY				
Corticobulbar tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of cranial nerve nuclei in brainstem	Brainstem	Conscious motor control of skeletal muscles
Lateral corticospinal tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior horns of spinal cord	Pyramids of medulla oblongata	Conscious motor control of skeletal muscles
Anterior corticospinal tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior horns of spinal cord	Level of lower motor neuron	Conscious motor control of skeletal muscles
MEDIAL PATHWAY				
Vestibulospinal tracts	Vestibular nuclei (at border of pons and medulla oblongata)	Lower motor neurons of anterior horns of spinal cord	None (uncrossed)	Subconscious regulation of balance and muscle tone
Tectospinal tracts	Tectum (midbrain: superior and inferior colliculi)	Lower motor neurons of anterior horns (cervical spinal cord only)	Brainstem (midbrain)	Subconscious regulation of eye, head, neck, and upper limb position in response to visual and auditory stimuli
Reticulospinal tracts	Reticular formation (network of nuclei in brainstem)	Lower motor neurons of anterior horns of spinal cord	None (uncrossed)	Subconscious regulation of reflex activity
LATERAL PATHWAY				
Rubrospinal tracts	Red nuclei of midbrain	Lower motor neurons of anterior horns of spinal cord	Brainstem (midbrain)	Subconscious regulation of upper limb muscle tone and movement

The Basal Nuclei and Patterns of Movement

The **basal nuclei** of the cerebrum provide the background patterns of movement involved in voluntary motor activities. For example, they may control muscles that determine the background position of the trunk or limbs, or they may direct rhythmic cycles of movement, as in walking or running. These nuclei do not exert direct control over lower motor neurons. Instead, they adjust the activities of upper motor neurons in the various motor pathways based on input from all portions of the cerebral cortex, as well as from the substantia nigra.

The basal nuclei adjust or establish patterns of movement by two major pathways:

- One group of axons synapses on thalamic neurons, whose axons extend to the *premotor cortex*, the motor association area that directs activities of the primary motor cortex. This arrangement creates a feedback loop that changes the sensitivity of the pyramidal cells and alters the pattern of instructions carried by the corticospinal tracts.
- A second group of axons synapses in the reticular formation, altering the excitatory or inhibitory output of the reticulospinal tracts.

Two distinct populations of interneurons exist in the basal nuclei: one that stimulates neurons by releasing acetylcholine (ACh), and another that inhibits neurons by releasing gamma aminobutyric acid (GABA). Under normal conditions, the excitatory interneurons are kept inactive, and the axons leaving the basal nuclei have an inhibitory effect on upper motor neurons. In *Parkinson's disease*, the excitatory neurons become more active, leading to problems with the voluntary control of movement. ↩ p. 109

If the primary motor cortex is damaged, the person loses fine motor control over skeletal muscles. However, the basal nuclei can still control some voluntary movements. In effect, the medial and lateral pathways function as they usually do, but the corticospinal pathway cannot fine-tune the movements. For example, after damage to the primary motor cortex, the basal nuclei can still receive information about planned movements from the prefrontal cortex and can perform preparatory movements of the trunk and limbs. But because the corticospinal pathway is inoperative, precise movements of the forearms, wrists, and hands cannot occur. An individual in this condition can stand, maintain balance, and even walk, but all movements are hesitant, awkward, and poorly controlled.

The Cerebellum and Movement Adjustments

Whenever movement is occurring, the cerebellum monitors proprioceptive (position) sensations, visual information from the eyes, and vestibular (balance) sensations from the internal ear. Axons within the spinocerebellar tracts deliver proprioceptive information to the cerebellar cortex. Visual information is relayed from the superior colliculi, and balance information is relayed from the vestibular nuclei. During this process the cerebellum is comparing the arriving sensations with those experienced during previous movements.

When motor commands are issued, all motor pathways also send information to the cerebellum. In general, any voluntary movement begins with the activation of far more motor units than are required. The cerebellum then acts like a brake, adjusting the activities of the upper motor neurons involved to inhibit the number of motor commands used for that movement. The output of the cerebellum affects upper motor neuron activity in

the corticospinal, medial, and lateral pathways. The pattern and degree of inhibition changes from moment to moment, making the movement efficient, smooth, and precisely controlled.

The patterns of cerebellar activity are learned by trial and error, over many repetitions. Many of the basic patterns are established early in life. Examples include the fine balancing adjustments you make while standing and walking. The ability to fine-tune a complex pattern of movement improves with practice, until the movements become fluid and automatic. Consider the relaxed, smooth movements of acrobats, golfers, and sushi chefs. These people move without thinking about the details of their movements. Conversely, think about what happens when you concentrate on voluntary control of various movements. The rhythm and pattern of the movement usually fall apart as your primary motor cortex starts overriding the commands of the basal nuclei and cerebellum.

Checkpoint

11. **What is the anatomical basis for the fact that the left side of the brain controls motor function on the right side of the body?**
12. **An injury involving the superior portion of the motor cortex affects which region of the body?**
13. **What effect would increased stimulation of the motor neurons of the red nucleus have on muscle tone?**

15 Chapter Review

Study Outline

An Introduction to Sensory Pathways and the Somatic Nervous System p. 513

1. The nervous system works as an integrated unit. This chapter considers sensory pathways (sensory receptors and sensory processing centers in the brain) and motor pathways (including both conscious and subconscious motor functions). *(Figure 15–1)*

15-1 Sensory stimuli cause signals to be sent along sensory pathways, and in response motor commands are sent along motor pathways p. 513

2. The brain, spinal cord, and peripheral nerves continuously communicate with each other and with the internal and external environments. Information arrives by sensory receptors and ascends within the afferent division, while motor commands descend and are distributed by the efferent division.

15-2 Sensory receptors connect our internal and external environments with the nervous system p. 514

3. A sensory receptor is a specialized cell or cell process that monitors specific conditions within the body or in the external environment. Arriving information is a **sensation**; awareness of a sensation is a **perception**.
4. The **general senses** are our sensitivity to temperature, pain, touch, pressure, vibration, and proprioception. Receptors for these senses are distributed throughout the body. **Special senses**, located in specific **sense organs**, are structurally more complex.
5. Each receptor cell monitors a specific *receptive field*. *Transduction* begins when a large enough stimulus depolarizes the *receptor potential* or *generator potential* to the point where action potentials are produced. *(Figure 15–2)*
6. A **labeled line** is a link between a peripheral receptor and a cortical neuron. **Tonic receptors** are always active. **Phasic receptors** provide information about the intensity and rate of change of a stimulus. **Adaptation** is a reduction in sensitivity in the presence of a constant stimulus. Phasic receptors are **fast-adapting receptors**, while tonic receptors are **slow-adapting receptors**. *(Figure 15–3)*

15-3 General sensory receptors can be classified by the type of stimulus that excites them p. 517

7. Three types of **nociceptors** in the body provide information on pain as related to extremes of temperature, mechanical damage, and dissolved chemicals. Myelinated Type A fibers carry **fast pain**. Unmyelinated Type C fibers carry **slow pain**.
8. **Thermoreceptors** are found in the dermis. **Mechanoreceptors** are sensitive to distortion of their membranes, and include **tactile receptors**, **baroreceptors**, and **proprioceptors**. There are six types of tactile receptors in the skin, and three kinds of proprioceptors. **Chemoreceptors** include **carotid bodies** and **aortic bodies**. *(Figures 15–4, 15–5, 15–6)*

15-4 The afferent division is made up of separate somatic sensory and visceral sensory pathways that deliver sensory information to the CNS p. 522

9. Sensory neurons that deliver sensation to the CNS are referred to as **first-order neurons**. These synapse on **second-order neurons** in the brainstem or spinal cord. The next neuron in this chain is a **third-order neuron**, found in the thalamus.
10. Three major somatic sensory pathways carry sensory information from the skin and musculature of the body wall, head, neck, and limbs: the *spinothalamic pathway*, the *posterior column pathway*, and the *spinocerebellar pathway*. *(Figure 15–7)*

11. The **spinothalamic pathway** carries poorly localized ("crude") sensations of touch, pressure, pain, and temperature. The axons involved decussate in the spinal cord and ascend within the **anterior** and **lateral spinothalamic tracts** to the ventral nuclei of the thalamus. Abnormalities along the spinothalamic pathway can lead to **phantom limb syndrome**, painful sensations that are perceived despite a missing limb, and **referred pain**, inaccurate localizations of the source of pain. *(Spotlight Figure 15–8, Figure 15–9; Table 15–1)*
12. The **posterior column pathway** carries fine touch, pressure, and proprioceptive sensations. The axons ascend within the **gracile fasciculus** and **cuneate fasciculus** and relay information to the thalamus by the **medial lemniscus**. Before the axons enter the medial lemniscus, they cross over to the opposite side of the brainstem. This crossing over is called **decussation**. *(Spotlight Figure 15–8; Table 15–1)*
13. The **spinocerebellar pathway**, including the **posterior** and **anterior spinocerebellar tracts**, carries sensations to the cerebellum concerning the position of muscles, tendons, and joints. *(Spotlight Figure 15–8; Table 15–1)*
14. Visceral sensory pathways carry information collected by interoceptors. Sensory information from cranial nerves V, VII, IX, and X is delivered to the **solitary nucleus** in the medulla oblongata. Posterior roots of spinal nerves T_1–L_2 carry visceral sensory information from organs between the diaphragm and the pelvic cavity. Posterior roots of spinal nerves S_2–S_4 carry sensory information from more inferior structures.

15-5 The somatic nervous system is an efferent division made up of somatic motor pathways that control skeletal muscles p. 527

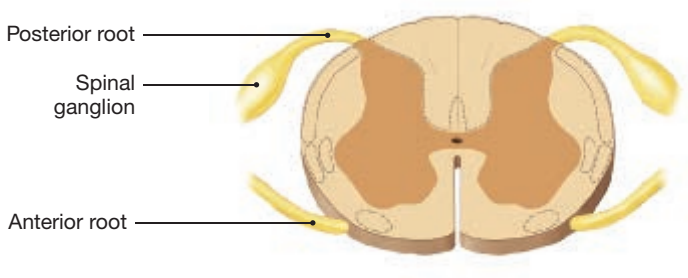
15. Somatic motor (descending) pathways always involve an **upper motor neuron** (whose cell body lies in a CNS processing center) and a **lower motor neuron** (whose cell body is located in a nucleus of the brainstem or spinal cord). *(Figure 15–10)*
16. The neurons of the primary motor cortex are *pyramidal cells*. The **corticospinal pathway** provides voluntary skeletal muscle control. The **corticobulbar tracts** end at the cranial nerve nuclei. The **corticospinal tracts** synapse on lower motor neurons in the anterior horns of the spinal cord. The corticospinal tracts are visible along the medulla oblongata as a pair of thick bands, the **pyramids**, where most of the axons decussate to enter the descending **lateral corticospinal tracts**. Those that do not cross over enter the **anterior corticospinal tracts**. The corticospinal pathway provides a rapid, direct mechanism for controlling skeletal muscles. *(Figure 15–11; Table 15–2)*
17. The **medial** and **lateral pathways** include several other centers that issue motor commands as a result of processing performed at a subconscious level. *(Table 15–2)*
18. The medial pathway primarily controls gross movements of the neck, trunk, and proximal limbs. It includes the vestibulospinal, tectospinal, and medial and lateral reticulospinal tracts. The **vestibulospinal tracts** carry information related to maintaining balance and posture. Commands carried by the **tectospinal tracts** change the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises. Motor commands carried by the **reticulospinal tracts** vary according to the region stimulated. *(Table 15–2)*
19. The lateral pathway consists of the **rubrospinal tracts**, which primarily control muscle tone and movements of the distal muscles of the upper limbs. *(Table 15–2)*
20. The basal nuclei adjust the motor commands issued in other processing centers and provide background patterns of movement involved in voluntary motor activities.
21. The cerebellum monitors proprioceptive sensations, visual information, and vestibular (balance) sensations. The integrative activities performed by neurons in the cortex and nuclei of the cerebellum are essential for the precise control of movements.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The larger the receptive field, the **(a)** larger the stimulus needed to stimulate a sensory receptor, **(b)** fewer sensory receptors there are, **(c)** harder it is to locate the exact point of stimulation, **(d)** larger the area of the somatosensory cortex in the brain that deals with the area, **(e)** closer together the receptor cells.
2. _____ receptors are normally inactive, but become active for a short time whenever there is a change in the modality that they monitor.
3. The CNS interprets information entirely on the basis of the **(a)** number of action potentials that it receives, **(b)** kind of action potentials that it receives, **(c)** line over which sensory information arrives, **(d)** intensity of the sensory stimulus, **(e)** number of sensory receptors that are stimulated.
4. The area of primary somatosensory cortex devoted to a body region is relative to the **(a)** size of the body area, **(b)** distance of the body area from the brain, **(c)** density of motor units in the area of the body, **(d)** density of sensory receptors in the area of the body, **(e)** size of the nerves that serve the area of the body.
5. Identify and shade in the locations of all the ascending sensory tracts in the following diagram of the spinal cord.



6. Identify six types of tactile receptors located in the skin, and describe their sensitivities.
7. What three types of mechanoreceptors respond to stretching, compression, twisting, or other distortions of their plasma membrane?
8. What are the three major somatic sensory pathways and their functions?
9. Which three pairs of descending tracts make up the corticospinal pathway?
10. Which three motor tracts make up the medial pathway?
11. What are the two primary functional roles of the cerebellum?
12. The corticospinal tract **(a)** carries motor commands from the cerebral cortex to the spinal cord, **(b)** carries sensory information from the spinal cord to the brain, **(c)** starts in the spinal cord and ends in the brain, **(d)** does all of these.
13. What three steps are necessary for transduction to occur?

LEVEL 2 Reviewing Concepts

14. Differentiate between a tonic receptor and a phasic receptor.
15. What is a motor homunculus? How does it differ from a sensory homunculus?
16. Describe the relationship among first-order, second-order, and third-order neurons in a sensory pathway.
17. Damage to the posterior spinocerebellar tract on the left side of the spinal cord at the L_1 level would interfere with the coordinated movement of which limb(s)?
18. What effect does injury to the primary motor cortex have on peripheral muscles?
19. By which structures and in which part of the brain is the level of muscle tone in the body's skeletal muscles controlled? How is this control exerted?
20. Explain the phenomenon of *referred pain* in terms of labeled lines and organization of sensory tracts and pathways.

LEVEL 3 Critical Thinking and Clinical Applications

21. Kayla is having difficulty controlling her eye movements and has lost some control of her facial muscles. After an examination and testing, Kayla's physician tells her that her cranial nerves are perfectly normal but that a small tumor is putting pressure on certain fiber tracts in her brain. This pressure is the cause of Kayla's symptoms. Where is the tumor most likely located?
22. Harry, a construction worker, suffers a fractured skull when a beam falls on his head. Diagnostic tests indicate severe damage to the primary motor cortex. His wife is anxious to know if he will ever be able to move or walk again. What would you tell her?
23. Denzel had to have his arm amputated at the elbow after an accident. He tells you that he can sometimes still feel pain in his fingers even though the hand is gone. He says this is especially true when he bumps the stub. How can this be?

15

+ CLINICAL CASE Wrap-Up Living with Cerebral Palsy

Communication between the periphery and the central nervous system follows neural pathways. Somatic sensory tracts are ascending, ending in the brain. Somatic motor tracts are descending, beginning in the brain. Between the input and the output, nerve impulses are analyzed, influenced, and modified in various parts of the brain, including the cerebrum, cerebellum, basal nuclei, hippocampus, and thalamus. These were the very areas of Michael's brain that were injured during birth.

The damage affected the sensory and motor processing centers in the brain. As a result, Michael's voluntary movements, muscle tone, postural muscle control, and balance were all affected. These deficits were stable and did not get worse. There was no limit to the development of the rest of Michael's brain, or how brilliant he could become.

In spite of his disabilities, Michael chose to define himself in terms of his abilities. He earned his Ph.D. in special education. He was a pioneer and became a catalyst in introducing the concept of self-determination to the field of education. He has been an educator, writer, and motivator his entire life. He is not just living, but thriving despite his cerebral palsy.

1. Name the principal descending motor pathways that carry information that would be affected by the brain damage causing Michael's cerebral palsy.
2. Besides aspiration pneumonia, what other difficulties could result from poor motor control of the muscles used in swallowing?

See the blue Answers tab at the back of the book.

Related Clinical Terms

analgesia: The inability to feel pain while still conscious.
flaccid paralysis: Weakness or loss of muscle tone as a result of disease or injury to the nerves innervating the muscles.
hyperalgesia: Increased sensitivity to pain that may be caused by damage to nociceptors or peripheral nerves.
pain threshold: The lowest intensity of stimulation at which pain is experienced. It can vary among individuals.
pain tolerance: The maximum pain level an individual can withstand. It can vary among individuals.
spastic paralysis: The chronic pathological condition in which muscles are affected by persistent spasms and exaggerated tendon reflexes due to damage to motor nerves of the central nervous system.
syphilis: A sexually transmitted disease (STD), also called a sexually transmitted infection (STI), caused by the bacterium *Treponema pallidum*. Many of the signs and symptoms are indistinguishable from those of other diseases. Late-stage untreated syphilis can cause progressive degeneration of the posterior column pathway, spinocerebellar pathway, and posterior roots of the spinal cord.

16 The Autonomic Nervous System and Higher-Order Functions

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

16-1 ■ Compare the organization of the autonomic nervous system with that of the somatic nervous system, and name the divisions and major functions of the ANS. p. 536

16-2 ■ Describe the structures and functions of the sympathetic division of the autonomic nervous system. p. 538

16-3 ■ Describe the types of neurotransmitters and receptors and explain their mechanisms of action. p. 543

16-4 ■ Describe the structures and functions of the parasympathetic division of the autonomic nervous system. p. 545

16-5 ■ Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues. p. 546

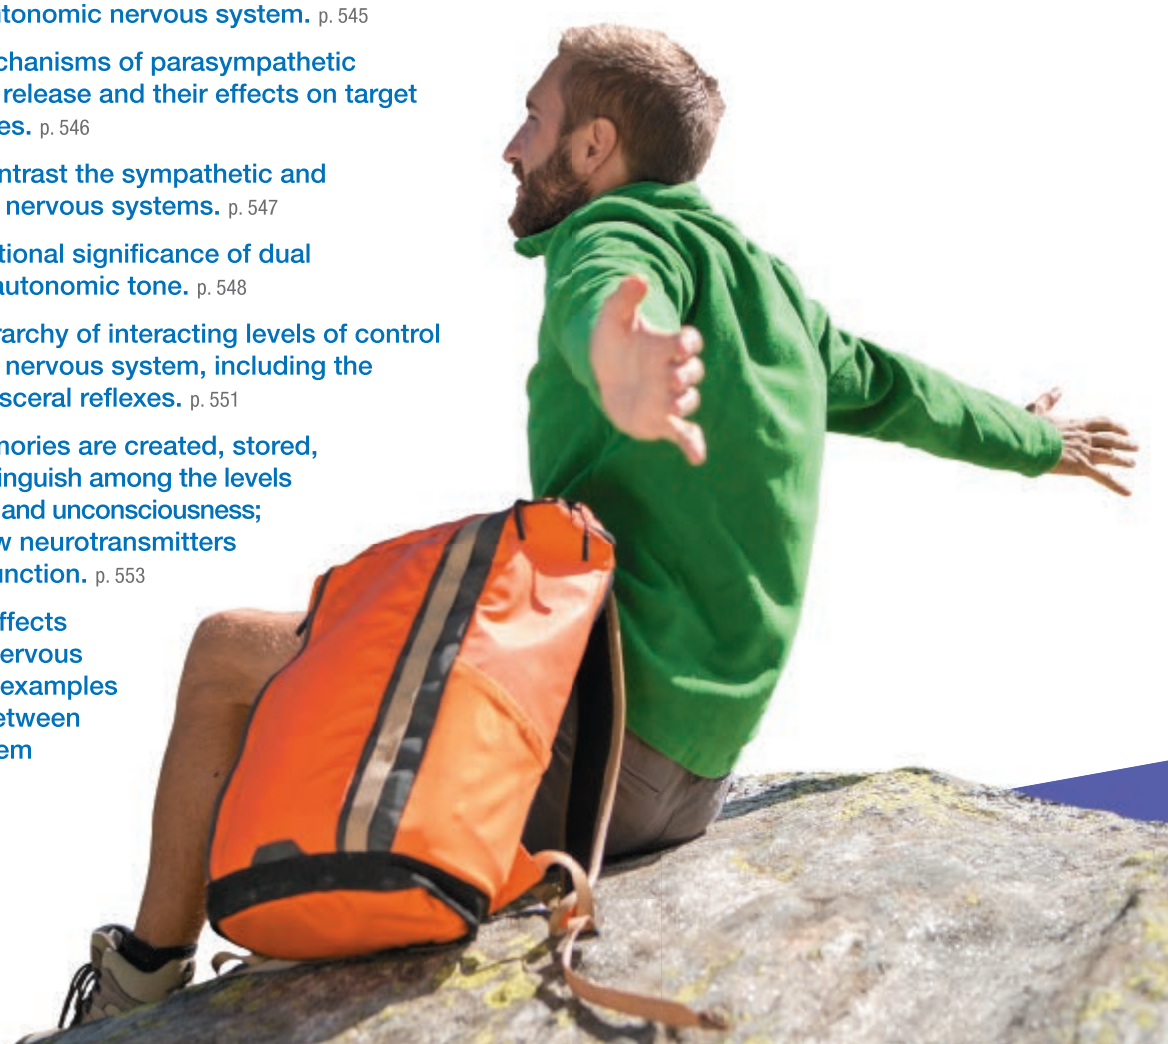
16-6 ■ Compare and contrast the sympathetic and parasympathetic nervous systems. p. 547

16-7 ■ Discuss the functional significance of dual innervation and autonomic tone. p. 548

16-8 ■ Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes. p. 551

16-9 ■ Explain how memories are created, stored, and recalled; distinguish among the levels of consciousness and unconsciousness; and describe how neurotransmitters influence brain function. p. 553

16-10 ■ Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems. p. 558



CLINICAL CASE Remember Me?

It started with the little things. Helen kept misplacing her keys. I'd try and get her to think, "When did you last have them?" I could tell it upset her. She was always so organized when she was raising our four kids. She'd be fine for a while. Then she'd get turned around in the neighborhood grocery store. The day she turned 60, she forgot we were having her big birthday celebration. She was anxious; I was worried. We made an appointment with the doctor.

Our family doctor has known us for years. She listened carefully to Helen and me and so was able to trace the start of the problem back to a year ago. Her physical exam turned out normal. Then Doc performed a little test. She told Helen a list of three things and had her repeat them back. Later in the appointment, Doc asked her again to repeat the items. You could see Helen try to concentrate, but she could only remember one.

Well, it went downhill from there, slowly but steadily. Doc gave us a medication to try and it helped for a while. I'm retired and I could do a lot for Helen. We used the adult day care at the senior center so she'd have something fun to do in the mornings and I could get a few errands done. Then Helen needed more and more attention. She was restless. She didn't talk anymore. When our son moved back home to help, she was afraid of him. This is hardest on Helen, I guess, but it is hard on all of us, really. We've lost the Helen we knew. **Why can't Helen remember? To find out, turn to the Clinical Case Wrap-Up on p. 564.**

16

An Introduction to the Autonomic Nervous System and Higher-Order Functions

In this chapter we focus on the *autonomic nervous system*, or *visceral motor system*, which adjusts our basic life support systems without our conscious control. We also consider aspects of higher-order functions such as consciousness, learning, and intelligence. Finally, we look at the effects of aging on the nervous system and conclude with an overview of interactions between the nervous system and other body systems.

16-1 The autonomic nervous system, which has sympathetic and parasympathetic divisions, is involved in the unconscious regulation of visceral functions

Learning Outcome Compare the organization of the autonomic nervous system with that of the somatic nervous system, and name the divisions and major functions of the ANS.

Your conscious thoughts, plans, and actions are a tiny fraction of what the nervous system does. If all consciousness were eliminated, your vital physiological processes would continue virtually unchanged. After all, a night's sleep is not a life-threatening event. Longer, deeper states of unconsciousness are not necessarily more dangerous, as long as you get nourishment and other basic care. People with severe brain injuries can survive in a coma for decades.

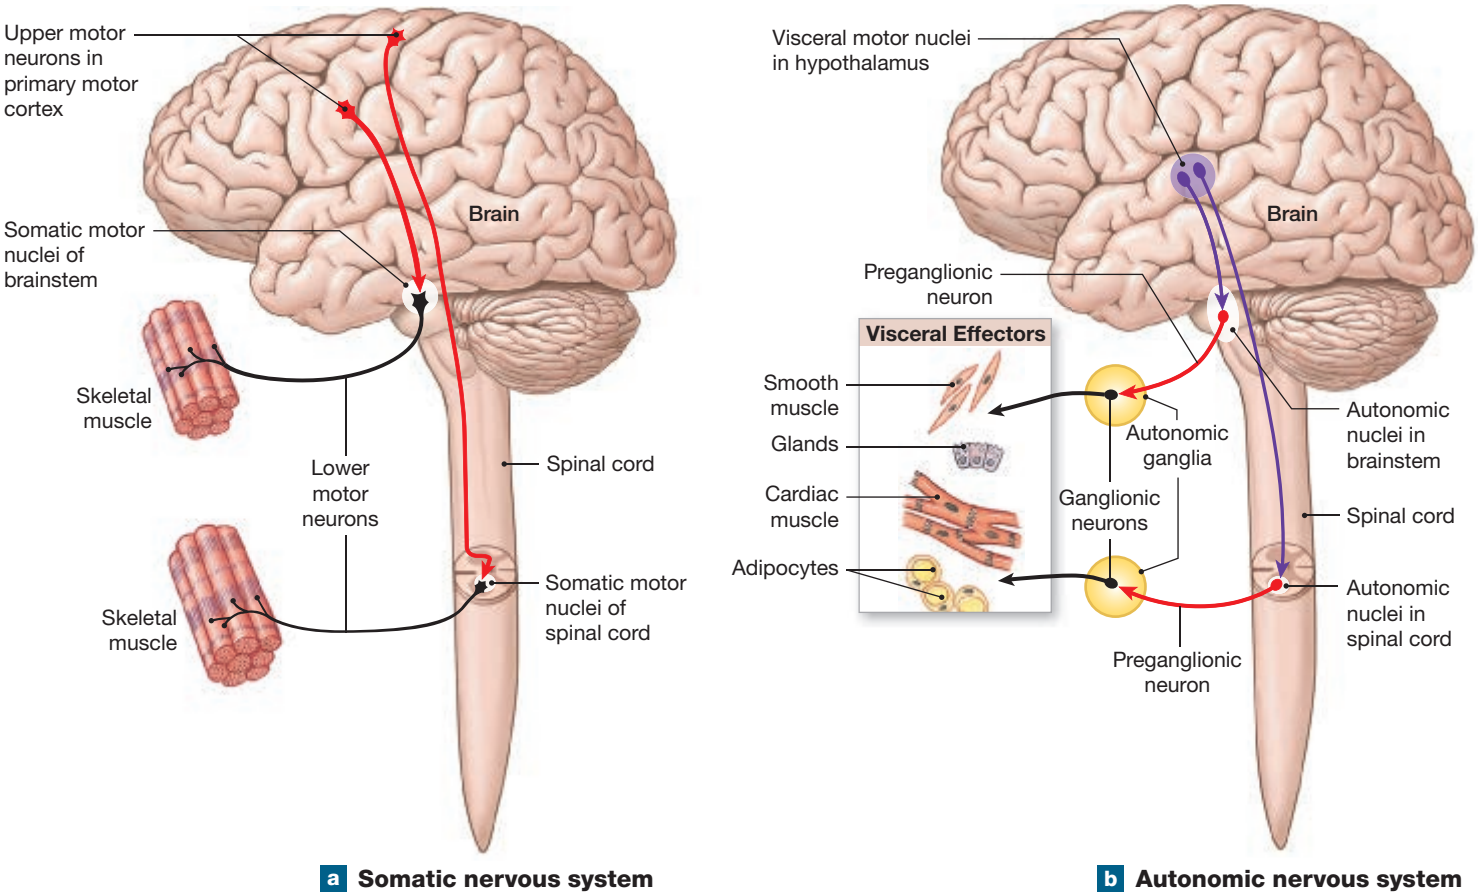
How do people survive under these conditions? Their survival is possible because the **autonomic nervous system (ANS)** makes routine homeostatic adjustments in physiological systems without instructions or interference from the conscious mind. By itself the ANS coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions. It also adjusts internal water, electrolyte, nutrient, and dissolved gas concentrations in body fluids.

Somatic or visceral sensory information can trigger *visceral reflexes* (responses to stimuli in visceral organs), and the ANS distributes the motor commands of those reflexes. Sometimes those motor commands control the activities of target organs. For example, in cold weather, the ANS stimulates the arrector pili muscles that give you "goosebumps." ↩ p. 166 In other cases, the motor commands may alter some ongoing activity. A sudden, loud noise can startle you and make you jump, but thanks to the ANS, that sound can also increase your heart rate dramatically and temporarily stop all digestive gland secretion. These changes in visceral activity take place in response to *neurotransmitters* released by neurons of the ANS. As noted in Chapter 12, a specific neurotransmitter may stimulate or inhibit activity, depending on the response of particular plasma membrane receptors. We consider the major types of receptors in Section 16-3. Let's begin our examination of the ANS by comparing its organization with that of the somatic nervous system, and then go on to look at the ANS divisions and their overall functions.

Comparison of the Somatic and Autonomic Nervous Systems

Figure 16–1 compares the functional organization of the somatic and autonomic nervous systems. Both are efferent divisions that carry motor commands. The *somatic nervous system (SNS)* allows for voluntary control of skeletal muscles, while the ANS

Figure 16–1 Comparison of the Functional Organizations of the Somatic and Autonomic Nervous Systems.



? The somatic nervous system affects skeletal muscles. Name effectors of the autonomic nervous system.

is responsible for involuntary control of visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The primary structural difference between the two is that in the SNS, motor neurons of the central nervous system (CNS) exert direct control over skeletal muscles (Figure 16–1a). In the ANS, by contrast, motor neurons of the CNS synapse on visceral motor neurons in autonomic ganglia (clusters of nerve cell bodies in the ANS), and these ganglionic neurons control visceral effectors (Figure 16–1b).

Organization of the ANS

The hypothalamus contains the integrative centers for autonomic activity. The neurons in these centers are comparable to the upper motor neurons in the SNS. Visceral motor neurons in the brainstem and spinal cord are known as **preganglionic neurons** because they extend to ganglia. These neurons are part of *visceral reflex arcs*. Most of their activities represent direct reflex responses, rather than responses to commands from the hypothalamus. The axons of preganglionic neurons are called **preganglionic fibers**.

Preganglionic fibers leave the CNS and synapse on **ganglionic neurons**, or **postganglionic neurons**—visceral motor neurons in peripheral ganglia. These ganglia, which contain hundreds to thousands of ganglionic neurons, are called **autonomic ganglia**. Ganglionic neurons innervate visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The axons of ganglionic neurons are called **postganglionic fibers**, because they begin at the autonomic ganglia and extend to the peripheral target organs.

Tips & Tools

Each autonomic ganglion functions somewhat like a baton handoff zone in a relay race. Within the ganglion, one runner (the preganglionic fiber) hands off the baton (a neurotransmitter) to the next runner (the postganglionic fiber), who then continues on toward the finish line (the target effector).

Divisions of the ANS

In Chapter 12 we introduced the two main subdivisions of the ANS: the **sympathetic division** and the **parasympathetic division**. The two divisions work both separately and together:

- Most often, these two divisions have opposing effects. For example, if the sympathetic division causes excitation in an effector, the parasympathetic causes inhibition in that same effector.
- The two divisions may also work independently. Only one division innervates some structures.
- The two divisions may work together, with each controlling one stage of a complex process.

In general, the sympathetic division "kicks in" only during exertion, stress, or emergency, and t he parasympathetic division predominates under resting conditions. Let's take a closer look at the overall functions of these divisions.

The Sympathetic Division

An increase in sympathetic activity, called the "fight or flight" response, prepares the body to deal with emergencies. Imagine walking down a long, dark alley and hearing strange noises in the darkness ahead. Your body responds right away, and you become more alert and aware of your surroundings. Your metabolic rate increases quickly, up to twice its resting level. Your digestive and urinary processes stop temporarily, and more blood flows to your skeletal muscles. You begin breathing more quickly and more deeply. Both your heart rate and blood pressure increase, circulating your blood more rapidly. You feel warm and begin to perspire. We can summarize this general pattern of responses to an increased level of sympathetic activity as follows: (1) heightened mental alertness, (2) increased metabolic rate, (3) decreased digestive and urinary functions, (4) activation of energy reserves, (5) increased respiratory rate and dilation of respiratory passageways, (6) increased heart rate and blood pressure, and (7) activation of sweat glands.

The Parasympathetic Division

The parasympathetic division stimulates visceral activity. For example, it brings about the state of "rest and digest" after you eat a big dinner. Your body relaxes, energy demands are minimal, and both your heart rate and blood pressure are relatively low. Meanwhile, your digestive organs are highly stimulated. The overall pattern of responses to increased parasympathetic activity is as follows: (1) decreased metabolic rate, (2) decreased heart rate and blood pressure, (3) increased secretion by salivary and digestive glands, (4) increased motility and blood flow in the digestive tract, and (5) stimulation of urination and defecation.

In this chapter, we focus primarily on the sympathetic and parasympathetic divisions, which integrate and coordinate visceral functions throughout the body. We consider the enteric nervous system in Section 16-8, when we discuss visceral reflexes, and again when we examine the control of digestion in Chapter 24.

Checkpoint

1. **Identify the two major divisions of the ANS.**
2. **How many motor neurons are needed to carry an action potential from the spinal cord to smooth muscles in the wall of the intestine?**
3. **While out for a walk, Julie suddenly meets an angry dog. Which division of the ANS is responsible for the physiological changes that occur in Julie as she turns and runs?**

See the blue Answers tab at the back of the book.

16-2 The sympathetic division has short preganglionic fibers and long postganglionic fibers and is involved in using energy and increasing metabolic rate

Learning Outcome Describe the structures and functions of the sympathetic division of the autonomic nervous system.

Spotlight Figure 16–2a shows the overall organization of the sympathetic division of the ANS, which is responsible for mobilizing the body's energy and resources to respond to stressful situations. This division consists of:

- *Short Preganglionic Fibers in Thoracic and Lumbar Segments of the Spinal Cord.* This division is also called the *thoracolumbar division* because its preganglionic neurons are located between segments T_1 and L_2 of the spinal cord. The cell bodies of the preganglionic neurons are in the lateral horns, and their axons enter the anterior roots of these segments.
- *Ganglionic Neurons in Ganglia near the Spinal Cord.* The preganglionic fibers are relatively short because the ganglia are located near the spinal cord. They release acetylcholine (ACh), stimulating ganglionic neurons.
- *Long Postganglionic Fibers to Target Organs.* The postganglionic fibers are relatively long. (An exception occurs at the adrenal medullae, which we discuss later in this section.)

Functional Organization of the Sympathetic Division

Spotlight Figure 16–2a provides a detailed view of the sympathetic division as a whole. The left side of the figure shows the somatic distribution to the skin, skeletal muscles, and other tissues of the body wall. The right side shows the innervation of visceral organs.

Sympathetic preganglionic fibers originate from the lateral horns and become part of the spinal anterior roots. We described the basic pattern of sympathetic innervation in these regions in **Spotlight Figure 13–8**, pp. 444–445. After passing through the intervertebral foramen, each anterior root gives rise to a myelinated white ramus communicans, which carries myelinated preganglionic fibers into a nearby *sympathetic chain ganglion* found on either side of the vertebral column. These fibers diverge extensively, with one preganglionic fiber synapsing on two dozen or more ganglionic neurons. Preganglionic fibers running between the sympathetic chain ganglia interconnect them, making the chain look like a string of pearls. Each sympathetic chain ganglion innervates a particular body organ or group of organs.

Where ganglionic neurons synapse, or which pathway they follow, determines which target organs they will affect. These neurons may synapse in three locations: within the sympathetic chain ganglia, and/or at one of the collateral ganglia, or in the adrenal medullae (**Figure 16–3**).

- *Sympathetic Chain Ganglia.* **Sympathetic chain ganglia**, also called *paravertebral ganglia*, lie on each side of the vertebral column (**Figure 16–3a**). Neurons in these ganglia control effectors in the body wall, the thoracic cavity, head, neck, and limbs.
- *Collateral Ganglia.* **Collateral ganglia**, also known as *prevertebral ganglia*, are anterior to the vertebral column (**Figure 16–3b**). Collateral ganglia contain ganglionic neurons that innervate abdominopelvic tissues and viscera.
- *Adrenal Medullae.* The center of each adrenal (*ad-*, near + *renal*, kidney) gland, the **adrenal medulla**, is a modified sympathetic ganglion (**Figure 16–3c**). The ganglionic neurons of the adrenal medullae have very short axons. When these medullary cells are stimulated, they secrete neurotransmitters directly into the bloodstream, not at a synapse. This mode of release allows the neurotransmitters to function as *hormones*, affecting target cells throughout the body.

Sympathetic Chain Ganglia Pathway: Upper Body

If a preganglionic fiber carries motor commands targeting structures in the body wall, thoracic cavity, head, neck, or limbs, it synapses in one or more sympathetic chain ganglia. Each sympathetic chain contains 3 cervical, 10–12 thoracic, 4–5 lumbar, and 4–5 sacral ganglia, plus 1 coccygeal ganglion. (The numbers vary because adjacent ganglia sometimes fuse.) Preganglionic neurons are limited to spinal cord segments T_1–L_2, and these spinal nerves have both *white rami* communicantes (myelinated preganglionic fibers) and *gray rami* communicantes (unmyelinated postganglionic fibers). The neurons in the cervical, inferior lumbar, and sacral sympathetic chain ganglia are innervated by preganglionic fibers that run along the axis of the chain. In turn, these chain ganglia provide postganglionic fibers, through gray rami communicantes, to the cervical, lumbar, and sacral spinal nerves. As a result, only spinal nerves T_1–L_2 have white rami communicantes, and every spinal nerve has a gray ramus communicans that carries sympathetic postganglionic fibers for distribution in the body wall.

The unmyelinated postganglionic fibers then follow one of two different paths, depending on where their targets lie:

- Postganglionic fibers that control visceral effectors in the body wall, head, neck, or limbs enter the gray ramus communicans and return to the spinal nerve for subsequent distribution (see **Figure 16–3a**, right). These postganglionic fibers innervate sweat glands, smooth muscles in superficial blood vessels, and arrector pili muscles in the skin (see **Spotlight Figure 16–2a**).
- Postganglionic fibers innervating visceral organs in the thoracic cavity, such as the heart and lungs, form bundles known as **sympathetic nerves** (see **Figure 16–3a**, left).

For the sake of clarity, **Figure 16–3a** shows sympathetic nerves on the left side and spinal nerve distribution on the right but in reality *both* innervation patterns occur on *each* side of the body.

The spinal nerves provide somatic motor innervation to skeletal muscles of the body wall and limbs, but they also distribute sympathetic postganglionic fibers (see **Figure 16–3a** and **Spotlight Figure 16–2a**). About 8 percent of the axons in each spinal nerve are sympathetic postganglionic fibers. In the head and neck, sympathetic postganglionic fibers leaving the superior cervical sympathetic ganglia supply the regions and structures innervated by cranial nerves III, VII, IX, and X. ↩ pp. 497, 500, 502

In summary:

- The cervical, inferior lumbar, and sacral chain ganglia receive preganglionic fibers from spinal segments T_1–L_2.
- Only the thoracic and superior lumbar ganglia (T_1–L_2) receive preganglionic fibers from white rami communicantes.
- Every spinal nerve receives a gray ramus communicans from a ganglion of the sympathetic chain.

Collateral Ganglia Pathway: Abdominopelvic Cavity

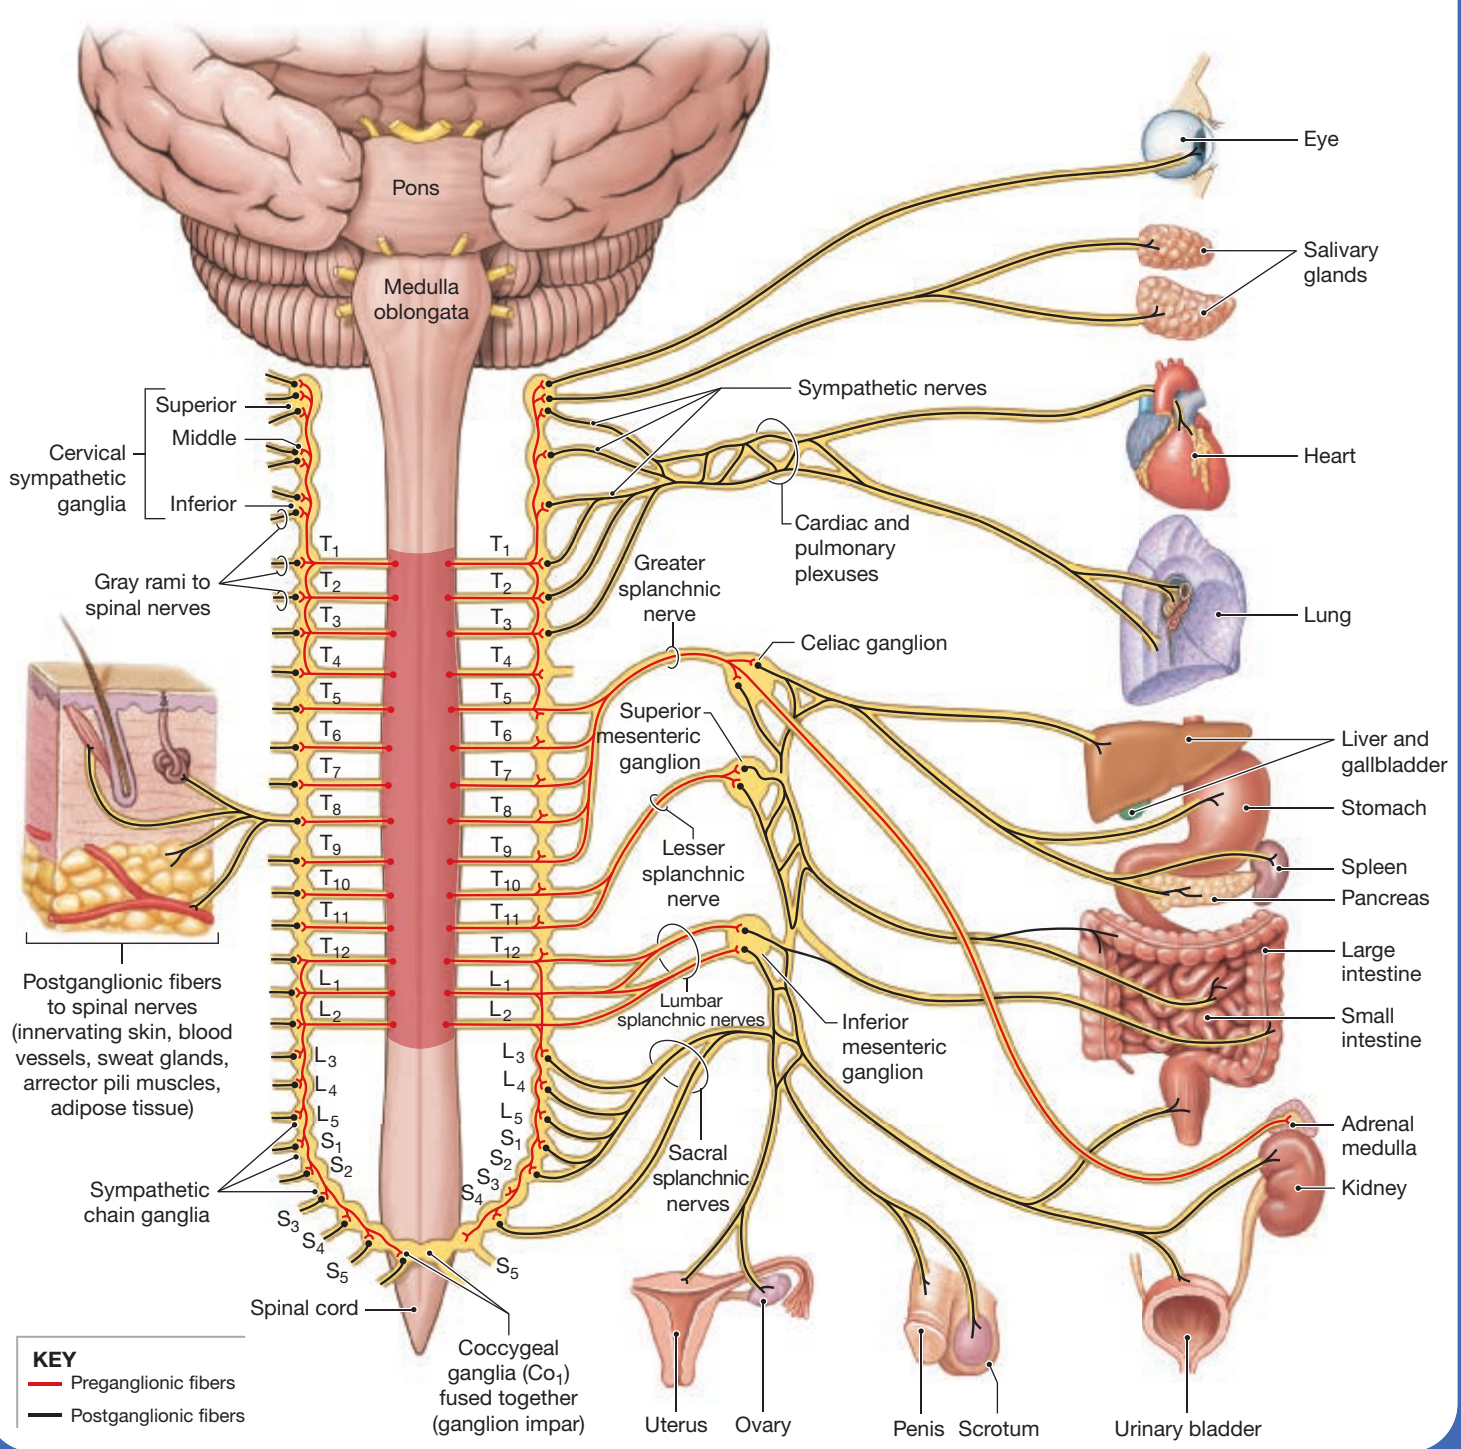
The abdominopelvic viscera receive sympathetic innervation by sympathetic preganglionic fibers that synapse in separate collateral ganglia (**Figure 16–3b**). These fibers pass through the sympathetic chain without synapsing. They form the *splanchnic* (SPLANK-nik) *nerves*, which lie in the posterior wall of the abdominal cavity. In adults the collateral ganglia are typically

Figure 16–2
The Autonomic Nervous System

AUTONOMIC NERVOUS SYSTEM

Consists of two divisions

a Sympathetic Division (Thoracolumbar Division)



b Parasympathetic Division (Craniosacral Division)

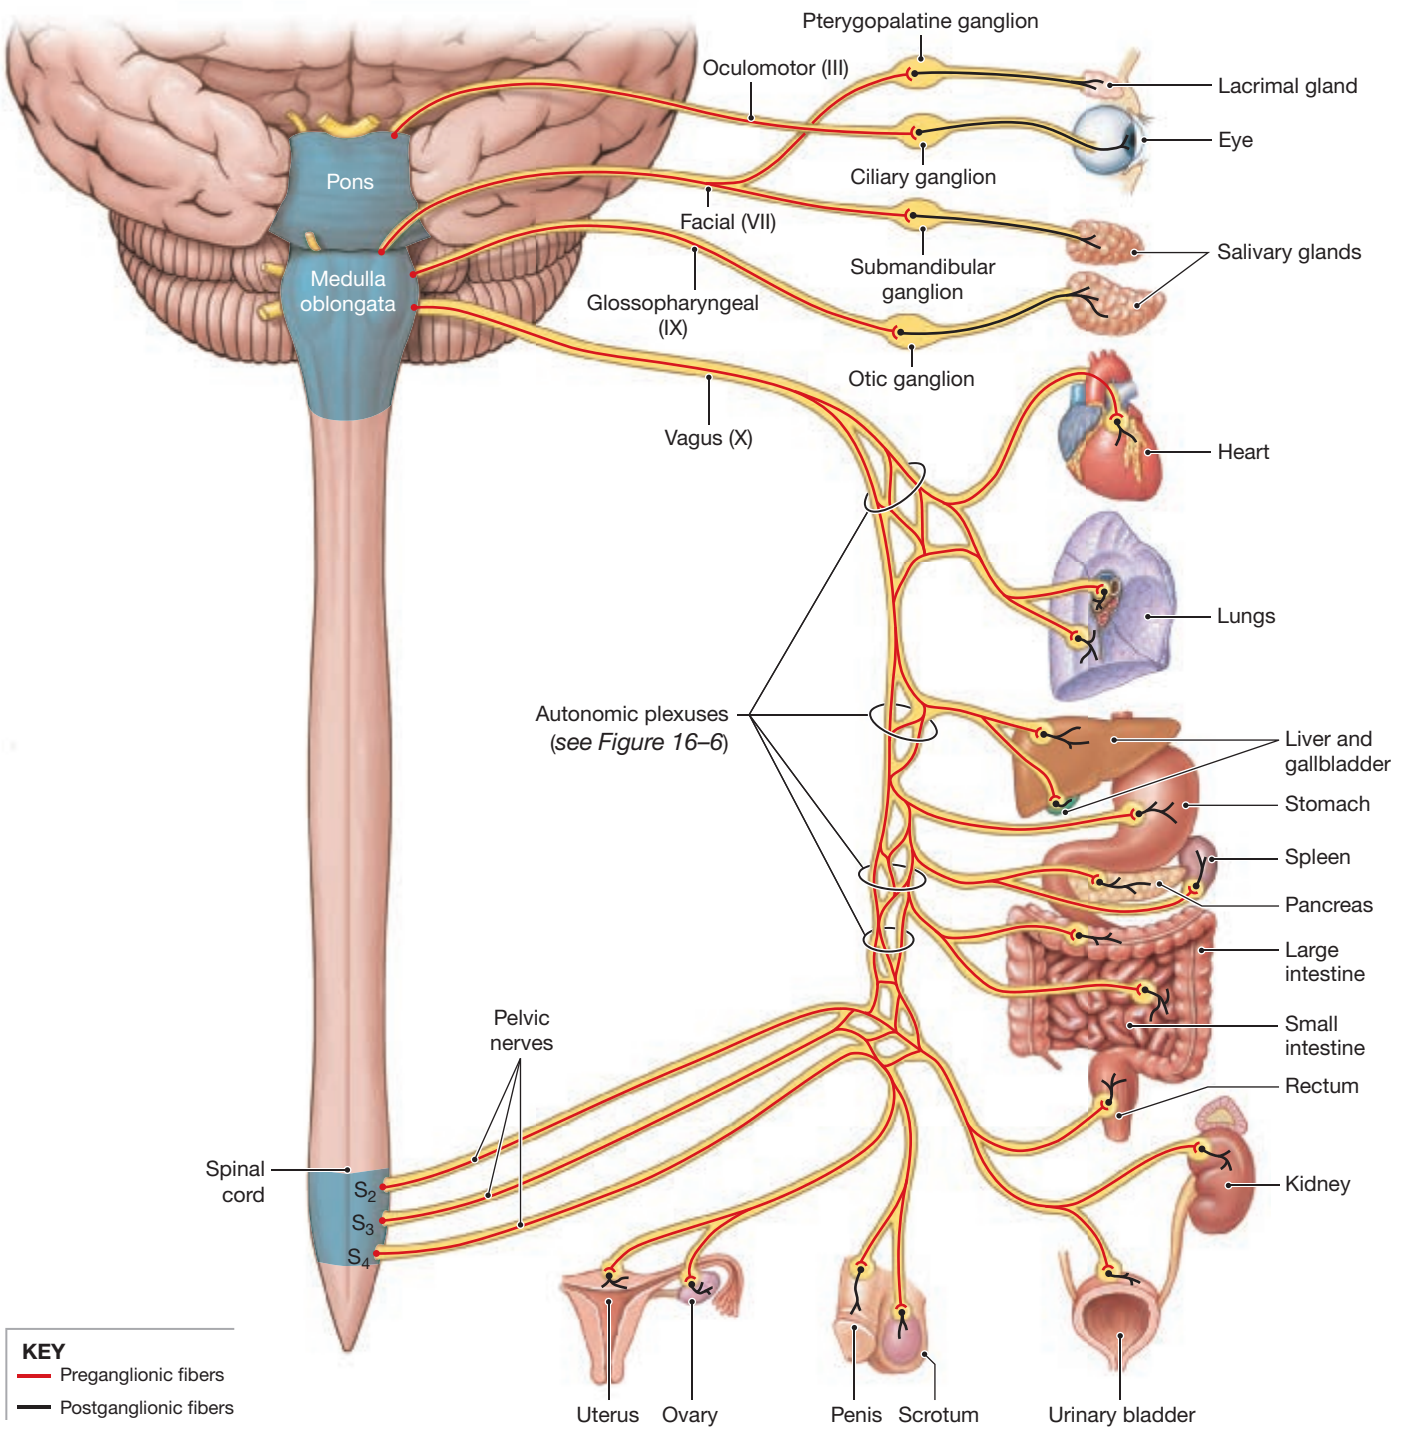


Figure 16–3 Sites of Ganglia in Sympathetic Pathways. Inferior views of sections through the thoracic spinal cord, showing the three major patterns of distribution for preganglionic and postganglionic fibers.

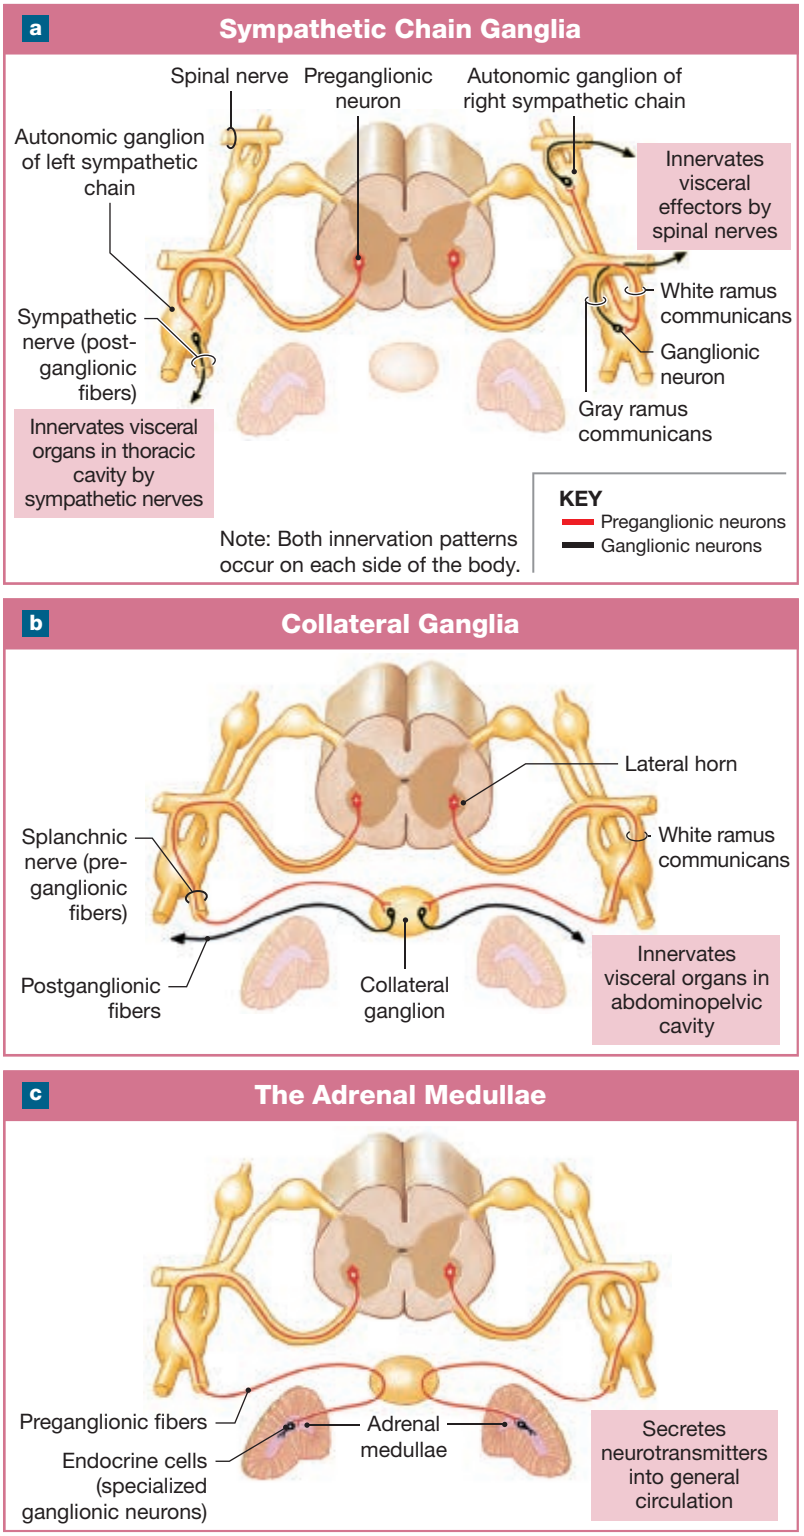

? Which type of ganglionic neuron innervates visceral organs in the abdominopelvic cavity?

single rather than paired. They originate as paired ganglia (left and right), but the two usually fuse.

Postganglionic fibers leaving the collateral ganglia extend throughout the abdominopelvic cavity, innervating a variety of visceral tissues and organs. Their general function is to (1) reduce blood flow and energy use by organs that are not important to immediate survival (such as the digestive tract) and (2) release stored energy.

The preganglionic **splanchnic nerves** innervate three collateral ganglia. Preganglionic fibers from the seven inferior thoracic spinal segments end at either the *celiac* (SĒ-lē-ak) *ganglion* or the *superior mesenteric ganglion* (see **Spotlight Figure 16–2a**). Preganglionic fibers from the lumbar segments form splanchnic nerves that end at the *inferior mesenteric ganglion*. All three ganglia are named after nearby arteries:

- The **celiac ganglion** is named after the *celiac trunk*, a major artery and its branches supplying the stomach, spleen, and liver. The celiac ganglion commonly consists of a pair of interconnected masses of gray matter located at the base of that artery. The celiac ganglion may also form a single mass or many small, interwoven masses. Postganglionic fibers from this ganglion innervate the stomach, liver, gallbladder, pancreas, and spleen.
- The **superior mesenteric ganglion** is found near the base of the *superior mesenteric artery*, which provides blood to the stomach, small intestine, and pancreas. Postganglionic fibers leaving the superior mesenteric ganglion innervate the small intestine and the proximal two-thirds of the large intestine.
- The **inferior mesenteric ganglion** is located near the base of the *inferior mesenteric artery*, which supplies the large intestine and other organs in the inferior portion of the abdominopelvic cavity. Postganglionic fibers from this ganglion provide sympathetic innervation to the kidneys, urinary bladder, terminal segments of the large intestine, and the sex organs.

Adrenal Medulla Pathway: Metabolic Effects

Preganglionic fibers entering an adrenal gland proceed to the central **adrenal medulla** (see **Figure 16–3c** and **Spotlight Figure 16–2a**). In this modified sympathetic ganglion, preganglionic fibers synapse on secretory cells that secrete the neurotransmitters *epinephrine* (or *adrenaline*) and *norepinephrine* (or *noradrenaline*). Epinephrine makes up 75–80 percent of the secretory output; the rest is norepinephrine.

The bloodstream carries the neurotransmitters throughout the body, where they cause changes in the metabolic activities of many different cells. These effects resemble those produced by the stimulation of sympathetic postganglionic fibers. They differ, however, in two respects: (1) Cells not innervated by sympathetic postganglionic fibers are affected; and (2) the effects last much longer than those produced by direct sympathetic innervation, because the chemicals continue to diffuse out of the bloodstream for an extended period.

Sympathetic Activation

The sympathetic division can change the activities of tissues and organs by releasing norepinephrine at peripheral synapses, and by distributing epinephrine and norepinephrine throughout the body in the bloodstream. The visceral motor fibers that target specific effectors, such as smooth muscle fibers in blood vessels of the skin, can be activated in reflexes that do not involve other visceral effectors.

In a crisis, however, the entire division responds. This event, called **sympathetic activation**, is controlled by sympathetic centers in the hypothalamus. The effects are not limited to peripheral tissues, because sympathetic activation also alters CNS activity. When sympathetic activation occurs, a person experiences the following changes:

- Increased alertness by stimulation of the reticular activating system, causing the individual to feel "on edge."
- A feeling of energy and euphoria, often associated with a disregard for danger and a temporary insensitivity to painful stimuli.
- Increased activity in the cardiovascular and respiratory centers of the pons and medulla oblongata, which increases blood pressure, heart rate, breathing rate, and depth of respiration.
- A general elevation in muscle tone through stimulation of the medial and lateral pathways, so the person *looks* tense and may begin to shiver.
- The mobilization of energy reserves, through the accelerated breakdown of glycogen in muscle and liver cells and the release of lipids by adipose tissues.

These changes, plus the peripheral changes already noted, prepare the person to cope with a stressful situation.

4. **Describe the positions of the sympathetic chain ganglia and collateral ganglia relative to the vertebral column.**
5. **Where do the nerves that synapse in collateral ganglia originate?**

See the blue Answers tab at the back of the book.

16-3 Different types of neurotransmitters and receptors lead to different sympathetic effects

Learning Outcome Describe the types of neurotransmitters and receptors and explain their mechanisms of action.

We have examined the structure of the sympathetic division of the ANS and the general effects of sympathetic activation. Now let's consider the cellular basis of these effects on peripheral organs.

When stimulated, sympathetic preganglionic neurons release *acetylcholine (ACh)* at synapses with ganglionic neurons. Synapses that use ACh as a transmitter are called *cholinergic.* p. 418 The effect on the ganglionic neurons is always excitatory.

These ganglionic neurons then release neurotransmitters at specific target organs. The axon terminals differ from those at neuromuscular (nerve to muscle cell) junctions of the somatic nervous system. In the sympathetic nervous system, the telodendria form a branching network, with each branch resembling a string of pearls. Each "pearl" is a swollen segment called a **varicosity** that is packed with neurotransmitter vesicles (Figure 16–4). Chains of varicosities are found along or near the surfaces of effector cells such as smooth muscle cells. These cells have no specialized postsynaptic membranes, such as the motor end plates in skeletal muscle cells. Instead, membrane receptors are scattered across the surfaces of the target cells.

Most sympathetic ganglionic neurons release norepinephrine (NE) at their varicosities. Neurons that release NE are called *adrenergic.* p. 420 A small but significant number of ganglionic neurons in the sympathetic division release ACh rather than NE. Varicosities releasing ACh are located in the body wall, the skin, the brain, and skeletal muscles.

The NE released by varicosities affects its targets until it is reabsorbed or inactivated by enzymes. Fifty to 80 percent of the NE is reabsorbed by varicosities and is either reused or broken down by the enzyme *monoamine oxidase (MAO).* The rest of the NE diffuses out of the area or is broken down by the enzyme *catechol-O-methyltransferase (COMT)* in surrounding tissues.

In general, the effects of NE on the postsynaptic membrane last for a few seconds, significantly longer than the 20-msec duration of ACh effects. (As usual, the responses of the target cells vary with the nature of their receptors.) When the adrenal medullae release norepinephrine (NE) and epinephrine (E) into the bloodstream, the effects last even longer because (1) the bloodstream does not contain MAO or COMT, and (2) most tissues contain relatively low concentrations of those enzymes. After the adrenal medullae are stimulated, tissue concentrations of norepinephrine and epinephrine throughout the body may remain elevated for as long as 30 seconds, and the effects may persist for several minutes. Let's look at the nature of the receptors that these neurotransmitters stimulate, and the effects of such stimulation.

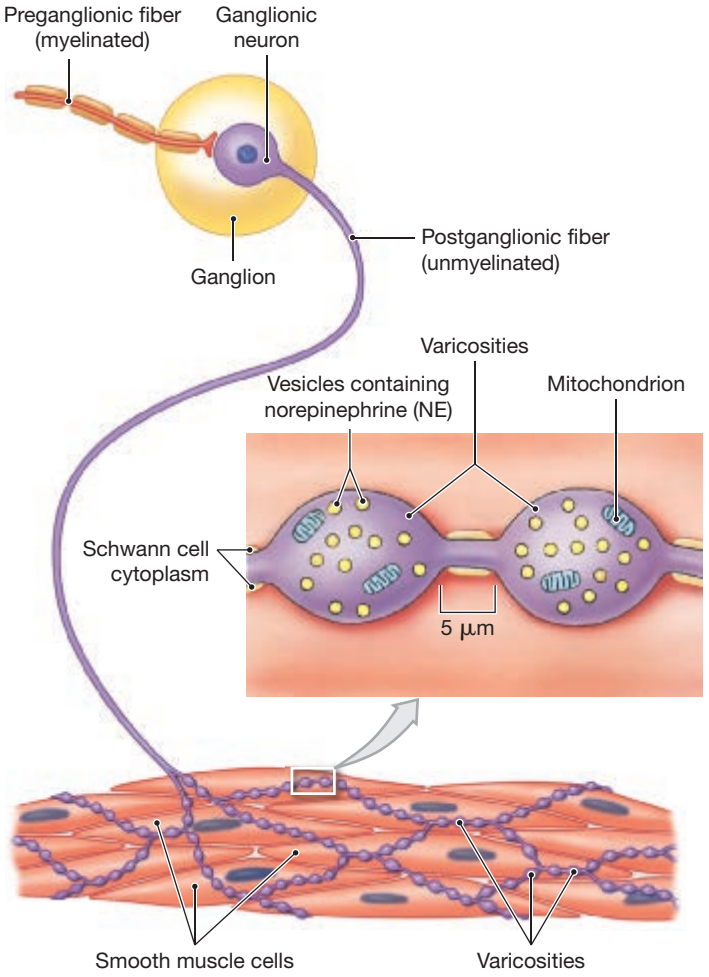
Figure 16–4 Sympathetic Varicosities.



? What neurotransmitter is released from most varicosities in the sympathetic division?

Effects of Sympathetic Stimulation of Adrenergic Synapses and Receptors

The effects of sympathetic stimulation result primarily from the interactions of NE and E with adrenergic membrane receptors. There are two classes of these receptors: *alpha receptors* and *beta receptors.* In general, NE stimulates alpha receptors to a greater degree than it does beta receptors, and E stimulates both classes of receptors. For this reason, localized sympathetic activity, involving the release of NE at varicosities, primarily affects nearby alpha receptors. By contrast, generalized sympathetic activation and the release of E by the adrenal medullae affect both alpha and beta receptors throughout the body.

Alpha receptors and beta receptors are *G-protein–coupled receptors.* As we saw in Chapter 12, the effects of stimulating such a receptor depend on the production of *second messengers*, intracellular intermediaries with varied functions. ↩ p. 421

Alpha Receptors

The stimulation of **alpha (α) receptors** activates their associated G proteins on the cytoplasmic surface of the plasma membrane. There are two types of alpha receptors: *alpha-1* (α_1) and *alpha-2* (α_2).

- Alpha-1 receptors, the more common type of alpha receptor, are found primarily in smooth muscle cells of many different organs. The stimulation of this receptor results in G protein activation that brings about the release of intracellular calcium ions into the cytosol from reserves in the endoplasmic reticulum. This action generally has an excitatory effect on the target cell. For example, the stimulation of α_1 receptors on smooth muscle cells causes peripheral blood vessels to constrict and sphincters along the digestive tract and urinary bladder to close.
- Alpha-2 receptors are found on preganglionic sympathetic neurons. Stimulation of α_2 receptors and G protein activation result in a lowering of the cyclic-AMP (cAMP) level in the cytoplasm. Cyclic-AMP is an important second messenger that can activate or inactivate key enzymes. ↩ p. 424 This decrease generally has an inhibitory effect on the cell. The presence of α_2 receptors in the parasympathetic division helps coordinate sympathetic and parasympathetic activities. When the sympathetic division is active, the NE released binds to α_2 receptors at parasympathetic neuromuscular and neuroglandular junctions and inhibits their activity.

Beta Receptors

Beta (β) receptors are located on the plasma membranes of cells in many organs, including skeletal muscles, the lungs, the heart, and the liver. The stimulation of beta receptors and G protein activation trigger changes in the metabolic activity of the target cell. These changes occur indirectly, as G protein activation results in an increase in intracellular cAMP levels. There are three major types of beta receptors: *beta-1* (β_1), *beta-2* (β_2), and *beta-3* (β_3).

- The stimulation of β_1 receptors leads to an increase in metabolic activity. For example, the stimulation of β_1 receptors in skeletal muscles accelerates the metabolic activities of the muscles. The stimulation of β_1 receptors in the heart increases heart rate and force of contraction.
- The stimulation of β_2 receptors causes inhibition, triggering the relaxation of smooth muscles along the respiratory tract. As a result, respiratory passageways dilate, making breathing easier. The inhalers used to treat asthma trigger this response.
- The β_3 receptor is found in adipose tissue. Stimulation of β_3 receptors leads to *lipolysis*, the breakdown of triglycerides stored within adipocytes. The fatty acids generated through lipolysis are released into the bloodstream for use by other tissues.

Effects of Sympathetic Stimulation on Other Types of Synapses

The vast majority of sympathetic postganglionic fibers are adrenergic (release NE), but as we noted, a few are cholinergic (release ACh). These postganglionic fibers innervate skin sweat glands and the blood vessels to skeletal muscles and the brain. The activation of these sympathetic fibers stimulates sweat gland secretion and dilates the blood vessels.

In some areas of the body, the sympathetic division requires the use of two types of synapses. For example, in the body wall and skeletal muscles, both ACh and NE are needed to regulate visceral functions with precision. ACh causes most small peripheral arteries to dilate (*vasodilation*), and NE causes them to constrict (*vasoconstriction*). This means that the sympathetic division can increase blood flow to skeletal muscles by releasing ACh to activate cholinergic synapses. At the same time, it can reduce the blood flow to other tissues in the body wall, by releasing NE to stimulate adrenergic synapses.

The sympathetic division also includes *nitroxidergic synapses*, which release *nitric oxide (NO)* as a neurotransmitter. Such synapses occur where neurons innervate smooth muscles in the walls of blood vessels in many regions, notably in skeletal muscles and the brain. The activity of these synapses produces vasodilation and increased blood flow through these regions.

Checkpoint

16-4 The parasympathetic division has long preganglionic fibers and short postganglionic fibers and is involved in conserving energy and lowering metabolic rate

Learning Outcome Describe the structures and functions of the parasympathetic division of the autonomic nervous system.

The parasympathetic division of the ANS is responsible for conserving the body's energy and maintaining the resting metabolic rate. This division (**Spotlight Figure 16–2b**) consists of:

- *Long Preganglionic Fibers in the Brainstem and in Sacral Segments of the Spinal Cord.* All parts of the brainstem, the midbrain, pons, and medulla oblongata, contain autonomic nuclei associated with several cranial nerves. In sacral segments of the spinal cord, the parasympathetic nuclei lie in the lateral horns of spinal segments S_2–S_4. This divided pattern of neuron locations explains why the parasympathetic division is also called the *craniosacral division*.
- *Ganglionic Neurons in Peripheral Ganglia within or Adjacent to Target Organs.* Preganglionic fibers of the parasympathetic division do not diverge as extensively as do those of the sympathetic division. A typical preganglionic fiber synapses on six to eight ganglionic neurons, all in the same ganglion. The ganglion may be a **terminal ganglion**, located near the target organ, or an **intramural** (*murus*, wall) **ganglion**, embedded in the tissues of the target organ. Terminal ganglia are usually paired. Intramural ganglia typically consist of interconnected masses and clusters of ganglion cells.
- *Short Postganglionic Fibers in or near Target Organs.* The postganglionic fibers then extend from the terminal or intramural ganglion to the target organ. Having the ganglia and postganglionic neurons near the target organs makes the effects of parasympathetic stimulation very specific and localized.

Let's look at the organization of this division more closely, and at what happens when the division is activated.

Functional Organization of the Parasympathetic Division

Parasympathetic fibers innervate organs of three main regions: the cranial, trunk, and pelvic regions.

Parasympathetic preganglionic fibers leave the brain in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus) (**Spotlight Figure 16–2b**). These fibers carry the cranial parasympathetic output to visceral structures in the head. These fibers synapse in the *ciliary*, *pterygopalatine*, *submandibular*, and *otic ganglia*. pp. 497, 499, 500 Short postganglionic fibers continue to their peripheral targets.

The vagus nerve alone provides roughly 75 percent of all parasympathetic outflow (output from nerves leaving the CNS). It supplies preganglionic parasympathetic innervation to structures in the neck and in the thoracic and abdominopelvic cavities as distant as the distal portion of the large intestine. The many branches of the vagus nerve mingle with preganglionic and postganglionic fibers of the sympathetic division, forming plexuses comparable to those formed by spinal nerves innervating the limbs. We consider these plexuses in Section 16-7.

The preganglionic fibers in the sacral segments of the spinal cord carry the sacral parasympathetic output. These fibers do not join the anterior roots of the spinal nerves. Instead, they form distinct **pelvic nerves**, which innervate intramural ganglia in the walls of the kidneys, urinary bladder, terminal portions of the large intestine, and sex organs.

Parasympathetic Activation

The functions of the parasympathetic division center on relaxation, food processing, and nutrient absorption. This division has been called the *anabolic system* (*anabole*, a raising up), because its stimulation leads to a general increase in the nutrient content of the blood. In response to this increase, cells throughout the body absorb nutrients and use them to support growth and cell division and to create energy reserves in the form of lipids or glycogen.

The major effects of the parasympathetic division include the following:

- Constriction of the pupils (to restrict the amount of light that enters the eyes) and focusing of the lenses of the eyes on nearby objects.
- Secretion by digestive glands, including salivary glands, gastric glands, duodenal glands, intestinal glands, the pancreas (exocrine and endocrine), and the liver.
- The secretion of hormones that promote the absorption and use of nutrients by peripheral cells.
- Changes in blood flow and glandular activity associated with sexual arousal.
- An increase in smooth muscle activity along the digestive tract.
- The stimulation and coordination of defecation.
- Contraction of the urinary bladder during urination.
- Constriction of the respiratory passageways.
- A reduction in heart rate and force of contraction.

16-5 Different types of receptors lead to different parasympathetic effects

Learning Outcome Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues.

All parasympathetic neurons release ACh as a neurotransmitter. The effects on the postsynaptic cell can vary widely, however, due to different types of receptors or to the nature of the second messenger involved.

Effects of Parasympathetic Stimulation of Cholinergic Receptors

When parasympathetic neurons release ACh, the neurotransmitter may affect neurons, muscle fibers, or effector cells. The effects of stimulation are both localized and short lived. Most of the ACh released is inactivated at the synapse by *acetylcholinesterase (AChE)*. Any ACh diffusing into the surrounding tissues is inactivated by the enzyme *tissue cholinesterase*.

The effects of ACh release depend to a large degree on what type of cholinergic receptor is stimulated. Two types of cholinergic receptors occur on the postsynaptic membranes: *nicotinic* and *muscarinic*.

Nicotinic Receptors

Nicotinic (nik-ō-TIN-ik) **receptors** occur on ganglion cells of both the parasympathetic and sympathetic divisions. (They also occur at neuromuscular junctions of the somatic nervous system.) When ACh activates nicotinic receptors, it opens chemically gated Na^+ channels in the postsynaptic membrane of the ganglionic neuron or motor end plate of the muscle fiber, which always causes excitation of that cell.

Muscarinic Receptors

Muscarinic (mus-kah-RIN-ik) **receptors** occur at cholinergic neuromuscular or neuroglandular junctions in the parasympathetic division. They also occur at the few cholinergic junctions in the sympathetic division. Muscarinic receptors are G protein–coupled receptors. Their stimulation and G protein activation produce longer-lasting effects than does the stimulation of nicotinic receptors. The response can be excitatory or inhibitory, depending on the activation or inactivation of specific enzymes.

Effects of Toxins on Cholinergic Receptors

The names *nicotinic* and *muscarinic* originated with researchers who found that dangerous environmental toxins bind to these receptor sites. Nicotinic receptors bind *nicotine*, a powerful toxin obtained from a variety of sources, including tobacco leaves. Muscarinic receptors are stimulated by *muscarine*, a toxin produced by some poisonous mushrooms.

These toxins have completely separate actions. Nicotine targets the autonomic ganglia and skeletal neuromuscular junctions. Muscarine acts at the parasympathetic neuromuscular or neuroglandular junctions. They produce dangerously exaggerated, uncontrolled responses due to abnormal stimulation of cholinergic or adrenergic receptors.

Nicotine poisoning occurs if as little as 50 mg of the compound is ingested or absorbed through the skin. (The highest nicotine level in tobacco is about 3 mg per gram.) The signs reflect widespread autonomic activation. They include vomiting, diarrhea, high blood pressure, rapid heart rate, sweating, and profuse salivation. Convulsions may occur because the neuromuscular junctions of the somatic nervous system are also stimulated. In severe cases, the stimulation of nicotinic receptors inside the CNS can lead to coma and death within minutes.

The signs and symptoms of muscarine poisoning are almost entirely restricted to the parasympathetic division. They include salivation, nausea, vomiting, diarrhea, constriction

Table 16–1 Adrenergic and Cholinergic Receptors of the ANS

Receptor	Location	Response	Mechanism
ADRENERGIC			
α_1	Widespread, found in most tissues	Excitation, stimulation of metabolism	Enzyme activation; intracellular release of Ca^{2+}
α_2	Sympathetic neuromuscular or neuroglandular junctions	Inhibition of effector cell	Reduction of cAMP concentration
α_2	Parasympathetic neuromuscular or neuroglandular junctions	Inhibition of neurotransmitter release	Reduction of cAMP concentration
β_1	Heart, kidneys, liver, adipose tissue*	Stimulation, increased energy consumption	Enzyme activation
β_2	Smooth muscle in vessels of heart and skeletal muscle; smooth muscle layers in intestines, lungs, bronchi	Inhibition, relaxation	Enzyme activation
CHOLINERGIC			
Nicotinic	All autonomic synapses between preganglionic and ganglionic neurons; neuromuscular junctions of SNS	Stimulation, excitation; muscular contraction	Opening of chemically gated Na^+ channels
Muscarinic	All parasympathetic and cholinergic sympathetic neuromuscular or neuroglandular junctions	Variable	Enzyme activation causing changes in membrane permeability to K^+

*Adipocytes also contain an additional receptor type, β_3, not found in other tissues. Stimulation of β_3 receptors causes lipolysis.

of respiratory passages, low blood pressure, and an abnormally slow heart rate (bradycardia). Sweating, a sympathetic response, is also prominent. For this reason, *Amanita muscaria*, commonly known as the fly-agaric mushroom, is used in very small amounts in some Native American sweat lodge rituals.

Table 16–1 summarizes details about the adrenergic and cholinergic receptors of the ANS.

Checkpoint

10. What neurotransmitter is released by all parasympathetic neurons?
11. Name the two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons.
12. How would the stimulation of muscarinic receptors in cardiac muscle affect the heart?

See the blue Answers tab at the back of the book.

16-6 The differences in the organization of sympathetic and parasympathetic structures lead to widespread sympathetic effects and specific parasympathetic effects

Learning Outcome Compare and contrast the sympathetic and parasympathetic nervous systems.

Figure 16–5 and Table 16–2 compare key structural features of the sympathetic and parasympathetic divisions of the ANS. The differences in structure lead to differences in functions. The sympathetic division has widespread impact, reaching organs and tissues throughout the body. The parasympathetic division innervates only visceral structures that are supplied by the cranial nerves or that lie within the abdominopelvic cavity.

Figure 16–5 A Summary Comparison of the Sympathetic and Parasympathetic Divisions.

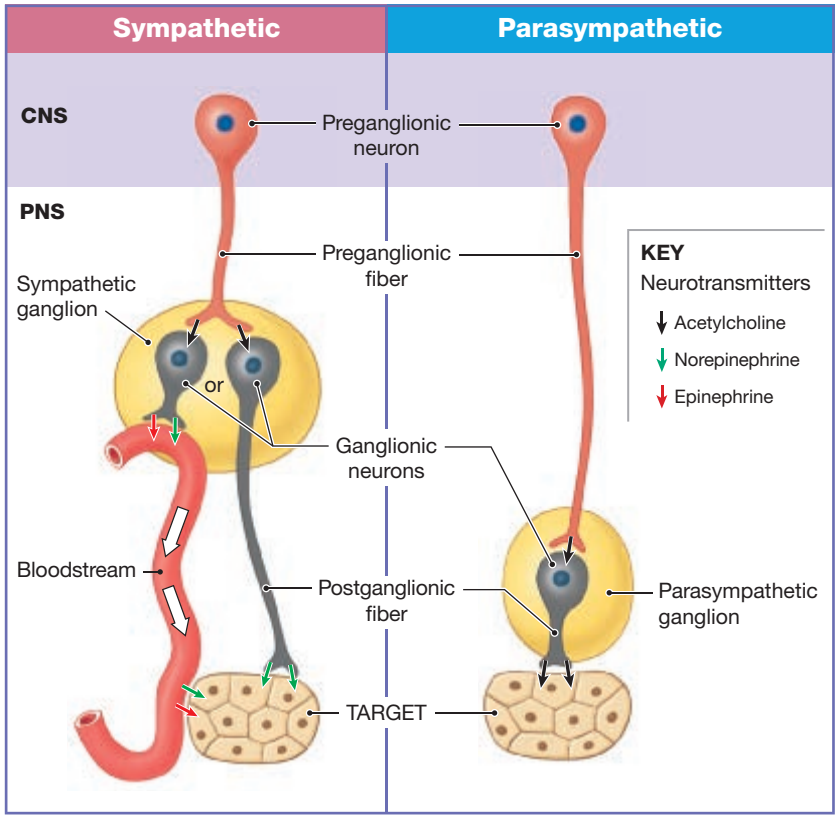

Table 16–2 A Structural Comparison of the Sympathetic and Parasympathetic Divisions of the ANS

Characteristic	Sympathetic Division	Parasympathetic Division
Location of CNS visceral motor neurons	Lateral horns of spinal segments T_1–L_2	Brainstem and spinal segments S_2–S_4
Location of PNS ganglia	Near vertebral column	Typically intramural
Preganglionic fibers		
Length	Relatively short	Relatively long
Neurotransmitter released	Acetylcholine	Acetylcholine
Postganglionic fibers		
Length	Relatively long	Relatively short
Neurotransmitter released	Normally NE; sometimes NO or ACh	Acetylcholine
Neuromuscular or neuroglandular junction	Varicosities and enlarged axonic terminals that release transmitter near target cells	Junctions that release transmitter to special receptor surface
Degree of divergence from CNS to ganglion cells	Approximately 1:32	Approximately 1:6
General function	Stimulates metabolism; increases alertness; prepares for emergency ("fight or flight")	Promotes relaxation, nutrient uptake, energy storage ("rest and digest")

Summary of the Sympathetic Division

16

To summarize:

- The sympathetic division of the ANS includes two sets of sympathetic chain ganglia, one on each side of the vertebral column; three collateral ganglia anterior to the vertebral column; and two adrenal medullae.
- The preganglionic fibers are short, because the ganglia are close to the spinal cord. The postganglionic fibers are longer and extend a considerable distance to their target organs. (In the case of the adrenal medullae, very short axons end at capillaries that carry their secretions to the bloodstream.)
- The sympathetic division shows extensive divergence. That is, a single preganglionic fiber may innervate (form synapses with) two dozen or more ganglionic neurons in different ganglia. As a result, a single sympathetic motor neuron in the CNS can control a variety of visceral effectors and can produce a complex and coordinated response.
- All preganglionic neurons release ACh at their synapses with ganglionic neurons. Most postganglionic fibers release NE, but a few release ACh or NO.
- The effector response depends on the second messengers triggered by G protein activation when NE or E binds to alpha receptors or beta receptors.

Summary of the Parasympathetic Division

In summary:

- The parasympathetic division includes visceral motor nuclei associated with cranial nerves III, VII, IX, and X, and with sacral segments S_2–S_4.
- Ganglionic neurons are located in ganglia within or next to their target organs.
- The parasympathetic division innervates regions serviced by the cranial nerves and organs enclosed by the thoracic and abdominopelvic cavities.
- The parasympathetic division has approximately one-fifth as much divergence as the sympathetic division.
- All parasympathetic neurons are cholinergic. Ganglionic neurons have nicotinic receptors, which are excited by ACh. Muscarinic receptors at neuromuscular or neuroglandular junctions produce either excitation or inhibition, depending on the action of enzymes triggered by G protein activation when ACh binds to the receptor.
- The effects of parasympathetic stimulation are generally brief and restricted to specific organs and sites.

Let's explore next how these different functions provide coordinated responses to changing bodily environments.

Checkpoint

13. **Compare the anatomy of the sympathetic division with that of the parasympathetic division.**
14. **Compare the amount of divergence of the sympathetic division with the parasympathetic division and explain the significance of divergence.**

See the blue Answers tab at the back of the book.

16-7 Dual innervation of organs allows the sympathetic and parasympathetic divisions to coordinate vital functions

Learning Outcome Discuss the functional significance of dual innervation and autonomic tone.

Some organs are innervated by either the sympathetic or parasympathetic division, but most vital organs receive **dual innervation**,

so they receive instructions from both divisions. Where dual innervation exists, the two divisions commonly have opposing effects. Dual innervation with opposing effects is most obvious in the digestive tract, heart, and lungs. At other sites, the responses may be separate or complementary. Table 16–3 provides a functional comparison of the two divisions, noting the effects of sympathetic or parasympathetic activity on specific organs and systems. We also discuss *autonomic tone* in this section, the background level of ANS activation, both with and without dual innervation.

Anatomy of Dual Innervation

In the head, parasympathetic postganglionic fibers from the ciliary, pterygopalatine, submandibular, and otic ganglia travel by the cranial nerves to their peripheral destinations. Sympathetic innervation reaches the same structures by traveling directly from the superior cervical ganglia of the sympathetic chain.

In the thoracic and abdominopelvic cavities, the sympathetic postganglionic fibers mingle with parasympathetic preganglionic fibers, forming a series of nerve networks collectively called *autonomic plexuses.* Nerves leaving these networks travel with the blood vessels and lymphatic vessels that supply visceral organs.

Autonomic fibers entering the thoracic cavity intersect at the **cardiac plexus** and the **pulmonary plexus** (Figure 16–6). These plexuses contain sympathetic and parasympathetic fibers to the heart and lungs, respectively, as well as the parasympathetic ganglia whose output affects those organs. The **esophageal plexus** contains descending branches of the vagus nerves and splanchnic nerves leaving the sympathetic chain on either side.

Figure 16–6 The Autonomic Plexuses and Ganglia.

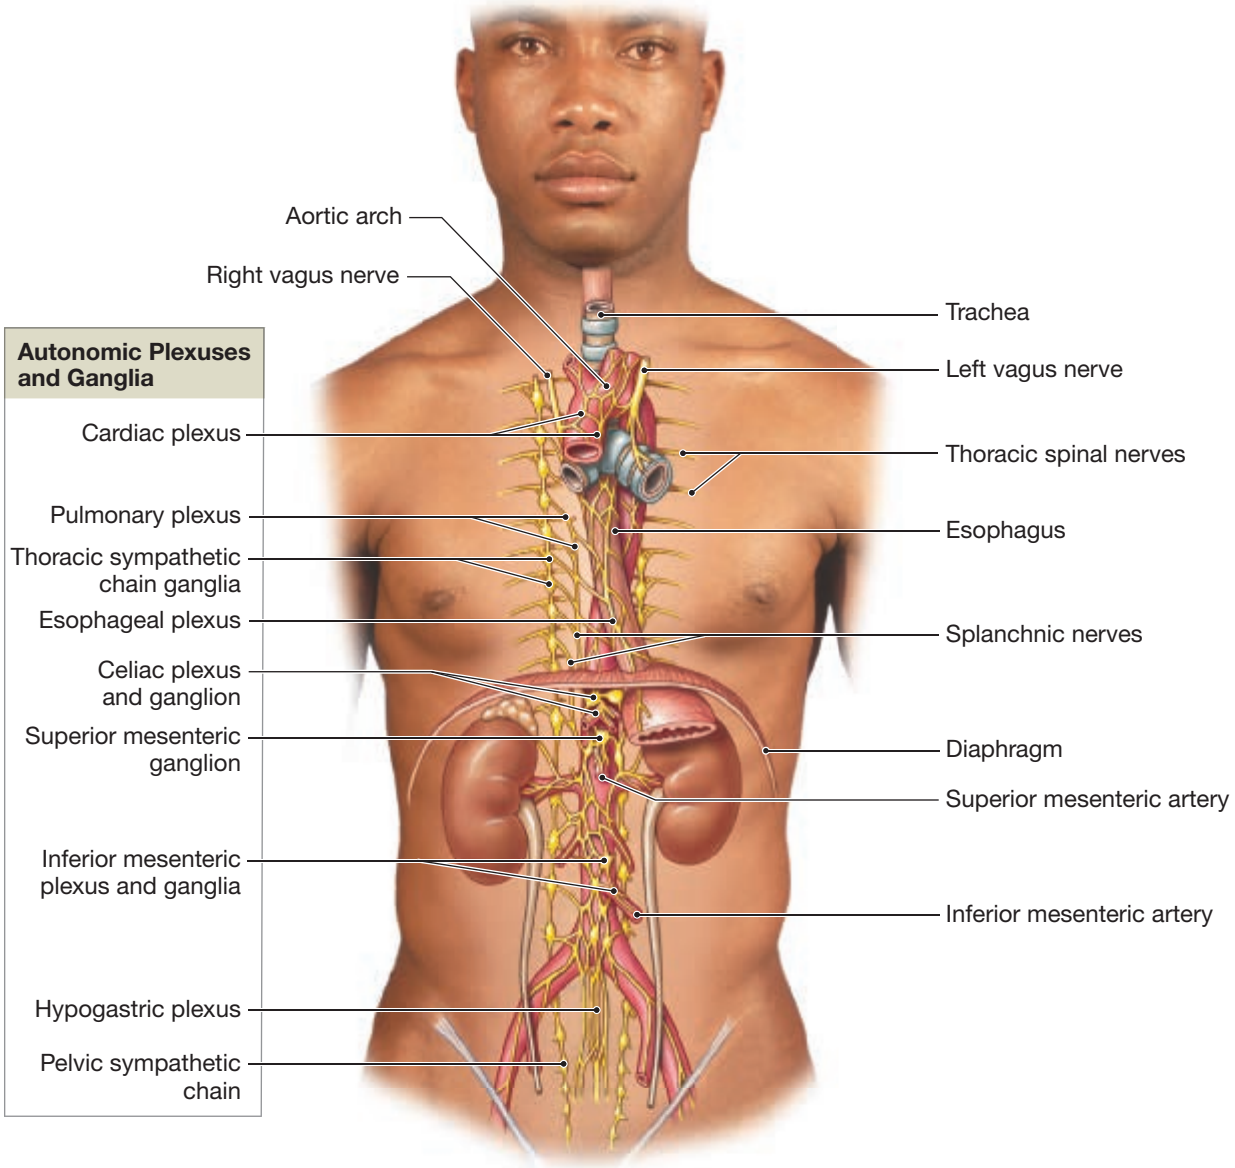

Table 16–3 A Functional Comparison of the Sympathetic and Parasympathetic Divisions of the ANS

Structure	Sympathetic Effects (receptor or synapse type)	Parasympathetic Effects (all muscarinic receptors)
EYE	Dilation of pupil (α_1); accommodation for distance vision (β_2)	Constriction of pupil; accommodation for close vision
Lacrimal glands	None (not innervated)	Secretion
SKIN		
Sweat glands	Increased secretion, palms and soles (α_1); generalized increase in secretion (cholinergic)	None (not innervated)
Arrector pili muscles	Contraction; erection of hairs (α_1)	None (not innervated)
CARDIOVASCULAR SYSTEM		
Blood vessels		None (not innervated)
To skin	Dilation (β_2 and cholinergic); constriction (α_1)	None (not innervated)
To skeletal muscles	Dilation (β_2 and cholinergic; nitroxidergic)	None (not innervated)
To heart	Dilation (β_2); constriction (α_1, α_2)	None (not innervated)
To lungs	Dilation (α_2); constriction (α_1)	None (not innervated)
To digestive viscera	Constriction (β_2); dilation (α_2)	None (not innervated)
To kidneys	Constriction, decreased urine production (α_1, α_2); dilation, increased urine production (β_1, β_2)	None (not innervated)
To brain	Dilation (cholinergic and nitroxidergic)	None (not innervated)
Veins	Constriction (α_1, β_2)	None (not innervated)
Heart	Increased heart rate, force of contraction, and blood pressure (α_1, β_1)	Decreased heart rate, force of contraction, and blood pressure
ENDOCRINE SYSTEM		
Adrenal gland	Secretion of epinephrine, norepinephrine by adrenal medulla	None (not innervated)
Posterior lobe of pituitary gland	Secretion of ADH (β_1, β_2)	None (not innervated)
Pancreas	Decreased insulin secretion (α_2)	Increased insulin secretion
Pineal gland	Increased melatonin secretion (β_1, β_2)	Inhibition of melatonin synthesis
RESPIRATORY SYSTEM		
Airways	Increased airway diameter (β_2)	Decreased airway diameter
Secretory glands	Mucus secretion (α_1)	None (not innervated)
DIGESTIVE SYSTEM		
Salivary glands	Production of viscous secretion (α_1, β_1) containing mucins and enzymes	Production of copious, watery secretion
Sphincters	Constriction (α_1)	Dilation
General level of activity	Decreased (α_2, β_2)	Increased
Secretory glands	Inhibition (α_2)	Stimulation
Liver	Glycogen breakdown, glucose synthesis and release (α_1, β_2)	Glycogen synthesis
Pancreas	Decreased exocrine secretion (α_1)	Increased exocrine secretion
SKELETAL MUSCLES		
	Increased force of contraction, glycogen breakdown (β_2)	None (not innervated)
	Facilitation of ACh release at neuromuscular junction (α_2)	None (not innervated)
ADIPOSE TISSUE	Lipolysis, fatty acid release (α_1, β_1, β_3)	None (not innervated)
URINARY SYSTEM		
Kidneys	Secretion of renin (β_1)	Uncertain effects on urine production
Urinary bladder	Constriction of internal sphincter; relaxation of urinary bladder (α_1, β_2)	Tensing of urinary bladder, relaxation of internal sphincter to eliminate urine
MALE REPRODUCTIVE SYSTEM	Increased glandular secretion and ejaculation (α_1)	Erection
FEMALE REPRODUCTIVE SYSTEM		
	Increased glandular secretion; contraction of pregnant uterus (α_1)	Variable (depending on hormones present)
	Relaxation of nonpregnant uterus (β_2)	Variable (depending on hormones present)

Parasympathetic preganglionic fibers of the vagus nerves enter the abdominopelvic cavity with the esophagus. There the fibers enter the **celiac plexus**, also known as the *solar plexus*. The celiac plexus and associated smaller plexuses, such as the **inferior mesenteric plexus**, innervate viscera within the abdominal cavity (see Figure 16–6). The **hypogastric plexus** innervates the digestive, urinary, and reproductive organs of the pelvic cavity. This plexus contains the parasympathetic outflow of the pelvic nerves, sympathetic postganglionic fibers from the inferior mesenteric ganglion, and splanchnic nerves from the sacral sympathetic chain.

Autonomic Tone

Even without stimuli, autonomic motor neurons show a resting level of spontaneous activity. This background level of activity determines an individual's **autonomic tone**. Autonomic tone is an important aspect of ANS function, just as muscle tone is a key aspect of SNS function. If a nerve is absolutely inactive under normal conditions, then all it can do is increase its activity on demand. But if the nerve maintains a background level of activity, then it can increase or decrease its activity, providing a greater range of control options.

Autonomic tone is significant where dual innervation occurs and the two ANS divisions have opposing effects. It is even more important where dual innervation does not occur. To demonstrate how autonomic tone affects ANS function, let's consider one example of each situation.

The heart receives dual innervation. Recall that the heart consists of cardiac muscle tissue, and that specialized pacemaker cells trigger its contractions. ↩ p. 144 The two autonomic divisions have opposing effects on heart function. Acetylcholine, released by postganglionic fibers of the parasympathetic division, causes a reduction in heart rate. Norepinephrine, released by varicosities of the sympathetic division, accelerates heart rate. Small amounts of both of these neurotransmitters are released continuously, creating autonomic tone. However, the parasympathetic division dominates under resting conditions. Heart rate can be controlled very precisely to meet the demands of active tissues through small adjustments in the balance between parasympathetic and sympathetic stimulation. In a crisis, stimulation of the sympathetic innervation and inhibition of the parasympathetic innervation accelerate the heart rate to the maximum extent possible.

The sympathetic control of blood vessel diameter demonstrates how autonomic tone allows fine adjustment of peripheral activities in target organs that are innervated by only one ANS division. Blood flow to specific organs must be controlled to meet the tissue demands for oxygen and nutrients. When a blood vessel dilates, blood flow through it increases; when it constricts, blood flow is reduced. Sympathetic postganglionic fibers release NE at the smooth muscle cells in the walls of peripheral vessels. This background sympathetic tone keeps these muscles partially contracted, so the blood vessels are ordinarily at about half their maximum diameter. When increased blood flow is needed, the rate of NE release decreases and sympathetic cholinergic fibers are stimulated. As a result, the smooth muscle cells relax, the vessels dilate, and blood flow increases. By adjusting sympathetic tone and the activity of cholinergic fibers, the sympathetic division can exert precise control of vessel diameter over its entire range.

Checkpoint

16-8 Various levels of autonomic regulation allow for the integration and control of autonomic functions

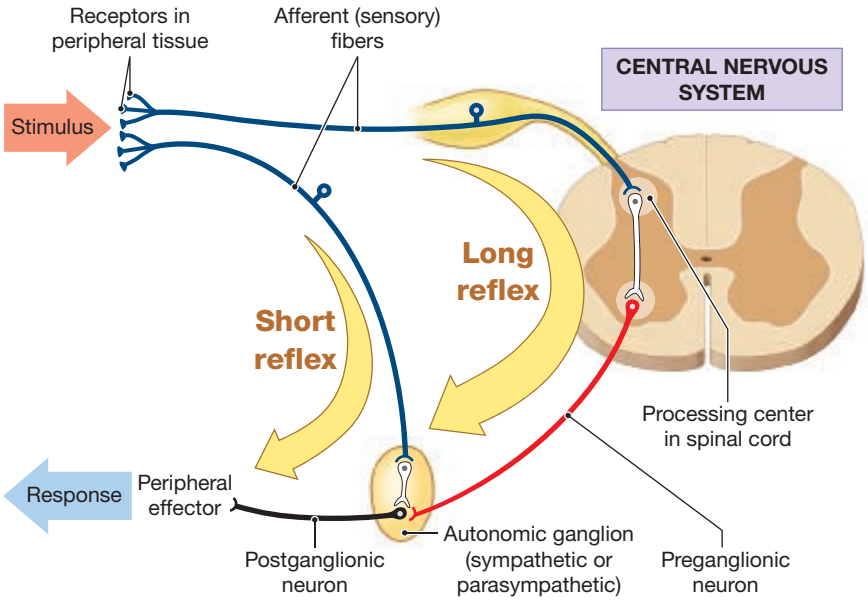
Learning Outcome Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes.

Recall that centers involved in somatic motor control are found in all portions of the CNS, from lower motor neurons involved in cranial and spinal reflex arcs to the pyramidal motor neurons of the primary motor cortex. Similarly, the ANS is also organized into a series of interacting levels. At the lowest level are visceral motor neurons in the lower brainstem and spinal cord that are involved in cranial and spinal visceral reflexes. **Visceral reflexes** are autonomic reflexes initiated in the viscera. As in the SNS, ANS simple reflexes based in the spinal cord respond rapidly and automatically to stimuli. At the highest level, centers in the brainstem that regulate specific visceral functions control the levels of activity of the sympathetic and parasympathetic divisions.

Visceral Reflexes

Visceral reflexes provide automatic motor responses that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus. For example, when a light is shone in one of your eyes, a visceral reflex constricts the pupils of *both* eyes (the *consensual light reflex*). The visceral motor commands are distributed by parasympathetic fibers. In darkness, your pupils dilate, but this *pupillary reflex* is directed by sympathetic fibers. However, the motor nuclei directing pupillary constriction or dilation are also controlled by hypothalamic centers concerned with emotional states. For example, when you are queasy or nauseated, your pupils constrict. When you are sexually aroused, your pupils dilate.

Figure 16–7 Visceral Reflexes. Visceral reflexes have the same basic components as somatic reflexes, but all visceral reflexes are polysynaptic. Note that short visceral reflexes bypass the CNS altogether.



? The short reflex bypasses what part of the nervous system?

Each **visceral reflex arc** consists of a receptor, a sensory neuron, a processing center (one or more interneurons), and two visceral motor neurons (Figure 16–7). All visceral reflexes are polysynaptic. They can be *long reflexes* or *short reflexes*.

Long reflexes are the autonomic equivalents of the polysynaptic reflexes introduced in Chapter 13. ↩ p. 459 Visceral sensory neurons deliver information to the CNS. It travels along the posterior roots of spinal nerves, within the sensory branches of cranial nerves, and within the autonomic nerves that innervate visceral effectors. The processing steps involve interneurons within the CNS. The ANS then carries the motor commands to the appropriate visceral effectors. Long reflexes typically coordinate the activities of an entire organ.

Short reflexes bypass the CNS entirely. They involve sensory neurons and interneurons whose cell bodies lie in autonomic ganglia. These interneurons synapse on postganglionic neurons, and their postganglionic fibers distribute the motor commands. Short reflexes control very simple motor responses with localized effects. In general, short reflexes may control patterns of activity in one small part of a target organ.

In most organs, long reflexes are most important in regulating visceral activities, but this is not the case with the digestive tract and its associated glands. In these areas, short reflexes provide most of the control and coordination for normal functioning. The neurons involved form the enteric nervous system, introduced previously. ↩ p. 391 The ganglia in the walls of the digestive tract contain the cell bodies of visceral sensory neurons, interneurons, and visceral motor neurons, and all their axons form extensive nerve nets. Parasympathetic innervation by visceral motor neurons can stimulate and coordinate various digestive activities, but the enteric nervous system is capable of controlling digestive functions independent of the CNS. We consider the functions of the enteric nervous system further in Chapter 24.

As we examine other body systems in later chapters, you will come across many examples of autonomic reflexes involved in respiration, cardiovascular function, and other visceral activities. Look at Table 16–4 to preview some of the most important ones. Notice that the parasympathetic division participates in a variety of reflexes that affect individual organs and systems. This specialization reflects its relatively restricted pattern of innervation. In contrast, fewer sympathetic reflexes exist. The sympathetic division is typically activated as a whole. One reason is that it has such a high degree of divergence. Another reason is that the release of hormones by the adrenal medullae produces widespread peripheral effects.

Higher Levels of Autonomic Control

Processing centers in the medulla oblongata of the brainstem coordinate more complex sympathetic and parasympathetic reflexes. In addition to the cardiovascular and respiratory centers, the medulla oblongata contains centers and nuclei involved with salivation, swallowing, digestive secretions, peristalsis, and urinary function. These centers are in turn subject to regulation by the hypothalamus. ↩ p. 482

The term *autonomic* was originally applied because the regulatory centers involved with the control of visceral function were thought to operate autonomously—that is, independent of other CNS activities. We now know that because the hypothalamus interacts with all other areas of the brain, activity in the limbic system, thalamus, or cerebral cortex can have dramatic effects on autonomic function. For example, what happens when you become angry? Your heart rate accelerates, your blood pressure rises, and your respiratory rate increases. What happens when you think about your next meal? Your stomach "growls" and your mouth waters.

The Integration of ANS and SNS Activities

Figure 16–8 and Table 16–5 show how the activities of the autonomic nervous system and the somatic nervous system are integrated. We have considered visceral and somatic motor

Table 16–4 Representative Visceral Reflexes

Reflex	Stimulus	Response	Comments
PARASYMPATHETIC REFLEXES			
Gastric and intestinal reflexes *(Chapter 24)*	Pressure and physical contact	Smooth muscle contractions that propel food materials and mix with secretions	Initiated by vagus nerves and controlled locally by ENS
Defecation *(Chapter 24)*	Distention of rectum	Relaxation of internal anal sphincter	Requires voluntary relaxation of external anal sphincter
Urination *(Chapter 26)*	Distention of urinary bladder	Contraction of walls of urinary bladder; relaxation of internal urethral sphincter	Requires voluntary relaxation of external urethral sphincter
Consensual light response *(Chapter 14)*	Bright light shining in eye(s)	Constriction of pupils of both eyes	
Swallowing reflex *(Chapter 24)*	Movement of food and liquids into pharynx	Smooth muscle and skeletal muscle contractions	Coordinated by medullary swallowing center
Coughing reflex *(Chapter 23)*	Irritation of respiratory tract	Sudden explosive ejection of air	Coordinated by medullary coughing center
Baroreceptor reflex *(Chapters 17, 20, 21)*	Sudden rise in carotid blood pressure	Reduction in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata
Sexual arousal *(Chapter 28)*	Erotic stimuli (visual or tactile)	Increased glandular secretions, sensitivity, erection	
SYMPATHETIC REFLEXES			
Cardioacceleratory reflex *(Chapter 21)*	Sudden decline in blood pressure in carotid artery	Increase in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata
Vasomotor reflexes *(Chapter 21)*	Changes in blood pressure in major arteries	Changes in diameter of peripheral vessels	Coordinated in vasomotor center in medulla oblongata
Pupillary light reflex *(Chapter 17)*	Light striking photoreceptors in one eye	Dilation of pupil	
Ejaculation (in males) *(Chapter 28)*	Erotic stimuli (tactile)	Skeletal muscle contractions ejecting semen	

Table 16–5 A Comparison of the ANS and SNS

Characteristic	ANS	SNS
Innervation	Visceral effectors, including cardiac muscle, smooth muscle, glands, adipocytes	Skeletal muscles
Activation	In response to sensory stimuli or from commands of higher centers	In response to sensory stimuli or from commands of higher centers
Relay and processing centers	Brainstem	Brainstem and thalamus
Headquarters	Hypothalamus	Cerebral cortex
Feedback received from	Limbic system and thalamus	Cerebellum and basal nuclei
Control method	Adjustment of activity in brainstem processing centers that innervate preganglionic neurons	Direct (corticospinal) and indirect (medial and lateral) pathways that innervate lower motor neurons
Reflexes	Polysynaptic (short and long)	Monosynaptic and polysynaptic (always long)

pathways separately, but the two have many parallels, in terms of both organization and function. Integration takes place at the level of the brainstem, and both systems are under the influence of higher centers.

Checkpoint

18. Define *visceral reflex.*
19. **Luke has a brain tumor that is interfering with the function of his hypothalamus. Explain why this tumor would interfere with autonomic function.**

See the blue Answers tab at the back of the book.

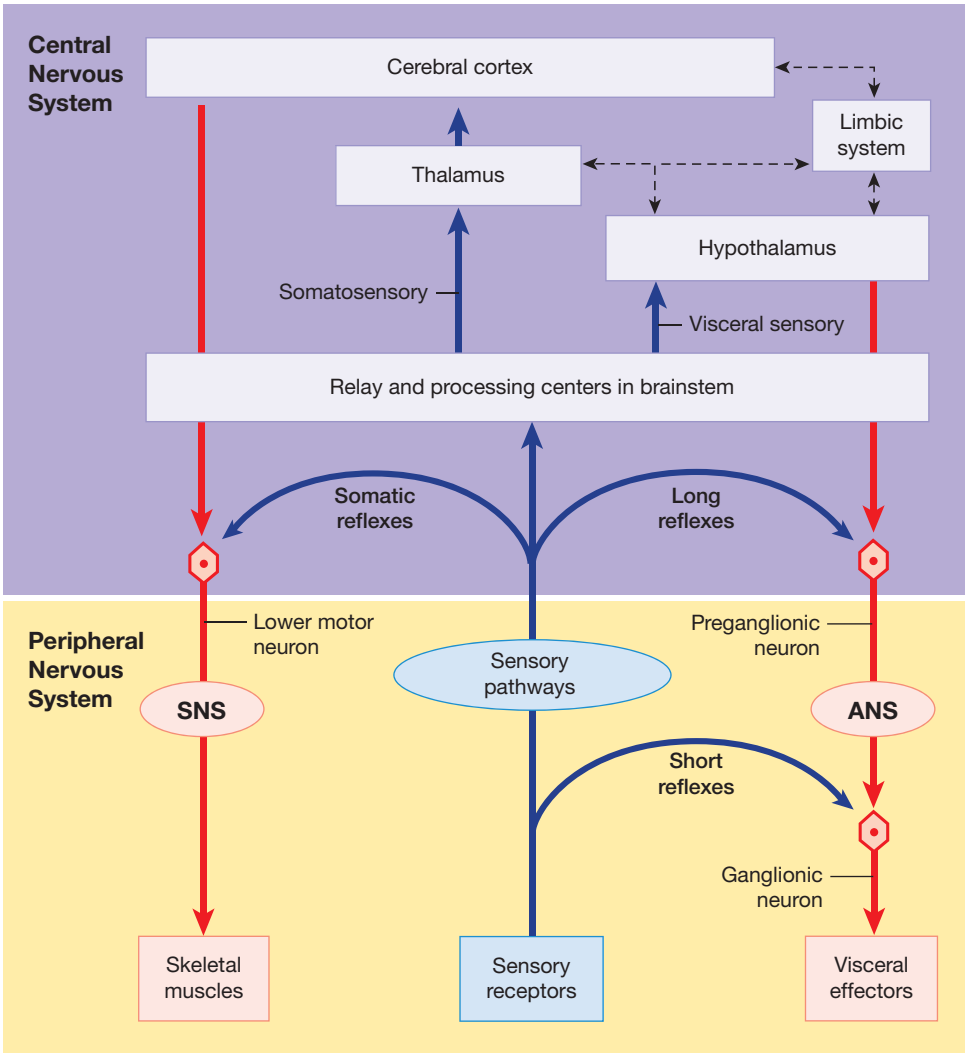
16-9 Higher-order functions include memory and states of consciousness, and neurotransmitters influence behavior

Learning Outcome Explain how memories are created, stored, and recalled; distinguish among the levels of consciousness and unconsciousness; and describe how neurotransmitters influence brain function.

Higher-order functions share three characteristics:

- The cerebral cortex is required for their performance. They involve complex interactions among areas of the cortex and between the cortex and other areas of the brain.

Figure 16–8 A Comparison of Somatic and Autonomic Function. The SNS and ANS have parallel organization and are integrated at the level of the brainstem. Blue arrows indicate ascending sensory information; red arrows, descending motor commands; dashed lines indicate pathways of communication and feedback among higher centers.



16

- They involve both conscious and unconscious information processing.
- Higher-order functions are subject to adjustment over time. They are not innate (inborn), fixed reflexive behaviors.

In Chapter 14, we considered functional areas of the cerebral cortex and also hemispheric lateralization. ↩ pp. 490–492 In this section, we consider the mechanisms of memory and learning. We also describe the neural interactions responsible for consciousness, sleep, and arousal.

Memory

What was the topic of the last sentence you read? What is your Social Security number? What does a hot dog taste like? To answer these questions, you access **memories**, stored bits of information gathered through experience. **Fact memories** are specific bits of information, such as the color of a stop sign or the smell of a perfume. **Skill memories** are learned motor behaviors. You can probably remember how to light a match or open a screw-top jar, for example. With repetition, skill memories become incorporated at the unconscious level. Skill memories related to innate behaviors, such as eating, are stored in appropriate portions of the brainstem. Complex skill memories, such as how to ski or play the violin, involve the integration of motor patterns in the basal nuclei, cerebral cortex, and cerebellum.

Two classes of memories are recognized, short term and long term (Figure 16–9). **Short-term memories** do not last long, but while they persist the information can be recalled immediately. Short-term memories contain small bits of information, such as a person's name or a telephone number. Repeating a phone number or other bit of information reinforces the original short-term memory and allows it to be converted to a long-term memory.

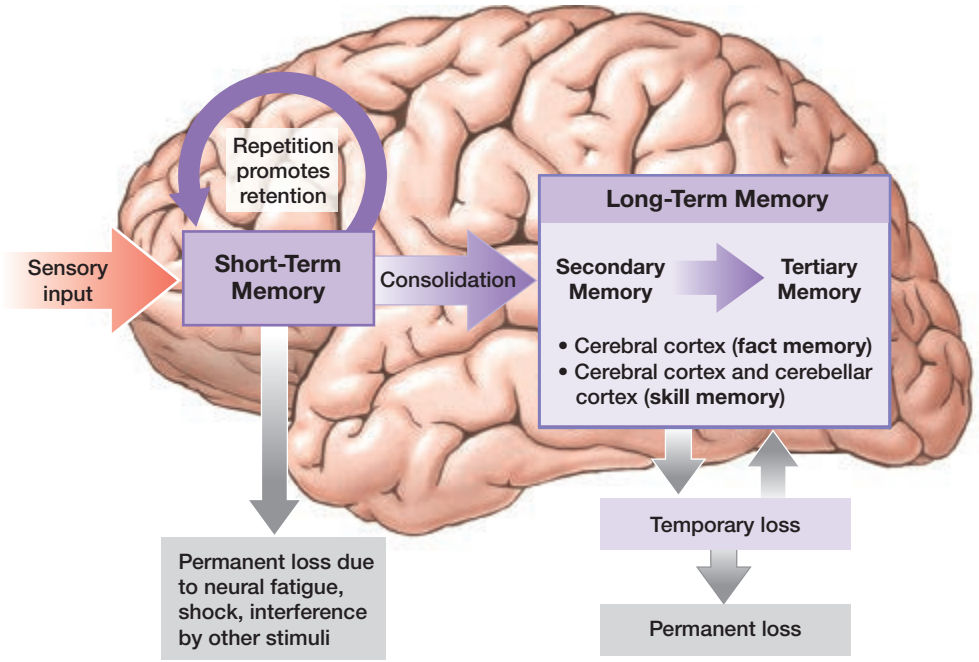
Long-term memories last much longer, in some cases for an entire lifetime. The conversion from short-term to long-term memory is called **memory consolidation**. There are two types of long-term memory: (1) *Secondary memories* are long-term memories that fade with time and may require considerable effort to recall. (2) *Tertiary memories* are long-term memories that are with you for a lifetime, such as your name or the contours of your own body.

Brain Regions Involved in Memory Consolidation and Access

The amygdaloid body (amygdala) and the hippocampus, two components of the limbic system (look back at Figure 14–12, p. 485), are essential to memory consolidation. Damage to the hippocampus leads to an inability to convert short-term memories to new long-term memories, although existing long-term memories remain intact and accessible. Tracts leading from the amygdaloid body to the hypothalamus may link memories to specific emotions.

The **nucleus basalis**, a cerebral nucleus near the diencephalon, plays an uncertain role in memory storage and retrieval. Tracts connect this nucleus with the hippocampus,

Figure 16–9 Memory Storage. Steps in the storage of memories and the conversion from short-term memory to long-term memory.



amygdaloid body, and all areas of the cerebral cortex. Damage to this nucleus is associated with changes in emotional states, memory, and intellectual function (as we see in the discussion of Alzheimer's disease later in this chapter).

Most long-term memories are stored in the cerebral cortex. Conscious motor and sensory memories are referred to the appropriate association areas. For example, visual memories are stored in the visual association area, and memories of voluntary motor activity are stored in the premotor cortex. Special portions of the occipital and temporal lobes are crucial to the memories of faces, voices, and words.

In at least some cases, a specific memory probably depends on the activity of a single neuron. For example, in one portion of the temporal lobe an individual neuron responds to the sound of one word and ignores others. A specific neuron may also be activated by the proper combination of sensory stimuli associated with a particular individual, such as your grandmother. As a result, these neurons are called "grandmother cells."

Information on one subject is parceled out to many different regions of the brain. Your memories of cows are stored in the visual association area (what a cow looks like, that the letters *c-o-w* mean "cow"), the auditory association area (the "moo" sound and how the word *cow* sounds), the speech center (how to say the word *cow*), and the frontal lobes (how big cows are, what they eat). Related information, such as how you feel about cows and what milk tastes like, is stored in other locations. If one of those storage areas is damaged, your memory will be incomplete in some way. How these memories are accessed and assembled on demand remains an area of active research.

Cellular Mechanisms of Memory Formation and Storage

Memory consolidation at the cellular level involves anatomical and physiological changes in neurons and synapses. For legal, ethical, and practical reasons, scientists do not conduct much research on these mechanisms with human subjects. Research on other animals, commonly those with relatively simple nervous systems, has indicated that the following mechanisms may be involved:

- *Increased Neurotransmitter Release.* A synapse that is frequently active increases the amount of neurotransmitter it stores, and it releases more with each stimulation. The more neurotransmitter released, the greater the effect on the postsynaptic neuron.
- *Facilitation at Synapses.* When a neural circuit is repeatedly activated, the axon terminals begin continuously releasing neurotransmitter in small quantities. The neurotransmitter binds to receptors on the postsynaptic membrane, producing a graded depolarization that brings the membrane closer to threshold. The facilitation that results affects all neurons in the circuit.
- *The Formation of Additional Synaptic Connections.* When one neuron repeatedly communicates with another, the axon tip branches and forms additional synapses on the postsynaptic neuron. As a result, stimulation of the presynaptic neuron has a greater effect on the membrane potential of the postsynaptic neuron.

Such processes create anatomical changes that facilitate communication along a specific neural circuit. This facilitated communication is thought to be the basis of memory storage. A single circuit that corresponds to a single memory has been called a **memory engram**. This definition is based on function rather than structure. We know too little about the organization and storage of memories to be able to describe the neural circuits involved. Memory engrams form as the result of experience and repetition. Repetition is crucial—that's why you probably need to read these chapters more than once before an exam.

Efficient conversion of a short-term memory into a memory engram takes time, usually at least an hour. Whether that conversion will occur depends on several factors. They include the nature, intensity, and frequency of the original stimulus. Very strong, repeated, or exceedingly pleasant or unpleasant events are most likely to be converted to long-term memories. Drugs that stimulate the CNS, such as caffeine and nicotine, may enhance

+ Clinical Note Insomnia

Insomnia (literally, "no sleep") includes trouble falling asleep, frequent awakenings with trouble falling back to sleep, and poor sleep quality. One in ten adults in the United States (more commonly females and older adults) suffers from chronic insomnia. This condition is more than a mere nuisance. Insomnia results in physical and mental disorders, job and relationship dysfunction, and diminished quality of life. The insomniac also suffers from constant hyperarousal, including an increased heart rate, elevated blood pressure, increased muscle tone, and disturbed sleep pattern, due to an overactive sympathetic nervous system.

Insomnia can be treated both medically and psychologically. An overnight sleep study can be used to collect objective data about sleep habits and behaviors. In such a study, sleep technicians record brain activity patterns. Psychologists use the "3P" model to evaluate insomnia: **p**redisposing factors (such as genetics and anxious personality type), **p**recipitating factors (such as a stressful life event), and **p**erpetuating factors (such as substance abuse and poor preparation for sleep). All of this information is then incorporated into a treatment plan.

16

memory consolidation through facilitation. We discussed the membrane effects of those drugs in Chapter 12. ↩ pp. 423, 425

The hippocampus plays a key role in consolidating memories. The mechanism remains unknown, but it is linked to the presence of *NMDA* (N-methyl D-aspartate) *receptors*, which are chemically gated calcium ion channels. When activated by the neurotransmitter *glutamate*, the gates open and calcium ions enter the cell. Blocking NMDA receptors in the hippocampus prevents long-term memory formation.

States of Consciousness

The difference between a conscious individual and an unconscious one might seem obvious. A conscious individual is alert and attentive, and an unconscious individual is not. Yet there are many degrees of both states. *Conscious* implies an awareness of and attention to external events and stimuli, but a healthy conscious person can be nearly asleep, wide awake, or high-strung and jumpy. *Unconscious* can refer to conditions ranging from the deep, unresponsive state induced by anesthesia before major surgery, to deep sleep, to the light, drifting "nod" that occasionally plagues students who are reading anatomy and physiology textbooks.

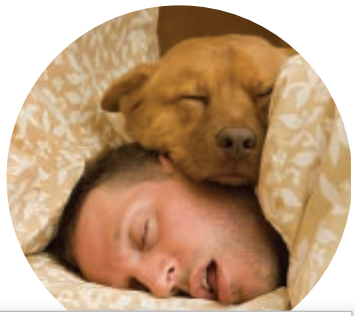
A person's degree of wakefulness at any moment indicates the level of ongoing CNS activity. When you are asleep, you are unconscious but can still be awakened by normal sensory stimuli. Healthy individuals cycle between the alert, conscious state and sleep each day. When CNS function becomes abnormal or depressed, the state of wakefulness can be affected. An individual in a *coma*, for example, is unconscious and cannot be awakened, even by strong stimuli.

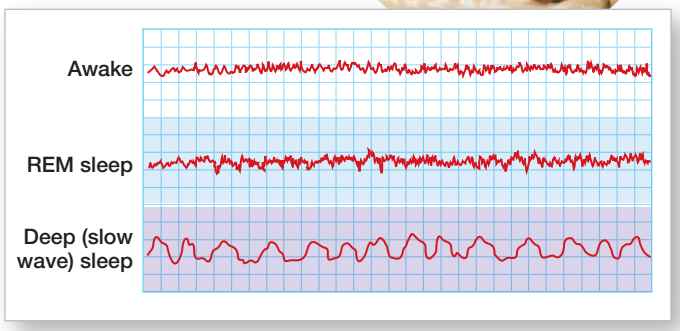
Sleep

We recognize two general levels of sleep, *deep* and *REM sleep*, each with characteristic patterns of brain wave activity (Figure 16–10a):

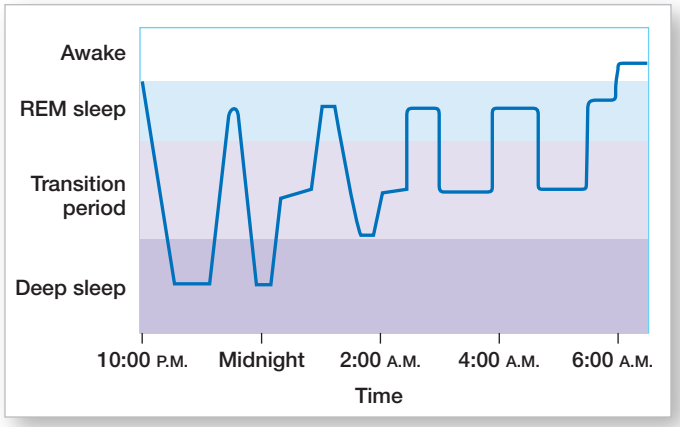
- In **deep sleep**, also called *slow wave* or *non-REM (NREM) sleep*, your entire body relaxes, and activity at the cerebral cortex is at a minimum. Heart rate, blood pressure, respiratory rate, and energy use decline by up to 30 percent.

Figure 16–10 States of Sleep.





a An EEG of the various sleep states. The EEG pattern during REM sleep resembles the alpha waves typical of awake adults.



b Typical pattern of sleep stages in a healthy young adult during a single night's sleep.

- During **rapid eye movement (REM) sleep**, you dream actively and your blood pressure and respiratory rate change. Although an EEG taken during REM sleep resembles that of the awake state, you become even less receptive to outside stimuli than in deep sleep, and your muscle tone decreases markedly. ↩ p. 493 Intense inhibition of somatic motor neurons probably prevents you from acting out the responses you envision while dreaming. The neurons controlling your eye muscles escape this inhibitory influence, and your eyes move rapidly as dream events unfold.

Periods of REM and deep sleep alternate throughout the night, beginning with deep sleep for about an hour and a half (Figure 16–10b). REM periods initially average about 5 minutes, but over an 8-hour night they gradually increase to about 20 minutes. Each night we probably spend less than 2 hours dreaming, but variation among individuals is significant. For example, children spend more time in REM sleep than do adults, and extremely tired individuals have very short and infrequent REM periods.

Sleep produces only minor changes in the physiological activities of other organs and systems, and none of these changes appear to be essential to normal function. The significance of sleep must lie in its impact on the CNS, but the physiological or biochemical basis remains to be determined. We do know that protein synthesis in neurons increases during sleep.

Extended periods without sleep lead to a variety of disturbances in mental function. Roughly 25 percent of the U.S. population experiences some form of *sleep disorder*. Examples include abnormal patterns or duration of REM sleep or unusual behaviors during sleep, such as sleepwalking. In some cases, these problems affect the individual's conscious activities. Slowed reaction times, irritability, and behavioral changes may result. Memory loss has also been linked to sleep disorders.

Arousal and the Reticular Activating System

Arousal, or awakening from sleep, appears to be one of the functions of the reticular formation. The reticular formation is especially well suited for providing "watchdog" services, because it has extensive interconnections with the sensory, motor, and integrative nuclei and pathways all along the brainstem.

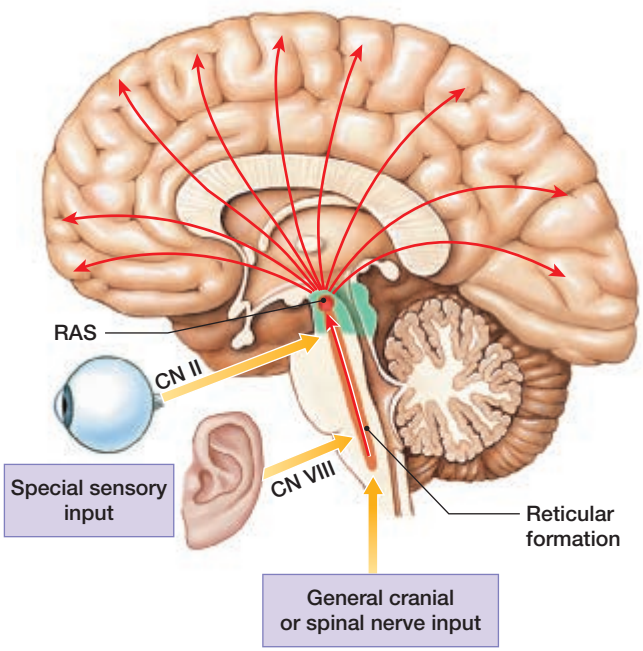
Your state of consciousness results from complex interactions between the reticular formation and the cerebral cortex. One of the most important brainstem components is the **reticular activating system (RAS)**. ↩ p. 478 This diffuse network in the reticular formation extends from the medulla oblongata to the midbrain (Figure 16–11). The output of the RAS projects to thalamic nuclei that influence large areas of the cerebral cortex. When the RAS is inactive, so is the cerebral cortex, and stimulation of the RAS produces a widespread activation of the cerebral cortex.

The midbrain portion of the RAS appears to be the "headquarters" of the system. Stimulating this area produces the most pronounced and long-lasting effects on the cerebral cortex. Stimulating other portions of the RAS seems to have an effect only to the degree that it changes the activity of the midbrain region. The greater the stimulation to the midbrain region of the RAS, the more alert and attentive the individual will be to incoming sensory information. The thalamic nuclei associated with the RAS may also play an important role in focusing attention on specific mental processes.

Sleep may be ended by any stimulus sufficient to activate the reticular formation and RAS. Arousal occurs rapidly, but the effects of a single stimulation of the RAS last less than a minute. After that, consciousness can be maintained by positive feedback, because activity in the cerebral cortex, basal nuclei, and sensory and motor pathways will continue to stimulate the RAS.

After many hours of activity, the reticular formation becomes less responsive to stimulation. You become less alert and more lethargic. The precise mechanism remains unknown, but neural fatigue probably plays a relatively minor role in the decreasing RAS activity. Evidence suggests that the regulation of sleep–wake cycles involves an interplay between brainstem nuclei that use different neurotransmitters. One group of nuclei stimulates the RAS with norepinephrine and maintains the awake, alert state. Another group depresses RAS activity with serotonin, promoting deep sleep. These "dueling" nuclei are located in the brainstem.

Figure 16–11 The Reticular Activating System (RAS). The midbrain "headquarters" of the reticular formation receives collateral inputs from a variety of sensory pathways. Stimulation of this region produces arousal and heightened states of attentiveness.



? Special sensory inputs arrive by which cranial nerves?

Clinical Note Summary of Nervous System Disorders

Nervous tissue is extremely delicate. The characteristics of its extracellular environment must be kept within narrow homeostatic limits. Signs and symptoms of neurological disorders appear when homeostatic regulatory mechanisms break down. This may happen under the stress of genetic or environmental factors, infection, or trauma.

Literally hundreds of disorders affect the nervous system. They can be categorized as:

- *Infections*, which include diseases such as rabies, meningitis, and polio
- *Congenital disorders*, such as spina bifida and hydrocephalus
- *Degenerative disorders*, such as Parkinson's disease and Alzheimer's disease
- *Tumors* of neural origin
- *Trauma*, such as spinal cord injuries and concussions
- *Toxins*, such as heavy metals and the neurotoxins found in certain seafoods
- *Secondary disorders*, which are problems resulting from dysfunction in other systems, for example, strokes and several demyelination disorders.

A standard physical examination includes a neurological component. The physician checks the general status of the CNS and PNS. In a *neurological examination*, a physician attempts to trace the location of a specific problem by evaluating the sensory, motor, behavioral, and cognitive functions of the nervous system.

Influence of Neurotransmitters on Brain Chemistry and Behavior

Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function and so behavior. For example, as we just discussed, the interplay between populations of neurons releasing norepinephrine and serotonin appears to be involved in regulating sleep–wake cycles. Another example is provided by the inherited disease called *Huntington's disease*, which involves the unexplained destruction of ACh-secreting and GABA-secreting neurons in the basal nuclei. Symptoms appear as the basal nuclei and frontal lobes slowly degenerate. A person with Huntington's disease has difficulty controlling movements, and intellectual abilities gradually decline. In many cases, the importance of a specific neurotransmitter was revealed while searching for the mechanism of action of other drugs. Three examples follow.

- *Serotonin.* An extensive network of tracts delivers serotonin to nuclei and higher centers throughout the brain, and variations in the serotonin level affect sensory interpretation and emotional states. Compounds that enhance the effects of serotonin produce hallucinations. For instance, *lysergic acid diethylamide (LSD)* is a powerful hallucinogenic drug that activates serotonin receptors in the brainstem, hypothalamus, and limbic system. Compounds that merely enhance the effects of serotonin also produce hallucinations, whereas compounds that inhibit serotonin production or block its action cause severe depression and anxiety. An effective antidepressive drug now in widespread use, *fluoxetine (Prozac)*, slows the removal of serotonin at synapses, causing an increase in the serotonin concentration at the postsynaptic membrane. Such drugs are classified as selective serotonin reuptake inhibitors (SSRIs). Other important SSRIs include *Celexa*, *Luvox*, *Paxil*, and *Zoloft*.
- *Norepinephrine.* Norepinephrine (NE) has pathways throughout the brain. Drugs that stimulate NE release cause exhilaration, while those that depress its release cause depression. One inherited form of depression has been linked to a defective enzyme involved in NE synthesis.
- *Dopamine.* Disturbances in dopamine transmission have been linked to several neurological disorders. We have already seen that inadequate dopamine causes the motor problems of Parkinson's disease. ↩ p. 478 Excessive production of dopamine may be associated with *schizophrenia*, a psychological disorder marked by pronounced disturbances of mood, thought patterns, and behavior. Amphetamines, or "speed," stimulate dopamine secretion and, in large doses, can produce symptoms resembling those of schizophrenia. Dopamine is thus important not only in the nuclei involved in the control of intentional movements, but in many other centers of the diencephalon and cerebrum.

Checkpoint

20. **List three characteristics of higher-order functions.**
21. **As you recall facts while you take your A&P test, which type of memory are you using?**
22. **What would happen if your RAS were suddenly stimulated while you were sleeping?**
23. **What would be an effect of a drug that substantially increases the amount of serotonin released in the brain?**
24. **Amphetamines stimulate the secretion of which neurotransmitter?**

See the blue Answers tab at the back of the book.

16-10 Aging produces various structural and functional changes in the nervous system

Learning Outcome Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems.

The aging process affects all body systems, and the nervous system is no exception. Anatomical and physiological changes probably begin by age 30 and accumulate over time. An estimated 85 percent of people above age 65 lead relatively normal lives, but they exhibit noticeable changes in mental performance and in CNS function. Common age-related anatomical changes in the nervous system include the following:

- *Reduction in Brain Size and Weight.* This reduction results primarily from a decrease in the volume of the cerebral cortex. The brains of elderly individuals have narrower gyri and wider sulci than do those of young people, and the subarachnoid space is larger.
- *Reduction in the Number of Neurons.* Brain shrinkage has been linked to a loss of cortical neurons, although evidence indicates that neurons are not lost (at least to the same degree) in brainstem nuclei.
- *Decrease in Blood Flow to the Brain.* With age, fatty deposits gradually build up in the walls of blood vessels. Just as a clog in a drain reduces water flow, these deposits reduce the rate of blood flow through arteries. (This process, called *arteriosclerosis*, affects arteries throughout the body, as we discuss further in Chapter 21.) Even if the reduction in blood flow is not large enough to damage neurons, arteriosclerosis increases the chances that the affected vessel wall will rupture, damaging the surrounding nervous tissue and producing signs and symptoms of a *cerebrovascular accident (CVA)*, also called a *stroke*.
- *Changes in the Synaptic Organization of the Brain.* In many areas, the number of dendritic branches, spines, and interconnections appears to decrease. Synaptic connections are lost, and the rate of neurotransmitter production declines.
- *Intracellular and Extracellular Changes in CNS Neurons.* Many neurons in the brain accumulate abnormal intracellular deposits, including lipofuscin and neurofibrillary tangles. **Lipofuscin** is a granular pigment with no known function. **Neurofibrillary tangles** are masses of neurofibrils that form dense mats inside the cell body and axon. **Plaques** are extracellular accumulations of fibrillar proteins, surrounded by abnormal dendrites and axons. Both plaques and tangles contain deposits of several peptides—primarily two forms of **amyloid (A) protein**, fibrillar and soluble. They appear in brain regions such as the hippocampus, specifically associated with memory processing. Their significance is unknown. Evidence indicates that they appear in all aging brains. In excess, they seem to be associated with clinical abnormalities.

The anatomical changes associated with aging of the nervous system affect all neural functions. For example, memory consolidation typically becomes more difficult, and secondary memories, especially those of the recent past, become harder to access. The sensory systems of elderly people—notably, hearing, balance, vision, smell, and taste—become less sensitive. Lights must be brighter, sounds louder, and smells stronger before they are perceived. Reaction rates are slowed, and reflexes—even some withdrawal reflexes—weaken or disappear. The precision of motor control decreases, and it takes longer for an elderly person to perform a given motor pattern than it did 20 years earlier.

For roughly 85 percent of the elderly population, these changes do not interfere with their abilities to function in society. But for reasons yet unknown, some elderly individuals become incapacitated by progressive CNS changes. These degenerative changes, which can include memory loss, anterograde amnesia, and emotional disturbances, are often lumped together as **senile dementia**, or *senility*. By far the most common and disabling form of senile dementia is **Alzheimer's disease**.

The relationships between the nervous system and the integumentary, skeletal, and muscular systems are shown in Build Your Knowledge Figure 16–12.

Checkpoint

25. **What are some possible reasons for the slower recall and loss of memory that occur with age?**
26. **Identify several common age-related anatomical changes in the nervous system.**
27. **Name the most common form of senile dementia.**
28. **Identify the relationships between the nervous system and the body systems studied so far.**

See the blue Answers tab at the back of the book.

Clinical Note Fainting

A stressful or emotional event may trigger a sudden and overwhelming loss of consciousness, commonly known as *fainting*. The technical term for fainting is the *vasovagal response* (*vaso*, vascular; *vagal*, vagus nerve).

This response is the result of a momentary malfunction of the sympathetic division, causing the parasympathetic division (sometimes called the "faint and freeze" division) to go into overdrive. In this process, parasympathetic stimulation of the vagus nerve causes it to release ACh at the cardiac plexus. However, without any counteracting stimulation from the sympathetic nervous system, the heart rate slows, the force of contractions decreases, and blood pressure drops. As a result, blood flow to the brain decreases, causing the fainting episode.

Rapid recovery begins as soon as the sympathetic division takes over, releasing norepinephrine at the cardiac plexus and throughout the body. Heart rate and blood pressure increase, as does level of consciousness.

To prevent a vasovagal response, a person beginning to feel faint should lie down before he or she falls down. This action will deliver more blood flow to the brain and help prevent an injury.

Build Your Knowledge

Figure 16–12 Integration of the NERVOUS system with the other body systems presented so far.

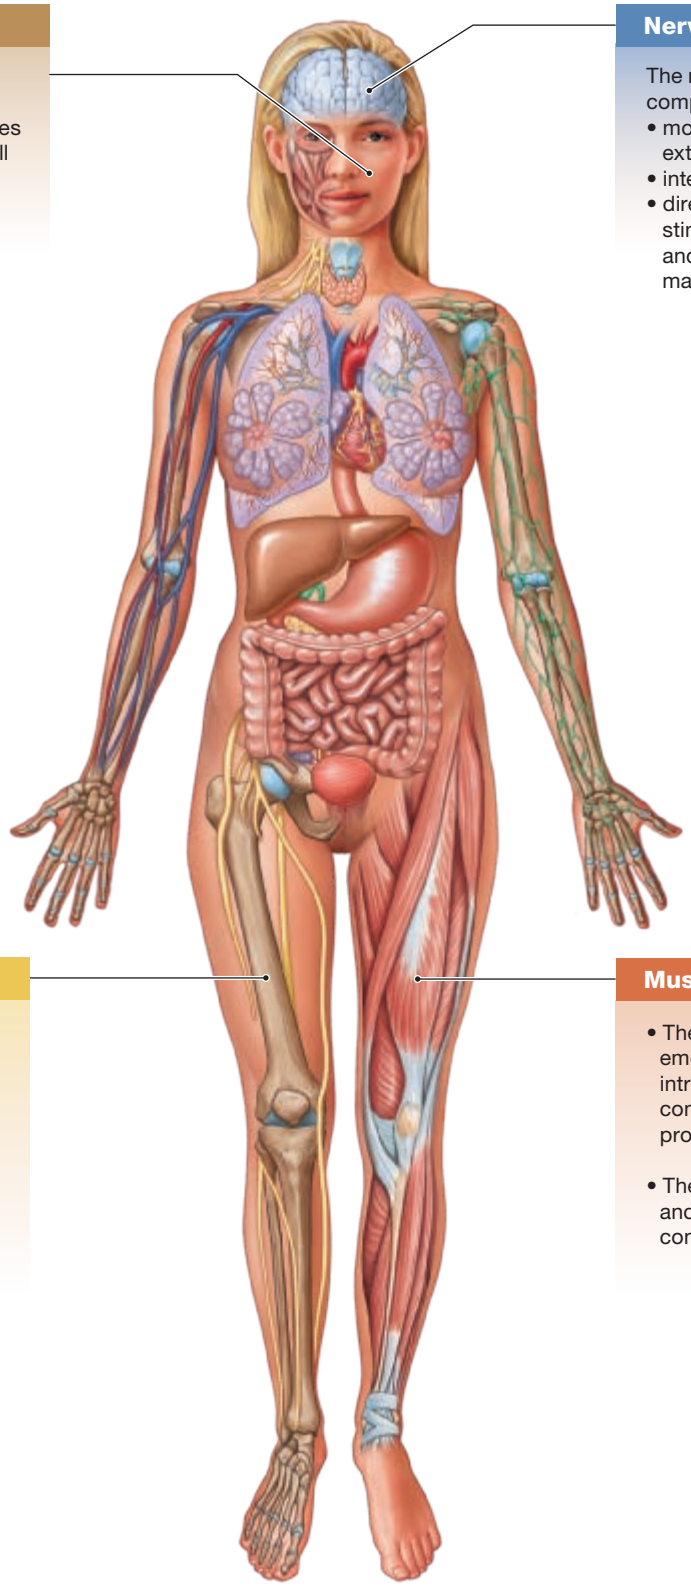
Integumentary System

- The Integumentary System provides sensations of touch, pressure, pain, vibration, and temperature; hair provides some protection and insulation for skull and brain; protects peripheral nerves
- The nervous system controls the contraction of arrector pili muscles and the secretion of sweat glands

Nervous System

The nervous system is your most complex organ system. It:

- monitors the body's internal and external environments
- integrates sensory information
- directs immediate responses to stimuli by coordinating voluntary and involuntary responses of many other organ systems



Skeletal System

- The Skeletal System provides calcium for neural function and protects the brain and spinal cord
- The nervous system affects bone thickening and maintenance by controlling muscle contractions

Muscular System

- The Muscular System expresses emotional states with facial muscles; intrinsic laryngeal muscles permit communication; muscle spindles provide proprioceptive sensations
- The nervous system controls voluntary and involuntary skeletal muscle contractions

16 Chapter Review

Study Outline

An Introduction to the Autonomic Nervous System and Higher-Order Functions p. 536

1. The autonomic nervous system adjusts our basic life support systems without conscious control.

16-1 The autonomic nervous system, which has sympathetic and parasympathetic divisions, is involved in the unconscious regulation of visceral functions p. 536

2. The **autonomic nervous system (ANS)** coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions.
3. **Preganglionic neurons** in the CNS send axons to synapse on **ganglionic neurons** in **autonomic ganglia** outside the CNS. *(Figure 16–1)*
4. Preganglionic fibers from the thoracic and lumbar segments form the **sympathetic division**, or *thoracolumbar division* ("fight or flight" system), of the ANS. Preganglionic fibers leaving the brain and sacral segments form the **parasympathetic division**, or *craniosacral division* ("rest and digest" system).

16-2 The sympathetic division has short preganglionic fibers and long postganglionic fibers and is involved in using energy and increasing metabolic rate p. 538

5. The sympathetic division consists of preganglionic neurons between segments T_1 and L_2, ganglionic neurons in ganglia near the vertebral column, and specialized neurons in the adrenal glands. *(Spotlight Figure 16–2a)*
6. The two types of sympathetic ganglia are **sympathetic chain ganglia** (*paravertebral ganglia*) and **collateral ganglia** (*prevertebral ganglia*). *(Figure 16–3)*
7. In spinal segments T_1–L_2, anterior roots give rise to the myelinated white ramus communicans, which, in turn, leads to the sympathetic chain ganglia. (*Spotlight Figure 16–2a, Figure 16–3)*
8. **Postganglionic fibers** targeting structures in the body wall and limbs rejoin the spinal nerves and reach their destinations by way of the posterior and anterior rami. *(Spotlight Figure 16–2a, Figure 16–3)*
9. Postganglionic fibers targeting structures in the thoracic cavity form **sympathetic nerves**, which go directly to their visceral destinations. Preganglionic fibers run between the sympathetic chain ganglia and interconnect them. *(Spotlight Figure 16–2a, Figure 16–3)*
10. The abdominopelvic viscera receive sympathetic innervation by preganglionic fibers that synapse within collateral ganglia. The preganglionic fibers that innervate the collateral ganglia form the **splanchnic nerves**. *(Spotlight Figure 16–2a, Figure 16–3)*

11. The **celiac ganglion** innervates the stomach, liver, gallbladder, pancreas, and spleen; the **superior mesenteric ganglion** innervates the small intestine and initial segments of the large intestine; and the **inferior mesenteric ganglion** innervates the kidneys, urinary bladder, the terminal portions of the large intestine, and the sex organs. *(Spotlight Figure 16–2a)*
12. Preganglionic fibers entering an adrenal gland synapse within the **adrenal medulla**. *(Spotlight Figure 16–2a, Figure 16–3)*
13. In a crisis, the entire sympathetic division responds—an event called **sympathetic activation**. Its effects include increased alertness, a feeling of energy and euphoria, increased cardiovascular and respiratory activities, a general elevation in muscle tone, and a mobilization of energy reserves.

16-3 Different types of neurotransmitters and receptors lead to different sympathetic effects p. 543

14. The stimulation of the sympathetic division has two distinctive results: the release of either ACh or *norepinephrine (NE)* at specific locations, and the secretion of *epinephrine (E)* and NE into the general circulation.
15. Sympathetic ganglionic neurons end in telodendria studded with **varicosities** containing neurotransmitters. *(Figure 16–4)*
16. The two types of sympathetic receptors are **alpha receptors** and **beta receptors**.
17. Most postganglionic fibers are *adrenergic*; a few are *cholinergic* or *nitroxidergic*. *(Table 16–1)*
18. The sympathetic division includes two sympathetic chain ganglia, three collateral ganglia, and two adrenal medullae. *(Figure 16–5; Tables 16–2, 16–3)*

16-4 The parasympathetic division has long preganglionic fibers and short postganglionic fibers and is involved in conserving energy and lowering metabolic rate p. 545

19. The parasympathetic division includes preganglionic neurons in the brainstem and sacral segments of the spinal cord, and ganglionic neurons in peripheral ganglia located within (**intramural**) or next to (**terminal**) target organs.
20. Preganglionic fibers leave the brain as components of cranial nerves III, VII, IX, and X. Those leaving the sacral segments form **pelvic nerves**. *(Spotlight Figure 16–2b)*
21. The effects produced by the parasympathetic division center on relaxation, food processing, and energy absorption.

16-5 Different types of receptors lead to different parasympathetic effects p. 546

22. All parasympathetic preganglionic and postganglionic fibers release ACh. The effects are short lived because ACh is inactivated by *acetylcholinesterase (AChE)* and by *tissue cholinesterase. (Figure 16–5)*
23. Postsynaptic membranes have two types of ACh receptors. The stimulation of **muscarinic receptors** produces a longer-lasting effect than does the stimulation of **nicotinic receptors**. *(Table 16–1)*

16-6 The differences in the organization of sympathetic and parasympathetic structures lead to widespread sympathetic effects and specific parasympathetic effects p. 547

24. The sympathetic division has widespread influence on visceral and somatic structures. *(Figure 16–5; Table 16–2)*
25. The parasympathetic division innervates areas serviced by cranial nerves and organs in the thoracic and abdominopelvic cavities. *(Figure 16–5; Table 16–2)*

16-7 Dual innervation of organs allows the sympathetic and parasympathetic divisions to coordinate vital functions p. 548

26. The parasympathetic division innervates only visceral structures that are serviced by cranial nerves or enclosed by the thoracic and abdominopelvic cavities. Organs with **dual innervation** receive input from both divisions. *(Tables 16–2, 16–3)*
27. The parasympathetic and sympathetic nerves intermingle in the thoracic and abdominopelvic cavities to form a series of characteristic *autonomic plexuses* (nerve networks): the **cardiac**, **pulmonary**, **esophageal**, **celiac**, **inferior mesenteric**, and **hypogastric plexuses**. *(Figure 16–6)*
28. Important physiological and functional differences exist between the sympathetic and parasympathetic divisions. *(Figure 16–5; Tables 16–2, 16–3)*
29. Even when stimuli are absent, autonomic motor neurons show a resting level of activation, the **autonomic tone**.

16-8 Various levels of autonomic regulation allow for the integration and control of autonomic functions p. 551

30. **Visceral reflex arcs** perform the simplest function of the ANS, and can be either **long reflexes** (with interneurons) or **short reflexes** (bypassing the CNS). *(Figure 16–7)*
31. Parasympathetic reflexes govern respiration, cardiovascular functions, and other visceral activities. *(Table 16–4)*
32. Levels of activity in the sympathetic and parasympathetic divisions of the ANS are controlled by centers in the brainstem that regulate specific visceral functions.
33. The SNS and ANS are organized in parallel. Integration occurs at the level of the brainstem and higher centers. *(Figure 16–8; Table 16–5)*

16-9 Higher-order functions include memory and states of consciousness, and neurotransmitters influence behavior p. 553

34. Higher-order functions (1) are performed by the cerebral cortex and involve complex interactions among areas of the cerebral cortex and between the cortex and other areas of the brain, (2) involve conscious and unconscious information processing, and (3) are subject to modification and adjustment over time.
35. Memories can be classified as **short term** or **long term**.
36. The conversion from short-term to long-term memory is **memory consolidation**. *(Figure 16–9)*
37. **Amnesia** is the loss of memory as a result of disease or trauma.
38. In **deep sleep** (*slow wave* or *non-REM sleep*), the body relaxes and cerebral cortex activity is low. In **rapid eye movement (REM) sleep**, active dreaming occurs. *(Figure 16–10)*
39. The **reticular activating system (RAS)**, a network in the reticular formation, is most important to arousal and the maintenance of consciousness. *(Figure 16–11)*
40. Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function.

16-10 Aging produces various structural and functional changes in the nervous system p. 558

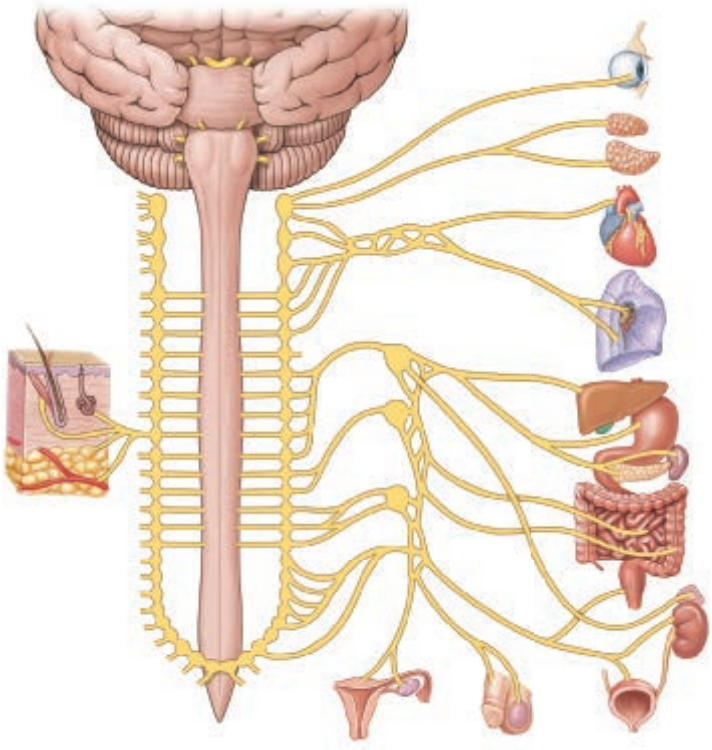
41. Age-related changes in the nervous system include a reduction in brain size and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons.
42. The nervous system monitors all other systems and issues commands that adjust their activities. The efficiency of these activities typically decreases with aging. *(Figure 16–12)*

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The preganglionic and ganglionic neurons are missing from the diagram below showing the distribution of sympathetic innervation. Indicate their distribution using red for the preganglionic neurons and black for the ganglionic neurons.



2. The autonomic division of the nervous system directs **(a)** voluntary motor activity, **(b)** conscious control of skeletal muscles, **(c)** unconscious control of skeletal muscles, **(d)** processes that maintain homeostasis, **(e)** sensory input from the skin.
3. The division of the ANS that prepares the body for activity and stress is the _____ division. **(a)** sympathetic, **(b)** parasympathetic, **(c)** craniosacral, **(d)** intramural, **(e)** somatomotor.
4. Effects produced by the parasympathetic branch of the ANS include **(a)** dilation of the pupils, **(b)** increased secretion by digestive glands, **(c)** dilation of respiratory passages, **(d)** increased heart rate, **(e)** increased breakdown of glycogen by the liver.
5. A progressive disorder characterized by the loss of higher-order cerebral functions is **(a)** Parkinson's disease, **(b)** parasomnia, **(c)** Huntington's disease, **(d)** Alzheimer's disease.
6. Starting in the spinal cord, trace an action potential through the sympathetic division of the ANS until it reaches a target organ in the abdominopelvic region.
7. Which four ganglia serve as origins for postganglionic fibers involved in control of visceral structures in the head?
8. What are the components of a visceral reflex arc?
9. What cellular mechanisms identified in animal studies are thought to be involved in memory formation and storage?
10. What physiological activities distinguish non-REM sleep from REM sleep?
11. What anatomical and functional changes in the brain are linked to alterations that occur with aging?
12. All preganglionic autonomic fibers release _____ at their axon terminals, and the effects are always _____. **(a)** norepinephrine, inhibitory, **(b)** norepinephrine, excitatory, **(c)** acetylcholine, excitatory, **(d)** acetylcholine, inhibitory.
13. The neurotransmitter at all synapses and neuromuscular or neuroglandular junctions in the parasympathetic division of the ANS is **(a)** epinephrine, **(b)** norepinephrine, **(c)** cyclic-AMP, **(d)** acetylcholine.
14. How does the emergence of sympathetic fibers from the spinal cord differ from the emergence of parasympathetic fibers?
15. Which three collateral ganglia serve as origins for ganglionic neurons that innervate organs or tissues in the abdominopelvic region?
16. What two distinctive results are produced by the stimulation of sympathetic ganglionic neurons?
17. Which four pairs of cranial nerves are associated with the cranial segment of the parasympathetic division of the ANS?
18. Which six plexuses in the thoracic and abdominopelvic cavities innervate visceral organs, and what are the effects of sympathetic versus parasympathetic stimulation?
19. What three characteristics are shared by higher-order functions?

LEVEL 2 Reviewing Concepts

20. Dual innervation refers to situations in which **(a)** vital organs receive instructions from both sympathetic and parasympathetic fibers, **(b)** the atria and ventricles of the heart receive autonomic stimulation from the same nerves, **(c)** sympathetic and parasympathetic fibers have similar effects, **(d)** all of these are correct.
21. Damage to the hippocampus, a component of the limbic system, leads to **(a)** a loss of emotion due to forgetfulness, **(b)** a loss of consciousness, **(c)** a loss of long-term memory, **(d)** an immediate loss of short-term memory.
22. Why does sympathetic function remain intact even when the anterior roots of the cervical spinal nerves are damaged?
23. During sympathetic stimulation, a person may begin to feel "on edge"; this is the result of **(a)** increased energy metabolism by muscle tissue, **(b)** increased cardiovascular activity, **(c)** stimulation of the reticular activating system, **(d)** temporary insensitivity to painful stimuli, **(e)** decreased levels of epinephrine in the blood.
24. Under which of the following circumstances would the diameter of peripheral blood vessels be greatest? **(a)** increased sympathetic stimulation, **(b)** decreased sympathetic stimulation, **(c)** increased parasympathetic stimulation, **(d)** decreased parasympathetic stimulation, **(e)** both increased parasympathetic and sympathetic stimulation.
25. A possible side effect of a drug used to open the airways of someone suffering from an asthma attack is **(a)** decreased activity of the digestive system, **(b)** diarrhea, **(c)** profuse urination, **(d)** increased blood pressure, **(e)** decreased heart rate.
26. You are home alone at night when you hear what sounds like breaking glass. What physiological effects would this experience probably produce, and what would be their cause?
27. Why is autonomic tone a significant part of ANS function?
28. Nicotine stimulates cholinergic receptors of the ANS. Based on this information, how would cigarette smoking affect the cardiovascular system?
29. The condition known as shock is characterized in part by a decreased return of venous blood to the heart. How could an upsetting situation, such as the sight of a tragic accident or very bad news, produce some temporary symptoms of shock?

LEVEL 3 Critical Thinking and Clinical Applications

30. Phil is stung on his cheek by a wasp. Because Phil is allergic to wasp venom, his throat begins to swell and his respiratory passages constrict. Would acetylcholine or epinephrine be more helpful in relieving his condition? Why?
31. While studying the activity of smooth muscle in blood vessels, Shelly discovers that, when applied to a muscle plasma membrane, a molecule chemically similar to a neurotransmitter triggers an increase in intracellular calcium ions. Which neurotransmitter is the molecule mimicking, and to which receptors is it binding?

CLINICAL CASE Wrap-Up Remember Me?

Helen has the progressive neurological disorder Alzheimer's disease. The hallmark of Alzheimer's is loss of memory. But patients also experience a gradual loss of cognitive functioning involving orientation, concentration, problem solving, judgment, and language. In the end stage, the person can no longer perform any activities of daily living and needs total care. This incurable disease can run for 5 or more years before the patient dies.

During life, the brain with Alzheimer's is deficient in the neurotransmitter acetylcholine (ACh). Diagnosis is established by ruling out other causes of memory loss. On autopsy Alzheimer's can be confirmed by an atrophied brain with wide sulci and shrunken gyri; under the microscope, we see abnormal plaques and neurofibrillary tangles that impair nerve transmission.

1. If memory loss is her first symptom, what part of Helen's brain is first affected? As her disease progresses, which additional brain regions become involved?
2. Helen's doctor will check her mental orientation. A normal result is "oriented x3," which means the patient recognizes the three attributes of person, place, and time. In which order did Helen lose her orientation as her disease worsened?
3. The doctor gave Helen a trial of the drug donepezil, a cholinesterase inhibitor. Why did this help? Where specifically did the drug act?

See the blue Answers tab at the back of the book.

16

Related Clinical Terms

alpha$_1$-receptor agonists: Drugs used to treat hypotension (low-blood pressure) by stimulating α_1 receptors to cause vasoconstriction of blood vessels.

alpha$_2$-receptor agonists: Drugs used to treat hypertension (high blood pressure) by stimulating α_2-adrenergic receptors to inhibit sympathetic vasomotor centers.

beta-adrenergic blockers: Drugs that decrease heart rate and force of contraction, lowering peripheral blood pressure by acting on beta-adrenergic receptors to diminish the effects of epinephrine.

parasympathetic blocking agents: Drugs that target the muscarinic receptors at neuromuscular or neuroglandular junctions.

parasympathomimetic drugs: Drugs that mimic parasympathetic stimulation and increase the activity along the digestive tract.

sympathetic blocking agents: Drugs that bind to receptor sites, preventing a normal response to neurotransmitters or sympathomimetic drugs.

sympathomimetic drugs: Drugs that mimic the effects of sympathetic stimulation.

17 The Special Senses

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

17-1 ■ Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination. p. 566

17-2 ■ Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination. p. 570

17-3 ■ Identify the internal and accessory structures of the eye, and explain the functions of each. p. 572

17-4 ■ Describe how refraction and the focusing of light on the retina lead to vision. p. 581

17-5 ■ Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain. p. 583

17-6 ■ Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain. p. 592

CLINICAL CASE A Chance to See

Makena is a 12-year-old Kenyan girl living with her family in a small village in sub-Saharan Africa. Their village is miles away from roads, electricity, and health care. Her family is very poor, and lives on less than $1.25 per day. Makena's daily chores include walking 2 hours to collect water, every morning before school and again after school. Water is so precious in this part of the world that nobody in Makena's village has ever taken a shower.

Makena is a bright girl, but she does not do well in school. She can't see the chalkboard in her classroom. She can't see the soccer ball when she tries to play with her classmates. She even has trouble seeing the path that leads to the dry riverbed where she collects water from a deep hole. She has no idea that other people can see these things better.

No one in Makena's village wears eyeglasses, and most do not even know what they are. Makena's teacher, however, studied at the University of Nairobi and knows that glasses can correct vision problems. The teacher thinks perhaps nearsightedness is a problem for Makena. **Can a desperately poor child, many miles away from health care of any kind, obtain glasses to correct her poor vision? To find out, turn to the Clinical Case Wrap-Up on p. 609.**

An Introduction to the Special Senses

17

Our knowledge of the world around us is limited to those characteristics that stimulate our sensory receptors. We may not realize it, but our picture of the environment is incomplete. Colors we cannot see guide insects to flowers. Sounds we cannot hear and smells we cannot detect give dolphins, dogs, and cats key information about their surroundings.

What we *do* perceive varies considerably with the state of our nervous system. For example, during sympathetic activation, you experience a heightened awareness of sensory information. You hear sounds that normally you would not notice. Yet, when concentrating on a difficult problem, you may be unaware of fairly loud noises.

Finally, our perception of any stimulus reflects activity in the cerebral cortex, but that activity can be generated by the nervous system itself. In cases of phantom pain syndrome, for example, a person feels pain in a missing limb. During an epileptic seizure, a person may experience sights, sounds, or smells that have no physical basis.

In our discussion of the general senses and sensory pathways in Chapter 15, we introduced basic principles of receptor function and sensory processing. We now turn to the five *special senses: olfaction* (smell), *gustation* (taste), *vision*, *equilibrium* (balance), and *hearing*. The sense organs involved are structurally more complex than those of the general senses, but the same basic principles of receptor function apply. That is, all of the special sense receptors also transduce an arriving stimulus into action potentials that are then sent to the CNS for interpretation and possible response. ↩ p. 515 ATLAS: Embryology Summary 13: The Development of Special Sense Organs

17-1 Olfaction, the sense of smell, involves olfactory receptors responding to airborne chemical stimuli

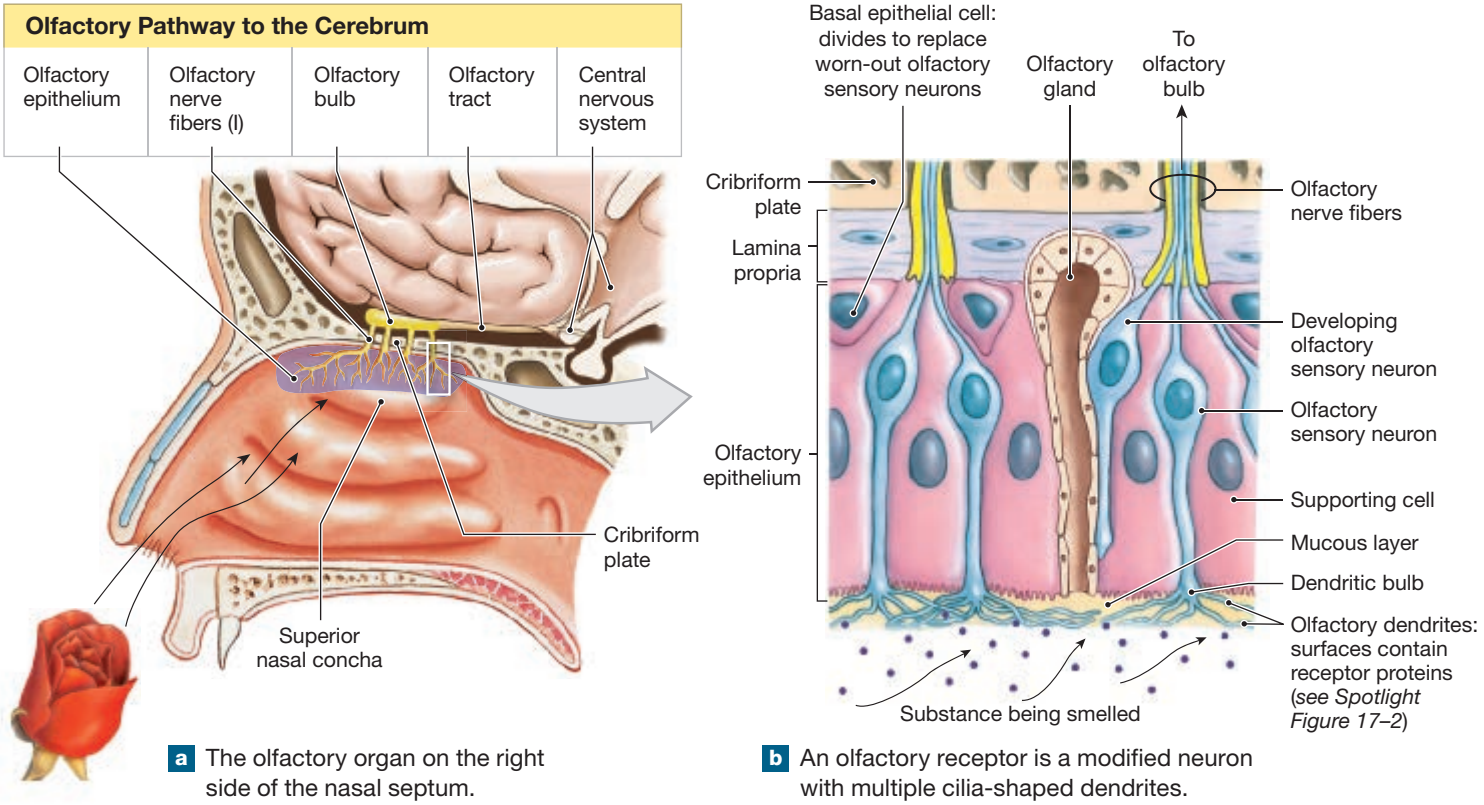
Learning Outcome Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination.

The sense of smell, called **olfaction**, is made possible by paired **olfactory organs**. These olfactory organs, which are located in the **nasal cavity** on either side of the nasal septum, contain *olfactory sensory neurons*. What happens when you inhale through your nose? The air swirls within your nasal cavity. This turbulence brings airborne substances, including water-soluble and lipid-soluble substances called *odorants*, to your olfactory organs. A normal, relaxed inhalation carries a small sample (about 2 percent) of the inhaled air to the olfactory organs. If you sniff repeatedly, you increase the flow of air and so odorants, increasing the stimulation of the olfactory receptors. Once these receptors are stimulated, they send signals to the *olfactory cortex*, which interprets them. Let's look more closely at this process.

Anatomy of the Olfactory Organs

The olfactory organs are made up of two layers: the *olfactory epithelium* and the *lamina propria* (Figure 17–1a). The **olfactory epithelium** contains the olfactory sensory neurons, supporting cells, and regenerative *basal epithelial cells* (*stem cells*) (Figure 17–1b). This epithelium covers the inferior surface of the cribriform plate, the superior portion of the perpendicular plate, and the superior nasal conchae of the ethmoid. ↩ p. 220 The second layer, the underlying lamina propria, consists of areolar tissue, numerous blood vessels, and nerves. This layer

Figure 17–1 The Olfactory Organs.



a The olfactory organ on the right side of the nasal septum.

b An olfactory receptor is a modified neuron with multiple cilia-shaped dendrites.

also contains **olfactory glands**. Their secretions absorb water and form thick, pigmented *mucus*.

Olfactory sensory neurons are highly modified nerve cells. The exposed tip of each sensory neuron forms a prominent dendritic bulb that projects beyond the epithelial surface (see Figure 17–1b). The dendritic bulb is a base for up to 20 cilia-shaped dendrites that extend into the surrounding mucus. These dendrites lie parallel to the epithelial surface, exposing their considerable surface area to odorants.

Between 10 and 20 million olfactory receptors fill an area of roughly 5 cm^2 (0.8 $in.^2$). If we take into account the exposed dendritic surfaces, the actual sensory area probably approaches that of our entire body surface.

Olfactory Receptors and the Physiology of Olfaction

Olfactory reception begins with the binding of an odorant to a G protein–coupled receptor in the plasma membrane of an olfactory dendrite. This creates a depolarization called a **generator potential**. This potential leads to the generation of action potentials, which are then carried to the CNS by sensory afferent fibers. Please study this process in Spotlight Figure 17–2a before reading on.

Olfactory Pathways

The olfactory pathway begins with afferent fibers leaving the olfactory epithelium that collect into 20 or more bundles. These bundles penetrate the cribriform plate of the ethmoid bone to reach the *olfactory bulbs* of the cerebrum, where the first synapse occurs (see Figure 17–1a). Efferent fibers from nuclei elsewhere in the brain also innervate neurons of the olfactory bulbs. Axons leaving the olfactory bulb travel along the olfactory tract to the **olfactory cortex** of the cerebral hemispheres, the hypothalamus, and portions of the limbic system.

Olfactory stimulation is the only type of sensory information that reaches the cerebral cortex directly. All other sensations are relayed from processing centers in the thalamus. Certain smells can trigger profound emotional and behavioral responses, as well as memories, due to the fact that olfactory information is also distributed to the limbic system and hypothalamus.

The activation of an afferent fiber does not guarantee an awareness of the stimulus. Considerable convergence takes place along the olfactory pathway, and inhibition at the intervening synapses can prevent the sensations from reaching the *olfactory cortex*. ↩ p. 491 As seen in Spotlight Figure 17–2a, the olfactory receptors themselves adapt very little to an ongoing stimulus.

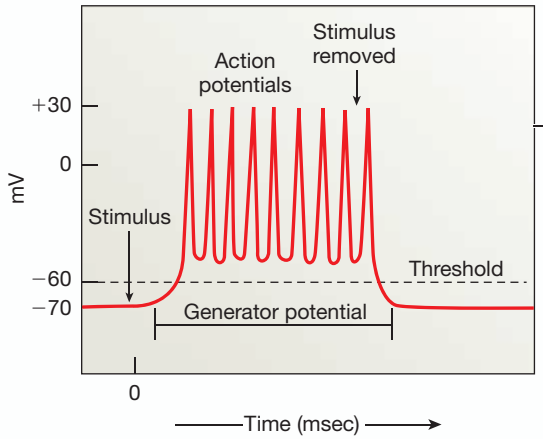
SPOTLIGHT

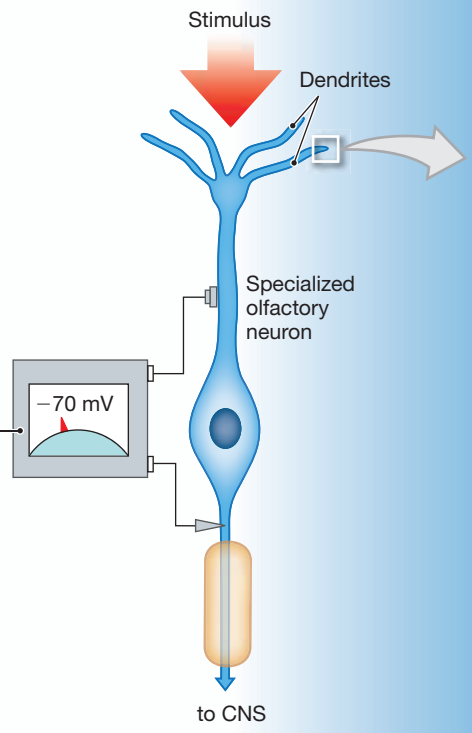
Figure 17–2
Olfaction and Gustation

Olfaction and gustation are special senses that give us vital information about our environment. Although the sensory information is diverse and complex, each special sense originates at specialized neurons or receptor cells that communicate with other sensory neurons.

a OLFACTION

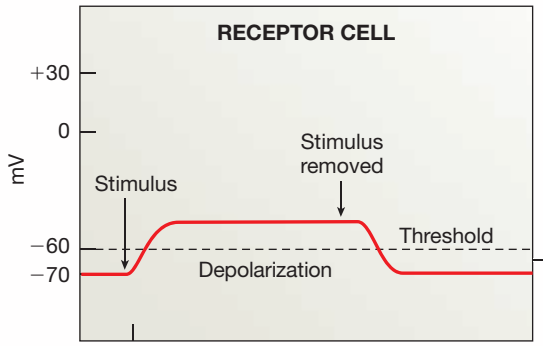
Olfactory receptors are the dendrites of specialized neurons. When odorant molecules bind to the olfactory receptors, a depolarization known as a **generator potential** results. This graph shows the action potentials produced by a generator potential.

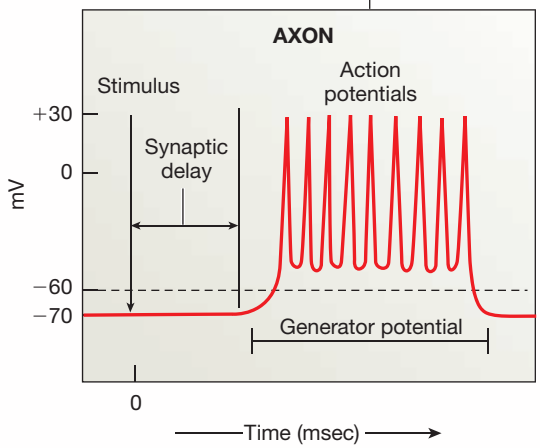


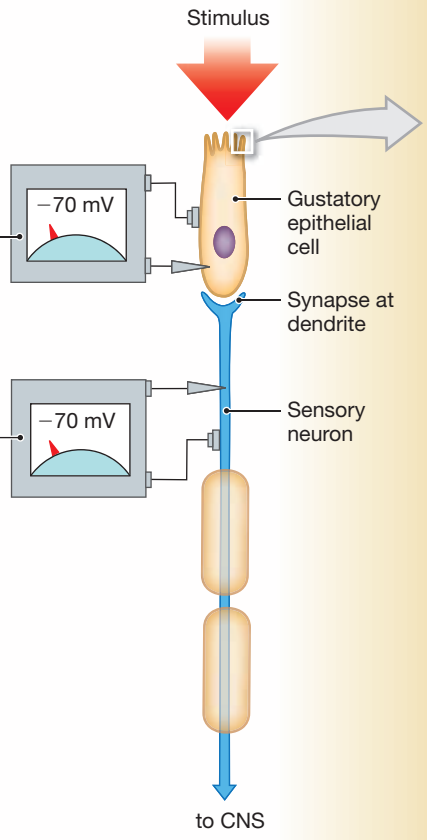


b GUSTATION

The receptors for the senses of taste, vision, equilibrium, and hearing are specialized cells that have unexcitable membranes and form synapses with the processes of sensory neurons. As this upper graph shows, the membrane of the stimulated receptor cell undergoes a graded depolarization that triggers the release of chemical transmitters at the synapse. These transmitters then depolarize the sensory neuron, creating a generator potential and action potentials that are propagated to the CNS. Because a synapse is involved, there is a slight synaptic delay. However, this arrangement permits modification of the sensitivity of the receptor cell by presynaptic facilitation or inhibition.



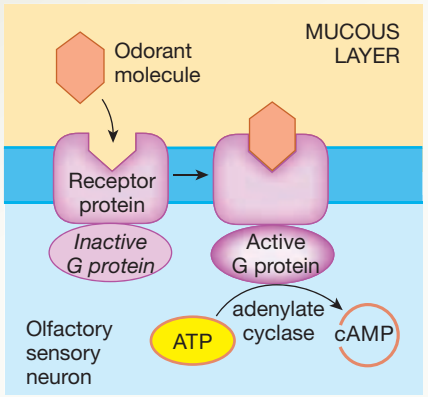




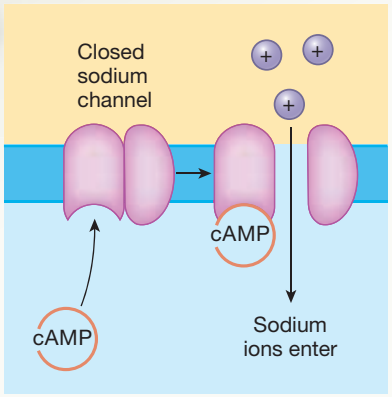
Olfactory reception occurs on the surface membranes of the olfactory dendrites. **Odorants**—substances that stimulate olfactory receptors—interact with receptors called odorant-binding proteins on the membrane surface.

In general, odorants are small organic molecules. The strongest smells are associated with molecules of either high water or high lipid solubilities. As few as four odorant molecules can activate an olfactory receptor.

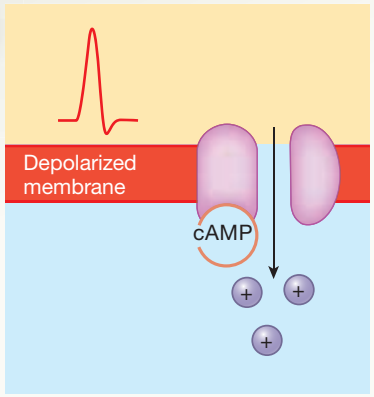
1 The binding of an **odorant** to its receptor protein leads to the activation of adenylate cyclase, the enzyme that converts ATP to cyclic AMP (cAMP).



2 The cAMP opens sodium ion channels in the plasma membrane, which then begins to depolarize.



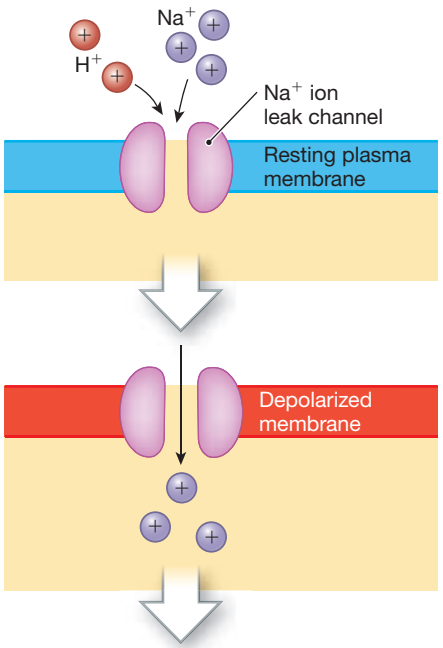
3 If sufficient depolarization occurs, an action potential is triggered in the axon, and the information is relayed to the CNS.



Some 90 percent of the gustatory epithelial cells respond to two or more different taste stimuli. The different tastes involve different receptor mechanisms. A salty stimulus involves the diffusion of Na^+ ions through a sodium ion leak channel common in epithelial cells. Stimuli for a sour or acidic taste include H^+ ions that diffuse through the same epithelial Na^+ channel. The intracellular increase in cations leads to depolarization and neurotransmitter release. Sweet, bitter, and umami stimuli bind to specific G protein–coupled receptors. The resulting multiple chemical pathways lead to depolarization and neurotransmitter release.

Salt and Sour Channels

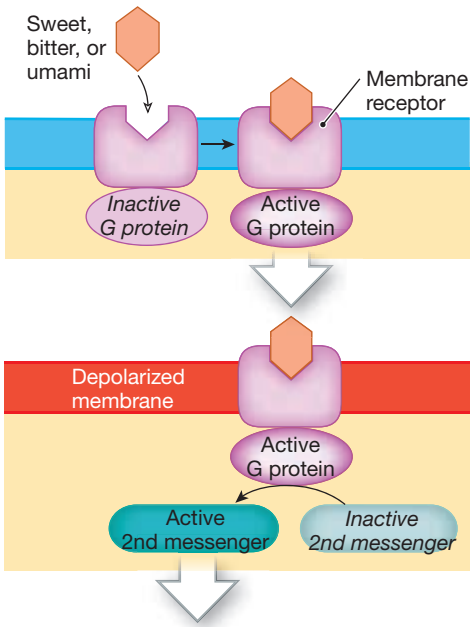
The diffusion of sodium ions from salt solutions or hydrogen ions from acids or sour solutions into the gustatory epithelial cell leads to depolarization.



Depolarization of membrane stimulates release of chemical neurotransmitters.

Sweet, Bitter, and Umami Receptors

Receptors responding to stimuli that produce sweet, bitter, and umami sensations are linked to G proteins called **gustducins** (GUST-doos- inz)—protein complexes that use second messengers to produce their effects.



Activation of second messengers stimulates release of chemical neurotransmitters.

Rather, central adaptation (provided by the innervation of the olfactory bulbs by other brain nuclei) ensures that you quickly lose awareness of a new smell but remain sensitive to others.

Olfactory Discrimination

The human olfactory system can discriminate between, or make subtle distinctions among, 2000–4000 chemical stimuli. Yet, our olfactory sensitivities cannot compare with those of other vertebrates such as dogs, cats, or fishes. A German shepherd dog sniffing for smuggled drugs or explosives has an olfactory receptor surface 72 times greater than that of the nearby customs inspector! Thus, the dog can smell 10,000 to 100,000 times better than a human.

No apparent structural differences exist among the human olfactory sensory neurons, but the epithelium as a whole contains populations with distinct sensitivities. Upwards of 50 "primary smells" are known, although it is almost impossible to describe these sensory impressions effectively. The CNS probably interprets each smell on the basis of the overall pattern of receptor activity.

Human olfactory organs can discriminate among many smells, but sensitivity varies widely, depending on the nature of the odorant. We can detect many odorants in amazingly small concentrations. One example is mercaptan, an odorant commonly added to natural gas, which is otherwise odorless. Because we can smell mercaptan at an extremely low concentration (a few parts per billion), its addition enables us to detect a gas leak almost at once.

The olfactory receptor population is replaced frequently. Basal epithelial cells in the epithelium divide and differentiate to produce new sensory neurons. This turnover is one of the few examples of neuronal replacement in adult humans. Despite this process, the total number of neurons declines with age, and those that remain become less sensitive. As a result, elderly people have difficulty detecting odors in low concentrations. This sensory neuron decline explains why Grandpa's aftershave smells so strong: He must apply more to be able to smell it.

Checkpoint

1. Define *olfaction*.
2. Trace the olfactory pathway, beginning at the olfactory epithelium.
3. When you first enter the A&P lab for dissection, you are very aware of the odor of preservatives. By the end of the lab period, the smell doesn't seem to be nearly as strong. Why?

See the blue Answers tab at the back of the book.

17-2 Gustation, the sense of taste, involves gustatory receptors responding to dissolved chemical stimuli

Learning Outcome Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination.

Gustation, or *taste*, provides information about the foods and liquids we eat and drink. *Gustatory* (GUS-ta-tor-ē) *epithelial cells*, or *taste receptors* are found in *taste buds* that are distributed over the superior surface of the tongue and adjacent portions of the pharynx and larynx. These receptors are stimulated by dissolved food molecules. This stimulation leads to action potentials that are sent to the *gustatory cortex* for interpretation. Let's look further into this process.

Anatomy of Papillae and Taste Buds

The surface of the tongue has numerous variously shaped epithelial projections called *lingual papillae* (pa-PIL-ē; *papilla*, a nipple-shaped mound). The human tongue has four types of lingual papillae (Figure 17–3a,b): (1) **filiform** (*filum*, thread) **papillae**, (2) **fungiform** (*fungus*, mushroom) **papillae**, (3) **vallate** (VAL-āt; *vallum*, wall) **papillae**, and (4) **foliate** (FŌ-lē-āt) **papillae**. The distribution of these lingual papillae varies by region. Their components also vary—most contain the sensory structures called **taste buds** (Figure 17–3c). Filiform papillae are found in the anterior two-thirds of the tongue running parallel to the *midline groove*. They do not contain taste buds, but they do provide an abrasive coat that creates friction to help move food around the mouth. Fungiform papillae are scattered around the tongue with concentration along the tip and sides. Each small fungiform papilla contains about 5 taste buds. Vallate papillae appear as an inverted "V" near the posterior margin of the tongue. There are up to 12 vallate papillae, and each contains as many as 100 taste buds. The foliate papillae are found as a series of folds along the lateral margins with taste buds embedded in their surfaces.

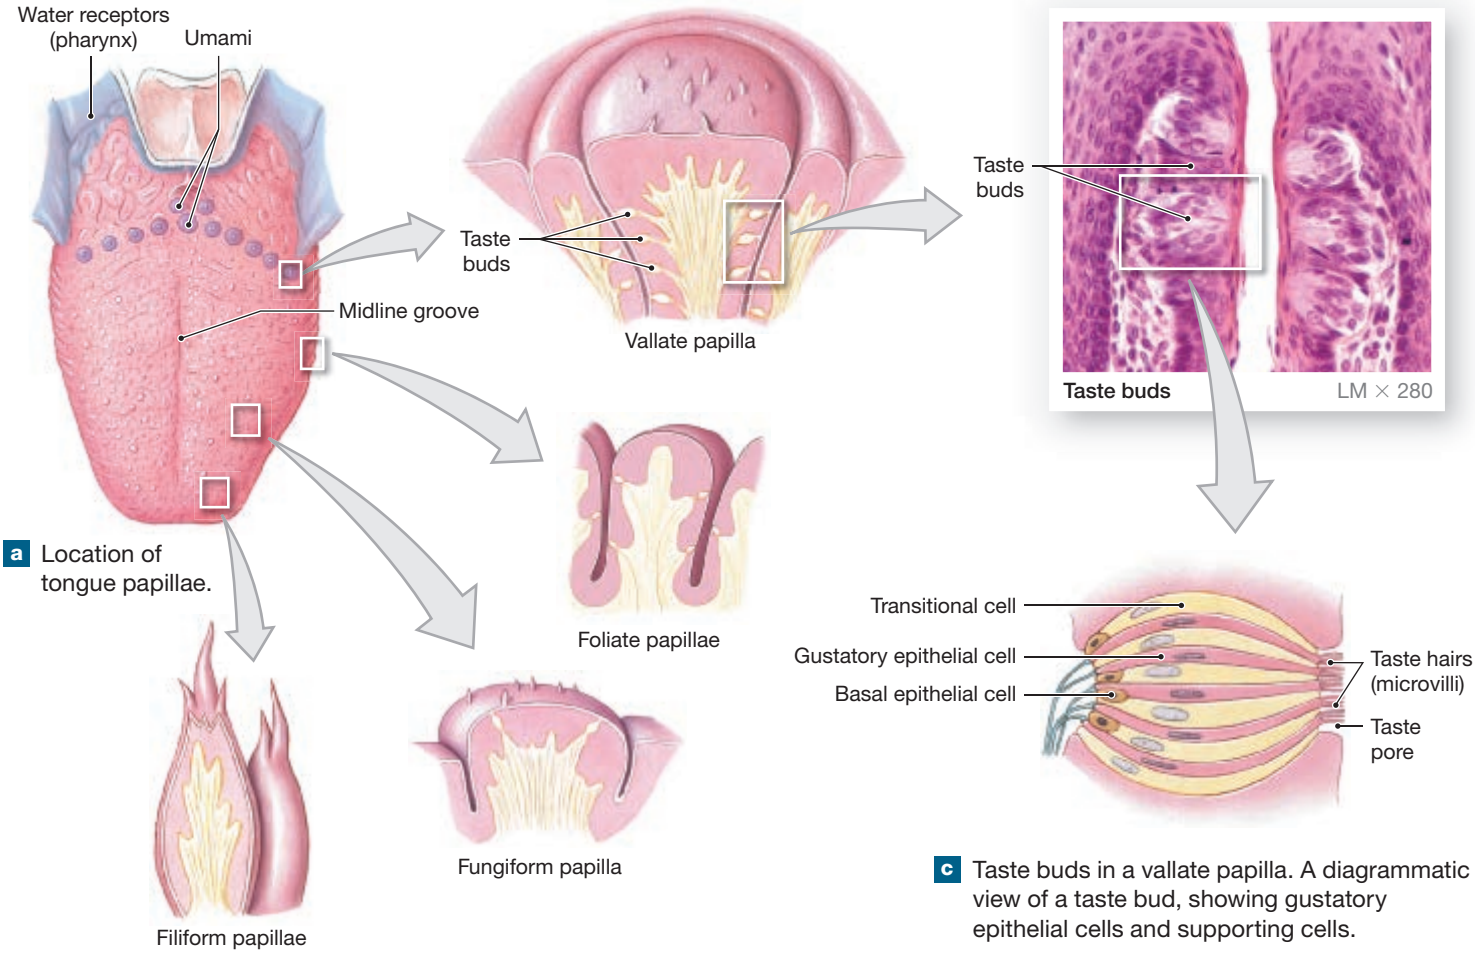
Gustatory Receptors

Taste buds are recessed into the surrounding epithelium, isolated from the unprocessed contents of the mouth. Each taste bud contains about 40–100 gustatory epithelial cells and many small stem cells called basal epithelial cells (see Figure 17–3b,c). The basal epithelial cells continually divide to produce daughter cells that mature in three stages—basal, transitional, and mature. Cells at all stages are innervated by sensory neurons. The mature cells of the last stage are the **gustatory epithelial cells**. Each gustatory epithelial cell extends microvilli, sometimes called *taste hairs*, into the surrounding fluids through the **taste pore**, a narrow opening. Despite this relatively protected position, it's still a hard life: A typical gustatory epithelial cell survives for only about 10 days before it is replaced.

Gustatory Pathways

The gustatory pathway starts with taste buds, which are innervated by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus). The facial nerve innervates all the taste buds located on the anterior two-thirds of the tongue, from the tip to the

Figure 17–3 Papillae, Taste Buds, and Gustatory Epithelial Cells.



a Location of tongue papillae.

b The structure and representative locations of the four types of lingual papillae. Taste receptors are located in taste buds, which form pockets in the epithelium of fungiform, foliate, and vallate papillae.

c Taste buds in a vallate papilla. A diagrammatic view of a taste bud, showing gustatory epithelial cells and supporting cells.

line of vallate papillae. The glossopharyngeal nerve innervates the vallate papillae and the posterior one-third of the tongue. The vagus nerve innervates taste buds scattered on the surface of the epiglottis.

The sensory afferent fibers carried by these cranial nerves synapse in the solitary nucleus of the medulla oblongata. The axons of the postsynaptic neurons then enter the medial lemniscus. There, the neurons join axons that carry somatic sensory information on touch, pressure, and proprioception. After another synapse in the thalamus, the information is sent to the appropriate portions of the gustatory cortex of the insula.

You have a conscious perception of taste as the brain correlates information received from the taste buds with other sensory data. Information about the texture of food, along with taste-related sensations such as "peppery," comes from sensory afferent fibers in the trigeminal cranial nerve (V).

In addition, the level of stimulation from the olfactory receptors plays a major role in taste perception. The combination of taste and smell is what provides the *flavor,* or distinctive quality of a particular food or drink. You are several thousand times more sensitive to "tastes" when your olfactory organs are fully functional. By contrast, when you have a cold and your nose is stuffed up, airborne molecules cannot reach your olfactory receptors, so meals taste dull and unappealing. The reduction in flavor happens even though the taste buds may be responding normally. Without accompanying olfactory sensations, you are now limited to the basic taste sensations provided by your gustatory receptors.

Gustatory Discrimination and Physiology of Gustation

You are probably already familiar with the four **primary taste sensations: sweet, salty, sour,** and **bitter**. There is some evidence for differences in sensitivity to tastes along the axis of the tongue, with greatest sensitivity to salty–sweet anteriorly and sour–bitter posteriorly. However, there are no differences in the structure of the taste buds. Taste buds in all portions of the tongue provide all four primary taste sensations.

Humans have two additional taste sensations that are less widely known. The first is called **umami** (oo-MAH-mē, derived from Japanese meaning "delicious"), a pleasant, savory taste imparted by the amino acid glutamate. The distribution of umami receptors is not known in detail, but they are present in taste buds of the vallate papillae. Second, although most people say that water has no flavor, research on humans and other vertebrates has demonstrated the presence of **water receptors**, especially in the pharynx. The sensory output of these receptors is processed in the hypothalamus and affects several systems that affect water balance and the regulation of blood volume. For example, the secretion of *antidiuretic hormone* (a hormone that regulates urination) is slightly reduced each time you take a long drink.

Gustation reception is described in Spotlight Figure 17–2b. The threshold for receptor stimulation varies for each of the primary taste sensations. Also, the taste receptors respond more readily to unpleasant than to pleasant stimuli. For example, we are almost a thousand times more sensitive to acids, which taste sour, than to either sweet or salty chemicals. We are a hundred times more sensitive to bitter compounds than to acids. This sensitivity has survival value, because acids can damage the mucous membranes of the mouth and pharynx, and many potent biological toxins have an extremely bitter taste.

Taste sensitivity differs significantly among individuals. Many conditions related to taste sensitivity are inherited. The best-known example involves sensitivity to the compound *phenylthiocarbamide* (PTC). This substance tastes bitter to some people, but is tasteless to others. PTC is not found in foods, but compounds related to PTC are found in Brussels sprouts, broccoli, cabbage, and cauliflower.

Our tasting abilities change with age. Many elderly people find that their food tastes bland and unappetizing, while children tend to find the same foods too spicy. What accounts for these differences? We begin life with more than 10,000 taste buds, but by the time we reach adulthood, the taste receptors on the pharynx, larynx, and epiglottis have decreased in number. By age 50, the number begins declining dramatically. The sensory loss becomes especially significant because, as we have already noted, older individuals also experience a decline in the number of olfactory receptors.

Checkpoint

4. Define *gustation*.
5. If you completely dry the surface of your tongue and then place salt or sugar on it, you can't taste the substance. Why not?
6. Your grandfather can't understand why foods he used to enjoy just don't taste the same anymore. How would you explain this to him?

See the blue Answers tab at the back of the book.

17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection

Learning Outcome Identify the internal and accessory structures of the eye, and explain the functions of each.

We rely more on **vision** than on any other special sense. Our eyes are elaborate structures containing our visual receptors that enable us not only to detect light, but also to create detailed visual images. We begin our discussion of these fascinating organs with the *accessory structures* of the eye (which provide protection, lubrication, and support), and then move on to the structures of the *eyeball*.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyelids and the superficial epithelium of the eye, as well as the structures involved with the production, secretion, and removal of tears. Figure 17–4 shows the superficial anatomy of the eye and its accessory structures.

Eyelids and Superficial Epithelium of the Eye

The **eyelids**, or *palpebrae*, are a continuation of the skin. Their continual blinking keeps the surface of the eye lubricated. They also act like windshield wipers, removing dust and debris. The eyelids can also close firmly to protect the delicate surface of the eye.

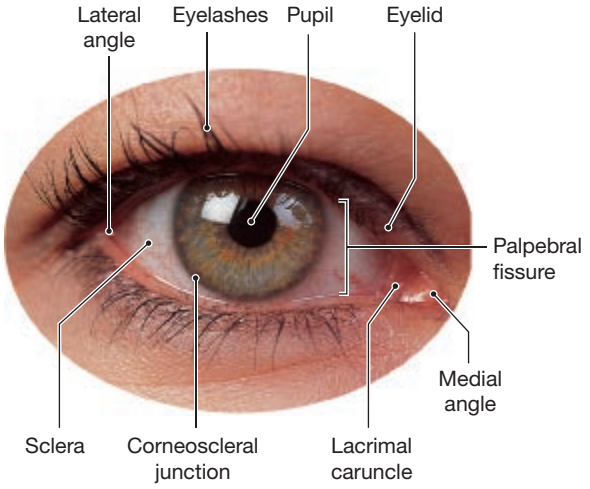
The **palpebral fissure** is the gap that separates the free margins of the upper and lower eyelids. The two eyelids are connected, however, at the **medial angle** (*medial canthus*) and the **lateral angle** (*lateral canthus*) (Figure 17–4a). The **eyelashes**, along the margins of the eyelids, are very robust hairs. They help prevent foreign matter (including insects) from reaching the surface of the eye.

The eyelashes are associated with unusually large sebaceous glands. Along the inner margin of the lid are small, modified sebaceous glands called **tarsal glands** (not shown in the figure), or *Meibomian* (mī-BŌ-mē-an) *glands*. They secrete a lipid-rich substance that helps keep the eyelids from sticking together. At the medial angle of eye, the **lacrimal caruncle** (KAR-ung-kul), a mass of soft tissue, contains glands producing the thick secretions that contribute to the gritty deposits that sometimes appear after a good night's sleep.

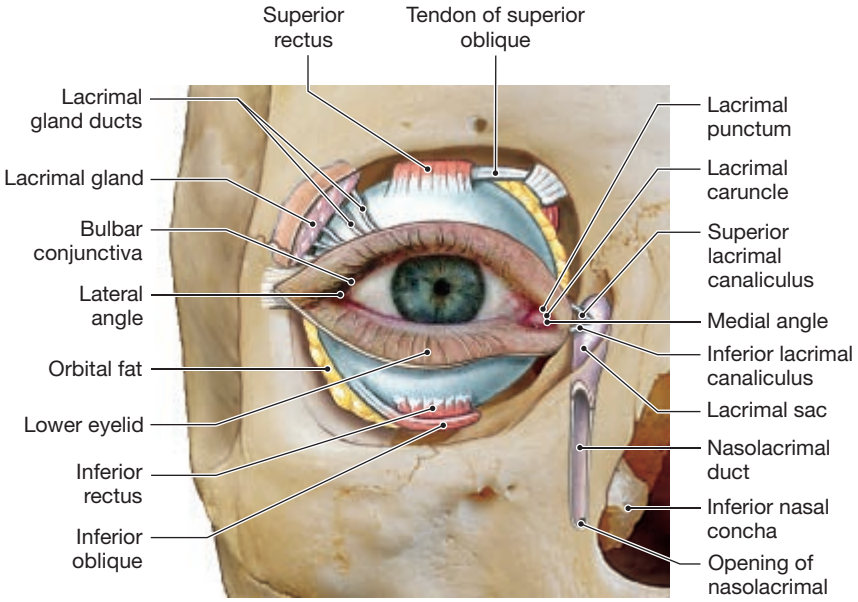
Bacteria occasionally invade and infect these various glands. A *chalazion* (kah-LĀ-zē-on; small lump) is a cyst that results from an infection of a tarsal gland. An infection in a sebaceous gland associated with an eyelash produces a painful localized swelling known as a *sty*.

The skin covering the visible surface of the eyelid is very thin. Deep to the skin lie the muscle fibers of the *orbicularis oculi* and *levator palpebrae superioris*. ↩ p. 350 These skeletal muscles close the eyelids and raise the upper eyelid, respectively.

Figure 17–4 External Features and Accessory Structures of the Eye. ATLAS: Plates 3c; 12a; 16a,b



a Gross and superficial anatomy of the accessory structures



b The organization of the lacrimal apparatus

? Choose the correct word from each pairing: The lacrimal gland is located (inferior, superior) and (lateral, medial) to the eye.

The epithelium covering the inner surfaces of the eyelids and the outer surface of the eyeball is called the **conjunctiva** (kon-junk-TĪ-vuh). It is a mucous membrane covered by a specialized stratified squamous epithelium. The **palpebral conjunctiva** covers the inner surface of the eyelids. The **bulbar conjunctiva**, or *ocular conjunctiva,* covers the anterior surface of the eye (Figure 17–4b).

The bulbar conjunctiva extends to the edges of the **cornea** (KOR-nē-uh), a transparent part of the outer fibrous layer of the eye. The cornea is covered by a very delicate squamous *corneal epithelium,* five to seven cells thick, that is continuous with the bulbar conjunctiva. A constant supply of fluid washes over the surface of the eyeball, keeping the bulbar conjunctiva and cornea moist and clean. Mucous cells in the epithelium assist the accessory glands in lubricating the surfaces of the conjunctiva to prevent drying out and friction.

Conjunctivitis, or *pinkeye,* is an inflammation of the conjunctiva. The most obvious sign, redness, is due to the dilation of blood vessels deep to the conjunctival epithelium. This condition may be caused by pathogenic infection or by physical, allergic, or chemical irritation of the conjunctival surface.

The Lacrimal Apparatus

A constant flow of tears keeps conjunctival surfaces moist and clean. Tears reduce friction, remove debris, prevent bacterial infection, and provide nutrients and oxygen to portions of the conjunctival epithelium. The **lacrimal apparatus** produces, distributes, and removes tears. The lacrimal apparatus of each eye consists of (1) a *lacrimal gland* with associated ducts, (2) paired *lacrimal canaliculi,* (3) a *lacrimal sac,* and (4) a *nasolacrimal duct* (see Figure 17–4b).

The **fornix** of the eye is a pocket created where the palpebral conjunctiva becomes continuous with the bulbar conjunctiva. The lateral portion of the superior fornix receives 10–12 ducts from the **lacrimal gland**, or tear gland (see Figure 17–4b). This gland is about the size and shape of an almond, measuring roughly 12–20 mm (0.5–0.75 in.). It nestles within a depression in the frontal bone, just inside the orbit and superior and lateral to the eyeball. ↩ p. 217

The lacrimal gland normally provides the key ingredients and most of the volume of the tears that bathe the conjunctival surfaces. The lacrimal secretions supply nutrients and oxygen to the corneal cells by diffusion. The lacrimal secretions are watery and slightly alkaline. They contain the antibacterial enzyme **lysozyme** and antibodies that attack pathogens before they enter the body.

Each lacrimal gland produces about 1 mL of tears each day. Once the lacrimal secretions have reached the ocular surface, they mix with the products of accessory glands and the oily secretions of the tarsal glands. The result is a superficial "oil slick" that aids lubrication and slows evaporation.

Blinking sweeps the tears across the ocular surface. Tears accumulate at the medial angle of eye in an area known as the *lacrimal lake,* or "lake of tears." The lacrimal lake covers the lacrimal caruncle, which bulges anteriorly. The **lacrimal puncta** (singular, *punctum*), two small pores, drain the lacrimal lake. They empty into the **lacrimal canaliculi**, small canals that in turn lead to the **lacrimal sac**, which nestles within the lacrimal sulcus of the orbit (see Figure 17–4b). ↩ p. 223

From the inferior portion of the lacrimal sac, the **nasolacrimal duct** passes through the *nasolacrimal canal,* formed by the lacrimal bone and the maxilla. This duct delivers tears to the nasal cavity on that side. The duct empties into the *inferior meatus,* a narrow passageway inferior and lateral to the inferior nasal concha. When a person cries, tears rushing into the nasal cavity produce a runny nose. If the lacrimal puncta can't provide enough drainage, the lacrimal lake overflows and tears stream across the face.

Anatomy of the Eyeball

17

Your eyes are extremely sophisticated visual instruments. They are more versatile and adaptable than the most expensive cameras, yet compact and durable. Each **eyeball** is a slightly irregular spheroid (Figure 17–5a), a little smaller than a Ping-Pong ball, with an average diameter of 24 mm (almost 1 inch) and also a weight of about 8 g (0.28 oz). Within the orbit, the eyeball shares space with the extrinsic eye muscles, the lacrimal gland, and the cranial nerves and blood vessels that supply the eye and adjacent portions of the orbit and face. **Orbital fat** cushions and insulates the eye.

The wall of the eyeball has three distinct layers, formerly called tunics (Figure 17–5b): (1) an outer *fibrous layer* (2) an intermediate *vascular layer (uvea),* and (3) a deep *inner layer (retina).* The visual receptors, or *photoreceptors,* are located in the inner layer.

The eyeball itself is hollow and filled with fluid. Its interior can be divided into two cavities, anterior and posterior (Figure 17–5c). The **anterior cavity** has two chambers, the *anterior chamber* (between the cornea and the iris) and the *posterior chamber* (between the iris and the transparent *lens*). A clear, watery fluid called *aqueous (Ā-kwē-us) humor* fills the entire anterior cavity. The **posterior cavity**, or *vitreous chamber,* contains a gelatinous substance called the *vitreous body.*

The Fibrous Layer

The **fibrous layer**, the outermost layer of the eyeball, consists of the whitish *sclera* (SKLER-uh) and the transparent *cornea.* The fibrous layer (1) supports and protects the eye, (2) serves as an attachment site for the extrinsic eye muscles, and (3) contains structures that assist in focusing.

The Sclera. The **sclera**, or "white of the eye," covers most of the ocular surface (see Figure 17–5c). The sclera consists of a dense fibrous connective tissue containing both collagen and elastic fibers. This layer is thickest over the posterior surface of the eye, near the exit of the optic nerve. The sclera is thinnest over the anterior surface. The six extrinsic eye muscles insert on the sclera, blending their collagen fibers with those of the fibrous layer. ↩ p. 349

The surface of the sclera contains small blood vessels and nerves that penetrate the sclera to reach internal structures. The network of small vessels interior to the bulbar conjunctiva generally does not carry enough blood to lend an obvious color to the sclera. On close inspection, however, the vessels are visible as red lines against the white background of collagen fibers.

The Cornea. The transparent **cornea** is structurally continuous with the sclera. The border between the two is called the **corneoscleral junction**, or *corneal limbus* (see Figure 17–5c). Deep to the delicate corneal epithelium, the cornea consists primarily of a dense matrix containing multiple layers of collagen fibers, organized so as not to interfere with the passage of light. The cornea has no blood vessels. Its superficial epithelial cells obtain oxygen and nutrients by diffusion from the tears that flow across their free surfaces. The cornea also has numerous free nerve endings, making it the most sensitive portion of the eye.

Damage to the cornea may cause blindness even though the functional components of the eye—including the photoreceptors—are perfectly normal. The cornea has a very restricted ability to repair itself. For this reason, corneal injuries must be treated immediately to prevent serious vision losses.

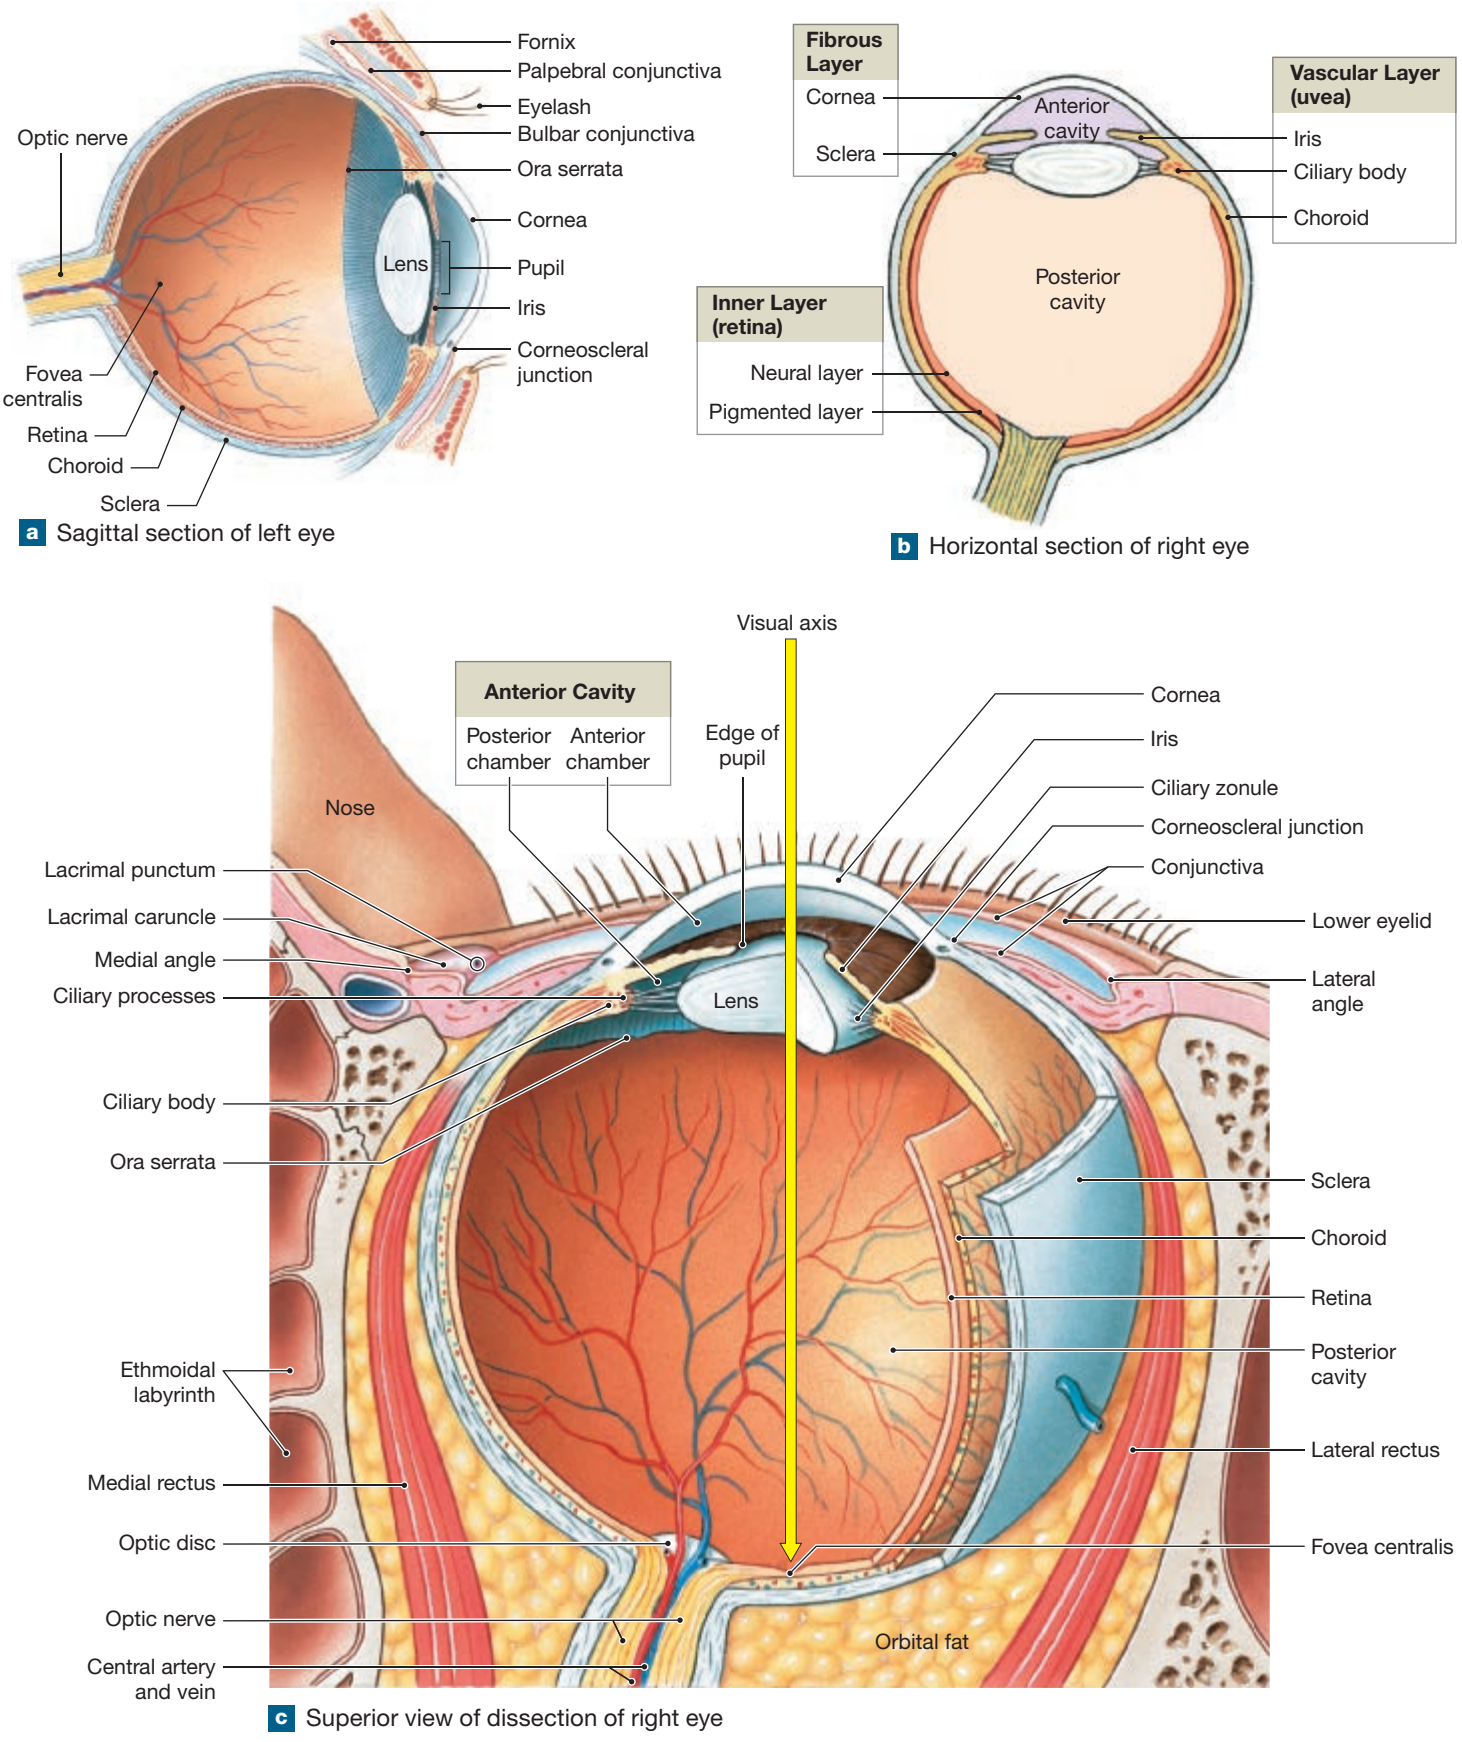
Restoring vision after corneal scarring generally requires replacing the cornea through a *corneal transplant*. Corneal replacement is probably the most common form of transplant surgery. Such transplants can be performed between unrelated individuals, because there are no blood vessels to carry white blood cells, which attack foreign tissues, into the area. Corneal grafts are obtained from donor eyes. For best results, the tissues must be removed within 5 hours after the donor's death.

The Vascular Layer

The **vascular layer**, or *uvea* (YŪ-vē-uh), is a pigmented region that includes the *iris*, *ciliary body*, and *choroid* (see Figure 17–5b,c). It contains numerous blood vessels, lymphatic vessels, and the intrinsic (smooth) muscles of the eye. This middle layer (1) provides a route for blood vessels and lymphatics that supply the tissues of the eye; (2) regulates the amount of light that enters the eye; (3) secretes and reabsorbs the aqueous humor that circulates within the chambers of the eye; and (4) controls the shape of the lens, an essential part of the focusing process.

The Iris. The **iris**, a pigmented, flattened ring structure, is visible through the transparent corneal surface. The iris contains blood vessels, pigment cells (melanocytes), and two layers

Figure 17–5 The Sectional Anatomy of the Eye. ATLAS: Plates 12a; 16a,b



17

of smooth muscle fibers called *pupillary muscles*. When these muscles contract, they change the diameter of the **pupil**, the central opening of the iris. There are two groups of pupillary muscles: *dilator pupillae* and *sphincter pupillae* (Figure 17–6). The autonomic nervous system controls both muscle groups. For example, in response to dim light, sympathetic activation causes the pupils to dilate. In response to bright light, parasympathetic activation causes the pupils to constrict. p. 550

How is eye color determined? Our genes influence the density and distribution of melanocytes in the iris, as well as the density of the pigmented epithelium. When the connective tissue of the iris contains few melanocytes, light passes through it and reflects off the pigmented epithelium. The eye then appears blue. Individuals with green, brown, or black eyes have increasing numbers of melanocytes in the body and on the surface of the iris. The eyes of people with albinism, whose cells do not produce melanin, appear a very pale gray or blue-gray.

The Ciliary Body. At its periphery, the iris attaches to the anterior portion of the **ciliary body**, a thickened region that begins deep to the corneoscleral junction. The ciliary body extends posteriorly to the level of the **ora serrata** (Ō-ra ser-RAH-tuh; serrated mouth), the serrated anterior edge of the neural layer of the retina (see Figure 17–5c). The bulk of the ciliary body consists of the **ciliary muscle**, a ring of smooth muscle that projects into the interior of the eye. The epithelium covering this muscle has numerous folds called **ciliary processes**. The **ciliary zonule** (*suspensory ligament*) is the ring of fibers that attaches the lens to the ciliary processes. The connective tissue fibers hold the lens in place posterior to the iris and centered on the pupil. As a result, any light passing through the pupil also passes through the lens.

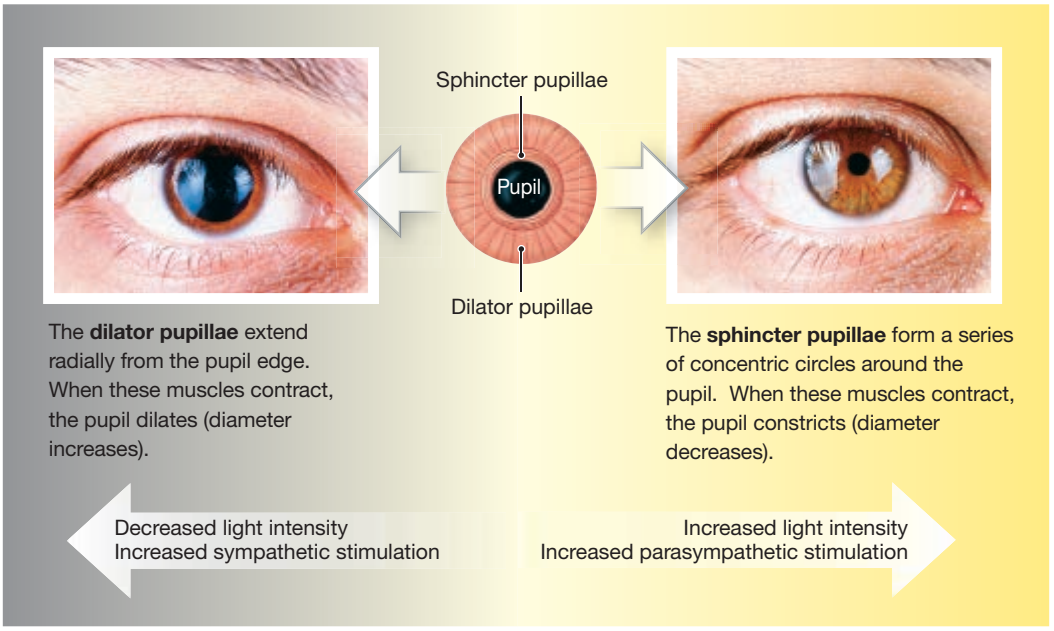
The Choroid. The **choroid** (KOR-oyd) is a vascular layer that separates the fibrous layer and the inner layer posterior to the ora serrata (see Figure 17–5c). The choroid is covered by the sclera and attached to the outermost layer of the retina. An extensive capillary network in the choroid delivers oxygen and nutrients to the retina. The choroid also contains melanocytes, which are especially numerous near the sclera.

The Inner Layer: The Retina

The **inner layer**, or **retina**, is the deepest of the three layers of the eye. It consists of a thin lining called the *pigmented layer*, and a thicker, covering called the *neural layer*. The pigmented layer contains pigment cells that support the functions of the photoreceptors, which are located in the neural layer of the retina. These two layers of the retina are normally very close together, but not tightly interconnected. The pigmented layer of the retina continues over the ciliary body and iris, but the neural layer extends anteriorly only as far as the ora serrata. The neural layer of the retina forms a cup that establishes the posterior and lateral boundaries of the posterior cavity (see Figure 17–5b,c).

Pigmented Layer of the Retina. The pigmented layer of the retina absorbs light that passes through the neural layer, preventing light from bouncing (reflecting) back through the neural layer and producing visual "echoes." The pigment cells also have important biochemical interactions with the retina's photoreceptors.

Figure 17–6 The Pupillary Muscles.



Neural Layer: Cellular Organization. In sectional view, the neural layer of the retina contains several layers of cells (Figure 17–7a). The inner layers of the retina contain supporting cells and neurons that do preliminary processing and integration of visual information. The outermost part, closest to the pigmented layer of the retina, contains the **photoreceptors**, the cells that detect light.

The eye has two main types of photoreceptors: rods and cones. **Rods** do not discriminate among colors of light. Highly sensitive to light, they enable us to see in dimly lit rooms, at twilight, and in pale moonlight. **Cones** give us color vision. Cones give us sharper, clearer images than rods do, but cones require more intense light. If you sit outside at sunset with your textbook open to a colorful illustration, you can detect the gradual shift in your visual system from cone-based vision (a clear image in full color) to rod-based vision (a relatively grainy image in black and white). A third type of photoreceptor is the *intrinsically photosensitive retinal ganglion cell* (ipRGC). The photopigment in the ipRGC is melanopsin. These cells are known to respond to different levels of brightness and influence the body's 24-hour circadian rhythm (biological clock).

Tips & Tools

Associate the **r** in **r**od with the **r** in da**r**k, and associate the **c** in **c**ones with the **c** in **c**olor and in a**c**uity (sharpness).

Rods and cones are not evenly distributed across the retina. Approximately 125 million rods form a broad band around the periphery of the retina. As you move toward the center of the retina, the density of rods gradually decreases. In contrast, most of the roughly 6 million cones are concentrated in the area where a visual image arrives after it passes through the cornea and lens. This region, known as the **macula** (MAK-yū-luh; spot), has no rods. The highest concentration of cones occurs at the center of the macula, an area called the **fovea centralis** (FŌ-vē-uh; shallow depression), or simply the **fovea** (Figure 17–7b). The fovea centralis is the site of sharpest color vision. When you look directly at an object, its image falls on this portion of the retina. An imaginary line drawn from the center of that object through the center of the lens to the fovea centralis establishes the **visual axis** of the eye (look back at Figure 17–5c).

What are some of the visual consequences of this distribution of photoreceptors? When you look directly at an object, you are placing its image on the fovea centralis. You see a very good image as long as there is enough light to stimulate the cones. But in very dim light, cones cannot function. That is why you can't see a dim star if you stare directly at it, but you can see it if you shift your gaze to one side or the other. Shifting your gaze moves the image of the star from the fovea centralis, where it does not provide enough light to stimulate the cones, to the periphery, where it can affect the more sensitive rods.

Rods and cones synapse with about 6 million neurons called **bipolar cells** (see Figure 17–7a). These cells in turn synapse within the layer of the 1 million neurons called **ganglion cells**, which lie adjacent to the posterior cavity. A network of **horizontal cells** extends across the neural layer of the retina at the level of the synapses between photoreceptors and bipolar cells. A comparable network of **amacrine** (AM-ah-krin) **cells** occurs where bipolar cells synapse with ganglion cells. Horizontal and amacrine cells can facilitate or inhibit communication between photoreceptors and ganglion cells, altering the sensitivity of the retina. These cells play an important role in the eye's adjustment to dim or brightly lit environments.

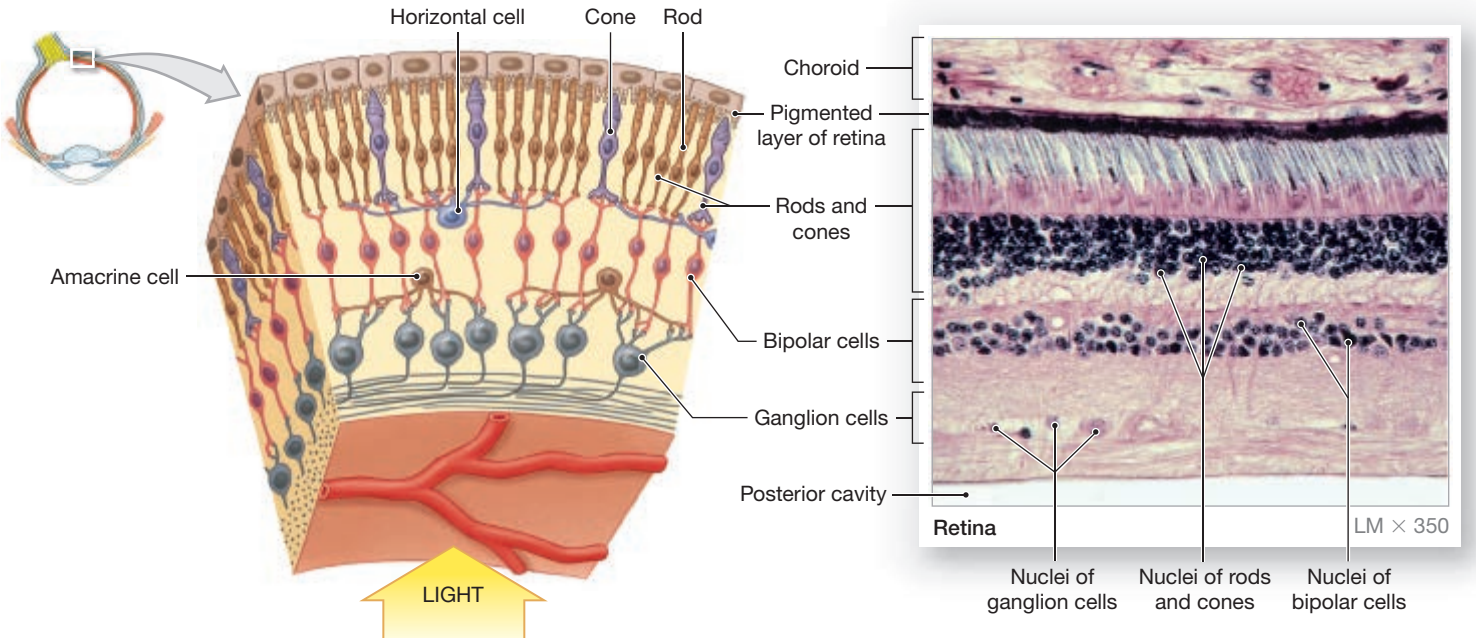
Neural Layer: The Optic Disc. Axons from an estimated 1 million ganglion cells converge on the **optic disc**, a circular region just medial to the fovea centralis. The optic disc is the origin of the optic nerve (II). From this point, the axons turn, penetrate the wall of the eye, and proceed toward the diencephalon (Figure 17–7c). The *central retinal artery* and *central retinal vein*, which supply the retina, pass through the center of the optic nerve and emerge on the surface of the optic disc (see Figure 17–7c).

The optic disc has no photoreceptors or other structures typical of the rest of the retina. Because light striking the optic disc goes unnoticed, this area is commonly called the **blind spot**. Why don't you see a blank spot in your field of vision?

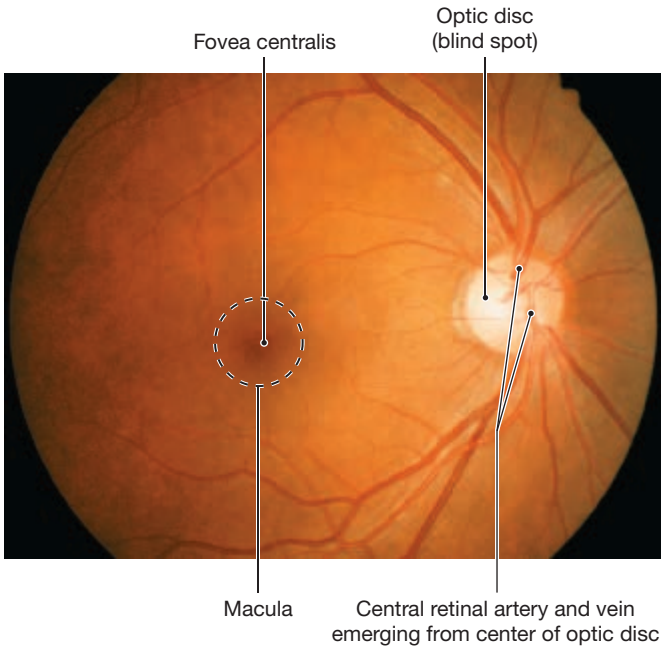
+ Clinical Note Diabetic Retinopathy

A *retinopathy* is a disease of the retina. **Diabetic retinopathy** develops in many people with *diabetes mellitus*, an endocrine disorder that interferes with glucose metabolism. Diabetes affects many systems and is a risk factor for heart disease. Diabetic retinopathy develops over years. It results from the blockage of small retinal blood vessels, followed by excessive growth of abnormal blood vessels. These blood vessels invade the retina and extend into the space between its two parts—the pigmented layer and the neural layer. Visual acuity is gradually lost through damage to photoreceptors (which are deprived of oxygen and nutrients), leakage of blood into the posterior cavity, and the overgrowth of blood vessels. Laser therapy can seal leaking vessels and block new vessel growth. The posterior cavity can be drained and the cloudy fluid replaced by a suitably clear substitute. However, these are only temporary, imperfect fixes. Diabetic retinopathy is the primary cause of blindness in the United States.

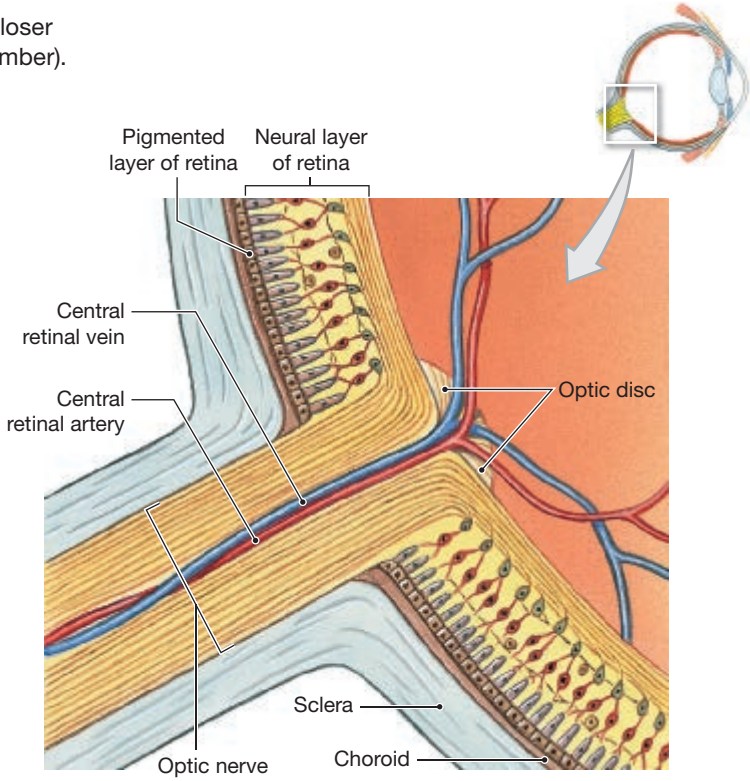
Figure 17–7 The Organization of the Retina.



a The cellular organization of the retina. The photoreceptors are closer to the choroid than they are to the posterior cavity (vitreous chamber).



b A photograph of the retina as seen through the pupil.



c The optic disc in diagrammatic sagittal section.

? Amacrine cells are found where what other types of cells synapse? Horizontal cells are found where what other types of cells synapse?

The reason is that involuntary eye movements keep the visual image moving and allow your brain to fill in the missing information. However, try the simple activity in Figure 17–8 to prove that a blind spot really exists in your field of vision.

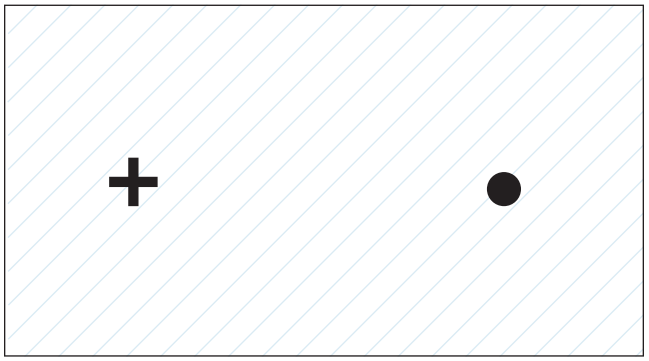
The Chambers of the Eye

Recall that the ciliary body and lens divide the interior of the eye into a large posterior cavity and a smaller anterior cavity made up of anterior and posterior chambers (look back at Figure 17–5c). Both chambers are filled with aqueous humor. The posterior cavity also contains aqueous humor, but the gelatinous *vitreous body* takes up most of its volume.

Aqueous Humor. Aqueous humor is a fluid that circulates within the anterior cavity. It passes from the posterior chamber to the anterior chamber through the pupil (Figure 17–9). It also freely diffuses through the posterior cavity and across the surface of the retina. Its composition resembles that of cerebrospinal fluid.

Aqueous humor forms through active secretion by epithelial cells of the ciliary body's ciliary processes. The epithelial

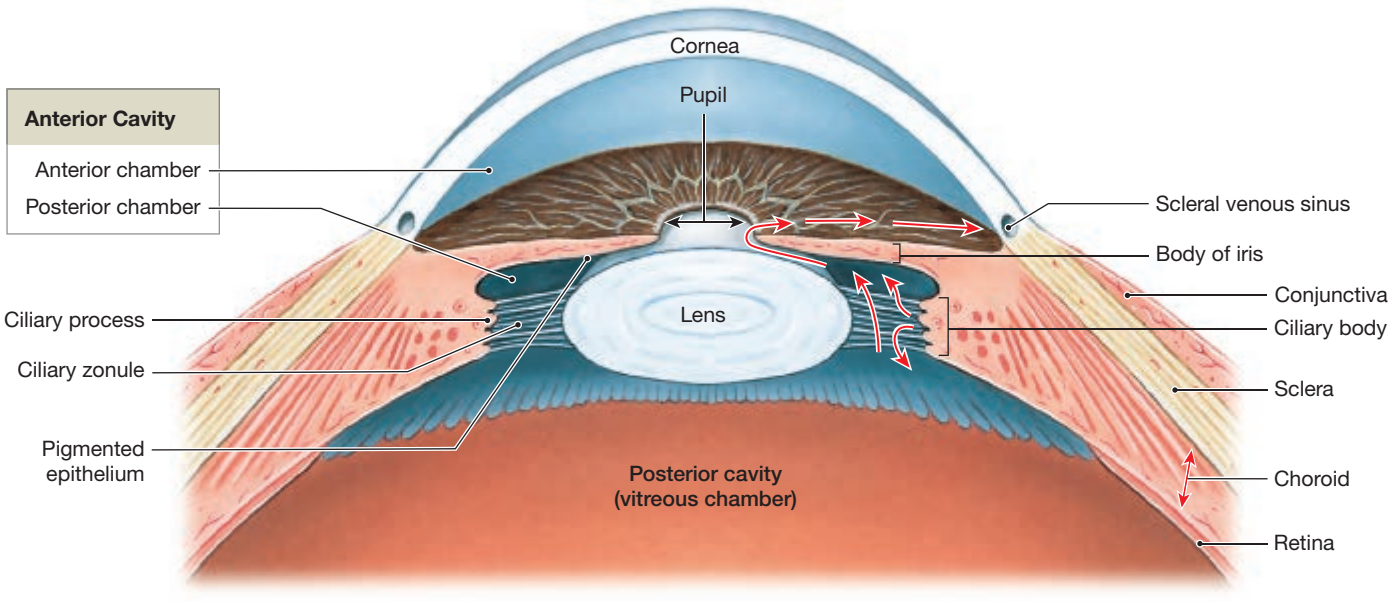
Figure 17–8 A Demonstration of the Presence of a Blind Spot. Close your left eye and stare at the plus sign with your right eye, keeping the plus sign in the center of your field of vision. Begin with the page a few inches away from your eye, and gradually increase the distance. The dot will disappear when its image falls on the blind spot, at your optic disc. To check the blind spot in your left eye, close your right eye and repeat the sequence while you stare at the dot.



+ Clinical Note Detached Retina

Photoreceptors depend entirely on the diffusion of oxygen and nutrients from blood vessels in the choroid. In a **detached retina**, the neural layer of the retina becomes separated from the pigmented layer. This condition can result from a variety of factors, including a sudden hard impact to the eye. This is a medical emergency—unless the two parts of the retina are reattached, the photoreceptors will degenerate and vision will be lost. Reattachment involves "welding" the two parts together using laser beams focused through the cornea. These beams heat the two parts, fusing them together at several points around the retina. However, the procedure destroys the photoreceptors at the "welds," producing permanent blind spots.

Figure 17–9 The Circulation of Aqueous Humor. Aqueous humor, which is secreted at the ciliary body, circulates through the posterior and anterior chambers before it is reabsorbed through the scleral venous sinus.



cells regulate its composition. Because aqueous humor circulates, it provides an important route for nutrient and waste transport. It also serves as a fluid cushion.

Because the eyeball is filled with aqueous humor, pressure provided by this fluid helps retain the eye's shape. Fluid pressure also stabilizes the position of the retina, pressing the neural layer against the pigmented layer. In effect, the aqueous humor acts like the air inside a balloon.

The eye's **intra-ocular pressure** can be measured in the anterior chamber, where the fluid pushes against the inner surface of the cornea. Intra-ocular pressure is usually checked by applanation tonometry whereby a small, flat disk is placed on the anesthetized cornea to measure the tension. Normal intraocular pressure ranges from 12 to 21 mm Hg.

Aqueous humor is secreted into the posterior chamber at a rate of 1–2 mL per minute. It leaves the anterior chamber at the same rate. After filtering through a network of connective tissues located near the base of the iris, aqueous humor enters the **scleral venous sinus** (*canal of Schlemm*), a passageway that extends completely around the eye at the level of the corneoscleral junction. Collecting channels then deliver the aqueous humor to veins in the sclera.

Aqueous humor is removed and recycled within a few hours of its formation. The rate of removal normally keeps pace with the rate of generation at the ciliary processes.

The Vitreous Body. The posterior cavity of the eye contains the **vitreous body**, a gelatinous mass. Its fluid portion is called **vitreous humor**. The vitreous body helps stabilize the shape of the eye. Otherwise, the eye might distort as the extrinsic eye muscles change its position within the orbit. Specialized cells embedded in the vitreous body produce the collagen fibers and proteoglycans that account for the gelatinous consistency of this mass. Unlike the aqueous humor, the vitreous body is formed during development and is not replaced.

Clinical Note Glaucoma

If aqueous humor cannot drain into the scleral venous sinus, intra-ocular pressure rises due to the continued production of aqueous humor, and **glaucoma** results. The sclera is a fibrous coat, so it cannot expand like an inflating balloon, but it does have one weak point—the optic disc, where the optic nerve penetrates the wall of the eye. Gradually the increasing pressure pushes the optic nerve outward, damaging its nerve fibers. When the intra-ocular pressure has risen to roughly twice the normal level, the distortion of the optic nerve fibers begins to interfere with the propagation of action potentials, and peripheral vision begins to deteriorate. If this condition is not corrected, tunnel vision and then complete blindness may result.

Although the primary factors responsible are not known, glaucoma is relatively common. For this reason, most eye exams include a test of intra-ocular pressure. Glaucoma may be treated by topical drugs that constrict the pupil and tense the edge of the iris, making the surface more permeable to aqueous humor. Surgical correction involves perforating the wall of the anterior chamber to encourage drainage.

The Lens

The **lens** is a transparent, biconvex (outwardly curving) flexible disc that lies posterior to the cornea and is held in place by the ciliary zonule that originates on the ciliary body of the choroid (see Figure 17–9). The primary function of the lens is to focus the visual image on the photoreceptors. The lens does so by changing its shape.

The lens consists of concentric layers of cells. A dense fibrous capsule covers the entire lens. Many of the capsular fibers are elastic. Unless an outside force is applied, they will contract and make the lens spherical. Around the edges of the lens, these capsular fibers intermingle with those of the ciliary zonule.

The cells in the interior of the lens are called **lens fibers**. These highly specialized cells have lost their nuclei and other organelles. They are long and slender and are filled with transparent proteins called **crystallins**. These proteins give the lens both its clarity and its focusing power. Crystallins are extremely stable proteins—they remain intact and functional for a lifetime.

The transparency of the lens depends on the crystallin proteins maintaining a precise combination of structural and biochemical characteristics. Because these proteins are not renewed, any modifications they undergo over time can accumulate and result in the lens losing its transparency. This abnormality is known as a **cataract**. Cataracts can result from injuries, UV radiation, or reaction to drugs. **Senile cataracts**, however, are a natural consequence of aging and are the most common form.

Over time, the lens turns yellowish and eventually begins to lose its transparency. As the lens becomes "cloudy," the individual needs brighter and brighter light for reading. Visual clarity begins to fade. If the lens becomes completely opaque, the person will be functionally blind, even though the photoreceptors are normal.

Cataract surgery involves removing the lens, either intact or after it has been shattered with high-frequency sound waves. The missing lens is then replaced by an artificial substitute. Vision is then fine-tuned with glasses or contact lenses.

17-4 The focusing of light on the retina leads to the formation of a visual image

Learning Outcome Describe how refraction and the focusing of light on the retina lead to vision.

Each of the millions of photoreceptors monitors the light striking a specific site on the retina. The processing of information from all the receptors produces a visual image. To understand how this happens, we need to look into the properties of light itself, and how light interacts with the structures of our eyes.

An Introduction to Light

Light energy is a form of *radiant energy* that travels in waves with characteristic *wavelengths* (distances between wave peaks). Let's look at the relationship between wavelengths and color, and learn what happens when light rays encounter an object such as our eyes.

Wavelength and Color

Our eyes are sensitive to wavelengths of 700–400 nm, the spectrum of visible light. Remember this spectrum, as seen in a rainbow, with the acronym ROY G. BIV (**R**ed, **O**range, **Y**ellow, **G**reen, **B**lue, **I**ndigo, **V**iolet). Visible light is also described as being made up of photons, small energy packets with characteristic wavelengths. Photons of red light carry the least energy and have the longest wavelength. Photons from the violet portion of the spectrum contain the most energy and have the shortest wavelength.

Refraction and Focusing of Light

The eye is often compared to a camera. To provide useful information, the lens of the eye, like a camera lens, must *focus* the arriving image. To say that an image is "in focus" means that the light rays arriving from an object strike the sensitive surface of the retina (or the semiconductor device that records light electronically in digital cameras) in precise order so as to form a miniature image of the object. If the rays are not perfectly focused, the image is blurry.

Focusing normally occurs in two steps, as light passes first through the cornea and then the lens. To focus the light on the retina, the lens must change shape, or undergo *accommodation*.

Refraction. Light is **refracted**, or bent, when it passes from one medium to another medium with a different density. You can see this effect if you stick a pencil into a glass of water. Notice that the shaft of the pencil appears to bend sharply at the air–water interface. This effect occurs when light is refracted as it passes into the air from the much denser water.

In the human eye, the greatest amount of refraction occurs when light passes from the air into the corneal tissues, which have a density close to that of water. When you open your eyes under water, you cannot see clearly because refraction at the corneal surface has been largely eliminated. Light passes unbent from one watery medium to another.

Additional refraction takes place when the light passes from the aqueous humor in the anterior chamber into the relatively dense lens. The lens provides the extra refraction needed to focus the light rays from an object toward a **focal point**—a specific point of intersection on the retina.

The distance between the center of the lens and its focal point is the **focal distance** of the lens. Whether in the eye or in a camera, the focal distance is determined by two factors:

- *The Distance of the Object from the Lens.* The closer an object is to the lens, the greater the focal distance (Figure 17–10a,b).
- *The Shape of the Lens.* The rounder the lens, the more refraction occurs. So, a very round lens has a shorter focal distance than a flatter one (Figure 17–10b,c).

If light passing through the cornea and lens is not refracted properly, the visual image will be distorted. In the condition called **astigmatism**, the degree of curvature in the cornea or lens varies from one axis to another. Minor astigmatism is very common. The image distortion may be so minimal that people are unaware of the condition.

Figure 17–10 Factors Affecting Focal Distance. Light rays from a source are refracted when they reach the lens of the eye. The rays are then focused onto a single focal point.

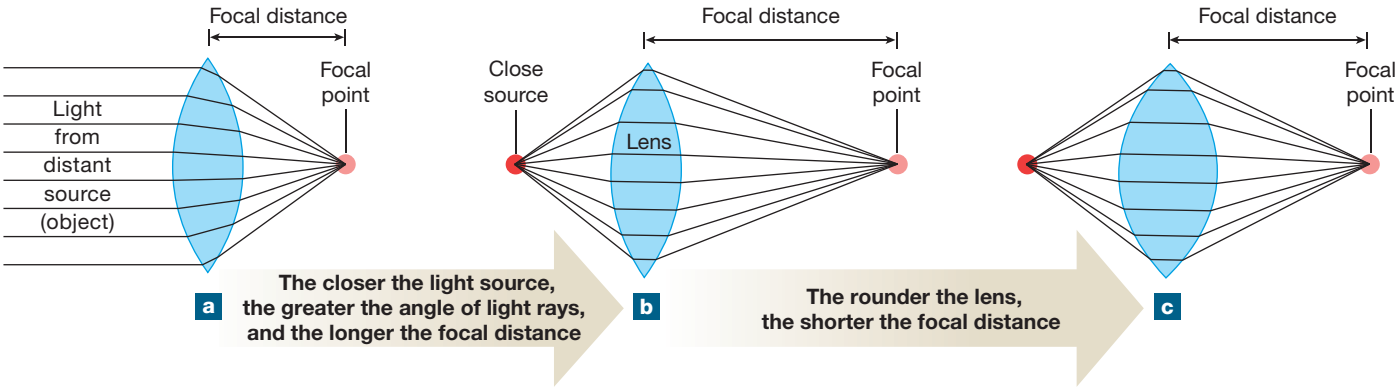

Figure 17–11 Accommodation. For the eye to form a sharp image, the lens becomes rounder for close objects and flatter for distant objects.

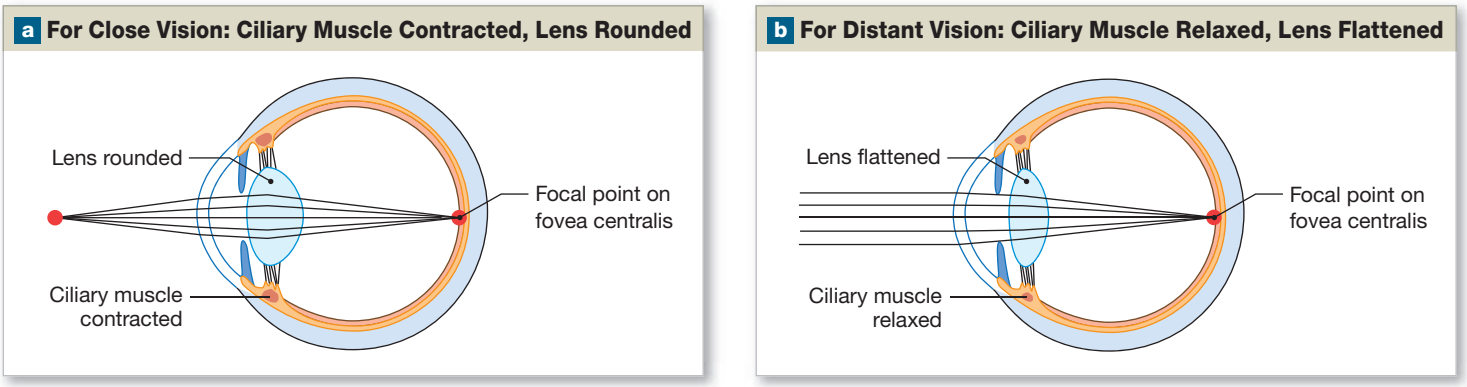


Accommodation. **Accommodation** is the automatic adjustment of the eye to give us clear vision (Figure 17–11). During accommodation, the lens becomes rounder to focus the image of a nearby object on the retina. The lens becomes flatter to focus the image of a distant object on the retina.

How does the lens change shape? The lens is held in place by the ciliary zonule that originates at the ciliary body. Smooth muscle fibers in the ciliary body act like sphincter muscles. When the ciliary muscle contracts, the ciliary body moves toward the lens, thereby reducing the tension in the ciliary zonule. The elastic capsule then pulls the lens into a rounder shape that increases the refractive (bending) power of the lens. This enables it to bring light from nearby objects into focus on the retina (see Figure 17–11a). When the ciliary muscle relaxes, the ciliary zonule pulls at the circumference of the lens, making the lens flatter (see Figure 17–11b).

The greatest amount of refraction is required to view objects that are very close to the lens. The inner limit of clear vision, known as the *near point of vision,* is determined by the degree of elasticity in the lens. Children can usually focus on something 7–9 cm (3–4 in.) from the eye, but over time the lens tends to become stiffer and less responsive. A young adult can usually focus on objects 15–20 cm (6–8 in.) away. As we age, this distance gradually increases. The near point at age 60 is typically about 83 cm (33 in.).

Image Formation and Reversal

We have been discussing light that originates at a single point, either near or far from the viewer. However, an object we see is really a complex light source that must be treated as a number of individual points. Light from each point is focused on the retina as in Figure 17–12a,b. The result is a miniature image of the original, but the image arrives upside down and reversed from left to right.

Why does an image arrive upside down? Consider Figure 17–12c, a sagittal section through an eye that is looking at a telephone pole. The image of the top of the pole lands at the bottom of the retina, and the image of the bottom hits the top of the retina. Now consider Figure 17–12d, a horizontal section through an eye that is looking at a picket fence. The image of the left edge of the fence falls on the right side of the retina, and the image of the right edge falls on the left side of the retina. The brain compensates for this image reversal, so you are not aware of any difference between the orientation of the image on the retina and that of the object.

Visual Acuity

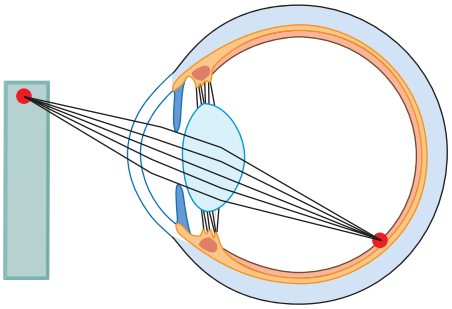
How well you see, or your **visual acuity**, is rated by comparison to a "normal" standard. The standard vision rating of 20/20 is defined as the level of detail seen at a distance of 20 feet by a person with normal vision. That is, a person with a visual acuity of 20/20 sees clearly at 20 feet what should normally be seen at 20 feet. Vision rated as 20/15 is better than average, because at 20 feet the person is able to see details that would be clear to a normal eye only at a distance of 15 feet. Conversely, a person with 20/30 vision must be 20 feet from an object to discern details that a person with normal vision could make out at a distance of 30 feet.

When visual acuity falls below 20/200, even with the help of glasses or contact lenses, the individual is considered to be legally blind. It is estimated that there are 1.3 million legally blind people in the United States, and more than half of those are over 65 years old. The term *blindness* implies a total absence of vision due to damage to the eyes or to the optic pathways. Common causes of blindness include diabetes mellitus, cataracts, glaucoma, corneal scarring, retinal detachment, accidental injuries, and hereditary factors that are still not understood.

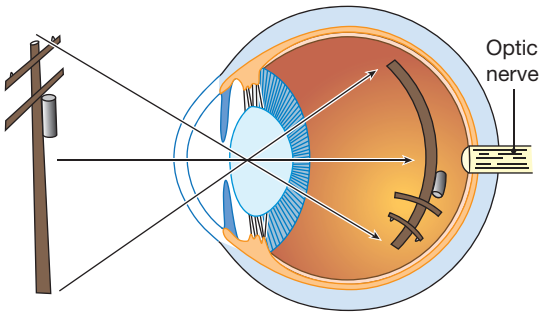
An abnormal blind spot, or **scotoma** (skō-TŌ-muh), may appear in the field of vision at positions other than at the optic disc. A scotoma is permanent and may result from compression of the optic nerve, damage to photoreceptors, or central damage along the visual pathway.

Floaters are small spots that drift across the field of vision. They are generally temporary and result from blood cells or cellular debris in the vitreous body. You may have seen floaters if you have ever stared at a blank wall or a white sheet of paper and noticed these little spots. Spotlight Figure 17–13 describes common visual abnormalities.

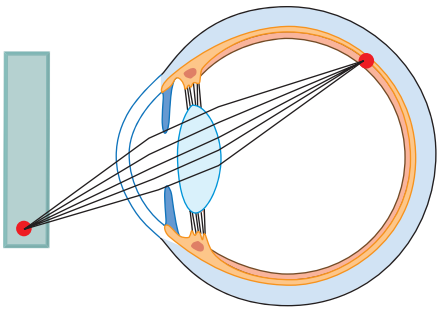
Figure 17–12 Image Formation. These illustrations are not drawn to scale because the fovea centralis occupies a small area of the retina, and the projected images are very tiny. As a result, the crossover of light rays is shown in the lens, but it actually occurs very close to the fovea centralis.



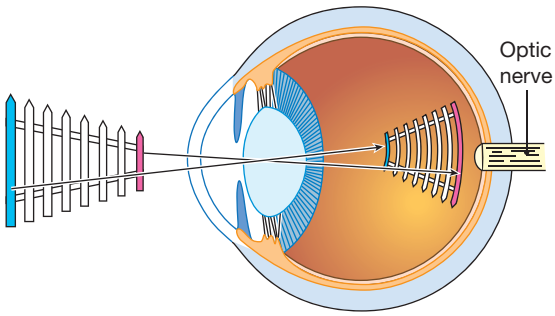
a Light from a point at the top of an object is focused on the lower retinal surface.



c Light rays projected from a vertical object show why the image arrives upside down. (Note that the image is also reversed.)



b Light from a point at the bottom of an object is focused on the upper retinal surface.



d Light rays projected from a horizontal object show why the image arrives with a left and right reversal. The image also arrives upside down.

Checkpoint

10. Define *focal point*.
11. When the lens of your eye is more rounded, are you looking at an object that is close to you or far from you?

See the blue Answers tab at the back of the book.

17-5 Photoreceptors transduce light into electrical signals that are then processed in the visual cortex

Learning Outcome Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain.

How does our special sense of vision work? Let's begin to answer this question by examining the structure of photoreceptors, and then the physiology of vision, the way in which photoreceptors function. Finally, we will consider the structure and function of the visual pathways.

Physiology of Vision

The rods and cones of the retina are called photoreceptors because they detect *photons*, basic units of visible light. Rods provide the central nervous system with information about the presence or absence of photons, with little regard to their wavelength. Cones provide information about the wavelength of arriving photons, giving us the perception of color.

Anatomy of Photoreceptors: Rods and Cones

Figure 17–14a compares the structures of **photoreceptors**, rods and cones. The names *rod* and *cone* refer to the shape of each photoreceptor's outer segment. Both rods and cones contain special organic compounds called *visual pigments*. These pigments are located in each photoreceptor's outer segment, in flattened membranous plates called *discs*. Please study this figure before reading on.

Physiology of Photoreceptors

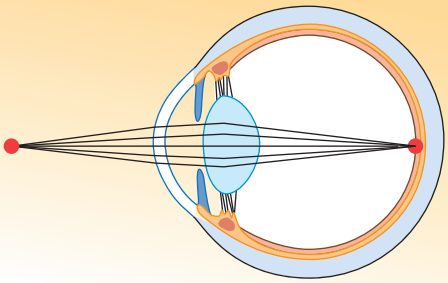
Visual pigments are able to absorb photons; this is the first key step in the process of **photoreception** —the detection of light. This section looks at the function of photoreceptors and the visual pigments they contain.

Visual Pigments. Visual pigments are derivatives of the compound **rhodopsin** (rō-DOP-sin), or *visual purple*, the visual pigment found in rods (Figure 17–14b). Rhodopsin consists of a protein, **opsin**, bound to the pigment **retinal** (RET-ih-nal),

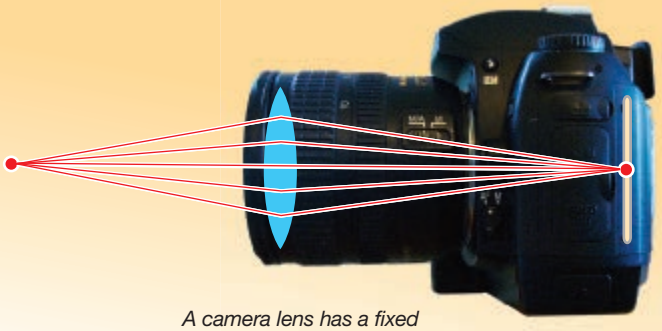
SPOTLIGHT

Figure 17–13
Refractive Problems

A camera focuses an image by moving the lens toward or away from the film or semiconductor device. This method cannot work in our eyes, because the distance from the lens to the macula cannot change. We focus images on the retina by changing the shape of the lens to keep the focal distance constant, a process called **accommodation**.



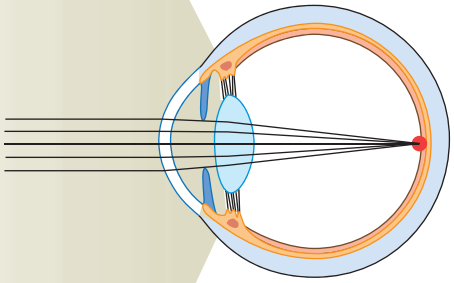
The eye has a fixed focal distance and focuses by varying the shape of the lens.

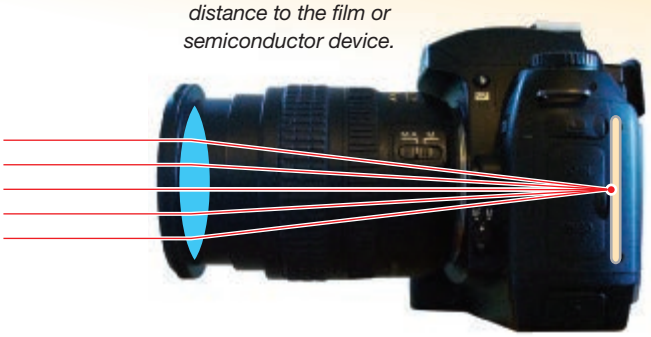


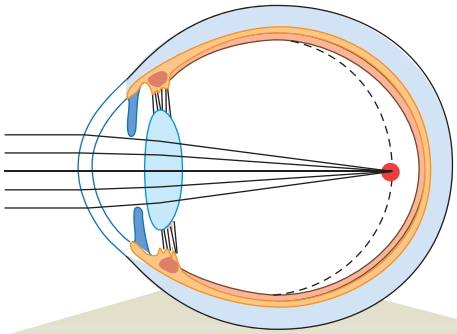
A camera lens has a fixed size and shape and focuses by varying the distance to the film or semiconductor device.

Emmetropia (normal vision)

In the healthy eye, when the ciliary muscle is relaxed and the lens is flattened, a distant image will be focused on the retina's surface. This condition is called **emmetropia** (*emmetro-*, proper + *opia,* vision).

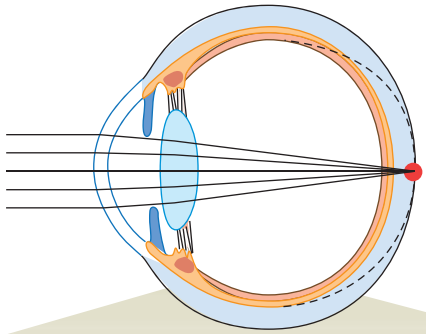






Myopia (nearsightedness)

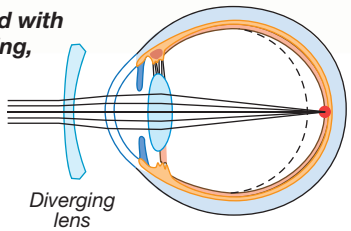
If the eyeball is too deep or the resting curvature of the lens is too great, the image of a distant object is projected in front of the retina. The person will see distant objects as blurry and out of focus. Vision at close range will be normal because the lens is able to round as needed to focus the image on the retina.



Hyperopia (farsightedness)

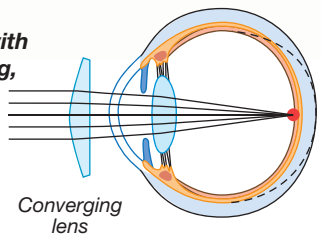
If the eyeball is too shallow or the lens is too flat, hyperopia results. The ciliary muscle must contract to focus even a distant object on the retina. And at close range the lens cannot provide enough refraction to focus an image on the retina. Older people become farsighted as their lenses lose elasticity, a form of hyperopia called **presbyopia** (*presbys*, old man).

Myopia corrected with a diverging, concave lens



Diverging lens

Hyperopia corrected with a converging, convex lens



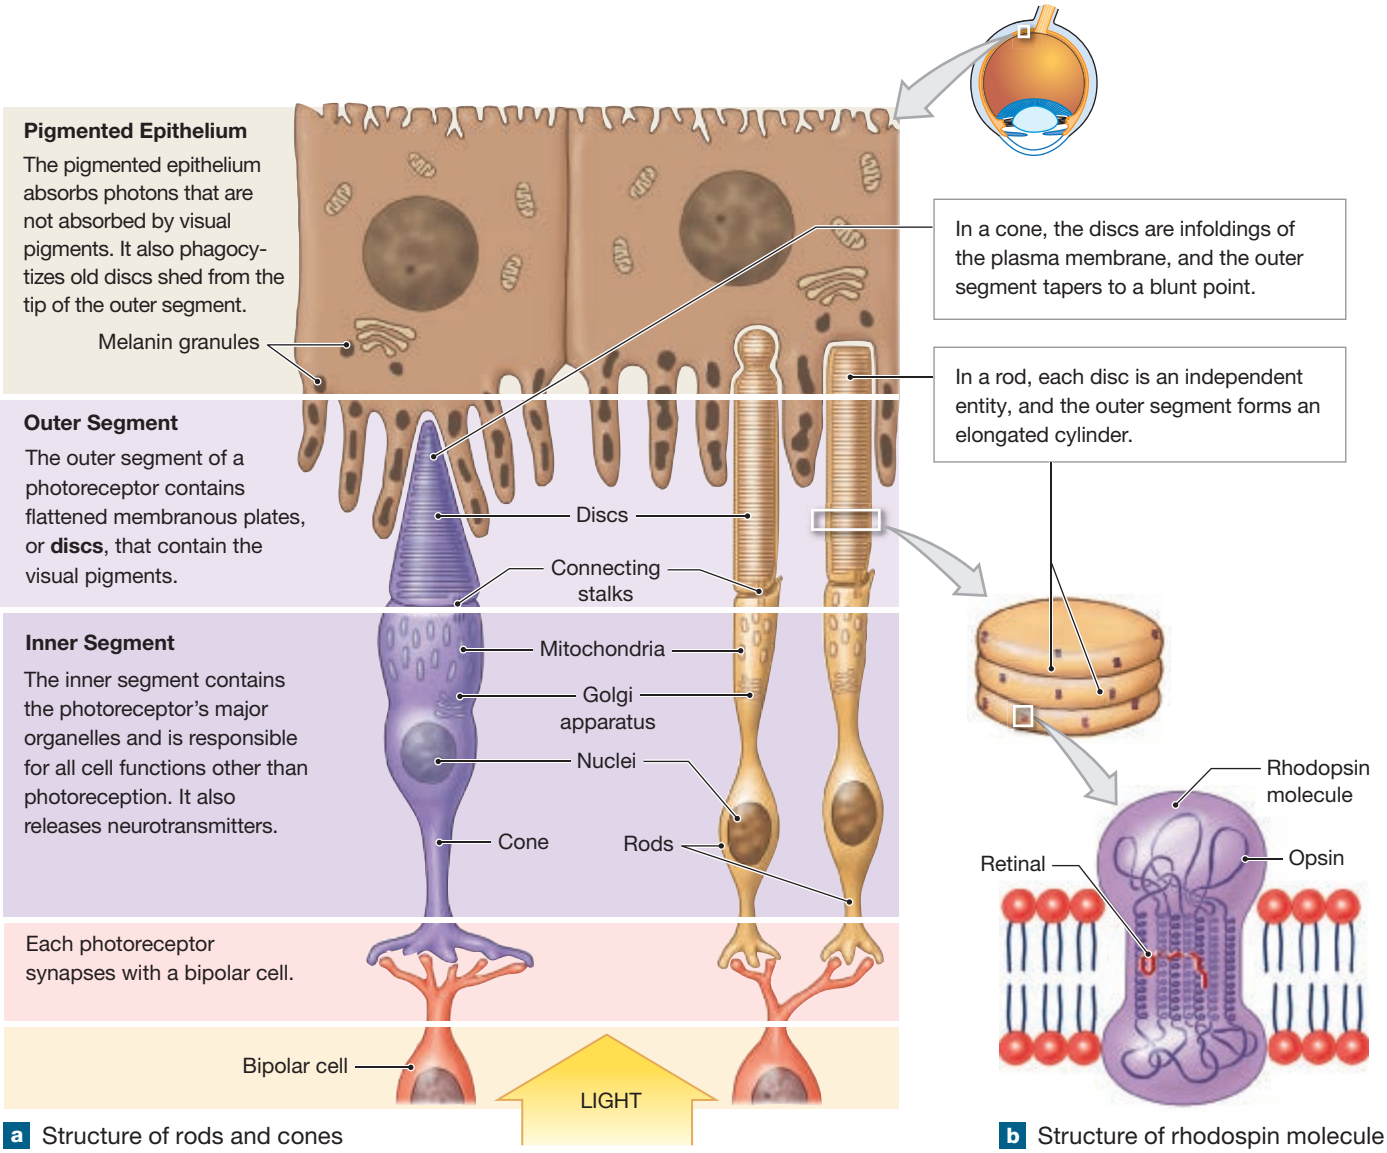
Converging lens

Surgical Correction

Variable success at correcting myopia and hyperopia has been achieved by surgery that reshapes the cornea. In **photorefractive keratectomy** (PRK) a computer-guided laser shapes the cornea to exact specifications. The entire procedure can be done in less than a minute. A variation on PRK is called *LASIK* (*Laser-Assisted in-Situ Keratomileusis*). In this procedure the interior layers of the cornea are reshaped and then re-covered by the flap of original outer corneal epithelium. Roughly 70 percent of LASIK patients achieve normal vision, and LASIK has become the most common form of refractive surgery.

Even after surgery, many patients still need reading glasses, and both immediate and long-term visual problems can occur.

Figure 17–14 Structure of Rods, Cones, and the Rhodopsin Molecule.



a Structure of rods and cones

b Structure of rhodospin molecule

which is synthesized from **vitamin A**. All rods contain the same form of opsin. Cones contain the same retinal pigment that rods do, but the retinal is attached to different forms of opsin.

We have three types of cones—**blue cones, green cones,** and **red cones**. Each type has a different form of opsin and is sensitive to a different range of wavelengths. Their sensitivities overlap, but each type is most sensitive to a specific portion of the visual spectrum (**Figure 17–15**). Their stimulation in various combinations is the basis for color vision. In an individual with normal vision, the cone population consists of 16 percent blue cones, 10 percent green cones, and 74 percent red cones.

The process of photoreception by visual pigments is described in **Spotlight Figure 17–16**. Please study this figure before moving on.

Figure 17–15 **Cone Types and Sensitivity to Color.** This graph compares the absorptive characteristics of blue, green, and red cones with those of typical rods.

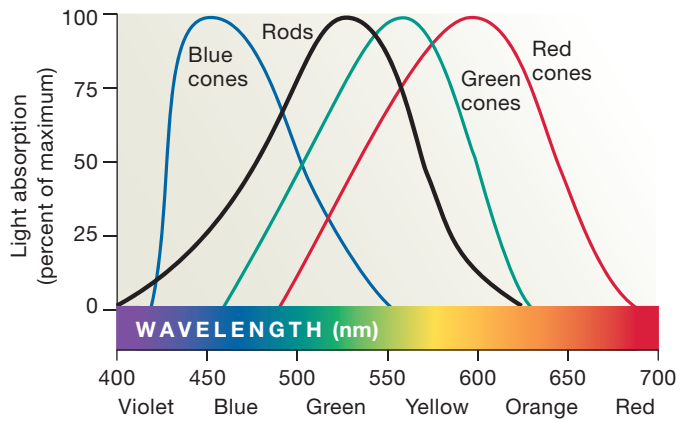


Figure 17–16
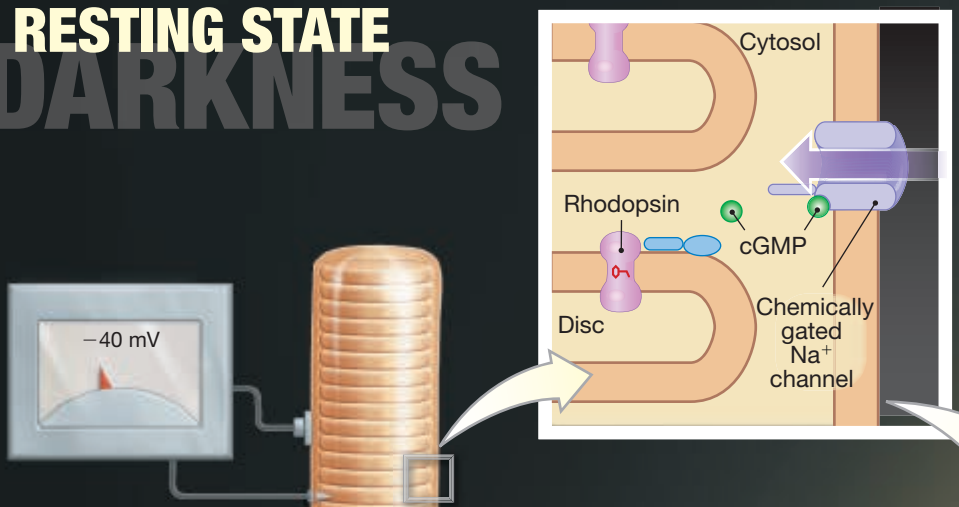
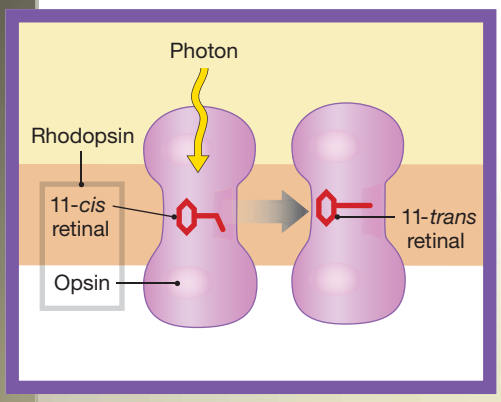
Photoreception

RESTING STATE
DARKNESS



1 Opsin activation occurs

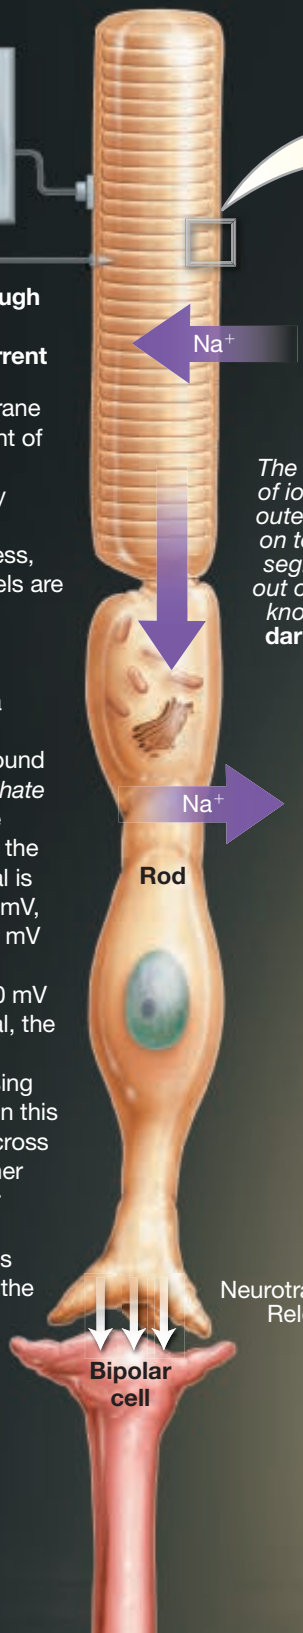
The bound retinal molecule has two possible configurations: the 11-*cis* form and the 11-*trans* form.



Normally, the molecule is in the curved 11-*cis* form; on absorbing light it changes to the more linear 11-*trans* form. This change activates the opsin molecule.

Sodium entry through gated channels produces dark current

The plasma membrane in the outer segment of the photoreceptor contains chemically gated sodium ion channels. In darkness, these gated channels are kept open in the presence of *cGMP (cyclic guanosine monophosphate)*, a derivative of the high-energy compound *guanosine triphosphate (GTP)*. Because the channels are open, the membrane potential is approximately –40 mV, rather than the –70 mV typical of resting neurons. At the –40 mV membrane potential, the photoreceptor is continuously releasing neurotransmitters (in this case, glutamate) across synapses at the inner segment. The inner segment also continuously pumps sodium ions out of the cytosol.

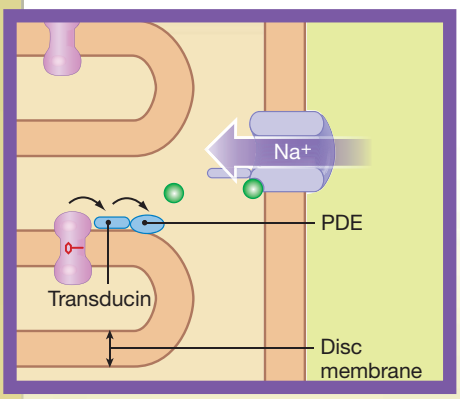


The movement of ions into the outer segment, on to the inner segment, and out of the cell is known as the **dark current**.

ACTIVE STATE IN LIGHT

2 **Opsin activates transducin, which in turn activates phosphodiesterase (PDE)**

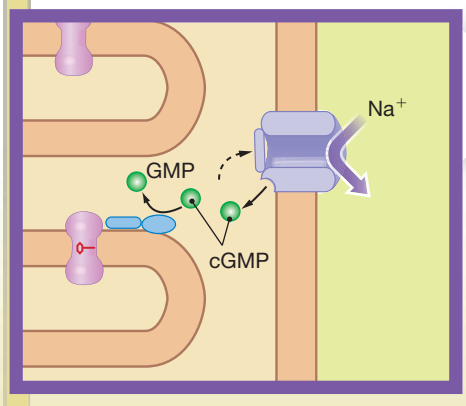
Transducin is a G protein—a membrane-bound enzyme complex



In this case, opsin activates transducin, and transducin in turn activates **phosphodiesterase** (**PDE**).

3 **Cyclic GMP levels decline and chemically gated sodium ion channels close**

Phosphodiesterase is an enzyme that breaks down cGMP.



The removal of cGMP from the chemically gated sodium ion channels results in their inactivation. The rate of Na^+ entry into the cytosol then decreases.

4 **Dark current is reduced and rate of neurotransmitter release declines**

The reduction in the rate of Na^+ entry reduces the dark current. At the same time, active transport continues to export Na^+ from the cytosol. When the sodium ion channels close, the membrane potential drops toward −70 mV. As the plasma membrane hyperpolarizes, the rate of neurotransmitter release decreases. This decrease signals the adjacent bipolar cell that the photoreceptor has absorbed a photon. After absorbing a photon, retinal does not spontaneously revert to the 11-*cis* form. Instead, the entire rhodopsin molecule must be broken down into retinal and opsin, in a process called *bleaching*. It is then reassembled.

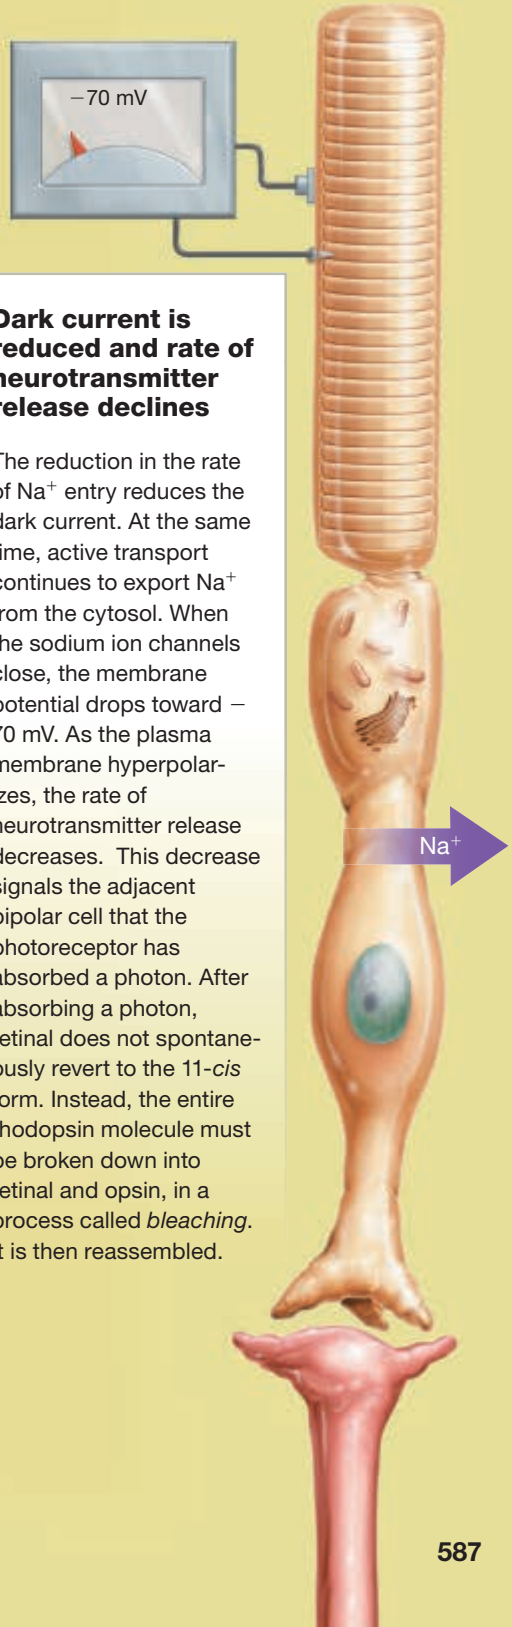


Figure 17–17 Bleaching and Regeneration of Visual Pigments.

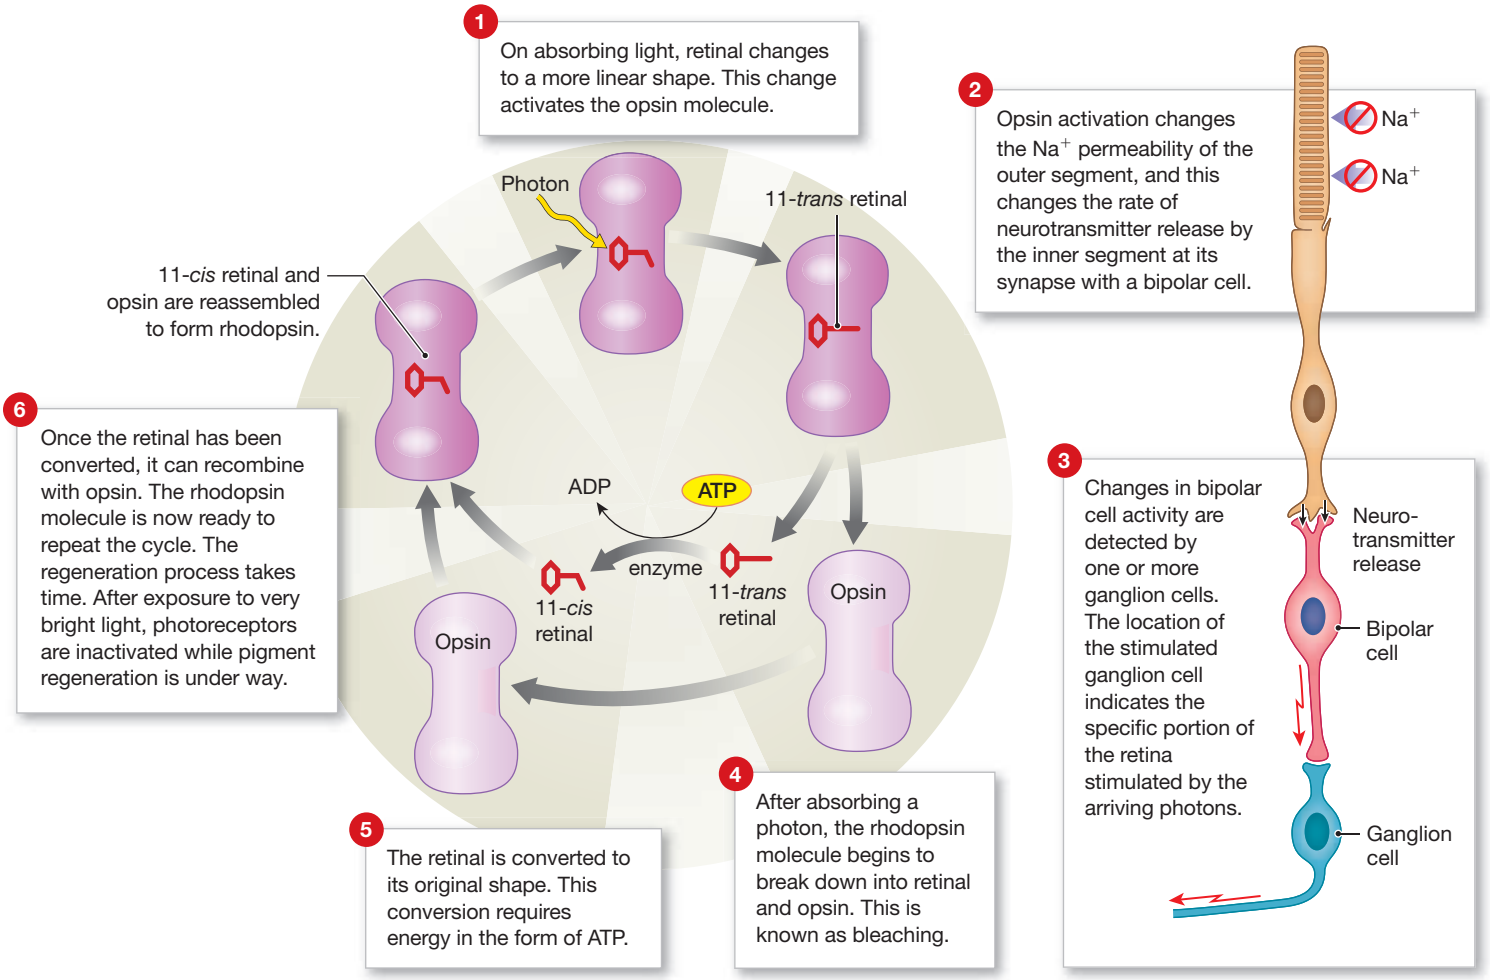


Bleaching and Regeneration of Visual Pigments. Rhodopsin is broken apart into retinal and opsin through a process called **bleaching** (Figure 17–17). Before recombining with opsin, the retinal must be enzymatically converted back to its original shape. This conversion requires energy in the form of ATP (adenosine triphosphate), and it takes time. Then rhodopsin is regenerated by being recombined with opsin. Bleaching and regeneration is a cyclical process.

Bleaching contributes to the lingering visual impression you have after you see a camera's flash. Following intense exposure to light, a photoreceptor cannot respond to further stimulation until its rhodopsin molecules have been regenerated. As a result, a "ghost" afterimage remains on the retina. We seldom notice bleaching under ordinary circumstances, because our eyes are constantly making small, involuntary changes in position that move the image across the retina's surface.

While the rhodopsin molecule is being reassembled (regenerated), membrane permeability of the outer segment is returning to normal. Opsin is inactivated when bleaching occurs, and the breakdown of cGMP halts as a result. As other enzymes generate cGMP in the cytosol, the chemically gated sodium ion channels reopen.

Synthesis and Recycling of Visual Pigments. The body contains vitamin A reserves sufficient to synthesize visual pigments for several months. A significant amount is stored in the cells of the pigmented layer of the retina.

New discs containing visual pigment are continuously assembled at the base of the outer segment of both rods and cones. A completed disc then moves toward the tip of the segment. After about 10 days, the disc is shed in a small droplet of cytoplasm. The pigment cells absorb droplets with shed discs, break down the disc membrane's components, and reconvert the retinal to vitamin A. The pigment cells then store the vitamin A for later transfer to the photoreceptors.

If dietary sources are inadequate, these reserves are gradually used up and the amount of visual pigment in the photoreceptors begins to decline. Daylight vision is affected, but in daytime the light is usually bright enough to stimulate any visual pigments that remain within the densely packed cone population of the fovea centralis. As a result, the problem first becomes apparent at night, when the dim light proves insufficient to activate the rods. This condition, known as **night blindness**, or **nyctalopia**, can be treated by eating a diet rich in vitamin A. The body can convert the carotene pigments in

many vegetables to vitamin A. Carrots are a particularly good source of carotene, leading to the old adage that carrots are good for your eyes.

Light and Dark Adaptation of Visual Pigments

The sensitivity of your visual system varies with the intensity of illumination. After 30 minutes or more in the dark, almost all visual pigments will have recovered from photobleaching. This state in which the pigments are fully receptive to stimulation is called the **dark-adapted state**. When dark adapted, the visual system is extremely sensitive. For example, a single rod will hyperpolarize in response to a single photon of light. Even more remarkable, if as few as seven rods absorb photons at one time, you will see a flash of light.

When the lights come on, at first they seem almost unbearably bright, but over the next few minutes your sensitivity decreases as bleaching occurs. Eventually, the rate of bleaching is balanced by the rate at which the visual pigments reassemble. This condition is the **light-adapted state**. If you moved from the depths of a cave to the full sunlight of midday, your receptor sensitivity would decrease by a factor of 25,000.

The autonomic nervous system adjusts to incoming light. The pupils constrict, reducing the amount of light entering your eye to 1/30th the maximum dark-adapted level. Conversely, dilating the pupil fully can produce a 30-fold increase in the amount of light entering the eye. In addition, facilitating some of the synapses along the visual pathway can perhaps triple its sensitivity. In these ways, the sensitivity of the entire system may increase by a factor of more than 1 million.

Retinitis pigmentosa (RP) is an inherited disease characterized by progressive retinal degeneration. As the visual receptors gradually deteriorate, blindness eventually results. The mutations that are responsible change the structure of the photoreceptors—specifically, the visual pigments of the membrane discs. We do not know how the altered pigments lead to the destruction of photoreceptors.

Color Vision

An ordinary lightbulb or the sun emits photons of all wavelengths, which stimulate both rods and cones. Your eyes also detect photons that reach your retina after they bounce off objects around you. If photons of all visible wavelengths bounce off an object, the object will appear white to you. If the object absorbs all the photons (so that none reaches the retina), the object will appear black.

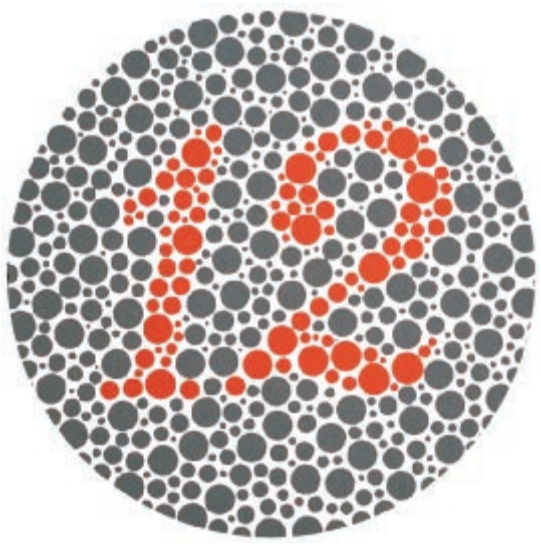
An object appears to have a particular color when it reflects (or transmits) photons from one portion of the visible spectrum and absorbs the rest. Color discrimination takes place through the integration of information arriving from all three types of cones: blue, green, and red. A person who sees these three primary colors has normal color vision. For example, you perceive yellow from a combination of inputs from highly stimulated green cones, less strongly stimulated red cones, and relatively unaffected blue cones (look back at Figure 17–15, p. 585). If all three cone populations are stimulated, we perceive the color as white. We also perceive white if rods, rather than cones, are stimulated. For this reason, everything appears black and white when you enter dimly lit surroundings or walk by starlight.

Persons who are unable to distinguish certain colors have a form of **color blindness**. The standard tests for color vision involve picking numbers or letters out of a complex colored picture such as the one shown in Figure 17–18. Color blindness occurs when one or more types of cones are nonfunctional. The cones may be absent, or they may be present but unable to manufacture the necessary visual pigments. In the most common type of color blindness (red–green color blindness), the red cones are missing, so the individual cannot distinguish red light from green light. Inherited color blindness involving one or two cone pigments is not unusual. Ten percent of all males show some color blindness, but only about 0.67 percent of all females have color blindness. Total color blindness is extremely rare. Only 1 person in 300,000 does not manufacture any cone pigments. We consider the inheritance of color blindness in Chapter 29.

The Visual Pathways

The visual pathways begin at the photoreceptors and end at the *visual cortex* of the cerebral hemispheres. In other sensory pathways we have examined, only one synapse lies between a receptor and a sensory neuron that delivers information to the CNS. In the visual pathways, the message must cross two synapses (photoreceptor to bipolar cell, and bipolar cell to ganglion cell). Only then does it move toward the brain. The extra synapse increases the synaptic delay, but it provides an opportunity for the processing and integration of visual information before it leaves the retina. Let's look at both retinal and cortical processing of visual signals.

Figure 17–18 A Standard Test for Color Vision. People who lack one or more types of cones cannot see the number 12 in this pattern.



Processing by the Retina

Each of the millions of photoreceptors in the retina monitors a specific receptive field. Given that there are also millions of bipolar and ganglion cells, a considerable amount of convergence must take place at the start of the visual pathway. The degree of convergence differs between rods and cones; rods have a large degree of convergence, whereas cones typically show very little. Regardless of the amount of convergence, each ganglion cell monitors a specific portion of the field of vision, its *receptive field*.

As many as a thousand rods may pass information by their bipolar cells to a single ganglion cell. The fairly large ganglion cells that monitor rods are called **M cells** (*magnocells; magnus,* great). They provide information about the general form of an object, motion, and shadows in dim lighting. Because so much convergence occurs, the activation of an M cell indicates that light has arrived in a general area rather than at a specific location.

The loss of specificity due to convergence from rod stimuli is partially overcome by the fact that the activity of ganglion cells varies according to the pattern of activity in their receptive field, which is usually shaped like a circle. Typically, a ganglion cell responds differently to stimuli that arrive in the center of its receptive field than to stimuli that arrive at the edges (Figure 17–19). Some ganglion cells, called **on-center neurons**, are excited by light arriving in the center of their receptive field and are inhibited when light strikes its edges. Others, known as **off-center neurons**, are inhibited by light in the central zone, but are stimulated by light at the edges. On-center and off-center neurons provide information about which portion of their receptive field is illuminated. This kind of retinal processing within ganglion receptive fields improves the detection of the edges of objects within the field of vision.

The processing of visual stimuli from cones is different because of their lack of convergence. In the fovea centralis, the ratio of cones to ganglion cells is 1:1. The ganglion cells that monitor cones, called **P cells** (*parvo cells; parvus,* small), are smaller and more numerous than M cells. P cells are active in bright light, and they provide information about edges, fine detail, and color. Because little convergence occurs, the activation of a P cell means that light has arrived at one specific location. As a result, cones provide more precise information about a visual image than do rods. We could say that images formed by rods have a coarse, grainy, pixelated appearance that blurs details. By contrast, images produced by cones are sharp, clear, and of high resolution.

Central Processing of Visual Information

Axons from the entire population of ganglion cells converge on the optic disc, penetrate the wall of the eye, and proceed toward the diencephalon as the optic nerve (II). The two optic nerves, one from each eye, reach the diencephalon after a partial crossover at the **optic chiasm** (Figure 17–20). From that point, approximately half the fibers proceed toward the lateral geniculate body of the same side of the brain, whereas the other half cross over to reach the lateral geniculate body of the opposite side. p. 482 From each lateral geniculate body, visual information travels to the **visual cortex** in the occipital lobe of the cerebral hemisphere on that side. The bundle of projection fibers linking the lateral geniculates with the visual cortex is known as the **optic radiation**. Collaterals from the fibers synapsing in the lateral geniculate continue to subconscious processing centers in the diencephalon and brainstem.

Figure 17–19 Convergence and Ganglion Cell Function. Photoreceptors are organized in groups within a receptive field. Each ganglion cell monitors a well-defined portion of that field. Some ganglion cells (on-center neurons, labeled A) respond strongly to light arriving at the center of their receptive field. Others (off-center neurons, labeled B) respond most strongly to illumination of the edges of their receptive field.

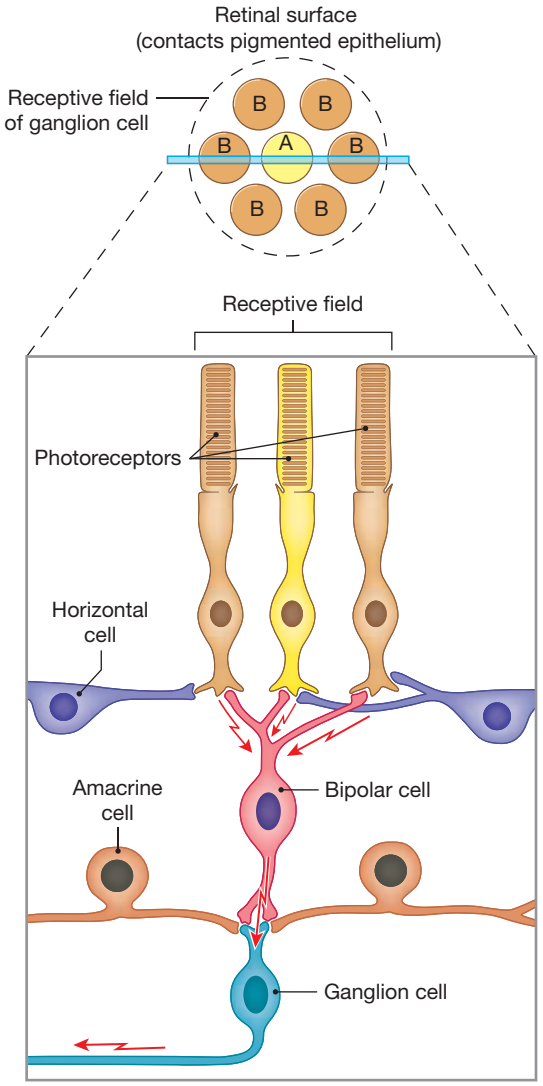


Figure 17–20 The Visual Pathways. The crossover of some nerve fibers occurs at the optic chiasm. As a result, each hemisphere receives visual information from the medial half of the field of vision of the eye on that side, and from the lateral half of the field of vision of the eye on the opposite side. Visual association areas integrate this information to develop a composite picture of the entire field of vision.

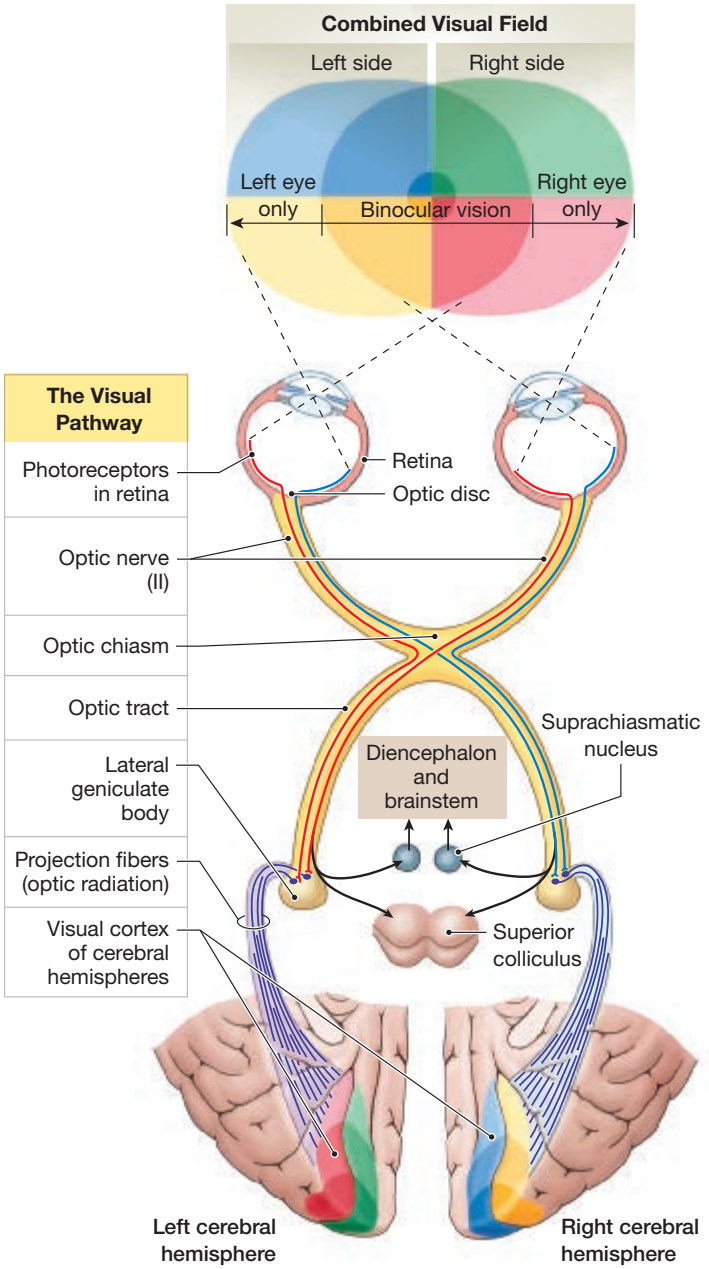

The Field of Vision. You perceive a visual image due to the integration of information that arrives at the visual cortex of the occipital lobes. Each eye receives a slightly different visual image. One reason is that the foveae in your two eyes are 5–7.5 cm (2–3.0 in.) apart. Another reason is that your nose and eye socket block the view of the opposite side. **Depth perception** is the ability to judge depth or distance by interpreting the three-dimensional relationships among objects in view. Your brain resolves it by comparing the relative positions of objects within the images received by your two eyes.

When you look straight ahead, the visual images from your left and right eyes overlap (see Figure 17–20); the combined areas are your **field of vision**. The image received by the fovea centralis of each eye lies in the center of the region of overlap. A vertical line drawn through the center of this region marks the division of visual information at the optic chiasm. Visual information from the left half of the combined field of vision reaches the visual cortex of your right occipital lobe. Visual information from the right half of the combined field of vision arrives at the visual cortex of your left occipital lobe.

The cerebral hemispheres thus contain a map of the entire field of vision. As in the case of the somatosensory cortex, the map does not faithfully duplicate the areas within the sensory field. For example, the area assigned to the macula and fovea centralis covers about 35 times the surface it would cover if the map were proportionally accurate. The map is also upside down and reversed, duplicating the orientation of the visual image at the retina.

The Brainstem and Visual Processing. Many centers in the brainstem receive visual information, either from the lateral geniculate bodies or through collaterals from the optic tracts. Collaterals that bypass the lateral geniculates synapse in the superior colliculi or in the hypothalamus. The superior colliculi of the midbrain issue motor commands that control unconscious eye, head, or neck movements in response to visual stimuli. For example, the pupillary reflexes and reflexes that control eye movement are triggered by collaterals carrying information to the superior colliculi.

Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brainstem nuclei. p. 484 The suprachiasmatic nucleus and the *pineal gland* of the epithalamus receive visual information and use it to establish a **circadian** (ser-KĀ-dē-an) **rhythm** (*circa*, about + *dies*, day), which is a daily pattern of visceral activity that is tied to the day–night cycle. This circadian rhythm affects your metabolic rate, endocrine function, blood pressure, digestive activities, sleep–wake cycle, and other physiological and behavioral processes.

17-6 Equilibrium sensations monitor head position and movement, while hearing involves the detection and interpretation of sound waves

Learning Outcome Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain.

Equilibrium sensations inform us of the position of the head in space by monitoring gravity, linear acceleration, and rotation. *Hearing* enables us to detect and interpret sound waves. Both of these senses are provided by the *internal ear,* a receptor complex located in the temporal bone of the skull.

The basic receptor mechanism for both senses is the same. The receptors, called *hair cells,* are mechanoreceptors. The complex structure of the internal ear and the different arrangement of accessory structures enable hair cells to respond to different stimuli. Once the hair cells have transduced these stimuli, equilibrium input is sent to the brainstem, while hearing input is sent to the brainstem and/or *auditory cortex* for processing and possible response. In this section, we look at the anatomy of the ear before going into the processes of equilibrium and hearing.

Anatomy of the Ear

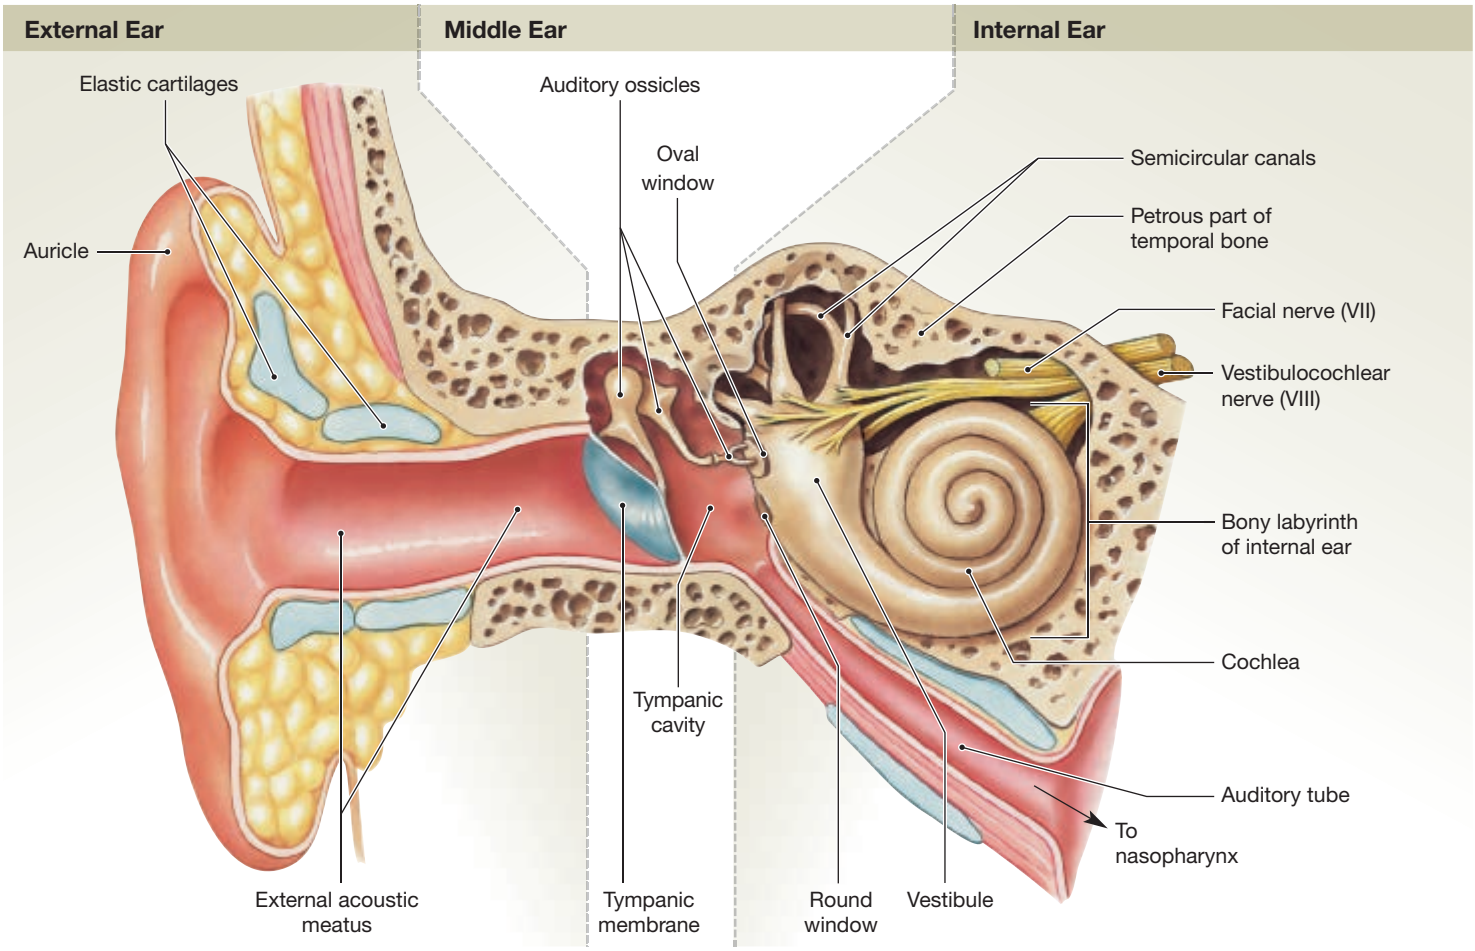
The **ear** is divided into three anatomical regions: the external ear, the middle ear, and the internal ear (Figure 17–21). The *external ear*—the visible portion of the ear—collects and directs sound waves toward the *middle ear,* a chamber located within the petrous part of the temporal bone. Structures of the middle ear collect sound waves and transmit them to an appropriate portion of the *internal ear,* which contains the sensory organs for both hearing and equilibrium.

The External Ear

The **external ear** includes the outer fleshy and cartilaginous **auricle** (OR-ih-kul), or *pinna,* which surrounds a passageway

17

Figure 17–21 The Anatomy of the Ear. The dashed lines indicate the boundaries separating the three anatomical regions of the ear (external, middle, and internal).



? The tympanic cavity and auditory ossicles are found in which anatomical region of the ear?

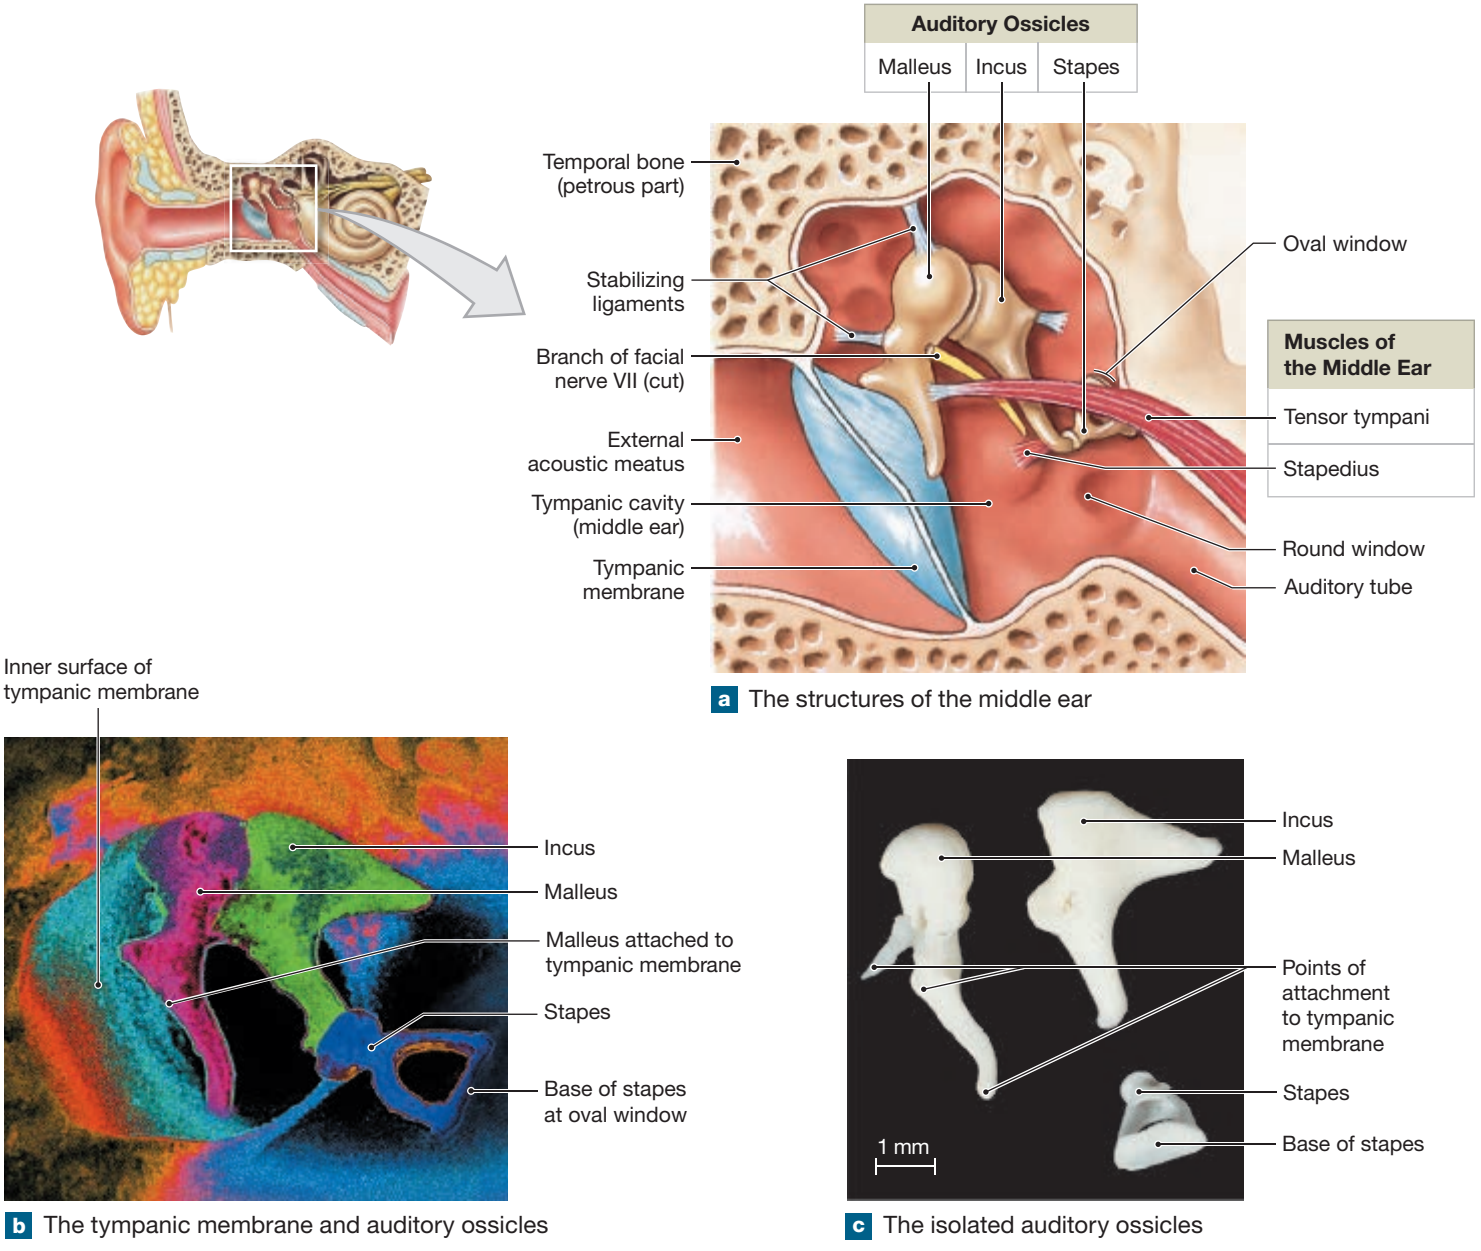
called the **external acoustic meatus**, or *auditory canal*. The auricle protects the opening of the canal and provides directional sensitivity. Sounds coming from behind the head are blocked by the auricle, but sounds coming from the side or front are collected and channeled into the external acoustic meatus. (When you "cup" your ear with your hand to hear a faint sound more clearly, you are exaggerating this effect.) The external acoustic meatus ends at the **tympanic membrane** (*tympanon*, drum), or *eardrum*. This thin, semitransparent sheet separates the external ear from the middle ear.

The tympanic membrane is very delicate. The auricle and the narrow external acoustic meatus provide some protection for it from accidental injury. In addition, **ceruminous glands**—integumentary glands along the external acoustic meatus—secrete a waxy material called **cerumen** (or *earwax*) that helps keep out foreign objects or small insects. Cerumen also slows the growth of microorganisms and so reduces the chances of infection. In addition, the canal is lined with many small, outwardly projecting hairs. These hairs trap debris and also provide increased tactile sensitivity through their root hair plexuses.

The Middle Ear

The **middle ear**, or **tympanic cavity**, is an air-filled chamber separated from the external acoustic meatus by the tympanic membrane (see Figure 17–21). The middle ear communicates both with the *nasopharynx* (the superior portion of the pharynx), through the *auditory tube*, and with the mastoid air cells, through a number of small connections (Figure 17–22a).

Figure 17–22 The Middle Ear.



a The structures of the middle ear

b The tympanic membrane and auditory ossicles

c The isolated auditory ossicles

The **auditory tube** (also called the *pharyngotympanic tube* or the *Eustachian tube) is* about 4 cm (1.6 in.) long and consists of two portions. The portion near the connection to the middle ear is narrow and is supported by elastic cartilage. The portion near the opening into the nasopharynx is broad and funnel shaped. The auditory tube equalizes pressure on either side of the tympanic membrane. Unfortunately, the auditory tube can also allow microorganisms to travel from the nasopharynx into the middle ear. Invasion by microorganisms can lead to an unpleasant middle ear infection known as *otitis media*.

The Auditory Ossicles. The middle ear contains three tiny ear bones, collectively called **auditory ossicles** (OS-ih-kulz). These ear bones connect the tympanic membrane with the internal ear (see Figure 17–21). The articulations between the auditory ossicles are the smallest synovial joints in the body. Each has a tiny joint capsule and supporting extracapsular ligaments. The three auditory ossicles are the malleus, the incus, and the stapes (Figure 17–22b,c). The **malleus** (*malleus,* hammer) attaches at three points to the interior surface of the tympanic membrane. The **incus** (*incus,* anvil), the middle ossicle, attaches the malleus to the **stapes** (STĀ-pēz; *stapes,* stirrup), the inner ossicle. The edges of the base of the stapes are bound to the edges of the *oval window,* an opening in the temporal bone that surrounds the internal ear.

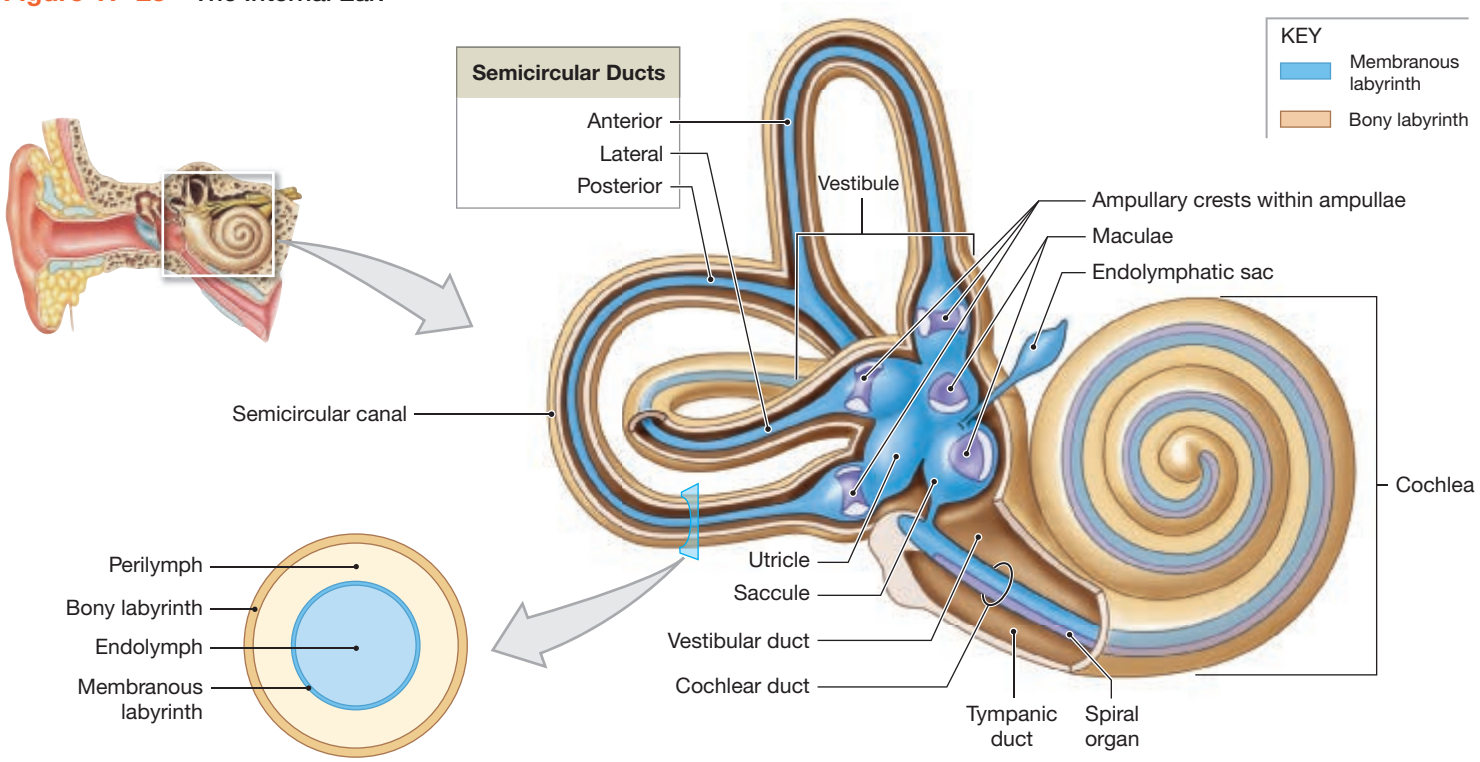
Muscles of the Middle Ear. When sound waves cause the tympanic membrane to vibrate, the ossicles conduct the vibrations to the internal ear. When we are exposed to very loud noises, two small muscles in the middle ear (see Figure 17–22a) protect the tympanic membrane and ossicles from violent movements:

- The **tensor tympani** (TEN-sor tim-PAN-ē) is a short ribbon of muscle originating on the petrous part of the temporal bone and the auditory tube, and inserting on the "handle" of the malleus. When the tensor tympani contracts, it pulls the malleus medially, stiffening the tympanic membrane. This increased stiffness reduces the amount of movement possible. The tensor tympani is innervated by motor fibers of the mandibular nerve (V_3), a division of the trigeminal nerve (V).
- The stapedius (sta-PĒ-dē-us), innervated by the facial nerve (VII), originates from the posterior wall of the middle ear and inserts on the stapes. Contraction of the stapedius pulls on the stapes, reducing its movement at the oval window.

The Internal Ear

The **internal ear** is a winding passageway called a **labyrinth** (*labyrinthos,* network of canals) (Figure 17–23). The superficial contours of the internal ear are formed by a layer of dense bone

Figure 17–23 The Internal Ear.



a A section through one of the semicircular canals, showing the relationship between the bony and membranous labyrinths, and the boundaries of perilymph and endolymph.

b The bony and membranous labyrinths. Areas of the membranous labyrinth containing sensory receptors (ampullary crests, maculae, and spiral organ) are shown in purple.

known as the **bony labyrinth**. The walls of the bony labyrinth are continuous with the surrounding temporal bone. The inner contours of the bony labyrinth are closely followed by the contours of the **membranous labyrinth**, a delicate, interconnected network of fluid-filled tubes. The receptors of the internal ear are found within these tubes.

Between the bony and membranous labyrinths flows **perilymph** (PEHR-ih-limf), while the membranous labyrinth contains **endolymph** (EN-dō-limf) (Figure 17–23a). Perilymph closely resembles cerebrospinal fluid. In contrast, endolymph has electrolyte concentrations that differ from those of typical body fluids. (See the Appendix for a chemical analysis of perilymph, endolymph, and other body fluids.)

We can subdivide the bony labyrinth into the *vestibule,* the *semicircular canals,* and the *cochlea* (KOK-lē-ah) (Figure 17–23b). The **vestibule** (VES-tih-byūl) consists of a pair of membranous sacs: the *saccule* (SAK-yūl) and the *utricle* (YŪ-trih-kul). Receptors in these sacs provide equilibrium sensations. The three **semicircular canals** enclose three slender *semicircular ducts.* The combination of vestibule and semicircular canals is called the *vestibular complex*. The fluid-filled chambers within the vestibule are continuous with those of the semicircular canals.

The **cochlea** (*cochlea,* a snail shell) is a spiral-shaped, bony chamber that contains the *cochlear duct* of the membranous labyrinth. Receptors within the cochlear duct provide the sense of hearing. The duct is sandwiched between a pair of perilymph-filled chambers. The entire complex spirals around a central bony hub, much like a snail shell.

The walls of the bony labyrinth consist of dense bone everywhere except at two small areas near the base of the cochlear spiral (see Figure 17–21). The **round window** is a thin, membranous partition that separates the perilymph of the cochlear chambers from the air-filled middle ear. Collagen fibers connect the bony margins of the opening known as the **oval window** to the base of the stapes.

Equilibrium

Equilibrium is the state of physical balance. We'll explore the structures within the internal ear that enable us to maintain this balance.

The Vestibular Complex and Physiology of Equilibrium

As just noted, receptors of the **vestibular complex** provide you with equilibrium sensations. In both the semicircular ducts and the vestibule, these receptors are **hair cells**. The hair cells of the semicircular ducts convey information about rotational movements of the head. The hair cells in the saccule and the utricle of the vestibule convey information about your position with respect to gravity, and tell you if you are accelerating or decelerating.

The Semicircular Ducts: Rotational Movements. The hair cells of the semicircular ducts are active during a rotational movement, but are quiet when the body is motionless. For example, when you turn your head to the left, receptors stimulated in the semicircular ducts tell you how rapid the movement is, and in which direction. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle (Figure 17–24a). Each semicircular duct contains an **ampulla**, an expanded region that contains the receptors. The region in the wall of the ampulla that contains the hair cells is known as the **ampullary crest** (Figure 17–24b). Each ampullary crest is bound to an **ampullary cupula** (KŪ-pū-luh), a gelatinous structure that extends the full width of the ampulla.

Hair cells are always surrounded by supporting cells and monitored by the dendrites of sensory neurons. The free surface of each hair cell supports 80–100 long **stereocilia**, which resemble very long microvilli (Figure 17–24d). Each hair cell in the vestibular complex also contains a single large cilium called a **kinocilium** (kī-nō-SIL-ē-um). At an ampullary crest, the kinocilia and stereocilia of the hair cells are embedded in the ampullary cupula (see Figure 17–24b).

Hair cells do not actively move their kinocilia or stereocilia. However, when an external force pushes against these processes, the distortion of the plasma membrane alters the rate at which the hair cell releases neurotransmitters. The action potentials generated in response to these neurotransmitters allow the hair cells to provide information about the direction and strength of mechanical stimuli. The stimuli involved, however, depend on the hair cell's location: gravity or acceleration in the vestibule and rotation in the semicircular canals (plus sound in the cochlea). The sensitivities of the hair cells differ, because each of these regions has different accessory structures that determine which stimulus will provide the force to deflect the kinocilia and stereocilia.

The ampullary cupula with its hair cells has a density very close to that of the surrounding endolymph, so it essentially floats above the receptor surface. When your head rotates in the plane of a semicircular duct, the movement of endolymph along the length of the duct pushes the ampullary cupula to the side and distorts the receptor processes (Figure 17–24c). Movement of fluid in one direction stimulates the hair cells, and movement in the opposite direction inhibits them. When the endolymph stops moving, the elastic nature of the ampullary cupula makes it return to its normal position.

Even the most complex movement can be analyzed in terms of motion in three rotational planes. Each semicircular duct responds to one of these rotational movements. A horizontal rotation, as in shaking your head "no," stimulates the hair cells of the lateral semicircular duct. Nodding "yes" excites the anterior duct, and tilting your head from side to side activates receptors in the posterior duct.

Figure 17–24 The Semicircular Ducts.

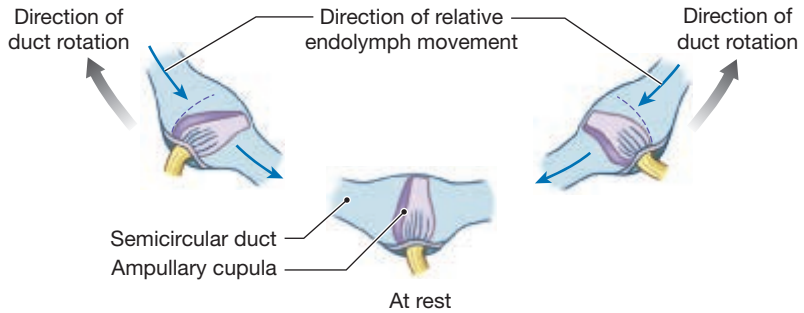
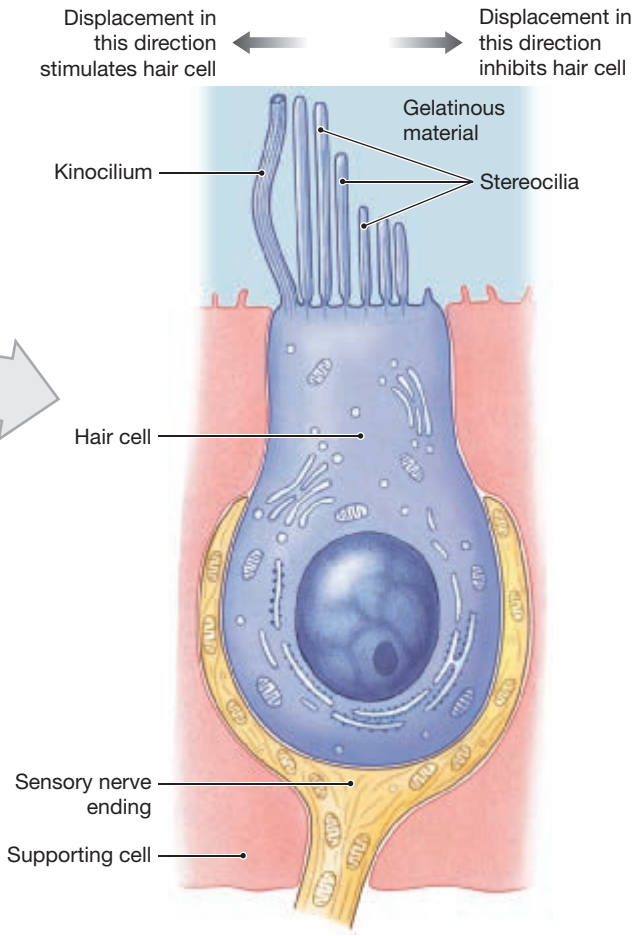
b A cross section through the ampulla of a semicircular duct.



c Endolymph movement along the length of the duct moves the ampullary cupula and stimulates the hair cells.



d A representative hair cell (receptor) from the vestibular complex. Bending the sterocilia toward the kinocilium depolarizes the cell and stimulates the sensory neuron. Displacement in the opposite direction inhibits the sensory neuron.

The Utricle and Saccule: Position and Acceleration. The hair cells of the **utricle** and **saccule** provide position and linear movement sensations, whether the body is moving or stationary. For example, if you stand with your head tilted to one side, these receptors report the angle involved and whether your head tilts forward or backward. The two chambers are connected by a slender passageway that is continuous with the narrow **endolymphatic duct** (see Figure 17–24a). This duct ends in a closed cavity called the **endolymphatic sac**. This sac projects through the dura mater that lines the temporal bone and into the subarachnoid space, where a capillary network surrounds it.

Portions of the endolymphatic duct secrete endolymph continuously, and excess fluid returns to the general circulation at the endolymphatic sac. There the capillaries absorb endolymph removed by a combination of active transport and vesicular transport.

The hair cells of the utricle and saccule are clustered in oval structures called **maculae** (MAK-yū-lē; *macula*, spot) (Figure 17–25a). The **macula of utricle** is sensitive to changes in horizontal movement. The **macula of saccule** is sensitive to changes in vertical movement. As in the ampullae, the hair cell processes are embedded in a gelatinous structure, here the *otolithic membrane*. This membrane's surface contains densely packed calcium carbonate crystals called **otoliths** ("ear stones").

The macula of utricle is diagrammed in Figure 17–25b. Its functioning is shown in Figure 17–25c. When your head is in the normal, upright position, the otoliths sit atop the otolithic membrane of macula of utricle 1. Their weight presses on the macular surface, pushing the hair cell processes down rather than to one side or another. When your head is tilted, the pull of gravity on the otoliths shifts them to the side, distorting the hair cell processes and stimulating the macular receptors 2. The change in receptor activity tells the CNS that your head is no longer level.

A similar mechanism accounts for your perception of linear acceleration when you are in a car that speeds up suddenly. The otoliths lag behind due to their inertia, and the effect on the hair cells is comparable to tilting your head back. Under normal circumstances, your nervous system distinguishes between the sensations of tilting and linear acceleration by integrating vestibular sensations with visual information. Many amusement

park rides confuse your sense of equilibrium by combining rapid rotation with changes in position and acceleration while providing restricted or misleading visual information.

Pathways for Equilibrium Sensations

Hair cells of the vestibule and semicircular ducts are monitored by sensory neurons located in adjacent **vestibular ganglia**. Sensory fibers from these ganglia form the **vestibular nerve**, a division of the vestibulocochlear nerve (VIII). p. 501 These fibers innervate neurons within the pair of **vestibular nuclei** at the boundary between the pons and the medulla oblongata.

The vestibular nuclei have four functions:

- Integrating sensory information about balance and equilibrium that arrives from both sides of the head.
- Relaying information from the vestibular complex to the cerebellum.
- Relaying information from the vestibular complex to the cerebral cortex, providing a conscious sense of head position and movement.
- Sending commands to motor nuclei in the brainstem and spinal cord.

The reflexive motor commands issued by the vestibular nuclei are distributed to the motor nuclei for cranial nerves involved with eye, head, and neck movements (CN III, IV, VI, and XI). Instructions descending in the *vestibulospinal tracts* of the spinal cord adjust peripheral muscle tone and complement the reflexive movements of the head or neck. p. 530 These pathways are indicated in Figure 17–26.

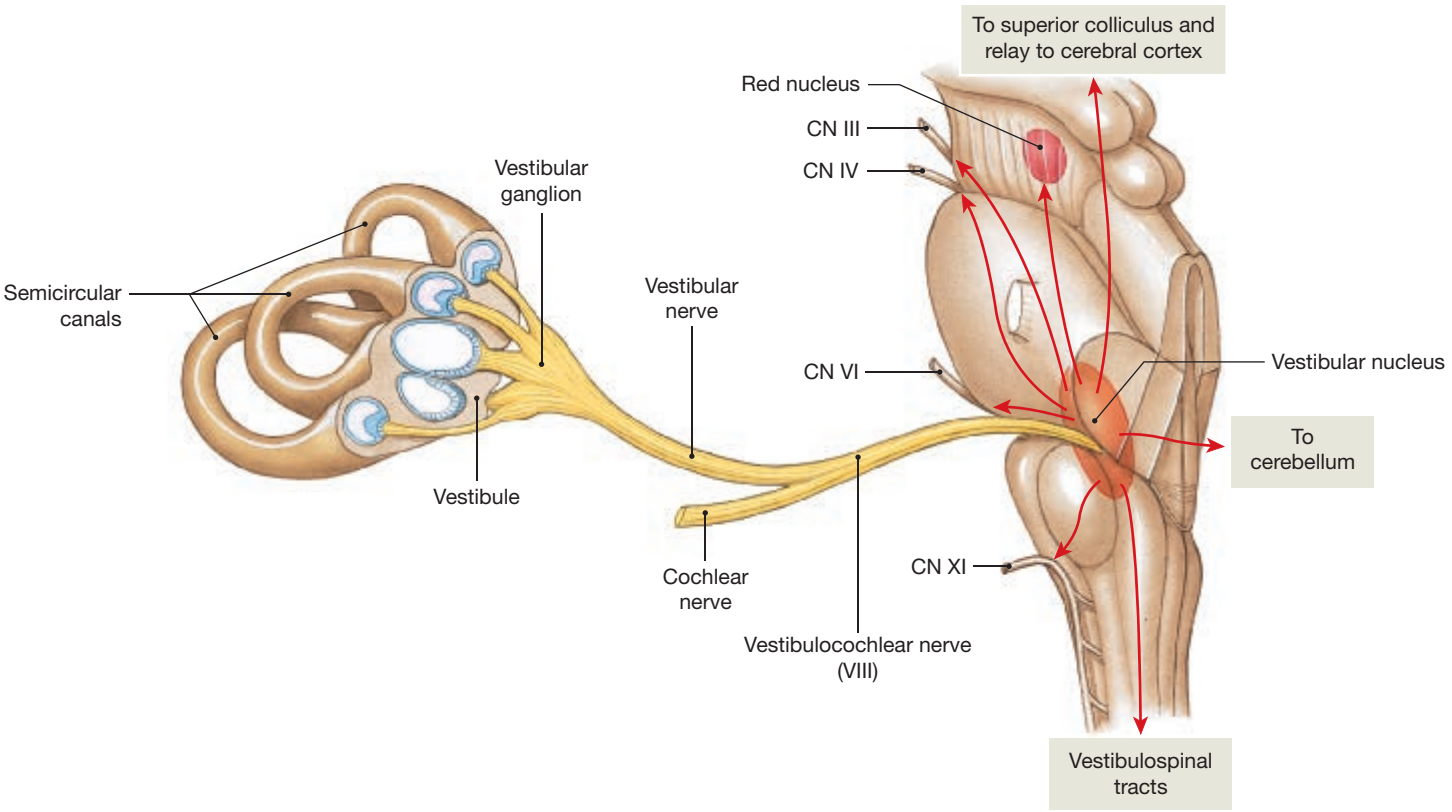
The automatic movements of the eyes in response to sensations of motion are directed by the *superior colliculi* of the midbrain. p. 478 These movements attempt to keep your gaze focused on a specific point in space, despite changes in body position and orientation. If your body is turning or spinning rapidly, your eyes will fix on one point for a moment and then jump ahead to another in a series of short, jerky movements.

If either the brainstem or the internal ear is damaged, this type of eye movement can occur even when the body is stationary. Individuals with this condition, which is called **nystagmus** (nis-TAG-mus), have trouble controlling their eye movements. Physicians commonly check for nystagmus by asking patients to watch a small penlight as it is moved across the field of vision.

Hearing

The receptors of the cochlear duct provide a sense of **hearing** that enables us to detect the quietest whisper, yet remain

Figure 17–26 Pathways for Equilibrium Sensations.

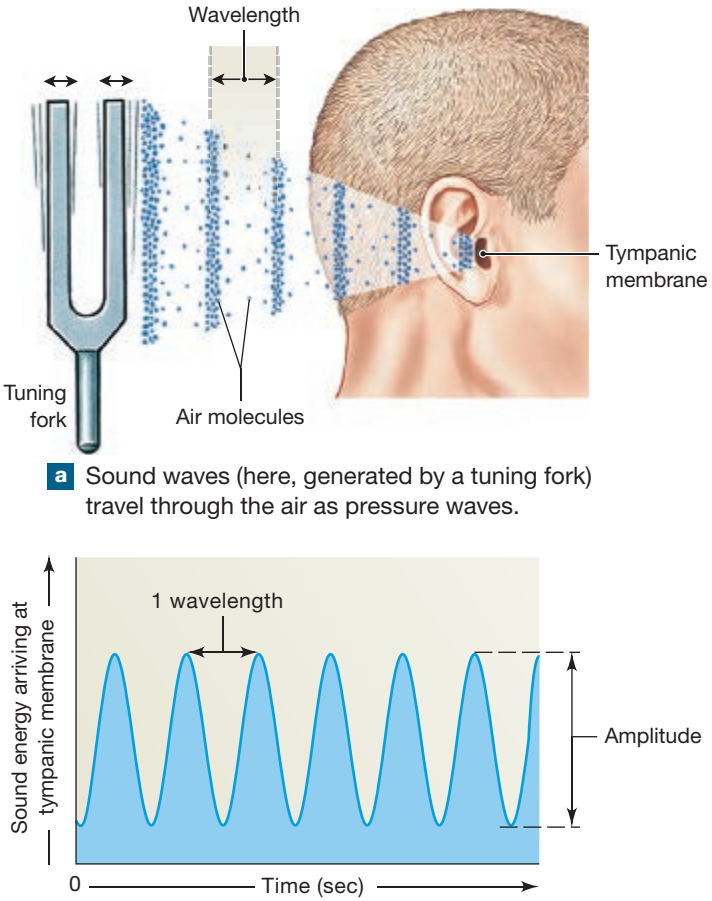


+ Clinical Note Motion Sickness

The signs and symptoms of **motion sickness** are exceedingly unpleasant. They include headache, sweating, facial flushing, nausea, vomiting, and various changes in mental perspective. Motion sickness may result when central processing stations, such as the tectum of the midbrain, receive conflicting sensory information. Why and how these conflicting reports result in nausea, vomiting, and other signs and symptoms are not known. Sitting below decks on a moving boat or reading in a car or airplane tends to provide the necessary conditions. Your eyes (which are tracking lines on a page) report that your position in space is not changing, but your semicircular ducts report that your body is lurching and turning. To counter this effect, seasick sailors watch the horizon rather than their immediate surroundings, so that their eyes will provide visual confirmation of the movements detected by their internal ears. It is not clear why some individuals are almost immune to motion sickness, but others find travel by boat or plane almost impossible.

Drugs commonly used to prevent motion sickness include dimenhydrinate (*Dramamine*), scopolamine (*Transderm Scop*), and promethazine. These drugs depress activity at the vestibular nuclei. Sedatives, such as prochlorperazine (*Compazine*), may also be effective.

Figure 17–27 The Nature of Sound.



a Sound waves (here, generated by a tuning fork) travel through the air as pressure waves.

b A graph showing the sound energy arriving at the tympanic membrane. The distance between wave peaks is the wavelength. The number of waves arriving each second is the frequency, which we perceive as pitch. Frequencies are reported in cycles per second (cps), or hertz (Hz). The amount of energy carried by the wave is its amplitude. The greater the amplitude, the louder the sound.

functional in a noisy room. The receptors responsible for auditory sensations are hair cells similar to those of the vestibular complex. However, their placement within the cochlear duct and the organization of the surrounding accessory structures shield them from stimuli other than sound.

In the process of hearing, arriving sound waves are converted into mechanical movements by vibration of the tympanic membrane. These vibrations are then conducted to the internal ear by the auditory ossicles. In the internal ear, the vibrations are converted to pressure waves in fluid, which eventually are detected by the hair cells in the cochlear duct. This sensory information is sent to the *auditory cortex* of the brain to be interpreted. Before discussing the mechanics of this remarkably elegant process, let's first look at the basic properties of sound, which are key to understanding this process.

An Introduction to Sound

Hearing is the perception of sound, but what is sound? It consists of waves of pressure conducted through a medium such as air or water. In air, each *pressure wave* consists of a region where the air molecules are crowded together and an adjacent zone where they are farther apart (Figure 17–27a). These waves are sine waves—that is, S-shaped curves that repeat in a regular pattern. They travel through the air at about 1235 km/h (768 mph).

The *wavelength* of sound is the distance between two adjacent wave crests (peaks), or the distance between two adjacent wave troughs (Figure 17–27b). The **frequency** of a sound is the number of waves that pass a fixed reference point in a given time. Physicists use the term **cycles** rather than *waves.* We measure the frequency of a sound in terms of the number of cycles per second (cps), a unit called **hertz (Hz)**. Wavelength and frequency are inversely related.

What we perceive as the **pitch** of a sound is our sensory response to its frequency. A *high-frequency* sound (high pitch, short wavelength) might have a frequency of 15,000 Hz or more. A very *low-frequency* sound (low pitch, long wavelength) could have a frequency of 100 Hz or less.

It takes energy to produce sound waves. When you strike a tuning fork, it vibrates, pushing against the surrounding air (see Figure 17–27a). It produces sound waves whose frequency depends on the instrument's frequency of vibration.

The harder you strike the tuning fork, the more energy you provide. The energy increases the **amplitude**, or height, of the sound wave (see Figure 17–27b). The amount of energy in a sound wave, its **intensity**, determines how loud it seems. The greater the energy content, the larger the amplitude, and the louder the sound. We report sound energy in **decibels** (DES-ih-belz, dB). Table 17–1 shows the decibel levels of familiar sounds.

When sound waves strike an object, their energy is a physical pressure. You may have seen windows move in a room where a stereo is blasting. The more flexible the object, the more easily it will respond to the pressure of sound waves. Even soft stereo music will vibrate a sheet of paper held in front of the speaker. Given the right combination of frequencies and amplitudes, an object, including your tympanic membrane, will begin to vibrate at the same frequency as the sound, a phenomenon called *resonance*.

17

Table 17–1 Intensity of Representative Sounds

Typical Decibel Level	Example	Dangerous Time Exposure
0	Lowest audible sound	
30	Quiet library; soft whisper	
40	Quiet office; living room; bedroom away from traffic	
50	Light traffic at a distance; refrigerator; gentle breeze	
60	Air conditioner at 20 feet; conversation; sewing machine in operation	
70	Busy traffic; noisy restaurant	Some damage if continuous
80	Subway; heavy city traffic; alarm clock at 2 feet; factory noise	More than 8 hours
90	Truck traffic; noisy home appliances; shop tools; gas lawn mower	Less than 8 hours
100	Chain saw; boiler shop; pneumatic drill	2 hours
120	"Heavy metal" rock concert; sandblasting; thunderclap nearby	Immediate danger
140	Gunshot; jet plane	Immediate danger
160	Rocket launching pad	Hearing loss inevitable

Anatomy of the Cochlear Duct

In sectional view (Figure 17–28), the **cochlear duct**, or **scala media**, lies between a pair of perilymphatic chambers, or *scalae:* the **scala vestibuli** (SKĀ-luh ves-TIB-yū-lē), or **vestibular duct**, and the **scala tympani** (TIM-pa-nē), or **tympanic duct**. The outer surfaces of all three ducts are encased by the bony labyrinth everywhere except at the oval window (the base of the scala vestibuli) and the round window (the base of the scala tympani). These scalae really form one long and continuous perilymphatic chamber because they are interconnected at the tip of the spiral-shaped cochlea. This chamber begins at the oval window; extends through the scala vestibuli, around the top of the cochlea, and along the scala tympani; and ends at the round window.

The hair cells of the cochlear duct are located in a structure called the **spiral organ** (**organ of Corti**) (Figures 17–28b and Figure 17–29). This sensory structure sits on the **basilar membrane**, a membrane that separates the cochlear duct from the scala tympani. The hair cells are arranged in a series of longitudinal rows. They lack kinocilia, and their stereocilia are in contact with the overlying **tectorial** (tek-TOR-ē-al; *tectum*, roof) **membrane**. This membrane is firmly attached to the inner wall of the cochlear duct.

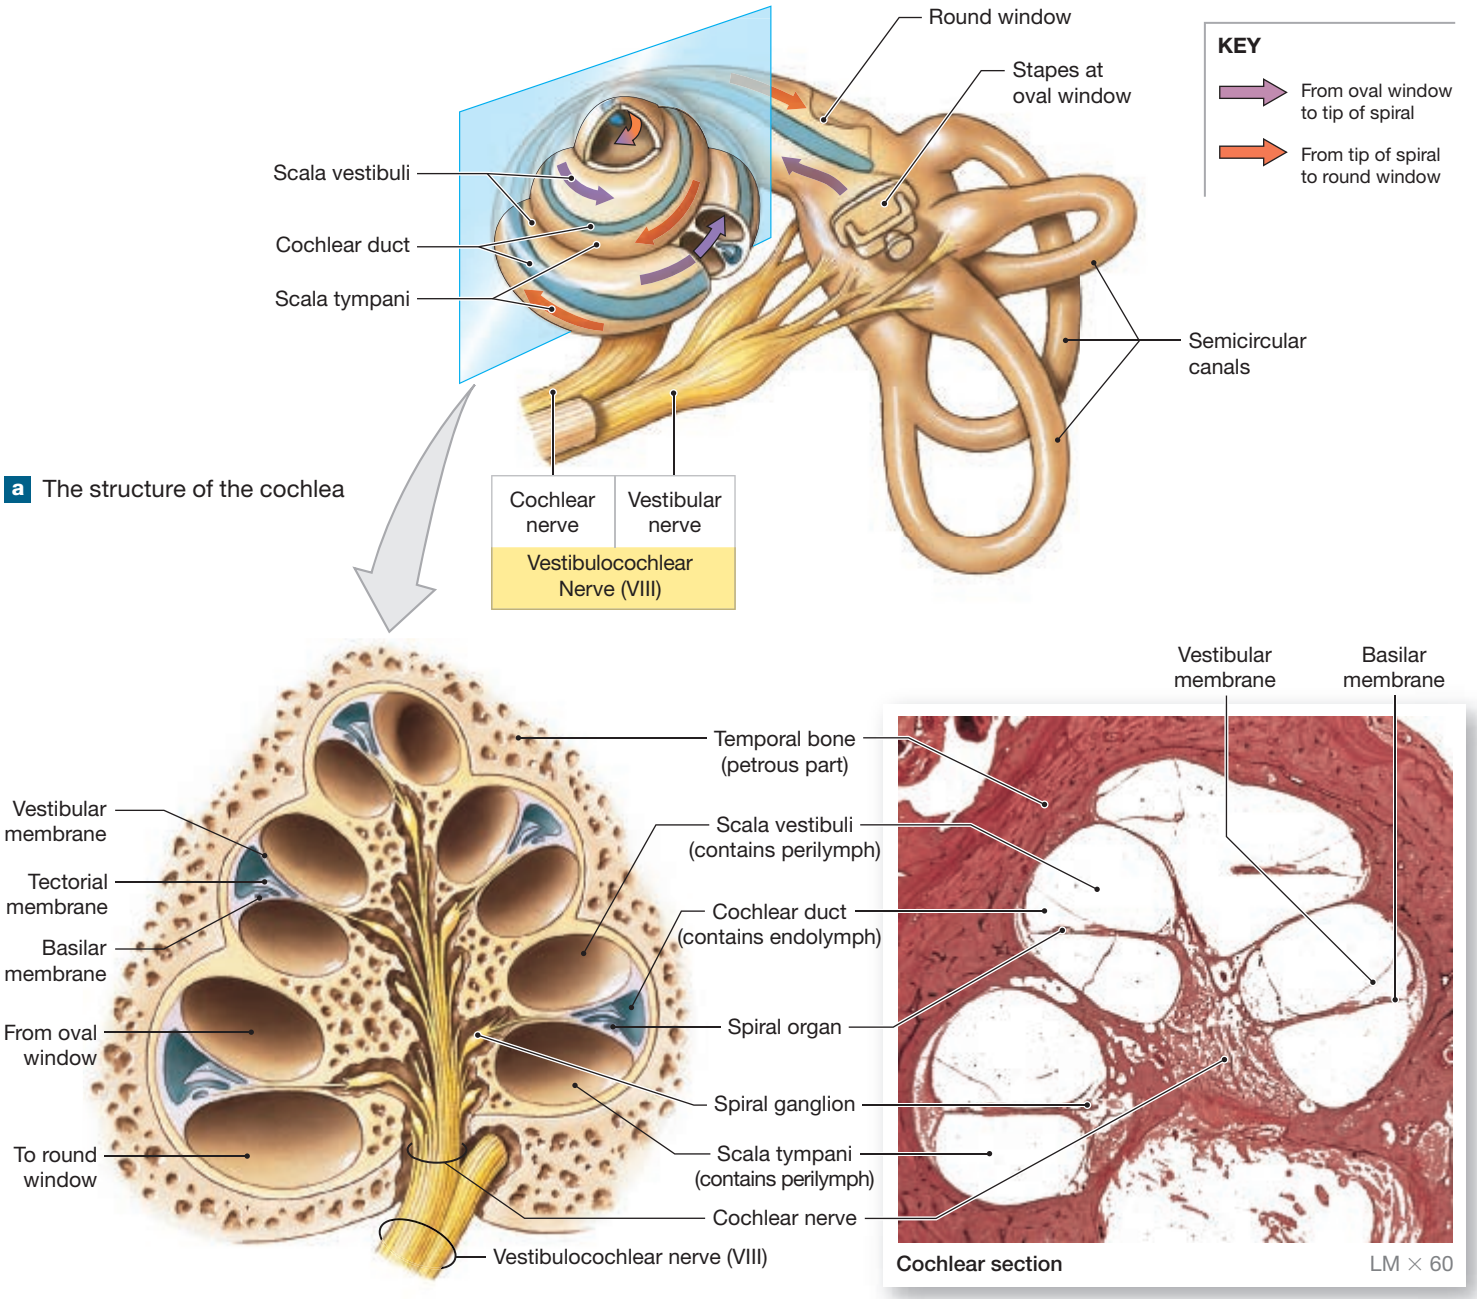
Auditory Discrimination

Our hearing abilities are remarkable, but it is difficult to assess the degree of auditory discrimination. The range from the softest audible sound to the loudest tolerable blast represents a trillion-fold increase in power. The receptor mechanism is so sensitive that, if we were to remove the stapes, we could, in theory, hear air molecules bouncing off the oval window. We never use the full potential of this system, because body movements and our internal organs produce squeaks, groans, thumps, and other sounds that are tuned out by central and peripheral adaptation. When other environmental noises fade away, the level of adaptation drops and the system becomes increasingly sensitive. For example, when you relax in a quiet room, your heartbeat seems to get louder and louder as the auditory system adjusts to the level of background noise.

Young children have the greatest hearing range: They can detect sounds ranging from a 20-Hz buzz to a 20,000-Hz whine. With age, damage due to loud noises or other injuries accumulates. The tympanic membrane gets less flexible, the articulations between the ossicles stiffen, and the round window may begin to ossify. As a result, older individuals show some degree of hearing loss.

Probably more than 6 million people in the United States have at least a partial hearing deficit, either congenital (inborn) or acquired. Such deficits are due to problems with the transfer of vibrations by the auditory ossicles, or damage to the receptors or the auditory pathways.

Figure 17–28 The Cochlea.



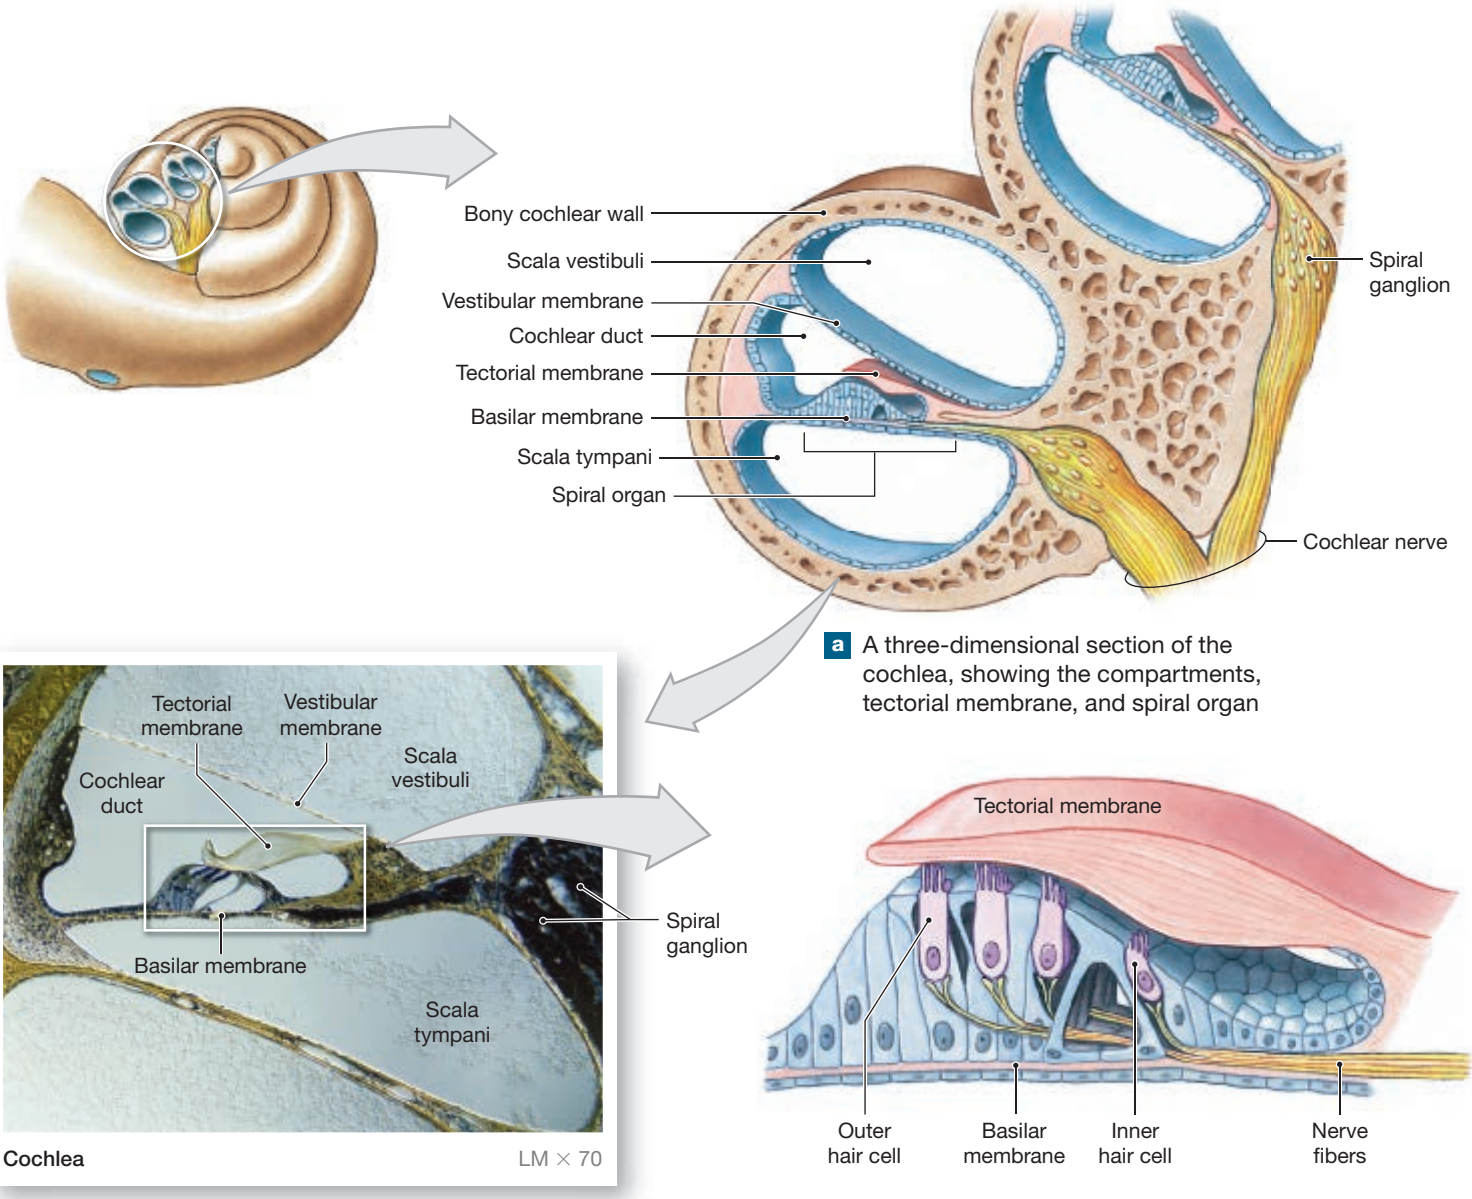
? The scala vestibuli and scala tympani contain a different fluid than the cochlear duct. What type of fluid does each chamber contain?

The Physiology of Hearing

We divide the process of hearing into six basic steps (Figure 17–30):

1 **Sound waves arrive at the tympanic membrane.** Sound waves enter the external acoustic meatus and travel toward the tympanic membrane. The orientation of this meatus, or canal, provides some directional sensitivity. Sound waves approaching a particular side of the head have direct access to the tympanic membrane on that side. Sounds arriving from another direction must bend around corners or pass through the auricle or other body tissues.

Figure 17–29 The Spiral Organ.



a A three-dimensional section of the cochlea, showing the compartments, tectorial membrane, and spiral organ

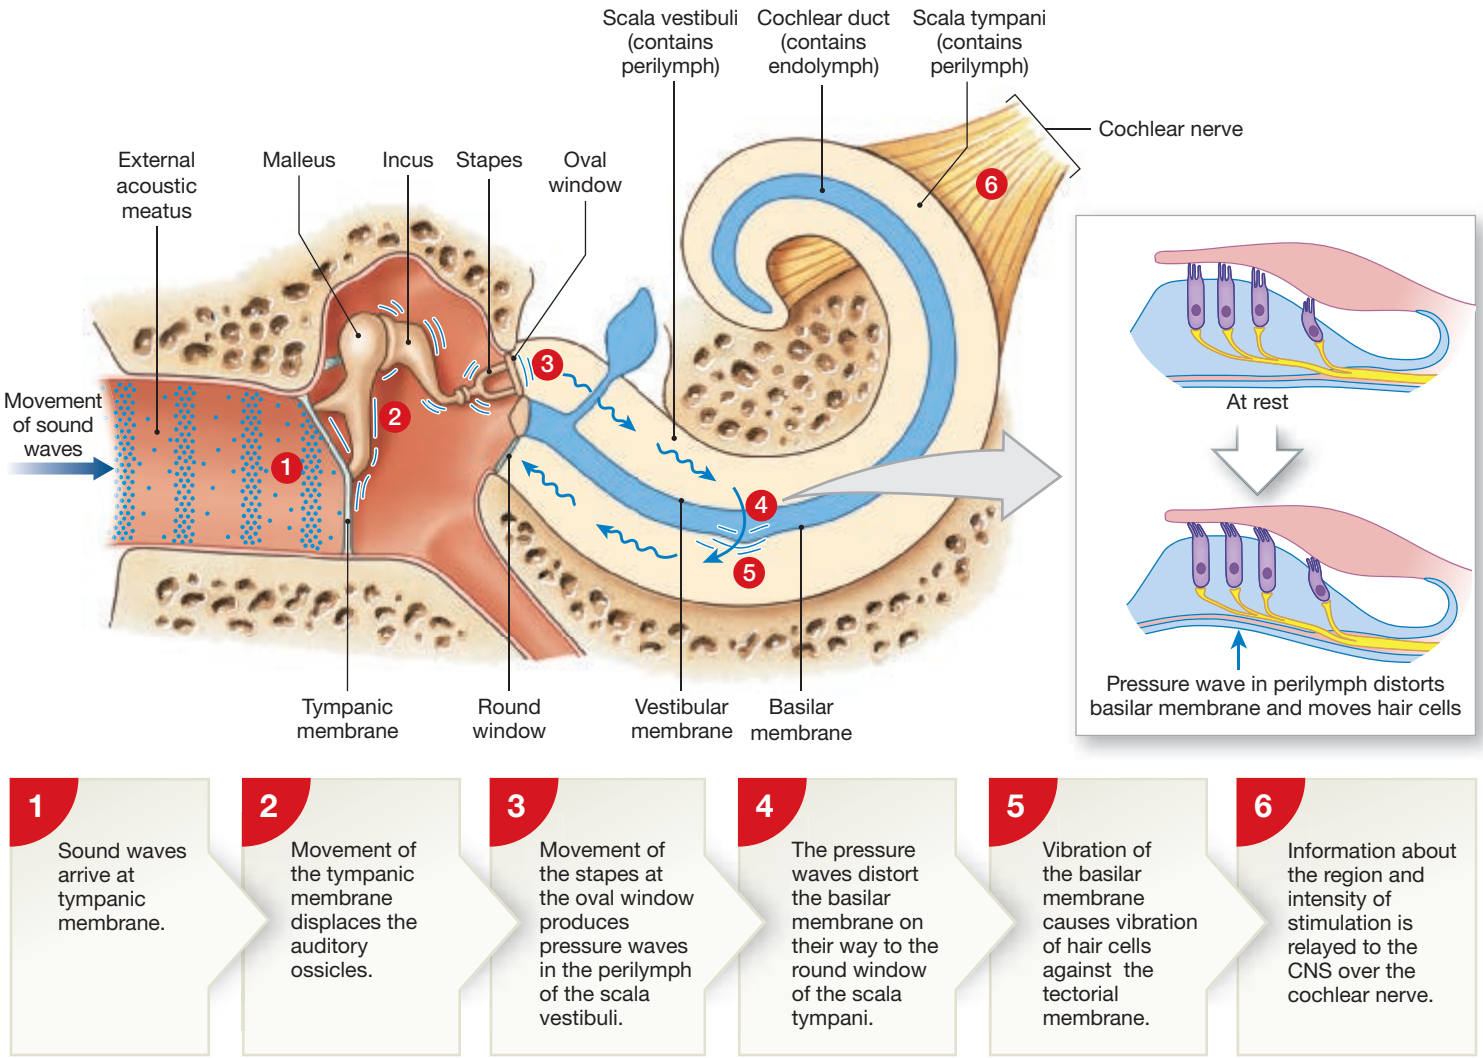
b Sectional view of the cochlea and spiral organ

c Diagram of the receptor hair cell complex of the spiral organ

2 Movement of the tympanic membrane displaces the auditory ossicles. The tympanic membrane provides a surface for the collection of sound. The membrane vibrates in resonance to sound waves with frequencies between approximately 20 and 20,000 Hz. When the tympanic membrane vibrates, so do the malleus, incus, and stapes. The ossicles are connected in such a way that an in–out movement of the tympanic membrane produces a rocking motion of the stapes. In this way, the sound is amplified.

3 Movement of the stapes at the oval window produces pressure waves in the perilymph of the scala vestibuli. Liquids are not compressible. If you squeeze one part of a water-filled balloon, it bulges somewhere else. Because the rest of the cochlea is sheathed in bone, pressure applied at the oval window can be relieved only at the round window. The movement of the stapes can be understood by focusing on just its in–out component. Basically, when the stapes moves inward, the round window bulges outward, into the middle ear cavity. As the stapes moves in and out,

Figure 17–30 Sound and Hearing. Steps in the reception and transduction of sound energy.



vibrating at the frequency of the sound arriving at the tympanic membrane, it produces pressure waves within the perilymph.

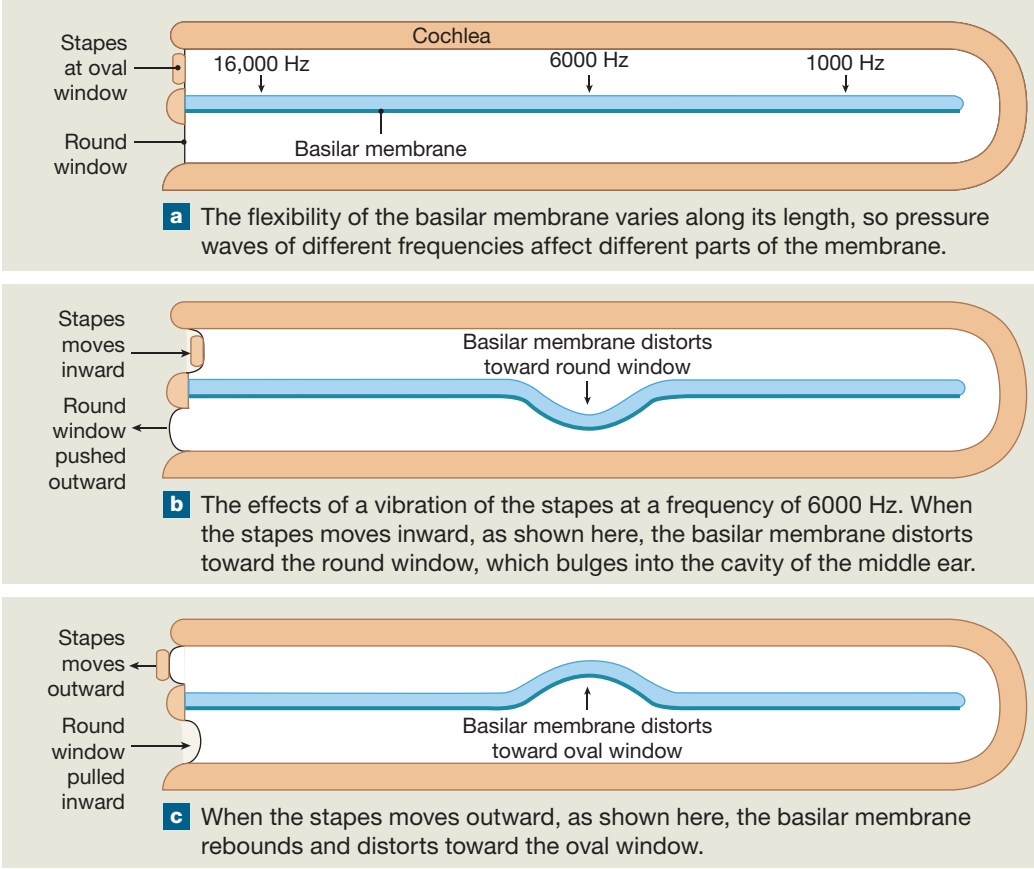
4 The pressure waves distort the basilar membrane on their way to the round window of the scala tympani. These pressure waves travel through the perilymph of the scala vestibuli and scala tympani to reach the round window. In doing so, the waves distort the basilar membrane. The location of maximum distortion varies with the frequency of the sound, due to regional differences in the width and flexibility of the basilar membrane along its length. High-frequency sounds, which have a very short wavelength, vibrate the basilar membrane near the oval window. The lower the frequency of the sound and the longer the wavelength, the farther the area of maximum distortion is from the oval window (Figure 17–31). In this way, information about frequency is translated into information about *position* along the basilar membrane.

The *amount* of movement at a given location depends on the amount of force applied by the stapes, which in turn depends on the energy content of the sound. The louder the sound, the more the basilar membrane moves.

5 Vibration of the basilar membrane causes hair cells to vibrate against the tectorial membrane. Vibration of the affected region of the basilar membrane moves hair cells against the tectorial membrane. This movement leads to the displacement of the stereocilia, which in turn opens ion channels in the plasma membranes of the hair cells. The resulting inrush of ions depolarizes the hair cells, leading to the release of neurotransmitters that stimulate sensory neurons.

The hair cells of the spiral organ are arranged in several rows. A very soft sound may stimulate only a few hair cells in a portion of one row. As the intensity of a sound increases, not only do these hair cells become more active, but additional hair

Figure 17–31 Frequency Discrimination.



cells—first in the same row and then in adjacent rows—are stimulated as well. The number of hair cells responding in a given region of the spiral organ provides information on the intensity of the sound.

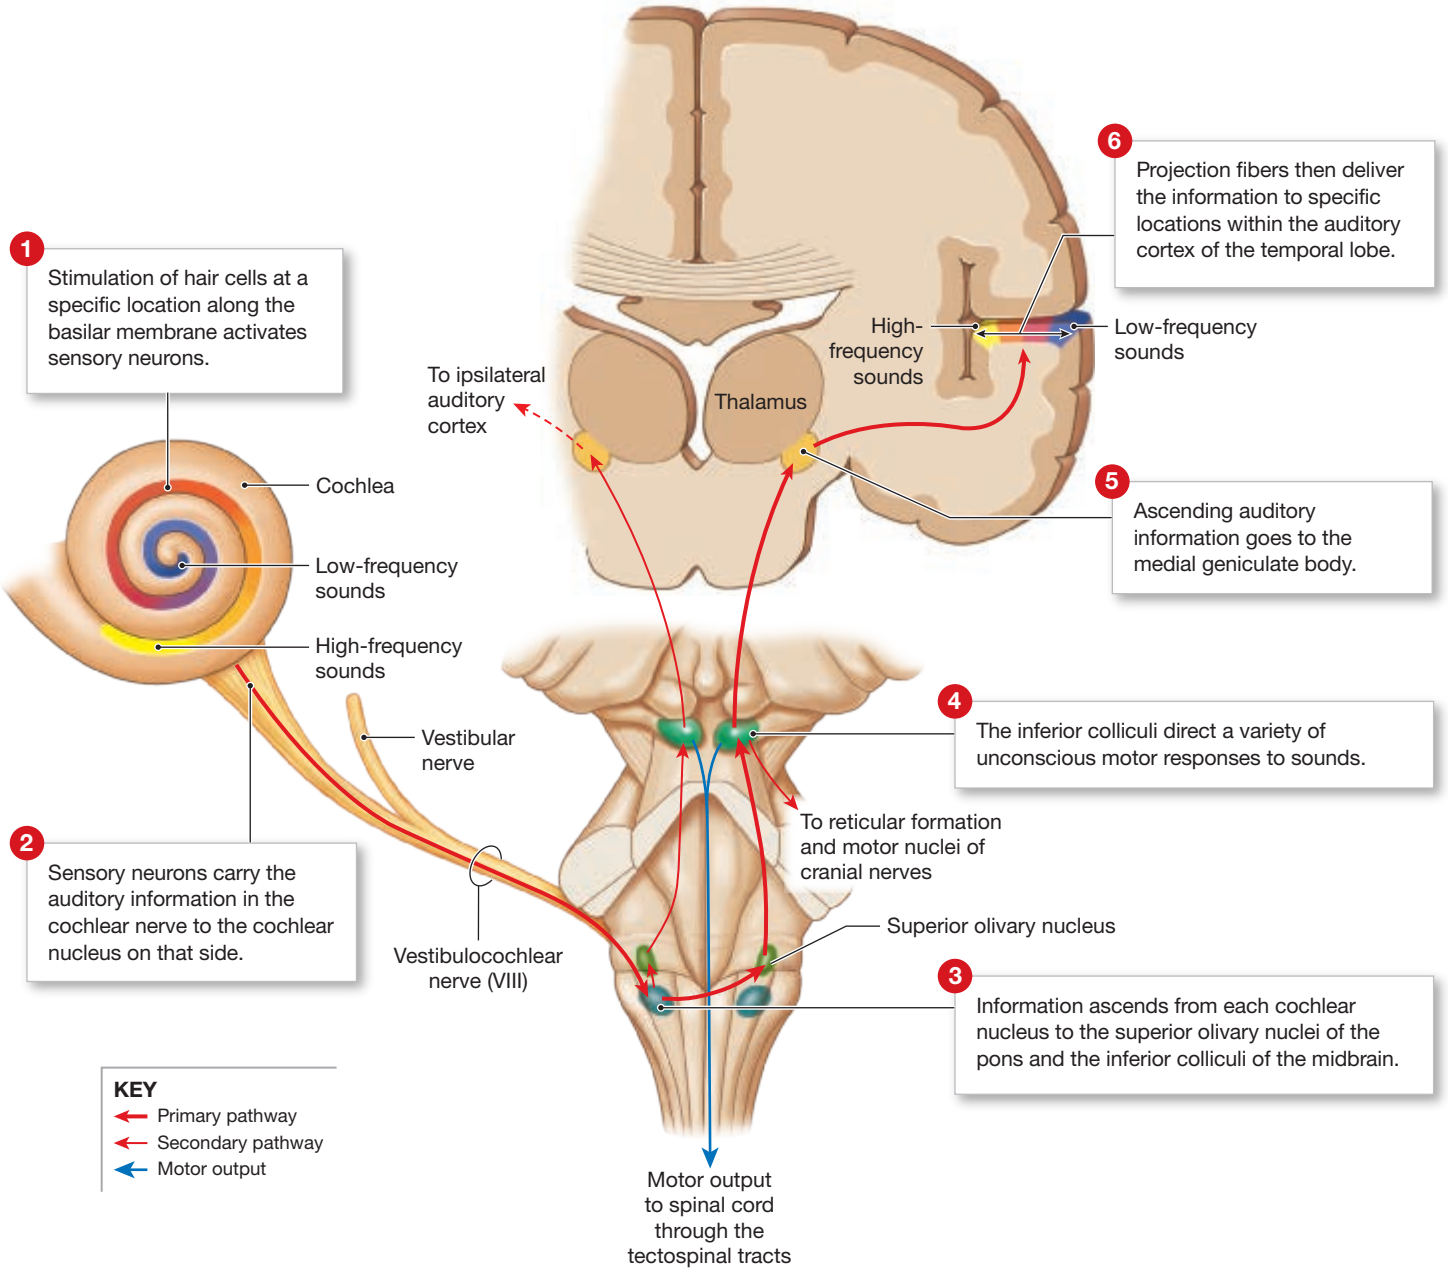
6 Information about the region and the intensity of stimulation is relayed to the CNS over the cochlear nerve, a division of cranial nerve VIII. The cell bodies of the bipolar sensory neurons that monitor the cochlear hair cells are located at the center of the bony cochlea, in the **spiral ganglion** (see Figure 17–29a). From there, the information is carried by the cochlear nerve to the cochlear nuclei of the medulla oblongata for distribution to other brain centers.

Auditory Pathways

The ascending pathways for auditory sensations are shown in Figure 17–32. Stimulation of hair cells along the basilar membrane activates sensory neurons whose cell bodies are in the adjacent spiral ganglion 1. The afferent fibers of those neurons form the **cochlear nerve**. These axons enter the medulla oblongata, where they synapse at the **cochlear nucleus** on that side 2. From there, information ascends to both **superior olivary nuclei** of the pons and both inferior colliculi of the midbrain 3. This midbrain processing center coordinates a variety of unconscious motor responses to acoustic stimuli, including auditory reflexes that involve skeletal muscles of the head, face, and trunk 4. These reflexes automatically change the position of your head in response to a sudden loud noise. You usually turn your head and your eyes toward the source of the sound.

Before reaching the cerebral cortex and your awareness, ascending auditory sensations synapse in the medial geniculate body of the thalamus 5. Projection fibers then deliver the information to the **auditory cortex** of the temporal lobe 6. Information travels to the cortex over labeled lines: High-frequency sounds activate one portion of the cortex, low-frequency sounds another. In effect, the auditory cortex contains a map of the spiral organ. So, information about frequency, translated into information about position on the basilar membrane, is projected in that form onto the auditory cortex. There it is interpreted to produce your subjective sensation of pitch.

Figure 17–32 Pathways for Auditory Sensations.



Most of the auditory information from one cochlea is projected to the auditory complex of the cerebral hemisphere on the opposite side of the brain. However, each auditory cortex also receives information from the cochlea on that side. These interconnections play a role in localizing left/right sounds. They can also reduce the functional impact of damage to a cochlea or ascending pathway.

An individual whose auditory cortex is damaged will respond to sounds and have normal acoustic reflexes, but will find it difficult or impossible to interpret the sounds and recognize a pattern in them. Damage to the adjacent auditory association area leaves the ability to detect the tones and patterns intact, but produces an inability to comprehend their meaning.

Checkpoint

15. **If the round window were not able to bulge out with increased pressure in the perilymph, how would the perception of sound be affected?**
16. **How would the loss of stereocilia from hair cells of the spiral organ affect hearing?**
17. **Why would blockage of the auditory tube produce an earache?**

See the blue Answers tab at the back of the book.

17 Chapter Review

Study Outline

An Introduction to the Special Senses p. 566

1. The sense organs responsible for the five *special senses—olfaction* (smell), *gustation* (taste), *vision*, *equilibrium* (balance), and *hearing*—are structurally more complex than those of the general senses, but the same basic principles of receptor function apply.

17-1 Olfaction, the sense of smell, involves olfactory receptors responding to airborne chemical stimuli p. 566

2. The **olfactory organs** contain the **olfactory epithelium** with **olfactory receptors**, supporting cells, and **basal (stem) cells**. The surfaces of the olfactory organs are coated with the secretions of the **olfactory glands**. *(Figure 17–1)*
3. The olfactory receptors are highly modified neurons.
4. In olfaction, the arriving information reaches the information centers without first synapsing in the thalamus. *(Figure 17–1)*
5. Olfactory reception involves detecting dissolved chemicals as they interact with odorant-binding proteins. *(Spotlight Figure 17–2)*
6. The olfactory system can distinguish thousands of chemical stimuli. The CNS interprets smells by the pattern of receptor activity.
7. The olfactory receptor population shows considerable turnover. The number of olfactory receptors declines with age.

17-2 Gustation, the sense of taste, involves gustatory receptors responding to dissolved chemical stimuli p. 570

8. **Gustatory epithelial cells** are clustered in **taste buds**.
9. Taste buds are associated with epithelial projections (*lingual papillae*) on the tongue. *(Figure 17–3)*
10. Each taste bud contains **basal epithelial cells** (stem cells) and **gustatory epithelial cells**, which extend *taste hairs* through a narrow **taste pore**. *(Figure 17–3)*
11. The taste buds are monitored by cranial nerves that synapse within the solitary nucleus of the medulla oblongata. Postsynaptic neurons carry the nerve impulses on to the thalamus, where third-order neurons project to the somatosensory cortex.
12. The **primary taste sensations** are sweet, salty, sour, and bitter. Receptors also exist for **umami** and **water**. *(Spotlight Figure 17–2)*
13. Taste sensitivity exhibits significant individual differences, some of which are inherited.
14. The number of taste buds declines with age.

17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection p. 572

15. The **accessory structures** of the eye include the **eyelids** (*palpebrae*), separated by the **palpebral fissure**, the **eyelashes**, and the **tarsal glands**. *(Figures 17–4, 17–5)*
16. An epithelium called the **conjunctiva** covers the inner surfaces of the eyelids and most of the exposed surface of the eye. The **cornea** is transparent. *(Figure 17–4, 17–5)*

17. The secretions of the **lacrimal gland** contain **lysozyme**. Tears collect in the *lacrimal lake* and reach the inferior meatus of the nose after they pass through the **lacrimal puncta**, the **lacrimal canaliculi**, the **lacrimal sac**, and the **nasolacrimal duct**. *(Figure 17–4)*
18. The eye has three layers, formerly called tunics: an outer **fibrous layer**, a middle **vascular layer** (uvea), and a deeper, **inner layer** (retina). *(Figure 17–5)*
19. The fibrous layer consists of the **sclera**, the **cornea**, and the **corneoscleral junction** (*corneal limbus*). *(Figure 17–5)*
20. The vascular layer, or **uvea**, includes the **iris**, the **ciliary body**, and the **choroid**. The iris contains muscle fibers that change the diameter of the **pupil**. The ciliary body contains the **ciliary muscle** and the **ciliary processes**, which attach to the **ciliary zonule** (*suspensory ligament*) of the lens. *(Figures 17–5, 17–6)*
21. The **inner layer**, or **retina**, consists of a thin lining called the *pigmented layer* and a thicker covering called the *neural layer*, which contains visual receptors and associated neurons. *(Figures 17–5, 17–7)*
22. The retina contains two types of **photoreceptors: rods** and **cones**.
23. Cones are densely clustered in the **fovea centralis** (*fovea*), at the center of the **macula**. *(Figure 17–7)*
24. The direct line to the CNS proceeds from the photoreceptors to **bipolar cells**, then to **ganglion cells**, and, finally, to the brain by the optic nerve. The axons of ganglion cells converge at the **optic disc**, or **blind spot**. **Horizontal cells** and **amacrine cells** modify the signals passed among other components of the retina. *(Figures 17–7, 17–8)*
25. The ciliary body and lens divide the interior of the eye into a large **posterior cavity**, or *vitreous chamber*, and a smaller **anterior cavity**. The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber**, between the iris and the ciliary body and lens. *(Figure 17–9)*
26. The fluid **aqueous humor** circulates within the eye and reenters the circulation after diffusing through the walls of the anterior chamber and into the **scleral venous sinus** (*canal of Schlemm*). *(Figure 17–9)*
27. The **lens** lies posterior to the cornea and forms the anterior boundary of the posterior cavity. This cavity contains the **vitreous body**, a clear, gelatinous mass that helps stabilize the shape of the eye and support the retina. *(Figure 17–9)*
28. The lens focuses a visual image on the photoreceptors. A **cataract** is the condition in which a lens has lost its transparency.

17-4 The focusing of light on the retina leads to the formation of a visual image p. 581

29. Light is **refracted** (bent) when it passes through the cornea and lens. During **accommodation**, the shape of the lens changes to focus an image on the retina. "Normal" **visual acuity** is rated 20/20. *(Figures 17–10* to *Spotlight Figure 17–13)*

17-5 Photoreceptors transduce light into electrical signals that are then processed in the visual cortex p. 583

30. The two types of photoreceptors are rods, which respond to almost any photon, regardless of its energy content, and cones, which have characteristic ranges of sensitivity. *(Figure 17–14)*
31. Each photoreceptor contains an **outer segment** with membranous **discs**. A narrow stalk connects the outer segment to the **inner segment**. Light absorption occurs in the **visual pigments**, which are derivatives of **rhodopsin** (opsin plus the pigment retinal, which is synthesized from vitamin A). *(Figure 17–14)*
32. Color sensitivity depends on the integration of information from **red**, **green**, and **blue** cones. **Color blindness** is the inability to detect certain colors. *(Figures 17–15, 17–18)*
33. In the absence of photons, a photoreceptor produces a dark current and constantly releases neurotransmitter. Photon absorption reduces the dark current and decreases the release of neurotransmitter to the bipolar cell. *(Spotlight Figure 17–16)*
34. During the process of **bleaching**, rhodopsin molecules are broken apart to regenerate retinal back to its photon-absorbing 11-*cis* form. *(Spotlight Figure 17–16, Figure 17–17)*
35. In the **dark-adapted state**, most visual pigments are fully receptive to stimulation. In the **light-adapted state**, the pupil constricts and bleaching of the visual pigments takes place.
36. The ganglion cells that monitor rods, called **M cells** (*magnocells*), are relatively large. The ganglion cells that monitor cones, called **P cells** *(parvo cells)*, are smaller and more numerous. *(Figure 17–19)*
37. Visual data from the left half of the combined field of vision arrive at the visual cortex of the right occipital lobe. Data from the right half of the combined field of vision arrive at the visual cortex of the left occipital lobe. *(Figure 17–20)*
38. **Depth perception** is resolved by comparing relative positions of objects between the left- and right-eye images. *(Figure 17–20)*
39. Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brainstem nuclei. This nucleus establishes a visceral **circadian rhythm**, which is tied to the day–night cycle and affects other metabolic processes.

17-6 Equilibrium sensations monitor head position and movement, while hearing involves the detection and interpretation of sound waves p. 592

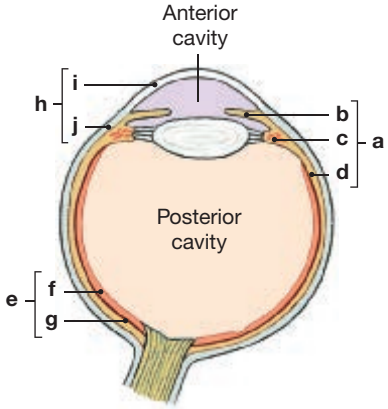
40. The receptors of the internal ear provide the senses of equilibrium and hearing.
41. The ear is divided into the **external ear**, the **middle ear**, and the **internal ear**. *(Figure 17–21)*
42. The external ear includes the **auricle**, or *pinna*, which surrounds the entrance to the **external acoustic meatus**, which ends at the **tympanic membrane** (*eardrum*). *(Figure 17–21)*
43. The middle ear communicates with the nasopharynx by the **auditory** (*pharyngotympanic*) **tube**. The middle ear encloses and protects the **auditory ossicles**. *(Figures 17–21, 17–22)*
44. The **membranous labyrinth** (the chambers and tubes) of the internal ear contains the fluid **endolymph**. The **bony labyrinth** surrounds and protects the membranous labyrinth and can be subdivided into the **vestibule**, the **semicircular canals**, and the **cochlea**. *(Figures 17–21, 17–23)*
45. The vestibule of the internal ear encloses the **saccule** and **utricle**. The semicircular canals contain the **semicircular ducts**. The cochlea contains the **cochlear duct**, an elongated portion of the membranous labyrinth. *(Figure 17–23)*
46. The **round window** separates the **perilymph** from the air spaces of the middle ear. The **oval window** is connected to the base of the stapes. *(Figure 17–21)*
47. The basic sensory receptors of the internal ear are **hair cells**, which provide information about the direction and strength of mechanical stimuli. *(Figure 17–24)*
48. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle. Each duct contains an **ampullary crest** with a gelatinous **ampullary cupula** and associated sensory receptors. *(Figures 17–23, 17–24)*
49. The saccule and utricle are connected by a passageway that is continuous with the **endolymphatic duct**. This duct terminates in the **endolymphatic sac**. In the saccule and utricle, hair cells cluster within **maculae**, where their hair cells contact the gelatinous *otolithic membrane*. The surface of the membrane contains calcium carbonate crystals called **otoliths**. *(Figures 17–24, 17–25)*
50. The vestibular receptors activate sensory neurons of the **vestibular ganglia**. The axons form the **vestibular nerve**, synapsing within the **vestibular nuclei**. *(Figure 17–26)*
51. The energy content of a sound determines its *intensity*, or loudness, measured in **decibels**. Sound waves travel toward the tympanic membrane, which vibrates, and the auditory ossicles then conduct these vibrations to the internal ear. Movement at the oval window applies pressure to the perilymph of the scala vestibuli. *(Figures 17–27, 17–30; Table 17–1)*
52. The **cochlear duct** (**scala media**) lies between the **scala vestibuli** (*vestibular duct*) and the **scala tympani** (*tympanic duct*). The hair cells of the cochlear duct lie within the **spiral organ** (**organ of Corti**). *(Figures 17–28, 17–29)*
53. Pressure waves distort the **basilar membrane** and push the hair cells of the spiral organ against the **tectorial membrane**. Two muscles, the **tensor tympani** and **stapedius**, contract to reduce the amount of motion when very loud sounds arrive. *(Figures 17–30, 17–31)*
54. The sensory neurons are located in the **spiral ganglion** of the cochlea. The afferent fibers of these neurons form the **cochlear nerve**, synapsing at their respective left or right **cochlear nucleus**. Ascending auditory information from each ear reaches the auditory cortex on both sides of the brain. *(Figure 17–32)*

Review Questions

See the blue Answers tab at the back of the book.

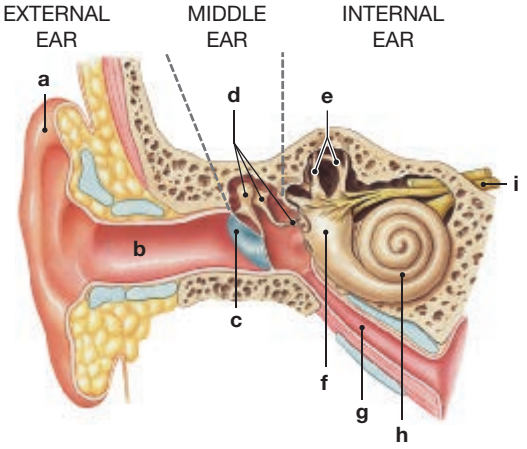
LEVEL 1 Reviewing Facts and Terms

1. Identify the structures in the following horizontal section of the eye.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____ **(j)** _____

2. A reduction in sensitivity in the presence of a constant stimulus is **(a)** transduction, **(b)** sensory coding, **(c)** line labeling, **(d)** adaptation.
3. A blind spot occurs in the retina where **(a)** the fovea centralis is located, **(b)** ganglion cells synapse with bipolar cells, **(c)** the optic nerve attaches to the retina, **(d)** rod cells are clustered to form the macula, **(e)** amacrine cells are located.
4. Sound waves are converted into mechanical movements by the **(a)** auditory ossicles, **(b)** cochlea, **(c)** oval window, **(d)** round window, **(e)** tympanic membrane.
5. The basic receptors in the internal ear are the **(a)** utricles, **(b)** saccules, **(c)** hair cells, **(d)** supporting cells, **(e)** ampullae.
6. The retina is also called **(a)** the vascular layer, **(b)** the fibrous layer, **(c)** the inner layer, **(d)** all of these.
7. At sunset, your visual system adapts to **(a)** fovea vision, **(b)** rod-based vision, **(c)** macular vision, **(d)** cone-based vision.
8. A better-than-average visual acuity rating is **(a)** 20/20, **(b)** 20/30, **(c)** 15/20, **(d)** 20/15.
9. The malleus, incus, and stapes are the tiny bones located in the **(a)** external ear, **(b)** middle ear, **(c)** internal ear, **(d)** membranous labyrinth.
10. Identify the structures of the external, middle, and internal ear in the following figure.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____

11. Receptors in the saccule and utricle provide sensations of **(a)** angular acceleration, **(b)** hearing, **(c)** vibration, **(d)** gravity and linear acceleration and deceleration.
12. The spiral organ is located in the _____ of the internal ear. **(a)** utricle, **(b)** bony labyrinth, **(c)** vestibule, **(d)** cochlea.
13. Auditory information about the frequency and intensity of stimulation is relayed to the CNS over the cochlear nerve, a division of cranial nerve **(a)** IV, **(b)** VI, **(c)** VIII, **(d)** X.
14. What are the four types of papillae on the human tongue?
15. **(a)** What structures make up the fibrous layer of the eye? **(b)** What are the functions of the fibrous layer?
16. What structures make up the vascular layer of the eye?
17. What are the three auditory ossicles in the middle ear, and what are their functions?

LEVEL 2 Reviewing Concepts

18. Trace the olfactory pathway from the time an odor reaches the olfactory epithelium until nerve impulses reach their final destination in the brain.
19. Why are olfactory sensations long lasting and an important part of our memories and emotions?
20. What is the usual result if a sebaceous gland of an eyelash or a tarsal gland becomes infected?
21. Displacement of stereocilia toward the kinocilium of a hair cell **(a)** produces a depolarization of the membrane, **(b)** produces a hyperpolarization of the membrane, **(c)** decreases the membrane permeability to sodium ions, **(d)** increases the membrane permeability to potassium ions, **(e)** does not affect the membrane potential of the cell.
22. Damage to the ampullary cupula of the lateral semicircular duct would interfere with the perception of **(a)** the direction of gravitational pull, **(b)** linear acceleration, **(c)** horizontal rotation of the head, **(d)** vertical rotation of the head, **(e)** angular rotation of the head.
23. When viewing an object *close* to you, your lens should be more _____. **(a)** rounded, **(b)** flattened, **(c)** concave, **(d)** lateral, **(e)** medial.

LEVEL 3 Critical Thinking and Clinical Applications

24. You are at a park watching some deer 35 feet away from you. A friend taps you on the shoulder to ask a question. As you turn to look at your friend, who is standing just 2 feet away, what changes would your eyes undergo?
25. Your friend Shelly suffers from myopia (nearsightedness). You remember from your physics class that concave lenses cause light waves to spread or diverge and that convex lenses cause light waves to converge. What type of corrective lenses would you suggest to your friend? **(a)** concave lenses, **(b)** convex lenses.
26. Tom has surgery to remove polyps (growths) from his sinuses. After he heals from the surgery, he notices that his sense of smell is not as keen as it was before the surgery. Can you suggest a reason for this?
27. For a few seconds after you ride the express elevator from the 20th floor to the ground floor, you still feel as if you are descending, even though you have come to a stop. Why?
28. Juan tells his physician that he has been feeling dizzy, especially when he closes his eyes. He is asked to stand with his feet together and arms extended forward. As long as he keeps his eyes open, he exhibits very little movement. But when he closes his eyes, his body begins to sway a great deal, and his arms tend to drift together toward the left side of his body. Why does this occur?

CLINICAL CASE Wrap-Up A Chance to See

Makena suffers from *myopia*, or nearsightedness. Due to the elongated shape of Makena's eyeballs, distant images are projected in front of her retina and appear blurry and out of focus to her. Glasses can correct this easily, but nobody in Makena's village has ever met an eye doctor of any kind. The closest optical shop is far out of this family's reach, both in distance and cost.

Makena's teacher sets up a makeshift eye clinic with the help of volunteers from the Centre for Vision in the Developing World, a group dedicated to correcting vision for poor children. To test her vision, Makena attempts to read from an eye chart taped to the wall of the school building 20 feet away. Makena's visual acuity tests at 20/200.

Next, Makena puts on a simple pair of universal glasses, made with a clear membrane filled with silicone oil, held between two plastic discs on each side. A removable syringe filled with silicone oil is attached to each side. With her right eye covered, Makena uses the syringe to inject more silicone into the left lens until her left eye can read the eye chart perfectly. Then she repeats the process for her right eye. The final step is to remove the syringes. Now she can see things she never knew she had been missing—and she gets to keep the glasses.

1. What does Makena's initial eye test finding of 20/200 mean?
2. If Makena's vision is corrected to a state of emmetropia, what does this mean?

See the blue Answers tab at the back of the book.

Related Clinical Terms

age-related macular degeneration: A disease associated with aging that gradually destroys sharp, central vision by affecting the macula, the part of the eye that allows a person to see fine detail. It is painless and in some cases can slowly worsen over time, causing little concern to the person, or it can rapidly progress and may cause blindness in both eyes. It is the leading cause of blindness in persons over the age of 60. It has two forms, wet and dry.

ageusia: A rare inability to taste. More common is hypogeusia, a disorder in which the person affected has trouble distinguishing between tastes.

anosmia: The complete loss of smell, which can be temporary (caused by an obstruction such as a polyp) or permanent (perhaps due to aging or a brain tumor).

blepharitis: Common and persistent inflammation of the eyelid caused by poor hygiene, excessive oil production by the glands of the eyelid, or a bacterial infection. Signs and symptoms include itching, flakes on the eyelashes, and a gritty, sandy feeling.

conductive hearing loss: Deafness resulting from conditions in the external or middle ear that block the transfer of vibrations from the tympanic membrane to the oval window.

hyposmia: A lessened sensitivity to odors.

mydriasis: Dilation of the pupils of the eye induced by medical eye drops or caused by disease.

ophthalmologist: A physician who specializes in ophthalmology, which is the branch of medicine dealing with the diseases and surgery of the visual pathways, including the eye, brain, and areas surrounding the eye.

optometrist: A primary eye care doctor who diagnoses, manages, and treats disorders of the visual system and eye diseases and who also measures vision for the purpose of correcting one's vision problems with specifically prescribed lenses.

otalgia: Pain in the ear; an earache.

photophobia: An oversensitivity to light possibly leading to tearing, discomfort, or pain. Causes include abrasions to the corneal area, inflammation, disease, and some medications.

sensorineural hearing loss: Deafness resulting from problems within the cochlea or along the auditory nerve pathway.

Snellen chart: A printed chart of block letters in graduated type sizes used to measure visual acuity.

strabismus: The abnormal alignment of one or both eyes that prevents the person from gazing on the same point with both eyes.

synesthesia: Abnormal condition in which sensory nerve messages connect to the wrong centers of the brain. For example, touching an object may produce the perception of a sound, while hearing a tone may produce the visualization of a color.

tinnitus: A buzzing, whistling, or ringing sound heard in the absence of an external stimulus. Causes include injury, disease, inflammation, or some drugs.

vertigo: A feeling that you are dizzily spinning or that things are dizzily turning about you. Vertigo is usually caused by a problem with the internal ear, but can also be due to vision problems.

18 The Endocrine System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing this chapter.

18-1 ■ Explain the importance of intercellular communication, describe the mechanisms involved, and compare the modes of intercellular communication that occur in the endocrine and nervous systems. p. 611

18-2 ■ Compare the cellular components of the endocrine system with those of other systems, contrast the major structural classes of hormones, and explain the general mechanisms of hormonal action on target organs. p. 613

18-3 ■ Describe the location, hormones, and functions of the pituitary gland, and discuss the effects of abnormal pituitary hormone production. p. 619

18-4 ■ Describe the location, hormones, and functions of the thyroid gland, and discuss the effects of abnormal thyroid hormone production. p. 627

18-5 ■ Describe the location, hormone, and functions of the parathyroid glands, and discuss the effects of abnormal parathyroid hormone production. p. 632

18-6 ■ Describe the location, structure, hormones, and general functions of the adrenal glands, and discuss the effects of abnormal adrenal hormone production. p. 634

18-7 ■ Describe the location of the pineal gland, and discuss the functions of the hormone it produces. p. 637

18-8 ■ Describe the location, structure, hormones, and functions of the pancreas, and discuss the effects of abnormal pancreatic hormone production. p. 637

18-9 ■ Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue. p. 641

18-10 ■ Explain how hormones interact to produce coordinated physiological responses and influence behavior, describe the role of hormones in the general adaptation syndrome, and discuss how aging affects hormone production and give examples of interactions between the endocrine system and other organ systems. p. 646

CLINICAL CASE Stones, Bones, and Groans

Monica is back in her doctor's office, following up on her lab results. She feels a little crazy, seeing a new family practitioner with so many vague complaints. She has a history of hypertension (high blood pressure) and heart palpitations (irregular heartbeats). She has had several kidney stones. She has osteopenia and suffers from nagging bone pain. Recently she has experienced vague abdominal pain with loss of appetite and constipation. Furthermore, she has been feeling chronic fatigue, some of which she attributes to having

trouble falling asleep and regularly awakening in the middle of the night. Monica has also noticed that her memory is getting worse and that she feels increasingly depressed. Worst of all, her husband of 40 years has complained that she is getting more irritable and cranky.

"Monica," says her doctor, "I think I know what is causing your symptoms. The answer is right here in your lab results." **What could be causing Monica's many complaints? To find out, turn to the Clinical Case Wrap-Up on p. 654.**

An Introduction to the Endocrine System

About 30 chemical messengers known as *hormones* regulate human activities such as sleep, body temperature, hunger, and stress management. These hormones are products of the *endocrine system*, which along with the nervous system, controls and coordinates our body processes.

In this chapter we examine the structural and functional organization of the endocrine system and compare it to the nervous system. After an overview of the endocrine system and the characteristics of the hormones it produces, we consider the structure and function of the body's various *endocrine glands*. Finally, we look at the ways in which hormones modify metabolic operations, and the interactions between the endocrine system and other body systems. Let's begin by considering the role of intercellular communication in maintaining homeostasis.

18-1 Homeostasis is preserved through intercellular communication by the nervous and endocrine systems

Learning Outcome Explain the importance of intercellular communication, describe the mechanisms involved, and compare the modes of intercellular communication that occur in the endocrine and nervous systems.

To preserve homeostasis, cellular activities must be coordinated throughout the body. Cells coordinate their activities by sending and receiving chemical messages. Both the nervous system, which we have explored in Chapters 12–17, and the endocrine system accomplish this coordination. However, they provide different types of coordination because of how their cells communicate. To understand how cellular messages are generated and interpreted, let's take a closer look at how cells communicate with one another.

Mechanisms of Intercellular Communication

In a few specialized cases, adjacent cells coordinate cellular activities by exchanging ions and molecules across gap junctions. This **direct communication** occurs between two cells of the same type, and the cells must be in extensive physical contact. The two cells communicate so closely that they function as a single entity. Gap junctions (1) coordinate ciliary movement among epithelial cells, (2) coordinate the contractions of cardiac muscle cells, and (3) facilitate the propagation of action potentials from one neuron to the next at electrical synapses.

Most communication between cells involves the release and receipt of chemical messages. When these messages occur between cells within a single tissue, this is called **paracrine communication**, and the chemicals involved are *paracrines*. Each cell continuously "talks" to its neighbors by releasing chemicals into the extracellular fluid. These chemicals tell cells what their neighbors are doing at any moment. The result is the coordination of tissue function locally (within the same tissue). An example of a paracrine is somatostatin, which is released by some pancreatic cells to inhibit the release of insulin by other pancreatic cells. **Autocrine communication** occurs when the messages affect the same cells that secrete them, and the chemicals involved are *autocrines*. Examples of autocrines include prostaglandins, which are secreted by smooth muscle cells to cause contraction of those cells.

Endocrine communication occurs when the endocrine system uses chemical messengers called **hormones** to relay information and instructions between cells in distant portions of the body. Endocrine cells release these hormones in one tissue, and they are then transported in the bloodstream and distributed throughout the body. Each hormone has **target cells**, specific cells in other tissues that have the *receptors* needed to bind and "read" the hormonal message when it arrives. These messages alter the operations of target cells by changing the types, quantities, or activities of important enzymes and structural proteins. A hormone can modify the physical structure or biochemical properties of its target cells. Because the target cells can be anywhere in the body, a single hormone can alter the metabolic activities of multiple tissues and organs at the same time.

Table18–1 Mechanisms of Intercellular Communication

Mechanism	Transmission	Chemical Mediators	Distribution of Effects
Direct communication	Through gap junctions	Ions, small solutes, lipid-soluble materials	Usually limited to adjacent cells of the same type that are interconnected by connexons
Paracrine communication 	Through extracellular fluid	Paracrines	Primarily limited to a local area, where paracrine concentrations are relatively high; target cells must have appropriate receptors
Autocrine communication 	Through extracellular fluid	Autocrines	Limited to the cell that secretes the hormone
Endocrine communication 	Through the bloodstream	Hormones	Target cells are primarily in other tissues and organs and must have appropriate receptors
Synaptic communication 	Across synapses	Neurotransmitters	Limited to very specific area; target cells must have appropriate receptors

Synaptic Communication

The nervous system, too, relies primarily on chemical communication, but it does not send messages through the bloodstream. Instead, as we have seen, in **synaptic communication** neurons release a neurotransmitter at a synapse very close to target cells that have the appropriate receptors. The signal then travels rapidly from one location to another in the form of action potentials propagated along axons. The nervous system can thus carry high-speed "messages" to specific destinations throughout the body.

Table 18–1 summarizes the five ways cells and tissues communicate with one another.

Comparison of Endocrine and Nervous Communication

How are the cellular communication mechanisms of the endocrine and nervous systems similar and different? Viewed from a general perspective, the differences between these systems seem relatively clear. In the nervous system, neurons use action potentials and neurotransmitters to control specific cells or groups of cells. This arrangement allows synaptic communication to provide crisis management in situations requiring split-second responses: If you are in danger of being hit by a speeding bus, the nervous system can coordinate and direct your leap to safety. Only a small fraction of all the cells in the body are innervated, however, and the commands from the nervous system are very specific and relatively short-lived. However, in the endocrine system, the hormones produced by endocrine cells reach almost every cell in the body. The effects of hormones on their target cells may be slow to appear, but they typically last for days. Consequently, endocrine communication is effective in coordinating cell, tissue, and organ activities such as growth and development or affecting metabolic activities on a sustained, long-term basis. These broad organizational and functional distinctions are the basis for treating the nervous and endocrine systems as separate systems.

Yet when we consider these two systems in detail, we see that they also have many similarities. For example:

- Both systems rely on the release of chemicals that bind to specific receptors on their target cells.

- The two systems share many chemical messengers. For example, norepinephrine and epinephrine are called hormones when released into the bloodstream, but neurotransmitters when released across synapses.
- Both systems are regulated mainly by negative feedback control mechanisms.
- The two systems share a common goal: to preserve homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

Next we introduce the components and functions of the endocrine system.

Checkpoint

1. **Define *hormone*.**
2. **Describe paracrine communication.**
3. **Identify five mechanisms of intercellular communication.**

See the blue Answers tab at the back of the book.

18-2 The endocrine system regulates physiological processes by releasing bloodborne hormones that bind to receptors on remote target organs

Learning Outcome Compare the cellular components of the endocrine system with those of other systems, contrast the major structural classes of hormones, and explain the general mechanisms of hormonal action on target organs.

Because of their wide-reaching and long-term effects, the hormones of the endocrine system can produce complex changes in the body's physical structure and physiological capabilities. The major processes that are affected by hormone actions include:

- Growth and development
- Reproduction
- Regulation of cell metabolism and energy balance
- Regulation of body water content and levels of electrolytes and organic nutrients
- Mobilization of body defenses.

Overview of Endocrine Organs and Tissues

The **endocrine system** includes all the endocrine cells and tissues of the body that produce hormones or paracrines with effects beyond their tissues of origin. As noted in Chapter 4, *endocrine cells* are glandular secretory cells that release their secretions into the extracellular fluid. This characteristic distinguishes them from *exocrine cells*, which secrete their products onto epithelial surfaces, generally by way of ducts. ↩ p. 122

Figure 18–1 introduces the tissues, organs, and hormones of the endocrine system. Notice that *endocrine organs* are scattered throughout the body rather than being clustered together like those of many systems. Some of these organs, such as the *pituitary gland*, have endocrine secretion as a primary function. Others, such as the *pancreas*, have many other functions in addition to endocrine secretion. We consider specific endocrine organs in later sections, and we cover them in more detail in chapters on other systems.

Classes of Hormones

We can divide hormones into three classes on the basis of their chemical structure: (1) *amino acid derivatives*, (2) *peptide hormones*, and (3) *lipid derivatives*.

Amino acid derivatives, sometimes known as *biogenic amines*, are relatively small molecules that are structurally related to amino acids, the building blocks of proteins. ↩ p. 53 These hormones are synthesized from the amino acids tyrosine and tryptophan. Those made from tyrosine include (1) *thyroid hormones*, produced by the *thyroid gland*, and (2) the compounds epinephrine (E), norepinephrine (NE), and dopamine, which are sometimes called the *catecholamines* (kat-eh-KŌ-lah-mēnz). The primary hormone made from tryptophan is *melatonin* (mel-ah-TŌ-nin), produced by the *pineal gland*.

We can divide peptide hormones into two groups. One group consists of glycoproteins, while the other is made up of short polypeptides and small proteins.

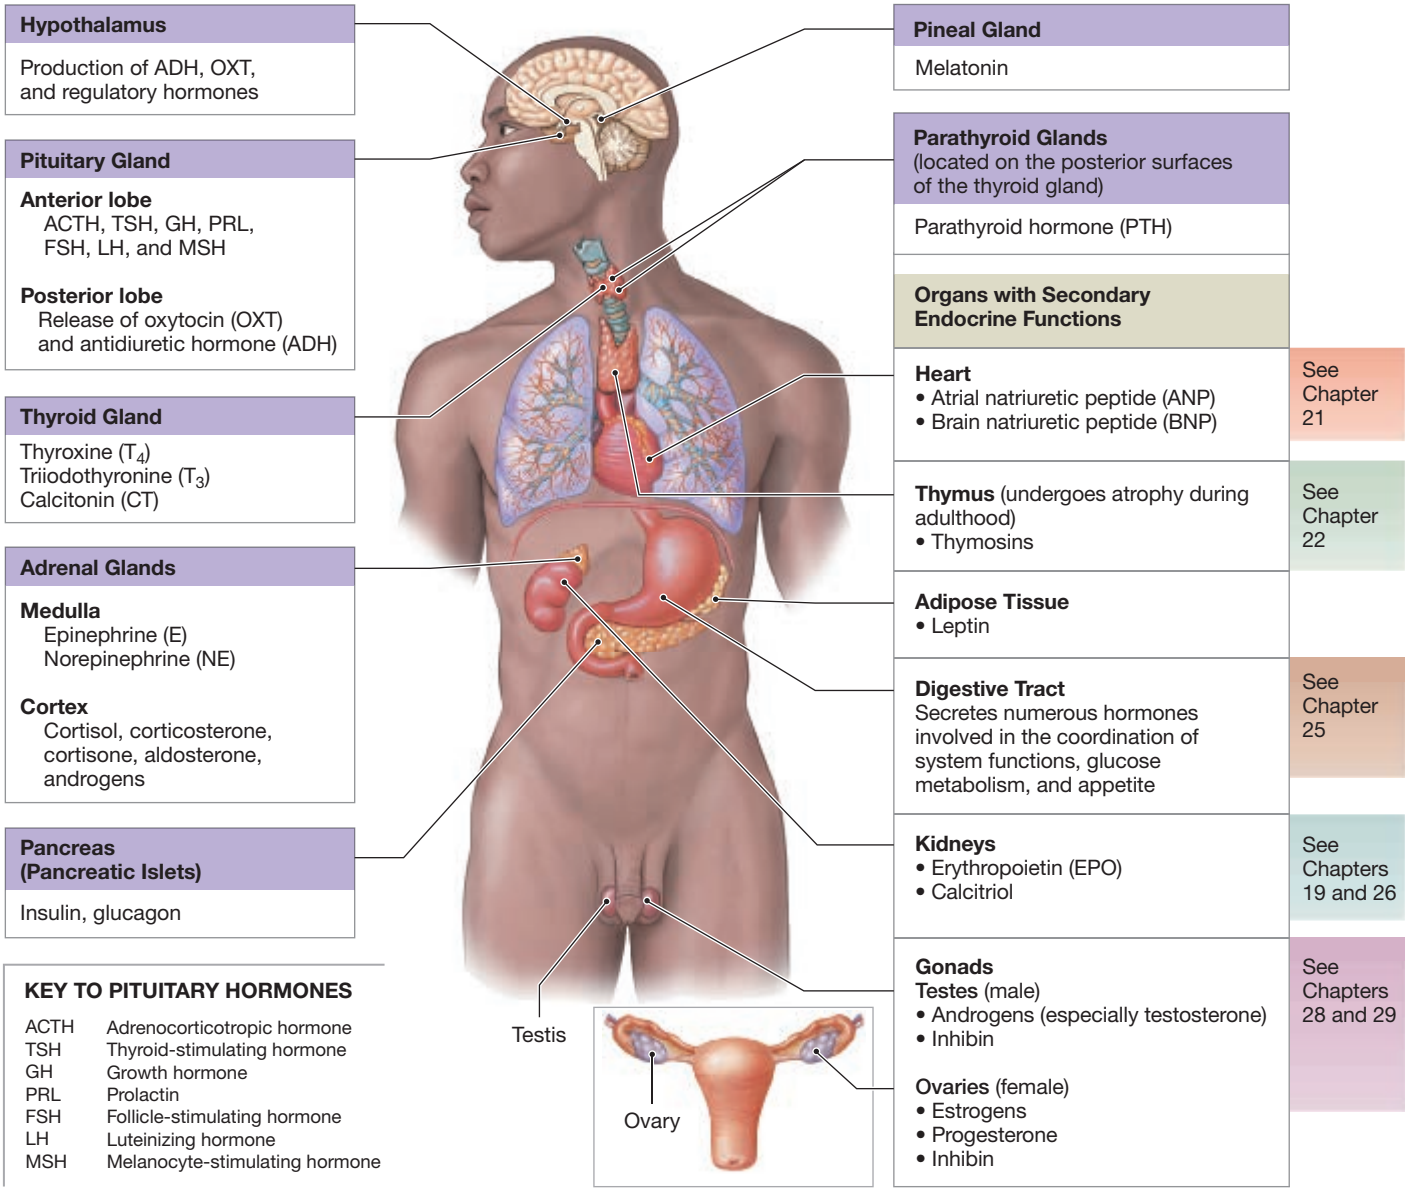
There are two groups of lipid derivatives: (1) *eicosanoids* and (2) *steroid hormones*. Eicosanoids are signaling molecules and include leukotrienes, **prostaglandins**, thromboxanes, and prostacyclins. We consider eicosanoids in chapters that discuss individual tissues and organs, including Chapters 19 (the blood), 22 (the lymphatic system), and 28 (the reproductive system). Steroid hormones are lipids structurally similar to cholesterol (look back at **Figure 2–18**, p. 50). The individual hormones differ in the side chains attached to the basic ring structure.

Spotlight Figure 18–2 summarizes the structural classification of hormones.

Transport and Inactivation of Hormones

Hormones are typically released where capillaries are abundant, and the hormones quickly enter the bloodstream for distribution throughout the body. Within the blood, hormones may circulate freely or travel bound to special carrier proteins. A freely circulating hormone remains functional for less than 1 hour, and sometimes for as little as 2 minutes. It is inactivated when (1) it diffuses out of the bloodstream and binds to receptors on target cells, (2) it is absorbed and broken down by cells of the liver or kidneys, or (3) it is broken down by enzymes in the blood or interstitial fluids.

Figure 18–1 Organs and Tissues of the Endocrine System.



Thyroid hormones and steroid hormones remain functional much longer, because when these hormones enter the bloodstream, more than 99 percent of them become attached to special transport proteins. For each hormone, an equilibrium state exists between its free and bound forms. As the free hormones are removed and inactivated, bound hormones are released to replace them. At any given time, the bloodstream contains a substantial reserve (several weeks' supply) of bound hormones.

Mechanisms of Hormone Action

In this chapter we focus on circulating hormones that function primarily to coordinate activities in many tissues and organs on a sustained basis. When such hormones bind to their specific receptors, this modifies cellular activities. Specifically, the binding of a hormone may:

- *Alter Genetic Activity.* The synthesis of an enzyme or a structural protein not already present in the cytoplasm may be stimulated by activating appropriate genes in the cell nucleus.
- *Alter the Rate of Protein Synthesis.* The rate of synthesis of a particular enzyme or other protein may be increased or decreased by changing the rate of transcription or translation.
- *Change Membrane Permeability.* An existing enzyme or membrane channel may be turned "on" or "off" by changing its shape or structure.

Figure 18–2
Structural Classification of Hormones

HORMONES

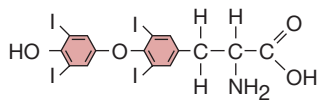
The hormones of the body can be divided into three classes on the basis of their chemical structure.

Amino Acid Derivatives

Amino acid derivatives are small molecules that are structurally related to amino acids, the building blocks of proteins.

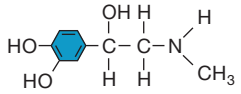
Derivatives of Tyrosine

Thyroid Hormones



Thyroxine (T4)

Catecholamines

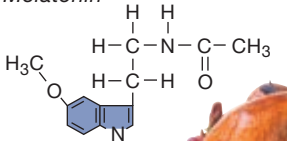


Epinephrine

Sources of tyrosine include meat, dairy, and fish.

Derivative of Tryptophan

Melatonin



Turkey is a well-known source of tryptophan. Other sources include chocolate, oats, bananas, dried dates, milk, cottage cheese, and peanuts.

Peptide Hormones

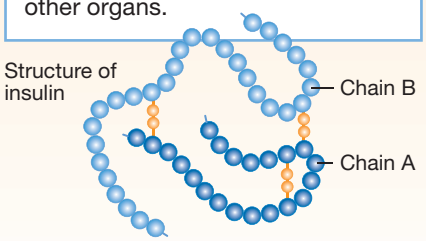
Peptide hormones are chains of amino acids. Most peptide hormones are synthesized as **prohormones**—inactive molecules that are converted to active hormones before or after they are secreted.

Glycoproteins

These proteins are more than 200 amino acids long and have carbohydrate side chains. The glycoproteins include thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) from the anterior lobe of the pituitary gland, as well as several hormones produced in other organs.

Short Polypeptides/ Small Proteins

This group of peptide hormones is large and diverse. It includes hormones that range from **short-chain polypeptides**, such as antidiuretic hormone (ADH) and oxytocin (OXT) (each 9 amino acids long), to **small proteins**, such as insulin (51 amino acids), growth hormone (GH; 191 amino acids), and prolactin (PRL; 198 amino acids). This group includes all the hormones secreted by the hypothalamus, heart, thymus, digestive tract, pancreas, and posterior lobe of the pituitary gland, as well as several hormones produced in other organs.

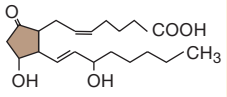


Lipid Derivatives

There are two classes of lipid derivatives: **eicosanoids**, derived from arachidonic acid, a 20-carbon fatty acid; and **steroid hormones**, derived from cholesterol.

Eicosanoids

Eicosanoids (ī-kō-sa-noydz) are important paracrines that coordinate cellular activities and affect enzymatic processes (such as blood clotting in extracellular fluids). Some eicosanoids, such as **leukotrienes** (lu-kō-TRĪ-ēns), have secondary roles as hormones. A second group of eicosanoids—**prostaglandins**—are involved primarily in coordinating local cellular activities. In some tissues, prostaglandins are converted to **thromboxanes** (throm-BOX-ānz) and **prostacyclins** (pros-ta-SĪ-klinz), which also have strong paracrine effects.

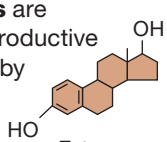


Prostaglandin E

Aspirin suppresses the production of prostaglandins.

Steroid Hormones

Steroid hormones are released by the reproductive organs (androgens by the testes in males, estrogens and progesterone by the ovaries in females), by the cortex of the adrenal glands (corticosteroids), and by the kidneys (calcitriol). Because circulating steroid hormones are bound to specific transport proteins in the plasma, they remain in circulation longer than do secreted peptide hormones.



Estrogen

To affect a target cell, a hormone must first interact with an appropriate receptor. A **hormone receptor**, like a neurotransmitter receptor, is a protein molecule to which a particular molecule binds strongly. Each cell has receptors for several different hormones, but cells in different tissues have different combinations of receptors. This arrangement is one reason hormones have different effects on different tissues. For every cell, the presence or absence of a specific receptor determines the cell's hormonal sensitivities. Cells throughout the body are exposed to hormones whether or not they have the necessary receptors. If a cell has a receptor that can bind a particular hormone, that cell responds to the hormone. If a cell lacks that receptor, the hormone has no effect on that cell.

The presence or absence of a hormone can also affect the nature and number of hormone receptor proteins. **Down-regulation** is a process in which the presence of a hormone triggers a decrease in the number of hormone receptors. In down-regulation, cells become *less* sensitive to high levels of a particular hormone. In contrast, **up-regulation** is a process in which the absence of a hormone triggers an increase in the number of hormone receptors. In up-regulation, cells become *more* sensitive to low levels of a particular hormone.

Hormone receptors are located either on plasma membranes (*extracellular receptors*) or within target cells (*intracellular receptors*). These different types of receptors respond with different mechanisms. Using a few specific examples, let's consider the basic mechanisms involved.

Hormones and Extracellular Receptors: Second Messengers

The receptors for catecholamines (E, NE, and dopamine) and peptide hormones are extracellular receptors. Catecholamines and peptide hormones cannot penetrate a plasma membrane because they are not lipid soluble. Instead, these hormones bind to receptor proteins at the *outer* surface of the plasma membrane of their target cells.

Communication between the hormone and the cell uses a mechanism involving first and second messengers. A *first messenger* is a hormone that binds to an extracellular receptor. A **second messenger** is an intermediary molecule that appears due to a hormone–receptor interaction. Important second messengers are (1) *cyclic AMP (cAMP)*, a derivative of ATP; (2) *cyclic GMP (cGMP)*, a derivative of GTP, another high-energy compound; and (3) calcium ions (Ca^{2+}).

When a small number of hormone molecules binds to extracellular receptors, thousands of second messengers may appear in a cell. This process, called *amplification*, magnifies the effect of a hormone on the target cell. Moreover, the arrival of a single hormone may promote the release of more than one type of second messenger, or the production of a linked sequence of enzymatic reactions known as a *receptor cascade*. Through such mechanisms, the hormone can alter many aspects of cell function at the same time.

The link between the first messenger and the second messenger generally involves a **G protein**, an enzyme complex coupled to a membrane receptor. (Roughly 80 percent of prescription drugs target receptors coupled to G proteins.) The name *G protein* refers to the fact that these proteins bind GTP. ↩ p. 421 A G protein is activated when a hormone binds to its receptor at the membrane surface. What happens next depends on the nature of the G protein and its effects on second messengers in the cytoplasm. **Spotlight Figure 18–3**, which focuses on cAMP and Ca^{2+}, diagrams three major patterns of response to G protein activation.

G Proteins and cAMP. **Spotlight Figure 18–3a** (left panel) shows the steps involved in *increasing* the cAMP level:

1. The activated G protein activates the enzyme **adenylate cyclase**.
2. Adenylate cyclase converts ATP to the ring-shaped molecule *cyclic AMP*.
3. Cyclic AMP then functions as a second messenger, typically by activating a *kinase* (KĪ-nās). A kinase is an enzyme that attaches a high-energy phosphate group ($-PO_4^{3-}$) to another molecule in a process called *phosphorylation*.
4. Generally, cyclic AMP activates kinases that phosphorylate proteins. The effect on the target cell depends on the nature of these proteins. The phosphorylation of plasma membrane proteins, for example, can open ion channels. In the cytoplasm, many important enzymes can be activated only by phosphorylation. One important example is the enzyme *glycogen phosphorylase*, which releases glucose from glycogen reserves in skeletal muscles and the liver.

Many hormones, including epinephrine, calcitonin, parathyroid hormone, ADH, ACTH, FSH, LH, TSH, and glucagon, produce their effects by this mechanism. The increase in the cAMP level is usually short-lived, because the cytoplasm contains another enzyme, **phosphodiesterase (PDE)**, which inactivates cyclic AMP by converting it to AMP (adenosine monophosphate).

Spotlight Figure 18–3a (center panel) depicts one way the activation of a G protein can *decrease* the concentration of cAMP within the cell. In this case, the activated G protein stimulates PDE activity and inhibits adenylate cyclase activity. The cAMP level then declines, because cAMP breakdown accelerates while cAMP synthesis is prevented. The decline has an inhibitory effect on the cell, because without phosphorylation, key enzymes remain inactive.

G Proteins and Calcium Ions. An activated G protein can trigger either the opening of calcium ion channels in the

Figure 18–3
G Proteins and Second Messengers

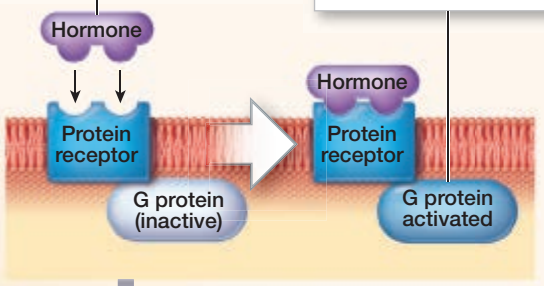
MECHANISM OF HORMONE ACTION

First and Second Messengers

A hormone that binds to receptors in the plasma membrane cannot directly affect the activities inside the target cell. For example, it cannot begin building a protein or catalyzing a specific reaction. Instead, the hormone uses an intracellular intermediary to bring about its effects. The hormone, or **first messenger**, does something that leads to the appearance of a **second messenger** in the cytoplasm. The second messenger may act as an enzyme activator, inhibitor, or cofactor. The net result is a change in the rates of various metabolic reactions. The two most important second messengers are cyclic AMP (cAMP), a derivative of ATP, and calcium ions (Ca^{2+}).

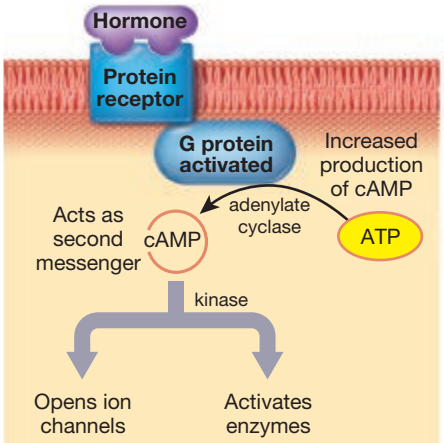
The first messenger (a peptide hormone, catecholamine, or eicosanoid) binds to a membrane receptor and activates a G protein.

A **G protein** is an enzyme complex coupled to a membrane receptor that serves as a link between the first and second messenger.



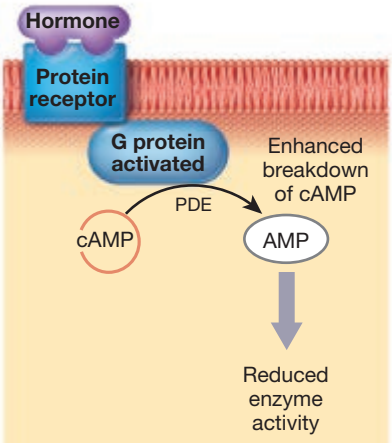
a Effects on cAMP Level

Many G proteins, once activated, exert their effects by changing the concentration of cyclic AMP, which acts as the second messenger within the cell.



If levels of cAMP increase, enzymes may be activated or ion channels may be opened, accelerating the metabolic activity of the cell.

First Messenger Examples
- Epinephrine and norepinephrine
- Calcitonin
- Parathyroid hormone
- ADH, ACTH, FSH, LH, TSH

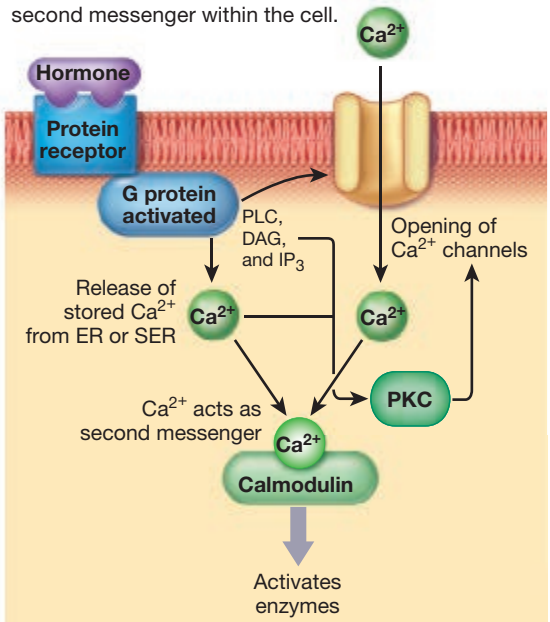


In some instances, G protein activation results in decreased levels of cAMP in the cytoplasm. This decrease has an inhibitory effect on the cell.

First Messenger Examples
- Epinephrine and norepinephrine

b Effects on Ca^{2+} Level

Some G proteins use Ca^{2+} as a second messenger within the cell.



First Messenger Examples
- Epinephrine and norepinephrine
- Oxytocin
- Regulatory hormones of hypothalamus
- Several eicosanoids

plasma membrane or the release of calcium ions from intracellular compartments. Spotlight Figure 18–3b (right panel) diagrams the steps involved:

1. The G protein first activates the enzyme **phospholipase C (PLC)**.
2. This enzyme triggers a receptor cascade that begins with the production of **diacylglycerol (DAG)** and **inositol trisphosphate (IP_3)** from membrane phospholipids.
3. IP_3 diffuses into the cytoplasm and triggers the release of Ca^{2+} from intracellular reserves, such as those in the smooth endoplasmic reticulum of many cells.
4. The combination of DAG and intracellular calcium ions activates a cytosolic protein: **protein kinase C (PKC)**. The activation of PKC leads to the phosphorylation of calcium ion channel proteins, a process that opens the channels and permits extracellular Ca^{2+} to enter the cell. This sets up a positive feedback loop that rapidly elevates the intracellular calcium ion concentration.
5. The calcium ions themselves serve as messengers, generally in combination with an intracellular protein called **calmodulin**. Once it has bound calcium ions, calmodulin can activate specific cytoplasmic enzymes. Calmodulin activation is also involved in the responses to oxytocin and to several regulatory hormones secreted by the hypothalamus.

18

Hormones and Intracellular Receptors: Gene Activation

Most hormones that target intracellular receptors are steroid or thyroid hormones. Steroid hormones can diffuse across the lipid part of the plasma membrane and bind to receptors in the cytoplasm or nucleus. The hormone–receptor complexes then activate or deactivate specific genes (Figure 18–4a). By this mechanism, steroid hormones can alter the rate of DNA transcription in the nucleus, and so change the pattern of protein synthesis. Alterations in the synthesis of enzymes or structural proteins directly affect both the metabolic activity and the structure of the target cell. For example, the sex hormone *testosterone* stimulates the production of enzymes and structural proteins in skeletal muscle fibers, causing muscle size and so strength to increase.

Thyroid hormones cross the plasma membrane primarily by a transport mechanism. Once in the cytoplasm, these hormones bind to receptors within the nucleus and on mitochondria (Figure 18–4b). The hormone–receptor complexes in the nucleus activate specific genes or change the rate of transcription. The change in transcription rate affects the metabolic activities of the cell by increasing or decreasing the concentration of specific enzymes. Thyroid hormones bound to mitochondria increase the mitochondrial rates of ATP production.

Control of Hormone Secretion

Hormone secretion, or endocrine activity, is mainly controlled by negative feedback. A stimulus triggers the production of a hormone whose direct or indirect effects reduce the intensity of the stimulus.

Hormone secretion can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions).

In the simplest case, only one hormone is involved. The endocrine cells involved respond directly to changes in the composition of the extracellular fluid by continuously releasing hormones. The secreted hormone adjusts the activities of target cells and restores homeostasis.

Hormone secretion by the heart, pancreas, parathyroid glands, and digestive tract are controlled by humoral stimuli. For example, when the blood glucose level increases, the pancreas increases its secretion of *insulin*, a hormone that stimulates glucose uptake and use. As the insulin level increases, the glucose level decreases, reducing the stimulation of the insulin-secreting cells. As the glucose level returns to normal, the rate of insulin secretion returns to resting levels. (We introduced this regulatory pattern, called *negative feedback*, in Chapter 1 when we considered the control of body temperature. ↩ p. 19)

Hormone secretion may also be controlled by hormonal stimuli, such as changes in the levels of circulating hormones. Such control may involve one or more intermediary steps and two or more hormones. However, the relationship between hormone concentration and target cell response is not always predictable. For instance, a hormone can have one effect at low concentrations and more exaggerated effects—or even different effects—at high concentrations. (We consider specific examples later in the chapter.)

Finally, hormone secretion can be triggered by neural stimuli when a neurotransmitter arrives at a neuroglandular junction. An important example of hormone secretion linked to neural stimuli involves the activity of the hypothalamus. It provides the highest level of endocrine control, as we discuss in the next section.

Checkpoint

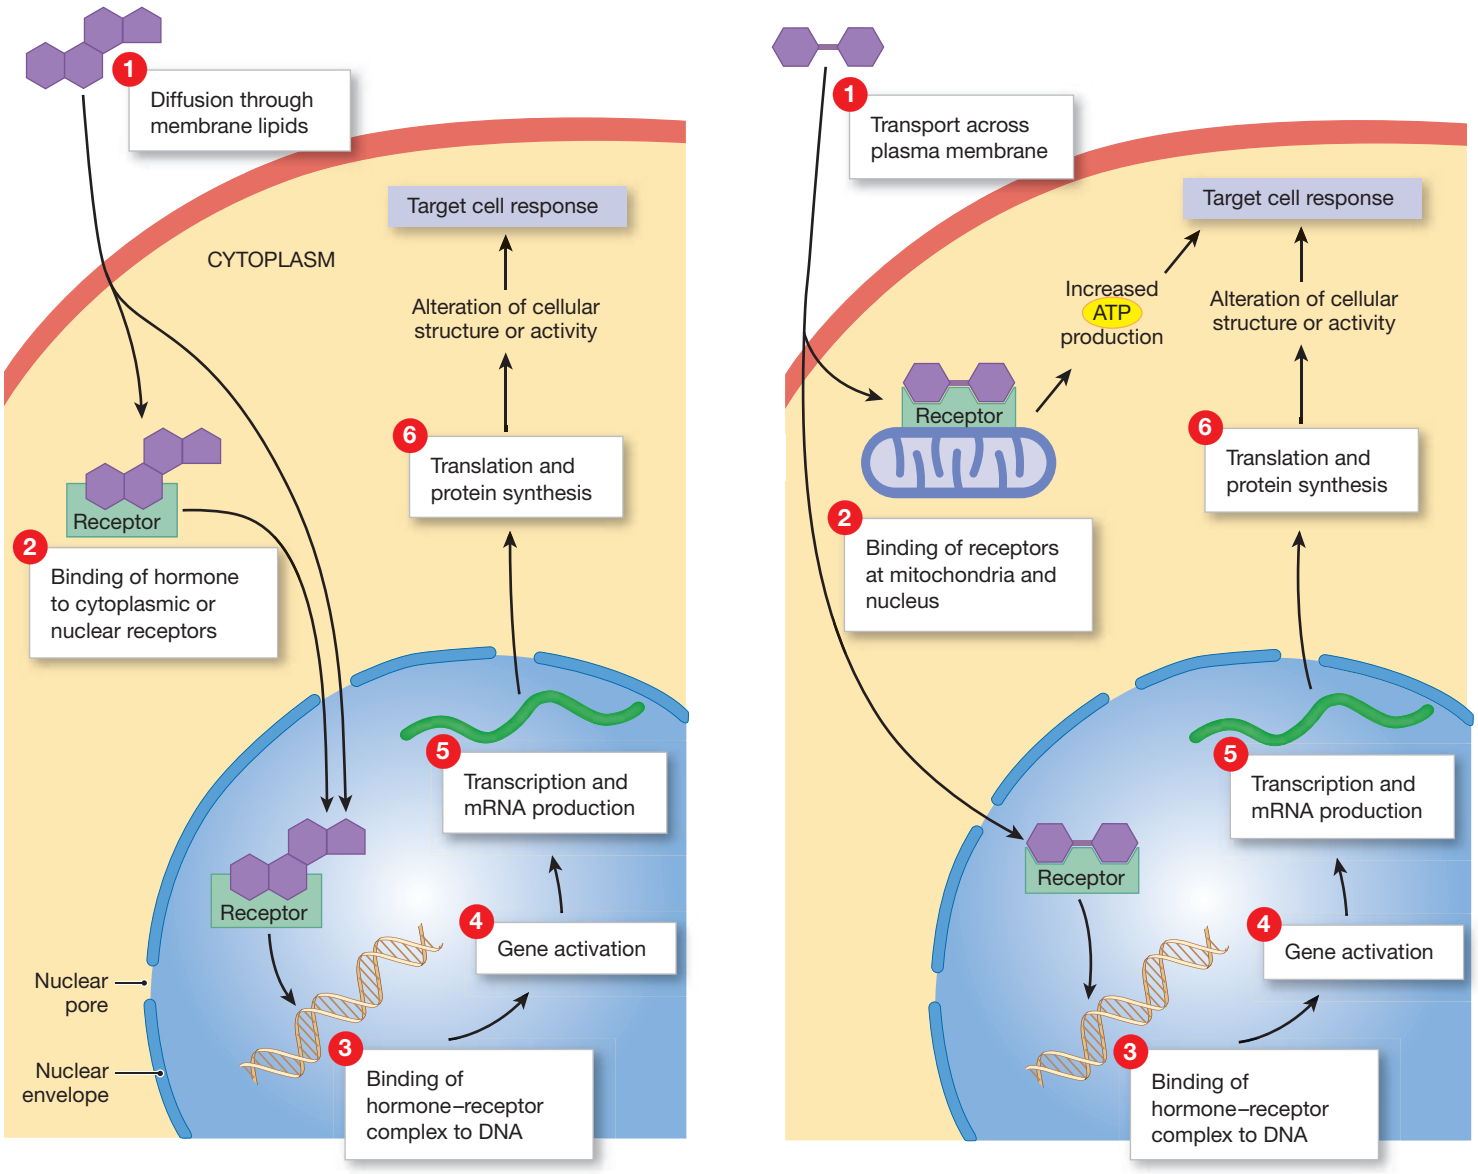
4. **What primary factor determines each cell's hormonal sensitivities?**
5. **How would the presence of a substance that inhibits the enzyme adenylate cyclase affect the activity of a hormone that produces its cellular effects by way of the second messenger cAMP?**
6. **Describe negative feedback as it relates to humoral stimuli.**

See the blue Answers tab at the back of the book.

Figure 18–4 Effects of Intracellular Hormone Binding.

a Steroid hormones diffuse through the plasma membrane and bind to receptors in the cytoplasm or nucleus. The complex then binds to DNA in the nucleus, activating specific genes.

b Thyroid hormones enter the cytoplasm and bind to receptors in the nucleus to activate specific genes. They also bind to receptors on mitochondria and accelerate ATP production.



18-3 The anterior lobe of the pituitary gland produces and releases hormones under hypothalamic control, while the posterior lobe releases hypothalamic hormones

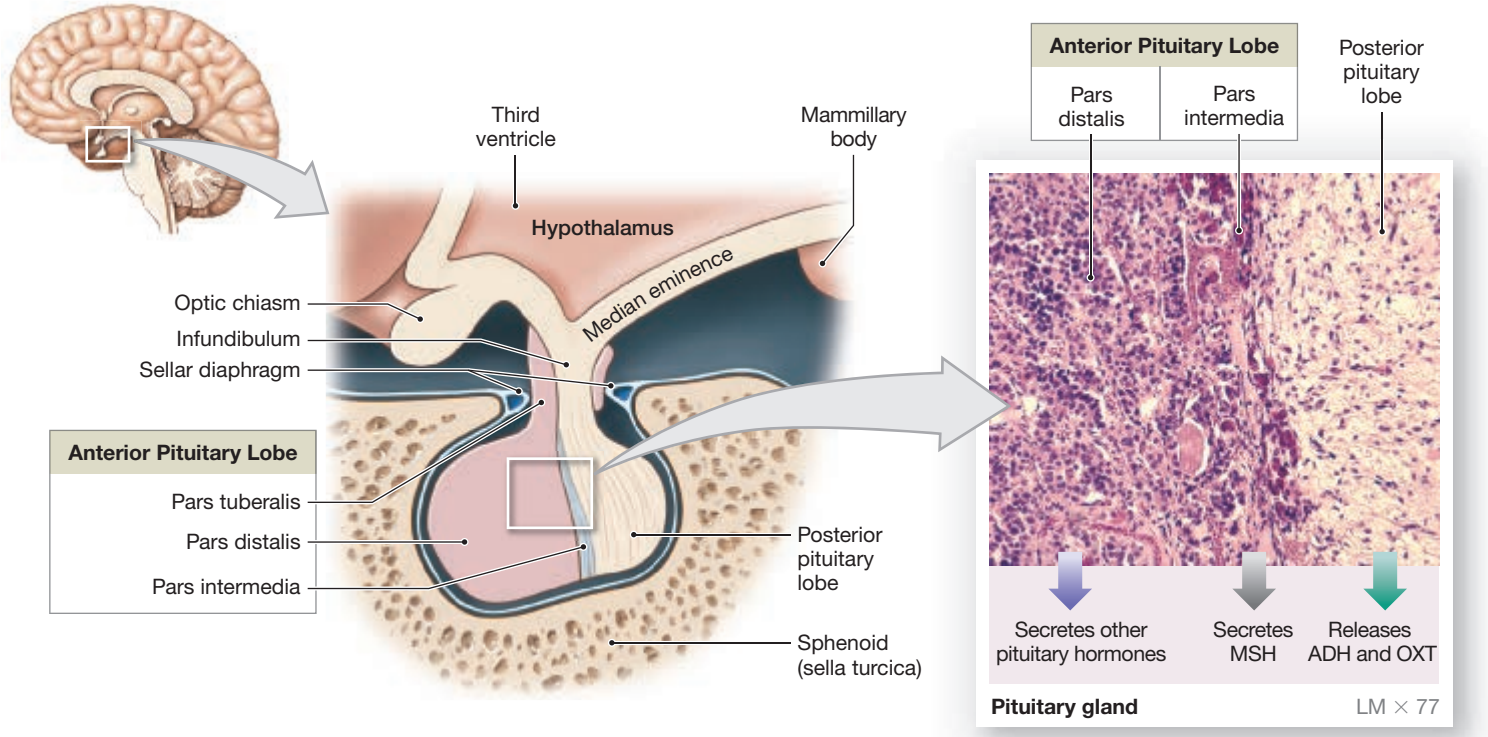
Learning Outcome Describe the location, hormones, and functions of the pituitary gland, and discuss the effects of abnormal pituitary hormone production.

The *pituitary gland* has *anterior* and *posterior lobes* that differ in function and developmental anatomy. It releases nine important peptide hormones; seven come from the anterior lobe and two from the posterior lobe. The *hypothalamus* has a close anatomical and functional relationship with both lobes of the pituitary gland. Let's start our exploration with the anatomy of these critical organs. ATLAS: Embryology Summary 14: The Development of the Endocrine System

Anatomy of the Hypothalamus and Pituitary Gland

The **hypothalamus**, which contains both brain centers and endocrine tissue, is found inferior to the thalamus (look back

Figure 18–5 The Orientation and Anatomy of the Pituitary Gland.



a Relationship of the pituitary gland to the hypothalamus

b Histology of the pituitary gland showing the anterior and posterior lobes

at Figure 14–11, p. 483). The hypothalamus is superior to the pituitary gland, and is connected to it by the slender, funnel-shaped structure called the **infundibulum** (in-fun-DIB-ū-lum; funnel).

Figure 18–5a shows the anatomy of the **pituitary gland**, or **hypophysis** (hī-POF-ih-sis). This small, bilobed gland lies nestled within the *sella turcica*, a depression in the sphenoid bone (look back at Figure 7–8, p. 219). The pituitary gland is held in position by the *sellar diaphragm*, a dural sheet that encircles the infundibulum. The sellar diaphragm isolates the pituitary gland from the cranial cavity.

Control of Pituitary Activity by the Hypothalamus

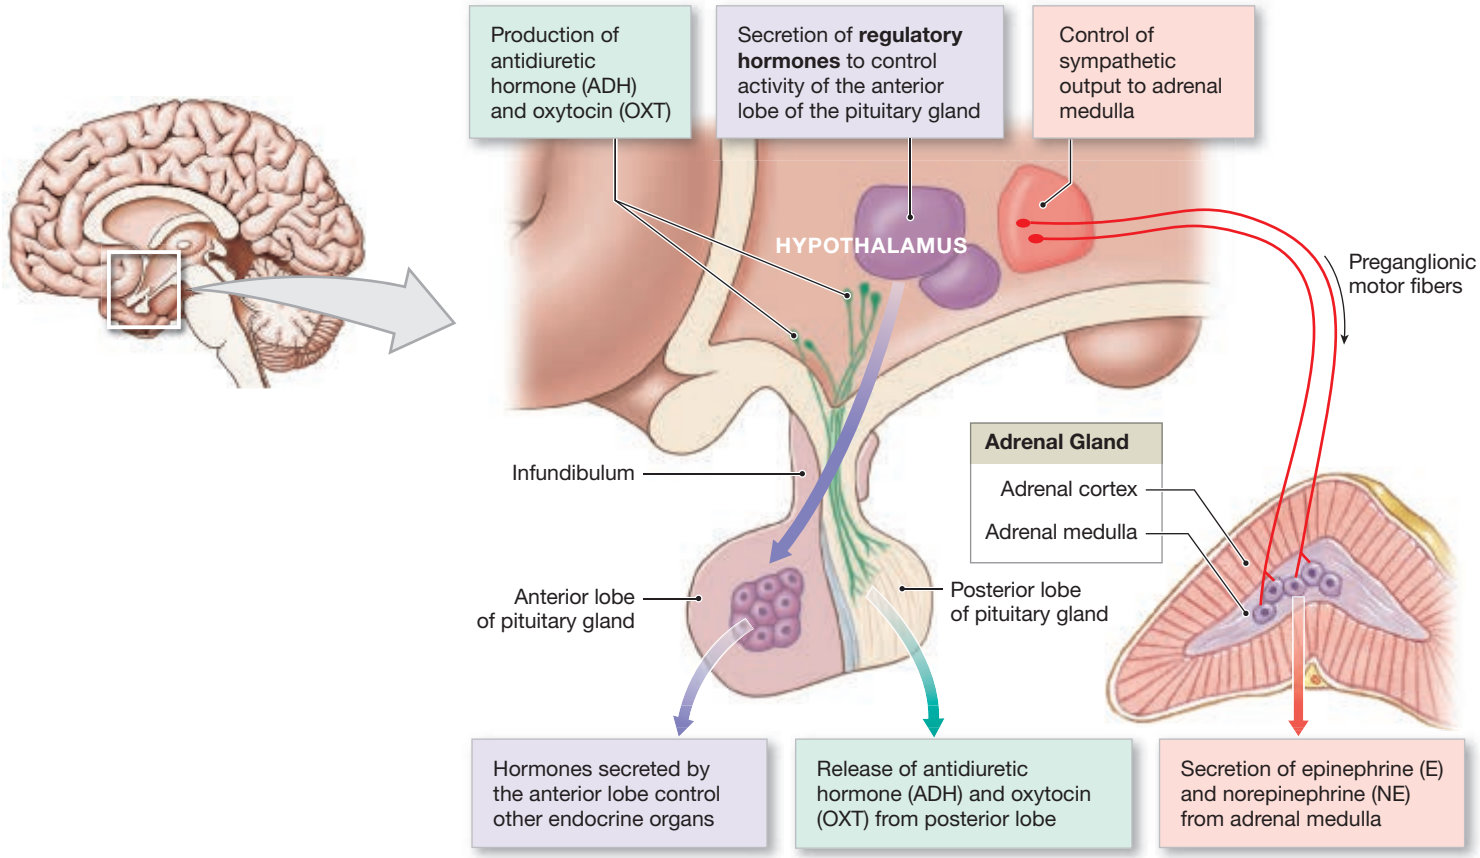
The hypothalamus regulates the functions of both the anterior and posterior lobes of the pituitary gland. It also integrates the activities of the nervous and endocrine systems in three ways (Figure 18–6):

- The hypothalamus itself acts as an endocrine organ. Hypothalamic neurons synthesize hormones and transport them along axons to the posterior lobe of the pituitary gland, where they are released into the circulation. We introduced these hormones, antidiuretic hormone (ADH) and oxytocin (ok-sih-TŌ-sin; OXT), in Chapter 14. ↩ p. 474 These hormones then go on to cause effects in their target organs.
- The hypothalamus secretes **regulatory hormones**. The hypothalamic regulatory hormones control the secretory activities of endocrine cells in the anterior lobe of the pituitary gland. In turn, the hormones from the anterior lobe control the activities of endocrine cells in target organs.
- The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medulla. When the sympathetic division is activated, the adrenal medulla releases the hormones epinephrine (E) and norepinephrine (NE) into the bloodstream.

The hypothalamus secretes regulatory hormones and ADH in response to changes in the composition of the circulating blood. The secretion of OXT, E, and NE involves both neural and hormonal mechanisms. For example, the adrenal medulla secretes E and NE in response to action potentials rather than to circulating hormones. Such pathways are called *neuroendocrine responses*, because they include both neural and endocrine components.

Several hypothalamic and pituitary hormones are released in sudden bursts called *pulses*, rather than continuously. When hormones arrive in pulses, target cells (such as the cells of the

Figure 18–6 Three Mechanisms of Hypothalamic Control over Endocrine Function.



? The regulatory hormones from the hypothalamus control secretion from endocrine cells, which are located where?

anterior lobe of the pituitary gland in response to hypothalamic regulatory hormones) may vary their response with the frequency of the pulses. For example, the target cell response to one pulse every 3 hours can differ from the response when pulses arrive every 30 minutes. The most complicated hormonal instructions from the hypothalamus involve changes in the frequency of pulses *and* in the amount secreted in each pulse.

The Anterior Lobe of the Pituitary Gland

Let's look at how the anatomy of the anterior lobe and its associated blood vessels facilitates its function. We then describe how the hypothalamus controls the secretion of anterior lobe hormones, and the actions of those secreted hormones.

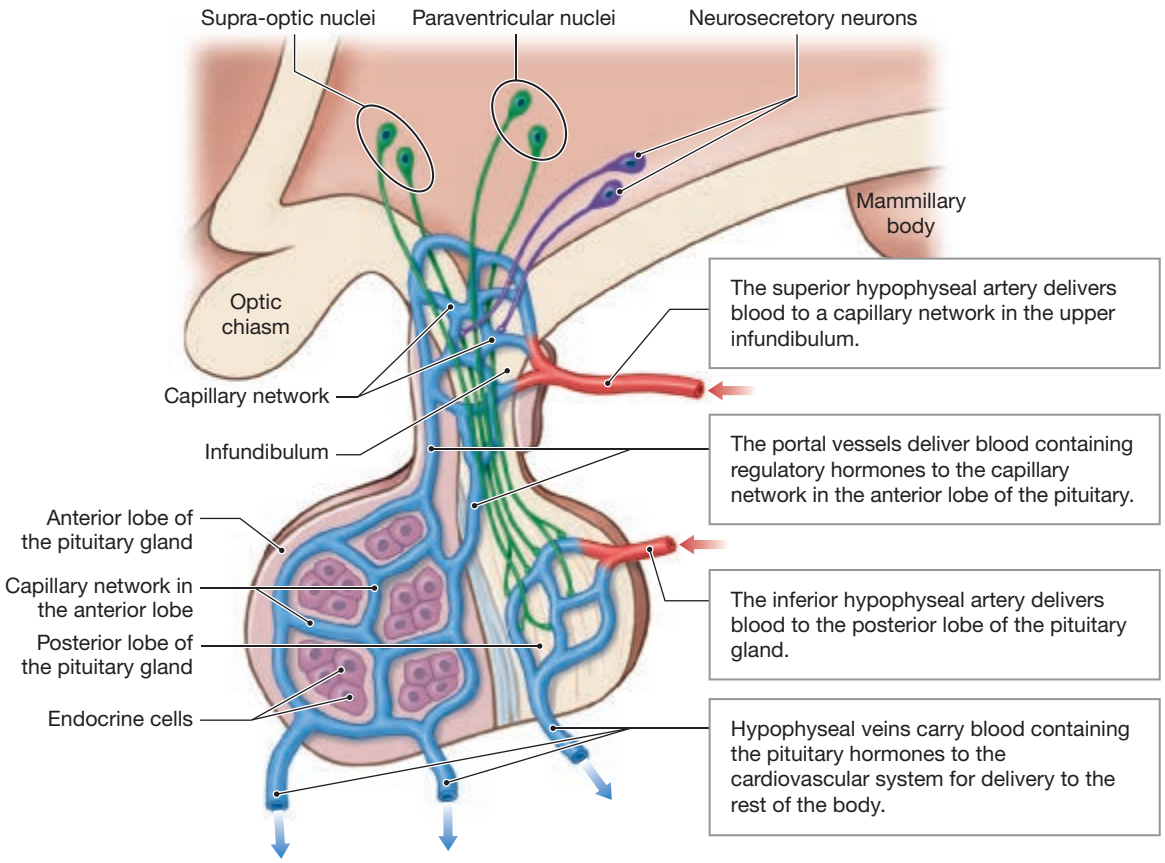
Histology of the Anterior Lobe

The **anterior lobe** of the pituitary gland, also called the **adenohypophysis** (ad-eh-nō-hī-POF-ih-sis), contains a variety of endocrine cells. The anterior lobe has three regions: (1) the **pars distalis** (dis-TAL-is; distal part), the largest and most anterior portion of the pituitary gland; (2) an extension called the **pars tuberalis**, which wraps around the adjacent portion of the infundibulum; and (3) the slender **pars intermedia**, a narrow band bordering the posterior lobe (Figure 18–5b). An extensive capillary network radiates through these regions, giving every endocrine cell immediate access to the bloodstream.

Hormone Secretion and the Hypophyseal Portal System

The hypothalamus controls the production of hormones in the anterior lobe of the pituitary gland by secreting specific regulatory hormones. At the *median eminence*, a swelling near the attachment of the infundibulum, hypothalamic neurons release regulatory hormones into the surrounding interstitial fluids. Their secretions enter the bloodstream quite easily, because the endothelial cells lining the capillaries in this region are unusually permeable. These **fenestrated** (FEN-es-trā-ted; **fenestra**, window) **capillaries** allow relatively large molecules to enter or leave the bloodstream. ↩ p. 473

Figure 18–7 The Hypophyseal Portal System and the Blood Supply to the Pituitary Gland.



The *superior hypophyseal artery* supplies the capillary networks in the median eminence (Figure 18–7). Before leaving the hypothalamus, the capillary networks unite to form a series of larger vessels that spiral around the infundibulum to reach the anterior lobe. In the anterior lobe, these vessels form a second capillary network that branches among the endocrine cells.

This vascular arrangement is unusual because it carries blood from one capillary network to another. In contrast, a typical artery conducts blood from the heart to a capillary network, and a typical vein carries blood from a capillary network back to the heart. Blood vessels that link two capillary networks are called **portal vessels**. In this case, they have the histological structure of veins, so they are also called *portal veins*. The entire complex is a **portal system**. Portal systems are named for their destinations. This particular network is the **hypophyseal** (hī-pō-FIZ-ē-al) **portal system**.

Portal systems provide an efficient means of chemical communication. This one ensures that all the hypothalamic hormones entering the portal vessels reach the target cells in the anterior lobe before being diluted through mixing with the general circulation. The communication is strictly one way, however. Any chemicals released by the cells "downstream" must do a complete circuit of the cardiovascular system before they reach the capillaries of the portal system.

Hypothalamic Control of the Anterior Lobe

Two classes of hypothalamic regulatory hormones exist: releasing hormones and inhibiting hormones. A **releasing hormone (RH)** stimulates the synthesis and secretion of one or more hormones at the anterior lobe. In contrast, an **inhibiting hormone (IH)** prevents the synthesis and secretion of hormones from the anterior lobe. Releasing hormones, inhibiting hormones, or some combination of the two may control an endocrine cell in the anterior lobe.

Once secreted, the anterior pituitary hormones then stimulate the cells of their target organs. Many of these organs are endocrine glands themselves, which then secrete hormones in response. In fact, the hormones of the anterior lobe are sometimes called *tropic hormones* (*trope*, a turning), because they "turn on" endocrine glands or support the functions of other organs. Then negative feedback from these target organ hormones controls the rate at which the hypothalamus secretes regulatory hormones. The primary regulatory patterns are diagrammed in Figure 18–8a–c, and we will refer to them as we examine specific pituitary hormones.

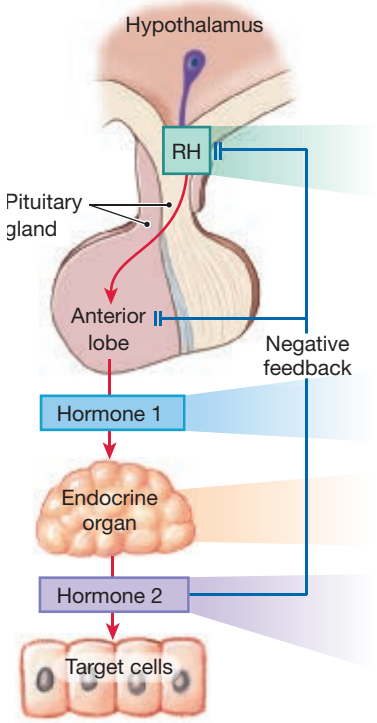
Hormones of the Anterior Lobe

The control mechanisms and functions of seven hormones from the anterior lobe are reasonably well understood. The regulation of *thyroid-stimulating hormone*, *adrenocorticotropic hormone*, and two gonadotropins called *follicle-stimulating hormone*

Figure 18–8 Feedback Control of Endocrine Secretion.

Typical pattern of regulation when multiple endocrine organs are involved

a The hypothalamus produces a releasing hormone (RH) to stimulate hormone production by other glands. Homeostatic control occurs by negative feedback.



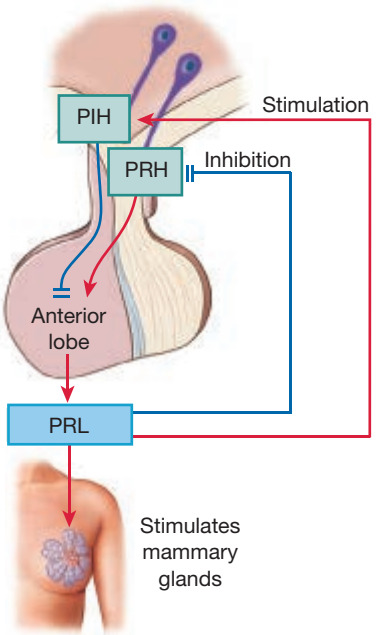
KEY
- Stimulation
- Inhibition

The effects of hypothalamic releasing hormones that follow the typical pattern of regulation

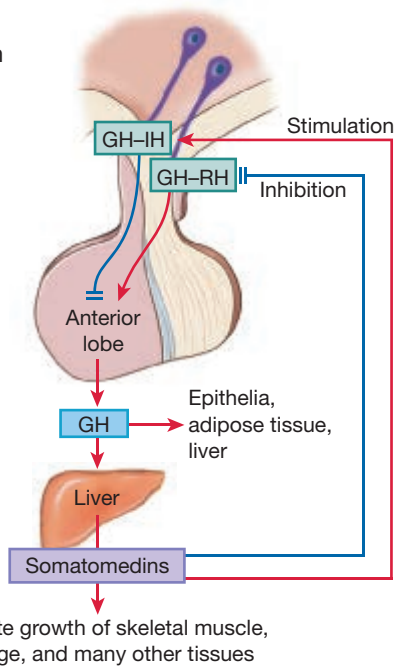
Releasing hormone (RH)	TRH	CRH	GnRH	
Hormone 1 (from pituitary)	TSH	ACTH	FSH	LH
Endocrine target organ	Thyroid gland	Adrenal cortex	Testes, Ovaries	Testes, Ovaries
Hormone 2 (from endocrine target organ)	Thyroid hormones	Glucocorticoids	Inhibin, Inhibin, Estrogens	Androgens, Progesterone, Estrogens

Variations on the typical pattern of regulation of endocrine organs by the hypothalamus and anterior pituitary lobe

b The regulation of prolactin (PRL) production by the anterior lobe. In this case, the hypothalamus produces both a releasing hormone (PRH) and an inhibiting hormone (PIH). When one is stimulated, the other is inhibited.



c The regulation of growth hormone (GH) production by the anterior lobe. When GH–RH release is inhibited, GH–IH release is stimulated.



? In a typical regulation pattern of endocrine secretion, which hormone is responsible for negative feedback?

and *luteinizing hormone* follows the typical regulatory pattern shown in Figure 18–8a. Two others, *prolactin* and *growth hormone*, follow the atypical patterns shown in Figures 18–8b and c, respectively. Of these six hormones, which are all produced by the pars distalis, four regulate the production of hormones by other endocrine glands such as the thyroid, adrenal cortex, and reproductive organs. A final hormone, *melanocyte-stimulating hormone*, is produced by the pars intermedia (and is not shown in the figure). All seven hormones bind to extracellular receptors, and all use cAMP as a second messenger.

Thyroid-Stimulating Hormone. Thyroid-stimulating hormone (TSH), or *thyrotropin*, targets the thyroid gland and triggers the release of thyroid hormones. TSH is released in response to *thyrotropin-releasing hormone (TRH)* from the hypothalamus. Then as circulating concentrations of thyroid hormones (called T_3 and T_4) rise, the rates of TRH and TSH production decline.

Adrenocorticotropic Hormone. Adrenocorticotropic hormone (ACTH), also known as *corticotropin*, stimulates the release of steroid hormones by the *adrenal cortex*, the outer portion of the adrenal gland. ACTH specifically targets cells that produce *glucocorticoids* (glū-kō-KOR-tih-koydz), hormones that affect glucose metabolism such as cortisol. ACTH release occurs under the stimulation of **corticotropin-releasing hormone (CRH)** from the hypothalamus. As glucocorticoid levels increase, the rates of CRH release and ACTH release decline.

Gonadotropins. The hormones called **gonadotropins** (gō-nad-ō-TRŌ-pinz) regulate the activities of the *gonads*. (These organs—the *testes* in males and the *ovaries* in females—produce reproductive cells as well as hormones.) **Gonadotropin-releasing hormone (GnRH)** from the hypothalamus stimulates production of gonadotropins. The two gonadotropins are follicle-stimulating hormone and luteinizing hormone:

- **Follicle-stimulating hormone (FSH)** promotes follicle development in females and, in combination with luteinizing hormone, stimulates the secretion of *estrogens* (ES-trō-jenz) by ovarian cells. *Estradiol* is the most important estrogen. In males, FSH stimulates *nurse cells*, specialized cells in the seminiferous tubules where sperm differentiate. In response, the nurse cells promote the physical maturation of developing sperm. FSH production is inhibited by *inhibin*, a peptide hormone released by cells in the testes and ovaries. (The role of inhibin in suppressing the release of GnRH as well as FSH is under debate.)
- **Luteinizing** (LŪ-tē-in-ī-zing) **hormone (LH)** induces *ovulation*, the release of a reproductive cell in females. It also promotes ovarian secretion of estrogens and *progesterone*, which prepare the body for possible pregnancy. In males, this gonadotropin stimulates the production of sex hormones by the *interstitial endocrine cells* of the testes. These male sex hormones are called **androgens** (AN-drō-jenz; *andros*, man). The most important one is *testosterone*.

  LH production, like FSH production, is stimulated by GnRH from the hypothalamus. Estrogens, progesterone, and androgens inhibit GnRH production.

An abnormally low production of gonadotropins results in **hypogonadism**. Children with this condition do not mature sexually, and adults with hypogonadism cannot produce functional sperm (males) or oocytes (females).

Prolactin. Prolactin (*pro-*, before + *lac*, milk) **(PRL)** helps to stimulate mammary gland development in females. Although PRL exerts the dominant effect on the glandular cells, normal development of the mammary glands is regulated by the interaction of several hormones. (We describe the functional development of the mammary glands in Chapter 28.) In pregnancy and during the nursing period that follows childbirth, PRL also stimulates milk production by the mammary glands. The functions of PRL in males are poorly understood, but evidence indicates that this hormone helps regulate androgen production by making interstitial endocrine cells more sensitive to LH.

Prolactin production is inhibited by the neurotransmitter dopamine, also known as **prolactin-inhibiting hormone (PIH)**. The hypothalamus also secretes **prolactin-releasing hormone (PRH)**. Circulating PRL stimulates PIH release and inhibits the secretion of PRH (see Figure 18–8b).

Growth Hormone. Growth hormone (GH), or **somatotropin**, stimulates cell growth and division by accelerating the rate of protein synthesis. Skeletal muscle cells and chondrocytes (cartilage cells) are particularly sensitive to GH, although virtually every tissue responds to some degree.

The stimulation of growth by GH involves two mechanisms, indirect and direct. The primary mechanism, which is indirect, is best understood. Liver cells respond to GH by synthesizing and releasing **somatomedins**, known also as *insulin-like growth factors (IGFs)*. These peptide hormones stimulate tissue growth by binding to receptors on a variety of plasma membranes (see Figure 18–8c). In skeletal muscle fibers, cartilage cells, and other target cells, somatomedins increase the uptake of amino acids and their incorporation into new proteins. These effects develop almost immediately after GH is released. They are particularly important after a meal, when the blood contains high concentrations of glucose and amino acids. In functional terms, cells can now obtain ATP easily through the aerobic metabolism of glucose, and amino acids are readily available for protein synthesis. Under these conditions, GH, acting through the somatomedins, stimulates protein synthesis and cell growth.

The direct actions of GH are more selective. They tend to appear after blood glucose and amino acid concentrations have returned to normal levels:

- In epithelia and connective tissues, GH stimulates stem cell divisions and the differentiation of daughter cells. (Somatomedins then stimulate the growth of these daughter cells.)

- In adipose tissue, GH stimulates the breakdown of stored triglycerides by adipocytes (fat cells), which then release fatty acids into the blood. As the level of circulating fatty acids rises, many tissues stop breaking down glucose to generate ATP and instead start breaking down fatty acids. This process is termed a **glucose-sparing effect**.
- In the liver, GH stimulates the breakdown of glycogen reserves by liver cells, which then release glucose into the bloodstream. Because most other tissues are now metabolizing fatty acids rather than glucose, the blood glucose concentration begins to climb to a level significantly higher than normal. This elevation of the blood glucose level by GH has been called a **diabetogenic effect**, because *diabetes mellitus*, an endocrine disorder we consider later in the chapter, is characterized by an abnormally high blood glucose concentration.

The production of GH is regulated by **growth hormone–releasing hormone (GH–RH)** and **growth hormone–inhibiting hormone (GH–IH)**, or *somatostatin*, from the hypothalamus. Somatomedins inhibit GH–RH and stimulate GH–IH.

Melanocyte-Stimulating Hormone. The pars intermedia may secrete two forms of **melanocyte-stimulating hormone (MSH)**. As the name indicates, MSH stimulates the melanocytes of the skin, increasing their production of melanin, a brown, black, or yellow-brown pigment. ↩ p. 161 Dopamine inhibits the release of MSH.

Melanocyte-stimulating hormone from the pituitary gland is important in the control of skin pigmentation in fishes, amphibians, reptiles, and many mammals other than primates. In humans, MSH is produced locally, within sun-exposed skin. The pars intermedia in adult humans is virtually nonfunctional, and the circulating blood usually does not contain MSH. However, the human pars intermedia secretes MSH (1) during fetal development, (2) in very young children, (3) in pregnant women, and (4) in the course of some diseases. The functional significance of MSH secretion under these circumstances is not known.

The Posterior Lobe of the Pituitary Gland

The **posterior lobe** of the pituitary gland, also called the **neurohypophysis** (nū-rō-hī-POF-ih-sis), contains the axons of hypothalamic neurons. Neurons of the **supra-optic** and **paraventricular nuclei** manufacture antidiuretic hormone (ADH) and oxytocin (OXT), respectively (see **Figure 18–7**). These hormones move along axons in the infundibulum to axon terminals, which end on the basement membranes of capillaries in the posterior lobe. They travel by means of axoplasmic transport. ↩ p. 393 The posterior lobe does not have a portal system. The *inferior hypophyseal artery* delivers blood to it, and the *hypophyseal veins* carry the blood and hormones away. At their target organs, both hormones bind to extracellular receptors, and both use cAMP as a second messenger.

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as *vasopressin (VP)*, is released in response to a variety of stimuli, most notably an increase in the solute concentration in the blood or a decrease in blood volume or blood pressure. An increase in the solute concentration stimulates specialized neurons in the hypothalamus. These neurons are called *osmoreceptors* because they respond to a change in the osmotic concentration of body fluids. The osmoreceptors then stimulate the neurosecretory neurons that release ADH.

The primary function of ADH is to act on the kidneys to retain water and decrease urination. With losses minimized, any water absorbed from the digestive tract will be retained, reducing the concentrations of electrolytes in the extracellular fluid. At a high concentration, ADH also causes *vasoconstriction*, a narrowing of peripheral blood vessels that helps elevate blood pressure. Alcohol inhibits ADH release, which explains why people find themselves making frequent trips to the bathroom after consuming alcoholic beverages.

Oxytocin

In women, **oxytocin** (*oxy-*, quick + *tokos*, childbirth) **(OXT)** stimulates smooth muscle contraction in the wall of the uterus, promoting labor and delivery. After delivery, oxytocin promotes the ejection of milk by stimulating the contraction of myoepithelial cells around the secretory alveoli and the ducts of the mammary glands.

Until the last stages of pregnancy, the uterine smooth muscles are relatively insensitive to oxytocin, but they become more sensitive as delivery approaches. The trigger for normal labor

+ Clinical Note Diabetes Insipidus

Diabetes occurs in several forms. All are characterized by excessive urine production (*polyuria*; pol-ē-YŪR-ē-ah). Most forms result from endocrine abnormalities, but physical damage to the kidneys can also cause diabetes. The two most prevalent forms are *diabetes insipidus* and *diabetes mellitus*. (We describe diabetes mellitus in the Spotlight figure on page 642.) **Diabetes insipidus** generally develops because the posterior lobe of the pituitary gland no longer releases adequate amounts of antidiuretic hormone (ADH). Water conservation by the kidneys is impaired, and excessive amounts of water are lost in the urine. As a result, the person is constantly thirsty, but the body does not retain the fluids consumed.

Mild cases of diabetes insipidus may not require treatment if fluid and electrolyte intake keep pace with urinary losses. In severe cases, the fluid losses can reach 10 liters per day (normal urinary output is about 1–2 liters per day), and dehydration and electrolyte imbalances are fatal without treatment. This condition can be effectively treated with desmopressin, a synthetic form of ADH.

and delivery is probably a sudden rise in the oxytocin level at the uterus. There is good evidence, however, that the uterus and fetus secrete most of the oxytocin involved. Oxytocin from the posterior lobe plays only a supporting role.

Oxytocin secretion and milk ejection are part of a neuroendocrine response reflex called the *milk ejection reflex (milk let-down reflex)*. Milk ejection occurs only in response to oxytocin release at the posterior lobe of the pituitary gland. The normal stimulus is an infant suckling at the breast, and sensory nerves innervating the nipples relay the information to the hypothalamus. Oxytocin is then released into the circulation at the posterior lobe, and the myoepithelial cells respond by squeezing milk from the secretory alveoli into large collecting ducts. Any factor that affects the hypothalamus can modify this reflex. For example, anxiety, stress, and other factors can prevent the flow of milk, even when the mammary glands are fully functional. In contrast, nursing mothers can become conditioned to associate a baby's crying with suckling. In these women, milk ejection may begin as soon as they hear a baby cry.

The functions of oxytocin in sexual activity remain uncertain, but it is known that the circulating concentration of oxytocin rises during sexual arousal and peaks at orgasm in both sexes. Evidence indicates that in men, oxytocin stimulates smooth muscle contractions in the walls of the *ductus deferens* (sperm duct) and prostate gland. These actions may be important in *emission*—the ejection of sperm, secretions of the prostate gland, and the secretions of other glands into the male reproductive tract before ejaculation. Studies suggest that the oxytocin released in females during intercourse may stimulate smooth muscle contractions in the uterus and vagina that promote the transport of sperm toward the uterine tubes.

Summary: The Hormones of the Pituitary Gland

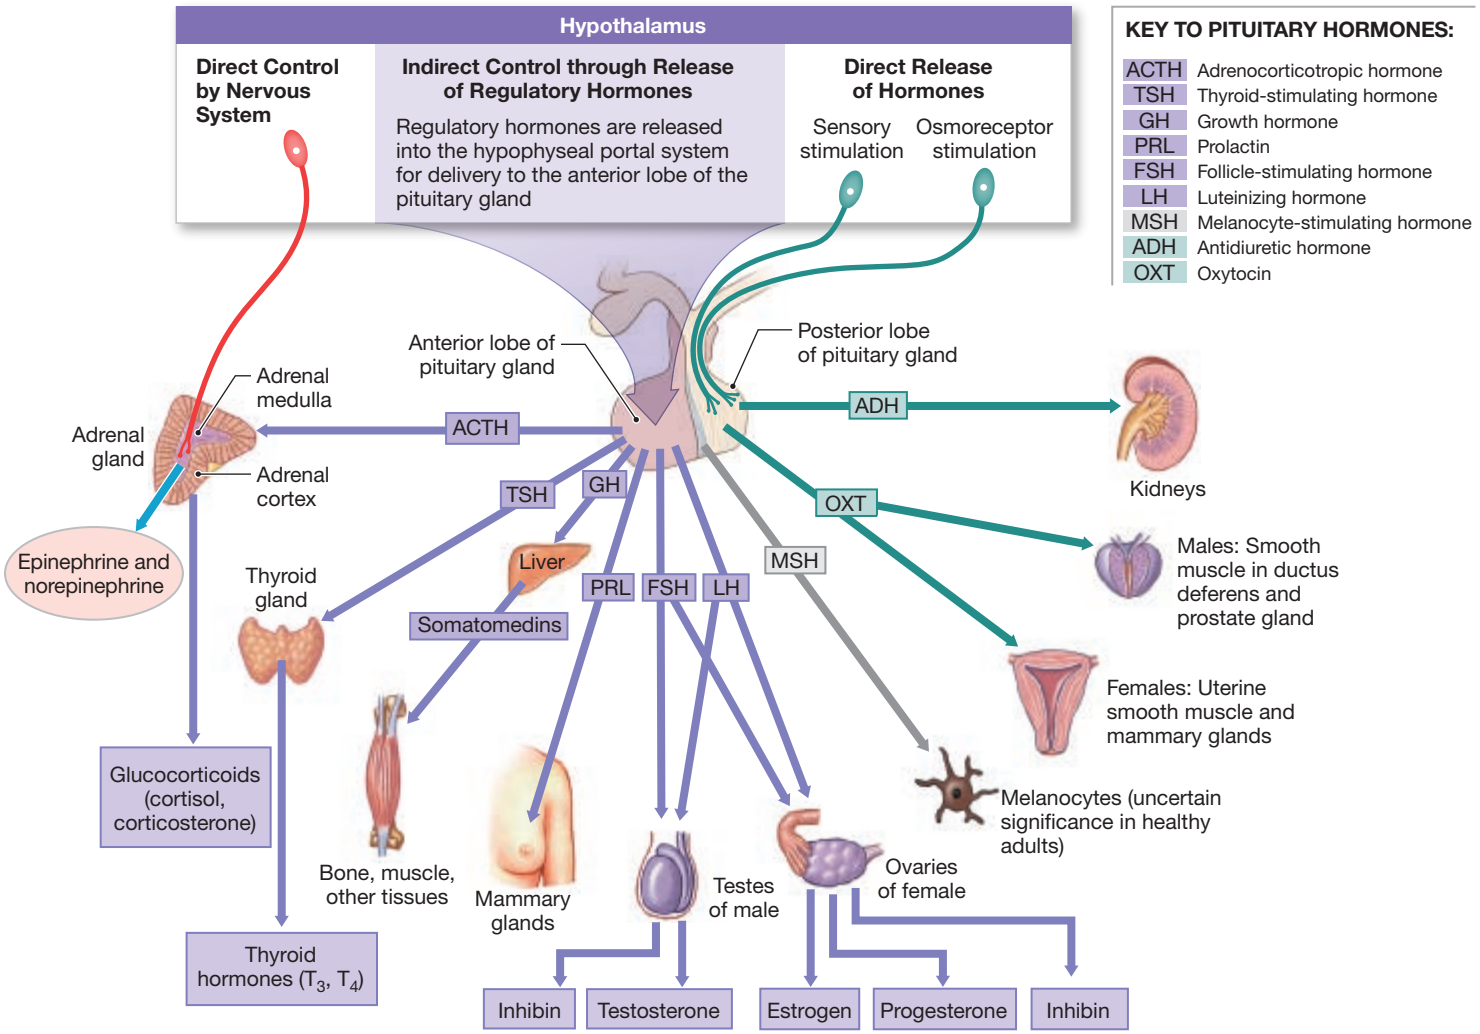
Table 18–2 and **Figure 18–9** summarize important information about the hormones of the pituitary gland. Review them carefully before considering the structure and function of other endocrine organs.

18

Table 18–2 The Pituitary Hormones

	Hormone	Target	Hormonal Effect	Hypothalamic Regulatory Hormone
ANTERIOR LOBE				
Pars distalis	**Thyroid-stimulating hormone (TSH)**	Thyroid gland	Secretion of thyroid hormones	Thyrotropin-releasing hormone (TRH)
	Adrenocorticotropic hormone (ACTH)	Adrenal cortex (zona fasciculata)	Secretion of glucocorticoids (cortisol, corticosterone, and cortisone)	Corticotropin-releasing hormone (CRH)
	Gonadotropins:			
	Follicle-stimulating hormone (FSH)	Follicle cells of ovaries	Secretion of estrogen, follicle development	Gonadotropin-releasing hormone (GnRH)
		Nurse cells of testes	Stimulation of sperm maturation	Gonadotropin-releasing hormone (GnRH)
	Luteinizing hormone (LH)	Follicle cells of ovaries	Ovulation, formation of corpus luteum, secretion of progesterone	Gonadotropin-releasing hormone (GnRH)
		Interstitial endocrine cells of testes	Secretion of testosterone	Gonadotropin-releasing hormone (GnRH)
	Prolactin (PRL)	Mammary glands	Production of milk	Prolactin-releasing factor (PRF)
				Prolactin-inhibiting hormone (PIH)
	Growth hormone (GH)	All cells	Growth, protein synthesis, lipid mobilization and catabolism	Growth hormone–releasing hormone (GH–RH)
				Growth hormone–inhibiting hormone (GH–IH)
Pars intermedia (not active in normal adults)	**Melanocyte-stimulating hormone (MSH)**	Melanocytes	Increased melanin synthesis in epidermis	Melanocyte-stimulating hormone–inhibiting hormone (MSH–IH)
POSTERIOR LOBE				
	Antidiuretic hormone (ADH)	Kidneys	Reabsorption of water, elevation of blood volume and pressure	None; transported along axons from supra-optic nucleus to the posterior lobe of the pituitary gland
	Oxytocin (OXT)	Uterus, mammary glands (females)	Labor contractions, milk ejection	None; transported along axons from paraventricular nucleus to the posterior lobe of the pituitary gland
		Ductus deferens and prostate gland (males)	Contractions of ductus deferens and prostate gland	

Figure 18–9 Pituitary Hormones and Their Targets.



? What hormones are released from the posterior lobe of the pituitary gland and how does their release differ from hormones released by the anterior lobe of the pituitary gland?

Checkpoint

7. Identify the two lobes of the pituitary gland.
8. If a person were dehydrated, how would the amount of ADH released by the posterior pituitary lobe change?
9. The release of which pituitary hormone would lead to an increased level of somatomedins in the blood?
10. What effect would an elevated circulating level of cortisol, a steroid hormone from the adrenal cortex, have on the pituitary secretion of ACTH?

See the blue Answers tab at the back of the book.

18-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism

Learning Outcome Describe the location, hormones, and functions of the thyroid gland, and discuss the effects of abnormal thyroid hormone production.

The thyroid gland is a ductless gland in the neck that secretes hormones regulating growth, development, and metabolism. Cells of this gland extract iodine from the blood to synthesize thyroid hormones. Let's look first at the anatomy.

Anatomy of the Thyroid Gland

The **thyroid gland** curves across the anterior surface of the trachea just inferior to the *thyroid* ("shield-shaped") *cartilage*, which forms most of the anterior surface of the larynx (Figure 18–10a). The two **lobes** of the thyroid gland are united by a slender connection, the **isthmus** (IS-mus). You can feel the gland with your fingers. The size of the gland varies, depending on heredity and environmental and nutritional factors, but its average weight is about 34 g (1.2 oz). When something goes wrong with this gland, it typically becomes visible as it enlarges and distorts the surface of the neck.

The thyroid gland contains large numbers of **thyroid follicles**, hollow spheres lined by a simple cuboidal epithelium (Figure 18–10b,c). The follicle cells encircle a **follicle cavity** that holds a viscous *colloid*, a fluid containing large quantities of dissolved proteins. A network of capillaries surrounds each follicle, delivering nutrients and regulatory hormones to the glandular cells and accepting their secretory products and metabolic wastes.

The thyroid also contains a second population of endocrine cells. These cells are the **C (clear) cells**, or *parafollicular cells* (see Figure 18–10c). They lie sandwiched between the cuboidal follicle cells and their basement membrane. They are larger than the cells of the follicular epithelium and do not stain as clearly.

Tips & Tools

The structure of a thyroid follicle is similar to that of a gel capsule: The simple cuboidal epithelium is comparable to the capsule itself, and the colloid to the capsule's viscous contents.

Synthesis and Regulation of Thyroid Hormones

The thyroid gland produces two types of **thyroid hormones**, called T_3 and T_4. *Thyroid-stimulating hormone* (*TSH*) regulates both the synthesis and release of thyroid hormones. The synthesis of these hormones requires iodine, which we obtain from the food we eat.

Thyroid Hormone Synthesis

Follicle cells synthesize a globular protein called **thyroglobulin** (thī-rō-GLOB-yū-lin) and secrete it into the colloid of the thyroid follicles. Thyroglobulin molecules contain the amino acid tyrosine, the building block of thyroid hormones. The formation of thyroid hormones involves the following basic steps (Figure 18–11a, p. 630):

1 *Iodide ions* (I^-) are absorbed from the diet by the digestive tract, and the bloodstream delivers them to the thyroid gland. TSH-sensitive carrier proteins in the basement membrane of the follicle cells actively transport iodide ions into the cytoplasm.

2 The iodide ions diffuse to the apical surface of each follicle cell, where they lose an electron and are converted to an atom of iodine (I^0) by the enzyme *thyroid peroxidase*. This reaction sequence, which occurs at the apical membrane surface, also attaches 1 or 2 iodine atoms to the tyrosine portions of a thyroglobulin molecule within the follicle cavity.

3 Tyrosine molecules with attached iodine atoms become linked by covalent bonds, forming molecules of thyroid hormones that remain incorporated into thyroglobulin. Thyroid peroxidase probably carries out the pairing process. The hormone **thyroxine** (thī-ROK-sēn), also known as *tetraiodothyronine*, or $\mathbf{T_4}$, contains 4 iodine atoms. A related molecule called **triiodothyronine**, or $\mathbf{T_3}$, contains 3 iodine atoms. Eventually, each molecule of thyroglobulin contains 4 to 8 molecules of T_3 or T_4, or both.

Hypothalamic Regulation of Thyroid Hormone Synthesis and Release

TSH plays a key role in both the synthesis and the release of thyroid hormones. TSH stimulates the active transport of iodide into the follicle cells. The resulting increase in the rate of iodide movement into the cytoplasm of these cells accelerates the formation of thyroglobulin and thyroid peroxidase, and so of thyroid hormones. TSH acts as a first messenger, binding to plasma membrane receptors and, by stimulating the second messenger adenylate cyclase, activating key enzymes involved in thyroid hormone production (look back at Spotlight Figure 18–3a). In the absence of TSH, the thyroid follicles become inactive, and neither synthesis nor secretion occurs.

The major factor controlling the rate of thyroid hormone release is the concentration of TSH in the circulating blood (Figure 18–11b). Under the influence of TSH, the following steps occur (see Figure 18–11a):

4 Follicle cells remove thyroglobulin from the follicles by endocytosis.

5 Lysosomal enzymes break down the thyroglobulin, and the amino acids and thyroid hormones enter the cytoplasm. The amino acids are then recycled and used to synthesize more thyroglobulin.

6 The released molecules of T_3 and T_4 diffuse across the basement membrane and enter the bloodstream. About 90 percent of all thyroid secretions is T_4, and T_3 is secreted in comparatively small amounts.

7 About 75 percent of the T_4 molecules and 70 percent of the T_3 molecules entering the bloodstream become attached to transport proteins called **thyroid-binding globulins (TBGs)**. Most of the rest of the T_4 and T_3 in circulation is attached to **transthyretin**, or to *albumin*, one of the plasma proteins.

Figure 18–10 Anatomy of the Thyroid Gland.

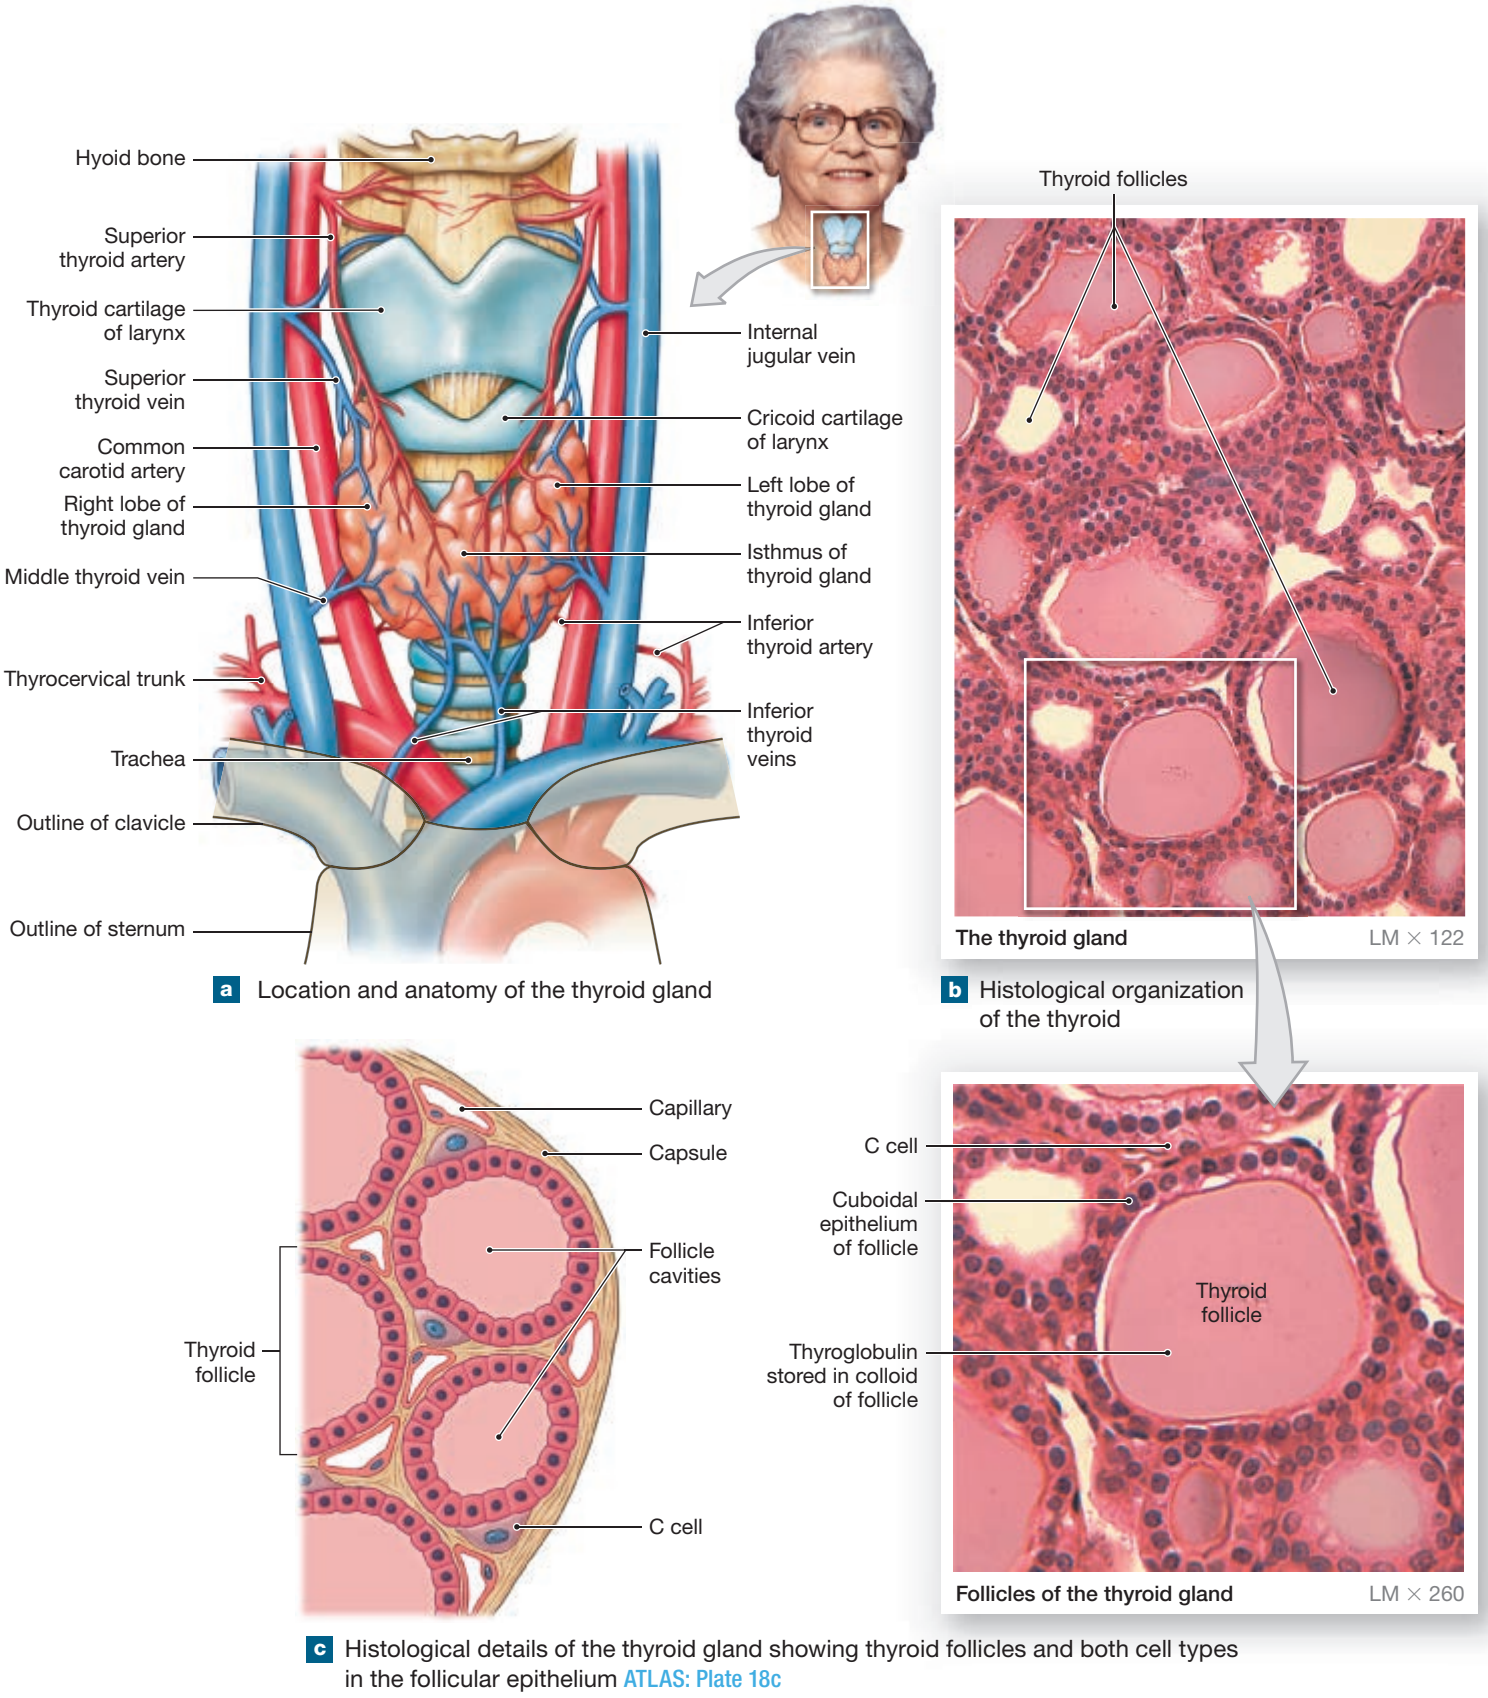


Figure 18–11 Synthesis and Regulation of Thyroid Hormones.

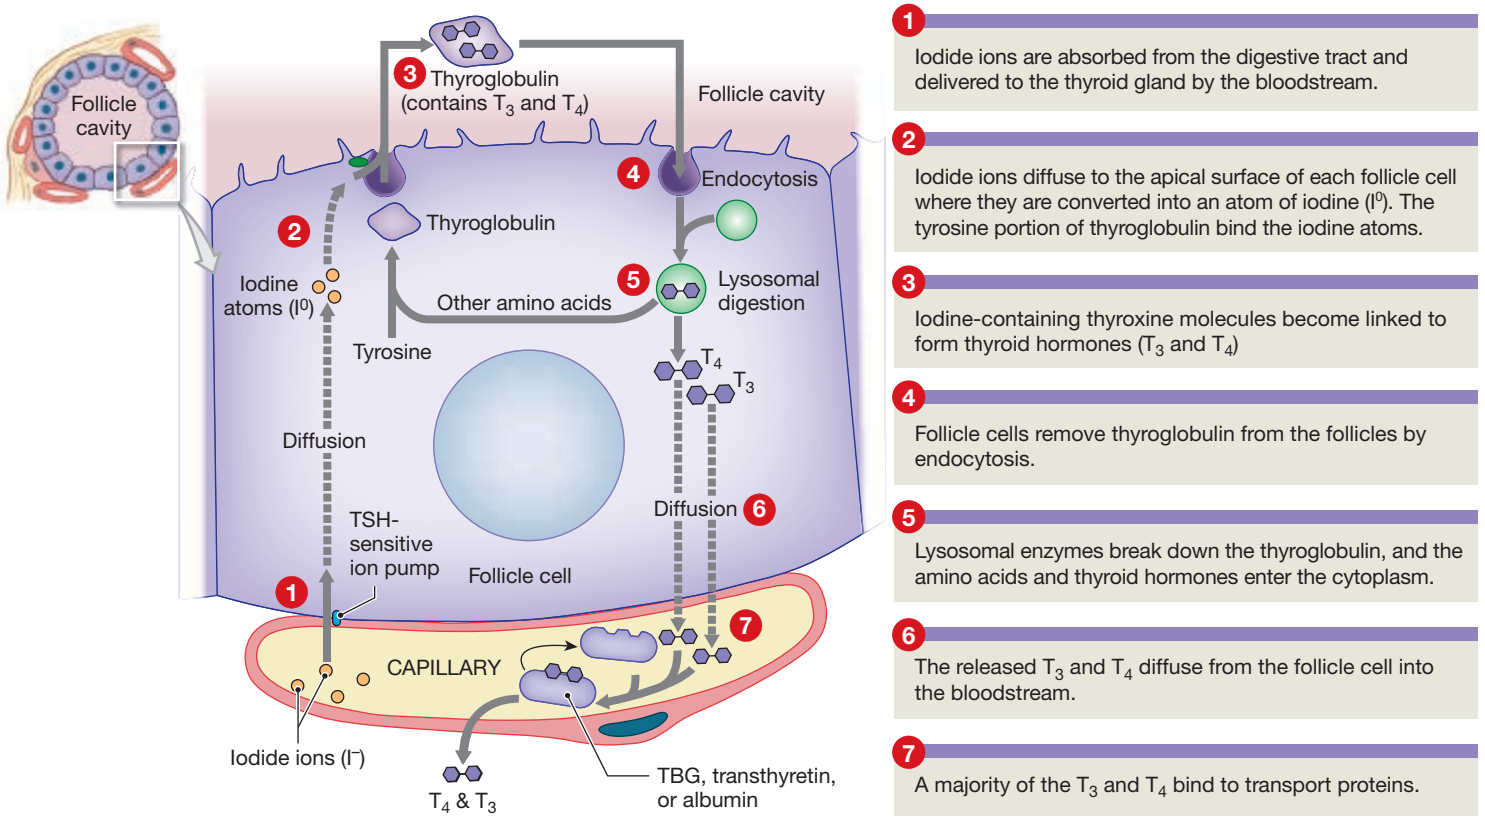
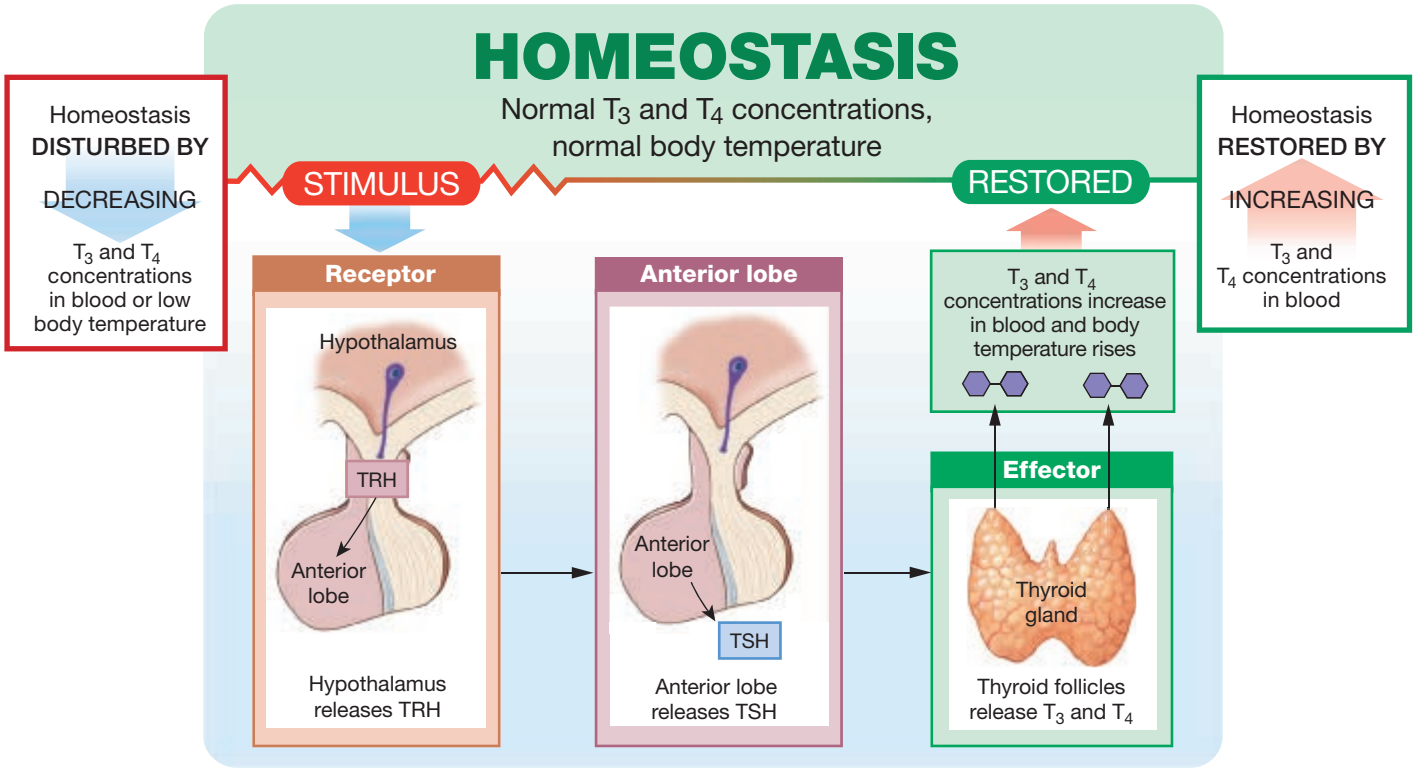


a The synthesis, storage, and secretion of thyroid hormones.



b The regulation of thyroid secretion.

Only the relatively small quantities of thyroid hormones that remain unbound—roughly 0.3 percent of the circulating T_3 and 0.03 percent of the circulating T_4—are free to diffuse into peripheral tissues.

Equilibrium exists between the amount of bound and unbound thyroid hormones. At any moment, free thyroid hormones are being bound to transport proteins at the same rate at which bound hormones are being released. When unbound thyroid hormones diffuse out of the bloodstream and into other tissues, the equilibrium is disturbed. The transport proteins then release additional thyroid hormones until a new equilibrium is reached. The bound thyroid hormones make up a substantial reserve: The bloodstream normally has more than a week's supply of thyroid hormones.

Iodine and Thyroid Hormones

Each day the follicle cells in the thyroid gland absorb 120–150 μg of **iodine ions (I^-)**, the minimum dietary amount needed to maintain normal thyroid function. As a result, the concentration of I^- inside thyroid follicle cells is generally about 30 times higher than that in the blood. If the blood I^- level rises, so does its level inside the follicle cells. The thyroid follicles contain most of the iodide reserves in the body.

The typical diet in the United States provides approximately 500 μg of iodide per day, about three times the minimum daily requirement. Much of the excess is due to the I^- added to table salt (iodized salt), which is consumed in large quantities in processed foods. For this reason, iodide deficiency is seldom responsible for limiting the rate of thyroid hormone production. (This is not necessarily the case in other countries.) The kidneys remove excess I^- from the blood and eliminate them in the urine. Each day the liver excretes a small amount of I^- (about 20 μg) into the *bile*, an exocrine product stored in the gallbladder. The I^- excreted in bile is then eliminated in the feces. Because the losses in the bile continue even if the diet contains less than the minimum iodide requirement, this process can gradually deplete the iodide reserves in the thyroid. Thyroid hormone production then declines, regardless of the circulating TSH level.

Functions of Thyroid Hormones

Thyroid hormones affect almost every cell in the body; they produce a strong, immediate, and short-lived increase in the rate of cellular metabolism. They enter target cells by means of an energy-dependent transport system. Inside a target cell, they bind to receptors in three locations: (1) in the cytoplasm, (2) on the surfaces of mitochondria, and (3) in the nucleus.

- Thyroid hormones bound to cytoplasmic receptors are essentially held in storage. If intracellular levels of thyroid hormones decline, the bound thyroid hormones are released into the cytoplasm.
- The thyroid hormones binding to mitochondria increase the rates of mitochondrial ATP production.
- The binding to receptors in the nucleus activates genes that control the synthesis of enzymes involved in energy transformation and use. One specific effect is the accelerated production of *sodium–potassium ATPase*. Recall that this membrane protein ejects intracellular sodium ions and recovers extracellular potassium ions. As noted in Chapter 3, this exchange pump uses large amounts of ATP. ↩ p. 97

Thyroid hormones also activate genes that code for enzymes involved in glycolysis and ATP production. Coupled with the direct effect of thyroid hormones on mitochondria, this effect increases the metabolic rate of the cell. The effect is called the **calorigenic effect** (*calor*, heat) of thyroid hormones because the cell consumes more energy and generates more heat. In young children, TSH production increases in cold weather, and the calorigenic effect may help them adapt to cold climates. (This response does not occur in adults.) In growing children, thyroid hormones are also essential to normal development of the skeletal, muscular, and nervous systems.

The thyroid gland produces large amounts of T_4, but T_3 is primarily responsible for the observed effects of thyroid hormones. At any moment, T_3 released from the thyroid gland accounts for only 10–15 percent of the T_3 in peripheral tissues. However, enzymes in the liver, kidneys, and other tissues convert T_4 to T_3. Roughly 85–90 percent of the T_3 that reaches the target cells comes from the conversion of T_4 within peripheral tissues. Table 18–3 summarizes the effects of thyroid hormones on major organs and systems.

Synthesis and Functions of Calcitonin

The C cells of the thyroid gland produce the hormone **calcitonin (CT)**, which helps to regulate the Ca^{2+} concentration in body fluids. We introduced the functions of this hormone in Chapter 6. ↩ p. 199 Calcitonin stimulates Ca^{2+} excretion by the kidneys and prevents Ca^{2+} absorption by the digestive tract.

Calcitonin might be most important during childhood, when it stimulates bone growth and skeletal mineral deposition.

Table 18–3 Effects of Thyroid Hormones on Major Organs and Systems

- Elevate rates of oxygen consumption and energy consumption; in children, may cause a rise in body temperature
- Increase heart rate and force of contraction; generally results in a rise in blood pressure
- Increase sensitivity to sympathetic stimulation
- Maintain normal sensitivity of respiratory centers to changes in oxygen and carbon dioxide concentrations
- Stimulate red blood cell formation and thus enhances oxygen delivery
- Stimulate activity in other endocrine tissues
- Accelerate turnover of minerals in bone

It also appears to be important in reducing the loss of bone mass (1) during prolonged starvation and (2) in the late stages of pregnancy. Late in pregnancy, the maternal skeleton competes with the developing fetus for calcium ions from the diet. The role of calcitonin on the bones of the skeleton in the healthy nonpregnant adult is unclear.

In several chapters you have seen the importance of Ca^{2+} in controlling muscle cell and neuron activities. The calcium ion concentration also affects the sodium ion permeabilities of excitable membranes. At a high Ca^{2+} concentration, sodium ion permeability decreases and membranes become less responsive. Such problems are relatively rare.

Lower-than-normal Ca^{2+} concentrations are dangerous. When the calcium ion concentration declines, sodium ion permeabilities increase. As a result, cells become extremely excitable. If the calcium ion level falls too far, convulsions or muscular spasms can result. The *parathyroid glands* and *parathyroid hormone* are largely responsible for maintaining an adequate blood calcium level.

Checkpoint

11. Identify the hormones of the thyroid gland.
12. What signs and symptoms would you expect to see in a person whose diet lacks iodine?
13. When a person's thyroid gland is removed, signs of decreased thyroid hormone concentration do not appear until about 1 week later. Why?

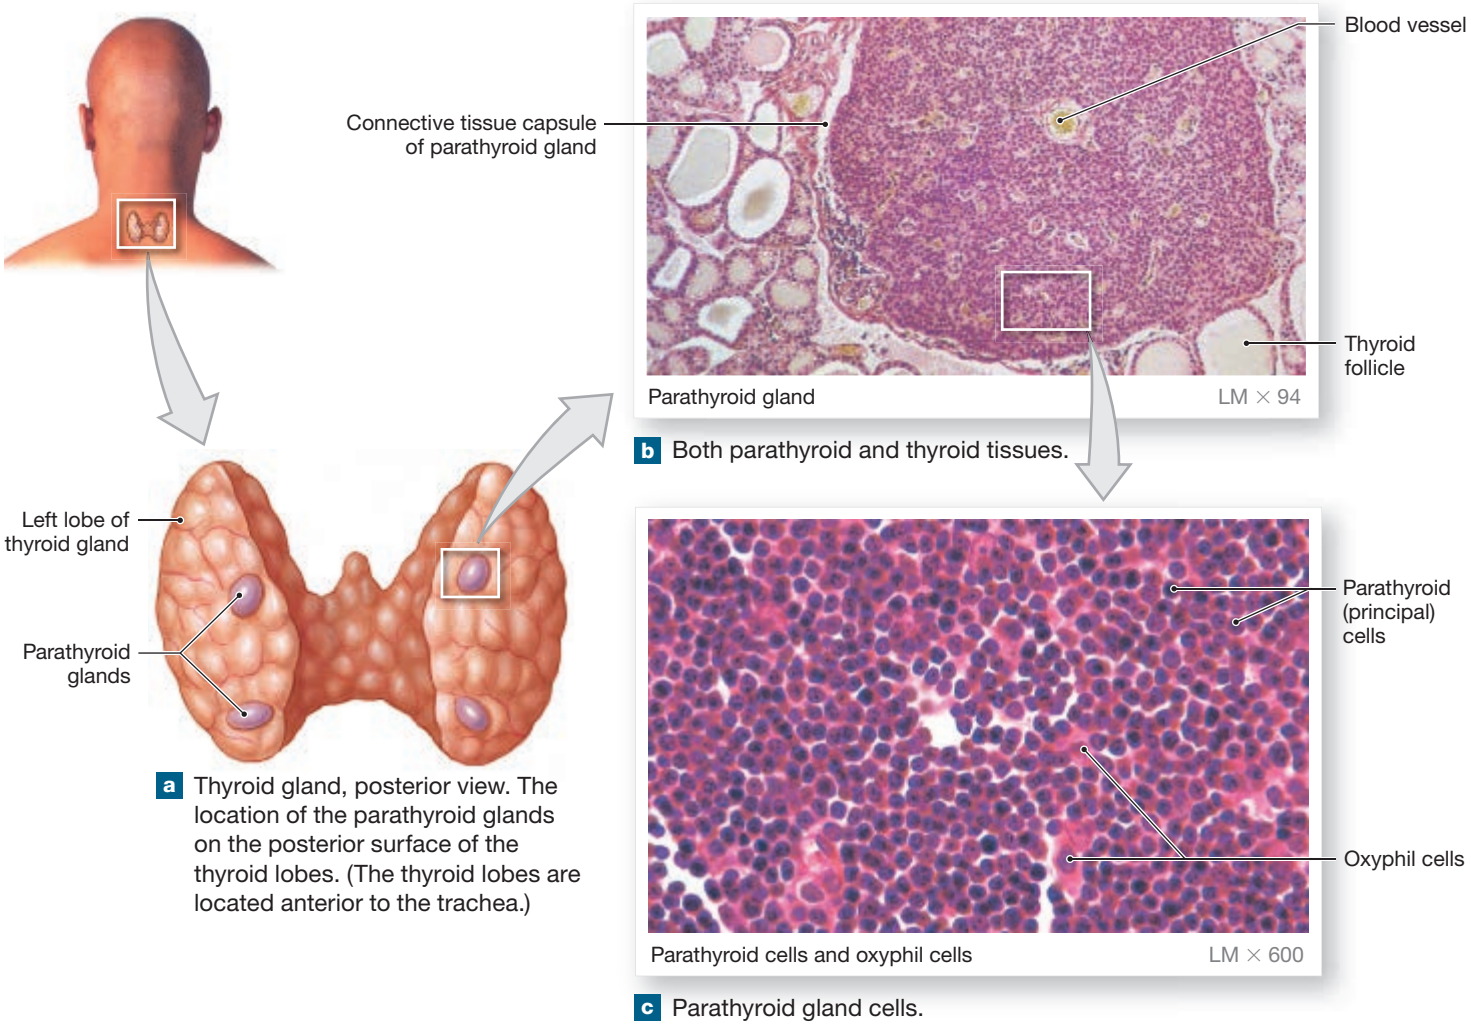
See the blue Answers tab at the back of the book.

18-5 The four parathyroid glands secrete parathyroid hormone, which increases the blood calcium ion level

Learning Outcome Describe the location, hormone, and functions of the parathyroid glands, and discuss the effects of abnormal parathyroid hormone production.

There are normally two pairs of **parathyroid glands** embedded in the posterior surfaces of the thyroid gland (Figure 18–12a). A dense capsule surrounding each parathyroid gland separates

Figure 18–12 Anatomy of the Parathyroid Glands.



a Thyroid gland, posterior view. The location of the parathyroid glands on the posterior surface of the thyroid lobes. (The thyroid lobes are located anterior to the trachea.)

b Both parathyroid and thyroid tissues.

c Parathyroid gland cells.

it from the cells of the thyroid gland. Altogether, the four parathyroid glands weigh a mere 1.6 g (0.06 oz). The histology of a single parathyroid gland is shown in Figure 18–12b,c. The parathyroid glands have at least two cell populations. The **parathyroid (principal) cells** produce parathyroid hormone. The functions of the other cells, called *parathyroid oxyphil cells*, are unknown. They do not appear until after puberty, and then their numbers increase with age.

Like the C cells of the thyroid gland, the parathyroid cells monitor the circulating concentration of calcium ions. When the Ca^{2+} concentration of the blood falls below normal, the parathyroid cells secrete **parathyroid hormone (PTH)**, or *parathormone*. The net result of PTH secretion is an increase in Ca^{2+} concentration in body fluids. Parathyroid hormone has three major effects:

- It mobilizes calcium from bone by affecting osteoblast and osteoclast activity. PTH stimulates osteoblasts to secrete a growth factor known as RANKL (receptor activator of nuclear factor-kappa-B ligand). Osteoclasts have no PTH receptors, but both precursor and mature osteoclasts have RANKL receptors. This growth factor results in an increase in osteoclasts and osteoclast activity. With more active osteoclasts, the rates of mineral turnover and Ca^{2+} release accelerate. As bone matrix erodes, the blood Ca^{2+} level rises.
- It enhances the resorption of Ca^{2+} by the kidneys, reducing urinary losses.
- It stimulates the formation and secretion of *calcitriol* by the kidneys. In general, the effects of calcitriol complement or enhance those of PTH, but calcitriol also enhances Ca^{2+} and PO_4^{3-} absorption by the digestive tract. ↩ p. 197

Figure 18–13 illustrates the role of PTH in regulating the blood Ca^{2+} concentration. PTH, aided by calcitriol, is probably the primary regulator of the circulating calcium ion concentration in healthy adults.

Information about the hormones of the thyroid gland and parathyroid glands is summarized in Table 18–4.

Figure 18–13 Homeostatic Regulation of the Blood Calcium Ion Concentration.

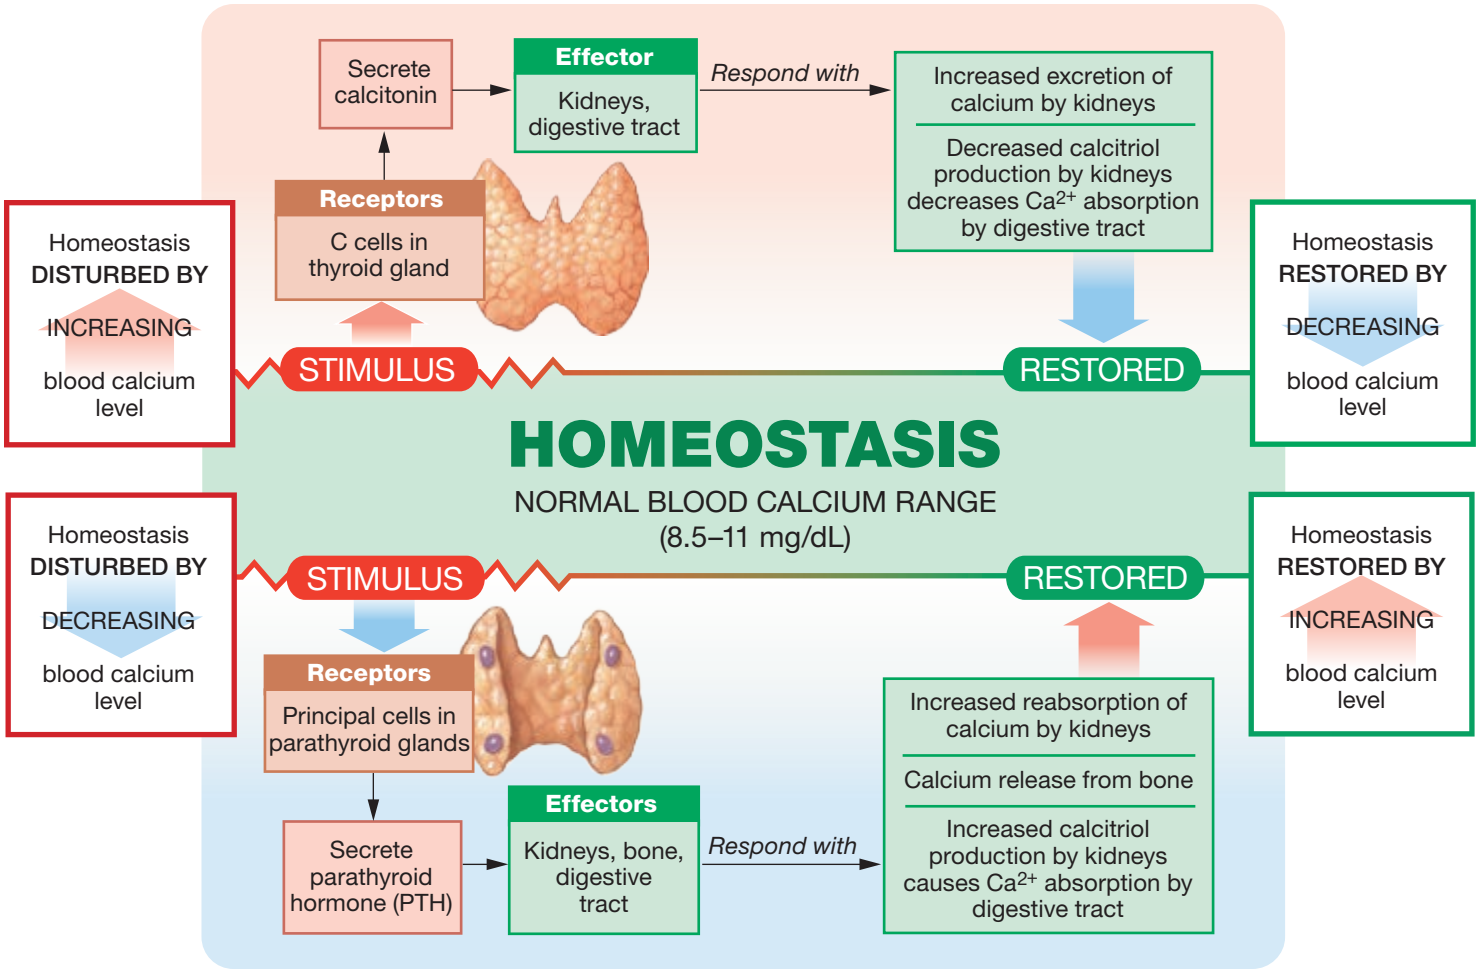


Table 18–4 Hormones of the Thyroid Gland and Parathyroid Glands

Gland/Cells	Hormone	Target	Hormonal Effect	Regulatory Control
THYROID GLAND				
Follicular epithelium	Thyroxine (T_4) Triiodothyronine (T_3)	Most cells	Increases energy utilization, oxygen consumption, growth, and development	Stimulated by TSH from the anterior lobe of the pituitary gland
C cells	Calcitonin (CT)	Kidneys, bone (mechanism unclear)	Decreases Ca^{2+} concentrations in body fluids	Stimulated by elevated blood Ca^{2+} levels; actions opposed by PTH
PARATHYROID GLANDS				
Parathyroid (principal) cells	Parathyroid hormone (PTH)	Bone, kidneys	Increases Ca^{2+} concentrations in body fluids	Stimulated by low blood Ca^{2+} levels; PTH effects enhanced by calcitriol and opposed by calcitonin

Checkpoint

14. **Describe the location of the parathyroid glands.**
15. **Identify the hormone secreted by the parathyroid glands.**
16. **The removal of the parathyroid glands would result in a decrease in the blood concentration of which important mineral?**

See the blue Answers tab at the back of the book.

18-6 The paired adrenal glands secrete several hormones that affect electrolyte balance and stress responses

Learning Outcome Describe the location, structure, hormones, and general functions of the adrenal glands, and discuss the effects of abnormal adrenal hormone production.

The *adrenal glands* are found superior to each kidney. This section looks at the anatomy of the adrenal glands, and then the hormones produced by each of its component parts, which have effects on both the electrolyte balance of body fluids and on our responses to stress.

Anatomy of the Adrenal Glands

A yellow, pyramid-shaped **adrenal** (ad-RĒ-nal) **gland** (*ad-*, near + *ren*, kidney), or *suprarenal gland*, sits on the superior border of each kidney (Figure 18–14a). Each adrenal gland lies near the level of the 12th rib. A dense fibrous capsule firmly attaches each adrenal gland to the superior portion of each kidney. The adrenal gland on each side nestles among the kidney, the diaphragm, and the major arteries and veins that run along the posterior wall of the abdominopelvic cavity. The adrenal glands project into the peritoneal cavity, and their anterior surfaces are covered by a layer of parietal peritoneum. Like other endocrine glands, the adrenal glands are highly vascularized.

A typical adrenal gland weighs about 5.0 g (0.18 oz), but its size can vary greatly as secretory demands change. The adrenal gland has two regions with separate endocrine functions: a superficial *adrenal cortex* and an inner *adrenal medulla* (Figure 18–14b).

Corticosteroids of the Adrenal Cortex

The yellowish color of the adrenal cortex is due to stored lipids, especially cholesterol and various fatty acids. The **adrenal cortex** produces more than two dozen steroid hormones that are collectively called **corticosteroids**. In the bloodstream, these hormones are bound to transport proteins called *transcortins*.

Corticosteroids are vital. If the adrenal glands are destroyed or removed, the person will die unless corticosteroids are administered. Like other steroid hormones, corticosteroids exert their effects by turning on transcription of certain genes in the nuclei of their target cells and determining their transcription rates. The resulting changes in the nature and concentration of enzymes in the cytoplasm affect cellular metabolism.

Deep to the adrenal capsule are three distinct zones in the adrenal cortex (Figure 18–14c): (1) an outer *zona glomerulosa*; (2) a middle *zona fasciculata*; and (3) an inner *zona reticularis*. Each zone synthesizes specific steroid hormones.

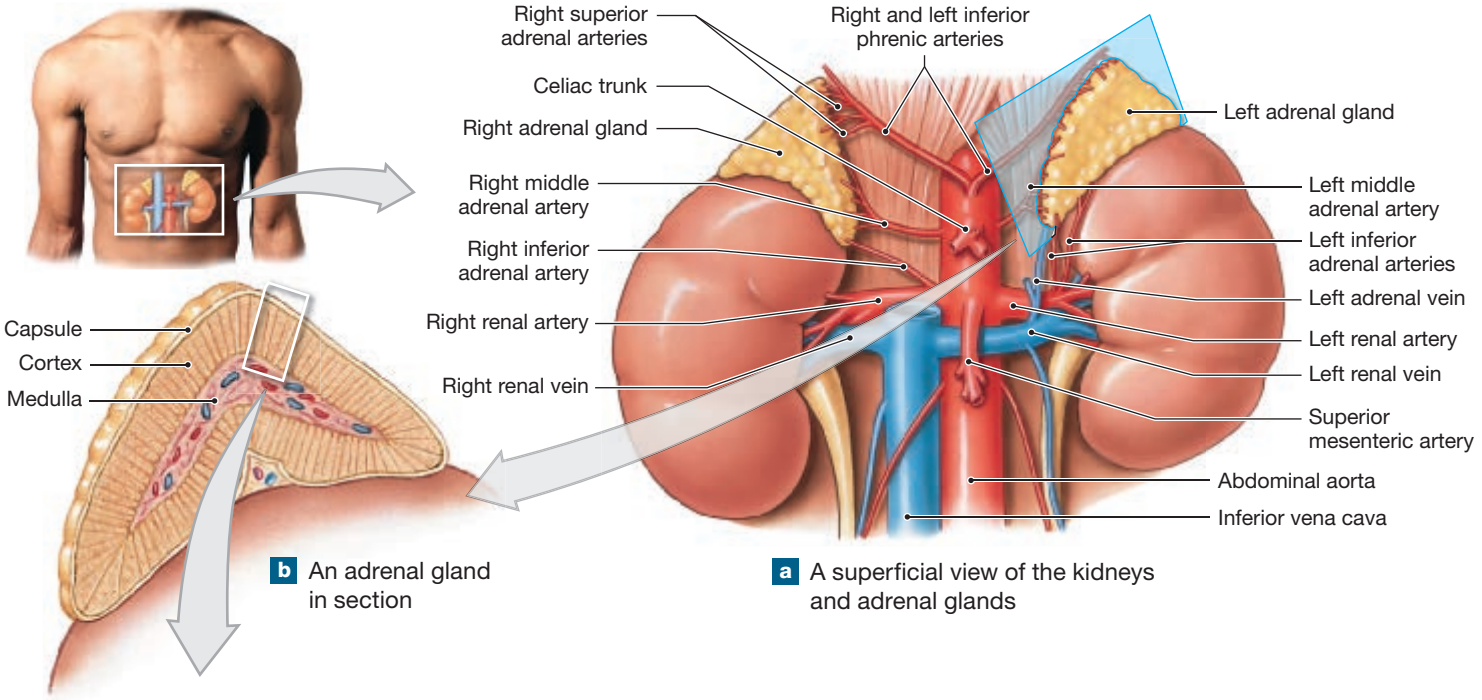
Mineralocorticoids of the Zona Glomerulosa

The **zona glomerulosa** (glō-mer-yū-LŌ-suh) is the outer region of the adrenal cortex. The zona glomerulosa accounts for about 15 percent of the volume of the adrenal cortex (Figure 18–14c). A *glomerulus* is a little ball, and as the term *zona glomerulosa* implies, the endocrine cells in this region form small, dense knots or clusters. This zone extends from the capsule to the radiating cords of the deeper zona fasciculata.

The zona glomerulosa produces **mineralocorticoids**, steroid hormones that affect the electrolyte composition of body fluids. **Aldosterone** is the main mineralocorticoid of the zona glomerulosa.

Aldosterone stimulates the conservation of sodium ions and the elimination of potassium ions. This hormone targets cells that regulate the ionic composition of excreted fluids. It causes the retention of sodium ions by the kidneys, sweat glands, salivary glands, and pancreas, preventing sodium ion loss in urine, sweat, saliva, and digestive secretions. A loss of K^+ accompanies this retention of Na^+. As a secondary effect, the retention of Na^+ enhances the osmotic reabsorption of water

Figure 18–14 The Adrenal Gland and Adrenal Hormones. ATLAS: Plates 61a,b; 62b



b An adrenal gland in section

a A superficial view of the kidneys and adrenal glands

The Adrenal Hormones

Region/Zone	Hormones	Primary Target	Hormonal Effects	Regulatory Control
Adrenal capsule; Zona glomerulosa (Adrenal cortex)	Mineralocorticoids, primarily aldosterone	Kidneys	Increase renal reabsorption of Na^+ and water (especially in the presence of ADH), and accelerate urinary loss of K^+	Stimulated by angiotensin II, elevated blood K^+ or fall in blood Na^+; inhibited by ANP and BNP
Zona fasciculata (Adrenal cortex)	Glucocorticoids (cortisol, corticosterone, and cortisone)	Most cells	Increase rates of glucose and glycogen formation by the liver; release of amino acids from skeletal muscles, and lipids from adipose tissues; promote peripheral utilization of lipids; anti-inflammatory effects	Stimulated by ACTH from the anterior lobe of the pituitary gland
Zona reticularis (Adrenal cortex)	Androgens	Most cells	Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty.	Androgen secretion is stimulated by ACTH.
Adrenal medulla	Epinephrine (E), norepinephrine (NE)	Most cells	Increases cardiac activity, blood pressure, glycogen breakdown, blood glucose levels; releases lipids by adipose tissue	Stimulated by sympathetic preganglionic fibers

Adrenal gland LM × 140

c The major regions and zones of an adrenal gland and the hormones they produce

? Which zone of the adrenal cortex produces mineralocorticoids and what is the primary mineralocorticoid?

by the kidneys, sweat glands, salivary glands, and pancreas. The effect at the kidneys is most dramatic when a normal level of ADH is present. In addition, aldosterone increases the sensitivity of salt receptors in the taste buds of the tongue. As a result, a person's interest in (and consumption of) salty food increases.

Aldosterone secretion occurs in response to a drop in blood Na^+ content, blood volume, or blood pressure, or to a rise in blood K^+ concentration. Changes in either Na^+ or K^+ concentration have a direct effect on the zona glomerulosa, but the secretory cells are most sensitive to changes in the K^+ level. A rise in the K^+ level is very effective in stimulating the release of aldosterone. Aldosterone release also occurs in response to *angiotensin II*. We discuss this hormone, part of the *renin-angiotensin-aldosterone system*, later in this chapter.

Glucocorticoids of the Zona Fasciculata

The **zona fasciculata** (fah-sik-yū-LAH-tuh; *fasciculus*, little bundle) produces steroid hormones collectively known as **glucocorticoids**, due to their effects on glucose metabolism. This zone begins at the inner border of the zona glomerulosa and extends toward the adrenal medulla (see Figure 18–14c). It contributes about 78 percent of the cortical volume. The endocrine cells are larger and contain more lipids than those of the zona glomerulosa, and the lipid droplets give the cytoplasm a pale, foamy appearance. The cells of the zona fasciculata form individual cords composed of stacks of cells. Adjacent cords are separated by flattened blood vessels (sinusoids) with fenestrated walls.

The Glucocorticoids. When stimulated by ACTH from the anterior lobe of the pituitary gland, the zona fasciculata secretes primarily **cortisol** (KOR-tih-sol) along with smaller amounts of the related steroid **corticosterone** (kor-tih-KOS-tehr-ōn) and **cortisone**. Negative feedback regulates glucocorticoid secretion: The glucocorticoids released have an inhibitory effect on the production of corticotropin-releasing hormone (CRH) in the hypothalamus, and on ACTH in the anterior pituitary lobe (see Figure 18–8a).

Effects of Glucocorticoids. Glucocorticoids speed up the rates of glucose synthesis and glycogen formation, especially in the liver. Adipose tissue responds by releasing fatty acids into the blood, and other tissues begin to break down fatty acids and proteins instead of glucose. This process is another example of a glucose-sparing effect. ↩ p. 625

Glucocorticoids also show **anti-inflammatory** effects. That is, they inhibit the activities of white blood cells and other components of the immune system. "Steroid creams" are commonly used to control irritating allergic rashes, such as poison ivy rash, and injections of glucocorticoids may be used to control more severe allergic reactions. How do these treatments work? Glucocorticoids slow the migration of phagocytic cells into an injury site and cause phagocytic cells already in the area to become less active. In addition, mast cells exposed to these steroids are less likely to release histamine and other chemicals that promote inflammation. ↩ pp. 145–147 As a result, swelling and further irritation are dramatically reduced. On the negative side, the rate of wound healing decreases, and the weakening of the region's defenses makes it more susceptible to infectious organisms. For that reason, the topical steroids used to treat superficial rashes should never be applied to open wounds.

Androgens of the Zona Reticularis

The **zona reticularis** (re-tik-ū-LAR-is; *reticulum*, network) forms a narrow band bordering each adrenal medulla (see Figure 18–14c). This zone accounts for only about 7 percent of the total volume of the adrenal cortex. The endocrine cells of the zona reticularis form a folded, branching network, and fenestrated blood vessels wind among the cells.

Under stimulation by ACTH, the zona reticularis normally produces small quantities of *androgens*, the sex hormones produced in large quantities by the testes in males. Once in the bloodstream, some of the androgens from the zona reticularis are converted to *estrogens*, the dominant sex hormones in females. Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty. Adrenal androgens are not important in adult men, but in adult women they promote muscle mass and blood cell formation, and support the sex drive.

Catecholamines of the Adrenal Medulla

The boundary between the adrenal cortex and the adrenal medulla is irregular, and the supporting connective tissues and blood vessels are extensively interconnected. The **adrenal medulla** is pale gray or pink, due in part to the many blood vessels in the area. It contains large, rounded cells—similar to cells in sympathetic ganglia that are innervated by preganglionic sympathetic fibers. The sympathetic division of the autonomic nervous system controls secretion by the adrenal medulla. ↩ p. 539

The adrenal medulla contains two populations of secretory cells: One produces epinephrine (E), the other norepinephrine (NE), both catecholamines. Evidence suggests that the two types of cells are distributed in different areas and that their secretory activities can be independently controlled. The secretions are packaged in vesicles that form dense clusters just inside plasma membranes. The hormones in these vesicles are continuously released at low levels by exocytosis. Sympathetic stimulation dramatically accelerates the rate of exocytosis and hormone release.

Epinephrine makes up 75–80 percent of the secretions from the adrenal medulla. The rest is norepinephrine. These hormones interact with alpha and beta receptors on plasma membranes, as we described in Chapter 16. ↩ p. 544 Stimulation of α_1 and β_1 receptors, the most common types, speeds up the use of cellular energy and the mobilization of energy reserves.

Activation of the adrenal medulla has the following effects:

- In skeletal muscles, E and NE trigger mobilization of glycogen reserves and accelerate the breakdown of glucose to provide ATP. This combination increases both muscular strength and endurance.
- In adipose tissue, stored fats are broken down into fatty acids, which are released into the bloodstream for other tissues to use for ATP production.
- In the liver, glycogen molecules are broken down. The resulting glucose molecules are released into the bloodstream, primarily for use by nervous tissue, which cannot shift to fatty acid metabolism.
- In the heart, the stimulation of β_1 receptors triggers an increase in the rate and force of cardiac muscle contraction.

The metabolic changes that follow the release of E and NE reach their peak about 30 seconds after adrenal stimulation, and they persist for several minutes. As a result, the effects of stimulating the adrenal medulla outlast the other signs of sympathetic activation.

Checkpoint

17. **Identify the two regions of the adrenal gland, and cite the hormones secreted by each.**
18. **List the three zones of the adrenal cortex.**
19. **What effect would an elevated cortisol level have on the blood glucose level?**

See the blue Answers tab at the back of the book.

18-7 The pineal gland secretes melatonin, which affects the circadian rhythm

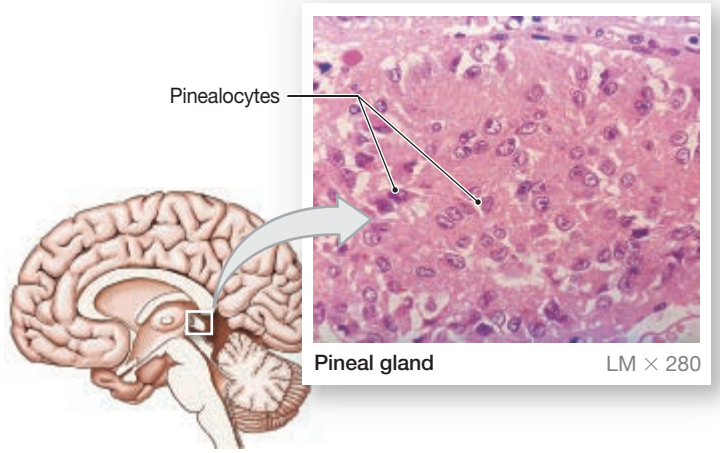
Learning Outcome Describe the location of the pineal gland, and discuss the functions of the hormone it produces.

The **pineal gland**, the main part of the epithalamus, lies in the posterior portion of the roof of the third ventricle (Figure 18–15). The pineal gland contains neurons, neuroglia, and special secretory cells called **pinealocytes** (pin-Ē-al-ō-sīts). These cells synthesize the hormone **melatonin** from molecules of the neurotransmitter *serotonin*. Collaterals from the visual pathways enter the pineal gland and affect the rate of melatonin production. This rate is lowest during daylight hours and highest at night.

Among the functions suggested for melatonin in humans are the following:

- *Influencing Circadian Rhythms.* Because its activity is cyclical, the pineal gland may be involved in maintaining basic *circadian rhythms*—daily changes in physiological processes that follow a regular day–night pattern. ↩ p. 484 Increased melatonin secretion in darkness has been suggested as a primary cause of *seasonal affective disorder (SAD)*. This condition can develop during the winter in people who live at high latitudes, where sunlight is scarce or lacking. It is characterized by changes in mood, eating habits, and sleeping patterns.
- *Inhibiting Reproductive Functions.* In some mammals, melatonin slows the maturation of sperm, oocytes, and reproductive organs by reducing the rate of GnRH secretion. The significance of this effect in humans remains unclear. Circumstantial evidence suggests that melatonin may play a role in the timing of human sexual maturation. The melatonin level in the blood declines at puberty, and pineal tumors that eliminate melatonin production cause premature puberty in young children.
- *Protecting against Damage by Free Radicals.* Melatonin is a very effective *antioxidant*. It may protect CNS neurons from free radicals, such as nitric oxide (NO) or hydrogen peroxide (H_2O_2), that may form in active nervous tissue.

Figure 18–15 Anatomy of the Pineal Gland.



Checkpoint

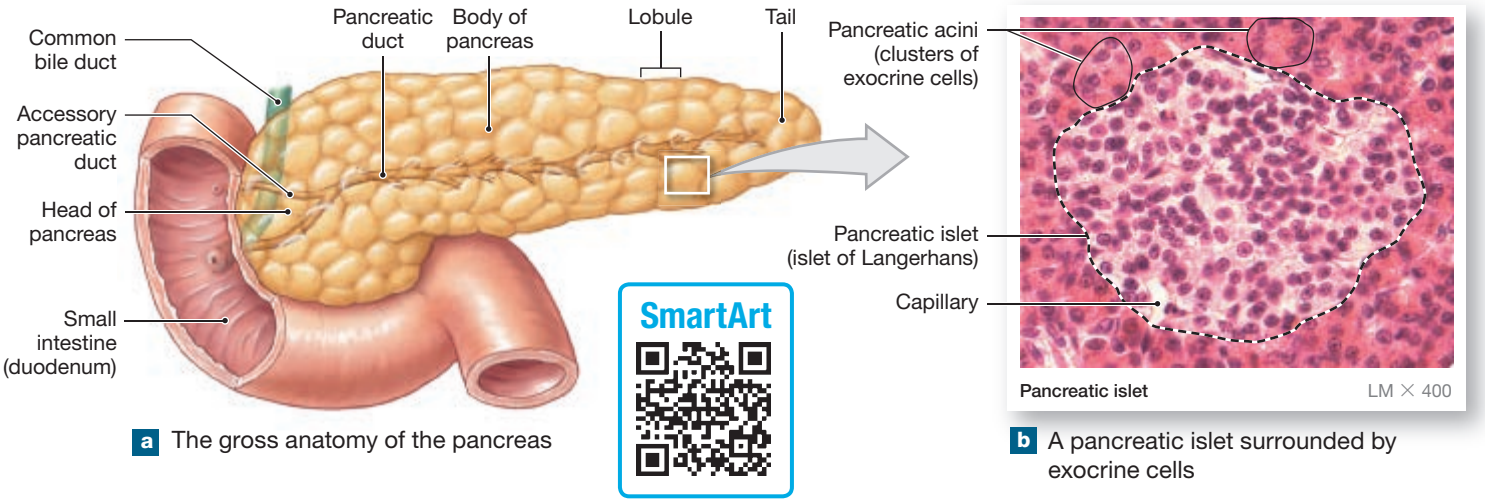
20. **Identify the hormone-secreting cells of the pineal gland.**
21. **Increased amounts of light would inhibit the production of which hormone?**
22. **List three possible functions of melatonin.**

18-8 The pancreas is both an exocrine organ and an endocrine gland that produces hormones affecting the blood glucose level

Learning Outcome Describe the location, structure, hormones, and functions of the pancreas, and discuss the effects of abnormal pancreatic hormone production.

The pancreas is a large gland located within the first fold of the small intestine (duodenum), close to the stomach. As an exocrine organ, it secretes digestive enzymes into the duodenum.

Figure 18–16 Anatomy of the Pancreas. ATLAS: Plate 49e



a The gross anatomy of the pancreas

b A pancreatic islet surrounded by exocrine cells

18

Embedded in the pancreas are endocrine cells that secrete two hormones, insulin and glucagon, into the bloodstream. Our discussion begins with the anatomy of the pancreas.

Anatomy of the Pancreas

The **pancreas** is mostly retroperitoneal and lies in the loop between the inferior border of the stomach and the proximal portion of the small intestine (see Figure 18–1). It is a slender, pale organ with a nodular (lumpy) texture (Figure 18–16a). The pancreas is 20–25 cm (8–10 in.) long and weighs about 80 g (2.8 oz) in adults.

The pancreas is made up of both exocrine and endocrine cells. The **exocrine pancreas** consists of clusters of gland cells, called *pancreatic acini*, and their attached ducts. The exocrine pancreas takes up roughly 99 percent of the pancreatic volume. Together the gland and duct cells secrete large quantities of an alkaline, enzyme-rich fluid that reaches the lumen of the digestive tract through a network of secretory ducts. We consider its anatomy further in Chapter 24.

The **endocrine pancreas** consists of small groups of cells scattered among the exocrine cells. The endocrine clusters are known as **pancreatic islets**, or the *islets of Langerhans* (LAHNG-er-hanz) (Figure 18–16b). Pancreatic islets account for only about 1 percent of all cells in the pancreas. Nevertheless, a typical pancreas contains approximately 2 million pancreatic islets. The pancreatic islets are surrounded by an extensive, fenestrated capillary network.

Functions of Pancreatic Islet Cells

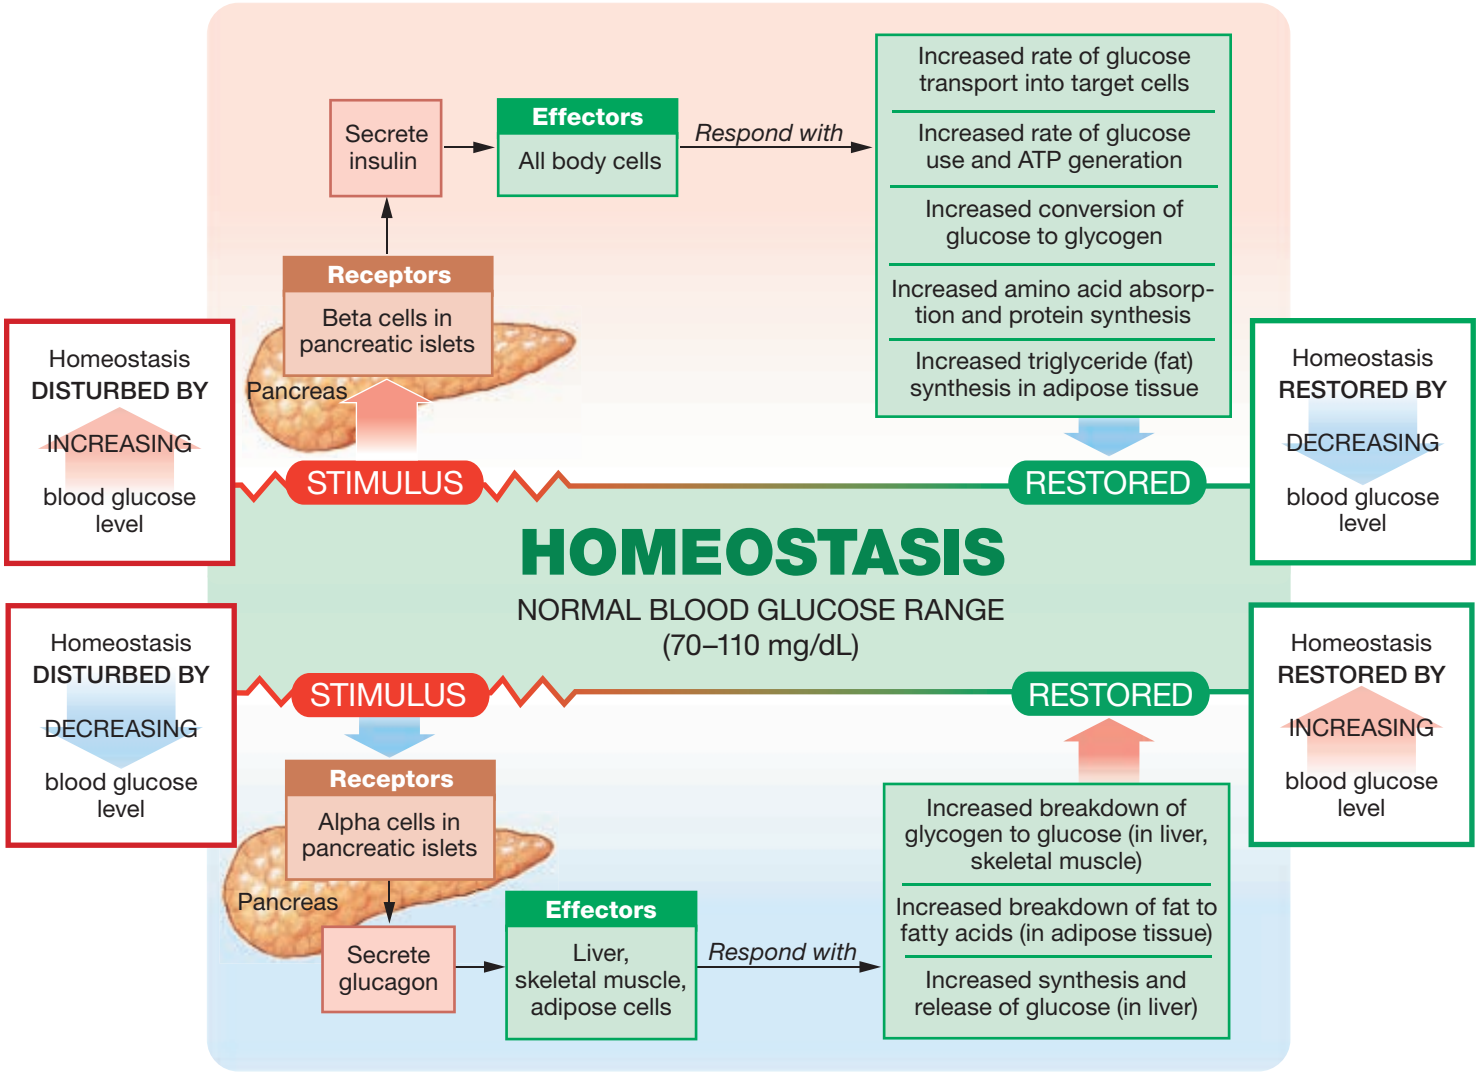
The hormones secreted by the pancreatic islet cells into the bloodstream are vital to our survival. Each islet contains four types of cells:

- **Alpha (α) cells** produce the hormone *glucagon* (GLŪ-kah-gon). Glucagon raises the blood glucose level by increasing the rates of glycogen breakdown and glucose release by the liver.
- **Beta (β) cells** produce the hormone *insulin* (IN-suh-lin). Insulin lowers the blood glucose level by increasing the rate of glucose uptake and use by most body cells, and by increasing glycogen synthesis in skeletal muscles and the liver. Beta cells also secrete *amylin*, a peptide hormone whose level rises after a meal.
- **Delta (δ) cells** produce a peptide hormone identical to growth hormone–inhibiting hormone (GH–IH), a hypothalamic regulatory hormone. GH–IH suppresses the release of glucagon and insulin by other islet cells and slows the rates of food absorption and enzyme secretion along the digestive tract.
- **Pancreatic polypeptide cells (PP cells)** produce the hormone pancreatic polypeptide (PP). PP inhibits gallbladder contractions and regulates the production of some pancreatic enzymes. It may also help control the rate of nutrient absorption by the digestive tract.

Hormones That Regulate the Blood Glucose Level

The hormones that regulate the blood glucose level are insulin and glucagon (Figure 18–17). When the blood glucose level increases, beta cells secrete insulin, which then stimulates the transport of glucose across plasma membranes and into target cells. When the blood glucose level decreases, alpha cells secrete glucagon, which stimulates glycogen breakdown and glucose release by the liver.

Figure 18–17 Homeostatic Regulation of the Blood Glucose Concentration.



? Which pancreatic cells secrete glucagon? List the effects of glucagon.

Tips & Tools

To help in differentiating between the polysaccharide storage molecule "glycogen" and the pancreatic hormone "glucagon," remember that glyco**gen** literally means "**gen**erates sugar"; and associate gluca**gon** with the Penta**gon**, both of which "issue orders."

Insulin

Insulin is a peptide hormone released by beta cells when the blood glucose concentration exceeds the normal range (70–110 mg/dL). Elevated levels of some amino acids, including arginine and leucine, also stimulate secretion of insulin. This hormone affects cellular metabolism in a series of steps that begins when insulin binds to receptor proteins on the plasma membrane of a target cell. Binding activates the receptor, which functions as a kinase, attaching phosphate groups to intracellular enzymes. These enzymes then produce primary and secondary effects in the cell. The biochemical details of these effects remain unresolved.

One of the most important effects of insulin is the enhancement of glucose absorption and use. Insulin receptors are present in most plasma membranes, and cells that have them are called *insulin dependent*. However, cells in the brain and kidneys, cells in the lining of the digestive tract, and red blood cells lack insulin receptors. These cells are called *insulin independent*, because they can absorb and use glucose without insulin stimulation.

These are the effects of insulin on its target cells:

- *Accelerating Glucose Uptake (All Target Cells)*. This effect results from an increase in the number of glucose transport proteins in the plasma membrane. These proteins move glucose into the cell by facilitated diffusion, which follows the concentration gradient for glucose and does not require ATP.
- *Accelerating Glucose Use (All Target Cells) and Enhanced ATP Production*. This effect occurs for two reasons: (1) The rate of glucose use is proportional to its availability, so when more glucose enters the cell, more is used. (2) Second messengers activate a key enzyme involved in the initial steps of glycolysis.
- *Stimulating Glycogen Formation (Skeletal Muscle Fibers and Liver Cells)*. When excess glucose enters these cells, it is stored as glycogen.
- *Stimulating Amino Acid Absorption and Protein Synthesis (All Target Cells)*. This helps to maintain the glucose level by preventing the conversion of amino acids to glucose.
- *Stimulating Triglyceride Formation (Adipocytes)*. Insulin stimulates the absorption of fatty acids and glycerol by adipocytes, which store these components as triglycerides. Adipocytes also increase their absorption of glucose, and excess glucose is used in the synthesis of additional triglycerides.

To summarize, the pancreas secretes insulin when glucose is abundant. The hormone stimulates glucose use to support growth and to build carbohydrate (glycogen) and lipid (triglyceride) reserves. The accelerated use of glucose soon brings the circulating glucose level within normal limits.

Tips & Tools

The function of **in**sulin is to get glucose **in**to cells.

Glucagon

When the glucose concentration decreases below the normal range, alpha cells release **glucagon** to mobilize energy reserves. When glucagon binds to a receptor in the target cell's plasma membrane, the hormone activates adenylate cyclase. As we have seen, cAMP acts as a second messenger that activates cytoplasmic enzymes (look back at **Spotlight Figure 18–3**, p. 617). The primary effects of glucagon are as follows:

- *Stimulating the Breakdown of Glycogen (Skeletal Muscle Fibers and Liver Cells)*. The glucose molecules released are either metabolized for energy (in skeletal muscle fibers) or released into the bloodstream (by liver cells).
- *Stimulating the Breakdown of Triglycerides (Adipocytes)*. The adipocytes then release the fatty acids into the bloodstream for use by other tissues.
- *Stimulating the Production and Release of Glucose (Liver Cells)*. Liver cells absorb amino acids from the bloodstream, convert them to glucose, and release the glucose into the circulation. This process of glucose synthesis in the liver is called *gluconeogenesis* (glū-kō-nē-ō-JEN-eh-sis).

The results are a reduction in glucose use and the release of more glucose into the bloodstream. The blood glucose concentration soon increases toward the normal range.

Pancreatic alpha cells and beta cells monitor the blood glucose concentration, and they secrete glucagon and insulin without endocrine or nervous instructions. Yet because the alpha cells and beta cells are highly sensitive to changes in the blood glucose level, any hormone that affects the blood glucose concentration indirectly affects the production of both insulin and glucagon. Autonomic activity also influences insulin production: Parasympathetic stimulation enhances insulin release, and sympathetic stimulation inhibits it. Information about insulin, glucagon, and other pancreatic hormones is summarized in **Table 18–5**.

Table 18–5 Hormones Produced by the Pancreatic Islets

Structure/Cells	Hormone	Primary Targets	Hormonal Effect	Regulatory Control
PANCREATIC ISLETS				
Alpha (α) cells	Glucagon	Liver, adipose tissue	Mobilizes lipid reserves; promotes glucose synthesis and glycogen breakdown in liver; elevates blood glucose concentration	Stimulated by low blood glucose concentrations; inhibited by GH–IH from delta cells
Beta (β) cells	Insulin	Most cells	Facilitates uptake of glucose by target cells; stimulates formation and storage of lipids and glycogen	Stimulated by high blood glucose concentrations, parasympathetic stimulation, and high levels of some amino acids; inhibited by GH–IH from delta cells and by sympathetic activation
Delta (δ) cells	Somatostatin (GH–IH)	Other islet cells, digestive epithelium	Inhibits insulin and glucagon secretion; slows rates of nutrient absorption and enzyme secretion along digestive tract	Stimulated by protein-rich meal; mechanism unclear
Pancreatic polypeptide cells	Pancreatic polypeptide (PP)	Digestive organs	Inhibits gallbladder contraction; regulates production of pancreatic enzymes; influences rate of nutrient absorption by digestive tract	Stimulated by protein-rich meal and by parasympathetic stimulation

Diabetes Mellitus

Whether glucose is absorbed by the digestive tract or manufactured and released by the liver, very little glucose leaves the body once it has entered the bloodstream. The kidneys reabsorb virtually all glucose, so glucose does not appear in the urine. However, in **diabetes mellitus**, glucose accumulates in the blood and urine as a result of faulty glucose metabolism.

Diabetes mellitus can be caused by genetic abnormalities, and some of the genes responsible have been identified. Mutations that result in inadequate insulin production, the synthesis of abnormal insulin molecules, or the production of defective receptor proteins produce comparable symptoms. Under these conditions, obesity accelerates the onset and severity of the disease. Diabetes mellitus can also result from other pathological conditions, injuries, immune disorders, or hormonal imbalances.

The two major types of diabetes mellitus are Type 1 diabetes (previously known as juvenile diabetes) and Type 2 diabetes. This disorder is described in **Spotlight Figure 18–18**.

Checkpoint

23. **Identify the types of cells in the pancreatic islets and the hormones produced by each.**
24. **Why does a person with Type 1 or Type 2 diabetes urinate frequently and have increased thirst?**
25. **What effect would an increased blood glucagon level have on the amount of glycogen stored in the liver?**

See the blue Answers tab at the back of the book.

18-9 Many organs have secondary endocrine functions

Learning Outcome Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.

As we noted earlier, many organs of other body systems have secondary endocrine functions. Examples are the intestines (digestive system), the kidneys (urinary system), the heart (cardiovascular system), the thymus (lymphatic system), and the *gonads*—the testes in males and the ovaries in females (reproductive system).

Several new hormones from these endocrine tissues have been identified. In many cases, their structures and modes of action remain uncertain, and we have not described them in this chapter. However, in one instance, researchers traced a significant new hormone to an unexpected site of origin, leading to the realization that the body's adipose tissue has important endocrine functions. We include the endocrine functions of adipose tissue in this section, although all the details have yet to be worked out. **Table 18–6** provides an overview of some of the hormones those organs of other systems produce.

The Intestines

The intestines process and absorb nutrients. They release a variety of hormones that coordinate the activities of the digestive system. Most digestive processes are hormonally controlled locally, although the autonomic nervous system can affect the pace of digestive activities. We describe these hormones in Chapter 24.

The Kidneys

The kidneys release the steroid hormone *calcitriol*, the peptide hormone *erythropoietin*, and the enzyme *renin*. Calcitriol is important for calcium ion homeostasis. Erythropoietin and renin are involved in the regulation of blood volume and blood pressure.

Calcitriol

Calcitriol is a steroid hormone secreted by the kidneys in response to parathyroid hormone (PTH) (**Figure 18–19a**). *Cholecalciferol* (vitamin D_3) is a related steroid that is synthesized in the skin or absorbed from the diet. Cholecalciferol is converted to calcitriol, although not directly. The term *vitamin D* applies

Table 18–6 Representative Hormones Produced by Organs of Other Systems

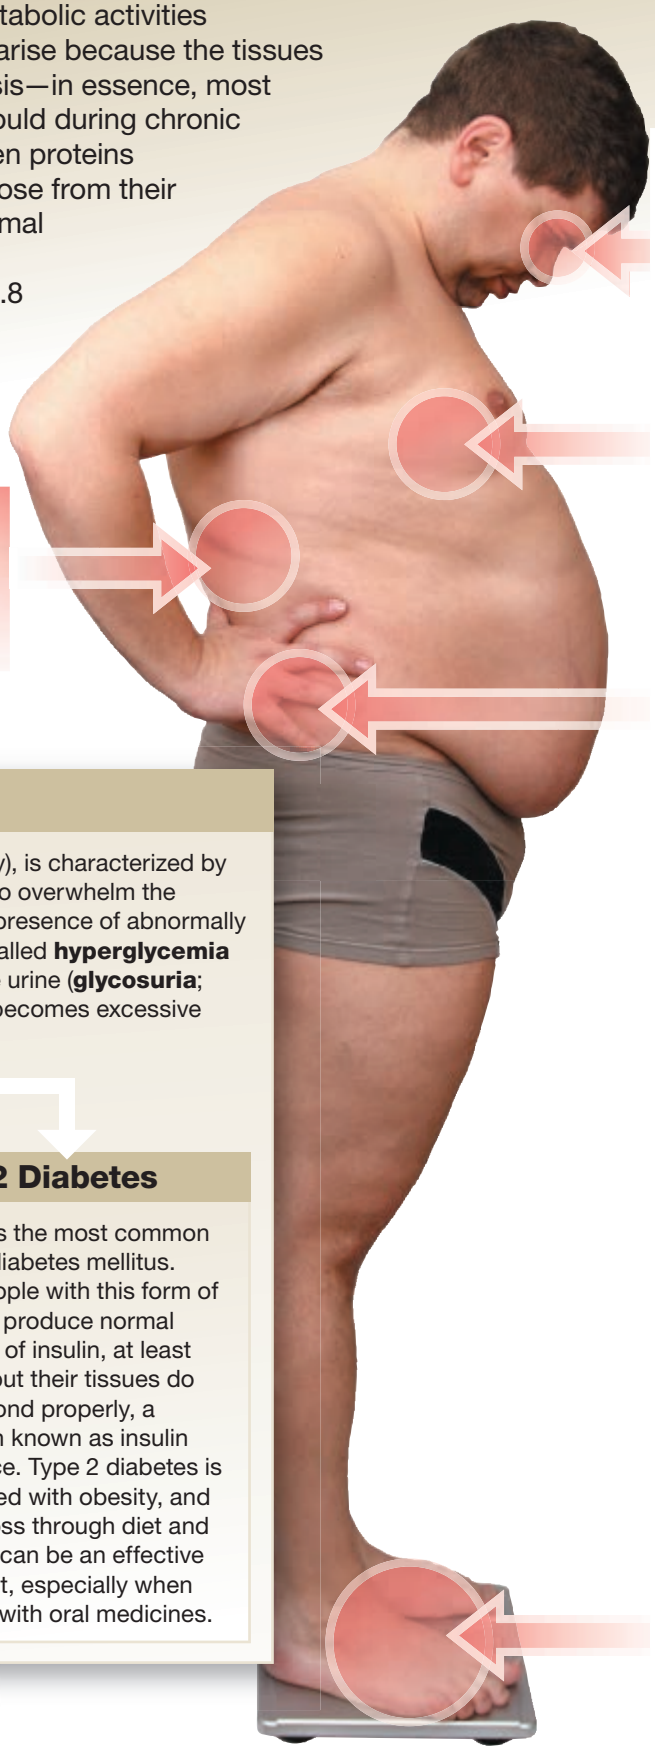
Organ	Hormone	Primary Target	Hormonal Effect
Intestines	Many (secretin, gastrin, cholecystokinin, etc.)	Other regions and organs of the digestive system	Coordinate digestive activities
Kidneys	Erythropoietin (EPO) Calcitriol	Red bone marrow Intestinal lining, bone, kidneys	Stimulates red blood cell production Stimulates calcium and phosphate absorption; stimulates Ca^{2+} release from bone; inhibits PTH secretion
Heart	Natriuretic peptides (ANP and BNP)	Kidneys, hypothalamus, adrenal gland	Increase water and salt loss at kidneys; decrease thirst; suppress secretion of ADH and aldosterone
Thymus	Thymosins (many)	Lymphocytes and other cells of the immune response	Coordinate and regulate immune response
Gonads	*See Table 18–7*		
Adipose tissue	Leptin	Hypothalamus	Suppression of appetite; permissive effects on GnRH and gonadotropin synthesis

Go to MasteringA&P™ > Study Area > Menu > Lab Tools > PhysioEx 9.1 > Exercise 4: Endocrine System Physiology > Activity 2: Plasma Glucose, Insulin, and Diabetes Mellitus

SPOTLIGHT

Figure 18–18
Diabetes Mellitus

Untreated diabetes mellitus disrupts metabolic activities throughout the body. Clinical problems arise because the tissues involved are experiencing an energy crisis—in essence, most of the tissues are responding as they would during chronic starvation, breaking down lipids and even proteins because they are unable to absorb glucose from their surroundings. Problems involving abnormal changes in blood vessel structure are particularly dangerous. An estimated 25.8 million people in the United States have some form of diabetes.



Retinal Damage

The proliferation of capillaries and hemorrhaging at the retina may cause partial or complete blindness. This condition is called **diabetic retinopathy**.

Early Heart Attacks

Degenerative blockages in cardiac circulation can lead to early heart attacks. For a given age group, heart attacks are three to five times more likely in people with diabetes than in nondiabetic people.

Peripheral Nerve Problems

Abnormal blood flow to neural tissues is probably responsible for a variety of neural problems with peripheral nerves, including abnormal autonomic function. These disorders are collectively termed **diabetic neuropathies**.

Kidney Degeneration

Degenerative changes in the kidneys, a condition called **diabetic nephropathy**, can lead to kidney failure.

Diabetes Mellitus

Diabetes mellitus (mel-Ī-tus; *mellitum*, honey), is characterized by glucose concentrations that are high enough to overwhelm the reabsorption capabilities of the kidneys. (The presence of abnormally high glucose levels in the blood in general is called **hyperglycemia** [hī-per-glī-SĒ-mē-ah].) Glucose appears in the urine (**glycosuria**; glī-kō-SYŪ-rē-a), and urine volume generally becomes excessive (**polyuria**).

subdivided into

Type 1 Diabetes

Type 1 is characterized by inadequate insulin production by the pancreatic beta cells. Persons with Type 1 diabetes require insulin to live and usually require multiple injections daily, or continuous infusion through an insulin pump or other device. This form of diabetes accounts for approximately 5% of cases. It usually develops in children and young adults.

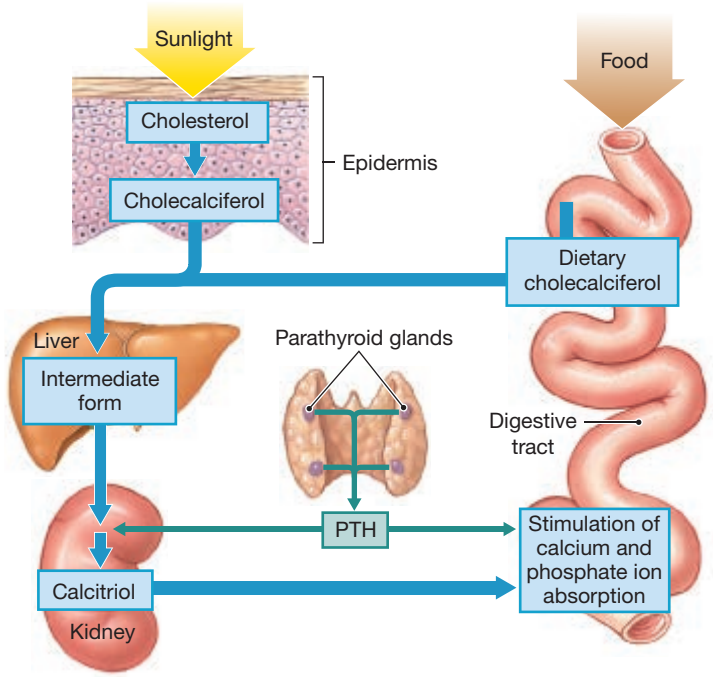
Type 2 Diabetes

Type 2 is the most common form of diabetes mellitus. Most people with this form of diabetes produce normal amounts of insulin, at least initially, but their tissues do not respond properly, a condition known as insulin resistance. Type 2 diabetes is associated with obesity, and weight loss through diet and exercise can be an effective treatment, especially when coupled with oral medicines.

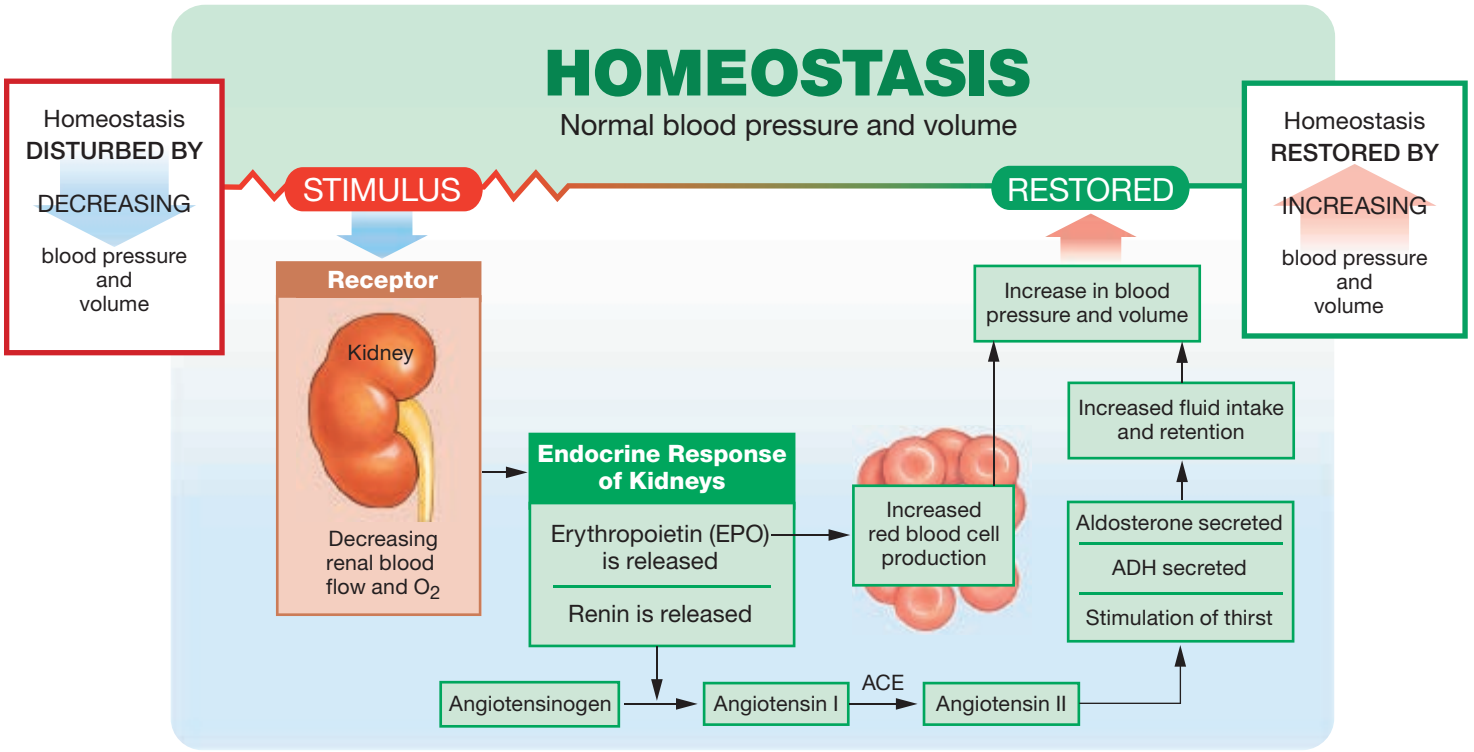
Peripheral Tissue Damage

Blood flow to the distal portions of the limbs is reduced, and peripheral tissues may suffer as a result. For example, a reduction in blood flow to the feet can lead to tissue death, ulceration, infection, and loss of toes or a major portion of one or both feet.

Figure 18–19 Endocrine Functions of the Kidneys.



a The production of calcitriol



b The release of renin and erythropoietin, and an overview of the renin-angiotensin-aldosterone system beginning with the activation of angiotensinogen by renin

to the entire group of related steroids, including calcitriol, cholecalciferol, and various intermediate products.

The best-known function of calcitriol is to stimulate calcium and phosphate ion absorption along the digestive tract. The effects of PTH on Ca^{2+} absorption result primarily from stimulation of calcitriol release. Calcitriol's other effects on calcium metabolism include (1) stimulating the formation and differentiation of osteogenic cells and osteoclasts, (2) stimulating bone resorption by osteoclasts, (3) stimulating Ca^{2+} reabsorption by the kidneys, and (4) suppressing PTH production.

Evidence indicates that calcitriol also affects lymphocytes and keratinocytes in the skin, but these effects have nothing to do with regulating calcium levels.

Erythropoietin

Erythropoietin (e-rith-rō-POY-e-tin; *erythros*, red + *poiesis*, making), or **EPO**, is a peptide hormone released by the kidneys in response to low oxygen levels in kidney tissues. EPO stimulates the red bone marrow to produce red blood cells. The increase in the number of red blood cells elevates blood volume. Because these cells transport oxygen, this increase also improves oxygen delivery to peripheral tissues. We consider EPO again in Chapter 19.

Renin

Specialized kidney cells called *juxtaglomerular cells* release **renin** (RĒ-nin) in response to (1) sympathetic stimulation or (2) a decline in renal blood flow. Once in the bloodstream, renin functions as an enzyme that starts an enzymatic cascade known as the *renin-angiotensin-aldosterone system (RAAS)* (Figure 18–19b). RAAS is involved with blood pressure regulation and electrolyte metabolism. First, renin converts **angiotensinogen**, a plasma protein produced by the liver, to angiotensin I. In the capillaries of the lungs, angiotensin-converting enzyme (ACE) modifies **angiotensin I** to the hormone **angiotensin II**. This hormone, in turn, stimulates the secretion of aldosterone by the adrenal cortex and ADH by the posterior lobe of the pituitary gland. The combination of aldosterone and ADH acts to retain salt and water by restricting their loss by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. For these reasons, drugs known as *ACE inhibitors* are used to treat hypertension.

Because renin plays such a key role in the renin-angiotensin-aldosterone system, many physiological and endocrinological references consider renin to be a hormone. We take a closer look at the renin-angiotensin-aldosterone system when we examine the control of blood pressure and blood volume in Chapter 21.

The Heart

The endocrine cells in the heart are cardiac muscle cells in the walls of the *atria* (chambers that receive blood from the veins) and the *ventricles* (chambers that pump blood to the rest of the body). If blood volume becomes too great, these cells are stretched excessively, to the point at which they begin to secrete **natriuretic peptides** (nā-trē-ū-RET-ik; *natrium*, sodium + *ouresis*, urination). In general, the effects of natriuretic peptides oppose those of angiotensin II: Natriuretic peptides promote the loss of Na^+ and water by the kidneys, and inhibit renin release and the secretion of ADH and aldosterone. They also suppress thirst and prevent angiotensin II and norepinephrine from elevating blood pressure. The net result is a reduction in both blood volume and blood pressure, thereby reducing the stretching of the cardiac muscle cells in the heart walls. We discuss two natriuretic peptides—*ANP* (atrial natriuretic peptide) and *BNP* (brain natriuretic peptide)—when we consider the control of blood pressure and volume in Chapters 21 and 26.

The Thymus

The **thymus** is located in the mediastinum, generally just deep to the sternum. This gland produces several hormones that are important in developing and maintaining immune defenses. **Thymosin** (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of *lymphocytes*, the white blood cells responsible for immunity. The extract actually contains a blend of several complementary hormones. The term *thymosins* is sometimes used to refer to all thymic hormones. We consider the histological organization of the thymus and the functions of the thymosins in Chapter 22.

The Gonads

Information about reproductive hormones is presented in Table 18–7. In males, the **interstitial endocrine cells** of the testes produce male hormones called *androgens*. Testosterone (tes-TOS-ter-ōn) is an important androgen. During embryonic

Table 18–7 Hormones of the Reproductive System

Structure/Cells	Hormone	Primary Target	Hormonal Effect	Regulatory Control
TESTES				
Interstitial endocrine cells	Androgens	Most cells	Support functional maturation of sperm, protein synthesis in skeletal muscles, male secondary sex characteristics, and associated behaviors	Stimulated by LH from the anterior lobe of the pituitary gland
Nurse cells	Inhibin	Pituitary gland	Inhibits secretion of FSH	Stimulated by FSH from the anterior lobe
OVARIES				
Follicular cells	Estrogens	Most cells	Support follicle maturation, female secondary sex characteristics, and associated behaviors	Stimulated by FSH and LH from the anterior lobe of the pituitary gland
	Inhibin	Pituitary gland	Inhibits secretion of FSH	Stimulated by FSH from anterior lobe
Corpus luteum	Progesterone	Uterus, mammary glands	Prepares uterus for implantation; prepares mammary glands for secretory activity	Stimulated by LH from the anterior lobe of the pituitary gland

Clinical Note Endocrine Disorders

Regulation of hormone levels often involves negative feedback control mechanisms. These mechanisms involve the endocrine organ, neural regulatory factors, and the target tissues. Hormone overproduction (*hypersecretion*) or underproduction (*hyposecretion*) may cause problems. Abnormal cellular sensitivity to the hormone can also lead to problems.

Primary disorders arise from problems within the endocrine organ. The underlying cause may be a metabolic factor. Hypothyroidism due to a lack of dietary iodine is an example. An endocrine organ may also malfunction due to physical damage that destroys cells or disrupts the normal blood supply. Congenital problems may also affect the regulation, production, or release of hormones by endocrine cells.

Secondary disorders are due to problems in other organs or target tissues. Such disorders often involve the hypothalamus or pituitary gland. For example, secondary hypothyroidism occurs when the hypothalamus or pituitary gland doesn't produce enough TRH and/or TSH.

Abnormalities in target cells can affect their sensitivity or responsiveness to a particular hormone. For example, Type 2 diabetes is due to the target cells' decreased sensitivity to insulin.

Endocrine disorders often reflect either abnormal hormone production or abnormal cellular sensitivity to hormones. The signs and symptoms highlight the significance of normally "silent" hormonal contributions. The characteristics of these disorders are summarized in **Table 18–8**.

Table 18–8 Clinical Implications of Endocrine Malfunctions

Hormone	Underproduction or Tissue Insensitivity	Principal Signs and Symptoms	Overproduction or Tissue Hypersensitivity	Principal Signs and Symptoms
Growth hormone (GH)	Pituitary growth failure	Retarded growth, abnormal fat distribution, low blood glucose hours after a meal	Gigantism, acromegaly	Excessive growth
Antidiuretic hormone (ADH) or vasopressin (VP)	Diabetes insipidus	Polyuria, dehydration, thirst	SIADH (syndrome of inappropriate ADH secretion)	Increased body weight and water content
Thyroxine (T_4), triiodothyronine (T_3)	Hypothyroidism, infantile hypothyroidism, myxedema	Low metabolic rate; low body temperature; impaired physical and mental development	Hyperthyroidism, Graves disease	High metabolic rate and body temperature
Parathyroid hormone (PTH)	Hypoparathyroidism	Muscular weakness, neurological problems, formation of dense bones, tetany due to low blood Ca^{2+} concentration	Hyperparathyroidism	Neurological, mental, muscular problems due to high blood Ca^{2+} concentration; weak and brittle bones
Insulin	Diabetes mellitus (Type 1)	High blood glucose, impaired glucose utilization, dependence on lipids for energy; glycosuria	Excess insulin production or administration	Low blood glucose levels, possibly causing coma
Mineralocorticoids (MCs)	Hypoaldosteronism	Polyuria, low blood volume, high blood K^+, low blood Na^+ concentration	Aldosteronism	Increased body weight due to Na^+ and water retention; low blood K^+ concentration
Glucocorticoids (GCs)	Addison disease	Inability to tolerate stress, mobilize energy reserves, or maintain normal blood glucose concentration	Cushing disease	Excessive breakdown of tissue proteins and lipid reserves; impaired glucose metabolism
Epinephrine (E), norepinephrine (NE)	None identified		Pheochromocytoma	High metabolic rate, body temperature, and heart rate; elevated blood glucose level
Estrogens (females)	Hypogonadism	Sterility, lack of secondary sex characteristics	Adrenogenital syndrome	Overproduction of androgens by zona reticularis of adrenal cortex leads to masculinization
			Precocious puberty	Premature sexual maturation and related behavioral changes
Androgens (males)	Hypogonadism	Sterility, lack of secondary sex characteristics	Adrenogenital syndrome (gynecomastia)	Abnormal production of estrogen, due to adrenal or interstitial endocrine cell tumors; leads to breast enlargement
			Precocious puberty	Premature sexual maturation and related behavioral changes

development, the production of testosterone affects the development of CNS structures, including hypothalamic nuclei, which will later influence sexual behaviors. **Nurse cells** (*Sertoli cells*) in the testes support the differentiation and physical maturation of sperm. Under FSH stimulation, these cells secrete the hormone **inhibin**. It inhibits the secretion of FSH at the anterior lobe of the pituitary gland and perhaps suppresses GnRH release at the hypothalamus.

In females, steroid hormones called **estrogens** are produced in the ovaries under FSH and LH stimulation. **Estradiol** is the main estrogen. Circulating FSH stimulates the secretion of inhibin by ovarian cells, and inhibin suppresses FSH release through a feedback mechanism comparable to that in males.

At ovulation, follicles in the ovary release an immature gamete, or oocyte. The remaining follicle cells then reorganize into a *corpus luteum* (LŪ-tē-um; "yellow body") that releases a mixture of estrogens and **progesterone** (prō-JES-ter-ōn). During pregnancy, the placenta and uterus produce additional hormones that interact with those produced by the ovaries and the pituitary gland to promote normal fetal development and delivery. We consider the hormonal aspects of pregnancy in Chapter 29.

Adipose Tissue

Recall from Chapter 4 that adipose tissue is a type of loose connective tissue. ↩ p. 130 Adipose tissue produces a peptide hormone, called **leptin**, that has several functions. Its best known function is feedback control of appetite. When we eat, adipose tissue absorbs glucose and lipids and synthesizes triglycerides for storage. At the same time, it releases leptin into the bloodstream. Leptin binds to hypothalamic neurons involved with emotion and appetite control. The result is a sense of fullness (satiation) and the suppression of appetite.

Leptin was first discovered in a strain of obese mice that had a defective leptin gene. When treated with leptin, these overweight mice quickly turned into slim, athletic animals. The initial hope that leptin could be used to treat human obesity was soon dashed, however. Most obese people appear to have defective leptin receptors (or leptin pathways) in the appetite centers of the CNS. Their circulating leptin levels are already several times higher than those in individuals of normal body weight. Additional leptin would have no effect. Researchers are now investigating the structure of the receptor protein and the biochemistry of the pathway triggered by leptin binding.

Leptin must be present for normal levels of GnRH and gonadotropin synthesis to take place. This explains why (1) thin girls commonly enter puberty relatively late, (2) an increase in body fat can improve fertility, and (3) women stop menstruating when their body fat content becomes very low.

Checkpoint

26. **Identify two hormones secreted by the kidneys.**
27. **Identify a hormone released by adipose tissue.**
28. **Describe the action of renin in the bloodstream.**

See the blue Answers tab at the back of the book.

18-10 Hormones interact over our lifetime to produce coordinated physiological responses

Learning Outcome Explain how hormones interact to produce coordinated physiological responses and influence behavior, describe the role of hormones in the general adaptation syndrome, and discuss how aging affects hormone production and give examples of interactions between the endocrine system and other organ systems.

We usually study hormones individually, but the extracellular fluids contain a mixture of hormones whose concentrations change daily or even hourly. As a result, cells never respond to only one hormone. Instead, they respond to multiple hormones. When a cell receives instructions from two hormones at the same time, four outcomes are possible:

- The two hormones may have opposing, or **antagonistic, effects**, as in the case of insulin and glucagon. The net result depends on the balance between the two hormones. In general, when two antagonistic hormones are present, the observed effects are weaker than those produced by either hormone acting unopposed.
- The two hormones may have additive effects, so that the net result is greater than the effect that each would produce acting alone. In some cases, the net result is greater than the *sum* of the hormones' individual effects. This interaction is a **synergistic effect** (sin-er-JIS-tik; *sunergos*, working together). An example is the glucose-sparing action of GH and glucocorticoids.
- One hormone can have a **permissive effect** on another. In such cases, the first hormone is needed for the second to produce its effect. For example, epinephrine does not change energy consumption unless thyroid hormones are also present in normal concentrations.
- Finally, hormones may produce different, but complementary, results in specific tissues and organs. These **integrative effects** are important in coordinating the activities of diverse physiological systems. The differing effects of calcitriol and parathyroid hormone on tissues involved in calcium metabolism are an example.

When multiple hormones regulate a complex process, it is very difficult to determine whether a hormone has synergistic, permissive, or integrative effects. Next we consider three examples of processes regulated by complex hormonal interactions: growth, the response to stress, and behavior.

Role of Hormones in Growth

Several endocrine organs work together to bring about normal growth. Several hormones—GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones—are especially important. Many others have secondary effects on growth. The circulating concentrations of these hormones are regulated independently. Every time the hormonal mixture changes, metabolic operations are modified to some degree. The modifications vary in duration and intensity, producing unique individual growth patterns.

- *Growth Hormone (GH).* The effects of GH on protein synthesis and cellular growth are most apparent in children. GH supports their muscular and skeletal development. In adults, growth hormone helps to maintain normal blood glucose concentrations and to mobilize lipid reserves in adipose tissue. GH is not the primary hormone involved, however. An adult with a GH deficiency but normal levels of thyroxine (T_4), insulin, and glucocorticoids will have no physiological problems.
- *Thyroid Hormones.* Normal growth also requires appropriate levels of thyroid hormones. If these hormones are absent during fetal development or for the first year after birth, the nervous system fails to develop normally, and developmental delay results. If T_4 concentrations decline later in life but before puberty, normal skeletal development does not continue.
- *Insulin.* Growing cells need adequate supplies of energy and nutrients. Without insulin, the passage of glucose and amino acids across plasma membranes stops or is drastically reduced.
- *Parathyroid Hormone (PTH) and Calcitriol.* Parathyroid hormone and calcitriol promote the absorption of calcium salts from the bloodstream for deposition in bone. Without adequate levels of both hormones, bones can still enlarge, but are poorly mineralized, weak, and flexible. For example, *rickets* is a condition typically caused by inadequate calcitriol production due to vitamin D deficiency in growing children. As a result, the lower limb bones are so weak that they bend under the body's weight. ↩ p. 164
- *Reproductive Hormones.* The presence or absence of reproductive hormones (androgens in males, estrogens in females) affects the activity of osteoblasts in key locations and the growth of specific cell populations. Androgens and estrogens stimulate cell growth and differentiation in their target tissues, but their targets differ. The differential growth induced by each accounts for gender-related differences in skeletal proportions and secondary sex characteristics.

The Hormonal Responses to Stress

Any condition—physical or emotional—that threatens homeostasis is a form of **stress**. Specific homeostatic adjustments oppose many stresses. For example, a decrease in body temperature leads to shivering or changes in the pattern of blood flow, which can restore normal body temperature.

In addition, the body has a *general* response to stress that can occur while other, more specific responses are under way. A wide variety of stress-causing factors produce the same general pattern of hormonal and physiological adjustments. These responses are part of the **general adaptation syndrome (GAS)**, also known as the **stress response**. GAS has three phases: the *alarm phase*, the *resistance phase*, and the *exhaustion phase* (**Spotlight Figure 18–20**).

The Effects of Hormones on Behavior

As we have seen, the hypothalamus regulates many endocrine functions, and hypothalamic neurons monitor the levels of many circulating hormones. Other portions of the CNS are also quite sensitive to hormonal stimulation.

We can see the behavioral effects of specific hormones most clearly in individuals whose endocrine glands are oversecreting or undersecreting. But even normal changes in circulating hormone levels can cause behavioral changes. For example, in *precocious* (premature) *puberty*, sex hormones are produced at an inappropriate time, perhaps as early as age 5 or 6. Not only does an affected child begin to develop adult secondary sex characteristics, but the child's behavior also changes. The "nice little kid" disappears, and the child becomes aggressive and assertive due to the effects of sex hormones on CNS function. In normal teenagers, these behaviors are usually attributed to environmental stimuli, such as peer pressure, but here we can see that they have a physiological basis as well. In adults, changes in the mixture of hormones reaching the CNS can affect intellectual capabilities, memory, learning, and emotional states.

We now briefly turn to the effects of aging on hormone production.

Aging and Hormone Production

The endocrine system undergoes few functional changes with age. An exception is the decline in the concentrations of reproductive hormones. We noted the effects of these hormonal changes on the skeletal system in Chapter 6 ↩ p. 204, and we continue the discussion in Chapter 29.

Blood and tissue concentrations of many other hormones, including TSH, thyroid hormones, ADH, PTH, prolactin, and glucocorticoids, do not change with advancing age. Circulating hormone levels may remain within normal limits, but some endocrine tissues become less responsive to stimulation. For example, in elderly people, smaller amounts of GH and insulin are secreted after a carbohydrate-rich meal. The reduced levels of GH and other tropic hormones affect tissues throughout the body. These hormonal effects involve the reductions in bone density and muscle mass noted in earlier chapters.

Finally, age-related changes in peripheral tissues may make them less responsive to some hormones. This loss of sensitivity has been documented in the case of glucocorticoids and ADH.

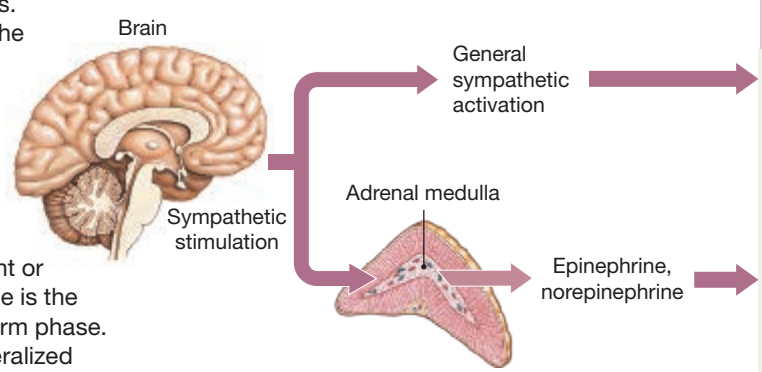
SPOTLIGHT

Figure 18–20
The General Adaptation Syndrome

Alarm Phase ("Fight or Flight")

ALARM

During the **alarm phase**, an immediate response to the stress occurs. The sympathetic division of the autonomic nervous system directs this response. In the alarm phase, (1) energy reserves are mobilized, mainly in the form of glucose, and (2) the body prepares to deal with the stress-causing factor by "fight or flight" responses. Epinephrine is the dominant hormone of the alarm phase. Its secretion is part of a generalized sympathetic activation.



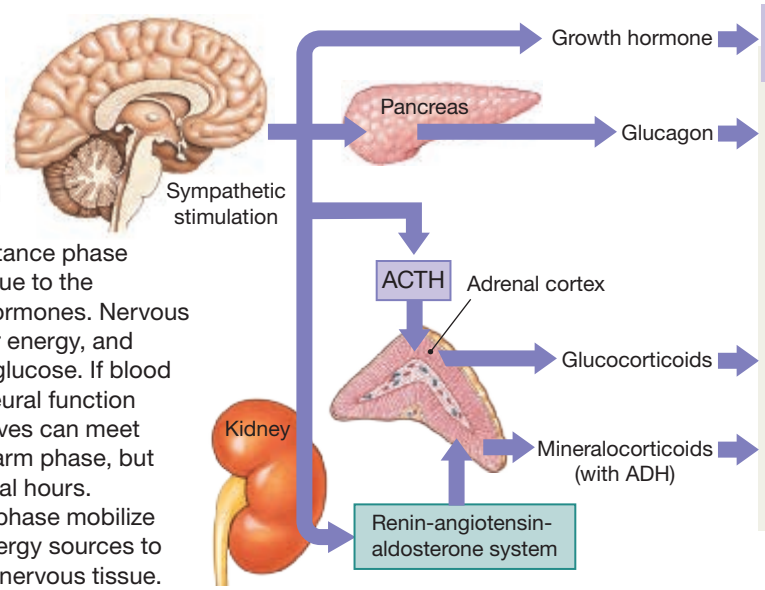
Immediate Short-Term Responses to Crises

- Increased mental alertness
- Increased energy use by all cells
- Mobilization of glycogen and lipid reserves
- Changes in circulation
- Decreased digestive activity and urine production
- Increased sweat gland secretion
- Increased heart rate and respiratory rate

Resistance Phase

RESISTANCE

If a stress lasts longer than a few hours, the person enters the **resistance phase** of GAS. Glucocorticoids are the dominant hormones of the resistance phase. Epinephrine, GH, and thyroid hormones are also involved. Energy demands in the resistance phase remain higher than normal, due to the combined effects of these hormones. Nervous tissue has a high demand for energy, and requires a reliable supply of glucose. If blood glucose level falls too low, neural function deteriorates. Glycogen reserves can meet neural demand during the alarm phase, but become depleted after several hours. Hormones of the resistance phase mobilize lipids and amino acids as energy sources to conserve glucose for use by nervous tissue.



Long-Term Metabolic Adjustments

- Mobilization of remaining energy reserves: Lipids are released by adipose tissue; amino acids are released by skeletal muscle
- Conservation of glucose: Peripheral tissues (except nervous) break down lipids to obtain energy
- Elevation of blood glucose concentration: Liver synthesizes glucose from other carbohydrates, amino acids, and lipids
- Conservation of salts and water, loss of K^+ and H^+

Exhaustion Phase

EXHAUSTION

The body's lipid reserves are sufficient to maintain the resistance phase for weeks or even months. But when the resistance phase ends, homeostatic regulation breaks down and the **exhaustion phase** begins. Unless corrective actions are taken almost immediately, the failure of one or more organ systems will prove fatal. The production of aldosterone throughout the resistance phase results in a conservation of Na^+ at the expense of K^+. As the body's K^+ content decreases, a variety of cells begin to malfunction. The underlying problem of the exhaustion phase is the body's inability to sustain the endocrine and metabolic adjustments of the resistance phase.

Collapse of Vital Systems

- Exhaustion of lipid reserves
- Cumulative structural or functional damage to vital organs
- Inability to produce glucocorticoids
- Failure of electrolyte balance

Clinical Note Hormones and Athletic Performance

The use of hormones to improve athletic performance is widely banned. The International Olympic Committee, the U.S. Olympic Committee, the National Collegiate Athletic Association, Major League Baseball, and the National Football League all ban it. The American Medical Association and the American College of Sports Medicine condemn the practice. Yet athletes such as Lance Armstrong, the seven-time winner of the Tour de France cycling event, admit to "doping." Athletes most often use anabolic steroids, growth hormone, erythropoietin, and a variety of synthetic hormones.

Androgen Abuse

The use of *anabolic steroids* (synthetic androgens) has become popular with many amateur and professional athletes. The goal of steroid use is to increase muscle mass, endurance, and "competitive spirit." One supposed justification for steroid use is the unfounded opinion that compounds made in the body are not only safe, but good for you. In reality, the administration of natural or synthetic androgens in abnormal amounts carries unacceptable health risks. Androgens are known to produce several complications. These problems include (1) premature closure of epiphyseal cartilages, (2) various liver dysfunctions (such as jaundice and liver tumors), (3) prostate gland enlargement and urinary tract obstruction, and (4) testicular atrophy and infertility. Links to heart attacks, impaired cardiac function, and strokes have also been suggested.

The normal regulation of androgen production involves a feedback mechanism comparable to that described for adrenal steroids earlier in this chapter. GnRH stimulates the production of LH, and LH stimulates the secretion of testosterone and other androgens by the interstitial endocrine cells of the testes. Circulating androgens, in turn, inhibit the production of both GnRH and LH. For this reason, high doses of synthetic androgens can suppress the normal production of testosterone and depress the manufacture of GnRH by the hypothalamus. *This suppression of GnRH release can be permanent*.

The use of androgens as "bulking agents" by female bodybuilders may add muscle mass, but it can also alter muscular proportions and secondary sex characteristics. For example, women taking steroids can develop irregular menstrual periods and changes in body hair distribution (such as baldness). Finally, androgen abuse can depress the immune system.

Erythropoietin Abuse

Erythropoietin (EPO) is readily available because it is now synthesized by recombinant DNA techniques. Endurance athletes, such as cyclists and marathon runners, sometimes use it to boost the number of oxygen-carrying red blood cells in the bloodstream. This effect increases the oxygen content of the blood, but it also makes the blood more viscous. For this reason, the heart must work harder to push the "thicker" blood through the blood vessels. This effort can result in death due to heart failure or stroke in young and otherwise healthy individuals. Lance Armstrong admitted publicly to repeated use of performance-enhancing drugs including EPO, testosterone, and growth hormone. He was stripped of all seven cycling titles and has been banned from the sport for life.

Androgens and EPO are hormones with reasonably well-understood effects. Drug testing is now widespread in amateur and professional sports, but athletes interested in "getting an edge" are experimenting with drugs not easily detected by standard tests. The long-term and short-term effects of these drugs are difficult to predict.

Gamma-hydroxybutyrate Use

Another drug used by amateur athletes is *gamma-hydroxybutyrate (GHB)*. It was tested for use as an anesthetic in the 1960s, but rejected in part because it was linked to seizures. In 1990, the drug appeared in health-food stores. It was sold as an anabolic agent and diet aid. It has also been used as a "date rape" drug. According to the FDA, GHB and related compounds—sold or distributed under the names Renewtrient, Revivarant, Blue Nitro, Firewater, and Serenity—have recently been responsible for serious illnesses and even deaths. Signs and symptoms include reduced heart rate, lowered body temperature, confusion, hallucinations, seizures, and coma at doses from 0.25 teaspoon to 4 tablespoons.

Extensive integration occurs between the endocrine system and other body systems. For all systems, the endocrine system adjusts metabolic rates and use of substrates such as glucose, triglycerides, and amino acids. It also regulates growth and development. Build Your Knowledge **Figure 18–21** shows the functional relationships between the endocrine system and other body systems we have studied so far.

Checkpoint

29. **Insulin decreases the blood glucose level and glucagon increases the blood glucose level. This is an example of which type of hormonal interaction?**
30. **The lack of which hormones would inhibit skeletal formation?**
31. **Why do levels of GH–RH and CRH rise during the resistance phase of the general adaptation syndrome?**
32. **Discuss the general role of the endocrine system in the functioning of other body systems.**
33. **Discuss the functional relationship between the endocrine system and the muscular system.**

Build Your Knowledge

Figure 18–21 Integration of the ENDOCRINE system with the other body systems presented so far.

Integumentary System

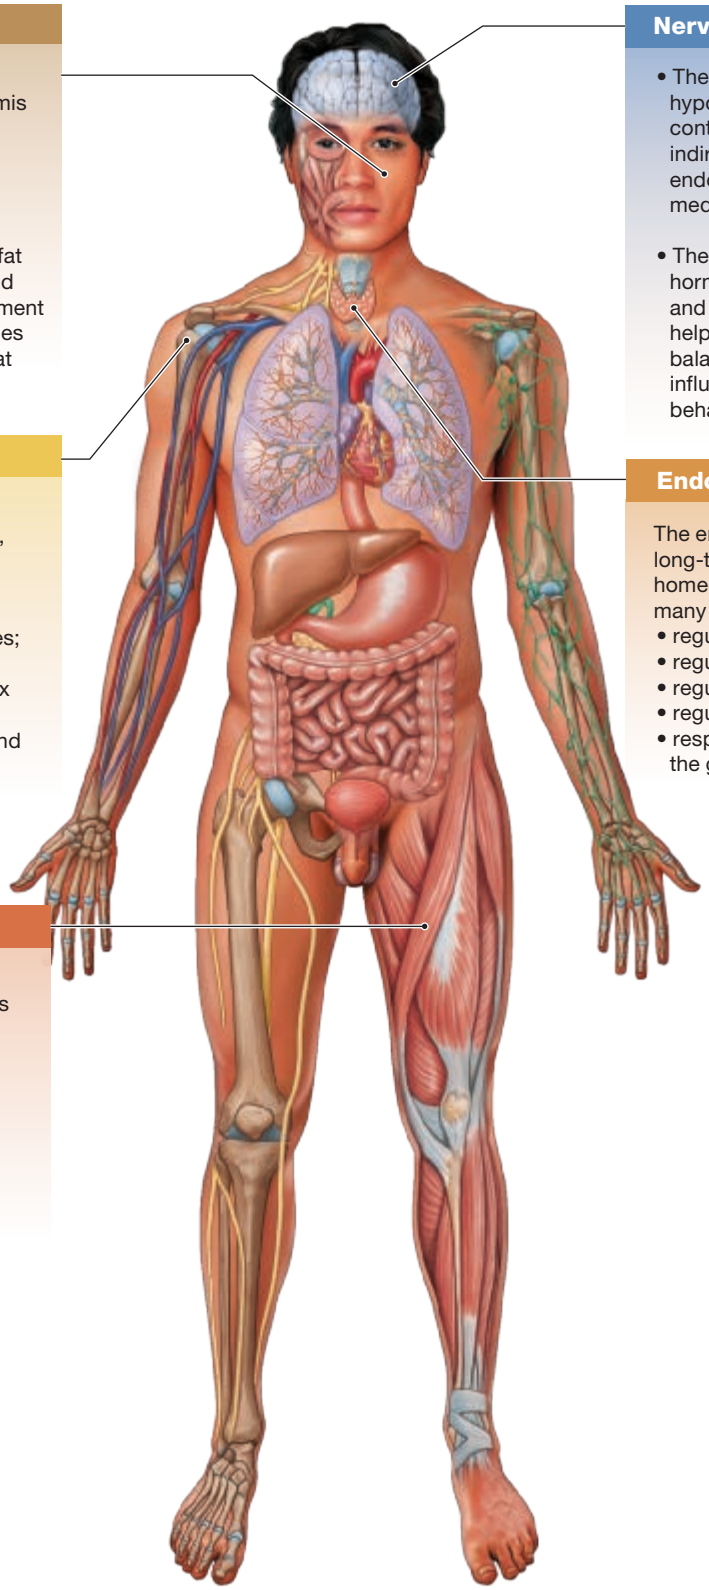
- The Integumentary System protects superficial endocrine organs; epidermis synthesizes vitamin D_3 (precursor to calcitriol production)
- The endocrine system secretes sex hormones that stimulate sebaceous gland activity, influence hair growth, fat distribution, and apocrine sweat gland activity; PRL that stimulates development of mammary glands; adrenal hormones that alter dermal blood flow; MSH that stimulates melanocyte activity

Skeletal System

- The Skeletal System protects endocrine organs, especially in brain, chest, and pelvic cavity
- The endocrine system regulates skeletal growth with several hormones; calcium homeostasis regulated primarily by parathyroid hormone; sex hormones speed growth and closure of epiphyseal cartilages at puberty and help maintain bone mass in adults

Muscular System

- The Muscular System provides protection for some endocrine organs
- The endocrine system secretes hormones that adjust muscle metabolism, energy production, and growth; regulate calcium and phosphate levels in body fluids; speed skeletal muscle growth



Nervous System

- The Nervous System produces hypothalamic hormones that directly control pituitary secretions and indirectly control secretions of other endocrine organs; controls adrenal medulla; secretes ADH and oxytocin
- The endocrine system secretes several hormones that affect neural metabolism and brain development; hormones that help regulate fluid and electrolyte balance; reproductive hormones that influence CNS development and behaviors

Endocrine System

The endocrine system provides long-term regulation and adjustments of homeostatic mechanisms that affect many body functions. It:

- regulates fluid and electrolyte balance
- regulates cell and tissue metabolism
- regulates growth and development
- regulates reproductive functions
- responds to stressful stimuli through the general adaptation syndrome (GAS)

18 Chapter Review

Study Outline

An Introduction to the Endocrine System p. 611

1. Chemical messengers known as *hormones* regulate human activities such as sleep, body temperature, hunger, and stress management. They are products of the *endocrine system*, which along with the nervous system, controls and coordinates our body processes.

18-1 Homeostasis is preserved through intercellular communication by the nervous and endocrine systems p. 611

2. In general, the nervous system performs short-term "crisis management," whereas the endocrine system regulates longer-term, ongoing metabolic processes.
3. **Paracrine communication** involves the use of chemical signals to transfer information from cell to cell within a single tissue. **Autocrine communication** involves chemicals affecting the same cell that secreted them.
4. **Endocrine communication** results when chemicals, called **hormones**, are released into the circulation by *endocrine cells*. The hormones alter the metabolic activities of many tissues and organs simultaneously by modifying the activities of **target cells**. *(Table 18–1)*

18-2 The endocrine system regulates physiological processes by releasing bloodborne hormones that bind to receptors on remote target organs p. 613

5. The endocrine system includes all the cells and endocrine tissues of the body that produce hormones or paracrine factors. *(Figure 18–1)*
6. Hormones can be divided into three classes according to their chemical structure: *amino acid derivatives*; *peptide hormones*; and *lipid derivatives*, including **steroid hormones** and **eicosanoids**. *(Spotlight Figure 18–2)*
7. Hormones may circulate freely or bound to transport proteins. Free hormones are rapidly removed from the bloodstream.
8. Receptors for *catecholamines*, peptide hormones, and eicosanoids are in the plasma membranes of target cells. Thyroid and steroid hormones cross the plasma membrane and bind to receptors in the cytoplasm or nucleus, activating or inactivating specific genes. *(Spotlight Figure 18–3, Figure 18–4)*
9. Hormone secretion can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions).

18-3 The anterior lobe of the pituitary gland produces and releases hormones under hypothalamic control, while the posterior lobe releases hypothalamic hormones p. 619

10. The **hypothalamus** contains both brain centers and endocrine tissue. It is connected to the **pituitary gland**, or **hypophysis**, by the **infundibulum**. *Figure 18–5)*

11. The **anterior lobe** of the pituitary gland, or **adenohypophysis**, can be subdivided into the **pars distalis**, the **pars intermedia**, and the **pars tuberalis**. *(Figure 18–5)*
12. The hypothalamus regulates the activities of the nervous and endocrine systems. It acts as an endocrine organ by releasing hormones into the bloodstream at the posterior lobe of the pituitary gland; secreting **regulatory hormones**, which control the activities of endocrine cells in the anterior lobe of the pituitary gland; and exerting direct neural control over the endocrine cells of the adrenal medulla. *(Figure 18–6)*
13. At the median eminence of the hypothalamus, neurons release regulatory hormones (either **releasing hormones**, **RH**, or **inhibiting hormones**, **IH**) into the surrounding interstitial fluids through **fenestrated capillaries**. *(Figure 18–7)*
14. The **hypophyseal portal system** ensures that these regulatory hormones reach the intended target cells in the pituitary before they enter the general circulation. *(Figure 18–7)*
15. The pituitary gland releases nine important peptide hormones; seven come from the anterior lobe and two from the posterior lobe. The tropic hormones of the anterior lobe "turn on" endocrine glands or support the functions of other organs. *(Figure 18–8; Table 18–2)*
16. **Thyroid-stimulating hormone (TSH)** triggers the release of thyroid hormones. *Thyrotropin-releasing hormone (TRH)* from the hypothalamus promotes the pituitary's secretion of TSH. *(Figure 18–9)*
17. **Adrenocorticotropic hormone (ACTH)** stimulates the release of *glucocorticoids* by the adrenal cortex. Corticotropin-releasing hormone (CRH) from the hypothalamus causes the pituitary to secrete ACTH. *(Figure 18–9)*
18. **Follicle-stimulating hormone (FSH)** stimulates follicle development and estrogen secretion in females and sperm production in males. **Luteinizing hormone (LH)** causes *ovulation* and *progesterone* production in females, and androgen production in males. Gonadotropin-releasing hormone (GnRH) from the hypothalamus promotes the pituitary's secretion of both FSH and LH. *(Figure 18–9)*
19. **Prolactin (PRL)** from the pituitary, together with other hormones, stimulates both the development of the mammary glands and milk production. *(Figure 18–9)*
20. **Growth hormone** (**GH**, or **somatotropin**) from the pituitary stimulates cell growth and replication through the release of **somatomedins**, also called **insulin-like growth factors (IGFs)** from liver cells. The production of GH is regulated

by **growth hormone–releasing hormone (GH–RH)** and **growth hormone–inhibiting hormone (GH–IH)** from the hypothalamus. *(Figure 18–9)*

21. **Melanocyte-stimulating hormone (MSH)** may be secreted by the pars intermedia of the pituitary during fetal development, early childhood, pregnancy, or certain diseases. This hormone stimulates melanocytes to produce melanin.
22. The **posterior lobe** of the pituitary gland, or **neurohypophysis**, contains the unmyelinated axons of hypothalamic neurons. Neurons of the **supra-optic** and **paraventricular nuclei** manufacture **antidiuretic hormone (ADH)** and **oxytocin (OXT)**, respectively. ADH decreases the amount of water lost at the kidneys and, in higher concentrations, elevates blood pressure. In women, oxytocin stimulates contractile cells in the mammary glands and has a stimulatory effect on smooth muscles in the uterus. *(Figure 18–9; Table 18–2)*

18-4 The thyroid gland synthesizes thyroid hormones that affect the rate of metabolism p. 627

23. The thyroid gland lies anterior to the *thyroid cartilage* of the larynx and consists of two **lobes** connected by a narrow **isthmus**. *(Figure 18–10)*
24. The thyroid gland contains numerous **thyroid follicles**. Thyroid follicles release several hormones, including **thyroxine** and **triiodothyronine**. *(Figures 18–10, 18–11; Table 18–4)*
25. Most of the thyroid hormones entering the bloodstream are attached to special **thyroid-binding globulins (TBGs)**; the rest are attached to either **transthyretin** or albumin. *(Figure 18–11)*
26. In target cells, thyroid hormones are held in storage in the cytoplasm, bound to mitochondria (where they increase ATP production), or bound to receptors activating genes that control energy utilization. They also exert a **calorigenic effect**. *(Table 18–3)*
27. The **C cells** of the thyroid follicles produce **calcitonin (CT)**, which possibly helps regulate Ca^{2+} concentrations in body fluids, especially during childhood and pregnancy. *(Figure 18–10; Table 18–4)*

18-5 The four parathyroid glands secrete parathyroid hormone, which increases the blood calcium ion level p. 632

28. Four **parathyroid glands** are embedded in the posterior surfaces of the thyroid gland. **Parathyroid (principal) cells** produce **parathyroid hormone (PTH)** in response to lower-than-normal concentrations of Ca^{2+}. The parathyroid glands, aided by *calcitriol*, are the primary regulators of blood calcium levels in healthy adults. *(Figures 18–12, 18–13; Table 18–4)*

18-6 The paired adrenal glands secrete several hormones that affect electrolyte balance and stress responses p. 634

29. One **adrenal** *(suprarenal)* **gland** lies along the superior border of each kidney. The gland is subdivided into the superficial **adrenal cortex** and the inner **adrenal medulla**. *(Figure 18–14)*
30. The adrenal cortex manufactures steroid hormones called **corticosteroids**. The cortex can be subdivided into three areas: (1) the **zona glomerulosa**, which releases **mineralocorticoids**, principally **aldosterone**; (2) the **zona fasciculata**, which produces **glucocorticoids**, notably **cortisol**, **corticosterone, and cortisone**; and (3) the **zona reticularis**, which produces androgens under ACTH stimulation. *(Figure 18–14)*
31. The adrenal medulla produces epinephrine (75–80 percent of medullary secretion) and norepinephrine (20–25 percent). *(Figure 18–14)*

18-7 The pineal gland secretes melatonin, which affects the circadian rhythm p. 637

32. The **pineal gland** contains **pinealocytes**, which synthesize **melatonin**. Suggested functions include inhibiting reproductive functions, protecting against damage by free radicals, and setting circadian rhythms. *(Figure 18–15)*

18-8 The pancreas is both an exocrine organ and an endocrine gland that produces hormones affecting the blood glucose level p. 637

33. The pancreas contains both exocrine and endocrine cells. Cells of the endocrine pancreas form clusters called **pancreatic islets** *(islets of Langerhans)*. These islets contain **alpha (α) cells**, which secrete the hormone **glucagon; beta (β) cells,** which secrete **insulin; delta (δ) cells**, which secrete **somatostatin (GH–IH)**; and **pancreatic polypeptide (PP) cells**, which secrete **pancreatic polypeptide**. *(Figure 18–16; Table 18–5)*
34. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells; glucagon raises blood glucose by increasing the rates of glycogen breakdown and glucose manufacture in the liver. *(Figure 18–17; Table 18–5)*
35. **Diabetes mellitus** is an endocrine disorder characterized by high blood glucose levels. *(Spotlight Figure 18–18)*

18-9 Many organs have secondary endocrine functions p. 641

36. The intestines produce hormones important in coordinating digestive activities. *(Table 18–6)*
37. Endocrine cells in the kidneys produce the hormones *calcitriol* and *erythropoietin* and the enzyme *renin*. *(Table 18–6)*
38. **Calcitriol** stimulates calcium and phosphate ion absorption along the digestive tract. *(Figure 18–19)*
39. **Erythropoietin (EPO)** stimulates red blood cell production by the red bone marrow. *(Figure 18–19)*
40. In the *renin-angiotensin-aldosterone system (RAAS)*, **renin** converts **angiotensinogen** to **angiotensin I**. In the capillaries of the lungs, angiotensin-converting enzyme (ACE) converts angiotensin I to **angiotensin II**, a hormone that (1) stimulates the adrenal production of aldosterone, (2) stimulates the pituitary release of ADH, (3) promotes thirst, and (4) elevates blood pressure. *(Figure 18–19)*
41. Specialized muscle cells in the heart produce **natriuretic peptides** (*ANP* and *BNP*) when blood volume becomes excessive. In general, their actions oppose those of angiotensin II. *(Table 18–6)*
42. The thymus produces several hormones, collectively known as **thymosins**, which play a role in developing and maintaining normal immune defenses. *(Table 18–6)*

43. The **interstitial endocrine cells** of the testes produce androgens. **Testosterone** is the most important sex hormone in males. *(Table 18–7)*
44. In females, *oocytes* develop in follicles, and follicle cells produce **estrogens**, especially **estradiol**. After ovulation, the remaining follicle cells reorganize into a *corpus luteum*. Those cells release a mixture of estrogens and **progesterone**. *(Table 18–7)*
45. Adipose tissue secretes **leptin** (a feedback control for appetite). *(Table 18–6)*

18-10 Hormones interact over our lifetime to produce coordinated physiological responses p. 646

46. Endocrine system hormones often interact, producing **antagonistic** (opposing) **effects**; **synergistic** (additive) **effects**; **permissive effects**, in which one hormone is necessary for another to produce its effect; or **integrative effects**, in which hormones produce different, but complementary, results.
47. Normal growth requires the cooperation of several endocrine organs. Several hormones are especially important: GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones.
48. Any condition that threatens homeostasis is a **stress**. Our bodies respond to a variety of stress-causing factors through the **general adaptation syndrome (GAS)**, or **stress response**.
49. The GAS can be divided into three phases: (1) the **alarm phase** (an immediate, "fight or flight" response, under the direction of the sympathetic division of the ANS); (2) the **resistance phase**, dominated by glucocorticoids; and (3) the **exhaustion phase**, the eventual breakdown of homeostatic regulation and failure of one or more organ systems. *(Spotlight Figure 18–20)*
50. Many hormones affect the CNS. Changes in the normal mixture of hormones can significantly alter intellectual capabilities, memory, learning, and emotional states.
51. The endocrine system undergoes few functional changes with advanced age. The major changes include a decline in the concentration of growth hormone and reproductive hormones.
52. The endocrine system provides long-term regulation and homeostatic adjustments that affect many body systems. *(Figure 18–21)*

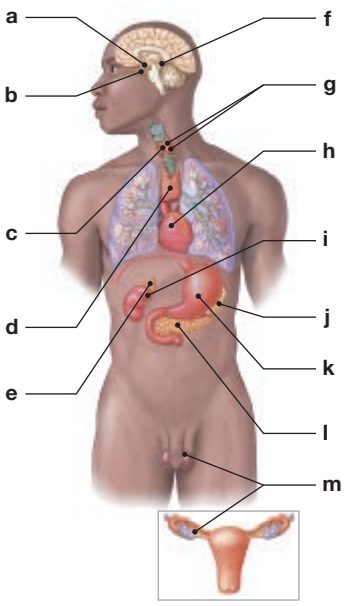
Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The use of a chemical messenger to transfer information from cell to cell within a single tissue is referred to as _____ communication. **(a)** direct, **(b)** paracrine, **(c)** hormonal, **(d)** endocrine.
2. Cyclic AMP functions as a second messenger to **(a)** build proteins and catalyze specific reactions, **(b)** activate adenylate cyclase, **(c)** open ion channels and activate key enzymes in the cytoplasm, **(d)** bind the hormone–receptor complex to DNA segments.
3. Adrenocorticotropic hormone (ACTH) stimulates the release of **(a)** thyroid hormones by the hypothalamus, **(b)** gonadotropins by the adrenal glands, **(c)** growth hormones by the hypothalamus, **(d)** steroid hormones by the adrenal glands.
4. FSH production in males supports **(a)** the maturation of sperm by stimulating nurse cells, **(b)** the development of muscles and strength, **(c)** the production of male sex hormones, **(d)** an increased desire for sexual activity.
5. The two hormones released by the posterior lobe of the pituitary gland are **(a)** GH and gonadotropin, **(b)** estrogen and progesterone, **(c)** GH and prolactin, **(d)** ADH and oxytocin.
6. All of the following are true of the endocrine system, *except* that it **(a)** releases chemicals into the bloodstream for distribution throughout the body, **(b)** releases hormones that simultaneously alter the metabolic activities of many different tissues and organs, **(c)** produces effects that can last for hours, days, and even longer, **(d)** produces rapid, local, brief-duration responses to specific stimuli, **(e)** functions to control ongoing metabolic processes.
7. A cell's hormonal sensitivities are determined by the **(a)** chemical nature of the hormone, **(b)** quantity of circulating hormone, **(c)** shape of the hormone molecules, **(d)** presence or absence of appropriate receptors, **(e)** thickness of its plasma membrane.
8. Identify the endocrine glands and tissues in the following diagram.



(a) _____
(b) _____
(c) _____
(d) _____
(e) _____
(f) _____
(g) _____

9. In what three ways is the hypothalamus involved in integrating the activities of the nervous and endocrine systems?
10. Which seven hormones are released by the anterior lobe of the pituitary gland?

11. What six hormones primarily affect growth?
12. What five primary effects result from the action of thyroid hormones?
13. What effects does parathyroid hormone have on blood calcium level?
14. What three zones make up the adrenal cortex, and what kind of hormones does each zone produce?
15. Which two hormones are released by the kidneys, and what is the importance of each hormone?
16. What are the four opposing effects of natriuretic peptides and angiotensin II?
17. What four cell populations make up the endocrine pancreas? Which hormone does each type of cell produce?

LEVEL 2 Reviewing Concepts

18. What is the primary difference in the way the nervous and endocrine systems communicate with their target cells?
19. In what ways can a hormone modify the activities of its target cells?
20. How would blocking the activity of phosphodiesterase (PDE) affect a cell that responds to hormonal stimulation by the cAMP second messenger system?
21. How does control of the adrenal medulla differ from control of the adrenal cortex?
22. A researcher observes that stimulation by a particular hormone induces a marked increase in the activity of G proteins in the target plasma membrane. The hormone being studied is probably **(a)** a steroid, **(b)** a peptide, **(c)** testosterone, **(d)** estrogen, **(e)** aldosterone.
23. Decreased blood calcium level would result in *increased* **(a)** secretion of calcitonin, **(b)** secretion of PTH, **(c)** elimination of calcium by the kidneys, **(d)** osteoclast activity, **(e)** excitability of neural membranes.
24. In Type 2 diabetes, insulin levels are frequently normal, yet the target cells are less sensitive to the effects of insulin. This suggests that the target cells **(a)** are impermeable to insulin, **(b)** may lack enough insulin receptors, **(c)** cannot convert insulin to an active form, **(d)** have adequate internal supplies of glucose, **(e)** both b and c.

LEVEL 3 Critical Thinking and Clinical Applications

25. Roger has been extremely thirsty. He drinks numerous glasses of water every day and urinates a great deal. Name two disorders that could produce these signs and symptoms. What test could a clinician perform to determine which disorder Roger has?
26. Julie is pregnant but is not receiving prenatal care. She has a poor diet consisting mostly of fast food. She drinks no milk, preferring colas instead. How would this situation affect Julie's parathyroid hormone level?
27. Sherry tells her physician that she has been restless and irritable lately. She has a hard time sleeping and complains of diarrhea and weight loss. During the examination, her physician notices a higher-than-normal heart rate and a fine tremor in her outstretched fingers. What tests could the physician perform to make a positive diagnosis of Sherry's condition?
28. What are two benefits of having a portal system connect the median eminence of the hypothalamus with the anterior lobe of the pituitary gland?
29. Pamela and her teammates are considering taking anabolic steroids (synthetic hormones derived from testosterone) to enhance their competitive skills. What natural effects of testosterone are they hoping to gain? What additional side effects might these women expect should they begin an anabolic steroid regime?

CLINICAL CASE Wrap-Up Stones, Bones, and Groans

The doctor jokes with Monica that she has a case of "stones, bones, and groans." He then shows her the lab results, which indicate an elevated blood calcium (Ca^{2+}) level—a pivotal key to diagnosing Monica's condition.

Calcium is critical in the control of many systems. It provides the means for cholinergic synapses to work, including those in the CNS, all neuron-to-neuron synapses in the PNS, and all neuromuscular junctions. Calcium also plays an essential role in the muscular contraction cycles of all skeletal, smooth, and cardiac muscles. In addition, it strengthens the skeleton, which acts as a Ca^{2+} storage system. Calcium is the most closely regulated element in our bodies.

The parathyroid glands function to increase the blood calcium ion concentration. Normally the four small parathyroid glands produce parathyroid hormone (PTH). Their principal cells monitor the circulating concentration of Ca^{2+} and produce PTH in a negative feedback control system.

It turns out that one of Monica's parathyroid glands has a benign tumor that is producing PTH without feedback control. The excess PTH causes the elevated blood Ca^{2+} level, osteopenia, and bone pain. The elevated blood Ca^{2+} is responsible for Monica's heart palpitations, kidney stones, muscle fatigue, memory loss, depression, and irritability.

Outpatient surgery is performed to remove the tumor. The remaining three parathyroid glands take over normal Ca^{2+} regulation. Monica soon begins to feel like herself again.

1. In addition to mobilizing calcium from bone, how else does PTH increase the blood calcium ion level?
2. What hormone counteracts PTH and decreases the blood Ca^{2+} level?

See the blue Answers tab at the back of the book. Note also that calcium homeostasis was introduced in Chapter 6 and can be reviewed in Figure 6–16.

Related Clinical Terms

adrenalectomy: Surgical removal of an adrenal gland.
empty sella syndrome: Condition in which the pituitary gland becomes shrunken or flattened.
exophthalmos: Abnormal protrusion of the eyeballs.
galactorrhea: A milky discharge from the nipple unrelated to normal breast feeding.
Hashimoto disease: Disorder that affects the thyroid gland, causing the immune system to attack the thyroid gland. It is the most common cause of hypothyroidism in the United States; also known as *chronic lymphocytic thyroiditis*.
hirsutism: Excessive growth of facial or body hair in a woman. Hirsutism is a sign of hyperandrogenism, or the presence of abnormally high levels of androgens. It may be a sign of polycystic ovarian syndrome, congenital adrenal hyperplasia (CAH), or androgen-secreting tumors, all of which may cause infertility in women.
hypocalcemic tetany: Muscle spasms affecting the face and upper extremities; caused by low Ca^{2+} concentrations in body fluids.
hypophysectomy: Surgical removal of the pituitary gland.
posttraumatic stress disorder (PTSD): A common anxiety disorder that develops after being exposed to a life-threatening situation or terrifying event.
prolactinoma: Noncancerous pituitary tumor that produces prolactin, resulting in too much prolactin in the blood.
psychosocial dwarfism: Growth disorder occurring between the ages of 2 and 15, caused by extreme emotional deprivation or stress; also called *deprivation dwarfism*.
thyroid function tests: Blood and radionuclide tests to determine thyroid gland activity.
thyroidectomy: Surgical removal of all or part of the thyroid gland.
thyrotoxicosis: A condition caused by the oversecretion of thyroid hormones (hyperthyroidism). Signs and symptoms include increases in metabolic rate, blood pressure, and heart rate; excitability and emotional instability; and lowered energy reserves.
virilism: A disorder of females in which there is development of secondary male sexual characteristics such as hirsutism and lowered voice caused by a number of conditions that affect hormone regulation.

19 Blood

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

19-1 ■ **Describe the components and major functions of blood, identify blood collection sites, list the physical characteristics of blood, and specify the composition and functions of plasma.** p. 657

19-2 ■ **List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, explain erythropoiesis, and discuss respiratory gas transport.** p. 659

19-3 ■ **Explain the importance of blood typing and the basis for ABO and Rh incompatibilities.** p. 666

19-4 ■ **Categorize white blood cell types based on their structures and functions, and discuss the factors that regulate the production of each type.** p. 670

19-5 ■ **Describe the structure, function, and production of platelets.** p. 678

19-6 ■ **Discuss the mechanisms that control blood loss after an injury, and describe the reaction sequences responsible for blood clotting.** p. 678

CLINICAL CASE Crisis in the Blood

She feels that same pain she had as a child: This time it comes from her legs, sharp and desperate. Clare has let things get out of control and she knows better. It was just hard to manage with the pressures of her classes in the pre-nursing program and her part-time job. She is exhausted, isn't eating well, and has badly neglected her fluid intake. Clare looks down at her legs and sees how red and swollen they look. Her feet feel icy. She winces as the bone-deep pain surges along her shins. Now that she is studying anatomy and physiology, Clare understands better than ever what is happening in her own bloodstream. Clare knows she is in for another trip to the hospital.

Her roommate gives her a ride to the local emergency room. They don't know her here like they did at home. The nurse practitioner listens carefully and learns about Clare's medical history. On physical examination, Clare is running a temperature, and her heart rate and blood pressure are elevated. Her sunken eyes and loss of skin elasticity reveal significant dehydration. The nurse practitioner sends a sample of blood to the lab to confirm Clare's blood condition. Clare's leg pain has become so severe that she is given a dose of morphine (an opioid painkiller) and is admitted for stabilization. **What crisis is occurring in Clare's blood? To find out, turn to the Clinical Case Wrap-Up on p. 686.**

An Introduction to Blood and the Cardiovascular System

In this chapter we discuss the nature of *blood*, the fluid connective tissue of the **cardiovascular system**. This body system also includes a pump (the heart) that circulates the fluid and a series of conducting hoses (the blood vessels) that carry it throughout the body. In this chapter we take a close look at the structure and functions of blood. We discuss the heart in Chapter 20 and the blood vessels in Chapter 21.

19-1 Blood, composed of plasma and formed elements, provides transport, regulation, and protective services to the body

Learning Outcome Describe the components and major functions of blood, identify blood collection sites, list the physical characteristics of blood, and specify the composition and functions of plasma.

Blood is a specialized connective tissue that contains cells suspended in a fluid matrix. In Chapter 4 we introduced the components and properties of this tissue. ↩ p. 135 In this chapter we cover the components of blood, and the processes of these components that allow this fluid tissue to perform its functions.

Functions of Blood

The blood of the cardiovascular system performs many vital roles. These services are essential to each of the body's roughly 75 trillion cells—so much so that any cell deprived of circulation may die in a matter of minutes. Let's look a bit closer at these functions of blood:

- *Transporting Dissolved Gases, Nutrients, Hormones, and Metabolic Wastes.* Circulating blood contains *red blood cells* that carry oxygen from the lungs to peripheral tissues, and carbon dioxide from those tissues back to the lungs. Blood distributes nutrients absorbed by the digestive tract or released from storage in adipose tissue or in the liver. It carries hormones from endocrine glands toward their target cells, as noted in Chapter 18. It also absorbs the wastes produced by tissue cells and carries them to the kidneys for excretion.
- *Regulating the pH and Ion Composition of Interstitial Fluids.* Diffusion between interstitial fluids and blood eliminates local deficiencies or excesses of ions, such as calcium or potassium. Blood also absorbs and neutralizes acids, such as lactic acid, generated by active skeletal muscles.
- *Restricting Fluid Losses at Injury Sites.* Blood contains enzymes and other substances that respond to breaks in vessel walls by initiating the *clotting* process. A blood clot acts as a temporary patch that prevents further blood loss.
- *Defending against Toxins and Pathogens.* Blood transports *white blood cells*, specialized cells that migrate into other tissues to fight infections or remove debris. Blood also delivers *antibodies*, proteins that specifically attack invading pathogens.
- *Stabilizing Body Temperature.* Blood absorbs the heat generated by active skeletal muscles and redistributes it to other tissues. If body temperature is already high, that heat will be lost across the skin surface. If body temperature is too low, the warm blood is directed to the brain and to other temperature-sensitive organs.

Characteristics of Blood

Whole blood from any source—veins, capillaries, or arteries—has the same basic physical characteristics:

- Blood temperature is about 38°C (100.4°F), slightly above normal body temperature.
- Blood is five times as viscous as water—that is, five times as sticky, five times as cohesive, and five times as resistant to flow as water. The high viscosity results from interactions among dissolved proteins, formed elements, and water molecules in plasma.
- Blood is slightly alkaline, with a pH between 7.35 and 7.45.

Adult males typically have more blood than do adult females. We can estimate blood volume in liters for a person of either sex by calculating 7 percent of the body weight in kilograms. For example, a 75-kg (165-lb) person would have a blood volume of approximately 5.25 liters (5.4 quarts).

Components of Blood

Spotlight Figure 19–1 (p. 660) describes the composition of **whole blood**, which is made up of fluid *plasma* and *formed elements* (cells and cell fragments). The components of whole blood can be **fractionated**, or separated, for analytical or clinical purposes.

Plasma

As shown in the top half of Spotlight Figure 19–1, **plasma** makes up about 55 percent of the volume of whole blood. The components of plasma include plasma proteins, other solutes (primarily nutrients, electrolytes, and wastes), and water.

Plasma Proteins. Plasma contains significant quantities of dissolved proteins, namely *albumins*, *globulins*, and *fibrinogen*. These three types make up more than 99 percent of the plasma proteins. (The remaining 1 percent of plasma proteins is composed of enzymes and hormones whose levels vary widely.)

- **Albumins** (al-BYŪ-minz) make up the majority of the plasma proteins. Thus, they are the major contributors to plasma osmolarity and osmotic pressure. Albumins are also important for transporting fatty acids, thyroid hormones, some steroid hormones, and other substances.
- **Globulins** are the second most-abundant proteins in plasma. Examples of plasma globulins include antibodies (*immunoglobulins*) that aid in body defense and *transport globulins*. We cover antibodies in depth with immunity in Chapter 22. Transport globulins bind small ions, hormones, and substances that might otherwise be removed by the kidneys or that have very low water solubility. Transport globulins include *hormone-binding proteins*, which provide a reserve of hormones in the bloodstream. Examples include thyroid-binding globulin and transthyretin, which transport thyroid hormones, and transcortin, which transports ACTH. There are also *metalloproteins* that transport metal ions. Later we will see an example of this in transferrin, which transports iron (Fe^{2+}). In addition, *apolipoproteins* (ap-ō-lip-ō-PRŌ-tēnz) carry triglycerides and other lipids in blood. When bound to lipids, an apolipoprotein becomes a *lipoprotein* (LĪ-pō-prō-tēn). Finally, *steroid-binding proteins* transport steroid hormones in blood. For example, testosterone-binding globulin (TeBG) binds and transports testosterone.
- The third major type of plasma protein, **fibrinogen**, functions in clotting. If steps are not taken to prevent clotting in a blood sample, fibrinogen (a soluble protein) will be converted to *fibrin* (an insoluble protein). This conversion removes the clotting proteins, leaving a fluid known as **serum**. The clotting process also removes calcium ions and other materials from solution, so plasma and serum differ in several significant ways. (See Appendix.) Therefore, the results of a blood test generally indicate whether a sample was plasma or serum.

+ Clinical Note Plasma Expanders

Plasma expanders can be used to increase blood volume temporarily, over a period of hours. They are often used to buy time for lab work to determine a person's blood type. (Transfusion of the wrong blood type can kill the recipient.) Isotonic electrolyte solutions such as normal (physiological) saline can be used as plasma expanders, but their effects are short-lived due to diffusion into interstitial fluid and cells. This fluid loss is slowed by the addition of solutes that cannot freely diffuse across plasma membranes. One example is lactated *Ringer's solution*, an isotonic saline also containing lactate, potassium chloride, and calcium chloride ions. The effects of Ringer's solution fade gradually as the liver, skeletal muscles, and other tissues absorb and metabolize the lactate ions. Another option is isotonic saline solution containing purified human albumin.

However, the plasma expanders in clinical use often contain large carbohydrate molecules, rather than proteins, to maintain proper osmotic concentration. These carbohydrates are not metabolized, but phagocytes gradually remove them from the bloodstream, and blood volume slowly declines. Plasma expanders are easily stored. Their sterile preparation avoids viral or bacterial contamination, which can be a problem with donated plasma. Note that plasma expanders provide a temporary solution to low blood volume, but they do not increase the amount of oxygen carried by the blood. Red blood cells are needed for that function.

Origins of the Plasma Proteins. The liver synthesizes and releases more than 90 percent of the plasma proteins, including all albumins and fibrinogen, most globulins, and various proenzymes. Hence, liver disorders can alter the composition and functional properties of blood. For example, some forms of liver disease can lead to uncontrolled bleeding due to the inadequate synthesis of fibrinogen and other proteins involved in clotting.

Formed Elements

The **formed elements** of blood are made up primarily of red blood cells, white blood cells, and cell fragments known as *platelets*. Formed elements make up about 45 percent of whole blood volume. The percentage of a blood sample that consists of formed elements (most of which are red blood cells) is known as the *hematocrit* (hē-MAH-tō-krit). Formed elements are produced in the process of **hemopoiesis** (hē-mō-POY-eh-sis). Please study the bottom half of Spotlight Figure 19–1 now for an introduction to these elements and hemopoiesis. Most of the rest of this chapter discusses the functions of the formed elements, starting with red blood cells.

Checkpoint

1. List five major functions of blood.
2. Identify the three types of formed elements in blood.
3. List the three major types of plasma proteins.
4. What would be the effects of a decrease in the amount of plasma proteins?

See the blue Answers tab at the back of the book.

19-2 Red blood cells, formed by erythropoiesis, contain hemoglobin that transports respiratory gases

Learning Outcome List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, explain erythropoiesis, and discuss respiratory gas transport.

The most abundant blood cells are the **red blood cells (RBCs)**, also called **erythrocytes** (eh-RITH-rō-sītz), which account for 99.9 percent of the formed elements. These cells give whole blood its deep red color because they contain the red pigment *hemoglobin* (HĒ-mō-glō-bin), which binds and transports the respiratory gases oxygen and carbon dioxide.

Abundance of RBCs: The Hematocrit

RBCs make up roughly one-third of all cells in the human body. A standard blood test reports the number of RBCs per microliter (μL) of whole blood as the *red blood cell count*. In adult males, 1 microliter, or 1 *cubic millimeter* (mm^3), of whole blood contains 4.5–6.3 million RBCs. In adult females, 1 microliter contains 4.2–5.5 million. A single drop of whole blood contains approximately 260 million RBCs. The blood of an average adult has 25 trillion RBCs.

The **hematocrit** is determined by spinning a blood sample in a centrifuge so that all the formed elements come out of suspension. Whole blood contains about 1000 red blood cells for each white blood cell. After centrifugation, the white blood cells and platelets form a very thin *buffy coat* above a thick layer of RBCs.

Many conditions can affect the hematocrit. For example, the hematocrit increases during dehydration, due to a decrease in plasma volume, or after stimulation with the hormone *erythropoietin* (eh-rith-rō-POY-eh-tin). ↩ p. 644 The hematocrit decreases as a result of internal bleeding or problems with RBC formation. So, the hematocrit alone does not provide specific diagnostic information. Still, an abnormal hematocrit is an indication that other, more specific tests are needed. (Examples of such tests are described in Table 19–1 on p. 665.)

Relationship of RBC Structure to RBC Function

Red blood cells are among the most specialized cells of the body. A red blood cell is very different from the "typical cell" discussed in Chapter 3. Each RBC is a biconcave disc with a thin

Clinical Note Collecting Blood for Analysis

Fresh whole blood is generally collected from a superficial vein, such as the *median cubital vein* on the anterior surface of the elbow. The procedure is called **venipuncture** (VĒN-i-punk-chur; *vena*, vein + *punctura*, a piercing). It is a common sampling technique because (1) superficial veins are easy to locate, (2) the walls of veins are thinner than those of comparably sized arteries, and (3) blood pressure in the venous system is relatively low, so the puncture wound seals quickly. The most common clinical procedures examine venous blood.

A small drop of blood can be used to prepare a *blood smear*, a thin film of blood on a microscope slide. The blood smear is then stained with special dyes to show each type of formed element. Blood from peripheral capillaries can be obtained by puncturing the tip of a finger, an earlobe, or (in infants) the great toe or heel. Small amounts of capillary blood can also be used to test glucose, cholesterol, and hemoglobin levels. This method is valuable when veins are difficult to access.

An **arterial puncture**, or "arterial stick," can be used for blood gas analysis, an indicator of lung function. Samples are generally drawn from the *radial artery* at the wrist or the *brachial artery* at the elbow.

SPOTLIGHT

Figure 19–1
The Composition of Whole Blood

A Fluid Connective Tissue

Blood is a fluid connective tissue with a unique composition. It consists of a matrix called **plasma** (PLAZ-muh) and formed elements (cells and cell fragments). The term **whole blood** refers to the combination of plasma and the formed elements. The cardiovascular system of an adult male contains 5–6 liters (5.3–6.4 quarts) of whole blood. An adult female contains 4–5 liters (4.2–5.3 quarts). The sex differences in blood volume primarily reflect differences in average body size.

The **hematocrit** (he-MAT-ō-krit) is the percentage of formed elements in a sample of blood. The normal hematocrit, or **packed cell volume (PCV)**, in adult males is 46 and in adult females is 42. The sex difference in hematocrit primarily reflects the fact that androgens (male hormones) stimulate red blood cell production, whereas estrogens (female hormones) do not.

PLASMA

Plasma, the fluid matrix of blood, makes up 46–63% of the volume of whole blood. In many respects, the composition of plasma resembles that of interstitial fluid. This similarity exists because water, ions, and small solutes are continuously exchanged between plasma and interstitial fluids across the walls of capillaries. The primary differences between plasma and interstitial fluid involve (1) the levels of respiratory gases (oxygen and carbon dioxide, due to the respiratory activities of tissue cells), and (2) the concentrations and types of dissolved proteins (because plasma proteins cannot cross capillary walls).

Plasma

55%
(Range 46-63%)

consists of

+

Formed Elements

45%
(Range 37–54%)

Plasma Proteins	7%
Other Solutes	1%
Water	92%
Platelets	< .1%
White Blood Cells	
Red Blood Cells	< .1%
	99.9%

Formed elements are blood cells and cell fragments that are suspended in plasma. These elements account for 37–54% of the volume of whole blood. Three types of formed elements exist: platelets, white blood cells, and red blood cells. Formed elements are produced through the process of **hemopoiesis** (hē-mō-poy-Ē-sis), also called **hematopoiesis**. Two populations of stem cells—myeloid stem cells and lymphoid stem cells—are responsible for the production of formed elements.

FORMED ELEMENTS

Plasma Proteins

Plasma proteins are in solution rather than forming insoluble fibers like those in other connective tissues, such as loose connective tissue or cartilage. On average, each 100 mL of plasma contains 7.6 g of protein, almost five times the concentration in interstitial fluid. The large size and globular shapes of most blood proteins prevent them from crossing capillary walls, so they remain trapped within the bloodstream. The liver synthesizes and releases more than 90% of the plasma proteins, including all albumins and fibrinogen, most globulins, and various proenzymes.

Albumins (al-BŪ-minz) constitute about 60% of the plasma proteins. As the most abundant plasma proteins, they are major contributors to the osmotic pressure of plasma.

Globulins (GLOB-ū-linz) account for approximately 35% of the proteins in plasma. Important plasma globulins include antibodies and transport globulins. **Antibodies**, also called **immunoglobulins** (i-mū-nō-GLOB-ū-linz), attack foreign proteins and pathogens. **Transport globulins** bind small ions, hormones, and other compounds.

Fibrinogen (fī-BRIN-ō-jen) functions in clotting, and normally accounts for roughly 4% of plasma proteins. Under certain conditions, fibrinogen molecules interact, forming large, insoluble strands of **fibrin** (FĪ-brin) that form the basic framework for a blood clot.

Plasma also contains enzymes and hormones whose concentrations vary widely.

Other Solutes

Other solutes are generally present in concentrations similar to those in the interstitial fluids. However, because blood is a transport medium there may be differences in nutrient and waste product concentrations between arterial blood and venous blood.

Organic Nutrients: Organic nutrients are used for ATP production, growth, and cell maintenance. This category includes lipids (fatty acids, cholesterol, glycerides), carbohydrates (primarily glucose), and amino acids.

Electrolytes: Normal extracellular ion composition is essential for vital cellular activities. The major plasma electrolytes are Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, HPO_4^-, and SO_4^{2-}.

Organic Wastes: Wastes are carried to sites for breakdown or excretion. Examples of organic wastes include urea, uric acid, creatinine, bilirubin, and ammonium ions.

Platelets

Platelets (PLĀT-lets) are small, membrane-bound cell fragments that contain enzymes and other substances important for clotting.

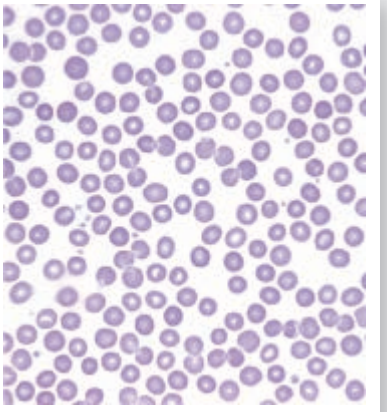
White Blood Cells

White blood cells (**WBCs**), or **leukocytes** (LŪ-kō-sīts; *leukos*, white + *-cyte*, cell), play a role in the body's defense mechanisms. There are five classes of leukocytes, each with slightly different functions that will be explored later in the chapter.

Red Blood Cells

Red blood cells (**RBCs**), or **erythrocytes** (e-RITH-rō-sīts; *erythros*, red + *-cyte*, cell), are the most abundant blood cells. These specialized cells are essential for the transport of oxygen in the blood.

Figure 19–2 The Structure of Red Blood Cells.



Blood smear LM × 477

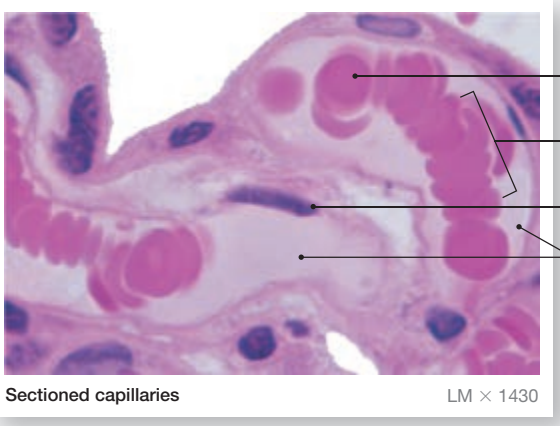
c A sectional view of a mature RBC, showing the normal ranges for its dimensions.



Sectioned capillaries LM × 1430

d When traveling through relatively narrow capillaries, RBCs may stack like dinner plates.

central region and a thicker outer margin (**Figure 19–2a–c**). An average RBC has a diameter of 7.8 μm and a maximum thickness of 2.85 μm, although the center thins to about 0.8 μm. In addition, the cytoplasmic surface of an RBC plasma membrane is a meshwork of flexible proteins.

The biconcave shape and flexible plasma membrane have three important effects on RBC function:

- *Gives Each RBC a Large Surface-Area-to-Volume Ratio.* Each RBC carries oxygen bound to intracellular proteins. That oxygen must be absorbed or released quickly as the RBC passes through the capillaries of the lungs or peripheral tissues. The greater the surface area per unit volume, the faster the exchange between the RBC's interior and the surrounding plasma. The total surface area of all the RBCs in the blood of a typical adult is about 3800 square meters (nearly 4600 square yards), some 2000 times the total surface area of the body.
- *Enables RBCs to Form Stacks That Smooth Blood Flow through Narrow Blood Vessels.* These stacks of RBCs are like stacks of dinner plates (**Figure 19–2d**). Known as *rouleaux* (rū-LŌ; singular, *rouleau*,), the stacks form and dissociate repeatedly without affecting the cells involved. An entire stack can pass along a blood vessel that is only slightly larger than the diameter of a single RBC. In contrast, individual cells would bump the walls, bang together, and form logjams that could restrict or prevent blood flow.
- *Enables RBCs to Bend and Flex When Entering Small Capillaries.* Red blood cells are very flexible. By changing shape, individual RBCs can squeeze through capillaries as narrow as 4 μm.

When a developing red blood cell differentiates, it loses any organelle not directly associated with its primary function: the transport of respiratory gases. Mature RBCs are **anucleate**, without nuclei; they retain only the cytoskeleton. Without nuclei and ribosomes, circulating RBCs cannot divide or synthesize structural proteins or enzymes. As a result, the RBCs cannot repair themselves, so their life span is relatively short—normally less than 120 days. With few organelles and no ability to synthesize proteins, their energy demands are low. Without mitochondria, they obtain the energy they need through the anaerobic metabolism of glucose that is absorbed from the surrounding plasma. The lack of mitochondria ensures that absorbed oxygen will be carried to peripheral tissues, not "stolen" by mitochondria in the RBC.

Hemoglobin

Hemoglobin (Hb or **Hgb)** is responsible for the red blood cell's ability to transport oxygen and carbon dioxide. Molecules

of hemoglobin make up more than 95 percent of its intracellular proteins. The hemoglobin content of whole blood is reported in grams of Hb per deciliter (100 mL) of whole blood (g/dL). Normal ranges are 14–18 g/dL in males and 12–16 g/dL in females.

Hemoglobin Structure

Hemoglobin molecules have a complex quaternary structure. ↩ p. 55 Each Hb molecule has two *alpha* (α) *chains* and two *beta* (β) *chains* of polypeptides (Figure 19–3). Each chain is a globular protein subunit that resembles the myoglobin in skeletal and cardiac muscle cells. Like myoglobin, each Hb chain contains a single molecule of **heme**, a nonprotein pigment complex that forms a ring. Each heme unit holds an iron ion in such a way that the iron can interact with an oxygen molecule, forming **oxyhemoglobin**, **HbO_2**. Blood that contains RBCs filled with oxyhemoglobin is bright red.

The binding of an oxygen molecule to the iron in a heme unit is reversible. The iron–oxygen interaction is very weak. The iron and oxygen can easily dissociate without damaging the heme unit or the oxygen molecule. A hemoglobin molecule whose iron is not bound to oxygen is called **deoxyhemoglobin**. Blood containing RBCs filled with deoxyhemoglobin is dark red.

The RBCs of an embryo or a fetus contain a different form of hemoglobin, known as *fetal hemoglobin*. It binds oxygen more readily than does adult hemoglobin. For this reason, a developing fetus can "steal" oxygen from the maternal bloodstream at the placenta. The conversion from fetal hemoglobin to the adult form begins shortly before birth and continues over the next year. The production of fetal hemoglobin can be stimulated in adults by the administration of drugs such as *hydroxyurea* or *butyrate*. This is one method of treatment for *sickle cell disease* (SCD), a group of conditions that result from the production of abnormal forms of adult hemoglobin.

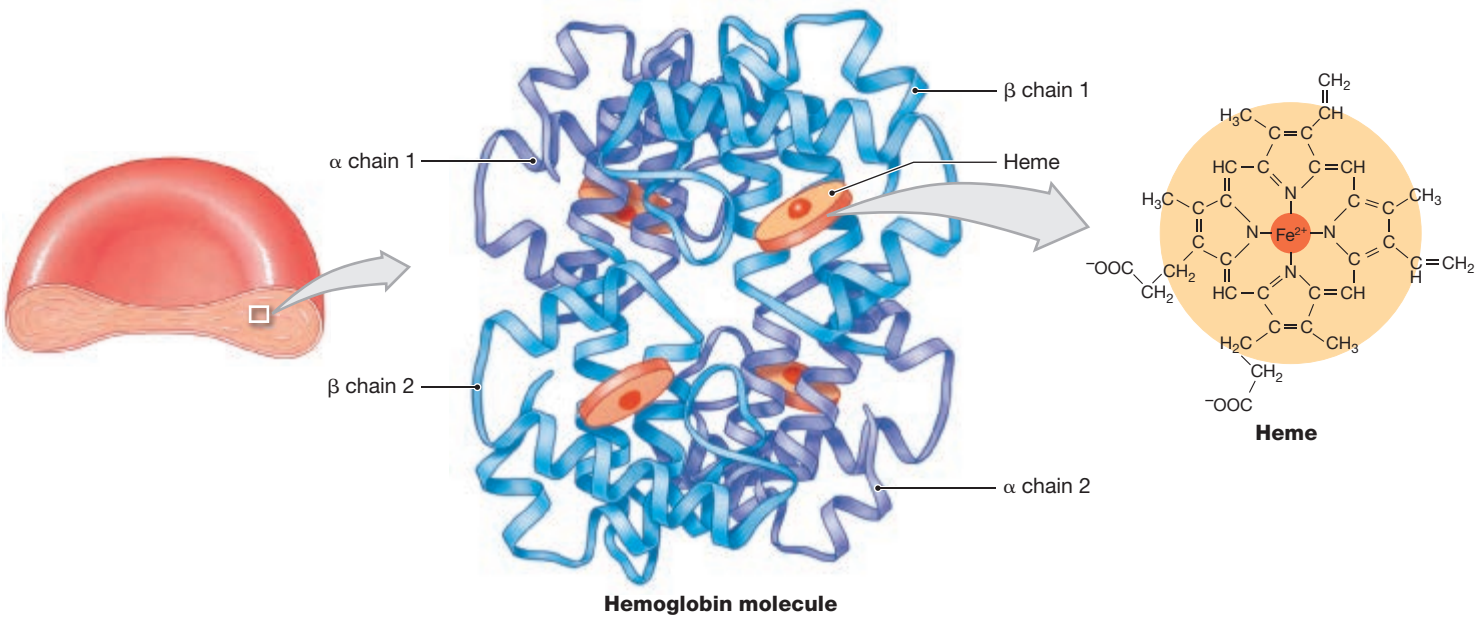
Hemoglobin Function: Binding and Releasing Oxygen and Carbon Dioxide

Each RBC contains about 280 million Hb molecules. Because 1 Hb molecule contains 4 heme units, each RBC can potentially carry more than a billion molecules of oxygen at a time. Roughly 98.5 percent of the oxygen carried by the blood is bound to Hb molecules inside RBCs.

The amount of oxygen bound to hemoglobin depends mostly on the oxygen content of the plasma. When the plasma oxygen level is low, hemoglobin releases oxygen. Under these conditions, typical of peripheral capillaries, the plasma carbon dioxide level is elevated. The alpha and beta chains of hemoglobin then bind carbon dioxide, forming **carbaminohemoglobin**. In the lung capillaries, the plasma oxygen level is high and the carbon dioxide level is low. Upon reaching these capillaries, RBCs absorb oxygen (which is then bound to hemoglobin) and release carbon dioxide. We revisit these processes in Chapter 23.

19

Figure 19–3 The Structure of Hemoglobin. Hemoglobin consists of four globular protein subunits. Each subunit contains a single molecule of heme—a nonprotein ring surrounding a single ion of iron.



? Each molecule of heme contains a single ion of what element?

Normal activity levels can be sustained only when the tissue oxygen level is kept within normal limits. If the hematocrit is low or the Hb content of the RBCs is reduced, a condition known as **anemia** results. Anemia interferes with oxygen delivery to peripheral tissues. Every system is affected as organ function deteriorates due to oxygen starvation. Anemic individuals become weak and lethargic. They may also become confused, because the brain is affected as well.

RBC Formation and Turnover

An RBC is exposed to severe physical stresses. A single round-trip from the heart, through the peripheral tissues, and back to the heart usually takes less than a minute. In that time, the RBC gets pumped out of the heart and forced along vessels, where it bounces off the walls and collides with other RBCs. It forms stacks, contorts, and squeezes through tiny capillaries. Then it is rushed back to the heart to make another round trip.

With all this wear and tear and no repair mechanisms, a typical RBC has a short life span. After it travels about 700 miles in 120 days, either its plasma membrane ruptures or some other damage is detected by phagocytes of the spleen, liver, and red bone marrow, which engulf it. The continuous elimination of RBCs usually goes unnoticed, because new ones enter the bloodstream at a comparable rate. About 1 percent of the circulating RBCs are replaced each day, and in the process approximately 3 million new RBCs enter the bloodstream *each second*!

RBC Production: Erythropoiesis

19

Erythropoiesis is the formation of RBCs and it occurs throughout life. Many factors stimulate this process, such as a decreased oxygen level or increased erythropoietin. Let's look at erythropoiesis in detail.

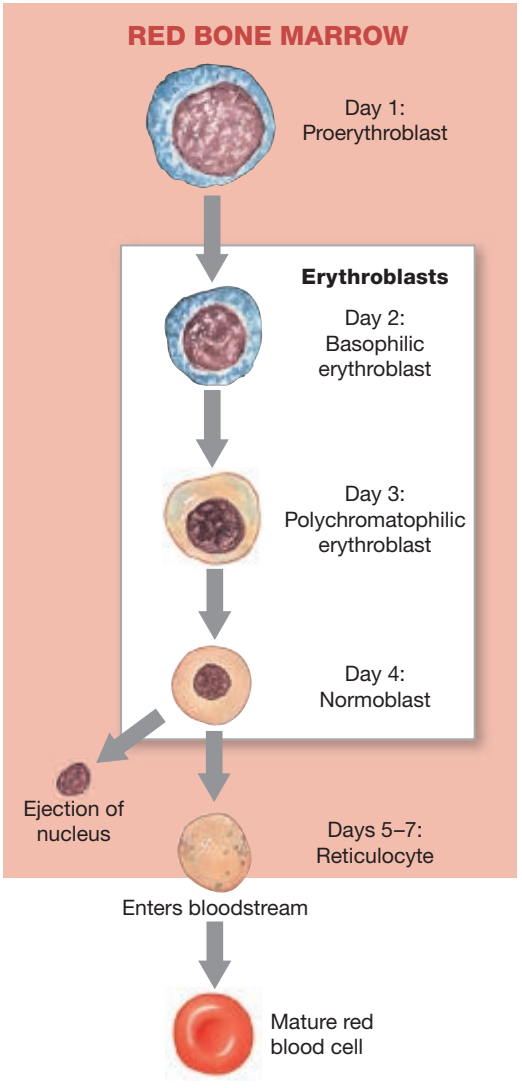
Erythropoiesis in the Fetal and Adult Periods. Embryonic blood cells appear in the bloodstream during the third week of development. These cells divide repeatedly, rapidly increasing in number. Blood forms primarily in the vessels of the embryonic *yolk sac* (an early membranous structure) during the first 8 weeks of development. As other organ systems appear, some of the embryonic blood cells move out of the bloodstream and into the liver, spleen, thymus, and bone marrow. These embryonic cells differentiate into **stem cells** that divide to produce blood cells. The liver and spleen are the primary sites of hemopoiesis from the second to fifth months of development, but as the skeleton enlarges, the bone marrow becomes increasingly important.

In adults, red blood cell formation, or **erythropoiesis** (e-rith-rō-poy-Ē-sis), takes place only in *red bone marrow*, or **myeloid** (MĪ-e-loyd; *myelos*, marrow) **tissue**. This tissue is located in portions of the vertebrae, sternum, ribs, skull, scapulae, pelvis, and proximal limb bones. Other marrow areas contain a fatty tissue known as *yellow bone marrow*. ↩ p. 188 Under extreme stimulation, such as severe and sustained blood loss, areas of yellow marrow can convert to red marrow, increasing the rate of RBC formation.

Stages of RBC Maturation. For RBCs to be produced, first cells called **hemocytoblasts** (*hemo-*, blood + *cyte*, cell + *blastos*, precursor), or **hematopoietic stem cells (HSCs)**, in the red bone marrow must divide. These stem cells produce two types of cells: (1) **myeloid stem cells**, which in turn divide to produce red blood cells and several classes of white blood cells, and (2) **lymphoid stem cells**, which divide to produce white blood cells called lymphocytes.

In the red bone marrow, a red blood cell matures in a series of stages. Blood specialists, known as **hematologists** (hē-mah-TOL-ah-jists), have named six key developmental stages that occur over about a week (Figure 19–4). On day 1, cells destined to become RBCs first differentiate into **proerythroblasts**, and then on days 2 and 3 proceed through various **erythroblast**

Figure 19–4 Stages of RBC Maturation: Erythropoiesis. Red blood cells are produced in the red bone marrow. The color density in the cytoplasm indicates the abundance of hemoglobin. Note the reductions in the sizes of the cell and nucleus leading up to the formation of a reticulocyte.



stages. Erythroblasts, which actively synthesize hemoglobin, are named based on total size, amount of hemoglobin, and size and appearance of the nucleus.

After day 4, the erythroblast, now called a *normoblast*, sheds its nucleus and becomes a **reticulocyte** (re-TIK-yū-lō-sīt), which contains 80 percent of the Hb of a mature RBC. Hemoglobin synthesis then continues for days 5–7. During this period, while the cell is synthesizing Hb and other proteins, its cytoplasm still contains RNA, which can be seen under the microscope with certain stains. After 2 days in the red bone marrow, the reticulocyte enters the bloodstream. At this time, reticulocytes normally account for about 0.8 percent of the RBC population in the blood and can still be detected by staining. After a final day in circulation, the reticulocytes complete their maturation and become indistinguishable from other mature RBCs.

Regulation of Erythropoiesis

Erythropoiesis is stimulated directly by the hormone **erythropoietin (EPO)** (↩ p. 644) and indirectly by several hormones, including thyroxine, androgens, and growth hormone. As noted earlier in **Spotlight Figure 19–1** on pp. 660–661, estrogens do not stimulate erythropoiesis. This fact accounts for the differences in hematocrit values between males and females.

Erythropoietin is a glycoprotein formed by the kidneys and liver. EPO appears in the plasma when peripheral tissues, especially the kidneys, are exposed to a low concentration of oxygen. A low oxygen level in tissues is called **hypoxia** (hī-POKS-ē-uh; *hypo-*, below + *oxy-*, presence of oxygen). Erythropoietin is released (1) during anemia; (2) when blood flow to the kidneys declines; (3) when the oxygen content of air in the lungs declines, due to disease or high altitude; and (4) when the respiratory surfaces of the lungs are damaged.

Once in the bloodstream, EPO travels to the red bone marrow, where it stimulates stem cells and developing RBCs. Erythropoietin has two major effects: (1) It stimulates cell division rates in erythroblasts and in the stem cells that produce erythroblasts, and (2) it speeds up the maturation of RBCs, mainly by accelerating Hb synthesis. Under maximum EPO stimulation, red bone marrow can increase RBC formation 10-fold, to about 30 million cells per second.

The ability to increase the rate of blood formation quickly and dramatically is important to a person recovering from a severe blood loss. But if EPO is administered to a healthy person, the hematocrit may rise to 65 or more. Such an increase can place an intolerable strain on the heart. Similar problems can occur after **blood doping**, a practice in which athletes elevate their hematocrits by re-infusing packed RBCs that were removed and stored at an earlier date. The goal is to improve oxygen delivery to muscles, thereby enhancing performance. The strategy can be dangerous, however, because it makes blood more viscous and increases the workload on the heart.

One more factor may limit red blood cell formation. For erythropoiesis to proceed normally, the red bone marrow needs adequate supplies of amino acids, iron, and vitamins (including B_{12}, B_6, and folic acid) for protein synthesis. We obtain **vitamin B_{12}** from dairy products and meat. To absorb vitamin B_{12}, we need *intrinsic factor*, which is produced in the stomach. Without vitamin B_{12} from the diet, normal stem cell divisions cannot occur and *pernicious anemia* results. Thus, pernicious anemia may be caused by a vitamin B_{12} deficiency, a problem with the production of intrinsic factor, or a problem with the absorption of vitamin B_{12} bound to intrinsic factor.

Blood tests provide information about the general health of an individual, usually with a minimum of trouble and expense. Several common blood tests, called *RBC tests*, assess the number, size, shape, and maturity of circulating RBCs, indicating the erythropoietic activities under way. The tests can also be useful in detecting problems, such as internal bleeding, that may not produce other obvious signs or symptoms. **Table 19–1** lists examples of important red blood cell tests and related terms. (These tests are performed as part of a *complete blood count*, or *CBC*).

Table 19–1 RBC Tests and Related Terminology

Test	Determines	Terms Associated with Abnormal Values	
		Elevated	Depressed
Hematocrit (Hct)	Percentage of formed elements in whole blood Normal = 37–54%	Polycythemia (may reflect erythrocytosis or leukocytosis)	Anemia
Reticulocyte count (Retic.)	Percentage of circulating reticulocytes Normal = 0.8%	Reticulocytosis	Diminished erythropoiesis
Hemoglobin concentration (Hb; Hgb)	Concentration of hemoglobin in blood Normal = 12–18 g/dL	Polycythemia	Anemia
RBC count	Number of RBCs per μL of whole blood Normal = 4.2–6.3 million cells/μL	Erythrocytosis/polycythemia	Anemia
Mean corpuscular volume (MCV)	Average volume of one RBC Normal = 82–101 μm^3/cell (normocytic)	Macrocytic	Microcytic
Mean corpuscular hemoglobin (MCH)	Average weight of Hb in one RBC Normal = 27–34 pg/RBC (normochromic)	Hyperchromic	Hypochromic

Hemoglobin Recycling

Macrophages of the spleen, liver, and red bone marrow play a central role in recycling red blood cell components. These phagocytes engulf aged red blood cells and also detect and remove Hb molecules from **hemolyzed**, or ruptured, RBCs (Figure 19–5). Hemoglobin remains intact only inside RBCs. If the Hb released by hemolysis is not phagocytized, its components will not be recycled.

Once a phagocytic cell has engulfed and broken down an RBC, each part of the Hb molecule has a different fate (see Figure 19–5). The alpha and beta chains of Hb are filtered by the kidneys and eliminated in urine. The globular proteins are broken apart into their component amino acids, which are then either metabolized by the cell or released into the bloodstream for use by other cells. Only the iron of each heme unit is recycled. The remaining portion is processed separately.

When abnormally large numbers of RBCs break down in the bloodstream, urine may turn red or brown. This condition is called **hemoglobinuria**. The presence of intact RBCs in urine—a sign called **hematuria** (hē-mah-TYŪ-rē-uh)—occurs only after kidney damage or damage to vessels along the urinary tract.

Fate of Heme. Each heme unit is stripped of its iron and converted to **biliverdin** (bil-ih-VER-din), an organic compound with a green color. (Bad bruises commonly develop a greenish tint when biliverdin forms in the blood-filled tissues.) Biliverdin is then converted to **bilirubin** (bil-ih-RŪ-bin), an orange-yellow pigment, and released into the bloodstream. There, the bilirubin binds to albumin and is transported to the liver for excretion in bile.

If the bile ducts are blocked or the liver cannot absorb or excrete bilirubin, the circulating level of the compound climbs rapidly. Bilirubin then diffuses into peripheral tissues, giving them a yellow color that is most apparent in the skin and over the sclera of the eyes. This combination of yellow skin and eyes is **jaundice** (JAWN-dis).

In the large intestine, bacteria convert bilirubin to related pigments called *urobilinogens* (yūr-ō-bī-LIN-ō-jens) and *stercobilinogens* (ster-kō-bī-LIN-ō-jens). Some of the urobilinogens are absorbed into the bloodstream and are then excreted into urine. When exposed to oxygen, some of the urobilinogens and stercobilinogens are converted to **urobilins** (ūr-ō-BĪ-lins) and **stercobilins** (ster-kō-BĪ-lins).

Recycling of Iron. Large quantities of free iron are toxic to cells, so in the body iron is generally bound to transport or storage proteins. Iron ions (Fe^{2+}) extracted from heme molecules may be bound and stored in a phagocytic cell or released into the bloodstream, where they bind to **transferrin** (trans-FER-in), a plasma protein. Red blood cells developing in the red bone marrow absorb the amino acids and transferrins from the bloodstream and use them to synthesize new Hb molecules. Excess transferrins are removed in the liver and spleen, and the iron is stored in two special iron–protein complexes: **ferritin** (FER-ih-tin) and **hemosiderin** (hē-mō-SID-eh-rin).

This recycling system is remarkably efficient. Although roughly 26 mg of iron is incorporated into new Hb molecules each day, a dietary supply of 1–2 mg can keep pace with the incidental losses that occur at the kidneys and digestive tract.

Any impairment in iron uptake or metabolism can cause serious clinical problems, because RBC formation will be affected. For example, *iron-deficiency anemia* results from a lack of iron in the diet or from problems with iron absorption. Too much iron can also cause problems, due to excessive buildup in secondary storage sites, such as the liver and cardiac muscle tissue. Excessive iron deposition in cardiac muscle cells has been linked to heart disease.

19-3 The ABO and Rh blood groups are based on antigen–antibody responses

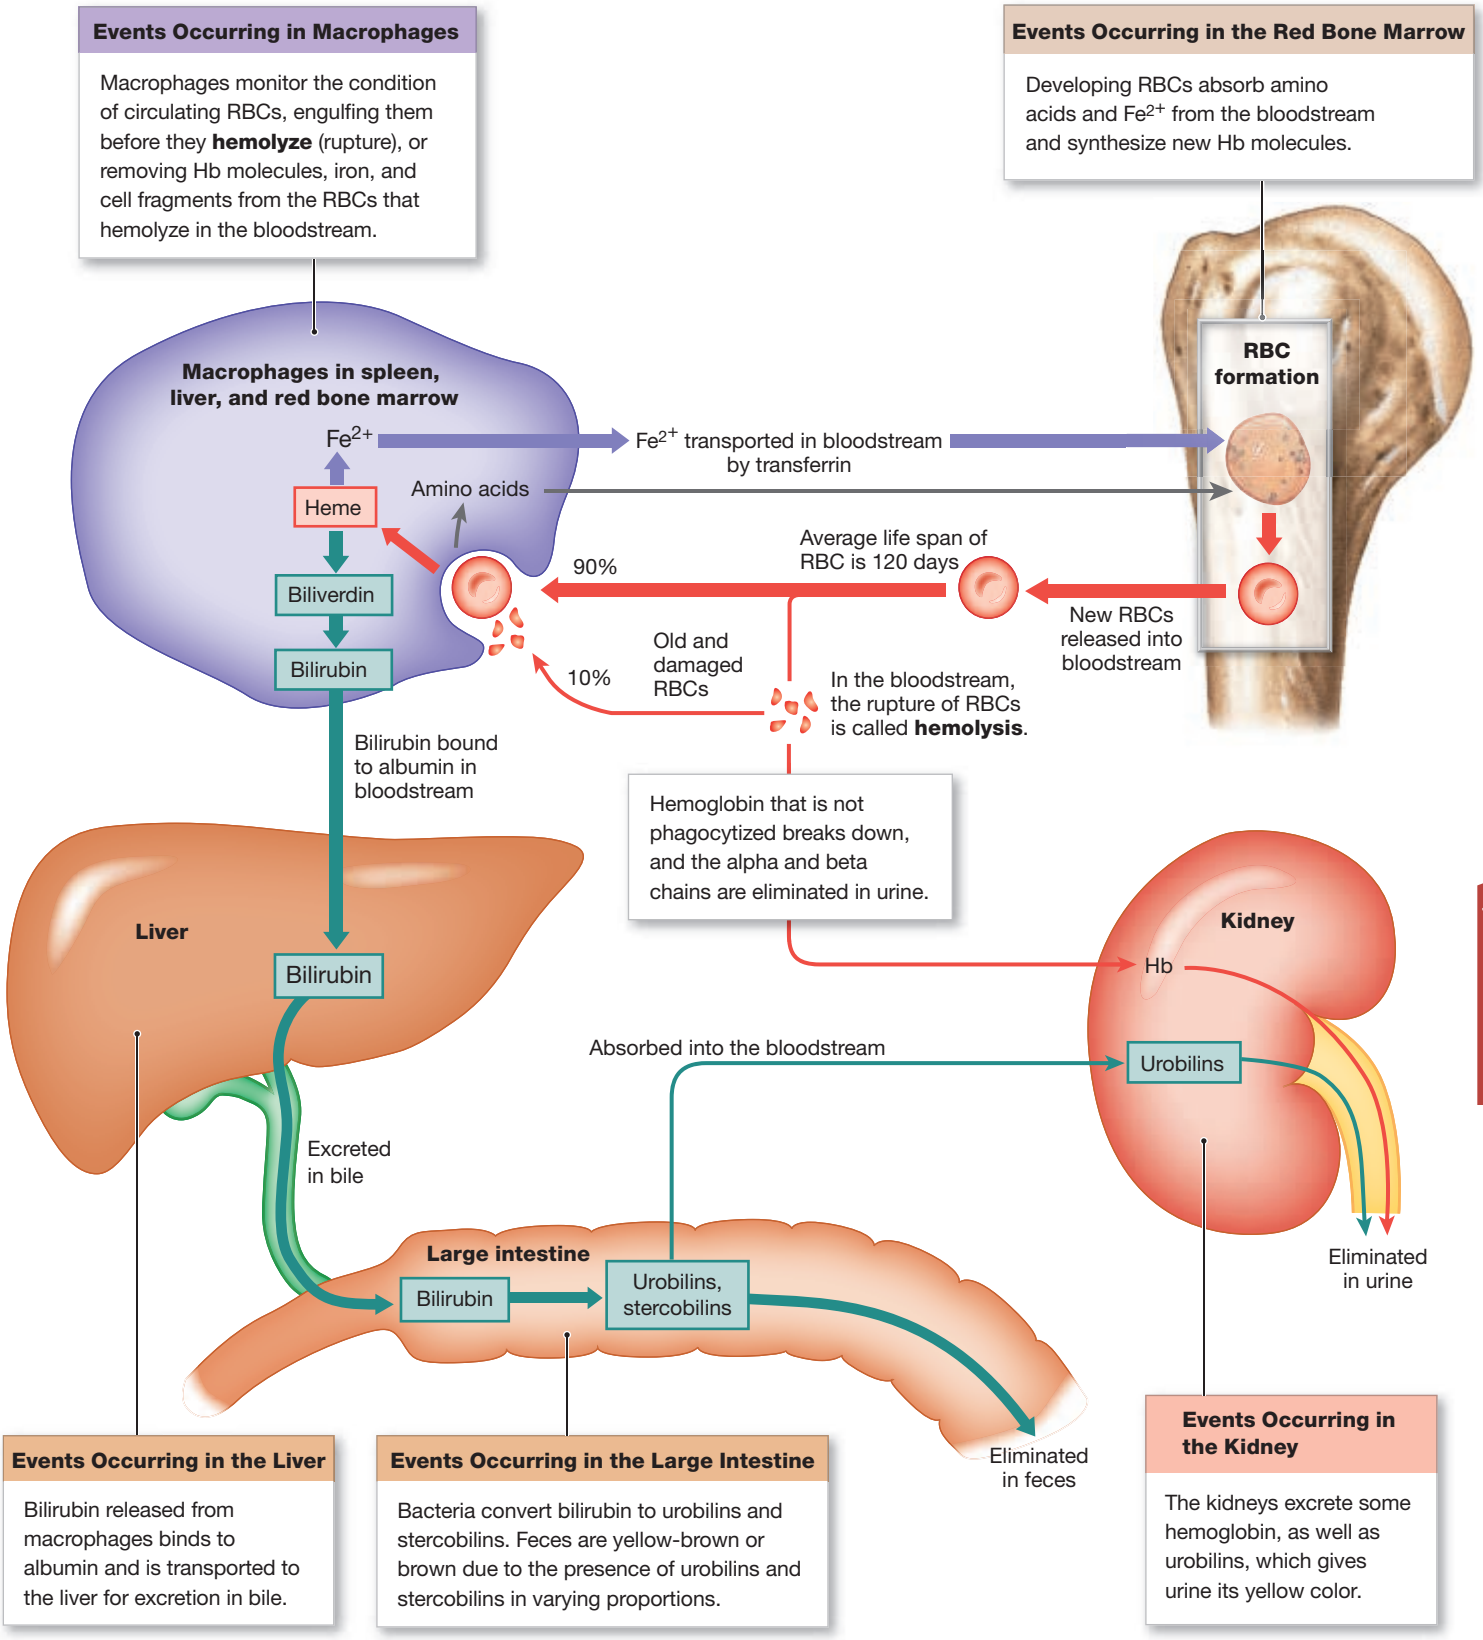
Learning Outcome Explain the importance of blood typing and the basis for ABO and Rh incompatibilities.

Antigens are substances that can trigger a protective defense mechanism called an *immune response.* Most antigens are proteins, but some other types of organic molecules are antigens as well. Your plasma membranes contain **surface antigens**, substances that your immune system recognizes as "normal," or "self." In other words, your immune system ignores these substances rather than attacking them as "foreign." Let's look at how surface antigens on red blood cells determine *blood type.* Blood type then determines how blood reacts during *transfusions.*

ABO and Rh Blood Groups

Your **blood type** is determined by the presence or absence of specific surface antigens in RBC plasma membranes. The surface antigens involved are integral membrane glycoproteins whose characteristics are genetically determined. Red blood cells have at least 50 kinds of surface antigens, but three surface antigens are of particular importance: **A**, **B**, and **Rh** (or **D**).

Figure 19–5 Recycling of Red Blood Cell Components.

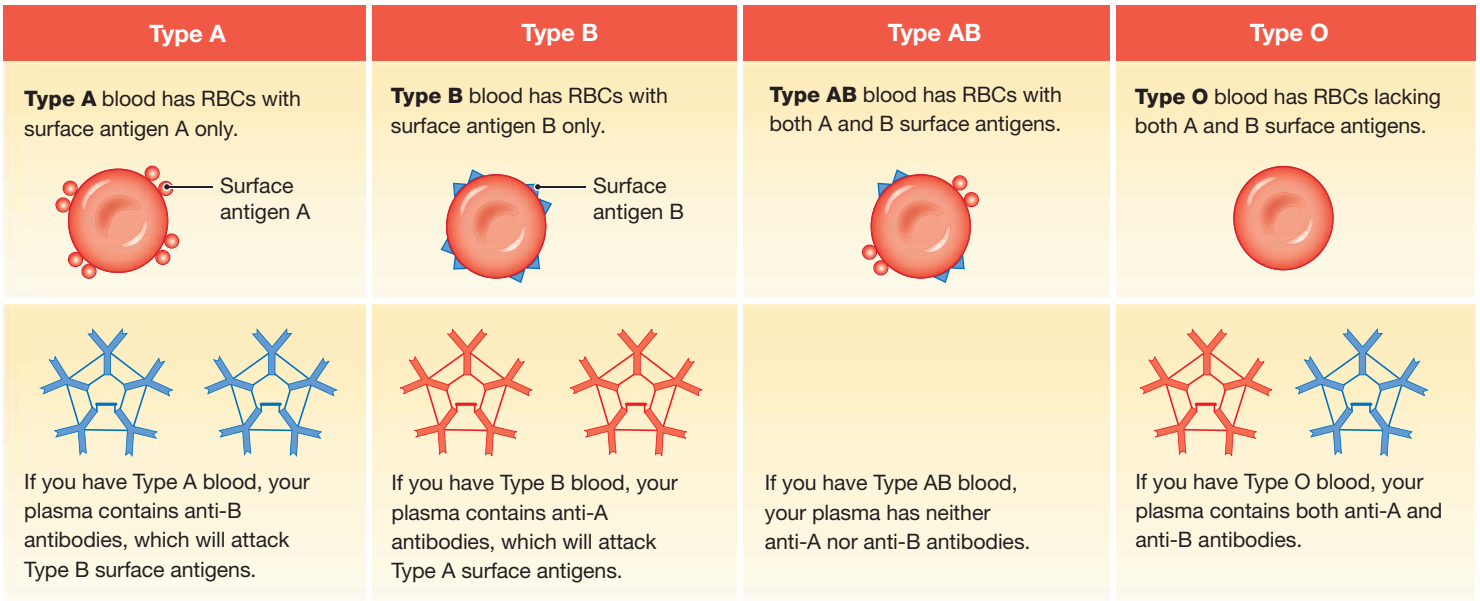


? Where are red blood cells produced?

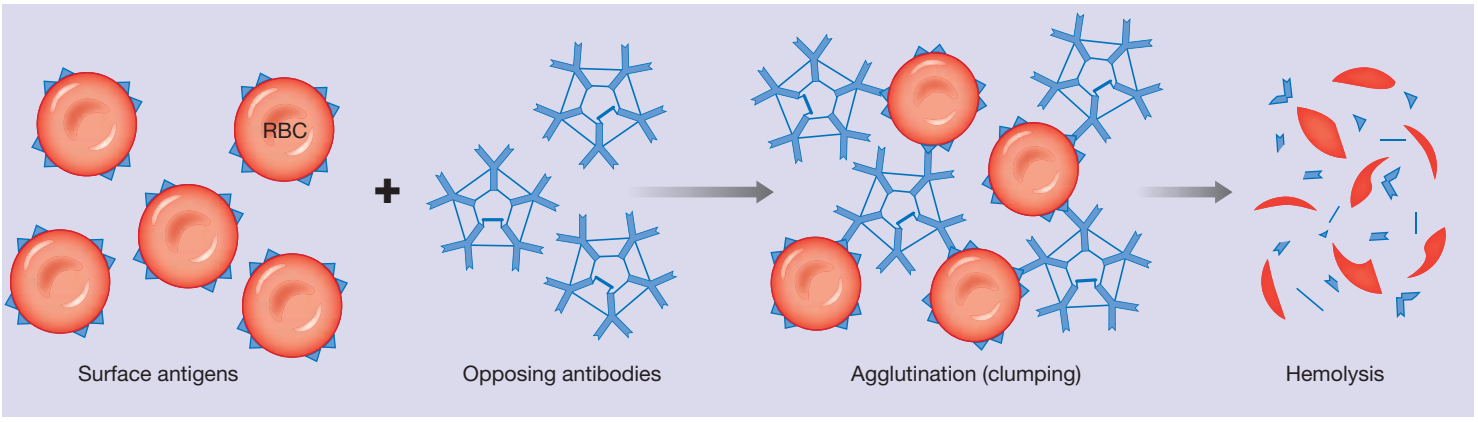
The *ABO blood group* is based on the presence or absence of the A and B surface antigens. According to this group, there are four blood types (Figure 19–6a): **Type A** blood has RBCs with surface antigen A only, **type B** has surface antigen B only, **type AB** has both A and B, and **type O** has neither A nor B. Individuals with these blood types are not evenly distributed throughout the world. The average percentages for various populations in the United States are given in Table 19–2.

The *Rh blood group* is based on the presence or absence of the Rh surface antigen. The term **Rh positive (Rh^+)** indicates the presence of the Rh surface antigen, commonly called the *Rh factor*. The absence of this antigen is indicated as **Rh negative (Rh^-)**. When the complete blood type is recorded, the term *Rh* is usually omitted, and a positive or negative sign is used. For example, the types are reported as O negative (O^-), A positive (A^+), and so on. Type O^+ is the most common blood type.

Figure 19–6 Blood Types and Cross-Reactions.



a Blood type depends on the presence of surface antigens (agglutinogens) on RBC surfaces. The plasma contains antibodies (agglutinins) that will react with foreign surface antigens.



b In a cross-reaction, antibodies react with their target antigens causing agglutination and hemolysis of the affected RBCs. In this example, anti-B antibodies encounter B surface antigens, which cause the RBCs bearing the B surface antigens to clump together and break up.

? Type A blood has what type of RBC surface antigen and what type of opposing antibodies?

Table 19–2 Differences in Blood Group Distribution

Population	Percentage with Each Blood Type				
	O	A	B	AB	Rh^+
UNITED STATES					
Black American	49	27	20	4	95
Caucasian	45	40	11	4	85
Chinese American	42	27	25	6	100
Filipino American	44	22	29	6	100
Hawaiian	46	46	5	3	100
Hispanic	57	31	10	2	92
Japanese American	31	39	21	10	100
Korean American	32	28	30	10	100
NATIVE NORTH AMERICAN	79	16	4	1	100
NATIVE SOUTH AMERICAN	100	0	0	0	100
AUSTRALIAN ABORIGINE	44	56	0	0	100

As in the distribution of A and B surface antigens, Rh type differs by ethnic group and by region (see Table 19–2).

Your immune system ignores these surface antigens—called **agglutinogens** (ah-glū-TIN-ō-jenz)—on your own RBCs. However, your plasma contains antibodies, sometimes called **agglutinins** (ah-GLŪ-tih-ninz), that will attack the antigens on "foreign" RBCs. When these antibodies attack, the foreign cells *agglutinate*, or clump together; this process is called **agglutination**. If you have type A blood, your plasma contains anti-B antibodies, which will attack type B surface antigens. If you have type B blood, your plasma contains anti-A antibodies. The RBCs of an individual with type O blood have neither A nor B surface antigens, and that person's plasma contains both anti-A and anti-B antibodies. A type AB individual has RBCs with both A and B surface antigens, and the plasma does not contain anti-A or anti-B antibodies. The presence of anti-A and/or anti-B antibodies is genetically determined. These antibodies are present throughout life, regardless of whether the individual has ever been exposed to foreign RBCs.

In contrast, the plasma of an Rh-negative individual does not contain anti-Rh antibodies. These antibodies are present only if the individual has been **sensitized** by previous exposure to Rh^+ RBCs. Such exposure can occur accidentally during a transfusion, but it can also accompany a seemingly normal pregnancy involving an Rh^- mother and an Rh^+ fetus. (We cover this process in more detail later in this section.)

Transfusions

A **transfusion** is the process of transferring whole blood or blood plasma from one person to another. If the donor's cells and the recipient's plasma are not compatible, a potentially life-threatening *cross-reaction* can occur. Such cross-reactions can be prevented by testing to make sure that the blood types of the donor and the recipient are **compatible**—that is, that the donor's blood cells and the recipient's plasma will not cross-react.

Cross-Reactions

During a transfusion, if an antibody meets its specific surface antigen, the RBCs agglutinate and may also hemolyze. This is called a **cross-reaction**, or *transfusion reaction* (Figure 19–6b). For instance, an anti-A antibody that encounters A surface antigens will cause the RBCs bearing the A surface antigens to clump or even break up. Clumps and fragments of RBCs under attack form drifting masses that can plug small blood vessels in the kidneys, lungs, heart, or brain, damaging or destroying affected tissues.

In practice, the surface antigens on the donor's cells are more important in determining compatibility than are the antibodies in the donor's plasma. Why? Unless large volumes of whole blood or plasma are transferred, cross-reactions between the donor's plasma and the recipient's blood cells will not produce significant agglutination. This is because the donated plasma is diluted quickly through mixing with the larger plasma volume of the recipient. (One unit of whole blood, 500 mL, contains roughly 275 mL of plasma, only about 10 percent of normal plasma volume.) When the goal is to increase the blood's oxygen-carrying capacity rather than its plasma volume, packed RBCs, with a minimal amount of plasma, are often transfused. This practice minimizes the risk of a cross-reaction.

Compatibility Testing

To avoid cross-reactions, a compatibility test is usually performed in advance of any transfusion. This process normally involves two steps: (1) a determination of blood type and (2) a cross-match test.

Figure 19–7 Blood Type Testing. Test results for blood samples from four individuals. Drops of blood are mixed with solutions containing antibodies to the surface antigens A, B, AB, and Rh. Anti-A antibodies agglutinate A antigens. Anti-B antigens agglutinate B antigens. The tested person's blood types are shown at right.

Anti-A	Anti-B	Anti-Rh	Blood type
Clumping	No clumping	Clumping	A^+
No clumping	Clumping	Clumping	B^+
Clumping	Clumping	Clumping	AB^+
No clumping	No clumping	No clumping	O^-

The standard test for blood type considers only the three surface antigens most likely to produce dangerous cross-reactions: A, B, and Rh (Figure 19–7). The test involves taking drops of blood and mixing them separately with solutions containing anti-A, anti-B, and anti-Rh (anti-D) antibodies. Any cross-reactions are then recorded. For example, if an individual's RBCs clump together when exposed to anti-A and to anti-B antibodies, the individual has type AB blood. If no reactions occur after exposure, that person must have type O blood. The presence or absence of the Rh surface antigen is also noted, and the individual is classified as Rh positive or Rh negative on that basis.

Standard blood typing of both donor and recipient can be completed in a matter of minutes. However, in an emergency, there may not be time for preliminary testing. For example, a person with a severe gunshot wound may require 5 *liters* or more of blood before the damage can be repaired. Under these circumstances, type O blood (preferably O^-) will be administered. Because the donated RBCs lack both A and B surface antigens, the recipient's blood can have anti-A antibodies, anti-B antibodies, or both and still not cross-react with the donor's blood. Because cross-reactions with type O blood are very unlikely, type O individuals are sometimes called *universal donors*. Type AB individuals were once called *universal recipients*, because they lack anti-A and anti-B antibodies that would attack donated RBCs, and so can safely receive blood of any type. However, now that blood supplies are usually adequate and compatibility testing is regularly done, the term has largely been dropped. If the recipient's blood type is known to be AB, type AB blood will be administered.

Enzymes can now be used to strip off the A or B surface antigens from RBCs and create type O blood in the laboratory. The procedure is expensive and time consuming and has limited use in emergency treatment. Still, cross-reactions can occur, even to type O^- blood, because at least 48 other surface antigens are present. For this reason, whenever time and facilities permit, further testing is performed to ensure complete compatibility between donor blood and recipient blood. **Cross-match testing** involves exposing the donor's RBCs to a sample of the recipient's plasma under controlled conditions. This procedure reveals significant cross-reactions involving surface antigens other than A, B, or Rh. Another way to avoid compatibility problems is to replace lost blood with synthetic blood substitutes, which do not contain surface antigens that can trigger a cross-reaction.

Because blood groups are inherited, blood tests are also used as paternity tests and in crime detection. The blood collected cannot prove that a particular individual *is* a certain child's father or *is* guilty of a specific crime, but it can prove that the individual is *not* involved. For example, an adult with type AB blood cannot be the parent of an infant with type O blood. Testing for additional surface antigens, other than the standard ABO groups, can increase the accuracy of the conclusions. When available, DNA identity testing, which has nearly 100 percent accuracy, has replaced blood type identity testing.

Spotlight Figure 19–8 describes a serious condition known as *hemolytic disease of the newborn* (*HDN*). Hemolytic disease of the newborn does not involve a transfusion; rather it involves Rh incompatibility between a pregnant mother and her developing fetus.

19-4 The various types of white blood cells contribute to the body's defenses

Learning Outcome Categorize white blood cell types based on their structures and functions, and discuss the factors that regulate the production of each type.

Unlike red blood cells, **white blood cells (WBCs)**, or **leukocytes**, have nuclei and other organelles, and they lack hemoglobin.

White blood cells help defend the body against invasion by pathogens. They also remove toxins, wastes, and abnormal or damaged cells.

A typical microliter of blood contains 5000 to 10,000 WBCs, compared with 4.2 to 6.3 million RBCs. Most of the WBCs in the body at any moment are in connective tissue proper or in organs of the lymphatic system. Circulating WBCs are only a small fraction of the total WBC population.

WBC Characteristics and Functions

Unlike RBCs, WBCs circulate for only a short time during their life span. White blood cells migrate through the loose and dense connective tissues of the body. They use the bloodstream to travel from one organ to another and for rapid transportation to areas of infection or injury. As they travel along the miles of capillaries, WBCs can detect the chemical signs of damage to surrounding tissues. When these cells detect problems, they leave the bloodstream and enter the damaged area.

Circulating WBCs have the following functional characteristics:

- *All Can Migrate Out of the Bloodstream.* When WBCs in the bloodstream are activated, they contact and adhere to the vessel walls in a process called *margination*. After further interaction with endothelial cells, the activated WBCs squeeze between adjacent endothelial cells and enter the surrounding tissue. This process is called *emigration*, or *diapedesis* (dī-ah-peh-DĒ-sis; *dia*, through + *pedesis*, a leaping).
- *All Are Capable of Amoeboid Movement. Amoeboid movement* is a gliding motion made possible by the flow of cytoplasm into slender cellular processes extended in the direction of movement. (The movement is so named because it is similar to that of an *amoeba*, a type of protozoan.) The mechanism is not fully understood, but it involves the continuous rearrangement of bonds between actin filaments in the cytoskeleton. It also requires calcium ions and ATP. This mobility allows WBCs to move through the endothelial lining and into peripheral tissues.
- *All Are Attracted to Specific Chemical Stimuli.* This characteristic, called **positive chemotaxis** (kē-mō-TAK-sis), guides WBCs to invading pathogens, damaged tissues, and other active WBCs.

In addition, keep in mind that some types of WBCs are capable of phagocytosis. These WBCs may engulf pathogens, cell debris, or other materials.

Types of WBCs

Several types of WBCs can be distinguished microscopically in a blood smear by using either of two standard stains: *Wright's stain* or *Giemsa* (JEM-suh) *stain*. Traditionally, WBCs have been divided into two groups based on their appearance after staining: (1) *granular leukocytes*, or *granulocytes* (with abundant stained granules)—the *neutrophils*, *eosinophils*, and *basophils*; and (2) *agranular leukocytes*, or *agranulocytes* (with few, if any, stained granules)—the *monocytes* and *lymphocytes*. This categorization is convenient but somewhat misleading. In reality, the granules in "granular leukocytes" are secretory vesicles and lysosomes, and the "agranular leukocytes" also contain vesicles and lysosomes, but they are just smaller and difficult to see with a light microscope.

Neutrophils, eosinophils, basophils, and monocytes are part of the body's *nonspecific defenses*. A variety of stimuli activate such defenses, which do not discriminate between one type of threat and another. Neutrophils and eosinophils are sometimes called *microphages*, to distinguish them from the larger macrophages in connective tissues. Macrophages are monocytes that have moved out of the bloodstream and have become actively phagocytic. ↩ p. 129 Lymphocytes, in contrast, are responsible for *specific defenses*, which mount a counterattack against specific types of invading pathogens or foreign proteins. We discuss the interactions among WBCs and the relationships between specific and nonspecific defenses in Chapter 22.

Neutrophils

Fifty to 70 percent of the circulating WBCs are **neutrophils** (NŪ-trō-filz). This name reflects the fact that the granules of these WBCs are chemically neutral and thus are difficult to stain with either acidic or basic (alkaline) dyes. A mature neutrophil has a very dense, segmented nucleus with two to five lobes resembling beads on a string (Figure 19–9a). This structure has given neutrophils another name: **polymorphonuclear** (pol-ē-mor-fō-NŪ-klē-ar) **leukocytes** (*poly*, many + *morphe*, form), or *PMNs*. "Polymorphs," or "polys," as they are often called, are roughly 12 µm in diameter. Their cytoplasm is packed with pale granules containing lysosomal enzymes and bactericidal (bacteria-killing) compounds.

Neutrophils are highly mobile. They are generally the first of the WBCs to arrive at the site of an injury. These very active phagocytic cells specialize in attacking and digesting bacteria that have been "marked" with antibodies or with *complement proteins*—plasma proteins involved in tissue defenses. (We discuss the complement system in Chapter 22.)

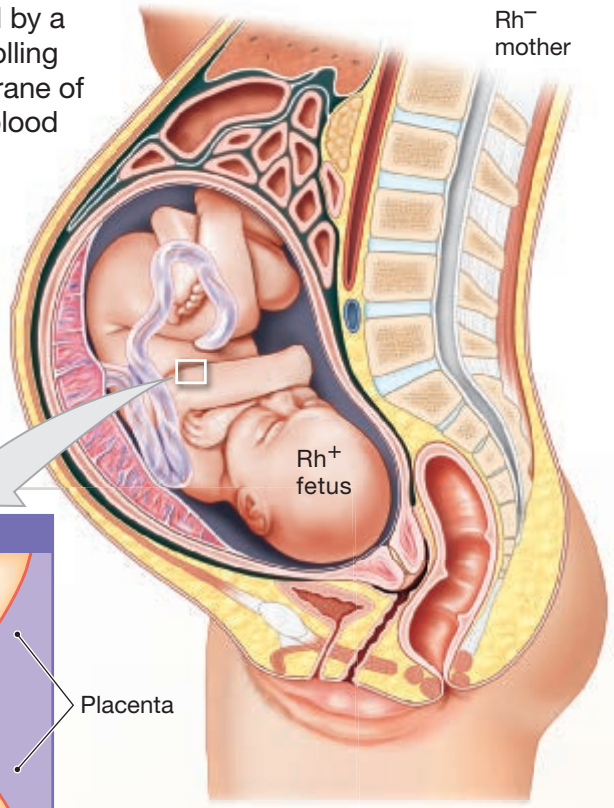
When a neutrophil encounters a bacterium, it quickly engulfs the invader, and the metabolic rate of the neutrophil increases dramatically. Along with this *respiratory burst*, the neutrophil produces highly reactive, destructive chemical agents, including hydrogen peroxide (H_2O_2) and superoxide anions (O_2^-), which can kill bacteria.

Meanwhile, the vesicle containing the engulfed pathogen fuses with lysosomes that contain digestive enzymes and small peptides called *defensins*. This process is called **degranulation** because it reduces the number of granules in the cytoplasm.

SPOTLIGHT

Figure 19–8
Hemolytic Disease of the Newborn

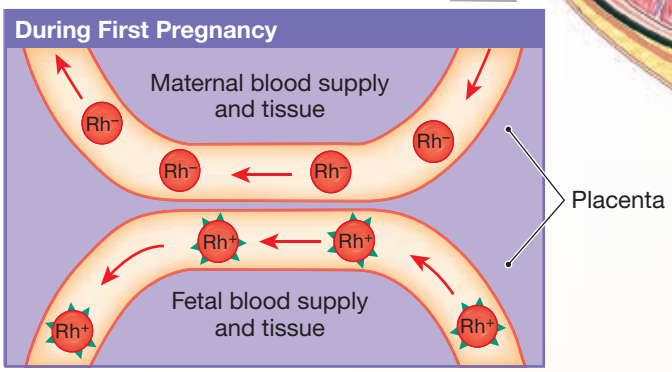
Hemolytic disease of the newborn is an RBC-related disorder caused by a cross-reaction between fetal and maternal blood types. Genes controlling the presence or absence of any surface antigen in the plasma membrane of a red blood cell are provided by both parents, so a child can have a blood type different from that of either parent. During pregnancy, when fetal and maternal vascular systems are closely intertwined, the mother's antibodies may cross the placenta, attacking and destroying fetal RBCs. The resulting condition, called **hemolytic disease of the newborn (HDN)**, has many forms, some quite dangerous and others so mild as to remain undetected.



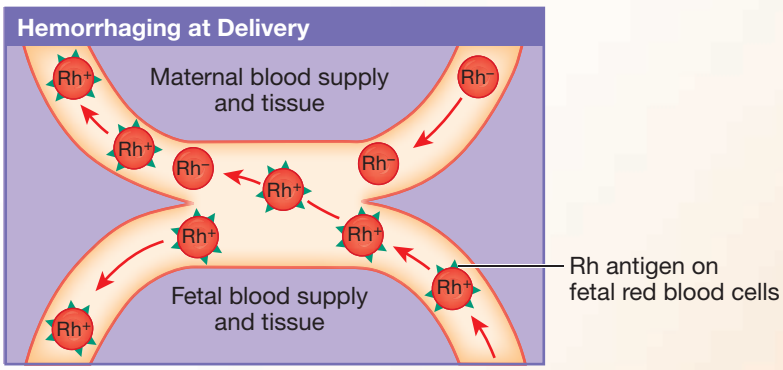
The most common form of hemolytic disease of the newborn develops after an Rh⁻ woman has carried an Rh⁺ fetus.

FIRST PREGNANCY

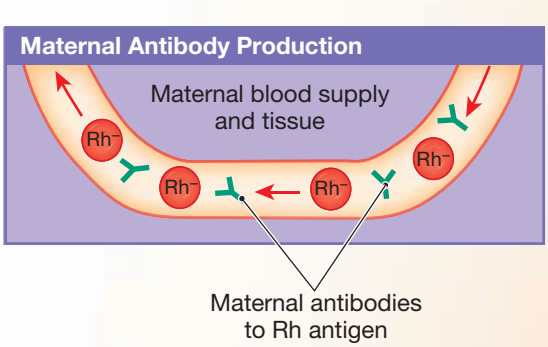
1 Problems seldom develop during a first pregnancy, because very few fetal cells enter the maternal bloodstream then, and thus the mother's immune system is not stimulated to produce anti-Rh antibodies.



2 Exposure to fetal red blood cell antigens generally occurs during delivery, when bleeding takes place at the placenta and uterus. Such mixing of fetal and maternal blood can stimulate the mother's immune system to produce anti-Rh antibodies, leading to sensitization.



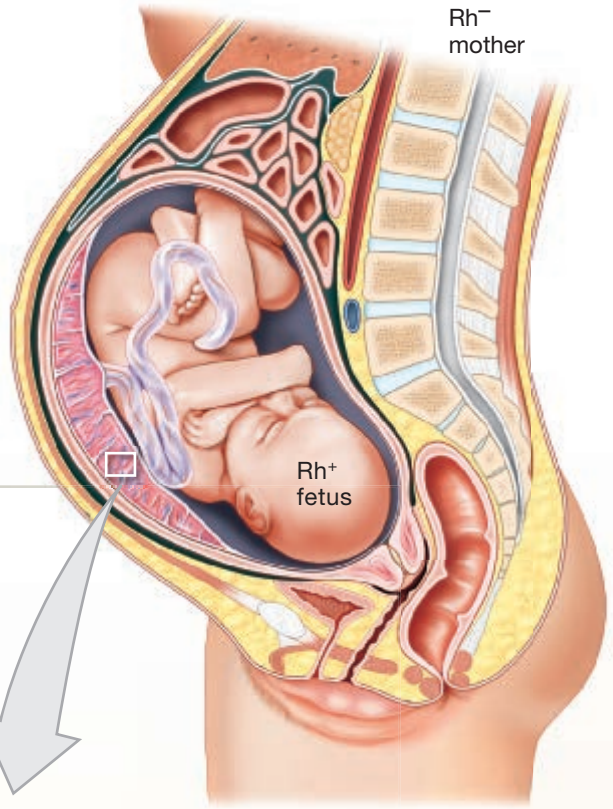
3 About 20% of Rh⁻ mothers who carried Rh⁺ children become sensitized within 6 months of delivery. Because the anti-Rh antibodies are not produced in significant amounts until after delivery, a woman's first infant is not affected.



SECOND PREGNANCY

4

If a future pregnancy involves an Rh^+ fetus, maternal anti-Rh antibodies produced after the first delivery cross the placenta and enter the fetal bloodstream. These antibodies destroy fetal RBCs, producing a dangerous anemia. The fetal demand for blood cells increases, and they leave the bone marrow and enter the bloodstream before completing their development. Because these immature RBCs are erythroblasts, HDN is also known as **erythroblastosis fetalis** (e-rith-rō-blas-TŌ-sis fē-TAL-is). Without treatment, the fetus may die before delivery or shortly thereafter. A newborn with severe HDN is anemic, and the high concentration of circulating bilirubin produces jaundice. Because the maternal antibodies remain active in the newborn for 1 to 2 months after delivery, the infant's entire blood volume may require replacement to remove the maternal anti-Rh antibodies, as well as the damaged RBCs. Fortunately, the mother's anti-Rh antibody production can be prevented if such antibodies (available under the name RhoGAM) are administered to the mother in weeks 26–28 of pregnancy and during and after delivery. These antibodies destroy any fetal RBCs that cross the placenta before they can stimulate a maternal immune response. Because maternal sensitization does not occur, no anti-Rh antibodies are produced. In the United States, this relatively simple procedure has almost entirely eliminated HDN mortality caused by Rh incompatibilities.



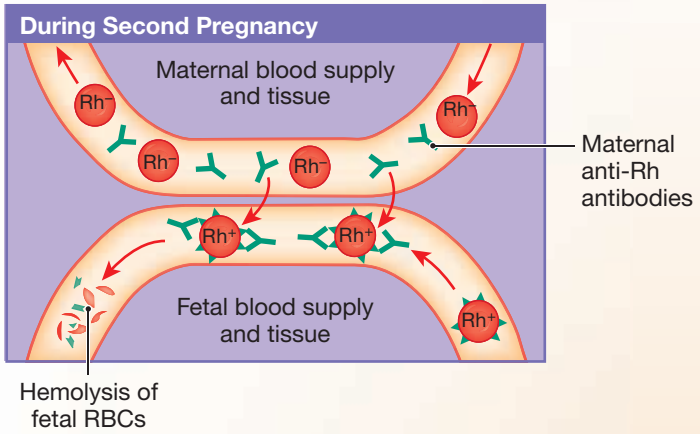


Figure 19–9 Types of White Blood Cells.

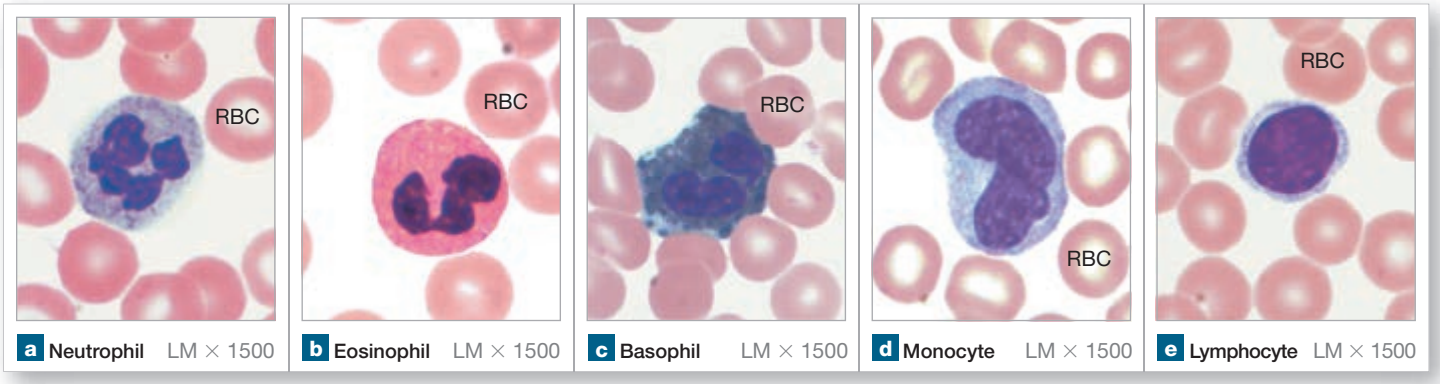


Defensins kill a variety of pathogens, including bacteria, fungi, and enveloped viruses, by combining to form large channels in their plasma membranes. The digestive enzymes then break down the bacterial remains.

While actively attacking bacteria, a neutrophil releases prostaglandins and leukotrienes. ↩ p. 615 The prostaglandins increase capillary permeability in the affected region, contributing to local inflammation and restricting the spread of injury and infection. Leukotrienes are hormones that attract other phagocytes and help coordinate the immune response.

Most neutrophils have a short life span. They survive in the bloodstream for only about 10 hours. When actively engulfing debris or pathogens, they may last 30 minutes or less. A neutrophil dies after engulfing one to two dozen bacteria, but its breakdown releases chemicals that attract other neutrophils to the site. A mixture of dead neutrophils, cellular debris, and other wastes form the *pus* associated with infected wounds.

19

Tips & Tools

Remember that **neu**trophils are the most **nu**merous of the white blood cells.

Eosinophils

Eosinophils (ē-ō-SIN-ō-filz) have granules that stain darkly with *eosin*, a red dye. The granules also stain with other acid dyes, so the name **acidophils** (ah-SID-ō-filz) applies as well. Eosinophils generally represent 2–4 percent of the circulating WBCs. They are similar in size to neutrophils. However, the combination of deep red granules and a typically bilobed (two-lobed) nucleus makes eosinophils easy to identify (**Figure 19–9b**).

Eosinophils attack objects that are coated with antibodies. These phagocytic cells will engulf antibody-marked bacteria, protozoa, or cellular debris, but their primary mode of attack is the exocytosis of toxic compounds, including nitric oxide and cytotoxic enzymes. This is particularly effective against multicellular parasites that are too big to engulf, such as flukes or parasitic roundworms. The number of circulating eosinophils increases dramatically during a parasitic infection.

Eosinophils increase in number during allergic reactions as well, because they are sensitive to circulating *allergens* (materials that trigger allergies). Eosinophils are also attracted to sites of injury, where they release enzymes that reduce inflammation produced by mast cells and neutrophils. This controls the spread of inflammation to adjacent tissues.

Basophils

Basophils (BĀ-sō-filz; *baso-*, base + *phileo*, to love) have numerous granules that stain darkly with basic dyes. In a standard blood smear, the inclusions are deep purple or blue (**Figure 19–9c**). Measuring 8–10 µm in diameter, basophils are smaller than neutrophils or eosinophils. They are also relatively rare, accounting for less than 1 percent of the circulating WBC population.

Basophils migrate to injury sites and cross the capillary **endothelium** to accumulate in the damaged tissues. There they discharge their granules into the interstitial fluids. The granules contain *histamine*, which dilates blood vessels, and *heparin*, a compound that prevents blood clotting. Stimulated basophils release these chemicals into the interstitial fluids to enhance the local inflammation initiated by mast cells. ↩ p. 129 Although mast cells release the same compounds in damaged connective tissues, mast cells and basophils are distinct populations. Stimulated basophils also release other chemicals that attract eosinophils and other basophils to the area.

Monocytes

Monocytes (MON-ō-sīts) are spherical cells that may exceed 15 µm in diameter, nearly twice the diameter of a typical RBC. When flattened in a blood smear, they look even larger, so monocytes are fairly easy to identify. The nucleus is large and tends to be oval or kidney bean–shaped rather than lobed (**Figure 19–9d**). Monocytes normally account for 2–8 percent of circulating WBCs.

An individual monocyte is transported in the bloodstream. It remains in circulation for only about 24 hours before entering peripheral tissues to become a tissue macrophage. Macrophages are aggressive phagocytes. They often attempt to engulf items as large as or larger than themselves. When active, they release chemicals that attract and stimulate neutrophils, monocytes, and other phagocytic cells. Active macrophages also secrete substances that draw fibroblasts into the region. The fibroblasts then begin producing scar tissue to wall off the injured area. Macrophages are discussed further in Chapter 22.

Tips & Tools

A **mon**ocyte is the **mon**ster cell that engulfs debris and pathogens.

Lymphocytes

Typical **lymphocytes** (LIM-fō-sīts) are slightly larger than RBCs and lack abundant, deeply staining granules. In blood smears, lymphocytes typically have a large, round nucleus surrounded by a thin halo of cytoplasm (Figure 19–9e).

Lymphocytes account for 20–40 percent of the circulating WBC population. Lymphocytes continuously migrate from the bloodstream, through peripheral tissues, and back to the bloodstream. Circulating lymphocytes represent only a small fraction of all lymphocytes. At any moment, most of your body's lymphocytes are in other connective tissues and in organs of the lymphatic system.

The circulating blood contains three functional classes of lymphocytes. These classes cannot be distinguished using just a light microscope. They are as follows:

- **T cells** (T lymphocytes) are responsible for *cell-mediated immunity*, a specific defense mechanism against invading foreign cells, and for the coordination of the immune response. T cells either enter peripheral tissues and attack foreign cells directly, or control the activities of other lymphocytes.
- **B cells** (B lymphocytes) are responsible for *humoral immunity*, a specific defense mechanism that involves the production of antibodies. These antibodies are distributed by blood, lymph, and interstitial fluid and are capable of attacking foreign antigens throughout the body. Activated B cells differentiate into **plasma cells**, which are specialized to synthesize and secrete antibodies. The T cells responsible for cellular immunity must migrate to their targets, but the antibodies produced by plasma cells in one location can destroy antigens almost anywhere in the body.
- **Natural killer (NK) cells** carry out *immune surveillance*—the detection and subsequent destruction of abnormal cells. NK cells, sometimes known as *large granular lymphocytes*, are important in preventing cancer.

Tips & Tools

To remember the various white blood cell populations, think "Never let monkeys eat bananas" for neutrophils, lymphocytes, monocytes, eosinophils, and basophils.

The Differential Count and Changes in WBC Profiles

A variety of conditions, including infection, inflammation, and allergic reactions, cause characteristic changes in circulating populations of WBCs. By examining a stained blood smear, we can obtain a **differential count** of the WBC population. The values reported provide a *WBC profile* indicating the number of each type of cell in a sample of 100 WBCs. The normal range of abundance for each type of WBC is shown in Table 19–3.

The term **leukopenia** (lū-kō-PĒ-nē-uh; *penia*, poverty) indicates inadequate numbers of WBCs. **Leukocytosis** (loo-kō-sī-TŌ-sis) refers to excessive numbers of WBCs. A modest leukocytosis is normal during an infection. Extreme leukocytosis (100,000/µL or more) generally indicates the presence of some form of **leukemia** (lū-KĒ-mē-uh), a cancer of the WBCs.

WBC Production: Leukopoiesis

The process of WBC production is called **leukopoiesis** (lū-kō-POY-eh-sis). Stem cells that produce WBCs originate in the red bone marrow, with the divisions of hemocytoblasts (Figure 19–10). As we have noted, hemocytoblast divisions produce myeloid stem cells and lymphoid stem cells. Myeloid stem cells divide to create **progenitor cells**, which give rise to all the formed elements except lymphocytes. One type of progenitor cell produces daughter cells that mature into RBCs. A second type produces cells that manufacture platelets. A third type produces daughter cells that develop into neutrophils, eosinophils, basophils, and monocytes.

Granulocytes (basophils, eosinophils, and neutrophils) complete their development in the red bone marrow. These WBCs go through a series of maturational stages, proceeding from *blast cells* to *myelocytes* to *band cells* before becoming mature WBCs. For example, a cell differentiating into a neutrophil goes from a *myeloblast* to a *neutrophilic myelocyte* and then becomes a *neutrophilic band cell*. Some band cells enter the bloodstream before completing their maturation. Normally, 3–5 percent of all circulating WBCs are band cells.

Monocytes begin to differentiate in the red bone marrow. Then they enter the bloodstream and complete development when they become free macrophages in peripheral tissues.

The process of lymphocyte production is called **lymphocytopoiesis**. Some lymphocytes are derived from lymphoid stem cells that remain in red bone marrow. These lymphocytes differentiate into either B cells or natural killer cells.

Table 19–3 Formed Elements of the Blood

Cell	Abundance (average number per μL)	Appearance in a Stained Blood Smear	Functions	Remarks
RED BLOOD CELLS	5.2 million (range: 4.2–6.3 million)	Flattened, circular cell; no nucleus, mitochondria, or ribosomes; red	Transport oxygen from lungs to tissues and carbon dioxide from tissues to lungs	Remain in bloodstream; 120-day life expectancy; amino acids and iron recycled; produced in red bone marrow
WHITE BLOOD CELLS	7000 (range: 5000–10,000)			
Neutrophils	4150 (range: 1800–7300) Differential count: 50–70%	Round cell; nucleus lobed and may resemble a string of beads; cytoplasm contains large, pale inclusions	Phagocytic: Engulf pathogens or debris in tissues, release cytotoxic enzymes and chemicals	Move into tissues after several hours; may survive minutes to days, depending on tissue activity; produced in red bone marrow
Eosinophils	165 (range: 0–700) Differential count: 2–4%	Round cell; nucleus generally in two lobes; cytoplasm contains large granules that generally stain bright red	Phagocytic: Engulf antibody-labeled materials, release cytotoxic enzymes, reduce inflammation; increase in allergic and parasitic situations	Move into tissues after several hours; survive minutes to days, depending on tissue activity; produced in red bone marrow
Basophils	44 (range: 0–150) Differential count: <1%	Round cell; nucleus generally cannot be seen through dense, blue-stained granules in cytoplasm	Enter damaged tissues and release histamine and other chemicals that promote inflammation	Survival time unknown; assist mast cells of tissues in producing inflammation; produced in red bone marrow
Monocytes	456 (range: 200–950) Differential count: 2–8%	Very large cell; kidney bean–shaped nucleus; abundant pale cytoplasm	Enter tissues to become macrophages; engulf pathogens or debris	Move into tissues after 1–2 days; survive for months or longer; produced primarily in red bone marrow
Lymphocytes 	2185 (range: 1500–4000) Differential count: 20–40%	Generally round cell, slightly larger than RBC; round nucleus; very little cytoplasm	Cells of lymphatic system, providing defense against specific pathogens or toxins	Survive for months to decades; circulate from blood to tissues and back; produced in red bone marrow and lymphatic tissues
PLATELETS	350,000 (range: 150,000–500,000)	Round to disc-shaped cytoplasmic fragment; contain enzymes, proenzymes, actin, and myosin; no nucleus	Hemostasis: Clump together and stick to vessel wall (platelet phase); activate intrinsic pathway of coagulation phase	Remain in bloodstream or in vascular organs; remain intact for 7–12 days; produced by megakaryocytes in red bone marrow

Many of the lymphoid stem cells that produce lymphocytes migrate from the red bone marrow to peripheral **lymphatic tissues**, including the thymus, spleen, and lymph nodes. As a result, lymphocytes are produced in these organs as well as in the red bone marrow. Lymphoid stem cells migrating to the thymus mature into T cells.

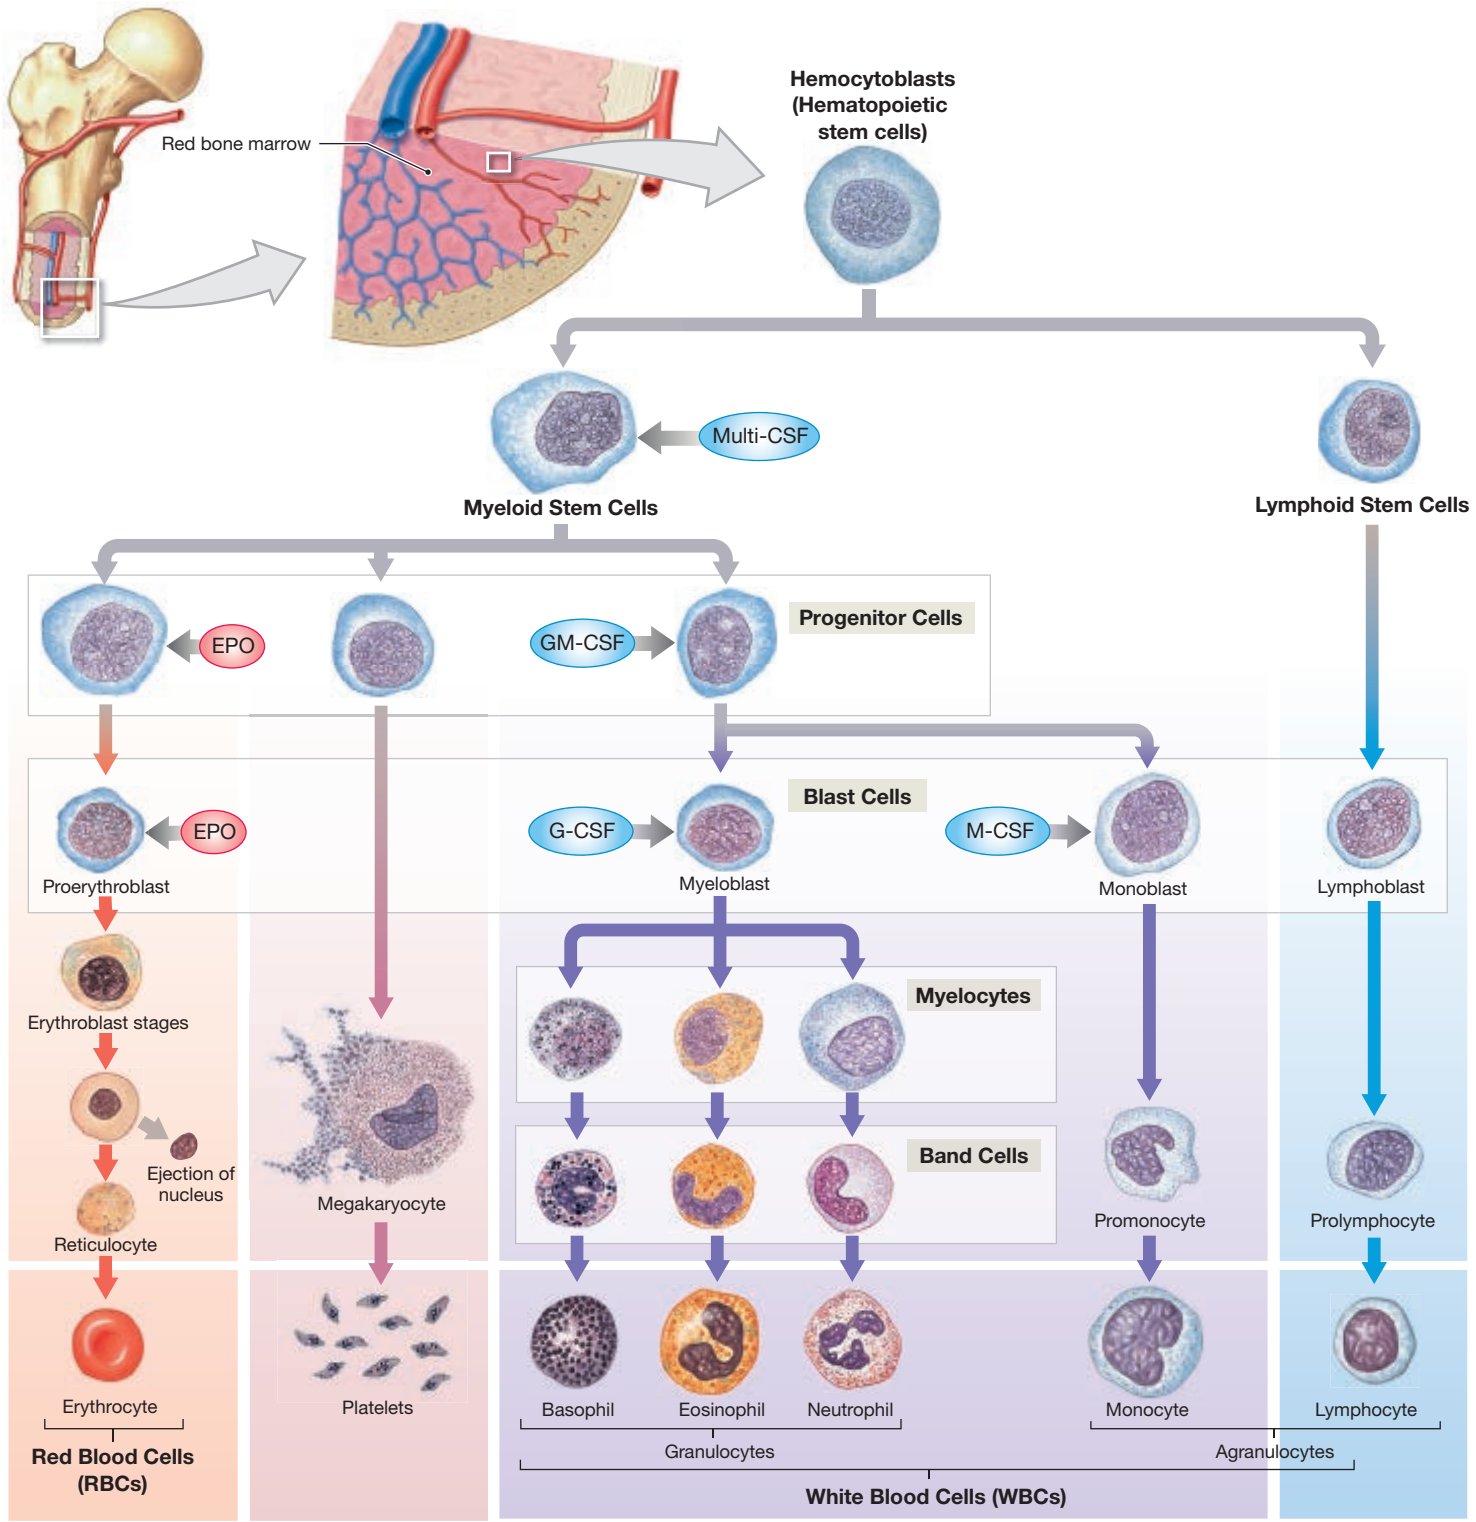
Regulation of WBC Production

Factors that regulate lymphocyte maturation are incompletely understood. Until adulthood, hormones produced by the thymus promote the differentiation and maintenance of T cell populations. The importance of the thymus in adults, especially with respect to aging, remains unclear. In adults, the production of B and T lymphocytes is regulated primarily by exposure to antigens (foreign proteins, cells, or toxins). When antigens appear, lymphocyte production escalates. We describe the control mechanisms in Chapter 22.

Several hormones, called **colony-stimulating factors** (**CSFs**), are involved in regulating other WBC populations. Four CSFs have been identified. Each stimulates the formation of WBCs or both WBCs and RBCs. The designation for each factor indicates its target, as shown in the blue ovals in Figure 19–10:

- **Multi-CSF** accelerates the production of granulocytes, monocytes, platelets, and RBCs.

Figure 19–10 The Origins and Differentiation of Formed Elements. Hemocytoblast divisions give rise to myeloid stem cells or lymphoid stem cells. Myeloid stem cells produce progenitor cells that divide to produce red blood cells, platelets, and white blood cells except for lymphocytes. The targets of erythropoietin (EPO) and the four colony-stimulating factors (CSFs) are indicated. Lymphoid stem cells produce the various lymphocytes.



? Granulocytes consist of what three types of mature cells and from what blast cell do granulocytes differentiate?

- **GM-CSF** stimulates the production of both granulocytes and monocytes. **G-CSF** stimulates the production of granulocytes (neutrophils, eosinophils, and basophils)
- **M-CSF** stimulates the production of monocytes.

Chemical communication between lymphocytes and other WBCs helps to coordinate the immune response. For example, active macrophages release chemicals that make lymphocytes more sensitive to antigens and also accelerate the development of specific immunity. In turn, active lymphocytes release multi-CSF and GM-CSF, reinforcing nonspecific defenses.

Immune system hormones are under intensive study because of their potential clinical importance. The molecular structures of many of the stimulating factors have been identified, and several are produced by genetic engineering.

Checkpoint

12. **Identify the five types of white blood cells.**
13. **Which type of white blood cell would you find in the greatest numbers in an infected cut?**
14. **Which type of cell would you find in elevated numbers in a person who is producing large amounts of circulating antibodies to combat a virus?**
15. **How do basophils respond to an injury?**

See the blue Answers tab at the back of the book.

19-5 Platelets, disc-shaped cell fragments, function in the clotting process

Learning Outcome Describe the structure, function, and production of platelets.

In a blood smear, **platelets** appear as disc-shaped cell fragments (see Figure 19–10). They average about 3 µm in diameter and are roughly 1 µm thick. Platelets, or *thrombocytes*, play a major role in a vascular *clotting system* that also includes plasma proteins and the cells and tissues of the blood vessels.

Platelets are continuously replaced. Each platelet circulates for 9–12 days before being removed by phagocytes, mainly in the spleen. Each microliter of circulating blood contains 150,000–500,000 platelets; the average concentration is 350,000/µL. About one-third of the platelets in the body at any moment are in the spleen and other vascular organs, rather than in the bloodstream. These reserves are mobilized during a circulatory crisis, such as severe bleeding.

Platelet Functions

The functions of platelets include:

- *Releasing Chemicals Important to the Clotting Process.* By releasing enzymes and other factors at the appropriate times, platelets help initiate and control the clotting process.
- *Forming a Temporary Patch in the Walls of Damaged Blood Vessels.* Platelets clump together at an injury site, forming a *platelet plug*, which can slow blood loss while clotting takes place.
- *Reducing the Size of a Break in a Vessel Wall.* Platelets contain filaments of actin and myosin. After a blood clot has formed, platelet filaments contract to shrink the clot and reduce the size of the break in the vessel wall.

Platelet Production

Platelet production, or **thrombocytopoiesis** (throm-bō-sī-tō-POY-eh-sis), takes place in the red bone marrow. Normal red bone marrow contains **megakaryocytes** (meg-ah-KAR-ē-ō-sīts; *mega-*, big + *karyon*, nucleus + *-cyte*, cell), enormous cells (up to 160 µm in diameter) with large nuclei (see Figure 19–10). During their development and growth, megakaryocytes manufacture structural proteins, enzymes, and membranes. They then begin shedding cytoplasm in small membrane-enclosed packets. These packets are the platelets that enter the bloodstream. A mature megakaryocyte gradually loses all of its cytoplasm, producing about 4000 platelets before phagocytes engulf its nucleus for breakdown and recycling.

Three substances influence the rate of megakaryocyte activity and platelet formation. They are (1) *thrombopoietin* (*TPO*), or *thrombocyte-stimulating factor*, a peptide hormone produced in the kidneys (and perhaps other sites) that accelerates platelet formation and stimulates the production of megakaryocytes; (2) *interleukin-6* (*IL-6*), a hormone that stimulates platelet formation; and (3) multi-CSF, which stimulates platelet production by promoting megakaryocyte formation and growth.

Checkpoint

16. **Define *thrombocytopoiesis*.**
17. **List the three primary functions of platelets.**

See the blue Answers tab at the back of the book.

19-6 The process of blood clotting, or hemostasis, stops blood loss

Learning Outcome Discuss the mechanisms that control blood loss after an injury, and describe the reaction sequences responsible for blood clotting.

The process of **hemostasis** (*haima*, blood + *stasis*, halt), the stopping of bleeding, halts the loss of blood through the walls of damaged vessels. At the same time, it establishes a framework for tissue repairs. Hemostasis has three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase* (Figure 19–11). The boundaries of these phases are somewhat arbitrary. In reality, hemostasis is a complex *cascade*, or chain reaction, in which many things happen at once, and all of them interact to some degree. The end of the process is *clot retraction*.

The Vascular Phase

Cutting the wall of a blood vessel triggers a contraction in the smooth muscle fibers of the vessel wall (see Figure 19–11 1). This local contraction of the vessel is a **vascular spasm**, which decreases the diameter of the vessel at the site of injury. Such a constriction can slow or even stop blood loss through the wall of a small vessel. The vascular spasm lasts about 30 minutes, a period called the **vascular phase** of hemostasis.

During the vascular phase, changes take place in the endothelium of the vessel at the injury site:

- *The Endothelial Cells Contract and Expose the Underlying Basement Membrane to the Bloodstream.*
- *The Endothelial Cells Begin Releasing Chemical Factors and Local Hormones.* We will discuss several of these factors, including *ADP*, *tissue factor*, and *prostacyclin*, later in this section. Endothelial cells also release peptide hormones called **endothelins**. These local hormones (1) stimulate smooth muscle contraction and promote vascular spasms, and (2) stimulate the division of endothelial cells, smooth muscle cells, and fibroblasts to accelerate the repair process.
- *The Endothelial Plasma Membranes Become "Sticky."* A tear in the wall of a small artery or vein may be partially sealed off by the attachment of endothelial cells on either side of the break. In small capillaries, endothelial cells on opposite sides of the vessel may stick together and prevent blood flow along the damaged vessel. The stickiness is also important because it helps platelets to attach as the platelet phase gets under way.

The Platelet Phase

The attachment of platelets to sticky endothelial surfaces, to the basement membrane, and to exposed collagen fibers marks the start of the **platelet phase** of hemostasis (see Figure 19–11 2). The attachment of platelets to exposed surfaces is called **platelet adhesion**. As more and more platelets arrive, they begin sticking to one another as well. This process, called **platelet aggregation**, forms a **platelet plug** that may close the break in the vessel wall if the damage is not severe or the vessel is relatively small. Platelet aggregation begins within 15 seconds after an injury occurs.

As platelets arrive at the injury site, they become activated. The first sign of this activation is that the platelets become more spherical and develop cytoplasmic processes that extend toward nearby platelets. At this time, the platelets begin releasing a wide variety of compounds. These compounds include (1) *adenosine diphosphate (ADP)*, which stimulates platelet aggregation and secretion; (2) *thromboxane* A_2 and *serotonin*, which stimulate vascular spasms; (3) *clotting factors*, proteins that play a role in blood clotting; (4) *platelet-derived growth factor (PDGF)*, a peptide that promotes vessel repair; and (5) calcium ions, which are required for platelet aggregation and in several steps in the clotting process.

The platelet phase proceeds quickly, as ADP, thromboxane, and calcium ions released from each arriving platelet stimulate further aggregation. This positive feedback loop ultimately produces a platelet plug that will be reinforced as clotting occurs. ↩ p. 22 However, platelet aggregation must be controlled and restricted to the injury site.

Several key factors limit the growth of the platelet plug: (1) **prostacyclin**, a prostaglandin that inhibits platelet aggregation and is released by endothelial cells; (2) inhibitory compounds released by WBCs entering the area; (3) circulating plasma enzymes that break down ADP near the plug; (4) compounds that, when abundant, inhibit plug formation (for example, serotonin, which at a high concentration blocks the action of ADP); and (5) the development of a blood clot, which reinforces the platelet plug but isolates it from the general circulation.

The Coagulation Phase

The vascular and platelet phases begin within a few seconds after the injury. The **coagulation** (kō-ag-yū-LĀ-shun) **phase**, or **blood clotting**, does not start until 30 seconds or more after the vessel has been damaged. Figure 19–11 3) shows the sequence of steps involved in the formation and structure of a blood clot.

Clotting Factors

Normal blood clotting depends on the presence of **clotting factors**, or **procoagulants**, in the plasma. Important clotting factors include Ca^{2+} and 11 different proteins (Table 19–4).

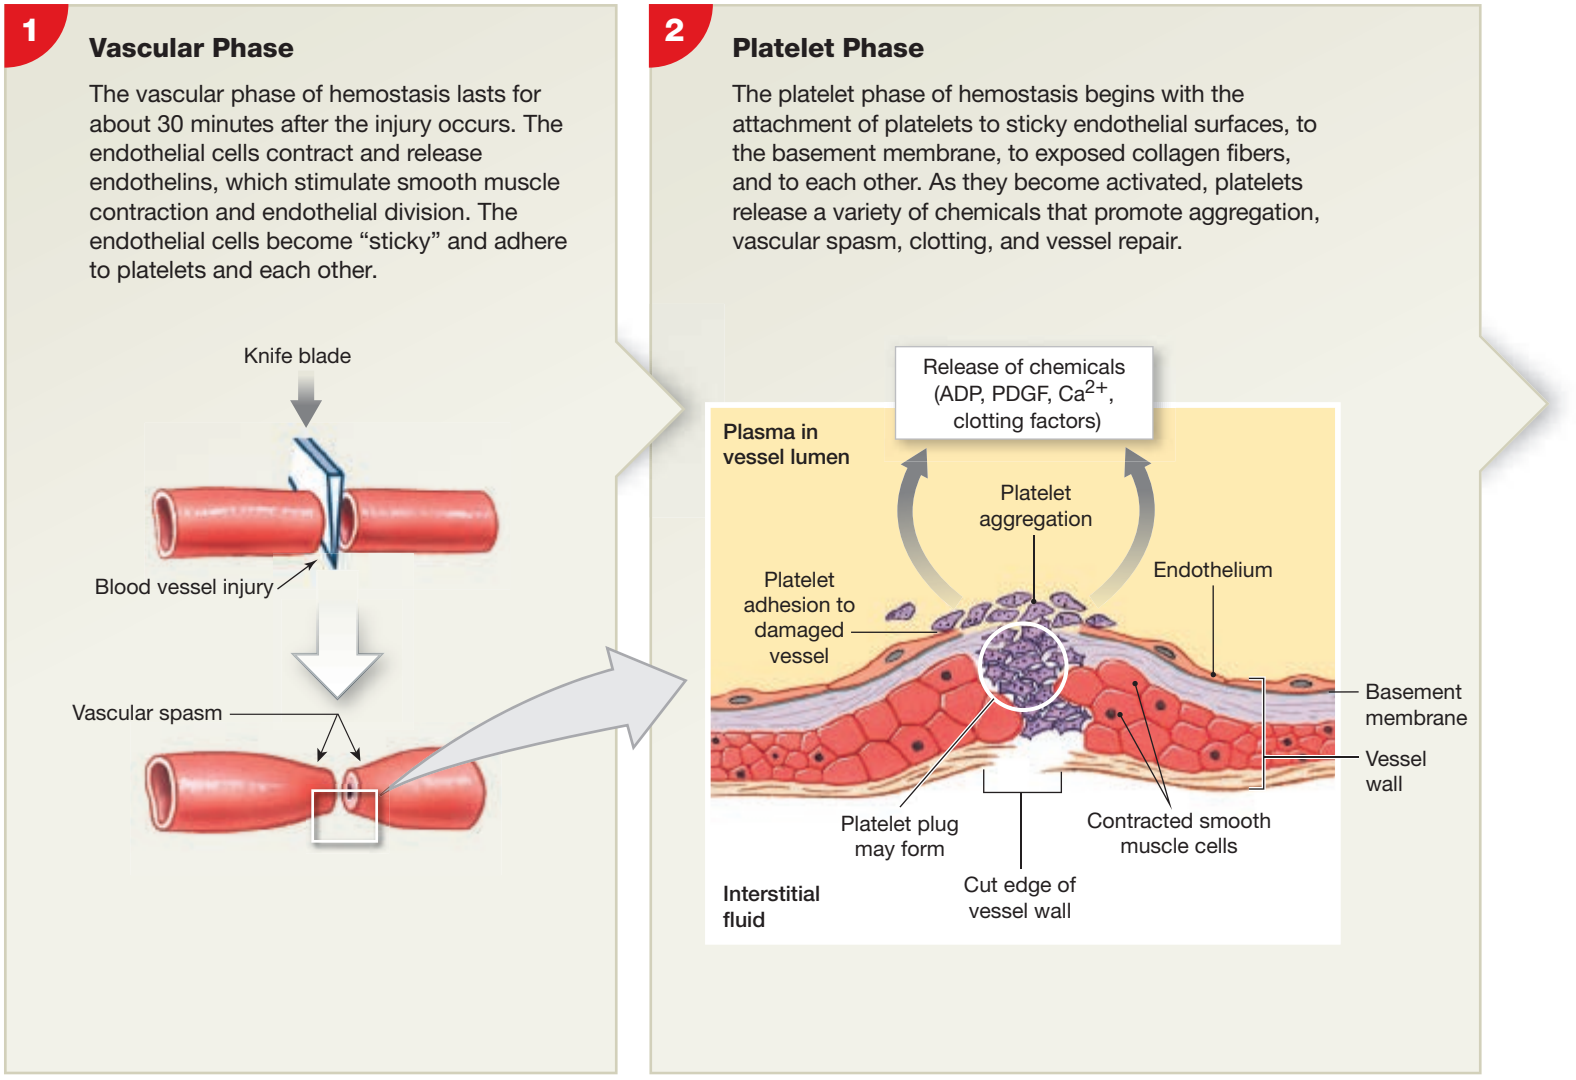
Many of the clotting proteins are **proenzymes**, or inactive enzymes. When converted to active enzymes, these proteins direct essential reactions in the **clotting response**. During the coagulation phase, enzymes and proenzymes interact successively. The activation of one proenzyme commonly creates an enzyme that activates a second proenzyme, and so on in a cascade.

The Coagulation Process

The process of coagulation involves the chain reactions of the *extrinsic*, *intrinsic*, and *common pathways* (see Figure 19–11 3). The extrinsic pathway begins outside the bloodstream, in the vessel wall. The intrinsic pathway begins inside the bloodstream, with the activation of a circulating proenzyme. These two pathways converge at the common pathway.

The Extrinsic Pathway. The **extrinsic pathway** begins when damaged endothelial cells or peripheral tissues release **Factor III**, also termed *tissue factor* or *thromboplastin*. The greater the damage, the more tissue factor is released and the faster clotting takes place. Factor III then combines with Ca^{2+} and another

FIGURE 19–11 The Phases of Hemostasis (Vascular, Platelet, and Coagulation) and Clot Retraction.



clotting factor (Factor VII) to form an enzyme complex capable of activating Factor X, the first step in the common pathway.

The Intrinsic Pathway. The **intrinsic pathway** begins with the activation of proenzymes (usually Factor XII) exposed to collagen fibers at the injury site (or to a glass surface of a slide or collection tube). This pathway proceeds with the assistance of **PF-3**, a platelet factor released by aggregating platelets. Platelets also release a variety of other factors that accelerate the reactions of the intrinsic pathway. After a series of linked reactions, activated Factors VIII and IX combine to form an enzyme complex capable of activating Factor X.

The Common Pathway. The **common pathway** begins when enzyme complexes from either pathway activate Factor X. Activated Factor X activates a complex called **prothrombin activator**. Prothrombin activator converts the proenzyme prothrombin into the enzyme **thrombin**. Thrombin then completes the clotting process by converting fibrinogen, a soluble plasma protein, to insoluble strands of **fibrin**, producing a **blood clot** (see the SEM in Figure 19–11 3).

Interactions among the Pathways

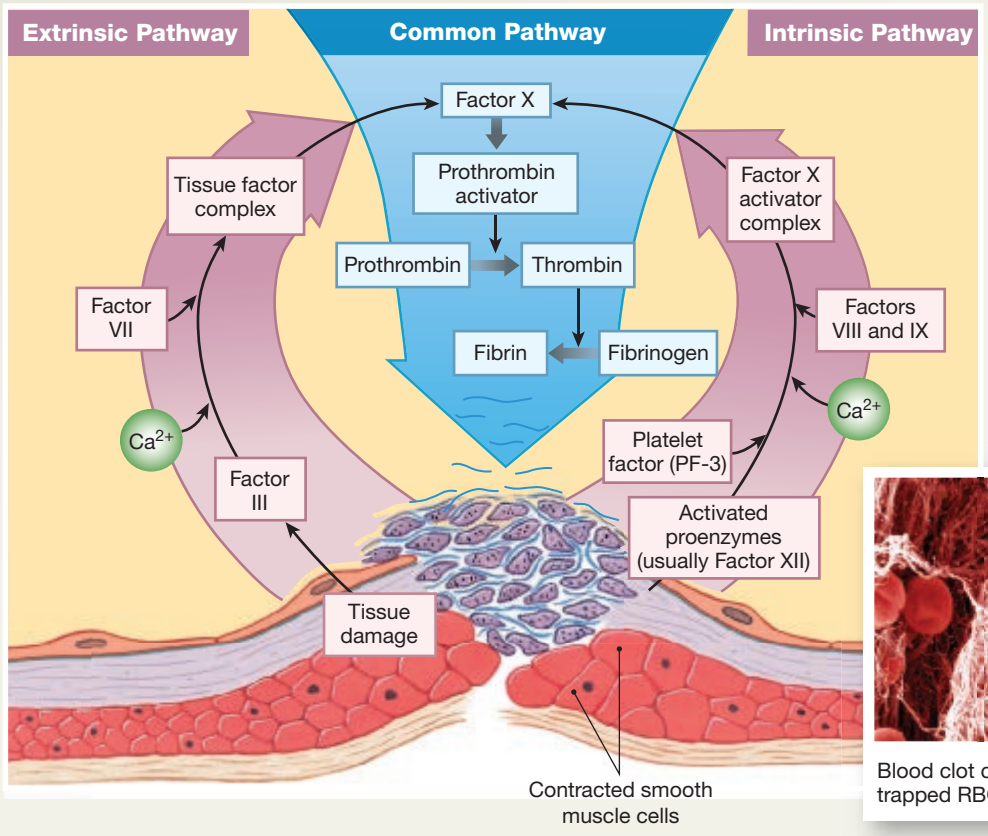
When a blood vessel is damaged, both the extrinsic and intrinsic pathways respond. The extrinsic pathway is shorter and faster than the intrinsic pathway, and it is usually the first to initiate clotting by the common pathway. In essence, the extrinsic pathway stimulates the common pathway to produce a small amount of thrombin very quickly. This quick patch is reinforced by the intrinsic pathway, which later stimulates the common pathway to produce more thrombin.

Then the activity of the common pathway in turn stimulates both the intrinsic and extrinsic pathways. Thrombin

3

Coagulation Phase

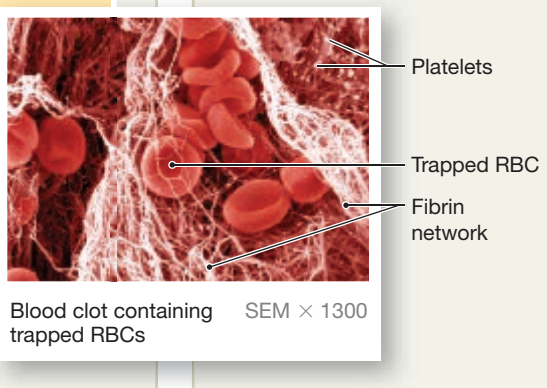
Coagulation, or blood clotting, involves a complex sequence of steps leading to the conversion of circulating fibrinogen (a soluble protein) into fibrin (an insoluble protein). As the fibrin network grows, blood cells and additional platelets are trapped in the fibrous tangle, forming a **blood clot** that seals off the damaged portion of the vessel.



4

Clot Retraction

Once the fibrin meshwork has formed, platelets and red blood cells stick to the fibrin strands. The platelets then contract, and the entire clot begins to undergo clot retraction, a process that continues over 30–60 minutes.



Blood clot containing trapped RBCs SEM × 1300

generated in the common pathway stimulates blood clotting by (1) stimulating the formation of tissue factor and (2) stimulating the release of PF-3 by platelets (see Figure 19–11 3). This positive feedback loop accelerates the clotting process, and speed can be very important in reducing blood loss after a severe injury.

The time required to complete clot formation varies with the site and the nature of the injury. In tests of the clotting system, blood held in fine glass tubes normally clots in 8–18 minutes (the *coagulation time*). A small puncture wound typically stops bleeding in 1–4 minutes (the *bleeding time*).

Feedback Control of Blood Clotting

Blood clotting is restricted by substances that either deactivate or remove clotting factors and other stimulatory agents from the blood. Examples include the following:

- Normal plasma contains several **anticoagulants**—enzymes that inhibit clotting. One, **antithrombin-III**, inhibits several clotting factors, including thrombin.
- **Heparin**, a compound released by basophils and mast cells, is a cofactor that accelerates the activation of antithrombin-III. Heparin is also used clinically to impede or prevent clotting.
- **Thrombomodulin** is released by endothelial cells. This protein binds to thrombin and converts it to an enzyme that activates protein C. **Protein C** is a plasma protein that inactivates several clotting factors and stimulates the formation of *plasmin*, an enzyme that gradually breaks down fibrin strands.
- Prostacyclin released during the platelet phase inhibits platelet aggregation and opposes the stimulatory action of thrombin, ADP, and other factors.

Table 19–4 Clotting Factors

Factor	Structure	Name	Source	Concentration in Plasma (µg/mL)	Pathway
I	Plasma protein	Fibrinogen	Liver	2500–3500	Common
II	Plasma protein	Prothrombin	Liver, requires vitamin K	100	Common
III	Glycoprotein	Tissue factor (TF)	Damaged tissue, activated platelets	0	Extrinsic
IV	Ion	Calcium ions (Ca^{2+})	Bone, diet, platelets	100	Entire process
V	Protein	Pro-accelerin	Liver, platelets	10	Extrinsic and intrinsic
VI	(No longer used)				
VII	Plasma protein	Proconvertin	Liver, requires vitamin K	0.5	Extrinsic
VIII	Plasma protein	Antihemophilic factor (AHF)	Liver, lung endothelial cells	15	Intrinsic
IX	Plasma protein	Plasma thromboplastin component (PTC), Christmas factor	Liver, requires vitamin K	3	Intrinsic
X	Plasma protein	Stuart–Prower factor	Liver, requires vitamin K	10	Extrinsic and intrinsic
XI	Plasma protein	Plasma thromboplastin antecedent (PTA)	Liver	<5	Intrinsic
XII	Plasma protein	Hageman factor	Liver	<5	Intrinsic; also activates plasmin
XIII	Plasma protein	Fibrin-stabilizing factor (FSF)	Liver, platelets	20	Stabilizes fibrin, slows fibrinolysis

Clinical Note Bleeding and Clotting Extremes

In a healthy circulation pattern, blood moves relatively freely through smooth blood vessels. Both the composition of the blood and the structure of the vessels must be normal to support ideal blood flow.

Bleeding problems occur when the blood lacks platelets, or when clotting proteins are deficient or defective. The most common reason for bleeding is **thrombocytopenia**, a condition in which the platelet count is too low. This may result from drug toxicity, underlying bone marrow disease, or for unknown reasons. **Hemophilia** is a genetic disorder seen in males and characterized by the lack of clotting factors such as Factor VIII or IX. When hemostasis is activated (for example, due to trauma), the coagulation pathway cannot proceed, and so the fibrin clot cannot form. The person experiences bleeding that may prove fatal depending on the severity of the injury.

Clotting problems are called **thrombophilia**. When clots form in the venous system, the serious condition **deep vein thrombosis (DVT)** can result. These clots can loosen, travel through the circulation, and end up wedged in blood vessels of the lungs. The lungs are then hampered in oxygenating the blood. This condition, called *pulmonary embolism*, is fatal in 30 percent of cases.

The clotting process involves a complex chain of events, and disorders that affect any individual clotting factor can disrupt the entire process. For this reason, managing many clinical conditions involves controlling or manipulating the clotting response. *Aspirin*, for example, is a common drug that interferes with blood clotting and prolongs bleeding time. It acts by inhibiting platelets from producing prostaglandins and thromboxane A_2, which stimulates new platelet activation and aggregation.

Calcium Ions, Vitamin K, and Blood Clotting

Calcium ions and **vitamin K** affect almost every aspect of the clotting process. All three pathways (intrinsic, extrinsic, and common) require Ca^{2+}, so any disorder that lowers the plasma Ca^{2+} concentration will impair blood clotting.

Adequate amounts of vitamin K must be present for the liver to synthesize four of the clotting factors, including prothrombin. Vitamin K is a fat-soluble vitamin, present in green vegetables, grain, and organ meats, that is absorbed with dietary lipids. We obtain roughly half of our daily requirement from the diet. Bacteria in the large intestine manufacture the other half. A vitamin K deficiency may arise from a diet inadequate in fats or in vitamin K, or a disorder that affects fat digestion and absorption (such as problems with bile production), or prolonged use of antibiotics that kill normal intestinal bacteria. Vitamin K deficiency will cause the eventual breakdown of the common pathway due to a lack of clotting factors. Ultimately, the deficiency can deactivate the entire clotting system.

Clot Retraction

Clot retraction pulls the torn edges of the vessel closer together (see Figure 19–11 4). This process reduces residual bleeding and stabilizes the injury site. The process also reduces the size of the damaged area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to complete repairs.

Fibrinolysis

As the repairs proceed, the clot gradually dissolves in a process called **fibrinolysis** (fī-brih-NOL-uh-sis). The process begins when two enzymes activate the proenzyme **plasminogen** (plaz-MIN-ō-jen). These enzymes are thrombin, produced by the common pathway, and **tissue plasminogen activator (t-PA)**, released by damaged tissues at the site of injury. The activation of plasminogen produces the enzyme **plasmin**, which begins digesting the fibrin strands and eroding the clot.

To perform its vital functions, blood must be kept in motion. On average, an RBC completes two circuits around the cardiovascular system each minute. Blood begins to circulate in the third week of embryonic development and continues throughout life. If the blood supply is cut off, dependent tissues may die in a matter of minutes. In Chapter 20, we examine the structure and function of the heart—the pump that maintains this vital blood flow.

Checkpoint

18. **A decreased number of megakaryocytes would interfere with what body process?**
19. **How could a fat-free diet affect blood clotting?**
20. **Unless chemically treated, whole blood will coagulate in a test tube. This clotting process begins when Factor XII becomes activated. Which clotting pathway is involved in this process?**

19 Chapter Review

Study Outline

An Introduction to Blood and the Cardiovascular System p. 657

1. The **cardiovascular system** enables the rapid transport of nutrients, respiratory gases, waste products, and cells within the body.

19-1 Blood, composed of plasma and formed elements, provides transport, regulation, and protective services to the body p. 657

2. **Blood** is a specialized fluid connective tissue. Its functions include (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending the body against toxins and pathogens; and (5) regulating body temperature by absorbing and redistributing heat.
3. Blood contains **plasma** and **formed elements—red blood cells (RBCs)**, **white blood cells (WBCs)**, and **platelets**. The plasma and formed elements make up **whole blood**, which can be **fractionated** for analytical or clinical purposes. *(Spotlight Figure 19–1)*

- PhysioEx PhysioEx 9.1

4. **Hemopoiesis** is the process of blood cell formation. Myeloid and lymphoid stem cells divide to form all types of blood cells. *(Spotlight Figure 19–1)*
5. Whole blood from any region of the body has roughly the same temperature, viscosity, and pH.
6. Plasma accounts for 55 percent of the volume of blood; roughly 92 percent of plasma is water. *(Spotlight Figure 19–1)*
7. Plasma differs from interstitial fluid in terms of its oxygen and carbon dioxide levels and the concentrations and types of dissolved proteins.
8. The three major types of plasma proteins are *albumins*, *globulins*, and *fibrinogen*.

Go to MasteringA&P™ > Study Area > Menu > Lab Tools > PhysioEx 9.1 > Exercise 11: Blood Analysis > Activity 5: Blood Cholesterol

9. **Albumins** make up about 60 percent of plasma proteins. **Globulins** constitute roughly 35 percent of plasma proteins; they include **antibodies (immunoglobulins)**, which attack foreign proteins and pathogens, and **transport globulins**, which bind ions, hormones, and other compounds. **Fibrinogen** molecules are converted to **fibrin** in the clotting process. **Serum** is plasma without fibrinogen.
10. The liver synthesizes and releases more than 90 percent of the plasma proteins.

19-2 Red blood cells, formed by erythropoiesis, contain hemoglobin that transports respiratory gases p. 659

11. Red blood cells make up slightly less than half of the blood volume and 99.9 percent of the formed elements. The **hematocrit** value indicates the percentage of formed elements within whole blood. It is commonly reported as the *packed cell volume (PCV)*. *(Spotlight Figure 19–1; Table 19–1)*
12. Each RBC is a biconcave disc, providing a large surface-to-volume ratio. This shape and a flexible plasma membrane allow RBCs to stack, bend, and flex. *(Figure 19–2)*
13. Red blood cells lack most organelles, including mitochondria and nuclei, retaining only the cytoskeleton. They typically degenerate after about 120 days in the bloodstream.
14. Molecules of **hemoglobin (Hb; Hgb)** make up more than 95 percent of the proteins in RBCs. Hemoglobin is a globular protein formed from two pairs of polypeptide subunits. Each subunit contains a single molecule of **heme**, which also has an iron atom that can reversibly bind an oxygen molecule.
15. **Erythropoiesis**, the formation of red blood cells, occurs only in *red bone marrow* (**myeloid tissue**). The process speeds up under stimulation by erythropoietin (EPO or **erythropoiesis-stimulating hormone**). Stages in RBC development include **erythroblasts** and **reticulocytes**. *(Figure 19–4)*
16. Phagocytes recycle RBCs. Damaged RBCs are continuously replaced at a rate of approximately 3 million new RBCs entering the bloodstream per second. They are replaced before they **hemolyze**. *(Figure 19–5)*
17. The components of hemoglobin are individually recycled. The heme is stripped of its iron and converted to **biliverdin**, which is converted to **bilirubin**. If bile ducts of the liver are blocked, bilirubin builds up in skin and eyes, resulting in **jaundice**. *(Figure 19–5)*
18. Iron is recycled by being stored in phagocytic cells or transported through the bloodstream, bound to **transferrin**.

19-3 The ABO and Rh blood groups are based on antigen–antibody responses p. 666

19. **Blood type** is determined by the presence or absence of specific **surface antigens** (*agglutinogens*) in the RBC plasma membranes: antigens **A**, **B**, and **Rh (D)**. Antibodies (*agglutinins*) in the plasma will react with RBCs that have different surface antigens. When an antibody meets its specific surface antigen, a **cross-reaction** results. *(Figures 19–6 to Spotlight Figure 19–8; Table 19–2)*

19-4 The various types of white blood cells contribute to the body's defenses p. 670

20. White blood cells, or **leukocytes**, have nuclei and other organelles. They defend the body against pathogens and remove toxins, wastes, and abnormal or damaged cells.
21. White blood cells are capable of *margination*, amoeboid movement, and **positive chemotaxis**. Some WBCs are also capable of *phagocytosis*.
22. *Granular leukocytes (granulocytes)* are subdivided into **neutrophils**, **eosinophils**, and **basophils**. Fifty to 70 percent of circulating WBCs are neutrophils, which are highly mobile phagocytes. The much less common eosinophils are phagocytes attracted to foreign compounds that have reacted with circulating antibodies. The fairly rare basophils migrate to damaged tissues and release *histamine* and *heparin*, aiding the inflammatory response. *(Figure 19–9)*
23. *Agranular leukocytes (agranulocytes)* include **monocytes** and **lymphocytes**. Monocytes that migrate into peripheral tissues become tissue macrophages. Lymphocytes, the primary cells of the lymphatic system, include **T cells** (which enter peripheral tissues and attack foreign cells directly, or affect the activities of other lymphocytes); **B cells** (which produce antibodies); and **natural killer (NK) cells** (which destroy abnormal cells). *(Figure 19–9; Table 19–3)*
24. A **differential count** of the WBC population can indicate a variety of disorders. **Leukemia** is indicated by extreme **leukocytosis**—that is, excessive numbers of WBCs. *(Table 19–3)*
25. Granulocytes and monocytes are produced by myeloid stem cells in the red bone marrow that divide to create **progenitor cells**. Lymphoid stem cells also originate in the red bone marrow, but many migrate to peripheral **lymphatic tissues**. *(Figure 19–10)*
26. Factors that regulate lymphocyte maturation are not completely understood. Several **colony-stimulating factors (CSFs)** are involved in regulating other WBC populations and in coordinating RBC and WBC production. *(Figure 19–10)*

19-5 Platelets, disc-shaped cell fragments, function in the clotting process p. 678

27. Platelets are disc-shaped cell fragments. They circulate for 9–12 days before being removed by phagocytes. *(Figure 19–11)*
28. The functions of platelets include (1) releasing chemicals important to the clotting process, (2) forming a temporary patch in the walls of damaged blood vessels, and (3) reducing the size of a break in a vessel wall.
29. During **thrombocytopoiesis**, **megakaryocytes** in the red bone marrow release packets of cytoplasm (platelets) into the circulating blood. The rate of platelet formation is stimulated by thrombopoietin or thrombocyte-stimulating factor, interleukin-6, and multi-CSF.

19-6 The process of blood clotting, or hemostasis, stops blood loss p. 678

30. **Hemostasis** halts the loss of blood through the walls of damaged vessels. It consists of three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*.

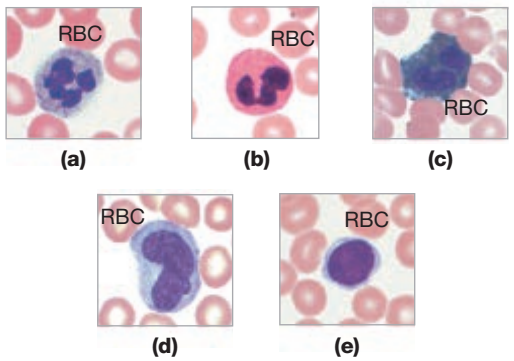
31. The **vascular phase** is a period of local blood vessel constriction, or **vascular spasm**, at the injury site. *(Figure 19–11)*
32. The **platelet phase** follows as platelets are activated, aggregate at the site, and adhere to the damaged surfaces. *(Figure 19–11)*
33. The **coagulation phase** occurs as factors released by platelets and endothelial cells interact with **clotting factors** (through either the **extrinsic pathway**, the **intrinsic pathway**, or the **common pathway**) to form a **blood clot**. In this reaction sequence, soluble fibrinogen is converted to large, insoluble fibers of fibrin. *(Figure 19–11; Table 19–4)*
34. During **clot retraction**, platelets contract and pull the torn edges of the damaged vessel closer together. *(Figure 19–11)*
35. During **fibrinolysis**, the clot gradually dissolves through the action of **plasmin**, the activated form of circulating **plasminogen**.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the five types of white blood cells in the following photographs,



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____

2. The formed elements of the blood include **(a)** plasma, fibrin, and serum, **(b)** albumins, globulins, and fibrinogen, **(c)** WBCs, RBCs, and platelets, **(d)** all of these.
3. Blood temperature is approximately _____, and blood pH averages _____. **(a)** 36°C, 7.0, **(b)** 39°C, 7.8, **(c)** 38°C, 7.4, **(d)** 37°C, 7.0.
4. Plasma contributes approximately _____ percent of the volume of whole blood, and water accounts for _____ percent of the plasma volume. **(a)** 55, 92, **(b)** 25, 55, **(c)** 92, 55, **(d)** 35, 72.
5. Serum is **(a)** the same as blood plasma, **(b)** plasma minus the formed elements, **(c)** plasma minus the proteins, **(d)** plasma minus fibrinogen, **(e)** plasma minus the electrolytes.
6. A hemoglobin molecule is composed of **(a)** two protein chains, **(b)** three protein chains, **(c)** four protein chains and nothing else, **(d)** four protein chains and four heme groups, **(e)** four heme groups but no protein.
7. The following is a list of the phases involved in the process of hemostasis.
   (1) coagulation
   (2) fibrinolysis
   (3) vascular spasm
   (4) retraction
   (5) platelet phase
   The correct sequence of these phases is **(a)** 5, 1, 4, 2, 3, **(b)** 3, 5, 1, 4, 2, **(c)** 2, 3, 5, 1, 4, **(d)** 3, 5, 4, 1, 2, **(e)** 4, 3, 5, 2, 1.
8. Stem cells responsible for lymphocytopoiesis are located in **(a)** the thymus and spleen, **(b)** the lymph nodes, **(c)** the red bone marrow, **(d)** all of these structures.
9. _____ and _____ affect almost every aspect of the clotting process. **(a)** Calcium, vitamin K, **(b)** Calcium, vitamin B_{12}, **(c)** Sodium, vitamin K, **(d)** Sodium, vitamin B_{12}.
10. What five major functions are performed by blood?
11. Name the three major types of plasma proteins and identify their functions,
12. Which type of antibodies does plasma contain for each of the following blood types? **(a)** type A, **(b)** type B, **(c)** type AB, **(d)** type O.
13. What four characteristics of WBCs are important to their response to tissue invasion or injury?
14. Which kinds of WBCs contribute to the body's nonspecific defenses?
15. Name the three types of lymphocytes and identify their functions,
16. What is the difference between prothrombin and thrombin?
17. What four conditions cause the release of erythropoietin?
18. What contribution from the intrinsic and the extrinsic pathways is necessary for the common pathway to begin?

LEVEL 2 Reviewing Concepts

19. Dehydration would **(a)** cause an increase in the hematocrit, **(b)** cause a decrease in the hematocrit, **(c)** have no effect on the hematocrit, **(d)** cause an increase in plasma volume.
20. Erythropoietin directly stimulates RBC formation by **(a)** increasing rates of mitotic divisions in erythroblasts, **(b)** speeding up the maturation of red blood cells, **(c)** accelerating the rate of hemoglobin synthesis, **(d)** all of these.
21. The waste product bilirubin is formed from **(a)** transferrin, **(b)** globin, **(c)** heme, **(d)** hemosiderin, **(e)** ferritin.
22. A difference between the A, B, and O blood types and the Rh factor is **(a)** Rh agglutinogens are not found on the surface of red blood cells, **(b)** Rh agglutinogens do not produce a cross-reaction, **(c)** individuals who are Rh^- do not carry agglutinins to Rh factor unless they have been previously sensitized, **(d)** Rh agglutinogens are found free in the plasma, **(e)** Rh agglutinogens are found bound to plasma proteins.
23. How do red blood cells differ from white blood cells in both form and function?
24. How do elements of blood defend against toxins and pathogens in the body?
25. What is the role of blood in the stabilization and maintenance of body temperature?
26. Relate the structure of hemoglobin to its function,
27. Why is aspirin sometimes prescribed for the prevention of vascular problems?

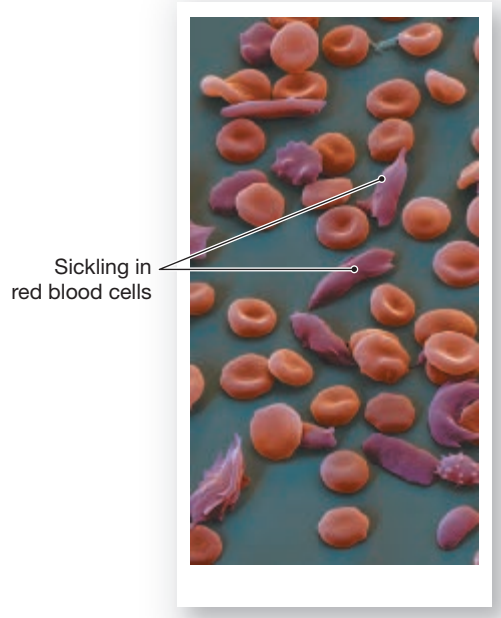
LEVEL 3 Critical Thinking and Clinical Applications

28. A test for prothrombin time is used to identify deficiencies in the extrinsic clotting pathway; prothrombin time is prolonged if any of the factors are deficient. A test for activated partial thromboplastin time is used in a similar fashion to detect deficiencies in the intrinsic clotting pathway. Which factor would be deficient if a person had a prolonged prothrombin time but a normal partial thromboplastin time?
29. In the disease mononucleosis ("mono"), the spleen enlarges because of increased numbers of phagocytes and other cells. Common signs and symptoms of this disease include pale complexion, a tired feeling, and a lack of energy sometimes to the point of not being able to get out of bed. What might cause these signs and symptoms?
30. Almost half of our vitamin K is synthesized by bacteria that inhabit the large intestine. Based on this information, how could taking a broad-spectrum antibiotic for a long time cause frequent nosebleeds?
31. After Randy was diagnosed with stomach cancer, nearly all of his stomach had to be removed. Postoperative treatment included regular injections of vitamin B_{12}. Why was this vitamin prescribed, and why were injections specified?

CLINICAL CASE Wrap-Up Crisis in the Blood

Clare knows what her blood test will show. Instead of looking like tiny, double-dimpled Frisbees, many of her RBCs look sharp and crescent shaped like the "sickles" for which they are named. Inside her RBCs the hemoglobin molecule has a malformation in the globular protein subunit called the beta chain. The quaternary structure of the molecule is disrupted and is responsible for the distorted shape of the red blood cell. Clare has **sickle cell disease (SCD)**.

In **SCD**, two copies of a gene called hemoglobin-S are inherited, one from each parent. The gene mutation for SCD evolved in Africa where the sickle shape prevented the malarial parasite from continuing its life cycle in the blood, and so conferred a survival advantage against malaria. Anemia frequently accompanies SCD because sickled red blood cells live only 10–20 days (as compared to 120 days for normal RBCs) and the red bone marrow is not able to keep up with their replacement.



Clare's trip to the hospital was brought on by a sickle cell crisis. The crisis occurred in the large bones of her leg, the tibia and fibula.

1. Why is Clare in such pain?
2. Why must she be careful to stay hydrated?

See the blue Answers tab at the back of the book.

Related Clinical Terms

arterial stick: The taking of a blood sample from an artery rather than a vein. It is usually more painful due to arteries being deeper, having more nerves, and having thicker walls.

blood bank: Place where blood is collected, typed, separated into components, stored, and prepared for transfusion to recipients.

bone marrow biopsy: The removal of a small piece of bone marrow for either laboratory analysis, to diagnose and stage some forms of cancer, to diagnose other blood disorders, to find the source of unexplained fever, or to diagnose fibrosis of bone marrow or myeloma, a tumor composed of cells normally found in the bone marrow.

disseminated intravascular coagulation: A serious disorder in which the proteins that control blood clotting become abnormally active, causing small blood clots to form, which can prevent blood from reaching vital organs.

dyscrasia: An abnormal condition, especially of the blood.

ecchymosis: Skin discoloration caused by the escape of blood into tissues from ruptured blood vessels.

embolism: A condition in which a drifting blood clot (an embolus) becomes stuck in a blood vessel, blocking circulation to the area downstream.

hematology: The science concerned with the medical study of blood and blood-producing organs.

hemochromatosis: A rare metabolic disorder wherein the skin has a bronze coloration; accompanied by cirrhosis and severe diabetes mellitus; caused by the deposit of the iron–protein complex hemosiderin in tissues.

hemophilia: Inherited disorders characterized by the inadequate production of clotting factors.

hemopoietic growth factor: A group of proteins that cause blood cells to grow and mature.

hemosiderosis: An increase in tissue iron stores without any associated damage.

hypervolemic: Having an excessive blood volume.

hypovolemic: Having a low blood volume.

iron overload: Pathology in which iron accumulates in the tissues; characterized by bronzed skin, enlarged liver, diabetes mellitus, and abnormalities of the pancreas.

myeloproliferative disorder: A group of slow-growing blood cancers, including chronic myelogenous leukemia, characterized by large numbers of abnormal RBCs, WBCs, or platelets growing and spreading in the bone marrow and the peripheral blood.

normovolemic: Referring to a normal blood volume.

phlebotomist: Medical technician who extracts blood by venipuncture for treatment or for laboratory analysis.

plaque: An abnormal accumulation of large quantities of lipids within a blood vessel wall.

plasmapheresis: A procedure consisting of the removal of blood from a person, separating the blood cells from plasma, and returning these blood cells to the person's circulation, diluted with fresh plasma or a substitute. Used to treat autoimmune disorders.

Schilling test: The test to determine whether the body absorbs vitamin B_{12} normally.

septicemia: Systemic toxic illness due to bacterial invasion of the bloodstream from a local infection. Signs and symptoms include chills, fever, and exhaustion. The disorder is treated with massive doses of antibiotics. Also known as *blood poisoning*.

thrombolytic: An agent that causes the breakup of a thrombus (clot).

thrombus: A blood clot attached to the luminal (inner) surface of a blood vessel.

20 The Heart

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

20-1 ■ Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves. p. 689

20-2 ■ Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram. p. 702

20-3 ■ Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle. p. 711

20-4 ■ Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity. p. 716

CLINICAL CASE A Needle to the Chest

It has been a slow night in the emergency room. Dr. Jim is reading an emergency medicine journal and nodding off. He perks up when he hears the speakerphone crackle.

"We have a male, mid-40s, driver of a vehicle involved in a head-on collision with a truck," reports an EMT. "He was unconscious at the scene, but is now semi-alert, complaining of severe chest pain. His respirations are 30 and shallow. His blood pressure is 80/58. Pulse 130. Carotid pulses in the neck are present, but barely palpable (able to be felt). He has massive jugular venous distension (the veins in his neck are backed up with blood). The seat belt was broken and he has a steering wheel contusion on his anterior chest."

Dr. Jim instructs the EMTs to take the victim directly into Trauma Room 1. The patient is loaded supine on the trauma cart and Dr. Jim quickly introduces himself to the barely conscious man. A chest x-ray shows a fractured sternum and several fractured ribs, but the heart shadow (outline on the x-ray) appears normal. The heart sounds are distant and muffled through a stethoscope. After a rapid bedside ultrasound, Dr. Jim puts on sterile gloves, does a skin prep of the patient's anterior chest, and sticks a large-bore needle with a 100-mL syringe attached into the man's sub-xiphoid space, directing the needle toward his left shoulder. The syringe fills with dark blood twice. **What is Dr. Jim doing?**

To find out, turn to the Clinical Case Wrap-Up on p. 726.

An Introduction to the Heart as Part of the Cardiovascular System

The *heart*, along with the *blood* and *blood vessels*, is part of the **cardiovascular system**, as we introduced in Chapter 19. This system functions to distribute oxygen and nutrients to the cells of the body, and to take away carbon dioxide and other wastes.

In this chapter we consider the structure and function of the heart, a small organ about the size of your clenched fist. This extraordinary organ beats approximately 100,000 times each day. Each day the heart pumps about 8000 liters of blood—enough to fill forty 55-gallon drums, or 8800 quart-sized milk cartons. Try transferring a gallon of water with a cooking baster, and you'll appreciate just how hard the heart has to work to keep you alive. Let's look first at the structure of this organ, and then at several important aspects of its function.

20-1 The heart is a four-chambered organ that pumps blood through the systemic and pulmonary circuits

Learning Outcome Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.

The heart is a hollow muscular organ that pumps oxygen-poor blood to the lungs within the *pulmonary circuit* and oxygen-rich blood to the rest of the body within the *systemic circuit*. The pulmonary circuit carries oxygen-poor blood from the heart's lower right chamber (right ventricle), through the pulmonary arteries, to the lungs, and oxygen-rich blood back through the pulmonary veins to the heart's upper left chamber (left atrium). The systemic circuit carries oxygen-rich blood from the heart's lower left chamber (left ventricle), through the systemic arteries, and oxygen-poor blood through systemic veins back to the heart's upper right chamber (right atrium). Let's start with an overview of heart function.

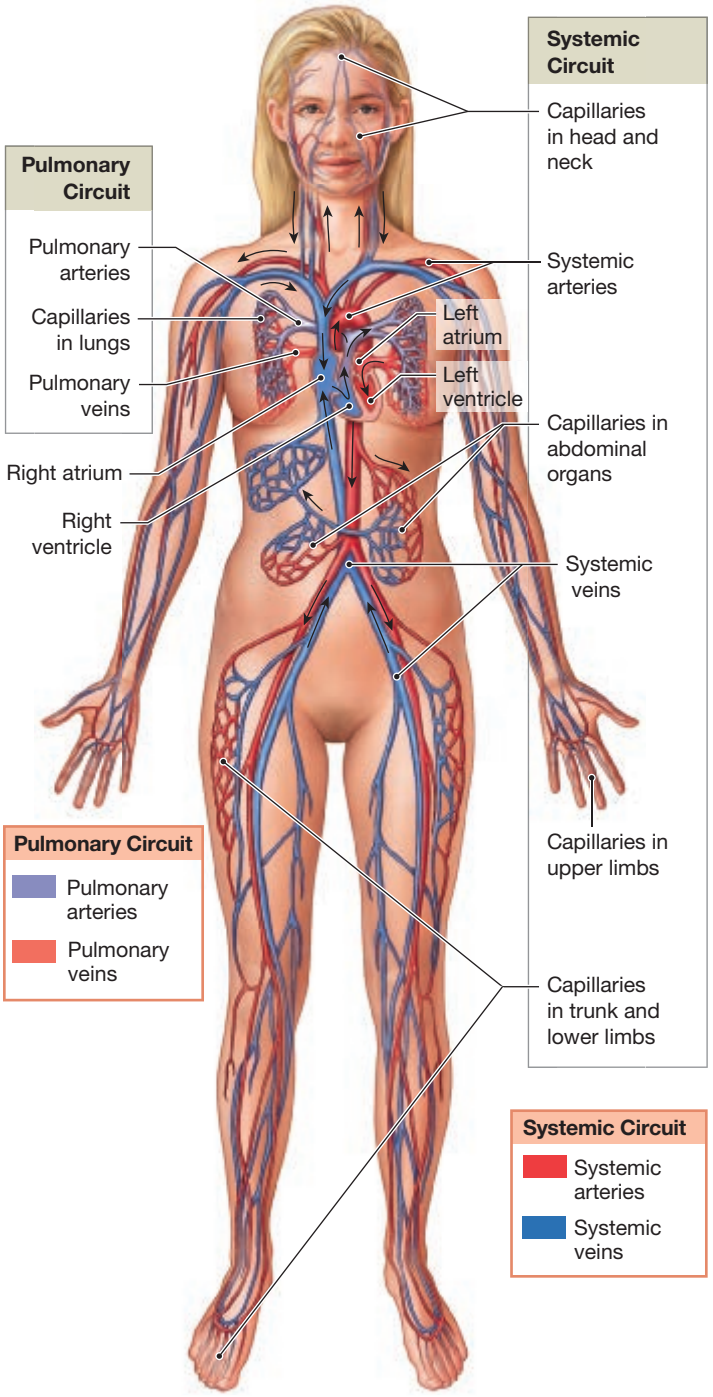
Overview of Heart Function: The Pulmonary and Systemic Circuits

In the cardiovascular system, blood flows through a network of blood vessels that extend between the heart and peripheral tissues. Those blood vessels make up a **pulmonary circuit**, which carries blood to and from the gas exchange surfaces of the lungs, and a **systemic circuit**, which transports blood to and from the rest of the body (Figure 20–1). Each circuit begins and ends at the heart, and blood travels through these circuits in sequence. Thus, blood returning to the heart from the systemic circuit must complete the pulmonary circuit before reentering the systemic circuit.

The blood vessels of both circuits include arteries, capillaries, and veins. *Arteries* carry blood away from the heart, and *veins* return blood to the heart. The *great vessels* are the largest veins and arteries in the body, those connected to the heart. Microscopic thin-walled vessels called *capillaries* interconnect the smallest arteries and the smallest veins. Capillaries are called *exchange vessels*, because their thin walls permit the exchange of nutrients, dissolved gases (called *gas exchange*), and wastes between the blood and surrounding tissues.

The **heart** has four muscular chambers, two associated with each circuit—in essence, the heart is two side-by-side pumps. The *right atrium* (Ā-trē-um; entry chamber; plural, *atria*) receives blood from the systemic circuit and passes it to the *right ventricle* (VEN-tri-kul; little belly), which then pumps blood into the pulmonary circuit. The *left atrium* collects blood from the pulmonary circuit and empties it into the *left ventricle*, which pumps blood into the systemic circuit. When the heart beats,

Figure 20–1 An Overview of the Cardiovascular System. Driven by the pumping of the heart, blood flows through the pulmonary and systemic circuits in sequence. Each circuit begins and ends at the heart and contains arteries, capillaries, and veins.



? The _____ side of the heart supplies blood to the systemic circuit, while the _____ side of the heart supplies blood to the pulmonary circuit.

first the atria contract, and then the ventricles contract. The two ventricles contract at the same time and eject equal volumes of blood into the pulmonary and systemic circuits.

Heart Location and Position

The heart is located in the thoracic cavity near the anterior chest wall, directly posterior to the sternum (Figure 20–2a,b). The great vessels, both veins and arteries, are connected to the superior end of the heart at its base. The **base** sits posterior to the sternum at the level of the third costal cartilage, centered about 1.2 cm (0.5 in.) to the left side (Figure 20–3a). The inferior, pointed tip of the heart is the **apex** (Ā-peks). Standard measurements for determining heart size take into account age, height, weight, and sex. A midsagittal section through the trunk does not divide the heart into two equal halves. Note that the center of the base lies slightly to the left of the midline.

The heart sits in the anterior portion of the **mediastinum**, the region between the two pleural cavities. The mediastinum contains the great vessels, which are attached at the base of the heart, as well as the thymus, esophagus, and trachea. Figure 20–2b is a superior view that shows the position of the heart relative to other structures in the mediastinum.

Heart Superficial Anatomy, Heart Wall, and Cardiac Skeleton

The walls of the heart, from deep to superficial, are the *endocardium* (inner layer whose simple squamous epithelium is continuous with the endothelial lining of blood vessels), *myocardium* (spiral bundles of cardiac muscle cells), and *pericardium* (fibrous pericardium and serous pericardium that protect, anchor, and prevent overfilling). The two-layered serous pericardium is made up of a parietal layer and a visceral layer (epicardium). These layers are separated by a fluid-filled pericardial cavity. Another structure, the *cardiac skeleton*, is a crisscrossing, interlacing layer of dense connective tissue that anchors muscle fibers, supports the great vessels and heart valves, and limits the spread of action potentials. Our discussion begins with the pericardium.

Outer Covering of the Heart: The Pericardium

The **pericardium** (pehr-ih-KAR-dē-um) surrounds the heart and consists of an outer *fibrous pericardium* and an inner *serous pericardium*. The fibrous pericardium contains a dense network of collagen fibers that stabilize the position of the heart and associated vessels within the mediastinum.

The inner **serous pericardium** is a two-layered membrane composed of an outer **parietal layer** and an inner **visceral layer**. The visceral layer is also known as the *epicardium*. The potential, fluid-filled space between these two serous layers is the **pericardial cavity**.

The pericardial cavity normally contains 15–50 mL of **pericardial fluid**, secreted by the pericardial membranes. This fluid acts as a lubricant, reducing friction between the opposing visceral and parietal surfaces as the heart beats. To visualize

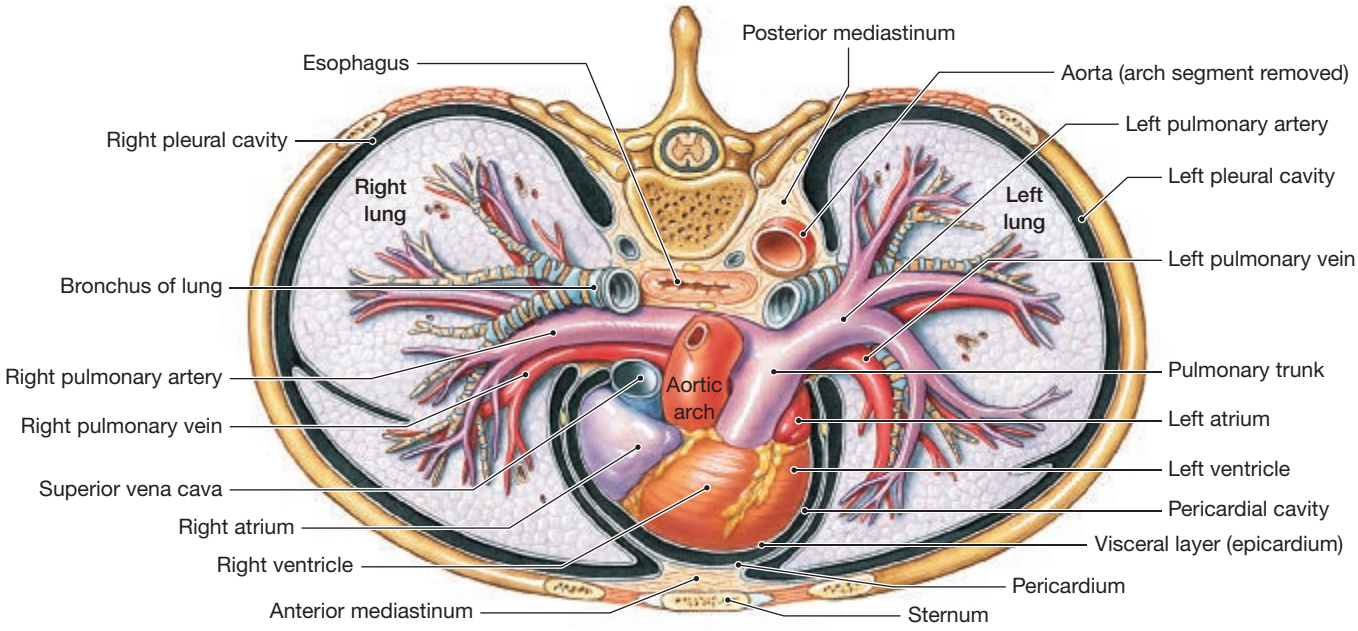
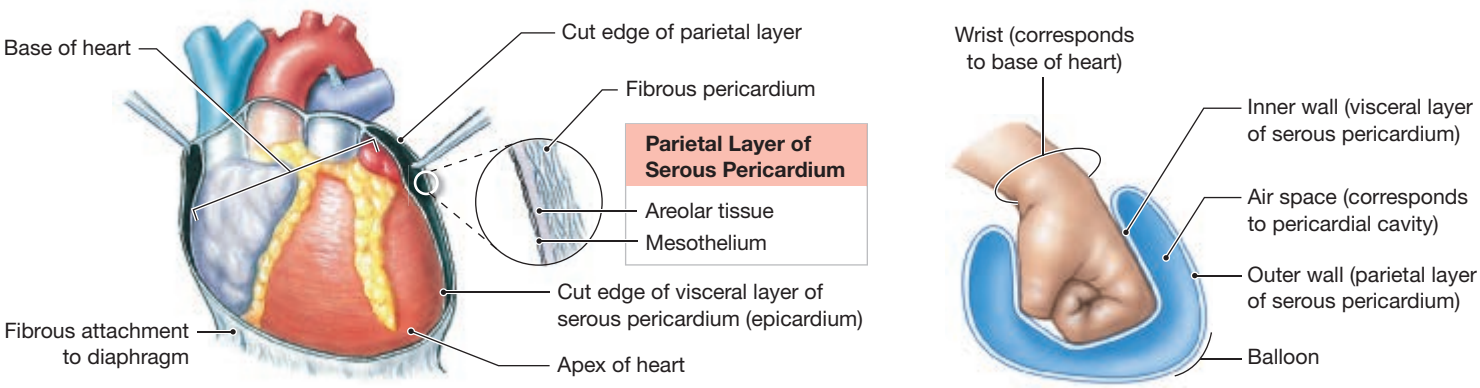
a An anterior view of the chest, showing the position of the heart and major blood vessels relative to the ribs, lungs, and diaphragm.

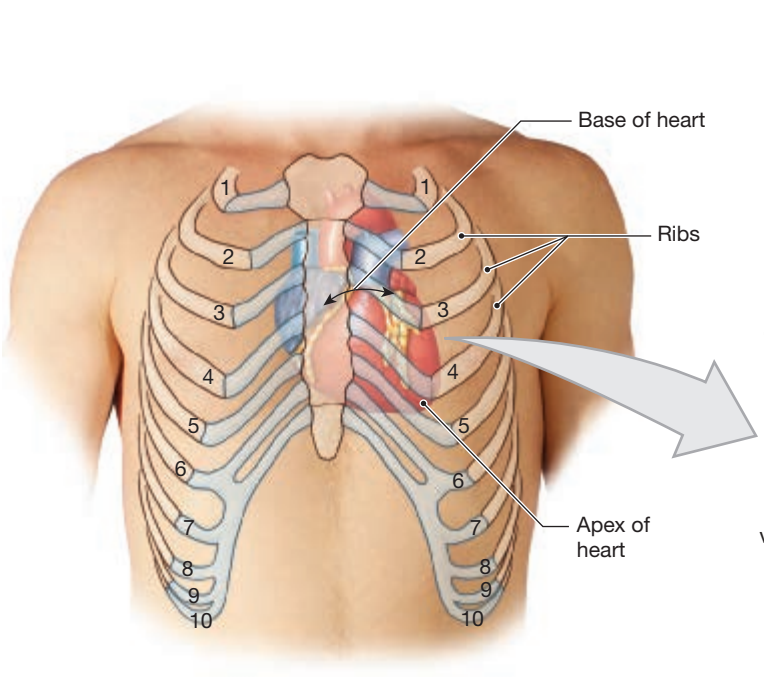


b A superior view of the organs in the mediastinum; portions of the lungs have been removed to reveal blood vessels and airways. The heart is located in the anterior part of the mediastinum, immediately posterior to the sternum.

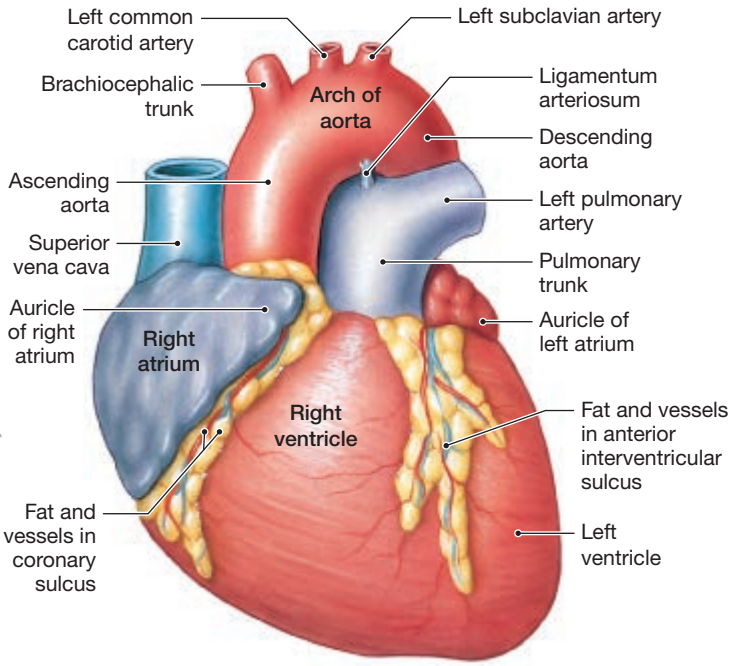


c The relationship between the heart and the pericardial cavity; compare with the fist-and-balloon example.

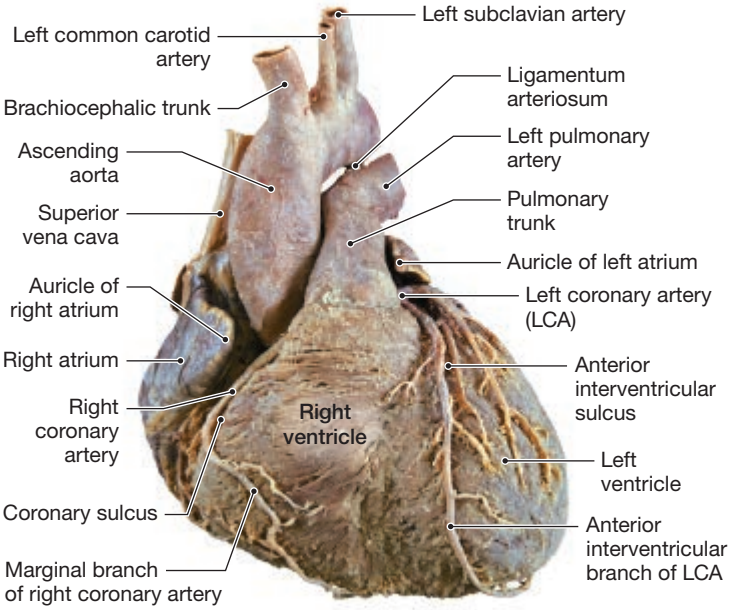
Figure 20–3 The Position and Superficial Anatomy of the Heart.



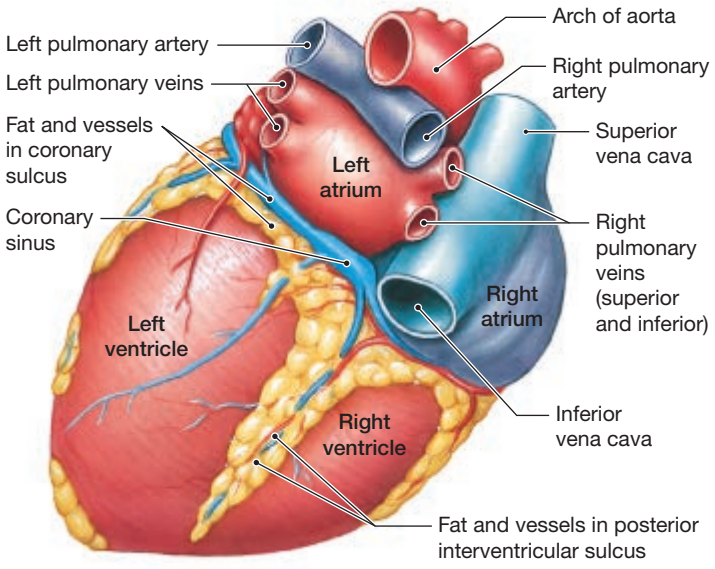
a Heart position relative to the rib cage.



b Major anatomical features on the anterior surface.



c Anterior surface of the heart, cadaver dissection.



d Major anatomical features on the posterior surface. Coronary arteries (which supply the heart itself) are shown in red; coronary veins are shown in blue.

the relationship between the heart and the pericardial cavity, imagine pushing your fist toward the center of a large, partially inflated balloon. The balloon represents the pericardium, and your fist is the heart. Your wrist, where the balloon folds back on itself, corresponds to the base of the heart (Figure 20–2c).

Pathogens can infect the pericardium, producing inflammation and the condition **pericarditis**. The inflamed pericardial surfaces rub against one another, making a distinctive scratching sound (called a *friction rub*) that can be heard through an instrument called a *stethoscope* that is placed on the chest. The pericardial inflammation also commonly results in increased production of pericardial fluid. Fluid then collects in the pericardial cavity, restricting the movement of the heart. This condition, called **cardiac tamponade** (tam-pō-NĀD; *tampon*, plug), can also result from traumatic injuries (such as stab wounds) that produce bleeding into the pericardial cavity.

Superficial Anatomy of the Heart

The four chambers of the heart can be identified in a superficial view (see Figure 20–3). The two atria have relatively thin muscular walls and are highly expandable. When not filled with blood, the outer portion of each atrium deflates and becomes a lumpy, wrinkled flap. This expandable extension of an atrium is called an **auricle** (AW-rih-kul; *auris*, ear), because it reminded early anatomists of the external ear (Figure 20–3b).

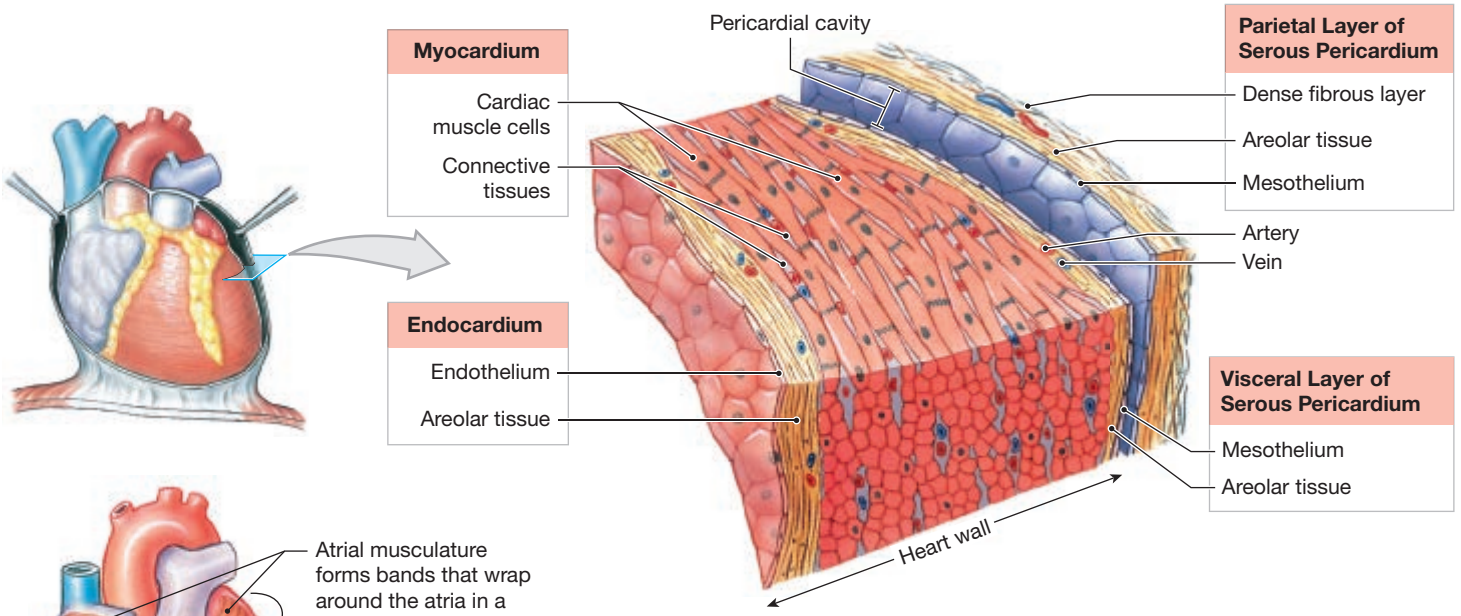
The **coronary sulcus**, a deep groove, marks the border between the atria and the ventricles. The **anterior interventricular sulcus** and the **posterior interventricular sulcus** are shallower depressions that mark the boundary between the left and right ventricles (Figure 20–3b–d). Substantial amounts of fat generally lie in the coronary and interventricular sulci. In fresh or preserved hearts, this fat must be stripped away to expose the underlying grooves. These sulci also contain the arteries and veins that carry blood to and from the cardiac muscle.

The Heart Wall

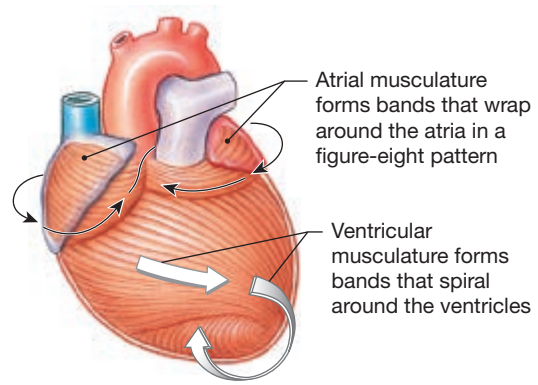
A section through the wall of the heart reveals three distinct layers: the outer epicardium, a middle myocardium, and an inner endocardium (Figure 20–4a). The details of these three layers, from superficial to deep, are covered in the following list.

1. The **visceral layer of serous pericardium** (**epicardium**) covers the surface of the heart. This serous membrane consists of an exposed mesothelium and an underlying layer of areolar connective tissue that is attached to the myocardium. The **parietal layer of serous pericardium** consists of an outer dense fibrous layer, an areolar layer, and an inner mesothelium.
2. The **myocardium** is cardiac muscle tissue that forms the atria and ventricles. This muscular layer contains cardiac muscle cells, connective tissues, blood vessels, and nerves. The atrial myocardium contains muscle bundles that wrap around the atria and form figure eights that encircle the great vessels (Figure 20–4b). Superficial ventricular muscles wrap around both ventricles, and deeper muscle layers spiral around and between the ventricles toward the apex in a figure-eight pattern.
3. The **endocardium** covers the inner surfaces of the heart, including those of the heart valves. It is made up of a simple squamous epithelium and underlying areolar tissue. This simple squamous epithelium, or endothelium, is continuous with the endothelium of the attached great vessels.

Figure 20–4 The Heart Wall.



a A diagrammatic section through the heart wall, showing the relative positions of the myocardium, pericardium, and endocardium. The proportions are not to scale; the thickness of the myocardial wall has been greatly reduced.



b Cardiac muscle tissue forms concentric layers that wrap around the atria or spiral within the walls of the ventricles.

Connective Tissues and the Cardiac Skeleton

The connective tissues of the heart include large numbers of collagen and elastic fibers. Each cardiac muscle cell is wrapped in a strong, but elastic, sheath. Adjacent cells are tied together by fibrous cross-links, or "struts." These fibers are, in turn, interwoven into sheets that separate the superficial and deep muscle layers. The connective tissue fibers (1) provide physical support for the cardiac muscle fibers, blood vessels, and nerves of the myocardium; (2) help distribute the forces of contraction; (3) add strength and prevent overexpansion of the heart; and (4) provide elasticity that helps return the heart to its original size and shape after a contraction.

The **cardiac skeleton** (sometimes called the *fibrous skeleton*) of the heart consists of four dense bands of tough elastic tissue that encircle the heart valves and the bases of the pulmonary trunk and aorta (look ahead to Figure 20–7). These bands stabilize the positions of the heart valves and ventricular muscle cells. They also electrically insulate the ventricular cells from the atrial cells.

Heart Chambers, Valves, and Great Vessels

Next let's examine the major landmarks and structures visible on the interior surface of the heart. In a sectional view, you can see that the right atrium communicates with the right ventricle, and the left atrium with the left ventricle (Figure 20–5a,b). The chambers of the heart are separated by muscular partitions called *septa* (singular *septum*, wall). The atria are separated by the **interatrial septum**, and the ventricles are separated by the much thicker **interventricular septum**. The heart also has *valves*, covered openings that direct the flow of blood between chambers and vessels. The cardiac skeleton stabilizes the positions of these valves. The two **atrioventricular (AV) valves** (tricuspid and mitral) are folds of fibrous tissue that extend into the openings between the atria and ventricles. These valves permit blood to flow only in one direction: from the atria to the ventricles. There are also two **semilunar valves** (pulmonary and aortic) between the ventricles and their great vessels, which ensure blood flows into these vessels.

The Vena Cavae, Right Atrium, and Tricuspid Valve

The **right atrium** receives blood from the systemic circuit through the two great veins: the **superior vena cava** (VĒ-nah KĀ-vuh; *venae cavae*, plural) and the **inferior vena cava**. The superior vena cava opens into the posterior and superior portion of the right atrium. It delivers blood to the right atrium from the head, neck, upper limbs, and chest. The inferior vena cava opens into the posterior and inferior portion of the right atrium. It carries blood to the right atrium from the rest of the trunk, the viscera, and the lower limbs. Note there are no valves between the venae cavae and the right atrium.

From the fifth week of embryonic development until birth, an oval opening called the **foramen ovale** penetrates the interatrial septum and connects the two atria of the fetal heart. Before birth, the foramen ovale permits blood to flow from the right atrium to the left atrium while the lungs are developing. At birth, the foramen ovale closes, and the opening is permanently sealed off within 3 months of delivery. (If the foramen ovale does not close, serious cardiovascular problems may result. We consider these in Chapter 21.) A small, shallow depression called the **fossa ovalis** remains at this site in the adult heart (see Figure 20–5a).

ATLAS: Embryology Summary 15: The Development of the Heart

The posterior walls of the right atrium and the interatrial septum have smooth surfaces. In contrast, the anterior atrial wall and the inner surface of the auricle contain prominent muscular ridges called the **pectinate muscles** (*pectin*, comb) (see Figure 20–5a).

Blood travels from the right atrium into the right ventricle through a broad opening bordered by three fibrous flaps. These flaps, called **cusps**, are part of the **tricuspid** (trī-KUS-pid; *tri*, three) **valve**, also known as the *right atrioventricular (AV) valve*. The free edge of each cusp is attached to connective tissue fibers called the **chordae tendineae** (KOR-dē TEN-dih-nē-ē; tendinous cords). The fibers originate at the **papillary** (PAP-ih-lehr-ē) **muscles**, conical muscular projections that arise from the inner surface of the right ventricle (Figure 20–5c).

Tips & Tools

The saying "To tug on your heartstrings" may help you remember the functions of the papillary muscles and the chordae tendineae: Contractions of the papillary muscles pull on the chordae tendineae, which "tug" on your heart's valves.

The Right Ventricle, Pulmonary Valve, and Pulmonary Trunk

The internal surface of the **right ventricle** contains a series of muscular ridges: the **trabeculae carneae** (trah-BEK-yū-lē KAR-nē-ē; *carneus*, fleshy). The *moderator band* is a muscular ridge that extends horizontally from the inferior portion of the interventricular septum and connects to the anterior papillary muscle. The moderator band delivers the stimulus for contraction to the papillary muscles. As a result, they begin tensing the chordae tendineae before the rest of the ventricle contracts.

The superior end of the right ventricle tapers to the **conus arteriosus**, a cone-shaped pouch that ends at the **pulmonary valve**, or *pulmonary semilunar valve*. The pulmonary valve consists of three semilunar (half-moon shaped) cusps of thick connective tissue. Blood flowing from the right ventricle passes through this valve into the **pulmonary trunk**, the start of the pulmonary circuit. Once in the pulmonary trunk, blood flows into the **left pulmonary arteries** and the **right pulmonary arteries**. These vessels branch repeatedly within the lungs before supplying the capillaries, where gas exchange occurs.

? Beginning with the right atrium, what is the order of the valves through which blood will pass?

20

The Pulmonary Veins, Left Atrium, and Mitral Valve

From the respiratory capillaries, blood collects into small veins that ultimately unite to form the four pulmonary veins. The posterior wall of the **left atrium** receives blood from two **left** and two **right pulmonary veins**. Again there is no valve between the pulmonary veins and the left atrium. Like the right atrium, however, the left atrium has an auricle.

A valve, the **mitral** (MĪ-tral; *mitre*, a bishop's hat) **valve** (also called the *left atrioventricular [AV] valve*, or *bicuspid valve*) guards the entrance to the left ventricle (see Figure 20–5a,c). As the name *bicuspid* implies, the left AV valve contains two cusps, not three. The mitral valve permits blood to flow from the left atrium into the left ventricle.

Tips & Tools

To remember the locations of the tricuspid and bicuspid (mitral) valves, think "***try*** to be ***right***" for the ***tri***cuspid, and associate the ***l*** in mitral with the ***l*** in ***l***eft.

The Left Ventricle, Aortic Valve, and Ascending Aorta

The internal organization of the **left ventricle** resembles that of the right ventricle, but it has no moderator band (see Figure 20–5a). The trabeculae carneae are prominent. A pair of large papillary muscles tenses the chordae tendineae that anchor the cusps of the mitral valve and prevent blood from flowing back into the left atrium.

Blood leaves the left ventricle through the **aortic valve**, or *aortic semilunar valve*, and enters the **ascending aorta**. The arrangement of cusps in the aortic valve is the same as that in the pulmonary valve. Adjacent to each cusp of the aortic valve are saclike expansions of the base of the ascending aorta called **aortic sinuses**. From the ascending aorta, blood flows through the **aortic arch** and into the **descending aorta** (see Figure 20–5a). The pulmonary trunk is attached to the aortic arch by the *ligamentum arteriosum*, a fibrous band left over from an important fetal blood vessel that once linked the pulmonary and systemic circuits.

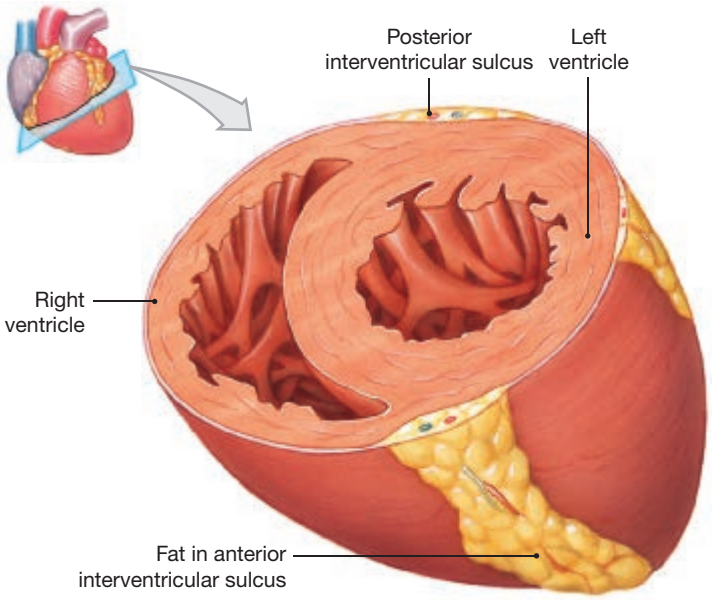
Structural and Functional Differences between the Left and Right Ventricles

The function of the atria is to collect blood that is returning to the heart and to convey it to the ventricles. The demands on the right and left atria are similar, and the two chambers look almost identical. The demands on the right and left ventricles, however, are very different, and the two have significant structural differences. Even though the two ventricles hold and pump equal amounts of blood, the left ventricle is much larger than the right ventricle. What's the reason? It has thicker walls. These thick, muscular walls enable the left ventricle to push blood through the body's extensive systemic circuit. In contrast, the right ventricle needs to pump blood, at lower pressure, only about 15 cm (6 in.) to and from the lungs.

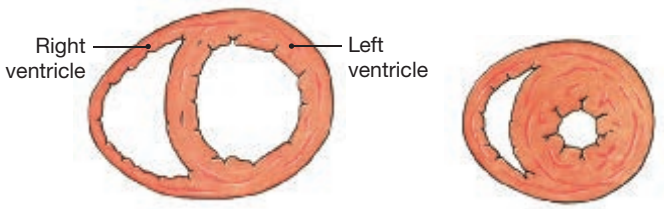
Anatomical differences between the left and right ventricles are easiest to see in a three-dimensional view (Figure 20–6a). The lungs are close to the heart, and the pulmonary blood vessels are relatively short and wide. For these reasons, the right ventricle normally does not need to work very hard to push blood through the pulmonary circuit. Accordingly, the muscular wall of the right ventricle is relatively thin. In sectional view, it resembles a pouch attached to the massive wall of the left ventricle. When the right ventricle contracts, it acts like a bellows, squeezing the blood against the thick wall of the left ventricle. This action moves blood very efficiently with minimal effort, but it develops relatively low pressures.

A comparable pumping arrangement would not work well for the left ventricle. Four to six times as much pressure must be exerted to push through the systemic circuit as through the pulmonary circuit. The left ventricle has an extremely thick

Figure 20–6 Structural Differences between the Left and Right Ventricles. ATLAS: Plate 45d



a A diagrammatic sectional view through the heart, showing the relative thicknesses of the two ventricular walls. Note the pouchlike shape of the right ventricle and the greater thickness of the left ventricular muscle.



b Diagrammatic views of the ventricles just before a contraction (dilated) and just after a contraction (contracted).

muscular wall and is round in cross section (see Figure 20–6a). When this ventricle contracts, it shortens and narrows. In other words, (1) the distance between the base and apex decreases, and (2) the diameter of the ventricular chamber decreases. The effect is similar to simultaneously squeezing and rolling up the end of a toothpaste tube. The pressure generated is more than enough to open the aortic valve and eject blood into the ascending aorta.

As the powerful left ventricle contracts, it bulges into the right ventricular cavity (Figure 20–6b). This action increases the pumping efficiency of the right ventricle. Individuals with severe damage to the right ventricle may survive, because the contraction of the left ventricle helps push blood into the pulmonary circuit. We return to this topic in Chapter 21, where we consider the integrated functioning of the cardiovascular system.

Blood Flow through the Heart Valves

As we have seen, the heart has two pairs of one-way valves. These valves prevent the backflow of blood as the chambers contract. Let's look at the function of these heart valves, and the path of blood flow through each half of the heart.

The AV Valves: Atria to Ventricles

The atrioventricular (AV) valves prevent the backflow of blood from the ventricles to the atria when the ventricles are contracting. The chordae tendineae and papillary muscles play important roles in the normal function of the AV valves. When the ventricles are relaxed, the chordae tendineae are loose, and the AV valves offer no resistance as blood flows from the atria into the ventricles (Figure 20–7a). When the ventricles contract, blood moving back toward the atria swings the cusps together, closing the valves (Figure 20–7b). At the same time, the contraction of the papillary muscles tenses the chordae tendineae, stopping the cusps before they swing into the atria. If the chordae tendineae were cut or the papillary muscles were damaged, backflow, called **regurgitation**, of blood into the atria would occur each time the ventricles contracted.

+ Clinical Note Faulty Heart Valves

Each of the four heart valves must open and close crisply and precisely to permit the proper flow of blood through the heart.

The most common valve to falter is the mitral valve. One scenario responsible for mitral malfunction is an untreated bacterial or viral infection that infiltrates the valve cusps. The cusps become inflamed and later scar, resulting in a faulty valve.

A valve can malfunction in one of three ways: (1) It can become rigid (a *stenotic* valve) so that it does not open fully, (2) it can fail to close properly (a *regurgitant* valve), or (3) it can actually flop backwards (a *prolapsed* valve). Faulty valves are heard as *heart murmurs* with a stethoscope.

The Semilunar Valves: Ventricles to Great Vessels

The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles, respectively. Unlike the AV valves, the semilunar valves do not need muscular braces, because the arterial walls do not contract and the relative positions of the cusps are stable. When the semilunar valves close, the three symmetrical cusps support one another like the legs of a tripod (see Figure 20–7a). When the aortic valve opens, the aortic sinuses prevent the individual cusps from sticking to the wall of the aorta (see Figure 20–7b).

Serious valve problems can interfere with the working of the heart. If valve function deteriorates to the point at which the heart cannot maintain adequate circulatory flow, symptoms of **valvular heart disease (VHD)** appear. Congenital malformations may be responsible, but in many cases the condition develops after **carditis**, an inflammation of the heart, occurs. One important cause of carditis is **rheumatic** (rū-MAT-ik) **fever**, an inflammatory autoimmune response to an infection by streptococcal bacteria. It most often occurs in children.

The Blood Supply to the Heart

The heart works continuously, so cardiac muscle cells need reliable supplies of oxygen and nutrients. A great volume of blood flows through the chambers of the heart, but the myocardium has its own, separate blood supply. The **coronary circulation** supplies blood to the muscle tissue of the heart. During maximum exertion, the heart's demand for oxygen rises considerably. The blood flow to the myocardium may then increase to nine times that of the resting level. The coronary circulation includes an extensive network of coronary blood vessels, both arteries and veins (Figure 20–8).

The Coronary Arteries

The left and right **coronary arteries** originate at the base of the ascending aorta, at the aortic sinuses (Figure 20–8a). Blood pressure here is the highest in the systemic circuit. When the left ventricle contracts and forces blood into the aorta, the high pressure of this blood stretches the elastic walls of the aorta. When the left ventricle relaxes, blood no longer flows into the aorta, pressure declines, and the walls of the aorta recoil. This recoil, called *elastic rebound*, pushes blood both forward, into the systemic circuit, and backward, through the left and right aortic sinuses and then into the respective coronary arteries. In this way, the combination of elevated blood pressure and elastic rebound ensures a continuous flow of blood to meet the demands of active cardiac muscle tissue.

The *right* and *left coronary arteries*, which deliver blood to the myocardium, originate at the right and left aortic sinuses. The **right coronary artery** follows the coronary sulcus around the heart (see Figure 20–8). It supplies blood to (1) the right atrium, (2) portions of both ventricles, and (3) portions of the

Figure 20–7 Valves of the Heart and Blood Flow. Red (oxygenated) and blue (deoxygenated) arrows indicate blood flow into or out of a ventricle, smaller red arrows show blood flow into an atrium, and green arrows indicate contraction of the ventricles.

electrical conducting system of the heart. Inferior to the right atrium, the right coronary artery generally gives rise to one or more **marginal arteries**, which extend across the surface of the right ventricle. The right coronary artery then continues across the posterior surface of the heart. It supplies the **posterior interventricular artery**, or *posterior descending artery*, which runs toward the apex within the posterior interventricular sulcus. The posterior interventricular artery supplies blood to the interventricular septum and adjacent portions of the ventricles.

The **left coronary artery** supplies blood to the left ventricle, left atrium, and interventricular septum (see Figure 20–8). As it reaches the anterior surface of the heart, it gives rise to a circumflex branch and an anterior interventricular branch. The **circumflex artery** curves to the left around the coronary sulcus. It eventually meets and fuses with small branches of the right coronary artery.

The much larger **anterior interventricular artery**, or *left anterior descending artery (LAD)*, swings around the pulmonary trunk and runs along the surface within the anterior interventricular sulcus. The anterior interventricular artery supplies small tributaries continuous with those of the posterior interventricular artery. Such interconnections between arteries are called **arterial anastomoses** (ah-nas-tō-MŌ-sēz; *anastomosis*, outlet). Because the arteries are interconnected in this way, the blood supply to the cardiac muscle remains relatively constant despite pressure fluctuations in the left and right coronary arteries as the heart beats.

Coronary artery disease is characterized by interrupted blood flow to the myocardium. Spotlight Figure 20–9 describes this condition, along with myocardial infarction.

The Cardiac Veins

The various cardiac veins are also shown in Figure 20–8. The **great cardiac vein** begins on the anterior surface of the

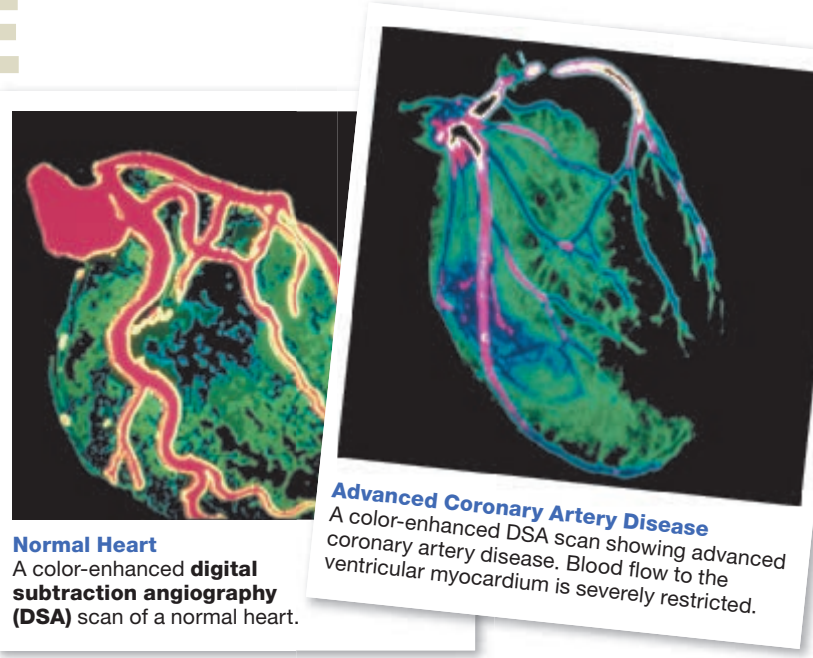
SPOTLIGHT

Figure 20–9
Heart Disease and Heart Attacks

Coronary Artery Disease

HEART DISEASE

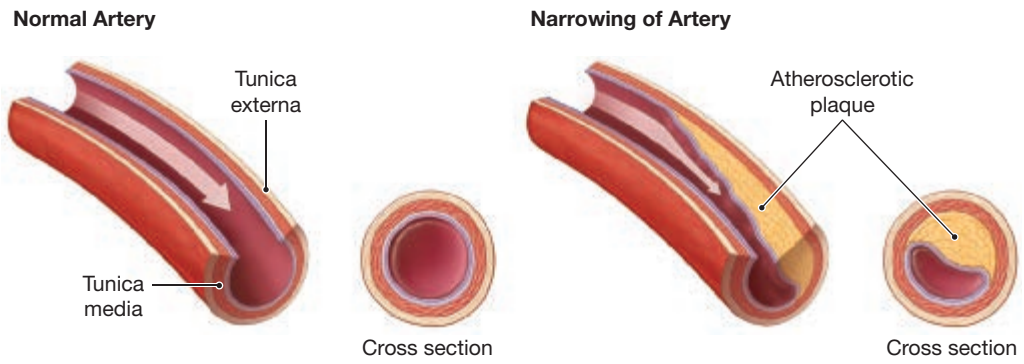
The term **coronary artery disease (CAD)** refers to areas of partial or complete blockage of coronary circulation. Cardiac muscle cells need a constant supply of oxygen and nutrients, so any reduction in blood flow to the heart muscle produces a corresponding reduction in cardiac performance. Such reduced circulatory supply, known as **coronary ischemia** (iss-KĒ-mē-uh), generally results from partial or complete blockage of the coronary arteries. The usual cause is the formation of a fatty deposit, or *atherosclerotic plaque*, in the wall of a coronary vessel. The plaque, or an associated *thrombus* (clot), then narrows the passageway and reduces blood flow. Spasms in the smooth muscles of the vessel wall can further decrease or even stop blood flow. One of the first symptoms of CAD is commonly **angina pectoris** (an-JĪ-nuh PEK-tor-is; *angina*, pain spasm + *pectoris*, of the chest). In its most common form, a temporary ischemia develops when the workload of the heart increases. Although the individual may feel comfortable at rest, exertion or emotional stress can produce a sensation of pressure, chest constriction, and pain that may radiate from the sternal area to the arms, back, and neck.



Normal Heart
A color-enhanced **digital subtraction angiography (DSA)** scan of a normal heart.

Advanced Coronary Artery Disease
A color-enhanced DSA scan showing advanced coronary artery disease. Blood flow to the ventricular myocardium is severely restricted.

*Plaques may be visible by **angiography** or high-resolution ultrasound, and the effects on coronary blood flow can be detected in digital subtraction angiography (DSA) scans of the heart as shown above.*



Left: *Chest pain or discomfort is a common symptom of angina pectoris. Although similar symptoms may accompany a heart attack, during a heart attack, pain often radiates down the left arm.*

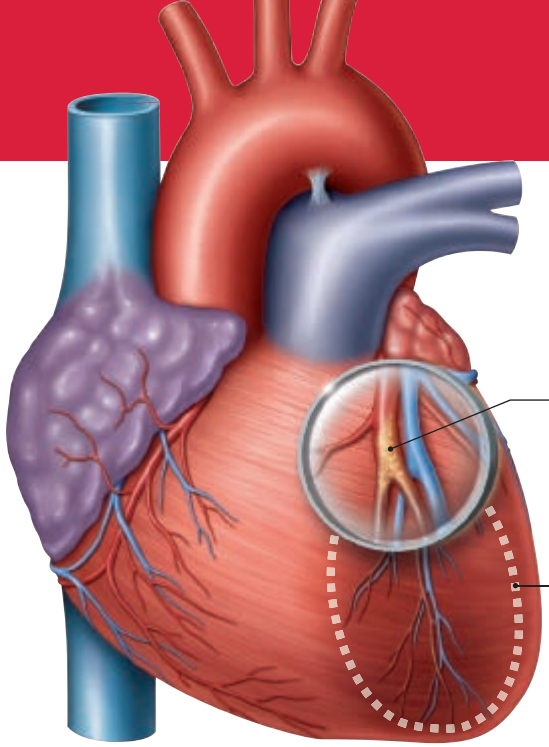
Below: *The presence of any two of these coronary risk factors more than doubles the risk of heart attack.*

Risk Factors for CAD and Myocardial Infarction

SMOKING • HIGH BLOOD PRESSURE • HIGH CHOLESTEROL •
• MALE OVER AGE 70 • SEVERE EMOTIONAL STRESS • OB

Myocardial Infarction

HEART ATTACK



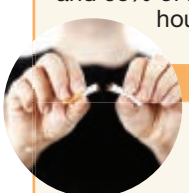
In a **myocardial** (mī-ō-KAR-dē-al) **infarction (MI)**, or *heart attack*, part of the coronary circulation becomes blocked, and cardiac muscle cells die from lack of oxygen. The death of affected tissue creates a nonfunctional area known as an *infarct*. Heart attacks most commonly result from severe coronary artery disease (CAD). The consequences depend on the site and nature of the circulatory blockage. If it occurs near the start of one of the coronary arteries, the damage will be widespread and the heart may stop beating. If the blockage involves one of the smaller arterial branches, the individual may survive the immediate crisis but may have many complications such as reduced contractility and cardiac arrhythmias.

A crisis often develops as a result of thrombus formation at a plaque (the most common cause of an MI), a condition called **coronary thrombosis**. A vessel already narrowed by plaque formation may also become blocked by a sudden spasm in the smooth muscles of the vascular wall.

Individuals having an MI experience intense pain, similar to that felt in angina, but persisting even at rest. However, pain does not always accompany a heart attack, and silent heart attacks may be even more dangerous than more apparent attacks, because the condition may go undiagnosed and may not be treated before a fatal MI occurs. A myocardial infarction can usually be diagnosed with an electrocardiogram (ECG) and blood studies. Damaged myocardial cells release enzymes into the circulation, and these elevated enzymes can be measured in diagnostic blood tests. The enzymes include **cardiac troponin T**, **cardiac troponin I**, and a special form of creatinine phosphokinase, **CK-MB**.

Treatment of CAD and Myocardial Infarction

About 25% of MI patients die before obtaining medical assistance, and 65% of MI deaths among those under age 50 occur within an hour after the initial infarction.



Risk Factor Modification

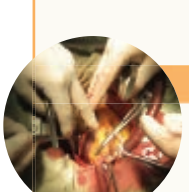
Stop smoking, treat high blood pressure, adjust diet to lower cholesterol and promote weight loss, reduce stress, and increase physical activity.

Drug Treatment

- Drugs that reduce coagulation and therefore the risk of thrombosis, such as aspirin and coumadin
- Drugs that block sympathetic stimulation (propranolol or metoprolol)
- Drugs that cause vasodilation, such as **nitroglycerin** (nī-trō-GLIS-er-in)
- Drugs that block calcium ion movement into the cardiac and vascular smooth muscle cells (calcium ion channel blockers)
- In a myocardial infarction, drugs to relieve pain, fibrinolytic agents to help dissolve clots, and oxygen

Noninvasive Surgery

- **Atherectomy**. Blockage by a single, soft plaque may be reduced with the aid of a long, slender **catheter** (KATH-e-ter) inserted into a coronary artery to the plaque. A variety of surgical tools can be slid into the catheter, and the plaque can then be removed.
- **Balloon angioplasty** (AN-jē-ō-plas-tē; *angeion*, vessel). In balloon angioplasty, the tip of the catheter contains an inflatable balloon. Once in position, the balloon is inflated, pressing the plaque against the vessel walls. Because plaques commonly redevelop after angioplasty, a fine tubular wire mesh called a *stent* may be inserted into the vessel, holding it open.



Coronary Artery Bypass Graft (CABG)

In a **coronary artery bypass graft**, a small section is removed from either a small artery or a peripheral vein and is used to create a detour around the obstructed portion of a coronary artery. As many as four coronary arteries can be rerouted this way during a single operation. The procedures are named according to the number of vessels repaired, so we speak of single, double, triple, or quadruple coronary bypasses.

DIABETES • HIGH CIRCULATING LOW-DENSITY LIPOPROTEIN
ESITY • SEDENTARY LIFESTYLE • GENETIC PREDISPOSITIO

+ Clinical Note Broken-Heart Syndrome

The popular notion that grief can "break your heart" finds support in the novel diagnosis of *broken-heart syndrome*, also called *stress-induced cardiomyopathy*. First noted in Japan in the early 2000s, elderly women were presenting with apparent heart attacks. The precipitating event was an acute emotional stress, such as the death of a loved one. The women's ECGs were abnormal; their left ventricles were significantly dilated. But their coronary arteries—the site of the lesions responsible for heart attacks—were clear! All of these changes reverted to normal within a month of supportive care.

ventricles, along the interventricular sulcus. This vein drains blood from the region supplied by the anterior interventricular artery, a branch of the left coronary artery. The great cardiac vein reaches the level of the atria and then curves around the left side of the heart within the coronary sulcus.

The cardiac veins draining the myocardium return blood to the **coronary sinus**, a large, thin-walled vein. The coronary sinus opens into the right atrium near the base of the inferior vena cava.

Other cardiac veins empty into the great cardiac vein or the coronary sinus. These veins include (1) the **posterior vein of left ventricle**, draining the area served by the circumflex artery; (2) the **middle cardiac vein**, draining the area supplied by the posterior interventricular artery; and (3) the **small cardiac vein**, which receives blood from the posterior surfaces of the right atrium and ventricle. The **anterior cardiac veins** (also called the *anterior veins of right ventricle*), which drain the anterior surface of the right ventricle, empty directly into the right atrium.

20

√ Checkpoint

1. **Damage to the semilunar valve of the right ventricle would affect blood flow into which vessel?**

20-2 The cells of the conducting system distribute electrical impulses through the heart, causing cardiac contractile cells to contract

Learning Outcome Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram.

Next we start to look at how the heart works—cardiac physiology. Then we examine the structure and function of the different types of cardiac muscle cells. Some form the *conducting system*, an internal network that uses electrical signals to coordinate the contractions of cardiac muscle cells. The electrical events of the heart can then be recorded in an *electrocardiogram (ECG)*. Finally we discuss the contraction of the heart at the cellular level.

Cardiac Physiology: Electrical Impulses Leading to the Contractions Making Up a Heartbeat

In a single cardiac contraction, or **heartbeat**, all of the chambers of the heart contract in series—first the atria and then the ventricles. Two types of cardiac muscle cells are involved in a normal heartbeat: (1) Specialized *autorhythmic cells* (pacemaker and conducting) of the conducting system control and coordinate the heartbeat, and (2) *contractile cells* produce the powerful contractions that propel blood. The electrical impulses of the conducting system initiate the contraction of the heart chambers.

Each heartbeat begins with an action potential generated by cells of the conducting system. Other cells of this system then propagate and distribute this electrical impulse to stimulate contractile cells to push blood in the right direction at the proper time. The arrival of an electrical impulse at a cardiac contractile cell's plasma membrane produces an action potential that is comparable to an action potential in a skeletal muscle fiber. As in a skeletal muscle fiber, this action potential triggers the contraction of the cardiac contractile cell. The actual contraction lags behind the beginning of the action potential. Because of the coordination provided by the conducting system, the atria contract first, driving blood into the ventricles through the AV valves, and the ventricles contract next, driving blood out of the heart through the semilunar valves.

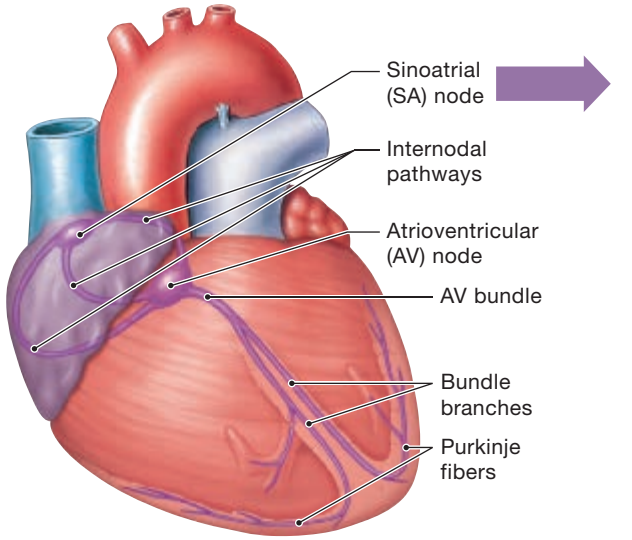
A heartbeat lasts only about 370 milliseconds (msec). Although brief, it is a very busy period! Let's follow the steps that produce a single heartbeat.

The Conducting System: Pacemaker and Conducting Cells

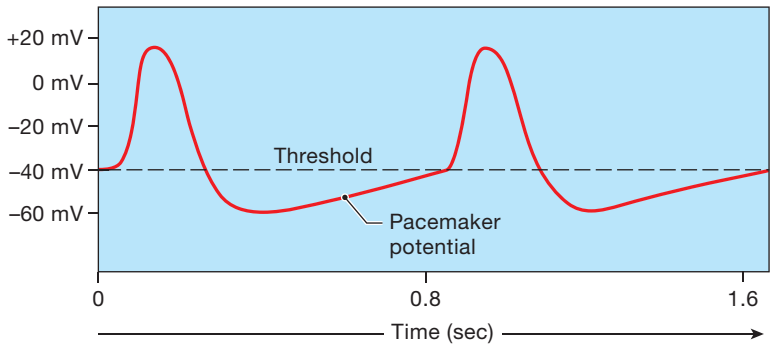
Unlike skeletal muscle, cardiac muscle tissue contracts on its own, without neural or hormonal stimulation; this property is called **autorhythmicity**. The cells that initiate and distribute the stimulus to contract are part of the heart's **conducting system.** This system is a network of specialized cardiac muscle cells, called *pacemaker cells* and *conducting cells*, that initiates and distributes electrical impulses. Let's look at these types of cells, and how they function in the conducting system.

> Go to MasteringA&P™ > Study Area > Menu > Lab Tools > Bone and Dissection Videos > Sheep Heart: External

Figure 20–10 The Conducting System of the Heart and the Pacemaker Potential



a Components of the conducting system.



b Changes in the membrane potential of a pacemaker cell in the SA node that is establishing a heart rate of 72 beats per minute. Note the pacemaker potential, a gradual spontaneous depolarization.

Components of the Conducting System

The specialized cardiac cells of the conducting system are collected in various locations. This section introduces the components of this system (Figure 20–10a).

Pacemaker Cells in the Sinoatrial and Atrioventricular Nodes. Pacemaker cells are essential to establishing the normal *heart rate*. They are also called *nodal cells* because they are found in two nodes, or locations:

- The **sinoatrial** (sī-nō-Ā-trē-al) **(SA) node** is embedded in the posterior wall of the right atrium, near the entrance of the superior vena cava. Because the SA node is the primary driver of the heart rate, it is also known as the *cardiac pacemaker*.
- The relatively large **atrioventricular (AV) node** is located at the junction between the atria and ventricles, near the opening of the coronary sinus. The pacemaker cells of this node send on signals from the cells of the SA node, and act as backup to the SA node pacemaker cells.

Conducting Cells in the Internodal Pathways, AV Bundles, Bundle Branches, and Purkinje Fibers. Conducting cells interconnect the SA and AV nodes, and distribute the contractile stimulus throughout the myocardium. These cells are found in two main locations:

- In the atria, conducting cells are found in **internodal pathways** in the atrial walls. These pathways distribute the contractile stimulus to atrial muscle cells as this electrical impulse travels from the SA node to the AV node.
- In the ventricles, conducting cells include those in the **atrioventricular (AV) bundle** (also called the *bundle of His*) and the **bundle branches** that run between the ventricles, as well as the **Purkinje** (pur-KIN-jē) **fibers**, which distribute the stimulus to the ventricular myocardium.

Most of the cells of the conducting system are smaller than the contractile cells of the myocardium and contain very few myofibrils. Purkinje fibers, however, are much larger in diameter than the contractile cells.

Pacemaker Cells and Heart Rate

Pacemaker cells of the SA and AV nodes share a special characteristic: Their excitable membranes do not have a stable resting membrane potential. Each time a pacemaker cell repolarizes, its membrane potential drifts toward threshold. This gradual depolarization is called a **pacemaker potential** (Figure 20–10b). The pacemaker potential results from a slow inflow of Na^+ without a compensating outflow of K^+.

The rate of spontaneous depolarization differs in various parts of the conducting system. It is fastest at the SA node. Without neural or hormonal stimulation, the SA node generates action potentials at a rate of 60–100 per minute. Isolated cells of the AV node depolarize more slowly, generating 40–60 action potentials per minute. Because the SA node reaches threshold first, it establishes the basic *heart rhythm*, or **sinus rhythm**. (While heart rhythm is essential to heart rate, the heart rate is the number of beats per minute.) In other words, the impulse generated by the SA node brings the AV pacemaker cells to threshold faster than does the pacemaker potential of the AV pacemaker cells. The normal resting heart rate is somewhat slower than 80–100 beats per minute (bpm), however, due to the effects of parasympathetic innervation. (We discuss the influence of autonomic innervation on heart rate in Section 20–4.)

The pacemaker cells of the AV node can conduct impulses at a maximum rate of 230 per minute. Because each impulse results in a ventricular contraction, this value is the maximum normal heart rate. Even if the SA node generates impulses at a faster rate, the ventricles will still contract at 230 bpm. This limitation is important, because mechanical factors (discussed later) begin to decrease the pumping efficiency of the heart at rates above approximately 180 bpm. Rates above 230 bpm occur only when the heart or the conducting system has been damaged or stimulated by drugs. As ventricular rates increase toward their theoretical maximum limit of 300–400 bpm, pumping effectiveness becomes dangerously, if not fatally, reduced.

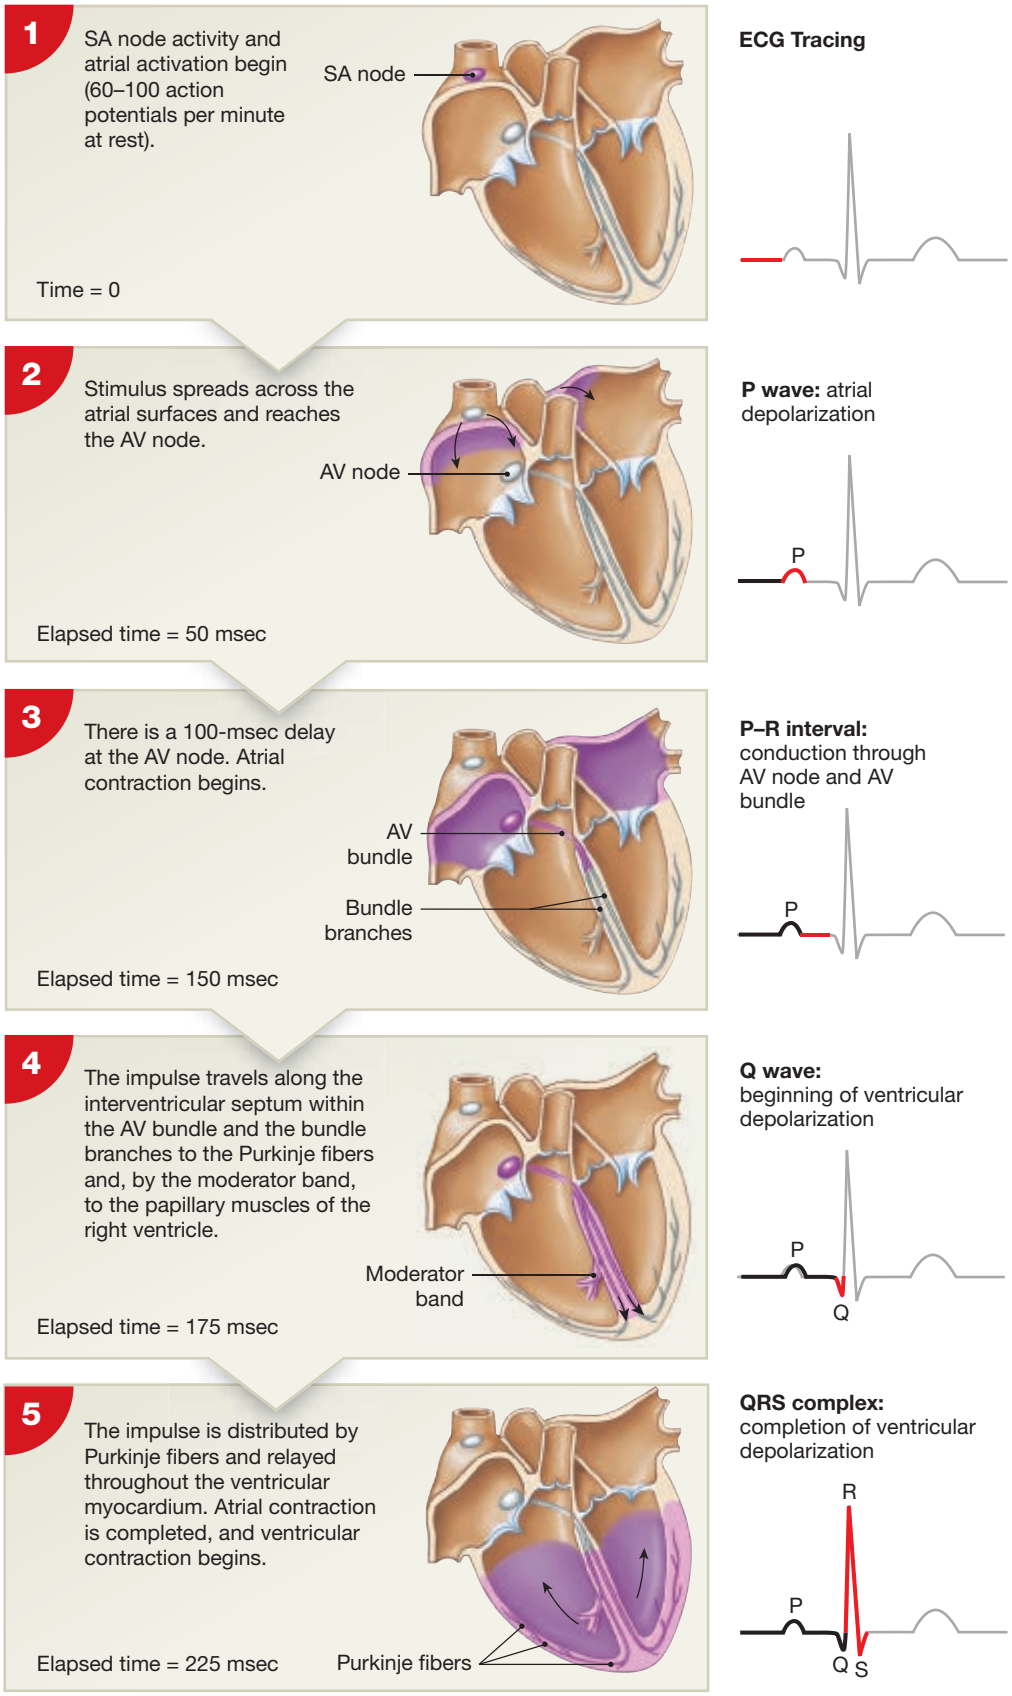
Impulse Conduction through the Heart

Now let's trace the path of an impulse from its initiation at the SA node, examining its effects on the surrounding myocardium as we proceed.

Functions of the Pacemaker Cells. An action potential produced by the pacemaker cells of the SA node (Figure 20–11 1) takes approximately 50 msec to travel to the AV node along the internodal pathways. Along the way, the conducting cells pass the stimulus to contractile cells of both atria. The action potential then spreads across the atrial surfaces by cell-to-cell contact (Figure 20–11 2). The stimulus affects only the atria, because the cardiac skeleton isolates the atrial myocardium from the ventricular myocardium.

The impulse slows as it leaves the internodal pathways and enters the AV node, because the nodal cells are smaller in diameter than the conducting cells. (Chapter 12 discussed

Figure 20–11 Impulse Conduction through the Heart and Accompanying ECG Tracings. The ECG tracings are explained in the next section and in Figure 20–12 on page 706. After reading about the electrocardiogram, come back to this figure to integrate the electrical activity of the heart and atrial and ventricular contractions.



? What happens to the electrical impulse when it reaches the AV node?

the relationship between axon diameter and propagation speed. ↩ p. 416) In addition, the connections between pacemaker cells are less efficient than those between conducting cells at relaying the impulse from one cell to another. As a result, the impulse takes about 100 msec to pass through the AV node (Figure 20–11 3). This delay is important because it allows the atria to contract before the ventricles do. (The delay is a result of the time it takes for calcium ions to enter the sarcoplasm and activate the contraction process, as described in Chapter 10. ↩ p. 306) Otherwise, contraction of the powerful ventricles would close the AV valves and prevent blood flow from the atria into the ventricles.

Functions of the Conducting Cells. After the brief delay at the AV node, the impulse is conducted along the AV bundle and the bundle branches to the Purkinje fibers and the papillary muscles (Figure 20–11 4). The connection between the AV node and the AV bundle is normally the only electrical connection between the atria and the ventricles. Once an impulse enters the AV bundle, it travels to the interventricular septum and enters the **right** and **left bundle branches**. The left bundle branch, which supplies the massive left ventricle, is much larger than the right bundle branch. Both branches extend toward the apex of the heart, turn, and fan out deep to the endocardial surface.

As the bundle branches diverge, they conduct the impulse to both the Purkinje fibers and, through the moderator band, to the papillary muscles of the right ventricle. Because the impulse is delivered to the papillary muscles directly, these muscles begin contracting before the rest of the ventricular musculature does. Contraction of the papillary muscles applies tension to the chordae tendineae, bracing the AV valves. This tension limits the movement of the cusps, preventing the backflow of blood into the atria when the ventricles contract.

The Purkinje fibers then distribute the impulse to the ventricular myocardium (Figure 20–11 5). Purkinje fibers, which radiate from the apex toward the base of the heart, conduct action potentials very rapidly—as fast as small myelinated axons. Within about 75 msec, the signal to begin a contraction has reached all the ventricular cardiac contractile cells, and ventricular contraction begins. By this time, the atria have completed their contractions and ventricular contraction can safely occur. Because of the location of the Purkinje fibers, the ventricles contract in a wave that begins at the apex of the heart and spreads toward the base. The contraction pushes blood toward the base, into the aorta and pulmonary trunk.

In summary, each time the heart beats, a wave of depolarization spreads through the atria, pauses at the AV node, then travels down the interventricular septum to the apex, turns, and spreads through the ventricular myocardium toward the base (see Figure 20–11). The entire process, from the generation of an impulse at the SA node to the complete depolarization of the ventricular myocardium, normally takes around 225 msec.

Disturbances in Heart Rhythm

A number of clinical problems result from abnormal pacemaker function. **Bradycardia** (brād-ē-KAR-dē-uh; *brady*s, slow) is a condition in which the heart rate is slower than normal. **Tachycardia** (tak-ē-KAR-dē-uh; *tachys*, swift) is a faster-than-normal heart rate. These terms are relative, and in clinical practice the definitions vary with the normal resting heart rate of the individual.

Damage to the conducting pathways disturbs the normal rhythm of the heart. The resulting problems are called *conduction deficits*. If the SA node or any of the internodal pathways becomes damaged, the heart continues to beat, but at a slower rate, usually 40–60 bpm, as dictated by the AV node. Certain cells in the Purkinje fiber network depolarize spontaneously at an even slower rate. If the rest of the conducting system is damaged, these cells can stimulate a heart rate of 20–40 bpm. Under normal conditions, cells of the AV bundle, the bundle branches, and most Purkinje fibers do not depolarize spontaneously. If, due to damage or disease, these cells *do* begin depolarizing spontaneously, the heart may no longer pump blood effectively. Death can result if the problem persists.

If an abnormal conducting cell or ventricular contractile cell begins generating action potentials at a higher rate, the impulses can override those of the SA or AV node. The origin of these abnormal signals is called an **ectopic** (ek-TOP-ik; out of place) **pacemaker**. The activity of an ectopic pacemaker partially or completely bypasses the conducting system, disrupting the timing of ventricular contraction. The result may be a dangerous reduction in the pumping efficiency of the heart. Such conditions are commonly diagnosed with the aid of an electrocardiogram.

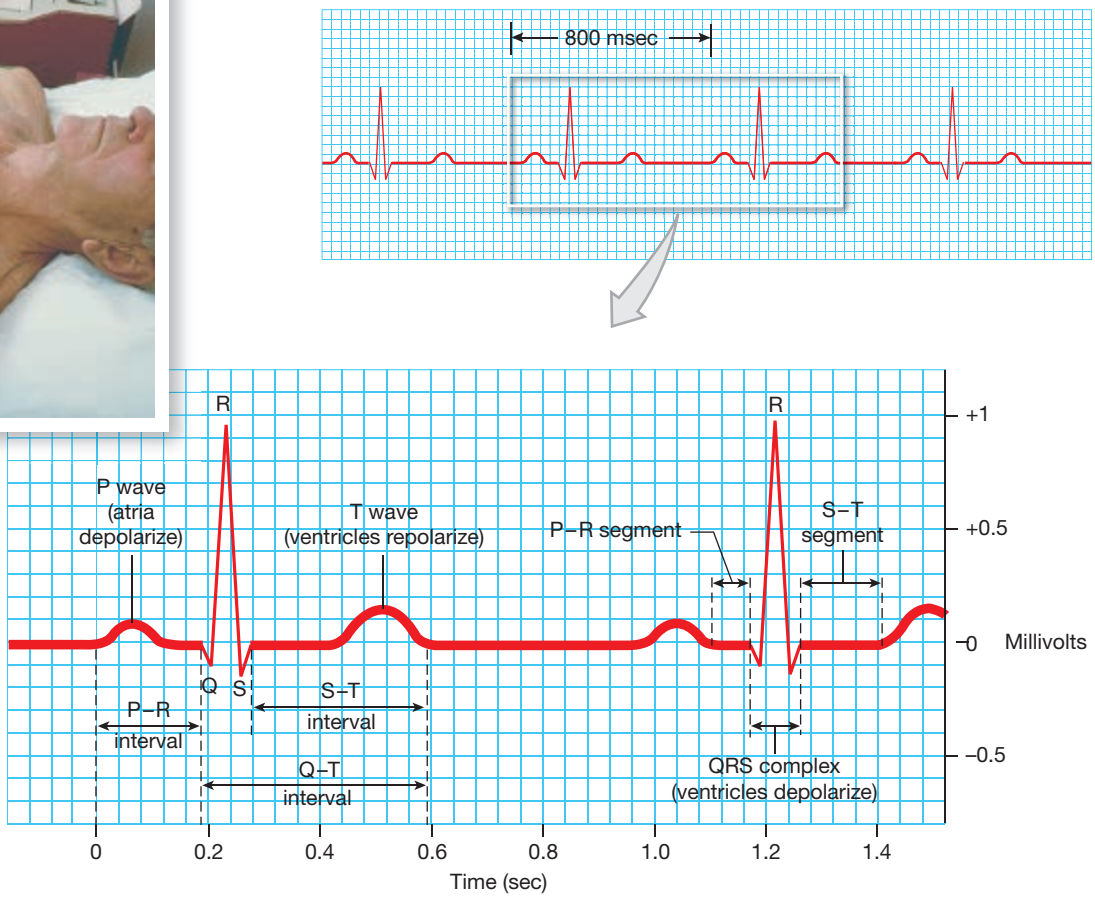
The Electrocardiogram (ECG)

The electrical events in the heart are powerful enough to be detected by electrodes on the body. A procedure known as *electrocardiography* can monitor the electrical events of the conducting system. A recording of these events is an **electrocardiogram** (ē-lek-trō-KAR-dē-ō-gram), also called an **ECG**, or **EKG** (from the German term). Clinicians can use an ECG to assess the functions of specific pacemaker, conducting, and contractile cells. When a portion of the heart has been damaged by a heart attack, for example, the ECG reveals an abnormal pattern of impulse conduction.

The monitoring electrodes for an ECG are placed at different locations on the body surface. The appearance of the ECG varies with the placement of the monitoring electrodes, or *leads*. Figure 20–12a shows the leads in one of the standard configurations. Figure 20–12b depicts the important features of

Figure 20–12 An Electrocardiogram (ECG).

a Electrode placement for recording a standard ECG.



b An ECG printout is a strip of graph paper containing a record of the electrical events monitored by the electrodes. The placement of electrodes on the body surface affects the size and shape of the waves recorded. The example is a normal ECG; the enlarged section indicates the major components of the ECG and the measurements most often taken during clinical analysis.

an ECG recorded with that configuration. Note the following ECG features:

- The small **P wave**, which accompanies the depolarization of the atrial contractile cells. Depolarization of these cells causes atrial contraction. (Also see Figure 20–11 2.)
- The **QRS complex**, which appears as the ventricle contractile cells depolarize. This electrical signal is relatively strong, because the ventricular muscle is much more massive than that of the atria. It is also a complex signal, largely because of the complex pathway that the spread of depolarization takes through the ventricles. The ventricles begin contracting shortly after the peak of the **R wave**. Atrial repolarization takes place while the ventricles are depolarizing and it is obscured by the more powerful QRS complex. (Also see Figure 20–11 4 and 5.)
- The smaller **T wave**, which indicates repolarization of the ventricular contractile cells.

To analyze an ECG, you must measure the size of the voltage changes and determine the durations and temporal (time) relationships of the various components. The amount of depolarization during the P wave and the QRS complex is particularly important in making a diagnosis. For example, an excessively large QRS complex often indicates that the heart has become enlarged. A smaller-than-normal electrical signal may mean that the mass of the heart muscle has decreased (although monitoring problems are more often responsible). The size and shape of the T wave may also be affected by any condition that slows ventricular repolarization. For example, starvation and low cardiac energy reserves, coronary ischemia (inadequate blood flow to cardiac cells), or abnormal ion concentrations reduce the size of the T wave.

The times between waves are reported as *segments* and *intervals*. Segments generally extend from the end of one wave to the start of another. Intervals are more variable, but always include at least one entire wave. Commonly used segments and

intervals are labeled in Figure 20–12b. The names, however, can be somewhat misleading. For example:

- The **P–R interval** extends from the start of atrial depolarization to the start of the QRS complex (ventricular depolarization) rather than to R, because in abnormal ECGs the peak at R can be difficult to determine. Extension of the P–R interval to more than 200 msec can indicate damage to the AV node or conducting pathways.
- The **Q–T interval** indicates the time required for the ventricles to undergo a single cycle of depolarization and repolarization. It is usually measured from the end of the P–R interval rather than from the bottom of the Q wave. The Q–T interval can be lengthened by electrolyte disturbances, some medications, conduction problems, coronary ischemia, or myocardial damage. A congenital heart defect that can cause sudden death without warning may be detectable as a prolonged Q–T interval.

An *arrhythmia* (ā-RITH-mē-uh) is an irregularity in the normal rhythm or force of the heartbeat. Serious arrhythmias may indicate damage to the myocardium, injuries to the pacemaker cells or conducting cell pathways, exposure to drugs, or abnormalities in the electrolyte composition of extracellular fluids. Spotlight Figure 20–13 describes cardiac arrhythmias.

Cardiac Contractions: Contractile Cells

The Purkinje fibers distribute the stimulus to the **cardiac contractile cells**, which form the bulk of the atrial and ventricular walls. These cells account for about 99 percent of the muscle cells in the heart. As noted in Chapter 10, cardiac contractile cells are interconnected by **intercalated** (in-TER-kah-lā-ted) **discs** (Figure 20–14a). Intercalated discs transfer the force of contraction from cell to cell and propagate action potentials. At an intercalated disc, the interlocking membranes of adjacent cells are held together by desmosomes and linked by gap junctions (Figure 20–14b,c). The desmosomes prevent cells from separating during contraction, while the gap junctions allow ions to pass and electrically couple adjacent cells. This allows the heart muscle to behave as a *functional syncytium* (sin-SI-shē-um), a mechanically, chemically, and electrically coupled, multinucleate tissue.

Tips & Tools

The term *intercalated* means "inserted between other elements." So, intercalated discs appear to have been inserted between cardiac muscle cells.

Cardiac Contractile Cells Compared with Skeletal Muscle Fibers

Table 20–1 provides a review of the structural and functional differences between cardiac contractile cells and skeletal muscle fibers. Histological characteristics that distinguish cardiac contractile cells from skeletal muscle fibers include (1) small size; (2) a single, centrally located nucleus; (3) branching interconnections between cells; and (4) the presence of intercalated discs.

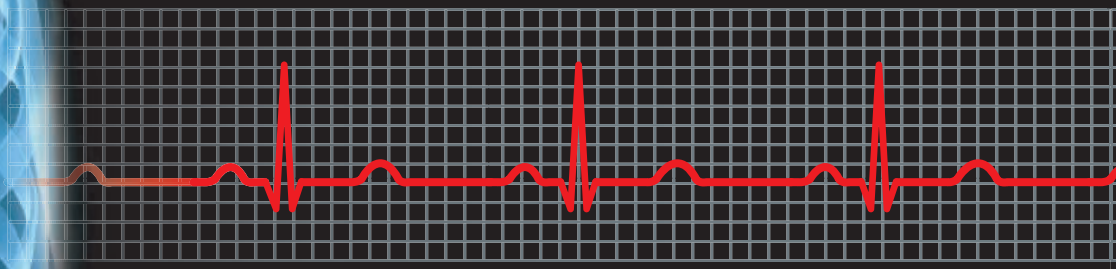
Table 20–1 Structural and Functional Differences between Cardiac Contractile Cells and Skeletal Muscle Fibers

Feature	Cardiac Contractile Cells	Skeletal Muscle Fibers
Size	10–20 μm × 50–100 μm	100 μm × up to 40 cm
Nuclei	Typically 1 (rarely 2–5)	Multiple (hundreds)
Contractile proteins	Sarcomeres along myofibrils	Sarcomeres along myofibrils
Internal membranes	Short T tubules; no triads formed with sarcoplasmic reticulum	Long T tubules form triads with cisternae of the sarcoplasmic reticulum
Mitochondria	Abundant (25% of cell volume)	Much less abundant
Inclusions	Myoglobin, lipids, glycogen	Little myoglobin, few lipids, but extensive glycogen reserves
Blood supply	Very extensive	More extensive than in most connective tissues, but sparse compared with supply to cardiac muscle cells
Metabolism (resting)	Not applicable	Aerobic, primarily lipid based
Metabolism (active)	Aerobic, primarily using lipids and carbohydrates	Anaerobic, through breakdown of glycogen reserves
Contractions	Twitches with brief relaxation periods; long refractory period prevents tetanic contractions	Usually sustained contractions
Stimulus for contraction	Autorhythmicity of pacemaker cells generates action potentials	Activity of somatic motor neuron generates action potentials in sarcolemma
Trigger for contraction	Calcium ion entry from the extracellular fluid and calcium ion release from the sarcoplasmic reticulum	Calcium ion release from the sarcoplasmic reticulum
Intercellular connections	Branching network with plasma membranes locked together at intercalated discs; connective tissue fibers tie adjacent layers together	Adjacent fibers tied together by connective tissue fibers

SPOTLIGHT

Figure 20–13
Cardiac Arrhythmias

Despite the variety of sophisticated equipment available to assess or visualize cardiac function, in the majority of cases the ECG provides the most important diagnostic information. ECG analysis is especially useful in detecting and diagnosing **cardiac arrhythmias** (ā-RITH-mē-uz)—abnormal patterns of cardiac electrical activity. Momentary arrhythmias are not inherently dangerous, but clinical problems appear when arrhythmias reduce the pumping efficiency of the heart.



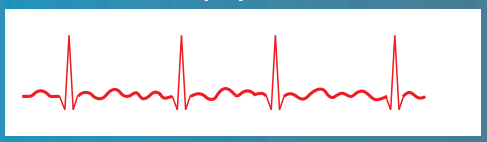
Premature Atrial Contractions (PACs)

Premature atrial contractions (PACs) often occur in healthy individuals. In a PAC, the normal atrial rhythm is momentarily interrupted by a "surprise" atrial contraction. Stress, caffeine, and various drugs may increase the incidence of PACs, presumably by increasing the permeabilities of the SA pacemakers. The impulse spreads along the conduction pathway, and a normal ventricular contraction follows the atrial beat.

Paroxysmal Atrial Tachycardia (PAT)

In **paroxysmal** (par-ok-SIZ-mal) **atrial tachycardia**, or **PAT**, a premature atrial contraction triggers a flurry of atrial activity. The ventricles are still able to keep pace, and the heart rate jumps to about 180 beats per minute.

Atrial Fibrillation (AF)

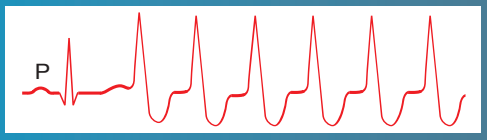


During **atrial fibrillation** (fib-ri-LĀ-shun), the impulses move over the atrial surface at rates of perhaps 500 beats per minute. The atrial wall quivers instead of producing an organized contraction. The ventricular rate cannot follow the atrial rate and may remain within normal limits. Even though the atria are now nonfunctional, their contribution to ventricular end-diastolic volume (the maximum amount of blood the ventricles can hold at the end of atrial contraction) is so small that the condition may go unnoticed in older individuals.

Premature Ventricular Contractions (PVCs)

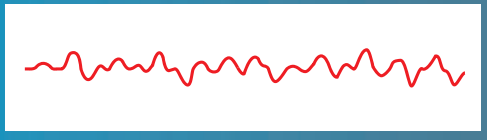
Premature ventricular contractions (PVCs) occur when a Purkinje cell or ventricular myocardial cell depolarizes to threshold and triggers a premature contraction. Single PVCs are common and not dangerous. The cell responsible is called an **ectopic pacemaker**. The frequency of PVCs can be increased by exposure to epinephrine, to other stimulatory drugs, or to ionic changes that depolarize cardiac muscle plasma membranes.

Ventricular Tachycardia (VT)



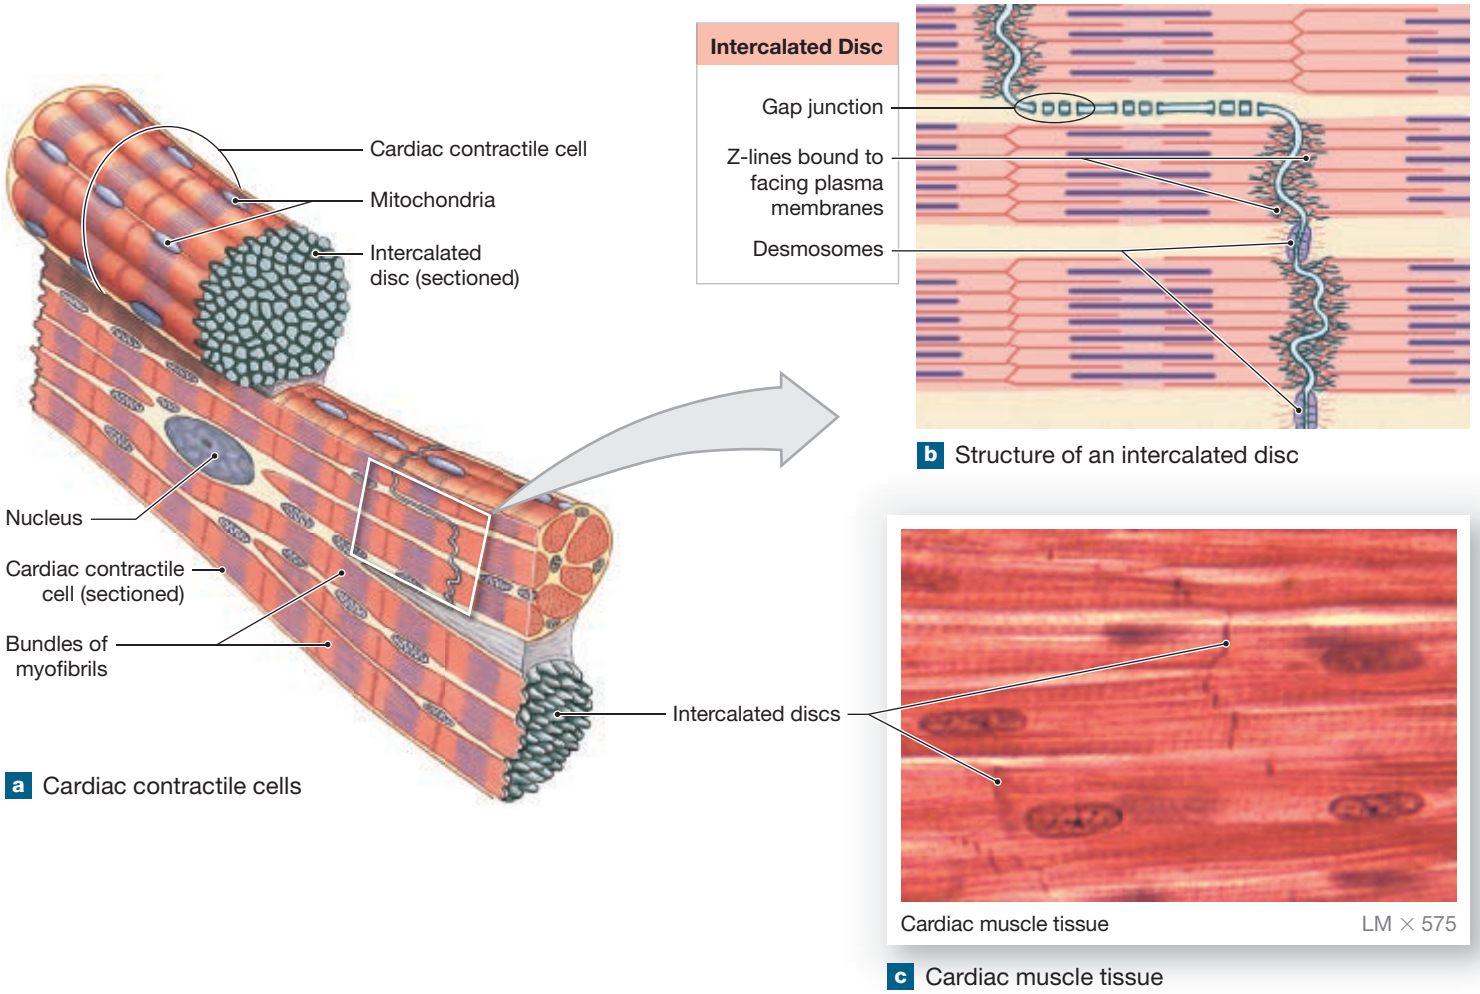
Ventricular tachycardia is defined as four or more PVCs without intervening normal beats. It is also known as **VT** or **V-tach**. Multiple PVCs and VT may indicate that serious cardiac problems exist.

Ventricular Fibrillation (VF)



Ventricular fibrillation (VF) is responsible for the condition known as **cardiac arrest**. VF is rapidly fatal, because the ventricles quiver and stop pumping blood.

Figure 20–14 Cardiac Contractile Cells.



The functions of cardiac contractile cells and skeletal muscle cells are similar but have some differentiating characteristics. In both types of cells, (1) an action potential leads to the appearance of Ca^{2+} among the myofibrils, and (2) the binding of Ca^{2+} to troponin on the thin filaments initiates the contraction. But cardiac contractile cells and skeletal muscle fibers differ in terms of the nature of the action potential, the source of the Ca^{2+}, and the duration of the resulting contraction. ↩ p. 331

The Action Potential in Cardiac Contractile Cells

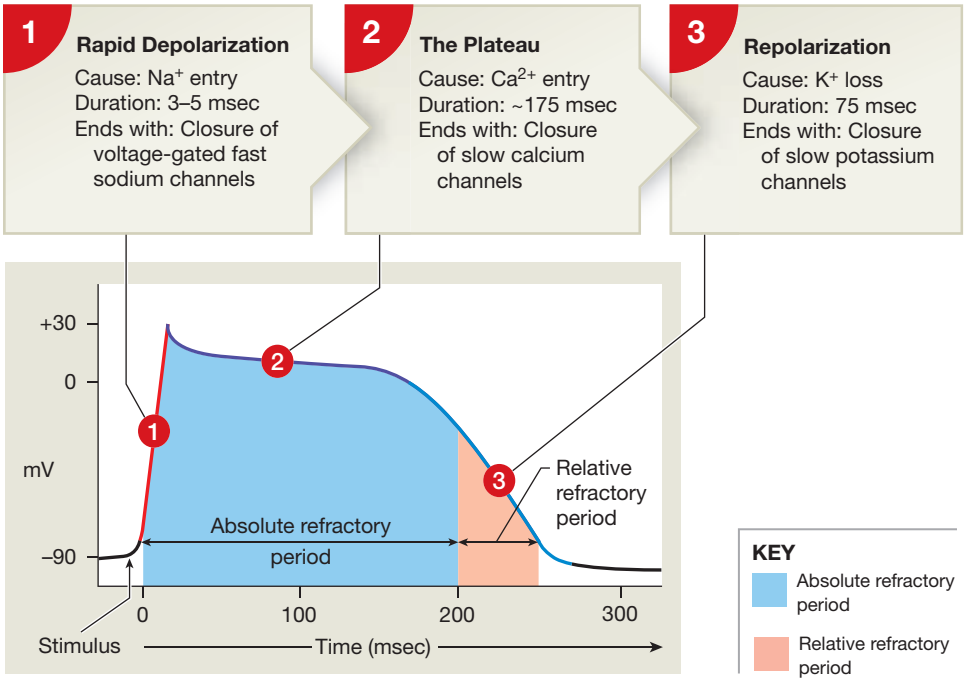
The resting membrane potential of a ventricular contractile cell is approximately −90 mV, comparable to that of a resting skeletal muscle fiber (−85 mV). (The resting membrane potential of an atrial contractile cell is about −80 mV, but the basic principles described here apply to atrial cells as well.)

Process of the Action Potential. An action potential begins when the membrane of the ventricular contractile cell reaches threshold, usually at about −75 mV. Threshold is normally reached in a portion of the membrane next to an intercalated disc. The typical stimulus is the excitation of an adjacent contractile cell. Once threshold has been reached, the action potential proceeds in three basic steps (Figure 20–15a):

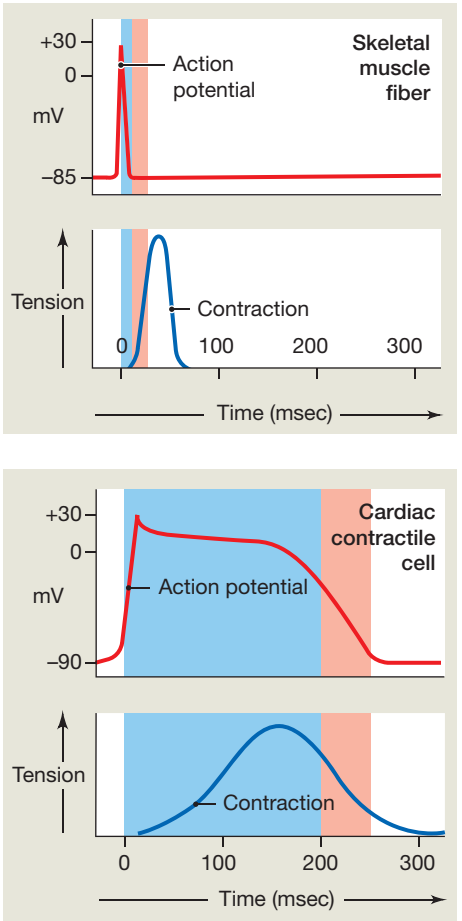
1 **Rapid Depolarization.** The stage of *rapid depolarization* in a cardiac contractile cell resembles that in a skeletal muscle fiber. At threshold, voltage-gated sodium ion channels open, and the membrane suddenly becomes permeable to Na^+. A massive influx of sodium ions rapidly depolarizes the sarcolemma. The channels involved are called **fast sodium channels**, because they open quickly and remain open for only a few milliseconds.

2 **The Plateau.** A partial repolarization takes place as some potassium ions (K^+) leave the cell before most K^+ channels close. Voltage-gated calcium channels then open and *extracellular* calcium ions (Ca^{2+}) enter the cytosol. The **slow calcium channels** remain open for a relatively long period—roughly 175 msec. The inflow of positive charges (Ca^{2+}) and reduced outflow of K^+ delay repolarization, causing the membrane

Figure 20–15 Action Potentials in Cardiac Contractile Cells and Skeletal Muscle Fibers.



a Events in an action potential in a ventricular contractile cell.



b Action potentials and twitch contractions in a skeletal muscle fiber (above) and cardiac contractile cell (below). The shaded areas indicate the durations of the absolute (blue) and relative (beige) refractory periods.

? Which ion's entry causes rapid depolarization? Which ion's entry causes the plateau? Which ion's exit causes repolarization?

potential to remain near 0 mV for an extended period. This portion of the action potential is called the *plateau*. The extracellular calcium ions initiate contraction and also delay repolarization. Their increased concentration within the cell also triggers the release of Ca^{2+} from reserves in the sarcoplasmic reticulum (SR), which continues the contraction.

3 Repolarization. As the plateau continues, slow calcium channels begin closing, and **slow potassium channels** begin opening. As these channels open, potassium ions (K^+) rush out of the cell, and the net result is a period of rapid repolarization that restores the resting membrane potential.

The Refractory Period. As with skeletal muscle fiber contractions, the membrane of a cardiac contractile cell will not respond normally to a second stimulus for some time after an action potential begins. This time is called the **refractory period**. Initially, in the *absolute refractory period*, the membrane cannot respond at all, because the sodium ion channels are either already open or closed and inactivated. In a ventricular contractile cell, the absolute refractory period lasts approximately 200 msec. It includes the plateau and the initial period of rapid repolarization.

The absolute refractory period is followed by a shorter (50-msec) *relative refractory period*. During this period, the

voltage-gated sodium ion channels are closed, but can open. The membrane will respond to a stronger-than-normal stimulus by initiating another action potential. In total, an action potential in a ventricular contractile cell lasts 250–300 msec, about 30 times as long as a typical action potential in a skeletal muscle fiber.

The Role of Calcium Ions in Cardiac or Skeletal Muscle Contractions

The appearance of an action potential in the cardiac contractile cell plasma membrane produces a contraction by causing an increase in the concentration of Ca^{2+} around the myofibrils. This process takes place in two steps:

1. Extracellular calcium ions crossing the plasma membrane during the plateau phase of the action potential provide roughly 20 percent of the Ca^{2+} required for a contraction.
2. The arrival of extracellular Ca^{2+} triggers the release of additional Ca^{2+} from reserves in the sarcoplasmic reticulum (SR).

Extracellular calcium ions thus have both direct and indirect effects on cardiac contractile cell contraction. For this reason, cardiac muscle tissue is highly sensitive to changes in the Ca^{2+} concentration of the extracellular fluid.

In a skeletal muscle fiber, the action potential is relatively brief and ends as the resulting twitch contraction begins (**Figure 20–15b**). The twitch contraction is short and ends as the SR reclaims the Ca^{2+} it released. In a cardiac contractile cell, as we have seen, the action potential is prolonged, and calcium ions continue to enter the cell throughout the plateau. As a result, the cell actively contracts until the plateau ends. As the slow calcium channels close, the intracellular calcium ions are pumped back into the SR or out of the cell, and the contractile cell relaxes.

In skeletal muscle fibers, the refractory period ends before peak tension develops. As a result, twitches can summate and tetanus can occur. In cardiac contractile cells, the absolute refractory period continues until relaxation is under way. Because summation is not possible, tetanic contractions cannot occur in a normal cardiac contractile cell, regardless of the frequency or intensity of stimulation. This feature is vital: A heart in tetany could not pump blood. With a single twitch lasting 250 msec or longer, a normal cardiac contractile cell could reach 300–400 contractions per minute under maximum stimulation. This rate is not reached in a normal heart, due to limitations imposed by the conducting system.

The Energy for Cardiac Contractions

When a normal heart is beating, it gets energy as the mitochondria break down fatty acids (stored as lipid droplets) and glucose (stored as glycogen). These aerobic reactions can occur only when oxygen is readily available. ↩ p. 320

In addition to obtaining oxygen from the coronary circulation, cardiac contractile cells maintain their own sizable reserves of oxygen. In these cells, oxygen molecules are bound to the heme units of *myoglobin* molecules. (We discussed this globular protein, which reversibly binds oxygen molecules, and its function in skeletal muscle fibers in Chapter 10.) ↩ p. 323 Normally, the combination of circulatory supplies plus myoglobin reserves is enough to meet the oxygen demands of the heart, even when it is working at maximum capacity.

20-3 The contraction–relaxation events that occur during a complete heartbeat make up a cardiac cycle

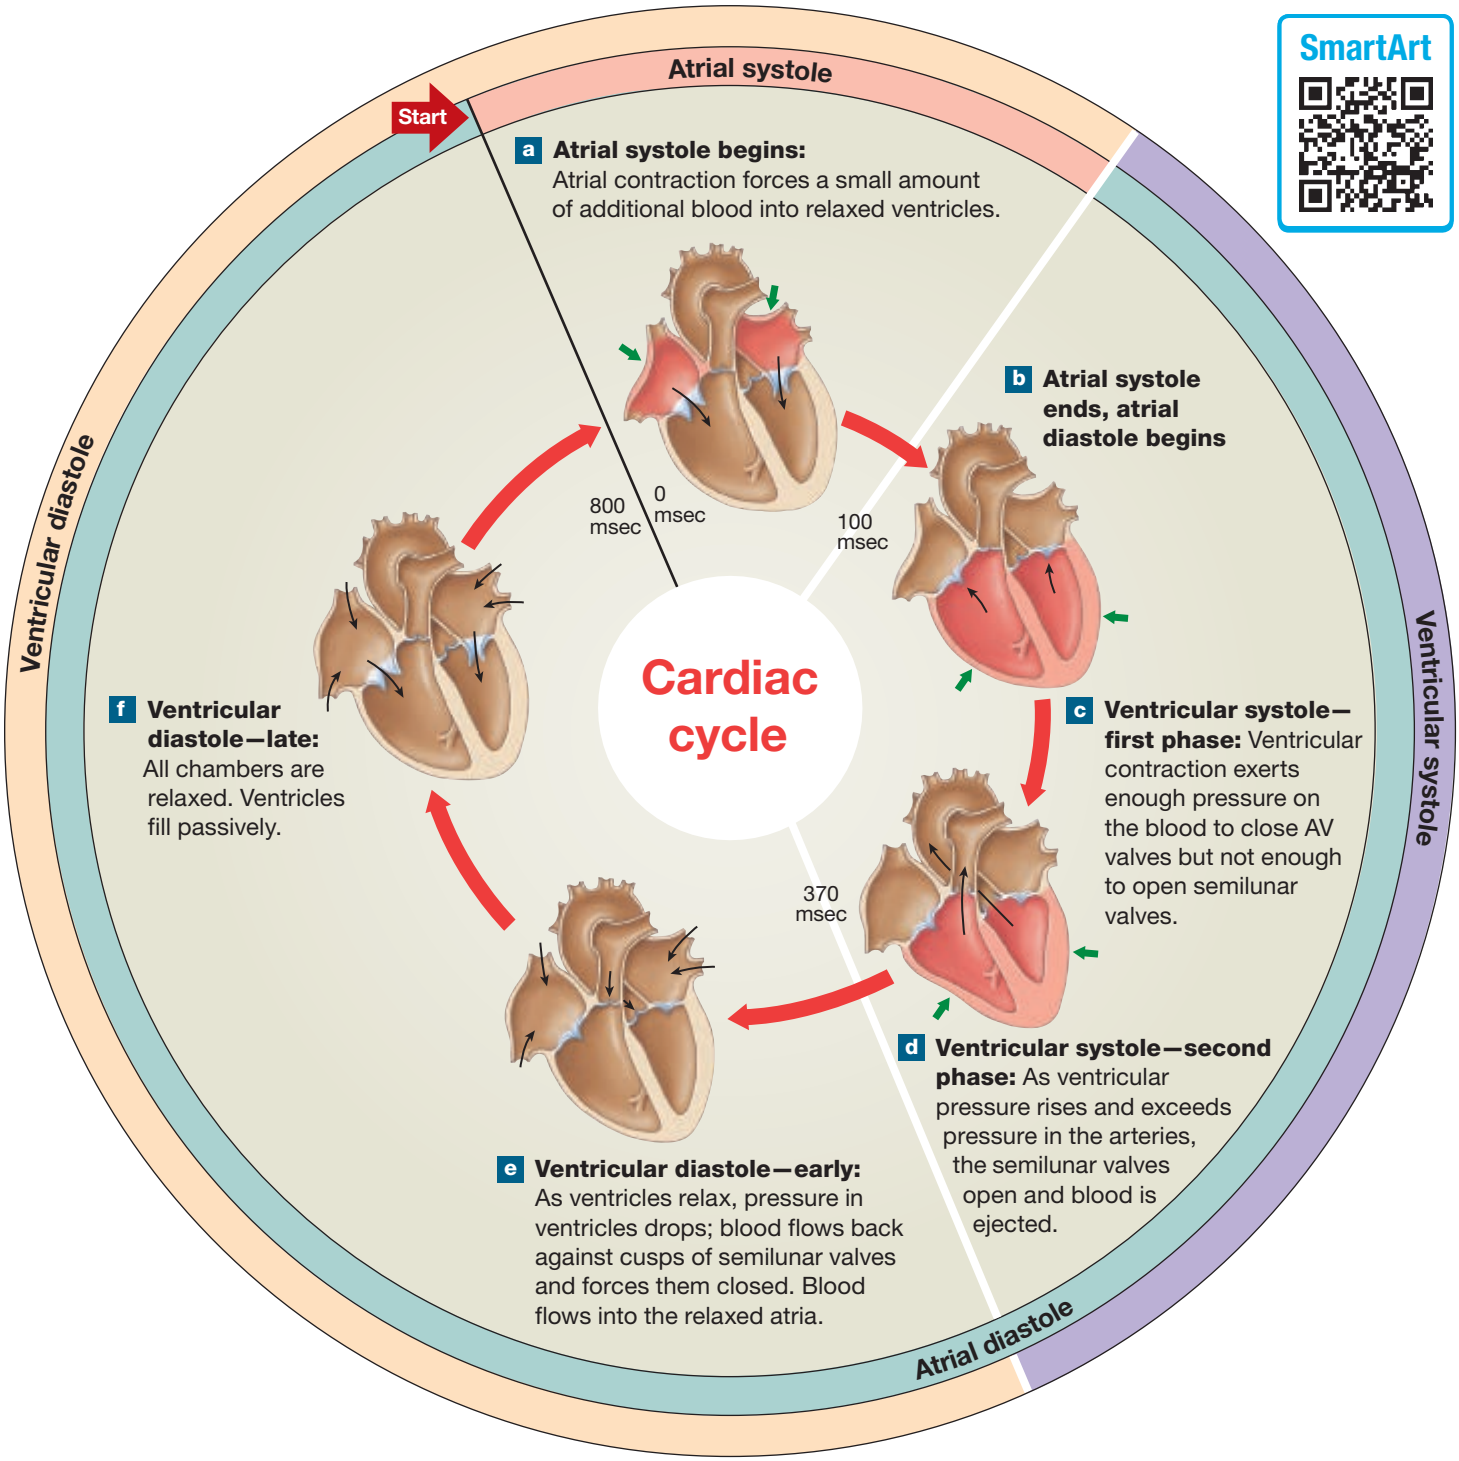
Learning Outcome Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.

The electrical events of the conducting system initiate the mechanical events of heart contraction. A brief resting phase follows each heartbeat, allowing time for the chambers to relax and prepare for the next heartbeat. The period between the start of one heartbeat and the beginning of the next is a single **cardiac cycle**. It includes alternating periods of contraction and relaxation. For any one chamber in the heart, the cardiac cycle can be divided into two phases: systole and diastole. During **systole** (SIS-tō-lē), or contraction, the chamber contracts and pushes blood into an adjacent chamber or into an arterial trunk. Systole is followed by **diastole** (dī-AS-tō-lē), or relaxation. During diastole, the chamber fills with blood and prepares for the next cardiac cycle.

An Introduction to Pressure and Flow in the Heart

Fluids flow from an area of higher pressure to an area of lower pressure. In the cardiac cycle, the blood pressure within each chamber rises during systole and falls during diastole. Valves between adjacent chambers help ensure that blood flows in the required direction, but blood flows from one chamber to another only if the pressure in the first chamber exceeds that in the second. This basic principle governs the movement of blood between atria and ventricles, between ventricles and arterial trunks, and between major veins and atria.

Figure 20–16 Phases of the Cardiac Cycle. Thin black arrows indicate blood flow, green arrows indicate contractions, and the red-hued areas indicate which heart chambers are in systole.



The correct pressure relationships depend on the careful timing of contractions. For example, blood could not move in the proper direction if an atrium and its attached ventricle contracted at precisely the same moment. The heart's elaborate pacemaking and conducting systems normally provide the required spacing between atrial systole and ventricular systole.

Phases of the Cardiac Cycle

The phases of the cardiac cycle—*atrial systole*, *atrial diastole*, *ventricular systole*, and *ventricular diastole*—are diagrammed in Figure 20–16 for a representative heart rate of 75 bpm. At this heart rate, a sequence of systole and diastole in either the atria or the ventricles lasts 800 msec. When the cardiac cycle begins,

all four chambers are relaxed, and the ventricles are partially filled with blood.

Let's start by focusing on the atria. During **atrial systole**, the atria contract, filling the ventricles completely with blood (Figure 20–16a,b). Atrial systole lasts 100 msec. The atria next enter **atrial diastole**, which continues until the start of the next cardiac cycle.

Ventricular systole begins at the same time as atrial diastole. Ventricular systole lasts 270 msec. During this period, the ventricles push blood through the systemic and pulmonary circuits and toward the atria (Figure 20–16c,d). The heart then enters **ventricular diastole** (Figure 20–16e,f), which lasts 530 msec (the 430 msec remaining in this cardiac cycle, plus the first 100 msec of the next, when the atria are again contracting). For the rest of this cycle, filling occurs passively, and both the atria and the ventricles are relaxed. The next cardiac cycle begins with atrial systole, which completes the filling of the ventricles.

When the heart rate increases, all the phases of the cardiac cycle are shortened. The greatest reduction occurs in the length of time spent in diastole. When the heart rate climbs from 75 bpm to 200 bpm, the time spent in systole drops by less than 40 percent, but the duration of diastole is reduced by almost 75 percent.

Pressure and Volume Changes in the Cardiac Cycle

Figure 20–17 plots the pressure and volume changes during the cardiac cycle. It also shows an ECG for the cardiac cycle. The circled numbers in the figure correspond to numbered paragraphs in the text. The figure shows pressure and volume within the left atrium and left ventricle, but our discussion applies to both sides of the heart. Although pressures are lower in the right atrium and right ventricle, both sides of the heart contract at the same time, and they eject equal volumes of blood.

Atrial Systole

In atrial systole:

1 Atrial contraction begins. At the start of atrial systole, the ventricles are already filled to about 70 percent of their normal capacity, due to passive blood flow during the end of the previous cardiac cycle.

2 Atria eject blood into the ventricles. As the atria contract, rising atrial pressures provide the remaining 30 percent by pushing blood into the ventricles through the open right and left AV valves. Atrial systole essentially "tops off" the ventricles. Over this period, blood cannot flow into the atria from the veins because atrial pressure exceeds venous pressure. Yet there is very little backflow into the veins, even though the connections with the venous system lack valves. The reason is that blood takes the path of least resistance. Resistance to blood flow through the wide opening between the atria and ventricles is less than that through the smaller, angled openings of the large veins.

At the end of atrial systole, each ventricle contains the maximum amount of blood that it will hold in this cardiac cycle. That quantity is called the *end-diastolic volume (EDV)*. In an adult who is standing at rest, the end-diastolic volume is typically about 130 mL (about 4.4 oz).

Ventricular Systole and Atrial Diastole

In ventricular systole:

3 Atrial systole ends; AV valves close. As atrial systole ends, ventricular systole begins. As the pressures in the ventricles rise above those in the atria, the AV valves are pushed closed.

4 Isovolumetric ventricular contraction occurs. During the early stage of ventricular systole, the ventricles are contracting, but blood flow has yet to occur. Ventricular pressures are not yet high enough to force open the semilunar valves and push blood into the pulmonary or aortic trunk. Over this period, the ventricles contract isometrically; in other words, they generate tension and pressures rise inside them, but blood does not flow out. The ventricles are in **isovolumetric contraction**: All the heart valves are closed, the volumes of the ventricles do not change, and ventricular pressures are rising.

5 Ventricular ejection occurs. Once pressure in the ventricles exceeds that in the arterial trunks, the semilunar valves are pushed open and blood flows into the pulmonary and aortic trunks. This point marks the beginning of **ventricular ejection**. The ventricles now contract isotonically: The muscle cells shorten, and tension production remains relatively constant. (To review isotonic versus isometric contractions, look back at Figure 10–18, p. 317.)

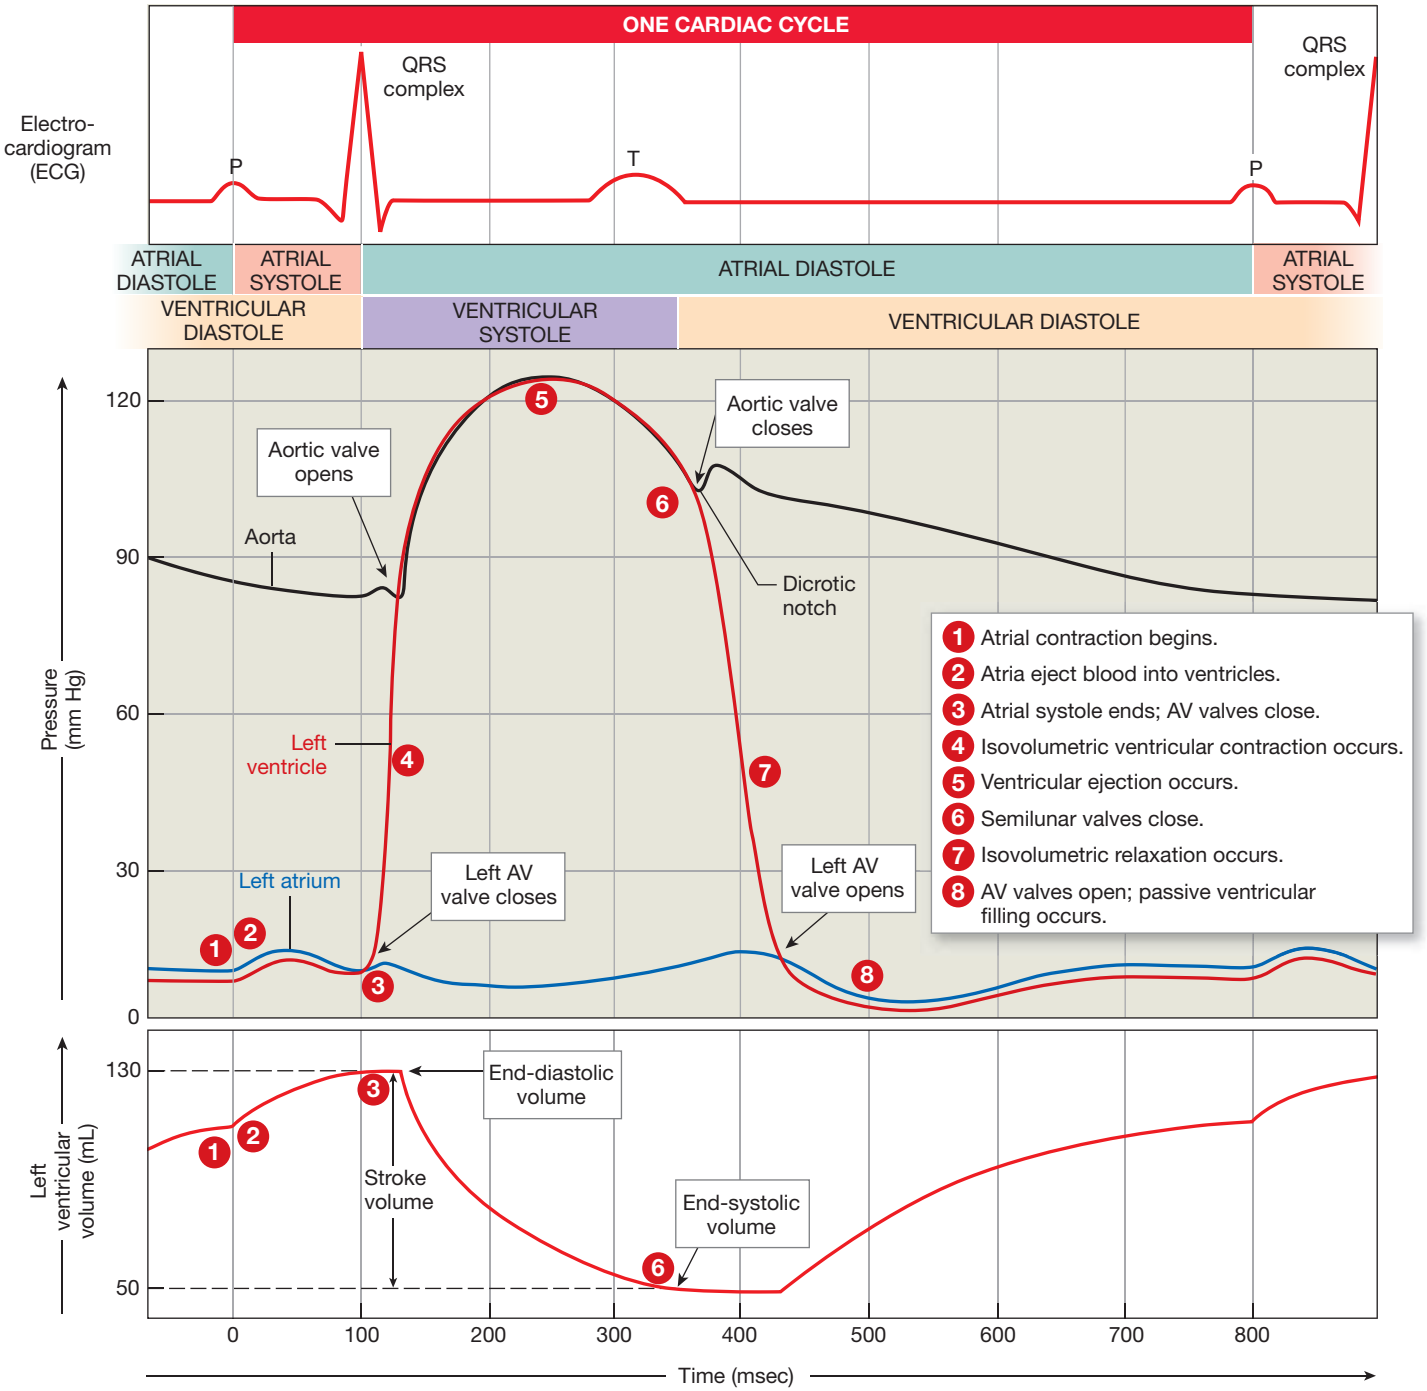
During ventricular ejection, each ventricle ejects 70–80 mL of blood, the *stroke volume (SV)* of the heart. The stroke volume at rest is roughly 60 percent of the end-diastolic volume.

After reaching a peak, ventricular pressures gradually decline near the end of ventricular systole. Figure 20–17 shows values for the left ventricle and aorta. The right ventricle also undergoes periods of isovolumetric contraction and ventricular ejection.

6 Semilunar valves close. As the end of ventricular systole approaches, ventricular pressures fall rapidly. Blood in the aorta and pulmonary trunk now starts to flow back toward the ventricles, and this movement closes the semilunar valves. As the backflow begins, pressure decreases in the aorta. When the semilunar valves close, pressure rises again as the elastic arterial walls recoil. This small, temporary rise produces a valley in the aortic pressure tracing, called a *dicrotic* (dī-KROT-ik; *dikrotos*, double beating) *notch*.

The amount of blood remaining in the ventricle when the semilunar valve closes is the *end-systolic volume (ESV)*. At rest, the end-systolic volume is 50 mL, about 40 percent of the end-diastolic volume.

Figure 20–17 Pressure and Volume Relationships in the Cardiac Cycle. Major features of the cardiac cycle are shown for a heart rate of 75 bpm. The circled numbers correspond to those in the associated box. For further details, see the numbered list in the text (pp. 713–715).



Ventricular Diastole

The period of ventricular diastole lasts for the remainder of the current cardiac cycle and continues through atrial systole in the next cycle.

7 Isovolumetric relaxation occurs. All the heart valves are now closed, and the ventricular myocardium is relaxing. Because ventricular pressures are still higher than atrial pressures, blood cannot flow into the ventricles. This is **isovolumetric relaxation**. Ventricular pressures drop rapidly over this period, because the elasticity of the connective tissues of the heart and cardiac skeleton helps re-expand the ventricles toward their resting dimensions.

8 AV valves open; passive ventricular filling occurs. When ventricular pressures fall below those of the atria, the atrial pressures force the AV valves open. Blood now flows from the atria into the ventricles. Both the atria and the ventricles are in diastole, but the ventricular pressures continue to fall as the ventricular chambers expand. Throughout this period, pressures in the ventricles are so far below those in the major veins that blood pours through the relaxed atria and on through the open AV valves into the ventricles. This passive flow of blood is the primary method of ventricular filling. The ventricles become nearly three-quarters full before the cardiac cycle ends.

The relatively minor contribution that atrial systole makes to ventricular volume explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to pump enough blood through peripheral tissues and organs. A condition of **heart failure** then exists.

Heart Sounds

Listening to the heart, a technique called *auscultation* (aws-kul-TĀ-shun), is a simple and effective method of cardiac assessment. Clinicians use an instrument called a **stethoscope** to listen for normal and abnormal heart sounds. Where the stethoscope is placed depends on which valve is under examination (Figure 20–18a). Valve sounds must pass through the pericardium, surrounding tissues, and the chest wall, and some tissues muffle sounds more than others. For this reason, the placement of the stethoscope differs somewhat from the position of the valve under review.

There are four heart sounds, named S_1 through S_4 (Figure 20–18b). If you listen to your own heart with a stethoscope, you will clearly hear the *first* and *second heart sounds*. These sounds accompany the closing of your heart valves. The first heart sound (S_1), known as "lubb," lasts a little longer than the second (S_2), called "dupp." S_1 marks the start of ventricular contraction, when the AV valves close and the semilunar valves open. S_2 occurs at the beginning of ventricular filling, when the semilunar valves close and the AV valves open. The *third* and *fourth heart sounds* are usually very faint and are seldom audible in healthy adults. These sounds are associated with blood flowing into the ventricles (S_3) and atrial contraction (S_4), rather than with valve action.

If the valve cusps are malformed or there are problems with the papillary muscles or chordae tendineae, the heart valves may not close properly. AV valve regurgitation then occurs during ventricular systole. The surges, swirls, and eddies of turbulent blood flow that accompany regurgitation create a rushing, gurgling sound known as a **heart murmur**. Minor heart murmurs are common and inconsequential.

20-4 Cardiac output is determined by heart rate and stroke volume

Learning Outcome Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

When considering cardiac function over time, physicians generally are most interested in the **cardiac output (CO)**, the amount of blood pumped by the left ventricle in 1 minute. In essence, cardiac output is an indication of the blood flow through peripheral tissues—and without adequate blood flow, homeostasis cannot be maintained. The cardiac output provides a useful indication of ventricular efficiency over time.

Figure 20–19 summarizes the factors involved in the normal regulation of cardiac output. Cardiac output can be adjusted by changes in either heart rate or stroke volume. The **heart rate (HR)**, the number of heartbeats per minute, can be adjusted by the activities of the autonomic nervous system or by circulating hormones. **Stroke volume (SV)** is the amount of blood pumped out of a ventricle during each contraction.

We can calculate cardiac output by multiplying the heart rate by the average stroke volume:

CO	=	HR	×	SV
cardiac output		heart rate		stroke volume
(mL/min)		(beats/min)		(mL/beat)

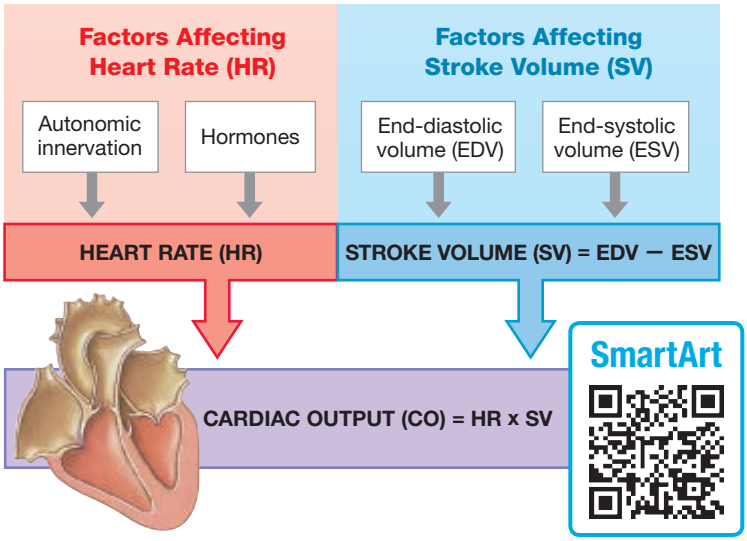
For example, if the heart rate is 75 bpm and the stroke volume is 80 mL per beat, the cardiac output is

$$75 \text{ bpm} \times 80 \text{ mL/beat} = 6000 \text{ mL/min } (6 \text{ L/min}) \text{ CO}$$

Let's look more into stroke volume, as it is the most important factor in an examination of a single cardiac cycle. Stroke volume can be expressed as SV = EDV − ESV, where EDV is **end-diastolic volume** and ESV is **end-systolic volume**. EDV is the amount of blood in each ventricle at the end of ventricular diastole, while ESV is the amount of blood remaining in each ventricle at the end of ventricular systole. The *ejection fraction* is the percentage of EDV that is ejected during a ventricular contraction.

If the heart were a simple hand pump, the stroke volume would be the amount of water pumped in one up–down cycle of the handle (Figure 20–20). Where you stop when you lift the handle determines how much water the pump contains—the EDV. How far down you push the handle determines how much water remains in the pump at the end of the cycle—the ESV. You pump the maximum amount of water when you pull the handle all the way to the top and then push it all the way to the bottom. In other words, you get the largest stroke volume when the EDV is as large as it can be and the ESV is as small as it can be.

Figure 20–19 Factors Affecting Cardiac Output.



The body precisely adjusts cardiac output to supply peripheral tissues with enough blood as conditions change. When necessary, the heart rate can increase by 250 percent, and stroke volume in a normal heart can almost double. (In addition, a variety of other factors can influence cardiac output under abnormal circumstances.) For convenience, the discussions in this section consider heart rate and stroke volume independently. However, changes in cardiac output generally reflect changes in both factors.

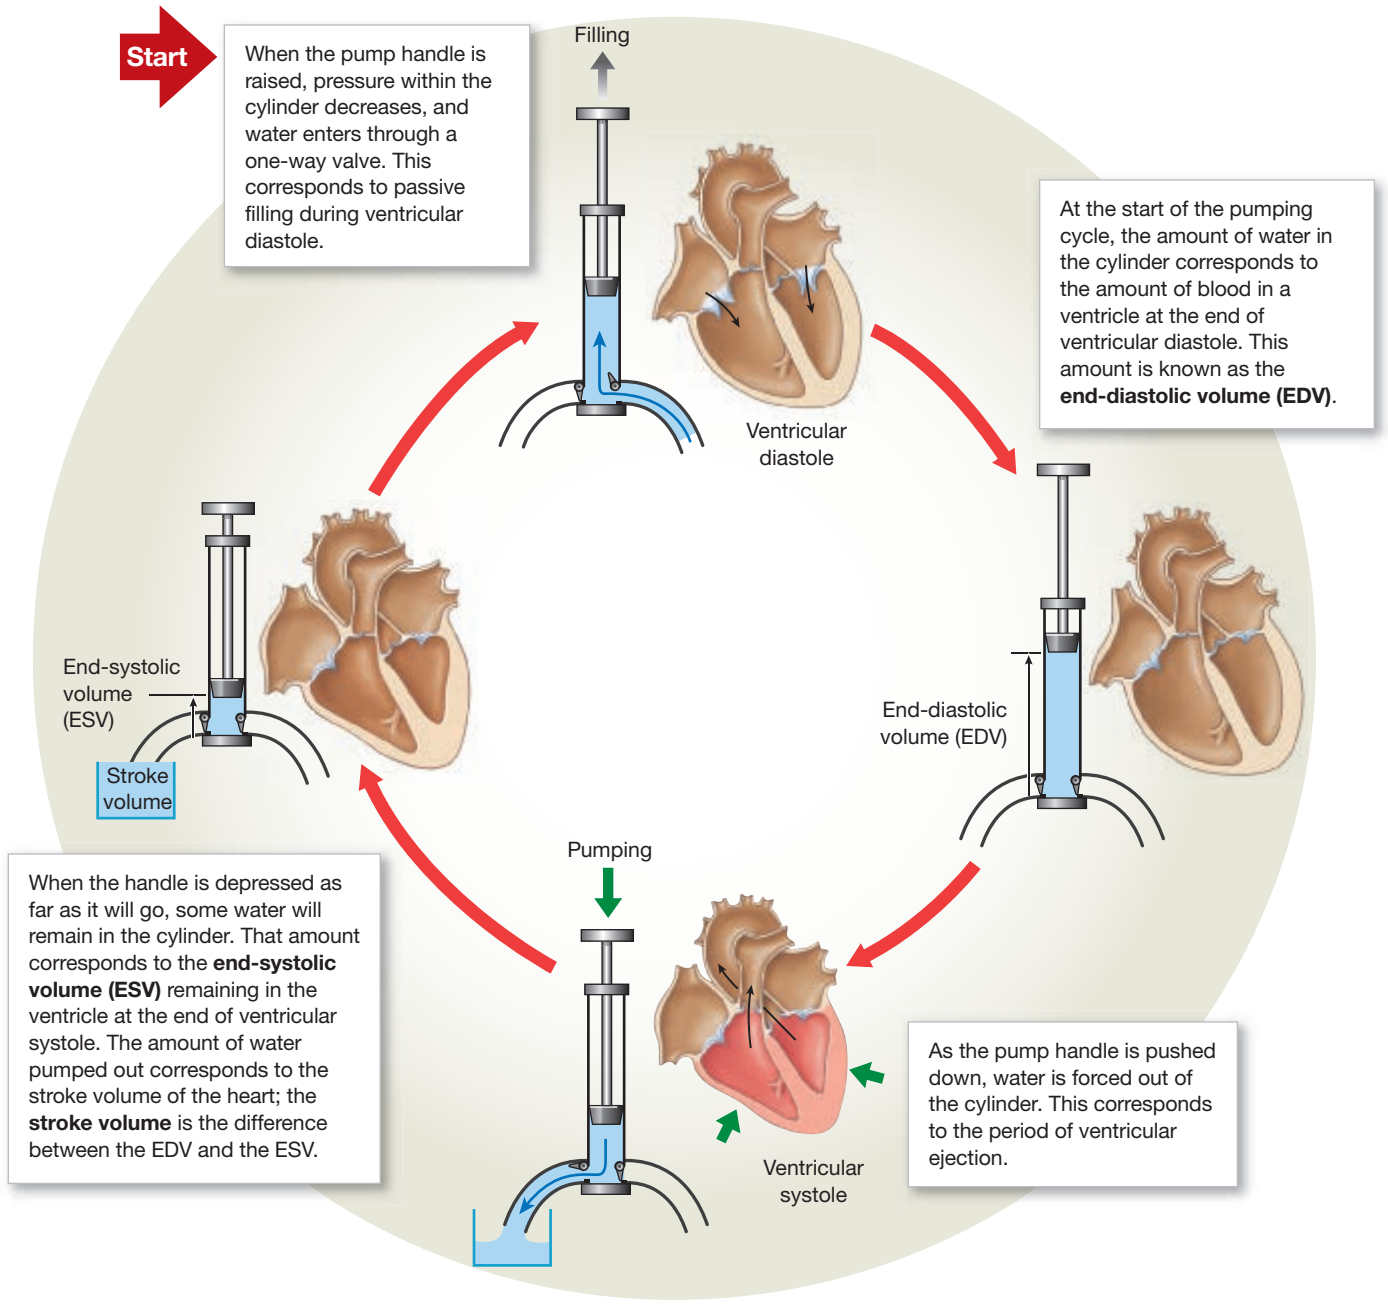
Factors Affecting the Heart Rate

Under normal circumstances, autonomic activity and circulating hormones make homeostatic adjustments to the heart rate as cardiovascular demands change, thereby adjusting cardiac output. These factors act by modifying the autorhythmicity of the heart. Even a heart removed for a heart transplant continues to beat unless it is kept chilled in a preservation solution.

Autonomic Innervation

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the heart by means of the nerve network known as the *cardiac plexus* (Figure 16–6,

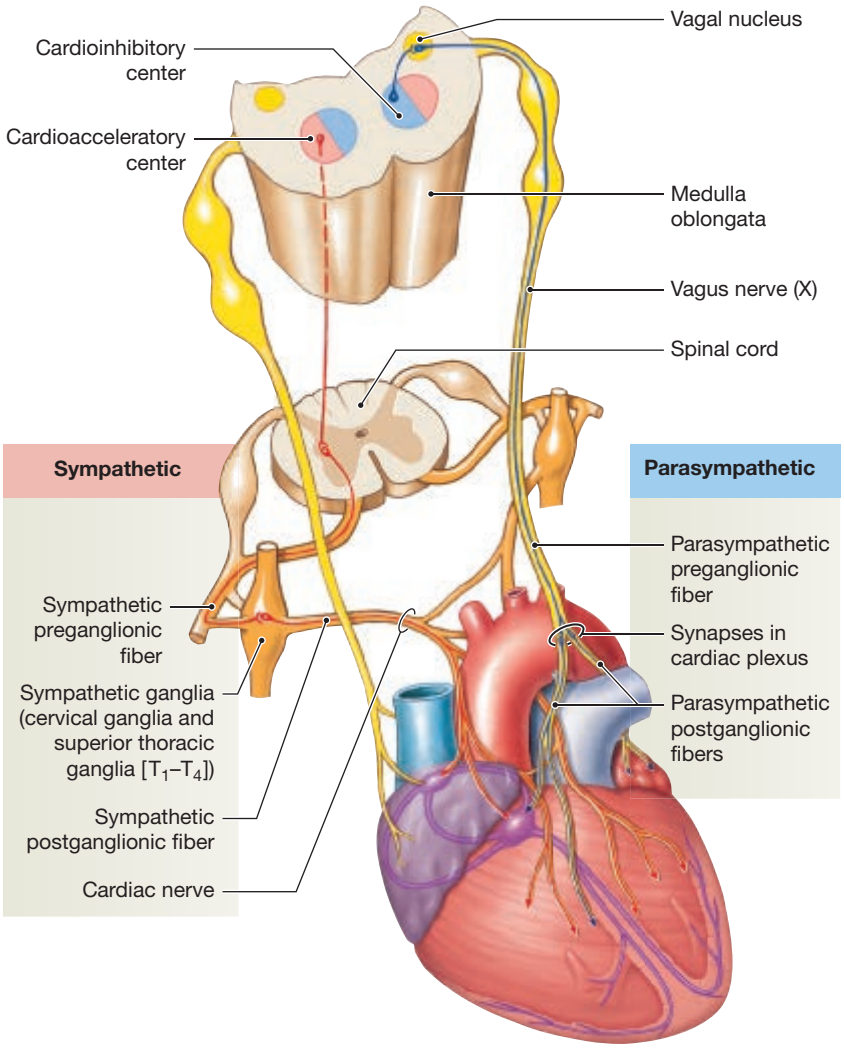
Figure 20–20 A Simple Model of Stroke Volume. The stroke volume of the heart can be compared to the amount of water ejected from a simple pump. The amount of water ejected varies with the amount of movement of the pump handle.



p. 549, and Figure 20–21). Postganglionic sympathetic neurons are located in the cervical and upper thoracic ganglia. The vagus nerves (CN X) carry parasympathetic preganglionic fibers to small ganglia in the cardiac plexus. Both ANS divisions innervate the SA and AV nodes and the atrial contractile cells. Both divisions also innervate ventricular contractile cells, but sympathetic fibers far outnumber parasympathetic fibers there.

The *cardiac centers* of the medulla oblongata contain the autonomic headquarters for cardiac control. ↩ p. 474 The **cardioacceleratory center** controls sympathetic neurons that increase the heart rate. The adjacent **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. Reflex pathways regulate the cardiac centers. They also receive input from higher centers, especially from the parasympathetic and sympathetic centers in the hypothalamus.

Figure 20–21 Autonomic Innervation of the Heart.



? Which division of the autonomic nervous system would increase heart rate?

Tips & Tools

To remember the effect of the sympathetic nervous system on cardiac performance, remember that ***s***ympathetic input ***s***peeds and ***s***trengthens the heartbeat.

Cardiac Reflexes. Information about the status of the cardiovascular system arrives over visceral sensory fibers accompanying the vagus nerve and the sympathetic nerves of the cardiac plexus. The cardiac centers monitor baroreceptors and chemoreceptors innervated by the glossopharyngeal (IX) and vagus (X) nerves. ↩ pp. 502, 503 On the basis of the information received, the cardiac centers adjust the heart's activity to maintain adequate circulation to vital organs, such as the brain.

The cardiac centers respond to changes in blood pressure as reported by baroreceptors, and to changes in arterial concentrations of dissolved oxygen and carbon dioxide as reported by chemoreceptors. For example, a decline in the blood pressure or oxygen concentration or an increase in the carbon dioxide level generally means that the heart must work harder to meet the demands of peripheral tissues. The cardiac centers then call for an increase in cardiac activity. We detail these reflexes and their effects on the heart and peripheral vessels in Chapter 21.

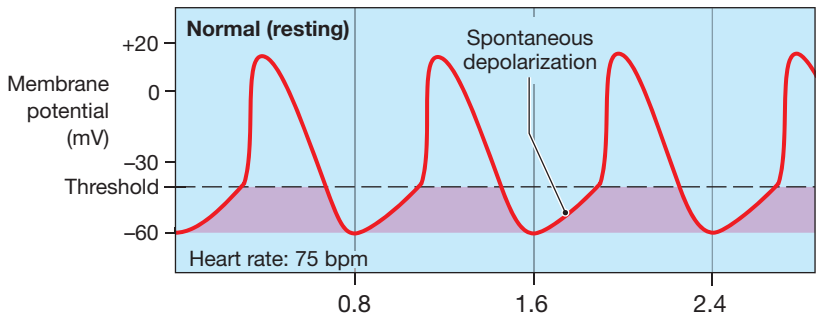
Autonomic Tone. Like other organs with dual innervation, the heart has a resting autonomic tone. Both autonomic divisions are normally active at a steady background level, releasing acetylcholine (ACh) and norepinephrine (NE) at the nodes and into the myocardium. For this reason, cutting the vagus nerves increases the heart rate, and sympathetic blocking agents slow the heart rate.

Parasympathetic effects dominate in a healthy, resting individual. Without autonomic innervation, the pacemaker cells of the SA node establish the heart rate. Such a heart beats at a rate of 80–100 bpm. At rest, a typical adult heart with normal innervation beats more slowly, at 70–80 bpm, due to activity in the parasympathetic nerves innervating the SA node. If parasympathetic activity increases, the heart rate declines further. Conversely, the heart rate increases if parasympathetic activity decreases, or if sympathetic activation occurs. Through dual innervation and adjustments in autonomic tone, the ANS can make very delicate adjustments in cardiovascular function to meet the demands of other systems.

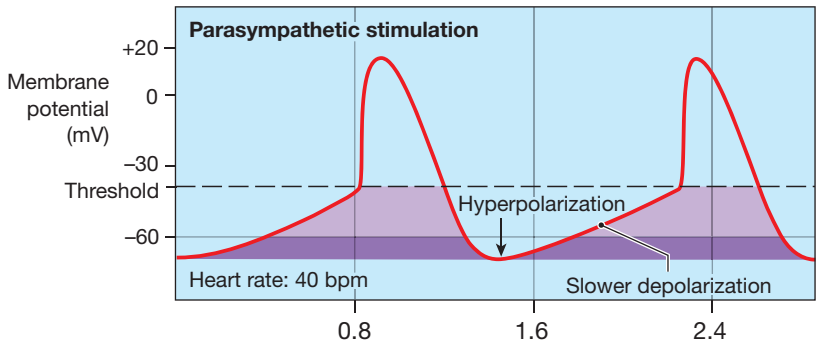
Effects on the Pacemaker Cells of the SA Node. How do the sympathetic and parasympathetic divisions alter the heart rate? They do so by changing the ionic permeabilities of cells in the conducting system. The most dramatic effects take place at the SA node, which affects the heart rate through changes in the rate at which impulses are generated.

Consider the SA node of a resting individual whose heart is beating at 75 bpm (Figure 20–22a). Any factor that changes the rate of spontaneous depolarization or the duration of repolarization in pacemaker cells will alter the heart rate by changing the time required for these cells to reach threshold. Acetylcholine released by parasympathetic neurons opens chemically gated K^+ channels in the plasma membrane. Then K^+ leaves the pacemaker cells, dramatically slowing their rate of spontaneous depolarization and also slightly extending their duration of repolarization (Figure 20–22b). As a result, heart rate declines.

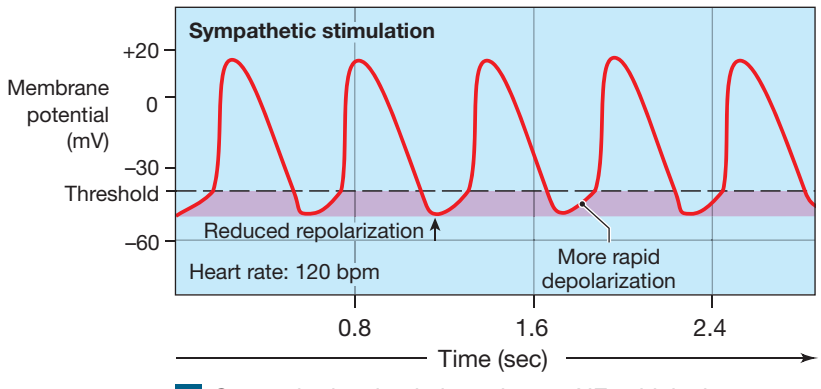
Figure 20–22 Autonomic Regulation of Pacemaker Cell Function.



a Pacemaker cells have membrane potentials closer to threshold than those of cardiac contractile cells (–60 mV versus –90 mV). Their plasma membranes spontaneously depolarize to threshold, producing action potentials at a frequency determined by (1) the membrane potential and (2) the rate of depolarization.



b Parasympathetic stimulation releases ACh, which extends repolarization and decreases the rate of spontaneous depolarization. The heart rate slows.



c Sympathetic stimulation releases NE, which shortens repolarization and accelerates the rate of spontaneous depolarization. As a result, the heart rate increases.

Norepinephrine released by sympathetic neurons binds to beta-1 receptors, leading to the opening of sodium ion and calcium ion channels. Then an influx of positively charged ions increases the rate of depolarization and shortens the period of repolarization. The pacemaker cells reach threshold more quickly, and the heart rate increases (Figure 20–22c).

Venous Return and the Bainbridge Reflex

Venous return is the amount of blood returning to the heart through veins. Venous return directly affects pacemaker cells. When venous return increases, the atria receive more blood and the walls are stretched. Stretching of the cardiac pacemaker cells of the SA node leads to more rapid depolarization and an increase in the heart rate.

Venous return also has an indirect effect on heart rate. The **Bainbridge reflex**, or *atrial reflex*, involves adjustments in heart rate in response to an increase in the venous return. When the walls of the right atrium are stretched, stretch receptors there trigger a reflexive increase in heart rate by stimulating sympathetic activity (see Figure 20–22). Thus, when the rate of venous return to the heart increases, so does the heart rate, and for this reason the cardiac output increases as well.

Hormones and Factors Affecting Heart Rate

Epinephrine (E), norepinephrine (NE), and thyroid hormone (T_3,) increase heart rate by their effects on the SA node. The effects of E on the pacemaker cells of the SA node are similar to those of NE. Epinephrine also affects the cardiac contractile cells. After massive sympathetic stimulation of the adrenal medullae, the myocardium may become so excitable that abnormal contractions occur. Factors that increase the heart rate are *positively chronotropic* (*chrono-*, time) and factors that decrease the heart rate are *negatively chronotropic*.

20

Factors Affecting the Stroke Volume

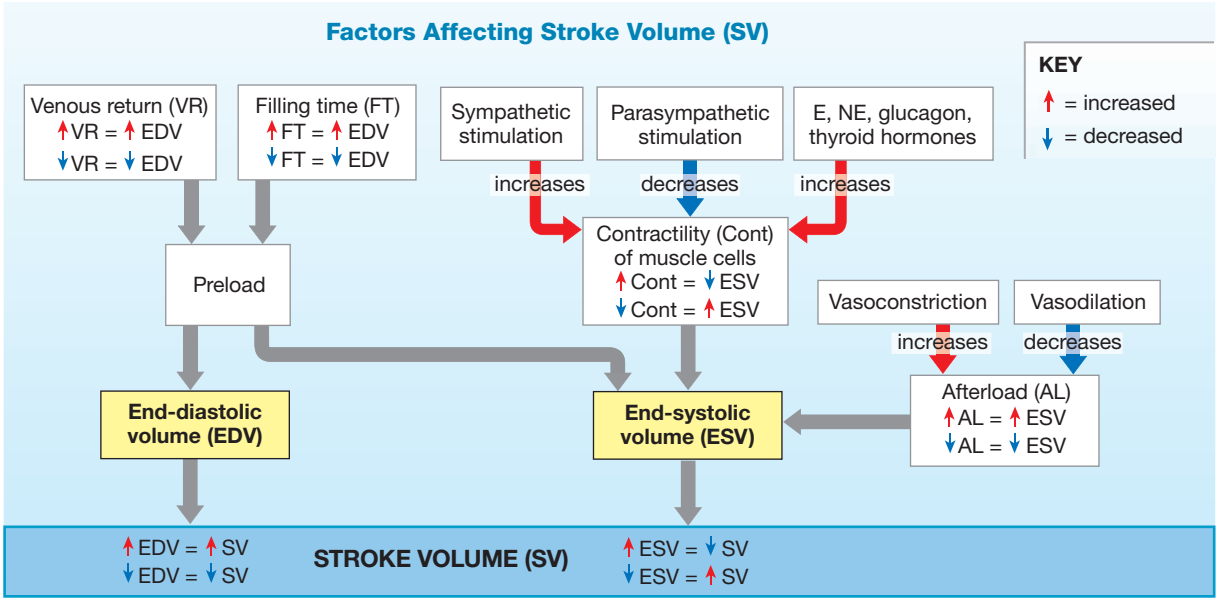
Changes in either EDV or ESV can change the stroke volume, and thus cardiac output. The factors involved in the regulation of stroke volume are indicated in Figure 20–23.

The End-Diastolic Volume (EDV)

Two factors affect the EDV, the amount of blood in a ventricle at the end of diastole: the filling time and the venous return. **Filling time** is the duration of ventricular diastole. It depends entirely on the heart rate: The faster the heart rate, the shorter the filling time. Venous return is variable over this period. It varies in response to changes in cardiac output, blood volume, peripheral circulation, skeletal muscle activity, and other factors that affect the rate of blood flow back to the heart. (We explore these factors in Chapter 21.)

Preload. The degree of stretching in ventricular muscle cells during ventricular diastole is called the **preload**. The preload is directly proportional to the EDV: The greater the EDV,

Figure 20–23 Factors Affecting Stroke Volume.



the larger the preload. Preload matters because it affects the ability of muscle cells to produce tension. As sarcomere length increases past resting length, the amount of force produced during systole increases.

The amount of preload, and hence the degree of myocardial stretching, varies with the demands on the heart. When you are standing at rest, your EDV is low. The ventricular muscle is stretched very little, and the sarcomeres are relatively short. During ventricular systole, the cardiac contractile cells develop little power, and the ESV (the amount of blood in the ventricle after contraction) is relatively high because the contractile cells contracted only a short distance. If you begin exercising, venous return increases and more blood flows into your heart. Your EDV increases, and the myocardium stretches further. As the sarcomeres approach optimal lengths, the ventricular contractile cells can contract more efficiently and produce more forceful contractions. They also shorten more, and more blood is pumped out of your heart.

The EDV and Stroke Volume: The Frank–Starling Principle. In general, the greater the EDV, the larger the stroke volume. Stretching the cardiac contractile cells *past* their optimal length would *reduce* the force of contraction, but this degree of stretching does not normally take place. Myocardial connective tissues, the cardiac skeleton, and the pericardium all limit the expansion of the ventricles.

The relationship between the amount of ventricular stretching and the contractile force means that, within normal physiological limits, increasing the EDV results in a corresponding increase in the stroke volume. This general rule of "more in = more out" is known as the **Frank–Starling principle**.

Autonomic adjustments to cardiac output normally make the effects of the Frank–Starling principle difficult to see. However, we can see the effects more clearly in heart transplant patients, because the implanted heart is not innervated by the ANS. So, the outputs of the left and right ventricles remain balanced under a variety of conditions.

Consider, for example, a person at rest, with the two ventricles ejecting equal volumes of blood. Although the ventricles contract together, they work in series: When the heart contracts, blood leaving the right ventricle heads to the lungs. During the next ventricular diastole, that volume of blood passes through the left atrium, to be ejected by the left ventricle at the next contraction. If the venous return decreases, the EDV of the right ventricle will decrease. During ventricular systole, the right ventricle will then pump less blood to the lungs. In the next cardiac cycle, the EDV of the left ventricle will be reduced, and that ventricle will eject a smaller volume of blood. The output of the two ventricles will again be in balance, but both will have smaller stroke volumes than they did initially.

The End-Systolic Volume (ESV)

After the ventricle has contracted and ejected the stroke volume, the amount of blood that remains in the ventricle at the end of ventricular systole is the ESV. Three factors that influence the ESV are preload, ventricular contractility, and afterload.

Contractility. Contractility is the amount of force produced during a contraction, at a given preload. Under normal circumstances, autonomic innervation or circulating hormones can alter contractility. Under special circumstances, drugs or abnormal ion concentrations in the extracellular fluid can alter contractility.

Factors that strengthen heart contraction are *positively inotropic* (Ī-nō-trō-pik) (*ino-*, fiber). Factors that weaken heart contraction are *negatively inotropic*. Positive inotropic agents typically stimulate Ca^{2+} entry into cardiac contractile cells, thus increasing the force and duration of ventricular contractions. Negative inotropic agents may block Ca^{2+} movement or depress cardiac muscle metabolism. Positive and negative inotropic factors include ANS activity, hormones, and changes in extracellular ion concentrations.

Effects of Autonomic Activity on Contractility. Autonomic activity alters the degree of contraction and changes the ESV in the following ways:

- Sympathetic stimulation has a positive inotropic effect. It causes the release of norepinephrine (NE) by postganglionic fibers of the cardiac nerves and the secretion of epinephrine (E) and NE by the adrenal medullae. These hormones affect heart rate. They also stimulate alpha and beta receptors in cardiac contractile cell plasma membranes. This stimulation increases the metabolism of these cells. The net effect is that the ventricles contract more forcefully, increasing the ejection fraction and decreasing the ESV.
- Parasympathetic stimulation from the vagus nerves has a negative inotropic effect. The primary effect of acetylcholine (ACh) is at the cardiac contractile cell membrane surface, where it produces hyperpolarization and inhibition. As a result, the force of cardiac contractions is reduced. The atria show the greatest changes in contractile force because the ventricles are not extensively innervated by the parasympathetic division. However, under strong parasympathetic stimulation or with drugs that mimic ACh, the ventricles contract less forcefully, the ejection fraction decreases, and the ESV becomes larger.

Hormones Affecting Contractility. Many hormones affect heart contractility. For example, epinephrine, norepinephrine, glucagon, and thyroid hormones are positively inotropic. Before synthetic inotropic drugs were available, glucagon was used to stimulate cardiac function. It is still used in cardiac emergencies and to treat some forms of heart disease.

The drugs *isoproterenol*, *dopamine*, and *dobutamine* mimic E and NE by stimulating beta-1 receptors on cardiac contractile cells. Dopamine (at high doses) and dobutamine also stimulate Ca^{2+} entry through alpha-1 receptor stimulation. *Digitalis* elevates the intracellular Ca^{2+} concentration by interfering with Ca^{2+} removal from the cytosol of cardiac contractile cells.

Many of the drugs used to treat *hypertension* (high blood pressure) are negatively inotropic. Beta-blocking drugs such as *propranolol*, *metoprolol*, *atenolol*, and *labetalol* block beta receptors, alpha receptors, or both, and prevent sympathetic stimulation of the heart. Calcium-channel blockers such as *nifedipine* or *verapamil* are negatively inotropic.

Afterload. The **afterload** is the amount of tension that the contracting ventricle must produce to force open the semilunar valve and eject blood. Afterload increases with increased resistance to blood flow out of the ventricle. The greater the afterload, the longer the period of isovolumetric contraction, the shorter the duration of ventricular ejection, and the larger the ESV. In other words, as the afterload increases, the stroke volume decreases.

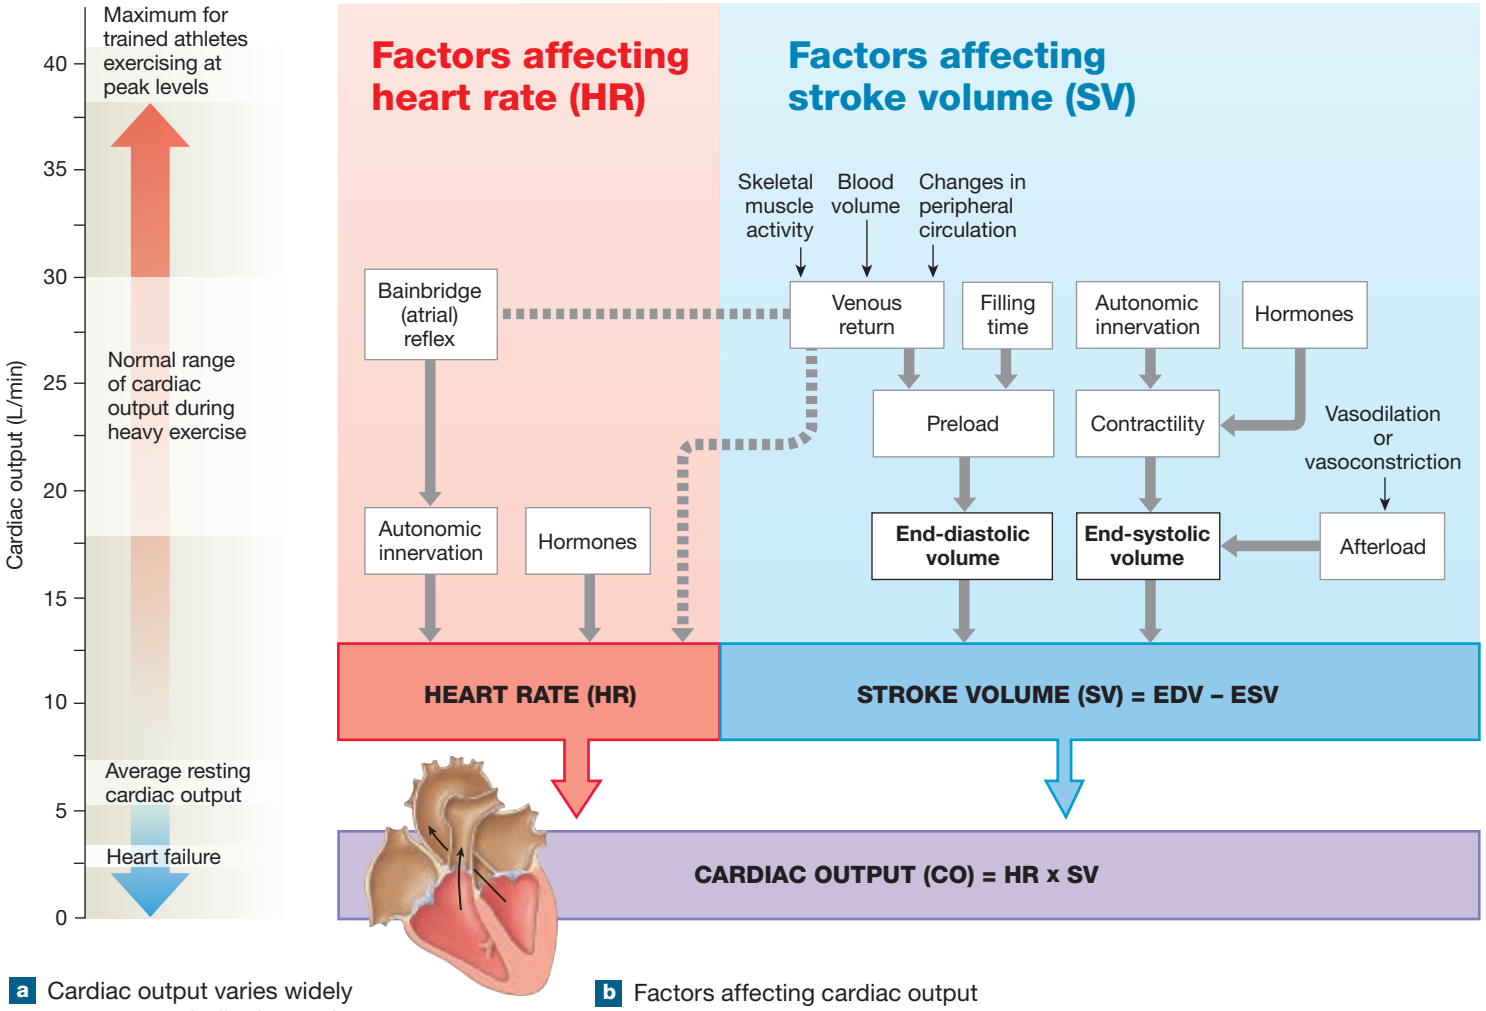
Any factor that restricts blood flow through the arterial system increases afterload. For example, either the constriction of peripheral blood vessels or a circulatory blockage elevates arterial blood pressure and increases the afterload. If the afterload is too great, the ventricles cannot eject blood. Such a high afterload is rare in a normal heart. However, damage to the heart muscle can weaken the myocardium enough that even a modest rise in arterial blood pressure can decrease the stroke volume to a dangerously low level, producing heart failure. Damage to the semilunar valve that restricts blood flow will also increase afterload.

Summary: The Control of Cardiac Output

Figure 20–24 summarizes the factors that regulate heart rate and stroke volume, which interact to determine cardiac output. The heart rate is influenced by the autonomic nervous system, circulating hormones, and venous return.

- Sympathetic stimulation increases the heart rate, and parasympathetic stimulation decreases it. Under resting conditions, parasympathetic tone dominates, and the heart rate is slightly slower than the intrinsic heart rate. When the activity level rises, venous return increases and triggers the Bainbridge reflex. The result is an increase in sympathetic tone and an increase in heart rate.
- Circulating hormones, specifically E, NE, and T_3, accelerate heart rate.
- An increase in venous return stretches the pacemaker cells and increases heart rate.
- The stroke volume (SV) is the difference between the end-diastolic volume (EDV) and the end-systolic volume (ESV).
- The EDV is determined by the available filling time and the rate of venous return.
- The ESV is determined by the amount of preload (the degree of myocardial stretching), the degree of contractility (adjusted by hormones and autonomic innervation), and the afterload (the arterial resistance to blood flow out of the heart).

Figure 20–24 A Summary of the Factors Affecting Cardiac Output.



a Cardiac output varies widely to meet metabolic demands

b Factors affecting cardiac output

? What is considered a "normal" cardiac output when resting? Please provide units.

During exercise, increasing both the stroke volume and the heart rate can increase the cardiac output by 300–500 percent, to 18–30 L/min. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. Trained athletes exercising at maximal levels may increase cardiac output by nearly 700 percent, to 40 L/min.

Cardiac output cannot increase indefinitely, primarily because the available filling time shortens as the heart rate increases. At heart rates up to 160–180 bpm, the combination of increased venous return rate and increased contractility compensates for the reduced filling time. Over this range, cardiac output and heart rate increase together. But if the heart rate continues to climb, the stroke volume begins to drop. Cardiac output first plateaus and then declines.

The Heart and the Vessels of the Cardiovascular System

The purpose of cardiovascular regulation is to maintain adequate blood flow to all body tissues. The heart cannot accomplish this by itself, and it does not work in isolation. For example, when blood pressure changes, the cardiac centers adjust not only the heart rate but also the diameters of peripheral blood vessels. These adjustments work together to keep the blood pressure within normal limits and to maintain circulation to vital tissues and organs. In Chapter 21 we complete this story by detailing the cardiovascular responses to changing activities and circulatory emergencies. We then conclude our discussion of the cardiovascular system by examining the anatomy of the pulmonary and systemic circuits.

20 Chapter Review

Study Outline

An Introduction to the Heart as Part of the Cardiovascular System p. 689

1. The blood vessels can be subdivided into the **pulmonary circuit** (which carries blood to and from the lungs) and the **systemic circuit** (which transports blood to and from the rest of the body).
2. **Arteries** carry blood away from the heart; **veins** return blood to the heart. **Capillaries**, or *exchange vessels*, are thin-walled, narrow-diameter vessels that connect the smallest arteries and veins. *(Figure 20–1)*
3. The heart has four chambers: the **right atrium** and **right ventricle**, and the **left atrium** and **left ventricle**.

20-1 The heart is a four-chambered organ that pumps blood through the pulmonary and systemic circuits p. 689

4. The heart is surrounded by the **pericardium** and lies within the anterior portion of the **mediastinum**, which separates the two pleural cavities. *(Figure 20–2)*
5. The pericardial cavity is lined by the **pericardium**. The **visceral layer of serous pericardium (epicardium)** covers the heart's outer surface, and the **parietal layer of serous pericardium** lines the inner surface. *(Figure 20–2)*
6. The **coronary sulcus**, a deep groove, marks the boundary between the atria and the ventricles. Other surface markings also provide useful reference points in describing the heart and associated structures. *(Figure 20–3)*
7. The bulk of the heart consists of the muscular **myocardium**. The **endocardium** lines the inner surfaces of the heart, and the **visceral layer of serous pericardium** covers the outer surface. The endothelium of the endocardium is continuous with the endothelium of the attached great vessels. *(Figure 20–4)*
8. The atria are separated by the **interatrial septum**, and the ventricles are divided by the **interventricular septum**. The right atrium receives blood from the systemic circuit via two large veins, the **superior vena cava** and the **inferior vena cava**. (The atrial walls contain the **pectinate muscles**, prominent muscular ridges.) *(Figure 20–5)*
9. Blood flows from the right atrium into the right ventricle by the **tricuspid valve (right atrioventricular valve)**. This opening is bounded by three **cusps** of fibrous tissue braced by the **chordae tendineae**, which are connected to **papillary muscles**. *(Figure 20–5)*
10. Blood leaving the right ventricle enters the **pulmonary trunk** after passing through the **pulmonary valve**. The pulmonary trunk divides to form the **left** and **right pulmonary arteries**. The **left** and **right pulmonary veins** return blood from the lungs to the left atrium. Blood leaving the left atrium flows into the left ventricle through the **mitral valve (left atrioventricular valve** or *bicuspid valve*). Blood leaving the left ventricle passes through the **aortic valve** and into the systemic circuit by the **ascending aorta**. *(Figure 20–5)*
11. Anatomical differences between the ventricles reflect the functional demands placed on them. The wall of the right ventricle is relatively thin, whereas the left ventricle has a massive muscular wall. *(Figure 20–6)*
12. The connective tissues of the heart (mainly collagen and elastic fibers) and the **cardiac skeleton** support the heart's valves and ventricular muscle cells. *(Figure 20–7)*
13. Valves normally permit blood flow in only one direction, preventing the **regurgitation** (backflow) of blood. *(Figure 20–7)*
14. The **coronary circulation** meets the high oxygen and nutrient demands of cardiac muscle cells. The **coronary arteries** originate at the base of the ascending aorta. Interconnections between arteries, called **arterial anastomoses**, ensure a constant blood supply. The **great**, **posterior**, **small**, **anterior**, and **middle cardiac veins** are epicardial vessels that carry blood from the coronary capillaries to the **coronary sinus**. *(Figure 20–8)*
15. In **coronary artery disease (CAD)**, portions of the coronary circulation undergo partial or complete blockage. A **myocardial infarction (MI)**, or heart attack, occurs when part of the coronary circulation becomes blocked and muscle tissue dies when it cannot be oxygenated. *(Spotlight Figure 20–9)*

20-2 The cells of the conducting system distribute electrical impulses through the heart, causing cardiac contractile cells to contract p. 702

16. Two general classes of cardiac muscle cells are involved in the normal **heartbeat**: **autorhythmic cells** and **contractile cells**.
17. The **conducting system** is composed of the *sinoatrial node*, the *atrioventricular node*, and *conducting cells*. The conducting system initiates and distributes electrical impulses within the heart. Nodal cells establish the rate of cardiac contraction, and conducting cells distribute the contractile stimulus from the SA node to the atrial myocardium and the AV node (along *internodal pathways*), and from the AV node to the ventricular myocardium. *(Figure 20–10)*
18. Unlike skeletal muscle, cardiac muscle contracts without neural or hormonal stimulation. **Pacemaker cells** in the **sinoatrial (SA) node** (*cardiac pacemaker*) normally establish the rate of contraction. From the SA node, the stimulus travels to the **atrioventricular (AV) node**, and then to the **AV bundle**, which divides into **bundle branches**. From there, **Purkinje fibers** convey the impulses to the ventricular myocardium. *(Figures 20–10, 20–11)*
19. A recording of electrical activities in the heart is an **electrocardiogram (ECG** or **EKG)**. Important landmarks of an ECG include the **P wave** (atrial depolarization), the **QRS complex** (ventricular depolarization), and the **T wave** (ventricular repolarization). *(Figure 20–12)*
20. **Cardiac arrhythmias** are abnormal patterns of electrical activity in the heart. *(Spotlight Figure 20–13)*
21. **Cardiac contractile cells** are interconnected by **intercalated discs**, which convey the force of contraction from cell to cell and conduct action potentials. *(Figure 20–14;* Table 20–1*)*
22. **Contractile cells** form the bulk of the atrial and ventricular walls. Cardiac contractile cells have a long refractory period, so rapid stimulation produces twitches rather than tetanic contractions. *(Figure 20–15)*

20-3 The contraction–relaxation events that occur during a complete heartbeat make up a cardiac cycle p. 711

23. The **cardiac cycle** includes periods of **atrial** and **ventricular systole** (contraction) and **atrial** and **ventricular diastole** (relaxation). *(Figure 20–16)*
24. When the heart beats, the two ventricles eject equal volumes of blood. *(Figure 20–17)*
25. The closing of valves and rushing of blood through the heart cause characteristic heart sounds, which can be heard during *auscultation*. *(Figure 20–18)*

20-4 Cardiac output is determined by heart rate and stroke volume p. 716

26. Cardiac output can be adjusted by changes in either heart rate or stroke volume. *(Figure 20–19)*
27. The amount of blood ejected by a ventricle during a single beat is the **stroke volume (SV)**. The amount of blood pumped by a ventricle each minute is the **cardiac output (CO)**. *(Figure 20–20)*
28. The **cardioacceleratory center** in the medulla oblongata activates sympathetic neurons; the **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. These cardiac centers receive inputs from higher centers and from receptors monitoring blood pressure and the concentrations of dissolved gases. *(Figure 20–21)*
29. The basic heart rate is established by the pacemaker cells of the SA node, but it can be modified by the autonomic nervous system. The **Bainbridge reflex** *(atrial reflex)* accelerates the heart rate when the walls of the right atrium are stretched. *(Figure 20–22)*
30. Sympathetic activity increases the force of contraction (contractility), which reduces the ESV. Parasympathetic stimulation slows the heart rate, reduces contractility, and raises the ESV.
31. Cardiac output is affected by various factors, including autonomic innervation and hormones. *(Figure 20–22)*
32. The stroke volume is the difference between the **end-diastolic volume (EDV)** and the **end-systolic volume (ESV)**. The **filling time** and **venous return** interact to determine the EDV. Normally, the greater the EDV, the more powerful the succeeding contraction (the **Frank–Starling principle**). *(Figure 20–23)*
33. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. *(Figure 20–24)*
34. The heart does not work in isolation in maintaining adequate blood flow to all tissues.

Review Questions

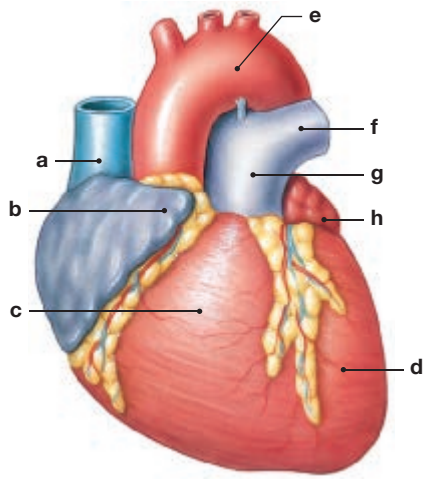
See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The great cardiac vein drains blood from the heart muscle to the **(a)** left ventricle, **(b)** right ventricle, **(c)** right atrium, **(d)** left atrium.
2. The autonomic centers for cardiac function are located in **(a)** the myocardial tissue of the heart, **(b)** the cardiac centers of the medulla oblongata, **(c)** the cerebral cortex, **(d)** all of these structures.
3. The serous membrane covering the outer surface of the heart is the **(a)** parietal layer of the serous pericardium, **(b)** endocardium, **(c)** myocardium, **(d)** visceral layer of the serous pericardium.
4. The simple squamous epithelium covering the heart valves is the **(a)** epicardium, **(b)** endocardium, **(c)** myocardium, **(d)** endothelium.
5. The heart is surrounded by the **(a)** pleural cavity, **(b)** peritoneal cavity, **(c)** abdominopelvic cavity, **(d)** mediastinum, **(e)** abdominal cavity.
6. The cardiac skeleton of the heart has which *two* of the following functions? **(a)** It physically isolates the muscle fibers of the atria from those of the ventricles. **(b)** It maintains the normal shape of the heart. **(c)** It helps distribute the forces of cardiac contraction. **(d)** It allows more rapid contraction of the ventricles. **(e)** It strengthens and helps prevent overexpansion of the heart.
7. Cardiac output is equal to the **(a)** difference between the end-diastolic volume and the end-systolic volume, **(b)** product of heart rate and

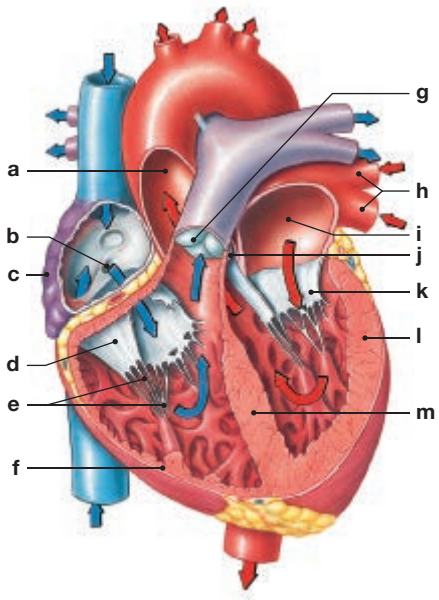
stroke volume, **(c)** difference between the stroke volume at rest and the stroke volume during exercise, **(d)** stroke volume less the end-systolic volume, **(e)** product of heart rate and blood pressure.

8. Identify the superficial structures in the following diagram of the heart.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____

9. Identify the structures in the following diagram of a sectional view of the heart.



(a) _____ **(b)** _____ **(c)** _____
(d) _____ **(e)** _____ **(f)** _____
(g) _____ **(h)** _____ **(i)** _____
(j) _____ **(k)** _____ **(l)** _____
(m) _____

10. During diastole, a chamber of the heart **(a)** relaxes and fills with blood, **(b)** contracts and pushes blood into an adjacent chamber, **(c)** experiences a sharp increase in pressure, **(d)** reaches a pressure of approximately 120 mm Hg.
11. During the cardiac cycle, the amount of blood ejected from the left ventricle when the semilunar valve opens is the **(a)** stroke volume (SV), **(b)** end-diastolic volume (EDV), **(c)** end-systolic volume (ESV), **(d)** cardiac output (CO).
12. What role do the chordae tendineae and papillary muscles play in the normal function of the AV valves?
13. Describe the three distinct layers that make up the heart wall.
14. What are the valves in the heart, and what is the function of each?
15. Trace the normal pathway of an electrical impulse through the conducting system of the heart.
16. What is the cardiac cycle? What phases and events are necessary to complete a cardiac cycle?
17. What three factors regulate stroke volume to ensure that the left and right ventricles pump equal volumes of blood?

LEVEL 2 Reviewing Concepts

18. The cells of the conducting system differ from the contractile cells of the heart in that **(a)** conducting cells are larger and contain more myofibrils, **(b)** contractile cells exhibit pacemaker potentials, **(c)** contractile cells do not normally exhibit autorhythmicity, **(d)** both a and b are correct.
19. Which of the following is *longer*? **(a)** the refractory period of a cardiac contractile cell, **(b)** the refractory period of skeletal muscle fiber.
20. If the papillary muscles fail to contract, **(a)** the ventricles will not pump blood, **(b)** the atria will not pump blood, **(c)** the semilunar valves will not open, **(d)** the AV valves will not close properly, **(e)** none of these happen.
21. Cardiac output cannot increase indefinitely because **(a)** the available filling time becomes shorter as the heart rate increases, **(b)** the cardiovascular centers adjust the heart rate, **(c)** the rate of spontaneous depolarization decreases, **(d)** the ion concentrations of pacemaker plasma membranes decrease.
22. Describe the function of the SA node in the cardiac cycle. How does this function differ from that of the AV node?
23. What are the sources and significance of the four heart sounds?
24. Differentiate between stroke volume and cardiac output. How is cardiac output calculated?
25. What factors influence cardiac output?
26. What effect does sympathetic stimulation have on the heart? What effect does parasympathetic stimulation have on the heart?
27. Describe the effects of epinephrine, norepinephrine, glucagon, and thyroid hormones on the contractility of the heart.

LEVEL 3 Critical Thinking and Clinical Applications

28. Vern is suffering from cardiac arrhythmias and is brought into the emergency room of a hospital. In the emergency room he begins to exhibit tachycardia and as a result loses consciousness. Explain why Vern lost consciousness.
29. Harvey has a heart murmur in his left ventricle that produces a loud "gurgling" sound at the beginning of systole. Which valve is probably faulty?
30. The following measurements were made on two individuals (the values recorded remained stable for 1 hour):
Person 1: heart rate, 75 bpm; stroke volume, 60 mL
Person 2: heart rate, 90 bpm; stroke volume, 95 mL
Which person has the greater venous return? Which person has the longer ventricular filling time?
31. Karen is taking the medication verapamil, a drug that blocks the calcium channels in cardiac muscle cells. What effect should this medication have on Karen's stroke volume?

CLINICAL CASE Wrap-Up A Needle to the Chest

With the force of the head-on collision, the patient's chest first broke the seat belt and then collided with the steering wheel. This caused fractures of the anterior chest wall, including the sternum and ribs.

The heart, located just deep to the sternum, then hit the steering wheel hard enough to cause bleeding into the pericardial cavity. As the delicate parietal and visceral pericardial linings bled into the pericardial cavity, the tough, fibrous connective tissue of the parietal layer itself did not expand.

The blood in the pericardial cavity compressed the heart, squeezing the atria and ventricles. During atrial diastole, the atria could not fill. This caused a backup of the venous system that was obvious in the veins of the patient's neck. The compressed ventricles could not fill with blood during ventricular diastole. Because the end-diastolic volume (EDV) was so low, the stroke volume (SV) was also very low. This was evident in the blood pressure of 80/58, with a narrow difference between the systolic blood pressure and the diastolic blood pressure. The ultrasound confirmed fluid in the pericardial cavity that was compressing the heart.

Dr. Jim knew this victim was suffering from cardiac tamponade due to blood in the pericardial space. He also knew the problem was severe enough that with the decreasing stroke volume, the heart could not pump adequate blood to the patient's brain. So he removed the blood from the pericardial space with a needle, a procedure known as *pericardiocentesis*, and saved this patient's life.

1. Why do you think the heart sounds were muffled and distant?
2. What other cardiac structures were likely to be injured by this collision?

See the blue Answers tab at the back of the book.

Related Clinical Terms

artificial pacemaker: A small, battery-operated device that keeps one's heart beating in a regular rhythm. It may be permanently implanted or temporarily placed externally.

asystole: The absence of cardiac activity with no contraction and no output.

automated external defibrillator (AED): A device that, when applied, automatically checks the function of the heart. Upon detecting a condition that may respond to an electric shock, it delivers a shock to restore normal heartbeat rhythm.

automatic implantable cardioverter defibrillator (AICD): A surgically implanted battery-operated device that monitors the function of the heart. Upon detecting a condition that may respond to an electric shock, such as a disorganized heartbeat, the device delivers a shock to restore normal heartbeat rhythm.

cardiac arrest: Sudden stopping of the pumping action of the heart causing the loss of arterial blood pressure.

cardiology: The branch of medicine dealing with the diagnosis and treatment of heart disorders and related conditions.

cardiomegaly: An enlarged heart, which is a sign of some other condition such as stress, weakening of the heart muscle, coronary artery disease, heart valve problems, or abnormal heart rhythms.

cardiomyoplasty: A surgical procedure that uses stimulated latissimus dorsi muscle to assist with cardiac function. The latissimus dorsi muscle is relocated and wrapped around the left and right ventricles and stimulated to contract during cardiac systole by means of an implanted burst-stimulator.

commotio cordis: Sudden cardiac arrest as the result of a blunt hit or impact to the chest.

congestive heart failure: The heart condition of weakness, edema, and shortness of breath caused by the inability of the heart to maintain adequate blood circulation in the peripheral tissues and the lungs.

cor pulmonale: Weakness of the right ventricle of the heart due to prolonged high blood pressure in the pulmonary artery and right ventricle; or any disease or malfunction that affects the pulmonary circuit in the lungs.

echocardiography: A noninvasive diagnostic test that uses ultrasound to make images of the heart chambers, valves, and surrounding structures. This diagnostic tool can also measure cardiac output, detect inflammation around the heart, identify abnormal anatomy, and detect infections of the heart valves.

endocarditis: Inflammation or infection of the endocardium, the inner lining of the heart muscle.

fibrillation: Fast twitching of the heart muscle fibers with little or no movement of the muscle as a whole. Atrial fibrillation occurs in the atria of the heart and is characterized by chaotic quivers and irregular ventricular beating with both atria and ventricles being out of sync.

heart block: Delay in the normal electrical pulses that cause the heart to beat.

mitral valve prolapse: A condition in which the mitral (bicuspid) valve cusps do not close properly and are pushed back toward the left atrium.

myocarditis: Inflammation of the myocardium, the middle layer of the heart wall tissue.

palpitation: Irregular and rapid beating of the heart.

percutaneous transluminal coronary angioplasty (PTCA): The surgical use of a balloon-tipped catheter to enlarge a narrowed artery.

sick sinus syndrome: A group of heart rhythm disorders or problems in which the sinoatrial node does not work properly to regulate the heart rhythms.

21 Blood Vessels and Circulation

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

21-1 ■ Distinguish among the types of blood vessels based on their structure and function. p. 728

21-2 ■ Describe the factors that influence blood pressure, and explain how and where fluid and dissolved materials enter and leave the cardiovascular system. p. 737

21-3 ■ Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues. p. 745

21-4 ■ Identify the principal blood vessels and functions of the special circulation to the brain, heart, and lungs, and explain the cardiovascular system's homeostatic response to exercise and hemorrhaging. p. 752

21-5 ■ Describe the pulmonary and systemic circuits of the cardiovascular system. p. 756

21-6 ■ Identify the major arteries and veins of the pulmonary circuit. p. 757

21-7 ■ Identify the major arteries and veins of the systemic circuit. p. 758

21-8 ■ Identify the differences between fetal and adult circulation patterns, and describe the changes in the patterns of blood flow that occur at birth. p. 775

21-9 ■ Discuss the effects of aging on the cardiovascular system, and give examples of interactions between the cardiovascular system and other organ systems. p. 778

CLINICAL CASE Did Ancient Mummies Have Atherosclerosis?

Dr. Iacullo is part of a research team studying ancient mummies from Egypt, Peru, New Mexico, and the Aleutian Islands in Alaska. The study spans 4000 years of human history and cultures from three different continents. Some of the mummies were once members of Egypt's upper class, while others were likely common people from the Americas. Their diets varied greatly and included nuts, berries, farmed corn, domesticated animals, wild game, sea otters, and whales. Their activity patterns varied—the wealthy Egyptians, for instance, were much more sedentary than the hunter-gatherers of the Americas.

Dr. Iacullo is studying the incidence of atherosclerosis (the buildup of arterial plaque) in mummies. Her team uses computerized tomography (CT) scans to look for calcifications in the walls of the mummies' arteries. They discover that one-third of the mummies have CT evidence of plaque buildup. This finding spans all four geographic populations, all diets, and all lifestyle activity levels. **Why do you think these ancient people developed atherosclerosis, which today we usually associate with the unhealthy diet and inactivity of a modern lifestyle? To find out, turn to the Clinical Case Wrap-Up on p. 783.**

An Introduction to Blood Vessels and Circulation

Blood circulates throughout the body, moving from the heart through the tissues and back to the heart, in tubular structures called *blood vessels*. In this chapter we examine the organization of blood vessels and consider the integrated functions of the cardiovascular system as a whole. We begin with the histology of *arteries*, *capillaries*, and *veins*. Then we explore the functions of these vessels, the basic principles of cardiovascular regulation, and the distribution of major blood vessels in the body.

21

21-1 Arteries, which are elastic or muscular, and veins, which contain valves, have three-layered walls; capillaries have thin walls with only one layer

Learning Outcome Distinguish among the types of blood vessels based on their structure and function.

The cardiovascular system has five general classes of blood vessels: arteries, arterioles, capillaries, venules, and veins. **Arteries** carry blood away from the heart. As they enter peripheral tissues, they branch repeatedly, and the branches decrease in diameter. The smallest arterial branches are called **arterioles** (ar-TĒR-ē-ōlz). From the arterioles, blood moves into **capillaries**, where diffusion between blood and interstitial fluid takes place. From the capillaries, blood enters small **venules** (VEN-yūlz), which unite to form larger **veins** that return blood to the heart.

Blood leaves the heart through the pulmonary trunk (which originates at the right ventricle) and the aorta (which originates at the left ventricle). The pulmonary arteries that branch from the pulmonary trunk carry blood to the lungs. The systemic arteries that branch from the aorta distribute blood to all other organs. Within these organs, the vessels branch into several hundred million tiny arterioles that supply blood to more than 10 billion capillaries. These capillaries are barely the diameter of a single red blood cell. If all the capillaries in your body were placed end to end, their combined length would be more than 25,000 miles—that's enough to circle the planet!

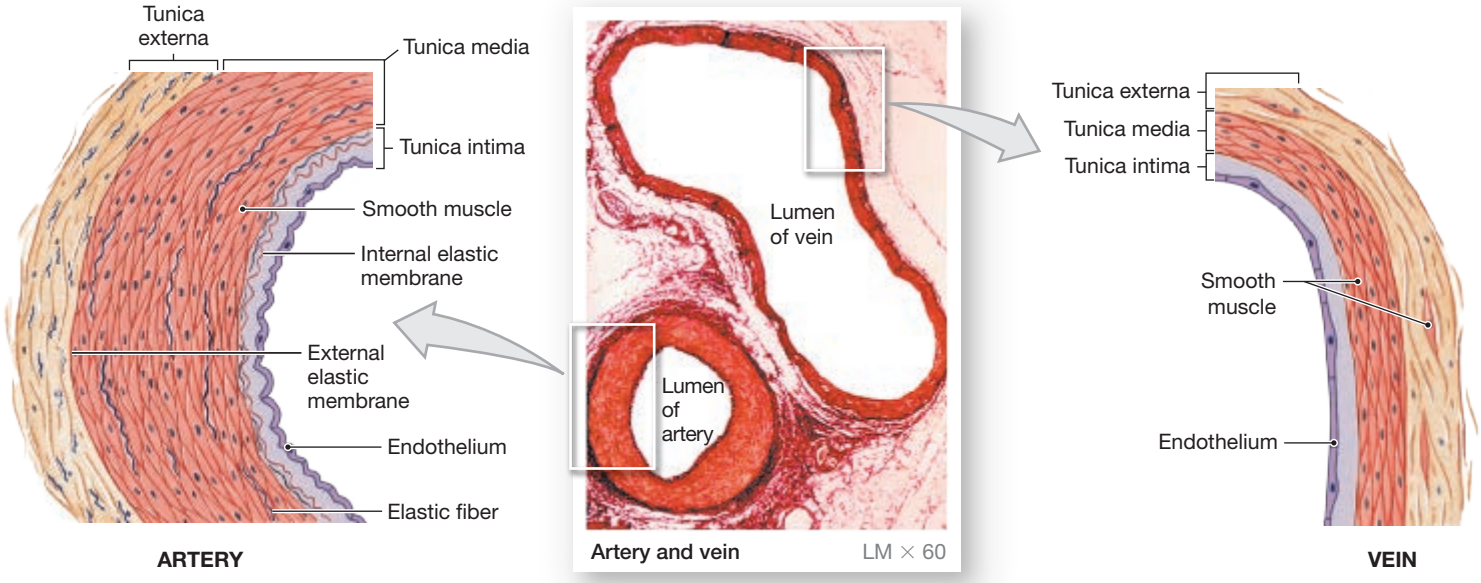
Blood vessels must be resilient enough to withstand changes in pressure, and flexible enough to move with underlying tissues and organs. The pressures inside vessels vary with distance from the heart, and the structures of different vessels reflect this fact. The functional differences between arteries, veins, and capillaries are associated with distinctive anatomical features.

Vessel Wall Structure in Arteries and Veins

The walls of arteries and veins have three distinct layers, from deep to superficial—the *tunica intima*, *tunica media*, and *tunica externa* (Figure 21–1):

1. The **tunica intima** (IN-ti-muh) is the inner layer of a blood vessel. It includes the endothelial lining and a surrounding layer of connective tissue with a variable number of elastic fibers. In arteries, the outer margin of the tunica intima contains a thick layer of elastic fibers called the **internal elastic membrane**.
2. The **tunica media** is the middle layer of a blood vessel. It contains concentric sheets of smooth muscle tissue in a framework of loose connective tissue. The collagen fibers bind the tunica media to the tunica intima and tunica externa. The tunica media is commonly the thickest layer in a small artery. It is separated from the surrounding tunica externa by a thin band of elastic fibers called the **external elastic membrane**. The smooth muscle cells of the tunica media encircle the endothelium that lines the **lumen** (interior space) of the blood vessel. Large arteries also contain layers of longitudinally arranged smooth muscle cells.

Figure 21–1 Comparison of a Typical Artery and a Typical Vein.



Feature	Typical Artery	Typical Vein
GENERAL APPEARANCE IN SECTIONAL VIEW	Usually round, with relatively thick wall	Usually flattened or collapsed, with relatively thin wall
TUNICA INTIMA		
Endothelium	Usually rippled, due to vessel constriction	Often smooth
Internal elastic membrane	Present	Absent
TUNICA MEDIA	Thick, dominated by smooth muscle cells and elastic fibers	Thin, dominated by smooth muscle cells and collagen fibers
External elastic membrane	Present	Absent
TUNICA EXTERNA	Collagen and elastic fibers	Collagen and elastic fibers and smooth muscle cells

3. The **tunica externa** (eks-TER-nuh), or *tunica adventitia* (ad-ven-TISH-uh), is the outer layer of a blood vessel. It is a connective tissue sheath. In arteries, it contains collagen fibers with scattered bands of elastic fibers. In veins, it is generally thicker than the tunica media and contains networks of elastic fibers and bundles of smooth muscle cells. The connective tissue fibers of the tunica externa typically blend into those of adjacent tissues, stabilizing and anchoring the blood vessel.

Their layered walls give arteries and veins considerable strength. The muscular and elastic components also permit controlled changes in diameter as blood pressure or blood volume changes. When the smooth muscle of the tunica media contracts, the vessel decreases in diameter, and when it relaxes, the diameter increases. However, the walls of arteries and veins are too thick to allow diffusion between the bloodstream and surrounding tissues, or even between the blood and the tissues of the vessel itself. For this reason, the walls of large vessels contain small arteries and veins that supply the smooth muscle cells and fibroblasts of the tunica media and tunica externa. These blood vessels are called the **vasa vasorum** ("vessels of vessels").

Differences between Arteries and Veins

Arteries and veins supplying the same region lie side by side (see the light micrograph in Figure 21–1). In sectional view, you can distinguish arteries and veins by the following features:

- *Vessel Walls.* In general, the walls of arteries are thicker than the walls of veins. The tunica media of an artery contains more smooth muscle and elastic fibers than a vein does. These components help resist the arterial pressure generated by the heart as it pumps blood into the pulmonary trunk and aorta.
- *Vessel Lumen.* When not opposed by blood pressure, the elastic fibers in the arterial walls recoil, which constricts the lumen. Thus, seen on dissection or in sectional view, the lumen of an artery often looks smaller than that of the

corresponding vein. Because the walls of arteries are relatively thick and strong, they keep their circular shape when sectioned. In contrast, cut veins tend to collapse. In section, these veins often look flattened.

- *Vessel Lining.* The endothelial lining of an artery cannot contract, so when an artery constricts, its endothelium folds. Therefore, the sectioned arteries have a pleated appearance. The lining of a vein lacks these folds.
- *Valves.* Veins typically contain *valves*—internal structures that prevent the backflow of blood toward the capillaries. In a vein, the valve is apparent by a slight distension of the vessel wall.

Arteries

There are three main types of arteries: elastic, muscular, and arterioles. Their relatively thick, muscular walls make arteries elastic and contractile. Elasticity allows the vessel diameter to change passively in response to changes in blood pressure. For example, it allows arteries to absorb the surging pressure waves that accompany the contractions of the ventricles. Arteries carry blood under great pressure, and their walls are adapted to handle that pressure.

When arterial walls actively change diameter, this change takes place by actions of the sympathetic nervous system. When stimulated, arterial smooth muscles contract, constricting the artery—a process called **vasoconstriction**. When these smooth muscles relax, the diameter of the lumen increases—a process called **vasodilation**. Vasoconstriction and vasodilation affect (1) the afterload on the heart, (2) peripheral blood pressure, and (3) capillary blood flow. We explore these effects in Section 21-3. Vessel contractility is also important during the vascular phase of hemostasis, when the contraction of a damaged vessel wall helps reduce bleeding. ↩ p. 679

In traveling from the heart to peripheral capillaries, blood passes through *elastic arteries*, *muscular arteries*, and *arterioles* (Figure 21–2). Keep in mind that vessel characteristics change gradually with distance from the heart. Each type of vessel described here actually represents the midpoint in a portion of a continuum. For example, the largest muscular arteries contain a considerable amount of elastic tissue, and the smallest resemble heavily muscled arterioles.

Elastic Arteries

Elastic arteries carry large volumes of blood away from the heart. They are large vessels with an internal, or *luminal*, diameter up to 2.5 cm (1 in.) (see Figure 21–2). The pulmonary trunk and aorta, as well as their major branches (the *pulmonary*, *common carotid*, *subclavian*, and *common iliac arteries*), are elastic arteries.

The walls of elastic arteries are extremely resilient because the tunica media contains a high density of elastic fibers and relatively few smooth muscle cells. As a result, elastic arteries can tolerate the pressure changes of the cardiac cycle. We have already seen that *elastic rebound* in the aorta helps to maintain blood flow in the coronary arteries. ↩ p. 697 Elastic rebound also occurs to some degree in all elastic arteries. During ventricular systole, pressures rise rapidly and the elastic arteries expand as the stroke volume is ejected. During ventricular diastole, blood pressure within the arterial system falls and the elastic fibers recoil to their original dimensions. Their expansion cushions the sudden rise in pressure during ventricular systole, and their recoil slows the drop in pressure during ventricular diastole. In this way, elastic arteries help to make blood flow continuous.

This function is important because blood pressure is the driving force behind blood flow: The greater the fluctuations in pressure, the greater the changes in blood flow. The elasticity of the arterial system dampens the pressure peaks and valleys that accompany the heartbeat. By the time blood reaches the arterioles, the pressure fluctuations have disappeared, and blood flow is continuous.

Muscular Arteries

Muscular arteries, or *medium-sized arteries*, distribute blood to the body's skeletal muscles and internal organs. Most of the vessels of the arterial system are muscular arteries. They are characterized by a thick tunica media, which contains more smooth muscle cells than the tunica media of elastic arteries (see Figure 21–2). A typical muscular artery has a luminal diameter of approximately 4 mm (0.16 in.), but some have diameters as small as 0.5 mm. The *external carotid arteries* of the neck, the *brachial arteries* of the arms, the *mesenteric arteries* of the abdomen, and the *femoral arteries* of the thighs are examples of muscular arteries.

Superficial muscular arteries are important as *pressure points*—places in the body where muscular arteries can be pressed against deeper bones to reduce blood flow and control severe bleeding. Major arterial pressure points are the common carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsal pedal.

Arterioles

Arterioles, with an internal diameter of 30 µm or less, are considerably smaller than muscular arteries. Arterioles have a poorly defined tunica externa. In the larger arterioles, the tunica media consists of one or two layers of smooth muscle cells (see Figure 21–2). The wall of an arteriole with a luminal diameter of 30 µm can have a 20-µm-thick layer of smooth muscle. In the smallest arterioles, the tunica media contains scattered smooth muscle cells that do not form a complete layer.

The luminal diameters of smaller muscular arteries and arterioles change in response to local conditions or to sympathetic or endocrine stimulation. For example, arterioles in most

? Which type of blood vessel has (a) the largest lumen and (b) the thickest tunica media?

+ Clinical Note Arteriosclerosis

Arteriosclerosis (ar-tēr-ē-ō-skler-Ō-sis; *arterio-*, artery + *sklerosis*, hardness) is a thickening and toughening of arterial walls. Complications related to arteriosclerosis account for about half of all deaths in the United States. For example, arteriosclerosis of coronary vessels is responsible for *coronary artery disease (CAD)*, and arteriosclerosis of arteries supplying the brain can lead to strokes, or *cerebrovascular accidents* (*CVA*s). ↩ p. 700

Arteriosclerosis takes two major forms:

- **Atherosclerosis** (ath-er-ō-skler-Ō-sis; *athero-*, fatty degeneration) is the formation of lipid deposits (plaque) in the tunica media associated with damage to the endothelial lining. It is the most common form of arteriosclerosis.
- **Focal calcification** is the deposition of calcium salts following the gradual degeneration of smooth muscle in the tunica media. Some focal calcification is a part of the aging process. It may also develop in association with atherosclerosis.

A normal coronary artery is shown in **Figure a**, and a typical lesion, called a *plaque* (PLAK), is shown in **Figures b** and **c**. Elderly people—especially elderly men—are most likely to develop atherosclerotic plaques. Estrogen may slow plaque formation. After menopause, when estrogen production decreases, the risks of CAD, myocardial infarctions (heart attacks), and CVAs in women increase markedly.

In addition to advanced age and male sex, other important risk factors for atherosclerosis include high blood cholesterol level, high blood pressure, and cigarette smoking. Diabetes mellitus, obesity, and stress can promote the development of atherosclerosis in both men and women. Evidence also indicates that at least some forms of atherosclerosis may be linked to chronic infection with *Chlamydia pneumoniae*, a bacterium responsible for several types of respiratory infections, including some forms of pneumonia.

Potential treatments for atherosclerotic plaques include catheterization with balloon angioplasty and stenting, and bypass surgery. ↩ p. 701 In the many cases where changes in diet do not lower circulating cholesterol level sufficiently, drug therapies can bring them under control.

Without question, the best approach to atherosclerosis is to avoid it by eliminating or reducing associated risk factors. Suggestions include (1) reducing your intake of dietary cholesterol, saturated fats, and trans fatty acids by restricting consumption of fatty meats, egg yolks, and cream; (2) not smoking; (3) checking your blood pressure and taking steps to lower it if necessary; (4) having your blood cholesterol level checked annually; (5) controlling your weight; and (6) exercising regularly.

b A cross-sectional view of a large plaque

c A section of a coronary artery narrowed by plaque formation

tissues vasodilate when the blood oxygen level is low. Also, as we saw in Chapter 16, arterioles vasoconstrict under sympathetic stimulation. ↩ p. 544 Changes in their luminal diameter affect the amount of force required to push blood around the cardiovascular system: More pressure is required to push blood through a constricted vessel than through a dilated one. The force opposing blood flow is called *resistance*, so arterioles are also called **resistance vessels**.

Occasionally, local blood pressure exceeds the capacity of the elastic components of the arterial walls. The result is an **aneurysm** (AN-yū-rizm), or bulge in the weakened wall of an artery. The bulge is like a bubble in the wall of a tire—and like a bad tire, the artery can suffer a catastrophic blowout. The most dangerous aneurysms occur in arteries of the brain (where they cause strokes) or in the aorta (where a rupture will cause fatal bleeding in a matter of minutes).

Capillaries

When we think of the cardiovascular system, we think first of the heart or the great blood vessels connected to it. But the microscopic capillaries that permeate most tissues do the real work of the cardiovascular system. These delicate vessels weave throughout active tissues, forming intricate networks that surround muscle fibers. Capillaries radiate through connective tissues, and branch beneath the basement membrane of epithelia.

A typical capillary consists of an endothelial tube inside a thin basement membrane. Neither a tunica media nor a tunica externa is present (see Figure 21–2). The average luminal diameter of a capillary is a mere 8 μm, very close to that of a single red blood cell.

Types of Capillaries

The two major types of capillaries are *continuous capillaries* and *fenestrated capillaries*. *Sinusoids* are a third type of capillary, related in structure and function to fenestrated capillaries.

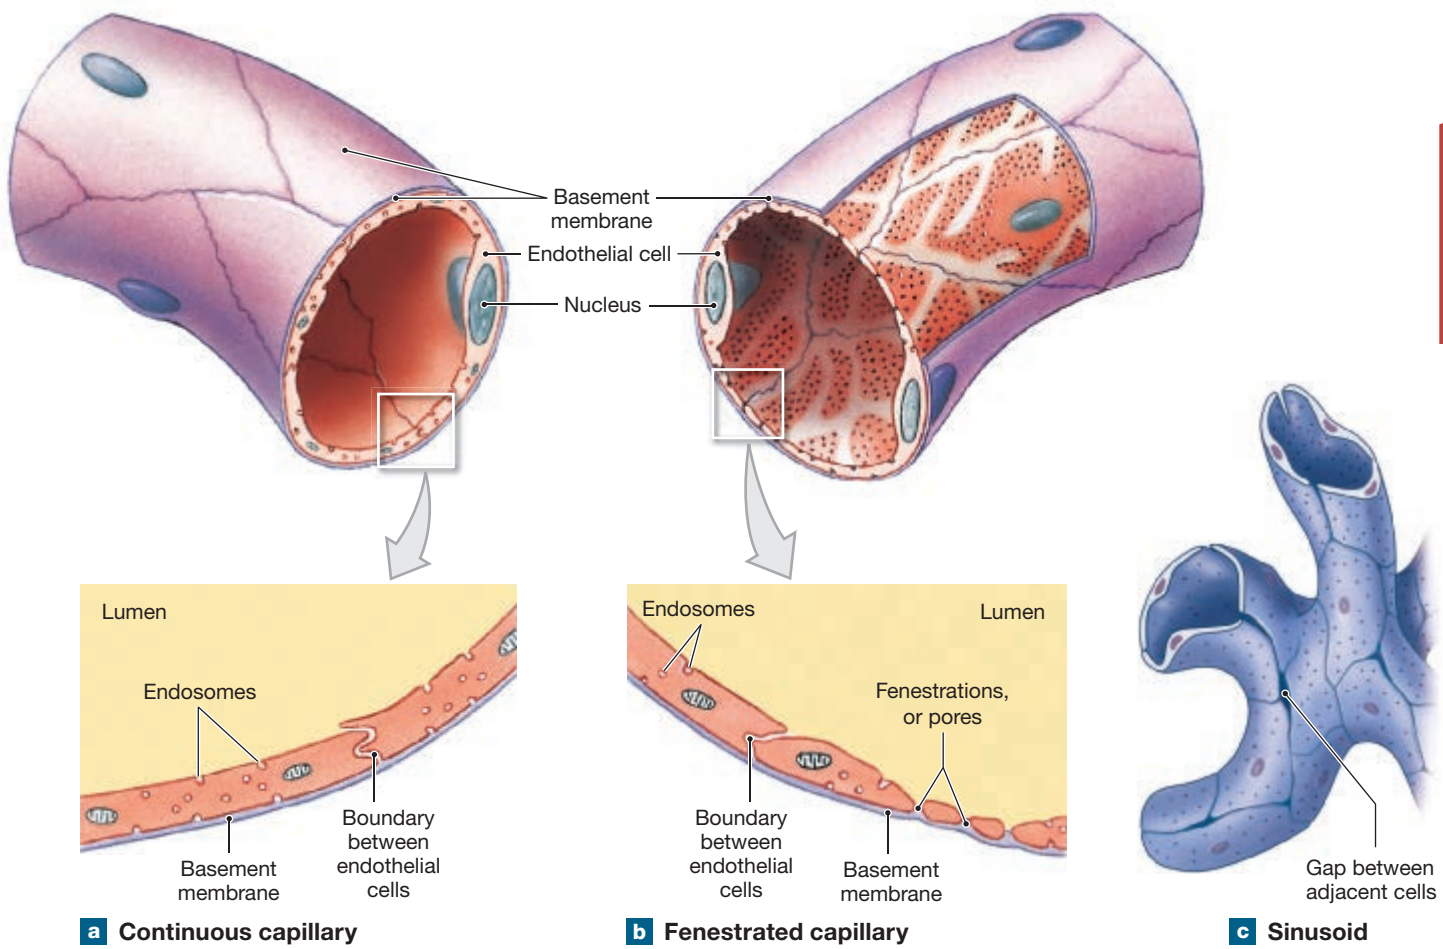
Continuous Capillaries. Continuous capillaries supply most regions of the body. In a **continuous capillary**, the endothelium is a complete lining. A cross section through a large continuous capillary cuts across several endothelial cells (Figure 21–3a). In a small continuous capillary, a single endothelial cell may completely encircle the lumen.

Continuous capillaries are located in all tissues except epithelia and cartilage. Continuous capillaries permit water, small solutes, and lipid-soluble substances to diffuse into the interstitial fluid. At the same time, they prevent the loss of blood cells and plasma proteins. In addition, some exchange may occur between blood and interstitial fluid by *bulk transport*—the movement of materials by endocytosis or exocytosis at the inner endothelial surface. ↩ p. 97

In specialized continuous capillaries in most of the central nervous system and in the thymus, the endothelial cells are bound together by tight junctions. These capillaries have very restricted permeability. We discussed one example—the capillaries responsible for the *blood brain barrier*—in Chapters 12 and 14. ↩ pp. 396, 473

Fenestrated Capillaries. Fenestrated (FEN-es-trā-ted; *fenestra*, window) **capillaries** contain "windows," or pores, that penetrate the endothelial lining (Figure 21–3b). The pores allow

Figure 21–3 Capillary Structure.



a Continuous capillary **b** Fenestrated capillary **c** Sinusoid

rapid exchange of water and solutes between blood and interstitial fluid. Examples of fenestrated capillaries include the *choroid plexus* of the brain and the blood vessels in a variety of endocrine organs, such as the hypothalamus and the pituitary, pineal, and thyroid glands. Fenestrated capillaries are also found along absorptive areas of the intestinal tract and at filtration sites in the kidneys. Both the number of pores and their permeability vary from one region of the capillary to another.

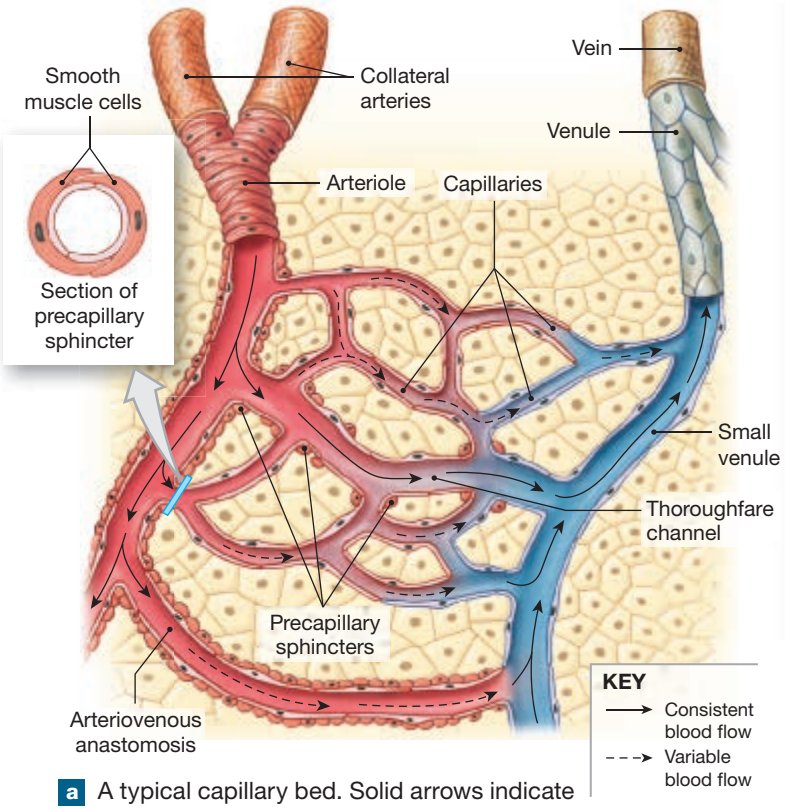
Sinusoids. Sinusoids (SĪ-nuh-soydz), or **sinusoidal capillaries**, resemble fenestrated capillaries that are flattened and irregularly shaped (Figure 21–3c). In contrast to continuous and fenestrated capillaries, they have a discontinuous endothelium. In addition to being fenestrated, sinusoids commonly have gaps between adjacent endothelial cells, and the basement membrane is either thinner or absent. As a result, sinusoids permit the free exchange of water and solutes, such as plasma proteins, between blood and interstitial fluid.

Blood moves through sinusoids relatively slowly, maximizing the time available for exchange across the sinusoidal walls. Sinusoids occur in the liver, bone marrow, spleen, and many endocrine organs, including the pituitary and adrenal glands. At liver sinusoids, plasma proteins secreted by liver cells enter the bloodstream. Along sinusoids of the liver, spleen, and bone marrow, phagocytic cells monitor the passing blood, engulfing damaged red blood cells, pathogens, and cellular debris.

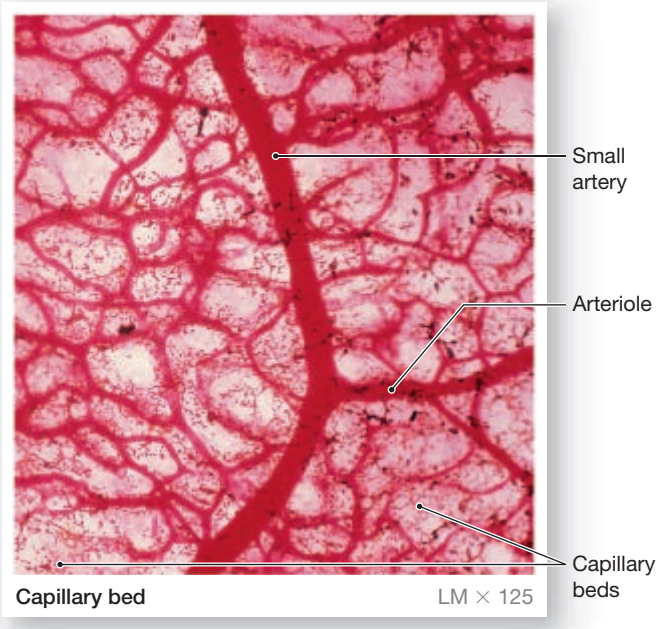
Capillary Beds

Capillaries function as part of an interconnected collective network called a **capillary bed** (Figure 21–4). A single arteriole generally gives rise to dozens of capillaries, which empty into several venules. A **precapillary sphincter** surrounds the entrance of a capillary and controls arterial blood flow to the tissues. Contraction of the smooth muscle cells of this sphincter narrows the capillary entrance, reducing or stopping the flow of blood. When one precapillary sphincter constricts, blood is diverted into other branches of the network. When a precapillary sphincter relaxes, the entrance dilates, and blood flows into the capillary. The central passageway in the arteriole system is the **thoroughfare channel**. Blood flow through this channel is controlled by the sphincter effect of the arteriole.

Figure 21–4 The Organization of a Capillary Bed.



a A typical capillary bed. Solid arrows indicate consistent blood flow; dashed arrows indicate variable or pulsating blood flow.



b A micrograph of a number of capillary beds.

Anastomoses and Angiogenesis

More than one artery may supply blood to a capillary bed. The multiple arteries are called **collaterals**. They fuse before giving rise to arterioles. The fusion of two collateral arteries that supply a capillary bed is an example of an **arterial anastomosis**. (An *anastomosis* is the joining of blood vessels.) The interconnections between the *anterior* and *posterior interventricular arteries* of the heart are arterial anastomoses. ↩ p. 699 An arterial anastomosis acts like an insurance policy: If one artery is blocked, capillary circulation will continue.

Arteriovenous (ar-tēr-ē-o-VĒ-nus) **anastomoses** are direct connections between arterioles and venules. When an arteriovenous anastomosis is dilated, blood bypasses the capillary bed and flows directly into the venous circulation. The pattern of blood flow through an arteriovenous anastomosis is regulated primarily by sympathetic innervation under the control of the cardiovascular center of the medulla oblongata.

Angiogenesis (an-jē-ō-JEN-e-sis; *angio-*, blood vessel + *genesis*, production) is the formation of new blood vessels from preexisting vessels and occurs under the direction of **vascular endothelial growth factor (VEGF)**. Angiogenesis occurs during embryonic and fetal development as tissues and organs develop. It may also occur at other times in any body tissue in response to factors released by oxygen-starved cells. Clinically, angiogenesis is probably most important in cardiac muscle, where it takes place in response to a chronically constricted or occluded vessel.

Veins

Veins collect blood from all tissues and organs and return it to the heart. The walls of veins can be thinner than those of corresponding arteries because the blood pressure in veins is lower than that of arteries. We classify veins on the basis of their size. Even though their walls are thinner, in general veins have larger luminal diameters than their corresponding arteries. (Review Figure 21–2 to compare arteries and veins.)

Types of Veins

Types of veins include venules, medium-sized veins, and large veins.

Venules. Venules, which are the smallest veins, collect blood from capillary beds. They vary widely in size and structure. An average venule has a luminal diameter of roughly 20 µm. Venules smaller than 50 µm lack a tunica media, and the smallest venules resemble expanded capillaries.

Medium-Sized and Large Veins. Medium-sized veins are comparable in size to muscular arteries. They range from 2 to 9 mm in luminal diameter. Their tunica media is thin and contains relatively few smooth muscle cells. The thickest layer of a medium-sized vein is the tunica externa, which contains longitudinal bundles of elastic and collagen fibers.

Large veins include the superior and inferior venae cavae and their branches within the abdominopelvic and thoracic cavities. All large veins have all three layers. The slender tunica media is surrounded by a thick tunica externa composed of a mixture of elastic and collagen fibers.

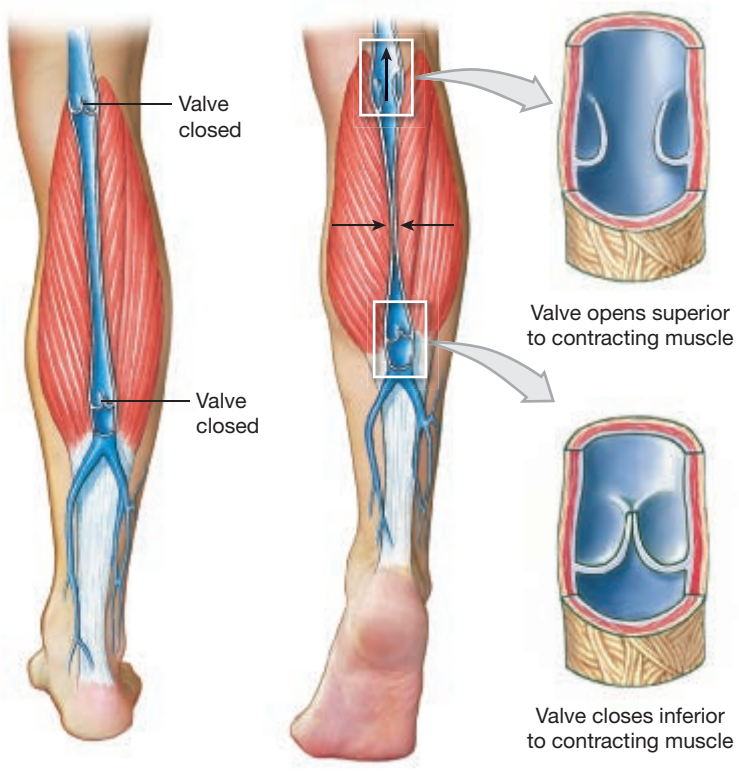
Venous Valves

The arterial system is a high-pressure system: Almost all the force developed by the heart is required to push blood along the network of arteries and through miles of capillaries. However, blood pressure in a peripheral venule is only about 10 percent of that in the ascending aorta, and pressures continue to fall along the venous system.

The blood pressure in venules and medium-sized veins is so low that it cannot overcome the force of gravity. In the limbs, veins of this size contain **valves**, folds of the tunica intima that project from the vessel wall into the lumen and point in the direction of blood flow. These valves, like those in the heart, permit blood flow in one direction only. Venous valves prevent blood from moving back toward the capillaries (Figure 21–5).

As long as the valves function normally, any movement that compresses a vein pushes blood toward the heart. This effect improves *venous return*, the amount of blood per unit of time returning to the heart. ↩ p. 719 Valves compartmentalize the blood within the veins, dividing the weight of the blood among the compartments.

Figure 21–5 The Function of Valves in the Venous System.



If the walls of the veins near the valves weaken or become stretched, the valves may not work properly. Blood then pools in the veins, and the vessels become grossly distended. The effects range from mild discomfort and a cosmetic problem, as in superficial *varicose veins* in the thighs and legs, to painful distortion of adjacent tissues, as in **hemorrhoids** (HEM-uh-roydz).

The Distribution of Blood

Our total blood volume is unevenly distributed among arteries, veins, and capillaries (Figure 21–6). The heart, arteries, and capillaries in the pulmonary and systemic circuits normally contain 30–35 percent of the blood volume (roughly 1.5 liters of whole blood). The venous system contains the rest (65–70 percent, or about 3.5 liters). About one-third of the blood in the venous system (about a liter) is circulating within the liver, bone marrow, and skin. These organs have extensive venous networks that at any moment contain large volumes of blood.

Veins are much more *distensible*, or expandable, than arteries because their walls are thinner, with less smooth muscle. For a given rise in blood pressure, a typical vein stretches about eight times as much as a corresponding artery. The *capacitance* of a blood vessel is the relationship between the volume of blood it contains and the blood pressure. Veins behave like a balloon, expanding easily at low pressures, and they have high capacitance. Arteries behave more like a truck tire, expanding only at high pressures, and they have low capacitance. Veins are called **capacitance vessels**. Because veins have high capacitance, they act as **blood reservoirs**, which can accommodate large changes in blood volume. If the blood volume rises or falls, the elastic walls stretch or recoil, changing the volume of blood in the venous system.

If serious hemorrhaging (profuse blood loss) occurs, sympathetic nerves stimulate smooth muscle cells in the walls of medium-sized veins in the systemic system to constrict. This process, called **venoconstriction** (vē-nō-kon-STRIK-shun), decreases the amount of blood within the venous system, increasing the volume within the arterial system and capillaries. Venoconstriction can keep the blood volume within the arteries and capillaries at near-normal levels despite a significant blood loss. As a result, blood flow to active skeletal muscles and delicate organs, such as the brain, can be increased or maintained.

Clinical Note Varicose Veins

Distended veins run like thick, blue ropes up the lower leg and popliteal region in some people. These **varicose veins** have a familial link and are more commonly found in people who stand for long time periods. The veins are unsightly, but superficial varicose veins are only a cosmetic issue. Minimally invasive techniques such as *sclerotherapy* (the injection of an irritant chemical) can shut down the dilated veins and improve the appearance of the legs.

However, varicosity of deep leg veins poses a threat. Here venous blood flow slows to a crawl and triggers coagulation. The result is **deep vein thrombosis (DVT)**. The *thrombus*, or clot, can impair venous return to the right atrium. Worse still, multiple DVTs can dislodge and become *emboli*, or traveling clots. The clots may end up in the lungs, producing a potentially fatal condition called **pulmonary embolism**.

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange

Learning Outcome Describe the factors that influence blood pressure, and explain how and where fluid and dissolved materials enter and leave the cardiovascular system.

Adequate amounts of blood must flow to the capillary beds in organs and peripheral tissues. Under normal circumstances, blood flow is equal to cardiac output. When cardiac output increases, blood flow through capillary beds increases, and when cardiac output decreases, capillary blood flow decreases.

Introduction to Pressure and Flow in Blood Vessels

Capillary blood flow is determined by the interplay between **pressure (*P*)** and **resistance (*R*)** in the cardiovascular network. To keep blood moving, the heart must generate enough pressure to overcome the resistance to blood flow in the pulmonary and systemic circuits. In general terms, **flow (*F*)** is directly proportional to the pressure (increased pressure → increased flow), and inversely proportional to resistance (increased resistance → decreased flow). However, the absolute pressure is less important than the pressure *gradient*—the difference in pressure from one end of the vessel to the other. This relationship can be summarized as

$$F \propto \frac{\Delta P}{R}$$

where the symbol ∝ means "is proportional to" and Δ means "the difference in." The largest pressure gradient is found between the base of the aorta and the proximal ends of peripheral capillary beds. The cardiovascular center can alter this pressure gradient, and change the rate of capillary blood flow, by adjusting cardiac output and peripheral resistance.

Blood leaving the peripheral capillaries enters the venous system. The pressure gradient across the venous system is relatively small, but venous resistance is very low. The low venous blood pressure—aided by valves, skeletal muscle contraction, gravity, and other factors—is enough to return the blood to the heart. When necessary, cardiovascular control centers can raise venous pressure (through venoconstriction) to improve venous return and maintain adequate cardiac output.

We begin this section by examining blood pressure and resistance more closely. We then consider the mechanisms of *capillary exchange*, the transfer of liquid and solutes between the blood and interstitial fluid. Capillary exchange provides tissues with oxygen and nutrients and removes the carbon dioxide and wastes generated by active cells.

Active tissues need more blood flow than inactive ones. Even something as simple as a change in position—going from sitting to standing, for instance—triggers a number of cardiovascular changes. We end this section with a discussion of what those changes are and how they are coordinated.

Pressures Affecting Blood Flow

When talking about cardiovascular pressures, three values are important:

- *Blood Pressure.* The term **blood pressure (BP)** refers to arterial pressure, usually reported in millimeters of mercury (mm Hg). Systemic arterial pressures in adults average 120 mm Hg at the entrance to the aorta to roughly 35 mm Hg at the start of a capillary network.
- *Capillary Hydrostatic Pressure. Hydrostatic pressure* is the force exerted by a fluid pressing against a wall. **Capillary hydrostatic pressure (CHP)**, or *capillary pressure*, is the pressure of blood within capillary walls. Along the length of a typical capillary, pressures decline from roughly 35 mm Hg to about 18 mm Hg.
- *Venous Pressure.* **Venous pressure** is the pressure of the blood within the venous system. Venous pressure is quite low: The pressure gradient from the venules to the right atrium is only about 18 mm Hg.

The difference in pressure (ΔP) across the entire systemic circuit, sometimes called the *circulatory pressure*, averages about 100 mm Hg.

Total Peripheral Resistance

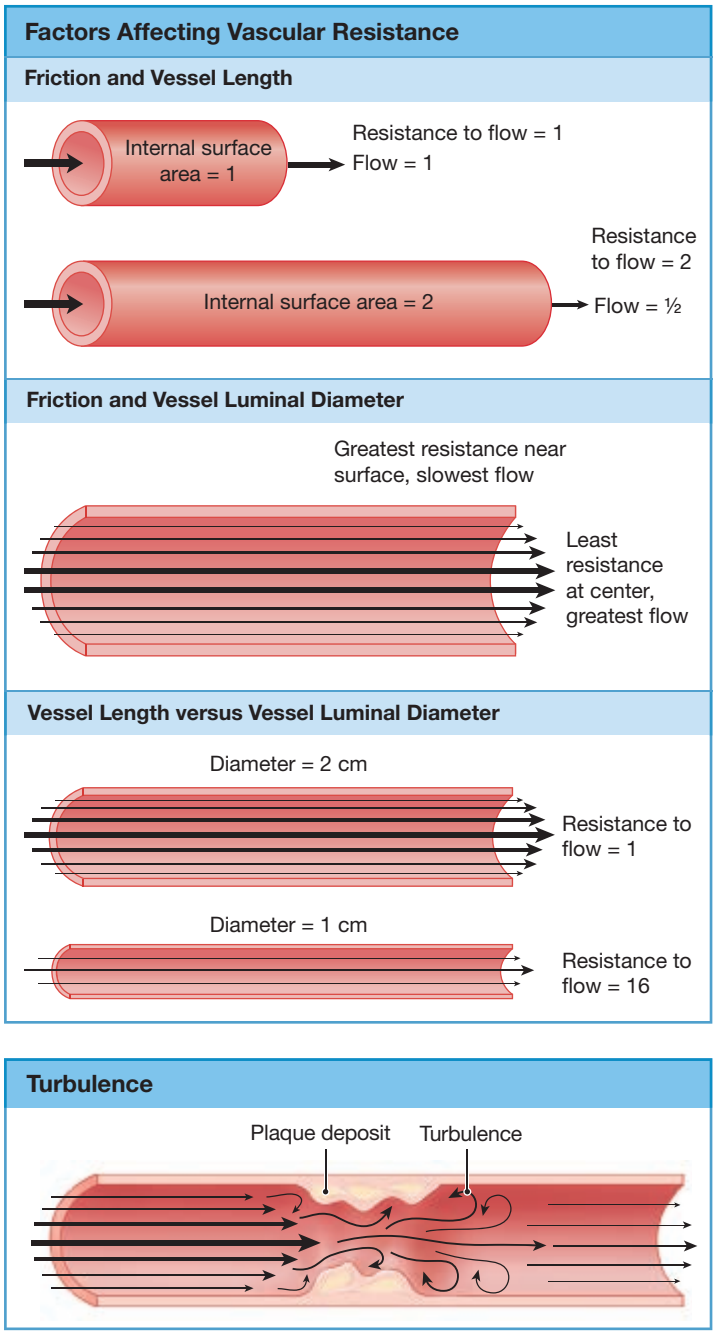
For circulation to occur, the circulatory pressure must overcome the **total peripheral resistance**—the resistance of the entire cardiovascular system. The arterial network has by far the largest pressure gradient (85 mm Hg), and this primarily reflects the relatively high resistance of the arterioles. The total peripheral resistance of the cardiovascular system reflects a combination of factors: *vascular resistance*, *blood viscosity*, and *turbulence*.

Vascular Resistance

Vascular resistance, the forces that oppose blood flow in the blood vessels, is the largest component. The most important factor in vascular resistance is **friction** between blood and the vessel walls. The amount of friction depends on two factors: vessel length and internal vessel diameter (Figure 21–7).

Vessel Length. Increasing the length of a blood vessel increases friction: The longer the vessel, the greater the surface area in contact with blood. You can easily blow the water out of a snorkel that is 2.5 cm (1 in.) in diameter and 25 cm (10 in.) long, but you cannot blow the water out of a 15-m (16-yard)-long garden hose, because the total friction is too great. The most dramatic changes in blood vessel length occur between birth and maturity, as individuals grow to adult size. In adults, vessel length can increase or decrease gradually when individuals gain or lose weight, but on a day-to-day basis this component of vascular resistance can be considered constant.

Figure 21–7 Factors Affecting Friction and Vascular Resistance.



? Which of the following would *increase* vascular resistance? increased vessel length, increased vessel luminal diameter, turbulence.

Vessel Luminal Diameter. The effects of friction on blood act in a narrow zone closest to the internal vessel wall. In a small-diameter vessel, friction with the luminal wall slows nearly all the blood. Resistance is therefore relatively high. Blood near the center of a large-diameter vessel does not encounter friction with the luminal wall, so the resistance in large vessels is fairly low.

Differences in diameter have much more significant effects on resistance than do differences in length. If two vessels are equal in radius (one-half the diameter) but one is twice as long as the other, the longer vessel offers twice as much resistance to blood flow. But for two vessels of equal length, one twice the radius of the other, the narrower one offers 16 times as much resistance to blood flow. This relationship, expressed in terms of the vessel radius r and resistance R, can be summarized as $R \propto 1/r^4$.

More significantly, there is no way to control vessel length, but vessel luminal diameter can change quickly through vasoconstriction or vasodilation. Most of the peripheral resistance occurs in arterioles. When these smooth muscles contract or relax, peripheral resistance increases or decreases, respectively. Because a small change in luminal diameter produces a large change in resistance, mechanisms that alter the diameters of arterioles provide control over peripheral resistance and blood flow.

Blood Viscosity

Viscosity is the resistance to flow caused by interactions among molecules and suspended materials in a liquid. Liquids of low viscosity, such as water (viscosity 1.0), flow at low pressures. Syrupy fluids, such as molasses (viscosity 300), flow only under higher pressures. Whole blood has a viscosity about five times that of water, due to its plasma proteins and blood cells. Under normal conditions, the viscosity of blood remains stable. Anemia, polycythemia, and other disorders that affect the hematocrit also change blood viscosity, and thus peripheral resistance.

Turbulence

High flow rates, irregular surfaces, and sudden changes in vessel luminal diameter upset the smooth flow of blood, creating eddies and swirls. This phenomenon, called **turbulence**, increases resistance and slows blood flow.

Turbulence normally occurs when blood flows between the atria and the ventricles, and between the ventricles and the aortic and pulmonary trunks. It also develops in large arteries, such as the aorta, when cardiac output and arterial flow rates are very high. However, turbulence seldom occurs in smaller vessels unless their walls are damaged. For example, an atherosclerotic plaque creates abnormal turbulence and restricts blood flow (Figure 21–7). Because turbulence makes a distinctive sound, or *bruit* (brū-Ē), plaques in large blood vessels can often be detected with a stethoscope.

Table 21–1 provides a review of the terms and relationships discussed in this section.

Table 21–1 Key Terms and Relationships Pertaining to Blood Circulation

Blood flow (*F*)	The volume of blood flowing per unit of time through a vessel or a group of vessels; may refer to circulation through a capillary, a tissue, an organ, or the entire vascular network. Total blood flow is equal to cardiac output.
Blood pressure (BP)	The hydrostatic pressure in the arterial system that pushes blood through capillary beds.
Circulatory pressure	The pressure difference between the base of the ascending aorta and the entrance to the right atrium.
Hydrostatic pressure	A pressure exerted by a liquid in response to an applied force.
Peripheral resistance (PR)	The resistance of the arterial system; affected by such factors as vascular resistance, viscosity, and turbulence.
Resistance (*R*)	A force that opposes movement (in this case, blood flow).
Total peripheral resistance	The resistance of the entire cardiovascular system.
Turbulence	A resistance due to the irregular, swirling movement of blood at high flow rates or exposure to irregular surfaces.
Vascular resistance	A resistance due to friction within a blood vessel, primarily between the blood and the vessel walls. Increases with increasing length or decreasing diameter; vessel length is constant, but vessel diameter can change.
Venous pressure	The hydrostatic pressure in the venous system.
Viscosity	A resistance to flow due to interactions among molecules within a liquid.
RELATIONSHIPS AMONG THE PRECEDING TERMS	
$F \propto \Delta P$	Flow is proportional to the pressure gradient.
$F \propto 1/R$	Flow is inversely proportional to resistance.
$F \propto \Delta P/R$	Flow is directly proportional to the pressure gradient, and inversely proportional to resistance.
$F \propto BP/PR$	Flow is directly proportional to blood pressure, and inversely proportional to peripheral resistance.
$R \propto 1/r^4$	Resistance is inversely proportional to the fourth power of the vessel radius.

An Overview of Cardiovascular Pressures

Look at the graphs in Figure 21–8 for an overview of the vessel luminal diameters, cross-sectional area of vessel lumen, pressures, and velocity of blood flow in the systemic circuit.

- *Vessel Luminal Diameters.* As blood flows from the aorta toward the capillaries, vessels diverge. The arteries branch repeatedly, and each branch is smaller in luminal diameter than the preceding one (Figure 21–8a). As blood flows from the capillaries toward the venae cavae, vessels converge. Vessel luminal diameters increase as venules combine to form small and medium-sized veins.
- *Total Cross-Sectional Areas.* Although arterioles, capillaries, and venules are small in luminal diameter, the body has large numbers of them. All the blood flowing through the aorta also flows through peripheral capillaries. Blood pressure and the speed of blood flow are proportional to the cross-sectional area of the vessels involved. What is important is not the cross-sectional area of each individual vessel, but the *combined* cross-sectional area of *all* the vessel lumens (Figure 21–8b). In effect, your blood moves from one big pipe (the aorta, with a cross-sectional area of 4.5 cm^2) into countless tiny ones (the peripheral capillaries, with a total cross-sectional area of 5000 cm^2), and then blood travels back to the heart through two large pipes (the venae cavae).
- *Pressures.* As arteries branch, their total cross-sectional area increases, and blood pressure falls rapidly (Figure 21–8c). Most of the decline takes place in the small arteries and arterioles. Venous pressures are relatively low.
- *Velocity of Blood Flow.* As the total cross-sectional area of the vessel lumens increases from the aorta toward the capillaries, the velocity of blood flow decreases (Figure 21–8d). Blood flow velocity then increases as the total cross-sectional area decreases from the capillaries toward the venae cavae.

Figure 21–9 graphs the blood pressure throughout the cardiovascular system. Systemic pressures are highest in the aorta, peaking at about 120 mm Hg. Pressures reach a minimum of 2 mm Hg at the entrance to the right atrium. Pressures in the pulmonary circuit are much lower than those in the systemic circuit. The right ventricle does not ordinarily develop high pressures because the pulmonary vessels are much shorter and more distensible than the systemic vessels, thus providing less resistance to blood flow. Let's look at pressures throughout the systemic circuit.

Arterial Blood Pressure

Arterial pressure is important because it maintains blood flow through capillary beds. To do this, it must always be high enough to overcome the peripheral resistance. Arterial pressure is not constant. Rather, it rises during ventricular systole and falls during ventricular diastole. The peak blood pressure measured during ventricular systole is called **systolic pressure**, and the minimum blood pressure at the end of ventricular diastole is called **diastolic pressure**. In recording blood pressure, we separate systolic and diastolic pressures by a slash, as in "120/80" ("one-twenty over eighty") or "110/75."

Figure 21–8 Relationships among Vessel Luminal Diameter, Cross-Sectional Area, Blood Pressure, and Blood Velocity within the Systemic Circuit.

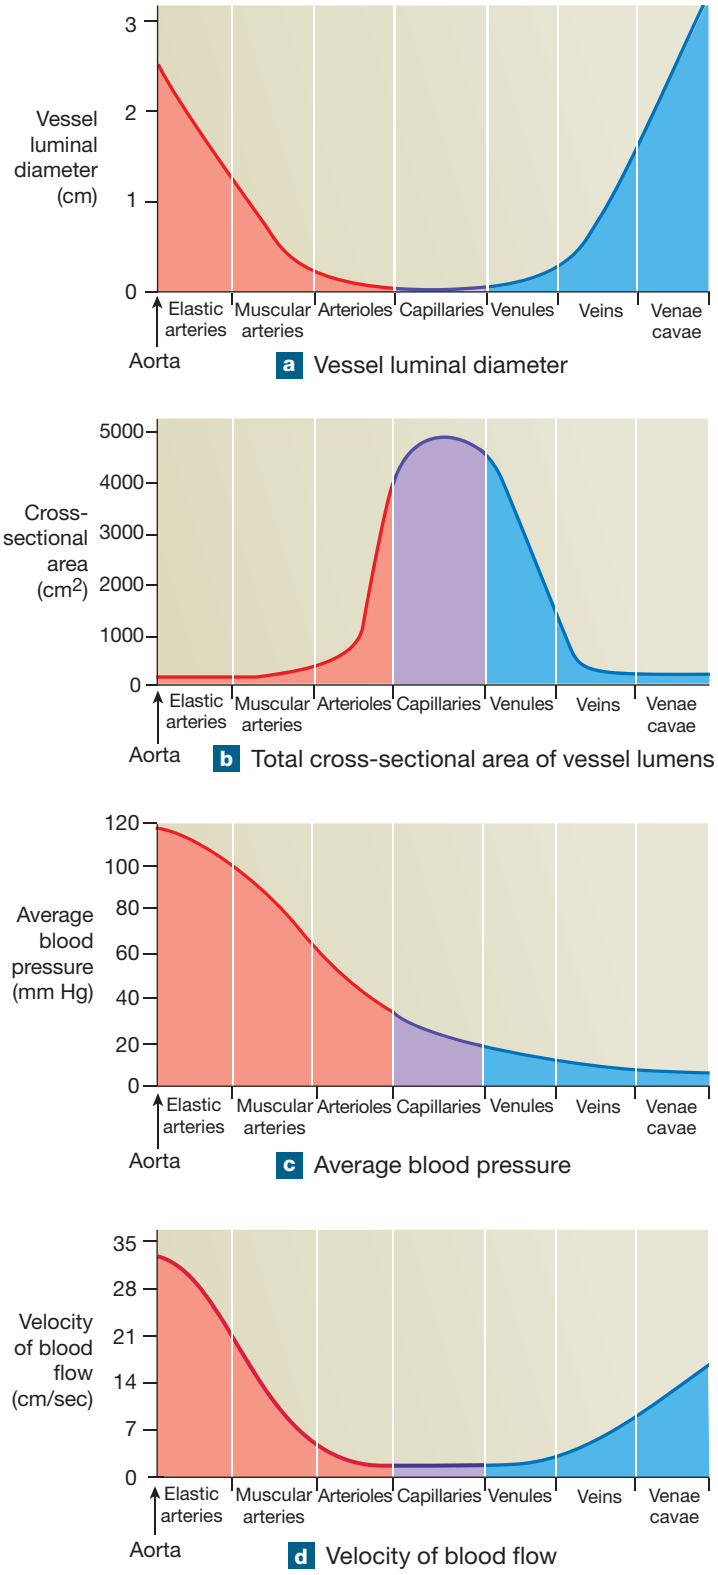


Figure 21–9 Pressures within the Systemic Circuit. Note the general reduction in circulatory pressure within the systemic circuit and the elimination of the pulse pressure within the arterioles.

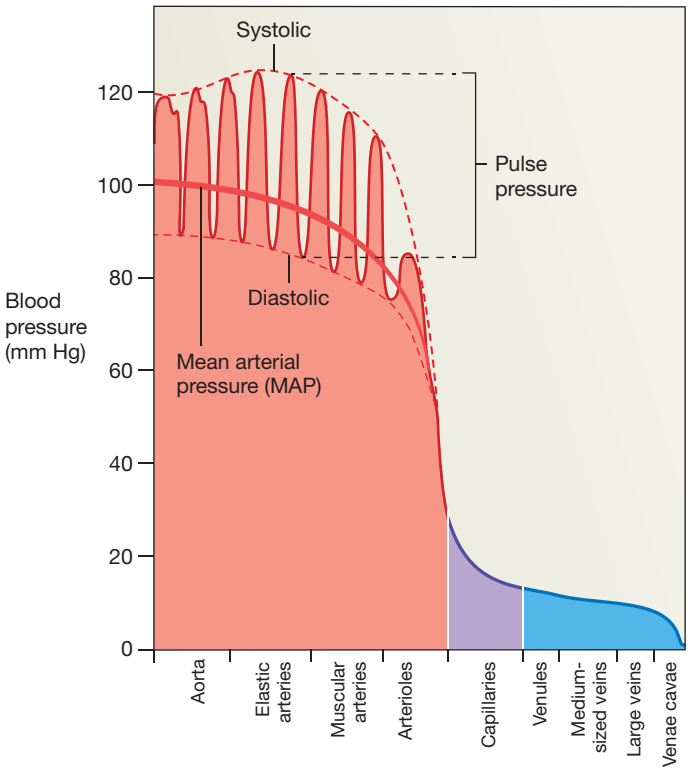


A *pulse* is a rhythmic fluctuation in pressure that accompanies each heartbeat. The difference between the systolic and diastolic pressures is the **pulse pressure** (Figure 21–9). To report a single blood pressure value, we use the **mean arterial pressure (MAP)**. It is calculated for someone at rest by adding one-third of the pulse pressure to the diastolic pressure:

$$\text{MAP} = \text{diastolic pressure} + \frac{\text{pulse pressure}}{3}$$

For a systolic pressure of 120 mm Hg and a diastolic pressure of 90 mm Hg, we calculate MAP as follows:

$$\text{MAP} = 90 + \frac{(120 - 90)}{3} = 90 + 10 = 100\,\text{mm Hg}$$

A normal range of systolic and diastolic pressures occurs in healthy individuals. When pressures shift outside the normal range, clinical problems develop. Abnormally high blood pressure is termed **hypertension**. Abnormally low blood pressure is **hypotension**. Hypertension is much more common. In fact, many cases of hypotension result from overly aggressive drug treatment for hypertension.

The usual criterion established by the American Heart Association for stage 1 hypertension in adults is a systolic blood pressure range of 140–159 and a diastolic range of 90–99.

Values from 120–139 for systolic pressure and 80–89 for diastolic pressure indicate *pre-hypertension*. Blood pressure less than 120/80 is normal. Cardiologists often recommend some combination of diet modification and drug therapy for people whose blood pressures are consistently pre-hypertensive.

Cardiac workload is how hard the heart has to work to pump blood throughout the body. Hypertension significantly increases the workload on the heart, and the left ventricle gradually enlarges. More muscle mass means a greater demand for oxygen. When the coronary circulation cannot keep pace, signs and symptoms of *coronary ischemia* appear. ↩ p. 700 Increased arterial pressures also place a physical stress on the walls of blood vessels throughout the body. This stress promotes or accelerates the development of arteriosclerosis. It also increases the risk of aneurysms, heart attacks, and strokes.

Elastic Rebound in Arteries

As systolic pressure climbs, the arterial walls stretch, just as an extra puff of air expands a partially inflated balloon. This expansion allows the arterial system to accommodate some of the blood ejected during ventricular systole. When diastole begins and blood pressures fall, the arteries recoil to their original dimensions. This phenomenon is called **elastic rebound**. Some blood is forced back toward the left ventricle, closing the aortic valve and helping to drive additional blood into the coronary arteries. However, most of the push from elastic rebound forces blood toward the capillaries. This maintains blood flow along the arterial network while the left ventricle is in diastole.

Pressures in Muscular Arteries and Arterioles

The mean arterial pressure and the pulse pressure become smaller as the distance from the heart increases (see Figure 21–9):

- The mean arterial pressure declines as the arterial branches become smaller and more numerous. In essence, blood pressure decreases as it overcomes friction and produces blood flow.
- The pulse pressure lessens due to the cumulative effects of elastic rebound along the arterial system. The effect can be likened to a series of ever-softer echoes following a loud shout. Each time an echo is produced, the reflecting surface absorbs some of the sound energy. Eventually, the echo disappears. The pressure surge accompanying ventricular ejection is like the shout, and it is reflected by the wall of the aorta, echoing down the arterial system until it finally disappears at the level of the small arterioles. By the time blood reaches a precapillary sphincter, no pressure fluctuations remain, and the blood pressure is steady at approximately 35 mm Hg.

Venous Pressure and Venous Return

Venous pressure, although low, determines **venous return**—the amount of blood arriving at the right atrium each minute. Venous return has a direct impact on cardiac output. ↩ p. 718 Blood pressure at the start of the venous system is only about one-tenth that at the start of the arterial system, but the blood must still travel through a vascular network as complex as the arterial system before returning to the heart.

Pressures at the entrance to the right atrium fluctuate, but they average about 2 mm Hg. Thus, the effective pressure in the venous system is roughly 16 mm Hg (from 18 mm Hg in the venules to 2 mm Hg in the venae cavae). This venous pressure gradient compares with 65 mm Hg in the arterial system (from 100 mm Hg at the aorta to 35 mm Hg at the capillaries). Yet, although venous pressures are low, veins offer comparatively little resistance, so pressure declines very slowly as blood moves through the venous system. As blood moves toward the heart, the veins become larger, resistance drops, and the velocity of blood flow increases (look back at Figure 21–8).

When you stand, the venous blood returning from your body inferior to the heart must overcome gravity as it travels up the inferior vena cava. Two factors assist the low venous pressures in propelling blood toward your heart: *muscular compression* of peripheral veins and the *respiratory pump* during inhalation.

Muscular Compression. The contractions of skeletal muscles near a vein compress it, helping to push blood toward the heart. The valves in small and medium-sized veins ensure that blood flows in one direction only (look back at Figure 21–5). When you are standing and walking, the cycles of contraction and relaxation that accompany your normal movements assist venous return. The mechanism is particularly important when you are standing, because blood returning from your feet must overcome gravity to ascend to the heart. Although you are probably not aware of it, when you stand, your leg muscles undergo cycles of rapid contraction and relaxation, helping to push blood toward the trunk. When you lie down, venous valves play a smaller part in venous return, because your heart and major vessels are at the same level.

If you stand at attention, with knees locked and leg muscles immobilized, that assistance is lost. The reduction in venous return then leads to a decline in cardiac output, which reduces the blood supply to the brain. This decline is sometimes enough to cause **fainting**, a temporary loss of consciousness. You would then collapse, but while you were in the horizontal position, both venous return and cardiac output would return to normal.

The Respiratory Pump. As you inhale, your thoracic cavity expands, reducing the pressure within the thoracic cavity. When the pressure in the thoracic cavity drops below atmospheric pressure, air will enter the lungs. At the same time, the drop in venous pressure in the chest makes it easier to force blood into the inferior vena cava and right atrium from the smaller veins of your abdominal cavity and lower body. The effect on venous

return through the superior vena cava is less noticeable, because blood in that vessel is normally assisted by gravity. As you exhale, your thoracic cavity decreases in size. Internal pressure then rises, forcing air out of your lungs and pushing venous blood into the right atrium. This mechanism is called the **respiratory pump**. Such pumping action becomes more important during heavy exercise, when respirations are deep and frequent.

Capillary Exchange and Capillary Pressures

The vital functions of the cardiovascular system depend entirely on events at the capillary level: All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls. This process, called **capillary exchange**, plays a key role in homeostasis. Cells rely on capillary exchange to obtain nutrients and oxygen and to remove metabolic wastes, such as carbon dioxide and urea.

Exchange takes place very rapidly, because the distances involved are very short. Few cells lie more than 125 µm (0.005 in.) from a capillary. In addition, blood flows through capillaries fairly slowly, allowing time for the diffusion or active transport of materials across the capillary walls. In this way, the histological structure of capillaries permits a two-way exchange of substances between blood and interstitial fluid. Capillaries are the *only* blood vessels whose walls permit such exchange. The most important processes that move materials across typical capillary walls are *diffusion*, *filtration*, and *reabsorption*.

Diffusion

As we saw in Chapter 3, *diffusion* is the net movement of ions or molecules from an area where their concentration is higher to an area where their concentration is lower. ↩ p. 90 The difference between the high and low concentrations represents a *concentration gradient*. Diffusion tends to eliminate that gradient. Diffusion occurs most rapidly when (1) the distances involved are short, (2) the concentration gradient is steep, and (3) the ions or molecules involved are small.

Different substances diffuse across capillary walls by different routes:

- *Water, ions, and small organic molecules, such as glucose, amino acids, and urea,* can usually enter or leave the bloodstream by diffusion between adjacent endothelial cells or through the pores of fenestrated capillaries.
- *Many ions, including sodium, potassium, calcium, and chloride,* can diffuse across endothelial cells by passing through channels in plasma membranes.
- *Large water-soluble compounds* are unable to enter or leave the bloodstream except at fenestrated capillaries, such as those of the hypothalamus, the kidneys, many endocrine organs, and the intestinal tract.
- *Lipids, such as fatty acids and steroids, and lipid-soluble materials, including soluble gases such as oxygen and carbon dioxide,* can cross capillary walls by diffusion through the endothelial plasma membranes.
- *Plasma proteins* are normally unable to cross the endothelial lining anywhere except in sinusoids, such as those of the liver, where plasma proteins enter the bloodstream.

Filtration

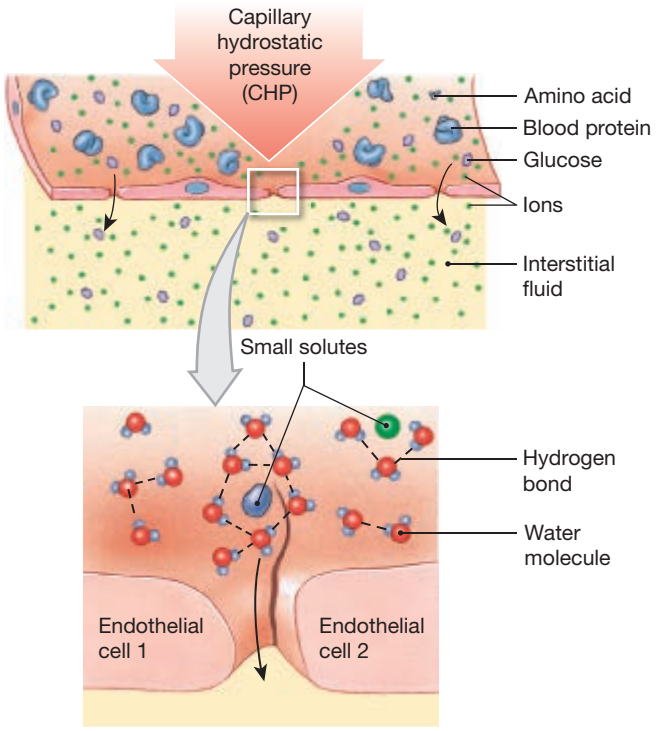
Filtration is the removal of solutes as a solution flows across a porous membrane. Solutes too large to pass through the pores are filtered out of the solution. The driving force for filtration is hydrostatic pressure. As we saw earlier, it pushes water from an area of higher pressure to an area of lower pressure.

In *capillary filtration*, water and small solutes are forced across a capillary wall, leaving larger solutes and suspended proteins in the bloodstream (Figure 21–10). The solute molecules that leave the bloodstream are small enough to pass between adjacent endothelial cells or through the pores in a fenestrated capillary. Filtration takes place primarily at the arterial end of a capillary, where capillary hydrostatic pressure (CHP) is highest.

Reabsorption

Reabsorption occurs as the result of osmosis. *Osmosis* is the diffusion of water across a selectively permeable membrane that

Figure 21–10 Capillary Filtration. Capillary hydrostatic pressure (CHP) forces water and solutes through the gaps between adjacent endothelial cells in continuous capillaries. The sizes of solutes that move across the capillary wall are determined by the dimensions of the gaps.



separates two solutions of differing solute concentrations. Water molecules tend to diffuse across a membrane *toward* the solution containing the higher solute concentration (look back at Figure 3–16, ↩ p. 93).

The **osmotic pressure (OP)** of a solution represents the pressure that must be applied to prevent osmotic movement across a membrane. The higher the solute concentration of a solution, the greater the solution's osmotic pressure. Suspended proteins that cannot cross capillary walls creates an osmotic pressure called *blood colloid osmotic pressure (BCOP)*. Clinicians often use the term *oncotic pressure* (*onkos*, a swelling) when referring to the colloid osmotic pressure of body fluids. The two terms are equivalent. Osmotic water movement continues until either the solute concentrations are equalized or an opposing hydrostatic pressure prevents the movement.

Bulk Flow: The Interplay between Filtration and Reabsorption

Now let's look at how filtration and reabsorption function together along the length of a typical capillary. The continuous net movement of water out of the capillaries, through peripheral tissues, and then back to the bloodstream by way of the lymphatic system is known as *bulk flow*. This process has four important functions:

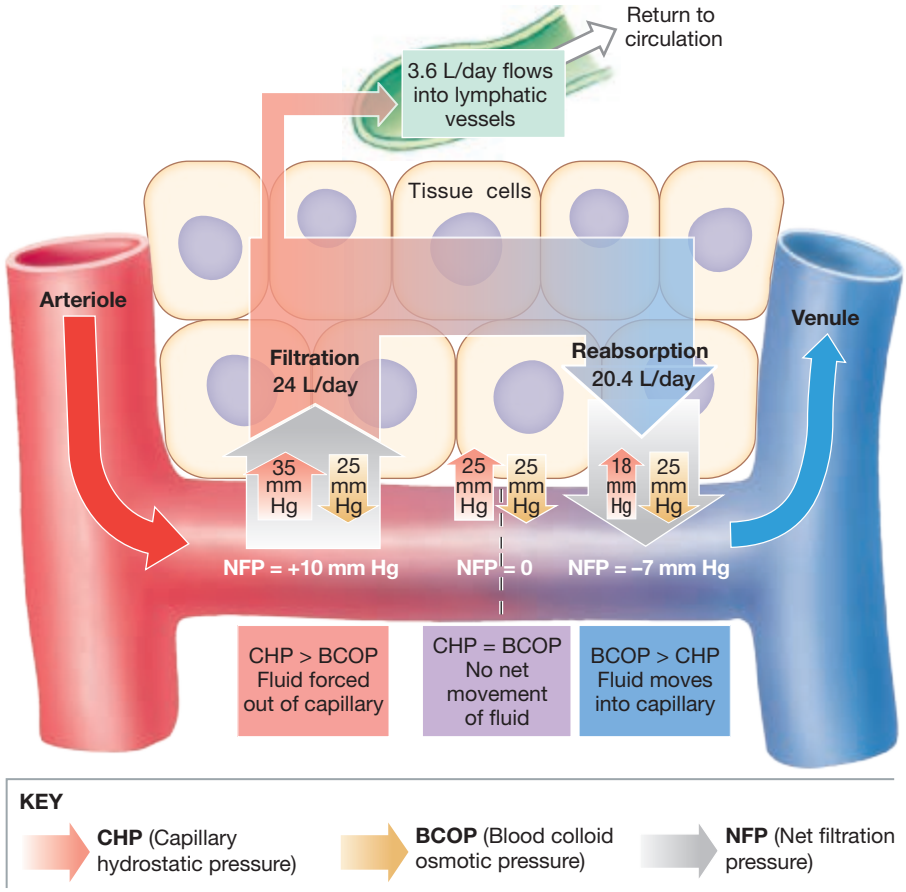
- It ensures that plasma and interstitial fluid, two major components of extracellular fluid, communicate and exchange materials constantly.
- It accelerates the distribution of nutrients, hormones, and dissolved gases throughout tissues.
- It assists in the transport of insoluble lipids and tissue proteins that cannot cross the capillary walls and enter the bloodstream.
- It flushes out bacterial toxins and other chemicals, carrying them to lymphatic tissues and organs responsible for immunity to disease.

Capillary blood pressure declines as blood flows from the arterial end to the venous end of a capillary. As a result, the rates of filtration and reabsorption gradually change as blood passes along the length of a capillary. The factors involved are diagrammed in Figure 21–11.

The *net capillary hydrostatic pressure* is the difference between the hydrostatic pressure inside the capillary and the hydrostatic pressure outside the capillary. This pressure tends to push water and solutes out of capillaries and into the interstitial fluid. Factors that contribute to the net hydrostatic pressure include

- the capillary hydrostatic pressure (CHP), which ranges from 35 mm Hg at the arterial end of a capillary to 18 mm Hg at the venous end, and
- the *interstitial fluid hydrostatic pressure (IHP)*. Measurements of IHP have yielded very small values that differ from tissue to tissue—from +6 mm Hg in the brain to –6 mm Hg in subcutaneous tissues. A positive IHP opposes CHP, so in this situation the tissue hydrostatic pressure must be overcome before fluid can move out of a capillary. A negative IHP assists CHP, and additional fluid will leave the capillary. However, under normal circumstances the average IHP is 0 mm Hg, and we can assume that the net hydrostatic pressure is equal to CHP. (For this reason, IHP is not included in Figure 21–11.)

Figure 21–11 Forces Acting across Capillary Walls. At the arterial end of a capillary, capillary hydrostatic pressure (CHP) is greater than blood colloid osmotic pressure (BCOP), so fluid moves out of the capillary (filtration). Near the venule, CHP is lower than BCOP, so fluid moves into the capillary (reabsorption). In this model, interstitial fluid colloid osmotic pressure (ICOP) and interstitial fluid hydrostatic pressure (IHP) are assumed to be 0 mm Hg and so are not shown.



Plasma proteins in capillary blood create capillary colloid osmotic pressure. The *net capillary colloid osmotic pressure* tends to cause water and solutes, by bulk flow, to enter the capillary from the interstitial fluid. The net colloid osmotic pressure is the difference between

- the *blood colloid osmotic pressure (BCOP)*, which is about 25 mm Hg, and
- the *interstitial fluid colloid osmotic pressure (ICOP)*. The ICOP is as variable and low as the IHP, because the interstitial fluid in most tissues contains negligible quantities of suspended proteins. Reported values of ICOP are from 0 to 5 mm Hg, within the range of pressures recorded for the IHP. It is thus safe to assume that under normal circumstances the net colloid osmotic pressure is equal to the BCOP. (For this reason, ICOP is not included in Figure 21–11.)

The **net filtration pressure (NFP)** is the difference between the net hydrostatic pressure and the net osmotic pressure. In terms of the factors just listed, this means that

$$\begin{array}{ccccc} \text{net filtration pressure} & = & \text{net hydrostatic pressure} & - & \text{net colloid osmotic pressure} \\ \text{NFP} & = & (\text{CHP} - \text{IHP}) & - & (\text{BCOP} - \text{ICOP}) \end{array}$$

At the arterial end of a capillary, the net filtration pressure can be calculated as follows:

$$\text{NFP} = (35 - 0) - (25 - 0) = 35 - 25 = 10 \text{ mm Hg}$$

Because this value is positive, it indicates that fluid will tend to move *out of* the capillary and into the interstitial fluid.

At the venous end of the capillary, the net filtration pressure will be

$$\text{NFP} = (18 - 0) - (25 - 0) = 18 - 25 = -7 \text{ mm Hg}$$

The minus sign indicates that fluid tends to move *into* the capillary; that is, reabsorption is occurring.

The transition between filtration and reabsorption occurs where the CHP is 25 mm Hg, because at that point the hydrostatic and osmotic forces are equal—that is, the NFP is 0 mm Hg. If the maximum filtration pressure at the arterial end of the capillary were equal to the maximum reabsorption pressure at the venous end, this transition point would lie midway along the length of the capillary. Under these circumstances, filtration would occur along the first half of the capillary, and an identical amount of reabsorption would occur along the second half. However, the maximum filtration pressure is higher than the maximum reabsorption pressure, so the transition point between filtration and reabsorption normally lies closer to the venous end of the capillary than to the arterial end. As a result, more filtration than reabsorption occurs along the capillary. Of the nearly 24 liters of fluid that move out of the plasma and into the interstitial fluid each day, 20.4 liters (85 percent) are reabsorbed. The remainder (3.6 liters) flows through the tissues and into lymphatic vessels, for eventual return to the venous system (see Figure 21–11).

Any condition that affects hydrostatic or osmotic pressures in the blood or tissues will shift the balance between hydrostatic and osmotic forces. We can predict the effects of these changes on the basis of an understanding of capillary dynamics. For example:

- If hemorrhaging occurs, both blood volume and blood pressure decrease. This reduction in CHP lowers the NFP and increases the amount of reabsorption. The result is a decrease in the volume of interstitial fluid and an increase in the circulating plasma volume. This process is known as a *recall of fluids*.
- If dehydration occurs, the plasma volume decreases due to water loss, and the concentration of plasma proteins increases. The increase in BCOP accelerates reabsorption and a recall of fluids that delays the onset and severity of clinical signs and symptoms.
- If the CHP rises or the BCOP declines, fluid moves out of the blood and builds up in peripheral tissues, a condition called *edema*.

+ Clinical Note Edema

Edema (eh-DĒ-muh) is an abnormal accumulation of interstitial fluid. The underlying problem in all types of edema is a disturbance in the normal balance between hydrostatic and osmotic forces at the capillary level. For instance:

- You usually have swelling at a bruise. When a capillary is damaged, plasma proteins cross the capillary wall and enter the interstitial fluid. The resulting rise in the interstitial fluid colloid osmotic pressure (ICOP) reduces the rate of capillary reabsorption and produces a localized edema.
- In starvation, the liver cannot synthesize enough plasma proteins to maintain normal concentrations in the blood, so the blood colloid osmotic pressure (BCOP) declines. Fluids then begin moving from the blood into peripheral tissues. In children, fluid builds up in the abdominopelvic cavity, producing the swollen bellies typical of starvation victims. BCOP is also reduced after severe burns and in several types of liver and kidney diseases.
- In the U.S. population, most serious cases of edema result from increases in arterial blood pressure, venous pressure, or total circulatory pressure. The increase may be due to heart problems such as heart failure or venous blood clots that elevate venous pressures. The net result is an increase in capillary hydrostatic pressure (CHP) that accelerates fluid movement into the tissues.

Checkpoint

5. Identify the factors that contribute to total peripheral resistance.
6. In a healthy person, where is blood pressure greater: at the aorta or at the inferior vena cava? Explain.
7. While standing in the hot sun, Lailah begins to feel lightheaded and faints. Explain what happened.
8. Mike's blood pressure is 125/70. What is his mean arterial pressure (MAP)?

See the blue Answers tab at the back of the book.

21-3 Blood flow and pressure in tissues are controlled by both autoregulation and central regulation

Learning Outcome Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.

Homeostatic mechanisms regulate cardiovascular activity to ensure that the amount of blood flow through tissues, called **tissue perfusion**, is adequate to meet the demand for oxygen and nutrients. The factors that affect tissue perfusion are (1) cardiac output, (2) peripheral resistance, and (3) blood pressure. We discussed cardiac output in Chapter 20. ↩ p. 716 We considered peripheral resistance and blood pressure earlier in this chapter.

Most cells are relatively close to capillaries. When a group of cells becomes active, the circulation to that region must increase to bring the necessary oxygen and nutrients, and to carry away the wastes and carbon dioxide they generate. The purpose of cardiovascular regulation is to ensure that these blood flow changes occur (1) at an appropriate time, (2) in the right area, and (3) without drastically changing blood pressure and blood flow to vital organs. Let's look first at how blood is distributed to capillaries, and then at the regulatory mechanisms that control how that distribution occurs.

Vasomotion

Although blood normally flows from arterioles to venules at a constant rate, the flow within each capillary is quite variable. Each precapillary sphincter alternately contracts and relaxes, perhaps a dozen times per minute. These rhythmic changes in vessel diameter are called **vasomotion**. As a result, the blood flow within any capillary occurs in pulses rather than as a steady and constant stream. The net effect is that blood may reach the venules by one route now and by a different route later.

When you are at rest, blood flows through about 25 percent of the vessels within a typical capillary bed in your body. Your cardiovascular system does not contain enough blood to maintain adequate blood flow to all the capillaries in all the capillary beds in your body at the same time. As a result, when many tissues become active, the blood flow through capillary beds must be coordinated.

Overview of Autoregulation and Central Regulation

Homeostatic mechanisms operating at the local, regional, and systemic levels adjust blood flow through the capillaries to meet the demands of peripheral tissues. We can group these mechanisms as follows:

- *Autoregulation.* Local factors change the pattern of blood flow within capillary beds as precapillary sphincters open and close in response to chemical changes in interstitial fluids. This is an example of autoregulation at the tissue level. Autoregulation causes immediate, localized homeostatic adjustments.

  If autoregulation fails to normalize conditions at the tissue level, *central regulation*, involving both neural and endocrine mechanisms, is activated. These central regulation mechanisms focus on controlling cardiac output and blood pressure to restore adequate blood flow after blood pressure decreases.
- *Neural Mechanisms.* Neural mechanisms respond to changes in arterial pressure or blood gas levels sensed at specific sites. When those changes occur, the cardiovascular center of the autonomic nervous system makes short-term adjustments to cardiac output and peripheral resistance to maintain blood pressure and ensure adequate blood flow.
- *Endocrine Mechanisms.* The endocrine system releases hormones that enhance short-term adjustments and that direct long-term changes in cardiovascular performance.

Now let's see how each of these regulatory mechanisms responds to inadequate perfusion of skeletal muscles. The regulatory relationships are diagrammed in **Figure 21–12**.

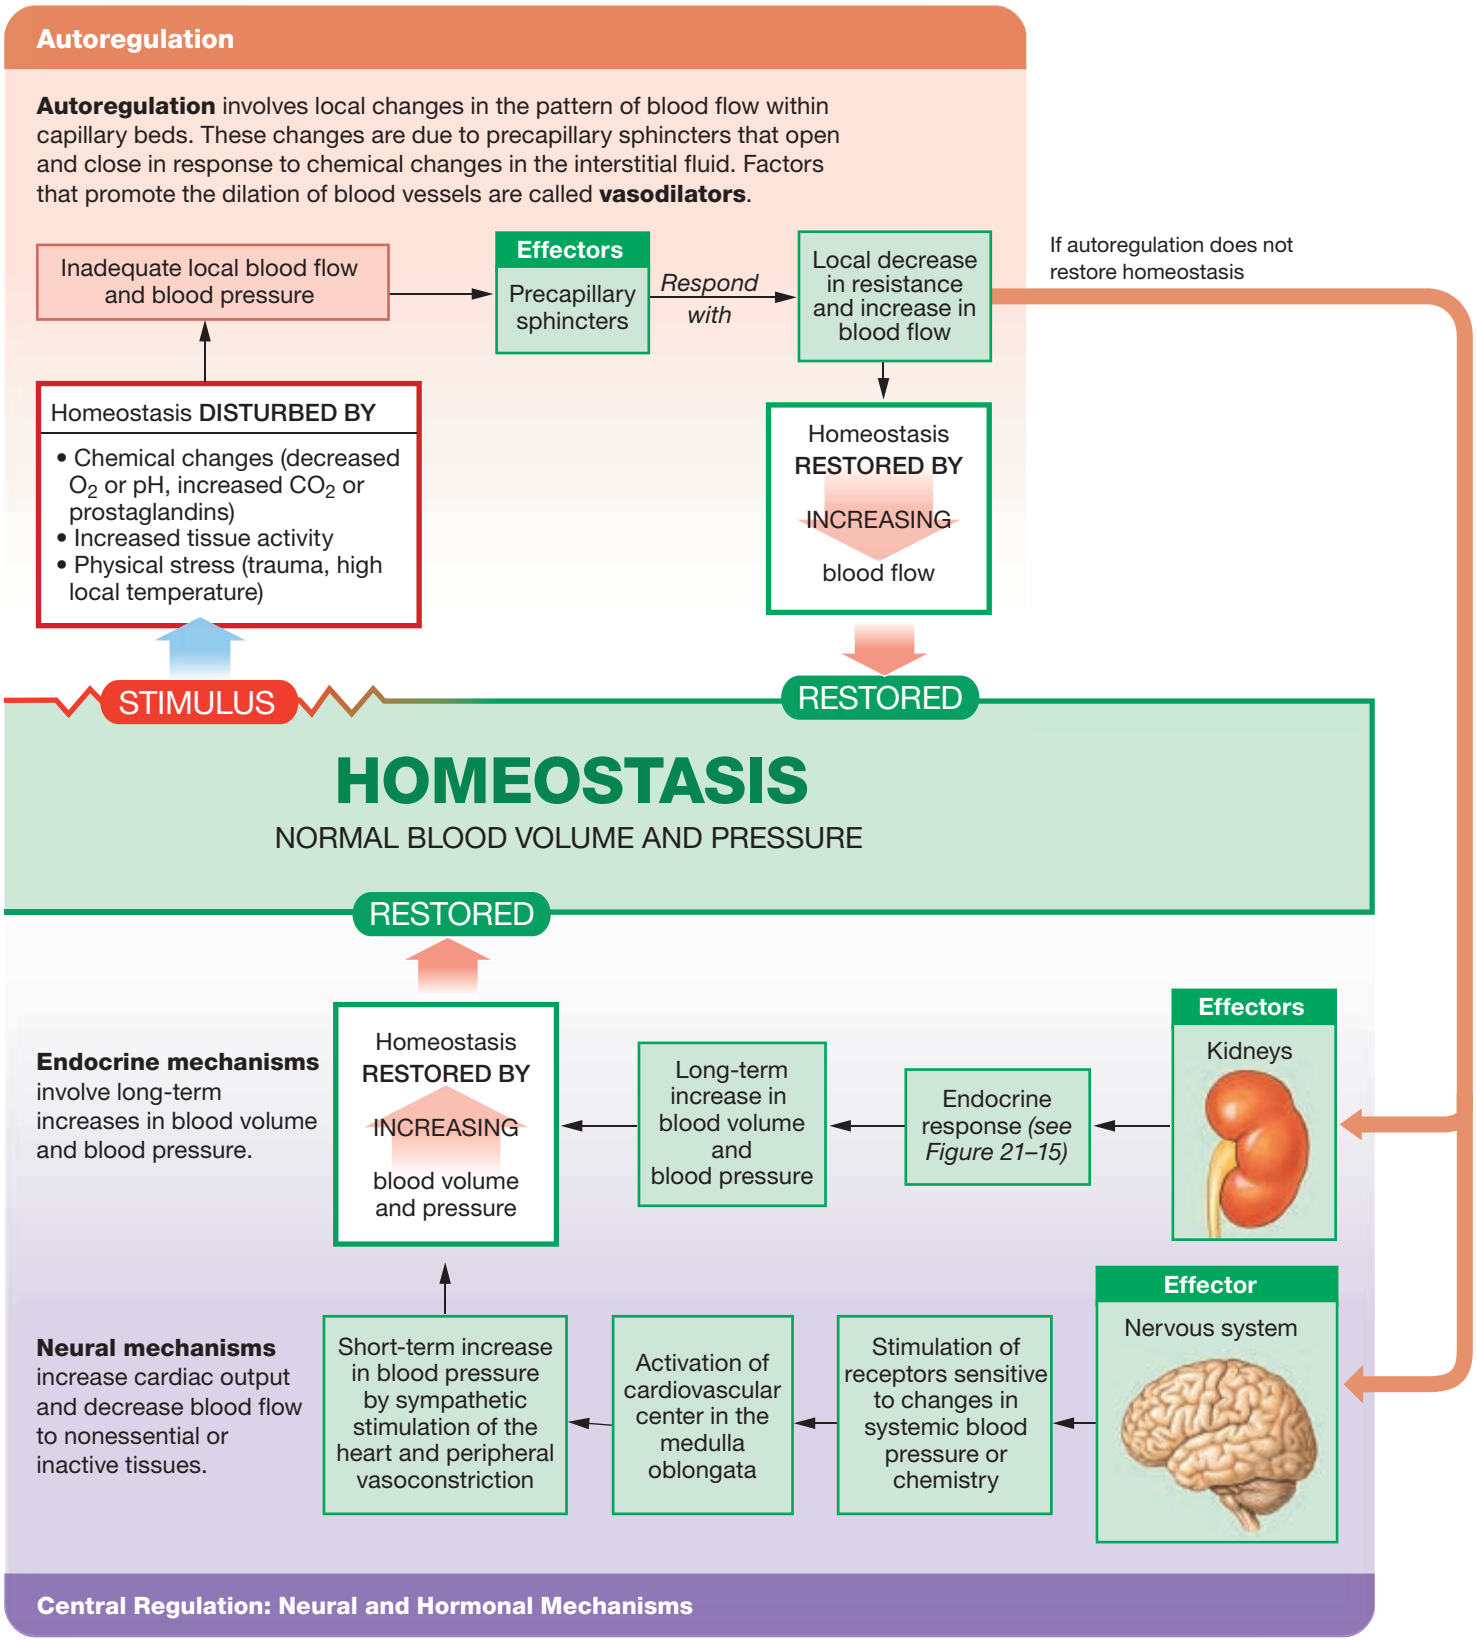
Autoregulation of Blood Flow within Tissues

Under normal resting conditions, cardiac output remains stable, and peripheral resistance within individual tissues is adjusted to control local blood flow. Vasomotion is controlled locally by changes in the concentrations of chemicals and dissolved gases in the interstitial fluids. This process is an example of capillary **autoregulation**.

Factors that promote the dilation of precapillary sphincters are called **vasodilators**. For example, when the dissolved oxygen concentration decreases within a tissue, **local vasodilators** cause the capillary sphincters to relax, so blood flow to the area increases. Local vasodilators include the following:

- Decreased oxygen level or increased CO_2 level in tissue.
- Lactate generated by tissue cells.
- Nitric oxide (NO) released from endothelial cells.

Figure 21–12 Short-Term and Long-Term Cardiovascular Responses. This diagram indicates general mechanisms that compensate for a decrease in blood flow, blood volume, and blood pressure.



? For blood flow to be autoregulated, what types of stimuli signal inadequate local blood flow and blood pressure?

- Rising concentration of potassium ions or hydrogen ions in the interstitial fluid.
- Chemicals released during local inflammation, including histamine. ↩ p. 147
- Elevated local temperature.

The presence of any of these vasodilators indicates that tissue conditions are in some way abnormal. The increase in blood flow, which brings oxygen, nutrients, and buffers, may be sufficient to restore homeostasis.

As noted in Chapter 19, aggregating platelets and damaged tissues produce compounds that stimulate precapillary sphincters to constrict. These compounds are **local vasoconstrictors**. Examples include prostaglandins and thromboxanes released by activated platelets and white blood cells, and the endothelins released by damaged endothelial cells.

Local vasodilators and vasoconstrictors control blood flow within a single capillary bed (look back at Figure 21–4). In high concentrations, these factors also affect arterioles, increasing or decreasing blood flow to all the capillary beds in a given area.

Central Regulation: Neural Mechanisms

The nervous system adjusts cardiac output and peripheral resistance to maintain adequate blood flow to vital tissues and organs. The center primarily responsible for these regulatory activities is the **cardiovascular (CV) center** of the medulla oblongata. The CV center is made up of the *cardiac centers* and the *vasomotor center*. Although these centers are difficult to distinguish anatomically (↩ p. 474), in functional terms, they often act independently.

The cardiac centers are composed of the cardioinhibitory center and the cardioacceleratory center. As noted in Chapter 20, the *cardioacceleratory center* increases cardiac output through sympathetic innervation. The *cardioinhibitory center* decreases cardiac output through parasympathetic innervation. ↩ p. 717 The vasomotor center directs vasomotor responses in blood vessels. Let's look at the functions of these centers.

The Vasomotor Center and Vasomotor Tone

The vasomotor center contains two populations of neurons: (1) a very large group responsible for widespread vasoconstriction and (2) a smaller group responsible for the vasodilation of arterioles in skeletal muscles and the brain. The vasomotor center controls the activity of sympathetic motor neurons:

- *Control of Vasoconstriction.* The neurons innervating peripheral blood vessels in most tissues are *adrenergic*; that is, they release the neurotransmitter norepinephrine (NE). NE stimulates smooth muscles in the walls of arterioles, producing vasoconstriction.
- *Control of Vasodilation.* Vasodilator neurons innervate blood vessels in skeletal muscles and in the brain. The stimulation of these neurons relaxes smooth muscle cells in the walls of arterioles, producing vasodilation. This relaxation is triggered by the appearance of NO in the surroundings. The vasomotor center may control NO release indirectly or directly. The most common vasodilator synapses are *cholinergic*—their axon terminals release ACh. In turn, ACh stimulates endothelial cells in the area to release NO, causing local vasodilation. Other vasodilator synapses are *nitroxidergic*—their axon terminals release NO as a neurotransmitter. Nitric oxide has an immediate and direct relaxing effect on the vascular smooth muscle cells in the area.

In Chapter 16, we saw how autonomic tone sets a background level of neural activity that can increase or decrease on demand. ↩ p. 551 The sympathetic vasoconstrictor nerves are always active, producing a significant **vasomotor tone**. This vasoconstrictor activity normally keeps the arterioles partially constricted. Under maximal stimulation, arterioles constrict to about half their resting diameter. (To dilate fully, an arteriole increases its resting diameter by about 1.5 times.)

Constriction has a large effect on resistance, because, as we saw earlier, resistance increases sharply as the luminal diameter of a vessel decreases. The resistance of a maximally constricted arteriole is roughly 80 *times* that of a fully dilated arteriole. Because blood pressure varies directly with peripheral resistance, the vasomotor center can control arterial blood pressure very effectively by making modest adjustments in vessel diameters. Extreme stimulation of the vasomotor center also produces venoconstriction and mobilizes the venous blood reservoirs.

Reflex Control of Cardiovascular Function by the Cardiovascular Center

The cardiovascular (CV) center detects changes in tissue demand by monitoring arterial blood, especially its blood pressure, pH, and concentrations of dissolved gases. The *baroreceptor reflexes* (*baro-*, pressure) respond to changes in blood pressure, and the *chemoreceptor reflexes* (*chemo-*, chemical) monitor changes in the chemical composition of arterial blood. These reflexes are regulated through a negative feedback loop: The stimulation of a receptor by an abnormal condition leads to a short-term response that counteracts the stimulus and restores normal conditions.

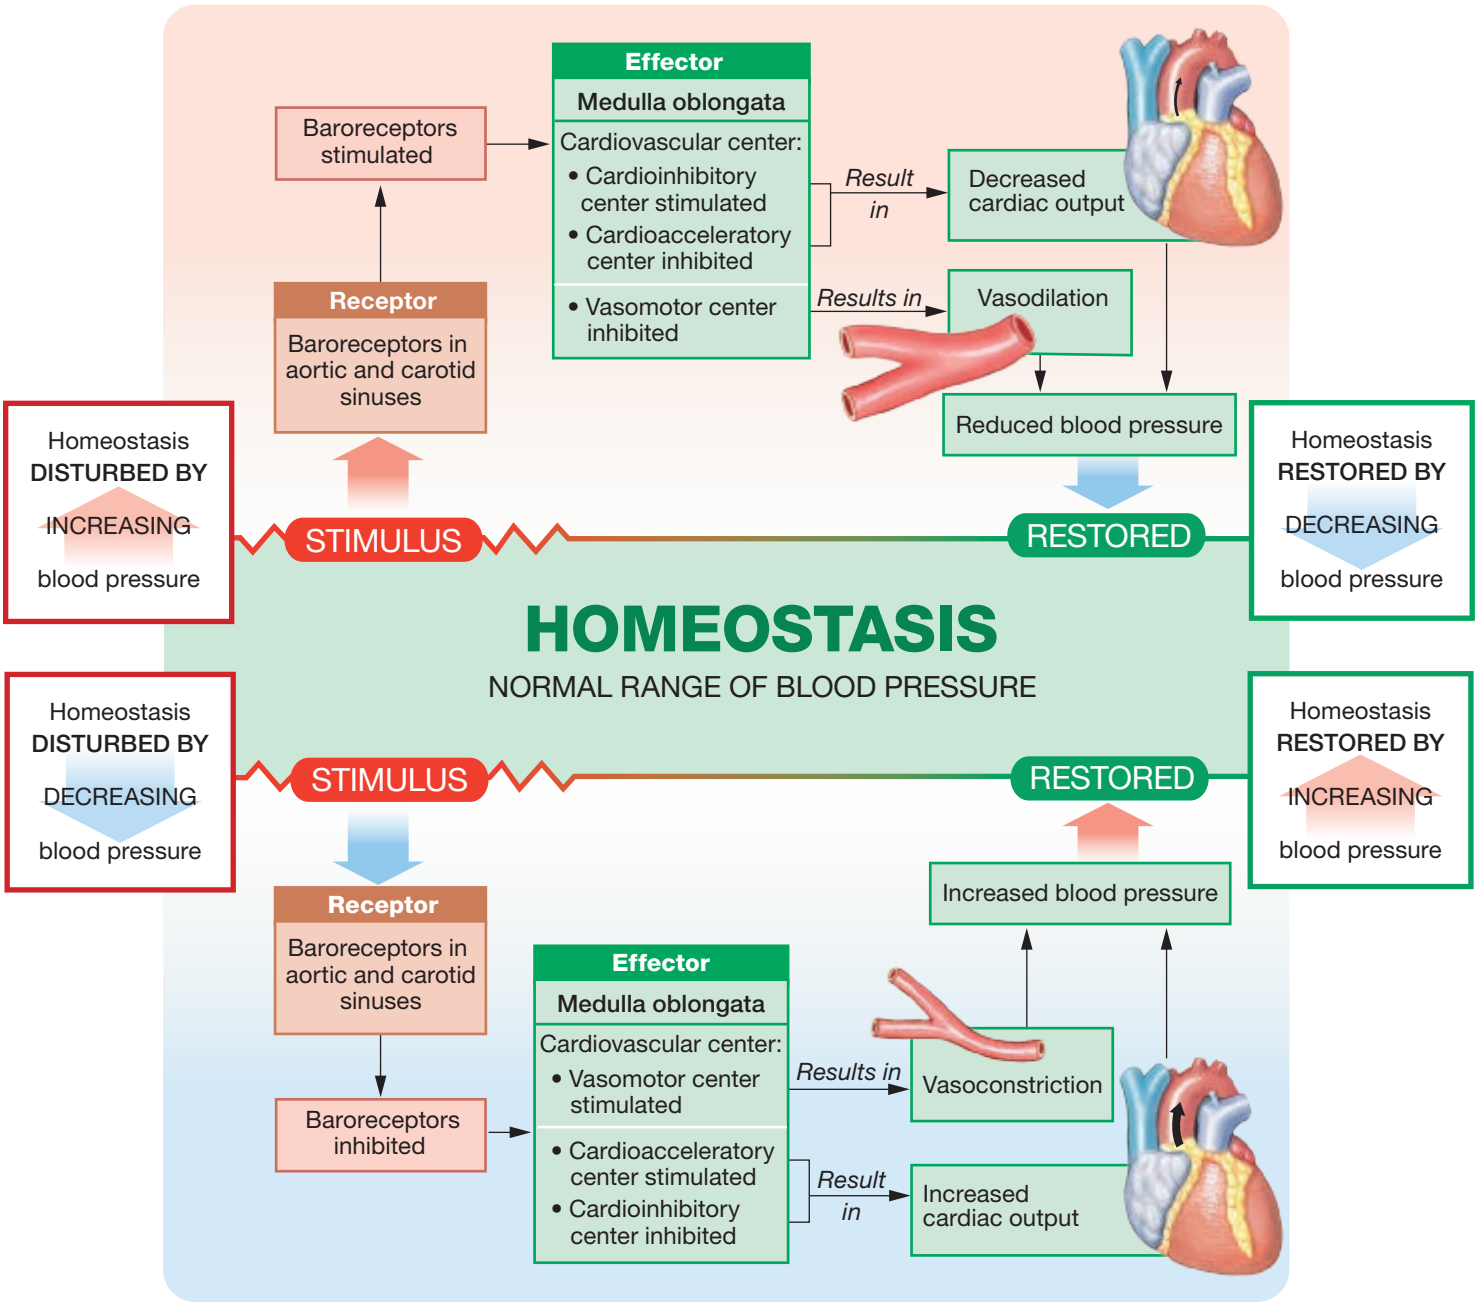
Baroreceptor Reflexes. Baroreceptors are specialized receptors that monitor the degree of stretch in the walls of expandable organs. ↩ p. 520 The baroreceptors involved in cardiovascular regulation are found in the walls of (1) the **carotid sinuses**, expanded chambers near the bases of the *internal carotid arteries* of the neck (look ahead to Figure 21–21); (2) the **aortic sinuses**, pockets in the walls of the ascending aorta adjacent to the heart (look back at Figure 20–7b, p. 698); and (3) the wall of the right atrium. These receptors are part of the **baroreceptor reflexes**, which adjust cardiac output and peripheral resistance to maintain normal arterial pressures.

Aortic baroreceptors monitor blood pressure within the ascending aorta. Any changes trigger the **aortic reflex**, which adjusts blood pressure to maintain adequate blood pressure and blood flow through the systemic circuit. Carotid sinus baroreceptors trigger reflexes that maintain adequate blood flow to the brain. The carotid sinus receptors are extremely sensitive because blood flow to the brain must remain constant. Figure 21–13 presents the basic organization of the baroreceptor reflexes triggered by changes in blood pressure at the carotid and aortic sinuses.

When blood pressure rises, the increased output from the baroreceptors alters activity in the CV center and produces two major effects (see the top half of Figure 21–13):

- *A decrease in cardiac output*, due to parasympathetic stimulation and the inhibition of sympathetic activity. This results from the stimulation of the cardioinhibitory center and the inhibition of the cardioacceleratory center.
- *Widespread peripheral vasodilation*, due to the inhibition of excitatory neurons in the vasomotor center.

Figure 21–13 Baroreceptor Reflexes of the Carotid and Aortic Sinuses.



The decrease in cardiac output reflects primarily a reduction in heart rate due to the release of acetylcholine at the sinoatrial (SA) node. p. 718 The widespread vasodilation lowers peripheral resistance, and this effect, combined with a reduction in cardiac output, leads to a fall in blood pressure to a normal level.

When blood pressure falls below normal, baroreceptor output is reduced accordingly (see the lower half of **Figure 21–13**). This change has two major effects working together to raise blood pressure:

- *An increase in cardiac output*, through the stimulation of sympathetic innervation to the heart. This results from stimulation of the cardioacceleratory center that is accompanied by inhibition of the cardioinhibitory center.
- *Widespread peripheral vasoconstriction*, caused by the stimulation of sympathetic vasoconstrictor neurons by the vasomotor center.

The effects on the heart result from the release of NE by sympathetic neurons innervating the SA node, the atrioventricular (AV) node, and the general myocardium. In a crisis, such as significant blood loss, sympathetic activation occurs, and its effects are enhanced by the release of both NE and epinephrine (E) from the adrenal medullae. The net effect is an immediate increase in heart rate and stroke volume, and a corresponding increase in cardiac output.

The vasoconstriction, which also results from the release of NE by sympathetic neurons, increases peripheral resistance. These adjustments—increased cardiac output and increased peripheral resistance—work together to raise blood pressure.

Atrial baroreceptors monitor blood pressure at the end of the systemic circuit—at the venae cavae and the right atrium. Recall from Chapter 20 that the **Bainbridge reflex** responds to a stretching of the wall of the right atrium. p. 719

Under normal circumstances, the heart pumps blood into the aorta at the same rate at which blood arrives at the right atrium. When blood pressure rises at the right atrium, blood is arriving at the heart faster than it is being pumped out. The atrial baroreceptors correct the situation by stimulating the CV center to increase cardiac output until the backlog of venous blood is removed. Atrial pressure then returns to normal.

A procedure known as the Valsalva maneuver is a simple way to check for normal cardiovascular responses to changes in arterial pressure and venous return. The *Valsalva maneuver* involves trying to exhale forcefully with closed lips and nostrils so that no air can leave the lungs and pressure in the thoracic cavity rises sharply. This action causes reflexive changes in blood pressure and cardiac output due to increased intrathoracic pressure, which impedes venous return to the right atrium. When internal pressures rise, the venae cavae collapse, and venous return decreases. The resulting drop in cardiac output and blood pressure stimulates the aortic and carotid baroreceptors, causing a reflexive increase in heart rate and peripheral vasoconstriction. When the glottis opens and pressures return to normal, venous return increases suddenly and so does cardiac output. Because vasoconstriction has occurred, blood pressure rises sharply, and this inhibits the baroreceptors. As a result, cardiac output, heart rate, and blood pressure quickly return to normal levels.

Chemoreceptor Reflexes. The **chemoreceptor reflexes** respond to changes in carbon dioxide, oxygen, or pH levels in blood and cerebrospinal fluid (CSF) (**Figure 21–14**). The chemoreceptors involved are sensory neurons. They are located in the **carotid bodies**, situated in the neck near the carotid sinus, and the **aortic bodies**, near the arch of the aorta. p. 521 These receptors monitor the composition of arterial blood. Additional chemoreceptors located on the ventrolateral surfaces of the medulla oblongata monitor the composition of CSF.

When chemoreceptors in the carotid bodies or aortic bodies detect either an increase in the carbon dioxide concentration or a decrease in the pH of arterial blood, the cardioacceleratory and vasomotor centers are stimulated. At the same time, the cardioinhibitory center is inhibited. This dual effect causes an increase in cardiac output, peripheral vasoconstriction, and an increase in blood pressure. A decrease in the oxygen level at the aortic bodies has the same effects. Strong stimulation of the carotid or aortic chemoreceptors causes widespread sympathetic activation, with more dramatic increases in heart rate and cardiac output.

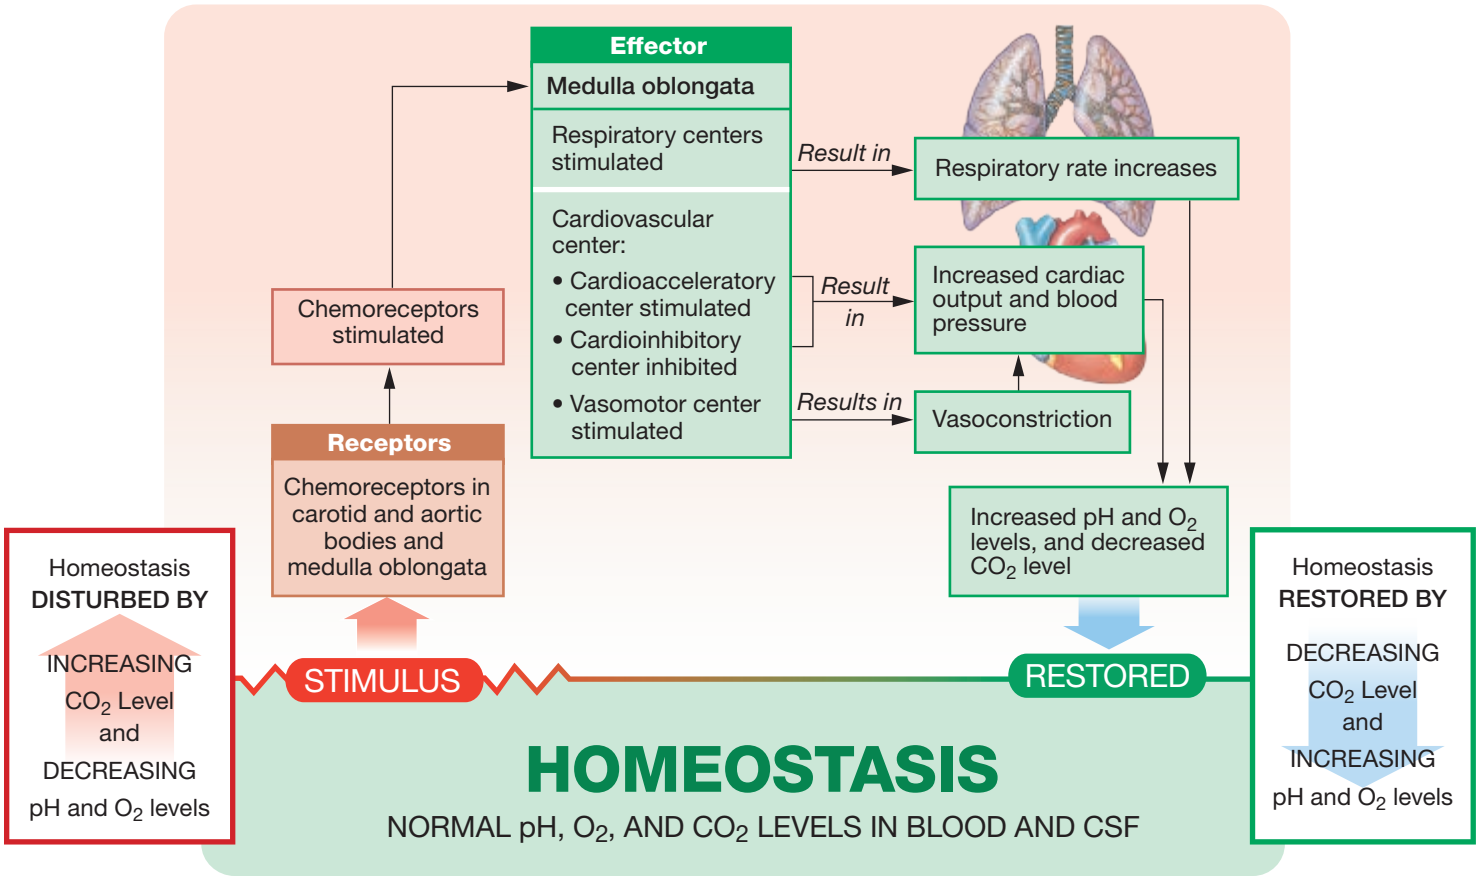
The chemoreceptors of the medulla oblongata are involved primarily with the control of respiratory function, and secondarily with regulating blood flow to the brain. For example, a steep rise in the CSF carbon dioxide level triggers the vasodilation of cerebral vessels, but produces vasoconstriction in most other organs. The result is increased blood flow—and increased oxygen delivery—to the brain.

Coordination of cardiovascular and respiratory activities is vital, because accelerating blood flow in the tissues is useful only if the circulating blood contains an adequate amount of oxygen. The arterial CO_2 level can be decreased and the O_2 level increased most effectively by coordinating cardiovascular and respiratory activities. Chemoreceptor stimulation also stimulates the respiratory centers, and the increase in cardiac output and blood pressure is associated with an increased respiratory rate. In addition, an increase in the respiratory rate accelerates venous return through the action of the respiratory pump. (We consider other aspects of chemoreceptor activity and respiratory control in Chapter 23.)

The Cardiovascular Center and CNS Activities

The output of the cardiovascular center can also be influenced by activities in other areas of the brain. For example,

Figure 21–14 The Chemoreceptor Reflexes.



21

the activation of either division of the autonomic nervous system affects output from the cardiovascular center. A general sympathetic activation stimulates the cardioacceleratory and vasomotor centers. As a result, cardiac output and blood pressure increase. In contrast, when the parasympathetic division is activated, the cardioinhibitory center is stimulated. The result is a decrease in cardiac output. Parasympathetic activity does not directly affect the vasomotor center, but vasodilation takes place as sympathetic activity declines.

The higher brain centers can also affect blood pressure. Our thought processes and emotional states can produce significant changes in blood pressure by influencing cardiac output and vasomotor tone. For example, strong emotions of anxiety, fear, and rage are accompanied by an increase in blood pressure, due to cardiac stimulation and vasoconstriction.

Central Regulation: Endocrine Mechanisms

The endocrine system regulates cardiovascular performance in both the short term and the long term. As we have seen, E and NE from the adrenal medullae stimulate cardiac output and peripheral vasoconstriction. Here we will look at other hormones important in regulating cardiovascular function: (1) antidiuretic hormone (ADH), (2) angiotensin II, (3) erythropoietin (EPO), and (4) the natriuretic peptides (ANP and BNP). ↩ p. 644 All four are concerned primarily with the long-term regulation of blood volume (**Figure 21–15**). ADH and angiotensin II also affect blood pressure.

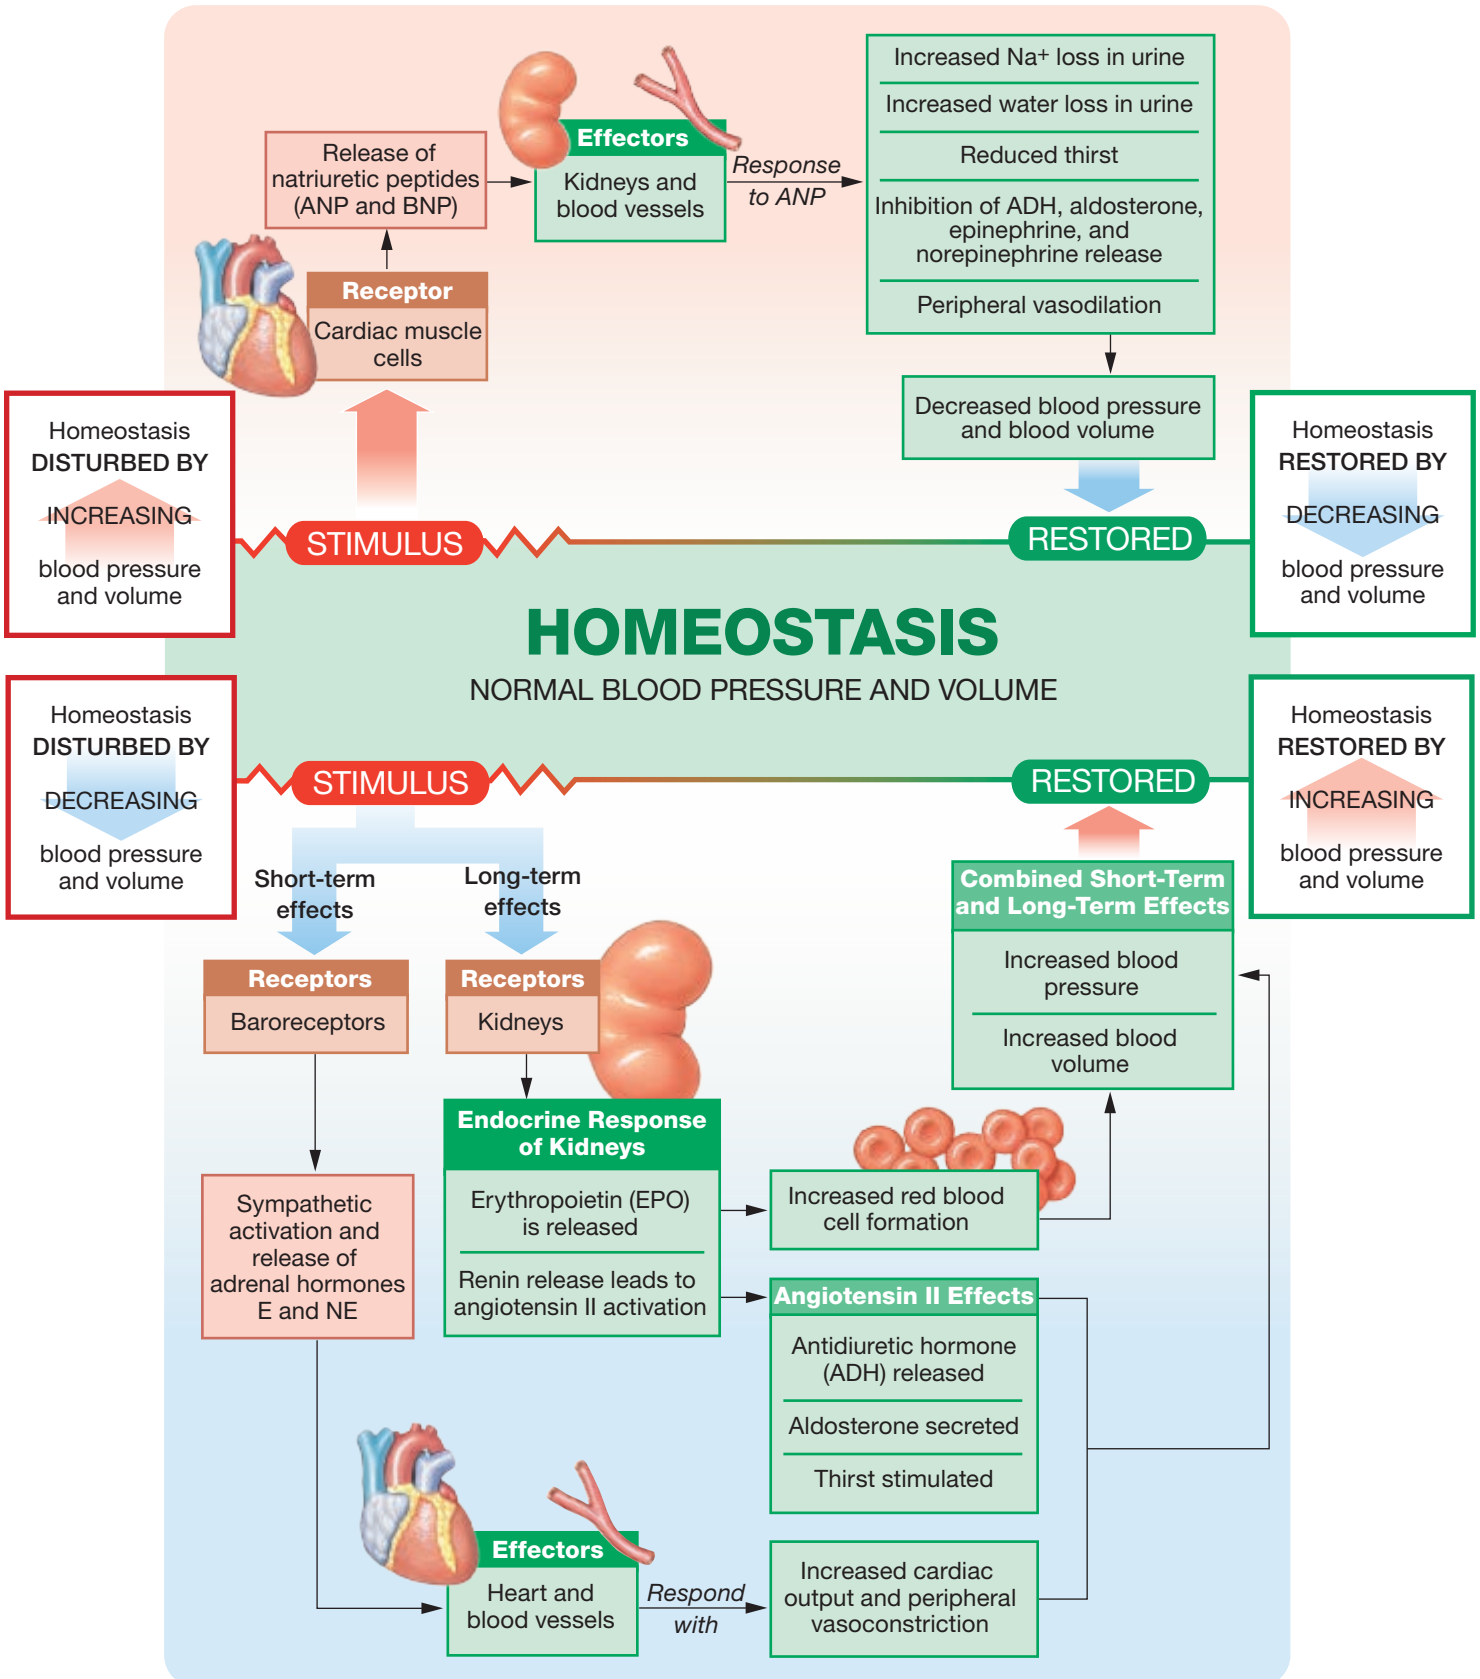
Antidiuretic Hormone

Antidiuretic hormone (ADH) is released at the posterior lobe of the pituitary gland in response to a decrease in blood volume, to an increase in the osmotic concentration of the plasma, or (secondarily) to circulating angiotensin II. It brings about a peripheral vasoconstriction that elevates blood pressure. This hormone also stimulates water conservation by the kidneys, thus preventing a reduction in blood volume that would further reduce blood pressure (see **Figure 21–15**).

Angiotensin II

Angiotensin II appears in the blood when specialized cells in kidney arterioles, called *juxtaglomerular cells*, release the enzyme *renin* (RĒ-nin) in response to a decrease in renal blood pressure (see **Figure 21–15**). Once in the bloodstream, renin starts an enzymatic chain reaction. In the first step, renin converts *angiotensinogen*, a plasma protein produced by the liver, to *angiotensin I*.

Figure 21–15 The Hormonal Regulation of Blood Pressure and Blood Volume.



? What hormones are released as a short-term response to a decrease in blood pressure and blood volume?

In the capillaries of the lungs, *angiotensin-converting enzyme (ACE)* then modifies angiotensin I to angiotensin II, an active hormone with diverse effects.

Angiotensin II has four important functions:

- It stimulates the adrenal production of aldosterone, causing Na^+ reabsorption and K^+ loss by the kidneys.
- It stimulates the secretion of ADH, in turn stimulating water reabsorption by the kidneys and complementing the effects of aldosterone.
- It stimulates thirst, resulting in increased fluid consumption. (The presence of ADH and aldosterone ensures that the additional water consumed will be retained, increasing blood volume.)
- It stimulates cardiac output and triggers the constriction of arterioles, in turn increasing the systemic blood pressure. The effect of angiotensin II on blood pressure is four to eight times greater than the effect of norepinephrine.

Erythropoietin

The kidneys release *erythropoietin (EPO)* if blood pressure falls or if the oxygen content of the blood becomes abnormally low (see **Figure 21–15**). EPO acts directly on blood vessels, causing vasoconstriction, thereby increasing blood pressure. EPO also stimulates the production and maturation of red blood cells. These cells increase the volume and viscosity of the blood and improve its oxygen-carrying capacity.

Natriuretic Peptides

Cardiac muscle cells in the wall of the right atrium of the heart produce *atrial natriuretic peptide* (nā-trē-yū-RET-ik; *natrium*, sodium + *ouresis*, urination), or *ANP*, in response to excessive stretching during diastole. Ventricular muscle cells exposed to comparable stimuli produce a related hormone called *brain natriuretic peptide*, or *BNP*. These peptide hormones reduce blood volume and blood pressure. They do so by (1) increasing sodium ion excretion by the kidneys; (2) promoting water loss by increasing the volume of urine produced; (3) reducing thirst; (4) blocking the release of ADH, aldosterone, epinephrine, and norepinephrine; and (5) stimulating peripheral vasodilation (see **Figure 21–15**). As blood volume and blood pressure decrease, the stresses on the walls of the heart are reduced, and natriuretic peptide production ceases.

Checkpoint

9. **Describe the actions of vasodilators and local vasodilators.**
10. **How would applying slight pressure to the common carotid artery affect your heart rate?**
11. **What effect would vasoconstriction of the renal artery have on blood pressure and blood volume?**

21-4 The cardiovascular system adapts to physiological stress while maintaining a special vascular supply to the brain, heart, and lungs

Learning Outcome Identify the principal blood vessels and functions of the special circulation to the brain, heart, and lungs, and explain the cardiovascular system's homeostatic response to exercise and hemorrhaging.

In this chapter and the previous two, we have considered the blood, the heart, and the blood vessels of the cardiovascular system as individual entities. Yet in our day-to-day lives, the cardiovascular system operates as an integrated complex. These interactions are very important when physical or physiological conditions are changing rapidly. In this section we begin by looking at the patterns of blood supply to the brain, heart, and lungs, in which blood flow is controlled by separate mechanisms. We then look at the patterns of cardiovascular responses to exercise and hemorrhaging.

Vascular Supply to Special Regions

The vasoconstriction that takes place in response to a decrease in blood pressure or an increase in CO_2 level affects many tissues and organs at the same time. The term *special circulation* refers to the vascular supply through organs in which blood flow is controlled by separate mechanisms. Let's consider three important examples: the blood flow to the brain, the heart, and the lungs.

Blood Flow to the Brain

In Chapter 14, we noted that the blood brain barrier isolates most CNS tissue from the general circulation. ↩ p. 473 The brain has a very high demand for oxygen and receives a substantial supply of blood. Under a variety of conditions, blood flow to the brain remains steady at about 750 mL/min. That means that about 12 percent of the cardiac output is delivered to an organ that makes up less than 2 percent of body weight.

Neurons do not have significant energy reserves, and in functional terms the cardiovascular system treats blood flow to the brain as the top priority. Even during a cardiovascular crisis, blood flow through the brain remains as near normal as possible: While the cardiovascular center is calling for widespread peripheral vasoconstriction, the cerebral vessels are instructed to dilate.

Total blood flow to the brain remains relatively constant, but blood flow to specific regions of the brain changes from moment to moment. These changes occur in response to local changes in the composition of interstitial fluid that accompany neural activity. When you read, write, speak, or walk, specific regions of your brain become active. Blood flow to those regions increases almost instantaneously. These changes ensure that the active neurons will receive the oxygen and nutrients they require.

The brain receives arterial blood through four arteries. A slowly developing interruption of flow in any one of these large vessels may not significantly reduce blood flow to the brain as a whole, because these arteries form anastomoses inside the cranium and other vessels may enlarge or establish alternative routes. However, a plaque or a blood clot may still block a small artery, and weakened arteries may rupture. Such incidents temporarily or permanently shut off blood flow to a localized area of the brain, damaging or killing the dependent neurons. Signs and symptoms of a *stroke*, or *cerebrovascular accident (CVA)*, then appear.

Blood Flow to the Heart

The coronary arteries arise at the base of the ascending aorta, where systemic pressures are highest (see Chapter 20 ↩ p. 697). Each time the heart contracts, it squeezes the coronary vessels, so blood flow is reduced. In the left ventricle, systolic pressures are high enough that blood can flow into the myocardium only during diastole. Over this period, elastic rebound helps drive blood along the coronary vessels. Cardiac contractile cells can tolerate these brief circulatory interruptions because they have substantial oxygen reserves.

When you are at rest, coronary blood flow is about 250 mL/min. When the workload on your heart increases, local factors, such as reduced O_2 and increased lactate levels, dilate the coronary vessels and increase blood flow. Epinephrine released during sympathetic stimulation promotes the vasodilation of coronary vessels. It also increases heart rate and the strength of cardiac contractions. As a result, coronary blood flow increases while vasoconstriction occurs in other tissues.

For reasons that are not clear, some people have *coronary spasms*. These spasms can temporarily restrict coronary circulation and produce symptoms of angina. The heart's ability to increase its output, even under maximal stimulation, can be limited by certain conditions. These conditions include a permanent restriction or blockage of coronary vessels (as in coronary artery disease) and tissue damage (as caused by a myocardial infarction). When the cardiac workload increases much above the resting level, individuals with these conditions experience signs and symptoms of *heart failure*.

Blood Flow to the Lungs

The lungs have about 300 million *alveoli* (al-VĒ-ō-lī; *alveolus*, sac), delicate epithelial pockets where gas exchange takes place. An extensive capillary network surrounds each alveolus. Local responses to the oxygen level within each alveolus regulate blood flow through the lungs. How does this local regulation work? When an alveolus contains plenty of oxygen, its blood vessels dilate. Blood flow then increases, promoting the absorption of oxygen from air inside the alveolus. When the oxygen content of the air is very low, the vessels constrict. They shunt blood to other alveoli that contain more oxygen. This local mechanism makes the respiratory system very efficient. There is no benefit in circulating blood through the capillaries of an alveolus that contains little oxygen.

This mechanism is precisely the opposite of that in other tissues, where a decline in the oxygen level causes local vasodilation rather than vasoconstriction. The difference makes functional sense, but its physiological basis remains unclear.

Blood pressure in pulmonary capillaries (average: 10 mm Hg) is lower than that in systemic capillaries. The BCOP (25 mm Hg) is the same as elsewhere in the bloodstream. As a result, reabsorption exceeds filtration in pulmonary capillaries. Fluid moves continuously into the pulmonary capillaries across the alveolar surfaces. This flow prevents fluid from building up in the alveoli and interfering with the diffusion of respiratory gases. If the blood pressure in pulmonary capillaries rises above 25 mm Hg, fluid enters the alveoli, causing *pulmonary edema*.

The Cardiovascular Response to Exercise

At rest, cardiac output averages about 5800 mL/min (5.8 L/min). That amount changes dramatically during exercise. In addition, the pattern of blood distribution changes markedly, as detailed in Table 21–2.

Light Exercise

Before you begin to exercise, your heart rate increases slightly due to a general rise in sympathetic activity as you think about the workout ahead. As you begin light exercise, three interrelated changes take place:

- *Extensive vasodilation occurs* as skeletal muscles consume oxygen more quickly. Peripheral resistance decreases, blood flow through the capillaries increases, and blood enters the venous system at a faster rate.
- *The venous return increases* as skeletal muscle contractions squeeze blood along the peripheral veins and faster breathing pulls blood into the venae cavae by the respiratory pump.
- *Cardiac output rises*, primarily in response to (1) increased venous return (the Frank–Starling principle) and (2) atrial

Table 21–2 Changes in Blood Distribution at Rest and during Exercise

	Tissue Blood Flow (mL/min)		
Organ	Rest	Light Exercise	Strenuous Exercise
Skeletal muscles	1200	4500	12,500
Heart	250	350	750
Brain	750	750	750
Skin	500	1500	1900
Kidney	1100	900	600
Abdominal viscera	1400	1100	600
Miscellaneous	600	400	400
Total cardiac output	5800	9500	17,500

stretching (the Bainbridge reflex). ↩ p. 719 Some sympathetic stimulation occurs, leading to increases in heart rate and contractility, but the sympathetic nervous system is not greatly activated. The increased cardiac output keeps pace with the elevated demand, and arterial pressures are maintained despite the drop in peripheral resistance.

This regulation by venous feedback produces a gradual increase in cardiac output to about double resting levels. The increase supports accelerated blood flow to skeletal muscles, cardiac muscle, and the skin. The flow to skeletal and cardiac muscles increases as arterioles and precapillary sphincters dilate in response to local factors. The flow to the skin increases in response to the rise in body temperature.

Heavy Exercise

At higher levels of exertion, other physiological adjustments take place as the cardiac and vasomotor centers activate the sympathetic nervous system. Cardiac output increases toward maximal levels. Major changes in the peripheral distribution of blood improve blood flow to active skeletal muscles.

Under intense sympathetic stimulation, the cardioacceleratory center can increase cardiac output to levels as high as 20–25 L/min. But that is still not enough to meet the demands of active skeletal muscles unless the vasomotor center severely restricts the blood flow to "nonessential" organs, such as those of the digestive system. During exercise at maximal levels, your blood essentially races between the skeletal muscles and the lungs and heart. Although blood flow to most tissues is diminished, skin perfusion increases further, to cool the body as body temperature continues to climb. Only the blood supply to the brain remains unaffected.

Exercise, Cardiovascular Fitness, and Health

Cardiovascular performance improves significantly with training. **Table 21–3** compares the cardiac performance of athletes with that of nonathletes. Trained athletes have larger hearts and greater stroke volumes than do nonathletes. These functional differences are important—recall that cardiac output is equal to the stroke volume times the heart rate. For the same cardiac output, the person with a greater stroke volume has a slower heart rate. An athlete at rest can maintain normal blood flow to peripheral tissues at a heart rate as low as 32 bpm (beats per minute). When necessary, the athlete's cardiac output can increase to levels 50 percent higher than those of nonathletes. Thus, a trained athlete can tolerate sustained levels of activity that are well beyond the capabilities of nonathletes.

Exercise and Cardiovascular Disease

Regular exercise can lower the risk of cardiovascular disease. Even a moderate exercise routine (jogging 5 miles a week, for example) can lower total blood cholesterol levels. Exercise lowers cholesterol by stimulating enzymes that help move *low-density lipoproteins* (*LDLs*, or so-called "bad cholesterol") from the blood to the liver. In the liver, the cholesterol is converted to bile and excreted from the body. Exercise also increases the size of the lipoprotein particles that carry cholesterol, making it harder for small proteins to lodge in the vessel walls. A high cholesterol level is one of the major risk factors for atherosclerosis, which leads to cardiovascular disease and strokes. In addition, a healthy lifestyle that includes regular exercise, a balanced diet, weight control, and not smoking reduces stress, lowers blood pressure, and slows the formation of plaques.

Regular moderate exercise (30 minutes most days of the week) may cut the incidence of heart attack, or *myocardial infarction*, almost in half. However, only an estimated 8 percent of adults in the United States currently exercise at the recommended level. Exercise also speeds recovery after a heart attack. Regular light-to-moderate exercise (such as walking, jogging, or bicycling), coupled with a low-fat diet and a low-stress lifestyle, reduces symptoms of *coronary artery disease* (such as *angina*, an-JĪ-nuh; chest pain). Such exercise also improves a person's mood and overall quality of life. However, exercise does not remove underlying medical problems. For example, atherosclerotic plaques, described on p. 732, do not disappear and seldom grow smaller with exercise.

There is no evidence that *intense* athletic training lowers the incidence of cardiovascular disease. On the contrary, the strains placed on all body systems—including the cardiovascular system—during an ultramarathon, Ironman Triathlon, or other extreme athletic event can be severe. People with congenital aneurysms, cardiomyopathy (chronic disease of heart muscle), or cardiovascular disease risk fatal cardiovascular problems, such as an arrhythmia or heart attack, during severe exercise. Even healthy individuals can develop acute physiological disorders, such as kidney failure, after extreme exercise.

Table 21–3 Effects of Training on Cardiovascular Performance

Subject	Heart Weight (g)	Stroke Volume (mL)	Heart Rate (bpm)	Cardiac Output (L/min)	Blood Pressure (systolic/diastolic)
Nonathlete (rest)	300	60	83	5.0	120/80
Nonathlete (maximum)		104	192	19.9	187/75
Trained athlete (rest)	500	100	53	5.3	120/80
Trained athlete (maximum)		167	182	30.4	200/90*

* Diastolic pressures in athletes during maximal activity have not been accurately measured.

The Cardiovascular Response to Hemorrhaging and Shock

In Chapter 19, we considered the local cardiovascular reaction to a break in the wall of a blood vessel. ↩ p. 679 When hemostasis fails to prevent significant blood loss, the entire cardiovascular system makes adjustments (Figure 21–16). The immediate problem is to maintain adequate blood pressure and peripheral blood flow. The long-term problem is to restore normal blood volume.

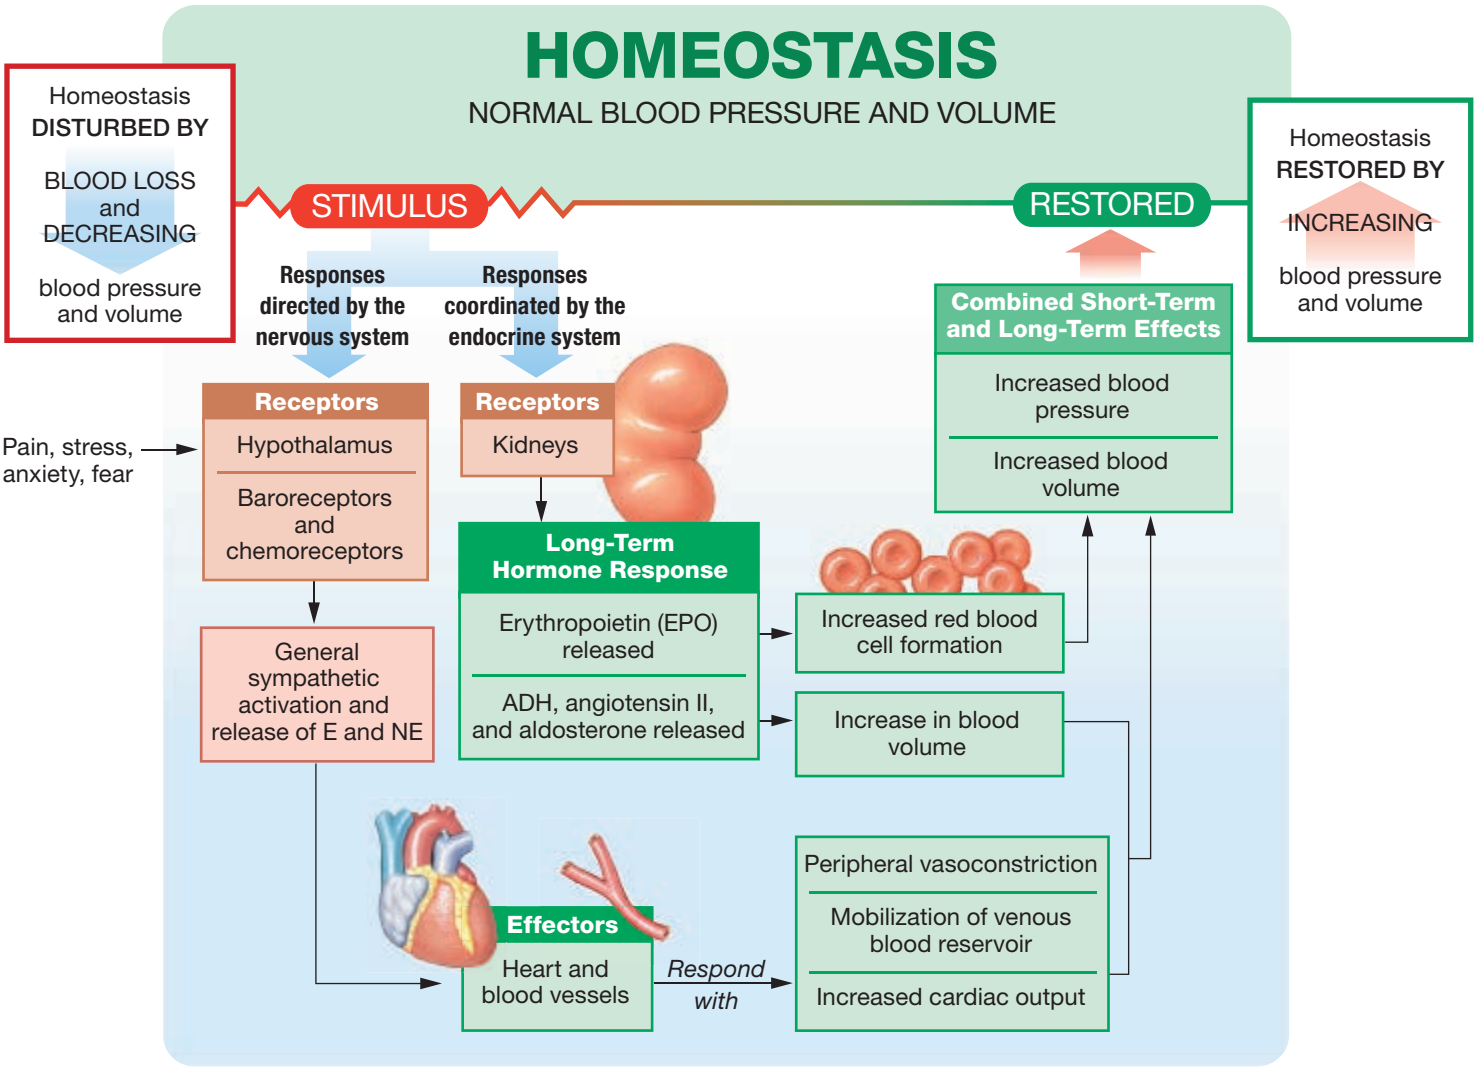
Short-Term Elevation of Blood Pressure

Almost as soon as the pressure starts to decrease, several short-term responses appear:

- In the initial neural response, carotid and aortic reflexes increase cardiac output and cause peripheral vasoconstriction. With blood volume reduced, an increase in heart rate, typically up to 180–200 bpm, maintains cardiac output.
- The combination of stress and anxiety stimulates the sympathetic nervous system headquarters in the hypothalamus, which in turn triggers a further increase in vasomotor tone, constricting the arterioles and raising blood pressure. At the same time, venoconstriction mobilizes the venous blood reservoirs and quickly improves venous return.
- Short-term hormonal effects also occur. For instance, sympathetic activation causes the adrenal medullae to secrete E and NE. These hormones increase cardiac output and extend peripheral vasoconstriction.

This combination of short-term responses elevates blood pressure and improves peripheral blood flow. It often restores normal arterial pressures and peripheral circulation after blood losses of up to 20 percent of total blood volume. Such adjustments are more than enough to compensate for the blood loss when you donate blood. (Most blood banks collect 500 mL of

Figure 21–16 Cardiovascular Responses to Blood Loss. These mechanisms cope with blood losses equivalent to approximately 30 percent of total blood volume.



whole blood, roughly 10 percent of your total blood volume.) If compensatory mechanisms fail, the individual develops signs of *shock*.

Long-Term Restoration of Blood Volume

Short-term responses temporarily compensate for a reduction in blood volume. Long-term responses are geared to restoring normal blood volume. This process can take several days after a serious hemorrhage. The responses include the following:

- The decrease in capillary blood pressure triggers a recall of fluids from the interstitial spaces.
- Aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing a further reduction in blood volume.
- Thirst increases, and the digestive tract absorbs additional water. This intake of fluid increases the blood volume and ultimately replaces the interstitial fluids "borrowed" at the capillaries.
- Erythropoietin targets the red bone marrow. It stimulates the maturation of red blood cells, which increases blood volume and improves oxygen delivery to peripheral tissues.
- ADH release by the posterior lobe of the pituitary gland and the production of angiotensin II enhance vasoconstriction.

Checkpoint

12. **Why does blood pressure increase during exercise?**
13. **Name the immediate and long-term problems related to the cardiovascular response to hemorrhaging.**
14. **Explain the role of aldosterone and ADH in long-term restoration of blood volume.**

See the blue Answers tab at the back of the book.

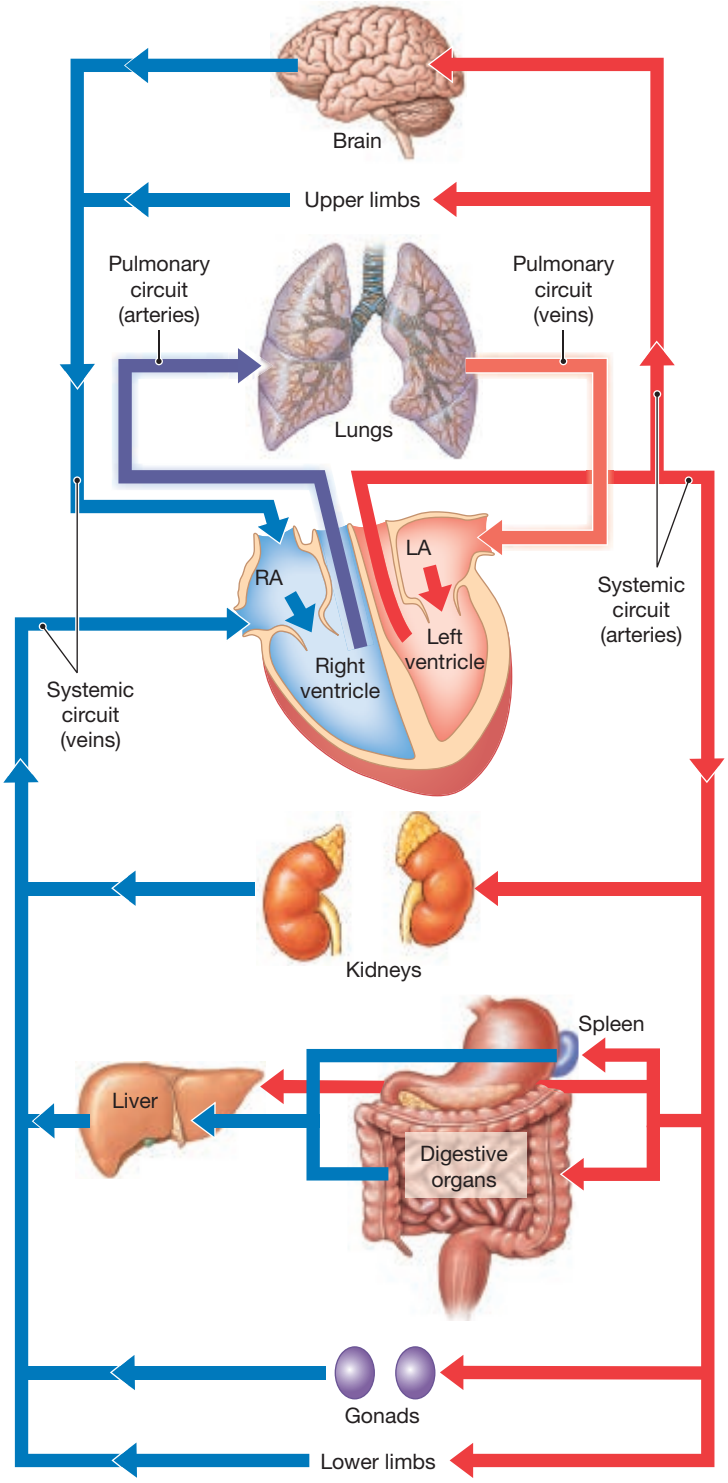
21-5 The vessels of the cardiovascular system make up both pulmonary and systemic circuits

Learning Outcome Describe the pulmonary and systemic circuits of the cardiovascular system.

You already know that the cardiovascular system consists of the *pulmonary circuit* and the *systemic circuit*. The pulmonary circuit consists of arteries and veins that transport blood between the heart and the lungs. This circuit begins at the right ventricle and ends at the left atrium. From the left ventricle, the arteries of the systemic circuit transport oxygenated blood and nutrients to all organs and tissues. Veins of the systemic circuit ultimately return deoxygenated blood to the right atrium. Figure 21–17 summarizes the main distribution routes within the pulmonary and systemic circuits.

In the pages that follow, we examine the vessels of the pulmonary and systemic circuits further. As you study these vessels, keep in mind some general observations about their organization. First, the peripheral distributions of arteries and veins on the body's left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles. Corresponding arteries and veins usually follow the same path. For example, the left and right subclavian *arteries* parallel the left and right subclavian *veins*. In addition, a single

Figure 21–17 A Schematic Overview of the Pattern of Circulation. RA stands for right atrium, LA for left atrium.



vessel may have several names as it crosses specific anatomical boundaries. These names make accurate anatomical descriptions possible when the vessel extends far into the periphery. For example, the *external iliac artery* becomes the *femoral artery* as it leaves the trunk and enters the lower limb. Finally, several arteries and veins usually service tissues and organs. Often, anastomoses between adjacent arteries or veins reduce the impact of a temporary or even permanent blockage, or *occlusion*, in a single blood vessel.

Checkpoint

15. **Identify the two circuits of the cardiovascular system.**
16. **Identify the major patterns of blood vessel organization seen in the pulmonary and systemic circuits of the cardiovascular system.**

See the blue Answers tab at the back of the book.

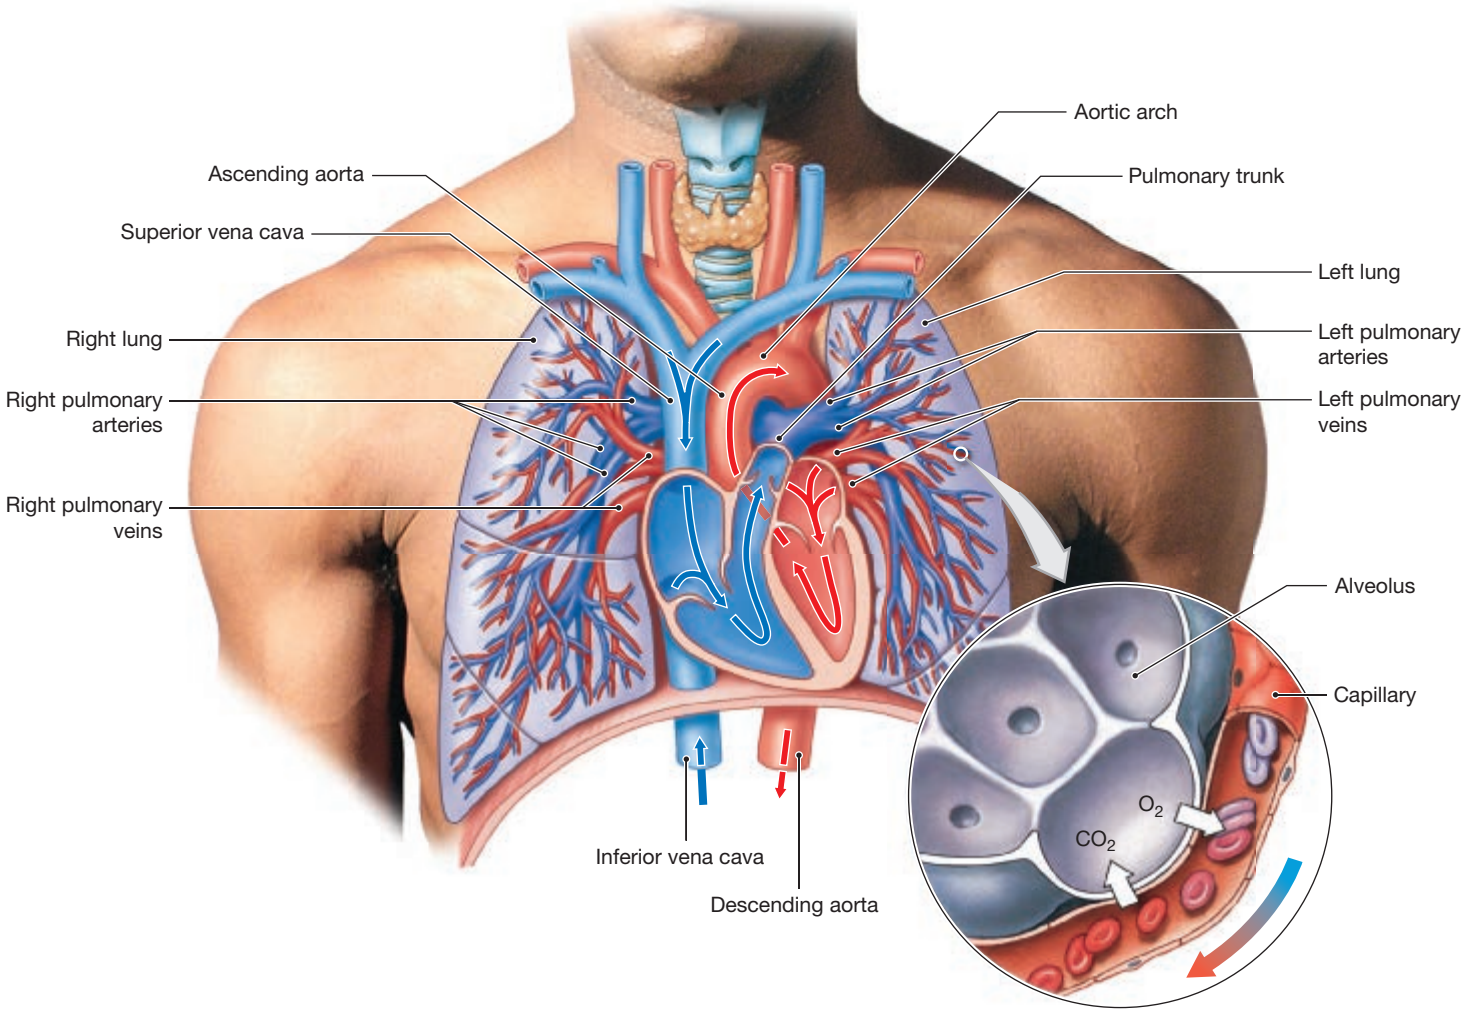
21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins

Learning Outcome Identify the major arteries and veins of the pulmonary circuit.

Blood entering the right atrium has just returned from the peripheral capillary beds, where it released oxygen and absorbed carbon dioxide. After traveling through the right atrium and ventricle, this deoxygenated blood enters the pulmonary trunk, the start of the pulmonary circuit (Figure 21–18). At the lungs, oxygen is replenished, and carbon dioxide is released. The oxygenated blood returns to the heart for distribution by the systemic circuit.

Compared with the systemic circuit, the pulmonary circuit is short: The base of the pulmonary trunk and the lungs are only about 15 cm (6 in.) apart.

Figure 21–18 The Pulmonary Circuit. The pulmonary circuit consists of pulmonary arteries, which deliver deoxygenated blood from the right ventricle to the lungs; pulmonary capillaries, where gas exchange occurs; and pulmonary veins, which deliver oxygenated blood to the left atrium. As the enlarged view shows, diffusion across the capillary walls at alveoli removes carbon dioxide and provides oxygen to the blood. ATLAS: Plates 42a; 44c; 47b



The arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry deoxygenated blood. (For this reason, these color-coded diagrams show the pulmonary arteries in blue, the same color as systemic veins.) As the pulmonary trunk curves over the superior border of the heart, it gives rise to the **left** and **right pulmonary arteries**. These large arteries enter the lungs before branching repeatedly, giving rise to smaller and smaller arteries. The smallest branches, the *pulmonary arterioles*, provide blood to capillary networks that surround *alveoli*. The walls of these small air pockets are thin enough for gas to be exchanged between the capillary blood and inspired air. As oxygenated blood leaves the alveolar capillary network, it enters venules that in turn unite to form larger vessels carrying blood toward the **pulmonary veins**. These four veins, two from each lung, empty into the left atrium, to complete the pulmonary circuit.

Tips & Tools

Arteries and veins are defined by the direction of blood flow relative to the heart, not by the oxygen content of the blood they carry. So if you remember that ***a***rteries carry blood ***a***way from the heart, and veins carry blood toward the heart, you can remember that the pulmonary ***a***rteries carry oxygen-poor blood ***a***way from the heart to the lungs, and the pulmonary veins deliver oxygen-rich blood to the heart.

Checkpoint

17. **Name the blood vessels that enter and exit the lungs, and whether they contain primarily oxygenated or deoxygenated blood.**
18. **Trace the path of a drop of blood through the lungs, beginning at the right ventricle and ending at the left atrium.**

See the blue Answers tab at the back of the book.

21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the lungs, and returns deoxygenated blood to the right atrium

Learning Outcome Identify the major arteries and veins of the systemic circuit.

The systemic circuit supplies the capillary beds in all parts of the body not serviced by the pulmonary circuit. This circuit begins at the left ventricle and ends at the right atrium. At any moment the systemic circuit contains about 84 percent of total blood volume.

Systemic Arteries

Figure 21–19 provides an overview of the systemic arterial system and shows the relative locations of major systemic arteries. Figures 21–20 to 21–25 show the detailed distribution of these vessels and their branches. By convention, several large arteries are called *trunks*. Examples are the *pulmonary*, *brachiocephalic*, *thyrocervical*, and *celiac trunks*. Most of the major arteries are paired, with one artery of each pair on each side of the body. For this reason, the terms *right* and *left* appear in figures only when the arteries on both sides are labeled.

The Ascending Aorta

The **ascending aorta** (Figure 21–20) begins at the aortic valve of the left ventricle. The left and right coronary arteries originate in the aortic sinus at the base of the ascending aorta, just superior to the aortic valve. The distribution of coronary vessels was described in Chapter 20 and illustrated in Figure 20–8, p. 699.

The Aortic Arch

The **aortic arch** curves like the handle of a cane across the superior surface of the heart, connecting the ascending aorta with the *descending aorta* (see Figure 21–19). Three elastic arteries originate along the aortic arch and deliver blood to the head, neck, shoulders, and upper limbs: (1) the **brachiocephalic** (brā-kē-ō-se-FAL-ik) **trunk**, (2) the **left common carotid artery**, and (3) the **left subclavian artery** (Figure 21–21). The brachiocephalic trunk, also called the *innominate artery* (i-NOM-i-nat; unnamed), ascends for a short distance before branching to form the **right subclavian artery** and the **right common carotid artery**.

We have only one brachiocephalic trunk, with the left common carotid and left subclavian arteries arising separately from the aortic arch. However, in terms of their peripheral distribution, the vessels on the left side are mirror images of those on the right side. Figures 21–20 and 21–22 illustrate the major branches of these arteries.

The Subclavian Arteries. The subclavian arteries supply blood to the arms, chest wall, shoulders, back, and CNS (see Figures 21–19 and 21–20). Three major branches arise before a subclavian artery leaves the thoracic cavity: (1) the **internal thoracic artery**, supplying the pericardium and anterior wall of the chest; (2) the **vertebral artery**, which provides blood to the brain and spinal cord; and (3) the **thyrocervical trunk**, which provides blood to muscles and other tissues of the neck, shoulder, and upper back.

After leaving the thoracic cavity and passing across the superior border of the first rib, the subclavian is called the **axillary artery**. This artery crosses the axilla to enter the arm, where it gives rise to *humeral circumflex arteries*, which supply structures near the head of the humerus. Distally, it becomes the **brachial artery**, which supplies blood to the rest of the upper limb. The brachial artery gives rise to the *deep brachial artery*, which supplies deep structures on the posterior aspect of the arm, and the *ulnar collateral arteries*, which supply the area around the elbow.

Figure 21–19 An Overview of the Major Systemic Arteries.

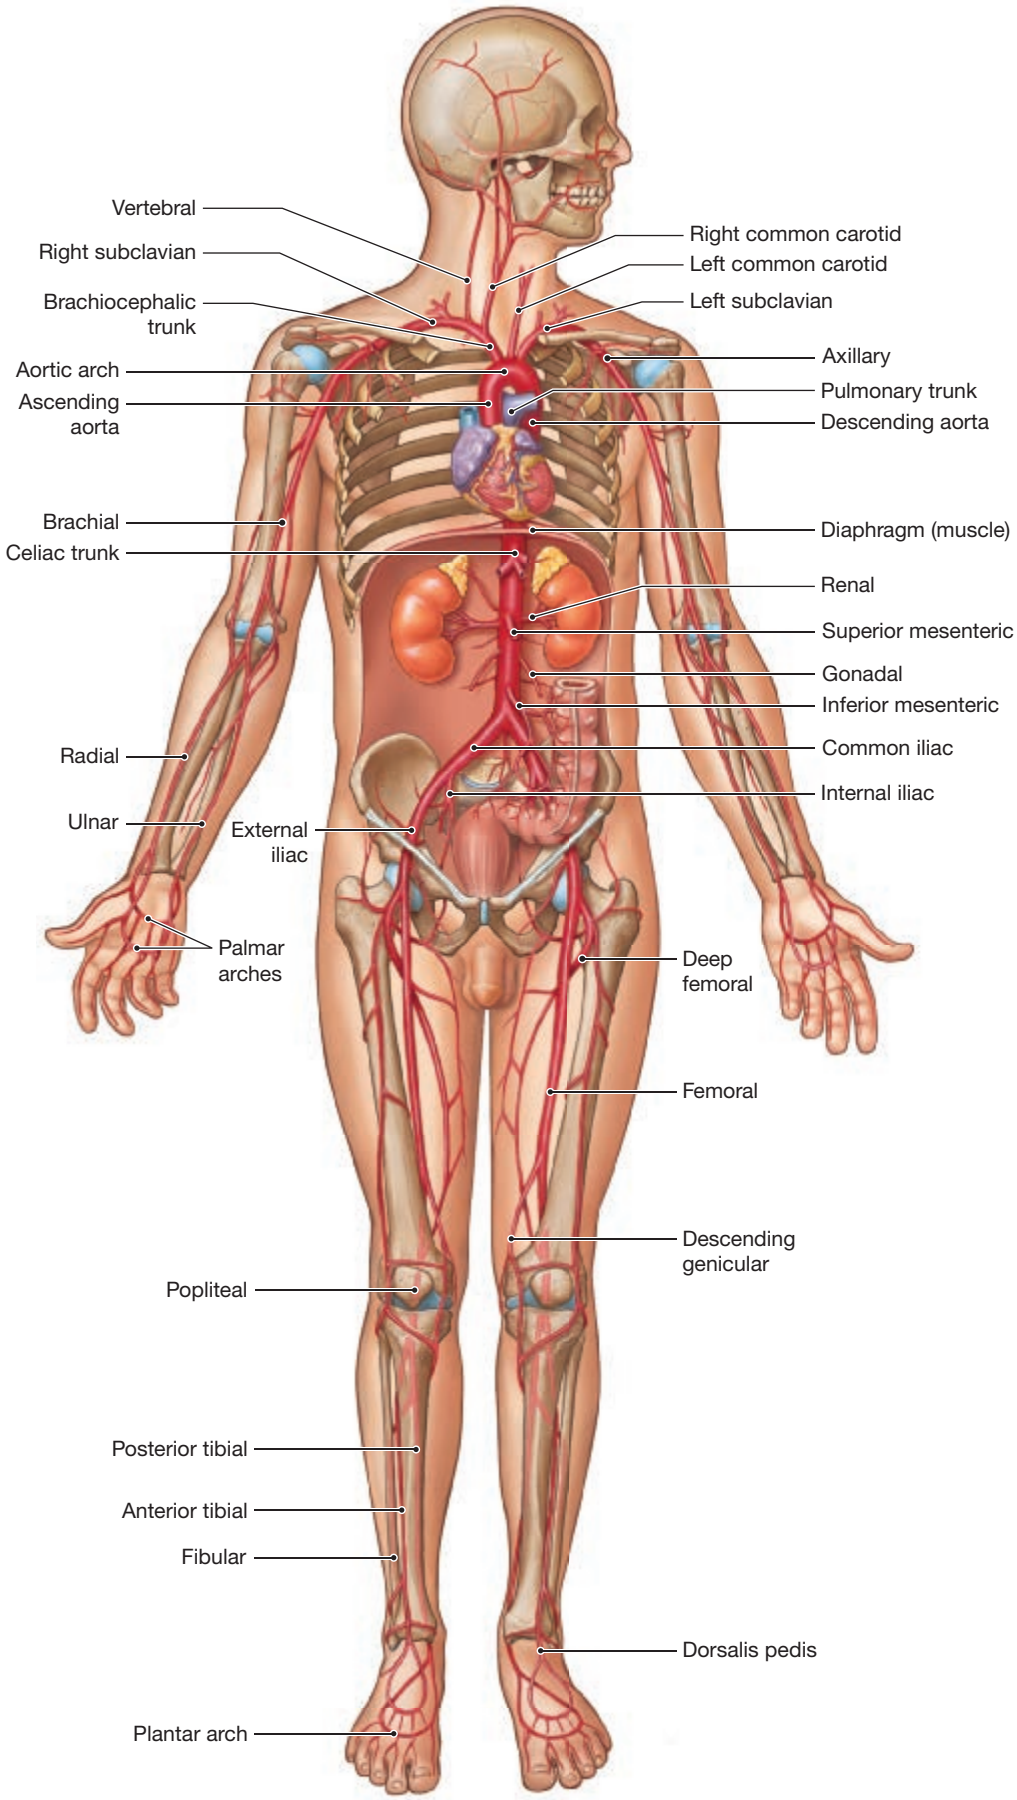


Figure 21–20 Arteries of the Chest and Upper Limb. ATLAS: Plates 27a–c; 29c; 30; 45a

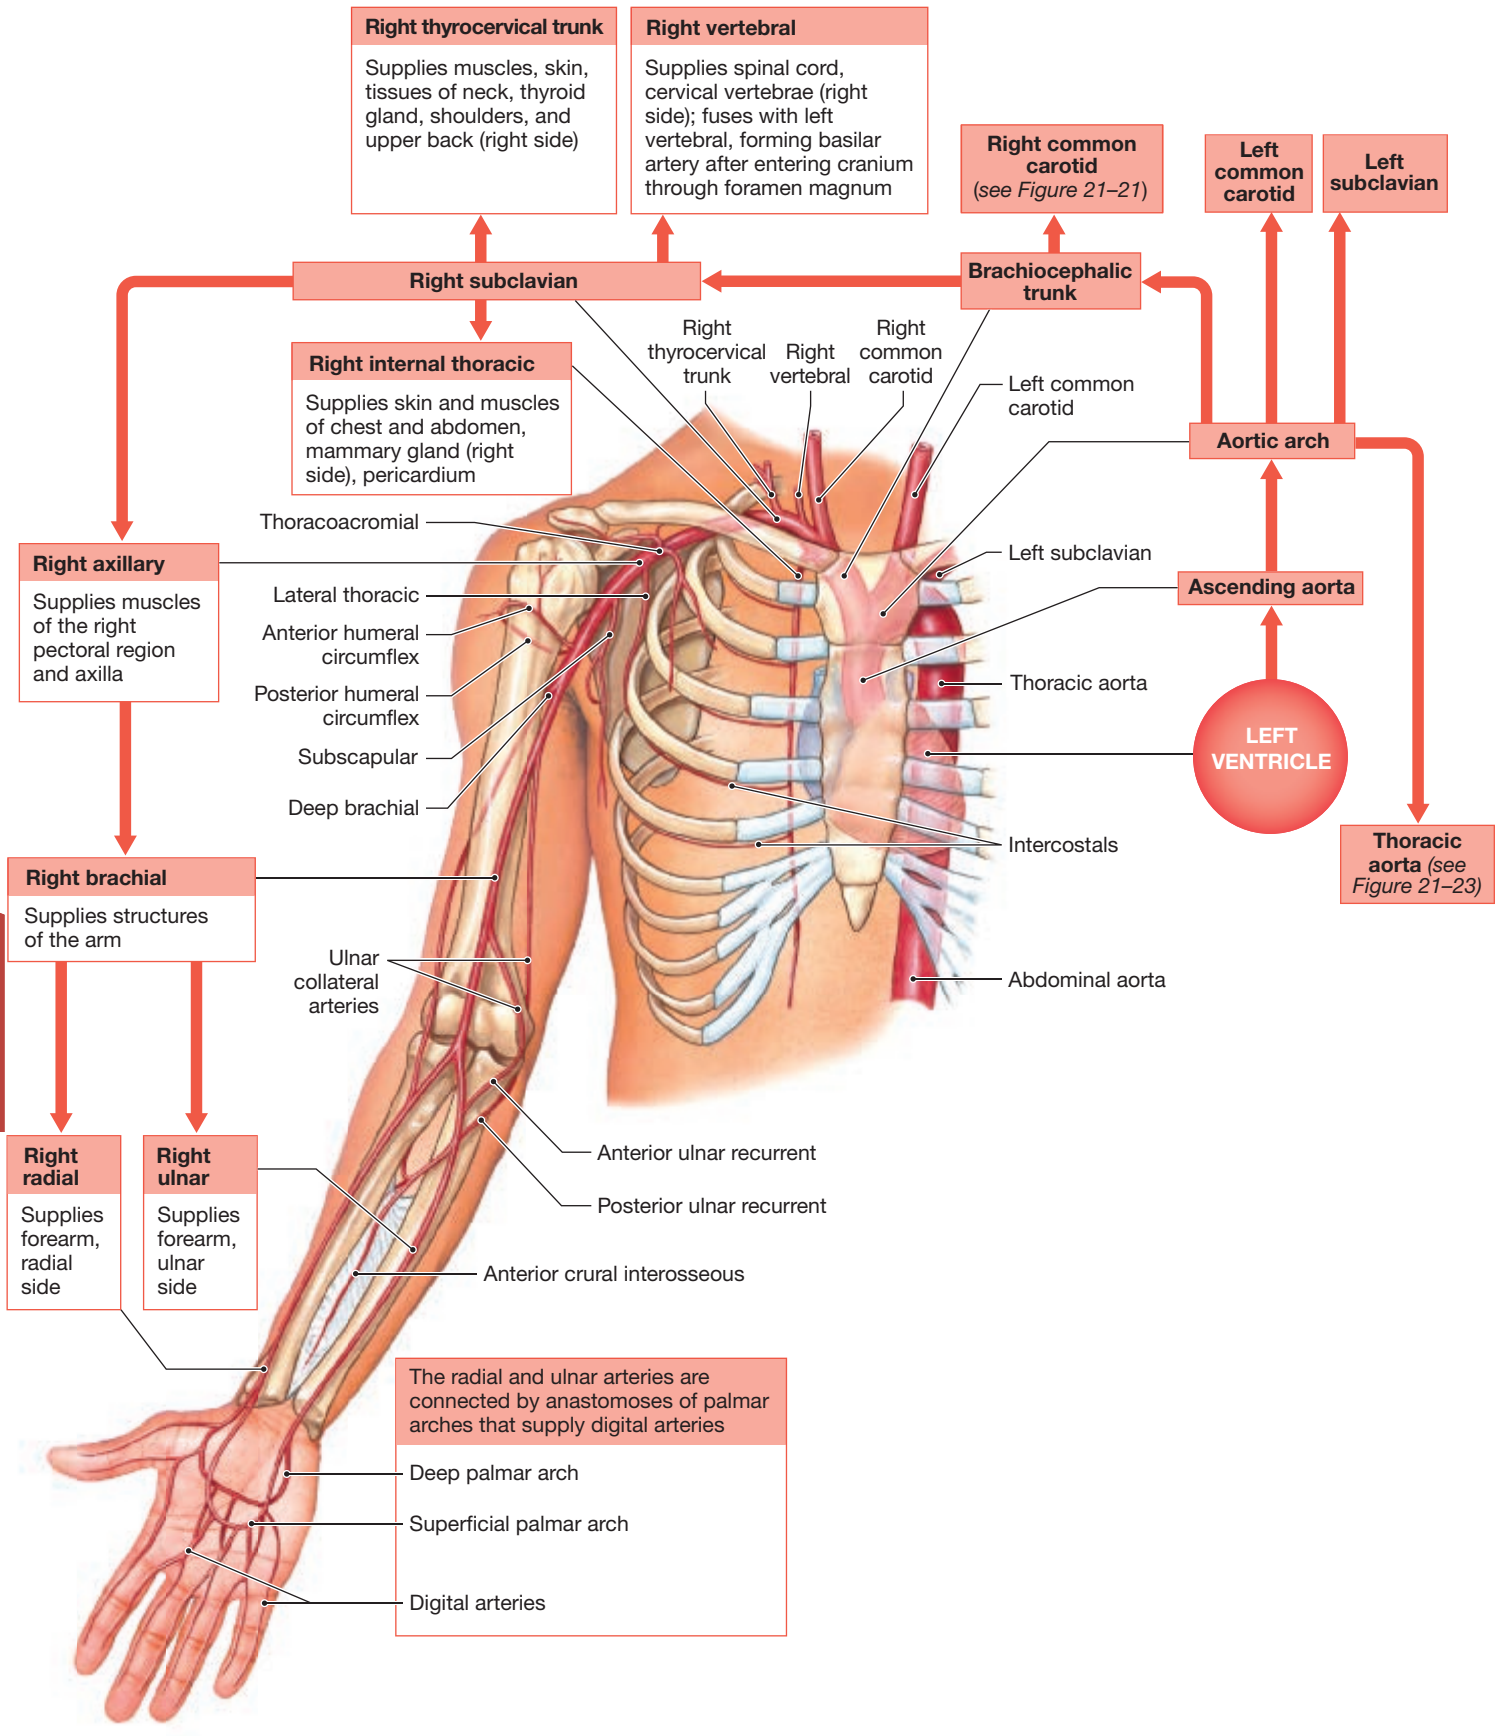

Figure 21–21 Arteries of the Neck and Head. Shown as seen from the right side. ATLAS: Plates 3c,d; 15b; 18a–c; 45a

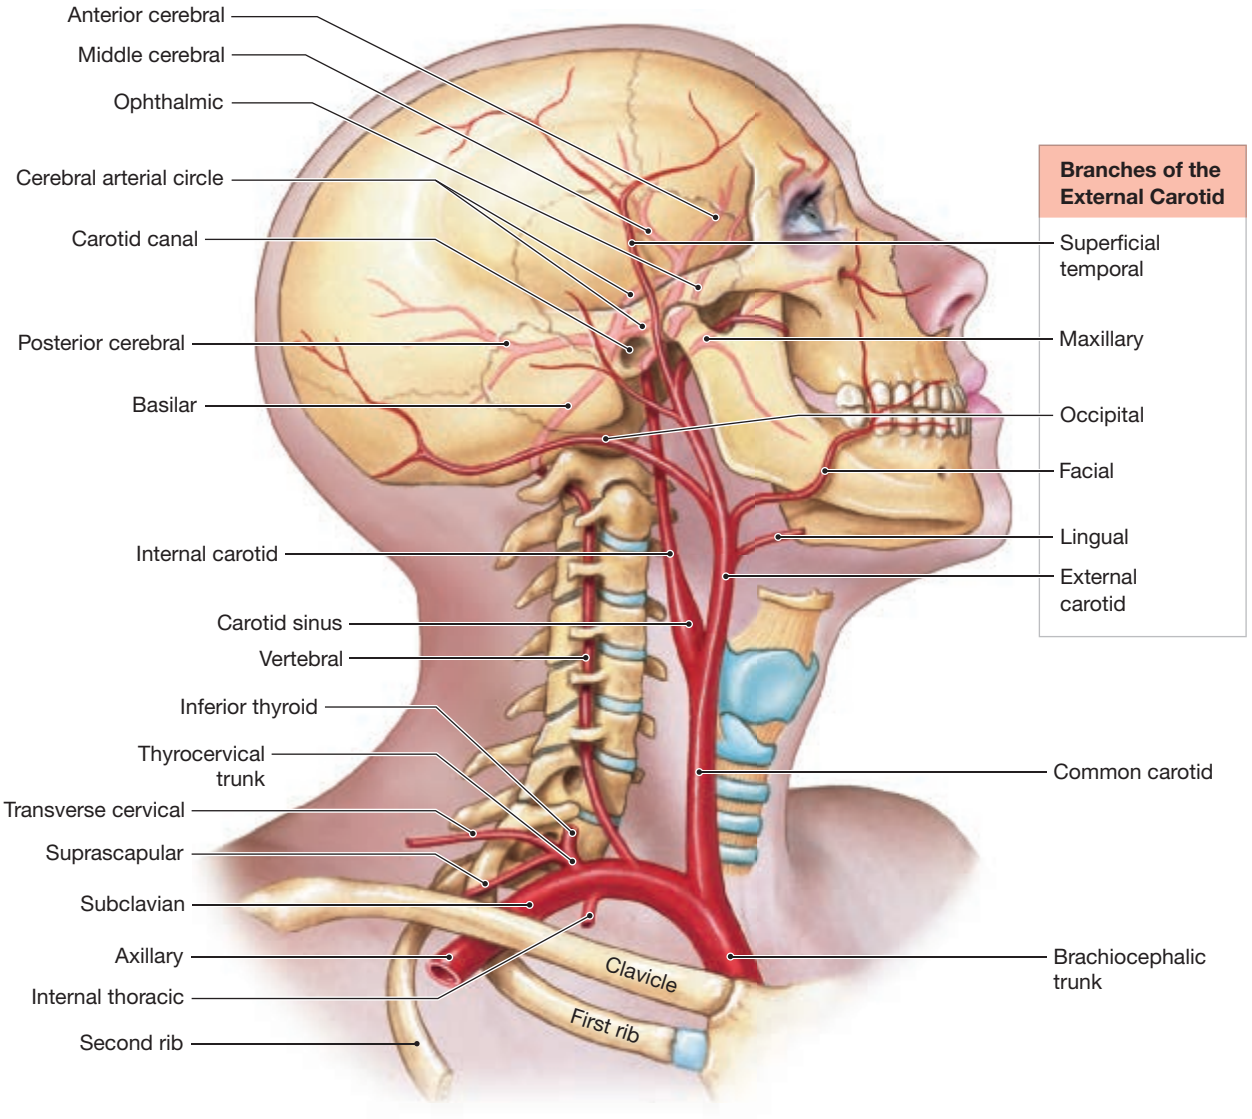


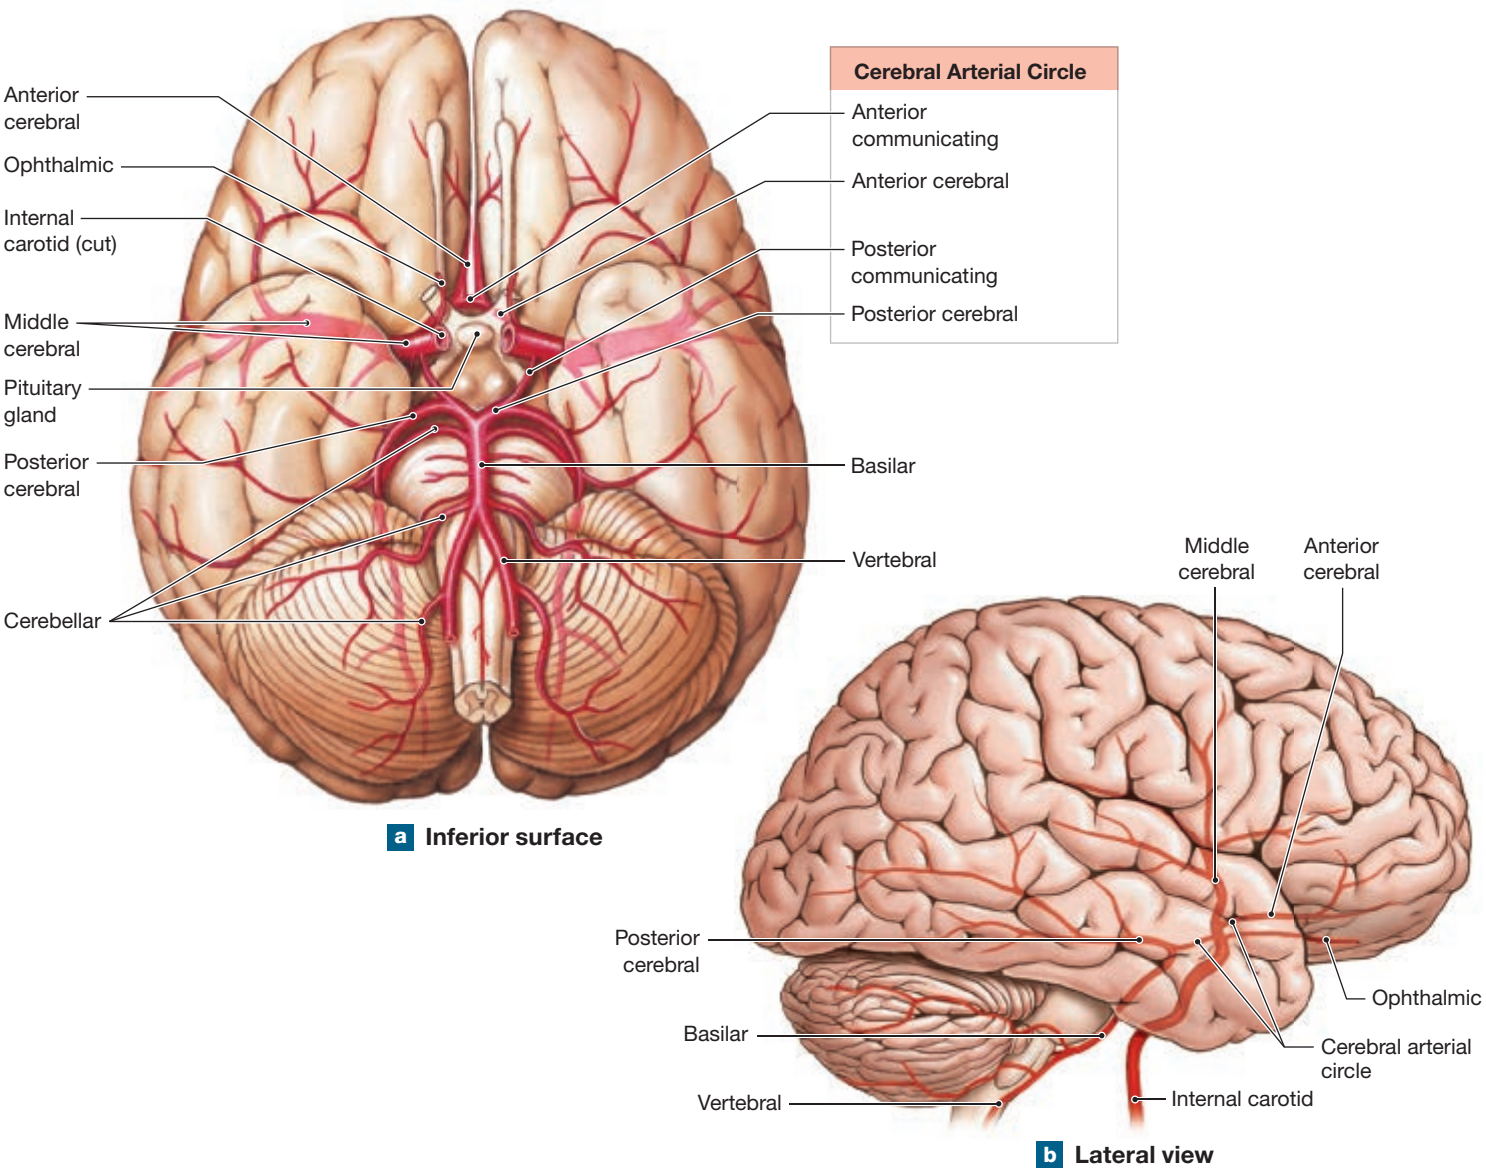
? The superficial temporal, maxillary, occipital, facial, and lingual arteries are all branches of what carotid artery?

As it approaches the coronoid fossa of the humerus, the brachial artery divides into the **radial artery**, which follows the radius, and the **ulnar artery**, which follows the ulna to the wrist. These arteries supply blood to the forearm and, through the *ulnar recurrent arteries*, the region around the elbow. At the wrist, the radial and ulnar arteries fuse to form the **superficial** and **deep palmar arches**, which supply blood to the hand and to the **digital arteries** of the thumb and fingers.

The Carotid Artery and the Blood Supply to the Brain. The common carotid arteries ascend deep in the tissues of the neck. You can usually locate the carotid artery by pressing gently along either side of the windpipe (trachea) until you feel a strong pulse.

Each common carotid artery divides into an **external carotid artery** and an **internal carotid artery** (Figure 21–21). The *carotid sinus*, located at the base of the internal carotid artery, may extend along a portion of the common carotid. The external carotid arteries supply blood to the structures of the neck, esophagus, pharynx, larynx, lower jaw, and face. The internal carotid arteries enter the skull through the carotid canals of the temporal bones, delivering blood to the brain (see Figure 7–3 and Spotlight Figure 7–4, pp. 212–215).

Figure 21–22 Arteries of the Brain. ATLAS: Plates 15a–c



Tips & Tools

Remember that the *external* carotid artery supplies the face (which is external), and that the *internal* carotid supplies the brain (which is internal).

The internal carotid arteries ascend to the level of the optic nerves, where each artery divides into three branches: (1) an **ophthalmic artery**, which supplies the eyes; (2) an **anterior cerebral artery**, which supplies the frontal and parietal lobes of the brain; and (3) a **middle cerebral artery**, which supplies the midbrain and lateral surfaces of the cerebral hemispheres (see Figures 21–21 and 21–22).

The brain is extremely sensitive to changes in blood supply. An interruption of blood flow for several seconds produces unconsciousness. After 4 minutes some permanent neural damage can occur. Such crises are rare, because blood reaches the brain through the vertebral arteries as well as by way of the internal carotid arteries. The left and right vertebral arteries arise from the subclavian arteries and ascend within the transverse foramina of the cervical vertebrae (look back at Figure 7–19b,c, p. 231). The vertebral arteries enter the cranium at the foramen magnum, where they fuse along the ventral surface of the medulla oblongata to form the **basilar artery**. The vertebral arteries and the basilar artery supply blood to the spinal cord, medulla oblongata, pons, and cerebellum. They then divide into the **posterior cerebral arteries**, which in turn branch off into the **posterior communicating arteries** (Figure 21–22).

The internal carotid arteries normally supply the arteries of the anterior half of the cerebrum, and the rest of the brain

receives blood from the vertebral arteries. But this pattern of blood flow can easily change, because the internal carotid arteries and the basilar artery are interconnected. They form a ring-shaped anastomosis called the **cerebral arterial circle**, or *circle of Willis*, which encircles the optic chiasm and the infundibulum of the pituitary gland (see Figure 21–22). With this arrangement, the brain can receive blood from either the carotid or the vertebral arteries, reducing the likelihood of a serious interruption of circulation.

Strokes, or *cerebrovascular accidents (CVAs)*, are interruptions of the vascular supply to a portion of the brain. The *middle cerebral artery*, a major branch of the cerebral arterial circle, is the most common site of a stroke. Superficial branches deliver blood to the temporal lobe and large portions of the frontal and parietal lobes. Deep branches supply the basal nuclei and portions of the thalamus. If a stroke blocks the middle cerebral artery on the left side of the brain, aphasia and a sensory and motor paralysis of the right side of the body result. In a stroke affecting the middle cerebral artery on the right side, the individual experiences a loss of sensation and motor control over the left side of the body and has difficulty drawing or interpreting spatial relationships. Strokes affecting vessels that supply the brainstem also produce distinctive symptoms. Strokes affecting the lower brainstem are commonly fatal.

The Descending Aorta

The **descending aorta** is continuous with the aortic arch. The diaphragm divides the descending aorta into a superior **thoracic aorta** and an inferior **abdominal aorta** (look ahead to Figures 21–23 and 21–24).

The Thoracic Aorta. The thoracic aorta begins at the level of vertebra T_5 and penetrates the diaphragm at the level of vertebra T_{12}. It travels within the mediastinum, on the posterior thoracic wall, slightly to the left of the vertebral column. This vessel supplies blood to branches that service the tissues and organs of the mediastinum, the muscles of the chest and the diaphragm, and the thoracic spinal cord.

We group the branches of the thoracic aorta anatomically as either visceral or somatic (Figure 21–23):

- *Visceral branches* supply the organs of the chest. The **bronchial arteries** supply the tissues of the lungs not involved in gas exchange. The **pericardial arteries** supply the pericardium. The **esophageal arteries** supply the esophagus, and the **mediastinal arteries** supply the tissues of the mediastinum.
- *Somatic branches* supply the chest wall. The **intercostal arteries** supply the chest muscles and the vertebral column area. The **superior phrenic** (FREN-ik) **arteries** deliver blood to the superior surface of the diaphragm, which separates the thoracic and abdominopelvic cavities.

+ Clinical Note Aortic Aneurysm

Over a period of many years, atherosclerosis and hypertension may take their toll on the aorta. The wall of the aorta becomes damaged and stretches out to form a pouch, or aneurysm. This structural change can weaken the aorta so much that it tears. The ensuing pain can come on without warning. Picture the path of the aorta as it plunges deep through the thorax and abdomen, and you will appreciate how daunting it is to reach a ruptured aortic aneurysm in order to stop the loss of blood and save the life of a patient.

The Abdominal Aorta. The abdominal aorta is a continuation of the thoracic aorta (see Figure 21–23). It begins immediately inferior to the diaphragm and descends slightly to the left of the vertebral column but posterior to the peritoneal cavity. A cushion of adipose tissue commonly surrounds the abdominal aorta. At the level of vertebra L_4, the abdominal aorta splits into two major arteries—the *left* and *right common iliac arteries*—that supply deep pelvic structures and the lower limbs. The region where the abdominal aorta splits is called the *terminal segment of the aorta*.

The abdominal aorta delivers blood to all the abdominopelvic organs and structures. The major branches to visceral organs are unpaired. They arise on the anterior surface of the abdominal aorta and extend into the mesenteries. By contrast, branches to the body wall, the kidneys, the urinary bladder, and other structures outside the peritoneal cavity are paired. They originate along the lateral surfaces of the abdominal aorta. Figure 21–23 shows the major arteries of the trunk after most thoracic and abdominal organs have been removed. Figure 21–24 shows the distribution of those arteries to abdominopelvic organs.

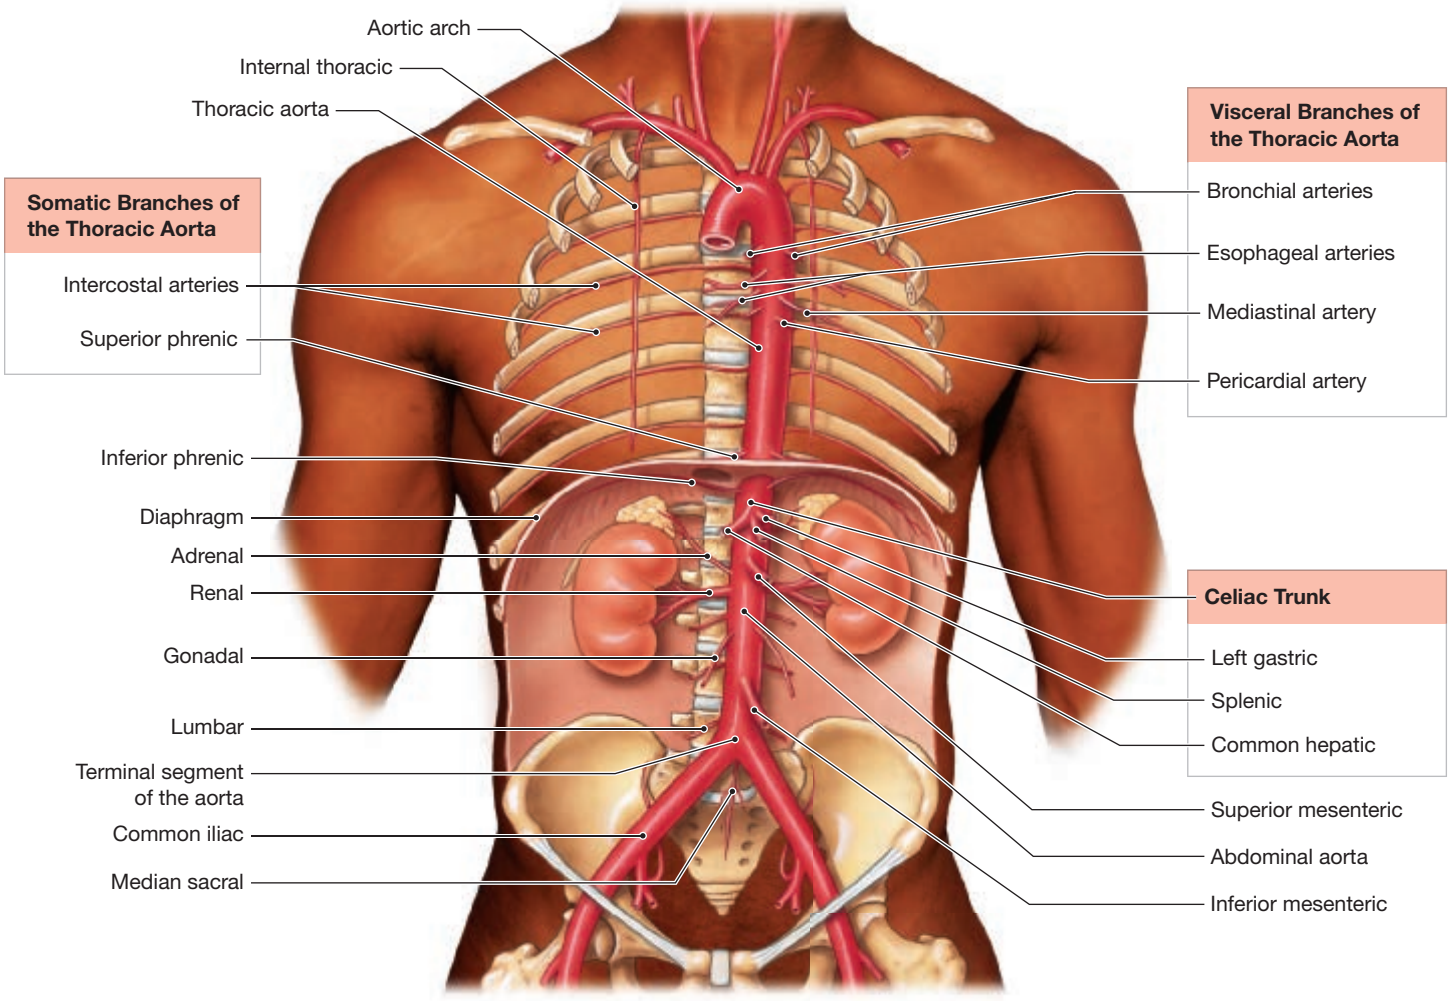
Tips & Tools

The aorta resembles a walking cane: the ascending aorta, aortic arch, and the start of the descending aorta form the cane's handle, while the thoracic and abdominal segments of the descending aorta form the cane's shaft.

The abdominal aorta gives rise to three unpaired arteries (see Figures 21–23 and 21–24).

1. The **celiac** (SĒ-lē-ak) **trunk** delivers blood to the liver, stomach, and spleen. The celiac trunk divides into three branches: (a) The **left gastric artery** supplies the stomach and the inferior portion of the esophagus. (b) The **splenic artery** supplies the spleen and arteries to the stomach (*left gastro-epiploic artery*) and pancreas (*pancreatic arteries*). (c) The **common hepatic artery** supplies arteries to the liver (*hepatic artery proper*), stomach (*right gastric artery*), gallbladder

Figure 21–23 Major Arteries of the Trunk. ATLAS: Plates 47d; 53c,e; 62a,b



a A diagrammatic view, with most of the thoracic and abdominal organs removed

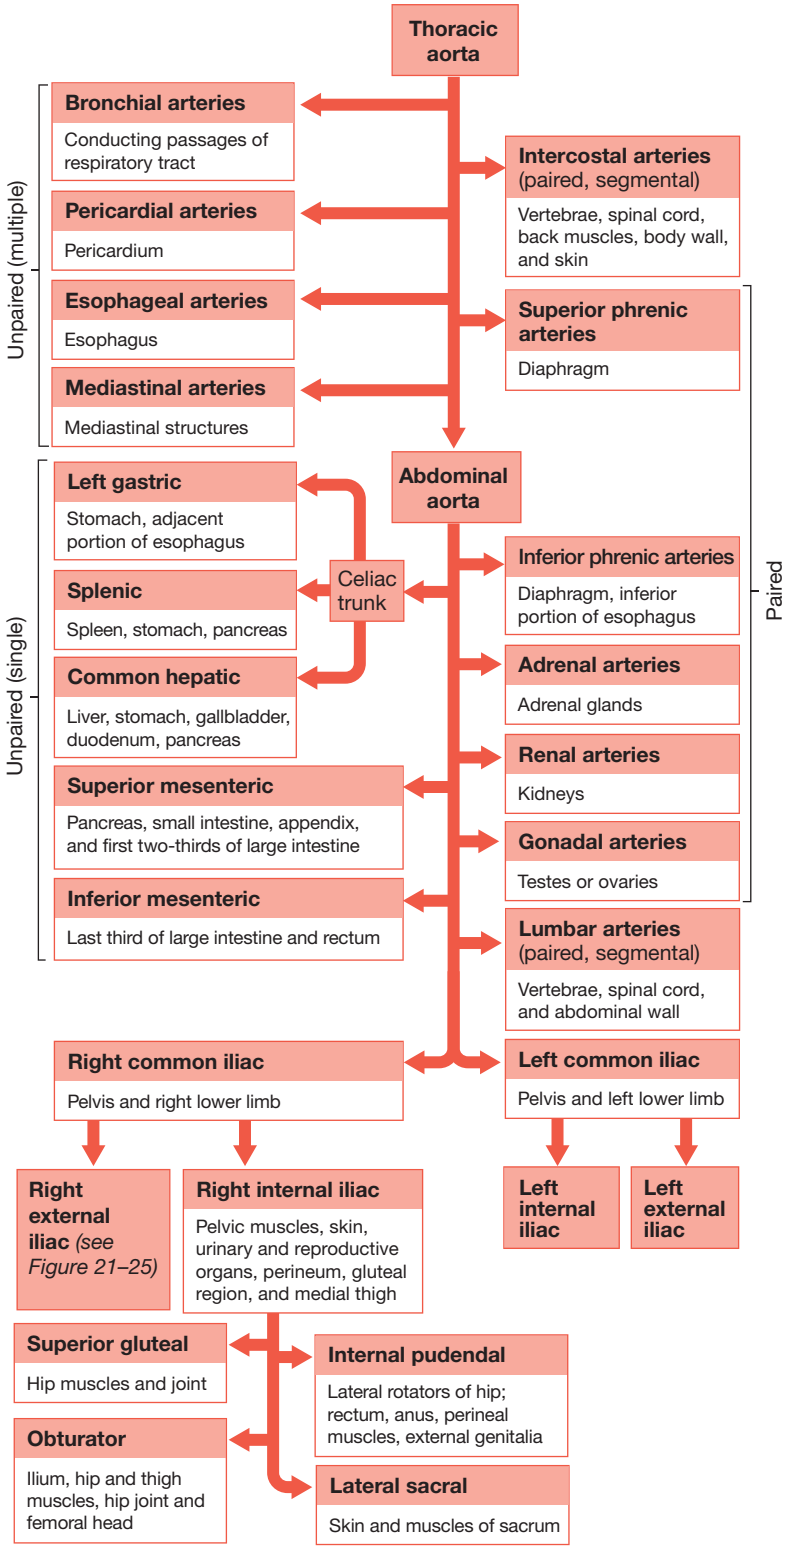
(*cystic artery*), and duodenal area (*gastroduodenal, right gastroepiploic,* and *superior pancreaticoduodenal arteries*).

2. The **superior mesenteric** (mez-en-TER-ik) **artery** arises about 2.5 cm (1 in.) inferior to the celiac trunk. It supplies arteries to the pancreas and duodenum (*inferior pancreaticoduodenal artery*), small intestine (*intestinal arteries*), and most of the large intestine (*right* and *middle colic* and the *ileocolic arteries*).
3. The **inferior mesenteric artery** arises about 5 cm (2 in.) superior to the terminal aorta. It delivers blood to the terminal portions of the colon (*left colic* and *sigmoid arteries*) and the rectum (*rectal arteries*).

The abdominal aorta also gives rise to five paired arteries (Figure 21–23):

1. The **inferior phrenic arteries** supply the inferior surface of the diaphragm and the inferior portion of the esophagus.
2. The **adrenal arteries** originate on either side of the aorta near the base of the superior mesenteric artery. Each adrenal artery supplies one adrenal gland, which caps the superior part of a kidney.
3. The short (about 7.5 cm) **renal arteries** arise along the posterolateral surface of the abdominal aorta, about 2.5 cm (1 in.) inferior to the superior mesenteric artery. They travel posterior to the peritoneal lining to reach the adrenal glands and kidneys.
4. The **gonadal** (gō-NAD-al) **arteries** originate between the superior and inferior mesenteric arteries. In males, they are called *testicular arteries* and are long, thin arteries that supply blood to the testes and scrotum. In females, they are termed *ovarian arteries* and supply blood to the ovaries, uterine tubes, and uterus. The distribution of gonadal vessels (both arteries and veins) differs by sex.
5. Small **lumbar arteries** arise on the posterior surface of the aorta. They supply the vertebrae, spinal cord, and abdominal wall.

Figure 21–23 Major Arteries of the Trunk. (*Continued*)



b A flowchart showing major arteries of the trunk

Arteries of the Pelvis and Lower Limbs

Near the level of vertebra L_4, the terminal segment of the abdominal aorta divides to form a pair of elastic arteries—the **right** and **left common iliac** (IL-ē-ak) **arteries**—plus the small **median sacral artery** (Figure 21–23a). The common iliac arteries carry blood to the pelvis and lower limbs. They descend posterior to the cecum and sigmoid colon along the inner surface of the ilium. At the level of the lumbosacral joint, each common iliac divides to form an **internal iliac artery** and an **external iliac artery** (Figure 21–23b). The internal iliac arteries enter the pelvic cavity to supply the urinary bladder, the internal and external walls of the pelvis, the external genitalia, the medial side of the thigh, and, in females, the uterus and vagina. The major branches of the internal iliac artery are the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral arteries*. The external iliac arteries supply blood to the lower limbs. They are much larger in diameter than the internal iliac arteries.

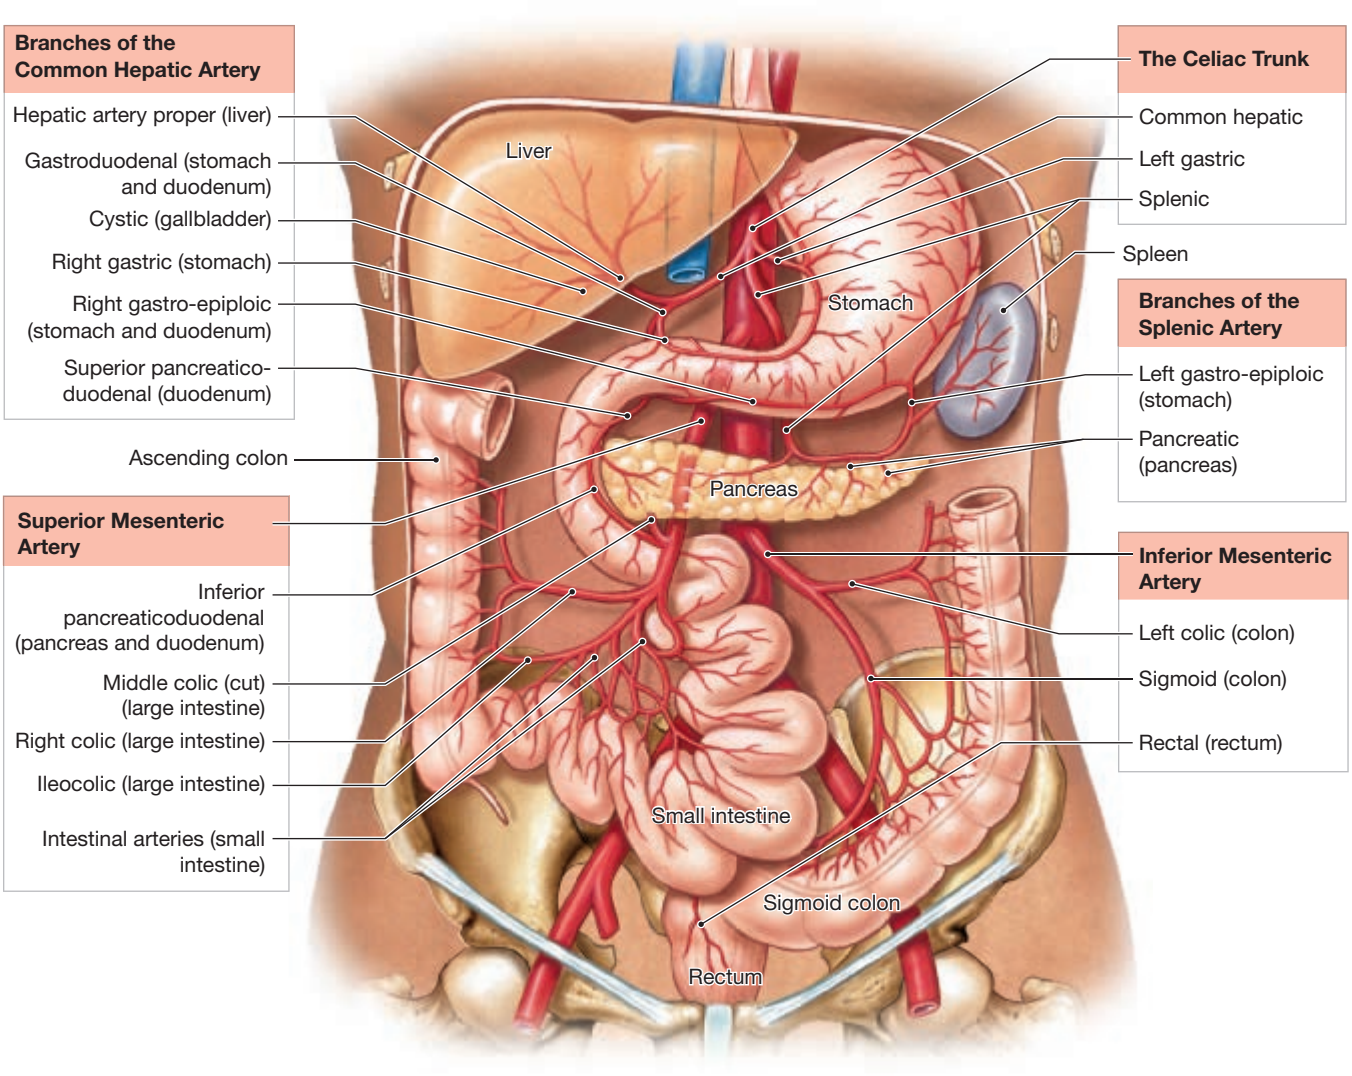
Arteries of the Thigh and Leg. Each external iliac artery crosses the surface of an iliopsoas muscle and penetrates the abdominal wall midway between the anterior superior iliac spine and the pubic symphysis on that side. It emerges on the anterior, medial surface of the thigh as the **femoral artery** (Figure 21–25a,b). Roughly 5 cm (2 in.) distal to the emergence of the femoral artery, the **deep femoral artery** branches off its lateral surface. The deep femoral artery supplies blood to the ventral and lateral regions of the skin and deep muscles of the thigh. It gives rise to the *femoral circumflex arteries*.

The femoral artery continues inferiorly and posterior to the femur. As it approaches the knee, it gives rise to the *descending genicular artery*, which supplies the area around the knee. At the popliteal fossa, posterior to the knee joint, the femoral artery becomes the **popliteal** (pop-LIT-ē-al) **artery**, which then branches to form the **posterior** and **anterior tibial arteries**. The posterior tibial artery gives rise to the **fibular artery**, or *peroneal* (*perone*, fibula) *artery*, and then continues inferiorly along the posterior surface of the tibia. The anterior tibial artery passes between the tibia and fibula. It emerges on the anterior surface of the tibia. As it descends toward the foot, the anterior tibial artery provides blood to the skin and muscles of the anterior portion of the leg.

Arteries of the Foot. At the ankle, the anterior tibial artery becomes the **dorsalis pedis artery**. It then branches repeatedly, supplying the ankle and dorsal portion of the foot (see Figure 21–25a,b). Figure 21–25c charts the flow of blood from the external iliac artery to the lower limbs.

At the ankle, the posterior tibial artery divides to form the **medial** and **lateral plantar arteries**. They supply blood to the plantar surface of the foot. These arteries are connected to the dorsalis pedis artery through a pair of

Figure 21–24 Arteries Supplying the Abdominopelvic Organs. *(See also Figure 24–24, p. 922.)* ATLAS: Plates 53a–e; 54c; 55



anastomoses. The arrangement produces a **dorsal arch** (*arcuate arch*) and a **plantar arch**. Small arteries branching off these arches supply the distal portions of the foot and the toes.

Systemic Veins

Veins collect blood from the tissues and organs of the body by means of an elaborate venous network that drains into the right atrium of the heart by the superior and inferior venae cavae (Figure 21–26). The branching pattern of peripheral veins is much more variable than is the branching pattern of arteries. We base the discussion that follows on the most common arrangement of veins. Complementary arteries and veins commonly run side by side. In many cases they have comparable names.

One significant difference between the arterial and venous systems involves the distribution of major veins in the neck and limbs. Arteries in these areas are deep beneath the skin, protected by bones and surrounding soft tissues. In contrast, the neck and limbs generally have two sets of peripheral veins, one superficial and the other deep. This dual venous drainage is important for controlling body temperature. In hot weather, venous blood flows through superficial veins, where heat can easily be lost. In cold weather, blood is routed to the deep veins to minimize heat loss.

The Superior Vena Cava

All the body's systemic veins (except the cardiac veins) ultimately drain into either the superior vena cava or the inferior vena cava. The **superior vena cava (SVC)** receives blood from the tissues and organs of the head, neck, chest, shoulders, and upper limbs.

Venous Return from the Cranium. Numerous veins drain the cerebral hemispheres. The *superficial cerebral veins* and small veins of the brainstem empty into a network of dural sinuses (Figure 21–27a,b). These sinuses include the *superior* and *inferior sagittal sinuses*, the *petrosal sinuses*, the *occipital sinus*, the *left* and *right transverse sinuses*, and the *straight sinus* (Figure 21–27c).

Figure 21–25 Arteries of the Lower Limb. ATLAS: Plates 68c; 70b; 78b–g

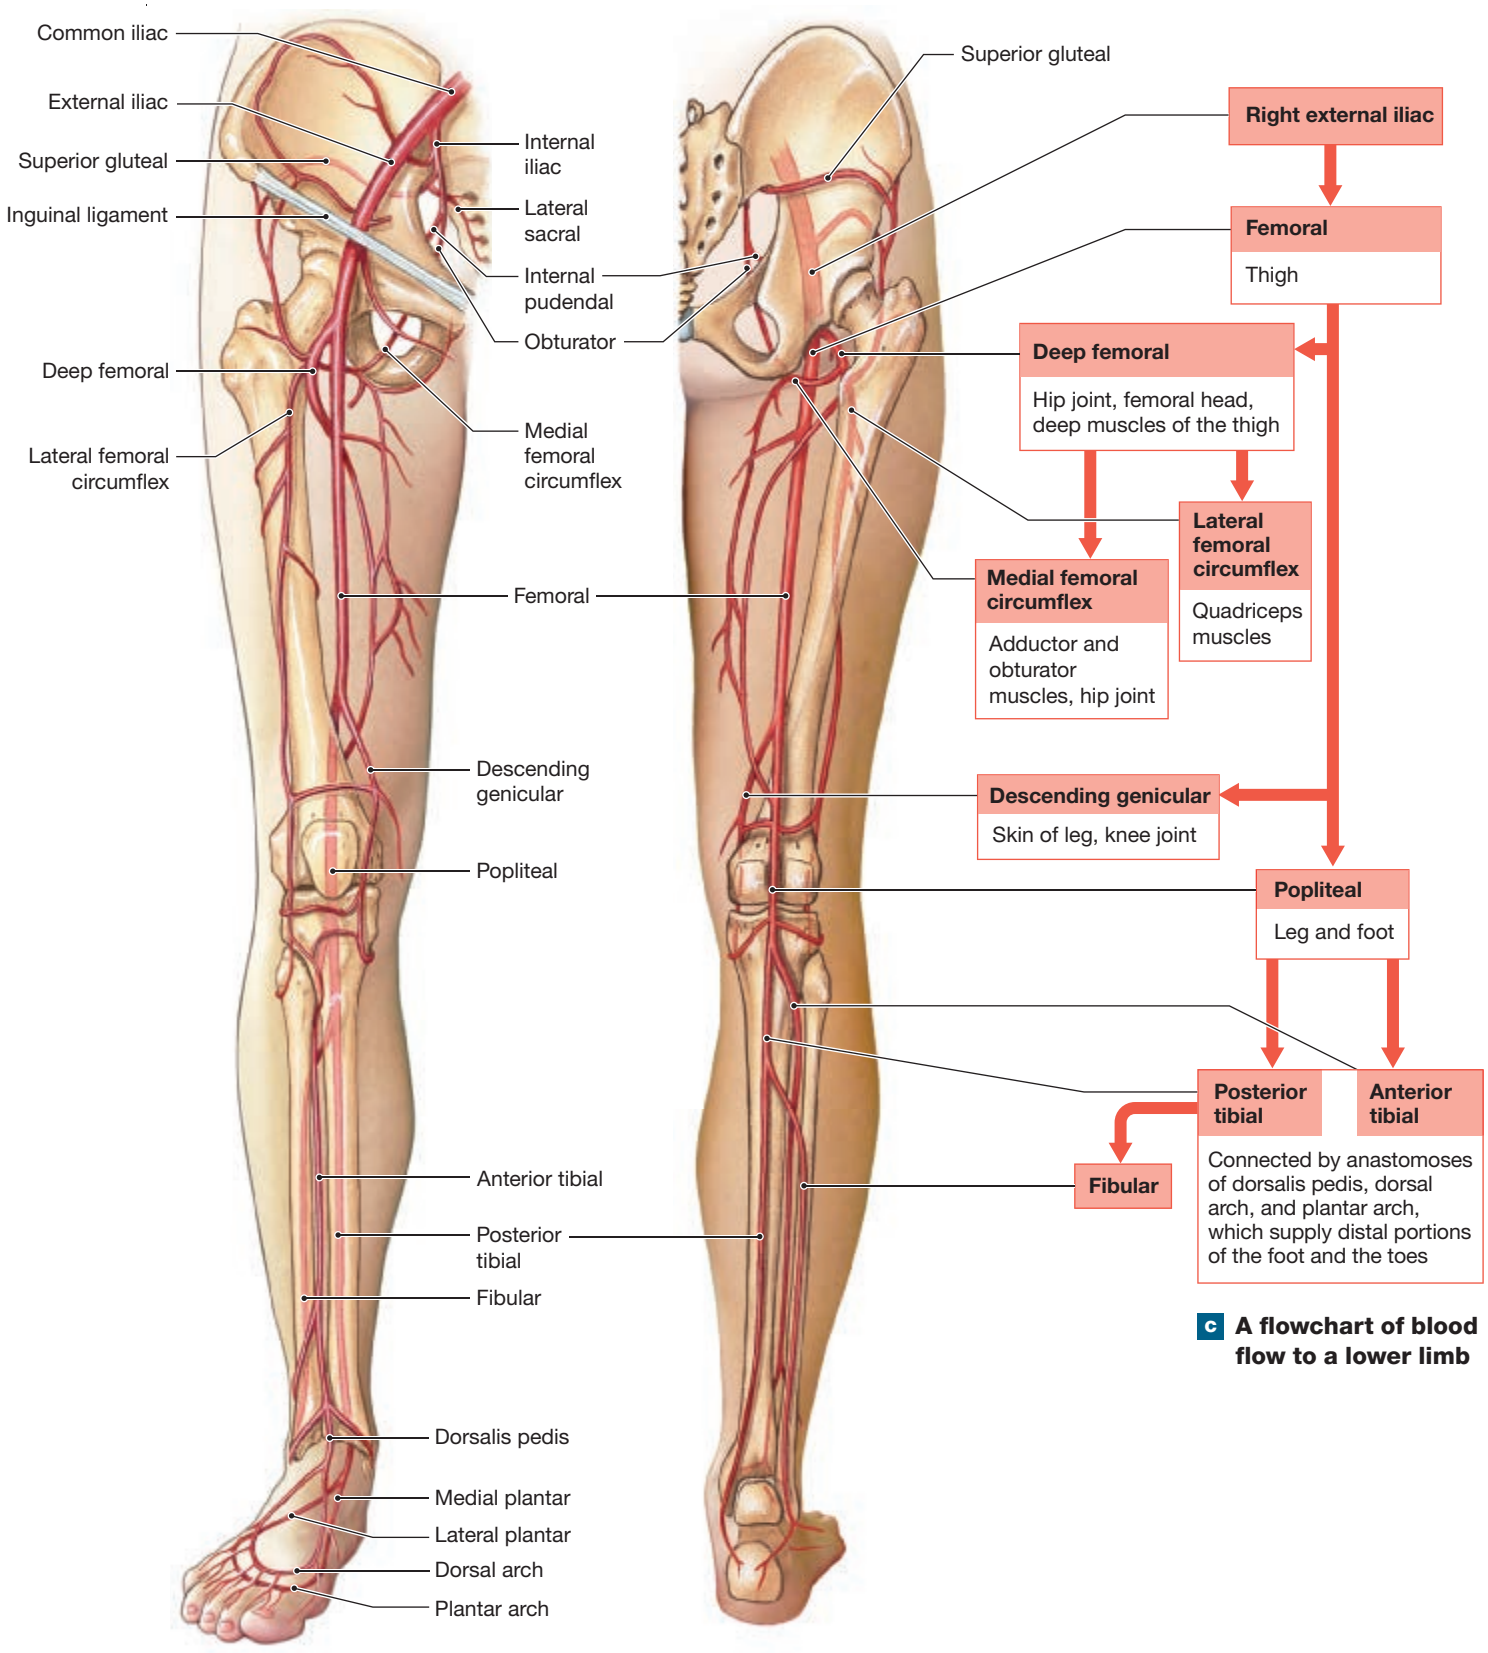


Figure 21–26 An Overview of the Major Systemic Veins.

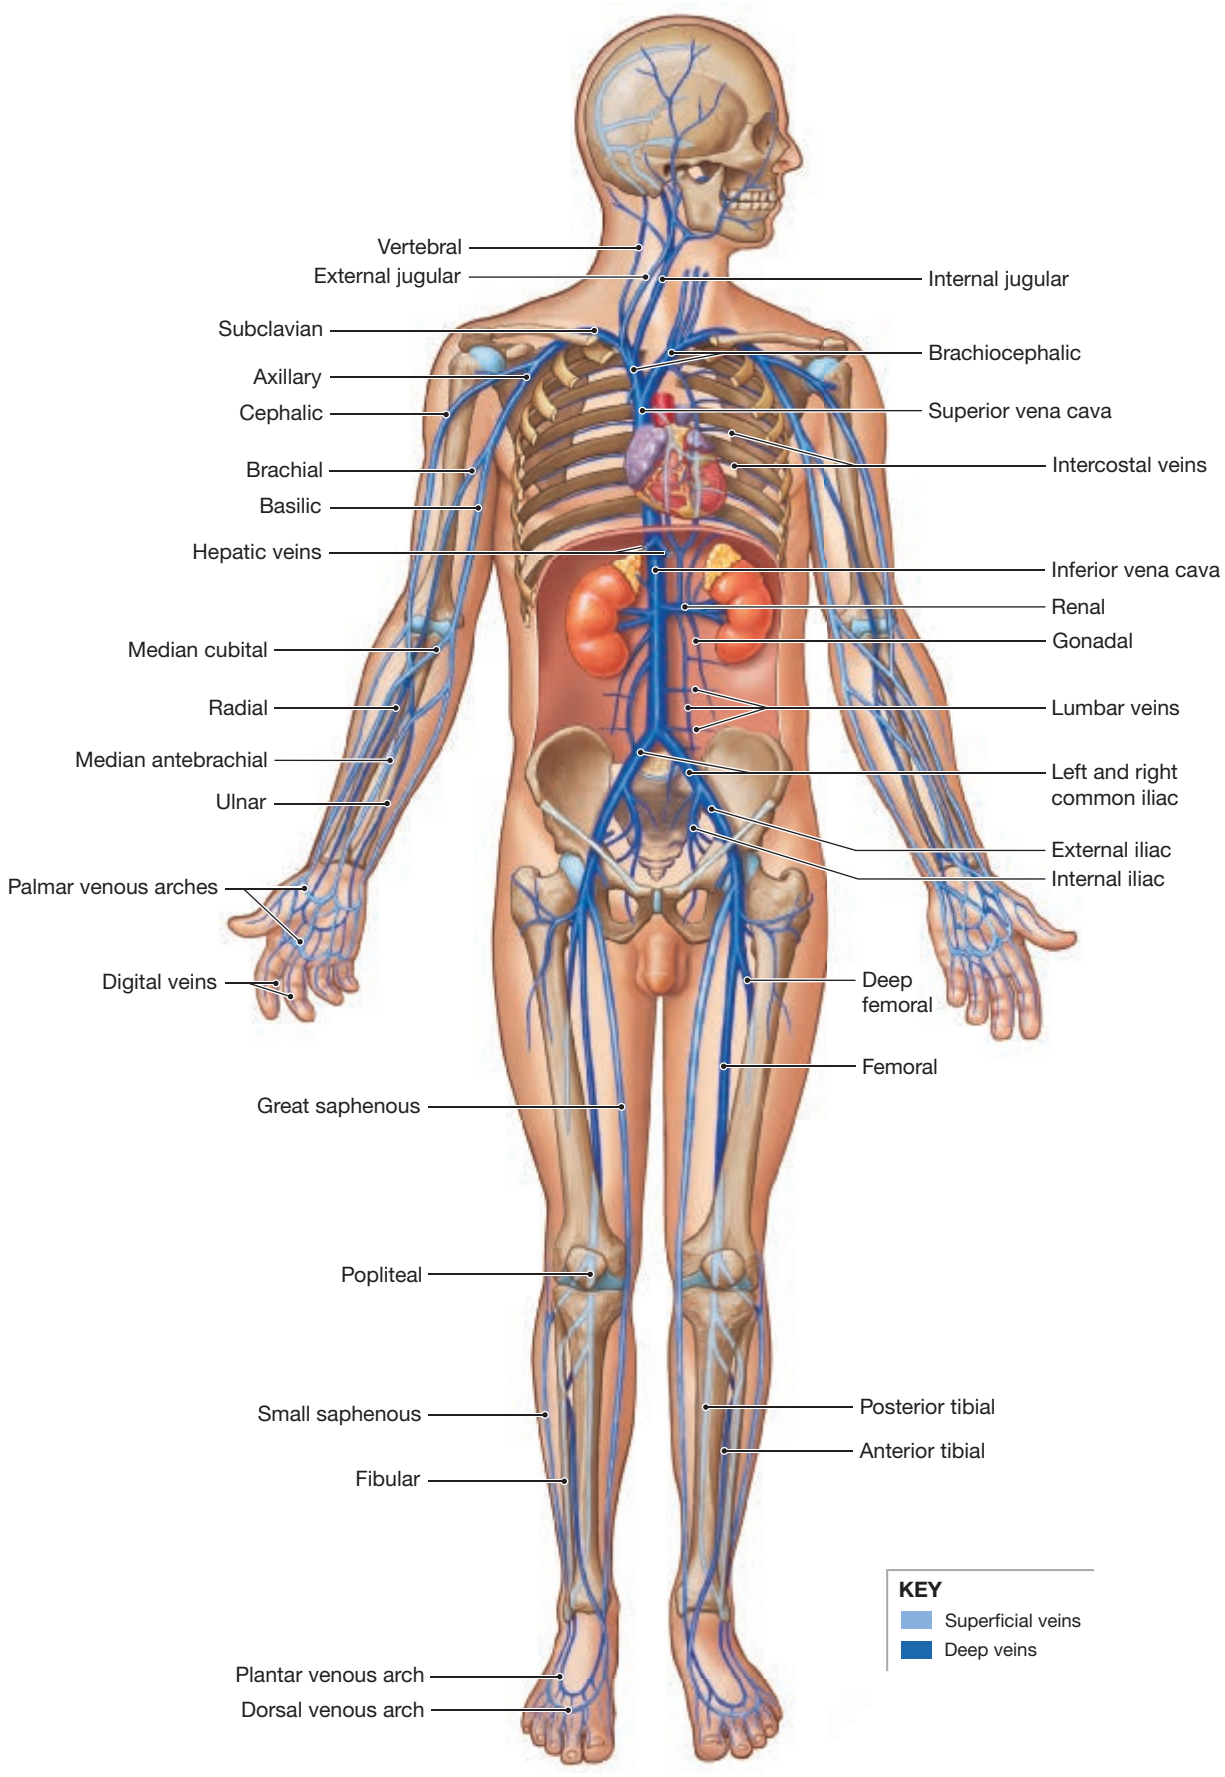

Figure 21–27 Major Veins of the Head, Neck, and Brain. ATLAS: Plates 3c,d; 18a–c

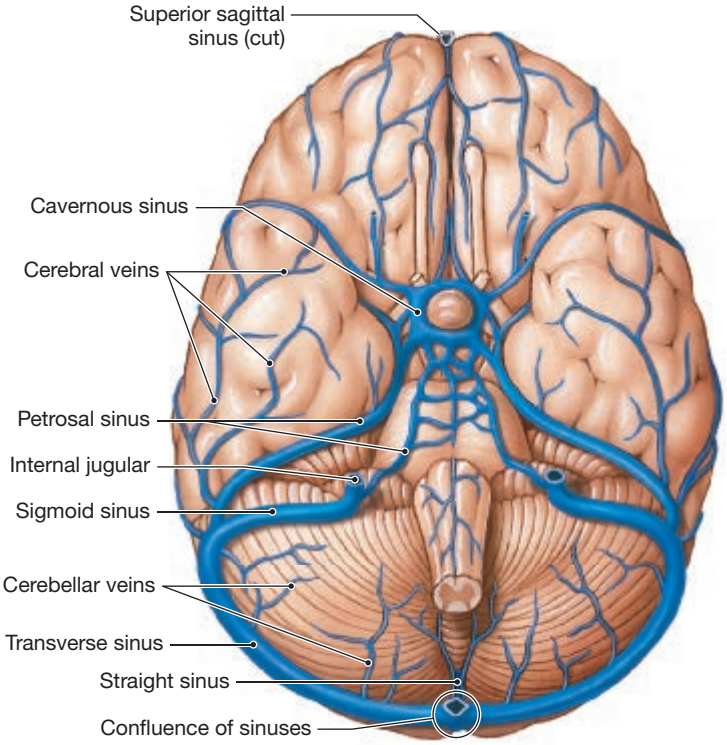
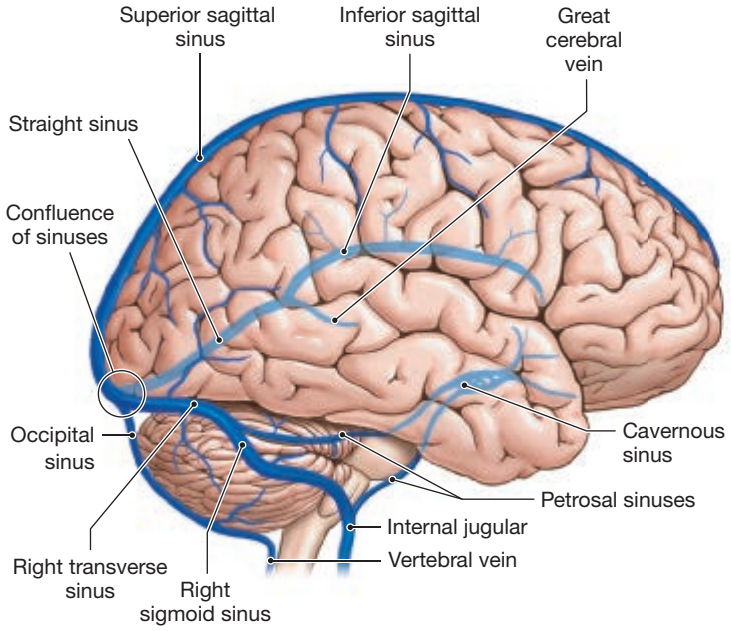
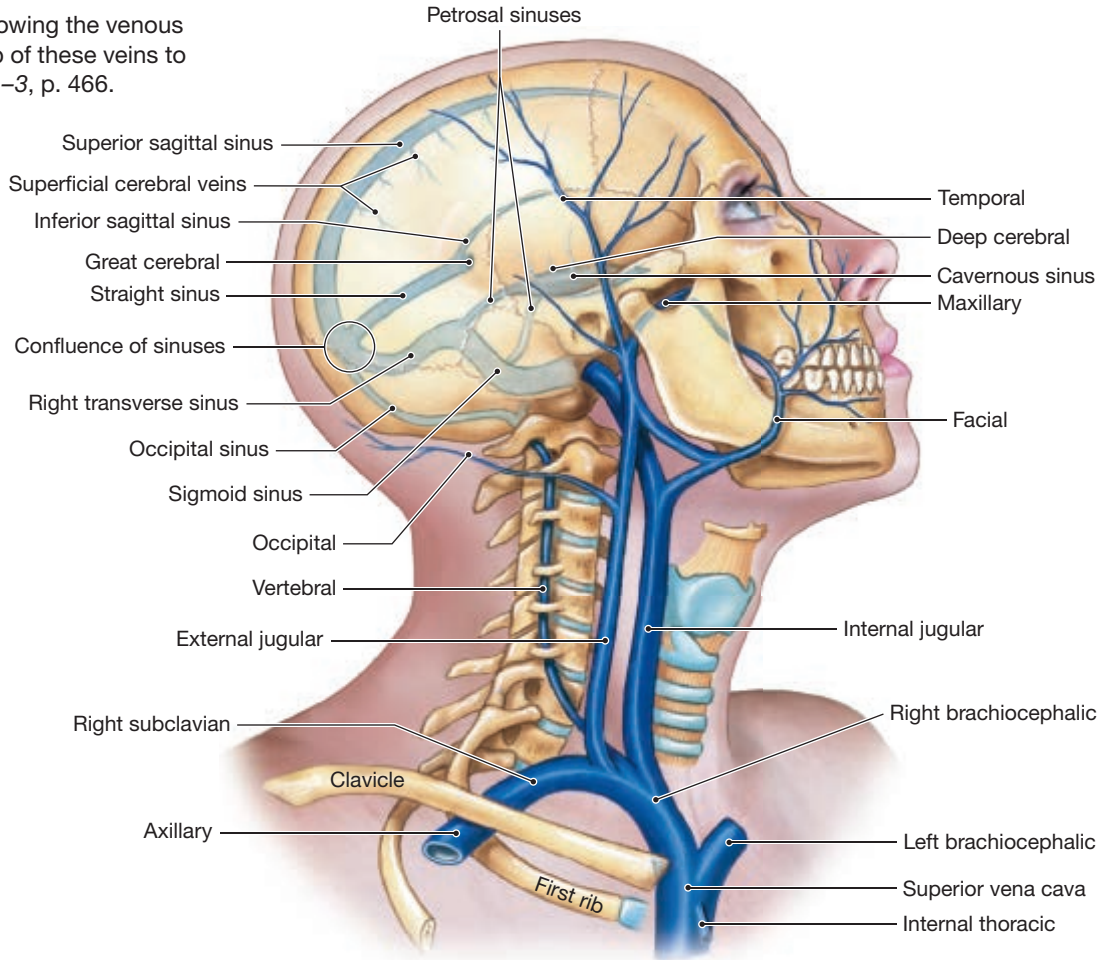


a An inferior view of the brain, showing the venous distribution. For the relationship of these veins to meningeal layers, *see Figure 14–3*, p. 466.



b A lateral view of the brain showing the venous distribution.



c Veins draining the brain and the superficial and deep portions of the head and neck.

The superior sagittal sinus, occipital sinus, straight sinus, and two transverse sinuses connect at the *confluence of sinuses*. The largest, the **superior sagittal sinus**, is in the falx cerebri (look back at Figure 14–3, p. 470). Most of the *inferior cerebral veins* converge within the brain to form the **great cerebral vein**. It delivers blood from the interior of the cerebral hemispheres and the choroid plexus to the **straight sinus**. Other cerebral veins drain into the **cavernous sinus** with numerous small veins from the orbit. Blood from the cavernous sinus reaches the internal jugular vein through the petrosal sinuses.

The venous sinuses converge within the dura mater in the region of the lambdoid suture. The left and right transverse sinuses begin at the confluence of the occipital, sagittal, and straight sinuses. Each transverse sinus drains into a **sigmoid sinus**, which penetrates the jugular foramen and leaves the skull as the **internal jugular vein**. It descends parallel to the common carotid artery in the neck. ↩ p. 761

Vertebral veins drain the cervical spinal cord and the posterior surface of the skull. These vessels descend within the transverse foramina of the cervical vertebrae, along with the vertebral arteries. The vertebral veins empty into the *brachiocephalic veins* of the chest (discussed later in the chapter).

Superficial Veins of the Head and Neck. The superficial veins of the head converge to form the **temporal**, **facial**, and **maxillary veins** (see Figure 21–27c). The temporal vein and the maxillary vein drain into the **external jugular vein**. The facial vein drains into the internal jugular vein. A broad anastomosis between the external and internal jugular veins at the angle of the mandible provides dual venous drainage of the face, scalp, and cranium. The external jugular vein descends toward the chest just deep to the skin on the anterior surface of the sternocleidomastoid muscle. Posterior to the clavicle, the external jugular vein empties into the *subclavian vein*. In healthy individuals, the external jugular vein is easily palpable. A *jugular venous pulse (JVP)* is sometimes detectable at the base of the neck.

Venous Return from the Upper Limbs. The **digital veins** empty into the **superficial** and **deep palmar veins** of the hand, which interconnect to form the **palmar venous arches** (Figure 21–28). The superficial arch empties into the **cephalic vein**, which ascends along the radial side of the forearm; the **median antebrachial vein**; and the **basilic vein**, which ascends on the ulnar side. Anterior to the elbow is the superficial **median cubital vein**, which passes from the cephalic vein, medially and at an oblique angle, to connect to the basilic vein. (Venous blood samples are typically collected from the median cubital.) From the elbow, the basilic vein passes superiorly along the medial surface of the biceps brachii muscle.

The deep palmar veins drain into the **radial vein** and the **ulnar vein**. These veins fuse to form the **brachial vein**, running parallel to the brachial artery. As the brachial vein continues toward the trunk, it merges with the basilic vein and becomes the **axillary vein**, which enters the axilla.

Formation of the Superior Vena Cava. The cephalic vein joins the axillary vein on the lateral surface of the first rib, forming the **subclavian vein**, which continues into the chest. The subclavian vein passes superior to the first rib and along the superior margin of the clavicle. It merges with the external and internal jugular veins of that side. This fusion creates the **brachiocephalic vein**, or *innominate vein*, which penetrates the body wall and enters the thoracic cavity.

Each brachiocephalic vein receives blood from the vertebral vein of the same side, which drains the back of the skull and spinal cord. Near the heart, at the level of the first and second ribs, the left and right brachiocephalic veins join, creating the superior vena cava. Close to the point of fusion, the **internal thoracic vein** empties into the brachiocephalic vein.

The **azygos** (AZ-ī-gos) **vein** is the major branch of the superior vena cava. This vein ascends from the lumbar region over the right side of the vertebral column to enter the thoracic cavity through the diaphragm. The azygos vein joins the superior vena cava at the level of vertebra T_2. On the left side, the azygos receives blood from the smaller **hemi-azygos vein**, which in many people also drains into the left brachiocephalic vein through the *highest intercostal vein*.

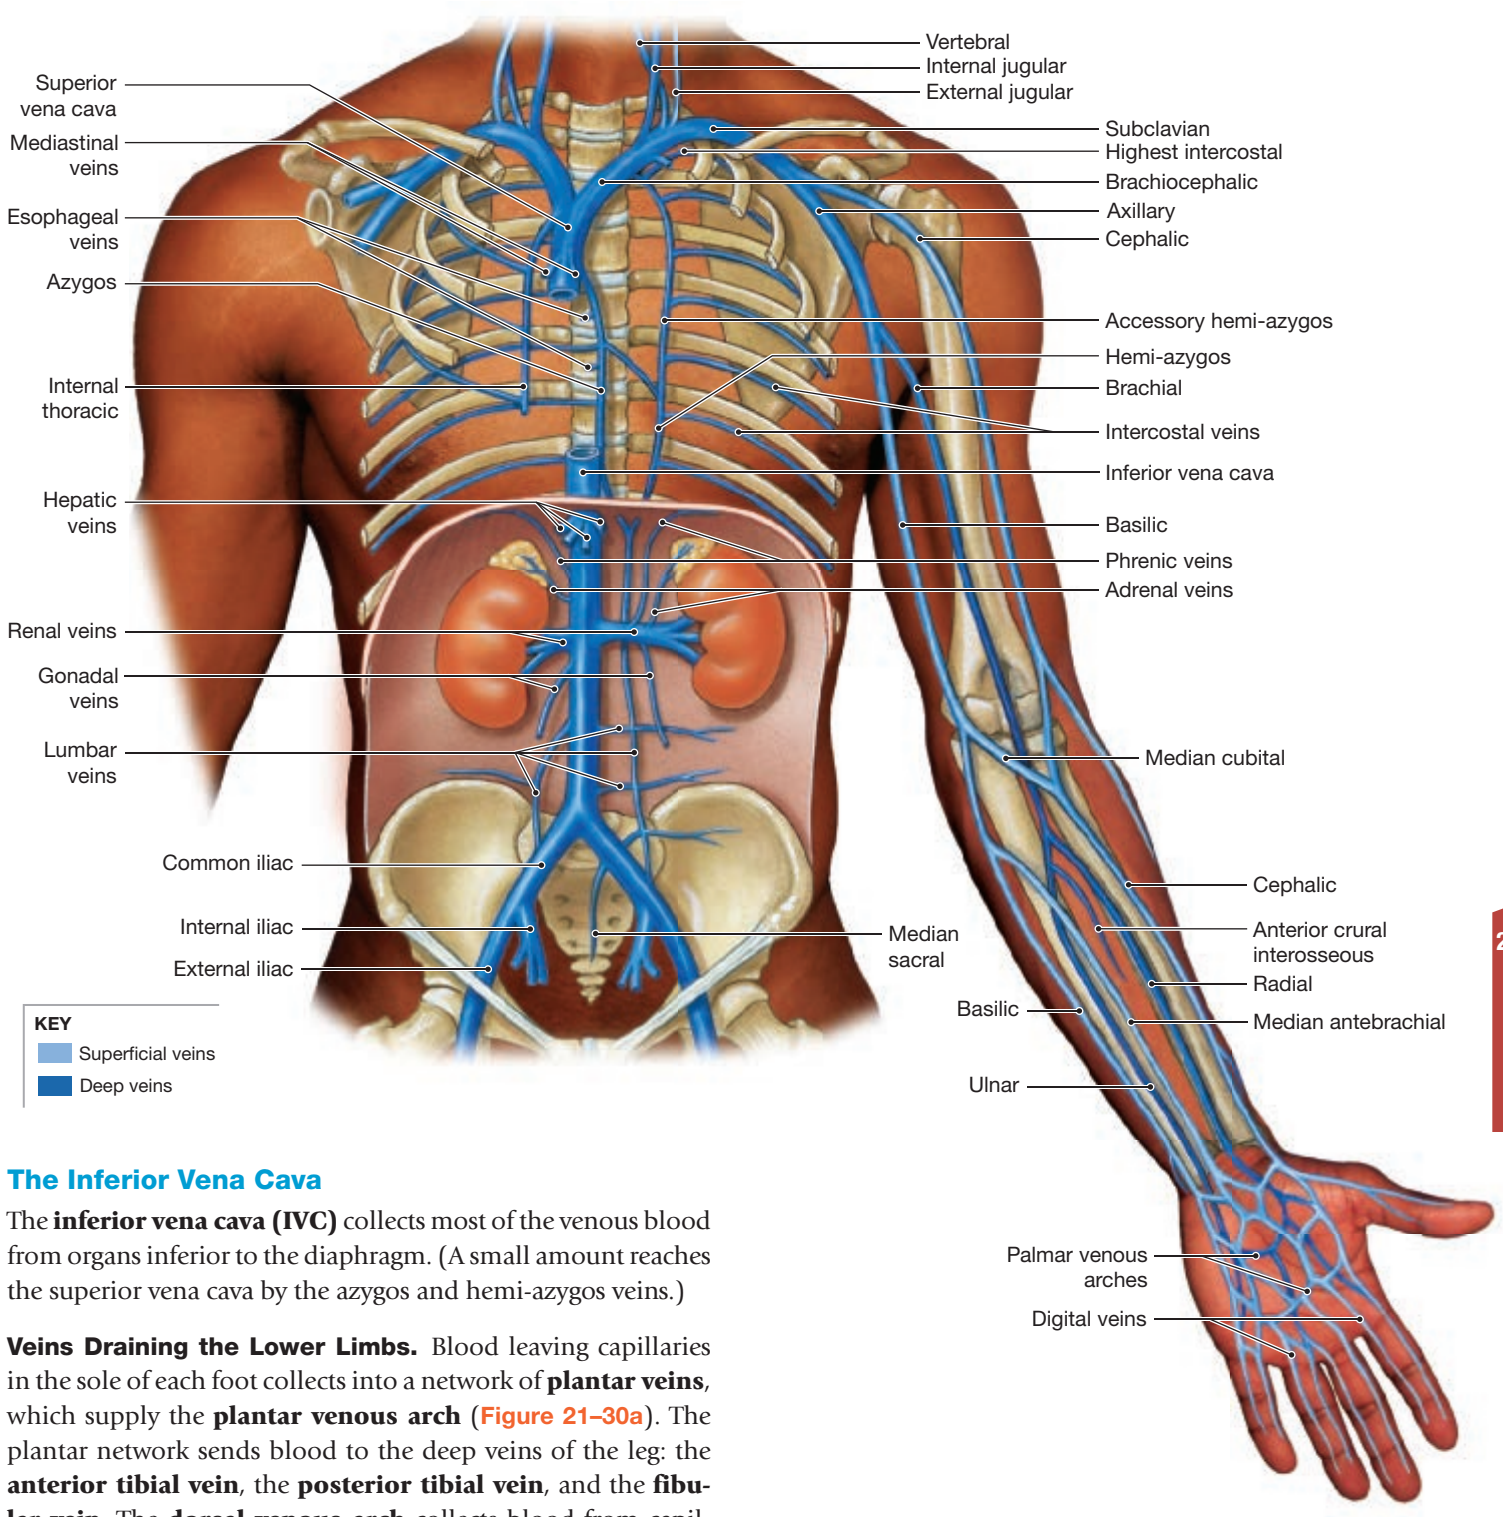
The azygos and hemi-azygos veins are the chief collecting vessels of the thorax. They receive blood from (1) **intercostal veins**, which in turn receive blood from the chest muscles; (2) **esophageal veins**, which drain blood from the inferior portion of the esophagus; and (3) smaller veins draining other mediastinal structures.

Figure 21–29 diagrams the venous branches of the superior vena cava.

Clinical Note Preparing the Circulation for Dialysis

When a patient's kidneys fail from chronic disease (diabetes mellitus, for example), the patient requires **dialysis** to cleanse the blood as the kidneys would normally do. A minor outpatient surgical procedure called an **arteriovenous fistula** prepares the circulation for successful dialysis. The surgeon connects a large vein, usually in the arm, to the nearby artery. Soon the higher pressure in the artery acts on the vein to enlarge its diameter. In a few weeks, the fistula has healed and can accept a dialysis needle. The patient's "dirty" blood (blood containing nitrogenous waste, such as urea) is withdrawn from his or her artery, "cleaned" in the dialysis machine, and returned easily to their enlarged vein. The fistula can last for several years before a new one needs to be created at another site.

Figure 21–28 The Venous Drainage of the Abdomen and Chest. ATLAS: Plates 27c; 29c; 47b,d; 61a; 62a,b



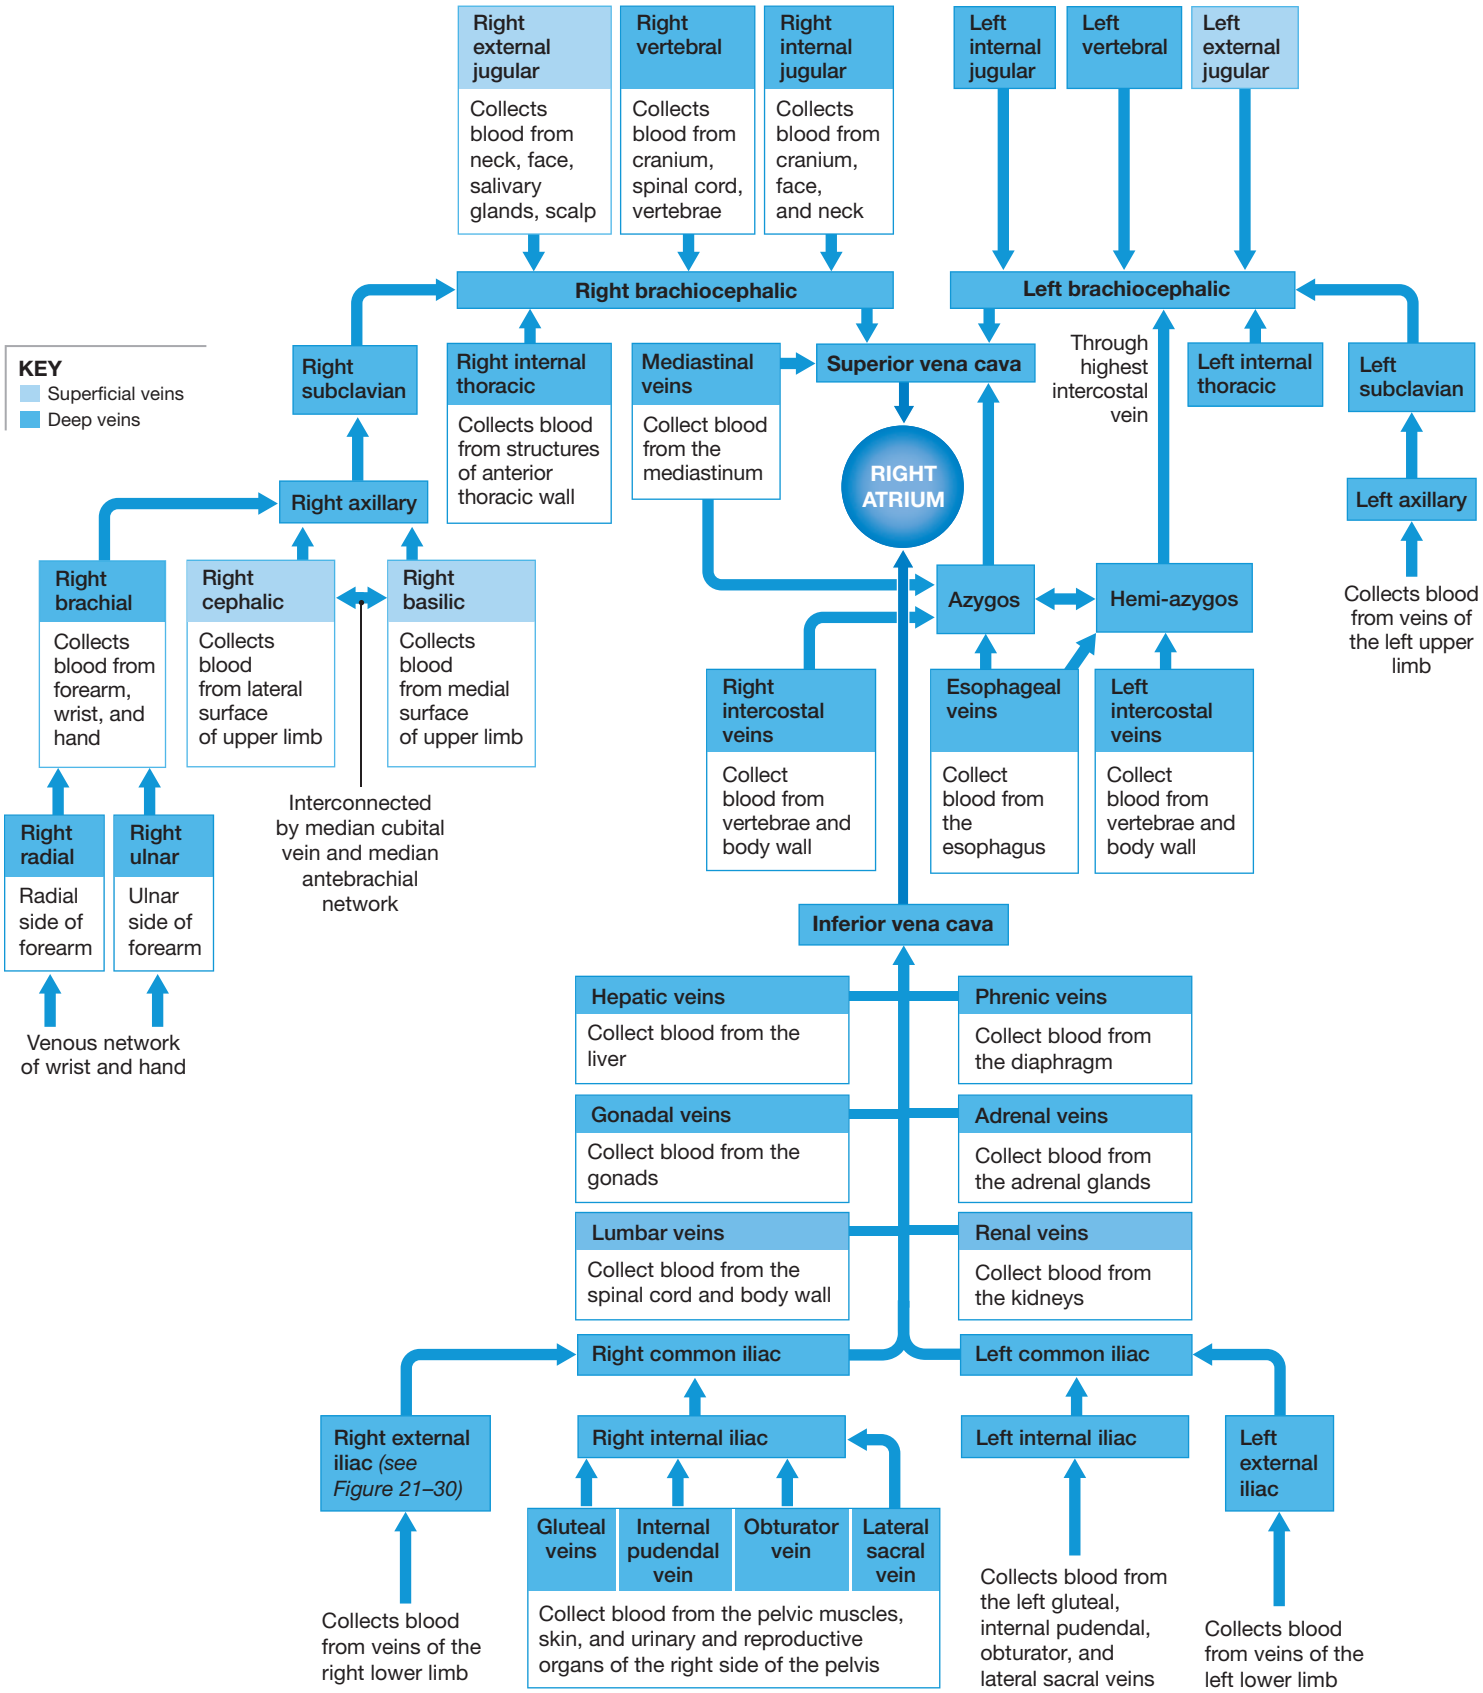
The Inferior Vena Cava

The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (A small amount reaches the superior vena cava by the azygos and hemi-azygos veins.)

Veins Draining the Lower Limbs. Blood leaving capillaries in the sole of each foot collects into a network of **plantar veins**, which supply the **plantar venous arch** (Figure 21–30a). The plantar network sends blood to the deep veins of the leg: the **anterior tibial vein**, the **posterior tibial vein**, and the **fibular vein**. The **dorsal venous arch** collects blood from capillaries on the superior surface of the foot and the **digital veins** of the toes. The plantar arch and the dorsal arch are extensively interconnected, and the path of blood flow can easily shift from superficial to deep veins.

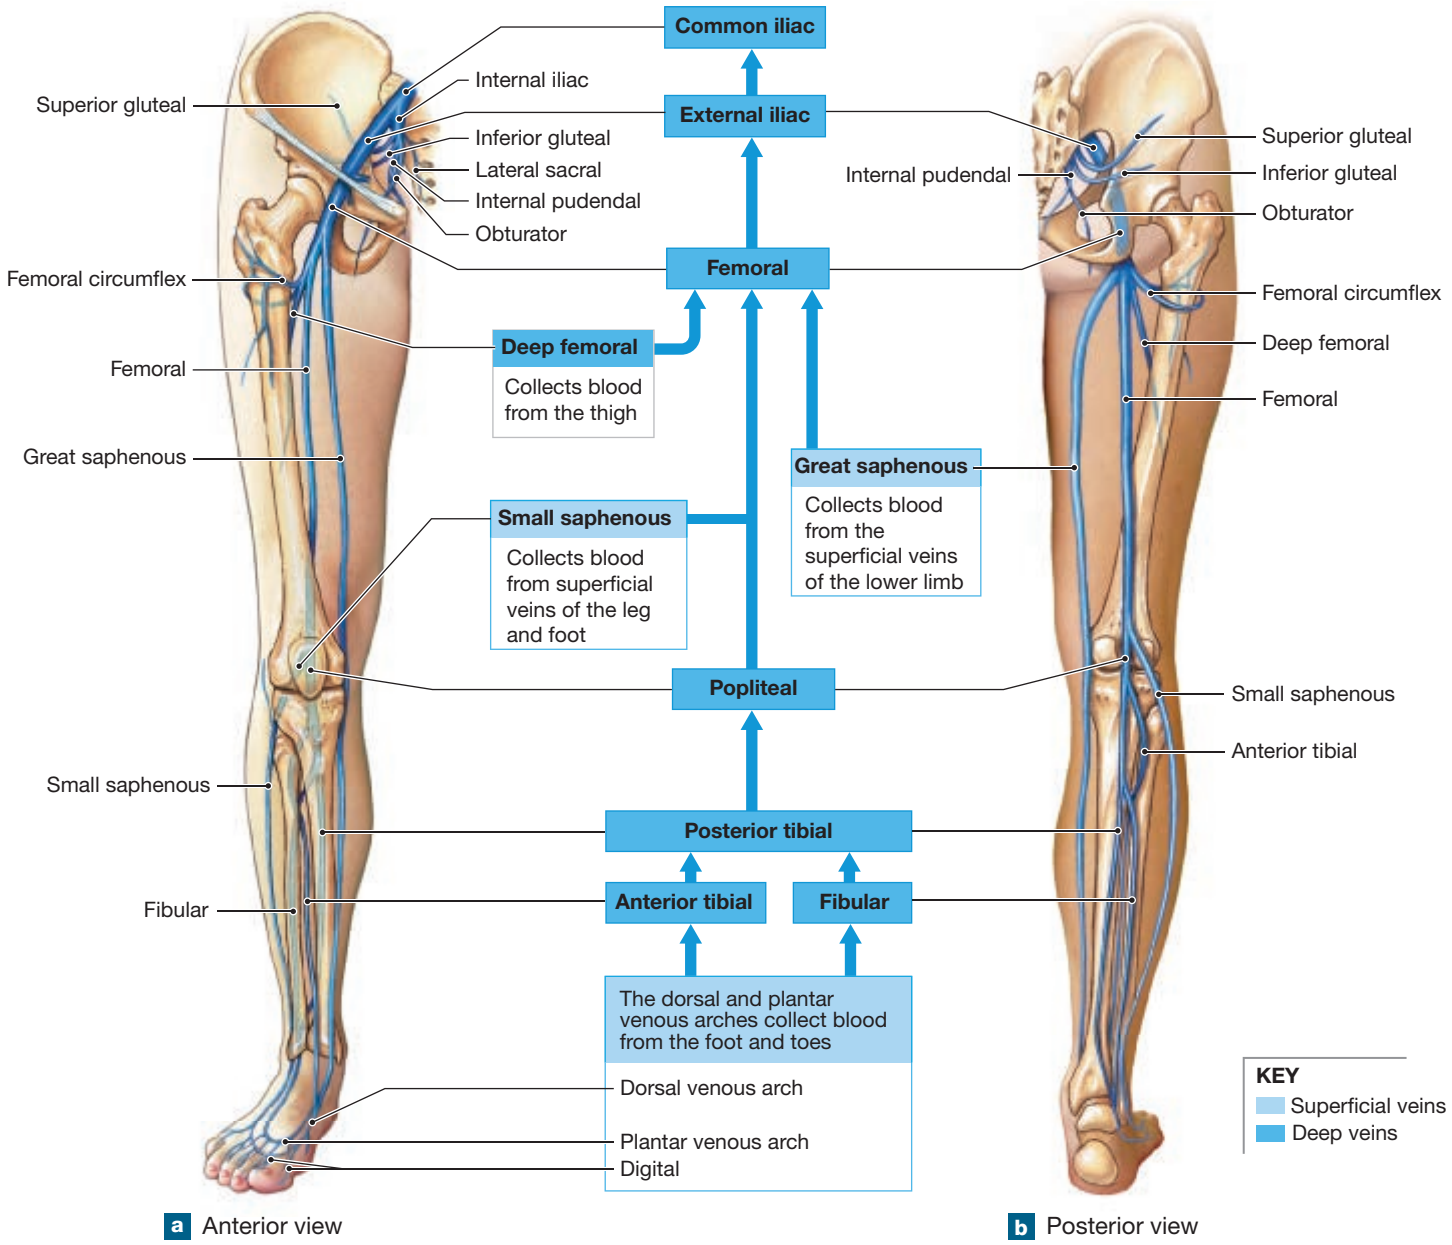
Two superficial veins drain the dorsal venous arch: the **great saphenous** (sa-FĒ-nus; *saphenes*, prominent) **vein** and the **small saphenous vein**. The great saphenous vein ascends along the medial aspect of the leg and thigh, draining into the *femoral vein* near the hip joint. The small saphenous vein arises from the dorsal venous arch and ascends along the posterior and lateral aspect of the calf. This vein then enters the popliteal fossa, where it meets the **popliteal vein**, formed by the union

Figure 21–29 Flowchart of Circulation to the Superior and Inferior Venae Cavae.



? What veins are shown draining directly into the superior vena cava?

Figure 21–30 Venous Drainage from the Lower Limb. ATLAS: Plates 70b; 74; 78a–g



of the fibular and both tibial veins (Figure 21–30a,b). The popliteal vein is easily palpated in the popliteal fossa adjacent to the adductor magnus muscle. At the femur, the popliteal vein becomes the **femoral vein**, which ascends along the thigh, next to the femoral artery. Immediately before penetrating the abdominal wall, the femoral vein receives blood from (1) the great saphenous vein; (2) the **deep femoral vein**, which collects blood from deeper structures in the thigh; and (3) the **femoral circumflex vein**, which drains the region around the neck and head of the femur. The femoral vein penetrates the body wall and emerges in the pelvic cavity as the **external iliac vein**.

Veins Draining the Pelvis. The external iliac veins receive blood from the lower limbs, the pelvis, and the lower abdomen. As the left and right external iliac veins cross the inner surface of the ilium, they are joined by the **internal iliac veins**, which drain the pelvic organs (see Figure 21–29). The internal iliac veins are formed by the fusion of the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral veins* (Figure 21–30a).

The union of external and internal iliac veins forms the **common iliac vein**. Its right and left branches ascend at an oblique angle. The left common iliac vein receives blood from the *median sacral vein*, which drains the area supplied by the median sacral artery (see Figure 21–28). Anterior to vertebra L_5, the common iliac veins unite to form the inferior vena cava.

Veins Draining the Abdomen. The inferior vena cava ascends posterior to the peritoneal cavity, parallel to the aorta. The abdominal portion of the inferior vena cava collects blood from six major veins (see Figures 21–28 and 21–29):

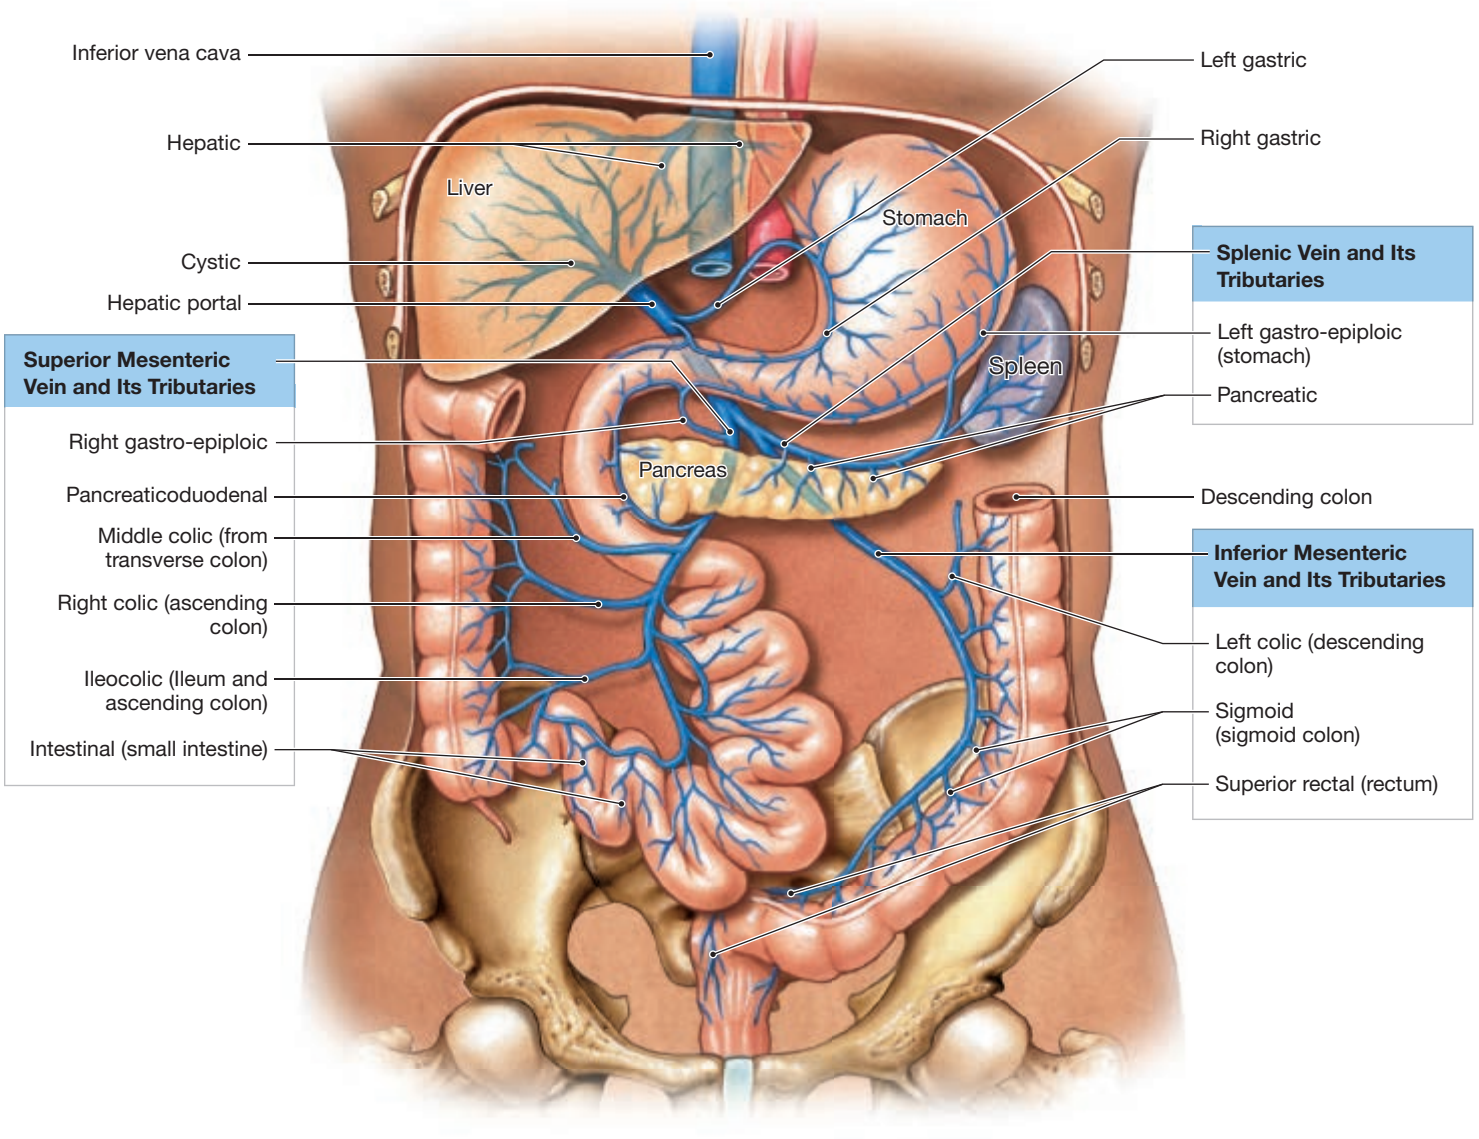
- **Lumbar veins** drain the lumbar portion of the abdomen, including the spinal cord and body wall muscles. Superior branches of these veins are connected to the azygos vein (right side) and hemi-azygos vein (left side), which empty into the superior vena cava.
- **Gonadal** (*ovarian* or *testicular*) **veins** drain the ovaries or testes. The right gonadal vein empties into the inferior vena cava. The left gonadal vein generally drains into the left renal vein.
- **Hepatic veins** from the liver empty into the inferior vena cava at the level of vertebra T_{10}.
- **Renal veins**, the largest branches of the inferior vena cava, collect blood from the kidneys.
- **Adrenal veins** drain the adrenal glands. In most people, only the right adrenal vein drains into the inferior vena cava. The left adrenal vein drains into the left renal vein.
- **Phrenic veins** drain the diaphragm. Only the right phrenic vein drains into the inferior vena cava. The left drains into the left renal vein.

Figure 21–29 diagrams the branches of the inferior vena cava.

The Hepatic Portal System

The **hepatic portal system** begins in the capillaries of the digestive organs and ends in the liver sinusoids (Figure 21–31).

Figure 21–31 **The Hepatic Portal System.** *(See also Figure 24–24, p. 922.)* ATLAS: Plates 53b; 54a–c; 55; 57a,b



(As you may recall from Chapter 18, a blood vessel connecting two capillary beds is called a *portal vessel*. The network is a *portal system*.) Blood flowing in the hepatic portal system is quite different from blood in other systemic veins, because it contains substances absorbed from the stomach and intestines. For example, levels of blood glucose and amino acids in the hepatic portal vein often exceed those found anywhere else in the cardiovascular system. The hepatic portal system delivers these and other absorbed compounds directly to the liver for storage, metabolic conversion, or excretion.

The largest vessel of the hepatic portal system is the **hepatic portal vein** (see Figure 21–31). It delivers venous blood to the liver. It receives blood from three large veins draining organs within the peritoneal cavity:

- The **inferior mesenteric vein** collects blood from capillaries along the inferior portion of the large intestine. Its branches include the *left colic vein*, *sigmoid vein*, and the *superior rectal veins*. They drain the descending colon, sigmoid colon, and rectum.
- The **splenic vein** is formed by the union of the inferior mesenteric vein and veins from the spleen, the lateral border of the stomach (*left gastro-epiploic vein*), and the pancreas (*pancreatic veins*).
- The **superior mesenteric vein** collects blood from veins draining the stomach (*right gastro-epiploic vein*), the small intestine (*intestinal* and *pancreaticoduodenal veins*), and two-thirds of the large intestine (*ileocolic*, *right colic*, and *middle colic veins*).

The hepatic portal vein forms through the fusion of the superior mesenteric, inferior mesenteric, and splenic veins. The superior mesenteric vein normally contributes the greater volume of blood and most of the nutrients. As it proceeds, the hepatic portal vein receives blood from the left and right **gastric veins**, which drain the medial border of the stomach, and from the **cystic vein** of the gallbladder.

After passing through liver sinusoids, blood collects in the hepatic veins, which empty into the inferior vena cava.

The composition of the blood in the systemic circuit is relatively stable despite changes in diet and digestive activity. The reason for this stability is that blood from the intestines goes to the liver first, and the liver regulates the nutrient content of the blood before it enters the inferior vena cava.

Checkpoint

19. **A blockage of which branch from the aortic arch would interfere with blood flow to the left arm?**
20. **Why would compression of the common carotid arteries cause a person to lose consciousness?**
21. **Isabella is in an automobile accident, and her celiac trunk is ruptured. Which organs will be affected most directly by this injury?**
22. **Whenever Noah gets angry, a large vein bulges in the lateral region of his neck. Which vein is this?**
23. **A thrombus that blocks the popliteal vein would interfere with blood flow in which other veins?**

See the blue Answers tab at the back of the book.

21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials; the fetal cardiovascular system changes to function independently after birth

Learning Outcome Identify the differences between fetal and adult circulation patterns, and describe the changes in the patterns of blood flow that occur at birth.

The fetal cardiovascular system differs from the adult cardiovascular system because the fetus and the adult have different sources of respiratory and nutritional support. Most strikingly, the fetal lungs are collapsed and nonfunctional, and the digestive tract has nothing to digest. Instead, diffusion across the placenta provides for the respiratory and nutritional needs of the fetus. This situation changes dramatically at birth, when the newborn's system is separated from that of the mother.

Fetal Circulatory Route and Placental Blood Supply

Fetal patterns of blood flow are diagrammed in Figure 21–32a. Blood flows to the placenta through a pair of **umbilical arteries**. They arise from the internal iliac arteries and enter the umbilical cord. Blood returns from the placenta in the single **umbilical vein**, bringing oxygen and nutrients to the developing fetus. The umbilical vein drains into the **ductus venosus**, a vascular connection to an intricate network of veins within the developing liver. The ductus venosus collects blood from the veins of the liver and from the umbilical vein, and empties into the inferior vena cava.

Fetal Heart and Great Vessels

One of the most interesting aspects of cardiovascular development is that of the heart, which reflects the differences between the life of an embryo or fetus and that of an infant. The interatrial and interventricular septa develop early in fetal life, but the interatrial partition remains functionally incomplete until birth. The **foramen ovale**, or *interatrial opening*, is associated with a long flap that acts as a valve. Blood can flow freely from the right atrium to the left atrium, but any backflow closes the valve and isolates the two chambers from one another. Thus, blood entering the heart at the right atrium can bypass the pulmonary circuit. A second short-circuit exists between the pulmonary and

a Blood flow to and from the placenta in full-term fetus (before birth)

b Blood flow through the neonatal (newborn) heart after delivery

aortic trunks. This connection, the **ductus arteriosus**, consists of a short, muscular vessel. ATLAS: Embryology Summary 16: The Development of the Cardiovascular System

With the lungs collapsed, the capillaries are compressed and little blood flows through the lungs. During diastole, blood enters the right atrium and flows into the right ventricle, but it also passes into the left atrium through the foramen ovale. About 25 percent of the blood arriving at the right atrium bypasses the pulmonary circuit in this way. In addition, more than 90 percent of the blood leaving the right ventricle passes through the ductus arteriosus and enters the systemic circuit rather than continuing to the lungs.

Cardiovascular Changes at Birth

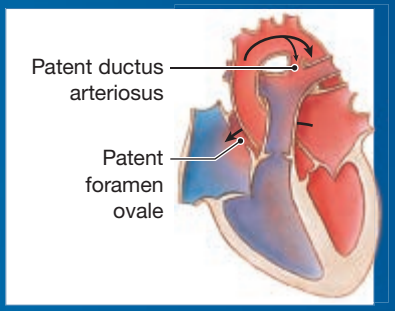
At birth, dramatic changes take place. When the placental connection is broken at birth, blood stops flowing in the umbilical vessels, and they soon degenerate. Remnants of these vessels persist throughout life as fibrous cords. When an infant takes the first breath, the lungs expand, and so do the pulmonary vessels. The resistance in the pulmonary circuit declines suddenly, and blood rushes into the pulmonary vessels. Within a few seconds, rising O_2 levels stimulate the constriction of the ductus arteriosus, isolating the pulmonary and aortic trunks from one another. As pressures rise in the left atrium, the valvular flap closes the foramen ovale. In adults, the interatrial septum bears the *fossa ovalis*, a shallow depression that marks the site of the foramen ovale (look back at **Figure 20–5a,** p. 695). The remnants of the ductus arteriosus persist throughout life as the *ligamentum arteriosum*, a fibrous cord.

If the proper cardiovascular changes do not take place at birth or shortly after, problems eventually develop. Their severity depends on which connection remains open and on the size of the opening. Treatment may involve surgery to close the foramen ovale, the ductus arteriosus, or both. Other congenital heart defects result from abnormal cardiac development or inappropriate connections between the heart and major arteries and veins. **Spotlight Figure 21–33** focuses on congenital heart problems.

SPOTLIGHT

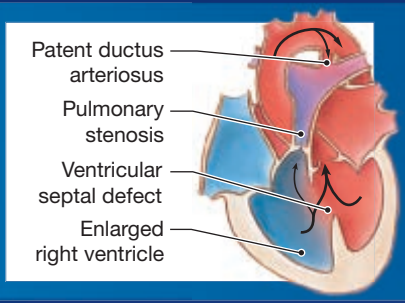
Figure 21–33
Congenital Heart Problems

Although minor individual variations in the vascular network are quite common, congenital heart problems serious enough to threaten homeostasis are relatively rare.



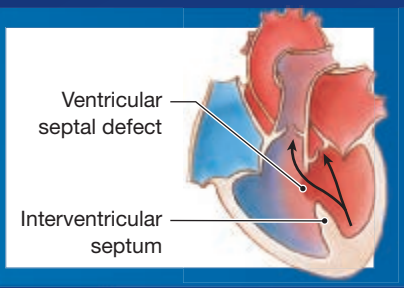
Patent Foramen Ovale and Patent Ductus Arteriosus

If the foramen ovale remains open, or *patent*, blood recirculates through the pulmonary circuit instead of entering the left ventricle. The movement, driven by the relatively high systemic pressure, is called a "left-to-right shunt." Arterial oxygen content is normal, but the left ventricle must work much harder than usual to provide adequate blood flow through the systemic circuit. Hence, pressures rise in the pulmonary circuit. If the pulmonary pressures rise enough, they may force blood into the systemic circuit through the ductus arteriosus. This condition—a patent ductus arteriosus—creates a "right-to-left shunt." Because the circulating blood is not adequately oxygenated, it develops a deep red color. The skin then develops the blue tones typical of cyanosis and the infant is known as a "blue baby."



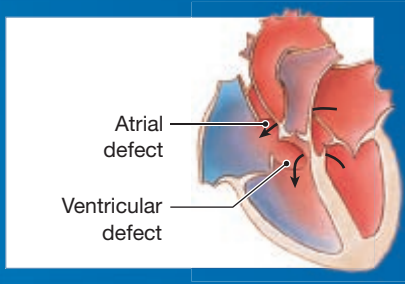
Tetralogy of Fallot

The tetralogy of Fallot (fa-LŌ) is a complex group of heart and circulatory defects that affect 0.10% of newborn infants. In this condition, (1) the pulmonary trunk is abnormally narrow (pulmonary stenosis), (2) the interventricular septum is incomplete, (3) the aorta originates where the interventricular septum normally ends, and (4) the right ventricle is enlarged and both ventricles thicken in response to the increased workload.



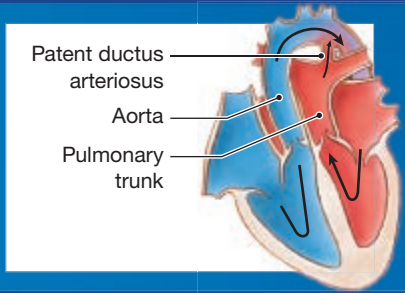
Ventricular Septal Defect

A ventricular septal defect is an abnormal opening in the wall (septum) between the left and right ventricles. It affects 0.12% of newborns. The opening between the two ventricles has an effect similar to a connection between the atria: When the more powerful left ventricle beats, it ejects blood into the right ventricle and pulmonary circuit.



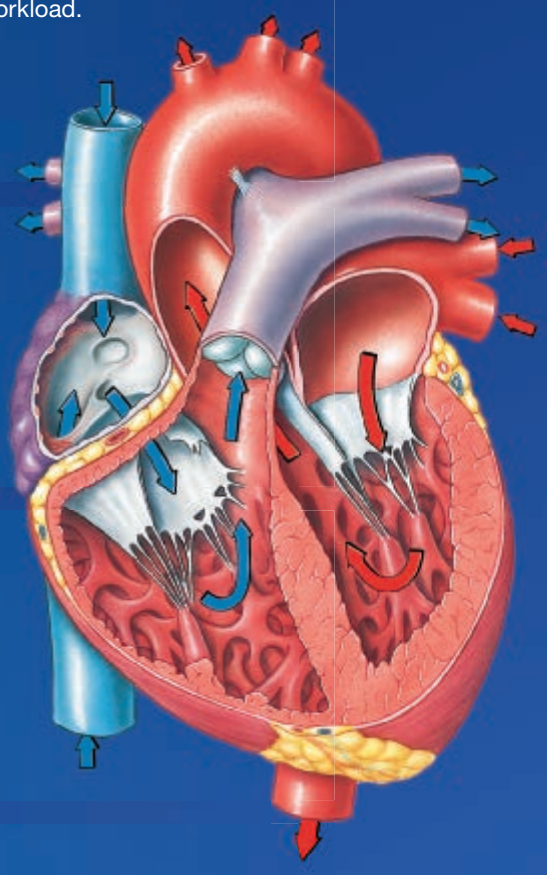
Atrioventricular Septal Defect

In an atrioventricular septal defect, both the atria and ventricles are incompletely separated. The results are quite variable, depending on the extent of the defect and the effects on the atrioventricular valves. This type of defect most commonly affects infants with Down syndrome, a disorder caused by the presence of an extra copy of chromosome 21.



Transposition of the Great Vessels

In the transposition of the great vessels, the aorta is connected to the right ventricle instead of to the left ventricle, and the pulmonary artery is connected to the left ventricle instead of the right ventricle. This malformation affects 0.05% of newborn infants.



Normal Heart Structure
Most congenital heart problems result from abnormal formation of the heart or problems with the connections between the heart and the great vessels.

Checkpoint

24. Name the three vessels that carry blood to and from the placenta.
25. A blood sample taken from an umbilical cord contains high levels of oxygen and nutrients, and low levels of carbon dioxide and waste products. Is this sample from an umbilical artery or the umbilical vein? Explain.
26. Name the structures in the fetal circulation that stop functioning at birth. What becomes of these structures?

See the blue Answers tab at the back of the book.

21-9 Aging affects the blood, heart, and blood vessels

Learning Outcome Discuss the effects of aging on the cardiovascular system, and give examples of interactions between the cardiovascular system and other organ systems.

The capabilities of the cardiovascular system gradually decline. As you age, your cardiovascular system undergoes the following major changes:

- **Age-related changes in blood** may include (1) a decreased hematocrit; (2) constriction or blockage of peripheral veins by a stationary blood clot called a *thrombus*, which can become detached, pass through the heart, and become wedged in a small artery (commonly in the lungs), causing *pulmonary embolism*; and (3) pooling of blood in the veins of the legs because valves are not working effectively.
- **Age-related changes in the heart** include (1) a reduction in maximum cardiac output, (2) changes in the activities of pacemaker and conducting cells, (3) a reduction in the elasticity of the cardiac (fibrous) skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac contractile cells by scar tissue.
- **Age-related changes in blood vessels** may be linked to arteriosclerosis: (1) The inelastic walls of arteries become less tolerant of sudden pressure increases, which can lead to an aneurysm, whose rupture may (depending on the vessel) cause a cerebrovascular accident (CVA), myocardial infarction, or massive blood loss; (2) calcium salts can be deposited on weakened vascular walls, increasing the risk of a CVA or myocardial infarction; (3) lipid deposits in the tunica media associated with a damaged endothelial lining and calcium salts can form atherosclerotic plaques; and (4) thrombi can form at atherosclerotic plaques.

The cardiovascular system is both anatomically and functionally linked to all other systems. Build Your Knowledge Figure 21–34 shows the functional relationships between the cardiovascular system and the other body systems we have studied so far. We are now ready to consider the organization and function of the lymphatic system, the focus of Chapter 22.

Checkpoint

27. Identify components of the cardiovascular system that are affected by age.
28. Define *thrombus*.
29. Define *aneurysm*.
30. Describe what the cardiovascular system provides for all other body systems.
31. What is the relationship between the skeletal system and the cardiovascular system?

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 21–34 Integration of the CARDIOVASCULAR system with the other body systems presented so far.

Integumentary System

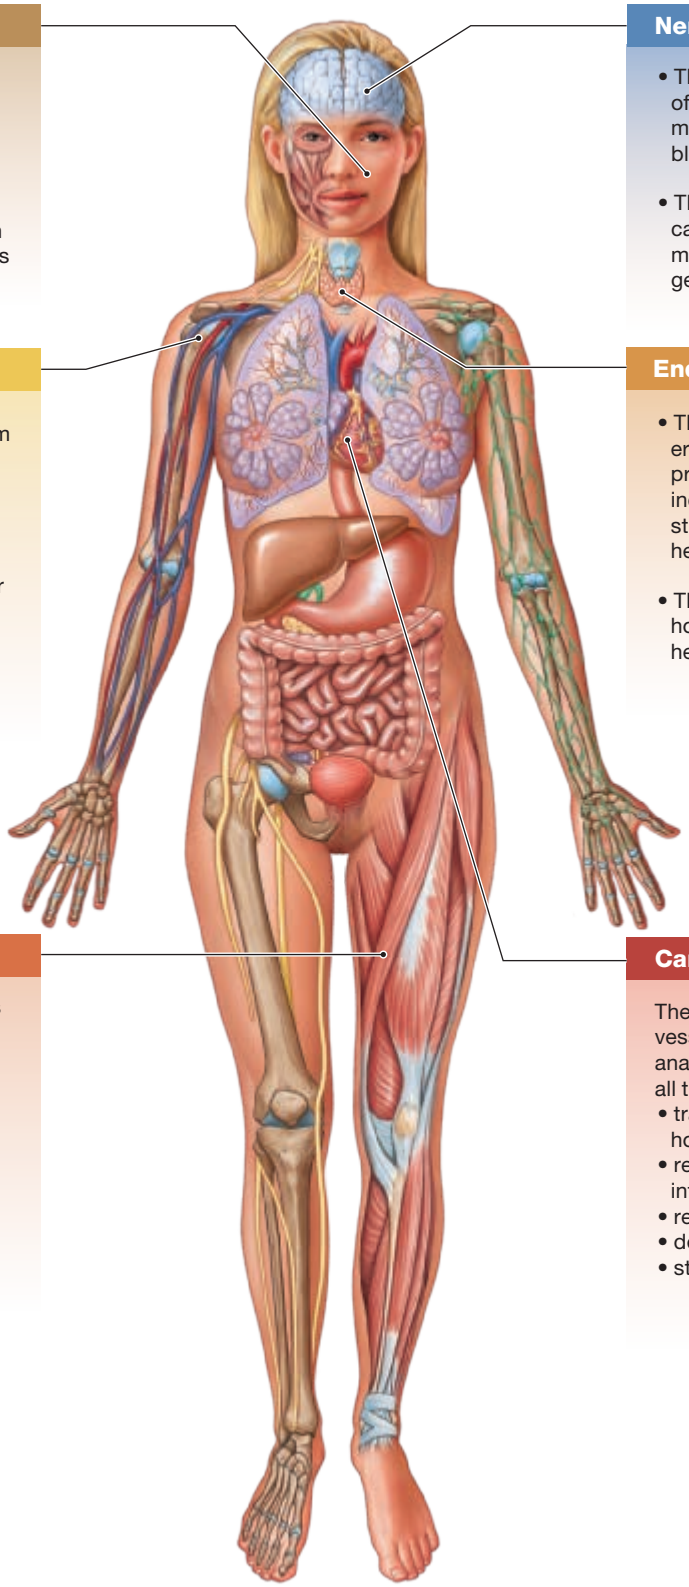
- The Integumentary System has mast cells that trigger localized changes in blood flow and capillary permeability
- The cardiovascular system delivers immune system cells to injury sites; clotting response seals breaks in skin surface; carries away toxins from sites of infection; provides heat

Skeletal System

- The Skeletal System provides calcium needed for normal cardiac muscle contraction; protects blood cells developing in red bone marrow
- The cardiovascular system transports calcium and phosphate for bone deposition; delivers EPO to red bone marrow, parathyroid hormone and calcitonin to osteoblasts and osteoclasts

Muscular System

- The Muscular System assists venous circulation through skeletal muscle contractions; protects superficial blood vessels, especially in neck and limbs
- The cardiovascular system delivers oxygen and nutrients, removes carbon dioxide, lactate, and heat during skeletal muscle activity



Nervous System

- The Nervous System controls patterns of circulation in peripheral tissues; modifies heart rate and regulates blood pressure; releases ADH
- The cardiovascular system has capillaries whose endothelial cells maintain the blood brain barrier; helps generate CSF

Endocrine System

- The Endocrine System produces erythropoietin (EPO), which regulates production of RBCs; several hormones increase blood pressure; epinephrine stimulates cardiac muscle, increasing heart rate and force of contraction
- The cardiovascular system distributes hormones throughout the body; the heart secretes ANP and BNP

Cardiovascular System

The cardiovascular system has blood vessels that provide extensive anatomical connections between it and all the other organ systems. It:

- transports dissolved gases, nutrients, hormones, and metabolic wastes
- regulates pH and ion composition of interstitial fluid
- restricts fluid losses at injury sites
- defends against toxins and pathogens
- stabilizes body temperature

21 Chapter Review

Study Outline

An Introduction to Blood Vessels and Circulation p. 728

1. Blood circulates throughout the body, moving from the heart, then through the body tissues, and then back to the heart, in tubular structures called *blood vessels*.

21-1 Arteries, which are elastic or muscular, and veins, which contain valves, have three-layered walls; capillaries have thin walls with only one layer p. 728

2. Blood flows through a network of arteries, veins, and capillaries. All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls.
3. **Arteries** and **veins** form an internal distribution system through which the heart propels blood. Arteries branch repeatedly, decreasing in size until they become **arterioles**. From the arterioles, blood enters **capillary** networks. Blood flowing from the capillaries enters small **venules** before entering larger veins.
4. The walls of arteries and veins contain three layers: the innermost **tunica intima**, the **tunica media**, and the outermost **tunica externa**. *(Figure 21–1)*
5. In general, the walls of arteries are thicker than those of veins. Arteries constrict when blood pressure does not distend them, but veins constrict very little. The endothelial lining cannot contract, so when constriction occurs, the lining of an artery becomes folded. *(Figure 21–1)*
6. The arterial system includes the large **elastic arteries**, medium-sized **muscular arteries**, and smaller **arterioles**. As blood proceeds toward the capillaries, the number of vessels increases, but the luminal diameters of the individual vessels decrease and the walls become thinner. *(Figure 21–2)*
7. **Atherosclerosis**, a type of **arteriosclerosis**, is associated with changes in the endothelial lining of arteries. Fatty masses of tissue called **plaques** typically develop during atherosclerosis.
8. Capillaries are the only blood vessels whose walls are thin enough to permit an exchange between blood and interstitial fluid. Capillaries are **continuous** or **fenestrated**. **Sinusoids** have fenestrated walls, a discontinuous endothelium, and form networks that allow very slow blood flow. Sinusoids occur in the liver and in various endocrine organs. *(Figure 21–3)*
9. Capillaries form interconnected networks called **capillary beds.** A band of smooth muscle, the **precapillary sphincter**, adjusts the blood flow into each capillary. The entire capillary bed may be bypassed by blood flow through **arteriovenous anastomoses**. *(Figure 21–4)*
10. Venules collect blood from the capillaries and merge into **medium-sized veins** and then **large veins**. The arterial system is a high-pressure system; blood pressure in veins is much lower. **Valves** in veins prevent the backflow of blood. *(Figures 21–1, 21–2, 21–5)*
11. Veins expand easily at low pressures and have high **capacitance**. Veins act as **blood reservoirs** and can accommodate large changes in blood volume. Peripheral **venoconstriction** helps maintain adequate blood volume in the arterial system after a hemorrhage. *(Figure 21–6)*

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange p. 737

12. Cardiovascular regulation involves the manipulation of blood pressure and resistance to control the rates of blood flow and capillary exchange.
13. Blood flows from an area of higher pressure to one of lower pressure, and blood flow is proportional to the pressure gradient. The **circulatory pressure** is the pressure gradient across the systemic circuit. It is reported as three values: arterial **blood pressure (BP)**, **capillary hydrostatic pressure (CHP)**, and **venous pressure**.
14. The **resistance (*R*)** determines the rate of blood flow through the systemic circuit. The major determinant of blood flow rate is the **peripheral resistance**—the resistance of the arterial system. Neural and hormonal control mechanisms regulate blood pressure and peripheral resistance.
15. **Vascular resistance** is the resistance of blood vessels. It is the largest component of peripheral resistance and depends on vessel length and vessel luminal diameter. *(Figure 21–7)*
16. **Viscosity** and **turbulence** also contribute to peripheral resistance. *(Table 21–1)*
17. The high arterial pressures overcome peripheral resistance and maintain blood flow through peripheral tissues. Capillary pressures are normally low, and small changes in capillary pressure determine the rate of movement of fluid into or out of the bloodstream. Venous pressure, normally low, determines **venous return** and affects cardiac output and peripheral blood flow. *(Figures 21–8, 21–9; Table 21–1)*
18. Arterial blood pressure rises during ventricular systole and falls during ventricular diastole. The difference between these two blood pressures is the **pulse pressure**. *(Figures 21–8, 21–9)*
19. Valves, muscular compression, and the **respiratory pump** help the relatively low venous pressures propel blood toward the heart. *(Figures 21–5, 21–8)*
20. At the capillaries, hydrostatic pressure (blood pressure) forces water and solutes out of the plasma, across capillary walls. Water moves out of the capillaries, through the peripheral tissues, and back to the bloodstream by way of the lymphatic system. Water movement across capillary walls is determined by the interplay between hydrostatic pressures and osmotic pressures. *(Figure 21–10)*

21. **Osmotic pressure (OP)** is a measure of the pressure that must be applied to prevent osmotic movement across a membrane. Osmotic water movement continues until either solute concentrations are equalized or the movement is prevented by an opposing hydrostatic pressure.
22. The rates of filtration and reabsorption gradually change as blood passes along the length of a capillary, as determined by the **net filtration pressure** (the difference between the net hydrostatic pressure and the net osmotic pressure). *(Figure 21–11)*

21-3 Blood flow and pressure in tissues are controlled by both autoregulation and central regulation p. 745

23. Homeostatic mechanisms ensure that **tissue perfusion** (blood flow) delivers adequate oxygen and nutrients.
24. Autoregulation, neural mechanisms, and endocrine mechanisms influence the coordinated regulation of cardiovascular function. Autoregulation involves local factors changing the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. Neural mechanisms respond to changes in arterial pressure or blood gas levels. Hormones can assist in short-term adjustments (changes in cardiac output and peripheral resistance) and long-term adjustments (changes in blood volume that affect cardiac output and gas transport). *(Figure 21–12)*
25. Peripheral resistance is adjusted at the tissues by local factors that result in the dilation or constriction of precapillary sphincters. *(Figure 21–4)*
26. **The cardiovascular (CV) center** of the medulla oblongata is responsible for adjusting cardiac output and peripheral resistance to maintain adequate blood flow. Its vasomotor center contains one group of neurons responsible for controlling vasoconstriction, and another group responsible for controlling vasodilation. Its cardiac centers include a *cardioacceleratory center* (which increases cardiac output through sympathetic innervation) and *cardioinhibitory center* (which decreases cardiac output through parasympathetic innervation).
27. **Baroreceptor reflexes** monitor the degree of stretch within expandable organs. Baroreceptors are located in the **carotid sinuses**, the **aortic sinuses**, and the right atrium. *(Figure 21–13)*
28. **Chemoreceptor reflexes** respond to changes in the oxygen or CO_2 levels in the blood. They are triggered by sensory neurons located in the **carotid bodies** and the **aortic bodies**. *(Figure 21–14)*
29. The endocrine system provides short-term regulation of cardiac output and peripheral resistance with epinephrine and norepinephrine from the adrenal medullae. Hormones involved in the long-term regulation of blood pressure and volume are *antidiuretic hormone (ADH)*, *angiotensin II*, *erythropoietin (EPO)*, and *natriuretic peptides (ANP* and *BNP)*. *(Figure 21–15)*

21-4 The cardiovascular system adapts to physiological stress while maintaining a special vascular supply to the brain, heart, and lungs p. 752

30. The blood brain barrier, the coronary circulation, and the capillary network in the lungs are examples of special circulations, in which cardiovascular dynamics and regulatory mechanisms differ from those in other tissues.
31. During exercise, blood flow to skeletal muscles increases at the expense of blood flow to nonessential organs, and cardiac output rises. Cardiovascular performance improves with training. Athletes have larger stroke volumes, slower resting heart rates, and larger cardiac reserves than do nonathletes. *(Tables 21–2, 21–3)*
32. Blood loss lowers blood volume and venous return and decreases cardiac output. Compensatory mechanisms include an increase in cardiac output, mobilization of venous blood reservoirs, peripheral vasoconstriction, and the release of hormones that promote the retention of fluids and the manufacture of erythrocytes. *(Figure 21–16)*

21-5 The vessels of the cardiovascular system make up both pulmonary and systemic circuits p. 756

33. The peripheral distributions of arteries and veins are generally identical on both sides of the body, except near the heart. *(Figure 21–17)*

21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins p. 757

34. The pulmonary circuit includes the pulmonary trunk, the **left** and **right pulmonary arteries**, and the **pulmonary veins**, which empty into the left atrium. *(Figure 21–18)*

21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the lungs, and returns deoxygenated blood to the right atrium p. 758

35. The **ascending aorta** gives rise to the coronary circulation. The **aortic arch** communicates with the **descending aorta**. *(Figures 21–19 to 21–25)*
36. Three elastic arteries originate along the aortic arch: the **left common carotid artery**, the **left subclavian artery**, and the **brachiocephalic trunk**. *(Figures 21–20 to 21–22)*
37. The remaining major arteries of the body originate from the **descending aorta**. *(Figures 21–23 to 21–25)*
38. Arteries in the neck and limbs are deep beneath the skin; in contrast, there are generally two sets of peripheral veins, one superficial and one deep. This dual venous drainage is important for controlling body temperature. *(Figure 21–26)*
39. The **superior vena cava** receives blood from the head, neck, chest, shoulders, and arms. *(Figures 21–26 to 21–29)*
40. The **inferior vena cava** collects most of the venous blood from organs inferior to the diaphragm. *(Figures 21–28 to 21–30)*
41. The **hepatic portal system** directs blood from the other digestive organs to the liver before the blood returns to the heart. *(Figure 21–31)*

21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials; the fetal cardiovascular system changes to function independently after birth p. 775

42. Blood flows to the placenta in a pair of **umbilical arteries** and from the placenta in a single **umbilical vein**. *(Figure 21–32)*
43. The interatrial partition remains functionally incomplete until birth. The **foramen ovale** allows blood to flow freely from the right to the left atrium, and the **ductus arteriosus** short-circuits the pulmonary trunk.
44. At birth, the foramen ovale closes, leaving the fossa ovalis. The ductus arteriosus constricts, leaving the ligamentum arteriosum. *(Figure 21–32)*
45. Congenital cardiovascular problems generally reflect abnormalities of the heart or of interconnections between the heart and great vessels. *(Spotlight Figure 21–33)*

21-9 Aging affects the blood, heart, and blood vessels p. 778

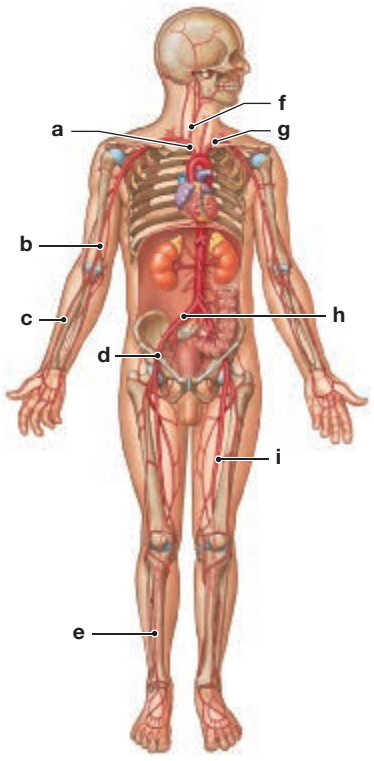
46. Age-related changes in the blood include (1) a decreased hematocrit, (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), and (3) pooling of blood in the veins of the legs because valves are not working effectively.
47. Age-related changes in the heart include (1) a reduction in the maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the elasticity of the cardiac skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) the replacement of damaged cardiac muscle cells by scar tissue.
48. Age-related changes in blood vessels, commonly related to arteriosclerosis, include (1) a weakening in the walls of arteries, potentially leading to the formation of an *aneurysm*; (2) deposition of calcium salts on weakened vascular walls, increasing the risk of a stroke or myocardial infarction; (3) lipid deposits in the tunica media associated with damaged endothelial lining and calcium salts forming atherosclerotic plaques; and (4) the formation of a thrombus at atherosclerotic plaques.
49. The cardiovascular system is anatomically and functionally connected to all other body systems. *(Figure 21–34)*

Review Questions

See the blue Answers tab at the back of the book.

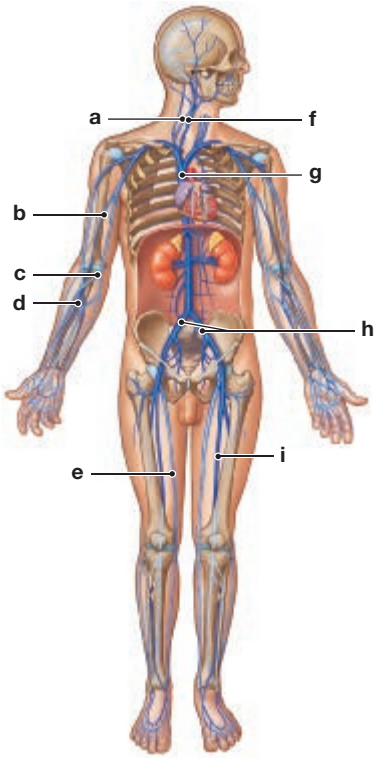
LEVEL 1 Reviewing Facts and Terms

1. Identify the major arteries in the following diagram.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____

2. The blood vessels that play the most important role in regulating blood pressure and blood flow to a tissue are the **(a)** arteries, **(b)** arterioles, **(c)** veins, **(d)** venules, **(e)** capillaries.
3. Cardiovascular function is regulated by all of the following *except* **(a)** local factors, **(b)** neural factors, **(c)** endocrine factors, **(d)** venous return, **(e)** conscious control.
4. Baroreceptors that function in the regulation of blood pressure are located in the **(a)** left ventricle, **(b)** brainstem, **(c)** carotid sinus, **(d)** common iliac artery, **(e)** pulmonary trunk.
5. The two-way exchange of substances between blood and body cells occurs only through **(a)** arterioles, **(b)** capillaries, **(c)** venules, **(d)** all of these.
6. Large molecules such as peptides and proteins move into and out of the bloodstream by way of **(a)** continuous capillaries, **(b)** fenestrated capillaries, **(c)** thoroughfare channels, **(d)** venules.
7. The local control of blood flow due to the action of precapillary sphincters is **(a)** vasomotion, **(b)** autoregulation, **(c)** selective resistance, **(d)** turbulence.
8. Blood is transported through the venous system by means of **(a)** skeletal muscle contractions, **(b)** decreasing blood pressure, **(c)** the respiratory pump, **(d)** a and c.
9. Identify the major veins in the following diagram.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____

10. The most important factor in vascular resistance is **(a)** the viscosity of the blood, **(b)** the diameter of the lumen of blood vessels, **(c)** turbulence due to irregular surfaces of blood vessels, **(d)** the length of the blood vessels.
11. Net hydrostatic pressure forces water _____ a capillary; net osmotic pressure reabsorbs water _____ a capillary. **(a)** into, out of, **(b)** out of, into, **(c)** out of, out of, **(d)** into, into.
12. The two arteries formed by the division of the brachiocephalic trunk are the **(a)** aorta and internal carotid, **(b)** axillary and brachial, **(c)** external and internal carotid, **(d)** common carotid and subclavian.
13. The unpaired arteries supplying blood to the visceral organs include **(a)** the adrenal, renal, and lumbar arteries, **(b)** the iliac, gonadal, and femoral arteries, **(c)** the celiac and superior and inferior mesenteric arteries, **(d)** all of these.
14. The paired arteries supplying blood to the body wall and other structures outside the abdominopelvic cavity include the **(a)** left gastric, hepatic, splenic, and phrenic arteries, **(b)** adrenal, colic, lumbar, and gonadal arteries, **(c)** iliac, femoral, and lumbar arteries, **(d)** celiac, left gastric, and superior and inferior mesenteric arteries.
15. The vein that drains the dural sinuses of the brain is the **(a)** cephalic vein, **(b)** great saphenous vein, **(c)** internal jugular vein, **(d)** superior vena cava.
16. The vein that collects most of the venous blood inferior to the diaphragm is the **(a)** superior vena cava, **(b)** great saphenous vein, **(c)** inferior vena cava, **(d)** azygos vein.
17. What are the primary forces that cause fluid to move **(a)** out of a capillary at its arterial end and into the interstitial fluid, **(b)** into a capillary at its venous end from the interstitial fluid?
18. What cardiovascular changes occur at birth?

LEVEL 2 Reviewing Concepts

19. A major difference between the arterial and venous systems is that **(a)** arteries are usually more superficial than veins, **(b)** in the limbs there is dual venous drainage, **(c)** veins are usually less branched compared to arteries, **(d)** veins exhibit a much more orderly pattern of branching in the limbs, **(e)** veins are not found in the abdominal cavity.
20. Which of the following conditions would have the *greatest* effect on peripheral resistance? **(a)** doubling the length of a vessel, **(b)** doubling the diameter of a vessel, **(c)** doubling the viscosity of the blood, **(d)** doubling the turbulence of the blood, **(e)** doubling the number of white cells in the blood.
21. Which of the following is *greater*? **(a)** the osmotic pressure of the interstitial fluid during inflammation, **(b)** the osmotic pressure of the interstitial fluid during normal conditions, **(c)** neither is greater.
22. Relate the anatomical differences between arteries and veins to their functions.
23. Why do capillaries permit the diffusion of materials, whereas arteries and veins do not?
24. How is blood pressure maintained in veins to counter the force of gravity?
25. How do pressure and resistance affect cardiac output and peripheral blood flow?
26. Why is blood flow to the brain relatively continuous and constant?
27. Compare the effects of the cardioacceleratory and cardioinhibitory centers on cardiac output and blood pressure.

LEVEL 3 Critical Thinking and Clinical Applications

28. Bob is sitting outside on a warm day and is sweating profusely. Mary wants to practice taking blood pressures, and he agrees to play the patient. Mary finds that Bob's blood pressure is elevated, even though he is resting and has lost fluid from sweating. (She reasons that fluid loss should lower blood volume and, thus, blood pressure.) Why is Bob's blood pressure high instead of low?
29. People with allergies commonly take antihistamines with decongestants to relieve their symptoms. The container warns that individuals who are being treated for high blood pressure should not take the medication. Why not?
30. Jolene awakens suddenly to the sound of her alarm clock. Realizing that she is late for class, she jumps to her feet, feels light-headed, and falls back on her bed. What probably caused this reaction? Why doesn't this happen all the time?

21

+ CLINICAL CASE Wrap-Up Did Ancient Mummies Have Atherosclerosis?

The majority of American men and women today have atherosclerotic plaques in their arteries by the age of 50. The disease is usually thought of as a modern one, the result of too many cheeseburgers and hours spent in front of computers and flat-screen TVs. But what could account for its incidence in the ancient mummies?

The degree of atherosclerosis discovered in the mummies turns out to be correlated with their age at death. The mean age at death for mummies without visible atherosclerosis is only 32. Among the mummies of people over age 40 that were examined, 50 percent had atherosclerosis.

Atherosclerosis is a vascular disease that progresses over many years. It is influenced by both genetics and environment. The most important risk factor, however, seems to be increasing age. Sex, diet, high levels of cholesterol in the blood, smoking, hypertension, and obesity are additional risk factors.

The prevalence of atherosclerosis in varied, preindustrial populations raises the possibility of a basic, human predisposition to the disease. Atherosclerosis appears to have been stalking humans for millennia.

1. Why does the finding of calcium, which is easily seen on a CT scan, within systemic arteries indicate the presence of atherosclerosis?
2. Why do you think atherosclerosis is never seen in veins?

See the blue Answers tab at the back of the book.

Related Clinical Terms

angiogram: An x-ray of a blood vessel that becomes visible due to a prior injection of dye into the subject's bloodstream.
carotid sinus massage: A procedure that involves rubbing the large part of the arterial wall at the point where the common carotid artery divides into its two main branches.
intermittent claudication: A limp that results from cramping leg pain that is typically caused by obstruction of the arteries.
Korotkoff sounds: Distinctive sounds, caused by turbulent arterial blood flow, heard through the stethoscope while measuring blood pressure .
normotensive: Having normal blood pressure.
orthostatic hypotension: A form of low blood pressure that occurs when you stand up from sitting or lying down. It can cause dizziness or a light-headed feeling.
phlebitis: Inflammation of a vein.
Raynaud phenomenon: A condition resulting in the discoloration of the fingers and/or the toes when a person is subjected to changes in temperature or to emotional stress.
sclerotherapy: The treatment of varicose veins in which an irritant is injected to cause inflammation, coagulation of blood, and a narrowing of the blood vessel wall.
sphygmomanometer: A device that measures blood pressure using an inflatable cuff placed around a limb.
syncope: A temporary loss of consciousness due to a sudden drop in blood pressure.
thrill: A vibration felt in a blood vessel that usually occurs due to abnormal blood flow. It is also often noticed at the fistula of a hemodialysis patient.
thrombophlebitis: An inflammation in a vein associated with the formation of a thrombus (clot).
vascular murmur: Periodic abnormal sounds heard upon auscultation that are produced as a result of turbulent blood flow.
white coat hypertension: A short-term increase in blood pressure triggered by the sight of medical personnel in white coats or other medical attire.

22 The Lymphatic System and Immunity

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

22-1 ■ Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes. p. 786

22-2 ■ Distinguish between innate (nonspecific) and adaptive (specific) immunity, and explain the role of lymphocytes in the immune response. p. 796

22-3 ■ List the body's innate defenses, and describe the components, mechanisms, and functions of each. p. 797

22-4 ■ Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity. p. 805

22-5 ■ Discuss the types of T cells and their roles in the adaptive immune response, and describe the mechanisms of T cell activation and differentiation. p. 809

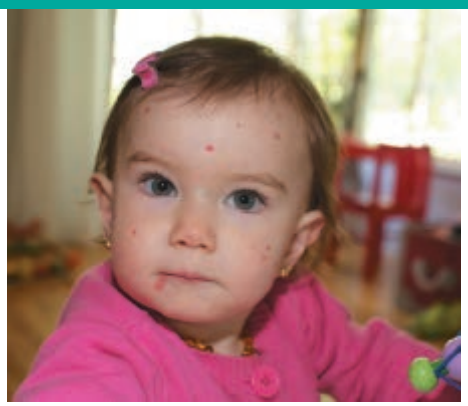
22-6 ■ Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure. p. 816

22-7 ■ Describe the development of immunocompetence, discuss the effects of stress on immune function, and list and explain examples of immune disorders and allergies. p. 821

22-8 ■ Describe the effects of aging on the lymphatic system and the immune response. p. 827

22-9 ■ Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response. p. 829

CLINICAL CASE Isn't There a Vaccine for That?



Baby Ruthie is standing and holding on to a play table when her mother arrives to pick her up from day care. Ruthie is 11 months old and not yet walking. She hasn't had an appetite since yesterday, and last night she had a fever. When her mother gives Ruthie a hug, she notices a small blister near the corner of Ruthie's mouth. She also notices that Ruthie seems feverish again.

"Ruthie didn't do much today," reports the day care attendant. "Did you notice this little blister on her face?" asks Ruthie's mother. "No. It must have just appeared," the attendant replies. "Tommy, one of our older kids, had a little blister like that on his cheek just last week. He hasn't been back since."

That night, Ruthie's fever worsens. She won't eat and seems to have a sore throat when trying to swallow. She is listless. When her mother undresses her for bed, she notices more small blisters on Ruthie's face, abdomen, and back. She takes her straight to the Urgent Care Center.

"This looks like chickenpox," says the doctor. "Thanks to vaccines, we don't see this disease very often any more." **Ruthie's mother is certain that Ruthie is current on all her vaccinations. How could Ruthie have come down with chickenpox? To find out, turn to the Clinical Case Wrap-Up on p. 833.**

An Introduction to the Lymphatic System and Immunity

The world is not always kind to the human body. Accidental bumps, cuts, and scrapes; chemical and thermal burns; extreme cold; and ultraviolet radiation are just a few of the hazards in our physical environment. Making matters worse, the world around us contains an assortment of viruses, bacteria, fungi, and parasites capable of not only surviving but thriving inside our bodies—and potentially causing us great harm. These disease-causing organisms, called **pathogens**, are responsible for many diseases. Each pathogen has a different lifestyle and attacks the body in a specific way. For example, viruses spend most of their time hidden within cells, which they often eventually destroy. Many bacteria multiply in interstitial fluids, where they release foreign proteins—enzymes or toxins—that can damage cells, tissues, even entire organ systems. Some large parasites, such as roundworms, actually burrow through internal organs. And as if that were not enough, we are constantly at risk from renegade body cells that have the potential to produce lethal cancers. p. 107

Many organs and systems work together to keep us alive and healthy. One system that plays a central role in the ongoing struggle to maintain health is the lymphatic system. The **lymphatic system** (also called the *lymphoid system*) includes the cells, tissues, and organs responsible for defending the body. This system acts both against environmental hazards, such as various pathogens, and against internal threats, such as cancer cells. We introduced *lymphocytes*, the primary cells of the lymphatic system, in Chapters 4 and 19. pp. 136, 675 These cells are vital to the body's ability to resist or overcome infection and disease.

The ability to resist infection and disease is called **immunity**. All the cells and tissues involved in producing immunity are part of the **immune system**. The immune system is a *functional* system, and it includes parts of the integumentary, skeletal, lymphatic, cardiovascular, respiratory, and digestive systems.

We begin by examining the organization of the lymphatic system, lymphoid tissues, and lymphoid organs, and then we look at how this system interacts with other systems to defend the body against infection and disease.

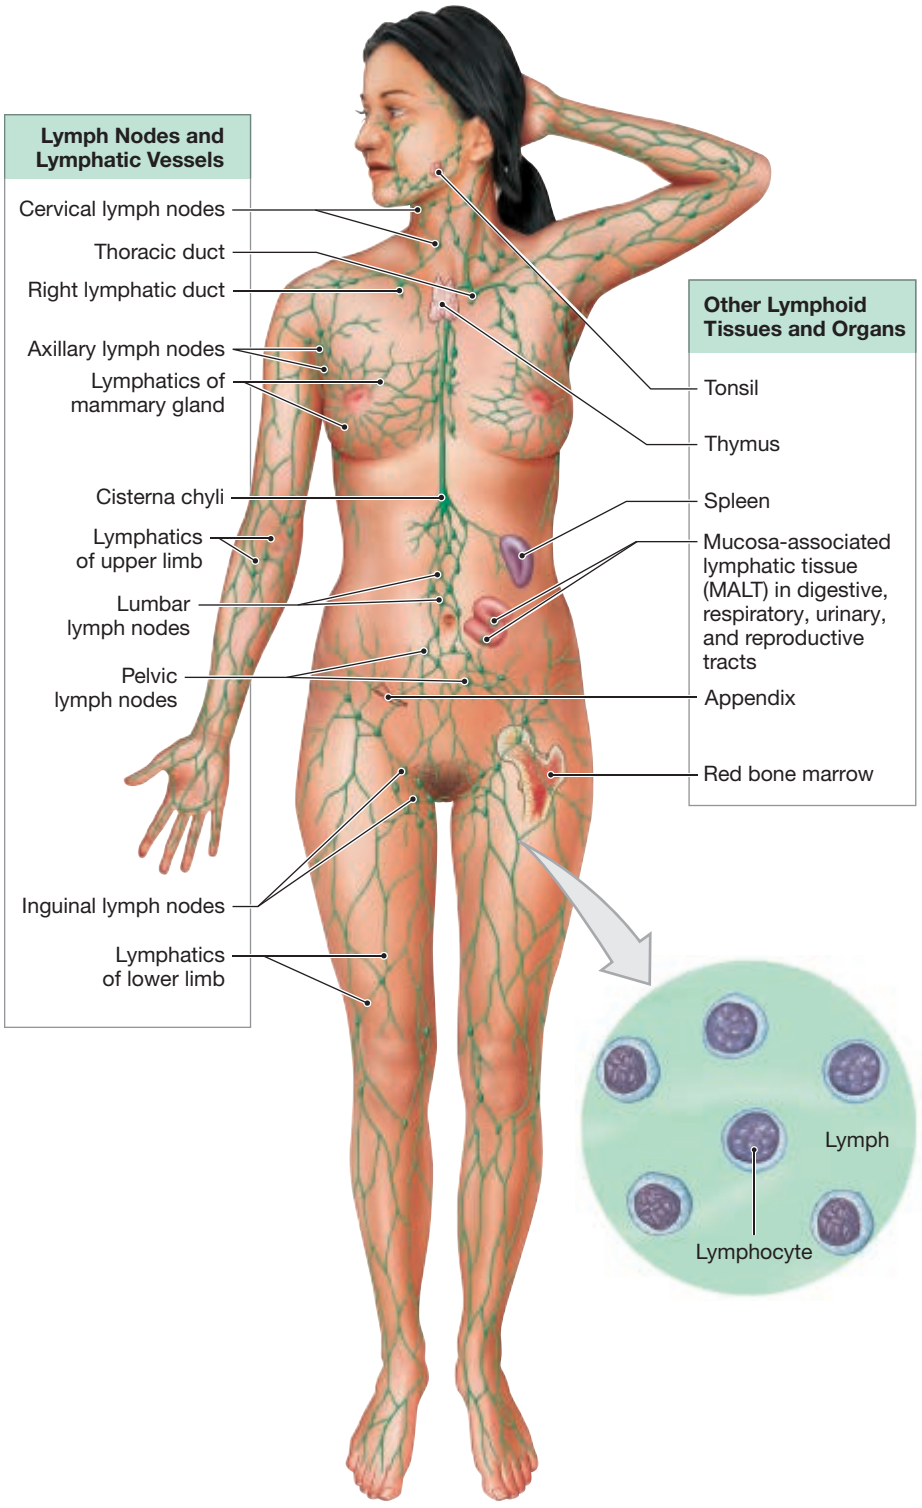
22-1 The vessels, tissues, and organs of the lymphatic system maintain fluid volume and function in body defenses

Learning Outcome Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes.

The lymphatic system consists of (1) *lymph*, a fluid that resembles plasma but contains a much lower concentration of suspended proteins; (2) a network of *lymphatic vessels*, which begin in peripheral tissues and connect to veins; (3) an array of **lymphoid tissues** and **lymphoid organs** scattered throughout the body; and (4) *lymphoid cells*, including lymphocytes and smaller numbers of phagocytes and other cells.

Primary lymphoid tissues and organs are sites where lymphocytes are formed and mature. They include *red bone marrow* and the *thymus*. Recall that red bone marrow, covered in Chapter 19, is where other defense cells, the monocytes and macrophages, are also formed. p. 674 *Secondary lymphoid tissues and organs* are where lymphocytes are activated. These structures include the *tonsils*, *MALT* (mucosa-associated

Figure 22–1 The Components of the Lymphatic System.



lymphatic tissue), *lymph nodes*, and the *spleen*. Figure 22–1 provides a general overview of the components of the lymphatic system.

Functions of the Lymphatic System

The primary function of the lymphatic system is to produce, maintain, and distribute lymphocytes and other lymphoid cells that provide defense against infections and foreign substances. To provide an effective defense, lymphocytes must detect problems, and they must be able to reach the site of injury or infection. Lymphocytes and other cells circulate within the blood. They are able to enter or leave the capillaries that supply most of the body's tissues.

As noted in Chapter 21, capillaries normally deliver more fluid to peripheral tissues than they carry away. ↩ p. 743 The excess fluid returns to the bloodstream through lymphatic vessels. This continuous circulation of extracellular fluid helps transport lymphocytes and white blood cells from one organ to another. In the process, it maintains normal blood volume. It also eliminates local variations in the composition of the interstitial fluid by distributing hormones, nutrients, and wastes from their tissues of origin to the general circulation.

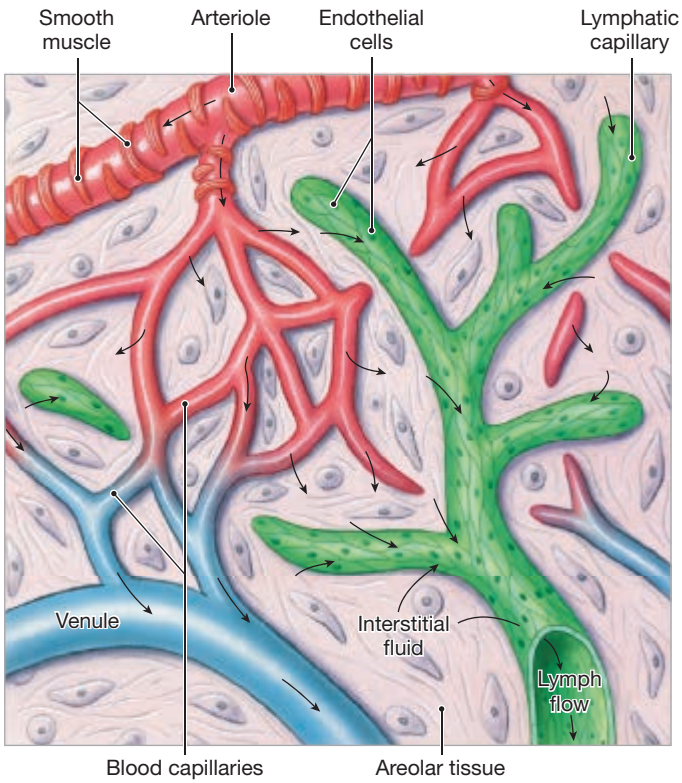
Lymphatic Vessels and Circulation of Lymph

Lymphatic vessels, often called *lymphatics*, carry lymph from peripheral tissues to the venous system. **Lymph** is interstitial fluid that has entered lymphatic vessels, which vary in size. Lymph first enters lymphatic capillaries and then drains into larger *major lymph-collecting vessels*, known as *trunks* and *ducts*.

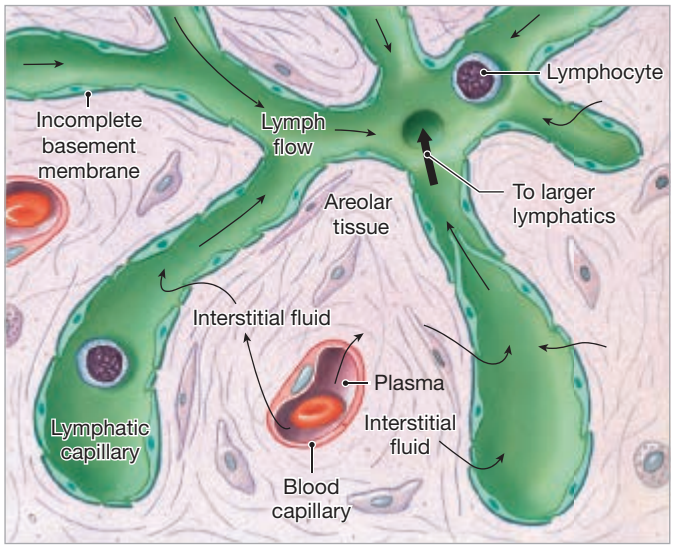
Lymphatic Capillaries

The lymphatic network begins with **lymphatic capillaries**, which branch through peripheral tissues. Lymphatic capillaries differ from blood capillaries in several ways. They (1) are closed at one end rather than forming continuous tubes, (2) have larger luminal diameters, (3) have thinner

Figure 22–2 Lymphatic Capillaries.



a The interwoven network formed by blood capillaries and lymphatic capillaries. Arrows indicate the movement of fluid out of blood capillaries and the net flow of interstitial fluid and lymph.



b A sectional view indicating the movement of fluid from the plasma, through the tissues as interstitial fluid, and into the lymphatic system as lymph.

walls, and (4) typically have a flattened or irregular outline in sectional view (Figure 22–2).

Lymphatic capillaries are lined by endothelial cells, but the basement membrane is incomplete or absent. The endothelial cells of a lymphatic capillary are not bound tightly together, but they do overlap. The region of overlap acts as a one-way valve. It permits fluids and solutes (including proteins) to enter, along with viruses, bacteria, and cell debris, but it prevents them from returning to the intercellular spaces.

Lymphatic capillaries are present in almost every tissue and organ in the body. Important lymphatic capillaries in the small intestine, called *lacteals*, transport lipids absorbed by the digestive tract. Lymphatic capillaries are absent in areas without a blood supply, such as the cornea of the eye.

Small Lymphatic Vessels

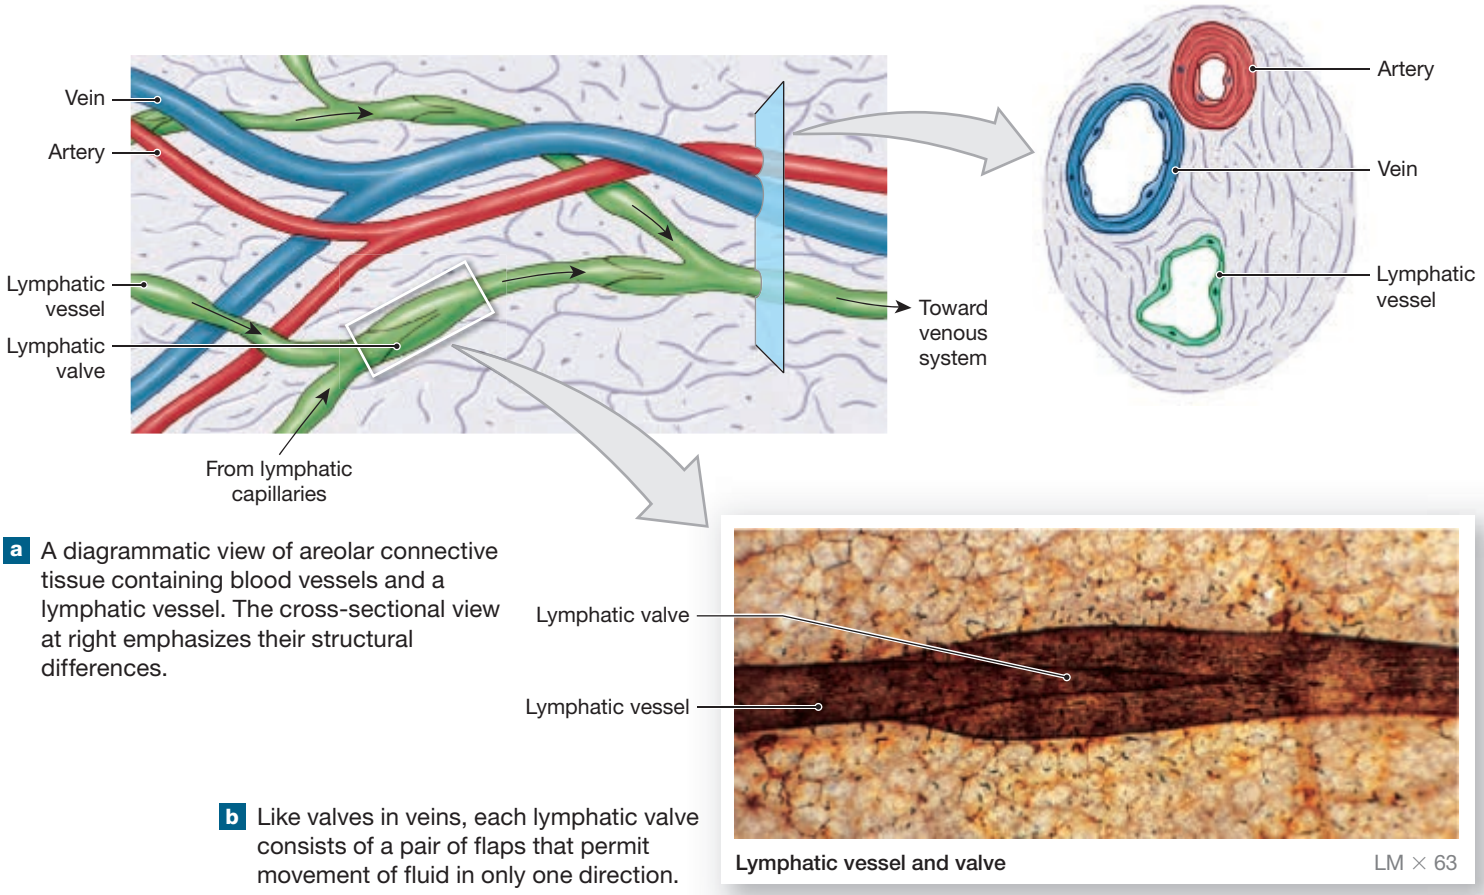
From the lymphatic capillaries, lymph flows into larger lymphatic vessels that lead toward the body's trunk. The walls of these vessels contain three layers comparable to those of veins. Small to medium-sized lymphatic vessels also contain valves (Figure 22–3). The valves are quite close together, and produce noticeable bulges. As a result, some lymphatic vessels have a beaded appearance due to an irregular lumen (see Figure 22–3a). The valves prevent the backflow of lymph within lymphatic vessels, especially in the limbs. Pressures within the lymphatic system are minimal, and the valves are essential to maintaining normal lymph flow toward the thoracic cavity. Contractions of skeletal muscles surrounding the lymphatic vessels aid lymph flow.

Lymphatic vessels are often associated with blood vessels (see Figure 22–3a). Differences in size, general appearance, and branching pattern distinguish lymphatic vessels from arteries and veins. We can see characteristic color differences in living tissues. Most arteries are bright red, veins are dark red (although usually illustrated as blue to distinguish them from arteries), and lymphatic vessels are a pale golden color. In general, a tissue contains many more lymphatic vessels than veins, but the lymphatic vessels are much smaller.

Major Lymph-Collecting Vessels

Two sets of lymphatic vessels collect lymph from the lymphatic capillaries: superficial lymphatics and deep lymphatics. **Superficial lymphatics** are located in the subcutaneous layer deep to the skin; in the areolar tissues of the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts; and in the areolar tissues of the serous membranes lining the pleural, pericardial, and peritoneal cavities. **Deep lymphatics** are larger lymphatic vessels that accompany deep arteries and veins supplying skeletal muscles and other organs of the neck, limbs, and trunk, and the walls of visceral organs.

Figure 22–3 Lymphatic Vessels and Valves.



a A diagrammatic view of areolar connective tissue containing blood vessels and a lymphatic vessel. The cross-sectional view at right emphasizes their structural differences.

b Like valves in veins, each lymphatic valve consists of a pair of flaps that permit movement of fluid in only one direction.

Lymphatic vessel and valve LM × 63

? What feature do lymphatic vessels share with veins that allows lymph to flow in only one direction?

Superficial and deep lymphatics converge to form even larger vessels called **lymphatic trunks**. The trunks in turn empty into two large collecting vessels: the thoracic duct and the right lymphatic duct. The **thoracic duct** collects lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm. The smaller **right lymphatic duct** collects lymph from the right side of the body superior to the diaphragm (Figure 22–4a).

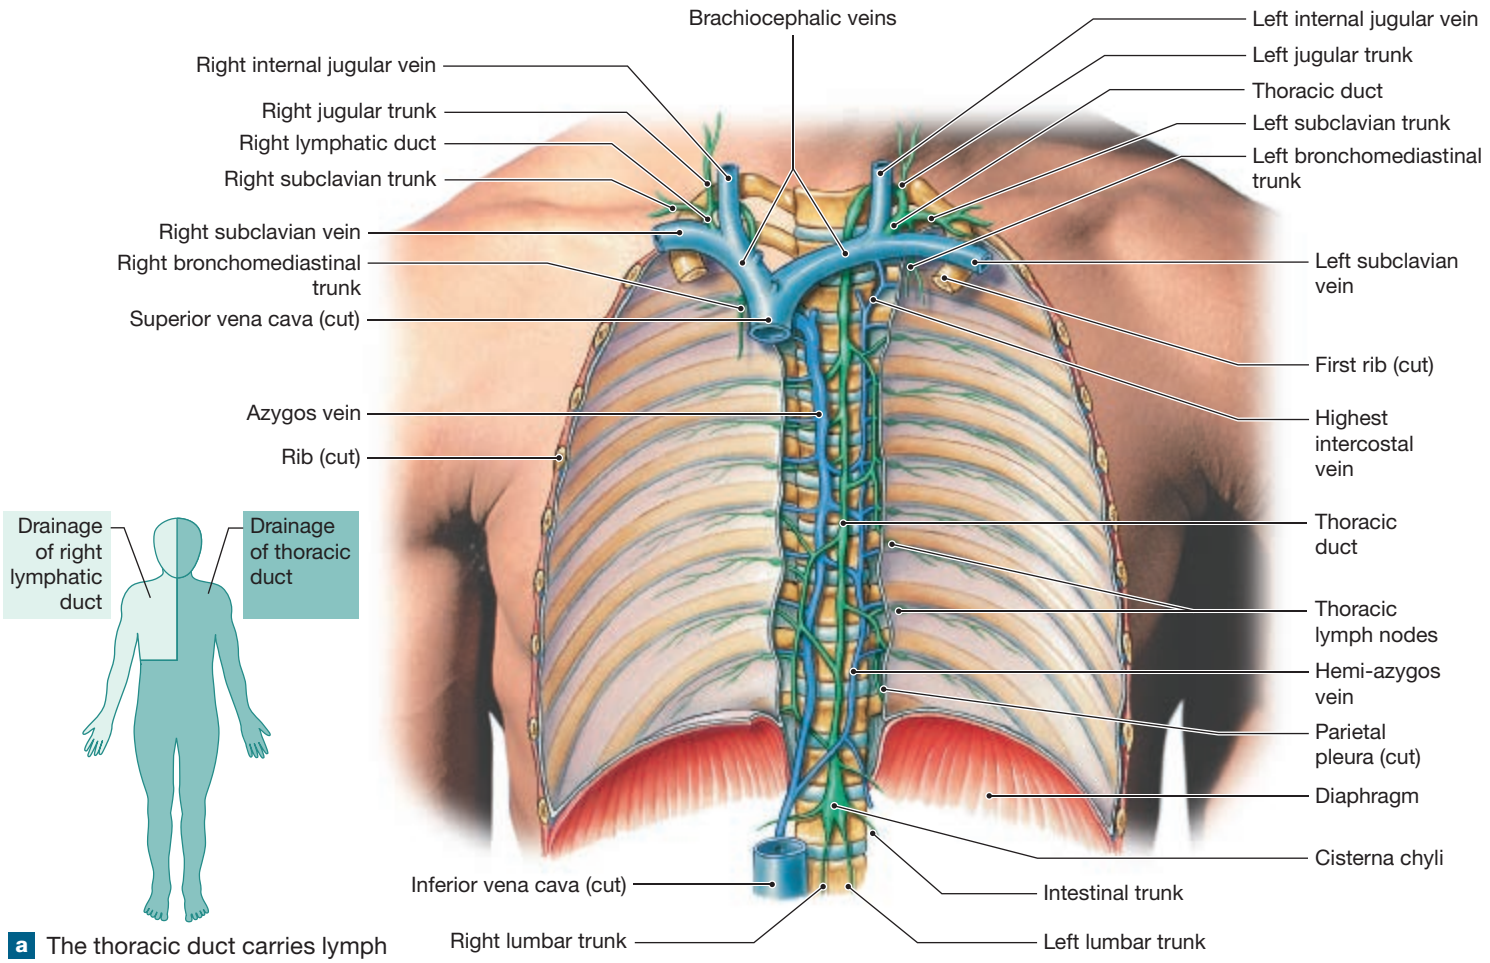
The thoracic duct begins inferior to the diaphragm at the level of vertebra L_2 (Figure 22–4b). The base of the thoracic duct is an expanded, saclike chamber called the **cisterna chyli** (KĪ-lī; *chylos*, juice). The cisterna chyli receives lymph from the inferior part of the abdomen, the pelvis, and the lower limbs by way of the *right* and *left lumbar trunks* and the *intestinal trunk*.

The inferior segment of the thoracic duct lies anterior to the vertebral column. From the second lumbar vertebra, it passes posterior to the diaphragm alongside the aorta. It then ascends along the left side of the vertebral column to the level of the left clavicle. It collects lymph from the *left bronchomediastinal trunk*, the *left subclavian trunk*, and the *left jugular trunk*, and then empties into the left subclavian vein near the left internal jugular vein (see Figure 22–4b). In this way, lymph reenters the venous circulation from the left side of the head, neck, and thorax, as well as from the entire body inferior to the diaphragm.

The *right lymphatic duct* is formed by the merging of the *right jugular*, *right subclavian*, and *right bronchomediastinal trunks* in the area near the right clavicle. This duct empties into the right subclavian vein, delivering lymph from the right side of the body superior to the diaphragm.

Obstruction of lymphatic vessels produces **lymphedema** (limf-e-DĒ-muh), as large amounts of lymph accumulate in the affected region. This causes swelling, especially in subcutaneous tissues. If the condition persists, the connective tissues lose their elasticity and the swelling becomes permanent. Lymphedema by itself does not pose a major threat to life. The danger comes from

Figure 22–4 The Relationship between the Lymphatic Ducts and the Venous System. ATLAS: Plates 48a,b



a The thoracic duct carries lymph from tissues inferior to the diaphragm and from the left side of the upper body. The smaller right lymphatic duct carries lymph from the rest of the body.

b The thoracic duct empties into the left subclavian vein. The right lymphatic duct empties into the right subclavian vein.

the constant risk that an uncontrolled infection will develop in the affected area. Because the interstitial fluids are essentially stagnant, toxins and pathogens can accumulate and overwhelm local defenses without fully activating the immune system.

Lymphoid Cells

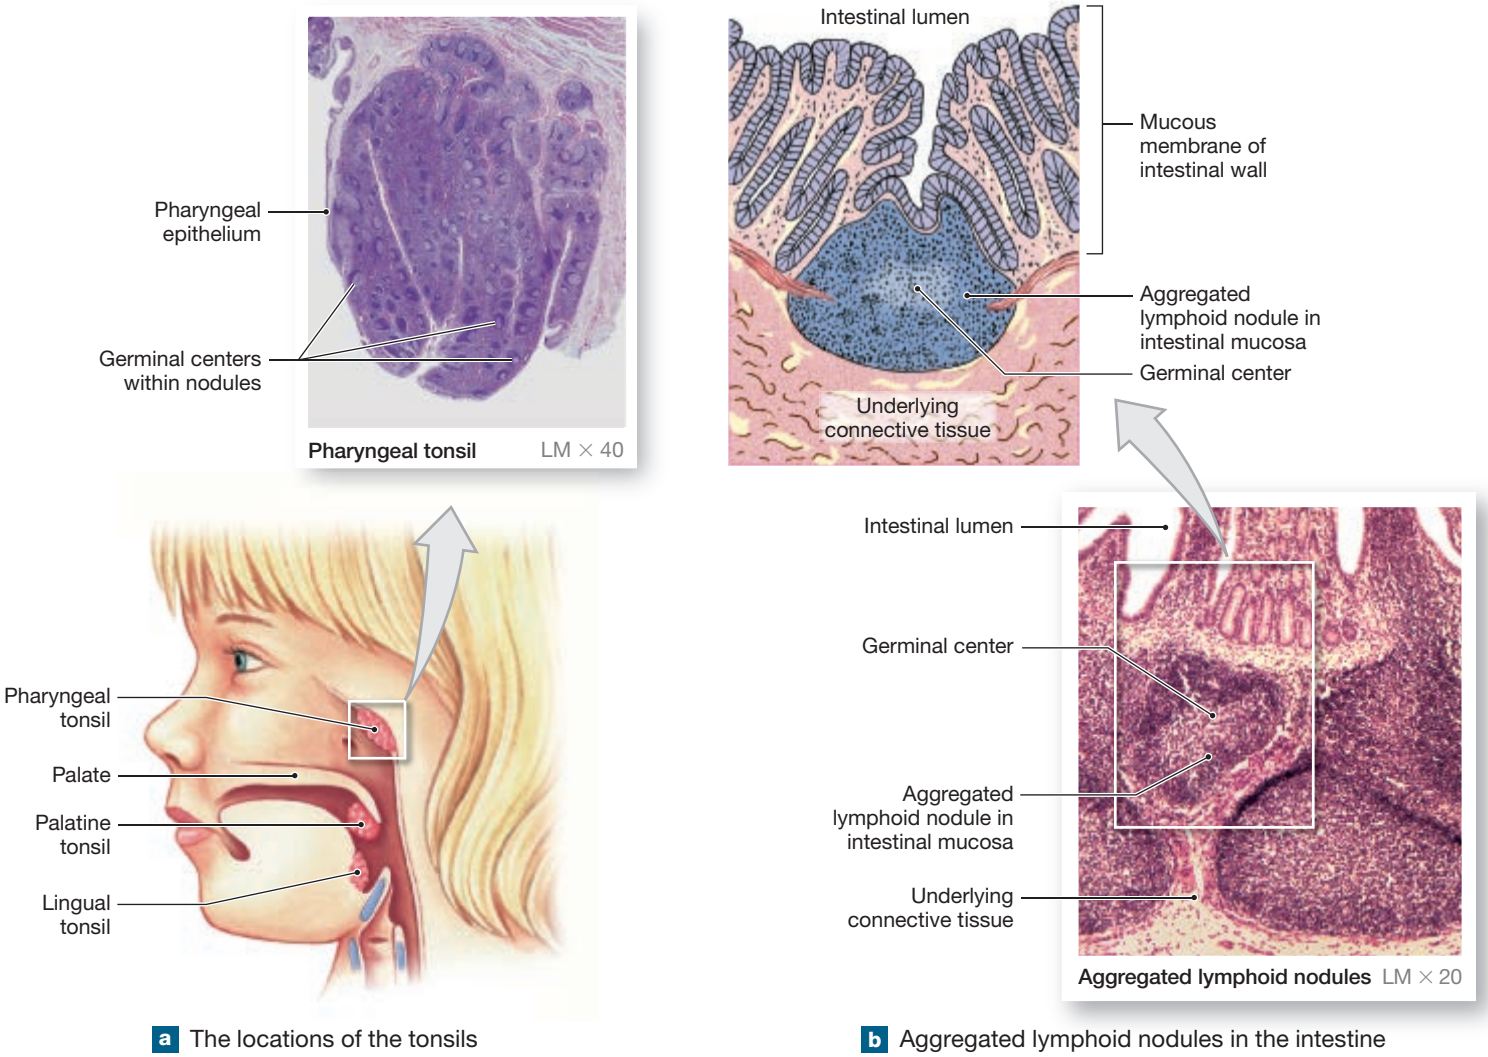
Lymphoid cells consist of immune system cells found in lymphoid tissues and the cells that support those tissues. Immune system cells that function in defense include phagocytes and lymphocytes. Phagocytes include cell types such as *macrophages* and *microphages*. These cells function as a general first line of defense against pathogens (such as bacteria or viruses).

Lymphocytes respond to specific invading pathogens, as well as to abnormal body cells (such as virus-infected cells or cancer cells) and foreign proteins (such as the toxins released by some bacteria). They eliminate these threats or render them harmless through a combination of physical and chemical attacks. Lymphocytes account for 20–40 percent of circulating leukocytes. Three classes of lymphocytes circulate in blood: (1) *T* (thymus-dependent) *cells*, (2) *B* (bone marrow–derived) *cells*, and (3) *NK* (natural killer) *cells*. Each type has distinctive biochemical and functional properties. However, circulating lymphocytes are only a small fraction of the total lymphocyte population. The body contains some 10^{12} lymphocytes, with a combined weight of more than a kilogram (2.2 lb).

Lymphoid Tissues

Lymphoid tissues are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, or *lymphatic nodule*, the lymphocytes are densely packed in an area of areolar tissue. In many areas, lymphoid nodules form large clusters. Lymphoid nodules occur in the connective tissue deep to the epithelia

Figure 22–5 Lymphoid Nodules.



a The locations of the tonsils

b Aggregated lymphoid nodules in the intestine

lining the respiratory tract, where they are known as *tonsils*, and along the digestive, respiratory, urinary, and reproductive tracts (Figure 22–5). They are also found within more complex lymphoid organs, such as lymph nodes or the spleen.

A single nodule averages about a millimeter in diameter. Its boundaries are not distinct, because no fibrous capsule surrounds it. Each nodule often has a central zone called a **germinal center**, which contains dividing lymphocytes (see Figure 22–5).

Tonsils

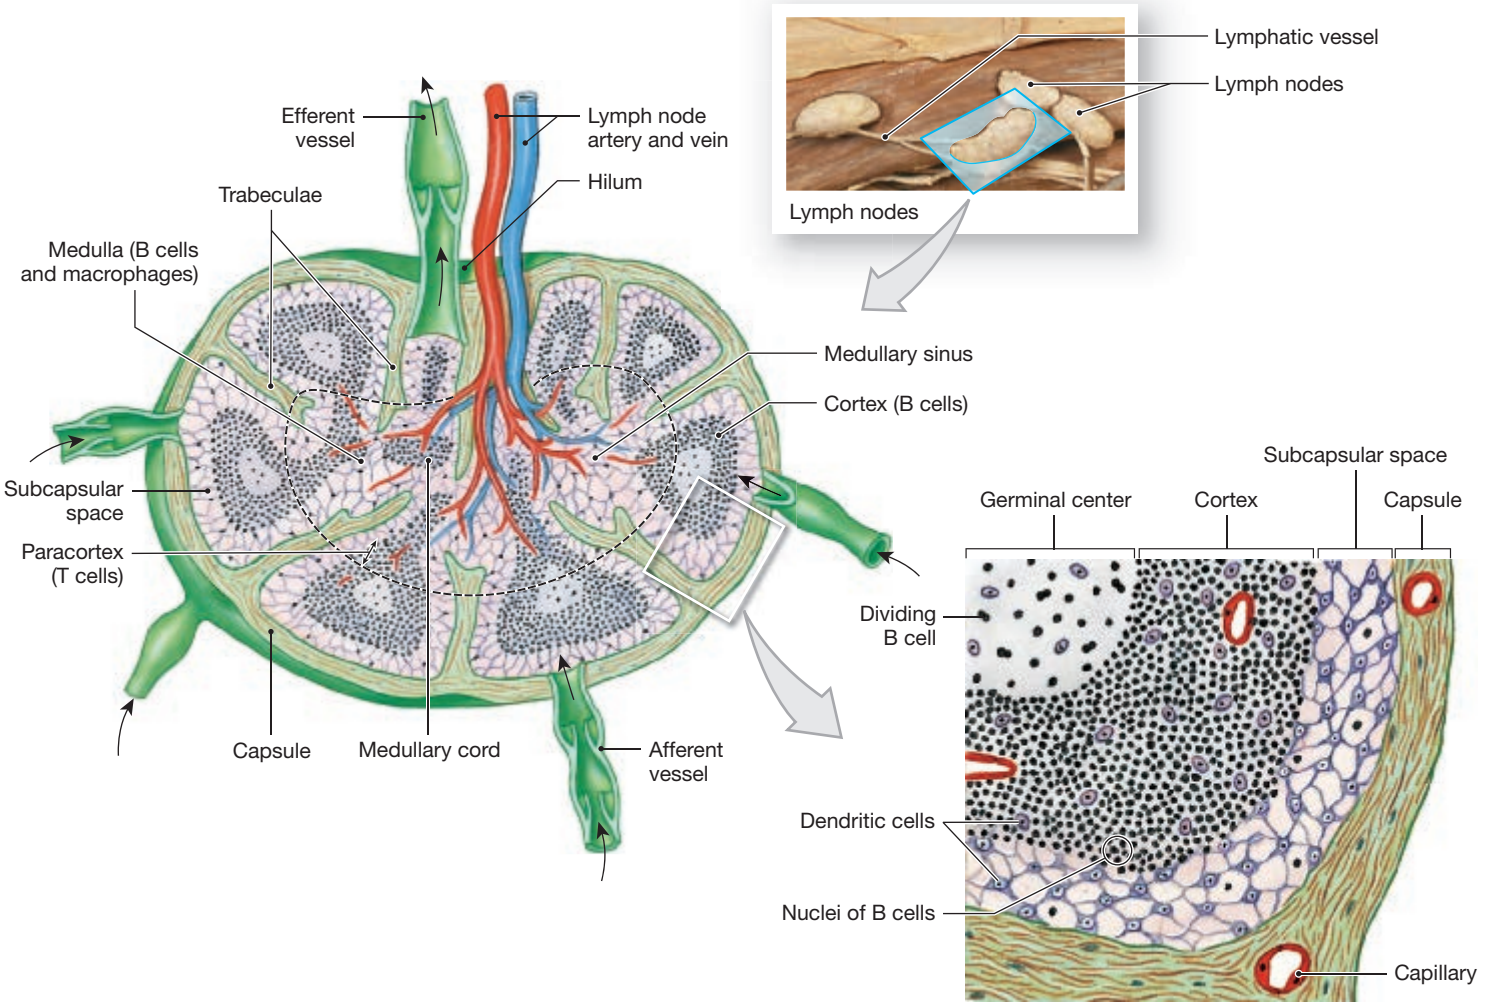
The **tonsils** are large lymphoid nodules in the walls of the pharynx (Figure 22–5a). Most people have five tonsils. A single **pharyngeal tonsil**, often called the *adenoid*, lies in the posterior superior wall of the nasopharynx. Left and right **palatine tonsils** are located at the posterior, inferior margin of the oral cavity, along the boundary of the pharynx. A pair of **lingual tonsils** lies deep to the mucous epithelium covering the base (pharyngeal portion) of the tongue. Because of their location, the lingual tonsils are usually not visible unless they become infected and swollen. **Tonsillitis** is an inflammation of the tonsils (especially the palatine tonsils) although the other tonsils may also be affected. Tonsils reach their largest size by puberty and then begin to atrophy.

MALT

The collection of lymphoid tissues that protect the epithelia of the digestive, respiratory, urinary, and reproductive systems is called the **mucosa-associated lymphoid tissue (MALT)**. Clusters of lymphoid nodules deep to the epithelial lining of the intestine are known as **aggregated lymphoid nodules**, or *Peyer's patches* (Figure 22–5b). Other examples of MALT include the appendix and the tonsils.

The *appendix*, or *vermiform* ("worm-shaped") *appendix*, is a tube-shaped sac opening into the junction between the small and large intestines. Its walls contain a mass of fused lymphoid nodules.

Figure 22–6 The Structure of a Lymph Node. ATLAS: Plate 70a



Lymphoid Organs

Lymphoid organs include the lymph nodes, thymus, and spleen. A fibrous connective tissue capsule separates these organs from surrounding tissues.

Lymph Nodes

Lymph nodes are small lymphoid organs ranging in diameter from 1 mm to 25 mm (to about 1 in.). The greatest number of lymph nodes is located in the neck, axillae, and groin, where they defend us against bacteria and other invaders. Look back at Figure 22–1 to see the general pattern of lymph node distribution in the body.

A dense connective tissue capsule covers each lymph node (Figure 22–6). Bundles of collagen fibers extend from the capsule into the interior of the node. These fibrous partitions are called **trabeculae** (*trabecula*, a beam).

The typical lymph node is shaped like a kidney bean (see Figure 22–6). Blood vessels and nerves reach the lymph node at a shallow indentation called the **hilum**. Two sets of lymphatic vessels, afferent lymphatics and efferent lymphatics, are connected to each lymph node. **Afferent** (*afferens*, to bring to) **lymphatics** bring lymph to the lymph node from peripheral tissues. The afferent lymphatics penetrate the capsule of the lymph node on the side opposite the hilum. **Efferent** (*efferens*, to bring out) **lymphatics** leave the lymph node at the hilum. These vessels carry lymph away from the lymph node and toward the venous circulation.

Lymph Flow through Nodes. Lymph from the afferent lymphatics flows through the lymph node within a network of sinuses, open passageways with incomplete walls. The lymph node interior is divided into an outer cortex, an inner medulla, and a region between the two called the paracortex (see Figure 22–6). Lymph first enters a *subcapsular space* that contains a meshwork of branching reticular fibers, macrophages, and dendritic cells. *Dendritic cells* are involved in starting an immune response. Lymph passes through the subcapsular space and then flows through the

cortex of the node. The periphery of the cortex contains B cells within germinal centers similar to those of lymphoid nodules.

Lymph then continues through lymph sinuses toward an ill-defined area known as the **paracortex**, which is dominated by T cells. Here lymphocytes leave the bloodstream and enter the lymph node by crossing the walls of blood vessels.

After flowing through the sinuses of the paracortex, lymph continues into the core, or **medulla**. The medulla contains B cells and macrophages. Elongated masses of dense lymphoid tissue between the sinuses in the medulla are known as **medullary cords**. Lymph passes through a network of sinuses in the medulla and then enters the efferent lymphatics at the hilum.

Lymph Node Function. A lymph node functions like a kitchen water filter: It purifies lymph before it reaches the veins. As lymph flows through a lymph node, at least 99 percent of the antigens (foreign substances) in the lymph are removed. Fixed macrophages in the walls of the lymphatic sinuses engulf debris or pathogens in lymph as it flows past.

In addition to filtering, lymph nodes function as an early-warning defense system. Any infection or other abnormality in a peripheral tissue puts antigens into the interstitial fluid, and thus into the lymph leaving the area. These antigens then stimulate macrophages and lymphocytes in nearby lymph nodes. Antigens are also carried by dendritic cells from peripheral tissues to lymph nodes.

To protect a house against intruders, you might guard all the entrances and exits or place locks on the windows and doors. The distribution of lymphoid tissues and lymph nodes follows such a pattern. The largest lymph nodes are located where peripheral lymphatics connect with the trunk, such as in the groin, the axillae, and the base of the neck. These nodes are often called *lymph glands*. Because lymph is monitored in these nodes, potential problems can be detected and dealt with before they affect the vital organs of the trunk. The mesenteries of the gut also have aggregations of lymph nodes, located near the trachea and passageways leading to the lungs, and in association with the thoracic duct. These lymph nodes protect against pathogens and other antigens within the digestive and respiratory systems.

A minor infection commonly produces a slight enlargement of the nodes along the lymphatic vessels draining the region. This sign is often called "swollen glands." It typically indicates inflammation in peripheral structures. The enlargement generally results from an increase in the number of lymphocytes and phagocytes in the node. Inflammation of lymph nodes is termed *lymphadenitis*.

The Thymus

The thymus is a primary lymphoid organ. It is necessary in early life for immunity, but later in life it atrophies and becomes inactive. We begin this section by describing its anatomy.

+ Clinical Note Lymphadenopathy

We have approximately 600 lymph nodes scattered throughout our bodies. Some are superficial, but many are deep; few are *palpable* (able to be felt). Abnormal lymph nodes that are palpable may come to our attention during a physical examination. Any disease that affects lymph nodes is termed **lymphadenopathy** (lim-fad-e-NOP-a thē).

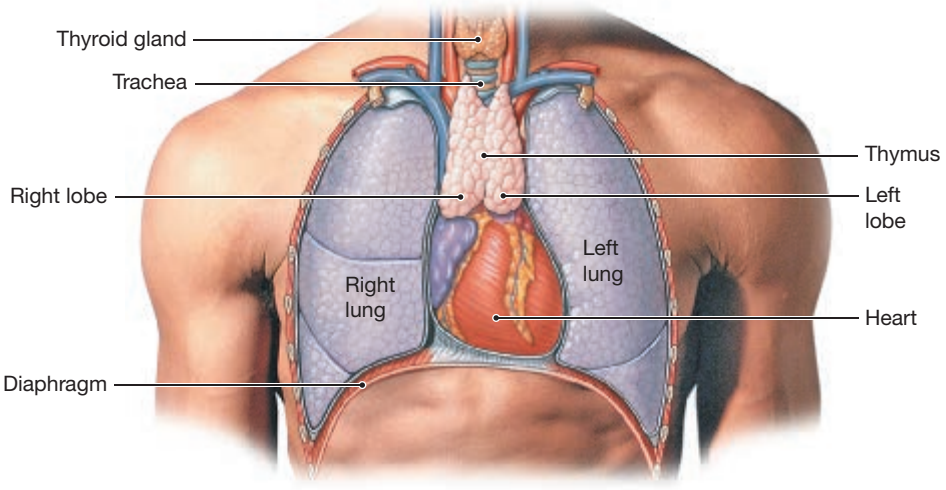
Most enlarged lymph nodes are benign and reflect an underlying localized infection. Think of *pharyngitis* (a sore throat) draining to nodes in the cervical region, or a sinus infection infiltrating submandibular nodes. An infected cut on the hand will show up in the axillary nodes, whereas a sexually transmitted disease will invade the inguinal nodes.

Generalized lymphadenopathy should always be evaluated. It may be evidence of something more serious, such as *lymphoma* (a primary cancer of the lymph nodes) or metastatic cancer (cancerous nodes caused by cancer spreading from another site).

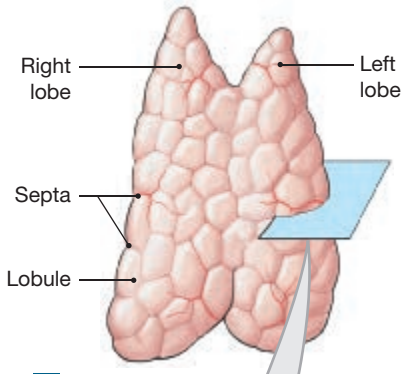
Anatomy of the Thymus. The **thymus** is a pink, grainy organ located in the mediastinum, generally just posterior to the sternum (Figure 22–7a,b). In newborn infants and young children, the thymus is relatively large. It commonly extends from the base of the neck to the superior border of the heart. The thymus reaches its greatest size relative to body size in the first year or two after birth. (The organ continues to increase in mass throughout childhood, but the body as a whole grows even faster, so the size of the thymus relative to that of the other organs in the mediastinum gradually decreases.)

The thymus reaches its maximum absolute size, at a weight of about 40 g (1.4 oz), just before puberty. After puberty, it gradually diminishes in size and becomes increasingly fibrous and fatty, a process called *involution*. By the time a person reaches age 50, the thymus may weigh less than 12 g (0.3 oz).

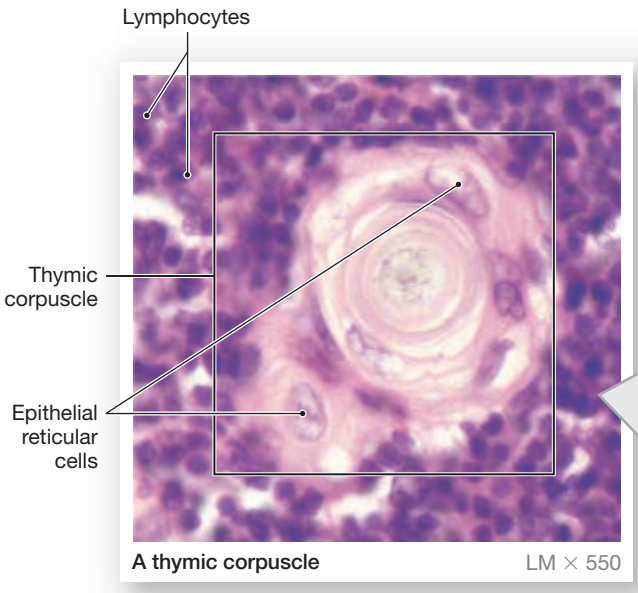
Figure 22–7 The Thymus. ATLAS: Plate 47a



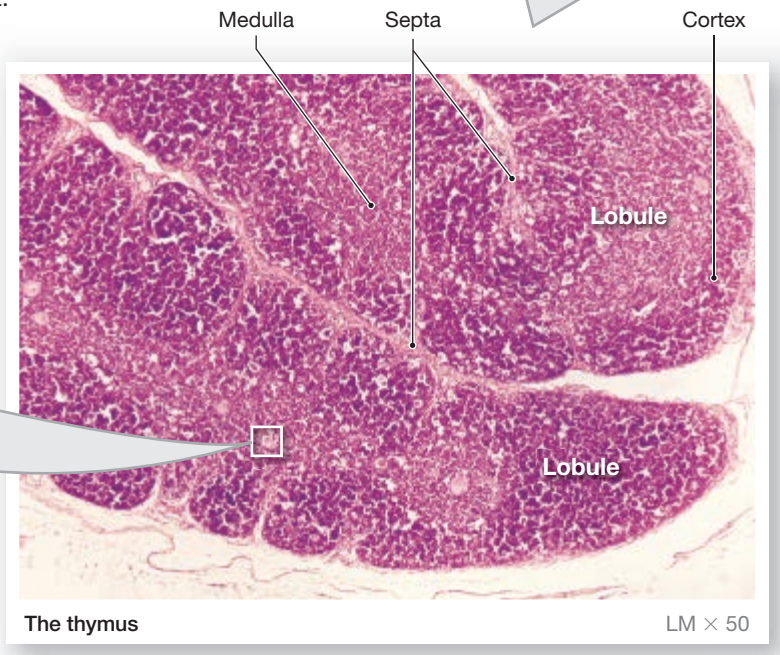
a The appearance and position of the thymus in relation to other organs in the chest.



b Anatomical landmarks on the thymus.



d Higher magnification reveals the unusual structure of thymic corpuscles. The small cells are lymphocytes in various stages of development.



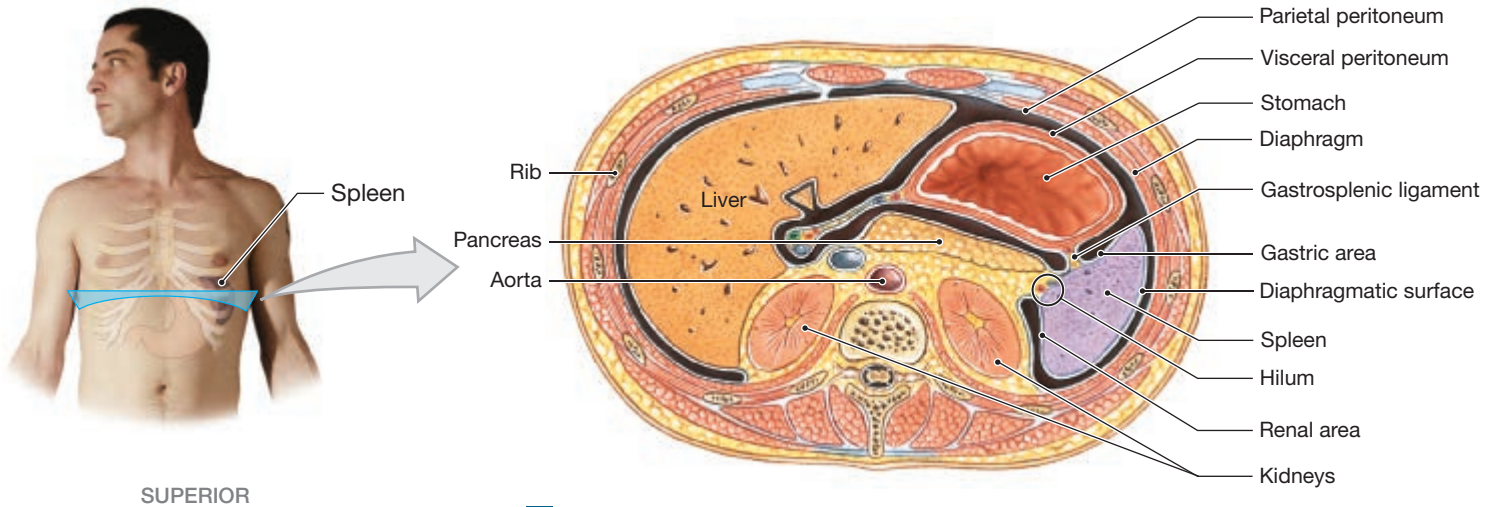
c Fibrous septa divide the tissue of the thymus into lobules resembling interconnected lymphoid nodules.

The capsule that covers the thymus divides it into two thymic **lobes** (Figure 22–7b). Fibrous partitions called **septa** (singular, *septum*) originate at the capsule and divide the lobes into **lobules** averaging 2 mm in diameter (Figure 22–7b,c). Each lobule consists of an outer **cortex** densely packed with lymphocytes and a paler, central **medulla**.

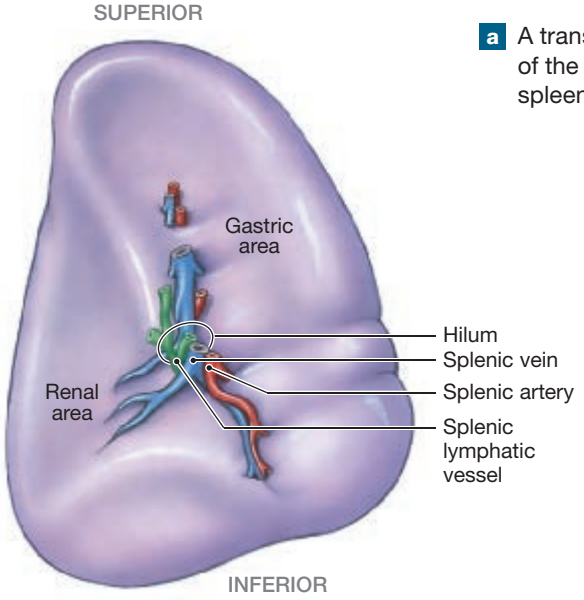
Lymphocytes in the cortex are arranged in clusters that are completely surrounded by **epithelial reticular cells**. The epithelial reticular cells in the medulla cluster together in concentric layers, forming distinctive structures known as **thymic (Hassall's) corpuscles** (Figure 22–7d). Epithelial reticular cells also encircle the blood vessels of the cortex.

Function of the Thymus. The cortex contains actively dividing T cell lymphocytes (T lymphocytes). Epithelial reticular cells maintain the **blood thymus barrier** around the blood vessels of the cortex, which separates developing T cells from the general circulation. These epithelial cells also regulate T cell development and function. Maturing T cells leave the cortex and enter the medulla of the thymus. The medulla has no blood thymus barrier. After about 3 weeks, these T cells leave the thymus by entering one of the medullary blood vessels. T cells in the medulla can enter or leave the bloodstream across the walls of blood vessels in this region or within one of the efferent lymphatics that collect lymph from the thymus.

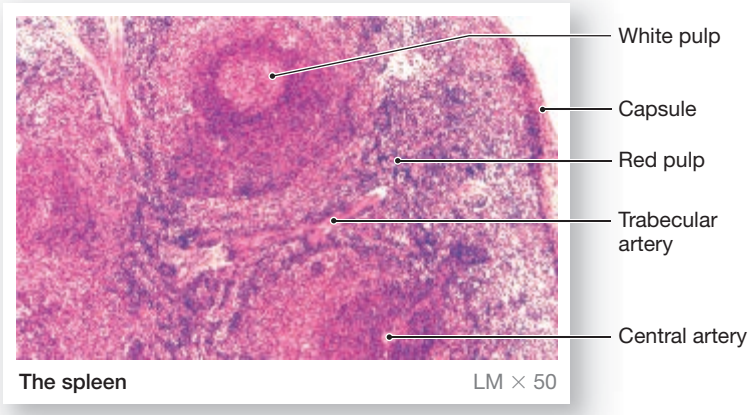
Figure 22–8 The Spleen. ATLAS: Plates 49e; 55; 56e,f; 57a,b



a A transverse section through the trunk, showing the typical position of the spleen projecting into the peritoneal cavity. The shape of the spleen conforms to the shapes of adjacent organs.



b A posterior view of the surface of an intact spleen, showing major anatomical landmarks.



c White pulp is dominated by lymphocytes; it appears purple because the nuclei of lymphocytes stain very darkly. Red pulp contains large numbers of red blood cells.

? What types of cells are found in the white pulp of the spleen and in the red pulp of the spleen?

Thymic Hormones. The thymus produces several hormones that are important to the development and maintenance of T cells for normal immunological defenses. *Thymosin* (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of T cells. This extract actually contains several complementary hormones. They include *thymosin-a*, *thymosin-b*, *thymosin V*, *thymopoietin*, and *thymulin*. The plural term *thymosins* is sometimes used to refer to all thymic hormones.

The Spleen

The adult **spleen** contains the largest collection of lymphoid tissue in the body. In essence, the spleen performs the same functions for blood that lymph nodes perform for lymph. Functions of the spleen can be summarized as (1) removing abnormal blood cells and other blood components by phagocytosis, (2) storing iron recycled from red blood cells, and (3) initiating immune responses by B cells and T cells in response to antigens in circulating blood.

Anatomy and Histology of the Spleen. The spleen is about 12 cm (5 in.) long and weighs, on average, nearly 160 g (5.6 oz). In gross dissection, the spleen is deep red, due to the blood it contains. The spleen lies along the curving lateral border of the stomach, extending between the 9th and 11th ribs on the left side. It is attached to the lateral border of the stomach by the **gastrosplenic ligament**, a broad band of mesentery (Figure 22–8a).

The spleen has a soft texture, so its shape reflects the shapes of the structures around it. The spleen is in contact with the muscular diaphragm, the stomach, and the left kidney. The *diaphragmatic surface* is smooth and convex, conforming to the shape of the diaphragm and body wall. The *visceral surface* contains indentations that conform to the shape of the stomach (the *gastric area*) and the kidney (the *renal area*) (Figure 22–8b). Splenic blood vessels (the *splenic artery* and *splenic vein*) and lymphatic vessels communicate with the spleen on the visceral surface at the **hilum**, a groove marking the border between the gastric and renal areas.

The spleen is surrounded by a capsule containing collagen and elastic fibers. The cellular components within make up the **pulp** of the spleen (Figure 22–8c). **Red pulp** contains large quantities of red blood cells, and **white pulp** resembles lymphoid nodules. Interestingly, the spleens of dogs, cats, and other mammals have extensive smooth muscle layers that contract to eject blood into the bloodstream. The human spleen lacks these muscles and therefore cannot contract.

The splenic artery enters at the hilum and branches to produce a number of arteries that radiate outward toward the capsule. These **trabecular arteries** in turn branch extensively, and their finer branches are surrounded by areas of white pulp. Capillaries then discharge the blood into the red pulp.

The cell population of the red pulp includes all the normal components of circulating blood, plus fixed and free macrophages. The structural framework of the red pulp consists of a network of reticular fibers. The blood passes through this meshwork and enters large sinusoids, also lined by fixed macrophages. The sinusoids empty into small veins, which ultimately collect into **trabecular veins** that continue toward the hilum.

This circulatory arrangement gives the phagocytes in the spleen an opportunity to identify and engulf damaged or infected cells in circulating blood. Macrophages are scattered throughout the red pulp, and the area surrounding the white pulp has a high concentration of lymphocytes and dendritic cells. For this reason, any microorganism or other antigen in the blood quickly triggers an immune response.

Rupture of the Spleen. The spleen tears so easily that a seemingly minor hit to the left side of the abdomen can rupture the capsule. The result is serious internal bleeding and eventual circulatory shock. Such an injury is a known risk of contact sports (such as football, hockey, and rugby) and of more individual athletic activities, such as skiing and sledding.

Because the spleen is so fragile, it is very difficult to repair surgically. (Sutures typically tear out before they have been tensed enough to stop the bleeding.) A severely ruptured spleen is removed, a process called a **splenectomy** (splē-NEK-tō-mē). A person can survive without a spleen but lives with an increased risk of bacterial infection.

Checkpoint

1. Define *pathogen*.
2. List the components of the lymphatic system.
3. How would blockage of the thoracic duct affect lymph circulation?
4. If the thymus failed to produce thymic hormones, development of which population of lymphocytes would be affected?
5. Why do lymph nodes enlarge during some infections?

22-2 Lymphocytes are important to innate (nonspecific) and adaptive (specific) immunity

Learning Outcome Distinguish between innate (nonspecific) and adaptive (specific) immunity, and explain the role of lymphocytes in the immune response.

Immunity (i-MYŪ-ni-tē) is the body's ability to resist and defend against infectious organisms or other substances that could damage tissues and organs. The body's reaction to these infectious agents and other abnormal substances is known as the **immune** (*immune*, protected) **response**. The closely associated process is **resistance**, which is the ability of the body to maintain its immunity. We have two types of immunity that collaborate to protect the human body. These types are *innate (nonspecific) immunity* and *adaptive (specific) immunity*. Each of these types has specific lymphocytes associated with their function, although as we will discover in this section, innate immunity uses other forms of defense as well. We also take a closer look at the origin, distribution, and general functions of the three classes of lymphocytes involved in the immune response.

Types of Immunity

Humans have two types of immunity: innate (natural and "one-size-fits all") and adaptive (acquired and specific). Both function to defend us against foreign organisms or substances.

1. *Innate (Nonspecific) Immunity.* The body has several physical barriers and internal defense processes that either prevent or slow the entry of infectious organisms, or attack them if they do enter. For example, the skin serves as a physical barrier, and phagocytes attack invading bacteria. This type of immunity is called *innate* because you are born with it, and *nonspecific* because it does not distinguish one potential threat from another. Therefore, this category of immunity is called **innate (nonspecific) immunity** and it depends on a class of lymphocytes called NK cells.
2. *Adaptive (Specific) Immunity.* In contrast, two classes of lymphocytes, T cells and B cells, respond to specific antigens. If a bacterial pathogen invades peripheral tissues,

these lymphocytes organize a defense against that particular type of bacterium, but not other bacteria and viruses. More importantly, this type of immunity also protects us against further attacks by the same type of pathogen. For this reason, we say that T cells and B cells provide an *adaptive* defense. Many specific defenses develop after birth as a result of accidental or deliberate exposure to antigens. **Adaptive (specific) immunity** depends on the activities of specific lymphocytes—B cells and T cells.

Lymphocytes

In the previous section, we introduced the main classes of lymphocytes that circulate in blood. These are **B cells**, **T cells**, and **NK cells**. Most lymphocytes are T cells. These cells recognize various abnormal and foreign antigens, and produce a defensive, immune response. Let's look at the circulation and life span of these lymphocytes, as well as their production.

Circulation and Life Span of Lymphocytes

The various types of lymphocytes are not evenly distributed in the blood, red bone marrow, spleen, thymus, and peripheral lymphoid tissues. The ratio of B cells to T cells varies among tissues and organs. For example, B cells are seldom found in the thymus, and T cells outnumber B cells in blood by a ratio of 8:1.

The lymphocytes in these organs are visitors, not residents. All types of lymphocytes move throughout the body. They wander through tissues and then enter blood vessels or lymphatic vessels for transport.

T cells move quickly. For example, a wandering T cell may spend about 30 minutes in the blood, 5–6 hours in the spleen, and 15–20 hours in a lymph node. B cells move more slowly. A typical B cell spends about 30 hours in a lymph node before moving on.

Lymphocytes have relatively long life spans. About 80 percent survive 4 years, and some last 20 years or more. Throughout your life, you maintain normal lymphocyte populations by producing new lymphocytes in your red bone marrow and lymphoid tissues.

Lymphocyte Production

In Chapter 19, we discussed *hemopoiesis*—the formation of the formed elements of blood. ↩ pp. 660, 664, 675 In adults, red blood cell formation, or *erythropoiesis*, is normally confined to red bone marrow. In contrast, lymphocyte formation, or **lymphocytopoiesis** (lim-fō-SĪ-tō-poy-Ē-sis), involves the red bone marrow, thymus, and peripheral lymphoid tissues (Figure 22–9).

Red bone marrow plays the primary role in maintaining normal lymphocyte populations. Hemocytoblasts divide in the red bone marrow of adults to generate the lymphoid stem cells that produce all types of lymphocytes. The red bone marrow produces two distinct populations of lymphoid stem cells.

One group of lymphoid stem cells remains in the red bone marrow and the other group migrates to the thymus (see Figure 22–9). Lymphoid stem cells in the red bone marrow divide to produce immature B cells and NK cells. B cell development involves intimate contact with large *stromal cells* (not shown) in the red bone marrow. Bone marrow stromal cells provide a specialized microenvironment to control hemopoiesis. The cytoplasmic extensions of stromal cells contact or even wrap around the developing B cells. Stromal cells of the red bone marrow produce a cytokine called *interleukin-7*, which promotes the differentiation of B cells.

As they mature, B cells and NK cells enter the bloodstream and migrate to peripheral tissues (see Figure 22–9). Most of the B cells move into lymph nodes, the spleen, or other lymphoid tissues. The NK cells patrol the body, moving through peripheral tissues in search of abnormal cells.

The second group of lymphoid stem cells migrates to the thymus (see Figure 22–9). These stem cells and their descendants develop and mature in an environment that is isolated from the general circulation by the blood thymus barrier. Under the influence of thymic hormones, the lymphoid stem cells divide repeatedly, producing the various kinds of T cells. When the development of the T cells nears completion, they reenter the bloodstream and travel to peripheral tissues, including lymphoid tissues and organs, such as the spleen (see Figure 22–9).

The T cells and B cells that migrate from their sites of origin retain the ability to divide, producing daughter cells of the same type. For example, a dividing B cell produces other B cells, not T cells or NK cells. As we will see, the ability of specific types of lymphocytes to increase in number is crucial to the success of the immune response.

Checkpoint

6. **Compare immunity with resistance.**
7. **Explain the difference between innate immunity and adaptive immunity.**

See the blue Answers tab at the back of the book.

22-3 Innate defenses respond the same regardless of the invader

Learning Outcome List the body's innate defenses, and describe the components, mechanisms, and functions of each.

Innate (nonspecific) defenses make up the first line of defense in innate immunity. They include physical barriers, phagocytes, immune surveillance, interferons, complement, inflammation, and fever. These innate defenses are summarized in Figure 22–10.

Physical Barriers

To cause trouble, a foreign substance or pathogen must enter body tissues. In other words, it must cross an epithelium—either

Figure 22–9 The Origin and Distribution of Lymphocytes.

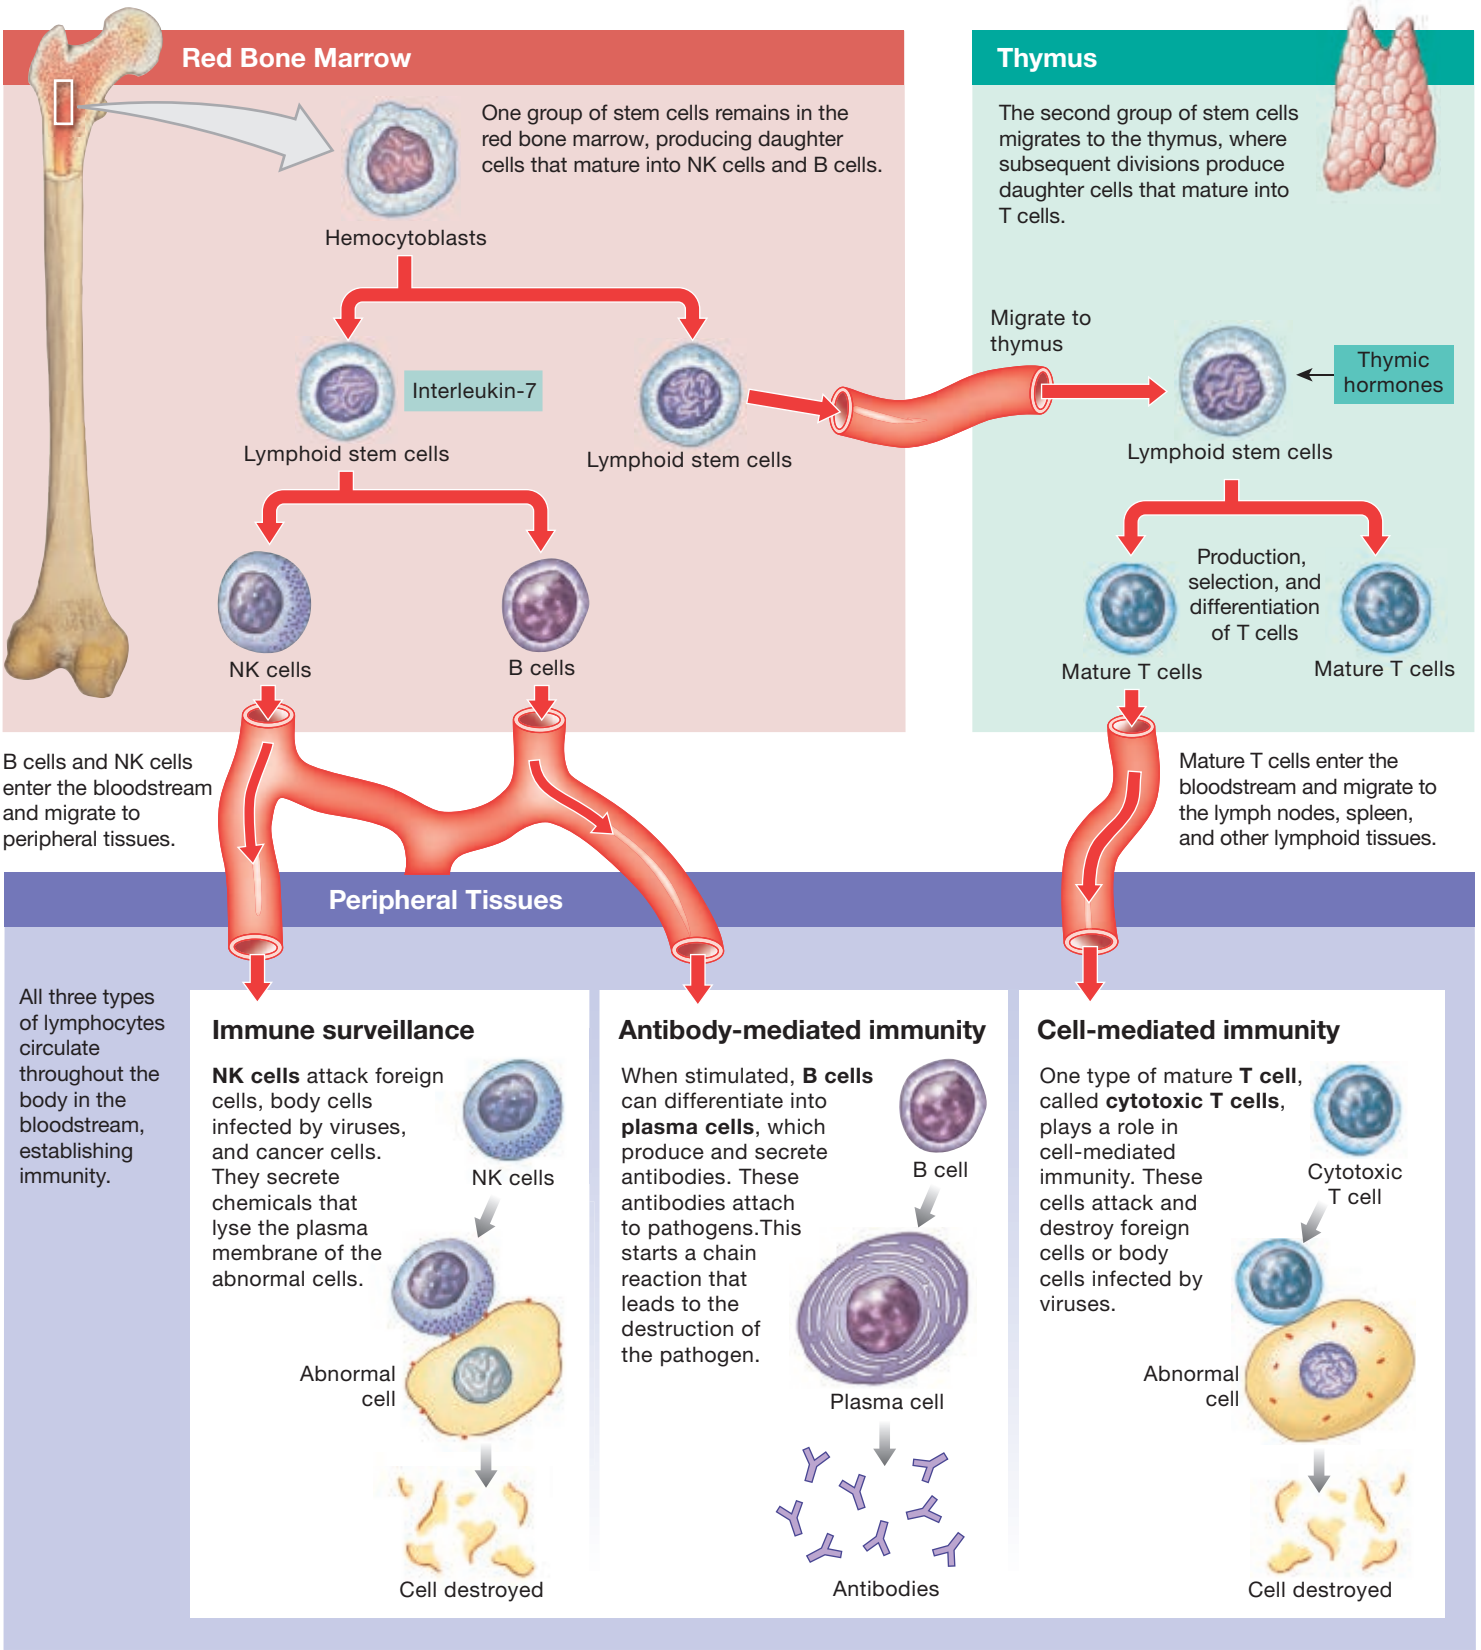

Figure 22–10 Innate Defenses. Innate (nonspecific) defenses deny pathogens access to the body or destroy them without distinguishing among specific types.

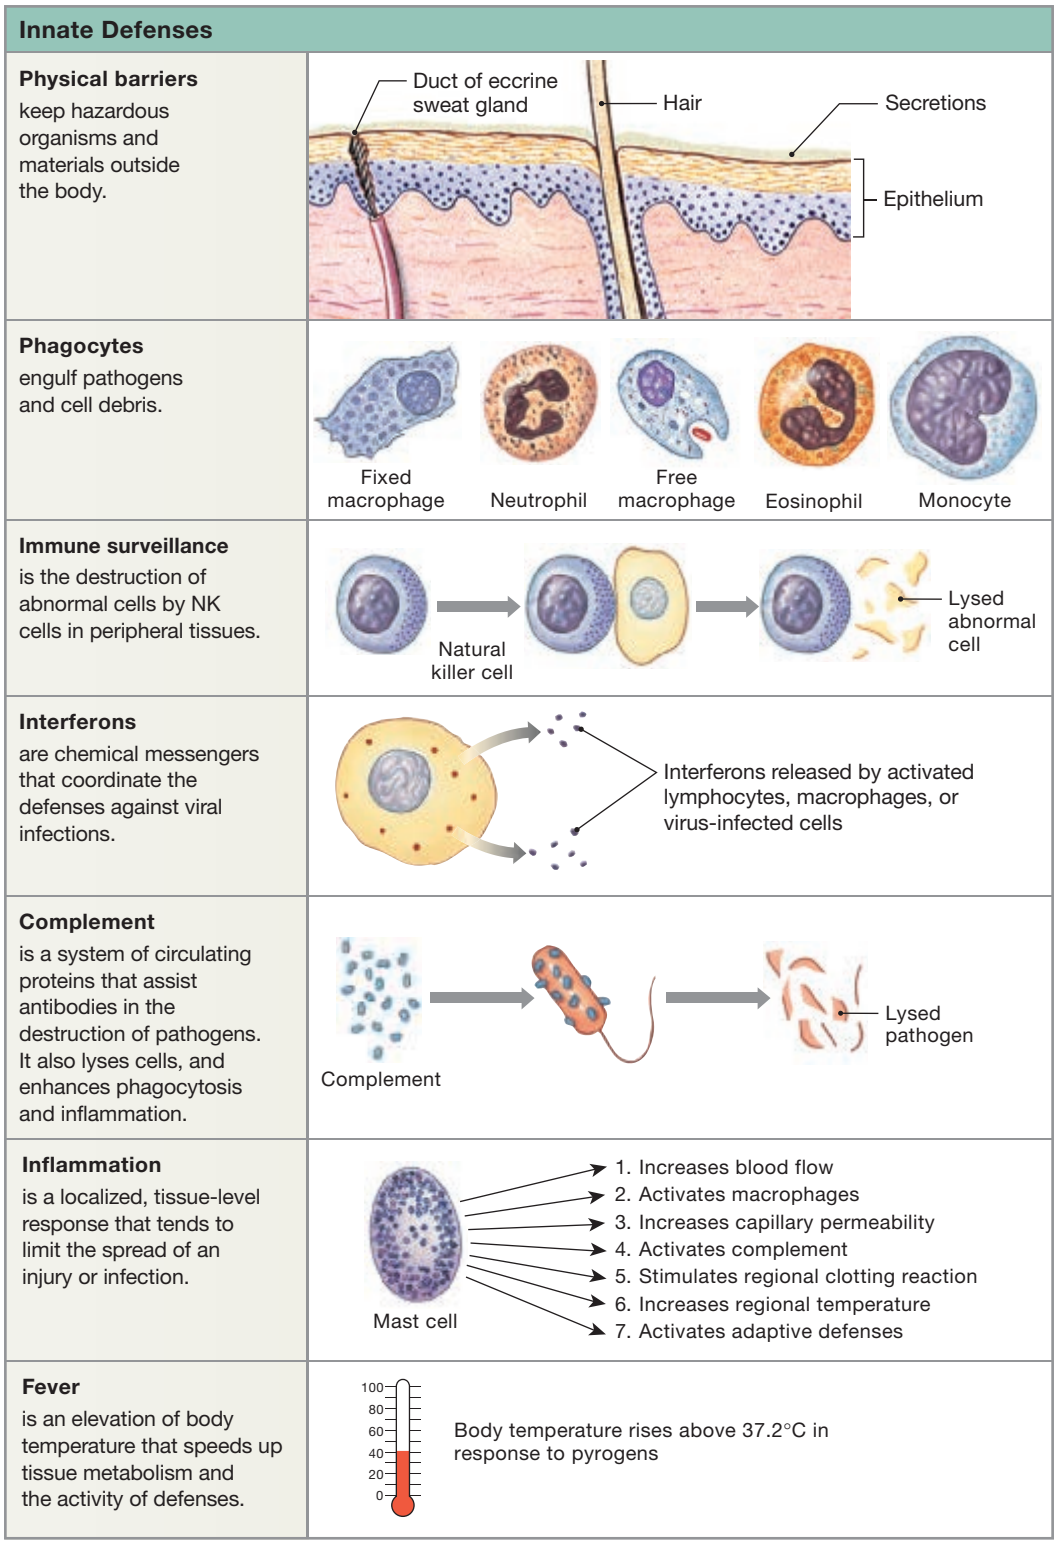


at the *skin* or across a *mucous membrane*. The epithelial covering of the skin has multiple layers, a keratin coating, and a network of desmosomes that lock adjacent cells together. ↺ pp. 118–119, 153–157 These physical barriers are very effective in protecting underlying tissues. Even along the more delicate internal passageways of the respiratory, digestive, urinary, and reproductive tracts, epithelial cells are tied together by tight junctions. These cells generally are supported by a dense and fibrous basement membrane.

In addition, specialized accessory structures and secretions protect most epithelia. The hairs on most areas of your body provide some protection against abrasion, especially on the scalp. They often prevent hazardous materials or insects from contacting your skin. The epidermal surface also receives the secretions of sebaceous and sweat glands. These secretions flush the surface and wash away microorganisms and chemicals. Such secretions may also contain chemicals that kill bacteria, destructive enzymes called *lysozymes*, and antibodies.

The epithelia lining the digestive, respiratory, urinary, and reproductive tracts are more delicate, but they are equally well defended. For example, mucus bathes most surfaces of your digestive and respiratory tracts, urine flushes the urinary tract, and glandular secretions do the same for the reproductive tract. Your stomach also contains a powerful acid that can destroy many pathogens.

Phagocytes

Phagocytes serve as janitors and police in peripheral tissues. They remove cellular debris and respond to invasion by foreign substances or pathogens. Many phagocytes attack and remove microorganisms even before lymphocytes detect them. The human body has two general classes of phagocytes: microphages and macrophages.

Microphages

Microphages are the neutrophils and eosinophils that normally circulate in the blood. These phagocytes leave the bloodstream and enter peripheral tissues that have been subjected to injury or infection. As noted in Chapter 19, neutrophils are abundant, mobile, and quick to phagocytize cellular debris or invading bacteria. ↩ p. 671 Eosinophils are less abundant. They target foreign substances or pathogens that have been coated with antibodies.

Macrophages

Macrophages are large, active phagocytes. Your body has several types of macrophages. Most are derived from the monocytes in circulating blood. Typically, macrophages are either fixed in position or freely mobile. As a result they are usually classified as fixed macrophages or free macrophages, but the distinction is not absolute. During an infection, fixed macrophages may lose their attachments and begin roaming around the damaged tissue.

No organs or tissues are dominated by phagocytes, but almost every tissue in the body shelters resident or visiting macrophages. This relatively diffuse collection of phagocytes is the **monocyte–macrophage system**, or the *reticuloendothelial system*.

How does an activated macrophage respond to a pathogen? It may:

- engulf a pathogen or other foreign object and destroy it with lysosomal enzymes.
- bind to or remove a pathogen from the interstitial fluid, but be unable to destroy the invader until assisted by other cells.
- destroy its target by releasing toxic chemicals, such as *tumor necrosis factor*, nitric oxide, or hydrogen peroxide, into the interstitial fluid.

We consider these responses further in a later section.

Fixed macrophages, or *histiocytes*, reside in specific tissues and organs. These cells are normally incapable of movement, so their targets must diffuse or otherwise move through the surrounding tissue until they are within range. Fixed macrophages are scattered among connective tissues, usually in close association with collagen or reticular fibers. They are found in the papillary and reticular layers of the dermis, in the subarachnoid space of the meninges, and in bone marrow. In some organs, the fixed macrophages have special names. **Microglia** are macrophages in the central nervous system, and **stellate macrophages** *(Kupffer cells)* are macrophages located on the luminal surface of liver sinusoids.

Free macrophages, or *wandering macrophages*, travel throughout the body. They arrive at the site of an injury by migrating through adjacent tissues or by leaving the circulating blood. Some tissues contain free macrophages. For example, **alveolar macrophages**, also known as *dust cells*, monitor the epithelial surfaces of the lungs for respiratory pathogens.

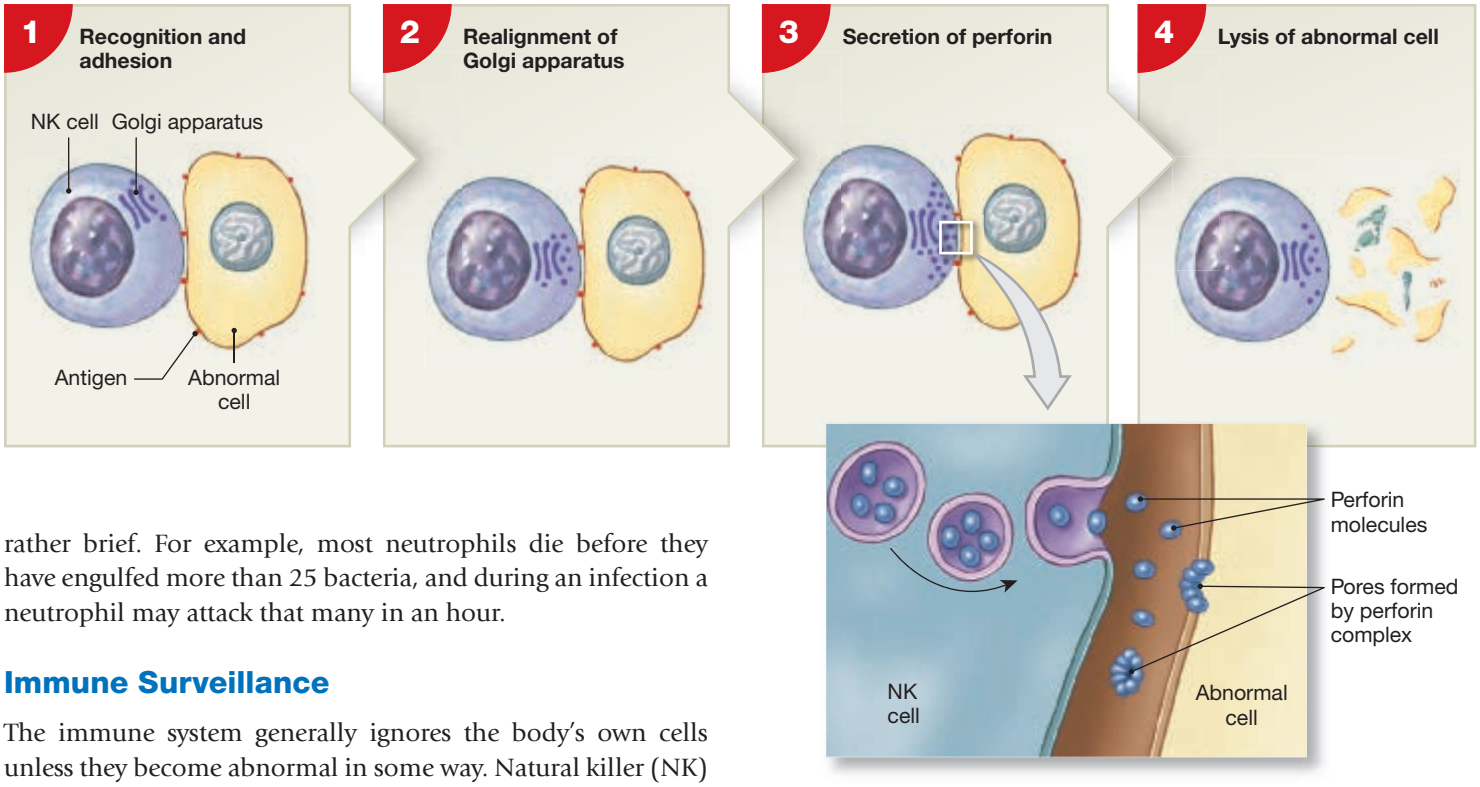
Functions of Phagocytes

Free macrophages and microphages function in similar ways:

- Both can move through capillary walls by squeezing between adjacent endothelial cells. This process is known as *emigration*. ↩ p. 671 The endothelial cells in an injured area develop membrane "markers" that signal passing blood cells that something is wrong. The phagocytes then attach to the endothelial lining and migrate into the surrounding tissues.
- Both may be attracted to or repelled by chemicals in the surrounding fluids, a phenomenon called **chemotaxis**. They are particularly sensitive to chemicals known as *cytokines* that are released by other body cells and to chemicals released by pathogens.
- For both, phagocytosis begins with **adhesion**, the attachment of the phagocyte to its target. In adhesion, receptors on the plasma membrane of the phagocyte bind to the surface of the target. Adhesion is followed by the formation of a vesicle containing the bound target (look back at Figure 3–22, p. 101). The contents of the vesicle are digested once the vesicle fuses with lysosomes or peroxisomes.

All phagocytes function in much the same way, although their targets may differ. The life span of a phagocyte can be

Figure 22–11 How Natural Killer Cells Kill Cellular Targets.



rather brief. For example, most neutrophils die before they have engulfed more than 25 bacteria, and during an infection a neutrophil may attack that many in an hour.

Immune Surveillance

The immune system generally ignores the body's own cells unless they become abnormal in some way. Natural killer (NK) cells, also known as *large granular lymphocytes*, are responsible for recognizing and destroying abnormal cells when they appear in peripheral tissues. Their continuous "policing" of peripheral tissues has been called **immune surveillance**.

The plasma membrane of an abnormal cell generally contains antigens that are not found on the membranes of normal cells. NK cells recognize an abnormal cell by detecting those antigens. NK cells are much less selective about their targets than are other lymphocytes: They respond to a *variety* of abnormal antigens that may appear anywhere on a plasma membrane. They also attack *any* membrane containing abnormal antigens. As a result, NK cells are highly versatile defenders. A single NK cell can attack bacteria in the interstitial fluid, body cells infected with viruses, or cancer cells.

NK cells respond much more rapidly than T cells or B cells. The activation of T cells and B cells involves a complex and time-consuming sequence of events. NK cells respond immediately on contact with an abnormal cell.

Activated NK cells react in a predictable way (Figure 22–11):

1 **Recognition and Adhesion.** If a cell has unusual components in its plasma membrane, an NK cell recognizes that cell as abnormal. This recognition activates the NK cell, which then adheres to its target cell.

2 **Realignment of Golgi Apparatus.** The Golgi apparatus moves around the nucleus until the maturing (*trans*) face points directly toward the abnormal cell. The process might be compared to the rotation of a tank turret to point the cannon toward the enemy. The Golgi apparatus then produces a flood of secretory vesicles that contain proteins called **perforins**. These vesicles move through the cytosol toward the cell surface.

3 **Secretion of Perforin.** The perforins are released at the NK cell surface by exocytosis and diffuse across the narrow gap between the NK cell and its target.

4 **Lysis of Abnormal Cell.** When perforin molecules reach the opposing plasma membrane, the perforins interact with one another and create a network of pores in it. These pores are large enough to allow the free passage of ions, proteins, and other intracellular materials. As a result, the target cell can no longer maintain its internal environment, and it quickly disintegrates.

Tips & Tools

Perforin gets its name because it ***perfor***ates the target cell.

Why doesn't perforin affect the plasma membrane of the NK cell? The answer is not clear, but NK cell membranes contain a second protein, called *protectin*. It may bind and inactivate perforin.

NK cells attack cancer cells and body cells infected with viruses. Cancer cells probably appear throughout life, but their plasma membranes generally contain unusual proteins called **tumor-specific antigens**, which NK cells recognize as abnormal. The NK cells then destroy the cancer cells, preserving the tissue.

Unfortunately, some cancer cells avoid detection, perhaps because they lack tumor-specific antigens or because these antigens are covered in some way. Other cancer cells are able to destroy the NK cells that detect them. This process of avoiding detection or neutralizing body defenses is called **immunological escape**. Once immunological escape has occurred, cancer cells can multiply and spread without interference by NK cells.

In viral infections, the viruses replicate inside cells, beyond the reach of circulating antibodies. However, infected cells incorporate viral antigens into their plasma membranes, and NK cells recognize these infected cells as abnormal. By destroying them, NK cells can slow or prevent the spread of a viral infection.

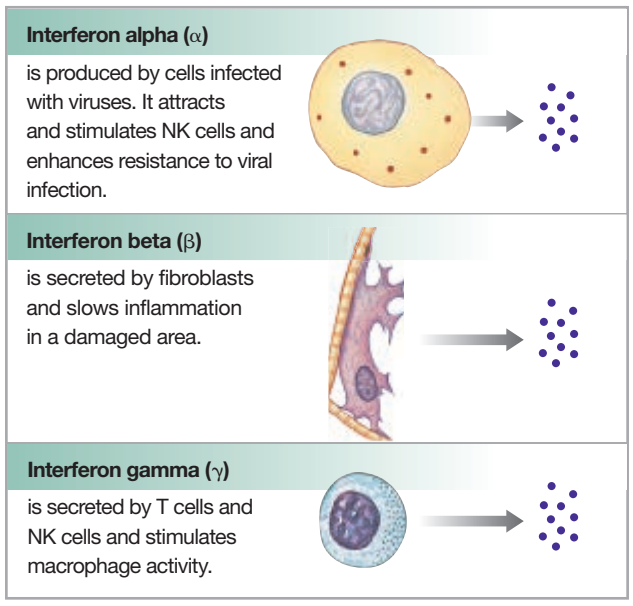
Interferons

Interferons (in-ter-FĒR-onz) **(IFNs)** are small proteins released by activated lymphocytes and macrophages, and by tissue cells infected with viruses. An interferon binds to surface receptors on the membrane of a normal cell and, by second messengers, triggers the production of antiviral proteins in the cytoplasm. Antiviral proteins do not prevent viruses from entering the cell. Instead, they interfere with viral replication inside the cell. In addition to slowing the spread of viral infections, IFNs stimulate the activities of macrophages and NK cells.

At least three types of interferons exist: **interferon alpha** (α), **interferon beta** (β), and **interferon gamma** (γ) (Figure 22–12). Most cells other than lymphocytes and macrophages respond to viral infection by secreting interferon beta.

22

Figure 22–12 Interferons.



? Which type of interferon attracts and stimulates NK cells as a way to enhance viral resistance to viral infection?

Interferons are examples of cytokines. **Cytokines** (SĪ-tō-kīnz) are chemicals that tissue cells release to coordinate local activities. Cytokines include hormones and paracrine-like glycoproteins important to the immune response. Most cells produce cytokines only for paracrine communication—that is, cell-to-cell communication within one tissue. ↩ p. 611 However, defense cells also release cytokines; we discuss their role in Section 22–5.

Complement System

Plasma contains over 30 special **complement proteins** that form the **complement system**. The term *complement* refers to the fact that this system complements, or enhances, the action of antibodies and phagocytes. The complement proteins interact with one another in chain reactions, or *cascades*, reminiscent of those of the clotting system.

The activation of complement can occur by three different routes: the *classical pathway*, the *lectin pathway*, and the *alternative pathway*. The **classical pathway** activates the complement system most rapidly and effectively. Its proteins are abbreviated "C" with a number that corresponds to its discovery. It begins with the binding of complement protein C1 to two nearby antibodies already attached to its specific antigen, such as a bacterial cell wall. The **lectin pathway** activates the complement system by the binding of the protein mannose-binding lectin (MBL) to carbohydrates on pathogen surfaces, such as bacterial cell walls. The **alternative pathway** also activates the complement system without antibody interactions. Its proteins are given specific names or called *factors*. The alternative pathway begins when several complement proteins—including **properdin** (*factor P*), *factor B*, and *factor D*—interact in the plasma. This interaction is triggered by exposure to foreign materials, such as the cell wall of a bacterium.

All three pathways involve the splitting of inactive C3 protein to activated C3b and C3a proteins. Complement activation brings about the following effects: killing of the pathogen by cell lysis, enhanced phagocytosis (**opsonization**), and enhanced inflammation (histamine release). Figure 22–13 shows the three pathways of complement activation and its effects.

Inflammation

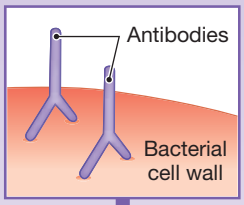
Inflammation is a localized tissue response to injury. ↩ p. 145 Inflammation produces local *redness*, *swelling*, *heat*, and *pain*. These are known as the so-called *cardinal signs and symptoms of inflammation*. Sometimes a fifth is included: *lost function*.

Many stimuli can produce inflammation. They include impact, abrasion, distortion, chemical irritation, infection by pathogens, and extreme temperatures (hot or cold). Each stimulus kills cells, damages connective tissue fibers, or injures the tissue in some other way. The changes alter the chemical composition of the interstitial fluid. Damaged cells release

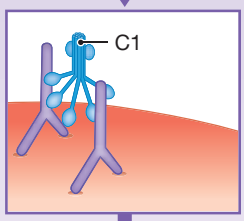
Figure 22–13 Pathways of Complement Activation.

Classical Pathway

The most rapid and effective activation of the complement system occurs through the classical pathway.

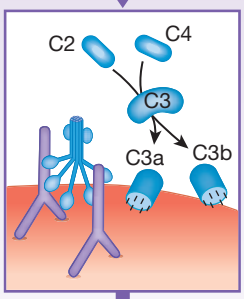


Antibodies bind to bacterial cell wall



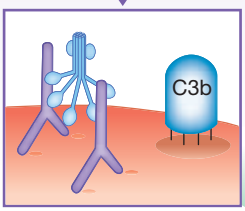
Attachment of C1

C1 must attach to two antibodies for its activation.



Activation and Cascade

The attached C1 protein acts as an enzyme, catalyzing a series of reactions involving other complement proteins that split C3 into C3a and C3b. C3a diffuses away and activates an inflammatory response.

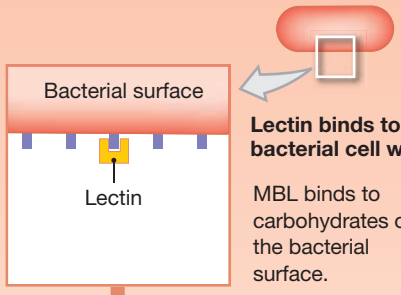


C3b Attachment (classical pathway)

C3b binds to the bacterial cell wall and enhances phagocytosis.

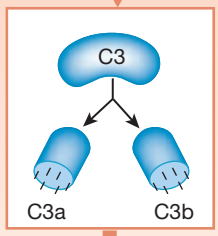
Lectin Pathway

The lectin pathway is activated by the protein mannose-binding lectin (MBL). MBL binds to carbohydrates on bacterial surfaces.



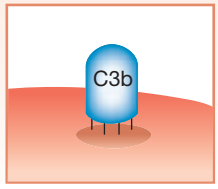
Lectin binds to bacterial cell wall

MBL binds to carbohydrates on the bacterial surface.



C3 Activation

Bound MBL forms a complex that splits C3 into C3a and C3b. C3a activates an inflammatory response.



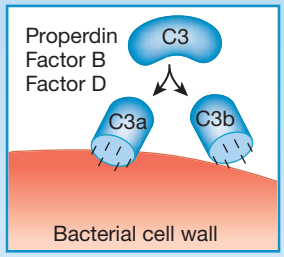
C3b Attachment (lectin pathway)

C3b binds to bacterial surface and enhances phagocytosis.

Alternative Pathway

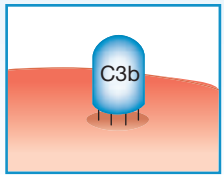
The alternative pathway is important in the defense against bacteria, some parasites, and virus-infected cells.

Complement proteins interact in plasma



The alternative pathway begins when several complement proteins, notably properdin, interact in the plasma causing C3 to split into C3a and C3b. This interaction can be triggered by exposure to foreign materials, such as the capsule of a bacterium. C3a activates an inflammatory response.

C3b Attachment (alternative pathway)

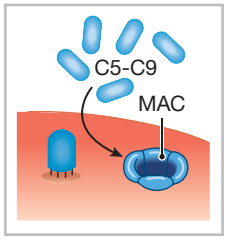


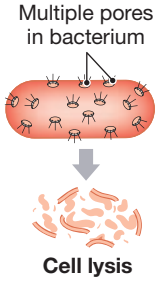
C3b protein binds to the bacterial cell wall.

Complement activation causes

Killing of Pathogen (Cell Lysis)

Once an activated C3b protein has attached to the cell wall, additional complement proteins may form a **membrane attack complex (MAC)** in the membrane that destroys the integrity of the target cell.





Enhanced Phagocytosis (Opsonization)

The attached C3b may also act to enhance phagocytosis. This enhancement of phagocytosis, a process called **opsonization**, occurs because macrophage membranes contain receptors that detect and bind to complement proteins and bound antibodies.

Inflammation (Histamine Release)

Release of histamine by mast cells and basophils increases the degree of local inflammation, attracts and activates phagocytes, and accelerates blood flow to the region.

22

prostaglandins, proteins, and potassium ions. The injury itself may have introduced foreign proteins or pathogens. These changes in the interstitial environment trigger the complex process of inflammation.

Inflammation has several effects:

- The injury is temporarily repaired, and additional pathogens are prevented from entering the wound.
- The spread of pathogens away from the injury is slowed.
- Local, regional, and systemic defenses are mobilized to overcome the pathogens and facilitate permanent repairs. This repair process is called *regeneration*.

Mast cells play a pivotal role in inflammation. **Figure 22–14** summarizes the events of inflammation in the skin. Comparable events take place in almost any tissue subjected to physical damage or infection.

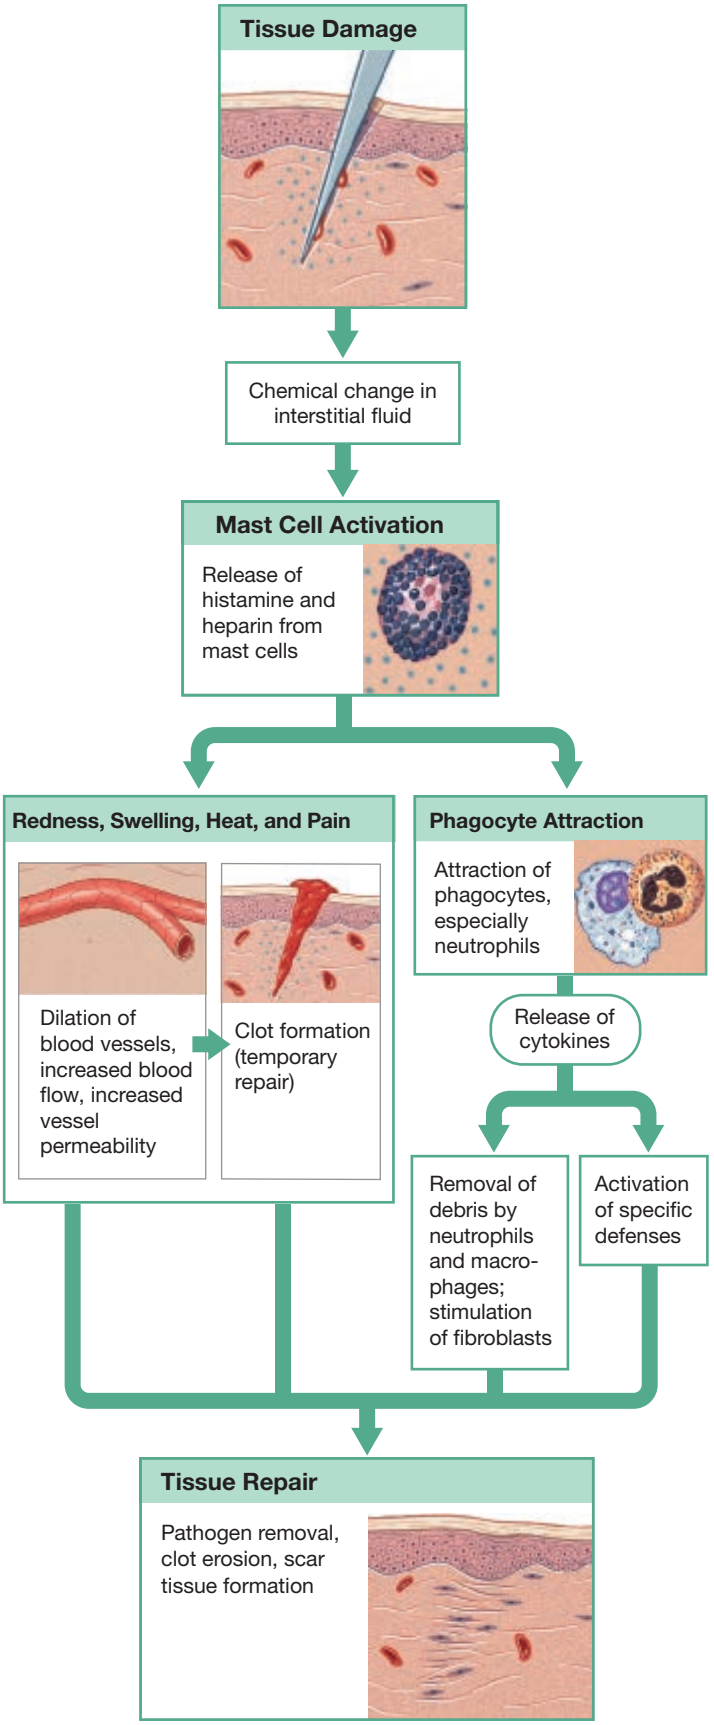
When stimulated by physical stress or chemical changes in the local environment, mast cells release histamine, heparin, prostaglandins, and other chemicals into interstitial fluid. The histamine makes capillaries more permeable and speeds up blood flow through the area. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates local sensory neurons, producing pain. The person then may take steps to limit the damage, such as removing a splinter or cleaning a wound.

The increased blood flow reddens the area and raises the local temperature. These changes increase the rate of enzymatic reactions and accelerate the phagocyte activity. The rise in temperature may also denature foreign proteins or vital enzymes of invading microorganisms.

Because vessel permeability has increased, clotting factors and complement proteins can leave the bloodstream and enter the injured or infected area. Clotting does not take place at the actual site of injury, due to the presence of heparin. However, a clot soon forms around the damaged area, both isolating the region and slowing the spread of the chemical or pathogen into healthy tissues. Meanwhile, complement activation through the alternative pathway breaks down bacterial cell walls and attracts phagocytes.

Neutrophils are drawn to the area by chemotaxis, where they attack debris and bacteria. As neutrophils circulate through a blood vessel in an injured area, they undergo *activation*. In this process (1) they stick to the side of the vessel and move into the tissue by emigration; (2) their metabolic rate goes up dramatically, and while this *respiratory burst* continues, they generate reactive compounds, such as nitric oxide and hydrogen peroxide, that can destroy engulfed pathogens; and (3) they secrete cytokines that attract other neutrophils and macrophages to the area. As inflammation proceeds, the foreign proteins, toxins, microorganisms, and active phagocytes in the area activate the body's specific defenses.

Figure 22–14 Inflammation and the Steps in Tissue Repair.



Fixed and free macrophages engulf pathogens and cell debris. At first, neutrophils outnumber these cells. Then, as the macrophages and neutrophils continue to secrete cytokines, the number of macrophages increases rapidly. Eosinophils may get involved if antibodies coat the foreign materials.

The cytokines released by active phagocytes stimulate fibroblasts in the area. The fibroblasts then begin forming scar tissue that reinforces the clot and slows the invasion of adjacent tissues. Over time, the clot is broken down and the injured tissues are either repaired or replaced by scar tissue. The process is essentially complete, although subsequent remodeling may take place over a period of years.

After an injury, tissue conditions generally become even more abnormal before they begin to improve. The tissue destruction that occurs after cells have been injured or destroyed is called **necrosis** (ne-KRŌ-sis). The destruction begins several hours after the initial event, and the damage is due to lysosomal enzymes. Lysosomes break down by autolysis, releasing digestive enzymes that first destroy the injured cells and then attack surrounding tissues. ↩ p. 80 As local inflammation continues, debris, fluid, dead and dying cells, and necrotic tissue components accumulate at the injury site. This viscous fluid mixture is known as **pus**. An accumulation of pus in an enclosed tissue space is called an **abscess**.

Fever

Fever is a body temperature greater than 37.2°C (99°F). Recall from Chapter 14 that the pre-optic area of the hypothalamus contains the temperature-regulating center. ↩ p. 484 Fever-inducing agents called **pyrogens** (PĪ-rō-jenz; *pyro-*, fever) can reset this thermostat and raise body temperature.

Bacteria, molds, viruses, and yeasts produce pyrogens and release them into the bloodstream. Several endogenous, or internally produced, pyrogens have been identified including interleukin-1, interferons, and tumor necrosis factor.

Within limits, a fever can be beneficial. High body temperatures may inhibit some viruses and bacteria. The most likely benefit is on body metabolism. For each 1°C rise in body temperature, metabolic rate increases by 10 percent. Cells can move faster, and enzymatic reactions take place more quickly. As a result, tissue defenses can be mobilized more rapidly and the repair process speeds up.

Checkpoint

8. What types of cells would be affected by a decrease in the number of monocyte-forming cells in red bone marrow?
9. A rise in the level of interferon in the body suggests what kind of infection?
10. What effects do pyrogens have in the body?

See the blue Answers tab at the back of the book.

22-4 Adaptive (specific) defenses respond to particular threats and are either cell mediated or antibody mediated

Learning Outcome Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.

Lymphocytes of Adaptive Immunity

Adaptive (specific) defenses result from the coordinated activities of T lymphocytes and B lymphocytes, known as T cells and B cells. Under proper stimulation, T cells differentiate into several types of cells, which attack antigens and help to increase the immune response.

The primary types of T cells are as follows (Figure 22–15):

- **Cytotoxic T cells** are involved in direct cellular attack. These cells enter peripheral tissues and attack antigens physically and chemically.
- **Helper T cells** stimulate the responses of both T cells and B cells. Helper T cells are absolutely vital to the immune response, because they must activate B cells before the B cells can produce antibodies. The reduction in the helper T cell population that occurs in AIDS is largely responsible for the loss of immunity. (We discuss AIDS on p. 827.)
- **Regulatory T cells** are a subset of T cells that moderate the immune response.
- **Memory T cells** respond to antigens they have already encountered by the cloning (producing identical cellular copies) of more lymphocytes to ward off the invader.

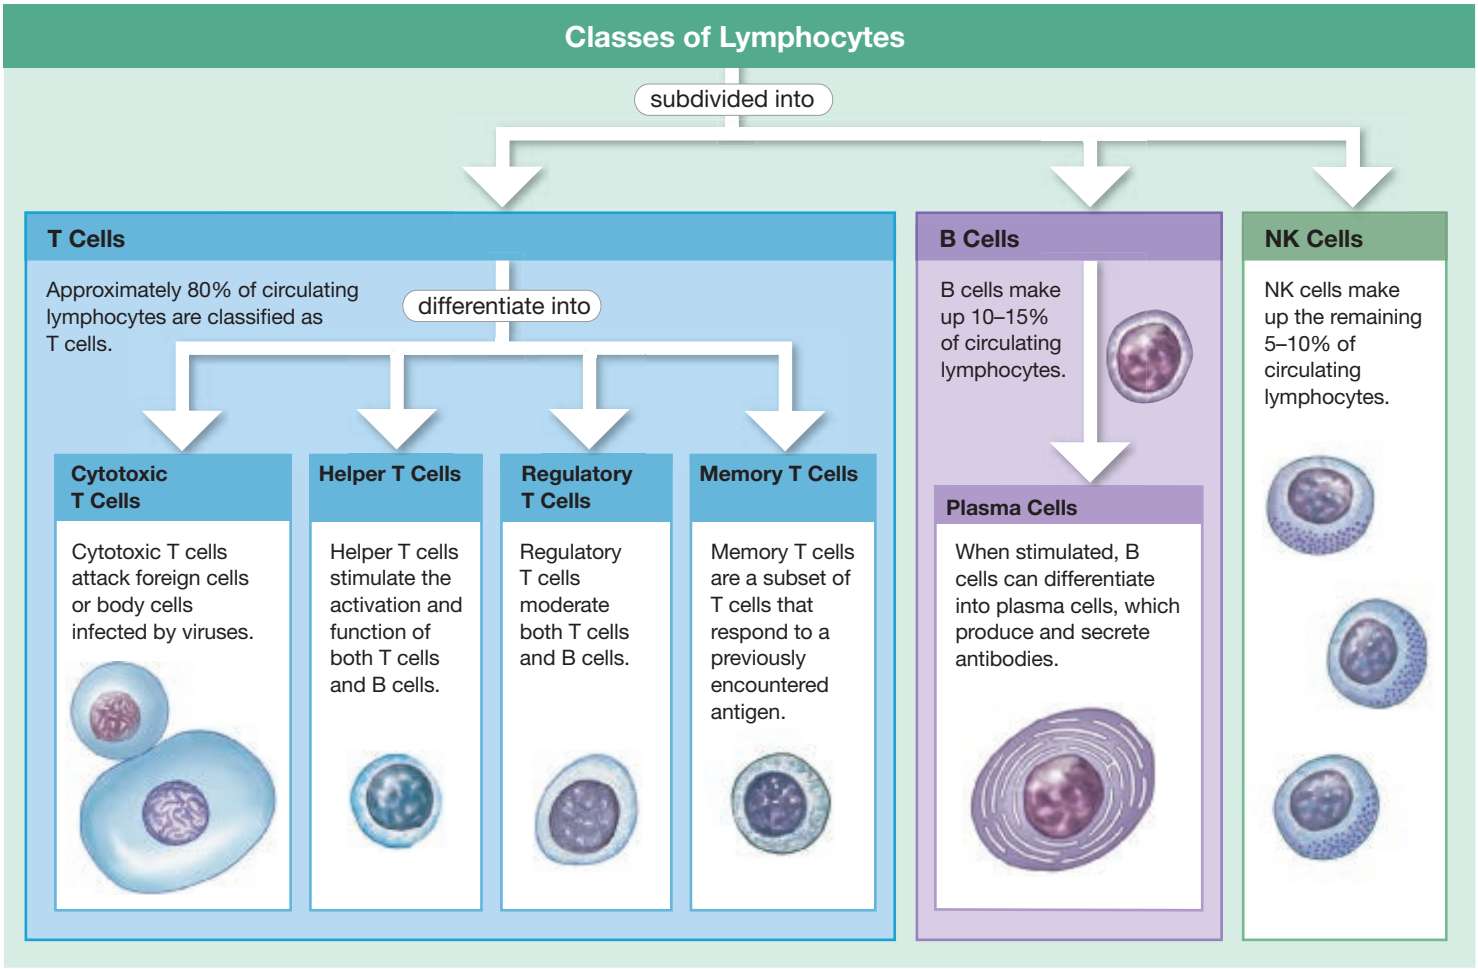
The interplay between helper T cells and regulatory T cells helps establish and control the sensitivity of the immune response. Other types of regulatory T cells also take part in the immune response. For example, *inflammatory T cells* stimulate regional inflammation and local defenses in an injured tissue. *Suppressor/inducer T cells* suppress B cell activity but stimulate other T cells.

When stimulated, B cells differentiate into *plasma cells* that secrete soluble proteins called *antibodies*. ↩ p. 661 The binding of an antibody to its target antigen leads to the destruction of the target invader.

Types of Adaptive Immunity

Adaptive (specific) defenses result from the coordinated activities of T cells and B cells. Cytotoxic T cells provide **cell-mediated immunity**, or *cellular immunity*, which defends against abnormal cells and pathogens inside cells. B cells provide **antibody-mediated immunity**, which defends against antigens and pathogens in body fluids.

Figure 22–15 Classes of Lymphocytes.



Antibody-mediated immunity is also known as *humoral* ("liquid") *immunity* because antibodies are found in body fluids.

Both kinds of immunity are important because they come into play under different circumstances. Both T and B cells respond to the presence of specific antigens. However, activated T cells do not respond to antigens in solution, and antibodies (produced by activated B cells) cannot cross plasma membranes. Moreover, helper T cells play a crucial role in antibody-mediated immunity by stimulating the activity of B cells.

An Introduction to Adaptive Immunity

Figure 22–16 provides an overview of adaptive immunity. When an antigen triggers an immune response, it usually activates both T cells and B cells. The activation of T cells generally occurs first, but only after phagocytes have been exposed to the antigen. Once activated, T cells attack the antigen and stimulate the activation of B cells. Activated B cells mature into cells that produce antibodies. Antibodies in the bloodstream then bind to and attack the antigen.

Antigens

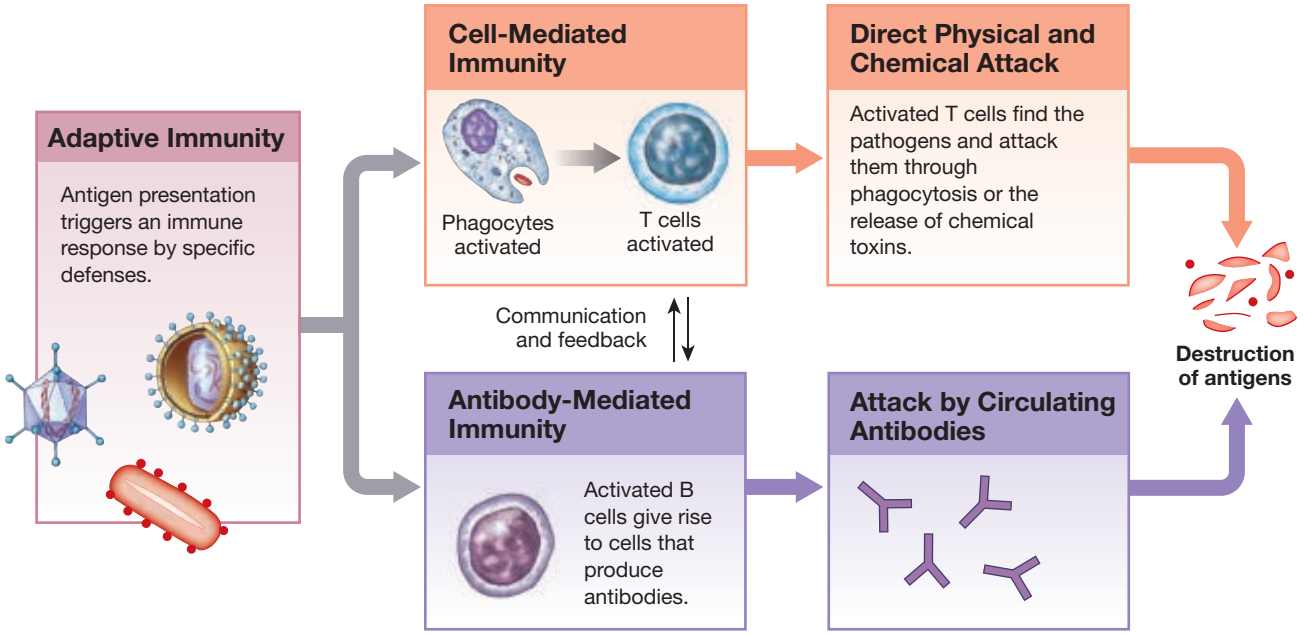
Specific chemical targets called **antigens** stimulate the immune response. Most antigens are pathogens, parts or products of pathogens, or other foreign substances. Antigens are usually proteins, but some lipids, polysaccharides, and nucleic acids are also antigens.

Lymphocyte Activation and Clonal Selection

A lymphocyte becomes **activated** when it has contact with an appropriate antigen. When activated, a lymphocyte begins to divide, producing more lymphocytes with the same specificity. All the identical cells produced by these divisions make up a **clone**, and all the members of that clone are sensitive to the same specific antigen.

To understand how this system works, think about running a commercial kitchen with only samples on display. You can display a wide selection because the samples don't take up much space, and you don't have to expend energy now preparing food that might never be eaten. When a customer selects

Figure 22–16 An Overview of Adaptive Immunity.



one of your samples and places an order for several dozen, you prepare them on the spot.

The same principle applies to the lymphatic system. Your body contains a small number of many different kinds of lymphocytes. When an antigen arrives, it "selects" only those lymphocytes sensitive to it. These lymphocytes become activated and divide to generate a large number of additional lymphocytes of the same type. This process of an antigen selecting particular lymphocytes for cloning is called **clonal selection**.

Forms of Adaptive Immunity

Adaptive immunity can be *active* or *passive* (Figure 22–17). These forms of immunity can be either naturally acquired or artificially acquired.

Active immunity develops after exposure to an antigen. It is a consequence of the immune response. In active immunity, the body responds to an antigen by making its own antibody. The immune system is *capable* of defending against a huge number of antigens. However, the appropriate defenses are mounted only after you encounter a particular antigen. Active immunity can result from natural exposure to an antigen in the environment (*naturally acquired active immunity*) or from deliberate exposure to an antigen (*artificially acquired active immunity*).

- **Naturally acquired active immunity** normally begins to develop after birth. It continues to build as you encounter "new" pathogens or other antigens. You might compare this process to the development of a child's vocabulary: The child begins with a few basic common words and learns new ones as they are encountered.
- **Artificially acquired active immunity** stimulates the body to produce antibodies under controlled conditions so that you will be able to overcome natural exposure to the pathogen in the future. This is the basic principle behind *immunization*, or *vaccination*, to prevent disease. A **vaccine** is a preparation designed to induce an immune response. It contains either a dead or an inactive pathogen, or antigens derived from that pathogen.

Passive immunity is produced by transferring antibodies from another source.

- In **naturally acquired passive immunity**, a baby receives antibodies from the mother, either during gestation (by crossing the placenta) or in early infancy (through breast milk).
- In **artificially acquired passive immunity**, a person receives antibodies to fight infection or prevent disease. For example, someone who has been bitten by a rabid animal gets injections containing antibodies against the rabies virus.

Properties of Adaptive Immunity

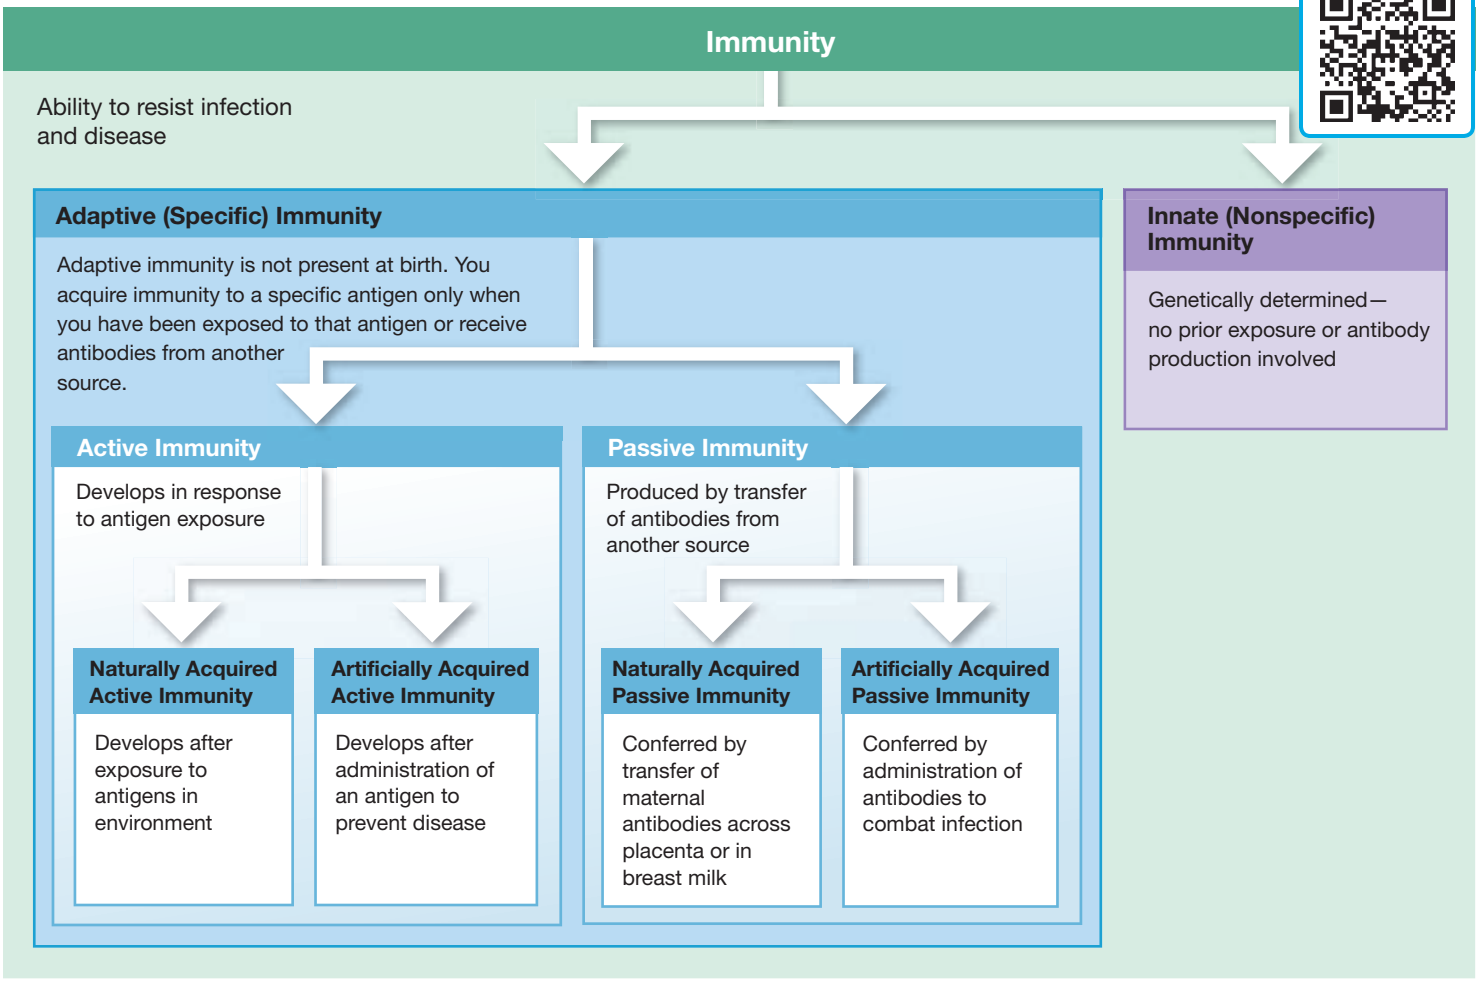
Regardless of the form, adaptive immunity has four general properties: (1) *specificity*, (2) *versatility*, (3) *memory*, and (4) *tolerance*.

Specificity

A specific defense is activated by a specific antigen, and the immune response targets that particular antigen and no others. **Specificity** results from the activation of appropriate lymphocytes and the production of antibodies with targeted effects. Specificity occurs because T cells and B cells respond to the

Figure 22–17 Forms of Immunity.

SmartArt



? What type of immunity develops after receiving a vaccine?

molecular structure of an antigen. The shape and size of the antigen determine which lymphocytes will respond to it. Each T cell or B cell has receptors that will bind to one specific antigen, ignoring all others. The response of an activated T cell or B cell is equally specific. Either lymphocyte will destroy or inactivate that antigen without affecting other antigens or normal tissues.

Versatility

Millions of antigens in the environment can pose a threat to health. Over a normal lifetime, you encounter only a fraction of that number—perhaps tens of thousands of antigens. Your immune system, however, has no way of anticipating which antigens it will encounter. It must be ready to confront *any* antigen at *any* time. **Versatility** results in part from the large diversity of lymphocytes present in the body, and in part from variability in the structure of synthesized antibodies.

During development, cells in the lymphatic system differentiate to produce a huge number of lymphocytes with varied antigen sensitivities. The trillion or more T cells and B cells in your body include millions of different lymphocyte populations, distributed throughout the body. Each population contains several thousand cells with receptors in their membranes that differ from the receptors of other lymphocyte populations. As a result, each population of lymphocytes responds to a different antigen.

Memory

As we just saw, during the initial response to an antigen, lymphocytes that are sensitive to it undergo repeated cycles of cell division. **Memory** exists because those cell divisions produce two groups of cells. One group attacks the invader immediately. Another group remains inactive unless it meets the same antigen at a later date. This inactive group is made up

of *memory cells* that enable your immune system to "remember" an antigen it has previously encountered, and to launch a faster, stronger, and longer-lasting counterattack if such an antigen appears again.

Tolerance

The immune system does not respond to all antigens. All cells and tissues in the body, for example, contain antigens that normally do not stimulate an immune response. We say that the immune system exhibits **tolerance** toward such antigens, called *self-antigens*.

During their differentiation in the red bone marrow (B cells) and thymus (T cells), any cells that react to self-antigens are destroyed. During this process up to 98 percent of developing T cells are deselected and undergo *apoptosis* (the process of genetically programmed cell death introduced in Chapter 3). ↩ p. 102 As a result, mature B cells and T cells ignore self-antigens, but attack foreign antigens, or *nonself-antigens*. Tolerance can also develop over time in response to chronic exposure to an antigen in the environment. Such tolerance lasts only as long as the exposure continues.

Checkpoint

11. **Explain the difference between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.**
12. **Identify the four major types of T cells.**
13. **Identify the two forms of active immunity and the two forms of passive immunity.**
14. **List the four general properties of adaptive immunity.**

See the blue Answers tab at the back of the book.

22-5 In cell-mediated adaptive immunity, presented antigens activate T cells, which respond by producing cytotoxic and helper T cells

Learning Outcome Discuss the types of T cells and their roles in the adaptive immune response, and describe the mechanisms of T cell activation and differentiation.

This section describes the mechanisms involved in antigen recognition by T cells and their subsequent activation, clonal selection, and mitotic divisions.

Activation and Clonal Selection of T Cells

Before an immune response can begin, T cells must be activated by exposure to an antigen. This activation seldom occurs through direct interaction between a T cell and the antigen. Foreign substances or pathogens entering a tissue commonly fail to stimulate an immediate immune response. T cells only recognize antigens when they are processed and "presented" by cells called *antigen-presenting cells*, most of which are phagocytes such as macrophages. This process—*antigen presentation*—is generally the first step in the activation of the immune response (look back at Figure 22–16). The next step is antigen recognition, and then differentiation and production of clones of the various defensive cells, such as cytotoxic T cells and helper T cells.

Antigen Presentation with MHC Proteins

For T cells to recognize an antigen, the antigen must be bound to glycoproteins in the plasma membrane of another cell, such as an antigen-presenting cell. Recall that glycoproteins are integral membrane components. ↩ p. 57 The structure of these glycoproteins is genetically determined, and these proteins identify the cell as "self" rather than foreign. The genes controlling their synthesis are located along one portion of chromosome 6, in a region called the **major histocompatibility complex (MHC)**. These membrane glycoproteins are therefore called **MHC proteins**, or *human leukocyte antigens (HLAs)*. **Antigen presentation** occurs when an antigen–MHC protein combination capable of activating T cells appears in a plasma membrane.

The amino acid sequences and the shapes of MHC proteins differ among individuals. Each MHC molecule has a distinct three-dimensional shape with a relatively narrow central groove. An antigen that fits into this groove can be held in position by hydrogen bonding.

Clinical Note Lab Tests for Organ Donation

A successful match between an organ donor and a recipient depends on the results of three tests: (1) blood type, (2) tissue type, and (3) cross-matching. Each of these tests seeks evidence of an immune response to a foreign antigen. Immune rejection either disqualifies the match or requires the recipient to receive more medication to suppress his or her immune response.

Blood typing establishes whether an individual has type O, A, B, or AB blood. Type O blood is the universal donor (all blood types can receive type O); type AB is the universal recipient (type AB can receive all blood types).

Tissue typing is performed by specialized laboratories. Also called histocompatibility testing, this test assesses HLAs, human leukocyte antigens. Out of more than 100 existing antigens, 6 have been determined to be the most important in organ donation, 3 inherited from each parent. Although it is rare to have a perfect 6-antigen match between donor and recipient, the higher the match, the better the success rate of organ or tissue transplantation.

Cross-matching tests for incompatibility between donor and recipient blood to avoid hemolytic reactions. It is done by mixing a sample of donor red blood cells with plasma from the recipient and mixing recipient red blood cells with plasma from the donor. If clumping occurs, donation is not possible because the blood types are incompatible.

Two major classes of MHC proteins are known: *class I* and *class II*. An antigen bound to a class I MHC protein acts like a red flag that in effect tells the immune system "I'm an abnormal cell—kill me!" An antigen bound to a class II MHC protein tells the immune system "This antigen is dangerous—get rid of it!"

Class I MHC Proteins. Class I MHC proteins are in the plasma membranes of all nucleated cells. These proteins are continuously synthesized and exported to the plasma membrane in vesicles formed by the Golgi apparatus. As they form, class I proteins pick up small peptides from the surrounding cytoplasm and carry them to the cell surface. If the cell is healthy and the peptides are normal, T cells ignore them. If the cytoplasm contains abnormal (non-self) peptides or viral proteins, they soon appear in the plasma membrane, and T cells will recognize them as foreign and be activated (Figure 22–18a).

Figure 22–18 Antigens and MHC Proteins.

c Antigen-presenting cell (APC).

+ Clinical Note Organ Donation

Each day in the United States, 79 people receive an organ donation and 22 people die waiting. Every 10 minutes, a new name is added to the current roster of 122,000 people on the National Transplant Waiting List. These names come from people with chronic disease, trauma, or birth defects. People need organs (kidneys, hearts, lungs, pancreases, livers) or tissues (such as bone marrow, bone, tendons, or corneas) to extend their life or improve its quality. Each donor organ or tissue must be scrupulously matched to the recipient to ensure the best chance of success.

Most living donors are female; most deceased donors are male, and most of these are accident victims. A single donor can save up to eight lives through the donation of multiple organs and tissues. In the case of a fatality, there is a window of 24 hours to initiate donation.

Individuals who are interested in becoming donors can sign up with a state registry or give their legal consent on their driver's license or in their living will. The U.S. Department of Health and Human Services (DHHS) sponsors the network for organ procurement and transplantation.

Ultimately, their activation leads to the destruction of the abnormal cells. This is the primary reason that donated organs are commonly rejected by the recipient. Despite preliminary cross-match testing, the recipient's T cells recognize the transplanted tissue as foreign.

Class II MHC Proteins and Antigen-Presenting Cells. **Class II MHC proteins** are present only in the plasma membranes of antigen-presenting cells and lymphocytes. **Antigen-presenting cells (APCs)** are specialized cells that activate T cell defenses against foreign cells (including bacteria) and foreign proteins. Antigen-presenting cells include all the phagocytes of the monocyte–macrophage group discussed in other chapters, including (1) free and fixed macrophages in connective tissues, (2) the stellate macrophages of the liver, and (3) the microglia in the central nervous system (see Chapter 12). ↩ pp. 129, 398 The **dendritic cells** of the skin (where they are also known as *Langerhans* cells) and those of the lymph nodes and spleen are APCs that are not phagocytic. ↩ p. 155

Antigen-presenting cells engulf and break down pathogens or foreign antigens. This **antigen processing** creates fragments of the antigen, which are then bound to class II MHC proteins and inserted into the plasma membrane (**Figure 22–18b,c**). Class II MHC proteins appear in the plasma membrane only when the cell is processing antigens. The APC then presents the combined class II MHC protein and processed antigen to appropriate T cells.

The dendritic cells remove antigenic materials from their surroundings by pinocytosis rather than phagocytosis. However, their plasma membranes still present antigens bound to class II MHC proteins. More important is that, unlike macrophages that do not migrate very far from an infection site, dendritic cells travel with their foreign antigens to lymphocyte-packed lymph nodes.

Antigen Recognition and CD Markers

How do T cells recognize antigens? Inactive T cells have receptors that can bind either class I or class II MHC proteins. These receptors also have binding sites for a specific target antigen. If an MHC protein contains any antigen other than the specific target of a particular kind of T cell, the T cell remains inactive. If the MHC protein contains the antigen that the T cell is programmed to detect, binding occurs. This process is called **antigen recognition**, because the T cell recognizes that it has found an appropriate target.

Some T cells can recognize antigens bound to class I MHC proteins, whereas others can recognize antigens bound to class II MHC proteins. Whether a T cell responds to antigens held by one class or the other depends on a type of protein in the T cell's own plasma membrane. The membrane proteins involved are members of a larger group of proteins called **CD** (*cluster of differentiation*) **markers**.

More than 350 types of CD markers exist, and each type is designated by a number. All T cells have a **CD3 receptor complex** in their plasma membranes, and this complex ultimately activates the T cell. Either of two other CD markers may be bound to the CD3 receptor complex, and these two CD markers are especially important in specific groups of T cells:

- **CD8** markers are found on cytotoxic T cells and regulatory T cells, which together are often called *CD8 T cells*. CD8 T cells respond to antigens presented by class I MHC proteins.
- **CD4** markers are found on helper T cells, often called *CD4 T cells*. CD4 T cells respond to antigens presented by class II MHC proteins.

T cells are not usually activated upon their first encounter with the antigen. Antigen recognition simply prepares the cell for activation.

Tips & Tools

You can remember that MHC class **I** and CD**8** go together, and MHC class *II* and CD*4* go together because both pairs multiplied are 8 ($1 \times 8 = 8$ and $2 \times 4 = 8$).

Costimulation and Clonal Selection

To proceed from recognition to activation, a T cell must also bind to the stimulating cell at a second site. This vital secondary

binding process, called *costimulation*, essentially confirms the initial activation signal.

Costimulation is like the safety on a gun: It helps prevent T cells from mistakenly attacking normal (self) tissues. If a cell displays an unusual antigen but does not display the "I am an active phagocyte" or "I am infected" signal, T cell activation will not occur. Costimulation is important only in determining whether a T cell will become activated.

Once activation has occurred, the "safety" is off and the T cell will undergo mitosis, producing clones of identical cells. The types of cells that are produced depend on the type of T cell that was activated.

Functions of Activated CD8 T Cells

Two different types of CD8 T cells are activated by exposure to antigens bound to class I MHC proteins. One type responds quickly, giving rise to clones containing large numbers of active cytotoxic T cells and inactive *memory T cells* (Figure 22–19). The other type responds more slowly and produces relatively small numbers of regulatory T cells.

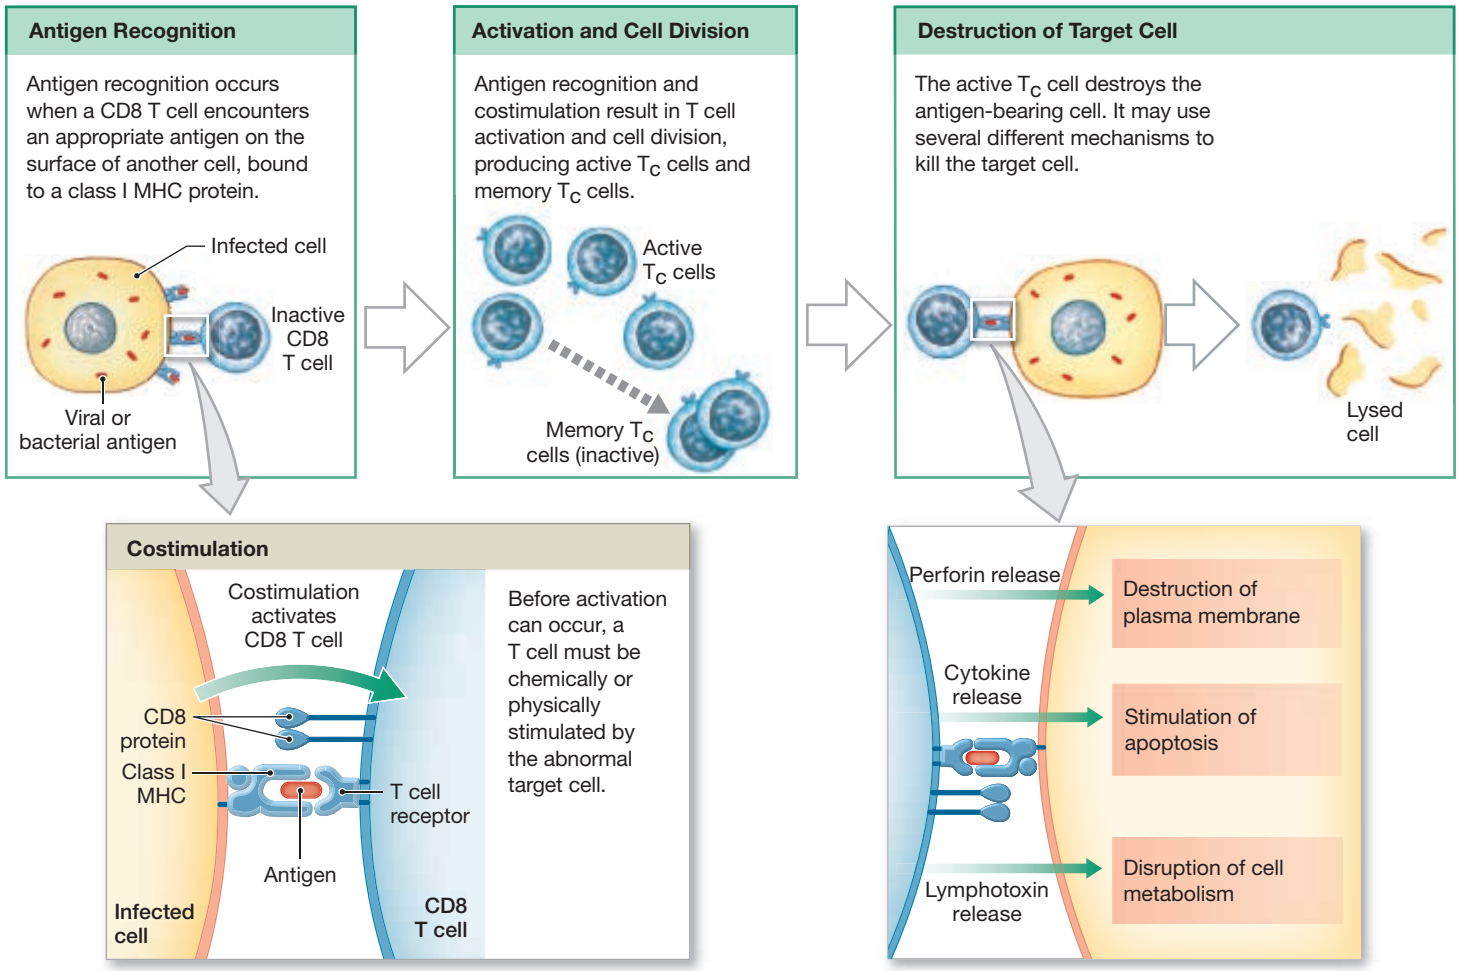
Cytotoxic T Cells (T_c)

Cytotoxic T (T_c) cells seek out and destroy abnormal and infected cells. They are highly mobile cells that roam throughout injured tissues. The constant monitoring of normal tissues by cytotoxic T cells and NK cells is called immune surveillance.

When a cytotoxic T cell encounters its target antigen bound to class I MHC proteins, it immediately destroys the target cell (see Figure 22–19). The T cell may (1) release perforins to destroy the target cell's plasma membrane, (2) release cytokines and activate genes in the target cell's nucleus telling that cell to undergo apoptosis, or (3) secrete a poisonous **lymphotoxin** (lim-fō-TOK-sin) to kill the target cell.

The entire sequence of events, from the appearance of the antigen in a tissue to cell destruction by cytotoxic T cells, takes a significant amount of time. After the first exposure to an antigen, 2 days or more may pass before the population of cytotoxic T cells reaches an effective level at the site of injury or infection. Over this period, the damage or infection may spread, making it more difficult to control.

Figure 22–19 Antigen Recognition and Activation of Cytotoxic T Cells.



Memory T_C Cells

The same cell divisions that produce cytotoxic T cells also produce thousands of **memory T_C cells**. These cells do not differentiate further the first time the antigen triggers an immune response. However, if the same antigen appears a second time, memory T_C cells *immediately* differentiate into cytotoxic T cells and undergo repeated mitotic divisions. They produce a prompt, effective cellular response that can overwhelm the invader before it becomes well established in the tissues.

Regulatory T Cells (T_{regs})

Regulatory T cells, referred to as T_{regs}, moderate the responses of other T cells and of B cells by secreting inhibitory cytokines called *suppression factors*. Suppression does not take place right away, because activation takes much longer for regulatory T cells than for other types of T cells. In addition, upon activation, most of the CD8 T cells in the bloodstream produce cytotoxic T cells rather than regulatory T cells. As a result, regulatory T cells act *after* the initial immune response. In effect, these cells limit the degree of immune system activation from a single stimulus.

Functions of Activated CD4 T Cells: Helper T (T_H) and Memory T_H Cells

Upon activation, helper T (T_H) cells with CD4 markers undergo a series of divisions that produce both active helper T cells and **memory T_H cells** (Figure 22–20). The memory T_H cells remain in reserve. The active helper T cells secrete a variety of cytokines, our next topic.

Tips & Tools

Helper T cells "help" translate the message from the antigen-presenting cells of the nonspecific response to the cells of the specific immune responses.

Cytokines of Adaptive Defenses

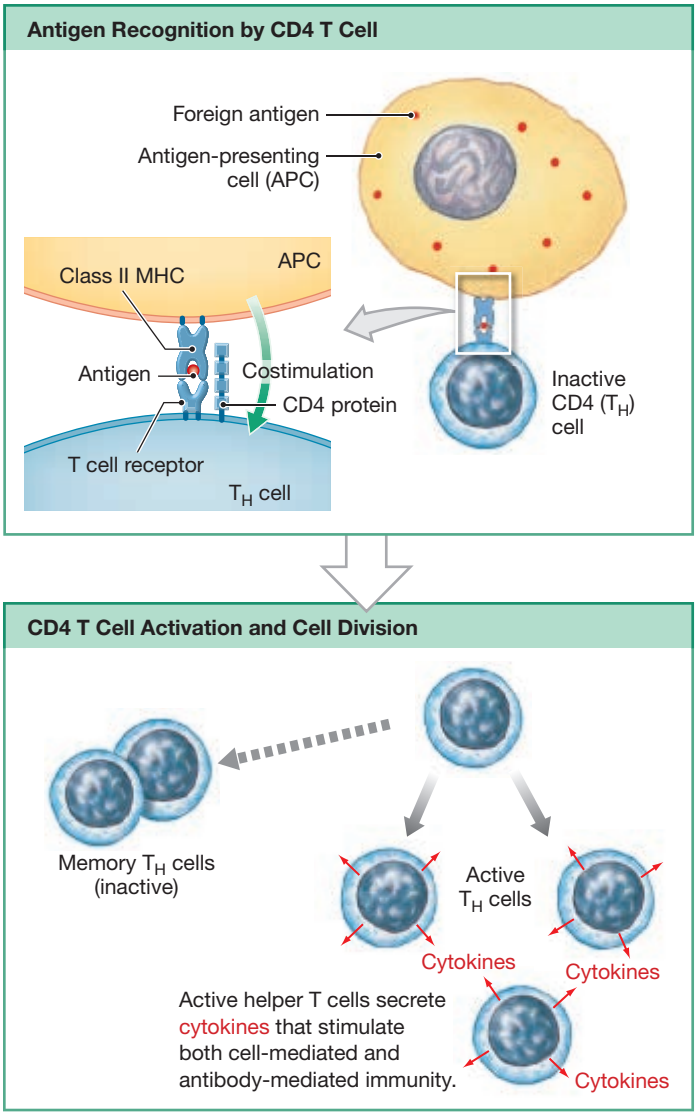
Lymphocytes and other defensive cells produce cytokines that act as hormones, affecting cells and tissues throughout the body. Interleukins and tumor necrosis factors are examples of cytokines used in adaptive defenses (Spotlight Figure 22–21).

Cytokines Produced by Helper T Cells

Helper T cells produce cytokines that coordinate specific and nonspecific defenses and stimulate cell-mediated and antibody-mediated immunities. These cytokines do the following:

- Stimulate the T cell divisions that produce memory T cells and speed the maturation of cytotoxic T cells.
- Enhance nonspecific defenses by attracting macrophages to the affected area, preventing their departure, and stimulating their phagocytic activity and effectiveness.

Figure 22–20 Antigen Recognition and Activation of Helper T Cells. Inactive CD4 T cells (T_H cells) must be exposed to appropriate antigens bound to class II MHC proteins. The T_H cells then undergo activation, dividing to produce active T_H cells and memory T_H cells.



- Attract and stimulate the activity of cytotoxic T cells, providing another means of destroying abnormal cells and pathogens.
- Promote the activation of B cells, leading ultimately to antibody production.

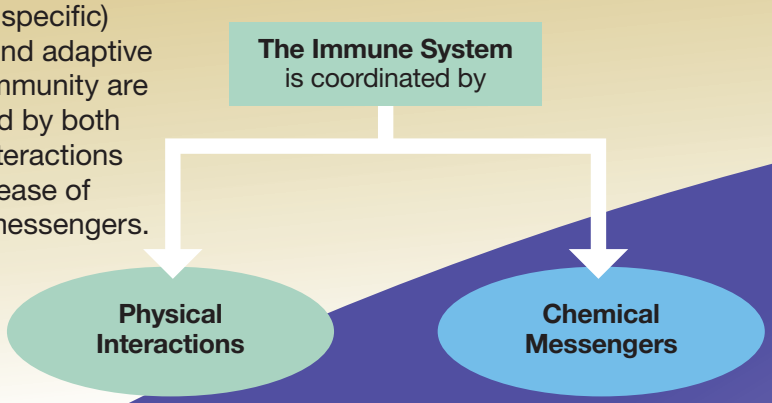
Summary of Cell-Mediated Adaptive Immunity

Figure 22–22 provides a review of the methods of antigen presentation and T cell stimulation. The plasma membranes of infected or otherwise abnormal cells trigger an immune response when CD8 T cells recognize antigens bound to class I MHC proteins. Extracellular pathogens or foreign proteins trigger an immune response when CD4 T cells recognize antigens displayed by

SPOTLIGHT

Figure 22–21
Cytokines of the Immune System

Innate (nonspecific) immunity and adaptive (specific) immunity are coordinated by both physical interactions and the release of chemical messengers.



CYTOKINES

Many types of cells involved in the immune response secrete chemicals known as cytokines. Six major groups of cytokines are described here.

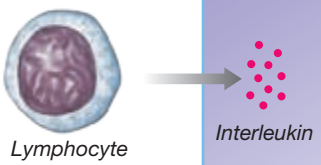
Interleukins

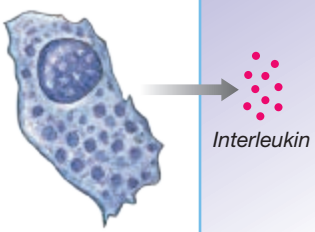
Interleukins may be the most diverse and important chemical messengers in the immune system. Nearly 20 types of interleukins have been identified. Lymphocytes and macrophages are the primary sources of interleukins, but endothelial cells, fibroblasts, and astrocytes also produce certain interleukins, such as interleukin-1 (IL-1).

The functions of interleukins include the following:

1. **Increasing T Cell Sensitivity to Antigens Exposed on Macrophage Membranes.** Heightened sensitivity speeds up the production of cytotoxic and regulatory T cells.
2. **Stimulating B Cell Activity, Plasma Cell Formation, and Antibody Production.** These events promote the production of antibodies and the development of antibody-mediated immunity.
3. **Enhancing Innate (Nonspecific) Immunity.** Known effects of interleukin production include (a) stimulation of inflammation, (b) formation of scar tissue by fibroblasts, (c) increasing body temperature by the pre-optic nucleus of the hypothalamus, (d) stimulation of mast cell formation, and (e) promotion of adrenocorticotropic hormone (ACTH) secretion by the anterior lobe of the pituitary gland.
4. **Moderating the Immune Response.** Some interleukins help suppress immune function and shorten the immune response.

Two interleukins, IL-1 and IL-2, are important in stimulating and maintaining the immune response. When released by activated macrophages and lymphocytes, these cytokines stimulate the activities of other immune cells and of the secreting cell. The result is a positive feedback loop that helps to recruit additional immune cells.





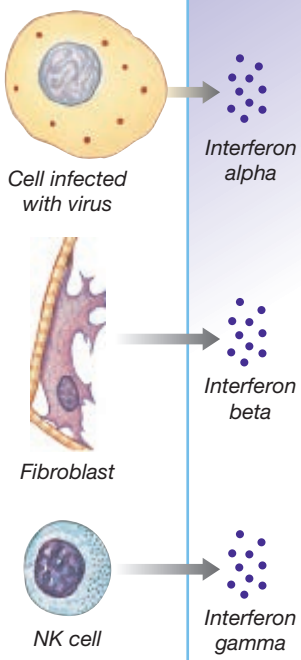
Although mechanisms exist to control the degree of stimulation, the regulatory process sometimes breaks down. Massive production of interleukins can cause problems at least as severe as those of the primary infection. For example, in *Lyme disease*, activated macrophages release IL-1 in response to a localized bacterial infection. This release produces fever, pain, skin rash, and arthritis throughout the entire body.

Some interleukins enhance the immune response, while others suppress it. The quantities secreted at any moment affect the nature and intensity of the response to an antigen. During a typical infection, the pattern of interleukin secretion changes constantly. Whether stimulatory interleukins or suppressive interleukins predominate plays a part in determining whether the individual overcomes the infection. For this reason, interleukins and their interactions are now the focus of intensive research.

Interferons

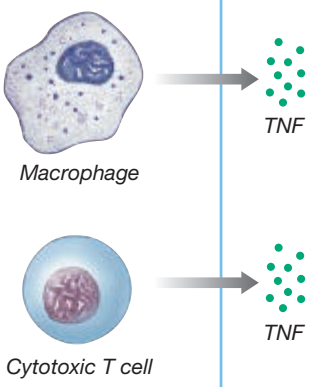
Interferons (IFNs) make the cell that synthesizes them, and that cell's neighbors, resistant to viral infection. In this way, IFNs slow the spread of a virus. They may have other beneficial effects as well. For example, interferon alpha (α) and interferon gamma (γ) attract and stimulate NK cells. Interferon beta (β) slows the progress of inflammation associated with viral infection. Interferon gamma also stimulates macrophages, making them more effective at killing bacterial or fungal pathogens.

Because they stimulate NK cell activity, interferons can be used to fight some cancers. For example, interferon alpha has been used to treat malignant melanoma, bladder cancer, ovarian cancer, and some forms of leukemia. Interferon alpha or gamma may be used to treat Kaposi's sarcoma, a cancer that typically develops in patients with AIDS.



Tumor Necrosis Factors

Tumor necrosis factors (TNFs) slow the growth of a tumor and kill sensitive tumor cells. Activated macrophages secrete one type of TNF and carry the molecules in their plasma membranes. Cytotoxic T cells produce a different type of TNF. In addition to their effects on tumor cells, TNFs stimulate granular leukocyte production, promote eosinophil activity, act as pyrogens and cause fever, and increase T cell sensitivity to interleukins.



Phagocyte-Activating Chemicals

Several cytokines coordinate immune defenses by adjusting the activities of phagocytic cells. These cytokines include factors that attract free macrophages and microphages and prevent their premature departure from the site of an injury.

Colony-Stimulating Factors

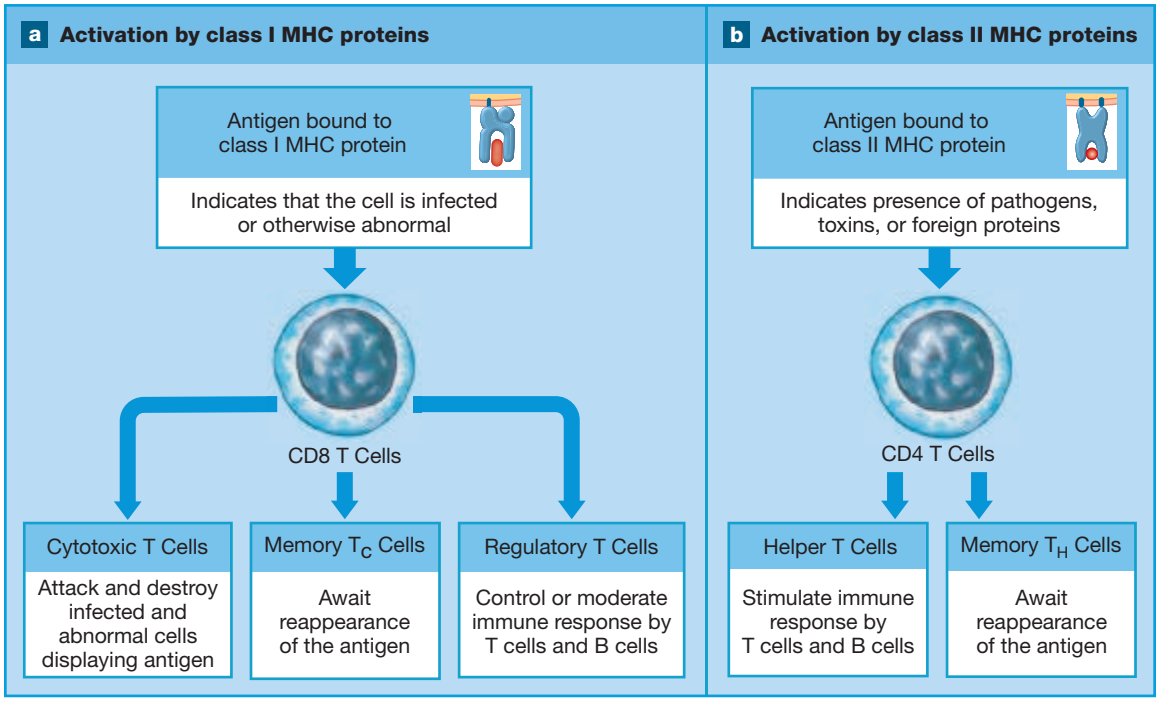
Colony-stimulating factors (CSFs) were introduced in Chapter 19. ↩ p. 676 These factors are produced by active T cells, cells of the monocyte–macrophage system, endothelial cells, and fibroblasts. CSFs stimulate the production of blood cells in red bone marrow and lymphocytes in lymphoid tissues and organs.

Miscellaneous Cytokines

This general category includes many chemicals discussed in earlier chapters. Examples include leukotrienes, lymphotoxins, perforin, hemopoiesis-stimulating factor, and suppression factors.

NOTE: Cytokines are often classified according to their origins. For example, *lymphokines* are produced by lymphocytes. *Monokines* are secreted by active monocytes, macrophages, and other antigen-presenting cells. These terms are misleading, however, because lymphocytes and macrophages may secrete the same cytokines. In addition, cells involved in adaptive immunity and tissue repair can also secrete cytokines.

Figure 22–22 A Summary of the Pathways of T Cell Activation.



class II MHC proteins. In the next section, we look at how the helper T cells derived from activated CD4 T cells in turn activate B cells that are sensitive to the same specific antigen.

22

22-6 In antibody-mediated adaptive immunity, sensitized B cells respond to antigens by producing specific antibodies

Learning Outcome Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure.

B cells are responsible for launching a chemical attack on antigens. They produce appropriate specific antibodies that eliminate the antigens. If the same antigens eliminated in the *primary response* reappear, a rapid *secondary response* is initiated by memory cells.

B Cell Sensitization and Activation

As noted earlier, the body has millions of B cell populations. Each B cell carries thousands of its own particular type of antibody molecules bound to its plasma membrane. If corresponding antigens appear in the interstitial fluid, they interact with these membrane-bound antibodies. When binding occurs, the B cell prepares to undergo activation. This preparatory process is called **sensitization** (Figure 22–23). Because B cells migrate throughout the body, pausing briefly in one lymphoid tissue or another, sensitization typically takes place within the lymph node nearest the site of infection or injury.

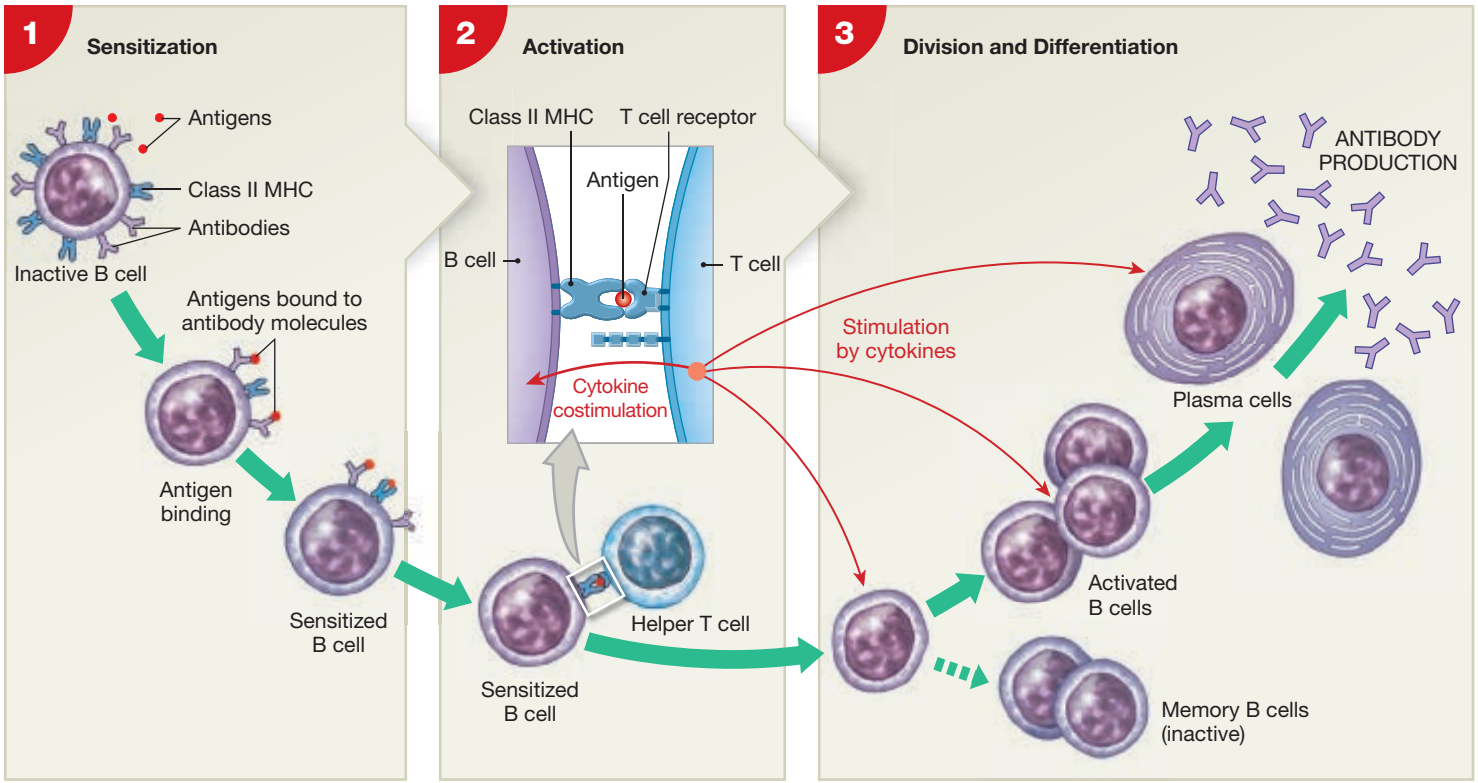
Recall that B cell plasma membranes contain class II MHC proteins. During sensitization, antigens are brought into the cell by endocytosis. The antigens subsequently appear on the surface of the B cell, bound to class II MHC proteins. The sensitized B cell is then on "standby" but generally does not undergo activation unless it receives the "OK" from a helper T cell. The need for activation by a helper T cell helps prevent inappropriate activation, the same way that costimulation acts as a "safety" in cell-mediated immunity.

What happens when a sensitized B cell meets a helper T cell that has already been activated by antigen presentation? The helper T cell binds to the B cell's MHC complex, recognizes the antigen, and begins secreting cytokines that promote B cell activation (see Figure 22–23).

Production of Plasma Cells, Antibodies, and Memory B Cells

The activated B cell typically divides several times, producing daughter cells that differentiate into **plasma cells** and *memory B cells* (see Figure 22–23). The plasma cells begin synthesizing

Figure 22–23 The Sensitization and Activation of B Cells. A B cell is sensitized by exposure to antigens. Once antigens are bound to antibodies in the B cell plasma membrane, the B cell displays those antigens on class II MHC proteins in its plasma membrane. Activated helper T cells encountering the antigens release cytokines that costimulate the sensitized B cell and trigger its activation. The activated B cell then divides, producing memory B cells and plasma cells that secrete antibodies.



and secreting large quantities of antibodies into the interstitial fluid. These antibodies have the same target as the membrane-bound antibodies on the surface of the sensitized B cell. After activation of the B cell, helper T cells secrete cytokines that stimulate B cell division, speed plasma cell formation, and enhance antibody production. A plasma cell can secrete up to 100 million antibody molecules each hour.

Memory B cells perform the same role in antibody-mediated immunity that memory T cells perform in cell-mediated immunity. Memory B cells do not respond to a threat on first exposure. Instead, they remain in reserve to deal with subsequent injuries or infections that involve the same antigens. On subsequent exposure, the memory B cells divide and differentiate into plasma cells that secrete antibodies in massive quantities.

Antibody Structure and Function

We have discussed that **antibodies** are soluble proteins. ↩ p. 661 The binding of an antibody to its target antigen starts a chain reaction that leads to the destruction of the target compound or organism.

Structure and Classes of Antibodies

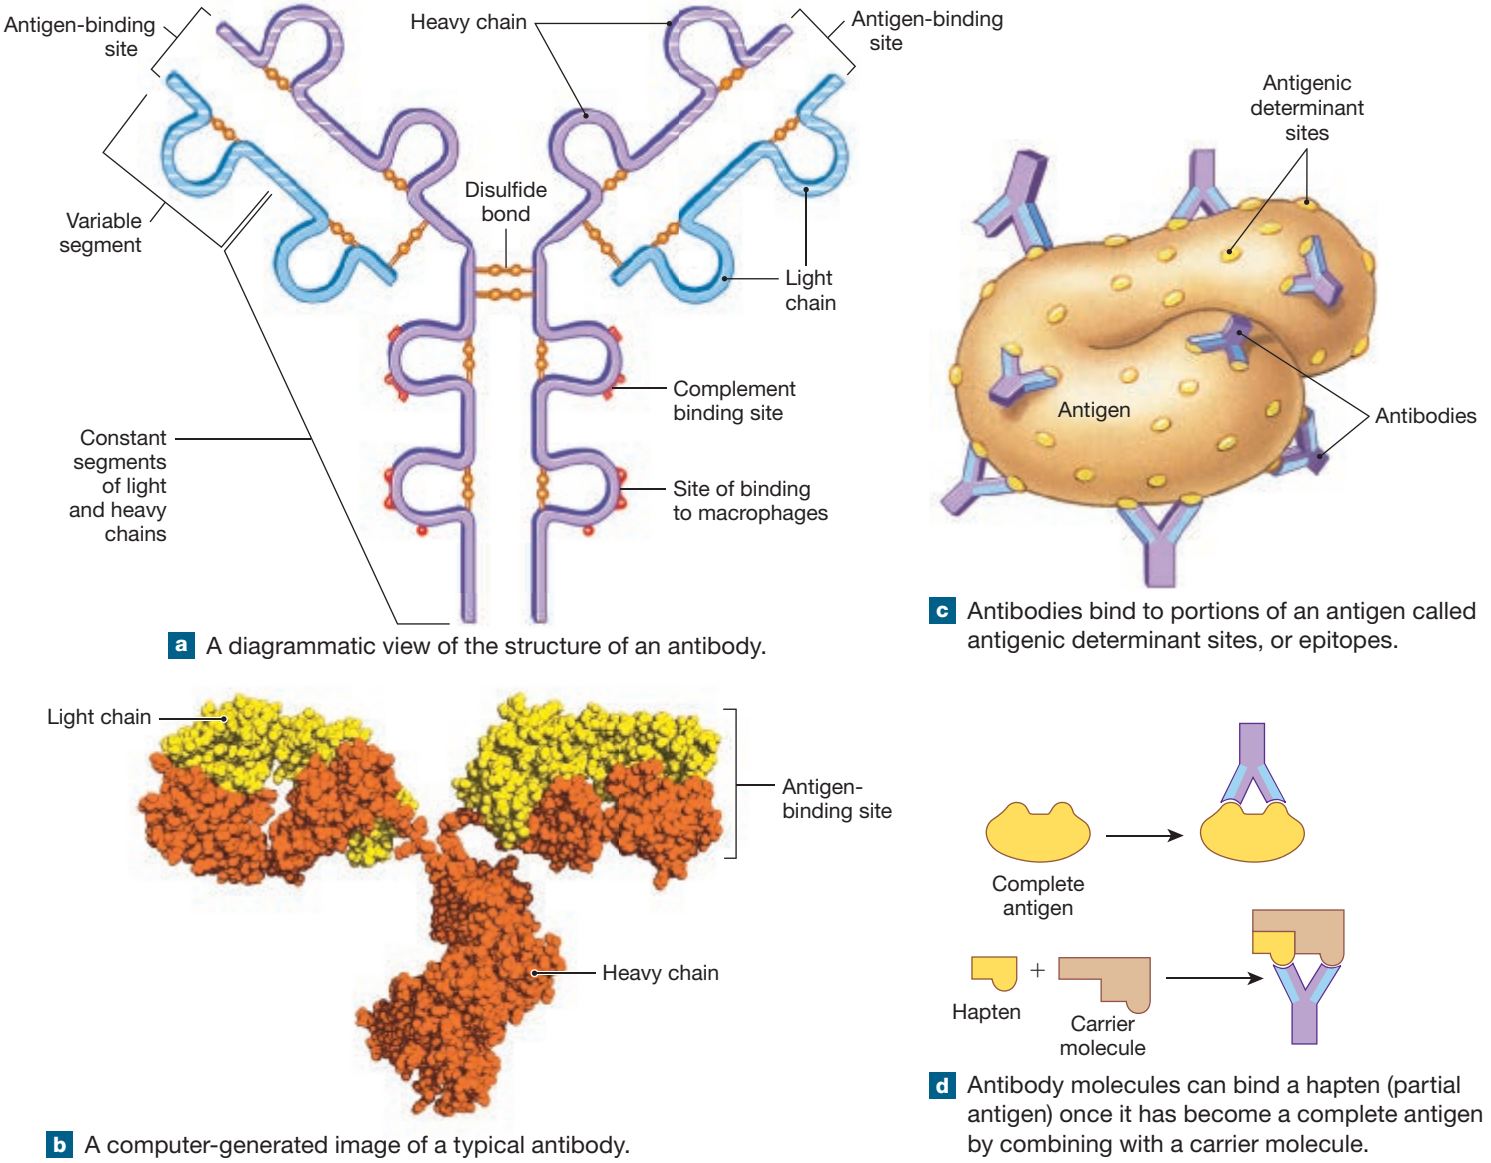
A Y-shaped antibody molecule consists of two pairs of polypeptide chains: one pair of **heavy chains** and one pair of **light chains** (Figure 22–24). Each chain contains both *constant segments* and *variable segments*.

The constant segments of the heavy chains form the base of the antibody molecule (see Figure 22–24a,b). B cells produce only five types of constant segments. These are the basis of a scheme that identifies five classes of antibodies, or **immunoglobulins (Igs)**: *IgG*, *IgE*, *IgD*, *IgM*, and *IgA* (Table 22–1). The structure of the constant segments of the heavy chains determines the way the antibody is secreted and how it is distributed within the body. For example, antibodies in one class circulate in body fluids, whereas those of another class bind to the membranes of basophils and mast cells.

Tips & Tools

The classes of immunoglobulins—Ig***M***, Ig***A***, Ig***D***, Ig***G***, Ig***E***—spell ***MADGE***.

Figure 22–24 Antibody Structure and Function.



a A diagrammatic view of the structure of an antibody.

c Antibodies bind to portions of an antigen called antigenic determinant sites, or epitopes.

b A computer-generated image of a typical antibody.

d Antibody molecules can bind a hapten (partial antigen) once it has become a complete antigen by combining with a carrier molecule.

The heavy-chain constant segments, which are bound to constant segments of the light chains, also contain binding sites that can activate the complement system. These binding sites are covered when the antibody is secreted but become exposed when the antibody binds to an antigen.

The specificity of an antibody molecule depends on the amino acid sequence of the variable segments of the light and heavy chains. The free tips of the two variable segments form the **antigen-binding sites** of the antibody molecule (see Figure 22–24a). The heavy-chain constant segments have no effect on the antibody's specificity, which is determined by the antigen-binding sites.

Small differences in the structure of the variable segments affect the precise shape of the antigen-binding site. These differences make antibodies specific for different antigens. The distinctions are the result of minor genetic variations that occur during the production, division, and differentiation of B cells. A normal adult body contains roughly 10 trillion B cells, which can produce an estimated 100 million types of antibodies, each with a different specificity.

The Antigen–Antibody Complex

When an antigen-binding site on an antibody molecule binds to its corresponding antigen molecule, an **antigen–antibody complex** is formed. Once the two molecules are in position, hydrogen bonding and other weak chemical forces lock them together. Antigen-binding sites interact with an antigen in the same way that the active site of an enzyme interacts with a substrate molecule. ↩ p. 55

Table 22–1 Classes of Antibodies

				IgG is the largest and most diverse class of antibodies. IgG antibodies account for 80 percent of all antibodies. They are responsible for resistance against many viruses, bacteria, and bacterial toxins. These antibodies can cross the placenta, and maternal IgG provides passive immunity to the fetus during embryonic development. However, the anti-Rh antibodies produced by Rh-negative mothers are also IgG antibodies and produce *hemolytic disease of the newborn*.	**IgE** attaches as an individual molecule to the exposed surfaces of basophils and mast cells. When a suitable antigen is bound by IgE molecules, the cell is stimulated to release histamine and other chemicals that accelerate inflammation in the immediate area. IgE is also important in the allergic response.	**IgD** is an individual molecule on the surfaces of B cells, where it can bind antigens in the extracellular fluid. This binding can play a role in the sensitization of the B cell involved.	**IgM** is the first class of antibody secreted after an antigen is encountered. IgM concentration declines as IgG production accelerates. Although plasma cells secrete individual IgM molecules, IgM circulates as a five-antibody starburst. The anti-A and anti-B antibodies responsible for the agglutination of incompatible blood types are IgM antibodies. IgM antibodies may also attack bacteria that are insensitive to IgG.	**IgA** is found primarily in glandular secretions such as mucus, tears, saliva, and semen. These antibodies attack pathogens before they gain access to internal tissues. IgA antibodies circulate in blood as individual molecules or in pairs. Epithelial cells absorb them from the blood and attach a *secretory piece*, which confers solubility, before secreting the IgA molecules onto the epithelial surface.

Antibodies do not bind to the entire antigen. Instead, they bind to specific portions of its exposed surface—regions called **antigenic determinant sites**, or **epitopes** (Figure 22–24c). The specificity of the binding depends initially on the three-dimensional "fit" between the variable segments of the antibody molecule and the corresponding antigenic determinant sites. A **complete antigen** has at least two antigenic determinant sites, one for each of the antigen-binding sites on an antibody molecule. Exposure to a complete antigen can lead to B cell sensitization and a subsequent immune response. Most environmental antigens have multiple antigenic determinant sites, and entire microorganisms may have thousands.

Haptens, or *partial antigens*, do not ordinarily cause B cell activation and antibody production. Haptens include short peptide chains, steroids and other lipids, and several drugs, including antibiotics such as *penicillin*. However, haptens may become attached to carrier molecules, forming combinations that can function as complete antigens (Figure 22–24d). In some cases, the carrier contributes an antigenic determinant site. Antibodies will then attack both the hapten and the carrier molecule. If the carrier molecule is normally present in the tissues, the antibodies may begin attacking and destroying normal cells. This process is the basis for several drug reactions, including allergies to penicillin.

Actions of Antibodies

The formation of an antigen–antibody complex may cause the elimination of the antigen in the following ways:

- *Neutralization.* Both viruses and bacterial toxins have specific sites that must bind to target regions on body cells before they can enter or injure those cells. Antibodies may bind to those sites, making the virus or toxin incapable of attaching itself to a cell. This mechanism is known as **neutralization**.
- *Precipitation and Agglutination.* Each antibody molecule has two antigen-binding sites, and most antigens have many antigenic determinant sites. If individual antigens (such as macromolecules or bacterial cells) are far apart, an antibody molecule will necessarily bind to two antigenic sites on the same antigen. However, if antigens are close together, an antibody can bind to antigenic determinant sites on two separate antigens. In this way, antibodies can link large numbers of antigens together. The three-dimensional structure created by such binding is known as an **immune complex**. When the antigen is a soluble molecule, such as a toxin, this process may create complexes that are too large to remain in solution. The formation of insoluble immune complexes is called **precipitation**. When the target antigen is on the surface of a cell or virus,

the formation of large complexes is called **agglutination**. We discussed an example of agglutination with the clumping of erythrocytes that occurs when incompatible blood types are mixed. ↩ p. 669

- *Activation of the Complement System.* When an antibody molecule binds to an antigen, portions of the antibody molecule change shape. This change exposes areas that bind complement proteins. The bound complement molecules then activate the complement system, which destroys the antigen (as discussed previously).
- *Attraction of Phagocytes.* Antigens covered with antibodies attract eosinophils, neutrophils, and macrophages. These cells phagocytize pathogens and destroy foreign or abnormal plasma membranes.
- *Opsonization.* A coating of antibodies and complement proteins increases the effectiveness of phagocytosis. This effect is called *opsonization*. Some bacteria have slick plasma membranes or capsules, but opsonization makes it easier for phagocytes to hold onto their prey before they engulf it. Phagocytes can bind more easily to antibodies and complement proteins than they can to the bare surface of a pathogen.
- *Stimulation of Inflammation.* Antibodies may promote inflammation by stimulating basophils and mast cells.
- *Prevention of Bacterial and Viral Adhesion.* Antibodies dissolved in saliva, mucus, and perspiration coat epithelia, adding an additional layer of defense. A covering of antibodies makes it difficult for pathogens to attach to and penetrate body surfaces.

Primary and Secondary Responses to Antigen Exposure

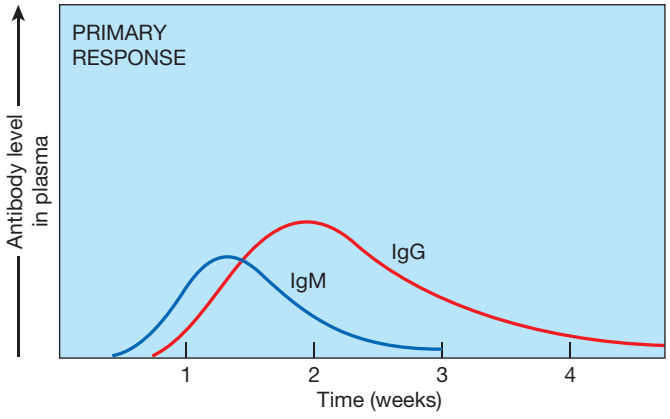
The initial immune response to an antigen is called the **primary response**. When the antigen appears again, it triggers a more extensive and prolonged **secondary response**. This response is due to the presence of large numbers of memory cells that are primed for the arrival of the antigen. Let's look at the pattern of antibody production over time to see the differences between the primary and secondary responses.

The Primary Response

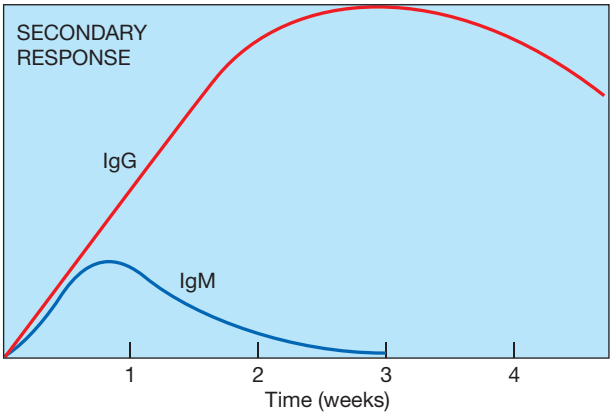
The primary response takes time to develop because the antigen must activate the appropriate B cells. These cells must then differentiate into plasma cells. As plasma cells differentiate and begin secreting, the concentration of circulating antibodies makes a gradual, sustained rise (Figure 22–25a).

During the primary response, the **antibody titer**, or level of antibodies in the plasma, does not peak until 1 to 2 weeks after the initial exposure. If the person is no longer exposed to the antigen, the antibody concentration then declines. The antibody titer declines because (1) plasma cells have very high metabolic rates and survive for only a short time, and (2) regulatory T cells release suppression factors that inhibit further production of plasma cells. However, regulatory T cell activity does not begin immediately after exposure to the antigen. Also, under normal conditions helper T cells outnumber regulatory T cells by more than 3 to 1. As a result, many B cells are activated before regulatory T cell activity has a noticeable effect.

Figure 22–25 The Primary and Secondary Responses in Antibody-Mediated Immunity.



a The primary response takes about 2 weeks to develop peak antibody levels (titers). IgM and IgG antibody levels do not remain elevated.



b The secondary response has a very rapid increase in IgG antibody concentration and rises to levels much higher than those of the primary response. Antibody levels remain elevated for an extended period after the second exposure to the antigen.

? During the primary response, which antibody peaks sooner? During the secondary response, which antibody level is higher?

Activated B cells start dividing immediately. At each cycle of division, some of the daughter cells differentiate into plasma cells, while others continue to divide. Molecules of *immunoglobulin M*, or *IgM*, are the first to appear in the bloodstream. The plasma cells that produce IgM differentiate after only a few cycles of B cell division. Levels of *immunoglobulin G*, or *IgG*, rise more slowly, because the plasma cells responsible differentiate only after repeated cell divisions that also generate large numbers of memory B cells. In general, IgM is less effective as a defense than IgG. However, IgM provides an immediate defense that can fight the infection until massive quantities of IgG can be produced.

The Secondary Response

Unless memory B cells are exposed to the same antigen a second time, they do not differentiate into plasma cells. If and when that exposure occurs, the memory B cells respond right away—faster than the B cells stimulated during the initial exposure. This response is immediate in part because memory B cells are activated at relatively low antigen concentrations. In addition, these cells synthesize more effective and destructive antibodies. Activated memory B cells divide and differentiate into plasma cells that secrete these antibodies in massive quantities. This secretion is the secondary response to antigen exposure.

During the secondary response, antibody concentrations and titers increase more rapidly and reach levels many times higher than they did in the primary response (Figure 22–25b). The secondary response appears even if the second exposure occurs years after the first. The reason is that memory cells may survive for 20 years or more.

The primary response develops slowly and does not produce antibodies in massive quantities. For these reasons, it may not prevent an infection the first time a pathogen appears in the body. However, a person who survives the first infection will probably be resistant to that pathogen in the future, thanks to a rapid and overwhelming secondary response. The effectiveness of the secondary response is one of the basic principles behind the use of immunization to prevent disease.

Tips & Tools

The antibody response is like ordering a custom suit. The first suit (the primary antibody response) takes time to make because the tailor (an activated B cell) must first make a pattern (a clone of memory cells). Subsequent suits (secondary responses) are made much more quickly because the pattern already exists.

22-7 Immunocompetence enables a normal immune response; abnormal responses result in immune disorders

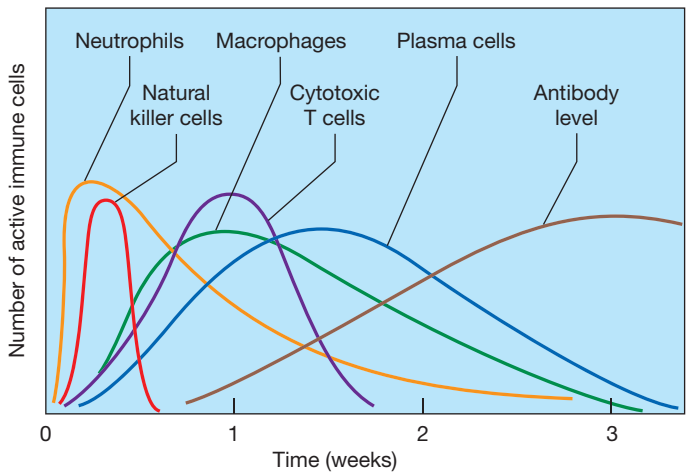
Learning Outcome Describe the development of immunocompetence, discuss the effects of stress on immune function, and list and explain examples of immune disorders and allergies.

We begin this section by summarizing the normal immune response. Next, we go on to explore **immunocompetence**, the ability to produce an immune response after exposure to an antigen. Then we examine the role of stress in immune responses. Finally, we consider some of the disorders that result when immune responses go wrong.

Summary of Innate and Adaptive Immunity

We have now examined the basic cellular and chemical interactions that follow after a foreign antigen appears in the body. Table 22–2 reviews the cells that participate in tissue defenses and Figure 22–26 gives a timeline for their appearance at the site of a bacterial infection.

Figure 22–26 The Course of the Body's Response to a Bacterial Infection. The basic sequence of events begins with the appearance of bacteria in peripheral tissues at time 0.



? After the appearance of bacteria in the body, which immune cell is present for the shortest amount of time?

> Go to MasteringA&P™ > Study Area > Lab Tools > PhysioEx 9.1 > Exercise 12: Serological Testing

Table 22–2 Cells That Participate in Tissue Defenses

Cell	Functions
Neutrophils	Phagocytosis; stimulation of inflammation
Eosinophils	Phagocytosis of antigen–antibody complexes; suppression of inflammation; participation in allergic response
Mast cells and basophils	Stimulation and coordination of inflammation by release of histamine, heparin, leukotrienes, prostaglandins
ANTIGEN-PRESENTING CELLS	
Macrophages (free and fixed macrophages, stellate macrophages, and microglia)	Phagocytosis; antigen processing; antigen presentation with class II MHC proteins; secretion of cytokines, especially interleukins and interferons
Dendritic cells	Pinocytosis; antigen processing; antigen presentation bound to class II MHC proteins
LYMPHOCYTES	
NK cells	Destruction of plasma membranes containing abnormal antigens
Cytotoxic T cells (CD8 marker)	Lysis of plasma membranes containing antigens bound to class I MHC proteins; secretion of perforins, defensins, lymphotoxins, and other cytokines
Helper T cells (CD4 marker)	Secretion of cytokines that stimulate cell-mediated and antibody-mediated immunity; activation of sensitized B cells
B cells	Differentiation into plasma cells, which secrete antibodies and provide antibody-mediated immunity
Regulatory T cells (CD8 marker)	Secretion of suppression factors that inhibit the immune response
Memory cells (T, B)	Produced during the activation of T cells and B cells; remain in tissues awaiting antigen reappearance

In the early stages of infection, neutrophils and NK cells migrate into the threatened area and destroy bacteria. Over time, cytokines draw increasing numbers of phagocytes into the region. Cytotoxic T cells appear as arriving T cells are activated by antigen presentation. Last of all, the population of plasma cells rises as activated B cells differentiate. This rise is followed by a gradual, sustained increase in the level of circulating antibodies.

Figure 22–27 provides an integrated review of the relationship between innate and adaptive immunity. The basic sequence of events is similar when a viral infection occurs. The initial steps are different, however, because cytotoxic T cells provide an adaptive defense and NK cells provide an innate defense. **Figure 22–28** contrasts the events involved in defending against bacterial infection with those involved in defending against viral infection.

The Development of Immunocompetence

Cell-mediated immunity can be demonstrated as early as the third month of fetal development. Active antibody-mediated immunity follows about 1 month later.

The first cells that leave the fetal thymus migrate to the skin and into the epithelia lining the mouth, the digestive tract, and, in females, the uterus and vagina. These cells take up residence in these tissues as antigen-presenting cells, such as the dendritic cells of the skin, whose primary function will be to help activate T cells. T cells that leave the thymus later in development populate lymphoid organs throughout the body.

The plasma membranes of the first B cells produced in the liver and bone marrow carry IgM antibodies. Sometime after the fourth month the fetus may produce IgM antibodies if exposed to specific pathogens. The developing fetus usually does not produce antibodies, however, because it has naturally acquired passive immunity due to IgG antibodies from the mother's bloodstream. These are the only antibodies that can cross the placenta. They include the antibodies responsible for the clinical problems due to Rh incompatibility, discussed in Chapter 19. ↩ p. 672 Problems with incompatibilities involving the ABO blood groups rarely occur. The reason is that anti-A and anti-B antibodies are IgM antibodies, which cannot cross the placenta.

The natural immunity provided by maternal IgG may not be enough to protect the fetus if the maternal defenses are overwhelmed by a bacterial or viral infection. For example, the microorganisms responsible for syphilis and rubella ("German measles") can cross from the maternal to the fetal bloodstream, producing a congenital infection that leads to the production of fetal antibodies. IgM provides only a partial defense, and these infections can result in severe developmental problems for the fetus.

Delivery eliminates the maternal supply of IgG. Although the mother provides IgA antibodies in breast milk, the infant gradually loses its passive immunity. The amount of maternal IgG in the infant's bloodstream declines rapidly over the first 2 months after birth. During this period, the infant becomes vulnerable to infection by bacteria or viruses that were previously overcome by maternal antibodies. The infant's immune system begins to respond to infections, environmental antigens, and vaccinations. As a result, the infant begins producing its own IgG. From birth to age 12, children encounter a "new" antigen on average every 6 weeks. (This fact explains why most parents, who were exposed to the same antigens when they were children, remain healthy while their children develop runny noses and colds.) Over this period, the concentration of circulating

Figure 22–27 An Integrated Summary of the Immune Response.

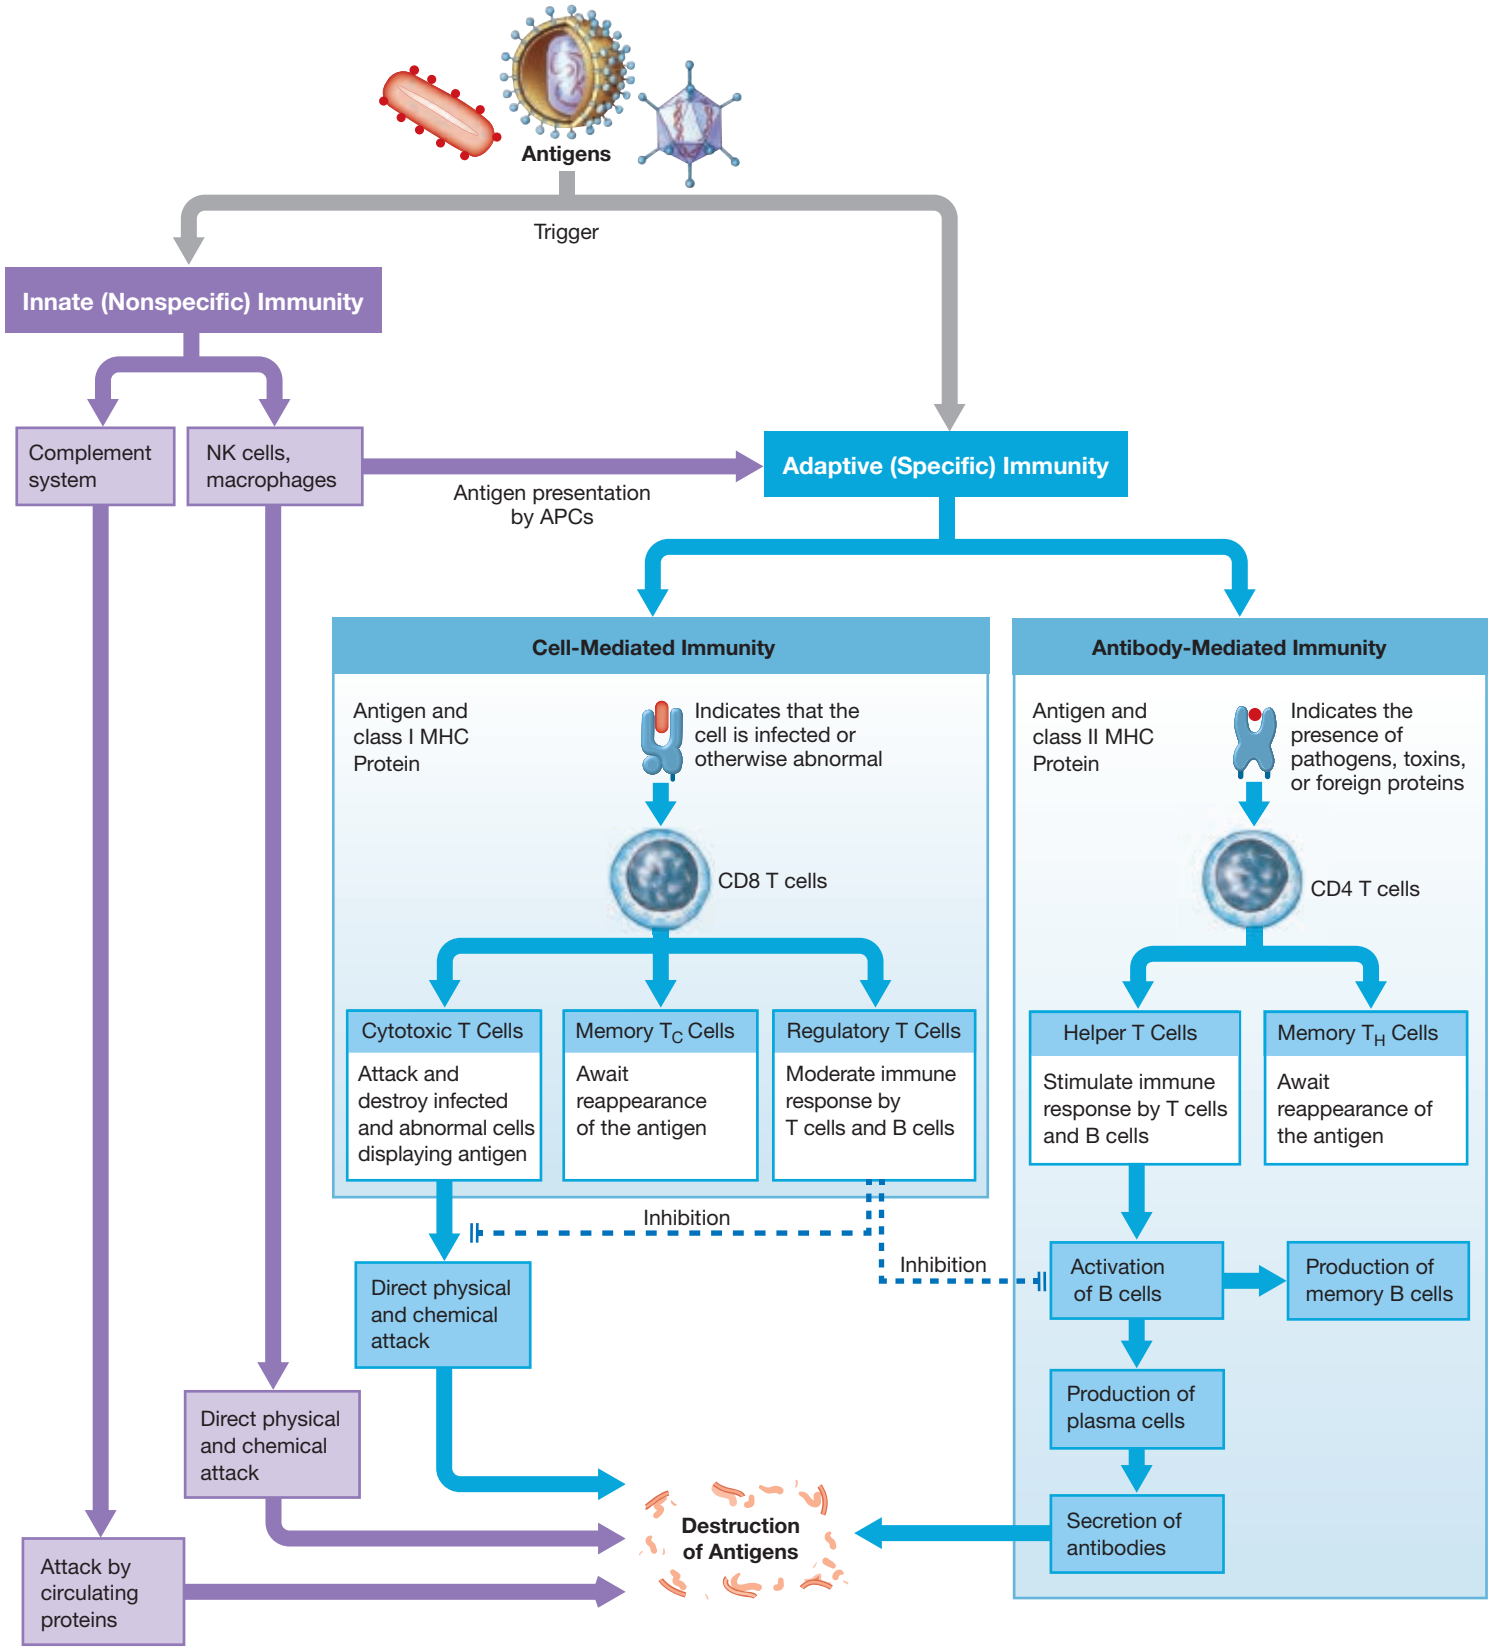


Figure 22–28 Defenses against Bacterial and Viral Pathogens.

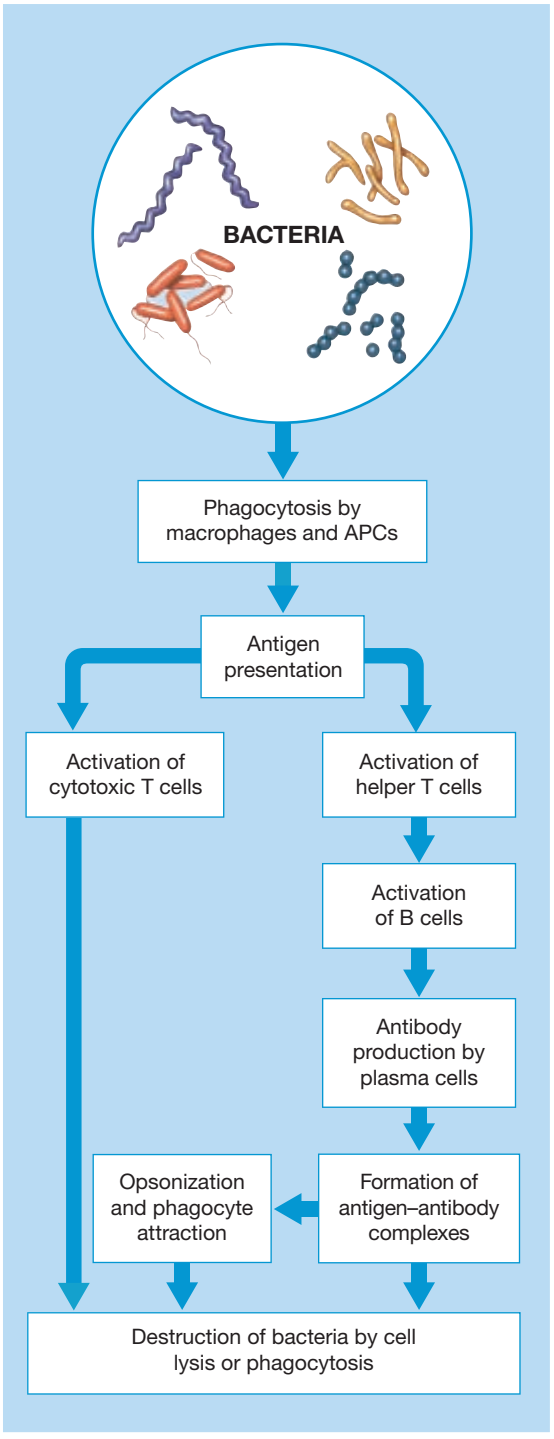
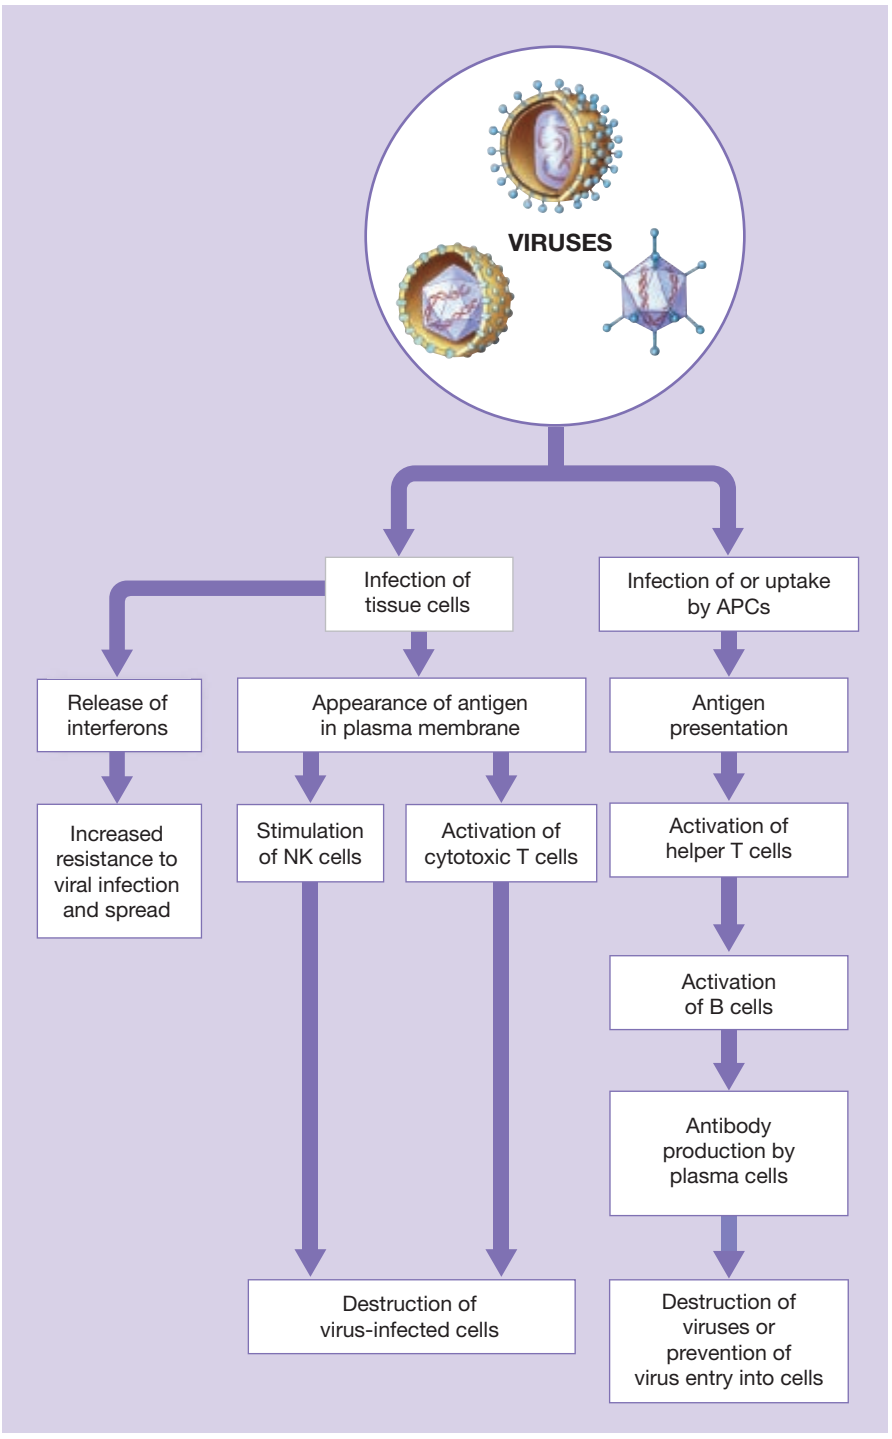


a Defenses against bacteria involve phagocytosis and antigen presentation by APCs.



b Defenses against viruses involve direct contact with virus-infected cells and antigen presentation by APCs.

antibodies gradually rises toward normal adult levels. Populations of memory B cells and T cells also increase.

Skin tests are sometimes used to determine whether an individual has been exposed to a particular antigen. In these procedures, small quantities of antigen are injected into the skin, generally on the anterior surface of the forearm. If resistance has developed, the region becomes inflamed over the next 2 to 4 days. Many states require a tuberculosis test, called a *tuberculin skin test*, before children enter public school. If the test is positive, further tests must then be performed to determine whether an infection is currently under way. Skin tests are also used to check for allergies to environmental antigens.

Stress and the Immune Response

One of the normal effects of interleukin-1 secretion is the stimulation of adrenocorticotropic hormone (ACTH) production by the anterior lobe of the pituitary gland. This hormone in turn prompts the secretion of glucocorticoids by the adrenal cortex. p. 636 The anti-inflammatory effects of the glucocorticoids may help control the extent of the immune response.

However, chronic stress depresses the immune system and can be a serious threat to health. The long-term secretion of glucocorticoids, as in the resistance phase of the *stress response*, can inhibit the immune response and lower a person's resistance to disease. p. 648 The effects of glucocorticoids that alter the effectiveness of innate and adaptive defenses include the following:

- *Depression of Inflammation.* Glucocorticoids inhibit mast cells and make capillaries less permeable. Inflammation becomes less likely. When it does occur, the reduced permeability of the capillaries slows the entry of fibrinogen, complement proteins, and cellular defenders into tissues.
- *Reduction in the Abundance and Activity of Phagocytes in Peripheral Tissues.* This reduction further impairs innate defense mechanisms. It also interferes with the processing and presentation of antigens to lymphocytes.
- *Inhibition of Interleukin Secretion.* A reduction in interleukin production depresses the response of lymphocytes, even to antigens bound to MHC proteins.

The mechanisms that bring about these changes are still under investigation.

Immune Disorders

Because the immune response is so complex, many opportunities exist for things to go wrong. A variety of clinical conditions result from disorders of the immune function. A common class of immune disorders is *allergies*, also called *hypersensitivities*. *Autoimmune disorders* develop when the immune response inappropriately targets normal body cells and tissues. In an *immunodeficiency disease*, either the immune system fails to develop normally or the immune response is blocked in some way. Autoimmune disorders and immunodeficiency diseases are fairly rare—clear evidence of the effectiveness of the immune system's control mechanisms.

Hypersensitivities

Hypersensitivities, commonly called allergies, are excessive immune responses to antigens. The sudden increase in cellular activity or antibody titers can have several unpleasant side effects. For example, neutrophils or cytotoxic T cells may destroy normal cells while they are attacking an antigen. Or the antigen–antibody complex may trigger massive inflammation. Antigens that set off allergic reactions are often called **allergens**.

There are several types of hypersensitivities. A complete classification has four categories: *immediate hypersensitivity (type I)*, *cytotoxic reactions (type II)*, *immune complex disorders (type III)*, and *delayed hypersensitivity (type IV)*. In Chapter 19 we discussed one example of a cytotoxic (type II) reaction: the cross-reaction that follows the transfusion of an incompatible blood type. p. 669 Here we focus on immediate hypersensitivity (type I). It is probably the most common type of allergy.

Immediate hypersensitivity is a rapid and especially severe response to an antigen. One form, *allergic rhinitis*, includes hay fever and environmental allergies. This form may affect 15 percent of the U.S. population. Sensitization to an allergen during the initial exposure leads to the production of large quantities of IgE. Genes may determine a person's tendency to produce IgE in response to particular allergens.

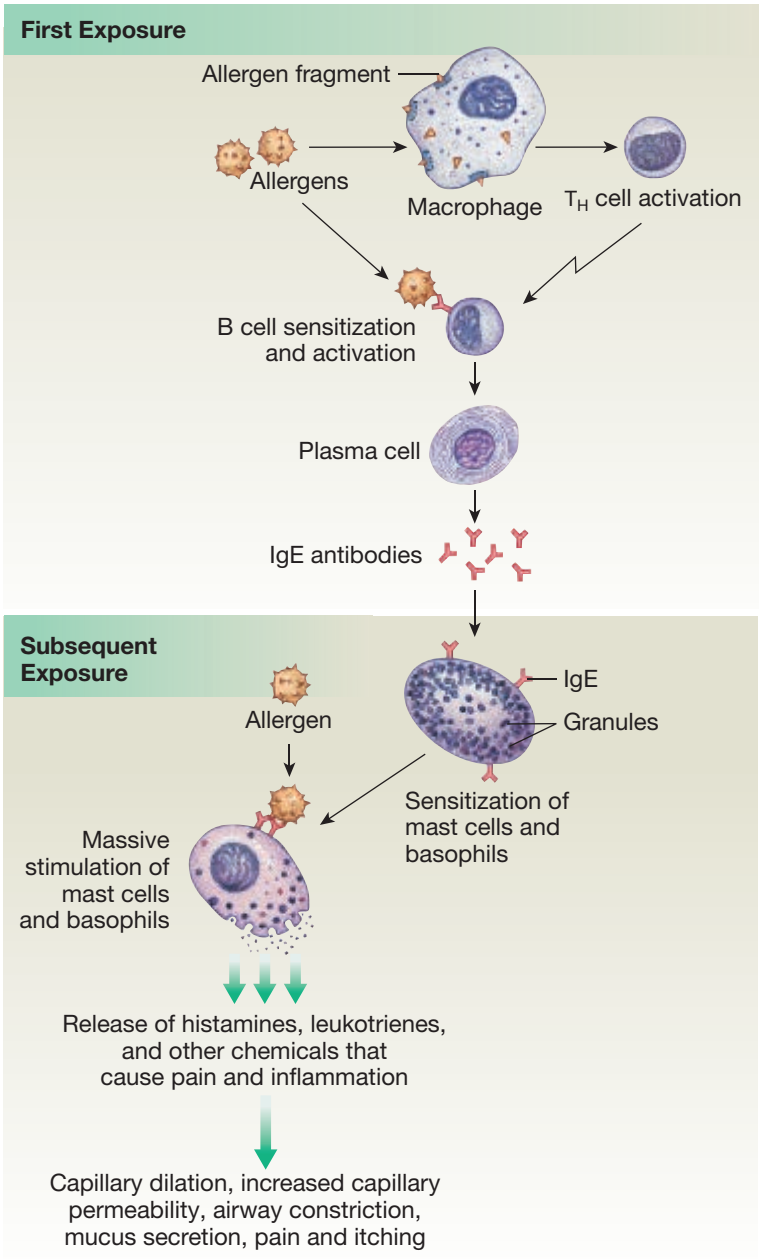
Due to the lag time needed to activate B cells, produce plasma cells, and synthesize antibodies, the first exposure to an allergen does not produce signs and symptoms. Instead, it sets the stage for the next encounter. After sensitization, the IgE molecules become attached to basophils and mast cells throughout the body. When the individual meets the same allergen again, the bound antibodies stimulate these cells to release histamine, heparin, several cytokines, prostaglandins, and other chemicals into the surrounding tissues. This results in a sudden, massive inflammation of the affected tissues.

The cytokines and other mast cell secretions draw basophils, eosinophils, T cells, and macrophages into the area. These cells release their own chemicals, extending and intensifying the responses initiated by mast cells. The severity of the allergic reaction depends on the individual's sensitivity and on the location involved. If allergen exposure occurs at the body surface, the response may be restricted to that area. If the allergen enters the bloodstream, the response could be lethal.

In **anaphylaxis** (an-uh-fuh-LAK-sis; *ana-*, again + *phylaxis*, protection), a circulating allergen affects mast cells throughout the body (Figure 22–29). In drug reactions, such as allergies to penicillin, IgE antibodies are produced in response to a hapten (partial antigen) bound to a larger molecule that is widely distributed within the body because the combination acts as an allergen. A wide range of signs and symptoms can develop within minutes. Changes in capillary permeabilities produce swelling and edema in the dermis, and raised welts, or *hives*, appear on the skin. Smooth muscles along the respiratory passageways contract, and the narrowed passages make breathing extremely difficult. In severe cases, an extensive peripheral vasodilation occurs, producing a drop in blood pressure that can lead to a circulatory collapse. This response is **anaphylactic shock**.

The prompt administration of drugs that block the action of histamine, known as **antihistamines** (an-tē-HIS-ta-mēnz), can prevent many of the signs and symptoms of immediate hypersensitivity. *Benadryl (diphenhydramine hydrochloride)* is a popular antihistamine that is available over the counter. Severe anaphylaxis is treated with injections of antihistamines, corticosteroids, and epinephrine.

Figure 22–29 The Mechanism of Anaphylaxis.



Autoimmune Disorders

Autoimmune disorders affect an estimated 5 percent of adults in North America and Europe. In previous chapters we have cited many examples of the effects of autoimmune disorders on the function of major systems.

The immune system usually recognizes but ignores antigens normally found in the body—self-antigens. When the recognition system does not work correctly, however, activated B cells make antibodies against other body cells and tissues. These "misguided" antibodies are called **autoantibodies**. The trigger may be a reduction in suppressor T cell activity, the excessive stimulation of helper T cells, tissue damage that releases large quantities of antigenic fragments, haptens bound to compounds normally ignored, viral or bacterial toxins, or a combination of factors.

The resulting condition depends on the antigen that the autoantibodies attack. For example:

- The inflammation of *thyroiditis* is due to autoantibodies against thyroglobulin.
- *Rheumatoid arthritis* occurs when autoantibodies form immune complexes in connective tissues around the joints.
- Type 1 diabetes develops when autoantibodies attack cells in the pancreatic islets.

Many autoimmune disorders appear to be cases of mistaken identity. For example, proteins associated with the measles, Epstein–Barr, influenza, and other viruses contain amino acid sequences that are similar to those of myelin proteins. As a result, antibodies that target these viruses may also attack myelin sheaths. This accounts for the neurological complications that sometimes follow a vaccination or a viral infection. It also may be responsible for *multiple sclerosis*.

For unknown reasons, the risk of autoimmune problems increases if an individual has an unusual type of MHC protein. At least 50 clinical conditions have been linked to specific variations in MHC structure.

Immunodeficiency Diseases

Immunodeficiency diseases result from (1) problems with the embryonic development of lymphoid organs and tissues; (2) an infection with a virus, such as HIV, that depresses immune function; or (3) treatment with, or exposure to, immunosuppressive agents, such as radiation or drugs.

Individuals born with **severe combined immunodeficiency disease (SCID)** fail to develop either cell-mediated or antibody-mediated immunity. Their lymphocyte populations are low, and normal B cells and T cells are absent. Such infants cannot produce an immune response, so even a mild infection can prove fatal. Total isolation offers protection but at great cost—extreme restrictions on lifestyle. Bone marrow transplants from a compatible donor, normally a close relative, have been used to colonize lymphoid tissues with functional lymphocytes. Gene-splicing techniques have led to therapies that can treat at least one form of SCID.

AIDS is an immunodeficiency disease that results from a viral infection that targets helper T cells. We discuss AIDS in the Clinical Note on the next page.

Immunosuppressive drugs have been used for many years to prevent graft rejection after transplant surgery. Unfortunately, immunosuppressive agents can destroy stem cells and lymphocytes and lead to a complete failure of the immune response.

+ Clinical Note AIDS

Acquired immunodeficiency syndrome (AIDS), or *late-stage HIV disease*, is caused by the **human immunodeficiency virus (HIV)**. This virus is a *retrovirus*: It carries its genetic information in RNA rather than in DNA. The virus enters human leukocytes by receptor-mediated endocytosis. ↩ p. 98 Specifically, the virus binds to CD4 T cells. HIV also infects several types of antigen-presenting cells, including those of the monocyte–macrophage line. It is the infection of helper T cells that leads to clinical problems.

The gradual destruction of helper T cells impairs the immune response, because these cells play a central role in coordinating cell-mediated and antibody-mediated responses to antigens. To make matters worse, regulatory T cells are relatively unaffected by the virus. Over time the excess of suppressing factors "turns off" the normal immune response. Circulating antibody levels decline and cell-mediated immunity is reduced. The body is left with impaired defenses against a wide variety of microbial invaders. Microorganisms that would ordinarily be harmless can now initiate lethal *opportunistic infections*. The risk of cancer also increases because immune surveillance is depressed.

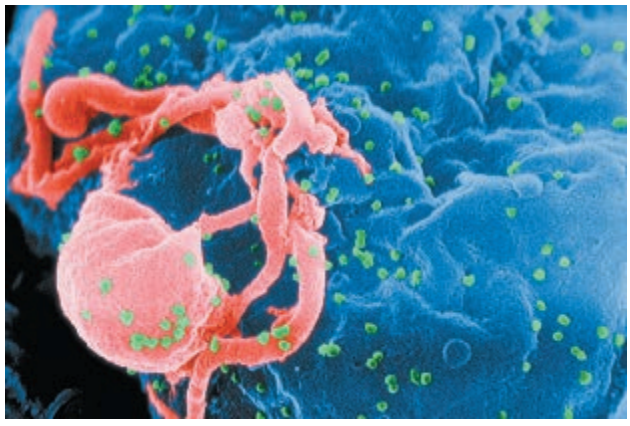
Infection with HIV occurs through intimate contact with the body fluids of infected individuals. The major routes of transmission involve contact with blood, semen, or vaginal secretions, although all body fluids may contain the virus. Worldwide, most individuals with AIDS become infected through sexual contact with an HIV-infected person (who may *not* necessarily show clinical signs of AIDS). The next largest group of infected individuals is intravenous drug users who shared contaminated needles. Relatively few individuals have become infected with the virus after receiving a transfusion of contaminated blood or blood products. Finally, an increasing number of infants are born with AIDS acquired from infected mothers.

AIDS continues to be a public health problem of massive proportions. Current statistics from the Centers for Disease Control and Prevention (CDC) show that more than 1.2 million people in the United States are infected with HIV.

The most effective ways to prevent HIV infection include abstinence, mutual monogamy of uninfected partners, male circumcision (to reduce the risk of transmission), and the avoidance of needle sharing. Circumcised men are up to 70 percent less likely to become infected than uncircumcised men. They are also less likely to infect their female partners. The use of latex condoms labeled "for the prevention of disease" has been shown to prevent the passage of HIV as well as the hepatitis and herpes viruses. Preexposure prophylaxis (PrEP) is a new HIV prevention method aimed at people who are not infected with HIV but who have a high risk of becoming infected. PrEP involves taking a pill that contains a combination of two HIV medications, tenofovir and emtricitabine. These drugs prevent HIV infection, but they must be taken every day and the person must be under the supervision of a health care provider.

Clinical signs and symptoms of AIDS may not appear until 5–10 years or more after infection. When they do appear, they are commonly mild, consisting of swollen lymph nodes and chronic, but nonfatal, infections. So far as is known, however, AIDS is almost always fatal.

Despite intensive efforts, a vaccine has yet to be developed that prevents HIV infection in an uninfected person exposed to the virus. The survival rate for AIDS patients has been steadily increasing. That is, more people are living longer before dying of AIDS or its complications. New drugs and drug combinations slow the progression of the disease, and improved antibiotic therapies help combat secondary infections.



HIV (green) budding from an infected T_H cell (blue) SEM × 40,000

22-8 The immune response diminishes as we age

Learning Outcome Describe the effects of aging on the lymphatic system and the immune response.

As we age, the immune system becomes less effective at combating disease. T cells become less responsive to antigens, so fewer cytotoxic T cells respond to an infection. This effect may be due to the gradual decrease in the size of functional tissue and secretory abilities of the thymus and to lower circulating levels of thymic hormones. Because the number of helper T cells is also reduced, B cells are less responsive, so antibody levels do not rise as quickly after antigen exposure. The net result is an increased susceptibility to viral and bacterial infections. For this reason, vaccinations for acute viral diseases such as the flu (influenza), and for pneumococcal pneumonia, are strongly recommended for elderly individuals. The increased incidence of cancer in elderly people reflects the fact that immune surveillance declines, so tumor cells are not eliminated as effectively.

Build Your Knowledge

Figure 22–30 Integration of the LYMPHATIC system with the other body systems presented so far.

Integumentary System

- The Integumentary System provides physical barriers to pathogen entry; dendritic cells in epidermis and macrophages in dermis resist infection and present antigens to trigger the immune response; mast cells trigger inflammation, mobilize cells of lymphatic system
- The lymphatic system provides IgA antibodies for secretion onto integumentary surfaces

Skeletal System

- The Skeletal System supports the production of lymphocytes and other cells involved in the immune response in red bone marrow
- The lymphatic system assists in repair of bone after injuries; osteoclasts differentiate from monocyte–macrophage cell line

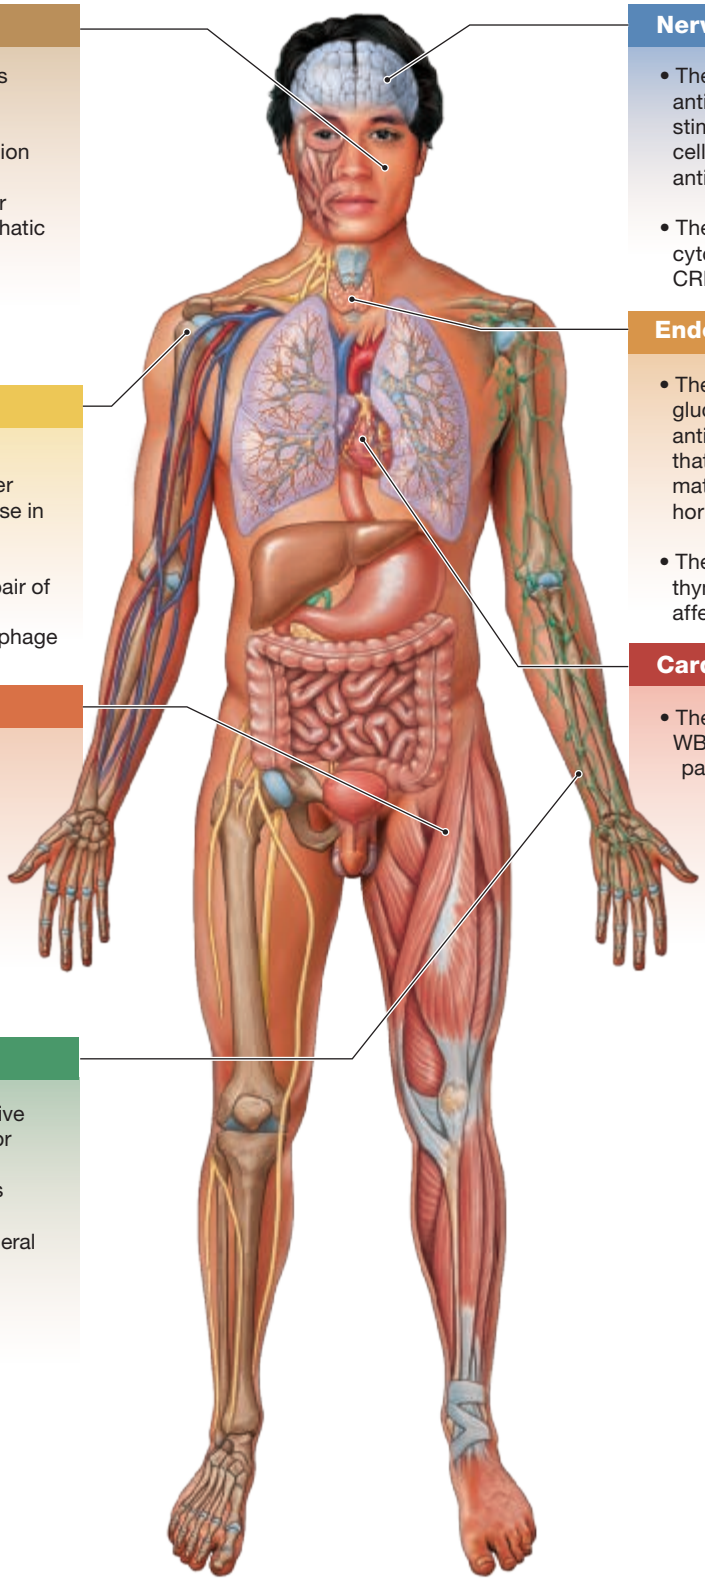
Muscular System

- The Muscular System protects superficial lymph nodes and the lymphatic vessels in abdominopelvic mesenteries; muscle contractions help propel lymph along lymphatic vessels
- The lymphatic system assists in repair after injuries

Lymphatic System

The lymphatic system provides adaptive (specific) defenses against infection for all body systems. It:

- produces, maintains, and distributes lymphocytes
- returns fluid and solutes from peripheral tissues to the blood
- distributes hormones, nutrients, and waste products from their tissues of origin to the general circulation



Nervous System

- The Nervous System has antigen-presenting microglia that stimulate adaptive defenses; glial cells secrete cytokines; innervates antigen-presenting cells
- The lymphatic system produces cytokines that affect production of CRH and TRH by hypothalamus

Endocrine System

- The Endocrine System produces glucocorticoids that have anti-inflammatory effects; thymosins that stimulate development and maturation of lymphocytes; many hormones that affect immune function
- The lymphatic system secretes thymosins from thymus; cytokines affect cells throughout the body

Cardiovascular System

- The Cardiovascular System distributes WBCs; carries antibodies that attack pathogens; clotting response helps restrict spread of pathogens; granulocytes and lymphocytes produced in red bone marrow
- The lymphatic system fights infections of cardiovascular organs; returns tissue fluid to circulation

Checkpoint

25. **Why are elderly people more susceptible to viral and bacterial infections?**
26. **What may account for the increased incidence of cancer among elderly people?**

See the blue Answers tab at the back of the book.

22-9 The nervous and endocrine systems influence the immune response

Learning Outcome Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response.

Build Your Knowledge **Figure 22–30** summarizes the interactions between the lymphatic system and other body systems we have studied so far. Interactions among elements of the immune response and the nervous and endocrine systems are now the focus of intense research. For example:

- The thymus secretes oxytocin, ADH, and endorphins as well as thymic hormones. The effects on the CNS are not known, but removal of the thymus lowers brain endorphin levels.
- Both thymic hormones and cytokines help establish the normal levels of CRH and TRH produced by the hypothalamus.
- Other thymic hormones affect the anterior lobe of the pituitary gland directly, stimulating the secretion of prolactin and GH.

Conversely, the nervous system can apparently adjust the sensitivity of the immune response:

- The PNS innervates dendritic cells in the lymph nodes, spleen, skin, and other antigen-presenting cells. The nerve endings release neurotransmitters that heighten local immune responses. For this reason, some skin conditions, such as *psoriasis*, worsen when a person is under stress.
- Neuroglia in the CNS produce cytokines that promote an immune response.
- A sudden decline in immune function can occur after even a brief period of emotional distress.

Checkpoint

27. **What is the relationship between the endocrine system and the lymphatic system?**
28. **Identify the role of the lymphatic system for all body systems.**

See the blue Answers tab at the back of the book.

22 Chapter Review

Study Outline

An Introduction to the Lymphatic System and Immunity p. 786

1. The cells, tissues, and organs of the **lymphatic system** play a central role in the body's defenses against a variety of **pathogens**, or disease-causing organisms.
2. **Immunity** is the ability to resist infection and disease. All the cells and tissues involved in producing immunity make up a functional **immune system.**

22-1 The vessels, tissues, and organs of the lymphatic system maintain fluid volume and function in body defenses p. 786

3. An array of **lymphoid tissues** and **lymphoid organs** is connected to lymphatics. **Primary lymphoid tissues and organs** are sites where lymphocytes are formed and mature. **Secondary lymphoid tissues and organs** are where lymphocytes are activated and cloned. The lymphatic system includes a network of **lymphatic vessels**, or *lymphatics*, that carry **lymph** (interstitial fluid that has entered lymphatic vessels). *(Figure 22–1)*

MasteringA&P™ Access more chapter study tools online in the MasteringA&P Study Area:
- Chapter Quizzes, Chapter Practice Test, MP3 Tutor Sessions, and Clinical Case Studies

- PhysioEx PhysioEx 9.1

4. The lymphatic system produces, maintains, and distributes lymphocytes (which attack invading organisms, abnormal cells, and foreign proteins); it also helps maintain blood volume and eliminate local variations in the composition of interstitial fluid.
5. Lymph flows along a network of lymphatic vessels, the smallest of which are the **lymphatic capillaries**. The lymphatic vessels empty into the **thoracic duct** and the **right lymphatic duct**. *(Figures 22–2 to 22–4)*
6. **Lymphoid cells** are immune system cells found in lymphoid tissues and the cells that support those tissues. Immune system cells that function in defense include phagocytes and

lymphocytes. **Lymphocytes** respond to specific invading pathogens, abnormal body cells, and foreign proteins. The three classes of lymphocytes are T (thymus-dependent) cells, B (bone marrow–derived) cells, and NK (natural killer) cells.

7. **Lymphoid tissues** are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, the lymphocytes are densely packed in an area of areolar tissue. The lymphoid tissue that protects the epithelia of the digestive, respiratory, urinary, and reproductive tracts is called **mucosa-associated lymphoid tissue (MALT)**. *(Figure 22–5)*
8. Important lymphoid organs include the **lymph nodes**, the **thymus**, and the **spleen**. Lymphoid tissues and organs are distributed in areas that are especially vulnerable to injury or invasion.
9. Lymph nodes are encapsulated masses of lymphoid tissue. The **paracortex** is dominated by T cells; the **cortex** and **medulla** contain B cells. *(Figure 22–6)*
10. The thymus lies behind the sternum, in the anterior mediastinum. **Epithelial reticular cells** regulate T cell development and function. *(Figure 22–7)*
11. The adult spleen contains the largest mass of lymphoid tissue in the body. The cellular components form the **pulp** of the spleen. **Red pulp** contains large numbers of red blood cells, and **white pulp** resembles lymphoid nodules. *(Figure 22–8)*

22-2 Lymphocytes are important to innate (nonspecific) and adaptive (specific) immunity p. 796

12. The lymphatic system is a major component of the body's defenses, which are classified as either (1) **innate (nonspecific) immunity**, which protects without distinguishing one threat from another, or (2) **adaptive (specific) immunity**, which protects against particular threats only. The body's reaction to infectious agents and other abnormal substances is known as the **immune response**.
13. Lymphocytes continuously migrate into and out of the blood through the lymphoid tissues and organs. **Lymphocytopoiesis** (lymphocyte production) involves the red bone marrow, thymus, and peripheral lymphoid tissues. *(Figure 22–9)*

22-3 Innate defenses respond the same regardless of the invader p. 797

14. Innate (nonspecific) defenses prevent the approach, deny the entry, or limit the spread of living or nonliving hazards. *(Figure 22–10)*
15. Physical barriers include skin, mucous membranes, hair, epithelia, and various secretions of the integumentary and digestive systems.
16. The two types of phagocytes are **microphages** and **macrophages** (cells of the **monocyte–macrophage system**). Microphages are neutrophils and eosinophils in circulating blood.
17. **Phagocytes** leave the bloodstream by *emigration* (migration between adjacent endothelial cells), and exhibit **chemotaxis** (sensitivity and orientation to chemical stimuli).
18. NK cells (also called **large granular lymphocytes**) attack foreign cells, normal cells infected with viruses, and cancer cells. NK cells provide *immune surveillance*.
19. **Immune surveillance** involves constant monitoring of normal tissues by NK cells that are sensitive to abnormal antigens on the surfaces of otherwise normal cells. NK cells kill cancer cells that have **tumor-specific antigens** on their surfaces. *(Figure 22–11)*
20. **Interferons (IFNs)**—small proteins released by cells infected with viruses—trigger the production of **antiviral proteins**, which interfere with viral replication inside the cell. IFNs are **cytokines**, which are chemical messengers released by tissue cells to coordinate local activities. *(Figure 22–12)*
21. At least 30 **complement proteins** make up the **complement system**. These proteins interact with each other in cascades to destroy target cell walls, enhance phagocytosis (opsonization), or stimulate inflammation. The complement system can be activated by either the **classical pathway**, the **lectin pathway**, or the **alternative pathway**. *(Figure 22–13)*
22. **Inflammation** is a localized tissue response to injury. *(Figure 22–14)*
23. **Fever** is a body temperature greater than 37.2°C (99°F). Fevers can inhibit pathogens and accelerate metabolic processes. **Pyrogens** can reset the body's thermostat and raise the temperature.

22-4 Adaptive (specific) defenses respond to particular threats and are either cell mediated or antibody mediated p. 805

24. T cells are responsible for **cell-mediated (cellular) immunity**. The primary types of T cells are **cytotoxic T cells, helper T cells**, **regulatory T cells**, and **memory T cells.** *(Figure 22–15)*
25. B cells provide **antibody-mediated (humoral) immunity**. B cells differentiate into plasma cells, which secrete antibodies. *(Figure 22–15)*
26. The **immune response** is triggered by the presence of specific antigens and includes cell-mediated and antibody-mediated defenses. *(Figure 22–16)*
27. Forms of immunity include **innate immunity** (genetically determined and present at birth) or **adaptive immunity** (produced by prior exposure to an antigen or antibody production). The two types of adaptive immunity are **active immunity** (which appears after exposure to an antigen) and **passive immunity** (produced by the transfer of antibodies from another source). *(Figure 22–17)*
28. Immunity exhibits four general properties: **specificity**, **versatility**, **memory**, and **tolerance**. Specificity occurs because T cells and B cells respond to the molecular structure of specific antigens. Versatility is based on the large diversity of lymphocytes in the body and from variability in the structure of synthesized antibodies. *Memory cells* enable the immune system to "remember" previous target antigens. Tolerance is the ability of the immune system to ignore some antigens, such as those of normal body cells.

22-5 In cell-mediated adaptive immunity, presented antigens activate T cells, which respond by producing cytotoxic and helper T cells p. 809

29. **Antigen presentation** occurs when an antigen–glycoprotein combination appears in the plasma membrane of an antigen-presenting cell (typically of a macrophage or dendritic cell). T cells sensitive to this combination are activated if they contact the membrane of the antigen-presenting cell.
30. All body cells have plasma membrane glycoproteins. The genes controlling their synthesis make up a chromosomal region called the **major histocompatibility complex (MHC)**. The membrane glycoproteins are called **MHC proteins**. **APCs (antigen-presenting cells)** are involved in antigen stimulation.
31. Lymphocytes are not activated by free antigens, but respond instead to an antigen bound to either a **class I** or a **class II** MHC protein in a process called **antigen recognition**. *(Figure 22–18)*

32. Class I MHC proteins are in all nucleated body cells. class II MHC proteins are only in antigen-presenting cells (APCs) and lymphocytes.
33. Whether a T cell responds to antigens held in class I or class II MHC proteins depends on the structure of the T cell plasma membrane. T cell plasma membranes contain proteins called **CD** (*cluster of differentiation*) **markers**. **CD3 markers** are present on all T cells. **CD8 markers** are on cytotoxic and regulatory T cells. **CD4 markers** are on all helper T cells.
34. One type of CD8 cell responds quickly to a class I MHC–bound antigen, giving rise to large numbers of cytotoxic T cells and memory T cells. The other type of CD8 cell responds more slowly, giving rise to small numbers of regulatory T cells.
35. Cytotoxic T cells seek out and destroy abnormal and infected cells, using three different methods, including the secretion of **lymphotoxin**. *(Figure 22–19)*
36. Cell-mediated immunity (cellular immunity) results from the activation of CD8 cells by antigens bound to class I MHCs. When activated, most of these T cells divide to generate cytotoxic T cells and **memory T cells**, which remain in reserve to guard against future such attacks. Regulatory T cells moderate the responses of other T cells and of B cells. *(Figures 22–19, 22–22)*
37. Helper T cells, or CD4 cells, respond to antigens presented by class II MHC proteins. When activated, helper T cells secrete cytokines that aid in coordinating adaptive and innate defenses and also regulate cell-mediated and antibody-mediated immunity. *(Figures 22–20, Spotlight Figure 22–21)*
38. Cytokines are chemical messengers coordinated by the immune system. **Interleukins** increase T cell sensitivity to antigens exposed on macrophage membranes; stimulate B cell activity, plasma cell formation, and antibody production; enhance innate defenses; and moderate the immune response. *(Spotlight Figure 22–21)*
39. Interferons (IFNs) slow the spread of a virus by making the synthesizing cell and its neighbors resistant to viral infections. *(Spotlight Figure 22–21)*
40. **Tumor necrosis factors (TNFs)** slow tumor growth and kill tumor cells, and act as pyrogens. *(Spotlight Figure 22–21)*
41. Several cytokines adjust the activities of phagocytes to coordinate innate and adaptive defenses. *(Spotlight Figure 22–21)*
42. **Colony-stimulating factors (CSFs)** are factors produced by active T cells, cells of the monocyte–macrophage group, endothelial cells, and fibroblasts. *(Spotlight Figure 22–21)*

22-6 In antibody-mediated adaptive immunity, sensitized B cells respond to antigens by producing specific antibodies p. 816

43. B cells become **sensitized** when antibody molecules in their plasma membranes bind antigens. The antigens are then displayed on the class II MHC proteins of the B cells, which become activated by helper T cells activated by the same antigen. *(Figure 22–23)*
44. An active B cell may differentiate into a plasma cell or produce daughter cells that differentiate into plasma cells and memory B cells. Antibodies are produced by plasma cells. *(Figure 22–23)*
45. A Y-shaped antibody molecule consists of two parallel pairs of polypeptide chains containing *constant* and *variable segments*. *(Figure 22–24)*
46. The five classes of antibodies **(immunoglobulins**, **Ig)** in body fluids are (1) **IgG**, responsible for resistance against many viruses, bacteria, and bacterial toxins; (2) **IgE**, which releases chemicals that accelerate local inflammation; (3) **IgD**, located on the surfaces of B cells; (4) **IgM**, the first type of antibody secreted after an antigen arrives; and (5) **IgA**, found in glandular secretions. *(Table 22–1)*
47. When antibody molecules bind to an antigen, they form an **antigen–antibody complex**. Effects that appear after binding include **neutralization** (antibody binding that prevents viruses or bacterial toxins from binding to body cells); **precipitation** (formation of an insoluble **immune complex**) and **agglutination** (formation of large complexes); *opsonization* (coating of pathogens with antibodies and complement proteins to enhance phagocytosis); stimulation of inflammation; and prevention of bacterial or viral adhesion. *(Figure 22–24)*
48. In humoral immunity, the antibodies first produced by plasma cells are the agents of the **primary response**. The maximum antibody level appears during the **secondary response** to antigen exposure. *(Figure 22–25)*
49. The initial steps in the immune responses to viral and bacterial infections differ. *(Figures 22–26* to *22–28; Table 22–2)*

22-7 Immunocompetence enables a normal immune response; abnormal responses result in immune disorders p. 821

50. **Immunocompetence** is the ability to produce an immune response after exposure to an antigen. A developing fetus acquires passive immunity from antibodies in the maternal bloodstream. After delivery, the infant begins developing active immunity following exposure to environmental antigens.
51. During periods of stress, interleukin-1 released by active macrophages triggers the release of ACTH by the anterior lobe of the pituitary gland. Glucocorticoids produced by the adrenal cortex moderate the immune response, but their long-term secretion can lower a person's resistance to disease.
52. **Hypersensitivities** (allergies) are inappropriate or excessive immune responses to **allergens** (antigens that trigger allergic reactions). The four types of allergies are *immediate hypersensitivity (type I)*, *cytotoxic reactions (type II)*, *immune complex disorders (type III)*, and *delayed hypersensitivity (type IV)*.
53. In **anaphylaxis**, a circulating allergen affects mast cells throughout the body. *(Figure 22–29)*
54. **Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues.
55. In an **immunodeficiency disease**, either the immune system does not develop normally or the immune response is blocked.

22-8 The immune response diminishes as we age p. 827

56. With aging, the immune system becomes less effective at combating disease.

22-9 The nervous and endocrine systems influence the immune response p. 829

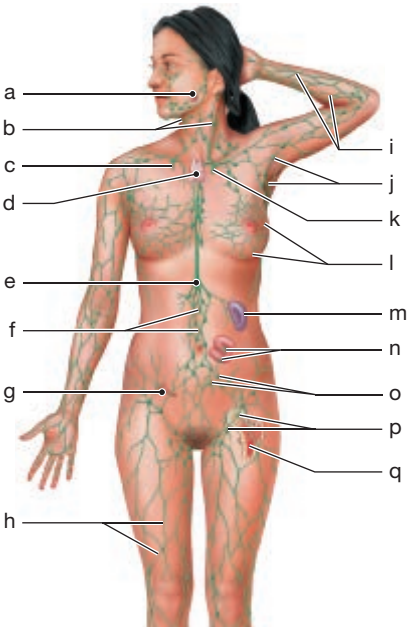
57. The lymphatic system has extensive interactions with the nervous and endocrine systems. *(Figure 22–30)*.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the lymphatic system in the following diagram.



(a) _____
(b) _____
(c) _____
(d) _____
(e) _____
(f) _____
(g) _____
(h) _____
(i) _____
(j) _____
(k) _____
(l) _____
(m) _____
(n) _____
(o) _____
(p) _____
(q) _____

2. Lymph from the right arm, the right half of the head, and the right chest is received by the **(a)** cisterna chyli, **(b)** right lymphatic duct, **(c)** right thoracic duct, **(d)** aorta.
3. Anatomically, lymphatic vessels resemble **(a)** elastic arteries, **(b)** muscular arteries, **(c)** arterioles, **(d)** medium veins, **(e)** the venae cavae.
4. The specificity of an antibody is determined by the **(a)** fixed segment, **(b)** antigenic determinants, **(c)** variable region, **(d)** size of the antibody, **(e)** antibody class.
5. The major histocompatibility complex (MHC) **(a)** is responsible for forming lymphocytes, **(b)** produces antibodies in lymph glands, **(c)** is a group of genes that codes for human leukocyte antigens, **(d)** is a membrane protein that can recognize foreign antigens, **(e)** is the antigen found on bacteria that stimulates an immune response.
6. Red blood cells that are damaged or defective are removed from the bloodstream by the **(a)** thymus, **(b)** lymph nodes, **(c)** spleen, **(d)** tonsils.
7. Phagocytes move through capillary walls by squeezing between adjacent endothelial cells, a process known as **(a)** diapedesis, **(b)** chemotaxis, **(c)** adhesion, **(d)** perforation.
8. Perforins are proteins associated with the activity of **(a)** T cells, **(b)** B cells, **(c)** NK cells, **(d)** plasma cells.
9. Complement activation **(a)** stimulates inflammation, **(b)** attracts phagocytes, **(c)** enhances phagocytosis, **(d)** achieves a, b, and c.
10. The most beneficial effect of fever is that it **(a)** inhibits the spread of some bacteria and viruses, **(b)** increases the metabolic rate by up to 10 percent, **(c)** stimulates the release of pyrogens, **(d)** achieves a and b.
11. CD4 markers are associated with **(a)** cytotoxic T cells, **(b)** regulatory T cells, **(c)** helper T cells, **(d)** all of these.
12. List the specific functions of each of the body's primary and secondary lymphoid tissues and organs.
13. Give a function for each of the following: **(a)** cytotoxic T cells, **(b)** helper T cells, **(c)** regulatory T cells, **(d)** plasma cells, **(e)** NK cells, **(f)** stromal cells, **(g)** epithelial reticular cells, **(h)** interferons, **(i)** pyrogens, **(j)** T cells, **(k)** B cells, **(l)** interleukins, **(m)** tumor necrosis factor, **(n)** colony-stimulating factors.
14. What are the three classes of lymphocytes, and where does each class originate?
15. What seven defenses, present at birth, provide the body with the defensive capability known as innate (nonspecific) immunity?

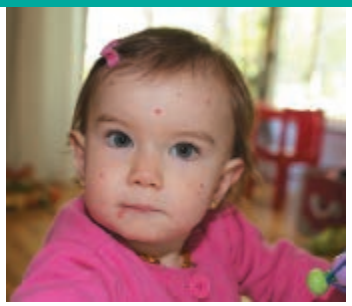
LEVEL 2 Reviewing Concepts

16. Compared with innate defenses, adaptive defenses **(a)** do not distinguish between one threat and another, **(b)** are always present at birth, **(c)** protect against threats on an individual basis, **(d)** deny the entry of pathogens to the body.
17. Blocking the antigen receptors on the surface of lymphocytes would interfere with **(a)** phagocytosis of the antigen, **(b)** that lymphocyte's ability to produce antibodies, **(c)** antigen recognition, **(d)** the ability of the lymphocyte to present antigen, **(e)** opsonization of the antigen.
18. A *decrease* in which population of lymphocytes would impair all aspects of an immune response? **(a)** cytotoxic T cells, **(b)** helper T cells, **(c)** regulatory T cells, **(d)** B cells, **(e)** plasma cells.
19. Skin tests are used to determine if a person **(a)** has an active infection, **(b)** has been exposed to a particular antigen, **(c)** carries a particular antigen, **(d)** has measles, **(e)** can produce antibodies.
20. Compare and contrast the effects of complement with those of interferon.
21. How does a cytotoxic T cell destroy another cell displaying antigens bound to class I MHC proteins?
22. How does the formation of an antigen–antibody complex cause the elimination of an antigen?
23. Give one example of each type of immunity: innate immunity, naturally acquired active immunity, artificially acquired active immunity, artificially acquired passive immunity, and naturally acquired passive immunity.
24. An anesthesia technician is advised that she should be vaccinated against hepatitis B, which is caused by a virus. She is given one injection and is told to come back for a second injection in a month and a third injection after 6 months. Why is this series of injections necessary?

LEVEL 3 Critical Thinking and Clinical Applications

25. An investigator at a crime scene discovers some body fluid on the victim's clothing. The investigator carefully takes a sample and sends it to the crime lab for analysis. On the basis of the analysis of antibodies, could the crime lab determine whether the sample is blood plasma or semen? Explain.
26. Ted finds out that he has been exposed to measles. He is concerned that he might have contracted the disease, so he goes to see his physician. The physician takes a blood sample and sends it to a lab for antibody levels and titers. The results show an elevated level and activity of IgM antibodies to rubella (measles) virus but very few IgG antibodies to the virus. Has Ted contracted the disease?
27. While walking along the street, you and your friend see an elderly woman whose left arm appears to be swollen to several times its normal size. Your friend wonders aloud what might be its cause. You say that it may be likely that the woman had a radical mastectomy (the removal of a breast because of cancer). Explain the rationale behind your answer.
28. Paula's grandfather is diagnosed as having lung cancer. His physician takes biopsies of several lymph nodes from neighboring regions of the body, and Paula wonders why, since his cancer is in the lungs. What would you tell her?
29. Willy is allergic to ragweed pollen and tells you that he read about a medication that can help his condition by blocking certain antibodies. Do you think that this treatment could help Willy? Explain.

CLINICAL CASE Wrap-Up? Isn't There a Vaccine for That?



Vaccinations against infectious diseases are one of the most successful medical advancements in the history of public health. A vaccine, containing weakened or dead forms of the infecting microbe (antigen), is administered orally, intranasally, subcutaneously, or intramuscularly. The antigens are not virulent enough to cause the disease, but they provoke the adaptive immune response in the body. This immune response involves B cells that differentiate into plasma cells and make antibodies. It also involves cytotoxic T cells and helper T cells. Regulatory T cells moderate the immune response. Memory T cells and memory B cells help the body remember the antigen so when the protected person is exposed to the real disease, a strong secondary immune response occurs.

Vaccinations are as varied as the diseases they protect against. Some are given as live, attenuated (greatly weakened) forms of a virus. Others are given as inactivated antigens, made from small pieces of killed bacteria. Some vaccines require repeat doses (booster shots) to boost the secondary immune response and keep immune memory alive.

Baby Ruthie is due for her chickenpox vaccination next month, at her 12-month checkup. She is not yet immune to the varicella-zoster virus that causes chickenpox. Disease control in babies not yet immunized depends on the rest of the population being immunized. This is known as "herd" immunity. Ruthie's day care classmate, Tommy, had never been vaccinated and was spreading chickenpox to other unprotected children in the class.

1. Is immunity to chickenpox, developed after vaccination, innate immunity, or adaptive immunity? Why?
2. Does baby Ruthie still need her chickenpox vaccine at her 12-month checkup?

See the blue Answers tab at the back of the book.

Related Clinical Terms

adenitis: Inflammation of the adenoid (pharyngeal tonsil).
allograft: Transplant between compatible recipient and donor of the same species.
anamnestic response: An immune response that is initiated by memory cells.
autograft: A transplant of tissue that is taken from the same person.
Burkitt lymphoma: A malignant cancer of B lymphocytes.
chronic fatigue syndrome: A complicated disorder most often characterized by extreme fatigue that does not improve with rest, and which may worsen with physical activity.
congenital thymic aplasia: Congenital (present at birth) absence of the thymus and parathyroid glands and a deficiency of immunity.
Coombs test: A medical test to detect antibodies or complement in the blood.
dermatomyositis: An autoimmune disease characterized by inflammation of the skin and muscles.
eczema: A genetic inflammatory skin disorder, often with crusts, papules, and leaky eruptions.
Hodgkin lymphoma: A malignant lymphoma affecting lymph nodes and lymph organs.
host versus graft disease: A pathological condition in which cells from the transplanted tissue of a donor initiate an immune response, attacking the cells and tissue of the recipient.
hybridoma: A tissue culture composed of cancer cells fused to lymphocytes to mass produce a specific antibody.
immunology: Branch of biomedicine concerned with the structure and function of the immune system.
infectious mononucleosis: An acute disease caused by the Epstein–Barr virus, producing fever, swelling of the lymph nodes, sore throat, and increased lymphocytes in the bloodstream.
latex allergy: Hypersensitivity to products made of the sap of the rubber plant.
polymyositis: An autoimmune disease characterized by inflammation and atrophy of muscles.
sentinel node: The first lymph node to receive drainage from a tumor. It is used to determine if there is lymphatic metastasis in some types of cancer.
splenomegaly: Enlargement of the spleen.
systemic lupus erythematosus (SLE): An autoimmune disease in which a person's immune system attacks and injures its own organs and tissues in virtually every system of the body.
xenograft: A transplant that is made between two different species.

23 The Respiratory System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

23-1 ■ Describe the primary functions and organization of the respiratory system, and explain how the delicate respiratory exchange surfaces are protected from pathogens, debris, and other hazards. p. 835

23-2 ■ Identify the organs of the upper respiratory system, and describe their functions. p. 838

23-3 ■ Describe the structure of the larynx, discuss its roles in normal breathing and in sound production, and identify the structures of the airways. p. 841

23-4 ■ Describe the functional anatomy of alveoli. p. 846

23-5 ■ Describe the superficial anatomy of the lungs and the structure of a pulmonary lobule. p. 848

23-6 ■ Define and compare the processes of external respiration and internal respiration. p. 851

23-7 ■ Summarize the physical principles controlling the movement of air into and out of the lungs, and describe the actions of the respiratory muscles. p. 852

23-8 ■ Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues. p. 860

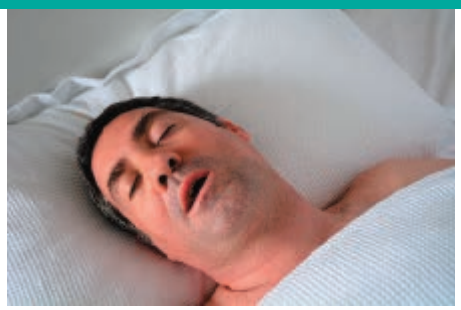
23-9 ■ Describe the structure and function of hemoglobin, and the transport of oxygen and carbon dioxide in the blood. p. 864

23-10 ■ List the factors that influence respiration rate, and discuss reflex respiratory activity and the brain centers involved in the control of respiration. p. 868

23-11 ■ Describe age-related changes in the respiratory system. p. 876

23-12 ■ Give examples of interactions between the respiratory system and other organ systems studied so far. p. 877

CLINICAL CASE No Rest for the Weary



Doug reads the boss's e-mail for the third time. It's 3 p.m. at the office and he's had trouble concentrating all day. The commute home gets downright dangerous when he catches himself nodding off behind the wheel.

Doug is a big man and could stand to lose 30 pounds. He enjoys a few beers after dinner every night. When he finally hits the hay, he's exhausted. Every couple of hours his wife nudges him. "Doug, turn over. You're making a racket!" she says. She lies awake and notices that now he's quiet. Too quiet. Finally, he takes another rattling breath. This is their sleep pattern during most nights. In the morning, Doug wakes up with a headache, and neither one of them feels rested.

Doug's doctor refers him to an ENT (an ear, nose and throat specialist, also called an *otorhinolaryngologist*), who finds that Doug has a lengthened soft palate with a prominent uvula. During an overnight sleep study, it's noted that Doug sleeps on his back. The sleep technician documents several episodes of *apnea* (cessation of breathing). **What is causing Doug's nighttime drama? To find out, turn to the Case Study Wrap-Up on p. 883.**

An Introduction to the Respiratory System

When we think of the respiratory system, we generally think of breathing—pulling air into and out of our bodies. However, an efficient respiratory system must do more than merely move air. Cells need energy for maintenance, growth, defense, and division. Our cells obtain that energy mainly through aerobic mechanisms that require oxygen and produce carbon dioxide.

Our cells obtain oxygen and release carbon dioxide when these gases diffuse across the thin respiratory exchange surfaces inside of the *lungs*—a warm, moist, protected environment. In this environment, diffusion takes place between the air and the blood. Circulating blood then carries oxygen from the lungs to peripheral tissues. Your blood also transports the carbon dioxide generated by those tissues, delivering it to the lungs. Therefore, the cardiovascular system is the link between your interstitial fluids and the exchange surfaces of your lungs. In this chapter we describe how air enters and exits the lungs by the actions of respiratory muscles, and how oxygen and carbon dioxide are exchanged within the lungs.

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, functions primarily to aid gas exchange

Learning Outcome Describe the primary functions and organization of the respiratory system, and explain how the delicate respiratory exchange surfaces are protected from pathogens, debris, and other hazards.

The **respiratory system** is composed of structures involved in *ventilation* (providing air) and *gas exchange*. In this section we consider its functions and structures.

Functions of the Respiratory System

The respiratory system has the following basic functions:

- Providing an extensive surface area for gas exchange between air and circulating blood.
- Moving air to and from the exchange surfaces of the lungs along the respiratory passageways.
- Protecting respiratory surfaces from dehydration, temperature changes, and pathogens.
- Producing sounds for speaking, singing, and other forms of communication.
- Detecting odors by olfactory receptors in the superior portions of the nasal cavity.

Organization of the Respiratory System

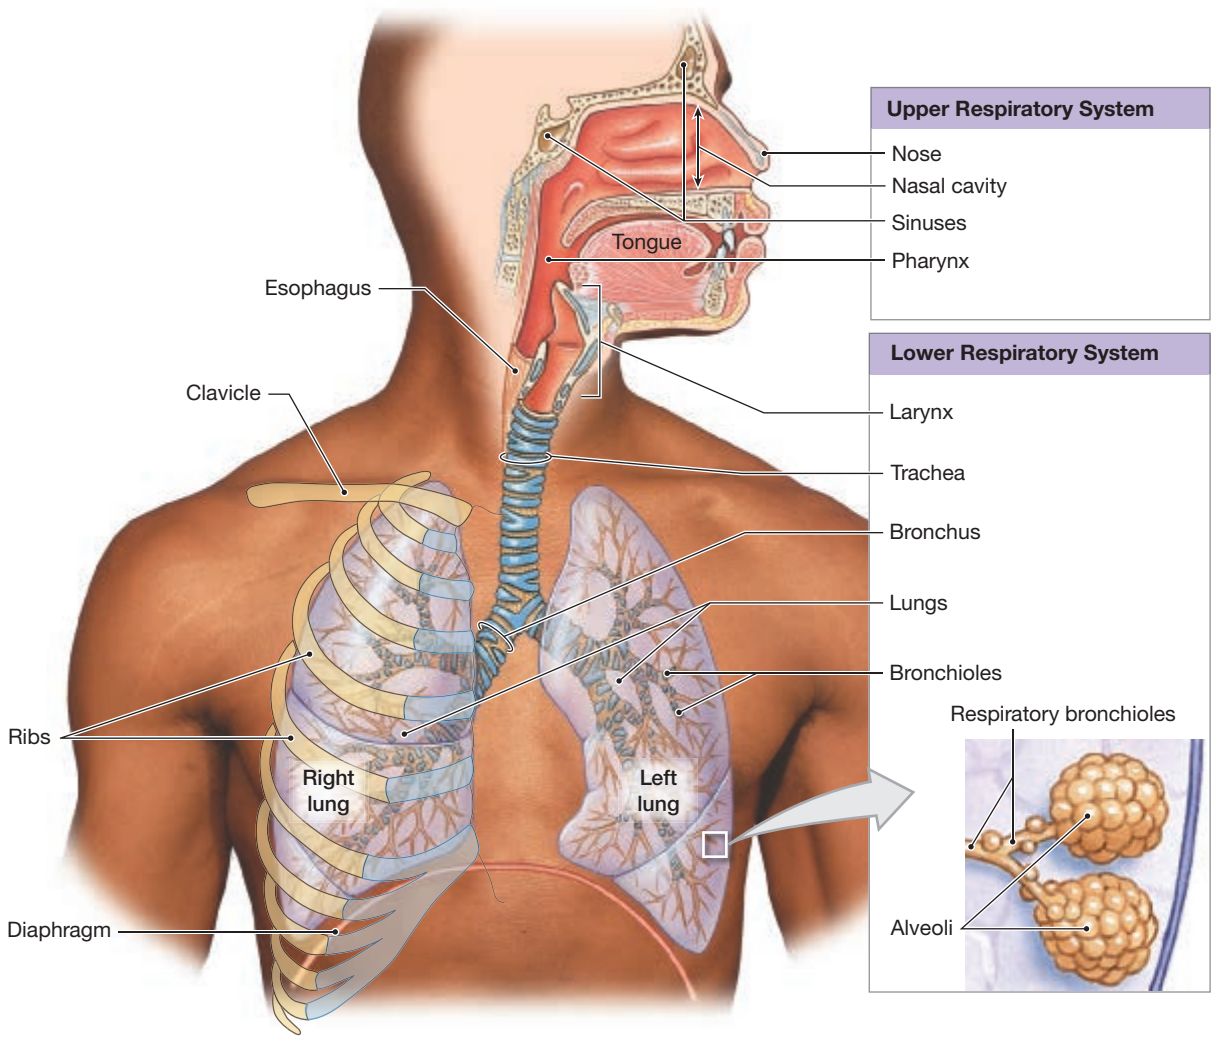
We can organize the respiratory system from either an anatomical or a functional perspective. Anatomically, we can divide the system into an upper respiratory system and a lower respiratory system (Figure 23–1). The **upper respiratory system** consists of the *nose*, *nasal cavity*, *paranasal sinuses*, and *pharynx* (throat). The **lower respiratory system** includes the *larynx* (voice box), *trachea* (windpipe), *bronchi* and *bronchioles* (air-conducting passageways), and *alveoli* (air-filled pockets within the lungs).

Tips & Tools

To recall the boundary between the upper and lower respiratory systems, remember that the ***l***ower respiratory system begins at the ***l***arynx.

From a functional perspective, the term **respiratory tract** refers to the passageways that carry air to and from the lung exchange surfaces. The *conducting portion* of the respiratory tract begins at the entrance to the nasal cavity and extends through the pharynx, larynx, trachea, bronchi, and larger

Figure 23–1 The Structures of the Respiratory System. ATLAS: Plates 47a,b



bronchioles. The *respiratory portion* of the tract includes the smallest, thinnest *respiratory bronchioles* and the associated **alveoli** (al-VĒ-ō-lī), where all gas exchange between air and blood takes place. The following sections combine these two methods of organization, so keep in mind that the upper respiratory system contains the upper part of the conducting portion, while the lower respiratory system includes the rest of the conducting portion and all of the respiratory portion of the respiratory system.

The passageways of the conducting portion of the upper respiratory system filter, warm, and humidify inhaled air, protecting the more delicate surfaces of the lower respiratory system. By the time air reaches the alveoli, most foreign particles and pathogens have been removed, and the humidity and temperature are within acceptable limits. The success of this "conditioning process" is due to the respiratory mucosa.

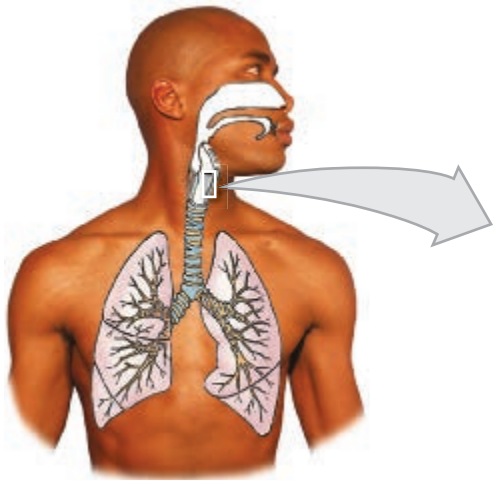
The Respiratory Mucosa and the Respiratory Defense System

The **respiratory mucosa** (myū-KŌ-suh) lines the conducting portion of the respiratory system. A *mucosa* is a *mucous membrane*, one of the four types of membranes introduced in Chapter 4. This mucosa, which changes along the length of the conducting portion, provides a series of filtration mechanisms that make up the **respiratory defense system**. This defense system reduces the amount of debris or pathogens in inhaled air, which can severely damage the exchange surfaces of the respiratory system.

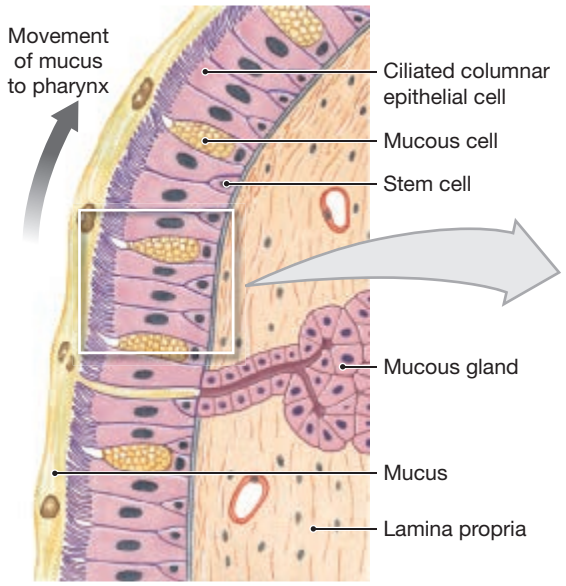
The Respiratory Mucosa

The respiratory mucosa consists of an epithelium and an underlying layer of areolar tissue. ↩ p. 140 The **lamina propria** (LAM-ih-nuh PRŌ-prē-uh) is the underlying layer of areolar

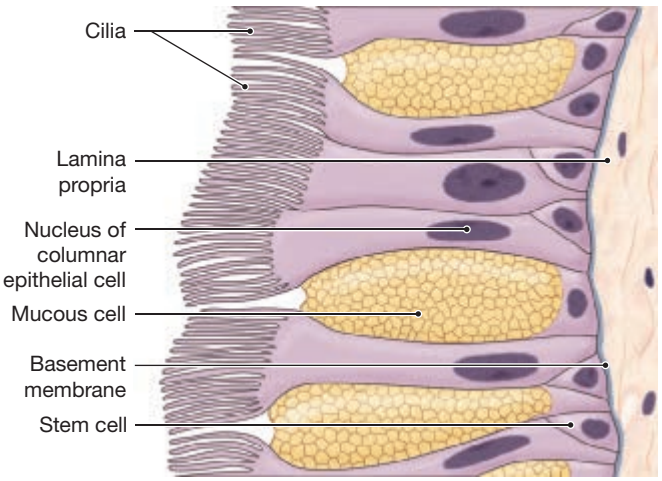
Figure 23–2 The Respiratory Epithelium of the Nasal Cavity and Conducting Portion of the Respiratory Tract.



a The cilia of the epithelial cells form a dense layer that resembles a shag carpet. Ciliary movement propels mucus across the epithelial surface.



b A diagrammatic view of the respiratory epithelium of the trachea, showing the direction of mucus transport inferior to the pharynx.



c A sectional view of the respiratory epithelium, a pseudostratified ciliated columnar epithelium.

? What type of epithelium lines the conducting portion of the respiratory tract?

tissue that supports the respiratory epithelium. In the upper respiratory system, trachea, and bronchi, the lamina propria contains mucous glands that discharge their secretions onto the epithelial surface (Figure 23–2). The respiratory mucosa of the trachea consists of a mucosa, submucosa, hyaline cartilage, and an adventitial layer. The lamina propria in the conducting portions of the lower respiratory system contains bundles of smooth muscle cells. In the bronchioles, the smooth muscles form thick bands that encircle or spiral around the lumen.

A pseudostratified ciliated columnar epithelium with numerous mucous cells lines the nasal cavity and the superior portion of the pharynx. ↩ p. 122 The epithelium lining inferior portions

of the pharynx is a stratified squamous epithelium similar to that of the oral cavity. These portions of the pharynx conduct air to the larynx and also carry food to the esophagus. The pharyngeal epithelium must therefore protect against abrasion and chemicals.

A pseudostratified ciliated columnar epithelium, comparable to that of the nasal cavity, lines the superior portion of the lower respiratory system. The smaller bronchioles have a cuboidal epithelium with scattered cilia. The exchange surfaces of the alveoli are made up of a simple squamous epithelium. Other, more specialized cells are scattered among the squamous cells and together they form the *alveolar epithelium*.

The Respiratory Defense System

Along much of the respiratory tract, mucous cells in the epithelium and mucous glands in the lamina propria produce a sticky mucus that bathes exposed surfaces. In the nasal cavity, cilia sweep that mucus and any trapped debris or microorganisms toward the pharynx. There it is swallowed and exposed to the acids and enzymes in the stomach. In the lower respiratory system, the cilia beat toward the pharynx, moving a carpet of mucus in that direction and cleaning the respiratory surfaces. This mechanism is the *mucociliary escalator* (see Figure 23–2b,c).

Tips & Tools

The mucus in the respiratory mucosa functions like sticky flypaper, but instead of flies, it traps particles and debris from the air that moves past it.

Filtration in the nasal cavity removes virtually all particles larger than about 10 μm from the inhaled air. Smaller particles may be trapped by the mucus of the nasopharynx or by secretions of the pharynx. The rate of mucus production in the nasal cavity and paranasal sinuses speeds up when exposed to unpleasant stimuli, such as noxious vapors, large quantities of dust and debris, allergens, or pathogens. (The familiar signs and symptoms of the "common cold" appear when any of more than 200 types of viruses invades the respiratory epithelium.)

Most particles 1–5 μm in diameter are trapped in the mucus coating the respiratory bronchioles or in the liquid covering the alveolar surfaces. These areas are outside of the mucociliary escalator, but the foreign particles can be engulfed by alveolar macrophages. Most particles smaller than about 0.5 μm remain suspended in the air.

Checkpoint

1. Identify several functions of the respiratory system.
2. List the two anatomical divisions of the respiratory system.
3. What membrane lines the conducting portion of the respiratory tract?

See the blue Answers tab at the back of the book.

Clinical Note Breakdown of the Respiratory Defense System

Large quantities of airborne particles may overload the respiratory defenses and produce a variety of illnesses. For example, irritants in the lining of the conducting passageways can provoke the formation of mucous plugs that block airflow and reduce pulmonary function. Damage to the epithelium in the affected area may allow irritants to enter the surrounding tissues of the lung. The irritants then produce local inflammation. Airborne irritants—such as those in cigarette smoke—are known to promote the development of lung cancer (p. 877).

Aggressive pathogens can also overwhelm respiratory defenses. **Tuberculosis** (tū-ber-kyū-LŌ-sis), or **TB**, results from an infection of the lungs by the bacterium called *Mycobacterium tuberculosis*. Bacteria may colonize the respiratory passageways, the interstitial spaces, the alveoli, or a combination of the three. Signs and symptoms generally include coughing and chest pain, plus fever, night sweats, fatigue, and weight loss. In 1900, TB, then known as "consumption" (because its victims wasted away), was the leading cause of death. An estimated one-third of the world's population is still infected with TB today.

The respiratory defense system can also fail due to inherited congenital defects affecting mucus production or transport. For example, **cystic fibrosis (CF)** is the most common lethal inherited disease in individuals of Northern European descent. It occurs in 1 in 3200 Caucasian births. The respiratory mucosa in these individuals produces dense, viscous mucus that cannot be transported by the respiratory defense system. The mucociliary escalator stops working, leading to frequent infections. Mucus also blocks the smaller respiratory passageways, making breathing difficult. The average life span for people with CF who live into adulthood is 37 years.

23-2 The conducting portion of the upper respiratory system filters, warms, and humidifies air

Learning Outcome Identify the organs of the upper respiratory system, and describe their functions.

As we have noted, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx (see Figure 23–1).

The Nose and Nasal Cavity

The nose provides an airway for breathing, moistens and warms entering air, filters and cleans inhaled air, serves as a resonating chamber for speech, and houses olfactory receptors. The nasal cavity filters coarse particles from inspired air and is lined with an olfactory mucosa.

The Nose

The **nose** is the primary passageway for air entering the respiratory system. Air normally enters through the paired **nostrils**, or **nares** (NĀ-res), which open into the *nasal cavity* (Figure 23–3a). The **nasal vestibule** is the space contained within the flexible tissues of the nose (Figure 23–3c). The epithelium of the vestibule contains coarse hairs that extend across the nostrils. Large airborne particles, such as sand, sawdust, or even insects, are trapped in these hairs and prevented from entering the nasal cavity.

The Nasal Cavity and Paranasal Sinuses

The **nasal cavity** is divided into left and right sides by the **nasal septum** (Figure 23–3b). The bony portion of the nasal septum is formed by the fusion of the perpendicular plate of the ethmoid and the vomer (look back at Figure 7–3d, p. 213). The anterior portion of the nasal septum is formed of hyaline cartilage. This cartilaginous plate supports the **dorsum of nose** (bridge) and the **apex of nose** (tip).

The maxillae, nasal bone, frontal bone, ethmoid, and sphenoid form the lateral and superior walls of the nasal cavity. The mucus produced in the *paranasal sinuses* (sinuses of the frontal bone, sphenoid, ethmoid, and paired maxillae and palatine bones) helps keep the surfaces of the nasal cavity moist and clean (look back at Figure 7–15, p. 226). The tears draining through the nasolacrimal ducts do so as well.

The *olfactory region* is the superior portion of the nasal cavity. It includes the areas lined by olfactory epithelium: (1) the inferior surface of the cribriform plate, (2) the superior portion of the nasal septum, and (3) the superior nasal conchae. Receptors in the olfactory epithelium provide your sense of smell. ⮌ p. 567 The *superior*, *middle*, and *inferior nasal conchae* project toward the nasal septum from the lateral walls of the nasal cavity. (Some references use the terms *superior*, *middle*, and *inferior turbinates*.) ⮌ pp. 220, 223 To pass from the vestibule to the **choanae** (KŌ-an-ē)—openings of the nasal cavity—air flows between adjacent conchae, through the **superior**, **middle**, and **inferior nasal meatuses** (mē-Ā-tus-ez;) (see Figure 23–3b). These are narrow grooves rather than open passageways. The incoming air bounces off the conchal surfaces and churns like a stream flowing over rocks. This turbulence serves several purposes. As the air swirls, small airborne particles are likely to come into contact with the mucus coating the nasal cavity. In addition, the turbulence provides extra time for warming and humidifying incoming air. It also creates circular air currents that bring olfactory stimuli to the olfactory receptors.

The bony **hard palate** is made up of portions of the paired maxillae and palatine bones. The hard palate forms the floor of the nasal cavity and separates it from the oral cavity. A fleshy **soft palate** extends posterior to the hard palate, marking the boundary between the superior *nasopharynx* (nā-zō-FAR-ingks) and the rest of the pharynx. The nasal cavity opens into the nasopharynx at the choanae.

Functions of the Nasal Mucosa

The mucosa of the nasal cavity prepares inhaled air for arrival at the lower respiratory system. Throughout much of the nasal cavity, the lamina propria contains an abundance of arteries, veins, and capillaries that bring nutrients and water to the secretory cells. The lamina propria of the nasal conchae also contains an extensive network of highly expandable veins. This vascularization warms and humidifies the incoming air (and dehumidifies and absorbs the heat of the outgoing air as well). As cool, dry air passes inward over the exposed surfaces of the nasal cavity, the warm epithelium radiates heat, and water in the mucus evaporates. In this way, air moving from your nasal cavity to your lungs is heated almost to body temperature. It is also nearly saturated with water vapor. These changes protect more delicate respiratory surfaces from chilling or drying out—two potentially disastrous events. If you breathe through your mouth, you eliminate much of these preliminary events. To avoid alveolar damage, patients breathing on a respirator (mechanical ventilator), which uses a tube to conduct air directly into the trachea, must receive air that has been externally filtered and humidified.

As air moves out of the respiratory tract, it again passes over the epithelium of the nasal cavity. This air is warmer and more humid than the air that enters. It warms the nasal mucosa, and moisture condenses on the epithelial surfaces. In this way, breathing through your nose helps prevent heat loss and water loss.

The extensive vascularization of the nasal cavity and the vulnerable position of the nose make a **nosebleed**, or *epistaxis* (ep-ih-STAK-sis), a fairly common event. (The leading cause of epistaxis in children is nose-picking.) This bleeding generally involves vessels of the mucosa covering the cartilaginous portion of the septum. Possible causes include trauma (such as a punch in the nose), drying, infections, allergies, or clotting disorders. Hypertension can also bring on a nosebleed by rupturing small vessels of the lamina propria.

The Pharynx

The **pharynx** (FAR-ingks), or throat, is a chamber shared by the digestive and respiratory systems. It extends between the choanae and the entrances to the larynx and esophagus. The curving superior and posterior walls of the pharynx are closely bound to the axial skeleton, but the lateral walls are flexible and muscular.

The pharynx is divided into three parts: the *nasopharynx*, the *oropharynx*, and the *laryngopharynx* (see Figure 23–3c).

1. The **nasopharynx** is the superior portion of the pharynx. It is connected to the posterior portion of the nasal cavity through the choanae. The soft palate separates it from the oral cavity. The nasopharynx is lined by the same pseudostratified ciliated columnar epithelium as in the nasal cavity. The *pharyngeal tonsil* is located on the posterior

wall of the nasopharynx. Each auditory tube opens into the nasopharynx at the **pharyngeal opening of auditory tube** on each side of the pharyngeal tonsil. pp. 593, 791

2. The **oropharynx** (*oris*, mouth) extends between the soft palate and the base of the tongue at the level of the hyoid bone. The posterior portion of the oral cavity connects directly with the oropharynx, as does the posterior inferior portion of the nasopharynx. At the boundary between the nasopharynx and the oropharynx, the epithelium changes from pseudostratified columnar epithelium to stratified squamous epithelium.
3. The narrow **laryngopharynx** (la-rin-gō-FAR-ingks) is the inferior part of the pharynx. It includes that portion of the pharynx between the hyoid bone and the entrance to the larynx and esophagus. Like the oropharynx, the laryngopharynx is lined with a stratified squamous epithelium that resists abrasion, chemicals, and pathogens.

23-3 The conducting portion of the lower respiratory system conducts air to the respiratory portion and produces sound

Learning Outcome Describe the structure of the larynx, discuss its roles in normal breathing and in sound production, and identify structures of the airways.

In this section we cover the conducting portion of the lower respiratory system. These structures include the larynx, which also allows us to produce sound. The trachea is a large air passageway that leads to the bronchi. The bronchi and their branching vessels form the *bronchial tree* that leads air into the lungs.

The Larynx

Inhaled air leaves the pharynx and enters the larynx through the *glottis*, a slit-like opening between the vocal cords. The glottis is the "voice box," of the larynx. The **larynx** (LAR-ingks) is a cartilaginous tube that surrounds and protects the glottis. The larynx begins at the level of vertebra C_4 or C_5 and ends at the level of vertebra C_6. Essentially a cylinder, the larynx has incomplete cartilages that are stabilized by ligaments and laryngeal muscles (Figure 23–4).

Cartilages and Ligaments of the Larynx

Three large, unpaired cartilages form the larynx: (1) the thyroid cartilage, (2) the cricoid cartilage, and (3) the epiglottis (see Figure 23–4). Made of hyaline cartilage, the **thyroid cartilage** is the largest laryngeal cartilage. It forms most of the anterior and lateral walls of the larynx. In section, this cartilage is U-shaped, and posteriorly, it is incomplete. You can easily see and feel the prominent anterior surface of the thyroid cartilage, called the *laryngeal prominence*, or *Adam's apple*. The inferior surface articulates with the cricoid cartilage. The superior surface has ligamentous attachments to the hyoid bone and to the epiglottis and smaller laryngeal cartilages.

Also made of hyaline cartilage, the **cricoid** (KRĪ-koyd) **cartilage** is the most inferior of the laryngeal cartilages. The posterior portion of the cricoid cartilage is expanded to provide support where there is no thyroid cartilage. The cricoid and thyroid cartilages protect the glottis and the entrance to the trachea. Their broad surfaces provide sites for the attachment of important laryngeal muscles and ligaments. Ligaments attach the inferior surface of the cricoid cartilage to the first tracheal cartilage. The superior surface of the cricoid cartilage articulates with the small, paired *arytenoid cartilages*.

Made of elastic cartilage, the shoehorn-shaped **epiglottis** (ep-ih-GLOT-is) projects superior to the glottis and forms a lid over it. It has ligamentous attachments to the anterior and superior borders of the thyroid cartilage and the hyoid bone. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing both liquids and solid food from entering the respiratory tract.

The larynx also contains three pairs of smaller hyaline cartilages: (1) The **arytenoid** (ar-ih-TĒ-noyd; ladle shaped) **cartilage** articulates with the superior border of the enlarged portion of the cricoid cartilage. (2) The **corniculate** (kor-NIK-yū-lāt; horn shaped) **cartilage** articulates with the arytenoid cartilage. The corniculate and arytenoid cartilages function in the opening and closing of the glottis and the production of sound. (3) An elongated, curving **cuneiform** (kyū-NĒ-ih-form; wedge shaped) **cartilage** is within the *ary-epiglottic folds*, tissue that extends between the lateral surface of each arytenoid cartilage and the epiglottis.

Ligaments bind together the various laryngeal cartilages. Additional ligaments attach the thyroid cartilage to the hyoid bone, and the cricoid cartilage to the trachea (cricotracheal ligament) (see Figure 23–4a,b). The *median cricothyroid ligament* attaches the thyroid cartilage to the cricoid cartilage. Because it has easily identifiable landmarks and is clear of the thyroid gland, this ligament is a common placement site for an emergency tracheostomy, a tracheal incision to bypass an airway obstruction. The **vestibular ligaments** and the **vocal ligaments** extend between the thyroid cartilage and the arytenoid cartilages.

The vestibular and vocal ligaments are covered by folds of laryngeal epithelium. The vestibular ligaments lie within the superior pair of folds, known as the **vestibular folds** (Figure 23–5). These folds are fairly inelastic and lie laterally to the glottis. The **glottis** (GLOT-is) is made up of the **vocal folds** and the space between them, called the *rima glottidis*. The vestibular folds help prevent foreign objects from entering the open glottis. They also protect the more inferior, delicate vocal folds of the glottis.

The vocal folds are highly elastic, because the vocal ligaments consist of elastic tissue. The vocal folds are involved with the production of sound. For this reason they are known as the **vocal cords**.

Muscles of the Larynx

The larynx is associated with two sets of muscles: (1) muscles of the neck and pharynx, which position and stabilize the

larynx (pp. 352–354), and (2) smaller intrinsic muscles that control tension in the glottal vocal folds or that open and close the glottis. These smaller muscles insert on the thyroid, arytenoid, and corniculate cartilages. The opening or closing of the glottis involves rotational movements of the arytenoid cartilages.

When you swallow, both sets of muscles work together to prevent food or drink from entering the glottis. Food is crushed and chewed into a pasty mass, known as a *bolus*, before being swallowed. Muscles of the neck and pharynx then elevate the larynx, bending the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. While this movement is under way, the glottis is closed.

Foods or liquids that touch the vestibular folds or glottis trigger the *coughing reflex*. In a cough, the glottis is kept closed while the chest and abdominal muscles contract, compressing the lungs. When the glottis is opened suddenly, a blast of air from the trachea ejects material that blocks the entrance to the glottis.

Sound Production

How do you produce sounds? Air passing through your open glottis vibrates its vocal folds and produces sound waves. The pitch of the sound depends on the diameter, length, and tension in your vocal folds. The diameter and length are directly related to the size of your larynx. You control the tension by contracting voluntary muscles that reposition the arytenoid cartilages relative to the thyroid cartilage. When the distance increases, your vocal folds tense and the pitch rises. When the distance decreases, your vocal folds relax and the pitch falls.

Children have slender, short vocal folds, so their voices tend to be high pitched. At puberty, the larynx of males enlarges much more than that of females. The vocal cords of an adult male are thicker and longer, so they produce lower tones than those of an adult female.

Sound production at the larynx is called *phonation* (fō-NĀ-shun; *phone*, voice). Phonation is one part of speech production. Clear speech also requires *articulation*, the modification of those sounds by voluntary movements of other structures, such as the tongue, teeth, and lips to form words. In a stringed instrument, such as a guitar, the quality of the sound produced does not depend solely on the nature of the vibrating string. Rather, the entire instrument becomes involved as the walls vibrate and the composite sound echoes within the hollow body. Similar amplification and resonance take place within your pharynx, oral cavity, nasal cavity, and paranasal sinuses. The combination gives you the particular and distinctive sound of your voice. That sound changes when you have a sinus infection and your nasal cavity and paranasal sinuses are filled with mucus rather than air.

Tips & Tools

Intelligible sound requires both phonation and articulation. Saying "ahhhh" while your tongue is depressed during a tonsil examination is an example of phonation. Saying "hot" adds articulation to that sound.

An infection or inflammation of the larynx is known as *laryngitis* (lar-in-JĪ-tis). It commonly affects the vibrational qualities of the vocal folds. Hoarseness is the most familiar result. Mild cases are temporary and seldom serious. However, bacterial or viral infections of the epiglottis can be very dangerous. The resulting swelling may close the glottis and cause suffocation. This condition, *acute epiglottitis* (ep-ih-glot-TĪ-tis), can develop rapidly after a bacterial infection of the throat. Young children are most likely to be affected.

The Trachea

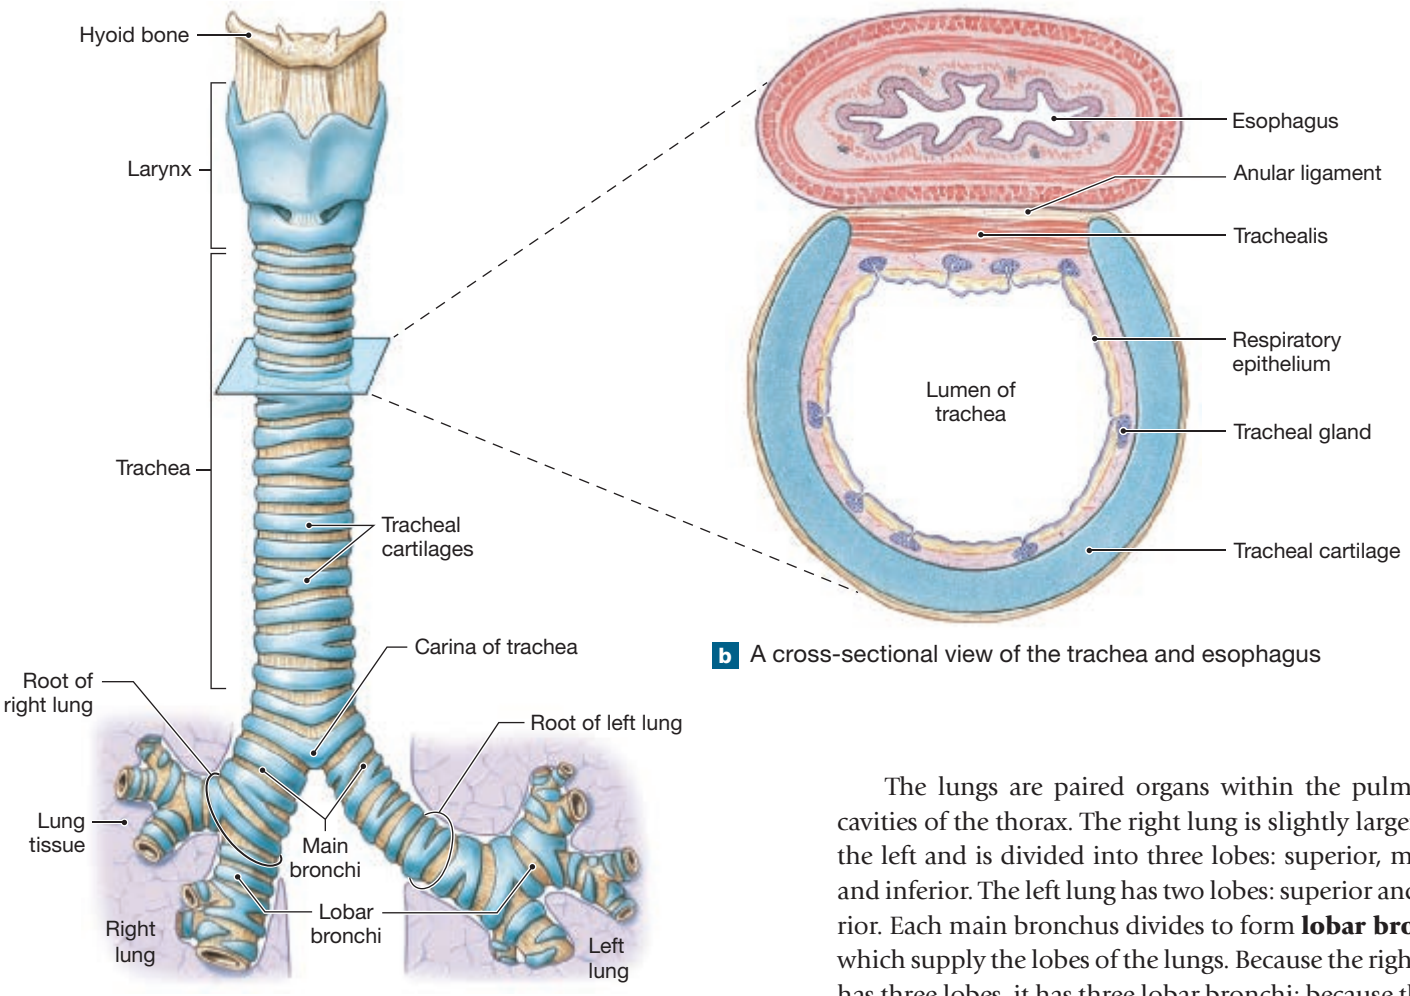
The **trachea** (TRĀ-kē-uh), or windpipe, is a tough, flexible tube with a diameter of about 2.5 cm (1 in.) and a length of about 11 cm (4.33 in.) (Figure 23–6). The trachea begins anterior to vertebra C_6 in a ligamentous attachment to the cricoid cartilage. It ends in the mediastinum, at the level of vertebra T_5, where it branches to form the *right* and *left main bronchi*.

The epithelium of the trachea is continuous with that of the larynx. The mucosa of the trachea resembles that of the nasal cavity and nasopharynx (look back at Figure 23–2a). The **submucosa** (sub-mū-KŌ-suh), a thick layer of connective tissue, surrounds the mucosa. The submucosa contains **tracheal glands** whose mucous secretions reach the tracheal lumen through a number of short ducts. The trachea contains 15–20 **tracheal cartilages** that stiffen the tracheal walls and protect the airway (see Figure 23–6a). They also prevent it from collapsing or overexpanding as pressure changes in the respiratory system.

Each tracheal cartilage is C-shaped. The closed portion of the C protects the anterior and lateral surfaces of the trachea. The open portion of the C faces posteriorly, toward the esophagus (see Figure 23–6b). Because these cartilages are not continuous, the posterior tracheal wall can easily distort when you swallow, allowing large masses of food to pass through the esophagus.

An elastic **anular ligament** and the **trachealis**, a band of smooth muscle, connect the ends of each tracheal cartilage (see Figure 23–6b). Contraction of the trachealis reduces the diameter of the trachea. This narrowing increases the tube's resistance to airflow. The normal diameter of the trachea changes from moment to moment, primarily under the control of the sympathetic division of the ANS. Sympathetic stimulation increases the diameter of the trachea and makes it easier to move large volumes of air along the respiratory passageways.

Figure 23–6 The Anatomy of the Trachea. ATLAS: Plates 42b,c



a A diagrammatic anterior view showing the plane of section for part (b)

b A cross-sectional view of the trachea and esophagus

The Bronchial Tree

The trachea branches within the mediastinum into the **right main bronchus** and **left main bronchus** (BRONG-kus; plural, *bronchi*). These main bronchi enter the right and left lungs, respectively, and divide to form smaller passageways, the *lobar bronchi* (see Figure 23–6a). Together, the main and lobar bronchi and their branches form the **bronchial tree**.

The Bronchi

The **carina** (kah-RĪ-nuh) **of trachea** is a ridge that separates the openings of the right and left main bronchi at their junction with the trachea (see Figure 23–6a). Like the trachea, the main bronchi have C-shaped rings, but the ends of the C overlap. The right main bronchus supplies the right lung, and the left supplies the left lung. The right main bronchus is larger in diameter than the left, and descends toward the lung at a steeper angle. For these reasons, most foreign objects that enter the trachea find their way into the right bronchus rather than the left.

The lungs are paired organs within the pulmonary cavities of the thorax. The right lung is slightly larger than the left and is divided into three lobes: superior, middle, and inferior. The left lung has two lobes: superior and inferior. Each main bronchus divides to form **lobar bronchi**, which supply the lobes of the lungs. Because the right lung has three lobes, it has three lobar bronchi; because the left lung has two lobes, it has two lobar bronchi. Each lobe is further divided internally into pulmonary lobules.

Figure 23–7a,b depicts the branching pattern of the left main bronchus as it enters the lung. (The number of branches has been reduced for clarity.) In each lung, the lobar bronchi branch to form **segmental bronchi**. The branching pattern differs between the two lungs, but each segmental bronchus ultimately supplies air to a single **bronchopulmonary segment**, a specific region of one lung (see Figure 23–7a). The right lung has 10 bronchopulmonary segments. During development, the left lung also has 10 segments, but adjacent segmental bronchi fuse, generally reducing the number to 8 or 9.

The walls of the main, lobar, and segmental bronchi contain progressively less cartilage. In the lobar and segmental bronchi, the cartilages form plates arranged around the lumen. These cartilages serve the same structural purpose as the rings of cartilage in the trachea and primary bronchi. As the amount of cartilage decreases, the amount of smooth muscle increases. With less cartilaginous support, the degree of tension in those smooth muscles exerts a proportionally greater effect on bronchial diameter and the resistance to airflow. During a respiratory

d SEM of lung tissue showing the appearance and organization of the alveoli

infection, the bronchi and bronchioles can become inflamed and constricted, increasing resistance. In this condition, called **bronchitis**, the person has difficulty breathing.

The Bronchioles

Each segmental bronchus branches several times within a bronchopulmonary segment, forming many **bronchioles**. These bronchioles then branch into the finest conducting branches, called **terminal bronchioles**. Nearly 6500 terminal bronchioles arise from each segmental bronchus. The lumen of each terminal bronchiole has a diameter of 0.3–0.5 mm.

The walls of bronchioles lack cartilage and are dominated by smooth muscle tissue (Figure 23–7c). In functional terms, bronchioles are to the respiratory system what arterioles are to the cardiovascular system. Changes in the diameter of the bronchioles control the resistance to airflow and the distribution of air in the lungs.

The autonomic nervous system controls the luminal diameter of the bronchioles by regulating the smooth muscle layer. Sympathetic activation leads to **bronchodilation**, the enlargement of the luminal diameter of the airway. Parasympathetic stimulation leads to **bronchoconstriction**, a reduction in the luminal diameter of the airway. Tension in the smooth muscles commonly causes the bronchiole mucosa to form a series of folds that limits airflow. Excessive stimulation, as in **asthma** (AZ-muh), can almost completely prevent airflow along the terminal bronchioles. Bronchoconstriction also takes place during allergic reactions such as anaphylaxis, in response to histamine released by activated mast cells and basophils. ↩ p. 825

23-4 The respiratory portion of the lower respiratory system is where gas exchange occurs

Learning Outcome Describe the functional anatomy of alveoli.

This section covers the structures of the respiratory portion of the lower respiratory system, including the respiratory bronchioles, the alveoli, and the blood air barrier. We cover much of the function of these structures in the following sections.

The Respiratory Bronchioles

Each terminal bronchiole delivers air to a single *pulmonary lobule*. Within the lobule, the terminal bronchiole branches to form several **respiratory bronchioles** (Figure 23–7c). The respiratory bronchioles are the thinnest and most delicate branches of the bronchial tree. They deliver air to the gas-exchange surfaces of the lungs.

Before incoming air moves beyond the terminal bronchioles, it has been filtered and humidified. Cuboidal epithelium lines the terminal bronchioles and respiratory bronchioles. There are only scattered cilia and no mucous cells or underlying mucous glands. If particulates or pathogens reach this part of the respiratory tract, there is little to prevent them from damaging the lung's delicate exchange surfaces.

Alveolar Ducts and Alveoli

Respiratory bronchioles are connected to individual alveoli and to multiple alveoli along regions called **alveolar ducts**. Alveolar ducts end at **alveolar sacs** (*alveolar saccules*), common chambers connected to multiple individual alveoli (Figure 23–8a). Each lung contains about 150 million alveoli. They give the lungs an open, spongy appearance (Figure 23–8b).

Each alveolus is associated with an extensive network of capillaries (see Figure 23–8a). A network of elastic fibers surrounds the capillaries. These fibers help maintain the relative positions of the alveoli and respiratory bronchioles. When these fibers recoil during exhalation, they reduce the size of the alveoli and help push air out of the lungs.

The alveolar cell layer consists mainly of simple squamous epithelium (Figure 23–8c). The squamous epithelial cells, called **pneumocytes type I** (*type I alveolar cells*), are unusually thin and are the sites of gas diffusion. Roaming **alveolar macrophages** patrol the epithelial surface. They engulf any particles that have eluded other defenses. Large **pneumocytes type II** (*type II alveolar cells*) are scattered among the squamous cells. Pneumocytes type II produce **surfactant** (sur-FAK-tant), an oily secretion containing phospholipids and proteins. Surfactant plays a key role in keeping the alveoli open.

Surfactant reduces surface tension in the thin layer of water coating the alveolar surface. Recall from Chapter 2 that *surface tension* results from the attraction between water molecules at an air–water boundary. ↩ p. 36 Surface tension not only keeps small objects from entering the water, but it also tends to collapse small air bubbles. Without surfactant, surface tension would collapse the alveoli in much the same way. Surfactant interacts with the water molecules, reducing surface tension and preventing the collapse of the alveoli.

If pneumocytes type II produce inadequate amounts of surfactant due to injury or genetic abnormalities, the alveoli collapse after each exhalation. Respiration then becomes difficult. With each breath, the inhalation must be forceful enough

Figure 23–8 Alveolar Organization and the Blood Air Barrier.

d The blood air barrier.

? What type of muscle wraps around a respiratory bronchiole and can change the diameter of the airway?

to open the alveoli. A person without enough surfactant is soon exhausted by the effort of inflating and deflating the lungs. This condition is called *respiratory distress syndrome*.

The Blood Air Barrier

Gas exchange occurs across the three-layered **blood air barrier** of the alveoli (Figure 23 –8d). This barrier is made up of (1) the alveolar cell layer, (2) the capillary endothelial layer, and (3) the fused basement membrane between them.

Gas exchange can take place quickly and efficiently at the blood air barrier because only a very short distance separates alveolar air from blood. Diffusion proceeds very rapidly because the distance is short and both oxygen and carbon dioxide are small, lipid-soluble molecules. In addition, the surface area of the blood air barrier is very large.

Certain diseases can compromise the function of the blood air barrier. **Pneumonia** (nū-MŌ-nē-uh) develops from an infection or any particle that causes inflammation within the lung. As inflammation occurs, fluids leak into the alveoli. The respiratory bronchioles swell, narrowing passageways and restricting the passage of air. Respiratory function deteriorates as a result. When bacteria are involved, they are generally types that normally inhabit the mouth and pharynx but have managed to evade the respiratory defenses.

Pneumonia becomes more likely when the respiratory defenses have already been compromised by other factors. Such factors include epithelial damage from smoking and the breakdown of the immune system in AIDS. The respiratory defenses of healthy individuals prevent infection and tissue damage, but the breakdown of those defenses in AIDS can lead to a massive, potentially fatal lung infection. The most common pneumonia that develops in individuals with AIDS results from infection by the fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*).

Checkpoint

11. **What would happen to the alveoli if surfactant were not produced?**
12. **Trace the path air takes in flowing from the glottis to the blood air barrier.**

See the blue Answers tab at the back of the book.

23-5 Enclosed by pleural cavities, the lungs are paired organs made up of multiple lobes

Learning Outcome Describe the superficial anatomy of the lungs and the structure of a pulmonary lobule.

The lungs contain both the bronchial tree and the respiratory portion of the lower respiratory system. The left and right **lungs** are surrounded by the left and right *pleural cavities*, respectively (Figure 23–9a). In this section we look at the anatomy of the lungs, including their blood supply.

Anatomy of the Lungs

Each lung is a blunt cone. Its tip, or apex, points superiorly. The apex on each side extends superior to the first rib. The broad concave inferior portion, or base, of each lung rests on the superior surface of the diaphragm.

Lobes and Surfaces of the Lungs

The lungs have distinct **lobes** that are separated by deep fissures (Figure 23–9b,c). The right lung has three lobes—*superior*, *middle*, and *inferior*—separated by the *horizontal* and *oblique fissures*. The left lung has only two lobes—*superior* and *inferior*—separated by the *oblique fissure*. The right lung is broader than the left, because most of the heart and great vessels project into the left thoracic cavity. However, the left lung is longer than the right lung, because the diaphragm rises on the right side to accommodate the liver.

The heart is located to the left of the midline, so its corresponding impression is larger in the left lung than in the right. In the lateral view, the medial edge of the right lung forms a vertical line, but the medial margin of the left lung is indented at the **cardiac notch** (see Figure 23–9b). The relationship between the lungs and the heart is shown in Figure 23–10.

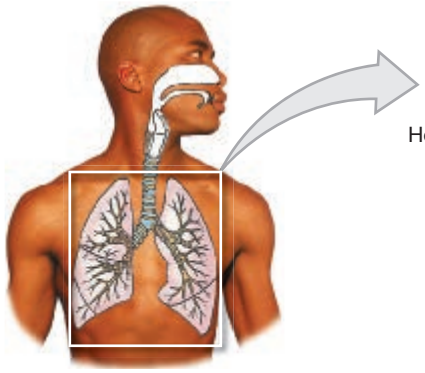
Along the mediastinal surface of each lung is a groove called the **hilum**. Each main bronchus travels along this groove. The hilum also provides access for entry to pulmonary vessels, nerves, and lymphatics (see Figure 23–9c). The entire array is firmly anchored in a meshwork of dense connective tissue. This complex is the **root of the lung** (look back at Figure 23–6a). The root attaches to the mediastinum and fixes the positions of the major nerves, blood vessels, and lymphatic vessels. The roots of the lungs are anterior to vertebrae T_5 (right) and T_6 (left).

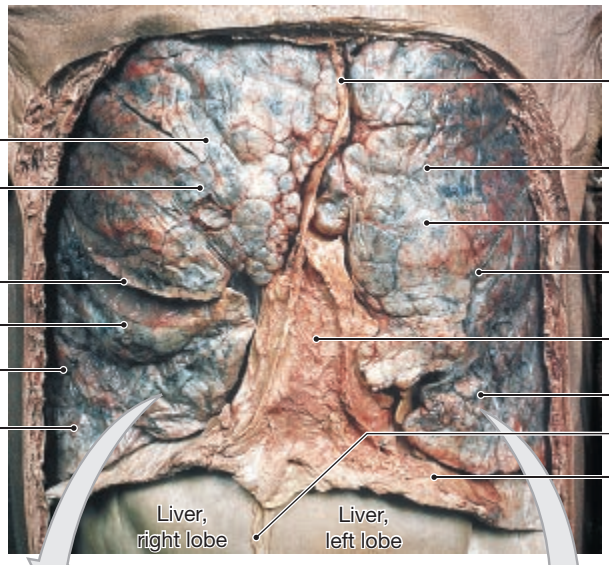
Pulmonary Lobules

The connective tissues of the root of each lung extend into the lung's *parenchyma*, or functional cells. These fibrous partitions, or *trabeculae*, contain elastic fibers, smooth muscles, and lymphatic vessels. The partitions branch repeatedly, dividing the lobes into ever-smaller compartments. The branches of the conducting passageways, pulmonary vessels, and nerves of the lungs follow these trabeculae.

The finest partitions, or **interlobular septa** (*septum*, a wall), divide the lung into **pulmonary lobules** (LOB-yūlz). Branches of the pulmonary arteries, pulmonary veins, and respiratory passageways supply each lobule. The connective tissues of the septa are, in turn, continuous with those of the *visceral pleura*, the serous membrane covering the lungs (see Figure 23–7).

Figure 23–9 The Gross Anatomy of the Lungs.
ATLAS: Plates 42–47

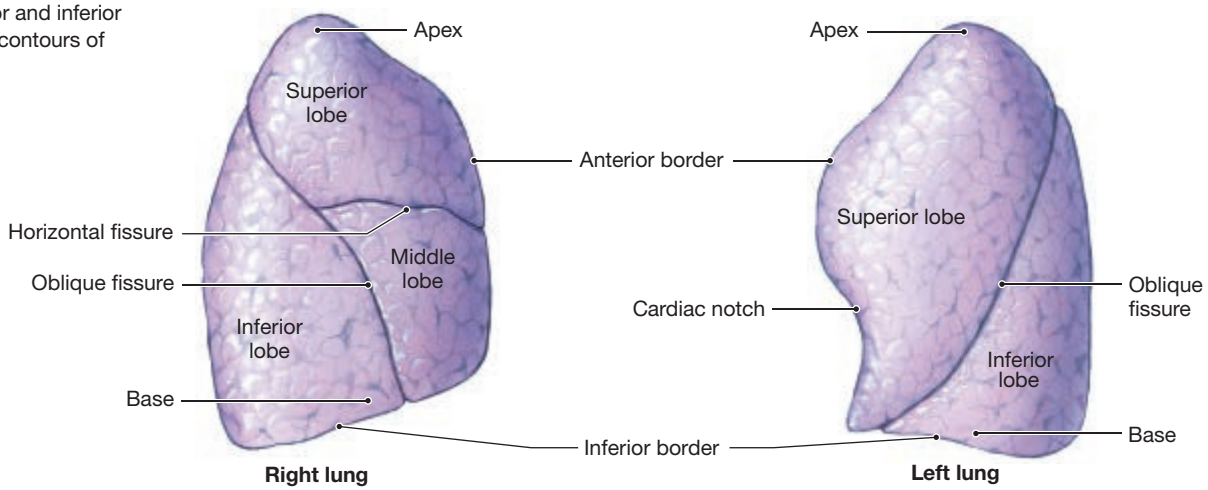




a Thoracic cavity, anterior view

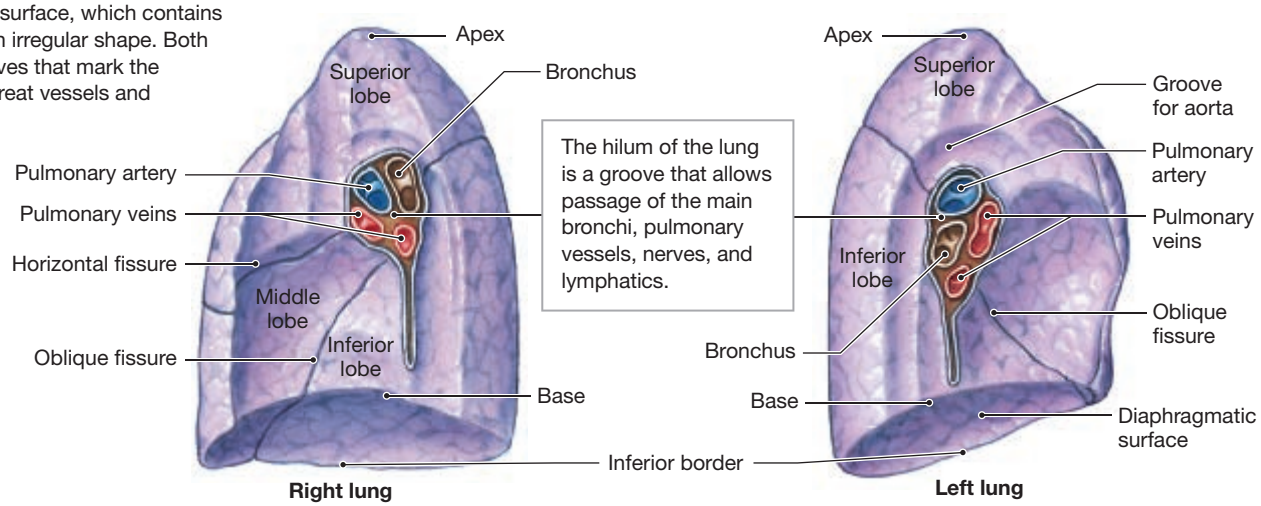
b Lateral Views

The curving anterior and inferior borders follow the contours of the rib cage.



c Medial Views

The mediastinal surface, which contains the hilum, has an irregular shape. Both lungs have grooves that mark the position of the great vessels and the heart.



? How many lobes does each lung have, and which lung has a cardiac notch?

Blood Supply to the Lungs

Two circuits nourish lung tissue. One supplies the *respiratory* portion of the lungs. The other perfuses the *conducting* portion.

The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The pulmonary arteries carry deoxygenated blood. They enter the lungs at the hilum and branch with the bronchi as they approach the lobules. Each lobule receives an arteriole and a venule, and a network of capillaries surrounds each alveolus as part of the blood air barrier. Oxygen-rich blood from the alveolar capillaries passes through the pulmonary venules and then enters the pulmonary veins, which deliver the blood to the left atrium.

In addition to providing for gas exchange, the endothelial cells of the alveolar capillaries are the primary source of *angiotensin-converting enzyme (ACE)*, which converts circulating angiotensin I to angiotensin II. This enzyme plays an important role in regulating blood volume and blood pressure. ↩ p. 750

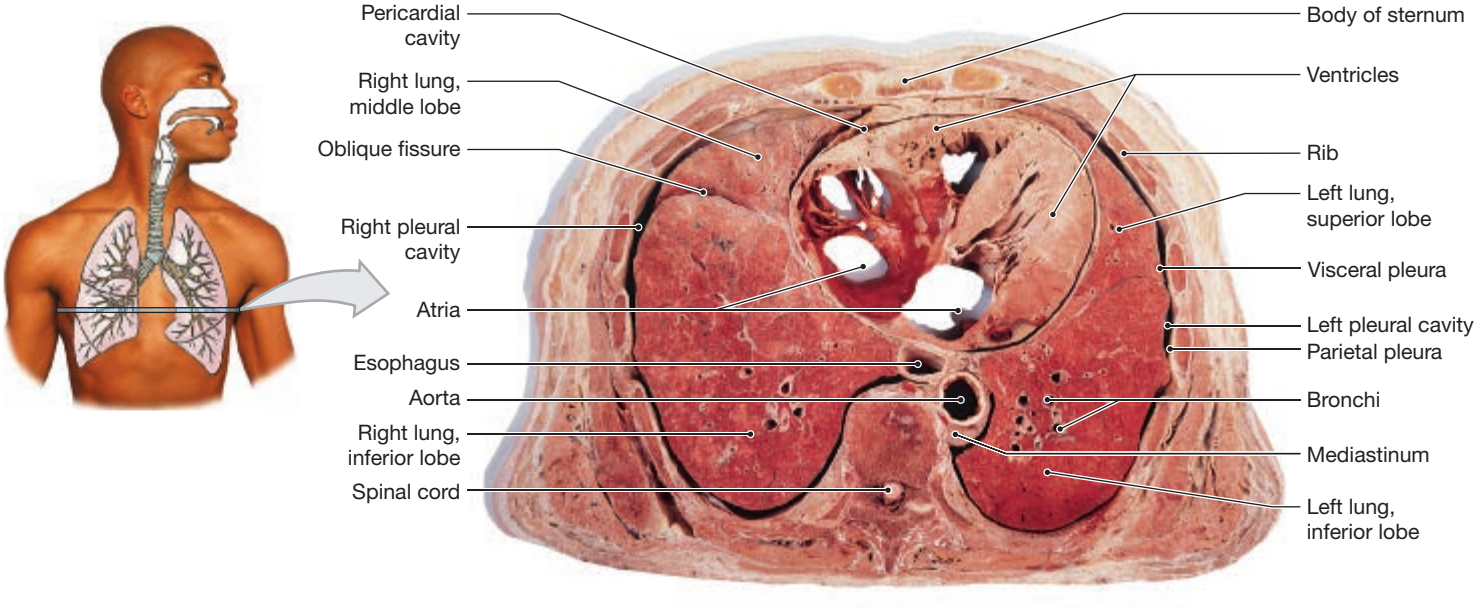
The conducting passageways receive oxygen and nutrients from bronchial capillaries supplied by the bronchial arteries, which branch from the thoracic aorta. ↩ p. 763 The venous blood from these bronchial capillaries may return to the heart by either the systemic circuit or pulmonary circuit. About one-eighth of the venous blood drains into bronchial veins, passes through the azygos, hemi-azygos, or highest intercostal vein, and enters the superior vena cava. The larger fraction of the venous blood enters anastomoses and drains into the pulmonary veins. This venous blood dilutes the oxygenated alveolar blood within the pulmonary veins.

Blood pressure in the pulmonary circuit is lower than that in the systemic circuit, so pulmonary vessels can easily become blocked by small blood clots, fat masses, or air bubbles in the pulmonary arteries. Because the lungs receive the entire cardiac output, any drifting objects in blood are likely to be trapped in the pulmonary arterial or capillary networks. Very small blood clots occasionally form in the venous system. These are usually trapped in the pulmonary (alveolar) capillary network, where they soon dissolve. Larger emboli are much more dangerous. Blocking a branch of a pulmonary artery stops blood flow to a group of lobules or alveoli. This condition is called a **pulmonary embolism**. If a pulmonary embolism is in place for several hours, the alveoli will permanently collapse. If the blockage occurs in a major pulmonary vessel rather than a minor branch, pulmonary resistance increases. The resistance places extra strain on the heart's right ventricle, which may be unable to maintain cardiac output, and congestive heart failure can result.

Pleural Cavities and Pleural Membranes

The thoracic cavity has the shape of a broad cone. Its walls are the rib cage, and the muscular diaphragm forms its floor. The two **pleural cavities** are separated by the mediastinum (Figure 23–10). Each lung is surrounded by a single pleural cavity, which is lined by a serous membrane called the **pleura** (PLOOR-uh; plural, *pleurae*). The pleura consists of two layers: the parietal pleura and the visceral pleura. The **parietal pleura** covers the inner surface of the thoracic wall

Figure 23–10 The Relationship between the Lungs and Heart. This transverse section was taken at the level of the cardiac notch.



and extends over the diaphragm and mediastinum. The **visceral pleura** covers the outer surfaces of the lungs, extending into the fissures between the lobes. Each pleural cavity actually represents a potential space rather than an open chamber, because the parietal and visceral pleurae are usually in close contact.

Both pleurae secrete a small amount of **pleural fluid**, a moist, slippery coating that lubricates. It reduces friction between the parietal and visceral surfaces as you breathe. Samples of pleural fluid, obtained through a long needle inserted between the ribs, are sometimes needed for diagnostic purposes. This sampling procedure is called *thoracentesis* (thōr-a-sen-TĒ-sis; *thora-*, thoracic + *centesis*, puncture). The extracted fluid is examined for bacteria, blood cells, or other abnormal components.

In some diseases, the normal coating of pleural fluid does not prevent friction between the pleural surfaces. The result is pain and pleural inflammation, a condition called *pleurisy*. When pleurisy develops, pleural fluid secretion may be excessive, or the inflamed pleurae may adhere to one another, limiting movement. In either case, breathing becomes difficult, and prompt medical attention is required.

23-6 External respiration and internal respiration allow gas exchange within the body

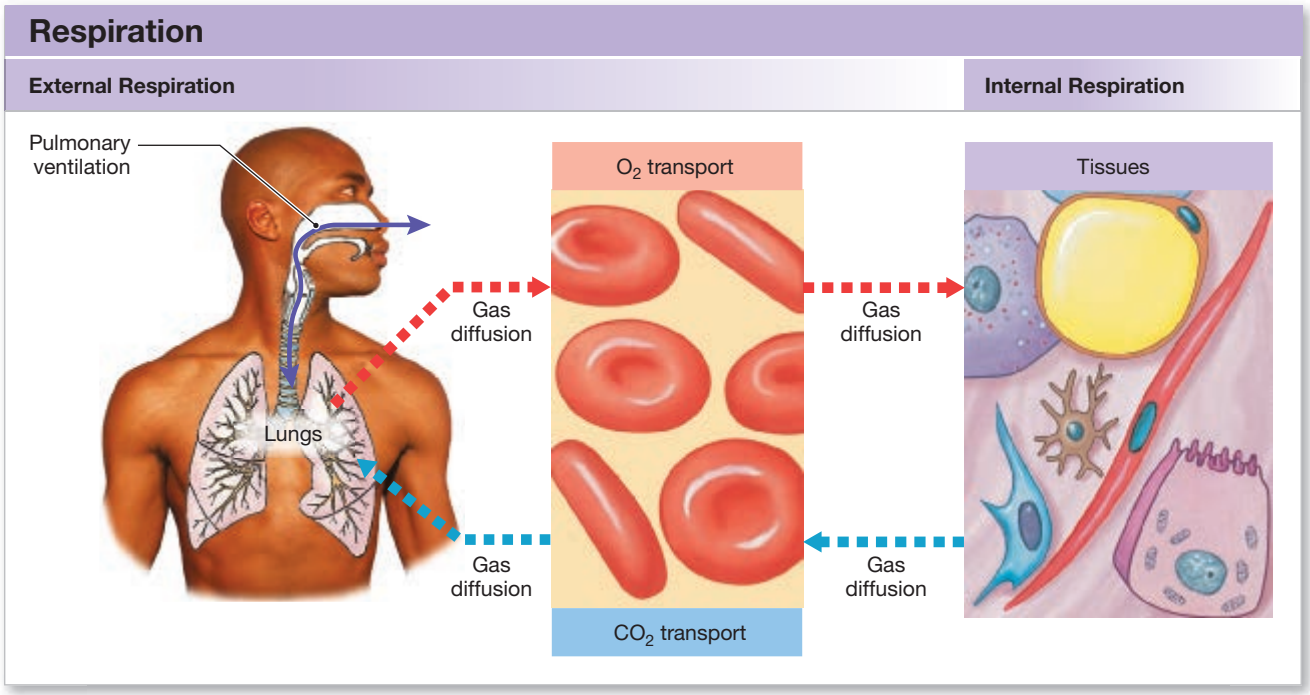
Learning Outcome Define and compare the processes of external respiration and internal respiration.

The general term **respiration** includes two integrated processes: *external respiration* and *internal respiration*. The definitions of these terms vary among references. In our discussion, **external respiration** includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. The purpose of external respiration—and the primary function of the respiratory system—is to meet the respiratory demands of cells. **Internal respiration** is the absorption of oxygen and the release of carbon dioxide by those cells. We consider the biochemical pathways responsible for oxygen consumption and for the generation of carbon dioxide by mitochondria—pathways known collectively as *cellular respiration*—in Chapter 25.

Our discussion here focuses on three integrated steps in external respiration (Figure 23–11):

- *Pulmonary ventilation*, or breathing, which physically moves air into and out of the lungs
- *Gas diffusion* across the blood air barrier between alveolar air spaces and alveolar capillaries, and across capillary walls between blood and other tissues
- *Transport of oxygen and carbon dioxide* between alveolar capillaries and capillary beds in other tissues.

Figure 23–11 An Overview of the Key Steps in Respiration.



Abnormalities affecting any of the steps involved in external respiration ultimately affect the concentration of gases in interstitial fluids, and thus cellular activities. If the oxygen level declines, the affected tissues will become starved for oxygen. **Hypoxia**, or a low tissue oxygen level, places severe limits on the metabolic activities of the affected area. For example, the effects of coronary ischemia result from chronic hypoxia affecting cardiac muscle cells. ↩ p. 700 If the oxygen supply is cut off completely, the condition called **anoxia** (an-OK-sē-uh; *an-*, without + *oxy-*, oxygen) results. Anoxia kills cells very quickly. Much of the damage from strokes and heart attacks results from local anoxia.

In the sections that follow, we examine each of the processes involved in external respiration in greater detail.

23-7 Pulmonary ventilation—air exchange between the atmosphere and the lungs—involves muscle actions and volume changes that cause pressure changes

Learning Outcome Summarize the physical principles controlling the movement of air into and out of the lungs, and describe the actions of the respiratory muscles.

Pulmonary ventilation (breathing) is the physical movement of air into and out of the respiratory tract. Its primary function is to maintain adequate *alveolar ventilation*—movement of air into and out of the alveoli. Alveolar ventilation prevents the buildup of carbon dioxide in the alveoli. It also ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream.

An Introduction to Airflow

Some basic physical principles govern the movement of air. One of the most basic is that the weight of Earth's atmosphere, the **atmospheric pressure (atm)**, compresses our bodies and everything around us. Let's look at the role of atmospheric pressure on breathing.

Airflow and Pressure Gradients

The presence of atmospheric pressure has several important physiological effects. For example, air moves into and out of the respiratory tract due to pressure gradients, as the air pressure in the lungs cycles between below atmospheric pressure and above atmospheric pressure. In other words, air flows from an area of higher pressure to an area of lower pressure.

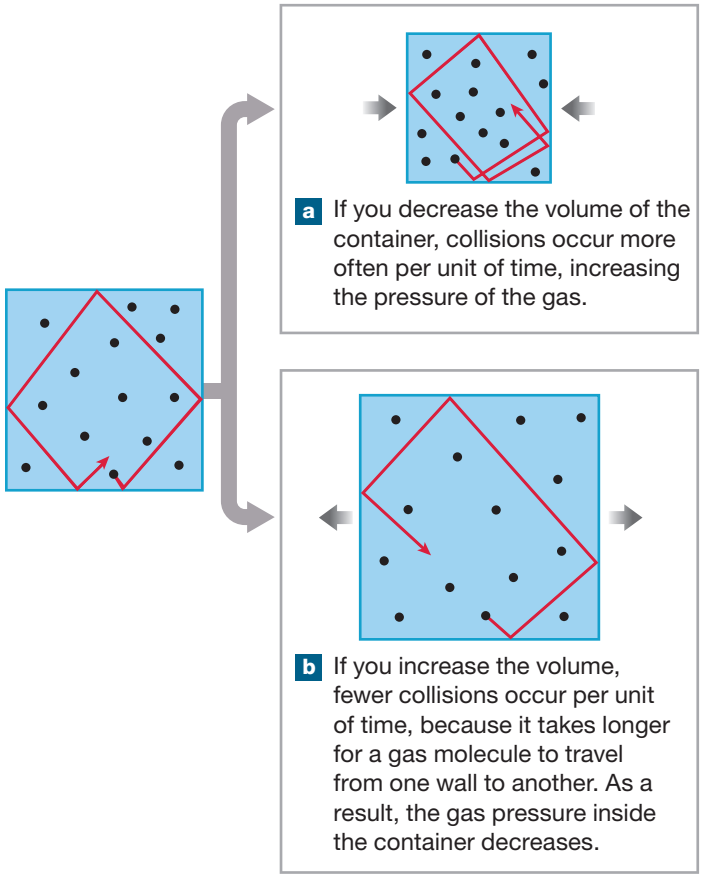
The Relationship between Gas Pressure and Volume (Boyle's Law)

The primary differences between liquids and gases reflect the interactions among individual molecules. The molecules in a liquid are in constant motion, but they are held closely together by weak interactions, such as the hydrogen bonding between adjacent water molecules. ↩ p. 36 Yet because the electrons of adjacent atoms tend to repel one another, liquids tend to resist compression. If you squeeze a balloon filled with water, it will change into a different shape, but the volumes of the two shapes will be the same.

In a gas, such as air, the molecules bounce around as independent objects. At normal atmospheric pressures, gas molecules are much farther apart than the molecules in a liquid. The forces acting between gas molecules are minimal because the molecules are too far apart for weak interactions to take place, so an applied pressure can push them closer together. Consider a sealed container of air at atmospheric pressure. The pressure exerted by the gas inside results from gas molecules bumping into the walls of the container. The greater the number of collisions, the higher the pressure.

You can change the gas pressure within a sealed container by changing the volume of the container, giving the gas molecules more or less room to bounce around. If you decrease the volume of the container, pressure increases (Figure 23–12a).

Figure 23–12 The Relationship between Gas Pressure and Volume.



If you increase the volume of the container, pressure decreases (Figure 23–12b).

For a gas in a closed container and at a constant temperature, pressure (P) is inversely proportional to volume (V). That is, *if you decrease the volume of a gas, its pressure will increase. If you increase the volume of a gas, its pressure will decrease*. In particular, the relationship between pressure and volume is reciprocal: If you double the external pressure on a flexible container, its volume will drop by half, and if you reduce the external pressure by half, the volume of the container will double. This relationship, $P = 1/V$, is called **Boyle's law** because it was first recognized by Robert Boyle in the 1600s.

Overview of Pulmonary Ventilation: Volume Changes and Pressure Gradients

The tendency of air to flow in response to pressure gradients, plus the pressure–volume relationship of Boyle's law, provides the basis for pulmonary ventilation. A single **respiratory cycle** consists of an *inspiration*, or inhalation, and an *expiration*, or exhalation. Inhalation and exhalation involve changes in the volume of the lungs. These volume changes create pressure gradients that move air into or out of the respiratory tract.

Each lung is surrounded by a pleural cavity. The parietal and visceral pleurae are separated by only a thin film of pleural fluid. The two membranes can slide across one another, but they are held together by that fluid film. You can see the same principle when you set a wet glass on a smooth tabletop. You can slide the glass easily, but when you try to lift it, you feel considerable resistance. As you pull the glass away from the tabletop, you create a powerful suction. The only way to overcome it is to tilt the glass so that air is pulled between the glass and the table, breaking the fluid bond.

A comparable fluid bond exists between the parietal pleura and the visceral pleura covering the lungs. For this reason, the surface of each lung sticks to the inner wall of the chest and to the superior surface of the diaphragm. Movements of the diaphragm or rib cage that change the volume of the thoracic cavity also change the volume of the lungs (Spotlight Figure 23–13):

- The diaphragm forms the floor of the thoracic cavity. The relaxed diaphragm has the shape of a dome that projects superiorly into the thoracic cavity. When the diaphragm contracts, it tenses and moves inferiorly. This movement increases the volume of the thoracic cavity, decreasing the pressure within it. When the diaphragm relaxes, it returns to its original position, and the volume of the thoracic cavity decreases.
- Due to the nature of the articulations between the sternum and ribs and between the ribs and vertebrae, raising the rib cage involves both superior and anterior movements. These movements increase both the depth and width of the thoracic cavity, increasing its volume. Return of the rib cage to its original position reverses the process, decreasing the volume of the thoracic cavity.

At rest just prior to inhalation, pressures inside and outside the thoracic cavity are identical, and no air moves into or out of the lungs (see Spotlight Figure 23–13). When the thoracic cavity enlarges, the lungs expand to fill the additional space. This increase in volume decreases the pressure inside the lungs. Air then enters the respiratory passageways, because the pressure inside the lungs (P_{inside}) is lower than atmospheric pressure ($P_{outside}$). Air continues to enter the lungs until their volume stops increasing and the internal pressure is the same as that outside. When the thoracic cavity decreases in volume, pressures increase inside the lungs, forcing air out of the respiratory tract.

Actions of the Respiratory Muscles

The most important muscles involved in breathing are the *diaphragm* and the *external intercostals*. These muscles are the **primary respiratory muscles** and are active during normal breathing at rest. The **accessory respiratory muscles** become active when the depth and frequency of breathing must be greatly increased (Figure 23–14).

Muscles Used in Inhalation

Inhalation is an active process. It involves one or more of the following actions:

- Contraction of the diaphragm flattens the floor of the thoracic cavity, increasing its volume and drawing air into the lungs. Contraction of the diaphragm contributes about 75% of the volume of air in the lungs at rest.
- Contraction of the external intercostal muscles assists in inhalation by raising the ribs. This action contributes approximately 25% of the volume of air in the lungs at rest.
- Contraction of accessory muscles, including the sternocleidomastoid, scalenes, pectoralis minor, and serratus anterior, can assist the external intercostal muscles in elevating the ribs. These muscles increase the speed and amount of rib movement.

Muscles Used in Exhalation

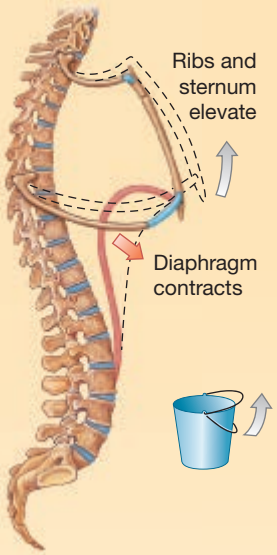
Exhalation is either passive or active, depending on the level of respiratory activity. When exhalation is active, it may involve one or more of the following actions:

- The internal intercostal muscle and transversus thoracis depress the ribs. This action reduces the width and depth of the thoracic cavity.
- The abdominal muscles, including the external and internal oblique, transversus abdominis, and rectus abdominis, can assist the internal intercostal muscles in exhalation by compressing the abdomen. This action forces the diaphragm upward.

SPOTLIGHT

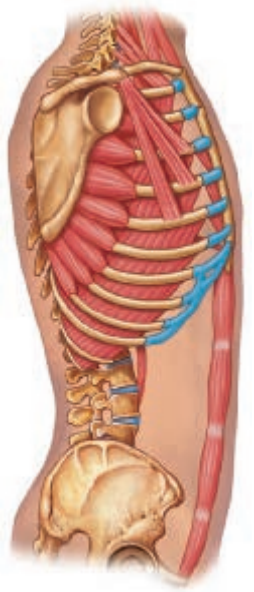
Figure 23–13
Pulmonary Ventilation

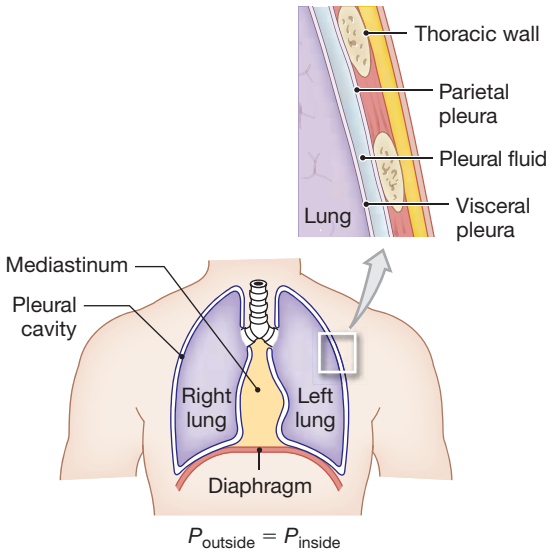
Pulmonary ventilation, or breathing, is the movement of air into and out of the respiratory system. It occurs by changing the volume of the lungs. Changes in lung volume take place through the contraction of skeletal muscles. The most important respiratory muscles are the diaphragm and the external intercostal muscles.



As the diaphragm is contracted or the rib cage (ribs and sternum) is elevated, the volume of the thoracic cavity increases and air moves into the lungs. The anterior movement of the ribs and sternum as they are elevated resembles the outward swing of a raised bucket handle.

AT REST

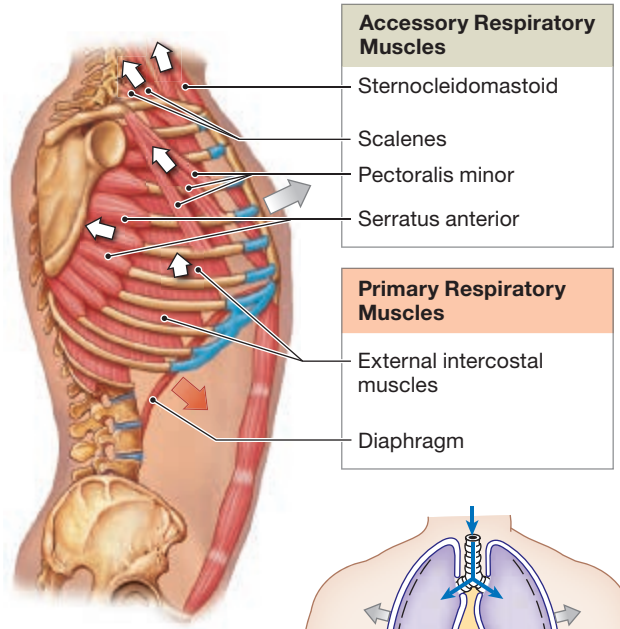




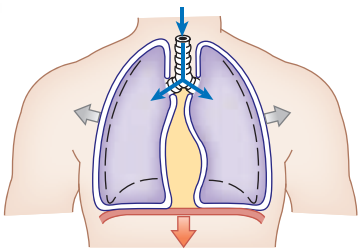
$P_{outside} = P_{inside}$

When the rib cage and diaphragm are at rest, the pressures inside and outside the lungs are equal, and no air movement occurs.

INHALATION



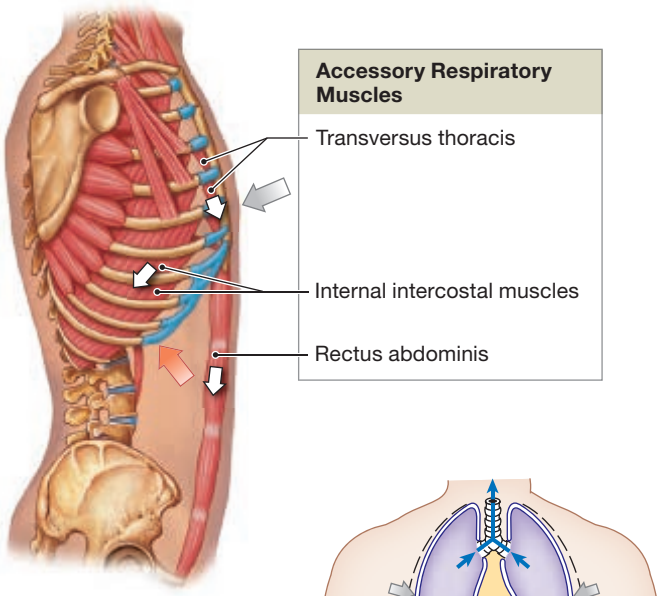
Elevation of the rib cage and contraction of the diaphragm increase the volume of the thoracic cavity. Pressure within the lungs decreases, and air flows in.



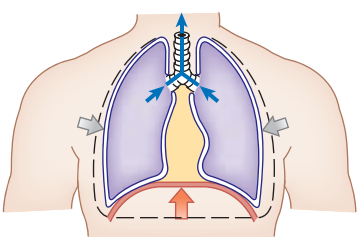
Thoracic cavity volume increases

$P_{outside} > P_{inside}$

EXHALATION



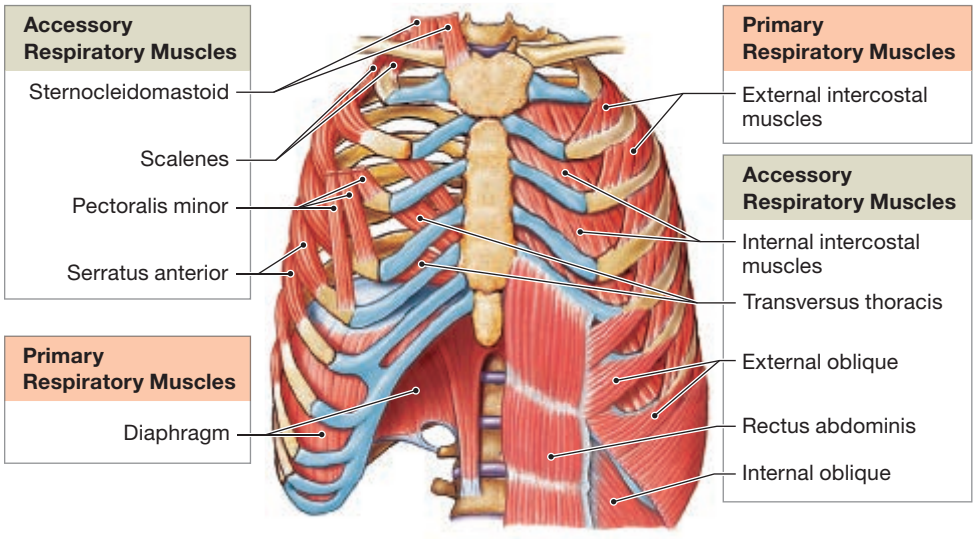
When the rib cage returns to its original position and the diaphragm relaxes, the volume of the thoracic cavity decreases. Pressure within the lungs increases, and air moves out.



Thoracic cavity volume decreases

$P_{outside} < P_{inside}$

Figure 23–14 Primary and Accessory Respiratory Muscles.



? Name the primary muscles of respiration.

Volume Changes in Pulmonary Ventilation

During pulmonary ventilation, we use the respiratory muscles in various combinations, depending on the volume of air that must be moved into or out of the system. We usually classify respiratory movements as *quiet breathing* or *forced breathing* according to the pattern of muscle activity during a single respiratory cycle.

Volume Changes in Quiet Breathing

In **quiet breathing**, or **eupnea** (YŪP-nē-uh; *eu-*, normal + *-pnea*, breath), inhalation involves muscular contractions, but exhalation is a passive process. Inhalation usually involves contracting both the diaphragm and the external intercostal muscles. The relative contributions of these muscles can vary:

- During **diaphragmatic breathing**, or **deep breathing**, contraction of the diaphragm provides the necessary change in thoracic volume. Air is drawn into the lungs as the diaphragm contracts. Air is exhaled passively when the diaphragm relaxes.
- In **costal breathing**, or **shallow breathing**, the thoracic volume changes because the rib cage alters its shape. Inhalation takes place when contractions of the external intercostal muscles raise the ribs and enlarge the thoracic cavity. Exhalation takes place passively when these muscles relax.

During quiet breathing, expansion of the lungs stretches their elastic fibers. In addition, elevation of the rib cage stretches opposing skeletal muscles and elastic fibers in the connective tissues of the body wall. When the muscles of inhalation relax, these elastic components recoil, returning the diaphragm, the rib cage, or both to their original positions. This action is called **elastic rebound**.

We typically use diaphragmatic breathing at minimal levels of activity. As we need increased volumes of air, our inspiratory movements become larger and the contribution of rib movement increases. Even when we are at rest, costal breathing can predominate when abdominal pressures, fluids, or masses restrict diaphragmatic movements. For example, pregnant women rely more and more on costal breathing as the enlarging uterus pushes the abdominal organs against the diaphragm.

Volume Changes in Forced Breathing

Forced breathing, or **hyperpnea** (hī-PERP-nē-uh), involves active inspiratory and expiratory movements. In forced breathing, our accessory muscles assist with inhalation, and exhalation involves contraction of the internal intercostal muscles. At an absolute maximum level of forced breathing, our abdominal muscles take part in exhalation. Their contraction compresses the abdominal contents, pushing them up against the diaphragm. This action further reduces the volume of the thoracic cavity.

Pressure Gradients in Pulmonary Ventilation

Let's look more closely at the pressures inside and outside the respiratory tract. We know outside is made up only of atmospheric pressure, but the pressure inside the lungs has several different components. We use millimeters of mercury (mm Hg) to measure these pressures, as we did for blood pressure. Atmospheric pressure is also measured in *atmospheres*. At sea level, 1 atmosphere (atm) of pressure is equivalent to 760 mm Hg.

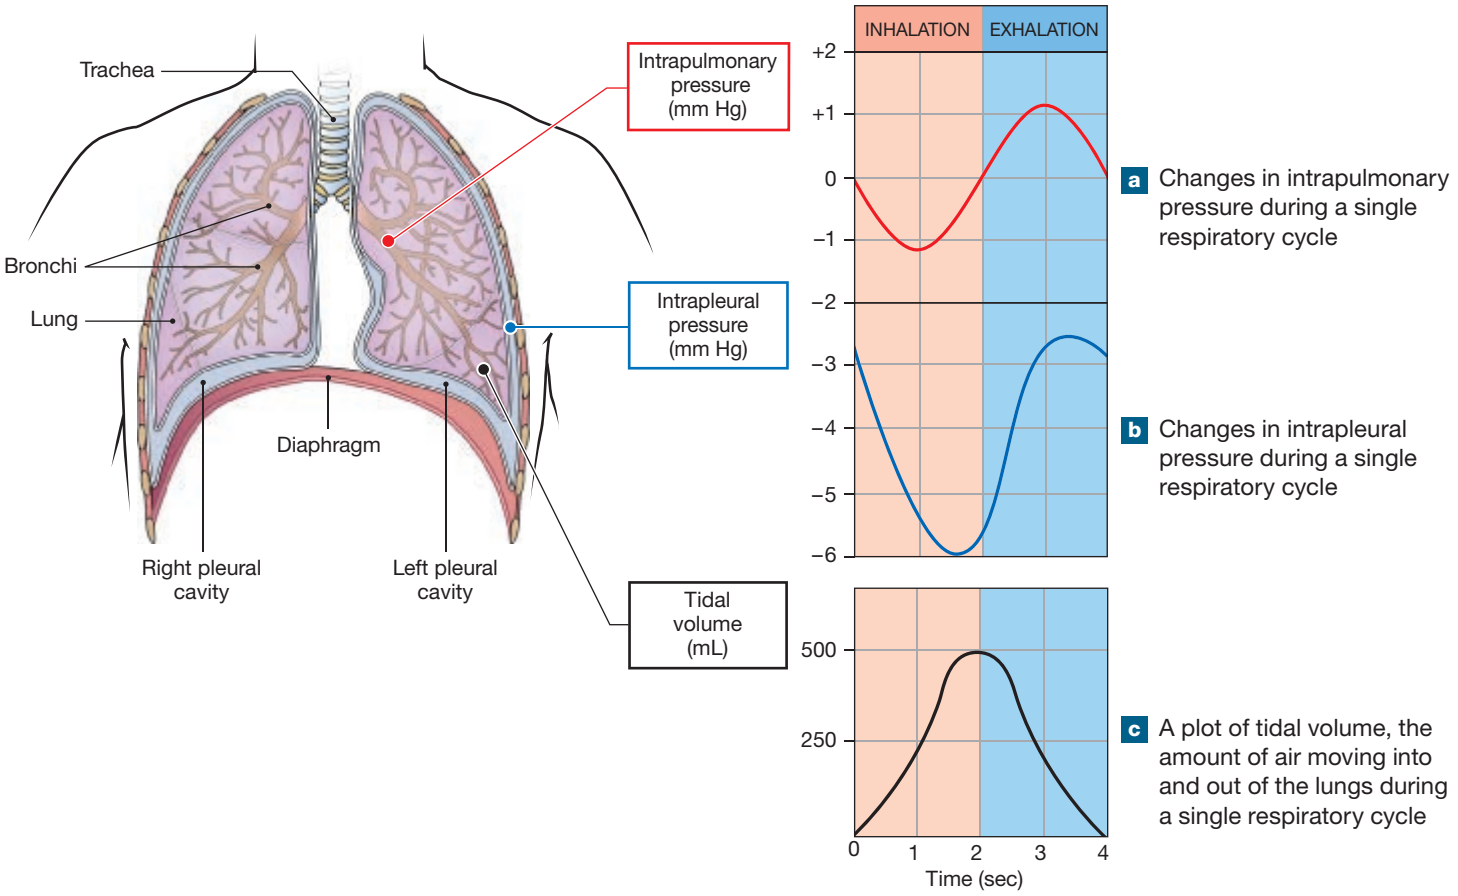
Intrapulmonary Pressure

The direction of airflow is determined by the relationship between atmospheric pressure and intrapulmonary pressure. **Intrapulmonary** (in-tra-PUL-mo-nār-ē) **pressure**, or **intra-alveolar** (in-tra-al-VĒ-ō-lar) **pressure**, is the pressure inside the respiratory tract, at the alveoli.

When you are relaxed and breathing quietly, the difference between atmospheric pressure and intrapulmonary pressure is relatively small. On inhalation, your lungs expand, and the intrapulmonary pressure drops to about 759 mm Hg. Because the intrapulmonary pressure is 1 mm Hg below atmospheric pressure, it is generally reported as −1 mm Hg. On exhalation, your lungs recoil, and intrapulmonary pressure rises to 761 mm Hg, or +1 mm Hg (Figure 23–15a).

The size of the pressure gradient increases when you breathe heavily. When a trained athlete breathes at maximum

FIGURE 23–15 Pressure and Volume Changes during Inhalation and Exhalation. One sequence of inhalation and exhalation makes up a single respiratory cycle.



capacity, the pressure differentials can reach –30 mm Hg during inhalation and +100 mm Hg if the individual is straining with the glottis kept closed. This is one reason you are told to exhale while lifting weights. Exhaling keeps your intrapulmonary pressures and peritoneal pressure from increasing so high that an alveolar rupture or hernia could occur.

23

Intrapleural Pressure

Intrapleural pressure is the pressure in the pleural cavity, between the parietal and visceral pleurae. Intrapleural pressure averages about −4 mm Hg (Figure 23–15b). During a powerful inhalation, it can reach –18 mm Hg. This pressure is below atmospheric pressure, due to the relationship between the lungs and the body wall.

Earlier, we noted that the lungs are highly elastic. In fact, they would collapse to about 5% of their normal resting volume if their elastic fibers could recoil completely. The elastic fibers cannot recoil so much, however. The reason is that they are not strong enough to overcome the fluid bond between the parietal and visceral pleurae. The elastic fibers continuously oppose that fluid bond and pull the lungs away from the chest wall and diaphragm, lowering the intrapleural pressure slightly. The elastic fibers remain stretched even after a full exhalation. For this reason, intrapleural pressure remains below atmospheric pressure throughout normal cycles of inhalation and exhalation. The cyclical changes in the intrapleural pressure create the *respiratory pump* that assists the venous return to the heart. ↩ p. 741

+ Clinical Note Pneumothorax

Air can enter the pleural cavity due to an injury to the chest wall that penetrates the parietal pleura, or a rupture of the alveoli that breaks through the visceral pleura. This condition, called **pneumothorax** (nū-mō-THOR-aks; *pneumo-*, air), breaks the fluid bond between the pleurae and allows the elastic fibers to recoil, resulting in a "collapsed lung," or **atelectasis** (at-e-LEK-ta-sis; *ateles*, incomplete + *ektasis*, extension). The other lung is not affected because it is enclosed by a separate pleura. The treatment for a collapsed lung involves putting a needle into the cavity and drawing out the air. This treatment lowers the intrapleural pressure and reinflates the lung.

Summary of Volume Changes and Pressure Gradients during a Respiratory Cycle

As we have just seen, you move air into and out of the respiratory system by changing the volume of the lungs. Those changes alter the pressure relationships, producing air movement. The curves in Figure 23–15a,b show the intrapulmonary and intrapleural pressures during a single respiratory cycle of an individual at rest. The graph in Figure 23–15c plots the *tidal volume*, the amount of air you move into or out of your lungs during a single respiratory cycle.

Tips & Tools

Tidal volume floods and ebbs like the ocean *tides*.

At the start of the respiratory cycle, the intrapulmonary and atmospheric pressures are equal, and no air is moving. Inhalation begins when the thoracic cavity expands, causing a fall of intrapleural pressure. This pressure gradually falls to approximately –6 mm Hg. Over this period, intrapulmonary pressure drops to just under –1 mm Hg. It then begins to rise as air flows into the lungs.

When exhalation begins, intrapleural and intrapulmonary pressures rise rapidly, forcing air out of the lungs. At the end of exhalation, air again stops moving when the difference between intrapulmonary and atmospheric pressures has been eliminated. The amount of air moved into the lungs during inhalation, the tidal volume, equals the amount moved out of the lungs during exhalation.

Physical Factors Affecting Pulmonary Ventilation

Bronchodilation and bronchoconstriction are ways of adjusting the **resistance** to airflow. These actions direct airflow toward or away from specific portions of the respiratory exchange surfaces.

Recall that pneumocytes type II secrete surfactant onto the alveolar surfaces to reduce surface tension. Surface tension is the reason small air bubbles in water collapse. Without surfactant, alveoli collapse in much the same way. The thin surface layer of surfactant interacts with the water molecules, keeping the alveoli open.

Tips & Tools

The term ***surfactant*** is derived from its purpose as a ***surf***ace **act**ive **a**gen***t***.

The **compliance** of the lungs is a measure of their expandability, or how easily the lungs expand in response to applied pressure. The lower the compliance, the greater the force required to fill the lungs. The greater the compliance, the easier it is to fill the lungs. Factors affecting compliance include the following:

- *The Connective Tissue of the Lungs.* The loss of supporting tissues due to alveolar damage, as in *emphysema*, increases compliance. This loss results in the alveoli increasing beyond their normal size, making the lungs easier to fill.
- *The Level of Surfactant Production.* On exhalation, the collapse of alveoli due to inadequate surfactant, as in respiratory distress syndrome, reduces compliance.
- *The Mobility of the Thoracic Cage.* Arthritis or other skeletal disorders that affect the articulations of the ribs or spinal column also reduce compliance.

At rest, the muscular activity involved in pulmonary ventilation accounts for 3–5% of the resting energy demand. If compliance is reduced, that figure climbs dramatically. An individual may become exhausted simply trying to continue breathing.

Measuring Respiratory Rates and Volumes

The respiratory system is extremely adaptable. You can be breathing slowly and quietly one moment, rapidly and deeply the next. The respiratory system adapts to meet the oxygen demands of the body by varying both the number of breaths per minute and the amount of air moved per breath. When you exercise at peak levels, the amount of air moving into and out of the respiratory tract can be 50 times the amount moved at rest.

Respiratory Rate

Your **respiratory rate** is the number of breaths you take each minute. As you read this, you are probably breathing quietly, with a low respiratory rate. The normal respiratory rate of a resting adult ranges from 12 to 18 breaths each minute, roughly one for every four heartbeats. Children breathe more rapidly, at rates of about 18–20 breaths per minute.

Respiratory Volumes

Recall that the **tidal volume**, symbolized V_T, is the amount of air moved into or out of the lungs during a single respiratory cycle. Let's look at the volumes that make up the tidal volume.

The Respiratory Minute Volume ($\dot{V}_E$). We can calculate the amount of air moved each minute, symbolized $\dot{V}_E$, by multiplying the respiratory rate f by the tidal volume V_T. This value is called the **respiratory minute volume**. The respiratory rate at rest averages 12 breaths per minute, and the tidal volume at rest averages around 500 mL per breath. On that basis, we calculate the respiratory minute volume as follows:

$$\begin{pmatrix}\dot{V}_E \\ \text{Volume of air moved} \\ \text{each minute}\end{pmatrix} = \begin{pmatrix} f \\ \text{breaths per} \\ \text{minute}\end{pmatrix} \times \begin{pmatrix} V_T \\ \text{tidal} \\ \text{volume}\end{pmatrix}$$

$$= 12 \text{ per minute} \times 500 \text{ mL}$$
$$= 6000 \text{ mL per minute}$$
$$= 6.0 \text{ liters per minute}$$

In other words, the respiratory minute volume at rest is approximately 6 liters per minute.

Alveolar Ventilation (V_A). The respiratory minute volume measures pulmonary ventilation. It provides an indication of how much air is moving into and out of the respiratory tract. However, only some of the inhaled air reaches the alveolar exchange surfaces. A typical inhalation pulls about 500 mL of air into the respiratory system. The first 350 mL of inhaled air travels along the conducting passageways and enters the alveolar spaces. The last 150 mL of inhaled air never gets that far. It stays in the conducting passageways and thus does not participate in gas exchange with blood. This "lagging" volume of air in the conducting passages is known as the **anatomic dead space**, denoted V_D. To calculate the anatomic dead space, multiply the tidal volume by 0.3. The example calculation below shows that with a tidal volume of 500 mL, anatomic dead space equals 150 mL.

$$V_D = V_T \times 0.3$$

$$V_D = 500\ mL \times 0.3 = 150\ mL$$

Alveolar ventilation, symbolized $\dot{V}_A$, is the amount of air reaching the alveoli each minute. The alveolar ventilation is less than the respiratory minute volume because some of the air never reaches the alveoli; it instead remains in the dead space of the lungs. We can calculate alveolar ventilation by subtracting the dead space from the tidal volume:

$$\dot{V}_A = f \times (\dot{V}_T - V_D)$$

$$\begin{pmatrix}\text{Alveolar}\\ \text{ventilation}\end{pmatrix} = \begin{pmatrix}\text{breaths}\\ \text{per minute}\end{pmatrix} \times \begin{pmatrix}\text{tidal}\\ \text{volume}\end{pmatrix} - \begin{pmatrix}\text{anatomic}\\ \text{dead space}\end{pmatrix}$$

At rest, alveolar ventilation rates are approximately 4.2 liters per minute (12 per minute × 350 mL). However, the gas arriving in the alveoli is significantly different from the surrounding atmosphere. The reason is that inhaled air always mixes with "used" air in the conducting passageways on its way in. The air in alveoli thus contains less oxygen and more carbon dioxide than does atmospheric air.

Relationships among Tidal Volume (V_T), ($\dot{V}_E$), and ($\dot{V}_A$). The respiratory minute volume can be increased by increasing either the tidal volume or the respiratory rate. In other words, you can breathe more deeply or more quickly or both. Under maximum stimulation, the tidal volume can increase to roughly 4800 mL, or 4.8 liters. At peak respiratory rates of 40–50 breaths per minute and maximum cycles of inhalation and exhalation, the respiratory minute volume can approach 200 liters per minute.

In functional terms, the alveolar ventilation rate is more important than the respiratory minute volume, because it determines the rate of delivery of oxygen to the alveoli. The respiratory rate and the tidal volume together determine the alveolar ventilation rate:

- For a given respiratory rate, increasing the tidal volume (breathing more deeply) increases the alveolar ventilation rate.
- For a given tidal volume, increasing the respiratory rate (breathing more quickly) increases the alveolar ventilation rate.

The alveolar ventilation rate can change independently of the respiratory minute volume. In our previous example, the respiratory minute volume at rest was 6 liters and the alveolar ventilation rate was 4.2 L/min. If the respiratory rate rises to 20 breaths per minute, but the tidal volume drops to 300 mL, the respiratory minute volume remains the same ($20 \times 300 = 6000$). However, the alveolar ventilation rate drops to only 3 L/min ($20 \times [300 - 150] = 3000$). For this reason, whenever the demand for oxygen increases, both the tidal volume *and* the respiratory rate must be regulated closely. (We focus on the mechanisms involved in a later section.)

Respiratory Performance and Volume Relationships

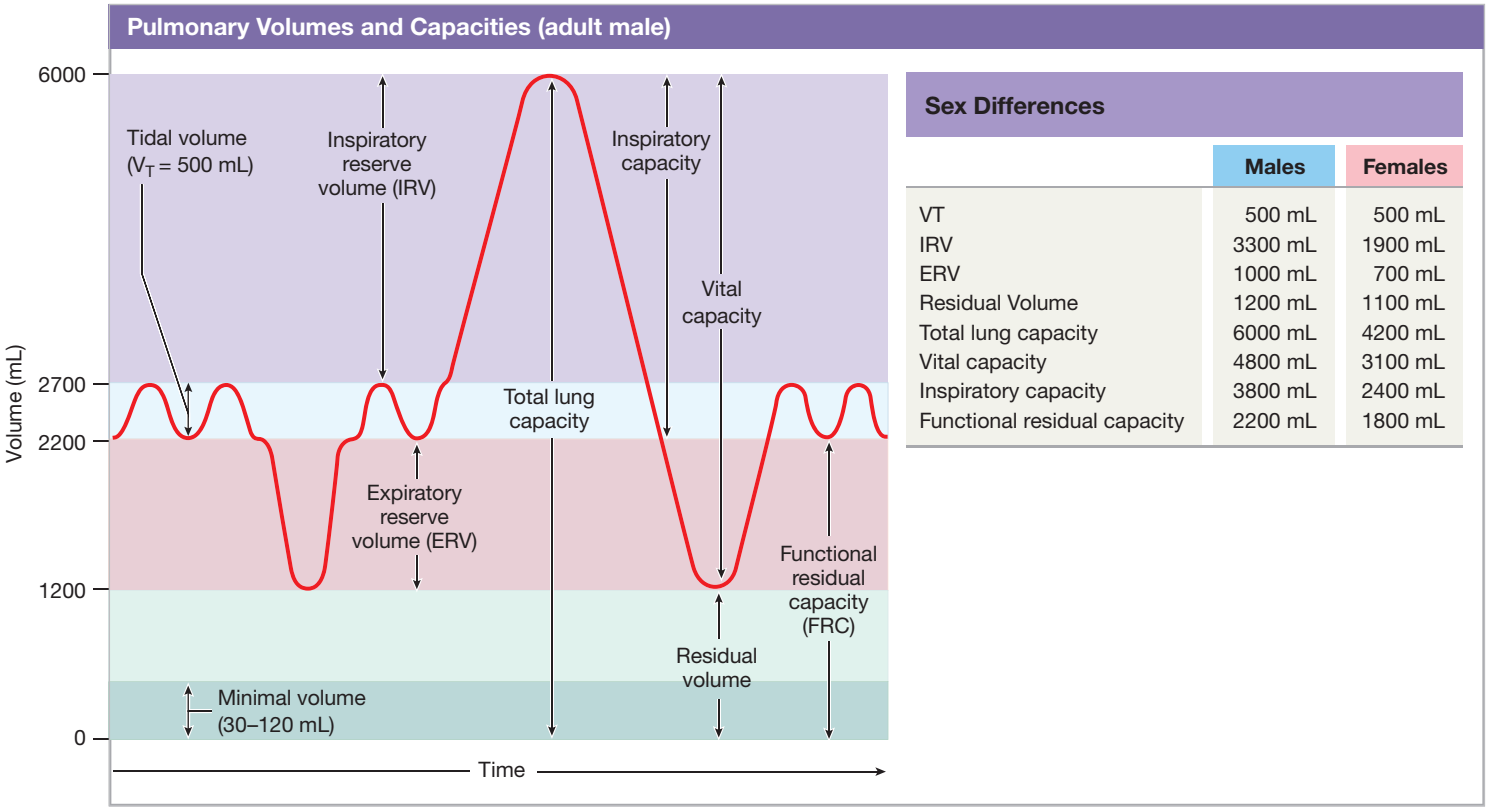
Pulmonary function tests monitor several aspects of respiratory function by measuring rates and volumes of air movement. We exchange only a small proportion of the air in our lungs during a single quiet respiratory cycle. We can increase the tidal volume by inhaling more vigorously and exhaling more completely.

We can divide the total volume of the lungs into a series of *volumes* and *capacities* (each the sum of various volumes), as indicated in Figure 23–16. These measurements are obtained by an instrument called a **spirometer**. Spirometry values are useful in diagnosing problems with pulmonary ventilation. Adult females, on average, have smaller bodies and thus smaller lung volumes than do males. As a result, there are sex-related differences in respiratory volumes and capacities. The table in the figure shows representative values for both sexes.

Pulmonary volumes include the following:

- The **tidal volume (V_T)**, which we have already covered, is the amount of air you move into or out of your lungs during a single respiratory cycle. The tidal volume averages about 500 mL in both males and females.
- The **expiratory reserve volume (ERV)** is the amount of air that you can voluntarily expel after you have completed a normal, quiet respiratory cycle. As an example, with maximum use of the accessory muscles, males can expel an additional 1000 mL of air, on average. Female expiratory reserve volume averages 700 mL.
- The **residual volume** is the amount of air that remains in your lungs even after a maximal exhalation—typically about 1200 mL in males and 1100 mL in females. The **minimal volume**, a component of the residual volume, is the amount of air that would remain in your lungs if they were allowed to collapse. The minimal volume ranges from

Figure 23–16 Pulmonary Volumes and Capacities. The red line indicates the volume of air within the lungs during breathing.



Sex Differences

	Males	Females
VT	500 mL	500 mL
IRV	3300 mL	1900 mL
ERV	1000 mL	700 mL
Residual Volume	1200 mL	1100 mL
Total lung capacity	6000 mL	4200 mL
Vital capacity	4800 mL	3100 mL
Inspiratory capacity	3800 mL	2400 mL
Functional residual capacity	2200 mL	1800 mL

? The inspiratory capacity is a total of what two pulmonary volumes?

30 to 120 mL. Unlike other volumes, it cannot be measured in a healthy person. The minimal volume and the residual volume are very different, because the fluid bond between the lungs and the chest wall normally prevents the recoil of the elastic fibers in the lungs. Some air remains in the lungs, even at minimal volume, because the surfactant coating the alveolar surfaces prevents their collapse.

- The **inspiratory reserve volume (IRV)** is the amount of air that you can take in over and above the tidal volume. On average, the lungs of males are larger than those of females. For this reason, the inspiratory reserve volume of males averages 3300 mL, compared with 1900 mL in females.

We can calculate respiratory capacities by adding the values of various volumes. Examples include the following:

- The **inspiratory capacity** is the amount of air that you can draw into your lungs after you have completed a quiet respiratory cycle. The inspiratory capacity is the sum of the tidal volume and the inspiratory reserve volume.
- The **functional residual capacity (FRC)** is the amount of air remaining in your lungs after you have completed a quiet respiratory cycle. The FRC is the sum of the expiratory reserve volume and the residual volume.
- The **vital capacity** is the maximum amount of air that you can move into or out of your lungs in a single respiratory cycle. The vital capacity is the sum of the expiratory reserve volume, the tidal volume, and the inspiratory reserve volume. It averages around 4800 mL in males and 3400 mL in females.
- The **total lung capacity** is the total volume of your lungs. We calculate it by adding the vital capacity and the residual volume. The total lung capacity averages around 6000 mL in males and 4200 mL in females.

Checkpoint

17. **Define *compliance* and identify the factors that affect it.**
18. **Name the various measurable pulmonary volumes.**
19. **Mark breaks a rib that punctures the chest wall on his left side. What is likely to happen to his left lung as a result?**
20. **In pneumonia, fluid accumulates in the alveoli of the lungs. How would this accumulation affect vital capacity?**

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of gas molecules

Learning Outcome Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues.

Pulmonary ventilation ensures both that your alveoli are supplied with oxygen and that the carbon dioxide arriving from your bloodstream is removed. The actual process of gas exchange takes place between blood and alveolar air across the blood air barrier. To understand these events, let's first consider (1) the *partial pressures* of the gases involved and (2) the diffusion of molecules between a gas and a liquid. Then we can discuss the movement of oxygen and carbon dioxide across the blood air barrier.

An Introduction to the Diffusion of Gases

Gases are exchanged between the alveolar air and the blood through diffusion, which takes place in response to concentration gradients. As we saw in Chapter 3, the rate of diffusion varies in response to a variety of factors, including the size of the concentration gradient and the temperature. ↩ p. 91 The principles that govern the movement and diffusion of gas molecules, such as those in the atmosphere, are relatively straightforward. These principles, known as *gas laws*, have been understood for about 250 years. You have already heard about Boyle's law, which determines the direction of air movement in pulmonary ventilation. In this section, you will learn about other gas laws and factors that determine the rate of oxygen and carbon dioxide diffusion across the blood air barrier.

Partial Pressures (Dalton's Law)

The air we breathe is a mixture of gases. Nitrogen molecules (N_2) are the most abundant, accounting for about 78.6% of atmospheric gas molecules. Oxygen molecules (O_2), the second most abundant, make up roughly 20.9% of air. Most of the remaining 0.5% consists of water molecules, with carbon dioxide (CO_2) contributing a mere 0.04%.

Atmospheric pressure, 760 mm Hg, represents the combined effects of collisions involving each type of molecule in air. At any moment, 78.6% of those collisions involve nitrogen molecules, 20.9% oxygen molecules, and so on. Thus, each of the gases contributes to the total pressure in proportion to its relative abundance. This relationship is known as **Dalton's law**.

The **partial pressure** of a gas is the pressure contributed by a single gas in a mixture of gases. The partial pressure is abbreviated by the symbol P or p. A subscript shows the gas in question. For example, the partial pressure of oxygen is abbreviated P_{O_2}.

All the partial pressures added together equal the total pressure exerted by a gas mixture. For the atmosphere, this relationship can be summarized as follows:

$$P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} = 760 \text{ mm Hg}$$

We can easily calculate the partial pressure of each gas because we know the individual percentages of each gas in air. For example, the partial pressure of oxygen, P_{O_2}, is 20.9 percent of 760 mm Hg, or roughly 159 mm Hg. **Table 23–1** lists the partial pressures and percentages of atmospheric gases in inhaled, alveolar, and exhaled air.

Diffusion between Liquids and Gases (Henry's Law)

Differences in pressure, which move gas molecules from one place to another, also affect the movement of gas molecules into and out of solution. At a given temperature, the amount of a particular gas in solution is directly proportional to the partial pressure of that gas. This principle is known as **Henry's law**.

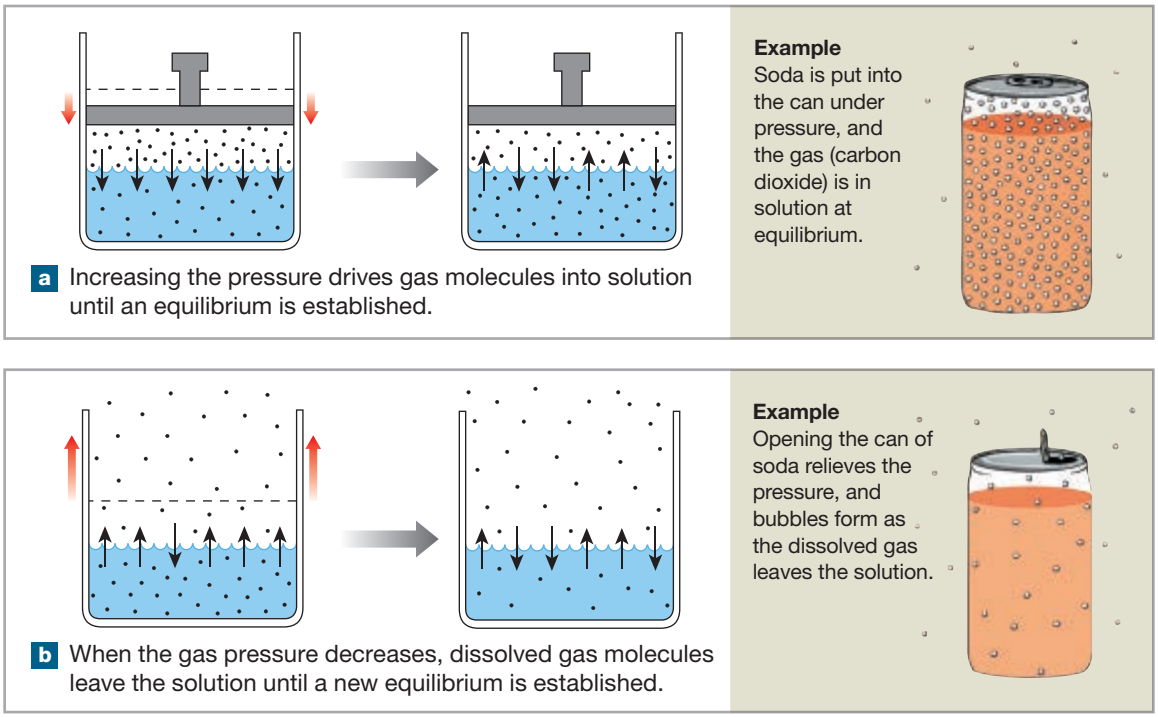
When a gas under pressure contacts a liquid, the pressure tends to force gas molecules into solution. At a given pressure, the number of dissolved gas molecules rises until an equilibrium is established. At equilibrium, gas molecules diffuse out of the liquid as quickly as they enter it, so the total number of gas molecules in solution remains constant. If the partial pressure increases, more gas molecules go into solution. If the partial pressure decreases, gas molecules come out of solution.

You see Henry's law in action whenever you open a can of soda. The soda was put into the can under pressure, and the gas (carbon dioxide) is in solution (**Figure 23–17a**). When you open the can, the pressure decreases and the gas molecules begin coming out of solution (**Figure 23–17b**). Theoretically, the process will continue until an equilibrium develops between the surrounding air and the gas in solution. In fact, the volume of the can is so small, and the volume of the atmosphere so great, that within a half hour or so virtually all the carbon dioxide comes out of solution. You are left with "flat" soda.

Table 23–1 Partial Pressures (mm Hg) and Normal Gas Concentrations (%) in Air

Source of Sample	Nitrogen (N_2)	Oxygen (O_2)	Carbon Dioxide (CO_2)	Water Vapor (H_2O)
Inhaled air (dry)	597 (78.6%)	159 (20.9%)	0.3 (0.04%)	3.7 (0.5%)
Alveolar air (saturated)	573 (75.4%)	100 (13.2%)	40 (5.2%)	47 (6.2%)
Exhaled air (saturated)	569 (74.8%)	116 (15.3%)	28 (3.7%)	47 (6.2%)

Figure 23–17 Henry's Law and the Relationship between Solubility and Pressure.



Solubility of Gases

The actual *amount* of a gas in solution at a given partial pressure and temperature depends on the solubility of the gas in that particular liquid. In body fluids, carbon dioxide is highly soluble, and oxygen is somewhat less soluble. Nitrogen has very limited solubility. The dissolved gas content is usually reported in milliliters of gas per 100 mL (1 dL) of solution. To see the differences in relative solubility of these three gases, we can compare the gas content of blood in the pulmonary veins with the partial pressure of each gas in the alveoli. In a pulmonary vein, plasma generally contains 2.62 mL/dL of dissolved CO_2 (P_{CO_2} = 40 mm Hg), 0.29 mL/dL of dissolved O_2 (P_{O_2} = 100 mm Hg), and 1.25 mL/dL of dissolved N_2 (P_{N_2} = 573 mm Hg). Thus even though the partial pressure of carbon dioxide is less than one-tenth the partial pressure of nitrogen, the plasma contains more than twice as much carbon dioxide as nitrogen in solution.

Diffusion of Gases across the Blood Air Barrier

Now, as part of our discussion of external respiration, let's consider how differing partial pressures and solubilities determine the direction and rate of gas diffusion in the lungs. This section covers the diffusion of oxygen and carbon dioxide across the blood air barrier that separates the air within the alveoli from the blood in alveolar capillaries.

The Composition of Alveolar Air

As we have noted, as soon as air enters the respiratory tract, its characteristics begin to change, being warmed, filtered, and humidified. When incoming air reaches the alveoli, it mixes with air remaining in the alveoli from the previous respiratory cycle. For this reason, alveolar air contains more carbon dioxide and less oxygen than does atmospheric air.

The last 150 mL of inhaled air never gets farther than the conducting passageways. It remains in the anatomic dead space of the lungs. During the next exhalation, the departing alveolar air mixes with air in the dead space, producing yet another mixture that differs from both atmospheric and alveolar samples. As mentioned, the differences in composition between atmospheric (inhaled) and alveolar air are given in **Table 23–1**.

Efficiency of Diffusion at the Blood Air Barrier

Gas exchange at the blood air barrier is efficient for the following reasons:

- *The differences in partial pressure across the blood air barrier are substantial.* This fact is important, because the greater the difference in partial pressure, the faster the rate of gas diffusion. Conversely, if P_{O_2} in alveoli decreases, the rate of oxygen diffusion into blood decreases. This is why many people feel light-headed at altitudes of 3000 m or more. The partial

+ Clinical Note Decompression Sickness

Decompression sickness is a painful condition that develops when a person is exposed to a sudden drop in atmospheric pressure. This condition is caused by nitrogen due to its high partial pressure in air. When the pressure drops, nitrogen comes out of solution, forming bubbles like those in a shaken can of soda. The bubbles may form in joint cavities, in the bloodstream, and in the cerebrospinal fluid. Individuals with decompression sickness typically curl up from the pain in affected joints. This reaction accounts for the condition's common name: *the bends*.

Decompression sickness most commonly affects scuba divers who return to the surface too quickly after breathing air under greater-than-normal pressure while submerged. It can also develop in airline passengers subject to sudden losses of cabin pressure.

pressure of oxygen in their alveoli has dropped so low that the rate of oxygen absorption is significantly reduced.

- *The distances involved in gas exchange are short.* The fusion of capillary and alveolar basement membranes reduces the distance for gas exchange to as little as 0.1 µm, with an average of 0.5 µm. Inflammation of the lung tissue or a buildup of fluid in alveoli increases the diffusion distance and impairs alveolar gas exchange.
- *The gases are lipid soluble.* Both oxygen and carbon dioxide diffuse readily through the surfactant layer and the alveolar and endothelial plasma membranes.
- *The total surface area is large.* To meet the metabolic requirements of peripheral tissues, the surface area for gas exchange in the lungs must be very large. Estimates of the surface area involved in gas exchange range from 70 m^2 to 140 m^2 (753 ft^2 to 1506 ft^2). It is about 35 times the surface area of your body, or slightly bigger than half a tennis court. Damage to alveolar surfaces, which occurs in emphysema, reduces the available surface area and the efficiency of gas transfer.
- *Blood flow and airflow are coordinated.* This close coordination makes both pulmonary ventilation and pulmonary circulation more efficient. For example, blood flow is greatest around alveoli with the highest P_{O_2} values, where oxygen uptake can proceed with maximum efficiency. This matching of alveolar ventilation with pulmonary blood perfusion is called the *ventilation-to-perfusion ratio* (or *V/Q ratio*). This ratio is the amount of air reaching the alveoli to the amount of blood reaching the alveoli. If the normal blood flow is impaired (as it is in *pulmonary embolism*), or if the normal airflow is interrupted (as it is in various forms of *pulmonary obstruction*), this coordination is lost and respiratory efficiency decreases.

Summary of Gas Exchange

We cover gas exchange as part of the processes of both external and internal respiration. **Figure 23–18** illustrates gas exchange due to the partial pressures of oxygen and carbon dioxide in the pulmonary and systemic circuits.

External Respiration

Notice that blood arriving from the pulmonary arteries has a lower P_{O_2} and a higher P_{CO_2} than does alveolar air (see **Figure 23–18a**). Diffusion between the alveolar gas mixture and the alveolar capillaries then increases the P_{O_2} of blood and decreases its P_{CO_2}. By the time the blood enters the pulmonary venules, it has reached equilibrium with the alveolar air. Blood departs the alveoli with a P_{O_2} of about 100 mm Hg and a P_{CO_2} of roughly 40 mm Hg.

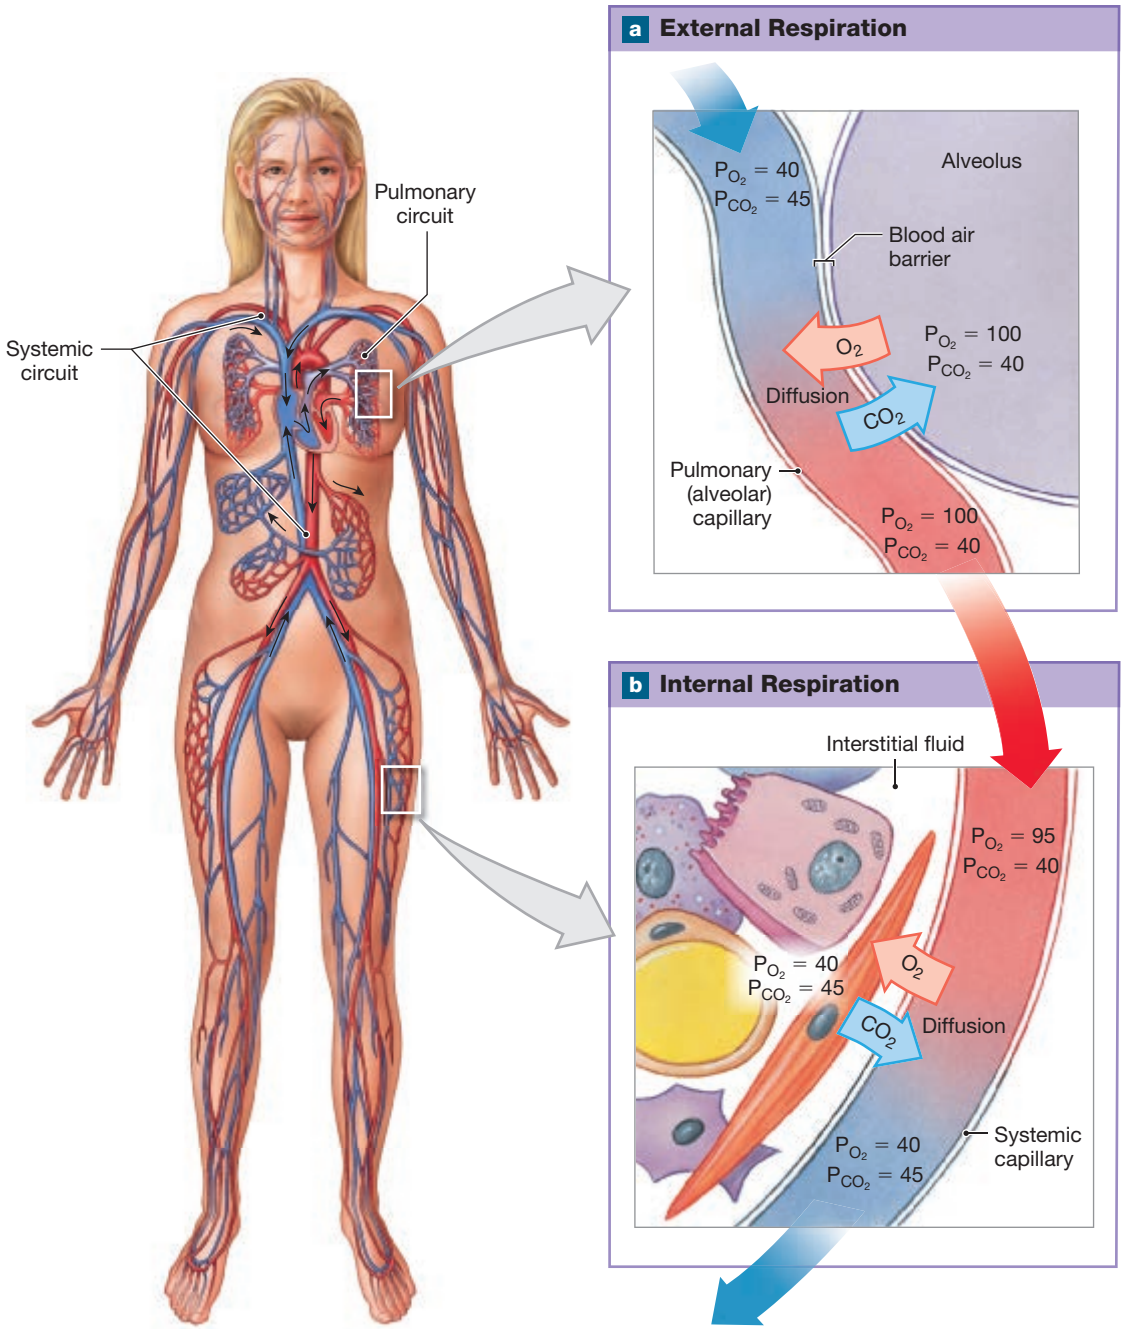
+ Clinical Note Blood Gas Analysis

Blood samples can be analyzed to determine their concentrations of dissolved gases. The usual tests include the determination of pH, P_{CO_2}, and P_{O_2} in an arterial sample. Such samples provide information about the degree of oxygenation in peripheral tissues. For example, if the arterial P_{CO_2} is very high and the P_{O_2} is very low, tissues are not receiving adequate oxygen. This problem may be solved by giving the patient a gas mixture that has a high P_{O_2} (or even pure oxygen, with a P_{O_2} of 760 mm Hg).

Blood gas measurements also provide information on the efficiency of gas exchange at the lungs. If the arterial P_{O_2} remains low despite the administration of oxygen, or if the P_{CO_2} is very high, pulmonary exchange problems may exist. Such problems may include pulmonary edema, asthma, or pneumonia.

Figure 23–18 A Summary of Respiratory Processes and Partial Pressures in Respiration.

SmartArt



Diffusion between alveolar air and blood in the alveolar capillaries occurs very rapidly. When you are at rest, a red blood cell moves through one of your alveolar capillaries in about 0.75 second. When you exercise, the passage takes less than 0.3 second. This amount of time is usually sufficient to reach an equilibrium between the alveolar air and the blood.

Internal Respiration

Oxygenated blood leaves the pulmonary (alveolar) capillaries to return to the heart, to be pumped into the systemic circuit. As this blood enters the pulmonary veins, it mixes with blood that flowed through capillaries around conducting passageways. Because gas exchange in the lungs occurs only at alveoli, the blood leaving the conducting passageways carries relatively little oxygen. The partial pressure of oxygen in the pulmonary veins therefore drops to about 95 mm Hg. This is the P_{O_2} in the blood that enters the systemic circuit. No further changes in partial pressure occur until the blood reaches the systemic capillaries (Figure 23–18b).

Normal interstitial fluid has a P_{O_2} of 40 mm Hg. As a result, oxygen diffuses out of the systemic capillaries until the capillary partial pressure is the same as that in the adjacent tissues.

Inactive peripheral tissues normally have a P_{CO_2} of about 45 mm Hg, whereas blood entering peripheral capillaries normally has a P_{CO_2} of 40 mm Hg. As a result, carbon dioxide diffuses into the blood as oxygen diffuses out (see Figure 23–18b).

23-9 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways

Learning Outcome Describe the structure and function of hemoglobin, and the transport of oxygen and carbon dioxide in the blood.

Oxygen and carbon dioxide have limited solubilities in blood plasma. For example, at the normal P_{O_2} of alveoli, 100 mL of plasma absorbs only about 0.3 mL of oxygen. The limited solubilities of these gases are a problem. The peripheral tissues need more oxygen and generate more carbon dioxide than the plasma alone can absorb and transport.

Red blood cells (RBCs) solve this problem. They remove dissolved O_2 and CO_2 molecules from plasma and bind them (in the case of oxygen) or mostly use them to manufacture soluble compounds (in the case of carbon dioxide). As the reactions in RBCs remove dissolved gases from blood plasma, these gases continue to diffuse into the blood, but never reach equilibrium. These reactions are both temporary and completely reversible. When the oxygen or carbon dioxide concentration in blood plasma is high, RBCs remove the excess molecules. When the plasma concentrations are falling, the RBCs release their stored reserves.

In this section we cover the transport of oxygen by RBCs, as well as the transport of carbon dioxide. CO_2 can be transported in three ways: as carbonic acid, bound to hemoglobin, or dissolved in plasma.

Oxygen Transport

Each 100 mL of blood leaving the alveolar capillaries carries away about 20 mL of oxygen. Only 1.5% (about 0.3 mL) of this amount is oxygen molecules in solution. The rest of the oxygen molecules are bound to *hemoglobin (Hb) molecules*. This section covers how hemoglobin carries oxygen in the blood and the factors that affect this process.

Transport of O_2 on Hemoglobin

Recall that the hemoglobin molecule consists of four globular protein subunits, each containing a heme unit. The oxygen molecules bind to the iron ions in the center of heme units. p. 663 Thus, each hemoglobin molecule can bind four molecules of oxygen, forming **oxyhemoglobin (HbO_2)**. We can summarize this process as

$$Hb + O_2 \rightleftharpoons HbO_2$$

This reversible reaction allows hemoglobin to pick up oxygen in the lungs and then release it to body tissues elsewhere.

Each red blood cell has approximately 280 million molecules of hemoglobin. With four heme units per hemoglobin molecule, each RBC potentially can carry more than a billion molecules of oxygen.

The percentage of heme units containing bound oxygen at any given moment is called the **hemoglobin saturation**. If all the Hb molecules in the blood are fully loaded with oxygen, saturation is 100%. If, on average, each Hb molecule carries two O_2 molecules, saturation is 50%.

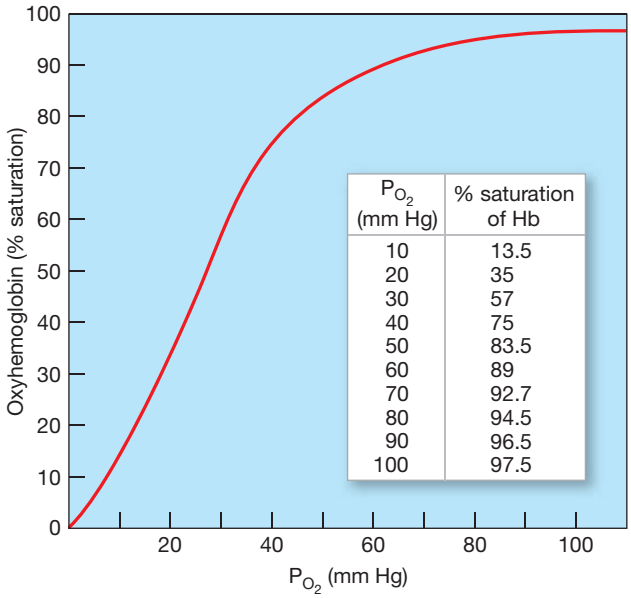
In Chapter 2, we saw that the shape and functional properties of a protein change in response to changes in its environment. p. 55 Hemoglobin is no exception. Any changes in shape can affect oxygen binding.

Effect of P_{O_2} on Hemoglobin Saturation

Normally, the most important factor affecting hemoglobin saturation is the P_{O_2} of blood. Hemoglobin in RBCs carries most of the oxygen in the bloodstream and releases it in response to changes in the partial pressure of oxygen in the surrounding plasma. If the P_{O_2} increases, hemoglobin binds oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen.

An **oxygen-hemoglobin saturation curve**, or *oxygen-hemoglobin dissociation curve*, is a graph that relates the hemoglobin saturation to the partial pressure of oxygen (Figure 23–19).

Figure 23–19 An Oxygen-Hemoglobin Saturation Curve. The saturation characteristics of hemoglobin at various partial pressures of oxygen under normal conditions (body temperature of 37°C and blood pH of 7.4).



P_{O_2} (mm Hg)	% saturation of Hb
10	13.5
20	35
30	57
40	75
50	83.5
60	89
70	92.7
80	94.5
90	96.5
100	97.5

The binding and dissociation, or release, of oxygen to hemoglobin is a typical reversible reaction. At equilibrium, oxygen molecules bind to heme at the same rate at which other oxygen molecules are being released. If the P_{O_2} increases, then more oxygen molecules bind to hemoglobin, and fewer are released. Referring to the equation given in the previous section, we say that the reaction shifts to the right. If the P_{O_2} decreases, more oxygen molecules are released from hemoglobin, while fewer oxygen molecules bind. In this case, we say that the reaction shifts to the left.

Notice that the graph of this relationship between P_{O_2} and hemoglobin saturation is a curve rather than a straight line. It is a curve because the shape of the hemoglobin molecule changes slightly each time it binds an oxygen molecule. This change in shape enhances the ability of hemoglobin to bind *another* oxygen molecule. In other words, the binding of the first oxygen molecule makes it easier to bind the second; binding the second promotes binding of the third; and binding the third enhances binding of the fourth.

Because each arriving oxygen molecule makes it easier for hemoglobin to bind the *next* oxygen molecule, the saturation curve takes the form shown in **Figure 23–19**. Once the first oxygen molecule binds to the hemoglobin, the slope rises rapidly until it levels off near 100% saturation. Where the slope is steep, a very small change in plasma P_{O_2} results in a large change in the amount of oxygen bound to Hb or released from HbO_2. Notice that hemoglobin will be more than 90% saturated if exposed to an alveolar P_{O_2} above 60 mm Hg. Thus, near-normal oxygen transport can continue even when the oxygen content of alveolar air decreases below normal, or P_{O_2} = 100 mm Hg. Without this ability, you could not survive at high altitudes. Conditions that significantly reduce pulmonary ventilation would be immediately fatal.

At normal alveolar pressures (P_{O_2} = 100 mm Hg), the hemoglobin saturation is very high (97.5%), but complete saturation does not occur until the P_{O_2} reaches an excessively high level (about 250 mm Hg). In functional terms, the maximum saturation is not as important as the ability of hemoglobin to provide oxygen over the normal P_{O_2} range in body tissues. Over that range—from 100 mm Hg at the alveoli to perhaps 15 mm Hg in active tissues—the saturation drops from 97.5% to less than 20%, and a small change in P_{O_2} makes a big difference in terms of the amount of oxygen bound to hemoglobin.

Note that the relationship between P_{O_2} and hemoglobin saturation remains valid whether the P_{O_2} is rising or falling. If the P_{O_2} increases, the saturation goes up and hemoglobin stores oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen into its surroundings. When oxygenated blood arrives in the peripheral capillaries, the blood P_{O_2} declines rapidly due to gas exchange with the interstitial fluid. As the P_{O_2} falls, hemoglobin gives up its oxygen.

The relationship between the P_{O_2} and hemoglobin saturation provides a mechanism for automatic regulation of oxygen delivery. Inactive tissues have little demand for oxygen, and the local P_{O_2} is usually about 40 mm Hg. Under these conditions, hemoglobin does not release much oxygen. As it passes through the capillaries, it goes from 97% saturation (P_{O_2} = 95 mm Hg) to 75% saturation (P_{O_2} = 40 mm Hg). Because hemoglobin still retains three-quarters of its oxygen, venous blood has a relatively large oxygen reserve. This reserve is important, because it can be mobilized if the tissue oxygen demand increases.

Active tissues use oxygen at an accelerated rate, so their P_{O_2} may drop to 15–20 mm Hg. Hemoglobin passing through these capillaries goes from 97% saturation to about 20% saturation. In practical terms, this means that as blood circulates through peripheral capillaries, active tissues receive 3.5 times as much oxygen as do inactive tissues.

Effect of Other Factors on Hemoglobin Saturation

At least three other factors may affect the oxygen saturation rate of hemoglobin. These factors are (1) blood pH, (2) temperature, and (3) the products of ongoing metabolic activity within RBCs.

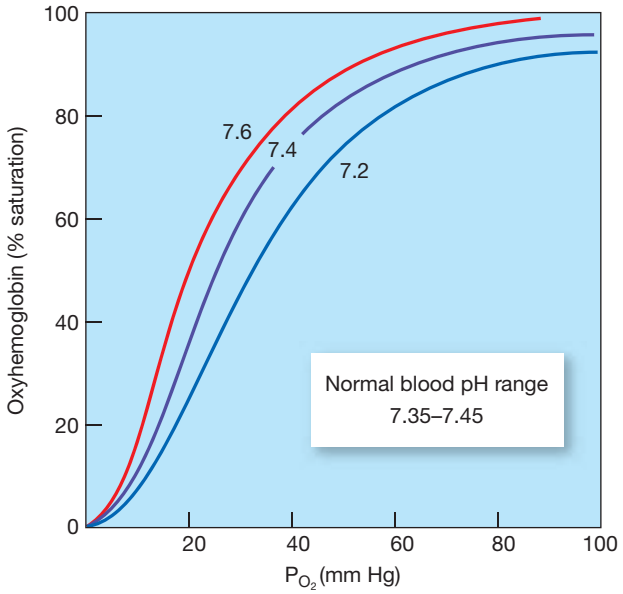
Hemoglobin and pH. Hemoglobin helps to buffer acids by binding hydrogen ions (H^+). At a given P_{O_2}, hemoglobin releases additional oxygen if the blood pH decreases. The oxygen–hemoglobin saturation curve in **Figure 23–19** was determined in normal blood, with a pH of 7.4 and a temperature of 37°C. In addition to consuming oxygen, active tissues generate acids that lower the pH of the interstitial fluid. When the pH decreases, the shape of hemoglobin molecules changes. As a result of this change, the molecules release their oxygen reserves more readily, so the slope of the hemoglobin saturation curve changes (**Figure 23–20a**). In other words, as pH decreases, the saturation declines. At a tissue P_{O_2} of 40 mm Hg, for example, you can see in **Figure 23–20a** that a pH decrease from 7.4 to 7.2 changes hemoglobin saturation from 75% to 60%. This means that hemoglobin molecules release 20% more oxygen in peripheral tissues at a pH of 7.2 than they do at a pH of 7.4. This effect of pH on the hemoglobin saturation curve is called the **Bohr effect**.

Carbon dioxide is the primary compound responsible for the Bohr effect. When CO_2 diffuses into the blood, it rapidly diffuses into red blood cells. There, an enzyme called **carbonic anhydrase** catalyzes the reaction of CO_2 with water molecules:

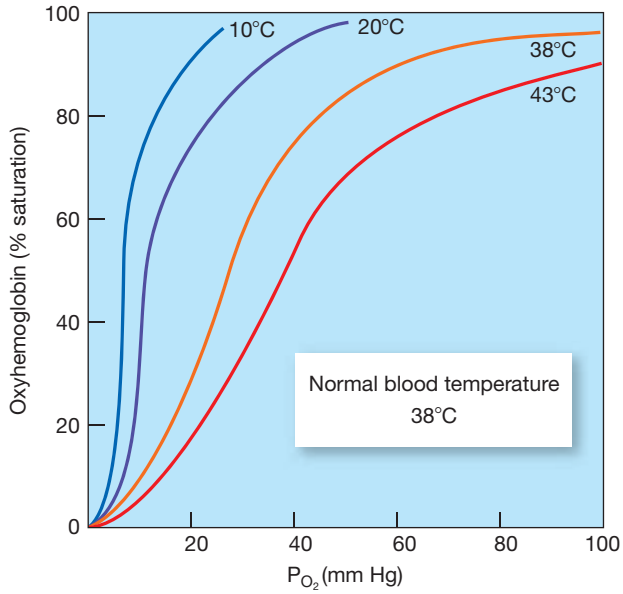
$$CO_2 + H_2O \overset{\text{carbonic anhydrase}}{\rightleftharpoons} H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The product of this enzymatic reaction, H_2CO_3, is called *carbonic acid*, because it dissociates into a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-). The rate of carbonic acid formation depends on the amount of carbon dioxide in solution, which, as noted earlier, depends on the P_{CO_2}. When the P_{CO_2} rises, the rate of carbonic acid formation accelerates and the reaction proceeds from left to right. The hydrogen ions that are generated diffuse out of the RBCs, and the pH of the plasma decreases. When the P_{CO_2} declines, hydrogen ions diffuse out of

Figure 23–20 The Effects of Blood pH and Temperature on Hemoglobin Saturation.



a **Effect of pH.** When the blood pH decreases below the normal range, more oxygen is released; the oxygen-hemoglobin saturation curve shifts to the right. When the pH increases, less oxygen is released; the curve shifts to the left.



b **Effect of temperature.** When the temperature increases, more oxygen is released; the oxygen-hemoglobin saturation curve shifts to the right. When the temperature decreases, the curve shifts to the left.

? According to these graphs, more oxygen is released when the pH is (higher or lower) than normal and when temperature is (higher or lower) than normal.

the plasma and into the RBCs. As a result, the pH of the plasma increases as the reaction proceeds from right to left.

Hemoglobin and Temperature. At a given P_{CO_2}, hemoglobin releases additional oxygen if the temperature of the blood increases. Changes in temperature affect the slope of the hemoglobin saturation curve (Figure 23–20b). As the temperature increases, hemoglobin releases more oxygen. As the temperature decreases, hemoglobin holds oxygen more tightly. Temperature effects are significant only in active tissues that are generating large amounts of heat. For example, active skeletal muscles generate heat, and the heat warms blood that flows through these organs. As the blood warms, the Hb molecules release more oxygen than the active muscle fibers can use.

Hemoglobin and BPG. Red blood cells lack mitochondria. These cells produce ATP only by glycolysis. As a result, lactate is formed, as we saw in Chapter 10. ↩ p. 322 The metabolic pathways involved in glycolysis in an RBC also generate the compound **2,3-bisphosphoglycerate** (biz-fos-fō-GLIS-er-āt), or **BPG**. This compound has a direct effect on oxygen binding and release. For any partial pressure of oxygen, the higher the concentration of BPG, the greater the release of oxygen by Hb molecules. Normal RBCs always contain BPG.

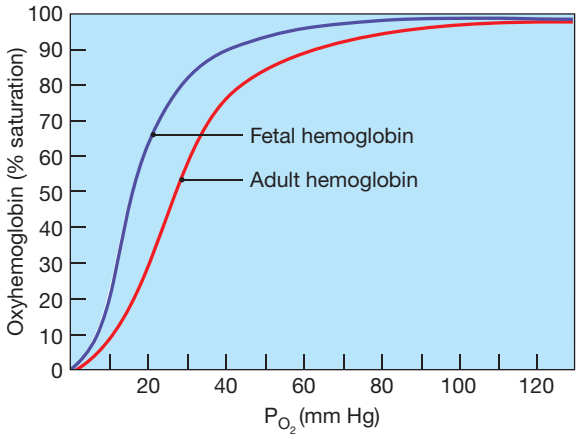
Both BPG synthesis and the Bohr effect improve oxygen delivery when the pH changes: The BPG level rises when the pH increases, and the Bohr effect appears when the pH decreases. The concentration of BPG can be increased by high blood pH, thyroid hormones, growth hormone, epinephrine, and androgens. When the plasma P_{O_2} level is low for an extended time, red blood cells generate more BPG. These factors improve oxygen delivery to the tissues, because when the BPG level is elevated, hemoglobin releases about 10% more oxygen at a given P_{O_2} than it would do otherwise.

The production of BPG decreases as RBCs age. For this reason, the level of BPG can determine how long a blood bank can store fresh whole blood. When the BPG level gets too low, hemoglobin becomes firmly bound to the available oxygen. The blood is then useless for transfusions, because the RBCs will no longer release oxygen to peripheral tissues, even at a disastrously low P_{O_2}.

Transport of O_2 by Fetal Hemoglobin

The RBCs of a developing fetus contain **fetal hemoglobin**. The structure of fetal hemoglobin differs from that of adult hemoglobin, giving it a much higher affinity for oxygen. At the same P_{O_2}, fetal hemoglobin binds more oxygen than does adult hemoglobin (Figure 23–21). This trait is key to transferring oxygen across the placenta.

Figure 23–21 A Functional Comparison of Fetal and Adult Hemoglobin.



A fetus obtains oxygen from the maternal bloodstream. At the placenta, maternal blood has a relatively low P_{O_2}, ranging from 35 to 50 mm Hg. If maternal blood arrives at the placenta with a P_{O_2} of 40 mm Hg, hemoglobin saturation is roughly 75%. The fetal blood arriving at the placenta has a P_{O_2} close to 20 mm Hg. However, because fetal hemoglobin has a higher affinity for oxygen, it is still 58% saturated.

As diffusion takes place between fetal blood and maternal blood, oxygen enters the fetal bloodstream until the P_{O_2} reaches equilibrium at 30 mm Hg. At this P_{O_2}, the maternal hemoglobin is less than 60% saturated, but the fetal hemoglobin is over 80% saturated, as you can see in **Figure 23–21**. The steeper slope of the saturation curve for fetal hemoglobin means that when fetal RBCs reach peripheral tissues of the fetus, the Hb molecules release a large amount of oxygen in response to a very small change in P_{O_2}.

Clinical Note Carbon Monoxide Poisoning

The exhaust from automobiles and other petroleum-burning engines, oil lamps, and fuel-fired space heaters contains *carbon monoxide (CO)*. Each winter entire families die from **carbon monoxide poisoning**. Carbon monoxide competes with oxygen molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins the competition. The reason is that at very low partial pressures it has a much stronger affinity for hemoglobin than does oxygen. The bond formed between CO and heme is extremely strong. As a result, the attachment of a CO molecule essentially makes that heme unit inactive for respiratory purposes.

If CO molecules make up just 0.1% of inhaled air, enough hemoglobin is affected that human survival becomes impossible without medical assistance. Treatment includes (1) preventing further CO exposure; (2) administering pure oxygen, because at sufficiently high partial pressures, the oxygen molecules gradually replace CO at the hemoglobin molecules; and, if necessary, (3) transfusing compatible red blood cells.

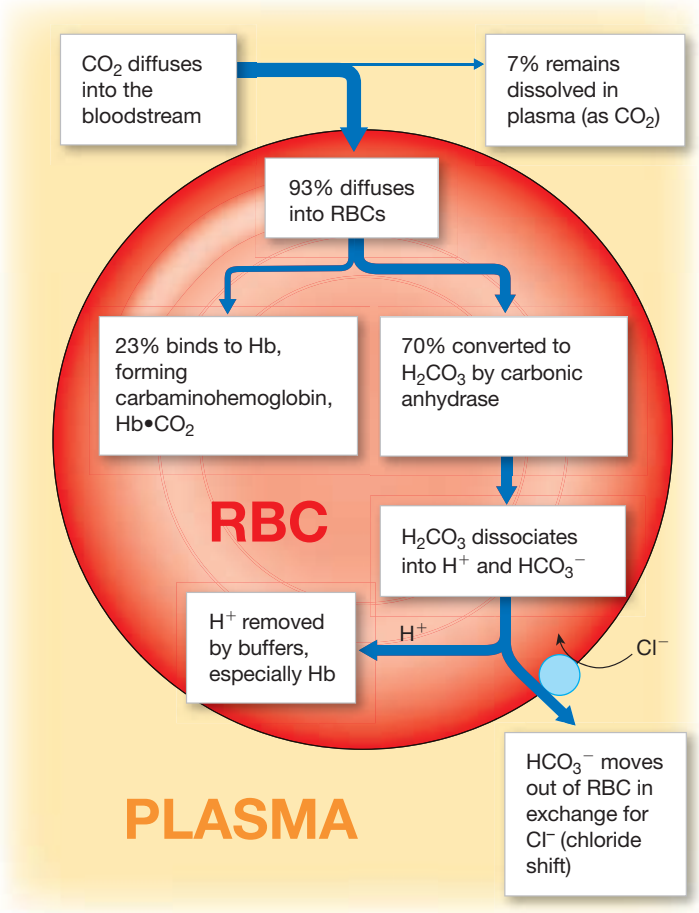
Carbon Dioxide Transport

Carbon dioxide is generated by aerobic metabolism in peripheral tissues. Carbon dioxide travels in the bloodstream in three different ways. After entering the blood, a CO_2 molecule either (1) is converted to a molecule of carbonic acid, (2) binds to hemoglobin within red blood cells, or (3) dissolves in plasma. All three reactions are completely reversible, allowing carbon dioxide to be picked up from body tissues and then delivered to the alveoli. Let's consider the events that take place as blood enters peripheral tissues in which the P_{CO_2} is 45 mm Hg.

Transport of CO_2 as Bicarbonate Ions

Roughly 70% of the carbon dioxide absorbed by blood is transported as bicarbonate ions (HCO_3^-). Most of the carbon dioxide that enters the bloodstream diffuses into RBCs. Within the RBCs, carbon dioxide and water are combined and converted to carbonic acid through the activity of the enzyme *carbonic anhydrase* (**Figure 23–22**). The carbonic acid molecules immediately dissociate into hydrogen ions and bicarbonate ions, as

Figure 23–22 Carbon Dioxide Transport in Blood.



described earlier (p. 865). We can ignore the intermediate steps in this sequence and summarize the reaction as

$$CO_2 + H_2O \overset{\text{carbonic anhydrase}}{\rightleftharpoons} H^+ + HCO_3^-$$

This reaction is completely reversible. In peripheral capillaries, it proceeds vigorously, tying up large numbers of CO_2 molecules. The reaction continues as carbon dioxide diffuses out of the interstitial fluids.

The hydrogen ions and bicarbonate ions have different fates. Most of the hydrogen ions bind to hemoglobin molecules, forming HbH^+. The Hb molecules function as pH buffers, tying up the released H^+ before the ions can leave the RBCs and lower the pH of the plasma. The bicarbonate ions move into the plasma with the aid of a countertransport mechanism that exchanges intracellular bicarbonate ions (HCO_3^-) for extracellular chloride ions (Cl^-). This exchange trades one anion for another and does not require ATP. The result is a mass movement of chloride ions into the RBCs, an event known as the **chloride shift**.

Transport of CO_2 on Hemoglobin

About 23% of the carbon dioxide carried by blood is bound to the protein portions of Hb molecules inside RBCs. These CO_2 molecules are attached to exposed amino groups ($-NH_2$) of the Hb molecules. The resulting compound is called **carbaminohemoglobin** (kar-BAM-ih-nō-hē-mō-glō-bin), $HbCO_2$. The formation of this compound decreases oxygen affinity to hemoglobin. We can summarize the reversible reaction as follows:

$$CO_2 + HbNH_2 \rightleftharpoons HbNHCOOH$$

We can abbreviate this reaction without the amino groups as

$$CO_2 + Hb \rightleftharpoons HbCO_2$$

Transport of CO_2 in Plasma

Plasma becomes saturated with carbon dioxide quite rapidly. Only about 7% of the carbon dioxide absorbed at peripheral capillaries is transported as dissolved gas molecules. RBCs absorb the rest and convert it using carbonic anhydrase or store it as carbaminohemoglobin.

Figure 23–22 summarizes carbon dioxide transport.

Summary of Gas Transport

Figure 23–23 summarizes the transport of oxygen and carbon dioxide in the respiratory and cardiovascular systems. Note that the top part of the figure shows oxygen pickup by hemoglobin in the alveoli, and delivery to peripheral tissues. The bottom part of the figure shows the carbon dioxide being picked up in peripheral tissues and delivered to the alveoli. The reactions we have just discussed then proceed in the reverse direction.

Gas transport is a dynamic process. Its responses can be varied to meet changing circumstances. Some of the responses are automatic and result from the basic chemistry of the transport mechanisms. Other responses require coordinated adjustments in the activities of the cardiovascular and respiratory systems. We consider those levels of control next.

23-10 Respiratory centers in the brainstem, along with respiratory reflexes, control respiration

Learning Outcome List the factors that influence respiration rate, and discuss reflex respiratory activity and the brain centers involved in the control of respiration.

Peripheral cells continuously absorb oxygen and generate carbon dioxide. Under normal conditions, the cellular rates of absorption and generation are matched by the capillary rates of delivery and removal. Both rates are identical to those of oxygen absorption and carbon dioxide excretion at the lungs.

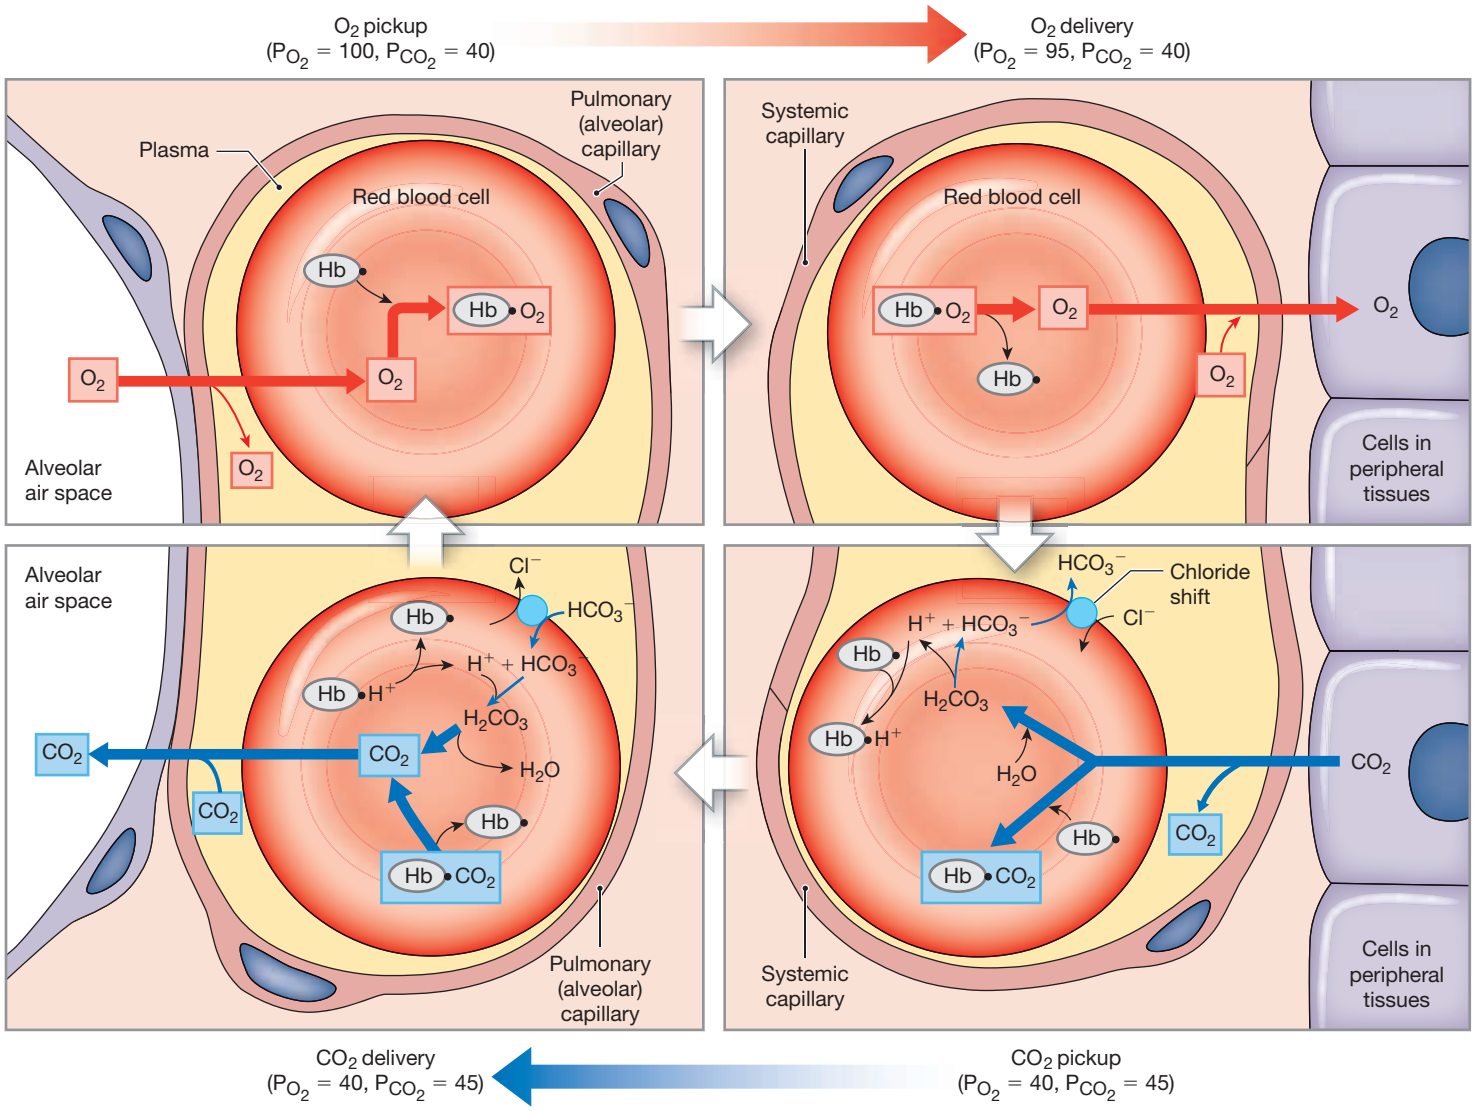
If diffusion rates at the peripheral and alveolar capillaries become unbalanced, homeostatic mechanisms intervene to restore equilibrium. Such mechanisms involve (1) local changes in oxygen delivery to peripheral tissues and in the ventilation-to-perfusion ratio in the lungs, and (2) changes in the depth and rate of respiration under the control of the brain's *respiratory centers*. The activities of the respiratory centers are coordinated with changes in cardiovascular function, such as fluctuations in blood pressure and cardiac output.

Local Regulation of Oxygen Delivery and Ventilation-to-Perfusion Ratio

The rate of oxygen delivery in each tissue and the efficiency of oxygen pickup at the lungs are largely regulated at the local level. For example, when a peripheral tissue becomes more active, the interstitial P_{O_2} falls and the P_{CO_2} rises. These changes increase the difference between the partial pressures in the tissues and in the arriving blood. As a result, more oxygen is delivered and more carbon dioxide is carried away. In addition, the rising P_{CO_2} level causes the relaxation of smooth muscles in the walls of arterioles and capillaries in the area, increasing local blood flow.

At the lungs, local factors coordinate (1) *lung perfusion*, or blood flow to the alveoli, with (2) *alveolar ventilation*, or airflow. This local coordination, called the **ventilation-to-perfusion ratio**, or **V/Q ratio**, takes place over a wide range of conditions

Figure 23–23 A Summary of the Primary Gas Transport Mechanisms.



and activity levels. As blood flows toward the alveolar capillaries, it is directed toward lobules with a relatively high P_{O_2}. This movement takes place because alveolar capillaries constrict when the local P_{O_2} is low. (This response is the opposite of that seen in peripheral tissues, as we noted in Chapter 21. ↩ p. 753)

Also in the lungs, smooth muscles in the walls of bronchioles are sensitive to the P_{CO_2} of the air they contain. When the P_{CO_2} goes up, the bronchioles increase in diameter (bronchodilation). When the P_{CO_2} declines, the bronchioles constrict (bronchoconstriction). Airflow is therefore directed to lobules with a high P_{CO_2}. These lobules get their carbon dioxide from blood and are actively engaged in gas exchange. The response of the bronchioles to P_{CO_2} is especially important, because improvements in airflow to functional alveoli can at least partially compensate for damage to pulmonary lobules.

Local adjustments improve the efficiency of gas transport by directing blood flow to alveoli with low CO_2 levels and increasing airflow to alveoli with high CO_2 levels. These adjustments in alveolar blood flow and bronchiole diameter take place automatically.

Neural Control of Respiration

When activity levels increase and the demand for oxygen rises, respiratory rates increase under neural control. Neural control of respiration has both involuntary and voluntary components. Your brain's involuntary *respiratory centers* set and adjust the respiratory rhythm by regulating the activities of the respiratory muscles.

The voluntary control of respiration reflects activity in the higher centers of the cerebral cortex. This activity affects the output of either the respiratory centers or motor neurons in the spinal cord that control respiratory muscles. These spinal motor neurons are generally controlled by *respiratory reflexes*, but they can also be controlled voluntarily through commands delivered by the corticospinal pathway. ↩ p. 528

Involuntary Control of the Basic Respiratory Rhythm

The respiratory centers are three pairs of nuclei in the reticular formation of the medulla oblongata and pons. These centers control the respiratory minute volume by adjusting the frequency and depth of pulmonary ventilation. They make these adjustments in response to sensory information arriving from your lungs and other parts of the respiratory tract, as well as from a variety of other sites.

Function of the Respiratory Rhythmicity Centers. We introduced the paired **respiratory rhythmicity centers** of the medulla oblongata in Chapter 14; these centers play a key role in establishing the respiratory rate and rhythm. ↩ p. 474 Each respiratory rhythmicity center can be subdivided into a **dorsal respiratory group (DRG)** and a **ventral respiratory group (VRG)**. The DRG is chiefly concerned with inspiration, whereas the VRG is primarily associated with expiration.

The DRG functions in every respiratory cycle, whether quiet or forced. The DRG's *inspiratory center* contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm.

The VRG functions only during forced breathing. It has an *expiratory center* consisting of neurons that innervate lower motor neurons controlling accessory respiratory muscles involved in active exhalation. Its inspiratory center contains neurons involved in maximal inhalation, such as gasping.

Reciprocal inhibition takes place between the neurons involved with inhalation and exhalation. ↩ p. 459 When the inspiratory neurons are active, the expiratory neurons are inhibited, and vice versa. The pattern of interaction between these groups differs between quiet breathing and forced breathing. During quiet breathing (Figure 23–24a):

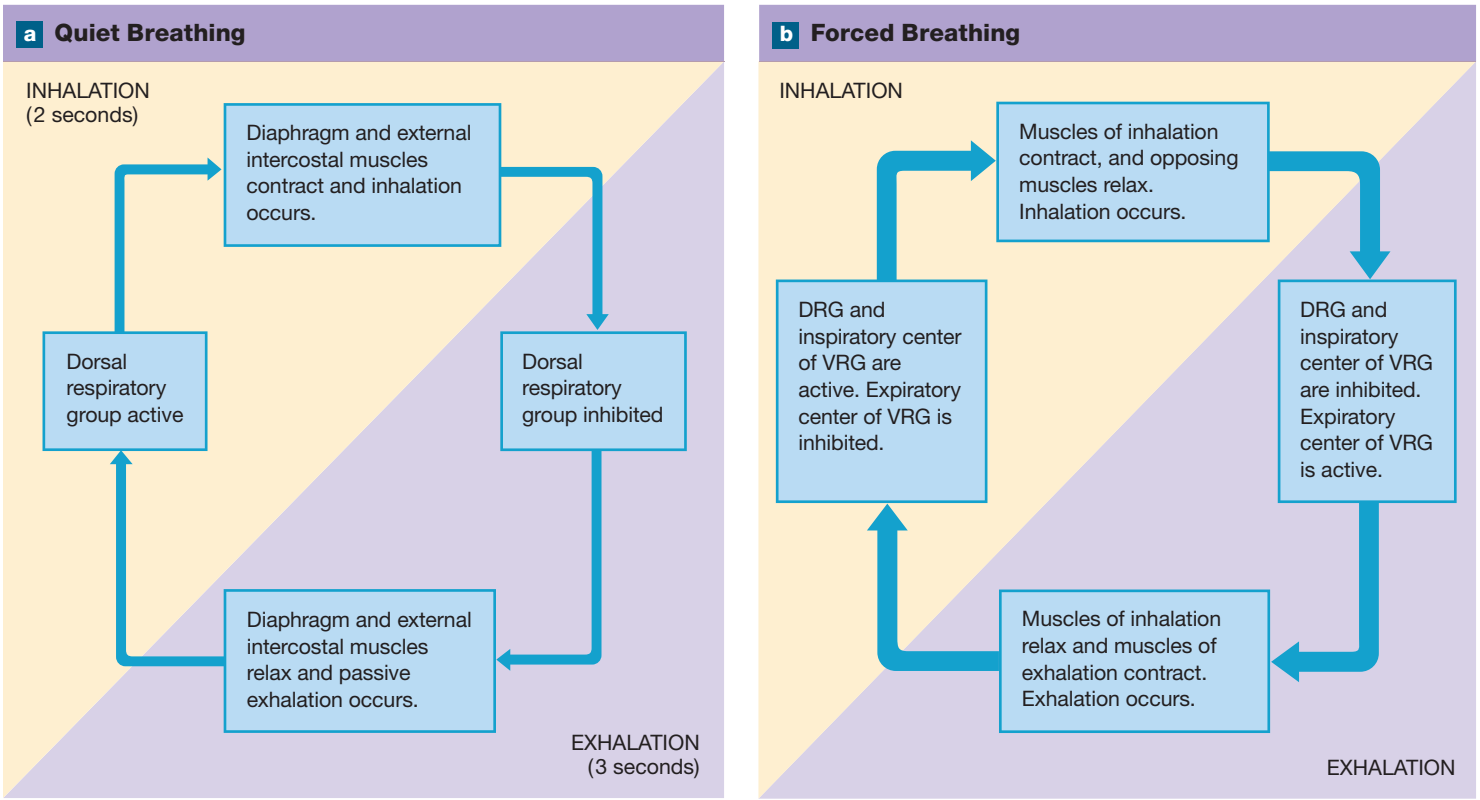
- Activity in the DRG increases over a period of about 2 seconds, stimulating the inspiratory muscles. Over this period, inhalation takes place.
- After 2 seconds, the DRG neurons become inactive. They remain quiet for the next 3 seconds and allow the inspiratory muscles to relax. Over this period, passive exhalation takes place.

During forced breathing (Figure 23–24b):

- Increases in the level of activity in the DRG stimulate neurons of the VRG that activate the accessory muscles involved in inhalation.
- After each inhalation, active exhalation takes place as the neurons of the expiratory center stimulate the appropriate accessory muscles.

The basic pattern of respiration thus reflects a cyclic interaction between the DRG and the VRG. However, the timing of this interaction is highly variable, and current research suggests that respiratory rate and rhythm cannot be attributed to a single area. The nuclei involved in respiratory control form a complex

Figure 23–24 Basic Regulatory Patterns of Respiration.



network that includes (1) the rhythmicity centers, (2) centers in the pons that are modulated by peripheral and higher central inputs, and (3) an area in the ventrolateral medulla, known as the pre-Bötzinger complex (*central pattern generator*), that is essential to all forms of breathing. There are reciprocal pathways between all these nuclei, so deciphering their communication is extremely difficult, especially because the patterns change with different situations. Central nervous system stimulants, such as amphetamines or even caffeine, increase the respiratory rate by facilitating the respiratory centers. These actions are opposed by CNS depressants, such as barbiturates or opiates.

Respiratory control is an area of intense study and our understanding of the interactions and mechanisms remains incomplete. Due to the brainstem locations, it is nearly impossible to study this mechanism in humans, and much of the work has been done in cats and newborn rodents.

Function of the Apneustic and Pneumotaxic Centers. The *apneustic centers* and *pneumotaxic centers* (also called the *pontine respiratory group*) of the pons regulate the depth and rate of respiration in response to sensory stimuli or input from other centers in the brain. Each apneustic center provides continuous stimulation to the DRG on that side of the brainstem. During quiet breathing, stimulation from the apneustic center helps increase the intensity of inhalation over the next 2 seconds. Under normal conditions, after 2 seconds the apneustic center is inhibited by signals from the pneumotaxic center on that side. During forced breathing, the apneustic centers also respond to sensory input from the vagus nerves regarding the amount of lung inflation.

The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. Centers in the hypothalamus and cerebrum can alter the activity of the pneumotaxic centers, as well as the respiratory rate and depth. However, essentially normal respiratory cycles continue even if the brainstem superior to the pons has been severely damaged.

In some cases, the inhibitory output of the pneumotaxic centers is cut off by a stroke or other damage to the brainstem, or sensory innervation from the lungs is eliminated due to damage to the vagus nerves. In these cases, the person inhales to maximum capacity and maintains that state for 10–20 seconds at a time. Intervening exhalations are brief, and little pulmonary ventilation occurs.

The CNS regions involved with respiratory control are diagrammed in **Spotlight Figure 23–25**. Interactions between the DRG and the VRG establish the basic rate and depth of respiration. The pneumotaxic centers modify that rate: An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation. A decrease in pneumotaxic output slows the respiratory rate, but increases the depth of respiration, because the apneustic centers are more active.

Sudden infant death syndrome (SIDS), also known as *crib death*, is the leading cause of death for babies 1–12 months old and kills an estimated 2250 infants each year in the United States alone. Most crib deaths occur between midnight and 9:00 a.m., in the late fall or winter, and involve infants 2 to 4 months old. Eyewitness accounts indicate that the sleeping infant suddenly stops breathing, turns blue, and relaxes. Genetic factors appear to be involved, but controversy remains as to the relative importance of other factors. The age at the time of death corresponds with a period when the pacemaker complex and respiratory centers are establishing connections with other portions of the brain. It has been suggested that SIDS results from a problem in the interconnection process that disrupts the reflexive respiratory pattern.

Modification of Respiratory Rhythm by Respiratory Reflexes

The activities of the respiratory centers are modified by sensory information from several sources:

- Chemoreceptors sensitive to the P_{CO_2}, pH, or P_{O_2} of the blood or cerebrospinal fluid;
- Baroreceptors in the aortic or carotid sinuses sensitive to changes in blood pressure;
- Stretch receptors that respond to changes in the volume of the lungs (the *Hering–Breuer reflexes*);
- Irritating physical or chemical stimuli in the nasal cavity, larynx, or bronchial tree; and
- Other sensations, including pain, changes in body temperature, and abnormal visceral sensations.

Information from these receptors alters the pattern of respiration. The induced changes have been called *respiratory reflexes*.

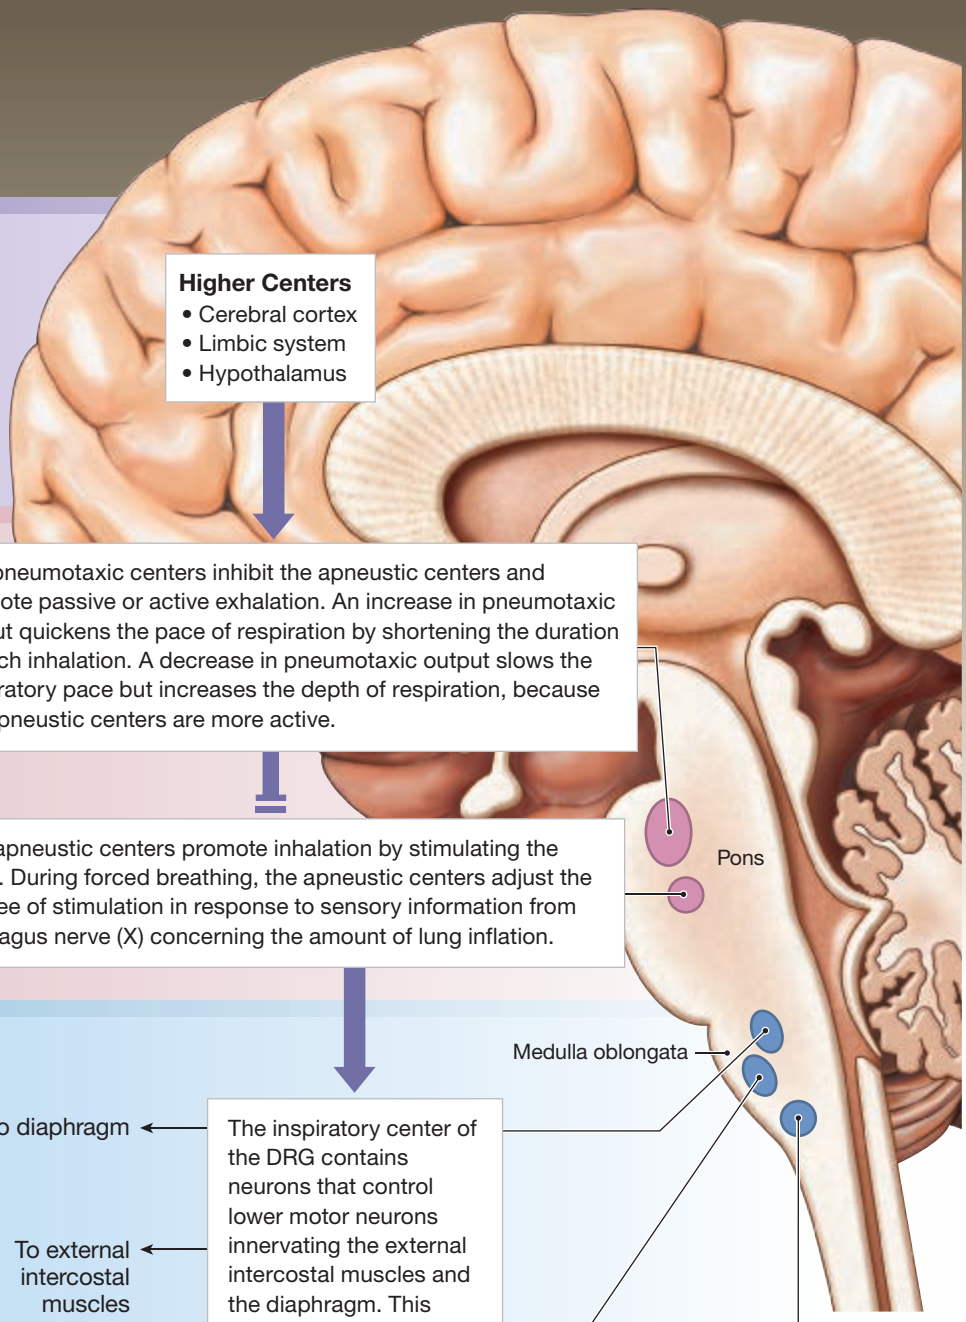
Chemoreceptor Reflexes. The respiratory centers are strongly influenced by chemoreceptor inputs from cranial nerves IX and X, and from receptors that monitor the composition of the cerebrospinal fluid (CSF):

- The glossopharyngeal nerves (IX) carry chemoreceptive information from the carotid bodies, adjacent to the carotid sinus. pp. 521, 758 The carotid bodies are stimulated by a decrease in the pH or P_{O_2} of blood. Because changes in P_{CO_2} affect pH, an increase in the P_{CO_2} indirectly stimulates these receptors.
- The vagus nerves (X) monitor chemoreceptors in the aortic bodies, near the aortic arch. pp. 521, 758 These receptors are sensitive to the same stimuli as the carotid bodies. Carotid and aortic body receptors are often called *peripheral chemoreceptors*.
- Chemoreceptors are located on the ventrolateral surface of the medulla oblongata in a region known as the *chemosensitive area*. The neurons in that area respond only to the P_{CO_2} and pH of the CSF. They are often called *central chemoreceptors*.

SPOTLIGHT

Figure 23–25
Control of Respiration

Respiratory control involves multiple levels of regulation. Most of the regulatory activities occur outside of our awareness.



LEVEL 3

Higher Centers

Higher centers in the cerebral cortex, limbic system, and hypothalamus can alter the activity of the pneumotaxic centers, but essentially normal respiratory cycles continue even if the brainstem superior to the pons has been severely damaged.

LEVEL 2

Apneustic and Pneumotaxic Centers in the Pons

The **apneustic** (ap-NŪ-stik) **centers** and the **pneumotaxic** (nū-mō-TAK-sik) **centers** of the pons are paired nuclei that adjust the output of the respiratory rhythmicity centers.

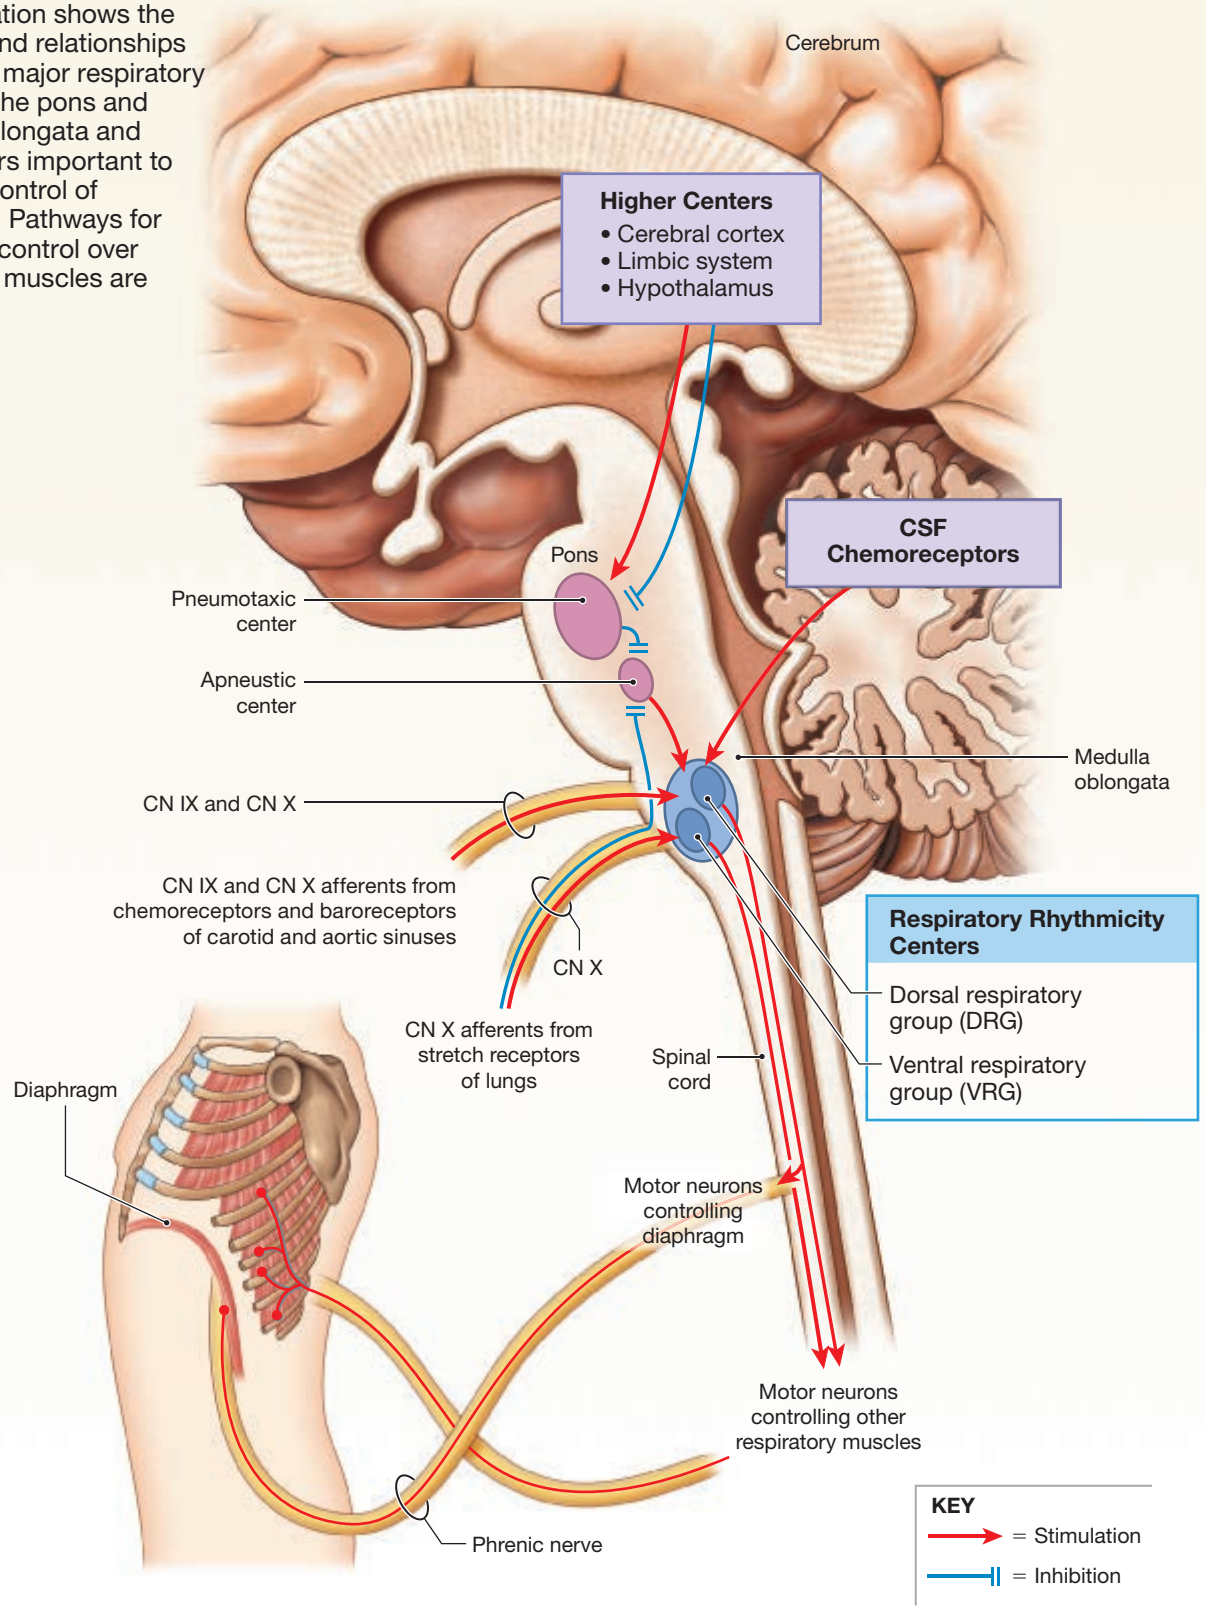
LEVEL 1

Respiratory Rhythmicity Centers in the Medulla Oblongata

The most basic level of respiratory control involves pacemaker cells in the medulla oblongata. These neurons generate cycles of contraction and relaxation in the diaphragm. The **respiratory rhythmicity centers** set the pace of respiration by adjusting the activities of these pacemakers and coordinating the activities of additional respiratory muscles. Each rhythmicity center can be subdivided into a **dorsal respiratory group (DRG)** and a **ventral respiratory group (VRG)**. The DRG is mainly concerned with inspiration and the VRG is primarily associated with expiration.The DRG modifies its activities in response to input from chemoreceptors and baroreceptors that monitor O_2, CO_2, and pH in the blood and CSF, and from stretch receptors that monitor the degree of stretching in the walls of the lungs.

Respiratory Centers and Reflex Controls

This illustration shows the locations and relationships among the major respiratory centers in the pons and medulla oblongata and other factors important to the reflex control of respiration. Pathways for conscious control over respiratory muscles are not shown.



We discussed chemoreceptors and their effects on cardiovascular function in Chapters 15 and 21. pp. 521, 749–750 Stimulation of these chemoreceptors leads to an increase in the rate and depth of respiration. Under normal conditions, a drop in arterial P_{O_2} has little effect on the respiratory centers, until the arterial P_{O_2} drops by about 40%, to below 60 mm Hg. If the P_{O_2} of arterial blood drops to 40 mm Hg (the level in peripheral tissues), the respiratory rate increases by only 50–70%. In contrast, a rise of just 10% in the arterial P_{CO_2} causes the respiratory rate to double, even if the P_{O_2} remains completely normal. The carbon dioxide level is therefore responsible for regulating respiratory activity under normal conditions.

Although the receptors monitoring the CO_2 level are more sensitive, oxygen and carbon dioxide receptors work together in a crisis. Carbon dioxide is generated during oxygen consumption, so when the oxygen concentration is falling rapidly, the CO_2 level is usually increasing. This cooperation breaks down only under unusual circumstances. For example, you can hold your breath longer than normal by taking deep, full breaths beforehand, but the practice is very dangerous. The danger lies in the fact that the increased ability is due not to extra oxygen, but to less carbon dioxide. If the P_{CO_2} is driven down far enough, your ability to hold your breath can increase to the point at which you become unconscious from oxygen starvation in the brain without ever feeling the urge to breathe.

The chemoreceptors are subject to adaptation—a decrease in sensitivity after chronic stimulation—if the P_{O_2} or P_{CO_2} remains abnormal for an extended period. This adaptation can complicate the treatment of chronic respiratory disorders. For example, if the P_{O_2} remains low for an extended period while the P_{CO_2} remains chronically elevated, the chemoreceptors will reset to those values. They will then oppose any attempts to return the partial pressures to the proper range.

Any condition altering the pH of blood or CSF affects respiratory performance because the chemoreceptors monitoring the CO_2 level are also sensitive to pH. The increase in the lactate level after exercise, for example, is accompanied by a decrease in pH that helps stimulate respiratory activity.

Hypercapnia is an increase in the P_{CO_2} of arterial blood. Figure 23–26a diagrams the central response to hypercapnia. Stimulation of chemoreceptors in the carotid and aortic bodies triggers this response. It is reinforced by the stimulation of CNS chemoreceptors. Carbon dioxide crosses the blood brain barrier quite rapidly. For this reason, a rise in arterial P_{CO_2} almost immediately increases the CO_2 level in the CSF, decreasing the pH of the CSF and stimulating the chemoreceptive neurons of the medulla oblongata.

These chemoreceptors stimulate the respiratory centers to increase the rate and depth of respiration. Your breathing becomes more rapid, and more air moves into and out of your lungs with each breath. Because more air moves into and out of the alveoli each minute, alveolar concentrations of carbon dioxide decline, accelerating the diffusion of carbon dioxide out of alveolar capillaries. In this way, homeostasis is restored.

The most common cause of hypercapnia is hypoventilation. In **hypoventilation**, the respiratory rate remains abnormally low and cannot meet the demands for normal oxygen delivery and carbon dioxide removal. Carbon dioxide then accumulates in the blood.

If the rate and depth of respiration exceed the demands for oxygen delivery and carbon dioxide removal, the condition called **hyperventilation** exists. Hyperventilation gradually leads to **hypocapnia**, an abnormally low P_{CO_2}. If the arterial P_{CO_2} drops below the normal level, chemoreceptor activity decreases and the respiratory rate falls (Figure 23–26b). This situation continues until the P_{CO_2} returns to normal and homeostasis is restored.

Baroreceptor Reflexes. We described the effects of carotid and aortic baroreceptor stimulation on systemic blood pressure in Chapter 21. pp. 747–748 The output from these baroreceptors also affects the respiratory centers. When blood pressure falls, the respiratory rate increases. When blood pressure rises, the respiratory rate decreases. These adjustments result from the stimulation or inhibition of the respiratory centers by sensory fibers in the glossopharyngeal nerves (IX) and vagus nerves (X) nerves.

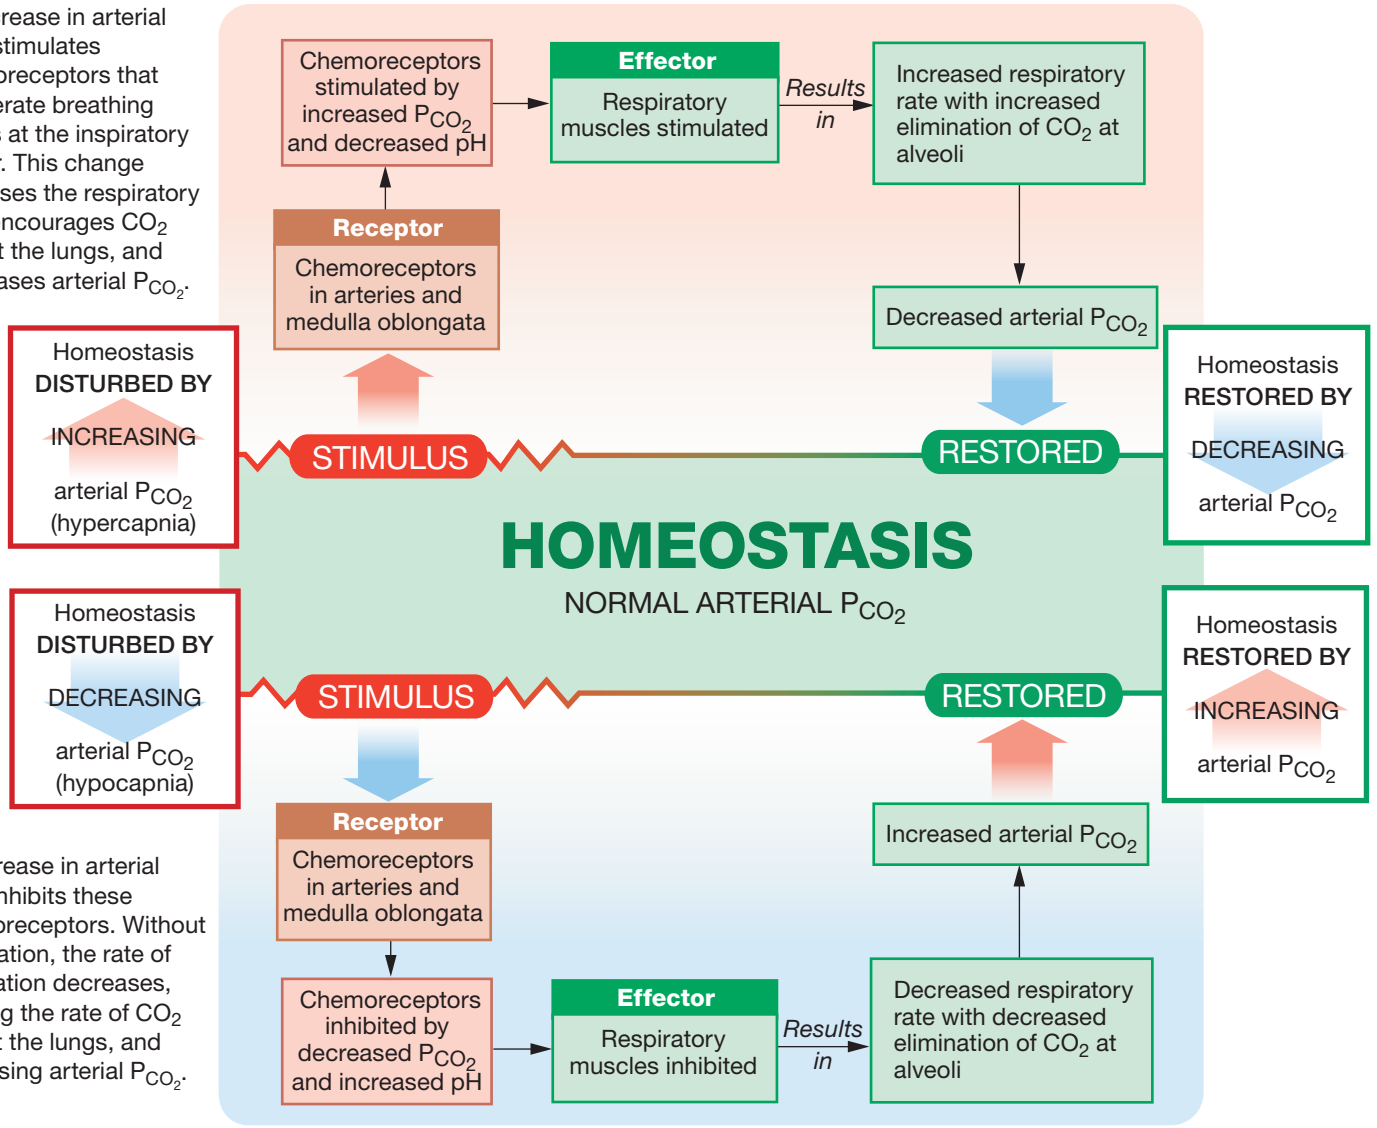
Hering–Breuer Reflexes. The **Hering–Breuer reflexes** are named after the physiologists who described them in 1865. The sensory information from these reflexes goes to the apneustic centers and the ventral respiratory group. The Hering–Breuer reflexes are *not* involved in normal quiet breathing or in tidal volumes under 1000 mL. There are two such reflexes:

- The **inflation reflex** prevents overexpansion of the lungs during forced breathing. Lung expansion stimulates stretch receptors in the smooth muscle tissue around bronchioles. Sensory fibers from the stretch receptors of each lung reach the respiratory rhythmicity center on the same side by the vagus nerve. As lung volume increases, the dorsal respiratory group is gradually inhibited, and the expiratory center of the VRG is stimulated. Inhalation stops as the lungs near maximum volume. Active exhalation then begins.
- The **deflation reflex** normally functions only during forced exhalation, when both the inspiratory and expiratory centers are active. This reflex inhibits the expiratory centers and stimulates the inspiratory centers when the lungs are deflating. These receptors are distinct from those of the inflation reflex. They are located in the alveolar wall near the alveolar capillary network. The smaller the volume of the lungs, the greater the degree of inhibition. Finally, exhalation stops and inhalation begins.

Figure 23–26 The Chemoreceptor Response to Changes in P_{CO_2}.

a An increase in arterial P_{CO_2} stimulates chemoreceptors that accelerate breathing cycles at the inspiratory center. This change increases the respiratory rate, encourages CO_2 loss at the lungs, and decreases arterial P_{CO_2}.

b A decrease in arterial P_{CO_2} inhibits these chemoreceptors. Without stimulation, the rate of respiration decreases, slowing the rate of CO_2 loss at the lungs, and increasing arterial P_{CO_2}.



? Inhibition of medulla oblongata chemoreceptors and respiratory muscles has what effect on respiratory rate, elimination of CO_2 at alveoli, and arterial P_{CO_2}?

Protective Reflexes. Protective reflexes operate when you are exposed to toxic vapors, chemical irritants, or mechanical stimulation of the respiratory tract. The receptors involved are located in the epithelium of the respiratory tract. Examples of protective reflexes include sneezing, coughing, and laryngeal spasms.

Sneezing is triggered by an irritation of the nasal cavity wall. *Coughing* is triggered by an irritation of the larynx, trachea, or bronchi. Both reflexes involve **apnea** (AP-nē-uh), a period in which respiration is suspended. A forceful expulsion of air usually follows to remove the offending stimulus. The glottis is forcibly closed while the lungs are still relatively full. The abdominal and internal intercostal muscles then contract suddenly, creating pressures that blast air out of the respiratory passageways when the glottis reopens. Air leaving the larynx can travel at 99 mph (160 kph), carrying mucus, foreign particles, and irritating gases out of the respiratory tract by the nose or mouth.

Laryngeal spasms result when chemical irritants, foreign objects, or fluids enter the area around the glottis. This reflex generally closes the airway temporarily. A very strong stimulus, such as a toxic gas, could close the glottis so powerfully that you could lose consciousness and die without taking another breath. Fine chicken bones or fish bones that pierce the laryngeal walls can also stimulate laryngeal spasms, swelling, or both, restricting the airway.

Voluntary Control of Respiration by Higher Brain Centers

Activity of the cerebral cortex has an indirect effect on the respiratory centers, as the following examples show:

- Conscious thought processes tied to strong emotions, such as rage or fear, affect the respiratory rate by stimulating centers in the hypothalamus.
- Emotional states can affect respiration by activating the sympathetic or parasympathetic division of the autonomic nervous system. Sympathetic activation causes bronchodilation and increases the respiratory rate. Parasympathetic stimulation has the opposite effects.
- An anticipation of strenuous exercise can trigger an automatic increase in the respiratory rate, along with increased cardiac output, by sympathetic stimulation.

Conscious control over respiratory activities may bypass the respiratory centers completely, using cortical pyramidal fibers that innervate the same lower motor neurons that are controlled by the DRG and VRG. This control mechanism is an essential part of speaking, singing, and swimming, when respiratory activities must be precisely timed. Higher centers can also have an inhibitory effect on the apneustic centers and on the DRG and VRG. This effect is important when you hold your breath.

Your abilities to override the respiratory centers have limits, however. The chemoreceptor reflexes are extremely powerful in stimulating respiration, and you cannot consciously suppress them. For example, you cannot kill yourself by holding your breath "till you turn blue." Once the P_{CO_2} increases to a critical level, you are forced to take a breath.

Checkpoint

26. **What effect does exciting the pneumotaxic centers have on respiration?**
27. **Are peripheral chemoreceptors more or less sensitive to the level of carbon dioxide than they are to the level of oxygen? Why?**

23-11 Respiratory performance changes over the life span

Learning Outcome Describe age-related changes in the respiratory system.

From birth to death, our respiratory system undergoes age-related changes. In healthy people, many of the changes associated with age may not lead to symptoms. Some changes may decrease one's ability to engage in vigorous exercise, but heart function is more likely to affect pulmonary function. Here we discuss some factors associated with respiratory performance.

Changes in the Respiratory System in Newborns

The respiratory systems of fetuses and newborns differ in several important ways. Before delivery, pulmonary arterial resistance is high, because the pulmonary vessels are collapsed. The rib cage is compressed, and the lungs and conducting passageways contain only small amounts of fluid and no air. During delivery, the lungs are compressed further. As the placental connection is lost, the blood oxygen level falls and the carbon dioxide level climbs rapidly.

At birth, the newborn infant takes a truly heroic first breath through powerful contractions of the diaphragm and external intercostal muscles. The inhaled air must enter the respiratory passageways with enough force to overcome surface tension and inflate the bronchial tree and most of the alveoli. The same drop in pressure that pulls air into the lungs also pulls blood into the pulmonary circulation. The changes in blood flow and rise in oxygen level lead to the closure of the *foramen ovale*, an interatrial connection, and the *ductus arteriosus*, the fetal connection between the pulmonary trunk and the aorta. ↩ pp. 775–776 ATLAS: Embryology Summary 18: The Development of the Respiratory System

The exhalation that follows does not empty the lungs completely, because the rib cage does not return to its former, fully compressed state. Cartilages and connective tissues keep the conducting passageways open, and surfactant covering the alveolar surfaces prevents their collapse. The next breaths complete the inflation of the alveoli.

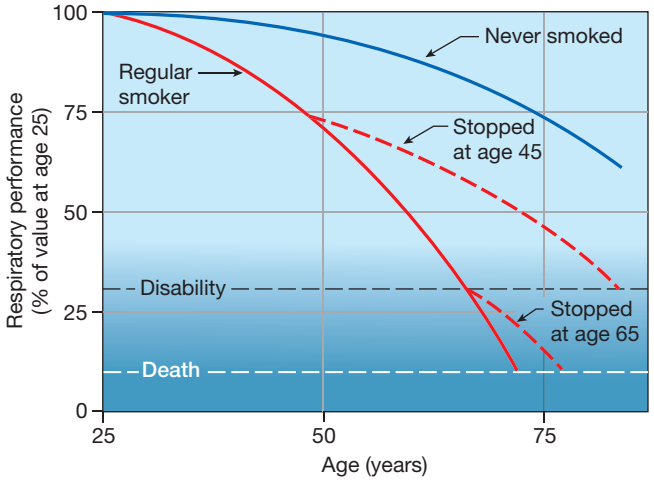
After a stillbirth, pathologists sometimes use these physical changes to determine whether the infant died before delivery or shortly thereafter. Before the first breath, the lungs are completely filled with amniotic fluid, and extracted lungs will sink if placed in water. After the infant's first breath, even the collapsed lungs contain enough air to keep them afloat.

Changes in the Respiratory System in Elderly Individuals

Many factors interact to reduce the efficiency of the respiratory system in elderly individuals. Here are three examples:

- With age, elastic tissue deteriorates throughout the body. These changes decrease lung compliance, lowering the vital capacity.
- Chest movements are restricted by arthritic changes in the rib articulations and by decreased flexibility at the costal cartilages. Along with elastic tissue deterioration, the stiffening and reduction in chest movement effectively limit the respiratory minute volume. This restriction contributes to the reduction in exercise performance and capabilities with increasing age.

Figure 23–27 Decline in Respiratory Performance with Age and Smoking. The relative respiratory performances of people who have never smoked, people who quit smoking at age 45, people who quit smoking at age 65, and lifelong smokers.



- Some degree of emphysema is normal in individuals over age 50. However, the extent varies widely with the lifetime exposure to cigarette smoke and other respiratory irritants. Figure 23–27 compares the respiratory performance of individuals who have never smoked with individuals who have smoked for various periods of time. The message is quite clear: Some decrease in respiratory performance is inevitable, but you can prevent serious respiratory deterioration by stopping smoking or never starting.

Checkpoint

29. **Name several age-related factors that affect the respiratory system.**

See the blue Answers tab at the back of the book.

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems

Learning Outcome Give examples of interactions between the respiratory system and other organ systems studied so far.

The goal of respiratory activity is to maintain homeostatic oxygen and carbon dioxide levels in peripheral tissues. Changes in respiratory activity alone are seldom enough to accomplish this. Coordinated changes in cardiovascular activity must also take place.

These examples highlight the integration between the respiratory and cardiovascular systems:

- At the local level, changes in lung perfusion in response to changes in alveolar P_{O_2} improve the efficiency of gas exchange within or among lobules.

+ Clinical Note Smoking and the Lungs

Emphysema and lung cancer are two relatively common disorders associated with cigarette smoking. **Emphysema** (em-fih-ZĒ-muh) is a chronic, progressive condition. It is characterized by shortness of breath and an inability to tolerate physical exertion. The underlying problem is the destruction of alveolar surfaces and inadequate surface area for oxygen and carbon dioxide exchange. The alveoli gradually expand and merge to form larger air spaces supported by fibrous tissue without alveolar capillary networks. As connective tissues are eliminated, compliance increases, so air moves into and out of the lungs more easily than before. But the loss of respiratory surface area restricts oxygen absorption, so the individual becomes short of breath.

Emphysema has been linked to breathing air that contains fine particles or toxic vapors, such as those in cigarette smoke. Genetic factors also predispose individuals to the condition. Some degree of emphysema is a normal consequence of aging. An estimated 66% of adult males and 25% of adult females have detectable areas of emphysema in their lungs.

Lung cancer is an aggressive class of malignancies. These cancers affect the epithelial cells that line conducting passageways, mucous glands, or alveoli. Signs and symptoms generally do not appear until tumors restrict airflow or compress adjacent structures. Chest pain, shortness of breath, a cough or a wheeze, and weight loss are common. Treatment varies with the cellular organization of the tumor and whether *metastasis* (cancer cell migration) has occurred. Surgery, radiation, or chemotherapy may be involved. According to the CDC, more people die from lung cancer than any other type of cancer.

- Chemoreceptor stimulation not only increases the respiratory rate, but it also causes blood pressure to rise and cardiac output to increase.
- The stimulation of baroreceptors in the lungs has secondary effects on cardiovascular function. For example, the stimulation of airway stretch receptors not only triggers the inflation reflex, but also increases heart rate. Thus, as the lungs fill, cardiac output rises and more blood flows through the alveolar capillaries.

The adaptations that take place at high altitudes are an excellent example of the functional interplay between the respiratory and cardiovascular systems. Atmospheric pressure decreases with increasing altitude, and so do the partial pressures of the component gases, including oxygen. People living in Denver or Mexico City function normally with alveolar oxygen pressures in the 80–90 mm Hg range. At higher elevations, alveolar P_{O_2} is even lower. At 3300 meters (10,826 ft),

Build Your Knowledge

Figure 23–28 Integration of the RESPIRATORY system with the other body systems presented so far.

Integumentary System

- The Integumentary System protects portions of upper respiratory tract; hairs guard entry to external nares
- The respiratory system provides oxygen to tissues and removes carbon dioxide

Endocrine System

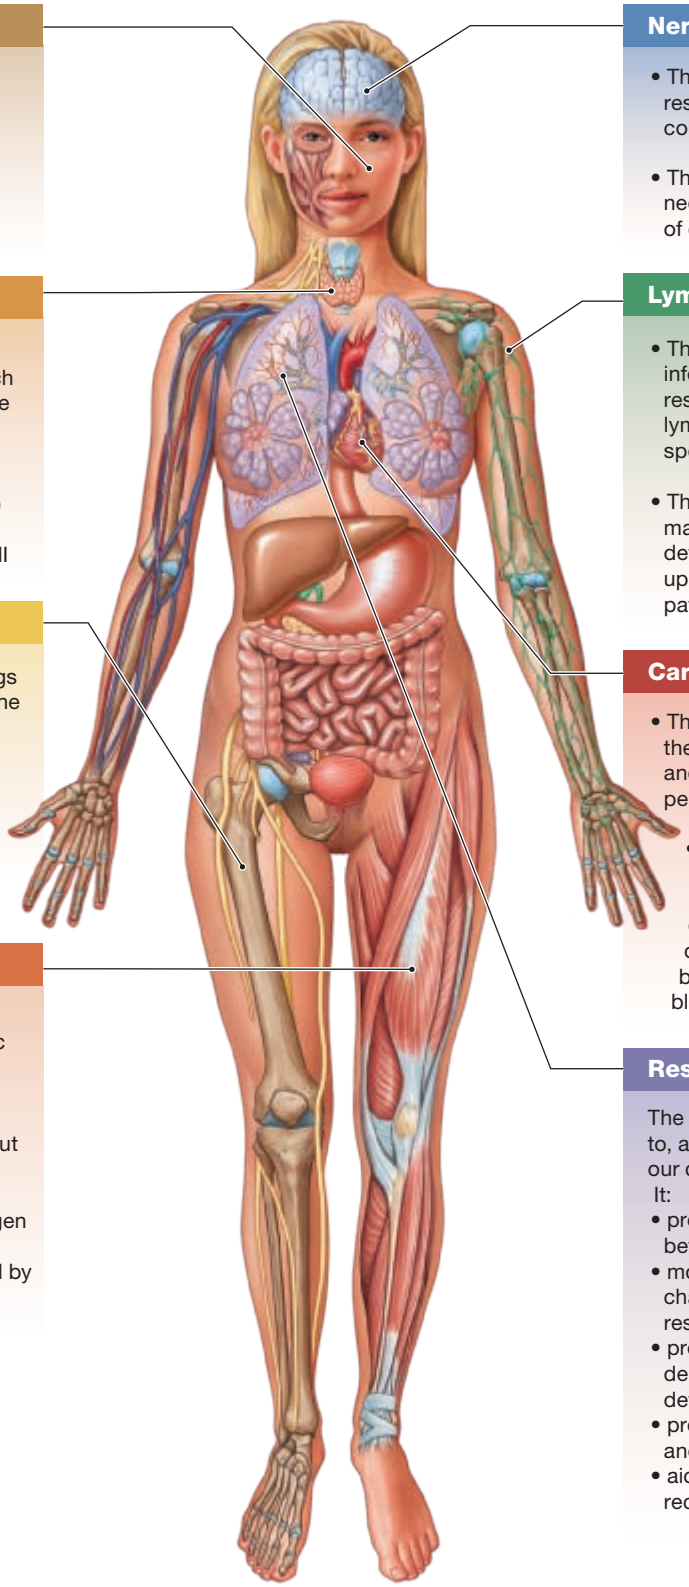
- The Endocrine System produces epinephrine and norepinephrine, which stimulate respiratory activity and dilate respiratory passageways
- The respiratory system produces angiotensin-converting enzyme (ACE) from capillaries in the lungs. ACE converts angiotensin I to angiotensin II

Skeletal System

- The Skeletal System protects the lungs with its axial division; movements of the ribs are important in breathing.
- The respiratory system provides oxygen to skeletal structures and disposes of carbon dioxide

Muscular System

- The Muscular System controls the entrances to respiratory tract; intrinsic laryngeal muscles control airflow through larynx and produce sounds; respiratory muscles change thoracic cavity volume so air moves into and out of lungs
- The respiratory system provides oxygen needed for muscle contractions and disposes of carbon dioxide generated by active muscles



Nervous System

- The Nervous System monitors respiratory volume and blood gas levels; controls pace and depth of respiration
- The respiratory system provides oxygen needed for neural activity and disposes of carbon dioxide

Lymphatic System

- The Lymphatic System protects against infection with tonsils at entrance to respiratory tract; lymph nodes monitor lymph drainage from lungs and provide specific defenses when infection occurs
- The respiratory system has alveolar macrophages that provide nonspecific defenses; mucous membrane lining the upper respiratory system traps pathogens and protects deeper tissues

Cardiovascular System

- The Cardiovascular System circulates the red blood cells that transport oxygen and carbon dioxide between lungs and peripheral tissues
- The respiratory system provides oxygen needed for heart muscle contraction; bicarbonate ions contribute to the buffering capability of blood; activation of angiotensin II by ACE is important in regulation of blood pressure and volume

Respiratory System

The respiratory system provides oxygen to, and eliminates carbon dioxide from, our cells.

It:

- provides a large area for gas exchange between air and circulating blood
- moves air to and from the gas-exchange surfaces of the lungs along the respiratory passageways
- protects the respiratory surfaces from dehydration, temperature changes, and defends against invading pathogens
- produces sounds for speaking, singing, and other forms of communication
- aids the sense of smell by the olfactory receptors in the nasal cavity

an altitude many hikers and skiers have experienced, alveolar P_{O_2} is about 60 mm Hg.

Despite the low alveolar P_{O_2}, millions of people live and work at altitudes this high or higher. Important physiological adjustments include an increased respiratory rate, an increased heart rate, an increased BPG level, and an elevated hematocrit. Thus, even though the hemoglobin is not fully saturated, the bloodstream holds more of it, and the round-trip between the lungs and the peripheral tissues takes less time. However, most of these adaptations take days to weeks to develop. As a result, athletes planning to compete in events at high altitude must begin training under such conditions well in advance.

The respiratory system is functionally linked to all other body systems as well. Build Your Knowledge **Figure 23–28** illustrates these interrelationships with the other body systems studied so far.

Checkpoint

30. **Identify the functional relationship between the respiratory system and all other organ systems.**
31. **Describe the functional relationship between the respiratory system and the lymphatic system.**

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, functions primarily to aid gas exchange p. 835

2. The functions of the **respiratory system** include (1) providing an area for gas exchange between air and circulating blood; (2) moving air to and from exchange surfaces; (3) protecting respiratory surfaces from environmental variations and defending the respiratory system and other tissues from invasion by pathogens; (4) producing sounds; and (5) facilitating the detection of olfactory stimuli.
3. The respiratory system includes the **upper respiratory system**, composed of the nose, nasal cavity, paranasal sinuses, and pharynx, and the **lower respiratory system**, which includes the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. *(Figure 23–1)*
4. The **respiratory tract** consists of the conducting airways that carry air to and from the **alveoli**. The passageways of the upper respiratory tract filter and humidify incoming air. The lower respiratory tract includes delicate conduction passages and the exchange surfaces of the alveoli.
5. The **respiratory mucosa** (respiratory epithelium and underlying connective tissue) lines the conducting portion of the respiratory tract.
6. The respiratory epithelium changes in structure along the respiratory tract. It is supported by the **lamina propria**, a layer of areolar tissue. *(Figure 23–2)*
7. Contamination of the respiratory system is prevented by the mucus and cilia of the **respiratory defense system**. *(Figure 23–2)*

23-2 The conducting portion of the upper respiratory system filters, warms, and humidifies air p. 838

8. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. *(Figures 23–1, 23–3)*
9. Air normally enters the respiratory system through the **nostrils**, which open into the *nasal cavity*. The **nasal vestibule** (entryway) is guarded by hairs that screen out large particles. *(Figure 23–3)*
10. Incoming air flows through the **superior**, **middle**, and **inferior meatuses** (narrow grooves) and bounces off the conchal surfaces. *(Figure 23–3)*
11. The **hard palate** separates the oral and nasal cavities. The **soft palate** separates the superior nasopharynx from the rest of the pharynx. The **choanae** connect the nasal cavity and nasopharynx.
12. The nasal mucosa traps particles, warms and humidifies incoming air, and dehumidifies and absorbs heat of outgoing air.
13. The **pharynx**, or throat, is a chamber shared by the digestive and respiratory systems. The **nasopharynx** is the superior part of the pharynx. The **oropharynx** is continuous with the oral cavity. The **laryngopharynx** includes the narrow zone between the hyoid bone and the entrance to the esophagus. *(Figure 23–3)*

23-3 The conducting portion of the lower respiratory system conducts air to the respiratory portion and produces sound p. 841

14. Inhaled air passes through the glottis on the way to the lungs; the **larynx** surrounds and protects the glottis, or vocal apparatus. *(Figure 23–4)*
15. The cylindrical larynx is composed of three large cartilages (the **median thyroid cartilage**, median **cricoid cartilage**, and **epiglottis**) and three smaller pairs of cartilages (the **arytenoid**, **corniculate**, and **cuneiform cartilages**). The epiglottis projects into the pharynx. *(Figures 23–4, 23–5)*
16. A pair of inelastic **vestibular folds** surrounds the glottis. The **glottis** includes the elastic **vocal folds** and the space between them, the *rima glottidis*. *(Figure 23–5)*
17. Air passing through the open glottis vibrates its vocal folds, producing sound. The pitch of the sound depends on the diameter, length, and tension of the vocal folds.
18. The muscles of the neck and pharynx position and stabilize the larynx. The smaller intrinsic muscles regulate tension in the vocal folds or open and close the glottis. During swallowing, both sets of muscles help prevent particles from entering the glottis.
19. The **trachea** extends from the sixth cervical vertebra to the fifth thoracic vertebra. The **submucosa** contains C-shaped **tracheal cartilages**, which stiffen the tracheal walls and protect the airway. The posterior tracheal wall can distort to permit large masses of food to pass through the esophagus. *(Figure 23–6)*
20. The trachea branches within the mediastinum to form the **right** and **left main bronchi**. Each bronchus enters a lung at the **hilum** (a groove). The **root of the lung** is a connective tissue mass that includes the bronchus, pulmonary vessels, and nerves. *(Figures 23–6, 23–9)*
21. The main bronchi and their branches form the **bronchial tree**. The **lobar** and **segmental bronchi** are branches within the lungs. As they branch, the amount of cartilage in their walls decreases and the amount of smooth muscle increases. *(Figure 23–7)*
22. Each tertiary bronchus supplies air to a single **bronchopulmonary segment**. *(Figure 23–7)*
23. **Bronchioles** within the bronchopulmonary segments ultimately branch into **terminal bronchioles**.

23-4 The respiratory portion of the lower respiratory system is where gas exchange occurs p. 846

24. Each terminal bronchiole delivers air to a single **pulmonary lobule** in which the terminal bronchiole branches into **respiratory bronchioles**. The connective tissues of the root of the lung extend into the parenchyma of the lung as a series of *trabeculae* (partitions) that branch to form **interlobular septa**, which divide the lung into lobules. *(Figure 23–7)*
25. The respiratory bronchioles open into **alveolar ducts**, where many alveoli are interconnected. The respiratory exchange surfaces are extensively connected to the circulatory system by the capillaries of the pulmonary circuit. *(Figure 23–7)*
26. The **blood air barrier** consists of a simple squamous epithelium, the endothelial cell lining an adjacent capillary, and their fused basement membranes. **Pneumocytes type II** (type II alveolar cells) scattered in the blood air barrier produce **surfactant** that reduces surface tension and keeps the alveoli from collapsing. **Alveolar macrophages** patrol the epithelium and engulf foreign particles. *(Figure 23–8)*

23-5 Enclosed by pleural cavities, the lungs are paired organs made up of multiple lobes p. 848

27. The **lobes** of the lungs are separated by fissures. The right lung has three lobes, the left lung two. *(Figure 23–9)*
28. The anterior and lateral surfaces of the lungs follow the inner contours of the rib cage. The concavity of the medial surface of the left lung is the **cardiac notch**, which conforms to the shape of the pericardium. *(Figures 23–9, 23–10)*
29. The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The conducting portions of the respiratory tract receive blood from the bronchial arteries. Most of the returning venous blood flows into the pulmonary veins, bypassing the rest of the systemic circuit and diluting the oxygenated blood leaving the alveoli.
30. Each lung is surrounded by a single **pleural cavity** lined by a **pleura** (serous membrane). The two types of pleurae are the **parietal pleura**, covering the inner surface of the thoracic wall, and the **visceral pleura**, covering the lungs.

23-6 External respiration and internal respiration allow gas exchange within the body p. 851

31. Respiratory physiology focuses on a series of integrated processes. **External respiration** is the exchange of oxygen and carbon dioxide between interstitial fluid and the external environment and includes *pulmonary ventilation* (breathing). **Internal respiration** is the exchange of oxygen and carbon dioxide between interstitial fluid and cells. If the oxygen content declines, the affected tissues suffer from **hypoxia**; if the oxygen supply is completely shut off, **anoxia** and tissue death result. *(Figure 23–11)*

23-7 Pulmonary ventilation—air exchange between the atmosphere and the lungs—involves muscle actions and volume changes that cause pressure changes p. 852

32. **Pulmonary ventilation** is the physical movement of air into and out of the respiratory tract.
33. Decreasing the volume of a gas increases its pressure. Increasing the volume of a gas decreases its pressure. This inverse relationship is **Boyle's law**. *(Figure 23–12)*
34. Movement of the diaphragm and ribs changes lung volume. **Primary respiratory muscles** are the diaphragm and external intercostal muscles. *(Spotlight Figure 23–13, Figure 23–14)*
35. The relationship between **intrapulmonary pressure** (the pressure inside the respiratory tract) and **atmospheric pressure(atm)** determines the direction of airflow. **Intrapleural pressure** is the pressure in the potential space between the parietal and visceral pleurae. *(Figure 23–15)*

36. A **respiratory cycle** is a single cycle of inhalation and exhalation. The amount of air moved in one respiratory cycle is the **tidal volume**. A **spirometer** is an instrument used to measure the capacity of the lungs. *(Figure 23–15)*
37. **Alveolar ventilation** is the amount of air reaching the alveoli each minute. The **vital capacity** includes the **tidal volume** plus the **expiratory** and **inspiratory reserve volumes**. The air left in the lungs at the end of maximum exhalation is the **residual volume**. *(Figure 23–16)*

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of gas molecules p. 860

38. In a mixture of gases, the individual gases exert a pressure proportional to their abundance in the mixture (**Dalton's law**). The pressure contributed by a single gas is its **partial pressure**. *(Table 23–1)*
39. The amount of a gas in solution is directly proportional to the partial pressure of that gas (**Henry's law**). *(Figure 23–17)*
40. Alveolar air and atmospheric air differ in composition. Gas exchange across the blood air barrier is efficient due to differences in partial pressures, the short diffusion distance, lipid-soluble gases, the large surface area of all the alveoli combined, and the coordination of blood flow and airflow. *(Figure 23–18)*

23-9 In gas transport, most oxygen is transported bound to hemoglobin, whereas carbon dioxide is transported in three ways p. 864

41. Blood entering peripheral capillaries delivers oxygen and absorbs carbon dioxide. The transport of oxygen and carbon dioxide in blood involves reactions that are completely reversible.
42. Oxygen is carried mainly by RBCs, reversibly bound to hemoglobin. At alveolar P_{O_2}, hemoglobin is almost fully saturated; at the P_{O_2} of peripheral tissues, it releases oxygen but still retains a substantial oxygen reserve. The effect of pH on the hemoglobin saturation curve is called the **Bohr effect**. When low plasma P_{O_2} continues for extended periods, red blood cells generate more **2,3-bisphosphoglycerate (BPG)**, which reduces hemoglobin's affinity for oxygen. *(Figures 23–19, 23–20)*
43. **Fetal hemoglobin** has a stronger affinity for oxygen than does adult hemoglobin, aiding the removal of oxygen from maternal blood. *(Figure 23–21)*
44. Aerobic metabolism in peripheral tissues generates CO_2. Roughly 70% is transported as bicarbonate ions (HCO_3^-), 23% is bound as **carbaminohemoglobin**, and about 7% of the CO_2 in blood is dissolved in the plasma. *(Figure 23–22)*
45. Driven by differences in partial pressure, oxygen enters the blood at the lungs and leaves it in peripheral tissues; similar forces drive carbon dioxide into the blood at the tissues and into the alveoli at the lungs. *(Figure 23–23)*

23-10 Respiratory centers in the brainstem, along with respiratory reflexes, control respiration p. 868

46. Normally, the cellular rates of gas absorption and generation are matched by the capillary rates of delivery and removal and are identical to the rates of oxygen absorption and carbon dioxide removal at the lungs. When these rates are unbalanced, homeostatic mechanisms restore equilibrium.
47. Local factors regulate alveolar blood flow (*lung perfusion*) and airflow (*alveolar ventilation*). Alveolar capillaries constrict under conditions of low oxygen, and bronchioles dilate under conditions of high carbon dioxide.
48. The **respiratory centers** include three pairs of nuclei in the reticular formation of the pons and medulla oblongata. The *respiratory rhythmicity centers* set the pace for respiration; the **apneustic centers** cause strong, sustained inspiratory movements; and the **pneumotaxic centers** inhibit the apneustic centers and promote exhalation. *(Figure 23–24, Spotlight Figure 23–25)*
49. Stimulation of the chemoreceptor reflexes is based on the level of carbon dioxide in the blood and CSF. *(Spotlight Figure 23–25, Figure 23–26)*
50. The **inflation reflex** prevents overexpansion of the lungs during forced breathing. The **deflation reflex** stimulates inhalation when the lungs are collapsing.
51. Conscious and unconscious thought processes can affect respiration by affecting the respiratory centers.

23-11 Respiratory performance changes over the life span p. 876

52. Before delivery, the fetal lungs are filled with body fluids and are collapsed. At the first breath, the lungs inflate and do not collapse completely thereafter.
53. The respiratory system is generally less efficient in elderly individuals because (1) elastic tissue deteriorates, lowering compliance and the vital capacity of the lungs; (2) movements of the chest are restricted by arthritic changes and decreased flexibility of costal cartilages; and (3) some degree of emphysema is generally present. *(Figure 23–27)*

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems p. 877

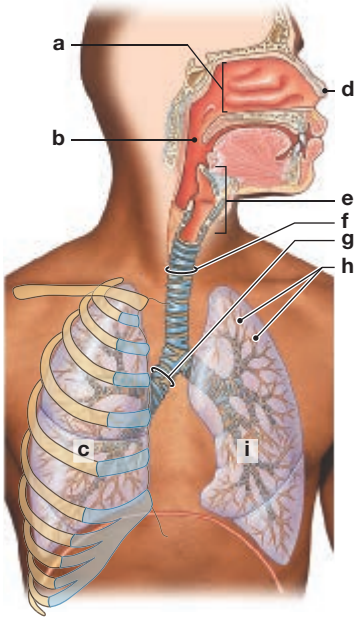
54. The respiratory system has extensive anatomical and physiological connections with the cardiovascular system. *(Figure 23–28)*

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Surfactant **(a)** protects the surface of the lungs, **(b)** phagocytizes small particulates, **(c)** replaces mucus in the alveoli, **(d)** helps prevent the alveoli from collapsing, **(e)** is not found in healthy lung tissue.
2. The hard palate separates the **(a)** nasal cavity from the larynx, **(b)** left and right sides of the nasal cavity, **(c)** nasal cavity and the oral cavity, **(d)** nostrils from the choanae, **(e)** soft palate from the nasal cavity.
3. Air moves into the lungs because **(a)** the gas pressure in the lungs is less than atmospheric pressure, **(b)** the volume of the lungs decreases with inspiration, **(c)** the thorax is muscular, **(d)** contraction of the diaphragm decreases the volume of the thoracic cavity, **(e)** the respiratory control center initiates active expansion of the thorax.
4. The glottis closes partway through an exhalation. The abdominal and internal intercostal muscles then contract suddenly, creating pressure that blasts the air out of the respiratory passages. This describes a **(a)** sneeze, **(b)** hiccough, **(c)** cough, **(d)** laryngeal spasm, **(e)** gag.
5. When the diaphragm and external intercostal muscles contract, **(a)** exhalation occurs, **(b)** intrapulmonary pressure increases, **(c)** intrapleural pressure decreases, **(d)** the volume of the lungs decreases, **(e)** the size of the thoracic cavity increases.
6. Identify the structures of the respiratory system in the figure below:



(a) _____
(b) _____
(c) _____
(d) _____
(e) _____
(f) _____
(g) _____
(h) _____
(i) _____

7. During the winter, Brad sleeps in a dorm room that lacks any humidifier for the heated air. In the mornings he notices that his nose is "stuffy" similar to when he has a cold, but after showering and drinking some water, the stuffiness disappears until the next morning. What might be the cause of Brad's nasal condition?
8. Distinguish the structures of the upper respiratory system from those of the lower respiratory system.
9. Name the three regions of the pharynx. Where is each region located?
10. List the cartilages of the larynx. What are the functions of each?
11. What three integrated steps are involved in external respiration?
12. What important physiological differences exist between fetal hemoglobin and maternal hemoglobin?
13. By what three ways is carbon dioxide transported in the bloodstream?

LEVEL 2 Reviewing Concepts

14. Which of the following does *not* occur in internal respiration? **(a)** Oxygen diffuses from the blood to the interstitial spaces. **(b)** Carbon dioxide diffuses from the interstitial spaces to the blood. **(c)** Hemoglobin binds more oxygen. **(d)** Bicarbonate ions are formed in red blood cells. **(e)** Chloride ions diffuse into red blood cells as bicarbonate ions diffuse out.
15. Gas exchange at the blood air barrier is efficient because **(a)** the differences in partial pressure are substantial, **(b)** the gases are lipid soluble, **(c)** the total surface area is large, **(d)** of all of these.
16. For any partial pressure of oxygen, if the concentration of 2,3-bisphosphoglycerate (BPG) increases, **(a)** the amount of oxygen released by hemoglobin will decrease, **(b)** the oxygen levels in hemoglobin will be unaffected, **(c)** the amount of oxygen released by hemoglobin will increase, **(d)** the amount of carbon dioxide carried by hemoglobin will increase.
17. An increase in the partial pressure of carbon dioxide in arterial blood causes chemoreceptors to stimulate the respiratory centers, resulting in **(a)** a decreased respiratory rate, **(b)** an increased respiratory rate, **(c)** hypocapnia, **(d)** hypercapnia.
18. Why is breathing through the nasal cavity more desirable than breathing through the mouth?
19. Correctly justify the statement "The bronchioles are to the respiratory system what the arterioles are to the cardiovascular system."
20. How are pneumocytes type II involved with keeping the alveoli from collapsing?
21. How does pulmonary ventilation differ from alveolar ventilation, and what is the function of each type of ventilation?
22. What is the significance of (a) Boyle's law, (b) Dalton's law, and (c) Henry's law to the process of respiration?
23. What happens to the process of respiration when a person is sneezing or coughing?
24. What are the differences between pulmonary volumes and respiratory capacities? How are pulmonary volumes and respiratory capacities determined?
25. What is the functional difference between the dorsal respiratory group (DRG) and the ventral respiratory group (VRG) of the medulla oblongata?

LEVEL 3 Critical Thinking and Clinical Applications

26. Billy's normal alveolar ventilation rate (AVR) during mild exercise is 6.0 L/min. While at the beach on a warm summer day, he goes snorkeling. The snorkel has a volume of 50 mL. Assuming that the water is not too cold and that snorkeling is mild exercise for Billy, what would his respiratory rate have to be for him to maintain an AVR of 6.0 L/min while snorkeling? (Assume a constant tidal volume of 500 mL and an anatomic dead space of 150 mL.)
27. Mr. B. has had chronic advanced emphysema for 15 years. While hospitalized with a respiratory infection, he goes into respiratory distress. Without thinking, his nurse immediately administers pure oxygen, which causes Mr. B. to stop breathing. Why?
28. Cary hyperventilates for several minutes before diving into a swimming pool. After he enters and begins swimming underwater, he blacks out and almost drowns. What caused this to happen?
29. Why do individuals who are anemic generally not exhibit an increase in respiratory rate or tidal volume, even though their blood is not carrying enough oxygen?
30. Doris has an obstruction of her right primary bronchus. As a result, how would the oxygen–hemoglobin saturation curve for her right lung compare with that for her left?

CLINICAL CASE Wrap-Up No Rest for the Weary

Doug has *obstructive sleep apnea*. During sleep his airway becomes blocked and he stops breathing. Several risk factors are promoting this condition. Doug's throat is tight due to the structure of his palate. Excess fat in his neck compresses his throat from the outside. When he falls asleep on his back, his pharyngeal muscles and tongue relax and drop back into his throat, helped by the muscle-relaxing effects of alcohol. As he breathes, especially on inhalation, the tissues in his throat vibrate and make the noise of snoring. The narrower a person's airway, the louder their snoring! Every time his throat collapses completely, Doug experiences apnea: He gets no oxygen for a period of multiple seconds to a minute, or more. Apnea puts strain on his heart and raises his blood pressure. His nighttime rest is disturbed and so is his daytime function. This is a serious problem.

The doctor wants Doug to reduce his risk factors by losing weight and avoiding alcohol at night. In the short term, the treatment of choice for sleep apnea is a CPAP (continuous positive airway pressure) machine. Doug wears the mask device at night. It keeps his airway open by blowing air into the back of his throat.

1. Which parts of the upper respiratory tract (URT) can contribute to obstructed breathing?
2. Children can snore too. A tonsillectomy might eliminate the snoring. Why?

See the blue Answers tab at the back of the book.

Related Clinical Terms

asbestosis: Pneumoconiosis, disease of the lungs, caused by the inhalation of asbestos particles over time.
asphyxia: Impaired oxygen–carbon dioxide exchange that results in suffocation.
aspirate: Drawing fluid from the body by suction; foreign material accidentally sucked into the lungs.
bronchography: A procedure in which radiopaque materials are introduced into the airways to improve x-ray imaging of the bronchial tree.
bronchoscope: A fiber-optic bundle small enough to be inserted into the trachea and finer airways; the procedure is called *bronchoscopy*.
cardiopulmonary resuscitation (CPR): The application of cycles of compression to the rib cage to restore cardiovascular and respiratory function.
Cheyne-Stokes breathing: Hyperpnea (deep, fast breathing) alternating with apnea (absence of breathing).
chronic obstructive pulmonary disease (COPD): A general term describing temporary or permanent lung disease of the bronchial tree.
dyspnea: The condition of labored breathing.
endotracheal tube: Tube that is passed through the mouth or nose to the trachea.
Heimlich maneuver or abdominal thrust: Sudden compression applied to the abdomen just inferior to the diaphragm, to force air out of the lungs to clear a blocked trachea or larynx.
hemoptysis: Coughing up blood or bloody mucus.
hemothorax: The condition of having blood in the pleural cavity.
hyperbaric oxygenation: Therapy to force more oxygen into the blood by use of a pressure chamber.
nasal polyps: Benign growths on the mucous lining of the nasal cavity.
orthopnea: Condition in which one has breathing difficulty except when in an upright position.
otorhinolaryngology: Branch of medicine dealing with disease and treatment of the ear, nose, and throat.
rales: Abnormal hissing or other respiratory sounds.
rhinitis: Inflammation of the nasal cavity.
rhinoplasty: Plastic surgery of the nose.
severe acute respiratory syndrome (SARS): A harsh viral respiratory illness caused by a coronavirus that typically progresses to pneumonia.
sputum: A mixture of saliva and mucus coughed up from the respiratory tract, often as the result of an infection.
stridor: Harsh, vibrating breathing sound caused by an obstruction in the windpipe or larynx.
stuttering: To speak with a continued involuntary repetition of sounds.
tachypnea: Rapid rate of breathing.
tussis: A cough.
wheeze: An audible whistling sound when breathing.

24 The Digestive System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

24-1 ■ Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion. p. 885

24-2 ■ Discuss the anatomy of the oral cavity, and list the functions of its major structures and regions. p. 893

24-3 ■ Describe the structure and functions of the pharynx and the esophagus. p. 898

24-4 ■ Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption. p. 901

24-5 ■ Describe the structure, functions, and regulation of the accessory digestive organs. p. 905

24-6 ■ Describe the anatomy and histology of the small intestine, and explain the functions and regulation of intestinal secretions. p. 915

24-7 ■ Describe the gross and histological structures of the large intestine, including its regional specializations and role in nutrient absorption. p. 921

24-8 ■ List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients. p. 926

24-9 ■ Summarize the effects of aging on the digestive system. p. 931

24-10 ■ Give examples of interactions between the digestive system and other body systems studied so far. p. 932

CLINICAL CASE An Unusual Transplant

Mirasol has been in the hospital and on antibiotics for a stubborn case of pneumonia for over a week. She desperately misses her grandchildren, and is feeling worse than ever. Her cough has resolved, but she has had watery diarrhea 10 times today. The last few times, there was blood in her stool. She has lost her appetite and feels crampy abdominal pain. She is dehydrated and unable to drink enough liquids to keep up with her fluid loss from diarrhea. She also has a fever and has lost weight.

Her doctor enters the room with results of recent tests performed on her stool. "I'm afraid the normal, helpful bacteria that live in your colon have been killed off by the antibiotics used to cure your pneumonia. Now, harmful bacteria have taken over and are causing your bloody diarrhea," reports the doctor. "Your colon is overgrown with *Clostridium difficile* bacteria. These bacteria are producing toxins that are causing your colitis (inflammation of the colon). The usual treatment for this condition is more antibiotics."

"Doctor," cries Mirasol, "I don't think I can take any more antibiotics. I feel worse now than when I arrived."

"Well, I have an idea that may work," the doctor replies. "A transplant, from one of your healthy, adult grandchildren. It's a little unusual, however. You need to keep an open mind." **What kind of transplant can possibly help Mirasol? To find out, turn to the Clinical Case Wrap-Up on p. 938.**

An Introduction to the Digestive System

All living organisms must get nutrients from their environment to sustain life. These nutrients are used as raw materials for synthesizing essential compounds (anabolism). They are also broken down to provide the energy that cells need to continue functioning (catabolism). pp. 37–38, 320–322 The *digestive system*, working with the cardiovascular and lymphatic systems, provides the needed nutrients in the form of organic molecules (such as carbohydrates, fats, or proteins). In effect, the digestive system supplies both the fuel that keeps all the body's cells functioning and the building blocks needed for cell growth and repair.

In this chapter we discuss the structure and function of the major body passage known as the *digestive tract*, as well as several accessory organs. We look at the process of digestion and how it breaks down large and complex organic molecules into smaller fragments that can be absorbed by the digestive epithelium. We also see how some types of organic wastes are removed from the body.

24-1 The digestive system, consisting of the digestive tract and accessory organs, functions primarily to break down and absorb nutrients from food and to eliminate wastes

Learning Outcome Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion.

The **digestive system** (*alimentary system*) consists of a muscular tube, the **digestive tract**, also called the *gastrointestinal (GI) tract* or *alimentary canal*, and various **accessory organs**. Figure 24–1 shows the major organs of the digestive system. The digestive tract begins at the *oral cavity* (mouth). It continues through the *pharynx* (throat), *esophagus*, *stomach*, *small intestine*, and *large intestine*, which opens to the exterior at the *anus*. Accessory digestive organs include the teeth, tongue, and various *glandular organs*, such as the *salivary glands*, *liver*, and *pancreas*, as well as the *gallbladder*, which only has a secretory function.

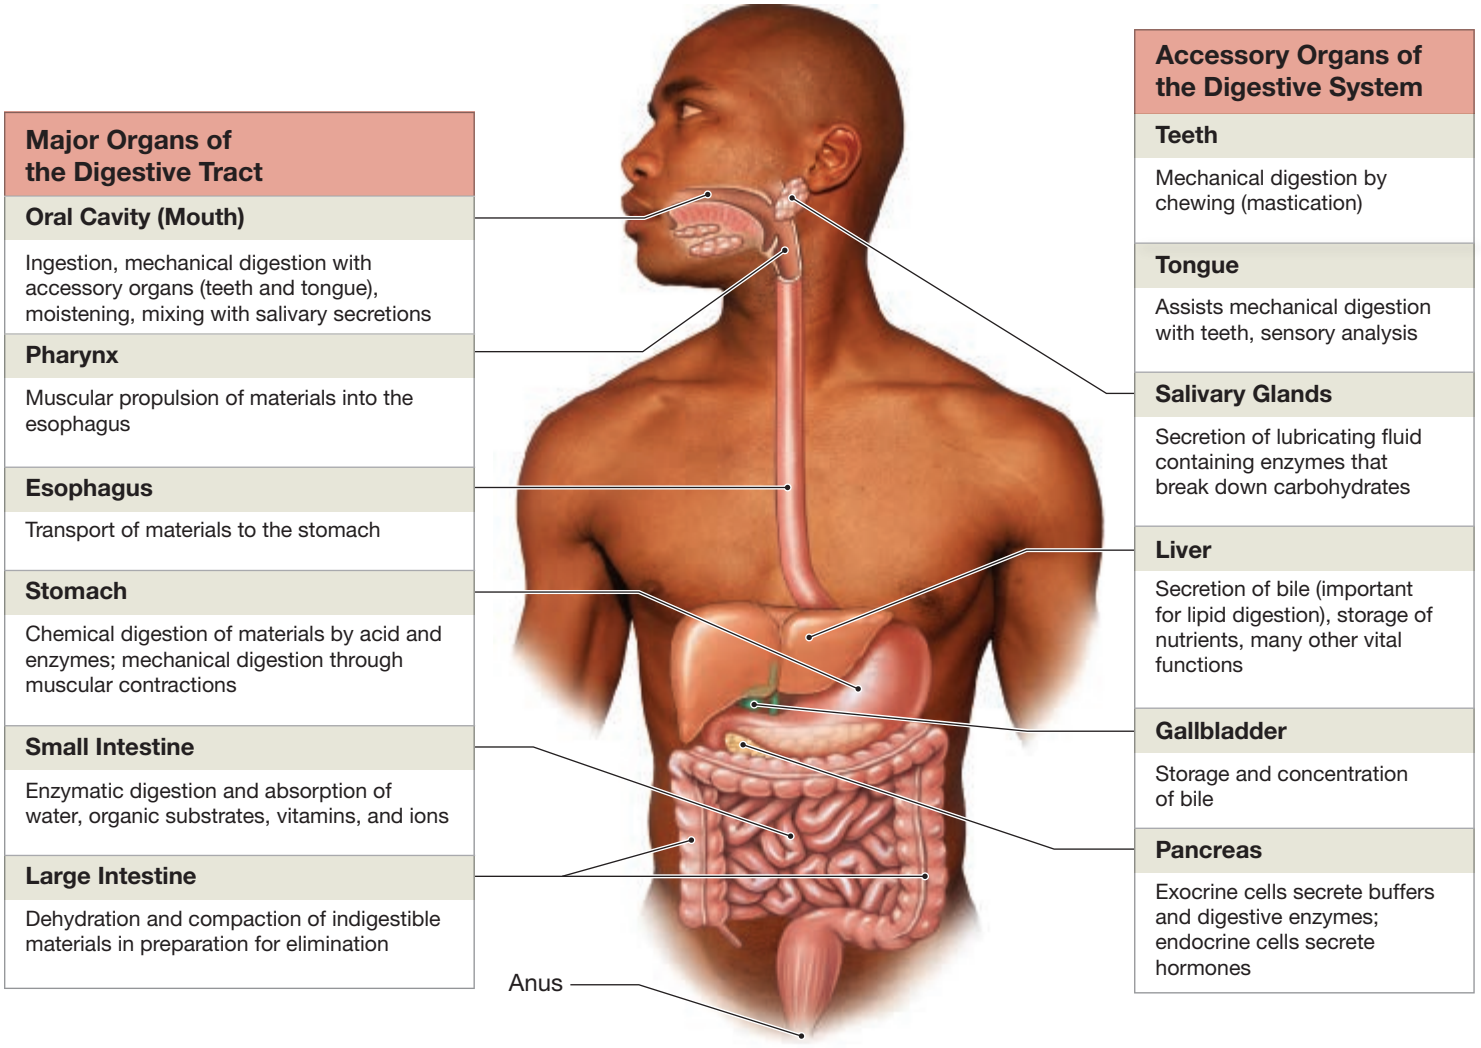
These structures have overlapping functions that all contribute to the main function of the digestive system, which is to break down food, absorb the nutrients that can be used by body cells, and eliminate the remaining waste. However, each of these structures also has certain areas of specialization and so shows distinctive histological characteristics. This section introduces the functions of the digestive system. We also look at several structural and functional characteristics of the system as a whole, including how its epithelial lining is specialized for absorption, how materials move through it, and how those movements are regulated.

Functions and Processes of the Digestive System

Food enters the digestive tract and passes along its length. Along the way, the digestive system performs six integrated processes. Let's take a look at these processes:

1. **Ingestion** takes place when food enters the oral cavity. Ingestion is an active process involving choices and decision making.
2. **Mechanical digestion and propulsion** involve the crushing and shearing of food and then propelling the food along the digestive tract. Mechanical digestion may not

Figure 24–1 Organs of the Digestive System.



be required before ingestion. You can swallow liquids immediately, but you must chew most solids first. Tearing and mashing with the teeth, followed by squashing and compressing by the tongue, are examples of preliminary mechanical digestion. Swirling, mixing, and churning motions of the stomach and intestines provide mechanical digestion after ingestion. Mechanical digestion also increases the surface area of ingested materials, making them more susceptible to the actions of enzymes.

3. **Chemical digestion** refers to the chemical breakdown of food into small organic and inorganic molecules suitable for absorption by the digestive epithelium. Simple molecules in food, such as glucose, can be absorbed intact. However, epithelial cells have no way to absorb molecules with the size and complexity of proteins, polysaccharides, or triglycerides. Digestive enzymes must first disassemble these molecules. For example, the starches in a potato are of no nutritional value until enzymes have broken them down to simple sugars.

4. **Secretion** is the release of water, acids, enzymes, buffers, and salts by the epithelium of the digestive tract, glandular organs, and the gallbladder. The glandular organs and gallbladder secrete their products into ducts that empty into the digestive tract.

5. **Absorption** is the movement of organic molecules, electrolytes (inorganic ions), vitamins, minerals, and water across the digestive epithelium. These materials are absorbed into the interstitial fluid of the digestive tract for distribution to body cells.

6. **Defecation** (def-eh-KĀ-shun) is the elimination of wastes from the body. The digestive tract and glandular and secretory organs discharge wastes in secretions that enter the lumen of the tract. Most of these wastes mix with the indigestible food of the digestive process. These wastes are dehydrated and compacted into matter called *feces* and ejected from the digestive tract through the anus.

This chapter explores these specific processes in more detail as we consider the structure and function of individual regions of the digestive system.

In addition to its main function, the digestive system also plays a protective role. The lining of the digestive tract safeguards surrounding tissues against (1) the corrosive effects of digestive acids and enzymes; (2) mechanical stresses, such as abrasion; and (3) bacteria that are swallowed with food or live in the digestive tract. The digestive epithelium and its secretions provide a nonspecific defense against these bacteria. When bacteria reach the underlying layer of areolar tissue, the *lamina propria*, macrophages and other cells of the immune system attack them.

Relationship between the Digestive Organs and the Peritoneum: The Mesenteries

The abdominopelvic cavity contains the *peritoneal cavity*, which is lined by a serous membrane called the **peritoneum**. This membrane consists of a superficial mesothelium covering a layer of areolar tissue. pp. 18, 140 We divide the peritoneum into two parts. The serosa, or *visceral peritoneum*, covers organs that project into the peritoneal cavity. The *parietal peritoneum* lines the inner surfaces of the body wall.

The serous membrane lining the peritoneal cavity continuously produces peritoneal fluid, which lubricates the surfaces. Because a thin layer of peritoneal fluid separates them, the parietal and visceral surfaces can slide without friction and resulting irritation. The membrane secretes and reabsorbs about 7 liters (7.4 quarts) of fluid each day, but the volume within the peritoneal cavity at any one time is very small. Liver disease, kidney disease, and heart failure can increase the rate at which fluids move into the peritoneal cavity. The buildup of fluid creates a characteristic abdominal swelling called **ascites** (a-SĪ-tēz). This fluid can distort internal organs and cause symptoms such as heartburn, indigestion, and lower back pain.

Portions of the digestive tract are suspended within the peritoneal cavity by sheets of serous membrane that connect the parietal peritoneum with the visceral peritoneum. These **mesenteries** (MEZ-en-ter-ēz) are double sheets of peritoneal membrane. The areolar tissue between the mesothelial surfaces provides a route to and from the digestive tract for blood vessels, nerves, and lymphatic vessels. Mesenteries stabilize the positions of the attached organs. The mesenteries also prevent the intestines from becoming entangled during digestive movements or sudden changes in body position.

During embryonic development, the digestive tract and accessory organs are suspended within the peritoneal cavity by *dorsal* and *ventral mesenteries* (Figure 24–2a). The ventral mesentery later disappears along most of the digestive tract. It persists in adults in only two places: on the ventral surface of the stomach, between the stomach and the liver (the *lesser omentum*) (Figure 24–2b,d); and between the liver and the anterior abdominal wall (the *falciform ligament*) (Figure 24–2c,d). The **lesser omentum** (ō-MEN-tum; *omentum*, apron) stabilizes the position of the stomach and provides an access route for blood vessels and other structures entering or leaving the liver. The **falciform** (FAL-si-form; *falx*, sickle + *forma*, form) **ligament** helps stabilize the position of the liver relative to the diaphragm and abdominal wall. ATLAS: Embryology Summary 19: The Development of the Digestive System

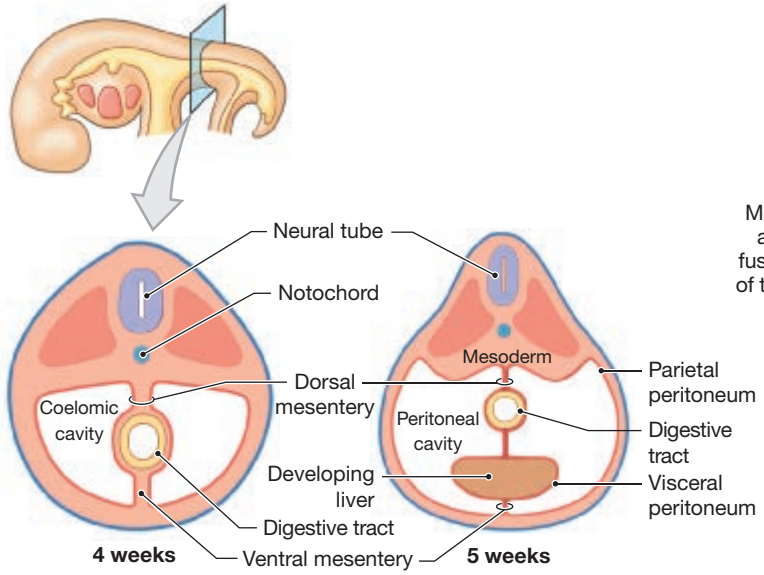
As the digestive tract elongates, it twists and turns within the crowded peritoneal cavity. The dorsal mesentery of the stomach becomes greatly enlarged and forms an enormous pouch that extends inferiorly between the body wall and the anterior surface of the small intestine. This pouch is the **greater omentum** (Figure 24–2b,d). It hangs like an apron from the lateral and inferior borders of the stomach. Adipose tissue in the greater omentum conforms to the shapes of the surrounding organs, providing padding and protection across the anterior and lateral surfaces of the abdomen. When a person gains weight, this adipose tissue contributes to the characteristic "beer belly." The lipids in the adipose tissue are an important energy reserve. The greater omentum also insulates the body, reducing heat loss across the anterior abdominal wall.

All but the first 25 cm (10 in.) of the small intestine is suspended by the **mesentery proper**, a thick mesenterial sheet. It provides stability, but permits some independent movement. The mesentery associated with the initial portion of the small intestine (the *duodenum*) and the pancreas fuses with the posterior abdominal wall and locks those structures in place. Only their anterior surfaces remain covered by peritoneum. We describe these organs as **retroperitoneal** (*retro*, behind) because their mass lies posterior to, rather than surrounded by, the peritoneal cavity.

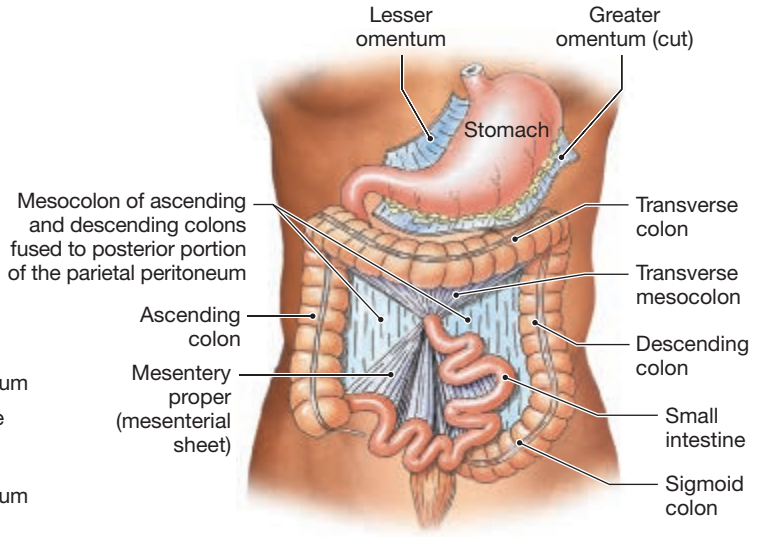
+ Clinical Note Peritonitis

An inflammation of the peritoneum, the serous membrane of the abdominopelvic cavity, is called **peritonitis** (pehr-ih-tō-NĪ-tis). This painful condition interferes with the normal functions of the affected organs. Physical damage, chemical irritation, and bacterial invasion of the peritoneum can lead to severe cases of peritonitis. Such cases can even be fatal. In untreated appendicitis, the appendix may rupture and release bacteria into the peritoneal cavity. This event may cause peritonitis. Peritonitis can also be a complication of any surgery that opens the peritoneal cavity. There is a danger of peritonitis in any disease or injury that perforates the stomach or intestines.

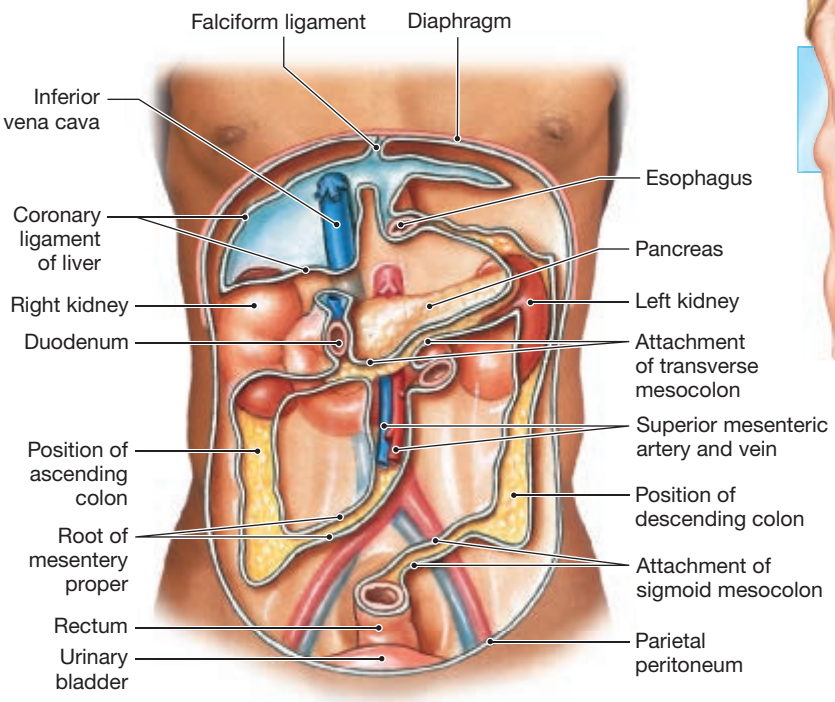
Figure 24–2 The Mesenteries.



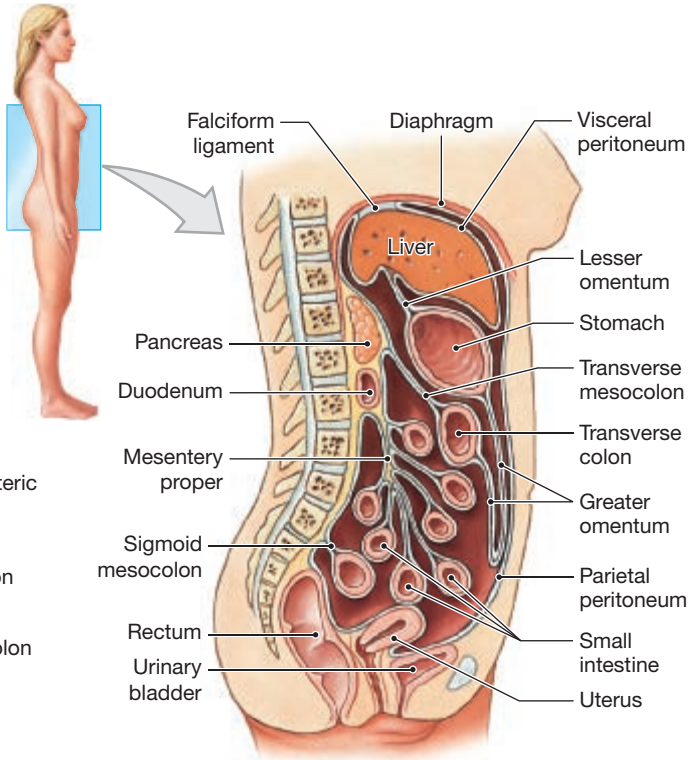
a During embryonic development, the digestive tube is initially suspended by dorsal and ventral mesenteries. In adults, the ventral mesentery is lost except at the lesser omentum between the stomach and liver and the falciform ligament between the liver and diaphragm (see part d).



b A diagrammatic view of the organization of mesenteries in an adult. As the digestive tract enlarges, mesenteries associated with the proximal portion of the small intestine, the pancreas, and the ascending and descending portions of the colon fuse to the body wall.



c An anterior view of the empty peritoneal cavity, showing the attachment of mesenteries to the posterior body wall. Some visceral organs that were originally suspended within the peritoneal cavity are now retroperitoneal due to fusion of the serosa with the parietal peritoneum.



d A sagittal section showing the mesenteries of an adult. Notice that the pancreas, duodenum, and rectum are retroperitoneal.

A **mesocolon** is a mesentery associated with a portion of the large intestine. During normal development, the mesocolon of the *ascending colon*, the *descending colon*, and the *rectum* of the large intestine fuse to the posterior body wall. These regions become locked in place. Thereafter, these organs are retroperitoneal. The visceral peritoneum covers only their anterior surfaces and portions of their lateral surfaces (see Figure 24–2b,c,d).

Histology of the Digestive Tract

The four major layers of the digestive tract are (1) the *mucosa*, (2) the *submucosa*, (3) the *muscular layer*, and (4) the *serosa*. The structure of these layers varies by region. Figure 24–3 is a composite view. It most closely resembles the small intestine, the longest segment of the digestive tract.

The lining of the digestive tract varies by region. For example, the stomach lining has longitudinal folds, which disappear as the tract fills. The lining of the small intestine has permanent transverse folds called *circular folds*, or *plicae* (PLĪ-sē; folds) *circulares* (see Figure 24–3). This folding, along with small mucosal projections called *villi*, increases the surface area available for absorption. The secretions of gland cells in the mucosa and submucosa—or in accessory glandular organs and the gallbladder—are carried to the epithelial surfaces by ducts.

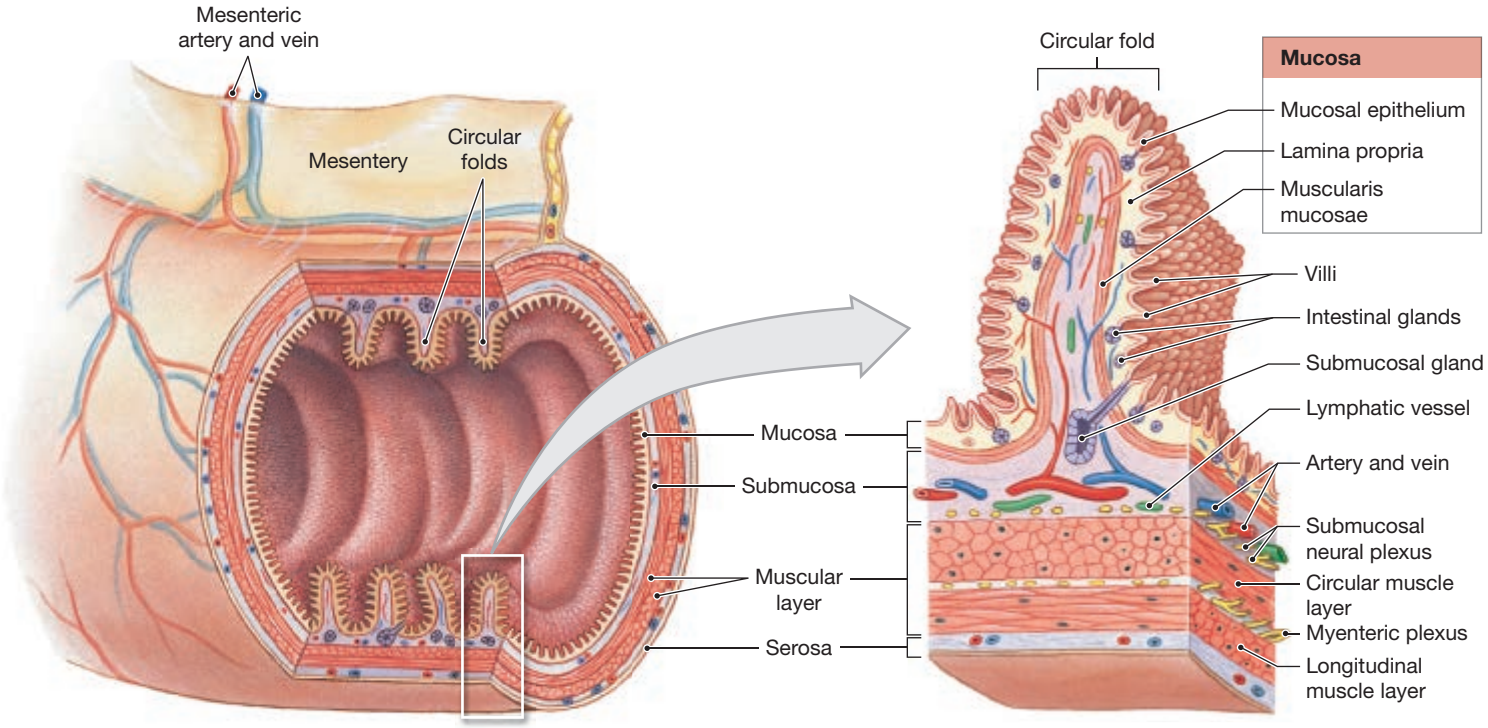
The Mucosa

The inner lining, or **mucosa**, of the digestive tract is a *mucous membrane*. It consists of an epithelium, moistened by glandular secretions, a *lamina propria* of areolar tissue, and a muscular *muscularis mucosae*.

The Digestive Epithelium. The mucosal epithelium is either simple or stratified, depending on its location and the stresses placed on it. Mechanical stresses are most severe in the oral cavity, pharynx, esophagus, and anal canal. These structures are lined by a stratified squamous epithelium. In contrast, the stomach, the small intestine, and almost the entire length of the large intestine have a simple columnar epithelium. In the stomach, this epithelium contains mucous cells, and in the intestines the epithelium contains goblet cells. Scattered among the columnar cells are **enteroendocrine cells**. They secrete hormones that coordinate the activities of the digestive tract and the accessory glands.

The Lamina Propria. The lamina propria is a layer of areolar tissue that also contains blood vessels, sensory nerve endings, lymphatic vessels, smooth muscle cells, and scattered lymphatic tissue. In the oral cavity, pharynx, esophagus, stomach, and the proximal portion of the small intestine, the lamina propria also contains the secretory cells of intestinal glands.

Figure 24–3 Histological Organization of the Digestive Tract. A diagrammatic view of a representative portion of the digestive tract. The features illustrated are typical of those of the small intestine.



Clinical Note Epithelial Renewal and Repair

The life span of a typical epithelial cell varies from 2 to 3 days in the esophagus to 6 days in the large intestine. Epithelial stem cells continuously divide to renew the lining of the entire digestive tract. These divisions normally keep pace with the rates of cell destruction and loss at epithelial surfaces. This high rate of cell division explains why radiation and anticancer drugs that inhibit mitosis have drastic effects on the digestive tract. Lost epithelial cells are no longer replaced. The cumulative damage to the epithelial lining quickly leads to problems in absorbing nutrients. In addition, the exposure of the lamina propria to digestive enzymes can cause internal bleeding and other serious problems.

The Muscularis Mucosae. In most areas of the digestive tract, deep to the lamina propria is a narrow sheet of smooth muscle and elastic fibers. This sheet is called the **muscularis** (mus-kyū-LAIR-is) **mucosae** (myū-KŌ-sē) (see Figure 24–3). The smooth muscle cells in the muscularis mucosae are arranged in two concentric layers. The inner layer encircles the lumen (the *circular muscle*), and the outer layer contains muscle cells arranged parallel to the long axis of the tract (the *longitudinal layer*). Contractions in these layers alter the shape of the lumen.

The Submucosa

The **submucosa** is a layer of dense irregular connective tissue that binds the mucosa to the muscular layer (see Figure 24–3). The submucosa has numerous blood vessels and lymphatic vessels. In some regions it also contains exocrine glands that secrete buffers and enzymes into the lumen of the digestive tract.

Along its outer margin, the submucosa contains a network of intrinsic nerve fibers and scattered neurons. This network is the **submucosal neural plexus**. It contains sensory neurons, parasympathetic ganglionic neurons, and sympathetic postganglionic fibers that innervate the mucosa and submucosa.

The Muscular Layer

The submucosal plexus lies along the inner border of the **muscular layer**. Smooth muscle cells dominate this region. Like the smooth muscle cells in the muscularis mucosae, those in the muscular layer are arranged in an inner circular layer and an outer longitudinal layer. These layers play an essential role in mechanical digestion and in moving materials along the digestive tract.

The movements of the digestive tract are coordinated primarily by the sensory neurons, interneurons, and motor neurons of the enteric nervous system (ENS). ↩ p. 552 The ENS is primarily innervated by the parasympathetic division of the ANS. Sympathetic postganglionic fibers also synapse here. Many of these fibers continue onward to innervate the mucosa and the **myenteric** (mī-en-TER-ik) **plexus** (*mys*, muscle + *enteron*, intestine). This plexus is a network of parasympathetic ganglia, sensory neurons, interneurons, and sympathetic postganglionic fibers. It lies sandwiched between the circular and longitudinal muscle layers. In general, parasympathetic stimulation *increases* muscle tone and activity. Sympathetic stimulation decreases muscle tone and activity.

Tips & Tools

Because the parasympathetic nervous system plays a dominant role in the digestive process, it is often referred to as the "rest and digest" division.

The Serosa

A serous membrane known as the **serosa** covers the muscular layer along most portions of the digestive tract enclosed by the peritoneal cavity (see Figure 24–3).

In areas where there is no serosa covering the muscular layer, a dense network of collagen fibers firmly attaches the digestive tract to adjacent structures. This fibrous sheath is called an ***adventitia*** (ad-ven-TISH-uh).

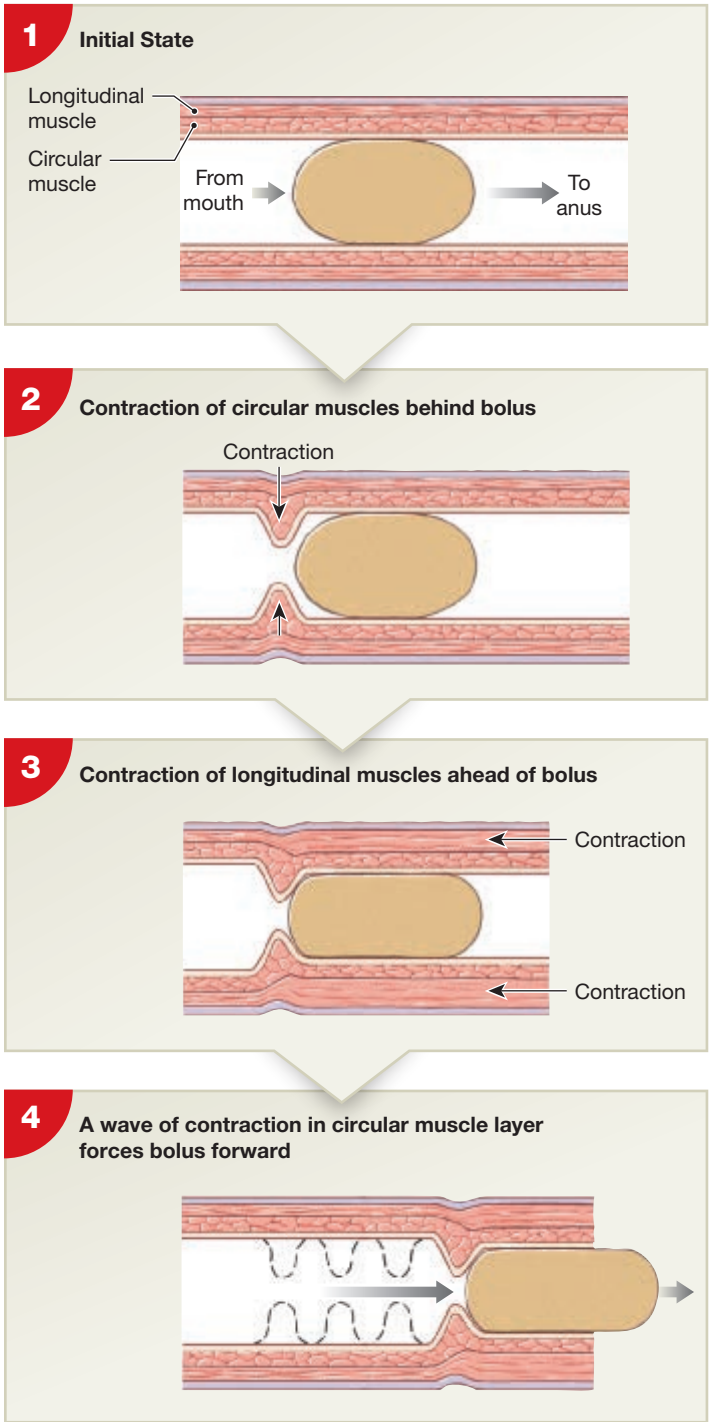
Motility of the Digestive Tract

The muscular layers of the digestive tract consist of *visceral smooth muscle tissue*, which we introduced in Chapter 10. ↩ p. 329 This visceral smooth muscle includes cells called *pacesetter cells* that are located in the muscularis mucosae and muscular layer, which surround the lumen of the digestive tract. Pacesetter cells undergo spontaneous depolarization, triggering a wave of contraction that spreads throughout the entire muscular sheet. The coordinated contractions of the muscular layer cause the digestive tract to rhythmically squeeze and move materials along the tract, a propulsion process called *peristalsis*. A related type of movement, or *motility*, called *segmentation*, also mechanically digests materials.

Propulsion: Peristalsis

The muscular layer propels materials from one portion of the digestive tract to another by contractions known as **peristalsis** (pehr-ih-STAL-sis). Peristalsis consists of waves of muscular contractions that move a *bolus* (BŌ-lus), or soft rounded ball of digestive contents, along the length of the digestive tract (Figure 24–4). During peristalsis, the circular muscles contract behind the bolus while circular muscles ahead of the bolus

Figure 24–4 Peristalsis. Peristalsis propels materials along the length of the digestive tract.



? Why do circular muscles contract behind the bolus while longitudinal muscles contract ahead of the bolus?

relax. Longitudinal muscles ahead of the bolus then contract, shortening adjacent segments. A wave of contraction in the circular muscles then forces the bolus forward.

Tips & Tools

Squeezing toothpaste out of a tube is similar to peristalsis: Your squeezing hand (contracting circular muscles) forces toothpaste (the bolus) along and out of the tube (the digestive tract).

Mechanical Digestion: Segmentation

Most areas of the small intestine and some portions of the large intestine undergo cycles of contraction that churn and fragment the bolus, mixing the contents with intestinal secretions. This activity, called **segmentation**, does not follow a set pattern. For this reason, segmentation does not push materials along the tract in any one direction.

Regulation of Digestive Functions

Local factors interact with neural and hormonal mechanisms to regulate the activities of the digestive system (Figure 24–5, p. 892).

Local Factors

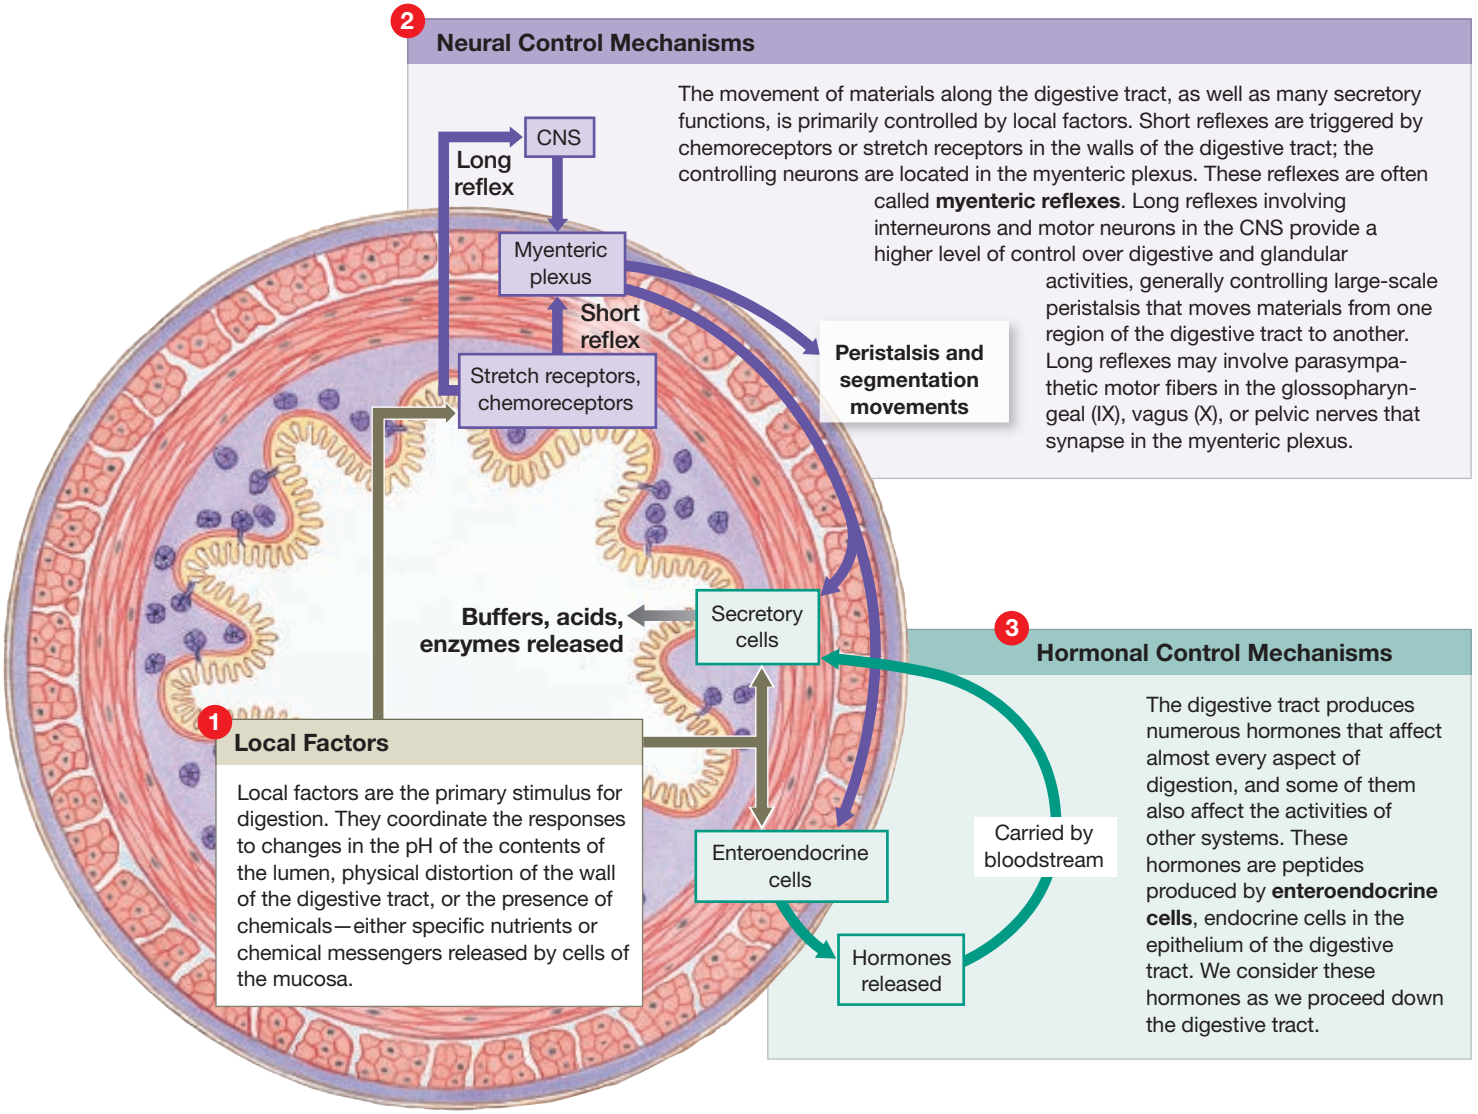
The initial regulation of digestive function occurs at the local level (1 Figure 24-5). Local environmental factors such as the pH, volume, or chemical composition of the intestinal contents can have a direct effect on digestive activity in that segment of the digestive tract. Some of these local factors have a direct effect on local digestive activities; for example, stretching of the intestinal wall can stimulate localized contractions of smooth muscles. In other cases, the local factors stimulate the release of chemicals. Prostaglandins, histamine, and other chemicals released into interstitial fluid may affect adjacent cells within a small segment of the tract. For example, the release of histamine in the lamina propria of the stomach stimulates the secretion of acid by cells in the adjacent epithelium.

Neural Mechanisms

Neural mechanisms control digestive tract movement (2 Figure 24-5). For example, sensory receptors in the walls of the digestive tract trigger peristaltic movements that are limited to a few centimeters. The visceral motor neurons that control smooth muscle contraction and glandular secretion are located in the myenteric plexus. These neurons are usually considered parasympathetic, because some of them synapse with parasympathetic preganglionic fibers. However, the plexus also contains sensory neurons, motor neurons, and interneurons responsible for local reflexes that operate entirely outside the control of the central nervous system. As we noted in Chapter 16, local reflexes are called *short reflexes*. p. 552

Go to MasteringA&P™ > Study Area > Menu > Lab Tools > PAL 3.0 > Human Cadaver and Anatomical Models > Digestive System

Figure 24–5 The Regulation of Digestive Activities.



In general, short reflexes control localized activities that involve small segments of the digestive tract. For example, they may coordinate local peristalsis and trigger secretion by digestive glands in response to the arrival of a bolus. Many neurons are involved. The enteric nervous system has about as many neurons as the spinal cord, and as many neurotransmitters as the brain. The specific functions and interactions of these neurotransmitters in the enteric nervous system are unknown.

Sensory information from receptors in the digestive tract also reaches the CNS. There it can trigger *long reflexes*, which involve interneurons and motor neurons in the CNS. ↩ p. 552

Hormonal Mechanisms

Digestive hormones can enhance or diminish the sensitivity of the smooth muscle cells to neural commands (3 Figure 24-5). These hormones, produced by enteroendocrine cells in the digestive tract, travel through the bloodstream to reach their target organs.

Checkpoint

1. Identify the organs of the digestive system.
2. What is the main function of the digestive system?
3. List and define the six primary processes of the digestive system.
4. What is the importance of the mesenteries?
5. Name the layers of the gastrointestinal tract beginning at the surface of the lumen.
6. Which is more efficient in propelling intestinal contents from one place to another: peristalsis or segmentation?
7. What effect would a drug that blocks parasympathetic stimulation of the digestive tract have on peristalsis?

See the blue Answers tab at the back of the book.

24-2 The oral cavity, which contains the tongue, teeth, and salivary glands, functions in the ingestion and mechanical digestion of food

Learning Outcome Discuss the anatomy of the oral cavity, and list the functions of its major structures and regions.

Let's start our exploration of the digestive tract with how ingested food is processed in the oral cavity. The process of chewing, or *mastication*, involves not only the tongue and teeth but also *saliva* produced by the salivary glands.

The Oral Cavity

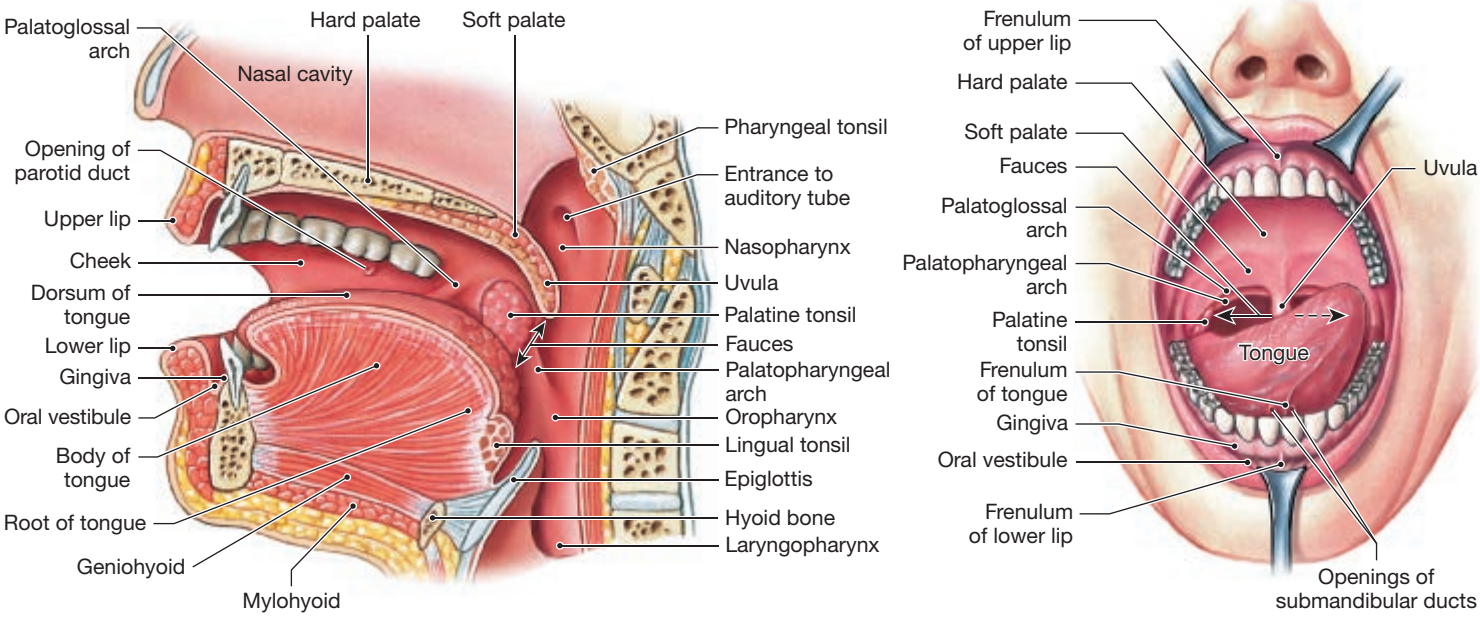
We begin at the **oral cavity** (mouth), (Figure 24–6). The functions of the oral cavity include (1) *sensory analysis* of food before swallowing; (2) *mechanical digestion* through the actions of the teeth, tongue, and palatal surfaces; (3) *lubrication* by mixing with mucus and saliva; and (4) limited *chemical digestion* of carbohydrates and lipids.

The oral cavity is lined by the **oral mucosa**, which has a stratified squamous epithelium. A layer of keratinized cells covers regions exposed to severe abrasion, such as the superior surface of the tongue and the opposing surface of the hard palate (part of the roof of the mouth). The epithelial lining of the cheeks, lips, and inferior surface of the tongue is relatively thin and nonkeratinized. Nutrients are not absorbed in the oral cavity, but the mucosa inferior to the tongue is thin enough and vascular enough to permit the rapid absorption of lipid-soluble drugs. *Nitroglycerin* may be administered by this route to treat acute angina pectoris. p. 701

The mucosae of the **cheeks**, or lateral walls of the oral cavity, are supported by buccal fat pads and the buccinator muscles. Anteriorly, the mucosa of each cheek is continuous with that of the **lips**. The **oral vestibule** is the space between the cheeks (or lips) and the teeth. The **gingivae** (JIN-ji-vē), or *gums*, are ridges of oral mucosa that surround the base of each tooth on the alveolar processes of the maxillae and the alveolar part of the mandible. In most regions, the gingivae are firmly bound to the periostea of the underlying bones. The *frenulum of lower lip* and the *frenulum of upper lip* are folds of mucosa that extends from the gingiva to the lower lip and upper lip respectively, attaching the lips to the gum.

The hard and soft palates form the roof of the oral cavity, while the tongue dominates its floor. The floor of the mouth inferior to the tongue gains extra support from the geniohyoid and mylohyoid muscles. p. 354 The palatine processes of the maxillae and the horizontal plates of the palatine bones form the *hard palate*. A prominent central ridge, or *palatine raphe* (RĀ-fee), extends along the midline of the hard palate. The mucosa lateral and anterior to the raphe is thick, with complex ridges. When your tongue compresses food against the hard palate, these ridges provide traction. The *soft palate* lies posterior to the hard palate. A thinner and more delicate mucosa covers the posterior margin of the hard palate and extends onto the soft palate.

Figure 24–6 Anatomy of the Oral Cavity. ATLAS: Plates 11a; 19



a A sagittal section of the oral cavity

b An anterior view of the oral cavity

The posterior margin of the soft palate supports the **uvula** (YŪ-vyū-luh), a dangling process that helps prevent food from entering the pharynx too soon (see Figure 24–6a). On either side of the uvula are two pairs of muscular *palatal arches* (see Figure 24–6b). The more anterior **palatoglossal** (pal-a-tō-GLOS-al) **arch** extends between the soft palate and the base of the tongue. The space between the oral cavity and the pharynx, bounded by the soft palate and the base of the tongue, is called the **fauces** (FAW-sēz). The more posterior **palatopharyngeal** (pal-ah-tō-fah-RIN-jē-al) **arch** extends from the soft palate to the pharyngeal wall. A palatine tonsil lies between the palatoglossal and palatopharyngeal arches on each side.

The Tongue

The **tongue** has four primary functions (see Figure 24–6): (1) mechanical digestion by compression, abrasion, and distortion; (2) manipulation to assist in chewing and to prepare food for swallowing; (3) sensory analysis by touch, temperature, and taste receptors; and (4) secretion of mucins and the enzyme *lingual lipase*.

We can divide the tongue into an anterior **body**, or *oral portion*, and a posterior **root**, or *pharyngeal portion*. The superior surface, or *dorsum*, of the body contains a forest of fine projections, the *lingual papillae*. ↩ p. 570 The thickened epithelium covering each papilla assists the tongue in moving materials. A V-shaped line of vallate papillae roughly marks the boundary between the body and the root of the tongue, which is located in the oropharynx (see Figure 24–6a).

The epithelium covering the inferior surface of the tongue is thinner and more delicate than that of the dorsum. Along the inferior midline is the **frenulum** (FREN-yū-lum; *frenum*, bridle) **of tongue**, or *lingual frenulum*, a thin fold of mucous membrane that connects the body of the tongue to the mucosa covering the floor of the oral cavity (see Figure 24–6b. Ducts from two pairs of salivary glands open on each side of the frenulum, which prevents extreme movements of the tongue. However, an overly restrictive frenulum hinders normal eating or speech. A shortened lingual frenulum causes a partial or complete fusion of the tongue to the floor of the mouth. This condition, called *ankyloglossia* (ang-kih-lō-GLOS-ē-uh), can be corrected surgically.

Secretions of small glands that extend into the underlying lamina propria flush the tongue's epithelium. These secretions contain water, mucins, and the enzyme **lingual lipase**. Lingual lipase works over a broad pH range (3.0–6.0) so lipid digestion begins immediately. Because the enzyme tolerates an acid environment, it can continue to break down lipids—specifically, triglycerides—for a considerable time after the food reaches the stomach.

The tongue contains two groups of skeletal muscles. The large **extrinsic tongue muscles** perform all gross movements of the tongue. ↩ p. 352 The smaller **intrinsic tongue muscles** change the shape of the tongue and assist the extrinsic muscles during precise movements, as in speech. Both intrinsic and extrinsic tongue muscles are under the control of the hypoglossal cranial nerves (XII).

The Teeth

Tongue movements are important in passing food across the **teeth** during chewing. Let's look at the different types and sets of teeth.

Anatomy of a Tooth

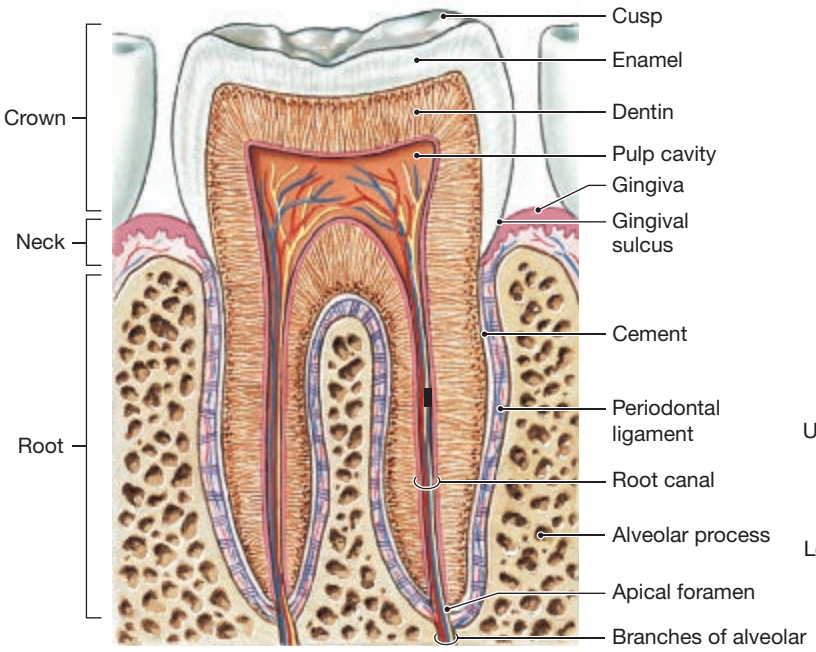
Figure 24–7a is a sectional view through an adult tooth. The bulk of each tooth consists of a mineralized matrix similar to that of bone. This material, called **dentin**, differs from bone in that it does not contain cells. Instead, cytoplasmic processes extend into the dentin from cells in the central **pulp cavity**, an interior chamber. The pulp cavity receives blood vessels and nerves through the **root canal**, a narrow tunnel located at the **root**, or base, of the tooth. Blood vessels and nerves enter the root canal through an opening called the **apical foramen** to supply the pulp cavity.

The root of each tooth sits in a bony cavity or socket called the *tooth socket* or a *tooth alveolus*. Collagen fibers of the **periodontal ligament** extend from the dentin of the root to the alveolar bone, creating a strong articulation known as a ***gomphosis***. ↩ p. 267 A layer of **cement** (sē-MENT) covers the dentin of the root. Cement protects and firmly anchors the periodontal ligament. Cement is histologically similar to bone and is less resistant to erosion than is dentin.

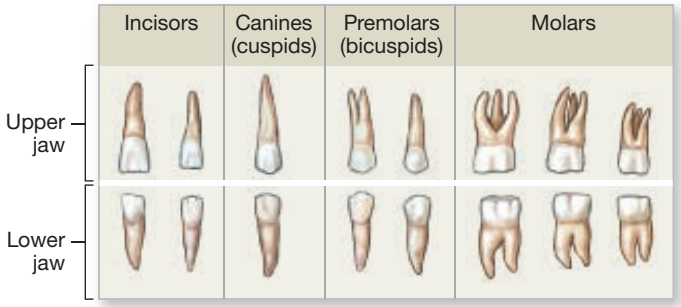
The **neck** of the tooth marks the boundary between the root and the **crown**, the exposed portion of the tooth that projects beyond the soft tissue of the gingiva. A shallow groove called the **gingival sulcus** surrounds the neck of each tooth. The mucosa of the gingival sulcus is very thin and is not tightly bound to the periosteum. The epithelium is bound to the tooth at the base of the sulcus. This epithelial attachment prevents bacterial access to the lamina propria of the gingiva and the relatively soft cement of the root. When you brush and massage your gums, you stimulate the epithelial cells and strengthen the attachment. A condition called *gingivitis*, an inflammation of the gingivae caused by bacterial infection, can occur if the attachment breaks down.

A layer of **enamel** covers the dentin of the crown. Enamel forms the **occlusal surface** of each tooth, which is the biting surface that grinds food against the opposing tooth surface. Elevations or projections of the occlusal surface are called **cusps**. Enamel, which contains calcium phosphate in a crystalline form, is the hardest biologically manufactured substance. Adequate amounts of calcium, phosphates, and vitamin D_3 during childhood are essential if the enamel coating is to be complete and resistant to decay.

Figure 24–7 The Teeth.



a A diagrammatic section through a typical adult tooth.



b The adult teeth from the right side of the upper and lower jaws. *Figure 24–8a,b* shows a view of the occlusal surfaces.

Tooth decay generally results from the action of bacteria that live in your mouth. Bacteria adhering to the surfaces of the teeth produce a sticky matrix that traps food particles and creates deposits known as *dental plaque*. Over time, this organic material can become calcified, forming a hard layer of *tartar*, or *dental calculus*, which can be difficult to remove. Tartar deposits most commonly develop at or near the gingival sulcus, where brushing cannot remove the soft plaque deposits.

Types of Teeth

The alveolar processes of the maxillae and the alveolar part of the mandible form the *maxillary dental arcade* and *mandibular dental arcade*, or upper and lower dental arcades, respectively. These arcades contain four types of teeth, each with specific functions (Figure 24–7b):

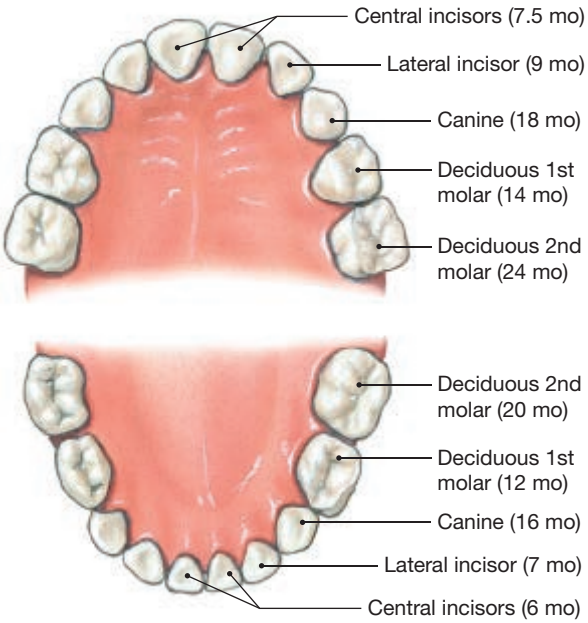
1. **Incisor** (in-SĪ-zer) **teeth** are blade-shaped teeth located at the front of the mouth. Incisors are useful for clipping or cutting, as when you nip off the tip of a carrot stick. These teeth have a single root.
2. **Canine** (KĀ-nīn) **teeth**, or *cuspids* (KUS-pidz), are conical with a single, pointed cusp. Also known as the "eyeteeth," because they lie directly under the eye, the canines are used for tearing or slashing. You might weaken a tough piece of celery using the clipping action of the incisors and then take advantage of the shearing action of the canines. Canines have a single root.
3. **Premolar teeth**, or *bicuspids* (bī-KUS-pidz), have flattened crowns with two prominent rounded cusps. They crush, mash, and grind. Bicuspids have one or two roots.
4. **Molar teeth** have very large, flattened crowns with four to five prominent rounded cusps adapted for crushing and grinding. You can usually shift a tough nut to your premolars and molars for successful crunching. Molars in the upper jaw typically have three roots while those in the lower jaw usually have two roots.

Sets of Teeth

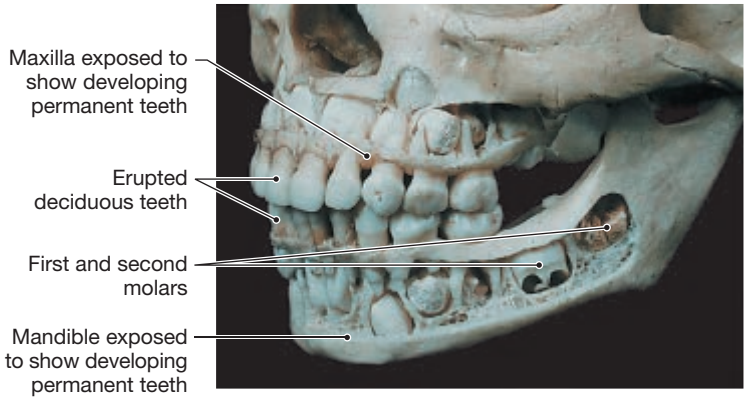
The teeth are collectively called the *dentition*. Two such dentitions form during development: deciduous and permanent. The first to appear are the **deciduous teeth** (de-SID-yū-us; *deciduus*, falling off). Deciduous teeth are also called *primary teeth*, *milk teeth*, or *baby teeth*. Most children have 20 deciduous teeth (Figure 24–8a). On each side of the upper or lower jaw, the deciduous teeth consist of two incisors, one canine, and a pair of deciduous molars for a total of 20 teeth.

These teeth are later replaced by the **permanent teeth** of the larger adult jaws. As replacement proceeds, the periodontal ligaments and roots of the deciduous teeth erode. The deciduous teeth either fall out or are pushed aside by the **eruption**, or emergence, of the permanent teeth (Figure 24–8b). The permanent premolars take the place of the deciduous molars, while the permanent molars extend the tooth rows as the jaw

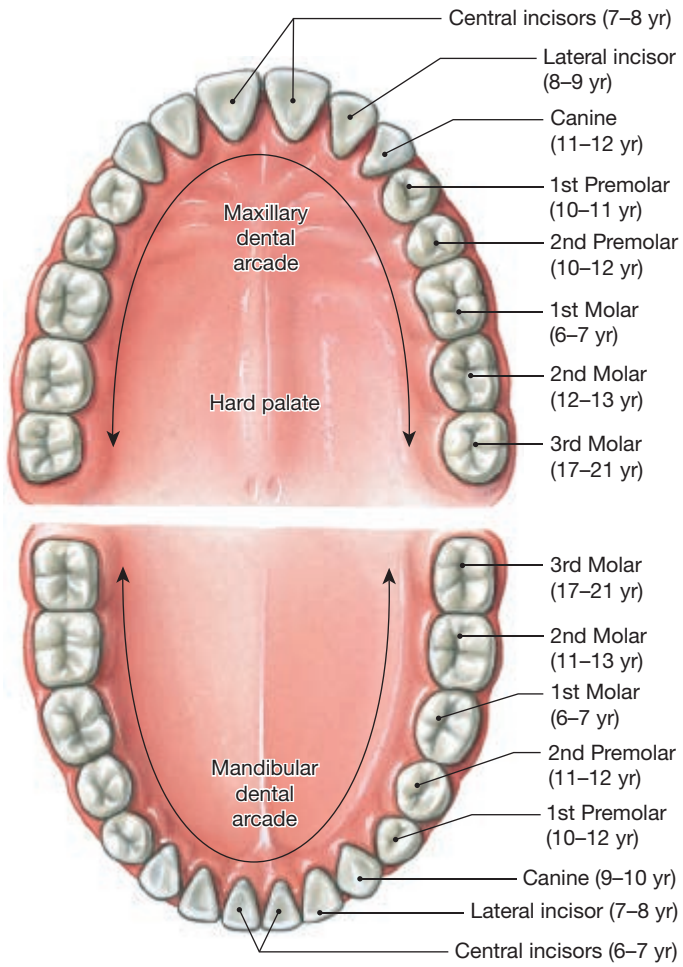
Figure 24–8 Deciduous and Permanent Dentitions.



a The deciduous teeth, with the age at eruption given in months



b Maxilla and mandible with unerupted teeth exposed



c The permanent teeth, with the age at eruption given in years

24

enlarges (Figure 24–8c). Three additional molars appear on each side of the upper and lower jaws as the person ages. These molars extend the rows of teeth posteriorly and bring the permanent tooth count to 32.

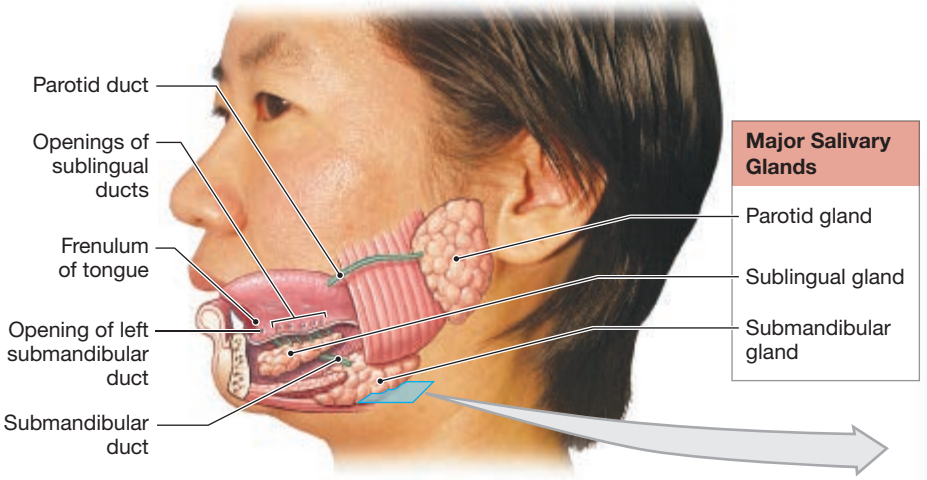
The third molars, or *wisdom teeth*, may not erupt before age 21. Wisdom teeth may not erupt because they develop in inappropriate positions or because there is not enough space. Any teeth that develop in locations that do not allow them to erupt are called *impacted teeth*. Impacted wisdom teeth can be surgically removed to prevent the formation of abscesses.

The Salivary Glands

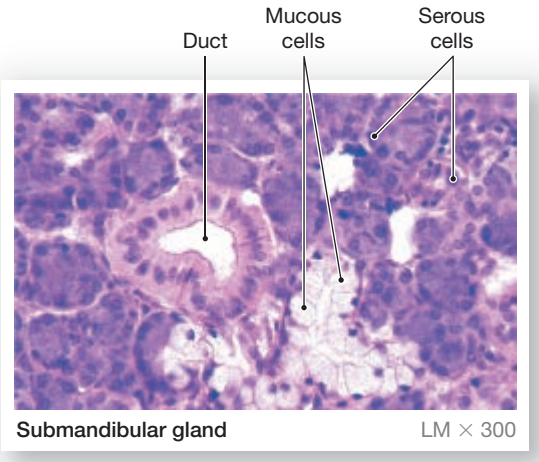
Three major pairs of salivary glands secrete into the oral cavity (Figure 24–9a). Each pair has a distinctive cellular organization and produces *saliva*, a mixture of glandular secretions, with slightly different properties:

- The large **parotid** (pah-ROT-id) **glands** lie inferior to the zygomatic arch deep to the skin covering the lateral and posterior surface of the mandible. Each gland has an irregular shape. It extends from the mastoid process of the temporal bone across the outer surface of the masseter. The parotid glands produce a serous secretion containing large amounts of *salivary amylase*. This enzyme breaks down starches (complex carbohydrates). The secretions of each parotid gland are drained by a **parotid duct**, which empties into the vestibule at the second upper molar.
- The **sublingual** (sub-LING-gwal) **glands** are covered by the mucous membrane of the floor of the mouth. These

Figure 24–9 Anatomy of the Salivary Glands. ATLAS: Plates 3c,d; 18a,b



a A lateral view, showing the relative positions of the major salivary glands and ducts on the left side of the head. For clarity, the left ramus and body of the mandible have been removed. For the positions of the parotid and submandibular ducts in the oral cavity, see *Figure 24–6*.



b The submandibular gland secretes a mixture of mucins, produced by mucous cells, and enzymes, produced by serous cells.

? Which type of salivary glands produces glycoproteins called mucins?

glands produce mucus that acts as a buffer and lubricant. Numerous **sublingual ducts** open along either side of the lingual frenulum.

- The **submandibular glands** lie along the inner surfaces of the mandible within a depression called the *mandibular groove*. Cells of the submandibular glands (**Figure 24–9b**) secrete a mixture of buffers, glycoproteins called *mucins*, and salivary amylase. The **submandibular ducts** open into the mouth on each side of the frenulum of tongue immediately posterior to the teeth (see **Figure 24–6b**).

Minor salivary glands include some 800–1000 submucosal glands in the oral cavity. These small (1–2 mm in diameter) glands may share an excretory duct and mainly secrete mucus.

Composition and Functions of Saliva

The salivary glands produce 1.0–1.5 liters of **saliva** each day. About 70 percent of saliva comes from the submandibular glands. Another 25 percent comes from the parotid glands, and 5 percent from the sublingual glands.

Saliva is 99.4 percent water. The remaining 0.6 percent includes electrolytes (mainly Na^+, Cl^-, and HCO_3^-), buffers, glycoproteins, antibodies, enzymes, and wastes. Mucins give saliva its lubricating action.

Saliva continuously flushes the oral surfaces, helping to keep them clean. Buffers in the saliva keep the pH of your mouth near 7.0. They prevent the buildup of acids produced by bacteria. In addition, saliva contains antibodies (IgA) and *lysozyme*. Both help control populations of oral bacteria. A reduction in or elimination of salivary secretions—caused by radiation, emotional distress, certain drugs, sleep, or other factors—triggers a bacterial population explosion. Such a proliferation can

+ Clinical Note Mumps

The *mumps virus* most often targets the major salivary glands, especially the parotid glands, but other organs can also be infected. Infection typically occurs at 5–9 years of age. The first exposure stimulates the production of antibodies and, in most cases, confers permanent immunity. In an adult male, mumps may infect the testes and cause sterility. Infection of the pancreas by the mumps virus can produce temporary or permanent diabetes. Other organ systems, including the central nervous system, are affected in severe cases. A mumps vaccine effectively confers active immunity. Widespread administration of that vaccine has almost eliminated mumps in the United States.

rapidly lead to recurring infections and progressive erosion of the teeth and gums.

The saliva produced when you eat has a variety of functions, including the following:

- Lubricating the mouth.
- Moistening and lubricating food in the mouth.
- Dissolving chemicals that can stimulate the taste buds and provide sensory information about the food.
- Beginning the digestion of complex carbohydrates before the food is swallowed. The enzyme involved is **salivary amylase**. Saliva also contains a small amount of lingual lipase secreted by the glands of the tongue.

Regulation of Salivary Secretions

The autonomic nervous system normally controls salivary secretions. Each salivary gland has parasympathetic and sympathetic innervation. The parasympathetic efferents originate in the **superior salivatory nucleus** and the **inferior salivatory nucleus** of the medulla oblongata and synapses in the submandibular and otic ganglia. Any object in your mouth can trigger a salivary reflex. It stimulates receptors monitored by the trigeminal nerve (V) or taste buds innervated by cranial nerve VII, IX, or X. Parasympathetic stimulation speeds up secretion by all the salivary glands. As a result, you produce large amounts of saliva. The role of sympathetic innervation is unclear. Evidence suggests that it provokes the secretion of small amounts of very thick saliva.

The salivatory nuclei are also influenced by other brainstem nuclei, as well as by the activities of higher centers. For example, chewing with an empty mouth, smelling food, or even thinking about food increases salivation. That is why chewing gum keeps your mouth moist. Irritating stimuli in the esophagus, stomach, or intestines also speed up production of saliva, as does nausea. Increased saliva production in response to unpleasant stimuli helps reduce the stimulus by dilution, rinsing, or buffering strong acids or bases.

Mechanical Digestion: Mastication (Chewing)

During **mastication**, you force food from the oral cavity to the vestibule and back, crossing and recrossing the occlusal surfaces of the teeth. This movement results in part from the action of the *muscles of mastication*, which close your jaws and slide or rock your lower jaw from side to side. ↩ p. 351 The complicated process of mastication can involve any combination of mandibular elevation/depression, protraction/retraction, and medial/lateral movement (try classifying the movements involved the next time you eat). Control would be impossible, however, without help from the muscles of the cheeks, lips, and tongue.

Mastication breaks down tough connective tissues in meat and the plant fibers in vegetables. It also helps saturate the food with salivary secretions and enzymes. Once the food is a satisfactory consistency, your tongue compacts it into a moist, cohesive **bolus** that is fairly easy to swallow.

We have now discussed how mechanical and chemical digestion occur in the oral cavity. However, chemical digestion is not completed in the oral cavity because no absorption of nutrients takes place across the oral epithelium. Let's move on to more structures of the digestive tract.

Checkpoint

8. Name the structures associated with the oral cavity.
9. Which type of epithelium lines the oral cavity?
10. The digestion of which nutrient would be affected by damage to the parotid salivary glands?
11. Which type of tooth is most useful for chopping off bits of rigid food?
12. Where are the fauces located?

See the blue Answers tab at the back of the book.

24-3 The pharynx and esophagus are passageways that transport the food bolus from the oral cavity to the stomach

Learning Outcome Describe the structure and functions of the pharynx and the esophagus.

The **pharynx** (FAR-ingks), or throat, is an anatomical space that serves as a common passageway for solid food, liquid, and air. Food normally passes through parts of the pharynx on its way to the esophagus. The **esophagus** is a hollow muscular tube that then conveys these ingested materials to the stomach.

The Pharynx

We described the regions of the pharynx—nasopharynx, oropharynx, and laryngopharynx—in Chapter 23. ↩ p. 839 These regions have a lining of stratified squamous epithelium similar to that of the oral cavity. The lamina propria contains scattered mucous glands and the lymphatic tissue of the pharyngeal, palatal, and lingual tonsils. Deep to the lamina propria lies a dense layer of elastic fibers, bound to the underlying skeletal muscles. Specific pharyngeal muscles work with muscles of the oral cavity to start swallowing, which pushes the bolus into the esophagus on its way to the stomach.

The Esophagus

Unlike the pharynx, the esophagus actively moves ingested materials down toward the stomach. Let's look at how its structure allows this function, and how this transport occurs.

Gross Anatomy of the Esophagus

The esophagus is approximately 25 cm (10 in.) in length and has a diameter of about 2 cm (0.80 in.) at its widest point. The esophagus begins posterior to the cricoid cartilage, at the level of vertebra C_6. It is narrowest at this point. The esophagus descends toward the thoracic cavity posterior to the trachea, continuing inferiorly along the posterior wall of the mediastinum. It then enters the abdominopelvic cavity through the **esophageal hiatus** (hī-Ā-tus), an opening in the diaphragm. The esophagus empties into the stomach anterior to vertebra T_7.

Histology of the Esophagus

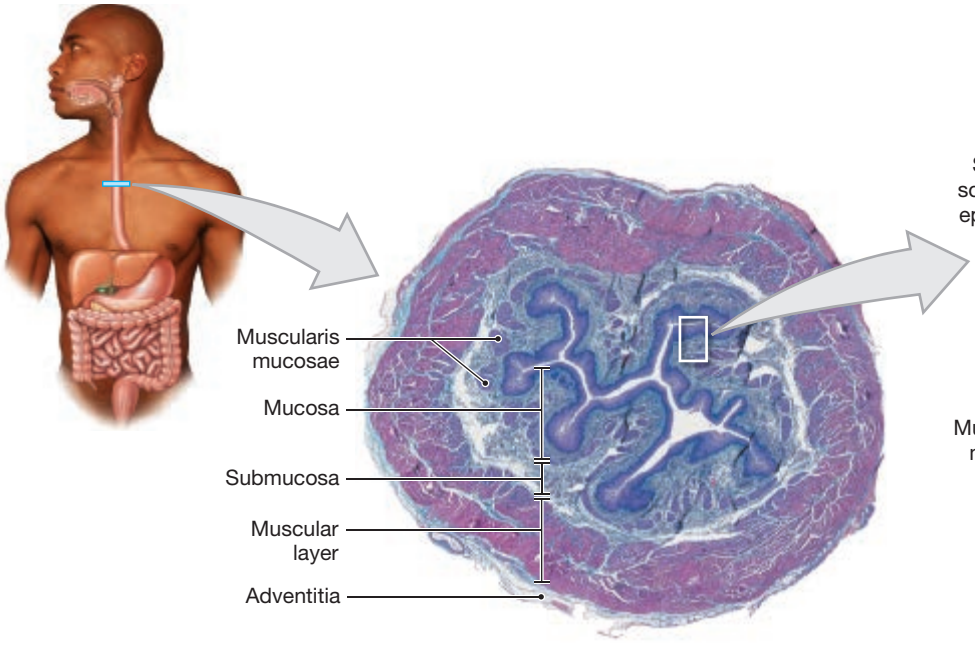
The wall of the esophagus contains a mucosa, submucosa, and muscular layer comparable to those shown in Figure 24–3. Distinctive features of the esophageal wall include the following (Figure 24–10):

- The mucosa of the esophagus contains a nonkeratinized, stratified squamous epithelium similar to that of the pharynx and oral cavity.
- The mucosa and submucosa are packed into large folds that extend the length of the esophagus. These longitudinal folds allow for expansion during the passage of a large bolus. Muscle tone in the walls keeps the lumen closed, except when you swallow.
- The muscularis mucosae consists of an irregular layer of smooth muscle.
- The submucosa contains scattered *esophageal glands*. They produce mucus that reduces friction between the bolus and the esophageal lining.
- The muscular layer has the usual inner circular and outer longitudinal layers. However, in the superior third of the esophagus, these layers contain skeletal muscle fibers. The middle third contains a mixture of skeletal and smooth muscle tissue. Along the inferior third, only smooth muscle occurs.
- An adventitia of connective tissue outside the muscular layer anchors the esophagus to the posterior body wall. Over the 1–2 cm (0.4–0.8 in.) between the diaphragm and stomach, the esophagus is retroperitoneal. Peritoneum covers the anterior and left lateral surfaces.

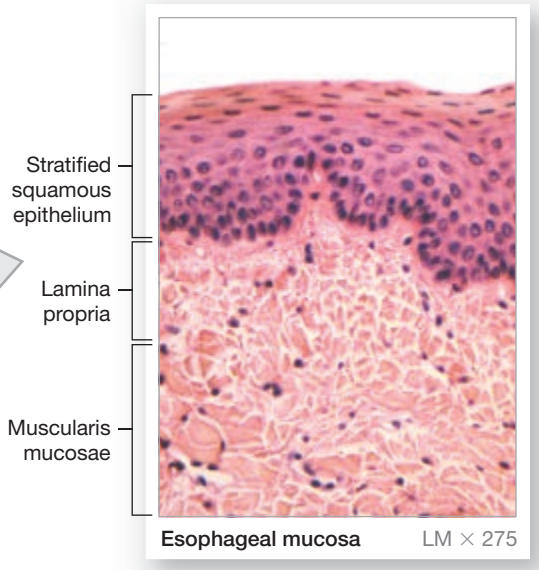
Physiology of the Esophagus

The esophagus is innervated by parasympathetic and sympathetic fibers from the esophageal plexus. ↩ p. 549 Resting muscle tone in the circular muscle layer in the superior 3 cm (1.2 in.) of the esophagus normally prevents air from entering the esophagus. A comparable zone at the inferior end of the esophagus normally remains in a state of active contraction. This state prevents the backflow (reflux) of materials from the stomach into the esophagus. Neither region has a well-defined sphincter muscle. Nevertheless, we often use the terms *upper esophageal sphincter* and *lower esophageal sphincter (cardiac sphincter)* to describe these regions, which are similar in function to other sphincters.

Figure 24–10 Anatomy of the Esophagus.



a A transverse section through an empty esophagus (LM × 5).



b This light micrograph illustrates the extreme thickness of the epithelial portion of the esophageal mucosal layer.

Ingestion: Deglutition (Swallowing)

Deglutition (dē-glū-TISH-un), or swallowing, is a complex process. We divide swallowing into buccal, pharyngeal, and esophageal phases, detailed in Figure 24–11. When you swallow, different pharyngeal muscles work together to prevent food or drink from entering the glottis. ↩ p. 352 Food is crushed and chewed into a bolus before being swallowed. When you are ready to swallow, the *palatal muscles* elevate the soft palate and adjacent portions of the pharyngeal wall. Muscles of the neck and pharynx, the *palatopharyngeus* and *stylopharyngeus*, then elevate the larynx. This bends the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. The *pharyngeal constrictor muscles* push the bolus toward and into the esophagus. While this movement is under way, the glottis is closed.

It takes less than a second for the pharyngeal muscles to propel the bolus into the esophagus. During this period, the respiratory centers are inhibited and breathing stops. Swallowing takes place at regular intervals as saliva collects at the back of the mouth. Each day you swallow approximately 2400 times.

Deglutition can be initiated voluntarily when you eat or drink, but proceeds automatically once it begins. The **swallowing reflex** begins when tactile receptors on the palatal arches and uvula are stimulated by the passage of the bolus. The information is relayed to the **swallowing center** of the medulla oblongata over the trigeminal nerves (V) and glossopharyngeal nerves (IX). Motor commands from this center then signal the pharyngeal musculature, producing a coordinated and stereotyped pattern of muscle contraction.

Primary peristaltic waves are peristaltic movements coordinated by afferent and efferent fibers in the glossopharyngeal nerves (IX) and vagus nerves (X). For a typical bolus, the entire trip along the esophagus takes about 9 seconds. Liquids may make the journey in a few seconds, flowing ahead of the peristaltic contractions with the assistance of gravity.

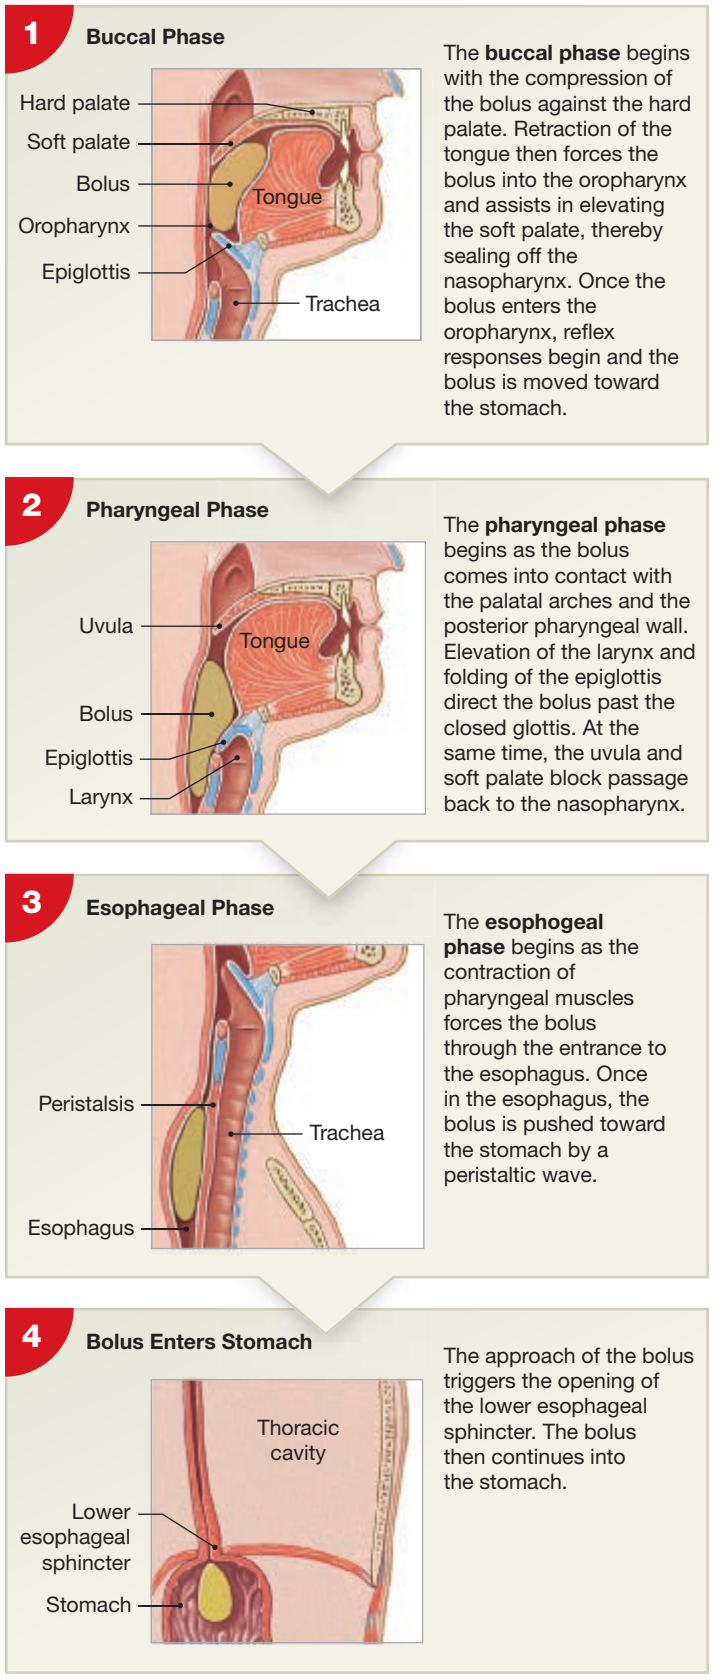
A dry or poorly lubricated bolus travels much more slowly. A series of *secondary peristaltic waves* may be required to push it all the way to the stomach. Secondary peristaltic waves are local reflexes triggered by the stimulation of sensory receptors in the esophageal walls.

Checkpoint

13. **Describe the structure and function of the pharynx.**
14. **Name the structure connecting the pharynx to the stomach.**
15. **Compared to other segments of the digestive tract, what is unusual about the muscular layer of the esophagus?**
16. **Identify the muscles associated with the pharynx and deglutition.**
17. **What is occurring when the soft palate and larynx elevate and the glottis closes?**

See the blue Answers tab at the back of the book.

Figure 24–11 The Process of Deglutition (Swallowing).
This sequence, based on a series of x-rays, shows the phases of swallowing and the movement of a bolus from the mouth to the stomach.



Tips & Tools

Just as security gates control the passage of people by opening and closing, sphincters control the passage of material through them by dilating and constricting.

24-4 The stomach is a J-shaped organ that receives the bolus and aids in its chemical and mechanical digestion

Learning Outcome Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.

The **stomach** is an expandable tubelike organ found in the upper left quadrant of the peritoneal cavity. The major functions of the stomach are to (1) temporarily store ingested food received from the esophagus, (2) mechanically digest food through muscular contractions, and (3) chemically digest food through the action of acid and enzymes. Ingested substances combine with the secretions of the stomach glands, producing a viscous, acidic, soupy mixture of partially digested food called **chyme** (KĪM). This section examines the anatomy of the stomach and then details these important functions.

Gross Anatomy of the Stomach

The stomach has the shape of an expanded J (Figure 24–12). A short **lesser curvature** forms the medial surface of the organ, and a long **greater curvature** forms the lateral surface. The anterior and posterior surfaces are rounded. The shape and size of the stomach can vary greatly from person to person and even from one meal to the next. In an "average" stomach, the lesser curvature is approximately 10 cm (4 in.) long, and the greater curvature measures about 40 cm (16 in.). The stomach typically extends between the levels of vertebrae T_7 and L_3.

We divide the stomach into the following four regions (see Figure 24–12):

- *The Cardia.* The **cardia** (KAR-dē-uh) is the smallest region of the stomach. It consists of the superior, medial portion of the stomach within 3 cm (1.2 in.) of the junction between the stomach and the esophagus. The cardia contains abundant mucous glands. Their secretions coat the connection with the esophagus and help protect that tube from the acid and enzymes of the stomach.
- *The Fundus.* The **fundus** is the region of the stomach that is superior to the junction between the stomach and the esophagus. The fundus contacts the inferior, posterior surface of the diaphragm (see Figure 24–12a).
- *The Body.* The area of the stomach between the fundus and the curve of the J is the **body**, the largest region of the stomach. The body acts as a mixing tank for ingested food and secretions produced in the stomach.
- *The Pyloric Part.* The **pyloric part** (pī-LOR-ick; *pyloros*, gatekeeper) forms the portion of the stomach between the body and the duodenum (first segment of the small intestine). It is divided into a **pyloric antrum**, which is connected to the body, a **pyloric canal**, which empties into the duodenum, and the **pylorus** (pī-LOR-us), which is the muscular tissue surrounding the **pyloric orifice** (stomach outlet).

  During digestion, the shape of the pyloric part changes often. A thickening of the circular layer of muscle within the pylorus, called the **pyloric sphincter**, regulates the release of chyme into the duodenum.

The stomach's volume increases while you eat and then decreases as chyme enters the small intestine. When the stomach is relaxed (empty), the mucosa has prominent longitudinal folds called **rugae** (RŪ-gē; wrinkles). These temporary features let the gastric lumen expand (see Figure 24–12b). The stomach can stretch up to 50 times its empty size. As the stomach fills, the rugae gradually flatten out until, at maximum distension, they almost disappear. (The world record, set in 2016, for eating hot dogs with buns was 73 1/2 in 10 minutes!) When empty, the stomach resembles a muscular tube with a narrow, constricted lumen. When full, it can contain 1–1.5 liters of material.

Tips & Tools

Both circular folds and rugae allow a large surface area to fit within a small volume, just as crumpling a sheet of paper rearranges its surface area so that it occupies a smaller space.

The muscularis mucosae and muscular layer of the stomach contain extra layers of smooth muscle cells in addition to the usual circular and longitudinal layers. The muscularis mucosae generally contain an outer, circular layer of muscle cells. The muscular layer has an inner, **oblique layer** of smooth muscle (see Figure 24–12b). The extra layers of smooth muscle strengthen the stomach wall and assist in the mixing and churning essential to the formation of chyme.

Histology of the Stomach

Simple columnar epithelium lines all portions of the stomach (Figure 24–13a). The epithelium is a *secretory sheet*, which produces a carpet of mucus that covers the interior surface of the stomach. The alkaline mucous layer protects epithelial cells against the acid and enzymes in the gastric lumen.

Figure 24–12 Gross Anatomy of the Stomach. ATLAS: Plates 49a–c; 50a–c

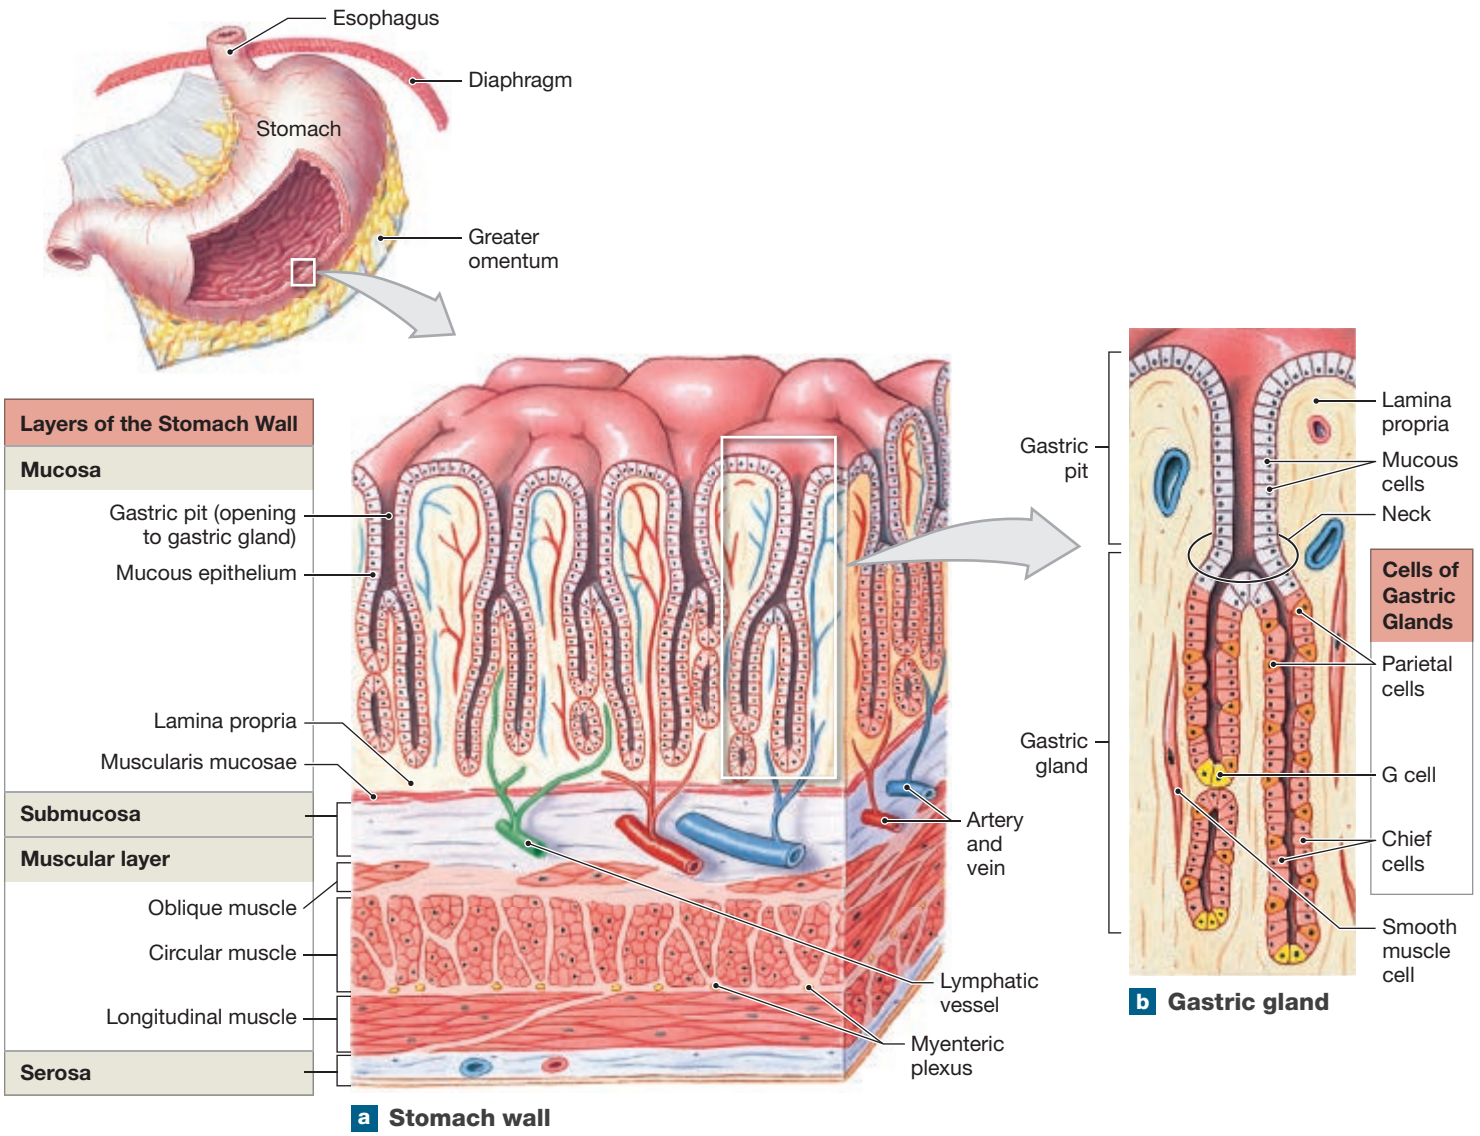
b The structure of the stomach wall

? Name the region of the stomach that connects to the esophagus.

Figure 24–13 Histology of the Stomach Lining.



Shallow depressions called **gastric pits** open onto the gastric surface (Figure 24–13b). The mucous cells at the base, or *neck*, of each gastric pit actively divide, replacing superficial cells that are shed into the chyme. A typical gastric epithelial cell has a life span of 3 to 7 days. Exposure to alcohol or other chemicals that damage or kill epithelial cells increases cell turnover.

Secretory Glands and Gastric Secretions

The gastric epithelium contains several types of glands that produce secretions needed for the function of the stomach. *Gastric* (*gaster*, stomach) *glands* in the fundus and body secrete most of the acid and enzymes involved in gastric digestion. Glands in the pyloric part secrete mucus and important digestive hormones, including *gastrin*, a hormone that stimulates gastric glands.

+ Clinical Note Gastritis and Peptic Ulcers

A superficial inflammation of the gastric mucosa is called *gastritis* (gas-TRĪ-tis). The condition can develop after a person has swallowed drugs, including alcohol and aspirin. Gastritis is also associated with smoking, severe emotional or physical stress, bacterial infection of the gastric wall, or ingestion of strongly acidic or alkaline chemicals. Over time, gastritis can lead to the erosion of the stomach or duodenal lining, and a *peptic ulcer* may form.

Gastric Glands and Gastric Juice

In the fundus and body of the stomach, each gastric pit communicates with several **gastric glands**, which extend deep into the underlying lamina propria (Figure 24–13b). Gastric glands are dominated by two types of secretory cells: *parietal cells* and *chief cells*. Together, they secrete about 1500 mL (1.6 qt) of **gastric juice** each day.

Parietal cells are especially common along the proximal portions of each gastric gland (Figure 24–13b). These cells secrete **intrinsic factor**, a glycoprotein that helps absorb vitamin B_{12} across the intestinal lining. p. 665

Parietal cells also indirectly secrete *hydrochloric acid (HCl)*. They do not produce HCl in the cytoplasm. This acid is so strong that it would erode a secretory vesicle and destroy the cell. Instead, these cells create the conditions for increasing the concentrations of both H^+ and Cl^-, the two dissociation products of HCl. Each ion exits parietal cells independently and by different mechanisms (Figure 24–14).

In the process of H^+ production, carbonic acid is formed within parietal cells. The dissociation of carbonic acid releases bicarbonate and hydrogen ions (1). The bicarbonate ions are exchanged for Cl^- from the interstitial fluid (2). When gastric glands are actively secreting, enough bicarbonate ions diffuse into the bloodstream from the interstitial fluid to increase the pH of the blood significantly. This sudden influx of bicarbonate ions has been called the *alkaline tide*. The chloride ions diffuse across the parietal cell and into the lumen of the gastric gland (3), and the H^+ are actively transported there as well (4).

The hydrochloric acid produced by these processes can keep the stomach contents at pH 1.5–2.0. Although this highly acidic environment does not by itself digest chyme, it has the following important functions:

- It kills most of the microorganisms ingested with food.
- It denatures proteins and inactivates most of the enzymes in food.
- It helps break down plant cell walls and the connective tissues in meat.

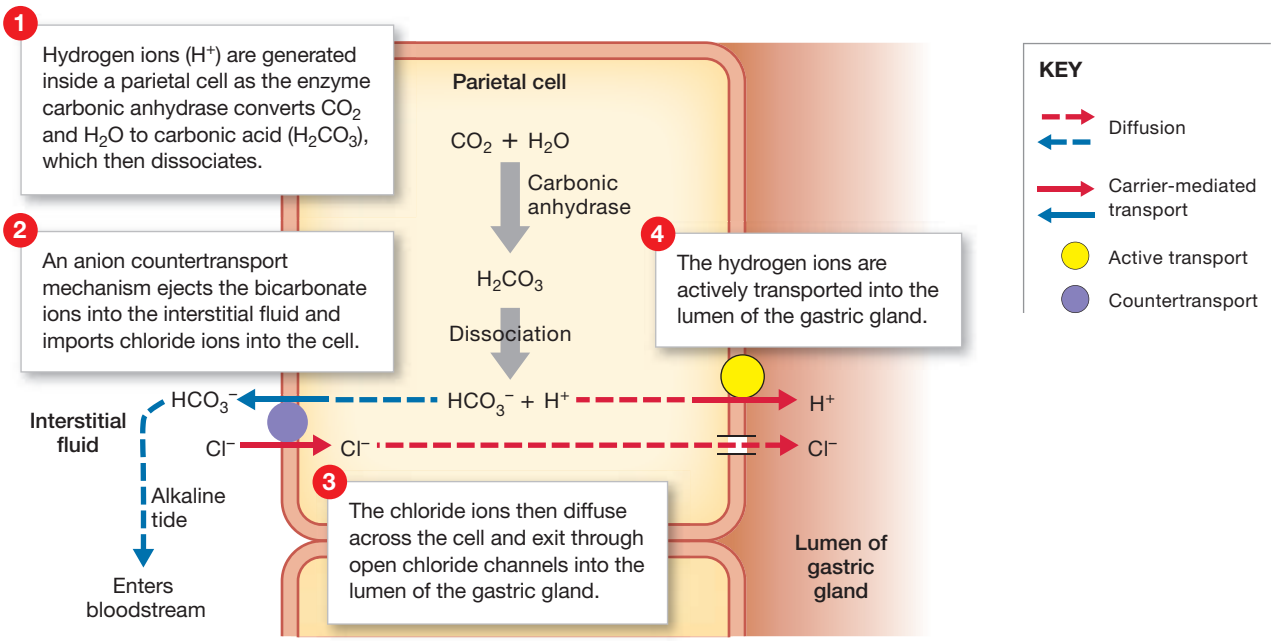
An acidic environment is also necessary for the function of gastric cells called chief cells. **Chief cells** are most abundant near the base of a gastric gland (see Figure 24–13b). These cells secrete **pepsinogen** (pep-SIN-ō-jen), an inactive proenzyme. Acid in the gastric lumen converts pepsinogen to **pepsin**, an active *proteolytic*, or protein-digesting, enzyme. Pepsin functions most effectively at a strongly acidic pH of 1.5–2.0.

In addition, the stomachs of newborn infants (but not of adults) produce **rennin**, also called *chymosin*, and **gastric lipase**. These enzymes are important for the digestion of milk. Rennin coagulates milk proteins. Gastric lipase initiates the digestion of milk fats.

Pyloric Glands, Enteroendocrine Cells, and Gastric Hormones

Glands in the pyloric part produce primarily mucous secretions, rather than enzymes or acid. In addition, several types of enteroendocrine cells are scattered among the mucus-secreting cells. These enteroendocrine cells produce at least

Figure 24–14 The Secretion of Hydrochloric Acid Ions.



seven hormones, most notably **gastrin**. Gastrin is produced by *G cells*, which are most abundant in the gastric pits of the pyloric antrum. Gastrin stimulates secretion by both parietal and chief cells, as well as contractions of the gastric wall that mix and stir the gastric contents.

The pyloric glands also contain *D cells*, which release **somatostatin**, a hormone that inhibits the release of gastrin. D cells continuously release their secretions into the interstitial fluid adjacent to the G cells. Neural and hormonal stimuli can override this inhibition of gastrin production when the stomach is preparing for digestion or is already engaged in digestion.

Several other hormones play a role in hunger and *satiety* (a feeling of not being hungry). The level of *ghrelin* (GREL-in), a hormone produced by *P/D1 cells* lining the fundic region of the stomach, increases before meals to initiate hunger. The ghrelin level decreases shortly after eating to curb appetite. Ghrelin is also antagonistic to *leptin*, a hormone derived from fat tissue that induces satiety. Another hormone from the stomach and small intestine, *obestatin*, is thought to decrease appetite and inhibit thirst. The same gene encodes both ghrelin and obestatin.

Tips & Tools

The stomach squeezes chyme into the small intestine just as you squeeze cake frosting out of a pastry bag.

Physiology of the Stomach: Chemical Digestion

The stomach is a holding tank in which food is saturated with gastric juices and exposed to stomach acid and the digestive effects of pepsin. When ingested food reaches the stomach, salivary amylase and lingual lipase continue the digestion of carbohydrates and lipids. These enzymes continue to work until the pH throughout the contents of the stomach falls below 4.5. They generally remain active 1 to 2 hours after a meal.

As the stomach contents become more fluid and the pH approaches 2.0, the preliminary digestion of proteins by pepsin increases. Protein digestion is not completed in the stomach, because time is limited and pepsin acts on only specific types of peptide bonds, not all of them. However, pepsin generally has enough time to break down complex proteins into smaller peptide and polypeptide chains before the chyme enters the duodenum.

Although partial or limited chemical digestion takes place in the stomach, nutrients are not absorbed there. This is because (1) the mucus covering the epithelial cells means that they are not directly exposed to chyme, (2) the epithelial cells lack the specialized transport mechanisms of cells that line the small intestine, (3) the gastric lining is somewhat impermeable to water, and (4) digestion has not been completed by the time chyme leaves the stomach. At this stage, most carbohydrates, lipids, and proteins are only partially broken down.

Some drugs can be absorbed in the stomach. For example, ethyl alcohol can diffuse through the mucous barrier and penetrate the lipid membranes of the epithelial cells. As a result, alcohol is absorbed in your stomach before any nutrients in a meal reach the bloodstream. Meals containing large amounts of fat slow the rate of alcohol absorption. Why? The reason is that alcohol is lipid soluble, and some of it will be dissolved in fat droplets in the chyme. Aspirin is another lipid-soluble drug that can enter the bloodstream across the gastric mucosa. Such drugs alter the properties of the mucous layer and can promote epithelial damage by stomach acid and enzymes. Prolonged use of aspirin can cause gastric bleeding, so individuals with stomach ulcers are usually advised to avoid aspirin.

Regulation of Gastric Activity in Phases of Digestion

The production of acid and enzymes by the gastric mucosa can be controlled by the CNS; regulated by short reflexes of the enteric nervous system, coordinated in the wall of the stomach; and regulated by hormones of the digestive tract. Gastric control proceeds in three overlapping phases. They are named according to the location of the control center: the *cephalic phase*, the *gastric phase*, and the *intestinal phase*. Please study **Spotlight Figure 24–15** carefully before moving on.

Checkpoint

18. **Name the four major regions of the stomach.**
19. **Discuss the significance of the low pH in the stomach.**
20. **How does a large meal affect the pH of blood leaving the stomach?**
21. **When a person suffers from chronic gastric ulcers, the branches of the vagus nerves that supply the stomach are sometimes cut in an attempt to provide relief. Why might this be an effective treatment?**

See the blue Answers tab at the back of the book.

24-5 Accessory digestive organs, such as the pancreas and liver, produce secretions that aid in chemical digestion

Learning Outcome Describe the structure, functions, and regulation of the accessory digestive organs.

The pancreas provides digestive enzymes, as well as buffers that help neutralize chyme. The liver secretes *bile*, a solution stored in the gallbladder for discharge into the small intestine. Bile contains buffers and *bile salts*, compounds that facilitate the digestion and absorption of lipids. Let's look at these accessory organs and their functions in more detail.

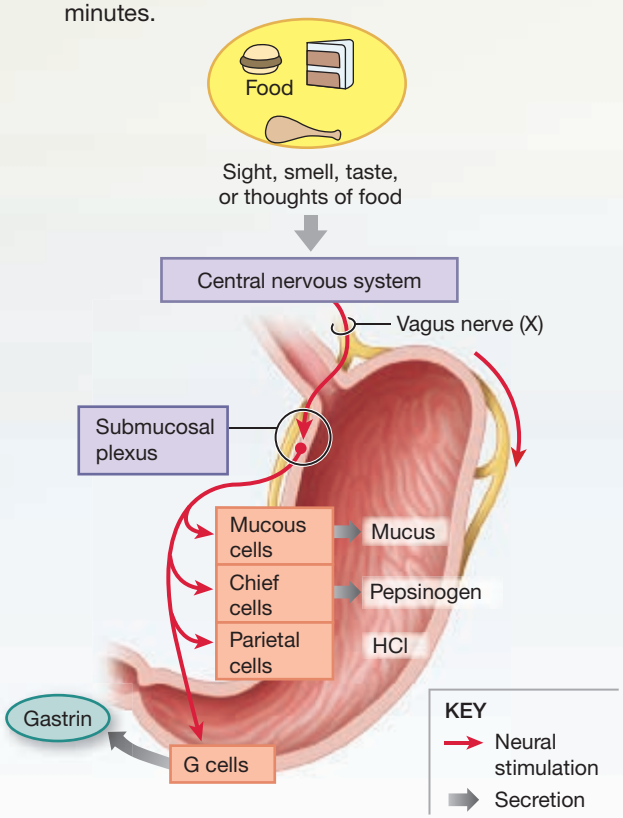
SPOTLIGHT

Figure 24–15
The Regulation of Gastric Activity

The duodenum plays a key role in controlling digestive function because it monitors the contents of the chyme and adjusts the activities of the stomach and accessory glands to protect the delicate absorptive surfaces of the jejunum. This pivotal role of the duodenum is apparent when you consider the three phases of gastric secretion. The phases are named according to the location of the control center involved.

1 CEPHALIC PHASE

The **cephalic phase** of gastric secretion begins when you see, smell, taste, or think of food. This phase, which is directed by the CNS, prepares the stomach to receive food. The neural output proceeds by way of the parasympathetic division of the autonomic nervous system. The vagus nerves (X) innervate the submucosal plexus of the stomach. Next, postganglionic parasympathetic fibers innervate mucous cells, chief cells, parietal cells, and G cells of the stomach. In response to stimulation, the production of gastric juice speeds up, reaching rates of about 500 mL/h, or about 2 cups per hour. This phase generally lasts only minutes.



Emotional states can exaggerate or inhibit the cephalic phase. For example, anger or hostility leads to excessive gastric secretion. On the other hand, anxiety, stress, or fear decreases gastric secretion and gastric contractions, or *motility.*

2 GASTRIC PHASE

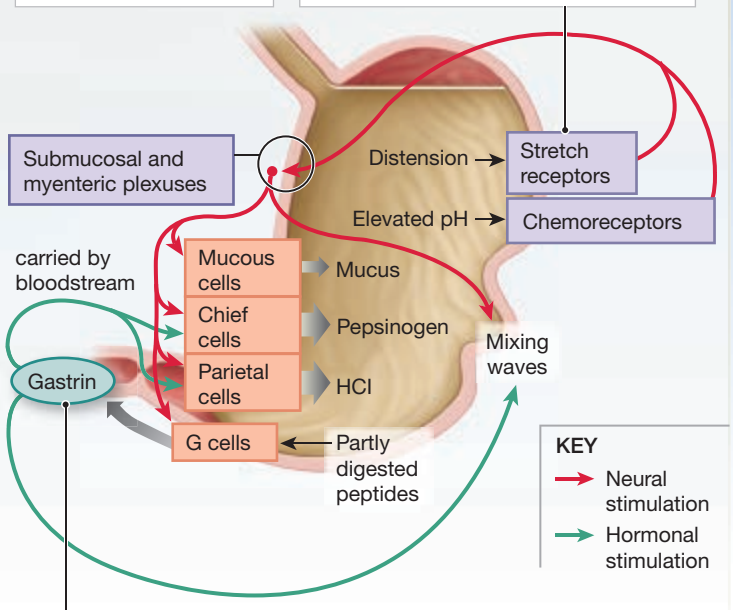
The **gastric phase** begins with the arrival of food in the stomach and builds on the stimulation provided during the cephalic phase. This phase may continue for three to four hours while the acid and enzymes process the ingested materials. The stimuli that initiate the gastric phase are (1) distension of the stomach, (2) an increase in the pH of the gastric contents, and (3) the presence of undigested materials in the stomach, especially proteins and peptides. The gastric phase consists of the following mechanisms:

Local Response

Distension of the gastric wall stimulates the release of histamine in the lamina propria, which binds to receptors on the parietal cells and stimulates acid secretion.

Neural Response

The stimulation of stretch receptors and chemoreceptors triggers short reflexes coordinated in the submucosal and myenteric plexuses. This in turn activates the stomach's secretory cells. The stimulation of the myenteric plexus produces powerful contractions called **mixing waves** in the muscularis externa.



Hormonal Response

Neural stimulation and the presence of peptides and amino acids in chyme stimulate the secretion of the hormone gastrin, primarily by G cells. Gastrin travels in the bloodstream to parietal and chief cells, whose increased secretions reduce the pH of the gastric juice. In addition, gastrin also stimulates gastric motility.

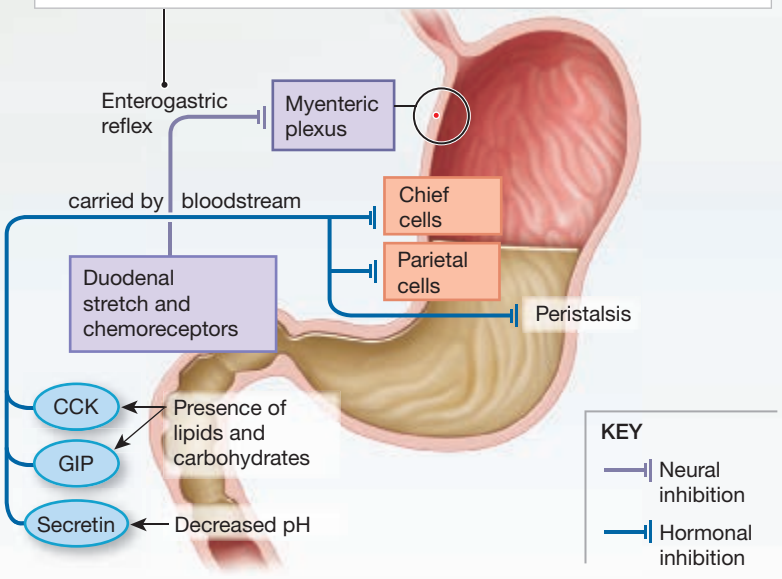
3

INTESTINAL PHASE

The **intestinal phase** of gastric secretion begins when chyme first enters the small intestine. The function of the intestinal phase is to control the rate of gastric emptying to ensure that the secretory, digestive, and absorptive functions of the small intestine can proceed with reasonable efficiency. Although here we consider the intestinal phase as it affects stomach activity, the arrival of chyme in the small intestine also triggers other neural and hormonal events that coordinate the activities of the intestinal tract, pancreas, liver, and gallbladder.

Neural Responses

Chyme leaving the stomach decreases the distension in the stomach, thereby reducing the stimulation of stretch receptors. Distension of the duodenum by chyme stimulates stretch receptors and chemoreceptors that trigger the **enterogastric reflex**. This reflex inhibits both gastrin production and gastric contractions and stimulates the contraction of the pyloric sphincter, which prevents further discharge of chyme. At the same time, local reflexes at the duodenum stimulate mucus production, which helps protect the duodenal lining from the arriving acid and enzymes.



Hormonal Responses

The arrival of chyme in the duodenum triggers hormonal responses:

- Arrival of lipids and carbohydrates stimulates the secretion of cholecystokinin (CCK) and gastric inhibitory peptide (GIP).
- A decrease in pH below 4.5 stimulates the secretion of secretin.
- Partially digested proteins in the duodenum stimulate G cells that secrete gastrin, which circulates to the stomach and speeds gastric processing.

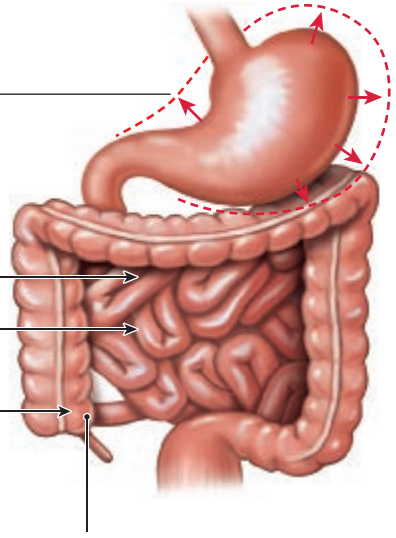
CENTRAL REFLEXES

Two central reflexes, the gastroenteric reflex and gastroileal reflex, are also triggered by the stimulation of stretch receptors in the stomach wall as it fills. These reflexes accelerate movement along the small intestine while the enterogastric reflex controls the rate of chyme entry into the duodenum.

Central Gastric Reflexes

The **gastroenteric reflex** stimulates motility and secretion along the entire small intestine.

The **gastroileal** (gas-trō-IL-ē-al) **reflex** triggers the opening of the ileocecal valve, allowing materials to pass from the small intestine into the large intestine.



The **ileocecal valve** controls the passage of materials into the large intestine.

In general, the rate of movement of chyme into the small intestine is highest when the stomach is greatly distended and the meal contains little protein. A large meal containing small amounts of protein, large amounts of carbohydrates (such as rice or pasta), wine (alcohol), or after-dinner coffee (caffeine) will leave your stomach very quickly. One reason is that both alcohol and caffeine stimulate gastric secretion and motility.

The *vomiting* reflex occurs in response to irritation of the fauces, pharynx, esophagus, stomach, or proximal segment of the small intestine. These sensations are relayed to the vomiting center of the medulla oblongata, which coordinates motor responses. In preparation for vomiting, the pyloric sphincter relaxes and the contents of the duodenum are discharged back into the stomach by strong peristaltic waves that travel toward the stomach. Vomiting, or **emesis** (EM-e-sis), then occurs as the gastroesophageal sphincter relaxes and the stomach regurgitates its contents through the esophagus and pharynx and out through the mouth.

The Pancreas

The **pancreas** lies posterior to the stomach. It extends laterally from the duodenum toward the spleen. The pancreas is primarily an exocrine organ that produces digestive enzymes and buffers.

Gross Anatomy of the Pancreas

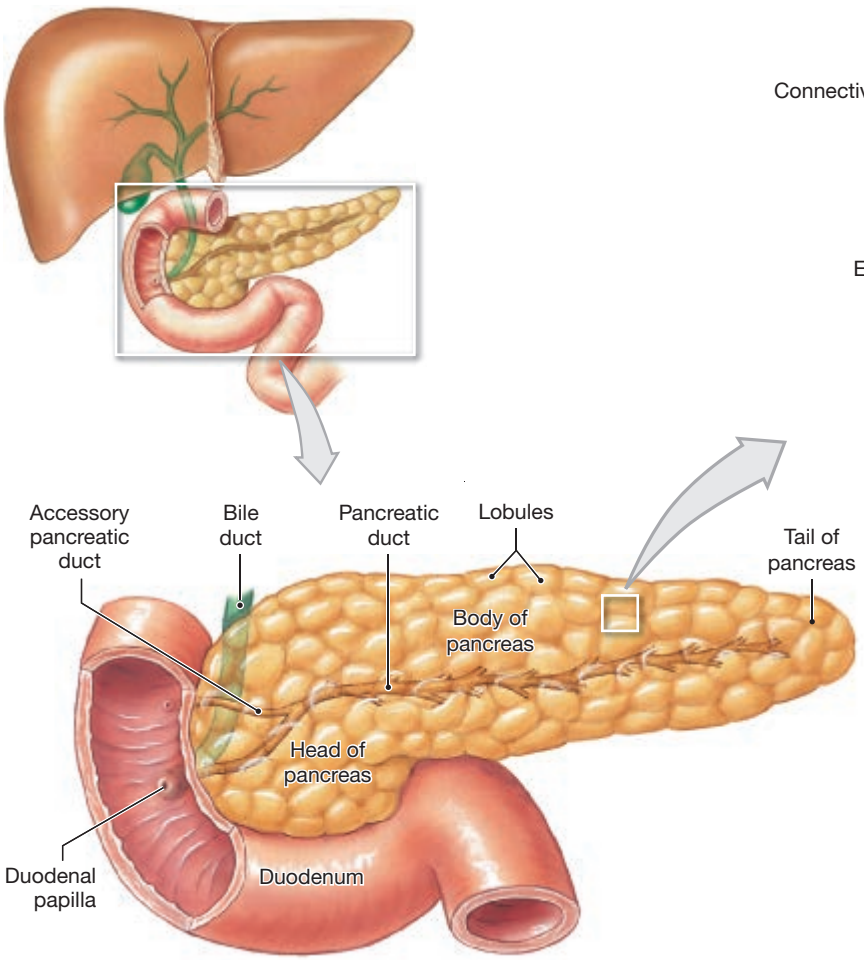
The pancreas is an elongate, pinkish-gray organ about 15 cm (6 in.) long and weighing about 80 g (3 oz) (Figure 24–16a). The broad **head** of the pancreas lies within the loop formed by the duodenum as it leaves the pyloric part. The slender **body** of the pancreas extends toward the spleen, and the **tail** is short and bluntly rounded. The pancreas is retroperitoneal and is firmly bound to the posterior wall of the abdominal cavity. The surface of the pancreas has a lumpy, lobular texture. A thin, transparent capsule of connective tissue wraps the entire organ. The pancreatic lobules, associated blood vessels, and excretory ducts are visible through the anterior capsule and the overlying layer of peritoneum. Arterial blood reaches the pancreas by way of branches of the splenic, superior mesenteric, and common hepatic arteries. The pancreatic arteries and pancreaticoduodenal arteries are the major branches from these vessels. The splenic vein and its branches drain the pancreas.

The large **pancreatic duct** delivers the secretions of the pancreas to the duodenum. (In 3–10 percent of the population, a small *accessory pancreatic duct* branches from the pancreatic duct.) The pancreatic duct extends within the attached mesentery to reach the duodenum, where it meets the *bile duct* from the liver and gallbladder (look ahead to Figure 24–19b). The two ducts then empty into the *duodenal ampulla*, a chamber located roughly halfway along the length of the duodenum. When present, the accessory pancreatic duct usually empties into the duodenum independently, outside the duodenal ampulla.

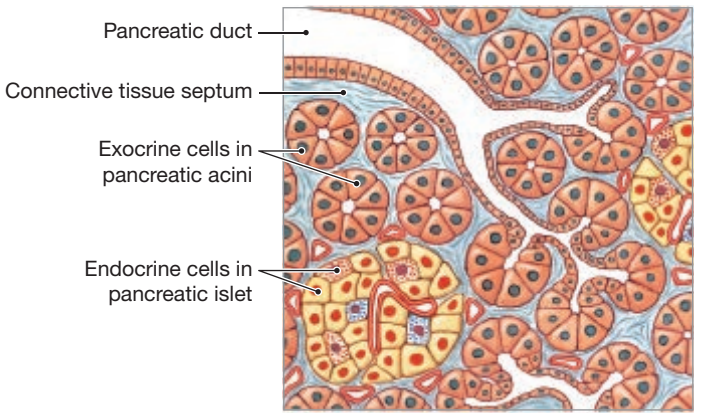
Histology of the Pancreas

Partitions of connective tissue divide the interior of the pancreas into distinct lobules. The blood vessels and tributaries of the pancreatic ducts are located within these connective tissue

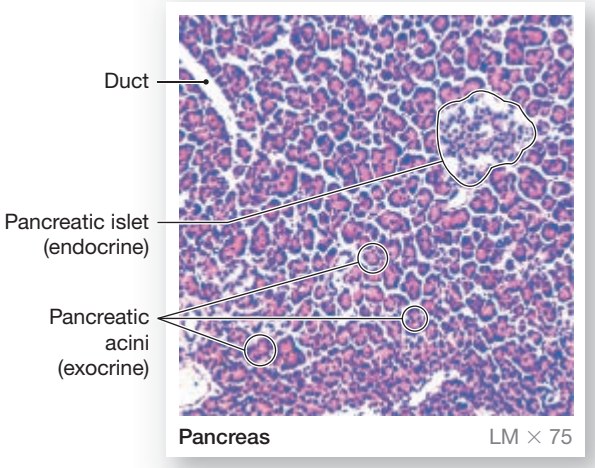
Figure 24–16 Anatomy of the Pancreas. ATLAS: Plates 54d; 55; 57a



a The gross anatomy of the pancreas. The head of the pancreas is tucked into a C-shaped curve of the duodenum that begins at the pylorus of the stomach.



b Diagram of the cellular organization of the pancreas.



c Light micrograph of the cellular organization of the pancreas.

septa (Figure 24–16b). The pancreas is an example of a *compound tubulo-alveolar gland*, a structure described in Chapter 4. p. 125 In each lobule, the ducts branch repeatedly before ending in pockets called **pancreatic acini** (AS-ih-nī). Each pancreatic acinus is lined with simple cuboidal epithelium. *Pancreatic islets*, the endocrine tissues of the pancreas, are scattered among the acini (Figure 24–16c). The islets account for only about 1 percent of the cell population of the pancreas.

Pancreatic Secretions

The pancreas has two distinct functions, one endocrine and the other exocrine. The endocrine cells of the pancreatic islets secrete insulin and glucagon into the bloodstream to control blood sugar. The exocrine cells include the acinar cells and the epithelial cells that line the duct system. Together, these exocrine cells secrete **pancreatic juice**—an alkaline mixture of digestive enzymes, water, and ions—into the small intestine. Acinar cells secrete pancreatic enzymes, which do most of the digestive work in the small intestine. Pancreatic enzymes break down ingested materials into small molecules suitable for absorption. The water and ions, secreted primarily by the cells lining the pancreatic ducts, help dilute and neutralize acid in the chyme.

Physiology of the Pancreas

Each day, the pancreas secretes about 1000 mL (about 1 qt) of pancreatic juice. Hormones from the duodenum control these secretory activities. When chyme arrives in the duodenum, it releases the hormone *secretin*. This hormone triggers the pancreatic secretion of a watery buffer solution with a pH of 7.5–8.8. Among its other components, the secretion contains bicarbonate and phosphate buffers that help raise the pH of the chyme.

Another duodenal hormone, *cholecystokinin (CCK)*, stimulates the production and secretion of pancreatic enzymes. Stimulation by the vagus nerves also increases the secretion of pancreatic enzymes. Recall that this stimulation takes place during the cephalic phase of gastric regulation, so the pancreas starts to synthesize enzymes before food even reaches the stomach. This head start is important, because enzyme synthesis takes much longer than the production of buffers. By starting early, the pancreatic cells are ready to meet the demand when chyme arrives in the duodenum.

The pancreatic enzymes include the following:

- **Pancreatic alpha-amylase**, a **carbohydrase** (kar-bō-HĪ-drās)—an enzyme that breaks down certain starches. Pancreatic alpha-amylase is almost identical to salivary amylase.
- **Pancreatic lipase**, which breaks down certain complex lipids, releasing products (such as fatty acids) that can be easily absorbed.
- **Nucleases**, which break down RNA or DNA.
- **Proteolytic enzymes**, which break apart proteins. These enzymes include **proteases** which break apart large protein complexes, and **peptidases**, which break small peptide chains into individual amino acids.

Proteolytic enzymes account for about 70 percent of total pancreatic enzyme production. These enzymes are secreted as inactive proenzymes. They are activated only after they reach the small intestine. Proenzymes discussed in previous chapters include pepsinogen, angiotensinogen, plasminogen, fibrinogen, and many of the clotting factors and enzymes of the complement system. pp. 644, 661, 683, 802 As in the stomach, the release of a proenzyme rather than an active enzyme protects the secretory cells from the destructive effects of their own products. Among the proenzymes secreted by the pancreas are **trypsinogen** (trip-SIN-ō-jen), **chymotrypsinogen** (kī-mo-trip-SIN-ō-jen) **procarboxypeptidase** (prō-kar-bok-sē-PEP-ti-dās), and **proelastase** (pro-ē-LAS-tās).

Inside the duodenum, trypsinogen is converted to **trypsin**, an active protease. Trypsin then activates the other proenzymes, producing **chymotrypsin**, **carboxypeptidase**, and **elastase**. Each enzyme breaks peptide bonds linking specific amino acids and ignores others. Together, these enzymes break down proteins into a mixture of dipeptides, tripeptides, and amino acids.

+ Clinical Note Pancreatitis

Pancreatitis (pan-krē-a-TĪ-tis) is an inflammation of the pancreas. The condition is extremely painful. The factors that may produce it include a blockage of the excretory ducts, bacterial or viral infections, ischemia, and drug reactions—especially those involving alcohol. These stimuli provoke a crisis by injuring exocrine cells in at least a portion of the organ. Then lysosomes in the damaged cells release enzymes causing autolysis (self-digestion of cells), which spreads to surrounding normal cells. In most cases, only a portion of the pancreas is affected. The condition usually subsides in a few days. But in 10–15 percent of cases, the process continues and may ultimately destroy the pancreas. If the islet cells are damaged, diabetes mellitus may result. p. 641

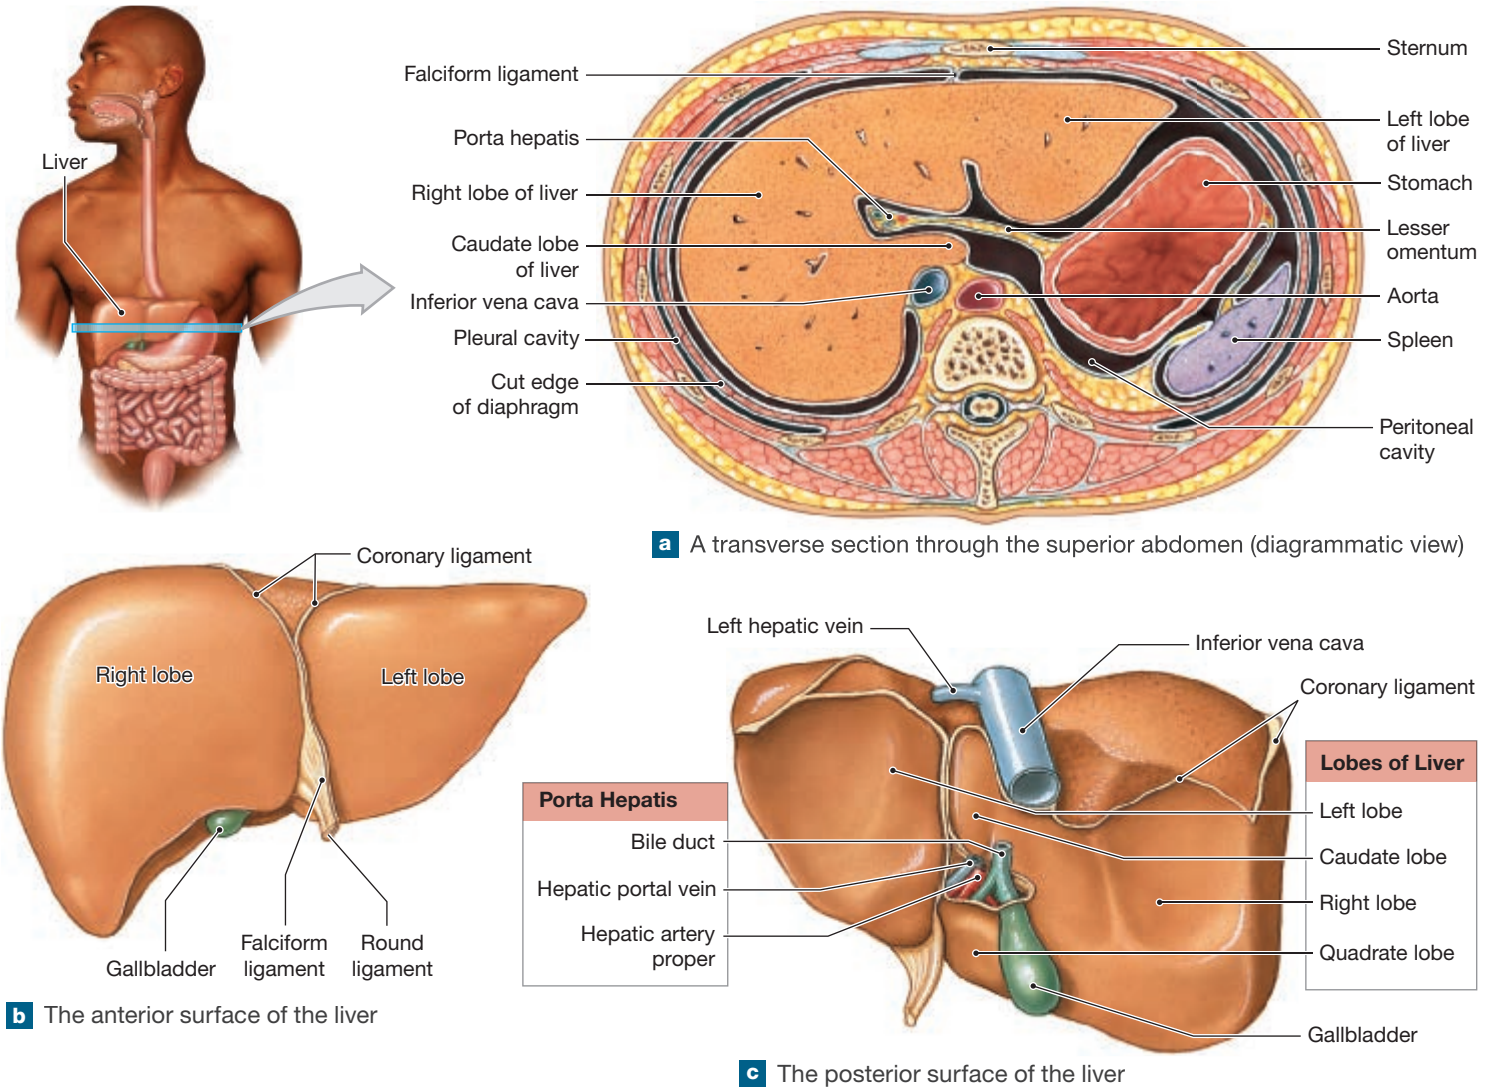
The Liver

The **liver** is the largest visceral organ, a firm, reddish-brown organ weighing about 1.5 kg (3.3 lb). Most of its mass lies in the right hypochondriac and epigastric regions, but it may extend into the left hypochondriac and umbilical regions as well. The versatile liver performs essential metabolic and synthetic functions.

Gross Anatomy of the Liver

Most of surface of the liver is wrapped in a tough fibrous capsule and is covered by a layer of visceral peritoneum. On the anterior surface, the **falciform ligament** marks the division between the organ's left and right lobes (Figure 24–17a,b). A thickening in the posterior margin of the falciform ligament

Figure 24–17 Gross Anatomy of the Liver. ATLAS: Plates 49a,b,e; 54a–c; 57a,b



is the **round ligament**, or *ligamentum teres*. This fibrous band marks the path of the fetal umbilical vein.

On the posterior surface of the liver, the impression left by the inferior vena cava marks the division between the right lobe and the small **caudate** (KAW-dāt) **lobe** (Figure 24–17c). Inferior to the caudate lobe lies the **quadrate lobe**, sandwiched between the left lobe and the gallbladder. Afferent blood vessels and other structures reach the liver by traveling within the connective tissue of the lesser omentum. They converge at a region called the **porta hepatis** ("doorway to the liver").

We discussed the circulation to the liver in Chapter 21 and summarized it in Figures 21-24 and 21-31, pp. 763, 774. Nearly one-third of the blood supply to the liver is arterial blood from the hepatic artery proper. The rest is venous blood from the hepatic portal vein. Liver cells, called **hepatocytes** (HEP-ah-tō-sīts), adjust circulating levels of nutrients through selective absorption and secretion. The blood leaving the liver returns to

+ Clinical Note Cirrhosis

Any condition that severely damages the liver is a serious threat to life. The liver has a high capacity to regenerate itself after injury. Even so, liver function does not fully recover unless the normal vascular pattern is restored. Examples of important types of liver disease include **cirrhosis** (sih-RŌ-sis), which is characterized by the replacement of lobules by fibrous tissue, and various forms of *hepatitis* caused by viral infections. In some cases, liver transplants are used to treat liver failure. Unfortunately, the supply of suitable donor tissue is limited. The success rate is highest in young, otherwise healthy individuals. A form of "liver dialysis" known as *ELAD* (extracorporeal liver assist device) is beneficial for individuals with liver failure or chronic liver disease.

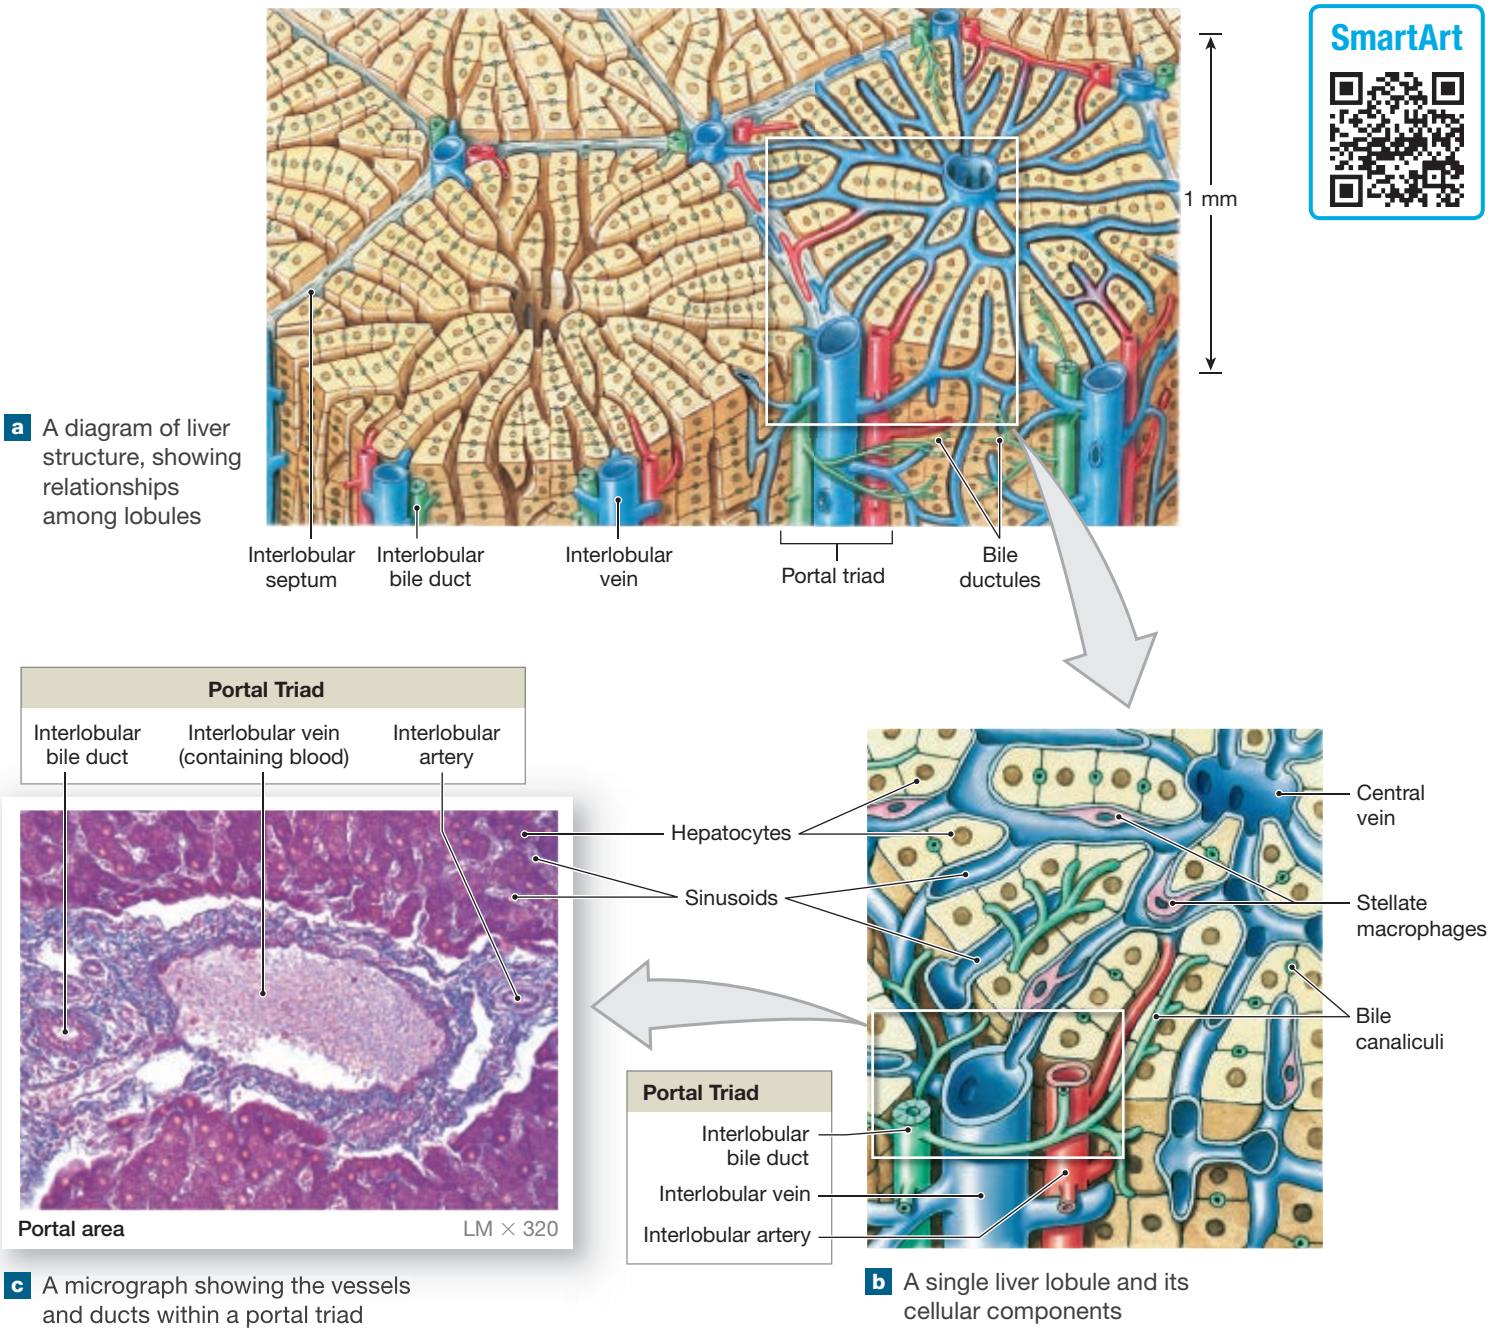
the systemic circuit through the hepatic veins. These veins open into the inferior vena cava.

Histology of the Liver

Connective tissue divides each lobe of the liver into approximately 100,000 liver **lobules**, the basic functional units of the liver. The histological organization and structure of a typical liver lobule are shown in Figure 24–18.

Each lobule is roughly 1 mm in diameter. Adjacent lobules are separated by an *interlobular septum*. The hepatocytes in a liver lobule form a series of irregular plates arranged like the spokes of a wheel (see Figure 24–18a,b). The plates are only one cell thick. Exposed hepatocyte surfaces are covered with short microvilli. Within a lobule, sinusoids between adjacent plates empty into the **central vein**. (We introduced sinusoids in Chapter 21. ↩ p. 734) The liver sinusoids lack a basement membrane, so large openings between the endothelial cells allow solutes—even those as large as plasma proteins—to pass out of the bloodstream and into the spaces surrounding the hepatocytes.

Figure 24–18 Histology of the Liver.



a A diagram of liver structure, showing relationships among lobules

c A micrograph showing the vessels and ducts within a portal triad

b A single liver lobule and its cellular components

The lining of the sinusoids contains typical endothelial cells and a large number of **stellate macrophages** (*Kupffer cells*). These phagocytic cells are part of the monocyte–macrophage system. They engulf pathogens, cell debris, and damaged blood cells. Stellate macrophages also store iron, some lipids, and heavy metals (such as tin or mercury) that are absorbed by the digestive tract.

The Hepatic Portal System. Blood enters the liver sinusoids from small branches of the hepatic portal vein and hepatic artery proper. A typical liver lobule has a hexagonal shape in cross section (see Figure 24–18a). There are six **portal triads**, one at each corner of the lobule. A portal triad contains three structures: (1) an interlobular vein, (2) an interlobular artery, and (3) an interlobular bile duct (see Figure 24–18a-c).

Branches from the arteries and veins deliver blood to the sinusoids of adjacent liver lobules (see Figure 24–18a,b). As blood flows through the sinusoids, hepatocytes absorb solutes from the plasma and secrete materials such as plasma proteins. Blood then leaves the sinusoids and enters the central vein of the lobule. The central veins ultimately merge to form the hepatic veins, which then empty into the inferior vena cava. Liver diseases, such as the various forms of *hepatitis*, and conditions such as alcoholism, can lead to degenerative changes in the liver tissue and constriction of the circulatory supply.

Pressures in the hepatic portal system are usually low, averaging 10 mm Hg or less. This pressure can increase markedly, however, if blood flow through the liver is restricted by a blood clot or damage to the organ. Such a rise in portal pressure is called *portal hypertension*. As pressures rise, small peripheral veins and capillaries in the portal system become distended. If they rupture, extensive bleeding can take place. Portal hypertension can also force fluid into the peritoneal cavity across the serosal surfaces of the liver and viscera, producing ascites.

The Bile Duct System. The liver secretes a fluid called **bile** into a network of narrow channels between the opposing membranes of adjacent liver cells. These passageways, called **bile canaliculi**, extend outward, away from the central vein (see Figure 24–18b). Eventually, they connect with fine bile ductules (DUK-tūlz), which carry bile to the bile ducts in the nearest portal area (see Figure 24–18a). The **right** and **left hepatic ducts** (Figure 24–19a) collect bile from all the bile ducts of the liver lobes. These ducts unite to form the **common hepatic duct**, which leaves the liver. The bile in the common hepatic duct either flows into the *bile duct*, which empties into the duodenal ampulla, or enters the *cystic duct*, which leads to the gallbladder (see Figure 24–19a–c).

The **bile duct** is formed by the union of the **cystic duct** and the common hepatic duct. The bile duct passes within the lesser omentum toward the stomach, turns, and penetrates the wall of the duodenum to meet the pancreatic duct at the duodenal ampulla (see Figure 24–19b).

Physiology of the Liver

The liver carries out more than 200 functions. They fall into three general categories: (1) *metabolic regulation*, (2) *hematological regulation*, and (3) *bile production*. In this discussion we provide a general overview.

Metabolic Regulation. The liver is the primary organ involved in regulating the composition of circulating blood. All blood leaving the absorptive surfaces of the digestive tract enters the hepatic portal system and flows into the liver. Liver cells extract nutrients or toxins from the blood before it reaches the systemic circulation through the hepatic veins. The liver removes and stores excess nutrients. It corrects nutrient deficiencies by mobilizing stored reserves or performing synthetic activities. The liver's regulatory activities affect the following:

- *Carbohydrate Metabolism.* The liver stabilizes the blood glucose level at about 90 mg/dL. If the blood glucose level decreases, hepatocytes break down glycogen reserves and release glucose into the bloodstream. They also synthesize glucose from other carbohydrates or from available amino acids. The synthesis of glucose from other compounds is called *gluconeogenesis*. If the blood glucose level climbs, hepatocytes remove glucose from the bloodstream. They either store it as glycogen or use it to synthesize lipids that can be stored in the liver or other tissues. Circulating hormones, such as insulin and glucagon, regulate these metabolic activities. ↩ pp. 638–640
- *Lipid Metabolism.* The liver regulates circulating levels of triglycerides, fatty acids, and cholesterol. When those levels decline, the liver breaks down its lipid reserves and releases the breakdown products into the bloodstream. When the levels are high, the lipids are removed for storage. However, this regulation takes place only after lipid levels have risen within the general circulation, because most lipids absorbed by the digestive tract bypass the hepatic portal circulation.
- *Amino Acid Metabolism.* The liver removes excess amino acids from the bloodstream. These amino acids can be used to synthesize proteins or can be converted to lipids or glucose for energy storage.
- *Waste Removal.* When converting amino acids to lipids or carbohydrates, or when breaking down amino acids to get energy, the liver strips off the amino groups. This process is called *deamination*. Ammonia, a toxic waste product, is formed. The liver neutralizes ammonia by converting it to *urea* (yū-RĒ-ah), a fairly harmless compound excreted by the kidneys. The liver also removes other waste products, circulating toxins, and drugs from the blood for inactivation, storage, or excretion.
- *Vitamin Storage.* Fat-soluble vitamins (A, D, E, and K) and vitamin B_{12} are absorbed from the blood and stored

d Physiology of the gallbladder.

in the liver. These reserves are used when your diet contains inadequate amounts of those vitamins.

- *Mineral Storage.* The liver converts iron reserves to ferritin and stores this protein–iron complex. ↩ p. 666
- *Drug Inactivation.* The liver removes and breaks down circulating drugs, limiting the duration of their effects.

When physicians prescribe a particular drug, they must take into account the rate at which the liver removes that drug from the bloodstream. For example, a drug that is absorbed relatively quickly must be administered every few hours to keep the blood concentration at a therapeutic level.

Hematological Regulation. The liver receives about 25 percent of cardiac output. It is also the largest blood reservoir in your body. As blood passes through it, the liver performs the following functions:

- *Phagocytosis and Antigen Presentation.* Stellate macrophages in the liver sinusoids engulf old or damaged red blood cells, cellular debris, and pathogens, removing them from the bloodstream. Stellate macrophages are antigen-presenting cells (APCs) that can stimulate an immune response. ↩ p. 811
- *Synthesis of Plasma Proteins.* Hepatocytes synthesize and release most of the plasma proteins. These proteins include the albumins (which contribute to the osmotic concentration of the blood), the various types of transport proteins, clotting proteins, and complement proteins.
- *Removal of Circulating Hormones.* The liver is the primary site for the absorption and recycling of epinephrine, norepinephrine, insulin, thyroid hormones, and steroid hormones, such as the sex hormones (estrogens and androgens) and corticosteroids. The liver also absorbs *cholecalciferol* (vitamin D_3) from the blood. Liver cells then convert the cholecalciferol, which may be synthesized in the skin or absorbed in the diet, into an intermediary product, 25-hydroxy-D_3, that is released back into the bloodstream. The kidneys absorb this intermediary and use it to generate *calcitriol*, a hormone important to Ca^{2+} metabolism. ↩ p. 641
- *Removal of Antibodies.* The liver absorbs and breaks down antibodies, releasing amino acids for recycling.
- *Removal or Storage of Toxins.* The liver absorbs lipid-soluble toxins in the diet, such as the insecticide DDT (banned in the United States since 1972, but still found in the environment), and stores them in lipid deposits, where they do not disrupt cellular functions. The liver removes other toxins from the bloodstream and either breaks them down or excretes them in the bile.

24

Production and Functions of Bile. The liver synthesizes bile and secretes it into the lumen of the duodenum. Hormonal and neural mechanisms regulate bile secretion. Bile consists mostly of water, with minor amounts of ions, *bilirubin* (a pigment derived from hemoglobin), cholesterol, and an assortment of lipids collectively known as **bile salts**. The water and ions help dilute and buffer acids in chyme as they enter the small intestine. Bile salts are synthesized from cholesterol in the liver. Several related compounds are involved. The most abundant are derivatives of the steroids *cholate* and *chenodeoxycholate*.

Bile salts play a role in the digestion of lipids. Most dietary lipids are not water soluble, so mechanical digestion in the stomach creates large drops containing a variety of lipids. Pancreatic lipase is not lipid soluble, so the enzymes can interact with lipids only at the surface of a lipid droplet. The larger the droplet, the more lipids are inside, isolated and protected from these enzymes. Bile salts break the droplets apart in a process called **emulsification** (ē-mul-sih-fih-KĀ-shun).

Emulsification creates tiny *emulsion droplets* with a superficial coating of bile salts. The formation of tiny droplets increases the total surface area available for enzymatic action. In addition, the layer of bile salts facilitates interaction between the lipids and lipid-digesting enzymes from the pancreas.

After lipid digestion has been completed, bile salts promote the absorption of lipids by the intestinal epithelium. More than 90 percent of the bile salts are themselves reabsorbed, primarily in the ileum of the small intestine, as lipid digestion is completed. The reabsorbed bile salts enter the hepatic portal circulation. The liver then collects and recycles them. The cycling of bile salts from the liver to the small intestine and back is called the **enterohepatic circulation** of bile.

The Gallbladder

The **gallbladder** is a hollow, pear-shaped organ that stores and concentrates bile prior to its secretion into the small intestine. This muscular sac is located in a fossa, or recess, in the posterior surface of the liver's right lobe (see Figure 24–19a).

Anatomy of the Gallbladder

The gallbladder is divided into three regions: (1) the **fundus**, (2) the **body**, and (3) the **neck**. The cystic duct extends from the gallbladder to the point where it unites with the common hepatic duct to form the bile duct. At the duodenum, the bile duct meets the pancreatic duct before emptying into a chamber called the **duodenal ampulla** (am-PUL-luh) (see Figure 24–19b), which receives buffers and enzymes from the pancreas and bile from the liver and gallbladder. The duodenal ampulla opens into the duodenum at the **duodenal papilla**, a small mound. The muscular **hepatopancreatic sphincter** encircles the lumen of the bile duct and, generally, the pancreatic duct and duodenal ampulla as well.

Physiology of the Gallbladder

A major function of the gallbladder is bile storage. Bile is released into the duodenum only under the stimulation of the intestinal hormone CCK (see Figure 24–19d). Without CCK, the hepatopancreatic sphincter remains closed, so bile exiting the liver in the common hepatic duct cannot flow through the bile duct and into the duodenum. Instead, it enters the cystic duct and is stored within the expandable gallbladder. Whenever chyme enters the duodenum, CCK is released, relaxing the hepatopancreatic sphincter and stimulating contractions of the gallbladder that push bile into the small intestine. The amount of CCK secreted increases markedly when the chyme contains large amounts of lipids.

The gallbladder also functions in bile modification. When full, the gallbladder contains 40–70 mL of bile. The composition of bile gradually changes as it remains in the gallbladder: Much of the water is absorbed, and the bile salts and other components of bile become increasingly concentrated.

If bile becomes too concentrated, crystals of insoluble minerals and salts begin to form. These deposits are called *gallstones*. Small gallstones are not a problem as long as they can be flushed down the bile duct and excreted. In *cholecystitis* (kō-lē-sis-TĪ-tis; *chole*, bile + *kystis*, bladder + *-itis*, inflammation), the gallstones are so large that they can damage the wall of the gallbladder or block the cystic duct or bile duct. In that case, the gallbladder may need to be surgically removed. This does not seriously impair digestion, because bile production continues at the normal level. However, the bile is more dilute, and its entry into the small intestine is not as closely tied to the arrival of food in the duodenum.

24-6 The small intestine primarily functions in the chemical digestion and absorption of nutrients

Learning Outcome Describe the anatomy and histology of the small intestine, and explain the functions and regulation of intestinal secretions.

The **small intestine** is a long muscular tube where chemical digestion is completed and the products of digestion are absorbed. Ninety percent of nutrient absorption takes place in the small intestine (most of the rest occurs in the large intestine). This section examines the anatomy and physiology of this critical organ.

Gross Anatomy of the Small Intestine

The small intestine, also known as the *small bowel*, averages 6 m (19.7 ft) in length (range: 4.5–7.5 m; 14.8–24.6 ft). Its diameter ranges from 4 cm (1.6 in.) at the stomach to about 2.5 cm (1 in.) at the junction with the large intestine.

The small intestine fills much of the peritoneal cavity. It occupies all abdominal regions except the right and left hypochondriac and epigastric regions (look back at Figure 1–4b, p. 11). Its position is stabilized by the mesentery proper, a broad mesentery attached to the posterior body wall (look back at Figure 24–2c,d). The stomach, large intestine, abdominal wall, and pelvic girdle restrict movement of the small intestine during digestion. Blood vessels, lymphatic vessels, and nerves reach the small intestine within the connective tissue of the mesentery. The primary blood vessels involved are branches of the superior mesenteric artery and the superior mesenteric vein. pp. 764, 775

The small intestine has three segments: the duodenum, the jejunum, and the ileum (Figure 24–20a). The **duodenum** (dū-ō-DĒ-num), 25 cm (10 in.) in length, is the segment closest to the stomach. This portion of the small intestine is a "mixing bowl." It receives chyme from the stomach and digestive secretions from the pancreas and liver. From its connection with the stomach, the duodenum curves in a C that encloses the pancreas. Except for the proximal 2.5 cm (1 in.), the duodenum is in a retroperitoneal position between vertebrae L_1 and L_4 (look back at Figure 24–2d).

A rather abrupt bend marks the boundary between the duodenum and the **jejunum** (jeh-JŪ-num). At this junction, the small intestine reenters the peritoneal cavity, supported by a sheet of mesentery. The jejunum is about 2.5 m (8.2 ft) long. The bulk of chemical digestion and nutrient absorption occurs there.

The (IL-ē-um), the final segment of the small intestine, is also the longest. It averages 3.5 m (11.5 ft) in length. The ileum ends at the **ileocecal** (il-ē-ō-SĒ-kal) **valve**. This sphincter controls the flow of material from the ileum into the *cecum* (SĒ-kum) of the large intestine.

Tips & Tools

To remember the order of the small intestine segments, beginning at the stomach, use this mnemonic: ***D***on't ***j***ump ***i***n—***d***uodenum, ***j***ejunum, and ***i***leum. Also, make sure not to confuse *ileum*, the last segment of the small intestine, with *ilium*, which is a bone.

Histology of the Small Intestine

The intestinal lining has a series of transverse folds called **circular folds** (see Figure 24–20b). Unlike the rugae in the stomach, the circular folds are permanent features—they do not disappear when the small intestine fills. The small intestine contains about 800 circular folds (roughly 2 per centimeter), which greatly increase the surface area available for absorption.

The Intestinal Villi

If the small intestine were a simple tube with smooth walls, it would have a total absorptive area of about 3300 cm^2 (3.6 ft^2). Instead, the mucosa contains circular folds. Each circular fold in turn has a series of fingerlike projections, the **intestinal villi** (Figure 24–21). The villi are covered by simple columnar epithelium that is carpeted with microvilli. The cells are said

Figure 24–20 Gross Anatomy and Segments of the Intestine. ATLAS: Plates 49a,b,d; 51a,b

b A representative view of the jejunum

to have a *brush border* because the microvilli project from the epithelium like the bristles on a brush (see Figure 24–21e). This arrangement increases the total area for absorption by a factor of more than 600, to approximately 2 million cm^2 (more than 2200 ft^2). This area is nearly the size of 10 lanes in a bowling alley.

The lamina propria of each villus contains an extensive network of capillaries that originate in a vascular network within the submucosa (see Figure 24–21d). These capillaries carry absorbed nutrients to the hepatic portal circulation for delivery to the liver.

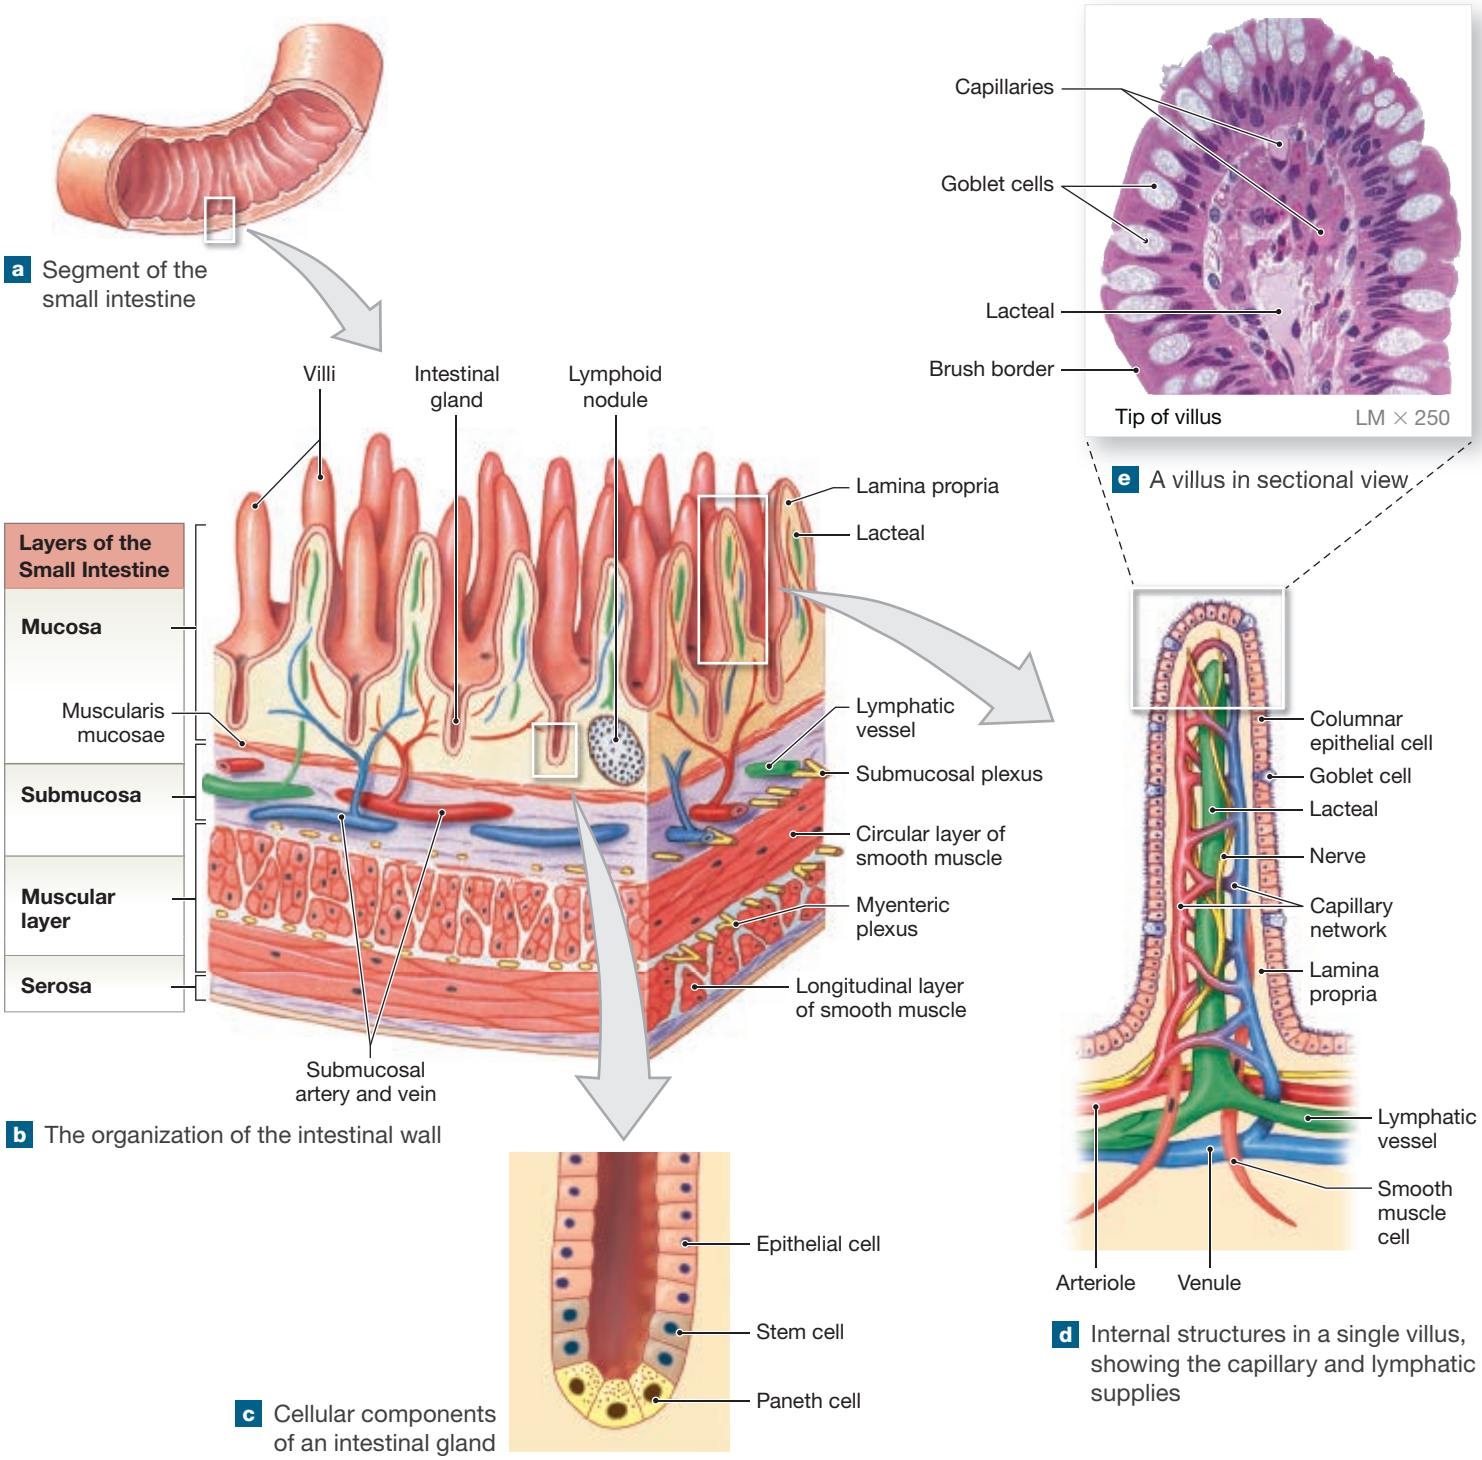
In addition to capillaries and nerve endings, each villus contains a central lymphatic vessel called a **lacteal** (LAK-tē-ul; *lacteus*, milky) (see Figure 24–21b,d). Lacteals transport materials that cannot enter blood capillaries. For example, absorbed fatty acids are assembled into protein–lipid packages that are too large to diffuse into the bloodstream. These packets, called *chylomicrons*, reach the venous circulation through the thoracic duct, which delivers lymph into the left subclavian vein. The name *lacteal* refers to the pale, milky appearance of lymph that contains large quantities of lipids.

Intestinal Glands and Their Secretions

The duodenum has numerous goblet cells, both in the epithelium and deep to it. Goblet cells between the columnar epithelial cells eject mucins onto the intestinal surfaces (see Figure 24–21d,e). At the bases of the villi are the entrances to the **intestinal glands**, also called *intestinal crypts*. These glandular pockets extend deep into the underlying lamina propria. Near the base of each intestinal gland, *stem cells* divide and produce new generations of epithelial cells, which are continuously displaced toward the intestinal surface. In a few days the new cells reach the tip of a villus and are shed into the intestinal lumen. This ongoing process renews the epithelial surface. The disintegration of the shed cells adds enzymes to the lumen. **Paneth cells** at the base of the intestinal glands have a role in innate (nonspecific) immunity, and release defensins and lysozyme (Figure 24–21b,c). These secretions kill some bacteria and allow others to live, thereby establishing the flora of the intestinal lumen. Intestinal glands also contain enteroendocrine cells that produce several intestinal hormones, including gastrin, cholecystokinin, and secretin.

In addition to intestinal glands, the intestinal submucosa contains **duodenal submucosal glands**. Duodenal submucosal glands produce copious quantities of mucus when chyme arrives from the stomach. The mucus protects the epithelium from the acidity of chyme and also contains bicarbonate ions that help raise the pH of the chyme. The duodenal submucosal glands also secrete the hormone *urogastrone*, which inhibits gastric acid production and stimulates the division of epithelial stem cells along the digestive tract (look back at Figure 24–3).

Figure 24–21 Histology of the Intestinal Wall. ATLAS: Plates 51a–d



Specializations of the Segments

The segments of the small intestine—the duodenum, jejunum, and ileum—are distinguished by both histological specialization and primary function. The duodenum has few circular folds, and their villi are small. The primary function of the duodenum is to receive chyme from the stomach and neutralize its acids before they can damage the absorptive surfaces of the small intestine.

Over the proximal half of the jejunum, however, circular folds and villi are very prominent. Thereafter, the circular folds and villi gradually decrease in size. This reduction parallels a reduction in absorptive activity: Most nutrient absorption takes

place before ingested materials reach the ileum. One rather drastic surgical method of promoting weight loss is the removal of a significant portion of the jejunum. The resulting reduction in absorptive area causes a marked weight loss and may not interfere with adequate nutrition, but the side effects can be very serious.

The distal portions of the ileum lack circular folds. The lamina propria there contains 20–30 masses of lymphoid tissue called aggregated lymphoid nodules, or *Peyer's patches*. ↩ p. 791 These lymphoid tissues are most abundant in the terminal portion of the ileum, near the entrance to the large intestine. The lymphocytes in the aggregated lymphoid nodules protect the small intestine from bacteria that normally inhabit the large intestine.

Physiology of the Small Intestine

The primary functions of the small intestine are the chemical digestion of chyme from the stomach and the absorption of nutrients across the mucosal surface. Fats are absorbed into the lymphatic system and other nutrients enter the bloodstream.

Chemical Digestion: Intestinal Secretions and Enzymes

Roughly 1.8 liters of watery **intestinal juice** enters the intestinal lumen each day. Intestinal juice moistens chyme, helps buffer acids, and keeps both the digestive enzymes and the products of digestion in solution. Much of this fluid arrives by osmosis, as water flows out of the mucosa and into the concentrated chyme. The rest is secreted by intestinal glands, stimulated by the activation of touch receptors and stretch receptors in the intestinal walls.

The mucosa of the small intestine produces only a few of the enzymes involved in chemical digestion. The most important of the enzymes introduced into the lumen comes from the apical portions of the intestinal cells. *Brush border enzymes* are integral membrane proteins on the surfaces of intestinal microvilli. These enzymes break down materials that come in contact with the brush border. The epithelial cells then absorb the breakdown products. Once the epithelial cells are shed, they disintegrate within the lumen, releasing both intracellular and brush border enzymes. *Enteropeptidase* (previously called *enterokinase*) is one brush border enzyme that enters the lumen in this way. It does not directly participate in digestion. Instead, it activates the key pancreatic proenzyme, trypsinogen.

The duodenal submucosal glands help protect the duodenal epithelium from gastric acids and enzymes. As chyme travels the length of the duodenum, its pH increases from 1–2 to 7–8. These glands increase their secretion in response to (1) local reflexes, (2) the release of the hormone *enterocrinin* by enteroendocrine cells of the duodenum, and (3) parasympathetic stimulation through the vagus nerves. The first two mechanisms operate only after chyme arrives in the duodenum. However, the duodenal glands begin secreting during the cephalic phase of gastric secretion, long before chyme reaches the pyloric sphincter. They do so because vagus nerve activity triggers their secretion. Thus, the duodenal lining has protection in advance.

Sympathetic stimulation inhibits the duodenal glands, leaving the duodenal lining unprepared for the arrival of chyme. This effect probably explains why chronic stress or other factors that promote sympathetic activation can cause duodenal ulcers.

Mechanical Digestion: Intestinal Motility

After chyme has arrived in the duodenum, weak peristaltic contractions move it slowly toward the jejunum. The contractions are myenteric reflexes that are not under CNS control. Their effects are limited to within a few centimeters of the site of the original stimulus. Motor neurons in the submucosal and myenteric plexuses control these short reflexes. In addition, some of the smooth muscle cells contract periodically, even without stimulation, establishing a basic contractile rhythm that then spreads from cell to cell.

The stimulation of the parasympathetic system increases the sensitivity of the weak myenteric reflexes and speeds up both local peristalsis and segmentation. More elaborate reflexes coordinate activities along the entire length of the small intestine. The gastroenteric and gastroileal reflexes speed up movement along the small intestine (see **Spotlight Figure 24–15**). This effect is the opposite from that of the **enterogastric reflex**, of which one result is constriction of the pyloric sphincter and the discharge of chyme.

Hormones released by the digestive tract can enhance or suppress reflexes. For example, the gastroileal reflex is triggered by stretch receptor stimulation. However, the degree of ileocecal valve relaxation is enhanced by gastrin, which is secreted in large quantities when food enters the stomach.

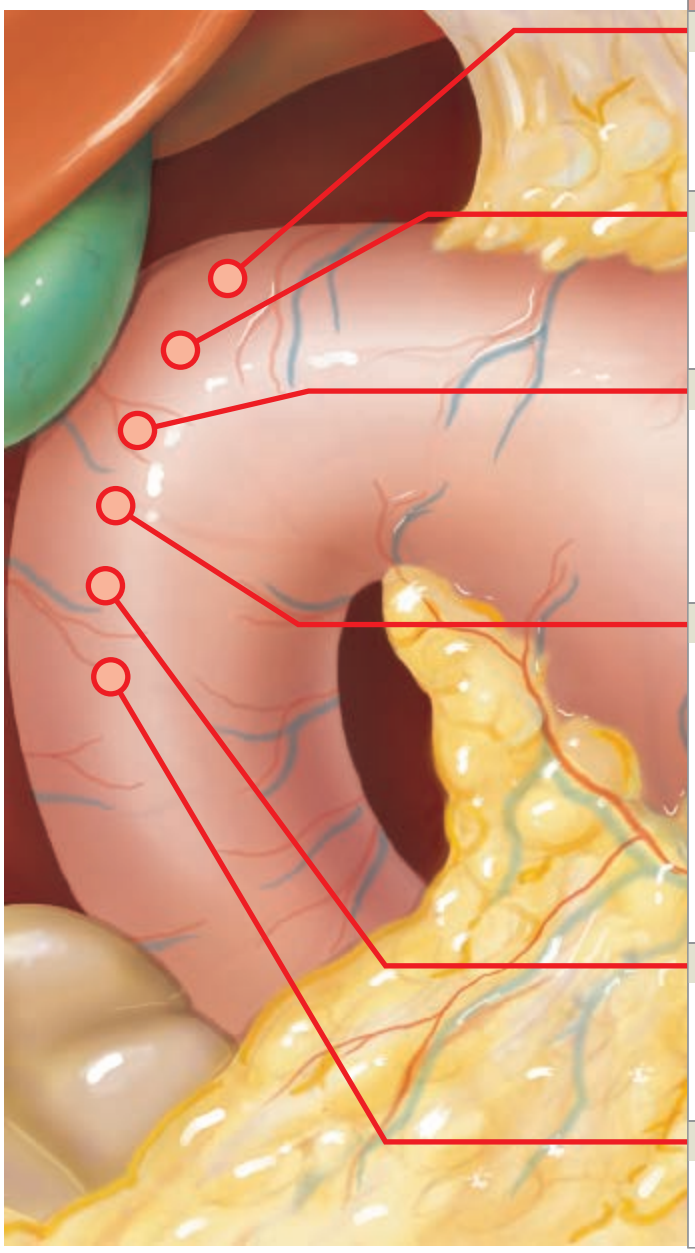
Regulation: Coordination of Secretion and Absorption in the Digestive Tract

A combination of neural and hormonal mechanisms coordinates the activities of the digestive glands. These regulatory mechanisms are centered on the duodenum, where acids must be neutralized and appropriate enzymes added.

Neural mechanisms involving the CNS prepare the digestive tract for activity (through parasympathetic innervation) or inhibit its activity (through sympathetic innervation). Neural mechanisms also coordinate the movement of materials along the length of the digestive tract (through the enterogastric, gastroenteric, and gastroileal reflexes).

In addition, motor neurons synapsing in the digestive tract release a variety of neurotransmitters. Many of these chemicals are also released in the CNS. In general, their functions are

Figure 24–22 The Secretion and Effects of Major Duodenal Hormones.



Major Hormones of the Duodenum

Gastrin

Gastrin is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins. The functions of gastrin include promoting increased stomach motility and stimulating the production of gastric acids and enzymes. (Gastrin is also produced by the stomach.)

Secretin

Secretin is released when chyme arrives in the duodenum. Secretin's primary effect is an increase in the secretion of buffers by the pancreas, which increase the pH of the chyme. Secondarily, secretin also stimulates secretion of bile by the liver and reduces gastric motility and gastric secretory rates.

Gastric Inhibitory Peptide (GIP)

Gastric inhibitory peptide is secreted when fats and carbohydrates—especially glucose—enter the small intestine. The inhibition of gastric activity is accompanied by the stimulation of insulin release at the pancreatic islets. GIP has several secondary effects, including stimulating duodenal gland activity, stimulating lipid synthesis in adipose tissue, and increasing glucose use by skeletal muscles.

Cholecystokinin (CCK)

Cholecystokinin is secreted when chyme arrives in the duodenum, especially when the chyme contains lipids and partially digested proteins. In the pancreas, CCK accelerates the production and secretion of all types of digestive enzymes. It also causes a relaxation of the hepatopancreatic sphincter and contraction of the gallbladder, resulting in the ejection of bile and pancreatic juice into the duodenum. Thus, the net effects of CCK are to increase the secretion of pancreatic enzymes and to push pancreatic secretions and bile into the duodenum. The presence of CCK in high concentrations has two additional effects: It inhibits gastric activity, and it appears to have CNS effects that reduce the sensation of hunger.

Vasoactive Intestinal Peptide (VIP)

Vasoactive intestinal peptide stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach. By dilating capillaries in active areas of the intestinal tract, VIP provides an efficient mechanism for removing absorbed nutrients.

Enterocrinin

Enterocrinin is released when chyme enters the duodenum. It stimulates alkaline mucus production by the submucosal glands.

poorly understood. Examples of neurotransmitters that may be important include substance P, enkephalins, and endorphins.

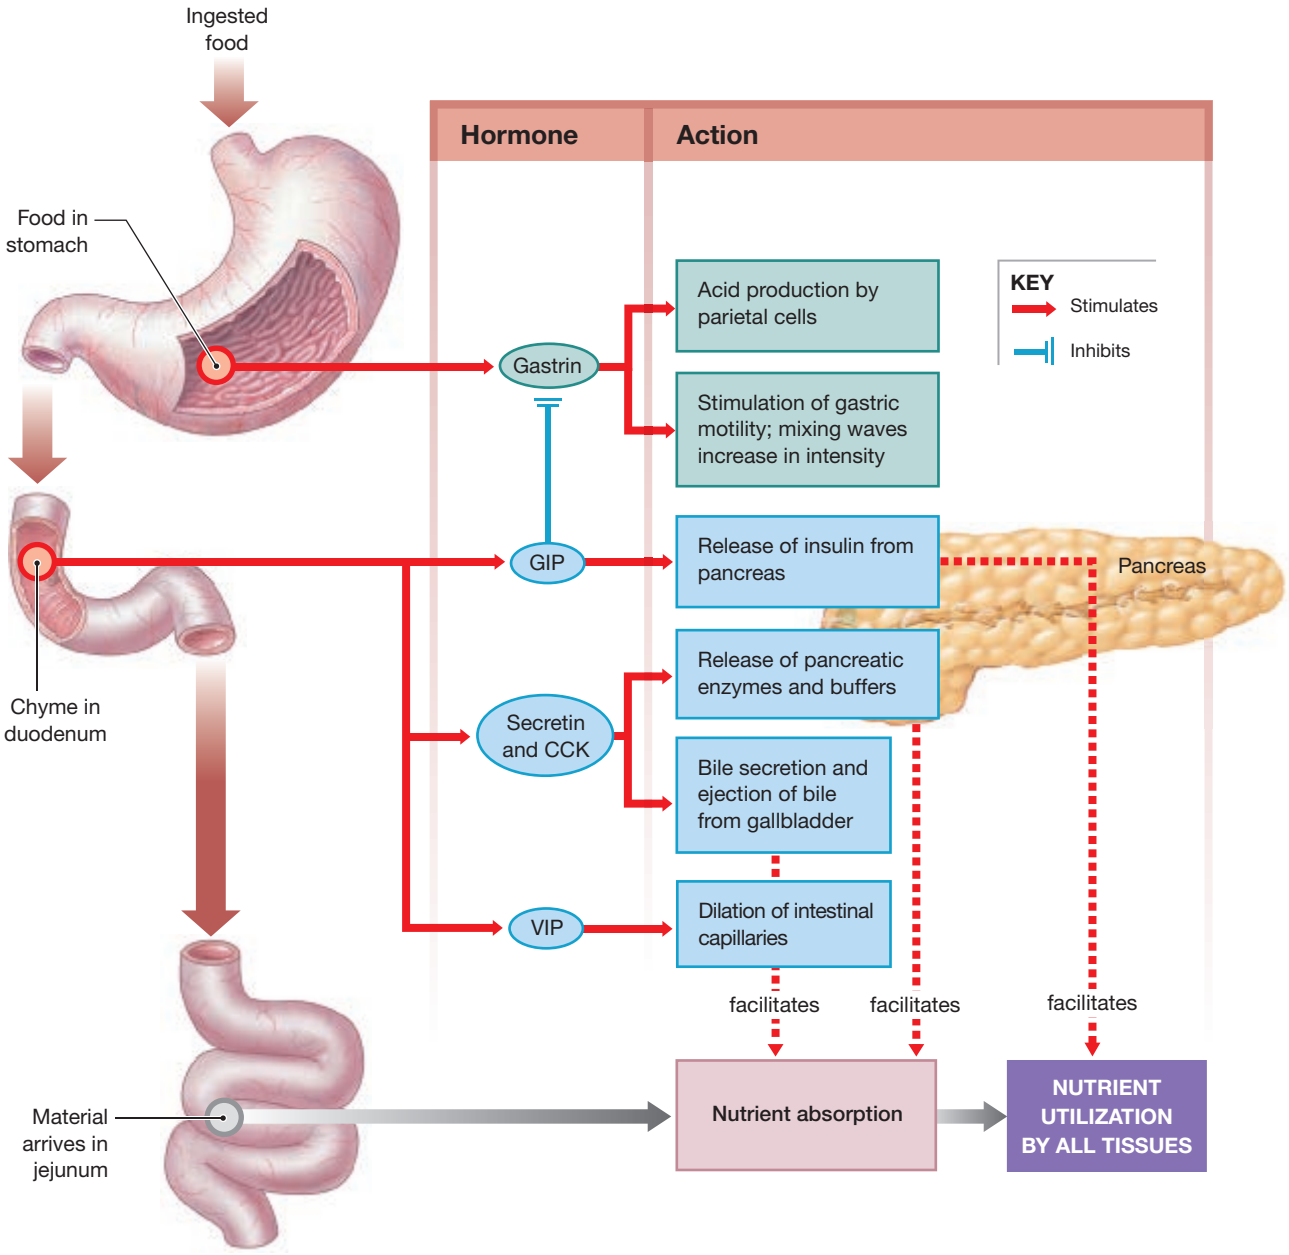
We now summarize the information presented thus far on the regulation of intestinal and glandular function. We also consider some additional details about the regulatory mechanisms involved.

Secretion and Effects of Intestinal Hormones

The intestinal tract secretes a variety of peptide hormones with similar chemical structures. Many of these hormones have multiple effects in several regions of the digestive tract, and in the accessory glandular organs as well. The origins and primary effects of these important digestive hormones are shown in Figure 24–22.

Other intestinal hormones are produced in relatively small quantities. Examples include *motilin*, which stimulates intestinal contractions; *villikinin*, which promotes the movement of villi and the associated lymph flow; and *somatostatin*, which inhibits gastric secretion. Functional interactions among gastrin, GIP, secretin, CCK, and VIP are diagrammed in Figure 24–23.

Figure 24–23 The Secretion and Effects of Major Digestive Tract Hormones. The primary effects of gastrin, GIP, secretin, CCK, and VIP are shown.



? Chyme in the duodenum stimulates the secretion of what hormones in the digestive tract?

Absorption in the Small Intestine

On average, it takes about 5 hours for materials to pass from the duodenum to the end of the ileum. The first of the materials to enter the duodenum after you eat breakfast may leave the small intestine at lunchtime. We discuss the absorption of nutrients later in **Spotlight Figure 24–27** on page 928.

Along the way, the organ's absorptive effectiveness is enhanced by the fact that so much of the mucosa is movable. The microvilli can be moved by their supporting microfilaments. The intestinal villi move back and forth, exposing the epithelial surfaces to the liquefied intestinal contents. Groups of villi are moved by the muscularis mucosae; and the muscularis mucosae and the muscular layer move the circular folds. These movements stir and mix the intestinal contents, making absorption more efficient by quickly eliminating local differences in nutrient concentration.

Checkpoint

25. Name the three regions of the small intestine from proximal to distal.
26. How is the small intestine adapted for nutrient absorption?
27. Does a high-fat meal raise or lower the level of cholecystokinin in the blood?
28. How would the pH of the intestinal contents be affected if the small intestine did not produce secretin?

See the blue Answers tab at the back of the book.

24-7 The large intestine, which is divided into three parts, absorbs water from digestive materials and eliminates the remaining waste as feces

Learning Outcome Describe the gross and histological structures of the large intestine, including its regional specializations and role in nutrient absorption.

The horseshoe-shaped **large intestine** begins at the end of the ileum and ends at the anus. The large intestine lies inferior to the stomach and liver and almost completely frames the small intestine (look back at Figure 24–1). The large intestine stores digestive wastes and reabsorbs water.

Gross Anatomy and Segments of the Large Intestine

The large intestine, also known as the *large bowel*, has an average length of about 1.5 meters (4.9 ft) and a width of 7.5 cm (3 in.). We can divide it into three segments: (1) the pouchlike *cecum*, the first portion of the large intestine; (2) the *colon*, the largest portion; and (3) the *rectum*, the last 15 cm (6 in.) of the large intestine and the end of the digestive tract (Figure 24–24a).

The Cecum and Appendix

Material arriving from the ileum first enters an expanded pouch called the **cecum**. The ileum attaches to the medial surface of the cecum and opens into the cecum at the *ileocecal valve* (see Figure 24–24a,b). The cecum collects and stores materials from the ileum and begins the process of compaction.

The slender, hollow **appendix**, or *vermiform appendix* (*vermis*, worm), is attached to the posteromedial surface of the cecum (see Figure 24–24a,b). The appendix is normally about 9 cm (3.6 in.) long, but its size and shape are quite variable. A small mesentery called the **meso-appendix** connects the appendix to the ileum and cecum. The primary function of the appendix is as an organ of the lymphatic system. Lymphoid nodules dominate the mucosa and submucosa of the appendix. Inflammation of the appendix is known as *appendicitis*.

The Colon

The **colon** has a larger diameter and a thinner wall than the small intestine. Distinctive features of the colon include the following (see Figure 24–24a):

- The wall of the colon forms a series of pouches, or **haustra** (HAWS-truh; singular, *haustrum*). The creases between the haustra affect the mucosal lining as well, producing a series of internal folds. Haustra permit the colon to expand and elongate.
- Three separate longitudinal bands of smooth muscle—called the **teniae coli** (TĒ-nē-ē KŌ-lē)—run along the outer surfaces of the colon just deep to the serosa. These bands correspond to the outer layer of the muscular layer in other portions of the digestive tract. Muscle tone within the teniae coli is what creates the haustra.
- The serosa of the colon contains numerous teardrop-shaped sacs of fat called **omental appendices** or the *fatty appendices of colon*.

We can subdivide the colon into four segments: the ascending colon, transverse colon, descending colon, and sigmoid colon (see Figure 24–24a).

1. The **ascending colon** begins at the superior border of the cecum and ascends along the right lateral and posterior wall of the peritoneal cavity to the inferior surface of the liver. There, the colon bends sharply to the left at the **right colic flexure**, or *hepatic flexure*. This bend marks the end of the ascending colon and the beginning of the transverse colon.
2. The **transverse colon** curves anteriorly from the right colic flexure and crosses the abdomen from right to left. The transverse colon is supported by the transverse mesocolon. It is separated from the anterior abdominal wall by the layers of the greater omentum. At the left side of the body, the transverse colon passes inferior to the greater curvature of the stomach. Near the spleen, the colon makes a 90° turn at the **left colic flexure**, or *splenic flexure*, and becomes the descending colon.
3. The **descending colon** proceeds inferiorly along the left side until reaching the iliac fossa formed by the inner surface of the left ilium. The descending colon is retroperitoneal and firmly attached to the abdominal wall. At the iliac fossa, the descending colon curves and becomes the sigmoid colon.
4. The **sigmoid** (SIG-moyd; *sigmeidos*, the Greek letter *S*) **colon** is an S-shaped segment that is only about 15 cm (6 in.) long. The sigmoid colon lies posterior to the urinary bladder, suspended from the sigmoid mesocolon. The sigmoid colon empties into the rectum.

The colon, and indeed the entire large intestine, receives blood from branches of the superior mesenteric and inferior mesenteric arteries. The superior mesenteric and inferior mesenteric veins collect venous blood from the large intestine.

c The rectum and anus

+ Clinical Note Colorectal Cancer

Colorectal cancer is relatively common in the United States. Aside from skin cancers, colorectal cancer is the third most common cancer in the United States, affecting both men and women. The American Cancer Society estimates that 95,270 new cases of colon cancer and 39,220 new cases of rectal cancer will occur in 2016. The death rate has declined over the past 20 years for both men and women.

The best defense appears to be early detection and prompt treatment. Standard screening involves checking the feces for blood. This simple procedure can be performed easily on a stool (fecal) sample as part of a routine physical. For individuals at increased risk because of family history, associated disease, or older age, visual inspection of the intestinal lumen by fiber-optic colonoscopy is prudent. Such examination can find polyps before they develop into cancers. The 5-year survival rate for people whose cancer is found at an early stage and treated immediately is greater than 90 percent.

The Rectum

The **rectum** (REK-tum) forms the last 15 cm (6 in.) of the digestive tract (see Figure 24–24a,c). It is an expandable organ for the temporary storage of **feces**.

The last portion of the rectum, the **anal canal**, contains small longitudinal folds called **anal columns**. The distal margins of these columns are joined by transverse folds that mark the boundary between the columnar epithelium of the proximal rectum and a stratified squamous epithelium like that in the oral cavity. The **anus** is the exit of the anal canal. There, the epidermis becomes keratinized and identical to the surface of the skin.

The circular layer of muscle in this region forms the **internal anal sphincter** (see Figure 24–24c). The smooth muscle cells of this sphincter are not under voluntary control. The **external anal sphincter**, which guards the anus, consists of a ring of skeletal muscle fibers that encircles the distal portion of the anal canal. This sphincter is under voluntary control.

The lamina propria and submucosa of the anal canal contain a network of veins. If venous pressures there rise too high due to straining during defecation or pregnancy, the veins can become distended, producing *hemorrhoids*.

Histology of the Large Intestine

The luminal diameter of the large intestine is about three times that of the small intestine, but its wall is much thinner. Large lymphoid nodules are scattered throughout the lamina propria and submucosa. The muscular layer of the large intestine is unusual, because the longitudinal layer has been reduced to the muscular bands of the teniae coli.

The major characteristics of the colon are the lack of villi, the abundance of goblet cells, and the presence of distinctive intestinal glands (Figure 24–25). The glands in the large intestine are deeper than those of the small intestine and are dominated by goblet cells. The mucus provides lubrication as the fecal material becomes drier and more compact. Mucus is secreted as local stimuli, such as friction or exposure to harsh chemicals, trigger short reflexes involving local nerve plexuses.

Physiology of the Large Intestine

Any digestion that occurs in the large intestine results from enzymes introduced in the small intestine or from bacterial action. Although less than 10 percent of the nutrient absorption in the digestive tract occurs in the large intestine, the absorptive operations that do occur in this segment of the digestive tract are nevertheless important. The mixing and propulsive contractions of the colon resemble those of the small intestine. The large intestine also prepares fecal material for defecation.

Absorption and the Microbiome in the Large Intestine

The reabsorption of water is an important function of the large intestine. Roughly 1500 mL of material enters the colon each day, but only about 200 mL of feces is ejected. To appreciate how efficient our digestion is, consider the average composition of feces: 75 percent water, 5 percent bacteria, and the rest a mixture of indigestible materials, small quantities of inorganic matter, and the remains of epithelial cells.

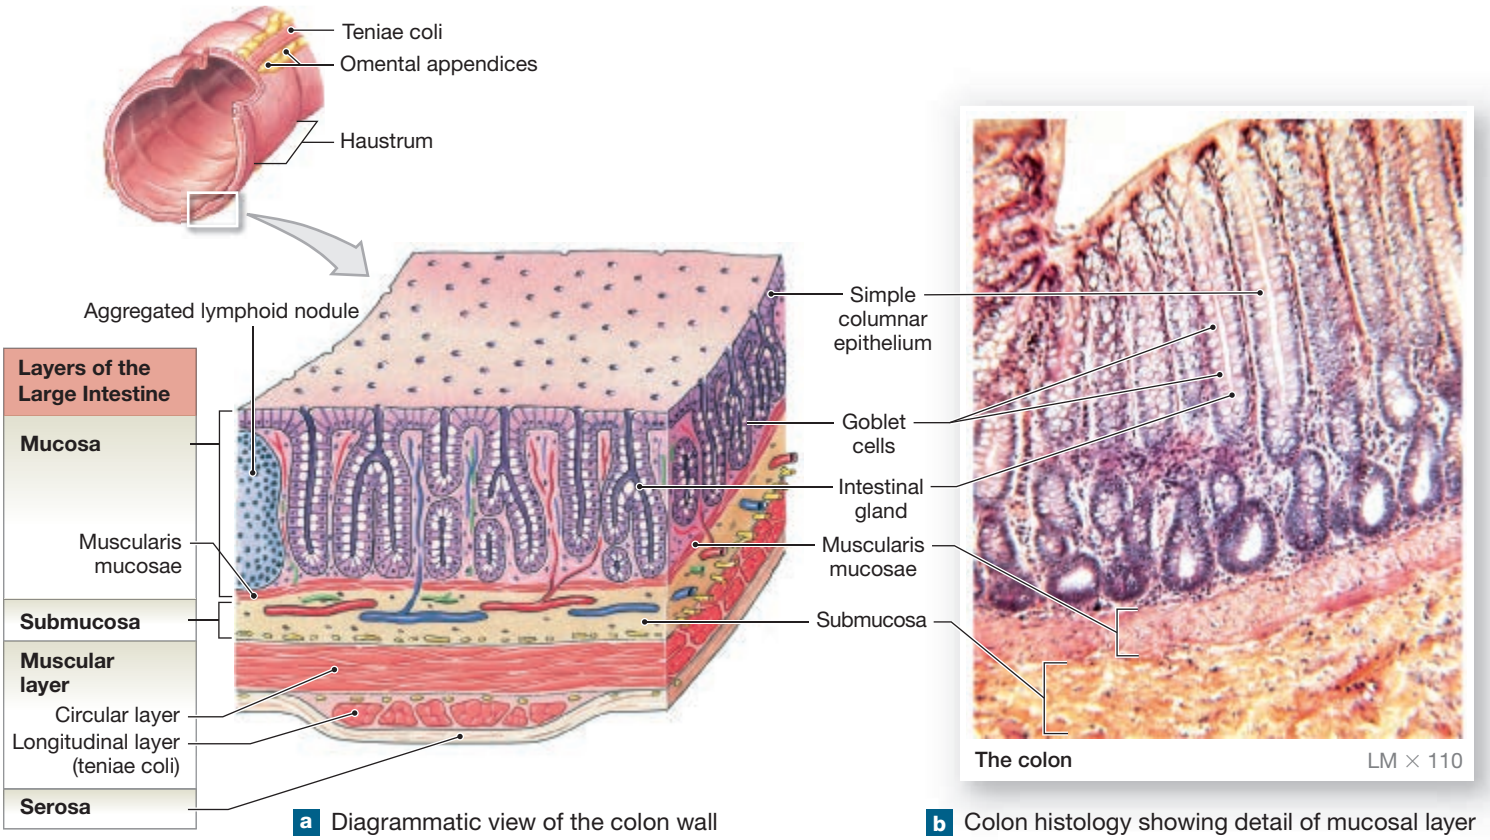
In addition, the large intestine absorbs a number of other substances that remain in the feces or were secreted into the digestive tract along its length. Examples include useful compounds such as bile salts and vitamins; organic wastes; and various toxins generated by bacterial action. Most of the bile salts entering the large intestine are promptly reabsorbed in the cecum and transported in blood to the liver for secretion into bile.

Bacteria that inhabit the large intestine contribute to our *microbiome*. The human **microbiome** is made up of the microbes (bacteria, fungi, and viruses) and their genes that live in and on the human body. Most of the gut bacteria live in the large intestine where they break down nutrients not absorbed in the small intestine and produce vitamins.

Vitamins. *Vitamins* are organic molecules required in very small quantities. The normal bacterial residents of the colon generate three vitamins that are absorbed in the large intestine:

- *Vitamin K*, a fat-soluble vitamin the liver requires for synthesizing four clotting factors, including prothrombin
- *Biotin*, a water-soluble vitamin important in various reactions, notably those of glucose metabolism

Figure 24–25 Histology of the Colon.



- *Vitamin* B_5 (pantothenic acid), a water-soluble vitamin required in the manufacture of steroid hormones and some neurotransmitters.

Intestinal bacteria produce about half of your daily vitamin K requirements. Vitamin K deficiencies lead to impaired blood clotting. They result from either (1) not enough lipids in the diet, which impairs the absorption of all fat-soluble vitamins; or (2) problems affecting lipid processing and absorption, such as inadequate bile production or chronic diarrhea (frequent, watery bowel movements). Because the intestinal bacteria generally produce sufficient amounts of biotin and vitamin B_5 to supplement any dietary shortage, disorders due to deficiencies of these vitamins are extremely rare after infancy.

Organic Wastes. We discussed the fate of bilirubin, a breakdown product of heme, in Chapter 19. ↩ p. 666 In the large intestine, bacteria convert bilirubin to *urobilinogens* and *stercobilinogens*. Some urobilinogens are absorbed into the bloodstream and then excreted in urine. The urobilinogens and stercobilinogens remaining within the colon are converted to **urobilins** and **stercobilins** by exposure to oxygen. These pigments in various proportions give feces a yellow-brown or brown color.

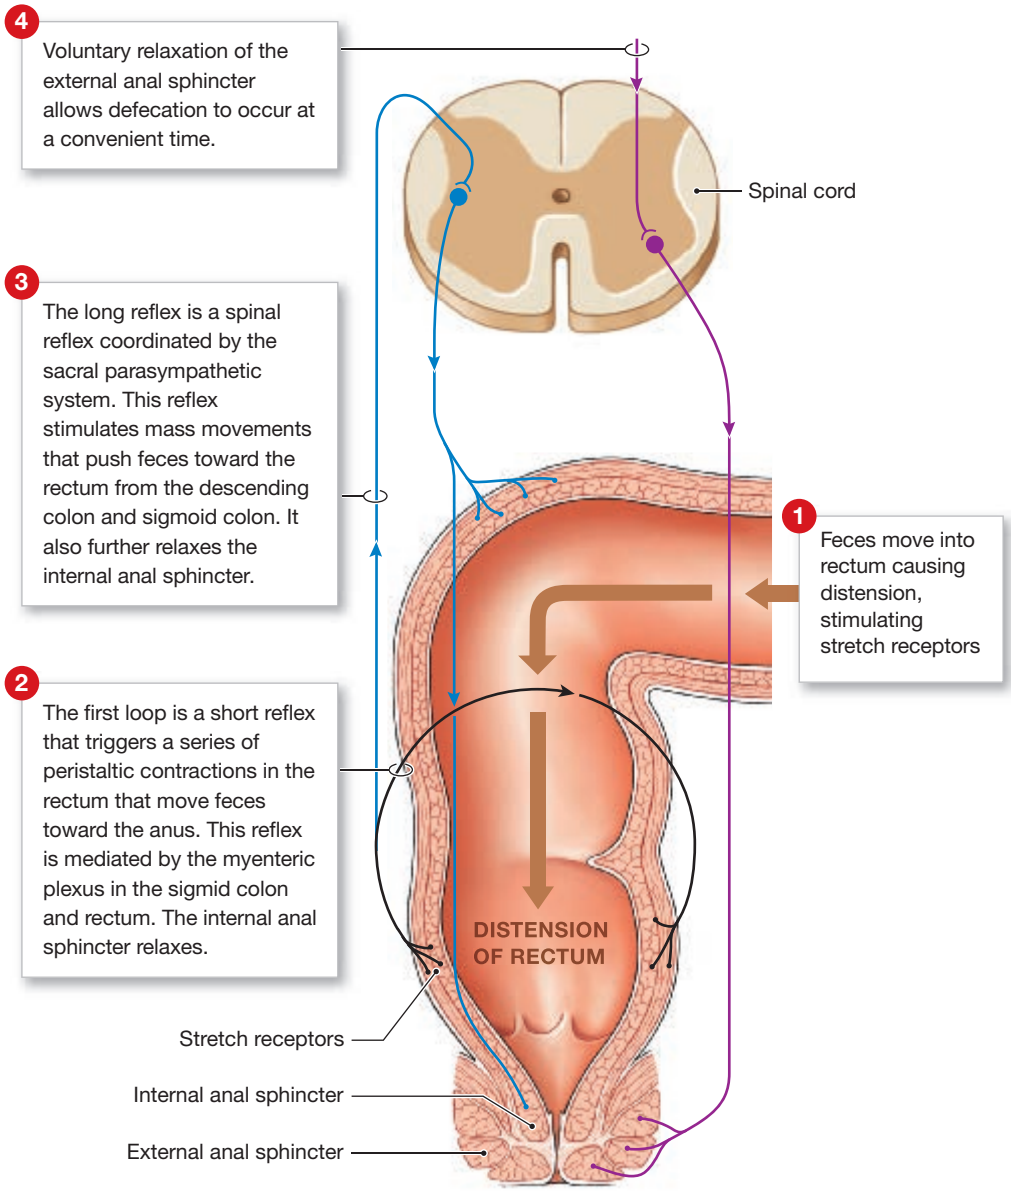
Bacterial action breaks down peptides that remain in the feces. This action generates (1) ammonia, in the form of soluble ammonium ions (NH_4^+); (2) *indole* and *skatole*, two nitrogen-containing compounds that are primarily responsible for the odor of feces; and (3) hydrogen sulfide (H_2S), a gas with a "rotten egg" odor. Significant amounts of ammonia and smaller amounts of other toxins cross the colonic epithelium and enter the hepatic portal circulation. The liver removes these toxins and converts them to relatively nontoxic compounds that can be released into the blood and excreted at the kidneys.

Intestinal enzymes do not alter indigestible carbohydrates, and the mucosa of the large intestine does not produce enzymes. These materials arrive in the colon virtually intact. These complex polysaccharides provide a reliable nutrient source for bacteria in the colon. The metabolic activities of these bacteria create small amounts of **flatus**, or intestinal gas. Foods with large amounts of indigestible carbohydrates (such as beans) stimulate bacterial gas production. Distension of the colon, cramps, and the frequent discharge of intestinal gases can result.

Motility of the Large Intestine and the Defecation Reflex

The gastroileal and gastroenteric reflexes move materials into the cecum while you eat. Movement from the cecum to the transverse colon is very slow, allowing hours for water absorption to convert the already thick material into a sludgy paste. Peristaltic waves move material along the length of the colon. Segmentation movements, called *haustral churning*, mix the contents of adjacent haustra. When the stomach and duodenum are distended, signals are relayed over the intestinal nerve plexuses. These signals cause

Figure 24–26 The Defecation Reflex.



? What stimulates stretch receptors in the rectum?

powerful peristaltic contractions called **mass movements** that move material from the transverse colon through the rest of the large intestine. The contractions force feces into the rectum. When feces move into the rectum, the distension on the rectal wall stimulates stretch receptors, initiating the *defecation reflex*.

The rectal chamber is usually empty, except when a mass movement forces feces out of the sigmoid colon into the rectum. The defecation reflex is an involuntary response to stimuli in the lower bowel that results in a bowel movement. This reflex involves two positive feedback loops, a short, *intrinsic myenteric defecation reflex* and a long, *parasympathetic defecation reflex* (Figure 24–26).

- *Intrinsic Myenteric Defecation Reflex.* In this short feedback loop, afferent fibers from the stretch receptors in the rectal walls stimulate the myenteric plexus to initiate a series of increased local peristaltic contractions in the sigmoid colon and rectum. The waves of contraction move feces toward the anus and further increase distension of the rectum. When the peristaltic contractions reach the anus, the internal anal sphincter relaxes.
- *Parasympathetic Defecation Reflex.* In this long feedback loop of the enteric nervous system, the stretch receptors in the rectal walls also stimulate parasympathetic motor neurons

+ Clinical Note Colonoscopy

Colonoscopy is the visual examination of the entire colon. This vital screening test can identify early colorectal cancer, the second leading cause of cancer death in the United States. On a personal crusade for colorectal cancer awareness in 2000 (after her husband died of the disease), news anchor Katie Couric underwent a now-famous live colonoscopy on the NBC Today Show.

A thorough preparation of the colon is required to properly evaluate the mucosal lining. One to two days before the procedure, the patient consumes a clear liquid diet, then takes laxatives and enemas to clear feces from the colon. After the patient is sedated in outpatient surgery, the gastroenterologist introduces a fiberoptic colonoscope (a flexible viewing tube) into the rectum and slides it back through the colon to the cecum, examining the interior and taking photos. Any lesions, such as polyps (abnormal fleshy growths), can be biopsied at the time and sent to pathology.

An initial colonoscopy is recommended after the age of 50. If the results are normal, and there are no significant risk factors, such as family history of colon cancer, the test can be repeated at 10-year intervals.

in the sacral spinal cord. These neurons stimulate increased peristalsis (mass movements) in the descending colon and sigmoid colon that pushes feces toward the rectum, which further increases rectal pressure and distension. The stimulated motor neurons send efferent impulses within the pelvic nerves that cause the internal anal sphincter to relax.

Both the internal and external anal sphincters must relax for feces to be eliminated. The actual release of feces requires activation of the somatic nervous system to consciously open the external sphincter. The pudendal nerves carry the somatic motor commands. However, because the parasympathetic defecation reflex magnifies the intrinsic myenteric defecation reflex, the force generated may be great enough to cause defecation, despite consciously controlling the voluntary external anal sphincter.

If the external anal sphincter remains constricted, the peristaltic contractions cease. As more feces enter the rectum, the expansion triggers further defecation reflexes. The urge to defecate usually develops when rectal pressure reaches about 15 mm Hg. If this pressure is more than 55 mm Hg, the external anal sphincter involuntarily relaxes and defecation takes place. This mechanism causes defecation in infants and in adults with spinal cord injuries.

In addition, other consciously directed activities can increase intra-abdominal pressure and help force fecal material out of the rectum. These activities include the *Valsalva maneuver*, a tensing of the abdominal muscles and an increase in intra-abdominal pressure by exhaling forcibly with a closed glottis.

24-8 Chemical digestion is the enzyme-mediated hydrolysis of food into nutrients that can be absorbed and used by the body

Learning Outcome List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients.

A balanced diet contains all the ingredients needed to maintain homeostasis. These ingredients include six nutrients: carbohydrates, lipids, proteins, vitamins, minerals, and water. This section describes the chemical events involved in the processing and absorption of these nutrients.

Hydrolysis of Nutrients by Enzymes

Food contains large organic molecules, many of them insoluble. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments. This disassembly eliminates any antigenic properties, so that the fragments do not trigger an immune response after absorption. Cells absorb the molecules released into the bloodstream and either (1) break them down to provide energy for the synthesis of ATP or (2) use these molecules to synthesize carbohydrates, proteins, and lipids. In this section we focus on the mechanics of chemical digestion and absorption. The fates of the compounds inside cells are the focus in Chapter 25.

Most ingested organic materials are complex chains, or polymers, of simpler molecules called monomers. In a typical dietary carbohydrate, the basic molecules are simple sugars. In a protein, the building blocks are amino acids. In lipids, they are generally fatty acids. And in nucleic acids, they are nucleotides. In a process called *hydrolysis*, digestive enzymes break the bonds between the component molecules of carbohydrates, proteins, lipids, and nucleic acids. ↩ pp. 38, 45

The classes of digestive enzymes differ with respect to their specific substrates. *Carbohydrases* break the bonds between simple sugars, *proteases* split the linkages between amino acids, and *lipases* separate fatty acids from glycerides. Some enzymes in each class are even more selective, breaking bonds between specific molecules. For example, a particular carbohydrase might

break the bond between two glucose molecules, but not those between glucose and another simple sugar.

Digestive enzymes secreted by the salivary glands, tongue, stomach, and pancreas are mixed into the ingested material as it passes along the digestive tract. These enzymes break down large carbohydrates, proteins, lipids, and nucleic acids into smaller fragments. Typically these fragments in turn must be broken down even further before absorption can occur. The final enzymatic steps involve brush border enzymes, which are attached to the exposed surfaces of intestinal microvilli.

The digestive fates of carbohydrates, lipids, and proteins, the major dietary components, are shown in **Spotlight Figure 24–27**. The major digestive enzymes and their functions are summarized in **Table 24-1**. Next we take a closer look at the digestion and absorption of carbohydrates, lipids, proteins, and nucleic acids.

Carbohydrate Digestion and Absorption

Carbohydrates are a large group of organic compounds, such as sugars, starch, and cellulose, found in food. Our bodies break down carbohydrates for use in cellular metabolism. This section discusses how these processes occur.

Chemical Digestion of Carbohydrates

The digestion of complex carbohydrates (simple polysaccharides and starches) proceeds in two steps. The first step involves carbohydrases produced by the salivary glands and pancreas. The second step uses brush border enzymes.

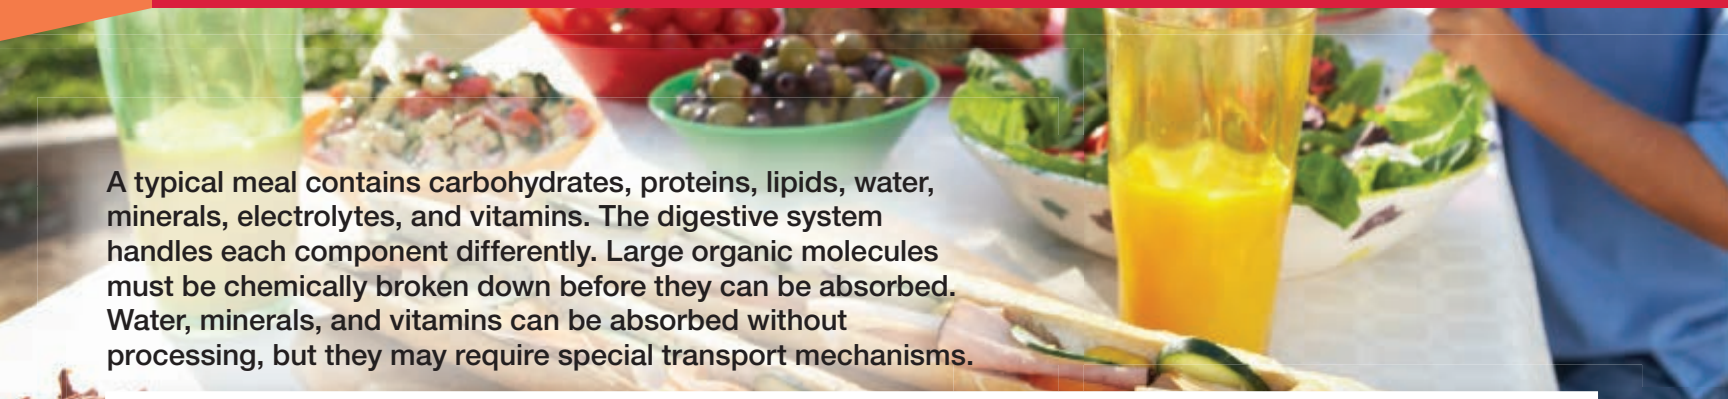
Actions of Salivary and Pancreatic Enzymes. The digestion of complex carbohydrates involves two enzymes—salivary amylase and pancreatic alpha-amylase (see **Spotlight Figure 24–27**). Both function effectively at a pH of 6.7–7.5. Carbohydrate digestion

Table 24-1 Digestive Enzymes and Their Functions

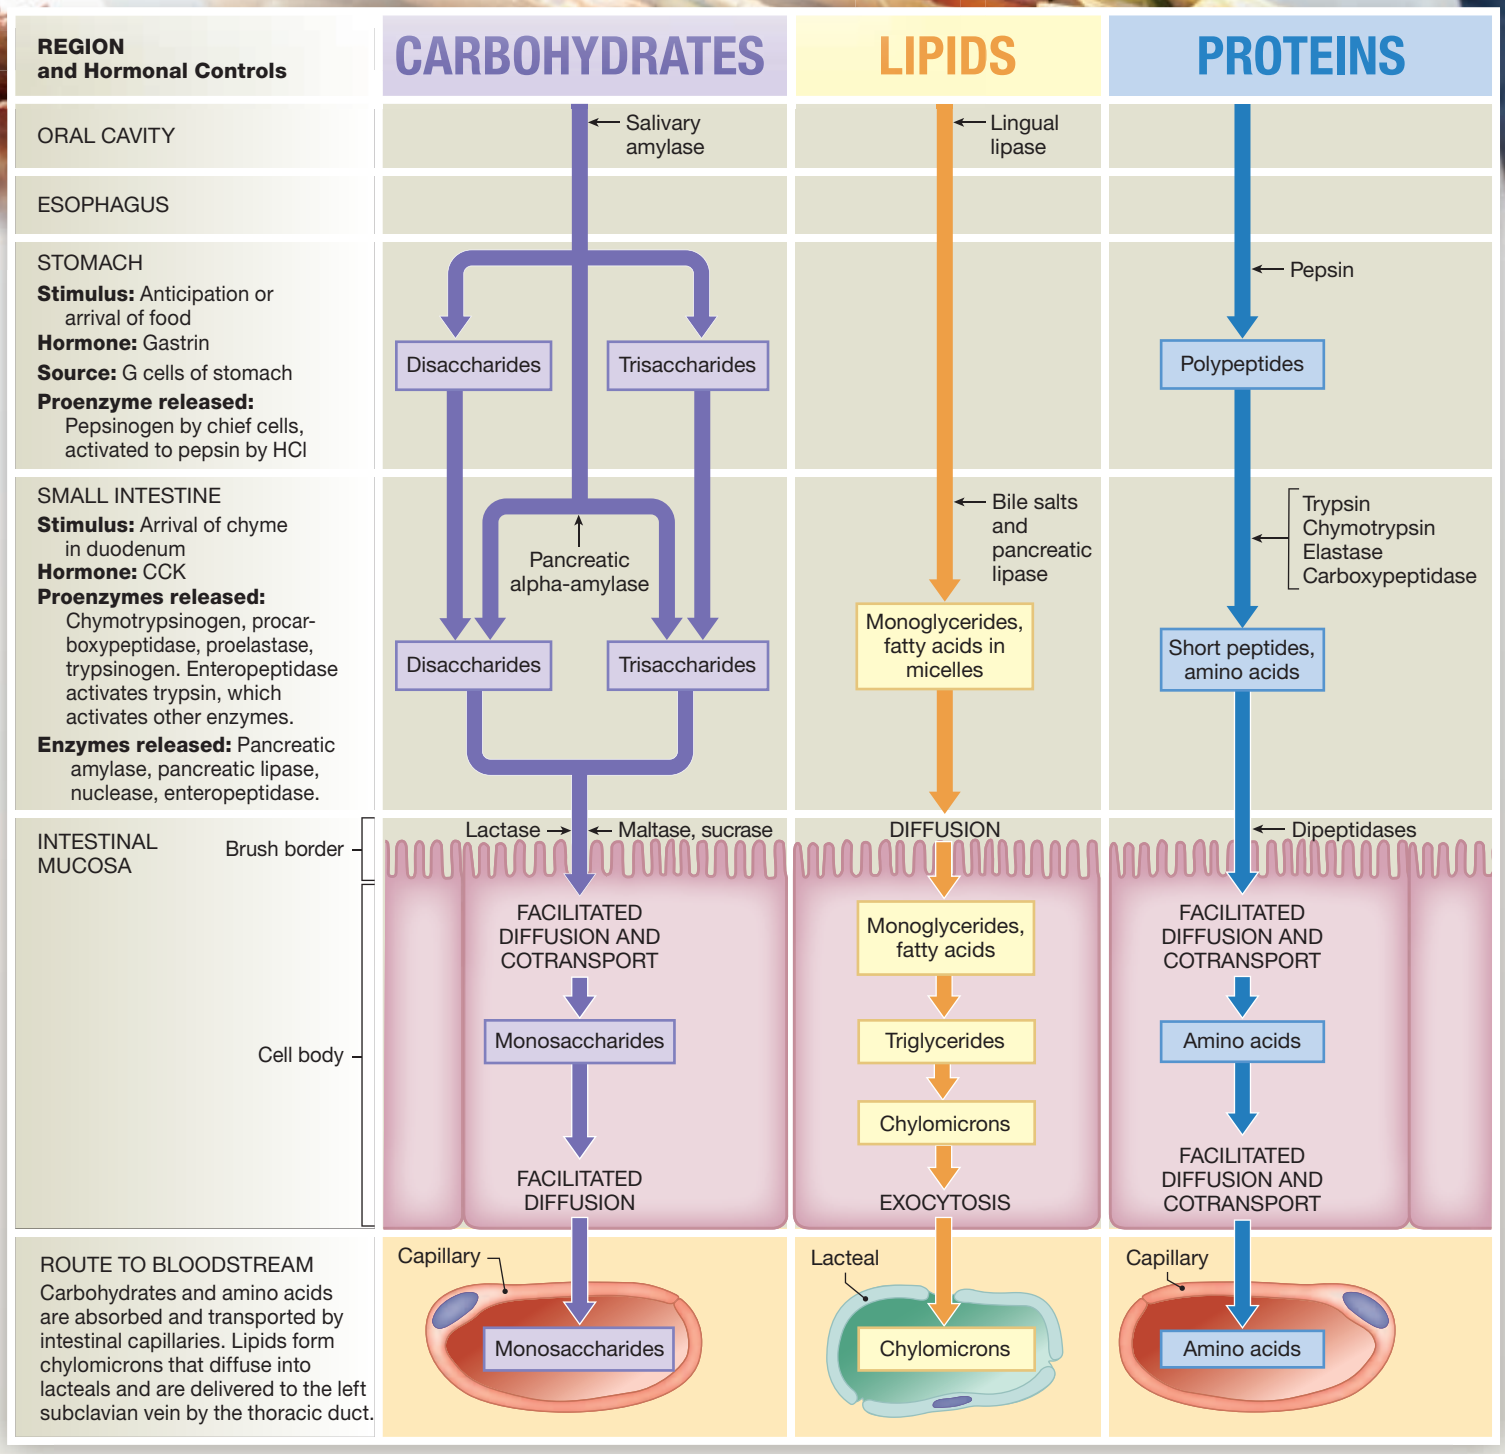
Enzyme (proenzyme)	Source	Optimal pH	Substrate	Products	Remarks
CARBOHYDRASES					
Maltase, sucrase, lactase	Brush border of small intestine	7–8	Maltose, sucrose, lactose	Monosaccharides	Found in membrane surface of microvilli
Pancreatic alpha-amylase	Pancreas	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between sugars
Salivary amylase	Salivary glands	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between sugars
PROTEASES					
Carboxypeptidase (procarboxypeptidase)	Pancreas	7–8	Proteins, polypeptides, amino acids	Short-chain peptides	Activated by trypsin
Chymotrypsin (chymotrypsinogen)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Activated by trypsin
Dipeptidases, peptidases	Brush border of small intestine	7–8	Dipeptides, tripeptides	Amino acids	Found in membrane surface of brush border
Elastase (proelastase)	Pancreas	7–8	Elastin	Short-chain peptides	Activated by trypsin
Enteropeptidase	Brush border and lumen of small intestine	7–8	Trypsinogen	Trypsin	Reaches lumen through disintegration of shed epithelial cells
Pepsin (pepsinogen)	Chief cells of stomach	1.5–2.0	Proteins, polypeptides	Short-chain polypeptides	Secreted as proenzyme pepsinogen; activated by H^+ in stomach acid
Rennin	Stomach	3.5–4.0	Milk proteins		Secreted only in infants; causes protein coagulation
Trypsin (trypsinogen)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Proenzyme activated by enteropeptidase; activates other pancreatic proteases
LIPASES					
Lingual lipase	Glands of tongue	3.0–6.0	Triglycerides	Fatty acids and monoglycerides	Begins lipid digestion
Pancreatic lipase	Pancreas	7–8	Triglycerides	Fatty acids and monoglycerides	Bile salts must be present for efficient action
NUCLEASES					
	Pancreas	7–8	Nucleic acids	Nitrogenous bases and simple sugars	Includes ribonuclease for RNA and deoxyribonuclease for DNA

SPOTLIGHT

Figure 24–27
The Chemical Events of Digestion



A typical meal contains carbohydrates, proteins, lipids, water, minerals, electrolytes, and vitamins. The digestive system handles each component differently. Large organic molecules must be chemically broken down before they can be absorbed. Water, minerals, and vitamins can be absorbed without processing, but they may require special transport mechanisms.



begins in the mouth during mastication, through the action of salivary amylase from the parotid and submandibular salivary glands. Salivary amylase breaks down starches (complex carbohydrates) into a mixture composed mostly of *disaccharides* (two simple sugars, or *monosaccharides*, joined together) and *trisaccharides* (three monosaccharides). Salivary amylase continues to digest the starches and glycogen in food for 1 to 2 hours before stomach acids render the enzyme inactive. Only a small amount of digestion takes place over this period because the enzymatic content of saliva is not high.

In the duodenum, pancreatic alpha-amylase breaks down the remaining complex carbohydrates. Any disaccharides or trisaccharides produced, and any present in the food, are not broken down further until they contact the intestinal mucosa.

Actions of Brush Border Enzymes. Brush border enzymes of the intestinal microvilli break disaccharides and trisaccharides into monosaccharides prior to absorption. The enzyme **maltase** splits bonds between the two glucose molecules of the disaccharide **maltose**. **Sucrase** breaks the disaccharide **sucrose** into glucose and *fructose*, another six-carbon sugar. **Lactase** hydrolyzes the disaccharide **lactose** into a molecule of glucose and one of *galactose*.

Lactose is the main carbohydrate in milk, so lactase provides an essential function in infancy and early childhood by breaking down lactose. If the intestinal mucosa stops producing lactase, the person becomes **lactose intolerant**. After ingesting milk and other dairy products, people with lactose-intolerance can experience a variety of unpleasant digestive problems, including lower abdominal pain, gas, diarrhea, and vomiting.

Absorption of Monosaccharides

The intestinal epithelium then absorbs the monosaccharides by facilitated diffusion and cotransport mechanisms (look back at Figure 3–18, p. 96). Both methods involve a carrier protein. Facilitated diffusion and cotransport differ in the following major ways:

- *Number of Transported Substances.* Facilitated diffusion moves only one molecule or ion through the plasma membrane at a time. Cotransport moves more than one molecule or ion through the membrane at the same time. In cotransport, the transported substances move in the same direction.
- *Concentration Gradients.* Facilitated diffusion does not take place if there is an opposing concentration gradient for the particular molecule or ion. By contrast, cotransport can take place despite an opposing concentration gradient for one of the transported substances. For example, cells lining the small intestine continue to absorb glucose when glucose concentrations inside the cells are much higher than they are in the intestinal contents.
- *ATP Requirement.* Facilitated diffusion is a passive process and does not require ATP. Cotransport by itself does not consume ATP. However, the cell must often expend ATP to preserve homeostasis in a process called *secondary active transport*. ↩ p. 97 For example, in the cotransport of glucose and sodium ions, the sodium ions must later be pumped out of the cell.

Glucose cotransport is an example of sodium-linked cotransport. Comparable cotransport mechanisms exist for other simple sugars and for some amino acids. These mechanisms deliver valuable nutrients to the cytoplasm, but they also bring in sodium ions that must be ejected by the sodium–potassium exchange pump.

The simple sugars that are transported into the intestinal epithelial cell at its apical surface diffuse through the cytoplasm. They then reach the interstitial fluid by facilitated diffusion across the basolateral surfaces. These monosaccharides diffuse into the capillaries of the villus for eventual transport to the liver in the hepatic portal vein.

Lipid Digestion and Absorption

Lipid digestion involves lingual lipase from glands of the tongue, and pancreatic lipase from the pancreas (see Spotlight Figure 24–27). The most important and abundant dietary lipids are *triglycerides*. They consist of three fatty acids attached to a single molecule of glycerol (see Figure 2–17, p. 50). The lingual and pancreatic lipases break off two of the fatty acids, leaving *monoglycerides*.

Lipases are water-soluble enzymes, and lipids tend to form large drops that exclude water molecules. As a result, lipases can only interact with the exposed surfaces of the lipid drops. Lingual lipase begins breaking down triglycerides in the mouth and continues for a variable time within the stomach. The lipid drops are so large, however, and the available time so short, that only about 20 percent of the lipids have been digested by the time the chyme enters the duodenum.

Bile salts improve chemical digestion by emulsifying the lipid drops into tiny emulsion droplets, thereby providing better access for pancreatic lipase. The emulsification takes place only after the chyme has been mixed with bile in the duodenum. Pancreatic lipase then breaks apart the triglycerides to form a mixture of monoglycerides and fatty acids. As these molecules are released, they interact with bile salts in the surrounding chyme to form small lipid–bile salt complexes called **micelles** (mī-SELZ). A micelle is only about 2.5 nm (0.0025 μm) in diameter.

When a micelle contacts the intestinal epithelium, the lipids diffuse across the plasma membrane and enter the cytoplasm. The intestinal cells synthesize new triglycerides from the monoglycerides and fatty acids. These triglycerides, together with absorbed steroids, phospholipids, and fat-soluble vitamins, are then coated with proteins. The resulting complexes are known as **chylomicrons** (kī-lō-MĪ-kronz; *chylos*, juice + *mikros*, small).

The intestinal cells then secrete the chylomicrons into interstitial fluid by exocytosis. The protein coating keeps the chylomicrons suspended in the interstitial fluid, but they are generally too large to diffuse into capillaries. Most of the chylomicrons diffuse into the intestinal lacteals, which lack basement membranes and have large gaps between adjacent endothelial

cells. From the lacteals, the chylomicrons proceed along the lymphatic vessels and through the thoracic duct. They finally enter the bloodstream at the left subclavian vein.

Most of the bile salts within micelles are reabsorbed by sodium-linked cotransport. Only about 5 percent of the bile salts secreted by the liver enters the colon. Only about 1 percent is lost in feces.

Protein Digestion and Absorption

Proteins have very complex structures, so protein digestion is both complex and time consuming. Proteases must access individual proteins, so the three-dimensional organization of food must first be disrupted. This step involves mechanical digestion in the oral cavity, through mastication, and chemical digestion in the stomach, through the action of hydrochloric acid. The strong acid in the stomach disrupts tertiary and secondary protein structure, exposing peptide bonds to enzymatic action.

The acidic content of the stomach also provides the proper environment for the activity of pepsin, the proteolytic enzyme secreted in an inactive form by chief cells of the stomach (see **Spotlight Figure 24–27**). Pepsin works effectively at a pH of 1.5–2.0. It breaks the peptide bonds within a polypeptide chain.

When chyme enters the duodenum, enteropeptidase from the small intestine triggers the conversion of trypsinogen to trypsin. Buffers increase the pH to 7–8. Pancreatic proteases can now begin working. Trypsin, chymotrypsin, and elastase are like pepsin in that they break specific peptide bonds within a polypeptide. For example, trypsin breaks peptide bonds involving the amino acids *arginine* or *lysine*. Chymotrypsin targets peptide bonds involving *tyrosine* or *phenylalanine*.

Carboxypeptidase also acts in the small intestine. This enzyme chops off the last amino acid of a polypeptide chain, no matter which amino acids are involved. Thus, while the other peptidases generate a variety of short peptides, carboxypeptidase produces free amino acids. The epithelial surfaces of the small intestine contain several peptidases, notably **dipeptidases**. These enzymes break short peptide chains into individual amino acids. (Dipeptidases break apart *dipeptides*.)

These amino acids, as well as those produced by the pancreatic enzymes, are absorbed through both facilitated diffusion and cotransport mechanisms. The amino acids diffuse through the cell to its basolateral surface. There they are released into interstitial fluid by facilitated diffusion and cotransport. Once in the interstitial fluid, the amino acids diffuse into intestinal capillaries for transport to the liver by means of the hepatic portal vein.

Nucleic Acid Digestion and Absorption

Nucleic acids are broken down into their component nucleotides. Brush border enzymes digest these nucleotides into sugars, phosphates, and nitrogenous bases that are absorbed by active transport. However, nucleic acids represent only a small fraction of all the nutrients absorbed each day.

Absorption of Water, Ions, and Vitamins

Water, electrolytes (inorganic ions), and vitamins are absorbed through various transport processes as they pass along the small and large intestines. Let's begin by looking at water absorption.

Water Absorption

Cells cannot actively absorb or secrete water. All movement of water across the lining of the digestive tract involves passive water flow down osmotic gradients. The production of glandular secretions also involves passive water flow down osmotic gradients. Recall that when a selectively permeable membrane separates two solutions, water tends to flow into the solution that has the higher concentration of solutes. ↩ p. 93 Osmotic movements are rapid, so interstitial fluid and the fluids in the intestinal lumen always have the same osmotic concentration of solutes, or *osmolarity*.

Intestinal epithelial cells continuously absorb nutrients and ions. These activities gradually lower the solute concentration in the lumen. As the solute concentration drops, water moves into the surrounding tissues, maintaining osmotic equilibrium.

Each day, about 2200 mL of water enters the digestive tract in the form of food and drink. Saliva, gastric secretions, bile, intestinal secretions, and mucus provide an additional 7200 mL. Of that total, only about 150 mL is lost in feces. The sites of secretion and absorption of water are shown in **Figure 24–28**.

Ion Absorption

Osmosis does not distinguish among solutes. All that matters is the total concentration of solutes. To maintain homeostasis, however, the concentrations of specific ions must be closely regulated. Thus, each ion must be handled individually, and the rate of intestinal absorption of each must be tightly controlled (**Table 24-2**). Many of the regulatory mechanisms controlling the rates of absorption are poorly understood.

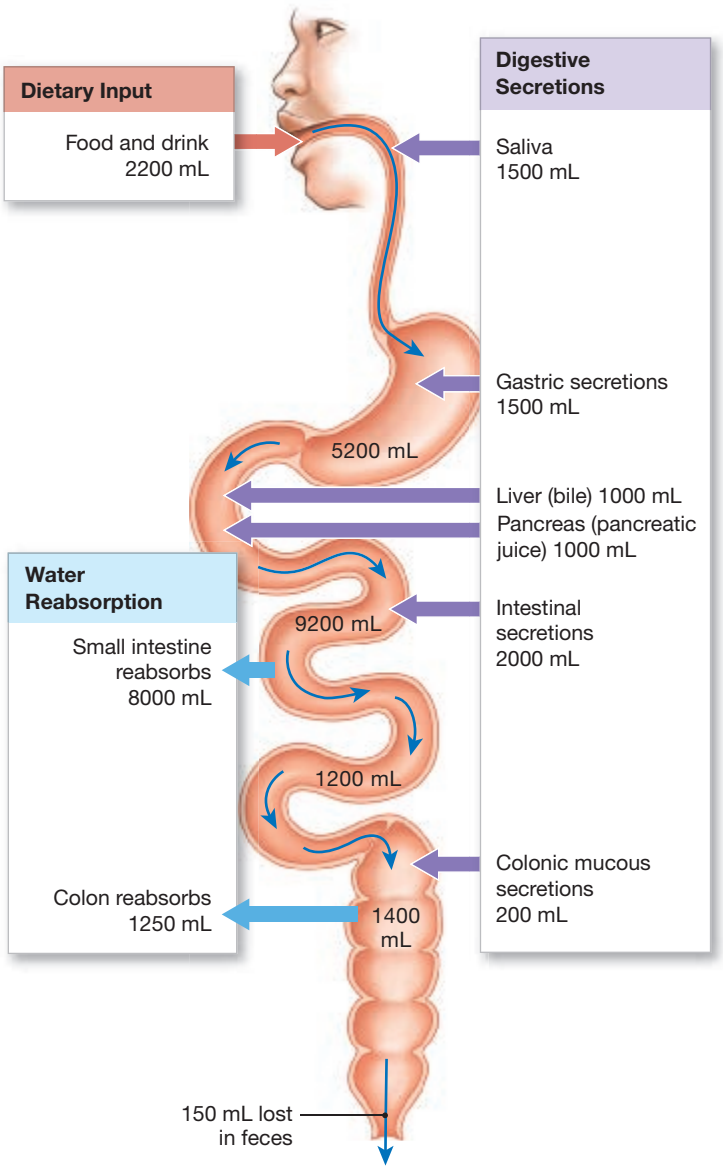
Sodium ions (Na^+) are usually the most abundant cations in food. They may enter intestinal cells by diffusion, by cotransport with another nutrient, or by active transport. These ions are then pumped into interstitial fluid across the base of the cell.

The rate of Na^+ uptake from the lumen is generally proportional to the concentration of Na^+ in the intestinal contents. As a result, eating heavily salted foods leads to increased sodium ion absorption and an associated gain of water through osmosis. The rate of sodium ion absorption by the digestive tract is increased by *aldosterone*, a steroid hormone from the adrenal cortex. ↩ p. 634

Calcium ion (Ca^{2+}) absorption involves active transport at the epithelial surface. Calcitriol speeds up the rate of transport. ↩ p. 633

As other solutes move out of the lumen, the concentration of potassium ions (K^+) increases. These ions can diffuse into the epithelial cells, driven by the concentration gradient. The absorption of magnesium (Mg^{2+}), iron (Fe^{2+}), and other cations involves specific carrier proteins. The cell must use

Figure 24–28 Digestive Secretion and Water Reabsorption in the Digestive Tract. The purple arrows indicate secretion, and the blue arrows show water ingestion and reabsorption.



ATP to obtain and transport these ions to interstitial fluid. Regulatory factors controlling their absorption are poorly understood.

The anions chloride (Cl^-), iodide (I^-), bicarbonate (HCO_3^-), and nitrate (NO_3^-) are absorbed by diffusion or carrier-mediated transport. Phosphate (PO_4^{3-}) and sulfate (SO_4^{2-}) ions enter epithelial cells only by active transport.

Vitamin Absorption

As we have already discussed, **vitamins** are organic compounds required in very small quantities. However, their role in the body is crucial, as they are important cofactors or coenzymes in many metabolic pathways. We consider the functions of vitamins and associated nutritional problems in detail in Chapter 25.

There are two major groups of vitamins: water-soluble and fat-soluble vitamins. The nine **water-soluble vitamins** include the B vitamins, common in milk and meats, and vitamin C, found in citrus fruits. All but one of the water-soluble vitamins are easily absorbed by diffusion across the digestive epithelium. The exception is vitamin B_{12}, which you may recall from Chapter 19 is essential for normal erythropoiesis. By itself vitamin B_{12} cannot be absorbed by the intestinal mucosa in normal amounts. This vitamin must be bound to intrinsic factor, as we said a glycoprotein secreted by the parietal cells of the stomach. The combination is then absorbed through active transport.

Vitamins A, D, E, and K are **fat-soluble vitamins**, which as their name suggests can dissolve in lipids. Fat-soluble vitamins in the diet enter the duodenum in fat droplets, mixed with triglycerides. The vitamins remain in association with these lipids as they form emulsion droplets and, after further digestion, micelles. The fat-soluble vitamins are then absorbed from the micelles along with the fatty acids and monoglycerides. As discussed, vitamin K produced in the colon is absorbed with other lipids released through bacterial action. Taking supplements of fat-soluble vitamins while you have an empty stomach, are fasting, or are on a low-fat diet is relatively ineffective. The reason is that proper absorption of these vitamins requires the presence of other lipids.

Checkpoint

32. **Name the nutrients the body requires.**
33. **What component of food would increase the number of chylomicrons in the lacteals?**
34. **The absorption of which vitamin would be impaired by the removal of the stomach?**
35. **Why is diarrhea potentially life threatening, but constipation (infrequent defecation) is not?**

See the blue Answers tab at the back of the book.

24-9 Many age-related changes affect digestion and absorption

Learning Outcome Summarize the effects of aging on the digestive system.

Normal digestion and absorption take place in elderly people. However, many changes in the digestive system parallel age-related changes we have already discussed in connection with other systems:

- *The Division Rate of Epithelial Stem Cells Declines.* The digestive epithelium becomes more susceptible to damage by abrasion, acids, or enzymes. Peptic ulcers therefore become more likely. Stem cells in the epithelium divide less frequently with age, so tissue repair is less efficient. In the mouth, esophagus, and anus, the stratified epithelium becomes thinner and more fragile.
- *Smooth Muscle Tone Decreases.* General motility decreases, and peristaltic contractions are weaker as a result of a decrease in smooth muscle tone. These changes slow the

Table 24-2 The Absorption of Ions and Vitamins

Ion or Vitamin	Transport Mechanism	Regulatory Factors
Na^+	Channel-mediated diffusion, cotransport, or active transport	Increased when sodium-linked cotransport is under way; stimulated by aldosterone
Ca^{2+}	Active transport	Stimulated by calcitriol and PTH
K^+	Channel-mediated diffusion	Follows concentration gradient
Mg^{2+}	Active transport	
Fe^{2+}	Active transport	
Cl^-	Channel-mediated diffusion or carrier-mediated transport	
I^-	Channel-mediated diffusion or carrier-mediated transport	
HCO_3^-	Channel-mediated diffusion or carrier-mediated transport	
NO_3^-	Channel-mediated diffusion or carrier-mediated transport	
PO_4^{3-}	Active transport	
SO_4^{2-}	Active transport	
Water-soluble vitamins (except B_{12})	Channel-mediated diffusion	Follows concentration gradient
Vitamin B_{12}	Active transport	Must be bound to intrinsic factor prior to absorption
Fat-soluble vitamins	Diffusion	Absorbed from micelles along with dietary lipids

rate of fecal movement and promote constipation. Sagging and inflammation of the haustra in the colon can occur. Straining to eliminate compacted feces can stress the less resilient walls of blood vessels, producing hemorrhoids. Problems are not restricted to the lower digestive tract. For example, weakening of muscular sphincters can lead to esophageal reflux and frequent bouts of "heartburn."

- *The Effects of Cumulative Damage Become Apparent.* A familiar example is the gradual loss of teeth due to *dental caries* (cavities) or gingivitis. Cumulative damage can involve internal organs as well. Toxins such as alcohol and other injurious chemicals that are absorbed by the digestive tract are transported to the liver for processing. The cells of the liver are not immune to these toxic compounds, and chronic exposure can lead to cirrhosis or other types of liver disease.
- *Cancer Rates Increase.* Cancers are most common in organs in which stem cells divide to maintain epithelial cell populations. Rates of colon cancer and stomach cancer rise with age. Oral, esophageal, and pharyngeal cancers are particularly common among elderly smokers.
- *Dehydration Is Common Among the Elderly.* One reason is that osmoreceptor sensitivity declines with age.
- *Changes in Other Systems Have Direct or Indirect Effects on the Digestive System.* For example, reductions in bone mass and calcium content in the skeleton are associated with erosion of the tooth sockets and eventual tooth loss. The decline in olfactory and gustatory sensitivities with age can lead to dietary changes that affect the entire body.

Checkpoint

36. **Identify general digestive system changes that occur with aging.**

See the blue Answers tab at the back of the book.

24-10 The digestive system is extensively integrated with other body systems

Learning Outcome Give examples of interactions between the digestive system and other body systems studied so far.

Build Your Knowledge Figure 24–29 summarizes the functional relationships between the digestive system and other body systems we have studied so far. The digestive system has particularly extensive anatomical and physiological connections to the nervous, cardiovascular, endocrine, and lymphatic systems. As we have seen, the digestive tract is also an endocrine organ that produces a variety of hormones. Many of these hormones, and some of the neurotransmitters produced by the digestive system, can enter the circulation, cross the blood brain barrier, and alter CNS activity. In this way, a continual exchange of chemical information takes place among these systems.

Checkpoint

37. **Identify the functional relationships between the digestive system and other body systems.**
38. **What body systems may be affected by inadequate calcium ion absorption?**

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 24–29 Integration of the DIGESTIVE system with the other body systems presented so far.

Integumentary System

- The Integumentary System provides vitamin D_3 needed for the absorption of calcium and phosphorus
- The digestive system provides lipids for storage by adipocytes in hypodermis

Skeletal System

- The Skeletal System (axial division and pelvic girdle) supports and protects parts of digestive tract; teeth are used in mechanical processing of food
- The digestive system absorbs calcium and phosphate ions for use in bone matrix; provides lipids for storage in yellow marrow

Cardiovascular System

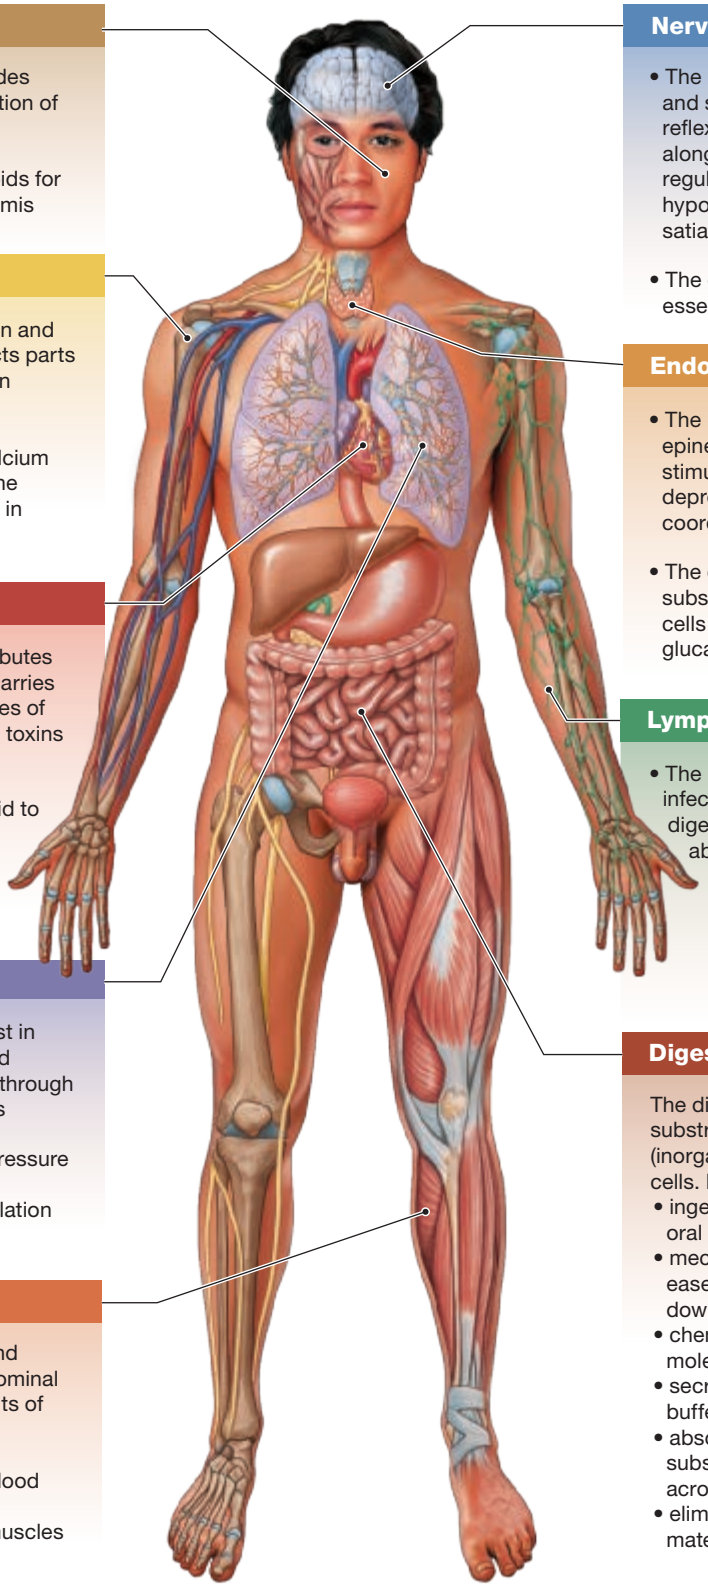
- The Cardiovascular System distributes hormones of the digestive tract; carries nutrients, water, and ions from sites of absorption; delivers nutrients and toxins to liver
- The digestive system absorbs fluid to maintain normal blood volume; absorbs vitamin K; liver excretes heme (as bilirubin), synthesizes blood clotting proteins

Respiratory System

- The Respiratory System can assist in defecation by producing increased thoracic and abdominal pressure through contraction of respiratory muscles
- The digestive system produces pressure with digestive organs against the diaphragm that can assist in exhalation and limit inhalation

Muscular System

- The Muscular System protects and supports digestive organs in abdominal cavity; controls entrances and exits of digestive tract
- The digestive system regulates blood glucose and fatty acid levels and metabolizes lactate from active muscles with the liver



Nervous System

- The Nervous System regulates movement and secretion with the ANS and ENS; reflexes coordinate passage of materials along tract; control over skeletal muscles regulates ingestion and defecation; hypothalamic centers control hunger, satiation, and feeding
- The digestive system provides compounds essential for neurotransmitter synthesis

Endocrine System

- The Endocrine System produces epinephrine and norepinephrine that stimulate constriction of sphincters and depress digestive activity; hormones coordinate activity along digestive tract
- The digestive system provides nutrients and substrates to endocrine cells; endocrine cells of pancreas secrete insulin and glucagon; liver produces angiotensinogen

Lymphatic System

- The Lymphatic System defends against infection and toxins absorbed from the digestive tract; lymphatic vessels carry absorbed lipids to the general circulation
- The digestive system secretes acids and enzymes that provide innate (nonspecific) immunity against pathogens

Digestive System

The digestive system provides organic substrates, vitamins, minerals, electrolytes (inorganic ions), and water required by all cells. It:

- ingests solid and liquid materials into the oral cavity of the digestive tract
- mechanically digests solid materials to ease their movement and propels them down the digestive tract
- chemically digests food into smaller molecules in the digestive tract
- secretes water, acids, enzymes, and buffers into the digestive tract
- absorbs small organic molecules (organic substrates), ions, vitamins, and water across the digestive epithelium
- eliminates wastes and indigestible materials from the body by defecation

24 Chapter Review

Study Outline

An Introduction to the Digestive Systemd p. 885

1. The digestive system supplies both the fuel that keeps all the body's cells functioning and the building blocks needed for cell growth and repair.

24-1 The digestive system, consisting of the digestive tract and accessory organs, functions primarily to break down and absorb nutrients from food and to eliminate wastes p. 885

2. The **digestive system** consists of the muscular **digestive tract** and various **accessory organs**. *(Figure 24–1)*
3. The general functions of the digestive system are **ingestion**, **mechanical digestion and propulsion**, **chemical digestion**, **secretion**, **absorption**, **and defecation.**
4. Double sheets of peritoneal membrane called **mesenteries** suspend the digestive tract. The **greater omentum** lies anterior to the abdominal viscera. Its adipose tissue provides padding, protection, insulation, and an energy reserve. *(Figure 24–2)*
5. The epithelium, *lamina propria*, and *muscularis mucosae* form the **mucosa** (mucous membrane) that lines the lumen of the digestive tract. Deep to the mucosa is the **submucosa**, the **muscular layer**, and a fibrous layer of connective tissue called the *adventitia*. For viscera projecting into the peritoneal cavity, the muscular layer is covered by a serous membrane called the **serosa**. *(Figure 24–3)*
6. The muscular layer propels materials through the digestive tract by the contractions of **peristalsis**. **Segmentation** movements in the small intestine churn digestive materials. *(Figure 24–4)*
7. Local factors, neural mechanisms, and hormonal mechanisms control digestive tract activities. *(Figure 24–5)*

24-2 The oral cavity, which contains the tongue, teeth, and salivary glands, functions in the ingestion and mechanical digestion of food p. 893

8. The functions of the **oral cavity** are (1) *sensory analysis* of foods; (2) *mechanical digestion* by the teeth, tongue, and palatal surfaces; (3) *lubrication*, by mixing with mucus and salivary gland secretions; and (4) limited *chemical digestion* of carbohydrates and lipids.
9. The oral cavity is lined by the **oral mucosa**. The *hard* and *soft palates* form the roof of the oral cavity, and the *tongue* forms its floor. *(Figure 24–6)*
10. **Intrinsic** and **extrinsic tongue muscles** are controlled by the hypoglossal nerves. *(Figure 24–6)*
11. **Mastication** (chewing) of the **bolus** occurs through the contact of the **occlusal** (opposing) **surfaces** of the **teeth**. The **periodontal ligament** anchors each tooth in an *alveolus*, or bony socket. **Dentin** forms the basic structure of a tooth. The **crown** is coated with **enamel**, the **root** with **cement**. *(Figure 24–7)*
12. During childhood and early adulthood, the 20 **deciduous teeth**, are replaced by 32 **permanent teeth**. *(Figure 24–8)*
13. The **parotid**, **sublingual**, and **submandibular salivary glands** discharge their secretions into the oral cavity. *(Figure 24–9)*

24-3 The pharynx and esophagus are passageways that transport the food bolus from the oral cavity to the stomach p. 898

14. The **pharynx** serves as a common passageway for solid food, liquid, and air.
15. The **esophagus** carries solids and liquids from the pharynx to the stomach through the **esophageal hiatus**, an opening in the diaphragm. *(Figure 24–10)*
16. The esophageal mucosa consists of a stratified epithelium. Mucous secretion by esophageal glands of the submucosa reduces friction during the passage of foods. The proportions of skeletal and smooth muscle of the muscular layer change from the pharynx to the stomach. *(Figure 24–10)*
17. Swallowing, or **deglutition**, can be divided into **buccal**, **pharyngeal**, and **esophageal phases**. Swallowing begins with the compaction of a bolus and its movement through the pharynx, from contractions of the *pharyngeal constrictor* and the *palatal muscles*, followed by the elevation of the larynx, reflection of the *epiglottis*, and closure of the *glottis*. After the *upper esophageal sphincter* is opened, peristalsis moves the bolus down the esophagus to the *lower esophageal sphincter*. *(Figure 24–11)*

24-4 The stomach is a J-shaped organ that receives the bolus and aids in its chemical and mechanical digestion p. 901

18. The four regions of the stomach are the **cardia**, **fundus**, **body**, and **pyloric part**. The **pyloric sphincter** guards the exit from the stomach. In a relaxed state, the stomach lining contains numerous **rugae** (ridges and folds). *(Figure 24–12)*
19. The **stomach** functions include the following: (1) storage of ingested food, (2) mechanical breakdown of food, and (3) disruption of chemical bonds by acid and enzymes.
20. Within the **gastric glands**, *parietal cells* secrete *intrinsic factor* and the ions of *hydrochloric acid*. **Chief cells** secrete **pepsinogen**, which is converted by acids in the gastric lumen to the enzyme **pepsin**. **Enteroendocrine** cells of the stomach secrete several compounds, notably the hormone **gastrin**. *(Figures 24–13, 24–14)*
21. Gastric control involves (1) the **cephalic phase**, which prepares the stomach to receive ingested materials; (2) the **gastric phase**, which begins with the arrival of food in the stomach; and (3) the **intestinal phase**, which controls the rate of gastric emptying. Vomiting, or **emesis**, is reverse peristalsis. *(Spotlight Figure 24–15)*

24-5 Accessory digestive organs, such as the pancreas and liver, produce secretions that aid in chemical digestion p. 905

22. The **pancreas** has a slender **body** and a short tail. The **pancreatic duct** penetrates the wall of the duodenum, the first section of the small intestine. Within each lobule, ducts branch repeatedly before ending in the **pancreatic acini** (pockets). *(Figure 24–16)*
23. The pancreas has two functions: endocrine (secreting insulin and glucagon into the blood) and exocrine (secreting **pancreatic juice** into the small intestine). Pancreatic enzymes include **carbohydrases**, **lipases**, **nucleases**, and **proteases**.
24. The **liver** performs metabolic and hematological regulation and produces **bile**. The bile ducts from all the **liver lobules** unite to form the **common hepatic duct**. That duct meets the **cystic duct** to form the **bile duct**, which empties into the duodenum. *(Figures 24–17 to 24–19)*
25. The liver lobule is the organ's basic functional unit. **Hepatocytes** form irregular plates arranged in the form of spokes of a wheel. **Bile canaliculi** carry bile to the **bile ductules**, which lead to **portal triads**. *(Figure 24–18)*
26. In **emulsification**, **bile salts** break apart large drops of lipids, making the lipids accessible to lipases secreted by the pancreas.
27. The liver is the primary organ involved in regulating the composition of circulating blood. All the blood leaving the absorptive surfaces of the digestive tract flows into the liver before entering the systemic circulation. The liver regulates metabolism as it removes and stores excess nutrients, vitamins, and minerals from the blood; mobilizes stored reserves; synthesizes needed nutrients; and removes wastes.
28. The liver's hematological activities include the monitoring of circulating blood by phagocytes and antigen-presenting cells; the synthesis of plasma proteins; the removal of circulating hormones and antibodies; and the removal or storage of toxins.
29. The liver synthesizes bile, which is composed of water, ions, bilirubin, cholesterol, and bile salts (an assortment of lipids).
30. The **gallbladder** stores, modifies, and concentrates bile. *(Figure 24–19)*

24-6 The small intestine primarily functions in the chemical digestion and absorption of nutrients p. 915

31. Most of the important digestive and absorptive functions occur in the **small intestine** (*small bowel*). The pancreas, liver, and gallbladder provide digestive secretions and buffers.
32. The small intestine consists of the **duodenum**, the **jejunum**, and the **ileum**. A sphincter, the **ileocecal valve**, marks the transition between the small and large intestines. *(Figure 24–20)*
33. The intestinal mucosa has transverse folds called **circular folds** (*plicae circulares*) and small projections called **intestinal villi**. These folds and projections increase the surface area for absorption. Each villus contains a terminal lymphatic called a **lacteal**. Pockets called **intestinal glands** are lined by enteroendocrine, mucous, paneth, and stem cells. *(Figures 24–20, 24–21)*
34. **Intestinal juice** moistens chyme, helps buffer acids, and holds digestive enzymes and digestive products in solution.
35. The **duodenal submucosal glands** of the duodenum produce mucus, bicarbonate ions, and the hormone **urogastrone**. The ileum contains masses of lymphoid tissue called **aggregated lymphoid nodules**, or *Peyer's patches*, near the entrance to the large intestine.
36. The **gastroenteric reflex**, initiated by stretch receptors in the stomach, stimulates motility and secretion along the entire small intestine. The **gastroileal reflex** triggers the relaxation of the ileocecal valve.
37. Neural and hormonal mechanisms coordinate the activities of the digestive glands. Gastrointestinal activity is stimulated by parasympathetic innervation and inhibited by sympathetic innervation. The **enterogastric**, **gastroenteric**, and **gastroileal reflexes** coordinate movement from the stomach to the large intestine.
38. Intestinal hormones include **secretin**, **cholecystokinin (CCK)**, **gastric inhibitory peptide (GIP)**, **vasoactive intestinal peptide (VIP)**, **gastrin**, and **enterocrinin**. *(Figures 24–22, 24–23)*

24-7 The large intestine, which is divided into three parts, absorbs water from digestive materials and eliminates the remaining waste as feces p. 921

39. The main functions of the **large intestine** are to (1) reabsorb water and compact materials into feces, (2) absorb vitamins produced by bacteria, and (3) store fecal material prior to defecation. The large intestine (*large bowel*) consists of the *cecum*, *colon*, and *rectum*. *(Figure 24–24)*
40. The **cecum** collects and stores material from the ileum and begins the process of compaction. The **appendix** is attached to the cecum. *(Figure 24–24)*
41. The **colon** has a larger diameter and a thinner wall than the small intestine. The colon bears **haustra** (pouches), **teniae coli** (longitudinal bands of muscle), and sacs of fat called **omental appendices**. *(Figure 24–24)*
42. The four regions of the colon are the **ascending colon**, **transverse colon**, **descending colon**, and **sigmoid colon**. *(Figure 24–24)*
43. The **rectum** terminates in the **anal canal**, leading to the **anus**. *(Figure 24–24)*
44. Histological characteristics of the colon include the absence of villi and the presence of goblet cells and deep intestinal glands. *(Figure 24–25)*
45. The large intestine reabsorbs water and other substances such as vitamins, urobilinogen, bile salts, and toxins. Most of the gut bacteria of the human *microbiome* live in the large intestine. Bacteria are responsible for intestinal gas, or **flatus**.
46. The gastroileal reflex moves materials from the ileum into the cecum while you eat. Distension of the stomach and duodenum stimulates **mass movements** of materials from the transverse colon through the rest of the large intestine and into the rectum. Muscular sphincters control the passage of fecal material to the anus. Distension of the rectal wall triggers the **defecation reflex**. *(Figure 24–26)*

24-8 Chemical digestion is the enzyme-mediated hydrolysis of food into nutrients that can be absorbed and used by the body p. 926

47. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments by *hydrolysis*. *(Spotlight Figure 24–27; Table 24–1)*
48. Salivary and pancreatic amylases break down complex carbohydrates into *disaccharides* and *trisaccharides*. These in turn are broken down into *monosaccharides* by enzymes at the epithelial surface. The monosaccharides are then absorbed by the intestinal epithelium by facilitated diffusion or cotransport. *(Spotlight Figure 24–27)*
49. *Triglycerides* are emulsified into lipid droplets that interact with bile salts to form **micelles**. The fatty acids and monoglycerides resulting from the action of pancreatic lipase diffuse from the micelles across the intestinal epithelium. Triglycerides are then synthesized and released into the interstitial fluid for transport to the general circulation by way of the lymphatic system. *(Spotlight Figure 24–27)*
50. Protein digestion involves a low pH (which breaks down tertiary and quaternary structure), the gastric enzyme pepsin, and various pancreatic proteases. Peptidases liberate amino acids

that are absorbed and exported to interstitial fluid. *(Spotlight Figure 24–27)*

51. About 2200 mL of water is ingested each day, and digestive secretions provide another 7200 mL. Nearly all is reabsorbed by osmosis. *(Figure 24–28)*
52. Various processes, including diffusion, cotransport, and carrier-mediated and active transport, are responsible for the movements of cations (sodium, calcium, potassium, and so on) and anions (chloride, iodide, bicarbonate, and so on) into epithelial cells. *(Table 24–2)*
53. The **water-soluble vitamins** (except B_{12}) diffuse easily across the digestive epithelium. **Fat-soluble vitamins** are enclosed within fat droplets and absorbed with the products of lipid digestion. *(Table 24–2)*

24-9 Many age-related changes affect digestion and absorption p. 931

54. Age-related changes include a thinner and more fragile epithelium due to a reduction in epithelial stem cell divisions, weaker peristaltic contractions as smooth muscle tone decreases, the effects of cumulative damage, increased cancer rates, and increased dehydration.

24-10 The digestive system is extensively integrated with other body systems p. 932

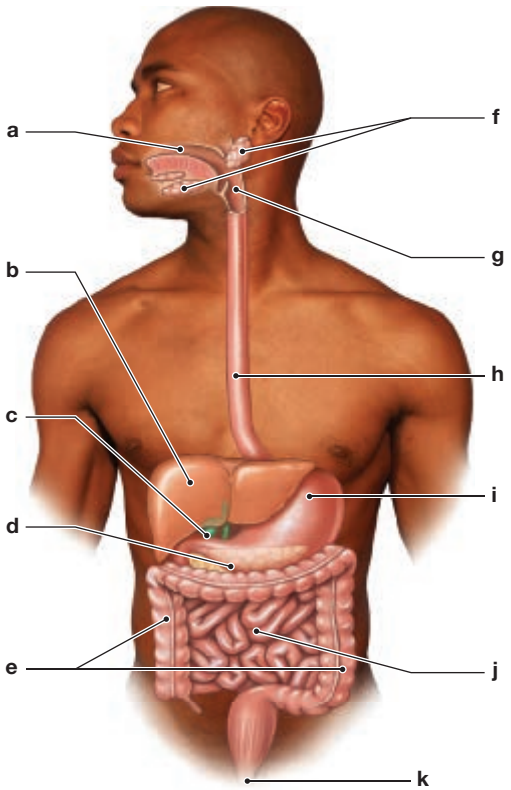
55. The digestive system has extensive anatomical and physiological connections to the nervous, endocrine, cardiovascular, and lymphatic systems. *(Figure 24–29)*

Review Questions

See the blue Answers tab at the back of the book.

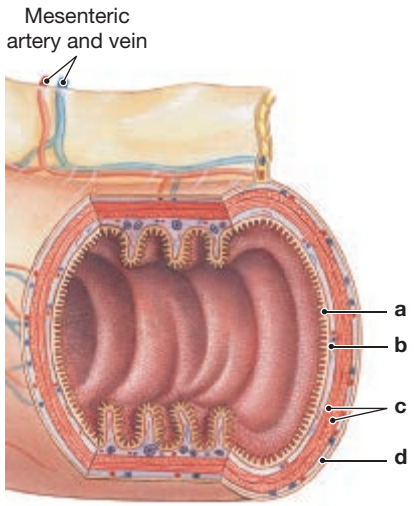
LEVEL 1 Reviewing Facts and Terms

1. The enzymatic breakdown of large molecules into their basic building blocks is called **(a)** absorption, **(b)** secretion, **(c)** mechanical processing, **(d)** chemical digestion.
2. The outer layer of the digestive tract is known as the **(a)** serosa, **(b)** mucosa, **(c)** submucosa, **(d)** muscularis.
3. Double sheets of peritoneum that provide support and stability for the organs of the peritoneal cavity are the **(a)** mediastina, **(b)** mucous membranes, **(c)** omenta, **(d)** mesenteries.
4. A branch of the hepatic portal vein, hepatic artery proper, and branch of the bile duct form **(a)** a liver lobule, **(b)** the sinusoids, **(c)** a portal triad, **(d)** the hepatic duct, **(e)** the pancreatic duct.
5. Label the digestive system structures in the following figure.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____ **(j)** _____
(k) _____

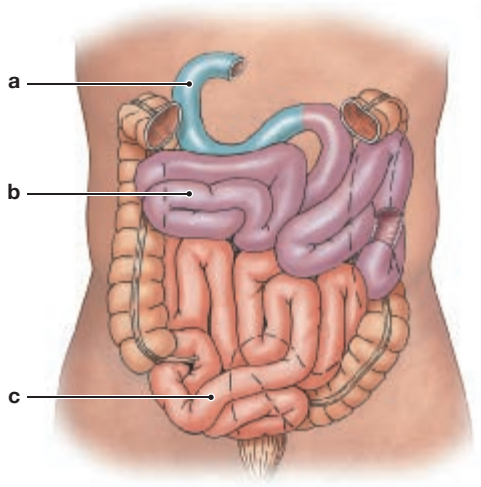
6. Label the four layers of the digestive tract in the following figure.



(a) _____ **(b)** _____
(c) _____ **(d)** _____

7. Most of the digestive tract is lined by _____ epithelium. **(a)** pseudostratified ciliated columnar, **(b)** cuboidal, **(c)** stratified squamous, **(d)** simple, **(e)** simple columnar.
8. Regional movements that occur in the small intestine and function to churn and fragment the digestive material are called **(a)** segmentation, **(b)** pendular movements, **(c)** peristalsis, **(d)** mass movements, **(e)** mastication.
9. Bile release from the gallbladder into the duodenum occurs only under the stimulation of **(a)** cholecystokinin, **(b)** secretin, **(c)** gastrin, **(d)** enteropeptidase.

10. Label the three segments of the small intestine in the following figure.



(a) _____ **(b)** _____ **(c)** _____

11. The major function(s) of the large intestine is (are) **(a)** reabsorption of water and compaction of feces, **(b)** absorption of vitamins liberated by bacterial action, **(c)** storage of fecal material prior to defecation, **(d)** all of these.
12. Vitamins generated by bacteria in the colon are **(a)** vitamins A, D, and E, **(b)** B complex vitamins and vitamin C, **(c)** vitamin K, biotin, and pantothenic acid, **(d)** niacin, thiamine, and riboflavin.
13. The final enzymatic steps in the digestive process are accomplished by **(a)** brush border enzymes of the intestinal microvilli, **(b)** enzymes secreted by the stomach, **(c)** enzymes secreted by the pancreas, **(d)** the action of bile from the gallbladder.
14. What are the six main processes of the digestive system?
15. Name and describe the layers of the digestive tract, proceeding from the innermost layer nearest the lumen to the outermost layer.
16. What three basic mechanisms regulate the activities of the digestive tract?
17. What are the three phases of swallowing, and how are they controlled?
18. What are the primary digestive functions of the pancreas, liver, and gallbladder?
19. Which hormones produced by duodenal enteroendocrine cells effectively coordinate digestive functions?
20. What are the three primary functions of the large intestine?
21. What two positive feedback loops are involved in the defecation reflex?

LEVEL 2 Reviewing Concepts

22. During defecation, **(a)** stretch receptors in the rectal wall initiate a series of peristaltic contractions in the colon and rectum, **(b)** stretch receptors in the rectal wall activate parasympathetic centers in the sacral region of the spinal cord, **(c)** the internal anal sphincter relaxes while the external anal sphincter contracts, **(d)** all of these occur, **(e)** only a and b occur.
23. *Increased* parasympathetic stimulation of the intestine would result in **(a)** decreased motility, **(b)** decreased secretion, **(c)** decreased sensitivity of local reflexes, **(d)** decreased segmentation, **(e)** none of these.
24. A drop in pH below 4.5 in the duodenum stimulates the secretion of **(a)** secretin, **(b)** cholecystokinin, **(c)** gastrin, **(d)** all of these.
25. Through which layers of a molar would an oral surgeon drill to perform a root canal (removal of the alveolar nerve in a severely damaged tooth)?
26. How is the stomach protected from digestion?
27. How does each of the three phases of gastric secretion promote and facilitate gastric control?
28. Nutritionists have found that after a heavy meal, the pH of blood increases slightly, especially in the veins that carry blood away from the stomach. What causes this increase in blood pH?

LEVEL 3 Critical Thinking and Clinical Applications

29. Some people with gallstones develop pancreatitis. How could this occur?
30. Harry is suffering from an obstruction in his colon. He notices that when he urinates, the color of his urine is much darker than normal, and he wonders if there is any relationship between the color of his urine and his intestinal obstruction. What would you tell him?
31. A condition known as lactose intolerance is characterized by painful abdominal cramping, gas, and diarrhea. The cause of the problem is an inability to digest the milk sugar lactose. How would this cause the observed signs and symptoms?
32. Recently, more people have turned to surgery to help them lose weight. One form of weight control surgery involves stapling a portion of the stomach shut, creating a smaller volume. How would such a surgery result in weight loss?

CLINICAL CASE Wrap-Up An Unusual Transplant

Normally the lining of the colon is slimy with mucus and covered with millions of beneficial bacteria. These friendly, "good" bacteria generate vitamins K, B_5, and biotin. They convert bilirubin (the breakdown product of blood) to urobilinogens and stercobilinogens for excretion. The bacteria also break down any remaining peptides in feces.

When these normal, beneficial intestinal bacteria have been killed by antibiotics, they are replaced by other bacteria. Often the replacement bacteria do harm by producing toxins, irritating the intestinal lining, and causing colitis. This is the case with *Clostridium difficile* infections.

One way of treating *C. difficile* infections is with a fecal transplant, as Mirasol's doctor suggests. Normal feces from a healthy donor contain populations of beneficial bacteria that usually colonize large intestines. With a minimal amount of processing, the donated feces can be infused through a nose tube (nasogastric tube). Then the normal intestinal bacteria can take up residence in the recipient's large intestine, crowd out the harmful *C. difficile* bacteria, and resume their usual work of protecting the lining of the large intestine, producing vitamins, and recycling nutrients.

After overcoming her initial disgust, Mirasol agrees to the transplant. She recovers completely and leaves the hospital 2 days after her treatment.

1. If Mirasol's *Clostridium difficile* colitis were not treated with a fecal transplant, what kind of health problems might she continue to experience?
2. If you could look inside Mirasol's large intestine with a colonoscope before the transplant, what would you likely see?

See the blue Answers tab at the back of the book.

Related Clinical Terms

borborygmus: A rumbling or gurgling sound made by the movement of fluids and gases in the intestines.
cathartics: Drugs that promote defecation.
cholelithiasis: The presence of gallstones in the gallbladder.
cholera: A bacterial infection of the digestive tract that causes massive fluid losses through diarrhea.
colitis: A general term for a condition characterized by inflammation of the colon.
Crohn's disease: An incurable chronic inflammatory bowel disease that can affect any part of the digestive tract, from the mouth to the anus. The presence of strictures, fistulas, and fissures is common.
diverticulitis: An infection and inflammation of mucosal pockets of the large intestine (diverticula).
diverticulosis: The formation of diverticula, generally along the sigmoid colon.
dysphagia: Difficulty or discomfort in swallowing due to disease.
esophageal varices: Swollen and fragile esophageal veins that result from portal hypertension.
fecal occult blood test: Test to check for hidden blood in feces.
gastrectomy: The surgical removal of the stomach, generally to treat advanced stomach cancer.
gastroesophageal reflux disease (GERD): Chronic condition in which the lower esophageal sphincter allows gastric acids to backflow into the esophagus, causing heartburn, acid indigestion, and possible injury to the esophageal lining.
gastroscope: A fiber-optic instrument inserted into the mouth and directed along the esophagus and into the stomach; used to examine the interior of the stomach and to perform minor surgical procedures.
halitosis: Bad breath that may be due to poor oral hygiene, an infection, diabetes, or other disease.
insoluble fiber: Indigestible plant carbohydrates that do not dissolve in water and pass through the GI tract unchanged. Found in many vegetables and the skins of fruits, insoluble fiber speeds up the passage of material in the GI tract. Individuals consuming diets rich in insoluble fiber decrease their risk for developing diabetes, atherosclerosis, and colorectal cancers, among other diseases.
irritable bowel syndrome (IBS): A common disorder affecting the large intestine, accompanied by cramping, abdominal pain, bloating, gas, diarrhea, and constipation.
pancreatic cancer: Malignancy of the pancreas that does not cause symptoms in its early stages, leading to late detection and a survival rate of only 4 percent.
periodontal disease: A loosening of the teeth within the alveolar sockets caused by erosion of the periodontal ligaments by acids produced through bacterial action.
polyps: Small growths with a stalk protruding from a mucous membrane that is usually benign.
pulpitis: An infection of the pulp of a tooth; treatment may involve a root canal procedure.
pyloric stenosis: Uncommon condition in which the muscle of the lower end of the stomach enlarges and prevents food from entering the small intestine.
pylorospasm: Spasm of the pyloric sphincter, accompanied by pain and vomiting.
root canal: Removal of the alveolar nerve in a severely damaged tooth.
soluble fiber: Indigestible plant carbohydrates found in beans, oats, and citrus fruits that dissolve in water when eaten, forming a gel within the digestive tract to slow the passage of material. Diets rich in soluble fiber lower blood cholesterol levels.

25 Metabolism, Nutrition, and Energetics

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

25-1 ■ Explain the relationship among metabolism, catabolism, and anabolism; and describe the energetics of an oxidation–reduction reaction. p. 940

25-2 ■ Describe the basic steps in glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, and summarize the energy yield of cellular respiration (glycolysis and aerobic metabolism). p. 943

25-3 ■ Describe the pathways involved in lipid metabolism, and summarize the mechanisms of lipid transport and distribution. p. 951

25-4 ■ Summarize the main processes of protein metabolism, and discuss the use of protein as an energy source. p. 956

25-5 ■ Differentiate between the absorptive and postabsorptive metabolic states, and summarize the characteristics of each. p. 957

25-6 ■ Explain what makes up a balanced diet and why such a diet is important. p. 959

25-7 ■ Define metabolic rate, discuss the factors involved in determining an individual's BMR, and discuss the homeostatic mechanisms that maintain a constant body temperature. p. 966

CLINICAL CASE The Miracle Supplement

Justine, a pregnant 30-year-old Kenyan woman, is walking home from the clinic after her final prenatal visit. As the sun sets, she realizes she is suddenly no longer able to see. Terrified, she manages to walk home blind, in rural Kenya, after dark. The next morning, her vision returns.

Justine knows children who have experienced night blindness. Many of them died young; in fact, every family in Justine's village has experienced childhood death. Several of the village's children also have stunted growth and delayed skeletal development. They seem to have weak immunity, and commonly develop malarial, respiratory, and diarrheal infections.

Fortunately, Justine goes on to deliver a healthy baby at the clinic. Shortly after giving birth, doctors treat Justine with a single high-dose vitamin supplement. She is told this will help her night blindness and ensure that there is enough of this vitamin in her breast milk to keep her baby healthy, too.

When Justine's baby is 6 months old, Justine takes her to get her first dose of vitamin supplement. This dose will be repeated every 6 months until the child is 5 years old. Costing only 2¢ per dose and reducing overall childhood mortality (death rate) by 23 percent, this vitamin supplement has been called the best public health investment ever. **What could this critical vitamin be? To find out, turn to Clinical Case Wrap-Up on p. 975.**

An Introduction to Metabolism, Nutrition, and Energetics

The amount and type of *nutrients*, essential elements and molecules, you get from food can vary widely. Your body builds energy reserves when nutrients are abundant. It mobilizes these reserves when nutrients are in short supply. The nervous and endocrine systems control the storage and mobilization of these energy reserves. These systems adjust and coordinate these reactions as part of their regulation of all of the *metabolic* activities of the body's tissues. In this chapter we examine (1) how the body obtains energy from the breakdown of organic molecules, stores it in the form of the energy transfer molecule *ATP*, and uses it to support intracellular processes such as the construction of new organic molecules; (2) the role of diet in physiological function; and (3) the *energetics* of how the body balances heat gains and losses to maintain homeostasis.

25

25-1 Metabolism is the sum of all the catabolic and anabolic reactions in the body, and energetics is the flow and transformation of energy

Learning Outcome Explain the relationship among metabolism, catabolism, and anabolism; and describe the energetics of an oxidation–reduction reaction.

Cells are chemical factories that break down organic molecules to obtain energy. Our cells can then use this energy to generate ATP from ADP and P_i. Reactions within mitochondria provide most of the energy a typical cell needs. ↩ p. 81 To carry out these reactions, cells must have a reliable supply of oxygen and nutrients, including *water*, *vitamins*, *mineral ions*, and *organic substrates*. Substrates are the substances acted on by an enzyme. ↩ p. 55

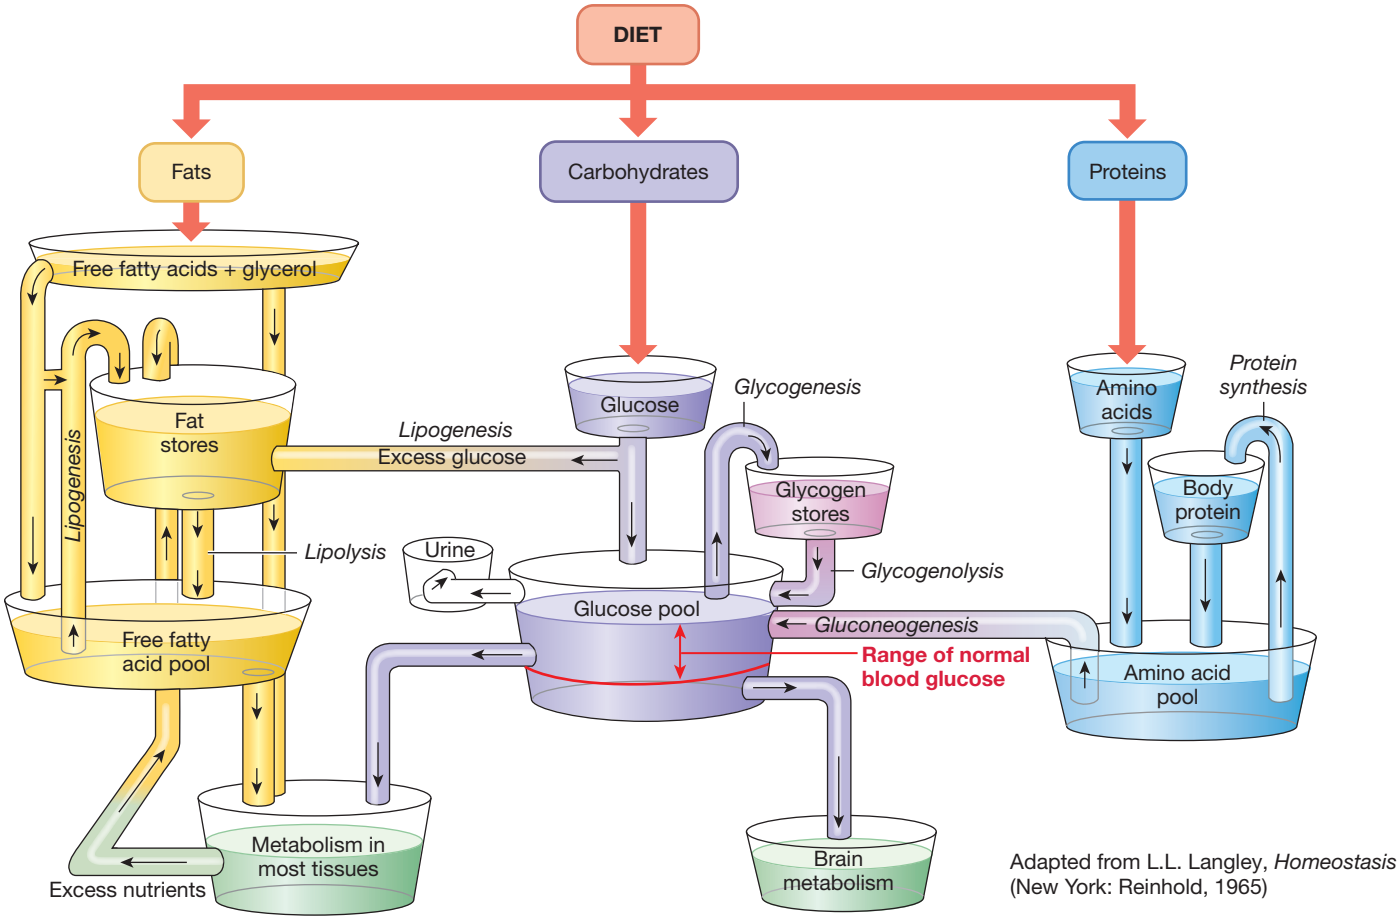
Metabolism

Metabolism is the sum of all chemical and physical changes that occur in body tissues. It consists of **catabolism** (catabolic reactions) and **anabolism** (anabolic reactions). Catabolism converts large molecules into smaller ones, and anabolism converts small molecules into larger ones. Energy-rich macromolecules are obtained in our diet—namely, the fats, carbohydrates, and proteins we eat. The pathways making up these reactions extract energy from nutrients, transfer and use energy, and build and store excesses for later use. Nutrients, the components in food, such as water, vitamins, mineral ions, carbohydrates, fats, and proteins, are necessary for normal physiological function. All the available nutrient molecules distributed in the blood form a **nutrient pool** (Figure 25–1).

Catabolism

Catabolism proceeds in a series of steps. In general, the first steps take place in the cytosol. Fats are broken down into fatty acids and glycerol; carbohydrates are broken down into glucose; and proteins are catabolized into amino acids. Different processes are involved in the catabolism of each nutrient. For example, fat catabolism involves *lipolysis* (fat breakdown), and carbohydrate catabolism involves *glycogenolysis* (breakdown of glycogen into glucose) and *glycolysis* (breakdown of glucose into pyruvate). Every day the lungs absorb oxygen, and the digestive tract absorbs nutrients. The cardiovascular system then carries these substances throughout the body in the blood, where our cells can absorb and use them to generate ATP. Figure 25–1 shows the relationships of the various metabolic pathways, which we discuss in greater detail later in the chapter.

Figure 25–1 Metabolism of Organic Nutrients and Nutrient Pools. This flowchart illustrates the major organic macromolecules in the diet and the relationships among the metabolic pathways and nutrient pools of their building blocks (monomers)—free fatty acids, glucose, and amino acids.



Anabolism

The ATP produced by mitochondria provides energy to support both *anabolism*, which is the synthesis of new organic molecules, and other cell functions. For example, muscle fibers need ATP to provide energy for contraction, but gland cells need ATP to synthesize and transport secretions. Here we focus on anabolism.

In terms of energy, anabolism is an "uphill" process that involves the formation of new chemical bonds. Cells synthesize new organic components for four basic reasons:

- *To Carry Out Structural Maintenance or Repairs.* All cells must expend energy for ongoing maintenance and repairs, because most structures in the cell are temporary rather than permanent. Cells continuously replace membranes, organelles, enzymes, and structural proteins in the process of *metabolic turnover* (see Appendix, Table 4).
- *To Support Growth.* Cells preparing to divide increase in size and synthesize extra proteins and organelles.
- *To Produce Secretions.* Secretory cells must synthesize their products and deliver them to the interstitial fluid.
- *To Store Nutrient Reserves.* Most cells "prepare for a rainy day"—a period of emergency, an interval of extreme activity, or a time when the supply of nutrients in the bloodstream is inadequate. Cells prepare for such times by building up nutrient reserves in a form that can be mobilized as needed. For example, in the process of *lipogenesis*, or fat formation, *triglycerides* (consisting primarily of *fatty acids*) are the most abundant storage form. In the process of *glycogenesis* (glycogen formation), carbohydrates are stored as *glycogen*, a branched chain of glucose molecules. If glucose is unavailable, it may be synthesized through the process of *gluconeogenesis*. Muscle cells and liver cells, for example, store glucose in the form of glycogen, but adipocytes and liver cells store triglycerides. Proteins are the most abundant organic components in the body. They perform a variety of vital functions for the cell. Anabolic activities require more amino acids than lipids, and few

carbohydrates. Therefore, when energy is available, cells synthesize additional proteins. When glucose and fatty acids are unavailable, cells can break down proteins into their component amino acids, and use the amino acids as an energy source. Proteins are so abundant and accessible that they represent an important "last-ditch" nutrient reserve (Figure 25–1).

Mitochondria provide the energy that supports cellular operations. The cell "feeds" its mitochondria from its nutrient pool. In return, the cell gets the ATP it needs. However, mitochondria are picky eaters: They accept only specific organic molecules for processing and energy production. For this reason, chemical reactions in the cytosol take whichever organic nutrients are available and break them down into smaller fragments that the mitochondria can process. The mitochondria then break the fragments down further, generating carbon dioxide, water, and ATP. Most of the ATP is formed as the result of a metabolic process called *oxidative phosphorylation*. This mitochondrial activity involves the *oxidation* of high-energy carrier molecules from the *citric acid cycle* and the phosphorylation of ADP to form ATP.

Energetics

Each tissue contains a unique mixture of various kinds of cells. As a result, the energy and nutrient requirements of any two tissues, such as loose connective tissue and cardiac muscle, can be quite different. Also, activity levels can change rapidly within a tissue, and such changes affect the body's requirements. For example, when skeletal muscles start contracting, oxygen demand increases dramatically. Thus, the energy and nutrient requirements vary from moment to moment (resting versus exercising), hour to hour (asleep versus awake), and year to year (growing child versus adult). Understanding energy requirements is one aspect of **energetics**, the study of the flow of energy and its transformation, or change, from one form to another.

25

Oxidation and Reduction

Most of the important energy changes in cells involve chemical reactions known as oxidation and reduction. Oxidation and reduction reactions may be described as transfers of oxygen, hydrogen, or electrons, but for our purposes the most important are those involving the transfer of electrons. A gain of oxygen, or a loss of hydrogen or electrons, is a form of **oxidation**, and the net result is a *decrease* in potential energy of the atom or molecule. A loss of oxygen, or a gain of hydrogen or electrons, is a form of **reduction**, and the net result is an *increase* in potential energy of the atom or molecule. The two reactions are always paired. When electrons pass from one molecule to another, the electron donor is *oxidized* and the electron recipient is *reduced*. Oxidation and reduction are important because electrons carry chemical energy. In a typical oxidation–reduction reaction, often called a *redox reaction*, the reduced atom or molecule gains energy at the expense of the oxidized atom or molecule.

Tips & Tools

To remember what occurs with electron transfer in oxidation and reduction reactions, think ***OIL RIG*** for ***o***xidation ***i***s ***l***oss and ***r***eduction ***i***s ***g***ain.

In such an exchange, the reduced molecule does not gain all the energy released by the oxidized molecule. Some energy is always released as heat. The remaining energy may be used to do physical or chemical work, such as forming ATP. By passing electrons through a series of oxidation–reduction reactions, cells can capture and use much of the energy that is released.

Mitochondria contain a series of protein complexes, called the *electron transport chain*, which pass electrons through a series of oxidation–reduction reactions. To maintain such a flow of electrons, a final electron acceptor is necessary. In mitochondria, this role is played by oxygen. Water is formed as the electrons ultimately combine with oxygen atoms and hydrogen ions.

Coenzymes play a key role in the flow of energy within a cell and its mitochondria. A **coenzyme** acts as an intermediary that accepts electrons from one molecule and transfers them to another molecule. For example, the coenzymes **NAD** (*nicotinamide adenine dinucleotide*) and **FAD** (*flavin adenine dinucleotide*) can remove hydrogen atoms from organic molecules. Each hydrogen atom consists of an electron (e^-) and a proton (a hydrogen ion, H^+). Thus, when a coenzyme accepts hydrogen atoms, the coenzyme is reduced and gains energy. The donor molecule loses electrons and energy as it gives up its hydrogen atoms.

The coenzyme FAD can accept 2 hydrogen atoms, gaining 2 electrons and forming $FADH_2$. The oxidized form of the coenzyme NAD has a positive charge (NAD^+). This coenzyme also gains 2 electrons as 2 hydrogen atoms are removed from the donor molecule, resulting in the formation of NADH and the release of a proton (H^+). For this reason, the reduced form of NAD is often described as "NADH + H^+."

In summary, the coenzymes NADH + H^+ and $FADH_2$ provide electrons to the electron transport chain. Oxygen accepts, or gains, those electrons. In other words, the coenzymes are oxidized and oxygen is reduced.

Checkpoint

1. Define *metabolism*, *catabolism*, and *anabolism*.
2. Compare oxidation and reduction.

See the blue Answers tab at the back of the book.

25-2 Carbohydrate metabolism generates ATP by glucose catabolism and forms glucose by gluconeogenesis

Learning Outcome Describe the basic steps in glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, and summarize the energy yield of cellular respiration (glycolysis and aerobic metabolism).

Carbohydrate metabolism is primarily concerned with glucose metabolism because most carbohydrates are converted to glucose. The steps involved in glucose catabolism and ATP production include glycolysis, the citric acid cycle, the electron transport chain, and chemiosmosis, whereas glucose anabolism involves gluconeogenesis and glycogenesis. We describe the important catabolic and anabolic cellular reactions for glucose in this section.

Overview of Glucose Catabolism

Most cells generate ATP and other high-energy compounds by breaking down carbohydrates, especially glucose. The complete oxidation of glucose to CO_2 and H_2O involves three major biochemical pathways: glycolysis, the citric acid cycle, and the electron transport chain. We can summarize the complete reaction as follows:

$$\underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{oxygen}}{6O_2} \longrightarrow \underset{\text{carbon dioxide}}{6CO_2} + \underset{\text{water}}{6H_2O}$$

This overall reaction is called **cellular respiration**. The breakdown of glucose takes place in a series of small steps. Several of these steps release sufficient energy to convert ADP to ATP. The complete catabolism of 1 molecule of glucose provides a typical body cell a net gain of 30–32 molecules of ATP.

Most ATP production occurs inside the mitochondria, but the first steps take place in the cytosol. In Chapter 10 we introduced the process of *glycolysis*, which breaks down glucose in the cytosol into smaller molecules that mitochondria can absorb and use. ↩ p. 320 These reactions are *anaerobic* because glycolysis does not require oxygen. The subsequent reactions take place in mitochondria and are *aerobic*. The mitochondrial activity responsible for ATP production is called *aerobic metabolism*. (The terms *cellular respiration* and *aerobic metabolism* are often considered interchangeable, however cellular respiration includes both anaerobic and aerobic reactions.)

Glucose Catabolism: Glycolysis

Glycolysis (glī-KOL-ih-sis; *glykus*, sweet + *lysis*, a loosening) is the breakdown of glucose. In this process, a series of enzymatic steps breaks the 6-carbon glucose molecule ($C_6H_{12}O_6$) into two 3-carbon molecules of **pyruvic acid** ($CH_3—CO—COOH$). (At the normal pH inside cells, each pyruvic acid molecule loses a hydrogen ion and exists as the negatively charged anion $CH_3—CO—COO^-$. This ionized form is called **pyruvate**.)

Glycolysis requires (1) glucose molecules; (2) appropriate cytosolic enzymes; (3) ATP and ADP; (4) inorganic phosphate groups (P_i); and (5) NAD, a coenzyme that removes hydrogen atoms during one of the enzymatic reactions. Recall from Chapter 2 that coenzymes are organic molecules that are essential to enzyme function. ↩ p. 56 If any of these participants is missing, glycolysis cannot take place.

Figure 25–2 provides an overview of the steps in glycolysis. The beginning of glycolysis "costs" the cell 2 ATP molecules. Glycolysis begins when an enzyme **phosphorylates**—that is, attaches a phosphate group to—the last (sixth) carbon atom of a **glucose** molecule, creating **glucose-6-phosphate** and using 1 ATP molecule. It has two important results: (1) It traps the glucose molecule within the cell, because phosphorylated glucose cannot cross the plasma membrane; and (2) it prepares the glucose molecule for further biochemical reactions. A second phosphorylation, using one more ATP molecule, takes place in the cytosol before the 6-carbon chain is broken into two 3-carbon fragments.

Then energy benefits begin to appear as these fragments are converted to pyruvate. Two of the steps release enough energy to generate ATP from ADP and inorganic phosphate (P_i). In addition, 2 molecules of NAD are reduced to NADH + H^+. (For convenience, we will use NAD for NAD+ and NADH for NADH + H^+ in our discussion.) The net reaction of glycolysis looks like this:

$$\text{Glucose} + 2\ \text{NAD} + 2\ \text{ADP} + 2\ P_i \longrightarrow 2\ \text{Pyruvate} + 2\ \text{NADH} + 2\ \text{ATP}$$

This reaction sequence is anaerobic (without oxygen) and provides the cell a net gain of 2 molecules of ATP for each glucose molecule converted to 2 pyruvate molecules.

A few highly specialized cells, such as red blood cells, lack mitochondria and derive all their ATP through glycolysis. Skeletal muscle fibers rely on glycolysis for ATP production during periods of active contraction. Most cells can survive for brief periods using the ATP provided by glycolysis alone.

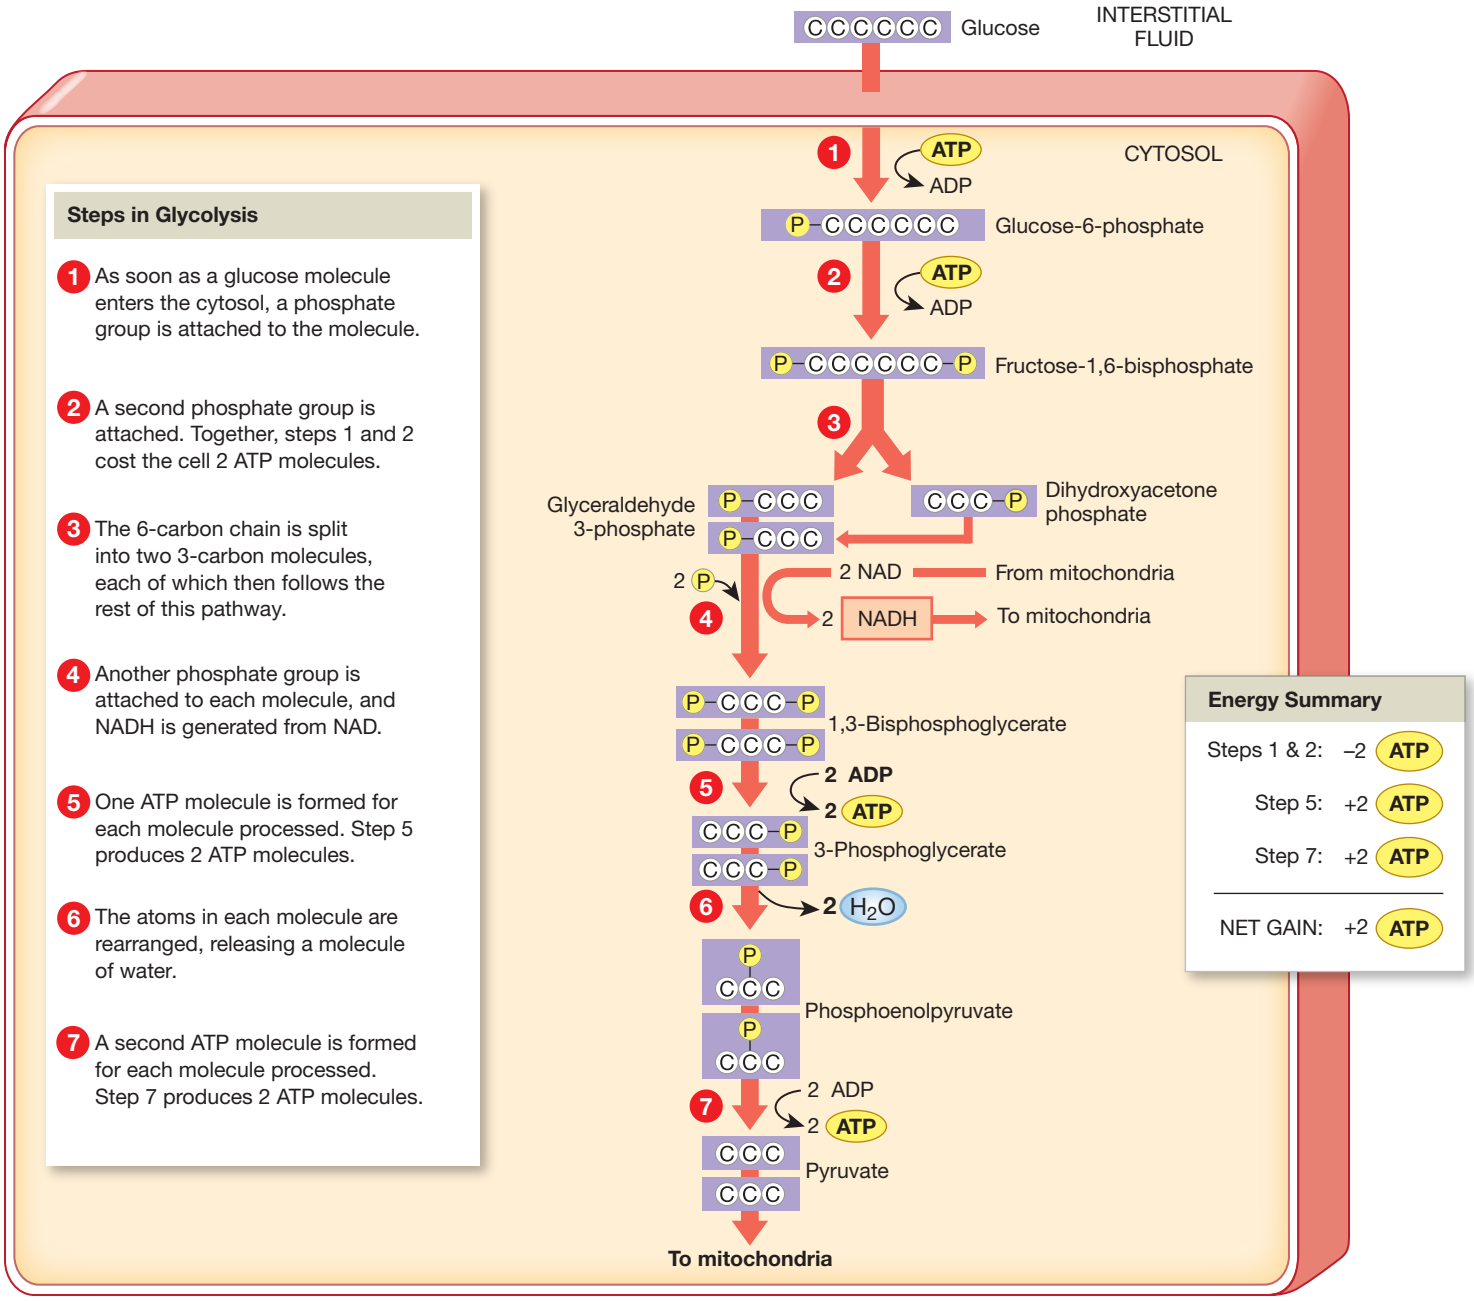
Here is a summary of the glycolytic pathway, which prepares glucose for the citric acid cycle:

1. One 6-carbon glucose molecule enters the pathway.
2. Two 3-carbon pyruvate molecules are produced.
3. Two molecules of ATP are produced from 2 ADP and 2 P_i.
4. Two pairs of high-energy electrons are passed to 2 NAD to form 2 NADH.
5. Specific enzymes catalyze each step of the process.

Glucose Catabolism: Fate of Pyruvate

A great deal of additional energy is still stored in the chemical bonds of pyruvate. The cell's ability to capture that energy depends on the availability of oxygen. If oxygen supplies are inadequate, pyruvate is reduced to form lactate and NAD is oxidized from NADH. Lactate formation from pyruvate does not

Figure 25–2 Glycolysis. Glycolysis breaks down a 6-carbon glucose molecule into two 3-carbon molecules of pyruvate through a series of enzymatic steps.



? Glycolysis produces how many pyruvate molecules and how many ATP molecules?

occur without the presence of NAD. If oxygen is readily available, mitochondrial activity provides most of the ATP that cells need.

Glucose Catabolism: Aerobic Metabolism

When oxygen supplies are adequate, mitochondria absorb the pyruvate molecules. Recall that a double membrane surrounds each mitochondrion. The *outer membrane* contains large pores that are permeable to ions and small organic molecules such as pyruvate. Ions and molecules easily enter the *intermembrane space* separating the outer membrane from the *inner membrane*. The inner membrane contains a carrier protein that moves pyruvate into the mitochondrial matrix.

Within the mitochondria, in the process of **aerobic metabolism**, pyruvate is broken down and the energy released is used to produce a large amount of ATP. This process involves two pathways: the *citric acid cycle* and the *electron transport chain*.

Citric Acid Cycle

The citric acid cycle begins with pyruvate, which is where glycolysis left off, and it occurs in the mitochondria. This cycle involves oxidation, reduction, and decarboxylation reactions. Each pyruvate molecule (CH_3—CO—COO^-) is oxidized as its hydrogen atoms are removed by coenzymes, which are then reduced. These hydrogen atoms are ultimately the source of most of the cell's energy gain. The carbon and oxygen atoms are removed and released as carbon dioxide in a process called **decarboxylation** (dē-kar-boks-i-LĀ-shun). In total, each molecule of pyruvate in this cycle produces 3 molecules of CO_2, 3 molecules of H_2O, 4 molecules of NADH, 1 molecule of $FADH_2$, and 1 molecule of GTP (equivalent to ATP in terms of energy). Let's look at the cycle in detail.

Upon entering the mitochondrion, a pyruvate molecule participates in a complex reaction involving NAD and another coenzyme called **coenzyme A (CoA)**. This reaction yields 1 molecule of CO_2, 1 of NADH, and 1 of **acetyl-CoA** (a-SĒ-til KŌ-ā)—a 2-carbon **acetyl group** (CH_3CO) bound to coenzyme A.

This sets the stage for a sequence of enzymatic reactions called the **citric acid cycle**. This cycle is also known as the *tricarboxylic* (trī-kar-bok-SIL-ik) *acid cycle* (TCA cycle) and the *Krebs cycle*. Because citric acid is the first substrate of the cycle, we will use citric acid cycle as the preferred term. The function of the citric acid cycle is to remove hydrogen atoms from organic molecules and transfer them to coenzymes. The overall pattern of the citric acid cycle is shown in Figure 25–3. (At physiological pH, the organic acids exist in their dissociated, ionized form.)

At the start of the citric acid cycle, the 2-carbon acetyl group carried by CoA is transferred to a 4-carbon oxaloacetate molecule to make the 6-carbon compound citric acid (citrate). Coenzyme A is released intact and can thus bind another acetyl group. A complete revolution or "turn" of the citric acid cycle removes 2 carbon atoms, regenerating the 4-carbon chain. (This is why the reaction sequence is called a *cycle*.) In the citric acid cycle, the coenzymes NAD and FAD remove hydrogen atoms from organic molecules, becoming reduced to NADH and $FADH_2$, respectively. We can summarize the fate of the atoms in the acetyl group as follows:

- The 2 carbon atoms are removed in enzymatic reactions that incorporate 4 oxygen atoms and form 2 molecules of carbon dioxide, a waste product.
- The hydrogen atoms are removed by the coenzymes NAD or FAD (see Figure 25–3).

Several of the steps in a turn of the citric acid cycle involve more than one reaction and require more than one enzyme. Water molecules are tied up in two of those steps. We can summarize the entire sequence as follows:

$$CH_3CO - CoA + 3NAD + FAD + GDP + P_i + 2H_2O \longrightarrow CoA + 2CO_2 + 3NADH + FADH_2 + 2H^+ + GTP$$

The only immediate energy benefit of one turn of the citric acid cycle is the formation of a single molecule of GTP (*guanosine triphosphate*) from GDP (*guanosine diphosphate*) and P_i. In practical terms, GTP is the equivalent of ATP, because GTP readily transfers a phosphate group to ADP, producing ATP:

$$GTP + ADP \longrightarrow GDP + ATP$$

The formation of GTP from GDP in the citric acid cycle is an example of **substrate-level phosphorylation**. In this process, an enzyme uses the energy released by a chemical reaction to transfer a phosphate group to a suitable acceptor molecule. GTP is formed in the citric acid cycle, but many reaction pathways in the cytosol phosphorylate ADP and form ATP directly. For example, the ATP produced during glycolysis is generated through substrate-level phosphorylation. Normally, however, substrate-level phosphorylation provides a relatively small amount of energy compared with *oxidative phosphorylation*, which we discuss next.

Oxidative Phosphorylation and the Generation of ATP

Oxidative phosphorylation is the generation of ATP as the result of the transfer of electrons from the coenzymes NADH and $FADH_2$ to oxygen by a sequence of electron carriers within mitochondria. The process produces more than 90 percent of the ATP used by body cells. The basis of oxidative phosphorylation is the formation of water, a very simple reaction:

$$2H_2 + O_2 \longrightarrow 2H_2O$$

Cells can easily obtain the ingredients for this reaction. Hydrogen is a component of all organic molecules, and oxygen is an atmospheric gas. The only problem is that the reaction releases a tremendous amount of energy all at once. In fact, this reaction releases so much energy that it is used to launch space shuttles into orbit. Cells cannot handle energy explosions. Instead, energy release must be gradual, as it is in oxidative phosphorylation. This powerful reaction proceeds in a series of small, enzymatically controlled oxidation–reduction reactions. These key reactions take place in the electron transport chain, a series of integral and peripheral protein complexes in the inner mitochondrial membrane. Under these controlled conditions, energy can be captured safely, and ATP generated.

Electron Transport Chain. The **electron transport chain (ETC)** is embedded in the inner mitochondrial membrane (Spotlight Figure 25–4). The ETC consists of four respiratory protein complexes, coenzyme Q, and electron carriers made up of a series of **cytochrome** (SĪ-tō-krōm; *cyto-*, cell + *chroma*, color) molecules (*b*, *c*, *a*, and a_3). Each cytochrome has two parts: a protein and a pigment. The protein is embedded in the inner membrane of a mitochondrion. The protein surrounds the pigment portion, which contains a metal ion, either iron (Fe^{3+}) or copper (Cu^{2+}).

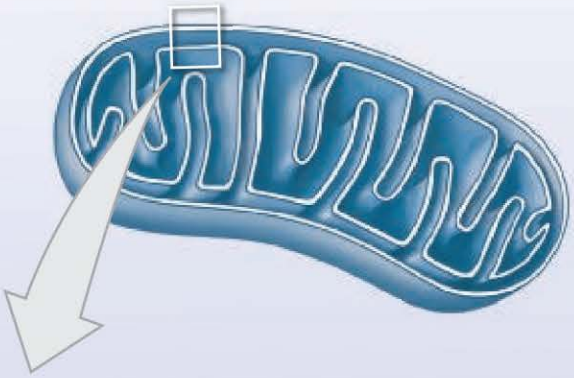
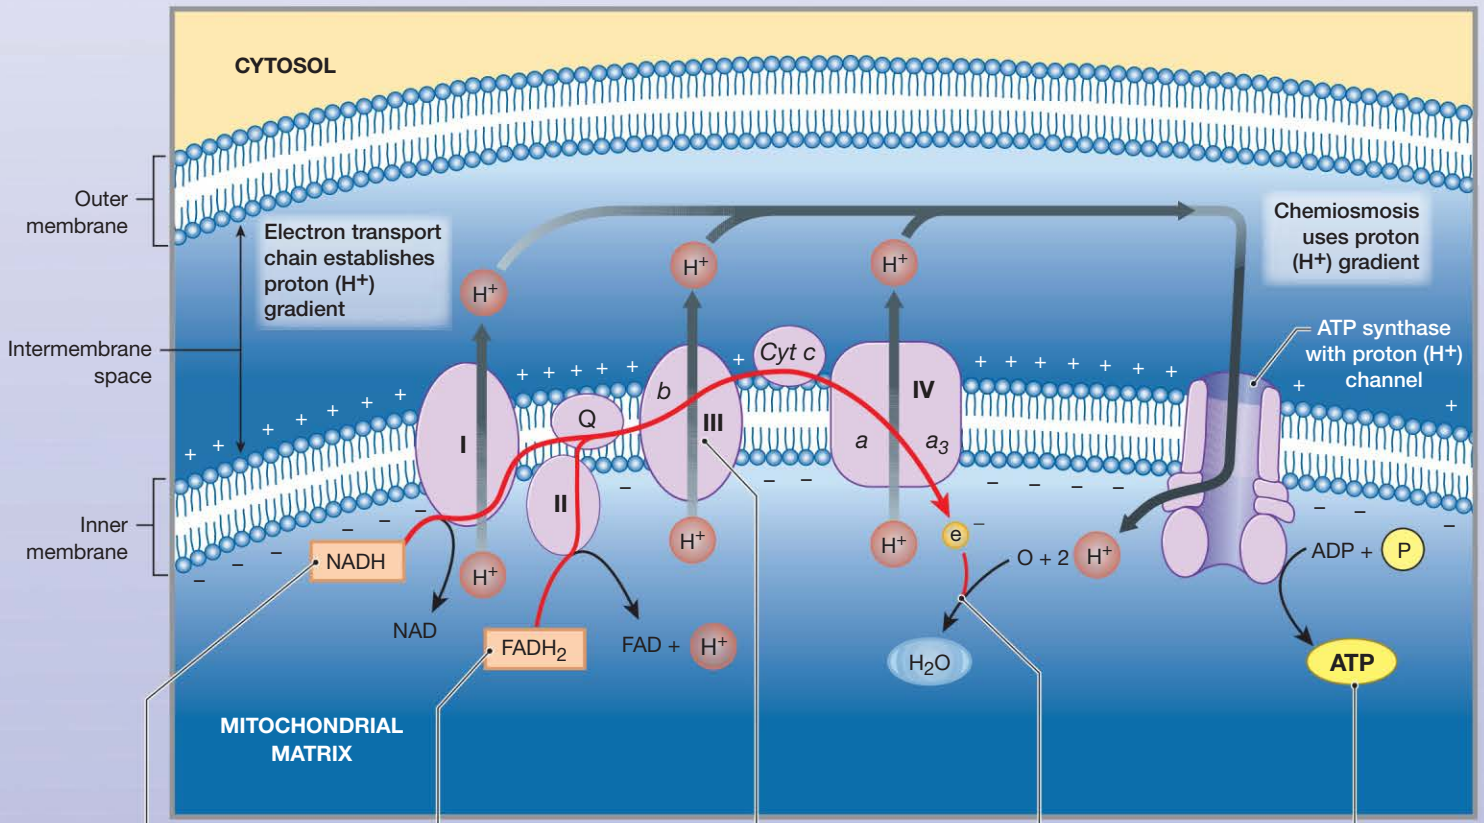
SPOTLIGHT

Figure 25–4
The Electron Transport Chain and ATP Formation

The final step in aerobic ATP production involves the indirect transfer of energy from the high-energy electrons carried by NADH and $FADH_2$ to ATP molecules. This energy transfer involves the electron transport chain and chemiosmosis along the inner mitochondrial membrane.



The electron transport chain consists of four respiratory complexes (I–IV), coenzyme Q, and cytochrome molecules (*b*, *c*, *a*, and a_3). Except for cytochrome c (*Cyt c*), these molecules are associated with respiratory complexes III and IV. The hydrogen atoms delivered by NADH and $FADH_2$ are first split into electrons (e^-) and protons (H^+). The high-energy electrons are passed along by redox reactions, such that their energy is released in a series of small steps. This energy is used to pump H^+ into the intermembrane space. The result is a proton (H^+) electrochemical gradient across the inner membrane. Chemiosmosis uses this proton (H^+) gradient to generate ATP through ATP synthase. The red line with the arrowhead indicates the paths and destination of the electrons.



1 The electrons from NADH pass from respiratory complex I to coenzyme Q. The energy released by the electrons is used to pump protons (H^+) from the matrix into the intermembrane space.

2 The electrons from $FADH_2$ are transferred to respiratory complex II and then directly to coenzyme Q.

3 The electrons are transferred from coenzyme Q to respiratory complex III. More electron energy is released and used to pump H^+ into the intermembrane space.

4 The electrons transferred to respiratory complex IV release their remaining energy to pump H^+ into the intermembrane space. The electrons are released into the matrix and combine with oxygen and H^+ to form water molecules.

5 H^+ pass through hydrogen ion channels into the matrix. Their movement provides the energy for the ATP synthase complex to combine ADP and P into ATP.

The Process of Oxidative Phosphorylation. During the citric acid cycle, hydrogen atoms are passed to the coenzymes NAD and FAD. The hydrogen atoms from the citric acid cycle do not enter the ETC intact. Only the electrons (which carry the energy) enter the electron transport chain. The protons (H^+) that accompany them are released into the mitochondrial matrix. The electrons, which carry the chemical energy, enter a sequence of oxidation–reduction reactions in the electron transport chain. This sequence ends with the transfer of electrons to oxygen and the formation of a water molecule. The electrons that travel along the electron transport chain release energy as they pass from **coenzyme Q** and along the series of cytochrome molecules. That energy is used to *indirectly* support the synthesis of ATP from ADP.

The red lines in **Spotlight Figure 25–4** show the paths and destinations of electrons. Those from NADH are transferred from respiratory protein complex I to coenzyme Q (*ubiquinone*). The electrons from $FADH_2$ enter the ETC at respiratory protein complex II and are passed to coenzyme Q. As a result, the electrons carried by NADH enter the ETC at a higher energy level than those carried by $FADH_2$. The electrons from both paths are passed from coenzyme Q to respiratory protein complex III, which contains cytochrome *b*. From there, the electrons are shuttled by cytochrome *c* to additional cytochromes within respiratory protein complex IV.

Notice that this reaction sequence starts with the removal of 2 hydrogen atoms from a substrate molecule and ends with the formation of water from 2 hydrogen ions and 1 oxygen ion. This is the reaction we described earlier as releasing too much energy if performed in a single step. However, because the reaction takes place in a series of small steps, the hydrogen and oxygen combine safely rather than explosively.

ATP Generation by Chemiosmosis. As we noted in Chapter 3, concentration gradients across membranes represent a form of potential energy that can be harnessed by the cell. The electron transport chain does not produce ATP directly. Instead, it creates the conditions necessary for ATP production. It creates a steep concentration gradient across the inner mitochondrial membrane. The electrons that travel along the electron transport chain release energy as they pass from coenzyme to cytochrome and from cytochrome to cytochrome. The energy released at each of several steps drives proton, or hydrogen ion, pumps. These pumps move hydrogen ions from the mitochondrial matrix into the intermembrane space between the inner and outer mitochondrial membranes. The pumps create a large electrochemical gradient for hydrogen ions across the inner membrane. This electrochemical gradient provides the energy to convert ADP to ATP.

Despite the electrochemical gradient, hydrogen ions cannot diffuse into the matrix because they are not lipid soluble. However, hydrogen ion channels in the inner membrane permit H^+ to diffuse into the matrix. These ion channels and their attached *coupling factors* make up a protein complex called **ATP synthase**. The kinetic energy of passing hydrogen ions generates ATP in a process known as **chemiosmosis** (kem-ē-oz-MŌ-sis), or *chemiosmotic phosphorylation*.

Spotlight Figure 25–4 diagrams the mechanism of ATP generation by chemiosmosis. Hydrogen ions are pumped into the intermembrane space at three places: (1) as respiratory complex I reduces coenzyme Q, (2) as cytochrome *b* reduces cytochrome *c*, and (3) as electrons are passed from cytochrome *a* to cytochrome a_3. For each pair of electrons removed from a substrate in the citric acid cycle by NAD, 6 hydrogen ions are pumped across the inner membrane of the mitochondrion and into the intermembrane space. Their reentry into the matrix provides the energy to generate 2.5 molecules of ATP. Alternatively, for each pair of electrons removed from a substrate in the citric acid cycle by FAD, 4 hydrogen ions are pumped across the inner membrane and into the intermembrane space. Their reentry into the matrix provides the energy to generate 1.5 molecules of ATP.

The Importance of Oxidative Phosphorylation. Oxidative phosphorylation is the most important cellular mechanism for generating ATP. It provides roughly 95 percent of the ATP needed to keep our cells alive. In most cases, if oxidative phosphorylation slows or stops, the cell dies. If many cells are affected, the individual may die. Oxidative phosphorylation requires both oxygen and electrons. For this reason, the rate of ATP generation is limited by the availability of either oxygen or electrons.

Cells obtain oxygen by diffusion from the extracellular fluid. If the supply of oxygen is cut off, mitochondrial ATP production stops, because reduced cytochrome a_3 will have no acceptor for its electrons. With the last reaction stopped, the entire ETC comes to a halt, like cars at a washed-out bridge. Oxidative phosphorylation can no longer take place, and cells quickly succumb to energy starvation. Because neurons have a high demand for energy, the brain is one of the first organs to be affected.

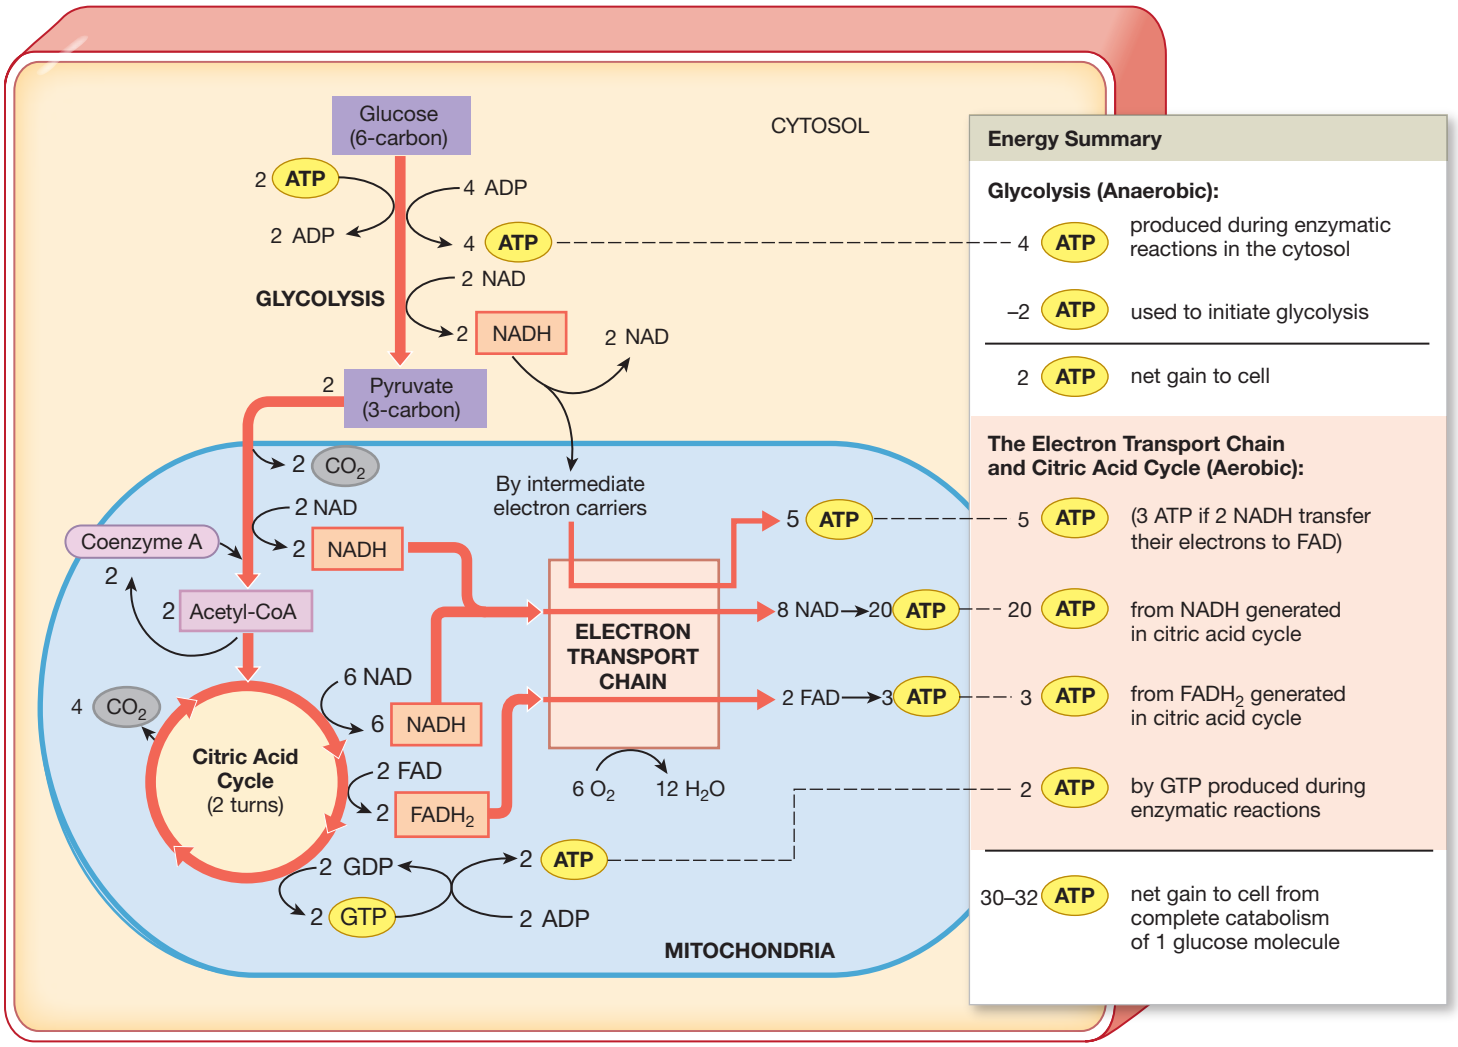
Hydrogen cyanide gas is sometimes used as a pesticide to kill rats or mice. In some states where capital punishment is legal, it is used to execute criminals. The cyanide ion (CN^-) binds to iron atoms in cytochrome a_3 and prevents the transfer of electrons to oxygen. As a result, cells die from energy starvation.

Glucose Catabolism: Energy Yield of Glycolysis and Aerobic Metabolism

For most cells, the main method of generating ATP is the complete reaction pathway that begins with glucose and ends with carbon dioxide and water. **Figure 25–5** summarizes the process in terms of energy production:

- *Glycolysis.* During glycolysis, the cell gains a net 2 molecules of ATP for each glucose molecule broken down anaerobically to 2 molecules of pyruvate. Two molecules of NADH are also produced. In most cells, electrons are passed from NADH to FAD by an intermediate electron carrier in the intermembrane space, producing $FADH_2$, and then to the electron transport chain.

Figure 25–5 A Summary of the Energy Yield of Glycolysis and Aerobic Metabolism. For each glucose molecule broken down by glycolysis, only 2 molecules of ATP (net) are produced. However, glycolysis, the formation of acetyl-CoA, and the citric acid cycle all yield molecules of reduced coenzymes (NADH or $FADH_2$). Many additional ATP molecules are produced when electrons from these coenzymes pass through the electron transport chain. In most cells, the 2 NADH molecules produced in glycolysis provide another 3–5 ATP molecules. The 8 NADH molecules produced in the mitochondria yield 20 ATP molecules, for a total of 23–25. Another 3 ATP molecules are gained from the 2 $FADH_2$ molecules generated in the mitochondria. The citric acid cycle generates an additional 2 ATP molecules in the form of GTP.



? The energy produced from aerobic metabolism comes from what two sources?

- *The Citric Acid Cycle.* Each of the two revolutions of the citric acid cycle required to break down the 2 pyruvate molecules completely yields 1 molecule of ATP by way of GTP. This cycling provides an additional gain of 2 molecules of ATP. This cycle also transfers hydrogen atoms to NADH and $FADH_2$. These coenzymes provide electrons to the electron transport chain.
- *The Electron Transport Chain.* For each molecule of glucose broken down, a total of 10 NADH and 2 $FADH_2$ deliver their high-energy electrons to the electron transport chain. Each NADH yields 2.5 ATP and each $FADH_2$ yields 1.5 ATP. The 2 $FADH_2$ molecules from glycolysis yield 3 ATP molecules and 2 water molecules. Each of the 8 molecules of NADH from the citric acid cycle yields 2.5 molecules of ATP and 1 water molecule. Thus, the shuffling from the citric acid cycle to the ETC yields 23 molecules of ATP.

Summing up, for each glucose molecule processed, the cell gains 30–32 molecules of ATP: 2 from glycolysis, 3–5 from the NADH generated in glycolysis, 2 from the citric acid cycle

(by means of GTP), and 23 from the electron transport chain. All but 2 of them are produced in the mitochondria.

Cardiac muscle cells and liver cells are able to gain an additional 2 ATP molecules for each glucose molecule broken down. They do so by increasing the energy yield from the 2 NADH generated during glycolysis. Although the NADH produced during glycolysis does not enter mitochondria in these cells, each NADH molecule passes its electrons to an intermediate molecule that can cross the mitochondrial membrane. Inside the matrix, NAD strips electrons from the intermediate molecule, forming NADH. The subsequent transfer of electrons to the electron transport chain results in the production of 5 ATP molecules, just as if the 2 NADH molecules formed during glycolysis had been generated in the citric acid cycle.

Glucose Anabolism: Gluconeogenesis

Some of the steps in the breakdown of glucose, or glycolysis, are essentially irreversible. For this reason, cells cannot generate glucose simply by using the same enzymes and reversing the steps of glycolysis. Glycolysis and the production of glucose, called *gluconeogenesis*, involve different sets of regulatory enzymes. As a result, the two processes are regulated independently.

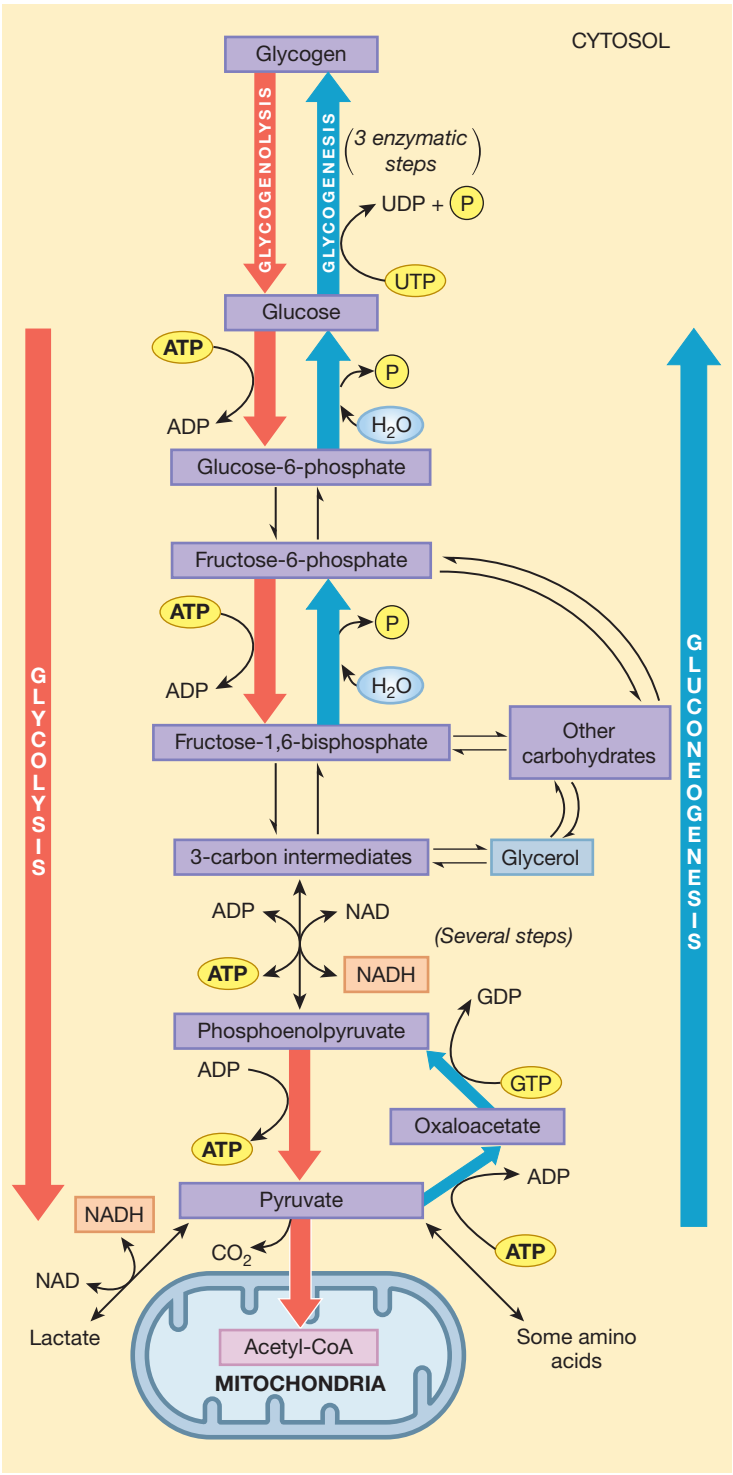
When too little glucose is available, liver cells can form glucose from noncarbohydrate molecules in a process known as **gluconeogenesis** (glū-kō-nē-ō-JEN-eh-sis). Fatty acids and other amino acids cannot be used for gluconeogenesis, because their catabolic pathways produce acetyl-CoA. Cells cannot use acetyl-CoA to make glucose, because the decarboxylation step (removal of CO_2) between pyruvate and acetyl-CoA cannot be reversed. So, some 3-carbon molecules other than pyruvate are used to synthesize glucose.

Glycogenesis and Glycogenolysis

Glucose molecules formed by gluconeogenesis can be used to manufacture other simple sugars, complex carbohydrates, proteoglycans, or nucleic acids. In the liver and in skeletal muscle, glucose molecules are stored as **glycogen**. Glycogen is an important energy reserve that can be broken down when the cell cannot obtain enough glucose from interstitial fluid. Glycogen molecules are large, but glycogen reserves take up very little space because they form compact, insoluble granules.

When the amount of available glucose exceeds cellular needs, cells can form glycogen from excess glucose in a process known as **glycogenesis** (glī-kō-JEN-e-sis). It involves several steps and requires the high-energy compound *uridine triphosphate (UTP)*. The breakdown of glycogen to monomers of glucose is called **glycogenolysis** (glī-kō-je-NOL-i-sis). It takes place quickly and involves a single enzymatic step (Figure 25–6).

Figure 25–6 Glycolysis and Gluconeogenesis. Many of the reactions are freely reversible, but separate regulatory enzymes control the key steps, which are indicated by colored arrows. Some amino acids, carbohydrates, lactate, and glycerol can be converted to glucose. The enzymatic reaction that converts pyruvate to acetyl-CoA cannot be reversed.



+ Clinical Note Carbohydrate Loading

Eating carbohydrates just before exercise does not improve your performance. In fact, it can decrease your endurance by slowing the mobilization of existing energy reserves. Runners or swimmers preparing for lengthy endurance events, such as a marathon or 5K swim, do not eat immediately before participating. For 2 hours before the event, they also limit their intake to just drinking water.

However, performance in endurance sports improves if muscles have large stores of glycogen. Endurance athletes try to build these stores by eating carbohydrate-rich diets for 3 days before competing. This practice is called *carbohydrate loading*. Studies in Sweden, Australia, and South Africa have recently shown that attempts to deplete stores by exercising to exhaustion before carbohydrate loading, a practice called *carbohydrate depletion/loading*, are less effective than 3 days of rest or minimal exercise during carbohydrate loading. The less intense approach improves mood and reduces the risks of muscle and kidney damage.

Tips & Tools

To make several similar-sounding terms easier to tell apart, learn these word parts: *genesis* means "the formation of," *lysis* means "a loosening," *glyco* and *gluco* refer to glucose, and *neo* means "new." So, ***gluconeogenesis*** is the formation of new glucose, ***glycogenesis*** is the formation of glycogen (the storage form of glucose), ***glycogenolysis*** is the breakdown of glycogen to glucose, and ***glycolysis*** is the breakdown of glucose to pyruvate.

25-3 Lipid metabolism provides long-term storage and release of energy

Learning Outcome Describe the pathways involved in lipid metabolism, and summarize the mechanisms of lipid transport and distribution.

Like carbohydrates, lipid molecules contain carbon, hydrogen, and oxygen, but the atoms are present in different proportions. **Triglycerides** are the most abundant lipid in the body, so our discussion focuses on pathways for triglyceride breakdown and synthesis (see Figure 25–1).

Lipid Catabolism: Lipolysis

Lipid metabolism involves the breakdown of fats into glycerol, fatty acids, and monoglycerides. During lipid catabolism, or **lipolysis**, lipids are broken down into pieces that can be either converted to pyruvate or channeled directly into the citric acid cycle (Figure 25–7). A triglyceride is split into its component parts by hydrolysis, yielding 1 molecule of glycerol and 3 fatty acid molecules. This catabolism occurs under the influence of growth hormone and thyroid hormone.

Conversion of Glycerol

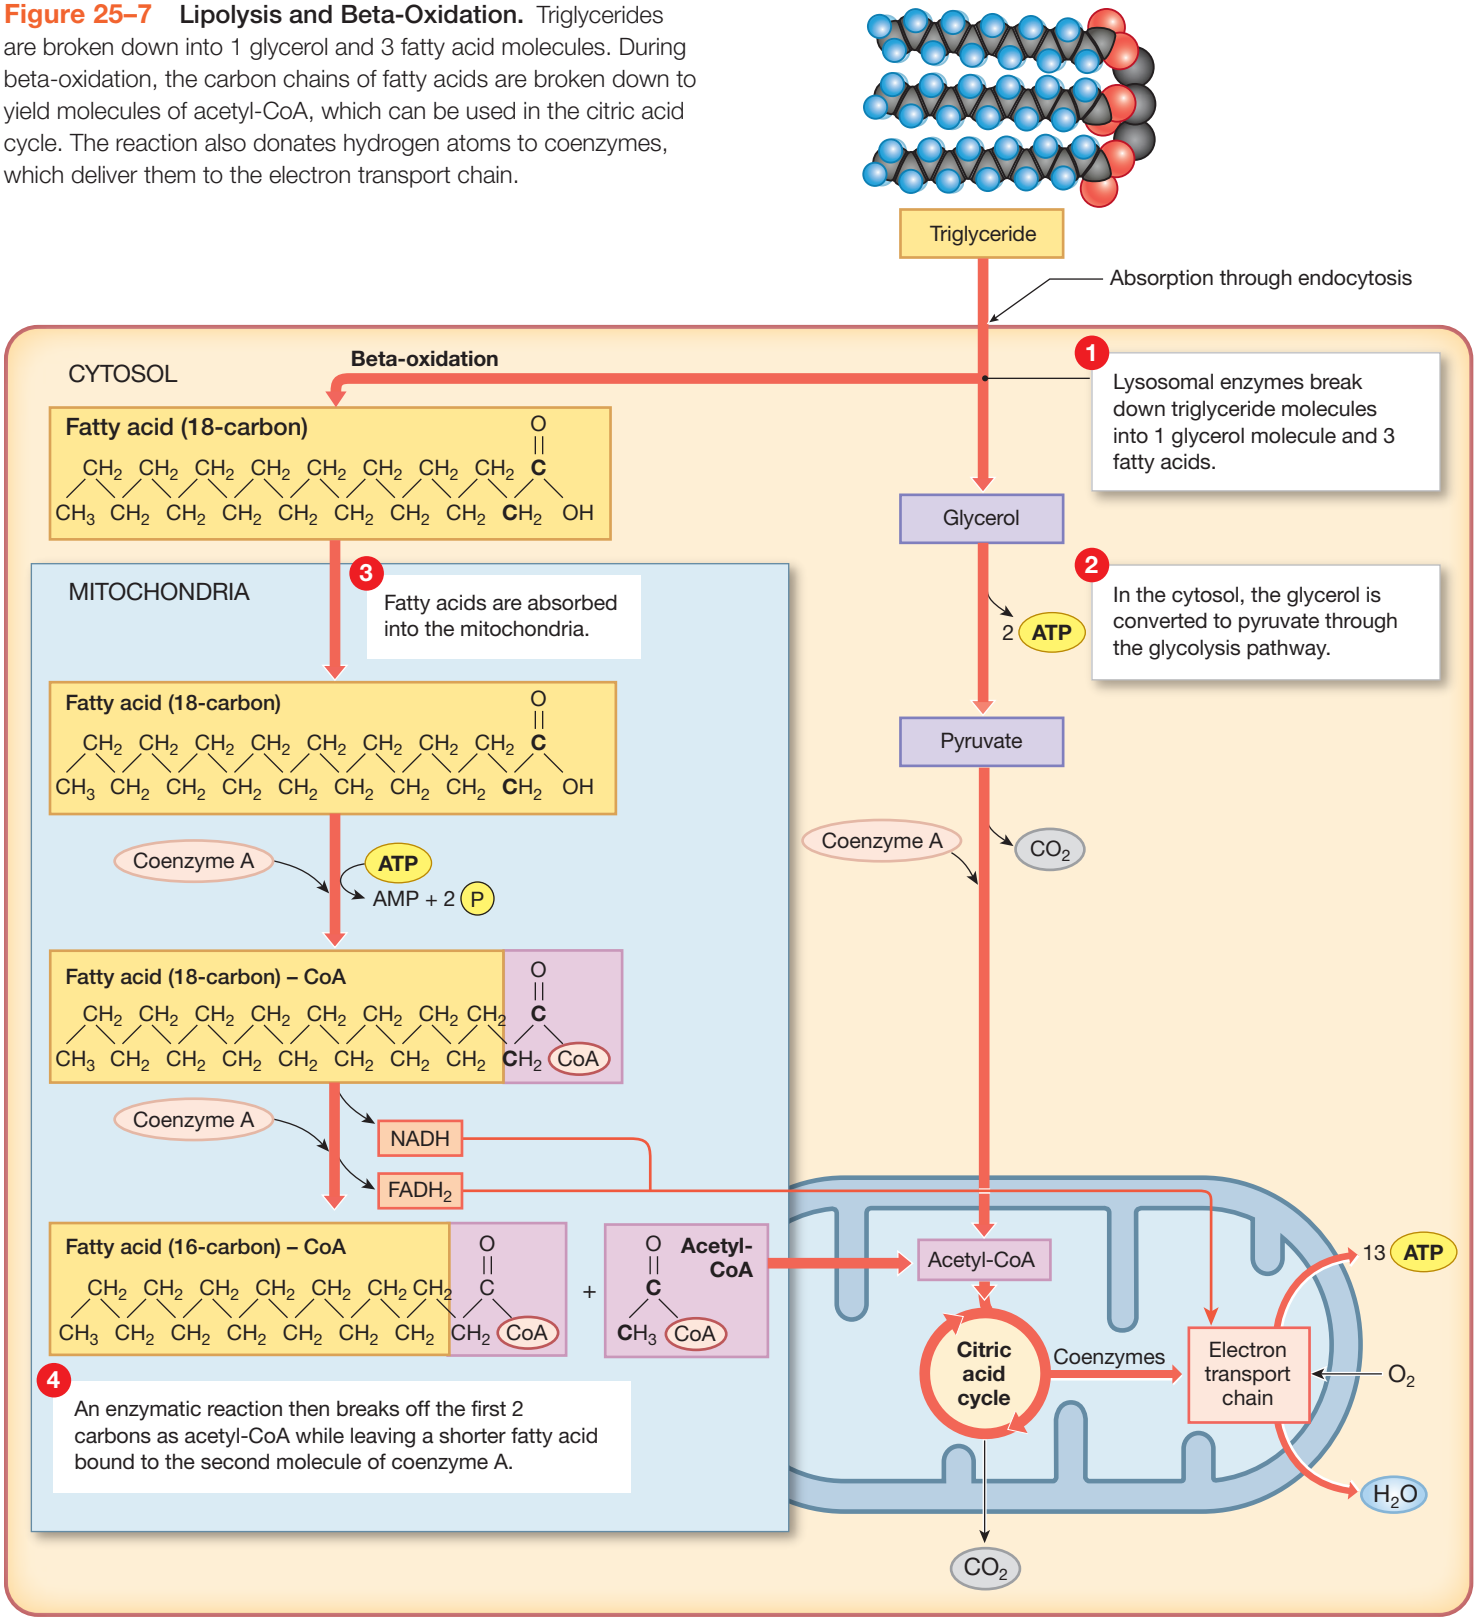
Enzymes in the cytosol convert glycerol to pyruvate. Assuming the presence of sufficient oxygen, the pyruvate is converted to acetyl-CoA and then enters the citric acid cycle.

Beta-Oxidation of Fatty Acids

The catabolism of fatty acids involves a process that generates acetyl-CoA directly. In the process of **beta-oxidation**, fatty acid molecules are broken down in a sequence of reactions into 2-carbon acetic acid fragments, and FAD and NAD^+ are reduced. Figure 25–7 diagrams one step in the process of beta-oxidation. Each step generates molecules of acetyl-CoA, NADH, and $FADH_2$, and leaves a shorter carbon chain bound to coenzyme A. This process takes place inside mitochondria, so the acetyl-CoA produced can enter the citric acid cycle immediately.

Beta-oxidation has substantial energy benefits. For example, 9 acetyl-CoA can be produced from one 18-carbon fatty acid. During the creation of an acetyl-CoA from a fatty acid, 1 NADH and 1 $FADH_2$ result. For an 18-carbon fatty acid, eight steps of beta-oxidation result in 9 acetyl-CoA and the formation of 8 NADH and 8 $FADH_2$. The breakdown of one acetyl-CoA yields 3 NADH, 1 GTP/ATP, and 1 $FADH_2$ in the citric acid cycle. So, the breakdown of 9 acetyl-CoA yields 27 NADH, 9 GTP/ATP, and 9 $FADH_2$. Recall that each NADH produces 2.5 ATP and each $FADH_2$ produces 1.5 ATP. The 35 NADH and 17 $FADH_2$ produce 113 ATP. Adding the 9 GTP/ATP makes a total of 122 ATP. Although one 1 ATP was required for activation, it counts as 2 ATP, because the result was an AMP, not an ADP. The cell can therefore gain 120 ATP molecules from the breakdown of one 18-carbon fatty acid molecule. By comparison, this yield of ATP molecules is almost 1.3 times the energy obtained by the complete breakdown of three 6-carbon glucose molecules (90–96 ATP). The catabolism of other lipids follows similar patterns, generally ending with the formation of acetyl-CoA.

Figure 25–7 Lipolysis and Beta-Oxidation. Triglycerides are broken down into 1 glycerol and 3 fatty acid molecules. During beta-oxidation, the carbon chains of fatty acids are broken down to yield molecules of acetyl-CoA, which can be used in the citric acid cycle. The reaction also donates hydrogen atoms to coenzymes, which deliver them to the electron transport chain.



? Where does beta-oxidation take place?

Lipid Anabolism: Lipogenesis

Lipogenesis (lip-ō-JEN-e-sis) is the synthesis of lipids (see Figure 25–1). It is stimulated by a diet high in carbohydrates and several hormones, including insulin. Glycerol is synthesized from *dihydroxyacetone phosphate*, one of the 3-carbon intermediate products shared by the pathways of glycolysis and gluconeogenesis. The synthesis of most types of lipids, including nonessential fatty acids and steroids, begins with acetyl-CoA. Lipogenesis can use almost any organic substrate, because lipids, amino acids, and carbohydrates can be converted to acetyl-CoA. In other words, the body can turn just about anything we eat into fat.

Fatty acid synthesis involves a reaction sequence quite distinct from that of beta-oxidation. Body cells cannot *build* every fatty acid they can break down. For example, **linoleic acid** and **linolenic acid** are both 18-carbon unsaturated fatty acids synthesized by plants. They cannot be synthesized in the human body. They are considered **essential fatty acids**, because they must be included in your diet. These fatty acids are also needed to synthesize prostaglandins and some of the phospholipids in plasma membranes throughout the body.

Lipid Storage and Energy Release

Lipids are important energy reserves because their breakdown provides large amounts of ATP. Lipids can be stored in compact droplets in the cytosol because they are insoluble in water. This storage method saves space, but when the lipid droplets are large, it is difficult for water-soluble enzymes to get at them. For this reason, lipid reserves are more difficult to access than carbohydrate reserves. Also, most lipids are processed inside mitochondria, and mitochondrial activity is limited by the availability of oxygen.

The net result is that lipids cannot provide large amounts of ATP quickly. However, cells with modest energy demands can shift to lipid-based energy production when glucose supplies are limited. Skeletal muscle fibers normally cycle between lipid metabolism and carbohydrate metabolism. At rest (when energy demands are low), these cells break down fatty acids. During activity (when energy demands are high and immediate), skeletal muscle fibers shift to glucose metabolism.

Lipid Transport and Distribution

Like glucose, lipids are needed throughout the body. For example, all cells need lipids to maintain their plasma membranes, and important steroid hormones must reach target cells in many different tissues. However, free fatty acids make up only a small percentage of the total circulating lipids. Because most lipids are not soluble in water, special transport mechanisms carry them from one region of the body to another. Most lipids, especially *cholesterol*, circulate through the bloodstream as *lipoproteins* (Figure 25–8).

Free Fatty Acids

Free fatty acids (FFAs) are lipids that can diffuse easily across plasma membranes. In the blood, free fatty acids are generally bound to albumin, the most abundant plasma protein. Sources of free fatty acids in the blood include the following:

- Fatty acids that are not used in the synthesis of triglycerides, but diffuse out of the intestinal epithelium and into the blood
- Fatty acids that diffuse out of lipid reserves (such as those in the liver and adipose tissue) when triglycerides are broken down.

Liver cells, cardiac muscle cells, skeletal muscle fibers, and many other body cells can metabolize free fatty acids. These lipids are an important energy source during periods of starvation, when glucose supplies are limited.

Lipoproteins and Cholesterol

Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and **cholesterol**. A superficial coating of phospholipids and proteins makes the entire complex soluble. Exposed proteins of the complexes bind to specific membrane receptors. For this reason, these membrane proteins determine which cells absorb the associated lipids.

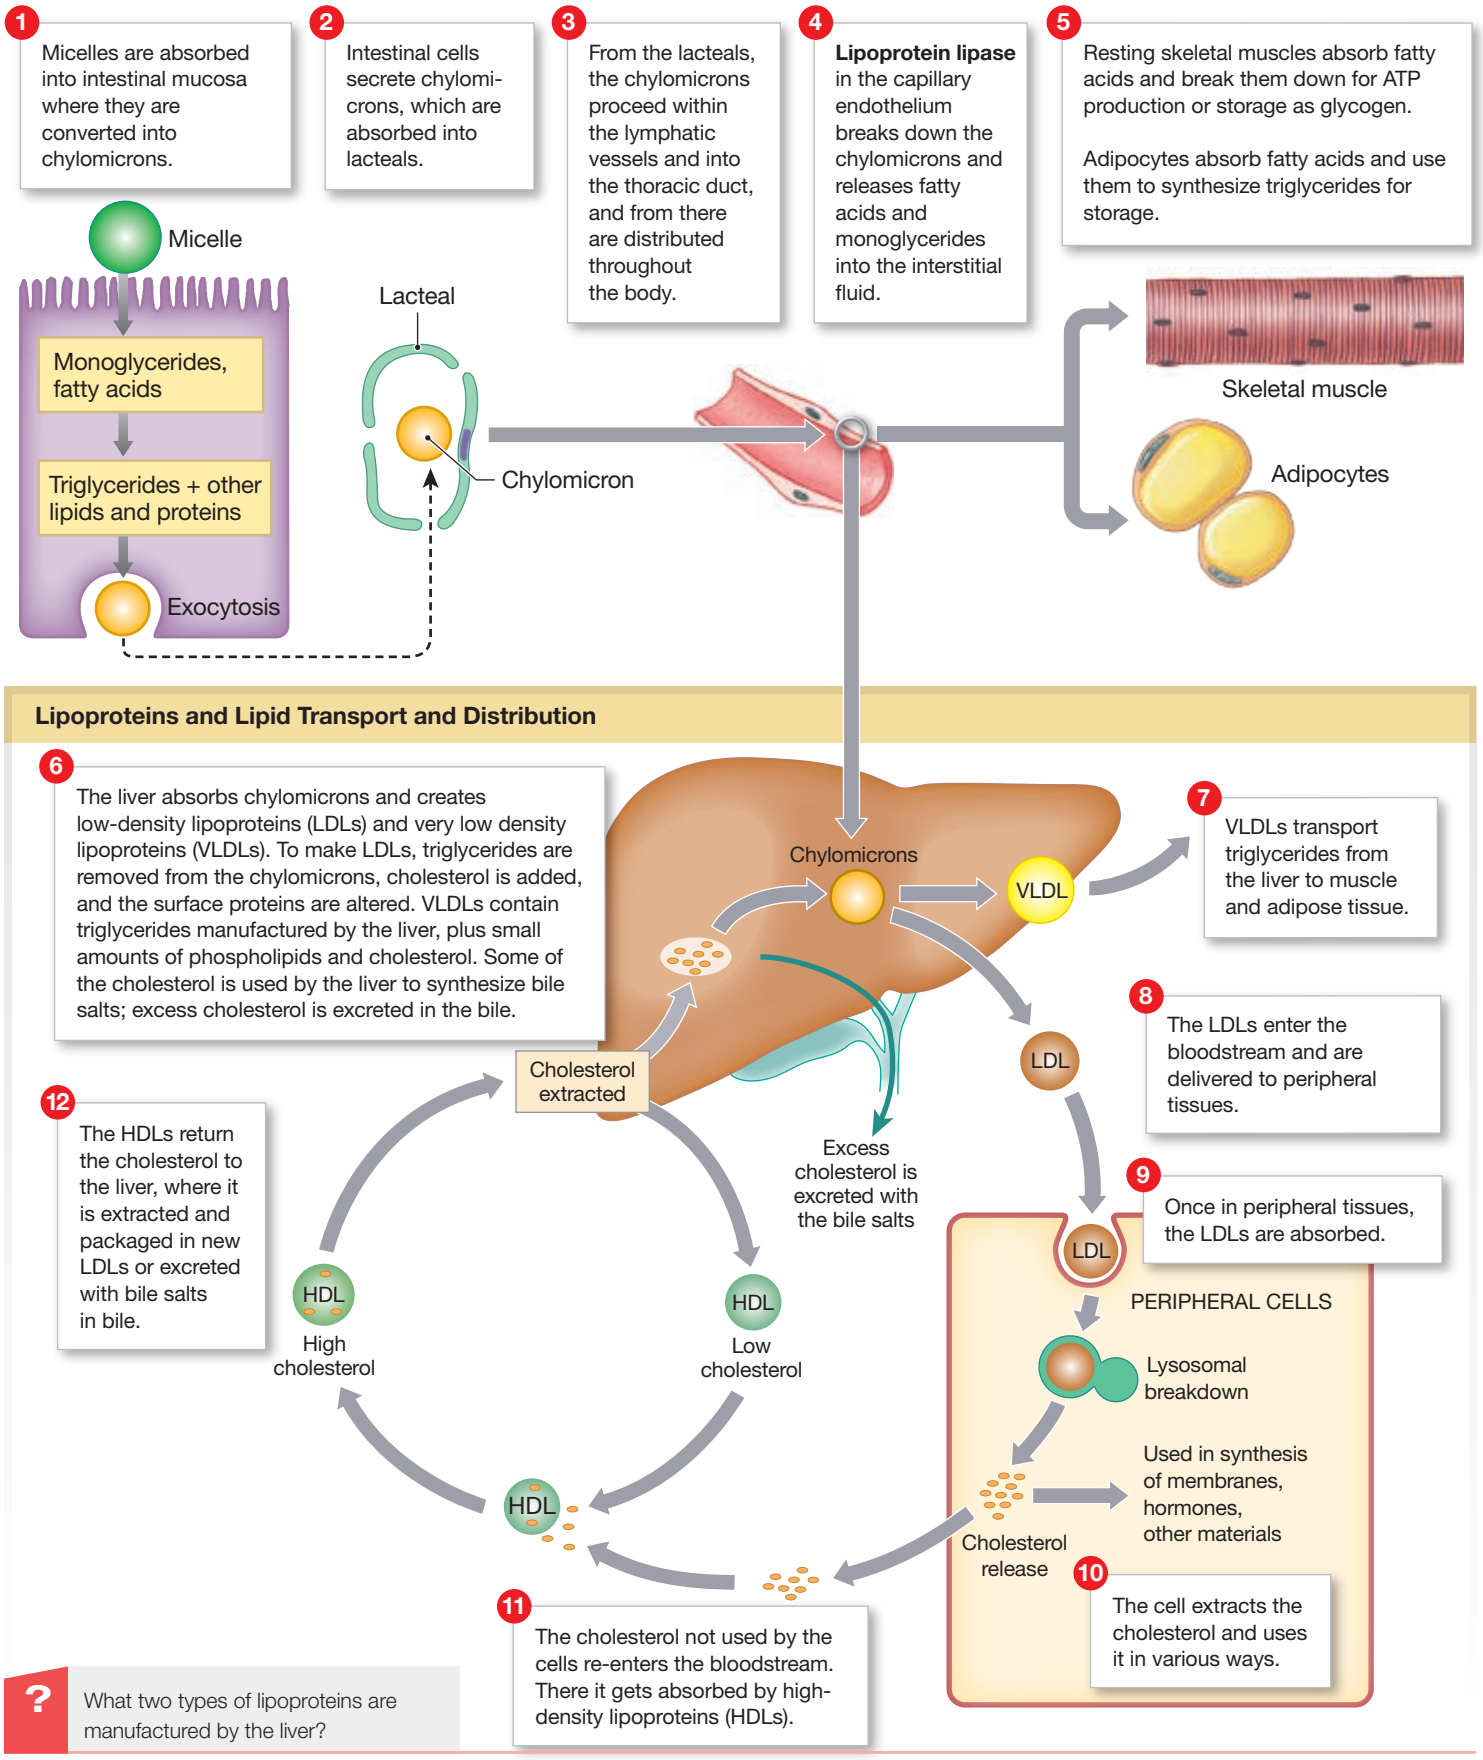
Lipoproteins are usually classified into the following four major groups according to size and the relative proportions of lipid and protein:

- *Chylomicrons.* ***Chylomicrons*** (kī-lō-MĪ-kronz) are the largest lipoproteins, ranging in diameter from 0.03 to 0.5 μm. About 95 percent of the weight of a chylomicron consists of triglycerides. They are produced by intestinal epithelial cells from the fats in food. ↩ p. 916 Chylomicrons carry absorbed lipids from the intestinal tract into the lymph and then to the bloodstream.

The liver is the primary source of all the other groups of lipoproteins, which shuttle lipids among various tissues:

- *Very Low Density Lipoproteins (VLDLs).* Very low density lipoproteins contain triglycerides manufactured by the liver, plus small amounts of phospholipids and cholesterol. The primary function of VLDLs is to transport these triglycerides to skeletal muscles and adipose tissues. The VLDLs range in diameter from 25 to 75 nm (0.025–0.075 μm).
- *Low-Density Lipoproteins (LDLs).* Low-density lipoproteins contain cholesterol, lesser amounts of phospholipids, and very few triglycerides. These lipoproteins are about 25 nm in diameter. They deliver cholesterol to peripheral tissues. LDL cholesterol is often called "bad cholesterol" because the cholesterol may wind up in arterial plaques.
- *High-Density Lipoproteins (HDLs).* **High-density lipoproteins** have roughly equal amounts of lipid and protein. The lipids

Figure 25–8 Lipid Transport and Use.



? What two types of lipoproteins are manufactured by the liver?

Clinical Note Dietary Fats and Cholesterol

Due to concerns about cholesterol, such phrases as "low cholesterol," "contains no cholesterol," and "cholesterol free" are now widely used in food packaging. Cholesterol content alone, however, does not tell the entire story:

- *Cholesterol has many vital functions in the human body.* Cholesterol serves as a waterproofing for the epidermis, a lipid component of all plasma membranes, a key constituent of bile, and the precursor of several hormones (estrogen and testosterone, for example) and vitamin D.
- *The cholesterol content of the diet is not the only source of circulating cholesterol.* The liver can manufacture cholesterol, accounting for about 20 percent of the cholesterol in the bloodstream. The rest comes from metabolism of saturated fats in the diet. If the diet contains an abundance of saturated fats, cholesterol levels in the blood rise because excess lipids are broken down to acetyl-CoA and used to synthesize cholesterol. Consequently, individuals trying to lower serum cholesterol levels through diet must also restrict other lipids, especially saturated fats.
- *Genetic factors affect each individual's cholesterol level.* If you reduce the cholesterol in your diet, your body synthesizes more to maintain cholesterol concentrations in the blood. Because individuals have different genes, their cholesterol levels can vary, even on similar diets. In virtually everyone, however, dietary restrictions can lower blood cholesterol significantly.
- *Cholesterol levels vary with age.* At age 19, males have fasting cholesterol levels (measured 8–12 hours after a meal) below 170 mg/dL, whereas females have levels below 175 mg/dL. As age increases, the cholesterol levels gradually climb. Cholesterol levels are considered unhealthy if they are higher than those of 90 percent of the population in that age group. For males, this level is 185 mg/dL at age 19 and 250 mg/dL at age 70. For females, the comparable levels are 190 mg/dL and 275 mg/dL, respectively.

The *2015-2020 Dietary Guidelines for Americans* recommends that we eat as little dietary cholesterol as possible. Healthy diets typically contain 100–300 mg of cholesterol.

are largely cholesterol and phospholipids. HDLs are about 10 nm in diameter. Their primary function is to transport excess cholesterol from peripheral tissues back to the liver for storage or excretion in the bile. HDL cholesterol is called "good cholesterol" because it is returning from peripheral tissues and does not cause circulatory problems. Actually, applying the terms *good* and *bad* to cholesterol can be misleading, for cholesterol metabolism is complex and variable. (For more details, see the Clinical Note "Dietary Fats and Cholesterol".) **Figure 25–8** also shows the relationship between LDL and HDL lipoproteins and the transport of cholesterol.

Exercise may lower cholesterol by several mechanisms. For example, exercise stimulates enzymes that move LDL from the blood into the liver and exercise increases the size of the protein particles that carry cholesterol in the bloodstream. Recent studies have also shown that vigorous exercise—the equivalent of 20 miles of jogging per week—lowered the LDL level even more than moderate exercise. However, the amount of exercise a person needs to experience the cholesterol-lowering benefit is still uncertain.

Checkpoint

6. **Define *beta-oxidation*.**
7. **Identify the four major groups of lipoproteins.**
8. **Why are high-density lipoproteins (HDLs) considered beneficial to health?**

See the blue Answers tab at the back of the book.

Clinical Note Blood Testing for Fat

When ordering a blood test for cholesterol, most physicians also request information about circulating triglycerides. In fasting individuals, triglycerides are usually found within the range of 40–150 mg/dL. (After a person has consumed a fatty meal, the triglyceride level may be temporarily elevated.)

When cholesterol levels are high, or when an individual has a family history of atherosclerosis or coronary artery disease (CAD), further tests and calculations may be performed. The **HDL** level is measured, and the **LDL** level is calculated as follows:

$$\text{LDL} = \text{cholesterol} - \text{HDL} - \frac{\text{triglycerides}}{5}$$

A high total cholesterol value linked to a high LDL level spells trouble. In effect, too much cholesterol is being exported to peripheral tissues. Problems can also exist in individuals with high total cholesterol—or even normal total cholesterol—but low HDL levels (below 35 mg/dL). In such cases, excess cholesterol delivered to the tissues cannot easily be returned to the liver for excretion. In either event, the amount of cholesterol in peripheral tissues—and especially in arterial walls—is likely to increase.

For years, LDL:HDL ratios were considered valid predictors of the risk of developing atherosclerosis. Risk-factor analysis and the LDL level are now thought to be more accurate indicators. For males with more than one risk factor, many clinicians recommend dietary changes and drug therapy if the LDL level exceeds 130 mg/dL, or even 100 mg/dL, regardless of the total cholesterol or HDL level.

25-4 Protein metabolism provides amino acids and synthesizes proteins

Learning Outcome Summarize the main processes of protein metabolism, and discuss the use of protein as an energy source.

The body can synthesize 100,000 to 140,000 different proteins. They have various functions and structures. Yet, each protein contains some combination of the same 20 **amino acids**. Amino acids enter body cells by active transport, and growth hormone influences the entry of amino acids into cells. The amino acids are synthesized into proteins that function as enzymes, hormones, structural elements, and neurotransmitters. Very little protein is used as an energy source. Let's begin with amino acid catabolism.

Amino Acid Catabolism

Before protein catabolism occurs, proteins must be converted to substances that can enter the citric acid cycle. This conversion involves transamination (removal of an amino group from an amino acid and its transfer to a keto acid), deamination (removal of an amino group), and the urea cycle (producing urea from ammonium ions derived from deamination reactions and carbon dioxide). Amino acids may be converted into glucose, fatty acids, and ketone bodies. The first step in amino acid catabolism is the removal of the amino group ($-NH_2$). This step requires a coenzyme derivative of **vitamin B_6** (*pyridoxine*).

Transamination

Transamination (tranz-am-i-NĀ-shun) is a reversible chemical reaction that transfers the amino group of an amino acid to a **keto acid**. Keto acids resemble amino acids except that the second carbon binds to an oxygen atom rather than to an amino group (Figure 25–9a). This transfer converts the keto acid into an amino acid that can leave the mitochondrion and enter the cytosol. There it can be used for protein synthesis. In the process, the original amino acid becomes a keto acid that can be broken down in the citric acid cycle.

Cells perform transamination in order to synthesize many of the amino acids needed for protein synthesis. For example, cells of the liver, skeletal muscles, heart, lung, kidney, and brain are particularly active in protein synthesis, so they carry out many transamination reactions.

Deamination

Deamination (dē-am-i-NĀ-shun) prepares an amino acid for breakdown in the citric acid cycle (Figure 25–9b). Deamination is the removal of an amino group and a hydrogen atom in a reaction that generates a toxic ammonium ion (NH_4^+). Liver cells are the primary sites of deamination. They also have enzymes that remove ammonium ions by synthesizing **urea**, a fairly harmless water-soluble compound excreted in urine. The **urea cycle** is the reaction sequence that produces urea (Figure 25–9c).

Several inherited metabolic disorders result from an inability to produce specific enzymes involved in amino acid metabolism. For example, individuals with *phenylketonuria* (fen-il-kē-tō-NŪ-rē-uh), or *PKU*, have a defect in the enzyme *phenylalanine hydroxylase*. They cannot convert phenylalanine to tyrosine. This reaction is an essential step in the synthesis of norepinephrine, epinephrine, dopamine, and melanin. If the enzyme is absent, phenylalanine undergoes a transamination and makes phenylpyruvic acid, which can be detected in urine. If PKU is not detected in infancy, phenylalanine and its deaminated products build up and central nervous system development is inhibited. Severe brain damage results. The condition is common enough that a warning is printed on the packaging of products that contain phenylalanine, such as diet drinks.

Amino Acids and ATP Production

When glucose supplies are low and lipid reserves are inadequate, mitochondria can generate ATP by breaking down amino acids in the citric acid cycle. Liver cells break down internal proteins and absorb additional amino acids from the blood (see Figure 25–1). The amino acids are deaminated, and their carbon chains are sent to the mitochondria. Not all amino acids enter the cycle at the same point, however, so the ATP benefits vary. Nonetheless, the average ATP yield per gram is comparable to that of carbohydrate catabolism.

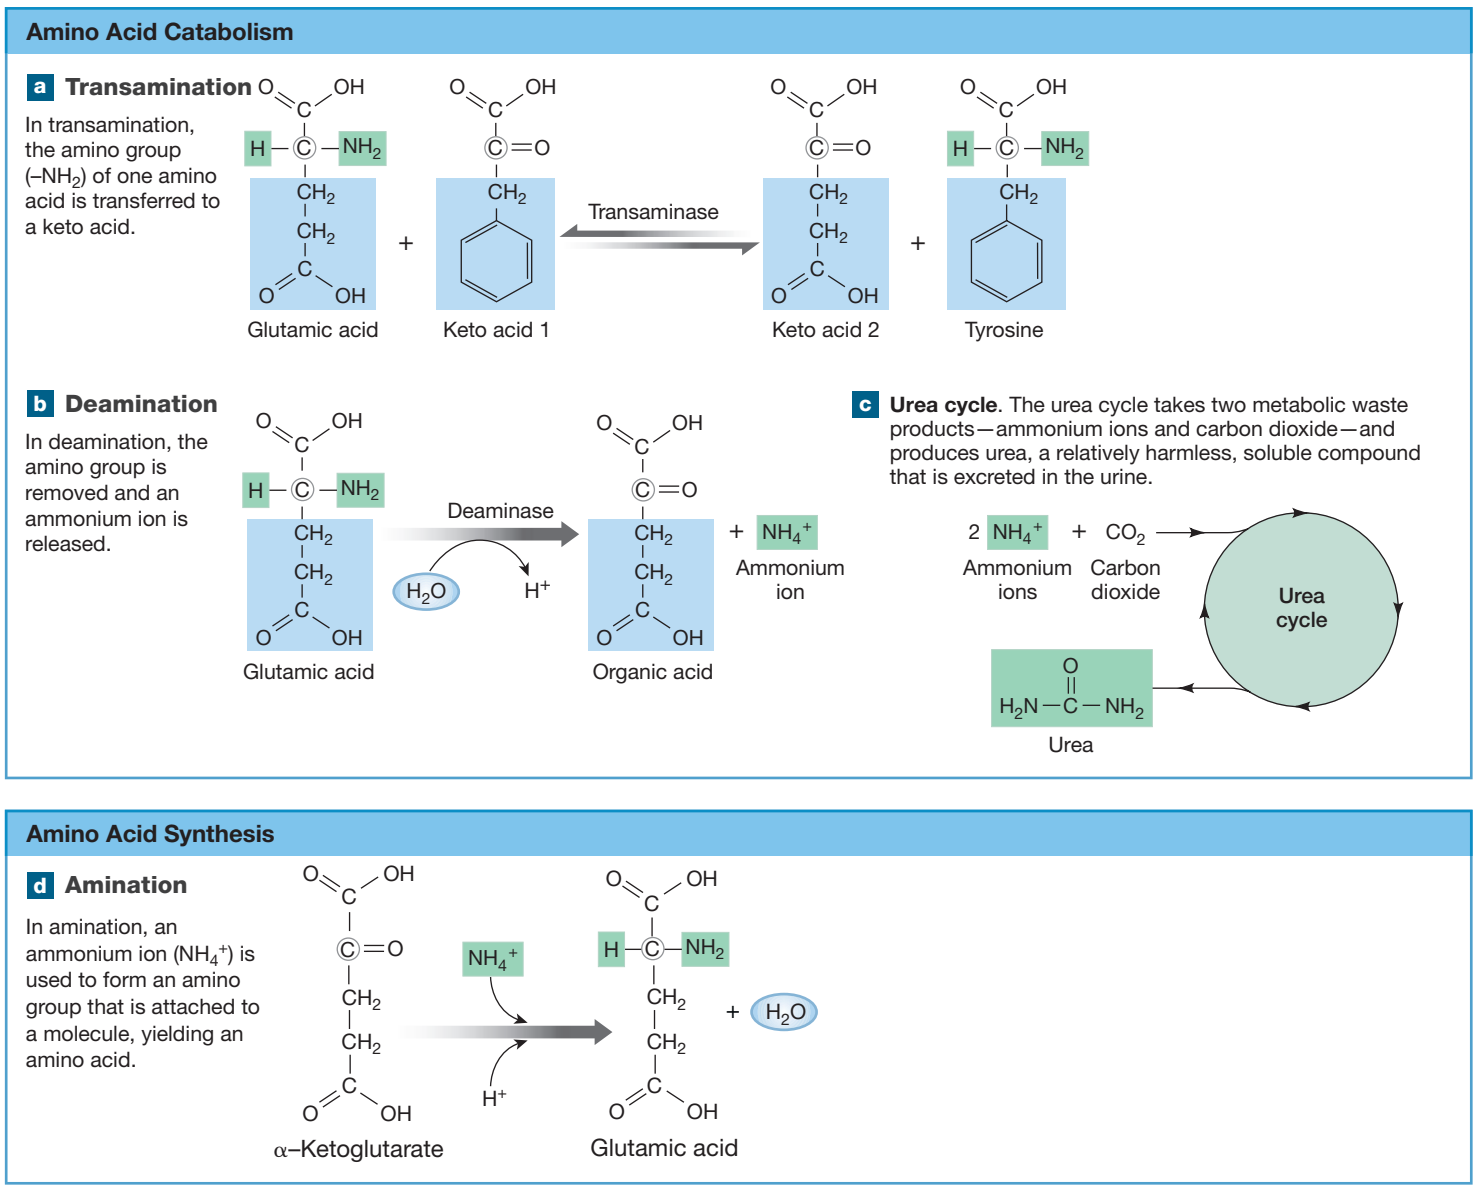
However, three factors make protein catabolism an impractical source of quick energy:

- Proteins are more difficult to break apart than are complex carbohydrates or lipids.
- One of the by-products, ammonium ions, is toxic to cells.
- Proteins form the most important structural and functional components of any cell. Extensive protein catabolism threatens homeostasis at both the cellular and system levels.

Protein Synthesis

We discussed the basic mechanism for protein synthesis in Chapter 3 (look back at Figures 3–12 and 3–13, (↩ pp. 86, 88–89). Your body can synthesize about half of the various amino acids needed to build proteins. There are 10 **essential amino acids**, which must come from the diet. Your body cannot synthesize eight of them (*isoleucine*, *leucine*, *lysine*, *threonine*, *tryptophan*, *phenylalanine*, *valine*, and *methionine*). The other two (*arginine* and *histidine*) can be synthesized, but not in the amounts that growing children need.

Figure 25–9 Amino Acid Catabolism and Synthesis.



Other amino acids are called **nonessential amino acids** because the body can make them on demand. Your body cells can readily synthesize their carbon frameworks. Then an amino group can be added by **amination**—using an ammonium ion as a reactant (Figure 25–9d).

Checkpoint

9. Define *transamination* and *deamination*.
10. How would a diet that is deficient in pyridoxine (vitamin B_6) affect protein metabolism?

See the blue Answers tab at the back of the book.

25-5 The body experiences two patterns of metabolic activity: energy storage in the absorptive state and energy release in the postabsorptive state

Learning Outcome Differentiate between the absorptive and postabsorptive metabolic states, and summarize the characteristics of each.

The nutrient requirements of each tissue vary with the types and quantities of enzymes present in the cytosol of cells. From a metabolic standpoint, we consider the body to have

distinctive components: the liver, adipose tissue, skeletal muscle, nervous tissue, and other peripheral tissues:

- *The Liver.* The liver is the focal point of metabolic regulation and control. Liver cells contain a great diversity of enzymes, so they can break down or synthesize most of the carbohydrates, lipids, and amino acids needed by other body cells. Liver cells have an extensive blood supply, so they are in an excellent position to monitor and adjust the nutrient composition of circulating blood. The liver also contains significant energy reserves in the form of glycogen.
- *Adipose Tissue.* Adipose tissue stores lipids, primarily as triglycerides. Adipocytes are located in many areas: in areolar tissue, in mesenteries, within red and yellow bone marrows, in the epicardium, and around the eyes and the kidneys.
- *Skeletal Muscle.* Skeletal muscle accounts for almost half of a healthy person's body weight. Skeletal muscle fibers maintain substantial glycogen reserves. In addition, if other nutrients are unavailable, their contractile proteins can be broken down and the amino acids used as an energy source.
- *Nervous Tissue.* Nervous tissue has a high demand for energy, but the cells do not maintain reserves of carbohydrates, lipids, or proteins. Neurons must have a reliable supply of glucose, because they are generally unable to metabolize other molecules. If the blood glucose level becomes too low, nervous tissue in the central nervous system cannot continue to function, and the person falls unconscious.
- *Other Peripheral Tissues.* Other peripheral tissues do not maintain large metabolic reserves, but they are able to metabolize glucose, fatty acids, or other substrates. Their preferred source of energy varies according to instructions from the endocrine system.

To understand the interrelationships among these five components, let's consider events over a typical 24-hour period. During this time, the body experiences two broad patterns of metabolic activity: the *absorptive state* and the *postabsorptive state*. In the absorptive state that follows a meal, cells absorb nutrients to be used for growth, maintenance, and energy reserves. Hours later, in the postabsorptive state, metabolic reactions are focused on maintaining the blood glucose level that meets the needs of nervous tissue.

Spotlight Figure 25–10 summarizes the metabolic pathways for lipids, carbohydrates, and proteins. The diagrams show the reactions in a "typical" cell. Note, however, that no one cell can carry out all the anabolic and catabolic operations and interconversions required by the body as a whole. As cells differentiate, each type develops its own set of enzymes. These enzymes determine the cell's metabolic capabilities. In the face of such cellular diversity, homeostasis can be preserved only when the metabolic activities of tissues, organs, and organ systems are coordinated.

25

Tips & Tools

The absorptive state is like harvest time: Food is being gathered and stored. The postabsorptive state corresponds to the time between harvests, when stored food is used for nourishment.

During the postabsorptive state, liver cells conserve glucose and break down lipids and amino acids. Both lipid catabolism and amino acid catabolism generate acetyl-CoA. As the concentration of acetyl-CoA rises, compounds called *ketone bodies* begin to form. A **ketone body** is an organic compound produced by fatty acid metabolism that dissociates in solution, releasing a hydrogen ion. There are three such compounds: (1) **acetoacetate** (as-eh-tō-AS-eh-tāt), (2) **acetone** (AS-eh-tōn), and (3) **betahydroxybutyrate** (bā-tah-hī-droks-ē-BŪ-teh-rāt). Liver cells do not catabolize any of the ketone bodies. Instead, these compounds diffuse through the cytosol and into the general circulation. Cells in peripheral tissues then absorb the ketone bodies and reconvert them to acetyl-CoA for breakdown in the citric acid cycle.

In healthy individuals, the liver continuously produces ketone bodies, but the blood concentration is about 1 mg/dL (normal range 0.3–2.0 mg/dL). Ketone bodies are undetectable by routine urinalysis. During even a brief period of fasting, the increased production of ketone bodies results in *ketosis* (kē-TŌ-sis), a high concentration of ketone bodies in body fluids. The appearance of ketone bodies in the bloodstream—*ketonemia*—lowers blood pH, which must be controlled by buffers. During prolonged starvation, the level of ketone bodies continues to rise. Eventually, buffering capacities are exceeded and a dangerous drop in pH takes place. This acidification of the blood by ketone bodies is called ***ketoacidosis*** (kē-tō-as-ih-DŌ-sis). In severe ketoacidosis, the circulating concentration of ketone bodies can reach 200 mg/dL, and the pH may drop below 7.05. A pH that low can disrupt tissue activities and cause coma, cardiac arrhythmias, and death.

In summary, during the postabsorptive state, the liver acts to stabilize the blood glucose concentration. It does so first by the breakdown of glycogen reserves and later by gluconeogenesis. Over the remainder of the postabsorptive state, the combination of lipid and amino acid catabolism provides the necessary ATP. These processes generate large quantities of ketone bodies that diffuse into the bloodstream. Amino acid catabolism results in the release of toxic ammonium ions, which become tied up in the formation of urea.

Changes in the activity of the liver, adipose tissue, skeletal muscle, and other peripheral tissues ensure a steady supply of glucose to the nervous system. The supply remains steady despite daily or even weekly changes in nutrient availability. Only after a prolonged period of starvation does nervous tissue begin to metabolize ketone bodies and lactate molecules, as well as glucose.

25-6 Adequate nutrition allows normal physiological functioning

Learning Outcome Explain what makes up a balanced diet and why such a diet is important.

The postabsorptive state can be maintained for a considerable period. For homeostasis to be maintained indefinitely, however, the digestive tract must regularly absorb enough fluids, organic nutrients, minerals, and vitamins to keep pace with cellular demands. The absorption of nutrients from food is called **nutrition**.

The body's requirement for each nutrient varies from day to day and from person to person. *Nutritionists* attempt to analyze a diet in terms of its ability to meet the needs of a specific individual. Food supplies the necessary nutrients to ensure normal functions. Absorbed nutrients enter the bloodstream and lymph and are transported to body tissues. When a person is in good health and maintains a healthy diet, energy needs are met by absorbed nutrients. An important healthy diet consideration is *nitrogen balance*. Since proteins contain a great deal of nitrogen, nitrogen balance equals protein balance, or simply, protein anabolism equals protein catabolism. This section discusses the food groups, positive and negative nitrogen balance, and minerals and vitamins.

Food Groups and a Balanced Diet

A **balanced diet** contains all the ingredients needed to maintain homeostasis. Such a diet must include adequate essential amino acids and fatty acids, minerals and vitamins, and substrates for energy generation. In addition, the diet must include enough water to replace losses in urine, feces, and evaporation. A balanced diet prevents **malnutrition**, an unhealthy state resulting from inadequate or excessive absorption of one or more nutrients.

One way of avoiding malnutrition is to consume a balanced diet (Figure 25–11 and Table 25–1). The U.S. Department of Agriculture offers guidelines for healthy eating. In 2015, new dietary guidelines and the new MyPlate, MyWins Healthy Eating Solutions for Everyday Life were established. The color-coded food group slices indicate the proportions of food we should consume from **five food groups**: grains (orange), vegetables (green), fruits (red), dairy products (blue), and protein (purple) (see Figure 25–11). For more information, visit www.choosemyplate.gov/MyWins.

What is most important is that you take in nutrients in sufficient *quantity* (adequate to meet your energy needs) and *quality* (including all nutrients of a balance diet). The key is making intelligent choices about what you eat. Poor choices can lead to malnutrition even if all food groups are represented.

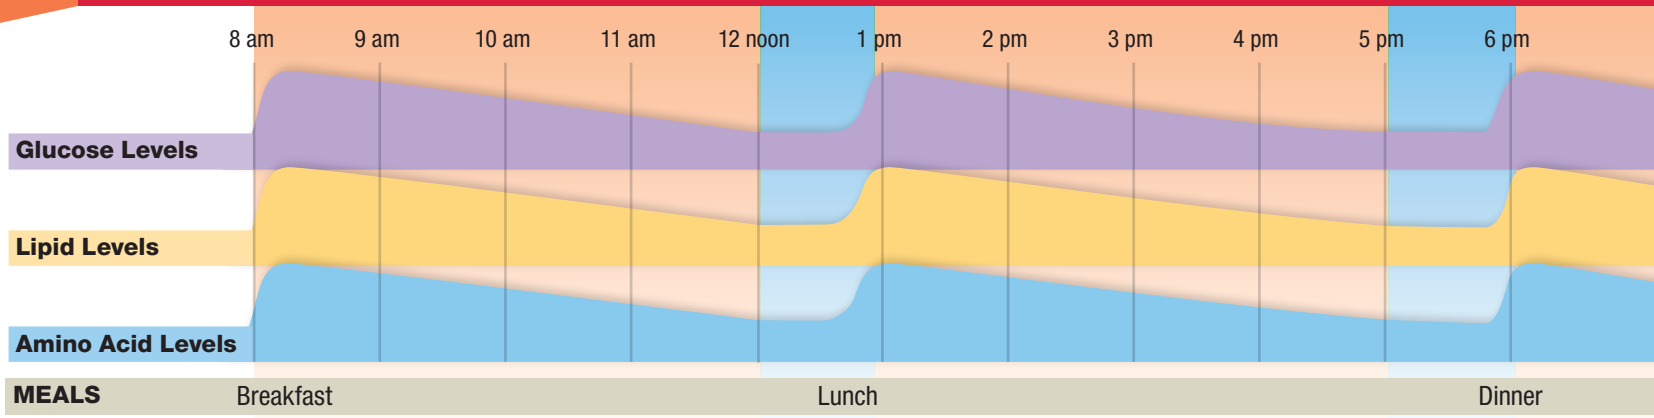
For example, consider the essential amino acids. p. 956 The liver cannot synthesize any of these amino acids, so you must obtain them from your diet. Some foods in the dairy and protein groups—specifically, beef, fish, poultry, eggs, and milk—provide all the essential amino acids in sufficient quantities. They are said to contain **complete proteins**. Many plants also supply adequate *amounts* of protein but contain **incomplete proteins**, which are deficient in one or more of the essential amino acids. People who follow a *vegetarian diet*, which is largely restricted to the grains, vegetables, and fruits groups

Table 25–1 Basic Food Groups and Their General Effects on Health

Nutrient Group	Provides	Health Effects
Grains (recommended: at least half of the total eaten as whole grains)	Carbohydrates; vitamins E, thiamine, niacin, folate; calcium; phosphorus; iron; sodium; dietary fiber	Whole grains prevent rapid rise in blood glucose levels, and consequent rapid rise in insulin levels
Vegetables (recommended: especially dark-green and orange vegetables)	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate) and prostate cancer (lycopene in tomatoes)
Fruits (recommended: a variety of fruit each day)	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate)
Dairy (recommended: low-fat or fat-free milk, yogurt, and cheese)	Complete proteins; fats; carbohydrates; calcium; potassium; magnesium; sodium; phosphorus; vitamins A, B_{12}, pantothenic acid, thiamine, riboflavin	Whole milk: high in calories, may cause weight gain; saturated fats correlated with heart disease
Protein (recommended: lean meats, fish, poultry, eggs, dry beans, nuts, legumes)	Complete proteins; fats; calcium; potassium; phosphorus; iron; zinc; vitamins E, thiamine, B_6	Fish and poultry lower risk of heart disease and colon cancer (compared to red meat). Consumption of up to one egg per day does not appear to increase incidence of heart disease; nuts and legumes improve blood cholesterol ratios, lower risk of heart disease and diabetes

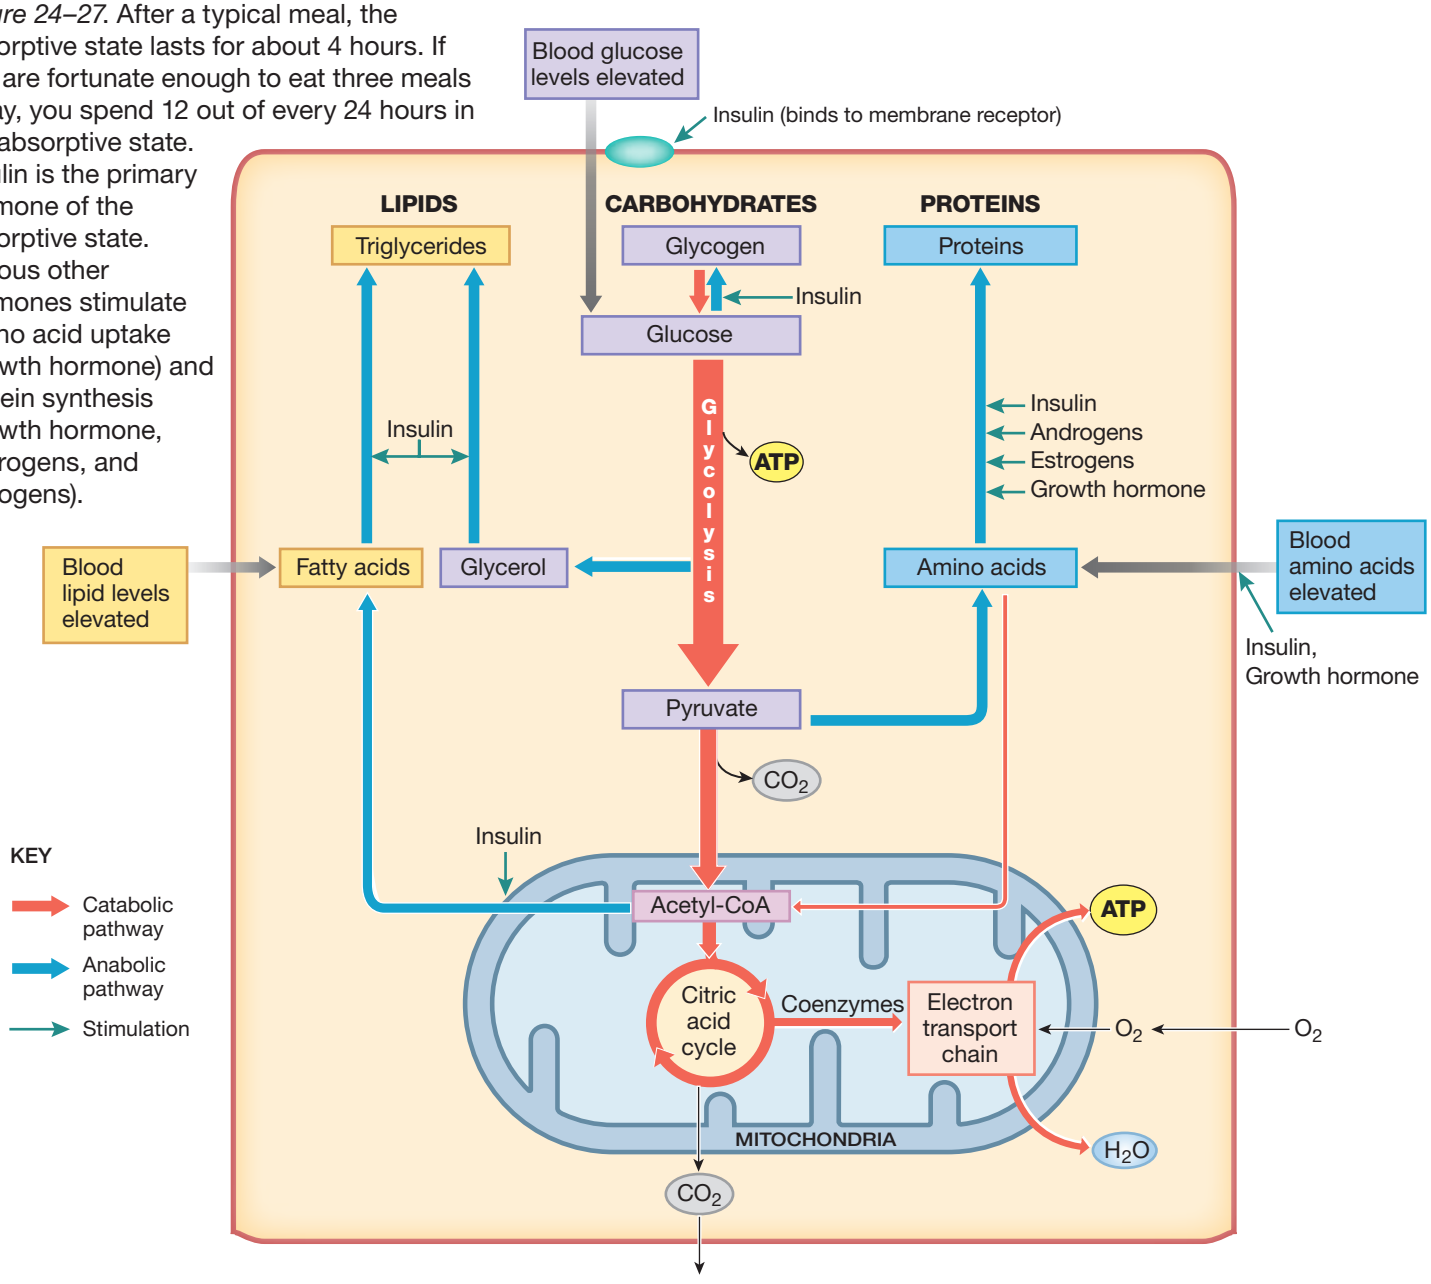
SPOTLIGHT

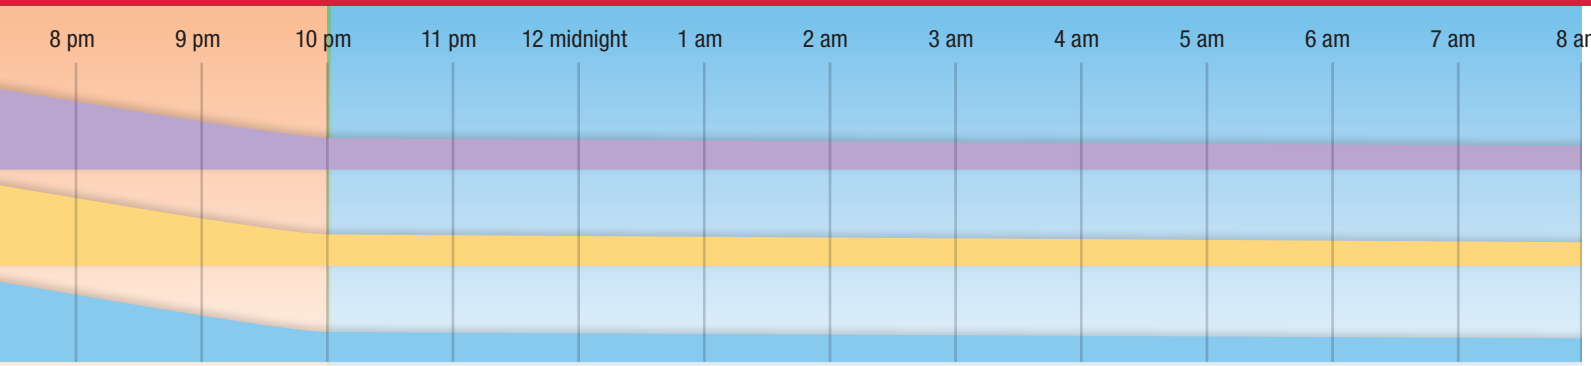
Figure 25–10
Absorptive and Postabsorptive States



ABSORPTIVE STATE

The **absorptive state** is the time following a meal, when nutrient absorption is under way. Nutrient absorption was outlined in *Spotlight Figure 24–27*. After a typical meal, the absorptive state lasts for about 4 hours. If you are fortunate enough to eat three meals a day, you spend 12 out of every 24 hours in the absorptive state. Insulin is the primary hormone of the absorptive state. Various other hormones stimulate amino acid uptake (growth hormone) and protein synthesis (growth hormone, androgens, and estrogens).





POSTABSORPTIVE STATE

The **postabsorptive state** is the time when nutrients are not being absorbed and your body must rely on internal energy reserves to meet its energy demands. You spend about 12 hours each day in the postabsorptive state. If you skip meals, however, you can extend that time considerably. Metabolic activity in the postabsorptive state is focused on mobilizing energy reserves and maintaining normal blood glucose levels. Several hormones coordinate these activities. These hormones include glucagon, epinephrine, glucocorticoids, and growth hormone.

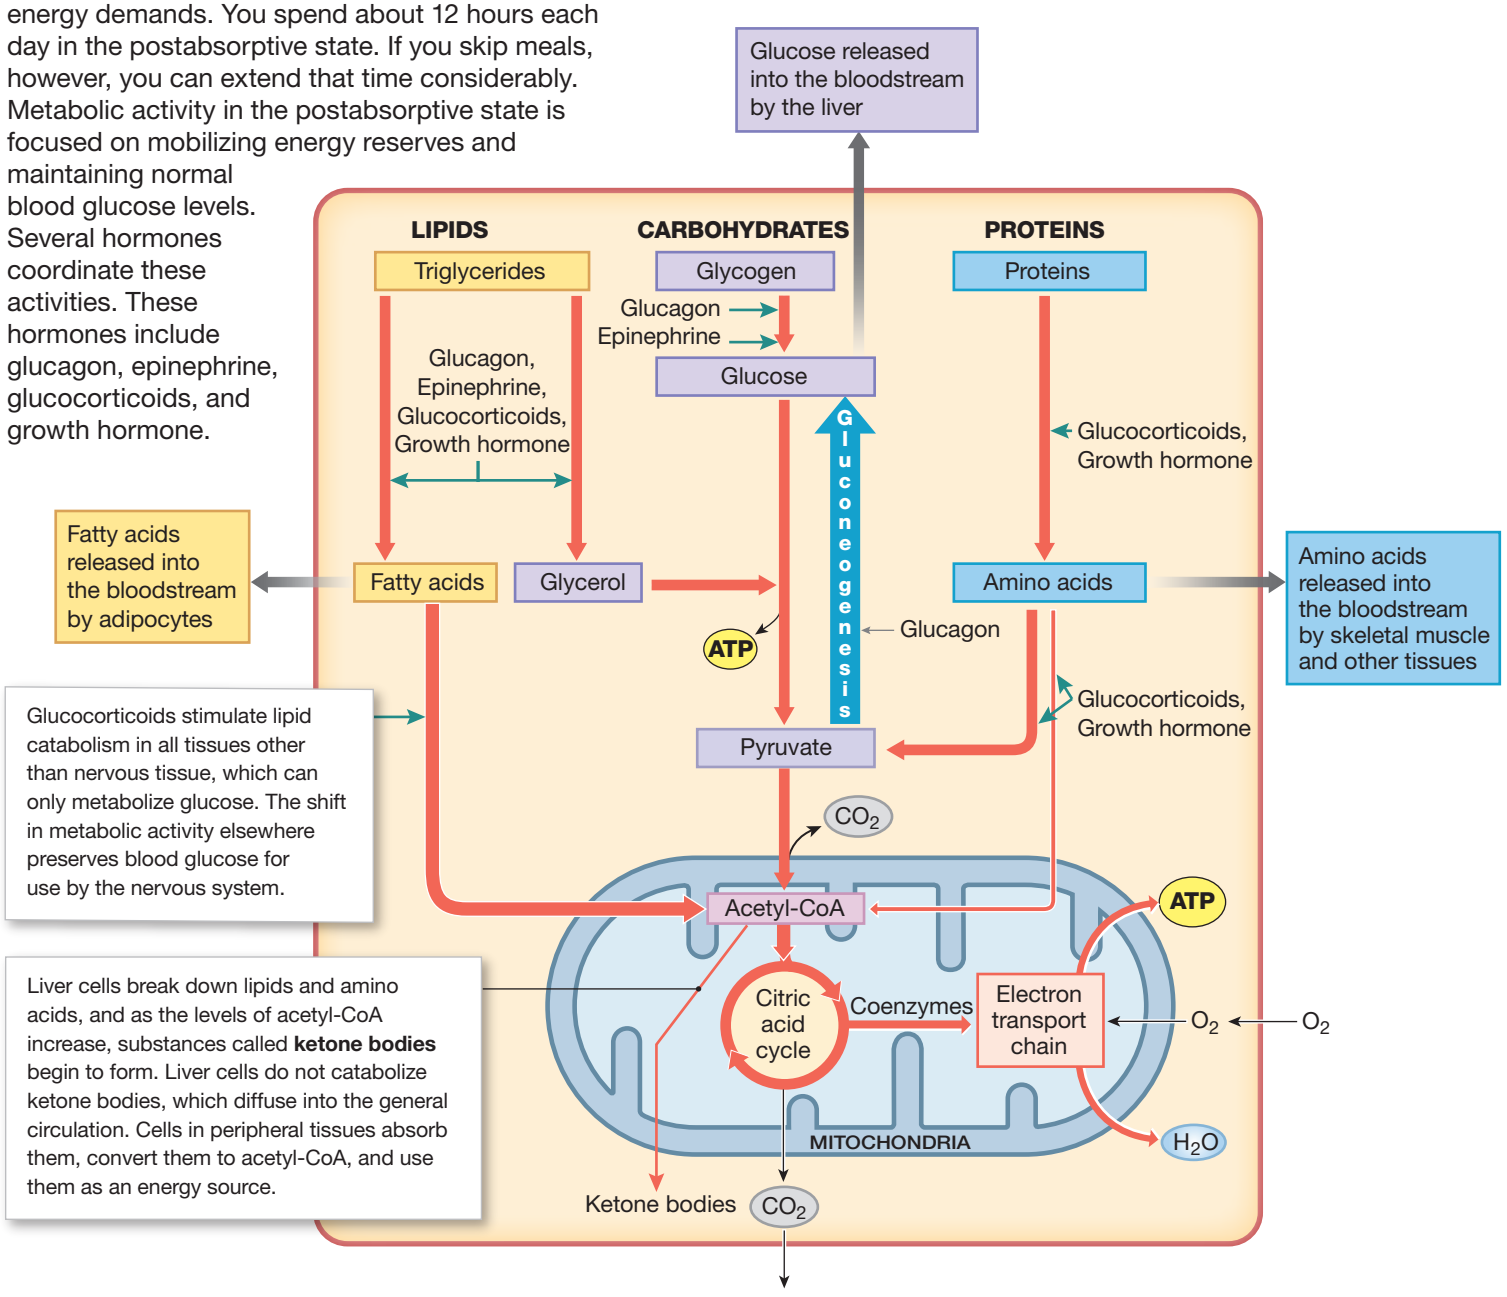


Figure 25–11 MyPlate, MyWins. The proportion of each food group is indicated by the size of its color-coded area. Foods should be consumed in proportions based on both the food group and the person's level of activity.

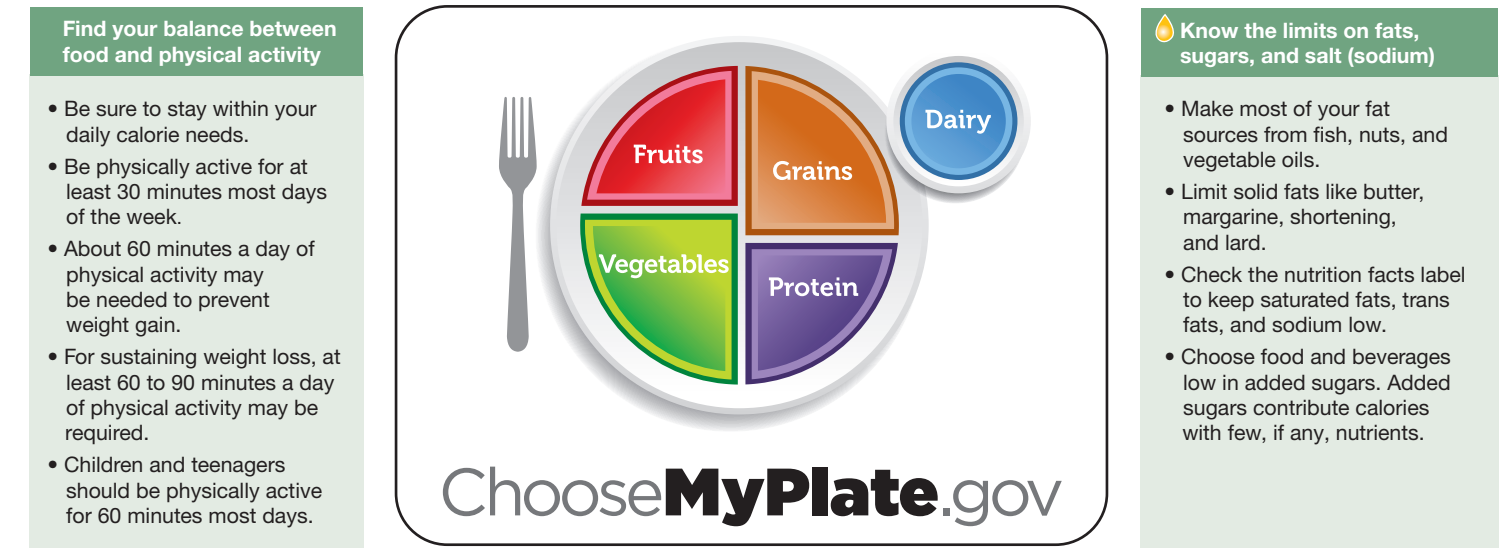


(with or without the dairy products group), must become adept at varying their food choices to include combinations of ingredients that meet all their amino acid requirements. Even with a proper balance of amino acids, people who eat a *vegan diet*, which avoids all animal products, face a significant problem, because vitamin B_{12} is obtained only from animal products or from fortified cereals or tofu.

Nitrogen Balance

Nitrogen balance is the difference between the total nitrogen you consume and the amount that you excrete in urine and feces. A variety of important compounds in the body contain nitrogen atoms. These include:

- Amino acids, which are part of the framework of all proteins and protein derivatives, such as glycoproteins and lipoproteins
- Purines and pyrimidines, the nitrogenous bases of RNA and DNA
- *Creatine*, important in energy storage in muscle tissue (as creatine phosphate)
- *Porphyrins* (por-FĒR-inz), complex ring-shaped molecules that bind metal ions and are essential to the function of hemoglobin, myoglobin, and the cytochromes.

Despite the importance of nitrogen to these compounds, your body neither stores nitrogen nor maintains nitrogen reserves, as it does carbohydrates (glycogen) and lipids (triglycerides). Your body can synthesize the carbon chains of the nitrogen compounds, but you must obtain nitrogen atoms either by recycling nitrogen compounds already in the body or by absorbing nitrogen from your diet. Nitrogen balance is a normal condition, and it means that the rates of synthesis and breakdown of nitrogen compounds are equivalent.

Growing children, athletes, people recovering from an illness or injury, and pregnant or lactating women actively synthesize nitrogen compounds. These individuals must absorb more nitrogen than they excrete. Such individuals are in a state of **positive nitrogen balance**.

When excretion exceeds ingestion, a **negative nitrogen balance** exists. The body contains only about a kilogram of nitrogen tied up in nitrogen compounds, and a decrease of one-third can be fatal. Even when energy reserves are mobilized (as during starvation), carbohydrates and lipid reserves are broken down first and nitrogen compounds are conserved.

The Role of Minerals and Vitamins

As we explained, a balanced diet includes both minerals and vitamins. However, your body cannot synthesize minerals, and your cells can generate only a small quantity of a very few vitamins.

Minerals

Minerals are inorganic ions released through the dissociation of electrolytes. Minerals are important for three reasons:

- *Ions such as sodium and chloride determine the osmotic concentrations of body fluids.* Potassium ions are important in maintaining the osmotic concentration of the cytosol inside body cells.
- *Ions in various combinations play major roles in important physiological processes.* As we have seen, these processes include the

maintenance of membrane potentials; the construction and maintenance of the skeleton; muscle contraction; the generation of action potentials; the release of neurotransmitters; hormone production; blood clotting; the transport of respiratory gases; buffer systems; fluid absorption; and waste removal.

- *Ions are essential cofactors in a variety of enzymatic reactions.* For example, calcium-dependent ATPase in skeletal muscle also requires the presence of magnesium ions. Another ATPase required for the conversion of glucose to pyruvate needs both potassium and magnesium ions. Carbonic anhydrase is important in CO_2 transport, buffering systems, and gastric acid secretion. This enzyme requires the presence of zinc ions. Finally, components of the electron transport chain require an iron atom. The final cytochrome (a_3) of the electron transport chain must bind a copper ion as well.

The major minerals and a summary of their functional roles are listed in Table 25–2. Your body contains reserves of several important minerals, and these reserves help reduce the effects of variations in the dietary supply. Chronic dietary reductions can lead to a variety of clinical problems. Alternatively, a dietary excess of mineral ions can be equally dangerous, because storage capabilities are limited.

Problems involving iron are particularly common. The body of a healthy man contains about 3.5 g of iron in the ionic form Fe^{2+}. Of that amount, 2.5 g is bound to the hemoglobin in circulating red blood cells. The rest is stored in the liver and red bone marrow. In women, the total body iron content averages 2.4 g, with about 1.9 g incorporated into red blood cells. Thus, a woman's iron reserves consist of only 0.5 g, half that of a typical man. For this reason, if the diet contains inadequate amounts of iron, premenopausal women are more likely to develop signs of iron deficiency than are men.

Vitamins

A **vitamin** is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. Vitamins are assigned to either of two groups based on their chemical structure and characteristics: *fat-soluble vitamins* or *water-soluble vitamins*.

Fat-Soluble Vitamins. Vitamins A, D, E, and K are the **fat-soluble vitamins**, which dissolve in lipids. You absorb these vitamins primarily from the digestive tract, along with the lipid contents of micelles. However, when exposed to sunlight, your skin can synthesize small amounts of vitamin D, and intestinal bacteria produce some vitamin K.

The mode of action of these vitamins is an area of active research. Vitamin A has long been recognized as a structural component of the visual pigment retinal. Its more general

Table 25–2 Minerals and Mineral Reserves

Mineral	Significance	Total Body Content	Primary Route of Excretion	Recommended Daily Allowance (RDA) in mg
BULK MINERALS				
Sodium	Major cation in body fluids; essential for normal membrane function	110 g, primarily in body fluids	Urine, sweat, feces	1500
Potassium	Major cation in cytoplasm; essential for normal membrane function	140 g, primarily in cytoplasm	Urine	4700
Chloride	Major anion in body fluids; functions in forming HCl	89 g, primarily in body fluids	Urine, sweat	2300
Calcium	Essential for normal muscle and neuron function and normal bone structure	1.36 kg, primarily in skeleton	Urine, feces	1000–1200
Phosphorus	In high-energy compounds, nucleic acids, and bone matrix (as phosphate)	744 g, primarily in skeleton	Urine, feces	700
Magnesium	Cofactor of enzymes, required for normal membrane functions	29 g (skeleton, 17 g; cytoplasm and body fluids, 12 g)	Urine	310–400
TRACE MINERALS				
Iron	Component of hemoglobin, myoglobin, and cytochromes	3.9 g (1.6 g stored as ferritin or hemosiderin)	Urine (traces)	8–18
Zinc	Cofactor of enzyme systems, notably carbonic anhydrase	2 g	Urine, hair (traces)	8–11
Copper	Required as cofactor for hemoglobin synthesis	127 mg	Urine, feces (traces)	0.9
Manganese	Cofactor for some enzymes	11 mg	Feces, urine (traces)	1.8–2.3
Cobalt	Cofactor for transaminations; mineral in vitamin B_{12} (cobalamin)	1.1 g	Feces, urine	0.0001
Selenium	Antioxidant	Variable	Feces, urine	0.055
Chromium	Cofactor for glucose metabolism	0.0006 mg	Feces, urine	0.02–0.035

Table 25–3 The Fat-Soluble Vitamins

Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
A	Maintains epithelia; required for synthesis of visual pigments; supports immune system; promotes growth and bone remodeling	Leafy green and yellow vegetables	0.7–0.9	Retarded growth, night blindness, deterioration of epithelial membranes	Liver damage, skin paling, CNS effects (nausea, anorexia)
D	Required for normal bone growth, intestinal calcium and phosphorus absorption, and retention of these ions at the kidneys	Synthesized in skin exposed to sunlight	0.005–0.015*	Rickets, skeletal deterioration	Calcium deposits in many tissues, disrupting functions
E	Prevents breakdown of vitamin A and fatty acids	Meat, milk, vegetables	15	Anemia, other problems suspected	Nausea, stomach cramps, blurred vision, fatigue
K	Essential for liver synthesis of prothrombin and other clotting factors	Vegetables; production by intestinal bacteria	0.09–0.12	Bleeding disorders	Liver dysfunction, jaundice

* Unless exposure to sunlight is inadequate for extended periods and alternative sources are unavailable.

metabolic effects are not well understood. Vitamin D is ultimately converted to calcitriol. This hormone binds to cytoplasmic receptors within the intestinal epithelium and helps to increase the rate of intestinal absorption of calcium and phosphorus ions. Vitamin E stabilizes intracellular membranes. Vitamin K is essential to the synthesis of several proteins, including at least three blood clotting factors. Information about the fat-soluble vitamins is summarized in Table 25–3.

Water-Soluble Vitamins. Most of the **water-soluble vitamins** (Table 25–4) are components of coenzymes. For example, NAD is derived from niacin (vitamin B_3), FAD from vitamin B_2 (riboflavin), and coenzyme A from vitamin B_5 (pantothenic acid). The liver synthesizes niacin from the essential amino acid tryptophan.

Water-soluble vitamins are rapidly exchanged between the fluid compartments of the digestive tract and the circulating

Table 25–4 The Water-Soluble Vitamins

Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
B_1 (thiamine)	Coenzyme in many pathways	Milk, meat, bread	1.1–1.2	Muscle weakness, CNS and cardiovascular problems, including heart disease; called *beriberi*	Hypotension
B_2 (riboflavin)	Part of FAD, involved in multiple pathways, including glycolysis and citric acid cycle	Milk, meat, eggs, and cheese	1.1–1.3	Epithelial and mucosal deterioration	Itching, tingling
B_3 (niacin)	Part of NAD, involved in multiple pathways	Meat, bread, potatoes	14–16	CNS, GI, epithelial, and mucosal deterioration; called *pellagra*	Itching, burning; vasodilation; death after large dose
B_5 (pantothenic acid)	Coenzyme A, in multiple pathways	Milk, meat	10	Retarded growth, CNS disturbances	None reported
B_6 (pyridoxine)	Coenzyme in amino acid and lipid metabolism	Meat, whole grains, vegetables, orange juice, cheese, and milk	1.3–1.7	Retarded growth, anemia, convulsions, epithelial changes	CNS alterations, perhaps fatal
B_9 (folic acid)	Coenzyme in amino acid and nucleic acid metabolism	Leafy vegetables, some fruits, liver, cereal, and bread	0.2–0.4	Retarded growth, anemia, gastrointestinal disorders, developmental abnormalities	Few noted, except at massive doses
B_{12} (cobalamin)	Coenzyme in nucleic acid metabolism	Milk, meat	0.0024	Impaired RBC production, causing *pernicious anemia*	Polycythemia
B_7 (biotin)	Coenzyme in many pathways	Eggs, meat, vegetables	0.03	Fatigue, muscular pain, nausea, dermatitis	None reported
C (ascorbic acid)	Coenzyme in many pathways	Citrus fruits	75–90; smokers add 35 mg	Epithelial and mucosal deterioration; called *scurvy*	Kidney stones

Clinical Note Vitamins

"If a little is good, a lot must be better" is a common—but dangerously incorrect—attitude about vitamins.

Too much of a vitamin can also have harmful effects. **Hypervitaminosis** (hī-per-vī-tuh-min-Ō-sis) occurs when dietary intake exceeds the body's ability to use, store, or excrete a particular vitamin. This condition usually involves one of the fat-soluble vitamins, because the excess is retained and stored in body lipids. Fat-soluble vitamins normally diffuse into plasma membranes and other lipids in the body, including the lipid inclusions in the liver and adipose tissue. As a result, your body contains a significant reserve of these vitamins. Normal metabolic operations can continue for several months after dietary sources have been cut off. For this reason, a dietary insufficiency of fat-soluble vitamins rarely causes signs and symptoms of **hypovitaminosis** (hī-pō-vi-ta-min-Ō-sis), or vitamin insufficiency. However, other factors can cause hypovitaminosis involving either fat-soluble or water-soluble vitamins. Problems may be due to an inability to absorb a vitamin from the digestive tract, inadequate storage, or excessive demand.

Clinical Note Alcohol by the Numbers

Alcohol is big business throughout the world. We see beer commercials on television, billboards advertising liquor, and TV or movie characters enjoying a drink. This cultural fondness for alcohol has serious medical consequences.

Consider these statistics provided by the Centers for Disease Control and Prevention (CDC) and the National Council on Alcoholism and Drug Dependence for people living in the United States:

- One in four children—over 7 million—grows up in a home where someone abuses alcohol.
- 17.6 million people—1 in every 12 adults—abuse alcohol.
- 79,000 deaths are attributed to alcohol use every year.
- Alcoholism is the third leading cause of lifestyle-related deaths.
- Alcohol is responsible for 60–90 percent of all liver disease in the United States.
- Women who consume 1 ounce of alcohol per day during pregnancy have a higher rate of spontaneous abortion and bear children with lower birth weights than do women who abstain.

Clinical Note Alcohol and Disease

Alcohol affects many organ systems. Major clinical symptoms of alcoholism include (1) disorientation and confusion (*nervous system*); (2) ulcers, diarrhea, and cirrhosis (*digestive system*); (3) cardiac arrhythmias, cardiomyopathy, and anemia (*cardiovascular system*); (4) depressed sexual drive and testosterone level (*reproductive system*); and (5) itching and angiomas (benign blood vessel or lymphatic vessel tumors) (*integumentary system*).

Alcohol affects developing fetuses. The toll on newborn infants has risen steadily since the 1960s as the number of female drinkers has increased. Women who drink heavily may have children with *fetal alcohol syndrome (FAS)*. Facial abnormalities, a small head, slow growth, and mental retardation characterize this irreversible condition.

Problems with alcohol are usually divided into those stemming from alcohol abuse and those involving alcoholism. The boundary between these conditions is hazy. *Alcohol abuse* is the general term for overuse and its behavioral and physical effects. *Alcoholism* is chronic alcohol abuse accompanied by the physiological changes associated with addiction to other CNS-active drugs. Alcoholism has received the most attention in recent years, but alcohol abuse—especially when combined with driving a car—is also in the spotlight. Alcohol abuse is considerably more widespread than alcoholism. The medical effects are less well documented, but they are clearly significant.

Several factors interact to produce alcoholism. The primary risk factors are sex (males are more likely to become alcoholics than are females) and a family history of alcoholism. There does appear to be a genetic component: A gene on chromosome 11 has been implicated in some inherited forms of alcoholism. The relative importance of genes versus social environment is difficult to assess. Both alcohol abuse and alcoholism probably are caused by a variety of factors.

blood. Excessive amounts are readily excreted in urine. For this reason, hypervitaminosis involving water-soluble vitamins is relatively uncommon, except among people who take large doses of vitamin supplements. Only vitamins B_{12} and C are stored in significant quantities. Insufficient intake of other water-soluble vitamins can lead to initial signs and symptoms of vitamin deficiency within a period of days to weeks.

The bacteria that live in the intestines help prevent deficiency diseases. They produce small amounts of five of the nine water-soluble vitamins, in addition to fat-soluble vitamin K. The intestinal epithelium can easily absorb all the water-soluble vitamins except B_{12}. Because the B_{12} molecule is large, it must be bound to *intrinsic factor* from the gastric mucosa before absorption can take place, as we discussed in Chapter 24. ↩ p. 904

Clinical Note Anorexia

Anorexia means lack of appetite. This is a common symptom of chronic disease. A patient with cancer loses his or her appetite and often loses body weight, too. The presence of anorexia can alert the health care worker to look for an underlying disease.

Anorexia nervosa, a more familiar term, refers to a specific mental health disorder in which an individual is obsessed with a desire to lose weight by refusing to eat. People with anorexia have a distorted body image: We see a skeletal appearance when we look at them, but they see themselves as fat. Repetitive starvation damages both body and brain. More common in females, anorexia nervosa has the highest mortality rate of any psychiatric condition.

Clinical Note Superfoods

Superfoods have star status! The health claims for superfoods attack us from advertisements everywhere: "Eat (*a specific food*) and banish (*a disease*)!" Oat bran is hyped for reversing high serum cholesterol, while pomegranates are touted to promote long life. What are we to make of these claims?

Some foods do in fact give more nutritional bang for the buck than other foods. Such foods may be nutrient dense. Raw almonds, for example, contain protein, anti-inflammatory omega-3 fats, and fiber. Other foods have high concentrations of a select nutrient. Red peppers, for example, are unusually high in vitamin C. The bright orange color of a sweet potato broadcasts its content of beta-carotene, a precursor of vitamin A. Dark leafy greens are rich plant sources of iron. Different foods confer different, and complementary, benefits.

However, the notion that foods have superpowers is more marketing ploy than nutrition science. A diet that incorporates a wide variety of whole foods is a powerful tool for nutritional health.

Checkpoint

14. **Identify the two classes of vitamins.**
15. **Would an athlete in intensive training try to maintain a positive or a negative nitrogen balance?**
16. **How would a decrease in the amount of bile salts in the bile affect the amount of vitamin A in the body?**

See the blue Answers tab at the back of the book.

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms

Learning Outcome Define metabolic rate, discuss the factors involved in determining an individual's BMR, and discuss the homeostatic mechanisms that maintain a constant body temperature.

A person's daily energy expenditures vary widely with activity. For example, a person who leads a sedentary life may have minimal energy demands, but someone who includes a single hour of swimming has a significantly increased daily energy use. Your average daily energy use give a clue to your *metabolic rate*. If your daily energy intake exceeds your total energy demands, you store the excess energy, primarily as triglycerides in adipose tissue. If your daily energy expenditures exceed your intake, the result is a net reduction in your body's energy reserves and a corresponding loss in weight. In this section, first we consider aspects of energy intake and expenditure. Then we turn to the topic of *thermoregulation*, how the body maintains a consistent internal temperature.

Energy Gains and Losses

When chemical bonds are broken, energy is released. Inside cells, a significant amount of energy may be used to synthesize ATP, but much of it is lost to the environment as heat.

Measuring Energy and the Energy Content of Food

The process of *calorimetry* (kal-ō-RIM-eh-trē) measures the total amount of energy released when the bonds of organic molecules are broken. The unit of measurement is the **calorie** (KAL-ō-rē) (cal), defined as the amount of energy required to raise the temperature of 1 g of water 1 degree Celsius (°C). One gram of water is not a very practical measure when you are interested in the metabolic processes that keep a 70-kg human alive, so we use the **kilocalorie** (KIL-ō-kal-ō-rē) (kcal), or **Calorie** (with a capital C, also known as the "large calorie,"). One kilocalorie is the amount of energy needed to raise the temperature of 1 kilogram (1 Liter) of water 1 °C. In human nutrition, the term "*calorie*" is commonly used instead of kilocalorie or Calorie to refer to a unit of food energy.

In cells, organic molecules are oxidized to carbon dioxide and water. Oxidation also takes place when something burns, and this process can be experimentally controlled. A known amount of food is placed in a chamber called a **calorimeter** (kal-ō-RIM-e-ter), which is filled with oxygen and surrounded by a known volume of water. Once the food is inside, the chamber is sealed and the contents are electrically ignited. When the material has completely oxidized and only ash remains in the

chamber, the number of Calories released can be determined by comparing the water temperatures before and after the test.

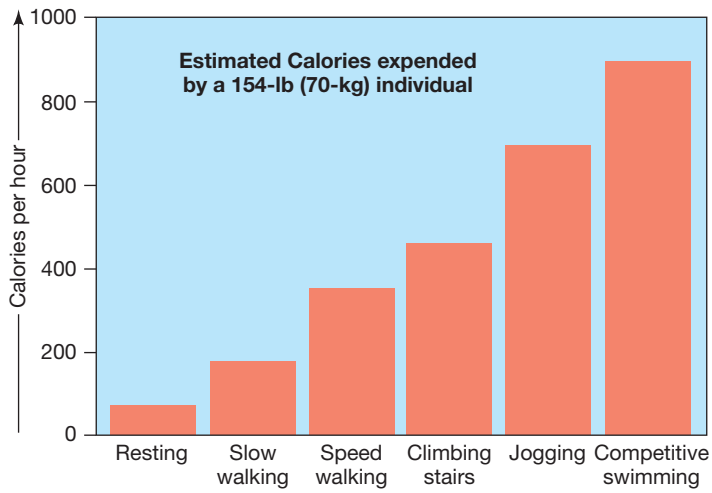
The energy potential of food is usually expressed in kilocalories per gram (kcal/g). The catabolism of lipids releases a considerable amount of energy, roughly 9.46 kcal/g. The catabolism of carbohydrates or proteins is not as productive, because many of the carbon and hydrogen atoms are already bound to oxygen. Their average yields are comparable: 4.18 kcal/g for carbohydrates and 4.32 kcal/g for proteins. Most foods are mixtures of fats, proteins, and carbohydrates, so the calculated values listed in a "calorie counter" vary.

Measuring Energy Expenditure: Metabolic Rate

Clinicians can examine your metabolic state and determine how many calories you are using. The result can be expressed as calories per hour, calories per day, or calories per unit of body weight per day. The **basal metabolic rate (BMR)** is a measurement of the rate at which the body expends energy while at rest to maintain vital functions, such as breathing and keeping warm. On average, the BMR is 1 kcal of energy per hour for each kilogram of body weight. The metabolic rate changes and is affected by exercise, age, sex, hormones, endocrine activity, and climate. For instance, measurements taken while a person is sprinting are quite different from those taken while a person is sleeping. Figure 25–12 shows the caloric expenditures for various common activities.

In an attempt to reduce the variations in studies of energetics and metabolism, physiologists and clinicians standardize the testing conditions. Ideally, the BMR is the minimum resting energy expenditure of an awake, alert person. A direct method of determining the BMR involves monitoring respiratory activity. In resting individuals, energy use is proportional to oxygen consumption. If we assume that average amounts of carbohydrates, lipids, and proteins are being catabolized, 4.825 kcal are expended per liter of oxygen consumed.

Figure 25–12 Caloric Expenditures for Various Activities.



An average individual has a BMR of 70 kcal per hour, or about 1680 kcal per day. Although the test conditions are standardized, many uncontrollable factors can influence the BMR. These factors include physical condition, body weight, and genetic differences.

Regulation of Energy Intake

The control of appetite is poorly understood. Stretch receptors along the digestive tract, especially in the stomach, play a role, but other factors are probably more significant. Social factors, psychological pressures, and dietary habits are important. Evidence also indicates that complex hormonal stimuli interact to affect appetite. For example, the hormones *cholecystokinin (CCK)* and *adrenocorticotropic hormone (ACTH)* suppress appetite. The hormones leptin and ghrelin also interact to affect hunger. *Leptin* is released into the bloodstream by adipose tissues as they synthesize triglycerides. When leptin binds to CNS neurons that function in emotion and appetite control, the result is a sense of satiation and appetite suppression. Leptin levels are lower in thin people and higher in overweight people. Obese people have resistance to the appetite-suppressing effects of leptin. *Ghrelin* (GREL-in), a hormone secreted from the gastric mucosa, stimulates appetite. The ghrelin level declines when the stomach is full, and increases during the fasting state. Some research suggests that leptin plays a role in regulating ghrelin, showing that these "hunger hormones" are complex and warrant further study. p. 905

Obesity is defined as body weight more than 20 percent above the ideal weight for a given individual. Currently, obesity is considered an epidemic and is taking its toll on the health of adults and children. Diseases associated with obesity include heart disease, cancer, and diabetes. For this reason, calorie counting and exercise are important in a weight-control program.

Thermoregulation

The BMR estimates the rate of energy use by the body. The energy that cells do not capture and harness is released as heat. This heat serves an important homeostatic purpose. Humans are subject to vast changes in environmental temperatures, but our complex biochemical systems have a major limitation. Our enzymes operate over only a relatively narrow temperature range. Accordingly, our bodies have anatomical and physiological mechanisms that keep body temperatures within acceptable limits, regardless of environmental conditions. This homeostatic process is called **thermoregulation**. Failure to control body temperature can result in a series of physiological changes. For example, a body temperature below 36°C (97°F) or above 40°C (104°F) can cause disorientation. A body temperature above 42°C (108°F) can cause convulsions and permanent cell damage.

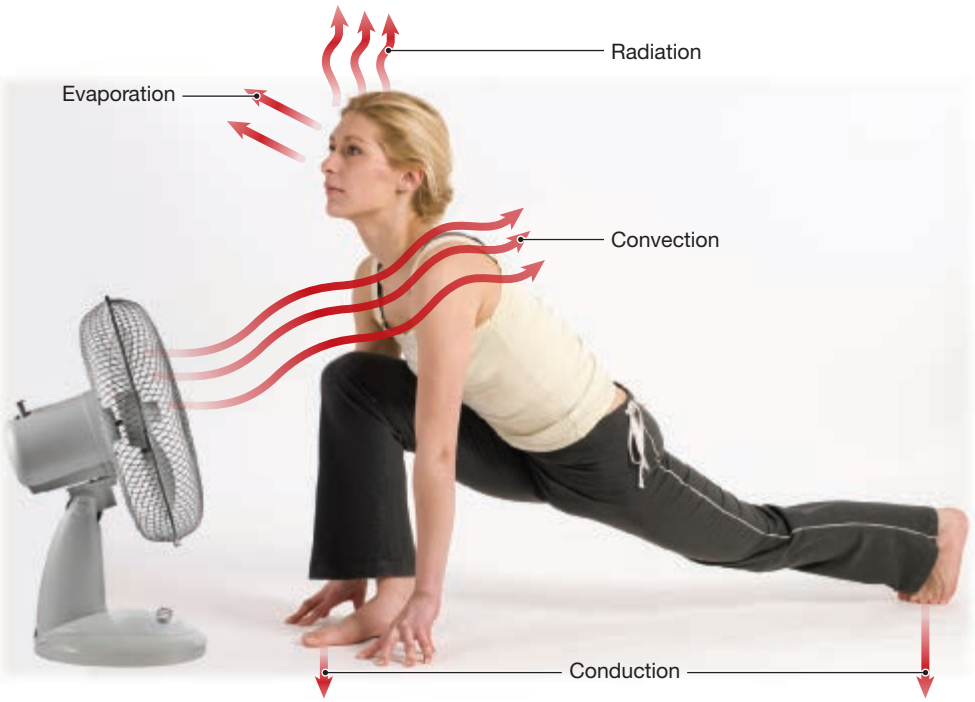
We continuously produce heat as a by-product of metabolism. When our energy use increases due to physical activity, or when our cells are more active metabolically (as they are during the absorptive state), additional heat is generated. The heat produced by biochemical reactions is retained by water, which makes up nearly two-thirds of body weight. Water is an excellent conductor of heat, so the heat produced in one region of the body is rapidly distributed by diffusion, as well as through the bloodstream. If body temperature is to remain constant, that heat must be lost to the environment at the same rate at which it is generated. When environmental conditions rise above or fall below "ideal," the body must control the gains or losses to maintain homeostasis.

Mechanisms of Heat Exchange

Heat exchange with the environment involves four basic processes: (1) *radiation*, (2) *convection*, (3) *evaporation*, and (4) *conduction* (Figure 25–13). Objects warmer than the environment lose heat as **radiation**. When you feel the heat from the sun, you are experiencing radiant heat. Your body loses heat the same way, but in proportionately smaller amounts. More than 50 percent of the heat you lose indoors is lost through radiation. The exact amount varies with both body temperature and skin temperature.

Convection is heat loss to the cooler air that moves across the surface of your body. As your body loses heat to the air next to your skin, that air warms and rises, moving away from the surface of the skin. Cooler air replaces it, and this air in turn becomes warmed. This pattern then repeats. Convection accounts for roughly 15 percent of the body's heat loss indoors but is insignificant as a mechanism of heat gain.

Figure 25–13 Mechanisms of Heat Exchange.



When water evaporates, it changes from a liquid to a vapor. **Evaporation** absorbs energy—about 0.58 kcal per gram of water evaporated—and cools the surface where evaporation occurs. The rate of evaporation at your skin is highly variable. Each hour, 20–25 mL of water crosses epithelia and evaporates from the alveolar surfaces and the surface of the skin. This *insensible water loss* remains relatively constant. At rest, it accounts for roughly 20 percent of your body's average indoor heat loss. The sweat glands responsible for *sensible perspiration* have a tremendous scope of activity, ranging from virtual inactivity to secretory rates of 2–4 liters (2.1–4.2 quarts) per hour. ↩ p. 157

Conduction is the direct transfer of energy through physical contact. When you come into an air-conditioned classroom and sit on a cold plastic chair, you are immediately aware of this process. Conduction is generally not an effective way of gaining or losing heat. Its impact depends on the temperature of the object and the amount of skin surface area involved. When you are lying on cool sand in the shade, conductive losses can be considerable. When you are standing on the same sand, conductive losses are negligible.

The Hypothalamus Regulates Heat Gain and Heat Loss

Heat loss and heat gain involve the activities of many systems. Those activities are coordinated by the **heat-loss center** and **heat-gain center**, respectively, in the pre-optic area of the anterior hypothalamus. ↩ p. 484 These centers modify the activities of other hypothalamic nuclei. The overall effect is to control temperature by influencing two processes: the rate of heat production and the rate of heat loss to the environment. Changes in behavior may also support these processes.

Mechanisms for Increasing Heat Loss. When the temperature at the pre-optic area rises above its set point, the heat-loss center is stimulated, producing major effects:

- *The inhibition of the vasomotor center causes peripheral vasodilation, and warm blood flows to the surface of the body.* The skin and/or mucous membranes take on a reddish color, skin temperatures rise, and radiative and convective losses increase.
- *As blood flow to the skin increases, sweat glands are stimulated to increase their secretory output.* The perspiration flows across the body surface, and evaporative heat losses accelerate. Maximal secretion, if completely evaporated, would remove 2320 kcal per hour.

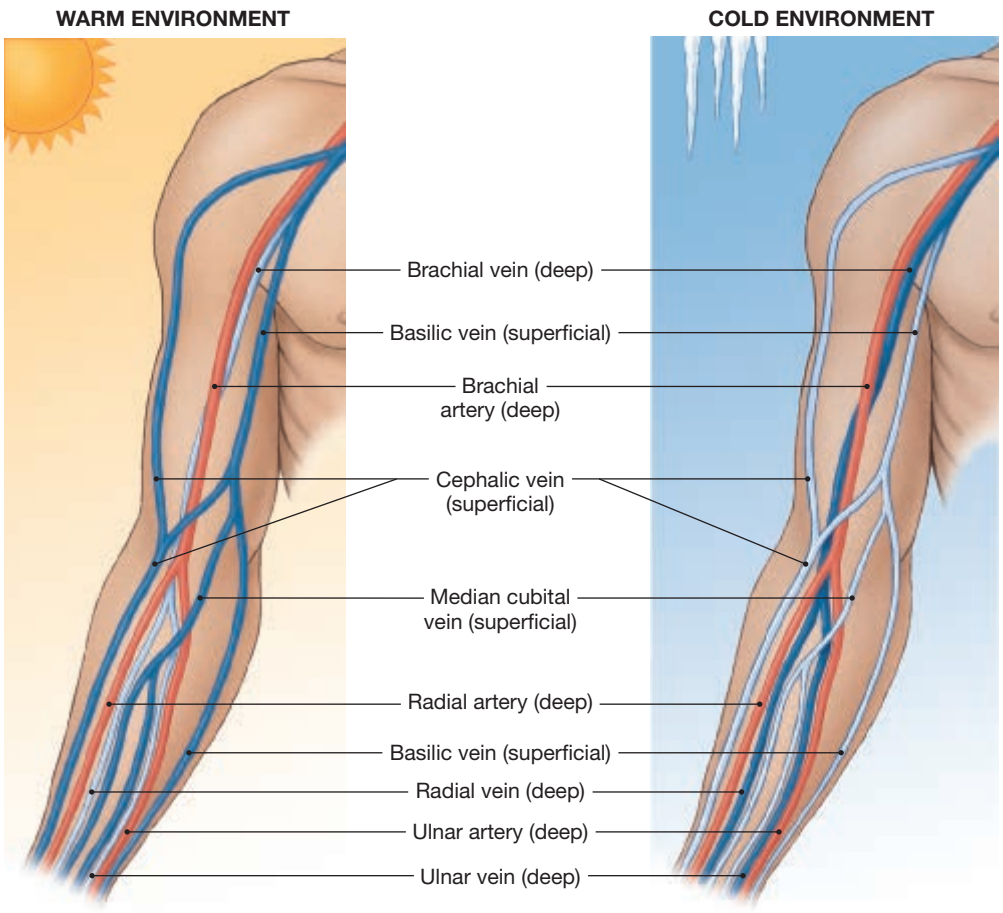
- *The respiratory centers are stimulated, and the depth of respiration increases.* Often, the individual begins breathing through an open mouth rather than through the nasal passageways. This increases evaporative heat losses through the lungs.

Mechanisms for Promoting Heat Gain. The function of the heat-gain center of the brain is to prevent **hypothermia** (hī-pō-THER-mē-uh), or below-normal body temperature. When the temperature at the pre-optic area drops below the acceptable level, the heat-loss center is inhibited and the heat-gain center is activated.

To conserve heat, the sympathetic vasomotor center decreases blood flow to the dermis, thereby reducing losses by radiation, convection, and conduction and allowing the skin to cool. With blood flow restricted, the skin in lighter-skinned individuals may take on a bluish or pale color. The epithelial cells are not damaged, because they can tolerate extended periods at temperatures as low as 25°C (77°F) or as high as 49°C (120°F).

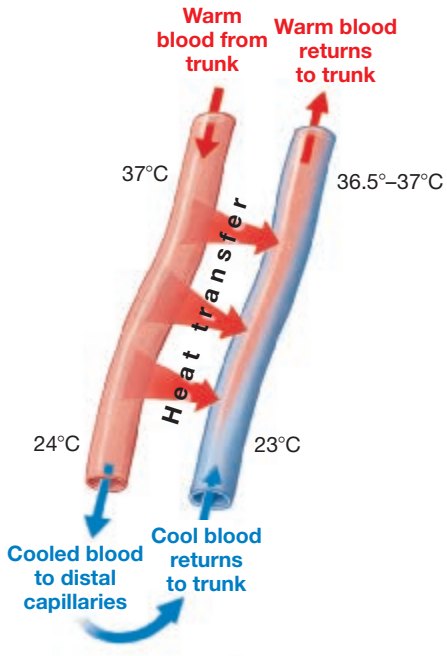
In addition, blood returning from the limbs is shunted into a network of deep veins. ↩ p. 766 Under warm conditions, blood flows in a superficial venous network (Figure 25–14a). In cold conditions, blood is diverted to a network of veins that lie deep to an insulating layer of subcutaneous fat (Figure 25–14b). This venous network wraps around the deep arteries, and heat is conducted from the warm blood flowing outward to the limbs to the cooler blood returning from the periphery (Figure 25–14c). This arrangement traps the heat close to the body core and restricts heat loss. Such exchange between fluids

Figure 25–14 Vascular Adaptations for Heat Loss and Conservation.



a Circulation through the blood vessels of the forearm in a warm environment. Blood enters the limb in a deep artery and returns to the trunk in a network of superficial veins that radiate heat to the environment through the overlying skin.

b Circulation through the blood vessels of the forearm in a cold environment. Blood now returns to the trunk by a network of deep veins that flow around the artery. The amount of heat loss is decreased, as shown in part c.



c Countercurrent heat exchange occurs as heat radiates from the warm arterial blood into the cooler venous blood flowing in the opposite direction. By the time the arterial blood reaches distal capillaries, where most heat loss to the environment occurs, it is already 13°C cooler than it was when it left the trunk. This mechanism decreases the rate of heat loss by conserving body heat within the trunk.

? In a warm environment, does more blood return to the trunk through deep or superficial veins? Why?

that are moving in opposite directions is called *countercurrent exchange*. (We return to this topic in Chapter 26.)

We can divide the mechanisms for generating heat into two broad categories: shivering thermogenesis and nonshivering thermogenesis. In **shivering thermogenesis** (ther-mō-JEN-eh-sis), a gradual increase in muscle tone increases the energy consumption of skeletal muscle tissue throughout your body. The more energy used, the more heat is produced. Both agonist and antagonist muscles are involved. The degree of stimulation varies with the demand.

If the heat-gain center is extremely active, muscle tone increases to the point at which stretch receptor stimulation will produce brief, oscillatory contractions of antagonistic muscles. In other words, you begin to **shiver**. Shivering increases the workload of the muscles and further elevates oxygen and energy consumption. The heat that is produced warms the deep vessels, to which blood has been shunted by the sympathetic vasomotor center. Shivering can elevate body temperature quite effectively, increasing the rate of heat generation by as much as 400 percent.

In contrast, *nonshivering thermogenesis* is a less immediate heat-gain process. In an adult, heat production increases by only 10–15 percent after a period of weeks. **Nonshivering thermogenesis** involves the release of hormones that increase the metabolic activity of all tissues:

- The heat-gain center stimulates the adrenal medullae through the sympathetic division of the autonomic nervous system. As a result, epinephrine is released. It increases the rates of glycogenolysis in liver and skeletal muscle, and the metabolic rate of most tissues. The effects are immediate.
- The pre-optic area regulates the production of thyrotropin-releasing hormone (TRH) by the hypothalamus. In children, when body temperatures are below normal, additional TRH is released. This hormone stimulates the release of thyroid-stimulating hormone (TSH) by the anterior lobe of the pituitary gland. In response to this release of TSH, the thyroid gland increases the rate of thyroxine release into the blood. Thyroxine increases not only the rate of carbohydrate catabolism, but also the rate of catabolism of all other nutrients. These effects develop gradually, over a period of days to weeks.

Clinical Note Hypothermia in the Operating Room

Hypothermia may be intentionally produced during surgery. The goal is to reduce the metabolic rate of a particular organ or of the patient's entire body. In controlled hypothermia, the patient is first anesthetized to prevent shivering, which would act to fight off hypothermia.

During open-heart surgery, the body is typically cooled to 25°C–32°C (79°F–89°F). This cooling reduces the metabolic demands of the body, which will be receiving blood from an external pump or oxygenator. The heart must be stopped completely during the operation, and it cannot be well supplied with blood over this period. For this reason, the heart is perfused with an *arresting solution* at 0°C–4°C (32°F–39°F) and maintained at a temperature below 15°C (60°F) during the operation. At these temperatures, the cardiac muscle can tolerate several hours of ischemia (inadequate blood supply) without damage.

When cardiac surgery is performed on infants, a deep hypothermia may be produced by cooling the entire body to temperatures as low as 11°C (52°F) for an hour or more. In effect, these conditions are similar to those experienced by victims of accidental drowning.

Sources of Individual Variation in Thermoregulation

The timing of thermoregulatory responses differs from person to person. A person may undergo **acclimatization** (ah-klī-mah-tih-ZĀ-shun)—a physiological adjustment to a particular environment over time. For example, natives of Tierra del Fuego (off the southernmost tip of South America) once lived naked in the snow, but Hawaii residents often unpack their sweaters when the temperature drops below 22°C (72°F).

Another source of variation is body size. Although heat *production* takes place within the mass of the body, heat *loss* takes place across a body surface. As an object (or person) gets larger, its surface area increases at a much slower rate than does its total volume. This relationship affects thermoregulation, because heat generated by the "volume" (that is, by internal tissues) is lost at the body surface. For this reason, small individuals lose heat more readily than do large individuals.

Brown Fat and Thermoregulation. Brown fat is thermogenic tissue containing fat droplets rich in heme, cytochromes, and mitochondria. These characteristics give the tissue a deep, rich color and an increased capacity to generate heat. The cells do not capture the energy released through fatty acid catabolism. Instead, the energy radiates into the surrounding tissues as heat. This heat quickly warms the blood passing through the surrounding network of vessels, and it is then distributed throughout the body.

It was once thought that brown fat was only present in infants, however, it is also found in adults. In newborns and infants, brown fat is important for thermoregulation, because their temperature-regulating mechanisms are not fully functional and they cannot shiver. Consequently, newborns must be dried promptly and kept bundled up. Babies born prematurely need a thermally regulated incubator. Infants also lose heat quickly as a result of their small size. So, the brown fat can very quickly speed up metabolic heat generation by 100 percent.

With increasing age and size, an infant's body temperature becomes more stable. As a result, brown fat becomes less important. With increased body size, skeletal muscle mass, and insulation, shivering thermogenesis becomes more effective in raising body temperature.

While we tend to lose brown fat as we age, everyone has brown fat nestled between areas of white fat, predominantly in the neck, upper chest, and shoulders. Although it is difficult to identify, PET scans are advancing the ability to recognize it. Interestingly, people who live in colder climates seem to have more brown fat than do people living in warmer climes, and thinner, younger people have more brown fat than do older, obese people. Hence, the role of brown fat—particularly its role in metabolism—is an area of active research.

Thermoregulatory Variations among Adults. Adults of a given body weight may differ in their thermal responses due to variations in body mass and tissue distribution. Adipose tissue is an excellent insulator. It conducts heat at only about one-third the rate of other tissues. As a result, people with a more substantial layer of subcutaneous fat may not begin to shiver until long after their thinner companions.

Two otherwise similar individuals may also differ in their response to temperature changes because their hypothalamic "thermostats" are at different settings. We all experience daily oscillations in body temperature. Temperatures peak during the day or early evening. They fall 1°C–2°C (1.8°F–3.6°F) at night. The ovulatory cycle also causes temperature fluctuations in women, as you will see in Chapter 28.

Individuals vary in the timing of their maximum temperature setting. Some have a series of peaks, with an afternoon low. The origin of these patterns is unclear. The patterns do not result from daily activity regimens. For example, the temperatures of people who work at night still peak during the same range of times as the rest of the population.

+ Clinical Note Excess Body Heat

Heat exhaustion and heat stroke are malfunctions of thermoregulatory mechanisms. With **heat exhaustion**, also known as *heat prostration*, excessive fluids are lost in perspiration, and the individual has difficulty maintaining blood volume. The heat-loss center in the hypothalamus stimulates sweat glands, whose secretions moisten the surface of the skin to provide evaporative cooling. As fluid losses mount, blood volume decreases. The resulting decline in blood pressure is not countered by peripheral vasoconstriction, because the heat-loss center is actively stimulating peripheral vasodilation. As blood flow to the brain declines, headache, nausea, and eventual collapse follow. Treatment is straightforward: provide fluids, salts, and a cooler place to be!

In **heat stroke**, body temperature rises uncontrollably because the thermoregulatory center stops functioning. The sweat glands are inactive, and the skin becomes hot and dry. Heat stroke is more serious and can follow an untreated case of heat exhaustion. Predisposing factors include any preexisting condition that affects peripheral circulation, such as heart disease or diabetes. Unless the problem is recognized in time, body temperature may climb to 41°C–45°C (106°F–113°F). Temperatures in this range quickly disrupt a variety of vital physiological systems and destroy brain, liver, skeletal muscle, and kidney cells. Effective treatment involves lowering the body temperature as rapidly as possible.

+ Clinical Note Deficient Body Heat

Hypothermia is below-normal body temperature. If body temperature drops significantly below the normal level, thermoregulatory mechanisms become less sensitive and less effective. Cardiac output and respiratory rate decrease. If the core temperature falls below 28°C (82°F), cardiac arrest is likely. The individual then has no heartbeat, no respiratory rate, and no response to external stimuli—even painful ones. The body temperature continues to decline, and the skin and/or mucous membranes turn blue or pale and cold.

At this point, people commonly assume that the person has died. But because metabolic activities have decreased system-wide, the victim may still be saved, even after several hours. Treatment consists of cardiopulmonary support and gradual rewarming, both external and internal. The skin can be warmed up to 45°C (113°F) without damage. Warm baths or blankets can be used. One effective method of raising internal temperatures involves the introduction of warm saline solution into the peritoneal cavity.

Hypothermia is a significant risk for people engaged in water sports. It may complicate the treatment of a drowning victim. Water absorbs heat about 27 times as fast as air does, and the body's heat-gain mechanisms are unable to keep pace over long periods or when faced with a large temperature gradient. But hypothermia in cold water does have a positive side. On several occasions, small children who have "drowned " in cold water have been successfully revived after periods of up to 4 hours. Children lose body heat quickly, and their systems soon stop functioning as their body temperature declines. This rapid drop in temperature prevents the oxygen starvation and tissue damage that would otherwise take place when breathing stops.

Resuscitation is not attempted if the person has actually frozen. Water expands roughly 7 percent during ordinary freezing. The process destroys plasma membranes throughout the body. Very small organisms can be frozen and subsequently thawed without ill effects, because their surface-to-volume ratio is enormous, and the freezing process occurs so rapidly that ice crystals never form.

Fevers

A **fever** is a body temperature greater than 37.2°C (99°F). We discussed fevers when we examined innate (nonspecific) immunity. p. 805 Fevers occur for a variety of reasons, not all of them pathological. In young children, transient fevers with no ill effects can result from exercise in warm weather. Similar exercise-related elevations were rarely seen in adults until running marathons became popular. Temperatures from 39°C to 41°C (103°F to 109°F) may result. For this reason, competitions are usually held when the air temperature is below 28°C (82°F).

Fevers can also result from the following factors:

- Abnormalities that affect the entire thermoregulatory mechanism, such as heat exhaustion or heat stroke
- Clinical problems that restrict blood flow, such as congestive heart failure
- Conditions that impair sweat gland activity, such as drug reactions and some skin conditions
- The resetting of the hypothalamic "thermostat" by circulating *pyrogens*—most notably, interleukin-1.

Checkpoint

17. **How would the BMR of a pregnant woman compare with her BMR before she became pregnant?**
18. **What effect does peripheral vasoconstriction on a hot day have on an individual's body temperature?**
19. **Why do infants have greater problems with thermoregulation than adults?**

See the blue Answers tab at the back of the book.

25 Chapter Review

Study Outline

An Introduction to Metabolism, Nutrition, and Energetics p. 940

1. The nutrients in food support the metabolic activities of the body. Your body builds energy reserves when nutrients are abundant and mobilizes them when nutrients are in short supply.

25-1 Metabolism is the sum of all the catabolic and anabolic reactions in the body, and energetics is the flow and transformation of energy p. 940

2. All the available nutrients distributed in the blood form a **nutrient pool**. **Catabolism** converts larger molecules into smaller ones, and **anabolism** converts small molecules into larger ones. Various metabolic pathways are involved with catabolism and anabolism. *(Figure 25–1)*
3. Anabolic reactions (1) perform structural maintenance or repairs, (2) support growth, (3) produce secretions, and (4) build and store nutrient reserves. *(Figure 25–1)*
4. **Energetics** is the study of the flow of energy and its transformation, or change, from one form to another.
5. Energy changes in cells involve chemical reactions known as oxidation and reduction. **Oxidation** is the gain of oxygen, or loss of hydrogen or electrons, and **reduction** is the loss of oxygen, or gain of hydrogen or electrons. Oxidation–reduction reactions occur together and are referred to as *redox reactions*.

25-2 Carbohydrate metabolism generates ATP by glucose catabolism and forms glucose by gluconeogenesis p. 943

6. Most cells generate ATP and other high-energy compounds by the catabolism of carbohydrates, especially glucose.
7. **Glycolysis** and **aerobic metabolism**, or **cellular respiration**, provide most of the ATP used by typical cells. In the anaerobic process of glycolysis, each molecule of glucose yields 2 molecules of **pyruvic acid** (as **pyruvate** ions), a net gain of 2 molecules of ATP, and 2 **NADH** molecules. *(Figure 25–2)*
8. In the presence of oxygen, pyruvate enters the mitochondria, where it is broken down completely in the **citric acid cycle**. Carbon and oxygen atoms are lost as carbon dioxide (**decarboxylation**); hydrogen atoms are passed to coenzymes, which initiate the oxygen-consuming and ATP-generating reaction **oxidative phosphorylation**. *(Figure 25–3)*
9. The **electron transport chain (ETC)** is embedded in the inner mitochondrial membrane. It is made up of four respiratory protein complexes, coenzyme Q, and cytochromes that eventually pass along electrons to oxygen to form water. Energy released by the passage of the electrons is used to pump H^+ from the matrix to the intermembrane space. *(Spotlight Figure 25–4)*
10. ATP is formed through **chemiosmosis**. During this process, H^+ pass through H^+ channels in the inner membrane from the intermembrane space to the mitochondrial matrix. Energy from the passage of the H^+ is used by *ATP synthase* to form ATP from ADP and P_i. *(Spotlight Figure 25–4)*
11. For each glucose molecule processed through glycolysis, the citric acid cycle, and the ETC, most cells gain 30–32 molecules of ATP. *(Figure 25–5)*

12. **Gluconeogenesis**, the synthesis of glucose from noncarbohydrate molecules, enables a liver cell to synthesize glucose molecules when carbohydrate reserves are depleted. Glucose molecules are stored as **glycogen** in liver and skeletal muscle cells. **Glycogenesis** is the process of glycogen formation. Glycogen is an important energy reserve. **Glycogenolysis** is the breakdown of glycogen to glucose molecules. *(Figures 25–1, 25–6)*

25-3 Lipid metabolism provides long-term storage and release of energy p. 951

13. During **lipolysis** (lipid catabolism), lipids are broken down into pieces that can be converted into pyruvate or channeled into the citric acid cycle.
14. **Triglycerides**, the most abundant lipids in the body, are split into glycerol and fatty acids. The glycerol is converted to pyruvate, and the fatty acids enter the mitochondria.
15. **Beta-oxidation** is the breakdown of a fatty acid molecule into 2-carbon fragments that enter the citric acid cycle. The steps of beta-oxidation cannot be reversed, and the body cannot manufacture all the fatty acids needed for normal metabolic operations. *(Figure 25–7)*
16. Lipids cannot provide large amounts of ATP quickly. However, cells can shift to lipid-based energy production when glucose reserves are limited.
17. In **lipogenesis** (the synthesis of lipids), almost any organic substrate can be used to form glycerol. **Essential fatty acids** are those that cannot be synthesized and must be included in the diet.
18. Most lipids circulate as **lipoproteins** (lipid–protein complexes that contain large glycerides and cholesterol). The largest lipoproteins, chylomicrons, carry absorbed lipids from the intestinal tract to the bloodstream. All other lipoproteins are derived from the liver and carry lipids to and from various tissues of the body. *(Figure 25–8)*
19. Capillary walls of adipose tissue, skeletal muscle, cardiac muscle, and the liver contain **lipoprotein lipase**, an enzyme that breaks down lipids, releasing a mixture of fatty acids and monoglycerides into the interstitial fluid. *(Figure 25–8)*

25-4 Protein metabolism provides amino acids and synthesizes proteins p. 956

20. If other energy sources are inadequate, mitochondria can break down amino acids in the citric acid cycle to generate ATP. In the mitochondria, the amino group can be removed by either **transamination** or by **deamination**. *(Figure 25–9)*
21. Protein catabolism is impractical as a source of quick energy.
22. Roughly half the amino acids needed to build proteins can be synthesized. There are 10 **essential amino acids**, which must be acquired through the diet. **Amination**, the attachment of an amino group to a carbon framework, is an important step in the synthesis of **nonessential amino acids**. (Figure 25–9*)*

25-5 The body experiences two patterns of metabolic activity: energy storage in the absorptive state and energy release in the postabsorptive state p. 957

23. No one cell of a human can perform all the anabolic and catabolic operations necessary to support life. Homeostasis can be preserved only when metabolic activities of different tissues are coordinated.
24. The body has five metabolic components: the liver, adipose tissue, skeletal muscle, nervous tissue, and other peripheral tissues. The liver is the focal point for metabolic regulation and control. Adipose tissue stores lipids, primarily in the form of triglycerides. Skeletal muscle contains substantial glycogen reserves, and the contractile proteins can be degraded and the amino acids used as an energy source. Nervous tissue does not contain energy reserves; glucose must be supplied to it for energy. Other peripheral tissues are able to metabolize glucose, fatty acids, or other substrates under the direction of the endocrine system.
25. For about 4 hours after a meal, nutrients enter the blood as intestinal absorption proceeds. *(Spotlight Figure 25–10)*
26. The liver closely regulates the circulating levels of glucose and amino acids.
27. The **absorptive state** exists when nutrients are being absorbed by the digestive tract. Adipocytes remove fatty acids and glycerol from the bloodstream and synthesize new triglycerides to be stored for later use. *(Spotlight Figure 25–10)*
28. During the absorptive state, glucose molecules are catabolized and amino acids are used to build proteins. Skeletal muscles may also catabolize circulating fatty acids, and the energy obtained is used to increase glycogen reserves.
29. The **postabsorptive state** extends from the end of the absorptive state to the next meal. *(Spotlight Figure 25–10)*
30. When blood glucose levels fall, the liver begins breaking down glycogen reserves and releasing glucose into the bloodstream. As the time between meals increases, liver cells synthesize glucose molecules from smaller carbon fragments and from glycerol molecules. Fatty acids undergo beta-oxidation; the fragments enter the citric acid cycle or combine to form **ketone bodies**. *(Spotlight Figure 25–10)*
31. Some amino acids can be converted to pyruvate and used for gluconeogenesis; others, including most of the essential amino acids, are converted to acetyl-CoA and are either catabolized or converted to ketone bodies.
32. Nervous tissue continues to be supplied with glucose as an energy source until blood glucose levels become very low.

25-6 Adequate nutrition allows normal physiological functioning p. 959

33. **Nutrition** is the absorption of nutrients from food. A **balanced diet** contains all the ingredients needed to maintain homeostasis; a balanced diet prevents **malnutrition**.
34. The **basic food groups** include grains, vegetables, fruits, dairy, and protein. These are arranged on a *plate* to reflect the recommended daily food consumption balanced with daily physical activity. *(Figure 25–11; Table 25–1)*
35. Amino acids, purines, pyrimidines, creatine, and porphyrins are **nitrogen compounds**, which contain nitrogen atoms. An adequate dietary supply of nitrogen is essential, because the body does not maintain large nitrogen reserves. **Nitrogen balance** is a state in which the amount of nitrogen absorbed equals that lost in urine and feces.
36. **Minerals** act as cofactors in a variety of enzymatic reactions. They also contribute to the osmotic concentration of body fluids and play a role in membrane potentials, action potentials, the release of neurotransmitters, muscle contraction, skeletal construction and maintenance, gas transport, buffer systems, fluid absorption, and waste removal. *(Table 25–2)*
37. Vitamins are needed in very small amounts. Vitamins A, D, E, and K are **fat-soluble vitamins**; taken in excess, they can lead to **hypervitaminosis**. **Water-soluble vitamins** are not stored in the body; a lack of adequate dietary supplies may lead to **hypovitaminosis**, or vitamin insufficiency). *(Tables 25–3, 25–4)*
38. A balanced diet can improve one's general health.

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms p. 966

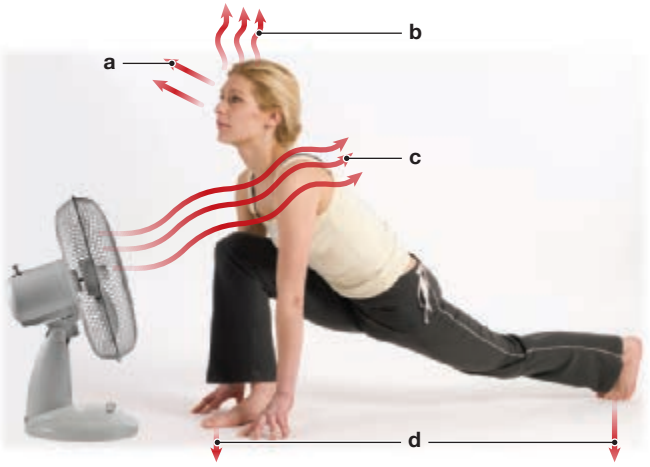
39. The energy content of food is usually expressed in **kilocalories (kcal)** per gram (kcal/g) or as **Calories** per gram (Cal/g).
40. The catabolism of lipids releases 9.46 kcal/g, about twice the amount released by equivalent weights of carbohydrates or proteins.
41. The **basal metabolic rate (BMR)** is a measurement of the rate at which the body expends energy while at rest to maintain vital functions, such as breathing and keeping warm. *(Figure 25–12)*
42. The homeostatic regulation of body temperature is **thermoregulation**. Heat exchange with the environment involves four processes: **radiation**, **convection**, **evaporation**, and **conduction**. *(Figure 25–13)*
43. The *pre-optic area* of the hypothalamus acts as the body's thermostat, affecting the **heat-loss center** and the **heat-gain center**.
44. Mechanisms for increasing heat loss include both physiological mechanisms (peripheral vasodilation, increased perspiration, and increased respiration) and behavioral modifications.
45. Responses that conserve heat include a decreased blood flow to the dermis and *countercurrent exchange*. *(Figure 25–14)*
46. Heat is generated by **shivering thermogenesis** and **nonshivering thermogenesis**.
47. Thermoregulatory responses differ among individuals. One important source of variation is **acclimatization** (a physiological adjustment to an environment over time).
48. **Fever**, a body temperature above 37.2°C (99°F), can result from problems with the thermoregulatory mechanism, circulation, or sweat gland activity, or from the resetting of the hypothalamic "thermostat" by circulating pyrogens.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Catabolism refers to **(a)** the creation of a nutrient pool, **(b)** the sum total of all chemical reactions in the body, **(c)** the production of organic compounds, **(d)** the breakdown of organic substrates.
2. The breakdown of glucose to pyruvate is an _____ process. **(a)** anaerobic, **(b)** aerobic, **(c)** anabolic, **(d)** oxidative, **(e)** both a and d.
3. The process that produces more than 90 percent of the ATP used by our cells is **(a)** glycolysis, **(b)** the citric acid cycle, **(c)** substrate-level phosphorylation, **(d)** oxidative phosphorylation.
4. The sequence of reactions responsible for the breakdown of fatty acid molecules is **(a)** beta-oxidation, **(b)** the citric acid cycle, **(c)** lipogenesis, **(d)** all of these.
5. The citric acid cycle must turn _____ time(s) to completely metabolize the pyruvate produced from one glucose molecule. **(a)** 1, **(b)** 2, **(c)** 3, **(d)** 4, **(e)** 5.
6. The largest metabolic reserves for the average adult are stored as **(a)** carbohydrates, **(b)** proteins, **(c)** amino acids, **(d)** triglycerides, **(e)** fatty acids.
7. Fill in the missing terms for the different mechanisms of heat transfer.



8. The vitamins generally associated with vitamin toxicity are **(a)** fat-soluble vitamins, **(b)** water-soluble vitamins, **(c)** the B complex vitamins, **(d)** vitamins C and B_{12}.
9. What is a lipoprotein? What are the major groups of lipoproteins, and how do they differ?

LEVEL 2 Reviewing Concepts

10. What is oxidative phosphorylation? Explain how the electron transport chain and chemiosmosis are involved in this process.
11. How are lipids catabolized in the body? How is beta-oxidation involved in lipid catabolism?
12. How do the absorptive and postabsorptive states maintain normal blood glucose levels?
13. Why is the liver the focal point for metabolic regulation and control?
14. Why are vitamins and minerals essential components of the diet?
15. Articles in the popular media often refer to "good cholesterol" and "bad cholesterol." To which types and functions of cholesterol do these terms refer? Explain your answer.

LEVEL 3 Critical Thinking and Clinical Applications

16. When blood levels of glucose, amino acids, and insulin are high, and glycogenesis is occurring in the liver, the body is in the _____ state. **(a)** fasting, **(b)** postabsorptive, **(c)** absorptive, **(d)** stress, **(e)** bulimic.
17. Charlie has a blood test that shows a normal level of LDLs but an elevated level of HDLs in his blood. Given that his family has a history of cardiovascular disease, he wonders if he should modify his lifestyle. What would you tell him?
18. Jill suffers from anorexia nervosa. One afternoon she is rushed to the emergency room because of cardiac arrhythmias. Her breath smells fruity, and her blood and urine samples contain high levels of ketone bodies. Why do you think she is having the arrhythmias?

CLINICAL CASE Wrap-Up The Miracle Supplement

Vitamin A is the miracle vitamin supplement that can reduce overall childhood mortality by 23 percent in high-risk areas like rural Kenya. Preschool-age children and pregnant women in their last trimester are the most vulnerable to vitamin A deficiency.

Like other fat-soluble vitamins, vitamin A is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. In the retina of the eye, *retinal* (made from vitamin A) combines with *opsin* to form *rhodopsin*, which is necessary for low-light and color vision. Vitamin A deficiency is the leading cause of preventable childhood blindness, affecting as many as half a million children worldwide. As a coenzyme, vitamin A is critical in many steps in the immune system. Vitamin A deficiency leads to a decreased immune response and increased vulnerability to malaria, respiratory infections, and diarrhea. Vitamin A is also critical for normal bone growth and development, and its deficiency can lead to stunting and skeletal deformities.

Vitamin A is found naturally in leafy green, yellow, and orange vegetables and fruits. Vitamin A is also available in milk, liver, eggs, and some fatty fish. None of these food items are available to Justine, who is among the very poor living in sub-Saharan Africa. But thanks to inexpensive vitamin A supplements, Justine's daughter will be protected from the health problems caused by vitamin A deficiency.

1. Other than diet and vitamin supplementation, is there any other available source of vitamin A?
2. If Justine's diet—which includes very little milk, liver, eggs, fish, leafy green, yellow, and orange vegetables, and fruits—is deficient in vitamin A, what other vitamin deficiencies might be expected?

See the blue Answers tab at the back of the book.

Related Clinical Terms

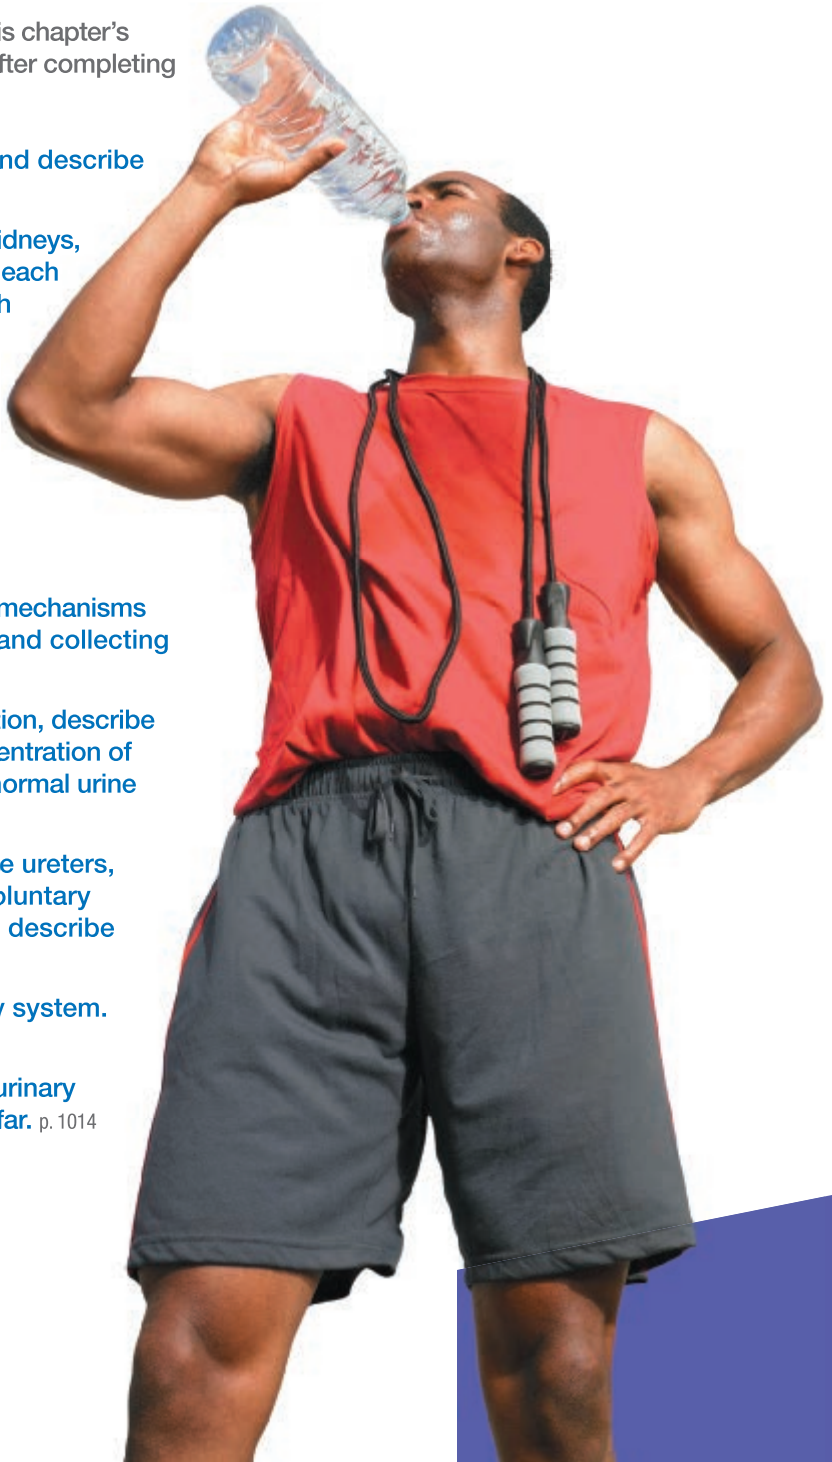
anorexia: Persistent loss of appetite.
anorexia nervosa: Eating disorder occurring primarily among girls and women characterized by a desire to lose, or not gain, weight through starvation, due to a distorted view of the person's own body. There are typically two types: strict diet and exercise, and binging and purging.
binge–purge syndrome: Eating disorder characterized by excessive eating followed by periods of fasting or self-induced vomiting.
bulimia: An eating disorder usually characterized by episodic binge eating that is followed by feelings of guilt, depression, and self-condemnation. It is often associated with steps taken to lose weight, such as self-induced vomiting, the use of laxatives, dieting, or fasting.
eating disorders: Psychological problems that result in inadequate or excessive food consumption. Examples include anorexia nervosa and bulimia.
familial hypercholesterolemia: The most common inherited type of hyperlipidemia characterized by high levels of lipids in one's blood. It affects 1 in every 500 children born, who then present with LDL levels in excess of 190.
heat cramps: A condition that usually follows heavy sweating due to strenuous activity that causes a loss of salt in the body and results in painful muscle spasms in the abdomen, arms, or legs.
hyperuricemia: A condition in which the plasma uric acid level exceeds 7.4 mg/dL. It can result in the condition called *gout*.
ketonuria: The presence of ketone bodies in the urine.
kwashiorkor: A form of malnutrition due to a protein deficiency in the diet that typically affects young children in tropical regions.
marasmus: Severe malnourishment that causes a child's weight to fall significantly below the standards set for children of similar age.
orexigenic: Having a stimulating effect on the appetite.
pica: Tendency or craving for substances other than normal food. Possible organic causes are iron deficiency, lead encephalopathy, pregnancy, and zinc deficiency.
protein-calorie malnutrition (PCM): A severe deficiency of protein in the diet in addition to inadequate caloric intake. It results in the condition termed *kwashiorkor*.
skin-fold test: Test to estimate the amount of body fat on a person.

26 The Urinary System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **26-1** Identify the organs of the urinary system, and describe the functions of the system. p. 977
- **26-2** Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, and describe the structure of a nephron. p. 978
- **26-3** Describe the basic processes that form urine. p. 987
- **26-4** Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation. p. 989
- **26-5** Identify the types and functions of transport mechanisms found along each segment of the nephron and collecting system. p. 993
- **26-6** Explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample. p. 1001
- **26-7** Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the urinary reflexes. p. 1009
- **26-8** Describe the effects of aging on the urinary system. p. 1013
- **26-9** Give examples of interactions between the urinary system and other organ systems studied so far. p. 1014



CLINICAL CASE A Case of "Hidden" Bleeding

The motorcycle accident scene is horrific. The driver is dead, and his passenger—a 14-year-old high school freshman named Mike—is unconscious, flung more than 50 feet from the wreckage. When emergency responders deliver Mike to the trauma center, he has no measurable blood pressure, in spite of the 4 liters of fluids they have infused. The trauma team begins administering whole blood transfusions, but Mike is bleeding faster than replacement blood can be supplied.

Noting Mike's bloated abdomen and the abrasions on his left posterior chest and flank, the trauma team suspects that the massive blood loss is due to intra-abdominal injuries. An x-ray of Mike's chest and abdomen shows fractured left 8th through 12th ribs and fractures of the left transverse processes of L_1, L_2, and L_3 vertebrae. A nurse inserts a urinary catheter into Mike's bladder, which drains clear urine.

When the surgeon opens Mike's abdomen through a midline incision, he encounters a copious amount of free blood. Clearing this blood quickly, and moving the abdominal structures out of the way, he finds a ruptured spleen that is bleeding profusely. The surgeon performs an emergency splenectomy. Rinsing the abdominal structures reveals no further visible bleeding, but the surgical team cannot stabilize Mike's blood pressure, no matter how quickly they transfuse blood. **Something is still bleeding, but what is it? To find out, turn to the Clinical Case Wrap-Up on p. 1019.**

An Introduction to the Urinary System

The **urinary system** removes most of the metabolic wastes produced by the body's cells. In this chapter, we describe the organs that make up the urinary system, and explain how the *kidneys* remove metabolic wastes from the circulation to produce *urine*. We also discuss the major regulatory mechanisms controlling urine production and concentration, and consider how urine is eliminated from the body.

26-1 The organs of the urinary system function in excreting wastes and regulating body fluids

Learning Outcome Identify the organs of the urinary system, and describe the functions of the system.

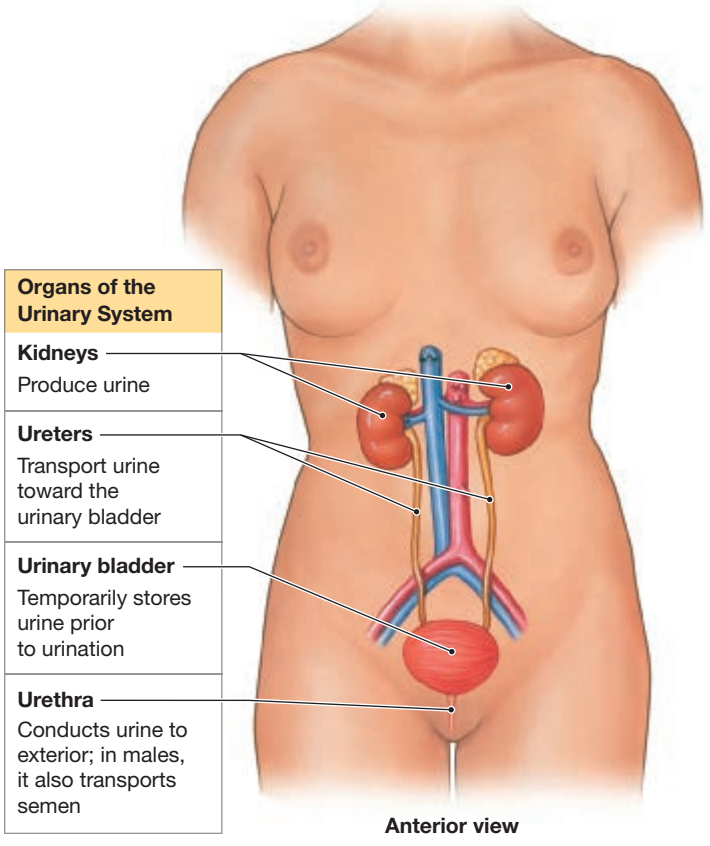
This section introduces the organs of the urinary system, as well as their major functions.

Organs of the Urinary System

The organs of the urinary system are shown in Figure 26–1. The paired **kidneys** have excretory functions in the urinary system. These organs produce **urine**, which is a fluid that contains water, ions, and small soluble compounds. Urine leaving the kidneys flows along the *urinary tract*. The **urinary tract** consists of paired tubes called **ureters** (yū-RĒ-terz); the **urinary bladder**, a muscular sac for temporary urine storage; and a tube called the **urethra** (yū-RĒ-thrah).

When the bladder is full, urine is eliminated from the body in the process of **urination**, or **micturition** (mik-chū-RISH-un). In this process, the urinary bladder contracts and forces urine through the urethra, which conducts the urine to the exterior. ATLAS: Embryology Summary 20: The Development of the Urinary System

Figure 26–1 An Overview of the Urinary System. An anterior view of the urinary system, showing the positions of its organs.



Urinary System Functions

We can see that the urinary system has the major functions of *excretion*, the removal of metabolic waste products from body fluids, and *elimination*, the discharge of these wastes out of the body. However, the urinary system also has a third major function: *homeostatic regulation* of the volume and solute concentration of blood. Essential to such homeostatic regulation are the following:

- *Regulating blood volume and blood pressure*, by adjusting the volume of water lost in urine, secreting erythropoietin, and releasing renin.
- *Regulating plasma concentrations of sodium, potassium, chloride, and other ions*, by influencing the quantities in urine. The kidneys also control the calcium ion level through the synthesis of calcitriol.
- *Helping to stabilize blood pH*, by controlling the concentrations of hydrogen and bicarbonate ions in urine.
- *Conserving valuable nutrients*, by preventing their loss in urine while removing metabolic wastes—especially the nitrogenous wastes *urea* and *uric acid*.
- *Assisting the liver* in detoxifying poisons and, during starvation, the deamination of amino acids for their metabolic use by other tissues.

These activities are carefully regulated to keep the composition of blood within acceptable limits. A disruption of any one of them has immediate consequences and can be fatal.

Checkpoint

1. **Name the major functions of the urinary system.**
2. **Identify the organs of the urinary system.**

See the blue Answers tab at the back of the book.

26-2 Kidneys are highly vascular organs containing functional units called nephrons

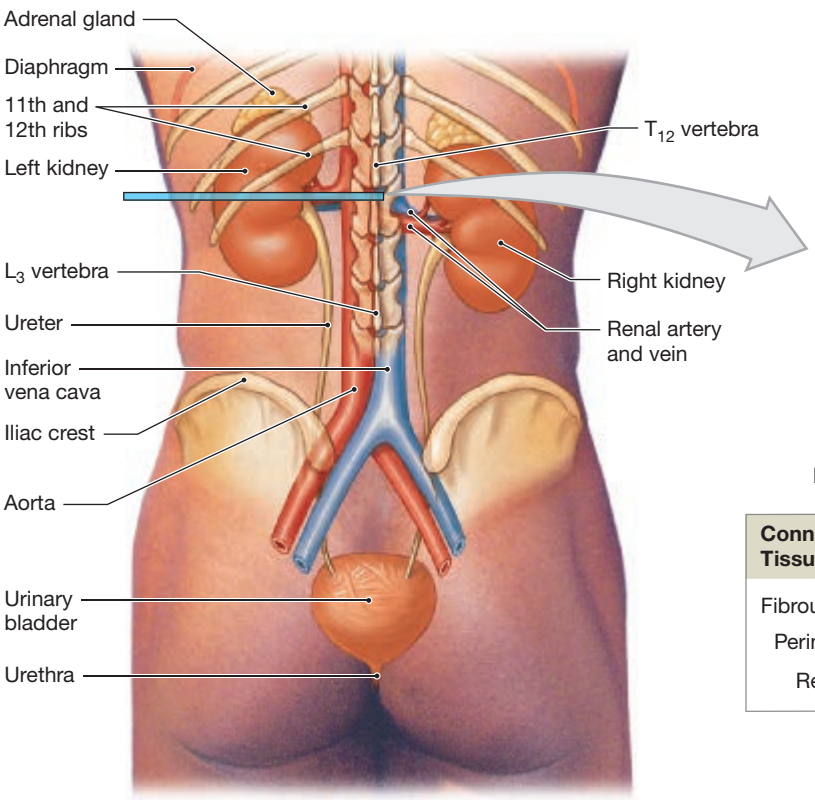
Learning Outcome Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, and describe the structure of a nephron.

The kidneys are major excretory organs located retroperitoneally in the superior lumbar region. Kidneys contain many functional units called nephrons.

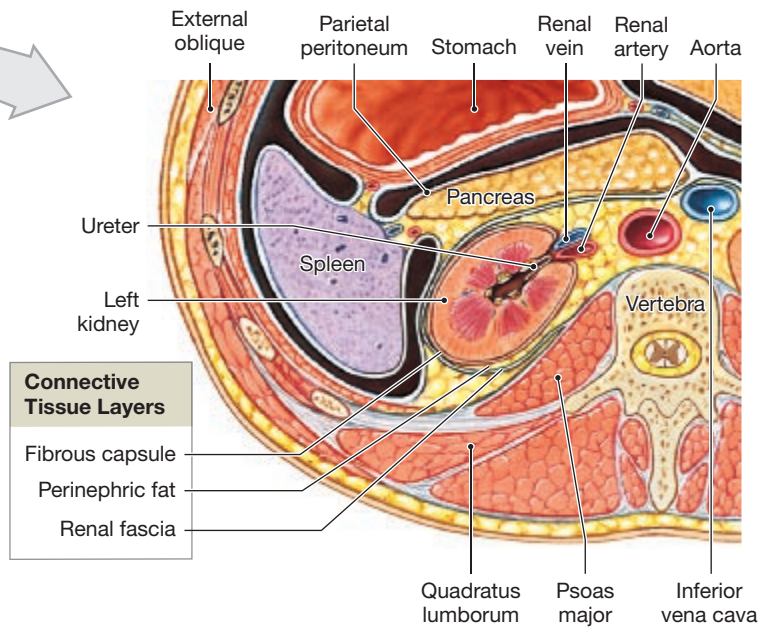
Position and Associated Structures of the Kidneys

The kidneys are located on either side of the vertebral column, between vertebrae T_{12} and L_3 (Figure 26–2a). The left kidney

Figure 26–2 The Position and Associated Structures of the Kidneys. ATLAS: Plates 57a,b



a A posterior view of the trunk



b A superior view of a transverse section at the level indicated in part a

Go to MasteringA&P™ > Study Area > Menu > Lab Tools > PAL 3.0 > Human Cadaver and Anatomical Models > Urinary System

lies slightly superior to the right kidney. The right kidney is slightly inferior due to the position of the right lobe of the liver.

The superior surface of each kidney is capped by an adrenal gland. The kidneys and adrenal glands lie between the muscles of the posterior body wall and the parietal peritoneum, in a retroperitoneal position (Figure 26–2b).

Tips & Tools

To visualize the kidneys' retroperitoneal positions, think of each kidney as a picture on the body wall that got covered over by wallpaper (the parietal peritoneum). To remember all the organs located entirely or partially retroperitoneally, use the mnemonic **SAD PUCKER** for **S**uprarenal (adrenal) glands, **A**orta and inferior vena cava, **D**uodenum, **P**ancreas, **U**reters, **C**olon, **K**idneys, **E**sophagus, **R**ectum.

The kidneys are held in position within the abdominal cavity by (1) the overlying peritoneum, (2) contact with adjacent visceral organs, and (3) supporting connective tissues. Three concentric layers of connective tissue protect and stabilize each kidney, which are, from deep to superficial (see Figure 26–2b):

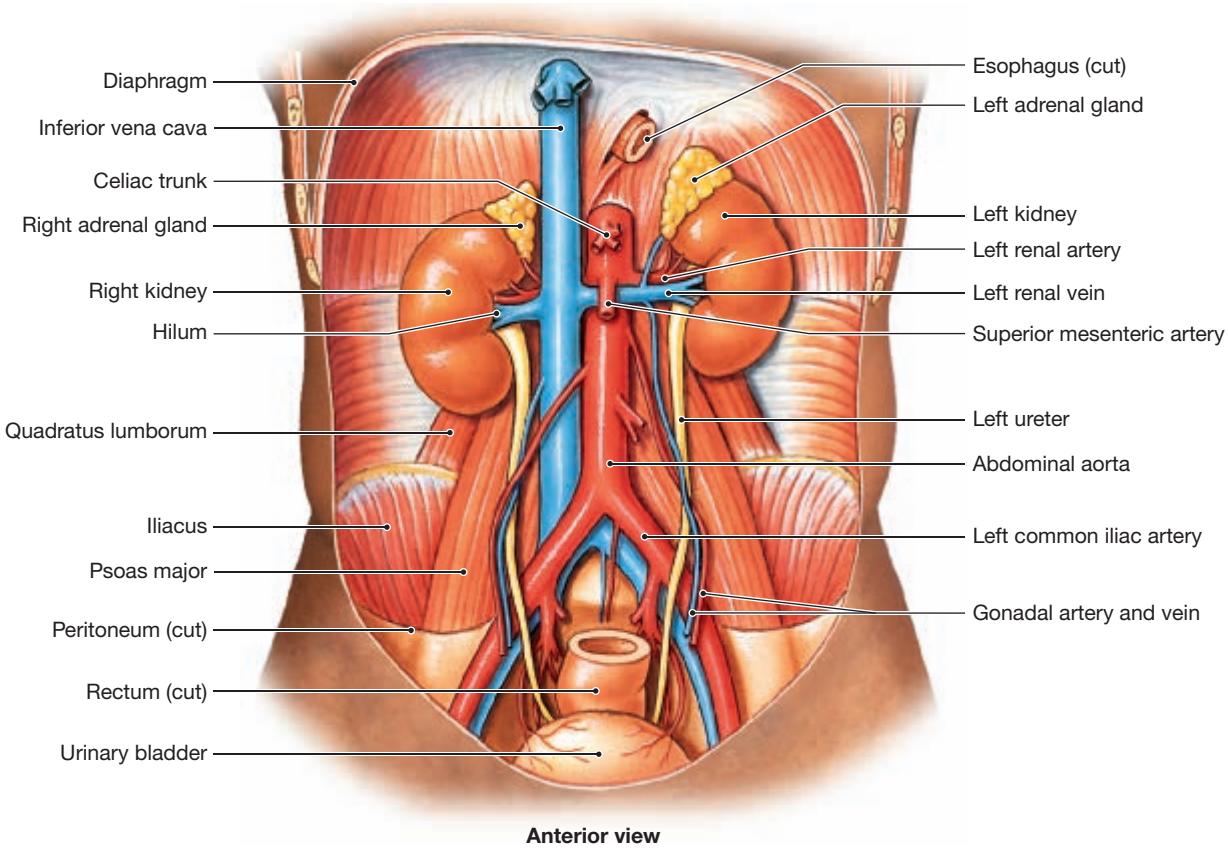
1. The **fibrous capsule**, a layer of collagen fibers that covers the outer surface of the entire organ
2. The **perinephric fat**, a cushioning, thick layer of adipose tissue that surrounds the fibrous capsule
3. The **renal fascia**, a dense, fibrous outer layer that anchors the kidney to surrounding structures. Collagen fibers extend outward from the fibrous capsule through the perinephric fat to this layer. Posteriorly, the renal fascia fuses with the deep fascia surrounding the muscles of the body wall. Anteriorly, the renal fascia forms a thick layer that fuses with the peritoneum.

In effect, each kidney hangs suspended by collagen fibers from the renal fascia and is packed in a soft cushion of adipose tissue. This arrangement prevents the jolts and shocks of day-to-day living from disturbing normal kidney function. If the suspensory fibers break or become detached, a slight bump or hit can displace the kidney and stress the attached vessels and ureter. This condition is called a *floating kidney*. It may cause pain or other problems from the distortion of the ureter or blood vessels.

Gross Anatomy of the Kidneys

As shown in Figure 26–3, the kidneys are bean-shaped organs served by renal blood vessels, lymphatics, and nerves adjacent to the proximal region of the ureters.

Figure 26–3 The Gross Anatomy of the Urinary System. The abdominopelvic cavity (with the digestive organs removed), showing the kidneys, ureters, urinary bladder, and blood supply to the urinary structures. ATLAS: Plates 61a; 62a,b



Anterior view

External Anatomy of the Kidneys

A typical adult kidney is reddish-brown and about 10 cm (4 in.) long, 5.5 cm (2.2 in.) wide, and 3 cm (1.2 in.) thick (see Figure 26–3). Each kidney weighs about 150 g (5.25 oz). The **hilum**, a prominent medial indentation, is the point of entry for the *renal artery* and *renal nerves*. The hilum is also the point of exit for the *renal vein* and the ureter.

Internal Anatomy of the Kidneys

The fibrous capsule covering the outer surface of the kidney also lines the **renal sinus**, an internal cavity within the kidney (Figure 26–4). The fibrous capsule is bound to the outer surfaces of the structures within the renal sinus. In this way, it stabilizes the positions of the ureter, renal blood vessels, and nerves.

The kidney has an outer *cortex* and an inner *medulla*. The **renal cortex** is the superficial region of the kidney, in contact with the fibrous capsule. The cortex is reddish-brown and granular.

The **renal medulla** consists of 6 to 18 distinct triangular structures called **renal pyramids**. The base of each pyramid touches the cortex. The tip of each pyramid—a region known as the **renal papilla**—projects into the renal sinus. Each pyramid has a series of fine grooves that converge at the papilla. Bands of cortical tissue called **renal columns** extend into the medulla and separate adjacent renal pyramids. The columns have a distinctly granular texture, similar to that of the cortex. A **kidney lobe** consists of a renal pyramid, the overlying area of renal cortex, and adjacent tissues of the renal columns.

Urine is produced in the kidney lobes. Ducts within each renal papilla discharge urine into a cup-shaped drain called a **minor calyx** (KĀ-liks). Four or five minor calyces (KAL-ih-sēz) merge to form a **major calyx**, and two or three major calyces combine to form the **renal pelvis**, a large, funnel-shaped chamber. The renal pelvis fills most of the renal sinus and is connected to the ureter, which drains the kidney.

Urine production begins in microscopic, tubular structures called *nephrons* (NEF-ronz). Two types of nephrons found in the kidney are *cortical nephrons* (in the renal cortex) and *juxtamedullary nephrons* (in the renal medulla). Each kidney has about 1.25 million nephrons, with a combined length of about 145 km (85 miles).

Blood Supply and Innervation of the Kidneys

The kidneys receive 20–25 percent of the total cardiac output. In healthy individuals, about 1200 mL of blood flow through the kidneys each minute—a phenomenal amount of blood for organs with a combined weight of less than 300 g (10.5 oz)!

Each kidney receives blood through a **renal artery**. This vessel originates along the lateral surface of the abdominal aorta near the level of the superior mesenteric artery (look back at Figure 21–23a, p. 764). As it enters the renal sinus, the renal artery provides blood to the five **segmental arteries** (Figure 26–5a). Segmental arteries further divide into a series of **interlobar arteries**. These arteries radiate outward through the renal columns between the renal pyramids. The interlobar arteries supply blood to the **arcuate** (AR-kyū-āt)

? In which region of the kidney is a glomerulus located?

arteries, which arch along the boundary between the cortex and medulla of the kidney. Each arcuate artery gives rise to a number of **cortical radiate arteries**, also called *interlobular arteries*. They supply the cortical regions of the adjacent kidney lobes. Branching from each cortical radiate artery are numerous **afferent arterioles**. These vessels deliver blood to the capillaries supplying individual nephrons (Figure 26–5b,c).

After passing through the capillaries of the nephrons, blood enters a network of venules and small veins that converge on the **cortical radiate veins**, also called *interlobular veins*

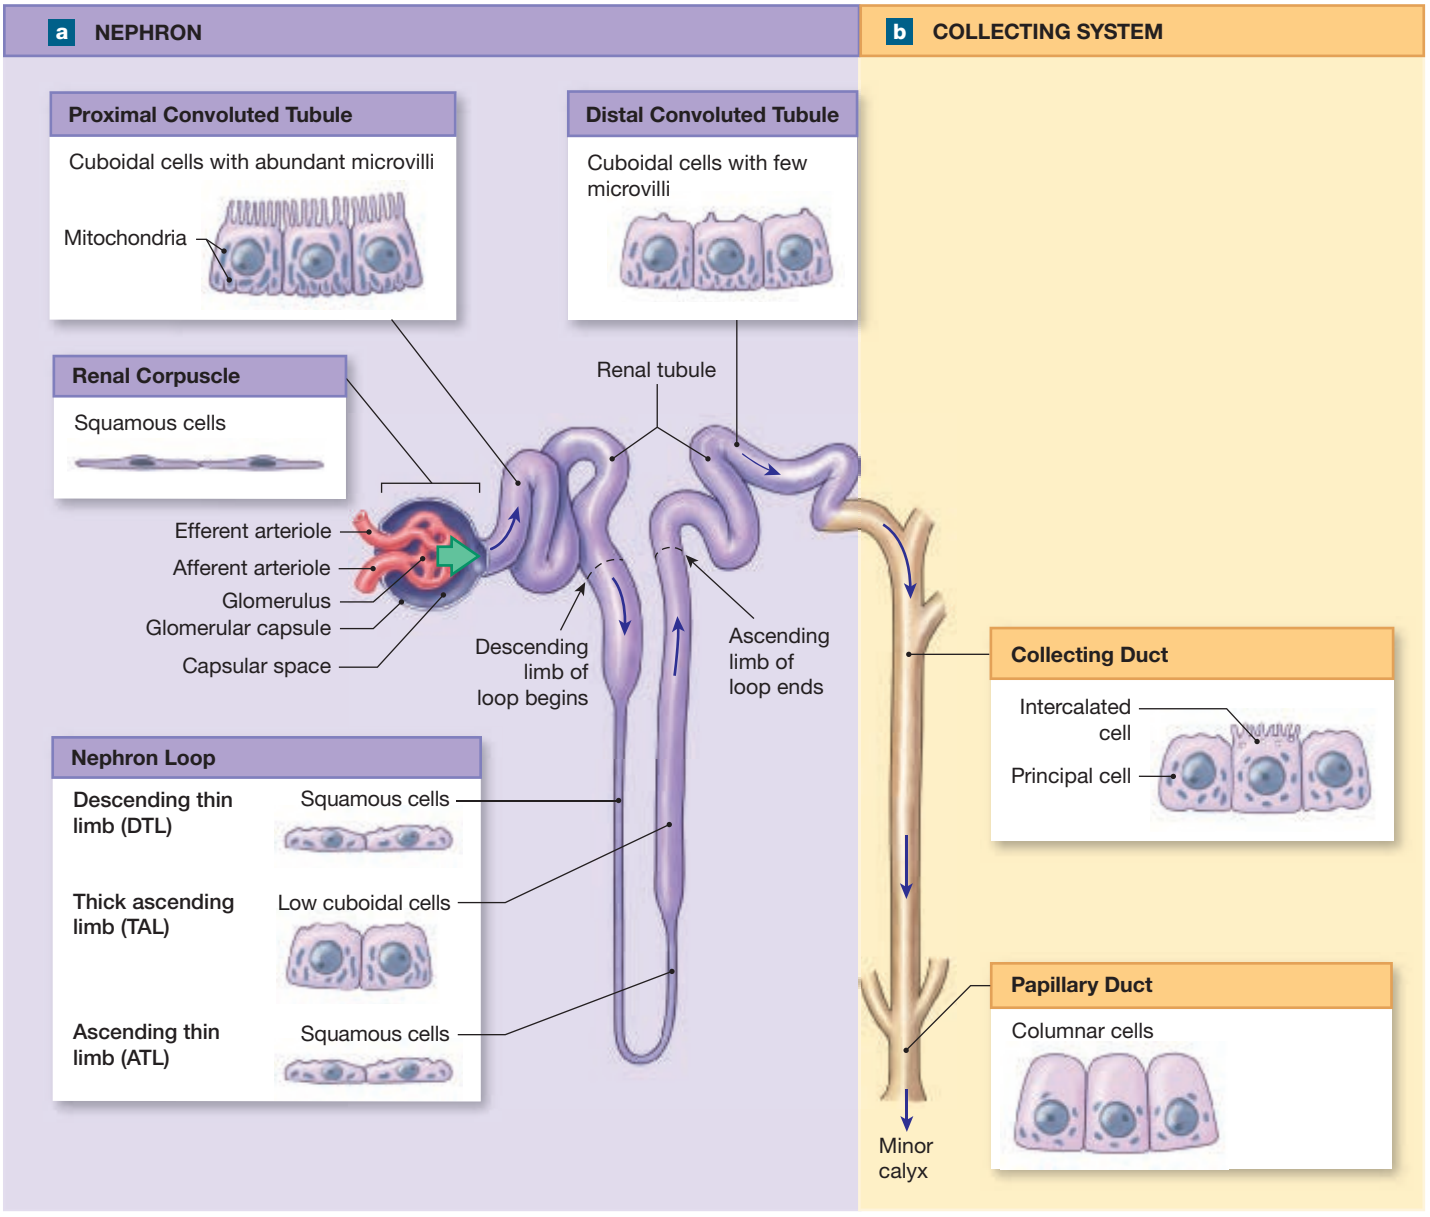
(see Figure 26–5a,c). The cortical radiate veins deliver blood to **arcuate veins**. These veins in turn empty into **interlobar veins**, which drain directly into the **renal vein**. There are no segmental veins.

Renal nerves innervate the kidneys and ureters. Most of the nerve fibers involved are sympathetic postganglionic fibers from the celiac plexus and the inferior splanchnic nerves. pp. 542, 549 A renal nerve enters each kidney at the hilum and follows the branches of the renal arteries to reach individual nephrons. The sympathetic innervation (1) adjusts rates of urine formation by changing blood flow at the nephron and (2) influences urine composition by stimulating release of the hormone *renin*.

Microscopic Anatomy of the Kidneys: The Nephron and Collecting System

In the kidneys, the functional units—the smallest structures that can carry out all the functions of the system—are the **nephrons**. Each nephron consists of a renal corpuscle and a renal tubule (Figure 26–6a). The *renal corpuscle* (KOR-pus-ul) is a spherical

Figure 26–6 The Anatomy of a Representative Nephron and the Collecting System. The characteristic cells of each segment of (a) the nephron (purple) and (b) the collecting system (tan) are noted. In this representative figure, the nephron has been significantly shortened and some components rearranged.



? What structure connects the proximal convoluted tubule to the distal convoluted tubule?

structure containing a capillary network that filters blood. The *renal tubule*, a long tubular passageway, begins at the renal corpuscle. Each renal tubule empties into the *collecting system*, a series of tubes that carry tubular fluid away from the nephron (Figure 26–6b). Let's examine the structure and basic functions of each segment of a representative nephron.

The Renal Corpuscle

Each **renal corpuscle** is 150–250 µm in diameter (Figure 26–7). It is made up of the *glomerular* (Bowman's) *capsule*, a cup-shaped chamber that envelopes the capillary network called the *glomerulus*.

The Glomerular Capsule and the Glomerulus. The outer wall of the renal corpuscle is formed by the **glomerular capsule**. This structure encapsulates the glomerular capillaries and is continuous with the initial segment of the renal tubule. The **glomerulus** (glo-MER-yū-lus; plural, *glomeruli*) consists of about 50 intertwined capillaries. Blood is delivered to the glomerulus by an afferent arteriole, and leaves the glomerulus in an **efferent arteriole** (see Figures 26–6, 26–7a).

The outer wall of the capsule is made up of a simple squamous epithelium and is called the **capsular outer layer** (see Figure 26–7a). This layer ends at the **visceral layer**, which covers the glomerular capillaries. The **capsular space** (*urinary space*) separates the capsular outer layer and visceral layer. The two layers are continuous where the glomerular capillaries are connected to the afferent arteriole and efferent arteriole. Therefore this space is continuous with the lumen of the renal tubule (look back at Figure 26–6a).

The visceral layer of the glomerulus consists of large cells with complex processes, or "feet," that wrap around the *dense layer*, a specialized basement membrane of the glomerular capillaries. These visceral cells of the capsule are called **podocytes** (PŌ-dō-sīts; *podos*, foot + *-cyte*, cell). Their feet are known as **foot processes**, or *pedicels* (see Figure 26–7b). There are narrow gaps called **filtration slits** between adjacent foot processes. These slits are only 6–9 nm wide.

b This cross section through a portion of the glomerulus shows the components of the filtration membrane of the nephron.

+ Clinical Note Glomerulonephritis

Glomerulonephritis (glo-mer-yū-lō-nef-RĪ-tis) is an inflammation of the glomeruli that impairs filtration in the kidneys. The condition is often an *immune complex disorder*. It may develop after an infection involving *Streptococcus* bacteria. The kidneys are not the sites of infection, but as the immune system responds, the number of circulating antigen–antibody complexes rapidly increases. These complexes are small enough to pass through the basement membrane, but too large to fit between podocyte foot processes of the filtration membrane. The complexes clog up the filtration mechanism. As a result, filtrate production decreases. Any condition that leads to a massive immune response, including viral infections and autoimmune disorders, can cause glomerulonephritis.

Intraglomerular mesangial cells are located among the glomerular capillaries (see Figure 26–7b). They are specialized cells derived from smooth muscle. Functions of these contractile cells include structural support, filtration, and phagocytosis. Their contraction decreases the luminal diameter of the capillaries. Their phagocytic activities help clear debris from the filtration membrane (discussed next).

The glomerular capillaries are fenestrated capillaries. That is, their endothelium contains pores ranging from 60 to 80 nm (0.06 to 0.08 μm) in diameter. The basement membrane of the endothelium differs from that in other capillary networks in that it may encircle more than one capillary.

The Filtration Membrane. Together, the fenestrated endothelium, the basement membrane, and the foot processes of podocytes form the **filtration membrane** (see Figure 26–7b). During *filtration*, which takes place in the renal corpuscle, blood pressure forces water and small dissolved solutes out of the glomerular capillaries through this membrane and into the capsular space. The larger solutes, especially plasma proteins, do not pass through. Filtration produces an essentially protein-free solution, known as a *filtrate*, that is otherwise similar to blood plasma. From the renal corpuscle, filtrate enters the renal tubule.

The Renal Tubule

The **renal tubule** may be 50 mm (1.97 in.) in length. This tubule has two convoluted (coiled or twisted) segments—the *proximal convoluted tubule (PCT)* and the *distal convoluted tubule (DCT)*. They are separated by a simple U-shaped tube, the *nephron loop*, also called the *loop of Henle* (HEN-lē). The convoluted segments lie in the cortex of the kidney, and the nephron loop dips at least partially into the medulla. For clarity, the nephron shown in Figure 26–6a has been shortened and straightened.

Tips & Tools

In the nephron, the terms *proximal tubule* and *distal tubule* refer to how far along the renal tubule these structures are located from the renal corpuscle. Think of *proximal* (nearer the renal corpuscle) as being first, and *distal* (farther from the renal corpuscle) as being last.

As the filtrate travels along the renal tubule, it is now called *tubular fluid*, and it gradually changes in composition. This is because the main functions of the renal tubule are reabsorption and secretion. When a substance is *reabsorbed*, it is "reclaimed," eventually reentering the blood. When a substance is *secreted*, it enters the tubular fluid from the blood. The changes that take place in the tubular fluid, and the characteristics of the urine that result, are due to the activities under way in each segment of the nephron.

The Proximal Convoluted Tubule. The **proximal convoluted tubule (PCT)** is the first segment (see Figure 26–6a). Its entrance lies almost directly opposite the point where the afferent and efferent arterioles connect to the glomerulus. The lining of the PCT is a simple cuboidal epithelium whose apical surfaces have microvilli. Reabsorption of critical ions is the primary function of the PCT.

The Nephron Loop. The PCT makes an acute bend that turns the renal tubule toward the renal medulla. This turn leads to the **nephron loop** (see Figure 26–6a). It is divided into a **descending limb** and an **ascending limb**. Fluid in the descending limb flows toward the renal pelvis. Fluid in the ascending limb flows toward the renal cortex. The limbs contain thin and thick segments: the *descending thin limb (DTL)*, the *ascending thin limb (ATL)*, and the *thick ascending limb (TAL)*. The terms *thick* and *thin* refer to the height of the epithelium, not to the diameter of the lumen. Thick limbs have cuboidal epithelium. Thin limbs are lined with squamous epithelium.

The Distal Convoluted Tubule. The thick ascending limb (TAL) of the nephron loop ends where it forms a sharp angle near the renal corpuscle. The **distal convoluted tubule (DCT)**, the third segment of the renal tubule, begins there. The initial portion of the DCT passes between the afferent and efferent arterioles (see Figure 26–7a).

In sectional view, the DCT differs from the PCT in that the DCT has a smaller luminal diameter and its epithelial cells lack microvilli. The primary function of the DCT is to reabsorb water and selected ions, as well as active secretion of undesirable substances.

The Juxtaglomerular Complex

The **juxtaglomerular complex (JGC)** is a structure that helps regulate blood pressure and filtrate formation. It consists of the

macula densa, *juxtaglomerular cells* (granular cells), and *extraglomerular mesangial cells*. The **macula densa** (MAK-yū-lah DEN-sah) is a group of tall, closely packed epithelial cells in the distal tubular epithelium. They function as either chemoreceptors or baroreceptors. The **juxtaglomerular cells** are modified smooth muscle cells in the wall of the afferent arteriole that secrete renin. These cells function as baroreceptors that monitor blood pressure in the afferent arteriole. **Extraglomerular mesangial cells** are located in the triangular space between the afferent and efferent glomerular arterioles. These cells provide feedback control between the macula densa and the juxtaglomerular cells (see Figure 26–7a).

The Collecting System

The distal convoluted tubule, the last segment of the nephron, opens into the **collecting system** (see Figure 26–6b). Many individual nephrons drain their tubular fluid into a nearby **collecting duct**. Each collecting duct begins in the cortex and descends into the medulla. Several collecting ducts then converge into a larger **papillary duct**, which in turn empties into a *minor calyx*. The epithelium lining the papillary duct is typically columnar.

Two main types of cells are found in the collecting duct: *intercalated cells* and *principal cells*. Intercalated cells are cuboidal cells with microvilli. Type A intercalated cells and Type B intercalated cells make up the population of intercalated cells. Together, these cells regulate the acid–base balance in the blood. Principal cells are cuboidal cells that lack microvilli and reabsorb water and secrete potassium ions.

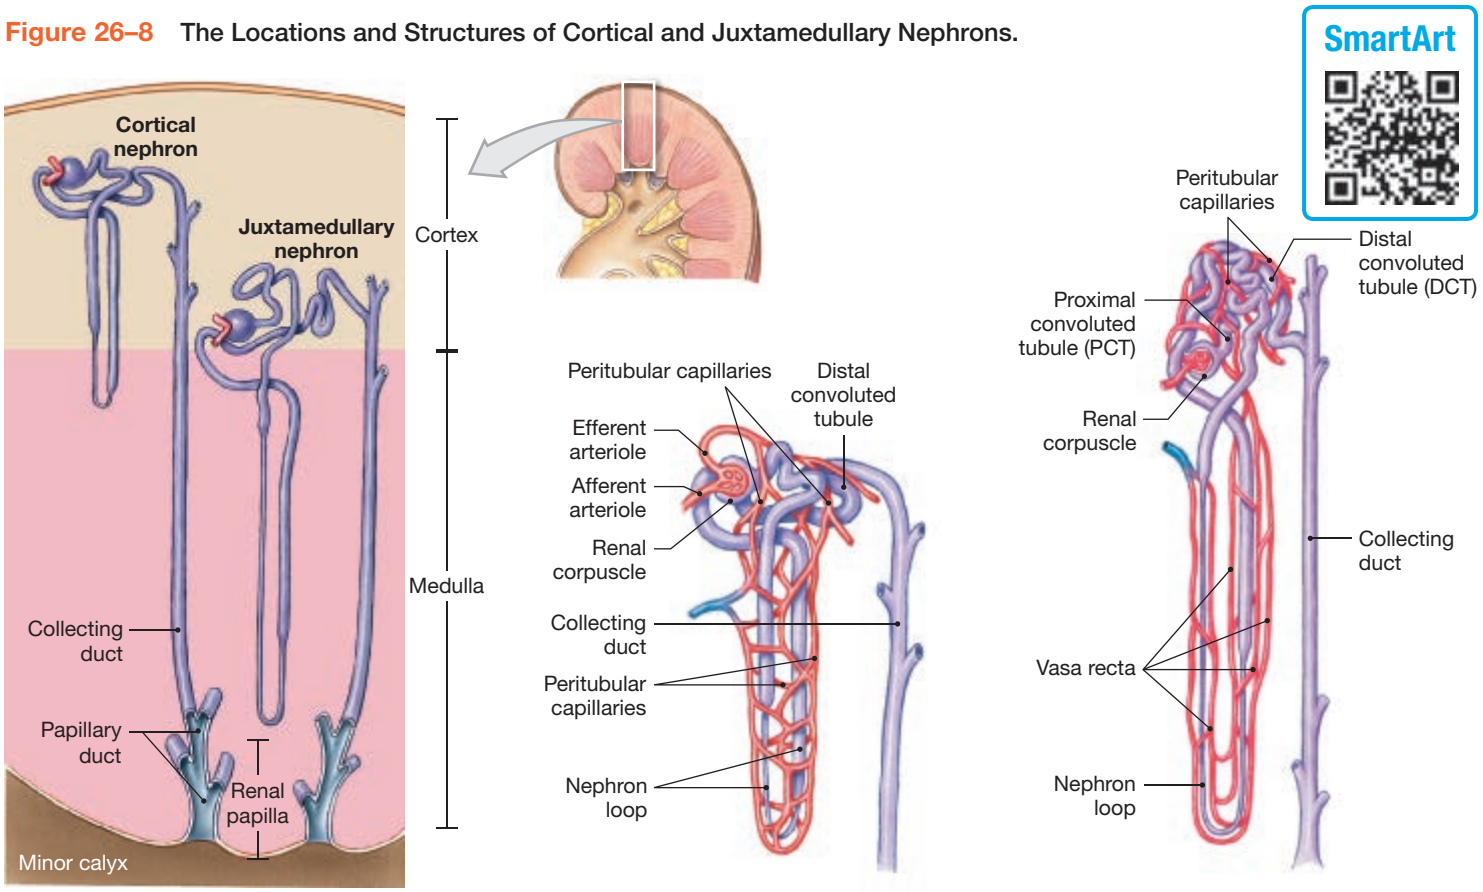
The collecting system transports tubular fluid from the nephrons to the renal pelvis. Along the way, it also adjusts the fluid's composition and determines the final osmotic concentration and volume of urine, the final product. We consider these activities of the collecting system later in the chapter.

Table 26–1 summarizes the regional specializations and general functions of the parts of the nephron and the collecting system.

Types of Nephrons

Nephrons from different locations within a kidney differ slightly in structure. Approximately 85 percent of all nephrons are **cortical nephrons**, located almost entirely within the superficial cortex of the kidney (Figure 26–8a,b). In a cortical nephron, the nephron loop is relatively short, and the efferent arteriole delivers blood to a network of **peritubular capillaries**, which surround the entire renal tubule. These capillaries drain

Figure 26–8 The Locations and Structures of Cortical and Juxtamedullary Nephrons.



a The general appearance and location of nephrons in the kidneys

b The circulation to a cortical nephron

c The circulation to a juxtamedullary nephron

Table 26–1 The Organization of the Nephron and Collecting System

Region	Histological Characteristics	Length	Diameter	Primary Function
NEPHRON				
Renal corpuscle 	Glomerulus (capillary knot), intraglomerular mesangial cells, and basement membrane, enclosed by the glomerular capsule; visceral layer (podocytes) and capsular outer layer (simple squamous epithelium) separated by capsular space	150–250 µm (spherical)	150–250 µm	Filtration of blood plasma
Renal tubule				
Proximal convoluted tubule (PCT) 	Cuboidal cells with microvilli	14 mm	60 µm	Reabsorption of ions, organic molecules, vitamins, water; secretion of drugs, toxins, acids
Nephron loop 	Squamous or cuboidal cells	30 mm	15 µm 30 µm	Descending limb: reabsorption of water from tubular fluid Ascending limb: reabsorption of ions; assists in creation of a concentration gradient in the renal medulla
Distal convoluted tubule (DCT) 	Cuboidal cells with few if any microvilli	5 mm	30–50 µm	Reabsorption of sodium ions and calcium ions; secretion of acids, ammonia, drugs, toxins
COLLECTING SYSTEM				
Collecting duct 	Cuboidal cells	15 mm	50–100 µm	Reabsorption of water, sodium ions; secretion or reabsorption of bicarbonate ions or hydrogen ions
Papillary duct 	Columnar cells	5 mm	100–200 µm	Conduction of tubular fluid to minor calyx; contributes to concentration gradient of the medulla

into small venules that carry blood to the cortical radiate veins (look back at Figure 26–5c).

The remaining 15 percent of nephrons, termed **juxtamedullary** (juks-tuh-MED-yū-lār-ē; *juxta*, near) **nephrons**, have long nephron loops that extend deep into the renal pyramids of the medulla (Figure 26–8a,c). The efferent arterioles of juxtamedullary nephrons connect to the **vasa recta** (*vasa*, vessel + *recta*, straight), long, straight capillaries that parallel the nephron loop.

Checkpoint

3. **Which parts of a nephron are in the renal cortex?**
4. **Why don't plasma proteins pass into the capsular space under normal circumstances?**
5. **Damage to which part of a nephron would interfere with the hormonal control of blood pressure?**

Go to MasteringA&P™ > Study Area > iP2™ > Urinary System: Glomerular Filtration

26-3 Different segments of the nephron form urine by filtration, reabsorption, and secretion

Learning Outcome Describe the basic processes that form urine.

Although you may not have thought of it this way, the primary function of urine production is to maintain homeostasis by regulating the volume and composition of blood. This process involves the excretion of solutes—specifically, **metabolic wastes**.

Metabolic Wastes

Our bodies form three important metabolic wastes:

- *Urea.* **Urea** is the most abundant organic waste. You generate approximately 21 g of urea each day, most of it through the breakdown of amino acids.
- *Creatinine.* Skeletal muscle tissue generates **creatinine** through the breakdown of *creatine phosphate*, a high-energy compound that plays an important role in muscle contraction. ↩ p. 320 Your body generates about 1.8 g of creatinine each day. Virtually all of it is excreted in urine.
- *Uric Acid.* **Uric acid** is a waste formed during the recycling of the nitrogenous bases from RNA molecules. You produce approximately 480 mg of uric acid each day.

These wastes are dissolved in the bloodstream. They can be eliminated only when dissolved in urine. For this reason, their removal involves an unavoidable water loss. The kidneys are usually capable of producing urine with an osmotic concentration more than four times that of plasma. If the kidneys were unable to concentrate the filtrate produced by filtration, fluid losses would lead to fatal dehydration in a matter of hours.

The kidneys also ensure that the fluid that *is* lost does not contain potentially useful substances that are present in blood plasma, such as sugars or amino acids. These valuable materials must be reabsorbed and retained for use by other tissues.

Basic Processes of Urine Formation

Let's look at the three distinct processes each nephron uses to produce urine:

1. *Filtration.* In **filtration**, blood pressure forces water and solutes across the walls of the glomerular capillaries and into the capsular space. Solute molecules small enough to pass through the filtration membrane are carried by the surrounding water molecules.
2. *Reabsorption.* **Reabsorption** is the removal of water and solutes from the filtrate, and their movement across the tubular epithelium and into the **peritubular fluid**, the interstitial fluid surrounding the renal tubule. Reabsorption takes place after the filtrate has left the renal corpuscle. Most of the reabsorbed substances are nutrients the body can use. Filtration is based solely on particle size, but reabsorption is a selective process. Reabsorption involves either simple diffusion or carrier proteins in the tubular epithelium. The reabsorbed substances in the peritubular fluid eventually reenter the blood. Water reabsorption takes place passively, through osmosis.
3. *Secretion.* **Secretion** is the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid. Secretion is necessary because filtration does not force all the dissolved substances out of the plasma. Tubular secretion, which removes substances from the blood, can further lower the plasma concentration of undesirable materials. It provides a backup process for filtration. Secretion is often the primary method of preparing substances, including many drugs, for excretion.

Figure 26–9 summarizes where these processes occur in the various segments of the nephron and collecting system. Most regions carry out a combination of reabsorption and secretion. Note that the balance between the two processes shifts from one region to another.

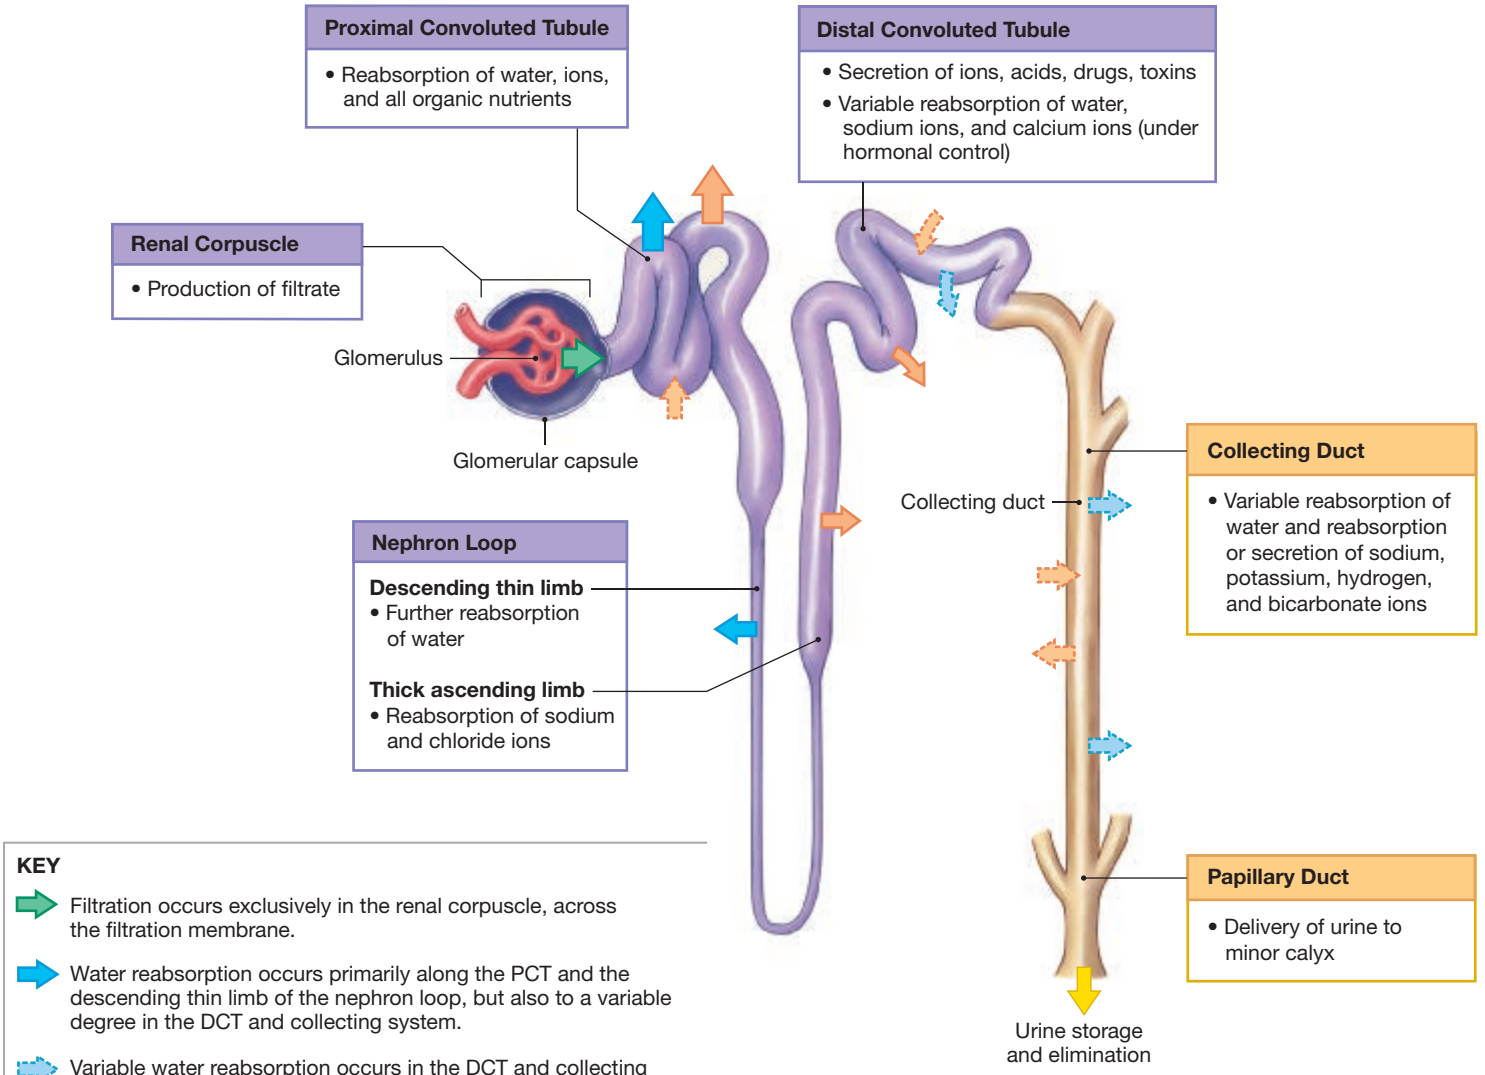
Together, these processes produce urine, a fluid that is very different from other body fluids. **Table 26–2** shows the functional efficiency of the kidneys by comparing the concentrations of solutes in urine and plasma.

Normal kidney physiology can continue only as long as filtration, reabsorption, and secretion function within relatively narrow limits. A disruption in kidney function has immediate effects on the composition of the circulating blood. If both kidneys are affected, death follows within a few days unless medical assistance is provided.

Table 26–2 Normal Laboratory Values for Solutes in Plasma and Urine

Solute	Plasma	Urine
IONS (mEq/L)		
Sodium (Na^+)	135–145	40–220
Potassium (K^+)	3.5–5.0	25–100
Chloride (Cl^-)	100–108	110–250
Bicarbonate (HCO_3^-)	20–28	1–9
METABOLITES AND NUTRIENTS (mg/dL)		
Glucose	70–110	0.009
Lipids	450–1000	0.002
Amino acids	40	0.188
Proteins	6–8 g/dL	0.000
NITROGENOUS WASTES (mg/dL)		
Urea	8–25	1800
Creatinine	0.6–1.5	150
Uric acid	2–6	40
Ammonia	<0.1	60

Figure 26–9 An Overview of Urine Formation.



In the next sections, we proceed along the nephron to consider the formation of filtrate and its subsequent changes in composition and concentration as it passes along the individual segments of the renal tubule. Most of what follows applies equally to cortical and juxtamedullary nephrons. The functions of the renal corpuscle and of the proximal and distal convoluted tubules are the same in all nephrons. Cortical nephrons do most of the reabsorption and secretion in the kidneys because they are more numerous than juxtamedullary nephrons.

However, as you will see later in the chapter, it is the juxtamedullary nephrons that enable the kidneys to produce concentrated urine. Their long nephron loops play a key role in water conservation and the formation of concentrated urine. This process is vitally important, affecting the tubular fluid produced by every nephron in the kidney. For this reason, we use a juxtamedullary nephron as our example.

Checkpoint

6. **Identify the three distinct processes that form urine in the kidney.**

See the blue Answers tab at the back of the book.

26-4 The glomerulus filters blood through the filtration membrane to produce filtrate; several pressures determine the glomerular filtration rate

Learning Outcome Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation.

In the body, the heart pushes blood around the cardiovascular system and generates *hydrostatic pressure*. As you have seen, this pressure causes filtration to occur across the walls of capillaries as water and dissolved materials are pushed into the interstitial fluids of the body (look back at Figure 21–10, p. 742). In kidney nephrons, this hydrostatic pressure drives *glomerular filtration*. Glomerular filtration is the vital first step for all other kidney functions. If filtration does not take place, wastes are not excreted, pH control is jeopardized, and an important mechanism for regulating blood volume is lost.

In this section we look at the pressures that affect the rate of glomerular filtration, and how that filtration is regulated. But first we revisit the filtration membrane, and take a closer look at how this process occurs.

Function of the Filtration Membrane

In **glomerular filtration**, blood plasma is forced through the pores of the specialized filtration membrane, and solute molecules small enough to pass through those pores are carried along. The filtration membrane restricts the passage of larger solutes and suspended materials from the plasma, producing filtrate.

We can see filtration in action in a drip coffee machine. Gravity forces hot water through the filter, and the water carries a variety of dissolved substances into the pot. The large coffee grounds never reach the pot, because they cannot fit through the pores of the filter. In other words, they are "filtered out" of the solution; the coffee we drink is the filtrate.

Recall that the filtration membrane has three parts: (1) the fenestrated endothelium, (2) the basement membrane, and (3) the foot processes of podocytes (Figures 26–7b and 26–10a). In glomerular filtration, water from the blood plasma is forced through all three parts of this membrane, with each filtering solutes of smaller size out of the final filtrate. The glomerular capillaries are made up of fenestrated endothelium with pores small enough to prevent the passage of blood cells, but too large to restrict the diffusion of solutes, even those the size of plasma proteins. The basement membrane is more selective: Only small plasma proteins, nutrients, and ions can cross it. The foot processes are the finest filters of all. The narrow gaps between the foot processes prevent the passage of most small plasma proteins. As a result, under normal circumstances only a few plasma proteins—such as albumin molecules, with an average diameter of 7 nm—can cross the filtration membrane and enter the capsular space. However, plasma proteins are all that stay behind, so the filtrate contains dissolved ions and small organic molecules in roughly the same concentrations as in plasma.

Filtration Pressures

We discussed the major forces that act across capillary walls in Chapters 21 and 22. (You may find it helpful to review Figures 21–10 and 21–11, pp. 742, 743, before you proceed.) The primary factor involved in glomerular filtration is basically the same one that regulates fluid and solute movement across capillaries throughout the body. This factor is the balance between **hydrostatic pressure**, or fluid pressure, and **colloid osmotic pressure**, or pressure due to materials in solution, on each side of the capillary walls.

Hydrostatic Pressure

Blood pressure is low in typical systemic capillaries. The reason is that capillary blood flows into the venous system, where resistance is fairly low. However, at the glomerulus, blood leaving the glomerular capillaries flows into an efferent glomerular arteriole, whose luminal diameter is *smaller* than that of the afferent glomerular arteriole. For this reason, the efferent arteriole offers considerable resistance. Relatively high pressures are needed to force blood into it. As a result, glomerular pressures are similar to those of small arteries. *Glomerular hydrostatic pressure* (*GHP*) averages about 50 mm Hg, instead of the 35 mm Hg typical of peripheral capillaries. GHP is shown with other pressures affecting glomerular filtration in Figure 26–10b.

Capsular hydrostatic pressure (*CsHP*) opposes glomerular hydrostatic pressure. The CsHP results from the resistance to flow along the nephron and the conducting system. (Before additional filtrate can enter the capsule, some of the filtrate already present must be forced into the PCT.) The CsHP averages about 15 mm Hg.

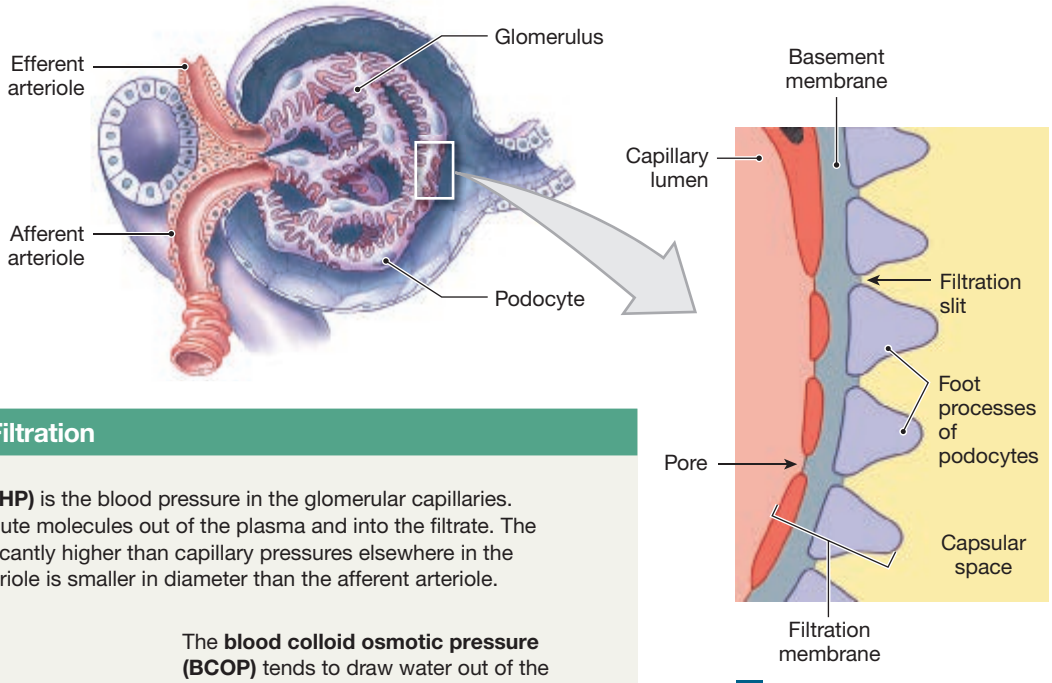
The *net hydrostatic pressure (NHP)* is the difference between the glomerular hydrostatic pressure, which tends to push water and solutes out of the bloodstream, and the capsular hydrostatic pressure, which tends to push water and solutes into the bloodstream. We can calculate net hydrostatic pressure as follows:

$$\begin{aligned} \text{NHP} = (\text{GHP} - \text{CsHP}) &= (50 \text{ mm Hg} - 15 \text{ mm Hg}) \\ &= 35 \text{ mm Hg} \end{aligned}$$

Colloid Osmotic Pressure

The *blood colloid osmotic pressure (BCOP)* is the osmotic pressure resulting from suspended proteins in the blood (see Figure 26–10b). Under normal conditions, very few plasma proteins enter the capsular space, so no opposing colloid osmotic pressure exists within the capsule. However, if the glomeruli are damaged by disease or injury, and plasma proteins begin passing into the capsular space, a *capsular colloid osmotic pressure* is created that promotes filtration and increases fluid losses in urine.

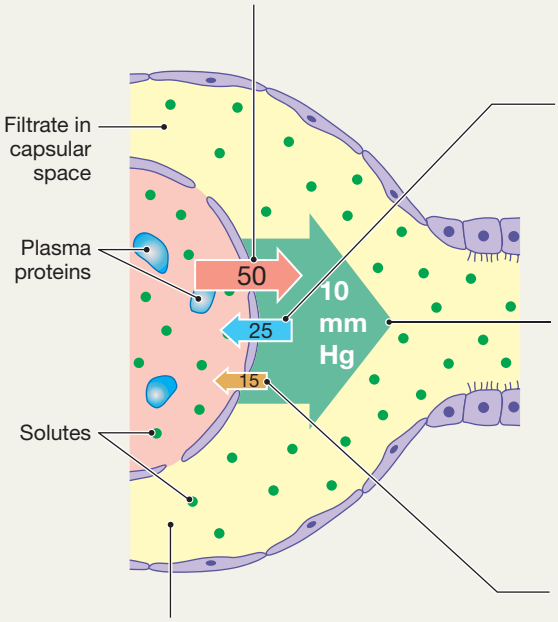
Figure 26–10 Glomerular Filtration.



a The glomerular filtration membrane

Factors Controlling Glomerular Filtration

The **glomerular hydrostatic pressure (GHP)** is the blood pressure in the glomerular capillaries. This pressure tends to push water and solute molecules out of the plasma and into the filtrate. The GHP, which averages 50 mm Hg, is significantly higher than capillary pressures elsewhere in the systemic circuit, because the efferent arteriole is smaller in diameter than the afferent arteriole.



The **capsular colloid osmotic pressure** is usually zero because few, if any, plasma proteins enter the capsular space.

The **blood colloid osmotic pressure (BCOP)** tends to draw water out of the filtrate and into the plasma; it thus opposes filtration. Over the entire length of the glomerular capillary bed, the BCOP averages about 25 mm Hg.

The **net filtration pressure (NFP)** is the net pressure acting across the glomerular capillaries. It represents the sum of the hydrostatic pressures and the colloid osmotic pressures. Under normal circumstances, the net filtration pressure is approximately 10 mm Hg. This is the average pressure forcing water and dissolved substances out of the glomerular capillaries and into the capsular space.

Capsular hydrostatic pressure (CsHP) opposes GHP. CsHP, which tends to push water and solutes out of the filtrate and into the plasma, results from the resistance of filtrate already present in the nephron that must be pushed toward the renal pelvis. The difference between GHP and CsHP is the *net hydrostatic pressure (NHP)*.

b Net filtration pressure

Net Filtration Pressure

The *net filtration pressure* (*NFP*) in the glomerulus is the difference between the net hydrostatic pressure and the blood colloid osmotic pressure acting across the glomerular capillaries. Under normal circumstances, we can summarize this relationship as

$$NFP = NHP - BCOP$$

or, using the values in Figure 26–10b,

$$NFP = 35 \text{ mm Hg} - 25 \text{ mm Hg} = 10 \text{ mm Hg}$$

This is the average pressure forcing water and dissolved substances out of the glomerular capillaries and into the capsular spaces (see Figure 26–10b). Problems that affect the net filtration pressure can seriously disrupt kidney function and cause a variety of clinical signs and symptoms.

The Glomerular Filtration Rate (GFR)

The **glomerular filtration rate (GFR)** is the amount of filtrate the kidneys produce each minute. Each kidney contains about

6 m^2—some 64 square feet—of filtration surface, and the GFR averages an astounding *125 mL per minute*. This means that nearly 10 percent of the fluid delivered to the kidneys by the renal arteries leaves the bloodstream and enters the capsular spaces. In the course of a single day, the glomeruli generate about 180 liters (48 gal) of filtrate, approximately 70 times the total plasma volume.

The glomerular filtration rate depends on the net filtration pressure across the glomerular capillaries. Any factor that alters the net filtration pressure also alters the GFR and affects kidney function. One of the most significant factors would be a decrease in renal blood pressure. If blood pressure at the glomeruli decreases by 20 percent (from 50 mm Hg to 40 mm Hg), kidney filtration stops, because the net filtration pressure falls to 0 mm Hg. For this reason, the kidneys are sensitive to changes in blood pressure that have little or no effect on other organs. Hemorrhaging, shock, and dehydration are relatively common clinical conditions that can cause a dangerous decrease in the GFR and lead to *acute renal failure* (loss of kidney function) (p. 1014).

Regulation of the GFR

Filtration depends on adequate blood flow to the glomerulus and on the maintenance of normal filtration pressures. Three interacting levels of control ensure that the GFR remains within normal limits: (1) *autoregulation* occurring at the local level, (2) *hormonal regulation* initiated by the kidneys, and (3) *autonomic regulation* maintained primarily by the sympathetic division of the autonomic nervous system.

Autoregulation of the GFR

Autoregulation (local blood flow regulation) maintains an adequate GFR despite changes in local blood pressure and blood flow. *Myogenic mechanisms*—how arteries and arterioles react to an increase or decrease in blood pressure—play a role in the autoregulation of blood flow. Changes to the luminal diameters of afferent arterioles, efferent arterioles, and glomerular capillaries maintain GFR.

The most important regulatory mechanisms stabilize the GFR when systemic blood pressure decreases. One of these mechanisms relies on the supporting intraglomerular mesangial cells. Actin-like filaments in these cells enable them to contract. In this way, these cells control capillary luminal diameter and the rate of glomerular capillary blood flow. ↩ p. 984

The GFR also remains relatively constant when systemic blood pressure increases. An increase in renal blood pressure stretches the walls of afferent glomerular arterioles, and the smooth muscle cells respond by contracting. The reduction in the luminal diameter of afferent glomerular arterioles decreases glomerular blood flow and keeps the GFR within normal limits.

If autoregulation is ineffective, the kidneys call for a wider response to increase the GFR (Figure 26–11).

Hormonal Regulation of the GFR

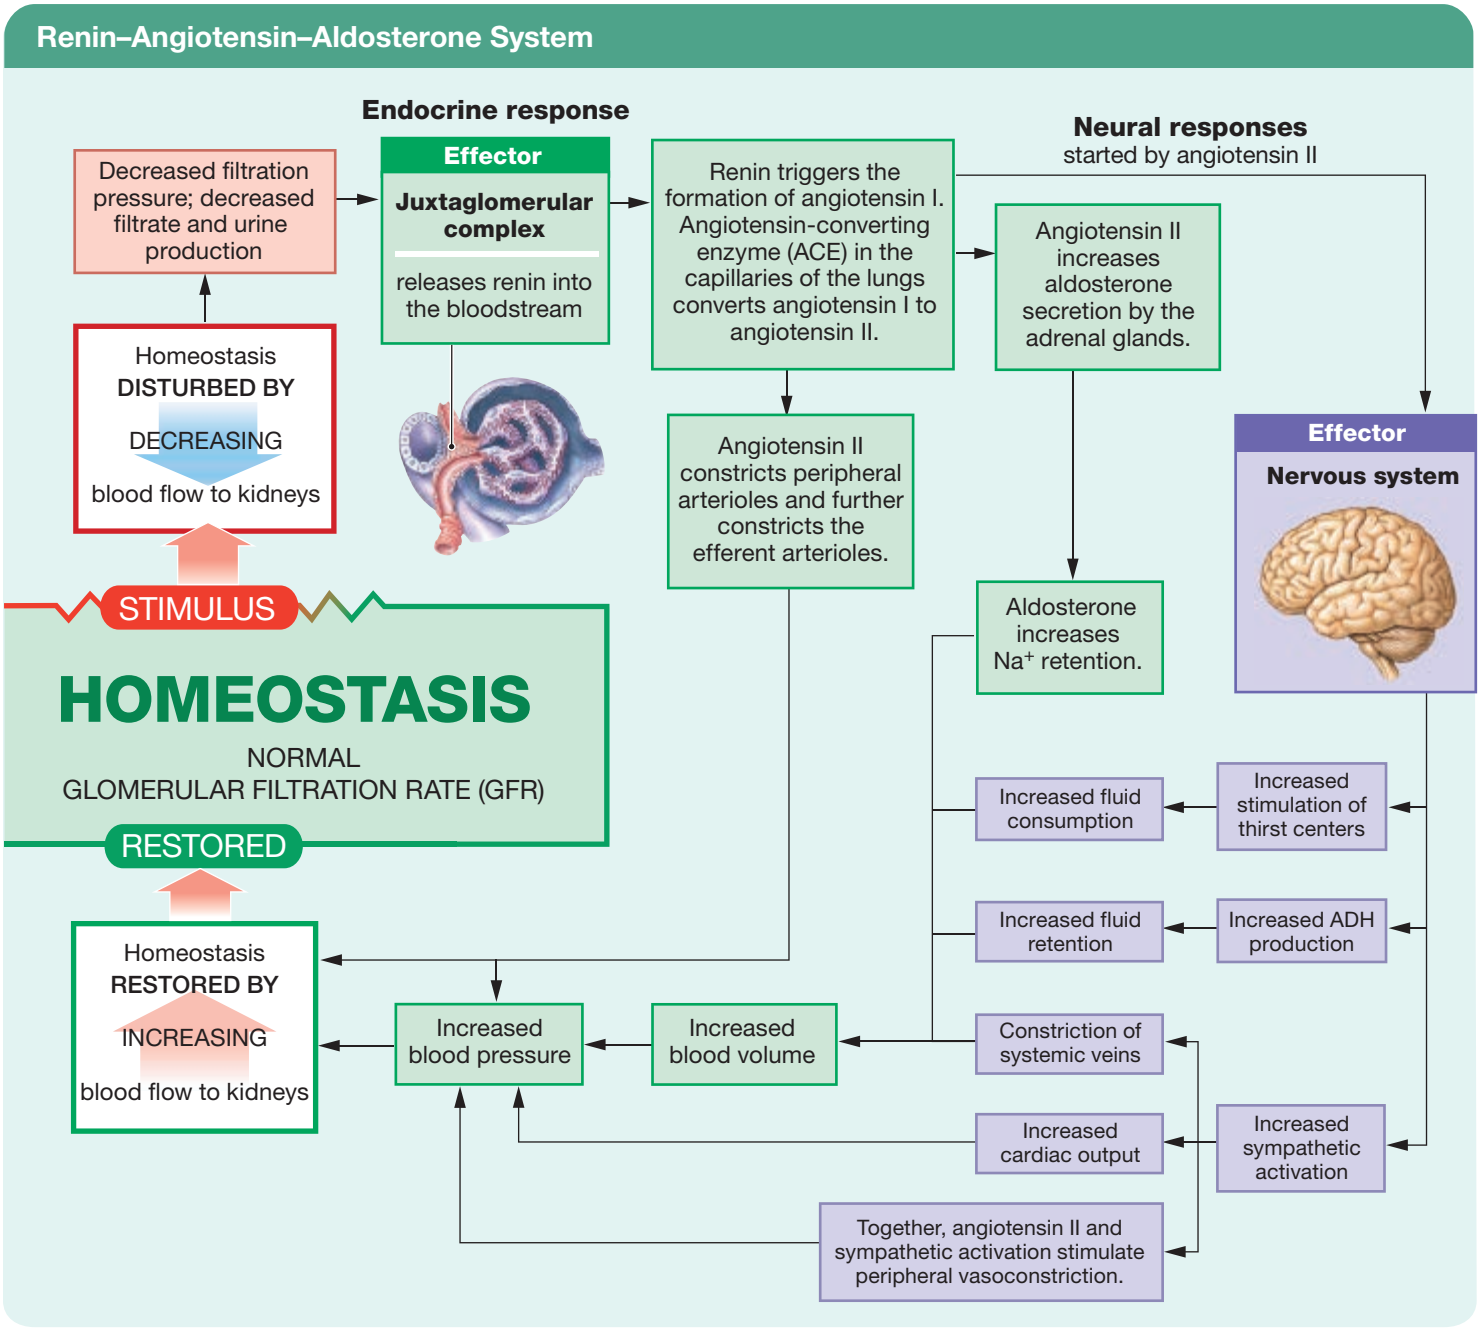
The GFR is regulated by the hormones of the **renin-angiotensin-aldosterone system (RAAS)** and the *natriuretic peptides*. We introduced these hormones and their actions in Chapters 18 and 21. ↩ pp. 641, 643–644, 749–752 The release of **renin** ultimately restricts water and salt loss in the urine by stimulating reabsorption by the nephron. There are three triggers for the release of renin by the juxtaglomerular complex (JGC): (1) a decrease in blood pressure at the glomerulus as the result of a decrease in blood volume, a decrease in systemic pressures, or a blockage in the renal artery or its branches; (2) stimulation of juxtaglomerular cells by sympathetic innervation; or (3) a decrease in the osmotic concentration of the tubular fluid at the macula densa.

These triggers are often interrelated. For example, a decrease in systemic blood pressure reduces the glomerular filtration rate, while baroreceptor reflexes cause sympathetic activation. Meanwhile, a decrease in the GFR slows the movement of tubular fluid along the nephron. As a result, the tubular fluid is in the ascending limb of the nephron loop longer, and the concentration of sodium and chloride ions in the tubular fluid reaching the macula densa and DCT becomes abnormally low.

Figure 26–11 shows how the renin-angiotensin-aldosterone system responds to a decrease in GFR. A decrease in GFR leads to the release of renin by the juxtaglomerular complex. Renin converts the inactive plasma protein angiotensinogen to angiotensin I. Angiotensin I is also inactive but is then converted to angiotensin II by **angiotensin-converting enzyme (ACE)**. This conversion takes place primarily in the capillaries of the lungs. Angiotensin II acts at the nephron, adrenal glands, and in the CNS. Angiotensin II stimulates contraction of vascular smooth muscle in peripheral capillary beds, promotes aldosterone production, and stimulates the sympathetic nervous system to increase arterial pressures throughout the body. The combined effect is an increase in systemic blood pressure and blood volume and the restoration of normal GFR.

If blood volume increases, the GFR increases automatically. This increase promotes fluid losses that help return blood volume to the normal level. If the increase in blood volume is severe, hormonal factors further increase the GFR and speed up fluid losses in the urine. As noted in Chapter 18, the heart releases natriuretic peptides when increased blood volume or blood pressure stretches the walls of the heart. For example, the atria release *atrial natriuretic peptide (ANP)*. ↩ p. 644 Among its other effects, this hormone triggers the dilation of afferent glomerular arterioles and the constriction of efferent glomerular arterioles. This mechanism increases glomerular pressures and increases the GFR. ANP also decreases sodium

Figure 26–11 The Response to a Decrease in the GFR.



? What four factors shown result in an increased blood volume?

reabsorption at the renal tubules. The net result is increased urine production and decreased blood volume and pressure.

Autonomic Regulation of the GFR

Most of the autonomic innervation of the kidneys consists of sympathetic postganglionic fibers. Sympathetic activation has a direct effect on the GFR. It produces powerful vasoconstriction of afferent glomerular arterioles, which decreases the GFR and slows the production of filtrate. In this way, the sympathetic activation triggered by an acute decrease in blood pressure or a heart attack overrides the local regulatory mechanisms that act to stabilize the GFR. As the crisis passes and sympathetic tone decreases, the filtration rate gradually returns to normal.

When the sympathetic division alters regional patterns of blood circulation, blood flow to the kidneys is often affected. For example, the dilation of superficial dermal blood vessels in warm weather shunts blood away from the kidneys. As a result, glomerular filtration decreases temporarily. The effect becomes especially pronounced during strenuous exercise. As the blood flow to your skin and skeletal muscles increases, kidney perfusion gradually decreases.

At a maximal level of exertion, renal blood flow may be less than 25 percent of the normal resting level. This reduction can create problems for endurance athletes. Metabolic wastes build up over the course of a long event. *Proteinuria* (protein in the urine) commonly occurs after such events because the glomerular cells have been injured by prolonged *hypoxia* (a low oxygen level). If the damage is substantial, *hematuria* (blood in the urine) occurs. Hematuria develops in about 18 percent of marathon runners. The cause is trauma to the bladder epithelium from the shocks of running. Proteinuria and hematuria generally disappear within 48 hours as the glomerular tissues are repaired. However, a small number of marathon and ultramarathon runners experience acute renal failure.

26-5 The renal tubule reabsorbs nutrients, ions, and water and secretes ions and wastes; the collecting system reabsorbs ions and water

Learning Outcome Identify the types and functions of transport mechanisms found along each segment of the nephron and collecting system.

Filtration by the renal corpuscle is both effective and energy efficient, but it has one major drawback: Useful substances such as glucose, free fatty acids, amino acids, vitamins, and other solutes enter the capsular space, in addition to metabolic wastes and excess ions.

The renal tubule has three specific functions: (1) reabsorbing all the useful organic nutrients in the filtrate; (2) reabsorbing more than 90 percent of the water in the filtrate; and (3) secreting into the tubule lumen any wastes that did not pass into the filtrate at the glomerulus. As filtrate passes through the renal tubules, about 99 percent of it is reabsorbed. Both reabsorption and secretion take place in every segment of the renal tubule and in the collecting system. However, their relative importance changes from segment to segment. Let's take a more detailed look at these critical processes, starting with the principles behind them.

Principles of Reabsorption and Secretion

The processes of reabsorption and secretion alter the composition of the filtrate produced by glomerular filtration. Tubular reabsorption returns nutrients, such as glucose, amino acids, water, and salt, from the tubular fluid to the blood. Tubular secretion is the reverse of reabsorption: it adds substances from the blood to the tubular fluid. We begin our discussion with reabsorption mechanisms.

Review of Carrier-Mediated Transport Mechanisms

The processes of reabsorption and secretion by the kidneys involve a combination of diffusion, osmosis, leak channels (channel-mediated diffusion), and carrier-mediated transport. We considered diffusion and osmosis in several other chapters. Here we briefly review *carrier-mediated transport* mechanisms.

Elsewhere in this text, we looked at four major types of carrier-mediated transport:

- In *facilitated diffusion*, a carrier protein transports a molecule across the plasma membrane without expending energy (look back at **Figure 3–18**, p. 96). Such transport always follows the concentration gradient for the ion or molecule transported.
- *Active transport* is driven by the hydrolysis of ATP to ADP on the inner plasma membrane surface (look back at **Figure 3–19**, p. 97). Exchange pumps and other carrier proteins are active along the renal tubules. Active transport can operate despite an opposing concentration gradient.
- In *cotransport*, carrier protein activity is not directly linked to the hydrolysis of ATP (look back at **Figure 3–20**, p. 98). Instead, two substrates (ions, molecules, or both) cross the membrane while bound to the carrier protein. The movement of the substrates always follows the concentration gradient of at least one of the transported substances. Cotransport is used for the reabsorption of organic and inorganic compounds from the tubular fluid.
- *Countertransport* resembles cotransport, except that the two transported ions move in *opposite* directions (look back at **Figures 23–23**, p. 869, and **24–14**, p. 904). Countertransport operates in the PCT, DCT, and collecting system.

All carrier-mediated processes share the following characteristics, which are important to understanding kidney physiology:

- *A specific substrate binds to a carrier protein that facilitates movement across the membrane.* The movement may be active or passive.
- *A given carrier protein typically works in one direction only.* In facilitated diffusion, the concentration gradient of the

substance being transported determines that direction. In active transport, cotransport, and countertransport, the location and orientation of the carrier proteins determine whether a particular substance is reabsorbed or secreted. The carrier protein that transports amino acids from the tubular fluid to the cytosol of the tubule cells, for example, will not carry amino acids back into the tubular fluid.

- *The distribution of carrier proteins can vary in different regions of the cell surface.* Transport between tubular fluid and peritubular fluid involves two steps. First, the material enters the cell at its apical surface. Then the material leaves the cell at its basolateral surface and enters the peritubular fluid. Each step involves a different carrier protein. For example, the apical surfaces of cells along the proximal convoluted tubule contain carrier proteins that bring amino acids, glucose, and many other nutrients into these cells by sodium ion–linked cotransport. In contrast, the basolateral surfaces contain carrier proteins that move those nutrients out of the cell by facilitated diffusion.
- *The membrane of a single tubular cell contains many types of carrier proteins.* Each cell can have multiple functions. A cell that reabsorbs one compound can secrete another.

The Transport Maximum (T_m) and the Renal Threshold

Recall that when an enzyme is *saturated*, further increases in substrate concentration have no effect on the rate of reaction. p. 56 Likewise, when a carrier protein is saturated, further increases in substrate concentration have no effect on the rate of transport across the plasma membrane. For any substance, the concentration at saturation is called the **transport maximum (T_m)**, or *tubular maximum*. The T_m reflects the number of available carrier proteins in the renal tubules. In healthy people, carrier proteins involved in tubular secretion seldom become saturated. However, carriers involved in tubular reabsorption are often at risk of saturation, especially during the absorptive state following a meal. When the carrier proteins are saturated, excesses of that substrate are excreted.

Normally, any plasma proteins and nutrients, such as amino acids and glucose, are removed from the tubular fluid by cotransport or facilitated diffusion. If the concentrations of these nutrients rise in the tubular fluid, the rate of reabsorption increases until the carrier proteins are saturated. A concentration higher than the transport maximum exceeds the reabsorptive abilities of the nephron. In this case, some of the material will remain in the tubular fluid and appear in the urine. The transport maximum thus determines the **renal threshold**—the plasma concentration at which a specific substance or ion begins to appear in the urine.

The renal threshold varies with the substance involved. The renal threshold for glucose is approximately 180 mg/dL. When the plasma glucose concentration exceeds 180 mg/dL, glucose appears in urine; this condition is called *glucosuria* (glū-kō-SYŪ-rē-uh) or *glycosuria*. After you have eaten a meal rich in carbohydrates, your plasma glucose level may exceed the glucose T_m for a brief period. However, the liver quickly lowers the circulating glucose level, and very little glucose is lost in your urine. Chronically increased plasma and urinary glucose concentrations are abnormal. (Glycosuria is one of the key signs of diabetes mellitus.p. 642)

The renal threshold for amino acids is lower than that for glucose. Amino acids appear in urine when their plasma concentrations exceed 65 mg/dL. Plasma amino acid levels commonly exceed the renal threshold after you have eaten a protein-rich meal, causing some amino acids to appear in your urine. This condition is termed *aminoaciduria* (am-ih-nō-as-ih-DYŪ-rē-uh).

The T_m values for water-soluble vitamins are relatively low. As a result, you excrete excess quantities of these vitamins in urine. (This is typically the fate of water-soluble vitamins in daily supplements.)

Measuring Osmotic Concentration

The osmotic concentration, or *osmolarity*, of a solution is the total number of solute particles in each liter. p. 94 We usually express osmolarity in **osmoles** per liter (Osm/L) or **milliosmoles** per liter (mOsm/L). If a liter of a fluid contains 1 mole of dissolved particles, the solute concentration is 1 Osm/L, or 1000 mOsm/L. Body fluids have an osmotic concentration of about 300 mOsm/L. For comparison, seawater is about 1000 mOsm/L and fresh water is about 5 mOsm/L. In a clinical setting, the osmolarity of urine is often reported as *osmolality*, expressed as milliosmoles per kilogram of water (mOsm/kg H_2O). When discussing osmotic concentrations in body fluids, these terms are often used interchangeably (1 liter of water has a mass of 1 kilogram).

Ion concentrations are often reported in *milliequivalents* per liter (mEq/L). Milliequivalents indicate the number of positive or negative charges in solution, rather than the number of solute particles. To convert mmol/L to mEq/L, multiply mmol/L by the number of charges on each ion. For example, each sodium ion has one charge only, so for Na^+, 1 mmol/L = 1 mEq/L; for Ca^{2+}, each ion has two charges, so 1 mmol/L = 2 mEq/L. The concentrations of large organic molecules are usually reported in grams, milligrams, or micrograms per unit volume of solution (typically, per deciliter, or dL).

An Overview of Reabsorbed and Secreted Substances

Table 26–3 lists some substances that are actively reabsorbed by the renal tubules. It also includes some of the substances secreted into tubular fluid by the proximal and distal convoluted tubules.

Table 26–3 Tubular Reabsorption and Secretion

Reabsorbed	Secreted	No Transport Mechanism
Ions Na^+, Cl^-, K^+, Ca_2^+, Mg^{2+}, SO_4^{2-}, HCO_3^-	**Ions** K^+, H^+, Ca^{2+}, PO_4^{3-}	Urea Water Urobilinogen Bilirubin
Metabolites Glucose Amino acids Proteins Vitamins	**Wastes** Creatinine Ammonia Metabolic acids and bases	
	Miscellaneous Neurotransmitters (ACh, NE, E, dopamine) Histamine Drugs (penicillin, atropine, morphine, many others)	

Note that cells of the renal tubule ignore a number of substances in the tubular fluid, because there are no transport mechanisms for them. These substances tend to be metabolic wastes. As water and other substances are removed, the concentrations of these wastes in the tubular fluid gradually rise.

Reabsorption and Secretion along the PCT

The cells of the proximal convoluted tubule normally reabsorb 60–70 percent of the volume of the filtrate produced in the renal corpuscle. The tubular cells reabsorb organic nutrients, ions, water, and plasma proteins (if present) from the tubular fluid. The reabsorbed materials enter the peritubular fluid, diffuse into peritubular capillaries, and are quickly returned to the bloodstream. The epithelial cells can also secrete substances into the lumen of the renal tubule.

The PCT has the following major functions:

- *Reabsorption of Organic Nutrients.* Under normal circumstances, before the tubular fluid enters the nephron loop, the PCT reabsorbs more than 99 percent of the glucose, amino acids, and other organic nutrients in the fluid. This reabsorption involves a combination of facilitated diffusion and cotransport.
- *Active Reabsorption of Ions.* The PCT actively transports several ions, including sodium, potassium, and bicarbonate ions, plus magnesium, phosphate, and sulfate ions (**Figure 26–12**). Although the ion pumps involved are individually regulated, they may be influenced by circulating ion or hormone levels. For example, angiotensin II stimulates sodium ion (Na^+) reabsorption along the PCT. By absorbing carbon dioxide (CO_2), the PCT indirectly recaptures about 90 percent of the bicarbonate ions (HCO_3^-) from tubular fluid. Bicarbonate ions are important in stabilizing blood pH. We examine this process further in Chapter 27.
- *Reabsorption of Water.* The reabsorptive processes have a direct effect on the solute concentrations inside and outside the tubules. The filtrate entering the PCT has the same osmotic concentration as that of the surrounding peritubular fluid. As reabsorption proceeds, the solute concentration of tubular fluid decreases, and that of peritubular fluid and adjacent capillaries increases. Water then moves out of the tubular fluid and into the peritubular fluid by osmosis. Along the PCT, this mechanism results in the reabsorption of about 108 liters of water each day.
- *Passive Reabsorption of Ions.* As active reabsorption of ions takes place and water leaves the tubular fluid by osmosis, the concentration of other solutes in the tubular fluid increases above that in the peritubular fluid. If the tubular cells are permeable to them, those solutes move across the tubular cells and into the peritubular fluid by passive diffusion. Urea, chloride ions, and lipid-soluble materials may diffuse out of the PCT in this way. Such diffusion further decreases the solute concentration of the tubular fluid and promotes additional water reabsorption by osmosis.
- *Secretion.* Active secretion of hydrogen ions first takes place along the PCT (see **Table 26–4** p. 996). Because the PCT and DCT secrete similar substances, and the DCT carries out comparatively little reabsorption, we will consider secretory mechanisms when we discuss the DCT.

Sodium ion reabsorption plays an important role in all of these processes. Sodium ions may enter tubular cells by diffusion through sodium ion leak channels; by the sodium ion–linked cotransport of glucose, amino acids, or other organic solutes; or by countertransport for hydrogen ions (see **Figure 26–12**). Once inside the tubular cells, sodium ions diffuse toward the basement membrane. The plasma membrane in this area contains sodium–potassium exchange pumps that eject sodium ions in exchange for extracellular potassium ions (K^+). Reabsorbed sodium ions then diffuse through the peritubular fluid and into adjacent peritubular capillaries.

The reabsorption of ions and compounds along the PCT involves many different carrier proteins. Some people have an inherited inability to manufacture one or more of these carrier proteins. For this reason, these individuals are unable to recover specific solutes from tubular fluid. In *renal glucosuria*, for example, a defective glucose carrier protein makes it impossible for the PCT to reabsorb glucose from tubular fluid.

Reabsorption and Secretion along the Nephron Loop

Approximately 60–70 percent of the volume of filtrate produced by the glomerulus has been reabsorbed before the tubular fluid reaches the nephron loop. In the process, useful organic substrates and many mineral ions have been reclaimed.

Table 26–4 Renal Structures and Their Functions

Segment	General Functions	Specific Functions	Mechanisms
Renal corpuscle	*Filtration* of plasma; generates approximately 180 L/day of filtrate similar in composition to blood plasma without plasma proteins	*Filtration* of water, inorganic and organic solutes from plasma; retention of plasma proteins and blood cells	Glomerular hydrostatic (blood) pressure working across capillary endothelium, dense layer, and filtration slits
Proximal convoluted tubule (PCT)	*Reabsorption* of 60%–70% of the water (108–116 L/day), 99%–100% of the organic substrates, and 60%–70% of the sodium and chloride ions in the original filtrate	*Active reabsorption*: Glucose, other simple sugars, amino acids, vitamins, ions (including sodium, potassium, calcium, magnesium, phosphate, and bicarbonate)	Carrier-mediated transport, including facilitated diffusion (glucose, amino acids), cotransport (glucose, ions), and countertransport (with secretion of H^+)
		Passive reabsorption: Urea, chloride ions, lipid-soluble materials, water	Diffusion (solutes) or osmosis (water)
		Secretion: Hydrogen ions, ammonium ions, creatinine, drugs, and toxins (as at DCT)	Countertransport with sodium ions
Nephron loop	*Reabsorption* of 25% of the water (45 L/day) and 20%–25% of the sodium and chloride ions present in the original filtrate; creation of the concentration gradient in the medulla	*Reabsorption*: Sodium and chloride ions	Active transport by Na^+–K^+/2 Cl^- transporter
		Water	Osmosis
Distal convoluted tubule (DCT)	*Reabsorption* of a variable amount of water (usually 5%, or 9 L/day), under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation	*Reabsorption*: Sodium and chloride ions	Cotransport
		Sodium ions (variable)	Countertransport with potassium ions; aldosterone-regulated
		Calcium ions (variable)	Carrier-mediated transport stimulated by parathyroid hormone and calcitriol
		Water (variable)	Osmosis; ADH-regulated
		Secretion: Hydrogen ions, ammonium ions	Countertransport with sodium ions
		Creatinine, drugs, toxins	Carrier-mediated transport
Collecting system	*Reabsorption* of a variable amount of water (usually 9.3%, or 16.8 L/day) under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation	*Reabsorption*: Sodium ions (variable)	Countertransport with potassium or hydrogen ions; aldosterone-regulated
		Bicarbonate ions (variable)	Diffusion, generated within tubular cells
		Water (variable)	Osmosis; ADH-regulated
		Urea (distal segments only)	Diffusion
		Secretion: Potassium and hydrogen ions (variable)	Carrier-mediated transport
Peritubular capillaries	*Redistribution* of water and solutes reabsorbed in the cortex	Return of water and solutes to the general circulation	Osmosis and diffusion
Vasa recta	*Redistribution* of water and solutes reabsorbed in the medulla and stabilization of the concentration gradient of the medulla	Return of water and solutes to the general circulation	Osmosis and diffusion

26

The nephron loop reabsorbs about half of the remaining water and two-thirds of the remaining sodium and chloride ions.

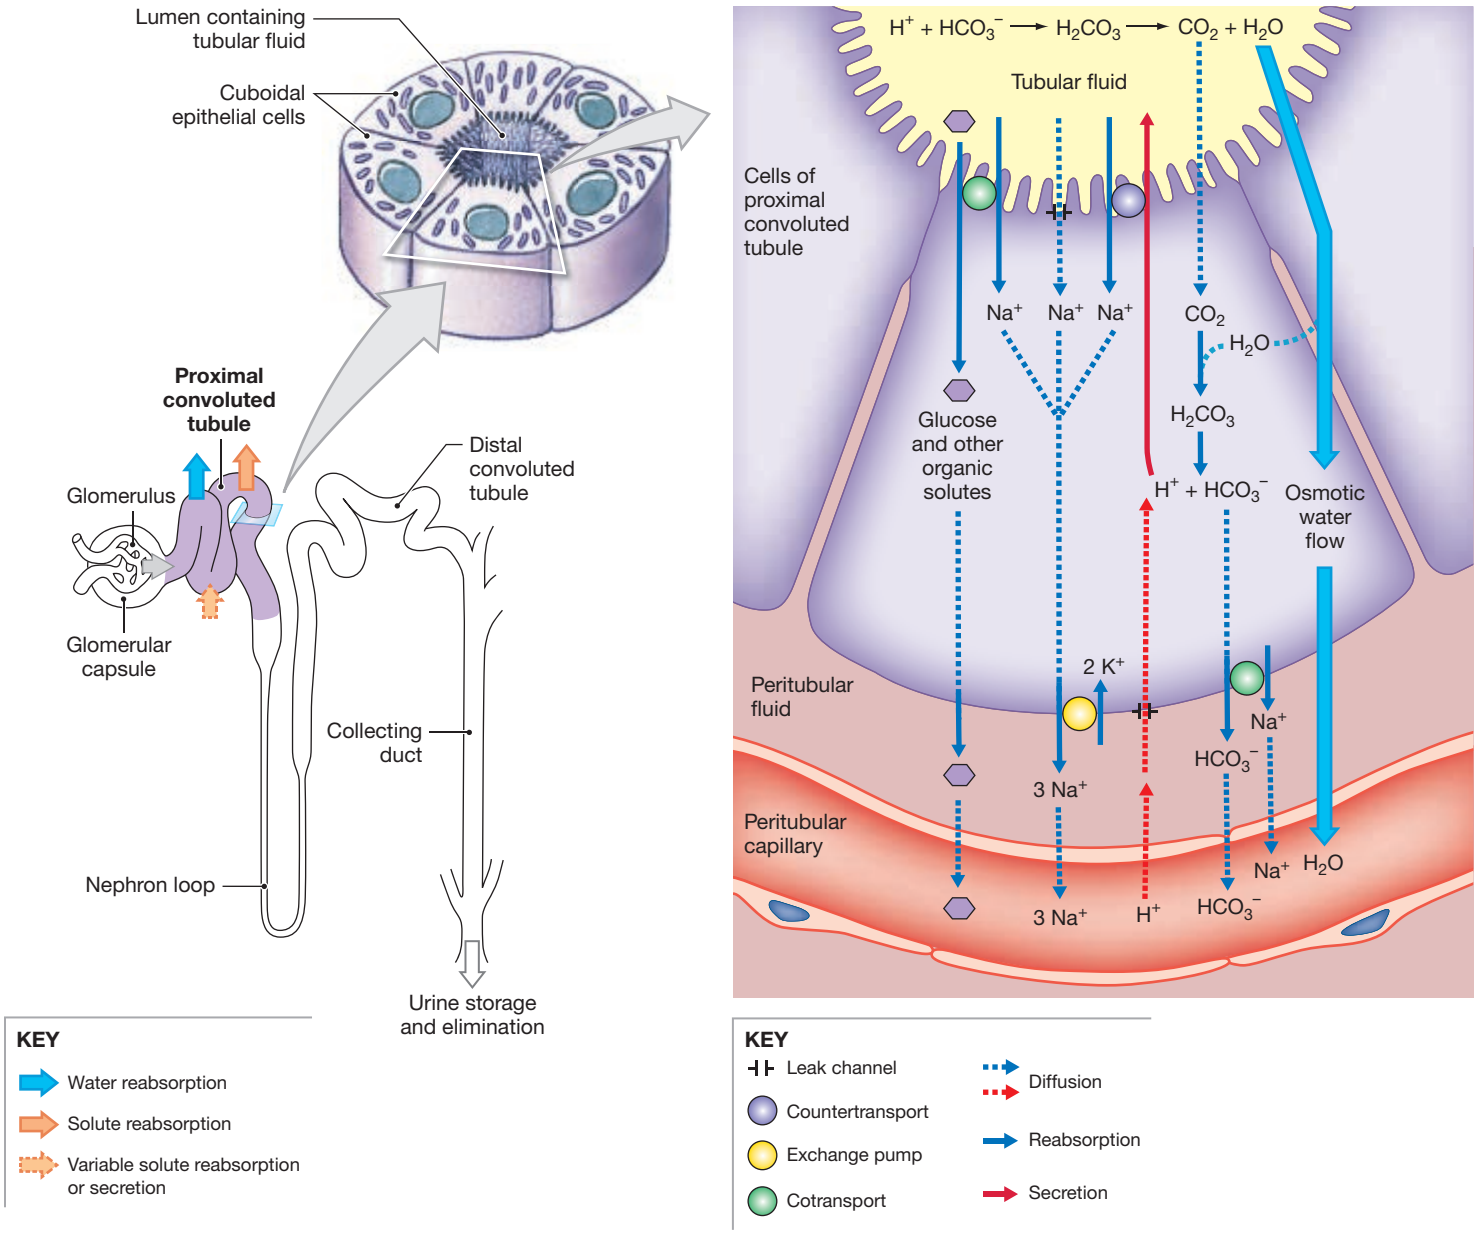
Recall that the nephron loop is made up of ascending and descending limbs, with thin and thick segments. The ascending limb is impermeable to water, but passively and actively removes sodium and chloride ions from the tubular fluid. Its ascending thin limb is permeable to sodium ions, which diffuse into the surrounding peritubular fluid. The thick ascending limb (TAL) actively transports sodium and chloride ions out of the tubular fluid. The effect of this movement is most noticeable in the renal medulla, where the long ascending limbs of juxtamedullary nephrons create unusually high solute concentrations in the peritubular fluid.

The entire descending limb is freely permeable to water, but not to solutes, such as sodium and chloride ions. The descending thin limb has functions similar to those of the PCT: It reabsorbs sodium and chloride ions out of the tubular fluid. Because of the ion concentration gradients created by the thick ascending limb, water moves out of the descending limb, helping to increase the solute concentration of the tubular fluid. This process, which allows the production of concentrated urine, will be discussed in detail in Section 26-6.

Tips & Tools

To remember the names and order of the limbs of the nephron loop, think "descending thin limb turns and sprouts up as the ascending thin limb and grows TAL (thick ascending limb)."

Figure 26–12 Transport Activities at the PCT. Sodium ions may enter a tubular cell from the filtrate by diffusion, cotransport, or countertransport. The sodium ions are then pumped into the peritubular fluid by the sodium–potassium exchange pump. Other reabsorbed solutes may be ejected into the peritubular fluid by separate active transport mechanisms. The absorption of bicarbonate is indirectly associated with the reabsorption of sodium ions and the secretion of hydrogen ions.



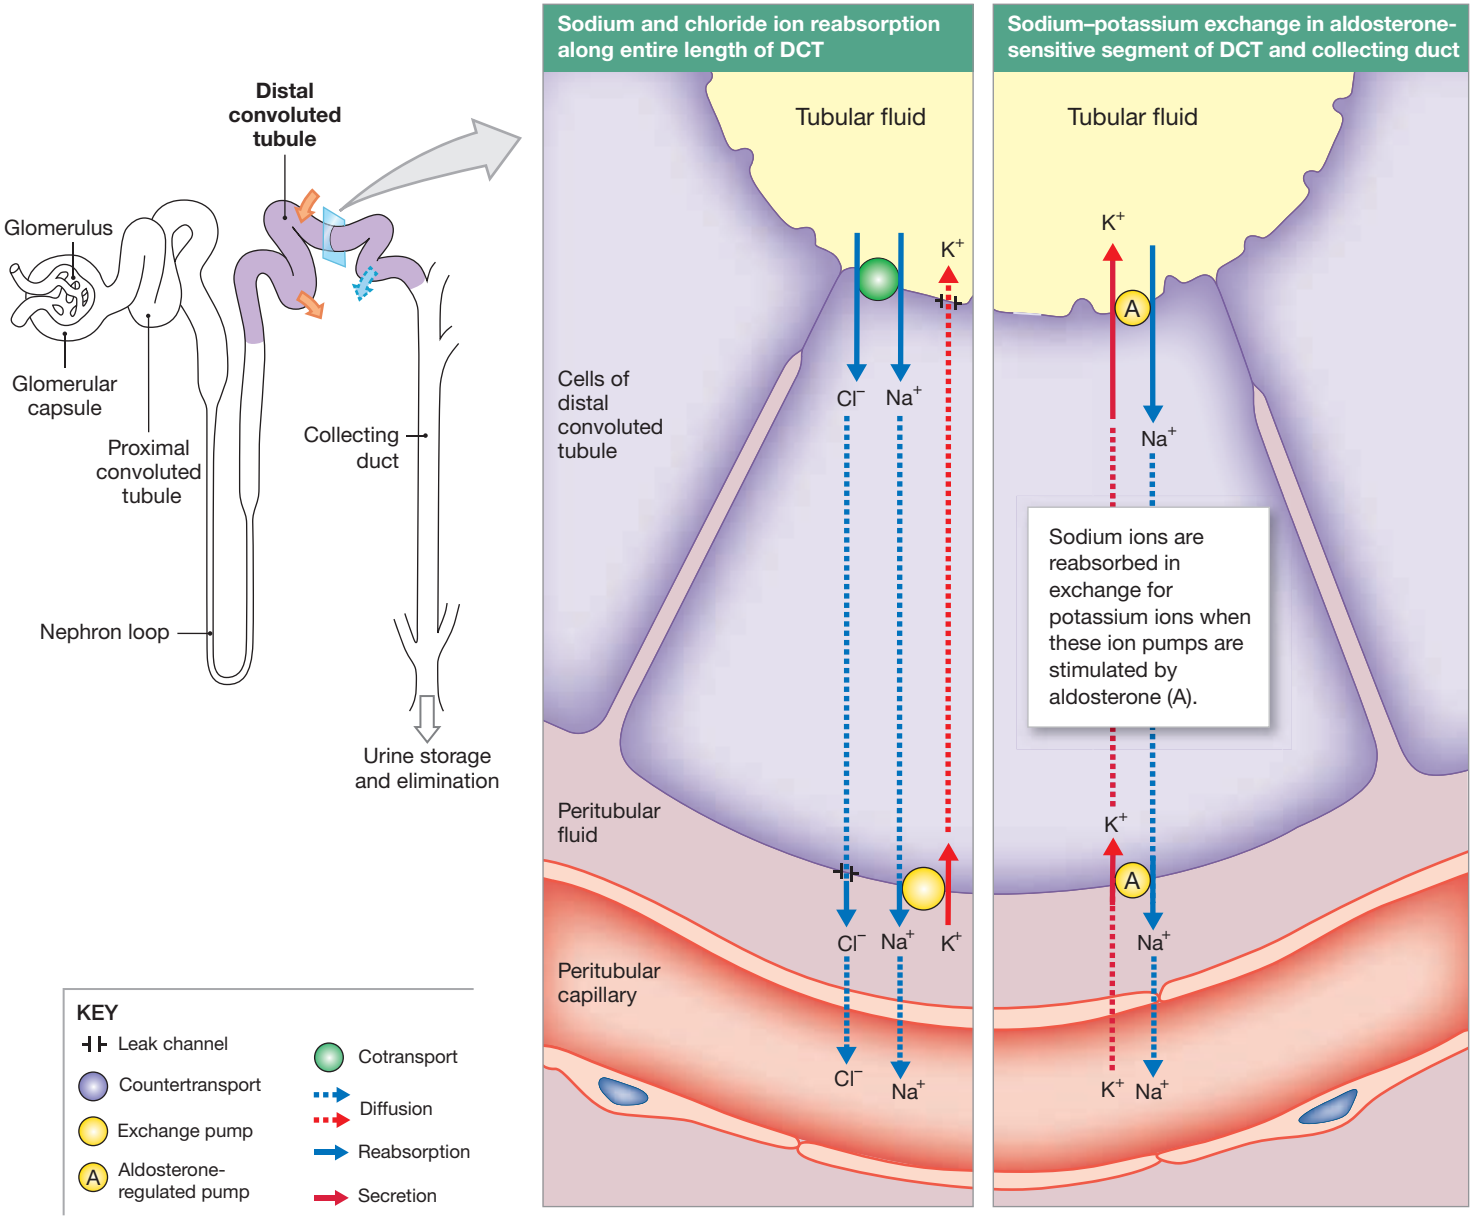
Reabsorption and Secretion along the DCT

As we have just seen, the composition and volume of tubular fluid change dramatically as it flows from the capsular space to the distal convoluted tubule. Only 15–20 percent of the initial filtrate volume reaches the DCT. The concentrations of electrolytes and metabolic wastes in the arriving tubular fluid no longer resemble the concentrations in blood plasma. Selective reabsorption or secretion, primarily along the DCT, makes the final adjustments in the solute composition and volume of the tubular fluid. The DCT is an important site for three vital processes: (1) the active secretion of ions, acids, drugs, and toxins into the tubule; (2) the selective reabsorption of sodium ions and calcium ions from tubular fluid; and (3) the selective reabsorption of water, which assists in concentrating the tubular fluid.

Reabsorption at the DCT

Throughout most of the DCT, the tubular cells actively transport sodium ions (Na^+) and chloride ions (Cl^-) out of the tubular

Figure 26–13 Tubular Secretion and Solute Reabsorption by the DCT.



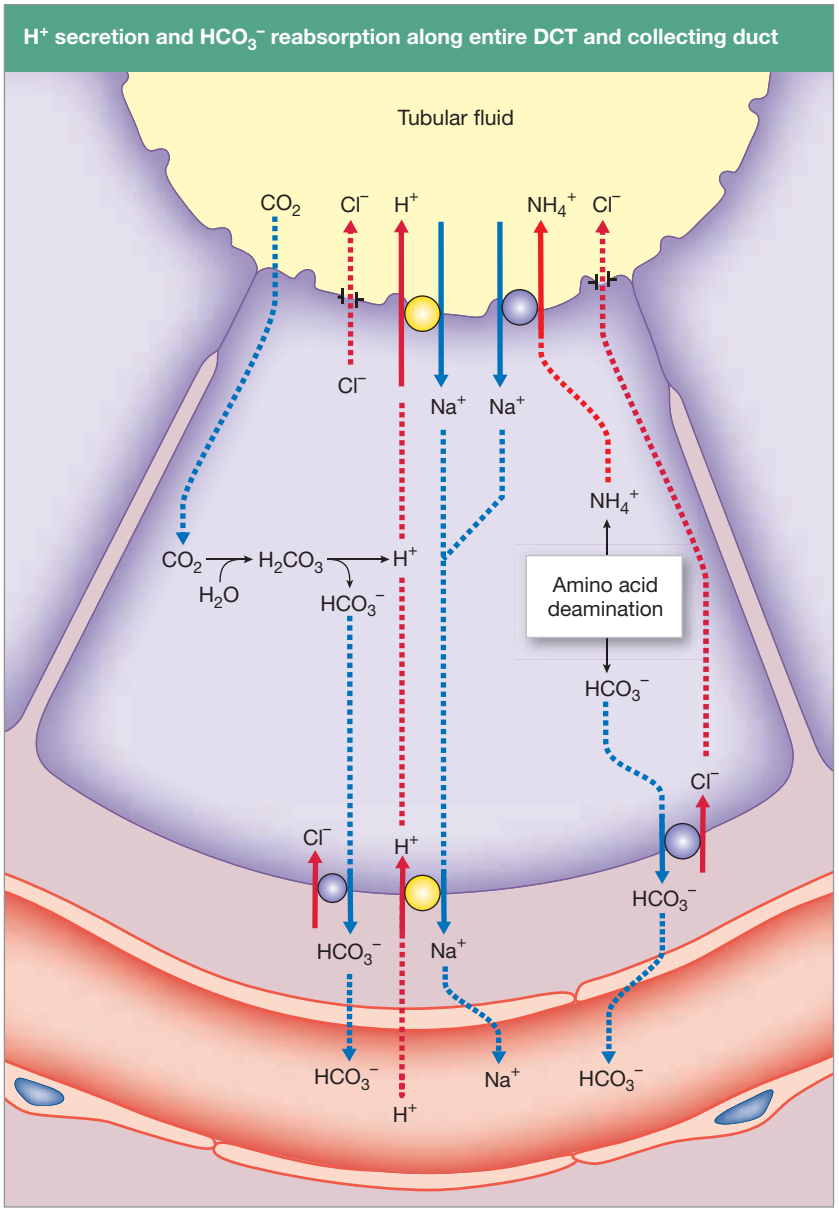
a The basic pattern of the reabsorption of sodium and chloride ions and the secretion of potassium ions.

b Aldosterone-regulated reabsorption of sodium ions, linked to the passive loss of potassium ions.

? Aldosterone-sensitive portions of the distal convoluted tubule and collecting duct allow for the exchange of which ions?

fluid (Figure 26–13a). Tubular cells along the distal regions of the DCT also contain ion pumps that reabsorb tubular sodium ions in exchange for another cation (usually potassium ions [K^+]) (Figure 26–13b). The hormone *aldosterone*, produced by the adrenal cortex, controls the sodium ion channels and the ion pump. This hormone stimulates the synthesis and incorporation of sodium ion channels and sodium ion pumps in plasma membranes along the DCT and collecting duct. The net result is a reduction in the number of sodium ions lost in urine.

However, Na^+ conservation is associated with K^+ loss. Prolonged aldosterone stimulation can therefore produce



c Hydrogen ion secretion and the acidification of urine occur by two routes. The central theme is the exchange of hydrogen ions in the cytosol for sodium ions in the tubular fluid, and the reabsorption of the bicarbonate ions generated in the process.

hypokalemia, a dangerous reduction in the plasma potassium ion concentration. The secretion of aldosterone and its actions on the DCT and collecting system are opposed by the natriuretic peptide ANP.

The DCT is also the primary site of calcium ion (Ca^{2+}) reabsorption. The circulating level of parathyroid hormone regulates this process. ↩ p. 633

Secretion at the DCT

The blood entering the peritubular capillaries still contains a number of potentially undesirable substances that did not cross the filtration membrane at the glomerulus. In most cases, the concentrations of these substances are too low to cause physiological problems. However, any ions or compounds in peritubular capillaries will diffuse into the peritubular fluid. If those concentrations become too high, the tubular cells may absorb these substances from the peritubular fluid and secrete them into the tubular fluid.

The rate of potassium and hydrogen ion secretion increases or decreases in direct response to changes in their concentrations in peritubular fluid. The higher their concentrations in the peritubular fluid, the higher the rate of secretion. Potassium and hydrogen ions merit special attention, because their concentrations in body fluids must be maintained within narrow limits.

Potassium Ion Secretion. Figure 26–13a,b diagrams the mechanism of potassium ion (K^+) secretion. In effect, tubular cells trade sodium ions (Na^+) in the tubular fluid for excess potassium ions in body fluids. Potassium ions are removed from the peritubular fluid in exchange for sodium ions from the tubular fluid. These potassium ions diffuse into the lumen of the DCT through potassium ion leak channels in the apical surfaces of the tubular cells.

Hydrogen Ion Secretion. Hydrogen ion (H^+) secretion is also associated with the reabsorption of sodium ions (Na^+). Figure 26–13c depicts two routes of secretion. Both involve the generation of carbonic acid (H_2CO_3) catalyzed by the enzyme *carbonic anhydrase*. ↩ pp. 865, 904 Hydrogen ions generated by the dissociation of the carbonic acid are secreted by sodium ion–linked countertransport in exchange for sodium ions in the tubular fluid. The bicarbonate ions (HCO_3^-) diffuse into the peritubular fluid and then into the bloodstream. There they help prevent changes in plasma pH.

Hydrogen ion secretion acidifies the tubular fluid while increasing the pH of the blood. Hydrogen ion secretion speeds up when the pH of the blood decreases. This can happen in metabolic acidosis (referred to as *lactic acidosis*), which can develop after exhaustive muscle activity, or *ketoacidosis*, which can develop in starvation or diabetes mellitus. ↩ p. 958 The combination of hydrogen ion removal and bicarbonate ion production by the kidneys plays an important role in the control of blood pH. Because one of the secretory pathways is aldosterone sensitive, aldosterone stimulates hydrogen ion secretion. Prolonged aldosterone stimulation can cause *alkalosis*, or abnormally high blood pH.

In Chapter 25, we noted that the production of lactate and ketone bodies during the postabsorptive state is associated with or could cause acidosis, respectively. Under these conditions,

+ Clinical Note Diuretics

Diuresis (dī-yū-RĒ-sis; *dia*, through + *ouresis*, urination) is the elimination of urine. *Urination* is an equivalent term in a general sense, but *diuresis* typically indicates the production of a large volume of urine. **Diuretics** (dī-yū-RET-iks) are drugs that promote water loss in urine. The usual goal in diuretic therapy is to decrease blood volume, blood pressure, extracellular fluid volume, or all three. The ability to control renal water losses with relatively safe and effective diuretics has saved the lives of many people, especially those with high blood pressure or congestive heart failure.

Diuretics have many mechanisms of action. However, all such drugs affect transport activities or water reabsorption along the nephron and collecting system. For example, consider the class of diuretics called *thiazides* (THĪ-uh-zīdz). These drugs increase water loss by decreasing sodium and chloride ion transport in the proximal and distal convoluted tubules.

Diuretic use for nonclinical reasons is on the rise. For example, some bodybuilders take large doses of diuretics to improve muscle definition temporarily. Some fashion models or horse jockeys do the same. Their goal is to reduce body weight for brief periods. This practice of "cosmetic dehydration" is extremely dangerous. It has caused several deaths due to electrolyte imbalance and consequent cardiac arrest.

the PCT and DCT deaminate amino acids in reactions that strip off the amino groups ($-NH_2$). The reaction sequence ties up hydrogen ions (H^+) and yields both **ammonium ions** (NH_4^+) and bicarbonate ions (HCO_3^-). As indicated in Figure 26–13c, the ammonium ions are then pumped into the tubular fluid by sodium ion–linked countertransport, and the bicarbonate ions enter the bloodstream by way of the peritubular fluid.

Tubular deamination thus has two major benefits. It provides carbon chains suitable for catabolism. It also generates bicarbonate ions that add to the buffering capacity of plasma.

26

Reabsorption and Secretion along the Collecting System

The collecting ducts receive tubular fluid from many nephrons and carry it toward the renal sinus. The normal amount of water and solute loss in the collecting system is hormonally regulated:

- By aldosterone, which controls sodium ion pumps along most of the DCT and the proximal portion of the collecting system. As we have noted, these actions are opposed by atrial natriuretic peptide (ANP).
- By ADH, which controls the permeability of the DCT and collecting system to water. The secretion of ADH is suppressed by ANP, and this—combined with the effects of atrial natriuretic peptide on aldosterone secretion and action—can dramatically increase urinary water losses.

The collecting system also has other reabsorptive and secretory functions. Many of them are important to the control of body fluid pH. For example, Type A intercalated cells secrete hydrogen ions and reabsorb bicarbonate ions, while Type B intercalated cells secrete bicarbonate ions and reabsorb hydrogen ions. Principal cells reabsorb water and secrete potassium ions.

Reabsorption at the Collecting System

The collecting system reabsorbs sodium ions, bicarbonate ions, and urea as follows:

- *Sodium Ion Reabsorption.* The collecting system contains aldosterone-sensitive ion pumps that exchange sodium ions (Na^+) in tubular fluid for potassium ions (K^+) in peritubular fluid (see Figure 26–13b).
- *Bicarbonate Ion Reabsorption.* Bicarbonate ions (HCO_3^-) are reabsorbed in exchange for chloride ions (Cl^-) in the peritubular fluid (see Figure 26–13c).
- *Urea Reabsorption.* The concentration of urea in the tubular fluid entering the collecting duct is relatively high. The fluid entering the papillary duct generally has the same osmotic concentration as that of interstitial fluid of the medulla—about 1200 mOsm/L—but contains a much higher concentration of urea. As a result, urea tends to diffuse out of the tubular fluid and into the peritubular fluid in the deepest portion of the medulla.

Secretion at the Collecting System

The collecting system is important in controlling the pH of body fluids through the secretion of hydrogen or bicarbonate ions. If the pH of the peritubular fluid decreases, carrier proteins pump hydrogen ions into the tubular fluid and reabsorb bicarbonate ions that help restore normal pH. If the pH of the peritubular fluid rises (a much less common event), the collecting system secretes bicarbonate ions and pumps hydrogen ions into the peritubular fluid. The net result is that the body eliminates a buffer and gains hydrogen ions that lower the pH. (We examine these responses in more detail in Chapter 27, when we consider acid–base balance.)

26-6 Countercurrent multiplication allows the kidneys to regulate the volume and concentration of urine

Learning Outcome Explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample.

The kidneys couple two countercurrent mechanisms to establish the conditions necessary to regulate the volume and concentration of urine. *Countercurrent* refers to the fact that the exchange takes place between fluids moving in opposite directions in two adjacent segments of the same tube. These two mechanisms are a *countercurrent multiplier* (filtrate flow in the nephron loop) and a *countercurrent exchanger* (blood flow in the vasa recta). These mechanisms establish and maintain an increasing osmotic gradient from the renal cortex through the medulla.

The Nephron Loop and Countercurrent Multiplication

The descending thin limb and the thick ascending limb of the nephron loop lie very close together. They are separated only by the peritubular fluid, which surrounds all the nephrons. The exchange of substances between these segments of a nephron is called **countercurrent multiplication**. Tubular fluid in the descending limb flows toward the renal pelvis, while tubular fluid in the ascending limb flows toward the cortex. *Multiplication* refers to the fact that the effect of the exchange increases as movement of the fluid continues.

Countercurrent multiplication performs two functions:

- It efficiently reabsorbs solutes and water before the tubular fluid reaches the DCT and collecting system.
- It establishes a concentration gradient in the peritubular fluid (called the *medullary osmotic gradient*) that permits the passive reabsorption of water from the tubular fluid in the collecting system. This allows the production of concentrated urine. The circulating level of antidiuretic hormone (ADH) regulates water reabsorption.

How does this occur? As we have indicated, the two parallel limbs of the nephron loop have very different permeability characteristics. The descending thin limb is permeable to water but relatively impermeable to solutes. The thick ascending limb is relatively impermeable to both water and solutes, but it contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.

Figure 26–14 shows an overview of countercurrent multiplication:

- Sodium ions (Na^+) and chloride ions (Cl^-) are pumped out of the thick ascending limb and into the peritubular fluid. This dilutes the tubular fluid.
- The pumping action increases the osmotic concentration in the peritubular fluid around the descending thin limb.
- This creates a small concentration difference between the tubular fluid and peritubular fluid in the renal medulla.
- The concentration difference results in an osmotic flow of water out of the descending thin limb and into the peritubular fluid. As a result, the solute concentration of the tubular fluid in the descending thin limb increases.
- The arrival of the highly concentrated tubular fluid in the thick ascending limb speeds up the transport of sodium and chloride ions into the peritubular fluid.

Solute pumping out of the tubular fluid in the thick ascending limb leads to higher solute concentrations in the tubular fluid in the descending thin limb, which then brings about increased solute pumping in the thick ascending limb. Notice that this process is a simple positive feedback loop that *multiplies* the concentration difference between the hypotonic tubular fluid in the thick ascending limb and the hypertonic peritubular fluid in the renal medulla.

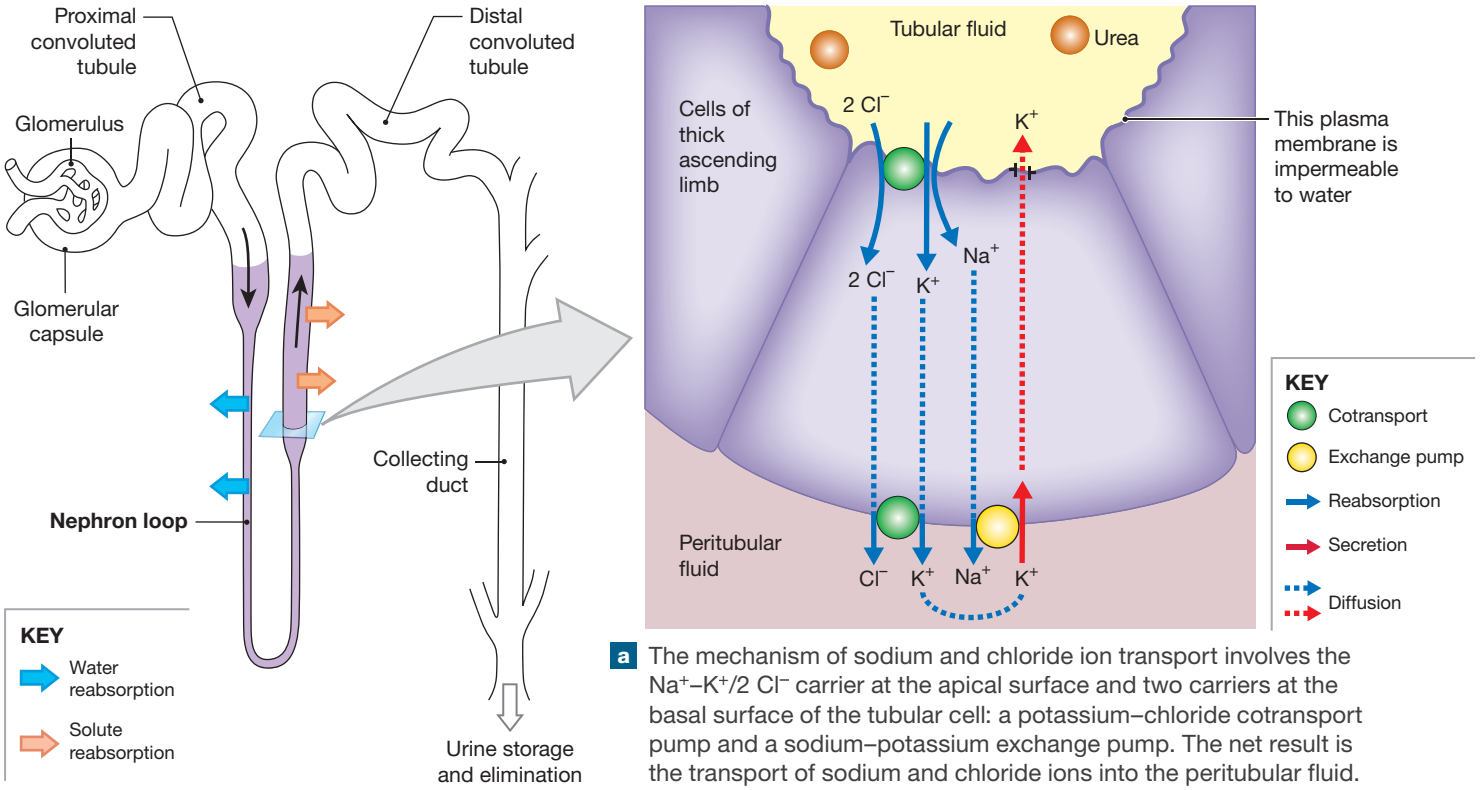
Creation of the Medullary Osmotic Gradient

The concentration gradient created in the peritubular fluid of the medulla is called the **medullary osmotic gradient**. We can now take a closer look at how this is produced. Figure 26–14a diagrams ion transport across the epithelium of the thick ascending limb (TAL). Active transport at the apical surface moves sodium, potassium, and chloride ions out of the tubular fluid. The carrier is called a **$Na^+ - K^+/2\ Cl^-$ transporter**, because each cycle of the pump carries a sodium ion, a potassium ion, and two chloride ions into the tubular cell. Then cotransport carriers pump potassium and chloride ions into the peritubular fluid. However, potassium ions are removed from the peritubular fluid as the sodium–potassium exchange pump moves sodium ions out of the tubular cell. The potassium ions then diffuse back into the lumen of the tubule through potassium ion leak channels. The net result is that sodium and chloride ions enter the peritubular fluid of the renal medulla.

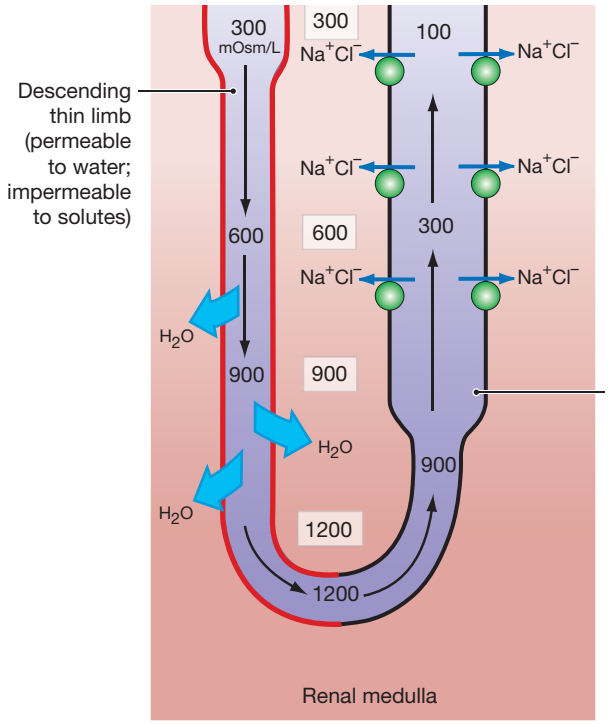
The removal of sodium and chloride ions from the tubular fluid in the ascending limb raises the osmotic concentration of the peritubular fluid around the descending thin limb (see Figure 26–14b). Recall that the descending thin limb is permeable to water but not to solutes. As tubular fluid travels deeper into the medulla within the descending thin limb, osmosis moves water into the peritubular fluid. Solutes remain behind. As a result, the tubular fluid at the turn of the nephron loop has a higher osmotic concentration than it did at the start.

The pumping mechanism of the TAL is highly effective. Almost two-thirds of the sodium and chloride ions that enter it are pumped out of the tubular fluid before that fluid reaches the DCT. In other tissues, differences in solute concentration are quickly resolved by osmosis. However, osmosis cannot take place

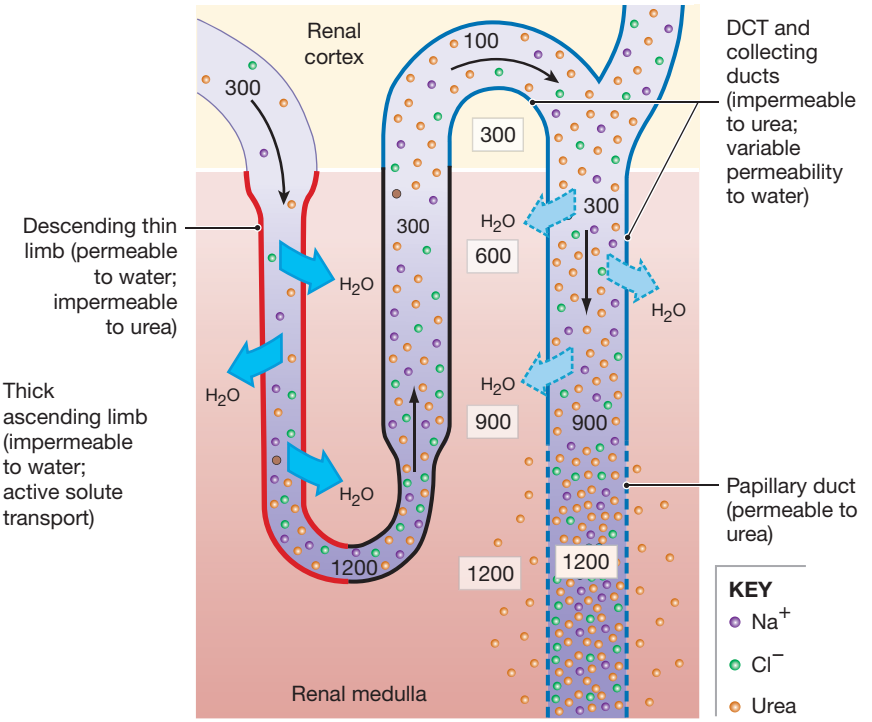
Figure 26–14 Countercurrent Multiplication and Urine Concentration.



a The mechanism of sodium and chloride ion transport involves the Na^+–K^+/2 Cl^- carrier at the apical surface and two carriers at the basal surface of the tubular cell: a potassium–chloride cotransport pump and a sodium–potassium exchange pump. The net result is the transport of sodium and chloride ions into the peritubular fluid.



b Transport of NaCl along the thick ascending limb results in the movement of water from the descending thin limb.



c The permeability characteristics of both the loop and the collecting duct tend to concentrate urea in the tubular fluid and in the medulla. The nephron loop, DCT, and collecting duct are impermeable to urea. As water reabsorption occurs, the urea concentration increases. Papillary duct permeability to urea results in urea making up nearly one-third of the solutes in the deepest portions of the medulla.

across the wall of the thick ascending limb, because the epithelium there is impermeable to water. So, as sodium and chloride ions are removed, the solute concentration in the tubular fluid decreases. Tubular fluid arrives at the DCT with an osmotic concentration of only about 100 mOsm/L. This value is one-third the concentration of the peritubular fluid of the renal cortex.

The rate of ion transport across the thick ascending limb is proportional to an ion's concentration in tubular fluid. As a result, more sodium and chloride ions are pumped into the medulla at the start of the thick ascending limb, where their ion concentrations are highest, than near the cortex. This regional difference in the rate of ion transport is the basis of the medullary osmotic gradient.

The Role of Urea

Normally, the maximum solute concentration of the peritubular fluid near the turn of the nephron loop is about 1200 mOsm/L. Sodium and chloride ions pumped out of the loop's thick ascending limb make up about two-thirds of that gradient (750 mOsm/L). The rest of the medullary osmotic gradient results from the presence of urea.

To understand how urea arrives in the medulla, let's look ahead to events in the last segments of the collecting system (**Figure 26–14c**). The thick ascending limb of the nephron loop, the DCT, and the collecting ducts are all impermeable to urea. As water is reabsorbed, the concentration of urea gradually increases in the tubular fluid. When the tubular fluid reaches the papillary duct, it typically contains urea at a concentration of about 450 mOsm/L. The papillary ducts are permeable to urea, so the urea concentration in the deepest parts of the medulla also averages 450 mOsm/L.

Summary of Countercurrent Multiplication

In summary, countercurrent multiplication is a way to either concentrate or dilute urine. The tubular fluid entering the descending limb of the nephron loop has an osmotic concentration of roughly 300 mOsm/L, due primarily to the presence of ions such as sodium and chloride. The concentration of organic wastes, such as urea, is low. About half of the tubular fluid entering the nephron loop is then reabsorbed along the descending thin limb. Two-thirds of the sodium and chloride ions are reabsorbed along the thick ascending limb. As a result, the DCT receives a reduced volume of tubular fluid with an osmotic concentration of about 100 mOsm/L. Urea and other organic wastes, which were not pumped out of the thick ascending limb, now represent a significant proportion of the dissolved solutes.

Regulation of Urine Volume and Osmotic Concentration: Production of Dilute and Concentrated Urine

Urine volume and osmotic concentration are regulated through the control of water reabsorption. Water is reabsorbed by osmosis along the proximal convoluted tubule and the descending limb of the nephron loop. The water permeabilities of these regions cannot be adjusted. As a result, water reabsorption takes place wherever the osmotic concentration of the peritubular fluid is greater than that of the tubular fluid. The ascending limb of the nephron loop is impermeable to water. In the distal convoluted tubule and collecting system, 1–2 percent of the volume of water in the original filtrate is recovered during sodium ion reabsorption. All these water movements represent *obligatory water reabsorption* because they cannot be prevented. This reabsorption usually recovers 85 percent of the volume of filtrate.

The volume of water lost in urine depends on how much of the remaining water in the tubular fluid is reabsorbed along the DCT and collecting system. (This remaining water represents 15 percent of the filtrate volume, or approximately 27 liters per day.) The amount reabsorbed can be precisely controlled by a process called *facultative water reabsorption*. Precise control is possible because these segments are relatively impermeable to water except when ADH is present. This hormone causes special *water channels*, or *aquaporins*, to be inserted into the apical plasma membranes. These water channels dramatically enhance the rate of osmotic water movement. The higher the circulating level of ADH, the greater the number of water channels, and the greater the water permeability of these segments.

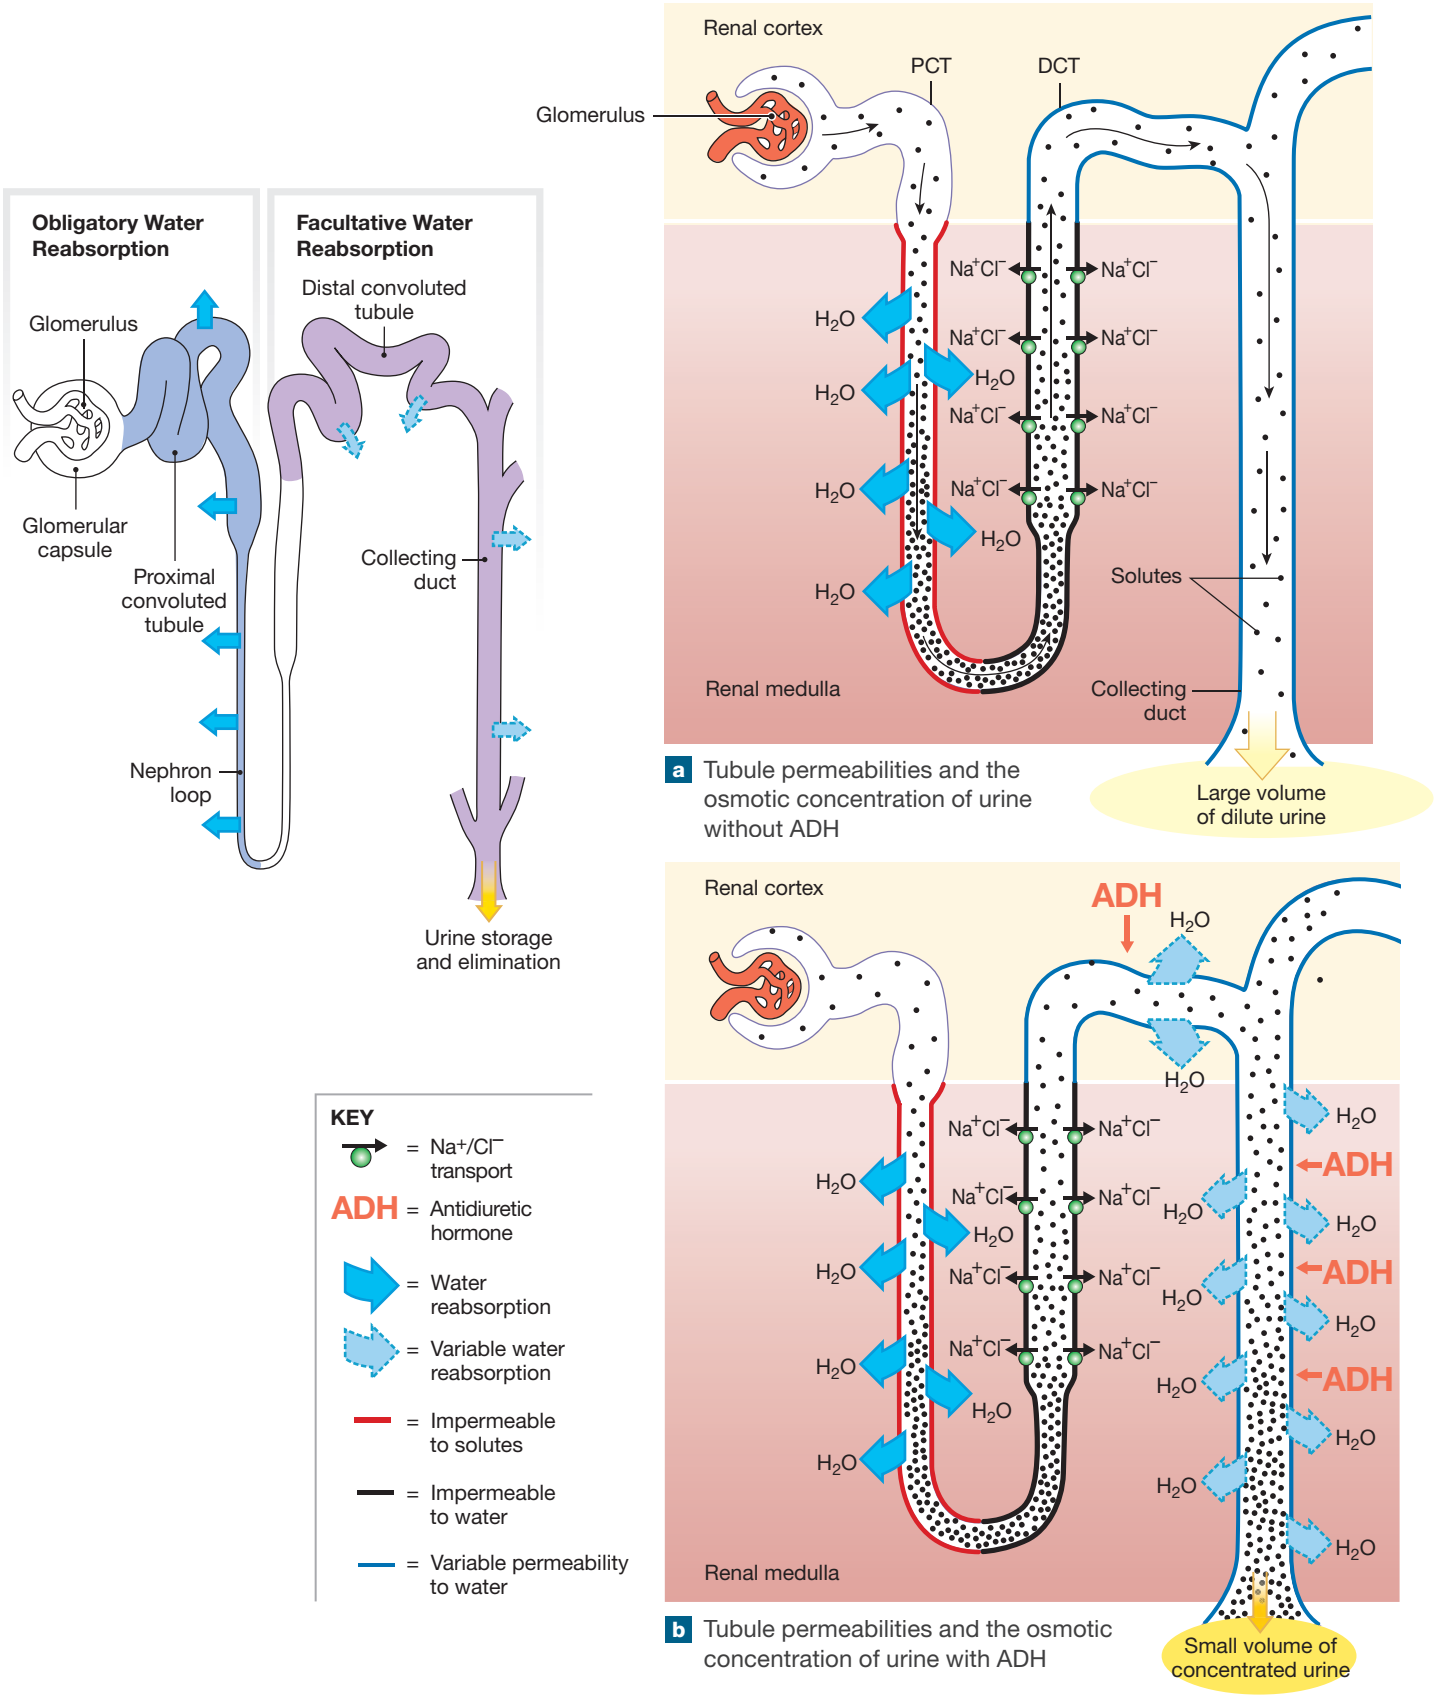
As noted earlier in this chapter, the tubular fluid arriving at the DCT has an osmotic concentration of only about 100 mOsm/L. In the presence of ADH, osmosis takes place. Water moves out of the DCT until the osmotic concentration of the tubular fluid equals that of the surrounding cortex (roughly 300 mOsm/L).

The tubular fluid then flows along the collecting duct, which passes through the concentration gradient of the medulla. Additional water is then reabsorbed. The urine reaching the minor calyx has an osmotic concentration closer to 1200 mOsm/L. How closely the osmotic concentration approaches 1200 mOsm/L depends on how much ADH is present.

Figure 26–15 diagrams the effects of ADH on the DCT and collecting system. Without ADH (**Figure 26–15a**), water is not reabsorbed in these segments, so all the fluid reaching the DCT is lost in the urine. The person then produces large amounts of very dilute urine. That is just what happens in cases of *diabetes insipidus*. ↩ p. 625 With this condition, urinary water losses may reach 24 liters (6.3 gal) per day and the urine osmotic concentration range is 30–400 mOsm/L.

As the ADH level rises (**Figure 26–15b**), the DCT and collecting system become more permeable to water. As a result, the amount of water reabsorbed increases. At the same time, the osmotic concentration of the urine climbs. Under maximum ADH stimulation, the DCT and collecting system become so permeable to water that the osmotic concentration of the urine equals that of the deepest portion of the medulla.

Figure 26–15 The Effects of ADH on the DCT and Collecting Duct.



? ADH creates a (*small* or *large*) volume of (*dilute* or *concentrated*) urine.

Note that the concentration of urine can never *exceed* that of the medulla, because the concentrating mechanism relies on osmosis.

The hypothalamus continuously secretes ADH at a low level. For this reason, the DCT and collecting system always have a significant degree of water permeability. At this low ADH level, the DCT reabsorbs approximately 9 liters of water per day, or about 5 percent of the original volume of filtrate produced by the glomeruli. At a normal ADH level, the collecting system reabsorbs about 16.8 liters per day, or about 9.3 percent of the original volume of filtrate. A healthy adult typically produces 1200 mL of urine per day (about 0.6 percent of the filtrate volume). Its osmotic concentration range is 855–1335 mOsm/L.

The effects of ADH are opposed by those of atrial natriuretic peptide (ANP). This hormone stimulates the production of a large volume of relatively dilute urine. This water loss reduces plasma volume to normal.

The Function of the Vasa Recta: Countercurrent Exchange

The solutes and water reabsorbed in the renal medulla must be returned to the bloodstream without disrupting the medullary osmotic gradient. This return is the function of the vasa recta, in a process called **countercurrent exchange**.

Recall that the vasa recta are long, straight capillaries that parallel the long nephron loops of juxtamedullary nephrons. Blood entering the vasa recta from the peritubular capillaries has an osmotic concentration of approximately 300 mOsm/L. As the blood descends into the medulla, it gradually increases in osmotic concentration as the solute concentration in the peritubular fluid increases. This increase in blood osmotic concentration involves both solute absorption and water loss. Solute absorption predominates, however, because the plasma proteins limit the osmotic flow of water out of the blood. ↩ p. 742

Blood ascending toward the cortex gradually decreases in osmotic concentration as the solute concentration of the peritubular fluid decreases. Again, this decrease involves both solute diffusion and osmosis. In this case osmosis predominates, because the presence of plasma proteins does not oppose the osmotic flow of water into the blood.

The net results are that (1) some of the solutes absorbed in the descending segment of the vasa recta do not diffuse out in the ascending segment and (2) more water moves into the ascending portion of the vasa recta than moves out in the descending segment. Thus, the vasa recta carries both water and solutes out of the medulla. Under normal conditions, the removal of solutes and water by the vasa recta precisely balances the rates of solute reabsorption and osmosis in the medulla.

Table 26–5 General Characteristics of Normal Urine

Characteristic	Normal Range
pH	4.5–8 (average: 6.0)
Specific gravity	1.003–1.030
Osmotic concentration (osmolarity)	855–1335 mOsm/L
Water content	93%–97%
Volume	700–2000 mL/day
Color	Pale yellow
Clarity	Clear
Odor	Varies with composition
Bacterial content	None (sterile)

Spotlight Figure 26–16 provides a summary of kidney function showing the major steps in the reabsorption of water and the production of concentrated urine. Please revisit **Table 26–4** on p. 996 for a detailed summary of the functions of the various renal structures.

Urine Composition and Analysis

Urine is the fluid and dissolved substances excreted by the kidney. The analysis of that urine by physical, chemical, and microscopic means is called *urinalysis*. This section considers urine analysis.

The Composition of Normal Urine

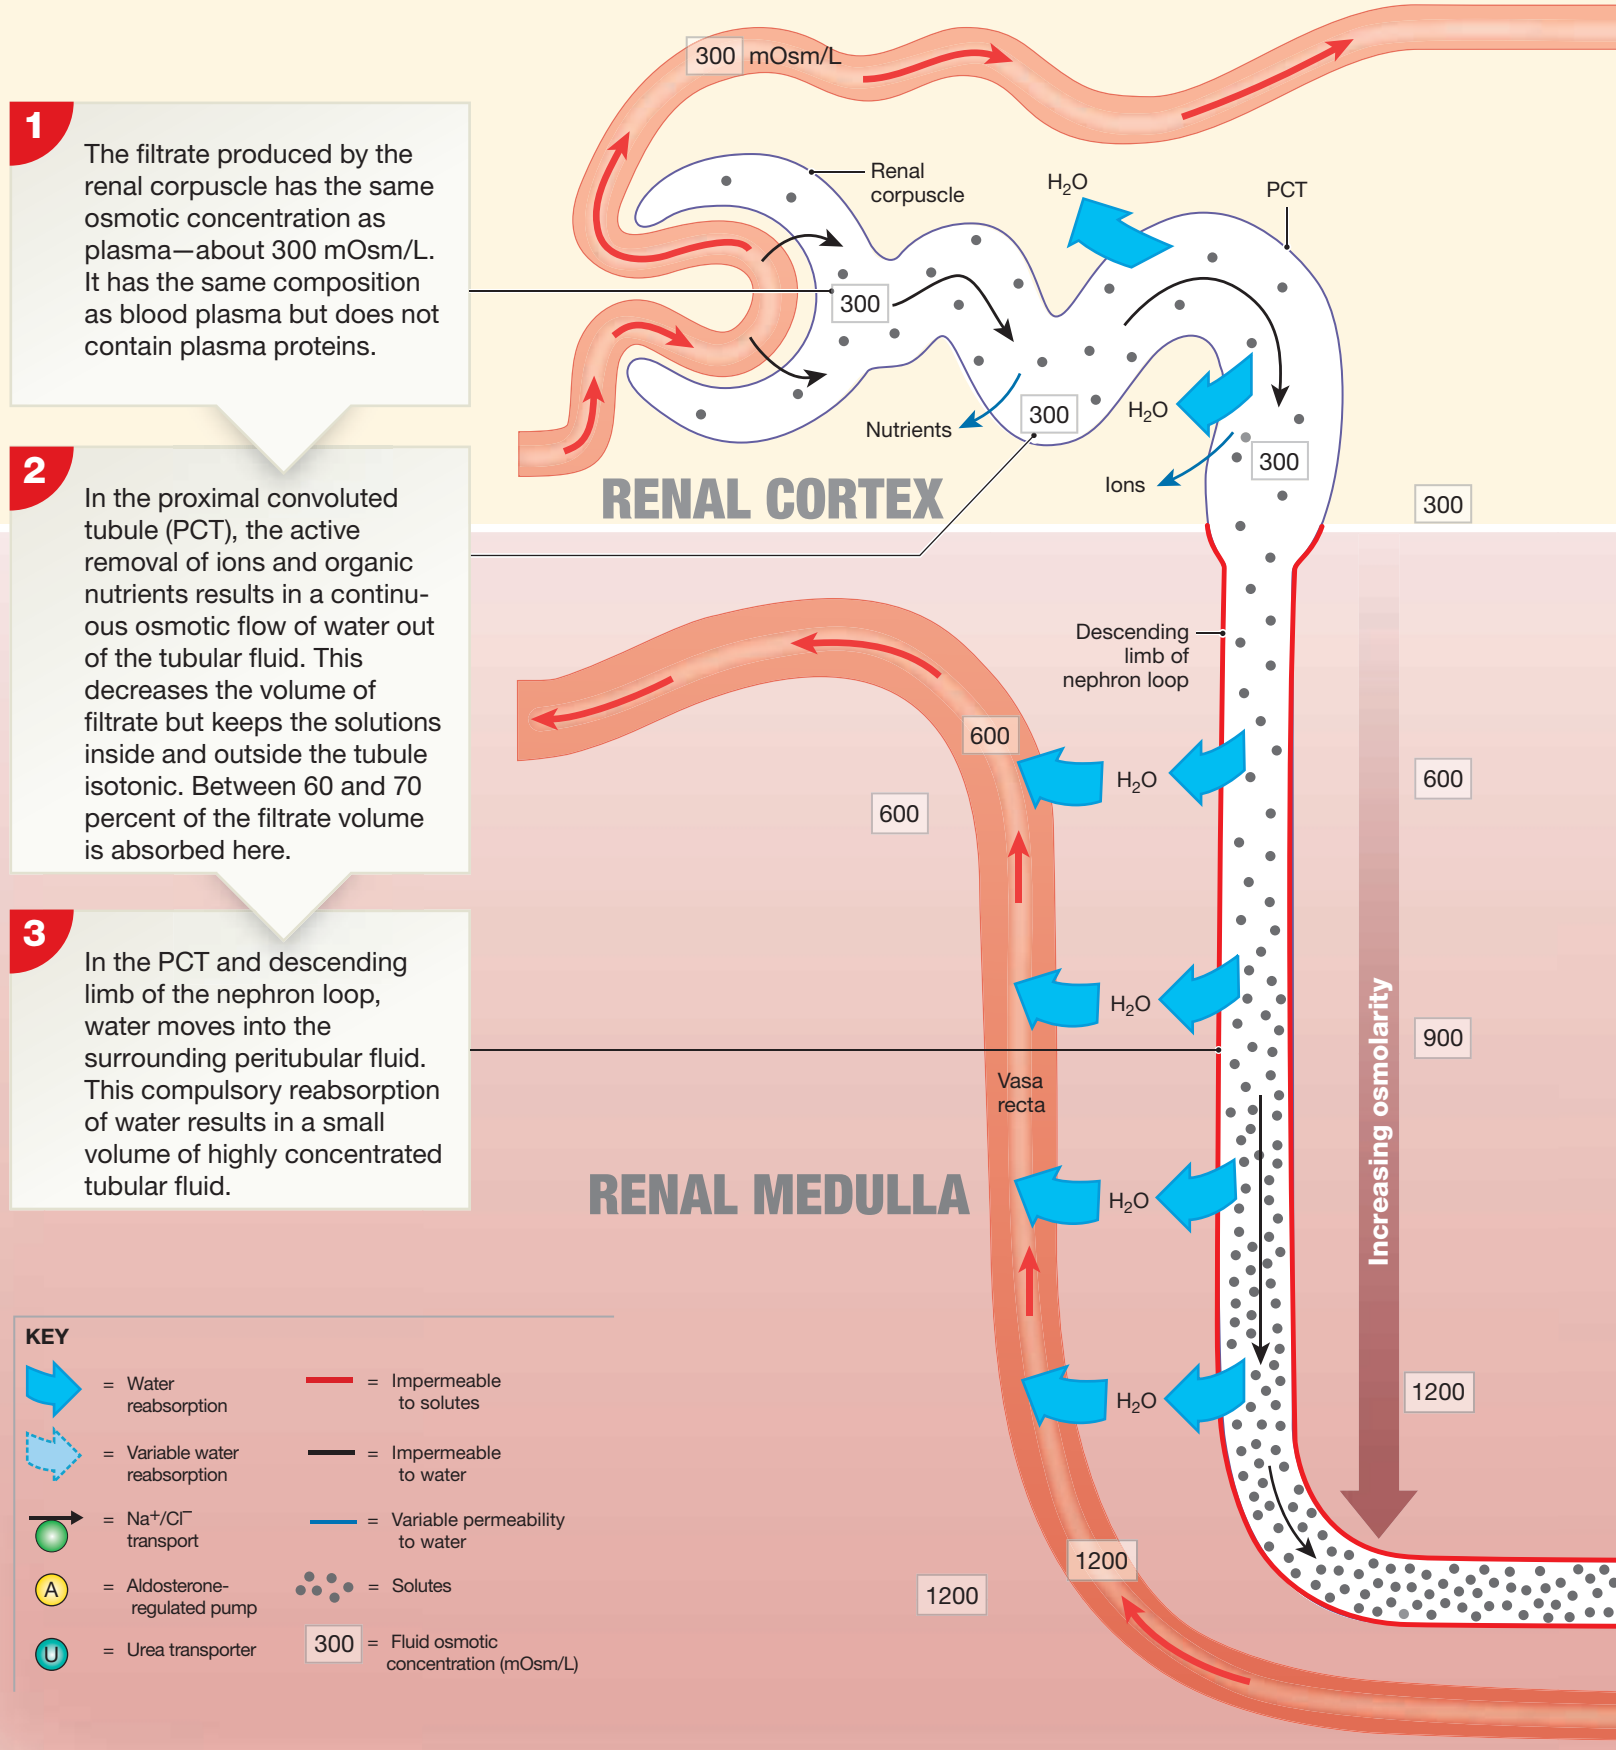
The general characteristics of normal urine are listed in **Table 26–5**. However, the composition of the urine produced each day varies with the metabolic and hormonal events under way.

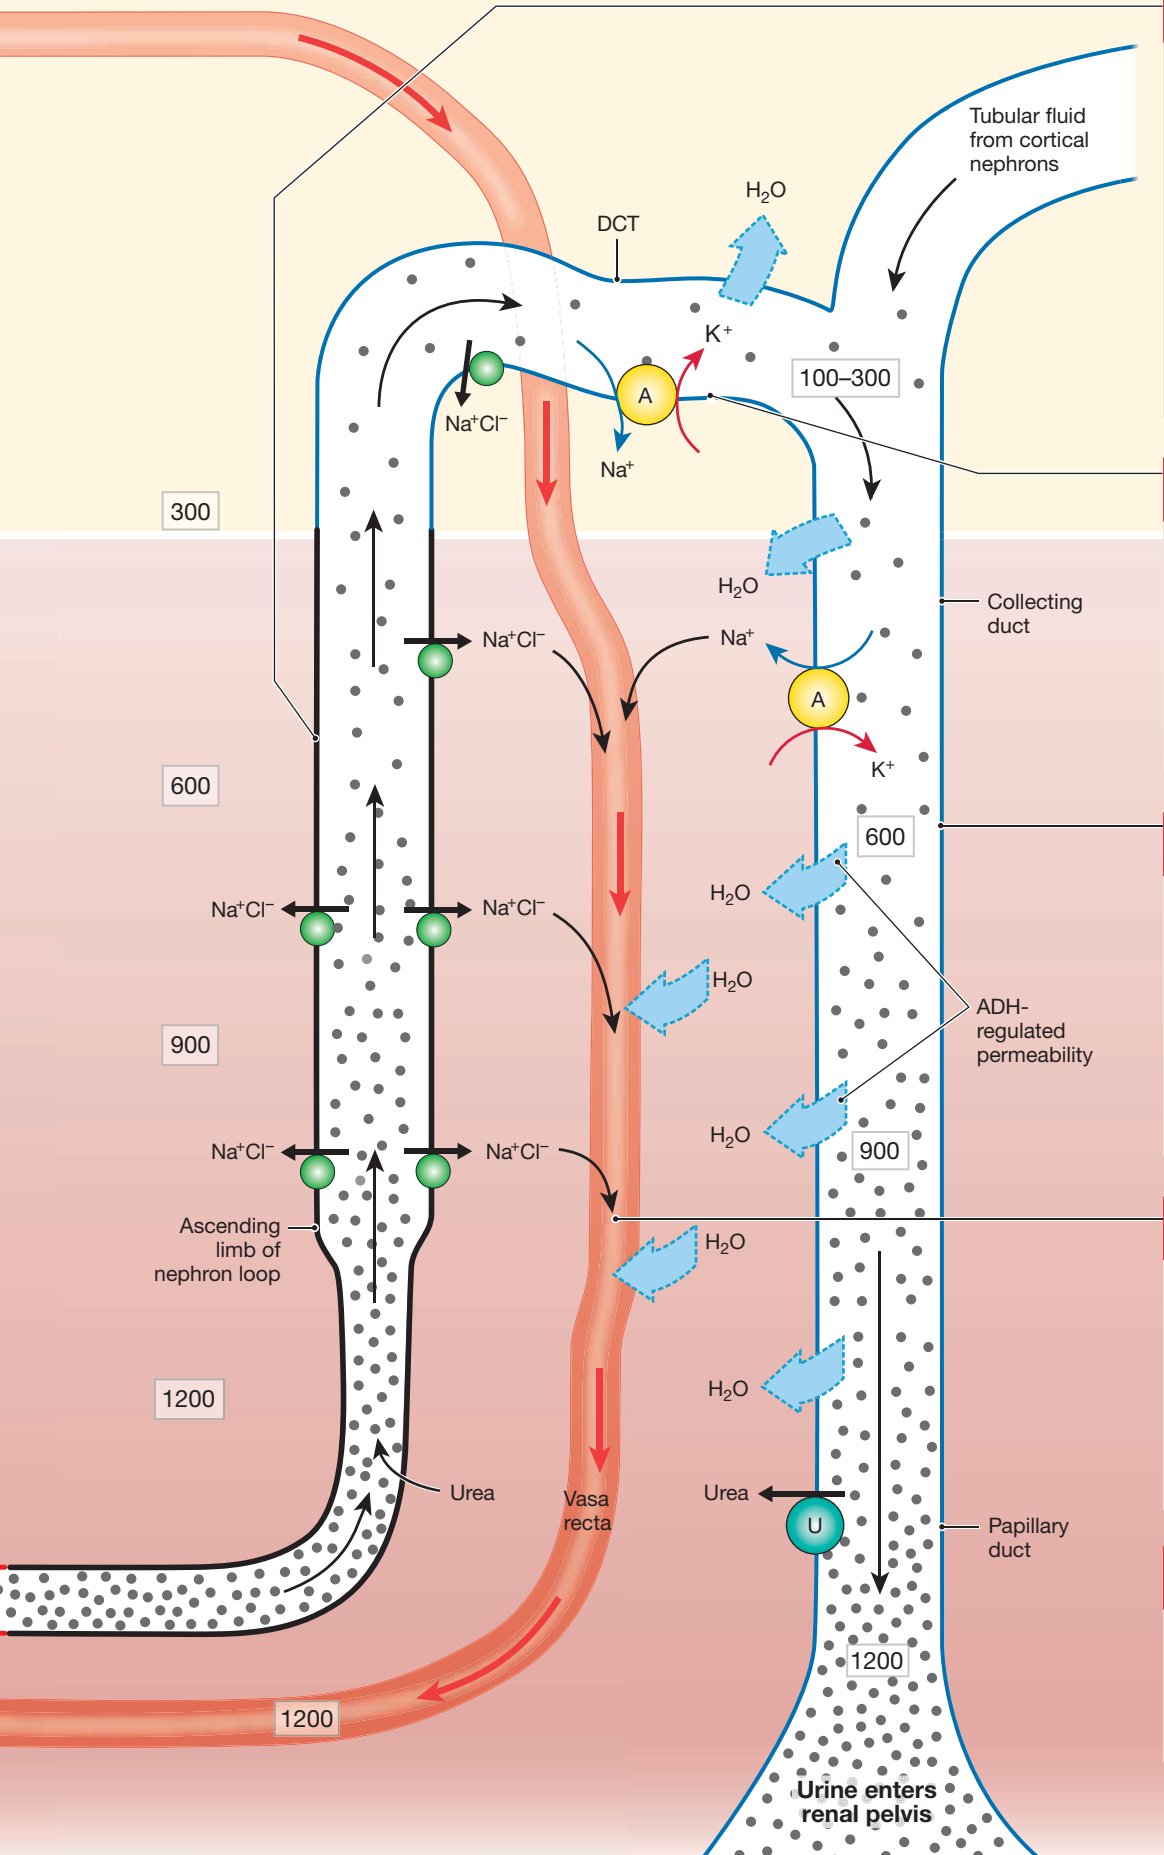
The composition and concentration of urine are two related but distinct properties. The *composition* of urine reflects the filtration, reabsorption, and secretion activities of the nephrons. Some substances (such as urea) are neither actively excreted nor reabsorbed along the nephron. In contrast, organic nutrients are completely reabsorbed. Other substances, such as creatinine, are missed by filtration but are actively secreted into the tubular fluid.

Filtration, reabsorption, and secretion determine the kinds and amounts of substances excreted in urine. The *concentration* of these substances in a given urine sample depends on the osmotic movement of water across the walls of the tubules and collecting ducts. Because the composition and concentration of urine vary independently, you can produce a small volume of concentrated urine or a large volume of dilute urine and still excrete the same amount of dissolved substances. For this reason, health care professionals who are interested in a detailed assessment of renal function commonly analyze the urine produced over a 24-hour period rather than a single urine sample.

SPOTLIGHT

Figure 26–16
Summary of Renal Function





4 The thick ascending limb (TAL) is impermeable to water and solutes. The tubule cells actively transport Na^+ and Cl^- out of the tubule, thereby decreasing the solute concentration of the tubular fluid. Because only Na^+ and Cl^- are removed, urea makes up a higher proportion of the total solute concentration at the end of the nephron loop.

5 Further adjustments in the composition of the tubular fluid occur in the DCT and the collecting system. The solute concentration of the tubular fluid can be adjusted through active transport (reabsorption or secretion).

6 The final adjustments in the volume and solute concentration of the tubular fluid are made by controlling the water permeabilities of the distal portions of the DCT and the collecting system. ADH levels determine the final urine volume and concentration.

7 The vasa recta absorbs the solutes and water reabsorbed by the nephron loop and the collecting ducts. By transporting these solutes and water into the bloodstream, the vasa recta maintain the concentration gradient of the renal medulla.

8 The papillary duct is permeable to urea, where its concentration is about 450 mOsm/L. This is the same value as in the deepest parts of the medulla.

Testing of Kidney Function

Diagnostic tests used to evaluate kidney function include urinalysis, creatinine clearance, and blood urea nitrogen (BUN). Urinalysis is used to detect the presence of microorganisms, disease, drugs, or other substances. A creatinine clearance test helps determine how well the kidneys are functioning by estimating the glomerular filtration rate (GFR). The blood urea nitrogen (BUN) test also measures renal function.

Urinalysis. Urinalysis is the chemical and physical analysis of a urine sample. It is an important diagnostic tool, even in high-technology medicine. A standard urinalysis includes an assessment of the color and appearance of urine. These two characteristics can be determined without specialized equipment, but quantitative analytical tests are also used.

Normal urine is a clear, sterile liquid. Its yellow color comes from the pigment urobilin. The kidneys generate this pigment from the urobilinogens produced by intestinal bacteria and absorbed in the colon (look back at **Figure 19–5**, p. 667). The characteristic odor of urine is due to the evaporation of small molecules, such as ammonia. Other substances not normally present, such as acetone or other ketone bodies, can also impart a distinctive smell. **Table 26–6** gives some typical values obtained from urinalysis.

Table 26–6 Typical Values Obtained from Standard Urinalysis

Compound	Primary Source	Daily Elimination*	Concentration	Remarks
NITROGENOUS WASTES				
Urea	Deamination of amino acids by liver and kidneys	21 g	1800 mg/dL	Increases if negative nitrogen balance exists
Creatinine	Breakdown of creatine phosphate in skeletal muscle	1.8 g	150 mg/dL	Proportional to muscle mass; decreases during atrophy or muscle disease
Ammonia	Deamination by liver and kidney, absorption from intestinal tract	0.68 g	60 mg/dL	
Uric acid	Breakdown of purines	0.53 g	40 mg/dL	Increases in gout, liver diseases
Hippuric acid	Breakdown of dietary toxins	4.2 mg	350 µg/dL	
Urobilin	Urobilinogens absorbed at colon	1.5 mg	125 µg/dL	Gives urine its yellow color
Bilirubin	Hemoglobin breakdown product	0.3 mg	20 µg/dL	Increase may indicate problem with liver elimination or excess production; causes yellowing of skin and mucous membranes in jaundice
NUTRIENTS AND METABOLITES				
Carbohydrates		0.11 g	9 µg/dL	Primarily glucose; *glycosuria* develops if T_m is exceeded
Ketone bodies		0.21 g	17 µg/dL	Ketonuria may occur during postabsorptive state
Lipids		0.02 g	0.002 mg/dL	May increase in some kidney diseases
Amino acids		2.25 g	188 µg/dL	Note relatively high loss compared with other metabolites due to low T_m; excess (*aminoaciduria*) indicates T_m problem
IONS				
Sodium		4.0 g	40–220 mEq/L	Varies with diet, urine pH, hormones, etc.
Potassium		2.0 g	25–100 mEq/L	Varies with diet, urine pH, hormones, etc.
Chloride		6.4 g	110–250 mEq/L	
Calcium		0.2 g	17 mg/dL	Hormonally regulated (PTH/CT)
Magnesium		0.15 g	13 mg/dL	
BLOOD CELLS‡				
RBCs		130,000/day	100/mL	Excess (*hematuria*) indicates vascular damage in urinary system
WBCs		650,000/day	500/mL	Excess (*pyuria*) indicates renal infection or inflammation

*Representative values for a 70-kg (154-lb) male.

‡Usually estimated by counting the cells in a sample of sediment after urine centrifugation.

Creatinine Clearance. Creatinine clearance compares the creatinine level in urine with the creatinine level in blood by estimating the GFR. It is used as an index of overall kidney function. For example, a GFR around 100 means the kidneys are working at 100%. Creatinine results from the breakdown of creatine phosphate in muscle tissue and is normally eliminated in urine. Creatinine enters the filtrate at the glomerulus and is not reabsorbed in significant amounts.

Consider, for example, a person who eliminates 84 mg of creatinine each hour and has a plasma creatinine concentration of 1.4 mg/dL. The GFR is equal to the amount secreted divided by the plasma concentration, so this person's GFR is

$$\frac{84 \text{ mg/h}}{1.4 \text{ mg/dL}} = 60 \text{ dL/h} = 100 \text{ mL/min}$$

The GFR is usually reported in milliliters per minute.

The value 100 mL/min is only an approximation of the GFR. The reason is that up to 15 percent of creatinine in the urine enters by means of active tubular secretion. When necessary, a more accurate GFR can be obtained by using the complex carbohydrate *inulin*. This compound is not metabolized in the body and is neither reabsorbed nor secreted by the kidney tubules.

BUN. A **BUN** (**blood urea nitrogen**) test measures the amount of urea in blood. Urea is created in the liver from the breakdown of proteins. As we have discussed, a critical role of the kidneys is to excrete nitrogenous wastes—urea, uric acid, and creatinine. We expect these wastes to appear in urine, but high levels of nitrogenous wastes should not remain in the blood.

Checkpoint

16. **What effect would a high-protein diet have on the composition of urine?**

See the blue Answers tab at the back of the book.

26-7 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra by urinary reflexes

Learning Outcome Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the urinary reflexes.

Filtrate modification and urine production end when the fluid enters the renal pelvis. The urinary tract (the ureters, urinary bladder, and urethra) transports, stores, and eliminates urine.

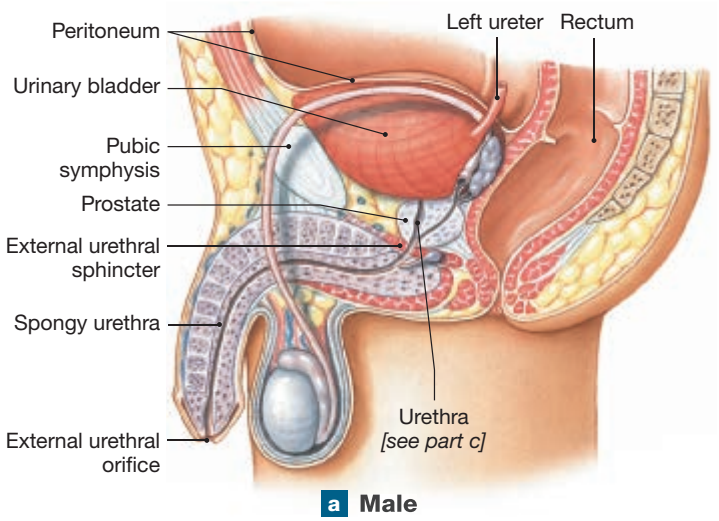
Figure 26–17 A Pyelogram. This anterior-posterior view of urinary system structures is color enhanced. ATLAS: Plate 62b

A **pyelogram** (PĪ-el-ō-gram) is an image of the urinary system (Figure 26–17). It is obtained by taking an x-ray of the kidneys after a radiopaque dye has been administered intravenously. Such an image provides an orientation to the relative sizes and positions of the main structures. Note that the sizes of the minor and major calyces, the renal pelvis, the ureters, the urinary bladder, and the proximal portion of the urethra are somewhat variable. These regions are lined by a *transitional epithelium* that can tolerate cycles of distension and relaxation without damage. ↩ p. 122

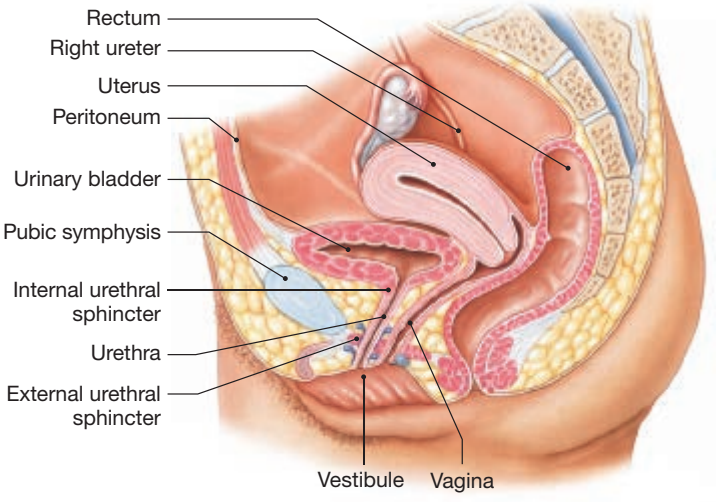
The Ureters

The ureters are a pair of muscular tubes that extend from the kidneys to the urinary bladder—a distance of about 30 cm (12 in.). Each ureter begins at the funnel-shaped renal pelvis (look back at Figure 26–4). The ureters extend inferiorly and medially, passing over the anterior surfaces of the *psoas major* (look back

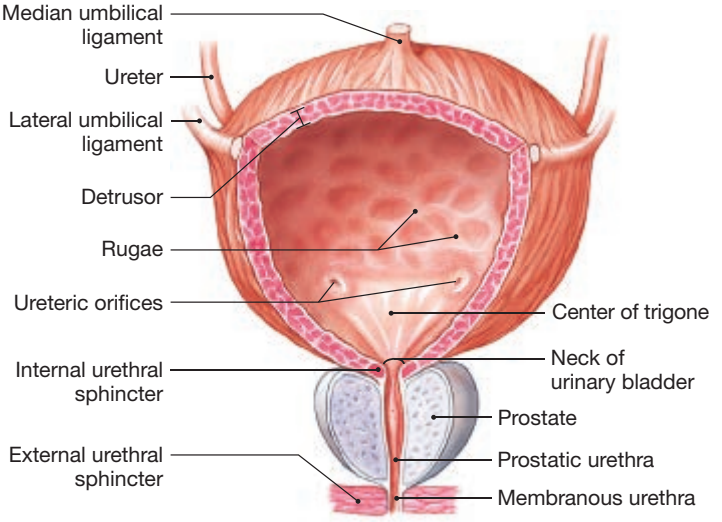
Figure 26–18 Organs for Conducting and Storing Urine. ATLAS: Plates 62b; 64; 65



a Male



b Female



c Urinary bladder in male

? The (*ureter* or *urethra*) transports urine *to* the bladder.

at Figure 26–3). The ureters are retroperitoneal and are firmly attached to the posterior abdominal wall. The paths taken by the ureters in men and women are different, due to variations in the nature, size, and position of the reproductive organs. In males, the base of the urinary bladder lies between the rectum and the pubic symphysis (Figure 26–18a). In females, the base of the urinary bladder sits inferior to the uterus and anterior to the vagina (Figure 26–18b).

The ureters penetrate the posterior wall of the urinary bladder without entering the peritoneal cavity. They pass through the bladder wall at an oblique angle. The **ureteric orifices** are slit-like rather than rounded (Figure 26–18c). This shape helps prevent the backflow of urine toward the ureter and kidneys when the urinary bladder contracts.

The wall of each ureter consists of three layers (Figure 26–19a): (1) an inner mucosa, made up of a transitional epithelium and the surrounding lamina propria; (2) a middle muscular layer made up of longitudinal and circular bands of smooth muscle; and (3) an outer connective tissue layer that is continuous with the fibrous capsule and peritoneum. About every 30 seconds, a peristaltic contraction begins at the renal pelvis. As it sweeps along the ureter, it forces urine toward the urinary bladder.

The Urinary Bladder

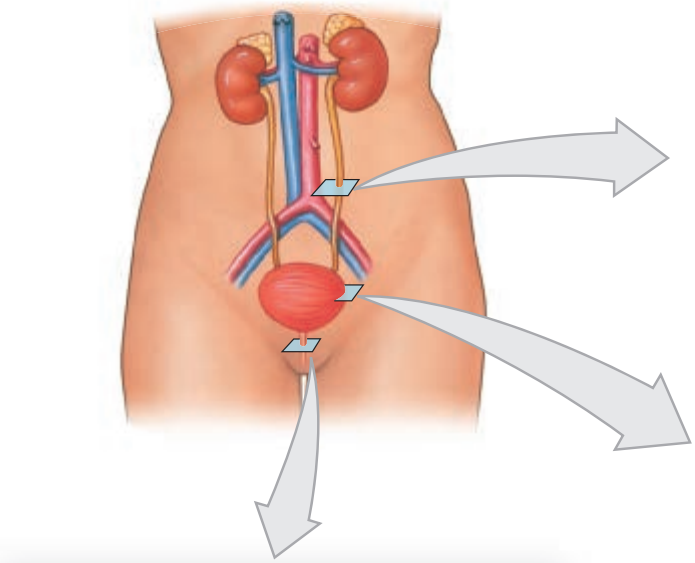
The urinary bladder is a hollow, muscular organ that serves as temporary storage for urine (see Figure 26–18c). The dimensions of the urinary bladder vary with its state of distension. A full urinary bladder can contain as much as a liter of urine.

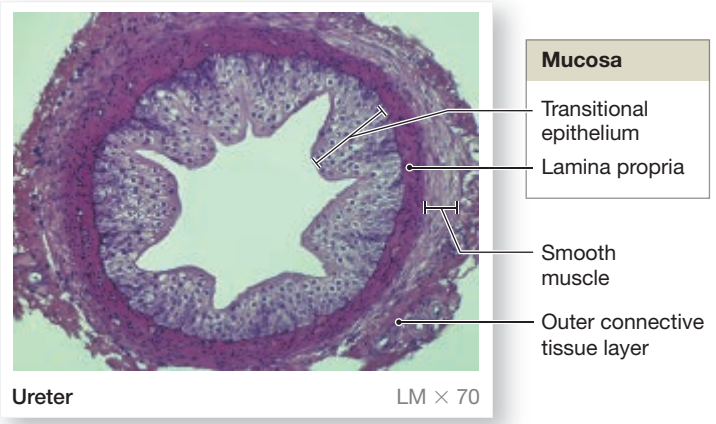
A layer of peritoneum covers the superior surfaces of the urinary bladder. Several peritoneal folds assist in stabilizing its position. The **median umbilical ligament** extends from the anterior, superior border toward the umbilicus (navel). The **lateral umbilical ligaments** pass along the sides of the bladder to the umbilicus. These fibrous cords are the vestiges of the two *umbilical arteries*, which supplied blood to the placenta during embryonic and fetal development. p. 775 The urinary bladder's posterior, inferior, and anterior surfaces lie outside the peritoneal cavity. In these areas, tough ligamentous bands anchor the urinary bladder to the pelvic and pubic bones.

In sectional view, the mucosa lining the urinary bladder usually has folds called **rugae** that disappear as the bladder fills. The triangular smooth area bounded by the openings of the ureters and the entrance to the urethra makes up a region called the **trigone** (TRĪ-gōn) of the urinary bladder. There, the mucosa is smooth and very thick. The trigone acts as a funnel that channels urine into the urethra when the urinary bladder contracts.

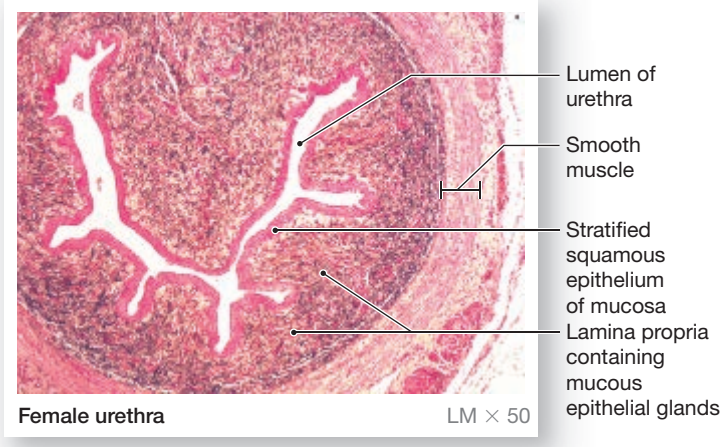
The urethral entrance lies at the apex of the trigone, at the most inferior point in the urinary bladder. The region

Figure 26–19 The Histology of the Ureter, Urinary Bladder, and Urethra.

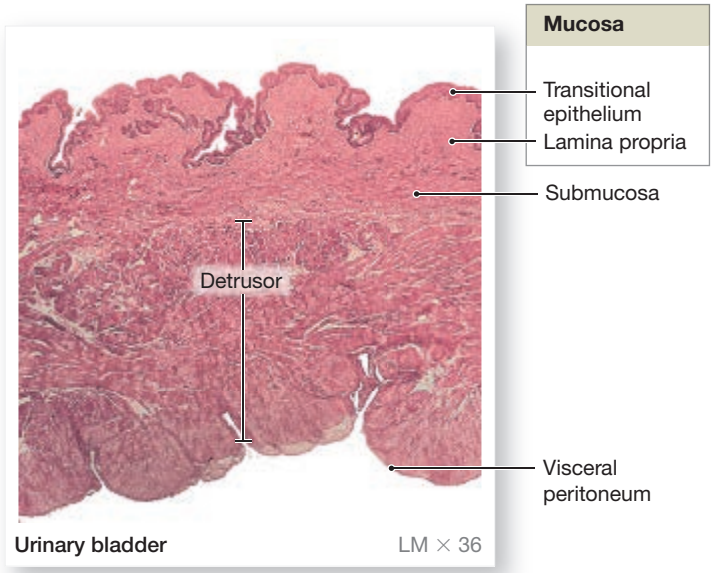




a A transverse section through the ureter.



c A transverse section through the female urethra. A thick layer of smooth muscle surrounds the lumen.



b The wall of the urinary bladder.

surrounding the urethral opening is known as the **neck** of the urinary bladder. It contains a muscular **internal urethral sphincter**. The smooth muscle fibers of this sphincter provide involuntary control over the discharge of urine from the bladder. The urinary bladder is innervated by postganglionic fibers from ganglia in the hypogastric plexus and by parasympathetic fibers from intramural ganglia that are controlled by branches of the pelvic nerves.

The wall of the urinary bladder contains mucosa, submucosa, and muscular layers (Figure 26–19b). The muscular layer consists of internal and external layers of longitudinal smooth muscle, with a circular layer between the two. Together, these layers form the powerful **detrusor** (de-TRŪ-sor), a muscle of the urinary bladder. When the detrusor contracts, it compresses the urinary bladder and expels urine into the urethra.

The Urethra

The urethra extends from the neck of the urinary bladder and transports urine to the exterior of the body. The male urethra and the female urethra differ in length and in function. In males, the urethra extends from the neck of the urinary bladder to the tip of the penis (look back at Figure 26–18a,c). This distance may be 18–20 cm (7–8 in.). The male urethra is subdivided into three segments: the prostatic urethra, the membranous urethra, and the spongy urethra. The **prostatic urethra** (*intermediate part of urethra*) passes through the center

of the prostate. The **membranous urethra** includes the short segment that penetrates the deep transverse perineal muscle of the pelvic floor. The **spongy urethra** extends from the distal border of the deep transverse perineal muscle to the external opening, or **external urethral orifice**, at the tip of the penis. In females, the urethra is very short. It extends 3–5 cm (1–2 in.) from the bladder to the vestibule (look back at Figure 26–18b). The external urethral orifice is near the anterior wall of the vagina.

Both sexes have a skeletal muscular band, called the **external urethral sphincter**, that acts as a valve. The external urethral sphincter is under voluntary control through the perineal branch of the pudendal nerve. This sphincter has a resting muscle tone and must be voluntarily relaxed to permit urination.

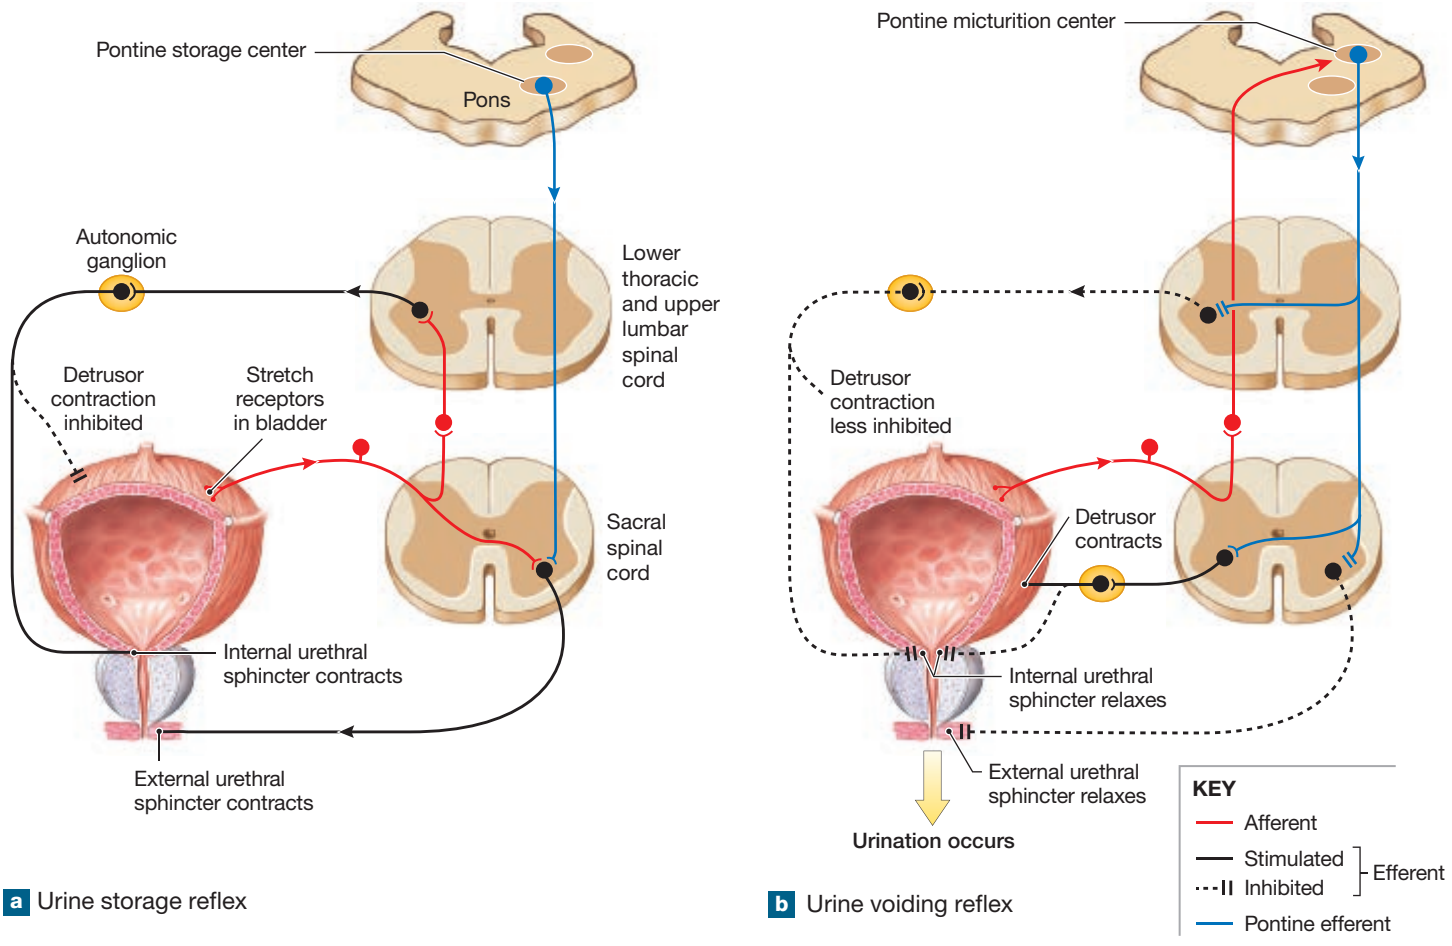
The urethral lining consists of a stratified epithelium that varies from transitional epithelium at the neck of the urinary bladder, to stratified columnar epithelium at the midpoint, to stratified squamous epithelium near the external urethral orifice. The lamina propria is thick and elastic. The mucosa is folded into longitudinal creases (Figure 26–19c). Mucus-secreting cells are located in the epithelial pockets. In males, the epithelial mucous glands may form tubules that extend into the lamina propria. Connective tissues of the lamina propria anchor the urethra to surrounding structures. In females, the lamina propria contains an extensive network of veins. Concentric layers of smooth muscle surround the entire complex.

Urinary Reflexes: Urine Storage and Urine Voiding

As we have seen, urine reaches the urinary bladder by peristaltic contractions of the ureters. The urge to urinate generally appears when your urinary bladder contains about 200 mL of urine. Whether or not we urinate depends on an interplay between spinal reflexes and higher centers in the brain that provide conscious control over urination. Two spinal reflexes control urination (micturition): the urine storage reflex and the urine voiding reflex. These must be considered together, because urine storage and release involve simultaneous, coordinated activities (Figure 26–20).

- *Urine Storage Reflex.* Urine storage occurs by spinal reflexes and the *pontine storage center*. When urine is being stored, afferent impulses from stretch receptors in the urinary

Figure 26–20 The Control of Urination.



a Urine storage reflex

b Urine voiding reflex

bladder stimulate sympathetic outflow to the detrusor and internal urethral sphincter, inhibiting contraction of the detrusor and stimulating contraction of the internal urethral sphincter (see Figure 26–20a). The pontine storage center inhibits urination by decreasing parasympathetic activity and increasing somatic motor nerve activity at the external urethral sphincter. Urine storage (continence) occurs as urine is unable to pass through the urethra.

- *Urine Voiding Reflex.* Urine voiding occurs by spinal reflexes and the *pontine micturition center*. The voiding reflex begins when afferent impulses from stretch receptors in the bladder stimulate interneurons that relay sensations to the pontine micturition center. This center initiates sacral spinal reflexes that (1) stimulate increased parasympathetic activity (detrusor contracts and internal urethral sphincter relaxes), (2) decrease sympathetic activity (detrusor contracts and internal urethral sphincter relaxes), and (3) decrease efferent somatic motor nerve activity (external urethral sphincter relaxes). Voiding (urination) occurs as urine passes through the urethra.

At the end of urination, less than 10 mL of urine remains in the urinary bladder.

Infants lack voluntary control over urination, because the necessary corticospinal connections have yet to be established. Accordingly, "toilet training" before age 2 often involves training the parent to anticipate the timing of the reflex rather than training the child to exert conscious control.

Incontinence (in-KON-tih-nens) is the inability to control urination voluntarily. Trauma to the internal or external urethral sphincter can contribute to incontinence in otherwise healthy adults. For example, some mothers develop *stress urinary incontinence* (SUI) if childbirth overstretches and damages the sphincter muscles. In this condition, increased intra-abdominal pressures—caused, for example, by a cough or sneeze—can overwhelm the sphincter muscles, causing urine to leak out. Incontinence can also develop in older people due to a general loss of muscle tone.

Damage to the central nervous system, the spinal cord, or the nerve supply to the urinary bladder or external urethral sphincter can also produce incontinence. For example, incontinence commonly accompanies Alzheimer's disease or spinal cord damage. In most cases, the affected individual develops an *automatic bladder*. The urinary reflexes remain intact, but voluntary control of the external urethral sphincter is lost, so the person cannot prevent the reflexive emptying of the urinary bladder. Damage to the pelvic nerves of the sacral spinal cord can destroy the urinary reflexes entirely, because those nerves carry both afferent and efferent fibers of both reflex arcs. The urinary bladder then becomes greatly distended with urine. It remains filled to capacity while the excess urine flows into the urethra in an uncontrolled stream. The insertion of a catheter is often needed to facilitate the discharge of urine.

Clinical Note Urinary Obstruction

Local blockages of the collecting ducts or ureters can result from *casts*—small blood clots, epithelial cells, lipids, or other materials—that form in the collecting ducts. Casts are commonly eliminated in urine. They are visible in microscopic analyses of urine samples. **Renal calculi** (KAL-kū-lī), or *kidney stones*, form within the urinary tract from calcium deposits, magnesium salts, or crystals of uric acid. The condition is called *nephrolithiasis* (nef-rō-lih-THĪ-uh-sis; *nephros*, kidney; *lithos*, stone). The blockage of the ureter by a stone or by other means (such as external compression) creates **urinary obstruction**. This problem is an emergency. In addition to causing extreme pain, it decreases or prevents filtration in the affected kidney by increasing the capsular hydrostatic pressure.

Calculi are generally visible on an x-ray. If urinary peristalsis and fluid pressures cannot dislodge them, they must be either surgically removed or destroyed. One nonsurgical procedure involves disintegrating the stones with a *lithotripter*, a device originally developed from machines used to de-ice airplane wings. Lithotripters focus sound waves on the stones, breaking them into smaller fragments that can be passed in the urine. Another nonsurgical approach is the insertion of a catheter armed with a laser that can shatter calculi with intense light beams.

Checkpoint

17. **Obstruction of a ureter by a kidney stone would interfere with the flow of urine between which two points?**
18. **The ability to control the urinary reflexes depends on your ability to control which muscle?**

See the blue Answers tab at the back of the book.

26-8 Age-related changes affect kidney function and urination

Learning Outcome Describe the effects of aging on the urinary system.

In general, aging is associated with an increased incidence of kidney problems. One example—*nephrolithiasis*, the formation of calculi, or kidney stones—is described in the Urinary Obstruction Clinical Note. Other age-related changes in the urinary system include the following:

- *A Decrease in the Number of Functional Nephrons.* The total number of kidney nephrons decreases by 30–40 percent between ages 25 and 85.
- *A Reduction in the GFR.* This reduction results from fewer glomeruli, cumulative damage to the filtration apparatus in the remaining glomeruli, and reduced renal blood flow.

Clinical Note Renal Failure and Kidney Transplant

Renal failure occurs when the kidneys cannot filter wastes from the blood and can no longer maintain homeostasis. When kidney filtration slows for any reason, urine production decreases. As the patient makes less and less urine, signs and symptoms of renal failure appear because water, ions, and metabolic wastes are retained. Virtually all systems in the body are affected. Blood pressure rises; anemia develops due to a decrease in erythropoietin production; and CNS problems can lead to sleeplessness, seizures, delirium, and even coma.

Acute renal failure occurs when filtration slows suddenly or stops due to renal ischemia, urinary obstruction, trauma, or nephrotoxic drugs. The reduction in kidney function takes place over a few days and may persist for weeks. Sensitized individuals can also develop acute renal failure after an allergic response to antibiotics or anesthetics.

In *chronic renal failure*, kidney function deteriorates gradually and problems accumulate over years. This condition generally cannot be reversed but only slowed. Eventually, symptoms of *end-stage renal failure* develop. *Hemodialysis* is a treatment that "cleanses" the blood by substituting for normal kidney functioning. It can relieve the symptoms of renal failure but is not a cure.

In terms of overall quality of life, the most satisfactory solution to end-stage renal failure is **kidney transplant**. This procedure involves implanting a new kidney from a living or deceased donor. According to the National Kidney Foundation, in January 2016, 83% of all people awaiting organ transplants were waiting for a kidney. Their median wait time is 3.6 years. The recipient's nonfunctioning kidney(s) may be removed, especially if an infection is present. The transplanted kidney and ureter are usually placed extraperitoneally in the pelvic cavity (within the iliac fossa). The ureter is connected to the recipient's urinary bladder. Patient survival is more than 90 percent at two years after the transplant.

- *A Reduced Sensitivity to ADH.* With age, the distal segments of the nephron and collecting system become less responsive to ADH. Water and sodium ions are reabsorbed at a reduced rate, and more sodium ions are lost in urine.
- *Problems with the Urinary Reflexes.* Three factors are involved in such problems: (1) The external sphincter loses muscle tone and become less effective at voluntarily retaining urine. This leads to incontinence, often involving a slow leakage of urine. (2) The ability to control urination can be lost due to a stroke, Alzheimer's disease, or other CNS problems affecting the cerebral cortex or hypothalamus. (3) In males, *urinary retention* may develop if the prostate enlarges and compresses the urethra, restricting the flow of urine.

Checkpoint

19. **List four age-related changes in the urinary system.**
20. **Define *nephrolithiasis*.**
21. **Describe how incontinence may develop in an elderly person.**

See the blue Answers tab at the back of the book.

26-9 The urinary system is one of several body systems involved in waste excretion

Learning Outcome Give examples of interactions between the urinary system and other organ systems studied so far.

The urinary system excretes wastes produced by other body systems, but it is not the only organ system involved in excretion. Indeed, the urinary, integumentary, respiratory, and digestive systems are together regarded as an anatomically diverse **excretory system** whose components perform all the excretory functions that affect the composition of body fluids:

- *Integumentary System.* Water losses and electrolyte losses in sensible perspiration can affect the volume and composition of the plasma. The effects are most apparent when losses are extreme, such as during peak sweat production. Small amounts of metabolic wastes, including urea, also are eliminated in perspiration.
- *Respiratory System.* The lungs remove the carbon dioxide generated by cells. Small amounts of other compounds, such as acetone and water, evaporate into the alveoli and are eliminated when you exhale.
- *Digestive System.* The liver excretes small amounts of metabolic waste products in bile. You lose a variable amount of water in feces.

These excretory activities have an impact on the composition of body fluids. For example, the removal of carbon dioxide by the respiratory system also affects the pH of blood plasma. Note that the excretory functions of these systems are not regulated as closely as are those of the kidneys. Under normal circumstances, the effects of integumentary and digestive excretory activities are minor compared with those of the urinary system.

Build Your Knowledge **Figure 26–21** summarizes the functional relationships between the urinary system and other systems we have studied so far. We explore many of these relationships further in Chapter 27 when we consider major aspects of fluid, pH, and electrolyte balance.

Checkpoint

22. **Identify the role the urinary system plays for all other body systems.**
23. **Name the body systems that make up the excretory system.**

See the blue Answers tab at the back of the book.

Build Your Knowledge

Figure 26–21 Integration of the URINARY system with the other body systems presented so far.

Integumentary System

- The Integumentary System prevents excessive fluid loss through skin surface; produces vitamin D_3, important for the renal production of calcitriol; sweat glands assist in elimination of water and solutes
- The urinary system excretes nitrogenous wastes; maintains fluid, electrolyte, and acid–base balance of blood that nourishes the skin

Respiratory System

- The Respiratory System assists in the regulation of pH by eliminating carbon dioxide
- The urinary system assists in the excretion of carbon dioxide; provides bicarbonate buffers that assist in pH regulation

Cardiovascular System

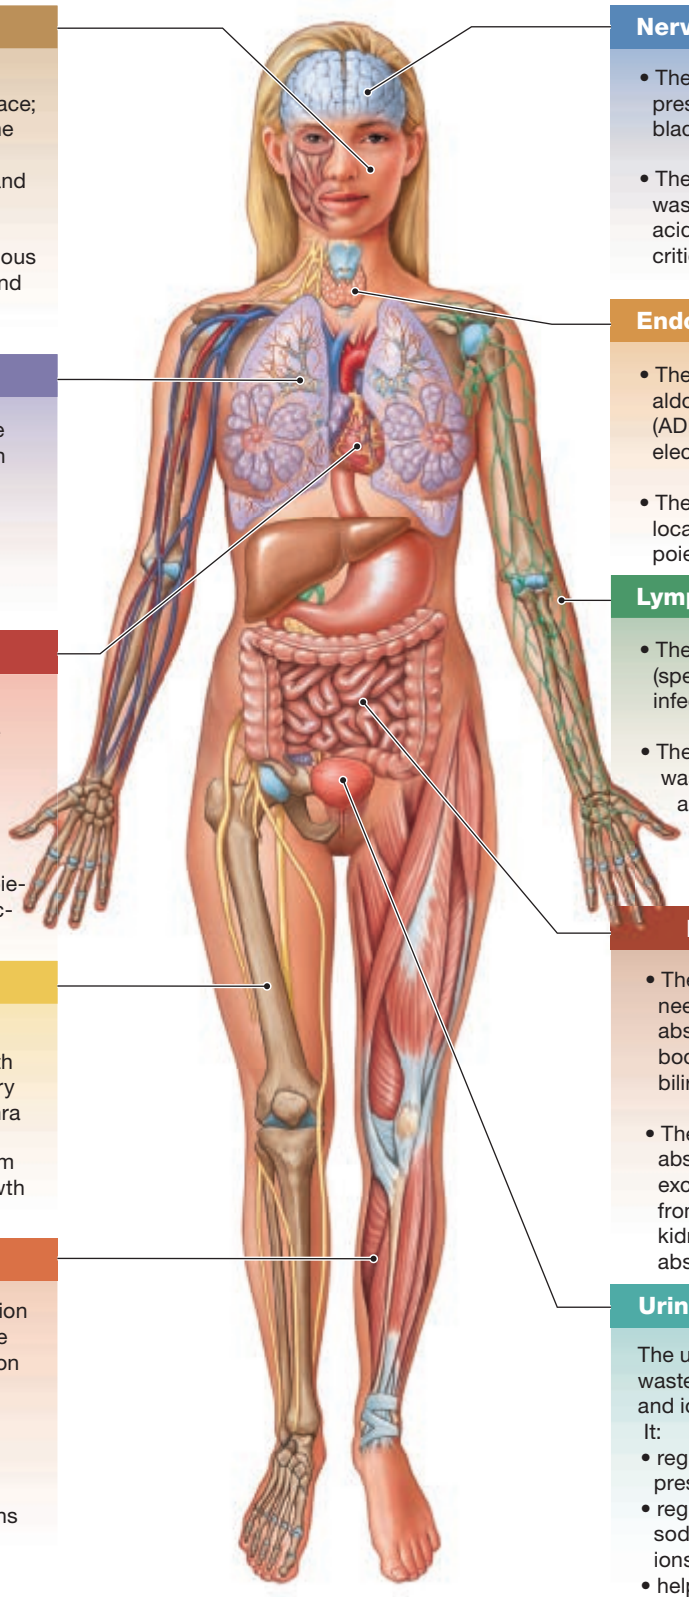
- The Cardiovascular System delivers blood to glomerular capillaries, where filtration occurs; accepts fluids and solutes reabsorbed during urine production
- The urinary system releases renin to elevate blood pressure and erythropoietin to accelerate red blood cell production

Skeletal System

- The Skeletal System provides some protection for kidneys and ureters with its axial divison; pelvis protects urinary bladder and proximal portion of urethra
- The urinary system conserves calcium and phosphate needed for bone growth

Muscular System

- The Muscular System controls urination by closing urethral sphincters. Muscle layers of trunk provide some protection for urinary organs
- The urinary system excretes waste products of muscle and protein metabolism; assists in regulation of calcium and phosphate concentrations



Nervous System

- The Nervous System adjusts renal blood pressure; monitors distension of urinary bladder and controls urination
- The urinary system eliminates nitrogenous wastes; maintains fluid, electrolyte, and acid–base balance of blood, which is critical for neural function

Endocrine System

- The Endocrine System produces aldosterone and antidiuretic hormone (ADH), which adjust rates of fluid and electrolyte reabsorption by kidneys
- The urinary system releases renin when local blood pressure drops and erythropoietin (EPO) when renal oxygen levels fall

Lymphatic System

- The Lymphatic System provides adaptive (specific) defense against urinary tract infections
- The urinary system excretes toxins and wastes generated by cellular activities; acid pH of urine provides innate (nonspecific) defense against urinary tract infections

Digestive System

- The Digestive System absorbs water needed to excrete wastes at kidneys; absorbs ions needed to maintain normal body fluid concentrations; liver removes bilirubin
- The urinary system excretes toxins absorbed by the digestive epithelium; excretes bilirubin and nitrogenous wastes from the liver; calcitriol production by kidneys aids calcium and phosphate absorption

Urinary System

The urinary system excretes metabolic wastes and maintains normal body fluid pH and ion composition.

It:

- regulates blood volume and blood pressure
- regulates plasma concentrations of sodium, potassium, chloride, and other ions
- helps to stabilize blood pH
- conserves valuable nutrients

26 Chapter Review

Study Outline

An Introduction to the Urinary System p. 977

1. The urinary system removes most physiological wastes and produces urine.

26-1 The organs of the urinary system function in excreting wastes and regulating body fluids p. 977

2. The urinary system includes two **kidneys**, two **ureters**, the **urinary bladder**, and the **urethra**. The kidneys produce **urine**, which is a fluid that contains water, ions, and soluble compounds. During **urination (micturition)**, urine is forced out of the body. *(Figure 26–1)*
3. The major functions of the **urinary system** are *excretion*, the removal of metabolic waste products from body fluids; *elimination*, the discharge of these waste products into the environment; and *homeostatic regulation* of the volume and solute concentration of blood plasma. Other homeostatic functions include regulating blood volume and pressure by adjusting the volume of water lost and releasing hormones; regulating plasma concentrations of ions; helping to stabilize blood pH; conserving nutrients; assisting the liver in detoxifying poisons; and, during starvation, deaminating amino acids so that they can be catabolized by other tissues.

26-2 Kidneys are highly vascular organs containing functional units called nephrons p. 978

4. The left kidney extends superiorly slightly more than the right kidney. Both kidneys and the adrenal gland superior to each kidney are retroperitoneal. *(Figures 26–1, 26–2, 26–3)*
5. The **hilum**, a medial indentation, provides entry for the *renal artery* and *renal nerves* and exit for the *renal vein* and the ureter. *(Figures 26–3, 26–4)*
6. The superficial region of the kidney, the cortex, surrounds the **medulla**. The ureter communicates with the **renal pelvis**, a chamber that branches into two **major calyces**. Each major calyx is connected to four or five **minor calyces**, which enclose the **renal papillae**. *(Figure 26–4)*
7. The blood supply to the kidneys includes the **renal**, **segmental**, **interlobar**, **arcuate**, and **cortical radiate arteries**. *(Figure 26–5)*
8. The **renal nerves**, which innervate the kidneys and ureters, are dominated by sympathetic postganglionic fibers.
9. The **nephron** is the basic functional unit in the kidney. It consists of the **renal corpuscle** and **renal tubule**. The renal tubule is long and narrow and divided into the *proximal convoluted tubule*, the *nephron loop*, and the *distal convoluted tubule*. **Filtrate** is produced at the renal corpuscle. The nephron empties **tubular fluid** into the **collecting system**, consisting of **collecting ducts** and **papillary ducts**. *(Figures 26–6, 26–7)*
10. The **proximal convoluted tubule (PCT)** actively reabsorbs nutrients, plasma proteins, and ions from the filtrate. These substances are released into the **peritubular fluid**, which surrounds the nephron. *(Figure 26–6)*
11. The **nephron loop**, also called the **loop of Henle**, includes a **descending limb** and an **ascending limb**. The *descending thin limb (DTL)* and the *ascending thin limb (ATL)* contain simple squamous epithelium and the *thick ascending limb (TAL)* contains cuboidal epithelium. The ascending limb delivers fluid to the **distal convoluted tubule (DCT)**, which actively secretes ions, toxins, and drugs, and reabsorbs sodium ions from the tubular fluid. *(Figures 26–6, 26–8)*
12. The renal tubule begins at the renal corpuscle, which includes a knot of intertwined capillaries called the **glomerulus**, surrounded by the **glomerular capsule**. Blood arrives at the glomerulus by the **afferent arteriole** and departs in the **efferent arteriole**. *(Figure 26–7)*
13. At the glomerulus, a **visceral layer** of **podocytes** cover the **basement membrane** of the capillaries that project into the **capsular space**. The **foot processes**, or *pedicels*, of the podocytes are separated by narrow **filtration slits**. Together, the fenestrated endothelium, basement membrane, and foot processes form the **filtration membrane**. **Intraglomerular mesangial cells** lie between adjacent capillaries and control capillary luminal diameter. *(Figure 26–7)*
14. Roughly 85 percent of the nephrons are **cortical nephrons**, located in the renal cortex. **Juxtamedullary nephrons** are closer to the renal medulla, with their *nephron loops* extending deep into the **renal pyramids**. *(Figure 26–8)*
15. Blood travels from the efferent arteriole to the **peritubular capillaries** and the **vasa recta**. *(Figure 26–8)*
16. Nephrons produce filtrate; reabsorb organic nutrients, water, and ions; and secrete various waste products into the tubular fluid. *(Table 26–1)*

26-3 Different segments of the nephron form urine by filtration, reabsorption, and secretion p. 987

17. Urine production maintains homeostasis by regulating blood volume and composition. In the process, metabolic

wastes —notably urea, creatinine, and uric acid—are excreted.

18. Urine formation involves **filtration**, **reabsorption**, and **secretion**.
19. Most regions of the nephron perform a combination of reabsorption and secretion. *(Figure 26–9; Table 26–2)*

26-4 The glomerulus filters blood through the filtration membrane to produce filtrate; several pressures determine the glomerular filtration rate p. 989

20. **Glomerular filtration** occurs as fluids and solutes move across the filtration membrane of the glomerulus into the capsular space in response to the **glomerular hydrostatic pressure (GHP)**—the hydrostatic (blood) pressure in the glomerular capillaries. This movement is opposed by the **capsular hydrostatic pressure (CsHP)** and by the **blood colloid osmotic pressure (BCOP)**. The **net filtration pressure (NFP)** at the glomerulus is the difference between the blood pressure and the opposing capsular and osmotic pressures. *(Figure 26–10)*
21. The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Any factor that alters the filtration pressure acting across the glomerular capillaries will change the GFR and affect kidney function.
22. A drop in filtration pressures stimulates the **juxtaglomerular complex (JGC)** to release renin and erythropoietin. *(Figure 26–11)*
23. Sympathetic activation (1) produces a powerful vasoconstriction of the afferent arterioles, decreasing the GFR and slowing the production of filtrate; (2) alters the GFR by changing the regional pattern of blood circulation; and (3) stimulates the release of renin by the juxtaglomerular complex. *(Figure 26–11)*
24. Glomerular filtration produces a filtrate with a composition similar to blood plasma, but with few, if any, plasma proteins.

26-5 The renal tubule reabsorbs nutrients, ions, and water, and secretes ions and wastes; the collecting system reabsorbs ions and water p. 993

25. Four types of *carrier-mediated transport (facilitated diffusion, active transport, cotransport,* and *countertransport)* are involved in modifying filtrate. The saturation limit of a carrier protein is its **transport maximum (T_m)**, which determines the **renal threshold**—the plasma concentration at which various substances will appear in urine. *(Table 26–2)*
26. The transport maximum determines the renal threshold for the reabsorption of substances in tubular fluid. *(Table 26–3)*
27. The cells of the PCT normally reabsorb sodium and other ions, water, and almost all the organic nutrients that enter the filtrate. These cells also secrete various substances into the tubular fluid. *(Figure 26–12)*
28. Water and ions are reclaimed from tubular fluid by the nephron loop. The entire descending limb of the nephron loop is freely permeable to water, but not to solutes, such as sodium and chloride ions. The ascending limb of the nephron loop is impermeable to water, but passively and actively removes sodium and chloride ions from the tubular fluid. Its ascending thin limb is permeable to sodium ions. The thick ascending limb (TAL) actively transports sodium and chloride ions out of the tubular fluid.
29. The DCT performs final adjustments by actively secreting or absorbing materials. Sodium ions are actively absorbed, in exchange for potassium or hydrogen ions discharged into tubular fluid. Aldosterone secretion increases the rate of sodium reabsorption and potassium loss. *(Figure 26–13)*
30. The amount of water and solutes in the tubular fluid of the collecting ducts is further regulated by aldosterone and ADH secretions. *(Figure 26–13)*

26-6 Countercurrent multiplication allows the kidneys to regulate the volume and concentration of urine p. 1001

31. The descending thin limb and the thick ascending limb of the nephron loop are close together and separated by peritubular fluid. The descending thin limb is permeable to water but relatively impermeable to solutes. The thick ascending limb is relatively impermeable to both water and solutes, but it contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.
32. The exchange of substances between the descending thin limb and the thick ascending limb of a nephron, called **countercurrent multiplication,** helps create the osmotic gradient in the medulla. The concentration gradient in the renal medulla encourages the osmotic flow of water out of the tubular fluid. As water is lost by osmosis and the volume of tubular fluid decreases, the urea concentration increases. *(Figure 26–14)*
33. Urine volume and osmotic concentration are regulated by controlling water reabsorption. Precise control over this occurs by *facultative water reabsorption*. *(Figure 26–15)*
34. Normally, the removal of solutes and water by the vasa recta precisely balances the rates of reabsorption and osmosis in the renal medulla.
35. More than 99 percent of the filtrate produced each day is reabsorbed before reaching the renal pelvis. *(*Table 26–5*)*
36. Each segment of the nephron and collecting system contributes to the production of concentrated urine. *(Spotlight Figure 26–16; Table 26–4)*
37. **Urinalysis** is the chemical and physical analysis of a urine sample. *(Table 26–6)*

26-7 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra by urinary reflexes p. 1009

38. Urine production ends when tubular fluid enters the renal pelvis. The rest of the urinary system transports, stores, and eliminates urine. *(Figure 26–17)*

39. The ureters extend from the renal pelvis to the urinary bladder. Peristaltic contractions by smooth muscles move the urine along the tract. *(Figures 26–18, 26–19)*
40. The urinary bladder is stabilized by the **middle umbilical ligament** and the **lateral umbilical ligaments**. Internal features include the **trigone**, the **neck**, and the **internal urethral sphincter**. The mucosal lining contains prominent **rugae** (folds). Contraction of the **detrusor** compresses the urinary bladder and expels urine into the urethra. *(Figures 26–18, 26–19)*
41. In both sexes, a circular band of skeletal muscles forms the **external urethral sphincter**, which is under voluntary control. *(Figure 26–18)*
42. **Urination** is coordinated by the **urine storage reflex** and the **urine voiding reflex**, which are initiated by stretch receptors in the wall of the urinary bladder. Voluntary urination involves coupling these reflexes with the voluntary relaxation of the external urethral sphincter, which allows the relaxation of the **internal urethral sphincter**. *(Figure 26–20)*

26-8 Age-related changes affect kidney function and urination p. 1013

43. Aging is generally associated with increased kidney problems. Age-related changes in the urinary system include (1) declining numbers of functional nephrons, (2) reduced GFR, (3) reduced sensitivity to ADH, and (4) problems with the urinary reflexes. (**Urinary retention** may develop in men whose prostate is enlarged.)

26-9 The urinary system is one of several body systems involved in waste excretion p. 1014

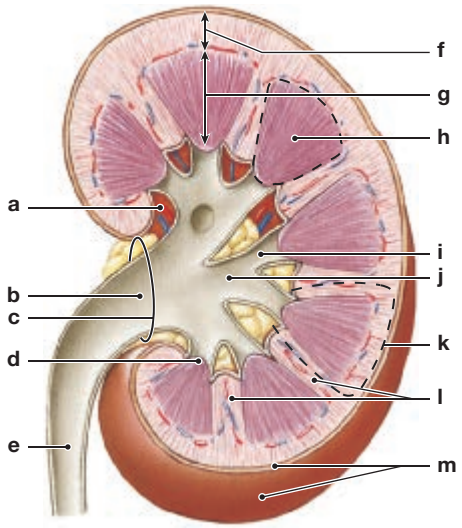
44. The urinary system is the major component of an anatomically diverse **excretory system** that includes the integumentary system, the respiratory system, and the digestive system. *(Figure 26–21)*

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the kidney in the following diagram.



(a) _____ **(b)** _____
(c) _____ **(d)** _____
(e) _____ **(f)** _____
(g) _____ **(h)** _____
(i) _____ **(j)** _____
(k) _____ **(l)** _____
(m) _____

2. The basic functional unit of the kidney is the **(a)** nephron, **(b)** renal corpuscle, **(c)** glomerulus, **(d)** nephron loop, **(e)** filtration unit.
3. The process of urine formation involves all of the following, *except* **(a)** filtration of plasma, **(b)** reabsorption of water, **(c)** reabsorption of certain solutes, **(d)** secretion of wastes, **(e)** secretion of excess lipoprotein and glucose molecules.
4. The glomerular filtration rate is regulated by all of the following, *except* **(a)** autoregulation, **(b)** sympathetic neural control, **(c)** cardiac output, **(d)** angiotensin II, **(e)** the hormone ADH.
5. The distal convoluted tubule is an important site for **(a)** active secretion of ions, **(b)** active secretion of acids and other materials, **(c)** selective reabsorption of sodium ions from the tubular fluid, **(d)** all of these.
6. Changing the luminal diameters of the afferent and efferent arterioles to alter the GFR can be an example of **(a)** hormonal regulation, **(b)** autonomic regulation, **(c)** autoregulation, **(d)** all of these.
7. What are the primary functions of the urinary system?
8. What organs make up the urinary system?
9. Trace the pathway of the protein-free filtrate from where it is produced in the renal corpuscle until it drains into the renal pelvis in the form of urine. (Use arrows to indicate the direction of flow.)
10. Name the segments of the nephron distal to the renal corpuscle, and state the functions of each.
11. What is the function of the juxtaglomerular complex?
12. Trace the path of a drop of blood from its entry into the renal artery until its exit at a renal vein.
13. Name and define the three distinct processes involved in the production of urine.
14. What are the primary effects of angiotensin II on kidney function and regulation?
15. Which structures of the urinary system are responsible for the transport, storage, and elimination of urine?

LEVEL 2 Reviewing Concepts

16. When the renal threshold for a substance exceeds its tubular maximum **(a)** more of the substance will be filtered, **(b)** more of the substance will be reabsorbed, **(c)** more of the substance will be secreted, **(d)** the amount of the substance that exceeds the tubular maximum will be found in the urine, **(e)** both a and d occur.
17. Sympathetic activation of nerve fibers in the nephron causes **(a)** the regulation of glomerular blood flow and pressure, **(b)** the stimulation of renin release from the juxtaglomerular complex, **(c)** the direct stimulation of water and Na^+ reabsorption, **(d)** all of these.
18. Sodium reabsorption in the DCT and in the cortical portion of the collecting system is accelerated by the secretion of **(a)** ADH, **(b)** renin, **(c)** aldosterone, **(d)** erythropoietin.
19. When ADH levels rise, **(a)** the amount of water reabsorbed increases, **(b)** the DCT becomes impermeable to water, **(c)** the amount of water reabsorbed decreases, **(d)** sodium ions are exchanged for potassium ions.
20. The control of blood pH by the kidneys during acidosis involves **(a)** the secretion of hydrogen ions and reabsorption of bicarbonate ions from the tubular fluid, **(b)** a decrease in the amount of water reabsorbed, **(c)** hydrogen ion reabsorption and bicarbonate ion loss, **(d)** potassium ion secretion.
21. How are proteins excluded from filtrate? Why is this important?
22. What interacting controls stabilize the glomerular filtration rate (GFR)?
23. What primary changes occur in the composition and concentration of filtrate as a result of activity in the proximal convoluted tubule?
24. Describe two functions of countercurrent multiplication in the kidney.
25. Describe the urine voiding reflex.

LEVEL 3 Critical Thinking and Clinical Applications

26. In a normal kidney, which of the following conditions would cause an increase in the glomerular filtration rate (GFR)? **(a)** constriction of the afferent arteriole, **(b)** a decrease in the pressure of the glomerulus, **(c)** an increase in the capsular hydrostatic pressure, **(d)** a decrease in the concentration of plasma proteins in the blood, **(e)** a decrease in the net glomerular filtration process.
27. In response to *excess* water in the body, **(a)** antidiuretic hormone is secreted by the anterior lobe of the pituitary gland, **(b)** the active transport mechanisms in the ascending thick limb of the nephron loop cease functioning, **(c)** the permeability of the distal convoluted tubules and collecting ducts to water is decreased, **(d)** the permeability of the ascending limb of the nephron loop is increased, **(e)** the glomerular filtration rate is reduced.
28. Sylvia is suffering from severe edema in her arms and legs. Her physician prescribes a diuretic (a substance that increases the volume of urine produced). Why might this help alleviate Sylvia's problem?
29. David's grandfather suffers from hypertension. His doctor tells him that part of his problem stems from renal arteriosclerosis. Why would this cause hypertension?
30. *Mannitol* is a sugar that is filtered, but not reabsorbed, by the kidneys. What effect would drinking a solution of mannitol have on the volume of urine produced?
31. The drug *Diamox* is sometimes used to treat mountain sickness. Diamox inhibits the action of carbonic anhydrase in the proximal convoluted tubule. Polyuria (excessive urine production resulting in frequent urination) is a side effect associated with the medication. Why does polyuria occur?

CLINICAL CASE Wrap-Up A Case of "Hidden" Bleeding

Normally, when a kidney is injured, the urine appears very bloody (*hematuria*). Mike has made very little urine since his injury and massive blood loss, but the urine in his catheter is clear. This reduces the initial suspicion of a renal injury.

However, when the surgeon opens the left retroperitoneal space, he finds another large collection of free blood. When the surgeon clears this blood away, the source of Mike's continued bleeding becomes apparent. His left renal artery, renal vein, and ureter have been completely torn away from the kidney at the hilum. The renal artery is briskly pumping what circulatory blood volume is left into the retroperitoneal space, where it is walled off from the abdominal space by the parietal peritoneum. Because the left ureter is completely torn from the damaged kidney, there is no visible blood in the urine.

This kidney is too damaged to heal. The surgeon quickly performs a left *nephrectomy* (kidney removal). If Mike survives this trauma, he will have to live with a solitary kidney. With the bleeding stopped, including the "hidden" bleeding, the trauma team is finally able to sustain an adequate circulating blood volume.

1. How could Mike's abdominal x-rays show that his kidneys might be injured?
2. What will likely happen to the glomerular filtration rate (GFR) of Mike's remaining right kidney if he survives this trauma?

See the blue Answers tab at the back of the book.

Related Clinical Terms

azotemia: The condition characterized by excessive urea or other nitrogen-containing compounds in the blood.
cystocele: Condition that occurs when the supportive tissue between a woman's bladder and vaginal wall weakens, stretches, and allows the bladder to bulge into the vagina.
cystoscopy: Diagnostic procedure using an optical instrument called a cystoscope that is inserted through the urethra to visually examine the bladder and lower urinary tract, to collect urine samples, or to view the prostate.
enuresis: Involuntary urination, especially that of a child while asleep.
nephroptosis: Condition in which the kidney is displaced downward from its usual and normal position; also called a *floating kidney*.
nephrotic syndrome: A kidney disorder that causes one to excrete excessive protein in the urine.
nephrotoxin: A toxin that has a specific harmful effect on the kidney.
polycystic kidney disease: An inherited abnormality that affects the development and structure of kidney tubules.
shock-wave lithotripsy: A noninvasive technique used to pulverize kidney stones by passing high-pressure shock waves through a water-filled tub in which the patient sits.
urologist: Physician who specializes in functions and disorders of the urinary system.

27 Fluid, Electrolyte, and Acid-Base Balance

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

27-1 ■ Explain what is meant by the terms fluid balance, electrolyte balance, and acid-base balance, and discuss their importance for homeostasis. p. 1022

27-2 ■ Compare the composition of ECF and ICF, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation. p. 1023

27-3 ■ Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment. p. 1027

27-4 ■ Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance. p. 1030

27-5 ■ Explain the buffer systems that balance the pH of the ICF and ECF, and describe the compensatory mechanisms involved in maintaining acid-base balance. p. 1036

27-6 ■ Identify the most frequent disturbances of acid-base balance, and explain how the body responds when the pH of body fluids varies outside normal limits. p. 1042

27-7 ■ Describe the effects of aging on fluid, electrolyte, and acid-base balance p. 1049

CLINICAL CASE When Treatment Makes You Worse

Marquis is a 43-year-old office worker who is slightly overweight. At his annual checkup, his blood pressure measures 150/96 mm Hg, which is considered moderately high. Marquis feels fine, but his doctor tells him it is time to treat his hypertension. Marquis's doctor advises him to improve his diet and get more exercise. He also prescribes a new medication, hydrochlorothiazide, or HCTZ, which he instructs him to take every morning. HCTZ is a diuretic that is commonly used to lower blood pressure.

Marquis begins taking HCTZ and continues to feel well, although he notices the medication makes him need to urinate more frequently. A few weeks later he and a group of coworkers eat some bad potato salad at the office picnic and come down with food poisoning. After 3 days of diarrhea, Marquis feels absolutely horrible. He is so weak he can barely get out of bed. His muscles ache and his legs and feet cramp a lot. Worst of all, he feels as if there is a frog jumping around in his chest. He is often dizzy when this happens.

After a week in bed, Marquis feels even weaker. He goes to see his doctor, who sends him to the lab for some tests. "I know why you feel so terrible," says his doctor when he sees the lab results. **What is happening to Marquis?**

An Introduction to Fluid, Electrolyte, and Acid-Base Balance

The next time you see a small pond, think about the fish in it. They live their entire lives totally dependent on the quality of that isolated environment. Severe water pollution will kill them, but even subtle changes can have equally grave effects. Changes in the volume of the pond, for example, can be quite important. If evaporation removes too much water, the fish become overcrowded. The oxygen and food supplies will run out, and the fish will suffocate or starve. The ionic concentration of the water is also crucial. Most of the fish in a freshwater pond will die if the water becomes too salty. Fish in a saltwater pond will die if the water becomes too dilute. The pH of the pond water, too, is a vital factor. This is another reason that acid rain is such a problem.

Your cells live in a pond whose shores are the exposed surfaces of your skin. Most of your body weight is water. Water makes up about 99 percent of the volume of the fluid outside cells, the *extracellular fluid* (*ECF*), and it is also an essential ingredient of the cytosol inside cells, the *intracellular fluid* (*ICF*). All of a cell's operations rely on water as a diffusion medium for the distribution of gases, nutrients, and wastes. If the water volume of the body changes, cellular activities are jeopardized. For example, if the water volume reaches a very low level, proteins denature, enzymes stop functioning, and cells die. In this chapter we discuss the homeostatic mechanisms that regulate volume, ion concentrations, and pH in these fluids that are so critical to cells.

27-1 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis

Learning Outcome Explain what is meant by the terms fluid balance, electrolyte balance, and acid-base balance, and discuss their importance for homeostasis.

To survive, we must maintain a normal volume and composition of both the ECF and the ICF. The ionic concentrations and *pH* (hydrogen ion concentration) of these fluids are as important as their absolute quantities. If the concentration of calcium ions or potassium ions in the ECF becomes too high, cardiac arrhythmias develop and death can result. A pH outside the normal range can also lead to a variety of serious problems. Low pH—*acidity*—is especially dangerous, because hydrogen ions break chemical bonds, change the shapes of complex molecules, disrupt plasma membranes, and impair tissue functions.

Tips & Tools

The "p" in pH refers to power. Hence, pH refers to the **p**ower of **H**ydrogen.

Three interrelated processes stabilize the volumes, solute concentrations, and pH of the ECF and the ICF:

- *Fluid Balance.* You are in *fluid balance* when the amount of water you gain each day is equal to the amount you lose to the environment. Maintaining normal fluid balance involves regulating the content and distribution of body water in the ECF and the ICF. The digestive system is the main source of water gains. Metabolic activity generates a small amount of additional water. The urinary system is the main route for water loss under normal conditions, but as we saw in Chapter 25, sweating can become important when body temperature is elevated. ↩ p. 968
- *Electrolyte Balance.* **Electrolytes** are ions released when inorganic compounds dissociate. They are so named because they can conduct an electrical current in a solution. ↩ p. 41 Each day, your body fluids gain electrolytes from the food and drink you consume. Your body fluids also lose electrolytes in urine, sweat, and feces. For each ion,

daily gains must balance daily losses. For example, if you lose 500 mg of Na^+ in urine and sweat, you need to gain 500 mg of Na^+ from food and drink to remain in sodium ion balance. If the gains and losses for every electrolyte are in balance, you are said to be in *electrolyte balance*. Electrolyte balance primarily involves balancing the rates of absorption across the digestive tract with rates of loss by the kidneys, although losses at sweat glands and other sites can play a secondary role.

- *Acid-Base Balance.* You are in *acid-base balance* when the production of hydrogen ions (H^+) in your body is precisely offset by their loss. When acid-base balance exists, the pH of body fluids remains within normal limits. ↩ p. 43 Preventing a decrease in pH is the primary problem, because your body generates a variety of acids during normal metabolic operations. The kidneys play a major role by secreting hydrogen ions into the urine and generating *buffers* (compounds that stabilize the pH of a solution) that enter the bloodstream. Such secretion takes place primarily in the distal segments of the distal convoluted tubule (DCT) and along the collecting system. ↩ p. 999 The lungs also play a key role by eliminating carbon dioxide.

In this chapter, we explore the dynamics of exchange among the various body fluids, and between the body and the external environment. Much of the information in this chapter should be familiar to you from discussions in earlier chapters about aspects of fluid, electrolyte, or acid-base balance that affect specific systems. Here we provide an overview that integrates those discussions to highlight important functional patterns.

The subjects discussed in this chapter have wide-ranging clinical importance: Steps to restore normal fluid, electrolyte, and acid-base balances must be part of the treatment of any serious illness affecting the nervous, cardiovascular, respiratory, urinary, or digestive system. Because this chapter builds on information in earlier chapters, we have included many references to relevant discussions and figures that can provide a quick review.

Checkpoint

1. **Identify the three interrelated processes essential to stabilizing body fluid volumes.**

See the blue Answers tab at the back of the book.

27-2 Extracellular fluid (ECF) and intracellular fluid (ICF) are fluid compartments with differing solute concentrations that are closely regulated

Learning Outcome Compare the composition of ECF and ICF, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation.

This section examines the composition of the ECF and ICF, how exchanges occur between them, and how these are regulated by hormones. But first let's take a look at the big picture of how much total water is found in the body.

Body Water Content

Figure 27–1a presents an overview of the body makeup of a 70-kg (154-lb) person with a minimum of body fat. The distribution is based on overall average values for males and females ages 18–40 years. In both sexes, the ICF contains a greater proportion of total body water than does ECF. However, there are some differences between the sexes in body water content (Figure 27–1b). Water makes up about 60 percent of the total body weight of an adult male, and 50 percent of that of an adult female. This difference between the sexes, which is mainly in the ICF, reflects the proportionately larger mass of adipose tissue in adult females, and the greater average muscle mass in adult males. (Adipose tissue is only 10 percent water, whereas skeletal muscle is 75 percent water.) Less striking differences occur in the ECF values, due to variations in the interstitial fluid volume of various tissues and the larger blood volume in males versus females.

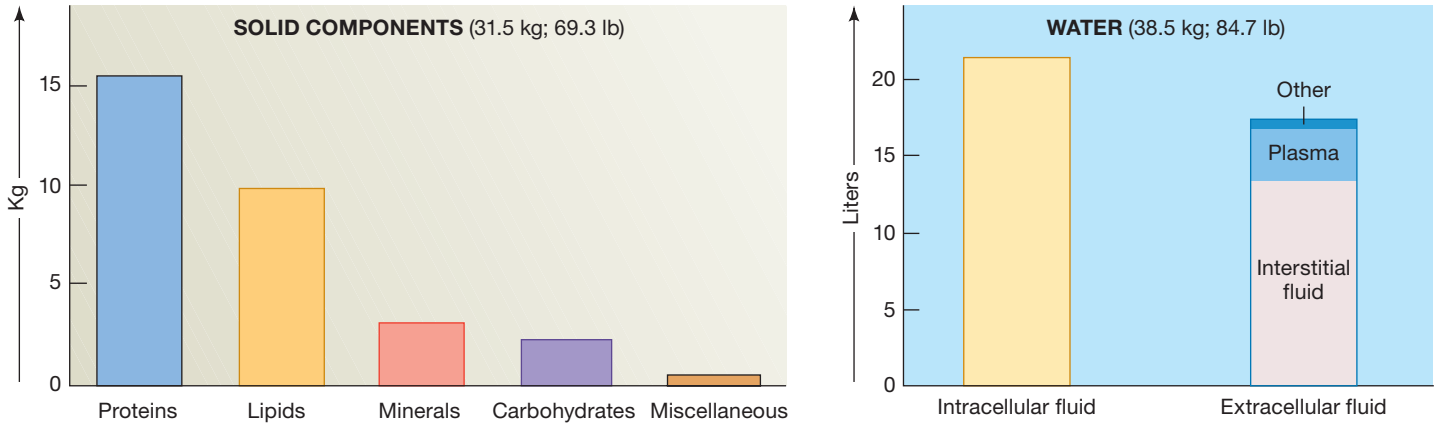
The Fluid Compartments of the ECF and ICF

The **extracellular fluid**, or **ECF**, is made up mostly of the interstitial fluid of peripheral tissues and the plasma of circulating blood; the **intracellular fluid**, or **ICF**, consists of the cytosol inside cells. Minor components of the ECF include lymph, cerebrospinal fluid (CSF), synovial fluid, serous fluids (pleural, pericardial, and peritoneal fluids), aqueous humor, perilymph, and endolymph.

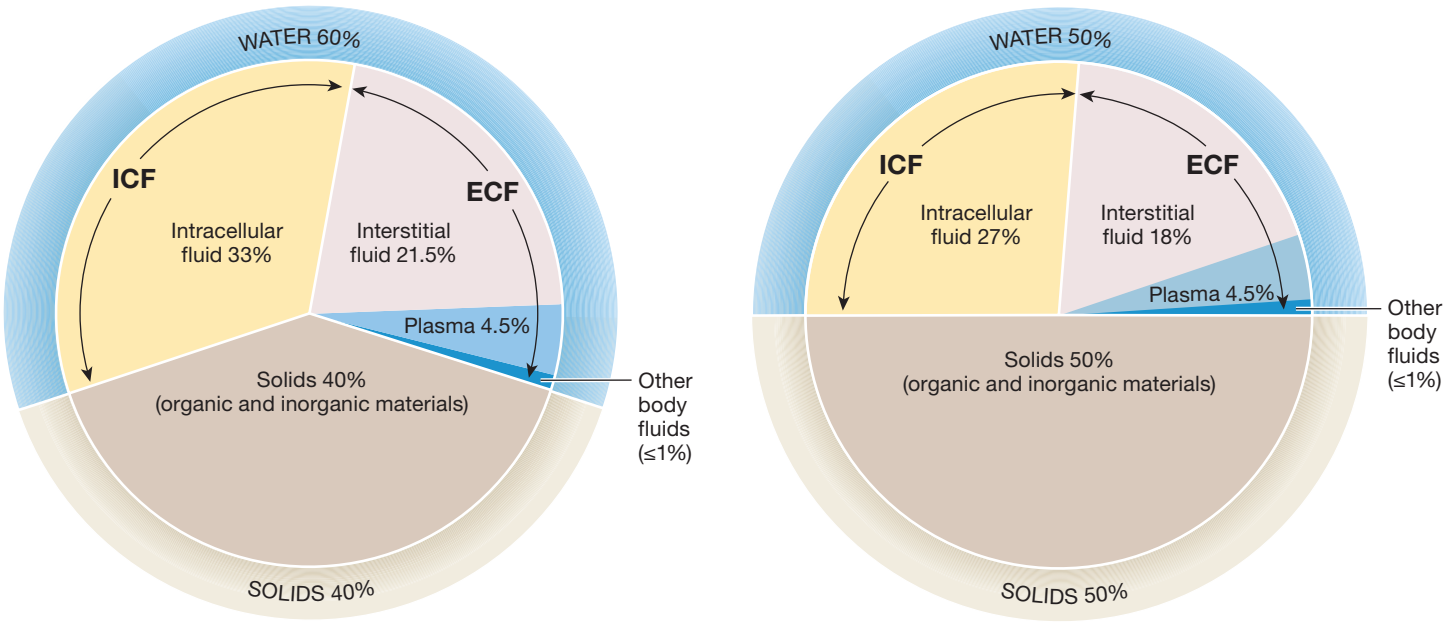
The ECF and ICF are called **fluid compartments** because they commonly behave as separate sections, maintaining different ionic compositions. The principal ions in the ECF are sodium, chloride, and bicarbonate (HCO_3^-). The ICF contains an abundance of potassium, magnesium, and phosphate ions (HPO_4^{2-}), plus large amounts of negatively charged proteins. Figure 27–2 compares the concentrations of the cations and anions of the ICF with those of the two major subdivisions of the ECF (plasma and interstitial fluid) in terms of milliequivalents per liter (mEq/L). This figure reflects the total number of positive and negative electrical charges in solution. Specific ions and substances, such as proteins, contribute more since they have more than a single electric charge (see Section 27-4).

The osmotic concentration, or osmolarity, of a solution depends on solute concentration, or the total number of solute particles per liter. ↩ p. 994 Despite the differences in the concentration of specific substances in Figure 27–2, the osmotic concentrations of the ICF and ECF are identical. This is because ions and proteins each count as one particle in solution, despite their number of electrical charges.

Figure 27–1 Composition of the Human Body.



a The body composition (by weight, averaged for both sexes) and major body fluid compartments of a 70-kg (154-lb) person. For technical reasons, it is extremely difficult to determine the precise size of any of these compartments; estimates of their relative sizes vary widely.



b A comparison of the body compositions of adult males and females, ages 18–40 years.

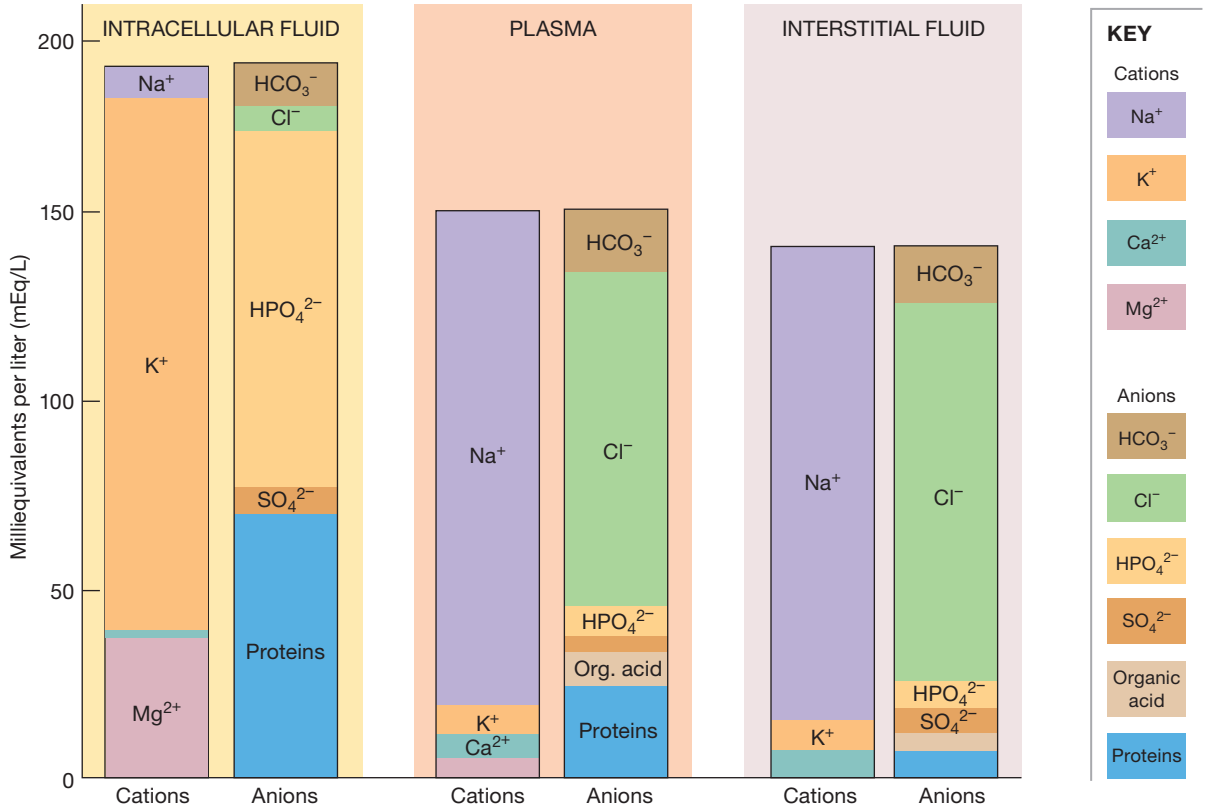
Osmosis eliminates minor differences in concentration almost at once, because most plasma membranes are freely permeable to water. (The only noteworthy exceptions are the apical surfaces of epithelial cells along the ascending limb of the nephron loop, the distal convoluted tubule, and the collecting system.)

Solute Exchanges between the ECF and the ICF

If the plasma membranes of cells were freely permeable, diffusion would continue until the ions in the ECF and ICF were evenly distributed across all of the membranes. But it does not, because plasma membranes are selectively permeable: Ions can enter or leave the cells only by specific membrane channels. Also, carrier mechanisms move specific ions into or out of the cells. Therefore, the exchange of ions between the ICF and the ECF takes place across plasma membranes by osmosis, diffusion, and carrier-mediated transport. (To review the mechanisms involved, look back at **Spotlight Figure 3–22**, p. 100.) The presence of a plasma membrane and active transport at the membrane surface enable cells to maintain internal environments with a composition that differs from their surroundings.

In addition to solute exchanges between the ECF and ICF, exchanges also occur among the subdivisions of the ECF. These exchanges occur primarily across the endothelial lining of

Figure 27–2 Cations and Anions in Body Fluids. Notice that each fluid compartment is electrically neutral and the ionic composition is markedly different between the ICF and ECF (plasma and interstitial fluid).



? Mg^{2+} and K^+ are found in higher concentrations in the (*intracellular*, *extracellular*) fluid, whereas Na^+ and Cl^- are found in higher concentrations in the (*intracellular*, *extracellular*) fluid.

capillaries. Fluid may also travel from the interstitial spaces to plasma through lymphatic vessels that drain into the venous system. ↩ p. 787 Such exchanges mean that the kinds and quantities of dissolved electrolytes, proteins, nutrients, and wastes in the ECF vary regionally. Still, the variations among the compartments of the ECF seem minor compared with the major differences between the ECF and the ICF (Figure 27–2).

In clinical situations, we usually estimate that two-thirds of the total body water is in the ICF and one-third in the ECF. This ratio underestimates the real volume of the ECF, because portions of the ECF—including the water in bone, in many dense connective tissues, and in many of the minor ECF components—are relatively isolated. Exchange between these fluid volumes and the rest of the ECF takes place more slowly than does exchange between plasma and other interstitial fluids. For this reason, they can be safely ignored in many cases. Clinical attention usually focuses on the rapid fluid and solute movements that accompany the administration of blood, plasma, or saline solutions to counteract blood loss or dehydration. Physiologists and clinicians pay particular attention to ionic distributions across membranes and to the electrolyte composition of body fluids. The Appendix at the end of the book reports normal physiological values in the units most often used in clinical reports.

An Overview of the Regulation of Fluid and Electrolyte Balance

The regulation of fluid balance and of electrolyte balance are tightly intertwined because changes in solute concentrations lead to immediate changes in water distribution. The following basic principles are key to understanding fluid and electrolyte balance:

- *All the homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF, not in the ICF.* Receptors monitoring the composition of two key components of the ECF—plasma and cerebrospinal fluid (CSF)—detect significant changes in their composition or volume and trigger appropriate nervous and endocrine responses. This arrangement makes functional

sense, because a change in one ECF component will spread rapidly throughout the entire ECF and affect all the body's cells. In contrast, the ICF is contained within trillions of individual cells that are physically and chemically isolated from one another by their plasma membranes. For this reason, changes in the ICF in one cell have no direct effect on the composition of the ICF in distant cells and tissues, unless those changes also affect the ECF.

- *No receptors directly monitor fluid or electrolyte balance.* In other words, receptors cannot detect how many liters of water, or grams of sodium, chloride, or potassium ions, the body contains. Nor can they count how many liters or grams we gain or lose throughout the day. But receptors *can* monitor *plasma volume* and *osmotic concentration*. The plasma volume and osmotic concentration are good indicators of the state of fluid balance and electrolyte balance for the body as a whole, because fluid continuously circulates between interstitial fluid and plasma, and because exchange occurs between the ECF and the ICF.
- *Cells cannot move water molecules by active transport.* All movement of water across plasma membranes and epithelia takes place passively, in response to osmotic gradients established by the active transport of specific ions, such as sodium and chloride. You may find it useful to remember that "water follows salt." As we saw in earlier chapters, when sodium and chloride ions (or other solutes) are actively transported across a membrane or epithelium, water follows by osmosis. ↩ p. 1001 This basic principle accounts for water absorption across the digestive epithelium, and for water conservation by the kidneys.
- *The body's content of water or electrolytes will increase if dietary gains exceed losses to the environment, and will decrease if losses exceed gains.* This basic rule is important when you consider the mechanics of fluid balance and electrolyte balance. Homeostatic adjustments affect the balance between urinary excretion and dietary absorption. As we saw in Chapter 26, circulating hormones regulate renal function. These hormones can also produce complementary changes in behavior, such as promoting thirst.

27

The Primary Hormones That Regulate Fluid and Electrolyte Balance

Three hormones mediate physiological adjustments to fluid balance and electrolyte balance: (1) *antidiuretic hormone (ADH)*, (2) *aldosterone*, and (3) the *natriuretic peptides (ANP* and *BNP)*.

Antidiuretic Hormone. Recall that **antidiuretic hormone (ADH)** is a pituitary hormone that promotes water retention by the kidneys. The hypothalamus contains specialized cells known as *osmoreceptors* that monitor the osmotic concentration of the ECF. These cells are very sensitive: A 2 percent change in osmotic concentration (approximately 6 mOsm/L) is enough to alter osmoreceptor activity.

The population of osmoreceptors includes neurons that secrete ADH. These neurons are located in the anterior hypothalamus. Their axons release ADH near fenestrated capillaries in the posterior lobe of the pituitary gland. The rate of ADH release varies directly with osmotic concentration: The higher the osmotic concentration, the more ADH is released.

Increased release of **ADH** has two important effects: (1) It stimulates water conservation by the kidneys, reducing urinary water losses and concentrating the urine; and (2) it stimulates the hypothalamic thirst center, promoting the intake of fluids. As we saw in Chapter 21, the combination of decreased water loss and increased water gain gradually restores the normal plasma osmotic concentration. ↩ pp. 750–752

Aldosterone. Recall that **aldosterone** is a corticosteroid that stimulates sodium absorption by the kidneys and so regulates water and sodium balance. Aldosterone secretion plays a major role in determining the rate of Na^+ absorption and K^+ loss along the distal convoluted tubule and collecting system of the kidneys. ↩ pp. 999–1000 The higher the plasma concentration of aldosterone, the more efficiently the kidneys conserve Na^+. Because "water follows salt," the conservation of Na^+ also increases water retention. As Na^+ is reabsorbed, Cl^- follows (look back at **Figure 26–13**, p. 998), and water follows by osmosis as sodium and chloride ions move out of the tubular fluid.

Aldosterone is secreted in response to an increasing K^+ or decreasing Na^+ level in the blood reaching the adrenal cortex, or in response to *renin-angiotensin-aldosterone system* activation. As we saw in earlier chapters, renin release occurs in response to any of three changes: (1) a decrease in plasma volume or blood pressure at the juxtaglomerular complex of the nephron; (2) a decrease in the osmotic concentration of tubular fluid at the DCT; or, as we will soon see, (3) a decreasing Na^+ or increasing K^+ concentration in the renal circulation.

Natriuretic Peptides. The **natriuretic** (*natrium*, sodium; *-uretic*, urine) **peptides**, *atrial natriuretic peptide (ANP)* and *B-type natriuretic peptide (BNP)*, are released by cardiac muscle cells in response to abnormal stretching of the heart walls. Increased blood pressure or increased blood volume causes this stretching. Among their other effects, these peptides reduce thirst and block the release of ADH and aldosterone that might otherwise lead to water and salt conservation. The resulting *diuresis* (fluid loss by the kidneys) decreases both blood pressure and plasma volume, eliminating the stretching.

The Interplay between Fluid Balance and Electrolyte Balance

At first glance, it can be difficult to distinguish between water balance and electrolyte balance. For example, when you lose body water, plasma volume decreases and electrolyte concentrations

increase. Conversely, when you gain or lose excess electrolytes, you also gain or lose water due to osmosis.

However, it is often useful to consider fluid balance and electrolyte balance separately because the regulatory mechanisms involved are quite different. This distinction is absolutely vital in a clinical setting, where problems with fluid balance and electrolyte balance must be identified and corrected promptly.

Checkpoint

2. **List the components of extracellular fluid (ECF) and intracellular fluid (ICF).**
3. **Name three hormones that play a major role in adjusting fluid and electrolyte balance in the body.**
4. **What effect might drinking a half-gallon of distilled water (water without minerals) have on the ADH level?**

See the blue Answers tab at the back of the book.

27-3 Fluid balance involves the regulation and distribution of water gains and losses

Learning Outcome Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.

As mentioned, **fluid balance** occurs when the amount of water gained each day is equal to the amount lost to the environment. We cannot easily determine the body's water content. However, the concentration of Na^+, the most abundant ion in the ECF, provides useful clues to the state of fluid balance (see Figure 27–2). When the body's water content increases, the Na^+ concentration of the ECF becomes abnormally low. And when the body's water content decreases, the Na^+ concentration becomes abnormally high. The body responds to such osmotic changes to ensure that fluid balance is maintained. Let's look at fluid gains and losses, and water movements.

Table 27–1 Water Gains and Losses

Gains	Daily Input (mL)
Water content of food	1000
Water consumed as liquid	1200
Metabolic water produced during catabolism	300
Total	**2500**
Losses	**Daily Output (mL)**
Urination	1200
Evaporation at skin	750
Evaporation at lungs	400
Loss in feces	150
Total	**2500**

Fluid Gains and Losses

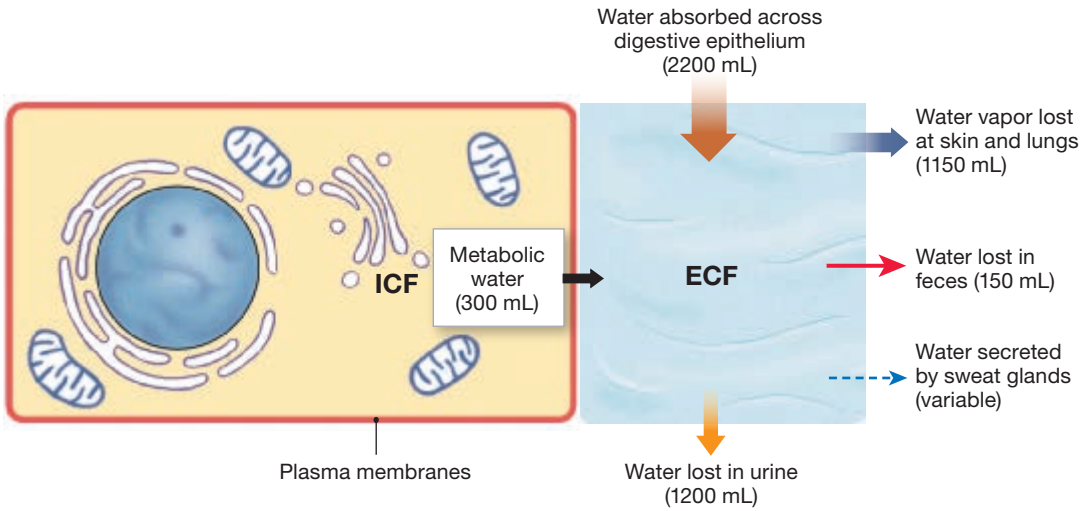
Table 27–1 lists the major water gains and losses involved in fluid balance. Figure 27–3 highlights the routes of fluid exchange between the fluid compartments and the environment.

Water Gains

A water gain of about 2500 mL/day is required to balance your average water losses. This value amounts to about 40 mL/kg (about 1.35 fl oz/lb) of body weight per day. You obtain water through eating (1000 mL), drinking (1200 mL), and *metabolic generation* (300 mL).

Metabolic generation of water is the production of water within cells, primarily as a result of oxidative phosphorylation in mitochondria during aerobic metabolism, (In Chapter 25

Figure 27–3 Exchanges between Fluid Compartments and the Environment. Fluid movements that maintain fluid balance in a normal person. The volumes are drawn to scale: The ICF is about twice as large as the ECF.



we described the synthesis of water at the end of the electron transport chain.↩ p. 947) When cells break down 1 g of lipid, 1.7 mL of water is generated. Breaking down proteins or carbohydrates yields much smaller amounts (0.41 mL/g and 0.55 mL/g, respectively).

A typical diet in the United States contains 46 percent carbohydrates, 40 percent lipids, and 14 percent protein. Such a diet produces approximately 300 mL of water per day, about 12 percent of your average daily requirement.

Water Losses

You lose about 2500 mL of water each day through urine, feces, and *insensible perspiration*—the evaporation of water across the epithelia of the skin and lungs. The losses due to *sensible perspiration*—evaporation due to the secretory activities of the sweat glands—vary with physical activity. Sensible perspiration can cause significant water deficits, with maximum perspiration rates reaching 4 liters per hour. ↩ p. 968 Fever can also increase water losses. For each degree that body temperature rises above normal, daily insensible water losses increase by 200 mL. The advice "Drink plenty of fluids" for anyone who is sick has a definite physiological basis.

Water Movement between Fluid Compartments

Recall that water movements occur between the ECF and ICF, and between the subdivisions of the ECF, but generally not within the ICF.

Water Movement between the ECF and ICF

Water can move between the ECF and the ICF. For example, a small amount of water moves from the ICF to the ECF each day, as the result of metabolic water generation (see **Figure 27–3**). However, under normal circumstances the ECF and the ICF are in osmotic equilibrium. For this reason, no large-scale circulation occurs between the two compartments.

27

Water Movement within the ECF

Water circulates freely within the ECF compartment. In our discussion of capillary dynamics in Chapter 21, we considered the basic principles that determine fluid movement among the subdivisions of the ECF. ↩ p. 742 Recall that the exchange between plasma and interstitial fluid, by far the largest components of the ECF, is due to the relationship between the net hydrostatic pressure, which tends to push water out of the plasma and into the interstitial fluid, and the net colloid osmotic pressure, which tends to draw water out of the interstitial fluid and into the plasma. The interaction between these opposing forces is diagrammed in **Figure 21–11** (p. 743). It results in the continuous filtration of fluid from the capillaries into the interstitial fluid. Some of that water is then reabsorbed along the distal portion of the capillary bed, and the rest enters lymphatic vessels for transport to the venous circulation. At any moment, interstitial fluid and minor fluid compartments contain approximately 80 percent of the ECF volume, and plasma contains the other 20 percent.

Any factor that affects the net hydrostatic pressure or the net colloid osmotic pressure will alter the distribution of fluid within the ECF. The movement of abnormal amounts of water from plasma into interstitial fluid results in *edema* (swelling). Pulmonary edema, for example, can result from an increase in the blood pressure in pulmonary capillaries. Generalized edema can result from a decrease in blood colloid osmotic pressure, as seen in advanced starvation, when plasma protein concentrations decrease. Localized edema can result from damage to capillary walls (as occurs in bruising), the constriction of regional venous circulation, or a blockage of the lymphatic drainage (as happens with *lymphedema*, introduced in Chapter 22). ↩ p. 789

In addition to these water movements between major components of the ECF, water also moves continuously among the smaller ECF subdivisions. The volumes involved in these water movements are very small, and the volume and composition of the fluids are closely regulated.

Fluid Shifts between the ECF and ICF

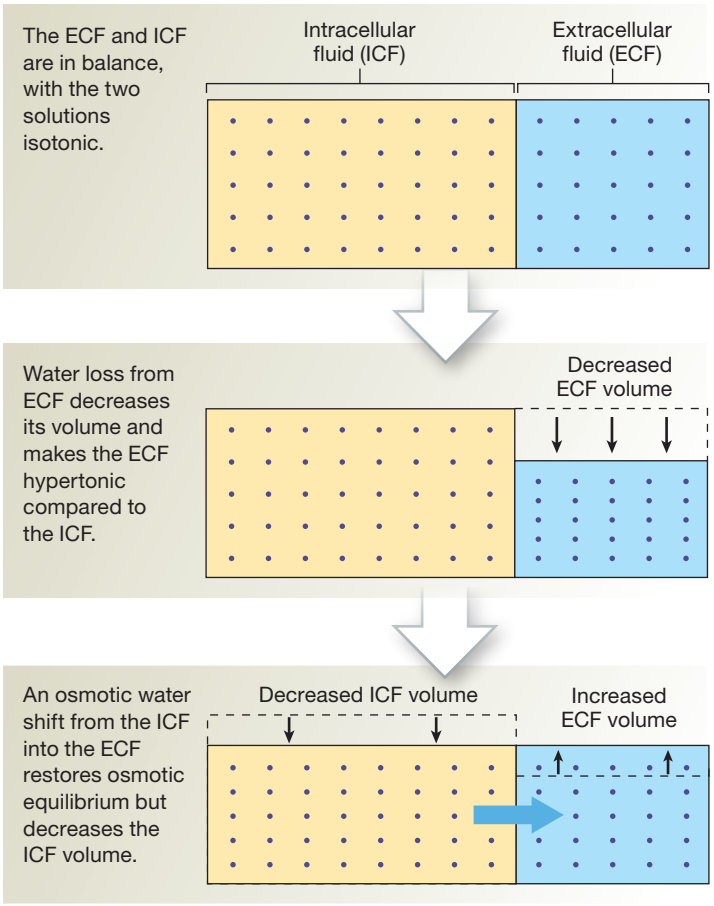
A **fluid shift** is a rapid water movement between the ECF and the ICF in response to an osmotic gradient. Such a gradient is produced by changes in the osmotic concentration of the ECF (**Figure 27–4**). Fluid shifts occur rapidly, reaching equilibrium within minutes to hours. This process happens in the following two situations:

- *If the osmotic concentration of the ECF increases, that fluid will become hypertonic compared to the ICF.* The osmotic concentration of the ECF will increase if you lose water but retain electrolytes. Water will then move from the cells into the ECF until osmotic equilibrium is restored.
- *If the osmotic concentration of the ECF decreases, that fluid will become hypotonic compared to the ICF.* The osmotic concentration of the ECF will decrease if you gain water but do not gain electrolytes. Water will then move from the ECF into the cells, and the ICF volume will increase.

To summarize, if the osmotic concentration of the ECF changes, a fluid shift between the ICF and ECF will tend to oppose the change. The ICF acts as a water reserve, because the volume of the ICF is much greater than that of the ECF. In effect, instead of a large change in the osmotic concentration of the ECF, smaller changes occur in both the ECF and ICF.

Let's now look at two examples of situations that cause changes in the osmotic concentration of the ECF: when you are dehydrated and when you drink a glass of water. These examples demonstrate how fluid shifts between the ECF and ICF help to maintain fluid balance.

Figure 27–4 Fluid Shifts between the ICF and ECF.



Clinical Note Water and Weight Loss

The safest way to lose weight is to reduce your intake of food while ensuring that all nutrient requirements are met. Water must be included on the list of nutrients, along with carbohydrates, fats, proteins, vitamins, and minerals. Nearly half of our normal water intake comes from food. For this reason, when you eat less, you become more dependent on drinking fluids and on whatever water is generated metabolically.

At the start of a diet, your body conserves water and catabolizes lipids. That is why the first week of dieting may seem rather unproductive. Over that week, the level of circulating ketone bodies gradually increases. In the weeks that follow, the rate of water loss by the kidneys increases in order to excrete wastes, such as the hydrogen ions released by ketone bodies and the urea and ammonia generated during protein catabolism. Your rate of fluid intake must also increase, or else you risk dehydration. While you are dieting, dehydration is especially serious, because as water is lost, the concentration of solutes in the ECF increases, further increasing the concentration of wastes and acids generated during the catabolism of energy reserves. This soon becomes a positive feedback loop: These wastes enter the filtrate at the kidneys, and their excretion draws additional water into the urine.

Allocation of Water Losses and Dehydration

Dehydration, or *water depletion*, develops when water losses outpace water gains. When you lose water but retain electrolytes, the osmotic concentration of the ECF increases. Water then moves out of the ICF and into the ECF by osmosis until the two solutions are again isotonic. At that point, both the ECF and ICF are somewhat more concentrated than normal, and both volumes are lower than they were before the fluid loss. Because the ICF has about twice the functional volume of the ECF, the net change in the ICF is small.

However, if the fluid imbalance continues unchecked, the loss of body water will produce severe thirst, dryness, and wrinkling of the skin. In the case of severe water losses such as excessive perspiration (as when you exercise in hot weather), inadequate water consumption, repeated vomiting, and diarrhea, water losses occur far in excess of electrolyte losses. Body fluids become increasingly concentrated, and the sodium ion concentration becomes abnormally high (a condition called *hypernatremia*). In addition, a significant decrease in plasma volume and blood pressure eventually occurs, and shock may develop.

Homeostatic responses to dehydration include physiological mechanisms (ADH and renin secretion) and behavioral changes (increasing fluid intake, preferably as soon as possible). Clinical therapies for acute dehydration include administering hypotonic fluids by mouth or intravenous infusion. These procedures rapidly increase ECF volume and promote the shift of water back into the ICF.

Distribution of Water Gains and Hyperhydration

When you drink a glass of water, your body's water content increases without a corresponding increase in the concentrations of electrolytes. As a result, the ECF increases in volume but becomes hypotonic compared to the ICF. A fluid shift then occurs, and the volume of the ICF increases at the expense of the ECF. Once again, the larger volume of the ICF limits the relative amount of osmotic change. After the fluid shift, the ECF and ICF have slightly larger volumes and slightly lower osmotic concentrations than they did originally.

Normally, this situation will be promptly corrected. The decreased plasma osmotic concentration decreases ADH secretion, discouraging fluid intake and increasing water losses in urine. If the situation is *not* corrected, a variety of clinical problems will develop as water shifts into the ICF, distorting cells, changing the solute concentrations around enzymes, and disrupting normal cell functions. This condition is called **hyperhydration**, or *water excess*. It can be caused by

(1) drinking a large volume of water or the infusion (injection into the bloodstream) of a hypotonic solution; (2) an inability to eliminate excess water in urine, due to chronic renal failure, heart failure, cirrhosis, or some other disorder; and (3) endocrine disorders, such as excessive ADH production.

The most obvious sign of hyperhydration is an abnormally low Na^+ concentration (*hyponatremia*). This reduction in Na^+ concentration in the ECF leads to a fluid shift into the ICF. The first signs are the effects on central nervous system (CNS) function. The individual initially acts drunk. This condition, called *water intoxication*, may sound odd, but is extremely dangerous. Untreated cases can rapidly progress from confusion to hallucinations, convulsions, coma, and then death. Treatment of severe hyperhydration generally involves administering diuretics and infusing a concentrated salt solution that promotes a fluid shift from the ICF to the ECF and returns the Na^+ concentration to a near-normal level.

See the blue Answers tab at the back of the book.

27-4 In electrolyte balance, the concentrations of sodium, potassium, calcium, magnesium, phosphate, and chloride ions in body fluids are tightly regulated

Learning Outcome Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance.

27

As we discussed, **electrolyte balance** occurs when gains and losses are equal for each electrolyte in the body. Electrolyte balance is important for these reasons:

- *Total electrolyte concentrations directly affect water balance*, as previously described.
- *The concentrations of individual electrolytes can affect cell functions.* We saw many examples in earlier chapters, including the effect of an abnormal Na^+ concentration on neuron activity and the effects of high or low Ca^{2+} and K^+ concentrations on cardiac muscle tissue.

This section pays particular attention to sodium and potassium ion balance because (1) they are major contributors to the osmotic concentrations of the ECF and the ICF, respectively, and (2) they directly affect the normal functioning of all cells.

Sodium is the main cation in the ECF. More than 90 percent of the osmotic concentration of the ECF results from sodium salts, mainly sodium chloride (NaCl) and sodium bicarbonate ($NaHCO_3$). Changes in the osmotic concentration of body fluids generally reflect changes in the Na^+ concentration.

Electrolytes in body fluids are measured in terms of *equivalents* (Eq). An **equivalent** (**Eq**) is the amount of a positive or negative ion that supplies 1 mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq). For example, 1 mole of potassium ions (K^+) and 1 mole of chloride ions (Cl^-) are each 1 Eq (1000 mEq), but 1 mole of Ca^{2+} is 2 Eq (2000 mEq) because the calcium ion has a charge of +2. p. 994

The Na^+ concentration in the ECF averages about 140 mEq/L, versus 10 mEq/L or less in the ICF. Potassium is the main cation in the ICF, where its concentration reaches 160 mEq/L. The concentration of K^+ in the ECF is generally very low, from 3.5 to 5.5 mEq/L (look back at **Figure 27–2**).

Two general rules concerning Na^+ and K^+ balance are worth noting:

- The most common problems with electrolyte balance are caused by an imbalance between gains and losses of Na^+.
- Problems with K^+ balance are less common but significantly more dangerous than problems related to Na^+ balance.

Let's look at the contributions of these ions to electrolyte balance.

Sodium Balance

The total amount of sodium ions in the ECF represents a balance between two factors:

- *Sodium Ion Uptake across the Digestive Epithelium.* Sodium ions enter the ECF by crossing the digestive epithelium through diffusion and carrier-mediated transport. The rate of absorption varies directly with the amount of sodium in the diet.
- *Sodium Ion Excretion by the Kidneys and Other Sites.* Sodium ion losses take place primarily by excretion in urine and through perspiration. The kidneys are the most important sites of Na^+ regulation. We discussed the mechanisms for Na^+ reabsorption by the kidneys in Chapter 26. pp. 995, 999

A person in sodium balance typically gains and loses 48–144 mEq (1.1–3.3 g) of Na^+ each day. When Na^+ gains exceed Na^+ losses, the total Na^+ content of the ECF increases. When losses exceed gains, the Na^+ content decreases. However, a change in the Na^+ content of the ECF does not produce a change in the Na^+ concentration. When Na^+ intake or output changes, a corresponding gain or loss of water tends to keep the Na^+ concentration constant. For example, if you eat a very salty meal, the osmotic concentration of the ECF will not increase. When Na^+ are pumped across the digestive epithelium, the solute concentration in that portion of the ECF increases, and that

of the intestinal contents decreases. Osmosis then occurs: Additional water enters the ECF from the digestive tract, increasing the blood volume and blood pressure. For this reason, people with high blood pressure or a renal salt sensitivity are advised to restrict the amount of salt in their diets.

Sodium Balance and ECF Volume

The sodium ion regulatory mechanism is diagrammed in **Figure 27–5.** It changes the ECF volume but keeps the Na^+ concentration fairly stable. If you consume large amounts of salt *without* adequate fluid, as when you eat salty potato chips without taking a drink, the plasma Na^+ concentration increases temporarily. A change in ECF volume soon follows, however. Fluid will exit the ICF in a fluid shift, increasing ECF volume and decreasing the Na^+ concentration somewhat. The secretion of ADH restricts water loss and stimulates thirst, promoting additional water consumption. Due to the inhibition of water receptors in the pharynx, ADH secretion begins even before Na^+ absorption occurs. The ADH secretion rate increases more after Na^+ absorption, due to osmoreceptor stimulation. pp. 572, 625

When sodium ion losses exceed gains, the volume of the ECF decreases. This reduction occurs without a significant change in the osmotic concentration of the ECF. Thus, if you perspire heavily but consume only water, you will lose Na^+, and the osmotic concentration of the ECF will decrease briefly. However, as soon as the osmotic concentration drops by 2 percent or more, ADH secretion decreases, so water losses by your kidneys increase. As water leaves the ECF in a fluid shift, the osmotic concentration returns to normal.

Minor changes in ECF volume do not matter, because they do not cause adverse physiological effects. If, however, regulation of the Na^+ concentration results in a large change in ECF volume, the situation will be corrected by the same homeostatic mechanisms responsible for regulating blood volume and blood pressure. This is the case because when ECF volume changes, so does plasma volume and, in turn, blood volume. If ECF volume increases, blood volume increases,

Figure 27–5 Homeostatic Regulation of Sodium Ion Concentration in Body Fluids.

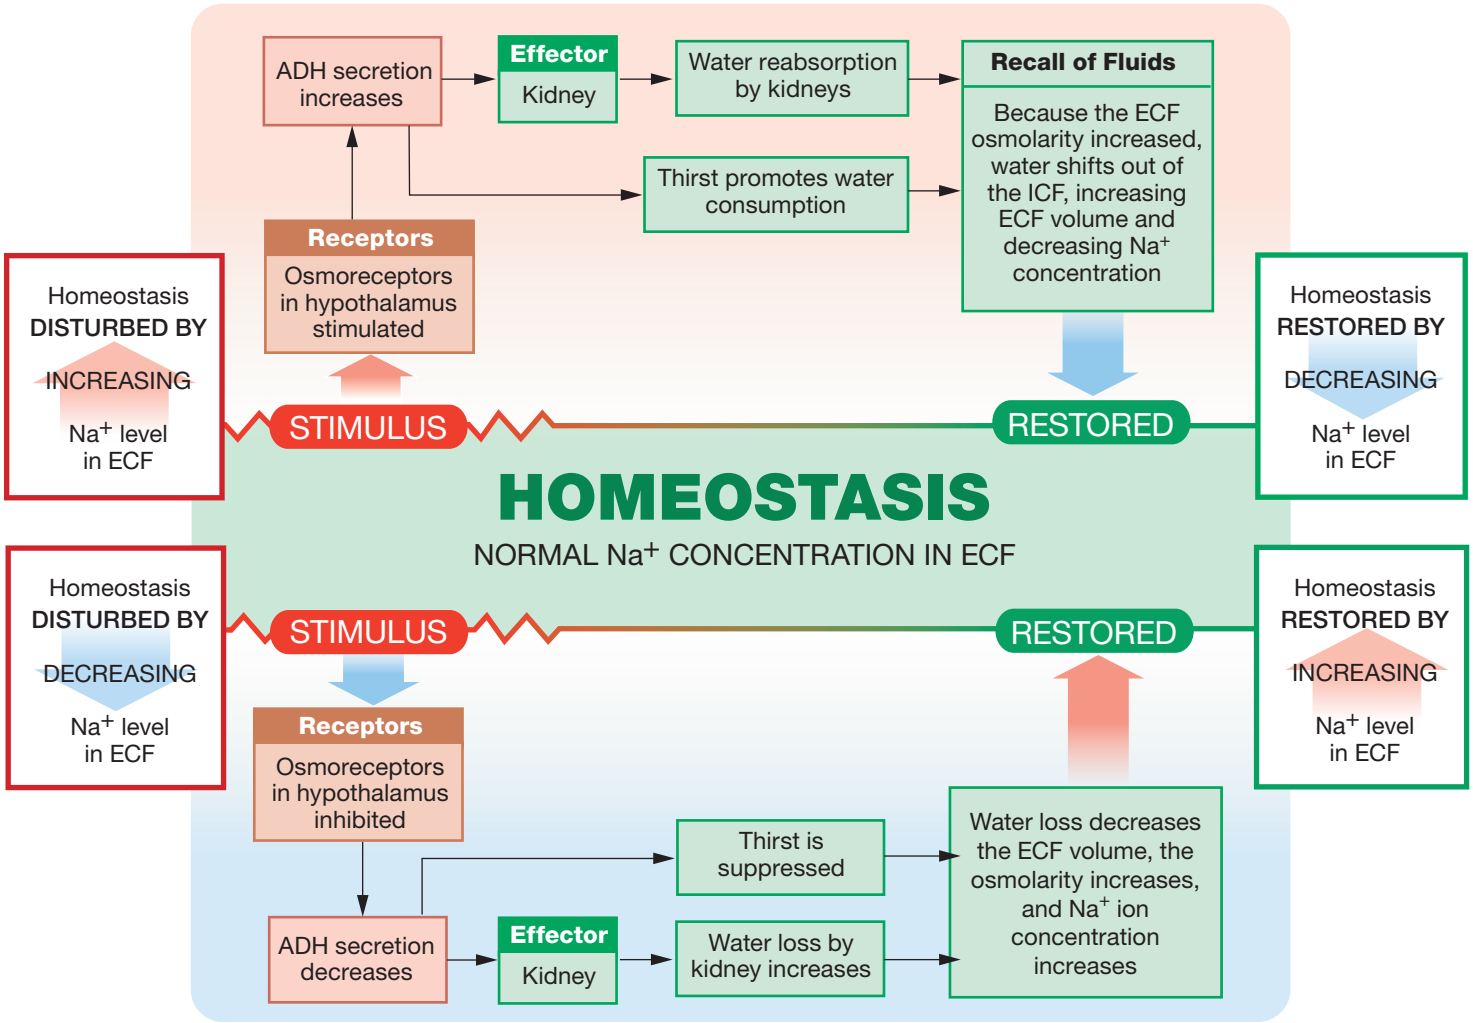

Figure 27–6 Integration of Fluid Volume Regulation and Sodium Ion Concentration in Body Fluids.

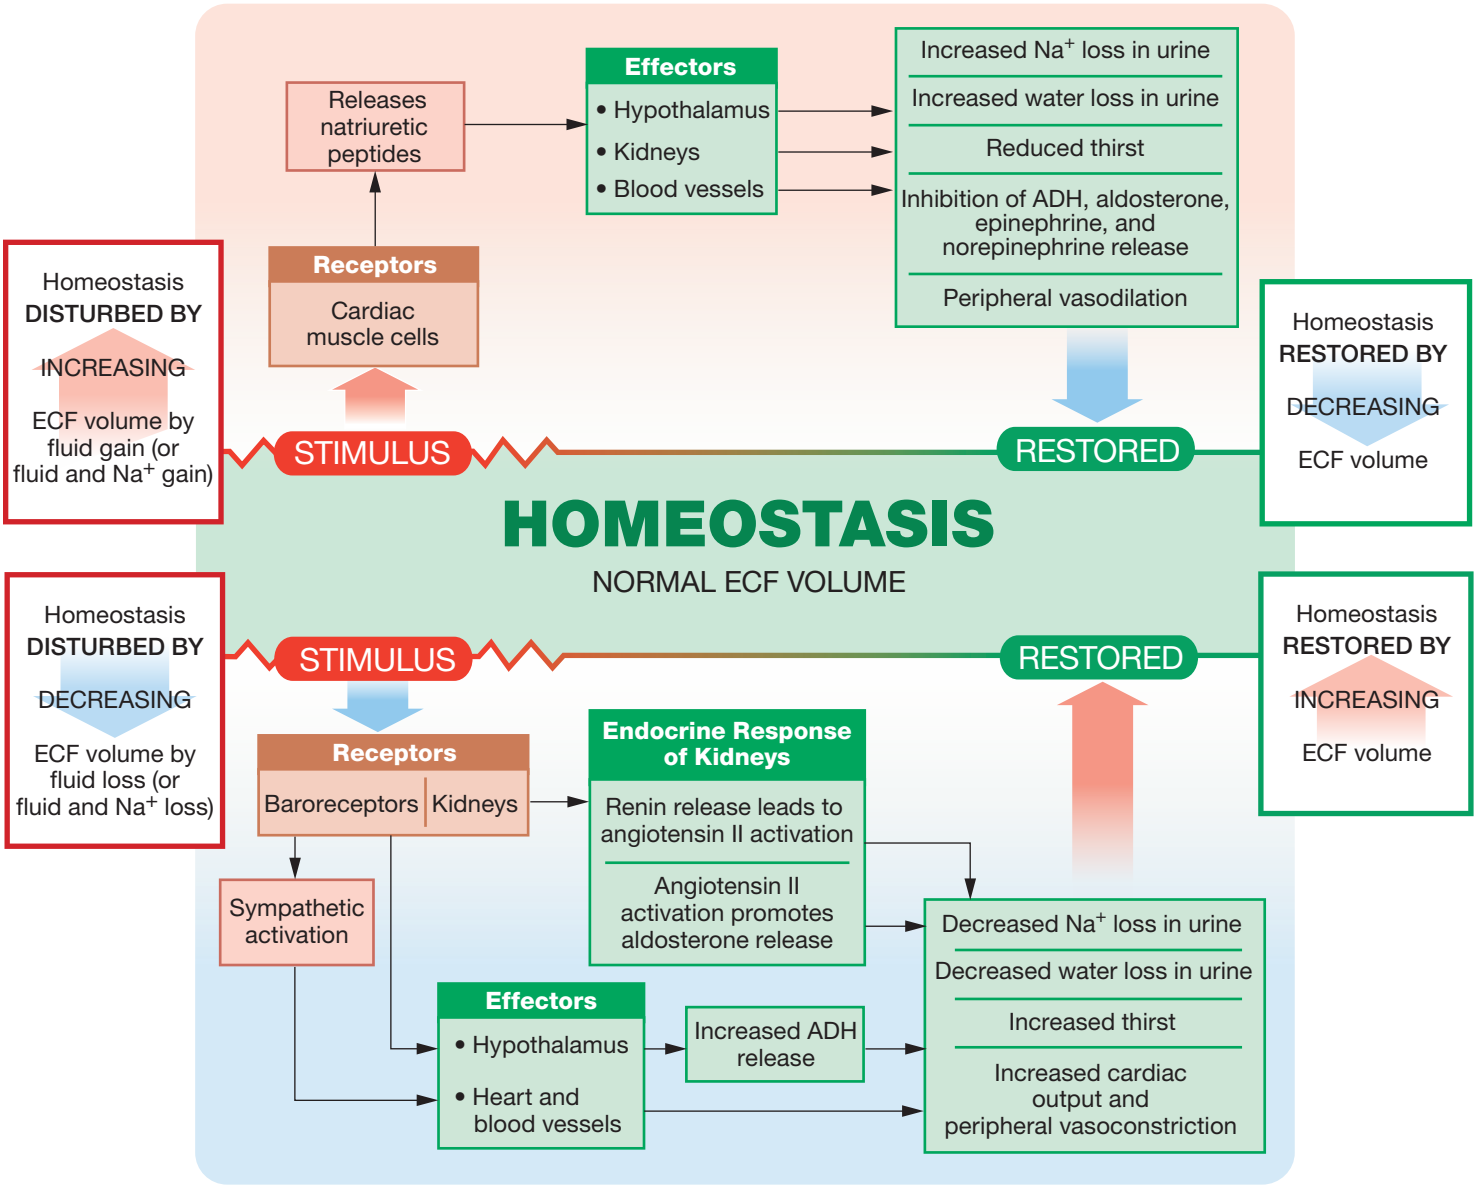

and if ECF volume decreases, blood volume decreases. As we saw in Chapter 21, blood volume has a direct effect on blood pressure. An increase in blood volume increases blood pressure, and a decrease in blood volume decreases blood pressure.

The net result is that homeostatic mechanisms can monitor ECF volume indirectly by monitoring blood pressure. The receptors involved are baroreceptors at the carotid sinus, the aortic sinus, and the right atrium. The regulatory steps involved are reviewed in Figure 27–6.

Disorders of Sodium Balance

Sustained abnormalities in the Na^+ concentration in the ECF occur only when there are severe problems with fluid balance, such as dehydration or hyperhydration. When the body's water content increases enough to decrease the Na^+ concentration of the ECF below 135 mEq/L, a state of **hyponatremia** (*natrium*, sodium) exists. When body water content decreases, the Na^+ concentration increases. When that concentration exceeds 145 mEq/L, **hypernatremia** exists.

If the ECF volume is inadequate, both blood volume and blood pressure decrease, and the renin-angiotensin-aldosterone system is activated. In response, losses of water and Na^+ are decreased, and gains of water and Na^+ are increased. The net result is that ECF volume increases. Although the total amount of Na^+ in the ECF is increasing (gains exceed losses), the Na^+ concentration in the ECF remains unchanged, because osmotic water movement accompanies Na^+ absorption.

If the plasma volume becomes abnormally large, venous return increases, stretching the atrial and ventricular walls and stimulating the release of natriuretic peptides (ANP and BNP). This in turn decreases thirst and blocks the secretion of ADH and aldosterone, which together promote water or salt conservation. As a result, salt and water loss by the kidneys increases and the volume of the ECF decreases.

Potassium Balance

About 98 percent of the body's potassium is in the ICF. Cells expend energy to recover K^+ as they diffuse across their plasma membranes and into the ECF. The K^+ concentration outside the cell is relatively low, and the concentration in the ECF at any moment represents a balance between (1) the rate of gain across the digestive epithelium and (2) the rate of loss into urine.

The K^+ concentration in the ECF is regulated by adjustments to K^+ losses in urine. This occurs by controlling the rate of active secretion by ion pumps along the distal convoluted tubule of the nephron and the collecting system. Whenever a Na^+ is reabsorbed from the tubular fluid, it generally is exchanged for a cation (typically K^+) from the peritubular fluid. ↩ p. 998 Urinary K^+ losses are usually limited to the amount gained by absorption across the digestive epithelium, typically 50–150 mEq (1.9–5.8 g) per day. (Potassium ion losses in feces and perspiration are negligible.)

The rate of tubular secretion of K^+ into urine varies in response to three factors:

- *Changes in the K^+ Concentration of the ECF.* In general, the higher the extracellular concentration of K^+, the higher the rate of secretion.
- *Changes in pH.* When the pH of the ECF decreases, so does the pH of peritubular fluid. The rate of K^+ secretion then decreases, because H^+, rather than K^+, are secreted in exchange for Na^+ in tubular fluid. The mechanisms for H^+ secretion were summarized in **Figure 26–13c** (p. 999).
- *The Level of Aldosterone.* The hormone aldosterone strongly affects the rate at which K^+ are lost in urine. The ion pumps that are sensitive to this hormone reabsorb Na^+ from tubular fluid in exchange for K^+ from peritubular fluid. Aldosterone secretion is stimulated by angiotensin II as part of the regulation of blood volume. A high plasma K^+ concentration also stimulates aldosterone secretion directly. Either way, under the influence of aldosterone, the amount of Na^+ conserved and the amount of K^+ excreted in urine are directly related.

Two disorders of K^+ imbalance are hypokalemia and hyperkalemia. **Hypokalemia** (*hypo-*, below + *kalium*, potassium) is a deficiency of K^+ in the bloodstream. **Hyperkalemia** (*hyper-*, above) is an elevated level of K^+ in the bloodstream (**Figure 27–7**).

+ Clinical Note Athletes and Salt Loss

Unfounded notions and rumors about water and salt requirements during exercise are common. Sweat is a hypotonic solution that contains Na^+ in lower concentration than the ECF. As a result, a person who is sweating profusely loses more water than salt. This loss leads to an increase in the Na^+ concentration of the ECF. The water content of the ECF decreases as the water loss occurs, so blood volume decreases. Clinically, this condition is often called *volume depletion*. Because volume depletion takes place at the same time that blood is being shunted away from the kidneys, kidney function is impaired. As a result, wastes accumulate in the blood.

To prevent volume depletion, exercising athletes should drink liquids at regular intervals. The primary problem in volume depletion is water loss. Research has revealed no basis for the rumor that cramps will result if you drink while exercising. The best choice for rehydration is plain water. Body reserves of electrolytes are sufficient to tolerate extended periods of strenuous activity. Problems with Na^+ balance are extremely unlikely, except during marathons or other activities that involve maximal exertion for more than 6 hours. However, both volume depletion (causing acute renal failure) and water intoxication (causing fatal hyponatremia) have occurred in marathon runners.

+ Clinical Note Sports Drinks

Some sports drinks contain sugars and vitamins as well as electrolytes. During endurance events (marathons, ultramarathons, and distance cycling), solutions containing less than 10 g/dL of glucose may improve performance if consumed late in the event, when metabolic reserves are exhausted. However, high sugar concentrations (above 10 g/dL) can cause cramps, diarrhea, and other problems. The benefit of "glucose polymers" (often cornstarch) in sports drinks has yet to be proved. Drinking beverages "fortified" with vitamins is actively discouraged: Vitamins are not lost during exercise, and the consumption of these beverages in large volumes could, over time, cause hypervitaminosis.

Tips & Tools

The chemical symbols for sodium (Na) and potassium (K) are derived from their Latin names, **Na**trium and **K**alium.

Figure 27–7 Major Factors Involved in Disturbances of Potassium Ion Balance.

When the blood concentration of K^+ falls below 2 mEq/L, extensive muscular weakness develops, followed by eventual paralysis. Severe hypokalemia is potentially lethal due to its effects on the heart.

Normal potassium range in blood: (3.5–5.0 mEq/L)

High K^+ concentration in the blood produces an equally dangerous condition known as hyperkalemia. Severe hyperkalemia occurs when the K^+ concentration exceeds 7 mEq/L, which results in cardiac arrhythmias.

Factors Promoting Hypokalemia	
Several diuretics can produce hypokalemia by increasing the volume of urine produced.	The endocrine disorder called aldosteronism, characterized by excessive aldosterone secretion, results in hypokalemia by overstimulating Na^+ retention and K^+ loss.

Factors Promoting Hyperkalemia		
Chronically low blood pH promotes hyperkalemia by interfering with K^+ excretion by the kidneys.	Kidney failure due to damage or disease will prevent normal K^+ secretion and thereby produce hyperkalemia.	Several drugs promote diuresis by blocking Na^+ reabsorption by the kidneys. When Na^+ reabsorption slows down, so does K^+ secretion, and hyperkalemia can result.

? What is a serious condition that could occur if the potassium ion concentration is >7 mEq/L?

Balance of Other Electrolytes

The ECF concentrations of other electrolytes are regulated as well. Here we will consider the most important ions involved: calcium, magnesium, phosphate, and chloride.

Calcium Balance

Calcium is the most abundant mineral in the body. A typical person has 1–2 kg (2.2–4.4 lb) of this element; ninety-nine percent of it is in the skeleton. In addition to forming the crystalline component of bone, calcium ions play key roles in controlling muscular and neural activities, in blood clotting, as cofactors for enzymatic reactions, and as second messengers.

As noted in Chapters 6 and 18, calcium homeostasis primarily reflects an interplay between the reserves in bone, the rate of absorption across the digestive tract, and the rate of loss by the kidneys. The hormones parathyroid hormone (PTH), calcitriol, and (to a lesser degree) calcitonin maintain calcium homeostasis in the ECF. Parathyroid hormone and calcitriol increase the Ca^{2+} concentration. Their actions are opposed by calcitonin. ↩ pp. 631–633

A small amount of Ca^{2+} is lost in the bile. Under normal circumstances, very few Ca^{2+} escape in urine or feces. To keep pace with these losses, an adult must absorb only 0.8–1.2 g/day of Ca^{2+}. That amount represents only about 0.03 percent of the calcium reserve in the skeleton. PTH from the parathyroid glands and calcitriol from the kidneys stimulate Ca^{2+} absorption by the digestive tract and Ca^{2+} reabsorption along the distal convoluted tubule of the kidneys.

Hypercalcemia exists when the Ca^{2+} concentration of the ECF exceeds 5.3 mEq/L. The primary cause of hypercalcemia in adults is *hyperparathyroidism*, a condition resulting from PTH oversecretion. Less common causes include malignant cancers of the breast, lung, kidney, and bone marrow, and excessive use of calcium or vitamin D supplements. Severe hypercalcemia (12–13 mEq/L) causes such signs and symptoms as fatigue, confusion, cardiac arrhythmias, and calcification of the kidneys and soft tissues throughout the body.

Hypocalcemia exists when the Ca^{2+} concentration is under 4.3 mEq/L. *Hypoparathyroidism* (undersecretion of PTH), vitamin D deficiency, or chronic renal failure is typically responsible for hypocalcemia. Signs and symptoms include muscle spasms, sometimes with generalized convulsions, weak heartbeats, cardiac arrhythmias, and osteoporosis.

Magnesium Balance

The adult body contains about 29 g of magnesium. Almost 60 percent of it is in the skeleton. The magnesium ions (Mg^{2+}) in body fluids are found primarily in the ICF. The cytosolic concentration of Mg^{2+} averages about 26 mEq/L. Magnesium ions are required as a cofactor for several important enzymatic reactions, including the phosphorylation of glucose within cells and the use of ATP by contracting muscle fibers.

The typical range of Mg^{2+} concentration in the ECF is 1.4–2.0 mEq/L, considerably lower than the level in the ICF. The proximal convoluted tubule reabsorbs magnesium ions very effectively. Keeping pace with the daily urinary loss requires a minimum dietary intake of only 24–32 mEq (0.3–0.4 g) per day.

Phosphate Balance

Phosphate ions (PO_4^{3-}) are required for bone mineralization. About 740 g are bound up in the mineral salts of the skeleton. In body fluids, the most important functions of PO_4^{3-} involve

Table 27–2 Electrolyte Balance for Average Adult

Ion and Normal ECF Range (mEq/L)	Disorder (mEq/L)	Signs and Symptoms	Causes	Treatments
Sodium (135–145)	Hypernatremia (>145)	Thirst, dryness and wrinkling of skin, reduced blood volume and pressure, eventual circulatory collapse	Dehydration; loss of hypotonic fluid	Ingestion of water or intravenous infusion of hypotonic solution
	Hyponatremia (<135)	Disturbed CNS function (water intoxication): confusion, hallucinations, convulsions, coma; death in severe cases	Infusion or ingestion of large volumes of hypotonic solution	Diuretic use and infusion of hypertonic salt solution
Potassium (3.5–5.0)	Hyperkalemia (>5.0)	Severe cardiac arrhythmias; muscle spasms	Renal failure; use of diuretics; chronic acidosis	Infusion of hypotonic solution; selection of different diuretics; infusion of buffers; dietary restrictions
	Hypokalemia (<3.5)	Muscular weakness and paralysis	Low-potassium diet; diuretics; hypersecretion of aldosterone; chronic alkalosis	Increase in dietary K^+ content; ingestion of K^+ tablets or solutions; infusion of potassium solution
Calcium (4.3–5.3)	Hypercalcemia (>5.3)	Confusion, muscle pain, cardiac arrhythmias, kidney stones, calcification of soft tissues	Hyperparathyroidism; cancer; vitamin D toxicity; calcium supplement overdose	Infusion of hypotonic fluid to lower $Ca^{2}{}_{1}$ levels; surgery to remove parathyroid gland; administration of calcitonin
	Hypocalcemia (<4.3)	Muscle spasms, convulsions, intestinal cramps, weak heartbeats, cardiac arrhythmias, osteoporosis	Poor diet; lack of vitamin D; renal failure; hypoparathyroidism; hypomagnesemia	Calcium supplements; administration of vitamin D
Magnesium (1.4–2.0)	Hypermagnesemia (>2.0)	Confusion, lethargy, respiratory depression, hypotension	Overdose of magnesium supplements or antacids (rare)	Infusion of hypotonic solution to lower plasma concentration
	Hypomagnesemia (<1.4)	Hypocalcemia, muscle weakness, cramps, cardiac arrhythmias, hypertension	Poor diet; alcoholism; severe diarrhea; kidney disease; malabsorption syndrome; ketoacidosis	Intravenous infusion of solution high in Mg^{2+}
Phosphate (1.8–3.0)	Hyperphosphatemia (>3.0)	No immediate symptoms; chronic elevation leads to calcification of soft tissues	High dietary phosphate intake; hypoparathyroidism	Dietary reduction; PTH supplementation
	Hypophosphatemia (<1.8)	Anorexia, dizziness, muscle weakness, cardiomyopathy, osteoporosis	Poor diet; kidney disease; malabsorption syndrome; hyperparathyroidism; vitamin D deficiency	Dietary improvement; vitamin D and/or calcitriol supplementation
Chloride (100–108)	Hyperchloremia (>108)	Acidosis, hyperkalemia	Dietary excess; increased chloride retention	Infusion of hypotonic solution to lower plasma concentration
	Hypochloremia (<100)	Alkalosis, anorexia, muscle cramps, apathy	Vomiting; hypokalemia	Diuretic use and infusion of hypertonic salt solution

the ICF. Inside cells these ions are required for the formation of high-energy compounds, the activation of enzymes, and the synthesis of nucleic acids.

The $PO_4{}^{3-}$ concentration of the plasma is usually 1.8–3.0 mEq/L. Phosphate ions are reabsorbed from tubular fluid along the proximal convoluted tubule. Calcitriol stimulates $PO_4{}^{3-}$ reabsorption along the PCT. Urinary and fecal losses of $PO_4{}^{3-}$ amount to 30–45 mEq (0.8–1.2 g) per day.

Chloride Balance

Chloride ions are the most abundant anions in the ECF. The normal plasma concentration is 100–108 mEq/L. In the ICF, the Cl^- concentration is usually low (3 mEq/L). Chloride ions are absorbed across the digestive tract together with Na^+. Several carrier proteins along the renal tubules reabsorb Cl^- with Na^+. ↩ pp. 1001–1003 The amount of Cl^- loss is small. A gain of 48–146 mEq (1.7–5.1 g) per day will keep pace with losses in urine and perspiration.

Additional information about sodium, potassium, and these other ions is listed in Table 27–2. This table also includes information about disorders that occur if we have too much or too little of them in the body.

Checkpoint

See the blue Answers tab at the back of the book.

27-5 In acid-base balance, buffer systems as well as respiratory and renal compensation regulate pH changes in body fluids

Learning Outcome Explain the buffer systems that balance the pH of the ICF and ECF, and describe the compensatory mechanisms involved in maintaining acid-base balance.

We introduced the topic of **pH**—a measure of the acidity or alkalinity of a solution—and the chemical nature of acids, bases, and buffers in Chapter 2. Table 27–3 reviews key terms important to the discussion that follows. For a more detailed review, refer to the appropriate sections of Chapter 2 before you proceed. pp. 43–44

The pH of body fluids reflects interactions among all the acids, bases, and salts in solution in the body. Therefore, the pH of body fluids can be altered by adding either acids or bases. The pH of the ECF normally remains within narrow limits, usually 7.35–7.45. Any deviation from the normal range is extremely dangerous. Changes in the H^+ concentration disrupt the stability of plasma membranes, alter the structure of proteins, and change the activities of important enzymes. You could not survive for long with an ECF pH below 6.8 or above 7.7.

When the pH of blood falls below 7.35, *acidemia* exists. The physiological state that results is called **acidosis**. When the pH of blood rises above 7.45, *alkalemia* exists. The physiological state that results is called **alkalosis**.

Acidosis and alkalosis affect virtually all body systems, but the nervous and cardiovascular systems are particularly sensitive to pH fluctuations. For example, severe acidosis (pH below 7.0) can be deadly, because (1) central nervous system function deteriorates, and the person may become comatose; (2) cardiac contractions grow weak and irregular, and signs and symptoms of heart failure may develop; and (3) peripheral vasodilation produces a dramatic decrease in blood pressure, potentially producing circulatory collapse.

The control of pH, or **acid-base balance**, is a homeostatic process of great physiological and clinical significance. Several mechanisms contribute to this process, including *buffer systems* and compensation by the respiratory and urinary systems. The *combination* of buffer systems and respiratory and renal mechanisms maintains body pH within narrow limits. Both acidosis and alkalosis are dangerous, but in practice, problems with acidosis are much more common. This is so because normal cellular activities generate several types of acids.

Table 27–3 A Review of Important Terms Relating to Acid-Base Balance

pH	The negative exponent (negative logarithm) of the hydrogen ion concentration [H^+]
Neutral	A solution with a pH of 7; the solution contains equal numbers of hydrogen ions and hydroxide ions
Acidic	A solution with a pH below 7; in this solution, hydrogen ions (H^+) predominate
Basic, or alkaline	A solution with a pH above 7; in this solution, hydroxide ions (OH^-) predominate
Acid	A substance that dissociates to release hydrogen ions, decreasing pH
Base	A substance that dissociates to release hydroxide ions or accept hydrogen ions, increasing pH
Salt	An ionic compound consisting of a cation other than hydrogen and an anion other than a hydroxide ion
Buffer	A substance that tends to oppose changes in the pH of a solution by removing or replacing hydrogen ions; in body fluids, buffers maintain blood pH within normal limits (7.35–7.45)

Types of Acids in the Body

There are three general categories of acids in the body: (1) **fixed acids**, which do not leave solution; (2) **metabolic acids**, which take part in or are produced by cellular metabolism; and (3) **volatile acids**, which can leave the body and enter the atmosphere through the lungs. Figure 27–8 gives examples of each. In general, fixed acids and metabolic acids do not greatly affect pH, so let's look at a volatile acid that might.

Carbonic acid (H_2CO_3) forms spontaneously from carbon dioxide (CO_2) and water in body fluids. This reaction proceeds much more rapidly in the presence of the enzyme *carbonic anhydrase*. This enzyme is found in the cytoplasm of red blood cells, liver and kidney cells, parietal cells of the stomach, and many other types of cells.

The partial pressure of carbon dioxide (P_{CO_2}) is the most important factor affecting the pH in blood. Most of the CO_2 in solution is converted to carbonic acid, and most of the carbonic acid dissociates into H^+ and **bicarbonate ions** (HCO_3^-). For this reason, the partial pressure of CO_2 and the pH are inversely related, as the seesaw illustrates in Figure 27–9. In other words, when the CO_2 level increases, additional H^+ and bicarbonate ions are released, so the pH decreases. (Recall that the pH is a *negative exponent*, so when the concentration of H^+ goes up, the pH value goes down.)

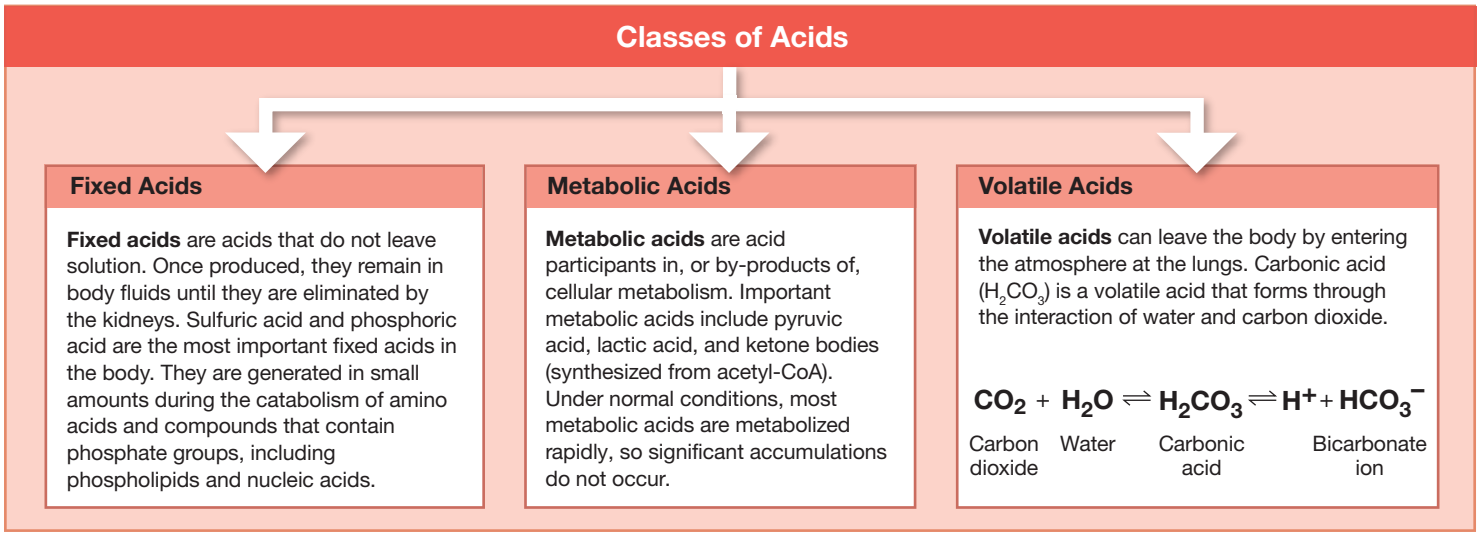
In contrast, as CO_2 leaves the bloodstream and diffuses into the alveoli, the number of H^+ and bicarbonate ions in the alveolar capillaries decreases, and blood pH increases.

Mechanisms of pH Control: Buffer Systems

To maintain acid-base balance over long periods of time, your body must balance gains and losses of H^+. Hydrogen ions are gained at the digestive tract and through metabolic activities within cells. Your kidneys eliminate H^+ by secreting them into urine. The lungs eliminate H^+ by forming water and CO_2 from H^+ and HCO_3^-. These sites of elimination are far removed from the sites of acid production. As the hydrogen ions travel through the body, they must be neutralized to avoid tissue damage.

Buffers in body fluids temporarily neutralize the acids produced by normal metabolic operations. To understand how

Figure 27–8 Three Classes of Acids Found in the Body.



buffers work, we need a bit of review of acids and bases. Recall from Chapter 2 that we can categorize **acids** and **bases** as either *strong* or *weak*:

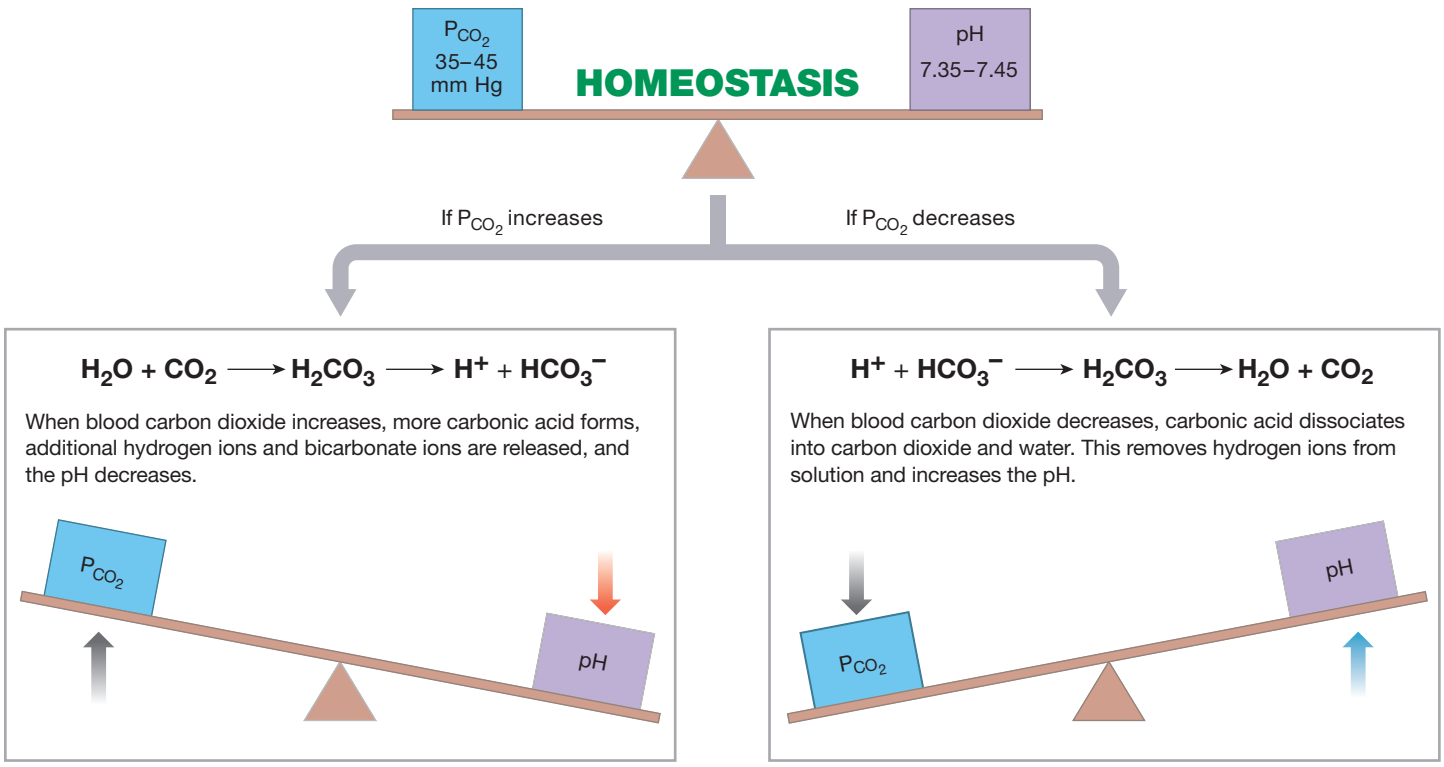
- **Strong acids** and **strong bases** dissociate completely in solution. For example, hydrochloric acid (HCl), a strong acid, dissociates in solution by the reaction

$$HCl \longrightarrow H^+ + Cl^-$$

- When **weak acids** or **weak bases** enter a solution, a significant number of molecules remain intact, so dissociation is not complete. For example, carbonic acid is a weak acid. At the normal pH of the ECF, an equilibrium exists, and the reaction can be diagrammed as follows:

$$\underset{\text{Carbonic acid}}{H_2CO_3} \rightleftharpoons \underset{\text{hydrogen ion}}{H^+} + \underset{\text{bicarbonate ion}}{HCO_3^-}$$

Figure 27–9 **The Basic Relationship between P_{CO_2} and Blood pH.** The P_{CO_2} is inversely related to the pH.



If you place the same concentration of a weak acid and a strong acid in separate solutions, the weak acid will release fewer hydrogen ions and have less effect on the pH of the solution than will the strong acid.

Buffers are dissolved compounds that stabilize the pH of a solution by adding or removing H^+. Buffers include weak acids that can donate H^+, and weak bases that can absorb H^+. A **buffer system** in body fluids generally consists of a combination of a weak acid and the anion released by its dissociation. The anion (here represented as Y) functions as a weak base. In solution, molecules of the weak acid exist in equilibrium with its dissociation products. In chemical notation, this relationship is represented as

$$HY \rightleftharpoons H^+ + Y^-$$

Adding H^+ to the solution upsets the equilibrium. As a result, additional molecules of the weak acid (HY) form, removing some of the H^+ from the solution.

The body has three major buffer systems: the *phosphate buffer system*, the *protein buffer systems*, and the *carbonic acid–bicarbonate buffer system*. Each has slightly different characteristics and distributions (Figure 27–10).

As we look more closely at these buffer systems, remember that they provide only a temporary solution to an acid-base imbalance. To preserve homeostasis, the H^+ that these systems capture must ultimately be either permanently tied up in water molecules, through the removal of CO_2 by the lungs, or removed from body fluids, through secretion by the kidneys. For that, respiratory and renal mechanisms are needed, as we will see later in this section.

The Phosphate Buffer System

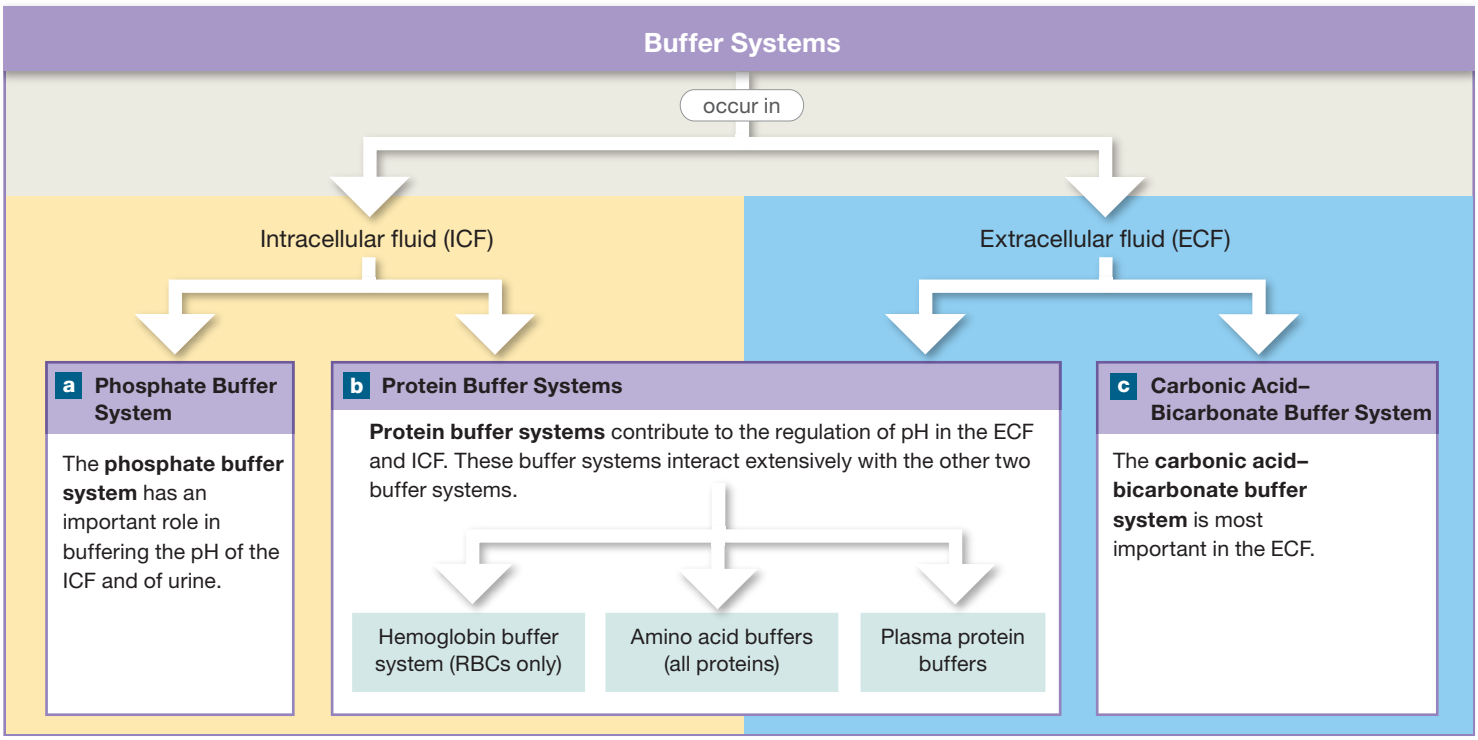
The **phosphate buffer system** consists of the weak acid *dihydrogen phosphate* ($H_2PO_4^-$) and the released anion *monohydrogen phosphate* (HPO_4^{2-}) (see Figure 27–10a). The reversible reaction involved is

$$\underset{\text{dihydrogen phosphate}}{H_2PO_4^-} \rightleftharpoons H^+ + \underset{\text{monohydrogen phosphate}}{HPO_4^{2-}}$$

In addition, cells contain a *phosphate reserve* in the form of the weak base *sodium monohydrogen phosphate* (Na_2HPO_4). The dissociation of this weak base provides additional monohydrogen phosphate for use by this buffer system:

$$2Na^+ + \underset{\text{monohydrogen phosphate}}{HPO_4^{2-}} \rightleftharpoons \underset{\text{sodium monohydrogen phosphate}}{Na_2HPO_4}$$

Figure 27–10 Buffer Systems in Body Fluids.



? In which body fluid do the phosphate and protein buffer systems help regulate the pH?

The phosphate buffer system is quite important in buffering the pH of the ICF. This system is also important in stabilizing the pH of urine. In the ECF, the phosphate buffer system plays only a supporting role in the regulation of pH, primarily because the concentration of bicarbonate ions far exceeds that of dihydrogen phosphate.

Protein Buffer Systems

Protein buffer systems depend on the ability of amino acids to respond to pH changes by accepting or releasing H^+, that is, by acting as a base or an acid (see Figure 27–10b). Such molecules are said to be *amphoteric* (*ampho*, both).

The effects of protein buffer systems are very important in both the ECF and the ICF. In the ICF of active cells, structural and other proteins provide an extensive buffering capability. Their buffering prevents destructive changes in pH when cellular metabolism produces metabolic acids, such as lactic acid or pyruvic acid. Because exchange occurs between the ICF and the ECF, the protein buffer systems can also help stabilize the pH of the ECF. For example, when the pH of the ECF decreases, cells pump H^+ out of the ECF and into the ICF, where intracellular proteins can buffer them. When the pH of the ECF increases, pumps in plasma membranes move H^+ out of the ICF and into the ECF. These mechanisms can assist in buffering the pH of the ECF, but the process is slow. Hydrogen ions must be individually transported across the plasma membrane. For this reason, the protein buffer systems in most cells cannot make rapid, large-scale adjustments in the pH of the ECF.

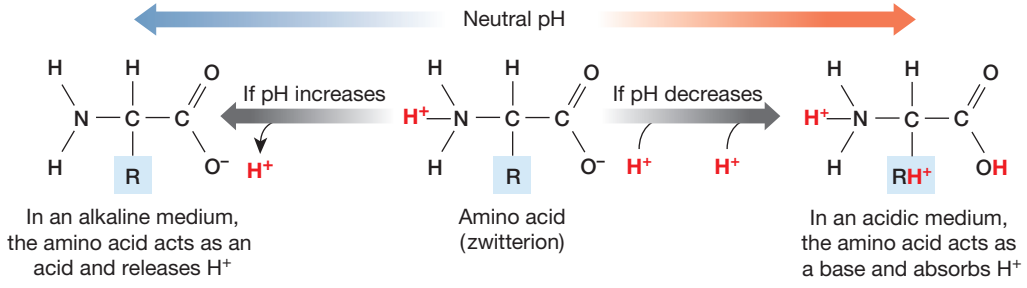
All proteins function as *amino acid buffers*. In addition, there are two specialized protein buffer systems that help to maintain the pH of blood: *plasma protein buffers* (which are covered in Figure 27–10b) and the *hemoglobin buffer system*.

Amino Acid Buffers. The underlying buffering mechanism of amino acids is shown in Figure 27–11:

- If pH increases (becomes more basic), the carboxyl group (—COOH) of the amino acid can dissociate, acting as a weak acid and releasing an H^+. The carboxyl group then becomes a carboxylate ion (—COO^-). At the normal pH of body fluids (7.35–7.45), the carboxyl groups of most amino acids have already given up their H^+. (Proteins carry negative charges mainly for that reason.) However, some amino acids, notably histidine and cysteine, have R groups (side chains) that will donate H^+ if the pH increases outside the normal range.
- In a neutral solution, an amino acid carries both positive and negative charges. This state is called a *zwitterion* (the term is derived from German meaning *hybrid ion*).
- If pH decreases (becomes more acidic), the carboxylate ion and the amino group (—NH_2) can act as weak bases and accept additional H^+, forming a carboxyl group (—COOH) and an amino ion (—NH_3^+), respectively. In free amino acids, both the main structural chain and the side chain can act as buffers. In a protein, most of the carboxyl and amino groups in the main chain are tied up in peptide bonds. Only the exposed amino group and carboxyl group at either end of a protein are available as buffers. So most of the buffering capacity of proteins is provided by the R groups of amino acids.

The Hemoglobin Buffer System. The situation is somewhat different for red blood cells. These cells, which contain approximately 5.5 percent of the ICF, are normally suspended in the plasma. They are densely packed with hemoglobin, and their cytoplasm contains large amounts of carbonic anhydrase. Red blood cells have a significant effect on the pH of the ECF, because they absorb CO_2 from the plasma and convert it to carbonic acid. Carbon dioxide can diffuse across the RBC membrane very quickly, so no transport mechanism is needed. As the carbonic acid dissociates within an RBC, the bicarbonate ions diffuse into the plasma in exchange for chloride ions, a swap known as the *chloride shift*. ↩ p. 868 Hemoglobin molecules buffer the hydrogen ions (look back at Figure 23–22, p. 867). In the lungs, the entire reaction sequence diagrammed in Figure 23–23 on p. 869 proceeds in reverse. This mechanism is known as the **hemoglobin buffer system**.

Figure 27–11 The Role of Amino Acid Buffers in Protein Buffer Systems. An amino acid in solution has both a negative and positive charge. Depending on the pH of their surroundings, amino acids either donate an H^+ (as at left) or accept an H^+ (as at right). An amino acid in solution is a zwitterion and has both a negative and positive charge. Additionally, several different R groups may release or absorb H^+.



The hemoglobin buffer system is the only intracellular buffer system that can have an immediate effect on the pH of the ECF. This buffer system helps prevent drastic changes in pH when the plasma P_{CO_2} is increasing or decreasing.

The Carbonic Acid–Bicarbonate Buffer System

Body cells generate CO_2 virtually 24 hours a day. (Exceptions are red blood cells, some cancer cells, and tissues temporarily deprived of oxygen.) As we have seen, most of the CO_2 is converted to carbonic acid, which then dissociates into a hydrogen ion and a bicarbonate ion (HCO_3^-). The carbonic acid and its dissociation products form the **carbonic acid–bicarbonate buffer system**. The primary role of this buffer system is to prevent changes in pH caused by metabolic acids and fixed acids in the ECF (see Figure 27–10c).

The carbonic acid–bicarbonate buffer system consists of the reaction introduced in our discussion of volatile acids (Figure 27–12a):

$$\underset{\text{carbon dioxide}}{CO_2} + \underset{\text{water}}{H_2O} \rightleftharpoons \underset{\text{carbonic acid}}{H_2CO_3} \rightleftharpoons \underset{\text{hydrogen ion}}{H^+} + \underset{\text{bicarbonate ion}}{HCO_3^-}$$

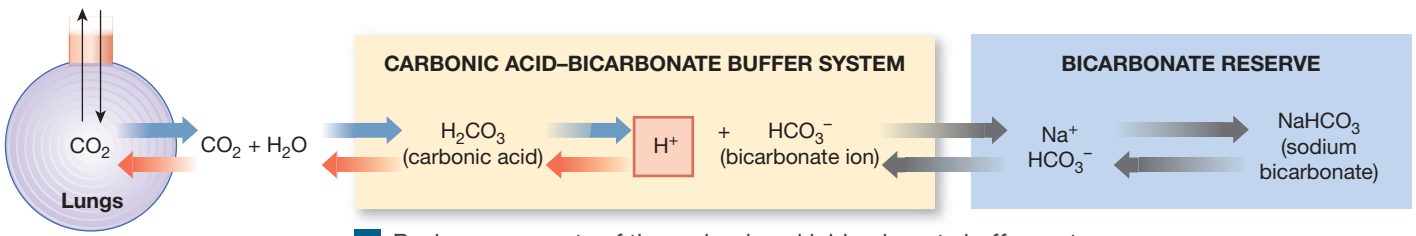
Because the reaction is freely reversible, a change in the concentration of any one component affects the concentrations of all others. For example, if H^+ are added, most of them will be removed by interactions with HCO_3^-, forming H_2CO_3. In the process, the HCO_3^- act as a weak base that buffers the excess H^+. The H_2CO_3 formed in this way in turn dissociates into CO_2 and H_2O (Figure 27–12b). The lungs can then excrete the extra CO_2. In effect, this reaction takes the H^+ released by a strong metabolic or fixed acid and generates a volatile acid that can easily be eliminated.

The carbonic acid–bicarbonate buffer system can also protect against increases in pH, although such changes are rare. If H^+ are removed from the plasma, the reaction is driven to the right: The P_{CO_2} decreases, and H_2CO_3 dissociates to replace the missing H^+.

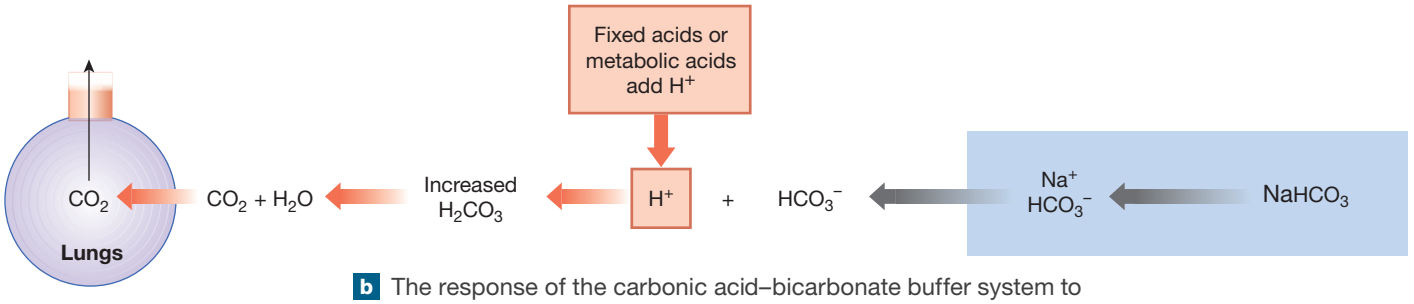
The carbonic acid–bicarbonate buffer system has three important limitations:

- *It cannot protect the ECF from changes in pH that result from an increased or decreased level of CO_2.* A buffer system cannot protect against changes in the concentration of its own weak acid. As Figure 27–12a indicates, an equilibrium exists among the components of this buffer system. Thus, in this system, the addition of excess H^+ from an outside source would drive the reaction to the left. But the addition of excess CO_2 would form H_2CO_3 and drive the reaction to the right. The dissociation of H_2CO_3 would release H^+ and HCO_3^-, decreasing the pH of the blood.
- *It can function only when the respiratory system and the respiratory control centers are working normally.* Normally, the increase in P_{CO_2} that occurs when fixed acids or metabolic acids are buffered stimulates an increase in the respiratory rate. This increase accelerates the removal of CO_2 by the lungs. The efficiency of the buffer system will be reduced if the respiratory passageways are blocked, or blood flow

Figure 27–12 The Carbonic Acid–Bicarbonate Buffer System.



a Basic components of the carbonic acid–bicarbonate buffer system, and their relationships to carbon dioxide and the bicarbonate reserve



b The response of the carbonic acid–bicarbonate buffer system to hydrogen ions generated by fixed or metabolic acids in body fluids

to the lungs is impaired, or the respiratory centers do not respond normally. This buffer system cannot eliminate H^+ and remove the threat to homeostasis unless the respiratory system is functioning normally.

- *The ability to buffer acids is limited by the availability of bicarbonate ions.* Every time an H^+ is removed from the plasma, an HCO_3^- goes with it. When all the HCO_3^- have been tied up, buffering capabilities are lost.

Problems due to a lack of bicarbonate ions are rare, for several reasons. First, body fluids contain a large reserve of HCO_3^-, mostly in the form of dissolved molecules of the weak base *sodium bicarbonate* ($NaHCO_3$). This readily available supply of HCO_3^- is known as the **bicarbonate reserve**. The reaction involved (see Figure 27–12a) is

$$Na^+ + \underset{\text{bicarbonate ion}}{HCO_3^-} \rightleftharpoons \underset{\text{sodium bicarbonate}}{NaHCO_3}$$

When H^+ enter the ECF, the HCO_3^- tied up in H_2CO_3 molecules are replaced by HCO_3^- from the bicarbonate reserve (see Figure 27–12b).

Second, additional HCO_3^- can be generated by the kidneys, through mechanisms described in Chapter 26 (look back at Figure 26–13c, p. 999). In the distal convoluted tubule of the nephron and collecting system, carbonic anhydrase converts CO_2 within tubular cells into H_2CO_3, which then dissociates. The H^+ is pumped into tubular fluid in exchange for a Na^+, and the HCO_3^- is transported into peritubular fluid in exchange for a Cl^-. In effect, tubular cells remove HCl from peritubular fluid in exchange for $NaHCO_3$.

Regulation of Acid-Base Balance

Buffer systems can tie up excess H^+, but they provide only a temporary solution to an acid-base imbalance. The H^+ are merely rendered harmless; they are not eliminated. To preserve homeostasis, the captured H^+ must ultimately be either permanently tied up in water molecules, through the removal of CO_2 by the lungs, or removed from body fluids, through secretion by the kidneys.

Suppose that a buffer molecule prevents a change in pH by binding an H^+ that enters the ECF. That buffer molecule is then tied up, reducing the capacity of the ECF to cope with any additional H^+. Eventually, all the buffer molecules are bound to H^+, and further pH control becomes impossible.

The situation can be resolved only by removing H^+ from the ECF (thereby freeing the buffer molecules) or by replacing the buffer molecules. Similarly, if a buffer provides an H^+ to maintain normal pH, homeostatic conditions will return only when either another H^+ has been obtained or the buffer has been replaced.

Regulating acid-base balance thus includes balancing H^+ gains and losses. This "balancing act" involves coordinating the actions of buffer systems with respiratory and renal compensation mechanisms. These mechanisms support the buffer systems by (1) secreting or absorbing H^+, (2) controlling the excretion of acids and bases, and, when necessary, (3) generating additional buffers. As we have noted, it is the combination of buffer systems and these respiratory and renal mechanisms that maintains body pH within narrow limits.

Respiratory Compensation

Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Respiratory compensation takes place whenever body pH strays outside normal limits. Such compensation works because respiratory activity has a direct effect on the carbonic acid–bicarbonate buffer system. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO_2}. When the P_{CO_2} increases, the pH decreases, because the addition of CO_2 drives the carbonic acid–bicarbonate buffer system to the right. When the P_{CO_2} falls, the pH increases because the removal of CO_2 drives that buffer system to the left.

We described the mechanisms responsible for the control of respiratory rate in Chapter 23. Here we present only a brief summary. (For a review, look back at Spotlight Figure 23–25, p. 872, and Figure 23–26, p. 875.)

Chemoreceptors of the carotid and aortic bodies are sensitive to the P_{CO_2} of circulating blood. Other receptors, located on the ventrolateral surfaces of the medulla oblongata, monitor the P_{CO_2} of the CSF. A rise in P_{CO_2} stimulates the chemoreceptors, leading to an increase in the respiratory rate. As the rate of respiration increases, more CO_2 is lost at the lungs, so the P_{CO_2} returns to a normal level. Conversely, when the P_{CO_2} of the blood or CSF decreases, the chemoreceptors are inhibited. Respiratory activity becomes depressed and the breathing rate decreases, causing an elevation of the P_{CO_2} in the ECF.

Renal Compensation

Renal compensation is a change in the rates of H^+ and HCO_3^- secretion or reabsorption by the kidneys in response to changes in plasma pH. Under normal conditions, the body generates enough metabolic and fixed acids to add about 100 mEq of H^+ to the ECF each day. An equivalent number of H^+ must be excreted in urine to maintain acid-base balance. In addition, the kidneys assist the lungs by eliminating any CO_2 that either enters the renal tubules during filtration or diffuses into the tubular fluid as it travels toward the renal pelvis.

Hydrogen ions are secreted into the tubular fluid along the proximal convoluted tubule (PCT), the distal convoluted tubule (DCT), and the collecting system.The basic mechanisms

involved are shown in Figures 26–12 and 26–13c (pp. 997, 999). The ability to eliminate a large number of H^+ in a normal volume of urine depends on the presence of buffers in the urine. The secretion of H^+ can continue only until the pH of the tubular fluid reaches 4.0–4.5. (At that point, the H^+ concentration gradient is so great that H^+ leak out of the tubule as fast as they are pumped in.)

If the tubular fluid lacked buffers to absorb the H^+, the kidneys could secrete less than 1 percent of the acid produced each day before the pH reached this limit. To maintain acid balance under these conditions, the kidneys would have to produce about 1000 liters of urine each day just to keep pace with the generation of H^+ in the body! Buffers in tubular fluid are extremely important, because they keep the pH high enough for H^+ secretion to continue. Metabolic acids are being generated continuously. Without these buffering mechanisms, the kidneys could not maintain homeostasis.

The Process of pH Regulation by Kidney Tubule Cells. Figure 27–13 diagrams the primary routes of H^+ secretion and the buffering mechanisms that stabilize the pH of tubular fluid. The three major buffers involved are the previously discussed carbonic acid–bicarbonate buffer system and phosphate buffer system, and the *ammonia buffer system* (Figure 27–13a). Glomerular filtration puts components of the carbonic acid–bicarbonate buffer system and the phosphate buffer system into the filtrate. Tubule cells (mainly those of the PCT) generate ammonia.

Figure 27–13a shows the secretion of H^+, which relies on carbonic anhydrase activity within tubular cells. The H^+ generated may be pumped into the lumen in exchange for Na^+, individually or together with Cl^-. The net result is the secretion of H^+, accompanied by the removal of CO_2 (from the tubular fluid, the tubule cells, and the ECF), and the release of sodium bicarbonate into the ECF.

Figure 27–13b shows the generation of ammonia within the tubules. As tubule cells use the enzyme *glutaminase* to break down the amino acid *glutamine*, amino groups are released as either ammonium ions (NH_4^+) or ammonia (NH_3). The NH_4^+ are transported into the lumen in exchange for Na^+ in the tubular fluid. The NH_3, which is highly volatile and also toxic to cells, diffuses rapidly into the tubular fluid. There it reacts with an H^+, forming NH_4^+.

This reaction buffers the tubular fluid and removes a potentially dangerous compound from body fluids. The carbon chains of the glutamine molecules are ultimately converted to HCO_3^-, which is cotransported with Na^+ into the ECF. The generation of ammonia by tubule cells ties up H^+ in the tubular fluid and releases sodium bicarbonate into the ECF, where it contributes to the bicarbonate reserve. These mechanisms of H^+ secretion and buffering are always functioning, but their levels of activity vary widely with the pH of the ECF.

Renal Responses to Acidosis and Alkalosis. Acidosis (low blood pH) develops when the normal plasma buffer mechanisms are stressed by excessive hydrogen ions. The kidney tubules do not distinguish among the various acids that may cause acidosis. Whether the decrease in pH results from the production of volatile, fixed, or metabolic acids, the renal contribution remains limited to (1) the secretion of H^+, (2) the activity of buffers in the tubular fluid, (3) the removal of CO_2, and (4) the reabsorption of sodium bicarbonate.

Tubule cells thus bolster the capabilities of the carbonic acid–bicarbonate ion buffer system. They do so by increasing the concentration of HCO_3^- in the ECF, replacing those already used to remove H^+ from solution. In a starving person, tubule cells break down amino acids, yielding ammonium ions that are pumped into the tubular fluid, bicarbonate ions to help buffer ketone bodies in the blood, and carbon chains for catabolism (see Figure 27–13b).

When alkalosis (high blood pH) develops, (1) the rate of H^+ secretion by the kidneys declines, (2) tubule cells do not reclaim the HCO_3^- in tubular fluid, and (3) the collecting system transports HCO_3^- into tubular fluid while releasing H^+ and Cl^- into the peritubular fluid (Figure 27–13c). The concentration of HCO_3^- in blood decreases, promoting the dissociation of H_2CO_3 and the release of H^+. The additional H^+ generated by the kidneys help return the pH to a normal level.

Checkpoint

12. **Identify the body's three major buffer systems.**
13. **What effect would a decrease in the pH of body fluids have on the respiratory rate?**
14. **Why must tubular fluid in nephrons be buffered?**

See the blue Answers tab at the back of the book.

27-6 Disorders of acid-base balance can be classified as respiratory or metabolic

Learning Outcome Identify the most frequent disturbances of acid-base balance, and explain how the body responds when the pH of body fluids varies outside normal limits.

For anyone considering a career in a health-related field, an understanding of acid-base dynamics is essential both in clinical diagnosis and patient management. Temporary shifts in the pH of body fluids occur frequently. For example, the *alkaline tide* following a meal causes a temporary increase in blood pH. p. 904 Rapid and complete return to normal pH involves a combination of buffer system activity and the respiratory and renal compensatory mechanisms (Figure 27–14). Together these mechanisms can generally control pH very precisely, so the pH of the ECF seldom varies more than 0.1 pH unit, from 7.35 to 7.45.

Figure 27–13 pH Regulation of Tubular Fluid by Kidney Tubule Cells.

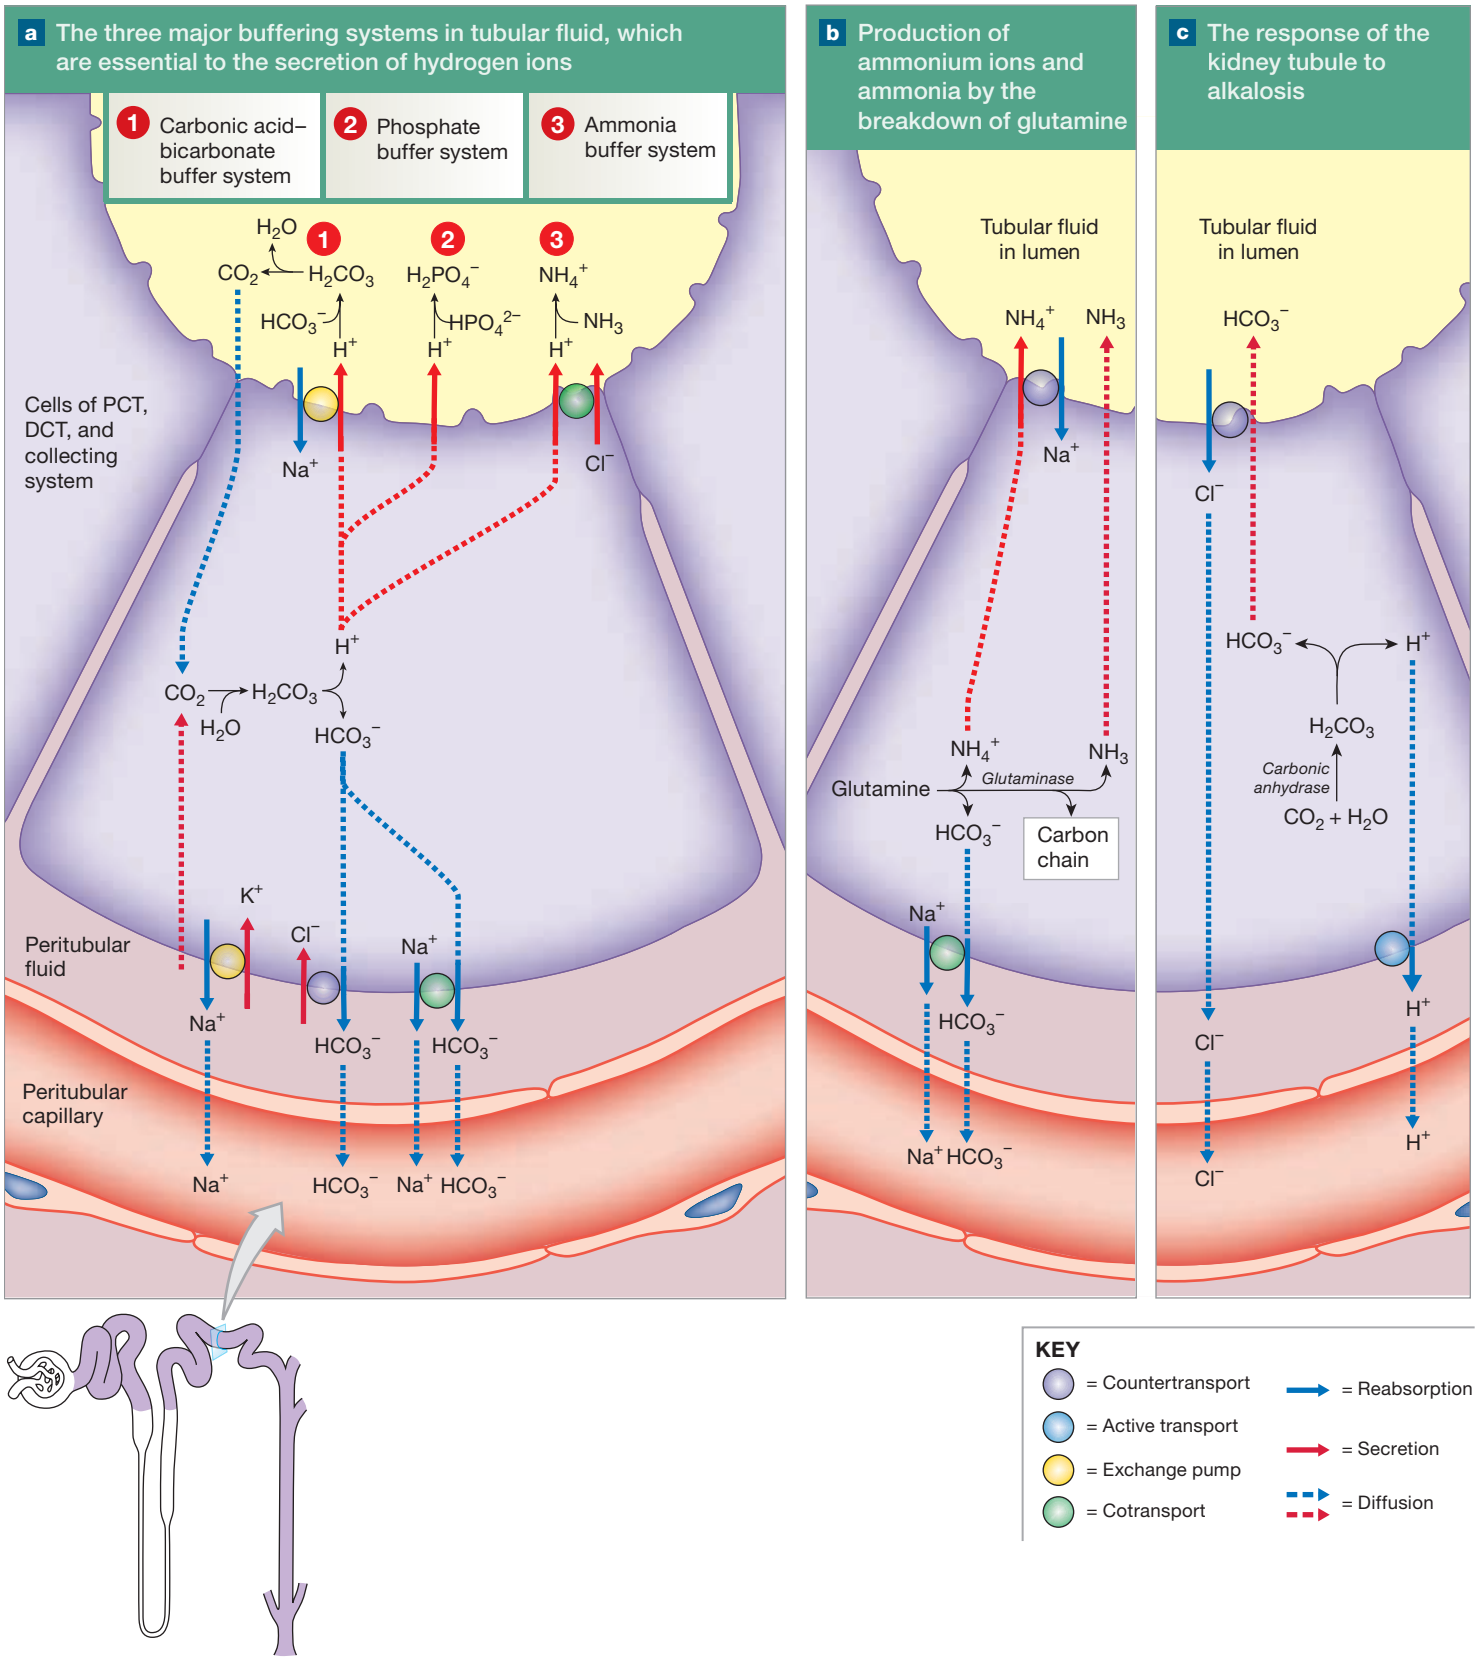


Figure 27–14 Interactions among the Carbonic Acid–Bicarbonate Buffer System and Respiratory and Renal Compensation Mechanisms in the Regulation of Plasma pH.

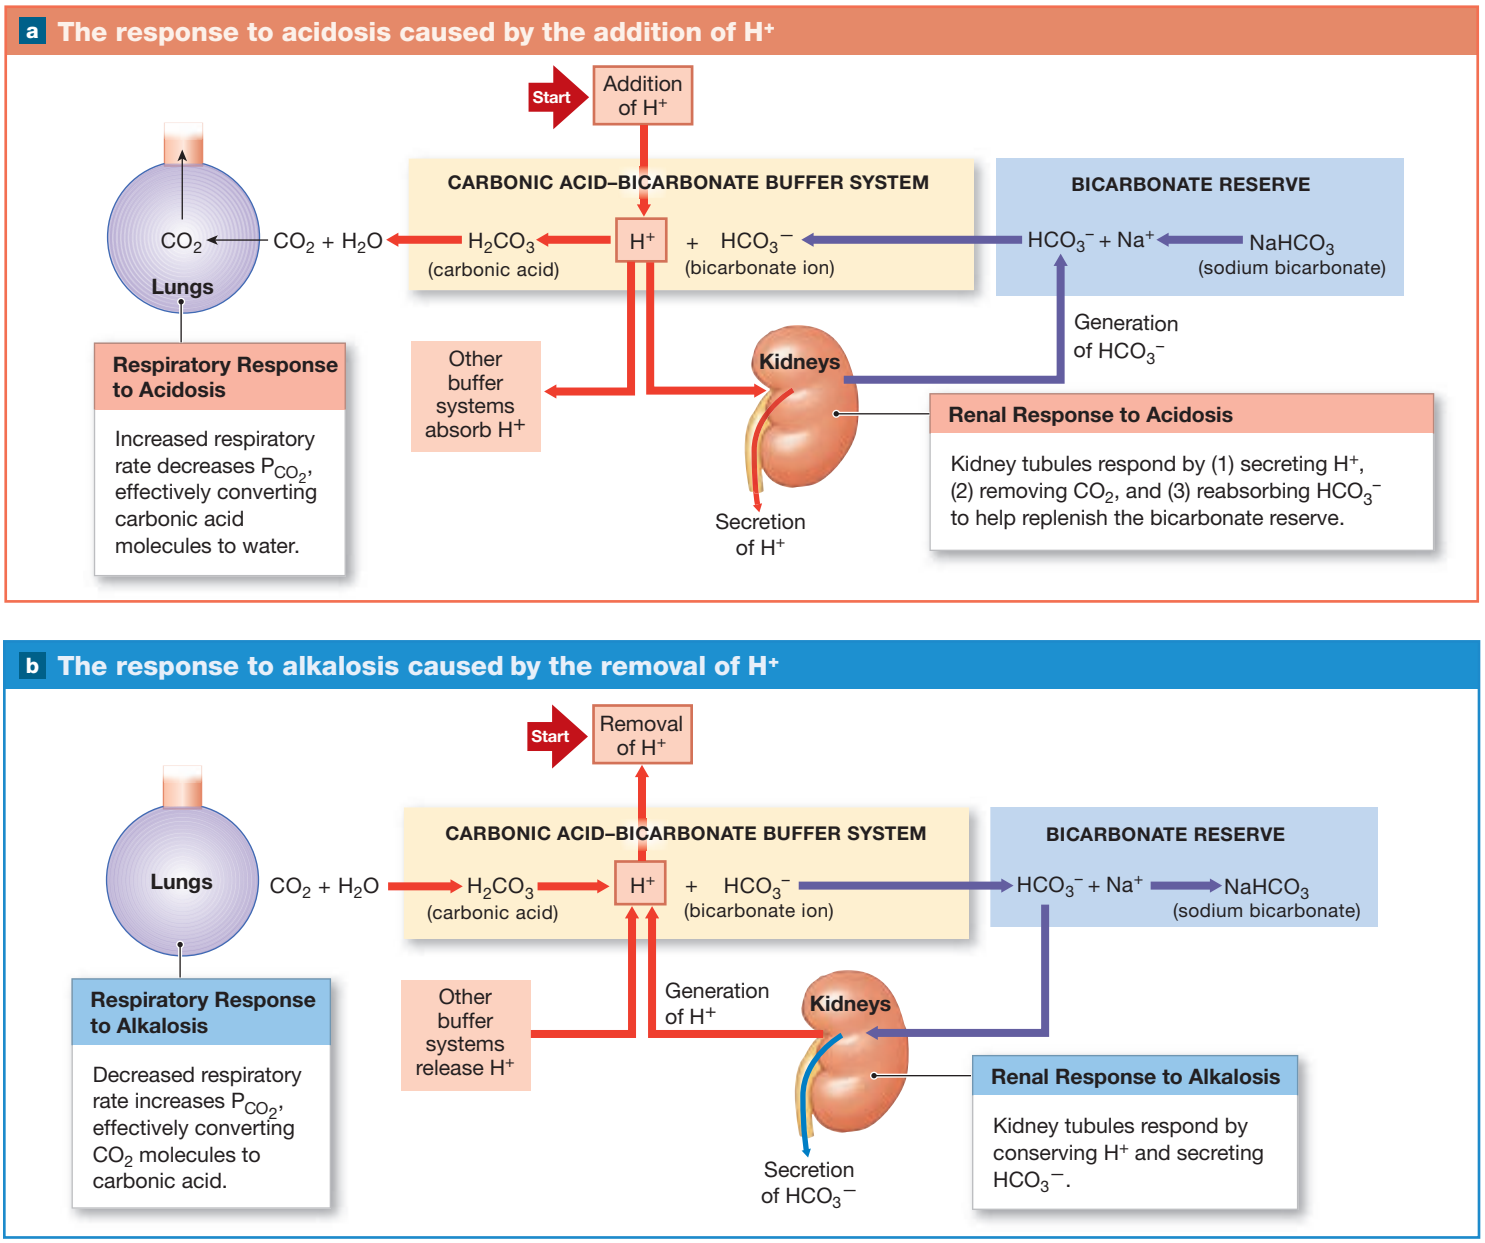


? What is the kidney's response to alkalosis caused by the removal of H^+?

When buffering mechanisms are severely stressed, however, the pH drifts outside these limits, producing signs and symptoms of alkalosis or acidosis. More serious and prolonged disturbances of acid-base balance can result with the following conditions:

- *Disorders Affecting Circulating Buffers, Respiratory Performance, or Renal Function.* Several conditions, including *emphysema* and *renal failure*, are associated with dangerous changes in pH. ↩ pp. 877, 1014
- *Cardiovascular Conditions.* Conditions such as *heart failure* or *hypotension* can affect the pH of internal fluids by causing fluid shifts and by changing the glomerular filtration rate and respiratory efficiency. ↩ pp. 715, 740
- *Conditions Affecting the Central Nervous System.* Neural damage or disease that affects the CNS can affect the respiratory and cardiovascular reflexes that are essential to normal pH regulation.

Serious abnormalities in acid-base balance generally have an initial *acute phase*, in which the pH moves rapidly out of the normal range. If the condition persists, physiological adjustments take place. The person then enters the *compensated phase*. However, unless the underlying problem is corrected, compensation typically cannot return the blood pH to the normal range. Even if the pH is returned to normal, the P_{CO_2} or HCO_3^- concentration can still be abnormal.

The name given to the resulting condition usually indicates the primary source of the problem:

- *Respiratory acid-base disorders* result from a mismatch between CO_2 generation in peripheral tissues and CO_2 excretion by the lungs. When a respiratory acid-base disorder is present, the CO_2 level of the ECF is abnormal.
- *Metabolic acid-base disorders* are caused by the generation of metabolic acids or fixed acids or by conditions affecting the concentration of HCO_3^- in the ECF.

Respiratory compensation alone may restore normal acid-base balance in persons with respiratory acid-base disorders. In contrast, compensation mechanisms for metabolic acid-base disorders may be able to stabilize pH, but other aspects of acid-base balance (buffer system function, bicarbonate ion and P_{CO_2} levels) remain abnormal until the underlying metabolic cause is corrected. Let's look further into both respiratory and metabolic acid-base disorders.

Respiratory Acid-Base Disorders

We can subdivide the respiratory acid-base disturbances into *respiratory acidosis* and *respiratory alkalosis*.

Respiratory Acidosis

Respiratory acidosis develops when the respiratory system cannot eliminate all the CO_2 generated by peripheral tissues. The primary sign is low blood pH due to **hypercapnia**, an increased blood P_{CO_2}. The usual cause is *hypoventilation*, an abnormally low respiratory rate. When the P_{CO_2} in the ECF rises, H^+ and HCO_3^- concentrations also begin rising as H_2CO_3 forms and dissociates. Other buffer systems can tie up some of the H^+, but once the combined buffering capacity has been exceeded, the pH begins to fall rapidly. The effects are diagrammed in Figure 27–15a.

Respiratory acidosis is the most common challenge to acid-base equilibrium. Body tissues generate CO_2 rapidly. Even a few minutes of hypoventilation can cause acidosis, reducing the pH of the ECF to as low as 7.0. Under normal circumstances, the chemoreceptors that monitor the P_{CO_2} of blood and of CSF eliminate the problem by stimulating an increase in breathing rate.

If the chemoreceptors do not respond, if the breathing rate cannot be increased, or if the circulatory supply to the lungs is inadequate, the pH will continue to decrease. If the decline is severe, **acute respiratory acidosis** develops. Acute respiratory acidosis is an immediate, life-threatening condition. It is especially dangerous in people whose tissues are generating large amounts of CO_2, or in those who are incapable of normal respiratory activity. For this reason, the reversal of acute respiratory acidosis is probably the major goal in the resuscitation of cardiac arrest or drowning victims. Thus, first-aid, CPR, and lifesaving courses always stress the "ABCs" of emergency care: *A*irway, *B*reathing, and *C*irculation.

Chronic respiratory acidosis develops when normal respiratory function has been compromised, but the compensatory mechanisms have not failed completely. For example, normal respiratory compensation may not occur in response to chemoreceptor stimulation in persons with CNS injuries and those whose respiratory centers have been desensitized by drugs such as alcohol or barbiturates. As a result, these people are prone to developing acidosis due to chronic hypoventilation.

Even when respiratory centers are intact and functional, damage to some parts of the respiratory system can prevent increased pulmonary exchange. Examples of conditions fostering chronic respiratory acidosis include emphysema, congestive heart failure, and pneumonia (which typically cause alveolar damage or blockage). Pneumothorax and respiratory muscle paralysis have a similar effect, because they, too, limit adequate breathing rate.

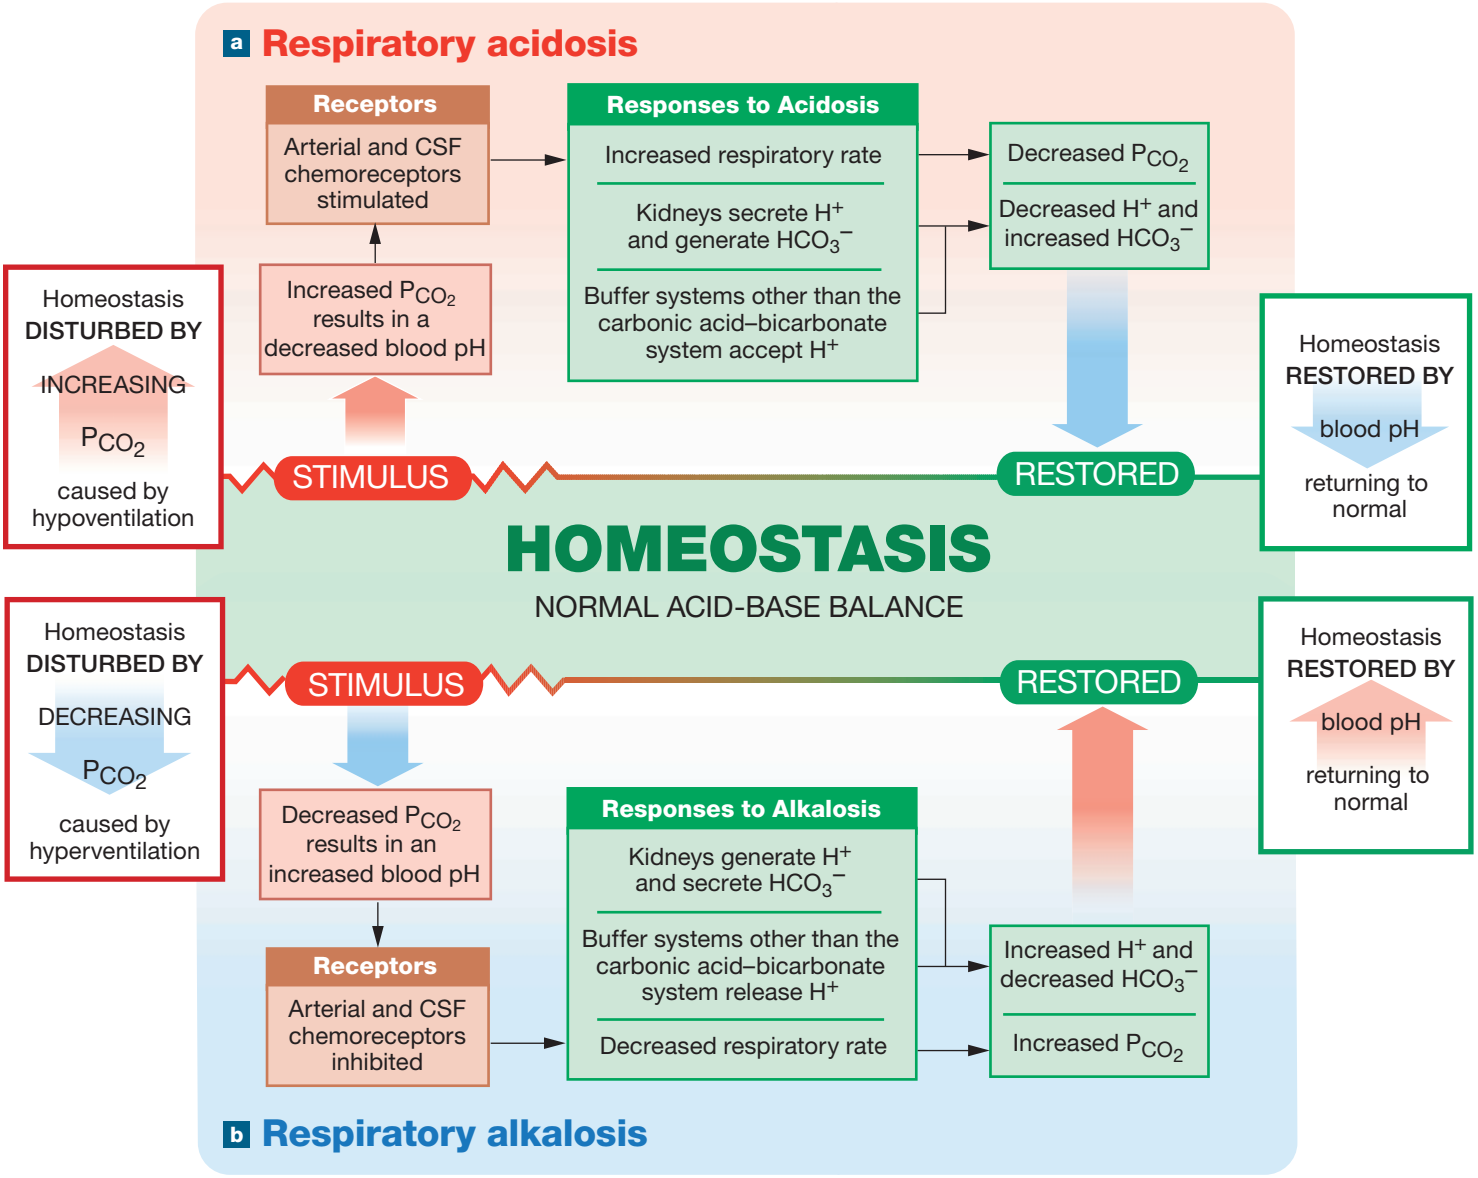
When the pulmonary response is abnormal, the kidneys respond by increasing the rate of H^+ secretion into tubular fluid. This response slows the rate of pH change. However, renal mechanisms alone cannot return the pH to normal until the underlying respiratory or circulatory problems are corrected.

The primary problem in respiratory acidosis is that the rate of pulmonary exchange is inadequate to keep the arterial P_{CO_2} within normal limits. Breathing efficiency can typically be improved temporarily by inducing bronchodilation or by using mechanical aids that provide air under positive pressure. If breathing has stopped, artificial respiration or a mechanical ventilator is required. These measures may restore normal pH if the respiratory acidosis was not severe or prolonged. Treatment of acute respiratory acidosis is complicated by the fact that, as we will soon see, it causes a complementary metabolic acidosis as oxygen-starved tissues generate lactate and H^+.

Respiratory Alkalosis

Problems resulting from **respiratory alkalosis** are fairly uncommon (Figure 27–15b). Respiratory alkalosis develops when respiratory activity lowers the blood P_{CO_2} to a below-normal level, a condition called **hypocapnia** (*-capnia*, presence of CO_2). A temporary hypocapnia can be produced by *hyperventilation* when increased respiratory activity leads to a reduction in the arterial P_{CO_2}. Continued hyperventilation can increase the pH to a level as high as 8.0. This condition generally corrects itself, because the reduction in P_{CO_2} halts the stimulation of the chemoreceptors,

Figure 27–15 Homeostatic Regulation of Acid-Base Balance.



so the urge to breathe fades until the CO_2 level has returned to normal. Respiratory alkalosis caused by hyperventilation seldom lasts long enough to cause a clinical emergency.

Common causes of hyperventilation include physical stresses such as pain, or psychological stresses such as extreme anxiety. Hyperventilation gradually increases the pH of the CSF, and CNS function is affected. The initial symptoms involve tingling sensations in the hands, feet, and lips. The person may also feel light-headed. If hyperventilation continues, the person may lose consciousness. Unconsciousness removes any contributing psychological stimuli, and the breathing rate decreases. The P_{CO_2} then increases until the pH returns to normal.

A simple treatment for respiratory alkalosis caused by hyperventilation is to have the person rebreathe air exhaled into a small paper bag. As the P_{CO_2} in the bag increases, so do the person's alveolar and arterial CO_2 concentrations. This change eliminates the problem and restores the pH to a normal level. Other problems with respiratory alkalosis are rare and involve primarily (1) persons adapting to high altitudes, where the low P_{O_2} promotes hyperventilation; (2) patients on mechanical respirators; or (3) persons whose brainstem injuries render them incapable of responding to shifts in the plasma CO_2 concentration.

Metabolic Acid-Base Disorders

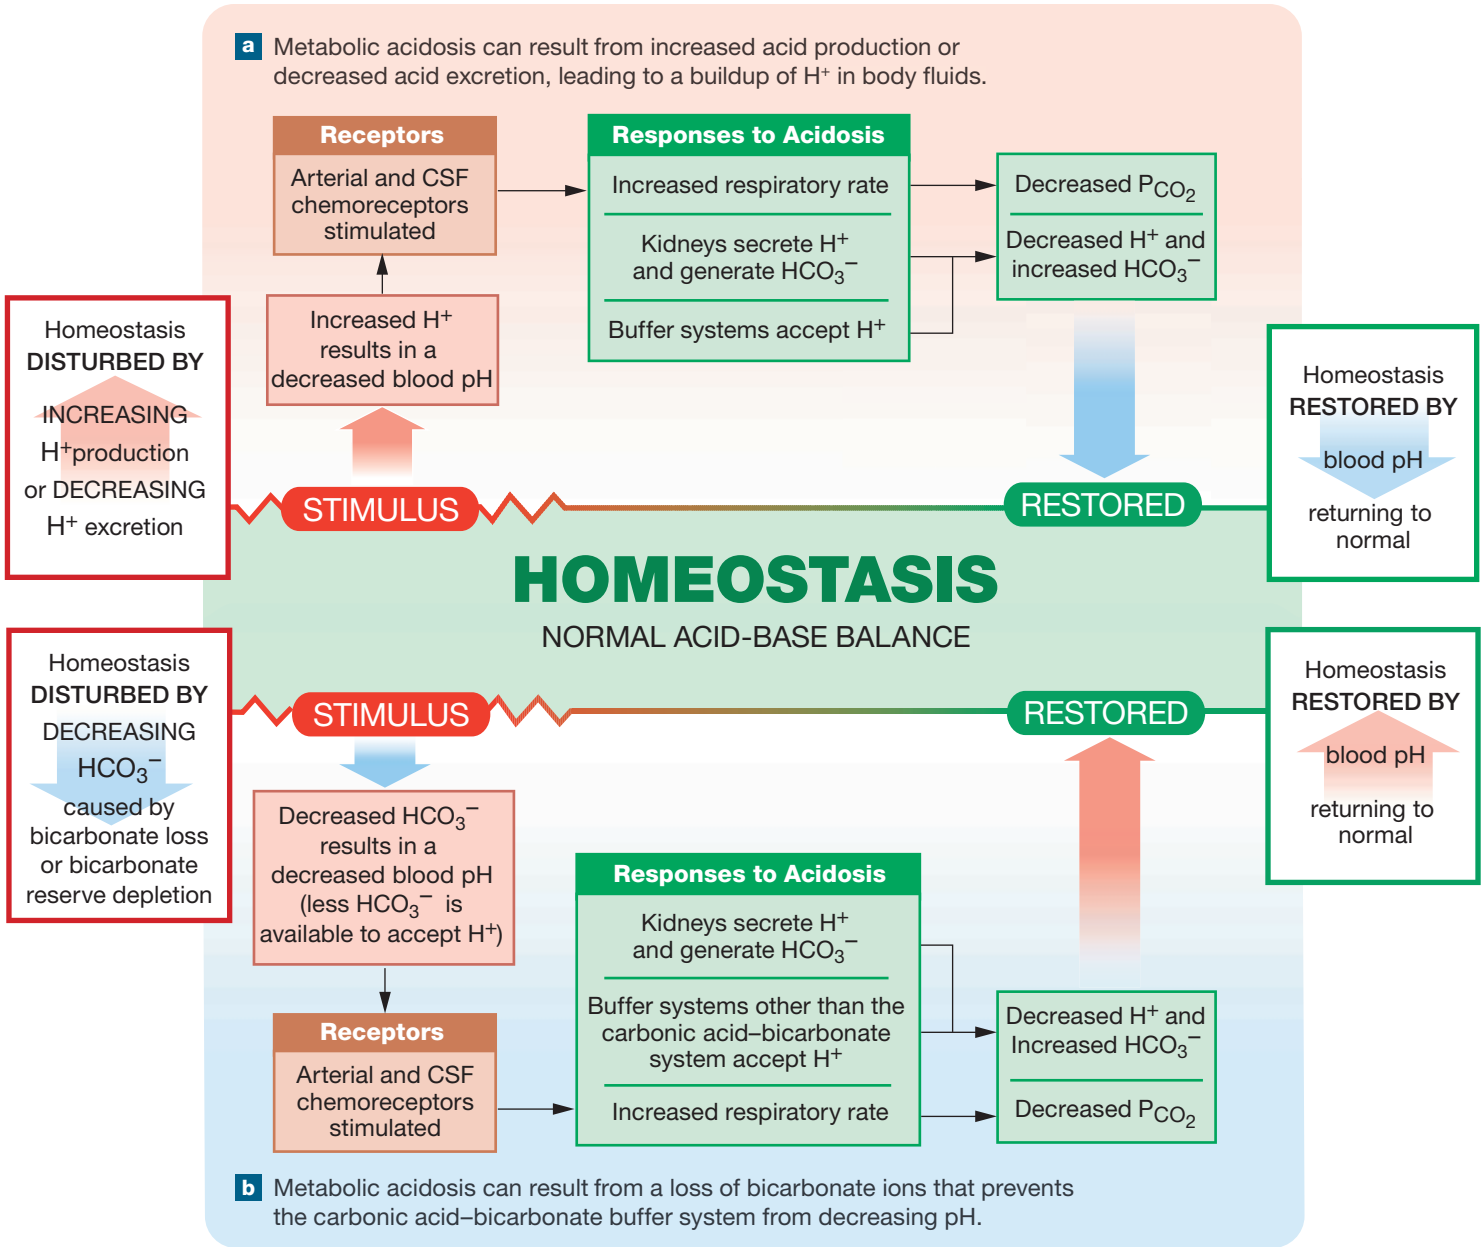
We can divide the metabolic acid-base disturbances into *metabolic acidosis* and *metabolic alkalosis*.

Metabolic Acidosis

Metabolic acidosis is the second most common type of acid-base imbalance (after respiratory acidosis). It has the following three major causes:

- The most widespread cause of metabolic acidosis is the production of a large number of fixed acids or metabolic acids. The H^+ released by these acids overload the carbonic acid–bicarbonate ion buffer system, so the pH begins to decrease (Figure 27–16a). We considered two examples of metabolic acidosis earlier:
- **Lactic acidosis** can develop after strenuous exercise or prolonged tissue *hypoxia* (oxygen starvation) as cells rely on anaerobic metabolism (look back at Figure 10–20, p. 321).
- **Ketoacidosis** results from the generation of large quantities of ketone bodies during the postabsorptive state of metabolism. Ketoacidosis is a problem in starvation, and a potentially lethal complication of poorly controlled diabetes mellitus. In either case, peripheral tissues cannot obtain adequate glucose from the bloodstream and they begin metabolizing lipids and ketone bodies.

Figure 27–16 Responses to Metabolic Acidosis.



? How do the lungs respond to metabolic acidosis?

- A less common cause of metabolic acidosis is an impaired ability to excrete H^+ by the kidneys (see Figure 27–16a). For example, conditions marked by severe kidney damage, such as *glomerulonephritis*, typically result in severe metabolic acidosis. ↺ p. 984 Diuretics that "turn off" the sodium–hydrogen transport system in the kidney tubules also cause metabolic acidosis. The secretion of H^+ is linked to the reabsorption of Na^+. When Na^+ reabsorption stops, so does H^+ secretion.
- Metabolic acidosis occurs after severe bicarbonate ion loss (Figure 27–16b). The carbonic acid–bicarbonate ion buffer system relies on bicarbonate ions to balance hydrogen ions that threaten pH balance. A decrease in the HCO_3^- concentration in the ECF makes this buffer system less effective, and acidosis soon develops. The most common cause of HCO_3^- depletion is chronic diarrhea. Under normal conditions, most of the HCO_3^- secreted into the digestive tract in pancreatic, hepatic, and mucous secretions are reabsorbed before the feces are eliminated. In diarrhea, these HCO_3^- are lost, so the HCO_3^- concentration of the ECF decreases.

The nature of the problem must be understood before treatment can begin. In some cases, the diagnosis is straightforward. For example, a patient with metabolic acidosis after a bicycle race probably has lactic acidosis. In other cases, potential causes are so varied that clinicians must piece together relevant clues to make a diagnosis.

Compensation for metabolic acidosis generally involves a combination of respiratory and renal mechanisms. Hydrogen ions interacting with bicarbonate ions form CO_2 molecules that are eliminated by the lungs. The kidneys excrete additional H^+ into the urine and generate HCO_3^- that are released into the ECF.

Metabolic Alkalosis

Metabolic alkalosis occurs when the HCO_3^- concentration is elevated (Figure 27–17). The HCO_3^- then interact with H^+ in solution, forming H_2CO_3. The resulting decrease in H^+ concentration causes signs of alkalosis.

Metabolic alkalosis is rare, but we noted one interesting cause in Chapter 24. ↺ p. 904 The phenomenon known as the *alkaline tide* is due to the influx into the ECF of large numbers of bicarbonate ions associated with the secretion of H^+ and Cl^- by the gastric mucosa. The alkaline tide temporarily increases the HCO_3^- concentration in the ECF during meals. But bouts of repeated vomiting may bring on serious metabolic alkalosis, because the stomach continues to generate stomach acids to replace those that are lost. As a result, the HCO_3^- concentration of the ECF continues to increase.

Compensation for metabolic alkalosis involves a decrease in the breathing rate, coupled with an increased loss of HCO_3^- in urine. Treatment of mild cases typically addresses the primary cause—generally by controlling the vomiting—and may involve administering solutions that contain sodium chloride (NaCl) or potassium chloride (KCl).

Figure 27–17 Responses to Metabolic Alkalosis. Metabolic alkalosis most commonly results from the loss of acids, especially stomach acid lost through vomiting. As replacement gastric acid is produced, the alkaline tide introduces many bicarbonate ions into the bloodstream, so pH increases.

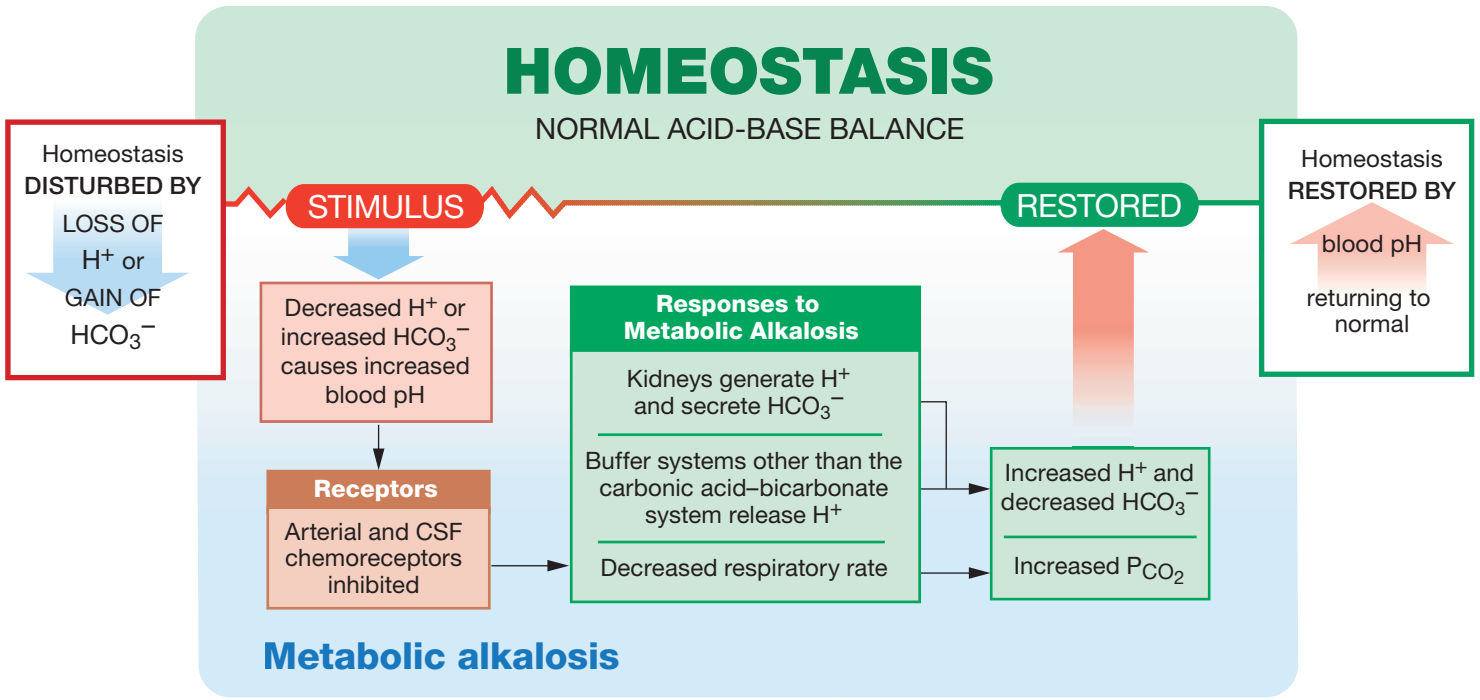


Table 27–4 Changes in Blood Chemistry Associated with the Major Classes of Acid-Base Disorders

Disorder	pH (normal 7.35–7.45)	HCO_3^- (mEq/L) (normal = 21–28)	P_{CO_2} (mm Hg) (normal = 35–45)	Remarks	Treatments
Respiratory acidosis	Decreased (below 7.35)	Acute: normal Compensated: increased (above 28)	Increased (above 45)	Generally caused by hypoventilation and CO_2 buildup in tissues and blood	Improve ventilation; in some cases, with bronchodilation and mechanical assistance
Metabolic acidosis	Decreased (below 7.35)	Decreased (below 24)	Acute: normal Compensated: decreased (below 35)	Caused by buildup of metabolic or fixed acid, impaired H^+ elimination at kidneys, or HCO_3^- loss in urine or feces	Administration of bicarbonate (gradual), with other steps as needed to correct primary cause
Respiratory alkalosis	Increased (above 7.45)	Acute: normal Compensated: decreased (below 24)	Decreased (below 35)	Generally caused by hyperventilation and reduction in plasma CO_2 levels	Reduce respiratory rate, allow rise in P_{CO_2}
Metabolic alkalosis	Increased (above 7.45)	Increased (above 28)	Increased (above 45)	Generally caused by prolonged vomiting and associated acid loss	pH below 7.55: no treatment; pH above 7.55: may require administration of NH_4Cl

Treatment of acute cases of metabolic alkalosis may involve administering ammonium chloride (NH_4Cl). Metabolism of the ammonium ion in the liver liberates an H^+, so in effect the introduction of NH_4Cl leads to the internal generation of H^+ and Cl^-. As the H^+ diffuses into the bloodstream, the pH falls toward a normal level.

For a summary of the patterns that characterize the four major categories of acid-base disorders, please see **Table 27–4**.

Combined Respiratory and Metabolic Acidosis

Respiratory acidosis and metabolic acidosis are typically linked, because oxygen-starved tissues generate large quantities of lactic acid (lactate and H^+) and because sustained hypoventilation leads to decreased arterial P_{O_2}. The problem can be especially serious in cases of near drowning, in which body fluids have high P_{CO_2}, low P_{O_2}, and a large amount of lactic acid generated by the muscles of the struggling person. Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance, coupled with intravenous infusion of an isotonic solution that contains sodium lactate, sodium gluconate, or sodium bicarbonate.

The Detection of Acidosis and Alkalosis

Spotlight Figure 27–18 shows the process of diagnosing acid-base disorders. Additional steps can help in identifying possible causes of the problem and in distinguishing compensated from uncompensated conditions. These steps may include determining the *anion gap* or using a diagnostic chart.

Checkpoint

15. **How would a prolonged fast affect the body's pH?**
16. **Why can prolonged vomiting produce metabolic alkalosis?**

See the blue Answers tab at the back of the book.

27-7 Aging affects fluid, electrolyte, and acid-base balance

Learning Outcome Describe the effects of aging on fluid, electrolyte, and acid-base balance.

Fetuses and infants have very different requirements for maintaining fluid, electrolyte, and acid-base balance than do adults. A fetus obtains the water, organic nutrients, and electrolytes it needs from the maternal bloodstream. Buffers in the fetal bloodstream provide short-term pH control, and the maternal kidneys eliminate the H^+ generated. A newborn's body water content is high: At birth, water makes up about 75 percent of body weight, compared with 50–60 percent in adults. Basic aspects of electrolyte balance are the same in newborns as in adults, but the effects of fluctuations in the diet are much more immediate in newborns because their reserves of minerals and energy sources are much smaller.

The descriptions of fluid, electrolyte, and acid-base balance in this chapter were based on the responses of healthy adults under age 40. Aging affects many aspects of fluid, electrolyte, and acid-base balance, including the following:

- Total body water content gradually decreases with age. Between ages 40 and 60, average total body water content declines slightly, to 55 percent for males and 47 percent for females. After age 60, the values decline further, to about 50 percent for males and 45 percent for females. Among other effects, each decrease reduces the dilution of wastes, toxins, and any drugs that have been administered.
- A decrease in the glomerular filtration rate and in the number of functional nephrons reduces the body's ability to regulate pH through renal compensation.
- The body's ability to concentrate urine declines, so more water is lost in urine. In addition, the rate of insensible perspiration increases as the skin becomes thinner and more delicate. Maintaining fluid balance therefore requires a

SPOTLIGHT

Figure 27–18
The Diagnosis of Acid-Base Disorders

ACID-BASE DISORDERS

Virtually anyone who has a problem that affects the cardiovascular, respiratory, urinary, digestive, or nervous system may develop potentially dangerous acid-base imbalances. For this reason, an arterial blood gas test is done to evaluate the body's acid-base balance. Standard tests measure arterial blood pH, partial pressure of carbon dioxide (P_{CO_2}), partial pressure of oxygen (P_{O_2}), and bicarbonate (HCO_3^-) levels. These measurements make diagnosing acid-base disorders relatively straightforward. The flowchart below shows the diagnostic steps used to determine whether a person has an acid-base disorder, and to further determine what type of acidosis or alkalosis exists.

Suspected Acid-Base Disorder

Check pH

Acidosis pH <7.35 (acidemia)

Check P_{CO_2}

Metabolic Acidosis

P_{CO_2} normal or decreased

*Check anion gap**

Acute Metabolic Acidosis

P_{CO_2} normal

Chronic (compensated) Metabolic Acidosis

P_{CO_2} decreased (<35 mm Hg)

Reduction due to respiratory compensation

Normal

Due to loss of HCO_3^- or to generation or ingestion of HCl

Example
- diarrhea

Increased

Due to generation or retention of metabolic or fixed acids

Examples
- lactic acidosis
- ketoacidosis
- chronic renal failure

Respiratory Acidosis

P_{CO_2} increased (>50 mm Hg)

Primary cause is hypoventilation

Check HCO_3^-

Chronic (compensated) Respiratory Acidosis

HCO_3^- increased (>28 mEq/L)

Examples
- emphysema
- asthma

Acute Respiratory Acidosis

HCO_3^- normal

Examples
- respiratory failure
- CNS damage
- pneumothorax

*The anion gap is defined as:
Na^+ concentration – (HCO_3^- concentration + Cl^- concentration)

Alkalosis pH >7.45 (alkalemia)

Check P_{CO_2}

Metabolic Alkalosis

P_{CO_2} increased (>45 mm Hg)

(HCO_3^- will be elevated)

Examples
- vomiting
- loss of gastric acid

Respiratory Alkalosis

P_{CO_2} decreased (<35 mm Hg)

Primary cause is hyperventilation

Check HCO_3^-

Acute Respiratory Alkalosis

Normal or slight decrease in HCO_3^-

Examples
- fever
- panic attacks

Chronic (compensated) Respiratory Alkalosis

Decreased HCO_3^- (<24 mEq/L)

Examples
- anemia
- CNS damage

higher daily water intake. A reduction in ADH and aldosterone sensitivity makes older people less able than younger people to conserve body water when losses exceed gains.

- Many people over age 60 experience a net loss in body mineral content as muscle mass and skeletal mass decrease. This loss can be prevented, at least in part, by a combination of exercise and an increased dietary mineral supply.
- The reduction in vital capacity that accompanies aging reduces the body's ability to perform respiratory compensation, increasing the risk of respiratory acidosis. This problem can be compounded by arthritis, which can reduce vital capacity by limiting rib movements, and by emphysema, another condition that, to some degree, develops with aging.
- Disorders affecting major systems become more common with increasing age. Most, if not all, of these disorders have some effect on fluid, electrolyte, and/or acid-base balance.

Checkpoint

17. **As a person ages, the glomerular filtration rate and the number of functional nephrons decreases. What effect would these changes have on pH regulation?**
18. **After the age of 40, does the total body water content increase or decrease?**

See the blue Answers tab at the back of the book.

27 Chapter Review

Study Outline

An Introduction to Fluid, Electrolyte, and Acid-base Balance p. 1022

1. The distribution of gases, nutrients, and wastes in the body are dependent on the homeostatic mechanisms that regulate volume, ion concentrations, and pH of body fluids.

27-1 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis p. 1022

2. Maintaining normal volume and composition of extracellular and intracellular fluids is vital to life. Three types of homeostasis are involved: **fluid balance**, **electrolyte balance**, and **acid-base balance**.

27-2 Extracellular fluid (ECF) and intracellular fluid (ICF) are fluid compartments with differing solute concentrations that are closely regulated p. 1023

3. The **intracellular fluid (ICF)** contains nearly two-thirds of the total body water. The **extracellular fluid (ECF)** contains the rest. Exchange occurs between the ICF and the ECF, but the two **fluid compartments** retain their distinctive characteristics. *(Figures 27–1, 27–2)*
4. Homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF.
5. No receptors directly monitor fluid or electrolyte balance. Receptors involved in fluid balance and in electrolyte balance respond to changes in plasma volume and osmotic concentration.
6. Body cells cannot move water molecules by active transport. All movements of water across plasma membranes and epithelia occur passively, in response to osmotic gradients.
7. The body's content of water or electrolytes will increase if intake exceeds outflow and will decrease if losses exceed gains.

8. ADH promotes water reabsorption by the kidneys and stimulates thirst. Aldosterone increases the rate of sodium reabsorption by the kidneys. Natriuretic peptides (ANP and BNP) oppose those actions and promote fluid and electrolyte losses in urine.
9. The regulatory mechanisms of fluid balance and electrolyte balance are quite different, and the distinction is clinically important.

27-3 Fluid balance involves the regulation and distribution of water gains and losses p. 1027

10. Water circulates freely within the ECF compartment.
11. Water losses are normally balanced by gains through eating, drinking, and **metabolic generation**. *(Figure 27–3; Table 27–1)*
12. Water movement between the ECF and ICF is called a **fluid shift**. If the ECF becomes hypertonic relative to the ICF, water will move from the ICF into the ECF until osmotic equilibrium has been restored. If the ECF becomes hypotonic relative to the ICF, water will move from the ECF into the cells, and the volume of the ICF will increase. *(Figure 27–4)*

27-4 In electrolyte balance, the concentrations of sodium, potassium, calcium, magnesium, phosphate, and chloride ions in body fluids are tightly regulated p. 1030

13. An **equivalent** (Eq) is the amount of a positive ion or negative ion that supplies 1 mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq).

14. Problems with electrolyte balance generally result from a mismatch between gains and losses of sodium. Problems with potassium balance are less common, but more dangerous.
15. The rate of sodium uptake across the digestive epithelium is directly proportional to the amount of sodium in the diet. Sodium losses occur mainly in urine and through perspiration. *(Figure 27–5)*
16. Shifts in sodium balance result in expansion or contraction of the ECF. Large variations in ECF volume are corrected by homeostatic mechanisms triggered by changes in blood volume. If the volume becomes too low, ADH and aldosterone are secreted; if the volume becomes too high, natriuretic peptides (ANP and BNP) are secreted. *(Figure 27–6)*
17. Potassium ion concentrations in the ECF are very low and not as closely regulated as are sodium ion concentrations. Potassium excretion increases as ECF concentrations rise, under aldosterone stimulation, and when the pH increases. Potassium retention occurs when the pH decreases. *(Figure 27–7)*
18. ECF concentrations of other electrolytes, such as calcium, magnesium, phosphate, and chloride, are also regulated. *(Table 27–2)*

27-5 In acid-base balance, buffer systems as well as respiratory and renal compensation regulate pH changes in body fluids p. 1036

19. Acids and bases are either **strong** or **weak**. *(Table 27–3)*
20. The pH of normal body fluids ranges from 7.35 to 7.45. Variations outside this relatively narrow range produce symptoms of **acidosis** or **alkalosis**.
21. **Volatile acids** can leave solution and enter the atmosphere. **Fixed acids** remain in body fluids until excreted by the kidneys. **Metabolic acids** are participants in, or are by-products of, cellular metabolism. *(Figure 27–8)*
22. Carbonic acid, a volatile acid, is the most important factor affecting the pH of the ECF. In solution, CO_2 reacts with water to form carbonic acid. An inverse relationship exists between pH and the partial pressure of CO_2. *(Figure 27–9)*
23. Sulfuric acid and phosphoric acid, the most important fixed acids, are generated during the catabolism of amino acids and compounds containing phosphate groups.
24. Metabolic acids include metabolic products such as lactic acid and ketone bodies.
25. A **buffer system** typically consists of a weak acid and the anion released by its dissociation. The anion functions as a weak base that can absorb H^+. The three major buffer systems are (1) the **phosphate buffer system** in the ICF and urine; (2) **protein buffer systems** in the ECF and ICF; and (3) the **carbonic acid–bicarbonate buffer system**, most important in the ECF. *(Figure 27–10)*
26. The phosphate buffer system plays a supporting role in regulating the pH of the ECF, but it is important in buffering the pH of the ICF and of urine.
27. In protein buffer systems, the initial, final, and R groups of component amino acids respond to changes in pH by accepting or releasing hydrogen ions. The **hemoglobin buffer system** is a protein buffer system that helps prevent drastic changes in pH when the P_{CO_2} is increasing or decreasing. *(Figure 27–11)*
28. The carbonic acid–bicarbonate buffer system prevents pH changes caused by metabolic acids and fixed acids in the ECF. The readily available supply of bicarbonate ions is the **bicarbonate reserve**. *(Figure 27–12)*
29. The lungs help regulate pH by affecting the carbonic acid–bicarbonate buffer system. A change in respiratory rate can raise or lower the P_{CO_2} of body fluids, affecting the body's buffering capacity. This process is called **respiratory compensation**.
30. In **renal compensation**, the kidneys vary their rates of hydrogen ion secretion and bicarbonate ion reabsorption, depending on the pH of the ECF. *(Figure 27–13)*

27-6 Disorders of acid-base balance can be classified as respiratory or metabolic p. 1042

31. Interactions among buffer systems, respiration, and renal function normally maintain tight control of the pH of the ECF, generally within a range of 7.35–7.45. *(Figure 27–14)*
32. *Respiratory acid-base disorders* result when abnormal respiratory function causes an extreme increase or decrease in CO_2 levels in the ECF. *Metabolic acid-base disorders* are caused by the generation of metabolic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF.
33. **Respiratory acidosis** results from excessive levels of CO_2 in body fluids. *(Figure 27–15a)*
34. **Respiratory alkalosis** is a relatively rare condition associated with hyperventilation. *(Figure 27–15b)*
35. **Metabolic acidosis** results from the depletion of the bicarbonate reserve, caused by an inability to excrete hydrogen ions by the kidneys, the production of large numbers of fixed and metabolic acids, or bicarbonate loss that accompanies chronic diarrhea. *(Figure 27–16)*
36. **Metabolic alkalosis** results when bicarbonate ion concentrations become elevated, as occurs during extended periods of vomiting. *(Figure 27–17)*
37. An arterial blood gas test evaluates blood pH, P_{CO_2}, P_{O_2}, and HCO_3^- levels to recognize and classify acidosis and alkalosis as either respiratory or metabolic in nature. *(Spotlight Figure 27–18; Table 27–4)*

27-7 Aging affects fluid, electrolyte, and acid-base balance p. 1049

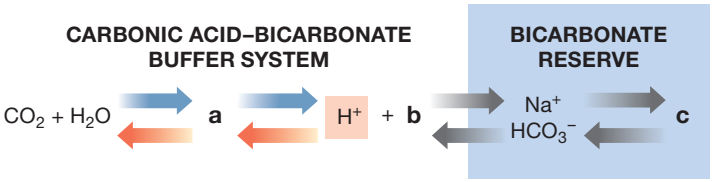
38. Age-related changes that affect fluid, electrolyte, and acid-base balance include (1) reduced total body water content, (2) impaired ability to perform renal compensation, (3) increased water demands due to decreased ability to concentrate urine and reduced sensitivity to ADH and aldosterone, (4) a net loss of minerals, (5) reductions in respiratory efficiency that affect respiratory compensation, and (6) increased incidence of conditions that secondarily affect fluid, electrolyte, or acid-base balance.

Review Questions

See the blue Answers tab at the back of the book.

LEVEL 1 Reviewing Facts and Terms

1. The primary components of the ECF are **(a)** lymph and cerebrospinal fluid, **(b)** plasma and serous fluids, **(c)** interstitial fluid and plasma, **(d)** all of these.
2. The principal anions in the ICF are **(a)** phosphate and proteins (Pr^-), **(b)** phosphate and bicarbonate, **(c)** sodium and chloride, **(d)** sodium and potassium.
3. Osmoreceptors in the hypothalamus monitor the osmotic concentration of the ECF and secrete _____ in response to higher osmotic concentrations. **(a)** BNP, **(b)** ANP, **(c)** aldosterone, **(d)** ADH.
4. Write the missing names and molecular formulas for the following reactions between the carbonic acid–bicarbonate buffer system and the bicarbonate reserve.



(a) _____
(b) _____
(c) _____

5. Calcium homeostasis primarily reflects **(a)** a balance between absorption in the gut and excretion by the kidneys, **(b)** careful regulation of the blood calcium level by the kidneys, **(c)** an interplay between parathyroid hormone and aldosterone, **(d)** an interplay among reserves in the bones, the rate of absorption, and the rate of excretion, **(e)** hormonal control of calcium reserves in the bones.
6. The *most* important factor affecting the pH of body tissues is the concentration of **(a)** lactic acid, **(b)** ketone bodies, **(c)** metabolic acids, **(d)** carbon dioxide, **(e)** hydrochloric acid.
7. Changes in the pH of body fluids are compensated for by all of the following *except* **(a)** an increase in urine output, **(b)** the carbonic acid–bicarbonate buffer system, **(c)** the phosphate buffer system, **(d)** changes in the rate and depth of breathing, **(e)** protein buffers.
8. Respiratory acidosis develops when the blood pH is **(a)** increased due to a decreased blood P_{CO_2} level, **(b)** decreased due to an increased blood P_{CO_2} level, **(c)** increased due to an increased blood P_{CO_2} level, **(d)** decreased due to a decreased blood P_{CO_2} level.
9. Metabolic alkalosis occurs when **(a)** bicarbonate ion concentrations become elevated, **(b)** a severe bicarbonate loss occurs, **(c)** the kidneys fail to excrete hydrogen ions, **(d)** ketone bodies are generated in abnormally large quantities.
10. Identify four hormones that mediate major physiological adjustments affecting fluid and electrolyte balance. What are the primary effects of each hormone?

LEVEL 2 Reviewing Concepts

11. Drinking a solution hypotonic to the ECF causes the ECF to **(a)** increase in volume and become hypertonic to the ICF, **(b)** decrease in volume and become hypertonic to the ICF, **(c)** decrease in volume and become hypotonic to the ICF, **(d)** increase in volume and become hypotonic to the ICF.
12. The osmotic concentration of the ECF decreases if an individual gains water without a corresponding **(a)** gain of electrolytes, **(b)** loss of water, **(c)** fluid shift from the ECF to the ICF, **(d)** all of these.
13. When the pH of body fluids begins to *decrease*, free amino acids and proteins will **(a)** release a hydrogen from the carboxyl group, **(b)** release a hydrogen from the amino group, **(c)** release a hydrogen at the carboxyl group, **(d)** bind a hydrogen at the amino group.
14. In a protein buffer system, if the pH increases, **(a)** the protein acquires a hydrogen ion from carbonic acid, **(b)** hydrogen ions are buffered by hemoglobin molecules, **(c)** a hydrogen ion is released and a carboxylate ion is formed, **(d)** a chloride shift occurs.
15. Differentiate among fluid balance, electrolyte balance, and acid-base balance, and explain why each is important to homeostasis.
16. What are fluid shifts? What is their function, and what factors can cause them?
17. Why should a person with a fever drink plenty of fluids?
18. Define and give an example of (a) a volatile acid, (b) a fixed acid, and (c) a metabolic acid. Which represents the greatest threat to acid-base balance? Why?
19. What are the three major buffer systems in body fluids? How does each system work?
20. How do respiratory and renal mechanisms support the buffer systems?
21. Differentiate between respiratory compensation and renal compensation.
22. Distinguish between respiratory and metabolic disorders that disturb acid-base balance.
23. What is the difference between metabolic acidosis and respiratory acidosis? What can cause these conditions?
24. The most recent advice from medical and nutritional experts is to monitor one's intake of salt so that it does not exceed the amount needed to maintain a constant ECF volume. What effect does excessive salt ingestion have on blood pressure?
25. Exercise physiologists recommend that adequate amounts of fluid be ingested before, during, and after exercise. Why is fluid replacement during extensive sweating important?

LEVEL 3 Critical Thinking and Clinical Applications

26. After falling into an abandoned stone quarry filled with water and nearly drowning, a young boy is rescued. In assessing his condition, rescuers find that his body fluids have high P_{CO_2} and lactate levels, and low P_{O_2} levels. Identify the underlying problem and recommend the necessary treatment to restore homeostatic conditions.
27. Dan has been lost in the desert for 2 days with very little water. As a result of this exposure, you would expect to observe which of the following? **(a)** increased ADH levels, **(b)** decreased blood osmolarity, **(c)** normal urine production, **(d)** increased blood volume, **(e)** cells enlarged with fluid.
28. Mary, a nursing student, has been caring for burn patients. She notices that they consistently show elevated levels of potassium in their urine and wonders why. What would you tell her?
29. While visiting a foreign country, Milly inadvertently drinks some water, even though she had been advised not to. She contracts an intestinal disease that causes severe diarrhea. How would you expect her condition to affect her blood pH, urine pH, and pattern of ventilation?
30. Yuka is dehydrated, so her physician prescribes intravenous fluids. The attending nurse becomes distracted and erroneously gives Yuka a hypertonic glucose solution instead of normal saline. What effect will this mistake have on Yuka's plasma ADH levels and urine volume?
31. Refer to the diagnostic flowchart in **Spotlight Figure 27–18**. Use information from the blood test results in the accompanying table to categorize the suspected acid-base disorders of the patients represented in the table.

Results	Patient 1	Patient 2	Patient 3	Patient 4
pH	7.5	7.2	7.0	7.7
P_{CO_2} (mm Hg)	32	45	60	50
Na^- (mEq/L)	138	140	140	136
HCO_3^- (mEq/L)	22	20	28	34
Cl^- (mEq/L)	106	102	101	91
Anion gap* (mEq/L)	10	18	12	11

*Anion gap = Na^+ concentration − (HCO_3^- concentration + Cl^- concentration).

CLINICAL CASE Wrap-Up When Treatment Makes You Worse

"You're having trouble with your potassium," the doctor tells Marquis.

Marquis had been in a state of electrolyte balance, in which the rates of gain and loss for each electrolyte are equal every day, but he had high blood pressure before beginning treatment. The hydrochlorothiazide diuretic he is taking works by inhibiting reabsorption of Na^+ and K^+ in the distal convoluted tubules. Recall that "water follows salt." The increased excretion of Na^+ and K^+ causes increased excretion of water, which reduces blood volume and therefore decreases pressure on the arterial walls. Ninety-eight percent of the body's K^+ is in the ICF, leaving only a small amount in the ECF that is critically controlled. The fecal loss of K^+ is usually negligible, but diarrhea causes significant K^+ loss. Three days of diarrhea, combined with the new "potassium-wasting" diuretic, have pushed Marquis into a state of hypokalemia. His blood K^+ measures only 2.5 mEq/L (normal 3.5–5.0 mEq/L).

Potassium ions are critical for a variety of cell functions, particularly in electrically active cells in the nervous system, skeletal muscle, and cardiac muscle. When the blood K^+ level is low, cells cannot repolarize and are unable to fire repeatedly. This causes muscle weakness, aching, and cramping. In cardiac muscle, hypokalemia increases the resting membrane potential and increases both the duration of the action potential and the duration of the refractory period, leading to cardiac arrhythmias.

1. How should Marquis's hypokalemia should be treated?
2. What is happening when Marquis complains of a sensation of a "frog jumping around" in his chest that is accompanied by dizziness?

See the blue Answers tab at the back of the book.

Related Clinical Terms

antacid: A substance used to counteract or neutralize stomach acid.

bicarbonate loading: In sports, the act of ingesting bicarbonates prior to an athletic event to neutralize acidic by-products produced during strenuous physical activity involving anaerobic metabolism.

enema: A procedure in which a liquid or gas is injected into the rectum, usually with the intention of having the rectum dispel its contents, but sometimes used as a way to introduce drugs or to permit x-ray imaging.

fluid replacement therapy: Procedure conducted with the intent to replace body fluids lost due to disease or restricted intake; or to maintain a higher-than-normal rate of fluid excretion to ensure the removal of toxins; or possibly to administer therapeutic or anesthetic agents slowly over time.

potassium adaptation: The tolerance to increasing amounts of potassium.

syndrome of inappropriate secretion of ADH (SIADH): A condition associated with excessive ADH secretion that results in the excretion of concentrated urine. It disturbs fluid and electrolyte balance, and causes nausea, vomiting, muscle cramps, confusion, and convulsions. This syndrome can occur with some forms of cancer, such as small cell lung cancer, pancreatic cancer, prostate cancer, and Hodgkin disease, and possibly due to a number of other disorders.

total body water: The sum of fluids within all compartments.

28 The Reproductive System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

28-1 ■ List the basic structures of the human reproductive system, and summarize the functions of each. p. 1056

28-2 ■ Describe the structures of the male reproductive system, and specify the composition of semen. p. 1057

28-3 ■ Explain the differences between meiosis and mitosis, describe the process of spermatogenesis, and summarize the hormonal mechanisms that regulate male reproductive functions. p. 1065

28-4 ■ Describe the anatomy and functions of the ovaries, the uterine tubes, the uterus, the vagina, and the structures of the female external genitalia. p. 1072

28-5 ■ Describe the ovarian roles in oogenesis, explain the complete ovarian and uterine cycles, and summarize all aspects of the female reproductive cycle. p. 1082

28-6 ■ Discuss the physiology of sexual intercourse in males and females. p. 1091

28-7 ■ Describe the reproductive system changes that occur with development and aging. p. 1093

28-8 ■ Give examples of interactions between the reproductive system and each of the other organ systems. p. 1096

CLINICAL CASE And Baby Makes Three?

The Millers long to have a baby. They are both 30 years old, have been married for 5 years, and have been trying desperately to get pregnant.

Susan waits and watches. Each time her period comes, her heart drops. Her period has never been like clockwork. Now she worries about the STD (sexually transmitted disease) she had in college. At that time, she was admitted to the infirmary with a high fever and pelvic pain. A course of antibiotics finally turned things around.

Her husband, Tim, rates his health as a "9" on a 10-point scale. He's a distance runner and clocks an average of 40 miles per week. He says exercise helps him manage the stress of his sales job. Neither of them drinks nor smokes. **When should this couple seek help for infertility? To find out, turn to the Clinical Case Wrap-Up on p. 1101.**

An Introduction to the Reproductive System

Approximately 7.4 billion people currently live on the Earth. This is an astonishing number given that our *reproductive system* is the only system that is not essential to the life of an individual. Its activities do, however, affect other systems and ensure continuation of our species. In this chapter we discuss how the male and female reproductive organs produce and store specialized reproductive cells called *gametes*. We also look at how various reproductive organs secrete hormones that play major roles in maintaining normal sexual function, allowing those gametes to come together to form new individuals.

28-1 Male and female reproductive system structures produce gametes that combine to form a new individual

Learning Outcome List the basic structures of the human reproductive system, and summarize the functions of each.

The human **reproductive system** ensures the continued existence of the human species—by producing, storing, nourishing, and transporting functional male and female reproductive cells. These cells are called **gametes** (GAM-ētes).

The reproductive system includes the following basic structures:

- **Gonads** (GŌ-nadz; *gone*, seed), reproductive organs that produce gametes and hormones
- Ducts that receive and transport the gametes
- Accessory glands and organs that secrete fluids into the reproductive system ducts or into other excretory ducts
- Perineal structures that are collectively known as the **external genitalia** (jen-ih-TĀ-lē-uh).

In both males and females, the ducts are connected to chambers and passageways that open to the outside. The structures involved make up the *reproductive tract*.

The male and female reproductive systems are functionally quite different, however. In adult males, the **testes** (TES-tēz; singular, *testis*), or *testicles*, are male gonads that secrete sex hormones called *androgens*. The main androgen is *testosterone*, which was introduced in Chapter 18. p. 644 The testes also produce the male gametes, called *sperm*. Males produce about one-half billion sperm each day. During *emission*, mature sperm travel along a lengthy duct system, where they are mixed with the secretions of accessory glands. The mixture created is known as *semen* (SĒ-men). During *ejaculation*, semen is expelled from the body.

In adult females, the **ovaries**, or female gonads, each month release only one immature gamete, called an **oocyte** (Ō-ō-sī-t). The ovaries also secrete female sex hormones, including *estrogens*. The released oocyte travels along one of two short *uterine tubes*, which end in the muscular organ called the *uterus* (YŪ-ter-us). A short passageway, the *vagina* (va-JĪ-nuh), connects the uterus with the exterior.

During *sexual intercourse*, ejaculation introduces semen into the vagina, and the sperm then ascend the female reproductive tract. If a sperm reaches the oocyte and starts the process of *fertilization*, the oocyte matures into an *ovum* (plural, *ova*). The uterus will then enclose and support the developing *embryo* as it grows into a *fetus* and prepares for birth (a process we cover in Chapter 29).

In this chapter we examine the anatomy of the male and female reproductive systems. We consider the physiological and hormonal mechanisms that regulate reproductive function. Earlier chapters introduced the anatomical reference points used in the discussions that follow. You may find it helpful to review the figures on the pelvic girdle (**Figures 8–7**, **8–8**, pp. 253, 254), perineal musculature (**Figure 11–13**, p. 360),

pelvic innervation (Figure 13–12, p. 450), and regional blood supply (Figures 21–24, 21–28, pp. 766, 771).

Checkpoint

1. Define *gamete*.
2. List the basic structures of the reproductive system.
3. Define *gonads*.

See the blue Answers tab at the back of the book.

28-2 The structures of the male reproductive system consist of the testes, duct system, accessory glands, and penis

Learning Outcome Describe the structures of the male reproductive system, and specify the composition of semen.

Figure 28–1 shows the main structures of the male reproductive system. Starting from a *testis*, the sperm travel within the male *reproductive duct system*, which consists of the *epididymis* (ep-ih-DID-ih-mus), the *ductus deferens* (DUK-tus DEF-eh-renz), and the *urethra* before leaving the body. Accessory glands—the *seminal* (SEM-i-nal) *glands*, the *prostate* (PROS-tāt), and the *bulbo-urethral* (bul-bō-yū-RĒ-thral) *gland*—secrete various fluids into the duct system. The *male external genitalia* consist of the *scrotum* (SKRŌ-tum), that encloses the testes, the urethra, and the *penis* (PĒ-nis), an erectile organ. The distal portion of the urethra passes through the penis. This section introduces the anatomy and basic functions of these structures.

The Testes and Associated Structures

Each testis is about 5 cm (2 in.) long, 3 cm (1.2 in.) wide, and 2.5 cm (1 in.) thick. Each weighs 10–15 g (0.35–0.53 oz). The testes hang within the **scrotum**, a fleshy pouch suspended inferior to the perineum. The scrotum is anterior to the anus, and posterior to the base of the penis (see Figure 28–1).

The Spermatic Cords

The **spermatic cords** are paired structures extending between the abdominopelvic cavity and the testes (Figure 28–2). Each spermatic cord begins at the entrance to the *inguinal canal* (a passageway through the abdominal musculature). After passing through the inguinal canal, the spermatic cord descends into the scrotum.

Figure 28–1 Sagittal Section of the Male Reproductive System. ATLAS: Plate 64

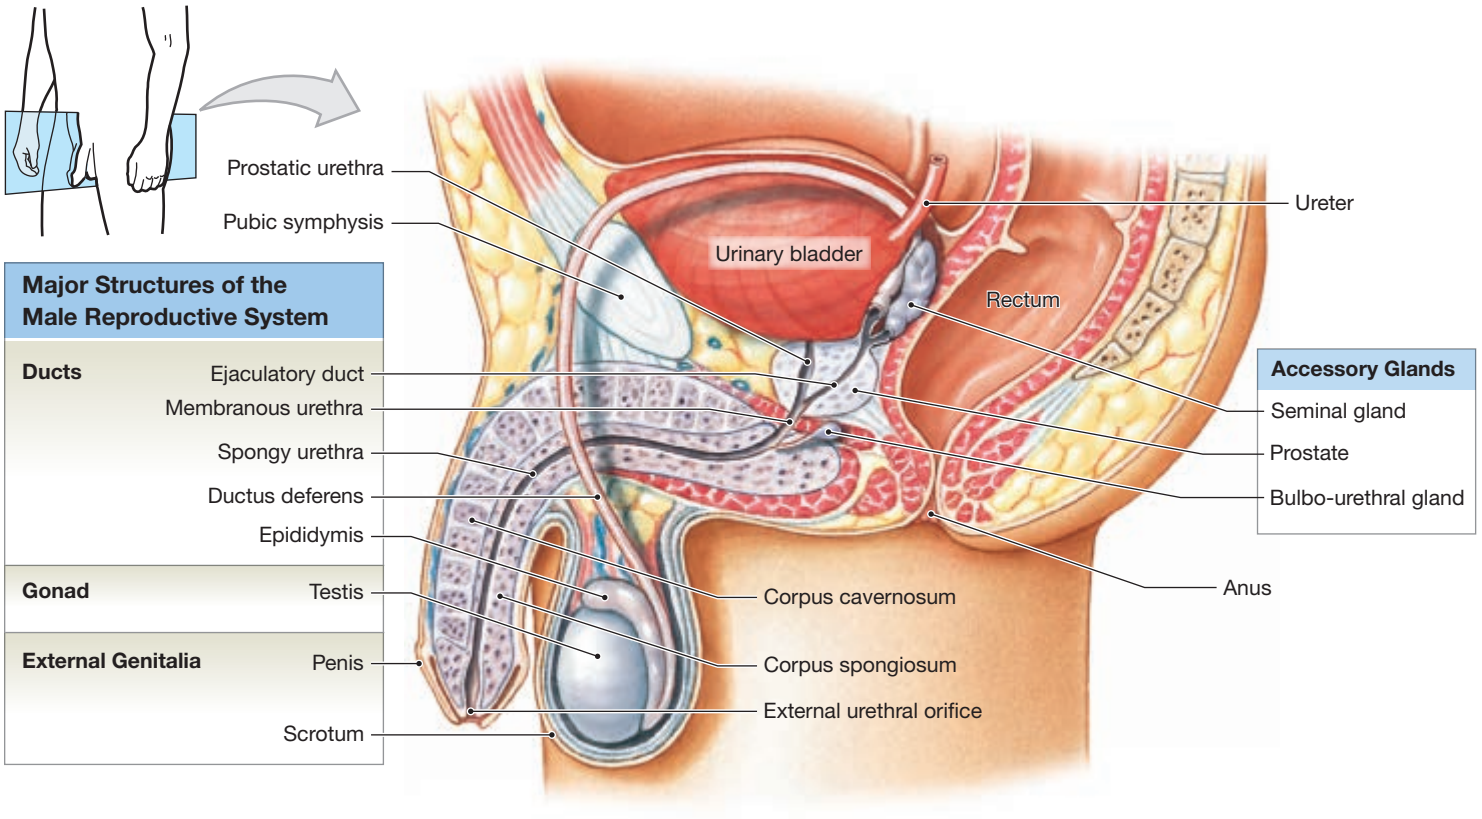


Figure 28–2 Anterior View of the Male Reproductive System. In the anatomical position, the penis is erect, and the dorsal surface is closest to the navel. When the penis is flaccid, its dorsal surface faces anteriorly.

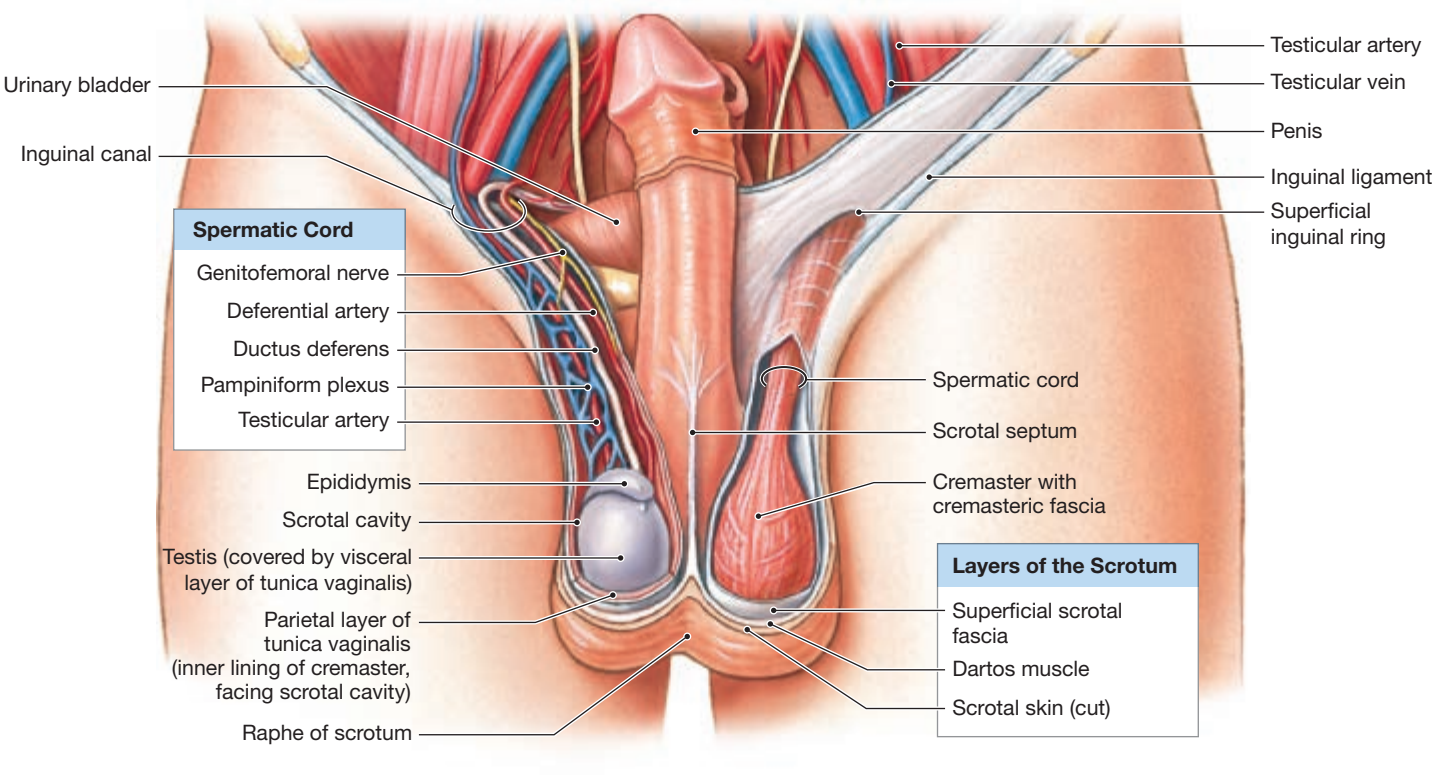

Each spermatic cord consists of layers of fascia and muscle enclosing the ductus deferens and the blood vessels, nerves, and lymphatic vessels that supply the testes. The blood vessels include the *deferential artery*, a *testicular artery*, and the **pampiniform** (pam-PIN-ih-form) **plexus** of a *testicular vein*. Branches of the *genitofemoral nerve* from the lumbar plexus provide innervation.

The inguinal canals form during development as the testes descend into the scrotum. At that time, these canals link the scrotal cavities with the peritoneal cavity. In normal adult males, the inguinal canals are closed, but the spermatic cords create weak points in the abdominal wall that remain throughout life. As a result, *inguinal hernias*—protrusions of visceral tissues or organs into the inguinal canal—are fairly common in males.

The Scrotum and the Position of the Testes

The scrotum is divided internally into two chambers. A raised thickening in the scrotal surface known as the **raphe** (RĀ-fē) **of scrotum** divides it in two (see Figure 28–2). Each testis lies in a separate chamber, or **scrotal cavity**. Because the scrotal cavities are separated by a partition, infection or inflammation of one testis does not normally spread to the other.

A narrow space separates the inner surface of the scrotum from the outer surface of the testis. The **tunica vaginalis** (TU-nih-ka vaj-ih-NAL-is), a serous membrane, lines the scrotal cavity and reduces friction between the opposing parietal (outer) layer and visceral (inner) layer (Figure 28–3a).

The scrotum consists of a thin layer of skin and the underlying superficial fascia. The dermis contains a layer of smooth muscle, the **dartos** (DAR-tōs) **muscle**. Resting muscle tone in the dartos muscle elevates the testes and causes wrinkling of the scrotal surface.

A layer of skeletal muscle, the **cremaster** (krē-MAS-ter), lies deep to the dermis. When the cremaster contracts during sexual arousal or in response to decreased temperature, it tenses the scrotum and pulls the testes closer to the body. The *cremasteric reflex* can be initiated by stroking the skin on the upper thigh, causing the scrotum to move the testes closer to the body.

For sperm to develop normally in the testes, the temperature must be about 1.1°C (2°F) lower than elsewhere in the body. The cremaster and dartos muscle relax or contract to move the testes away from or toward the body as needed to maintain acceptable testicular temperatures. When air or body temperature increases, these muscles relax and the testes move away from the body. When the scrotum cools suddenly,

a A transverse section of the scrotum and testes

b A section through a testis

as happens when jumping into a cold swimming pool, these muscles contract to pull the testes closer to the body and keep testicular temperatures from decreasing.

Gross Anatomy of the Testes

Deep to the tunica vaginalis covering the testis is the **tunica albuginea** (al-bū-JIN-ē-uh), a dense layer of connective tissue rich in collagen fibers (see Figure 28–3a). These fibers are continuous with those surrounding the adjacent epididymis and extend into the testis. There they form fibrous partitions, or *septa testis*, that converge toward the region nearest the entrance to the epididymis. The connective tissues in this region support the blood vessels and lymphatic vessels that supply and drain the testis, and the *efferent ductules*, which transport sperm to the epididymis.

Histology of the Testes

The septa testis subdivides the testis into a series of **lobules** (see Figure 28–3a). Distributed among the lobules are approximately 800 slender, tightly coiled **seminiferous** (sem-ih-NIF-er-us) **tubules** (Figure 28–3a,b). Each tubule averages about 80 cm (32 in.) in length. A typical testis contains nearly one-half mile of seminiferous tubules. Sperm production takes place within these tubules.

Each lobule contains several seminiferous tubules that merge into **straight tubules** that enter the mediastinum of the testis. Straight tubules are extensively interconnected, forming a maze of passageways called the **rete** (RĒ-tē; *rete*, a net) **testis** (see Figure 28–3a,b). Fifteen to 20 **efferent ductules** connect the rete testis to the epididymis.

Because the seminiferous tubules are tightly coiled, most tissue slides show them in transverse section (Figure 28–4a). A delicate connective tissue capsule surrounds each tubule, and areolar tissue fills the spaces between the tubules (Figure 28–4b). Within those spaces are numerous blood vessels and large **interstitial endocrine cells** (*Leydig cells*). Interstitial endocrine cells produce androgens (androsterone and testosterone), the dominant sex hormones in males. Testosterone is the most important androgen.

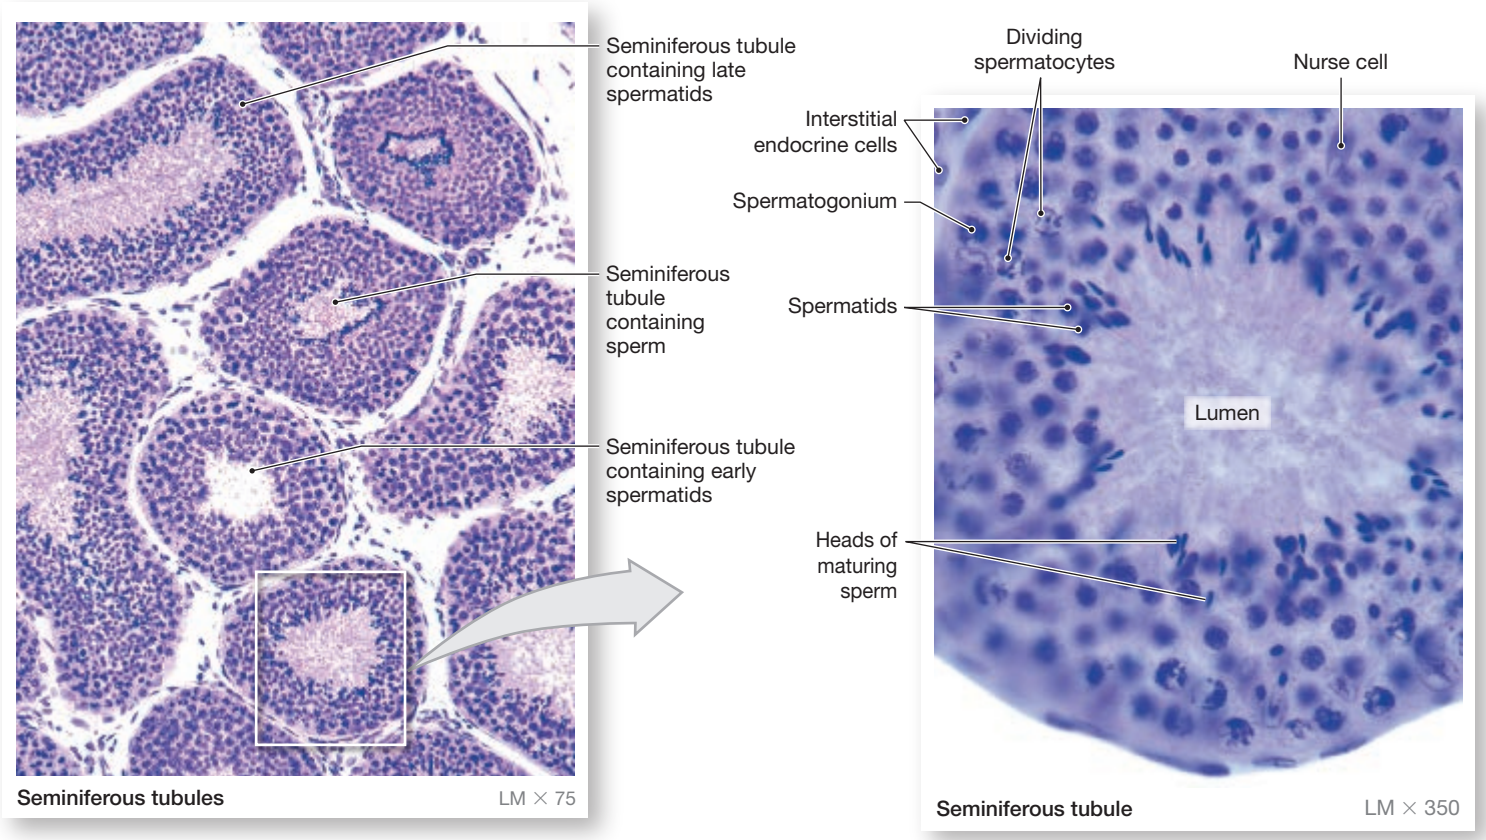
Functional Anatomy of the Male Reproductive Duct System

The testes produce sperm that are immobile and not yet capable of successfully fertilizing an oocyte. The male reproductive duct system is responsible for the functional maturation, nourishment, storage, and transport of sperm.

The Epididymis

These immobile sperm are transported into the epididymis by fluid currents created by the cilia that line the efferent ductules. The **epididymis** (ep-ih-DID-ih-mis; *epi*, on + *didymos*, twin) is the start of the male reproductive tract (Figure 28–5). It is a coiled tube bound to the posterior border of each testis.

Figure 28–4 Anatomy of the Seminiferous Tubules.



a A section through the seminiferous tubules.

b A cross section through a single tubule.

The epididymides (ep-ih-dih-DIM-ih-dēz) can be felt through the scrotal skin. Each epididymis is almost 7 m (23 ft) long, but it is coiled and twisted so it takes up very little space. It has a head, a body, and a tail (Figure 28–5a,c). The superior **head** is the largest part of the epididymis. The head receives sperm from the efferent ductules.

The **body** is the middle part that extends inferiorly from the head to the tail of the epididymis on the posterior surface of the testis. Near the inferior border of the testis, the number of coils decreases, marking the start of the **tail**. The tail re-curves, ascends, and connects to the ductus deferens. Sperm are stored primarily within the tail of the epididymis.

The epididymis has the following functions:

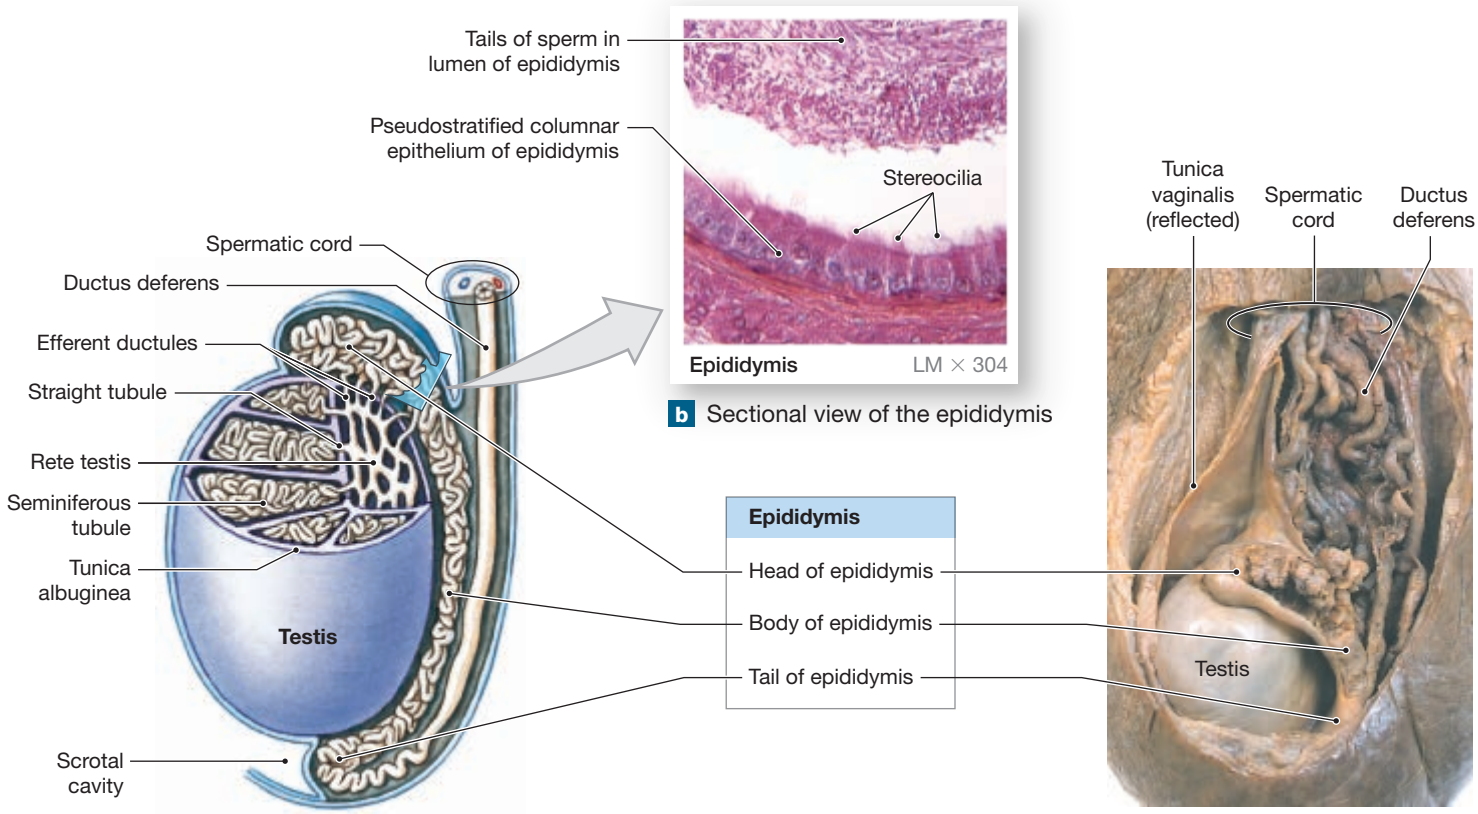
- *It monitors and adjusts the composition of the fluid produced by the seminiferous tubules.* The pseudostratified columnar epithelial lining of the epididymis has distinctive stereocilia (Figure 28–5b). These stereocilia increase the surface area available for absorption from, and secretion into, the fluid in the tubule.
- *It acts as a recycling center for damaged sperm.* Cellular debris and damaged sperm are absorbed in the epididymis. The products of enzymatic breakdown are released into the surrounding interstitial fluids for pickup by the epididymal blood vessels.
- *It stores and protects sperm and facilitates their functional maturation.* It takes up to 3 weeks for a sperm to pass through the epididymis and complete its functional maturation. During this time, sperm exist in a sheltered environment that is regulated by the surrounding epithelial cells.

Transport along the epididymis involves a combination of fluid movement and peristaltic contractions of smooth muscle in the epididymis. After passing along the tail of the epididymis, the sperm enter the ductus deferens.

The Ductus Deferens

Each **ductus deferens** (plural, *ductus deferentia*), also called the *vas deferens*, is 40–45 cm (16–18 in.) long. It begins at the tail of the epididymis (see Figure 28–5a,c). As part of the spermatic cord, it ascends through the inguinal canal (look back at Figure 28–2). Inside the abdominal cavity, the ductus deferens passes posteriorly, curving inferiorly along the lateral surface of the urinary bladder toward the superior and posterior margin

Figure 28–5 Anatomy of the Epididymis. ATLAS: Plate 60a



of the prostate (see Figure 28–6a). Just before the ductus deferens reaches the prostate and seminal glands, its lumen enlarges. This expanded portion is known as the **ampulla** (am-PUL-luh) **of ductus deferens**.

The wall of the ductus deferens contains a thick layer of smooth muscle (see Figure 28–6b). Peristaltic contractions in this layer propel sperm and fluid along the duct, which is lined by a pseudostratified ciliated columnar epithelium. In addition to transporting sperm, the ductus deferens can store sperm in the ampulla for several months. During this time, the sperm remain in a temporary state of inactivity with low metabolic rates.

The Male Urethra

In males, the **urethra** is a passageway that extends 18–20 cm (7–8 in.) from the urinary bladder to the tip of the penis. It is divided into *prostatic*, *membranous*, and *spongy* regions (Figures 28–1, 28–7b). The male urethra is used by both the urinary and reproductive systems. It conducts urine to the exterior and introduces semen into the female's vagina during sexual intercourse.

The Accessory Glands

The fluids secreted by the seminiferous tubules and the epididymis account for only about 5 percent of the volume of semen. The fluid component of semen is a mixture of secretions—each with distinctive biochemical characteristics—from many glands. Important glands include the *seminal glands*, the *prostate*, and the *bulbo-urethral glands*. All of these occur only in males.

Among the major functions of these glands are (1) activating sperm; (2) providing the nutrients sperm need for motility; (3) propelling sperm and fluids along the reproductive tract, mainly by peristaltic contractions; and (4) producing buffers that counteract the acidity of the urethral and vaginal environments.

The Seminal Glands (Seminal Vesicles)

The ductus deferens on each side ends at the junction between the ampulla of ductus deferens and the duct that drains the seminal gland (see Figure 28–6a). The **seminal glands**, also called the *seminal vesicles*, are tubular glands embedded in connective tissue on each side of the midline, sandwiched between the posterior

Figure 28–6 Anatomy of the Ductus Deferens and Accessory Glands.
