Increased capillary hydrostatic pressure is the most frequent cause of pulmonary edema and is often the result of an abnormally high pulmonary venous pressure (e.g., with mitral stenosis, left heart failure, or heart attack). The second major cause of pulmonary edema is *noncardiogenic* and is due to increased alveolar surface tension and/or increased permeability of the alveolar–capillary membrane. Both types of noncardiogenic result in excess fluid and plasma proteins flooding the interstitial spaces and alveoli. Protein leakage makes pulmonary edema more severe because additional water is pulled from the capillaries to the alveoli when plasma proteins enter the interstitial spaces and alveoli. Increased capillary permeability occurs with pulmonary vascular injury, usually from oxidant damage (e.g., oxygen therapy, ozone toxicity), an inflammatory reaction (endotoxins), or neurogenic shock (e.g., head injury). Loss of surfactant leads to high surface tension, which lowers the interstitial hydrostatic pressure with a concomitant increase in capillary fluid entering the interstitial space. Pulmonary edema is a hallmark of **acute respiratory distress syndrome** (**ARDS**) and is often associated with abnormally high surface tension. Pulmonary edema is a serious problem because excess fluid enters alveoli and hinders gas exchange, causing arterial PO_2 to fall below normal (i.e., PaO_2 <85 mm Hg) and arterial PCO_2 to rise above normal ($PaCO_2$ >45 mm Hg). As mentioned earlier, abnormally low arterial PO_2 produces hypoxemia and abnormally high arterial PCO_2 produces hypercapnia. Pulmonary edema can also flood small airways, thereby obstructing airflow and increasing airway resistance. Lung compliance is decreased with pulmonary edema because of interstitial swelling and the increase in alveolar surface tension. Decreased lung compliance, together with airway obstruction, greatly increases the work of breathing. The treatment of pulmonary edema is directed toward reducing pulmonary capillary hydrostatic pressure. This is accomplished by decreasing blood volume with a diuretic drug, increasing left ventricular function with digitalis, and administering a drug that causes vasodilation in systemic blood vessels.

Although freshwater drowning is often associated with aspiration of water into the lungs, the cause of death is not pulmonary edema but ventricular fibrillation. The low capillary pressure that normally keeps

the alveolar–capillary membrane free of excess fluid becomes a severe disadvantage when freshwater accidentally enters the lungs. The aspirated water is rapidly pulled into the pulmonary capillary circulation via the alveoli because of the low capillary hydrostatic pressure and high colloidal osmotic pressure. Consequently, the plasma is diluted and the hypotonic environment causes red cells to burst (hemolysis). The resulting elevation of plasma K^+ level and depression of Na^+ level alter the electrical activity of the heart. Ventricular fibrillation often occurs as a result of the combined effects of these electrolyte changes and hypoxemia. In saltwater drowning, the aspirated seawater is hypertonic, which leads to increased plasma Na^+ and pulmonary edema. The cause of death in this case is asphyxia.

CLINICAL FOCUS 20.2

Hypoxia-Induced Pulmonary Hypertension

Hypoxia has opposite effects on the pulmonary and systemic circulations. Hypoxia relaxes vascular smooth muscle in systemic vessels and elicits vasoconstriction in the pulmonary vasculature. Hypoxic pulmonary vasoconstriction is the major mechanism regulating the matching of regional blood flow to regional ventilation in the lungs. With regional hypoxia, the matching mechanism automatically adjusts regional pulmonary capillary blood flow in response to alveolar hypoxia and prevents blood from perfusing poorly ventilated regions in the lungs. Regional hypoxic vasoconstriction occurs without any change in pulmonary arterial pressure. However, when hypoxia affects all parts of the lung (generalized hypoxia), it causes pulmonary hypertension because all of the pulmonary vessels constrict. Hypoxia-induced pulmonary hypertension affects people who live at a high altitude (8,000 to 12,000 ft) and those with chronic obstructive pulmonary disease (COPD), especially patients with emphysema.

With chronic *hypoxia-induced pulmonary hypertension*, the pulmonary artery undergoes major remodeling during several days. An increase in wall thickness results from hypertrophy and hyperplasia of vascular smooth muscle and an increase in connective tissue. These structural changes occur in both large and small arteries. Also, there is abnormal extension of smooth muscle into peripheral pulmonary vessels, where muscularization is not normally present; this is especially pronounced in precapillary segments. These changes lead to a marked increase in pulmonary vascular resistance. With severe, chronic hypoxia-induced pulmonary hypertension, the obliteration of small pulmonary arteries and arterioles as well as pulmonary edema eventually occurs. The latter is caused, in part, by the hypoxia-induced vasoconstriction of pulmonary veins, which results in a significant increase in pulmonary capillary hydrostatic pressure.

A striking feature of the vascular remodeling is that both the pulmonary artery and the pulmonary vein constrict with hypoxia; however, only the arterial side undergoes major remodeling. The postcapillary segments and veins are spared the structural changes seen with hypoxia. Because of the hypoxia-induced vasoconstriction and vascular remodeling, pulmonary arterial pressure increases. Pulmonary hypertension eventually causes right heart hypertrophy and failure, the major cause of death in patients with COPD. ■

BLOOD FLOW DISTRIBUTION IN THE LUNGS

As mentioned previously, blood in the pulmonary vessels accounts for approximately half the weight of the lungs. The gravitational effect on pulmonary blood flow is dramatic and results in an uneven distribution of blood in the lungs. In an upright person, the gravitational pull on the blood is downward. Because the vessels are highly compliant, gravity causes the blood volume and flow to be greater at the bottom of the lung (the base) than at the top (the apex). Pulmonary vessels can be compared with a continuous column of fluid. The difference in arterial pressure between the apex and the base of the lungs is about 30 cm H_2O. Because the heart is situated midway between the top and the bottom of the lungs, the arterial pressure is about 11 mm Hg less (15 cm H_2O ÷ 1.36 cm H_2O per mm Hg = 11 mm Hg) at the lungs' apex (15 cm above the heart) and about 11 mm Hg more than the mean pressure in the middle of the lungs at the lungs' base (15 cm below the heart). As a result, the low pulmonary arterial pressure results in reduced blood flow in the capillaries at the lungs' apex, whereas capillaries at the base are distended because of increased pressure and blood flow is augmented.

Gravity causes lungs to be underperfused at the apex and overperfused at the base.

In an upright person, pulmonary blood flow decreases almost linearly from the base to the apex (Fig. 20.8). Blood flow distribution is affected by gravity and can be altered by changes in body positions. For example, when a person is lying down, blood flow is distributed relatively evenly from the base to the apex. The measurement of blood flow in a subject suspended upside down would reveal an apical blood flow exceeding basal flow in the lungs. Exercise tends to offset the gravitational effects in an upright person. As cardiac output increases with exercise, the increased pulmonary arterial pressure leads to capillary recruitment and distention in the lungs' apex, resulting in increased blood flow and minimizing regional differences in blood flow in the lungs.

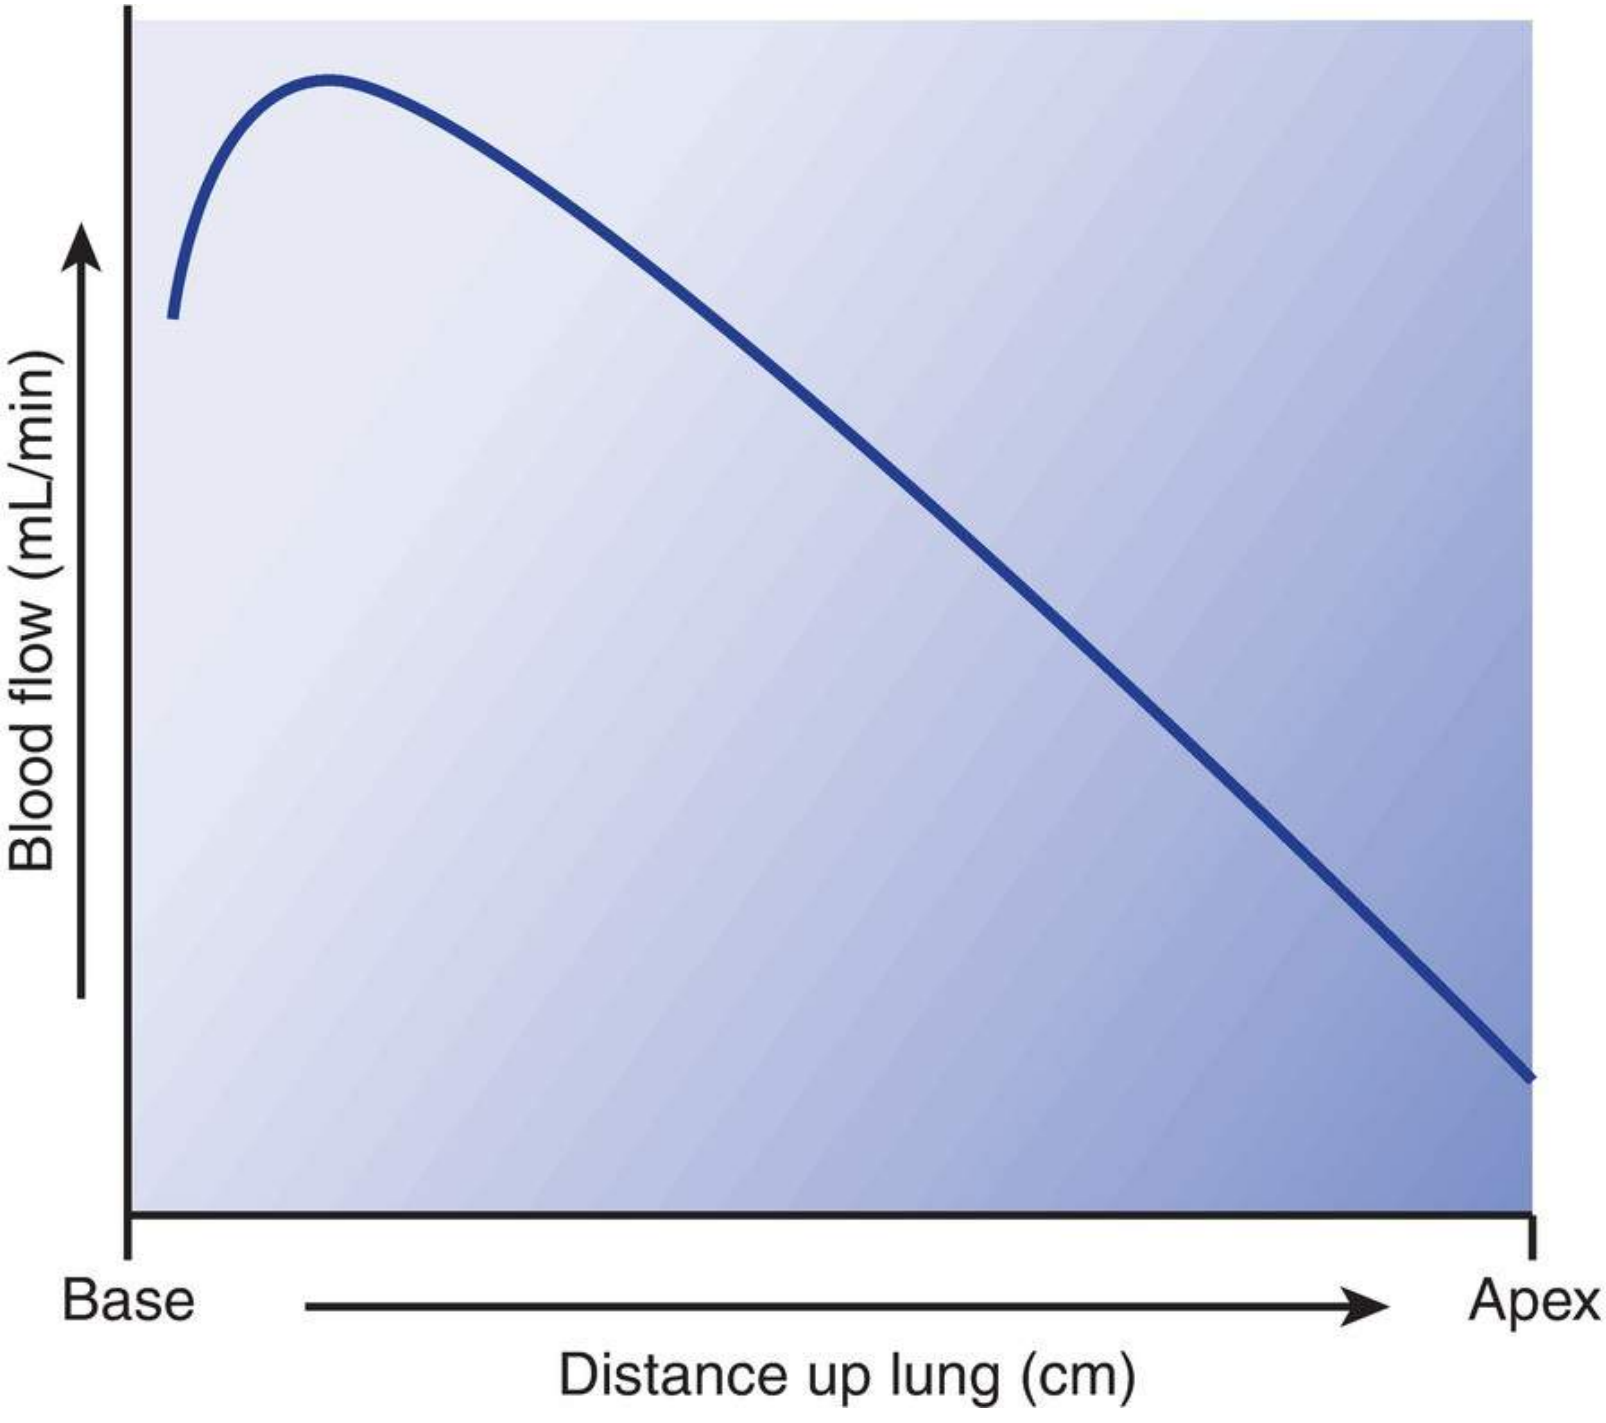

Figure 20.8 Gravity causes uneven pulmonary blood flow in the upright individual. The downward pull of gravity causes a lower blood pressure at the apex of the lungs. Consequently, pulmonary blood flow is low at the apex. Toward the base of the lungs, gravity has an added effect on blood pressure, causing an increase in blood flow.

Because gravity causes capillary beds to be underperfused in the apex and overperfused in the base, the lungs are often divided into zones to describe the effect of gravity on pulmonary capillary blood flow (Fig. 20.9). Zone 1 occurs when alveolar pressure is greater than pulmonary arterial pressure; pulmonary capillaries collapse and there is no blood flow. Pulmonary arterial pressure (Pa) is still greater than pulmonary venous pressure (Pv); hence, the pressure gradient in zone 1 is represented as PA > Pa > Pv. Zone 1 is usually small or nonexistent in healthy people because the pulsatile pulmonary arterial pressure is sufficient to keep the capillaries partially open at the apex. However, when zone 1 does occur, alveolar dead space is increased in the lungs. This occurs because, in zone 1, that region is still being ventilated but not perfused (no gas exchange). Zone 1 may easily be created by conditions that elevate alveolar pressure or decrease pulmonary arterial pressure. For example, a zone 1 condition can be created when a patient is placed on a mechanical ventilator, which results in an increase in alveolar pressure with positive ventilation pressures. Hemorrhage or low blood pressure can create a zone 1 condition by lowering pulmonary arterial pressure. A zone 1 condition can also be created in the lungs of astronauts during a spacecraft launching. The rocket acceleration makes the gravitational pull even greater, causing arterial pressure in the top part of the lung to fall. To prevent or minimize a zone 1 condition from occurring, astronauts are placed in a supine position during blastoff.

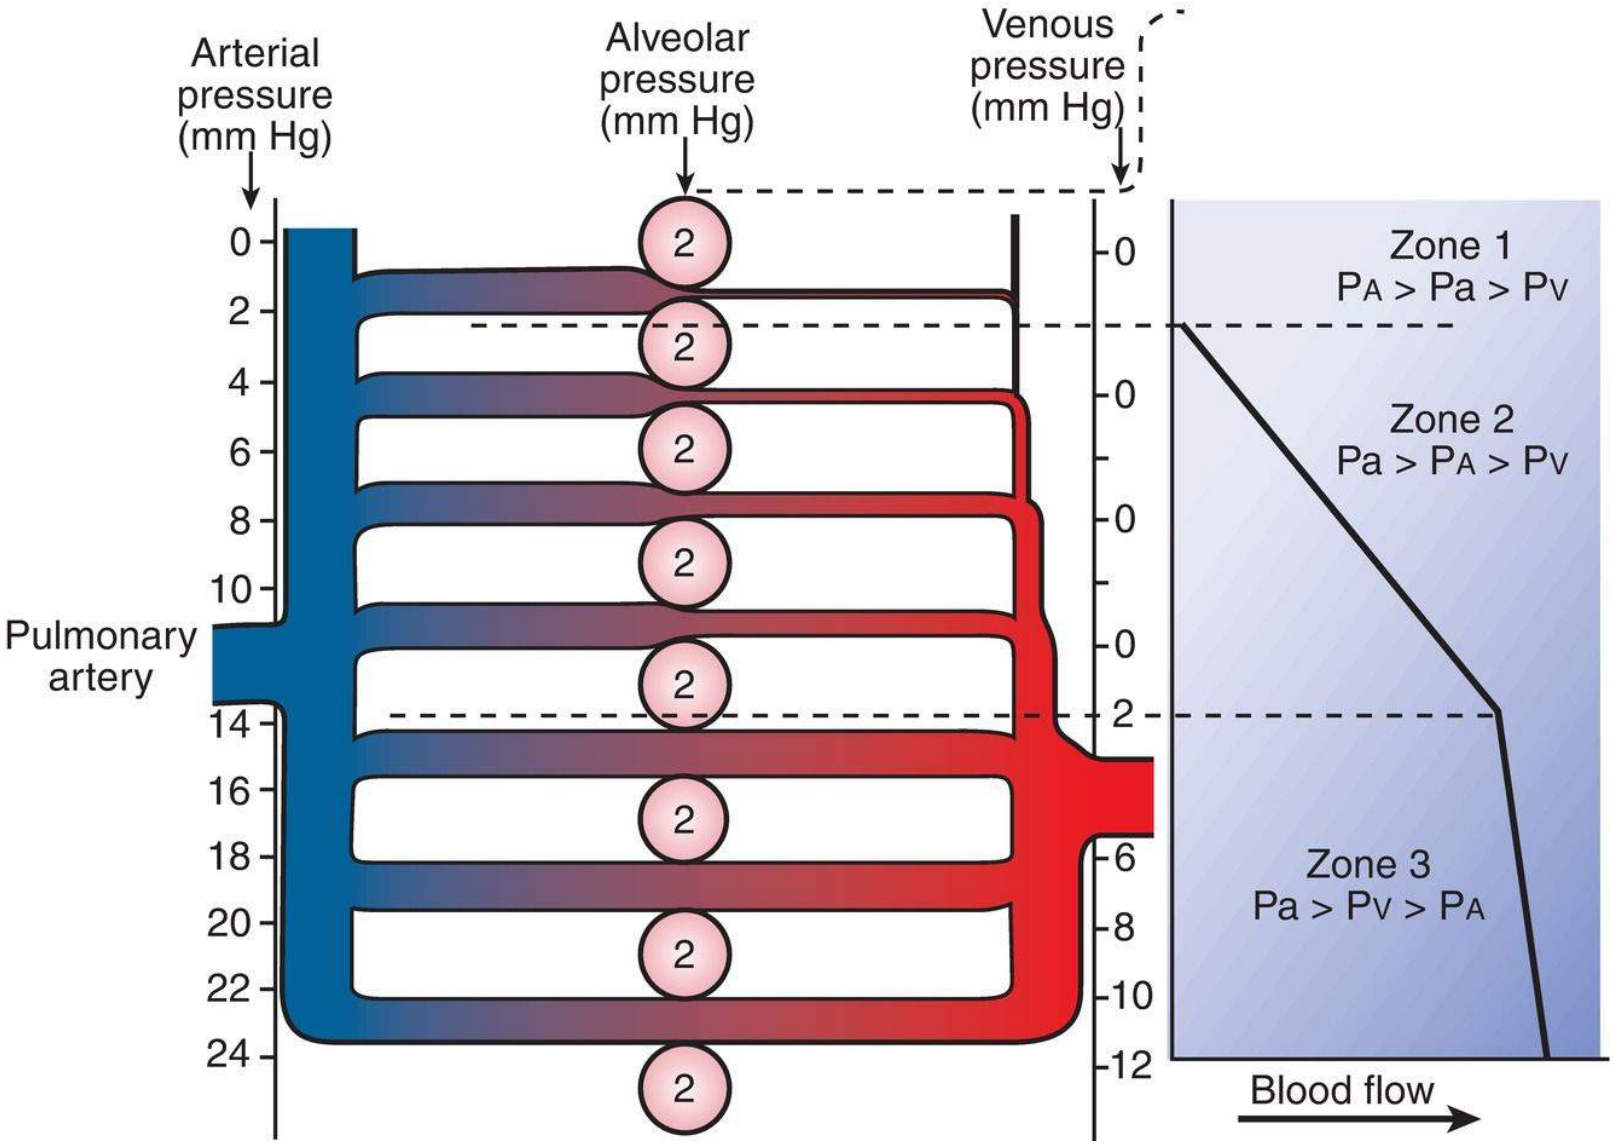

Figure 20.9 Zones are established as a result of gravitational effects. The three zones are established in an upright person and are dependent on the relationship between pulmonary arterial pressure (Pa), pulmonary venous pressure (PV), and alveolar pressure (PA). A zone 1 is established when alveolar pressure exceeds arterial pressure and there is no blood flow. Zone 1 occurs toward the apex of the lung and occurs only in abnormal conditions in which alveolar pressure is increased (e.g., positive pressure ventilation) or when arterial pressure is decreased below normal (e.g., the gravitational pull while standing at attention or during the launching of a spacecraft). A zone 2 is established when arterial pressure exceeds alveolar pressure, and blood flow depends on the difference between arterial and alveolar pressures. Blood flow is greater at the bottom than at the top of this zone. In zone 3, both arterial and venous pressures exceed alveolar pressure, and blood flow depends on the normal arterial–venous pressure difference. Note that arterial pressure increases down each zone, vessel transmural pressure also becomes greater, capillaries become more distended, and pulmonary vascular resistance falls.

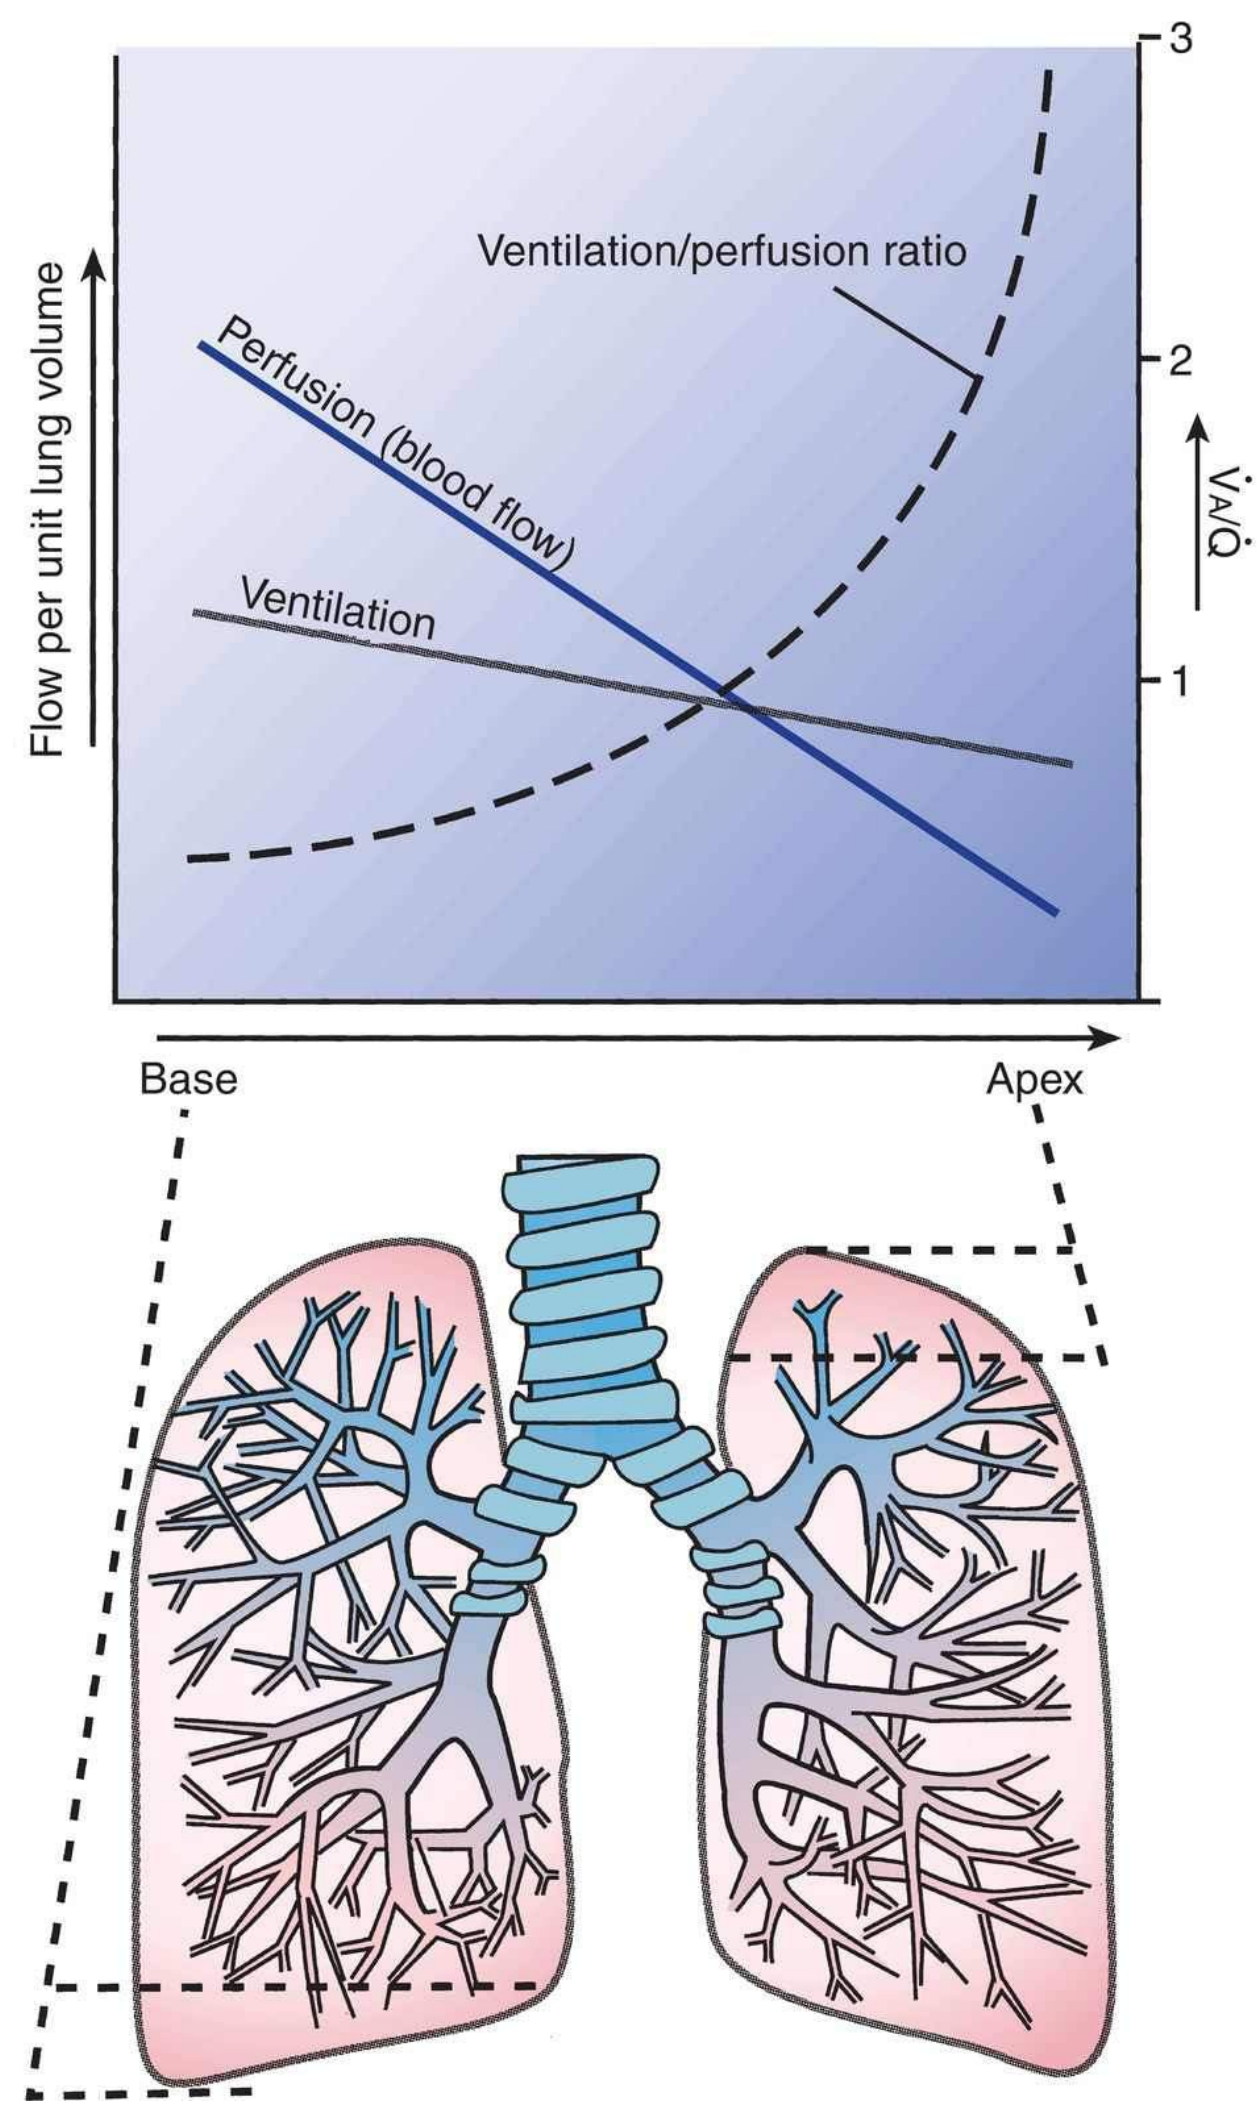
A zone 2 condition occurs in the middle of the lungs, where pulmonary arterial pressure, caused by the increased hydrostatic effect, is greater than alveolar pressure (see Fig. 20.9). Venous pressure is less than alveolar pressure. As a result, blood flow in a zone 2 condition is determined not by the arterial–venous pressure difference but by the difference between arterial pressure and alveolar pressure. The pressure gradient in zone 2 is represented as Pa > PA > Pv. The functional importance of this is that venous pressure in zone 2 has no effect on flow (i.e., lowering venous pressure will not increase capillary blood flow in this zone). In zone 3, venous pressure exceeds alveolar pressure and blood flow

is determined by the usual arterial–venous pressure difference. The increase in blood flow down this region is primarily a result of capillary distention.

Gravity causes a mismatch of regional ventilation and blood flow at the base and apex of the lungs.

Thus far, we have assumed that if ventilation and cardiac output are normal, gas exchange will also be normal because ventilation and blood flow are matched. Unfortunately, this is not the case. Even though total ventilation and total blood flow (i.e., cardiac output) may be normal, there are regions in the lung where ventilation and blood flow are not matched and so a certain fraction of the cardiac output is not fully oxygenated.

The matching of airflow and blood flow is best examined by considering the **ventilation/perfusion ratio** ($\dot{V}_A/\dot{Q}$ ratio), which compares alveolar ventilation with blood flow in lung regions. Because resting healthy people have an alveolar ventilation ($\dot{V}_A$) of 4 L/min and a cardiac output ($\dot{Q}$) of 5 L/min, the ideal alveolar ventilation/perfusion ratio ($\dot{V}_A/\dot{Q}$) should be 0.8 (there are no units, because this is a ratio). We have already seen that gravity can cause regional differences in blood flow and alveolar ventilation. In an upright person, the base of the lungs is better ventilated and better perfused than the apex. Regional alveolar ventilation and blood flow are illustrated in Figure 20.10. Three points are apparent from this figure:



Flow per unit lung volume
Ventilation/perfusion ratio
Perfusion (blood flow)
Ventilation
3
2
1
$\dot{V}_A/\dot{Q}$
Base
Apex

Figure 20.10 Gravity causes a mismatch of blood flow and ventilation in the lung. Both ventilation and perfusion are gravity dependent. At the base of the lungs, alveolar–capillary blood flow exceeds alveolar ventilation, resulting in a low ventilation/perfusion ($\dot{V}_A/\dot{Q}$) ratio. At the apex, the opposite occurs; alveolar ventilation is greater than capillary blood flow, resulting in a high ventilation/perfusion ($\dot{V}_A/\dot{Q}$) ratio.

- Ventilation and blood flow are both gravity dependent with airflow and blood flow increasing down the lung.
- There is a fivefold difference in blood flow between the top and the bottom of the lung, whereas ventilation shows about a twofold difference. This causes gravity-dependent regional variations in the $\dot{V}_A/\dot{Q}$ ratio, which range from 0.6 at the base to 3 or higher at the apex.
- Blood flow is proportionately greater than ventilation at the base, and ventilation is proportionately greater than blood flow at the apex.

The functional importance of lung ventilation/perfusion ratios is that the crucial factor in gas exchange is the matching of regional ventilation and blood flow, as opposed to total alveolar ventilation and total pulmonary blood flow. At the apical region, where the $\dot{V}_A/\dot{Q}$ ratio is >0.8, there is overventilation relative to blood flow. At the base, where the ratio is <0.8, the opposite occurs (i.e., overperfusion relative to ventilation). In the latter case in which blood flow exceeds alveolar ventilation, a fraction of the blood passes through the pulmonary capillaries at the base of the lungs without becoming fully oxygenated.

The effect of regional $\dot{V}_A/\dot{Q}$ ratio on blood gases is shown in Figure 20.11. At the apex, where the lungs are overventilated relative to blood flow, the PaO_2 is high, but the $PaCO_2$ is low in this region of the lungs. Oxygen tension (PO_2) in the blood leaving pulmonary capillaries at the base of the lungs is low because the blood is not fully oxygenated as a result of underventilation relative

to blood flow. Regional differences in ratios tend to localize some diseases to the top or bottom parts of the lungs. For example, tuberculosis tends to be localized in the apex because of a more favorable environment (i.e., higher oxygen levels for *Mycobacterium tuberculosis*).

$\dot{V}_A$ (L/min)	$\dot{Q}$ (L/min)	$\dot{V}_A / \dot{Q}$	Pao_2 (mm Hg)	$PaCO_2$ (mm Hg)	
0.25	0.07	3.6	130	28	Apex
0.8	1.3	0.6	88	42	Base

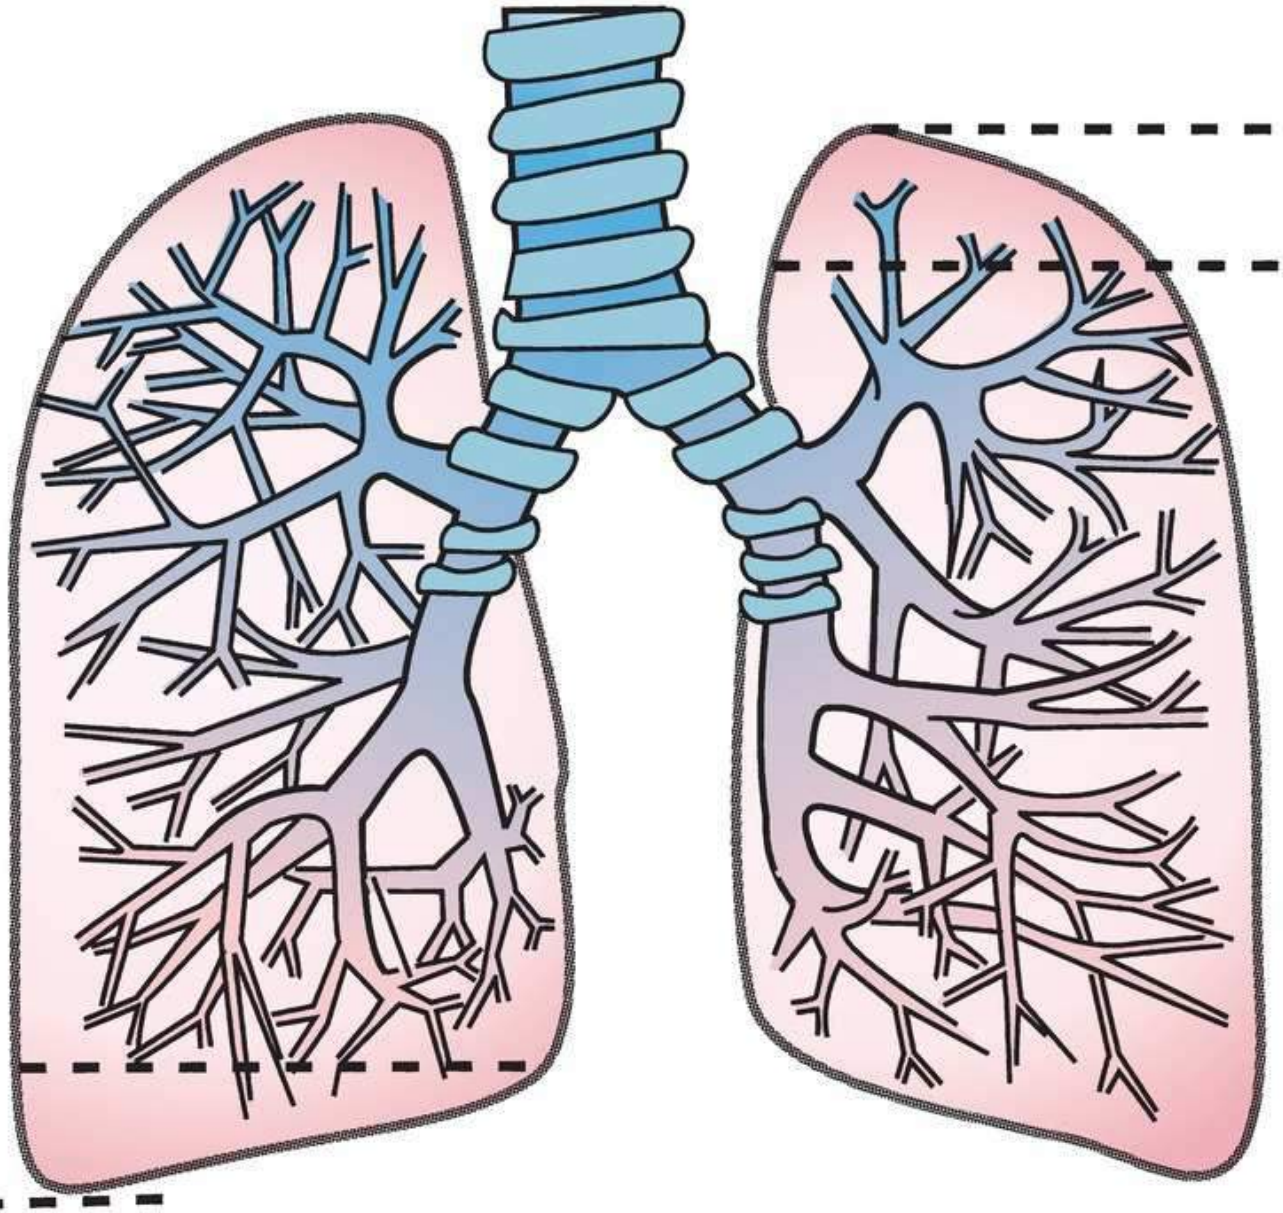


Figure 20.11 Ventilation/perfusion ratios ($\dot{V}_A/\dot{Q}$) affect capillary blood gas tension.

A high ($\dot{V}_A/\dot{Q}$) ratio leads to a high PaO_2 and a low $PaCO_2$ in the blood leaving the apex of the lung as a result of overventilation with respect to blood flow. Blood leaving the base of the lung has a low PaO_2 and a high $PaCO_2$ as a result of a low ($\dot{V}_A/\dot{Q}$) ratio. $PaCO_2$, arterial partial pressure of carbon dioxide; PaO_2, arterial partial pressure of oxygen; $\dot{Q}$, perfusion; $\dot{V}_A$, alveolar ventilation.

SHUNTS AND VENOUS ADMIXTURE

As a result of the mismatch of air and blood flow, there is “wasted air” in one side of the alveolar–capillary membrane (i.e., physiologic dead space), and on the other side, there is “wasted blood” (Fig. 20.12). Wasted blood refers to any fraction of the venous blood that does not get fully oxygenated. The mixing of unoxygenated blood with oxygenated blood is known as **venous admixture**. There are two causes for venous admixture: a **shunt** and a low $\dot{V}_A/\dot{Q}$ ratio.

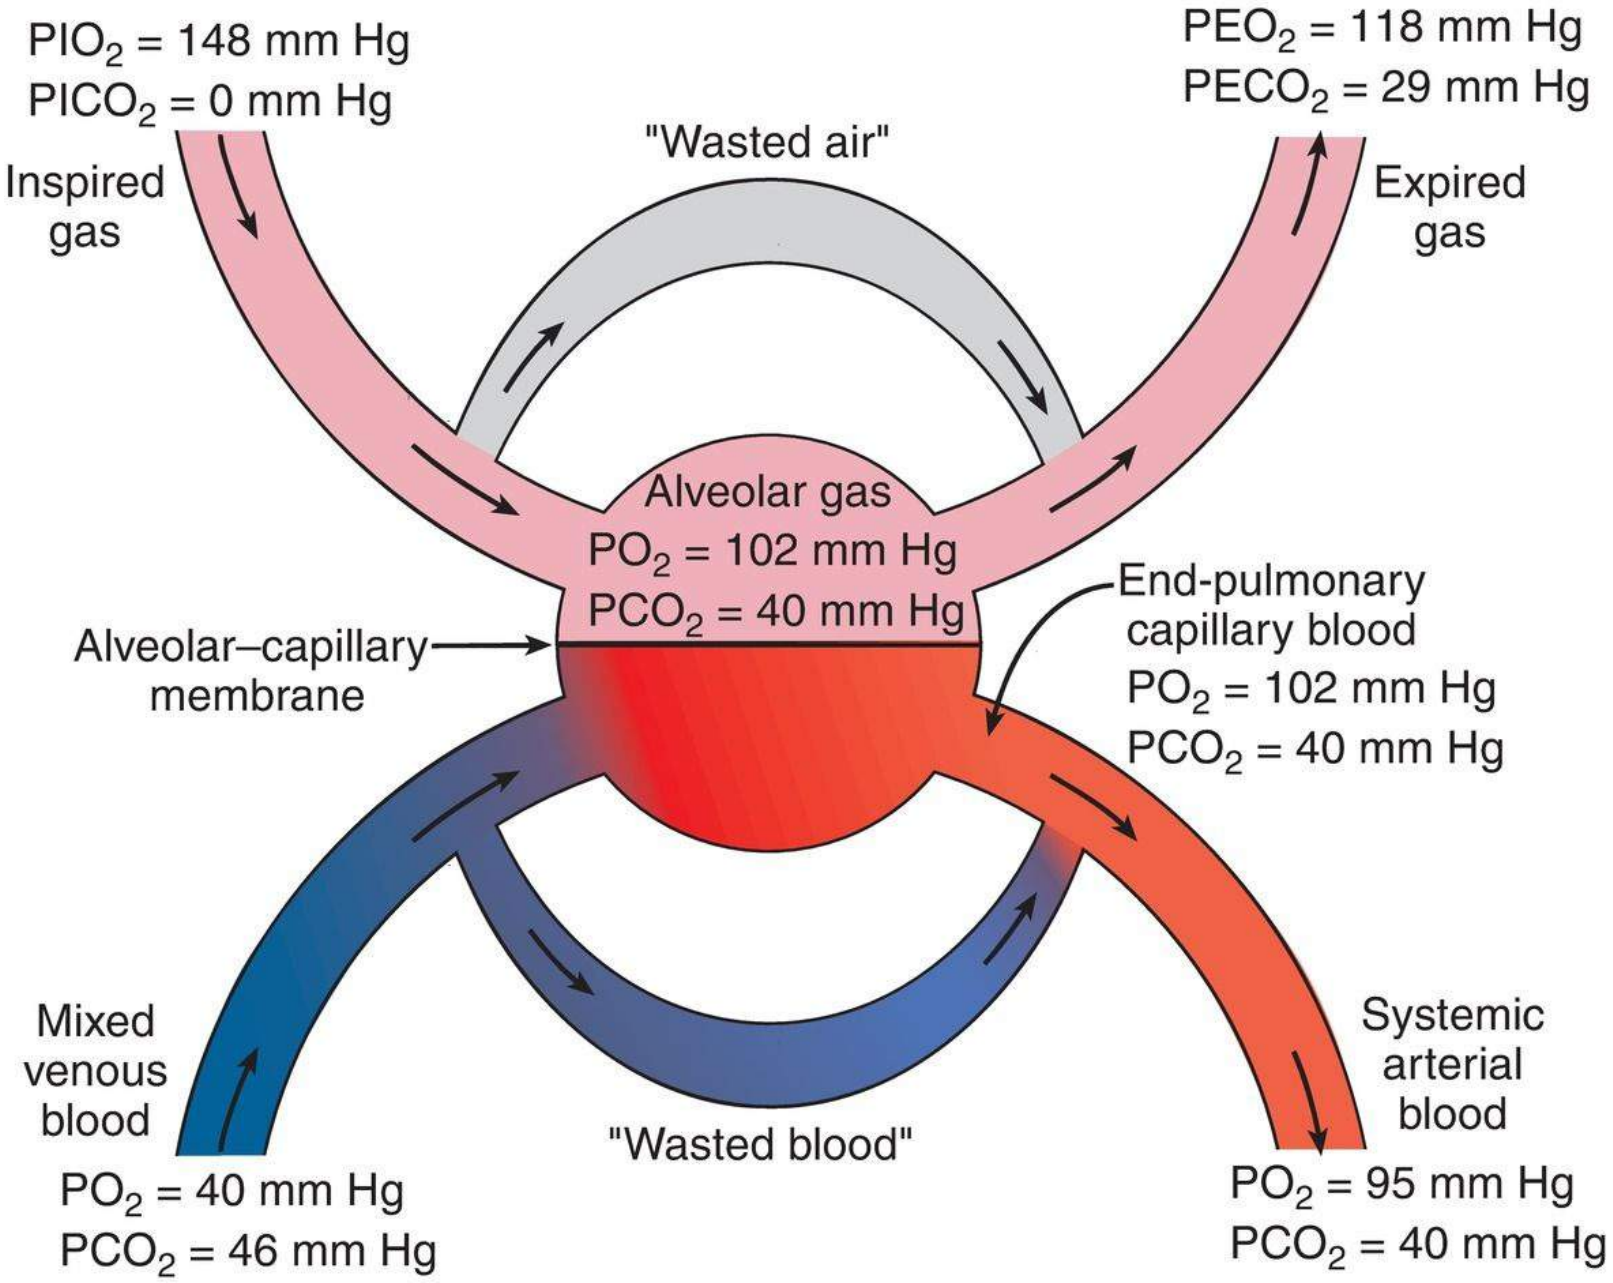

Figure 20.12 On one side of the alveolar–capillary membrane, there is some “wasted air” and on the other “wasted blood.” The plumbing on both sides of the alveolar–capillary membrane is imperfect. All of the inspired air does not participate in gas exchange, resulting in some “wasted air.” All of the blood entering the lung is not fully oxygenated, leading to some “wasted blood.” The total amount of wasted air

constitutes physiologic dead space, and the total amount of wasted blood (venous admixture) constitutes physiologic shunt. $PECO_2$, partial pressure of expired carbon dioxide; PEO_2, partial pressure of expired oxygen; $PICO_2$, partial pressure of inspired carbon dioxide; PIO_2, partial pressure of inspired oxygen.

An *anatomic shunt* has a structural basis and occurs when blood bypasses alveoli through a channel, such as from the right to left heart through an atrial or ventricular septal defect or from a branch of the pulmonary artery connecting directly to the pulmonary vein. An anatomic shunt is often called a *right-to-left shunt*. The bronchial circulation also constitutes shunted blood because bronchial venous blood (deoxygenated blood) drains directly into the pulmonary veins, which are carrying oxygenated blood.

The second cause for venous admixture is a low regional $\dot{V}_A/\dot{Q}$ ratio. This occurs when a portion of the cardiac output goes through the regular pulmonary capillaries, but there is insufficient alveolar ventilation to fully oxygenate all of the blood. In a healthy person, a low $\dot{V}_A/\dot{Q}$ ratio occurs at the base of the lung (i.e., gravity dependent). A low regional $\dot{V}_A/\dot{Q}$ ratio can also occur with a partially obstructed airway (Fig. 20.13), in which lung regions are underventilated with respect to blood flow, resulting in regional hypoventilation. A fraction of the blood passing through a hypoventilated region is not fully oxygenated, resulting in an increase in venous admixture.

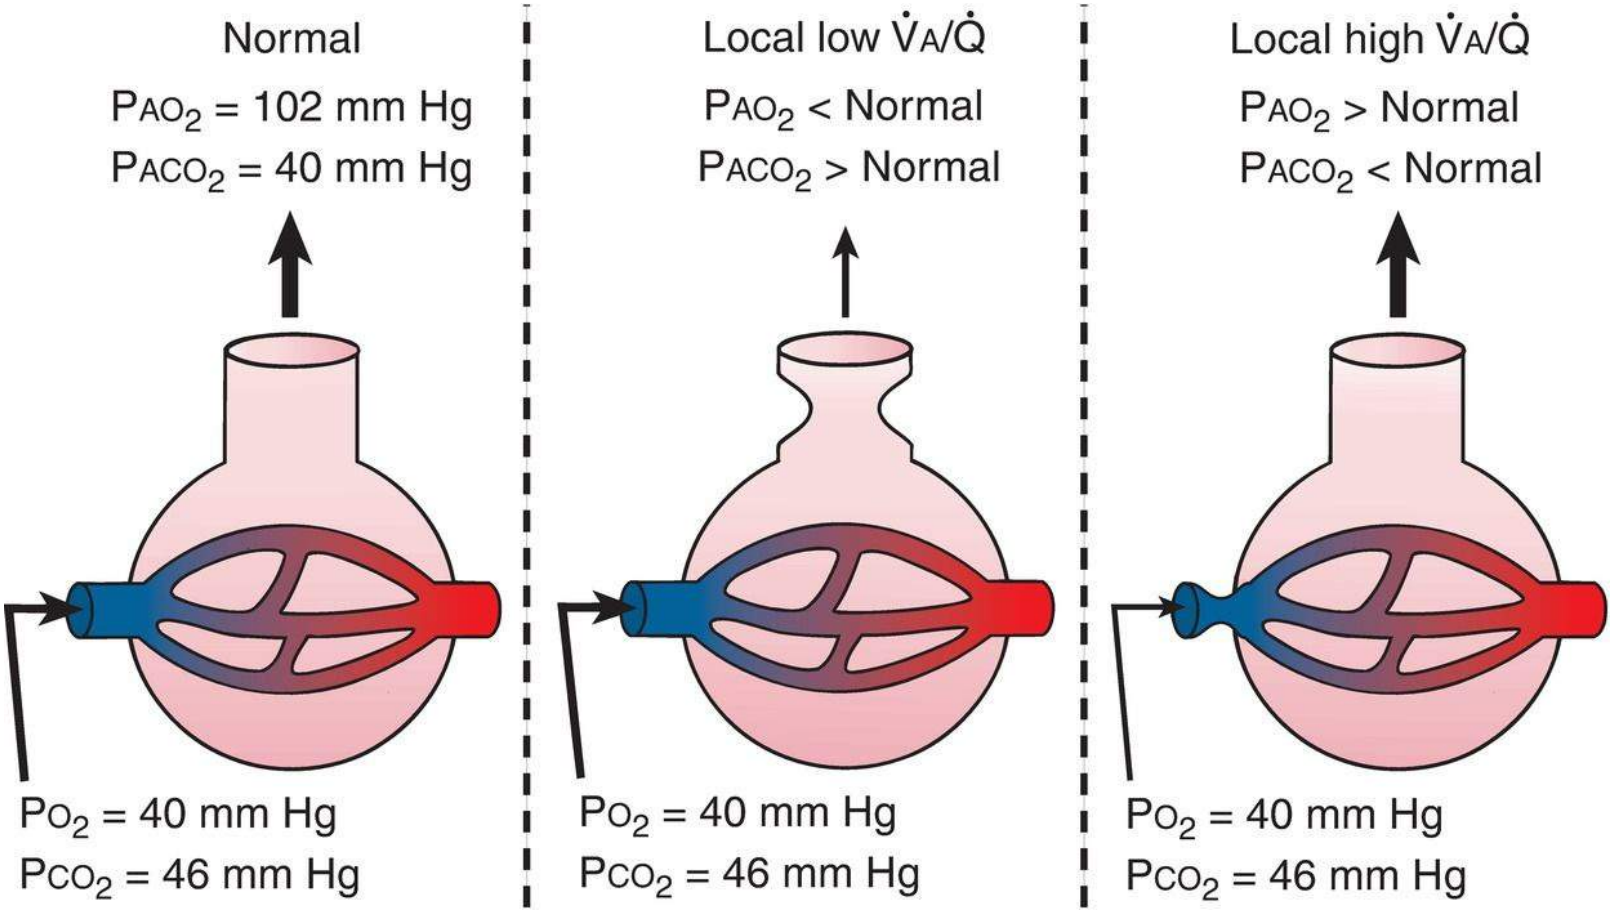

Figure 20.13 Airway obstruction lowers the ventilation/perfusion ($\dot{V}_A/\dot{Q}$) ratio and alters gas tensions. Airway obstruction (*middle panel*) causes a low regional ventilation/perfusion ($\dot{V}_A/\dot{Q}$) ratio. A partially blocked airway causes this region to be underventilated relative to blood flow. Note the alveolar gas composition. A low regional $\dot{V}_A/\dot{Q}$ ratio causes venous admixture and will increase the physiologic shunt. A partially obstructed pulmonary arteriole (*right panel*) will cause an abnormally high ($\dot{V}_A/\dot{Q}$) ratio in a lung region. Restricted blood flow causes this region to be overventilated relative to blood flow, which leads to an increase in physiologic dead space. $PACO_2$, alveolar partial pressure of carbon dioxide; PAO_2, alveolar partial pressure of oxygen.

The total amount of venous admixture as a result of anatomic shunt and a low

ratio equals physiologic shunt and represents the total amount of wasted blood that does not get fully oxygenated. *Physiological shunt* is analogous to physiologic dead space; the two are compared in Table 20.1, in which one represents wasted blood flow and the other represents wasted air. It is important to remember that in healthy people, there is some degree of physiologic dead space as well as physiologic shunt in the lungs.

TABLE 20.1 Shunts and Dead Spaces Compared

Shunt	Dead Space
Anatomic	Anatomic
+	+
Low ($\dot{V}_A/\dot{Q}$) ratio	Alveolar
=	=
Physiological shunt (calculated total "wasted blood")	Physiologic dead space (calculated total "wasted air")

In summary, venous admixture results from anatomic shunt and a low regional $\dot{V}_A/\dot{Q}$ ratio. In healthy people, ~50% of the venous admixture comes from an anatomic shunt (e.g., bronchial circulation) and 50% from a low $\dot{V}_A/\dot{Q}$ ratio at the base of the lungs as a result of gravity. Physiologic shunt (i.e., total venous admixture) represents about 1% to 2% of cardiac output in healthy people. This amount can increase up to 15% of cardiac output with some bronchial diseases, and, in certain congenital disorders, a right-to-left anatomic shunt can account for up to 50% of cardiac output. It is important to remember that any deviation of $\dot{V}_A/\dot{Q}$ ratio from the ideal condition (0.8) impairs gas exchange and lowers oxygen tension in the arterial blood. A good way to remember the importance of a shunt is that it always leads to venous admixture and reduces the amount of oxygen carried in the systemic blood.

INTEGRATED MEDICAL SCIENCES

Wheezing and Shortness of Breath

Jack was born June 15th, 2005. At 6½ lb, he was lighter than his two brothers. Jack had difficulty putting on weight after he was born. In fact, during the first month, he dropped to 6 lb. After a spell in the hospital in January 2006, when he was suffering from wheezing and a persistent cough, he was diagnosed with asthma. However, Jack's condition did not improve even with the medications he was taking for bronchitis and asthma. Jack also developed GI complications. After another spell in the hospital, Jack was given a sweat test for cystic fibrosis. The test confirmed that Jack had cystic fibrosis, although there was no history of cystic fibrosis on either side of the family.

This is a typical pattern with children who have been diagnosed with cystic fibrosis (CF) and is the second most common inherited disorder occurring in childhood in the United States, behind sickle cell anemia. More than 10 million Americans carry the defective CF gene without knowing it. About 1,000 new cases of CF are diagnosed each year.

Cystic fibrosis is a genetic disorder that changes a protein that regulates the movement of sodium chloride in and out cells. The specific defect is linked to the chloride ion channel. The result is thick, sticky mucus in the respiratory, digestive, and reproductive systems, as well as increased salt in sweat. The primary target organ is the lungs with long-term difficulties leading to shortness of breath, coughing, frequent lung infections, and hypoxemia. Other symptoms include sinus infections, poor growth, fatty stools, infertility, and clubbing of fingers. The latter is due to hypoxemia. Different patients may have different degrees of symptoms.

Digestive symptoms interfere with the pancreatic function. The thick mucus blocks the pancreatic ducts that carry the digestive enzymes from the pancreas to the small intestine. Without these digestive enzymes, the intestine is unable to absorb nutrients. This often results in foul smelling and greasy stools, poor weight gain and growth, and severe constipation. The blocked pancreatic ducts also lead to painful inflammation (pancreatitis). Also, because of malabsorption, there is poor uptake of vitamin D from the diet. Vitamin D deficiency can lead to osteoporosis in CF patients.

As a result of pancreatic damage, patients often develop diabetes. The diabetes induced by diabetes share characteristics that can be found in both type 1 and type 2 diabetics. Another complication is infertility. Approximately 97% of men with CF are infertile, but not sterile. The main cause of infertility in men is linked to the *vas deferens*, the tubes that connect the prostate gland to the ejaculatory ducts of the penis. With CF, the vas deferens is either blocked or missing entirely. Other mechanisms include poor sperm motility due to a defective chloride channel. About 20% of women with CF have fertility difficulties due to thickened cervical mucus and malnutrition. Malnutrition disrupts ovulation and also causes amenorrhea.

The pathophysiology is an autosomal recessive disorder for the protein, *cystic fibrosis transmembrane conductance regulator* (*CFTR*), which involves the production of sweat, mucus, and digestive fluids. When the CFTR is not functioning, the thin secretions become thick and sticky. The CFTR protein is anchored to the outer membrane of cells in the sweat glands, lungs, pancreas, and all other exocrine glands in the body. The protein acts as a channel connecting the cytoplasm inside the

cell to the extracellular fluid. This channel is primarily responsible for controlling NaCl from inside to outside the cell. When the CFTR becomes dysfunctional, the chloride is trapped inside the ducts of the sweat glands and is pumped to the skin. Because chloride is negatively charged, this creates an electrical potential difference across the cell membrane causing cations to move into the cell. Sodium is the most common cation in the extracellular fluid. The excess chloride within the sweat gland prevents sodium reabsorption by epithelial sodium channels and the combination of sodium and chloride creates salt, which is lost in high amounts in the sweat CF patients. The high salt content is the basis for the sweat test. In other organs, most of the damage in CF is due to blockage of narrow airways and ducts with thick secretions. The failure of CFTR protein leads to abnormal chloride movement that causes dehydration of mucus, pancreatic secretions, and biliary secretions.

There is no cure for cystic fibrosis. Pulmonary complications account for ~80% of the deaths. A number of treatment options are available to help reduce the progression of the disease. Airway clearance techniques are used to remove lung mucus, and bronchodilators/anti-inflammatory medicines are used to improve breathing. One technique used to clear mucus from the lungs is called *postural drainage and percussion*. The CF patient sits, stands, or lies in a position to help free up the mucus. The chest and back is then pounded to loosen the mucus. In the hospital setting, chest physiotherapy is utilized. A respiratory therapist percusses the patient's chest with his or her hands several times a day to loosen the mucus. Often, anti-inflammatory medicine, such as ibuprofen, is given to help reduce airway inflammation. Bronchodilators and inhaled hypertonic saline mist can also be beneficial. The dilators help to open the airways, and the hypertonic saline draws water into the small airways and thins the mucus.

Antibiotics for treating lung infections may be given orally, intravenously, or inhaled. Azithromycin is often used long term. Also, Pulmozyme, a mucus-thinning drug, an FDA-approved pharmaceutic agent, is prescribed to reduce lung infection and improve lung function. Digestive supplements include pancreatic enzyme replacement and fat-soluble vitamins can also be prescribed, especially young adults.

Lung transplantation often becomes necessary when lung function and exercise tolerance (e.g., walking up a set of stairs) decline in individuals with CF. A lung transplant is only recommended when the patient's lung function declines to the point that they have difficulty breathing on their own. Although single lung transplantation is advisable with certain lung diseases, individuals with CF must have both lungs replaced because of cross-bacteria contamination to the transplanted lung. In severe cases, a pancreatic and/or liver transplant may be performed at the same time in order to alleviate diabetes and severe GI complications. ■

Chapter Summary

- Pulmonary circulation is a high-flow, low-resistance, and low-pressure system.
- Capillary recruitment is the primary cause for pulmonary vascular resistance to decrease with increased cardiac output.
- Alveolar hypoxia is the major stimulus for pulmonary vasoconstriction.
- Hypoxia-induced pulmonary vasoconstriction shunts blood away from poorly ventilated regions of the lung.
- Gravity causes regional differences in ventilation/perfusion ( ) ratios in the lungs.
- Venous admixture occurs when venous blood mixes with oxygenated arterial blood.
- An abnormally low ventilation/perfusion ratio exists when a lung region is overperfused relative to airflow, resulting in an increase in venous admixture.
- Physiologic shunt (wasted blood) is analogous to physiologic dead space (wasted air).

Chapter Review Questions

1. Which of the following best characterizes the pulmonary circulation?

	Flow	Pressure	Resistance	Compliance
A.	Low	High	Low	High
B.	High	Low	High	Low
C.	Low	Low	Low	High
D.	High	Low	High	High
E.	High	Low	Low	High

The correct answer is E. Since the lung receives all of the cardiac output, it is characterized as a high-flow system. Vessel compliance is high, which allows for a low-resistance and a low-pressure system.

2. During moderate to heavy exercise, pulmonary vascular resistance in a healthy individual will:

A. Increase because cardiac output increases
B. Decrease because pulmonary arterial pressure decreases
C. Increase because PaO_2 increases
D. Decrease because of pulmonary capillary recruitment
E. Not change

The correct answer is D. With increase exercise, cardiac output increases. The increase flow results in capillary recruitment, which results in a decrease in pulmonary vascular resistance.

3. Which of the following changes would favor the formation of pulmonary edema?

A. Decreased hydrostatic interstitial pressure around the alveoli
B. Decreased pulmonary arterial pressure
C. Decreased pulmonary wedge pressure
D. Increased oncotic pressure in the pulmonary capillaries
E. Increased pulmonary blood flow

The correct answer is A. A decrease in pulmonary pressure, wedge pressure, or an increase in oncotic pressure would "pull" fluid from the interstitial space and would not cause edema.

4. A 65-year-old patient has a lung region in which the alveoli are well ventilated but are poorly perfused. This situation will cause alveoli in this region to have:

A. High PO_2 and a low PCO_2 with increased O_2 uptake
B. High PO_2 and a low PCO_2 with decreased O_2 uptake
C. Low PO_2 and a high PCO_2 with decreased O_2 uptake
D. High PO_2 and a high PCO_2 with increased O_2 uptake
E. Low PO_2 and a low PCO_2 with decreased O_2 uptake

The correct answer is B. A lung region that is overventilated with respect to blood flow will have an

alveolar gas tension in which the PO_2 is greater than normal and the PCO_2 is less than normal. However, the oxygen uptake is less even though the PO_2 is higher because oxygen uptake is most dependent on blood flow. If blood flow is less than normal, then the amount of oxygen taken up (mL/min) is less by the blood passing through this unit.

5. Which of the following best characterizes alveolar ventilation and blood flow at the base, compared with the apex, of the lungs of a healthy standing person?

	Ventilation	Blood Flow	Ventilation/ Perfusion Ratio
A.	Higher	Higher	Normal
B.	Lower	Higher	Lower
C.	Lower	Lower	Lower
D.	Higher	Lower	Higher
E.	Lower	Lower	Higher

The correct answer is B. At the base, the lung is being overperfused and underventilated, which leads to a low ventilation/perfusion ratio.

Clinical Application Exercises 20.1

WATER ON THE LUNGS

A 64-year-old CEO took early retirement and decided to travel. After returning from a monthlong trip, he complained of fatigue and loss of appetite. He saw his internist, and following a physical examination, he was given a CAT scan. The results showed malignant growth on one lobe of his liver. After further x-ray and additional CAT scans, he was diagnosed with primarily metastatic liver cancer in the upper lobe of his liver. The lobe was removed surgically, and the patient was dismissed after being followed by a surgeon and oncologist. Eight months following surgery, he felt tired and began to have difficulty breathing. Upon exertion, he became dyspneic. He was referred to pulmonary specialist and given a chest x-ray. The results confirmed that the patient had pleural effusion.

QUESTIONS

1. What is the pathophysiology of pleural effusion?
2. How is pleural effusion treated?

ANSWERS

1. Pleural effusion is an excess of fluid that accumulates in the pleural cavity, the fluid-filled space that surrounds the lungs. In healthy individuals, the fluid in each pleural space is <1 mL. Under normal conditions, fluid enters the pleural space from the capillaries in the parietal pleura and is removed via the lymphatics situated in the parietal pleura. Fluid can also enter from the interstitial spaces of the lung via the visceral pleura or from the peritoneal cavity through small

holes in the diaphragm. The lungs have the capacity to absorb 20 times more fluid than is normally formed. When this capacity is compromised, either through excess formation or decreased lymphatic absorption, pleural effusion develops. The excess fluid accumulations cause labored breathing and dyspnea upon exertion. More than 1 million cases of pleural effusion occur annually in the United States. Pleural effusion is classified into two types: The first type is classified as transudate due to systemic factors (left ventricular failure, pulmonary embolism, and liver cirrhosis). The second type is classified as exudative pleural effusion and is caused by alterations in local factors that influence the formation and absorption of pleural fluid (e.g., bacterial pneumonia, cancer, and viral infection). Pleural effusion is diagnosed based on family history and a physical exam and confirmed by chest x-ray. The type of pleural effusion (transudate or exudate) is based on fluid cytology. Pleural is drawn out of the pleural space in a process called thoracentesis. A needle is inserted through the back of the chest wall into the pleural space to remove fluid for the cytology.

Malignant pleural effusion, secondary to metastatic disease, is the second most common exudative pleural effusion. Over 75% of malignant pleural effusions are caused by lung carcinoma (30%), breast cancer (25%), and tumors of the lymphoma group (20%).

2. Treatment depends on the underlying cause of the pleural effusion. Therapeutic aspiration may be sufficient. However, larger effusions may require insertion of an intercostal drain. Repeated episodes of effusions may require a chemical (talc, bleomycin, or tetracycline/doxycycline) or surgical pleurodesis, in which the two pleural surfaces are fused to each other so that no fluid can accumulate between them.

21 Control of Ventilation

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe the major cell groups in the medulla controlling breathing.
- Describe how depth and rate of breathing are regulated.
- Describe how alveolar ventilation is matched to the metabolic needs of the body.
- Predict how changes in blood pH and arterial PCO_2 ($PaCO_2$) affect the control of breathing.
- Describe how the respiratory system responds to hypoxic-induced stimulation.
- Describe how breathing patterns change during sleep.
- Describe the ventilatory response to high-altitude acclimatization.
- Describe the sequence of events causing underwater blackout.

In the previous chapter, you learned that pulmonary circulation was a high-flow, low-resistance, and a low-pressure system. In addition, you learned the pulmonary circulation had two unique features that were different from systemic circulation. First, vascular resistance decreases with an increased cardiac output. Secondly, hypoxia was the major mechanism for pulmonary constriction. You also learned that pulmonary blood flow and alveolar ventilation were not matched throughout the lungs. The mismatch caused poor gas exchange because of a high ventilation/perfusion ratio at the apex and a low ventilation/perfusion ratio at the base of the lungs. You'll learn in this chapter that the control of breathing is centered primarily on maintaining adequate gas exchange to meet metabolic demands, and $PaCO_2$ is more a powerful stimulus in the regulation of breathing than PaO_2. This chapter examines how our basic rhythm and breathing pattern are modified to meet changes in body functions.

NEURAL AND VOLUNTARY CONTROL OF BREATHING

Under resting conditions, ventilation is controlled primarily by the autonomic nervous system and occurs without any conscious effort while we are awake, asleep, or under anesthesia. However, the automatic control can be overridden and conscious effort exerted over ventilation by voluntarily changing the rate and depth of breathing. We can also voluntarily stop breathing for a short period of time until carbon dioxide builds up in the blood, which then will stimulate breathing regardless of how hard we try to hold our breath. The basic pattern of breathing generated in the medulla is extensively modified by several control mechanisms. Figure 21.1 illustrates the overall control of breathing, with signals from the blood, higher cortical regions, and stretch receptors from within and outside the lung modulating our breathing. Minute ventilation is tightly controlled and determined primarily by blood gas levels of $PaCO_2$ and metabolic rate. Increased metabolism leads to higher levels of carbon dioxide, but also to a lower pH (increased H^+ concentration from lactic acid production and the dissociation $H_2CO_3 \rightarrow H^+ + CO_3^-$). During strenuous exercise, minute ventilation increases proportionately more because glycolysis facilities the release of excess lactic acid.

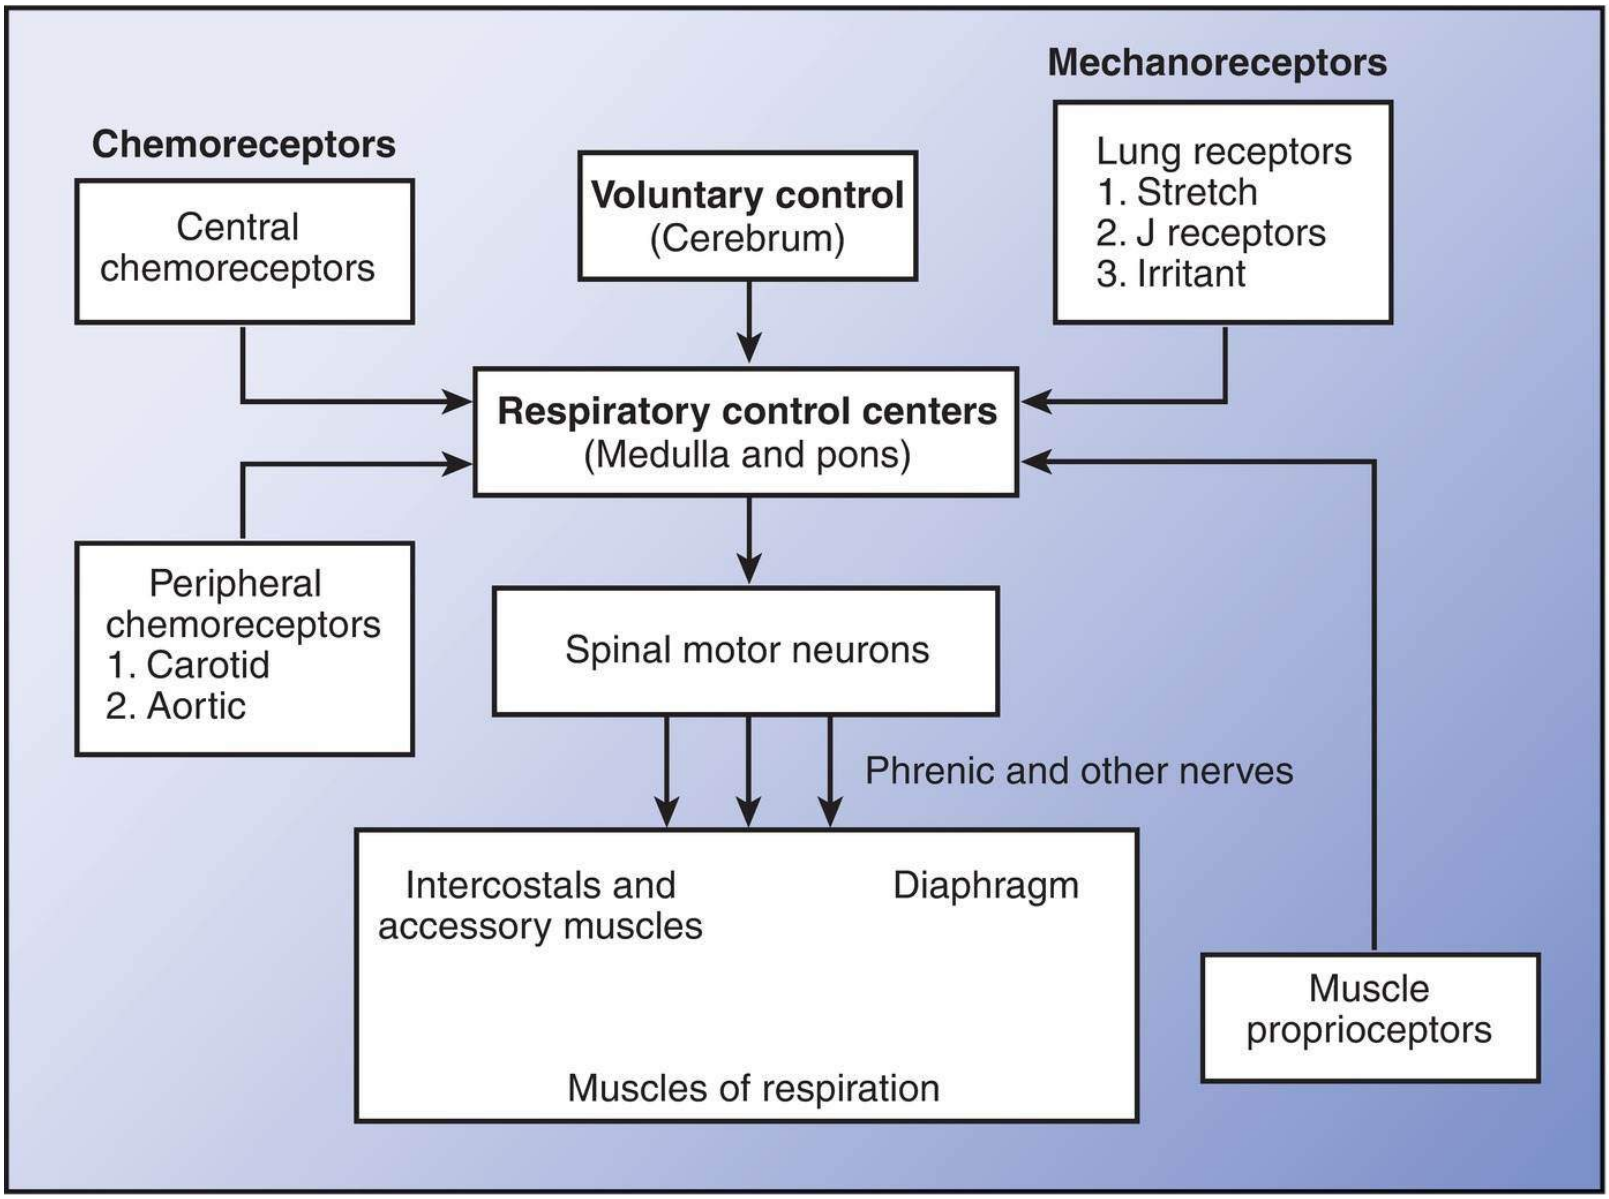

Figure 21.1 Breathing is regulated by various input signals. The schematic illustrates the overall

control of breathing with various mechanoreceptors, proprioceptors, and chemoreceptors that are involved in adjusting breathing to meet various metabolic demands.

The control of breathing is critical for understanding respiratory responses to activity, changes in the environment, and lung diseases. Our breathing depends on the cyclic excitation of many muscles that influences the volume of the thorax. Control of that excitation is the result of multiple neuronal interactions involving all levels of the nervous system. Furthermore, the muscles used for breathing must often be used for other purposes, as well. For example, talking while walking requires some muscles to simultaneously attend to the tasks of posturing, walking, phonation, and breathing. Because it is impossible to study extensively the subtleties of such a complex system in humans, much of what is known about the control of breathing has been obtained from the study using animal models. Much, however, remains unexplained.

The control of upper and lower airway muscles that affect airway tone is integrated with control of the muscles that start tidal air movements. During quiet breathing, inspiration is brought about by a progressive increase in electrical activation of the inspiratory muscles, most importantly the diaphragm, until tidal volume has been reached. At the end of inspiration, the inspiratory muscles relax, and expiration occurs passively due to the elastic recoil of the lungs and chest wall. However, as more ventilation is required—for example, during exercise—other inspiratory muscles (external intercostals, cervical muscles) are recruited. In addition, when ventilation is elevated, expiration becomes an active process through the use, most notably, of the muscles of the abdominal wall.

The respiratory centers are located within the pons and medulla.

The neural basis of the breathing patterns depends on the generation and subsequent tailoring of cyclic changes in the activity of cells primarily located in the medulla oblongata in the brain. Although the mechanism of generating ventilatory patterns is still not completely understood, but the integration on neural signals by respiratory control centers involve the medulla and pons. The central pattern for the basic breathing rhythm has been localized to fairly discrete areas within the medulla oblongata that discharge action potentials in a phasic pattern with respiration. Cells in the medulla oblongata associated with breathing have been identified by noting the correlation between their activity and mechanical events of the breathing cycle. Two different regions in the medulla control the breathing rhythm, and their anatomic locations are shown in Figure 21.2. The **dorsal respiratory group (DRG)**, named for its dorsal location in the region of the nucleus *tractus solitarii*, predominantly contains cells that are active during inspiration. The **ventral respiratory group (VRG)** is a column of cells in the general region of the *nucleus ambiguus* that extends caudally nearly to the *bulbospinal* border and cranially nearly to the *bulbopontine junction*. The VRG contains both inspiration- and expiration-related neurons. Both groups contain cells projecting ultimately to the bulbospinal motor neuron pools. The DRG and VRG are bilaterally paired, allowing for cross-communication. As a result, they can respond in synchrony allowing respiratory movements to be rhythmic. The DRG controls primarily inspiratory movements and rhythm. The VRG is primarily responsible for controlling voluntary forced inspiration and exhalation. The neural networks forming the central pattern generator for breathing are contained within the DRG/VRG complex. In terms of breathing, inspiratory motor neuron must be activated before expiratory motor neurons.

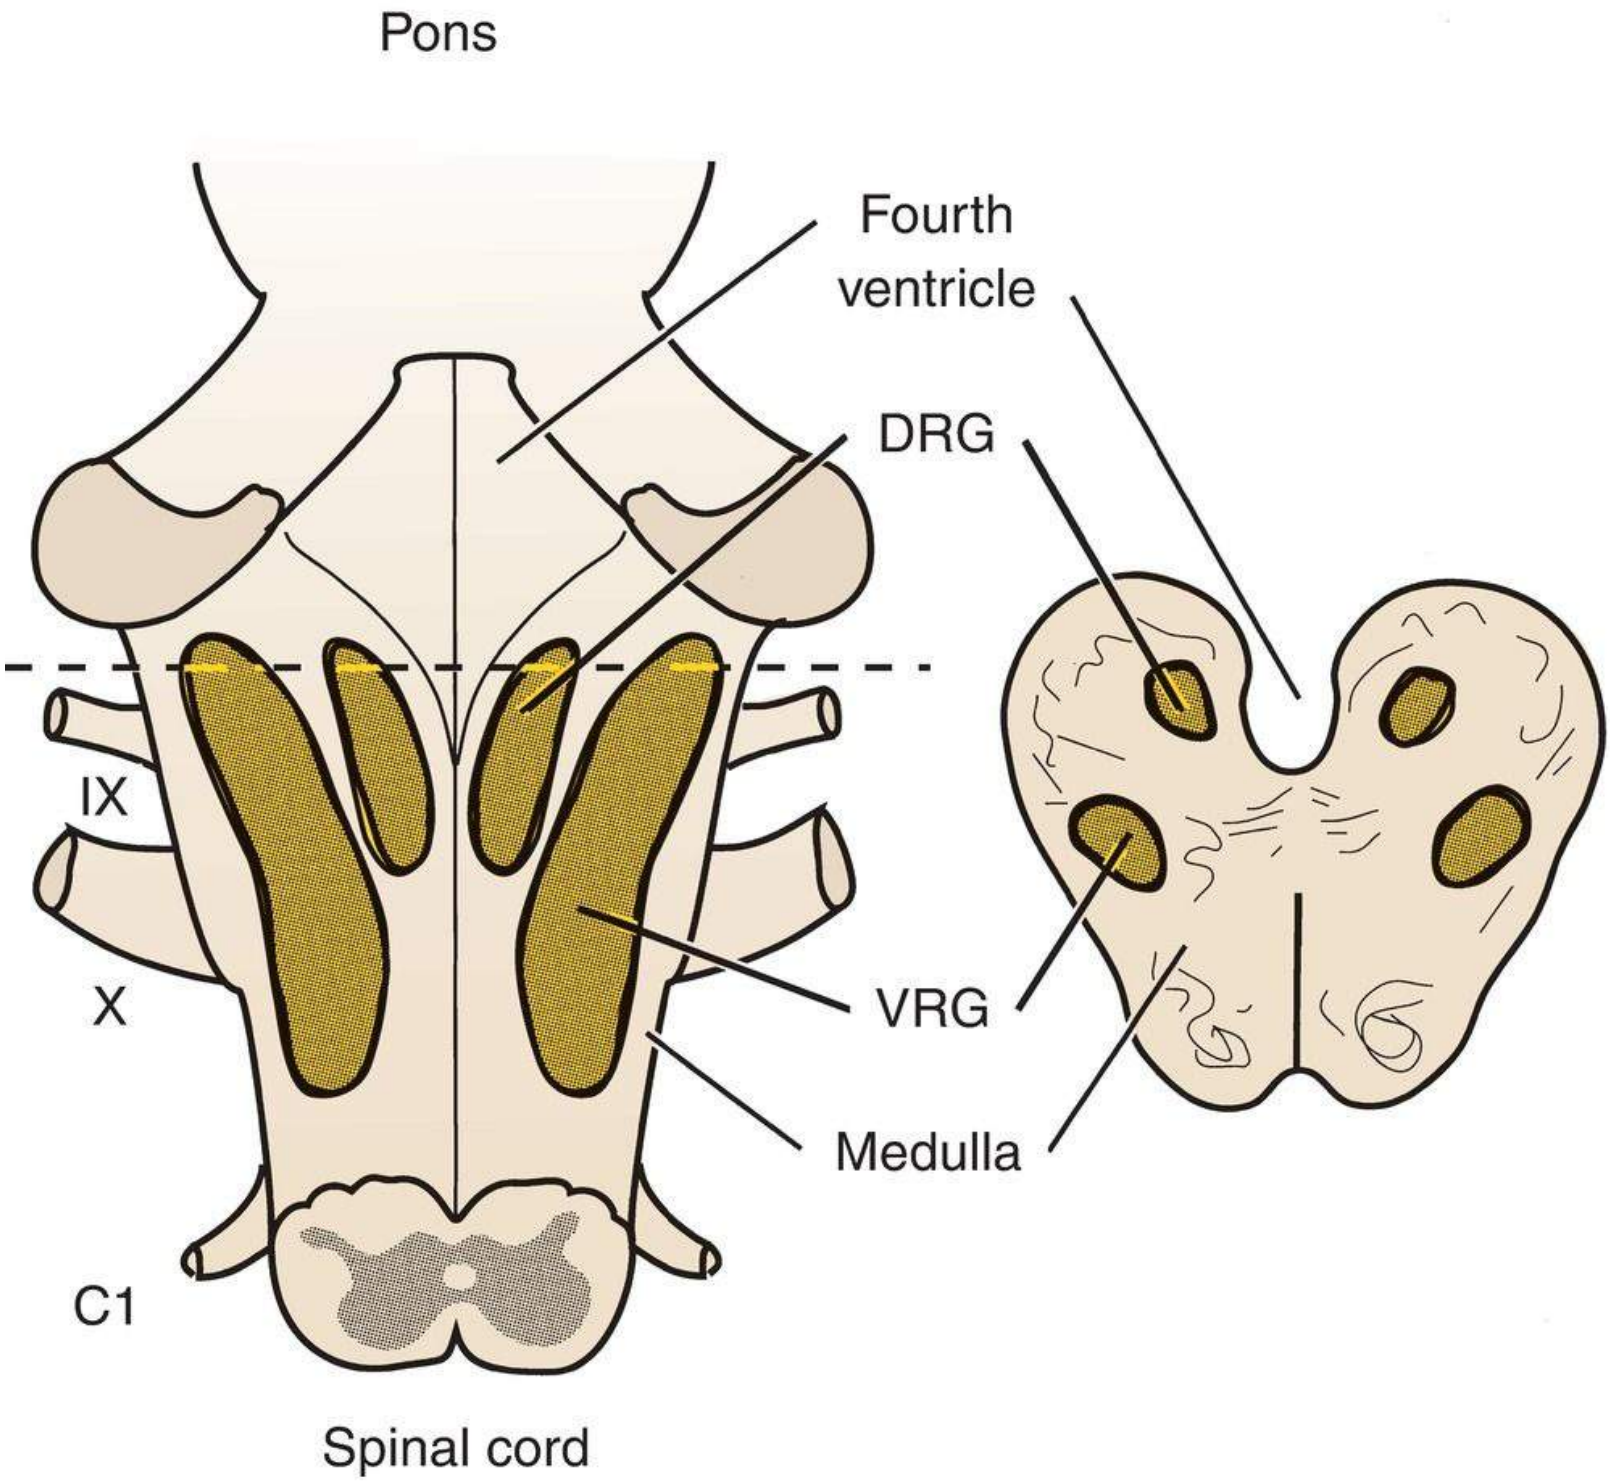

Figure 21.2 The dorsal respiratory group (DRG) and the ventral respiratory group (VRG) are located in the medulla. These drawings show the dorsal aspect of the medulla oblongata and the cross-section of the region of the fourth ventricle. C1, first cervical nerve; IX, glossopharyngeal nerve; X, vagus nerve.

Central pattern generation probably does not arise from a single pacemaker or by reciprocal inhibition of two pools of cells, one having inspiratory-related and the other having expiratory-related activity. Instead, the progressive rise and abrupt fall of inspiratory motor activity associated with each breath can be modeled by the starting, stopping, and resetting of an integrator of background ventilatory drive. A *rhythmic generator* is responsible for the normal breathing pattern. The rhythmic generator consists of a network of interneurons that communicates with another to effectively produce a repetitive motor pattern that produces a respiratory rhythm of 12 breaths/min. An integrator-based theoretical

model, as described below, is suitable for a first understanding of respiratory pattern generation. Many different signals (e.g., anxiety, musculoskeletal movements, pain, chemosensory activity, and hypothalamic temperature) provide a background ventilatory drive to the medulla. Inspiration begins by the abrupt release from inhibition of a group of cells, **central inspiratory activity (CIA) integrator** neurons, located within the medullary reticular formation that integrate this background drive (Fig. 21.3). Integration results in a progressive rise in the output of the integrator neurons, which, in turn, excites a similar rise in activity of inspiratory premotor neurons of the DRG/VRG complex. The rate of rising activity of inspiratory neurons and, therefore, the rate of inspiration itself can be influenced by changing the characteristics of the CIA integrator. Inspiration is ended by abruptly switching off the rising excitation of inspiratory neurons. The CIA integrator is reset before the beginning of each inspiration, so that activity of the inspiratory neurons begins each breath from a low level.

Figure 21.3 Inspiration is initiated by the medullary inspiratory generator. Inspiration begins by the abrupt release from inhibition of a group of cells called the central inspiratory activity (CIA) integrator.

Inspiratory activity is switched off to initiate expiration.

Two groups of neurons located within the VRG serve as an inspiratory off switch (see Fig. 21.3). Switching occurs abruptly when the sum of excitatory inputs to the off switch reaches a threshold. Adjustment of the threshold level is one of the ways in which depth of breathing can be varied. Two important excitatory inputs to the off switch are a progressively increasing activity from the CIA integrator's rising output and an input from lung stretch receptors, whose afferent activity increases progressively with rising lung volume. (The first of these is what allows the medulla to generate a breathing pattern on its own; the second is one of many reflexes that influence breathing.) Once the critical threshold is reached, off-switch neurons apply a powerful inhibition to the CIA integrator. The CIA integrator is thus reset by its own rising activity. Other inputs, both excitatory and inhibitory, act on the off switch and change its threshold. For example, chemical stimuli, such as hypoxemia and hypercapnia, are inhibitory, raising the threshold and causing larger tidal volumes.

An important excitatory input to the off switch comes from a group of spatially dispersed neurons in the rostral pons called the **pontine respiratory group**. Electrical stimulation in this region causes variable effects on breathing, dependent not only on the site of stimulation but also on the phase of the respiratory cycle in which the stimulus is applied. It is believed that the pontine respiratory group may serve to integrate many different autonomic functions in addition to breathing.

Expiration comprises two phases.

Shortly after the abrupt termination of inspiration, some activity of inspiratory muscles resumes. This activity serves to control expiratory airflow. This effect is greatest early in expiration and recedes as lung volume falls. Inspiratory muscle activity is essentially absent in the second phase of expiration, which includes continued passive recoil during quiet breathing and activation of expiratory muscles if more than quiet breathing is required.

The duration of expiration is determined by the intensity of inhibition of activity of inspiratory-related cells of the DRG/VRG complex. Inhibition is greatest at the start of expiration and falls progressively until it is insufficient to prevent the onset of inspiration. The progressive fall of inhibition amounts to a decline of threshold for initiating the switch from expiration to inspiration. The rate of decline of inhibition and the occurrence of events that trigger the onset of inspiration are subject to several influences. The duration of expiration can be controlled not only by neural information arriving during expiration but also in response to the pattern of the preceding inspiration. How the details of the preceding inspiration are stored and later recovered is unresolved.

Muscles of the upper airways are also under phasic control.

The same rhythm generator that controls the chest wall muscles also controls muscles of the nose, pharynx, and larynx. However, unlike the inspiratory ramplike rise of the stimulation of chest wall muscles, the excitation of upper airway muscles quickly reaches a plateau and is sustained until inspiration is ended. Flattening of the expected ramp excitation waveform probably results from progressive inhibition by the rising afferent activity of airway stretch reflexes as lung volume increases. Excitation during inspiration causes contractions of upper airway muscles, airway widening, and reduced resistance from the nostrils to the larynx.

During the first phase of quiet expiration, when expiration is slowed by renewed inspiratory muscle activity, there is also expiratory braking caused by active adduction of the vocal cords. However, during exercise-induced **hyperpnea** (increased depth and rate of breathing), the cords are separated during expiration and expiratory resistance is reduced.

Increasing metabolic demands require various control mechanisms to match alveolar ventilation.

Multiple controls provide a greater capability for regulating breathing under a larger number of conditions. Their interactions modify each other and provide for backup in case of failure. The set of strategies for controlling a given variable, such as minute ventilation, typically includes individual schemes that differ in several respects, including choices of sensors and effectors, magnitudes of effects, speeds of action, and optimum operating points. The use of multiple control mechanisms in breathing can be illustrated by considering some of the ways breathing changes in response to exercise. Perhaps the simplest strategies are feedforward mechanisms, in which breathing responds to some component of exercise but without recognition of how well the response meets the demand. One such mechanism would be for the central nervous system (CNS) to vary the activity of the medullary pattern generator in parallel with, and in proportion to, the excitation of the muscles used during exercise. Another prospective feedforward scheme involves sensing the magnitude of the carbon dioxide load delivered to the lungs by systemic venous return and then driving ventilation in response to the magnitude of that load. Experimental evidence supports this mechanism, but the identity of the required intrapulmonary sensor remains uncertain. Still another recognized feedforward mechanism is the enhancement of breathing in response to increased receptor activity in skeletal joints as joint motion increases with exercise.

NEURAL REFLEXES IN THE CONTROL OF BREATHING

Neural reflexes provide feedback for fine tuning, which adjusts frequency and tidal volume to minimize the work of breathing. Reflexes from the upper airways and lungs also act as defensive reflexes, protecting the lungs from injury and environmental insults. Receptors for these reflexes are located centrally and peripheral and consist of *chemoreceptors* and *mechanoreceptors*. Central chemoreceptors of the central nervous system, located in the medulla, are sensitive to changes in $[H^+]$. Peripheral chemoreceptors detect changes in PaO_2, $PaCO_2$, and arterial $[H^+]$. Mechanoreceptors located in airways, lung parenchyma, chest wall, and leg muscle/tendons also provide neural reflexes that are involved in the control of breathing (see Fig. 21.1).

Mechanoreceptors mediate reflexes that protect the lung.

Pulmonary mechanoreceptors are located in the airways, and lung parenchyma and can be divided into three groups: *pulmonary stretch*, *irritant*, and *J receptors* (see Fig. 21.1). Afferent fibers of all three types lie predominantly in the vagus nerves.

Pulmonary stretch receptors are sensory terminals of myelinated afferent fibers that lie within the smooth muscle layer of conducting airways. Stretch receptors fire in proportion to applied airway transmural pressure, and their usual role is to sense lung volume. When stimulated, an increased firing rate is sustained as long as stretch is imposed; that is, they adapt slowly and are also called *slowly adapting receptors*. Stimulation of these receptors causes an excitation of the inspiratory off switch and a prolongation of expiration. Because of these two effects, inflating the lungs with a sustained pressure at the mouth terminates an inspiration in progress and prolongs the time before a subsequent inspiration occurs.

This sequence is known as the *Hering-Breuer reflex or lung inflation reflex*. The Hering-Breuer reflex probably plays a more important role in infants than in adults. In adults, particularly in the awake state, this reflex may be overwhelmed by more prominent central control. Because increasing lung volume stimulates stretch receptors, which then excite the inspiratory off switch, it is easy to see how they could be responsible for a feedback signal that results in cyclic breathing. However, as already mentioned, feedback from vagal afferents is not necessary for cyclic breathing to occur. Instead, feedback modifies a basic pattern established in the medulla. The effect may be to shorten inspiration when tidal volume is larger than normal. The most important role of slowly adapting receptors is probably their participation in regulating expiratory time, expiratory muscle activation, and functional residual capacity. Stimulation of the stretch receptors also relaxes airway smooth muscle, reduces systemic vasomotor tone, increases heart rate, and, as previously noted, influences laryngeal muscle activity.

The *irritant receptors* are sensory terminals of myelinated afferent fibers that are found in the larger conducting airways. Also called **rapid adapting receptors**, they have nerve endings, which lie in the airway epithelium, and respond to irritation of the airways by touch or by noxious substances, such as smoke and dust. Irritant receptors are stimulated by histamine, serotonin, and prostaglandins released locally in response to allergy and inflammation. They are also stimulated by lung inflation and deflation, but their firing rate rapidly declines when a volume change is sustained. Because of this rapid adaptation, bursts of activity occur that are in proportion to the change of volume and the rate at which that change occurs. Acute congestion of the pulmonary vascular bed also stimulates these receptors, but, unlike the effect of inflation, their activity may be sustained when congestion is maintained.

Background activity of the irritant receptors is inversely related to lung compliance, and they are thought to serve as sensors of compliance change. These receptors are probably nearly inactive in normal quiet breathing. Based on what stimulates them, their role would seem to be to sense the onset of pathologic events. In spite of considerable information about what stimulates them, the effect of their stimulation remains controversial. As a general rule, stimulation causes excitatory responses such as coughing, gasping, and prolonged inspiration time.

Juxtapulmonary capillary receptors are sensory nerve endings located adjacent to the alveolar wall in juxtaposition to the pulmonary capillaries, hence the name. The shorten term for these receptors are called *J receptors*. These receptors are unmyelinated and also innervated by fibers from the vagus nerve. The J receptors are classified as two populations in the lungs. One group is located adjacent to the alveoli and is accessible from the pulmonary circulation and sometimes referred to as *pulmonary C fibers*. A

second group, *bronchial C fibers*, is accessible from the bronchial circulation and, consequently, is located in airways. Both groups play a protective role. The pulmonary C fibers are stimulated by physical engorgement of the pulmonary capillaries, such as pulmonary edema, pulmonary emboli, or congestive heart failure. When stimulated, they cause a reflex of increased in breathing rate. The bronchial C fibers are stimulated by hyperinflation of the lungs and to products of inflammation.

Proprioceptors provide information about the body's activity and muscle tension.

Proprioceptors are located in tendons and skeletal muscle and can play a role in breathing, particularly when more than quiet breathing is called for or when breathing efforts are opposed by increased airway resistance or reduced lung compliance. One type of proprioceptors, *muscle spindle receptors*, provides information about changes in muscle length. A considerable number of muscle spindles are located in the intercostal muscles, but not in the diaphragm. Another type, *Golgi tendon organ*, is located in the tendons that attach muscle to bone and provide information muscle tension. When both types of proprioceptors are stimulated, they cause a reflex of increased ventilation.

Central and peripheral chemoreceptors respond to changes in arterial blood gases and hydrogen ion concentration.

Another set of receptors that profoundly affect breathing are the **chemoreceptors** (see Fig. 21.1). These receptors are stimulated by the hydrogen ion concentration [H^+] and respiratory gas composition of the arterial blood. The general rule is that breathing activity is inversely related to arterial blood PO_2, but directly related to PCO_2 and [H^+]. Figures 21.4 and 21.5 show the ventilatory responses of a typical person when alveolar PCO_2 ($PACO_2$) and PO_2 are individually varied by controlling the composition of inspired gas. Responses to carbon dioxide and, to a lesser extent, blood pH depend on sensors in the brainstem, carotid arteries, and aorta. In contrast, responses to hypoxia are brought about only by the stimulation of arterial receptors.

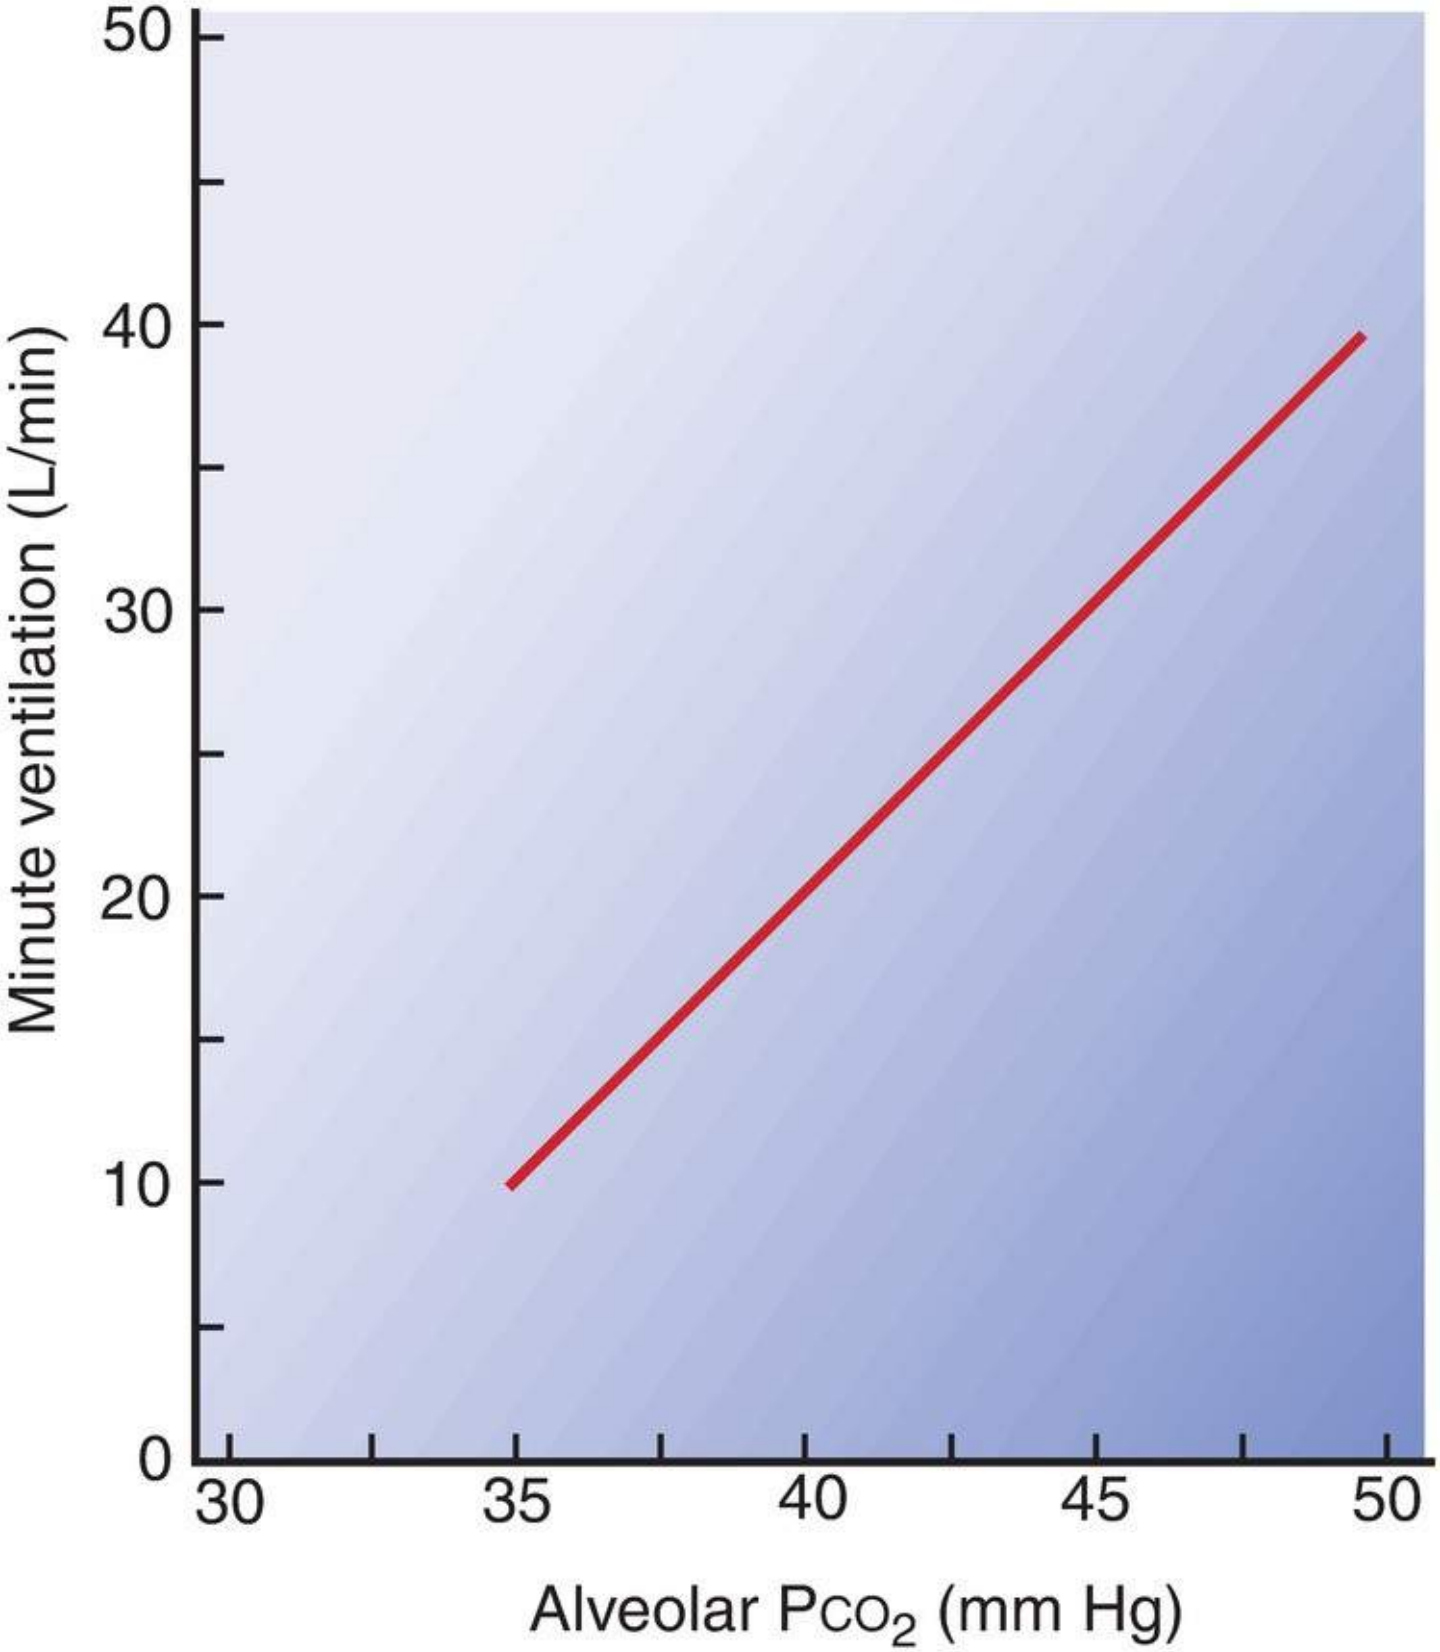

Figure 21.4 CO_2 is a powerful stimulus to ventilation. Ventilatory responses to increasing alveolar CO_2 tension are shown with the line, representing the response when alveolar PO_2 (PAO_2) is held at ≥100 mm Hg to essentially eliminate O_2-dependent activity of the chemoreceptors.

Figure 21.5 Ventilatory responses to hypoxia are mediated via the peripheral chemoreceptors. Inspired oxygen is lowered, while alveolar PCO_2 ($PACO_2$) is held at 40 mm Hg by adding CO_2 to the inspired air in order to eliminate the chemoresponse to CO_2-dependent activity. Note that when alveolar carbon dioxide is held constant at 43 mm Hg, minute ventilation does not significantly change until alveolar PO_2 is reduced to 60 mm Hg.

Cerebrospinal fluid [H^+] stimulates neuronal cells in the medulla.

Ventilatory drive is exquisitely sensitive to PCO_2 of blood perfusing the brain. The source of this chemosensitivity has been localized to bilaterally paired groups of cells just below the surface of the ventrolateral medulla immediately caudal to the pontomedullary junction. Each side contains a rostral and a caudal chemosensitive zone, separated by an intermediate zone in which the activities of the caudal and rostral groups converge and are integrated together with other autonomic functions. Exactly which cells exhibit chemosensitivity is unknown, but they are not the same as those of the DRG/VRG complex. Although specific cells have not been identified, the chemosensitive neurons that respond to the [H^+] of the surrounding interstitial fluid are referred to as **central chemoreceptors**. The H^+ concentration in the interstitial fluid is a function of PCO_2 in the cerebral arterial blood and the bicarbonate concentration of cerebrospinal fluid (CSF).

Cerebrospinal fluid has a weak buffering system and is sensitive to changes in carbon dioxide partial pressure.

CSF is an ultrafiltrate of plasma and is formed mainly by the **choroid plexuses** of the ventricular cavities of the brain. The epithelium of the choroid plexus provides a barrier between blood and CSF that severely limits the passive movement of large molecules, charged molecules, and inorganic ions. However, choroidal epithelium actively transports several substances, including ions, and this active transport participates in determining the composition of CSF. This selective barrier is termed the **blood–brain barrier** and is illustrated in Figure 21.6. CSF formed by the choroid plexuses is exposed to brain interstitial fluid across the surface of the brain and spinal cord, with the result that the composition of CSF away from the choroid plexuses is closer to that of interstitial fluid than it is to CSF as first formed. Brain interstitial fluid is also separated from blood by the blood–brain barrier (capillary endothelium), which has its own transport capability.

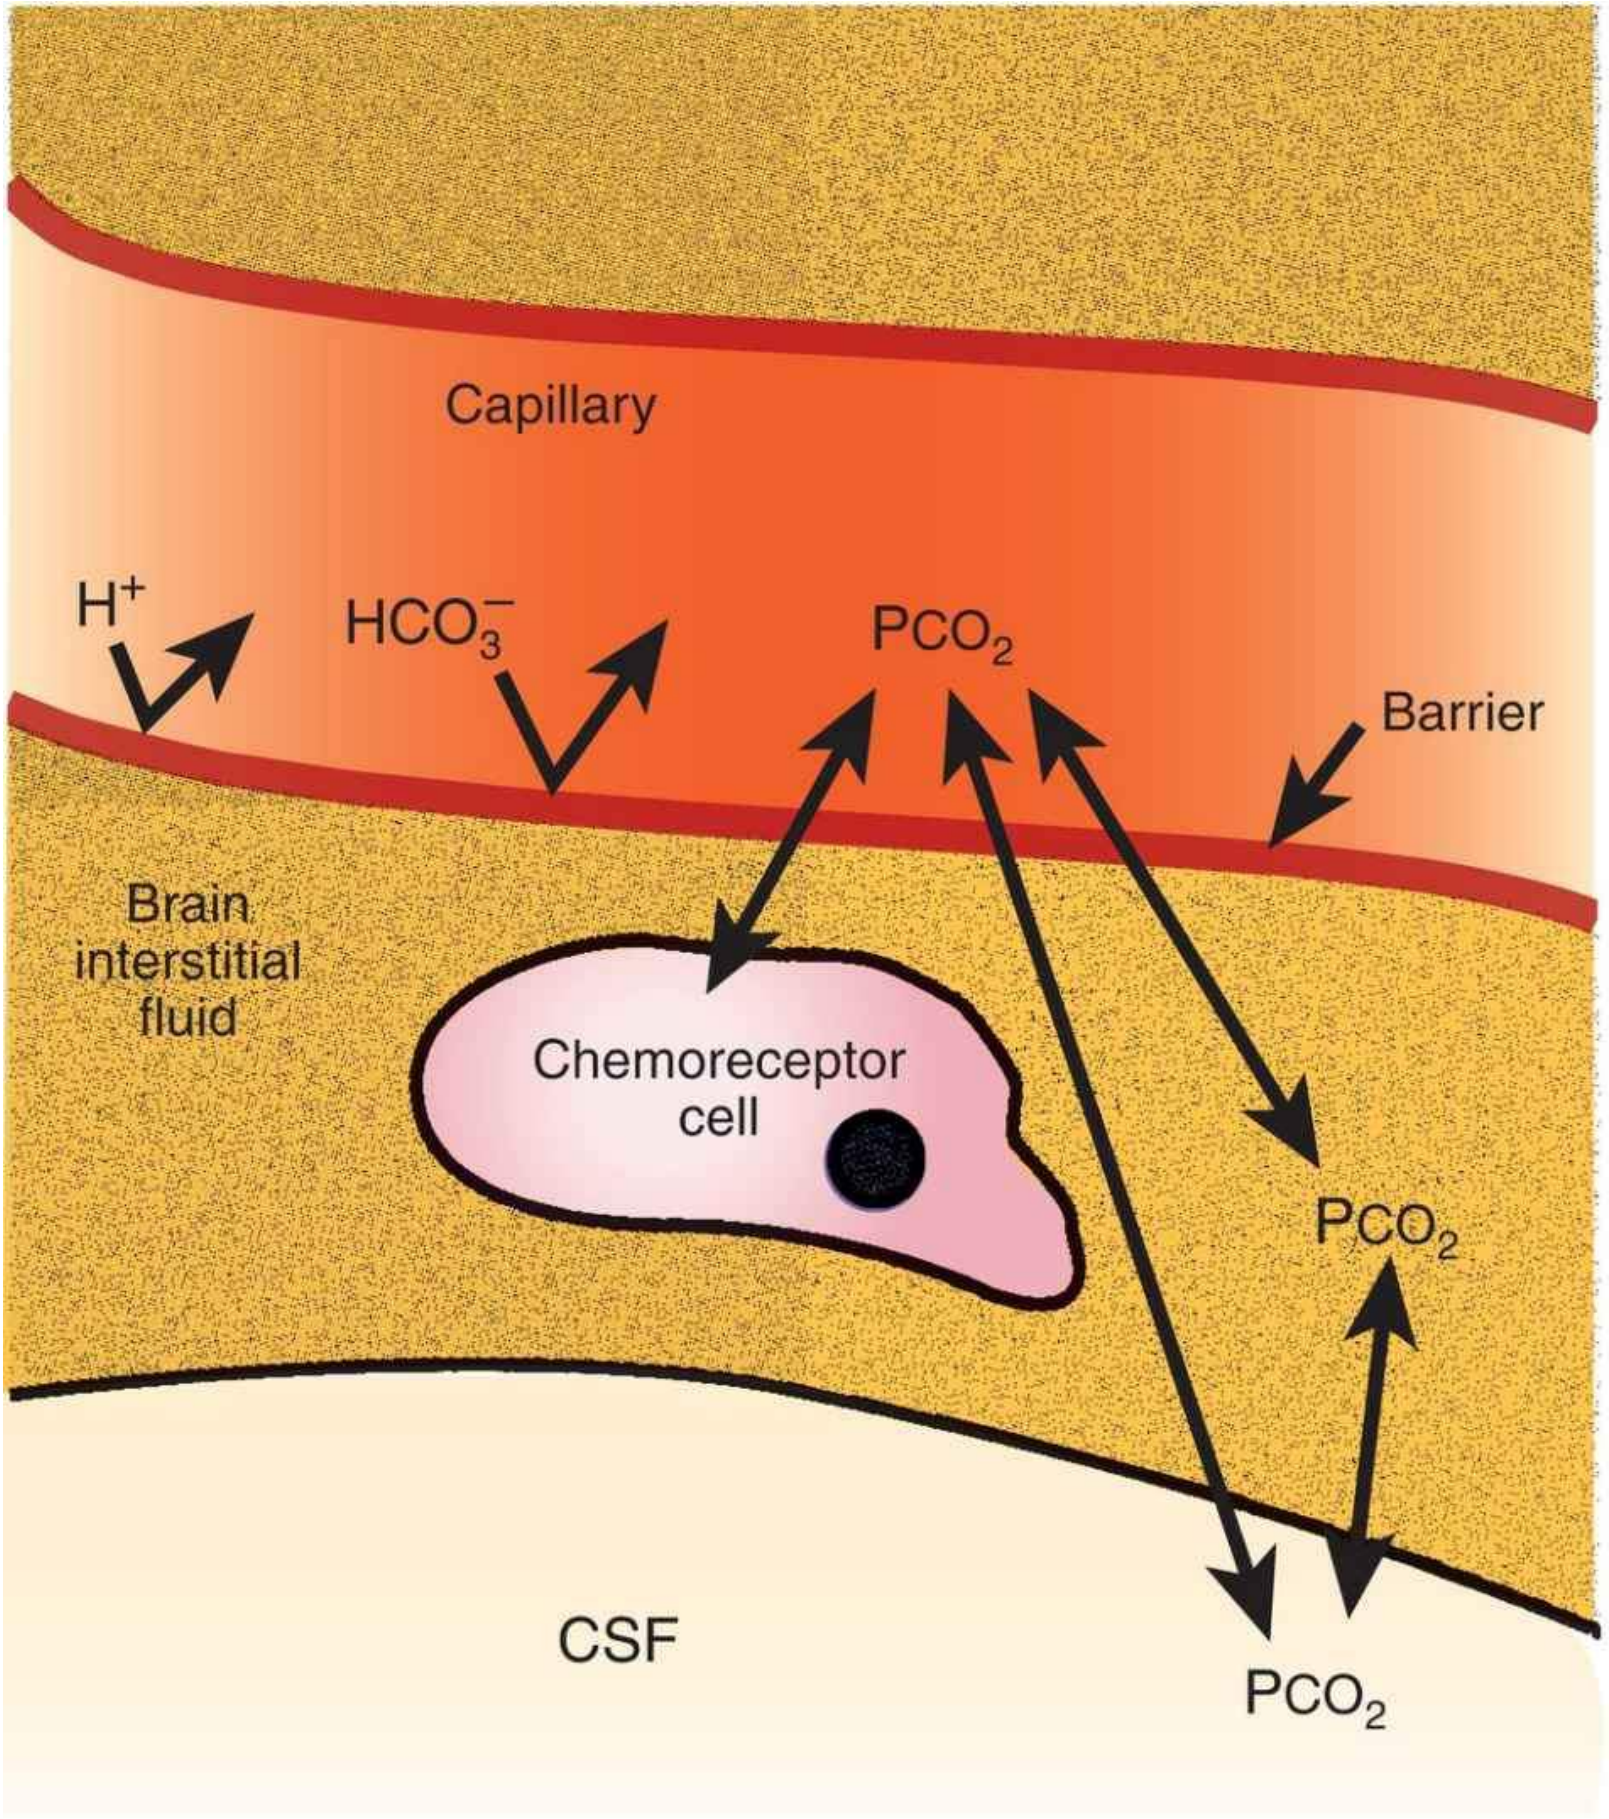

Figure 21.6 The **blood–brain barrier is impermeable to blood H^+ and HCO_3^-.** Movement of H^+, HCO_3^-, and molecular CO_2 is illustrated between capillary blood, brain interstitial fluid, and cerebrospinal fluid (CSF). Because the blood–brain barrier is permeable to CO_2 and not to H^+ and HCO_3^-, the acid–base status of the chemoreceptors can be quickly changed only by changing $PaCO_2$.

Because of the properties of the limiting membranes, CSF is essentially free of protein, but it is not just a simple ultrafiltrate of plasma. CSF differs most notably from an ultrafiltrate by its lower bicarbonate and higher sodium and chloride ion concentrations. Potassium, magnesium, and calcium ion concentrations also differ somewhat from plasma; moreover, they change little in response to marked changes in plasma concentrations of these cations. Most proposed regulatory mechanisms invoke the active transport of one or more ionic species by the epithelial and endothelial membranes. Because of the relative impermeabilities of the choroidal epithelium and capillary endothelium to H^+, changes in H^+ concentration of blood are poorly reflected in CSF. By contrast, molecular carbon dioxide diffuses readily; therefore, blood PCO_2 can influence the pH of CSF. The pH of CSF is primarily determined by its bicarbonate concentration and PCO_2. The relative ease of movement of molecular carbon dioxide in contrast to hydrogen ions and bicarbonate is depicted in Figure 21.6.

In healthy people, the PCO_2 of CSF is about 6 mm Hg higher than that of arterial blood, approximating that of brain tissue. The pH of CSF, normally slightly below that of blood, is held within narrow limits. CSF pH changes little in states of metabolic acid–base disturbances (see Chapter 24)—about 10% of that in plasma. In respiratory acid–base disturbances, however, the change in pH of the CSF may exceed that of blood. During chronic acid–base disturbances, the bicarbonate concentration of CSF changes in the same direction as in blood, but the changes may be unequal. In metabolic disturbances, the CSF bicarbonate changes are about 40% of those in blood, but with respiratory disturbances, CSF and blood bicarbonate changes are essentially the same. When acute acid–base disturbances are imposed, CSF bicarbonate changes more slowly than blood bicarbonate and may not reach a new steady state for hours or days. As already noted, the mechanism of bicarbonate regulation is unsettled. Irrespective of how it occurs, the bicarbonate regulation that occurs with acid–base disturbances is important because, by changing buffering, it influences the response to a given PCO_2.

Peripheral chemoreceptors respond to PO_2 and PCO_2 and $[H^+]$ in the arterial blood.

Peripheral chemoreceptors are located in the carotid and aortic bodies. They both detect changes in arterial blood plasma PO_2, PCO_2, and pH (see Fig. 21.1). **Carotid bodies** are small (~2 mm wide) sensory organs located bilaterally near the bifurcations of the common carotid arteries near the base of the skull. Afferent nerves travel to the CNS from the carotid bodies in the glossopharyngeal nerves. **Aortic bodies** are located along the arch of the aorta and are innervated by vagal afferents.

As with the medullary chemoreceptors, increasing $PaCO_2$ stimulates peripheral receptors. H^+ formed from H_2CO_3 within the peripheral chemoreceptors (glomus cells) is the stimulus and not molecular CO_2. About 40% of the effect of $PaCO_2$ on ventilation is brought about by peripheral chemoreceptors, whereas central chemoreceptors bring about the rest. Unlike the central sensor, peripheral chemoreceptors are sensitive to rising arterial blood H^+ and falling PO_2. They alone cause the stimulation of breathing by low oxygen; hypoxia in the brain has little effect on breathing unless it is severe, at which point breathing is depressed.

Carotid chemoreceptors play a more prominent role than do aortic chemoreceptors; because of this and their greater accessibility, they have been studied in greater detail. The discharge rate of carotid chemoreceptors (and the resulting minute ventilation) is approximately linearly related to $PaCO_2$. The linear behavior of the receptor is reflected in the linear ventilatory response to carbon dioxide illustrated in Figure 21.4. When expressed using pH, the response curve is no longer linear but shows a progressively increasing effect as pH falls below normal. This occurs because pH is a logarithmic function of $[H^+]$, so the absolute change in $[H^+]$ per unit change in pH is greater when brought about at a lower pH.

The response of peripheral chemoreceptors to oxygen depends on arterial PO_2 (PaO_2) and not oxygen content. Therefore, anemia or carbon monoxide poisoning, two conditions that exhibit reduced oxygen content but have normal PaO_2, have little effect on the response curve. The shape of the response curve is not linear; instead, hypoxia is of increasing effectiveness as PO_2 falls below about 90 mm Hg. The behavior of the receptors is reflected in the ventilatory response to hypoxia illustrated in Figure 21.5. The shape of the curve relating ventilatory response to PO_2 resembles that of the oxyhemoglobin equilibrium curve when plotted upside down (see Chapter 20). As a result, the ventilatory response is inversely related in an approximately linear fashion to arterial blood oxygen saturation.

The nonlinearities of the ventilatory responses to PO_2 and pH and the relatively low sensitivity across the normal ranges of these variables cause ventilatory changes to be apparent only when PO_2 and pH deviate significantly from the normal range, especially toward hypoxemia or acidemia. By contrast, ventilation is sensitive to PCO_2 within the normal range, and carbon dioxide is normally the dominant chemical regulator of breathing through the use of both central and peripheral chemoreceptors (compare Figs. 21.4 and 21.5).

There is a strong interaction among stimuli, which causes the slope of the carbon dioxide response curve to increase if determined under hypoxic conditions (see Fig. 21.4), causing the response to hypoxia to be directly related to the prevailing PCO_2 and pH (see Fig. 21.5). As discussed in the next section,

these interactions and interaction with the effects of the central carbon dioxide sensor profoundly influence the integrated chemoresponses to a primary change in arterial blood composition.

Carotid and aortic bodies can also be strongly stimulated by certain chemicals, particularly cyanide ion and other poisons of the metabolic respiratory chain. Changes in blood pressure have only a small effect on chemoreceptor activity, but responses can be stimulated if arterial pressure falls below about 60 mm Hg. This effect is more prominent in aortic bodies than in carotid bodies. Afferent activity of peripheral chemoreceptors is under some degree of efferent control capable of influencing responses by mechanisms that are not clear. Afferent activity from the chemoreceptors is also centrally modified in its effects by interactions with other reflexes, such as the lung stretch reflex and the systemic arterial baroreflex (see Chapter 17). Although the breathing interactions are not well understood in humans, they serve as examples of the complex interactions of cardiorespiratory regulation. Interactions among chemoreflexes, however, are easily demonstrated.

Figure 21.7 is a schematic summarizing the chemical control of ventilation by changes in arterial PO_2, PCO_2, and $[H^+]$.

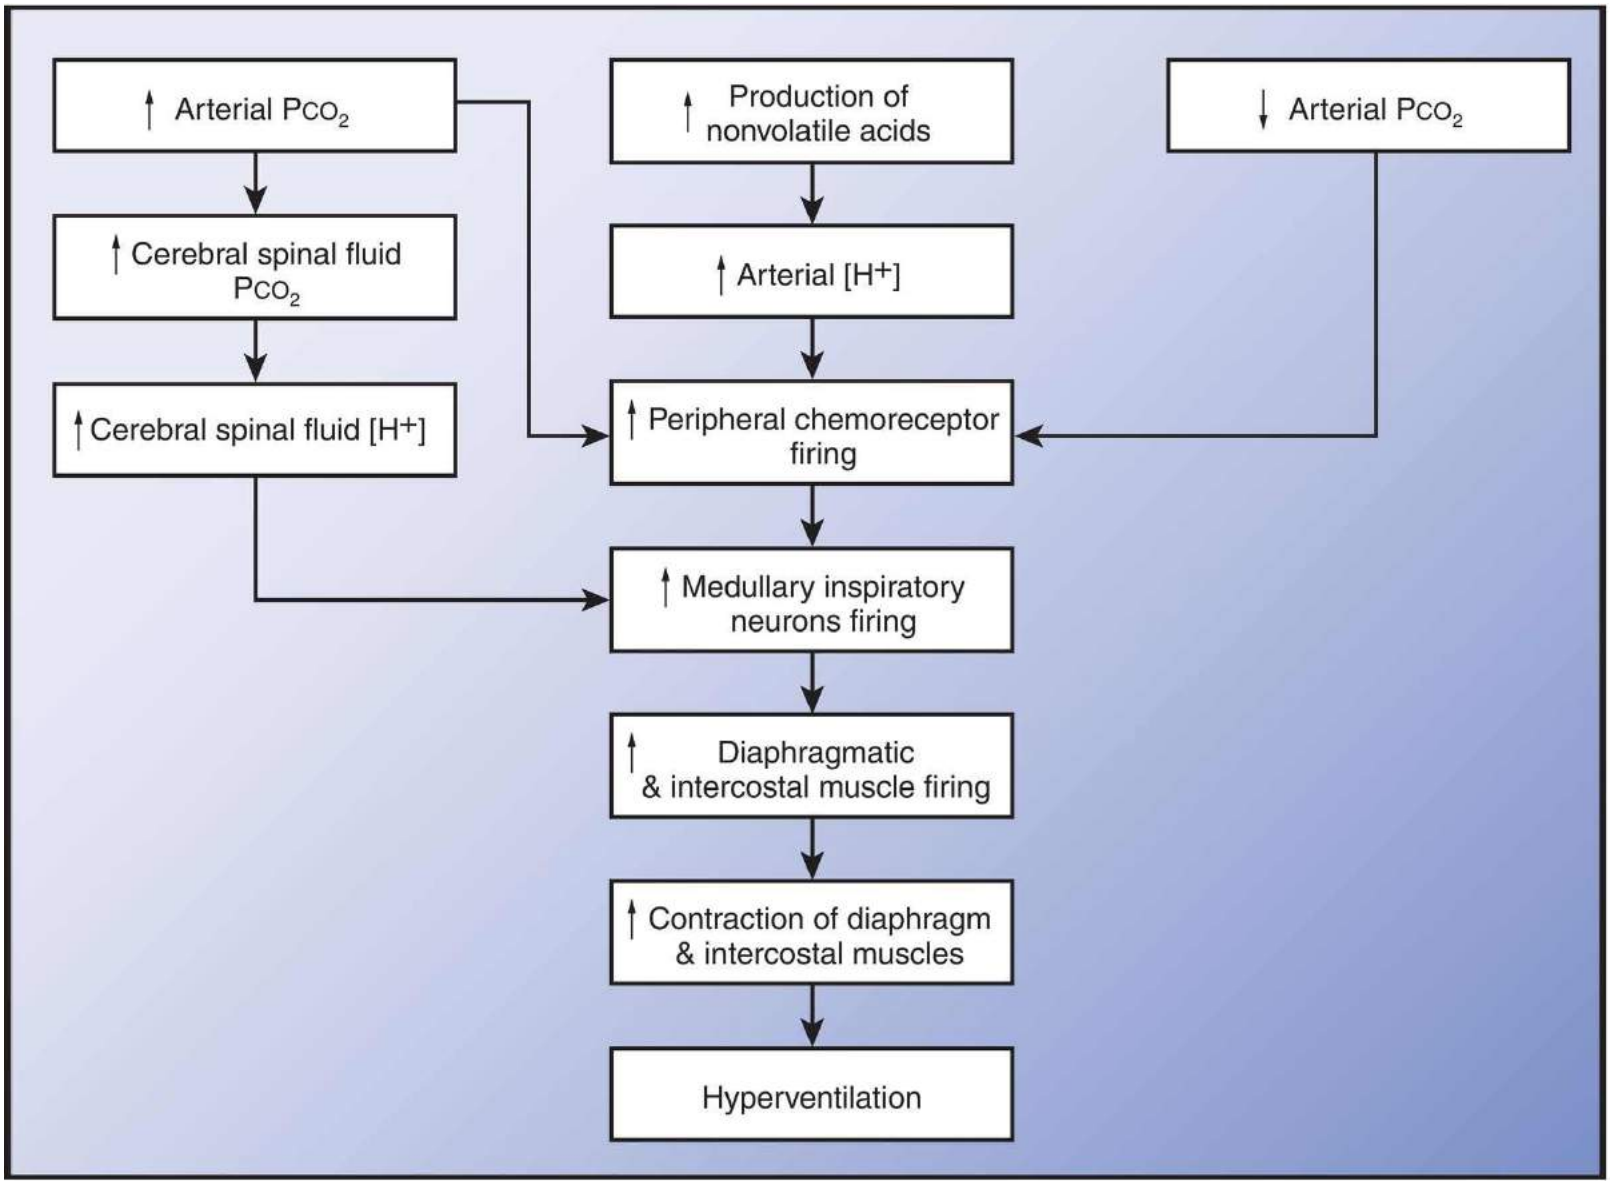

Figure 21.7 Summary of the chemical control of ventilation. This schematic illustrates the major chemical inputs that stimulate ventilation. An increase in arterial PCO_2 and $[H^+]$ and a decrease in arterial PO_2 stimulate ventilation. Conversely, when PO_2 is elevated and arterial PCO_2 and $[H^+]$ are decreased, ventilation is inhibited.

PHYSIOLOGIC RESPONSES TO ALTERED OXYGEN AND CARBON DIOXIDE

Before the interactions of the chemoresponses to oxygen and carbon dioxide are discussed, a brief review of terminology is order. Hypoxia leads to **hypoxemia** (a condition in which the PaO_2 is below normal). Hypoxemia stimulates respiration, causing **hyperventilation** (increased alveolar ventilation greater than required to meet metabolic needs). Hyperventilation results in excess carbon dioxide being blown off, which, in turn, leads to **hypocapnia** (a condition in which $PaCO_2$ is below normal). A low $PaCO_2$ decreases blood $[H^+]$, leading to **alkalosis** (a condition in which arterial blood pH is above normal). Because alkalosis in this case is caused by hyperventilation, the condition is termed **respiratory alkalosis**. When the lungs are underventilated, alveolar ventilation is less than required to meet metabolic needs (**hypoventilation**) leading to a concomitant decrease in PaO_2 and an elevated in $PaCO_2$ (**hypercapnia**). As a result of hypercapnia, there is an increase in arterial blood $[H^+]$ that leads to **acidosis** (a condition in which blood pH is below normal). Again, because the acidotic condition is caused by a respiratory dysfunction, the condition is referred to as **respiratory acidosis**. Another condition caused by metabolic accumulation of nonvolatile acids, such as lactic acid, leads to **metabolic acidosis**. Respiratory acidosis (accumulation of carbon dioxide) and metabolic acidosis (accumulation of lactic acid) both cause low arterial blood pH; the only difference between them is the cause of the acidotic condition; one is metabolic in nature and the other respiratory.

A distinction needs to be made between hyperventilation and **hyperpnea** (increased alveolar ventilation in proportion to elevated metabolism, e.g., exercise). Remember that *hyperventilation* is characterized by an increase in alveolar ventilation with a concomitant decrease in arterial PCO_2, whereas *hyperpnea* is an increase in alveolar ventilation relative to metabolic carbon dioxide production. The distinguishing feature of hyperpnea is increased ventilation with no change in arterial blood PCO_2, because alveolar ventilation increases in proportion to carbon dioxide production.

Responses to altered blood oxygen and carbon dioxide are interdependent.

The effect of PO_2 on the response to carbon dioxide and the effect of carbon dioxide on the response to PO_2 have already been noted. By virtue of this interdependence, the subsequent increased ventilation is blunted in a hyperventilatory response, unless $PACO_2$ is somehow maintained, because $PACO_2$ ordinarily falls as ventilation is stimulated (see Fig. 21.5). The central chemoreceptors, which respond more potently than the peripheral receptors to low $PACO_2$, are mainly responsible for blunting the stimulating effect of hyperventilation. The sequence of events in the response to hypoxia (e.g., ascent to high altitude) exemplifies interactions among chemoresponses. For example, if 100% oxygen is given to a person just arriving at high altitude, ventilation is quickly restored to its sea-level value. During the next few days, ventilation in the absence of supplemental oxygen progressively rises further, but it is no longer restored to sea-level value by breathing oxygen. Rising ventilation while acclimatizing to altitude could be explained by a reduction of blood and CSF bicarbonate concentrations. This would reduce the initial increase in pH created by the increased ventilation and allow the hypoxic stimulation to be less strongly opposed. However, this mechanism is not the full explanation of altitude acclimatization. CSF pH is not fully restored to normal, and the increasing ventilation raises PaO_2 while further lowering $PaCO_2$, changes that should inhibit the stimulus to breathe. In spite of much inquiry, the reason for persistent hyperventilation in altitude-acclimatized subjects, the full explanation for altitude acclimatization, and the explanation for the failure of increased ventilation in acclimatized subjects to be relieved promptly by restoring a normal PaO_2 are still unknown.

In *metabolic acidosis*, the increase in arterial blood $[H^+]$ initiates and sustains hyperventilation by stimulating the peripheral chemoreceptors (Fig. 21.8). Because of the restricted movement of H^+ into CSF, the fall in blood pH cannot directly stimulate the central chemoreceptors. The central effect of the hyperventilation, brought about by decreased pH via the peripheral chemoreceptors, results in a paradoxical rise of CSF pH (i.e., an alkalosis as a result of reduced $PaCO_2$) that actually restrains the hyperventilation. With time, CSF bicarbonate concentration is adjusted downward, although it changes less than that of blood, and the pH of CSF remains somewhat higher than pH of blood. Ultimately, ventilation increases more than it did initially as the paradoxical CSF alkalosis is removed.

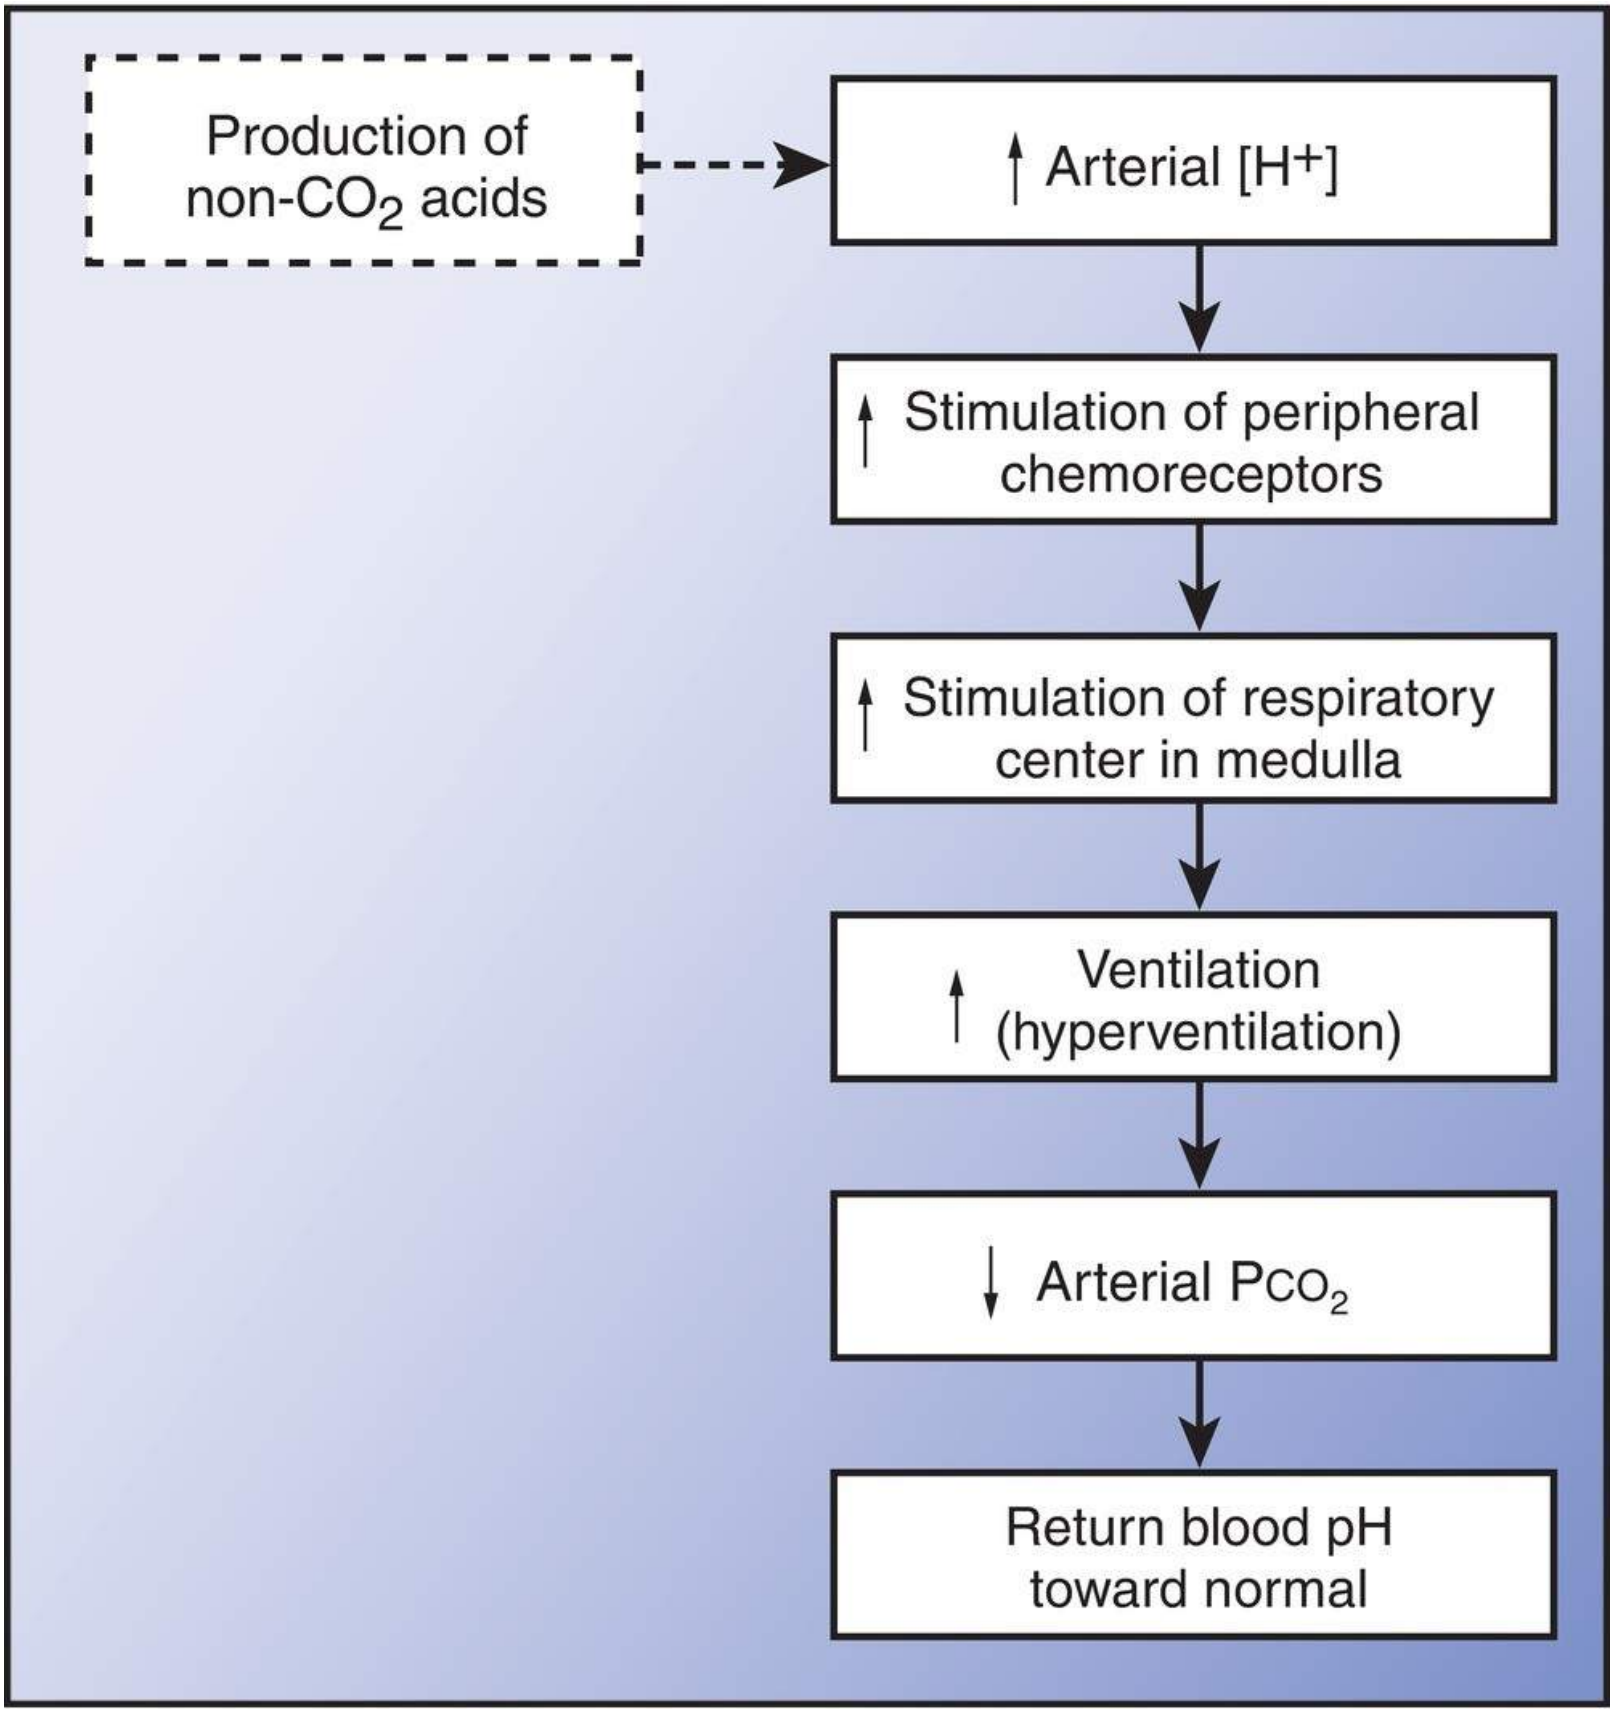

Figure 21.8 Metabolic acidosis stimulates hyperventilation via the peripheral chemoreceptors. The accumulation of non-CO_2 acids increases the blood [H^+] and stimulates breathing. The sustained hyperventilation occurs by stimulating the respiratory center in the medulla via the peripheral chemoreceptors. The sustained hyperventilation blows off alveolar CO_2, which lowers $PaCO_2$ and compensates by returning blood pH back toward normal.

Respiratory acidosis is rarely a result of elevated environmental CO_2, although this can occur in submarine mishaps, in wet limestone caves, and in physiology laboratories where responses to carbon dioxide are measured. Under these conditions, the response is a vigorous increase in minute ventilation proportional to the level of $PaCO_2$; PaO_2 actually rises slightly and arterial pH falls slightly, but these have relatively little effect. If mild hypercapnia can be sustained for a few days, the intense hyperventilation subsides, probably as CSF bicarbonate is raised. More commonly, respiratory acidosis occurs from generalized hypoventilation and results from failure of the controller to respond to carbon dioxide (e.g., during anesthesia, following brain injury, and in some patients with chronic obstructive lung disease). The hypoventilation response is illustrated in Figure 21.9. Another cause of respiratory acidosis is patients with obstructive lung disease. When these subjects breathe room air, hypercapnia caused by reduced alveolar ventilation is accompanied by significant hypoxia and acidosis. If the hypoxic component alone is corrected—for example, by breathing oxygen-enriched air—a significant reduction in the ventilatory stimulus may promote underventilation, thereby increasing hypercapnia and acidosis. A more appropriate treatment is providing mechanical assistance for restoring adequate ventilation.

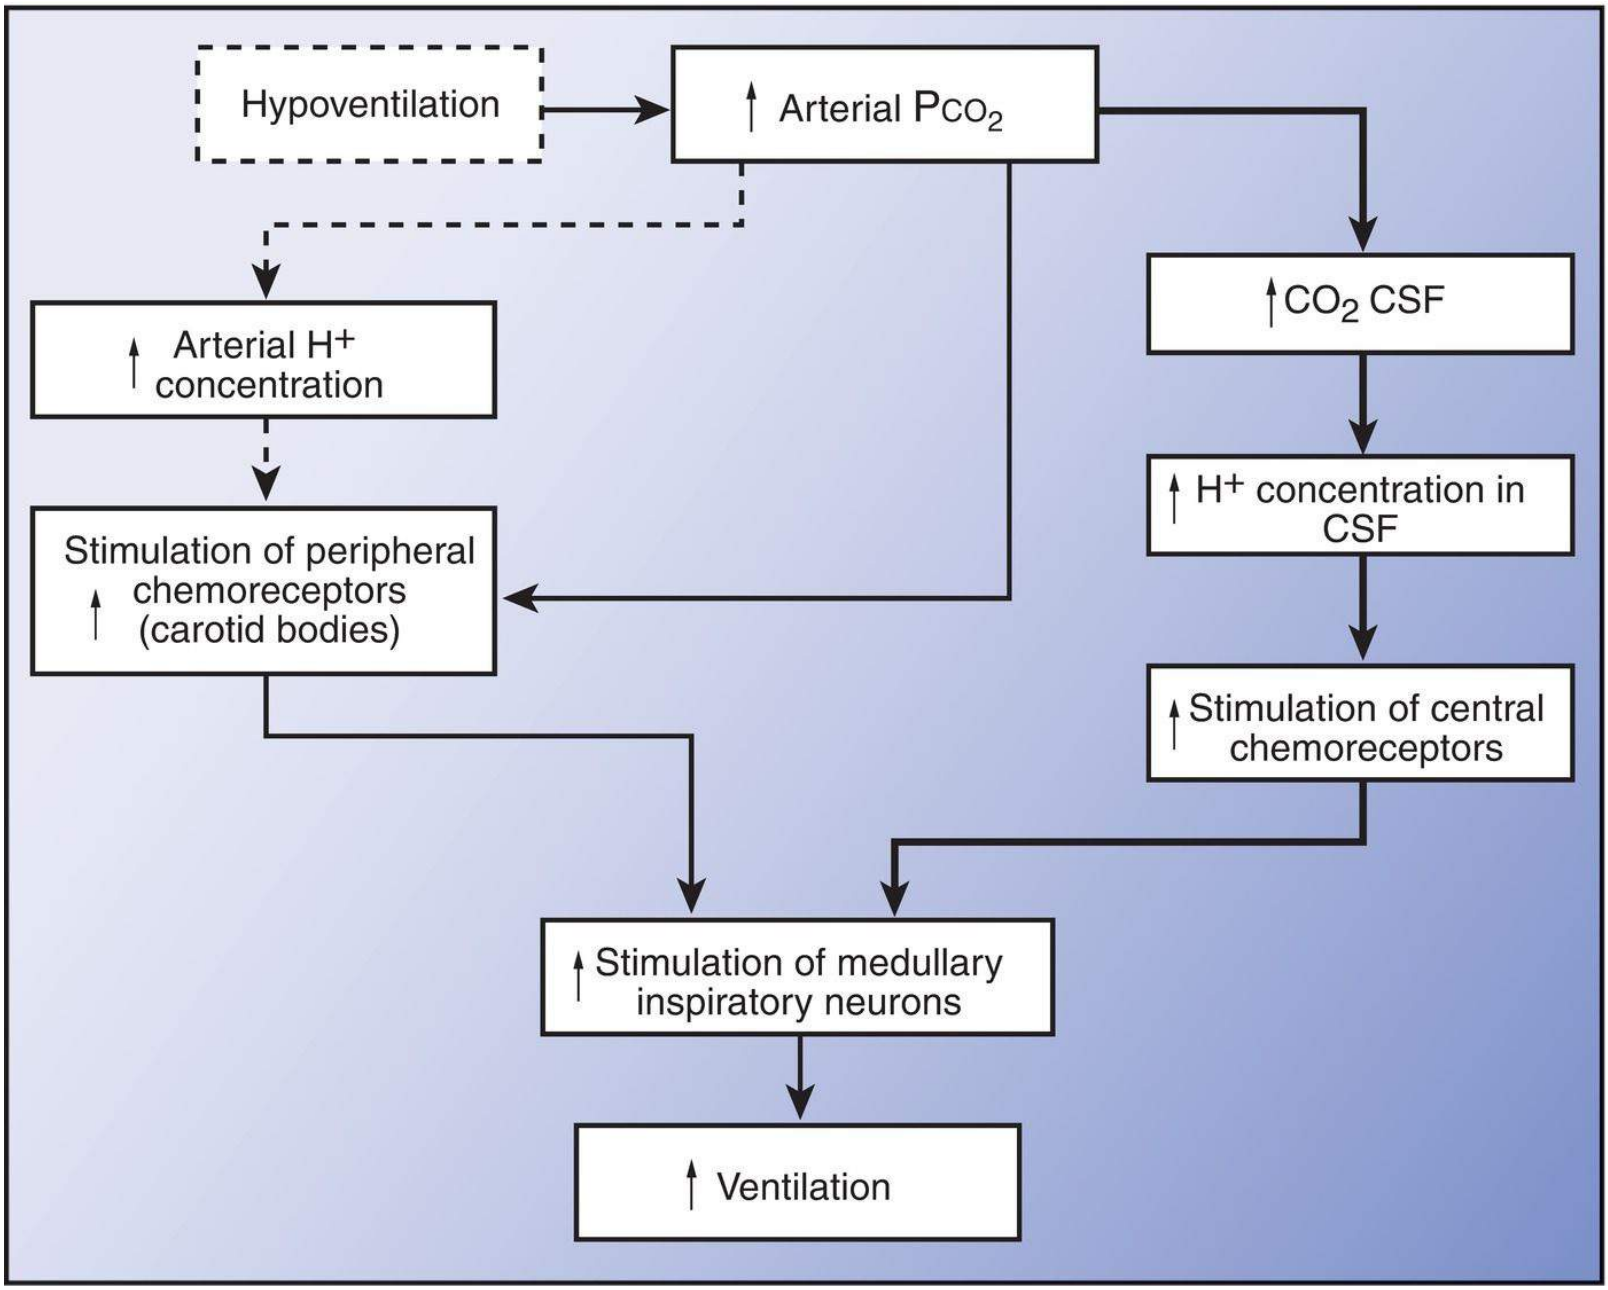

Figure 21.9 Generalized hypoventilation is the primary cause of respiratory acidosis. When the lungs are underventilated, arterial blood CO_2 rises (hypercapnia), leading to respiratory acidosis. The common cause for respiratory acidosis is failure of the controller to respond to carbon dioxide (e.g., anesthesia, head injury, and patients with severe chronic obstructive pulmonary disease). CSF, cerebrospinal fluid.

Exercise-induced hyperpnea is not stimulated by increased PCO_2, arterial pH, or decreased PaO_2.

With light-to-moderate exercise, PaO_2, PCO_2, and pH are essentially unchanged from normal values. Yet ventilation can be substantially increased in these exercise regimes. Even with heavy exercise, a person with a normal cardiovascular system does not become hypoxemic or acutely hypercapnic. What controls ventilation during exercise if chemoresponses to changes in PaO_2, PCO_2, and atrial pH are not involved? The answer to this question involves various control systems, many of which are not well defined. The control of breathing with exercise occurs in three phases and includes the *neurological phase (phase I)*, the *metabolic phase (phase II)*, and the *compensatory phase (phase III)*. In phase I, ventilation increases almost instantly with the onset of exercise and involves a neurologic response insofar as the increase occurs in the absence of any changes in blood gases and metabolism. The neurologic phase involves the medullary generator (see Fig. 21.4) and a feedforward mechanism. During this phase, depth and rate of breathing change in response to the activity of the medullary generator, which increases in parallel with the excitation of the muscles used during exercise. Another recognized feedforward mechanism is stimulation of ventilation in response to increased receptor activity to skeletal joints as joint motion increases with exercise.

In phase II, as exercise continues, ventilation increases linearly with the increase in carbon dioxide production. Exercise-induced hyperpnea occurs in this phase, because the increase in alveolar ventilation is proportional to carbon dioxide production, and as a result, there is no change in $PaCO_2$. Remember, not only $PaCO_2$ does not change with exercise-induced hyperpnea, but there is no change in PaO_2 and arterial pH as well. Although the increased ventilation is tightly coupled to carbon dioxide production, it is still not known how the medullary controller monitors carbon dioxide production. One hypothesis is that a feedforward scheme senses the magnitude of the carbon dioxide load delivered to the lungs by systemic venous blood, which in return drives ventilation. Experimental evidence supports this mechanism, but specific intrapulmonary sensors have not been identified.

In phase III, the intensity of exercise increases (i.e., exhaustive exercise), and the energy needs outstrip the ability of the cardiovascular system to supply sufficient oxygen for aerobic metabolism. Muscle cells shift to anaerobic metabolism with increased blood lactic acid as a by-product. Sustained ventilation is compensation for the development to metabolic acidosis, hence the term *compensatory phase*. During this phase, the sustained ventilation is driven by the acidotic condition.

CONTROL OF BREATHING DURING SLEEP

We spend about one third of our lives asleep. Sleep disorders and disordered breathing during sleep are common and often have physiologic consequences. Chapter 7 describes the two different neurophysiologic sleep states: **rapid eye movement (REM) sleep** and **slow-wave sleep**. Sleep is a condition that results from withdrawal of the wakefulness stimulus that arises from the brainstem reticular formation. This wakefulness stimulus is one component of the tonic excitation of brainstem respiratory neurons, and one would predict correctly that sleep results in a general depression of breathing. There are, however, other changes, and the effects of REM and slow-wave sleep on breathing differ.

Sleep changes the breathing frequency and inspiratory flow rate.

During *slow-wave sleep*, breathing frequency and inspiratory flow rate are reduced, and minute ventilation falls. These responses partially reflect the reduced physical activity that accompanies sleep. However, because of the small rise in $PaCO_2$ (about 3 mm Hg), there must also be a change in either the sensitivity or the set point of the carbon dioxide controller. In the deepest stage of slow-wave sleep (stage 4), breathing is slow, deep, and regular. But in stages 1 and 2, the depth of breathing sometimes varies periodically. The explanation is that during light sleep, withdrawal of the wakefulness stimulus varies over time in a periodic fashion. When the stimulus is removed, sleep is deepened and breathing is depressed; when returned, breathing is excited not only by the wakefulness stimulus but also by the carbon dioxide retained during the interval of sleep. This periodic pattern of breathing is known as **Cheyne-Stokes breathing** (Fig. 21.10).

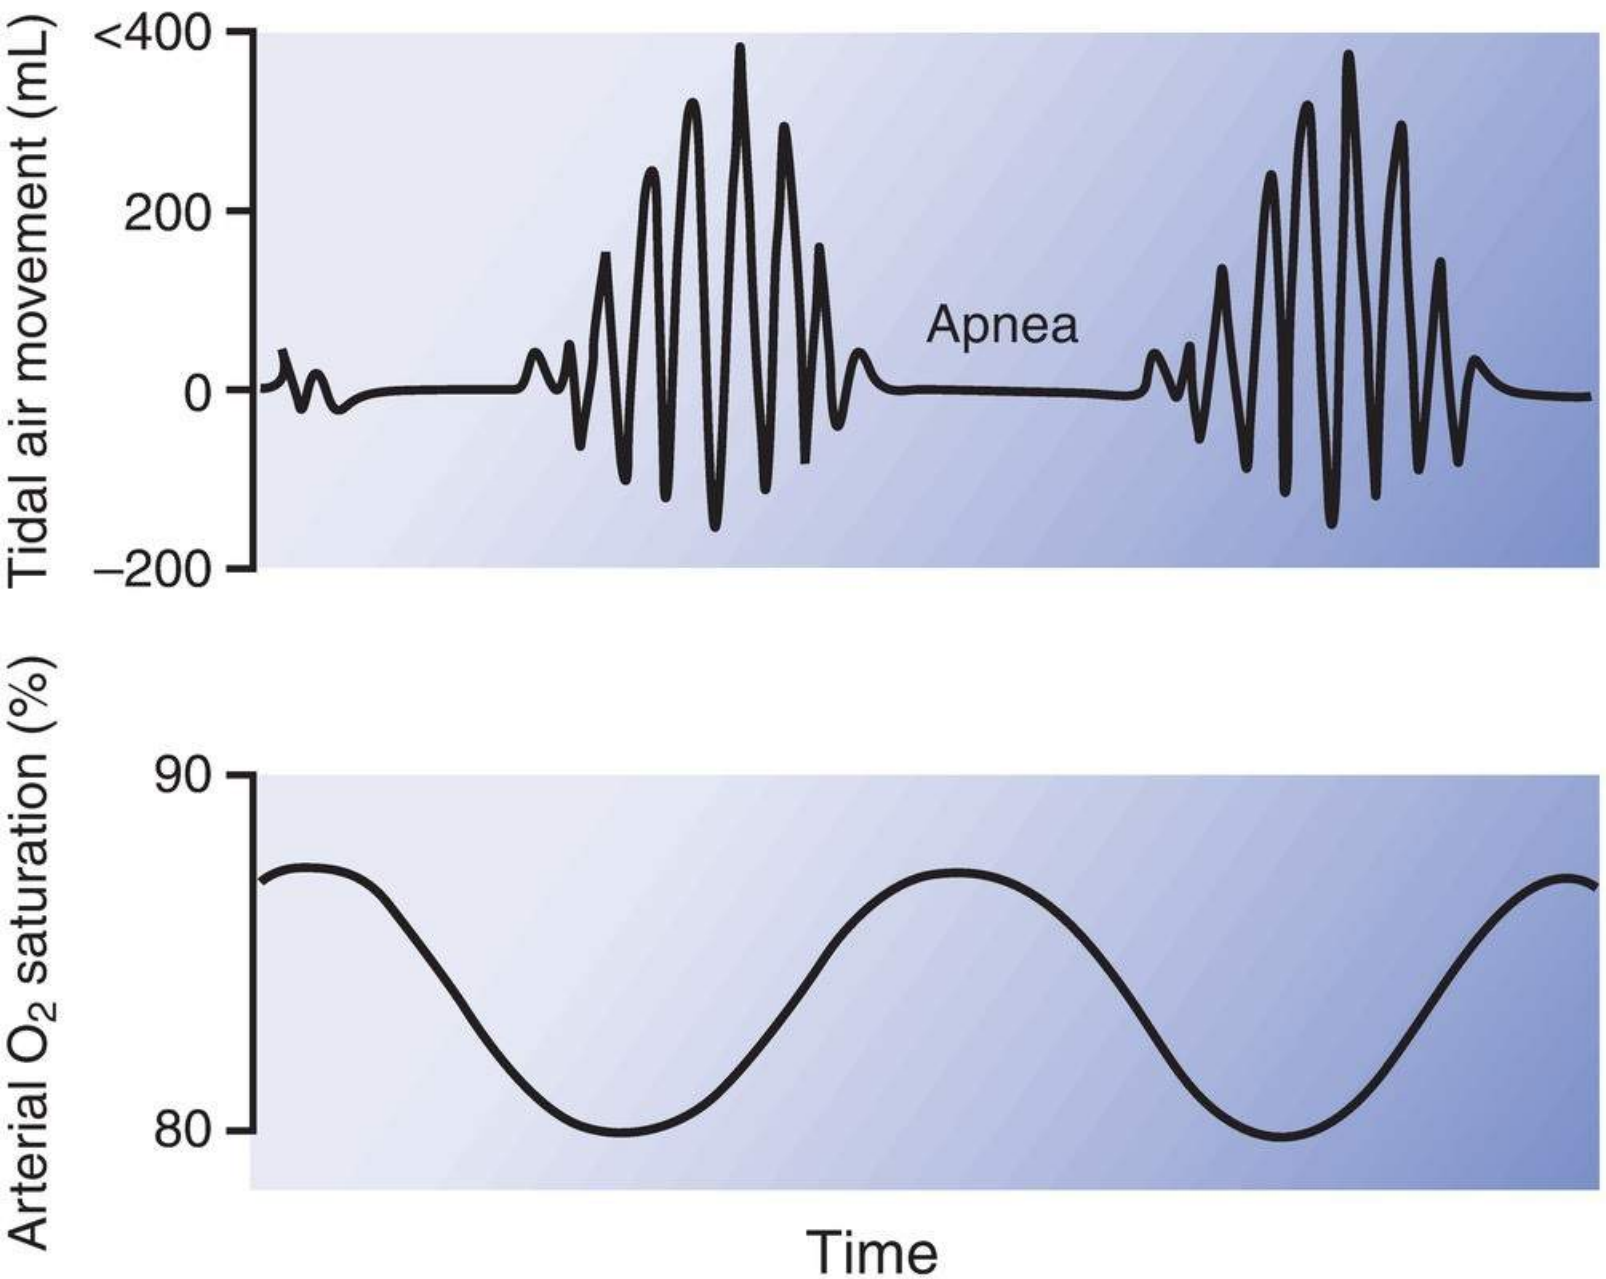

Figure 21.10 Cheyne-Stokes breathing lowers arterial O_2 saturation. Cheyne-Stokes breathing occurs frequently during sleep, especially in subjects at high altitude, as in this example. In the presence of

preexisting hypoxemia secondary to high altitude or other causes, the periods of apnea may result in further decreases of O_2 saturation to dangerous levels. Falling PO_2 and rising PCO_2 during the apnea intervals ultimately induce a response, and breathing returns, reducing the stimuli and leading to a new period of apnea.

In *REM sleep*, breathing frequency varies erratically, whereas tidal volume varies little. The net effect on alveolar ventilation is probably a slight reduction, but this is achieved by averaging intervals of frank **tachypnea** (excessively rapid breathing) with intervals of apnea. Unlike those in slow-wave sleep, the variations during REM sleep do not reflect a changing wakefulness stimulus but instead represent responses to increased CNS activity of behavioral, rather than autonomic or metabolic, control systems (Clinical Focus 21.1).

CLINICAL FOCUS 21.1

Sleep Apnea Syndrome

The analysis of multiple physiologic variables recorded during sleep, known as polysomnography, is an important method for research into the control of breathing and has been increasingly used in clinical evaluations of sleep disturbances. In normal sleep, reduced dilatory upper airway muscle tone may be accompanied by brief intervals of no breathing movements. Some people, typically overweight men, exhibit more severe disruption of breathing, referred to as **sleep apnea syndrome**. Sleep apnea is classified in two broad groups: obstructive and central.

In *central sleep apnea*, breathing movements cease for a longer-than-normal interval. In obstructive sleep apnea, the fault seems to lie in a failure of the pharyngeal muscles to open the airway during inspiration. This may be the result of decreased muscle activity, but the obstruction is worsened by an excessive amount of neck fat with which the muscles must contend. With *obstructive sleep apnea*, progressively larger inspiratory efforts eventually overcome the obstruction, and airflow is temporarily resumed, usually accompanied by loud snoring.

Some patients exhibit both central and obstructive sleep apneas. In both types, hypoxemia and hypercapnia develop progressively during the apnea intervals. Frequent episodes of repeated hypoxia may lead to pulmonary and systemic hypertension and to myocardial distress; the accompanying hypercapnia is thought to be a cause of the morning headache these patients often experience. There may be partial arousal at the end of the periods of apnea, leading to disrupted sleep and resulting in drowsiness during the day. Daytime sleepiness, often leading to dangerous situations, is probably the most common and most debilitating symptom. The cause of this disorder is multivariate and often obscure, but mechanically assisted ventilation during sleep often results in significant symptomatic improvement. ■

Sleep blunts the respiratory sensitivity to carbon dioxide.

Responsiveness to carbon dioxide is reduced during sleep. In slow-wave sleep, the reduction in sensitivity seems to be secondary to a reduction in the wakefulness stimulus and its tonic excitation of the brainstem rather than to a suppression of the chemosensory mechanisms. It is important to note that breathing remains responsive to carbon dioxide during slow-wave sleep, although at a less sensitive level, and that carbon dioxide stimulus may provide the major background brainstem excitation in the absence of the wakefulness stimulus or behavioral excitation. Hence, pathologic alterations in the carbon dioxide chemosensory system may profoundly depress breathing during slow-wave sleep.

During intervals of REM sleep in which there is little sign of increased activity, the breathing response to carbon dioxide is slightly reduced, as in slow-wave sleep. However, during intervals of increased activity, responses to carbon dioxide during REM sleep are significantly reduced, and breathing seems to be regulated by the brain's behavioral control system. It is interesting that regulation of breathing during REM sleep by the behavioral control system, rather than by carbon dioxide, is similar to the way breathing is controlled during speech.

Ventilatory responses to hypoxia are probably reduced during both slow-wave and REM sleep, especially in people who have high sensitivity to hypoxia while awake. There does not seem to be a difference between the effects of slow-wave and REM sleep on hypoxic responsiveness, and the irregular breathing of REM sleep is unaffected by hypoxia.

Both slow-wave and REM sleep cause an important change in responses to airway irritation. Specifically, a stimulus that causes cough, tachypnea, and airway constriction during wakefulness will cause apnea and airway dilation during sleep unless the stimulus is sufficiently intense to cause arousal. The lung stretch reflex appears to be unchanged or somewhat enhanced during arousal from sleep, but the effect of stretch receptors on upper airways during sleep may be important.

Arousal mechanisms protect the sleeper.

Several stimuli cause arousal from sleep; less intense stimuli cause a shift to a lighter sleep stage without frank arousal. In general, arousal from REM sleep is more difficult than from slow-wave sleep. In humans, hypercapnia is a more potent arousal stimulus than does hypoxia, the former requiring a $PaCO_2$ of about 55 mm Hg and the latter requiring a PaO_2 <40 mm Hg. Airway irritation and airway occlusion induce arousal readily in slow-wave sleep but much less readily during REM sleep.

All of these arousal mechanisms probably operate through the activation of a reticular arousal mechanism similar to the wakefulness stimulus. They play an important role in protecting the sleeper from airway obstruction, alveolar hypoventilation of any cause, and the entrance into the airways of irritating substances. Recall that coughing depends on the aroused state and without arousal airway irritation leads to apnea. Obviously, wakefulness altered by other-than-natural sleep—such as during drug-induced sleep, brain injury, or anesthesia—leaves the person exposed to risk because arousal from those states is impaired or blocked. From a teleological point of view, the most important role of sensors of the respiratory system may be to cause arousal from sleep.

Upper airway tone may be compromised during REM sleep.

A prominent feature during REM sleep is a general reduction in skeletal muscle tone. Muscles of the larynx, pharynx, and tongue share in this relaxation, which can lead to obstruction of the upper airways. Airway muscle relaxation may be enhanced by the increased effectiveness of the lung inflation reflex.

A common consequence of airway narrowing during sleep is snoring. In many people, usually men, the degree of obstruction may at times be sufficient to cause essentially complete occlusion. In these people, an intact arousal mechanism prevents suffocation, and this sequence is not in itself unusual or abnormal. In some people, obstruction is more complete and more frequent, and the arousal threshold may be raised. Repeated obstruction leads to significant hypercapnia and hypoxemia, and repeated arousals cause sleep deprivation that leads to excessive daytime sleepiness, often interfering with normal daily activities.

CONTROL OF BREATHING IN UNUSUAL ENVIRONMENTS

Changes in activity and the environment initiate integrated ventilatory responses that involve changes in the cardiopulmonary system. Examples include the response to exercise (see Chapter 29) and the response to altered gas tensions. The importance of understanding integrated ventilatory responses is that similar interactions occur under pathophysiologic conditions in patients with respiratory illnesses.

Breathing with low inspired oxygen tension (PIO_2) leads to low PAO_2 (**hypoxia**) to low PaO_2 (**hypoxemia**) and is frequently encountered during ascent to high altitudes. How the body responds to high altitude has fascinated physiologists for centuries. The French physiologist Paul Bert first recognized that the harmful effects of high altitude are caused by low-oxygen tension. Recall from Chapter 20 that the percentage of oxygen does not change at high altitude but PO_2 decreases due to a drop in barometric pressure (see Fig. 20.1). Thus, the hypoxic response at high altitude is caused by a decrease in PIO_2 resulting from a decrease in PB and not from a change in fraction of inspired oxygen (FIO_2).

In high-altitude physiology and medicine, three altitude regions are recognized that reflect the lowered PO_2 in the atmosphere: *high altitude* (1,500 to 3,500 m or 4,900 to 11,500 ft), *very high altitude* (3,500 to 5,500 m or 11,500 to 18,000 ft), and extreme altitude (above 5,500 m, 18,000 ft).

When the PIO_2 decreases and oxygen supply in the body is threatened, several compensations are made in an effort to deliver normal amounts of oxygen to the tissues. Somewhat surprising is the fact that hypoxia-induced hyperventilation is not significantly increased until the alveolar PO_2 decreases to <60 mm Hg (see Fig. 21.5). In a healthy adult, a drop in alveolar PO_2 to 60 mm Hg occurs at an altitude of ~4,500 m (14,000 ft). As altitude increases, the body makes noticeable efforts to deliver more oxygen to the tissues. Chief among these responses to altitude is induced hyperventilation—that is, deeper breaths taken more rapidly in which alveolar ventilation is increased. The sequence of events for hypoxia-induced hyperventilation is as follows: (1) a fall in PIO_2, (2) decreased alveolar tension (PAO_2), (3) decreased arterial oxygen tension (PaO_2), (4) increased firing of peripheral chemoreceptors (the carotid bodies), (5) hyperventilation, and (6) increased alveolar and arterial oxygen tension. As mentioned previously, the stimulus for ventilation during hypoxia is a decrease in PaO_2 rather than O_2 content or percent O_2 saturation. It is important to realize that there is also an immediate rise in cardiac output to match the increase in ventilation. The increase in cardiac output leads to an increase in pulmonary circulation.

Remember, an increase in pulmonary blood flow reduces both the capillary transit time and pulmonary vascular resistance. The latter is due to capillary recruitment, which occurs primarily in the top part of the lungs, resulting in more even blood flow throughout the lungs. As a result, regional blood flow and airflow in the lungs are better matched (i.e., improved ventilation/perfusion ratio). Thus, the increased cardiac output indirectly increases gas exchange by decreasing transit time and improving the overall ventilation/perfusion ratio in the lungs. Figure 21.11 shows how ventilation and $PACO_2$ change with hypoxia. The hypoxia-induced hyperventilation appears in two stages. First, there is an immediate increase in ventilation, which is primarily a result of hypoxia-induced stimulation via the carotid bodies. However, the increase in ventilation seen in the first stage is small compared with that of the second stage, in which ventilation continues to rise slowly over the next 8 hours. After 8 hours of hypoxia, minute ventilation is sustained. The reason for the small rise in ventilation seen in the first stage is that the hypoxic stimulation is strongly opposed by the decrease in $PaCO_2$ as a result of excess carbon dioxide

blown off with altitude-induced hyperventilation. Remember that hyperventilation elevates PaO_2 but significantly lowers $PaCO_2$, resulting in a concomitant increase in arterial pH. The hypocapnia (due to the decrease in arterial PCO_2) and the rise in blood pH work in concert to strongly blunt the hypoxic drive.

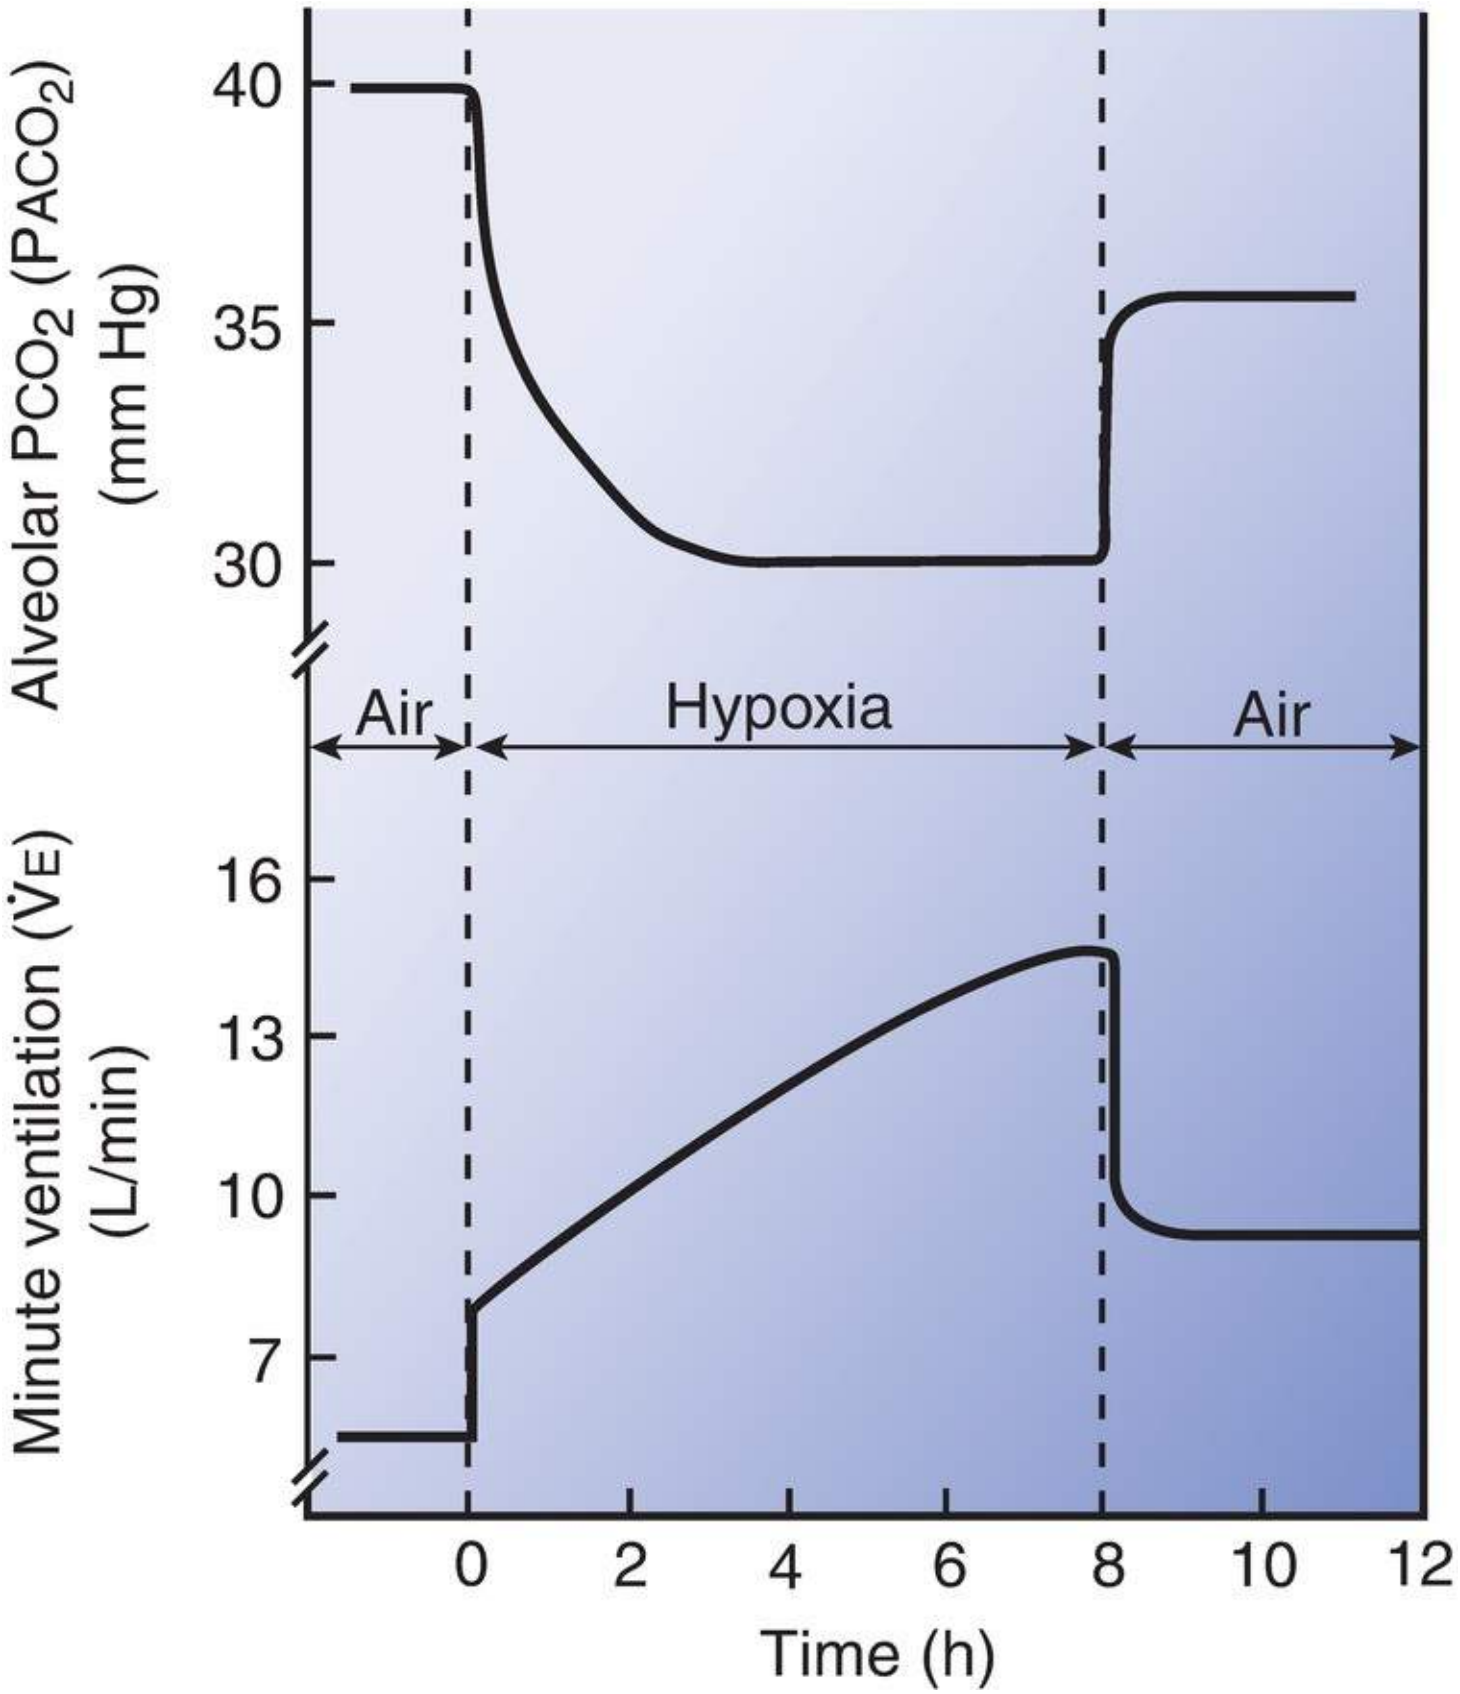

Figure 21.11 Hypoxia stimulates minute ventilation and causes hypocapnia. Hypoxia was induced by having a healthy subject breathe 12% O_2 for 8 hours. With hypoxia-induced hyperventilation, excess CO_2 is blown off, resulting in a decrease in alveolar PCO_2 and arterial PCO_2 with a concomitant rise in blood

pH. Minute ventilation remains elevated for awhile after the subject returns to room air.

CLINICAL FOCUS 21.2

Acute Mountain Sickness

Acute mountain sickness (AMS) is a pathophysiologic condition that is caused by acute exposure to high altitude. AMS is also known as *altitude sickness* and is caused by hypoxia resulting from a decrease in oxygen tension (PO_2) and not from a decrease in the percentage of oxygen in the inspired air.

AMS commonly occurs above 2,400 m (~8,000 ft) and dates back to 30 BCE as indicated by the mention of the "Great Headache Mountain" in Chinese documents. Symptoms are often manifested 6 to 10 hours after ascent and generally subside in 1 to 2 days. AMS symptoms include headache, dizziness, nausea, and sleep disturbance. In most cases, the symptoms are only temporary and usually abate with time as altitude acclimation occurs. Exertion aggravates the situation, and in extreme cases, pulmonary edema and cerebral edema can occur, which can be fatal. The rate of ascent, the altitude, the degree of physical activity, and individual susceptibility are contributing factors to the incidence and severity of AMS.

Many AMS symptoms are caused by hypoxia-induced cerebral blood vessel dilation, which puts pressure on adjacent neuronal tissue. The hypoxia-induced cerebral dilation accounts for the headache, dizziness, nausea, and sleep disturbance. Dehydration can exacerbate these symptoms. The most serious symptoms of AMS are a result of edema (abnormal fluid accumulation) in the lungs and brain. Severe hypoxia causes endothelial cells to become leaky. The edema that is the most life threatening is pulmonary edema. The problem arises because of the oxygen paradox (i.e., hypoxia causes blood vessels to dilate in systemic circulation but causes vasoconstriction in the pulmonary circulation). The hypoxia-induced pulmonary vasoconstriction increases pulmonary vascular resistance. The heart trying to pump blood through "water-soaked lungs" further complicates the situation. As the lungs fill up with water, victims become increasingly short of breath and often spit up foamy blood. Severe pulmonary edema causes death as a result of heart failure.

AMS can be avoided with care. One precaution is to avoid caffeine and alcohol, which tend to exacerbate AMS. A second precaution is to ascend the mountain slowly. Most AMS occurs following a rapid ascent. The third precaution of high-altitude climbing is to follow the climbers' "golden rule": climb high and sleep low, meaning that a climber should stay a few days at base camp to acclimatize, then climb slowly to a higher camp, and return to base camp for the night. This procedure is repeated a few times, each time extending the time spent at higher altitudes to let the body acclimatize to the lower oxygen tension. The general rule is not to ascend >300 m (1,000 ft) per day to sleep. This means a climber can climb from 3,000 m (10,000 ft) to 4,500 m (15,000 ft) in 1 day, but then descend back to 3,300 m (11,000 ft) to sleep. This explains why climbers need to spend days and/or weeks at a time to acclimatize before they can reach a high peak.

Acetazolamide may help speed up the acclimatization process and can treat mild cases of altitude sickness. It reduces fluid formation and helps reduce the severity of cerebral edema. The drug also

forces the kidneys to excrete bicarbonate, the base form of carbon dioxide, thus counteracting the effects of hyperventilation that occurs at altitude. ■

Acclimatization to altitude leads to a sustained increase in ventilation.

The sustained increased ventilation seen in the second stage is referred to as *ventilatory acclimatization*. Acclimatization occurs during prolonged exposure to hypoxia and is a physiologic response, as opposed to a genetic or evolutionary change over generations leading to a permanent **adaptation**. Ventilatory acclimatization is defined as a time-dependent increase in ventilation that occurs over hours to days of continuous exposure to hypoxia. After 2 weeks, the hypoxia-induced hyperventilation reaches a stable plateau.

Although the physiologic mechanisms responsible for ventilatory acclimatization are not completely understood, it is clear that two mechanisms are involved. One involves the chemoreceptors, and the second involves the kidneys. When ventilation is stimulated by hypoxia, CSF pH becomes more alkaline. The elevated CSF pH is brought closer to normal by the movement of bicarbonate out of the CSF. Also, during prolonged hypoxia, the carotid bodies increase their sensitivity to PaO_2. These changes result in a further increase in ventilation.

The second mechanism responsible for ventilatory acclimatization involves the kidneys. The alkaline blood pH resulting from the hypoxia-induced hyperventilation is antagonistic to the hypoxic drive. Blood pH is regulated by both the lungs and the kidneys (see Chapter 24), which is illustrated in the following equation:

$$pH = pK_a + \log\frac{[HCO_3^-]}{[H_2CO_3]} \quad (1)$$

Because pK_a stays constant and H_2CO_3 dissociates into CO_2 and H_2O, the equation can be represented by:

$$pH = \frac{[HCO_3^-]}{Paco_2}\,20\,\frac{\text{Kidney}}{1}\,\frac{\text{Kidney}}{\text{Lung}} \quad (2)$$

Equation 2 also illustrates that the blood $[HCO_3^-]$ is regulated primarily by the kidney and that the

$PaCO_2$ is regulated primarily by the lungs. A normal pH of 7.4 is maintained by a ratio of 20:1. The functional importance of the second equation illustrates that it is not the absolute amount of $[HCO_3^-]$ and $PaCO_2$ that is important in maintaining a normal pH but the 20:1 ratio. During hypoxic-induced hyperventilation, excess CO_2 is blown off, lowering $PaCO_2$, which, in turn, increases the ratio and makes the blood pH more alkaline. The kidneys compensate by excreting more bicarbonate, which brings the ratio back to a normal 20:1 and a blood pH toward 7.4. This process occurs over a 2- to 3-day period, and the antagonistic effect resulting from the hypoxia-induced alkaline pH is minimized, allowing the hypoxic drive to increase minute ventilation further. Thus, it is important to remember that the regulation of pH by ventilatory $PaCO_2$ is fast (seconds to minutes), whereas the regulation of pH by the kidney to adjust the sodium bicarbonate concentration is slow (hours to days).

Cardiovascular acclimatization improves the delivery of oxygen to the tissues.

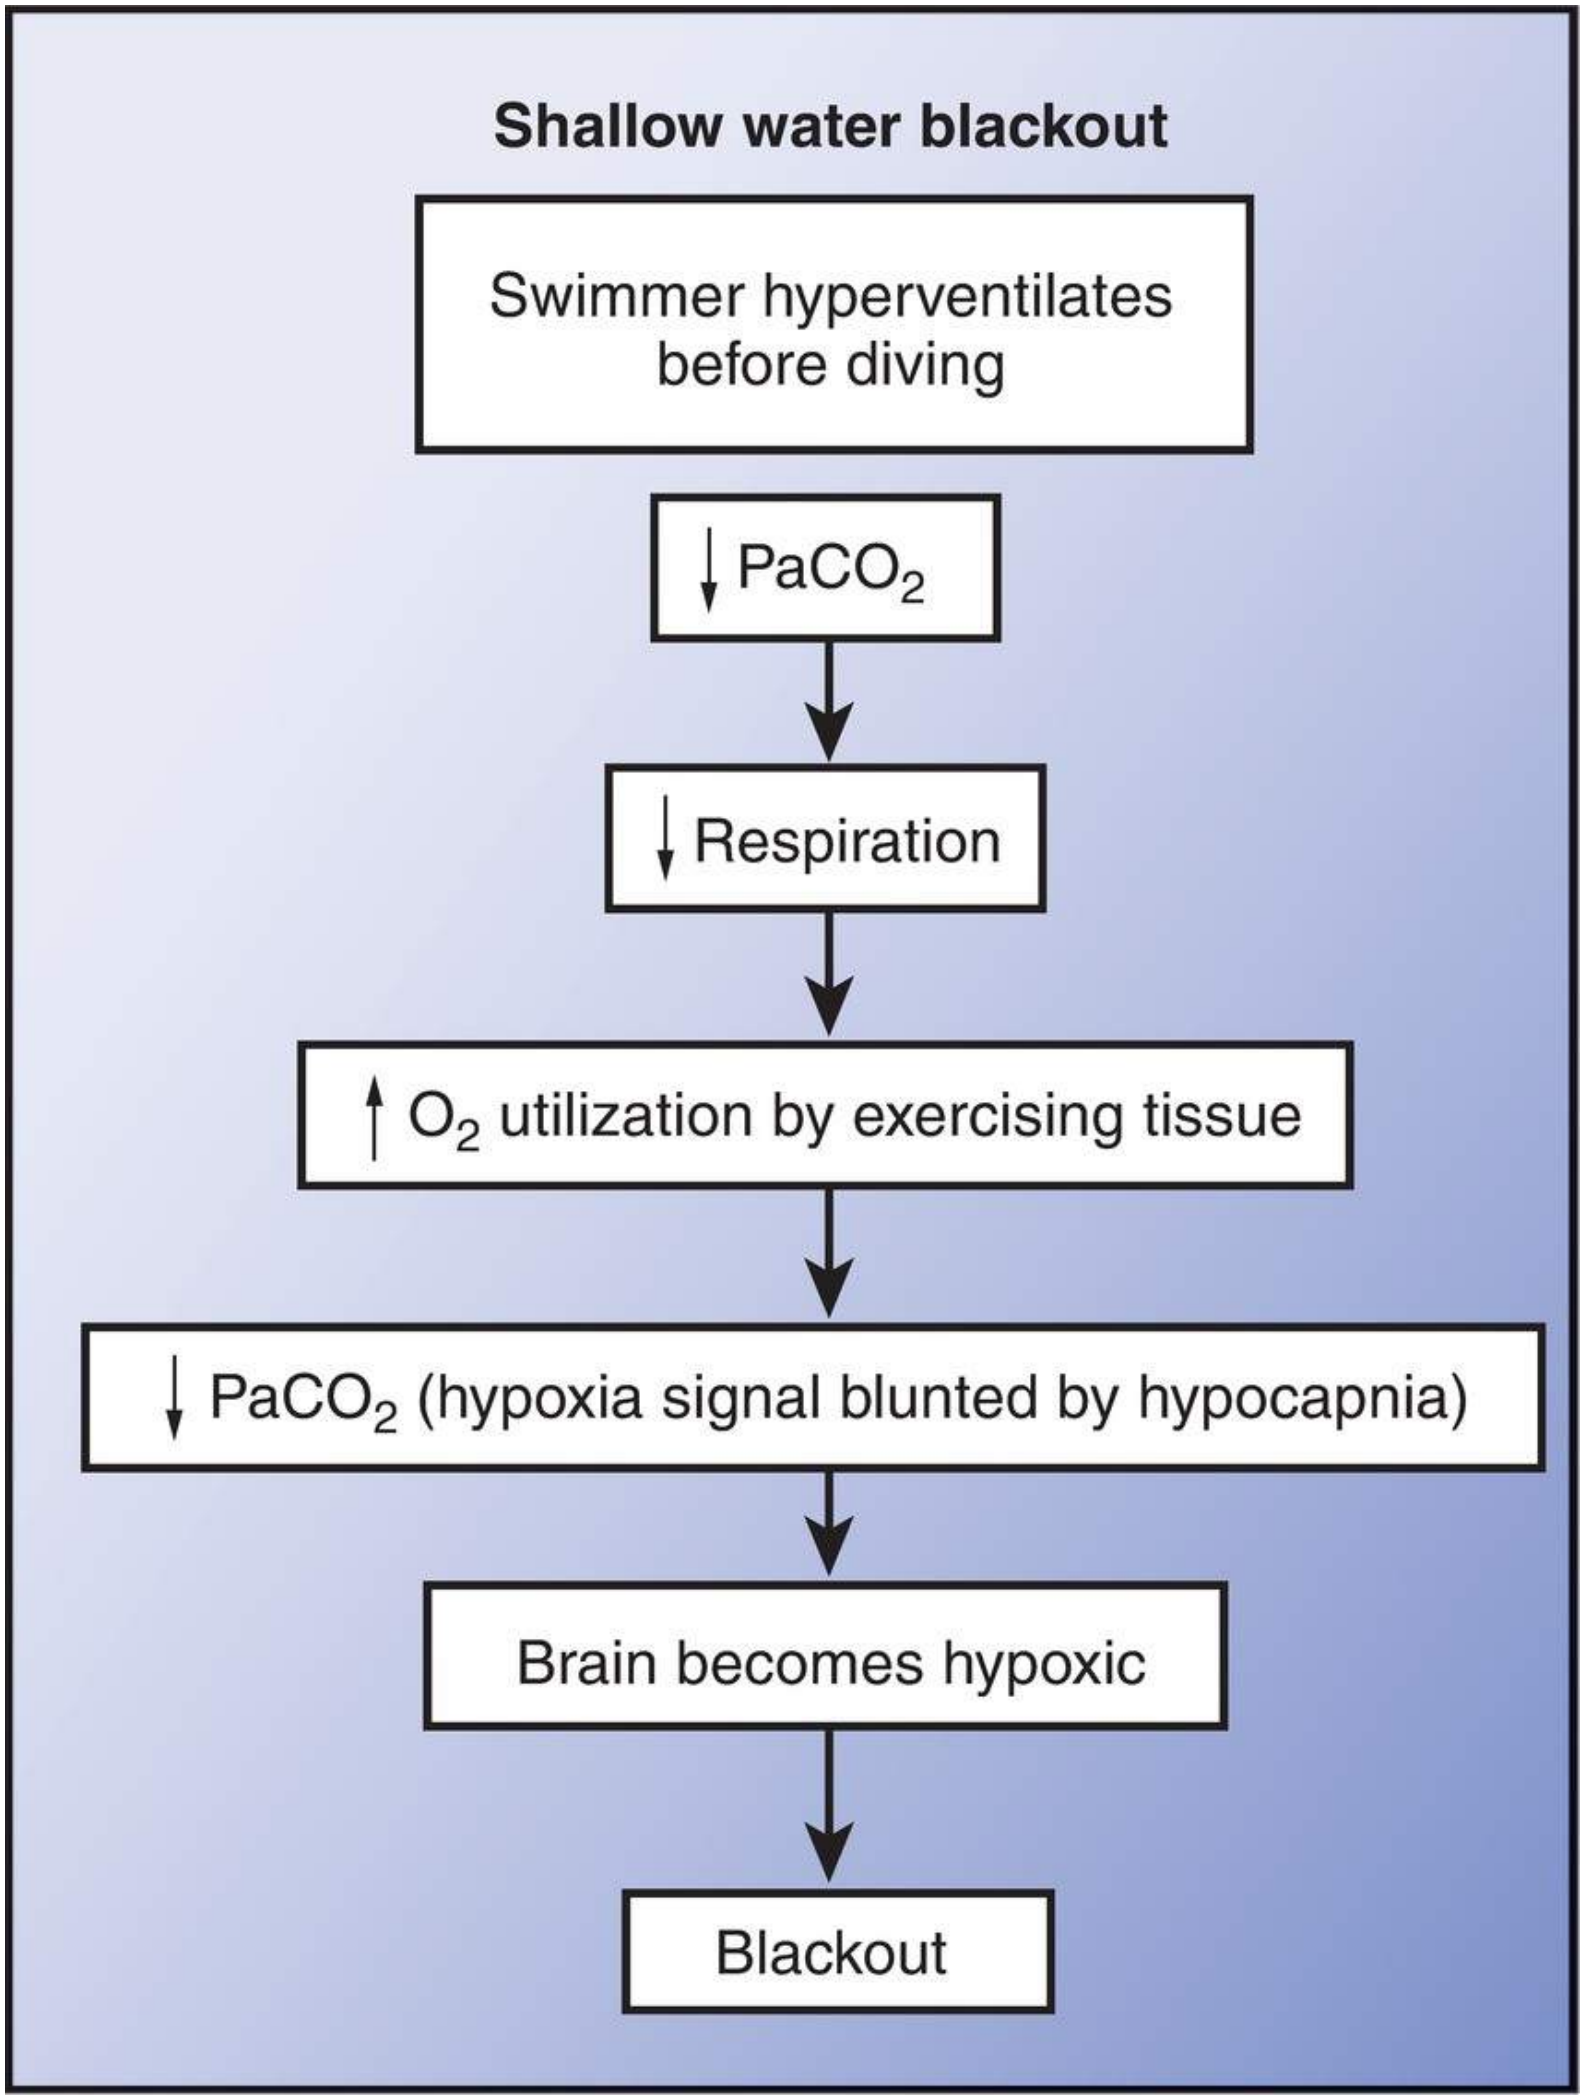
In addition to ventilatory acclimatization, the body undergoes other physiologic changes to acclimatize to low-oxygen levels. These include increased pulmonary blood flow, increased red cell production, and improved oxygen and carbon dioxide transport. There is an increase in cardiac output at high altitude, resulting in increased blood flow to the lungs and other organs of the body. As mentioned previously, the increase in pulmonary blood flow reduces capillary transit time and improves the overall ventilation/perfusion ratio in the lungs, both of which result in an increase in oxygen uptake by the lungs. Low PO_2 causes vasodilation in the systemic circulation. The increase in blood flow resulting from the combined increased vasodilation and increased cardiac output sustains oxygen delivery to the tissues at high altitude.

Erythropoiesis is also increased at high altitude, which improves oxygen delivery to the tissues. Hypoxia stimulates the kidneys to produce and releases a hormone into the circulation (**erythropoietin**), which stimulates the bone marrow to increase the rate production of erythrocytes. The increased hematocrit resulting from the hypoxia-induced **polycythemia** enables the blood to carry more oxygen to the tissues. However, the increased viscosity, as a result of the elevated hematocrit, tends to increase the workload on the heart. In some cases, the polycythemia becomes so severe (hematocrit >70%) at high altitude that blood has to be withdrawn periodically to permit the heart to pump effectively. Oxygen delivery to the cells is also favored by an increased concentration of 2,3-diphosphoglycerate in the red cells. Recall from Chapter 19 that 2,3-diphosphoglycerate shifts the oxyhemoglobin equilibrium curve to the right and favors the unloading of oxygen in the tissues. Although the body undergoes many physiological changes that favor acclimatization to high altitude, there are some undesirable effects. One of these is pulmonary hypertension. There is a hypoxia paradox in circulation. Hypoxia causes vasodilation in the systemic circulation and vasoconstriction in the pulmonary circulation, which results in an increase in pulmonary arterial pressure. Remember that regional hypoxia redirects blood away from poorly ventilated regions in the lung without any change in pulmonary pressure. However, with generalized hypoxia, pulmonary pressure rises because all of the prealveolar vessels constrict. In addition, prolonged hypoxia causes vascular remodeling in which pulmonary arterial smooth muscle cells undergo hypertrophy and hyperplasia. The vascular remodeling results in narrowing of the small pulmonary arteries and increases pulmonary vascular resistance, leading to a further significant increase in pulmonary vascular hypertension. With severe hypoxia, the pulmonary veins are also constricted. The increase in venous pressure elevates the filtration pressure in the alveolar capillary beds and under severe conditions causes **high-altitude pulmonary edema**. Pulmonary hypertension also increases the workload of the right heart, causing right heart hypertrophy, and under severe conditions often leads to death. Extreme altitude also causes **high-altitude cerebral edema**.

An altitude above certain point where the PO_2 is insufficient to sustain human life is referred to as the *death zone*. The death zone in mountaineering is generally tagged at 8,000 m (26,000 ft). For example, the summit of Mount Everest is in the death zone. Many deaths occur either directly (loss of vital functions) or indirectly (mistakes made under stress). In the death zone, the human body can no longer acclimate resulting in the loss of consciousness and, ultimately, death.

Diving reflex involves a number of cardiopulmonary responses.

Another respiratory movement is breath-holding, in which normal breathing patterns are voluntarily suspended. Breath-holding can occur until the $PaCO_2$ rises and overrides the conscious, voluntary effort. Breath-holding is a frequent maneuver with diving and is usually harmless. However, breath-holding becomes dangerous if hyperventilation precedes the event. For example, if a diver hyperventilates before going under water, the diver can hold his or her breath longer, because of the strong inhibitory effect of blowing off excess CO_2. The problem created with hyperventilation is that $PaCO_2$ is drastically decreased, with no appreciable change in oxygen content. As a result of the low arterial CO_2 tension, the respiratory centers become depressed. At the same time, the exercising muscles rapidly take up oxygen, which lowers both the arterial oxygen content and PO_2. However, the hypoxia-induced stimulation to the carotid chemoreceptors is overridden by the strong inhibitory effect of the low PCO_2. As a result, the brain becomes hypoxic, causing the swimmer to black out under water and drown, a condition commonly referred to as **shallow water blackout**, which is illustrated in Figure 21.12.



Shallow water blackout
Swimmer hyperventilates before diving
↓ $PaCO_2$
↓ Respiration
↑ O_2 utilization by exercising tissue
↓ $PaCO_2$ (hypoxia signal blunted by hypocapnia)
Brain becomes hypoxic
Blackout

Figure 21.12 Shallow water blackout is a result of failure of the controller to respond to low oxygen. When hyperventilation precedes underwater diving, hypocapnia occurs. The hypocapnia blunts the hypoxia-induced ventilation, causing severe hypoxia in the brain.

Another breathing pattern associated with underwater breathing is the **diving reflex**. The diving reflex is most pronounced in newborns and young children and can be elicited when the face is submerged in water. The diving reflex is a protective reflex that encompass a number of cardiopulmonary responses. The reflex causes the person to gasp; breathing stops (apnea), heart rate decreases (bradycardia), and blood flow to the peripheral tissue also decreases (peripheral vasoconstriction). Diverting blood away from the peripheral tissues allows for a heart–brain perfusion. The gasp component of the diving reflex stops breathing and prevents water from entering the lung. The reflex component that induces bradycardia reduces energy requirements for cardiac tissue, and the peripheral vasoconstriction conserves oxygen to the brain. A number of cases have been reported in which young children have broken through ice on a frozen pond or have fallen into a lake and survived under water for 20 to 30 minutes. Often, the diving reflex by itself is not enough to save victims who remain under water for longer periods of time than 10 to 15 minutes. Lowered body temperature caused by the cold water is equally important. A lower body temperature means a lower metabolic rate, which means less oxygen is required. The reason children survive better than adults is twofold. First, children have a more pronounced diving reflex. Second, their body temperature drops at a faster rate because of their high surface area to body weight ratio. For further details about the relationship between body temperature and surface area, see Chapter 28.

INTEGRATED MEDICAL SCIENCES

Traumatic Head Injury

A professional quarterback, in an attempt to recover a fumble, was hit twice, once in the head and once in the back, and was knocked unconscious. He was taken to the hospital, and upon transport to the hospital, he regained consciousness, but then lost consciousness again. In the emergency room, he displayed the *Cushing triad*, a slow heart rate with high blood pressure and respiratory depression. He was transferred to intensive care and given supplemental oxygen, a sedative, and IV injection containing mannitol. He regained consciousness again and was examined by a neurosurgeon. The patient complained of headache, nausea, and blurred vision and stated his breathing was becoming more difficult. A chest X-ray confirmed pulmonary contusion. The patient was diagnosed with mild to moderate head injury compounded with pulmonary contusion.

This case is a common presentation of traumatic head injury and is the major cause of death and disability worldwide, especially in children and adult males. Causes include car accidents, falls, violence, and contact sports. The brain trauma increases intracranial pressure and alters cerebral blood flow. Sign and symptoms are dependent on the severity of the injury. With mild to moderate traumatic brain injury (TBI), patients often remain conscious, but may lose consciousness for several minutes. Other symptoms include headache, vomiting, nausea, dizziness, difficulty with balance, and blurred vision. Patients frequently complain of ringing in the ears and often exhibit slurred speech and *aphasia* (difficulty finding words). A large percentage of patients that are killed by brain trauma do

not die right away. Rather than improving after being in intensive care, over 40% of these patients deteriorate as a result of cardiopulmonary complications and is the underlying cause of morbidity and mortality. Examples include hypertension, arrhythmias, ventricular dysfunction, pulmonary edema, shock, and sudden death.

In the present case, the patient exhibited the Cushing triad, which is a reflex that is responsible for increased systolic and pulse pressure, bradycardia, and depressed respiration. The three-part effect was named after an American neurosurgeon, Harvey Cushing. The Cushing triad is caused by the increased intracranial pressure that compresses cerebral vessels, especially the arterioles, causing cerebral ischemia. In addition, TBI causes a massive sympathetic stimulation to the cardiopulmonary system, which further exacerbates the problem by causing pulmonary edema and elevated systemic blood pressure.

In addition to TBI, this patient also suffered pulmonary contusion. A pulmonary contusion usually occurs from a blow to the front of chest. In this particular case, the patient was hit by a blow to his back. A blow to the back can cause contusion to the front of the lungs because a shock wave travels through the chest, which hits the front of the chest wall. This reflects the energy onto to the front of the lungs. A similar mechanism occurs when a blow occurs to the front of the chest causing a contusion in the back of the lungs. A pulmonary contusion further compounds the problem of a TBI by causing bleeding and fluid leakage into lung tissue and often leads to pulmonary edema. Patients with a pulmonary contusion have difficulty breathing due to a loss of lung elasticity and a decrease in lung compliance (stiff lungs). Contusion also lowers the ventilation–perfusion ratio because the fluid-filled alveoli cannot be filled with air. As a result, the hypoxemia becomes more acute due to pulmonary edema and ventilation–perfusion mismatch.

The pathogenesis can be divided into two phases: primary brain injury and secondary brain injury. The primary injury occurs at the moment of trauma when intracranial pressure increases causing cerebral ischemia and hypoxemia. Secondary injury occurs hours and days following the initial trauma and is caused by a biochemical cascade that leads to inflammation, free radical production, and the release of neurotransmitters. These cellular events are responsible for a series of pathophysiologic events that dramatically alters brain and other organ function. The pathophysiology includes damage to the blood–brain barrier, influx of calcium, and sodium into neuronal tissue, terminal membrane depolarization, and dysfunctional mitochondria. Together, these events lead to loss of cerebral vascular integrity, membrane degradation of neuronal tissue, and *apoptosis* (cell death).

Treatment usually begins in an intensive care unit. Treatment during transport and in the hospital centers on ensuring proper oxygen supply, maintaining adequate blood flow to the brain, and controlling the elevated intracranial pressure. Treatment of the increased intracranial pressure may be done by initially tilting the patient’s bed and straightening the head to promote blood flow from the brain through the neck veins. Mannitol, and osmotic diuretic, is often given to reduce the cerebral pressure. Once in intensive care, patients with moderate to severe injuries can have a catheter placed in the ventricle of the brain to drain the cerebrospinal fluid releasing the intracranial pressure. If blood oxygenation is low, endotracheal intubation and mechanical ventilation are used to improve gas exchange.

Approximately 30% to 50% of patients who survive posttraumatic brain injury (TBI) demonstrate endocrine complications. Diabetes insipidus following mild to moderate TBI indicates a posterior pituitary lesion. Anterior hypopituitarism is also associated with moderate to severe TBI that leads to a deficiency in growth hormone (GH), adrenocorticotropic hormone (ACTH), and thyroid-stimulating hormone (TSH). Growth hormone deficiency leads to a decrease in muscle mass, central obesity

(increase body fat around waist), and impaired attention and memory. Deficiency in ACTH leads to adrenal insufficiency, a lack of production of glucocorticoids such as cortisol. Chronic symptoms include fatigue, weight loss, and hypoglycemia and anemia. TSH deficiency leads to hypothyroidism (decreased production of thyroxine [T4] and triiodothyronine [T3]). Symptoms include tiredness, intolerance to cold, weight gain, hair loss, and low blood pressure. Finally, post-TBI often includes speech and cognitive disorders. Speech and language therapy, cognitive rehabilitation therapy, and occupational therapy are required for rehabilitation. ■

Chapter Summary

- Ventilation involves both automatic and voluntary control, in which both require negative and positive feedback systems.
- Automatic control is concerned with the exchange of oxygen and carbon dioxide as well as acid–base balance.
- Voluntary control is concerned with coordinated activities.
- Normal arterial blood gases are maintained, and the work of breathing is minimized despite changes in activity, the environment, and lung function.
- The neural structure responsible for automatic control resides primarily in the medulla.
- The basic breathing rhythm (minute-to-minute breathing) is generated by medullary neurons in the brainstem.
- The rate and depth of breathing are finely regulated by vagal nerve endings that are sensitive to lung stretch.
- The ventral respiratory group (VRG) controls forced exhalation and acts to increase the force of inspiration.
- The dorsal respiratory group (DRG) controls mostly inspiratory movements and their timing.
- Ventilatory rate (minute volume) is tightly controlled and determined primarily by blood levels of carbon dioxide as determined by metabolic rate.
- The autonomic nerves and vagal sensory nerves maintain local control of airway function.
- Mechanical or chemical irritation of the airways and lungs induces coughing, bronchoconstriction, shallow breathing, and excess mucus production.
- Arterial PCO_2 is more important than arterial PO_2 and $[H^+]$ in determining the ventilatory drive in healthy individuals at rest.
- Peripheral chemoreceptors detect changes in arterial PO_2, PCO_2, and pH, whereas central chemoreceptors detect changes only in arterial PCO_2.
- Control of breathing during exercise involves three phases (neurogenic, metabolic, and compensatory).
- Sleep is induced by the withdrawal of a wakefulness stimulus arising from the brainstem reticular formation and results in a general depression of breathing.
- The hypoxia-induced stimulation of ventilation is not significantly increased until the arterial PO_2 drops to <60 mm Hg.
- Chronic hypoxemia causes respiratory acclimatization that result in increased sustained breathing.
- The diving reflex invokes several cardiopulmonary responses.
- Shallow water blackout occurs when the diving reflex is overridden by hypoxia.

Chapter Review Questions

1. Generation of the basic cyclic pattern of breathing in the CNS requires participation of:
   - **A.** the pontine respiratory group.
   - **B.** vagal afferent input to the pons.
   - **C.** vagal afferent input to the medulla.
   - **D.** an inhibitory loop in the medulla.
   - **E.** an intact spinal cord.

The correct answer is D. The basic rhythm exists in the absence of the pontine respiratory group, afferent vagal input to the pons and medulla, or an intact spinal cord. These can modify the rhythm of breathing but are not required.

2. Quiet expiration is associated with:
   - **A.** a brief early burst by inspiratory neurons.
   - **B.** active abduction of the vocal cords.
   - **C.** an early burst of activity by expiratory muscles.
   - **D.** reciprocal inhibition of inspiratory and expiratory centers.
   - **E.** increased activity of slowly adapting receptors.

The correct answer is A. A brief early burst by the inspiratory neurons occurs with expiration.

3. The ventilatory response to hypoxia:
   - **A.** is independent of $PaCO_2$.
   - **B.** is more dependent on aortic than carotid chemoreceptors.
   - **C.** is exaggerated by hypoxia of the medullary chemoreceptors.
   - **D.** bears an inverse linear relationship to arterial oxygen content.
   - **E.** is a sensitive mechanism for controlling breathing in the normal range of blood gases.

The correct answer is D. An inverse relationship exists between hypoxia-induced hyperventilation and oxygen content. Hypoxia-induced hyperventilation is dependent on $PaCO_2$ and more on carotid than on aortic chemoreceptors.

4. Which of the following is not a consequence of stimulation of lung C fiber endings?
   - **A.** Bronchoconstriction
   - **B.** Apnea
   - **C.** Rapid shallow breathing
   - **D.** Systemic vasoconstriction
   - **E.** Skeletal muscle relaxation

The correct answer is D. Stimulation of lung C fibers will cause bronchoconstriction, apnea, rapid shallow breathing, and skeletal muscle relaxation.

5. Which of the following is true about cerebrospinal fluid?
   - **A.** Its protein concentration is equal to that of plasma.
   - **B.** Its PCO_2 equals that of systemic arterial blood.
   - **C.** It is freely accessible to blood hydrogen ions.
   - **D.** Its composition is essentially that of a plasma ultrafiltrate.
   - **E.** Its pH is a function of $PaCO_2$.

The correct answer is E. CSF and plasma differ in protein concentration, PCO_2, and electrolyte composition (including the $[H^+]$).

Clinical Application Exercises 21.1

PICKWICKIAN SYNDROME

A 45-year-old man is referred to the pulmonary function laboratory because of polycythemia (hematocrit of 57%). At the time of referral, he weighs 142 kg (312 lb), and his height is 175 cm (5 ft, 9 in). A brief history reveals that he frequently falls asleep during the day. His blood gas values are PaO_2, 69 mm Hg; SaO_2, 94%; PCO_2, 35 mm Hg; and pH, 7.44. A few days later, he is admitted as an outpatient in the hospital's sleep center. He is connected to an ear oximeter and to a portable heart monitor. Within 30 minutes, the patient falls asleep, and within another 30 minutes, his SaO_2 decreases from 92% to 47%, and his heart rate increases from 92 to 108 beats/min, with two premature ventricular contractions. During this time, his chest wall continues to move, but airflow at the mouth and nose is not detected.

QUESTIONS

1. How would this patient's test results be interpreted?
2. What is the cause of polycythemia?
3. How does hypoxia accelerate heart rate?

ANSWERS

1. This patient is suffering from what has been known as Pickwickian syndrome, a disorder that occurs with severely obese individuals because of their excessive weight. The Pickwickian syndrome was named after Joe, the overweight boy who was always falling asleep in Charles Dickens' novel *The Pickwick Papers*. Pickwickian patients suffer from hypoventilation and often suffer from sleep apnea as well. Pickwickian syndrome is no longer an appropriate name because it does not indicate what type of sleep disorder is involved. About 80% of sleep apnea patients are obese, and 20% are of relatively normal weight.
2. Polycythemia is the result of chronic hypoxemia from hypoventilation, as well as from sleep apnea.
3. An increase in sympathetic discharge is often associated with sleep apnea and is responsible for the accelerated heart rate.

PART VI RENAL PHYSIOLOGY AND BODY FLUIDS

22 Kidney Function

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain the mechanism by which the kidney removes or “clears” substances from plasma.
- Explain how glomerular filtration rate is measured and the factors that affect filtration rate.
- Describe how renal blood flow can be determined from the clearance of *p*-aminohippurate and the hematocrit and discuss the factors that influence renal blood flow.
- Determine whether there is net reabsorption or secretion of a plasma substance by the kidneys and quantify its value.
- Explain what is meant by tubular transport maximum, threshold, and splay for glucose.
- Explain and contrast the mechanisms of solute and water reabsorption in the proximal convoluted tubule, loop of Henle, and distal nephron.
- Predict the consequences of impairment of any transport process along the nephron.
- Explain how water and ion transport in any section of the nephron is altered by a change in sodium reabsorption in that section.
- Explain mechanisms responsible for secretion of organic anions, cations, acids, and bases by the nephron and how this secretion is altered by urine pH.
- Explain how arginine vasopressin increases collecting duct water permeability.
- Explain how countercurrent mechanisms create and maintain the vertical peritubular osmotic gradient surrounding the renal tubules in cortical and juxtamedullary nephrons.
- Explain how the interplay between the vertical peritubular osmotic gradient and the effect of ADH on the collecting duct allows the kidney to vary its net water reabsorption and the osmolality of the urine it forms.

The function and survival of cells depend on maintaining normal concentrations of NaCl, acids, and other electrolytes in the internal environment. The functional importance of maintaining a normal cellular and extracellular environment was explained in neurophysiology (Chapter 3), muscles (Chapter 8), and cardiovascular function (Chapter 12). The maintenance of normal hydration in cell function was also illuminated in Chapter 2. In the respiratory chapter (Chapter 19), the importance of maintaining a normal acid–base balance was elucidated. In the next three chapters, you will learn how the kidney regulates body fluids, maintains electrolyte balance, eliminates organic waste, and maintains the long-term regulation of acid–base conditions in the body. As you read about kidney function and regulation, you will encounter numerous examples of physiologic principles that have been presented in the Cellular, Neuromuscular, Cardiovascular, and Respiratory Physiology sections. The ability of the kidney to selectively remove waste and at the same time retain essential electrolytes, water, and nutrients is a hallmark of a general physiological principle of renal function.

Accordingly, these paired organs serve as the body’s main filtering system for the blood and extracellular fluid (ECF). They maintain normal concentrations of many plasma constituents, especially electrolytes. They maintain normal water volume and osmolarity (solute concentration) in the ECF while removing such metabolic waste products as urea and uric acid. They are also responsible for the reabsorption of filtered water, glucose, and amino acids. Finally, the kidneys produce hormones,

including calcitriol (the activated form of vitamin D), and erythropoietin as well as the enzyme renin. This chapter considers the basic renal processes that determine the excretion of various substances.

OVERVIEW OF RENAL FUNCTION

The architectural design of the urinary system consists of the urine-forming organs—the kidneys, the urinary bladder, ureter, and urethra. Peristaltic movements propel the urine down the ureters to the urinary bladder, which stores the urine until the bladder is emptied through the urethra. Each kidney is located in the back of the abdominal wall. The adult kidney weighs about 150 g and is roughly the size of one's fist. The kidneys are highly innervated and have a rich blood supply. Despite their relatively small size, they receive ~20% of the cardiac output. Each kidney is typically supplied by a single renal artery, which branches into anterior and posterior divisions. In turn, these two divisions give rise to a total of five segmental arteries (Fig. 22.1).

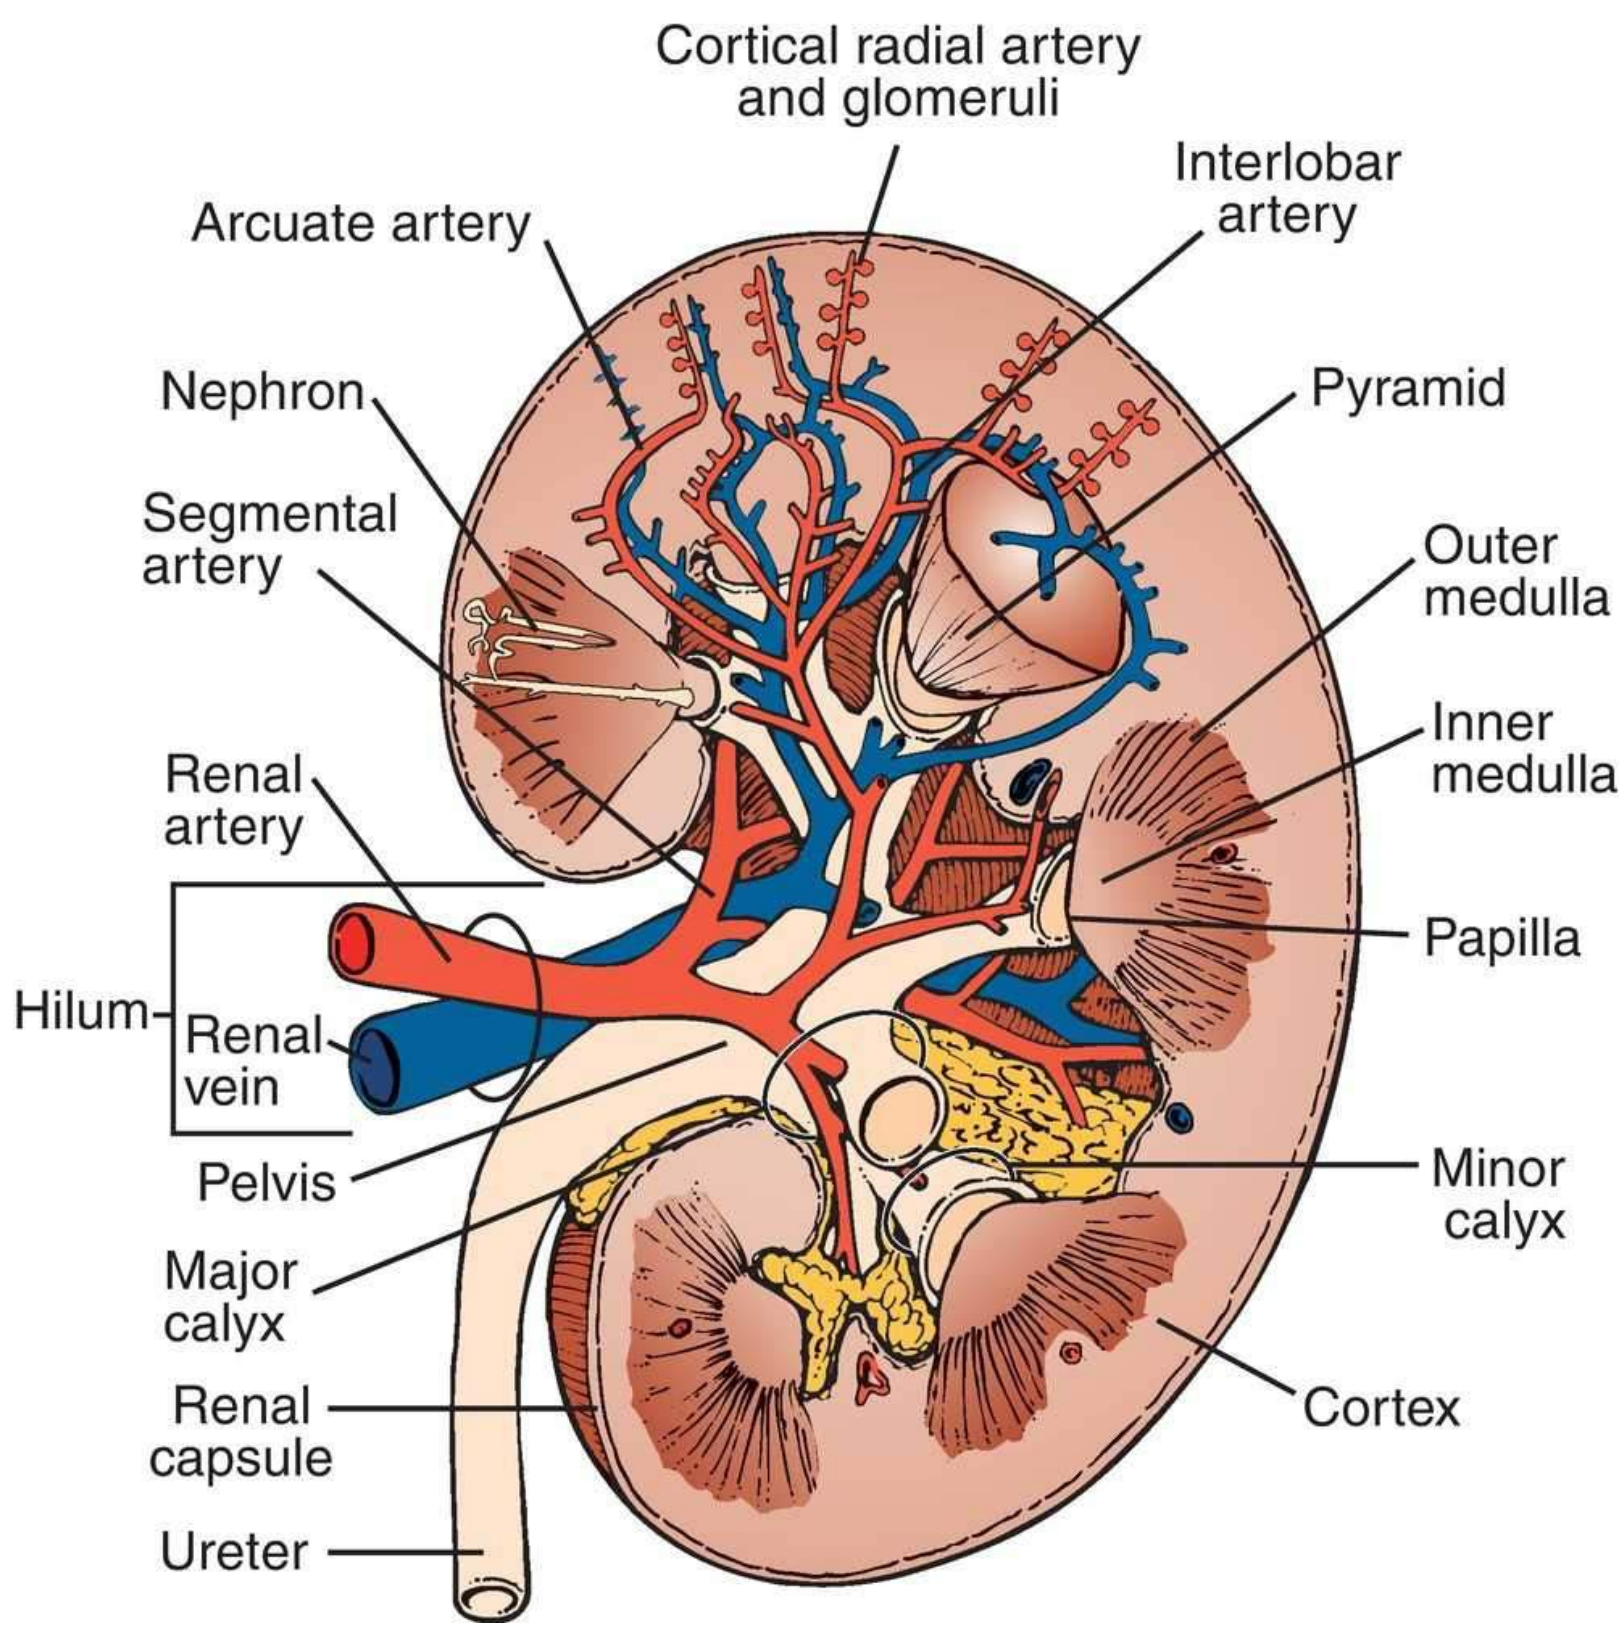

Figure 22.1 The human kidney, sectioned vertically.

Kidneys are highly innervated.

The kidneys are richly innervated by sympathetic nerve fibers, which travel to the kidneys mainly via the thoracic spinal nerves X, XI, and XII and lumbar spinal nerve I. Stimulation of sympathetic fibers causes constriction of renal blood vessels and a decrease in renal blood flow (RBF). Sympathetic nerve fibers also innervate tubular cells and may cause an increase in Na^+ reabsorption by a direct action on these cells. In addition, stimulation of sympathetic nerves increases the release of renin by the kidneys. Afferent (sensory) renal nerves are stimulated by mechanical stretch or by various chemicals in the renal parenchyma.

Kidneys perform a number of key functions.

The important functions performed by the kidneys include the following:

- They regulate the osmolarity of the body fluids by altering renal water reabsorption to excrete osmotically dilute or concentrated urine.
- They regulate the plasma concentrations of Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, phosphate, and sulfate.
- They play an essential role in acid–base balance by altering renal H^+ excretion and HCO_3^- reabsorption.
- They regulate the volume of the extracellular fluid by controlling Na^+ and water excretion.
- They help regulate arterial blood pressure by adjusting Na^+ excretion and producing various substances (e.g., renin) that can affect blood pressure.
- They eliminate the waste products of metabolism, including urea (the main nitrogen-containing end product of protein metabolism in humans), uric acid (an end product of purine metabolism), and creatinine (an end product of muscle metabolism).
- They remove many drugs (e.g., penicillin), drug metabolites, and foreign or toxic compounds.
- They are the major sites of production of certain hormones, including erythropoietin (see Chapter 9) and 1,25-dihydroxy vitamin D_3 (see Chapter 35).
- They degrade several polypeptide hormones, including insulin, glucagon, and parathyroid hormone.
- They synthesize ammonia, which plays a role in acid–base homeostasis (see Chapter 24).
- They synthesize substances that affect RBF and Na^+ excretion, including arachidonic acid derivatives (prostaglandins and thromboxane A_2) and kallikrein (a proteolytic enzyme that results in the production of kinins).

When the kidneys fail, a host of problems ensue. Dialysis and kidney transplantation are commonly used treatments for advanced (end-stage) renal failure.

NEPHRON: FUNCTIONAL UNIT OF THE KIDNEY

Each human kidney contains about 1 million microscopic units known as **nephrons** (Fig. 22.2), which consist of a *renal corpuscle* and a *renal tubule*. Each renal corpuscle is derived from a muscular *afferent arteriole* that forms a tuft of capillaries, the **glomerulus**, which is surrounded by the **Bowman capsule**. The glomerulus filters water and solutes from the blood plasma. The Bowman capsule, which cups around the glomerulus, collects the fluid filtered from the glomerulus. The blood leaving the glomerulus that was not filtered is carried via the *efferent arteriole*.

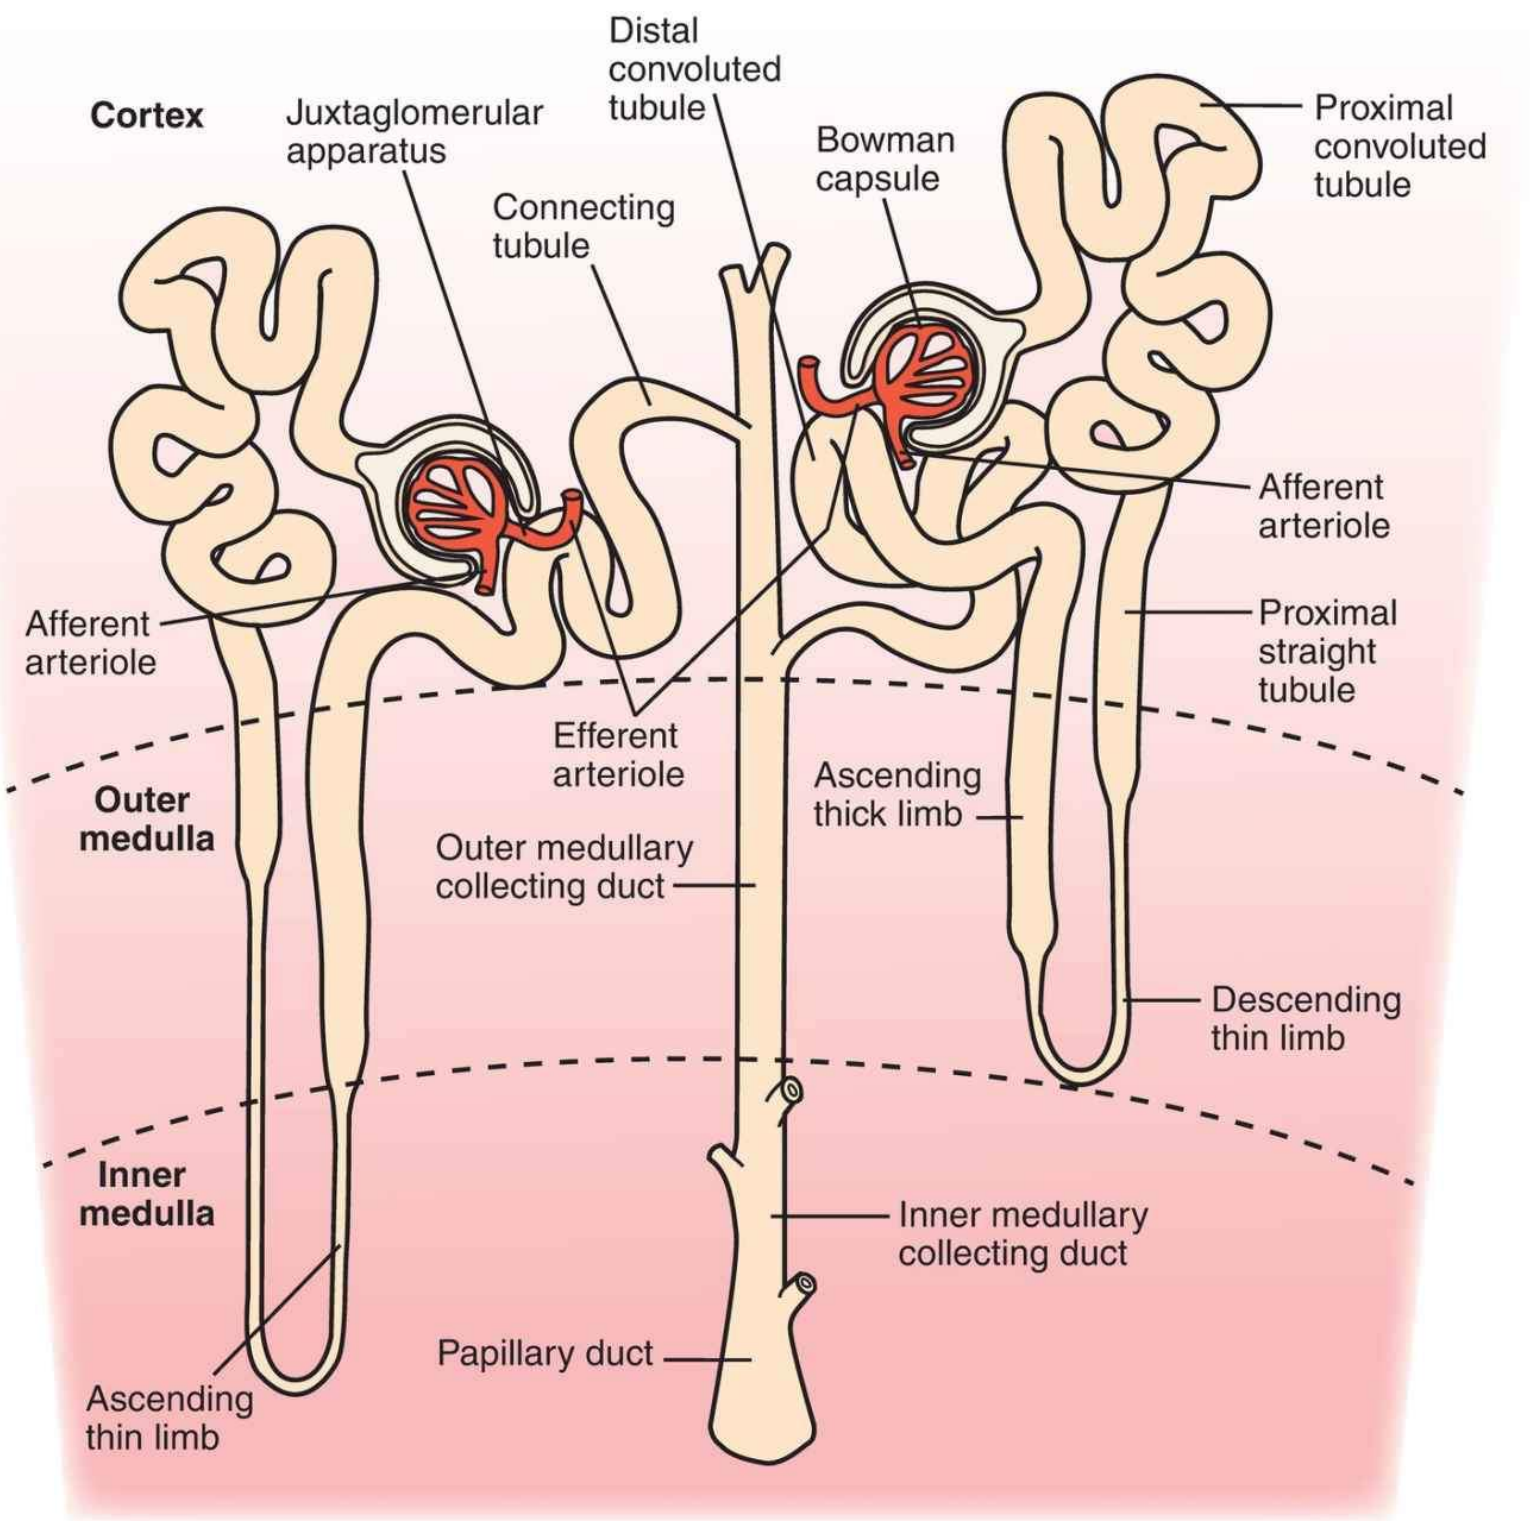

Figure 22.2 Components of the nephron and the collecting duct system. On the left is a long-looped juxtamedullary nephron; on the right is a superficial cortical nephron.

CLINICAL FOCUS 22.1

Dialysis and Transplantation

Chronic kidney disease is usually progressive and may lead to renal failure. Common causes include

diabetes mellitus, hypertension, inflammation of the glomeruli (glomerulonephritis), urinary reflux and infections (pyelonephritis), and polycystic kidney disease. Renal damage may occur over many years and may be undetected until a considerable loss of functioning nephrons has occurred. When glomerular filtration rate (GFR) has declined to 5% of normal or less, the internal environment becomes so disturbed that patients usually die within weeks or months if they are not dialyzed or provided with a functioning kidney transplant.

Most of the signs and symptoms of renal failure can be relieved by **dialysis**, the separation of smaller molecules from larger molecules in solution by diffusion of the small molecules through a selectively permeable membrane. Two methods of dialysis are commonly used to treat patients with severe, irreversible (end-stage) renal failure.

In **continuous ambulatory peritoneal dialysis**, the peritoneal membrane, which lines the abdominal cavity, acts as a dialyzing membrane. About 1 to 2 L of a sterile glucose/salt solution are introduced into the abdominal cavity, and small molecules (e.g., K^+ and urea) diffuse into the introduced solution, which is then drained and discarded. The procedure is usually done several times every day.

Hemodialysis is more efficient in terms of rapidly removing wastes. The patient's blood is pumped through an artificial kidney machine. The blood is separated from a balanced salt solution by a cellophane-like membrane, and small molecules can diffuse across this membrane. Excess fluid can be removed by applying pressure to the blood and filtering it. Hemodialysis is usually done three times a week (4 to 6 hours per session) in a medical facility or at home.

Dialysis can enable patients with otherwise fatal renal disease to live useful and productive lives. However, many physiologic and psychologic problems persist, including alteration of body calcium levels and bone disease, disorders of nerve function, hypertension, atherosclerotic vascular disease, sudden cardiac death due to plasma K^+ disturbances, and disturbances of sexual function. There is a constant risk of infection and, with hemodialysis, clotting and hemorrhage. Dialysis does not maintain normal growth and development in children. Anemia (primarily resulting from deficient erythropoietin production by damaged kidneys) was once a problem but can now be treated with recombinant human erythropoietin.

Renal transplantation is the only real cure for patients with end-stage renal failure. Patients who have had a kidney transplant have more energy, can enjoy a less restricted diet, have fewer complications, and live much longer than if they had stayed on dialysis. In 2015, over 100,000 patients were awaiting kidney transplants. In 2014, about 17,000 kidney transplantation operations were performed in the United States with about two thirds of the donated kidneys coming from living donors and the remaining third from deceased donors. At present, about 95% of kidneys grafted from a living donor related to the recipient function for 1 year; about 90% of kidneys from cadaver donors function for 1 year.

Several problems complicate kidney transplantation. The immunologic rejection of the kidney graft is a major challenge. The powerful drugs used to inhibit graft rejection compromise immune defensive mechanisms so that unusual and difficult-to-treat infections often develop. The limited supply of donor organs is also a major, unsolved problem; there are many more patients who would benefit from kidney transplantation than there are donors. In 2014, over 4,200 patients died awaiting kidney transplants with another 3,600 becoming too ill to receive a kidney transplant. The median waiting time for a kidney transplant is currently about 1,100 to 1,200 days. Finally, the cost of transplantation (or dialysis) is high. Fortunately, for people in the United States, Medicare covers the cost of dialysis and transplantation, but these lifesaving therapies are beyond the reach of most people in developing

countries. ■

Renal tubules contain unique features.

The renal tubule is divided into several segments (see Fig. 22.2). The part of the tubule nearest the glomerulus is the proximal tubule. This is subdivided into a *proximal convoluted tubule* followed by the *proximal straight tubule*. The straight portion heads toward the medulla, away from the surface of the kidney, and into the loop of Henle. The **loop of Henle** forms a U-shaped loop that dips toward the renal medulla. In nephrons contained within the renal cortex, the loop of Henle includes the proximal straight tubule, a *thin descending limb*, and a *thick ascending limb*. In juxtamedullary nephrons, which are a subgroup of nephrons whose loops of Henle descend deep into the renal medulla, a *thin ascending limb* is interposed between the thin descending and thick ascending limbs. The thick ascending limb of both types of nephrons leads into the next segment of the nephron called the *distal convoluted tubule*. The distal convoluted tubule extends from the **macula densa** (see below) to a connecting tubule, which is connected to the collecting duct system. Each duct in the system receives distal tubular fluid from several nephrons.

Juxtaglomerular apparatus is the site of renin production.

Approximately 12% of the total nephron population contain specialized sets of cells located between the renal corpuscle and the distal convoluted tubule. This specialized grouping is the **juxtaglomerular apparatus**, so named for its proximity to the glomerulus (Fig. 22.3). The juxtaglomerular apparatus consists of three cellular components: the macula densa of the distal convoluted tubule, **extraglomerular mesangial cells**, and **granular cells** (also known as *juxtaglomerular cells*). The macula densa (dense spot) consists of densely crowded tubular epithelial cells on the side of the thick ascending limb that faces the glomerular tuft; these cells monitor the composition of the fluid in the tubule lumen. The extraglomerular mesangial cells are continuous with mesangial cells of the glomerulus; they may transmit information from macula densa cells to the granular cells. The granular cells are modified vascular smooth muscle cells with an epithelioid appearance, located mainly in the afferent arterioles close to the glomerulus. These cells synthesize and release **renin**, an enzyme that hydrolyses angiotensinogen to form angiotensin I and thus participates in the body's **renin–angiotensin–aldosterone system**. This system contributes to the regulation of sodium and potassium concentration in the ECF (i.e., in blood plasma, lymph, and interstitial fluid), as well as the water volume contained within that fluid compartment. It also contributes to the regulation of arterial blood pressure (see Chapters 17 and 23). In addition to these regulatory roles, the juxtaglomerular apparatus is critical to regulating RBF, and the glomerular filtration rate (see below).

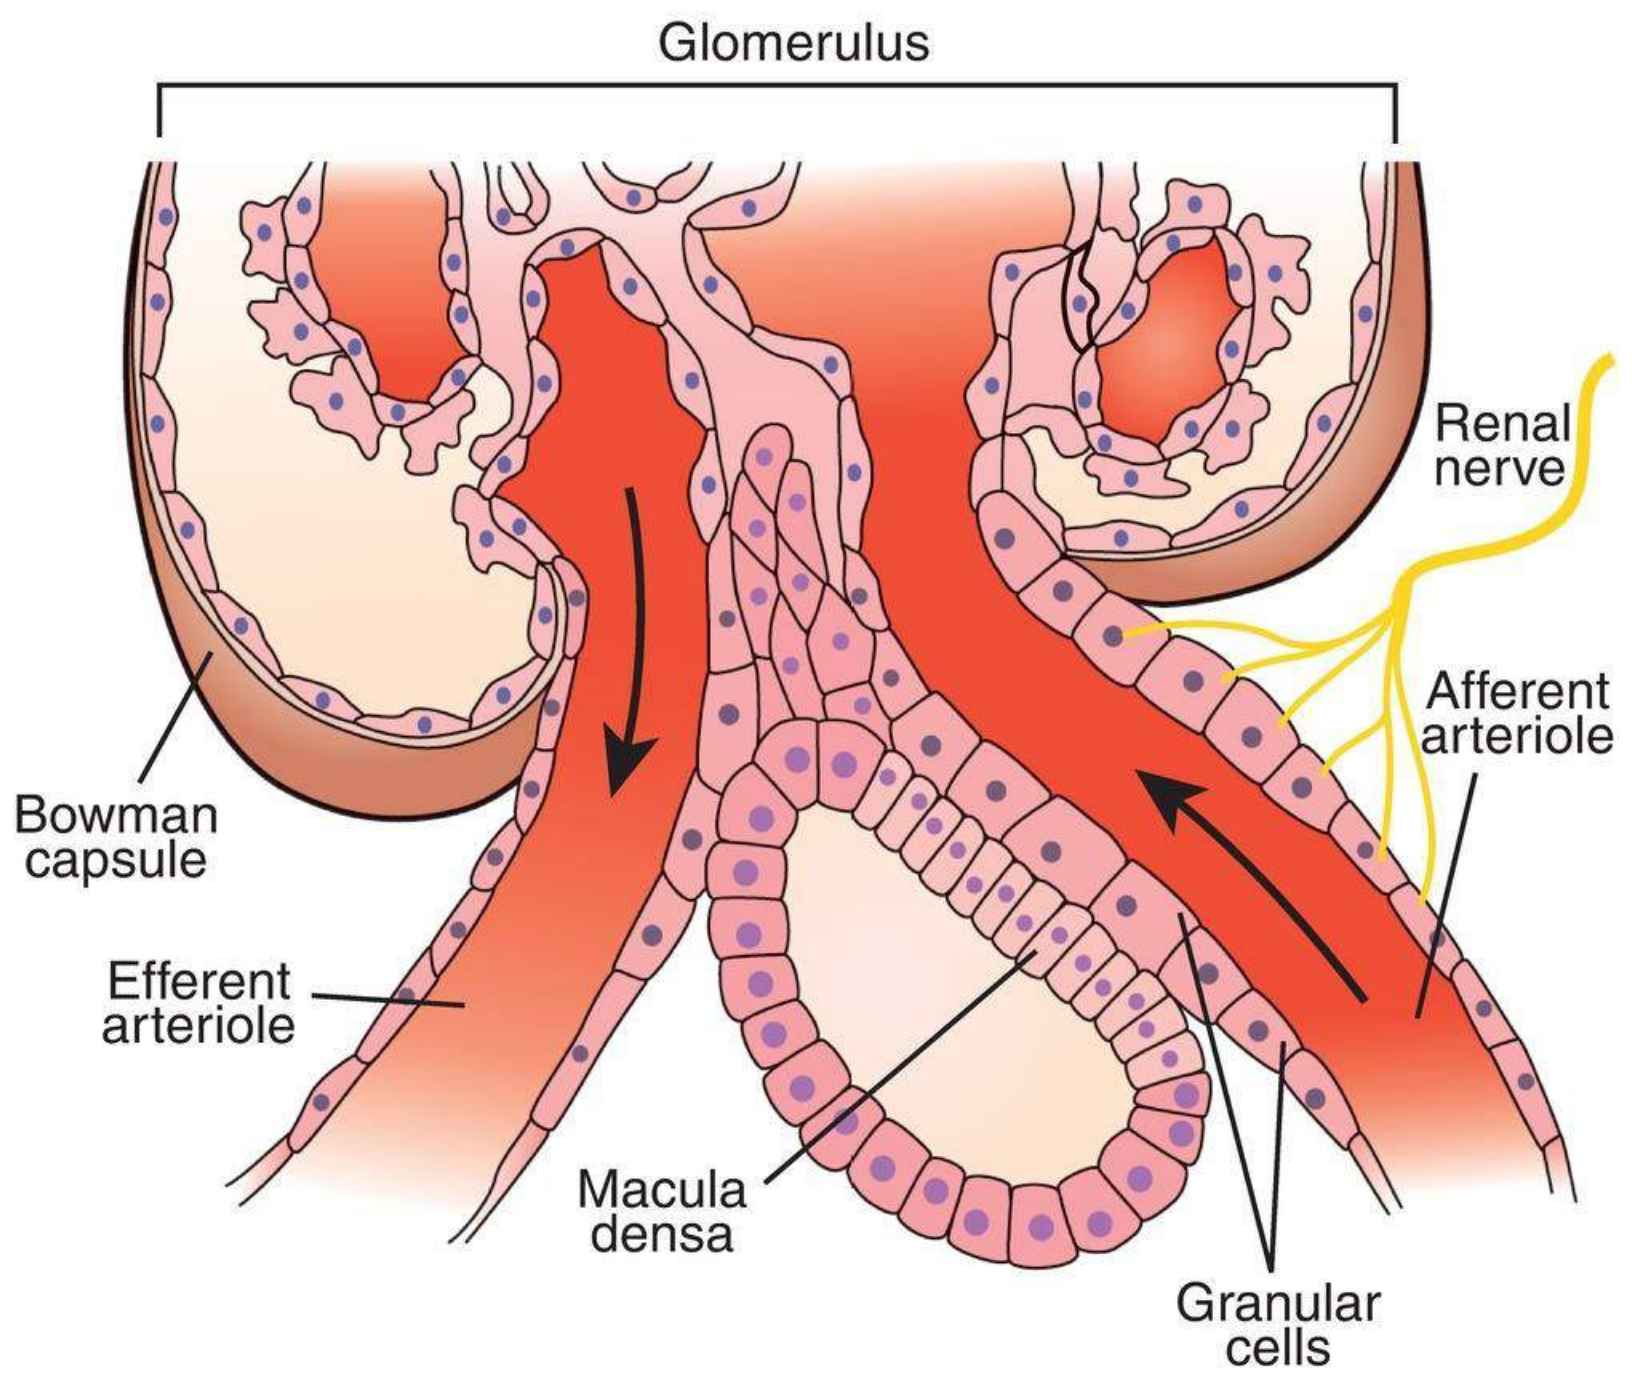

Figure 22.3 Histologic appearance of the juxtaglomerular apparatus. A cross-section through a thick ascending limb is below, and part of a glomerulus is on top.

Anatomical features of nephrons give rise to different regions in the kidney.

The arrangement of the nephrons within the kidney gives rise to two distinct regions: an outer part, called the **cortex**, and an inner part, called the **medulla** (see Fig. 22.1). The cortex is typically reddish brown and has a granulated appearance. All of the glomeruli, convoluted tubules, and cortical collecting ducts are located in the cortex. The medulla is lighter in color and has a striated appearance that results from the parallel arrangement of the loops of Henle, medullary collecting ducts, and blood vessels of the medulla. Nephrons are often classified into two main types: *cortical* and *juxtamedullary*. All nephrons originate in the cortex, but the glomeruli of the cortical nephrons lie in the outer layer of the cortex, whereas the glomeruli of the juxtamedullary nephrons lie in the inner layer of the cortex next to the medulla. Juxtamedullary nephrons differ in several ways from the other nephron types: they have a longer loop of Henle, longer thin limb (both descending and ascending portions), and different tubular permeability and transport properties.

Urine formation involves three basic processes.

The processes involved in forming urine are glomerular filtration, tubular reabsorption, and tubular secretion (Fig. 22.4). **Glomerular filtration** is the first step and involves filtration of the plasma across the glomerular capillaries. About 20% of the plasma flowing into the glomerulus is filtered into the Bowman capsule, and the remaining 80% flows through the efferent arteriole and into the peritubular capillaries. The filtrate enters the urinary space of the Bowman capsule and then flows downstream through the tubule lumen. The tubule epithelial cells decrease the volume and change the composition of the fluid in the tubule lumen. Approximately 180 L (~48 gallons) of plasma is filtered through the kidneys each day. The average plasma volume in the adult is about 2.75 L. This means the kidneys filters the body's plasma volume about 65 times per day. If everything filtered appeared as urine, the body's total plasma volume would be urinated in <30 minutes. This doesn't happen because of **tubular reabsorption**. Of the 180 L of plasma filtered per day, ~178.5 L is reabsorbed. The remaining 1.5 L is excreted as urine. In addition to reabsorption of water, tubular reabsorption also involves selective reabsorption of essential substances the body needs. These materials are reabsorbed by diffusion and cell membrane carrier–mediated transport. Reabsorption of material involves the movement of substances out of tubular urine back into the capillary blood, which surrounds the kidney tubules. Reabsorbed substances include many important ions (e.g., Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, and phosphate), water, important metabolites (e.g., glucose and amino acids), and even some waste products (e.g., urea and uric acid). The third renal process is **tubular secretion,** which also involves passive diffusion and cell membrane carrier–mediated transport of selective substances from the peritubular capillaries into the tubular urine. Tubular secretion provides a second route for a substance to enter the renal tubules from the bloodstream to be excreted, the first being by glomerular filtration. Tubular secretion provides a mechanism for selectively eliminating substance from the plasma. For example, many organic anions and cations are taken up by the tubular epithelium from the blood surrounding the tubules and added to the tubular urine. Some substances (e.g., H^+ and ammonia) are produced in the tubular cells and secreted into the tubular urine.

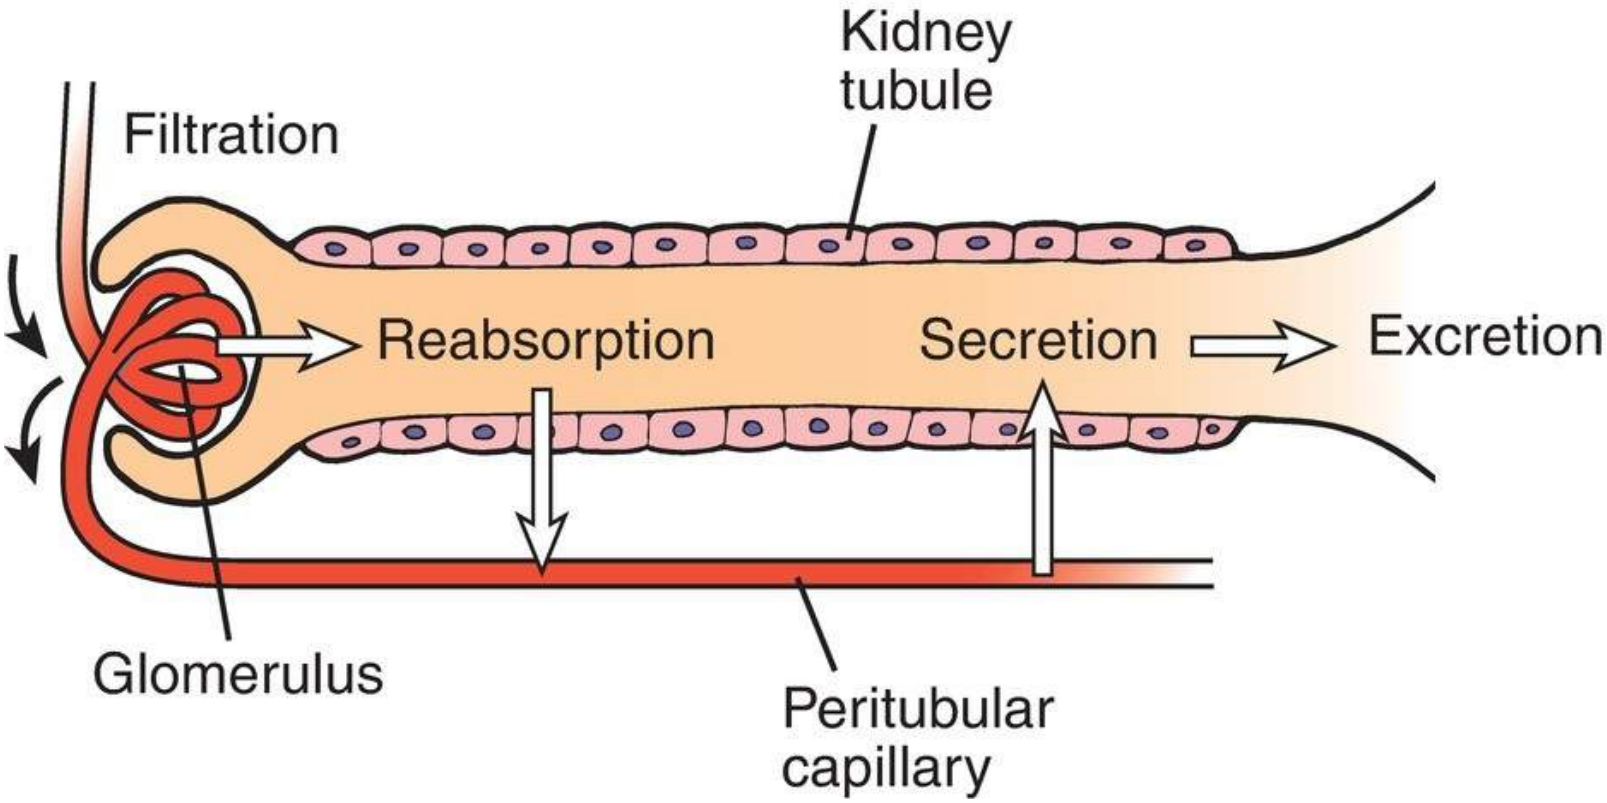

Figure 22.4 Processes involved in urine formation. This highly simplified diagram depicts the processes of filtration, reabsorption, secretion, and excretion.

The terms *reabsorption* and *secretion* indicate movement out of and into tubular urine, respectively. Tubular transport (reabsorption and secretion) may be either active or passive, depending on the particular substance and other conditions. **Excretion** refers to elimination via the urine. In general, the amount excreted is expressed by the following equation:

$$\text{Excreted} = \text{Filtered} - \text{Reabsorbed} + \text{Secreted} \quad (1)$$

The functional state of these processes in urine formation can be evaluated using several tests based on the renal clearance concept (see below).

RENAL BLOOD FLOW

Since the kidneys are the body's main filtering system for blood and ECF, they are highly dependent on blood flow. The kidneys have a high blood flow, which allows them to filter the blood plasma at a high rate. Like many other organs, RBF is affected by hormones, extrinsic neural stimulation, and local regulatory factors.

Optimal renal blood flow is maintained by autoregulation.

Autoregulation of blood flow is the mechanism that allows organs to maintain a constant blood flow during changes in mean arterial pressure (see Chapter 15). Although most organs show some degree of autoregulation, the mechanism is most clearly observed in the kidney, heart, and brain. Perfusion of these organs is essential for life and autoregulation allows for a continuous flow of blood despite wide fluctuations of arterial pressure. Autoregulation is an intrinsic property of the kidneys and is observed in an isolated perfused kidney devoid of external nerves. RBF in these isolated perfused kidneys can be kept relatively constant when perfusion pressure is varied from 80 to 180 mm Hg (Fig. 22.5). When the perfusion pressure is raised or lowered, the renal arterioles constrict or dilate, respectively, thereby maintaining a constant blood flow and capillary pressure.

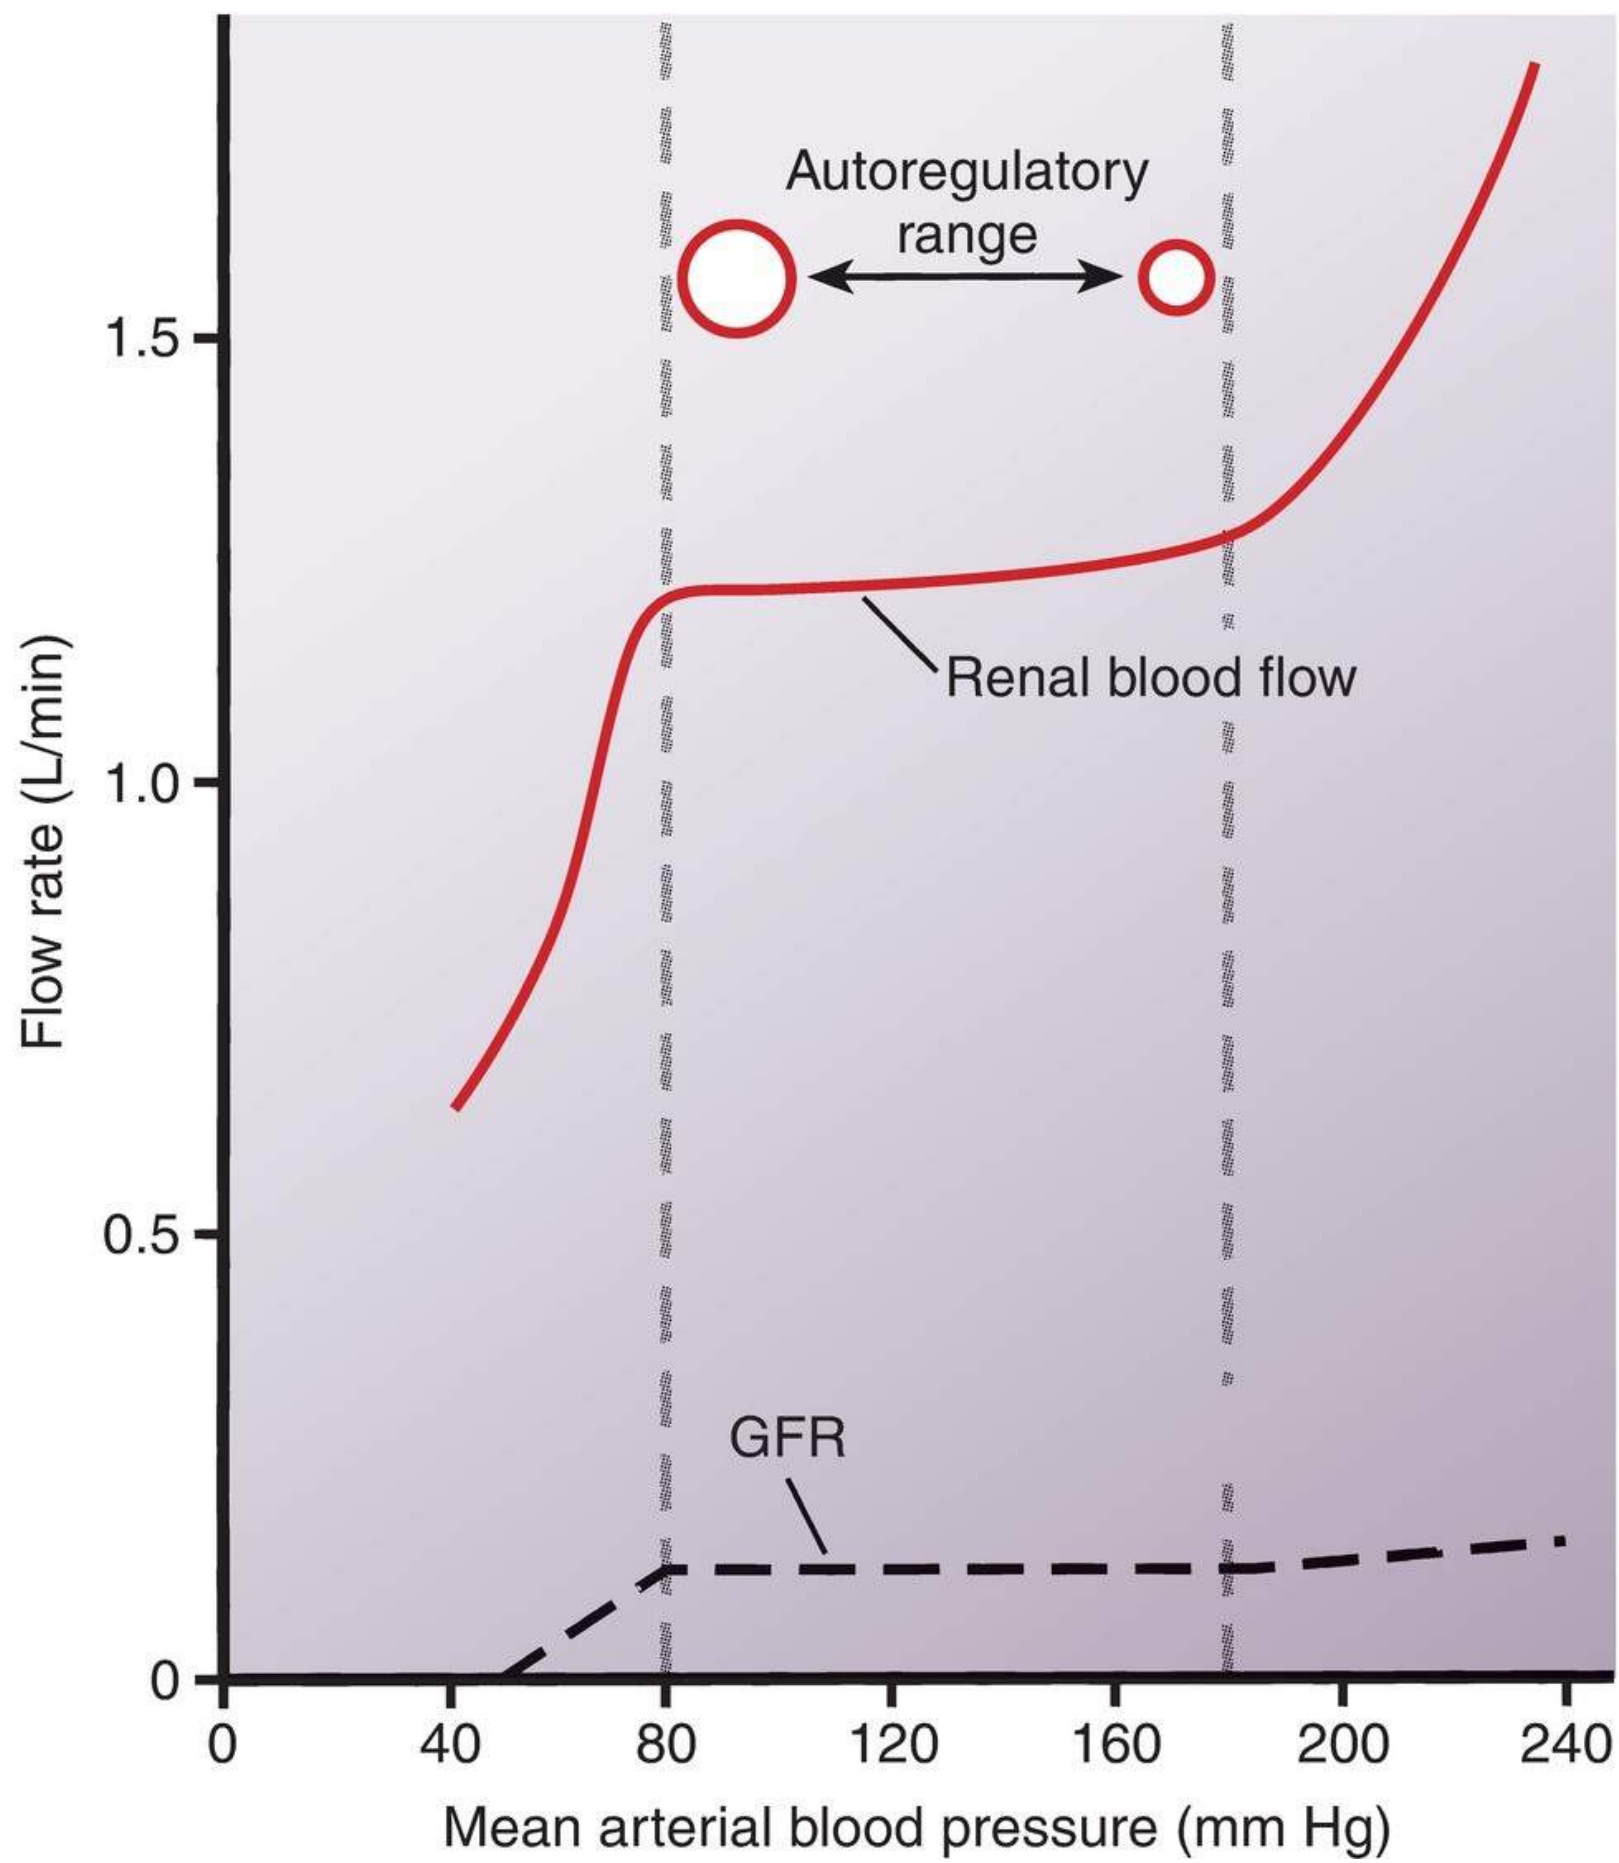

Figure 22.5 Renal autoregulation, based on measurements in isolated, denervated, perfused kidneys. In the autoregulatory range, renal blood flow and glomerular filtration rate (GFR) stay relatively constant despite changes in arterial blood pressure. This is accomplished by changes in the resistance (caliber) of preglomerular blood vessels. The circles indicate that vessel radius (r) is smaller when blood pressure is

high and larger when blood pressure is low. Because resistance to blood flow varies as r^4, changes in vessel caliber are greatly exaggerated in this figure.

Two mechanisms account for renal autoregulation: the **myogenic mechanism** and the **tubuloglomerular feedback mechanism**. In the myogenic mechanism, an increase in pressure stretches the afferent arteriolar walls, which then activate stretch-activated cation channels in the arteriolar smooth muscle cells. This causes intracellular Ca^{2+} to rise, resulting in smooth muscle contraction, a reduction in vessel lumen diameter, and an increase in vascular resistance. This counteracts the effect of high perfusion pressure, which would otherwise have increased RBF. Decreased blood pressure causes the opposite changes. In the **tubuloglomerular feedback mechanism** (Fig. 22.6), the transient increase in GFR resulting from an increase in blood pressure leads to increased NaCl delivery to the macula densa. This increases NaCl reabsorption and adenosine triphosphate (ATP) release from macula densa cells. ATP is metabolized to adenosine diphosphate (ADP), adenosine monophosphate (AMP), and adenosine in the juxtaglomerular interstitium. Adenosine combines with receptors in the afferent arteriole and causes vasoconstriction, and thus, blood flow and GFR are lowered to a more normal value. Sensitivity of the tubuloglomerular feedback mechanism is altered by changes in local renin activity, but adenosine, not angiotensin II, is the vasoconstrictor agent. The tubuloglomerular feedback mechanism is a negative feedback system that stabilizes RBF and GFR.

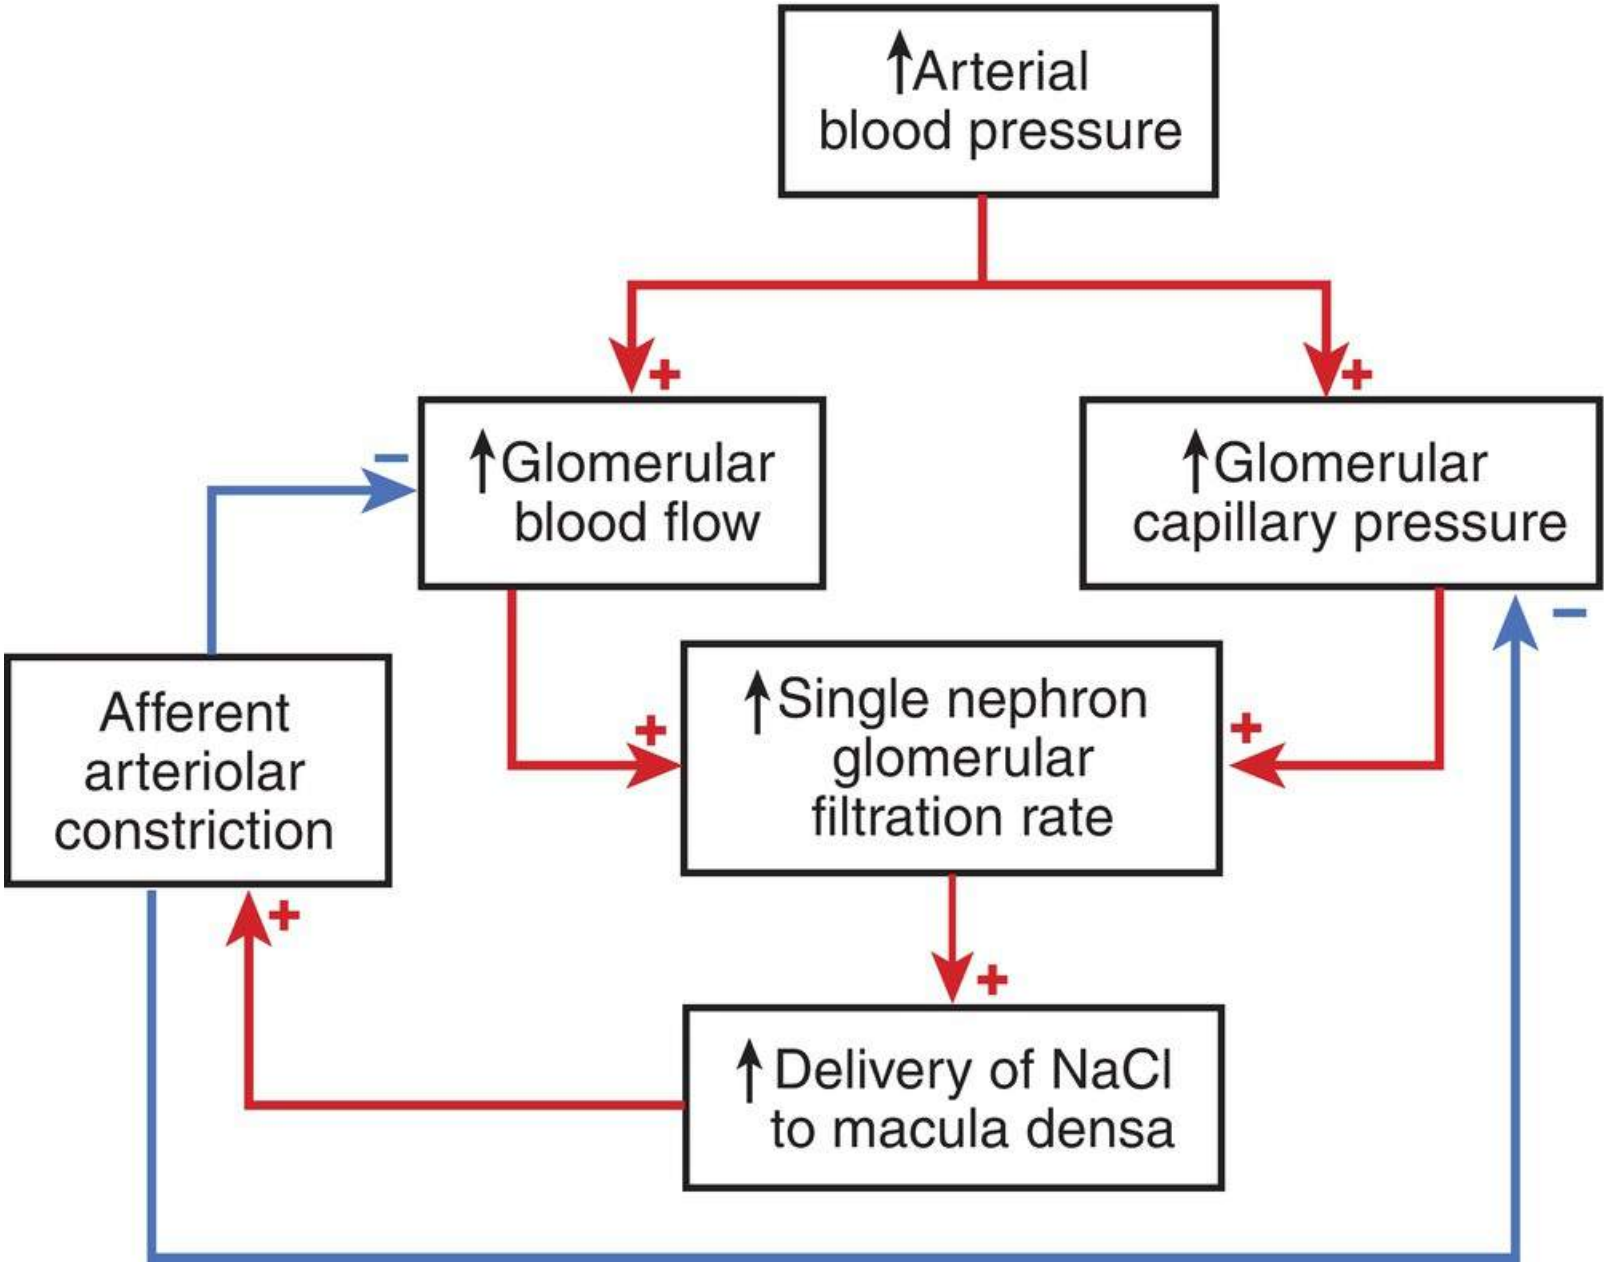

Figure 22.6 The tubuloglomerular feedback mechanism. When single-nephron glomerular filtration rate (GFR) is increased—for example, because of an increase in arterial blood pressure—more NaCl is delivered to and reabsorbed by the macula densa, leading to constriction of the nearby afferent arteriole. This negative feedback system plays a role in autoregulation of renal blood flow and GFR.

If NaCl delivery to the macula densa is increased experimentally by perfusing the lumen of the loop of Henle, filtration rate in the perfused nephron decreases. This suggests that the purpose of tubuloglomerular feedback may be to control the amount of Na^+ presented to distal nephron segments. These segments have a limited capacity to reabsorb Na^+; if they are overwhelmed, excessive urinary excretion of Na^+ might ensue.

Renal autoregulation is effected through altering the resistance of the afferent, not efferent, arteriole. In this manner, it minimizes the impact of changes in arterial blood pressure on RBF, GFR, and renal-filtered Na^+ load simultaneously. Without renal autoregulation, increases in arterial blood pressure would lead to dramatic increases in GFR and potentially serious losses of NaCl and water from the ECF.

Renal blood flow is altered by sympathetic nerve stimulation and hormones.

The stimulation of renal sympathetic nerves or the release of various hormones may change RBF. Sympathetic nerve stimulation causes vasoconstriction of the afferent and efferent arterioles and a consequent decrease in RBF. Renal sympathetic nerves are activated under stressful conditions, including cold temperatures, deep anesthesia, fearful situations, hemorrhage, pain, and strenuous exercise. In these conditions, renal vasoconstriction may be viewed as an emergency mechanism that helps increase total peripheral vascular resistance, raise arterial blood pressure, and allow more of the cardiac output to perfuse other vital organs, such as the brain and heart, which are more important for short-term survival.

Many substances cause vasoconstriction in the kidneys, including adenosine, angiotensin II, endothelin, epinephrine, norepinephrine, thromboxane A_2, and vasopressin. Other substances cause vasodilation in the kidneys, including atrial natriuretic peptide, dopamine, histamine, kinins, nitric oxide, and prostaglandins E_2 and I_2. Some of these substances (e.g., prostaglandins E_2 and I_2) are produced locally in the kidneys.

A sustained increase in sympathetic nerve activity or plasma angiotensin II concentration stimulates the production of renal vasodilator prostaglandins. These prostaglandins oppose the pure constrictor effect of chronic sympathetic nerve stimulation or angiotensin II, such as that seen in chronic heart failure. They can be viewed as a renal protective mechanism that prevents too severe a reduction in RBF in chronic pathological conditions that could cause renal damage. Antagonism of renal prostaglandin synthesis in these chronic conditions (e.g., through the use of NSAIDs) can cause acute renal failure by negating the renal protective effects of the renal prostaglandins.

GLOMERULAR FILTRATION

The filtration of plasma in the glomerulus is a process of bulk flow where water and low molecular weight substances move from the glomerular capillary across the filtration barrier and into the Bowman capsule. What is filtered is an **ultrafiltrate**. The term ultrafiltrate indicates that glomerular filtration barrier functions as a molecular sieve that allows filtration of small molecules but restricts the passage of macromolecules. The ultrafiltrate includes low molecular weight substances that are freely dissolved in plasma and includes various polar organic molecules such as glucose, amino acids, ions peptides, drugs, and waste products (e.g., creatinine and urea). Since filtration involves bulk flow, the concentration of the substance in the ultrafiltrate is the same as its concentration in the plasma. What are not filtered are blood cells, large proteins, and any small weight molecules that are bound to the large proteins.

The glomerular filtration barrier is more permeable than the capillaries.

The **glomerular filtration barrier** (Fig. 22.7) consists of three layers: two epithelial layers and basement membrane that lies between them. The first, the capillary **endothelium,** is perforated with large pores called the *lamina fenestra*. At about 50 to 100 nm in diameter, these pores are too large to restrict the passage of the smaller plasma proteins. The second layer, the **basement membrane**, consists of a meshwork of fine fibrils embedded in a gellike matrix. The basement membrane is negatively charged and repels plasma proteins, such as albumin, which are also negatively charged. The third layer is composed of **podocytes**, which constitute the visceral layer of the Bowman capsule. Podocytes ("foot cells") are epithelial cells with extensions that terminate in foot processes that rest on the outer layer of the basement membrane (see Fig. 22.7). The space between adjacent foot processes, called a **filtration slit**, and is about 40 nm wide. A structure called the **slit diaphragm**, is made up of various proteins that are synthesized by the podocytes and extends across the filtration slits. These proteins interconnect with adjacent podocytes to form a meshlike barrier that excludes proteins based on size. The slit diaphragm is an important barrier to the filtration of small proteins.

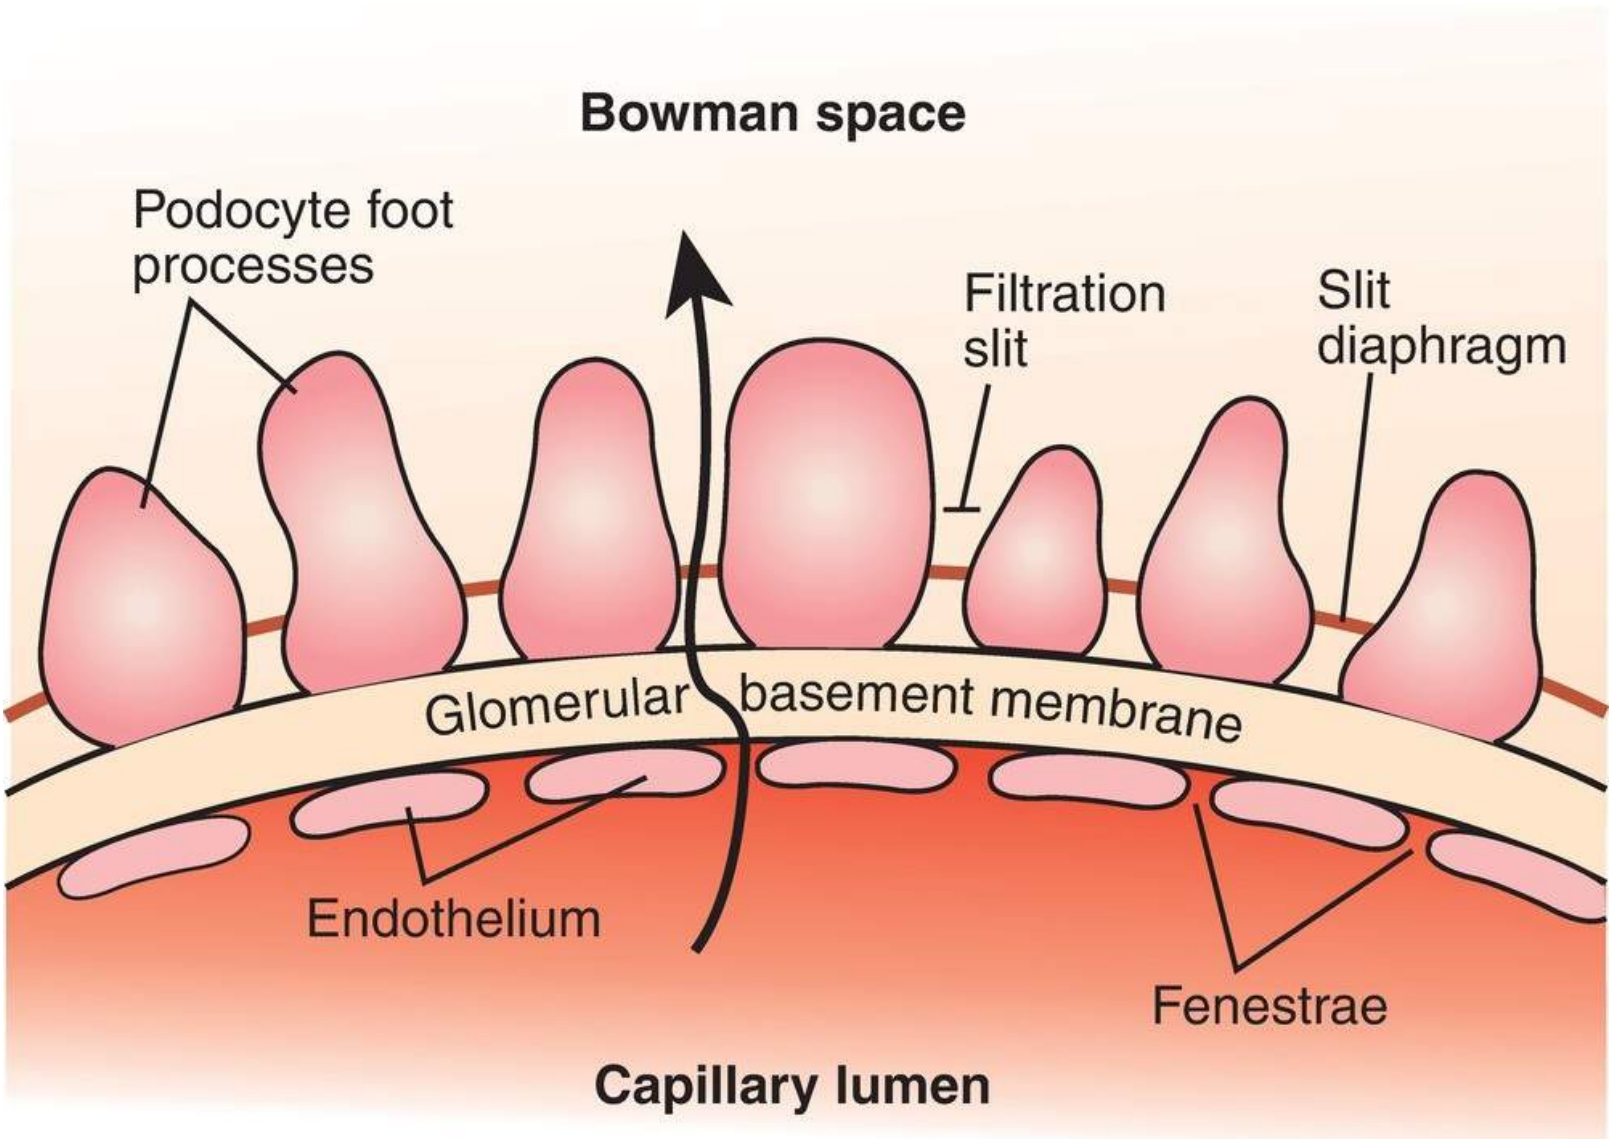

Figure 22.7 Schematic of the three layers of the glomerular filtration barrier: endothelium,

basement membrane, and podocytes. The pathway for filtration is indicated by the *arrow*.

Thus, the filtered route that substance takes across the glomerular filtration barrier is primarily a physical process and does not involve intracellular pumps. The first step is through the capillary pores, then through the basement membrane, and finally through the filtration slits. The ease in which material is filtered is dependent on molecular size, with large molecules such as albumin completely excluded.

CLINICAL FOCUS 22.2

Glomerular Disease

The kidney glomeruli may be injured by many immunologic, toxic, hemodynamic, and metabolic disorders. Glomerular injury impairs filtration barrier function and consequently increases the filtration and excretion of plasma proteins (proteinuria). Red cells may appear in the urine, and sometimes, the glomerular filtration rate (GFR) is reduced. Three general syndromes are encountered: nephritic diseases, nephrotic diseases (nephrotic syndrome), and chronic glomerulonephritis.

In the nephritic diseases, the urine contains red blood cells, red cell casts, and mild-to-modest amounts of protein. A red cell cast is a mold of the tubule lumen formed when red cells and proteins clump together; the presence of such casts in the final urine indicates that bleeding had occurred in the kidneys (usually in the glomeruli), not in the lower urinary tract. Nephritic diseases are usually associated with a fall in GFR, accumulation of nitrogenous wastes (urea, creatinine) in the blood, and hypervolemia (hypertension and edema). Most nephritic diseases are a result of immunologic damage. The glomerular capillaries may be injured by antibodies directed against the glomerular basement membrane, by deposition of circulating immune complexes along the endothelium or in the mesangium, or by cell-mediated injury (infiltration with lymphocytes and macrophages). A renal biopsy and tissue examination by light and electron microscopy and immunostaining are often helpful in determining the nature and severity of the disease and in predicting its most likely course.

Poststreptococcal glomerulonephritis is an example of a nephritic condition that may follow a sore throat caused by certain strains of streptococci. Immune complexes of antibody and bacterial antigen are deposited in the glomeruli, complement is activated, and polymorphonuclear leukocytes and macrophages infiltrate the glomeruli. Endothelial cell damage, accumulation of leukocytes, and the release of vasoconstrictor substances reduce the glomerular surface area and fluid permeability and lower glomerular blood flow, causing a fall in GFR.

Nephrotic syndrome is a clinical state that can develop as a consequence of many different diseases causing glomerular injury. It is characterized by heavy proteinuria (>3.5 g/d per 1.73 m^2 body surface area), hypoalbuminemia (<3 g/dL), generalized edema, and hyperlipidemia. Abnormal glomerular leakiness to plasma proteins leads to increased proximal tubular reabsorption and catabolism of filtered proteins and increased protein excretion in the urine. The resulting loss of protein (mainly serum albumin) leads to a fall in plasma protein concentration (and colloid osmotic pressure). The edema results from the hypoalbuminemia and renal Na^+ retention. Also, a generalized increase in capillary permeability to proteins (not just in the glomeruli) may lead to a decrease in the

effective colloid osmotic pressure of the plasma proteins and may contribute to the edema. The hyperlipidemia (elevated serum cholesterol and elevated triglycerides in severe cases) is probably a result of increased hepatic synthesis of lipoproteins and decreased lipoprotein catabolism. Most often, nephrotic syndrome in young children cannot be ascribed to a specific cause; this is called idiopathic nephrotic syndrome. Nephrotic syndrome in children or adults can be caused by infectious diseases, neoplasia, certain drugs, various autoimmune disorders (such as lupus), allergic reactions, metabolic disease (such as diabetes mellitus), or congenital disorders.

The distinctions between nephritic and nephrotic diseases are sometimes blurred, and both may result in chronic **glomerulonephritis**. This disease is characterized by proteinuria and/or hematuria (blood in the urine), hypertension, and renal insufficiency that progresses over years. Renal biopsy shows glomerular scarring and increased numbers of cells in the glomeruli and scarring and inflammation in the interstitial space. The disease is accompanied by a progressive loss of functioning nephrons and proceeds relentlessly even though the initiating insult may no longer be present. The exact reasons for disease progression are not known, but an important factor may be that surviving nephrons hypertrophy when nephrons are lost. This leads to an increase in blood flow and pressure in the remaining nephrons, a situation that further injures the glomeruli. Also, increased filtration of proteins causes increased tubular reabsorption of proteins, and the latter results in production of vasoactive and inflammatory substances that cause ischemia, interstitial inflammation, and renal scarring. Dietary manipulations (such as a reduced protein intake) or antihypertensive drugs (such as angiotensin-converting enzyme inhibitors) may slow the progression of chronic glomerulonephritis. Glomerulonephritis in its various forms is the major cause of renal failure in people. ■

GLOMERULAR HEMODYNAMIC FORCES

Glomerular filtration is accomplished by hemodynamic forces that drive part of the plasma in the glomerulus through the filtration barrier. No active transport mechanisms are involved in moving the fluid from the plasma across the glomerular filtration barrier into the lumen of the Bowman capsule. Since the glomerulus is a tuft of capillaries, the same hemodynamic forces apply here that causes ultrafiltration across other capillaries (see Chapter 15). Accordingly, **glomerular filtration rate (GFR)** depends on the Starling forces—the balance of hydrostatic and colloid osmotic pressures (COPs) acting across the glomerular filtration barrier.

Glomerular hemodynamics are characterized by high capillary pressure and low vascular resistance.

Figure 22.8 shows how pressures change along the length of a glomerular capillary, in contrast to those seen in a capillary in other vascular beds (in this case, skeletal muscle). Note that average capillary hydrostatic pressure in the glomerulus is much higher than in a skeletal muscle capillary (55 vs. 25 mm Hg). Also, capillary hydrostatic pressure declines little (perhaps 1 to 2 mm Hg) along the length of the glomerular capillary, because the glomerulus contains many (30 to 50) capillary loops in parallel, thereby making the resistance to blood flow in the glomerulus low. In the skeletal muscle capillary, there is a much higher resistance to blood flow, resulting in an appreciable fall in capillary hydrostatic pressure with distance. Finally, note that in the glomerulus, the COP increases substantially along the length of the capillary, because a large volume of filtrate (about 20% of the entering plasma flow) is pushed out of the capillary, and the proteins remain in the circulation. The increase in COP opposes the outward movement of fluid.

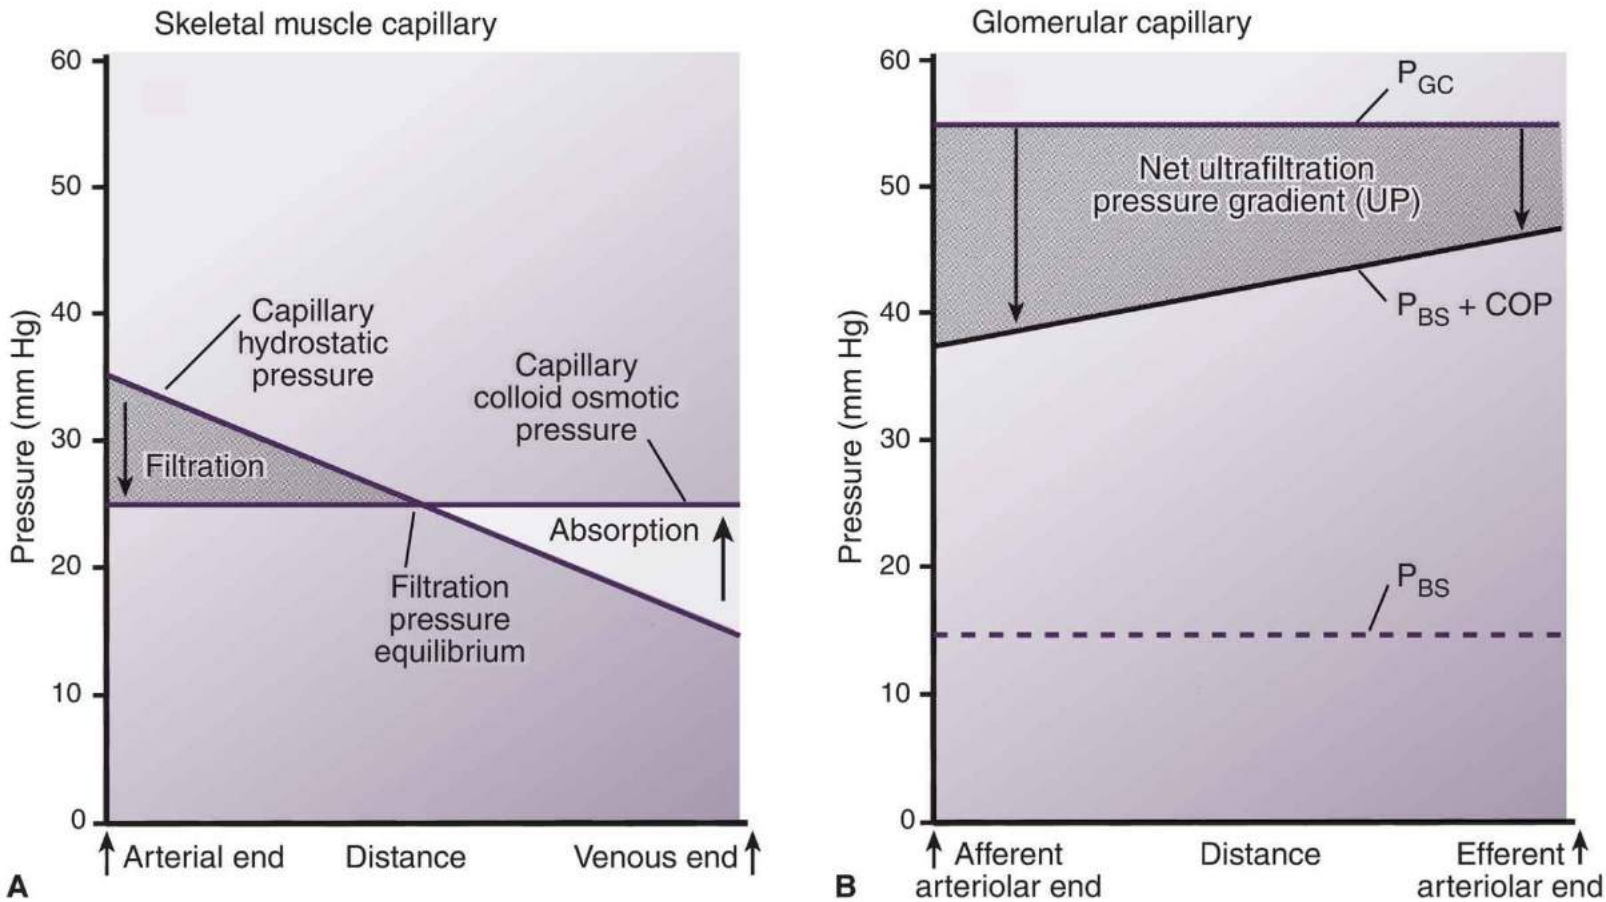

Figure 22.8 Pressure profiles along a skeletal muscle capillary and a glomerular capillary. (A) In the "typical" skeletal muscle capillary, filtration occurs at the arterial end and absorption at the venous end of the capillary. Interstitial fluid hydrostatic and colloid osmotic pressures (COPs) are neglected here because they are roughly equal and counterbalance each other. **(B)** In the glomerular capillary, glomerular hydrostatic pressure (P_{GC}) (*top line*) is high and declines only slightly with distance. The *bottom (dashed) line* represents the hydrostatic pressure in the Bowman capsule (P_{BS}). The *middle line* is the sum of P_{BS} and the glomerular capillary COP. The difference between P_{GC} and P_{BS} + COP is equal to the net ultrafiltration pressure gradient (UP). In the normal human glomerulus, filtration probably occurs

along the entire capillary. Assuming that K_f is uniform along the length of the capillary, filtration rate would be highest at the afferent arteriolar end and lowest at the efferent arteriolar end of the glomerulus.

Glomerular capillary pressure is the major force that determines glomerular filtration.

In the glomerulus, the driving force for fluid filtration is the glomerular capillary hydrostatic pressure (P_{GC}). This pressure ultimately depends on the blood pressure on the arterial side of the circulation. Filtration is opposed by the hydrostatic pressure in the space of the Bowman capsule (P_{BS}) and by the COP exerted by plasma proteins in glomerular capillary blood. Because the glomerular filtrate is virtually protein free, we neglect the COP of fluid in the Bowman capsule. The *net ultrafiltration pressure gradient* (UP) is equal to the difference between the pressures favoring and opposing filtration:

$$GFR = K_f \times UP = K_f \times (P_{GC} - P_{BS} - COP) \quad (2)$$

where K_f is the glomerular ultrafiltration coefficient. Estimates of average, normal values for pressures in the human kidney are as follows: P_{GC}, 55 mm Hg; P_{BS}, 15 mm Hg; and COP, 30 mm Hg. From these values, we calculate a net UP of +10 mm Hg (Table 22.1). As seen in the above equation, GFR varies with changes in K_f, hydrostatic pressures in the glomerular capillaries and the Bowman capsule, and the glomerular capillary COP.

TABLE 22.1 Summary Forces Involved in Glomerular Filtration

Force	Magnitude (mm Hg)	Effect
Glomerular capillary pressure	55	Favors filtration
Plasma colloidal osmotic pressure	30	Opposes filtration
Bowman capsule hydrostatic pressure	15	Opposes filtration
Net filtration pressure	10	Favors filtration
	55 – (30 + 15) = 10	

Changes in glomerular capillary hydrostatic pressure profoundly affect the GFR.

Glomerular capillary hydrostatic pressure (P_{GC}) is the driving force for filtration; it depends on the arterial blood pressure and the resistances of upstream and downstream blood vessels. Because of autoregulation, P_{GC} and GFR are maintained at relatively constant values when arterial blood pressure is varied from 80 to 180 mm Hg. Below a pressure of 80 mm Hg, however, P_{GC} and GFR decrease, and GFR ceases at a blood pressure of about 40 to 50 mm Hg. One of the classic signs of hemorrhagic or cardiogenic shock is an absence of urine output, which is a result of an inadequate arterial blood pressure, P_{GC}, and GFR.

The caliber of afferent and efferent arterioles can be altered by a variety of hormones and by sympathetic nerve stimulation, leading to changes in P_{GC}, glomerular blood flow, and GFR. Some hormones act preferentially on afferent or efferent arterioles. Afferent arteriolar dilation increases glomerular blood flow and P_{GC} and therefore produces an increase in GFR. Afferent arteriolar constriction produces the exact opposite effects. Efferent arteriolar dilation increases glomerular blood flow but leads to a fall in GFR because P_{GC} is decreased. Constriction of efferent arterioles increases P_{GC} and decreases glomerular blood flow. With modest efferent arteriolar constriction, GFR increases because of the increased P_{GC}. With extreme efferent arteriolar constriction, however, GFR decreases because of the marked decrease in glomerular blood flow.

Normally, about 20% of the plasma flowing through the kidneys is filtered in the glomeruli. This percentage (or fraction) is called the **filtration fraction**. Changes in filtration fraction will result from constriction or dilation of afferent or efferent arterioles. For example, afferent arteriolar dilation or efferent arteriolar constriction leads to an increase in filtration fraction. An increase in filtration fraction will increase the protein concentration of the blood exiting the glomerulus and hence will increase the COP in the peritubular capillaries. Such a change will increase sodium reabsorption in the kidneys (see Chapter 23).

Capillary osmotic pressure and hydrostatic pressure in the Bowman capsule oppose glomerular filtration.

Hydrostatic pressure in the Bowman capsule (P_{BS}) depends on the input of glomerular filtrate and the rate of removal of this fluid by the tubule. This pressure opposes filtration. It also provides the driving force for fluid movement down the length of the tubule. If there is obstruction anywhere along the urinary tract—for example, because of stones, ureteral obstruction, or prostate enlargement—then pressure upstream to the block is increased and GFR consequently falls. If tubular reabsorption of water is inhibited, pressure in the tubular system is increased because an increased pressure head is needed to force a large volume flow through the loops of Henle and collecting ducts. Consequently, a large increase in urine output caused by a diuretic drug may be associated with a tendency for GFR to fall.

The COP opposes glomerular filtration. Dilution of the plasma proteins (e.g., by intravenous infusion of a large volume of isotonic saline) lowers the plasma COP and leads to an increase in GFR. Part of the reason glomerular blood flow has important effects on GFR is that it changes the COP profile along the length of a glomerular capillary. Consider, for example, what would happen if glomerular blood flow were low. Filtering a small volume of fluid out of the glomerular capillary would lead to a sharp rise in COP early along the length of the glomerulus. As a consequence, filtration would soon cease and GFR would be low. On the other hand, a high blood flow would allow a high rate of filtrate formation with a minimal rise in COP. In general, then, RBF and GFR change hand in hand, but the exact relationship between GFR and RBF depends on the magnitude of the other factors that affect GFR.

Glomerular ultrafiltration coefficient depends on the properties of the glomerular filtration barrier.

The **glomerular ultrafiltration coefficient (K_f)** is the glomerular equivalent of the capillary filtration coefficient encountered in Chapter 15. Accordingly, K_f depends on both membrane permeability and surface area of the glomerular filtration barrier. Compared to typical systemic capillaries, the normal K_f for the glomerulus is very high. In chronic renal disease, functioning glomeruli are lost, leading to a reduction in surface area available for filtration and a fall in GFR. Acutely, a variety of drugs and hormones appear to change glomerular K_f and thus alter GFR, but the mechanisms are not completely understood.

In summary, the high GFR (180 L/d) in the human kidney is the result of several factors and far exceeds that in all other capillary beds for several reasons:

- The filtration coefficient is unusually high in the glomeruli. Compared with most other capillaries, the glomerular capillaries behave as though they have more pores per unit surface area; consequently, they have an unusually high hydraulic conductivity. The total glomerular filtration barrier area, about 2 m^2, is large.
- Capillary hydrostatic pressure is higher in the glomeruli than in any other capillaries.
- The high rate of RBF helps sustain a high GFR by limiting the rise in COP, thereby favoring filtration along the entire length of the glomerular capillaries.

In conclusion, glomerular filtration is high because the glomerular capillary blood is exposed to a large, porous surface and there is a high transmural pressure gradient favoring filtration.

Proteinuria is the hallmark of glomerular filtration barrier disorder.

When the filtration membrane is not functioning properly, it ceases to be an effective barrier. What then occurs is **proteinuria**, an abnormal accumulation of protein in the urine. A very small amount of protein gets filtered normally (~5 to 20 mg/d), but this is almost completely reabsorbed in the proximal tubule by endocytosis. If protein is detected in the urine, it usually means that there is a breakdown in the filtration barrier.

Proteinuria is a hallmark of glomerular disease. Proteinuria not only is a sign of kidney disease but also results in tubular and interstitial damage and contributes to the progression of chronic renal disease. This is due to the fact that high levels of proteins in the filtrate have a pathogenic effect on the renal tubules. Increased endocytosis of proteins by the renal tubular cells ultimately stimulates inflammation and fibrosis and leads to the loss of nephrons.

The major disorders that disrupt the glomerular filtration barrier are *diabetes mellitus*, *hypertension*, and *glomerulonephritis*. In diabetes mellitus, hyperglycemia and reduced insulin signaling trigger a set of changes in the filtration membrane that cause a loss of selectivity and result in proteinuria. Hypertension is damaging because the high pressure in the glomerular capillaries damages the filtration barrier. In glomerulonephritis, there is inflammatory damage to the filtration membrane due to an infection.

Severe proteinuria (>3.5 g/d) is called **nephrotic syndrome**. Excessive proteinuria manifests a number of symptoms. It causes low level of protein in the plasma, and this in combination with sodium retention leads to edema. Other symptoms include hyperlipidemia and hypertension.

TUBULAR REABSORPTION

All of the plasma constituents are filtered in the glomerulus with the exception of the larger proteins. Over 70% of the filtered solutes and water are reabsorbed along the proximal convoluted tubule. The reabsorption process involves selecting and retrieving nutrients, electrolytes, and other substances the body needs to function and survive. At the same time, waste products and other toxic substances are not reabsorbed and are eliminated in the urine.

The proximal tubule is responsible for reabsorbing all of the filtered glucose and amino acids. In addition, the proximal tubule reabsorbs the largest fraction of the filtered Na^+, K^+, Ca^{2+}, Cl^-, HCO_3^-, and water and secretes various organic anions and organic cations.

Tubular reabsorption involves diffusion and active transport.

Tubular reabsorption is highly selective and involves two types of tubular transport—*passive reabsorption and active reabsorption*. The steps in passive reabsorption involve no energy. The net movement of substances in the transepithelial transport from the tubular lumen to the plasma follows an electrochemical gradient. Active reabsorption involves transepithelial transport in the *basolateral membrane* of the proximal tubules. In general, these two reabsorption mechanisms allow the kidneys to have a high reabsorption capacity for substances needed by the body and a low reabsorptive capacity for waste products and toxic substances to be eliminated (Table 22.2).

TABLE 22.2 Selective Reabsorption of Various Substances Filtered by the Glomerulus

Substances	Percentage of Filtered Substances Reabsorbed	Percentage of Filtered Substances Excreted
Water	99	1
Sodium	99.5	0.5
Glucose	100	0
Urea (waste product from amino acids)	50	50
Phenol (metabolic waste product)	0	100

Water reabsorption occurs in all regions of the renal tubule with the exception of the ascending limb of the loop of Henle and the distal convoluted tubule. The thin and thick ascending limbs are water impermeable. The reason the ascending limb is impervious to water is not due to "tight junctions," but because of the lack of **aquaporins**, which are water channel proteins. These water channels do not exist in the cells of the ascending loop of Henle.

Urea reabsorption is dependent on the reabsorption of water in the proximal tubule.

The reabsorption of urea by the proximal tubules provides an example of reabsorption by passive diffusion. Because urea is freely permeable across the filtration barrier, urea concentration is the same within the Bowman capsule space as in the peritubular capillary and the adjacent interstitial fluid. As the filtered fluid flows through the proximal tubule, water is reabsorbed, and the reabsorption of water increases urea concentration within the tubular fluid. As a result, urea is higher than the surrounding interstitial fluid and peritubular capillaries. The proximal tubule is freely permeable to urea. Accordingly, urea diffuses down the concentration gradient from the tubular lumen to the peritubular capillaries. This is generally thought to occur by both transcellular (across cell membranes) and paracellular (between the cells) routes. Thus, urea reabsorption in the proximal tubule is highly dependent upon the reabsorption of water.

Active Na^+/K^+-ATPase pump is essential for sodium reabsorption.

In terms of energy expenditure, over 75% of the total energy used by the kidneys is for the active reabsorption of Na^+. Unlike other filtered solutes, Na^+ is reabsorbed throughout the entire tubule, with the exception of the descending loop of Henle. As seen from Table 22.2, 99.5% is reabsorbed. Of the Na^+ reabsorbed, most occurs in the proximal tubule (~65%), with 25% in the loop of Henle, and the remaining in the distal tubule and collecting ducts.

With the exception of the thin ascending limb of the loop of Henle, Na^+ reabsorption requires active transport throughout the renal tubule. Figure 22.9 is a model of a proximal tubule cell. Na^+ enters the cell from the lumen across the apical cell membrane and is pumped out across the basolateral cell membrane by the Na^+/K^+-ATPase. Anions, primarily Cl^- and HCO_3^-, accompany this sodium transport across the basolateral membrane. At the luminal cell membrane (brush border) of the proximal tubule cell, Na^+ enters the cell down combined electrical and chemical potential gradients. The inside of the cell is about −70 mV compared with tubular fluid, and intracellular Na^+ is about 30 to 40 mEq/L compared with a tubular fluid concentration of about 140 mEq/L. Na^+ entry into the cell occurs via a number of cotransport and antiport mechanisms. These mechanisms rely on the electrochemical gradient produced in part by the Na^+/K^+-ATPase and are therefore considered secondary active transport mechanisms. Na^+ is reabsorbed across the apical membrane together with glucose, amino acids, phosphate, and other solutes by way of separate, specific cotransporters. The downhill (energetically speaking) movement of Na^+ into the cell drives the uphill transport of these solutes. The sodium electrochemical energy available for this process can increase intracellular concentration of the cotransported substances 100 to 1,000 times greater than that in the tubule fluid. Glucose, amino acids, and phosphate, so accumulated in the cell, exit across the basolateral cell membrane by way of separate, Na^+-independent facilitated diffusion mechanisms. The sodium to solute cotransport mechanism in the proximal tubule accounts for reabsorption of all of glucose and amino acids filtered at the glomerulus along with about 7% of the filtered sodium.

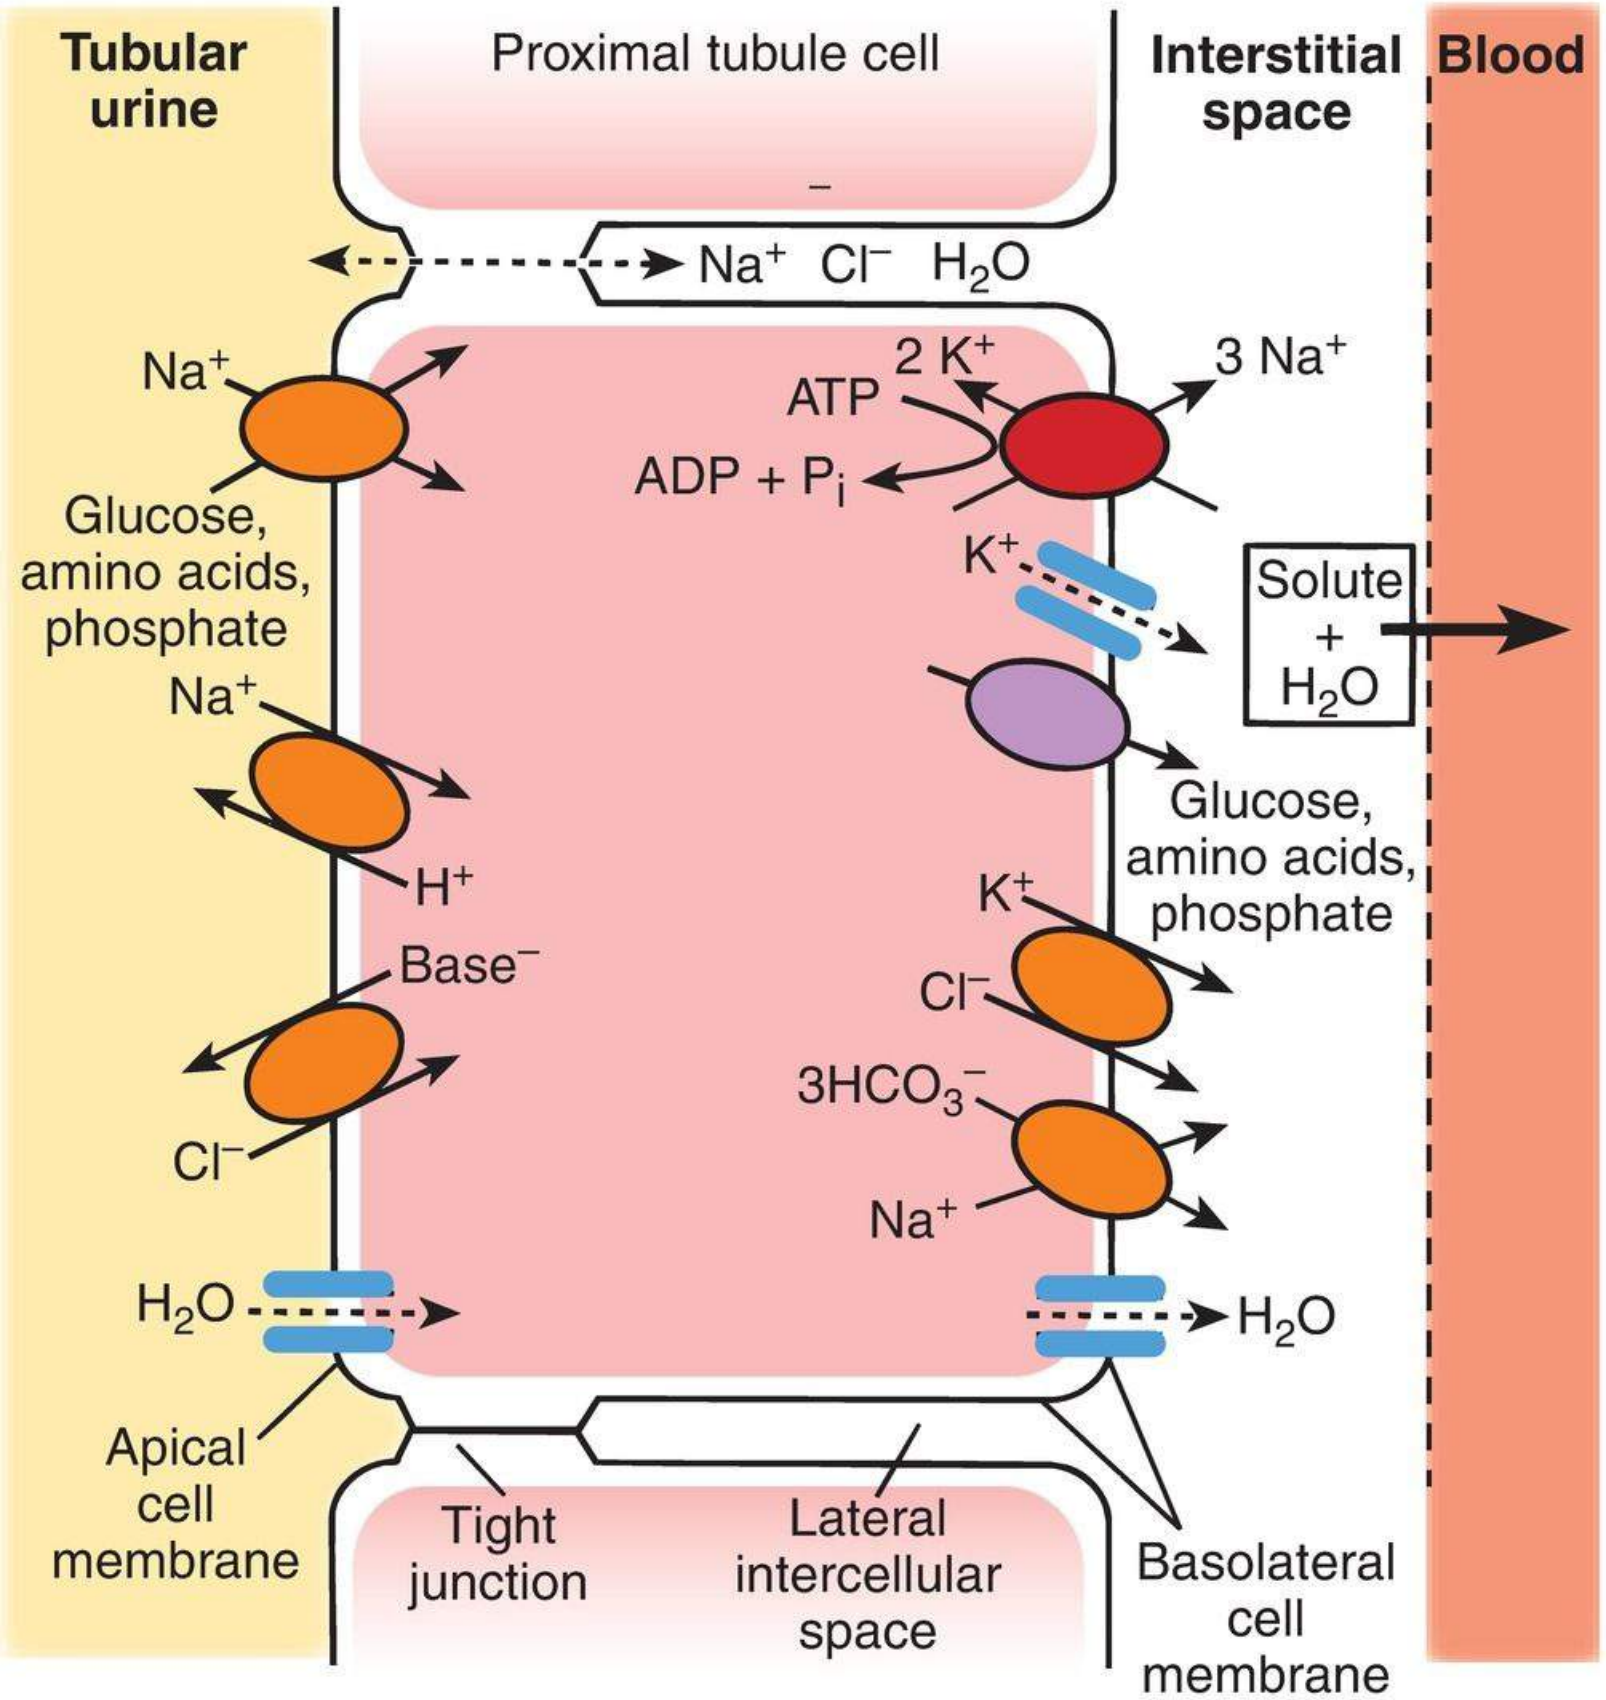

Figure 22.9 Cell model for transport in the proximal tubule. The luminal (apical) cell membrane in this nephron segment has a large surface area for transport because of the numerous microvilli that form the brush border (*not shown*). Glucose, amino acids, phosphate, and numerous other substances are transported by separate carriers. Sodium reabsorption across the apical membrane is accomplished through Na to solute cotransporters, H^+-driven sodium reabsorption, and paracellular Cl^--driven sodium transport. All sodium transport is dependent on the sodium ATPase pumps in the basolateral membrane. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Na^+ is also reabsorbed across the luminal cell membrane in exchange for H^+. The Na^+/H^+ exchanger, an antiporter, is a secondary active transport mechanism; the downhill movement of Na^+ into the cell energizes the uphill secretion of H^+ into the lumen. The H^+ in this exchange is derived primarily from two sources. One source is derived from carbonic acid production inside the tubule cells. Proximal tubule cells are richly endowed with carbonic anhydrase, which catalyzes the conversion of water and carbon dioxide (considered a cell "waste product") to carbonic acid (H_2CO_3). Intracellular carbonic acid so formed then quickly dissociates into H^+ and HCO_3^-. HCO_3^- accumulation in the cell is favored by removal of H^+ from the intracellular fluid by the Na^+/H^+ exchanger. A Na^+-HCO_3^- cotransporter uses accumulated bicarbonate to drive sodium from inside the cell into the peritubular fluid. The apical membrane Na^+/H^+ exchanger also removes H^+ formed from the dissociation of formic or oxalic acid within the tubule cell. The anions remaining from these acids are then used to bring Cl^- into the cell across the apical membrane via a Cl^-/base exchanger. Once in the tubular lumen, formate reassociates with any H^+ there. The newly reformed formic acid then diffuses back across the apical membrane where it dissociates and thus allows formate and acid to again exchange for Na^+ and Cl^-. The formic acid to formate anion mechanism is a key means by which Na^+ and Cl^- enter across the apical membrane. Cl^- may leave the cell across the basolateral membrane by way of an electrically neutral K–Cl cotransporter. In total, H^+-driven sodium reabsorption accounts for reabsorption of about 50% of the filtered sodium load at the glomerulus. (This mechanism is also important in the acidification of urine during acid–base homeostasis; see Chapter 24.)

The "tight junctions" between proximal tubule cells are not absolute and are sometimes called "leaky," or loose, tight junctions. Sodium, chloride, and water can pass through these junctions. In the latter part of the proximal tubule, the chloride concentration exceeds that of the peritubular fluid. Chloride is able to diffuse through the tight junctions, down its concentration gradient, and, in so doing, drags sodium with it. This is called chloride-driven sodium transport and accounts for the reabsorption of about 10% of the filtered sodium load.

The reabsorption of Na^+ with its accompanying anions and solutes establishes an osmotic gradient across the proximal tubule epithelium that is the driving force for water reabsorption. Because the water permeability of the proximal tubule epithelium is extremely high, only a small gradient (a few mOsm/kg H_2O) is needed to account for the observed rate of water reabsorption. Water crosses the proximal tubule epithelium through the cells (via water channel proteins—aquaporins—in the cell membranes) and between the cells (leaky tight junctions and lateral intercellular spaces). Upon reabsorption from the proximal tubule, the blood surrounding the tubules then takes up the Na^+, accompanying anions, and water. Filtered Na^+ salts and water are thus returned to the circulation.

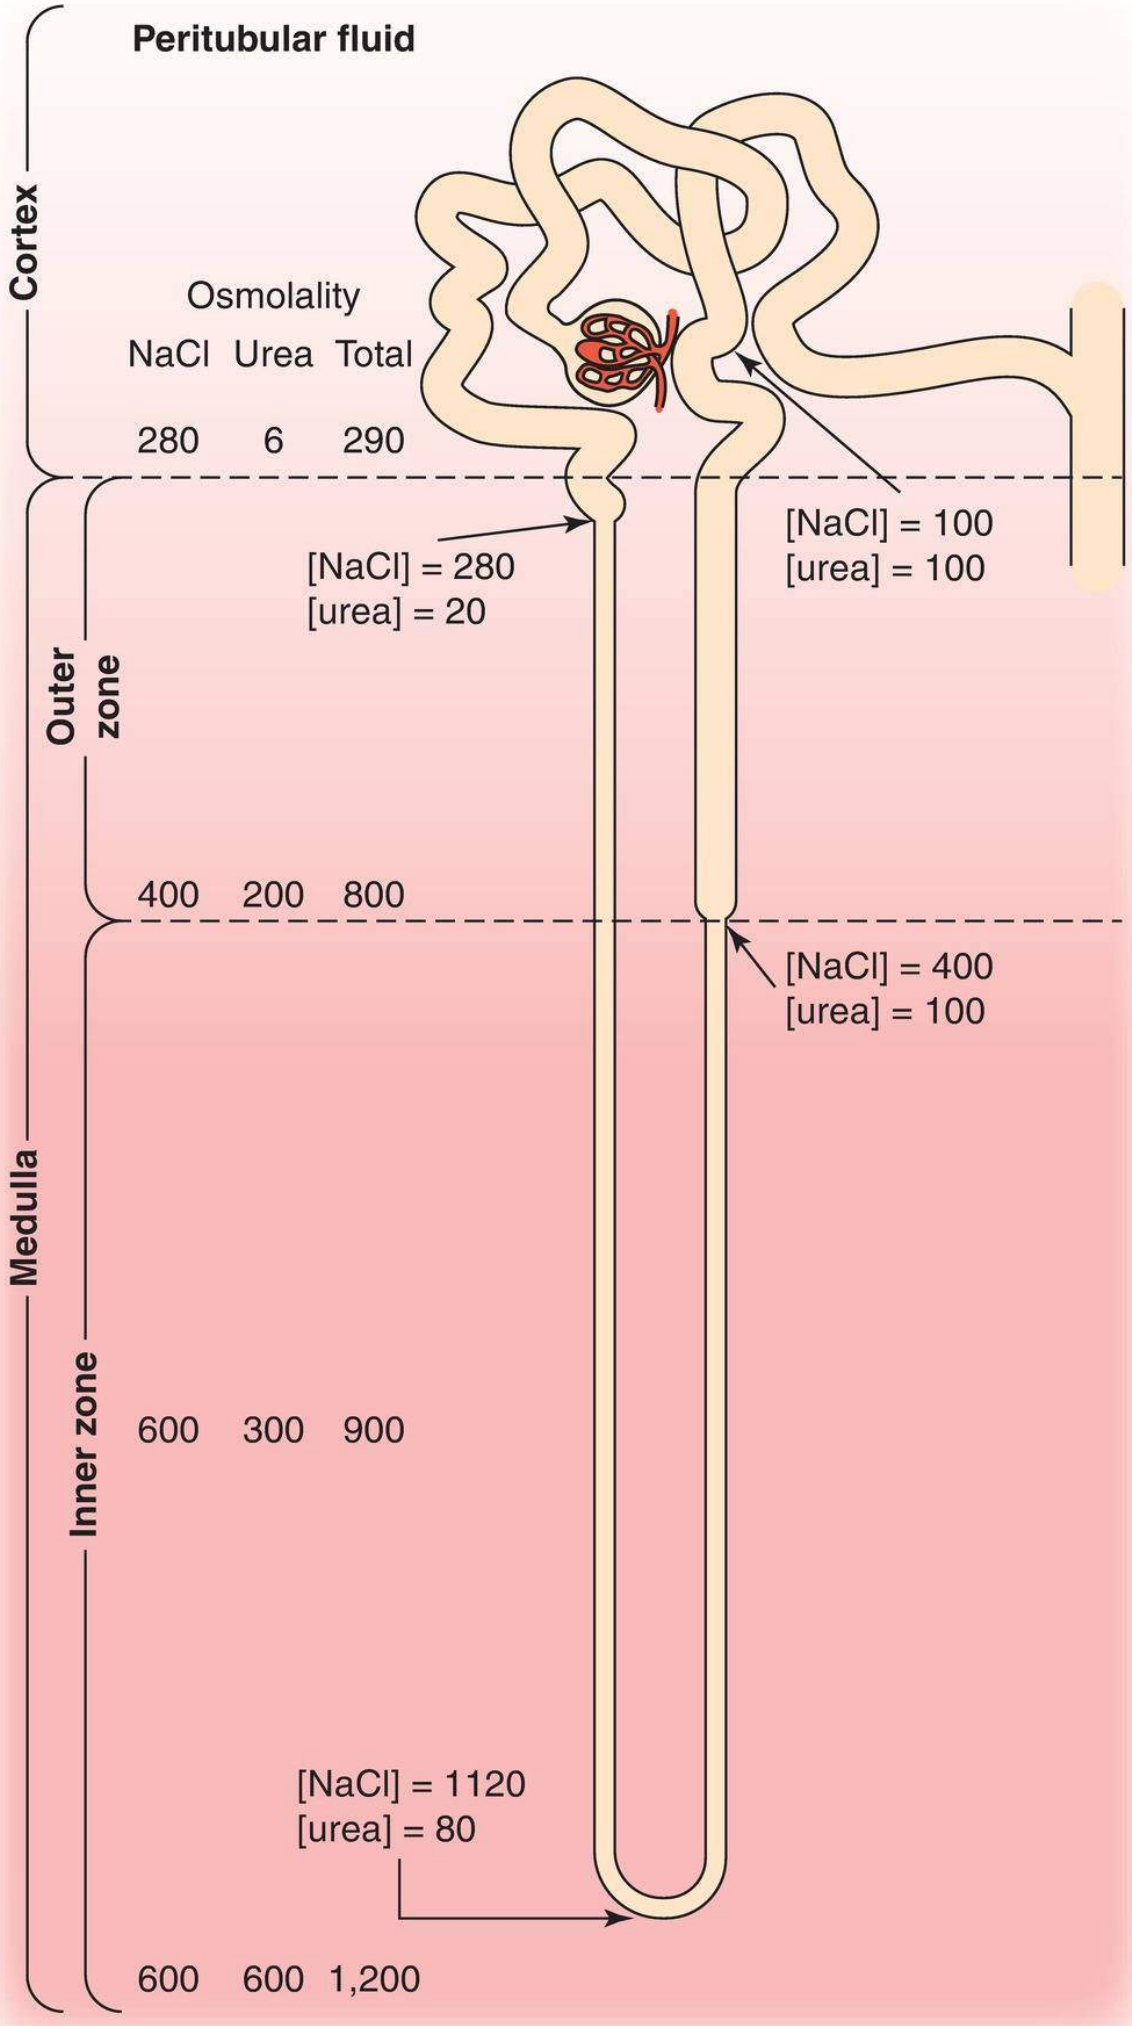
In total, the proximal tubule reabsorbs about two third of its filtered load of sodium and water. Because the tubule is freely permeable to water, the osmolarity of tubular fluid is the same as plasma with the sodium concentration being identical in both fluids. However, chloride concentration in the fluid exceeds that in plasma (~132 vs. 110 mM) whereas that for bicarbonate is lower (~8 vs. 24 mM). No amino acids or glucose exist in the tubular fluid exiting the proximal tubule but the reabsorption of water relative to the transport of urea in the tubule renders the tubule urea concentration higher than plasma (~20 vs. 6 mM).

An important feature of sodium reabsorption in the proximal tubule and, indeed, throughout the nephron is that its rate of transport is *load dependent*. In the proximal tubule, an increase in the filtered load of Na^+ from the glomerulus stimulates an increase in sodium reabsorption by the tubule such that the

percent of sodium reabsorbed remains the same. This phenomenon is called **glomerulotubular balance**, although it is also observed in the distal nephron when sodium load entering the distal nephron from upstream segments changes as well. This intrinsic renal tubular transport property has profound effects on salt and water balance in the body and contributes also to major side effects of renal excretion of ions other than sodium whenever sodium transport in the nephron is altered by disease or clinical drugs such as certain diuretics (see below and Chapter 23).

Transport of NaCl, urea, and water in the loop of Henle is determined by passive and active transport processes in individual sections of the tubule.

The transport of NaCl, urea, and water by the loop of Henle is complex due to differing epithelial permeabilities and transport properties as well as the unusual composition of the peritubular fluid surrounding the loop. The loops of Henle are surrounded by a progressively hyperosmotic **vertical osmotic gradient** in the medullary peritubular fluid (Fig. 22.10). In cortical or superficial nephrons, the loops descend from the cortex to the boundary of the outer and inner medulla. The peritubular fluid in the cortex is the same as plasma (~290 mOsm), but this osmolarity increases progressively to about 600 mOsm at the inner/outer boundary. In juxtamedullary nephrons, the loops are much longer and descend into the inner medullar where peritubular fluid reaches 1,200 to 1,400 mOsm. Medullary peritubular fluid osmolality is due to about 50% NaCl and 50% urea, in stark contrast to the osmolality of the end proximal tubular fluid, which is predominantly due to Na^+ and Cl^-. (The mechanisms responsible for creating and maintaining the medullary osmotic gradient in the kidney are explained later in this chapter.)



Peritubular fluid
Cortex
Osmolality
NaCl Urea Total
280 6 290
[NaCl] = 280
[urea] = 20
[NaCl] = 100
[urea] = 100

Inner zone
600 300 900
[NaCl] = 1120
[urea] = 80
600 600 1,200

Figure 22.10 Peritubular and tubular fluid osmolalities in the loop of Henle of a juxtamedullary nephron. A vertical gradient of increasing osmolality exists around the loop from the cortex to the renal medullary interstitium. The contribution to total osmolality from NaCl and urea are shown. Mechanisms responsible for differences in osmolality due to NaCl and urea within the lumen of the loop and in the peritubular fluids are explained in the text.

The thin descending limb contains no membrane active transport systems and is freely permeable to water, but it is impermeable to NaCl and urea. Therefore, as fluid from the proximal tubule travels down the thin descending limb, water is osmotically, passively, reabsorbed until its osmolarity is identical to the peritubular fluid surrounding the descending limb. In juxtamedullary nephrons, this equals about 1,200 to 1,400 mOsm or roughly a fourfold increase in osmolarity over fluid entering from the proximal tubule. This means about three quarters of the water entering the thin limb was osmotically reabsorbed by the time tubular fluid reaches the tip of the loop. This reabsorption of water concentrates NaCl, other solutes, and urea fourfold as well (about 1,120 mOsm due to NaCl and 80 mOsm due to urea).

The thin ascending limb of the loop of Henle is impermeable to water, but permeable to NaCl and somewhat permeable to urea, due to the presence of facilitated urea transporters (UT-A2) in the tubule epithelium. Consequently, as fluid in the loop ascends the limb, NaCl encounters progressively lower NaCl concentrations in the surrounding peritubular fluid and is passively reabsorbed. Urea, however, is slightly, passively secreted down its concentration gradient into the lumen as the tubular fluid ascends the limb. At the end of the ascending thin limb, its concentration reaches ~100 mM. Because this part of the tubule is impermeable to water, concentration changes for NaCl and urea are due solely to their passive transport. However, the reabsorption of NaCl exceeds the secretion of urea into the tubule so that by the end of the thin ascending limb, tubular fluid is hypotonic *relative to peritubular fluid* (about 500 vs. 600 total mOsm) but still hypertonic to plasma (~290 mOsm).

Sodium enters the luminal cell of the thick ascending limb by a Na–K–2Cl cotransporter.

The thick ascending limb of the loop of Henle is characterized by being impermeable to water, NaCl, and urea. However, cells of the thick limb are capable of actively transporting sodium out of the tubular fluid against a steep electrochemical gradient. Figure 22.11 is a model of a thick ascending limb cell. Na^+ enters the cell across the luminal cell membrane by an electrically neutral Na–K–2Cl cotransporter. This transporter, in particular Cl^- binding to this protein, is essential to sodium reabsorption in the thick ascending limb. It is specifically inhibited by "loop" diuretic drugs, such as bumetanide and furosemide, which then, through many steps, inhibits the ability of the kidney to reabsorb NaCl and water (see later sections in this chapter). The downhill movement of Na^+ into the cell results in secondary active transport of one K^+ and two Cl^-. Na^+ is pumped out of the basolateral cell membrane by a vigorous Na^+/K^+-ATPase. K^+ recycles back into the lumen via a luminal cell membrane K^+ channel. Cl^- leaves through the basolateral side by a K–Cl cotransporter or Cl^- channel. The luminal cell membrane is predominantly permeable to K^+, and the basolateral cell membrane is predominantly permeable to Cl^-. Diffusion of these ions out of the cell produces a transepithelial potential difference, with the lumen about +6 mV compared with the interstitial space around the tubules. This potential difference drives reabsorption of small cations (Na^+, K^+, Ca^{2+}, Mg^{2+}, and NH_4^+) out of the lumen, between the cells. The potential difference can be increased to about +9 mV by anything that stimulates sodium reabsorption in the thick ascending limb and decreased to about +3 when sodium transport is impaired. Thus, factors that affect sodium reabsorption in the thick ascending limb indirectly affect reabsorption of other small cations as well. By the end of the thick ascending limb, tubular fluid volume has been reduced by about 75% of that entering the loop and is hypotonic relative to peritubular fluid *and* plasma (about 100 mOsm due equally to NaCl and urea).

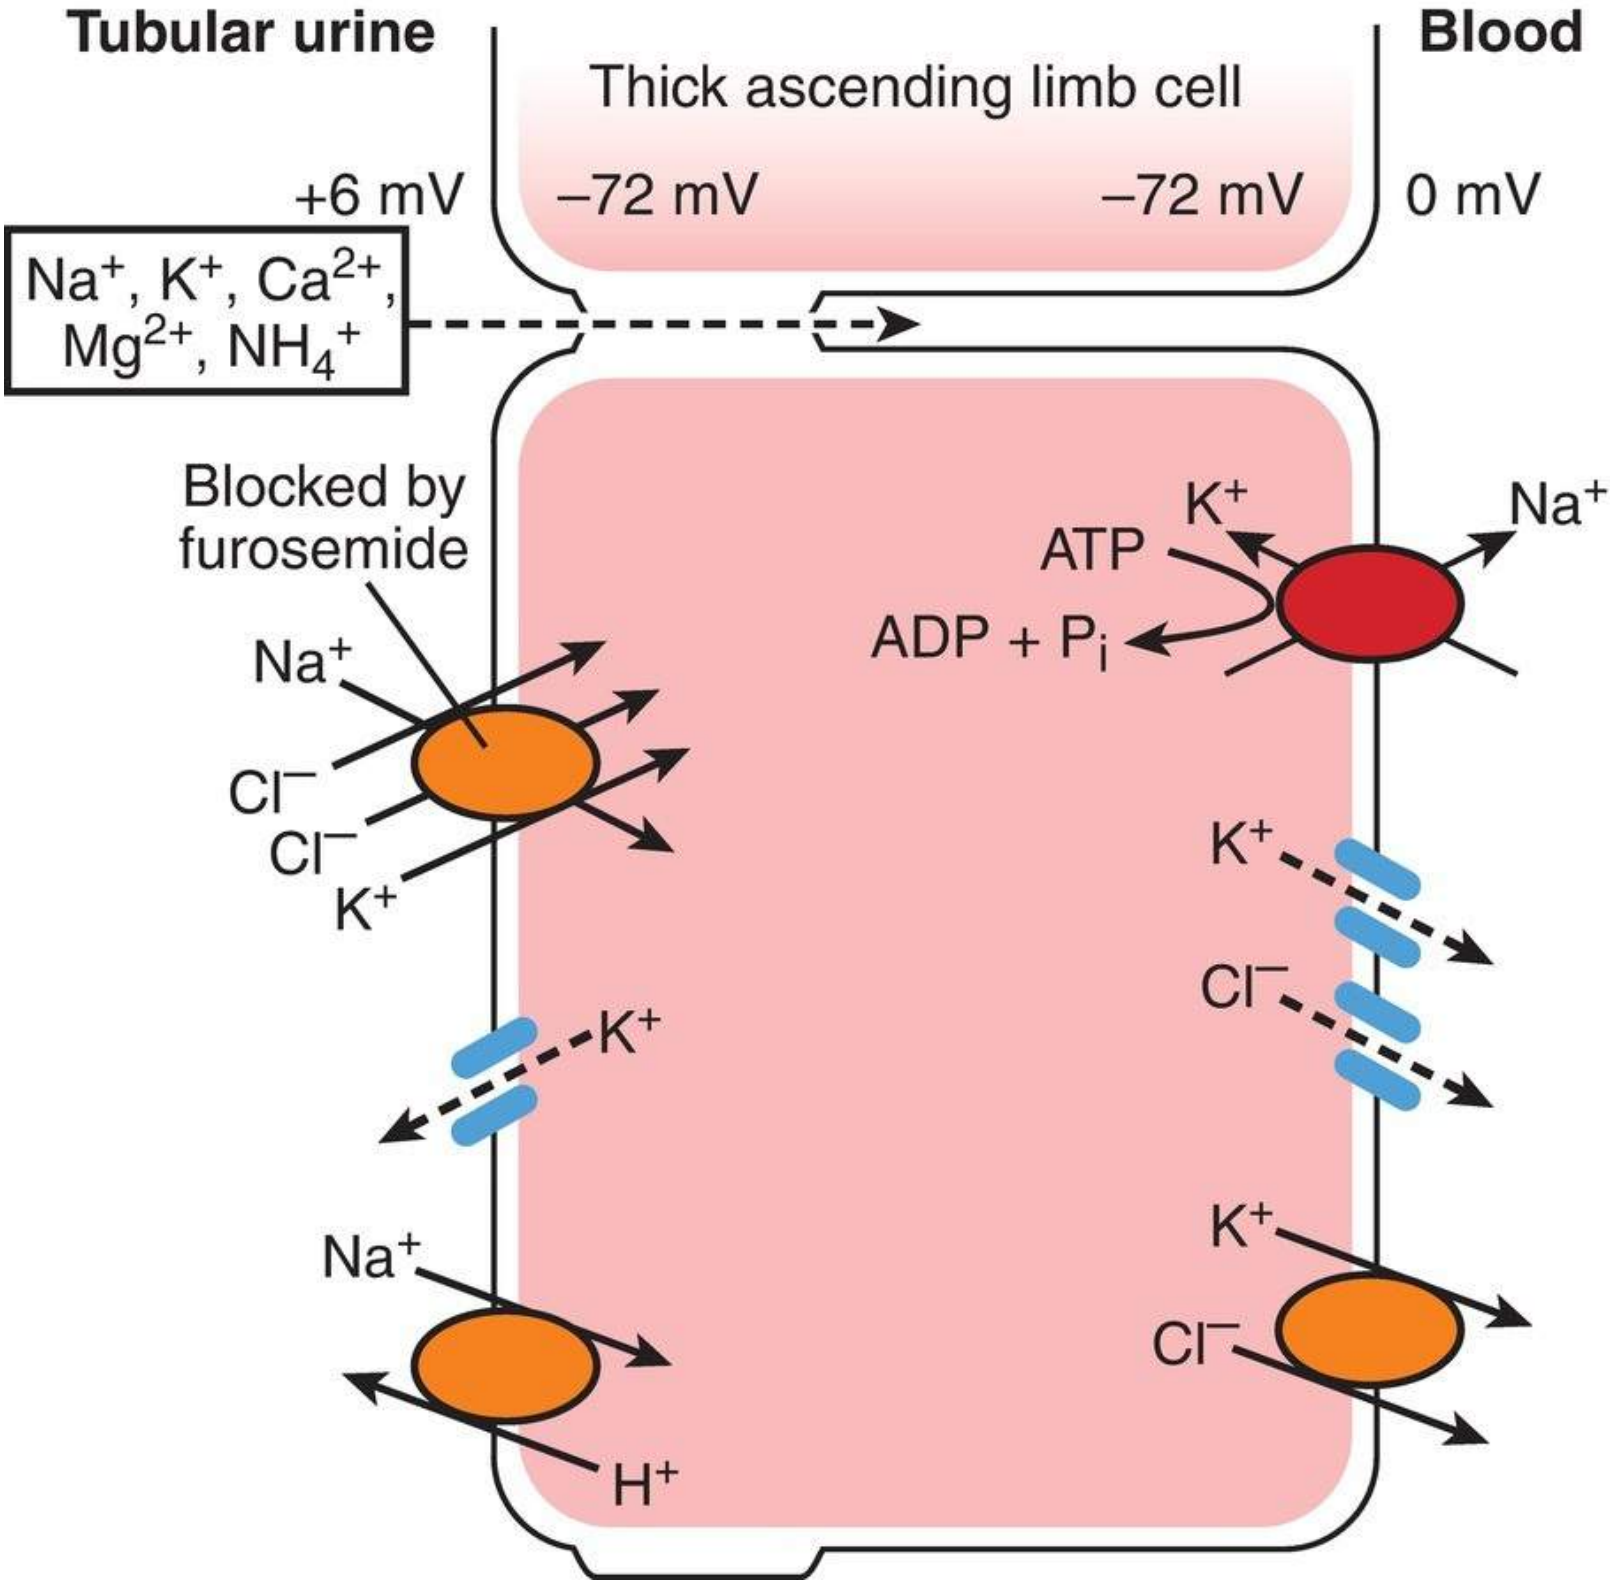

Figure 22.11 Cell model for ion transport in the thick ascending limb. Transport of sodium is critically dependent on uptake from the lumen by the Na–K–2Cl cotransporter in the apical membrane. This transporter is inhibited by loop diuretics. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

The final step in the overall reabsorption of solutes and water in the thin ascending limb is uptake by the peritubular capillaries. This mechanism involves the usual Starling forces that operate across capillary walls. Recall that blood in the peritubular capillaries was previously filtered in the glomeruli. Because a protein-free filtrate was filtered out of the glomeruli, the protein concentration (hence, COP) of blood in the peritubular capillaries is high, thereby providing an important driving force for the uptake of reabsorbed fluid. The hydrostatic pressure in the peritubular capillaries (a pressure that opposes the

capillary uptake of fluid) is low, because the blood has passed through upstream resistance vessels. The balance of pressures acting across peritubular capillaries favors the uptake of reabsorbed fluid from the interstitial spaces surrounding the tubules.

The distal nephron handles tubular reabsorption.

The so-called **distal nephron** includes several distinct segments: the distal convoluted tubule; the connecting tubule; and the cortical, outer medullary, and inner medullary collecting ducts (see Fig. 22.3). Note that the distal nephron includes the collecting duct system, which, strictly speaking, is not part of the nephron but, from a functional perspective, this is justified. Transport in the distal nephron differs from that in the proximal tubule in several ways:

- The distal nephron reabsorbs much smaller amounts of salt and water. Typically, the distal nephron reabsorbs 9% of the filtered Na^+ and 19% of the filtered water, compared with 70% for both substances in the proximal convoluted tubule.
- The distal nephron can establish steep gradients for salt and water. For example, the concentration of Na^+ in the final urine may be as low as 1 mEq/L (vs. 140 mEq/L in plasma) and the urine osmolality can be almost one tenth that of plasma. By contrast, the proximal tubule reabsorbs Na^+ and water along small gradients, and the Na^+ concentration and osmolality of its tubule fluid are normally close to those of plasma.
- The distal nephron has a “tight” epithelium, whereas the proximal tubule has a “leaky” epithelium (see Chapter 2). This explains why the distal nephron can establish steep gradients for small ions and water, whereas the proximal tubule cannot.
- Na^+ and water reabsorption in the proximal tubule are normally closely coupled, because epithelial water permeability is always high. By contrast, Na^+ and water reabsorption can be uncoupled in the distal nephron, because water permeability may be low and variable.

Proximal reabsorption overall can be characterized as a coarse operation that reclaims large quantities of salt and water along small gradients. By contrast, distal reabsorption is a finer process involved more in regulation of water and electrolyte balance in the body.

Sodium and chloride are actively reabsorbed through the luminal cell membrane of the distal convoluted tubule by a Na–Cl cotransporter.

The distal convoluted tubule has functionally "tight" junctions between epithelial cells. It is essentially impermeable to water and urea but can actively reabsorb NaCl against steep electrochemical gradients. Figure 22.12 is a simple model of sodium reabsorption in a distal convoluted tubule cell. In this nephron segment, Na^+ and Cl^- are transported from the lumen into the cell by a Na–Cl cotransporter. (This transporter can be inhibited clinically by thiazide diuretics.) Na^+ is pumped out the basolateral side by the Na^+/K^+-ATPase and chloride is thought to follow via a basolateral membrane channel. Sodium reabsorption coupled with the low water and urea permeability of the tubular epithelium further reduces the osmolality of the tubular fluid without changing its volume or urea concentration. Urea concentration is higher in distal tubules from juxtamedullary compared to cortical nephrons (about 100 vs. 40 mM) because the later nephrons are exposed to lower osmotic and urea concentrations surrounding their loops of Henle. Regardless of the type of nephron, by the end of the distal convoluted tubule, so little of the original filtered NaCl remains that the osmotic contribution of solutes other than NaCl is just as important as that from NaCl. Therefore, at this point in the tubule, osmolality is divided into that due to urea and that due to total **nonurea solutes** (about 50 mOsm).

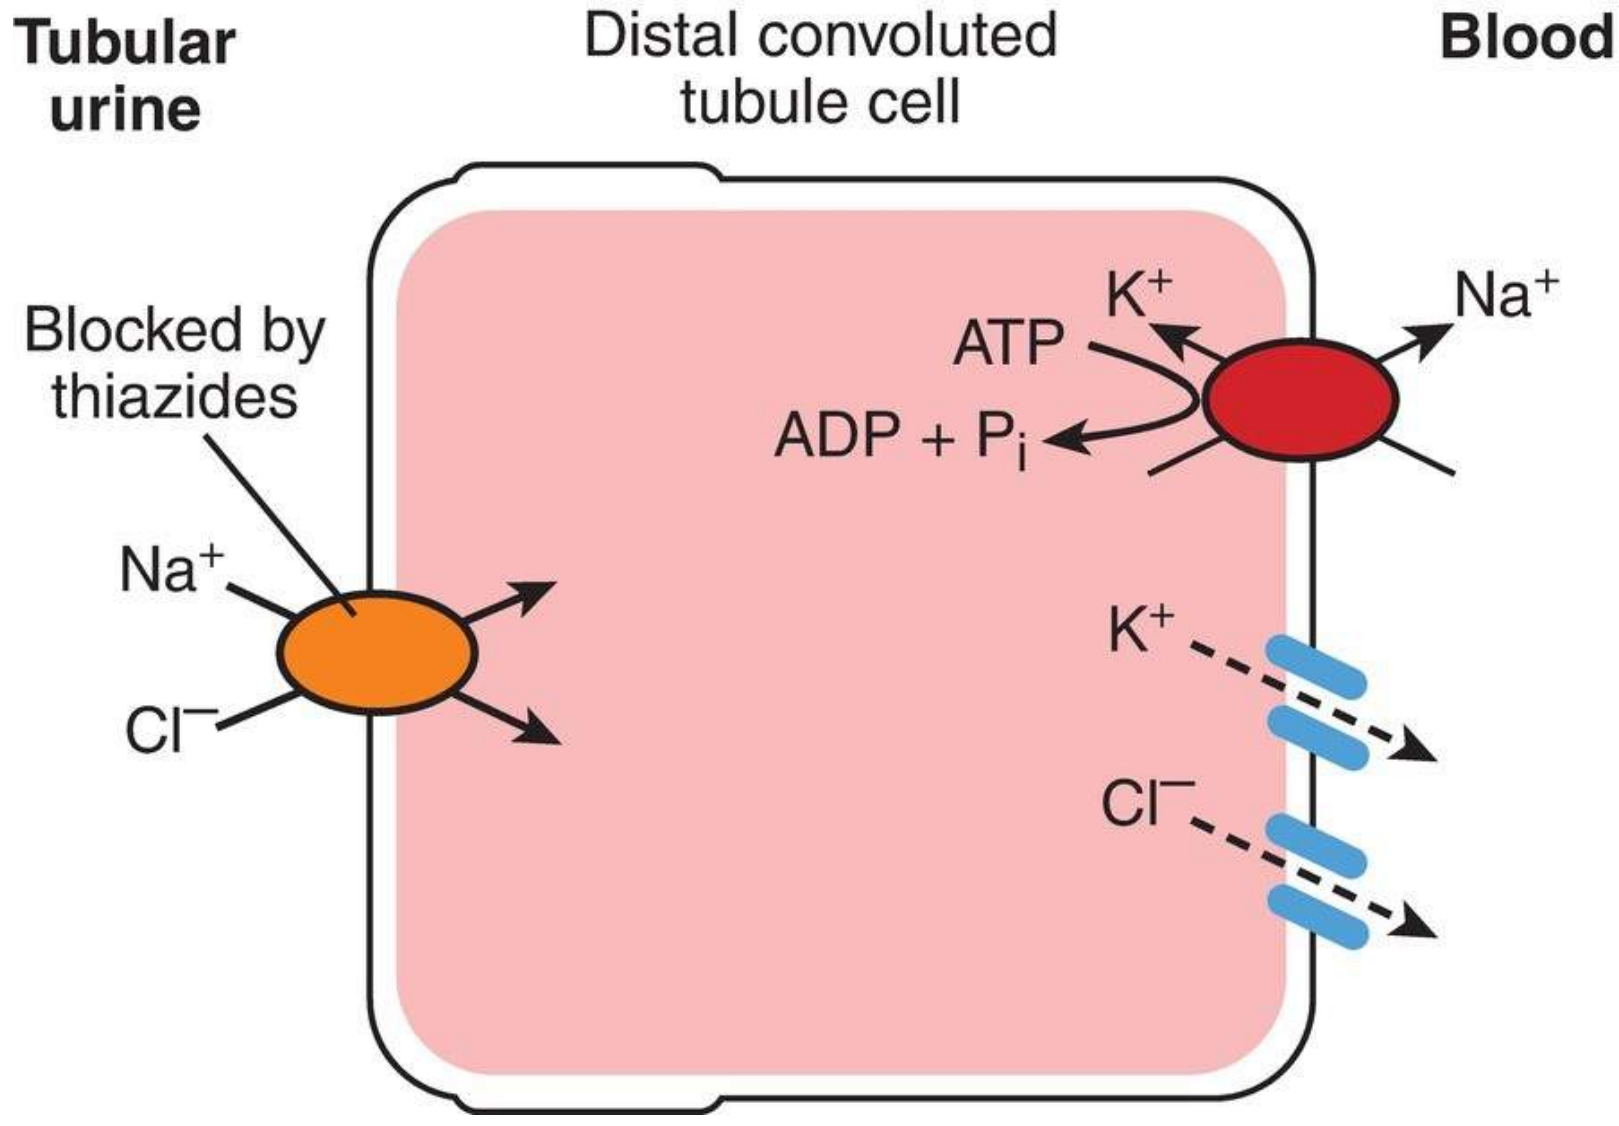

Figure 22.12 Cell model for ion transport in the distal convoluted tubule. ADP, transport of sodium is critically dependent on uptake from the lumen by the Na–Cl cotransporter in the apical membrane. This transporter is inhibited by thiazide diuretics. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Aldosterone stimulates Na^+ reabsorption in the collecting duct.

The collecting ducts are at the end of the nephron system, and what happens there determines the final excretion of Na^+, K^+, H^+, and water. Na^+ entry into the collecting duct cell is by diffusion through a Na^+ channel in collecting duct principal cells (Fig. 22.13). This channel has been cloned and sequenced and is known as **ENaC**, for **epithelial sodium (Na) channel**. The entry of Na^+ through this channel is rate-limiting for overall Na^+ reabsorption of the cells. The channel can be inhibited by amiloride and similar diuretics, which are known as potassium-sparing diuretics because they do not cause the potassium loss seen with other diuretic classes. Principal cell sodium reabsorption is quite variable due to the load dependency effect and creates a variable lumen-negative transepithelial potential across the tubule, which facilitates secretion of K^+ and H^+ by the collecting duct (see next section for details).

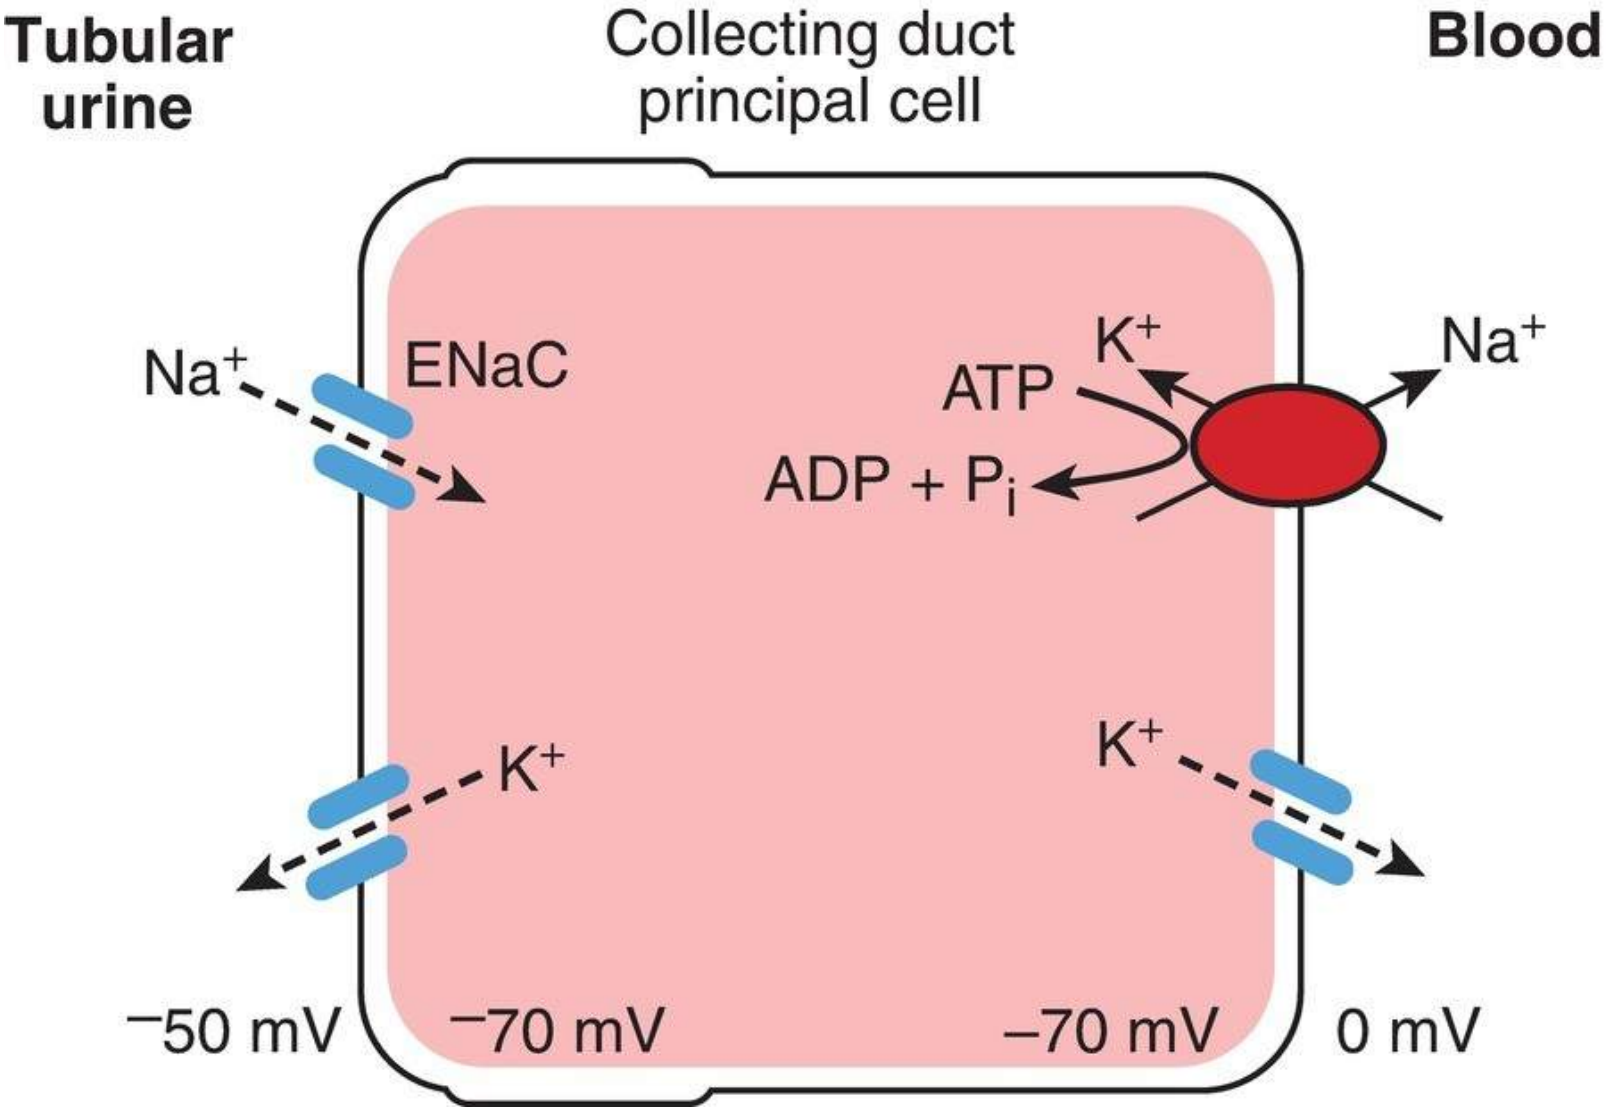

Figure 22.13 Model for Na^+ and K^+ transport by a collecting duct principal cell. Transport of sodium is critically dependent on uptake from the lumen by the ENaCl channel, which is inhibited by amiloride-type potassium-sparing diuretics. Sodium transport here is stimulated by the hormone aldosterone and linked to secretion of K^+ and H^+ by the collecting duct. Stimulation of sodium transport creates a negative transepithelial electrical potential. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Ionic transport in the collecting ducts is finely tuned by hormones. Specifically, aldosterone increases Na^+ reabsorption as well as K^+ and H^+ secretion with the secretory effects primarily occurring in the connecting ducts and cortical region of the collecting ducts. Another hormone, arginine vasopressin, also called antidiuretic hormone (ADH) increases water permeability in the collecting ducts. Intercalated cells are scattered among collecting duct principal cells; they are important in acid–base transport (see Chapter 24). A H^+/K^+-ATPase is present in the luminal cell membrane of α-intercalated cells and contributes to renal K^+ conservation when dietary intake of K^+ is deficient.

TUBULE SECRETION

Tubular secretion moves substance from the peritubular capillaries into the tubule lumen. Similar to glomerular filtration, tubular secretion establishes a pathway from the blood into the tubule. The most important constituents secreted are H^+, K^+, and Cl^-. For the most part, the amount excreted in the urine depends in large measure on the magnitude of tubular transport. Transport of various solutes and water differs in the various nephron segments. Here, we describe transport along the nephron and collecting duct system, starting with the proximal convoluted tubule.

Proximal tubule secretion eliminates many toxins and drugs from the blood.

Recall the proximal convoluted tubule is the first part of the renal tubule and comes right after the Bowman capsule. The proximal convoluted tubule makes up the first 60% of the length of the proximal tubule. Because the proximal straight tubule is inaccessible to study *in vivo*, most quantitative information about function in the living animal is confined to the convoluted portion. Studies on isolated tubules *in vitro* indicate that the two segments of the proximal tubule are functionally similar.

The proximal tubule, both convoluted and straight portions, secretes a large variety of organic anions and organic cations. Many of these substances are endogenous compounds, drugs, or toxins. The organic anions are mainly carboxylates and sulfonates (carboxylic and sulfonic acids in their protonated forms). A negative charge on the molecule appears to be important for secretion of these compounds. Examples of organic anions actively secreted in the proximal tubule include penicillin and PAH. Organic anion transport becomes saturated at high plasma organic anion concentrations (Fig. 22.14), and the organic anions compete with each other for secretion.

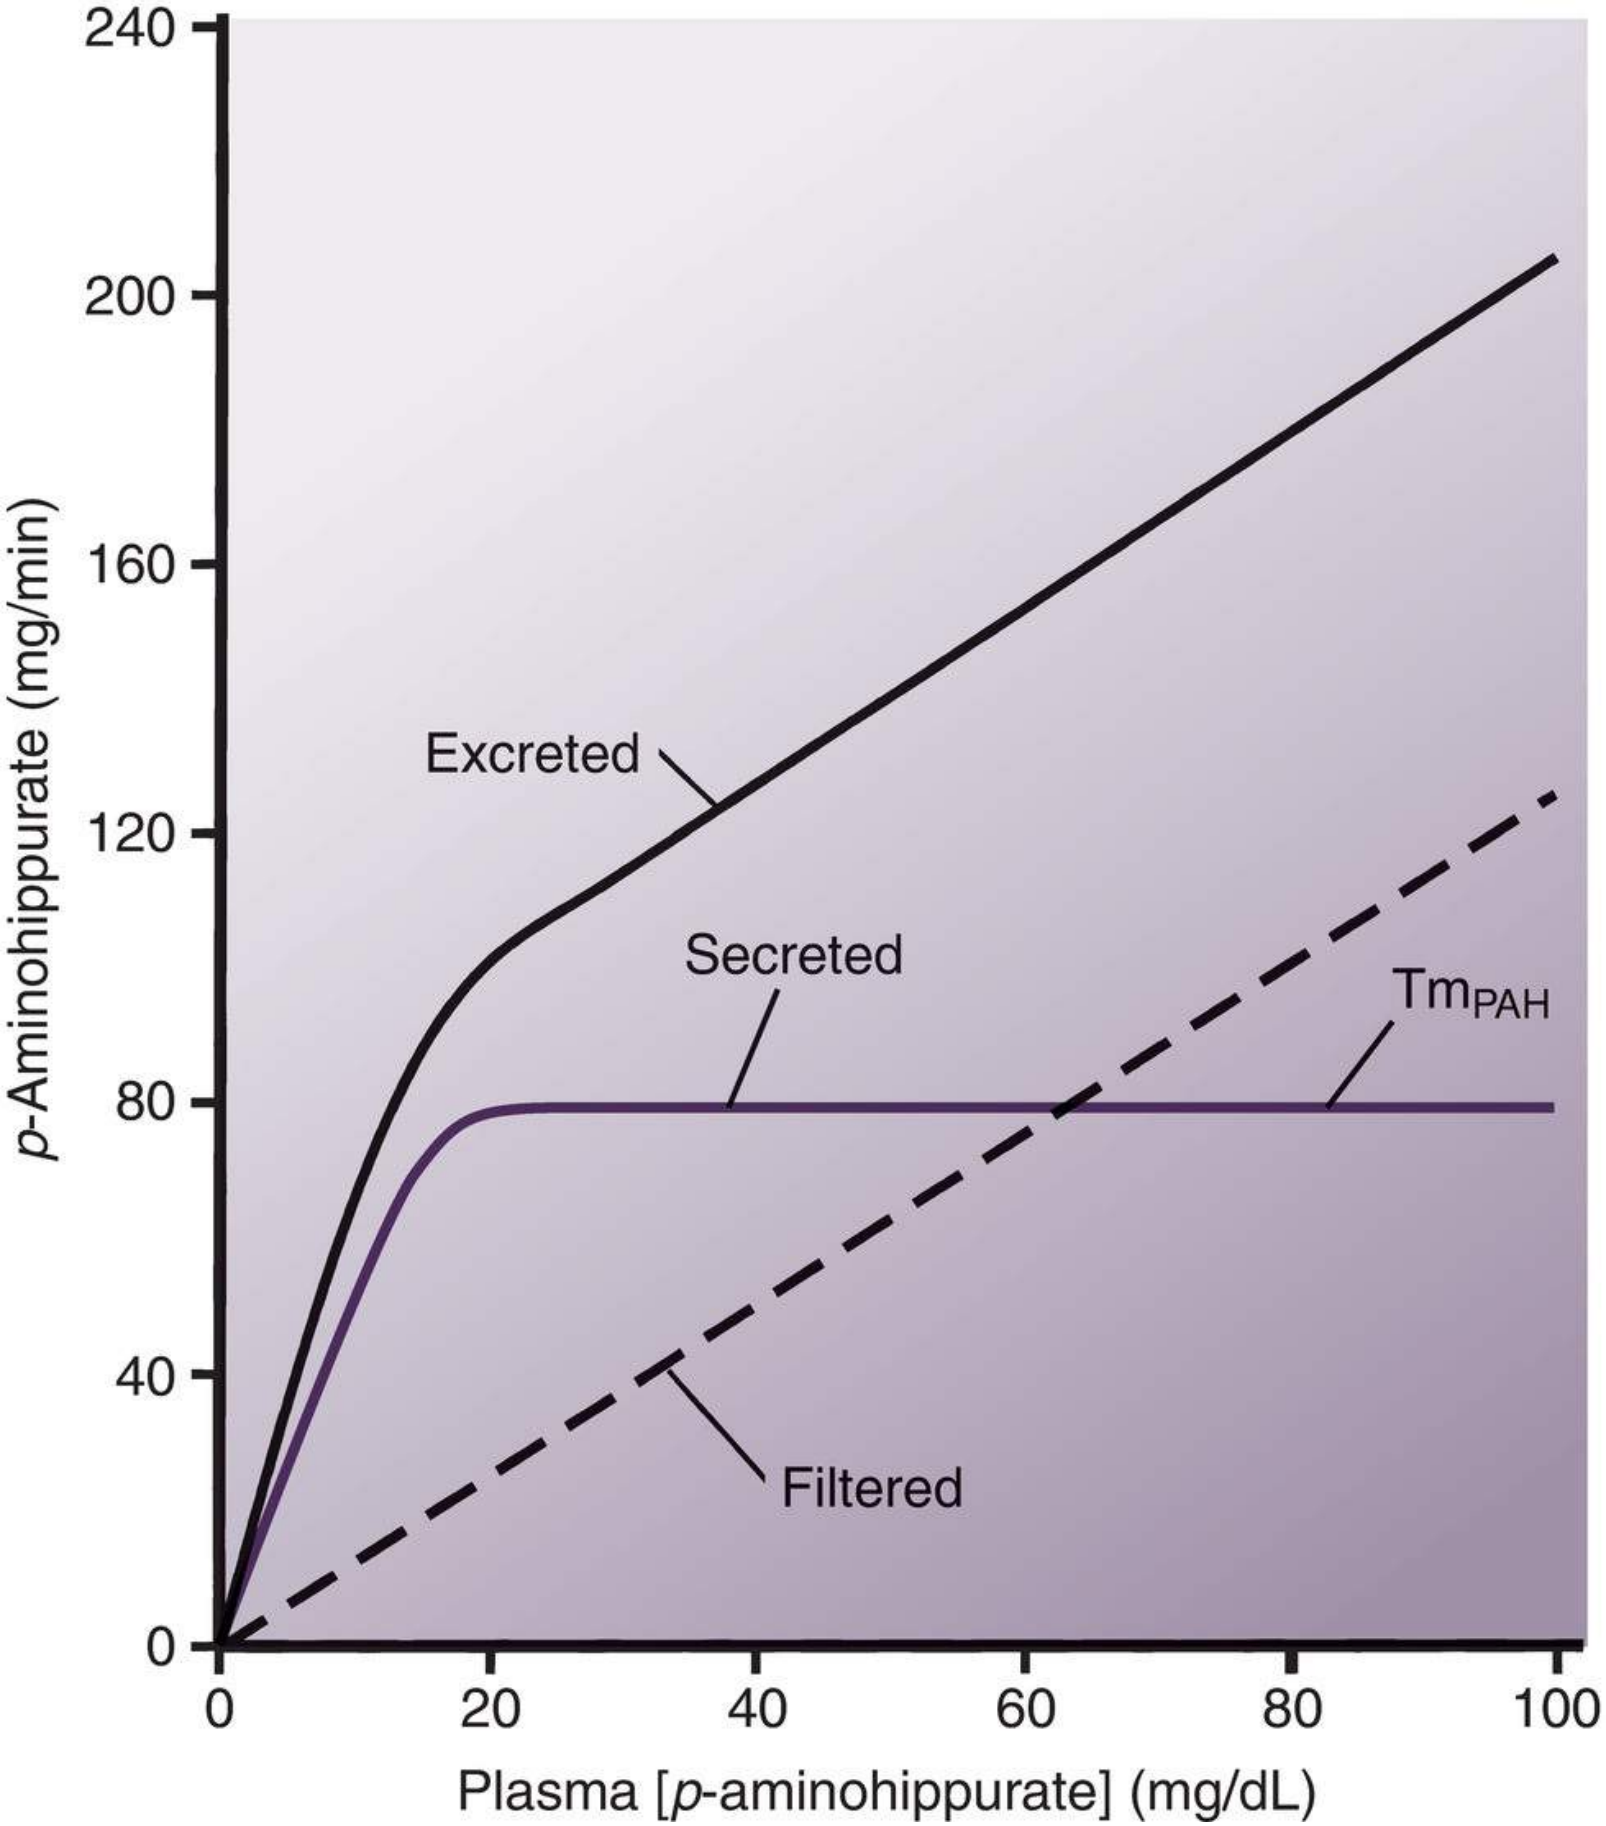

Figure 22.14 Rates of excretion, filtration, and secretion of *p*-aminohippurate (PAH) as a function of plasma PAH. More PAH is excreted than is filtered; the difference represents secreted PAH. Tm_{PAH}, tubular transport maximum for PAH.

Figure 22.15 shows a cell model for active secretion. Proximal tubule cells actively take up PAH from the blood side by exchange for cell α-ketoglutarate. This exchange is mediated by an organic anion transporter (OAT1). The cells accumulate α-ketoglutarate from metabolism and because of a cell membrane Na^+-dependent dicarboxylate transporters. PAH accumulates in the cells at a high concentration and then moves downhill into the tubular urine in an electrically neutral fashion, by exchanging for an inorganic anion (e.g., Cl^-) or an organic anion via another OAT. Organic anions may also be actively pumped into the tubular urine via a multidrug resistance–associated protein, which is an ATPase.

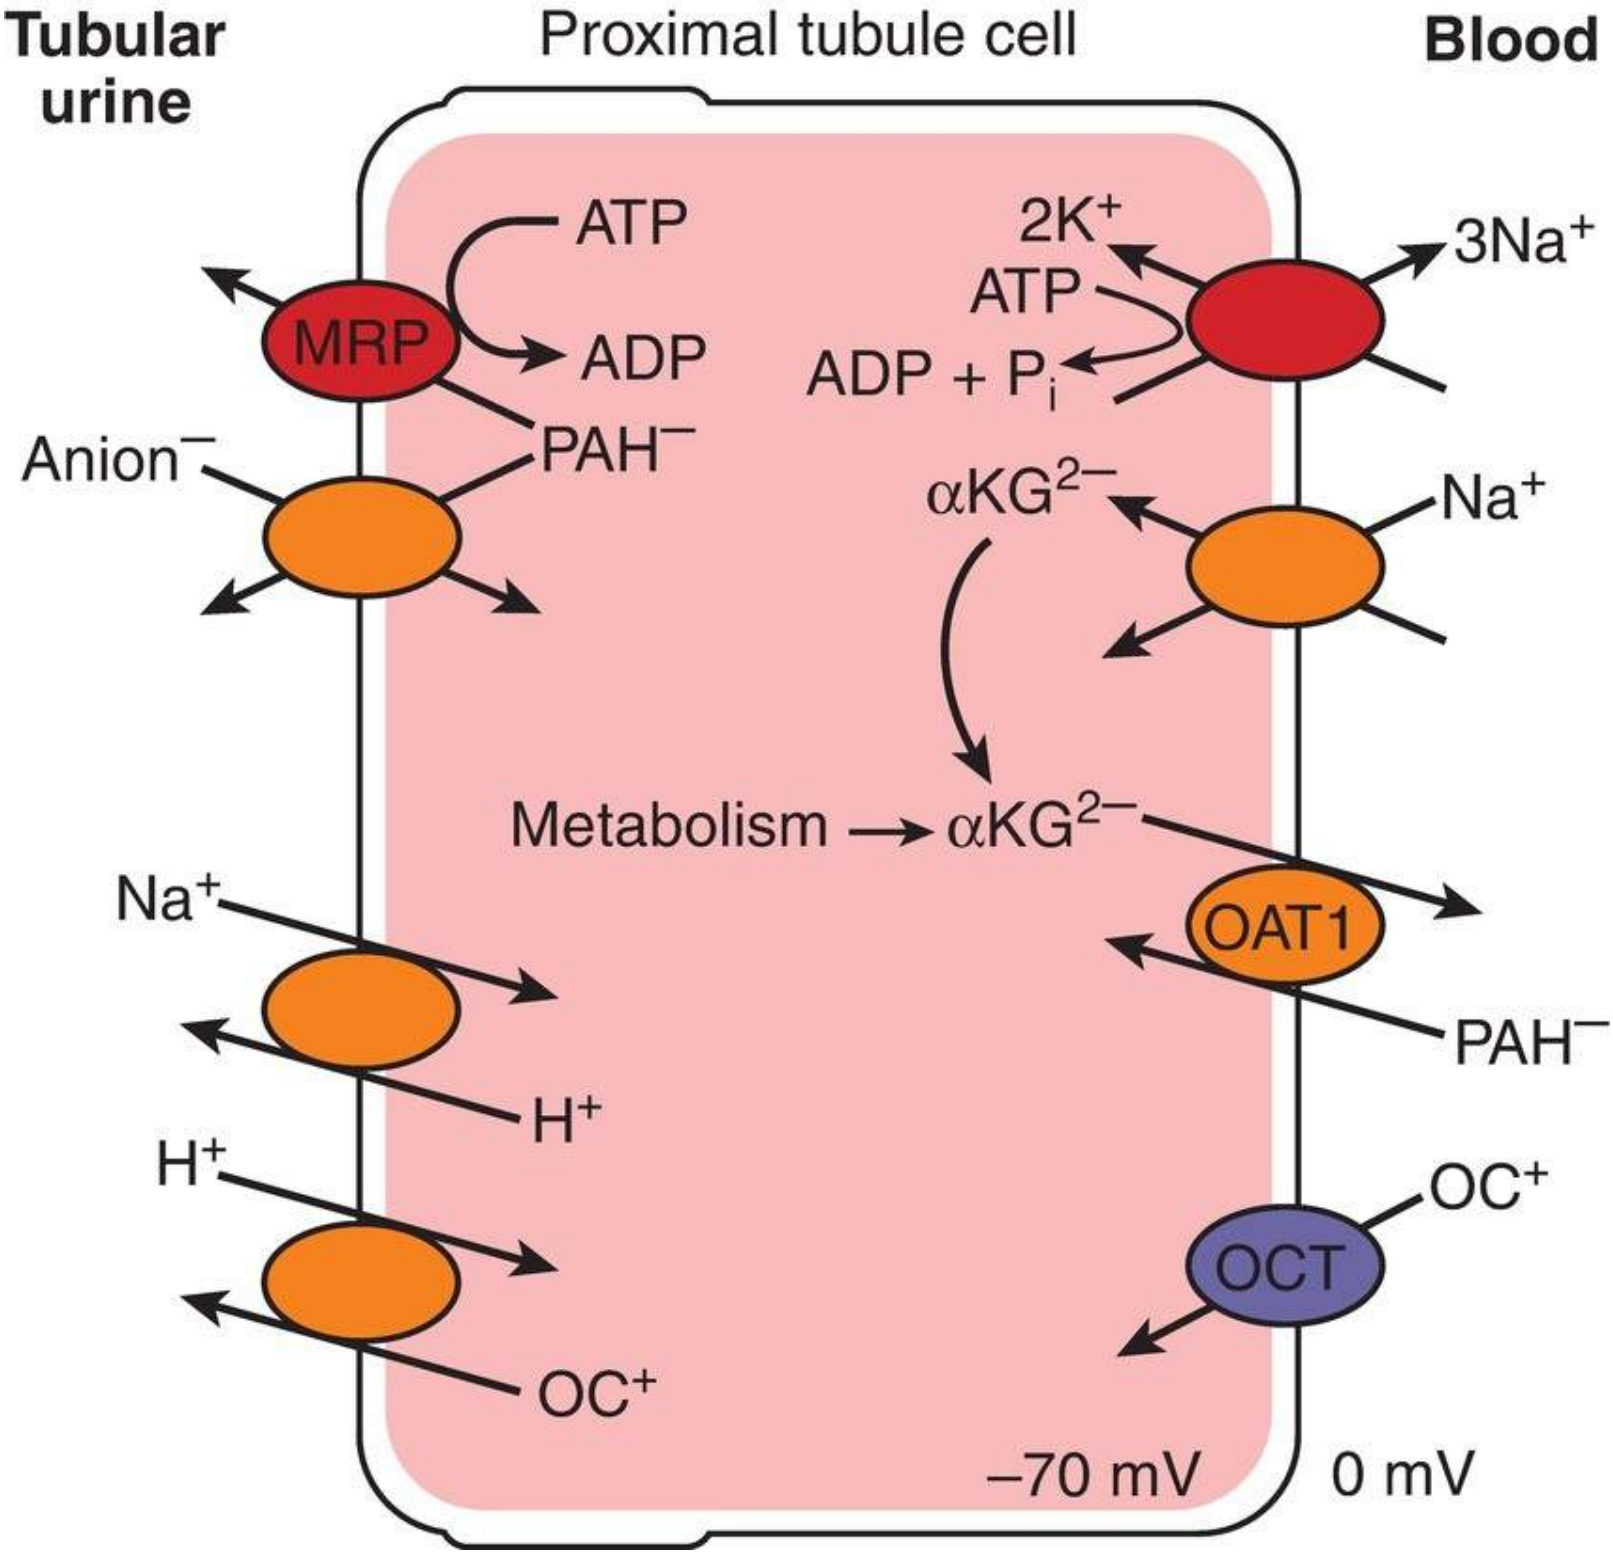

Figure 22.15 Cell model for the secretion of organic anions (*p*-aminohippurate [PAH]) and organic

cations in the proximal tubule. *Upward slanting arrows* indicate transport against an electrochemical gradient (energetically uphill transport) and *downward slanting arrows* indicate downhill transport. PAH accumulation in the cell is mediated by a basolateral membrane organic anion transporter (OAT) that exchanges PAH for α-ketoglutarate (α-KG^{2-}). The α-KG^{2-} level in the cell is higher than in the blood because of metabolic production and Na^+-dependent uptake of α-KG^{2-}. PAH exits the cell passively via a luminal membrane PAH/anion exchanger or can be actively pumped into the lumen by a multidrug resistance–associated protein (MRP) that consumes adenosine triphosphate (ATP). Organic cations (OC^+) enter the cell down the electrical gradient, a process mediated by a basolateral membrane organic cation transporter (OCT), and are transported uphill into the lumen by an organic cation/H^+ exchanger. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

The organic cations are mainly amine and ammonium compounds and are secreted by other transporters. Entry into the cell across the basolateral membrane is favored by the inside negative membrane potential and occurs via facilitated diffusion, mediated by an organic cation transporter. The exit of organic cations across the luminal membrane is accomplished by an organic cation/H^+ antiporter (exchanger) and is driven by the lumen-to-cell H^+ concentration gradient established by Na^+/H^+ exchange. The transporters for organic anions and organic cations show broad substrate specificity and accomplish the secretion of a large variety of chemically diverse compounds.

In addition to being actively secreted, some organic compounds passively diffuse across the tubular epithelium (Fig. 22.16). Organic anions can accept H^+ and organic cations can release H^+, so their charge is influenced by pH. The nonionized (uncharged) form, if it is lipid-soluble, can diffuse through the lipid bilayer of cell membranes down concentration gradients. The ionized (charged) form passively penetrates cell membranes with difficulty.

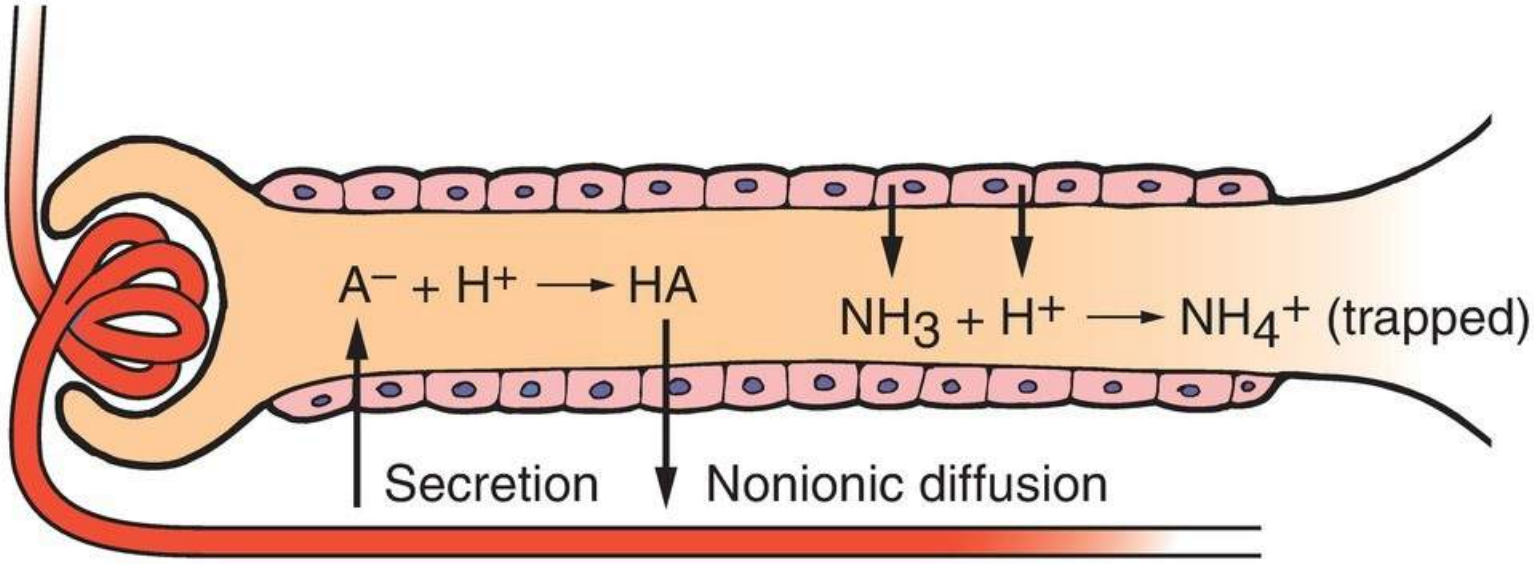

Figure 22.16 Nonionic diffusion of lipid-soluble weak organic acids and bases. Small nonionized forms of organic acids and bases can cross the tubular epithelium by simple diffusion whereas their ionized forms cannot. Acidification of the urine converts the organic anion A^- to the undissociated (nonionized) acid HA, which is reabsorbed by diffusion. NH_3, a lipid-soluble base, diffuses into the tubular urine,

where it is converted to NH_4^+, thereby trapping the ammonia in the acidic urine.

Consider, for example, the carboxylic acid probenecid (pK_a = 3.4). This compound is filtered by the glomeruli and secreted by the proximal tubule. When H^+ is secreted into the tubular urine (see Chapter 24), the anionic form (A^-) is converted to the nonionized acid (HA, in Fig. 22.15). The concentration of nonionized acid is also increased because of water reabsorption. A concentration gradient for passive reabsorption across the tubule wall is created, and appreciable quantities of probenecid are passively reabsorbed. This occurs in most parts of the nephron but particularly in those where pH gradients are largest and where water reabsorption has resulted in the greatest concentration (i.e., the collecting ducts; see next section). The excretion of probenecid is enhanced by making the urine more alkaline (e.g., by administering $NaHCO_3$) and by increasing urine flow rate (e.g., by drinking water). In the case of a lipid-soluble base, such as ammonia (NH_3), excretion is favored by making the urine more acidic and enhancing the urine flow.

Finally, a few organic anions and cations are also actively reabsorbed. For example, uric acid is both secreted and reabsorbed in the proximal tubule. Normally, the amount of uric acid excreted is equal to about 10% of the filtered uric acid, so reabsorption predominates. In **gout**, plasma levels of uric acid are increased. One treatment for gout is to promote urinary excretion of uric acid by administering drugs that inhibit its tubular reabsorption.

Cortical collecting duct is the primary site for potassium secretion.

Under normal circumstances, the cortical collecting ducts secrete most of the excreted K^+. With great K^+ excess (e.g., a high-K^+ diet), the cortical collecting ducts may secrete so much K^+ that more K^+ is excreted than was filtered. With severe K^+ depletion, the cortical collecting ducts reabsorb K^+.

K^+ secretion appears to be a function primarily of the collecting duct principal cell (see Fig. 22.13). K^+ secretion involves active uptake by a Na^+/K^+-ATPase in the basolateral cell membrane, followed by diffusion of K^+ through luminal membrane K^+ channels. Outward diffusion of K^+ from the cell is favored by concentration gradients and opposed by electrical gradients. However, the net electrochemical gradient for potassium across the luminal membrane favors its transport into the tubular lumen (i.e., its secretion). This is because the combined effects of epithelial tight junctions and the ENaC channel tend to separate sodium from tubular fluid anions rendering the tubular lumen negatively charged relative to the peritubular fluid. This creates a **negative transepithelial potential** across the tubule epithelium of about −50 mV. This potential favors secretion of K^+ and H^+ and is highly dependent on sodium reabsorption by the principal cells, being as low as −5 mV when sodium reabsorption is impaired to −70 mV when it is stimulated.

The magnitude of K^+ secretion is affected by several factors (see Fig. 22.13):

- The lumen-negative transepithelial electrical potential promotes K^+ and H^+ secretion.
- The activity of the basolateral membrane Na^+/K^+-ATPase is a key factor affecting secretion: the greater the pump activity, the higher the rate of secretion.
- A high plasma K^+ concentration promotes K^+ secretion.
- Increased amounts of Na^+ in the collecting duct lumen (e.g., as a result of inhibition of Na^+ reabsorption by a loop diuretic drug) result in increased entry of Na^+ into principal cells, increased activity of the Na^+/K^+-ATPase, a more negative transepithelial potential, and increased K^+ secretion.
- An increase in permeability of the luminal cell membrane to K^+ favors secretion. This is another effect of aldosterone, which plays a key role in K^+ homeostasis (see Chapter 23).
- A high fluid flow rate through the collecting duct lumen maintains the cell-to-lumen concentration gradient, which favors K^+ secretion.

URINARY CONCENTRATION MECHANISMS

The ability of the human kidney to concentrate and produce hyperosmotic urine is a major determinant in survival. This ability is the effect, or a reflection of, the kidney's ability to maximize reabsorption or "reclamation" of water and defend against dehydration. The human kidneys can reabsorb water to the extent of being able to form a maximal urine concentration of 1,200 to 1,400 mOsm/L, which is up to five times that of plasma (~290 mOsm/L). In this section, we describe the mechanisms by which the hyperosmolarity of the urine is accomplished.

The kidney's ability to concentrate urine osmotically is an important adaptation for survival.

The kidneys have the task of concentrating the urine to save water and at the same time get rid of excess solutes (e.g., urea and various salts), which requires the excretion of water. Suppose, for example, the kidneys were only capable of excreting urine that is isosmotic to plasma (300 mOsm/L), then we would need to excrete remaining solutes in 2.0 L H_2O/d. If we can excrete the solutes in urine that is four times more concentrated than plasma (1,200 mOsm/L), then only 0.5 L H_2O/d would be required. By excreting solutes in osmotically concentrated urine, the kidneys in effect save 1.5 L H_2O (2.0 to 0.5 L H_2O) for the body. The ability to concentrate the urine decreases the amount of water we are obliged to find and drink each day.

Urine-concentrating ability can be looked at in two ways. We can determine what the urine osmolality (or specific gravity) is compared to the plasma, or the U_{osm}/P_{osm} ratio. In people, a maximal value is about 4 to 5, a value that might be observed in a dehydrated, otherwise healthy, individual. Or we can calculate how much solute-free water per unit time the kidneys save or eliminate in the urine; this quantity is called the *free water clearance* (or *free water production*), abbreviated C_{H_2O}. C_{H_2O} is calculated from the following equation:

$$C_{H_2O} = \dot{V} - C_{osm} \quad (3)$$

where $\dot{V}$ is the urine flow rate and C_{osm} (the osmolal clearance) is defined as $U_{osm} \times \dot{V}/P_{osm}$. If we factor out $\dot{V}$ in equation 3, we get:

$$C_{H_2O} = \dot{V}\left(1 - U_{osm}/P_{osm}\right) \quad (4)$$

From Equation 12, we see that if the U_{osm}/P_{osm} ratio is >1 (osmotically concentrated urine), C_{H_2O} is negative; if U_{osm}/P_{osm} = 1 (urine isosmotic to plasma), then C_{H_2O} is zero; and if U_{osm}/P_{osm} is <1 (osmotically dilute urine), then C_{H_2O} is positive.

Arginine vasopressin is one mechanism that produces osmotically concentrated urine.

Changes in urine osmolality are normally brought about largely by changes in plasma levels of **arginine vasopressin** (**AVP**), also known as **antidiuretic hormone**, or **ADH** (see Chapter 31). In the absence of AVP, the kidney collecting ducts are relatively water impermeable. Continual active reabsorption of NaCl across a water-impermeable epithelium leads to further reduction of the already hypotonic tubular fluid and results in production of osmotically dilute urine (~70 mOsm) with a volume of almost 15% of the original filtered water at the glomerulus. In the presence of AVP, collecting duct water permeability is increased. Because the medullary interstitial fluid is hyperosmotic, water reabsorption in the medullary collecting ducts can lead to the production of osmotically concentrated urine (~1,200 mOsm in a volume of ~0.5% of the original filtered water).

A model for the action of AVP on cells of the collecting duct is shown in Figure 22.17. When plasma osmolality is increased, plasma AVP levels increase. The hormone binds to a specific vasopressin (V_2) receptor in the basolateral cell membrane of principal cells. By way of a guanine nucleotide stimulatory protein (G_s), the membrane-bound enzyme adenylyl cyclase is activated. This enzyme catalyzes the formation of cyclic AMP (cAMP) from ATP. cAMP then activates a cAMP-dependent protein kinase (protein kinase A, or *PKA*) that phosphorylates other proteins. This leads to the insertion, by exocytosis, of intracellular vesicles that contain water channels (aquaporin-2) into the luminal cell membrane. The resulting increase in number of luminal membrane water channels leads to an increase in water permeability. Water leaves the lumen and then exits the cells via aquaporin-3 and aquaporin-4 in the basolateral cell membrane. The solutes in the collecting duct lumen become concentrated as water leaves. This response to AVP occurs in minutes. AVP also has delayed effects on collecting ducts; it increases the transcription of aquaporin-2 genes and increases the total number of aquaporin-2 molecules per cell.

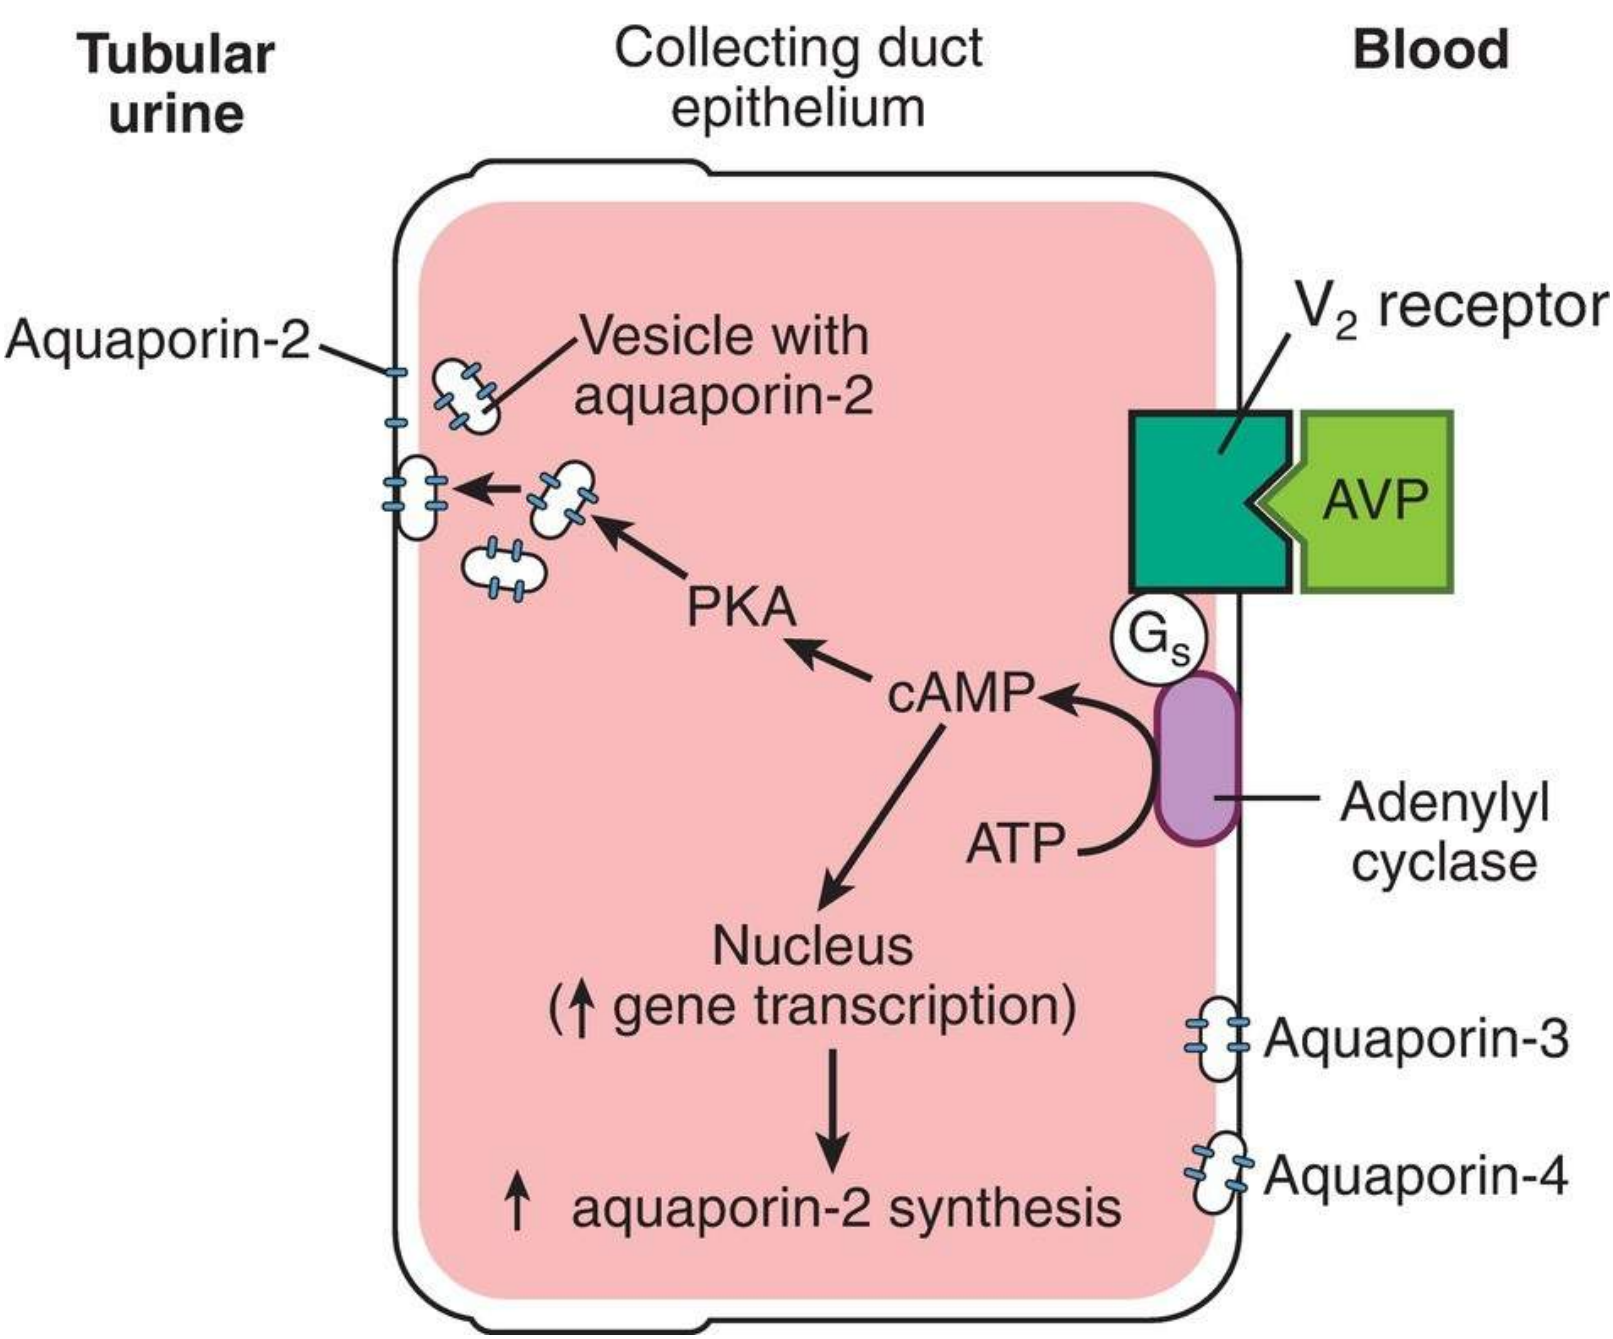

Figure 22.17 Model for the action of arginine vasopressin (AVP) on the epithelium of the collecting duct. The second messenger for AVP is cyclic adenosine monophosphate (cAMP). AVP has both prompt effects on luminal membrane water permeability (the movement of aquaporin-2–containing vesicles to the luminal cell membrane) and delayed effects (increased aquaporin-2 synthesis). ATP, adenosine triphosphate; G_s, guanine nucleotide stimulatory protein; PKA, protein kinase A; V_2, type 2 vasopressin receptor.

Countercurrent multiplication in the loops of Henle is the underlying mechanism for urine concentration.

The vertical osmotic gradient in the kidney medulla is created and maintained by the *countercurrent mechanism*. Two countercurrent processes occur in the kidney medulla—**countercurrent multiplication** and **countercurrent exchange**. The term *countercurrent* indicates a flow of fluid in opposite directions in adjacent structures (Fig. 22.18). The loops of Henle are *countercurrent multipliers*. Fluid flows toward the tip of the papilla along the descending limb of the loop and toward the cortex along the ascending limb of the loop. The loops of Henle create the osmotic gradient in the medulla (see below). The vasa recta are *countercurrent exchangers*. Blood flows in opposite directions along juxtaposed descending (arterial) and ascending (venous) vasa recta, and solutes and water are exchanged passively between these capillary blood vessels. The vasa recta help maintain the gradient in the medulla. The collecting ducts act as *osmotic equilibrating devices*; depending on the plasma level of AVP, the collecting duct urine is allowed to equilibrate more or less with the hyperosmotic medullary interstitial fluid.

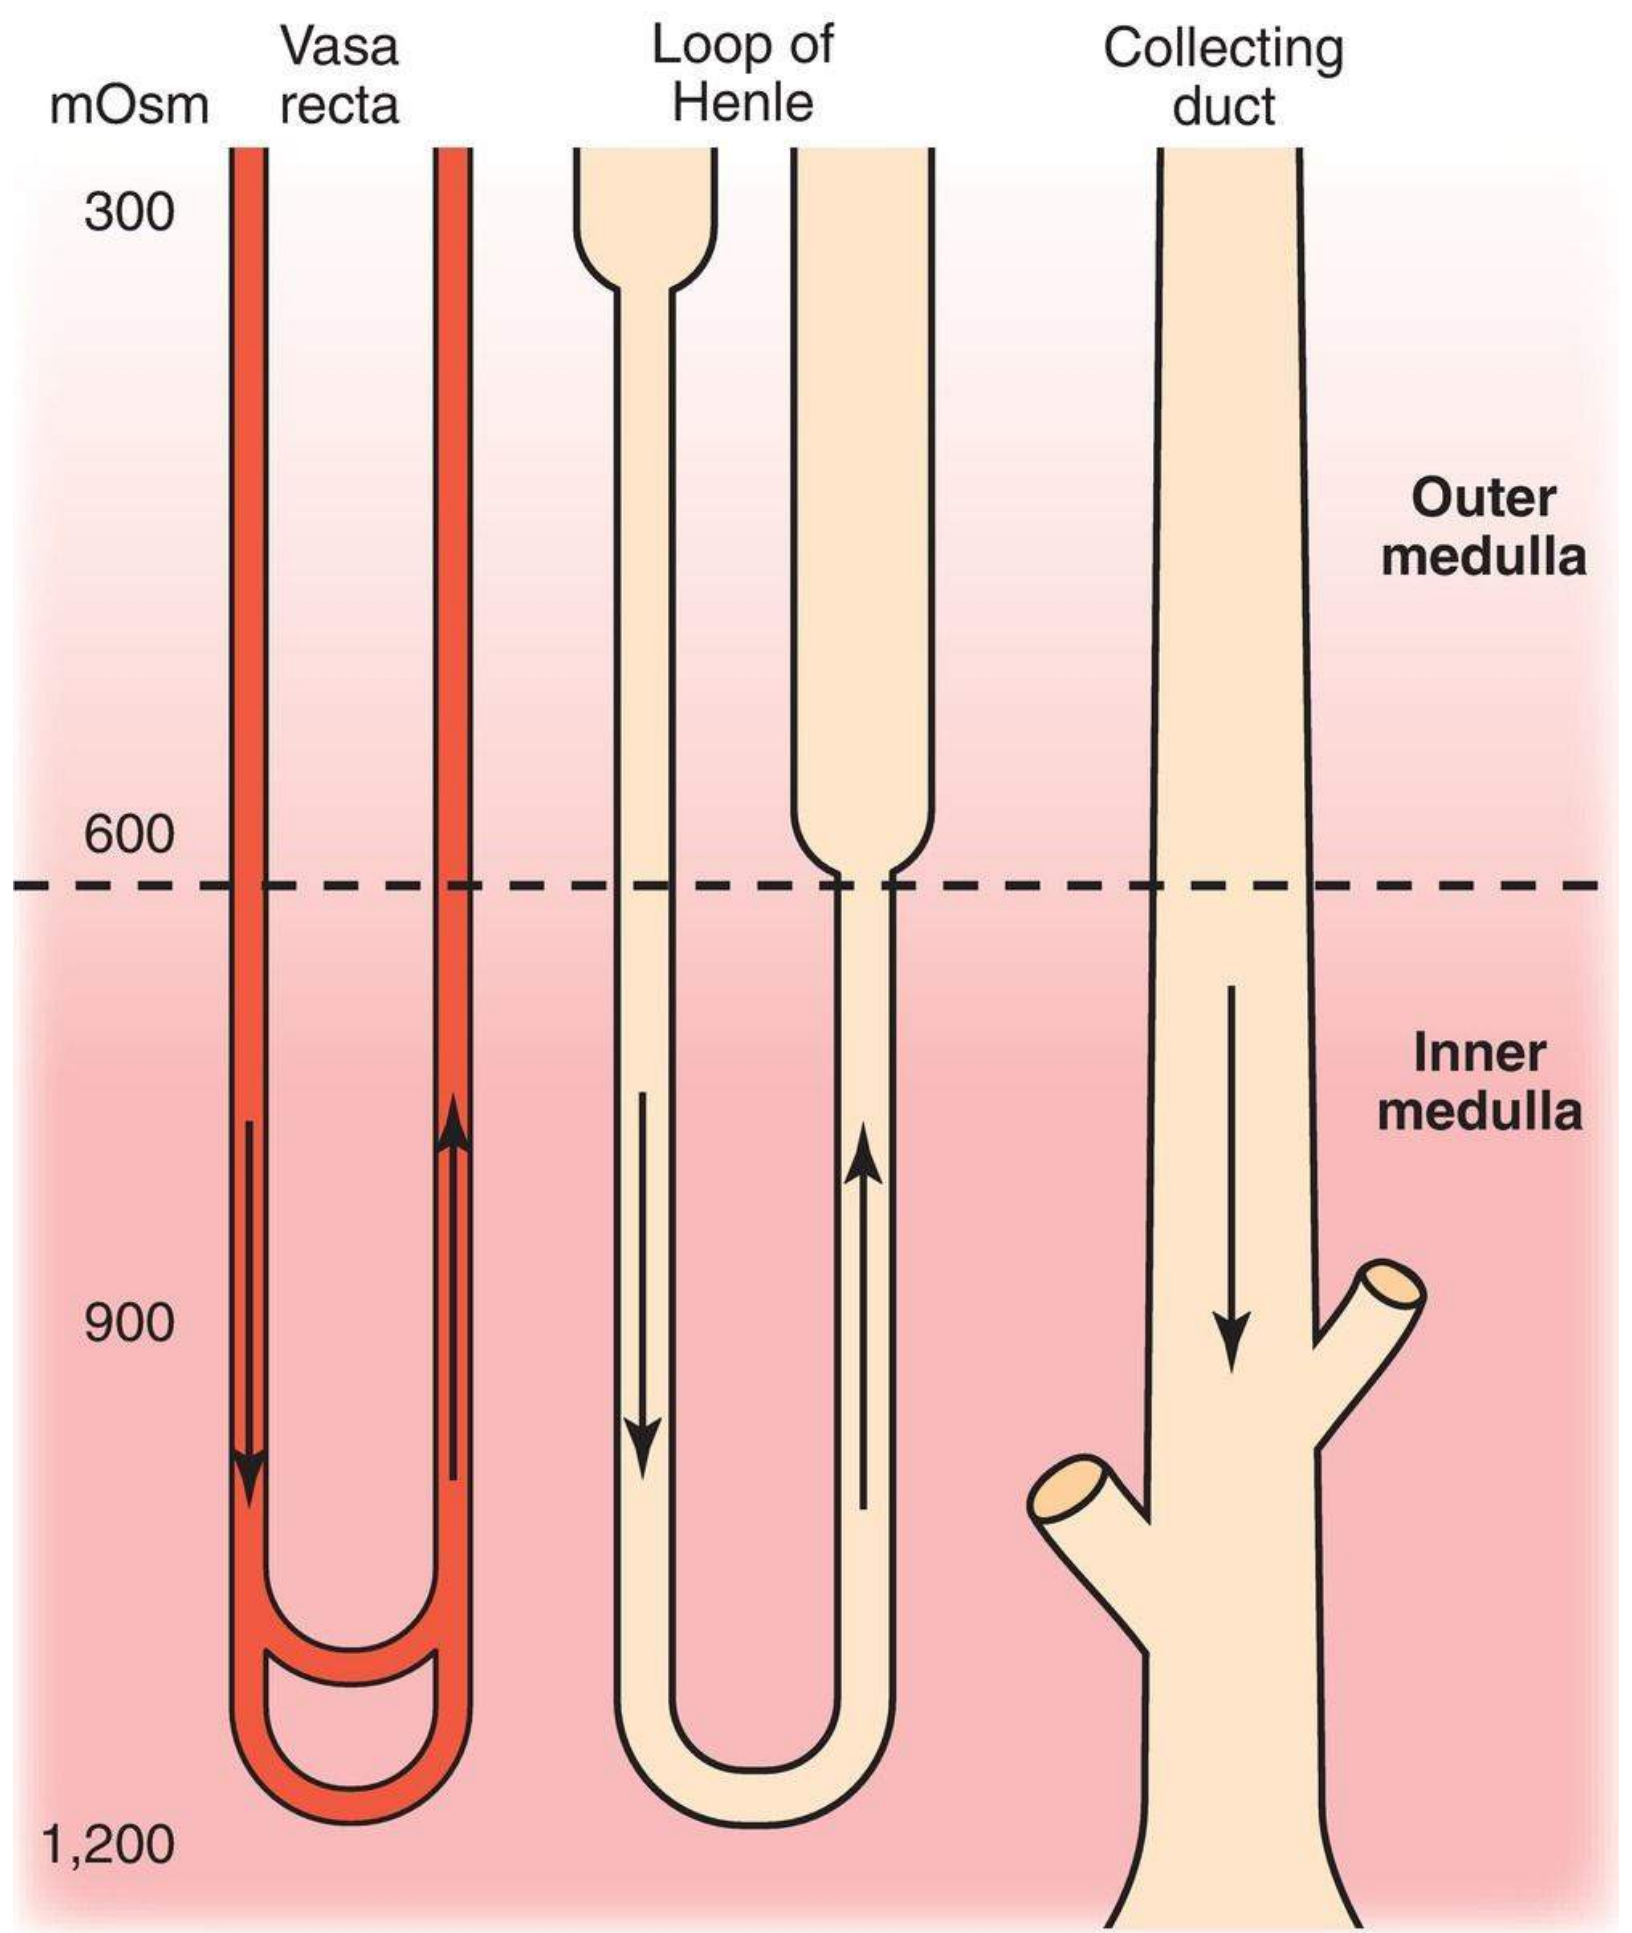

Figure 22.18 Elements of the urinary concentrating mechanism. The vasa recta are countercurrent exchangers, the loops of Henle are countercurrent multipliers, and the collecting ducts are osmotic equilibrating devices. Most loops of Henle and vasa recta do not reach the tip of the papilla but turn at

higher levels in the outer and inner medulla. There are no thick ascending limbs in the inner medulla.

Countercurrent multiplication is the process whereby a modest gradient established at any level of the loop of Henle is increased (multiplied) into a much larger gradient along the axis of the loop. A simplified model for countercurrent multiplication in the loop of Henle from a cortical nephron shows how this works (Fig. 22.19). Initially, the loop is filled with fluid isosmotic to plasma (~300 mOsm for this example; Fig. 22.19A). Next, we assume that at any level of the loop, the thick ascending limb of the loop can establish an osmotic gradient of 200 mOsm between the tubular and peritubular fluid (Fig. 22.19B). This so-called single effect occurs by active transport of solute (salt) out of the water-impermeable ascending limb and deposition of the salt in the tiny interstitial space. This osmotic gradient causes water to leave the water-permeable descending limb, which equilibrates osmotically with the interstitial space. Next, we add new fluid to the loop and push the fluid in the loop around the bend (Fig. 22.19C). We repeat the single effect (Fig. 22.19D) and continue the process (Fig. 22.19E–H). The final result (see Fig. 22.19H) is a much larger gradient (~400 mOsm/kg H_2O) along the axis of the loop. The interstitial space shares this axial gradient.

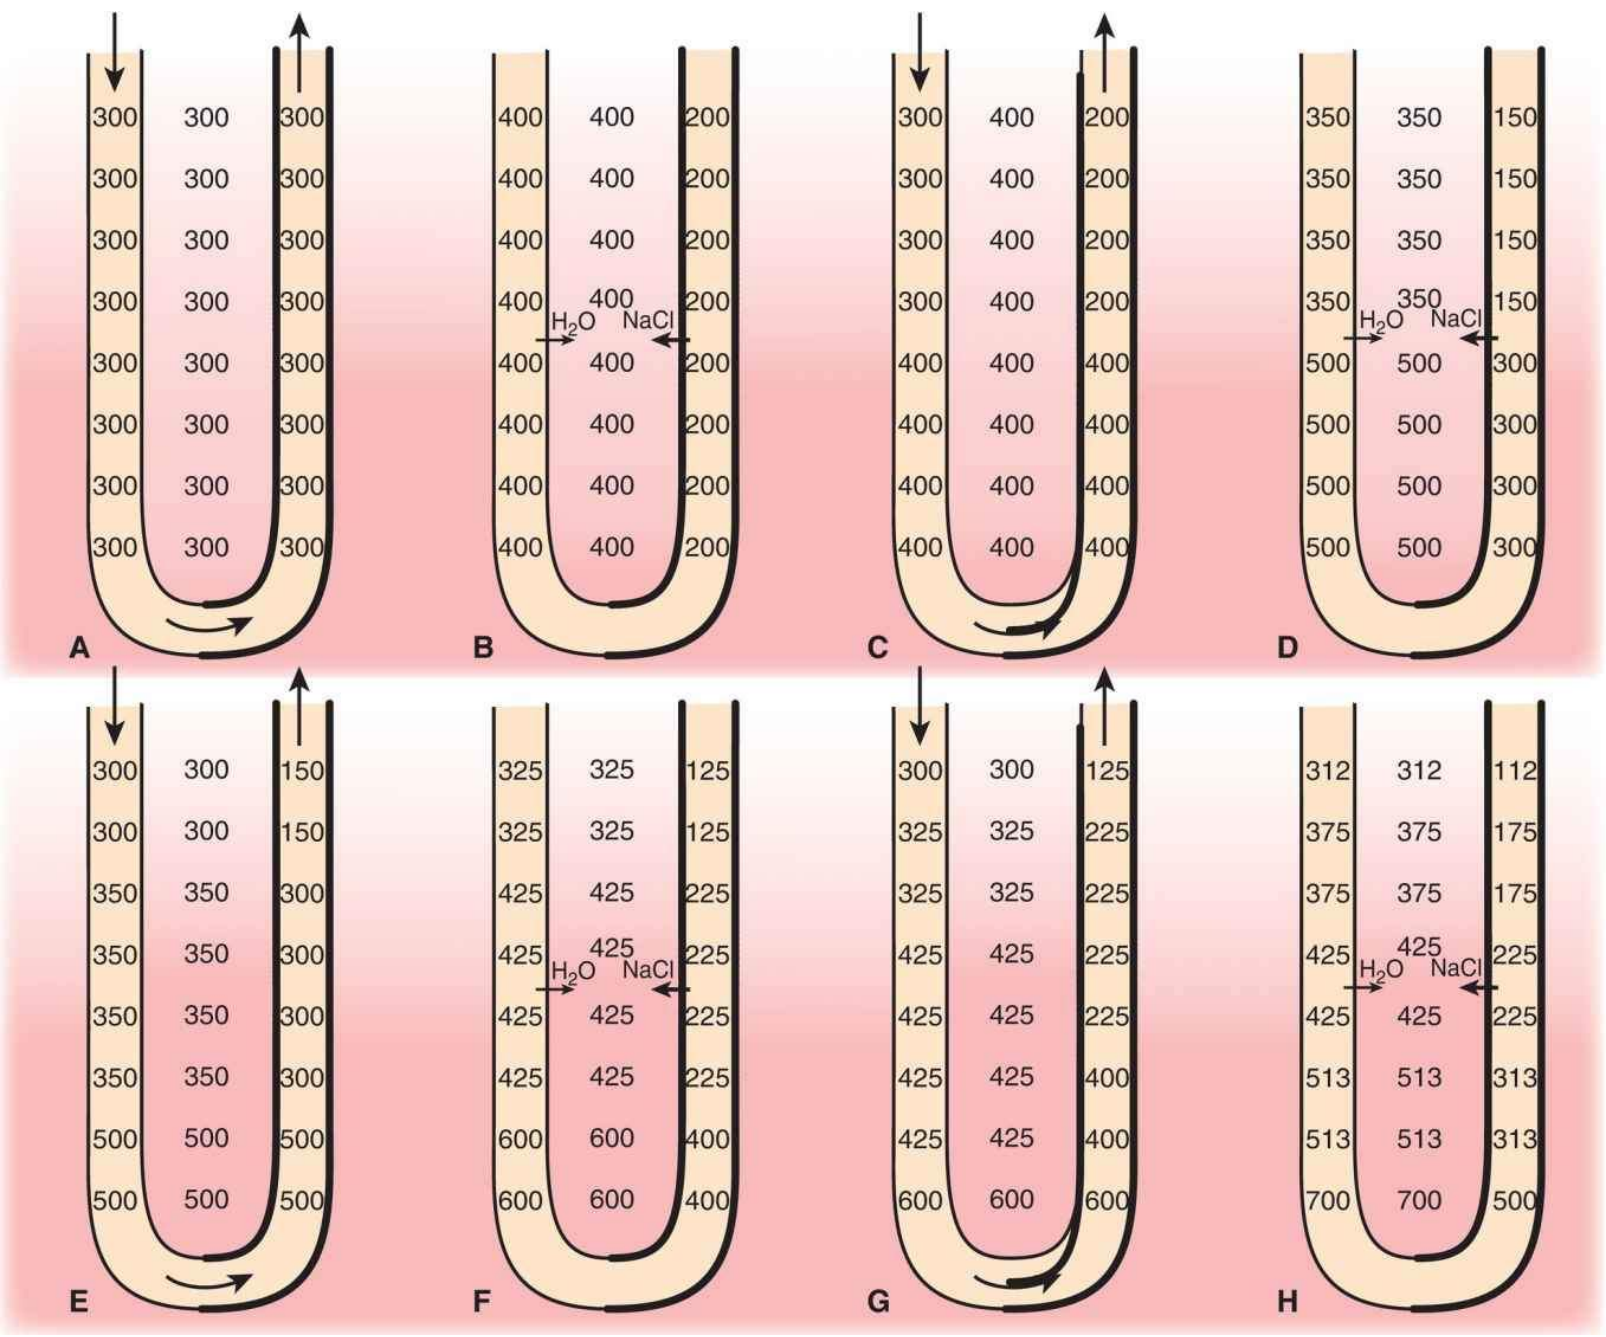

Figure 22.19 Model for countercurrent multiplication. The numbers represent osmolality (mOsm/kg H_2O) of tubule fluid and interstitium in a cortical nephron. The establishment of an osmotic gradient along the vertical axis of the loop (or with increasing depth in the medulla) is viewed as the resultant of two successive processes: (1) a shift of fluid within the loop (**A, C, E,** and **G**) and (2) development of an osmotic gradient of 200 mOsm/kg H_2O at any horizontal level of the loop, the so-called single effect (**B, D, F,** and **H**). The single effect involves active transport of solute (mostly NaCl) out of the ascending limb across a water-impermeable barrier (the latter is indicated by heavy outlining along the ascending limb of the loop of Henle) into a tiny interstitial space and osmotic withdrawal of water from the water-permeable descending limb. The single effect of 200 mOsm/kg H_2O is multiplied (magnified) into a larger (~400 mOsm/kg H_2O) gradient along the length of the loop by a stepwise shift of fluid, countercurrent flow, and repetition of the single effect. The interstitium of the medulla shares in the increased osmolality.

The countercurrent multiplication mechanism in juxtamedullary nephrons requires urea.

In the kidney, the highest osmolalities are reached at the bends of the longest loops of Henle belonging to juxtamedullary nephrons (i.e., deep within the inner medulla at the tips of the renal papillae). The countercurrent mechanism in these loops is slightly different than that just described for cortical nephrons. In juxtamedullary nephrons, sodium reabsorption in the thin ascending limb is passive, not active. Passive reabsorption of NaCl in the thin ascending limb occurs down concentration gradients between the tubular and peritubular fluid as the tubular fluid ascends through lower and lower peritubular NaCl concentrations. However, the very high tubular NaCl concentration at the start of the thin ascending limb gets that way by passive reabsorption of water from the thin descending limb, which in turn needs the vertical osmotic gradient in the medullary interstitium to draw water out of it in order to concentrate NaCl within the tubule. Thus, it would appear, paradoxically, that the countercurrent exchange mechanism in this portion of the juxtamedullary nephron, needed to set up the vertical osmotic gradient deep in the medulla, needs the vertical osmotic gradient in the medulla to start the exchange! This problem is solved by the addition of large quantities of urea into the deep medullary interstitium by the following mechanism. In the presence of ADH, water is reabsorbed by the collecting ducts, as described above. The collecting ducts above the level of the papillary medulla are impermeable to urea. Thus, water reabsorption above the papillary medulla concentrates urea within the duct. This level approaches 600 mM. ADH, however, increases the permeability of the papillary collecting duct to urea by stimulating facilitated transporters for urea there (UT-A1). Thus, initially, urea flows out of the duct at that location and into the papillary medullary interstitium, greatly increasing peritubular fluid osmolality there. It is this initial increase in osmolality that draw water out of the thin descending limb, concentrating NaCl there, which then powers the passive “reabsorption” of NaCl up the thin ascending limb. Thus, urea transport into the papillary medullary interstitium “kick starts” countercurrent exchange in juxtamedullary nephrons.

Countercurrent multiplication in all loops of Henle is ultimately dependent on energy derived from ATP, which powers active pumping of Na^+ by the Na^+/K^+-ATPase in the thick ascending limb. However, energy needed to power the single effect there is much less than that which would be needed to pump sodium directly against transtubular gradients seen at the tips of the Loop. Thus, the countercurrent exchanger builds very large osmotic concentrations deep in the kidney at a fraction of the energy that would otherwise be required by a direct active transtubular transport system there.

The extent to which countercurrent multiplication can establish a large axial gradient in a model of the kidney depends on several factors, including the magnitude of the single effect, the rate of fluid flow, and the length of the loop. The larger the single effect, the larger the axial gradient. If flow rate through the loop is too high, not enough time is allowed for establishing a significant single effect, and consequently, the axial gradient is reduced. Finally, if the loops are long, there is more opportunity for multiplication, and a larger axial gradient can be established.

Countercurrent exchange and the vasa recta maintain the vertical osmotic gradient in the renal medullary interstitium.

Countercurrent exchange is a common process in the vascular system. In many vascular beds, arterial and venous vessels lie close to each other, and exchanges of heat or materials can occur between these vessels. For example, because of the countercurrent exchange of heat between blood flowing toward and away from its feet, a penguin can stand on ice and yet maintain a warm body (core) temperature. Countercurrent exchange between descending and ascending vasa recta in the kidney reduces dissipation of the solute gradient in the medulla (see Fig. 22.18). The descending vasa recta tend to give up water to the more concentrated interstitial fluid. The ascending vasa recta, which come from more concentrated regions of the medulla, take up this water. In effect, then, much of the water in the blood short-circuits across the tops of the vasa recta and does not flow deep into the medulla, where it would tend to dilute the accumulated solute. The ascending vasa recta tend to give up solute as the blood moves toward the cortex. Solute enters the descending vasa recta and therefore tends to be trapped in the medulla. Countercurrent exchange is a purely passive process; it helps maintain a gradient established by some other means.

The generation of urine hyperosmolarity requires the integrated functioning of the loops of Henle, vasa recta, and collecting ducts.

Figure 22.20 summarizes the mechanisms involved in producing osmotically concentrated urine. A maximally concentrated urine, with an osmolality of 1,200 mOsm/kg H_2O and a low urine volume (0.5% of the original filtered water), is being excreted.

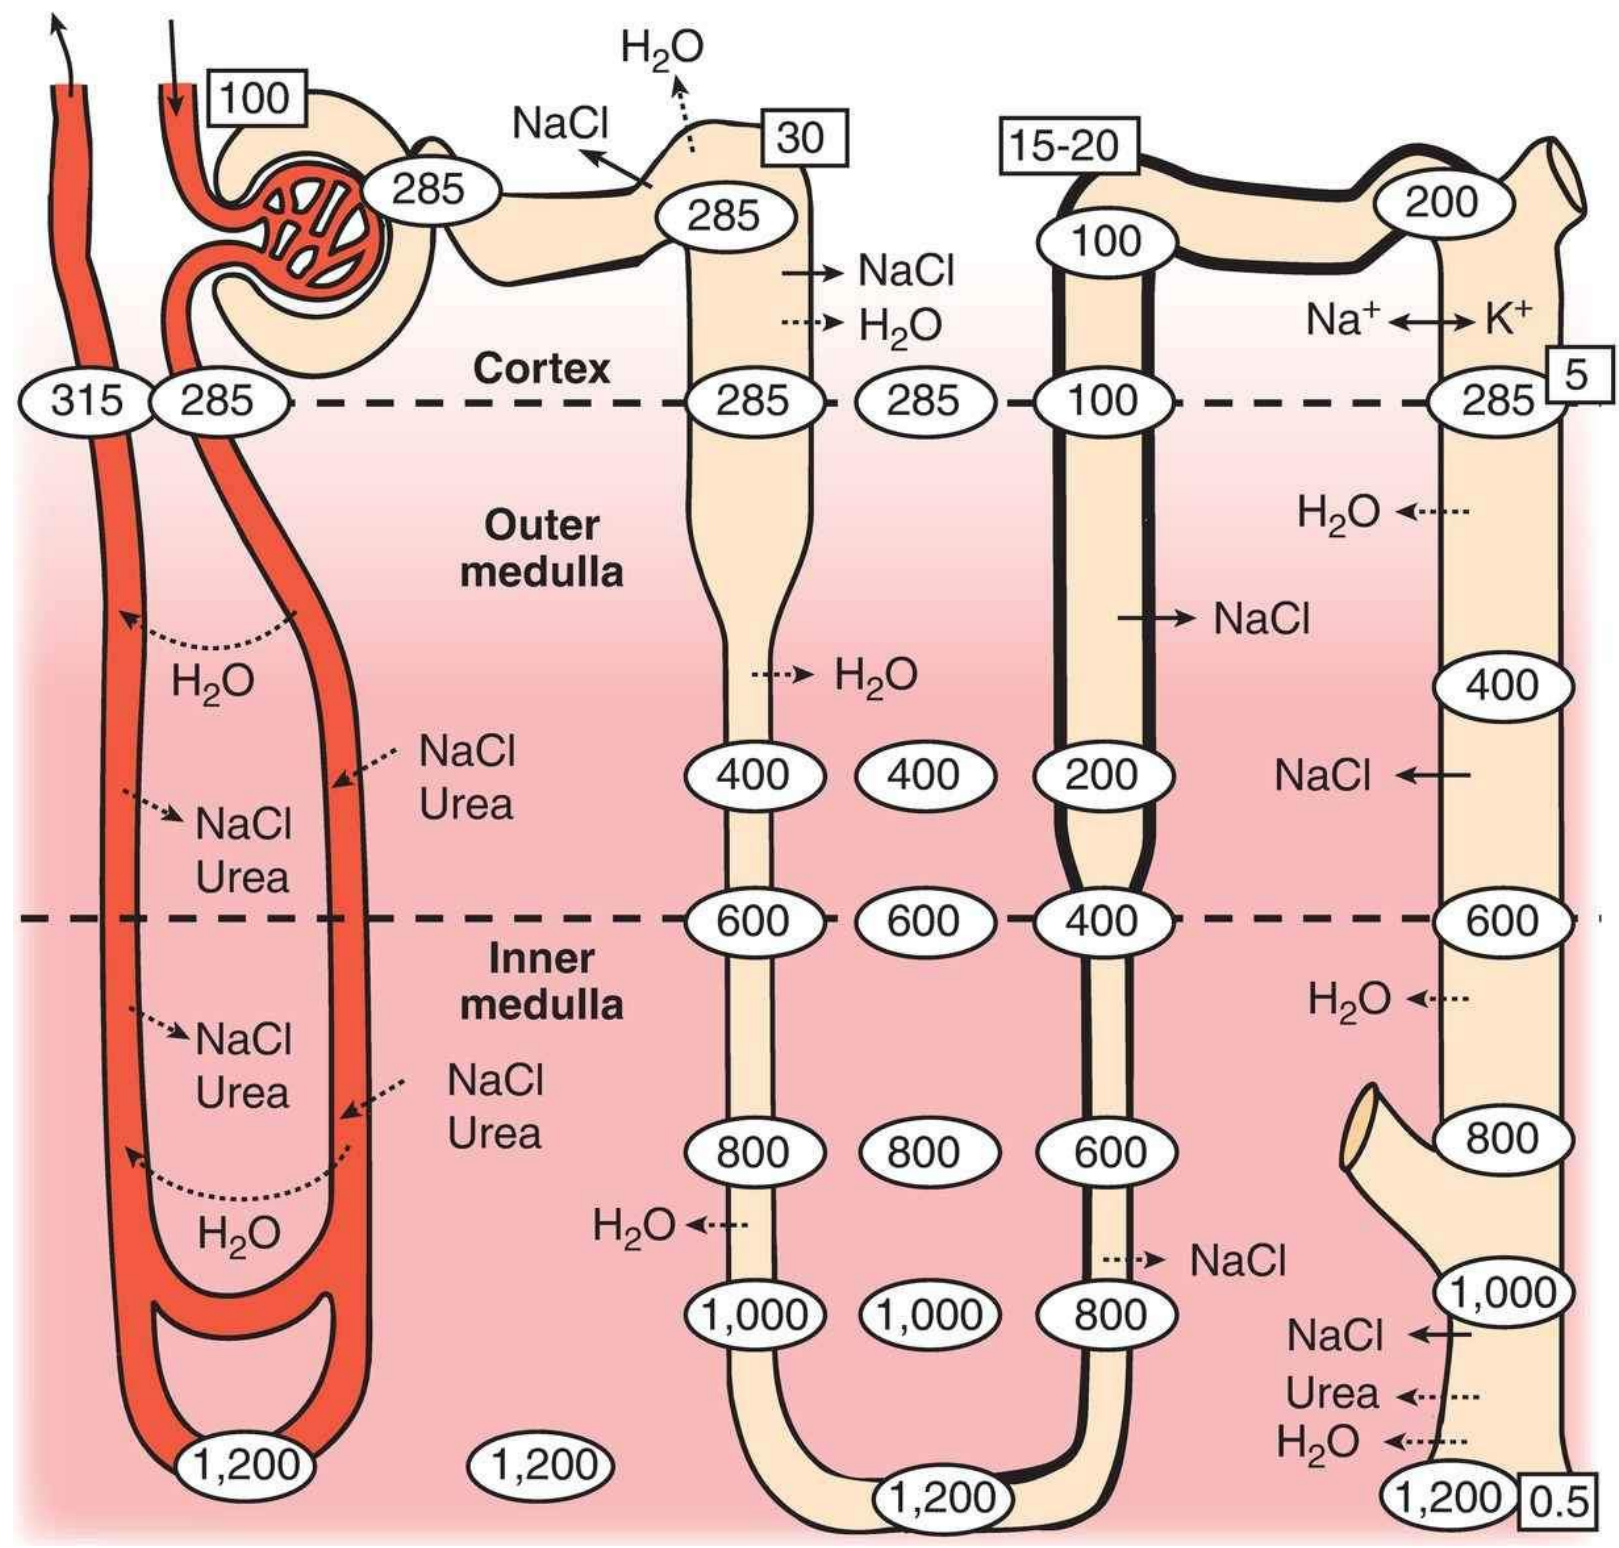

Figure 22.20 Formation of osmotically concentrated urine. This diagram summarizes movements of ions, urea, and water in the kidney during production of maximally concentrated urine (1,200 mOsm/kg H_2O). Numbers in *ovals* represent osmolality in mOsm/kg H_2O. Numbers in *boxes* represent relative amounts of water present at each level of the nephron. *Solid arrows* indicate active transport; *dashed arrows* indicate passive transport. The *heavy outlining* along the ascending limb of the loop of Henle and distal convoluted tubule indicates relative water impermeability.

About 70% of filtered water is reabsorbed along the proximal convoluted tubule, and so, 30% of the original filtered volume enters the loop of Henle. As discussed earlier, proximal reabsorption of water is essentially an isosmotic process, so fluid entering the loop is isosmotic to plasma. As the fluid moves along the descending limb of the loop of Henle in the medulla, it becomes increasingly concentrated. The

removal of water along the descending limb leads to a rise in NaCl concentration in the loop fluid to a value higher than in the interstitial fluid. In the thin ascending limb, NaCl is passively reabsorbed across a water-impermeable epithelium, and the NaCl is deposited in the medullary interstitial fluid. In the thick ascending limb, Na^+ transport is active and is powered by a vigorous Na^+/K^+-ATPase. The net addition of solute to the medulla by the loops is essential for the subsequent osmotic concentration of urine in the collecting ducts.

Fluid entering the distal convoluted tubule is hypoosmotic compared with plasma (see Fig. 22.20) because of the removal of solute without water along the ascending limb. In the presence of AVP (ADH), the cortical collecting ducts become water permeable and water is passively reabsorbed into the cortical interstitial fluid. The high blood flow to the cortex rapidly carries away this water, and so, there is no detectable lowering of cortical tissue osmolality. Before the tubular fluid reenters the medulla, it is isosmotic, and its volume is only about 5% of the original filtered volume. The reabsorption of water in the cortical collecting ducts is important for the overall operation of the urinary concentrating mechanism. If this water were not reabsorbed in the cortex, an excessive amount would enter the medulla. It would tend to wash out the gradient in the medulla, leading to an impaired ability to concentrate the urine maximally.

All nephrons drain into collecting ducts that pass through the medulla. In the presence of AVP, the medullary collecting ducts are permeable to water. Water moves out of the collecting ducts into the more concentrated interstitial fluid. At high levels of AVP, the fluid equilibrates with the interstitial fluid, and the final urine becomes as concentrated as the tissue fluid at the tips of the papillae.

Many different models for the countercurrent mechanism have been proposed; each must take into account the principle of conservation of matter (mass balance). In the steady state, the inputs of water and every nonmetabolized solute must equal their respective outputs. This principle must be obeyed at every level of the medulla. Figure 22.21 presents a simplified scheme that applies the mass balance principle to the medulla as a whole. It provides some additional insights into the countercurrent mechanism. Notice that fluids entering the medulla (from the proximal tubule, descending vasa recta, and at some point in the cortical collecting ducts) are isosmotic; they all have an osmolality of about 285 mOsm/kg H_2O. Fluid leaving the medulla in the urine is hyperosmotic. It follows from mass balance considerations that somewhere a hypo-osmotic fluid has to leave the medulla; this occurs in the ascending limb of the loop of Henle.

Figure 22.21 Mass balance considerations for the medulla as a whole. In the steady state, the inputs of water and solutes must equal their respective outputs. Water input into the medulla from the cortex (100 + 36 + 6 = 142 mL/min) equals water output from the medulla (117 + 24 + 1 = 142 mL/min). Solute input (28.5 + 10.3 + 1.7 = 40.5 mOsm/min) is likewise equal to solute output (36.9 + 2.4 + 1.2 = 40.5 mOsm/min).

The input of water into the medulla must equal its output. Because water is added to the medulla along the descending limbs of the loops of Henle and the collecting ducts, this water must be removed at an equal rate. The ascending limbs of the loops of Henle cannot remove the added water because they are water impermeable. The water is removed by the vasa recta; this is why blood flow in the ascending vasa recta exceeds blood flow in the descending vasa recta (see Fig. 22.21). Blood leaving the medulla is hyperosmotic because it drains a region of high osmolality.

A low-protein diet is associated with a decreased urea concentration in the kidney medulla. It has been known for many years that animals or humans on such a diet have an impaired ability to concentrate the urine maximally, demonstrating a key role for this solute in the urine-concentrating ability of the kidney.

Figure 22.22 shows how urea is handled along the nephron, expressed as a percent of the filtered load of urea. The proximal convoluted tubule is fairly permeable to urea and reabsorbs about 50% of the filtered urea. Fluid collected from the distal convoluted tubule, however, has as much urea as the amount filtered. Therefore, urea is secreted in the loop of Henle as described in previous sections.

The thick ascending limb, distal convoluted tubule, connecting tubule, cortical collecting duct, and outer medullary collecting duct are relatively impermeable to urea. As described earlier in the chapter, the urea concentration rises as water is reabsorbed along cortical and outer medullary collecting ducts. AVP (ADH) stimulates UT-A1 transporters in the deep medullary collecting duct allowing urea diffusion into the interstitial fluid of the inner medulla. The result is the delivery to the inner medulla of a concentrated urea solution. Urea may re-enter the loop of Henle and be recycled (Fig. 22.22), thereby building up its concentration in the inner medulla. Urea is also added to the inner medulla by diffusion from the urine surrounding the papillae (calyceal urine). Urea accounts for about half of the osmolality in the inner medulla. The urea in the interstitial fluid of the inner medulla counterbalances urea in the collecting duct urine, allowing the other solutes (e.g., NaCl) in the interstitial fluid to counterbalance osmotically the other solutes (e.g., creatinine and various salts) that need to be concentrated in the urine. This enhances the urinary concentrating ability and allows urea to be excreted with less water.

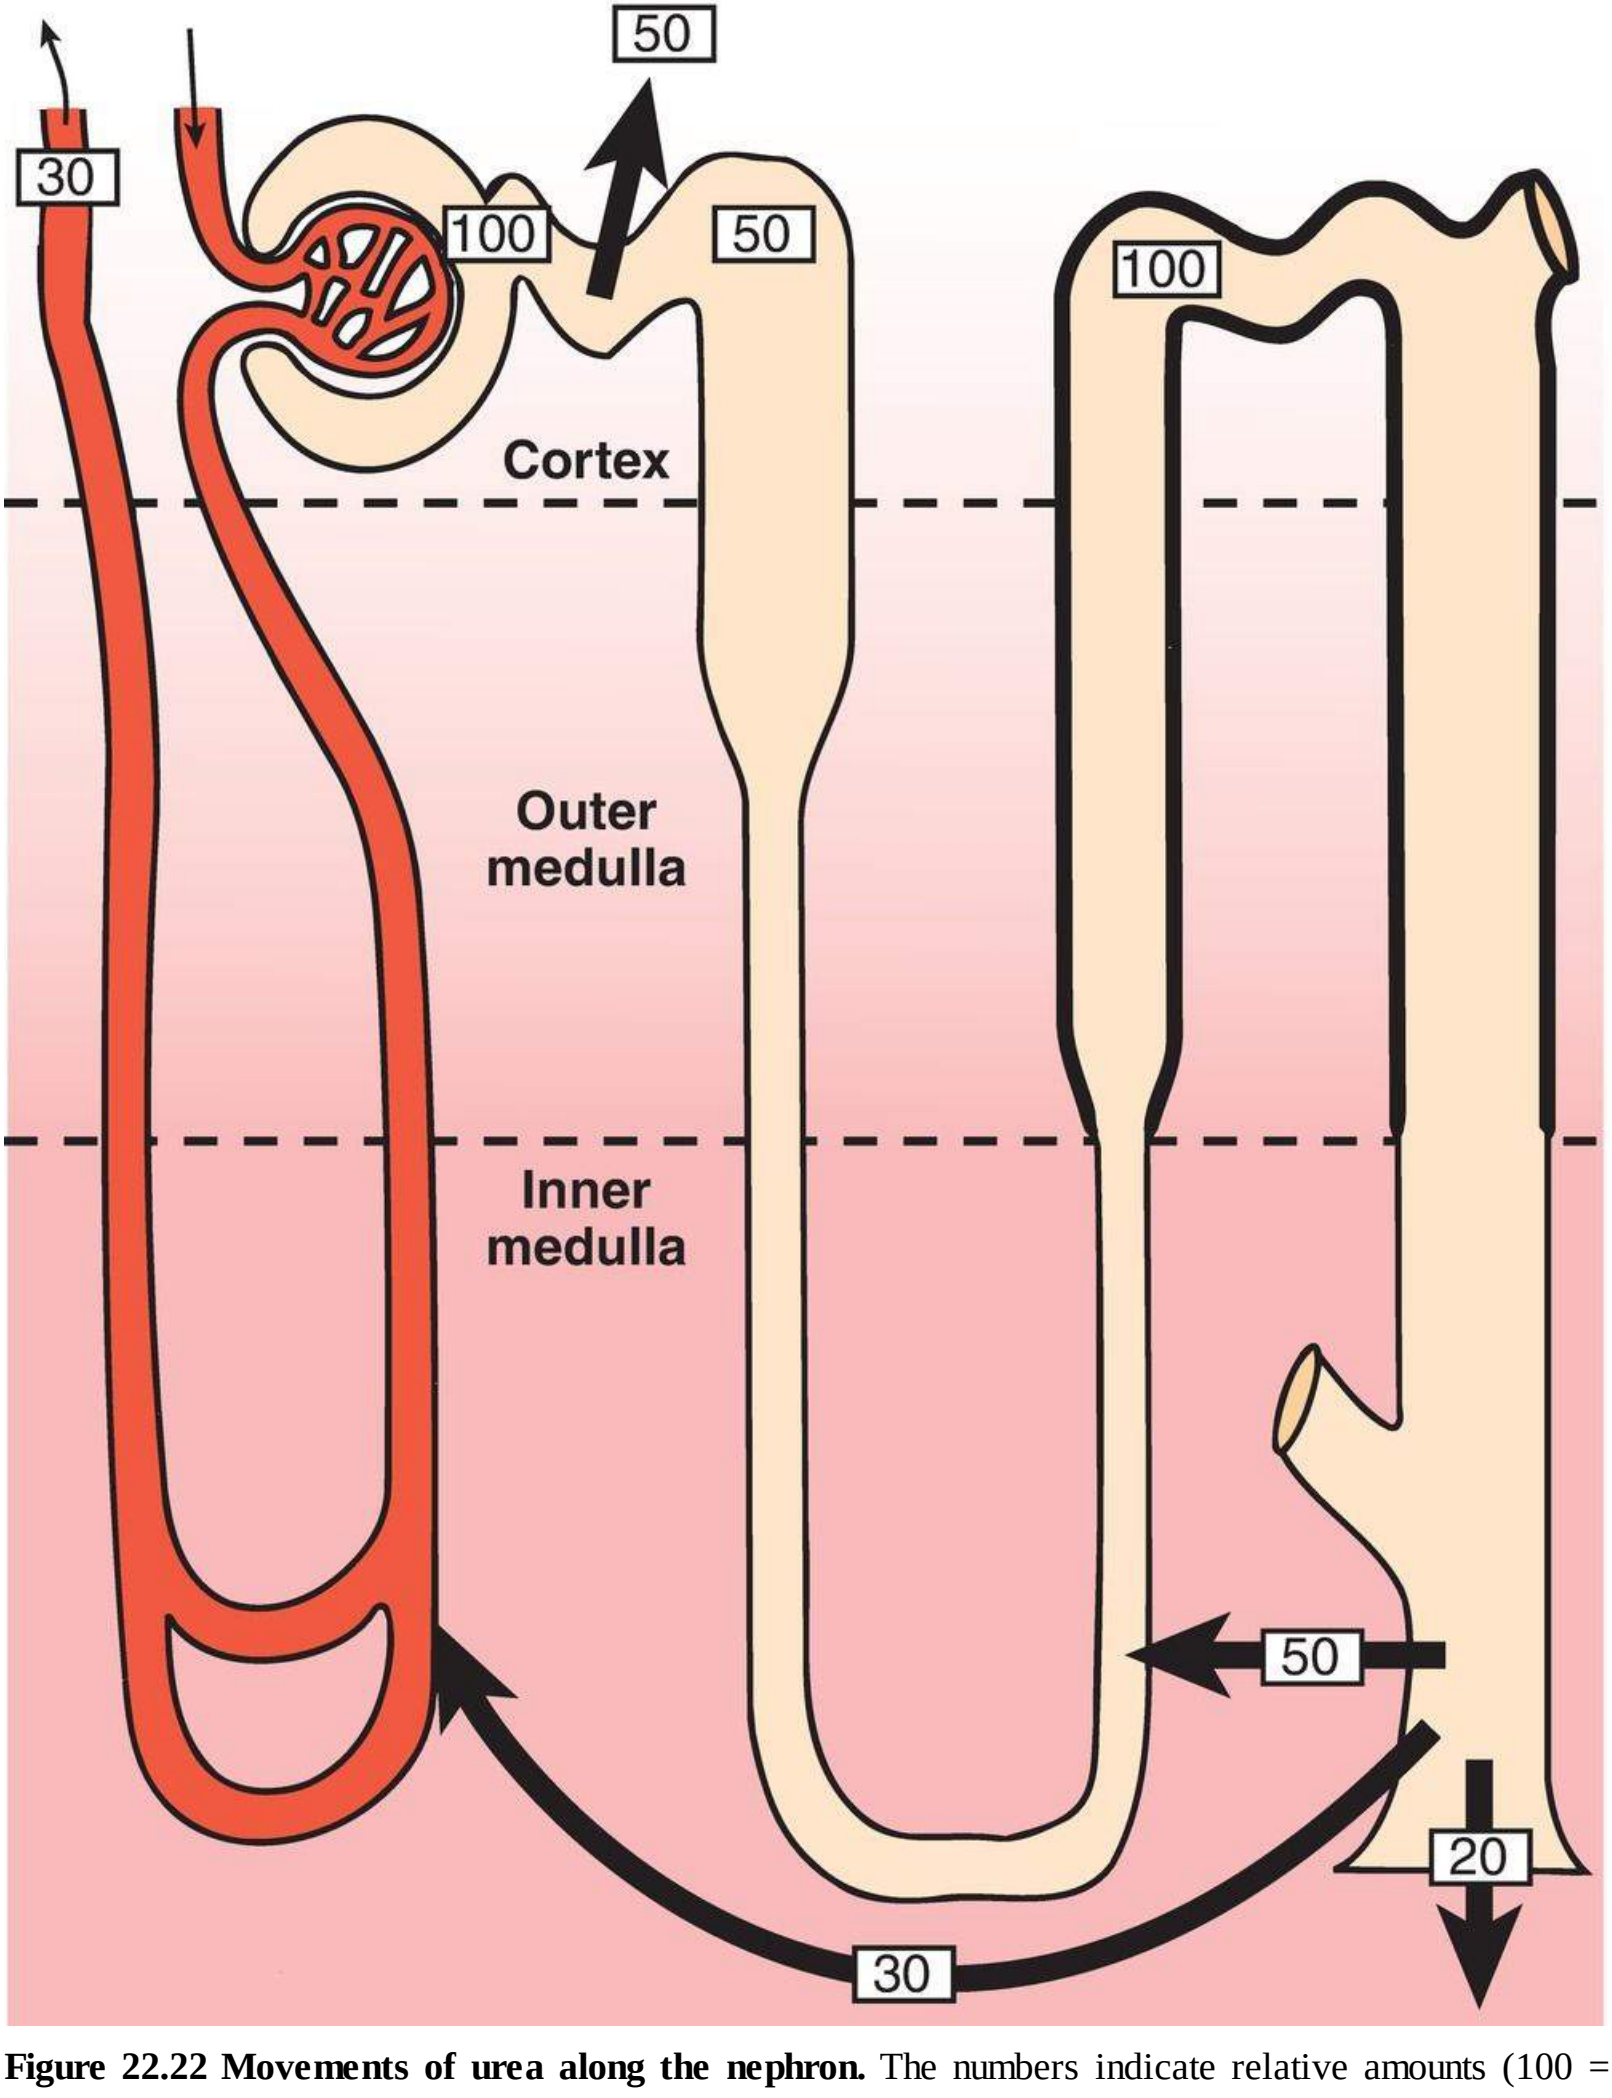

Figure 22.22 Movements of urea along the nephron. The numbers indicate relative amounts (100 =

filtered urea), not concentrations. The heavy outline from the thick ascending limb to the outer medullary collecting duct indicates relatively urea-impermeable segments. Urea is added to the inner medulla by its collecting ducts through UT-A1 channels, which are stimulated by AVP; most of this urea reenters the loop of Henle, and the vasa recta remove some.

Dilute urine is excreted when plasma AVP levels are low.

Figure 22.23 depicts osmolalities during excretion of dilute urine, as occurs when plasma AVP levels are low. Tubular fluid is diluted along the ascending limb and becomes even more dilute as solute is reabsorbed across the relatively water-impermeable distal portions of the distal convoluted tubules and collecting ducts. Because as much as 15% of filtered water is not reabsorbed, high urine flow rate results. In these circumstances, the osmotic gradient in the medulla is reduced but not abolished. The decreased gradient results from several factors. First, medullary blood flow is increased during a diuresis, which tends to wash out the osmotic gradient. Second, less urea is added to the inner medulla interstitium because the urea in the collecting duct urine is less concentrated than usual and there is less of a concentration gradient for passive reabsorption of urea. Furthermore, when AVP levels are low, the urea permeability of the inner medulla collecting ducts are low but not zero, and thus, some urea is able to be passively reabsorbed by the medullary collecting ducts. Finally, because of diminished water reabsorption in the cortical collecting ducts, too much water may enter and be reabsorbed in the medulla, lowering its osmotic gradient.

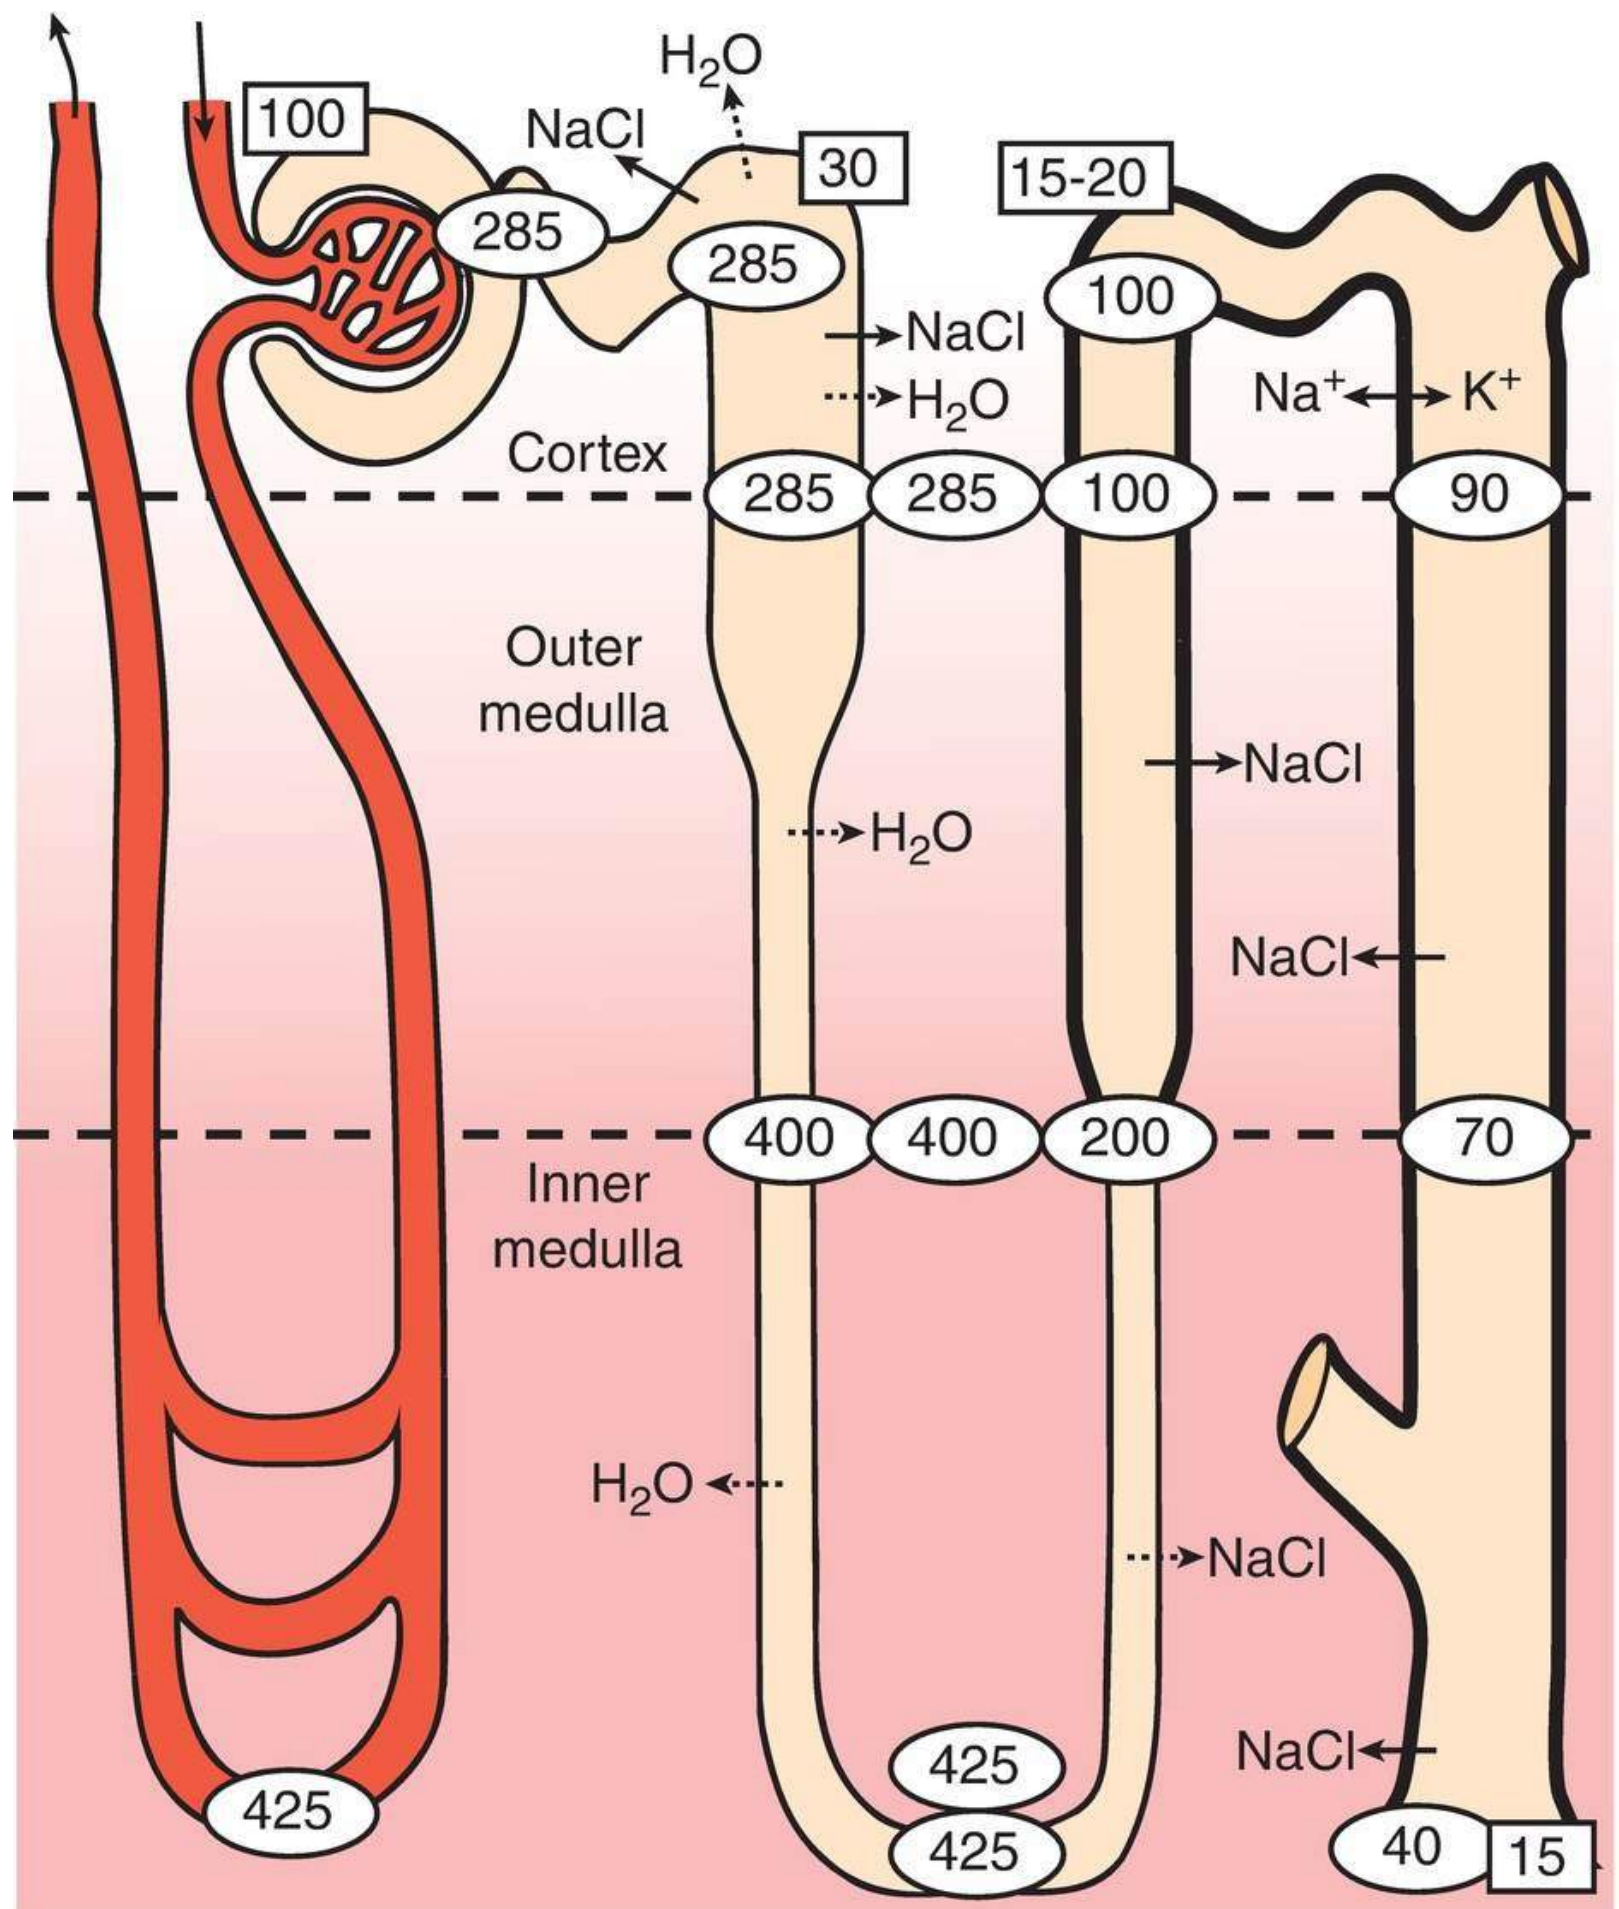

Figure 22.23 Osmotic gradients during excretion of osmotically dilute urine. The collecting ducts are relatively water impermeable (heavy outlining) because arginine vasopressin (AVP) is absent. The medulla is still hyperosmotic, but less so than in a kidney producing osmotically concentrated urine.

RENAL CLEARANCE AND ASSESSING GLOMERULAR FUNCTION

One of the key functions of the kidneys is their ability to remove or "clear" substances from plasma as a step in their elimination by excretion in the urine. **Renal clearance** of a substance is a key clinical measurement in pharmacotherapy and toxicology where quantification of such processes help the physician understand changes in drug concentrations in the plasma over time and the effectiveness of therapies used to remove toxins from the body. Renal clearance can also be used as an indirect way to measure glomerular function. These tests measure the rates of glomerular filtration, RBF, and tubular reabsorption or secretion of various substances. Measurement of glomerular filtration rate (GFR), in particular, is routinely used to evaluate kidney function.

However, clearance is an unusual measurement and often leads to confusion for students. Clearance is based on the concept that when a substance is excreted in the urine, it is as if a certain volume of plasma was completely cleared of the substance. Thus, renal clearance is defined as the volume of plasma from which a substance is completely removed (cleared) by the kidney per unit time (usually a minute), even though for many substances, the kidney does not actually remove *all* of that substance from the plasma (e.g., one can calculate the renal clearance of sodium, urea, drugs, etc., even though over the period of measurement, the kidney doesn't eliminate them completely from the plasma). For example, the clearance of urea is 65 mL/min. This means that the kidney removed urea from the plasma at a rate equivalent to that which would occur if all of the urea in 65 mL of plasma was removed in 1 minute. In the previous section, urea was shown to play a unique role in concentrating urine and urea clearance assumes physiological importance if the urea clearance is too high or too low.

The formula for renal clearance is:

$$C_X = \frac{U_X \times \dot{V}}{P_X} \quad (5)$$

where X is the substance of interest, C_X is the clearance of substance X, U_X is the urine concentration of substance X, P_X is the plasma concentration of substance X, and $\dot{V}$ is the urine flow rate. The

product of U_X times equals the excretion rate and has dimensions of amount per unit time (e.g., mg/min or mEq/d). Thus, clearance equals the urinary excretion rate divided by plasma concentration. The clearance of a substance can easily be determined by measuring the concentrations of a substance in urine and plasma and the urine flow rate (urine volume/time of collection) and substituting these values into the clearance formula.

Inulin clearance equals the glomerular filtration rate.

An important measurement in the evaluation of kidney function is the **glomerular filtration rate (GFR)**, the rate at which plasma is filtered by the kidney glomeruli. GFR is equal to the sum of the filtration rates of all functional nephrons and is used as index of renal function. A decrease in GFR generally indicates that kidney function is impaired. Thus, GFR is an important diagnostic tool to evaluate kidney disease.

If we had a substance that was cleared from the plasma only by glomerular filtration, it could be used to measure GFR. The ideal substance to measure GFR is **inulin**, a fructose polymer with a molecular weight of about 5,000. Inulin (IN) is suitable for measuring GFR for the following reasons: (1) IN is not bound to plasma proteins and is thus freely filtered by the glomeruli; (2) IN is not reabsorbed or secreted by the kidney tubules; (3) IN is not synthesized, destroyed, or stored in the kidneys; (4) IN is not toxic; and (5) IN concentration in plasma and urine can be determined by simple analysis.

The principle behind the use of IN is illustrated in Figure 22.24. The amount of IN filtered per unit time, the **filtered load**, is equal to the product of the plasma concentration of IN (P_{IN}) times GFR. The rate of IN excretion is equal to the urine IN concentration (U_{IN}) times , the urine flow rate. Because IN is not reabsorbed, secreted, synthesized, destroyed, or stored by the kidney tubules, the filtered IN load equals the rate of IN excretion. The equation can be rearranged by dividing by the plasma IN concentration. The expression U_{IN} /P_{IN} is defined as the **inulin clearance**. Therefore, IN clearance equals GFR. Normal values for IN clearance or GFR (corrected to a body surface area of 1.73 m^2) are 110 ± 15 (SD) mL/min for young adult women and 125 ± 15 mL/min for young adult men. In newborns, even when corrected for body surface area, GFR is low, about 20 mL/min per 1.73 m^2 body surface area. Adult values (when corrected for body surface area) are attained by the end of the first year of life. If GFR is 125 mL plasma/min, then the volume of plasma filtered in a day is 180 L (125 mL/min × 1,440 min/d). After the age of 45 to 50, GFR declines, and it is typically reduced by 30% to 40% by age 80.

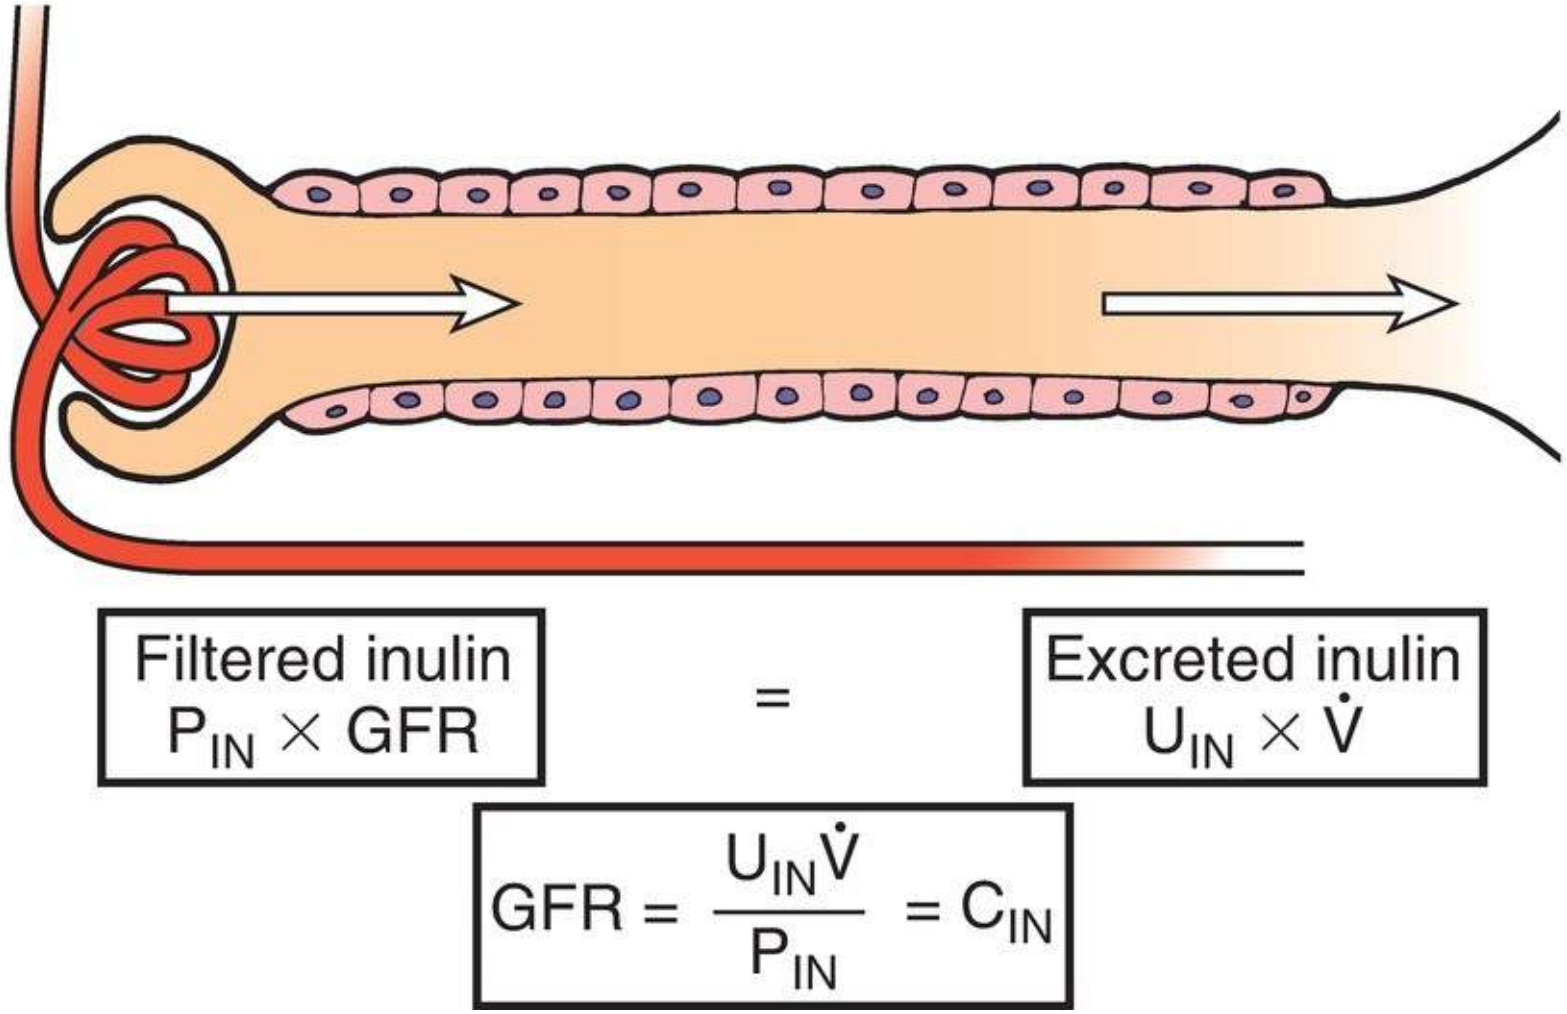

Figure 22.24 The principle behind the measurement of glomerular filtration rate (GFR). P_{IN}, plasma inulin concentration; U_{IN}, urine inulin concentration; , urine flow rate; C_{IN}, inulin clearance.

Plasma creatinine clearance is used clinically to estimate GFR.

IN clearance is the gold standard for measuring GFR and is used whenever highly accurate measurements of GFR are desired. It would be simpler, however, to use an endogenous substance (i.e., one native to the body) that is only filtered, is excreted in the urine, and normally has a stable plasma value that can be accurately measured. There is no such known substance, but creatinine comes close.

Creatinine is an end product of muscle metabolism, a derivative of muscle creatine phosphate. It is produced continuously in the body and is excreted in the urine. Long urine collection periods (e.g., a few hours) can be used, because creatinine concentrations in the plasma are normally stable and creatinine does not have to be infused; consequently, there is no need to catheterize the bladder. Plasma and urine concentrations can be measured using a simple colorimetric method. The **endogenous creatinine clearance** is calculated from the formula

$$C_{CREATININE} = \frac{U_{CREATININE} \times \dot{V}}{P_{CREATININE}} \quad (6)$$

or creatinine clearance equals the ratio of urine to plasma creatinine concentration times the urine flow rate. There are two potential drawbacks of using creatinine to measure GFR. First, creatinine is not only filtered but also secreted by the human kidney. This elevates urinary excretion of creatinine, normally causing a 20% increase in the numerator of the clearance formula. The second drawback is related to errors of measuring creatinine concentration in the plasma. The colorimetric method usually used also measures other plasma substances, such as glucose, leading to a 20% increase in the denominator of the clearance formula. Because both numerator and denominator are 20% too high, the two errors cancel, and so, the endogenous creatinine clearance fortuitously affords a good approximation of GFR when it is about normal. However, when GFR in an adult has been reduced to about 20 mL/min because of renal disease, the endogenous creatinine clearance may overestimate the GFR by as much as 50%. This results from higher plasma creatinine levels and increased tubular secretion of creatinine. Drugs that inhibit tubular secretion of creatinine or elevated plasma concentrations of chromogenic (color-producing) substances other than creatinine may cause the endogenous creatinine clearance to underestimate GFR.

Plasma creatinine concentration can be used to estimate GFR.

Because the kidneys continuously clear creatinine from the plasma by excreting it in the urine, the GFR and plasma creatinine concentration are inversely related. Figure 22.25 shows the steady-state relationship between these variables—that is, when creatinine production and excretion are equal. If the GFR is halved from a normal value of 180 to 90 L/d, it would result in a doubling of plasma creatinine concentration from a normal value of 1 to 2 mg/dL after a few days. A reduction in GFR from 90 to 45 L/d results in a greater increase in plasma creatinine, from 2 to 4 mg/dL. Figure 22.25 shows that with low GFR values, small absolute changes in GFR lead to much greater changes in plasma creatinine concentration than at high GFR values.

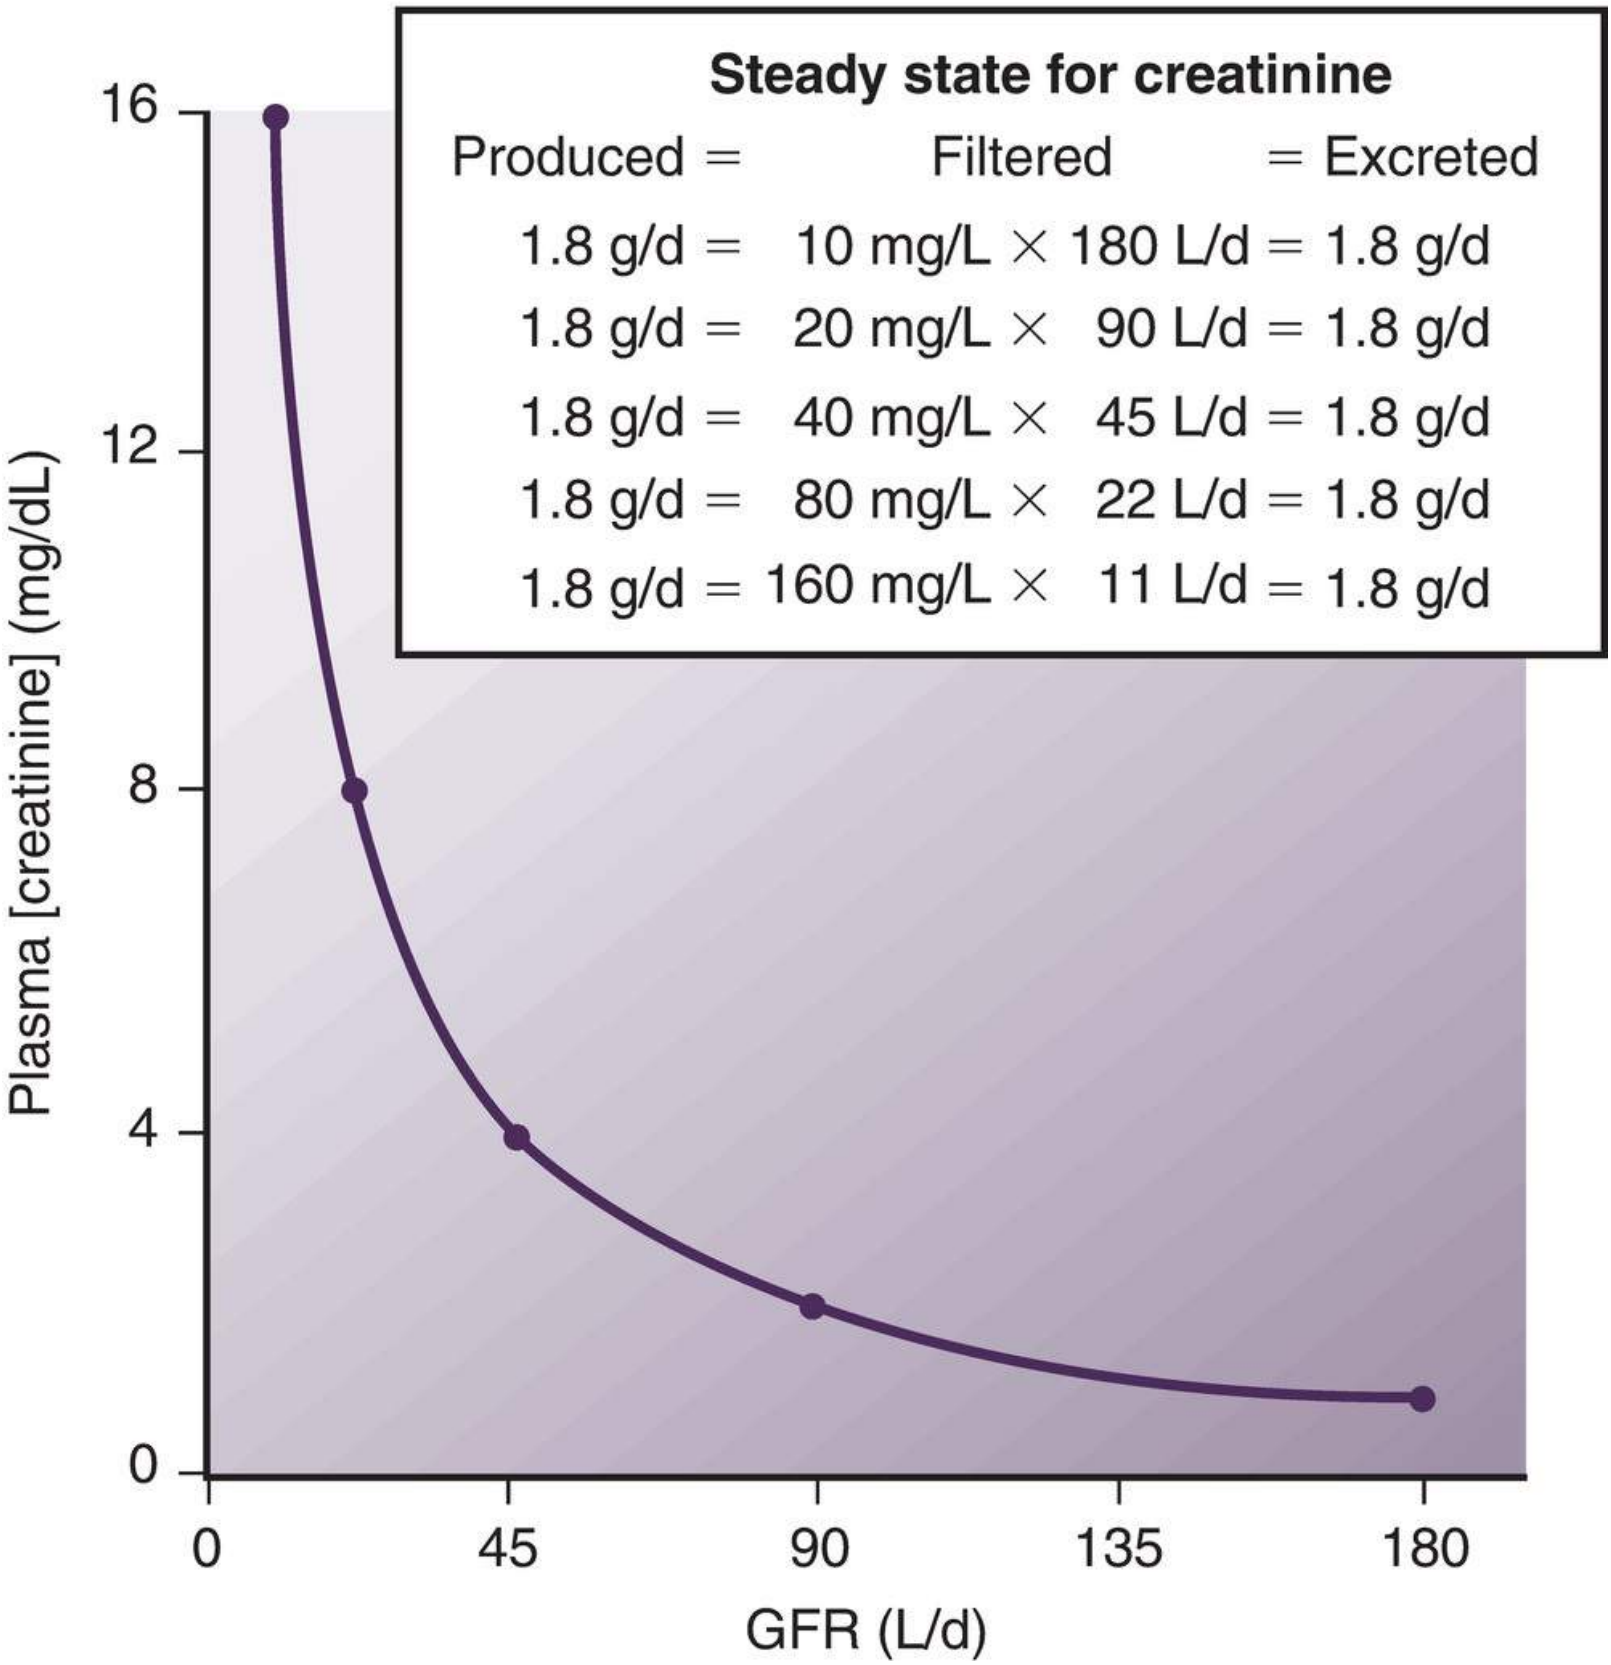

Figure 22.25 The inverse relationship between plasma creatinine concentration and glomerular filtration rate (GFR). If GFR is decreased by half, plasma creatinine concentration is doubled when the production and excretion of creatinine are in balance in a new steady state.

The inverse relationship between GFR and plasma creatinine concentration allows the use of plasma or serum creatinine to estimate GFR, provided that these three cautions are kept in mind:

1. It takes a certain amount of time for changes in GFR to produce detectable changes in plasma

creatinine concentration.

2. Plasma creatinine concentration is also influenced by muscle mass. A young, muscular man will have a higher plasma creatinine concentration than an older woman with reduced muscle mass.
3. Some drugs inhibit tubular secretion of creatinine, leading to a raised plasma creatinine, even though GFR may be unchanged.

The relationship between plasma creatinine and GFR is one example of how a substance's plasma concentration can depend on GFR. The same relationship is observed for several other substances whose excretion depends on GFR. For example, the plasma urea concentration or blood urea nitrogen rises when GFR falls. The plasma level of a 13-kDa protein molecule called *cystatin C* also rises when GFR falls, and it has been suggested that serum cystatin C levels can be used to estimate GFR.

Several empirical equations have been developed that allow physicians to estimate GFR from serum creatinine concentration. These equations often take into consideration such factors as age, gender, race, and body size. The equation for adults, GFR (in mL/min per 1.73 m^2) = 186 × (serum creatinine in mg/dL) $^{-1.154}$ × (age in years) $^{-0.203}$ × 0.742 (if the subject is female) or × 1.212 (if the subject is black), is recommended by the National Kidney Disease Education Program, which provides GFR calculators on its Web site: www.nih.nkdep.gov. Staging of chronic kidney disease is usually based on estimated GFR measurements; a value <60 mL/min may indicate renal disease.

Para-aminohippurate clearance estimates renal plasma flow.

Renal blood flow (**RBF**) can be determined from measurements of **renal plasma flow** (**RPF**) and blood hematocrit, using the following equation:

$$\mathrm{RBF} = \mathrm{RPF}/(1 - \mathrm{Hematocrit}) \tag{7}$$

The hematocrit is easily determined by centrifuging a blood sample. RPF is estimated by measuring the clearance of the organic anion *p*-aminohippurate (PAH), infused intravenously. PAH is filtered and so vigorously secreted that it is nearly completely cleared from all of the plasma flowing through the kidneys. The renal clearance of PAH, at low plasma PAH levels, approximates the RPF.

The equation for calculating the true value of the RPF is

$$\mathrm{RPF} = C_{\mathrm{PAH}} / E_{\mathrm{PAH}} \tag{8}$$

where C_{PAH} is the PAH clearance and E_{PAH} is the extraction ratio (see Chapter 15) for PAH—the difference between the arterial and renal venous plasma PAH concentrations ($P^{a}_{PAH} - P^{rv}_{PAH}$) divided by the arterial plasma PAH concentration (P^{a}_{PAH}). The equation is derived as follows. In the steady state, the amounts of PAH per unit time entering and leaving the kidneys are equal. The PAH is supplied to the kidneys in the arterial plasma and leaves the kidneys in urine and renal venous plasma, or:

$$\mathrm{PAH\ entering\ kidneys} = \mathrm{PAH\ leaving\ kidneys}$$

$$\mathrm{RPF} \times P^{a}_{\mathrm{PAH}} = U_{\mathrm{PAH}} \times \dot{V} + \mathrm{RPF} \times P^{rv}_{\mathrm{PAH}} \tag{9}$$

Rearranging, we get:

$$RPF = U_{PAH} \times \dot{V} / (P^{a}_{PAH} - P^{rv}_{PAH}) \quad (10)$$

P^{a}_{PAH},

If we divide the numerator and denominator of the right side of the equation by the numerator becomes C_{PAH} and the denominator becomes E_{PAH}.

If we assume extraction of PAH is 100% (E_{PAH} = 1.00), then the RPF equals the PAH clearance. When this assumption is made, the RPF is usually called the *effective RPF*, and the blood flow calculated is called the *effective RBF*. The extraction of PAH by healthy kidneys at low plasma PAH concentrations, however, is not 100% but averages about 91%, so the assumption of 100% extraction results in about a 10% underestimation of the true RPF. To calculate the true RPF or blood flow, it is necessary to sample renal venous blood to measure its plasma PAH concentration, a procedure not often done.

Net tubular reabsorption or secretion of a substance can be calculated from renal clearance.

The rate at which the kidney tubules reabsorb a substance can be calculated if we know how much is filtered and how much is excreted per unit time. If the filtered load of a substance exceeds the rate of excretion, the kidney tubules must have reabsorbed the substance. The equation is

$$T_{reabsorbed} = P_X \times GFR - U_X \times \dot{V} \quad (11)$$

where T is the tubular transport rate.

The rate at which the kidney tubules secrete a substance is calculated from this equation:

$$T_{secreted} = U_X \times \dot{V} - P_X \times GFR \quad (12)$$

Note that the quantity excreted exceeds the filtered load, because the tubules secrete X.

In equations 11 and 12, we assume that substance X is freely filterable. If, however, substance X is bound to the plasma proteins, which are not filtered, then it is necessary to correct the filtered load for this binding. For example, about 40% of plasma Ca^{2+} is bound to plasma proteins, and so, 60% of plasma Ca^{2+} is freely filterable.

Equations 11 and 12, which quantify tubular transport rates, yield the *net* rate of reabsorption or secretion of a substance. It is possible for a single substance to be both reabsorbed and secreted; the equations do not give unidirectional reabsorptive and secretory movements, only the net transport.

Renal clearance can estimate glucose reabsorption.

Insights into the nature of glucose handling by the kidneys can be derived from a glucose titration study (Fig. 22.26). The plasma glucose concentration is elevated to increasingly higher levels by the infusion of glucose-containing solutions. IN is infused to permit measurement of GFR and calculation of the filtered glucose load (plasma glucose concentration × GFR). The rate of glucose reabsorption is determined from the difference between the filtered load and the rate of excretion. At normal plasma glucose levels (about 100 mg/dL), all of the filtered glucose is reabsorbed and none is excreted. When the plasma glucose concentration exceeds a certain value (about 200 mg/dL in Fig. 22.26), significant quantities of glucose appear in the urine; this plasma concentration is called the **glucose threshold**. Further elevations in plasma glucose lead to progressively more excreted glucose. Glucose appears in the urine because the filtered amount of glucose exceeds the capacity of the tubules to reabsorb it. At high filtered glucose loads, the rate of glucose reabsorption reaches a constant maximal value, called the **tubular transport maximum (Tm)** for glucose (G). At Tm_G, the tubule glucose carriers are all saturated and transport glucose at the maximal rate.

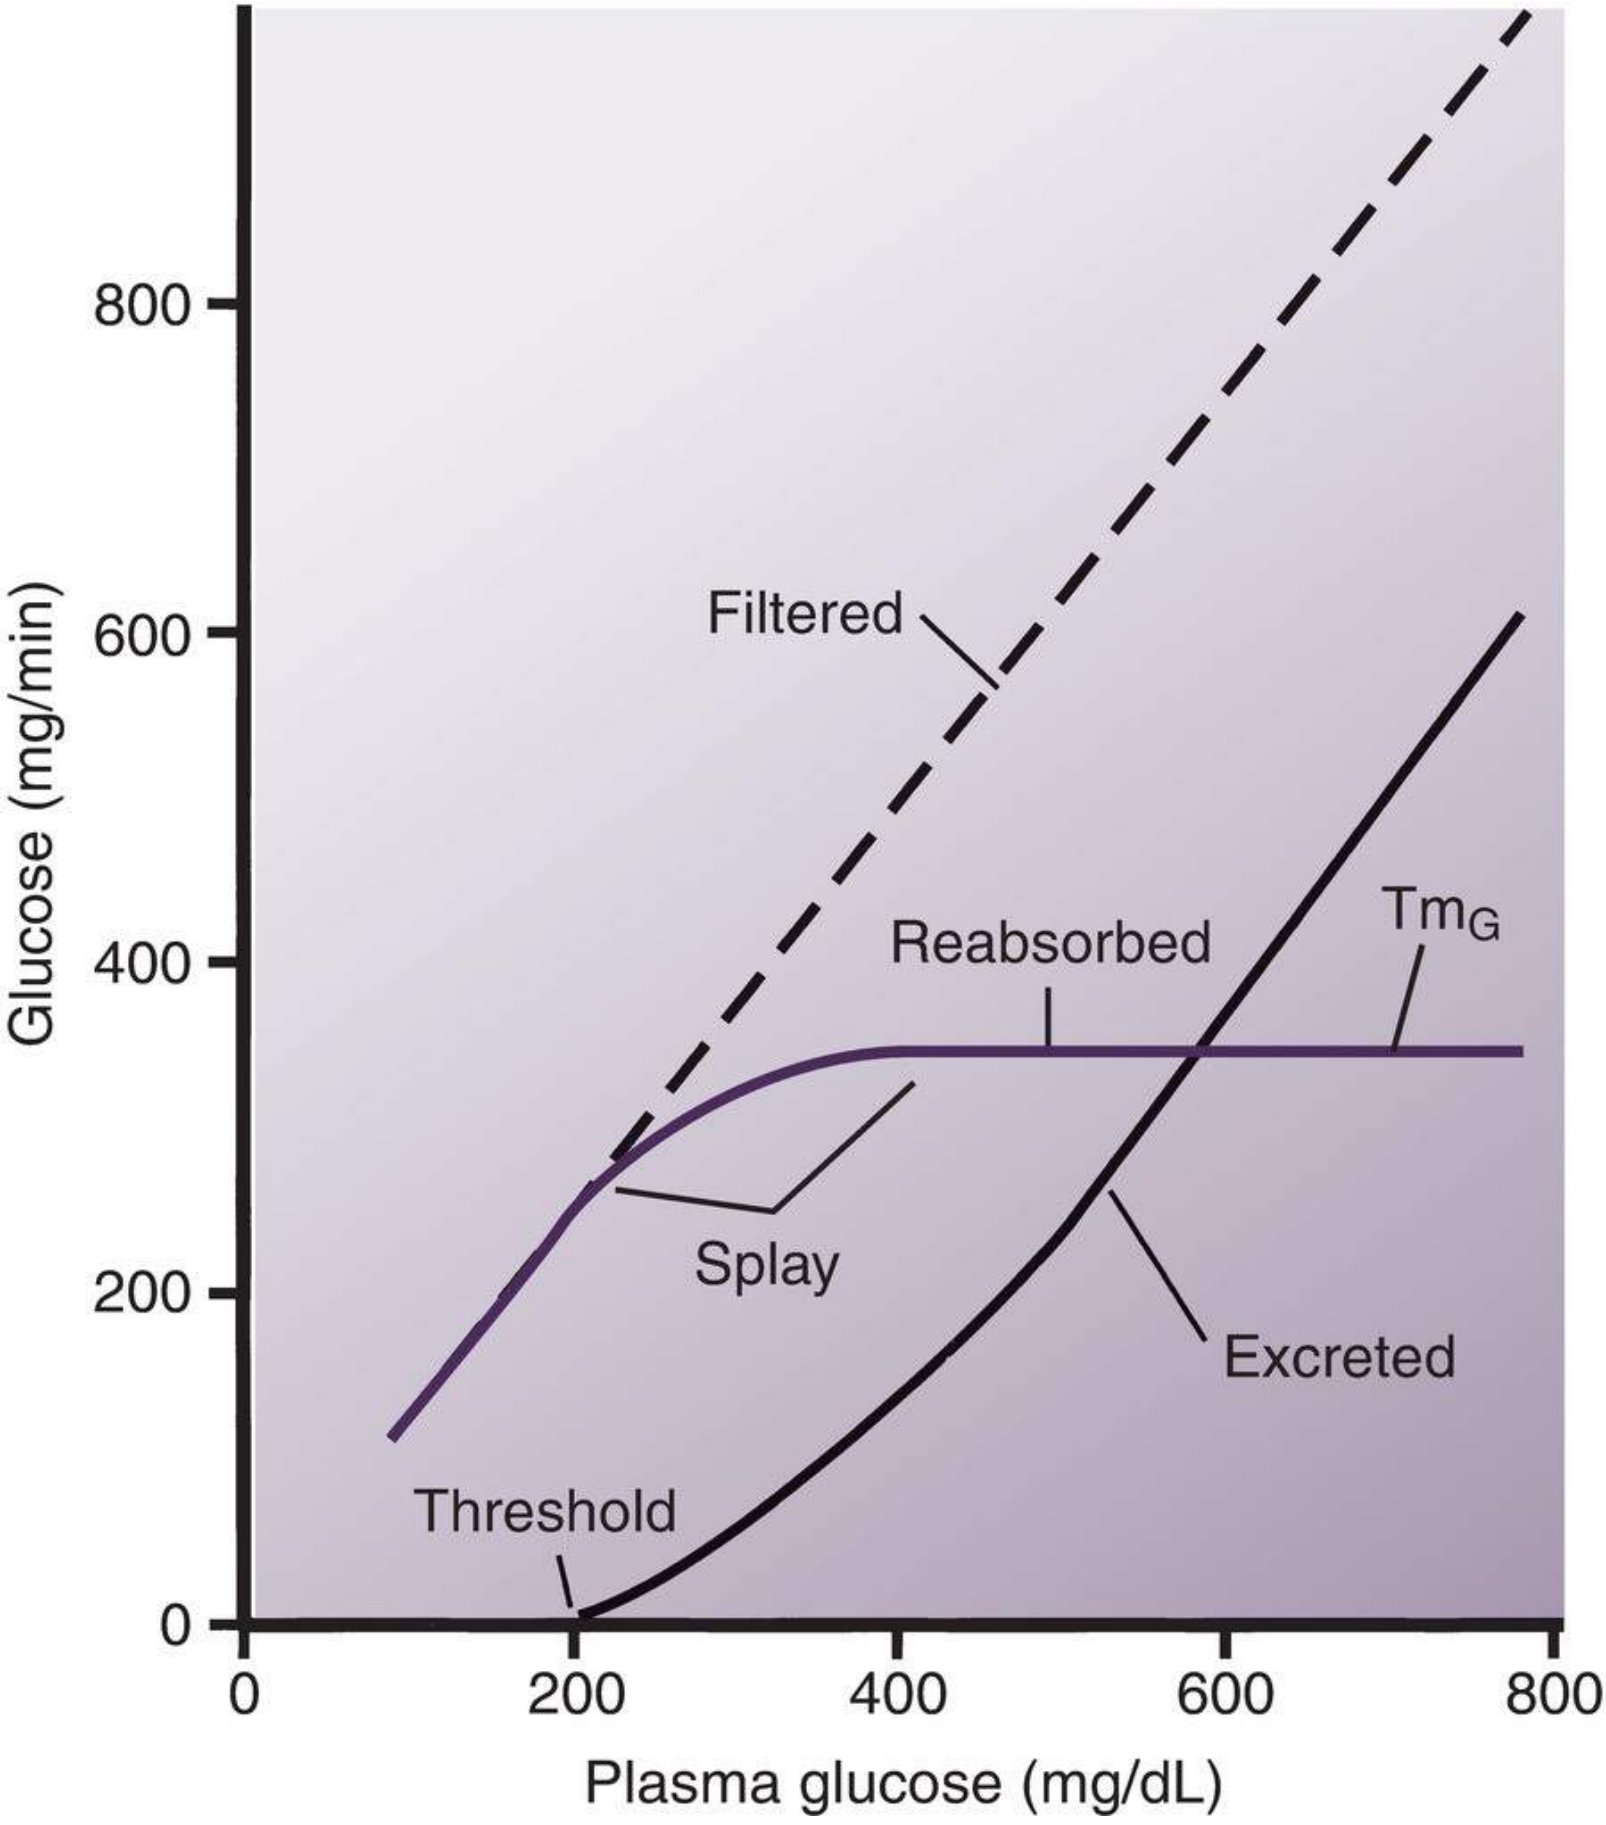

Figure 22.26 Glucose titration study in a healthy man. The plasma glucose concentration was elevated by infusing glucose-containing solutions. The amount of glucose filtered per unit time (*top dashed line*) is determined from the product of the plasma glucose concentration and glomerular filtration rate (measured with inulin). Excreted glucose (*bottom line*) is determined by measuring concentration of glucose in the urine and urine flow rate. Reabsorbed glucose is calculated from the difference between filtered and

excreted glucose. Tm_G, tubular transport maximum for glucose.

The glucose threshold is not a fixed plasma concentration but depends on three factors: GFR, Tm_G, and amount of splay. A low GFR leads to an elevated threshold, because the filtered glucose load is reduced and the kidney tubules can reabsorb all the filtered glucose despite an elevated plasma glucose concentration. A reduced Tm_G lowers the threshold, because the tubules have a diminished capacity to reabsorb glucose.

Splay is the rounding of the glucose reabsorption curve. Figure 22.26 shows that tubular glucose reabsorption does not abruptly attain Tm_G when plasma glucose is progressively elevated. One reason for splay is that not all nephrons have the same filtering and reabsorbing capacities. Thus, nephrons with relatively high filtration rates and low glucose reabsorptive rates excrete glucose at a lower plasma concentration than nephrons with relatively low filtration rates and high reabsorptive rates. A second reason for splay is the fact that the glucose carrier does not have an infinitely high affinity for glucose, so glucose escapes in the urine even before the carrier is fully saturated. An increase in splay causes a decrease in glucose threshold.

In uncontrolled **diabetes mellitus**, plasma glucose levels are abnormally elevated, so more glucose is filtered than can be reabsorbed. Urinary excretion of glucose, **glucosuria**, produces an osmotic diuresis or an increase in urine output caused by abnormal effective osmoles in the tubular fluid of the nephron. In osmotic diuresis, the increased urine flow results from the excretion of osmotically active solute. *Diabetes* (from the Greek for “siphon”) gets its name from this increased urine output and secondary increased water intake.

Tm for PAH provides a measure for functional proximal secretion.

PAH is secreted only by proximal tubules in the kidneys. At low plasma PAH concentrations, the rate of secretion increases linearly with the plasma concentration of PAH. At high plasma PAH concentrations, the secretory carriers are saturated and the rate of PAH secretion stabilizes at a constant maximal value, called the *tubular transport maximum* for *PAH* (Tm_{PAH}). The Tm_{PAH} is directly related to the number of functioning proximal tubules and therefore provides a measure of the mass of proximal secretory tissue. Figure 22.14 illustrates the pattern of filtration, secretion, and excretion of PAH observed when the plasma PAH concentration is progressively elevated by intravenous infusion.

MICTURITION

Recall that the urinary system includes two kidneys, two ureters, the bladder, the urethra, and two sphincter muscles. The kidneys form urine continuously, and urine flows through the ureters to the bladder. The movement of urine to the bladder is aided by the contraction of the smooth muscles in the ureter wall. The bladder is a balloon-like structure with walls containing smooth muscle that stores the urine. The bladder fills with urine at a low pressure but then empties during urination, or **micturition**. In this section, the function of the urinary tract is discussed.

Urinary tract provides the pathway for transporting, storing, and eliminating urine.

As mentioned previously, the **ureters** are muscular tubes that propel the urine from the pelvis of each kidney to the urinary bladder. Peristaltic movements originate in the region of the calices, which contain specialized smooth muscle cells that generate spontaneous pacemaker potentials. These pacemaker potentials trigger action potentials and contractions in the muscular regions of the renal pelvis that propagate distally to the ureter. Peristaltic waves sweep down the ureters at a frequency of one every 10 seconds to one every 2 to 3 minutes. The ureters are innervated by sympathetic and parasympathetic nerve fibers. Sensory fibers mediate the intense pain that is felt when a stone distends or blocks a ureter.

The **urinary bladder** is a distensible hollow vessel containing smooth muscle in its wall (Fig. 22.27). The muscle is called the *detrusor*, from Latin for "that which pushes down." The neck of the bladder, the involuntary internal sphincter, also contains smooth muscle. The parasympathetic pelvic nerves and sympathetic hypogastric nerves innervate the body of the bladder and bladder neck. The external sphincter is composed of skeletal muscle and is innervated by somatic nerve fibers that travel in the pudendal nerves. Pelvic, hypogastric, and pudendal nerves contain both motor and sensory fibers.

Figure 22.27 The innervation of the urinary bladder. The parasympathetic pelvic nerves arise from the S2 to S4 segments of the spinal cord and supply motor fibers to the bladder musculature and internal (involuntary) sphincter. Sympathetic motor fibers supply the bladder via the hypogastric nerves, which arise from lumbar segments of the spinal cord. The pudendal nerves supply somatic motor innervation to the external (voluntary) sphincter. Sensory afferents (*yellow dashed lines*) from the bladder travel mainly in the pelvic nerves but also to some extent in the hypogastric nerves.

The bladder has two functions: to serve as a distensible reservoir for urine and to empty its contents at appropriate intervals. When the bladder fills, it adjusts its tone to its content, so that minimal increases in bladder pressure occur. The external sphincter is kept closed by discharges along the pudendal nerves. The first sensation of bladder filling is experienced at a volume of 100 to 150 mL in an adult, and the first desire to void is elicited when the bladder contains about 150 to 250 mL of urine. A person becomes uncomfortably aware of a full bladder when the volume is 350 to 400 mL; at this volume, hydrostatic pressure in the bladder is about 10 cm H_2O. With further volume increases, bladder pressure rises steeply, in part because of reflex contractions of the detrusor. An increase in volume to 700 mL creates pain and, often, loss of control. The sensations of bladder filling, of conscious desire to void, and of painful distention are mediated by afferents in the pelvic nerves.

The **urethra** is a tube that connects the urinary bladder to the exterior of the body. In males, the urethra travels through the penis and carries both urine and semen. In females, the urethra is shorter and emerges in front of the vaginal opening.

Micturition (urination), the periodic emptying of the bladder, is a complex act involving both autonomic and somatic nerve pathways and several reflexes that can be either inhibited or facilitated by higher centers in the brain. The basic reflexes occur at the level of the sacral spinal cord and are modified by centers in the midbrain and cerebral cortex. Distention of the bladder is sensed by stretch receptors in the bladder wall; these induce reflex contraction of the detrusor and relaxation of the internal and external sphincters. This reflex is released by removing inhibitory influences from the cerebral cortex. Fluid flow through the urethra reflexively causes further contraction of the detrusor and relaxation of the external sphincter. Increased parasympathetic nerve activity stimulates contraction of the detrusor and relaxation of the internal sphincter. Sympathetic innervation is not essential for micturition. During micturition, the perineal and levator ani muscles relax, thereby shortening the urethra and decreasing urethral resistance. Descent of the diaphragm and contraction of abdominal muscles raise intra-abdominal pressure and aid in the expulsion of urine from the bladder.

Micturition is, fortunately, under voluntary control in healthy adults. In the young child, however, it is purely reflex and occurs whenever the bladder is sufficiently distended. At about age 2.5 years, it begins to come under cortical control, and, in most children, complete control is achieved by age 3 years.

Damage to the nerves that supply the bladder and its sphincters can produce abnormalities of micturition and incontinence. An increased resistance of the upper urethra commonly occurs in older men and is a result of enlargement of the surrounding prostate gland. This condition is called *benign prostatic hyperplasia* (also known as *BPH*), and it results in decreased urine stream, overdistention of the bladder as a result of incomplete emptying, and increased urgency and frequency of urination.

Urinary incontinence is loss of bladder control.

Urinary **incontinence** is a common and often an embarrassing problem. The severity ranges from an occasional leaking with a sneeze to having an urge to urinate that's so sudden and strong that you lose voluntary control. Incontinence is more common in women. The most common types include *stress incontinence* that results in urine leaks when pressure is exerted on the bladder by coughing, laughing, or lifting a heavy weight. The second type, *urge incontinence*, results from a sudden, intense urge to urinate, followed by an involuntary loss of urine. Urge incontinence often leads to frequent urination, especially throughout the night. The third common type is *overflow incontinence*. This form is characterized by frequent dribbling of urine due to a bladder that doesn't empty completely. Incontinence is aggravated with drinks that contain alcohol or caffeine and certain medications (blood pressure medications, sedatives, and muscle relaxants) because they can act as diuretics.

Often, the cause of incontinence is unknown in individual patients. However, urinary incontinence can be caused by urinary infection, which irritates the bladder, causing strong urges to urinate. Incontinence can also be caused by physical problems such as pregnancy, childbirth, hysterectomy, and enlarged prostate. During pregnancy, hormonal changes and increased weight of the uterus can lead to stress incontinence. With childbirth, vaginal delivery can weaken muscular control of the bladder and also damage the bladder nerves and supportive tissue. Hysterectomy can lead to damage to muscles supporting the bladder, which can also lead to incontinence. An enlarged prostate (BPH) often causes incontinence in older men.

Finally, neurological disorders, such as multiple sclerosis, Parkinson's disease, stroke, and spinal injury, interfere with neurological control of the bladder, causing urinary incontinence.

INTEGRATED MEDICAL SCIENCES

Glomerulonephritis

A 42-year-old man was admitted to emergency with puffiness of his face, eyes, and trunk. He previously had a 3-month history of intermittent swelling of his ankles and puffiness of his face. Upon exertion, he became short of breath (dyspnea). On examination, he was hypertensive (BP 170/75). His urine showed proteinuria and hematuria with a red cell cast. He was anemic (Hb 10.7 g/dL). His serum albumin was low (2.6 g/dL), and his creatinine clearance was 80 mL/min (NR male: 97 to 137 mL/min.). His serum immunoglobulin IgM and IgA, C3, and C4 levels were normal, but his IgG was low at 5.1 g/L (NR 7.2 to 19.0). Hepatitis B surface antigen was not detected.

These findings are typical of glomerulonephritis, which is an inflammation of the glomeruli. The first indication of glomerular dysfunction is altered fluid retention (edema in abdomen and lower extremities), fatigue from anemia, and altered urine. The dyspnea is the result of pulmonary edema due to fluid retention and high blood pressure. Urine is foamy due to excess protein, and the pink color is from red cells in urine.

Glomerulonephritis can be acute (a sudden inflammatory attack) or chronic that comes on

gradually. Nearly all forms of acute glomerulonephritis tend to progress to the chronic stage. The condition is characterized by irreversible and progressive glomerular and tubulointerstitial fibrosis. The condition is triggered by an immunologic reaction causing inflammation and proliferation of glomerular tissue that damages the base membrane and capillary endothelium. The inflammation ultimately leads to a reduction in the glomerular filtration rate (GFR) and retention of uremic toxins. The low GFR was confirmed with the creatinine clearance test, which provides a good estimate of the GFR. If the progression of the disease is not halted, it leads to chronic kidney disease with severe cardiovascular complications.

The cause of glomerulonephritis is due either to an infection or to an immune disorder. The types of infection include poststreptococcal, bacterial endocarditis, or viral infection. Glomerulonephritis can occur a week or two after recovery from strep throat infection. To fight the streptococcal infection, the body produces extra antibodies that often settle in the glomeruli. If glomerulonephritis occurs on its own, it is known as primary glomerulonephritis. If another disease, such as lupus or diabetes, is the cause, it is called secondary glomerulonephritis. Poststreptococcal renal complications are more likely to occur in children. Bacterial endocarditis is the result of a bacterial infection that spreads through the bloodstream and lodging in the heart, causing infection in one or more of the heart valves. Although there is a connection between endocarditis and glomerular dysfunction, the exact mechanism is not clear. Viral infections, such as the human immunodeficiency virus (HIV) and hepatitis B and C, can trigger glomerulonephritis. Immunological diseases such as lupus and Goodpasture syndrome can trigger glomerulonephritis. Lupus is a chronic inflammatory disease that affects many organs, such as the skin, joints, kidneys, heart, lungs, and blood. Goodpasture syndrome is a rare immunological lung disorder that can mimic pneumonia and causes bleeding in the lungs and glomeruli. ■

Chapter Summary

- The formation of urine involves glomerular filtration, tubular reabsorption, and tubular secretion.
- The kidneys, especially the cortex, have a high blood flow.
- Kidney blood flow is autoregulated; it is also profoundly influenced by nerves and hormones.
- The glomerular filtrate is an ultrafiltrate of plasma.
- Glomerular filtration rate is determined by the glomerular ultrafiltration coefficient, glomerular capillary hydrostatic pressure, hydrostatic pressure in the space of the Bowman capsule, and glomerular capillary colloid osmotic pressure.
- The proximal convoluted tubule reabsorbs about 70% of filtered Na^+, K^+, and water and nearly all of the filtered glucose and amino acids. It also secretes many organic anions and organic cations.
- The transport of water and most solutes across tubular epithelia is dependent on active reabsorption of Na^+.
- The thick ascending limb is a water-impermeable segment that reabsorbs Na^+ via a Na–K–2Cl cotransporter in the apical cell membrane and a vigorous Na^+/K^+-ATPase in the basolateral cell membrane.
- The distal convoluted tubule epithelium is water impermeable and reabsorbs Na^+ via a thiazide-sensitive apical membrane Na–Cl cotransporter.
- Cortical collecting duct principal cells reabsorb Na^+ and secrete K^+.
- The kidneys save water for the body by producing urine with a total solute concentration (i.e., osmolality) greater than that of plasma.
- The loops of Henle are countercurrent multipliers; they set up an osmotic gradient in the kidney medulla. Vasa recta are countercurrent exchangers; they passively help maintain the medullary gradient. Collecting ducts are osmotic equilibrating devices; they have a low water permeability, which is increased by arginine vasopressin.
- The renal clearance of a substance is equal to its rate of excretion divided by its plasma concentration.
- Inulin clearance provides the most accurate measure of glomerular filtration rate.
- The clearance of *p*-aminohippurate is equal to the effective renal plasma flow.
- The rate of net tubular reabsorption of a substance is equal to its filtered load minus its excretion rate. The rate of net tubular secretion of a substance is equal to its excretion rate minus its filtered load.
- The urinary bladder stores urine until it can be conveniently emptied. Micturition is a complex act involving both autonomic and somatic nerves.

Chapter Review Questions

1. An elderly, diabetic woman arrives at the hospital in a severely dehydrated condition and is breathing rapidly. Blood plasma (glucose) is 500 mg/dL (normal is ~100 mg/dL) and the urine (glucose) is zero (dipstick test). What is the most likely explanation for the absence of glucose in her urine?

A. The amount of splay in the glucose reabsorption curve is abnormally increased.
B. GFR is abnormally low.
C. The glucose Tm is abnormally high.
D. The glucose Tm is abnormally low.
E. The renal plasma glucose threshold is abnormally low.

The correct answer is B. The patient is elderly and severely dehydrated, so one can expect that the GFR is low. As a consequence, the proximal tubules may be able to reabsorb all of the filtered glucose (because the filtered load is reduced), even though the plasma (glucose) is elevated. If splay is increased, glucose Tm is low, or threshold is low, then glucose should be present (not absent) from the urine. An abnormally high glucose Tm would reduce glucose excretion, but in the scenario presented, this is not a likely cause of the absence of glucose in the urine.

2. In a suicide attempt, a nurse took an overdose of the sedative phenobarbital. This substance is a weak, lipid-soluble organic acid that is reabsorbed by nonionic diffusion in the kidneys. Which of the following would be the best way to promote urinary excretion of this substance?

A. Abstain from all fluids.
B. Acidify the urine by ingesting NH_4Cl tablets.
C. Administer a drug that inhibits tubular secretion of organic anions.
D. Alkalinize the urine by infusing a $NaHCO_3$ solution intravenously.
E. Increase the GFR.

The correct answer is D. Excretion of phenobarbital is promoted by increasing urine output and by making the urine more alkaline. The latter would keep phenobarbital in its anionic form, which is not reabsorbed by the kidney tubules. Increasing the GFR would increase the filtration and excretion of phenobarbital but is much less effective than is reducing tubular reabsorption of this compound.

3. A man has progressive, chronic kidney disease. Which of the following indicates the greatest absolute decrease in GFR?

A. Fall in plasma creatinine from 4 to 2 mg/dL
B. Fall in plasma creatinine from 2 to 1 mg/dL
C. Rise in plasma creatinine from 1 to 2 mg/dL
D. Rise in plasma creatinine from 2 to 4 mg/dL
E. Rise in plasma creatinine from 4 to 8 mg/dL

The correct answer is C. There is an inverse hyperbolic relationship between plasma (creatinine) and GFR and, therefore, a rise in plasma (creatinine) is associated with a fall in GFR (see Fig. 22.7). The greatest absolute change in GFR occurs when plasma (creatinine) doubles starting from a normal GFR and plasma (creatinine).

Clinical Application Exercises 22.1

NEPHROTIC SYNDROME

A 6-year-old boy is brought to the pediatrician by his mother because of a puffy face and lethargy. A few weeks before, he had an upper respiratory tract infection, probably caused by a virus. Body temperature is 36.8°C, blood pressure 95/65 mm Hg, and heart rate 90 beats/min. Puffiness around the eyes, abdominal swelling, and pitting edema in the legs are observed. A urine sample (dipstick) is negative for glucose but reveals 3+ protein. Microscopic examination of the urine reveals no cellular elements or casts. Plasma [Na^+] is 140 mEq/L, blood urea nitrogen concentration (BUN) 10 mg/dL, glucose 100 mg/dL, creatinine 0.8 mg/dL, serum albumin 2.3 g/dL (normal 3.0 to 4.5 g/dL), and cholesterol 330 mg/dL. A 24-hour urine sample has a volume of 1.10 L and contains 10 mEq/L Na^+, 60 mg/dL creatinine, and 0.8 g/dL protein.

The child is treated with the corticosteroid prednisone, and the edema and proteinuria disappear in 2 weeks. Puffiness and proteinuria recur 4 months later, and a renal biopsy is done. Glomeruli are normal by light microscopy, but effacement (obliteration) of podocyte foot processes and loss of filtration slits are seen with the electron microscope. No immune deposits or complement are seen after immunostaining. The biopsy indicates minimal change glomerulopathy.

QUESTIONS

1. What features in this case would lead you to suspect the presence of nephrotic syndrome?
2. What is the explanation for the proteinuria?
3. Why does the abnormally high rate of urinary protein excretion underestimate the rate of renal protein loss?
4. What is the endogenous creatinine clearance, and is it normal? (The boy's body surface area is 0.86 m^5.)
5. What is the explanation for the edema?

ANSWERS

1. The child has the classical feature of nephrotic syndrome: heavy proteinuria (8.8 g/d), hypoalbuminemia (<3 g/dL), generalized edema, and hyperlipidemia (plasma cholesterol 330 mg/dL).
2. Proteinuria is a consequence of an abnormally high permeability of the glomerular filtration barrier to the plasma proteins. This condition might be due to an increased physical size of "holes" or pores in the basement membrane and filtration slit diaphragms or a loss of fixed negative charges from the glomerular filtration barrier.
3. Proteins that have leaked across the glomerular filtration barrier are not only excreted in the urine but are reabsorbed by proximal tubules. The endocytosed proteins are digested in lysosomes to amino acids, which are returned to the circulation. Both increased renal catabolism by tubule cells and increased excretion of serum albumin in the urine contribute to the hypoalbuminemia. The liver, which synthesizes serum albumin, cannot keep up with the renal losses.
4. The endogenous creatinine (CR) clearance (an estimate of GFR) equals $(U_{CR} \times V)/P_{CR} = (60 \times 1.10)/0.8 = 82$ L/d. Normalized to a standard body surface area of 1.73 m^5, C_{CR} is 166 L/d per 1.73 m^5, which falls within the normal range (150 to 210 L/d per 1.73 m^5). Note that the permeability of the glomerular filtration barrier to macromolecules (plasma proteins) was abnormally high, but permeability to fluid was not increased. In some patients, a loss of filtration

slits may be marked and may lead to a reduced fluid permeability and GFR.

5. The edema is due to altered capillary Starling forces and renal retention of salt and water. The decline in plasma (protein) lowers the plasma colloid osmotic pressure, favoring fluid movement out of the capillaries into the interstitial compartment. The edema is particularly noticeable in the soft skin around the eyes (periorbital edema). The abdominal distention (in the absence of organ enlargement) suggests ascites (an abnormal accumulation of fluid in the abdominal cavity). The kidneys avidly conserve Na^+ (note the low urine [Na^+]) despite an expanded extracellular fluid (ECF) volume. Although the exact reasons for renal Na^+ retention are controversial, a decrease in the effective arterial blood volume may be an important stimulus (see Chapter 23). This leads to activation of the renin–angiotensin–aldosterone system and stimulation of the sympathetic nervous system, both of which favor renal Na^+ conservation. In addition, distal segments of the nephron reabsorb more Na^+ than usual because of an intrinsic change in the kidneys.

23 Regulation of Fluid and Electrolyte Balance

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Discuss the interrelationships among the major fluid compartments of the body and contrast their relative volumes for an average young adult man and woman.
- Explain the indicator–dilution principle and its application to the measurement of body fluid volumes.
- Describe and contrast the ionic composition of extracellular and intracellular fluids.
- Explain how arginine vasopressin and thirst regulate water balance.
- Compare the amounts of sodium filtered and excreted in a day. Compare the percentage of filtered sodium reabsorbed by the proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting ducts.
- Explain how the following affect renal sodium excretion: glomerular filtration rate, the renin–angiotensin–aldosterone system, intrarenal pressure, natriuretic hormones and factors, renal sympathetic nerve stimulation, estrogens, glucocorticoids, osmotic diuretics, poorly reabsorbed anions, and diuretic drugs.
- Explain the relation between sodium chloride, extracellular fluid volume (or effective arterial blood volume), and blood pressure.
- Discuss the importance, amount, and distribution of potassium in the body.
- Explain the mechanisms that affect renal excretion of potassium.
- Explain how the kidneys contribute to calcium, magnesium, and phosphate balance.
- Explain the effects of parathyroid hormone on renal tubular reabsorption of calcium and phosphate and on renal synthesis of $1,25(OH)_2$ vitamin D_3.

The kidneys play a critical role in homeostasis through their ability to regulate the volume, osmolality, electrolyte concentration, and acid–base status of the extracellular fluid (ECF). The kidney accomplishes these homeostatic functions both independently and in concert with other organ systems, especially the neuroendocrine system. Endocrine hormones involved in coordinating these functions include angiotensin II, aldosterone, antidiuretic hormone (ADH), and atrial natriuretic peptide (ANP).

The kidney's ability to regulate the volume and composition of the ECF starts with its prodigious capacity to access plasma through the process of filtration. On a daily basis, the kidneys generate ~180 L of filtrate; the equivalent of filtering an adult's entire plasma volume about 60 times each day. Although a large percentage of the filtrate is reabsorbed by the kidney and retained in the body, about 2 L/d is excreted as urine. The kidney plays a critical role in the regulation of extracellular fluid volume, osmolality, and electrolyte balance. Maintaining the right balance of electrolytes such as Na^+, Ca^{2+}, K^+, and Cl^- is essential for cellular functions, such as neural transmission and muscle contraction. Furthermore, regulating electrolyte concentration is essential for maintaining osmotic balance in the body, which can vary due to alterations in the amount of water in the ECF, that is, due to dehydration or overhydration. These variations can happen with sweating, diarrhea, vomiting, medications, renal disease, or excessive water intake.

This chapter discusses the location, size, and composition of fluid compartments in the body as well as renal function related to sodium, potassium, calcium, magnesium, and phosphate balance.

FLUID COMPARTMENTS OF THE BODY

There are two main fluid compartments in the human body: **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. The ICF compartment makes up ~60% to 67% of body water, and the ECF compartment makes up the other 33% to 40%. Water is the major solvent of all body fluid compartments. **Total body water** averages about 60% of body weight in young adult men and about 55% of body weight in young adult women (Table 23.1). The amount of adipose tissue (fat) a person has affects the percentage of body weight that water occupies. Adipose tissue contains a lower percentage of water (about 10%) than other tissues (e.g., muscle is about 75% water). Thus, an obese person has a lower percentage of body weight that is water than a lean person. Nonobese adult women have relatively less total body water than men, because, on average, they have more subcutaneous fat and less muscle mass. As people age, they tend to lose muscle and add adipose tissue; hence, water content declines with age. In contrast, newborns have a high percentage of body weight as water because of a relatively large ECF volume and little fat.

TABLE 23.1 Average Total Body Water and Its Distribution as a Percentage of Body Weight*

Total Body Water	Distribution of Total Body Water
Adult female = 55%	Intracellular = 30%; extracellular = 25%
Adult male = 60%	Intracellular = 33%; extracellular = 27%

*Based on an average young adult weighing 70 kg. Extracellular = fast + slow compartments.

Total body water is distributed between intracellular fluid and extracellular fluid compartments.

Total body water can be divided into ICF and ECF. ICF is found inside the bilayered cell plasma membrane. It is the medium in which cellular organelles are suspended and where many chemical reactions take place. Under normal circumstances, ICF is in osmotic equilibrium with the ECF.

The volume of fluid in the ICF is slightly greater than that in the ECF (see Table 23.1). However, these two fluids differ strikingly in terms of their electrolyte composition. Their total solute concentrations and thus osmolalities, however, are normally equal, because of the high water permeability of most cell membranes. Consequently, a momentary osmotic difference between cells and the ECF rapidly disappears.

The ECF is composed of fluid outside of the cells and consists of three subdivisions: the *interstitial compartment*, the *plasma compartment*, and the *third space*, or *transcellular, compartment*. The *interstitial compartment* is the fluid space that surrounds the cells of a given tissue. It is filled with interstitial fluid and comprises about 45% by volume of the ECF. Interstitial fluid provides the microenvironment that allows for movement of ions, proteins, and nutrients across the cell membrane. The fluid is not static but is continuously being turned over and recollected by the lymphatic channels. When excess fluid accumulates in the interstitial compartment, **edema** develops. The *intravascular plasma* is found within the vascular system and comprises ~18% by volume of the ECF (about 3.5 L for the average 70-kg male). The *third space* is part of the ECF compartment (~38%) where fluids are not easily exchangeable with other body water compartments. These fluids are sometimes called **transcellular fluids**. Major examples of such fluids include peritoneal fluid, pleural fluid, cerebrospinal fluid, digestive tract fluid, synovial fluid, renal tubular fluid, and aqueous humor. The collective volume of all transcellular fluids is only about 7 L, but these fluids are physiologically important (i.e., it functions as a lubricant in the pleural space and the fluid surrounding joints). There is a constant turnover of transcellular fluids; they are continuously formed and absorbed or removed. Impaired formation, abnormal loss from the body, or blockage of fluid removal can have serious consequences (e.g., hydrocephalus from excess fluid in the cerebral ventricles).

Indicator–dilution method measures fluid compartment size.

The **indicator–dilution method** can be used to determine the size of body fluid compartments. A known amount of a substance (the indicator), which should be confined to the compartment of interest, is administered. After allowing sufficient time for uniform distribution of the indicator throughout the compartment (e.g., total body water, ECF, or plasma), a plasma sample is collected. At equilibrium, the concentration of the indicator will be the same in the entire compartment, including the plasma. The plasma concentration is measured, and the distribution volume is calculated from this formula:

$$\text{Volume} = \frac{\text{Amount of indicator}}{\text{Concentration of indicator}} \quad (1)$$

If indicator was lost from the fluid compartment, the amount lost is subtracted from the amount administered.

To measure total body water, heavy water (deuterium oxide [D_2O]), tritiated water (HTO), or antipyrine (a drug that distributes throughout all of the body water) is used as an indicator. For example, suppose we want to measure total body water in a 60-kg woman, we inject 30 mL of D_2O as an isotonic saline solution into an arm vein. After a 2-hour equilibration period, a blood sample is withdrawn, and the plasma is separated and analyzed for D_2O. A concentration of 0.001 mL D_2O/mL plasma water is found. Suppose that, during the equilibration period, urinary, respiratory, and cutaneous losses of D_2O are 0.12 mL. Substituting these values into the indicator–dilution equation, we get: total body water = (30 to 0.12 mL D_2O) ÷ 0.001 mL D_2O/mL water = 29,880 mL or 30 L. Therefore, total body water as a percentage of body weight equals 50% in this woman.

To measure extracellular water volume, the ideal indicator should distribute rapidly and uniformly outside the cells and should not enter the cell compartment. Unfortunately, there is no such ideal indicator, and so the exact volume of the ECF cannot be measured. A reasonable estimate, however, can be obtained using two different classes of substances: impermeant ions and inert sugars. ECF volume has been determined from the volume of distribution of these ions: radioactive Na^+, radioactive Cl^-, radioactive sulfate, thiocyanate (SCN^-), and thiosulfate ($S_2O_3^{2-}$) of which radioactive sulfate ($^{35}SO_4^{2-}$) is probably the most accurate. However, ions are not completely impermeant; they slowly enter the cell compartment, and so measurements tend to lead to an overestimate of ECF volume. Measurements with inert sugars (such as mannitol, sucrose, and inulin) tend to lead to an underestimate of ECF volume, because they are excluded from some of the extracellular water—for example, the water in dense connective tissue and cartilage. In addition, special techniques are required when using these sugars because the kidneys rapidly filter and excrete them after their intravenous injection.

Cellular water cannot be determined directly with any indicator. It can, however, be calculated from the difference between measurements of total body water and extracellular water. The plasma water of the ECF is determined by using Evans blue dye, which avidly binds serum albumin, or radioiodinated serum albumin, and by collecting and analyzing a blood plasma sample. In effect, the plasma volume is measured from the distribution volume of serum albumin. The assumption is that serum albumin is

completely confined to the vascular compartment, but this is not entirely true. Indeed, serum albumin is slowly (3% to 4% per hour) lost from the blood by diffusive and convective transport through capillary walls. To correct for this loss, repeated blood samples can be collected at timed intervals, and the concentration of albumin at time zero (the time at which no loss would have occurred) can be determined by extrapolation. Alternatively, the plasma concentration of indicator 10 minutes after injection can be used; this value is usually close to the extrapolated value. If plasma volume and hematocrit are known, total circulating blood volume can be calculated. Unlike plasma volume, the other major component of the ECF, interstitial fluid and lymph volume, cannot be determined directly but can be calculated from the difference between ECF and plasma volumes.

Plasma and intracellular fluid composition are markedly different.

Body fluids contain many uncharged molecules (e.g., glucose and urea), but quantitatively speaking, **electrolytes** (ionized substances) contribute most to the total solute concentration and the effective osmolality of body fluids. Effective osmolality (i.e., the osmolality due to solutes that do not easily passively cross the cell membrane) is of prime importance in determining the distribution of water between ICF and ECF compartments.

The importance of ions (particularly Na^+) in determining the total plasma osmolality (P_{osm}) is exemplified by an equation that is of value in the clinic:

$$P_{osm} = 2 \times [Na^+] + \frac{[\text{glucose}] \text{ in mg/dL}}{18} + \frac{[\text{blood urea nitrogen}] \text{ in mg/dL}}{2.8} \quad (2)$$

If the plasma Na^+ level is 140 mmol/L, blood glucose level is 100 mg/dL (5.6 mmol/L), and blood urea nitrogen level is 10 mg/dL (3.6 mmol/L), then the calculated osmolality is 289 mOsm/kg H_2O. The equation indicates that Na^+ and its accompanying anions (mainly Cl^- and HCO_3^-) normally account for more than 95% of the plasma osmolality. In some special circumstances (e.g., alcohol intoxication), plasma osmolality calculated from the above equation may be much lower than the measured osmolality because of the presence of solutes other than sodium salts, glucose, and urea (e.g., ethanol).

The concentrations of various electrolytes in plasma and ICF are summarized in Table 23.2. The ICF values are based on determinations made in skeletal muscle cells. These cells account for about two thirds of the cell mass in the human body. Concentrations are expressed in terms of milliequivalents (mEq) per kilogram H_2O.

TABLE 23.2 Electrolyte Composition of Body Fluids

Electrolyte	Plasma Concentration (mEq/kg H_2O)	Intracellular Fluid* (mEq/kg H_2O)
Cations		
Na^+	153	10
K^+	4.2	159
Ca^{2+}	5.4	1
Mg^{2+}	2.2	40
Total	165	210
Anions		
Cl^-	111	3
HCO_3^-	27	7
Proteins	18	45
Others	9	155
Total	165	210

*Based on skeletal muscle cells.

An **equivalent** contains one mole of univalent ions, and a **milliequivalent (mEq)** is 1/1,000th of an equivalent. Equivalents are calculated as the product of moles times valence and represent the concentration of charged species. For singly charged (univalent) ions, such as Na^+, K^+, Cl^-, or HCO_3^-, 1 mmol is equal to 1 mEq. For doubly charged (divalent) ions, such as Ca^{2+}, Mg^{2+}, or SO_4^{2-}, 1 mmol is equal to 2 mEq. Some electrolytes, such as proteins, are polyvalent, and so there are several mEq per mmol. Sodium is the major cation in plasma, and Cl^- and HCO_3^- are the major anions. The plasma proteins (mainly serum albumin) bear net negative charges at physiologic pH. The electrolytes are actually dissolved in the plasma water, and so the values in Table 23.2 are expressed as concentrations

per kilogram H_2O. The water content of plasma is usually about 93%; about 7% of plasma volume is occupied by solutes, mainly the plasma proteins. Interstitial fluid is an ultrafiltrate of plasma. It contains all of the small electrolytes in essentially the same concentration as in plasma, but little protein. The proteins are largely confined to the plasma because of their large molecular size.

ICF composition (see Table 23.2) is different from plasma. The cells have higher K^+, Mg^{2+}, and protein concentrations than plasma. The intracellular Na^+, Ca^{2+}, Cl^-, and HCO_3^- levels are lower. The anions in skeletal muscle cells labeled "Others" are mainly organic phosphate compounds important in cell energy metabolism, such as creatine phosphate, adenosine triphosphate (ATP), and adenosine diphosphate (ADP). As described in Chapter 2, the high intracellular K^+ level and low intracellular Na^+ level are a consequence of plasma membrane Na^+/K^+-ATPase activity; this enzyme extrudes Na^+ from the cell and takes up K^+. The low intracellular Cl^- and HCO_3^- in skeletal muscle cells are primarily a consequence of the inside negative membrane potential (−90 mV), which favors the outward movement of these small negatively charged ions. The intracellular Mg^{2+} is high; most is not free but is bound to cell proteins. Intracellular Ca^{2+} is low; as discussed in Chapter 1, the cytosolic Ca^{2+} in resting cells is about 10^{-7} M (0.0002 mEq/L). Most of the cell Ca^{2+} is sequestered in organelles, such as the sarcoplasmic reticulum in skeletal muscle.

Changes in extracellular fluid osmolality cause changes in intracellular volume.

Despite the different compositions of ICF and plasma, the total solute concentration and osmolality of these two fluid compartments is normally the same. ICF and plasma are in osmotic equilibrium because the high water permeability of cell membranes prevents a sustained difference in osmolality. If the osmolality changes in one compartment, water moves so as to restore a new osmotic equilibrium (see Chapter 2).

The volumes of ICF and ECF depend primarily on the volume of water present in these compartments. But the latter depends on the amount of solute present and its osmolality. This fact follows from the definition of the term *concentration:* concentration = amount/volume; hence, volume = amount/concentration. The main osmotically active solute in cells is K^+; therefore, a loss of cell K^+ will cause cells to lose water and shrink (see Chapter 2). The main osmotically active solute in the ECF is Na^+; therefore, a gain or loss of Na^+ from the body will cause the ECF volume to swell or shrink, respectively.

The distribution of water between intracellular and extracellular compartments changes in various circumstances. However, it is important to recognize that, when such changes occur, the transcellular fluid compartments come into osmotic and volume equilibrium markedly slower than those comprising the intracellular fluid, plasma, and interstitial fluid. The transcellular fluid makes up about 17.5% of total body water by volume, and because of its slow equilibrating properties, it is sometimes called the *slow extracellular fluid compartment*. The remaining extracellular fluid compartments (plasma and interstitial fluid) can quickly equilibrate with the ICF. They are often called collectively the *fast extracellular fluid compartment* and comprise about 27.5% of the total body water. For practical homeostatic purposes, 82.5% of the total body water (55% for the ICF and 27.5% for the fast ECF) participates in rapid moment-to-moment changes in volume and osmolality between the ICF and ECF. The division of water between the ICF and the fast ECF is thus roughly two third for the ICF and one third for the ECF. Figure 23.1 provides some examples of changes in the ICF and fast ECF. For this illustration, total body water is divided into the two major rapidly equilibrating compartments, ICF and the combined plasma and interstitial compartments (simply called ECF for this illustration). The *y*-axis represents total solute concentration, and the *x*-axis represents the volume; the area of a box (concentration times volume) gives the amount of solute present in a compartment. Note that the height of the boxes is always equal because osmotic equilibrium maintained between these two divisions of total body water.

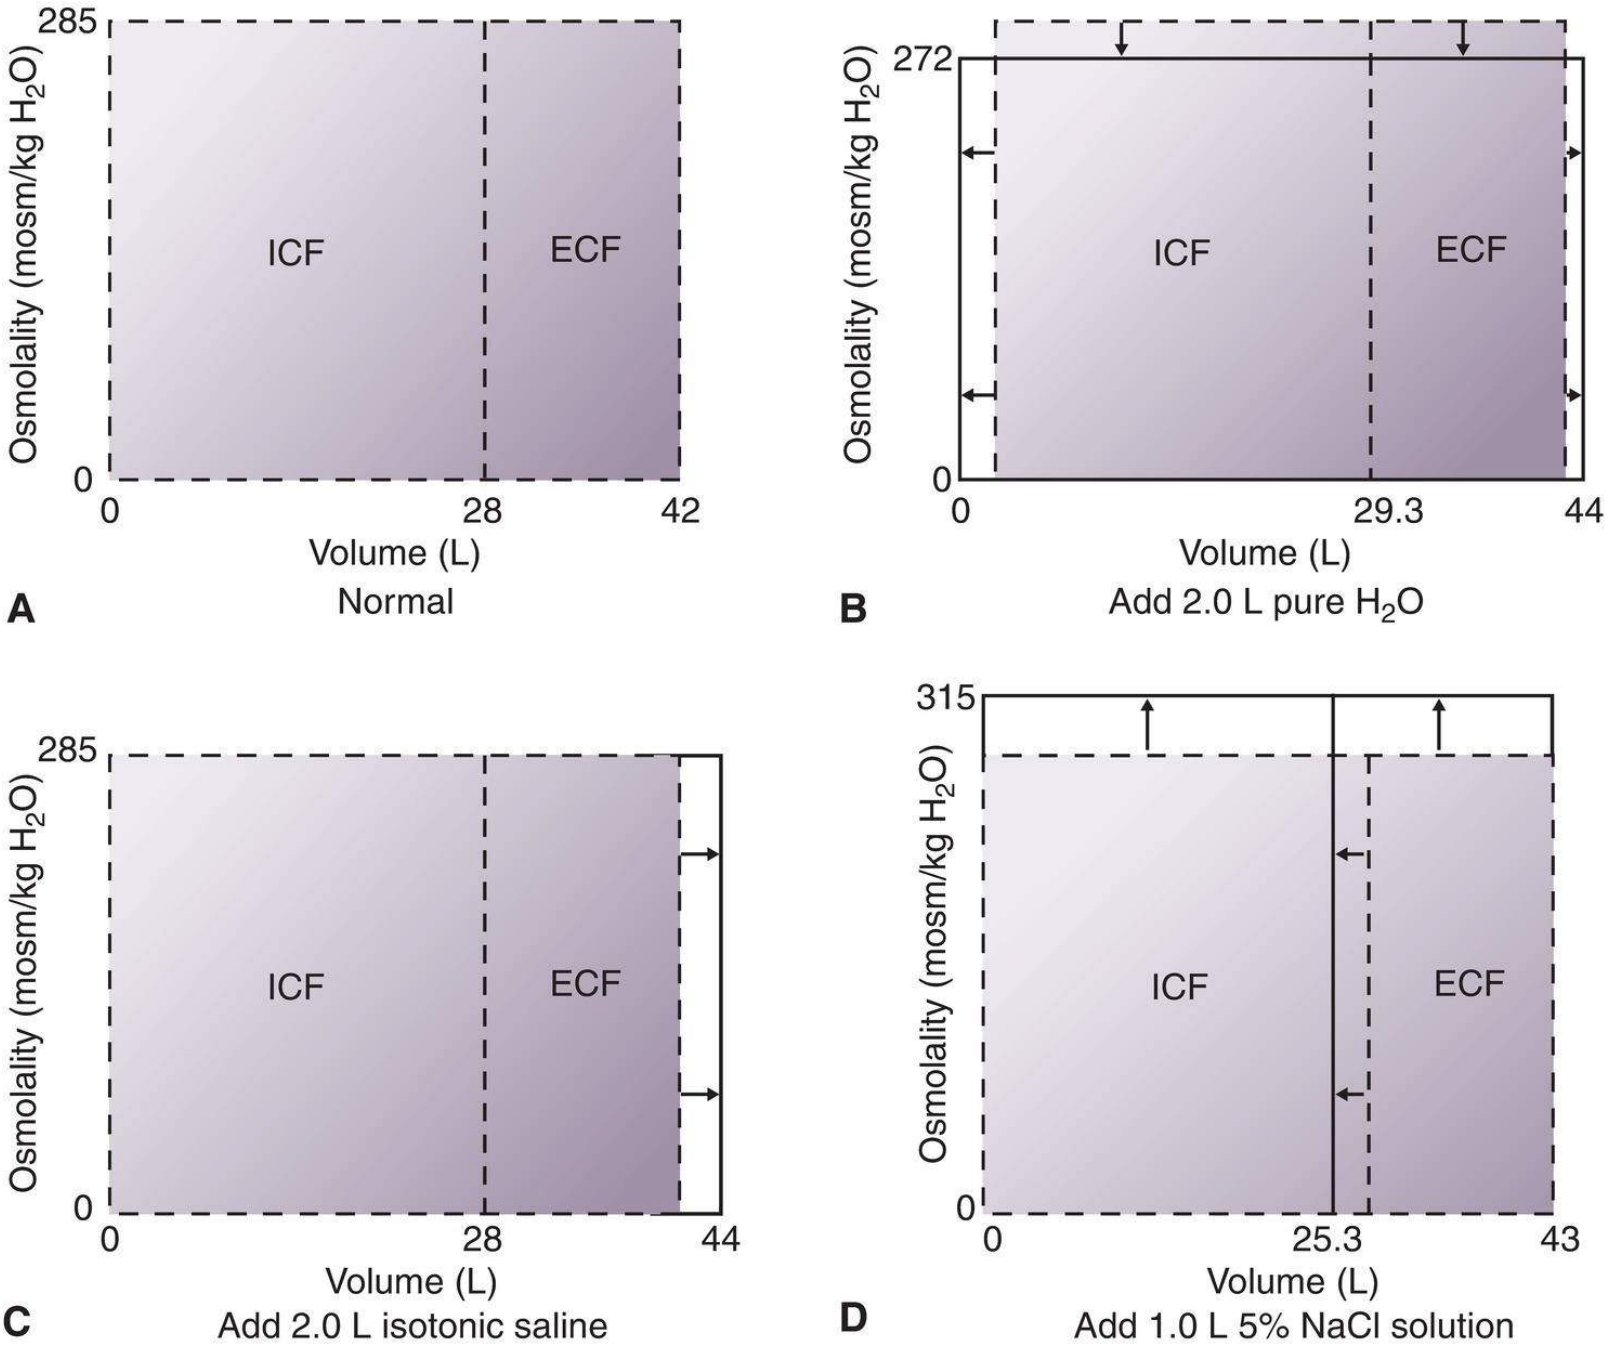

Figure 23.1 The effects of various disturbances on the osmolalities and volumes of intracellular fluid (ICF) and extracellular fluid (ECF). The *dashed lines* indicate the normal condition, and the *solid lines*, the situation after a new osmotic equilibrium has been attained. (See text for details.)

In the normal situation (shown in Fig. 23.1A), two thirds (28 L for a 70-kg man) of rapidly equilibrating total body water is in the ICF and one third (14 L) is in the ECF. The osmolality of both fluids is 285 mOsm/kg H_2O. Hence, the cell compartment contains 7,980 mOsm and the ECF contains 3,990 mOsm.

In Figure 23.1B, 2 L of pure water was added to the ECF (e.g., by drinking water). Plasma osmolality is thereby lowered initially, and water moves into the cell compartment along the osmotic gradient. The entry of water into the cells causes them to swell, and intracellular osmolality falls until a new equilibrium (*solid lines*) is achieved. Because 2 L of water was added to an original total body water volume of 42 L, the new total body water volume is 44 L. No solute was added, and so the new osmolality at equilibrium is (7,980 + 3,990 mOsm)/44 kg = 272 mOsm/kg H_2O. The volume of the ICF at

equilibrium is calculated by solving the following equation: 272 mOsm/kg H_2O × volume = 7,980 mOsm, or 29.3 L. The volume of the ECF at equilibrium is 14.7 L. From these calculations, we conclude that two thirds of the added water ends up in the cell compartment and one third stays in the ECF. Stated another way, addition of pure water to the total system distributed in proportion to the relative volume of the two compartments involved (two third of the 2 L to the ICF and one third to the ECF). Note that this description of events is somewhat artificial because in reality the kidneys would excrete the added water over the course of a few hours, thereby minimizing the fall in plasma osmolality and cell swelling.

In Figure 23.1C, 2 L of isotonic saline (0.9% NaCl solution) was added to the ECF. Isotonic saline is isosmotic to plasma or ECF and, by definition, can cause no change in cell volume. Furthermore, the sodium and chloride in the solution are effectively excluded from the intravascular compartment by the sodium/potassium ATPase pumps in the cell membranes and the low passive permeability of the membrane to sodium. Therefore, all of the added isotonic saline is retained in the ECF, and there is no change in osmolality.

Figure 23.1D shows the effect of intravenously infusing 1 L of a 5% NaCl solution (osmolality about 1,580 mOsm/kg H_2O). All the salt stays in the ECF. This exposes the cells to a hypertonic environment and thus water leaves the cells; the solutes left behind become more concentrated as water leaves. A new equilibrium will be established, with the final osmolality higher than normal but equal inside and outside of the cells. The final osmolality can be calculated from the amount of solute present (7,980 + 3,990 + 1,580 mOsm) divided by the final volume (28 + 14 + 1 L), which equals 315 mOsm/kg H_2O. The final volume of the ICF equals 7,980 mOsm divided by 315 mOsm/kg H_2O, or 25.3 L, which is 2.7 L less than the initial volume. The final volume of the ECF is 17.7 L, which is 3.7 L more than its initial value. Thus, the addition of hypertonic saline to the ECF led to its considerable expansion, in large part because of loss of water from the cell compartment.

FLUID BALANCE

Homeostatic fluid balance is dependent on maintaining a balance between input and output. Regulation of fluid balance involves both the control of ECF volume and ECF osmolality. Osmolality is the measure of solute particle concentration and is defined as the number of osmoles (Osm) of solute per kilogram of water (Osm/kg), whereas *osmolarity* is a measure of the osmoles of solute per liter of solution (Osm/L). These values are roughly equivalent in our body. The kidneys control ECF volume by regulating salt balance and control ECF osmolality by regulating water balance. As a result of these homeostatic mechanisms, body fluid volumes and plasma osmolality are kept remarkably constant.

Maintenance of extracellular fluid osmolality requires water input to equal its output.

A balance chart for water for an average 70-kg man is presented in Table 23.3. The person is in a stable balance (or steady state) when the total input and total output of water from the body are equal (about 2,000 mL/d). On the input side, water is found in the beverages we drink and in the foods we eat. Solid foods, which consist of animal or vegetable matter are, like our own bodies, mostly water. Water of oxidation is produced during metabolism; for example, when 1 mol of glucose is oxidized, 6 mol of water are produced. In a hospital setting, the input of water resulting from intravenous infusions would also need to be considered. On the output side, losses of water occur via the skin, lungs, gastrointestinal (GI) tract, and kidneys. We always lose water by simple evaporation from the skin and lungs; this is called **insensible water loss**.

TABLE 23.3 Typical Daily Water Inputs and Outputs (70-kg Male) and Common Abnormal Conditions Affecting Water Balance

Normal Inputs	Normal Outputs
Liquid consumption 1–2 L (up to 20 L)	Transpiration through skin, loss through exhalation 0.8–1 L
Water in food 0.8–1 L	Sweat 0.2 L
Oxidative metabolism 0.3–0.4 L	Fecal loss 0.2 L
	Renal output 1–2 L (up to 20 L)
Abnormal Water Gains	**Abnormal Water Losses**
Congestive heart failure	Diarrhea (can be as high as 5 L): vomiting; severe sweating (~10 L)
Renal failure	Hemorrhage
High sodium intake	Diuretics
Cirrhosis of the liver	Excessive urination (e.g., diabetes, excessive alcohol consumption).
Overinfusion of intravenous fluids	

Appreciable water loss from the skin, in the form of sweat, occurs at high temperatures or with heavy exercise. As much as 4 L of water per hour can be lost in sweat. Sweat, is a hypo-osmotic fluid that contains NaCl; excessive sweating can lead to significant losses of salt. GI losses of water are normally small (see Table 23.3), but with diarrhea, vomiting, or drainage of GI secretions, massive quantities of water and electrolytes may be lost from the body.

The kidneys are the sites of adjustment of water output from the body. Renal water excretion changes to maintain balance. If there is a water deficiency, the kidneys diminish the excretion of water and urine output falls. If there is water excess, the kidneys increase water excretion and urine flow, to remove the extra water. The renal excretion of water is controlled by **arginine vasopressin (AVP)**, which is also called **antidiuretic hormone** or **ADH**.

The water needs of an infant or young child, per kilogram body weight, are several times higher than

those of an adult. Children have, for their body weight, a larger body surface area and higher metabolic rate. As such they are much more susceptible to volume depletion.

AVP control of water balance is critical in regulating extracellular fluid osmolality.

AVP is a nonapeptide that is synthesized in hypothalamus, then transported via axons, and released from the posterior pituitary into the blood (see Chapter 31). As shown in Figure 23.2, the hormone travels by axoplasmic flow down the hypothalamic–neurohypophyseal tract and is stored in vesicles in nerve terminals in the median eminence and, mostly, the posterior pituitary. Action potentials reaching these nerve terminals release AVP, which then diffuses into nearby capillaries. The hormone is then carried by the bloodstream to the collecting ducts of the kidneys, where it increases water reabsorption (see Chapter 22).

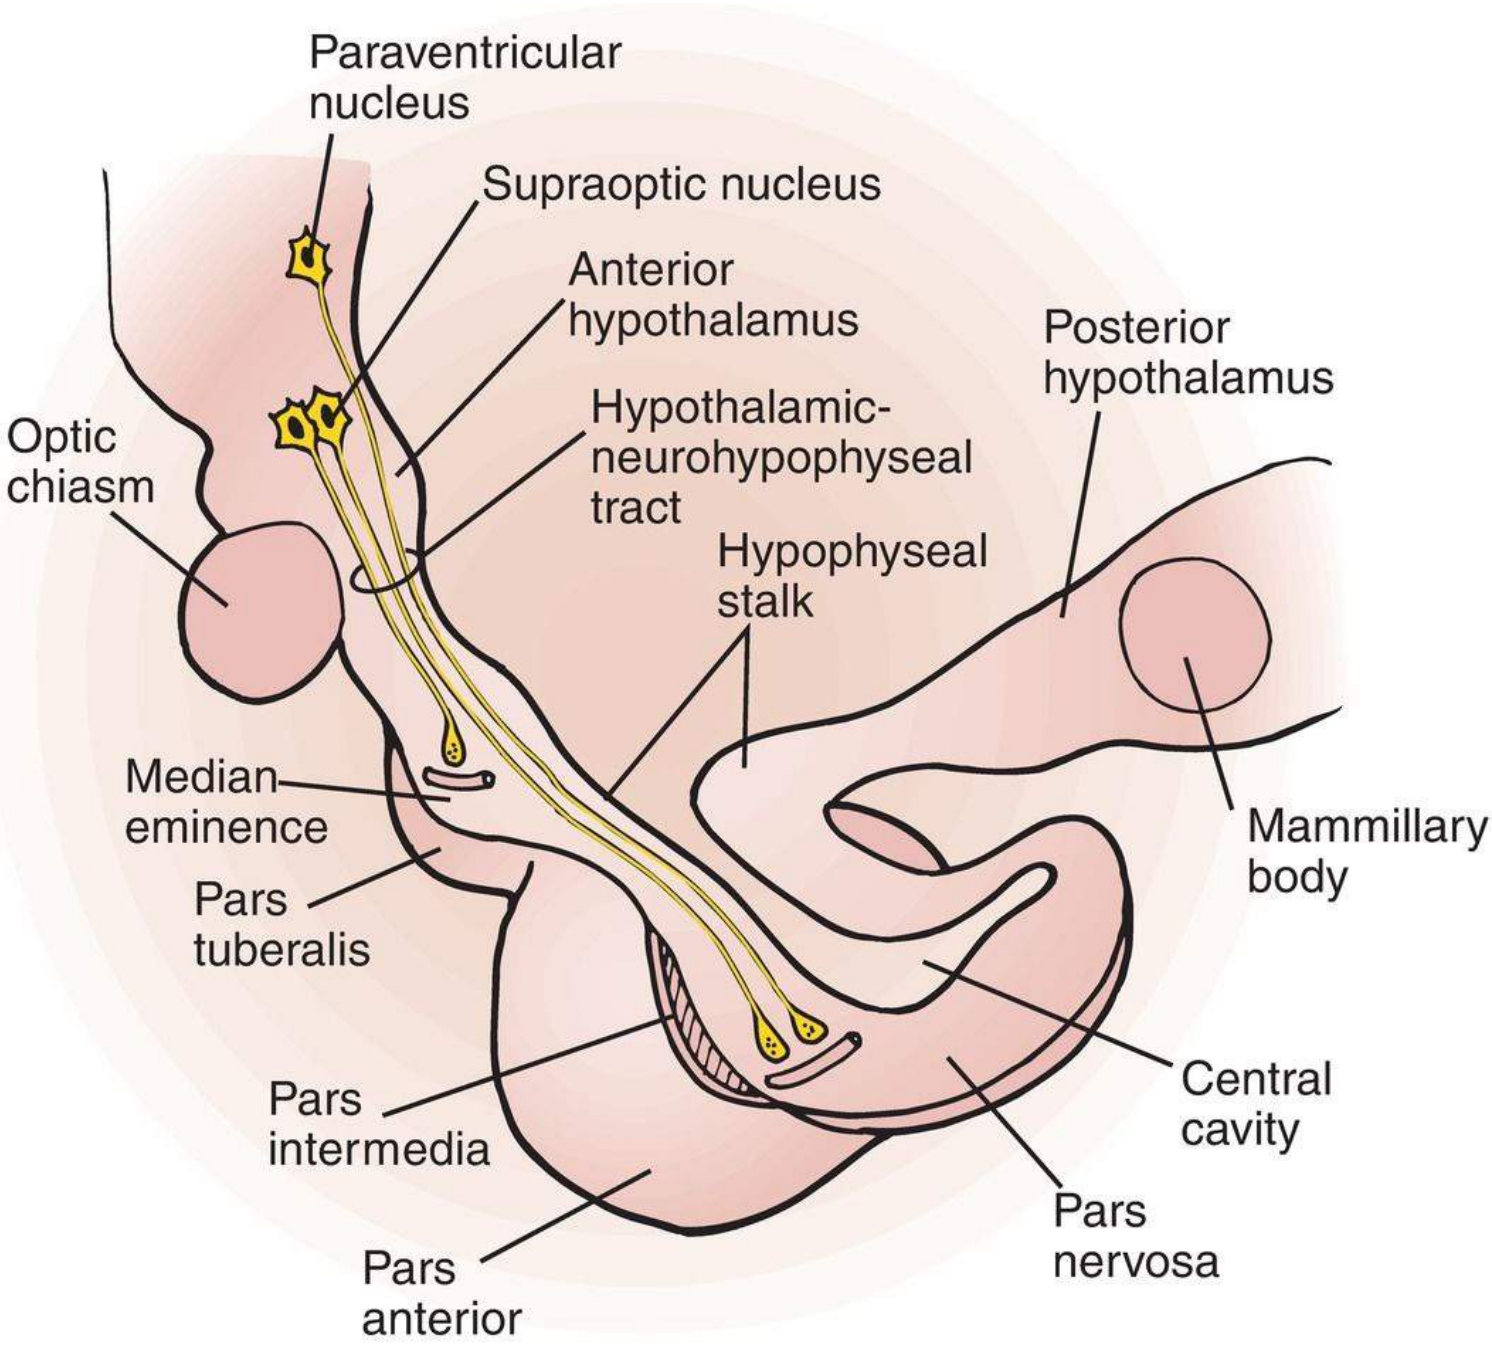

Figure 23.2 The pituitary and hypothalamus. Arginine vasopressin (AVP) is synthesized primarily in the supraoptic nucleus and to a lesser extent in the paraventricular nuclei in the anterior hypothalamus. It is then transported down the hypothalamic–neurohypophyseal tract and stored in vesicles in the median

eminence and posterior pituitary (pars nervosa), where it can be released into the blood.

Many factors increase the release of AVP, including pain, trauma, emotional stress, nausea, fainting, most anesthetics, nicotine, morphine, and angiotensin II. These conditions or agents therefore produce a decline in urine output and more concentrated urine. Ethanol and ANP decrease AVP release, leading to the excretion of a large volume of dilute urine.

The main mechanism controlling AVP release under ordinary circumstances is a change in plasma osmolality. Figure 23.3 shows how plasma AVP concentrations vary as a function of plasma osmolality. When plasma osmolality rises, neurons called **osmoreceptor cells**, located in the anterior hypothalamus, shrink. This stimulates the nearby neurons in the paraventricular and supraoptic nuclei to release AVP, and plasma AVP concentration rises. The result is the formation of osmotically concentrated urine by reabsorbing water from the collecting ducts back into the ECF. This reabsorption of solute-free water helps reduce the originally elevated plasma osmolality. It is important for students to understand that not all solutes are equally effective in stimulating the osmoreceptor cells. For example, cell membranes are permeable to urea, and urea is thus an ineffective osmole at hypothalamic osmoreceptors. Urea can enter these cells and therefore does not cause the osmotic withdrawal of water needed to shrink the cells and stimulate AVP release. Only solutes that cannot or do not rapidly cross the osmoreceptor cell membrane are able to change the volume of the osmoreceptor cells and thus affect AVP release. These solutes are called *effective* osmoles. Extracellular Na^+ and Cl^- are effective osmoles and thus stimulate AVP release.

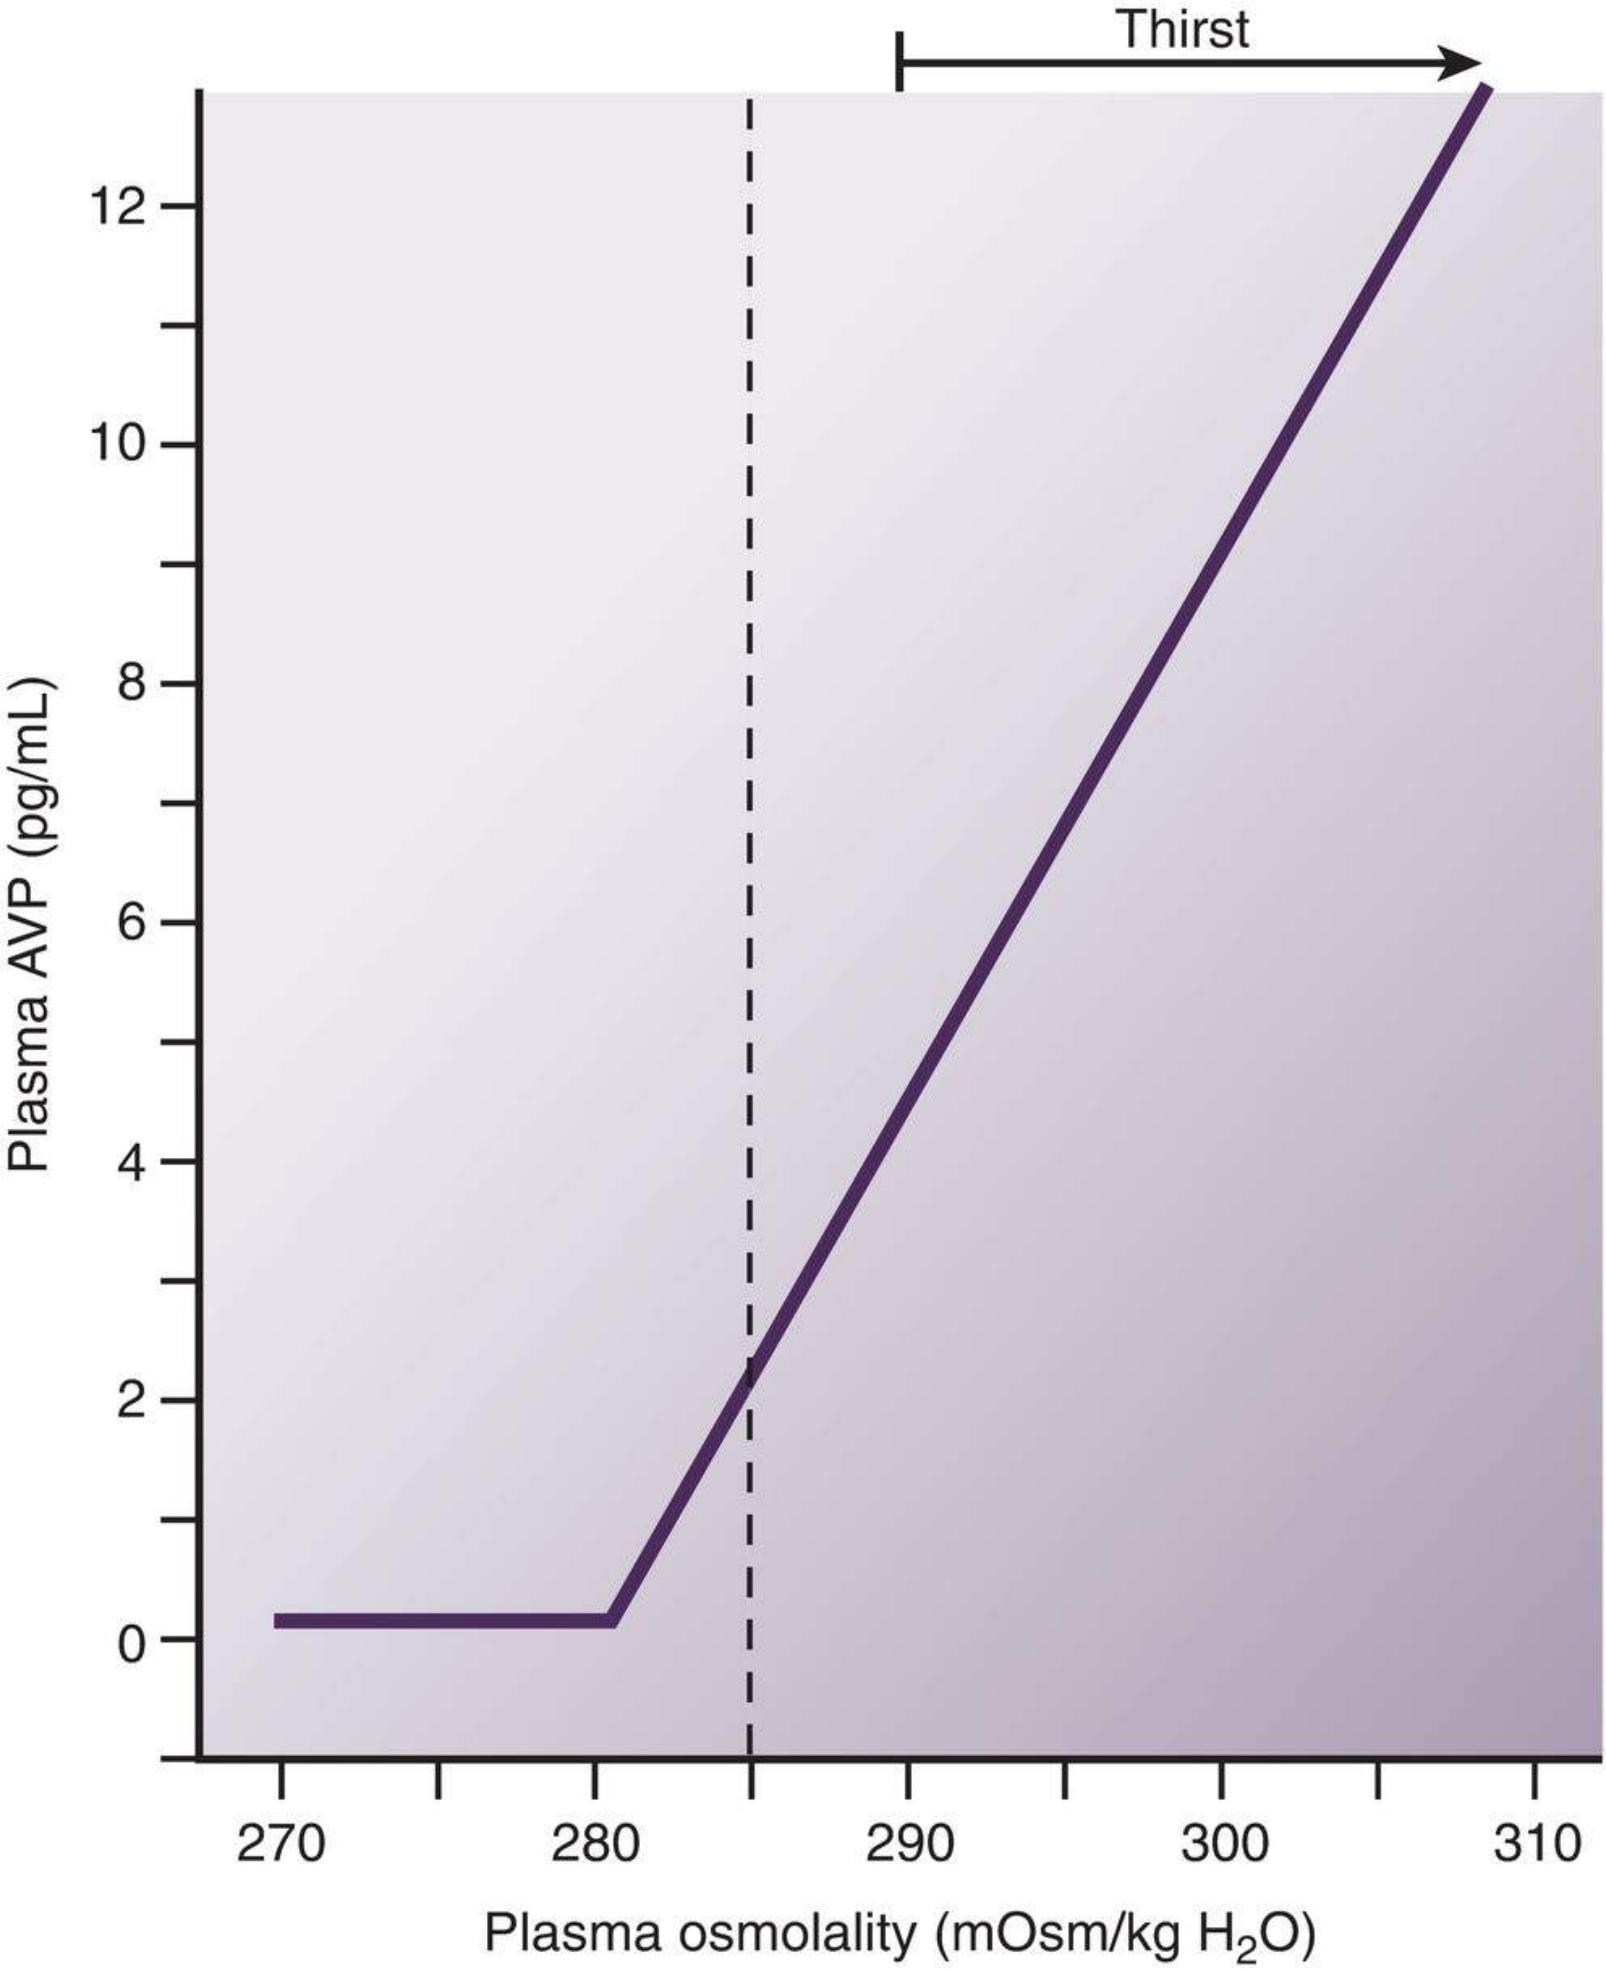

Figure 23.3 The relationship between plasma arginine vasopressin (AVP) level and plasma osmolality in healthy people. Decreases in plasma osmolality were produced by drinking water and

increases by fluid restriction. Plasma AVP levels were measured by radioimmunoassay. The plasma AVP level is essentially zero at plasma osmolalities <280 mOsm/kg H_2O. Above this plasma osmolality (threshold), plasma AVP increases linearly with plasma osmolality. Normal plasma osmolality averages about 285 mOsm/kg H_2O (*dashed vertical line*) and so we live above the threshold for AVP release. The thirst threshold is attained at a plasma osmolality of 290 mOsm/kg H_2O; the thirst mechanism is activated only when there is an appreciable water deficit. Changes in plasma AVP and consequent changes in renal water excretion are normally capable of maintaining a normal plasma osmolality below the thirst threshold.

When plasma osmolality falls in response to the addition of excess water, osmoreceptor cells swell, AVP release is inhibited, and plasma AVP levels fall. In this situation, the collecting ducts express their intrinsically low water permeability, less water is reabsorbed, a dilute urine is excreted (i.e., less water is reabsorbed by the collecting ducts back into the body) and plasma osmolality can be restored to normal by elimination of the excess water. Figure 23.4 shows that the entire range of urine osmolalities, from dilute to concentrated urine, is a linear function of plasma AVP in healthy people.

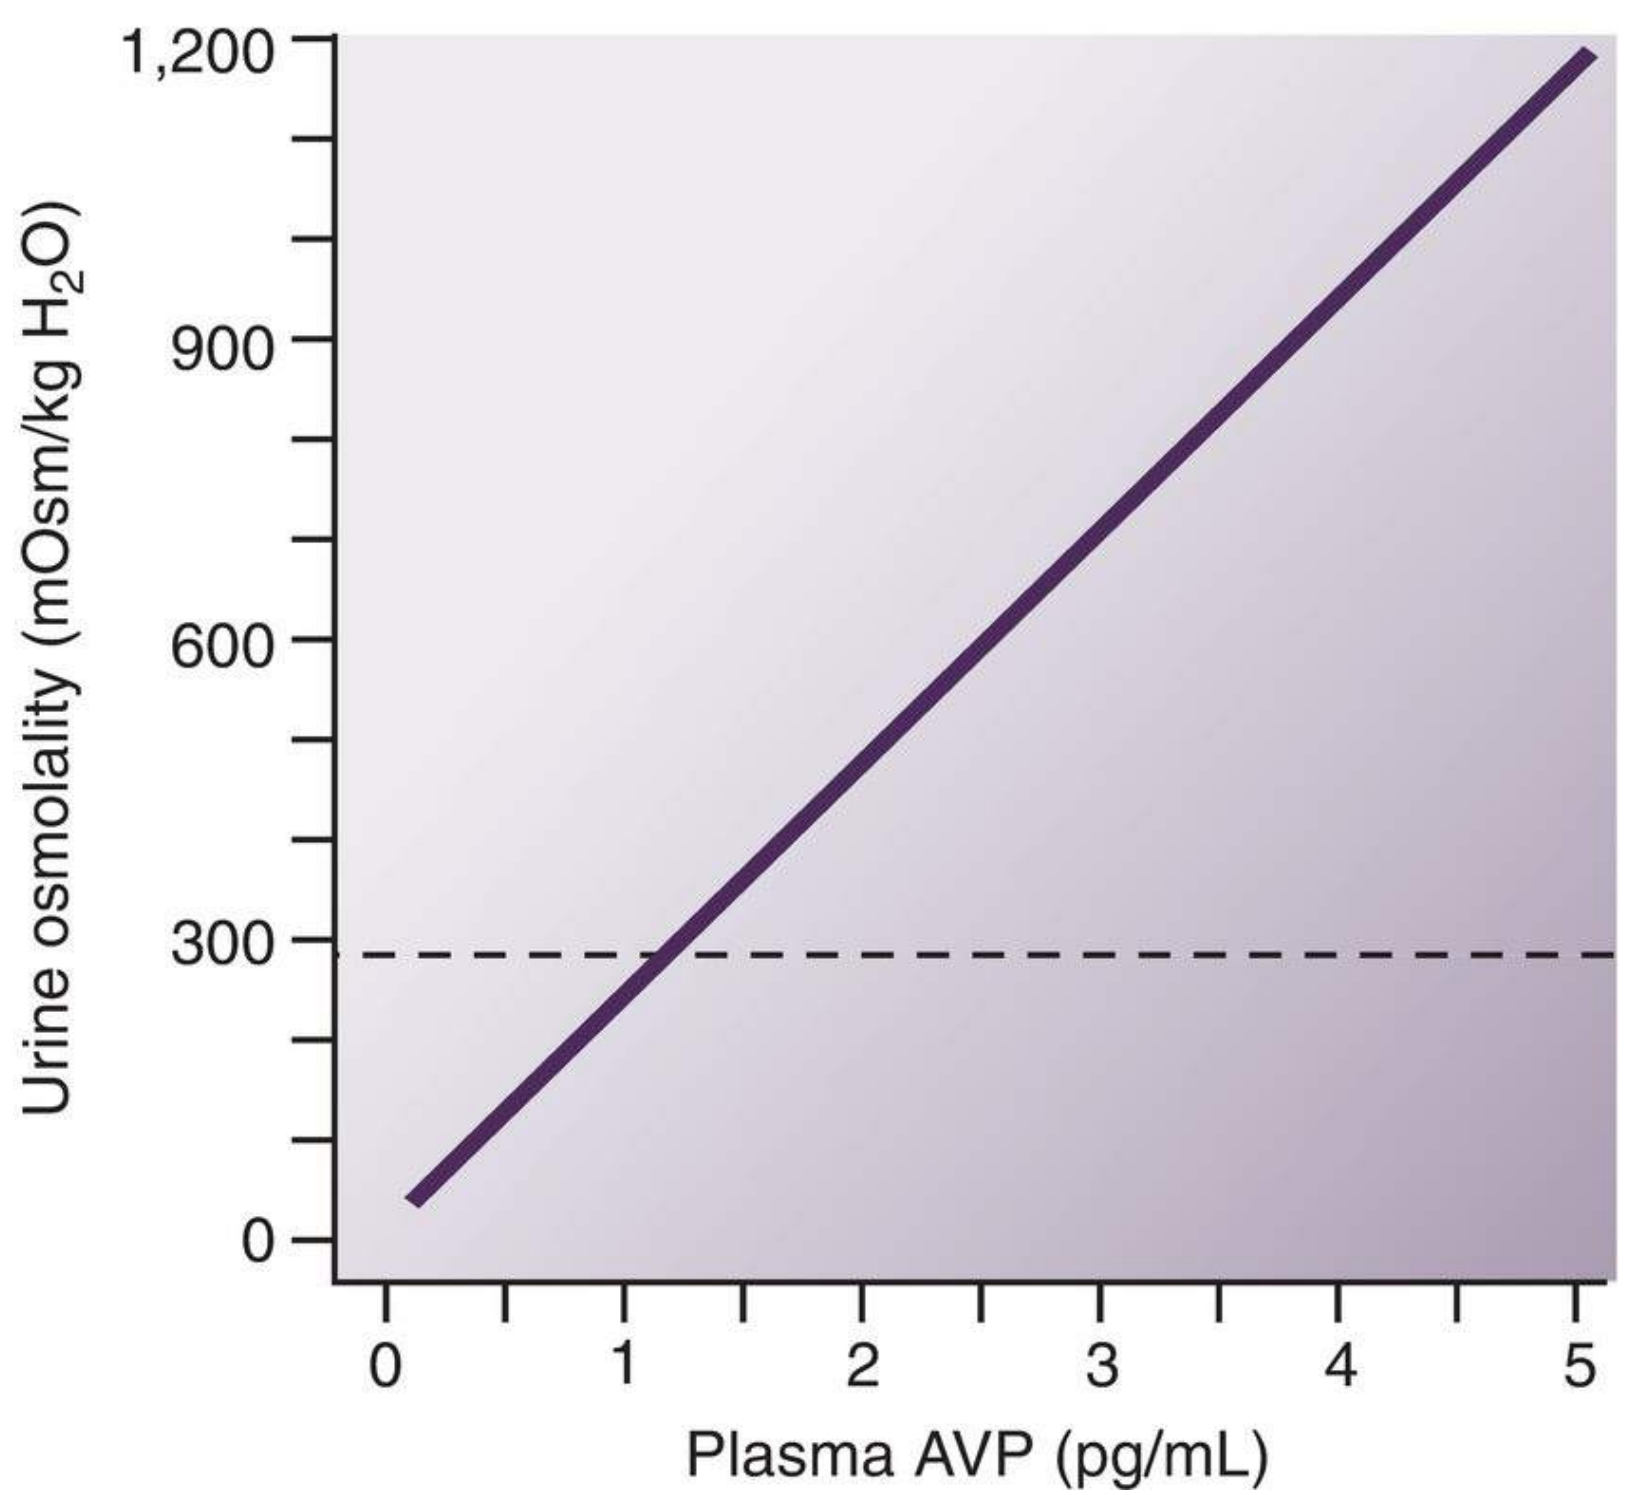

Figure 23.4 The relationship between urine osmolality and plasma arginine vasopressin (AVP) levels. The *dashed horizontal line* reports the normal plasma osmolality (285 mOsm/kg H_2O). With low plasma AVP levels, urine hypo-osmotic to plasma is excreted, and with high plasma AVP levels, hyperosmotic urine is excreted. Maximally concentrated urine (1,200 mOsm/kg H_2O) is produced when the plasma AVP level is about 5 pg/mL.

A second mechanism controlling AVP release is the blood volume—more precisely, the **effective arterial blood volume (EABV)**. An increased blood volume inhibits AVP release, whereas a decreased blood volume (**hypovolemia**) stimulates AVP release. Intuitively, this makes sense, because with excess volume, a low plasma AVP level would promote the excretion of water by the kidneys. With hypovolemia, a high plasma AVP level would promote reabsorption or conservation of water by the kidneys.

The receptors for blood volume include stretch receptors in the right atrium of the heart and in the

pulmonary veins within the pericardium. More stretch results in more impulses transmitted to the brain via vagal afferents, which inhibit AVP release. The common experiences of producing a large volume of dilute urine, a **water diuresis**—when lying down in bed at night, when exposed to cold weather, or when immersed in a pool during the summer—may be related to the activation of this pathway. In all these situations, an increased central blood volume stretches the atria. Arterial baroreceptors in the carotid sinuses and aortic arch also reflexly change AVP release; however, a fall in pressure at these sites stimulates AVP release. Finally, a decrease in renal blood flow stimulates renin release, which leads to increased angiotensin II production. Angiotensin II stimulates AVP release by acting on the brain.

Relatively large blood losses (more than 10% of blood volume) are required to increase AVP release significantly (Fig. 23.5). With a loss of 15% to 20% of total blood volume, however, very large increases in plasma AVP are observed. Plasma levels of AVP may rise to levels much higher (e.g., 50 pg/mL) than are needed to concentrate the urine maximally (e.g., 5 pg/mL) (compare Figs. 23.4 and 23.5.) With severe hemorrhage, this high circulating level of AVP exerts a significant vasoconstrictor effect, which helps compensate by raising the blood pressure.

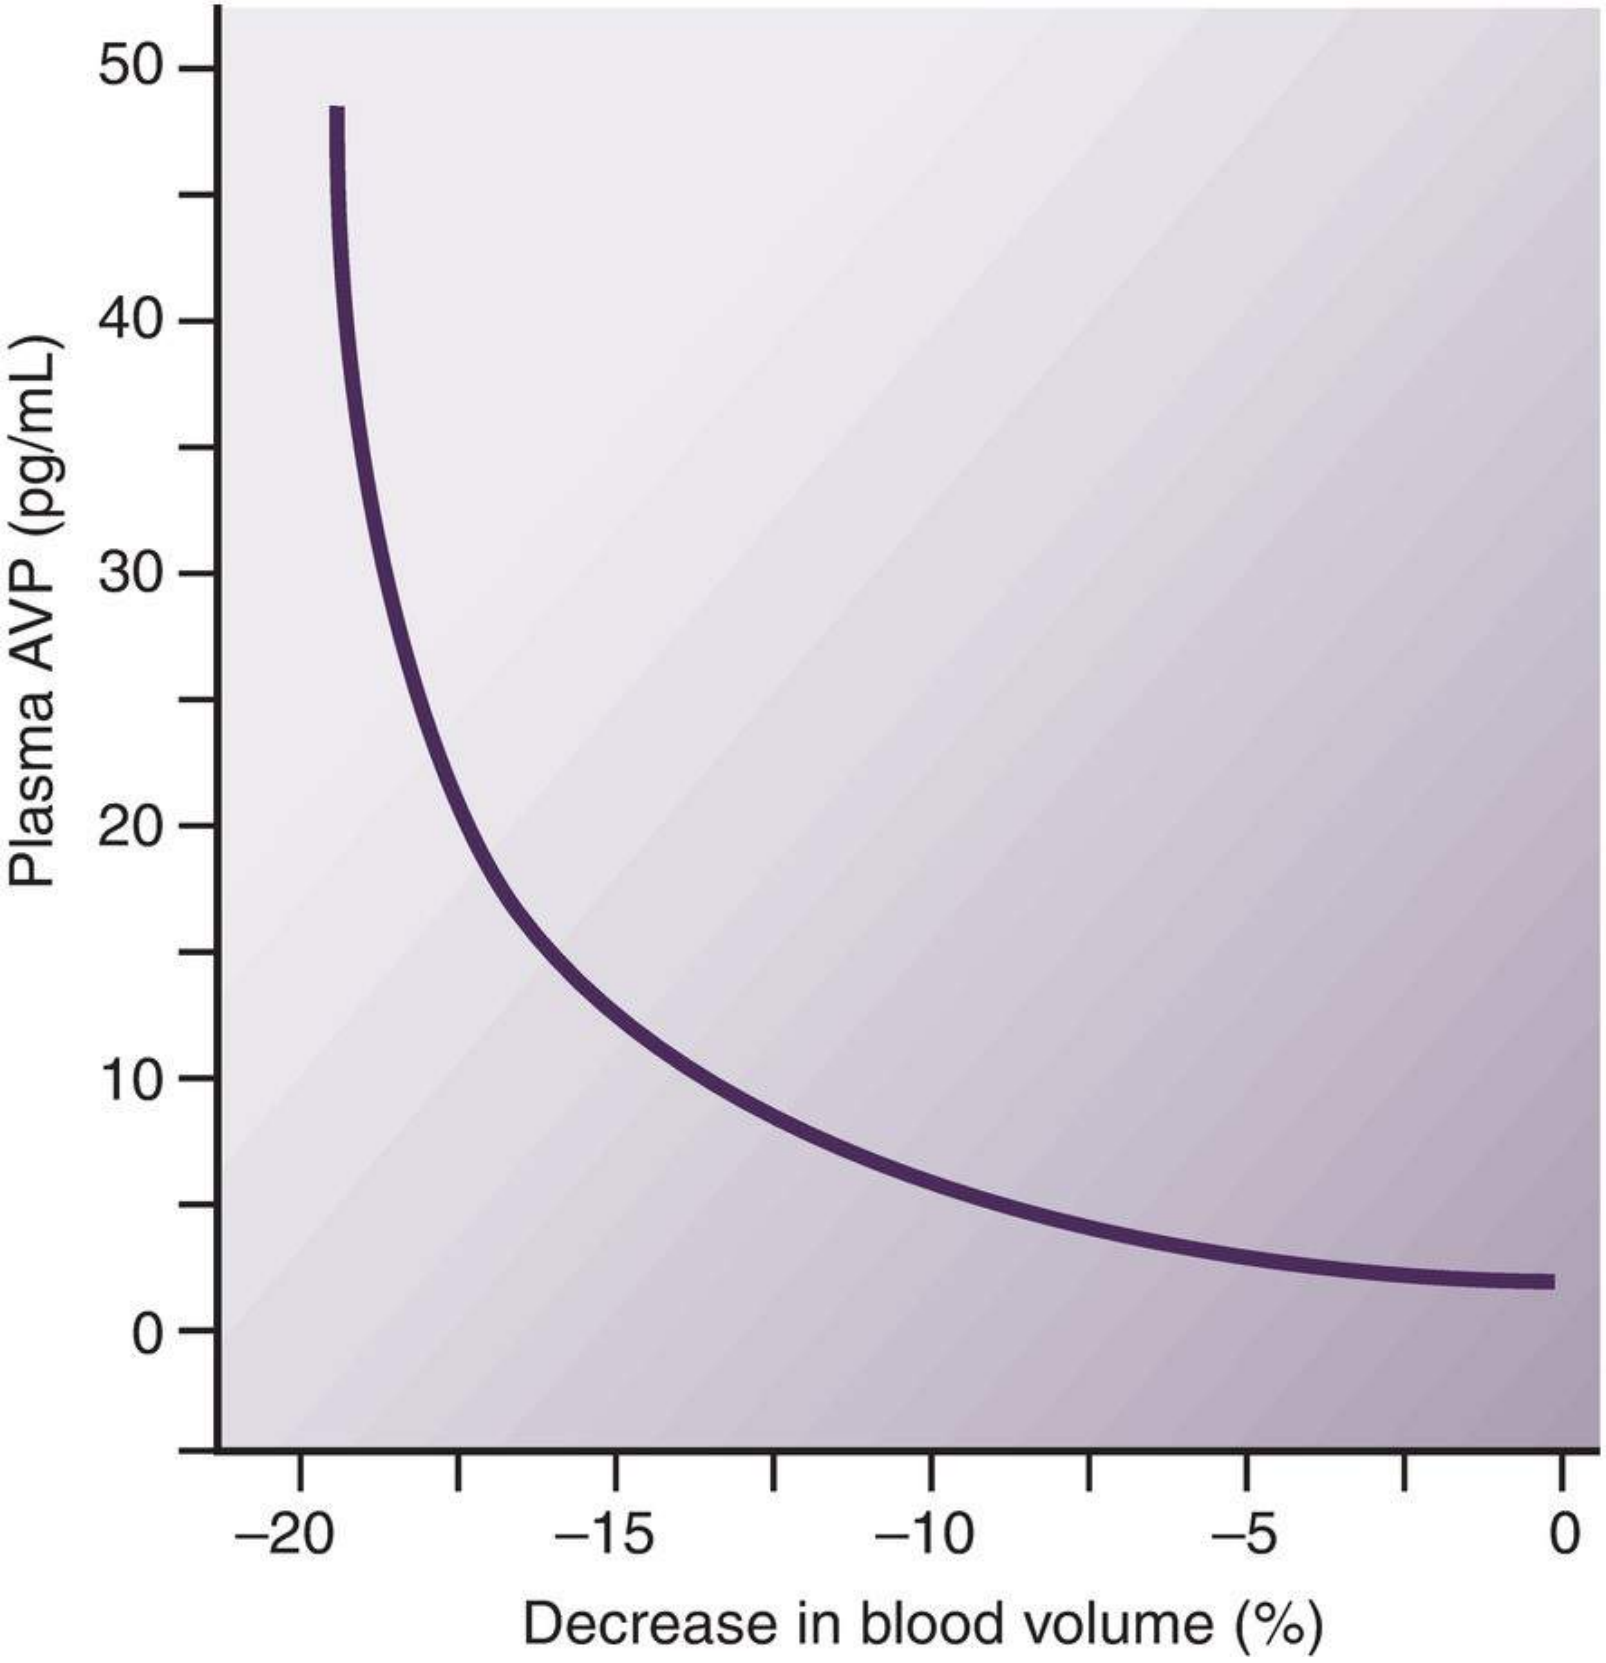

Figure 23.5 The relationship between plasma arginine vasopressin (AVP) and blood volume depletion in the rat. Severe hemorrhage (loss of 20% of total blood volume) causes a striking increase in plasma AVP. In this situation, the vasoconstrictor effect of AVP becomes significant and helps counteract the low blood pressure.

Plasma osmolality and blood volume work in concert to regulate AVP release.

The two stimuli, plasma osmolality and blood volume, most often work in concert to increase or decrease AVP release. For example, a great excess of water intake in a healthy person will inhibit AVP release because of both the fall in plasma osmolality and increase in blood volume. Conversely, AVP release will be stimulated with excess water loss (e.g., sweating during heavy exercise) because of the concomitant rise in plasma osmolality and decrease in blood volume. However, in certain important circumstances, there is a conflict between these two inputs. In the context of regulating AVP release, the osmoreceptors in the brain are more sensitive to changes in osmolality than are the pressure receptors that indirectly sense change in volume. However, the pressure receptors can elicit a stronger overall response. This relationship has been termed the *Volume Overrides Tonicity Principle*: that is, *AVP release (and thirst) will be stimulated, even if plasma is hypotonic, providing plasma volume is significantly decreased*. This usually occurs when plasma volume is decreased more than 10% to 5%. In this case, the need of the body to support the cardiovascular system, by correcting for volume loss and resulting reduced filling of the heart, takes precedence over using AVP and thirst suppression to try to correct for hypotonicity in the plasma. In general, the principle of volume changes overriding tonicity changes in regard to affecting AVP secretion and thirst is only seen in relatively severe conditions in the body such as hemorrhage, severe dehydration, and edema resulting from loss of fluid out of the CV system (i.e., exclusion of water from the central circulation).

Finally, certain clinical conditions can create a disconnect between plasma volume and osmolality. For example, severe congestive heart failure is characterized by a decrease in the EABV, even though total blood volume is greater than normal. This condition results because the heart does not pump sufficient blood into the arterial system to maintain adequate tissue perfusion. The arterial baroreceptors signal less volume, and AVP release is stimulated. The patient will produce osmotically concentrated urine and will also be thirsty from the decreased EABV, with consequent increased water intake. The combination of decreased renal water excretion and increased water intake leads to hypo-osmolality of the body fluids, which is reflected in a low plasma Na^+, or **hyponatremia**. Despite the hypo-osmolality, plasma AVP levels remain elevated and thirst persists. It appears that maintaining an EABV is of overriding importance, and so osmolality may be sacrificed in this condition. However, the hypo-osmolality can create new problems, such as the swelling of brain cells.

DISTURBANCES IN FLUID–ELECTROLYTE BALANCE

The maintenance of normal volume and normal electrolyte composition of the extracellular fluid is vital for life. In particular, electrolytes play a key role in maintaining homeostasis within the cells, tissues, and organs of the body. They help to regulate cellular secretions, as well as muscle and neurological functions. Fluid–electrolyte disturbances can occur with disease and illness. Examples include excessive ingestion, retention, or elimination of electrolytes. The most common cause of fluid–electrolyte disturbances is renal failure. Examples of causes for fluid loss and gain are shown in Table 23.3.

For a quick review, it is important to remember that: (1) although increased amounts of water and solutes are lost through sweating and breathing during exercise, the loss of excess water or excess solutes depends mainly on regulating excretion in the urine; (2) the extent of urinary secretion of electrolytes (e.g., Na^+ and Cl^- loss) is the main determinant of extracellular fluid volume; and (3) urinary water loss is the main determinant of extracellular fluid osmolarity.

Thirst center governs water intake.

One of the main ways the body regulates extracellular fluid volume is by adjusting the volume of water intake, mainly by drinking more or less fluid. The thirst center in the hypothalamus governs the urge to drink.

Thirst, a conscious desire to drink water, is basic instinct that arises from a lack of fluids or an increase in certain plasma electrolytes. Continuous dehydration can lead to renal problems and neurological problems, such as seizures. If the body's water volume falls below a certain threshold, or the effective osmolality of the plasma becomes too high, signals from the **thirst center** of the brain are activated. The thirst center is located in the anterior hypothalamus, close to the neurons that produce and control AVP release. This center relays impulses to the cerebral cortex, so that thirst becomes a conscious sensation.

Several factors affect the thirst sensation (Fig. 23.6). The major stimulus is an increase in effective osmolality of the blood plasma, which is detected by osmoreceptor cells in the hypothalamus. These cells are distinct from those that affect AVP release. An increase in effective plasma osmolality of 1% to 2% (i.e., about 3 to 6 mOsm/kg H_2O) is needed to reach the thirst threshold. NaCl is an effective stimulus. In contrast, ethanol and urea are not effective stimuli for the osmoreceptors because they readily penetrate these cells and therefore do not cause them to shrink.

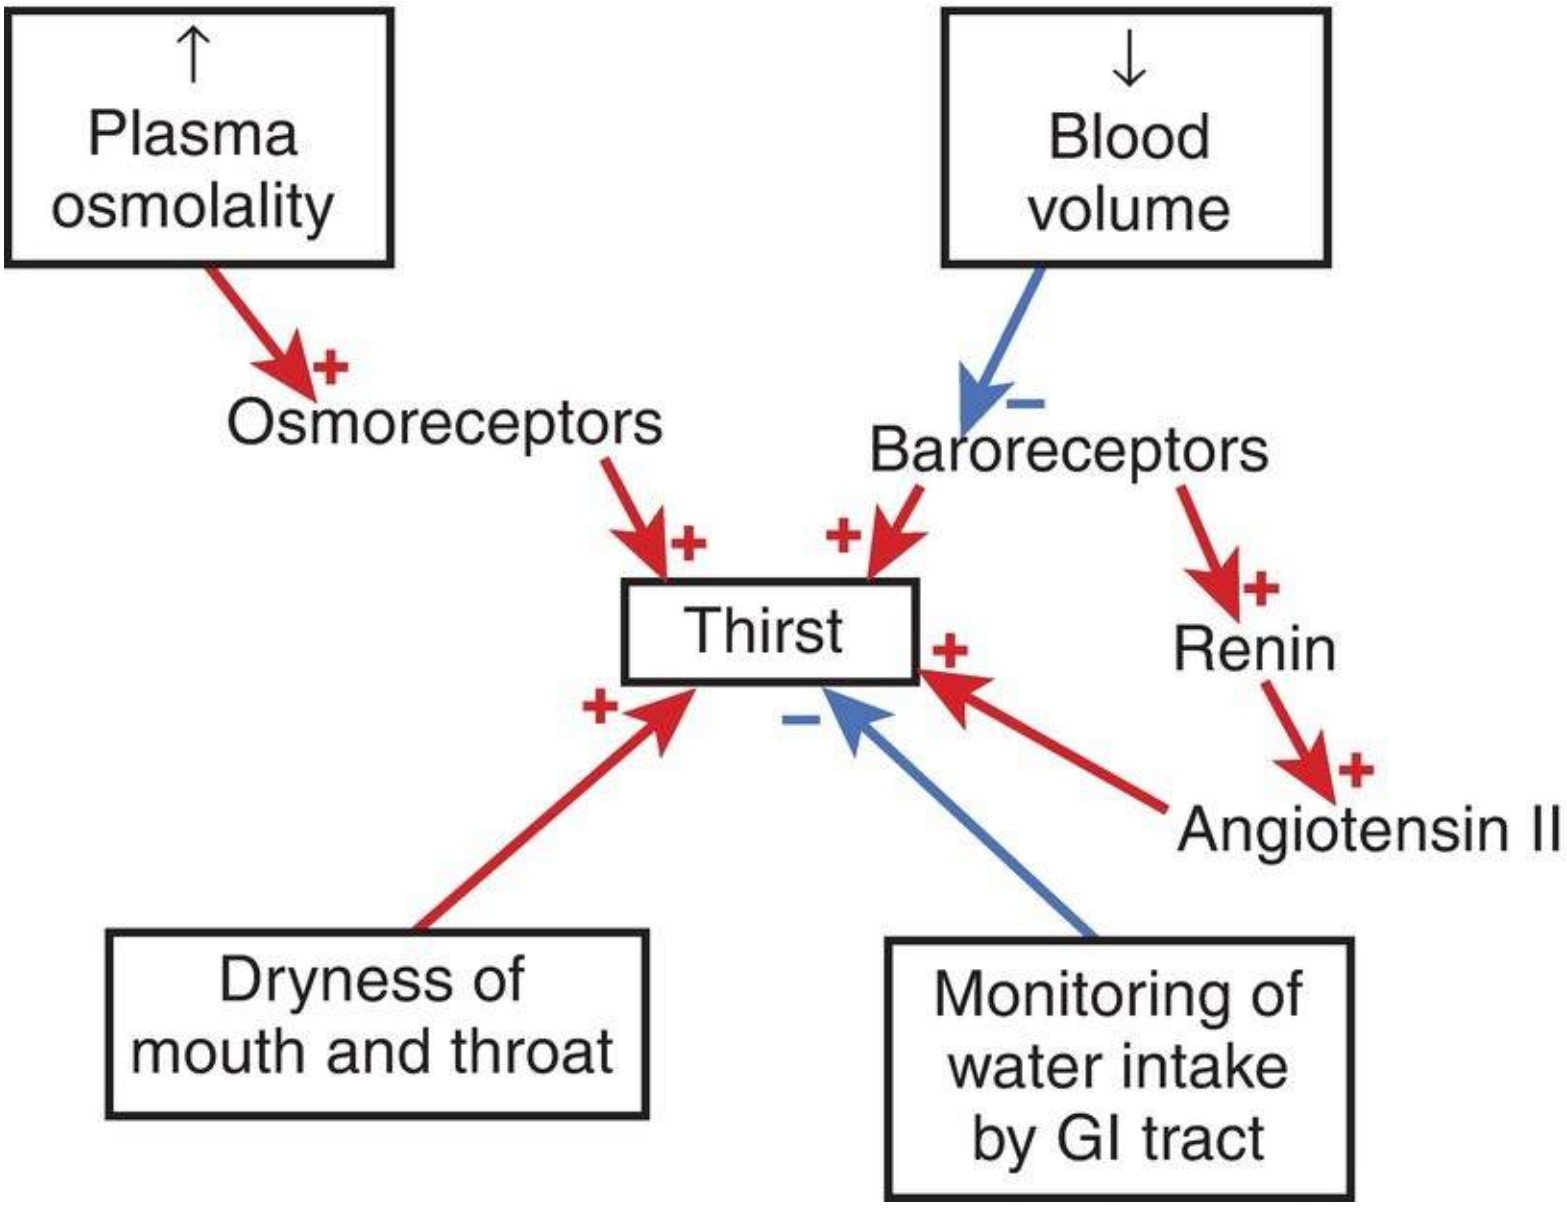

Figure 23.6 Factors affecting the thirst sensation. A plus sign indicates stimulation of thirst, whereas a minus sign indicates an inhibitory influence. GI, gastrointestinal.

Hypovolemia or a decrease in the effective arterial blood volume (EABV) stimulates thirst. Blood volume loss must be considerable for the thirst threshold to be reached; most blood donors do not become thirsty after donating 500 mL of blood (10% of blood volume). A larger blood loss (15% to 20% of blood volume), however, evokes *intense* thirst. A decrease in EABV resulting from severe diarrhea or vomiting or congestive heart failure may also provoke thirst.

The receptors for blood volume that stimulate thirst include the arterial baroreceptors in the carotid sinuses and aortic arch and stretch receptors in the cardiac atria and great veins in the thorax. The kidneys may also act as volume receptors. When blood volume is decreased, the kidneys release renin into the circulation. This results in production of angiotensin II, which acts on neurons near the third ventricle of the brain to stimulate thirst.

The thirst sensation is reinforced by dryness of the mouth and throat, which is caused by a reflex decrease in secretion by salivary and buccal glands in a water-deprived person. The GI tract also monitors water intake. Moistening of the mouth or distention of the stomach, for example, inhibits thirst, thereby preventing excessive water intake. For example, if a dog is deprived of water for some time and is then presented with water, it will commence drinking but will stop before all of the ingested water has

been absorbed by the small intestine. Monitoring of water intake by the mouth and stomach in this situation limits water intake, thereby preventing a dip in plasma osmolality below normal.

Polydipsia is excessive thirst and causes the excretion of large volumes of urine. The condition is most commonly found in diabetics. Polydipsia also occurs when the thirst center, situated in the hypothalamus, gets damaged. Polydipsia can also be caused by mental illness, such as schizophrenia and is termed psychogenic polydipsia. Diabetes insipidus is another disorder that can lead to extreme thirst and polyuria. (See the Integrated Medical Sciences box.)

CLINICAL FOCUS 23.1

Hyponatremia

Hyponatremia, defined as a plasma Na^+ level of <135 mEq/L, is the most common disorder of body fluid and electrolyte balance in hospitalized patients. Most often, it reflects a problem of too much water, not too little Na^+, in the plasma. Because Na^+ is the major solute in the plasma, it is not surprising that hyponatremia is usually associated with hypo-osmolality. Hyponatremia, however, may also occur with a normal or even elevated plasma osmolality.

Drinking large quantities of water (20 L/d) if not ingested too rapidly rarely causes frank hyponatremia because of the large capacity of the kidneys to excrete dilute urine. If, however, plasma arginine vasopressin (AVP) is not decreased when plasma osmolality is decreased or if the ability of the kidneys to dilute the urine is impaired, hyponatremia may develop even with a normal water intake.

Hyponatremia with hypo-osmolality can occur in the presence of a decreased, normal, or even increased total body Na^+. Hyponatremia and decreased body Na^+ content may be seen with increased Na^+ loss, such as with vomiting, diarrhea, and diuretic therapy. In these instances, the decrease in extracellular fluid (ECF) volume stimulates thirst and AVP release. More water is ingested, but the kidneys form osmotically concentrated urine and so plasma hypo-osmolality and hyponatremia result. Hyponatremia and normal body Na^+ content are seen in hypothyroidism, cortisol deficiency, and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). SIADH occurs with neurologic disease, severe pain, certain drugs (such as hypoglycemic agents), and some tumors. For example, a bronchogenic tumor may secrete AVP without control by plasma osmolality. The result is renal conservation of water that dilutes plasma sodium. Hyponatremia and increased total body Na^+ content are seen in edematous states, such as congestive heart failure, hepatic cirrhosis, and nephrotic syndrome. The decrease in effective arterial blood volume stimulates thirst and AVP release. Excretion of dilute urine may also be impaired because of decreased delivery of fluid to diluting sites along the nephron and collecting ducts. Although both Na^+ and water are retained by the kidneys in the edematous states, relatively more water is conserved, leading to a dilutional hyponatremia.

Hyponatremia and hypo-osmolality can cause a variety of symptoms, including muscle cramps, lethargy, fatigue, disorientation, headache, anorexia, nausea, agitation, hypothermia, seizures, and coma. These symptoms, mainly neurologic, are a consequence of the swelling of brain cells as plasma osmolality falls. Excessive brain swelling may be fatal or may cause permanent damage. Treatment requires identifying and then treating the underlying cause. If Na^+ loss is responsible for the

hyponatremia, isotonic or hypertonic saline or NaCl by mouth is usually given. If the blood volume is normal or the patient is edematous, water restriction is recommended. Hyponatremia should be corrected slowly and with constant monitoring, because too rapid correction can be harmful.

Hyponatremia in the presence of increased plasma osmolality is seen in hyperglycemic patients with uncontrolled diabetes mellitus. In this condition, the high plasma glucose causes the osmotic withdrawal of water from cells, and the extra water in the ECF space leads to hyponatremia. Plasma Na^+ level falls by 1.6 mEq/L for each 100-mg/dL rise in plasma glucose.

Hyponatremia and a normal plasma osmolality are seen with so-called **pseudohyponatremia**. This occurs when plasma lipids or proteins are greatly elevated. These molecules do not significantly elevate plasma osmolality. They do, however, occupy a significant volume of the plasma, and because the Na^+ is dissolved only in the plasma water, the Na^+ measured in the entire plasma is low. ■

SODIUM BALANCE

As seen from Table 23.2, Na^+ is the most abundant cation in the plasma and, along with its accompanying anions Cl^- and HCO_3^-, largely determines the osmolality of the ECF. Because AVP, the kidneys, and thirst closely regulate the osmolality of the ECF, it follows that the Na^+ content of the ECF compartment determines the amount of water in it (and hence its volume). The kidneys are primarily involved in the regulation of Na^+ balance. We consider first the renal mechanisms involved in Na^+ excretion and then overall Na^+ balance.

Kidneys excrete only a small percentage of the filtered sodium load.

Table 23.4 shows the magnitude of filtration, reabsorption, and excretion of ions and water for a healthy adult man on an average American diet. The amount of Na^+ filtered (the Na^+ filtered load) was calculated from the product of the plasma Na^+ concentration and the glomerular filtration rate (GFR) because sodium is freely filtered at the glomerulus. The quantity of Na^+ reabsorbed was calculated from the difference between the filtered and excreted amounts. Note that 99.6% (25,100 ÷ 25,200 mEq/d) of the filtered Na^+ was reabsorbed or, in other words, percentage excretion of Na^+ was only 0.4% of the filtered load. In terms of overall Na^+ balance for the body, the quantity of Na^+ excreted by the kidneys is of key importance, because ordinarily about 95% of the Na^+ that we consume is excreted by way of the kidneys. Tubular reabsorption of Na^+ must be finely regulated to keep us in Na^+ balance.

TABLE 23.4 Magnitudes of Daily Filtration, Reabsorption, and Excretion of Ions and Water in a Healthy Young Man on a Typical American Diet

Substance	Plasma (mEq/L)	GFR (L/d)	Filtered (mEq/d)	Excreted (mEq/d)	Reabsorbed (mEq/d)	% Reabsorbed
Sodium	140	180	25,200	100	25,100	99.6
Chloride	105	180	18,900	100	18,800	99.5
Bicarbonate	24	180	4,320	2	4,318	99.9
Potassium	4	180	720	100	620	86.1
Water	0.93*	180	167 L/d	1.5 L/d	165.5 L/d	99.1

*Plasma contains about 0.93 L H_2O/L.

GFR, glomerular filtration rate.

Figure 23.7 shows the percentage of *filtered* Na^+ reabsorbed in different parts of the nephron. Seventy percent of filtered Na^+ is reabsorbed in the proximal convoluted tubule. Because the proximal tubule is highly permeable to water, this percent of sodium reabsorption (along with its attendant anions) causes the tubule to reabsorb the same percentage of filtered water. The loop of Henle reabsorbs about 20% of filtered Na^+, but only 10% of filtered water because the ascending limbs are not permeable to water. The distal convoluted tubule reabsorbs about 6% of filtered Na^+ (and no water), and the collecting ducts reabsorb about 3% of the filtered Na^+ (and 19% of the filtered water, though this varies with plasma AVP levels). Only about 1% of the filtered Na^+ and water is usually excreted. The distal nephron (distal convoluted tubule, connecting tubule, and collecting duct) has a lower capacity for Na^+ transport than more proximal segments and can be overwhelmed if too much Na^+ fails to be reabsorbed in proximal segments. The distal nephron is of critical importance in determining the final excretion of Na^+.

1% Urine

Figure 23.7 The percentage of the filtered load of sodium reabsorbed along the nephron. About 1% of the filtered Na^+ is usually excreted.

Multiple factors affect renal Na^+ excretion; these are discussed in the subsections that follow. A factor may promote Na^+ excretion by increasing the amount of Na^+ filtered by the glomeruli, by decreasing the amount of Na^+ reabsorbed by the kidney tubules, or, in some cases, by affecting both processes.

Glomerulotubular balance prevents massive changes in Na excretion.

Theoretically, small changes in GFR, by increasing filtered sodium load, could potentially lead to massive changes in Na^+ excretion if the nephron could not adjust the amount of the filtered load it reabsorbed. If sodium reabsorption was constant, even a small change in GFR and filtered sodium load would lead to a large excretion, or loss, of sodium over time. However, Na^+ excretion tends to change in the same direction as GFR because of a phenomenon called **glomerulotubular balance** (Table 23.5). Proximal convoluted tubules and loops of Henle reabsorb an essentially *constant fraction, or percent*, of the filtered sodium load, not a constant amount. In other words, the tubules increase the rate of Na^+ reabsorption when GFR (and thus filtered sodium load) is increased and decrease the rate of Na^+ reabsorption when GFR is decreased (i.e., reabsorbing the same percent of a larger or smaller than normal filtered load yields, respectively, a greater or lesser absolute amount reabsorbed). Glomerulotubular balance reduces the impact of changes in GFR on Na^+ excretion and can be thought of a way of shielding potential alterations in sodium balance caused by changes in the cardiovascular system that alter GFR.

TABLE 23.5 Glomerulotubular Balance*

Period	Filtered (mEq/min)	– Reabsorbed (mEq/min)	= Excreted (mEq/min)
1	6.00	5.95	0.05
Increase GFR by one third			
2	8.00	7.90	0.10

*Results from an experiment performed on a 10-kg dog. In response to an increase in glomerular filtration rate (GFR) (produced by infusing a drug that dilated afferent arterioles), tubular reabsorption of Na^+ also increased, and so only a modest increase in Na^+ excretion occurred. If there had been no glomerulotubular balance and if tubular Na^+ reabsorption had stayed at 5.95 mEq/min, the kidneys would have excreted 2.05 mEq/min in period 2. If we assume that the extracellular fluid (ECF) volume in the dog is 2 L (20% of body weight) and if plasma Na^+ is 140 mEq/L, an excretion rate of 2.05 mEq/min would result in excretion of the entire ECF Na^+ (280 mEq) in a little over 2 h. The dog would have been dead long before this could happen, which underscores the importance of glomerulotubular balance.

Elevated renal capillary hydrostatic pressure increases Na^+ excretion.

The increased sodium and water excretion produced by an increase in intravascular pressure in the kidneys is called a *pressure* **natriuresis** and *pressure diuresis*, respectively. The term "natriuresis" means an increase in Na^+ excretion. Multiple factors appear to be involved in the mechanism of pressure diuresis. First, an increase in the hydrostatic pressure or a decrease in the colloid osmotic pressure (the so-called **Starling forces**) in peritubular capillaries results in reduced fluid uptake by the capillaries. Such changes would occur, for example, after intravenous infusion of a large volume of isotonic saline. The resulting accumulation of the reabsorbed fluid in the kidney interstitial spaces widens the tight junctions between proximal tubule cells, and the epithelium becomes even more leaky than normal. The result is increased back-leak of salt and water into the tubule lumen, an overall reduction in net reabsorption of those components of tubular fluid and a resulting increase in salt and water excretion. In addition, an increase in blood pressure rapidly causes Na^+/H^+ exchangers to be removed from the apical cell membrane of proximal tubule cells and internalized. Basolateral cell membrane Na^+/K^+-ATPase activity is also decreased. These two changes result in diminished tubular sodium reabsorption and enhanced sodium excretion. This transcellular pathway is another way the kidneys can dispose of excess sodium when arterial or intrarenal pressure is elevated.

Extracellular Na^+ is regulated by the renin–angiotensin–aldosterone system and atrial natriuretic peptide.

The **renin–angiotensin–aldosterone system** is a hormone system that regulates blood pressure and water balance. **Renin** is a proteolytic enzyme produced by granular cells, which are located in afferent arterioles in the kidneys (see Chapters 17 and 22). In addition, renin, angiotensinogen and ACE are present in some organs (e.g., the kidneys and brain), so that angiotensin II may also be formed and act locally.

To review, there are three main stimuli for renin release:

1. A decrease in pressure in the afferent arteriole (with the granular cells responding to stretch and functioning as an intrarenal **baroreceptor**)
2. Stimulation of sympathetic nerve fibers to the kidneys to activate β_2-adrenergic receptors on the granular cells
3. A decrease in luminal sodium chloride concentration at the macula densa region of the nephron, resulting, for example, from a decrease in GFR

All three of these pathways are activated and reinforce each other when there is a decrease in the EABV—for example, following hemorrhage, transudation of fluid out of the vascular system, diarrhea, severe sweating, or a low salt intake. Conversely, an increase in the EABV inhibits renin release. In addition, long-term stimulation causes vascular smooth muscle cells in the afferent arteriole to differentiate into granular cells and leads to further increases in renin supply.

Although the renin–angiotensin–aldosterone system is involved in control of blood pressure (see Chapter 17), this system is essentially a salt-conserving system (Fig. 23.8). Angiotensin II has several actions related to Na^+ and water balance:

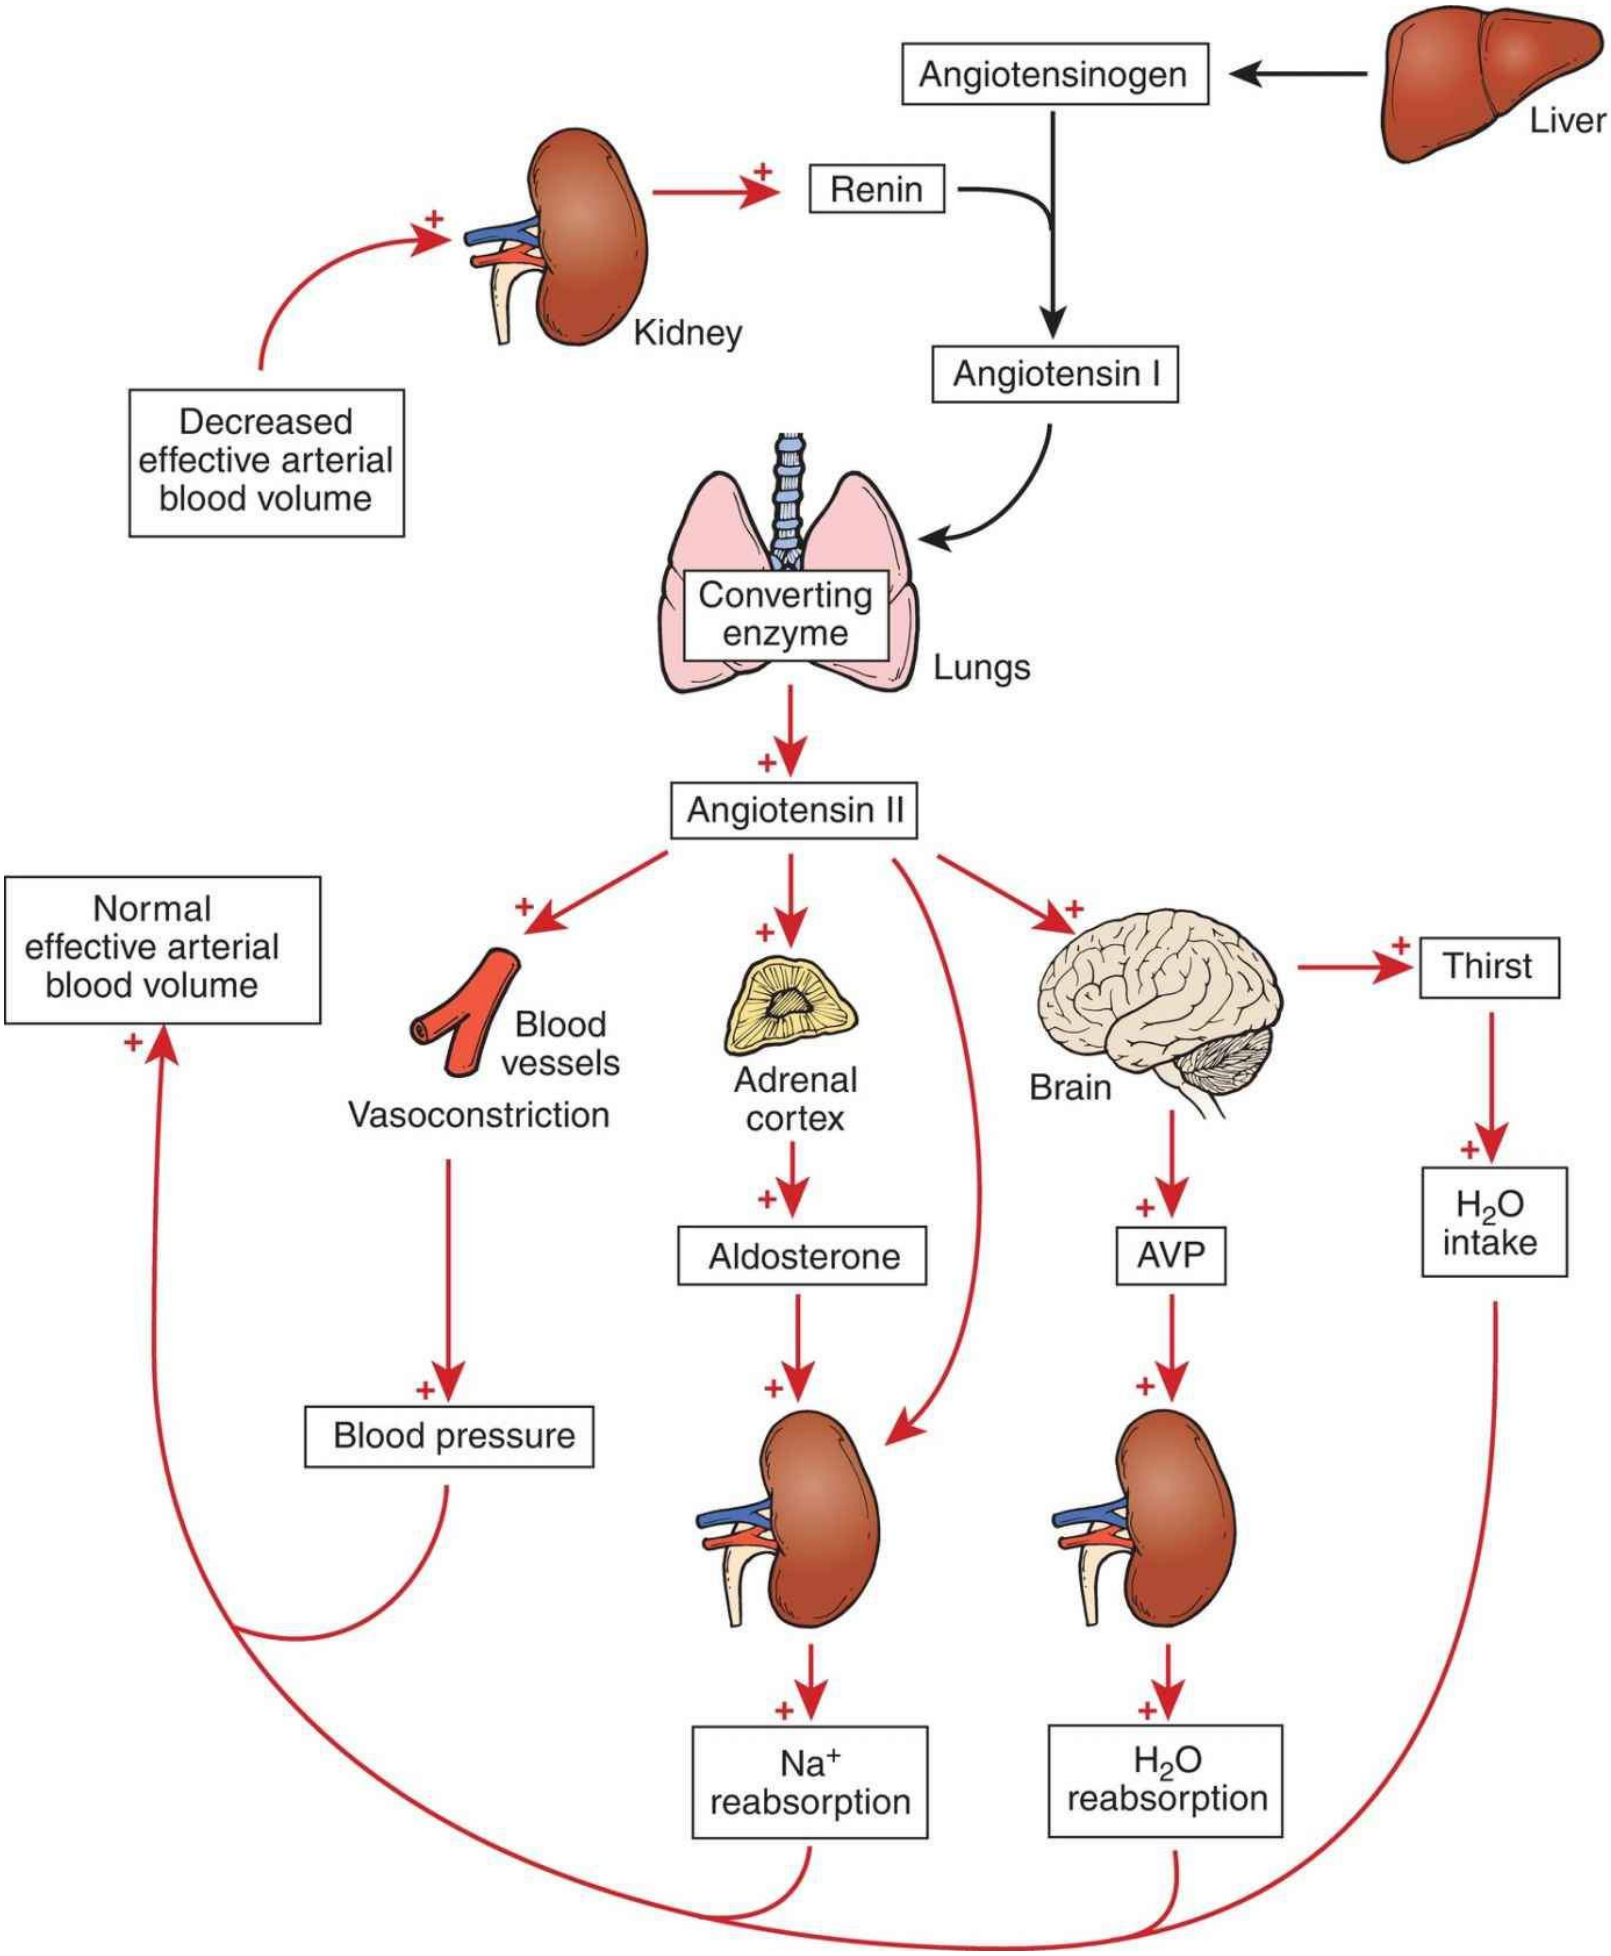

Figure 23.8 Components of the renin–angiotensin–aldosterone system. This system is activated by a decrease in the effective arterial blood volume (e.g., following hemorrhage) and results in compensatory

changes that help restore arterial blood pressure and blood volume to normal. AVP, arginine vasopressin.

- It stimulates the production and secretion of aldosterone from the zona glomerulosa of the adrenal cortex (see Chapter 33). This mineralocorticoid hormone then acts on the distal nephron to increase Na^+ reabsorption.
- Angiotensin II directly stimulates tubular Na^+ reabsorption by proximal tubules.
- Angiotensin II stimulates thirst and the release of AVP by the posterior pituitary.

Angiotensin II is also a potent vasoconstrictor of both resistance and capacitance vessels; increased plasma levels following hemorrhage, for example, help sustain blood pressure. Inhibiting angiotensin II production, by giving an ACE inhibitor or inhibiting the binding of angiotensin II to its receptor by using an angiotensin receptor blocker, lowers blood pressure and is used in the treatment of hypertension. Recently, an orally active nonpeptide renin inhibitor called *aliskiren* has been developed; this drug is an effective antihypertensive that may also slow the progression of chronic renal disease by inhibiting intrarenal renin activity.

The renin–angiotensin–aldosterone system plays an important role in the day-to-day control of Na^+ excretion. It favors Na^+ conservation by the kidneys when there is an Na^+ or volume deficit in the body. When there is an excess of Na^+ or fluid volume, diminished activity of the renin–angiotensin–aldosterone system permits enhanced Na^+ excretion. In the absence of aldosterone (e.g., in an adrenalectomized person) or in a person with adrenal cortical insufficiency, excessive amounts of Na^+ are lost in the urine; percentage reabsorption of Na^+ may decrease from a normal value of about 99.6% to a value of 98%. This change (1.6% of the filtered Na^+ load) may not seem like much, but if the kidneys filter 25,200 mEq/d (see Table 23.4) and excrete an extra $0.016 \times 25{,}200 = 403$ mEq/d, this is the amount of Na^+ in almost 3 L of ECF (assuming a Na^+ of 140 mEq/L). Such a loss of Na^+ would lead to a decrease in plasma and blood volume, circulatory collapse, and even death.

When there is an extra need for Na^+, people and many animals display a **sodium appetite**, an urge for salt intake, which can be viewed as a brain mechanism, much like thirst, that helps compensate for a deficit. Patients with primary adrenal cortical insufficiency (**Addison disease**) often show a well-developed sodium appetite, which helps keep them alive.

In the case of mineralocorticoid excess, large doses of a potent mineralocorticoid will cause a person to initially retain about 200 to 300 mEq Na^+ (equivalent to about 1.4 to 2 L of ECF) though no obvious edema is seen after retaining this much fluid. However, this sodium retention is not sustained indefinitely, even if dosing with mineralocorticoids is continued, because a sustained salt and water imbalance is not compatible with life. The escape from the salt-retaining action of the mineralocorticoid is called **mineralocorticoid escape**. The fact that the person will not continue to accumulate Na^+ and water is a result of numerous factors that promote renal Na^+ excretion when ECF volume is expanded. These factors overpower the salt-retaining action of mineralocorticoid hormones and include increases in GFR, changes in intrarenal pressures, and release of natriuretic factors (see below).

Atrial natriuretic peptide (ANP) is a 28–amino acid polypeptide synthesized and stored in myocytes of the cardiac atria (Fig. 23.9). It is released by stretch of the atria—for example, following volume expansion. This hormone has several actions that increase Na^+ excretion. ANP acts on the kidneys to increase glomerular blood flow and filtration rate. It also inhibits Na^+ reabsorption by the inner medullary collecting ducts. The second messenger for ANP in the collecting duct is cyclic guanosine

monophosphate (cGMP). ANP directly inhibits aldosterone secretion by the adrenal cortex and indirectly inhibits aldosterone secretion by diminishing renal renin release. ANP is a vasodilator and therefore lowers blood pressure. Some evidence suggests that ANP inhibits AVP secretion. The actions of ANP are in many respects just the opposite of those of the renin–angiotensin–aldosterone system; ANP promotes salt and water loss by the kidneys and lowers blood pressure, whereas activation of the renin–angiotensin–aldosterone system results in salt and water conservation and a higher blood pressure.

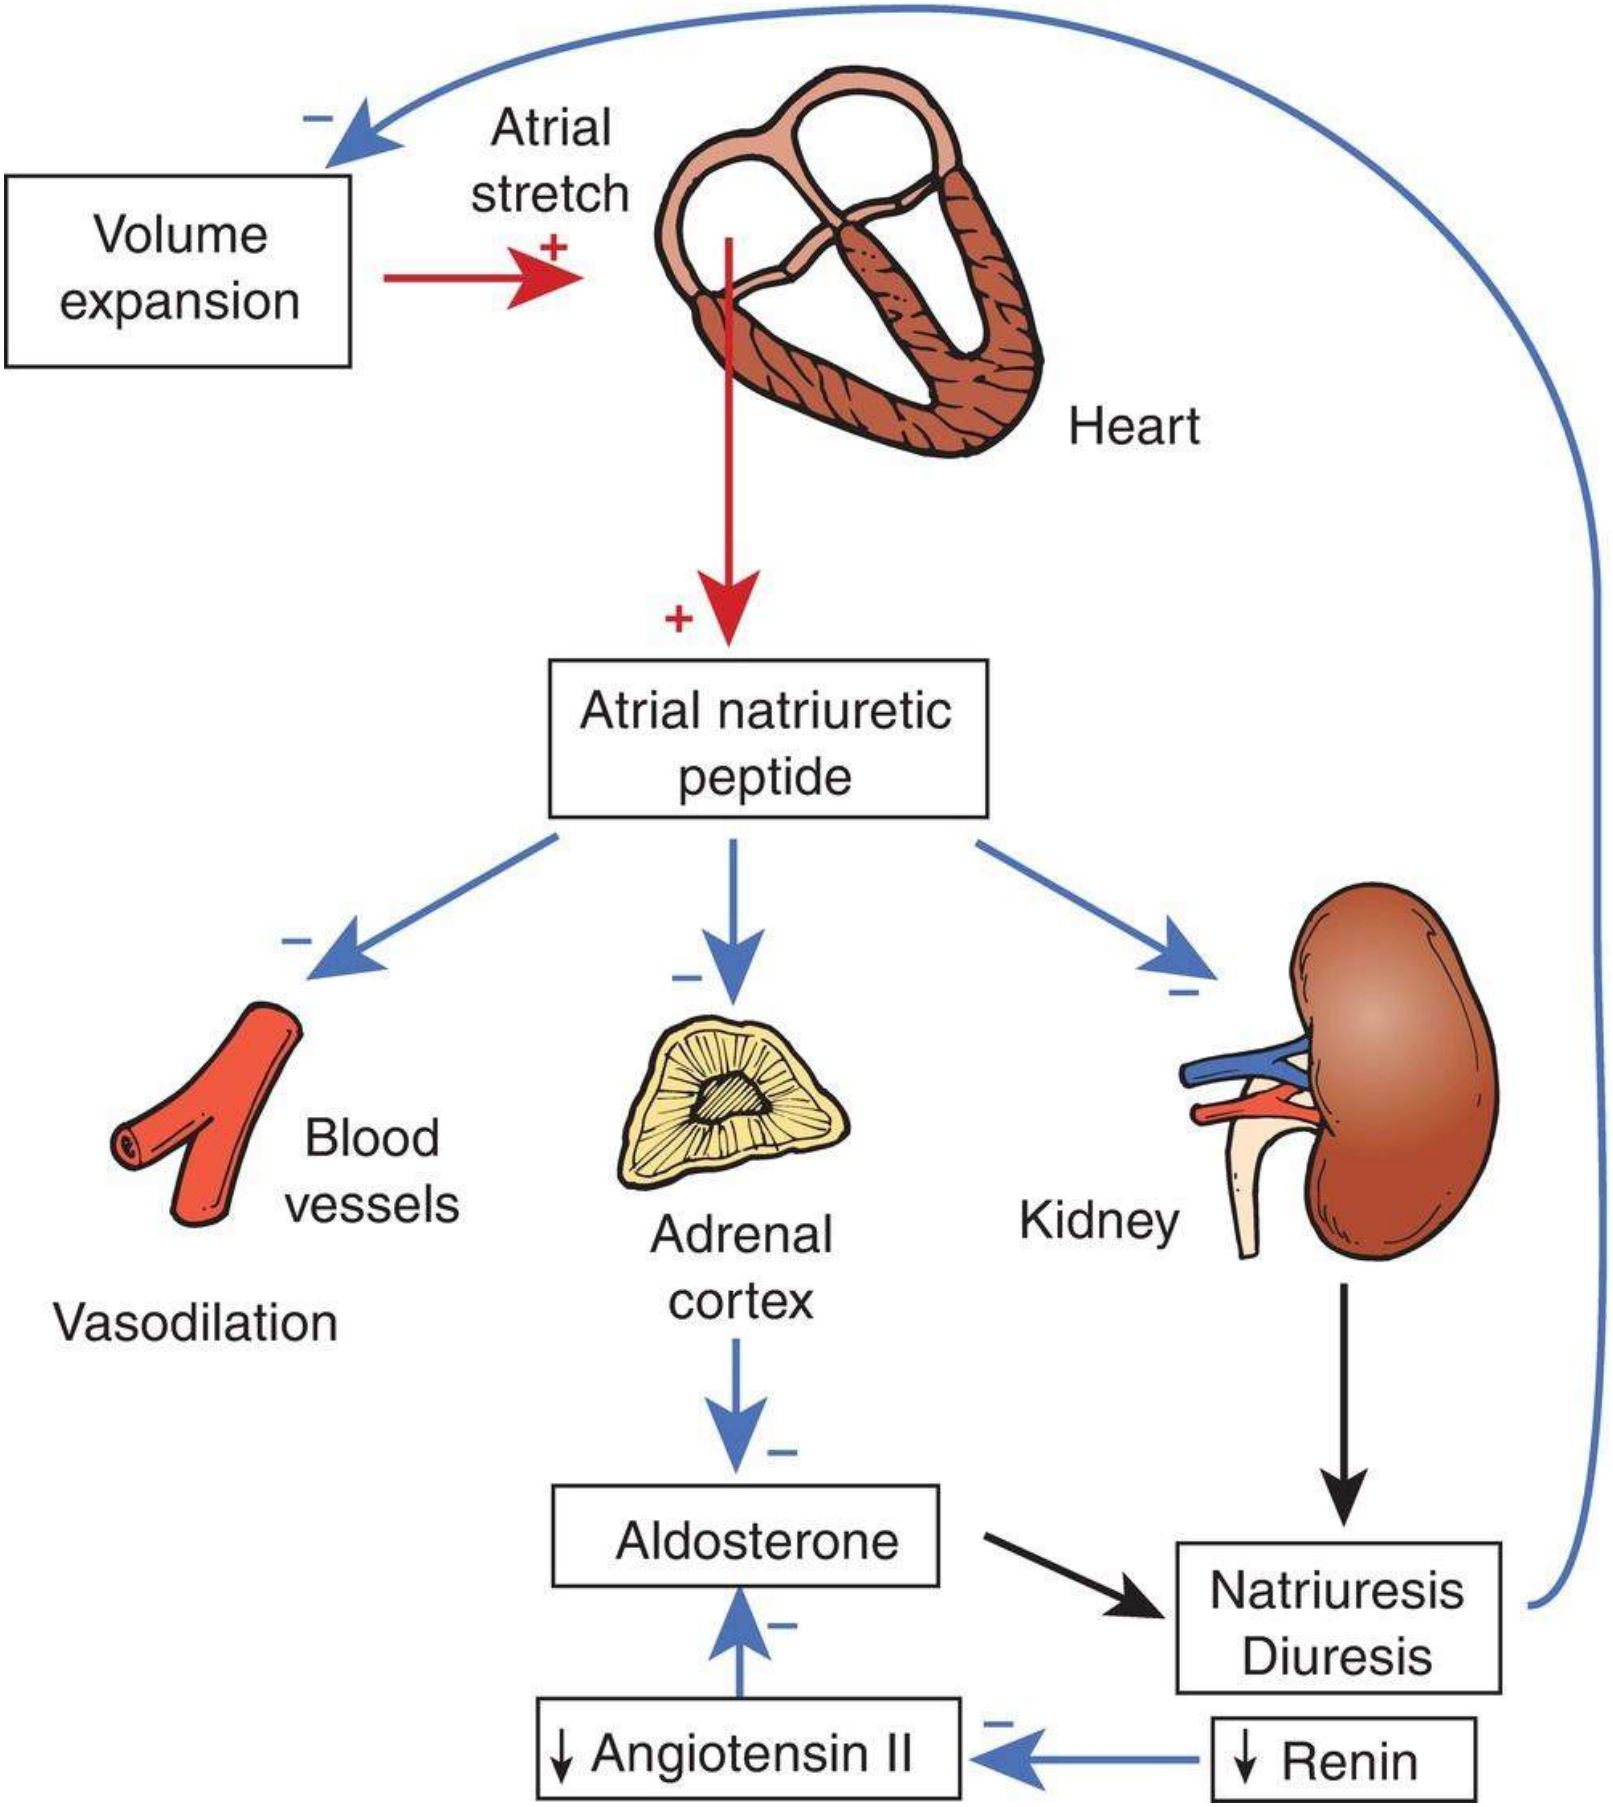

Figure 23.9 Atrial natriuretic peptide (ANP) and its actions. ANP release from the cardiac atria is stimulated by blood volume expansion, which stretches the atria. ANP produces effects that bring blood volume back toward normal, such as increased Na^+ excretion. *Red + arrows* indicate a stimulatory effect by an increase in the variable at the arrow tail.

Several other natriuretic hormones and factors have been described. **Urodilatin** (kidney natriuretic peptide) is a 32–amino acid polypeptide derived from the same prohormone as ANP. It is synthesized primarily by intercalated cells in the cortical collecting duct where it is secreted into the tubule lumen. It inhibits Na^+ reabsorption by inner medullary collecting ducts via cGMP. **Brain natriuretic peptide (BNP)** was first isolated from the brain but is also produced by myocytes in the cardiac ventricles. Increased plasma levels serve as a marker of cardiac injury and more recently as a measure of the severity of congestive heart failure. Recombinant BNP is used to promote renal sodium excretion in patients with decompensated congestive heart failure. **Guanylin** and **uroguanylin** are polypeptide hormones produced by the small intestine in response to salt ingestion. They activate guanylyl cyclase and produce cGMP as a second messenger, as their names suggest, and induce a natriuresis. **Bradykinin**, a tachykinin involved in inflammation, is produced locally in the kidneys and inhibits Na^+ reabsorption thus acting as a natriuretic agent.

Prostaglandins E_2 and **I_2** (prostacyclin) increase Na^+ excretion by the kidneys. These locally produced hormones are formed from arachidonic acid, which is liberated from phospholipids in cell membranes by the enzyme phospholipase A_2. A **cyclooxygenase (COX)** enzyme that has two isoforms, COX-1 and COX-2, mediates further processing. In most tissues, COX-1 is constitutively expressed, whereas COX-2 is generally induced by inflammation. In the kidney, COX-1 and COX-2 are both constitutively expressed in the cortex and medulla. In the cortex, COX-2 may be involved in macula densa–mediated renin release. COX-1 and COX-2 are present in high amounts in the renal medulla, where the main role of the prostaglandins is to inhibit Na^+ reabsorption. The inhibition of Na^+ reabsorption occurs via direct effects on the tubules and collecting ducts and via hemodynamic effects, because the prostaglandins (PGE_2, PGI_2) are vasodilators (see Chapter 22).

Synthesis of these prostaglandins is enhanced in chronic heart failure where they are thought to help support adequate renal blood flow in the face of continual exposure to the effects of activation of sympathetic nerves and the RAAS in that condition. Inhibition of the formation of prostaglandins in this situation, with common nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, may lead to a fall in renal blood flow or Na^+ retention and even renal failure.

In addition to the RAAS and atrial natriuretic peptide, there are other hormones that affect Na^+ balance. For example, estrogens decrease Na^+ excretion, probably by the direct stimulation of tubular Na^+ reabsorption. Most women tend to retain salt and water during pregnancy, which may be related, in part, to the high plasma estrogen levels during this time.

Glucocorticoids, such as cortisol (see Chapter 33), increase tubular Na^+ reabsorption but also cause an increase in GFR, which may mask the tubular effect. Usually, a decrease in Na^+ excretion is seen. Glucocorticoids circulate in the blood at much higher free concentrations than does aldosterone, and they can bind to and activate mineralocorticoid receptors in the kidney but their binding relative to aldosterone is weak. Furthermore, binding and actions in distal nephron cells are minimized by conversion, catalyzed by the enzyme 11β-hydroxysteroid dehydrogenase, to metabolites that do not bind the mineralocorticoid receptor. In general, glucocorticoids cause sodium retention and reduced excretion only at exceptionally high concentrations associated with pathological conditions.

Renal sympathetic nerve stimulation decreases Na^+ secretion.

Stimulation of renal sympathetic nerves reduces renal Na^+ excretion in at least three ways:

1. It produces a decline in GFR and renal blood flow, leading to a decreased filtered Na^+ load and peritubular capillary hydrostatic pressure, both of which favor sodium reabsorption and thus diminished Na^+ excretion.
2. It has a direct stimulatory effect on Na^+ reabsorption by the renal tubules.
3. It causes renin release, which results in increased plasma angiotensin II and aldosterone levels, both of which increase tubular Na^+ reabsorption.

Activation of the sympathetic nervous system occurs in a number of stressful circumstances (such as hemorrhage) in which the conservation of salt and water by the kidneys is of clear benefit.

Diuretics promote Na^+ secretion by the kidney.

Osmotic diuretics are solutes that are excreted in the urine and increase urinary excretion of Na^+ and K^+ salts and water. Examples are urea, glucose (when the reabsorptive capacity of the tubules for glucose has been exceeded), and mannitol (a six-carbon sugar alcohol used in the clinic to promote Na^+ excretion or cell shrinkage). Osmotic diuretics decrease the reabsorption of Na^+ in the proximal tubule. This response results from the development of a Na^+ concentration gradient (lumen Na^+ < plasma Na^+) across the proximal tubular epithelium when there is a high concentration of unreabsorbed solute in the tubule lumen. This gradient leads to significant back-leak of Na^+ into the tubule lumen and consequently decreased net Na^+ reabsorption. Because the proximal tubule is the place where most of the filtered Na^+ is normally reabsorbed, osmotic diuretics, by interfering with this process, can potentially cause the excretion of large amounts of Na^+. Osmotic diuretics may also increase Na^+ excretion by inhibiting distal Na^+ reabsorption (similar to the proximal inhibition) and by increasing medullary blood flow.

Most of the diuretic drugs used today are specific Na^+ transport inhibitors. For example, the loop diuretic drugs (furosemide, bumetanide) inhibit the Na–K–2Cl cotransporter in the thick ascending limb, the thiazide diuretics inhibit the Na–Cl cotransporter in the distal convoluted tubule, and amiloride blocks the epithelial Na^+ channel in the collecting ducts (see Chapter 22). Spironolactone promotes Na^+ excretion by competitively inhibiting the binding of aldosterone to the mineralocorticoid receptor. The diuretic drugs are really natriuretic drugs; they produce an increased urine output (diuresis) because water reabsorption is diminished whenever Na^+ reabsorption is decreased. The loop diuretic drugs produce an especially large increase in Na^+ excretion, because normally 20% of filtered Na^+ is reabsorbed in the loop of Henle. More importantly, however, is that by inhibiting reabsorption of NaCl in the thick ascending limb, loop diuretics reduce the medullary vertical osmotic gradient and thereby reduce the ability of the kidney to osmotically reabsorb water from the collecting ducts. This diminished osmotic gradient in the kidney medulla may result in a striking increase in urine output. Diuretics commonly are prescribed for treating hypertension, though the powerful loop diuretics are more often employed to alleviate severe edema.

The principle of glomerular tubular balance is responsible for notable side effects associated with osmotic, loop, and thiazide-type diuretics. Glomerular tubular balance works on loads within adjacent sections of the renal tubule as well as with the kidney as a whole. For example, if sodium reabsorption is inhibited in the thick ascending limb of the loop of Henle by a loop diuretic, that section of the nephron will reabsorb less sodium than normal and thus pass on a larger than normal sodium load to the distal convoluted tubule. Because of glomerular tubular balance, the distal convoluted tubule will then reabsorb more sodium than normal. This effect of glomerular tubular balance has far reaching consequences. Secretion of K^+ and H^+ is enhanced, and reabsorption of calcium reduced, when sodium reabsorption is enhanced in the distal nephron because sodium reabsorption there creates a negative transepithelial electrical potential; the larger the sodium reabsorption, the more negative the potential becomes. For this reason, the overall effect of inhibiting sodium reabsorption at the loop of Henle is to enhance excretion of K^+, H^+, and Ca^{2+}. This loss of other electrolytes with loop diuretics is one of the classic untoward effects of using those agents for treatment of conditions requiring diuresis. This effect is also seen with osmotic and thiazide-type diuretics as well but not with distal tubule sodium channel blockers (e.g., amiloride) or aldosterone antagonists (e.g., spironolactone). These latter diuretics are thus often called *potassium-sparing diuretics* because they cause a diuresis without concurrent enhanced excretion of potassium by the kidney.

Integrated control of sodium balance is by the kidney.

Figure 23.10 summarizes Na^+ balance in a healthy adult man. Dietary intake of Na^+ varies and in a typical American diet amounts to about 100 to 300 mEq/d, mostly in the form of NaCl. Ingested Na^+ is mainly absorbed in the small intestine and is added to the ECF, where it is the major determinant of the osmolality and the amount of water in (or volume of) this fluid compartment. About 50% of the body's Na^+ is in the ECF, about 40% in bone, and 10% within cells.

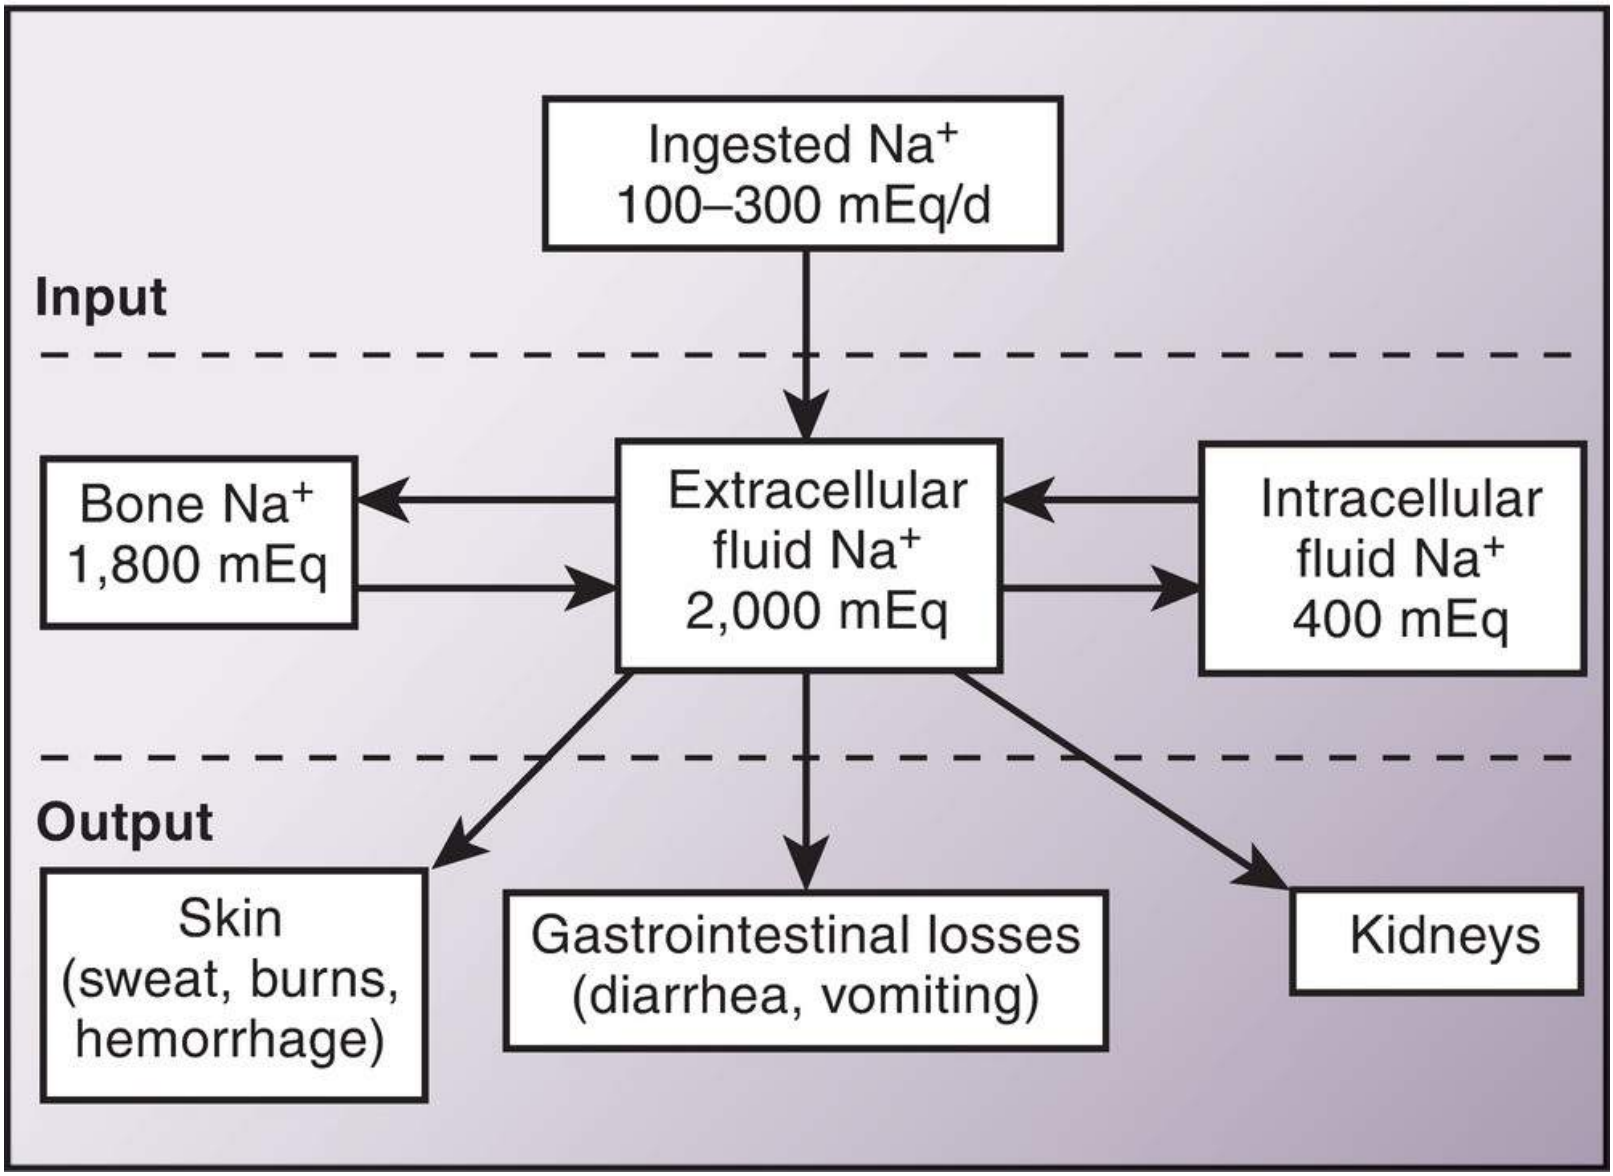

Figure 23.10 Sodium balance. Most of the Na^+ that we consume in our diet is excreted by the kidneys.

Losses of Na^+ occur via the skin, GI tract, and kidneys. Skin losses are usually small but can be considerable with sweating or burns. Likewise, GI losses are also usually small, but they can be large and serious with vomiting, diarrhea, or iatrogenic suction or drainage of GI secretions. The kidneys are ordinarily the major route of Na^+ loss from the body, excreting about 95% of the ingested Na^+ in a healthy person. Thus, the kidneys play a dominant role in the control of Na^+ balance. The kidneys can adjust Na^+ excretion over a wide range, reducing it to low levels when there is a Na^+ deficit and excreting more Na^+

when there is Na^+ excess in the body. Adjustments in Na^+ excretion occur by engaging many of the factors discussed above.

In a healthy person, one can think of the ECF volume as the regulated variable in a negative feedback control system (Fig. 23.11). The kidneys are the effectors, and they change Na^+ excretion in an appropriate manner. An increase in ECF volume inhibits renal sodium reabsorption and promotes renal Na^+ loss, which restores a normal volume. A decrease in ECF volume leads to enhanced renal sodium reabsorption and decreased renal Na^+ excretion. With continued dietary Na^+ intake, this Na^+ retention leads to the restoration of a normal ECF volume. Closer examination of this idea, particularly when considering pathophysiologic states, however, suggests that it is of limited usefulness. A more considered view suggests that the EABV is actually the regulated variable. In a healthy person, ECF volume and EABV usually change together in the same direction. In an abnormal condition, such as congestive heart failure, however, EABV is low when the ECF volume is abnormally increased. In this condition, there is a potent stimulus for renal Na^+ retention that clearly cannot be the ECF volume.

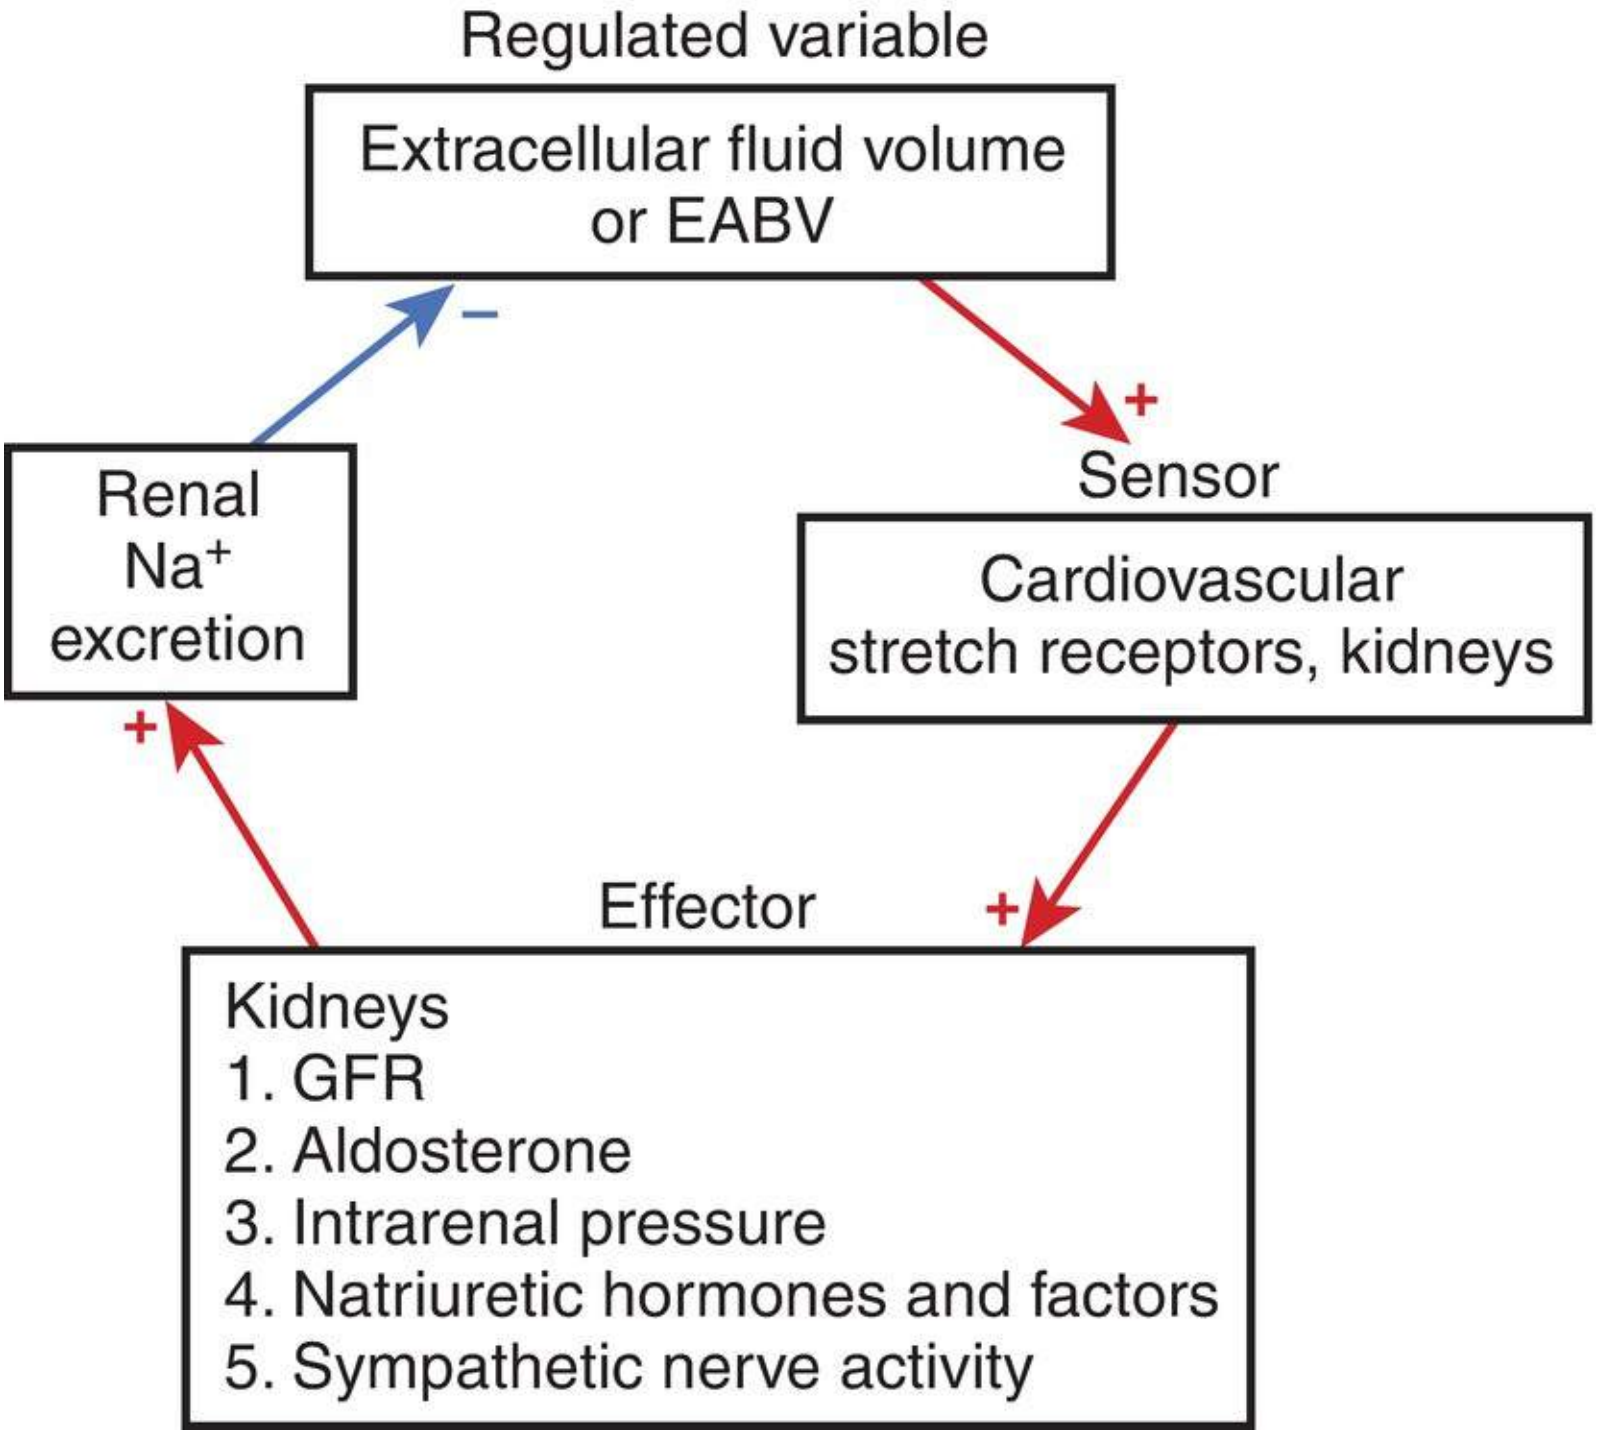

Figure 23.11 The regulation of extracellular fluid (ECF) volume or effective arterial blood volume (EABV) by a negative feedback control system. Arterial baroreceptors and the kidneys sense the degree of fullness of the arterial system. The kidneys are the effectors, and they change Na^+ excretion to restore EABV to normal. GFR, glomerular filtration rate.

When EABV is diminished, the degree of fullness of the arterial system is less than normal and tissue blood flow is inadequate. Arterial baroreceptors in the carotid sinuses and aortic arch sense the decreased arterial stretch. This will produce reflex activation of sympathetic nerve fibers to the kidneys, with consequent decreased GFR and renal blood flow and increased renin release. These changes favor renal Na^+ retention. Reduced EABV is also "sensed" in the kidneys in three ways:

1. A low pressure at the level of the afferent arteriole stimulates renin release via the intrarenal baroreceptor mechanism.

2. Decreases in renal perfusion pressure lead to a reduced GFR and hence diminished Na^+ excretion.
3. Decreases in renal perfusion pressure also reduce peritubular capillary hydrostatic pressure, thereby increasing the uptake of reabsorbed fluid and diminishing Na^+ excretion.

When kidney perfusion is threatened, the kidneys retain salt and water, a response that tends to improve their perfusion.

In a number of important diseases, including heart, liver, and some kidney diseases, abnormal renal retention of Na^+ contributes to the development of **generalized edema**, a widespread accumulation of salt and water in the interstitial spaces of the body. The condition is often not clinically evident until a person has accumulated more than 2.5 to 3 L of ECF in the interstitial space. Expansion of the interstitial space has two components: (1) an altered balance of Starling forces exerted across capillaries and (2) the retention of extra salt and water by the kidneys. Total plasma volume is only about 3.5 L; if edema fluid were derived solely from the plasma, hemoconcentration and circulatory shock would ensue. Conservation of salt and water by the kidneys is clearly an important part of the development of generalized edema.

Patients with congestive heart failure may accumulate many liters of edema fluid, which is easily detected as weight gain (because 1 L of fluid weighs 1 kg). Because of the effect of gravity, the ankles become swollen and pitting edema develops. As a result of heart failure, venous pressure is elevated, causing fluid to leak out of the capillaries because of their elevated hydrostatic pressure. Inadequate pumping of blood by the heart leads to a decrease in EABV, and so the kidneys retain salt and water. Alterations in many of the factors discussed above—decreased GFR, increased renin–angiotensin–aldosterone activity, changes in intrarenal pressures, and increased sympathetic nervous system activity—contribute to the renal salt and water retention. To minimize the accumulation of edema fluid, patients are often placed on a reduced Na^+ intake and given diuretic drugs.

POTASSIUM BALANCE

Potassium (K^+) is one of the major electrolytes in the body and the most abundant ion in the ICF compartment. It plays an important role in the electrophysiology of all nerve and muscle tissues and can affect acid–base balance in the body as well. Plasma K^+ concentration is closely regulated by the kidney. Because K^+ is the major osmotically active solute in cells, the amount of cellular K^+ is the major determinant of the amount of water in (and therefore the volume of) the ICF compartment, in the same way that extracellular Na^+ is a major determinant of ECF volume. When cells lose K^+ (and accompanying anions), they also lose water and shrink; the converse is also true.

The distribution of K^+ across cell membranes—that is, the ratio of intracellular to extracellular K^+ concentrations—is the major determinant of the resting membrane potential of cells and hence their excitability (see Chapter 3). Disturbances of K^+ balance often produce altered excitability of nerves and muscles. A low plasma K^+ level leads to membrane hyperpolarization and reduced excitability; muscle weakness is a common symptom. Excessive plasma K^+ levels lead to membrane depolarization and increased excitability. High plasma K^+ levels can cause cardiac arrhythmias and ventricular fibrillation, which is usually a lethal event.

K^+ balance is linked to acid–base balance in complex ways (see Chapter 24). K^+ depletion, for example, can lead to metabolic alkalosis, and K^+ excess can lead to metabolic acidosis. A primary disturbance in acid–base balance can also lead to abnormal K^+ balance. K^+ also affects the activity of enzymes involved in carbohydrate metabolism and electron transport. K^+ is needed for tissue growth and repair, whereas tissue breakdown or increased protein catabolism results in a loss of K^+ from cells.

Distribution of potassium between intracellular and extracellular fluid is tightly regulated.

Total body content of K^+ in a healthy, young adult, 70-kg man is about 3,700 mEq. About 2% of this, roughly 60 mEq, is in the functional ECF (blood plasma, interstitial fluid, and lymph). About 8% of the body's K^+ is in bone, dense connective tissue, and cartilage, and another 1% is in transcellular fluids. Ninety percent of the body's K^+ is in the cell compartment.

A normal plasma K^+ level ranges from 3.5 to 5.0 mEq/L. By definition, a plasma K^+ level below 3.5 mEq/L is **hypokalemia** and a plasma K^+ level above 5.0 mEq/L is **hyperkalemia**. The K^+ level in skeletal muscle cells is about 150 mEq/L of cell water. Skeletal muscle cells constitute the largest fraction of the cell mass in the human body and contain about two thirds of the body's K^+. One can easily appreciate that abnormal leakage of K^+ from muscle cells, as a result of trauma for example, may lead to dangerous hyperkalemia.

A variety of factors influence the distribution of K^+ between cells and ECF (Fig. 23.12):

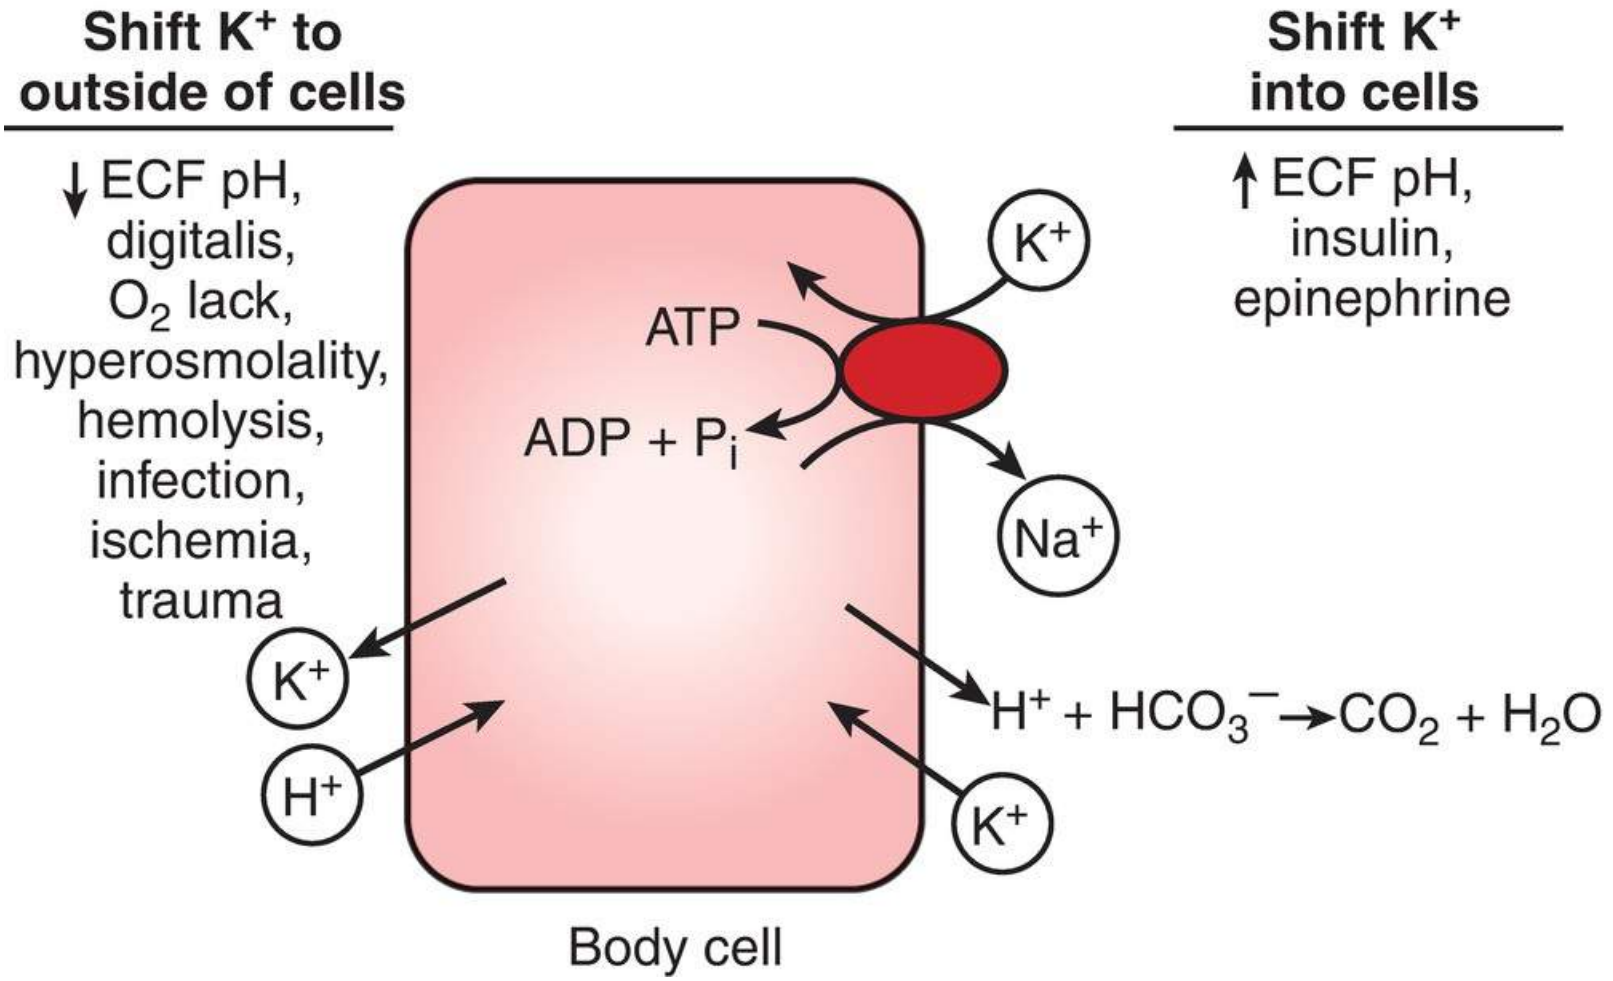

Figure 23.12 Factors influencing the distribution of potassium between intracellular and extracellular fluids. ADP, adenosine diphosphate; ATP, adenosine triphosphate; ECF, extracellular fluid; P_i, inorganic phosphate. K^+ and H^+ passively exchange for each other across the cell membrane.

- A key factor is the Na^+/K^+-ATPase, which pumps K^+ into cells. If this enzyme is inhibited—as a result of an inadequate tissue oxygen supply or digitalis overdose, for example—then hyperkalemia may result.
- A decrease in ECF pH (i.e., an increase in ECF H^+) tends to produce a rise in ECF K^+. This results from a passive exchange of extracellular H^+ for intracellular K^+ across the cell membrane. When a mineral acid such as HCl is added to the ECF, a fall of 0.1 unit in blood pH leads to roughly a 0.6-mEq/L rise in plasma K^+ level. When an organic acid (which can penetrate cell membranes) is added, the rise in plasma K^+ level for a given fall in blood pH is considerably less. The fact that blood pH influences plasma K^+ level is sometimes used in the emergency treatment of hyperkalemia; intravenous infusion of a $NaHCO_3$ solution (which makes the blood more alkaline) causes H^+ to move out of cells in exchange for K^+, which moves into cells.
- Insulin promotes the uptake of K^+ by skeletal muscle and liver cells. This effect appears to be a result of stimulation of cell membrane Na^+/K^+-ATPase pumps. Insulin (administered with glucose) is also used in the emergency treatment of hyperkalemia.
- Epinephrine increases K^+ uptake by cells, an effect mediated by β_2 receptors.
- Hyperosmolality (e.g., that resulting from hyperglycemia) tends to raise plasma K^+ level; hyperosmolality causes cells to shrink and raises intracellular K^+ level, which then favors outward diffusion of K^+ into the ECF.
- Tissue trauma, infection, ischemia, hemolysis, and severe exercise release K^+ from cells and can cause significant hyperkalemia. An artifactual increase in plasma K^+ level, **pseudohyperkalemia**, results if blood has been mishandled and red cells have been injured or lysed causing them to leak K^+.

The plasma K^+ level is sometimes taken as a rough guide to total body K^+ stores. For example, if a condition is known to produce an excessive loss of K^+ (such as taking a diuretic drug), a decrease of 1 mEq/L in plasma K^+ level may correspond to a loss of 200 to 300 mEq K^+. Clearly, however, many factors affect the distribution of K^+ between cells and ECF, and so in many circumstances, the plasma K^+ is not a good index of the amount of K^+ in the body.

Abnormal renal K^+ excretion is the major cause of potassium imbalance.

Figure 23.13 depicts K^+ balance for a healthy adult man. Most of the foods that we eat contain K^+. K^+ intake (50 to 150 mEq/d) and absorption by the small intestine are unregulated. On the output side, GI losses are normally small, but they can be large, especially with diarrhea. Diarrheal fluid may contain as much as 80 mEq K^+/L. K^+ loss in sweat is clinically unimportant. Normally, the kidneys excrete 90% of the ingested K^+.

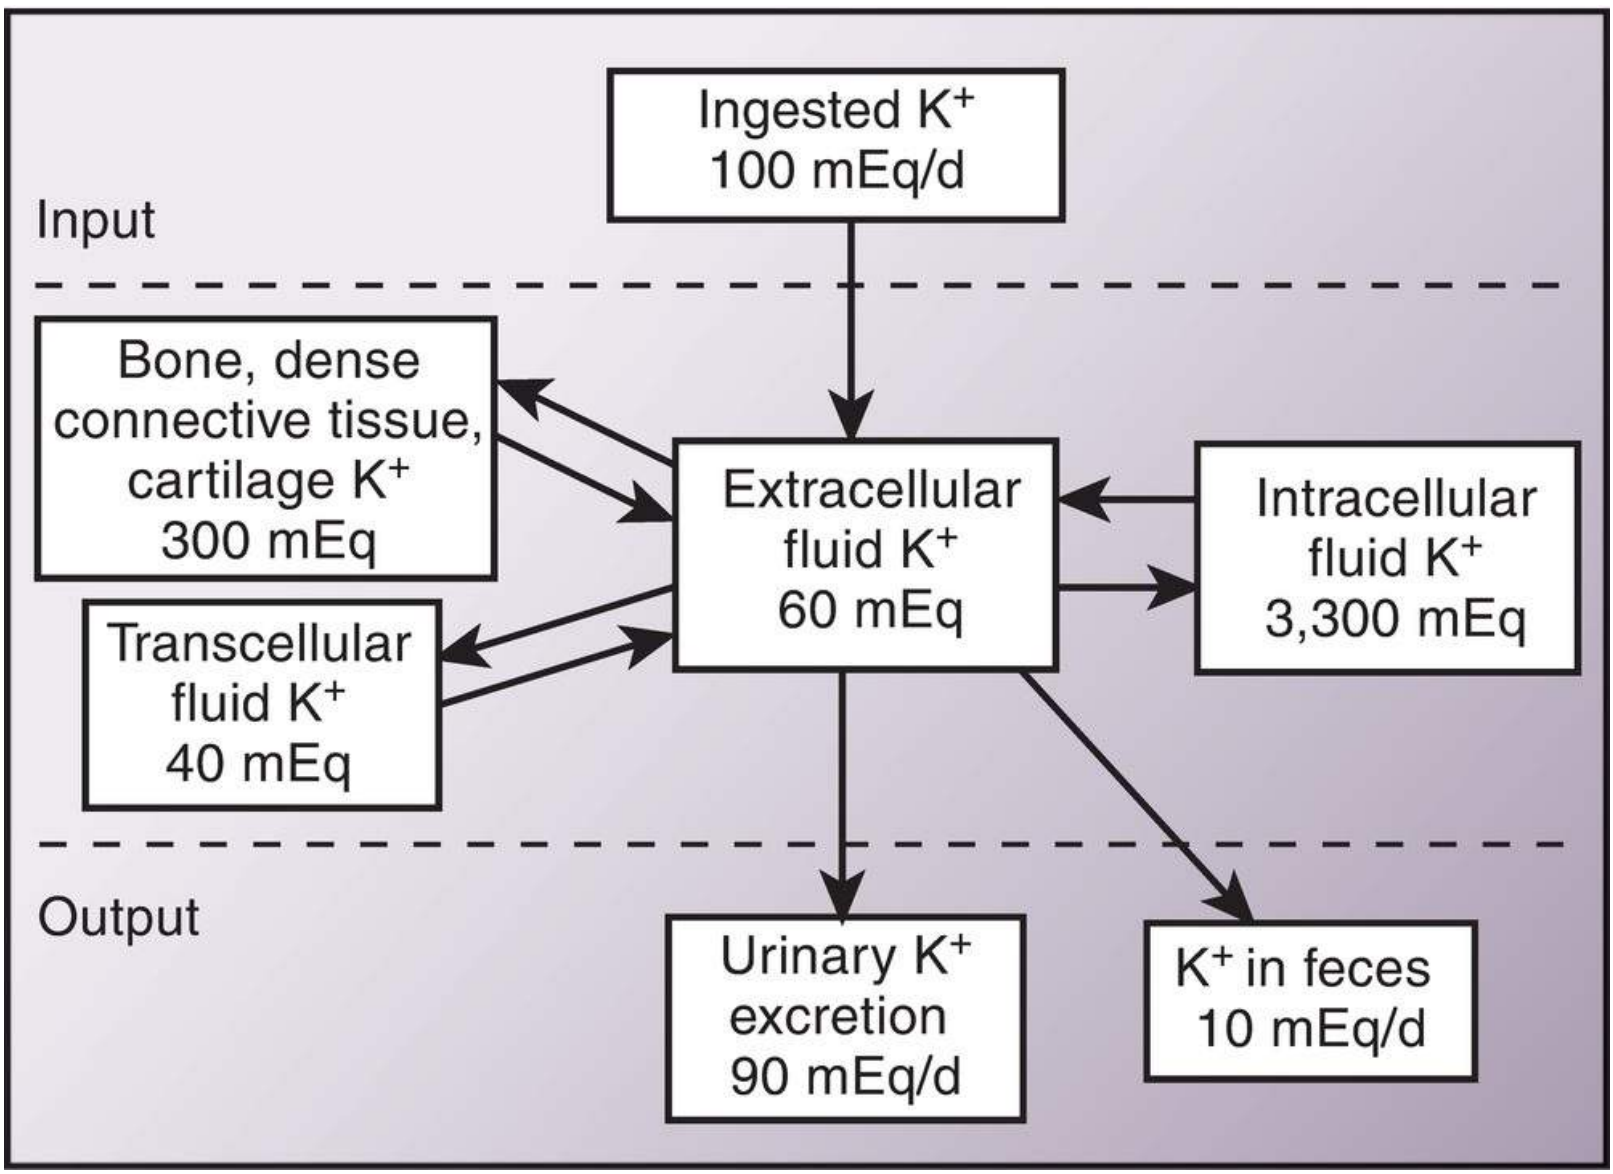

Figure 23.13 Potassium balance for a healthy adult. Most of the body's K^+ is in the cell compartment. Renal K^+ excretion is normally adjusted to keep a person in balance.

The kidneys are the major site of control of K^+ balance; they increase K^+ excretion when there is too much K^+ in the body and conserve K^+ when there is too little. The major cause of K^+ imbalances is abnormal renal K^+ excretion. If the kidneys excrete too little K^+ and the dietary intake of K^+ continues, hyperkalemia can result. For example, in Addison disease, a low plasma aldosterone level leads to

deficient K^+ excretion because aldosterone normally stimulates potassium secretion directly in the distal nephron and indirectly through stimulating sodium reabsorption, which increases the negative transepithelial electrical potential. Inadequate renal K^+ excretion also occurs with acute renal failure. Hyperkalemia resulting from inadequate renal excretion is often compounded by tissue trauma, infection, and acidosis, all of which raise plasma K^+ level. In chronic renal failure, hyperkalemia usually does not develop until the GFR falls below 15 to 20 mL/min, because of the remarkable ability of the kidney collecting ducts to adapt and increase K^+ secretion.

Excessive loss of K^+ by the kidneys leads to hypokalemia. The major cause of renal K^+ wasting is iatrogenic, an unwanted side effect of diuretic drug therapy. Hyperaldosteronism also causes excessive K^+ excretion. In uncontrolled diabetes mellitus, K^+ loss is increased because of the osmotic diuresis resulting from the glucosuria and an elevated rate of fluid flow in the cortical collecting ducts. Several rare inherited defects in tubular transport, including Bartter, Gitelman, and Liddle syndromes, also lead to excessive renal K^+ excretion and hypokalemia.

Changes in dietary potassium intake change renal potassium excretion in an appropriate direction.

As was discussed in Chapter 22, K^+ is filtered, reabsorbed, and secreted in the kidneys. Most of the filtered K^+ is reabsorbed in the proximal convoluted tubule (70%) and loop of Henle (25%), and most K^+ excreted in the urine is usually the result of secretion by cortical collecting duct principal cells. The percentage of filtered K^+ excreted in the urine is typically about 15% (Fig. 23.14). With prolonged K^+ depletion, the kidneys may excrete only 1% of the filtered load. On the other hand, excessive K^+ intake may result in the excretion of an amount of K^+ that exceeds the amount filtered; in this case, there is greatly increased K^+ secretion by cortical collecting ducts.

Figure 23.14 The percentage of the filtered load of potassium remaining in tubular fluid as it flows down the nephron. K^+ is usually secreted in the cortical collecting duct. With K^+ loading, this secretion is so vigorous that the amount of K^+ excreted may actually exceed the filtered load. With K^+ depletion, K^+ is reabsorbed by the collecting ducts.

When the dietary intake of K^+ is changed, renal excretion changes in the same direction. An important site for this adaptive change is the cortical collecting duct. Figure 23.15 shows the response to an increase in dietary K^+ intake. Two pathways are involved. First, an elevated plasma K^+ level leads to increased K^+ uptake by the basolateral cell membrane Na^+/K^+-ATPase in collecting duct principal cells, resulting in increased intracellular K^+, K^+ secretion, and then K^+ excretion. Second, an elevated plasma K^+ level has a direct effect (i.e., not mediated by renin and angiotensin) on the adrenal cortex to stimulate the synthesis and release of aldosterone. Aldosterone acts on collecting duct principal cells to (1) increase the Na^+ permeability of the luminal cell membrane, (2) increase the number and activity of basolateral cell membrane Na^+/K^+-ATPase pumps, (3) increase the luminal cell membrane K^+ permeability, and (4) increase cell metabolism. These changes increase the transepithelial negative potential as well as enhance K^+ conductance through the luminal membrane, which collectively result in increased K^+ secretion.

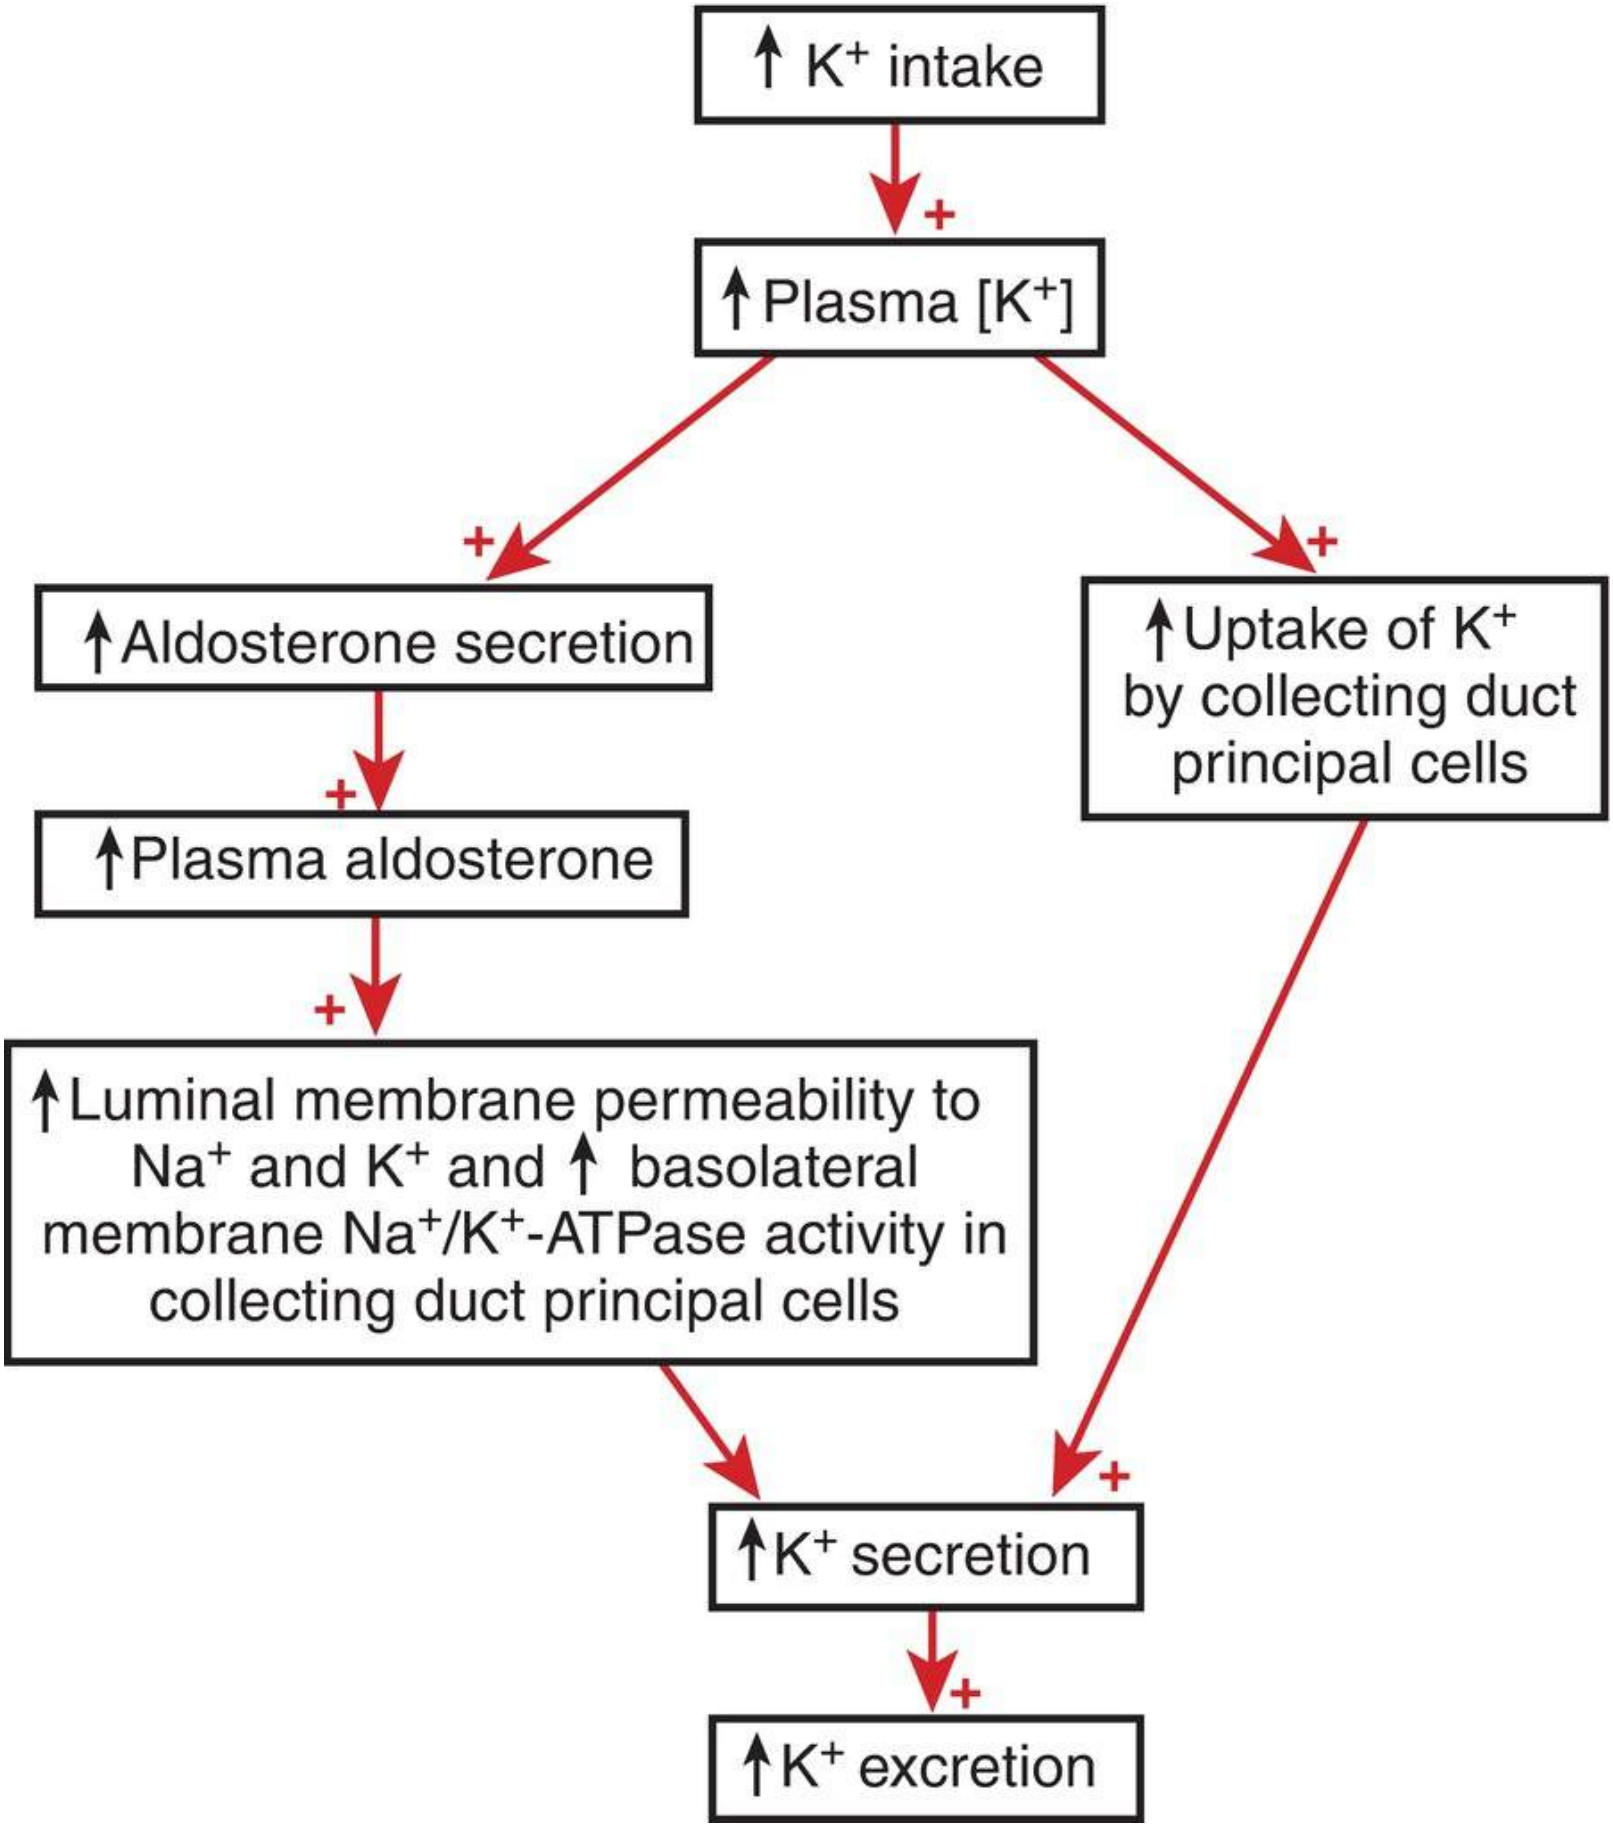

Figure 23.15 The effect of increased dietary potassium intake on potassium excretion. K^+ directly stimulates aldosterone secretion and leads to an increase in cell K^+ in collecting duct principal cells. Both effects lead to enhanced secretion and, hence, excretion of K^+.

In cases of decreased dietary K^+ intake or K^+ depletion, the activity of the luminal cell membrane H^+/K^+-ATPase found in alpha-intercalated cells is increased. This promotes K^+ reabsorption by the collecting ducts. The collecting ducts can greatly diminish K^+ excretion, but it takes a couple of weeks for K^+ loss to reach minimal levels.

Net renal potassium excretion may be determined by counterbalancing effects.

Sodium deprivation does not lead to potassium loss via the kidneys. Considering the fact that aldosterone stimulates both Na^+ reabsorption and K^+ secretion, why then does Na^+ deprivation, a stimulus that raises plasma aldosterone levels, not lead to enhanced K^+ excretion? The explanation is related to the fact that Na^+ deprivation tends to lower the GFR and increase proximal Na^+ reabsorption (Fig. 23.16). This response leads to a fall in Na^+ delivery and decreased fluid flow rate in the cortical collecting ducts, which diminishes K^+ secretion (see Chapter 22), counterbalancing the stimulatory effect of aldosterone. Consequently, K^+ excretion is unaltered.

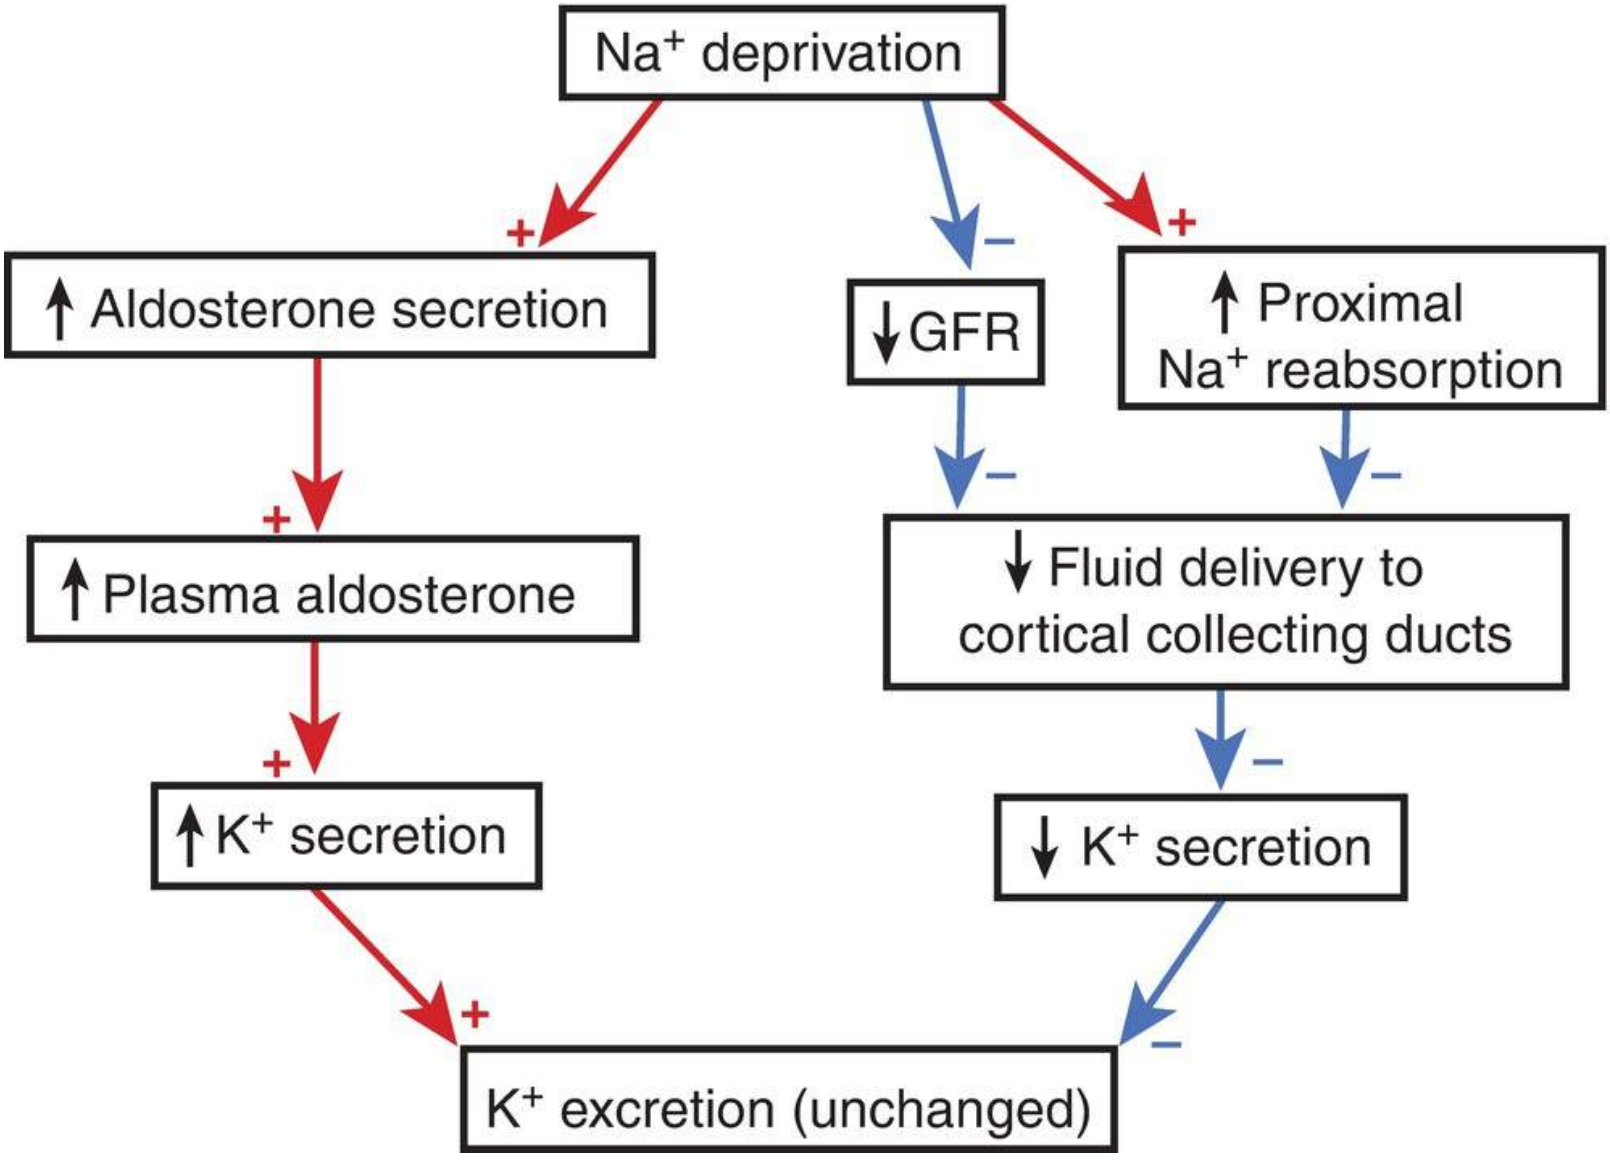

Figure 23.16 Why sodium depletion does not lead to enhanced potassium excretion. GFR, glomerular filtration rate.

Another puzzling question is why doesn't K^+ excretion increase during a water diuresis? In Chapter 22, we mentioned that an increase in fluid flow through the cortical collecting ducts increases K^+

secretion. AVP, in addition to its effects on water permeability, stimulates K^+ secretion by increasing the activity of luminal membrane K^+ channels in cortical collecting duct principal cells. Because plasma AVP levels are low during a water diuresis, this will reduce K^+ secretion, opposing the effects of increased flow, with the result that K^+ excretion hardly changes.

CALCIUM BALANCE

The kidneys play an important role in the maintenance of Ca^{2+} balance, but it is not the only factor involved. Endocrine effects in the GI tract and on bone metabolism also play key roles in overall calcium balance. Ca^{2+} intake is about 1,000 mg/d and mainly comes from dairy products in the diet. About 300 mg/d is absorbed by the small intestine, a process controlled by $1,25(OH)_2$ vitamin D_3. About 150 mg/d of Ca^{2+} is secreted into the GI tract (via saliva, gastric juice, pancreatic juice, bile, and intestinal secretions), so that net absorption is only about 150 mg/d. Fecal Ca^{2+} excretion is about 850 mg/d, and urinary excretion about 150 mg/d.

Most of the body's Ca^{2+} is in bone (99%), which constantly turns over. In a healthy adult, the rate of release of Ca^{2+} from old bone exactly matches the rate of deposition of Ca^{2+} in newly formed bone (500 mg/d). The kidney can only access calcium that is free in plasma. A normal plasma Ca^{2+} level is about 10 mg/dL, which is equal to 2.5 mmol/L or 5 mEq/L. About 40% of plasma Ca^{2+} is bound to plasma proteins (mainly serum albumin), which are not filtered at the glomerulus, 10% is bound to small diffusible anions (such as citrate, bicarbonate, phosphate, and sulfate), and 50% is free or ionized. It is the ionized Ca^{2+} in the blood that is physiologically important and closely regulated (see Chapter 35).

Ca^{2+} that is not bound to plasma proteins (i.e., 60% of the plasma Ca^{2+}) is freely filterable in the glomeruli. About 60% of the filtered Ca^{2+} is reabsorbed in the proximal convoluted tubule (Fig. 23.17). Two thirds is reabsorbed via a paracellular route in response to solvent drag and the small lumen-positive potential found in the late proximal convoluted tubule. One third is reabsorbed via a transcellular route that includes Ca^{2+} channels in the apical cell membrane and a primary Ca^{2+}-ATPase or 3 Na^+/1 Ca^{2+} exchanger in the basolateral cell membrane. About 30% of filtered Ca^{2+} is reabsorbed along the loop of Henle. Most of the Ca^{2+} reabsorbed in the thick ascending limb is reabsorbed by passive transport through the tight junctions, propelled by the lumen-positive potential there.

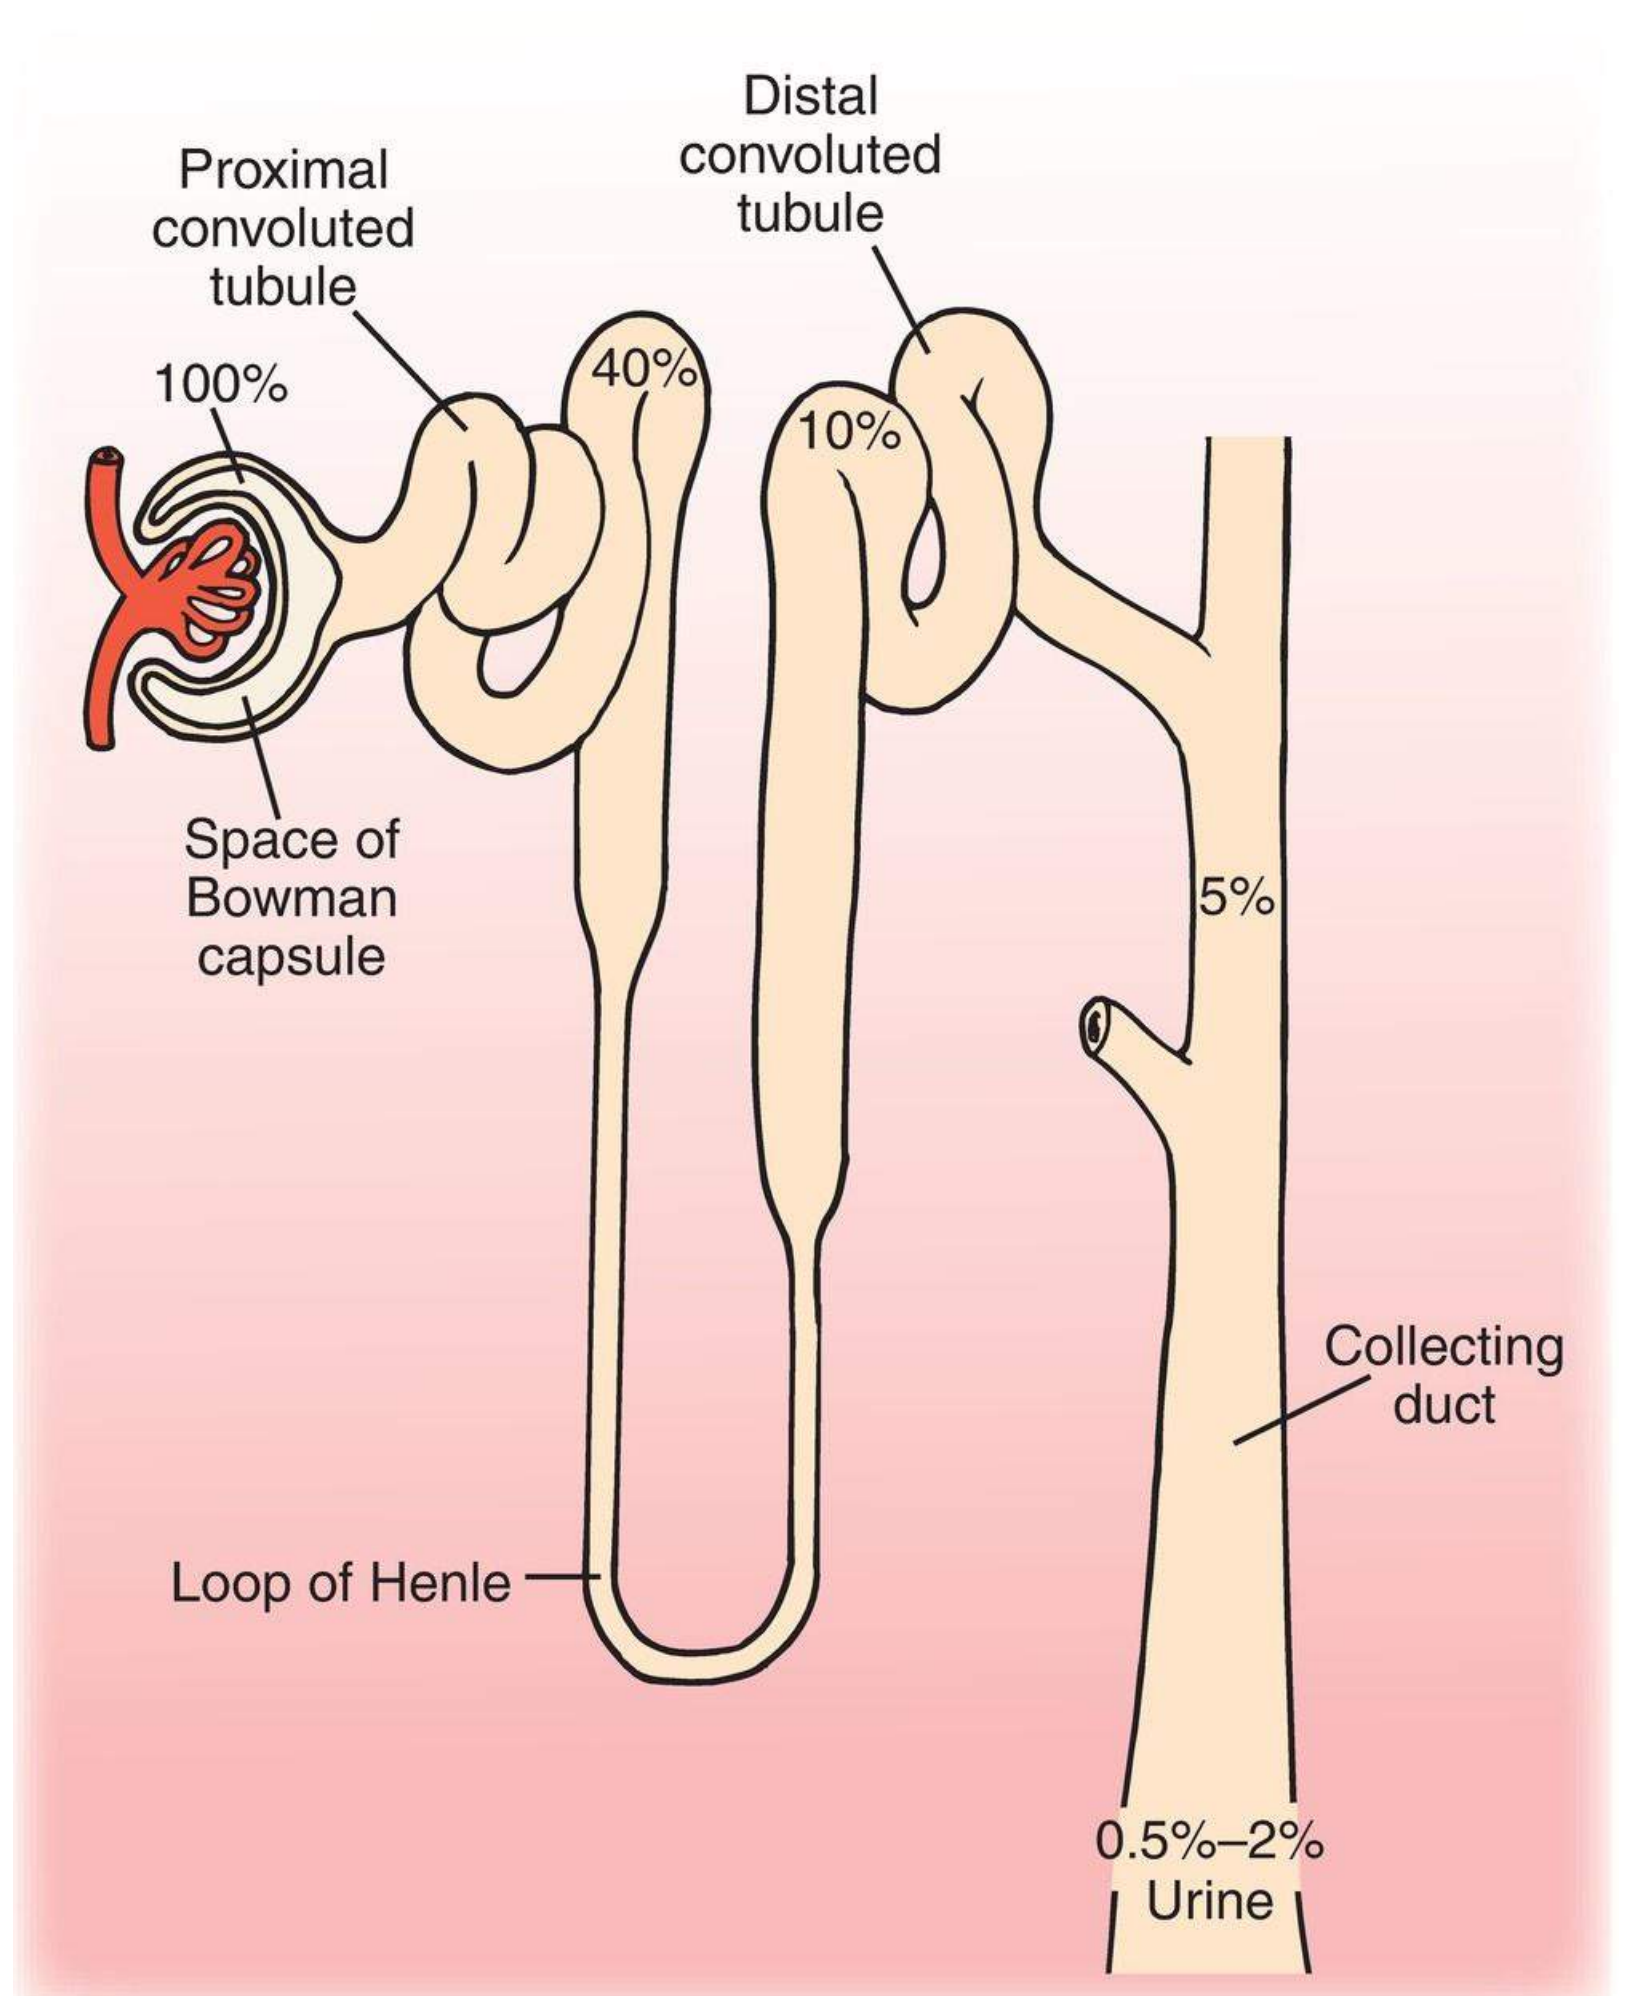

Figure 23.17 The percentage of the filtered load of calcium remaining in tubular fluid as it flows

down the nephron. The kidneys filter about 10,800 mg/d (0.6 × 100 mg/L × 180 L/d) and reabsorb about 60% of the filtered load in the proximal convoluted tubule and another 30% in the loop of Henle. About 0.5% to 2% of the filtered load (about 50 to 200 mg Ca^{2+}/d) is excreted.

Reabsorption continues along the distal convoluted tubule. Reabsorption here is increased by thiazide diuretics. Thiazides inhibit the luminal membrane Na–Cl cotransporter in distal convoluted tubule cells, which leads to a fall in intracellular Na^+ level. In turn, this promotes Na^+/Ca^{2+} exchange and increased basolateral extrusion of Ca^{2+} and, hence, increased Ca^{2+} reabsorption. For this reason, thiazide diuretics may be prescribed in cases of excess Ca^{2+} in the urine (**hypercalciuria**) and **nephrolithiasis** (kidney stone disease). Ca^{2+} reabsorption continues in the connecting tubules and collecting ducts.

The parathyroid hormone (PTH) is the primary hormonal regulator of Ca^{2+} excretion. PTH increases Ca^{2+} reabsorption in the thick ascending limb, distal convoluted tubule, and connecting tubule. Only about 0.5% to 2% of the filtered Ca^{2+} is usually excreted. (Chapter 35 discusses Ca^{2+} balance and its control by several hormones in more detail.)

MAGNESIUM BALANCE

An adult body contains about 2,000 mEq of Mg^{2+}, of which about 60% is present in bone, 39% is in cells, and 1% is in the ECF. Mg^{2+} is the second most abundant cation in cells, after K^+ (see Table 23.2). The bulk of intracellular Mg^{2+} is not free but is bound to a variety of organic compounds such as ATP. Mg^{2+} is present in the plasma at a concentration of about 1 mmol/L (2 mEq/L). About 20% of plasma Mg^{2+} is bound to plasma proteins, 20% is complexed with various anions, and 60% is free or ionized.

About 25% of the Mg^{2+} filtered by the glomeruli is reabsorbed in the proximal convoluted tubule (Fig. 23.18); this is a lower percentage than for Na^+, K^+, Ca^{2+}, or water. The proximal tubule epithelium is rather impermeable to Mg^{2+} under normal conditions, and so there is little passive Mg^{2+} reabsorption. The major site of Mg^{2+} reabsorption is the loop of Henle (mainly the thick ascending limb), which reabsorbs about 65% of filtered Mg^{2+}. Reabsorption here is mainly passive and occurs through the tight junctions, driven by the lumen-positive potential there. Recent studies have identified a tight junction protein that is a channel that facilitates Mg^{2+} movement. Changes in Mg^{2+} excretion result mainly from changes in loop transport. More distal portions of the nephron reabsorb only a small fraction of filtered Mg^{2+} and, under normal circumstances, appear to play a minor role in controlling Mg^{2+} excretion.

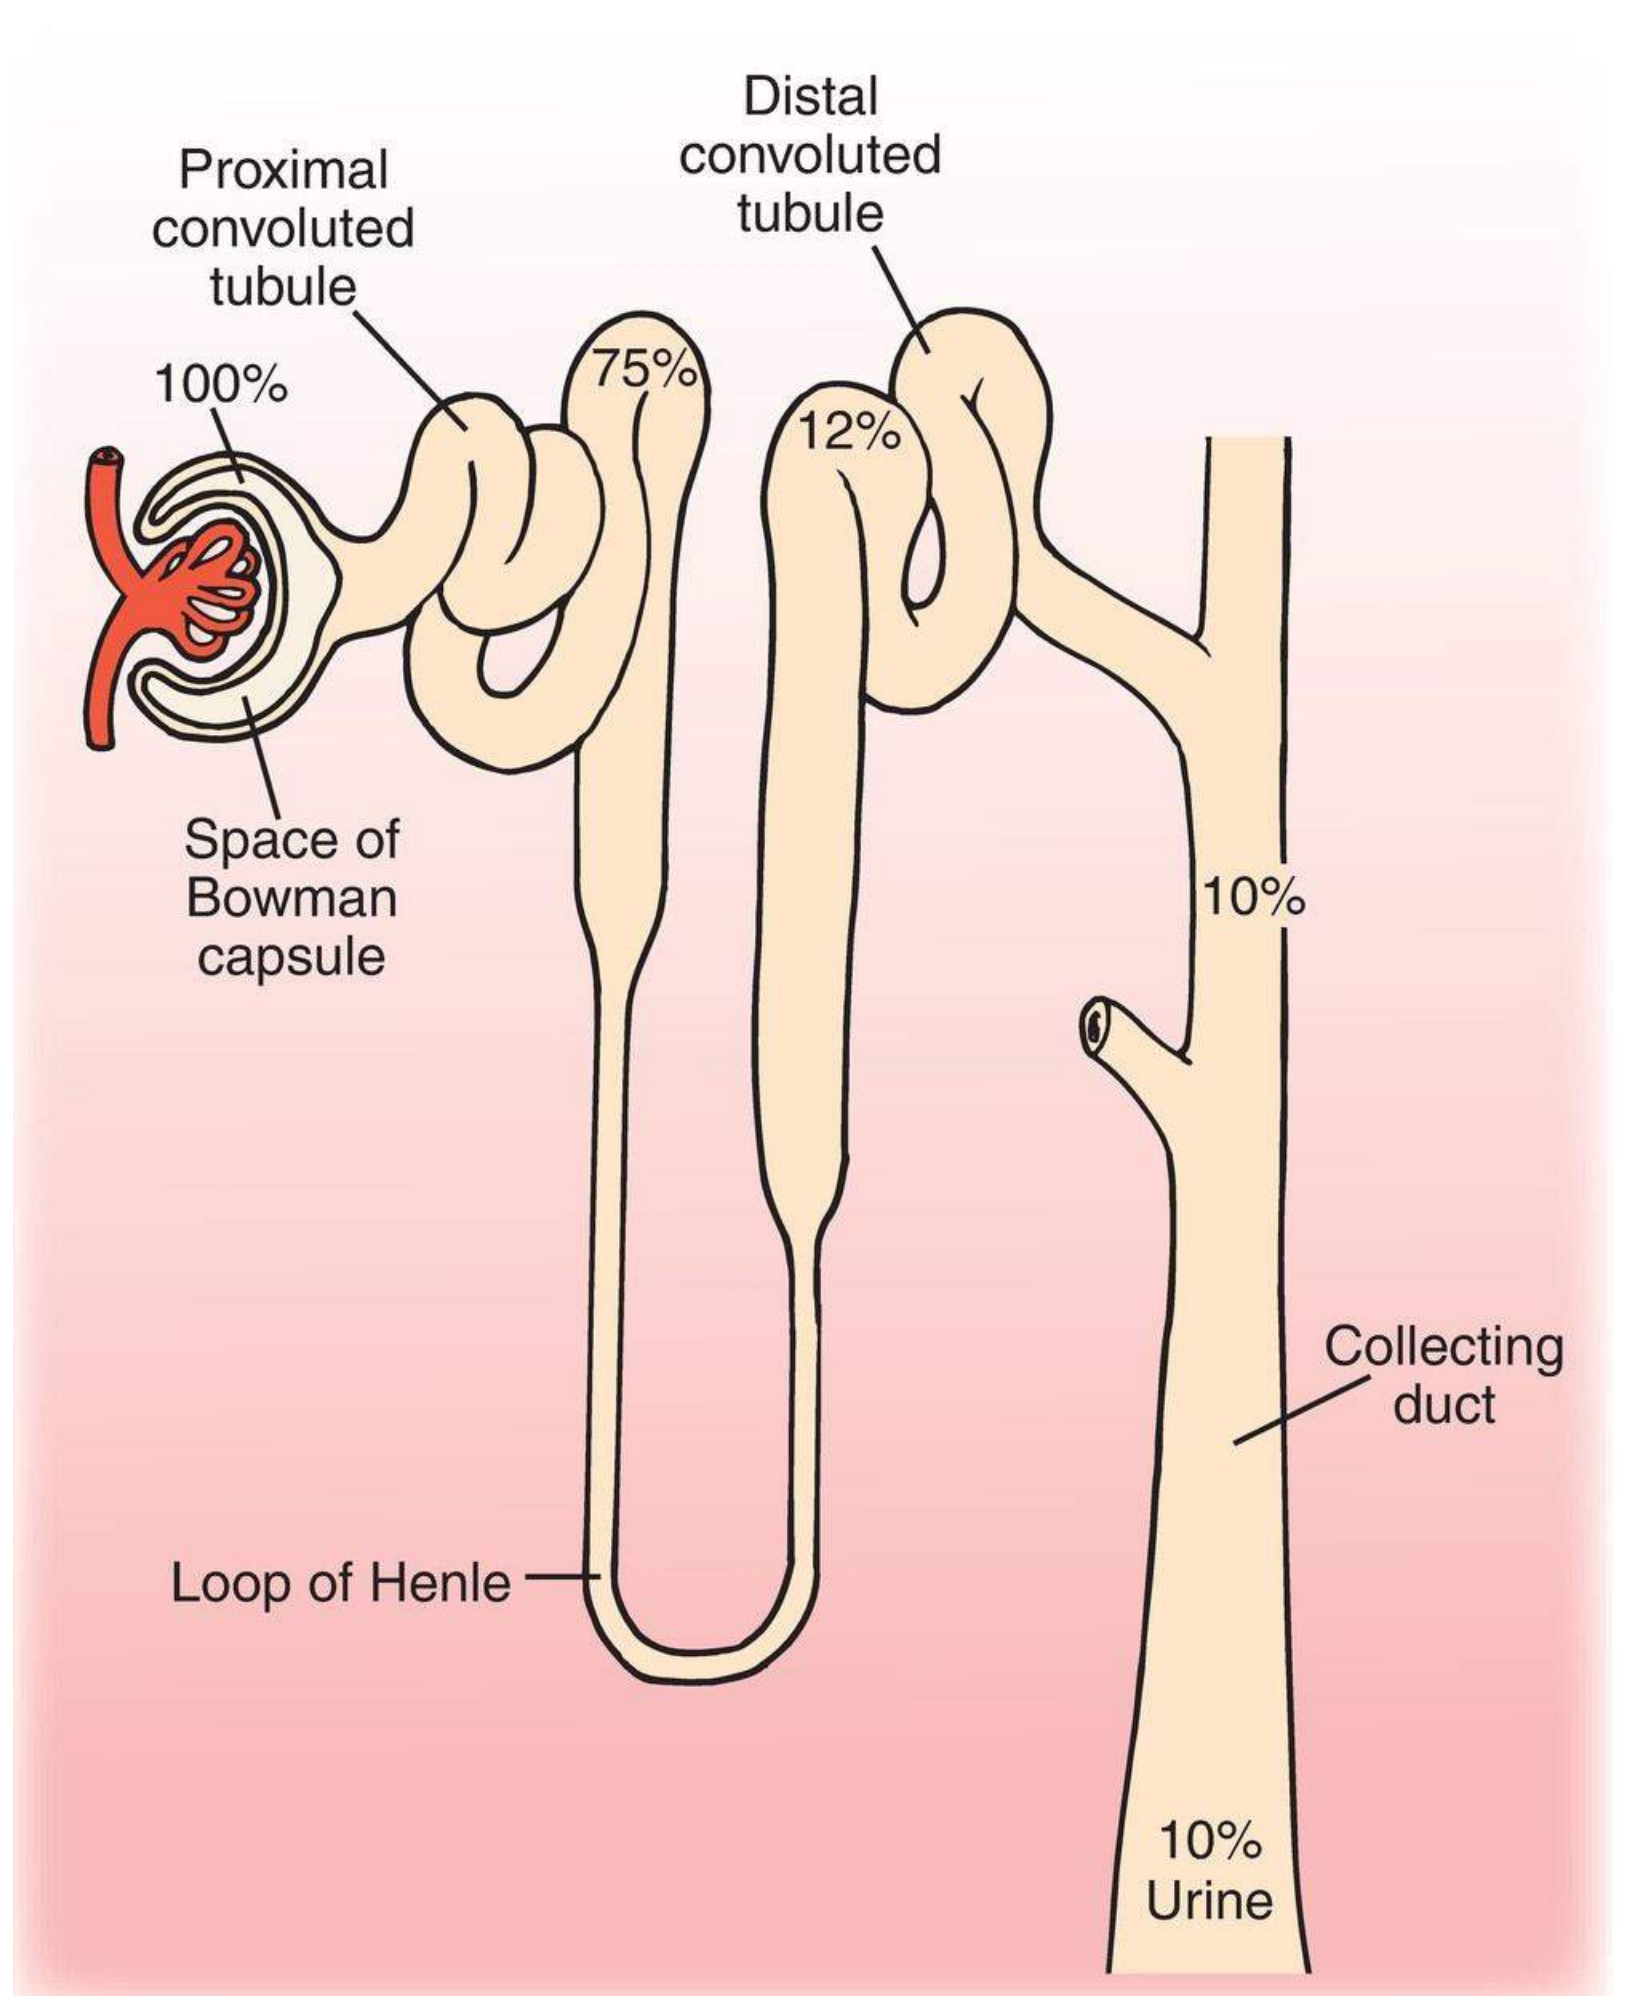

Figure 23.18 The percentage of the filtered load of magnesium remaining in tubular fluid as it flows

down the nephron. The loop of Henle, specifically the thick ascending limb, is the major site of reabsorption of filtered Mg^{2+}.

An abnormally low plasma Mg^{2+} level is characterized by neuromuscular and central nervous system hyperirritability and cardiac arrhythmias. Abnormally high plasma Mg^{2+} levels have a sedative effect and may cause cardiac arrest. Dietary intake of Mg^{2+} is usually 20 to 50 mEq/d; two thirds is excreted in the feces and one third in the urine. The kidneys are mainly responsible for regulating the plasma Mg^{2+} level. The kidneys rapidly excrete excess amounts of Mg^{2+}. In Mg^{2+}-deficient states, Mg^{2+} virtually disappears from the urine.

PHOSPHATE BALANCE

A normal plasma concentration of inorganic phosphate is about 1 mmol/L. At a normal blood pH of 7.4, 80% of the phosphate is present as HPO_4^{2-} and 20% is present as $H_2PO_4^-$. Phosphate plays a variety of roles in the body. It is an important constituent of bone; it plays a critical role in cell metabolism, structure, and regulation (as organic phosphates); and it is a pH buffer.

Phosphate is mainly unbound in the plasma and is therefore freely filtered by the glomeruli. The proximal tubule is the major site of phosphate reabsorption. About 60% to 70% of filtered phosphate is actively reabsorbed in the proximal convoluted tubule, and another 15% is reabsorbed by the proximal straight tubule via a Na^+–phosphate cotransporter in the luminal cell membrane (Fig. 23.19). The remaining portions of the nephron and collecting ducts reabsorb little, if any, phosphate. Only about 5% to 20% of filtered phosphate is usually excreted. Phosphate in the urine is an important pH buffer and contributes to titratable acid excretion (see Chapter 24).

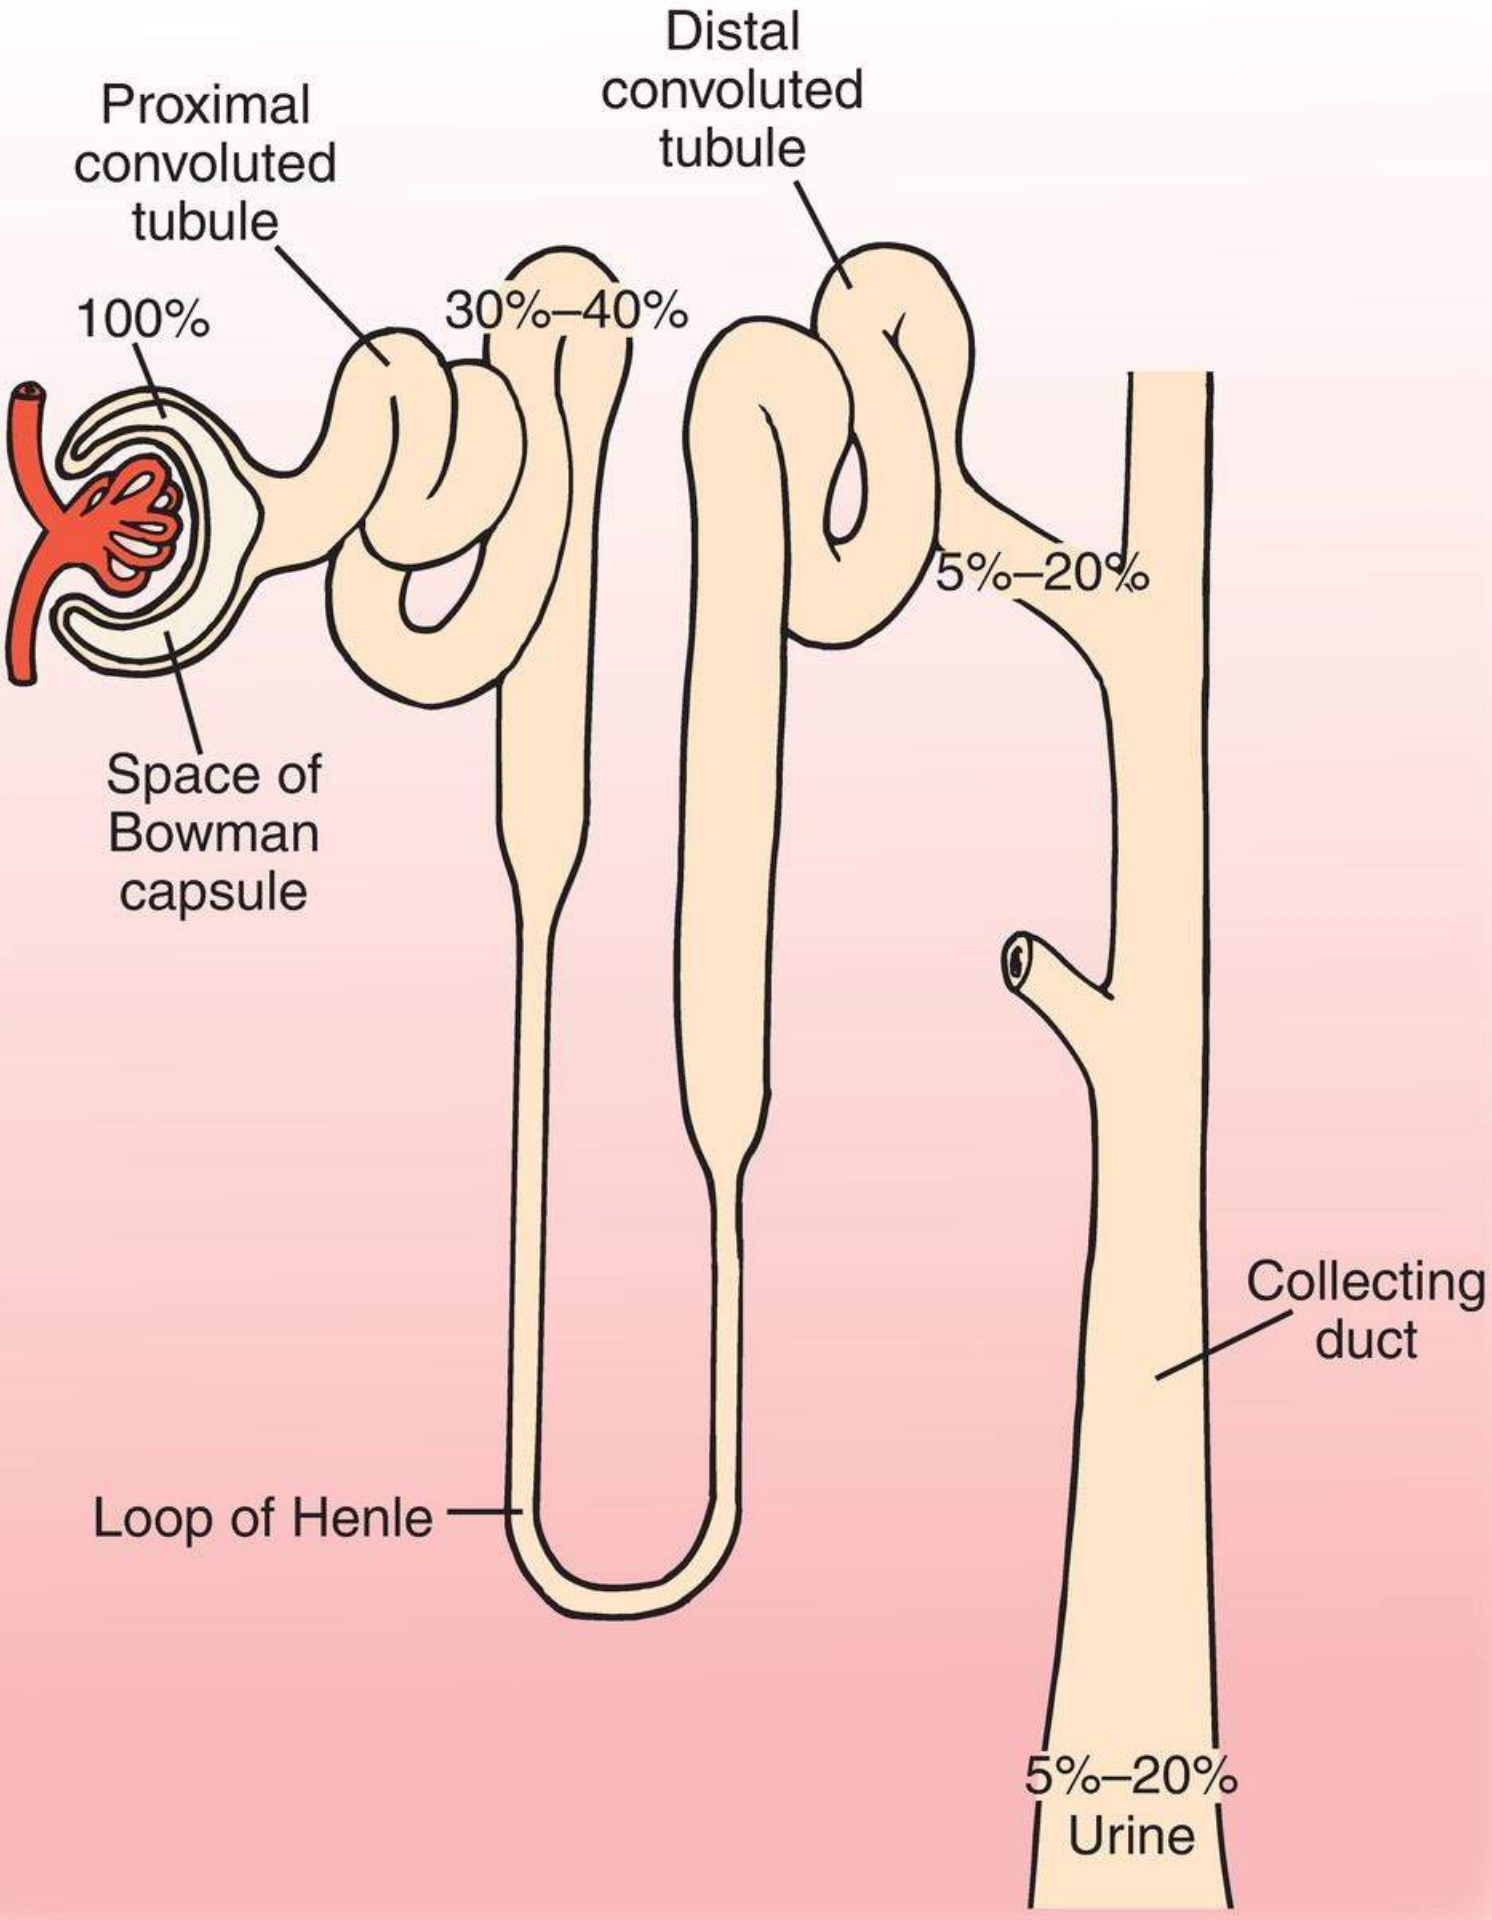

Figure 23.19 The percentage of the filtered load of phosphate remaining in tubular fluid as it flows

down the nephron. The proximal tubule is the major site of phosphate reabsorption, and downstream nephron segments reabsorb little, if any, phosphate.

Phosphate reabsorption is tubular transport maximum (Tm)–limited (see Chapter 22), and the amounts of phosphate filtered usually exceed the maximum reabsorptive capacity of the tubules for phosphate. This is different from the situation for glucose, in which normally less glucose is filtered than can be reabsorbed. If more phosphate is ingested and absorbed by the intestine, then plasma phosphate rises, more phosphate is filtered, and the filtered load exceeds the Tm more than usual, so the extra phosphate is excreted. Thus, the kidneys participate in regulating the plasma phosphate by an "overflow" type of mechanism. When there is an excess of phosphate in the body, they automatically increase phosphate excretion. In cases of phosphate depletion, the kidneys filter less phosphate and the tubules reabsorb a larger percentage of the filtered phosphate.

Phosphate reabsorption in the proximal tubule is controlled by a variety of factors. PTH is of particular importance; it decreases the phosphate Tm, thereby increasing phosphate excretion. The response to PTH is rapid (minutes) and involves endocytosis of Na^+–phosphate cotransporters from the apical cell membrane and subsequent degradation of the cotransporters in lysosomes. **Fibroblast growth factor 23 (FGF23)** is another protein hormone that inhibits tubular phosphate reabsorption; elevated plasma levels cause hypophosphatemia and, consequently, rickets or osteomalacia.

Patients with chronic renal disease often have an elevated plasma phosphate (**hyperphosphatemia**) level, depending on the severity of the disease. When the GFR falls, the filtered phosphate load is diminished and the tubules reabsorb phosphate more completely. Phosphate excretion is inadequate in the face of continued intake of phosphate in the diet. Hyperphosphatemia is dangerous because of the precipitation of calcium phosphate in soft tissues. For example, when calcium phosphate precipitates in the walls of blood vessels, blood flow is impaired. Hyperphosphatemia can lead to myocardial failure and pulmonary insufficiency.

When plasma phosphate level rises, the plasma ionized Ca^{2+} level tends to fall, for two reasons. First, phosphate forms a complex with Ca^{2+}. Second, hyperphosphatemia decreases production of 1, $25(OH)_2$ vitamin D_3 in the kidneys by inhibiting the 1α-hydroxylase enzyme that forms this hormone. This vitamin, which is a steroid that codes for a calcium-binding protein in intestinal enterocytes, stimulates uptake of calcium by the small intestine. With decreased plasma levels of 1, $25(OH)_2$ vitamin D_3, there is less Ca^{2+} absorption by the small intestine and hence a tendency for hypocalcemia.

A low plasma ionized Ca^{2+} level stimulates hyperplasia of the parathyroid glands and increased secretion of PTH. A high plasma phosphate level also stimulates PTH secretion directly. PTH then inhibits phosphate reabsorption by the proximal tubules, promotes phosphate excretion, and helps return plasma phosphate levels back to normal.

A primary elevation of PTH levels causes mobilization of both Ca^{2+} and phosphate from bone. Increased bone resorption results, and the bone minerals are replaced with fibrous tissue that renders the bone more susceptible to fracture. The effect of PTH on phosphate excretion in this case can be thought of a means of preventing precipitation of calcium phosphate when calcium and phosphate are coliberated from bone by PTH.

Patients with advanced chronic renal failure are often advised to restrict phosphate intake and consume substances (such as Ca^{2+} salts) that bind phosphate in the intestines, so as to avoid the many problems caused by hyperphosphatemia. Administration of synthetic $1,25(OH)_2$ vitamin D_3 may

compensate for deficient renal production of this hormone. This hormone opposes hypocalcemia and inhibits PTH synthesis and secretion. Parathyroidectomy is sometimes necessary in patients with advanced chronic renal failure (Clinical Focus 23.2).

CLINICAL FOCUS 23.2

Kidney Stone Disease (Nephrolithiasis)

A kidney stone is a hard mass that forms in the urinary tract. About 5% of American women and 12% of men develop a kidney stone some time in their life. A stone lodged in the ureter causes bleeding and intense pain. **Nephrolithiasis** causes considerable suffering and loss of time from work, and it may lead to kidney damage. Once a stone forms in a person, stone formation often recurs.

Stones form when poorly soluble substances in the urine precipitate out of solution, causing crystals to form, aggregate, and grow. About 80% of kidney stones are composed of insoluble Ca^{2+} salts of oxalate and phosphate. There may be excessive amounts of Ca^{2+} or oxalate in the urine as a result of diet, a genetic defect, or unknown causes. Stones may also form from precipitated ammonium magnesium phosphate (struvite), uric acid, and cystine. Struvite stones (about 10% of all stones) are the result of infection with bacteria, usually *Proteus* species. Uric acid stones (9% of all stones) may form in patients with excessive uric acid production and excretion, as occurs in some patients with gout. Defective tubular reabsorption of cystine (in patients with **cystinuria**) leads to cystine stones (1% of stones). The rather insoluble amino acid cystine was first isolated from a urinary bladder stone by Wollaston in 1810, hence its name. Since a low urine flow rate raises the concentration of all poorly soluble substances in the urine, thereby favoring precipitation, a key to prevention of kidney stones is to drink plenty of water and maintain a high urine output day and night.

Fortunately, most stones are small enough to be passed down the urinary tract and spontaneously eliminated. Microscopic and chemical examination of the eliminated stones is used to determine the nature of the stone and helps guide treatment. Sometimes, a change in diet is recommended to reduce the amount of potential stone-forming material (e.g., Ca^{2+}, oxalate, or uric acid). Thiazide diuretics are useful in reducing Ca^{2+} excretion if excessive urinary Ca^{2+} excretion (hypercalciuria) is the problem. Potassium citrate is useful in treating most stone disease, because citrate complexes Ca^{2+} in the urine and inhibits the crystallization of Ca^{2+} salts. It also makes the urine more alkaline (since citrate is oxidized to HCO_3^- in the body). This treatment is also helpful in reducing the risk of uric acid stones, because urates (favored in alkaline urine) are more soluble than uric acid (the form favored in acidic urine). Administering an inhibitor of uric acid synthesis, such as allopurinol, can help reduce the amount of uric acid in the urine.

If the stone is not passed spontaneously, extracorporeal shock wave lithotripsy, using a lithotripter, is widely used. The patient is placed in a tub of water, and the stone is localized by x-ray imaging. Sound waves are generated in the water by high-voltage electric discharges and are focused on the stone through the body wall. The shock waves break the stone into small pieces that can pass down the urinary tract and be eliminated. Some renal injury is produced by this procedure, and so it may not be entirely innocuous. Other procedures include passing a tube with an ultrasound transducer through the

skin into the renal pelvis; stone fragments can be removed directly. A ureteroscope with a laser can also be used to break up stones. ■

INTEGRATED MEDICAL SCIENCES

Pathological Causes of Excessive Urination

Polyuria is a condition that can be defined as excessive urine output of more than 3 L/d although it can often exceed this value considerably. This level of urine production results in frequent urination. There are multiple causes of polyuria, the simplest of which is excessive overconsumption of water well beyond that needed to maintain water balance in the body. Such consumption is sometimes seen as a compulsive drinking behavior associated with psychiatric disorders or, more recently, as part of dangerous fraternity hazing or party games involving "water chugging." The alimentary tract can absorb prodigious amounts of water, and although such addition of water to the ECF will result in a significant polyuria, it also risks rapidly diluting the ECF causing osmotic flux of water into all cells including those in the brain. Ensuing swelling of the brain can result in brain damage or death.

Consumptions of liquids containing ethanol can cause polyuria even if the volume consumption of the liquid containing alcohol is modest. Ethanol inhibits release of ADH by the posterior pituitary thereby leading to less water reabsorption in the renal collecting ducts and increased urine output.

Medicinal diuretics used in the treatment and management of hypertension, CHF, and edematous states (pulmonary or systemic) are common causes of polyuria although in this case the excess urine output is a desired effect of these agents. All diuretic classes produce a diuresis and natriuresis and thus produce increased urine output. Loop diuretics such as furosemide are especially potent diuretics because they reduce the vertical osmotic gradient in the renal medullary interstitium that is exploited to draw water from the collecting ducts. Overdose of diuretics or abuse of these agents can cause severe, rapid diuresis and polyuria. Diuretic abuse has become part of illegal drug use in sporting events as both a performance enhancer and as a masking agent in illegal drug blood doping schemes. Loop diuretics in particular have been used to create rapid weight loss to allow athletes to meet weight requirements in certain events. Diuretics are also employed to create large urine volumes to reduce the concentration of other performance enhancing drugs in the urine. Diuretics have been banned for use in athletes for competition since 1988. Diabetes mellitus is a disorder of glucose and lipid metabolism in which glucose uptake by cells is impaired, either because of reduced or absent pancreatic secretion of insulin (type I) or because tissues such as the liver and skeletal muscle are unresponsive to insulin (type II). In either case, plasma glucose concentration rises to abnormally high levels. This result in a high filtered load of glucose presented to the proximal tubules of the nephron. Normal physiological filtered loads of glucose are totally reabsorbed by the proximal tubule. However, the loads in diabetes mellitus exceed the T_m for glucose resulting in a significant amount of glucose remaining in the tubular fluid. This acts in an osmotic diuretic as well as a natriuretic, which eventually leads to polyuria.

Diabetes insipidus leads to polyuria. Diabetes insipidus does not involve disorders of glucose like diabetes mellitus, but it is characterized by intense thirst, despite ingestion of excess amounts of

fluid (polydipsia) and the excretion of large quantities of urine (polyuria). Diabetes insipidus is classified as three types: (1) central diabetes insipidus, (2) nephrogenic diabetes insipidus, and (3) gestational diabetes insipidus. The cause of *central diabetes insipidus* in adults is due to damage of the pituitary gland or to the hypothalamus. The damage is most commonly due to surgery, a tumor, inflammation (e.g., meningitis), head trauma, and injury. In children, the cause is often an inherited genetic disorder. The injury or disorder disrupts the normal synthesis, storage, and release of ADH such that ADH deficiency or absence results. In *nephrogenic diabetes insipidus*, ADH is made and available, but there is a defect in the kidney tubules, the site of water reabsorption, such that they are unresponsive to ADH. This subclass of diabetes insipidus results from the destruction of aquaporin channels. Nephrogenic diabetes insipidus can be due to a genetic disorder or renal infection but may also be caused by lithium toxicity (used to treat psychiatric disorders), the antibiotics amphotericin and tetracycline, hypercalcemia, or hypokalemia. *Gestational diabetes insipidus* occurs only during pregnancy when an enzyme made by the placenta destroys the mother's ADH. Regardless of its etiology, diabetes insipidus is characterized by intense thirst, despite drinking large amounts of fluid (polydipsia), the excretion of large volume of urine (polyuria), and the need to empty the bladder more frequently than the usual four to six times a day.

Tests used to diagnose a patient with polyuria include plasma osmolality, blood glucose, electrolyte levels, and urinalysis. Polyuria due to uncontrolled diabetes mellitus is easily identified by measuring glucose in the urine and the plasma glucose levels. A patient with diabetes insipidus tends to have an elevated plasma osmolality due to the excretion of excessive amounts of dilute urine. A *fluid deprivation test* is the common way to distinguish between the neurogenic and nephrogenic diabetes insipidus. The test involves depriving the patient of water for 8 to 12 hours and a measurement of urine osmolality. The patient is then given 5 units of vasopressin (ADH) subcutaneously, and 2 hours later, urine osmolality is measured. If the polyuria is due to neurogenic diabetes insipidus, the patient's urine osmolality that was persistently diluted (<200 mOsm/kg H_2O) during dehydration will significantly increase in response to the injected vasopressin. If the polyuria is nephrogenic, then the patient's urine osmolality stays diluted in the presence of both dehydration and the injected vasopressin.

Patients with neurogenic diabetes insipidus can be treated with an ADH analog called desmopressin. This agent, however, is useless in nephrogenic diabetes insipidus. Patients with this condition must be on low-salt diets to help reduce excessive urine formation. In addition, thiazide-type diuretics, paradoxically, have been shown to be effective in reducing polyuria in nephrogenic diabetes insipidus. ■

Chapter Summary

- Total body water is distributed in two major compartments: intracellular water and extracellular water. In an average young adult man, total body water, intracellular water, and extracellular water amount to 60%, 40%, and 20% of body weight, respectively. The corresponding figures for an average young adult woman are 50%, 30%, and 20% of body weight.
- The volumes of body fluid compartments are determined by using the indicator–dilution method and the following equation: volume = amount of indicator/concentration of indicator at equilibrium.
- Sodium (Na^+) is the major osmotically active solute in the extracellular fluid (ECF) compartment, and potassium (K^+) has the same role in the intracellular fluid compartment. Cells are typically in osmotic equilibrium with their external environment. The amount of water in (and hence volume of) cells depends on the amount of K^+ they contain, and similarly, the amount of water in (and hence volume of) the ECF is determined by its Na^+ content.
- Plasma osmolality is closely regulated by arginine vasopressin, which governs renal excretion of water, and by both habit and thirst, which govern water intake.
- Arginine vasopressin (AVP) synthesized in the hypothalamus, is released from the posterior pituitary gland and acts on the collecting ducts of the kidney to increase their water permeability.
- The major stimuli for the release of AVP are an increase in effective plasma osmolality (detected by osmoreceptors in the anterior hypothalamus) and a decrease in blood volume (detected by stretch receptors in the atria, carotid sinuses, and aortic arch).
- The kidneys are the primary site of control of Na^+ excretion. Only a small percentage of the filtered Na^+ is usually excreted in the urine, but this amount is of critical importance in overall Na^+ balance.
- Multiple factors affect Na^+ excretion, including glomerular filtration rate, angiotensin II, aldosterone, intrarenal pressures, natriuretic hormones, and renal sympathetic nerve activity. Changes in these factors may account for altered Na^+ excretion in response to excess Na^+ or Na^+ depletion.
- Estrogens, glucocorticoids, osmotic diuretics, poorly reabsorbed anions in the urine, and diuretic drugs also affect renal Na^+ excretion.
- A decrease in EABV leads to Na^+ retention by the kidneys and contributes to the development of generalized edema in pathophysiologic conditions such as congestive heart failure.
- The kidneys play a major role in the control of K^+ balance. K^+ is reabsorbed by the proximal convoluted tubule and loop of Henle and is secreted by cortical collecting duct principal cells. Inadequate renal K^+ excretion produces hyperkalemia, and excessive K^+ excretion produces hypokalemia.
- Calcium balance is regulated on both input and output sides. The absorption of Ca^{2+} from the small intestine is controlled by $1,25(OH)_2$ vitamin D_3, and the excretion of Ca^{2+} by the kidneys is controlled by parathyroid hormone.
- Magnesium is an important intracellular ion and the kidneys regulate the plasma Mg^{2+}.
- Filtered phosphate usually exceeds the maximal reabsorptive capacity of the kidney tubules for phosphate (Tm_{PO4}), and about 5% to 20% of filtered phosphate is usually excreted.
- Phosphate is an important pH buffer in the urine.

- Phosphate reabsorption occurs mainly in the proximal tubules and is inhibited by parathyroid hormone and fibroblast growth factor-23.
- Hyperphosphatemia is a significant problem in chronic renal failure.

Chapter Review Questions

1. A 60-kg woman is given 10 microcuries (mCi) (370 kilobecquerels) of radioiodinated serum albumin (RISA) intravenously. Ten minutes later, a venous blood sample is collected, and the plasma RISA activity is found to be 4 mCi/L. Her hematocrit ratio is 0.4. What is her blood volume?

A. 417 mL
B. 625 mL
C. 2.5 L
D. 4.17 L
E. 6.25 L

The correct answer is D. From the indicator–dilution method, the plasma volume = (10 mCi) 4 mCi/L = 2.5 L. If the hematocrit ratio is 0.4, then the blood volume = (2.5 L plasma) 0.6 L plasma/L blood = 4.17 L.

2. Which of the following leads to decreased Na^+ reabsorption by the kidneys?

A. An increase in central blood volume
B. An increase in colloid osmotic pressure in the peritubular capillaries
C. An increase in GFR
D. An increase in plasma aldosterone level
E. An increase in renal sympathetic nerve activity

The correct answer is A. An increase in central blood volume will stretch the atria, cause the release of atrial natriuretic peptide, and result in decreased Na^+ reabsorption. An increase in colloid osmotic pressure in the peritubular capillaries, an increase in GFR, an increase in plasma aldosterone level, or an increase in renal sympathetic nerve activity increases tubular Na^+ reabsorption.

3. A girl was trapped in the rubble of a collapsed building for 24 hours and both of her legs were crushed. Her plasma potassium concentration is 8 mEq/L, and her ECG does not look normal. She is not producing any urine. Which of the following treatments would be best?

A. Administer insulin without glucose.
B. Give an adrenergic blocker to block the action of epinephrine.
C. Infuse a sodium bicarbonate solution intravenously.
D. Infuse a solution of 0.1 M HCl into a central vein.
E. Increase her plasma osmolality be infusing a hypertonic mannitol solution.

The correct answer is C. Infusion of a sodium bicarbonate solution intravenously would lower the plasma $[K^+]$ by shifting K^+ into the cell compartment. Insulin administration would have the same effect, but giving insulin without glucose might produce hypoglycemia. Making the ECF more acidic, blocking the action of epinephrine, or raising plasma osmolality would all tend to increase, not decrease, the plasma $[K^+]$.

4. A dehydrated, hospitalized patient with uncontrolled diabetes mellitus has a plasma $[K^+]$ of 4.5 mEq/L (normal 3.5 to 5.0 mEq/L), a plasma (glucose) of 500 mg/dL, and an arterial blood pH of 7 (normal 7.35 to 7.45). These data suggest that the patient has:

A. a decreased total body store of K^+.
B. a normal total body store of K^+.

C. an increased total body store of K^+.
D. hypokalemia.
E. hyperkalemia.

The correct answer is A. The low blood pH and hyperglycemia (or hyperosmolality) would tend to raise plasma [K^+], yet the plasma [K^+] is normal. These findings suggest that the total body store of K^+ is reduced. Remember that most of the body's K^+ is within cells. In uncontrolled diabetes mellitus, the osmotic diuresis (increased Na^+ and water delivery to the cortical collecting ducts), increased renal excretion of poorly reabsorbed anions (ketone body acids), and elevated plasma aldosterone level (secondary to volume depletion) would all favor enhanced excretion of K^+ by the kidneys. The subject has normokalemia, not hypo- or hyperkalemia.

5. A 60-year-old woman is always thirsty and wakes up several times during the night to empty her bladder. Plasma osmolality is 295 mOsm/kg H_2O (normal range 281 to 297 mOsm/kg H_2O), urine osmolality is 100 mOsm/kg H_2O, and plasma AVP levels are higher than normal. The urine is negative for glucose. The most likely diagnosis is:
A. diabetes mellitus.
B. diuretic drug abuse.
C. nephrogenic diabetes insipidus.
D. neurogenic diabetes insipidus.
E. primary polydipsia.

The correct answer is C. Nephrogenic diabetes insipidus is characterized by increased output of dilute urine. Plasma AVP is elevated because of the volume depletion. Plasma osmolality is on the high side of the normal range, because of the loss of dilute fluid in the urine. The increased urine output is not due to diabetes mellitus because there is no glucose in the urine and the urine is very dilute. Diuretic drug abuse should not produce a very dilute urine, since Na^+ reabsorption is inhibited. Neurogenic diabetes insipidus is unlikely because the plasma AVP level is reduced in this case. Primary polydipsia produces output of a large volume of dilute urine, but plasma osmolality and AVP levels are decreased.

Clinical Application Exercises 23.1

A 60-year-old woman with a long history of mental illness was institutionalized after a violent argument with her son. She refused to eat anything since admission, but after maintaining a good fluid intake, she started to compulsively, repeatedly, drink water. She then experienced visual and auditory hallucinations. On one occasion, she ran naked through the ward screaming. On the fifth hospital day, she complained of a slight headache and nausea and had three episodes of vomiting. Later in the day, she was found on the floor in a semiconscious state, confused, and disoriented. She was pale and had cool extremities. Her pulse rate was 70/minute and blood pressure was 150/100 mm Hg. She was transferred to a general hospital, and during transfer, she had three grand mal seizures and arrived in a semiconscious, uncooperative state. A blood sample revealed a plasma [Na^+] of 103 mEq/L. Urine osmolality was 362 mOsm/kg H_2O, and urine [Na^+] was 57 mEq/L. She was given an intravenous infusion of hypertonic saline (1.8% NaCl) and placed on water restriction.

QUESTIONS

1. What is the likely cause of the severe hyponatremia?
2. How much of an increase in plasma [Na^+] would an infusion of 1 L of 1.8% NaCl (308 mEq Na^+/L) produce? Assume that her total body water is 25 L (50% of her body weight). Why is the total body water used as the volume of distribution of Na^+, even though the administered Na^+ is limited to the ECF compartment?
3. Why is the brain so profoundly affected by hypo-osmolality? Why should the hypertonic saline be administered slowly?

ANSWERS

1. Hyponatremia is low sodium concentration in the blood (<135 mEq/L) and is considered severe when the serum sodium gets below 125 mEq/L. Low serum sodium can be caused by heart, liver, and kidney failure. However, hyponatremia can also be caused by overhydration, which occurred with the patient in this case. Psychogenic problems started with ingestion of excessive amounts of water. Compulsive water drinking is a common problem in psychotic patients. The increased water intake, combined with an impaired ability to dilute the urine (note the inappropriately high urine osmolality), led to severe hyponatremia and water intoxication.
2. Addition of 1 L of 308 mEq Na^+/L to 25 L produces an increase in plasma [Na^+] of 12 mEq/L. The total body water is used in this calculation because hypertonic NaCl added to the ECF causes movement of water out of the cell compartment, which dilutes the extracellular Na^+.
3. The brain is enclosed in the nondistensible cranium, so when water moves into brain cells and causes them to swell, intracranial pressure can rise to very high values. This can damage nervous tissue directly or indirectly by impairing cerebral blood flow. The neurological symptoms seen in this patient (headache, semiconsciousness, grand mal seizures) are consequences of brain swelling. The increased blood pressure and cool and pale skin may be a consequence of sympathetic nervous system discharge resulting from increased intracranial pressure. Too rapid restoration of a normal plasma [Na^+] can produce serious damage to the brain (central pontine myelinolysis).

24 Acid–Base Homeostasis

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Define acid, base, acid dissociation constant, weak and strong acids, pKa, pH, and buffer.
- Describe the metabolic processes that produce and consume hydrogen ions, and explain why the body is threatened by net acid gain on a mixed diet.
- Explain the three mechanisms that defend blood pH.
- Explain the role and efficacy of the main chemical buffers present in extracellular fluid, intracellular fluid, and bone.
- Predict the blood pH, given values for plasma HCO_3^- and partial pressure of carbon dioxide (PCO_2).
- Explain why the bicarbonate/CO_2 buffer pair, with a less than an ideal pKa, is the most important pH buffering system in the body.
- Explain the isohydric principle and its significance in control of pH in systems containing multiple buffers.
- Explain the interrelationship between arterial blood pH, PCO_2, and ventilation as it relates to the role of ventilation in the control of arterial pH.
- Calculate renal net acid excretion from excretion of titratable acid, NH_4^+, and bicarbonate.
- Explain the roles of renal reabsorption of filtered bicarbonate, formation of titratable acid, excretion of NH_4^+, and urinary acidification in the kidney's ability to reclaim filtered bicarbonate and generate new bicarbonate to replace that lost titrating fixed acids in the body.
- Discuss the factors that influence renal secretion and excretion of hydrogen ions in the context of the kidney's role in maintaining acid–base balance.
- Explain how cells maintain stability of intracellular pH.
- List the four simple acid–base disturbances, and describe for each the primary defect, changes in arterial blood chemistry (pH, PCO_2, and plasma HCO_3^-), common causes, chemical buffering processes, and degree of respiratory and renal compensations.
- Identify the type of acid–base disturbance present from blood acid–base data and a patient history.
- Calculate the anion gap from plasma electrolyte concentrations, and interpret its meaning.

Metabolic and neural functions are highly sensitive to changes in H^+ concentrations. Outside the acceptable range of pH, protein conformation changes alter enzyme activity, transport proteins, and structural integrity of tissue. Nerve and cardiac function can be markedly impaired as well, which can ultimately result in death. Accordingly, it is not surprising that the H^+ concentration of extracellular fluid is tightly regulated. Acid–base regulation can be viewed in the same way as any other chemical balance, matching gains versus losses. In the case of arterial plasma pH, when loss exceeds gains, H^+ concentration decreases and pH increases above 7.4. When this occurs, it is termed **alkalosis**. Conversely, when gain exceeds loss, plasma H^+ concentration increases and the pH falls below 7.4. This is termed **acidosis**.

Most of this chapter discusses the regulation of H^+ in extracellular fluid (ECF), because ECF is easier to analyze than intracellular fluid (ICF) and it is the fluid used for clinical evaluation of acid–base chemistry. In practice, systemic *arterial* blood is used as the reference sample for this purpose. Measurements on whole blood with a pH meter give values for the H^+ of plasma and, therefore, provide an ECF pH measurement.

BASIC PRINCIPLES OF ACID–BASE INTERACTION

Understanding the physiologic importance of acid–base regulation requires appreciation of some basic laws of chemical reactions. In this section, we briefly review some basic principles of acid–base chemistry. H^+ ion assumes special significance because of the narrow range that must be maintained for optimal enzymatic and metabolic function. Physiologically important acids include carbonic acid (H_2CO_3), phosphoric acid (H_3PO_4), pyruvic acid ($C_3H_4O_3$), and lactic acid ($C_3H_6O_3$). Physiologically important bases include bicarbonate (HCO_3^-) and biphosphate (HPO_4^{2-}). Acid–base regulation in the body involves primarily two ions, hydrogen (H^+) and bicarbonate (HCO_3^-).

Acids dissociate to release hydrogen ions in solution.

An **acid** is a substance that can release, or donate, H^+; a **base** is a substance that can combine with, or accept, H^+. When an acid (generically written as HA) is added to water, it dissociates reversibly according to the reaction: $HA \rightleftharpoons H^+ + A^-$. The species A^- is a base, because it can combine with an H^+ to form HA. In other words, when an acid dissociates, it yields a free H^+ and its conjugate base. (*Conjugate* means "joined in a pair.")

At equilibrium, the rate of dissociation of an acid to form $H^+ + A^-$ and the rate of association of H^+ and base A^- to form HA are equal. The equilibrium constant (K_a), which is also called the *ionization constant* or **acid dissociation constant**, is given by the expression:

$$K_a = \frac{[H^+] \times [A^-]}{[HA]} \quad (1)$$

The higher the acid dissociation constant, the more an acid is ionized and the greater is its strength. Hydrochloric acid (HCl), for example, is a **strong acid**. It has a high K_a and is almost completely ionized in aqueous solutions. Other strong acids include sulfuric acid (H_2SO_4), phosphoric acid (H_3PO_4), and nitric acid (HNO_3).

An acid with a low K_a is a **weak acid**. For example, in a 0.1 M solution of acetic acid ($K_a = 1.8 \times 10^{-5}$) in water, most (99%) of the acid is nonionized, so that little (1%) is present as acetate$^-$ and H^+. The acidity (concentration of free H^+) of this solution is low. Other weak acids are lactic acid, carbonic acid (H_2CO_3), ammonium ion (NH_4^+), and dihydrogen phosphate ($H_2PO_4^-$).

Acid dissociation constants vary widely and often are small numbers. It is convenient to convert K_a to a logarithmic form, defining pK_a as:

$$pK_a = \log_{10}\left(1 / K_a\right) = -\log_{10} K_a \quad (2)$$

In aqueous solution, each acid has a characteristic pK_a, which varies slightly with temperature and the ionic strength of the solution. Note that pK_a is *inversely* proportional to acid strength. A strong acid has a high K_a and a low pK_a. A weak acid has a low K_a and a high pK_a.

pH is inversely related to hydrogen ion concentration.

pH expresses H^+ concentration in aqueous solutions and is often expressed in pH units. The following equation defines **pH**:

$$\mathrm{pH} = \log_{10}\left(1/[\mathrm{H}^+]\right) = -\log_{10}[\mathrm{H}^+] \quad (3)$$

where H^+ concentration is in mol/L. Note that pH is *inversely* related to H^+ concentration. Each whole number on the pH scale represents a 10-fold (logarithmic) change in acidity. A solution with a pH of 5 has 10 times the H^+ of a solution with a pH of 6.

For a solution containing an acid and its conjugate base, we can rearrange the equilibrium expression (equation 1) as:

$$\left[\mathrm{H}^+\right] = \frac{\mathrm{K_a} \times [\mathrm{HA}]}{\left[\mathrm{A}^-\right]} \quad (4)$$

If we take the negative logarithms of both sides:

$$-\log[\mathrm{H}^+] = -\log \mathrm{K_a} + \log \frac{[\mathrm{A}^-]}{[\mathrm{HA}]} \quad (5)$$

Substituting pH for $-\log [H^+]$ and pK_a for $-\log K_a$, we get:

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

(6)

This equation is known as the **Henderson-Hasselbalch equation**. It shows that the pH of a solution is determined by the pK_a of the acid and the ratio of the concentrations of conjugate base to acid.

Buffers protect the stability of the blood pH.

The stability of pH is protected by the action of buffers. A *pH buffer* is defined as an agent that *minimizes* the change in pH produced when an acid or base is added. Note that a buffer *does not prevent* a pH change. A **chemical pH buffer** is a mixture of a weak acid and its conjugate base (or a weak base and its conjugate acid). Following are examples of buffers:

Weak Acid		Conjugate Base	
H_2CO_3 (carbonic acid)	$\rightleftharpoons$	HCO_3^- (bicarbonate) + H^+	(7)
$H_2PO_4^-$ (dihydrogen phosphate)	$\rightleftharpoons$	HPO_4^{2-} (monohydrogen phosphate) + H^+	(8)
NH_4^+ (ammonium ion)	$\rightleftharpoons$	NH_3 (ammonia) + H^+	(9)

Generally speaking, the equilibrium expression for a buffer pair can be written in terms of the Henderson-Hasselbalch equation:

$$pH = pK_a + \log \frac{[\text{conjugate base}]}{[\text{acid}]} \quad (10)$$

For example, for $H_2PO_4^-/HPO_4^{2-}$:

$$\mathrm{pH} = 6.8 + \log \frac{\left[\mathrm{HPO_4^{2-}}\right]}{\left[\mathrm{H_2PO_4^-}\right]} \quad (11)$$

The effectiveness of a buffer—how well it minimizes pH changes when an acid or base is added—depends on its concentration and its pK_a. A good buffer is present in high concentrations and has a pK_a close to the desired pH.

Figure 24.1 shows a titration curve for the phosphate buffer system. As a strong acid or strong base is progressively added to the solution (shown on the *x*-axis), the resulting pH is recorded (shown on the *y*-axis). Going from right to left, as strong acid is added, H^+ combines with the basic form of phosphate: $H^+ + HPO_4^{2-} \rightleftharpoons H_2PO_4^-$. Going from left to right, as strong base is added, OH^- combines with H^+ released from the acid form of the phosphate buffer: $OH^- + H_2PO_4^- \rightleftharpoons HPO_4^{2-} + H_2O$. These reactions lessen the fall or rise in pH.

pH
HPO_4^{2-}
$pK_a = 6.8$
$H_2PO_4^-$
Amount of HCl added (mEq)
Amount of NaOH added (mEq)

Figure 24.1 Titration curve for a phosphate buffer. The pK_a for $H_2PO_4^-$ is 6.8. A strong acid (HCl) (*right to left*) or strong base (NaOH) (*left to right*) was added and the resulting solution pH recorded (*y*-axis). Notice that buffering is best (i.e., the change in pH on the addition of a given amount of acid or base is least) when the solution pH is equal to the pK_a of the buffer.

At the pK_a of the phosphate buffer, the ratio $HPO_4^{2-}/H_2PO_4^-$ is 1, and the titration curve is flattest (the change in pH for a given amount of an added acid or base is at a minimum). In most cases, pH buffering is effective when the solution pH is within ±1 pH unit of the buffer pK_a. Beyond that range, the pH shift that a given amount of acid or base produces may be quite large, so the buffer becomes relatively ineffective.

METABOLIC PRODUCTION OF ACIDS

Acids are continuously produced in the body and threaten the normal pH range of the ECF and ICF. Physiologically, acids fall into two groups: (1) H_2CO_3 (carbonic acid) and (2) all other acids (noncarbonic; also called “nonvolatile” or “fixed” acids). The distinction between these groups arises because H_2CO_3 is in equilibrium with the volatile gas CO_2, which can leave the body via the lungs. The concentration of H_2CO_3 in arterial blood is, therefore, affected by respiratory activity. By contrast, noncarbonic acids in the body are not directly affected by breathing. Noncarbonic acids are buffered in the body and are then excreted by the kidneys.

Cellular oxidation provides a constant source of carbon dioxide.

A normal adult produces about 300 L of CO_2 daily from metabolism. CO_2 from the tissues enters the capillary blood, where it reacts with water to form H_2CO_3, which dissociates instantly to yield H^+ and HCO_3^-: $CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$. Blood pH would rapidly fall to lethal levels if the H_2CO_3 formed from CO_2 was allowed to accumulate in the body.

Fortunately, H_2CO_3 is converted to CO_2 and water in the pulmonary capillaries and the CO_2 is expired (see Chapter 19). In the lungs, the reactions reverse:

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

(12)

As long as CO_2 is expired as fast as it is produced, then arterial blood CO_2 tension, H_2CO_3 concentration, and pH do not change.

Nonvolatile acids originate from incomplete metabolism of carbohydrates and fats.

Normally, carbohydrates and fats are completely oxidized to CO_2 and water. If carbohydrates and fats are *incompletely* oxidized, nonvolatile acids are produced. Incomplete oxidation of carbohydrates occurs when the tissues do not receive enough oxygen, as during strenuous exercise or hemorrhagic or cardiogenic shock. In such states, glucose metabolism yields lactic acid (pK_a = 3.9), which dissociates into lactate$^-$ and H^+, lowering the blood pH. Incomplete fatty acid oxidation occurs in uncontrolled diabetes mellitus, starvation, and alcoholism and produces ketone body acids (acetoacetic and β-hydroxybutyric acids). These acids have pK_a values around 4 to 5. At blood pH, they mostly dissociate into their anions and H^+, making the blood more acidic.

Diet of meat and vegetables produces a net acid gain that threatens acid–base balance.

The metabolism of dietary proteins is a major source of H^+. The oxidation of proteins and amino acids produces strong acids, such as H_2SO_4, HCl, and H_3PO_4. The oxidation of sulfur-containing amino acids (methionine, cysteine, and cystine) produces H_2SO_4, and the oxidation of cationic amino acids (arginine, lysine, and some histidine residues) produces HCl. The oxidation of phosphorus-containing proteins and nucleic acids produces H_3PO_4.

A diet containing both meat and vegetables results in a net production of acids, largely from protein oxidation. To some extent, acid-consuming metabolic reactions balance H^+ production. Food also contains basic anions, such as citrate, lactate, and acetate. When these are oxidized to CO_2 and water, hydrogen ions are consumed (or what amounts to the same thing, HCO_3^- is produced). The average adult who eats a mixed diet results in net production of acid, equivalent to about 1 mEq H^+/kg body weight per day. Vegetarians generally have less of a dietary acid burden and a more alkaline urine pH than nonvegetarians, because most fruits and vegetables contain large amounts of organic anions that are metabolized to HCO_3^-. The body generally has to dispose of more or less nonvolatile acid, a function performed by the kidneys.

Whether a particular food has an acidifying or an alkalinizing effect depends on whether and how its constituents are metabolized. Cranberry juice has an acidifying effect because of its content of benzoic acid, an acid that cannot be broken down in the body. Orange juice has an alkalinizing effect, despite its acidic pH of about 3.7, because it contains citrate, which is metabolized to HCO_3^-. The citric acid in orange juice is converted to CO_2 and water, has only a transient effect on blood pH, and has no effect on urine pH.

INTEGRATION OF THE BODY'S BUFFERING SYSTEMS

The body contains several different buffers that reversibly bind H^+ and blunt any change in pH. These buffers include bicarbonate, protein, phosphate, and others.

The bicarbonate buffering system is especially important, as carbon dioxide (CO_2) can be shifted through carbonic acid (H_2CO_3) to hydrogen ions and bicarbonate (HCO_3^-), as shown previously in equation 12. Figure 24.2 shows key buffering mechanisms that tightly regulate pH despite the daily net acid gain. Buffering is accomplished by chemical buffers, the lungs, and the kidneys.

Figure 24.2 The maintenance of normal blood pH by chemical buffers, the respiratory system, and the kidneys. On a mixed diet, pH is threatened by the production of strong acids (sulfuric, hydrochloric, and phosphoric) mainly as a result of protein metabolism. These strong acids are buffered in the body by chemical buffer bases, such as extracellular fluid (ECF) HCO_3^-. The kidneys eliminate hydrogen ions (combined with urinary buffers) and anions in the urine. At the same time, they add new HCO_3^- to the ECF to replace the HCO_3^- consumed in buffering strong acids. The respiratory system disposes of CO_2.

- *Chemical buffering*. Chemical buffers in ECF and ICF and in bone are the first line of defense of blood pH. Chemical buffering minimizes a change in pH but does not remove acid or base from the body.
- *Respiratory response*. The respiratory system is the second line of defense of blood pH. Normally, breathing removes CO_2 as fast as it is produced. Large loads of acid stimulate breathing (respiratory compensation), which removes CO_2 from the body and thus lowers the H_2CO_3 in arterial blood, reducing the acidic shift in blood pH.
- *Renal response*. The kidneys are the third line of defense of blood pH. Although chemical buffers in the body can bind H^+ and the lungs can change the H_2CO_3 of blood, the burden of removing excess H^+ falls directly on the kidneys. Hydrogen ions are excreted in combination with urinary buffers. At the same time, the kidneys add new HCO_3^- to the ECF to replace HCO_3^- used up in buffering strong acids. The kidneys also excrete the anions (phosphate, chloride, and sulfate) that are liberated from strong acids. The kidneys affect blood pH more slowly than other buffering mechanisms in the body; full renal compensation for an acid–base disturbance may take 1 to 3 days.

Phosphate, protein, and bicarbonate are the body's main buffers.

The body contains many conjugate acid–base pairs that act as chemical buffers (Table 24.1). In the ECF, the main chemical buffer pair is HCO_3^-/CO_2. Plasma proteins and inorganic phosphate are also ECF buffers. Cells have large buffer stores, particularly proteins and organic phosphate compounds. HCO_3^- is present in cells, although at a lower concentration than in ECF. Bone contains large buffer stores, specifically salts of phosphate and carbonate.

TABLE 24.1 Major Chemical pH Buffers in the Body

Buffer	Reaction
Extracellular fluid	
Bicarbonate/CO_2	$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$
Inorganic phosphate	$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$
Plasma proteins (Pr)	$HPr \rightleftharpoons H^+ + Pr^-$
Intracellular fluid	
Cell proteins (e.g., hemoglobin [Hb])	$HHb \rightleftharpoons H^+ + Hb^-$
Organic phosphates	Organic $HPO_4^- \rightleftharpoons H^+ +$ organic PO_4^{2-}
Bicarbonate/CO_2	$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$
Bone	
Mineral phosphates	$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$
Mineral carbonates	$HCO_3^- \rightleftharpoons H^+ + CO_3^{2-}$

When an acid or base is added to the body, the buffers just mentioned bind or release H^+, thereby minimizing the change in pH. Buffering in ECF occurs rapidly, in minutes. Acids or bases also enter cells and bone, but this generally occurs more slowly, over hours, allowing cell buffers and bone to share in buffering.

Phosphate is present as inorganic phosphate in the ECF. The pK_a for phosphate, $H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$, is 6.8, close to the desired blood pH of 7.4, so, chemically speaking, it would be a good ECF buffer. However, its concentration in the ECF is low (about 1 mmol/L), so it plays a minor role in extracellular buffering.

Phosphate, however, is an important intracellular buffer for two reasons. First, cells contain large amounts of phosphate in such organic compounds as adenosine triphosphate (ATP), adenosine diphosphate (ADP), and creatine phosphate. Although these compounds primarily function in energy metabolism, they also act as pH buffers. Second, intracellular pH is generally lower than the pH of ECF

and is closer to the pK_a of phosphate. (The cytosol of skeletal muscle, e.g., has a pH of 6.9.) Phosphate is thus more effective in this environment than in one with a pH of 7.4. Bone has large phosphate salt stores, which also help in buffering.

Proteins are the largest buffer pool in the body and are excellent buffers. Proteins can function as both acids and bases, so they are **amphoteric**. They contain many ionizable groups, which can release or bind H^+. Serum albumin and plasma globulins are the major extracellular protein buffers, present mainly in the blood plasma. Cells also have large protein stores. Recall that the buffering properties of hemoglobin play an important role in the transport of CO_2 and O_2 by the blood (see Chapter 19).

Bicarbonate–carbon dioxide system is a key physiologic buffer.

For several reasons, the HCO_3^-/CO_2 buffer pair is especially important in acid–base physiology:

- Its components are abundant; the concentration of HCO_3^- in plasma or ECF normally averages 24 mmol/L. Although the concentration of dissolved CO_2 is lower (1.2 mmol/L), metabolism provides a nearly limitless supply.
- Despite a pK of 6.10, a little far from the desired plasma pH of 7.40, it is effective because the system is "open" (i.e., its components can be added to or removed from the body at controlled rates).
- Each of its components can be independently controlled, CO_2 by the lungs and HCO_3^- by the kidneys.

CO_2 exists in the body in several different forms: as gaseous CO_2 in the lung alveoli and as dissolved CO_2, H_2CO_3, HCO_3^-, carbonate (CO_3^{2-}), and carbamino compounds in the body fluids. CO_3^{2-} is present at appreciable concentrations only in alkaline solutions, and so we will ignore it. We will also ignore any CO_2 that is bound to proteins in the carbamino form. The most important forms are gaseous CO_2, dissolved CO_2, H_2CO_3, and HCO_3^-.

Dissolved CO_2 in pulmonary capillary blood equilibrates with gaseous CO_2 in the lung alveoli. Consequently, the partial pressures of CO_2 (PCO_2) in alveolar air and systemic arterial blood are normally identical. The concentration of dissolved CO_2 ($CO_{2(d)}$) is related to the PCO_2 by the Henry law (see Chapter 19). The solubility coefficient for CO_2 in plasma at 37°C is 0.03 mmol CO_2/L per mm Hg PCO_2. Therefore, $CO_{2(d)} = 0.03 \times PCO_2$. If PCO_2 is 40 mm Hg, then $CO_{2(d)}$ is 1.2 mmol/L.

In aqueous solutions, $CO_{2\,(d)}$ reacts with water to form H_2CO_3: $CO_{2(d)} + H_2O \rightleftharpoons H_2CO_3$. The reaction to the right is called the **hydration reaction** and the reaction to the left is called the **dehydration reaction**. In many cells and tissues, such as the kidneys, pancreas, stomach, and red blood cells, the reactions are catalyzed by **carbonic anhydrase**. At equilibrium, $CO_{2(d)}$ is greatly favored; at body temperature, the ratio of $CO_{2(d)}$ to H_2CO_3 is about 400:1. If $CO_{2(d)}$ is 1.2 mmol/L, then H_2CO_3 equals 3 µmol/L. H_2CO_3 dissociates instantaneously into H^+ and HCO_3^-: $H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$. The Henderson-Hasselbalch expression for this reaction is as follows:

$$pH = 3.5 + \log \frac{[HCO_3^-]}{[H_2CO_3]} \quad (13)$$

Note that H_2CO_3 is a fairly strong acid ($pK_a = 3.5$). Its low concentration in body fluids lessens its

impact on acidity.

Because plasma H_2CO_3 is so low and hard to measure and because $H_2CO_3 = CO_{2(d)}/400$, we can use $CO_{2(d)}$ to represent the acid in the Henderson-Hasselbalch equation:

$$pH = 3.5 + \log \frac{[HCO_3^-]}{[CO_{2(d)}]/400} = 3.5 + \log 400 + \log \frac{[HCO_3^-]}{[CO_{2(d)}]}$$

$$= 6.1 + \log \frac{[HCO_3^-]}{[CO_{2(d)}]}$$

(14)

We can also use $0.03 \times PCO_2$ in place of $CO_{2(d)}$:

$$pH = 6.1 + \log \frac{[HCO_3^-]}{0.03\ P_{CO_2}}$$

(15)

This form of the Henderson-Hasselbalch equation is useful in understanding acid–base problems. Note that the "acid" in this equation appears to be $CO_{2(d)}$ but is really H_2CO_3 "represented" by CO_2. Therefore, this equation is valid only if $CO_{2(d)}$ and H_2CO_3 are in equilibrium with each other, which is usually (but not always) the case.

Many clinicians prefer to work with H^+ rather than pH. The following expression results if we take antilogarithms of the Henderson-Hasselbalch equation:

$$[H^+] = 24 \times PCO_2 / [HCO_3^-]$$

(16)

In this equation, H^+ is expressed in nmol/L, HCO_3^- in mmol/L or mEq/L, and PCO_2 in mm Hg. If the PCO_2 is 40 mm Hg and plasma HCO_3^- is 24 mmol/L, H^+ is 40 nmol/L.

As noted previously, the pK of the HCO_3^-/CO_2 system (6.10) is far from 7.40, the normal pH of arterial blood. From this, one might view this buffer pair as rather poor. On the contrary, it is remarkably effective because it operates in an "open" system; that is, the two buffer components can be added to or

removed from the body at controlled rates.

The HCO_3^-/CO_2 system is open in several ways:

- Metabolism provides an endless source of CO_2, which can replace any H_2CO_3 consumed by a base added to the body.
- The respiratory system can change the amount of CO_2 in body fluids by hyperventilation or hypoventilation.
- The kidneys can change the amount of HCO_3^- in the ECF by forming new HCO_3^- when excess acid has been added to the body or by excreting HCO_3^- when excess base has been added.

How the kidneys and respiratory system influence ECF pH by operating on the HCO_3^-/CO_2 system is described below. For now, the advantages of an open buffer system are best explained by an example (Fig. 24.3). Suppose we have 1 L of ECF containing 24 mmol of HCO_3^- and 1.2 mmol of dissolved $CO_{2(d)}$ (PCO_2 = 40 mm Hg). Using the special form of the Henderson-Hasselbalch equation described above, we find that the ECF pH is 7.40:

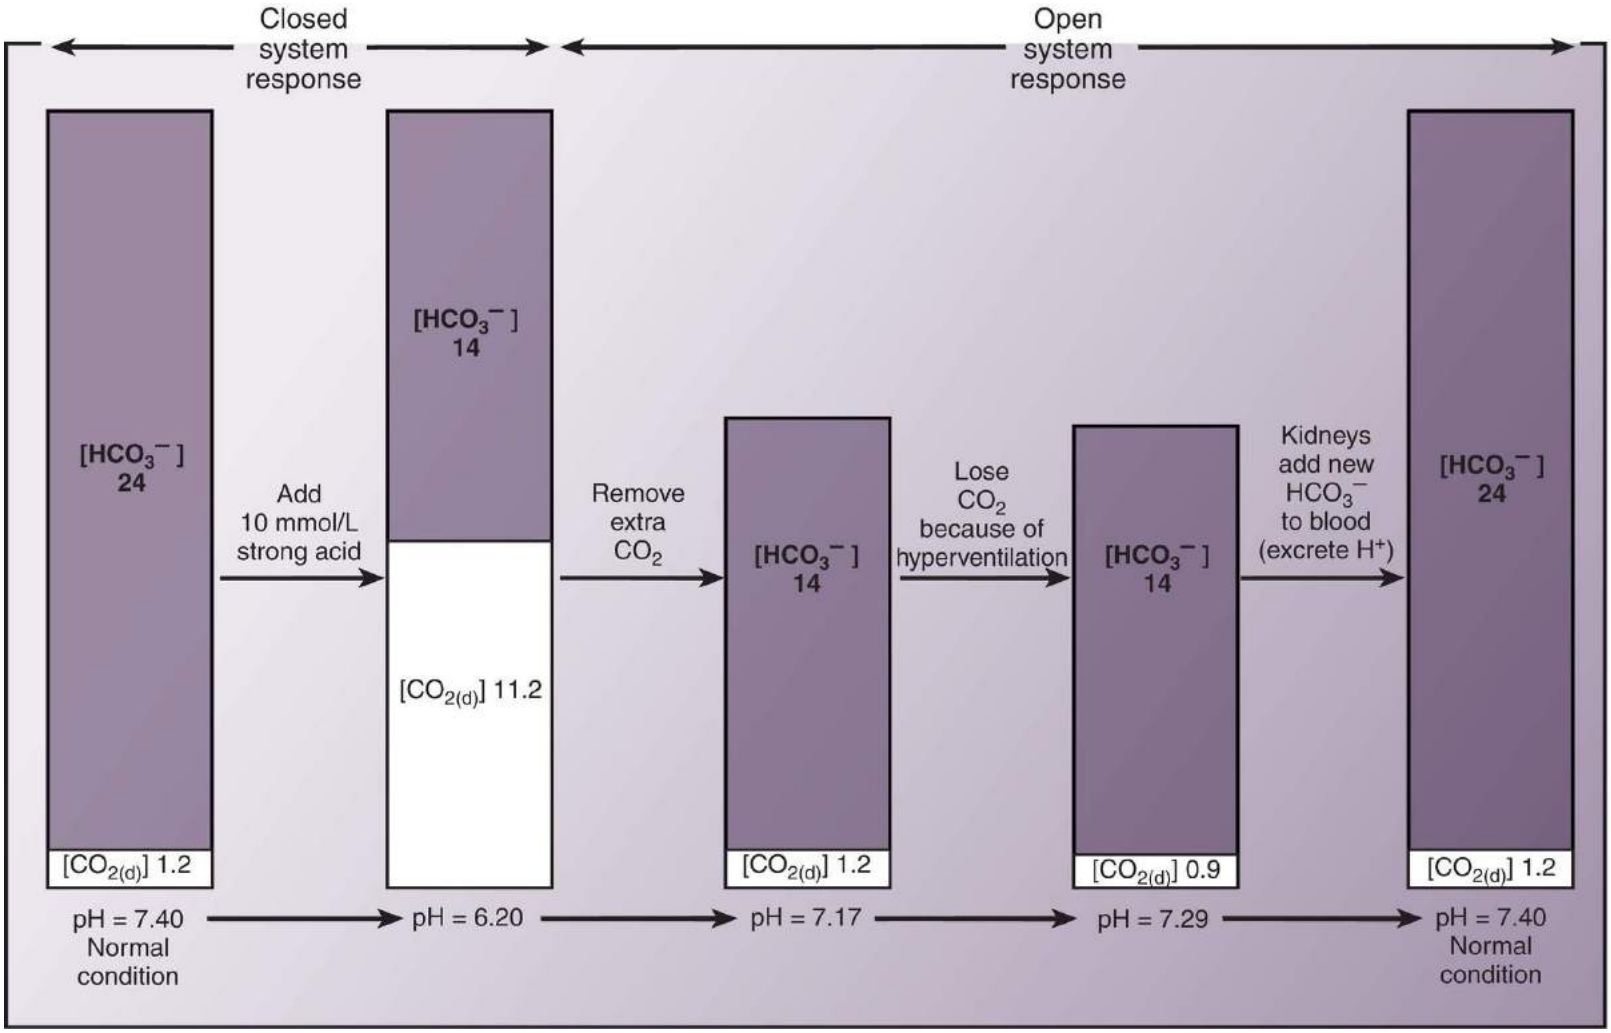

Figure 24.3 The HCO_3^-/CO_2 system. This system is remarkably effective in buffering added strong acid in the body, because it is open. HCO_3^- and $CO_{2(d)}$ are in mmol/L.

$$pH = 6.10 + \log \frac{[HCO_3^-]}{0.03 PCO_2} = 6.10 + \log \frac{[24]}{[1.2]} = 7.40 \quad (17)$$

Suppose we now add 10 mmol of HCl, a strong acid. HCO_3^- is the major buffer base in the ECF (we will neglect the contributions of other buffers). We predict that the HCO_3^- level will fall by nearly 10 mmol, and from the reaction $H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$, we predict that nearly 10 mmol of $CO_{2(d)}$ will form. If the system was closed and no CO_2 could escape, the new pH would be:

$$pH = 6.10 + \log \frac{[24 - 10]}{[1.2 + 10]} = 6.20 \quad (18)$$

This is an intolerably low—indeed a fatal—pH.

If the system is open, then CO_2 can escape into the air. If all of the extra CO_2 is expired by the lungs and the $CO_{2(d)}$ is kept at 1.2 mmol/L, then the pH would be:

$$pH = 6.10 + \log \frac{[24 - 10]}{[1.2]} = 7.17 \quad (19)$$

Although this pH is low, it is compatible with life.

Still, another mechanism promotes the escape of CO_2 from the body. An acidic blood pH stimulates breathing, which can make the PCO_2 lower than 40 mm Hg. If PCO_2 falls to 30 mm Hg ($CO_{2(d)}$ = 0.9 mmol/L), the pH would be:

$$pH = 6.10 + \log \frac{[24 - 10]}{[0.9]} = 7.29 \quad (20)$$

This pH is much closer to normal, demonstrating the effectiveness of an open system in buffering acid. The system is also open at the kidneys, and new HCO_3^- can be added to the plasma to correct the HCO_3^-. Once the pH of the blood is normal, the stimulus for hyperventilation disappears.

Blood pH is protected by a negative feedback of endogenous acids.

Another way in which blood pH may be protected is by changes in endogenous acid production (Fig. 24.4). An increase in blood pH caused by the addition of base to the body stimulates production of lactic acid and ketone body acids, which then reduces the alkaline shift in pH. A decrease in blood pH inhibits the production of lactic acid and ketone body acids, which diminishes the acidic shift in pH.

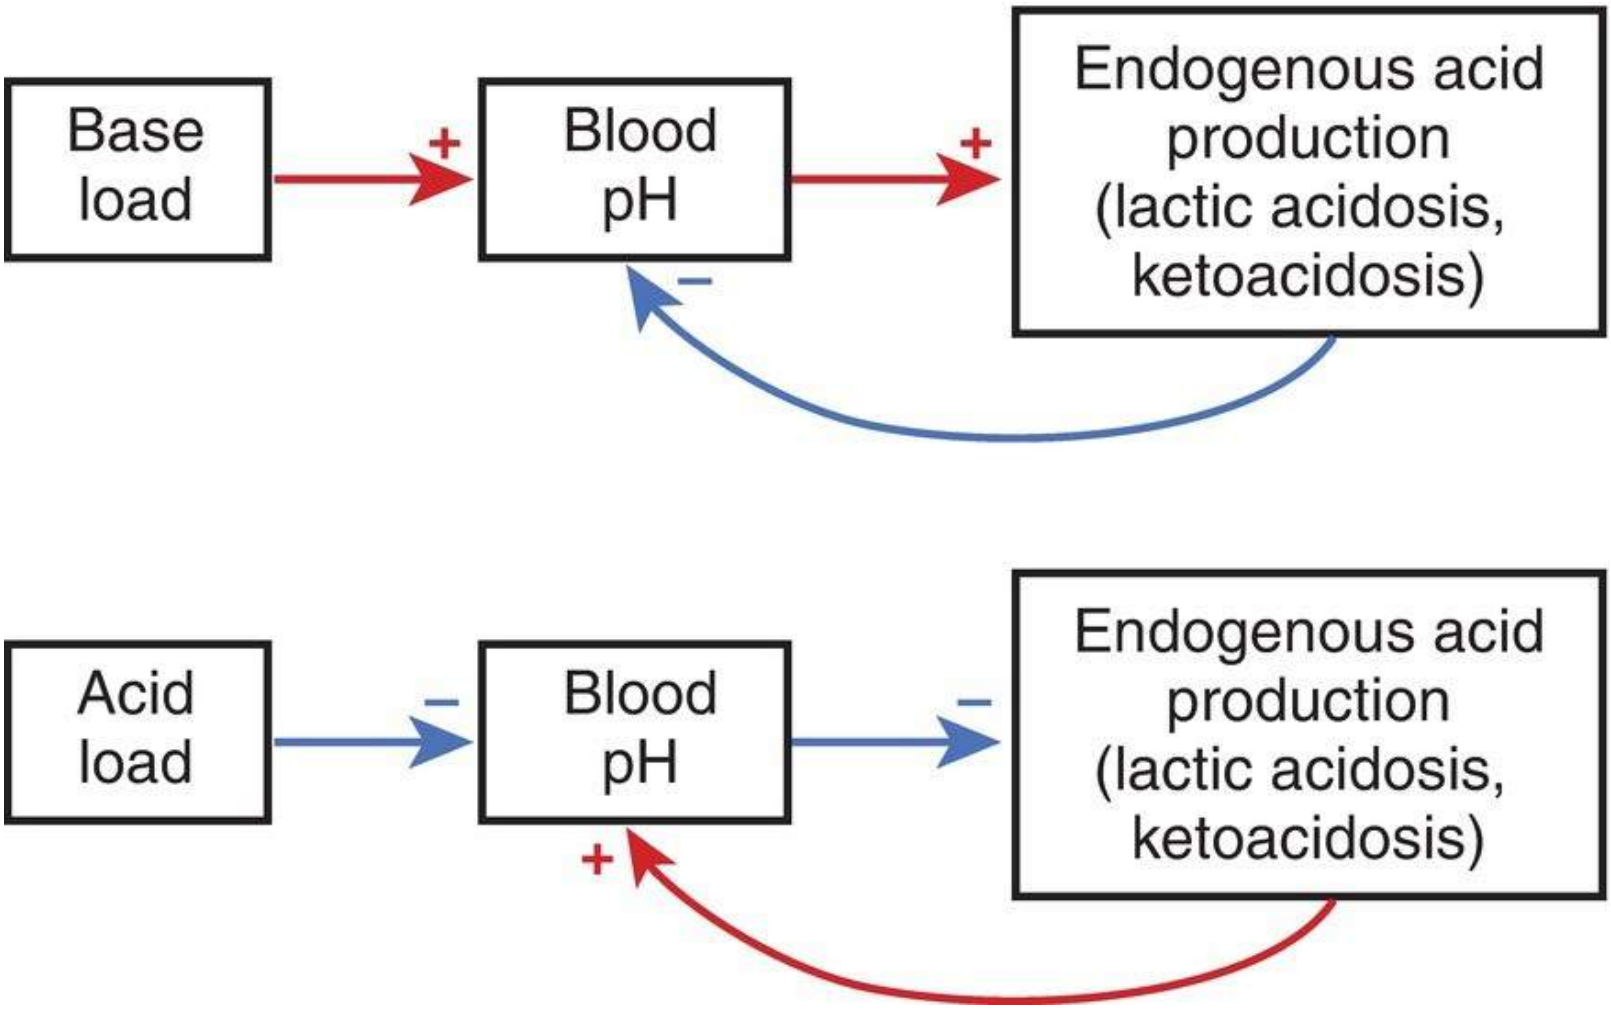

Figure 24.4 Negative feedback control of endogenous acid production. A base load, by raising pH, stimulates the endogenous production of acids. The addition of an exogenous acid load or increased endogenous acid production results in a fall in pH, which in turn inhibits the production of ketone body acids and lactic acid. These negative feedback effects attenuate changes in blood pH.

This scenario is especially important when the endogenous production of these acids is high, as occurs during strenuous exercise or other conditions of circulatory inadequacy (lactic acidosis) or during ketosis resulting from uncontrolled diabetes mellitus, starvation, or alcoholism. These effects of pH on endogenous acid production result from changes in enzyme activities brought about by the pH changes, and they are part of a negative feedback mechanism regulating blood pH.

We have discussed the various buffers separately, but in the body, they all work together. In a solution containing multiple buffers, all are in equilibrium with the same H^+ ions. This idea is known as the **isohydric principle** (*isohydric* means "same H^+"). For plasma, for example, we can write:

$$pH = 6.80 + \log\frac{[HPO_4^{2-}]}{[H_2PO_4^-]} = 6.10 + \log\frac{[HCO_3^-]}{0.03PCO_2}$$

$$= pK_{protein} + \log\frac{[proteinate^-]}{H-protein}$$

(21)

If an acid or a base is added to such a complex mixture of buffers, all buffers take part in buffering and shift from one form (base or acid) to the other. The relative importance of each buffer depends on its amount, pK, and availability.

The isohydric principle underscores the fact that it is the *concentration ratio* for any buffer pair, along with its pK, that sets the pH. We can focus on the concentration ratio for one buffer pair, and all other buffers will automatically adjust their ratios according to the pH and their pK values.

The rest of this chapter emphasizes the role of the HCO_3^-/CO_2 buffer pair in setting the blood pH. Other buffers, however, are present and participate in buffering. The HCO_3^-/CO_2 system is emphasized because physiologic mechanisms (lungs and kidneys) regulate pH by acting on components of this buffer system.

Lungs regulate blood pH by changing arterial CO_2 tension ($PaCO_2$).

The respiratory system can rapidly and profoundly affect blood pH. Reflex changes in ventilation help to defend blood pH by changing the arterial PCO_2 and hence H_2CO_3 of the blood. As discussed in Chapter 21, a fall in blood pH stimulates ventilation. An elevated arterial blood PCO_2 is a powerful stimulus to increase ventilation; it acts on both peripheral and central chemoreceptors but primarily on the latter. CO_2 diffuses into brain interstitial and cerebrospinal fluids, where it causes a fall in pH, which stimulates chemoreceptors in the medulla oblongata. When ventilation is stimulated, the lungs blow off more CO_2, thereby making the blood less acidic. Conversely, a rise in blood pH inhibits ventilation; the consequent rise in blood H_2CO_3 reduces the alkaline shift in blood pH. Respiratory responses to disturbed blood pH begin within minutes and are maximal in about 12 to 24 hours. However, respiratory responses to such disturbances are self-limiting because in the process of using ventilation to alter pH, the potent stimulant for respiration, PCO_2, is altered such that the change in ventilation needed to return pH toward normal is blunted. For this reason, the respiratory system alone can only bring a deviation of arterial pH to within 50% to 75% of normal arterial pH. Other systems, namely, those in the kidney, are needed to further help the body compensate for an acid–base disturbance.

Kidneys play a crucial role in maintaining the body's acid–base homeostasis.

The kidneys play a critical role in maintaining acid–base balance. First, the kidneys must reclaim HCO_3^- filtered at the glomerulus. Recall from the Henderson-Hasselbalch equation that a decrease in HCO_3^- decreases the pH of the ECF; removal of HCO_3^- is the equivalent of adding acid to the system. Thus, if the HCO_3^- filtered at the glomerulus were to be excreted in the urine, a systemic acidosis will result. Second, the kidneys must remove H^+ if there is excess acid in the body or HCO_3^- if there is excess base. The usual challenge is to remove excess strong acids formed by normal metabolism. As we have learned, body buffer bases, particularly HCO_3^-, first buffer the strong acids produced by metabolism. Thus, ECF HCO_3^- is lost by reacting with strong acids produced in the body. The kidneys then must restore the depleted HCO_3^- by creating "new" HCO_3^- and eliminate H^+ in the urine.

Little of the H^+ excreted in the urine is present as free H^+. For example, if the urine has its lowest pH value (pH = 4.5), the H^+ is only 0.03 mEq/L. With a typical daily urine output of 1 to 2 L, the amount of acid the body must dispose of daily (roughly 70 mEq) obviously is not excreted in the free form. Most of the H^+ combines with urinary buffers to be excreted as **titratable acid** and as NH_4^+. Titratable acid is measured in the clinical laboratory by titrating the urine with a strong base (NaOH) and measuring the number of milliequivalents of OH^- needed to bring the urine pH back to the pH of the blood (usually 7.40). It represents the amount of hydrogen ions that are excreted combined with urinary buffers, such as phosphate, creatinine, and other bases. The largest component of titratable acid is normally phosphate, that is, $H_2PO_4^-$.

Hydrogen ions secreted by the renal tubules also combine with the free base NH_3 and are excreted as NH_4^+. Ammonia (a term that includes both NH_3 and NH_4^+) is produced by the kidney tubule cells and is secreted into the urine. Because the pK_a for NH_4^+ is high (9.0), most of the ammonia in the urine is present as NH_4^+. For this reason, too, NH_4^+ is not appreciably titrated when titratable acid is measured. Urinary ammonia is measured by a separate, colorimetric or enzymatic, method.

Kidneys excrete excess acid to maintain acid–base balance.

In stable acid–base balance, *net acid excretion* by the kidneys equals the net rate of H^+ addition to the body by metabolism or other processes, assuming that other routes of loss of acid or base (e.g., gastrointestinal losses) are small and can be neglected. This is normally the case. The net loss of H^+ in the urine can be calculated from the following equation, which shows typical values in the parentheses:

$$\begin{aligned}\text{Renal net acid excretion (70 mEq/d)} \\ = \text{urinary titratable acid (24 mEq/d)} \\ + \text{urinary ammonia (48 mEq/d)} \\ - \text{urinary } HCO_3^- \text{ (2 mEq/d)}\end{aligned} \quad (22)$$

Urinary ammonia (as NH_4^+) ordinarily accounts for about two thirds of the excreted H^+ and titratable acid for about one third. Excretion of HCO_3^- in the urine represents a loss of base from the body. Therefore, it must be subtracted in the calculation of net acid excretion. If the urine contains significant amounts of organic anions such as citrate that potentially could have yielded HCO_3^- in the body, these should also be subtracted. Because the amount of free H^+ excreted is negligible, this is omitted from the equation

As the urine flows along the tubule, from the Bowman capsule on through the collecting ducts, three processes occur: filtered HCO_3^- is reabsorbed, titratable acid is formed, and ammonia is added to the tubular urine. All three processes involve H^+ secretion by the tubular epithelium that leads to increase urinary acidification. The nature and magnitude of these processes vary in different nephron segments. Figure 24.5 summarizes measurements of tubular fluid pH along the nephron and shows ammonia movements in various nephron segments.

Figure 24.5 Acidification along the nephron. The pH of tubular urine decreases along the proximal convoluted tubule, rises along the descending limb of the Henle loop, falls along the ascending limb, and reaches its lowest values in the collecting ducts. Ammonia ($NH_3 + NH_4^+$) is chiefly produced in proximal tubule cells and is secreted into the tubular urine. NH_4^+ is reabsorbed in the thick ascending limb and accumulates in the kidney medulla. NH_3 diffuses into acidic collecting duct urine, where it is trapped as NH_4^+.

The first step in the urinary acidification process starts in the proximal convoluted tubule. The pH of the glomerular ultrafiltrate is identical to that of the plasma from which it is derived (7.4). Hydrogen ions are secreted by the proximal tubule epithelium into the tubule lumen; about two thirds of this is accomplished by a Na^+/H^+ exchanger and about one third by an H^+-ATPase in the brush border membrane.

In spite of significant addition of H^+ into the tubular fluid, tubular fluid pH falls only to a value of about 6.7 by the end of the proximal convoluted tubule (see Fig. 24.5). The drop in pH is modest for two reasons: buffering of secreted H^+ and the high permeability of the proximal tubule epithelium to H^+. The glomerular filtrate and tubule fluid contain abundant buffer bases, especially HCO_3^-, which soak up secreted H^+, thereby minimizing a fall in pH. The proximal tubule epithelium is also rather "leaky" to H^+, so that any gradient from urine to blood, established by H^+ secretion, is soon limited by the diffusion of H^+ out of the tubule lumen into the blood surrounding the tubules.

Most of the hydrogen ions secreted by the nephron that are secreted in the proximal convoluted tubule are used to bring about the reabsorption of filtered HCO_3^-. Secreted hydrogen ions are also buffered by filtered phosphate to form titratable acid. Proximal tubule cells produce ammonia, mainly from the amino acid glutamine. Ammonia is secreted into the tubular urine by the diffusion of NH_3, which then combines with a secreted H^+ to form NH_4^+, or via the brush border membrane Na^+/H^+ exchanger, which can operate in a Na^+/NH_4^+ exchange mode.

The second step in urinary acidification involves the loop of Henle. Along the descending limb of the loop of Henle, the pH of tubular fluid rises (from 6.7 to 7.4). This rise is explained by an increase in intraluminal HCO_3^- caused by water reabsorption. Ammonia is secreted along the descending limb.

The tubular fluid is acidified by the secretion of H^+ along the ascending limb via a Na^+/H^+ exchanger. Along the thin ascending limb, ammonia is passively reabsorbed. Along the thick ascending limb, the Na–K–2Cl cotransporter in the luminal cell membrane actively reabsorbs NH_4^+ (NH_4^+ substitutes for K^+). Some NH_4^+ can be reabsorbed via a luminal cell membrane K^+ channel. Also, some NH_4^+ can be passively reabsorbed between cells in this segment; the driving force is the lumen-positive transepithelial electrical potential difference (see Chapter 22). Ammonia may undergo countercurrent multiplication in the loop of Henle, leading to an ammonia concentration gradient in the kidney medulla. The highest concentrations are at the tip of the papilla.

The final step in urinary acidification occurs in the distal nephrons. The distal nephron (distal convoluted tubule, connecting tubule, and collecting duct) differs from the proximal portion of the nephron in its H^+ transport properties. It secretes far fewer hydrogen ions, and they are secreted primarily via an electrogenic H^+-ATPase or an electroneutral H^+/K^+-ATPase. The distal nephron is also lined by "tight"

epithelia, so little secreted H^+ diffuses out of the tubule lumen, making steep urine-to-blood pH gradients possible (see Fig. 24.5). Final urine pH is typically around 6 but may be as low as 4.5.

The distal nephron usually almost completely reabsorbs the small quantities of HCO_3^- that were not reabsorbed by more proximal nephron segments. Considerable amounts of titratable acid are formed as the urine is acidified. Ammonia that was reabsorbed by the ascending limb of the loop of Henle and accumulated in the medullary interstitial space diffuses as lipid-soluble NH_3 into collecting duct urine and combines with secreted H^+ to form NH_4^+. The collecting duct epithelium is impermeable to the lipid-insoluble NH_4^+, so ammonia is trapped in an acidic urine and is excreted as NH_4^+ (see Fig. 24.5).

The **intercalated cells** of the collecting duct are involved in acid–base transport and are of two major types: an acid-secreting *α-intercalated cell* and a bicarbonate-secreting *β-intercalated cell*. The α-intercalated cell has a vacuolar type of H^+-ATPase (the same kind as is found in lysosomes, endosomes, and secretory vesicles) and a H^+/K^+-ATPase (similar to that found in stomach and colon epithelial cells) in the luminal cell membrane and a Cl^-/HCO_3^- exchanger in the basolateral cell membrane (Fig. 24.6). The β-intercalated cell has the opposite polarity.

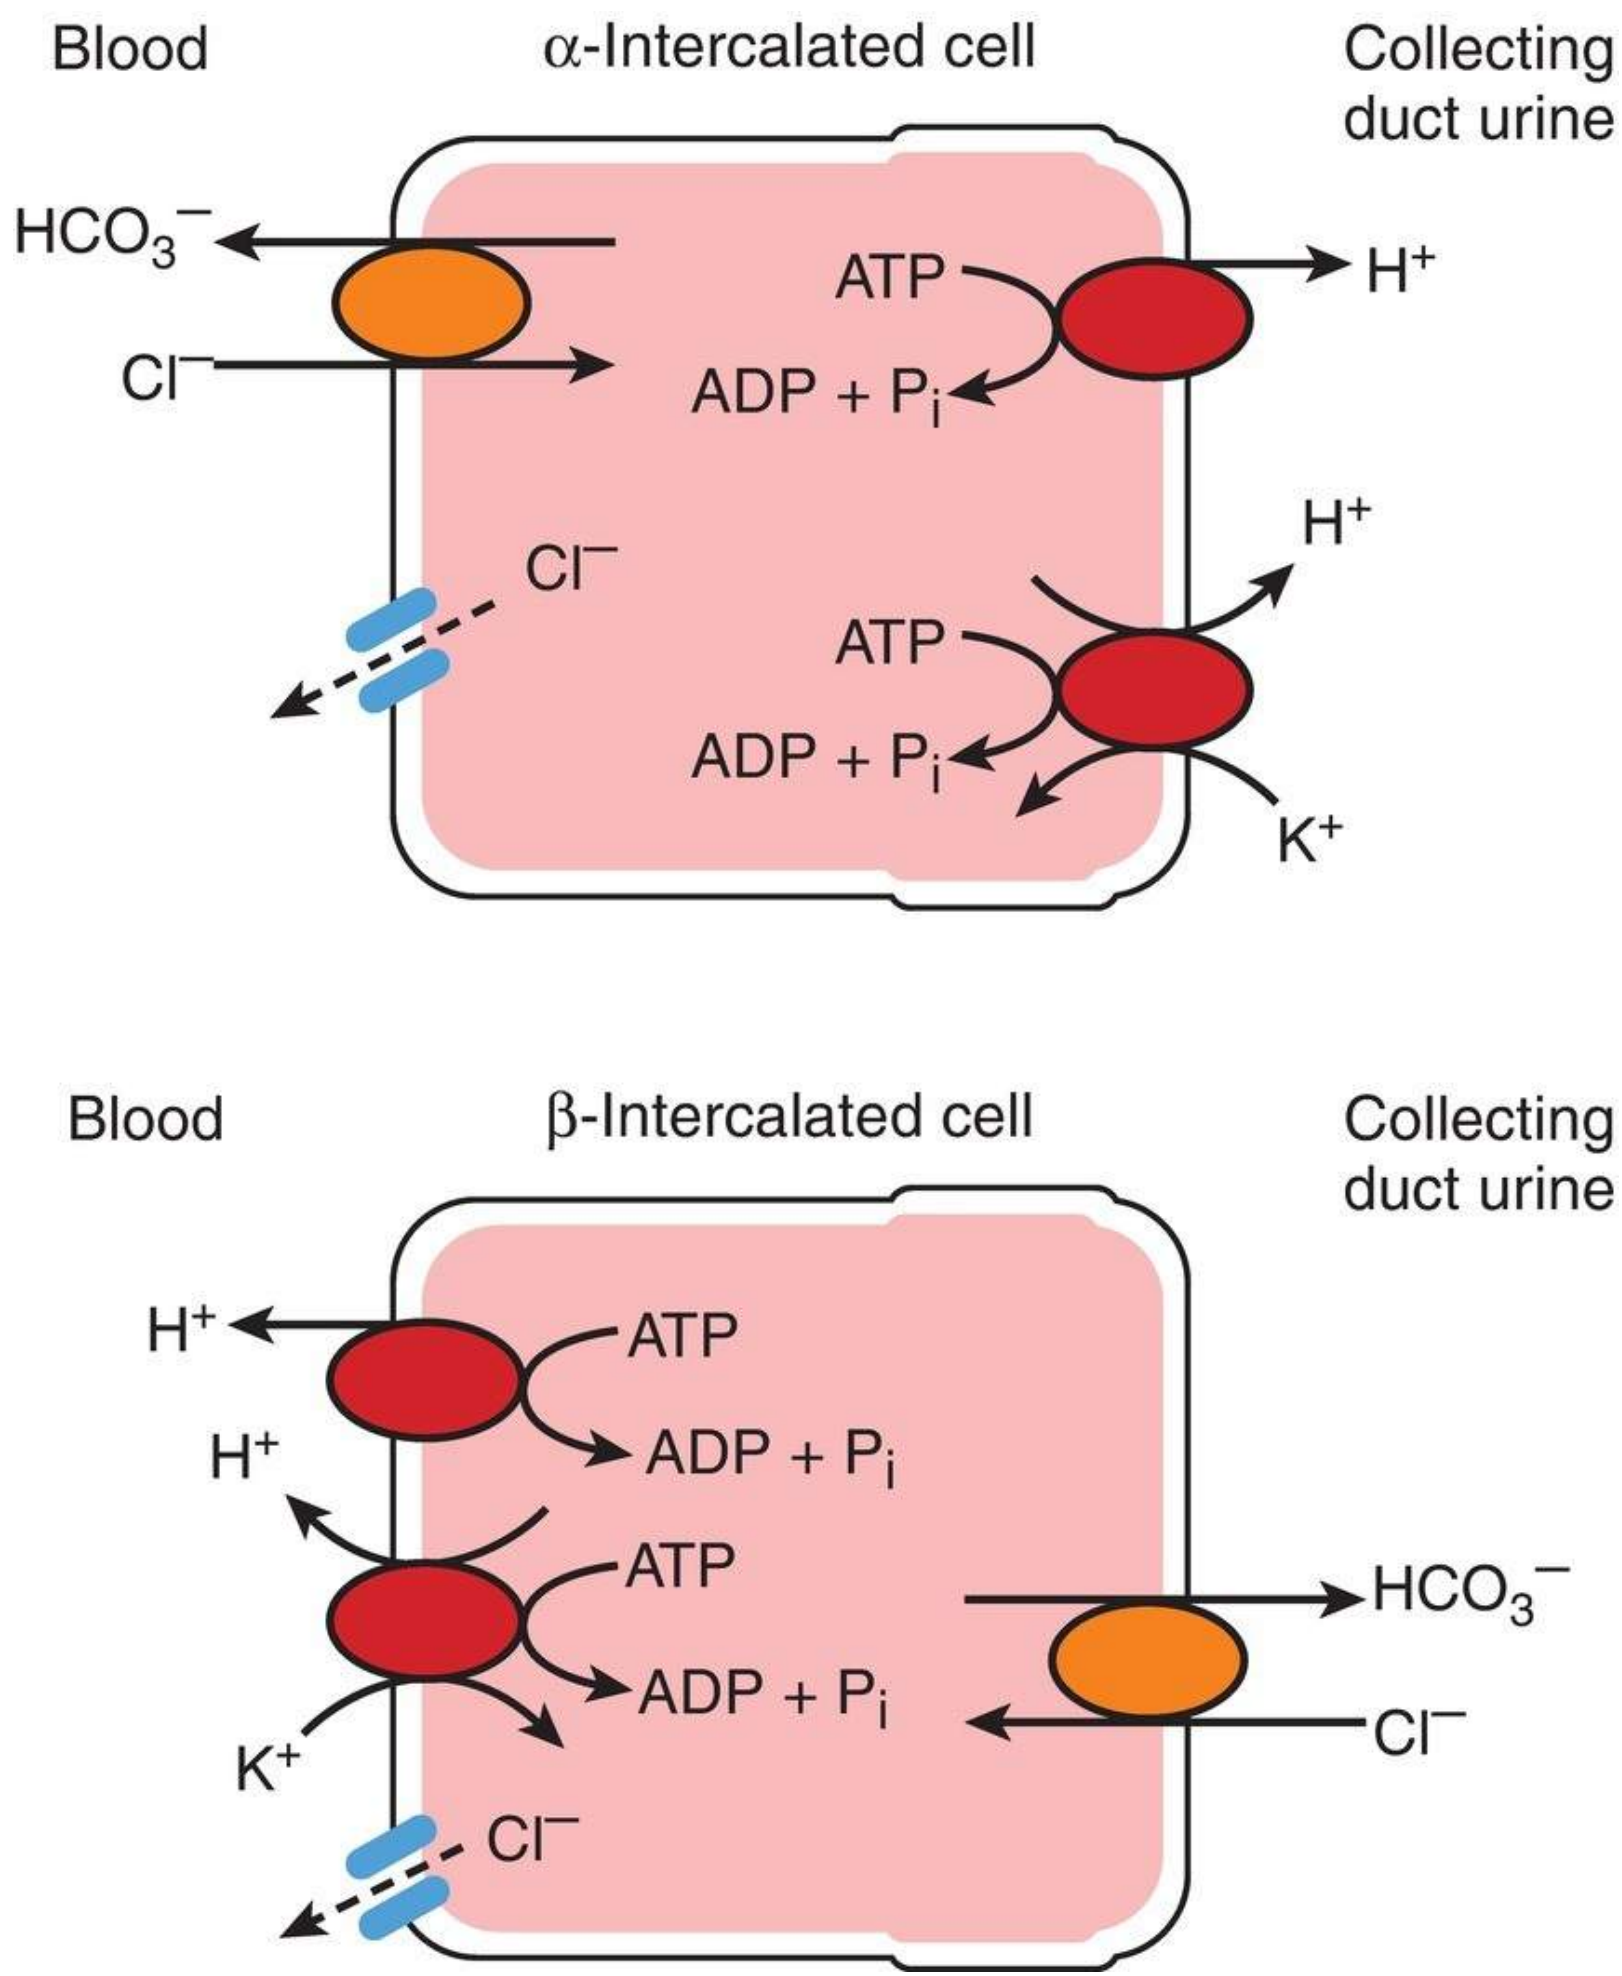

Figure 24.6 Collecting duct intercalated cells. The α-intercalated cell secretes H^+ via an electrogenic vacuolar H^+-ATPase and electroneutral H^+/K^+-ATPase and adds HCO_3^- to the blood via a basolateral

cell membrane Cl^-/HCO_3^- exchanger. The β-intercalated cell, which is located in cortical collecting ducts, has the opposite polarity and secretes HCO_3^-. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate.

A more acidic blood pH results in the insertion of cytoplasmic H^+ pumps into the luminal cell membrane of α-intercalated cells and enhanced H^+ secretion. If the blood is made alkaline, HCO_3^- secretion by β-intercalated cells is increased. Because the amounts of HCO_3^- secreted are ordinarily small compared with the amounts filtered and reabsorbed, HCO_3^- secretion will be omitted from the remaining discussion.

Kidneys regulate blood pH by reabsorbing filtered bicarbonate.

The kidney glomeruli filter about 4,320 mEq of HCO_3^- per day (180 L/d × 24 mEq/L). Recall from the Henderson-Hasselbalch equation that a reduction of HCO_3^- in the ECF will result in a reduction of pH; losing HCO_3^- therefore has the same effect as adding acid to the ECF. Urinary loss of even a small portion of this HCO_3^- will lead to an acidic blood and impair the body's ability to buffer its daily load of metabolically produced H^+. The kidney tubules have the important task of recovering the filtered HCO_3^- and returning it to the blood.

At the cellular level (Fig. 24.7), filtered HCO_3^- is not reabsorbed directly across the tubule's luminal cell membrane as is, for example, glucose. Instead, filtered HCO_3^- is reabsorbed indirectly via H^+ secretion, in the following way. About 90% of the filtered HCO_3^- is reabsorbed in the proximal convoluted tubule, and so we will emphasize events at this site. H^+ is secreted into the tubule lumen mainly via the Na^+/H^+ exchanger in the luminal membrane. It combines with filtered HCO_3^- to form H_2CO_3. Carbonic anhydrase (CA) in the luminal membrane (brush border) of the proximal tubule catalyzes the dehydration of H_2CO_3 to CO_2 and water in the lumen. The CO_2 diffuses back into the cell.

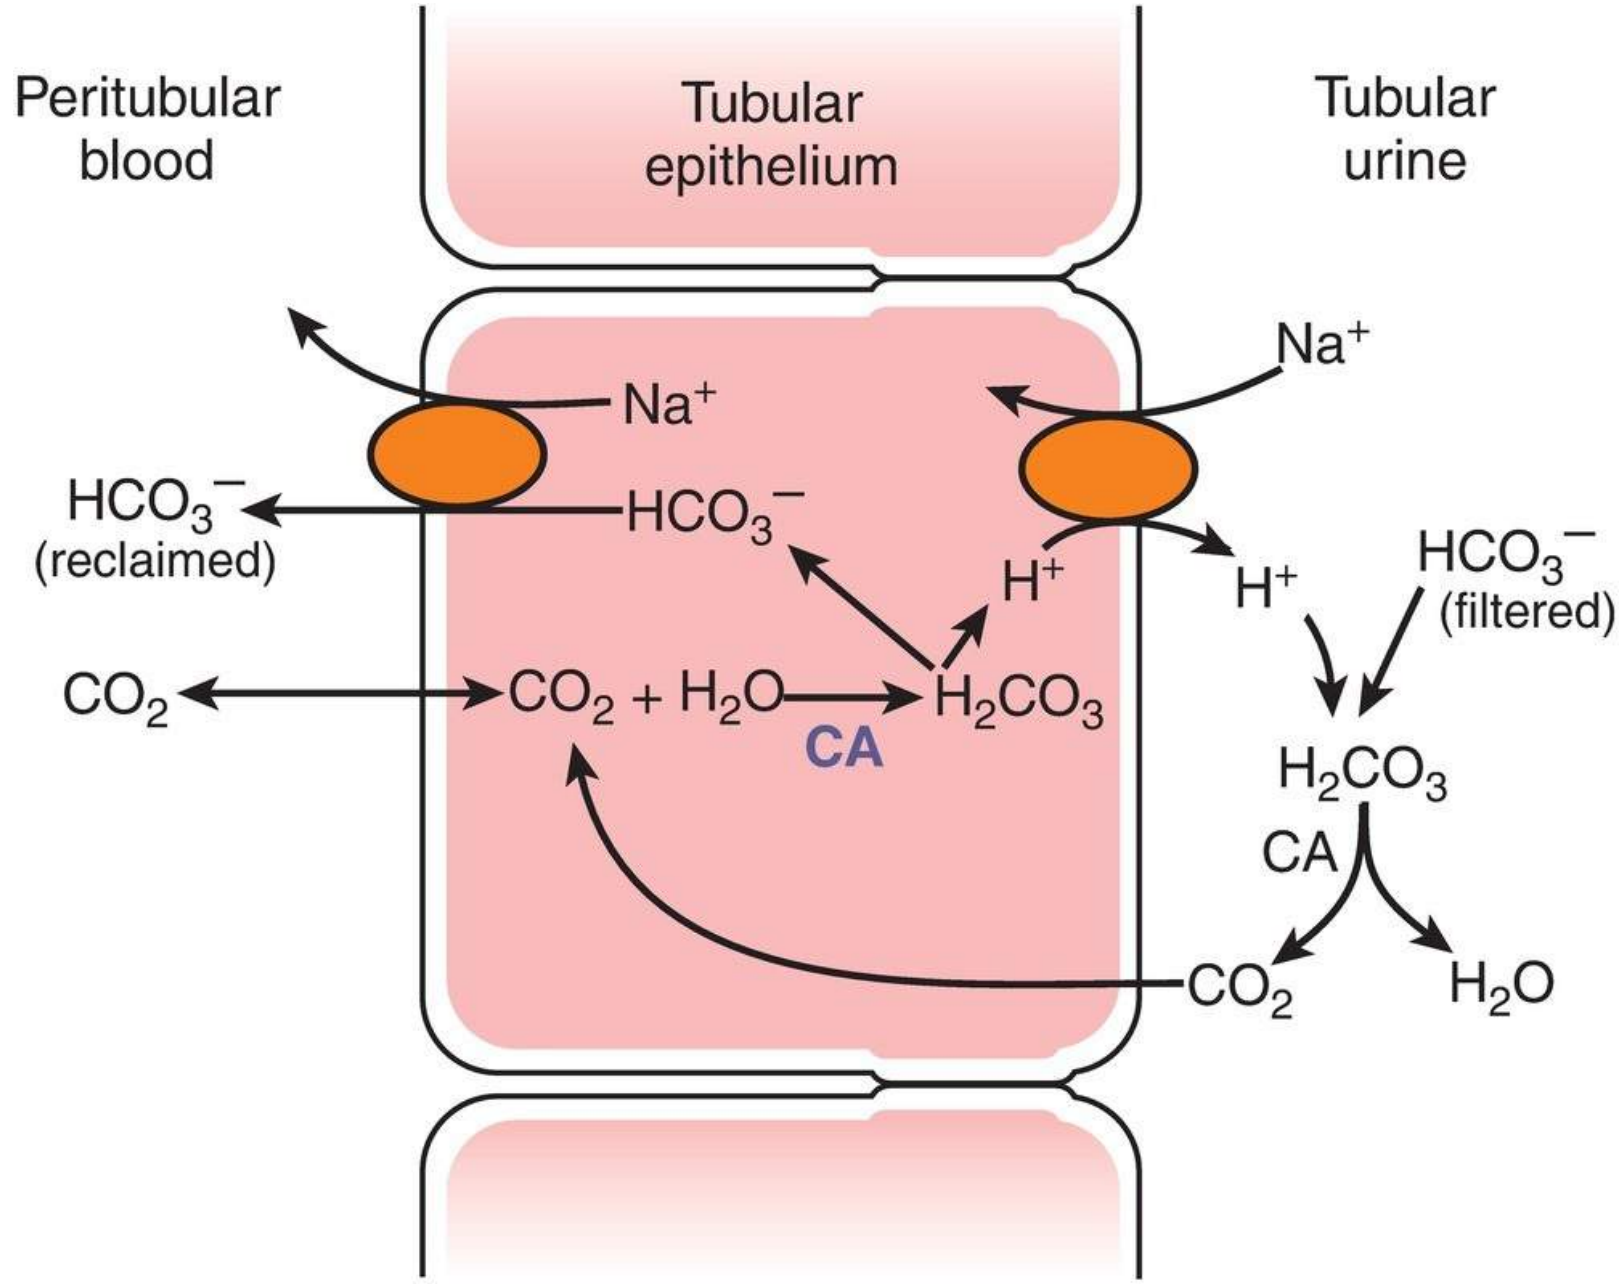

Figure 24.7 A cell model for HCO_3^- reabsorption. Filtered HCO_3^- combines with secreted H^+ and is reabsorbed indirectly. Carbonic anhydrase (CA) is present in the cells and, in the proximal tubule, on the brush border.

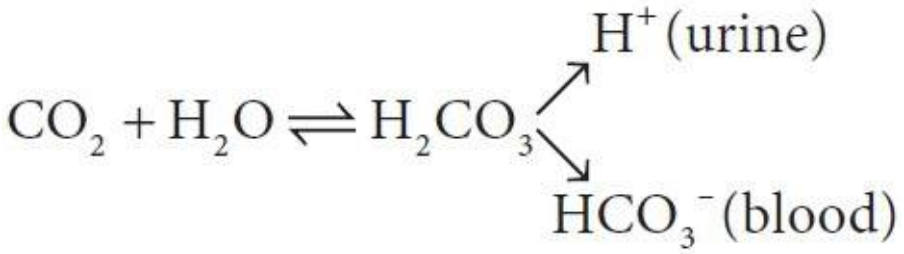
Inside the cell, the hydration of CO_2 (catalyzed by intracellular CA) yields H_2CO_3, which instantaneously forms H^+ and HCO_3^-. The H^+ is secreted into the lumen, and the HCO_3^- moves into the blood surrounding the tubules. In proximal tubule cells, this movement is favored by the inside negative membrane potential of the cell and by an electrogenic cotransporter in the basolateral membrane that simultaneously transports three HCO_3^- and one Na^+. In addition, HCO_3^- can leave the cell via a Cl^-/HCO_3^- exchanger in the basolateral cell membrane (not shown in Fig. 24.7).

The reabsorption of filtered HCO_3^- does not result in H^+ excretion or the formation of any "new" HCO_3^-. The secreted H^+ is not excreted because it combines with filtered HCO_3^- that is, indirectly, reabsorbed. There is no net addition of HCO_3^- to the body in this operation. *It is simply a recovery or reclamation process*. In contrast, when H^+ is excreted as titratable acid and ammonia, new HCO_3^- is

formed and is added to the blood. New HCO_3^- replaces the HCO_3^- used to buffer the strong acids produced by metabolism (see Fig. 24.2).

The formation of new HCO_3^- and the excretion of H^+ are like two sides of the same coin. This fact is apparent if we assume that H_2CO_3 is the source of H^+:



(23)

A loss of H^+ in the urine is equivalent to adding new HCO_3^- to the blood. The same is true if H^+ is lost from the body via another route such as by vomiting of acidic gastric juice. This process leads to a rise in plasma HCO_3^-. *Conversely, a loss of HCO_3^- from the body is equivalent to adding H^+ to the blood.*

Figure 24.8 shows a cell model for the formation of titratable acid. In this figure, $H_2PO_4^-$ is the titratable acid formed. H^+ and HCO_3^- are produced in the cell from H_2CO_3. The secreted H^+ combines with the basic form of the phosphate (HPO_4^{2-}) to form the acid phosphate ($H_2PO_4^-$). The secreted H^+ replaces one of the Na^+ ions accompanying the basic phosphate. The new HCO_3^- generated in the cell moves into the blood, together with Na^+. For each milliequivalent of H^+ excreted in the urine as titratable acid, a milliequivalent of new HCO_3^- is added to the blood. This process gets rid of H^+ in the urine, replaces ECF HCO_3^-, and helps to restore a normal blood pH.

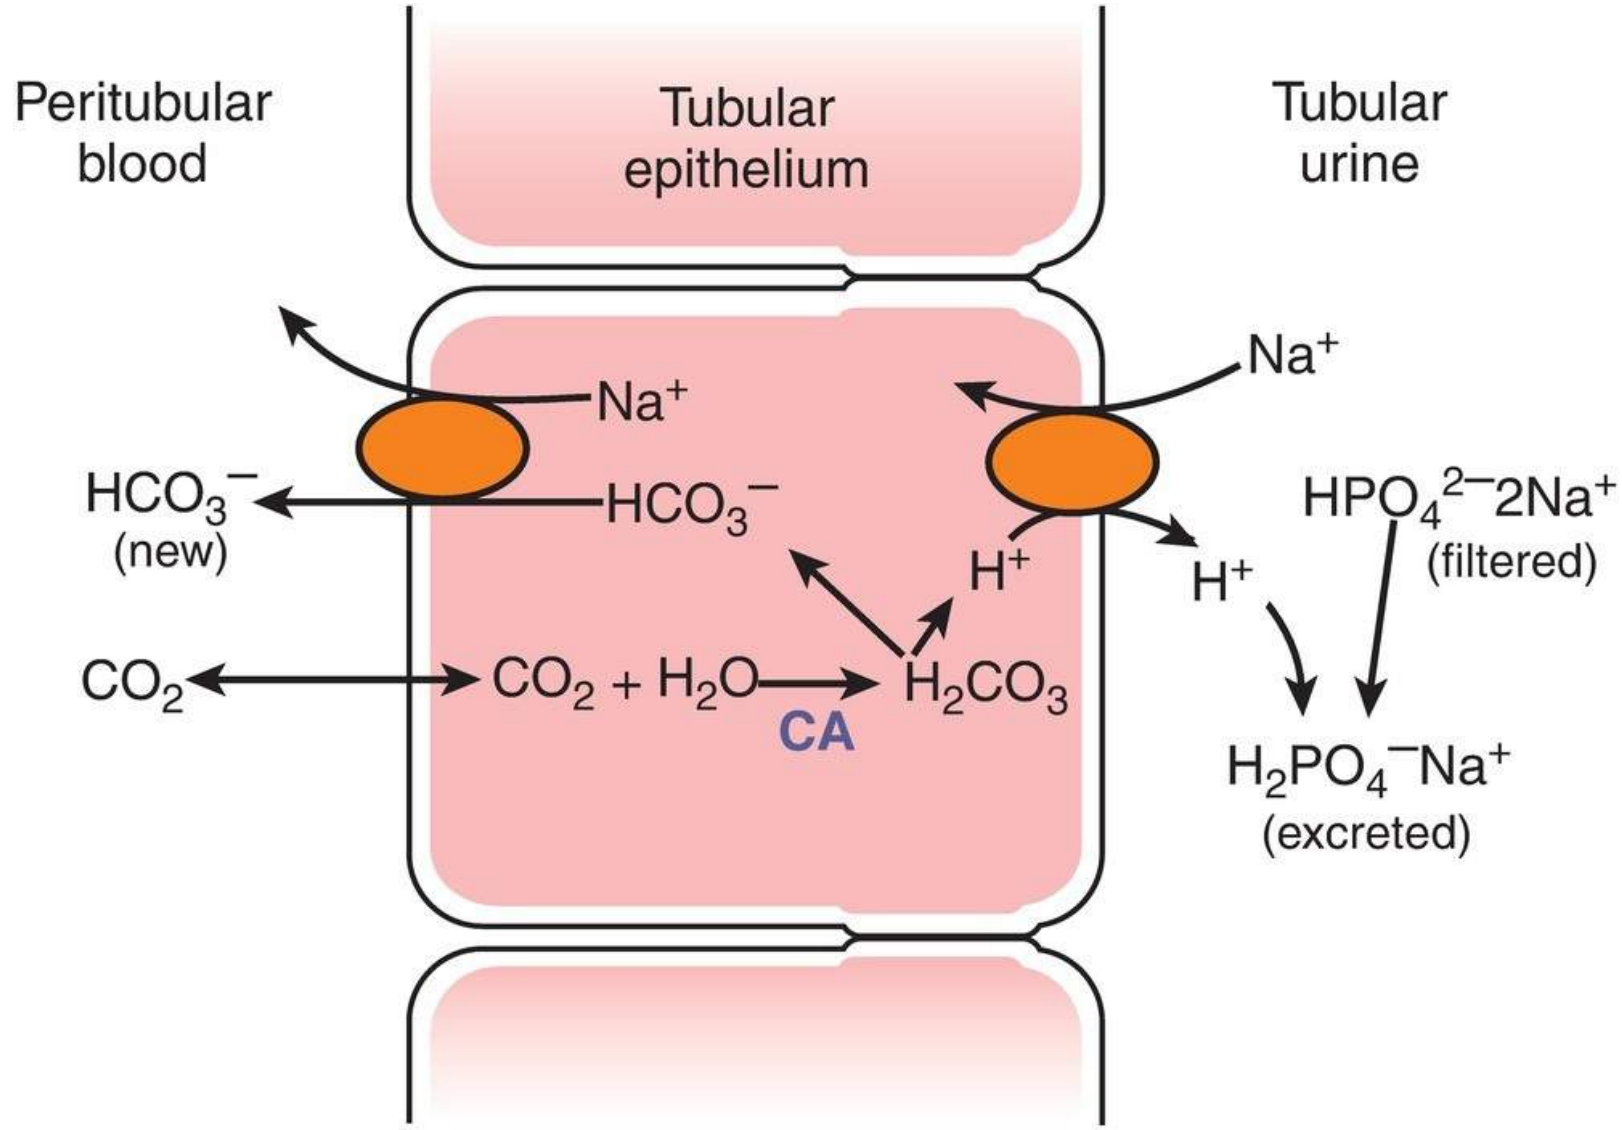


Figure 24.8 A cell model for the formation of titratable acid. Titratable acid (e.g., $H_2PO_4^-$) is formed when secreted H^+ is bound to a buffer base (e.g., HPO_4^{2-}) in the tubular urine. For each milliequivalent of titratable acid excreted, a milliequivalent of new HCO_3^- is added to the peritubular capillary blood. CA, carbonic anhydrase.

The amount of titratable acid excreted depends on two factors: the pH of the urine and the availability of buffer. If the urine pH is lowered, more titratable acid can form. However, the supply of phosphate and other buffers in the urine is usually limited. Therefore, to excrete large amounts of acid, the kidneys must rely on increased ammonia excretion.

Figure 24.9 shows a cell model for the excretion of ammonia. The majority of ammonia is synthesized in proximal tubule cells by deamidation and deamination of glutamine:

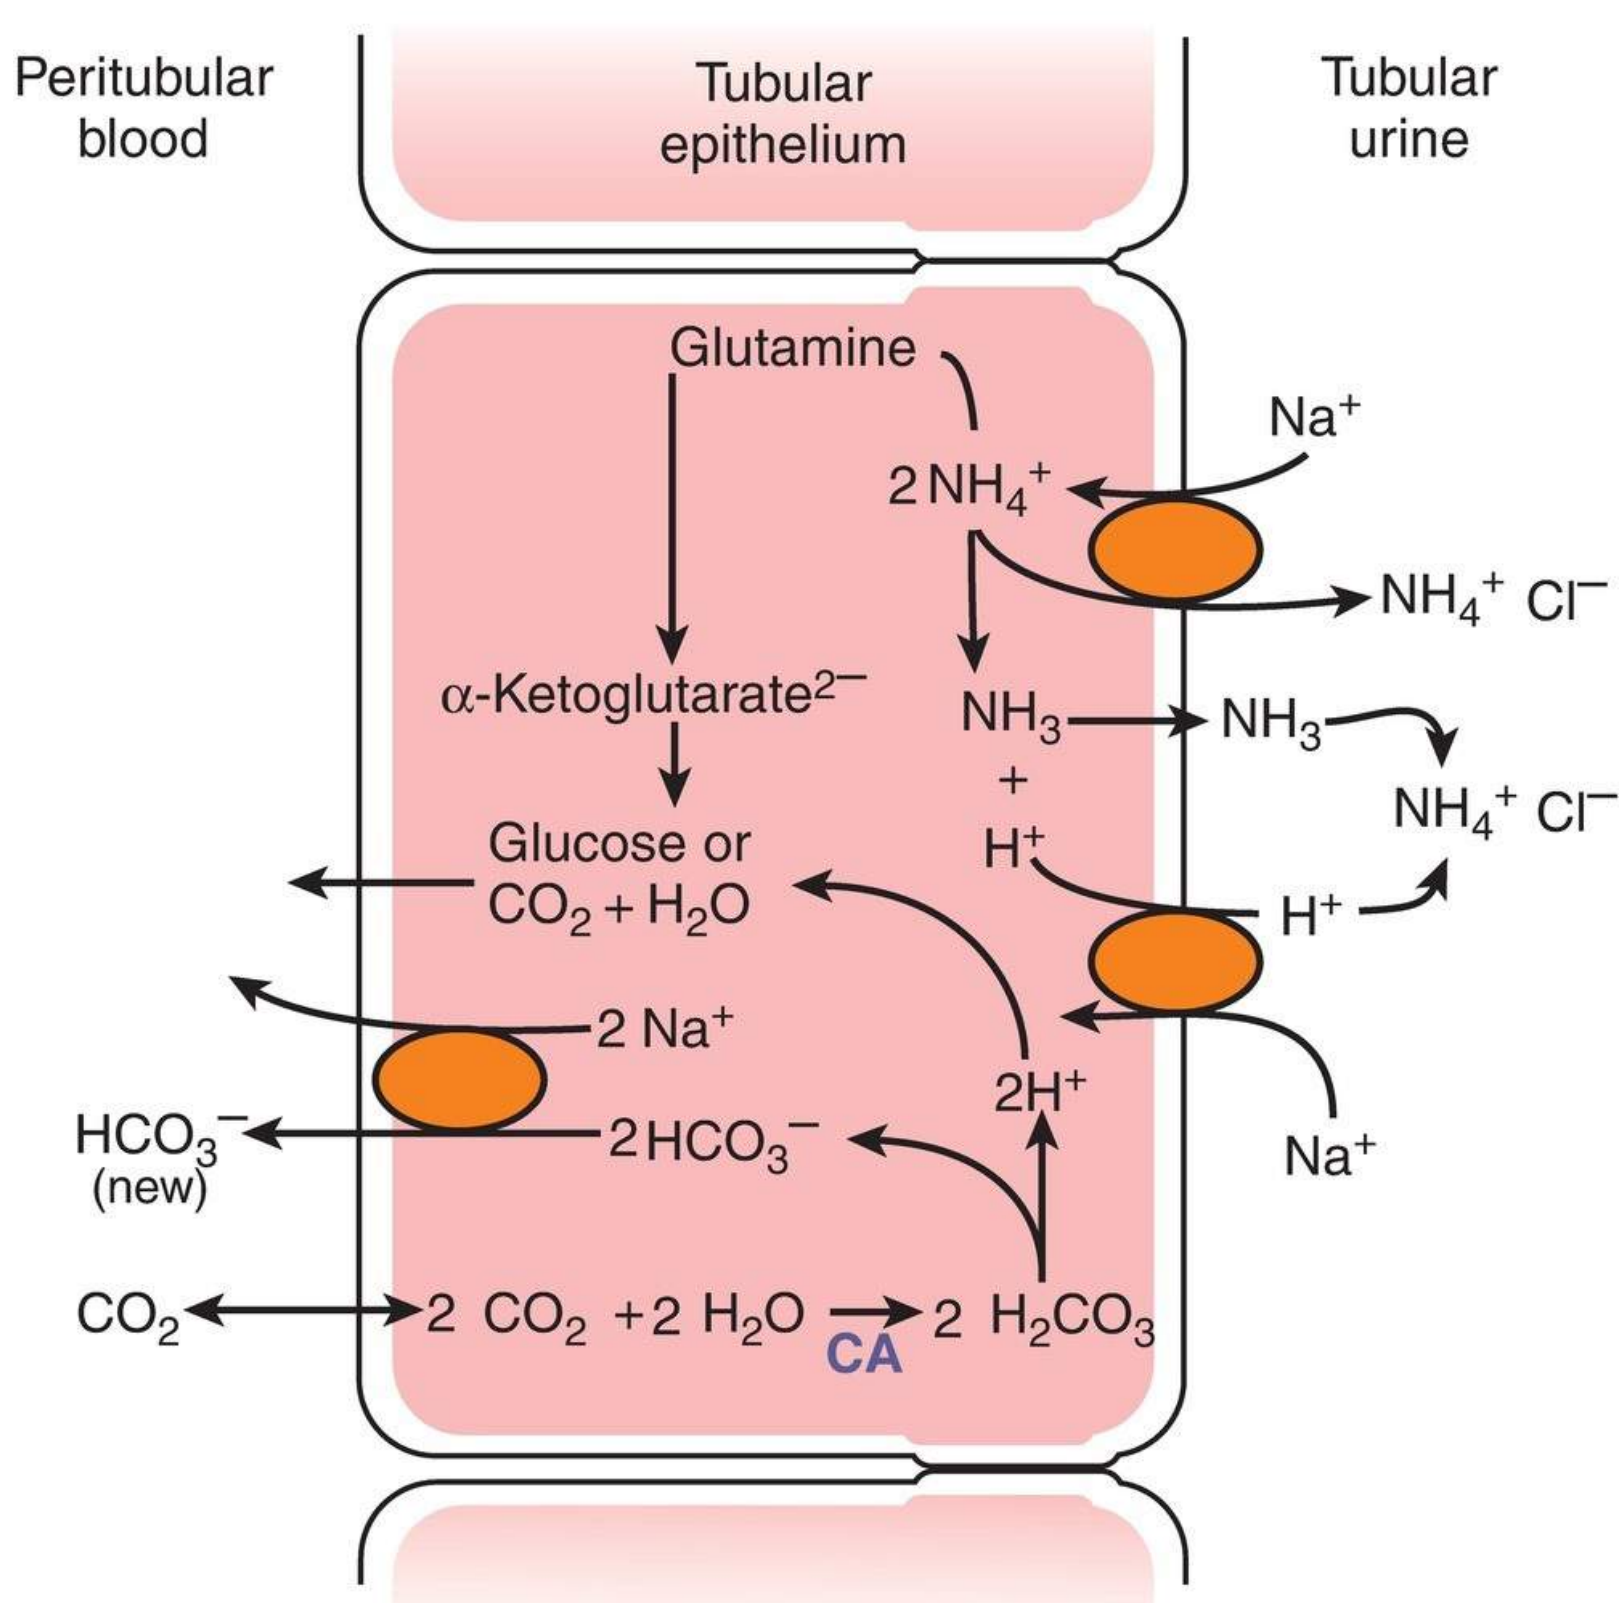

Figure 24.9 A cell model for renal synthesis and excretion of ammonia. Ammonium ions are formed from glutamine in the cell and are secreted into the tubular urine (**top**). H^+ from H_2CO_3 (**bottom**) is consumed when α-ketoglutarate is converted into glucose or CO_2 and H_2O. New HCO_3^- is added to the peritubular capillary blood—1 milliequivalent for each milliequivalent of NH_4^+ excreted in the urine. CA, carbonic anhydrase.

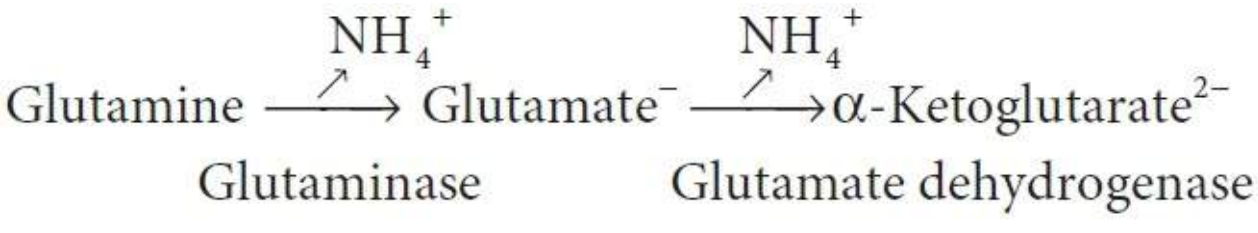

(24)

As discussed earlier, ammonia is secreted into the urine by two mechanisms. As NH_3, it diffuses into the tubular urine; as NH_4^+, it substitutes for H^+ on the Na^+/H^+ exchanger. In the lumen, NH_3 combines with secreted H^+ to form NH_4^+, which is excreted.

For each milliequivalent of H^+ excreted as NH_4^+, one milliequivalent of new HCO_3^- is added to the blood. The hydration of CO_2 in the tubule cell produces H^+ and HCO_3^-, as described earlier. Two H^+s are consumed when the anion α-ketoglutarate^{2-} is converted into CO_2 and water or into glucose in the cell. The new HCO_3^- returns to the blood along with Na^+.

If excess acid is added to the body, urinary ammonia excretion increases for two reasons. First, more acidic urine traps more ammonia (as NH_4^+) in the urine. Second, glutamine increases renal ammonia synthesis over a period of several days. Enhanced renal ammonia synthesis and excretion is a lifesaving adaptation, because it allows the kidneys to remove large H^+ excesses and add more new HCO_3^- to the blood. Also, the excreted NH_4^+ can substitute in the urine for Na^+ and K^+, thereby diminishing the loss of these cations. With severe metabolic acidosis, ammonia excretion may increase almost 10-fold.

Metabolic dynamics influence renal acid secretion.

Many metabolic factors influence the renal excretion of H^+ including (1) intracellular pH, (2) arterial blood PCO_2, (3) CA activity, (4) Na^+ reabsorption, (5) plasma K^+, and (6) aldosterone (Fig. 24.10).

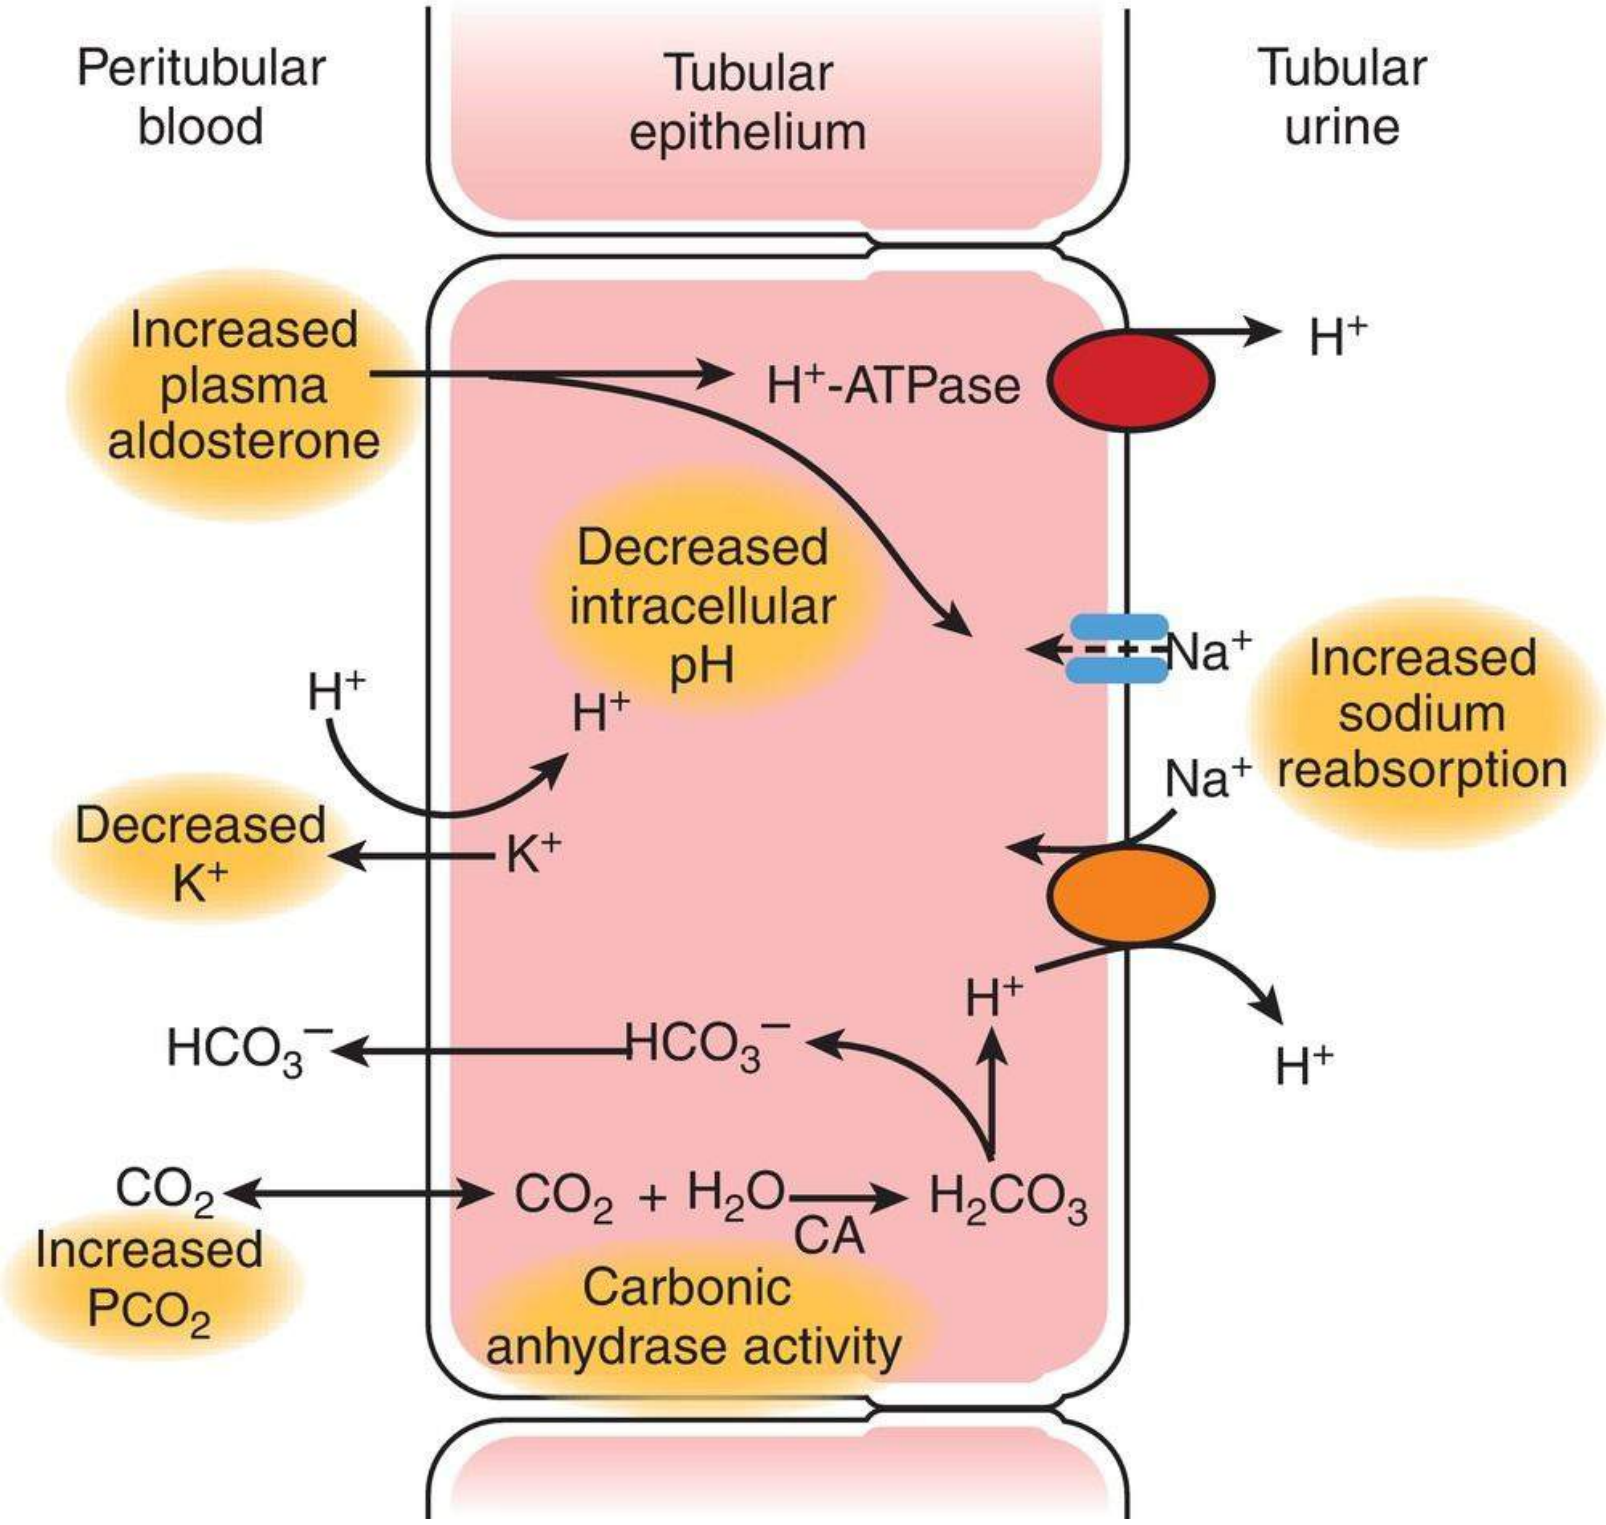

Figure 24.10 Factors leading to increased H^+ secretion by the kidney tubule epithelium. CA, carbonic anhydrase. (See text for details.)

The pH in kidney tubule cells is a key factor influencing the secretion and, therefore, the excretion of

H^+. A fall in pH (increased H^+) enhances H^+ secretion. A rise in pH (decreased H^+) lowers H^+ secretion. A decreased pH increases the activity of Na^+/H^+ exchangers in the luminal cell membrane. The activity of these exchangers is increased by the increased supply of H^+ and also by changes in exchanger conformation induced by binding of H^+. A low pH increases the recruitment of H^+-ATPases from intracellular vesicles and their insertion into the luminal membrane. A fall in intracellular pH also stimulates renal ammonia synthesis, which allows the kidneys to excrete more H^+ as NH_4^+.

An increase in arterial PCO_2 increases the formation of H^+ from H_2CO_3, leading to enhanced renal H^+ secretion and excretion—a useful compensation for any condition in which the blood contains too much H_2CO_3. (We will discuss this later when we consider respiratory acidosis.) A decrease in arterial PCO_2 results in lowered H^+ secretion and, consequently, less complete reabsorption of filtered HCO_3^- and a loss of base in the urine (a useful compensation for respiratory alkalosis, also discussed later).

The enzyme carbonic anhydrase catalyzes two key reactions in urinary acidification:

a. The hydration of CO_2 in the cells, forming H_2CO_3 and yielding H^+ for secretion
b. The dehydration of H_2CO_3 to H_2O and CO_2 in the proximal tubule lumen, an important step in the reabsorption of filtered HCO_3^-

Large amounts of filtered HCO_3^- may escape reabsorption if carbonic anhydrase is inhibited (usually by a drug). This situation leads to a fall in blood pH.

Another metabolic factor that is closely linked to acid secretion is Na^+ reabsorption. These two ions are directly linked, both being transported by the Na^+/H^+ exchanger in the luminal cell membrane. The relation is less direct in the collecting ducts. Enhanced Na^+ reabsorption in the ducts leads to a more negative intraluminal electrical potential, which favors H^+ secretion by its electrogenic H^+-ATPase. The avid renal reabsorption of Na^+ seen in states of volume depletion is accompanied by a parallel rise in urinary H^+ excretion, which can cause systemic alkalosis.

The fifth metabolic factor influencing renal excretion of H^+ is a change in plasma K^+ concentration. A fall in plasma K^+ favors the movement of K^+ from body cells into interstitial fluid (or blood plasma) and a reciprocal movement of H^+ into cells. In the kidney tubule cells, these movements lower intracellular pH and increase H^+ secretion. K^+ depletion also stimulates ammonia synthesis by the kidneys (probably by lowering the intracellular pH); this increases NH_4^+ excretion. Finally, low plasma K^+ results in increased expression and activity of the H^+/K^+-ATPase in α-intercalated cells; although this allows the kidneys to conserve K^+, it also enhances H^+ secretion. The result is the complete reabsorption of filtered HCO_3^- and the enhanced generation of new HCO_3^- as more titratable acid and ammonia are excreted. Consequently, hypokalemia (or a decrease in body K^+ stores) leads to increased plasma HCO_3^- (*metabolic alkalosis*).

Hyperkalemia (or excess K^+ in the body) results in the opposite changes: an increase in intracellular pH, a decreased in H^+ secretion, an incomplete reabsorption of filtered HCO_3^-, and a fall in plasma HCO_3^- (*metabolic acidosis*).

Finally, the sixth metabolic factor affecting acid secretion by the kidney is aldosterone. Aldosterone stimulates the collecting ducts to secrete H^+ by three actions:

1. It directly stimulates the H^+-ATPase in collecting duct α-intercalated cells.
2. It enhances collecting duct Na^+ reabsorption, which leads to a more negative intraluminal potential and consequently promotes H^+ secretion by the electrogenic H^+-ATPase.
3. It promotes K^+ secretion. This response leads to hypokalemia, which increases renal H^+ secretion.

Hyperaldosteronism results in enhanced renal H^+ excretion and an alkaline blood pH (metabolic alkalosis); the opposite occurs with **hypoaldosteronism**.

REGULATION OF INTRACELLULAR PH

The intracellular and ECF pH are linked by exchanges across cell membranes of H^+, HCO_3^-, various acids and bases, and CO_2. By stabilizing ECF pH, intracellular pH is maintained.

If hydrogen ions were passively distributed across cell membranes, intracellular pH would be lower than what is seen in most body cells. In skeletal muscle cells, for example, we can calculate from the Nernst equation (see Chapter 2) and a membrane potential of −90 mV that cytosolic pH should be 5.9 if ECF pH is 7.4; actual measurements, however, indicate a pH of 6.9. From this discrepancy, two conclusions are clear: hydrogen ions are not at equilibrium across the cell membrane, and the cell must use active mechanisms to extrude H^+.

Cellular pH is maintained by extruding hydrogen ions.

Cells are typically threatened by acidic metabolic end products and by the tendency for H^+ to diffuse into the cell down the electrical gradient (Fig. 24.11). H^+ is extruded by Na^+/H^+ exchangers, which are present in nearly all body cells. Eight different isoforms of these exchangers (designated NHE1, NHE2, etc.), with different tissue distributions, have been identified. These transporters exchange one H^+ for one Na^+ and therefore function in an electrically neutral fashion. Active extrusion of H^+ keeps the internal pH within narrow limits.

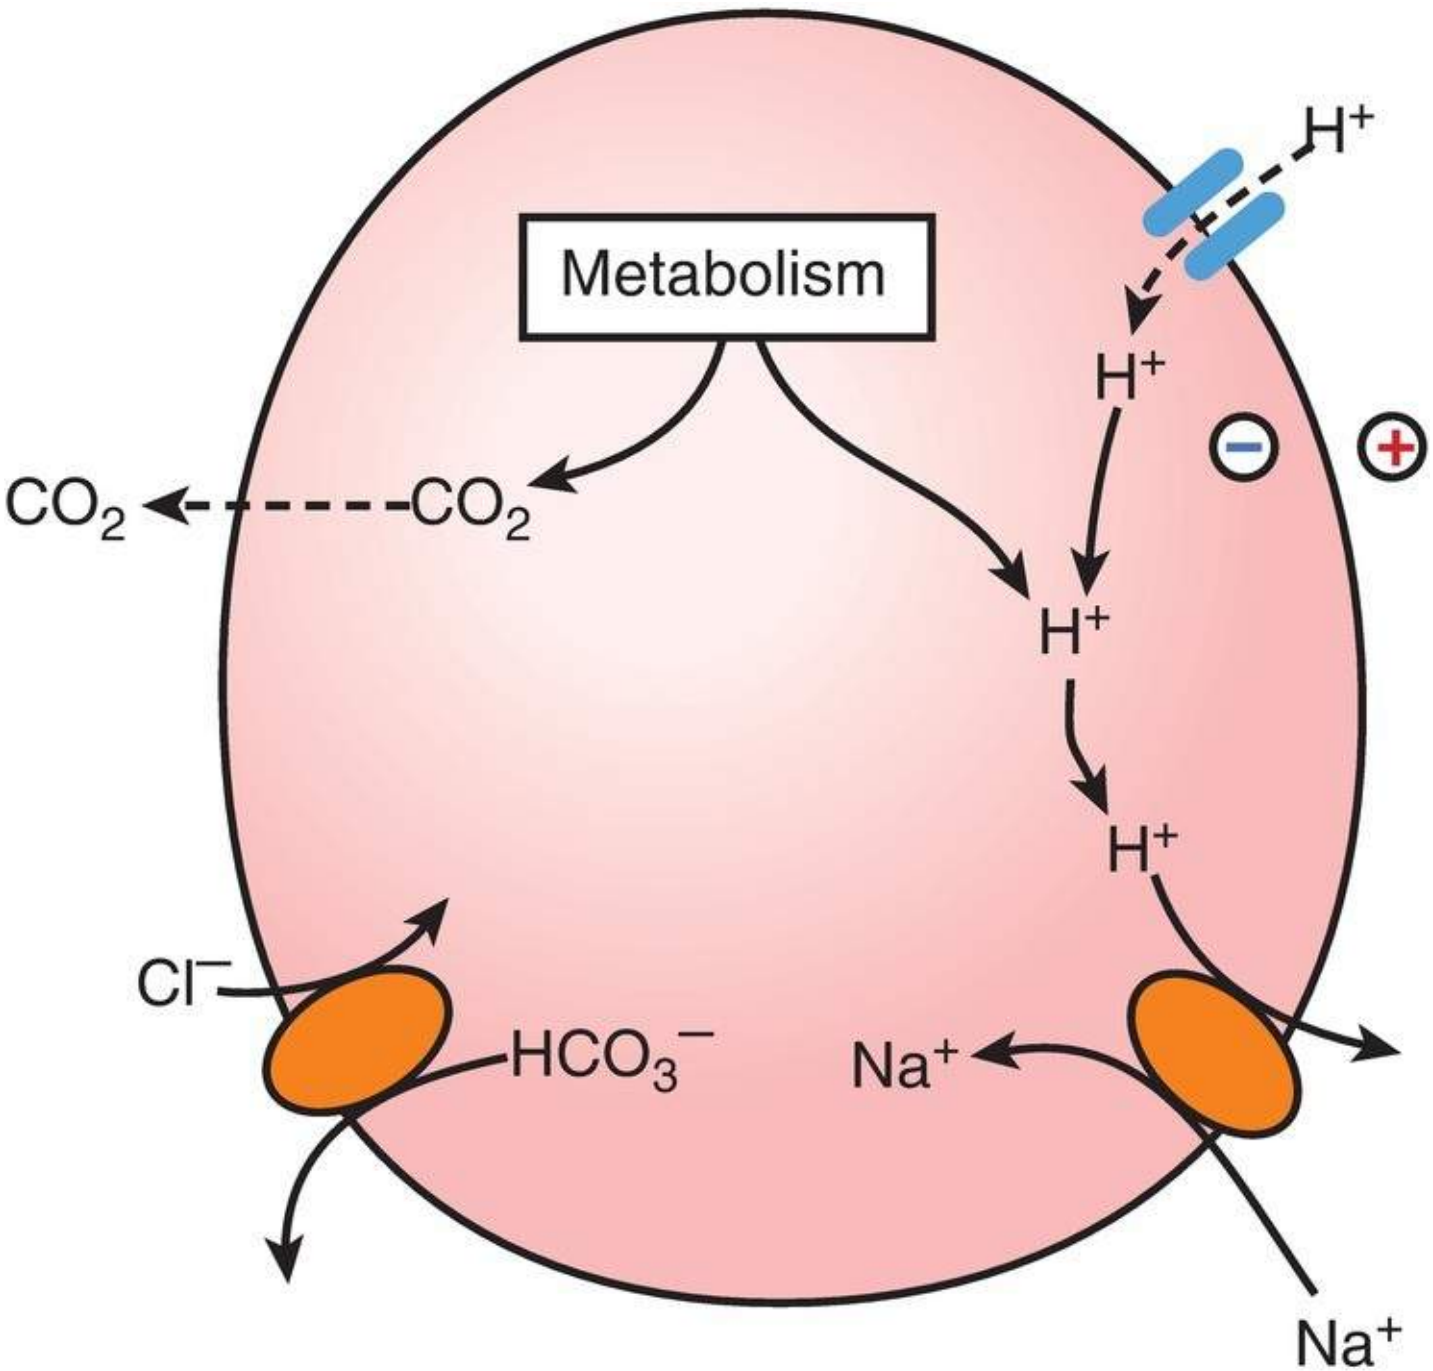

Figure 24.11 Cell acid–base balance. Body cells usually maintain a constant intracellular pH. The cell is acidified by the production of H^+ from metabolism and the influx of H^+ from the extracellular fluid (favored by the inside negative cell membrane potential). To maintain a stable intracellular pH, the cell must extrude hydrogen ions at a rate matching their input. Many cells also possess various HCO_3^-

transporters (one example is shown) that defend against excess acid or base.

The activity of the Na^+/H^+ exchanger is regulated by intracellular pH and a variety of hormones and growth factors. Not surprisingly, an increase in intracellular H^+ stimulates the exchanger, but not only because of more substrate (H^+) for the exchanger. H^+ also stimulates the exchanger by protonating an activator site on the cytoplasmic side of the exchanger, thereby making the exchanger more effective in dealing with the threat of intracellular acidosis. Many hormones and growth factors, via intracellular second messengers, activate various protein kinases that stimulate or inhibit the Na^+/H^+ exchanger. In this way, they produce changes in intracellular pH, which may lead to changes in cell activity.

Besides extruding H^+, the cell can deal with acids and bases in other ways. First, in some cells, various HCO_3^- transporters (e.g., Na^+-dependent and Na^+-independent Cl^-/HCO_3^- exchangers, electrogenic Na^+/HCO_3^- cotransporters) may be present in plasma membranes. These exchangers may be activated by changes in intracellular pH. Second, cells have large stores of protein and organic phosphate buffers, which can bind or release H^+. Third, various chemical reactions in cells can also use up or release H^+. For example, the conversion of lactic acid to CO_2 and water or to glucose effectively disposes of acid. Fourth, various cell organelles may sequester H^+. For example, H^+-ATPases in endosomes and lysosomes pump H^+ out of the cytosol into these organelles. In summary, ion transport, buffering mechanisms, and metabolic reactions all ensure a relatively stable intracellular pH.

PHYSIOLOGIC DISTURBANCES OF ACID–BASE BALANCE

Table 24.2 lists the normal values for the pH (or H^+), PCO_2, and HCO_3^- of arterial blood plasma. A blood pH below 7.35 (H^+ concentration >45 nmol/L) indicates **acidemia**. A blood pH above 7.45 (H^+ concentration <35 nmol/L) indicates **alkalemia**. The range of pH values compatible with life is ~6.8 to 7.8 (H^+ concentration = 160 to 16 nmol/L).

TABLE 24.2 Normal Arterial Blood Plasma Acid–Base Values

Measure	Mean	Range*
pH	7.40	7.35–7.45
$[H^+]$ (nmol/L)	40	45–35
P_{CO_2} (mm Hg)	40	35–45
$[HCO_3^-]$ (mEq/L)	24	22–26

*The range extends from two standard deviations below to two standard deviations above the mean and encompasses 95% of the population of healthy people.

P**CO**$_2$, partial pressure of carbon dioxide. Brackets denote concentration.

Four **simple acid–base disturbances** may lead to an abnormal blood pH: respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. The word "simple" indicates a single primary cause for the disturbance. **Acidosis** is an abnormal process that tends to produce acidemia. **Alkalosis** is an abnormal process that tends to produce alkalemia. If there is too much or too little CO_2, then a *respiratory disturbance* is present. If the problem is too much or too little HCO_3^-, then a *metabolic* (or *nonrespiratory*) *disturbance* of acid–base balance is present. Table 24.3 summarizes the changes in blood pH (or H^+ concentration), plasma HCO_3^- concentration, and PCO_2 that occur in each of the four simple acid–base disturbances.

TABLE 24.3 Directional Changes in Arterial Blood Plasma Values in the Four Simple Acid–Base Disturbances

	Arterial Plasma				
Disturbance	**pH**	**$[H^+]$**	**$[HCO_3^-]$**	**P_{CO_2}**	**Compensatory Response**
Respiratory acidosis	↓	↑	↑	↑↑	Kidneys increase H^+ excretion
Respiratory alkalosis	↑	↓	↓	↓↓	Kidneys increase HCO_3^- excretion
Metabolic acidosis	↓	↑	↓↓	↓	Alveolar hyperventilation; kidneys increase H^+ excretion
Metabolic alkalosis	↑	↓	↑↑	↑	Alveolar hypoventilation; kidneys increase HCO_3^- excretion

Double arrows indicate the main effect. Brackets denote concentration.

PCO_2, partial pressure of carbon dioxide.

In considering acid–base disturbances, it is helpful to recall the Henderson-Hasselbalch equation for HCO_3^-/CO_2:

$$pH = 6.10 + \log \frac{[HCO_3^-]}{0.03P_{CO_2}}$$

(25)

If the primary problem is a change in HCO_3^- concentration or PCO_2, the pH can be brought closer to normal by changing the other member of the buffer pair *in the same direction*. For example, if PCO_2 is primarily decreased, a decrease in plasma HCO_3^- concentration will minimize the change in pH. In various acid–base disturbances, the lungs adjust the blood PCO_2, and the kidneys adjust the plasma HCO_3^- concentration to reduce departures of pH from normal; these adjustments are called *compensations* (Table 24.3). Compensations attenuate, but do not correct the underlying disorder and often do not bring about a normal blood pH.

Respiratory acidosis and alkalosis are caused by altered levels of $PaCO_2$.

Hypoventilation is the condition when the level of breathing does not keep up with the metabolic production of carbon dioxide. As a result, **respiratory acidosis** occurs and is defined as an abnormal accumulation of CO_2 in the arterial blood. Recall from the control of breathing (Chapter 21) that the elevated arterial PCO_2 is referred to as **hypercapnia** that leads to increase in blood $[H^+]$. The CO_2 buildup pushes the following reactions to the right:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \quad (26)$$

Blood H_2CO_3 concentration increases, leading to an increase in H^+ concentration or a fall in pH. Respiratory acidosis is caused by a decrease in overall alveolar ventilation. Hypoventilation occurs with certain lung diseases, with a suppression of ventilation (e.g., excessive central anesthesia, drug overdose, etc.) or as a mismatch between ventilation and perfusion. Respiratory acidosis also occurs if a person breathes CO_2-enriched air (e.g., deep-sea diving or in a submarine).

Hyperventilation results in a decrease in $PaCO_2$. A low $PaCO_2$ (hypocapnia) decreases blood $[H^+]$ leading to alkalosis. When the alkalosis is caused by the lungs blowing off too much carbon dioxide, the condition is called respiratory alkalosis. This loss causes blood H_2CO_3 concentration and, thus, H^+ concentration to fall (pH rises). Loss of CO_2 from hyperventilation lowers alveolar and arterial blood PCO_2. Respiratory alkalosis can be caused by voluntary effort, anxiety, direct stimulation of the medullary respiratory center by some abnormality (e.g., meningitis, fever, and aspirin intoxication), or hypoxia resulting from severe anemia or high altitude. Although hyperventilation causes respiratory alkalosis, it also causes changes that inhibit ventilation (i.e., a fall in PCO_2 and a rise in blood pH) and, therefore, limit the extent of hyperventilation.

Respiratory acidosis and alkalosis are buffered primarily within cells.

With both respiratory acidosis and alkalosis, more than 95% of the chemical buffering occurs within cells. In the case of respiratory acidosis, the cells contain many proteins and organic phosphates that can bind H^+. For example, hemoglobin (Hb) in red blood cells combines with H^+ from H_2CO_3, thereby minimizing the increase in free H^+. Recall from Chapter 19 the buffering reaction:

$$H_2CO_3 + HbO_2^- \rightleftharpoons HHb + O_2 + HCO_3^- \quad (27)$$

This reaction raises the plasma HCO_3^-. In *acute* respiratory acidosis, such chemical buffering processes in the body lead to an increase in plasma HCO_3^- concentration of about 1 mEq/L for each 10 mm Hg increase in PCO_2 (Table 24.4). Bicarbonate is not a buffer for H_2CO_3 because the reaction

TABLE 24.4 Compensatory Responses in Acid–Base Disturbances*

Type	Response
Respiratory acidosis	
Acute	1 mEq/L increase in plasma [HCO_3^-] for each 10 mm Hg increase in Pco_2[†]
Chronic	4 mEq/L increase in plasma [HCO_3^-] for each 10 mm Hg increase in Pco_2[‡]
Respiratory alkalosis	
Acute	2 mEq/L decrease in plasma [HCO_3^-] for each 10 mm Hg decrease in Pco_2[†]
Chronic	4 mEq/L decrease in plasma [HCO_3^-] for each 10 mm Hg decrease in Pco_2[‡]
Metabolic acidosis	1.3 mm Hg decrease in Pco_2 for each 1 mEq/L decrease in plasma [HCO_3^-][**]
Metabolic alkalosis	0.7 mm Hg increase in Pco_2 for each 1 mEq/L increase in plasma [HCO_3^-][**]

[*] Empirically determined average changes measured in people with simple acid–base disorders.

[†] This change is primarily a result of chemical buffering.

[‡] This change is primarily a result of renal compensation.

[**] This change is a result of respiratory compensation.

PCO_2, partial pressure of carbon dioxide. Brackets denote concentration.

$$H_2CO_3 + HCO_3^- \rightleftharpoons HCO_3^- + H_2CO_3 \quad (28)$$

is simply an exchange reaction and does not affect the pH.

An example illustrates how chemical buffering reduces a fall in pH during respiratory acidosis. Suppose PCO_2 increased from a normal value of 40 to 70 mm Hg ($CO_{2(d)}$ = 2.1 mmol/L). If there were no

body buffer bases that could accept H^+ from H_2CO_3 (i.e., if there were no measurable increase in HCO_3^- concentration), the resulting pH would be 7.16:

$$pH = 6.10 + \log \frac{[24]}{[2.1]} = 7.16$$

(29)

In acute respiratory acidosis, a 3 mEq/L increase in plasma HCO_3^- concentration occurs with a 30 mm Hg rise in PCO_2 (see Table 24.4). Therefore, the pH is 7.21:

$$pH = 6.10 + \log \frac{[24 + 3]}{[2.1]} = 7.21$$

(30)

The pH of 7.21 is closer to a normal pH because body buffer bases (mainly intracellular buffers) such as proteins and phosphates combine with H^+ liberated from H_2CO_3.

As with respiratory acidosis, during respiratory alkalosis, most of the buffering occurs within cells. Cell proteins and organic phosphates liberate hydrogen ions, which are added to the ECF and lower the plasma HCO_3^- concentration, thereby reducing the alkaline shift in pH.

With *acute* respiratory alkalosis, plasma HCO_3^- concentration falls by about 2 mEq/L for each 10 mm Hg drop in PCO_2 (see Table 24.4). For example, if PCO_2 drops from 40 to 20 mm Hg ($CO_{2(d)}$ = 0.6 mmol/L), plasma HCO_3^- concentration falls by 4 mEq/L and the pH will be 7.62:

$$pH = 6.10 + \log \frac{[24 - 4]}{[0.6]} = 7.62$$

(31)

If plasma HCO_3^- had not changed, the pH would have been 7.70:

$$\mathrm{pH} = 6.10 + \log \frac{[24]}{[0.6]} = 7.70$$

(32)

Lungs and kidneys compensate for respiratory acidosis and alkalosis.

An initial rise in arterial PCO_2 leads to acidosis and a fall in pH. The lungs then compensate for the elevated arterial PCO_2 by increasing breathing (see Chapter 21), thereby diminishing the severity of the acidosis.

In addition, the kidneys compensate for respiratory acidosis by adding more H^+ to the urine and adding new HCO_3^- to the blood. The increased PCO_2 stimulates renal H^+ secretion, which allows the reabsorption of all filtered HCO_3^-. Excess H^+ is excreted as titratable acid and NH_4^+; these processes add new HCO_3^- to the blood, causing plasma HCO_3^- concentration to rise. This compensation takes several days to develop fully.

With *chronic* respiratory acidosis, plasma HCO_3^- increases, on the average, by 4 mEq/L for each 10 mm Hg rise in PCO_2 (see Table 24.4). This rise exceeds that seen with acute respiratory acidosis because of the renal addition of HCO_3^- to the blood. One would expect a person with chronic respiratory acidosis and a PCO_2 of 70 mm Hg to have an increase in plasma HCO_3^- of 12 mEq/L. The blood pH would be 7.33:

$$pH = 6.10 + \log \frac{[24+12]}{[2.1]} = 7.33 \quad (33)$$

With chronic respiratory acidosis, time for renal compensation is allowed, so blood pH (in this example, 7.33) is much closer to normal than that is observed during acute respiratory acidosis (pH 7.21).

The kidneys compensate for respiratory alkalosis by excreting HCO_3^- in the urine. A reduced PCO_2 reduces H^+ secretion by the kidney tubule epithelium. As a result, some of the filtered HCO_3^- is not reabsorbed. When the urine becomes more alkaline, titratable acid excretion vanishes, and little ammonia is excreted. The enhanced output of HCO_3^- causes plasma HCO_3^- concentration to fall.

Chronic respiratory alkalosis is accompanied by a 4 mEq/L fall in plasma HCO_3^- concentration for each 10 mm Hg drop in PCO_2 (see Table 24.4). For example, in a person with chronic hyperventilation and a PCO_2 of 20 mm Hg, the blood pH is:

$$\mathrm{pH} = 6.10 + \log \frac{[24 - 8]}{[0.6]} = 7.53$$

(34)

This pH is closer to normal than the pH of 7.62 of acute respiratory alkalosis. The difference between the two situations is largely a result of renal compensation.

Metabolic acidosis is a condition in which tissue and blood pH is abnormally low due to an increase in nonvolatile acids.

An increase in nonvolatile acids, such as lactic acid, leads to **metabolic acidosis**. This is an abnormal process characterized by a gain of acid (other than H_2CO_3) or a loss of HCO_3^-. With metabolic acidosis, both plasma HCO_3^- concentration and pH decrease. If a strong acid increases in the body, the reactions

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2 \quad (35)$$

are pushed to the right. The added H^+ consumes HCO_3^-. If much acid is infused rapidly, PCO_2 rises, as the equation predicts. This increase occurs only transiently, however, because the body is an open system, and the lungs exhaust CO_2 as it is generated. PCO_2 actually falls below normal because an acidic blood pH stimulates ventilation (see Fig. 24.3).

Many conditions can produce metabolic acidosis, including renal failure, uncontrolled diabetes mellitus, lactic acidosis, the ingestion of acidifying agents such as NH_4Cl, excessive renal excretion of HCO_3^-, and diarrhea. In renal failure, the kidneys cannot excrete H^+ fast enough to keep up with metabolic acid production, and in uncontrolled diabetes mellitus, the production of ketone body acids increases. Lactic acidosis results from tissue hypoxia. Ingested NH_4Cl is converted into urea and a strong acid, HCl, in the liver. Diarrhea causes a loss of alkaline intestinal fluids.

Metabolic acidosis is buffered by cellular fluid, bone, lungs, and kidneys.

Excess acid is chemically buffered in ECF and ICF and bone. In metabolic acidosis, roughly half the buffering occurs in cells and bone. HCO_3^- is the principal buffer in the ECF.

The acidic blood pH stimulates the respiratory system to lower blood PCO_2 by hyperventilation. This action lowers blood H_2CO_3 concentration and, thereby, tends to alkalinize the blood, opposing the acidic shift in pH. Metabolic acidosis is accompanied on average by a 1.3 mm Hg fall in PCO_2 for each 1 mEq/L drop in plasma HCO_3^- concentration (see Table 24.4). Suppose, for example, the infusion of a strong acid causes the plasma HCO_3^- concentration to drop from 24 to 12 mEq/L. If there were no respiratory compensation and the PCO_2 did not change from its normal value of 40 mm Hg, the pH would be 7.10:

$$pH = 6.10 + \log \frac{[12]}{[1.2]} = 7.10 \quad (36)$$

With respiratory compensation, the PCO_2 falls by 16 mm Hg (12 × 1.3) to 24 mm Hg ($CO_{2(d)}$ = 0.72 mmol/L) and pH is 7.32:

$$pH = 6.10 + \log \frac{[12]}{[0.72]} = 7.32 \quad (37)$$

This value is closer to normal than a pH of 7.10. The respiratory response develops promptly (within minutes) and is maximal after 12 to 24 hours.

The kidneys respond to metabolic acidosis, as well, by adding more H^+ to the urine. Because the plasma HCO_3^- concentration is primarily lowered by the metabolic acidosis, the filtered load of HCO_3^- drops, and the kidneys can accomplish the complete reabsorption of filtered HCO_3^- (see Fig. 24.7). In addition, more H^+ is excreted as titratable acid and NH_4^+. With chronic metabolic acidosis, the kidneys make more ammonia. The kidneys can therefore add more new HCO_3^- to the blood, to replace lost HCO_3^-. If the underlying cause of metabolic acidosis is corrected, then healthy kidneys can correct the blood pH in a few days.

Plasma anion gap is used to determine the etiology of metabolic acidosis.

The **anion gap** is a useful concept, especially when trying to determine the possible cause of metabolic acidosis. Plasma anion gap is calculated from sodium, chloride, and bicarbonate concentrations. In any body fluid, the sum of the cations and the sum of the anions are equal because solutions are electrically neutral. For blood plasma, we can write:

$$\sum \text{cations} = \sum \text{anions} \tag{38}$$

or

$$[Na^+] + [\text{unmeasured cations}] = [Cl^-] + [HCO_3^-] + [\text{unmeasured anions}] \tag{39}$$

The unmeasured cations include K^+, Ca^{2+}, and Mg^{2+} ions. Because these are present at relatively low concentrations (compared with Na^+) and are usually fairly constant, we choose to neglect them. The unmeasured anions include plasma proteins, sulfate, phosphate, citrate, lactate, and other organic anions. If we rearrange the above equation, we get:

$$[\text{unmeasured anions}] \text{ or } \text{“anion gap”} = [Na^+] - [Cl^-] - [HCO_3^-] \tag{40}$$

In a healthy person, the anion gap falls in the range of 8 to 14 mEq/L. For example, if plasma Na^+ concentration is 140 mEq/L, Cl^- concentration is 105 mEq/L, and if HCO_3^- concentration is 24 mEq/L, the anion gap is 11 mEq/L. If an acid such as lactic acid is added to plasma, the reaction of lactic acid + HCO_3^- ⇌ lactate$^-$ + H_2O + CO_2 will be pushed to the right. Consequently, the plasma HCO_3^- will be decreased, and because the Cl^- is not changed, the anion gap will be increased. The unmeasured anion in this case is lactate$^-$.

In several types of metabolic acidosis, the low blood pH is accompanied by a high anion gap (Table 24.5). (These can be remembered from the mnemonic MULEPAKS, formed from the first letters of this list.) In other types of metabolic acidosis, the low blood pH is accompanied by a normal anion gap (see

Table 24.5). For example, with diarrhea and a loss of alkaline intestinal fluid, plasma HCO_3^- concentration falls, but plasma Cl^- concentration rises, and the two changes counterbalance each other so the anion gap is unchanged. Again, the chief value of the anion gap concept is that it allows a clinician to narrow down possible explanations for metabolic acidosis in a patient.

TABLE 24.5 High and Normal Anion Gap Metabolic Acidosis

Condition	Explanation
High anion gap metabolic acidosis	
Methanol intoxication	Methanol metabolized to formic acid
Uremia	Sulfuric, phosphoric, uric, and hippuric acids retained as a result of renal failure
Lactic acid	Lactic acid buffered by HCO_3^- and accumulated as lactate
Ethylene glycol intoxication	Ethylene glycol metabolized to glyoxylic, glycolic, and oxalic acids
p-Aldehyde intoxication	*p*-Aldehyde metabolized to acetic and chloroacetic acids
Ketoacidosis	Production of β-hydroxybutyric and acetoacetic acids
Salicylate intoxication	Impaired metabolism leading to production of lactic acid and ketone body acids; accumulation of salicylate
Normal anion gap metabolic acidosis	
Diarrhea	Loss of HCO_3^- in stool; kidneys conserve Cl^-
Renal tubular acidosis	Loss of HCO_3^- in urine or inadequate excretion of H^+; kidneys conserve Cl^-
Ammonium chloride ingestion	NH_4^+ is converted to urea in the liver, a process that consumes HCO_3^-; excess Cl^- is ingested

CLINICAL FOCUS 24.1

Metabolic Acidosis in Diabetes Mellitus

Diabetes mellitus is a common disorder characterized by an insufficient secretion of insulin (type I) or insulin resistance by the major target tissues (skeletal muscle, liver, and adipocytes; type II). A severe **metabolic acidosis** may develop in uncontrolled diabetes mellitus.

Acidosis occurs because insulin deficiency leads to decreased glucose use, a diversion of metabolism toward the use of fatty acids, and an overproduction of ketone body acids (acetoacetic acid and β-hydroxybutyric acids). Ketone body acids are fairly strong acids (pK_a 4 to 5); they are neutralized in the body by HCO_3^- and other buffers. Increased production of these acids leads to a fall in plasma HCO_3^- concentration, an increase in plasma anion gap, and a fall in blood pH (acidemia).

Severe acidemia, whatever its cause, has many adverse effects on the body. It impairs myocardial contractility, resulting in a decrease in cardiac output. It causes arteriolar dilation, which leads to a fall in arterial blood pressure. Hepatic and renal blood flows are decreased. Re-entrant arrhythmias and a

decreased threshold for ventricular fibrillation can occur. The respiratory muscles show decreased strength and fatigue easily. Metabolic demands are increased, as a result in part of activation of the sympathetic nervous system, but at the same time, anaerobic glycolysis and ATP synthesis are reduced by acidemia. Hyperkalemia is favored and protein catabolism is enhanced. Severe acidemia causes impaired brain metabolism and cell volume regulation, leading to progressive obtundation and coma.

An increased acidity of the blood stimulates pulmonary ventilation, resulting in a compensatory lowering of alveolar and arterial blood partial pressure of carbon dioxide (PCO_2). The consequent reduction in blood H_2CO_3 concentration acts to move the blood pH back toward normal. The labored, deep breathing that accompanies severe uncontrolled diabetes is called **Kussmaul respiration**.

The kidneys compensate for metabolic acidosis by reabsorbing all the filtered HCO_3^-. They also increase the excretion of titratable acid, part of which is composed of ketone body acids. These acids can only be partially titrated to their acid form in the urine, because the urine pH cannot go below 4.5. Thus, ketone body acids are excreted mostly in their anionic form; because of the requirement of electroneutrality in solutions, increased urinary excretion of Na^+ and K^+ results.

An important compensation for the acidosis is increased renal synthesis and excretion of ammonia. This adaptive response takes several days to develop fully, but it allows the kidneys to dispose of large amounts of H^+ in the form of NH_4^+. The NH_4^+ in the urine can replace Na^+ and K^+ ions, thereby resulting in conservation of these valuable cations.

The severe acidemia, electrolyte disturbances, and volume depletion that accompany uncontrolled diabetes mellitus may be fatal. Correction of the acid–base disturbance is best achieved by addressing the underlying cause, rather than just treating the symptoms. Therefore, the administration of a suitable dose of insulin is usually the key element of therapy. In some patients with marked acidemia (pH < 7.10), $NaHCO_3$ solutions may be infused intravenously to speed recovery, but this does not correct the underlying metabolic problem. Losses of Na^+, K^+, and water should be replaced. ■

Metabolic alkalosis is a condition in which blood pH is abnormally high due to nonvolatile acid loss.

Metabolic alkalosis is characterized by a gain of a strong base or HCO_3^- or a loss of a nonvolatile acid (other than carbonic acid). Plasma HCO_3^- concentration and pH rise; PCO_2 rises because of respiratory compensation. These changes are opposite of those seen in metabolic acidosis (see Table 24.3). A variety of situations can produce metabolic alkalosis, including the ingestion of excessive amounts of antacids, vomiting of acidic gastric juice, and enhanced renal H^+ loss (e.g., resulting from hyperaldosteronism or hypokalemia).

Metabolic alkalosis is buffered primarily by lungs and kidneys.

Chemical buffers in the body limit the alkaline shift in blood pH by releasing H^+ as they are titrated in the alkaline direction. As a result, the buffering for metabolic alkalosis that occurs in cells is much smaller.

Both the lung and kidney are the major compensatory sites for metabolic acidosis. The respiratory compensation is hypoventilation. An alkaline blood pH inhibits ventilation, which in turn raises the blood PCO_2 and H_2CO_3 concentration. Hypoventilation thereby reduces the alkaline shift in pH. A 1 mEq/L rise in plasma HCO_3^- concentration caused by metabolic alkalosis is accompanied by a 0.7 mm Hg rise in PCO_2 (see Table 24.4). If, for example, the plasma HCO_3^- concentration rose to 40 mEq/L, what would the plasma pH be with and without respiratory compensation? With respiratory compensation, the PCO_2 should rise by 11.2 mm Hg (0.7 × 16) to 51.2 mm Hg ($CO_{2(d)}$ = 1.54 mmol/L). The pH is 7.51:

$$pH = 6.10 + \log \frac{[40]}{[1.54]} = 7.51 \quad (41)$$

Without respiratory compensation, the pH would be 7.62:

$$pH = 6.10 + \log \frac{[40]}{[1.2]} = 7.62 \quad (42)$$

Respiratory compensation for metabolic alkalosis is limited because hypoventilation leads to hypoxia and CO_2 retention, and both, in turn, increase breathing.

The kidneys respond to metabolic alkalosis by lowering the plasma HCO_3^- concentration. The plasma HCO_3^- concentration is primarily raised, so more HCO_3^- is filtered than can be reabsorbed (see Fig. 24.7); in addition, HCO_3^- is secreted in the collecting ducts. Both of these changes lead to increased urinary HCO_3^- excretion. If the cause of the metabolic alkalosis is corrected, the kidneys can often restore the plasma HCO_3^- concentration and pH to normal in a day or two. However, metabolic alkalosis accompanied by loss of fluid volume (e.g., severe vomiting) creates a unique complication to the body's compensatory mechanisms for that type of metabolic alkalosis. With a loss of fluid volume in the body, aldosterone will be produced to reabsorb sodium in the distal nephron. This though will also stimulate

acid secretion in that part of the nephron that will tend to extend or exacerbate the alkalosis in the body. Therefore, for the body to be able to best compensate for a metabolic alkalosis with a volume loss, the volume loss must be corrected first before compensatory mechanisms for alkalosis can be fully effective.

CLINICAL FOCUS 24.2

Vomiting and Metabolic Alkalosis

Vomiting of acidic gastric juice results in **metabolic alkalosis,** along with fluid and electrolyte disturbances. Gastric juice contains about 0.1 M HCl. The acid is secreted by stomach parietal cells; these cells have an H^+/K^+-ATPase in their luminal cell membrane and a Cl^-/HCO_3^- exchanger in their basolateral cell membrane. When HCl is secreted into the stomach lumen and lost to the outside, there is a net gain of HCO_3^- in the blood plasma and no change in the anion gap. The HCO_3^-, in effect, replaces lost plasma Cl^-.

Ventilation is inhibited by the alkaline blood pH, resulting in a rise in PCO_2. This respiratory compensation for the metabolic alkalosis, however, is limited, because hypoventilation leads to a rise in partial pressure of carbon dioxide (PCO_2) and a fall in partial pressure of oxygen (PO_2), both of which stimulate breathing.

The logical renal compensation for metabolic alkalosis is enhanced excretion of HCO_3^-. In people with persistent vomiting, however, the urine is sometimes acidic and renal HCO_3^- reabsorption is enhanced, thereby maintaining the elevated plasma HCO_3^-. This situation arises because vomiting is accompanied by losses of extracellular fluid (ECF) and K^+. Fluid loss leads to a decrease in effective arterial blood volume and engagement of mechanisms that reduce Na^+ excretion, such as decreased glomerular filtration rate and increased plasma renin, angiotensin, and aldosterone levels (see Chapter 23). Aldosterone stimulates H^+ secretion by collecting duct α-intercalated cells. Renal tubular Na^+/H^+ exchange is stimulated by volume depletion because the tubules reabsorb Na^+ more avidly than usual. With more H^+ secretion, more new HCO_3^- is added to the blood. The kidneys reabsorb filtered HCO_3^- completely, even though the plasma HCO_3^- level is elevated and maintain the metabolic alkalosis.

Vomiting results in K^+ depletion because of a loss of K^+ in the vomitus, decreased food intake, and, most important quantitatively, enhanced renal K^+ excretion. Extracellular alkalosis results in a shift of K^+ into cells (including renal cells) and thereby promotes K^+ secretion and excretion. Elevated plasma aldosterone levels also favor K^+ loss in the urine.

Treatment for the metabolic alkalosis primarily depends on eliminating the cause of vomiting. Correction of the alkalosis by administering an organic acid, such as lactic acid, does not make sense, because this acid would simply be converted to CO_2 and H_2O; this approach also does not address the Cl^- deficit. The ECF volume depletion and the Cl^- and K^+ deficits can be corrected by administering isotonic saline and appropriate amounts of KCl. Because replacement of Cl^- is a key component of therapy, this type of metabolic alkalosis is said to be “chloride responsive.” After Na^+, Cl^-, water, and

K^+ deficits have been replaced, excess HCO_3^- (accompanied by surplus Na^+) will be excreted in the urine, and the kidneys will return blood pH to normal. ■

pH–bicarbonate diagram is a useful way to determine acid–base disorder etiology.

Acid–base data should always be interpreted in the context of other information about a patient. For example, a low blood pH indicates acidosis; a high blood pH indicates alkalosis. If acidosis is present, for example, it could be either respiratory or metabolic. A low blood pH and elevated PCO_2 point to respiratory acidosis; a low pH and low plasma HCO_3^- indicate metabolic acidosis. If alkalosis is present, it could be either respiratory or metabolic. A high blood pH and low plasma PCO_2 indicate respiratory alkalosis; a high blood pH and high plasma HCO_3^- indicate metabolic alkalosis.

The pH–bicarbonate diagram (Fig. 24.12) is a useful way to look at arterial blood data and determine what type of acid–base disturbance may be present in a patient. The ellipse in the center of this diagram shows the normal range of values for arterial blood pH, PCO_2, and plasma bicarbonate concentration. Values on the left side of the diagram (acidemia, or a low blood pH) are caused by respiratory acidosis or metabolic acidosis. Values on the right side of the diagram (alkalemia, or an elevated blood pH) are caused by respiratory alkalosis or metabolic alkalosis. The curved lines that slope upward and to the right are PCO_2 isobars; all along each line, the PCO_2 is the same (*iso* = "same," *bar* = "pressure"). Each point on the diagram must satisfy the Henderson-Hasselbalch equation, so that, for example, if pH and HCO_3^- concentration are known, the PCO_2 is automatically defined. The shaded areas include 95% of people with the designated simple acid–base disturbance. Note that a distinction is made between acute and chronic *respiratory* disturbances of acid–base balance but not between acute and chronic *metabolic* disturbances of acid–base balance. This is because the renal compensation for a respiratory disturbance may take days, whereas the respiratory compensation for a metabolic disturbance is prompt (minutes to hours). Note that compensations tend to return the blood pH closer to normal. For example, if the PCO_2 is acutely raised (move to a higher PCO_2 isobar), then the pH will fall, but with chronic respiratory acidosis, the pH is closer to normal at the same PCO_2 (because of renal addition of bicarbonate to the blood). Mixed acid–base disturbances often, but do not always, fall outside of the shaded areas. For example, values for a patient with chronic respiratory acidosis (e.g., as a result of pulmonary disease) and metabolic acidosis (e.g., resulting from shock) might just happen to fall in the area that indicates acute respiratory acidosis. Values for a patient with a simple disturbance could fall outside the shaded area if insufficient time has elapsed, especially for renal compensation. For example, as illustrated in Figure 24.12 (*arrows on left*), data from a person might have been collected during the period of transition from acute to chronic respiratory acidosis. A complete history and physical examination provide important clues in deciding what acid–base disturbances may be present in a patient.

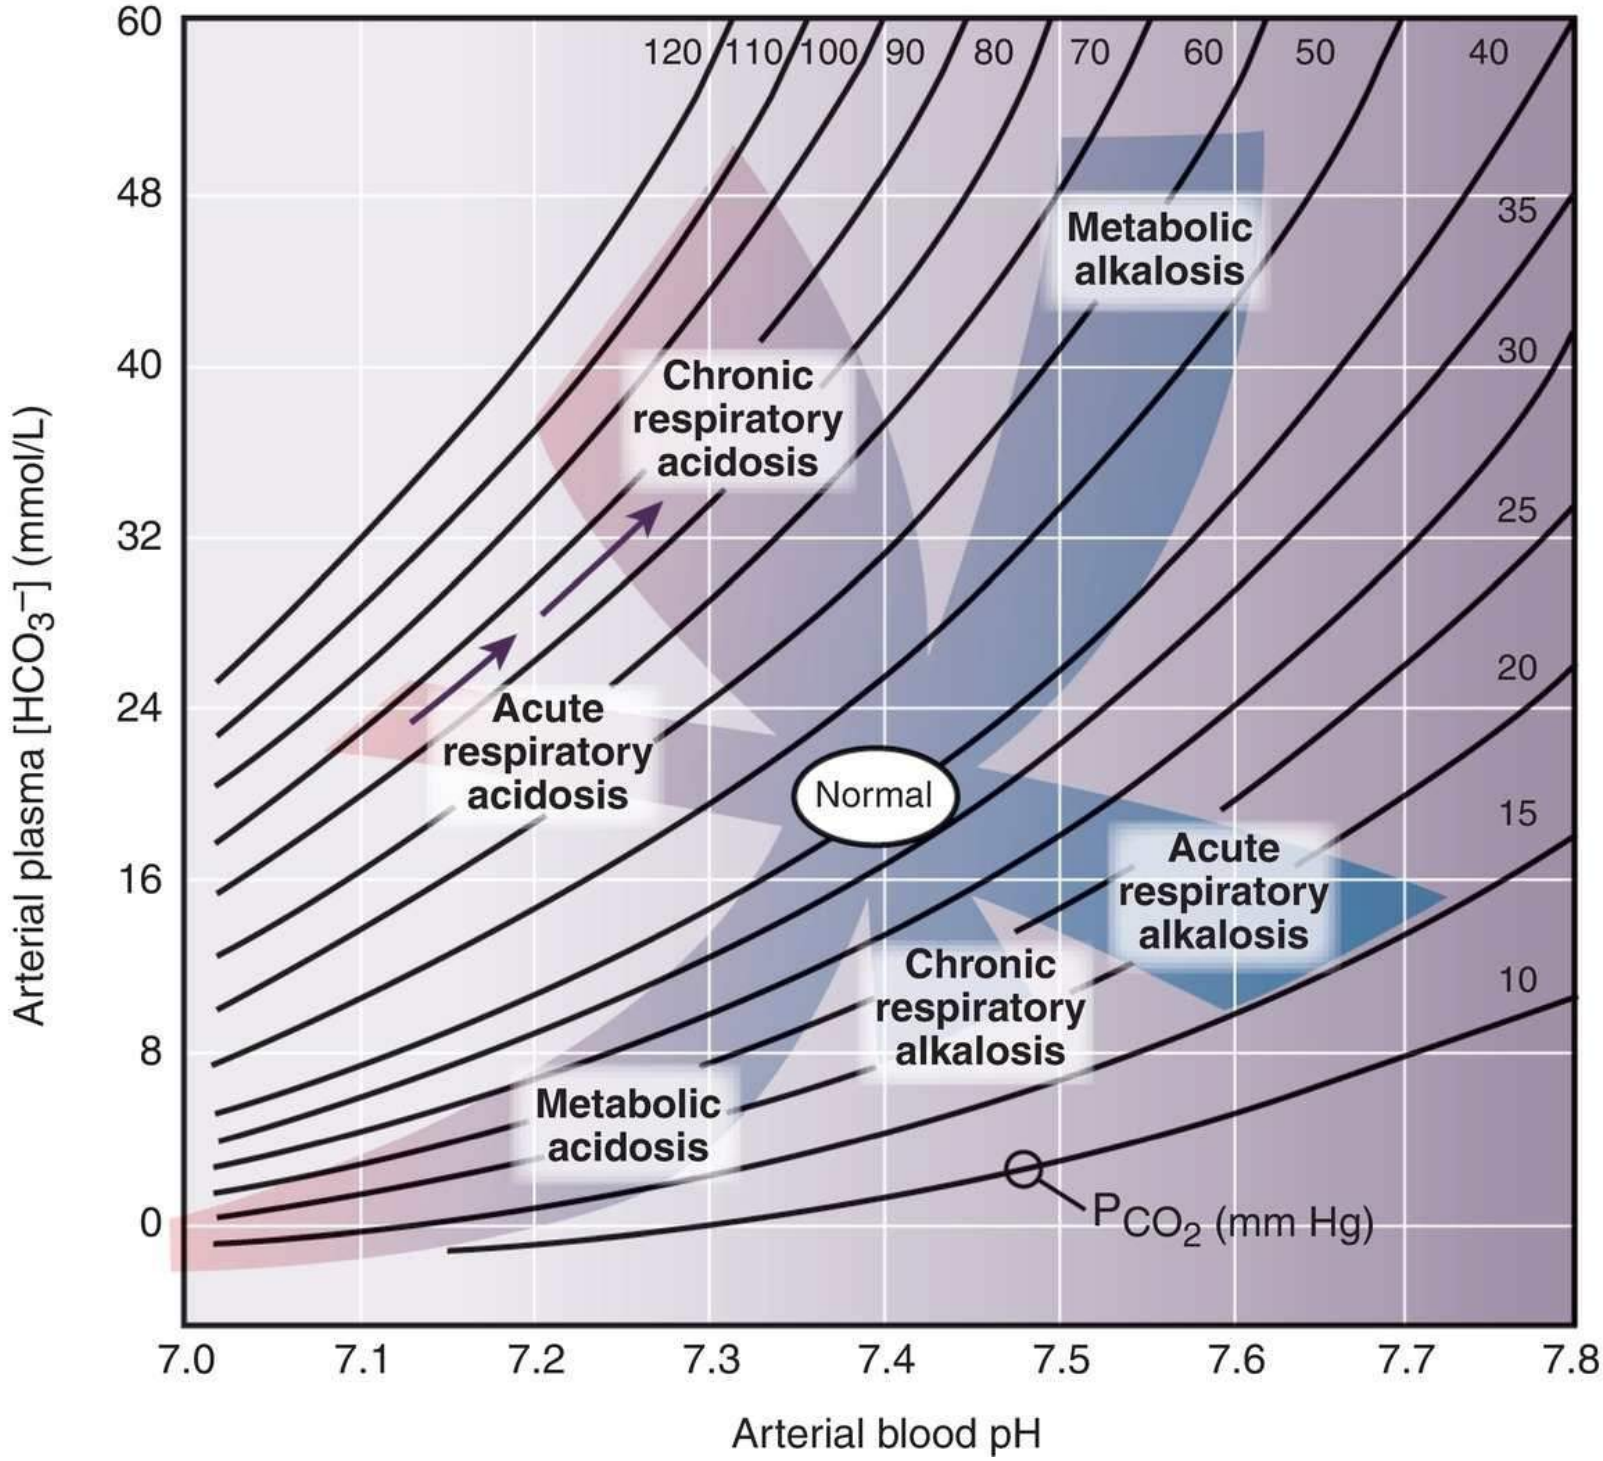

Figure 24.12 pH–bicarbonate diagram. The diagram shows the relationship between arterial pH, bicarbonate, and PCO_2 and provides a useful way of determining a patient's acid–base disturbance. Normal values are shown in the *elliptical area* in the center. Values to the left of normal represent acidemia, which may be caused by respiratory acidosis or metabolic acidosis. Values to the right of normal represent alkalemia, which may be caused by respiratory alkalosis or metabolic alkalosis. PCO_2, partial pressure of carbon dioxide (mm Hg).

Type 1 (Distal) Renal Tubular Acidosis

A 13-year-old girl, who was adopted at age 5, was evaluated for failure to grow and recurrent pathologic bone fractures. Her height was 1.13 m, and she weighed 21.5 kg. She had suffered several broken bones since the age of 5. Her legs were deformed, and at age 12, she passed the first of several urinary stones. Radiographs of the femurs revealed bowing (characteristic of rickets), a healed fracture, and extreme decalcification of the skeleton. An abdominal radiograph at the level of the kidneys showed dense calcium deposits in the medullas of both kidneys (nephrocalcinosis).

Her plasma [Na^+] was 139 mEq/L, [K^+] 3.2 mEq/L, [Ca^{2+}] 9.0 mg/dL, Cl^- 114 mEq/L, inorganic phosphate 1.9 mg/dL, BUN 10 mg/dL, and total (protein) 6.5 g/dL. Urinalysis showed a trace of protein, no glucose, specific gravity of 1.010, pH=7, no bacteria in cultured urine, and 25 white blood cells per high-power field.

Additional tests indicated an arterial blood pH of 7.30, PaO_2 106 mm Hg, $PaCO_2$ 27 mm Hg, bicarbonate 16 mmol/L, and SaO_2 96% confirming metabolic acidosis. Her estimated glomerular filtration rate was 56 mL/min/1.73 m^2 body surface area, a value below the normal range but not low enough to account for the abnormalities observed.

The urine pH appeared to be unduly high considering the presence of a metabolic acidosis. To test her ability to acidify the urine, she was given 0.1 g NH_4Cl/kg body weight orally, and urine pH was measured in samples collected over the next 6 hours. The minimum urine pH was 6. Failure to acidify her urine, the diagnosis of distal renal tubular acidosis (RTA) was made. The history of recurrent renal stones, metabolic acidosis, and alkaline urine was further in keeping with a diagnosis of type (distal) RTA.

The patient was started on a regimen of two glasses of milk, five drops of a vitamin D preparation, and 20 mL Shohl's solution, three times daily. When she was seen 7 months later, the changes were almost miraculous. She had completely recalcified her skeleton, and all radiographic evidence of active rickets had disappeared. The serum phosphate had risen to 5.3 mg/dL. From a frail, bed-ridden child, she had developed into a sturdy, but still undersized, young woman. Her weight increased by 9.5 kg and she had grown 8 cm in height. Her breasts had developed and she had her first menstrual period.

This patient illustrates the classical case for renal tubular acidosis. In RTA, the kidney tubules malfunction, resulting in excess levels of acids in the blood. The disorder is the failure of the distal nephrons to lower urinary pH, due to either a back diffusion of hydrogen ions from the lumen to the blood or inadequate transport of H^+. Electrolyte balance is also affected with RTA that often leads to low blood potassium levels, calcium deposits in the kidneys, dehydration, and painful softening/bending of bones. Muscle weakness and diminished reflexes, due to the electrolyte imbalance, often occur when the disorder has been present for a long time.

There are four types of renal tubular acidosis and are classified as type 1 through 4.

They are distinguished by the specific tubular abnormality that causes the acidosis. Type 3 is extremely rare. The diagnosis for type 1 and 2 RTA is based on the following symptoms: (1) muscle weakness and diminished reflexes, (2) high levels of acids, and (3) low levels of bicarbonate and potassium in the blood. The low blood potassium is the cause of muscle weakness and diminished reflexes. In type 1, kidney stones can develop causing renal damage. In type 4, renal tubular acidosis is associated with high potassium levels accompanied by high acid levels and low bicarbonate levels in the blood. The exact cause of the RTA in the patient is not known. Type 1 RTA may be the result of

an inherited defect, autoimmune disease, treatment with lithium or the antibiotic amphotericin B, or diseases of the kidney medulla. In patients with inherited type 1 RTA, genetic defects in Cl^-/HCO_3^- exchangers and in H^+-ATPases have been identified.

Bone contains large amounts of carbonate and phosphate salts that can be released when the blood becomes too acidic. These buffers help to minimize the fall in pH during metabolic acidosis but has a detrimental effect in demineralization of bone. Respiratory acidosis does not cause calcium to be release from bone, which suggests that the important underlying mechanism is the low plasma bicarbonate, as occurs in metabolic but not respiratory acidosis. Release of calcium from bone leads to increased urinary calcium excretion (hypercalciuria). Chronic metabolic acidosis also inhibits tubular reabsorption of calcium and reduces renal excretion of citrate. Citrate normally inhibits stone formation by complexing calcium and by inhibiting crystallization of calcium salts. A high rate of calcium excretion, low citrate level, and alkaline urine favors precipitation of calcium phosphate (hence the nephrocalcinosis and kidney stones). The deposition of calcium salts in the kidney medulla causes interstitial inflammation and explains the presence of white blood cells in the patient's urine. Blockage of tubules and collecting ducts would reduce the GFR, and damage to the renal medulla and hypokalemia result in an impaired ability to concentrate the urine (urine specific gravity was 1.010).

Mineralization and bone growth depend on multiple factors that can be adversely affected by acidosis: calcium and phosphate concentrations of the extracellular flu osteoblasts and osteoclasts, intestinal absorption of calcium and phosphate, renal excretion of calcium and phosphate, and activity of several hormones (parathyroid hormone, calcitonin, and 1,25-dihydroxy vitamin D3). Human growth hormone release may be trapping in the urine and less formation of titratable acid occurs, so that less new bicarbonate will be added to the blood to replenish this important ECF buffer base.

The treatment of types 1 and 2 includes correction of hypokalemia and alkali replacement.

The hypokalemia should be corrected first, as alkali replacement can worsen the hypokalemia with dangerous consequences. Correcting hypokalemia improves musculoskeletal symptoms, and early treatment also prevents recurrence of kidney stones and the progression of renal failure. The patient was given Shohl's solution, which is a mixture of sodium citrate and citric acid, which is taken orally. Citrate yields three bicarbonate ions when oxidized completely in the body, and this counteracts the acidosis. Citrate is also excreted in the urine and reduces calcium stone formation. Because the patient was also hypokalemic, potassium citrate could have been prescribed. The milk and vitamin D were prescribed to aid in mineralization of the patient's skeleton. ■

Chapter Summary

- The body is constantly threatened by acid resulting from diet and metabolism. The stability of blood pH is maintained by the concerted action of chemical buffers, the lungs, and the kidneys.
- Numerous chemical buffers (e.g., HCO_3^-/CO_2, phosphates, and proteins) work together to minimize pH changes in the body. The concentration ratio (base–acid) of any buffer pair, together with the pK of the acid, automatically defines the pH.
- The bicarbonate/CO_2 buffer system is an effective physiologic buffer in the body because its components are present in large amounts and the system is open.
- The respiratory system influences plasma pH by regulating the arterial PCO_2 through changes in alveolar ventilation. The kidneys influence plasma pH by excreting acid or base in the urine.
- Renal acidification involves three processes: reabsorption of filtered HCO_3^-, excretion of titratable acid, and excretion of ammonia. New HCO_3^- is added to the plasma and replenishes depleted HCO_3^- when titratable acid (normally mainly $H_2PO_4^-$) and ammonia (as NH_4^+) are excreted.
- The stability of intracellular pH is ensured by membrane transport of H^+ and HCO_3^-, by intracellular buffers (mainly proteins and organic phosphates), and by metabolic reactions.
- Respiratory acidosis is an abnormal process characterized by an accumulation of CO_2 and a fall in arterial blood pH. The kidneys compensate by increasing the excretion of H^+ in the urine and adding new HCO_3^- to the blood, thereby diminishing the severity of the acidemia.
- Respiratory alkalosis is an abnormal process characterized by an excessive loss of CO_2 and a rise in pH. The kidneys compensate by increasing the excretion of filtered HCO_3^-, thereby diminishing the alkalemia.
- Metabolic acidosis is an abnormal process characterized by a gain of acid (other than H_2CO_3) or a loss of HCO_3^-. Respiratory compensation is hyperventilation, and renal compensation is an increased excretion of H^+ bound to urinary buffers (ammonia and phosphate) and generation of new bicarbonate.
- Metabolic alkalosis is an abnormal process characterized by a gain of strong base or HCO_3^- or a loss of acid (other than H_2CO_3). Respiratory compensation is hypoventilation, and renal compensation is increased excretion of HCO_3^-.
- The plasma anion gap is equal to the plasma $Na^+ - Cl^- - HCO_3^-$ concentration and is most useful in narrowing down possible causes of metabolic acidosis.
- The pH–bicarbonate diagram is used clinically to determine the patient's acid–base disturbance.

Chapter Review Questions

1. A 50-kg woman excreted 20 mEq/d titratable acid, 45 mEq/d $NH4^+$, and 5 mEq/d bicarbonate in her urine. Assuming that she is in acid–base balance, what was the net production of nonvolatile acids in her body?

A. 20 mEq/d
B. 45 mEq/d
C. 60 mEq/d
D. 65 mEq/d
E. 70 mEq/d

The correct answer is C. Net acid excretion is calculated from urinary titratable acid + urinary $NH4^+$ − urinary HCO_3^- excretion = 20 + 45 − 5 = 60 mEq/d, in this case. The net acid excretion by the kidneys will be equal to the net renal production of nonvolatile acids in a person in acid–base balance, assuming that nonrenal losses from the body are negligible.

2. Which of the following causes increased tubular secretion of hydrogen ions?

A. A decrease in arterial PCO_2
B. Adrenal cortical insufficiency
C. Administration of a carbonic anhydrase inhibitor
D. An increase in intracellular pH
E. An increase in tubular sodium reabsorption

The correct answer is E. When Na^+ reabsorption is stimulated, Na^+/H^+ exchange is increased, resulting in greater H^+ secretion in the proximal tubule and loop of Henle. Additionally, increased Na^+ reabsorption in the collecting ducts renders the duct lumen more negative, which favors H^+ secretion. All of the other factors result in decreased H^+ secretion.

3. The hospital laboratory reports the following measurements on an acutely ill patient:

	Patient	Normal Range
Arterial blood pH	7.25	7.35–7.45
Pco_2, mm Hg	25	35–45
Plasma [HCO_3^-], mEq/L	11	22–26
Plasma [Na^+], mEq/L	140	136–145 mEq/L
Plasma [Cl^-], mEq/L	118	95–105 mEq/L
Anion gap		8–14 mEq/L

What is the most likely cause of the acid–base disturbance?

A. Cardiogenic shock
B. Methanol intoxication
C. Severe diarrhea
D. Uncontrolled diabetes mellitus
E. Vomiting of gastric juice

The correct answer is C. The data indicate a normal anion gap (or hyperchloremic) metabolic acidosis (anion gap = 140 − 118 − 11 = 11 mEq/L), with respiratory compensation. This could result from loss of bicarbonate (base) due to diarrhea. Cardiogenic shock (lactic acidosis), methanol intoxication, and uncontrolled diabetes mellitus (ketone body acid production) produce a high anion gap metabolic acidosis. Vomiting of acidic gastric juice produces a metabolic alkalosis.

4. Which of the following arterial blood values might be expected in a mountain climber who has been residing at a high-altitude base camp below the summit of Mt. Everest for 1 week?

	pH	PO_2, mm Hg	Pco_2, mm Hg Plasma	$[HCO_3^-]$, mEq/L
A.	7.18	95	24	9
B.	7.35	50	60	32
C.	7.47	40	20	14
D.	7.53	95	50	40
E.	7.62	40	20	20

The correct answer is C. At a high altitude, because of the low ambient barometric pressure and oxygen tension, hypoxia develops. Therefore, we can immediately rule out the options with a normal arterial blood oxygen tension (options A and D). Option B is a subject with hypoxia that resulted from inadequate ventilation; this subject has CO_2 retention and respiratory acidosis, but the response to high altitude is hyperventilation and consequently a low PCO_2 and respiratory alkalosis. Option E shows values for an acute respiratory alkalosis; the plasma $[HCO_3^-]$ has been lowered by 4 mEq/L, corresponding to the 20 mm Hg decrease below normal in PCO_2 (see Table 24.4). Option C shows typical values for a chronic (1 week) respiratory alkalosis; the kidneys have further lowered the plasma $[HCO_3^-]$ and have, therefore, reduced the severity of the alkalemia. The diagnosis of chronic respiratory alkalosis can be confirmed by plotting the values on the pH–bicarbonate diagram (see Fig. 24.12).

5. A 24-year-old nurse is brought to the emergency room shortly before midnight. Though somewhat drowsy, she was able to relate that a few hours before she had attempted to kill herself by swallowing the contents of a bottle of aspirin tablets. Which of the following set of arterial blood values is expected?

	pH	PO_2, mm Hg	Pco_2, mm Hg	HCO_3^-, mEq/L
A.	7.24	95	19	8
B.	7.29	55	60	28
C.	7.40	95	40	24
D.	7.59	95	15	14
E.	7.68	95	15	17

The correct answer is D. Aspirin (salicylate) intoxication produces a mixed acid–base disturbance—respiratory alkalosis (due to stimulation of the respiratory center) and metabolic acidosis (due to inhibition of oxidative metabolism and accumulation of lactic and ketone body acids). The respiratory alkalosis predominates during the first several hours in adults; metabolic acidosis occurs at the same time and becomes overwhelming late in the course of the intoxication. Option D shows the predominant respiratory alkalosis. Accumulation of organic acids in the blood contributes to the lowering of plasma [HCO_3^-]. Option A represents metabolic acidosis with normal respiratory compensation. Option B represents respiratory acidosis due to alveolar hypoventilation or a mismatch between alveolar ventilation and pulmonary capillary blood flow; note the abnormally low PO_2. Option C represents the normal condition for arterial blood. Option E represents a simple acute respiratory alkalosis. Confirm the correct answer by plotting the point on the pH–bicarbonate diagram (see Fig. 24.12).

Clinical Application Exercises 24.1

A 16-year-old girl was referred to an endocrinology unit with a provisional diagnosis of primary hyperaldosteronism. She had an elevated blood pressure (180/120 mm Hg), hypokalemia (serum K^+ of 2.6 mEq/L), and mild alkalosis. Despite her hypokalemia, she excreted approximately as much K^+ as she was ingesting (80 mEq/d). Her aldosterone secretion rate was found to be abnormally low, even when on a low-sodium diet. The same constellation of abnormalities was found in several of her 10 siblings, independent of gender. Both her mother and maternal grandmother had severe hypertension and died prematurely. The patient many years later developed renal failure, and at age 45, she received a kidney transplant. The transplant lowered her blood pressure and corrected her hypokalemia.

QUESTIONS

1. Why was primary aldosteronism first suspected as the problem in the patient?
2. What measurement is clearly inconsistent with primary hyperaldosteronism?

3. How can you explain the abnormally low aldosterone secretion rate?
4. Why does the patient have a metabolic alkalosis?
5. What is the genetic disorder in the patient?
6. How might one treat this disorder?
7. What strongly suggests that the patient's problem was an intrinsic renal defect?

ANSWERS

1. Primary aldosteronism typically results in hypertension (due to salt and water retention) and hypokalemia (due to excessive K^+ secretion by cortical collecting duct principal cells), features which were seen in the patient.
2. The aldosterone secretion rate was abnormally low.
3. The abnormally low aldosterone secretion rate was likely a secondary consequence of the electrolyte abnormalities; salt and water retention (volume expansion) would lead to suppression of the renin–angiotensin–aldosterone system, and low plasma [K^+] would inhibit aldosterone secretion by a direct effect on the adrenal cortex.
4. Hypokalemia produces metabolic alkalosis. This may be explained by reciprocal movements of K^+ out of body cells into the ECF and movement of ECF H^+ into cells. The increased [H^+] in kidney tubule cells would promote H^+ secretion and thereby lead to addition of new bicarbonate to the blood (see Chapter 24).
5. The patient has Liddle syndrome, a rare autosomal dominant disorder. The specific defect is a mutation in genes that encode the beta or gamma subunits of the epithelial sodium channel (ENaC), which is located in the luminal cell membrane of collecting duct principal cells. This defect reduces binding to an intracellular ubiquitin ligase that normally removes the sodium channel from the luminal cell membrane. The result is an increased number of ENaC in the luminal cell membrane and consequent excessive reabsorption of Na^+ and excessive secretion of K^+.
6. A low-sodium diet and the potassium-sparing diuretic drugs triamterene or amiloride, both of which block ENaC, are useful in treating this disorder.
7. The hypertension was improved and the patient had a normal plasma [K^+] after she received a new kidney.

PART VII GASTROINTESTINAL PHYSIOLOGY

25 Gastrointestinal System Functions

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe how salivary secretion is regulated.
- Explain the mechanism by which the stomach secretes hydrochloric acid.
- Describe the phases of acid secretion associated with digestion.
- Explain the phasic secretion of the pancreatic enzymes.
- Explain the role that bile salts play in the absorption of intestinal lipids.
- Describe the difference between primary and secondary bile acids.
- Explain why gallstones are usually formed in the gallbladder.
- Explain how enterocytes digest carbohydrates and transport the digestion products.
- Explain how enterocytes digest proteins and transport the digestion products.
- Explain how the enterocytes digest and transport triglycerides.
- Explain the function of the fat-soluble and the water-soluble vitamins.
- Explain the mechanism of iron absorption by the small intestine.

The digestive system is responsible for the absorption of ingested nutrients, water, minerals, vitamins, and other essential compounds. The digestive system is central to the regulation of the metabolic processes in all of the organs. Normal function of the digestive system is critical for growth, development, maintenance of individual organs, and survival. Moreover, the GI and the cardiovascular systems work in concert to provide and deliver nutrients to the millions of cells in the body. For example, during the process of digestion, blood flow is augmented to the gut by shunting blood from other organs.

Chapter 23 explained how the kidneys regulate water and electrolytes and how electrolyte balance is maintained by renal excretion. These same electrolytes as well as water, and nutrients, enter the body through absorption via the gut. The enteric nervous system first introduced in Chapter 3 interacts with other parts of the nervous and endocrine systems to send information to and from the brain to provide local control of the digestive system. For example, the pH of the stomach's contents is raised and lowered by hormones from the digestive system and neural signals from the peripheral nervous system. Also, the digestion of foods is dependent on basic chemical processes that follow the laws of chemistry. Finally, the interrelationship between structure and function in the unique architectural design of the small intestine creates an enormous surface area for the absorption of nutrients.

FUNCTIONAL OVERVIEW OF DIGESTIVE SYSTEM

The digestive system includes the oral cavity, the gastrointestinal (GI) tract, and associated accessory organs, glands, and specialized structures. The GI tract does not include the mouth or pharynx. It is the hollow, muscular tube starting where the pharynx connects to the upper esophagus and terminating at the anus. The digestive system is physically and functionally divided into regions specialized for digestion, secretion, absorption, motility, and compaction. The teeth, tongue, salivary glands, liver, gallbladder, and pancreas are accessory structures that contribute to the physical, chemical, and enzymatic breakdown processes that occur within the digestive system. Hormones (e.g., gastrin, cholecystokinin [CCK], and secretin) regulate digestive enzyme release, absorption, secretion, and smooth muscle contraction/relaxation along the GI tract. Nervous input (i.e., central nervous system [CNS] and enteric nervous system [ENS]) affects similar digestive system processes (see Chapter 27).

Small intestine is the primary site for digestion and absorption processes.

Enzymatic digestion is initiated in the mouth (i.e., carbohydrates) and absorption begins in the stomach (e.g., medium-chain fatty acids and some drugs). However, most digestion and absorption processes occur in the small intestine. Initial digestion and trituration in the stomach prepare the chyme for final digestion and absorption of nutrients in the small intestine. Specialized small intestine epithelial cells (**enterocytes**) absorb nutrients for transport into either the portal circulation or the lymphatic system. Villi and the brush border membrane of the enterocytes increase the total surface area for digestion and absorption from the lumen. Secretions from the salivary glands, stomach, pancreas, and liver facilitate the processes of digestion and absorption. Secretory glands serve two primary functions. First, digestive enzymes are secreted from salivary glands in the mouth, parietal cells in the gastric pits of the stomach, and the acini in the pancreas that empty into the small intestine. However, complete nutrient digestion only requires the action of pancreatic enzymes. Second, glands secrete mucus for lubrication and protection. Because the oral cavity and the surface of the GI tract are literally exposed to the external environment, the secreted mucus also plays a prominent role in immunity by preventing pathogens from entering the bloodstream and lymph (see Chapter 10 for review). This chapter discusses the basic structure, function, and regulation of digestive system secretion and the role the GI tract plays in the digestion and absorption of carbohydrate, fat, and protein and the absorption of fat-soluble and water-soluble vitamins, electrolytes, bile salts, and water.

SALIVARY SECRETION

Adults add ~7 to 10 L of gastric secretions, including about 1L of saliva in addition to gastric juice, pancreatic juice, and bile, to the GI tract daily for the digestion and absorption of nutrients.

Salivary glands are a heterogeneous group of **exocrine glands** with different proportions of **serous cells** and **mucous cells**. *Serous cells* produce a secretion containing *α-amylase*, an enzyme that breaks down starch, which is stored in **zymogen granules**. *Mucous cells* synthesize, store, and secrete **mucin**, which is composed of glycoproteins and important for lubrication and protection. Three pairs of *major salivary glands* (*extrinsic glands*), the (1) **parotid**, (2) **submandibular**, and (3) **sublingual glands**, connect to the oral cavity via secretory ducts (Fig. 25.1). *Minor salivary glands* (*intrinsic glands*), located in the oral submucosa, secrete mainly mucus and contribute < 10% to the total saliva volume. Salivary glands located on the tongue secrete lingual lipase. This enzyme initiates the digestion of triglycerides. Secretion of saliva is primarily regulated by parasympathetic and sympathetic nerves, but hormones, dry mouth, the temperature of drinks, and the presence of food in the mouth are examples of other stimuli that impact salivation.

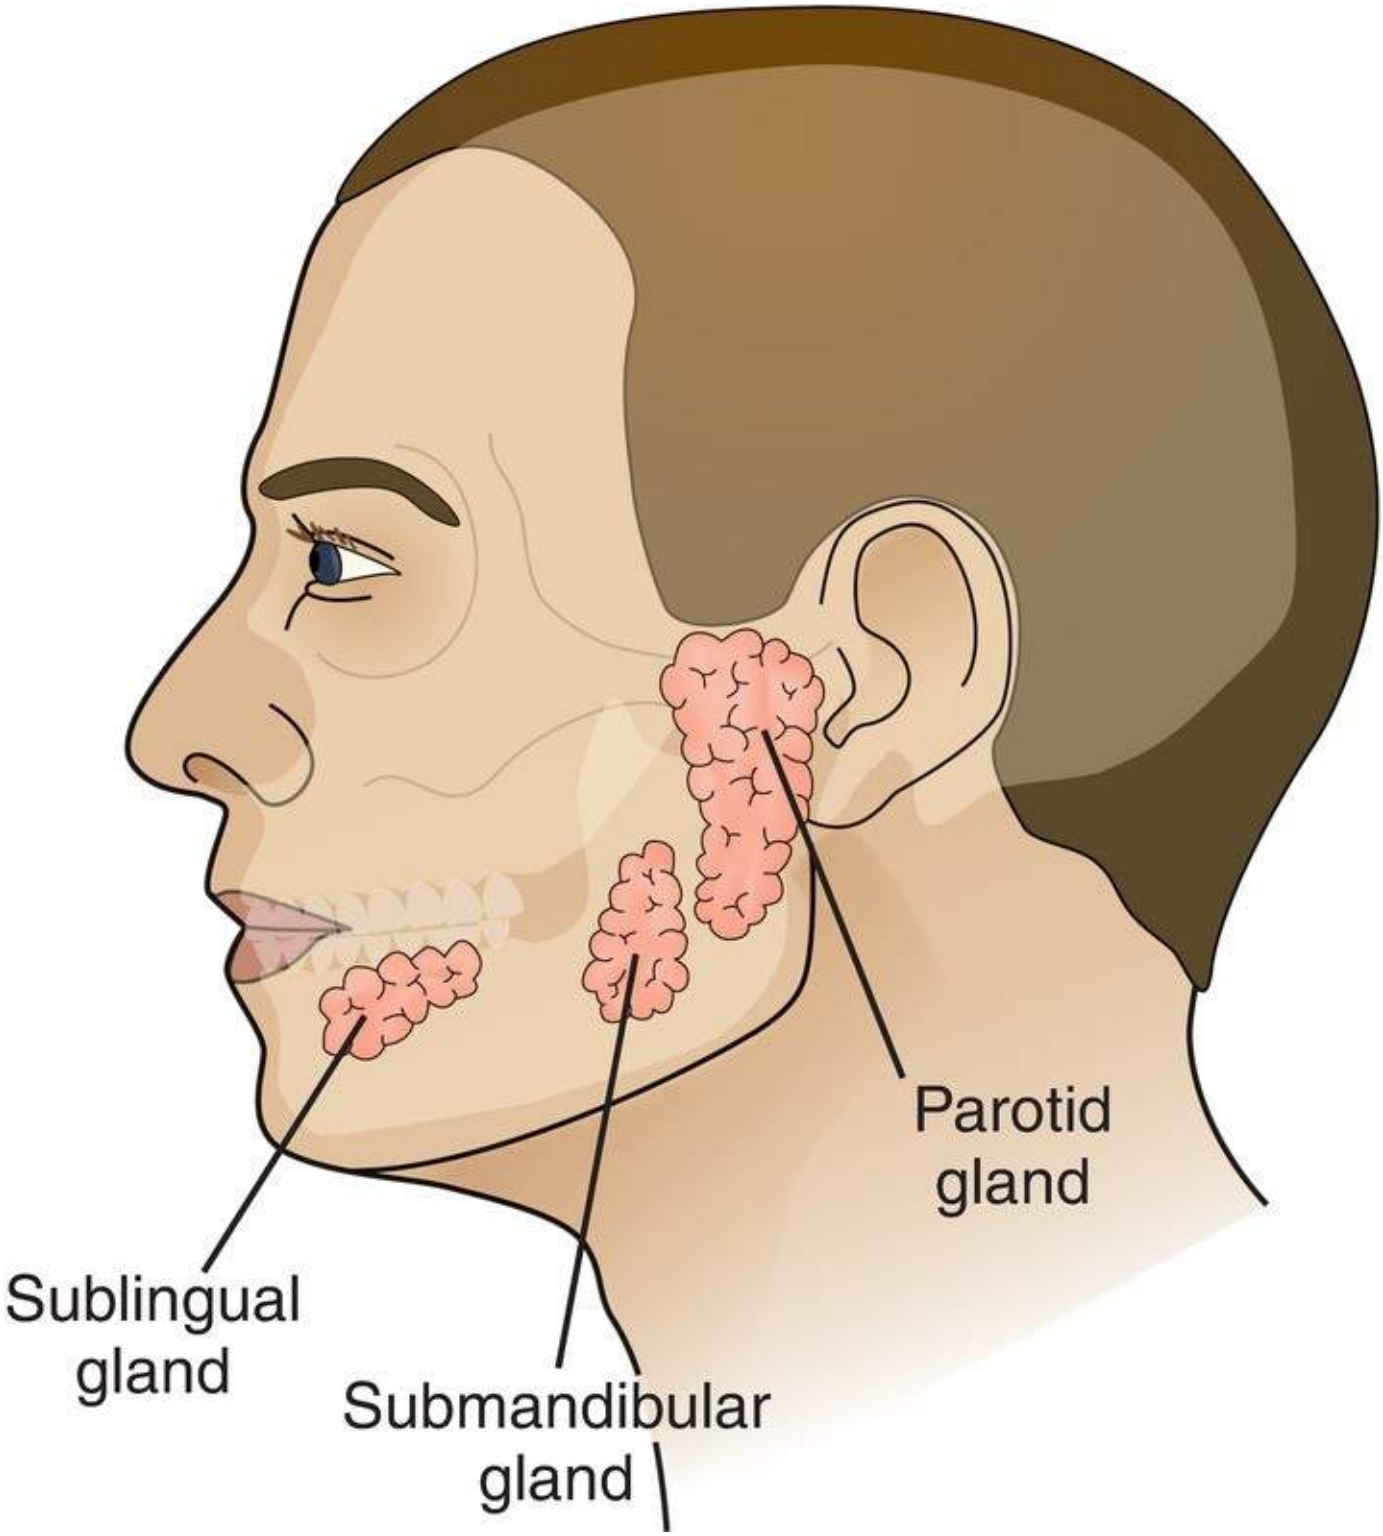

Figure 25.1 Salivary glands. The major salivary glands, which are paired, are shown in the above figure.

The secretions of the major glands differ significantly. *Parotid glands* secrete primarily a serous secretion that is rich in water and electrolytes, whereas the *submandibular* and *sublingual glands* produce both serous and mucous secretions. Salivary glands are endowed with a significant blood supply, and both the **parasympathetic** (**PNS**) and **sympathetic** (**SNS**) divisions of the **autonomic nervous system** (**ANS**) innervate them. ANS activity affects the quantity and composition of saliva. Although aldosterone is known to modify the ionic composition of saliva (i.e., Na^+ and K^+), it is generally believed that salivary secretion is mainly under ANS and not hormonal control.

Salivon is the functional unit of the salivary gland.

The functional unit of the salivary gland, the **salivon** (Fig. 25.2), consists of the **acinus**, the **intercalated duct**, and the **striated duct**. The specialized *serous cells* and *mucous cells* are organized as a single layer surrounding the saclike *acinus*. The serous cells contain an abundance of rough endoplasmic reticulum (RER), which reflects active protein synthesis, and numerous zymogen granules. Contractile cells (**myoepithelial cells**) are strategically organized around the acini and intercalated ducts. Contraction of these cells facilitates movement of the serous and mucus cell secretions into the ducts and expression of the duct contents in the oral cavity.

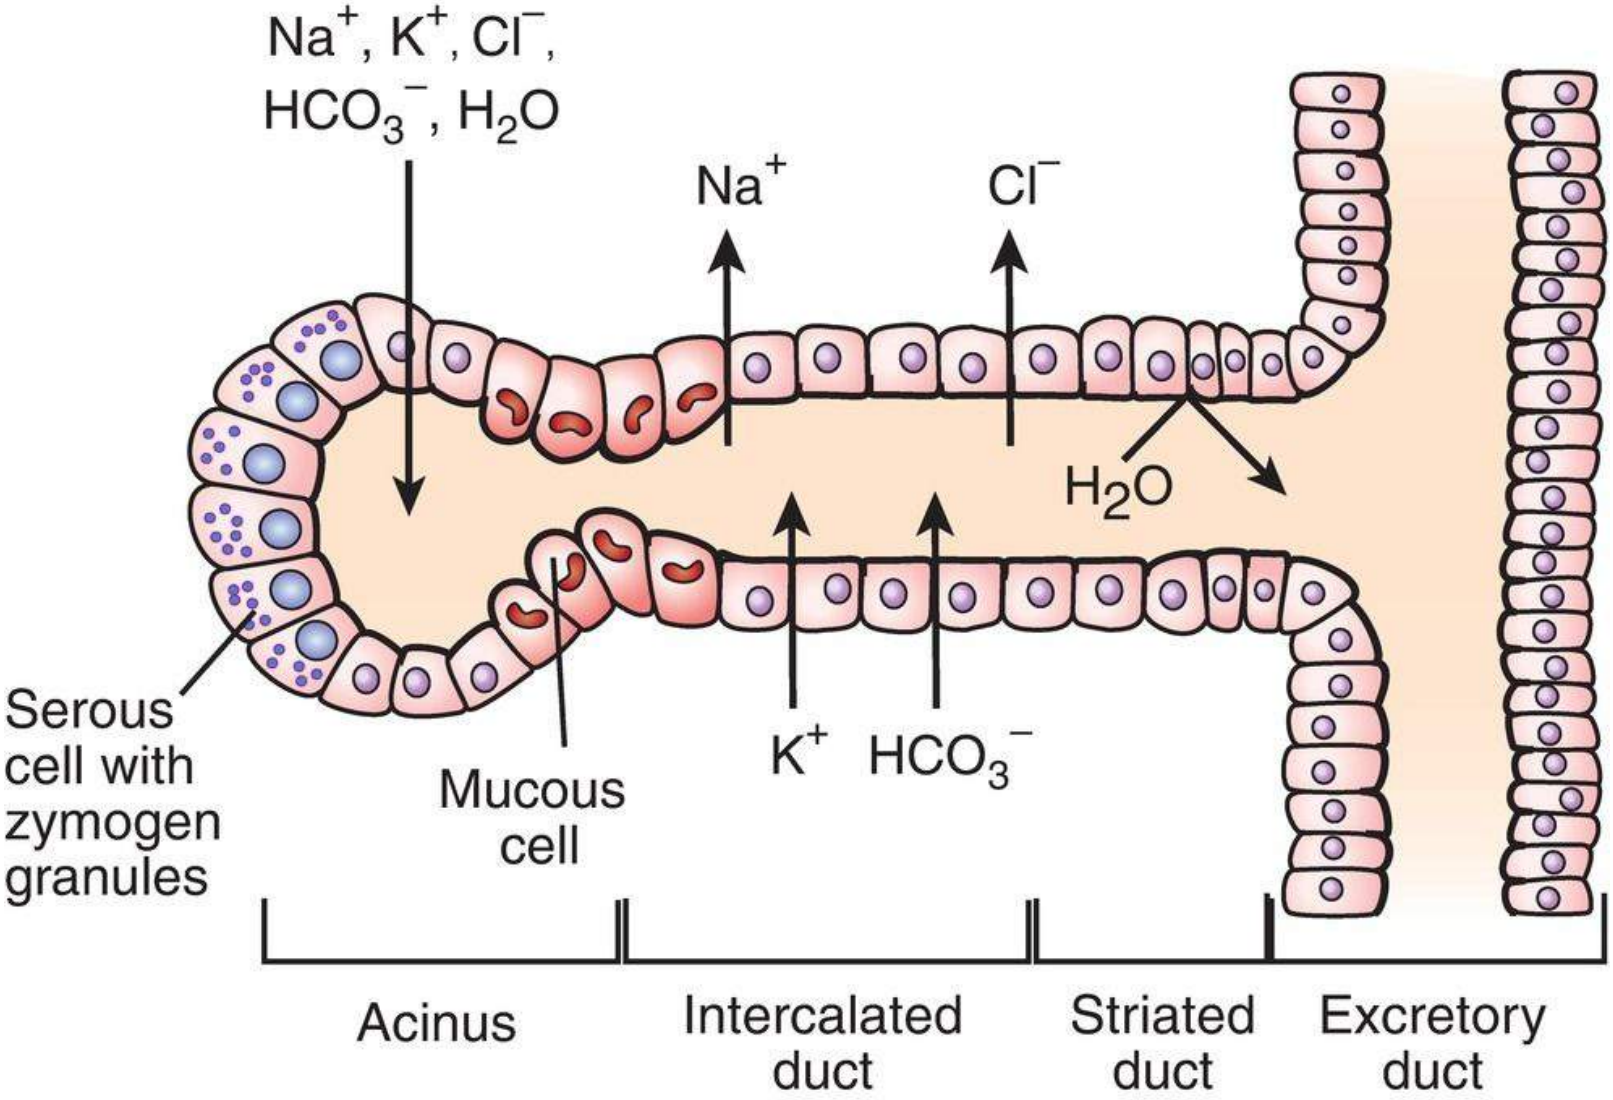

Figure 25.2 The salivon is the basic unit of the salivary gland. The acinus and associated ductal system form the salivon.

Salivary ducts

The intercalated ducts connect to the striated duct, which empties into the excretory duct. The *striated duct* and the large *excretory ducts* are lined with columnar cells and are involved in modifying the ionic composition of saliva. Although the acinar cells synthesize and secrete most salivary proteins, cells of the *intercalated ducts* contain secretory granules and synthesize several proteins, such as epidermal growth

factor, ribonuclease, α-amylase, and proteases.

Saliva electrolyte composition is modified when the striated ducts selectively reabsorb sodium and selectively secrete potassium and bicarbonate.

The primary secretion produced by the acinar cells and intercalated ducts resembles that of plasma. However, samples collected from the striated and excretory (collecting) ducts are hypotonic to plasma, indicating the primary secretion is modified in the striated ducts. Saliva has less Na^+ and Cl^- and more K^+ and HCO_3^- than does plasma, because the cells in the striated duct actively absorb Na^+ and actively secrete K^+ and HCO_3^- into the lumen (see Fig. 25.2). Cl^- ions leave the lumen either in exchange for HCO_3^- ions or by passive diffusion along the electrochemical gradient created by Na^+ absorption.

The electrolyte composition of saliva depends on the rate of secretion. As the secretion rate increases, the electrolyte composition of saliva approaches the ionic composition of plasma, but at low flow rates, it differs significantly. At low secretion rates, the ductal epithelium has more time to modify and, thus, reduce the osmolality of the primary secretion, so the saliva has a much lower osmolality than does plasma. The opposite is true at high secretion rates.

Although the absorption and secretion of ions may explain changes in the electrolyte composition of saliva, these processes do not explain why the osmolality of saliva is lower than that of the primary secretion of the acinar cells. Saliva is hypotonic to plasma because of a net absorption of ions by the ductal epithelium, a result of the action of an **Na^+/K^+-ATPase** in the basolateral cell membrane. The Na^+/K^+-ATPase transports three Na^+ ions out of the cell in exchange for two K^+ ions transported into the cell. The ductal epithelium is not permeable to H_2O, so H_2O does not follow the absorbed salt. This results in a net absorption of ions.

Salivary proteins

The two major proteins present in saliva are *α-amylase* (*ptyalin*) and *mucin*. Salivary α-amylase is produced predominantly by the parotid glands, and mucin is produced mainly by the sublingual and submandibular glands. Amylase is involved in the digestion of starch and catalyzes the hydrolysis of polysaccharides with α-1,4- glycosidic linkages. It is synthesized in the RER of acinar serous cells and transferred to the Golgi apparatus, where it is packaged into zymogen granules. The zymogen granules are stored at the apical region of the acinar cells and released with appropriate stimuli. Because some time usually passes before acids in the stomach can inactivate the amylase, a substantial amount of the ingested carbohydrate can be digested before reaching the duodenum. (Amylase activity is described later in this chapter.)

Mucin is the most abundant protein in saliva. The term describes a family of glycoproteins, each associated with varying amounts of different sugars. Mucin is responsible for most of saliva's viscosity. It coats the surface of the mouth and teeth. The tooth coating actually aids in the prevention of caries.

Saliva has unique qualities.

Saliva performs various functions. It facilitates chewing and swallowing by lubricating food and the mucosal surface. The lubrication reduces the frictional damage foods may cause, and it facilitates food movement within the oral cavity and down the esophagus. It helps small food particles stick together to form a bolus, making them easier to swallow. Moistening of the oral cavity facilitates speech. Saliva carries immunoglobulins that combat pathogens and lysozyme that kills bacteria. Salivary enzymes are involved in carbohydrate and fat digestion. Saliva plays an important role in water intake; the sensation of dryness of the mouth as a result of low salivary secretion urges a person to drink. Saliva can dissolve flavorful substances, stimulating the different taste buds located on the tongue. Interestingly, saliva is also involved in the maintenance of taste buds.

Saliva performs immunologic functions by lysing bacteria and killing HIV-infected leukocytes.

Saliva plays an important role in the general hygiene of the oral cavity. The pH of saliva ranges from pH 6.0 to almost neutral (pH 7.0). It contains HCO_3^- to neutralize acidic substances entering the oral cavity, including regurgitated gastric acid. Saliva also contains small amounts of **muramidase** (lysozyme) that breaks down peptidoglycans found in the cell walls of certain bacteria (e.g., *Staphylococcus*); **lactoferrin**, a protein that binds iron, depriving microorganisms of a source of iron for growth; **epidermal growth factor**, which stimulates gastric mucosal growth; *immunoglobulins* (mainly IgA); ABO blood group substances; and proteins with *antiviral* and *antifungal* activity (e.g., lysozyme, peroxidase, salivary agglutinin).

Research has indicated that the hypotonic property of saliva protects against certain infections. Hypotonic saliva has been shown to kill the human immunodeficiency virus (HIV)-infected mononuclear leukocytes and blocking further transmission of the virus. This helps to explain why HIV is rarely transmitted via kissing or normal oral contact. However, the beneficial property of hypotonic saliva is lost when the virus is introduced into the oral cavity via isotonic HIV-infected fluids (e.g., seminal fluid or breast milk).

Acidic food is a potent stimulus of salivary secretion.

In the resting state, salivary secretion is low, ~30 mL/h. The submandibular glands contribute about two thirds of resting salivary secretion, the parotid glands about one fourth, and the sublingual glands the remainder. Stimulation increases the rate of salivary secretion, most notably in the parotid glands, up to 400 mL/h. The most potent stimuli of salivary secretion are acidic-tasting substances (e.g., citric acid). Other stimuli include the smell of food, chewing, and what's in the mouth (i.e., smooth objects like round, hard candies stimulate salivation). Inhibitors of secretion include anxiety, fear, dehydration, medications (e.g., antihistamines), and rough objects.

Saliva secretion is under autonomic control.

As discussed, salivary secretion is predominantly under ANS control. Parasympathetic stimulation of the salivary glands increases activity of the acinar and ductal cells, leading to increased salivation. The PNS control centers are located in the medulla oblongata. Preganglionic fibers from the inferior salivatory nucleus are contained in cranial nerve IX and synapse in the otic ganglion. They send postganglionic fibers to the parotid glands. Preganglionic fibers from the superior salivatory nucleus course with cranial nerve VII and synapse in the submandibular ganglion. They send postganglionic fibers to the submandibular and sublingual glands.

Blood flow is low in resting salivary glands and can increase as much as 10-fold when salivary secretion is stimulated. This increase in blood flow is also under PNS control. Parasympathetic stimulation induces acinar cells to release the serine protease **kallikrein**. Kallikrein acts on the plasma globulin **kininogen** to release **lysyl-bradykinin** (**kallidin**). Kallidin stimulates dilation of the blood vessels supplying the salivary glands. Atropine, an anticholinergic agent, is a potent inhibitor of salivary secretion. Acetylcholinesterase inhibitors (e.g., pilocarpine) enhance salivary secretion. Some parasympathetic stimulation also increases blood flow to the salivary glands directly, apparently via the release of the neurotransmitter **vasoactive intestinal peptide** (**VIP**).

The SNS also innervates the salivary glands. Sympathetic fibers arise in the upper thoracic segments of the spinal cord and synapse in the **superior cervical ganglion**. Postganglionic fibers leave the superior cervical ganglion and innervate the acini, ducts, and blood vessels. Sympathetic stimulation often results in a short-lived and much smaller increase in salivary secretion than does parasympathetic stimulation. The increase in salivary secretion observed during sympathetic stimulation is mainly via β-adrenergic receptors, which are more involved in stimulating the contraction of myoepithelial cells to increase salivary flow. Although both sympathetic and parasympathetic stimulation increase salivary secretion, the products are different. Parasympathetic stimulation produces a secretion rich in electrolytes and salivary amylase. In contrast, sympathetic stimulation produces a secretion rich in mucus, making the saliva much more viscous.

Hormones affect saliva secretion.

Mineralocorticoid administration reduces the Na^+ concentration of saliva with a corresponding rise in K^+ concentration. Mineralocorticoids act mainly on the striated and excretory ducts. Arginine vasopressin (vasopressin) reduces the Na^+ concentration in saliva by increasing ductal Na^+ reabsorption. Some GI hormones (e.g., VIP and substance P) have been experimentally demonstrated to evoke salivary secretion.

GASTRIC SECRETION

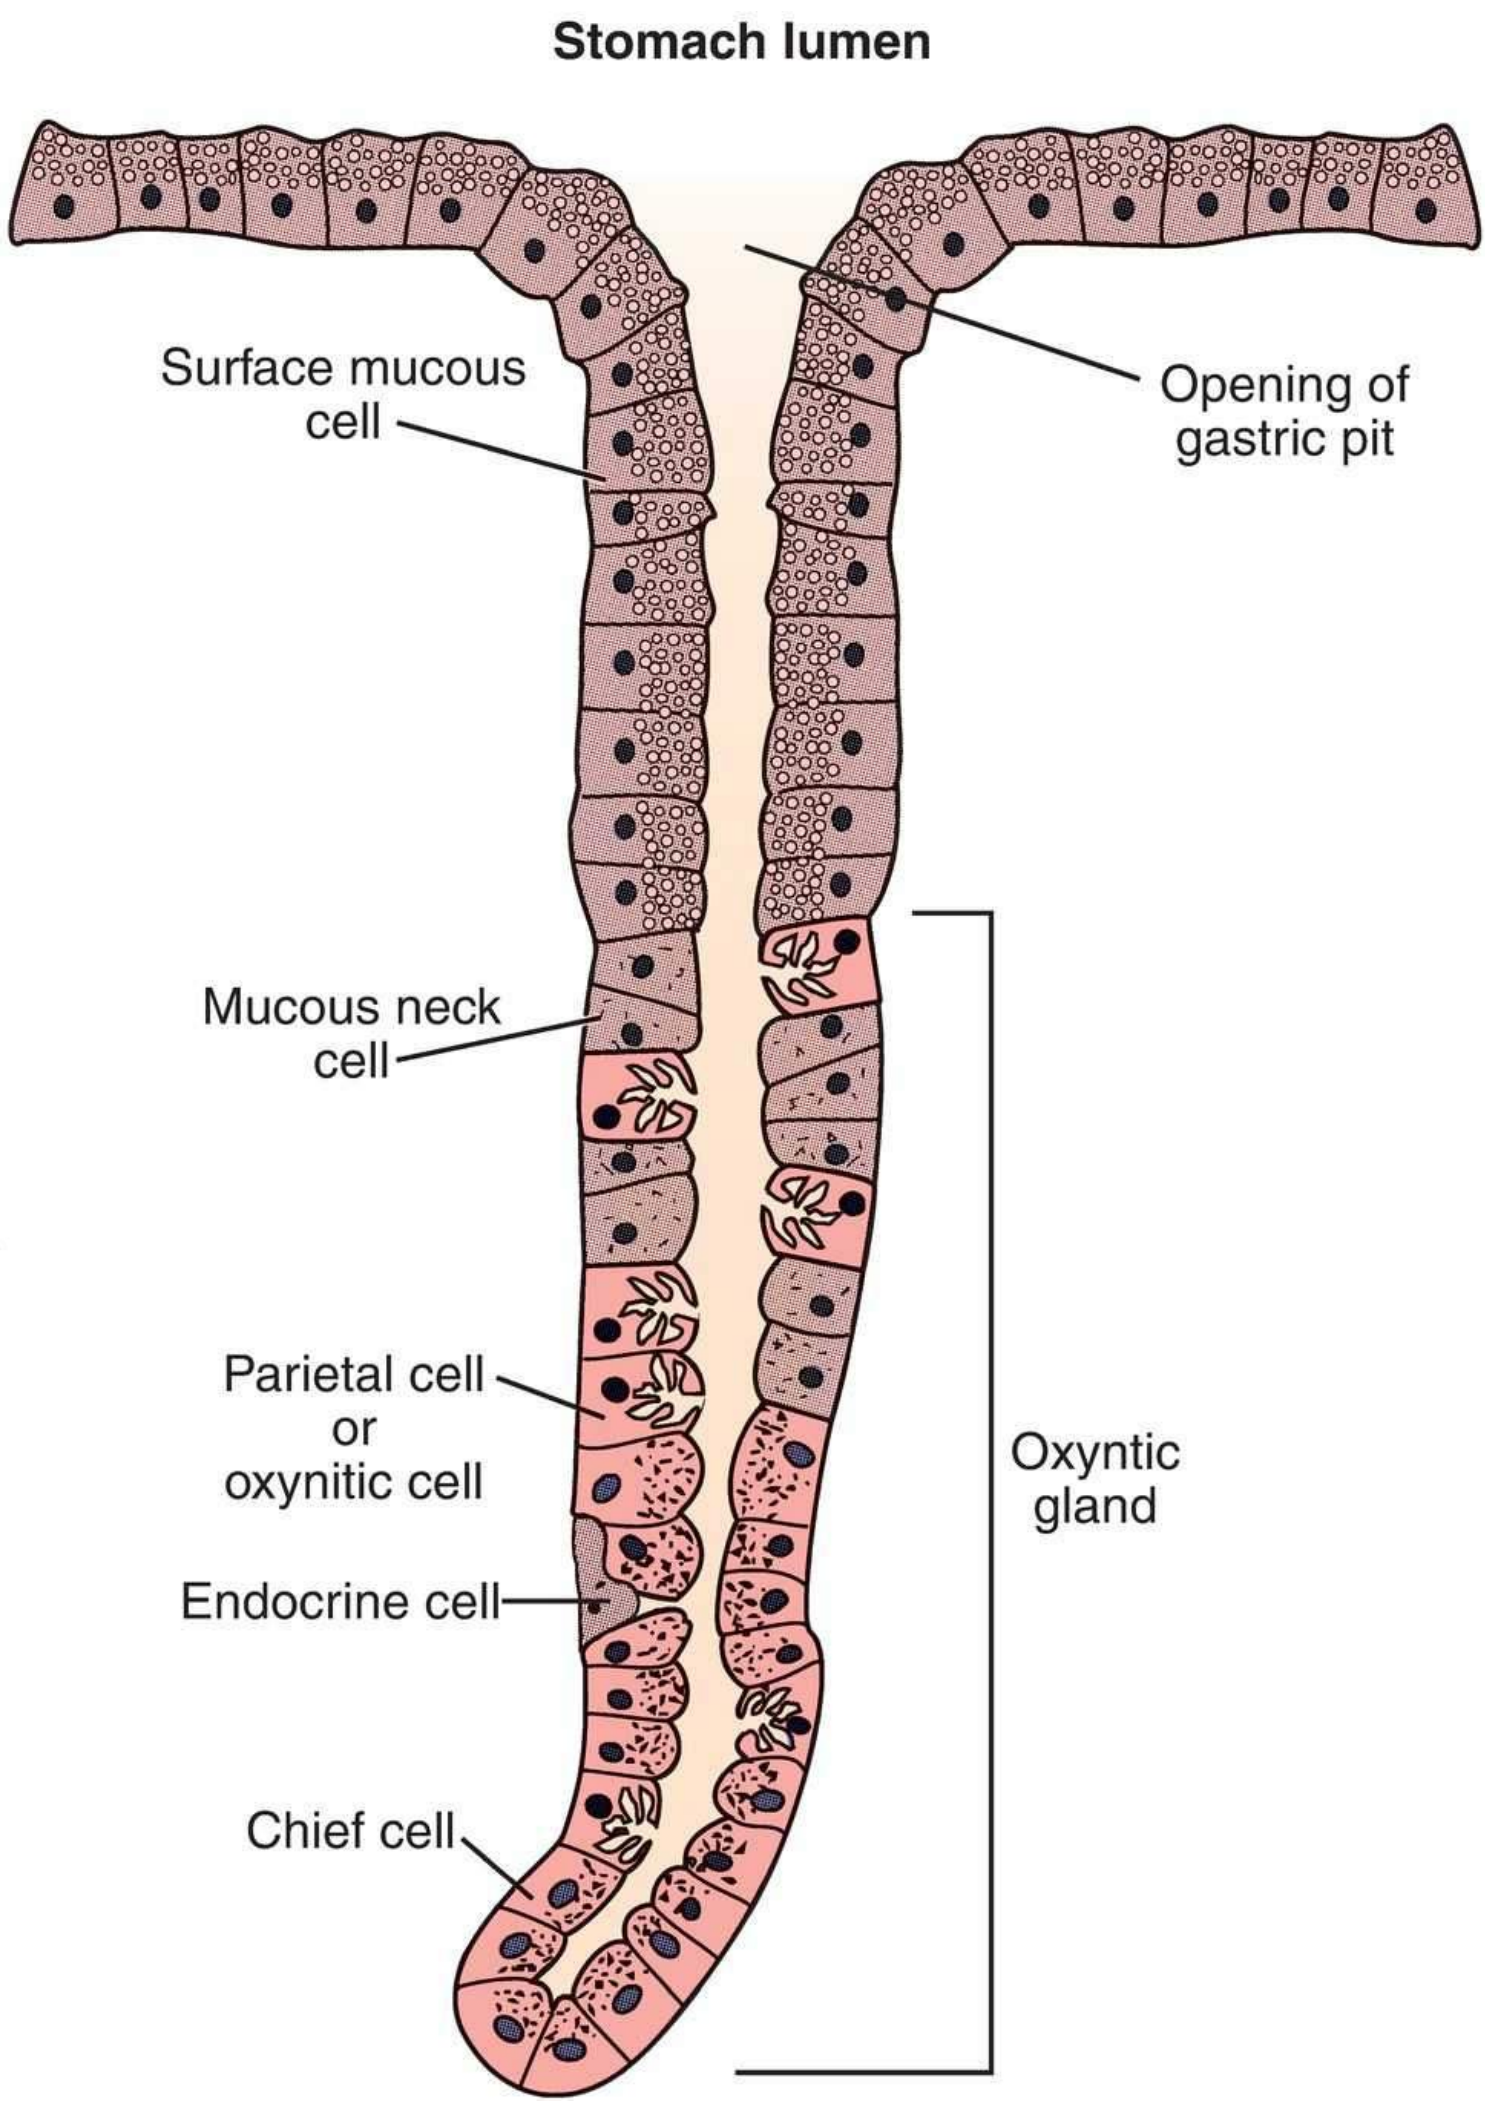
The stomach is a muscular, hollow, dilated part of the GI tract with multiple functions. The stomach transiently stores food, secretes HCl and proteolytic enzymes involved in the gastric digestion of foods, absorbs water-soluble and lipid-soluble substances (e.g., alcohol and some drugs), and prepares the **chyme** for digestion in the small intestine. Chyme, a partially digested semifluid of smaller particles, is produced through a combination of peristaltic movements of the stomach muscles and the chemical and enzymatic digestion initiated by the gastric secretions. A combination of the squirting of antral content into the duodenum, the grinding action of the antrum, and retropulsion provides much of the mechanical action necessary for the emulsification of dietary fat, which plays an important role in fat digestion. The propulsive, grinding, and retropulsive movements associated with antral peristalsis are discussed in Chapter 27.

Mucus and bicarbonate secreted by epithelial cells protect the stomach from the acidic condition in the lumen.

The stomach wall consists of four distinct layers (from inside to outside): (1) **gastric mucosa**, (2) **submucosa**, (3) **muscularis externa**, and (4) **serosa**. The mucosa layer consists of the epithelium that houses the secretory glands. The submucosa consists of fibrous connective tissue that separates the mucosa from the muscularis externa. The smooth muscle layer of the muscularis externa differs from other portions of the GI tract in that it contains three layers of smooth muscle instead of two. The serosa consists of connective tissue and is continuous with the peritoneum.

Epithelial mucosa

The gastric mucosa epithelium forms deep pits and contains two main types of glands: **pyloric** and **oxyntic** (**gastric**) (Fig. 25.3). *Pyloric glands* secrete gastrin (a hormone) and mucus for protection. They are located in the distal 20% of the stomach, the antral portion. *Pyloric glands* contain cells similar to mucous neck cells of oxyntic glands, but the presence of many *gastrin-producing cells* (*G cells*) makes them different. The *oxyntic glands* are the most abundant gastric glands. They are located in the fundus and the corpus, which occupies 80% of the stomach.



Stomach lumen
Surface mucous cell
Opening of gastric pit
Mucous neck cell
Parietal cell or oxynitic cell
Endocrine cell
Chief cell
Oxyntic gland

Figure 25.3 The oxyntic gland in the corpus of a mammalian stomach. Several cell types, including parietal (oxyntic) cells, open into a common pit and contribute to gastric secretion.

Parietal cells of the oxyntic glands secrete hydrochloric acid.

Oxyntic glands contain **parietal** (**oxyntic**) **cells**, **chief cells**, **mucous neck cells**, and some *endocrine cells* (see Fig. 25.3). Most of the mucous cells are located in the neck region, and the base of the oxyntic gland contains mostly chief cells, along with some parietal and endocrine cells. Parietal cells secrete mainly **hydrochloric acid** (**HCl**) and **intrinsic factor** in addition to leptin and growth factors. Chief cells secrete primarily **pepsinogen** along with leptin. (Intrinsic factor and pepsinogen are discussed later in this chapter.) Mucous neck cells secrete mucus.

HCl is secreted across the parietal cell microvillar membrane and flows out of the intracellular canaliculi into the oxyntic gland lumen (Fig. 25.4). The amount of HCl secreted is proportionate to parietal cell number. Surface mucous cells lining the entire surface of the gastric mucosa and the openings of the gastric glands secrete mucus and HCO_3^- to protect the gastric epithelium from the acidic environment. A surface mucous cell contains numerous mucus granules at its apex. The number of granules varies depending on synthesis and secretion. The mucous neck cells of the oxyntic glands resemble surface mucous cells.

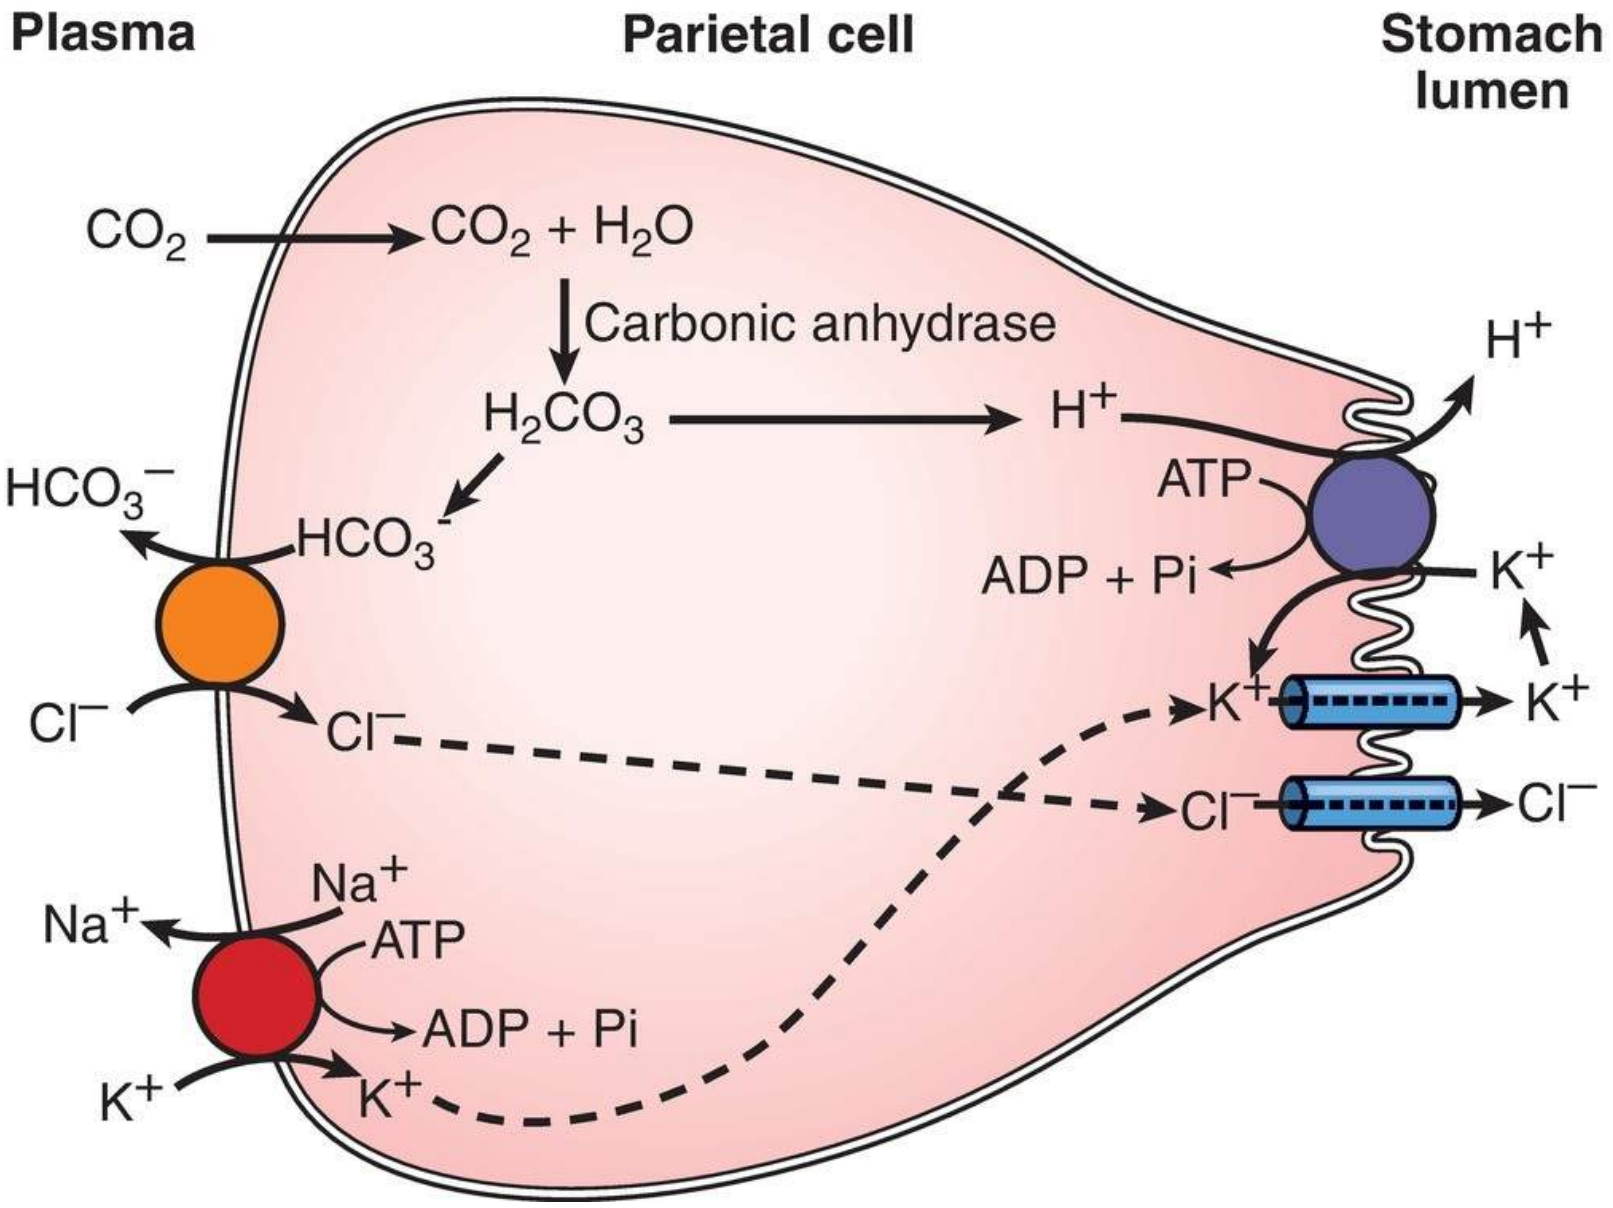


Figure 25.4 Parietal cells secrete gastric acid. The mechanism of HCl secretion is depicted in the figure

above. ATPase in the apical cell membrane pumps H^+ out of the cell and into the lumen in exchange for K^+. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

Chief cells are morphologically distinguished primarily by the presence of apical zymogen granules and an extensive RER. The zymogen granules contain pepsinogen that is released into the stomach and cleaved in the lumen to pepsin, the active enzyme, by HCl.

Also present in the stomach are various neuroendocrine cells, such as G cells, located predominantly in the antrum. G cells produce the hormone **gastrin**, which stimulates HCl secretion by gastric parietal cells. An overabundance of gastrin secretion (*Zollinger-Ellison syndrome*) results in gastric hypersecretion and peptic ulceration. In most cases, the tumors arise within the pancreas and/or the duodenum. **D cells**, also present in the antrum, produce **somatostatin**, another important GI hormone.

Mucous gel layer protects the gastric epithelium.

The pH of the stomach lumen becomes quite acidic with pH values reaching 0.7 to 3.8. This raises a question: How is the gastric mucosal surface protected from intrinsic damage? The answer lies in the mucus and HCO_3^- containing secretion produced by the surface mucous cells. The mucus forms a **mucous gel layer** that covers the mucosal surface, and the HCO_3^- trapped in the mucous gel layer neutralizes the HCl.

Hydrochloric acid is formed when the parietal cell pumps hydrogen out in exchange for potassium.

The mechanism of HCl production and secretion by parietal cells located in the corpus and fundus is depicted in Figure 25.4. An **H^+/K^+-ATPase** in the apical (luminal) cell membrane of the parietal cell actively pumps H^+ out of the cell in exchange for K^+ entering the cell. Omeprazole inhibits the H^+/K^+-ATPase. Omeprazole, an acid-activated prodrug that is converted in the stomach to the active drug, binds to two cysteines on the ATPase, resulting in an irreversible inactivation. Omeprazole is used to treat ulcers, gastroesophageal reflux disease (GERD) (often associated with heartburn), and other conditions resulting from HCl production by the stomach. Although the secreted H^+ is often depicted as being derived from carbonic acid (see Fig. 25.4), the source of H^+ is most likely the dissociation of H_2O that also occurs inside the parietal cells. Carbon dioxide (CO_2) and H_2O join to form carbonic acid (H_2CO_3) in a reaction catalyzed by carbonic anhydrase. Acetazolamide inhibits carbonic anhydrase. Metabolic sources inside the cell and diffusion from the blood provide the CO_2.

For the H^+/K^+-ATPase to work, an adequate supply of K^+ ions must exist outside the cell. Although the mechanism is still unclear, there is an increase in K^+ conductance (through K^+ channels) in the apical membrane of the parietal cells simultaneous with active HCl secretion. The H^+/K^+-ATPase recycles K^+ ions back into the cell in exchange for H^+ ions. As shown in Figure 25.4, the basolateral cell membrane has an electroneutral Cl^-/HCO_3^- exchanger that balances the entry of Cl^- into the cell with an equal amount of HCO_3^- entering the bloodstream. The Cl^- inside the cell then leaks down an electrochemical gradient into the lumen through Cl^- channels. Consequently, HCl is secreted into the lumen

The secretion of HCl by parietal cells is balanced by an equal amount of HCO_3^- added to the bloodstream. Therefore, the blood coming from the stomach during periods of active HCl secretion contains much HCO_3^-, a phenomenon called the **alkaline tide**. The osmotic gradient created by the HCl concentration in the gland lumen drives H_2O passively into the lumen, thereby maintaining the iso-osmolality of the gastric secretion.

Gastric secretion occurs in three phases.

Gastric secretion occurs in three phases: (1) **cephalic**, (2) **gastric**, and (3) **intestinal phase** (Table **25.1**). The phases are named accordingly to where the stimuli originate. The *cephalic phase* involves the CNS and accounts for about 40% of total acid secretion. Smelling, chewing, and swallowing food (or merely the thought of food) send impulses along parasympathetic fibers in the vagus nerves to enteric neurons in the stomach wall. Nerve input and hormones stimulate parietal cells to release HCl.

TABLE 25.1 The Three Phases of Stimulation of Acid Secretion after Ingesting a Meal

Phase	Stimulus	Pathway	Stimulus to Parietal Cell
Cephalic	Thought of food, smell, taste, chewing, and swallowing	Vagus nerve to: Parietal cells G cells	ACh Gastrin
Gastric	Stomach distention	Local (enteric) reflexes and vagovagal reflexes to: Parietal cells G cells	ACh Gastrin
Intestinal	Protein digestion products in duodenum Distention	Amino acids in blood Intestinal endocrine cell	Amino acids Entero-oxyntin

ACh, acetylcholine.

The *gastric phase* involves events occurring in the stomach post food intake and accounts for about 50% of total HCl secretion. It is initiated by gastric distention and chemical agents such as digested proteins. Mechanoreceptors located in the stomach wall detect the distention that accompanies the presence of food in the stomach lumen. They respond by stimulating the parietal cells directly through short local (enteric) reflexes and by long **vagovagal reflexes**. Afferent and efferent impulses traveling in the vagus nerve mediate vagovagal reflexes. The products of protein digestion are potent stimulators of HCl secretion, an effect mediated through gastrin release. Several other chemicals (e.g., alcohol and caffeine) stimulate HCl secretion through mechanisms that are not well understood. The stimulation of HCl secretion by alcohol does appear to be related to its alcohol content—beverages lower in alcohol content, such as beer, tend to stimulate acid secretion more effectively than do beverages with higher alcohol content.

The *intestinal phase*, initiated when circulating amino acids, produced during protein digestion in the duodenum, stimulate parietal cells, accounts for about 10% of the total gastric acid secretion. Distention of the small intestine, probably via the release of the hormone **entero-oxyntin** from intestinal endocrine cells, also stimulates HCl secretion.

Acid production in the stomach parallels rates of gastric secretion.

The electrolyte composition of gastric juice changes with secretion rate. At a low secretion rate, Na^+ and Cl^- concentrations are high and K^+ and H^+ concentrations are low. As the secretion rate increases, the concentration of Na^+ decreases whereas that of H^+ and Cl^- increases significantly (Fig. 25.5). The changes in electrolyte composition that accompany different secretion rates reflect the combined contributions of nonparietal cells and parietal cells to gastric juice. Secretion from nonparietal cells is probably constant; therefore, it is parietal cell secretion of HCl that significantly contributes to the changes in electrolyte composition at higher secretion rates.

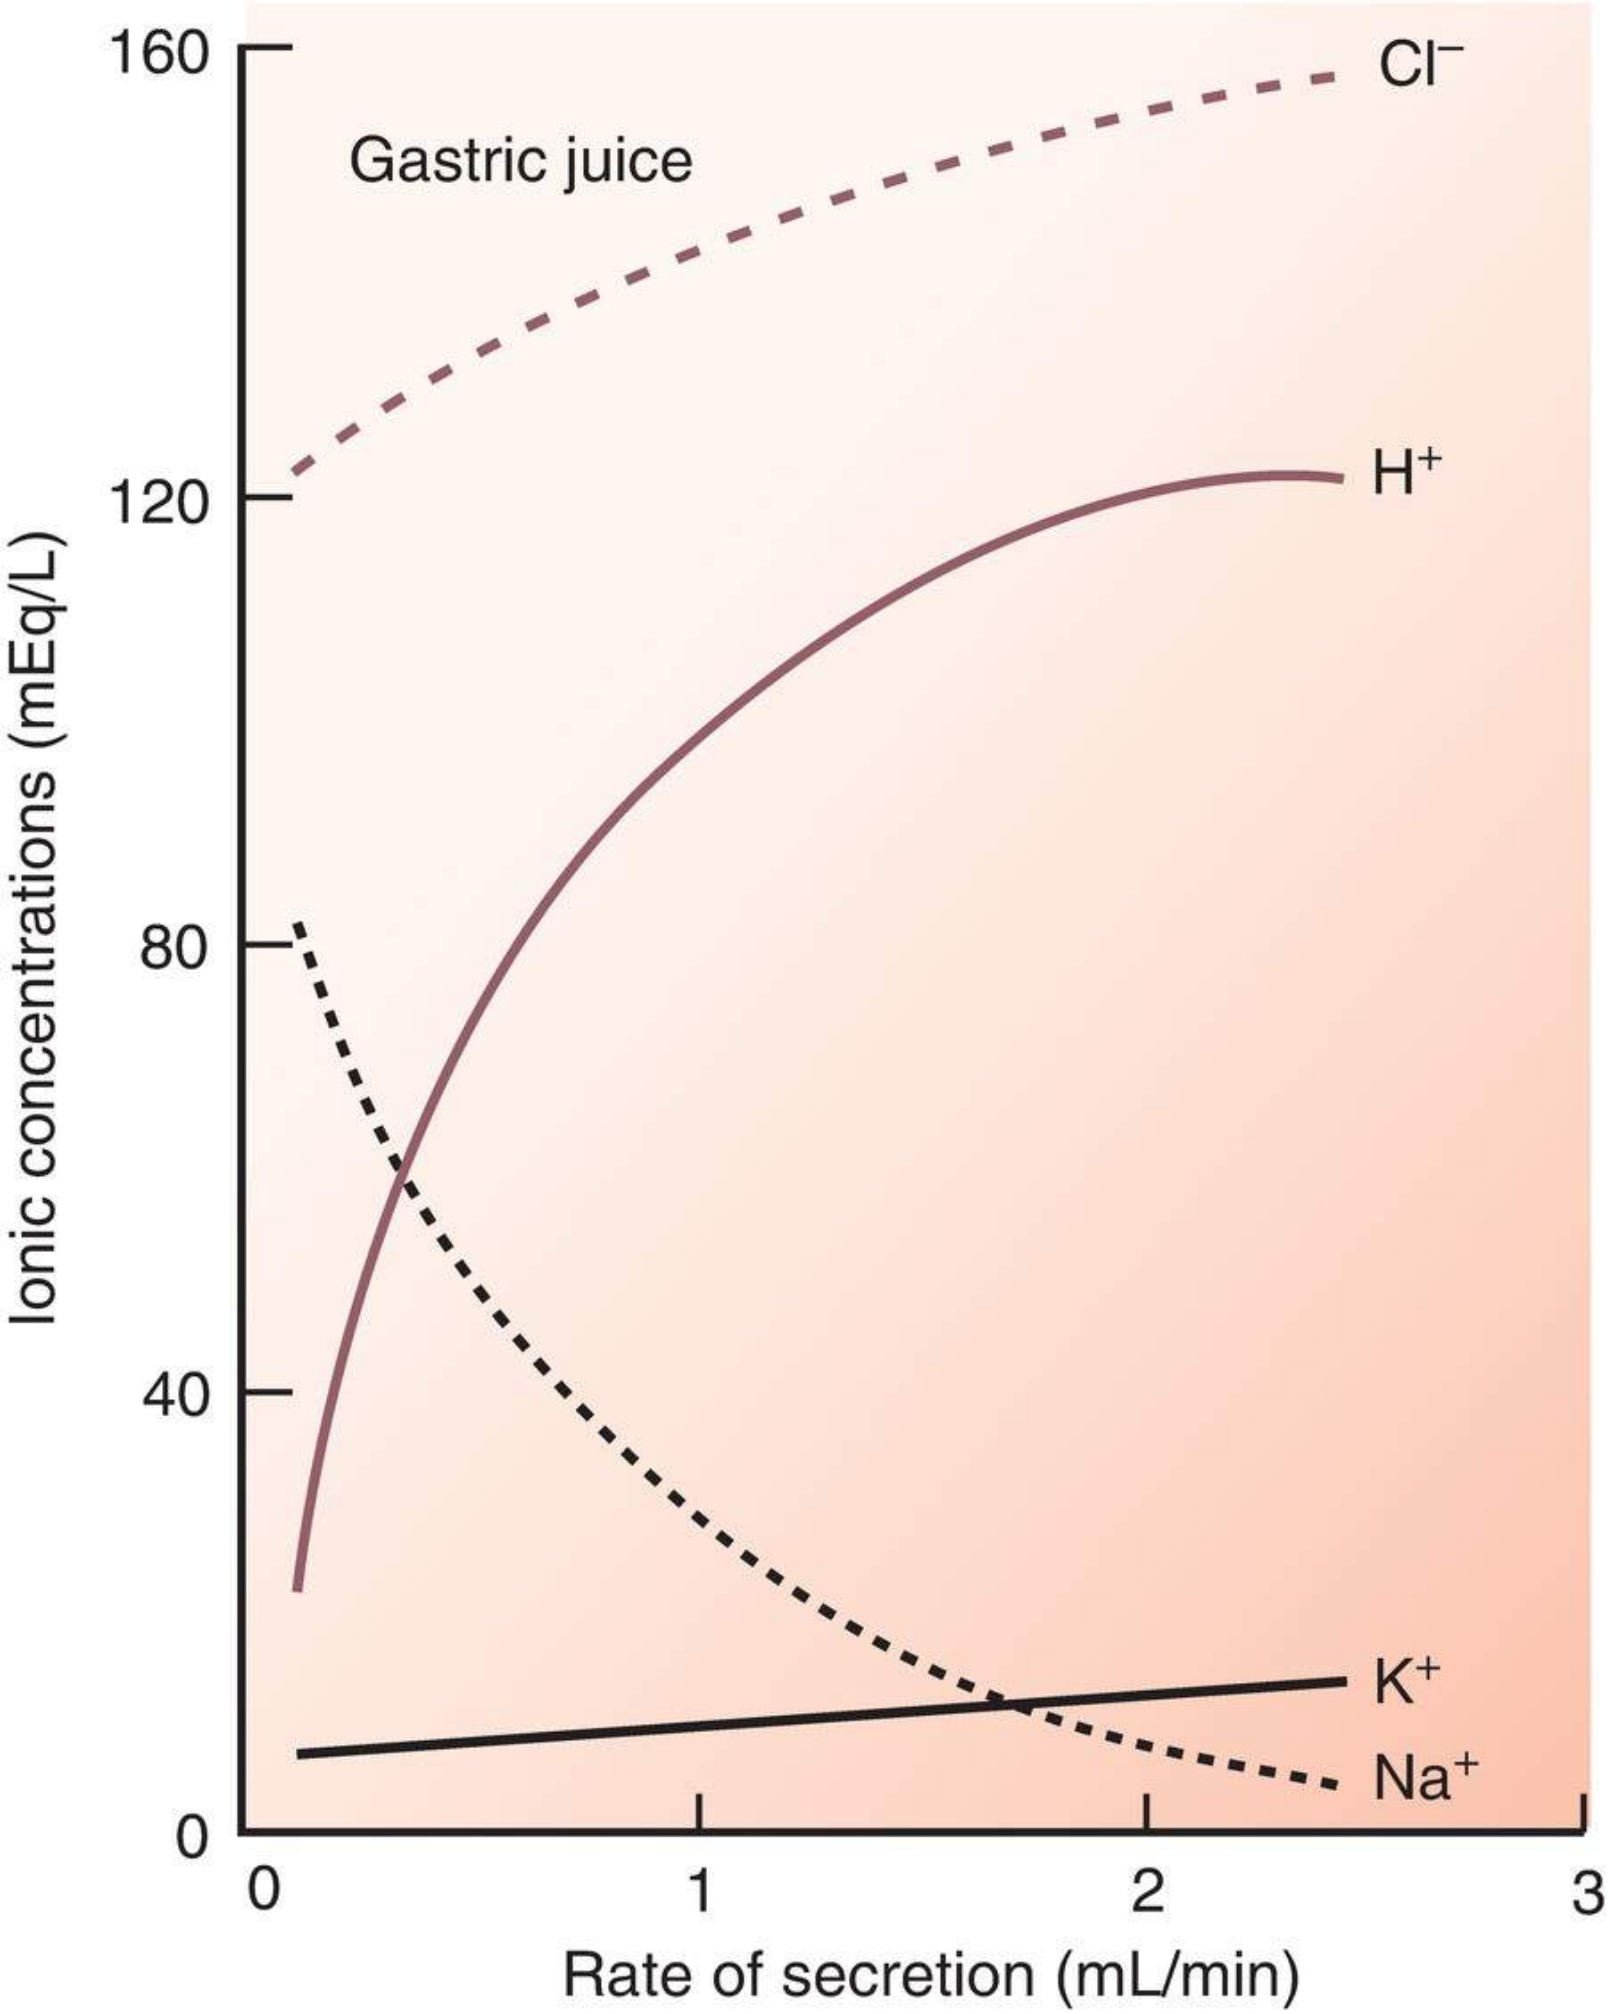

Figure 25.5 Rate of secretion affects the composition of the gastric juice. The concentration of

electrolytes in the gastric juice is depicted in a healthy young adult male. The K^+ and H^+ ion concentration parallel the secretion rates.

Pepsin is the main gastric enzyme in protein digestion.

The enzymes secreted in the stomach are called *gastric enzymes* and include **pepsin**, **gastric amylase**, **gastric lipase**, and **intrinsic factor**. *Pepsin*, an **endopeptidase**, is the main gastric enzyme that cleaves proteins into smaller peptides. The optimal pH for pepsin activity is 1.8 to 3.5; therefore, it is extremely active in the highly acidic medium of gastric juice. Pepsinogen is formed when HCl in the gastric lumen cleaves pepsinogen. Pepsin also catalyzes its own formation from pepsinogen.

Gastric amylase degrades starch, and gastric lipase acts almost exclusively on butter fat. Intrinsic factor, produced by the parietal cells, is necessary for the absorption of vitamin B_{12} in the terminal ileum. *Gastric lipase*, like lingual and pancreatic lipases, digests fats. *Intrinsic factor* is involved in vitamin B_{12} absorption in the intestine.

Gastric secretion is under neural and hormonal control.

Gastric secretion is mediated through neural and hormonal pathways. Vagus nerve stimulation is the neural effector; histamine and gastrin are the hormonal effectors (Fig. 25.6). Parasympathetic pathways in the vagus nerve connect to the stomach's enteric system. The enteric neurons have stimulatory connections with three cell types in the stomach: the *parietal cells*, the *G cells*, and the **enterochromaffin-like cells** (**ECL cells**), a type of neuroendocrine cells located mostly in the acid-secreting regions of the stomach. Enteric nerve endings release several different neurotransmitters including **acetylcholine** (**ACh**) and **gastrin-releasing peptide** (**GRP**) that stimulate secretion of HCl and **vasoactive intestinal polypeptide** (**VIP**) that inhibits HCl secretion. ACh directly stimulates HCl secretion by binding to muscarinic receptors (M_3) on the parietal cells, which elevates intracellular Ca^{2+}. GRP stimulates G cells to release gastrin.

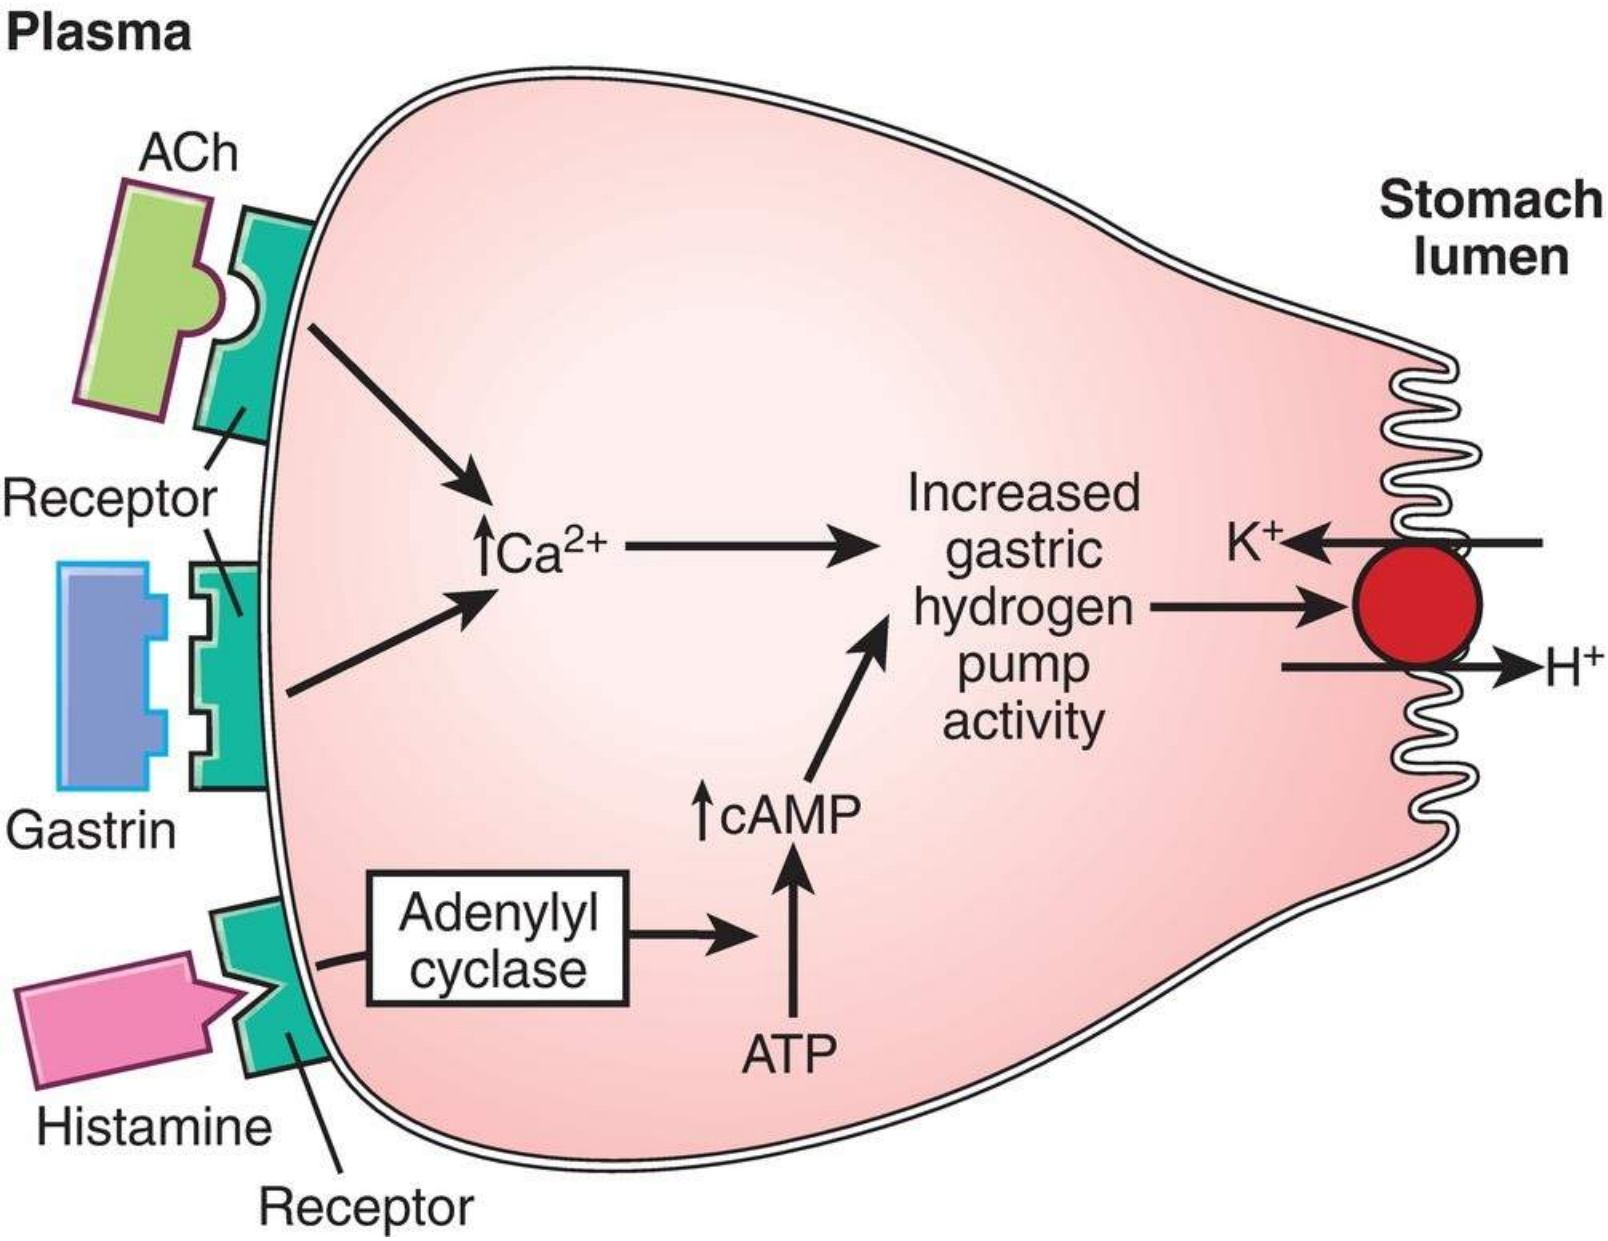

Figure 25.6 Acid secretion by the parietal cell is under neural and hormonal control. Vagus nerve stimulation results in the release of Ach. Histamine and gastrin are hormones. Acetylcholine (ACh), histamine, and gastrin stimulate acid secretion. cAMP, cyclic adenosine monophosphate; ATP, adenosine

triphosphate.

Several hormones including **histamine** and gastrin are effectors of HCl secretion (see Fig. 25.6). Parietal cells possess special histamine receptors, **H_2 receptors**, whose stimulation increases HCl secretion. ECLs are believed to be the source of this histamine, but the mechanisms that stimulate ECLs to release histamine are poorly understood. The effectiveness of cimetidine, an H_2 blocker, in reducing HCl secretion has indirectly demonstrated the importance of histamine as an effector of HCl secretion. H_2 blockers are commonly used for the treatment of peptic ulcer disease or GERD. Ranitidine, a longer-acting H_2-receptor antagonist with fewer side effects, has largely replaced cimetidine. Gastrin binds a G protein–coupled cholecystokinin (CCK_2) receptor on parietal cells, which elevates intracellular Ca^{2+} that in turn stimulates HCl release. Gastrin also stimulates histamine release by ECLs.

The effects of each of these three stimulants (ACh, gastrin, and histamine) augment those of the others, a phenomenon known as **potentiation**. Potentiation occurs when the effect of two stimulants is greater than the effect of either stimulant alone. For example, the interaction of gastrin and ACh molecules with their respective receptors results in an increase in intracellular Ca^{2+} concentration, and the interaction of histamine with its receptor results in an increase in cellular **cyclic adenosine monophosphate** (**cAMP**) production. The increased intracellular Ca^{2+} and cAMP interact in numerous ways to stimulate the gastric H^+/K^+-ATPase, which increases HCl secretion (see Fig. 25.6). Exactly how the increase in intracellular Ca^{2+} and cAMP enhances the effect of the other in stimulating HCl secretion is not well understood.

Gastric hormones inhibit acid secretion.

The inhibition of HCl secretion is physiologically important for two reasons. First, HCl secretion is important only during the digestion of food. Second, excess HCl can damage the gastric and the duodenal mucosal surfaces, causing ulcerative conditions. The body has an elaborate system for regulating HCl secretion by the stomach. Gastric luminal pH is a sensitive regulator of HCl secretion. Proteins in food provide buffering in the lumen; consequently, the gastric luminal pH is usually above 3 after a meal. However, if the buffering capacity of protein is exceeded or if the stomach is empty, the pH of the gastric lumen will fall below 3. When this happens, the endocrine cells (**D cells**) in the antrum secrete *somatostatin*, which inhibits the release of gastrin and, thus, HCl secretion.

Another mechanism for inhibiting HCl secretion is acidification of the duodenal lumen. Acidification stimulates the release of **secretin**, which inhibits the release of gastrin and several peptides, collectively known as **enterogastrones**. Enterogastrones are released by intestinal endocrine cells. Acid, fatty acids, and hyperosmolar solutions in the duodenum stimulate the release of enterogastrones. Two such hormones, **gastric inhibitory peptide** (**GIP**) and **cholecystokinin** (**CCK**), inhibit HCl secretion. CCK is released by "**I" cells** stimulating the release of *gastric somatostatin*, which then inhibits HCl.

PANCREATIC SECRETION

The pancreas is located adjacent to the duodenum and functions as both an endocrine and an exocrine gland (Fig. 25.7). The **endocrine** gland secretes several important hormones including insulin, glucagon, and somatostatin. (The endocrine function is further discussed in Chapter 34.) The **exocrine** gland secretes digestive enzymes that pass along the pancreatic duct and into the small intestine. These enzymes break down components present in the human diet including carbohydrates, proteins, fats, DNA, and RNA. The pancreatic enzymes responsible for protein digestion are **trypsin** (the most abundant), **chymotrypsin**, and *carboxypolypeptidase*. *Trypsin* and *chymotrypsin* cleave proteins into polypeptides, and *carboxypolypeptidase* cleaves the polypeptides into amino acids. **Pancreatic amylase** digests carbohydrates, and **pancreatic lipase** is the main enzyme for fat digestion (Table **25.2**). Some pancreatic enzymes are secreted as proenzymes, which are activated in the duodenal lumen to form the active enzymes. (The digestion of nutrients by these enzymes is discussed later in this chapter.).

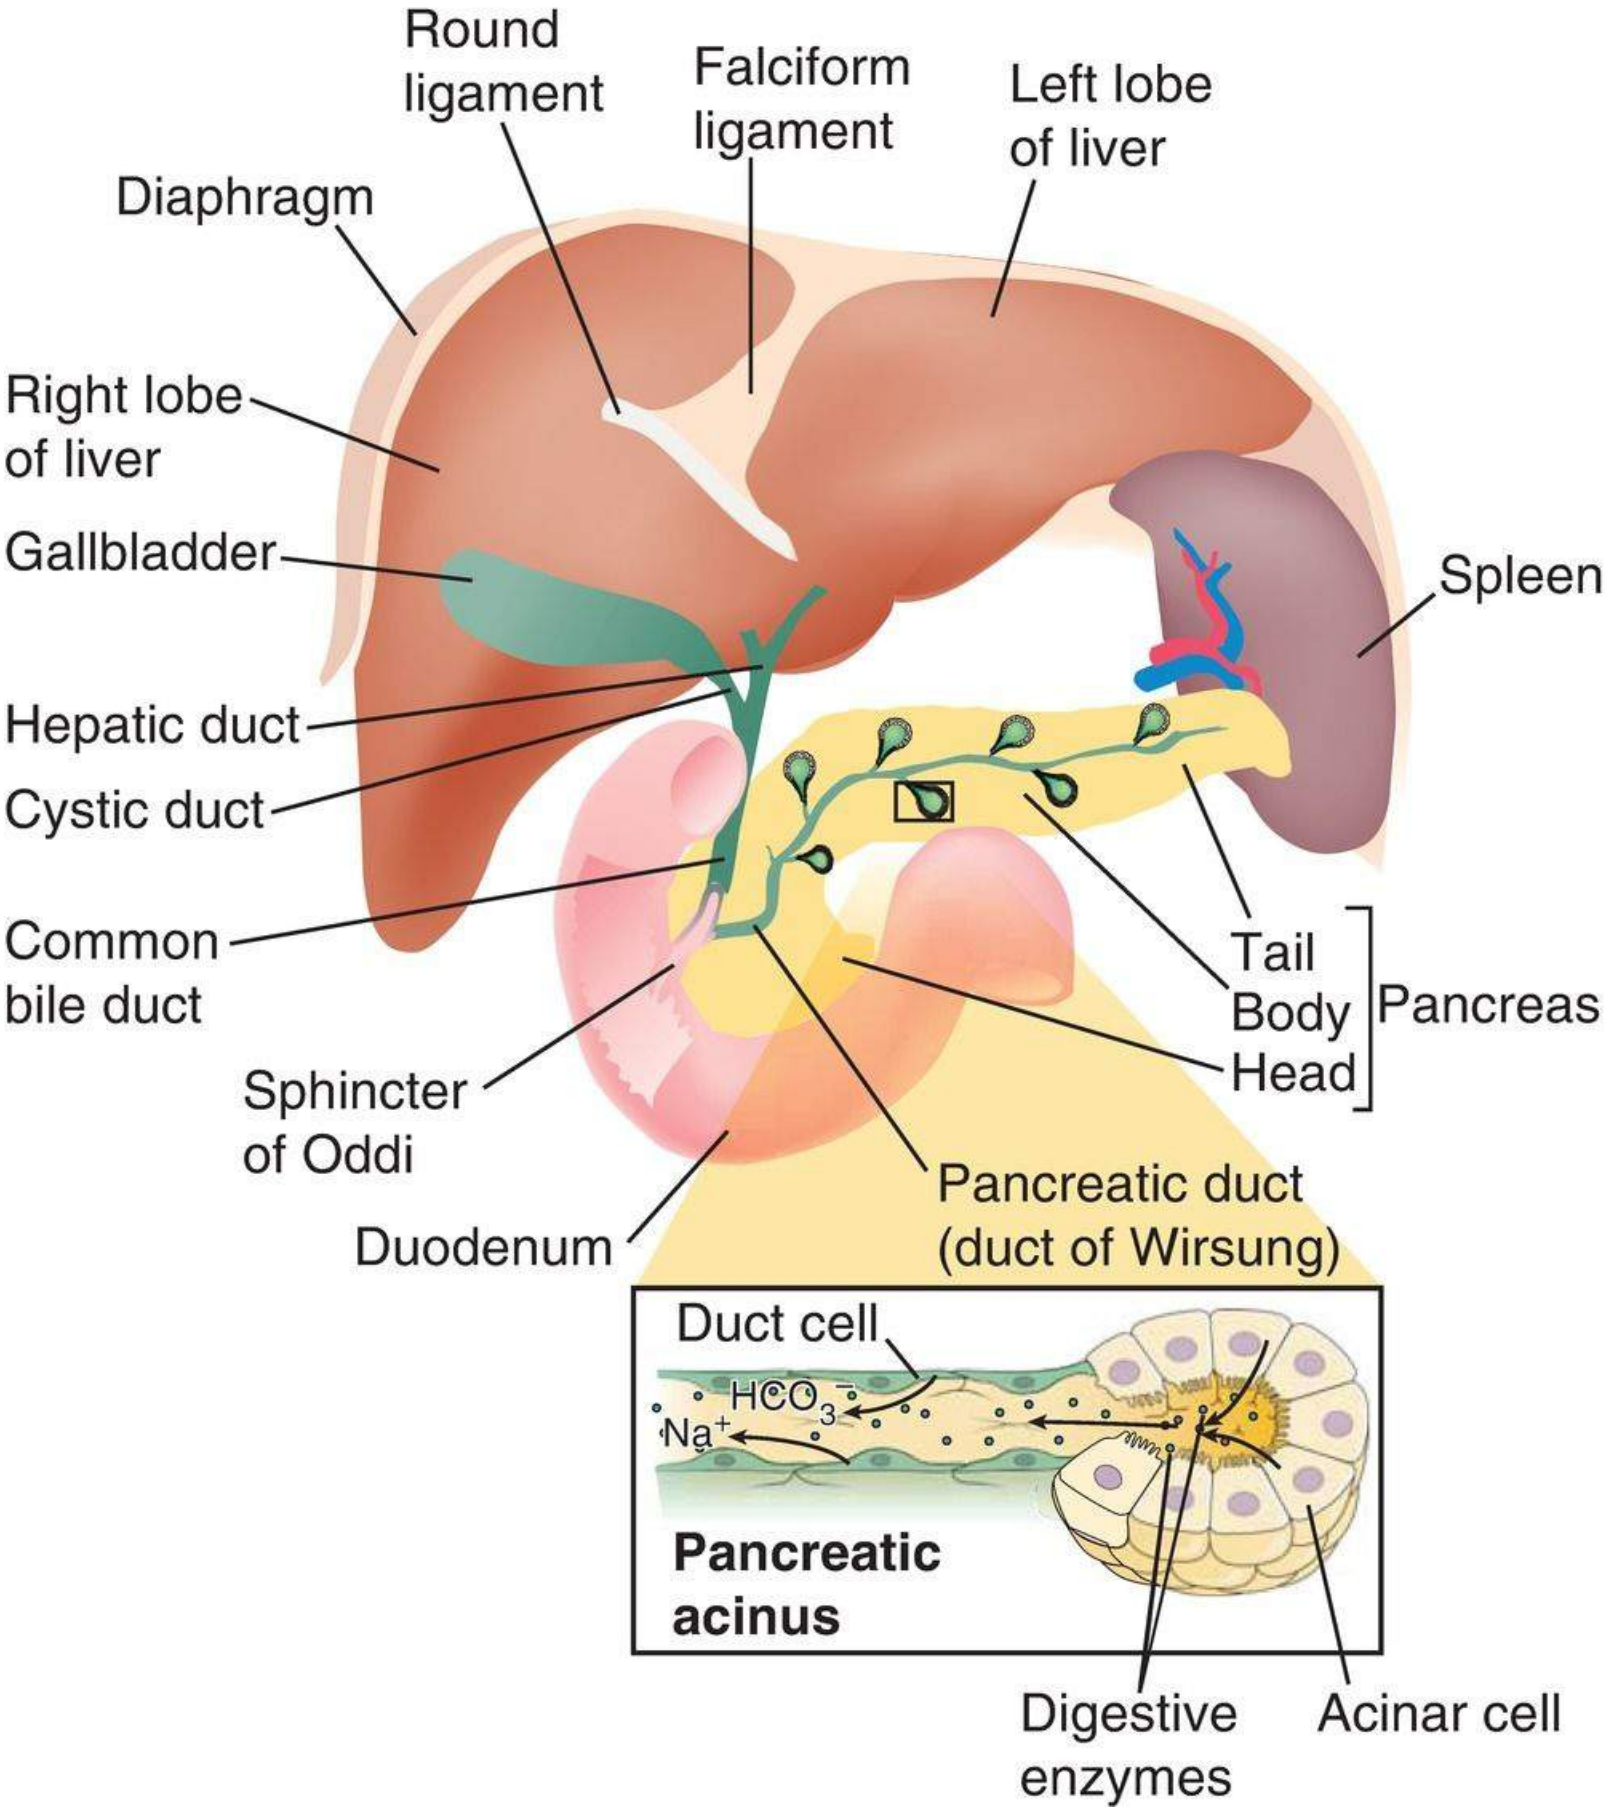

Figure 25.7 The pancreas performs both exocrine and endocrine functions. The exocrine cells of the pancreas secrete digestive juices into the duodenal lumen. Digestive enzymes are secreted by acinar cells, and an aqueous $NaHCO_3$ solution is secreted by duct cells (*inset*).

TABLE 25.2 The Pancreas is the Main Digestive Gland of the Body

Enzyme Secreted	Hydrolytic Action
Trypsin	Protease that breaks down proteins at the basic amino acids
Chymotrypsin	Protease that breaks down proteins at the aromatic amino acids
Lipase	Degrades triglycerides into fatty acids and glycerol
Carboxypeptidase	Protease that takes off the terminal acid group from a protein
Elastases	Degrade the protein elastin and some other proteins
Nucleases	Degrade nucleic acids, like DNAse and RNAse
Pancreatic amylase	Besides starch and glycogen, degrades most other carbohydrates; humans lack the enzyme to digest the carbohydrate cellulose

The chyme leaving the stomach is acidic. It needs to be neutralized to prevent damage to the duodenal epithelium and to bring the luminal contents to a near neutral pH, favorable for enzymes arriving from the pancreas. Pancreatic secretions contain HCO_3^- that raises the duodenal lumen pH.

Pancreatic secretion occurs in three phases.

Pancreatic secretion, like gastric secretion, occurs in three phases: (1) cephalic, (2) gastric, and (3) intestinal phase. Table 25.3 summarizes the stimulation of pancreatic secretion and secretory regulation by various hormonal and neural factors. The cephalic phase, stimulation of pancreatic secretion, is mainly mediated by direct efferent impulses sent by vagal centers in the brain to the pancreas and, to a minor extent, by the indirect effect of parasympathetic stimulation of gastrin release. The gastric phase is initiated when food enters the stomach and distends it. The vagovagal reflex then stimulates pancreatic secretion. Gastrin may also be involved in this phase. The most important phase, the intestinal phase, is initiated by the entry of acidic chyme from the stomach into the small intestine, which stimulates the intestinal endocrine cells. (See "Pancreatic enzyme secretion is under neural and hormonal control.")

TABLE 25.3 Factors Regulating Pancreatic Secretion after a Meal

Phase	Stimulus	Mediators	Response
Cephalic	Thought of food, smell, taste chewing, and swallowing	Release of ACh and gastrin by vagal stimulation	Increased secretion, with greater effect on enzyme output
Gastric	Protein in food	Gastrin	Increased secretion, with greater effect on enzyme output
	Gastric distention	ACh release by vagal stimulation	Increased secretion, with a greater effect on enzyme output
Intestinal	Acid in chyme	Secretin	Increased H_2O and HCO_3^- secretion
	Long-chain fatty acids	CCK and vagovagal reflex	Increased secretion, with greater effect on enzyme output
	Amino acids and peptides	CCK and vagovagal reflex	Increased secretion, with greater effect on enzyme output

Ach, acetylcholine; CCK cholecystokinin.

Pancreatic enzymes are produced in the acinar cells of the exocrine pancreas.

Like salivary glands, the exocrine pancreas is composed of numerous acini. Unlike the previously discussed salivary glands that contain two types of acinar cells, the pancreatic acini are composed of a single layer of pyramidal **acinar cells** (see Fig. 25.7). Both salivary and pancreatic acinar cells secrete an ion-rich fluid along with proteins and have elaborate RER and Golgi as well as apical zymogen granules. A few **centroacinar cells** line the lumen of the pancreatic acinus and modify the electrolyte composition of the secretion. Because the processes involved in the secretion or uptake of ions are active, centroacinar cells have numerous mitochondria.

The acini empty their secretions into intercalated ducts, which join to form intralobular and then interlobular ducts. The interlobular ducts empty into two pancreatic ducts: a major duct, the duct of Wirsung, and a minor duct, the duct of Santorini. The duct of Santorini enters the duodenum more proximally than does the duct of Wirsung, which enters the duodenum usually together with the common bile duct. A ring of smooth muscle, the **sphincter of Oddi**, surrounds the opening of the Wirsung and bile ducts at the point of entry into the duodenum and regulates the flow of bile and pancreatic juice into the duodenum. The sphincter also prevents the reflux of intestinal contents into the ducts (Clinical Focus 25.1).

CLINICAL FOCUS 25.1

Peptic Ulcers: When Bacteria Break the Barrier

Peptic ulcers, also known as **peptic ulcer disease**, are erosions of the mucosal lining of the stomach. Ulcerative lesions occur when the mucus barrier is disrupted, and pepsin and hydrochloric acid attack the stomach lining instead of digesting the food. Peptic ulcers affect ~4 million patients in the United States, where duodenal ulcers predominate. In Japan, however, gastric ulcers are more prevalent.

Symptoms include bloating, fullness, and abdominal pain. The symptoms are exacerbated with the ingestion of food (intensifies 3 hours after eating). In contrast, duodenal ulcers are classically relieved by food. If gastric ulcers go untreated, symptoms can escalate to include nausea and vomiting of blood that is accompanied by loss of appetite and weight loss. Many patients confuse heartburn with gastric ulcers. Heartburn, a burning sensation in the chest, is not associated with gastric ulcers. Heartburn is associated with regurgitation of gastric acid (gastric reflux), which is a major symptom of gastroesophageal reflux disease. Ulcers can also be caused or worsened by drugs such as aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit cyclooxygenase and most glucocorticoids (e.g., dexamethasone and prednisolone) for the treatment of arthritis. NSAIDs interfere with prostaglandin-mediated defense mechanisms against gastric acidity, mucus production, and bicarbonate secretion. Gastrointestinal bleeding is the most common complication. Sudden large bleeding can be life threatening and occurs when an ulcer erodes a blood vessel.

In the 1990s, a surprising discovery was made in the field of peptic ulcer disease linking

Helicobacter pylori infection to the cause of gastric and duodenal ulcers. As many as 70% to 90% of peptic ulcers are linked to *H. pylori*, a spiral-shaped bacterium that lives in the acidic environment of the stomach. *H. pylori* appears to be protected by producing large quantities of urease, which hydrolyzes urea to produce ammonia. The ammonia neutralizes acid in the gastric lumen, thus protecting the bacteria from the injurious effects of HCl. The underling mechanism that causes ulcerations appears to be the release of bacterial toxins that leads to chronic inflammation of the gastric mucosal lining. The immune system appears to be unable to clear the infection, despite the appearance of antibodies.

The investigator, Dr. Barry Marshall, who discovered this link, was awarded the Nobel Prize for Medicine and Physiology in 2005 for his pioneering discovery.

Recently, it has been demonstrated that H_2-receptor antagonists (i.e., cimetidine and ranitidine) have no effect on *H. pylori* infection. In contrast, omeprazole (an inhibitor of the H^+/K^+-ATPase) appears to be bacteriostatic. A combined therapy using omeprazole and the antibiotic amoxicillin appears to be quite effective in the eradication of *H. pylori* in 50% to 80% of patients with peptic ulcer disease, resulting in a significant reduction of duodenal ulcer recurrence. ■

Pancreatic secretions are rich in bicarbonate ions.

Pancreatic juice contains HCO_3^- and H_2O in addition to digestive enzymes (Fig. 25.8). The pancreas secretes about 1 L/day of HCO_3^--rich fluid to neutralize the acidic chyme that enters the duodenum. Unlike salivary fluid, the osmolality of pancreatic fluid equals that of plasma at all secretion rates. When compared to plasma, pancreatic juice has similar Na^+ and K^+ concentrations, is enriched with HCO_3^-, and has a relatively low Cl^- concentration. When the pancreas is stimulated, HCO_3^- concentration can increase to about five times that of plasma, reaching a maximal concentration close to 140 mEq/L and a pH of 8.2. A reciprocal relationship exists between the Cl^- and HCO_3^- concentrations in pancreatic juice. As the HCO_3^- concentration increases with secretion rate, the Cl^- concentration falls accordingly, resulting in a combined total anion concentration that remains relatively constant (150 mEq/L) regardless of the pancreatic secretion rate.

Figure 25.8 Pancreatic fluid pH and electrolytes are altered with flow. Pancreatic fluid is rich in bicarbonate ions. The HCO_3^- concentration and, hence, the pH parallel the increased rates of secretion. *Note*: Na^+, K^+, and pancreatic osmolality are independent of flow.

Two separate mechanisms have been proposed to explain the secretion of an HCO_3^--rich juice by the pancreas and the changes in HCO_3^- concentration. The first proposes that some cells, probably the acinar cells, secrete a plasma-like fluid containing predominantly Na^+ and Cl^-, whereas other cells, probably the centroacinar and duct cells, secrete an HCO_3^--rich solution when stimulated. Depending on the different rates of cellular secretion, the pancreatic juice can be rich in either HCO_3^- or Cl^-. The second depicts the primary secretion as rich in HCO_3^-. As the HCO_3^- solution moves down the ductal system, HCO_3^- ions are exchanged for Cl^- ions. When the flow is fast, there is little time for ion exchange, so the concentration of HCO_3^- is high. The opposite is true when the flow is slow.

The secretion of electrolytes by pancreatic duct cells is depicted in Figure 25.9. An Na^+/H^+ exchanger is located in the basolateral cell membrane. The energy required to drive the exchanger is provided by the Na^+/K^+-ATPase–generated Na^+ gradient. CO_2 diffuses into the cell and combines with H_2O to form H_2CO_3, a reaction catalyzed by carbonic anhydrase. H_2CO_3 dissociates to H^+ and HCO_3^-. The Na^+/H^+ exchanger extrudes the H^+, and HCO_3^- is exchanged for luminal Cl^- via a Cl^-/HCO_3^- exchanger. Also located in the luminal cell membrane is a protein called **cystic fibrosis transmembrane conductance regulator** (**CFTR**), an ion channel belonging to the ABC (**adenosine triphosphate** [**ATP**]-**binding cassette**) family of proteins. Regulated by ATP, its major function is to secrete Cl^- ions into the lumen. These ions are used by the Cl^-/HCO_3^- exchanger. The Na^+/K^+-ATPase removes intracellular Na^+ entering through the Na^+/H^+ antiporter. Na^+ from the interstitial space follows secreted HCO_3^- by diffusing through a paracellular path (between the cells). Movement of H_2O into the duct lumen is passive and driven by the osmotic gradient. The net result of pancreatic HCO_3^- secretion is the release of H^+ into the plasma; thus, pancreatic secretion is associated with an **acid tide** in the plasma.

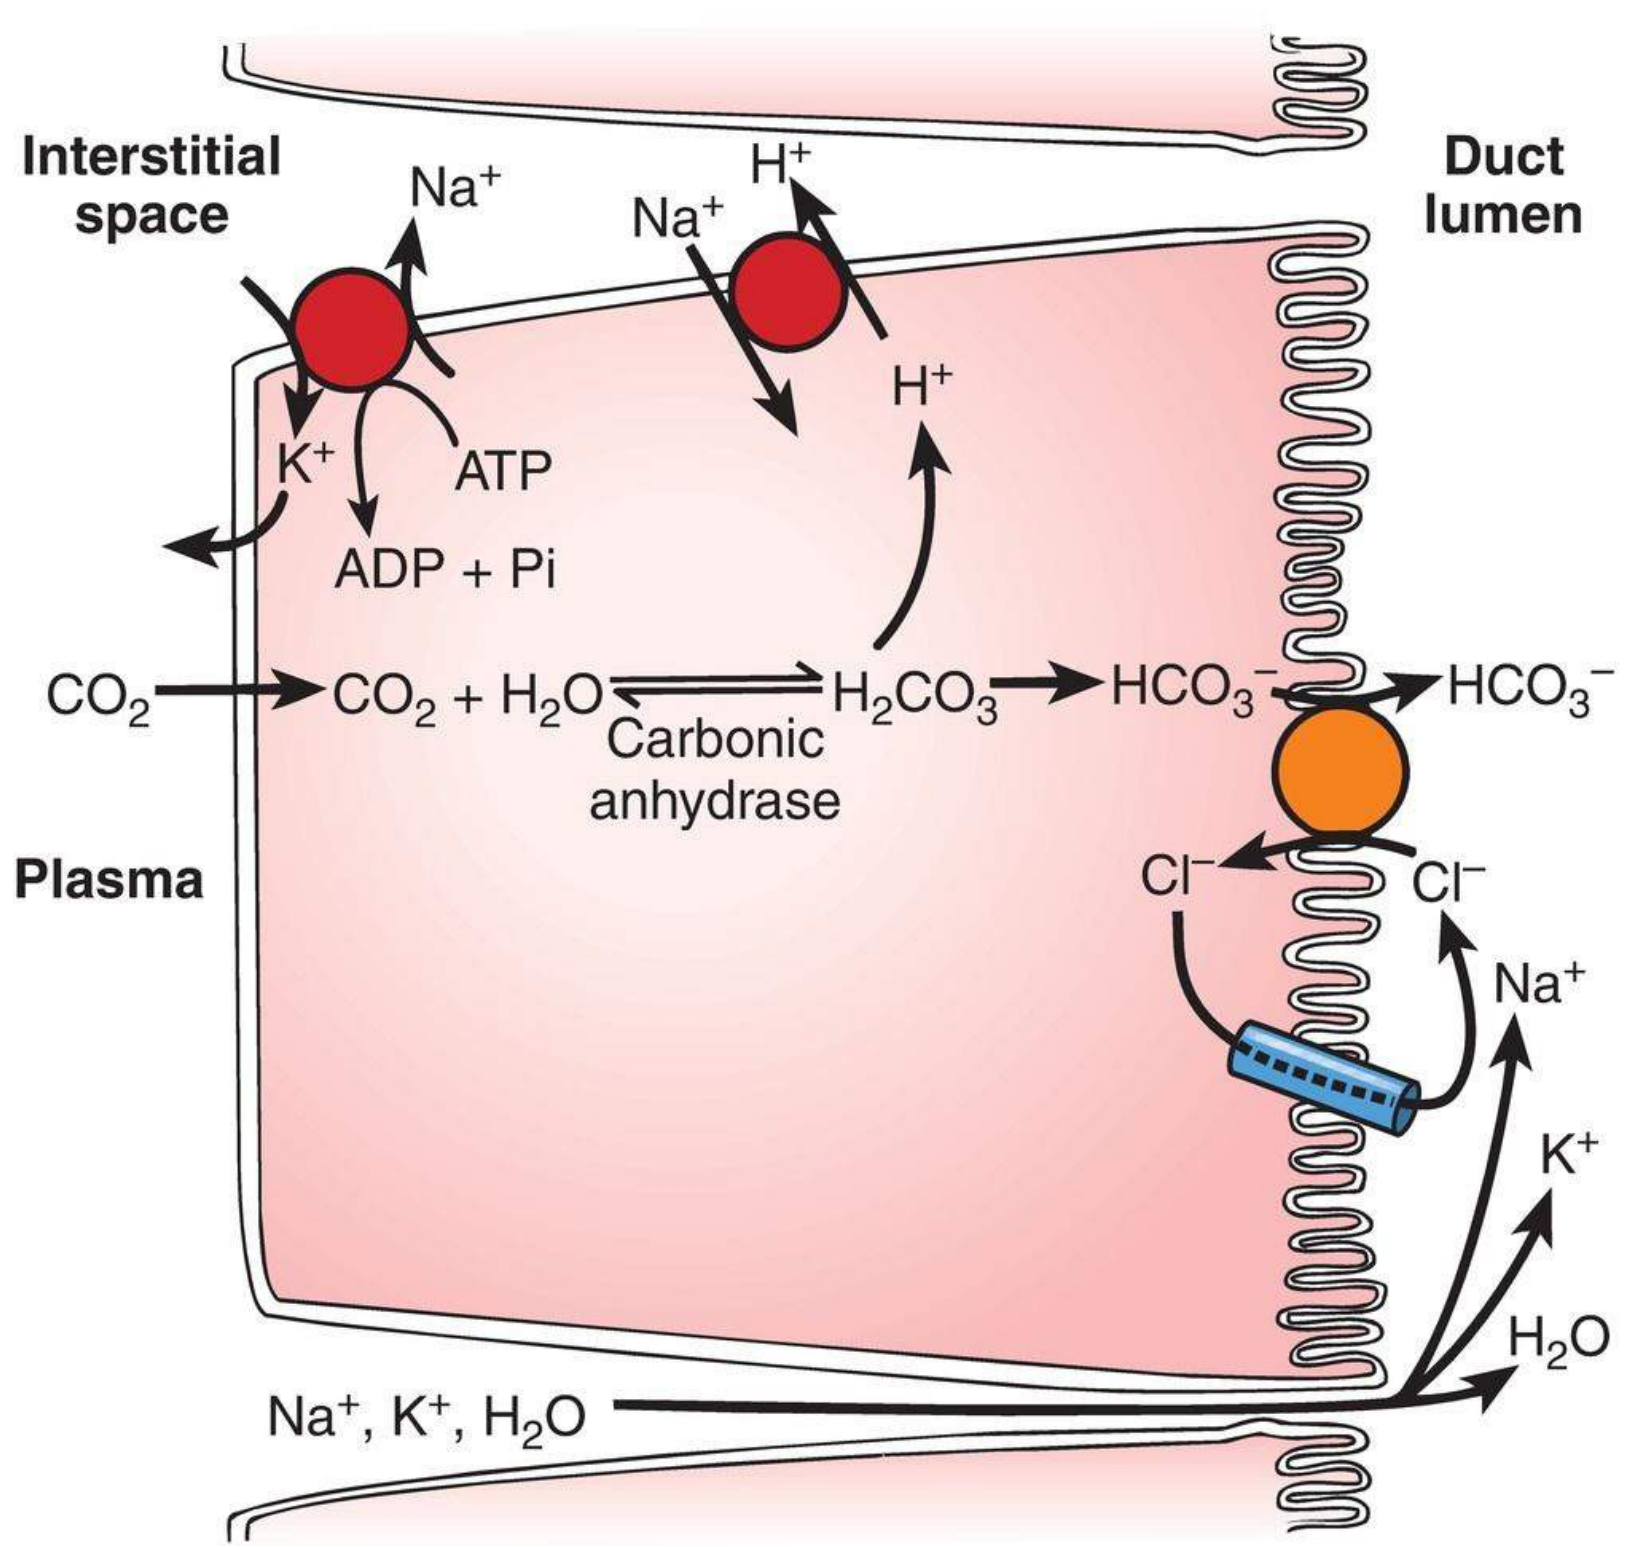

Figure 25.9 Pancreatic duct cells secrete electrolytes and water into pancreatic fluid. The above model depicts the mechanism for electrolyte secretion by pancreatic duct cells. The luminal membrane Cl^- channel is CFTR (cystic fibrosis transmembrane conductance regulator). ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

Pancreatic enzyme secretion is under neural and hormonal control.

Pancreatic secretion is mediated through neural and hormonal pathways that use Ach, CCK, and secretin as mediators. Neural stimulation occurs when **ACh**-releasing parasympathetic fibers in the vagus nerve stimulate pancreatic secretion, which results predominantly in an increase in enzyme secretion—fluid and HCO_3^- secretion are marginally stimulated or unchanged. Sympathetic nerve fibers mainly innervate the blood vessels supplying the pancreas and cause vasoconstriction. Stimulation of the sympathetic nerves neither stimulates nor inhibits pancreatic secretion, most likely due to the reduction in blood flow.

Circulating GI hormones, particularly **secretin** and **CCK**, greatly influence pancreatic secretion of electrolytes and enzymes. Both hormones are produced by the small intestine and bind receptors in the pancreas. *Secretin* is released during the intestinal phase by **S cells** (endocrine cells in the intestinal mucosa). The *secretin* concentration in the plasma increases when the luminal pH in the duodenum decreases. *Secretin* tends to stimulate a HCO_3^--rich secretion. Exposure of the intestinal mucosa to long-chain fatty acids (lipid digestion products) and free amino acids stimulates the release of CCK by the "**I" cells** (endocrine cells in the intestinal mucosa). Circulating CCK and parasympathetic stimulation increase the secretion of pancreatic enzymes through a vagovagal reflex.

Hormones that are structurally similar to secretin and CCK also have similar effects. For example, VIP, structurally similar to secretin, stimulates the secretion of HCO_3^- and H_2O. However, VIP produces a weaker pancreatic response when given together with secretin than when secretin is given alone. Gastrin, structurally similar to CCK, is only a weak agonist for pancreatic enzyme secretion.

Potentiation, as previously described for gastric secretion, also exists in the pancreas. Its effect in pancreatic secretion is a result of the different receptors binding ACh, CCK, and secretin. Secretin binding triggers an increase in adenylyl cyclase activity, which, in turn, stimulates the formation of cAMP (Fig. 25.10). ACh, CCK, and the neuropeptides gastrin-releasing peptide (GRP) and substance P bind to their respective receptors and trigger the release of Ca^{2+} from intracellular stores. The increase in intracellular Ca^{2+} and cAMP formation results in an increase in pancreatic enzyme secretion. The mechanism by which this occurs is not well understood.

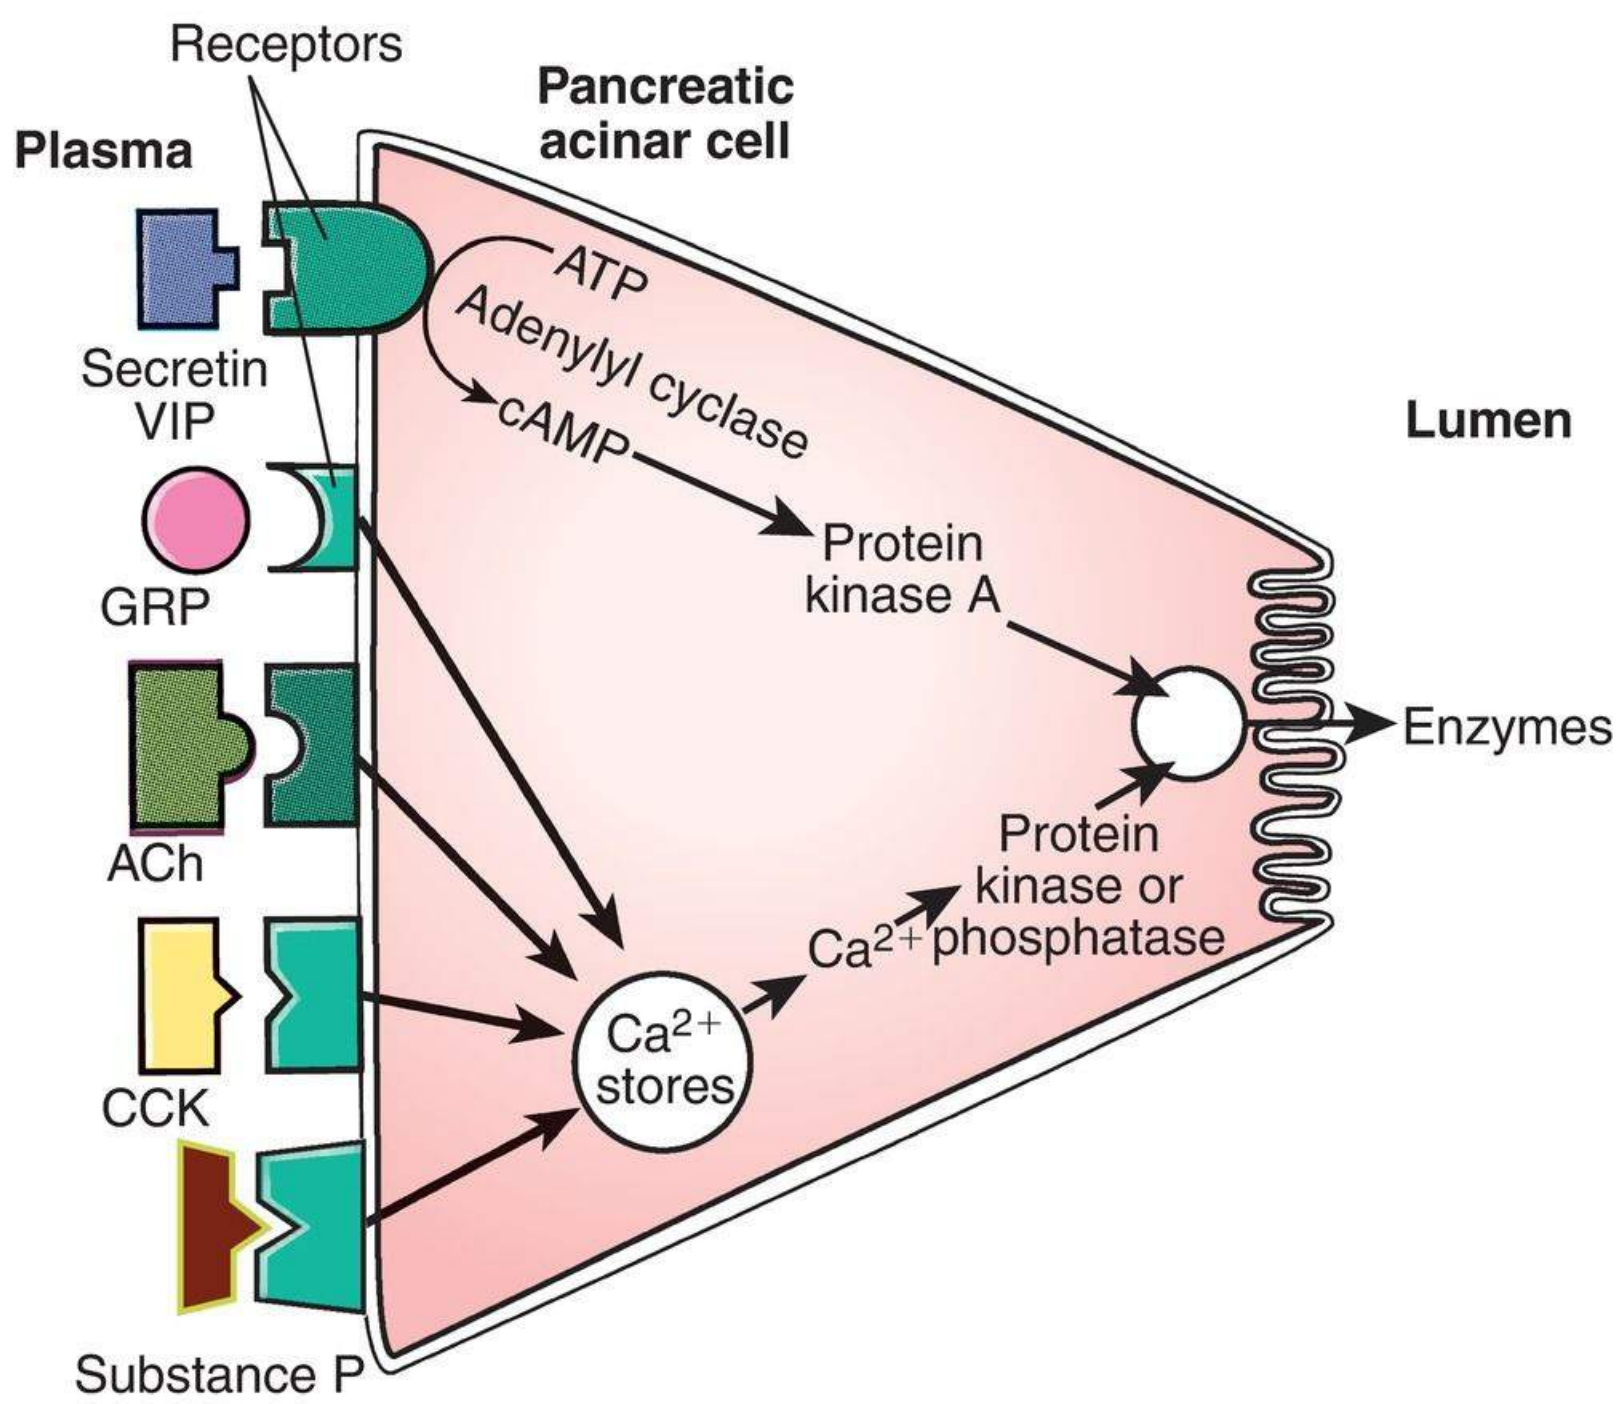

Figure 25.10 Calcium release from intracellular stores stimulates pancreatic enzyme secretion. This diagram illustrates the mechanisms involved in pancreatic secretion by hormones and neurotransmitters. ACh, acetylcholine; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; CCK, cholecystokinin; GRP, gastrin-releasing peptide; VIP, vasoactive intestinal peptide.

BILIARY SECRETION

Bile, a dark green to yellowish brown fluid produced by the **hepatocytes** in the liver, drains through the bile ducts penetrating the liver (see Chapter 26). Bile facilitates the digestion of lipids in the small intestine by emulsifying fat and forming aggregates around fat droplets called **micelles**. The dispersion of fat droplets into micelles greatly increases the surface area, enhancing the action of pancreatic lipase. Bile is stored in the gallbladder and, under nervous and hormonal control, is discharged into the duodenum. Depending on body size, the human liver can produce close to 1 L of bile a day. Bile contains bile salts, bile pigments (e.g., bilirubin), cholesterol, phospholipids, and proteins. Bile performs several important functions. For example, bile salts play an important role in the intestinal absorption of lipid. Bile salts are derived from cholesterol and, therefore, constitute a path for its excretion. Biliary secretion is an important route for the excretion of bilirubin from the body.

Bile secretion is under neural and hormonal control.

Parasympathetic and sympathetic nerves supply the biliary system. Parasympathetic (vagal) stimulation results in contraction of the gallbladder and relaxation of the sphincter of Oddi as well as increased bile formation. Bilateral vagotomy results in reduced bile secretion after a meal, suggesting that the PNS plays a role in mediating bile secretion. Stimulation of the SNS results in reduced bile secretion and relaxation of the gallbladder.

Gastrin stimulates bile secretion directly by affecting the liver and indirectly by stimulating increased HCl production that results in increased secretin release. When the mucosa of the small intestine is exposed to acidic chyme, it releases secretin. Secretin stimulates HCO_3^- secretion by the cells lining the bile ducts. As a result, bile contributes to the neutralization of acid in the duodenum.

Steroid hormones (e.g., estrogen and some androgens) inhibit bile secretion, and reduced bile secretion is a side effect associated with the therapeutic use of these hormones (e.g., administration of oral contraceptives or postmenopausal hormone replacement therapy). During pregnancy, high circulating levels of estrogen can reduce bile acid secretion.

Cholesterol metabolism in the liver involves the formation of bile acids.

Bile acids are formed in the liver by the cytochrome P450 oxidation of cholesterol. During the conversion, hydroxyl groups (OH^-) and a carboxyl group (COOH) are added to the steroid nucleus. Bile acids are classified as primary or secondary. The hepatocytes synthesize the *primary bile acids*, which include **cholic acid** and **chenodeoxycholic acid**. When bile enters the GI tract, bacteria present in the lumen convert primary bile acids to *secondary bile acids* by dehydroxylation. Cholic acid is converted to **deoxycholic acid** and chenodeoxycholic acid to **lithocholic acid**.

At a neutral pH, bile acids are mostly ionized and are referred to as **bile salts**. Conjugated bile acids ionize more readily than do unconjugated bile acids and, thus, usually exist as salts of various cations (e.g., sodium glycocholate). Bile salts are more polar than bile acids and have greater difficulty penetrating cell membranes. Consequently, the small intestine absorbs bile salts much more poorly than it does bile acids. This property of bile salts contributes significantly to their integral role in the intestinal absorption of lipid. Therefore, it is important that the small intestine absorb bile salts only after lipid absorption is completed.

The major lipids in bile are phospholipids and cholesterol. The predominant phospholipid species is phosphatidylcholine (lecithin). The phospholipid and cholesterol concentrations of hepatic bile are 0.3 to 11 mmol/L and 1.6 to 8.3 mmol/L, respectively. Because the gallbladder absorbs a significant amount of H_2O and electrolytes, the concentrations of these lipids in the gallbladder bile are even higher. Cholesterol in bile is responsible for the formation of cholesterol gallstones.

Total bile flow is composed of the ductular secretion and the canalicular bile flow. Cells lining the bile ducts actively secrete HCO_3^- into the lumen, which results in the movement of H_2O into the lumen. A cAMP-dependent Cl^- channel that secretes Cl^- into the ductule lumen may also contribute to ductular secretion of fluid. The electrolyte composition of human bile collected from the hepatic ducts is similar to that of blood plasma, except that the HCO_3^- concentration may be higher, resulting in an alkaline pH.

Cholecystokinin stimulates bile secretion from the gallbladder.

Bile **canaliculi** are fine tubular canals running between the hepatocytes. Bile flows from hepatocytes through the canaliculi to the bile ducts, which drain into the gallbladder. Between meals, the sphincter of Oddi is closed, thereby preventing bile from draining into the intestine and instead to flow into the gallbladder, where it is stored and concentrated from 5 to 10 times its original concentration.

When the products of protein and lipid digestion build up in the small intestine, “I” cells in the duodenum and jejunum are stimulated to release CCK. CCK causes contraction of the gallbladder, which, in turn, causes increased pressure in the bile ducts. As the bile duct pressure rises, the sphincter of Oddi relaxes (another effect of CCK), and the concentrated bile is delivered into the duodenal lumen to complete the digestion of fat. Canalicular bile flow can be conceptually divided into *bile acid–dependent* and *bile acid–independent secretion*.

Canalicular bile acid–dependent flow

Hepatocyte uptake of free and conjugated bile salts is Na^+-dependent and mediated by **bile salt–Na^+ symport** (Fig. 25.11). The transmembrane Na^+ gradient generated by the Na^+/K^+-ATPase, which provides the necessary energy, is a type of secondary active transport because the energy required for the active uptake of bile acid, or its conjugate, is not directly provided by ATP but by an ionic gradient. The free bile acids are reconjugated with taurine or glycine before secretion. Hepatocytes also make new bile acids from cholesterol and secrete bile salts by a carrier located at the canalicular membrane. This secretion is not Na^+-dependent; instead, it is driven by the electrical potential difference between the hepatocyte and the canaliculus lumen.

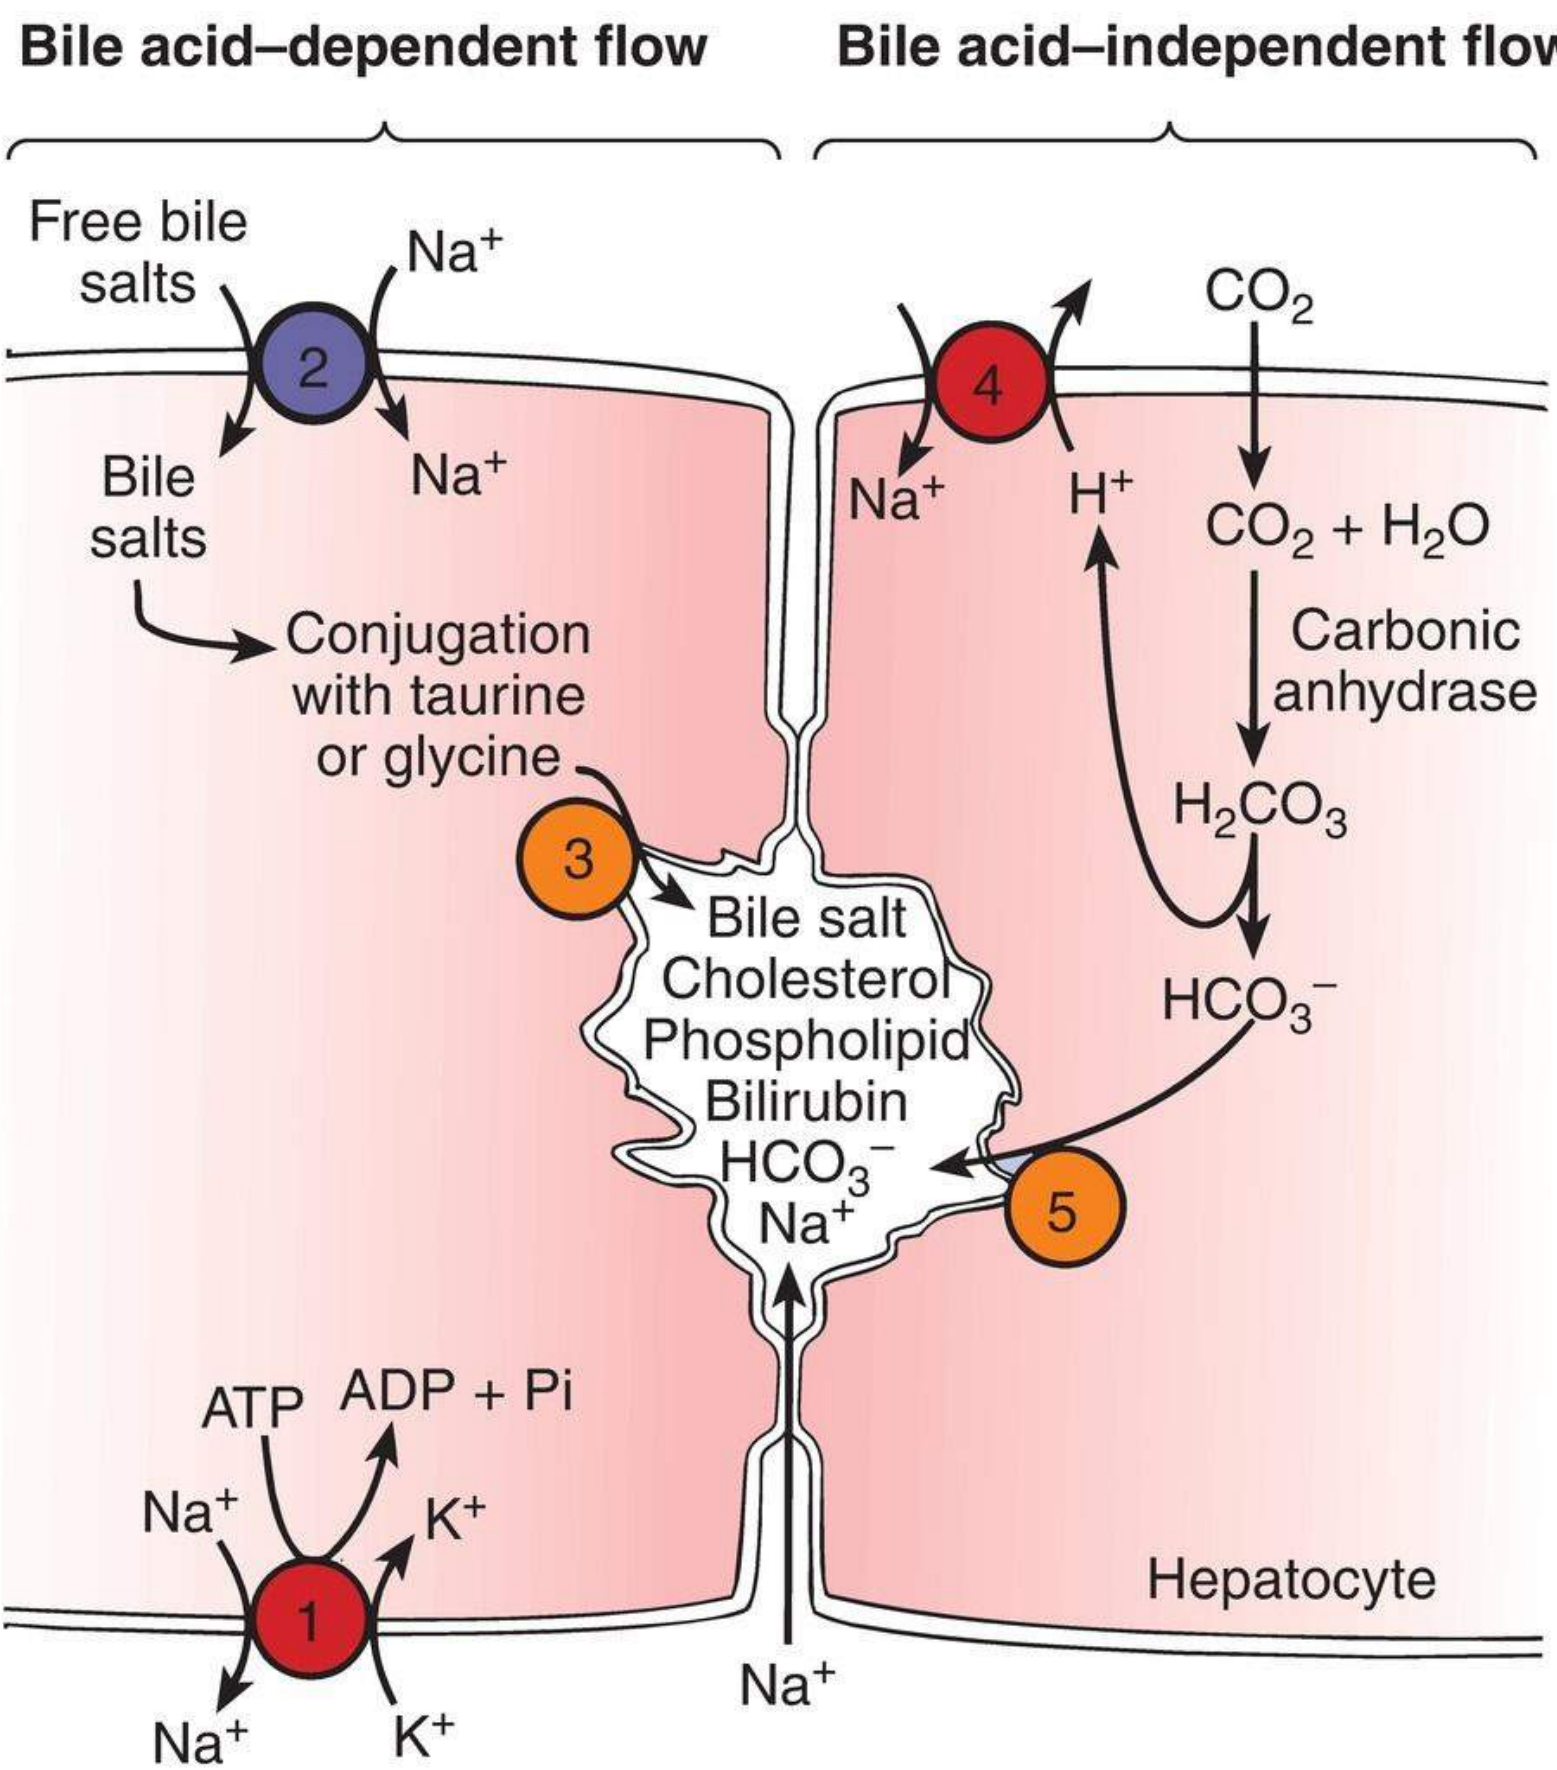

Figure 25.11 Bile salt secretions and bile flow are linked to Na^+/K^+-ATPase activity. This schematic illustrates the mechanism of bile acid secretion and flow. A marked reduction in flow and secretion occurs when Na^+/K^+-ATPase activity is inhibited. (1) Na^+/K^+-ATPase. (2) Bile salt-sodium symport. (3) Canalicular bile acid carrier. (4) Na^+/H^+ exchanger. (5) HCO_3^- transport system. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

Other major components of bile, such as phospholipid and cholesterol, are secreted in concert with bile salts. Hepatocytes secrete bilirubin via an active process involving a transporter. Although the secretion of cholesterol and phospholipid is not well understood, it is closely coupled to bile salt secretion. The osmotic pressure generated as a result of the secretion of bile salts draws H_2O into the canaliculus lumen through the paracellular pathway.

Canalicular bile acid–independent flow

As the name implies, this component of canalicular flow is not dependent on the secretion of bile acids (see Fig. 25.11). The Na^+/K^+-ATPase plays an important role in bile acid–independent bile flow, a role that is clearly demonstrated by the marked reduction in bile flow when an inhibitor of this enzyme is applied. Another mechanism responsible for bile acid–independent flow is canalicular HCO_3^- secretion.

Bile acids are potentially toxic to cells, and their concentrations are tightly regulated.

Because bile acids act like a detergent, their concentration is tightly regulated in order to prevent damage to the gut lining. The major determinant of bile acid synthesis and secretion by hepatocytes is the bile acid concentration in hepatic portal blood, which exerts a negative-feedback effect on the synthesis of bile acids from cholesterol. The concentration of bile acids in portal blood also determines bile acid–dependent secretion. Between meals, the portal blood concentration of bile salts is usually extremely low, resulting in increased bile acid synthesis but reduced bile acid–dependent flow. After a meal, there is increased delivery of bile salts in the portal blood, which not only inhibits bile acid synthesis but also stimulates bile acid–dependent secretion.

Gallbladder bile differs from hepatic bile.

Gallbladder bile is more highly concentrated than is hepatic bile. H_2O absorption by the gallbladder epithelium is the major mechanism involved in concentrating the stored hepatic bile. The process is passive and is secondary to active Na^+ transport via an Na^+/K^+-ATPase in the basolateral membrane of the epithelial cells lining the gallbladder. As a result of isotonic fluid absorption from the gallbladder bile, the concentration of the various unabsorbed components of hepatic bile increases as much as 20-fold.

Bile salts are recycled between the small intestine and the liver.

The **enterohepatic circulation** recycles bile acids between the small intestine, the liver, and bile. The **total bile acid pool** is the entire amount of bile acids in the body (primary or secondary, conjugated or free) at any given time. In healthy people, the bile acid pool ranges from 2 to 4 g. By cycling bile acids in this pool through the enterohepatic circulation several times during a meal, a relatively small bile acid pool can provide the body with sufficient amounts of bile salts to promote lipid absorption. In a light eater, the bile acid pool may circulate 3 to 5 times daily, whereas in a heavy eater, it may circulate 14 to 16 times a day.

Bile salts in the intestinal lumen are absorbed via four pathways (Fig. 25.12). First, a small fraction of the total amount of bile salts is absorbed throughout the entire small intestine by passive diffusion. Second, and most important, bile salts are absorbed in the terminal ileum by an extremely efficient, active carrier-mediated process that usually results in < 5% of the bile salts escaping into the colon. Third, bacteria in the terminal ileum and colon deconjugate the bile salts to form bile acids, which are much more lipophilic than are bile salts and, thus, can be absorbed passively. Fourth, these same bacteria are responsible for transforming the primary bile acids to secondary bile acids (deoxycholic and lithocholic acids) by dehydroxylation. Deoxycholic acid may be absorbed, but lithocholic acid is poorly absorbed.

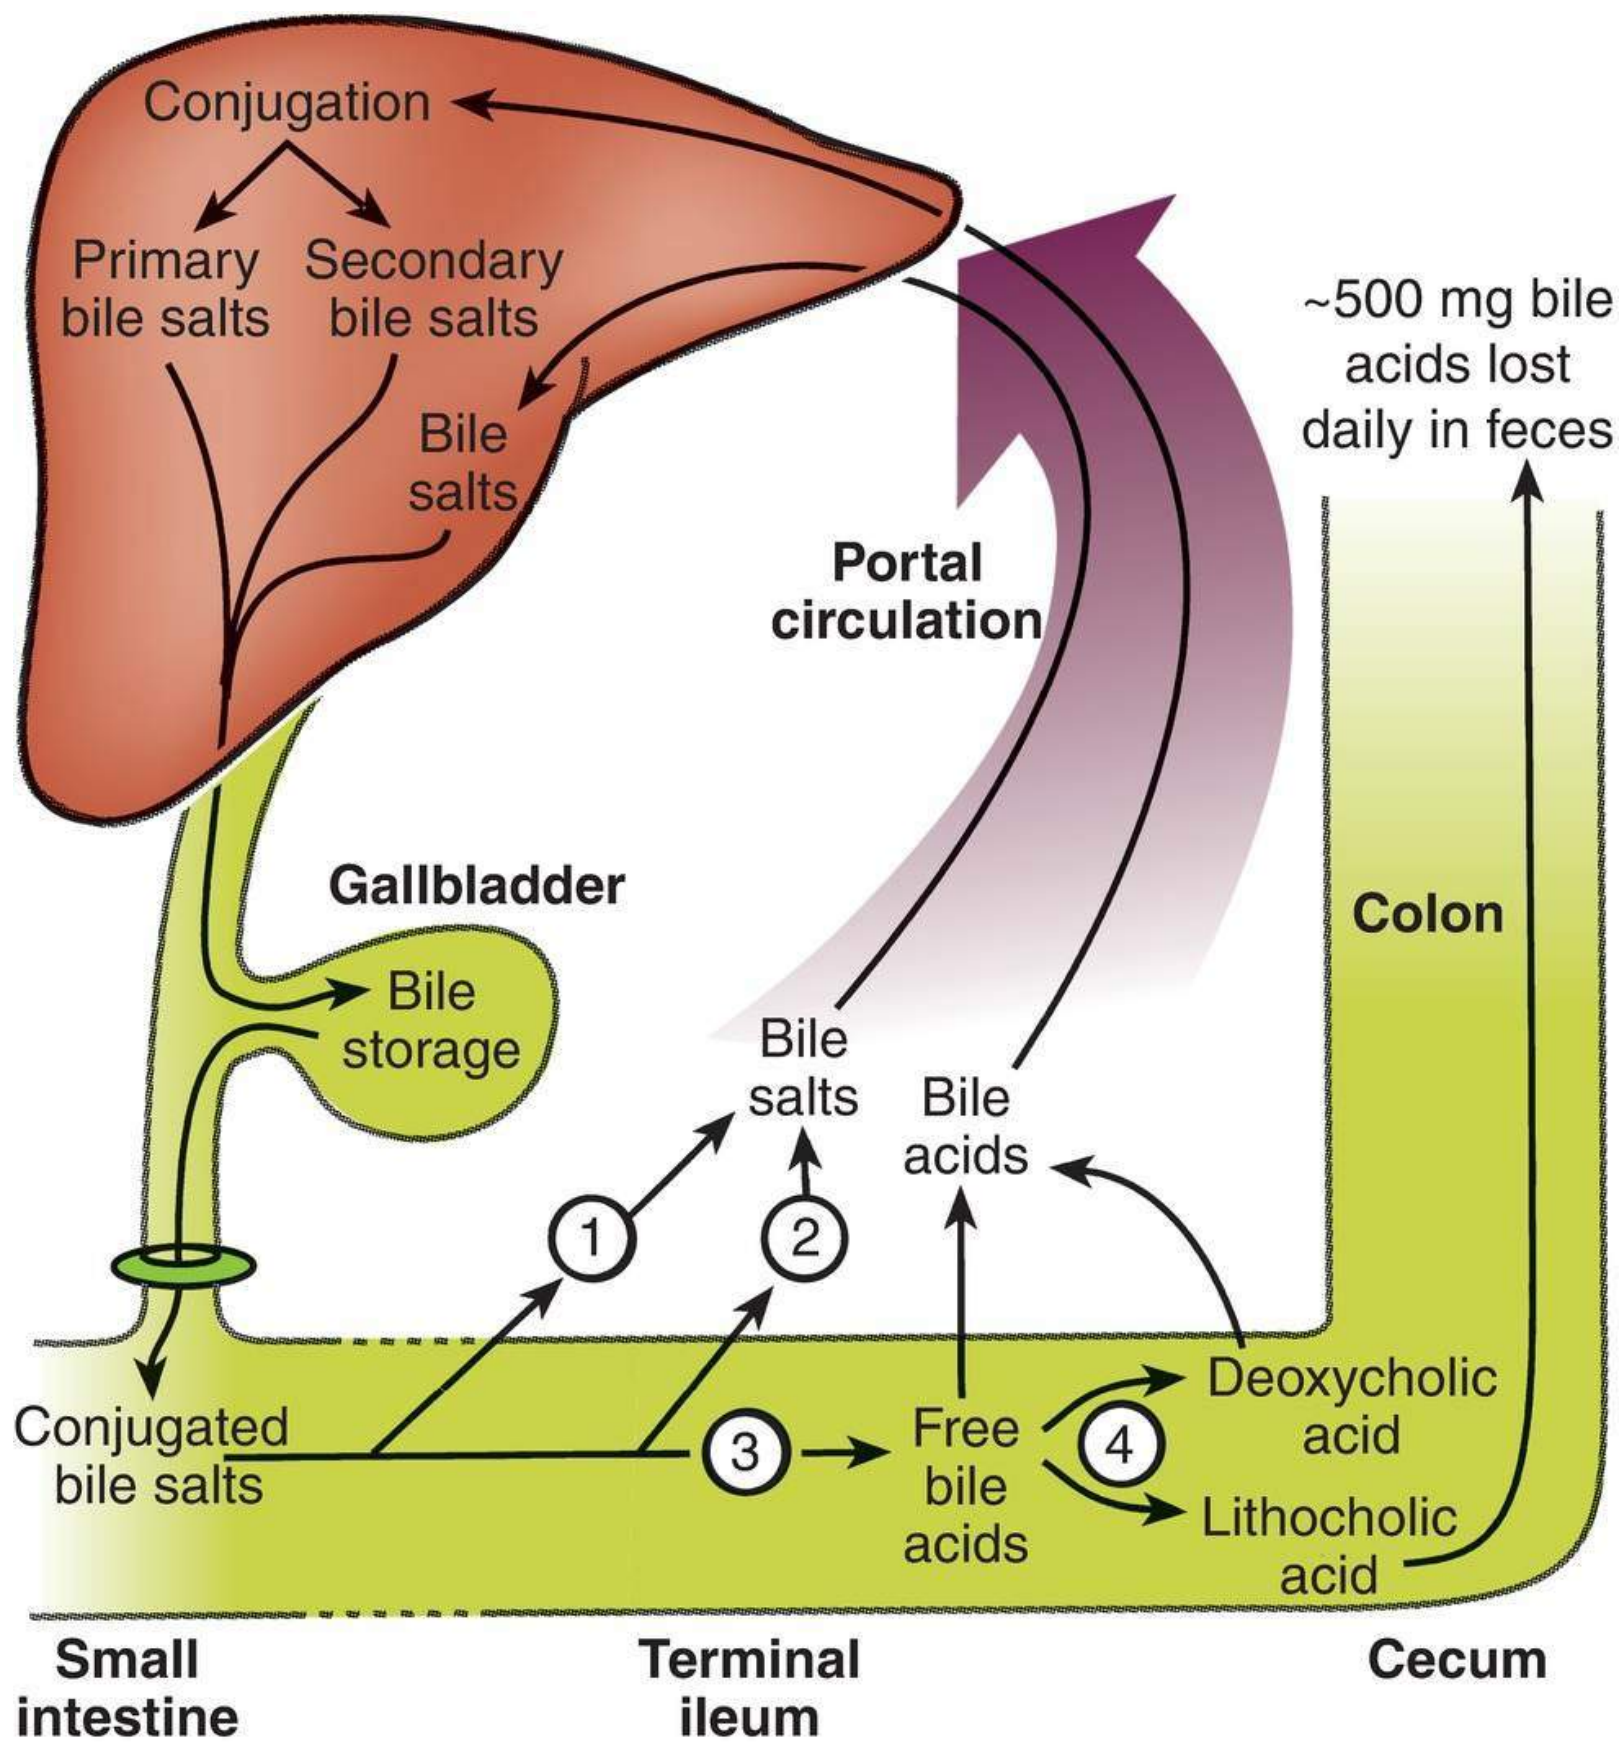

Figure 25.12 The enterohepatic recycling mechanisms for bile salt. Approximately 95% of the bile salts secreted are reabsorbed in the terminal ileum and recycled by four mechanisms: (**1**) passive diffusion along the small intestine (playing a relatively minor role), (**2**) carrier-mediated active absorption in the terminal ileum (the most important absorption route), (**3**) deconjugation to primary bile acids before being absorbed either passively or actively, and **(4)** conversion of primary bile acids to secondary bile acids with subsequent absorption of deoxycholic acid.

Although bile salt and bile acid absorption is extremely efficient, inflammation of the ileum can lead to their malabsorption and result in the loss of large quantities of bile salts in the feces. Depending on the severity of illness, malabsorption of fat may result. Regardless, some salts and acids are nonetheless lost with every cycle of the enterohepatic circulation. About 500 mg of bile acids are lost daily and replenished by the synthesis of new bile acids from cholesterol. The loss of bile acids in feces is, therefore, an efficient way to excrete cholesterol.

Absorbed bile salts are transported in the portal blood bound to albumin or **high-density lipoproteins** (**HDLs**). In just one pass through the liver, more than 80% of the bile salts in the portal blood is removed by the hepatocytes and then resecreted in bile. The uptake of bile salts is a primary determinant of bile salt secretion by the liver.

Bilirubin is the major component of bile pigments.

The major pigment present in bile is the orange compound **bilirubin**, an end product of hemoglobin degradation in the monocyte–macrophage system in the spleen, bone marrow, and liver (Fig. 25.13). Hemoglobin is first converted to biliverdin with the release of iron and globin. Biliverdin is then converted into bilirubin, which is transported in blood bound to albumin. The liver rapidly removes bilirubin from the circulation and conjugates it with glucuronic acid. The glucuronide is secreted into the bile canaliculi through an active carrier-mediated process.

Figure 25.13 Bilirubin is the end product of hemoglobin degradation. The liver removes the bile pigment, bilirubin, from the circulation and conjugates it with glucuronic acid.

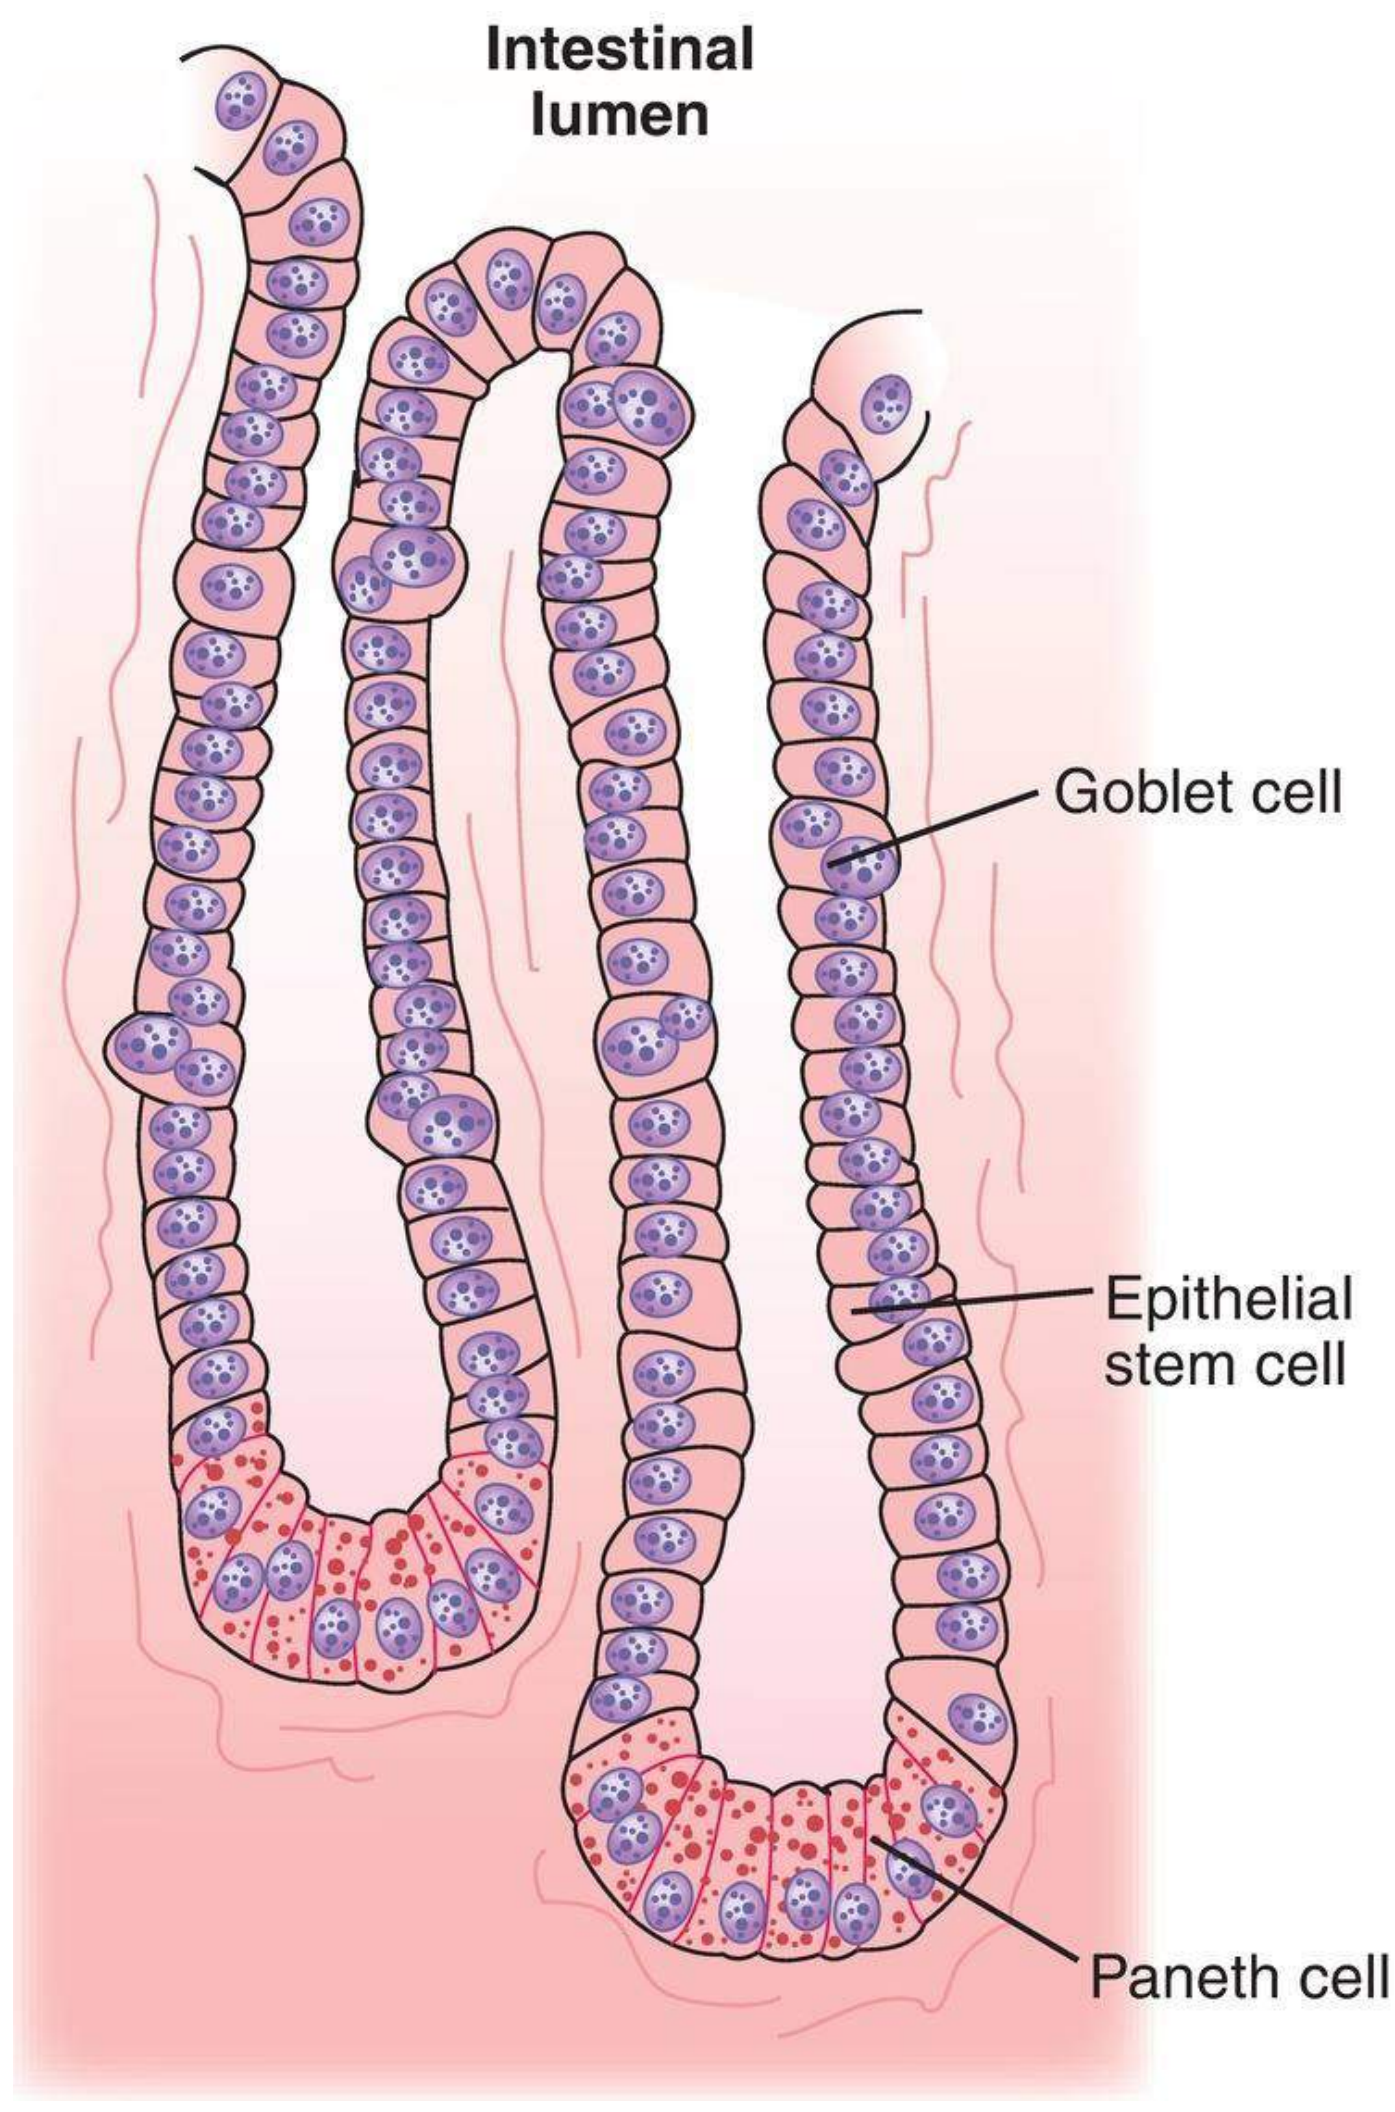
In the small intestine, bilirubin glucuronide is poorly absorbed. However, bacteria in the colon deconjugate it, and part of the bilirubin released is converted to the highly soluble, colorless compound called urobilinogen. Urobilinogen can be oxidized in the intestine to stercobilin or absorbed by the small intestine. It is excreted in either urine or bile. Stercobilin is responsible for the brown color of the stool.

Gallstones form when cholesterol becomes supersaturated.

Bile salts and lecithin in the bile help solubilize cholesterol. However, when bile contains too much cholesterol and not enough bile salts, it starts to crystallize and forms **gallstones**. Gallstones can occur anywhere within the biliary tree, including the gallbladder and the common bile duct. Obstruction of the biliary tree can cause jaundice, and obstruction of the outlet of the pancreatic exocrine system can cause pancreatitis. Gallstones can easily be detected on an x-ray image because Ca^{2+} deposits formed in the stones increase their opacity. Gallstones are more prevalent in women than in men.

INTESTINAL SECRETION

The small intestine is where the vast majority of digestion and absorption of food takes place. Duodenal cells secrete mucus as well as 2 to 3 L/d of isotonic alkaline fluid to aid in the digestive process. *Brunner glands* secrete HCO_3^- containing mucus and are located mainly in the proximal region of the duodenum between the entrance from the stomach and the sphincter of Oddi. These secretions aid in protecting the epithelium from HCl degradation as chyme enters the intestinal lumen. The **crypts of Lieberkühn**, tubular glands that dip down into the mucosal surface between the villi (Fig. 25.14), secrete a watery fluid. The intestinal crypts do not secrete digestive enzymes, but do secrete mucus, electrolytes, and H_2O. In addition, the *crypts of Lieberkühn* function to replace intestinal epithelial cells that are continually being sloughed off. Replacement occurs at a rapid rate due to the high mitotic index of epithelial stem cells in the crypts. The new epithelial cells migrate up the villi and replace older epithelial cells at the tips of the villi. The epithelial lining of the small intestine is replaced approximately every 3 days. Due to a high rate of cell division, the intestinal crypts are very sensitive to damage caused by radiation and to anticancer drugs used in chemotherapy. This is particularly problematic with patients who have been treated for colorectal cancer because their treatment is specially designed to target and kill tumors in the epithelial lining.



Intestinal lumen
Goblet cell
Epithelial stem cell
Paneth cell

Figure 25.14 Crypt of Lieberkühn. Intestinal crypts secrete intestinal fluid and are found in all regions of the small intestine sandwiched in between villi.

Intestinal secretions provide lubrication and protective functions.

The **Paneth cells** (see Fig. 25.14) are involved in the host defense system in the small intestine. They function like neutrophils and produce antimicrobial substances that provide a protective barrier. The *Paneth cells* are particularly important in protecting the stem cells from damage. **Goblet cells** secrete various mucins (mucoproteins) into the intestinal lumen. Mucins are extremely diverse in structure and are usually large molecules. Mucins are glycoproteins high in carbohydrate and they form gels in solution. The mucus lubricates the mucosal surface and protects it from mechanical damage by solid food particles. In the small intestine, it may also provide a physical barrier against the entry of microorganisms across the epithelial mucosa.

Intestinal secretions probably help maintain the fluidity of the chyme and may also play a role in diluting noxious agents and washing away infectious microorganisms. The HCO_3^- in intestinal secretions protects the intestinal mucosa by neutralizing any H^+ present in the lumen. While especially important in the duodenum, it is also important in the ileum, where bacteria degrade certain foods, which produces acids (e.g., dietary fibers to short-chain fatty acids).

Intestinal fluid hypersecretion is stimulated by toxins and other luminal stimuli.

The small intestine and colon usually absorb the fluid and electrolytes from intestinal secretions, but if secretion surpasses absorption (e.g., in cholera), watery diarrhea may result. If uncontrolled, this can lead to the loss of large quantities of fluid and electrolytes, which can result in dehydration and electrolyte imbalances and, ultimately, death. Several noxious agents, such as bacterial toxins (e.g., cholera toxin), can induce intestinal hypersecretion. Cholera toxin binds to the brush border membrane of crypt cells and increases intracellular adenylyl cyclase activity. Adenylyl cyclase synthesizes cAMP from ATP. The result is a dramatic increase in intracellular cAMP that stimulates active Cl^- and HCO_3^- secretion into the lumen. H_2O follows the osmotic gradient and enters the lumen.

It is well documented that tactile stimulation, or an increase in intraluminal pressure, stimulates intestinal secretion. Other potent stimuli are certain noxious agents and the toxins produced by microorganisms. With the exception of toxin-induced secretion, our understanding of the normal control of intestinal secretion is meager. VIP is known to be a potent stimulator of intestinal secretion. This is demonstrated by a form of endocrine tumor of the pancreas that results in the secretion of large amounts of VIP into the circulation. In this condition, intestinal secretion rates are high.

CARBOHYDRATE DIGESTION AND ABSORPTION

Carbohydrates are one of the main types of nutrients and the most important source of energy. The digestive system converts carbohydrates into glucose (blood sugar). Sucrose and lactose are two major sources of carbohydrate in the human diet. Sucrose (present in cane sugar and honey) is a disaccharide composed of glucose and fructose. Lactose (the main sugar in milk) is a disaccharide composed of galactose and glucose.

Starches, large polysaccharides, are the third major source of dietary carbohydrates. Starch is produced by all green plants and is the most important carbohydrate in the human diet. Sources include such staple foods as potatoes and most types of grain (e.g., wheat, corn, and rice). All three major dietary sources (sucrose, lactose, and starch) must be hydrolyzed to monosaccharides before they can be absorbed in the small intestine. Although some carbohydrates are digested in the mouth and stomach, most are digested in the small intestine by pancreatic enzymes.

To ensure the optimal absorption of carbohydrates and other nutrients, the GI tract has several unique features. For instance, after a meal, the small intestine undergoes rhythmic contractions called *segmentations* (see Chapter 27), which ensure proper mixing of the small intestinal contents, exposure of the contents to digestive enzymes, and maximum exposure of digestion products to the small intestinal mucosa. The rhythmic segmentation has a gradient along the small intestine, with the highest frequency in the duodenum and the lowest in the ileum. This gradient ensures slow but forward movement of intestinal contents toward the colon.

Another unique feature of the small intestine is its architecture. Spiral or circular concentric folds increase the surface area of the intestine by about three times (Fig. 25.15). Finger-like projections of the mucosal surface called **villi** further increase the surface area of the small intestine to 30 times. To amplify the absorptive surface further, numerous closely packed **microvilli** cover each epithelial cell, or **enterocyte**. The total surface area is increased to 600 times. The GI tract absorbs the various nutrients, vitamins, bile salts, and H_2O by passive, facilitated, or active transport. (The site and mechanism of absorption are discussed below.) The GI tract has a large reserve for the digestion and absorption of various nutrients and vitamins. Malabsorption of nutrients is usually not detected unless a large portion of the small intestine has been lost or damaged because of disease or surgical manipulation (e.g., certain bariatric surgery).

Figure 25.15 The unique architecture of the small intestine greatly enhances the surface area. Circular folds, villi, and microvilli are three functional features that greatly increase the surface area of the small intestine for the digestion and absorption of food.

The duodenum and jejunum absorb most nutrients and vitamins, but because bile salts are involved in the intestinal absorption of lipids, the small intestine has adapted to absorb the bile salts later in the terminal ileum through a bile salt transporter. The enterocytes along the villus that are involved in the absorption of nutrients are replaced every 2 to 3 days.

The digestion and absorption of dietary carbohydrates take place in the small intestine. These are extremely efficient processes, in that essentially all of the carbohydrates consumed are absorbed. Carbohydrates constitute about 45% to 50% of the typical Western diet and provide the greatest and least expensive source of energy. Carbohydrates must be digested to monosaccharides before absorption by the enterocytes.

Dietary fiber benefits gastrointestinal function.

Dietary fiber, sometimes called *roughage*, consists of nonstarch polysaccharides that arise from plants that the GI system cannot digest or absorb. Fiber is classified as soluble or insoluble. Soluble fiber dissolves in water to form a gel-like material and is found in oats, peas, beans, apples, carrots, and citrus fruits. The gel-like material that is formed absorbs sugars and certain fats and is beneficial in lowering blood cholesterol and glucose levels by excreting them in the feces. Insoluble fiber doesn't dissolve in water and is the fiber that increases bulk, softens stools, and shortens transit time in the intestinal tract, all of which facilitates motility and prevents constipation.

By shortening GI transit time, dietary fiber has also been shown to reduce the incidence of colon cancer. A shortened transit time inhibits the formation of carcinogenic bile acids, such as lithocholic acid, as well as reducing the contact time of ingested carcinogens to act on tissue. Some common sources include whole wheat flour, wheat bran, nuts, beans, and vegetables such as green beans.

Carbohydrates are defined by their chemical structure.

Dietary carbohydrates are called monosaccharides, disaccharides, oligosaccharides, and polysaccharides depending on their chemical structure. The monosaccharides are mainly hexoses (six-carbon sugars), and glucose is the most abundant of these. Glucose is obtained directly from the diet or from the digestion of disaccharides, oligosaccharides, or polysaccharides. The next most common monosaccharides are galactose, fructose, and sorbitol. Galactose is present in the diet only as milk lactose. Fructose is abundant in fruit and honey and is usually present as disaccharides or polysaccharides. Sorbitol is derived from glucose and is almost as sweet as glucose, but it is absorbed much more slowly and, thus, maintains a high blood sugar level for a longer period when similar amounts are ingested. It has been used as a weight reduction aid to delay the onset of hunger sensations and is often used in diet foods and diet drinks.

The digestible polysaccharides are starch, dextrins, and glycogen. Starch, by far the most abundant carbohydrate in the human diet, is made of amylose and amylopectin. Amylose is composed of a straight chain of glucose units; amylopectin is composed of branched glucose units. Dextrins, formed from heating (e.g., toasting bread) or the action of the enzyme amylase, are intermediate products of starch digestion. Glycogen is a highly branched polysaccharide that stores carbohydrates in the body. Normally, about 300 to 400 g of glycogen is stored in the liver and muscle, with more stored in muscle than in the liver. Muscle glycogen is used exclusively by muscle, and liver glycogen is used to provide blood glucose during fasting.

Carbohydrate digestion begins with salivary amylase.

The digestion of carbohydrates starts when food is mixed with saliva during chewing (Fig. 25.16). The enzyme salivary amylase acts on starches to release the disaccharide maltose. Because salivary amylase works best at neutral pH, its digestive action terminates rapidly after the bolus mixes with acid in the stomach. If the food is thoroughly mixed with amylase during chewing, a substantial amount of complex carbohydrates is digested before enzyme inactivation. **Pancreatic amylase** continues the digestion of the remaining carbohydrates. However, pancreatic secretions must first neutralize the chyme because pancreatic amylase works best at neutral pH. Pancreatic amylase digestion of polysaccharides also yields maltose, which is then converted to glucose by maltase (Clinical Focus 25.2).

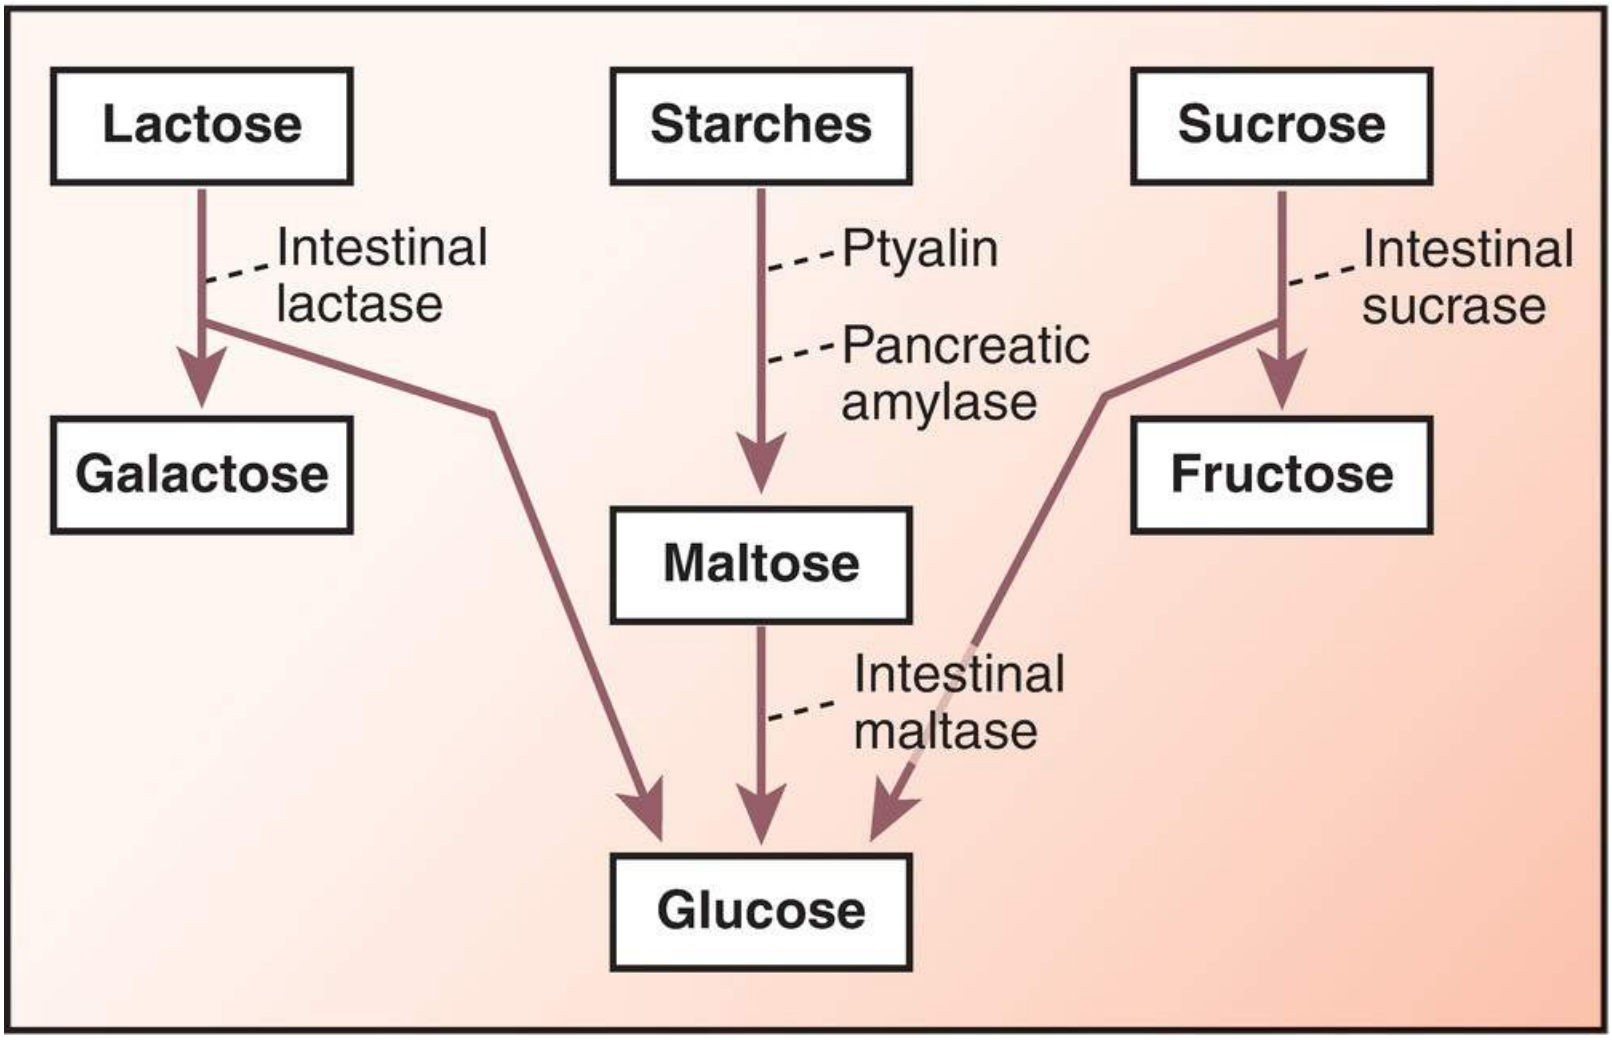

Figure 25.16 Salivary and pancreatic enzymes break down carbohydrates. Starch, sucrose, and lactose are the three main dietary sources of carbohydrates. All three are hydrolyzed to monosaccharides for absorption.

CLINICAL FOCUS 25.2

Celiac Sprue (Gluten-Sensitive Enteropathy)

Celiac sprue, also called **gluten-sensitive enteropathy**, is an autoimmune disorder of the small intestine that occurs in genetically predisposed individuals of all ages. The disease is caused by a reaction to a protein (gluten) found in grain (wheat, barley, oats, and rye). Upon exposure to gluten, the immune system cross-reacts, causing chronic inflammation and primary lesions of the intestinal mucosa. This disorder can result in the malabsorption of all nutrients as a result of the shortening or total loss of intestinal villi, which reduces the mucosal enzymes for nutrient digestion and the mucosal surface for absorption. For example, as the small intestine becomes more damaged, a degree of lactose intolerance may develop. Symptoms include diarrhea, weight loss, failure to gain weight (in young children), and anemia. The latter is due to iron malabsorption. Celiac sprue occurs in about 1 to 6 of 10,000 people in the Western world. The highest incidence is in Western Ireland, where the prevalence is as high as 3 of 1,000 people. People of African, Chinese, and Japanese descent are rarely diagnosed. Although the disease may occur at any age, it is more common during the first few years and the third to fifth decades of life. Celiac disease has been present since humans started harvesting grains in an organized fashion (about 5,000 BCE); however, the link to wheat was not discovered until the 1940s, by Dutch pediatrician, Dr. Wilhelm-Karel Dicke. He observed during World War II that when flour and bread were scarce, the death rate among children due to celiac sprue dropped to zero. The specific link to gluten was made later in 1952 by a team of physicians in England. The elimination of dietary gluten is a standard treatment for patients with celiac sprue. Occasionally, intestinal absorptive function and intestinal mucosal morphology of patients with celiac sprue are improved with glucocorticoid therapy. Presumably, such treatment is beneficial because of the immunosuppressive and anti-inflammatory actions of these hormones. ■

Enterocytes hydrolyze disaccharides and absorb monosaccharides.

Enterocytes are simple columnar cells lining the villi of the small intestine. Enzymes located at the brush border membrane (microvilli) of the enterocytes digest the disaccharides maltose, sucrose, and lactose (see Fig. 25.16). The final products glucose, fructose, and galactose are then absorbed. The intestinal enterocytes (absorptive cells) absorb monosaccharides using both active and facilitated transport processes. A sodium–glucose symporter (SGLT) (see Chapter 2), located on the brush boarder membrane of the enterocytes, transports two Na^+ for every molecule of monosaccharide and absorbs glucose and galactose via secondary active transport (Fig. 25.17). Since glucose and galactose share a common transporter, they compete with each other during absorption. The movement of Na^+ into the cell, down concentration and electrical gradients, affects the uphill movement of glucose into the cell. The basolateral membrane Na^+/K^+-ATPase maintains the low intracellular Na^+ concentration. The osmotic effects of sugars increase the Na^+/K^+-ATPase activity and the K^+ conductance of the basolateral membrane. Sugars accumulate in the cell at a higher concentration than in plasma and leave the cell by Na^+-independent facilitated transport via a glucose transporter (GLUT-2) or passive diffusion through the basolateral cell membrane.

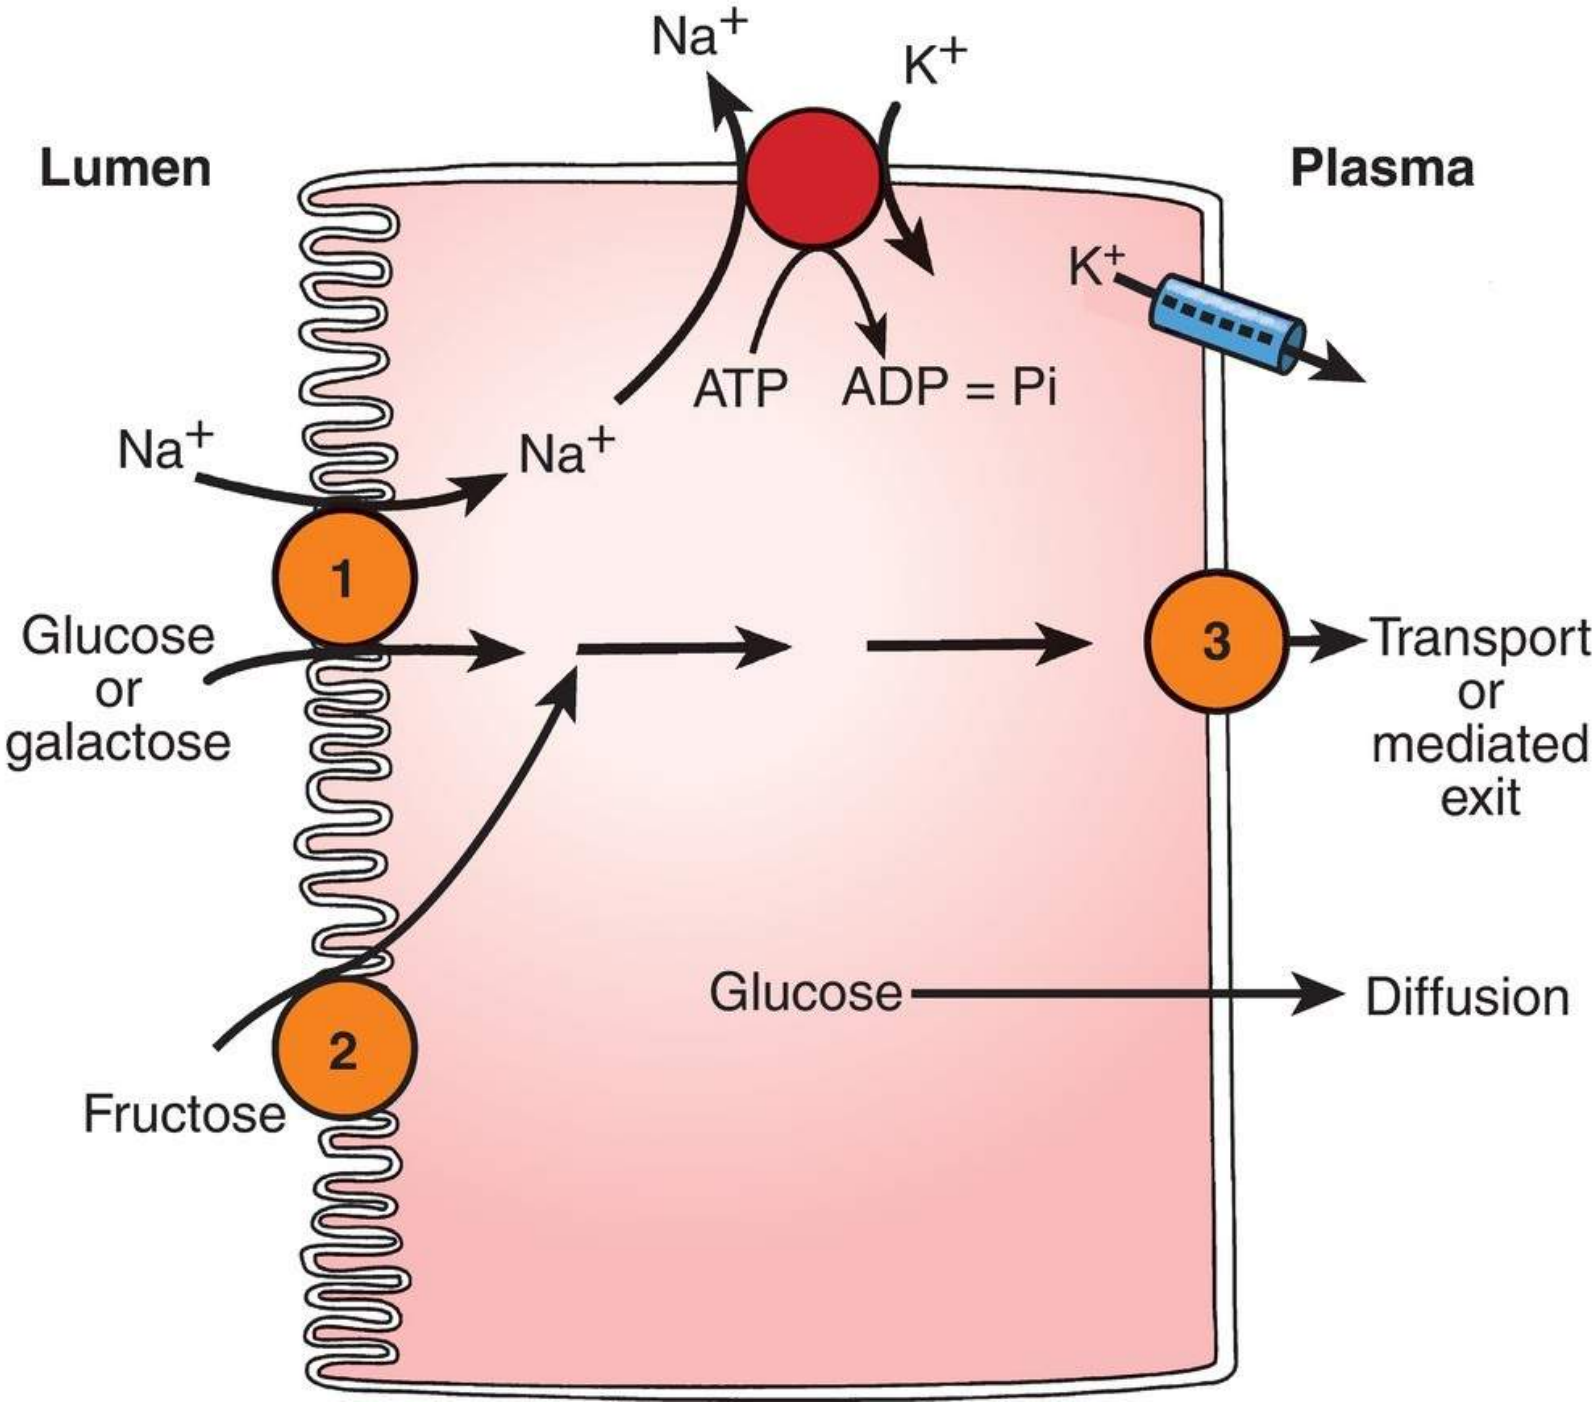

Figure 25.17 Sugar absorption depends on an Na^+-dependent carrier system. Sodium moves into the cell down a concentration and electrical gradient, which favors the uphill movement of glucose and galactose into the enterocytes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate. Transporters labeled 1, 2, and 3 are members of a family of hexose transporters. 1, SGLUT-1 ; 2, GLUT5; 3, GLUT 2.

Fructose is taken up by facilitated transport. This transporter, also in the family of glucose transporters, is named GLUT-5. Although facilitated transport is carrier-mediated, it is not an active process (see Chapter 2). Fructose absorption is much slower than glucose and galactose absorption and is not Na^+-dependent. In some animal species, both galactose and fructose can be converted to glucose in enterocytes, but this mechanism is probably not important in humans.

The portal blood transports the absorbed sugars to the liver, where they are converted to glycogen or remain in the blood. After a meal, the level of blood glucose rises rapidly, usually peaking at 30 to 60

minutes. Blood glucose levels can be as high as 150 mg/dL and even higher in diabetic patients. Although enterocytes can use glucose for fuel, glutamine is preferred. Both galactose and glucose are used in the glycosylation of proteins in the Golgi apparatus of the enterocytes.

Salivary or pancreatic dysfunction impairs carbohydrate absorption.

Impaired carbohydrate absorption caused by the absence of salivary or pancreatic amylase almost never occurs because these enzymes are usually present in great excess. However, impaired absorption as a result of a deficiency in membrane disaccharidases is common. Such deficiencies can be either genetic or acquired. Among congenital deficiencies, lactase deficiency is, by far, the most common. Affected people suffer from **lactose intolerance**, due to an inability to cleave lactose. Since disaccharides cannot be absorbed by the small intestine, the absence of lactase allows the ingested, uncleaved dairy products to pass into the colon. Bacteria in the colon quickly switch over to lactose metabolism, resulting in *in vivo* fermentation that produces copious amounts of gas. This, in turn, causes a number of abdominal symptoms including stomach cramps, bloating, and flatulence. Fermentation products also raise the osmotic pressure of the colon contents, resulting in excess fluid accumulation and diarrhea (Fig. 25.18).

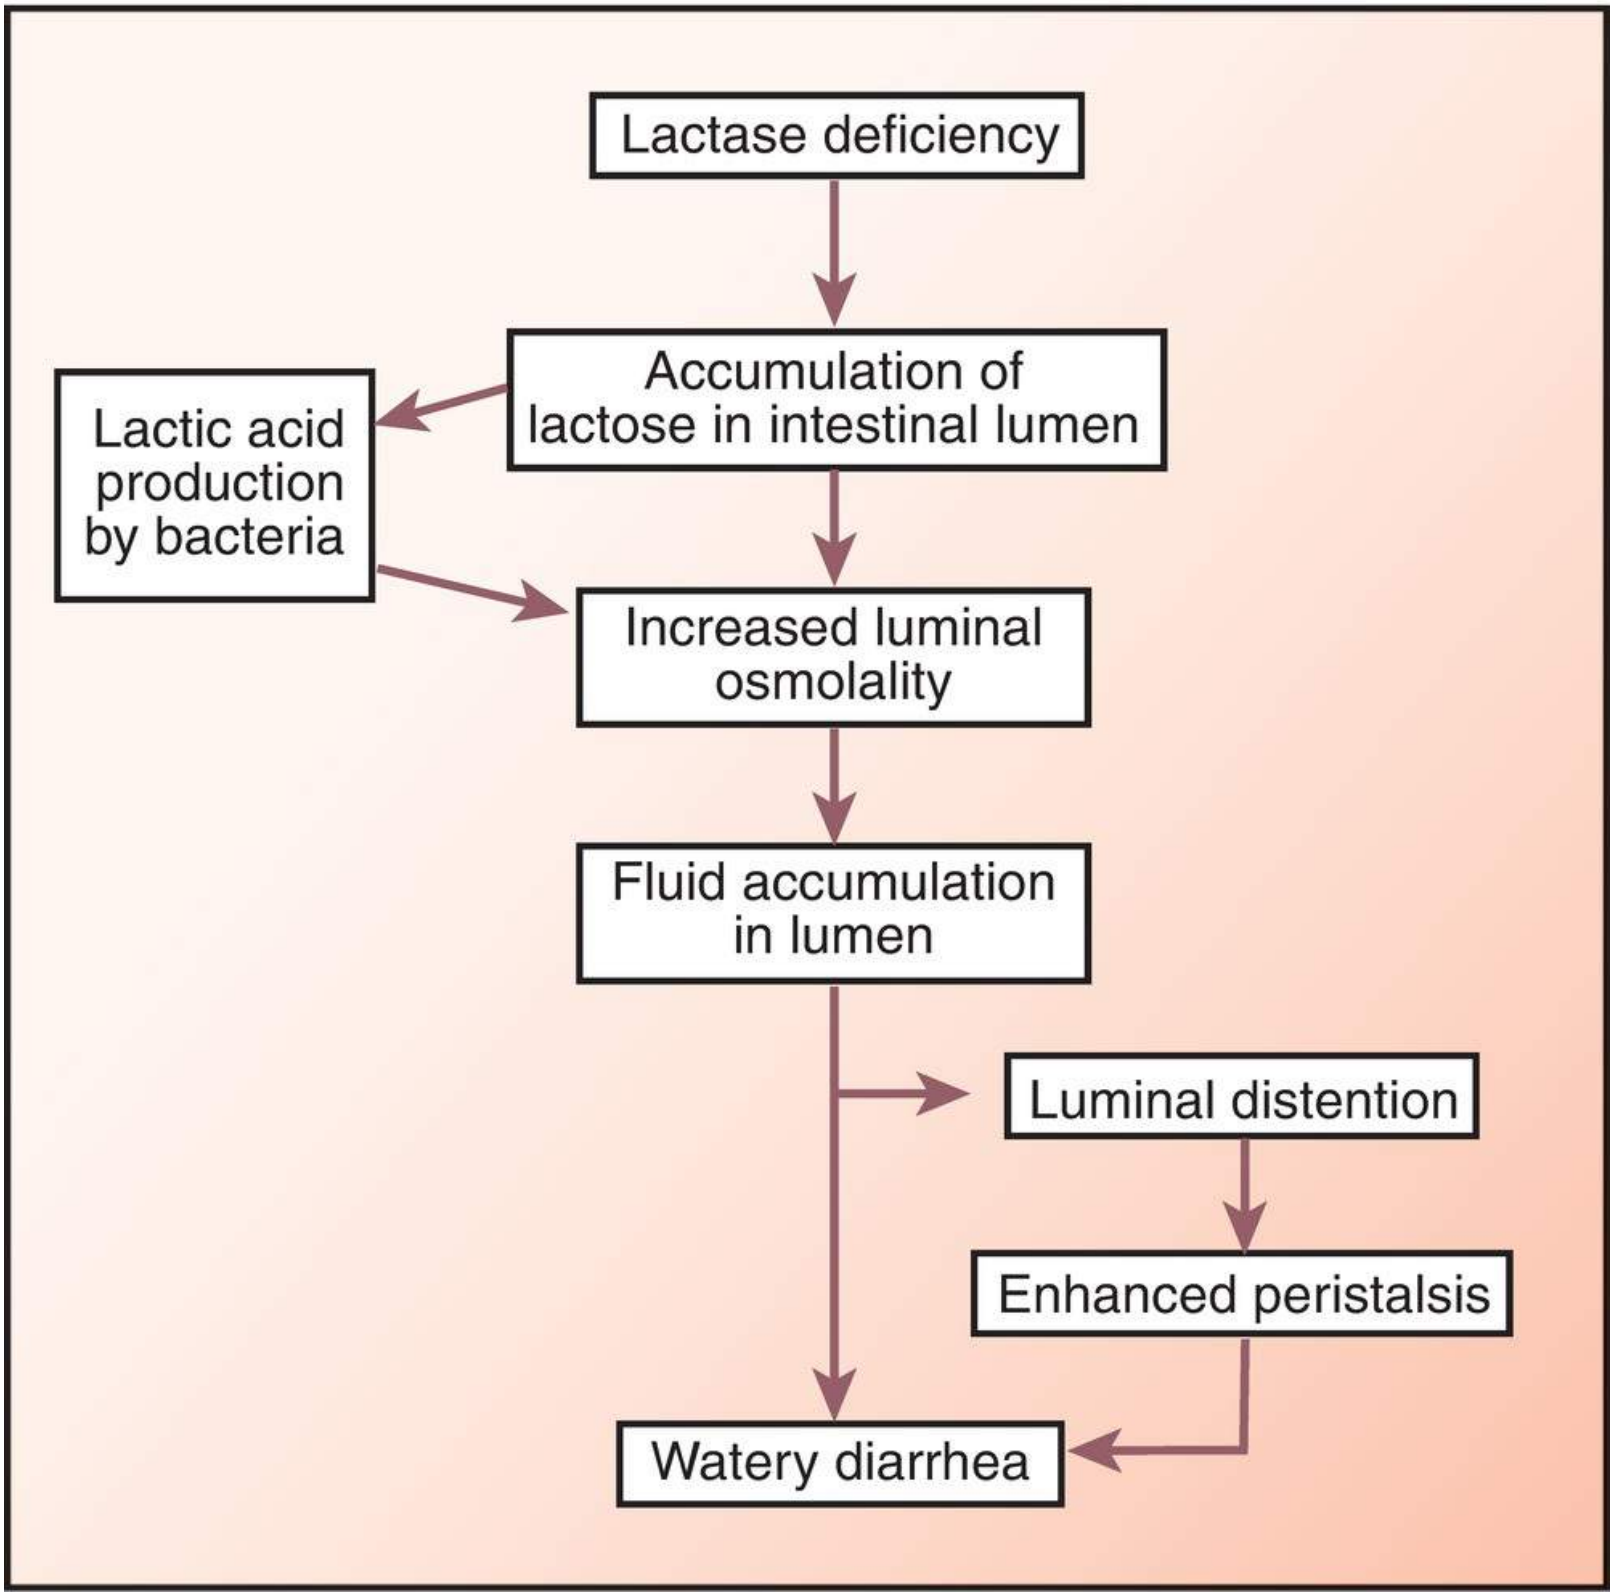

Figure 25.18 Lactase deficiency causes diarrhea. Undigested lactose increases the osmolality of the gut, which results in an increase in osmolality. The high osmolality leads to a concomitant increase in a net water secretion, causing diarrhea.

Congenital sucrase deficiency results in symptoms similar to those of lactase deficiency. Sucrase deficiency can be inherited or acquired through disorders of the small intestine, such as tropical sprue or Crohn's disease.

LIPID DIGESTION AND ABSORPTION

Lipids comprise several classes of compounds that are insoluble in H_2O but soluble in organic solvents. Lipids are a group of naturally occurring dietary molecules that include fats, sterols, monoglycerides, diglycerides, phospholipids, and fat-soluble vitamins (A, D, E, and K). The physiologic function of lipids includes energy storage, structural components for cell membranes, and cell signaling molecules. Although the term "lipid" is sometimes used synonymously with fats, fats are a subgroup of lipids called **triglycerides**. Triglycerides in adipose tissue are the major form of concentrated energy storage in animals. Triglycerides provide 30% to 40% of the daily caloric intake and more than 90% of the daily dietary lipid intake in the Western diet. The human body is capable of synthesizing most of the lipids it requires, with the exception of the **essential fatty acids**. Essential fatty acids must be ingested for normal cell function, because they cannot be synthesized from other foods. Recent studies suggest that the human body may also require dietary omega-3 fatty acids during development. In humans, the essential fatty acids are linolenic acid, linoleic acid, and arachidonic acid. Linolenic acid is an omega-3 fatty acid, and linoleic and arachidonic both omega-6 fatty acids. These essential fatty acids are abundant in seafood, flaxseed (linseed), soya oil, canola oil, sunflower seeds, leafy vegetables, and walnuts. Researchers have recently provided convincing evidence that **eicosapentaenoic acid** (C 20:5) and **docosahexaenoic acid** (C 22:6) are also essential for the normal development of vision in newborns. Docosahexaenoic acid is an important fatty acid present in the retina and parts of the brain.

The other lipids in the human diet are cholesterol and phospholipids. **Cholesterol** is a sterol derived exclusively from animal fat. Humans also ingest a small amount of plant sterols, notably β-sitosterol and campesterol. The phospholipid molecule is similar to a triglyceride, with fatty acids occupying the first two positions of the glycerol backbone (Fig. 25.19). However, the third position is occupied by a phosphate group coupled to a nitrogenous base (e.g., choline or ethanolamine), for which each type of phospholipid molecule is named. For example, phosphatidylcholine (lecithin) is an important phospholipid in cell membranes and lung surfactant.

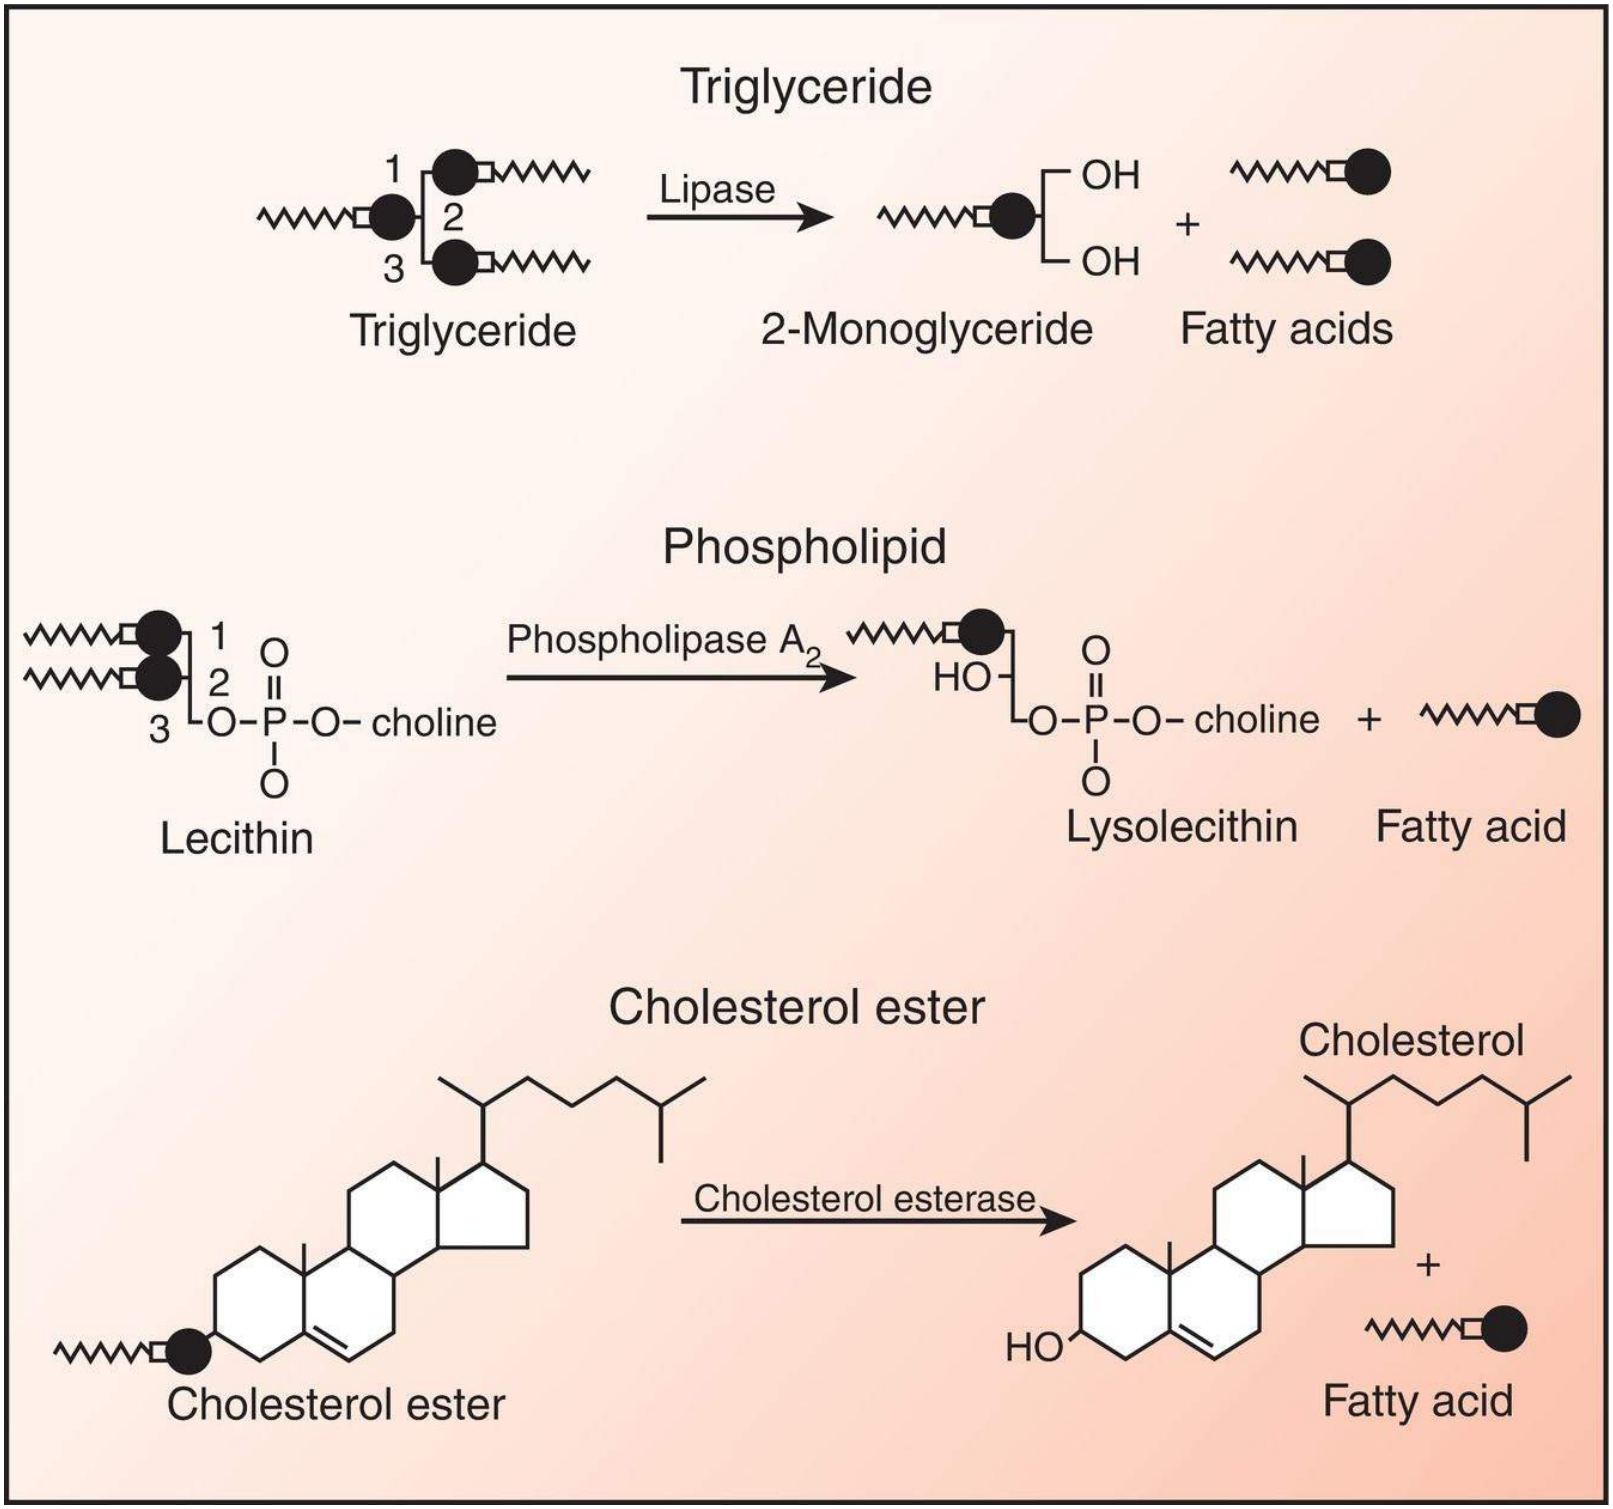

Figure 25.19 Pancreatic lipases digest dietary lipids. Different pancreatic lipases carry out lipid hydrolysis in the gut. *Solid circles* represent oxygen atoms.

Bile serves as an endogenous source of cholesterol and phospholipids. Bile contributes about 12 g/d of phospholipid to the intestinal lumen, mostly in the form of phosphatidylcholine, whereas dietary sources contribute 2 to 3 g/d. Another important endogenous source of lipid is desquamated intestinal villus epithelial cells.

Lipases are water-soluble enzymes that break down fats into monoglycerides and free fatty acids.

Fats are digested by lipases (acyl hydrolases). Since lipases are most active at the oil–water interface, the rate of lipolysis depends on the surface area of the interface, which is increased when oil droplets are formed (an emulsion). Emulsions are formed in the stomach, when churning action mixes proteins and the products of fat digestion, and in the intestine, when components present in bile mix with fats. Lipid digestion starts in the stomach when **gastric lipase** (an acidic lipase) comes in contact with fats. Gastric lipase digests 10% to 30% of the ingested lipids. It has optimal activity in a pH range of 3 to 7 and, therefore, function quite well at normal stomach pH values. Gastric lipase prefers triglycerides containing medium-chain fatty acids (8 to 10 carbons in length), which are abundant in milk. In infants, gastric lipase plays a very important role in the digestion of fat because infants do not have sufficient pancreatic lipase to digest milk fat, which is their major source of fat intake. In adults, gastric lipase is also involved in fat digestion, and the digestion products aid in the emulsification of fat, which greatly facilitates fat digestion by **pancreatic lipase** (**colipase-dependent lipase**) in the intestinal lumen where the majority of lipid digestion is. Humans secrete an overabundance of pancreatic lipase. Pancreatic lipase is optimally active at a pH of 7 to 8, and it works well in the intestinal lumen after the acidic contents entering from the stomach have been neutralized by pancreatic HCO_3^- secretion. Optimal pancreatic lipase activity requires the presence of the peptide **colipase** also present in pancreatic juice. Colipase binds lipase at a molar ratio of 1:1, thereby allowing the lipase to bind to the oil–water interface where it hydrolyzes the triglyceride molecule yielding a 2-monoglyceride and two fatty acids (see Fig. 25.19). Colipase also counteracts the inhibition of lipolysis by bile salts, which, despite their importance in intestinal fat absorption, prevent the attachment of pancreatic lipase to the oil–water interface.

Phospholipase A_2 and carboxyl ester hydrolase contribute to lipolytic activity.

Phospholipase A_2 is the major pancreatic enzyme for digesting phospholipids and forming lysophospholipids and fatty acids. For instance, phosphatidylcholine (lecithin) is hydrolyzed to form lysophosphatidylcholine (lysolecithin) and fatty acid (see Fig. 25.19).

Dietary cholesterol is present as the free sterol or as a sterol ester (cholesterol ester). The pancreatic enzyme *carboxyl ester hydrolase*, also called **cholesterol esterase**, catalyzes the hydrolysis of cholesterol ester (see Fig. 25.19). The digestion of cholesterol ester is important because cholesterol can be absorbed only as the free sterol.

Emulsification by bile acids is the first step in fat digestion.

A layer of poorly stirred fluid, the **unstirred water layer**, coats the surface of the intestinal villi (Fig. 25.20A). This layer reduces the absorption of lipid digestion products because they are H_2O insoluble. **Micellar emulsification** in the small intestinal lumen renders them H_2O soluble and enhances the concentration of these products in the unstirred water layer (Fig. 25.20B). Enterocytes then absorb the lipid digestion products, mainly by passive diffusion. Fatty acid and monoglyceride molecules are taken up individually. Similar mechanisms seem to operate for cholesterol and lysolecithin. However, recent evidence supports a transporter-mediated uptake of cholesterol. Ezetimibe, an antihyperlipidemic medication to lower blood cholesterol, is extremely effective in decreasing intestinal cholesterol absorption. The mechanism appears to involve the binding of this drug to the cholesterol transporter, thereby preventing the uptake of cholesterol.

Figure 25.20 Bile salts emulsify lipids for absorption. Bile acts as a detergent to emulsify fat. Micelles are formed from emulsified lipid, and the micellar solubilization enhances the delivery and absorption of lipid to the brush border membrane. (**A**) The absence of micelles when bile salt is absent. (**B**) The presence of micelles when bile salt is present.

Bile salts are derived from cholesterol, but unlike cholesterol, they are water-soluble. Bile salts have both hydrophilic and hydrophobic constituents, which makes them polar molecules with detergent-like properties. Polar molecules penetrate cell membranes poorly. This property ensures minimal absorption of bile salts by the jejunum, where most fat absorption takes place. At or above a certain concentration of bile salts, the **critical micellar concentration**, the salts aggregate to form micelles; the concentration of luminal bile salts is usually well above the critical micellar concentration. When bile salts alone are present in the micelle, it is called a **simple micelle**. Simple micelles incorporate the lipid digestion products—monoglyceride and fatty acids—to form **mixed micelles**, a process that renders the lipolytic products water-soluble. Mixed micelles diffuse across the unstirred water layer and deliver lipid digestion products to the enterocytes for absorption. This absorption pathway for lipolytic products is much more efficient than direct absorption from emulsions.

Enterocytes secrete chylomicrons and very low–density lipoproteins.

After entering the enterocytes, the fatty acids and monoglycerides migrate to the smooth endoplasmic reticulum (SER). A fatty acid–binding protein may be involved in the intracellular transport of fatty acids, but whether a protein carrier is involved in the intracellular transport of monoglycerides is still unclear. In the SER, monoglycerides and fatty acids are rapidly reconstituted to form triglycerides (Fig. 25.21). Fatty acids are first activated to form acyl-coenzyme A (acyl-CoA), which is then used to esterify monoglyceride to form diglyceride, which is then transformed into triglyceride. The lysolecithin absorbed by the enterocytes can be re-esterified in the SER to form lecithin.

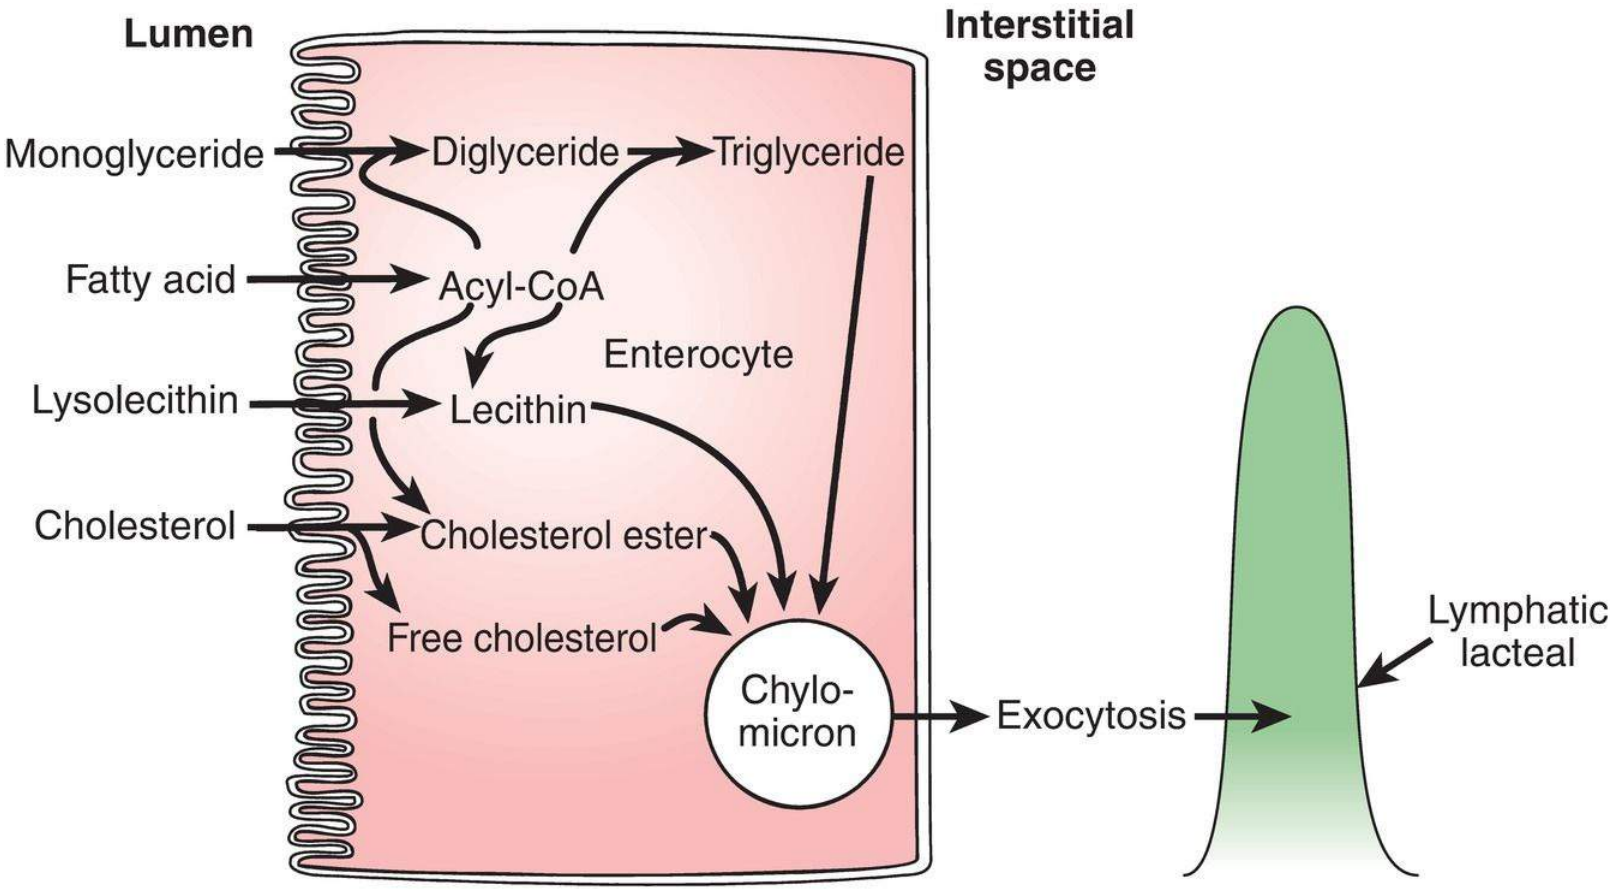

Figure 25.21 Endocytes form chylomicrons for lipid transport. Chylomicrons are large lipoproteins and transport exogenous lipids to the liver and to adipose, cardiac, and skeletal tissue. Chylomicrons are absorbed into a lymphatic lacteal. Acyl-CoA, acyl-coenzyme A.

Cholesterol can be transported out of the enterocytes as free cholesterol or as esterified cholesterol. The enzyme responsible for the esterification of cholesterol to form cholesterol ester is **acyl-CoA cholesterol acyltransferase**.

The reassembled triglycerides, lecithin, cholesterol, and cholesterol esters are then packaged into **lipoproteins** and exported from the enterocytes. The intestine produces two major classes of lipoproteins: **chylomicrons** and **very low–density lipoproteins** (**VLDLs**). Both are triglyceride-rich lipoproteins with densities <1.006 g/mL. The small intestine exclusively makes chylomicrons, and their primary function is to transport the large amount of dietary fat absorbed by the small intestine from the enterocytes to the

lymph. Chylomicrons are large, spherical lipoproteins with diameters of 80 to 500 nm. They contain less protein and phospholipid than do VLDLs and are, therefore, less dense than are VLDLs. The small intestine continuously makes VLDLs during both fasting and feeding, although the liver contributes significantly more VLDLs to the circulation. VLDL is converted in the bloodstream to **low-density lipoprotein** (**LDL**). Since cholesterol is carried by LDL, cholesterol content can be measured on LDL particles. High levels of LDL particles can promote medical problems and they are often referred to as *bad cholesterol* particles (as opposed to HDL, which is often referred to as *good cholesterol*). One of the functions of LDL particles is the transport of cholesterol into the arterial wall where it is retained by arterial proteoglycans. **Macrophages** are attracted to these sites and function to engulf the LDL particles. The process of engulfing LDL particles by macrophages initiates plaque formation in the arterial wall. Increased levels of plaque formation are linked to atherosclerosis. Over time, plaques become vulnerable to rupturing, which, in turn, activates blood clotting and leads to arterial stenosis.

Apoproteins—Apo A-I, Apo A-IV, and Apo B—are among the major proteins associated with the production of chylomicrons and VLDLs. Apo B is the only protein that seems to be necessary for the normal formation of intestinal chylomicrons and VLDLs. This protein is made in the small intestine. It has a molecular weight of 250,000 and is extremely hydrophobic. Apo A-I, also formed by intestinal cells, is involved in a reaction catalyzed by the plasma enzyme **lecithin cholesterol acyltransferase** (**LCAT**). Plasma LCAT is responsible for the esterification of cholesterol in the plasma to form cholesterol ester with the fatty acid derived from the 2-position of lecithin. After the chylomicrons and VLDLs enter the plasma, Apo A-I is rapidly transferred from chylomicrons and VLDLs to HDLs. Apo A-I is the major protein present in plasma HDLs. The small intestine and the liver make Apo A-IV. Recently, it was shown that Apo A-IV, secreted by the small intestine, may be an important factor contributing to anorexia after fat feeding.

Newly synthesized lipoproteins in the SER are transferred to the Golgi apparatus, where they are packaged into vesicles. Chylomicrons and VLDLs are released into the intercellular space by exocytosis. From there, they are transferred to the central lacteals (the beginnings of lymphatic vessels) by a process (transcellular or paracelluar route) that is not well understood. Intestinal lipid absorption is associated with a marked increase in lymph flow called the **lymphagogic effect** of fat feeding. This increase in lymph flow plays an important role in the transfer of lipoproteins from the intercellular spaces to the central lacteal.

Fatty acids can also travel in the blood bound to albumin. Whereas most of the long-chain fatty acids are transported from the small intestine as triglycerides packaged in chylomicrons and VLDLs, some are transported in the portal blood bound to serum albumin. Most of the medium-chain (8 to 12 carbons) and all of the short-chain fatty acids are transported via the hepatic portal route.

Altered lipase and bile secretion significantly impair lipid digestion and absorption.

In several clinical conditions, lipid digestion and absorption are impaired, resulting in the malabsorption of lipids and other nutrients and fatty stools. Abnormal lipid absorption can result in numerous problems because the body requires certain essential fatty acids (see previous discussion).

Pancreatic deficiency significantly reduces the ability of the exocrine pancreas to produce digestive enzymes. Because the pancreas normally produces an excess of digestive enzymes, enzyme production has to be reduced to about 10% of normal before symptoms of malabsorption develop. One characteristic of pancreatic deficiency is **steatorrhea** (fatty stool), resulting from the poor digestion of fat by pancreatic lipase. Normally, about 5 g/d of fat is excreted in human stool. With steatorrhea, as much as 50 g/d of fat can be excreted.

Fat absorption subsequent to the action of pancreatic lipase requires solubilization by bile salt micelles. Acute or chronic liver disease can cause defective biliary secretion, resulting in bile salt concentrations lower than that necessary for micelle formation. The normal absorption of fat is thereby inhibited.

Abetalipoproteinemia, an autosomal recessive disorder, is characterized by a complete lack of Apo B in the circulation, which is required for the formation and secretion of chylomicrons and VLDLs. Apo B–containing lipoproteins in the circulation, including chylomicrons, VLDLs, and LDLs, are absent. Plasma LDLs are absent because they are derived mainly from the metabolism of VLDLs. Because people with abetalipoproteinemia do not produce any chylomicrons or VLDLs in the small intestine, they are unable to transport absorbed fat, resulting in an accumulation of lipid droplets in the cytoplasm of enterocytes. They also suffer from a deficiency of fat-soluble vitamins (A, D, E, and K). Using molecular biologic techniques, it has been determined that Apo B deficiency is caused by a mutation of a transfer protein called microsomal triglyceride transfer protein. This protein facilitates the transfer of triglyceride formed in the cytoplasm to the ER.

PROTEIN DIGESTION AND ABSORPTION

Dietary proteins are basically long-chain amino acids that are joined together by peptide bonds between the carboxyl and amino groups. Proteins are fundamental structural components of cells and participate in every aspect of cell function. Aside from their role in cellular protein synthesis, amino acids are also an important nutritional source of nitrogen.

Proteins are primarily used in cell function and structure rather than as a source of energy. Most proteins are found in muscle, with the remainder in other cells, blood, body fluids, and body secretions. Enzymes and many hormones are proteins. Examples of their use in cellular function are shown in Table 25.4. Proteins are composed of amino acids and have molecular weights of a few thousand to a few hundred thousand. More than 20 common amino acids form the building blocks for proteins (Table 25.5). Of these, nine are considered essential and must be provided by the diet. Although the **nonessential amino acids** are also required for normal protein synthesis, the body can synthesize them from other amino acids.

TABLE 25.4 Proteins Have a Large Range of Cellular Functions in the Body

Function	Description	Example
Antibody	An antibody neutralizes pathogens such as viruses, bacteria, fungus, and parasites.	IgA, IgE, IgM
Enzyme	Enzymes are biological catalysts that accelerate over thousands of chemical reaction in cells.	Carbonic anhydrase, catalase, lactase
Messenger	Messenger proteins are usually hormones that transmit signals to different parts of the body to coordinate cellular function between different tissues and organs.	Growth hormone, oxytocin, vasopressin
Structural component	Structural proteins are fibrous proteins that provide structure and support for cells, tissues, and organs. On a larger scale, they also allow the body to move.	Actin, myosin, keratins, collagen
Transport proteins	These proteins function to move other molecules throughout the body. There are two types: those that carry molecules across impermeable membranes and those that carry molecules to distant locations in the body.	Na^+/K^+-ATPase, Ca^{2+} ATPase, serum albumin, hemoglobin

TABLE 25.5 Amino Acids Found in Proteins

Essential	Nonessential
Histidine	Alanine
Isoleucine	Arginine
Leucine	Aspartic acid
Lysine	Citrulline
Methionine	Glutamic acid
Phenylalanine	Glycine
Threonine	Hydroxyglutamic acid
Tryptophan	Hydroxyproline
Valine	Norleucine
	Proline
	Serine
	Tyrosine

Complete proteins are those that can supply all of the essential amino acids in amounts sufficient to support normal growth and body maintenance. Examples are eggs, poultry, and fish. The proteins in most vegetables and grains are called **incomplete proteins** because they do not provide all of the essential amino acids in amounts sufficient to sustain normal growth and body maintenance. Vegetarians need to eat a variety of vegetables and soy protein to avoid amino acid deficiencies.

Some dietary proteins are often the cause of allergies and/or allergic reactions. These reactions occur because the structure of each form of protein is slightly different. Some may trigger an immune response, whereas other structures are perfectly safe. For example, many individuals are allergic to gluten (the protein in wheat and other grains), to casein (the protein in milk), and to particular proteins found in peanuts. Some individuals are also allergic to shellfish and to specific proteins found in other types of seafood. Certain food additives and dyes (food coloring) may also stimulate an immune response.

Nondietary proteins derive from endogenous sources.

The average American adult takes in 70 to 110 g/d of protein. The minimum daily protein requirement for adults is about 0.8 g/kg body weight (e.g., 56 g for a 70-kg person). Pregnant and lactating women require 20 to 30 g of protein above the recommended daily allowance. A lactating woman can lose as much as 12 to 15 g of protein per day as milk protein. Children need more protein for body growth; the recommended daily allowance for infants is about 2 g/kg body weight, and young children may require as much as 4 g/kg body weight.

Although most of the protein entering the GI tract is dietary protein, there are also proteins derived from endogenous sources such as pancreatic, biliary, and intestinal secretions and the cells shed from the intestinal villi. About 20 to 30 g/d of protein enters the intestinal lumen in pancreatic juice and about 10 g/d in bile. Enterocytes of the intestinal villi are continuously shed into the intestinal lumen, and as much as 50 g/d of enterocyte proteins enter the intestinal lumen. An average of 150 to 180 g/d of total protein is presented to the small intestine, of which more than 90% is absorbed.

Digestion of proteins starts in the stomach and continues in the small intestine.

Most of the protein in the intestinal lumen is completely digested into amino acids, dipeptides, or tripeptides before it is taken up by the enterocytes (Fig. 25.22). Protein digestion typically begins in the stomach when **pepsinogen** is cleaved by HCl to yield **pepsin**. Pepsin hydrolyzes protein to form smaller polypeptides. This phase of protein digestion is normally not important except in people suffering from pancreatic exocrine deficiency.

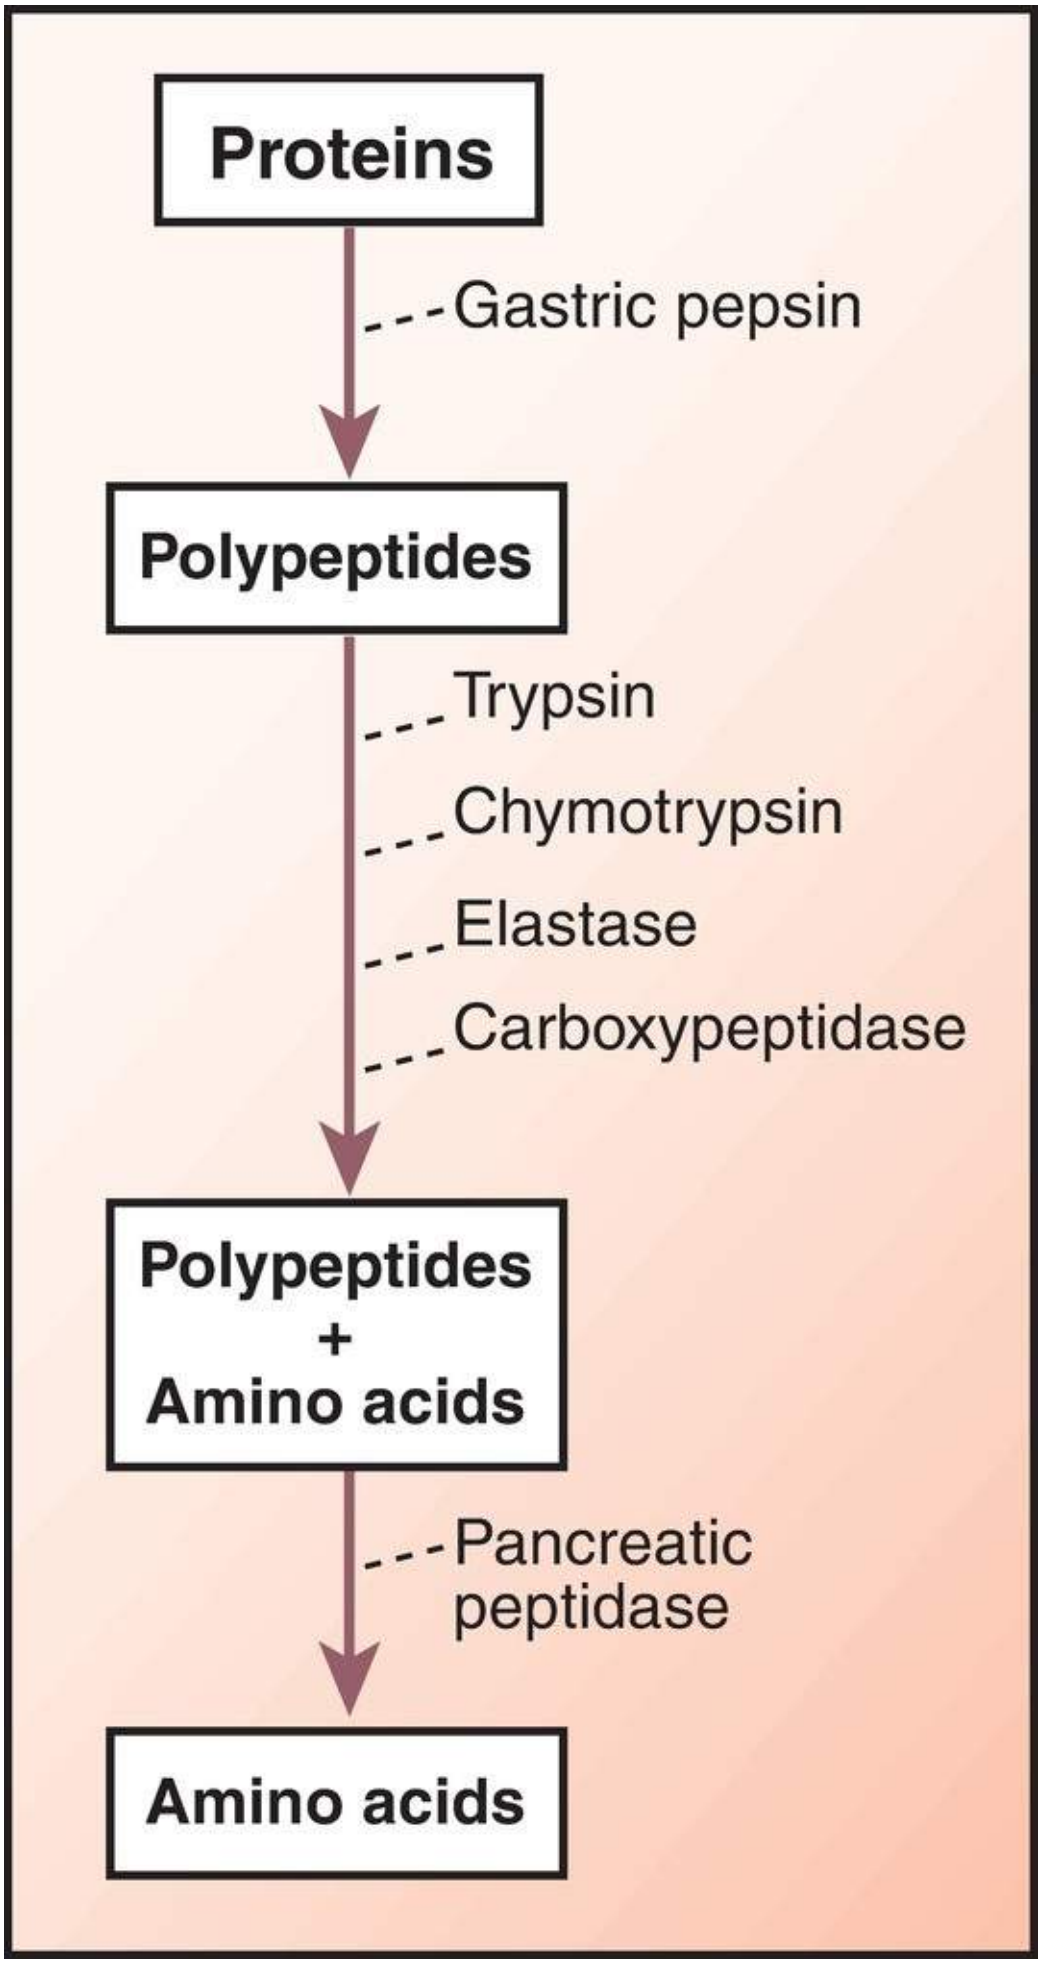

Figure 25.22 Protein absorption begins in the stomach. The first step involves the hydrolysis of proteins by gastric pepsin to form smaller polypeptides. Polypeptides are further acted upon by intestinal

enzymes and proteases from both the small intestine and pancreas.

Most of the digestion of proteins and polypeptides takes place in the small intestinal lumen by **trypsin** and **chymotrypsin**. Most proteases are secreted in the pancreatic juice as inactive proenzymes. After pancreatic juice enters the duodenum, **enteropeptidase** (**enterokinase**), an enzyme found on the luminal surface of enterocytes, cleaves trypsinogen to **trypsin**. Trypsin then cleaves the other proenzymes to yield active enzymes.

The pancreatic proteases are classified as endopeptidases or exopeptidases (see Table 25.2). **Endopeptidases** hydrolyze certain internal peptide bonds of proteins or polypeptides to release the smaller peptides. The three endopeptidases present in pancreatic juice are trypsin, chymotrypsin, and elastase. **Trypsin** splits off basic amino acids from the C-terminus of a protein, **chymotrypsin** attacks peptide bonds with an aromatic carboxyl terminal, and **elastase** attacks peptide bonds with a neutral aliphatic C-terminus. The **exopeptidases** in pancreatic juice are carboxypeptidase A and carboxypeptidase B. Like the endopeptidases, the exopeptidases are specific in their action. **Carboxypeptidase A** attacks polypeptides with a neutral aliphatic or aromatic C-terminus. **Carboxypeptidase B** attacks polypeptides with a basic C-terminus. The final products of protein digestion are amino acids and small peptides.

Intestinal enterocytes contain specific transporters to take up amino acids and peptides.

Enterocytes take up amino acids in the small intestine via secondary active transport. Six major amino acid carriers in the small intestine have been identified; they transport related groups of amino acids. The amino acid transporters favor the L-form over the D-form. As in the uptake of glucose, the uptake of amino acids depends on an Na^+ concentration gradient across the enterocyte brush border membrane.

The absorption of peptides by enterocytes was once thought to be less efficient than amino acid absorption. However, subsequent studies in humans clearly demonstrated that dipeptide and tripeptide uptake is significantly more efficient than the uptake of amino acids. Dipeptides and tripeptides use different transporters than those used by amino acids. The peptide transporter prefers dipeptides and tripeptides with either glycine or lysine residues. Furthermore, the peptide transporter only poorly transports tetrapeptides and more complex peptides. The **peptidases** (exopeptidases) located on the brush border of the enterocytes can further break down these peptides to dipeptides and tripeptides (see Fig. 25.22). Dipeptides and tripeptides are given to people suffering from malabsorption because they are absorbed more efficiently and are more palatable than free amino acids. Another advantage of peptides over amino acids is the smaller osmotic stress created as a result of delivering them.

In adults, a negligible amount of protein is absorbed as undigested protein. In some people, however, intact or partially digested proteins are absorbed, resulting in anaphylactic or hypersensitivity reactions. The pulmonary and cardiovascular systems are the major organs involved in anaphylactic reactions. For the first few weeks after birth, the newborn's small intestine absorbs considerable amounts of intact proteins. This is possible because of low proteolytic activity in the stomach, low pancreatic secretion of peptidases, and poor development of intracellular protein degradation by lysosomal proteases.

The absorption of immunoglobulins (predominantly IgG) plays an important role in the transmission of **passive immunity** from the mother's milk to the newborn in several animal species (e.g., ruminants and rodents). In humans, the absorption of intact immunoglobulins does not appear to be an important mode of transmission of antibodies for two reasons. First, passive immunity in humans is derived almost entirely from the intrauterine transport of maternal antibodies. Second, human **colostrum**, the thin, yellowish, milky fluid secreted by the mammary glands a few days before or after parturition, contains mainly IgA, which is poorly absorbed by the small intestine. The ability to absorb intact proteins is rapidly lost as the gut matures—a process called **closure**. Colostrum contains a factor that promotes the closure of the small intestine.

After the enterocytes take up dipeptides and tripeptides, peptidases in the cytoplasm break them down to amino acids, which are transported in the portal blood. The small amount of protein that is taken up by the adult intestine is largely degraded by lysosomal proteases, although some proteins escape degradation.

Genetic disorders lead to impaired protein absorption.

Although pancreatic deficiency has the potential to affect protein digestion, it does so only in severe cases and seems to affect lipid digestion more than protein digestion. There are several extremely rare genetic disorders of amino acid carriers. In **Hartnup disease**, the membrane carrier for neutral amino acids (e.g., tryptophan) is defective. **Cystinuria** involves the carrier for basic amino acids (e.g., lysine and arginine) and the sulfur-containing amino acids (e.g., cystine). Cystinuria was once thought to involve only the kidneys because of the excretion of amino acids such as cystine in urine, but the small intestine is involved as well.

Because the peptide transport system remains unaffected, disorders of some amino acid transporters can be treated with supplemental dipeptides containing these amino acids. However, this treatment alone is not effective if the kidney transporter is also involved, as in the case of cystinuria.

VITAMIN ABSORPTION

Vitamins are organic compounds required as a nutrient in small quantities by an animal. Thus, an organic compound is called a *vitamin* when it cannot be synthesized by the body and must be obtained from the diet. By convention, the term “vitamin” excludes dietary minerals, which are inorganic. Currently, 13 vitamins are universally recognized (Table **25.6**).

TABLE 25.6 Vitamins: Their Solubility and Dietary Sources

Vitamin	Solubility	Food Source
Vitamin A (retinol)	Fat	Cod liver oil, carrots
Vitamin B_1 (thiamine)	Water	Rice bran
Vitamin C (ascorbic acid)	Water	Citrus, most fresh foods
Vitamin D (calciferol)	Fat	Cod liver oil
Vitamin B_2 (riboflavin)	Water	Meat, eggs
Vitamin E (tocopherol)	Fat	Wheat germ oil, unrefined vegetable oils
Vitamin B_{12} (cobalamins)	Water	Liver, eggs, animal products
Vitamin K (phylloquinone/phytol naphthoquinone)	Fat	Leafy green vegetables
Vitamin B_5 (pantothenic acid)	Water	Meats, whole grains, and many foods
Vitamin B_7 (biotin)	Water	Meats, dairy products, eggs
Vitamin B_6 (pyridoxine)	Water	Meat, dairy products
Vitamin B_3 (niacin)	Water	Meat, eggs, grains
Vitamin B_9 (folic acid)	Water	Leafy green vegetables

Vitamins are classified in many ways, but, in terms of absorption, they are classified as either water-soluble or fat-soluble. In humans, there are 13 vitamins: 4 fat-soluble vitamins (A, D, E, and K) and 9 water-soluble vitamins (8 B vitamins and vitamin C). Because water-soluble vitamins are easily dissolved in H_2O, they are readily excreted from the body. Thus, urinary output is a strong predictor of B vitamin and C vitamin consumption.

Vitamins have many diverse cell functions, and many are essential for metabolic reactions.

Vitamins act as both catalysts and substrates in chemical reactions of the body. When acting as a catalyst, vitamins are bound to enzymes and are called cofactors (e.g., vitamin K forms part of the proteases involved in blood clotting). Vitamins can also act as coenzymes to carry chemical groups between enzymes (e.g., folic acid carries a carbon group methylene in the cell).

Fruits and vegetables are good sources of vitamins. Until the early 1900s, vitamins were obtained solely through food intake. Therefore, changes in diet often led to vitamin deficiencies and deadly diseases (e.g., lack of citrus fruit led to scurvy, a particularly deadly disease in which collagen is not properly formed and causes poor wound healing, bleeding gums, and severe pain). However, today, vitamins can be produced commercially and made widely available as inexpensive supplementation of dietary intake.

Fat-soluble vitamins: A, D, E, and K

The principal form of **vitamin A** is retinol; the aldehyde (retinal) and the acid (retinoic acid) are also active forms of vitamin A. Retinol can be derived directly from animal sources or through conversion from β-carotene (found abundantly in carrots) in the small intestine. Micellar solubilization renders vitamin A water-soluble, and the small intestine absorbs it passively. The unesterified retinol is then complexed with retinol-binding protein type 2, and the complex serves as a substrate for the re-esterification of the retinol by the enzyme lecithin: retinol acyltransferase. The retinyl ester is incorporated in chylomicrons and taken up by the liver. Vitamin A is stored in the liver and released to the circulation bound to retinol-binding protein only when needed. Vitamin A is important in the production and regeneration of rhodopsin of the retina and in the normal growth of the skin. People with vitamin A deficiency develop night blindness and skin lesions.

Vitamin D is a group of fat-soluble compounds collectively known as the *calciferols*. The human body has two main sources of vitamin D_3 (also called *cholecalciferol* or *activated dehydrocholesterol*)—the skin and the diet. The skin contains a rich source of 7-dehydrocholesterol, which is rapidly converted to cholecalciferol when exposed to ultraviolet light. Like vitamin A, vitamin D_3 is absorbed by the small intestine passively and is incorporated into chylomicrons. During the metabolism of chylomicrons, vitamin D_3 is transferred to a binding protein in plasma called the **vitamin D–binding protein**.

Unlike vitamin A, vitamin D is not stored in the liver but is distributed among the various organs depending on their lipid content. In the liver, vitamin D_3 is converted to 25-hydroxycholecalciferol, which is subsequently converted to the active hormone **1,25-dihydroxycholecalciferol** in the kidneys. The latter enhances Ca^{2+} and phosphate absorption by the small intestine and mobilizes Ca^{2+} and phosphate from bones.

Vitamin D is essential for normal development and growth and the formation of bones and teeth. Vitamin D deficiency can result in **rickets**, a disorder of normal bone ossification manifested by distorted bone movements during muscular action.

The major dietary **vitamin E** is α-tocopherol. Vegetable oils are rich in vitamin E. It is absorbed by the small intestine by passive diffusion and incorporated into chylomicrons. Unlike vitamins A and D,

vitamin E is transported in the circulation associated with lipoproteins and erythrocytes.

Vitamin E is a potent antioxidant and therefore prevents lipid peroxidation. Tocopherol deficiency is associated with increased red cell susceptibility to lipid peroxidation, which may explain why the red cells are more fragile in people with vitamin E deficiency than in healthy people.

Vitamin K can be derived from green vegetables in the diet or the gut flora. The vitamin K derived from green vegetables is in the form of **phylloquinones**. Vitamin K derived from bacteria in the small intestine is in **menaquinones**. The small intestine takes up phylloquinones via an energy-dependent process from the proximal small intestine. In contrast, menaquinones are absorbed from the small intestine passively, depending only on the micellar solubilization of these compounds by bile salts. Vitamin K is incorporated into chylomicrons. It is rapidly taken up by the liver and secreted together with VLDLs. No carrier protein for vitamin K has been identified.

Vitamin K is essential for the synthesis of various clotting factors by the liver. Vitamin K deficiency is associated with bleeding disorders.

Water-soluble vitamins: C, B_1, B_2, B_6, B_{12}, niacin, biotin, and folic acid

Most of the water-soluble vitamins are absorbed by the small intestine by both passive and active processes. The water-soluble vitamins are summarized in Table 25.6.

The major source of **vitamin C** (**ascorbic acid**) is green vegetables and fruits. It plays an important role in many oxidative processes by acting as a coenzyme or cofactor. It is absorbed mainly by active transport through the transporters in the ileum. The uptake process is sodium-dependent. Vitamin C deficiency is associated with **scurvy**, a disorder characterized by weakness, fatigue, anemia, and bleeding gums.

Vitamin B_1 (**thiamine**) plays an important role in carbohydrate metabolism. The jejunum absorbs thiamine passively as well as by an active, carrier-mediated process. Thiamine deficiency results in **beriberi**, characterized by anorexia and disorders of the nervous system and heart.

Vitamin B_2 (**riboflavin**) is a component of the two groups of flavoproteins—flavin adenine dinucleotide and flavin mononucleotide. Riboflavin plays an important role in metabolism. It is absorbed by a specific, saturable, active transport system located in the proximal small intestine. Its deficiency is associated with anorexia, impaired growth, impaired use of food, and nervous disorders.

Niacin plays an important role as a component of the coenzymes NAD(H) and NADP(H), which participate in a wide variety of oxidation–reduction reactions involving H^+ transfer.

At low concentrations, the small intestine absorbs niacin by Na^+-dependent, carrier-mediated facilitated transport. At high concentrations, it is absorbed by passive diffusion. Niacin has been used to treat hypercholesterolemia, for the prevention of coronary artery disease. It decreases plasma total cholesterol and LDL cholesterol yet increases plasma HDL cholesterol.

Niacin deficiency is characterized by many clinical symptoms including anorexia, indigestion, muscle weakness, and skin eruptions. Severe deficiency leads to **pellagra**, a disease characterized by dermatitis, dementia, and diarrhea.

Vitamin B_6 (**pyridoxine**) is involved in amino acid and carbohydrate metabolism. Vitamin B_6 is absorbed throughout the small intestine by simple diffusion. A deficiency of this vitamin is often associated with anemia and central nervous system disorders.

Biotin acts as a coenzyme for carboxylase, transcarboxylase, and decarboxylase enzymes, which play

an important role in the metabolism of lipids, glucose, and amino acids. At low luminal concentrations, biotin is absorbed by the small intestine by Na^+-dependent active transport. At high concentrations, biotin is absorbed by simple diffusion. Biotin is so common in food that deficiency is rarely observed. However, biotin deficiency occurs frequently when parenteral nutrition (nutrition administered intravenously) is administered for a long period.

Folic acid is usually found in the diet as polyglutamyl conjugates (pteroylpolyglutamates). It is required for the formation of nucleic acids, the maturation of red blood cells, and growth. An enzyme on the brush border degrades pteroylpolyglutamates to yield a monoglutamylfolate, which is taken up by enterocytes by facilitated transport. Once inside enterocytes, the monoglutamylfolate is released directly into the bloodstream or converted to 5-methyltetrahydrofolate before exiting the cell. A folate-binding protein binds the free and methylated forms of folic acid in plasma. Folic acid deficiency causes a fall in plasma and red cell folic acid content and, in its most severe form, the development of megaloblastic anemia, dermatologic lesions, and poor growth. A link between folic acid deficiency and spina bifida (opening in the spine) has been demonstrated. Consequently, the U.S. Public Health Service recommends that women of childbearing age should take 0.4 mg of folic acid daily during the first 3 months of pregnancy.

The discovery of **vitamin B_{12}** (**cobalamin**) followed from the observation that patients with **pernicious anemia** who ate large quantities of raw liver recovered from the disease. Subsequent analysis of liver components isolated the cobalt-containing vitamin, which plays an important role in the production of red blood cells. A glycoprotein called intrinsic *factor* is secreted by the parietal cells in the stomach and binds strongly with vitamin B_{12} to form a complex that is then absorbed in the terminal ileum through a receptor-mediated process (Fig. 25.23). Vitamin B_{12} is transported in the portal blood bound to the protein **transcobalamin**. People who lack the intrinsic factor fail to absorb vitamin B_{12} and develop pernicious anemia.

ELECTROLYTE AND MINERAL ABSORPTION

Nearly all of the dietary nutrients and ~95% to 98% of the H_2O and electrolytes that enter the upper small intestine are absorbed. The absorption of electrolytes and minerals involves both passive and active processes, resulting in the movement of electrolytes, H_2O, and metabolic substrates into the blood for distribution and use throughout the body.

Minerals are chemical elements required for physiologic function.

Minerals are chemical elements required by the body for normal function. They can be either bulk minerals (required in relatively large amounts) or trace minerals (required in minute amounts). Minerals can be acquired naturally in food or added to the diet (e.g., calcium carbonate or sodium chloride). Bulk minerals include calcium, magnesium, phosphorus, potassium, sodium, and sulfur. Trace minerals include chromium, cobalt, copper, fluorine, iodine, iron, manganese, molybdenum, selenium, and zinc.

Sodium

The GI system is well equipped to handle the large amount of Na^+ entering the GI lumen daily—on average, about 25 to 35 g of Na^+ every day. Around 5 to 8 g is derived from the diet and the rest from salivary, gastric, biliary, pancreatic, and small intestinal secretions. The GI tract is extremely efficient in conserving Na^+: only 0.5% of intestinal Na^+ is lost in the feces. The jejunum absorbs more than half of the total Na^+, and the ileum and colon absorb the remainder. The small intestine absorbs the bulk of the Na^+ presented to it, but the colon is most efficient in conserving Na^+.

Several different mechanisms operating at varying degrees in different parts of the GI tract absorb Na^+. When a meal that is hypotonic to plasma is ingested, considerable absorption of H_2O from the lumen to the blood takes place, predominantly through tight junctions and intercellular spaces between the enterocytes, resulting in the absorption of small solutes such as Na^+ and Cl^- ions. This mode of absorption, called **solvent drag**, is responsible for a significant amount of the Na^+ absorption by the duodenum and jejunum, but it probably plays a minor role in Na^+ absorption by the ileum and colon because more distal regions of the intestine are lined by a “tight” epithelium (see Chapter 2).

In the jejunum, an Na^+/K^+-ATPase actively pumps Na^+ out of the basolateral surface of enterocytes (Fig. 25.24A). The result is low intracellular Na^+ concentration, and the luminal Na^+ enters enterocytes down the electrochemical gradient, providing energy for the extrusion of H^+ into the lumen (via an Na^+/H^+ exchanger). The H^+ then reacts with HCO_3^- in bile and pancreatic secretions in the intestinal lumen to form H_2CO_3. Carbonic acid dissociates to form CO_2 and H_2O. The CO_2 readily diffuses across the small intestine into the blood. Another mode of Na^+ uptake is via a carrier located in the enterocyte brush border membrane, which transports Na^+ together with a monosaccharide (e.g., glucose) or an amino acid molecule (a symport type of transport).

Figure 25.24 Na^+ absorption in the gut depends on an Na^+/K^+-ATPase pump. Approximately 98% of the electrolytes in the gut are reabsorbed. An Na^+/K^+-ATPase actively pumps Na^+ across the basal lateral surface to be absorbed into the blood. (**A**) Na^+ absorption by the jejunum. (**B**) Na^+ absorption by the ileum. ATP, adenosine triphosphate.

In the ileum, the Na^+/K^+-ATPase in the basolateral membrane also creates a low intracellular Na^+ concentration, and luminal Na^+ enters enterocytes down the electrochemical gradient. Na^+ absorption by Na^+-coupled symporters is not as great as in the jejunum because the small intestine has already absorbed most of the monosaccharides and amino acids (see Fig. 25.24B). NaCl is transported via two exchangers located at the brush border membrane. One is a Cl^-/HCO_3^- exchanger, and the other is an Na^+/H^+ exchanger. The downhill movement of Na^+ into the cell provides the energy required for the uphill movement of the H^+ from the cell to the lumen. Similarly, the downhill movement of HCO_3^- out of the cell provides the energy for the uphill entry of Cl^- into the enterocytes. The Cl^- then leaves the cell through facilitated transport. This mode of Na^+ uptake is called Na^+/H^+– Cl^-/HCO_3^- countertransport.

In the colon, the mechanisms for Na^+ absorption are mostly similar to those described for the ileum. There is no sugar-coupled or amino acid–coupled Na^+ transport because most sugars and amino acids have already been absorbed. Na^+ is also absorbed here via Na^+-selective ion channels in the apical cell membrane (electrogenic Na^+ absorption).

Potassium

The average daily intake of K^+ is about 4 g. Absorption takes place throughout the intestine by passive diffusion through the tight junctions and lateral intercellular spaces of the enterocytes. The driving force for K^+ absorption is the difference between luminal and blood K^+ concentration. The absorption of H_2O results in an increase in luminal K^+ concentration, resulting in K^+ absorption by the intestine. In the colon, K^+ can be absorbed or secreted depending on the luminal K^+ concentration. With diarrhea, considerable K^+ can be lost. Prolonged diarrhea can be life threatening, because the dramatic fall in extracellular K^+ concentration can cause complications such as cardiac arrhythmias.

Chloride

Most of the Cl^- ions added to the GI tract from the diet and from the intestinal secretions are absorbed. Intestinal Cl^- absorption involves both passive and active processes. In the jejunum, active Na^+ absorption generates a potential difference across the small intestinal mucosa, with the serosal side more positive than the lumen. Cl^- follows this potential difference and enters the bloodstream via the tight junctions and lateral intercellular spaces. In the ileum and colon, enterocytes actively take up Cl^- via Cl^-/HCO_3^- exchange, as discussed above. The presence of other halides inhibits this absorption of Cl^-.

Bicarbonate

Bicarbonate ions are absorbed in the jejunum together with Na^+. In humans, the absorption of HCO_3^- by the jejunum stimulates the absorption of Na^+ and H_2O (Fig. 25.25A). Through an Na^+/H^+ exchanger, H^+ is secreted into the intestinal lumen, where H^+ and HCO_3^- react to form H_2CO_3, which then dissociates to

form CO_2 and H_2O. The CO_2 diffuses into the enterocytes, where it reacts with H_2O to form H_2CO_3 (catalyzed by carbonic anhydrase). H_2CO_3 dissociates into HCO_3^- and H^+, and the HCO_3^- then diffuses into the blood.

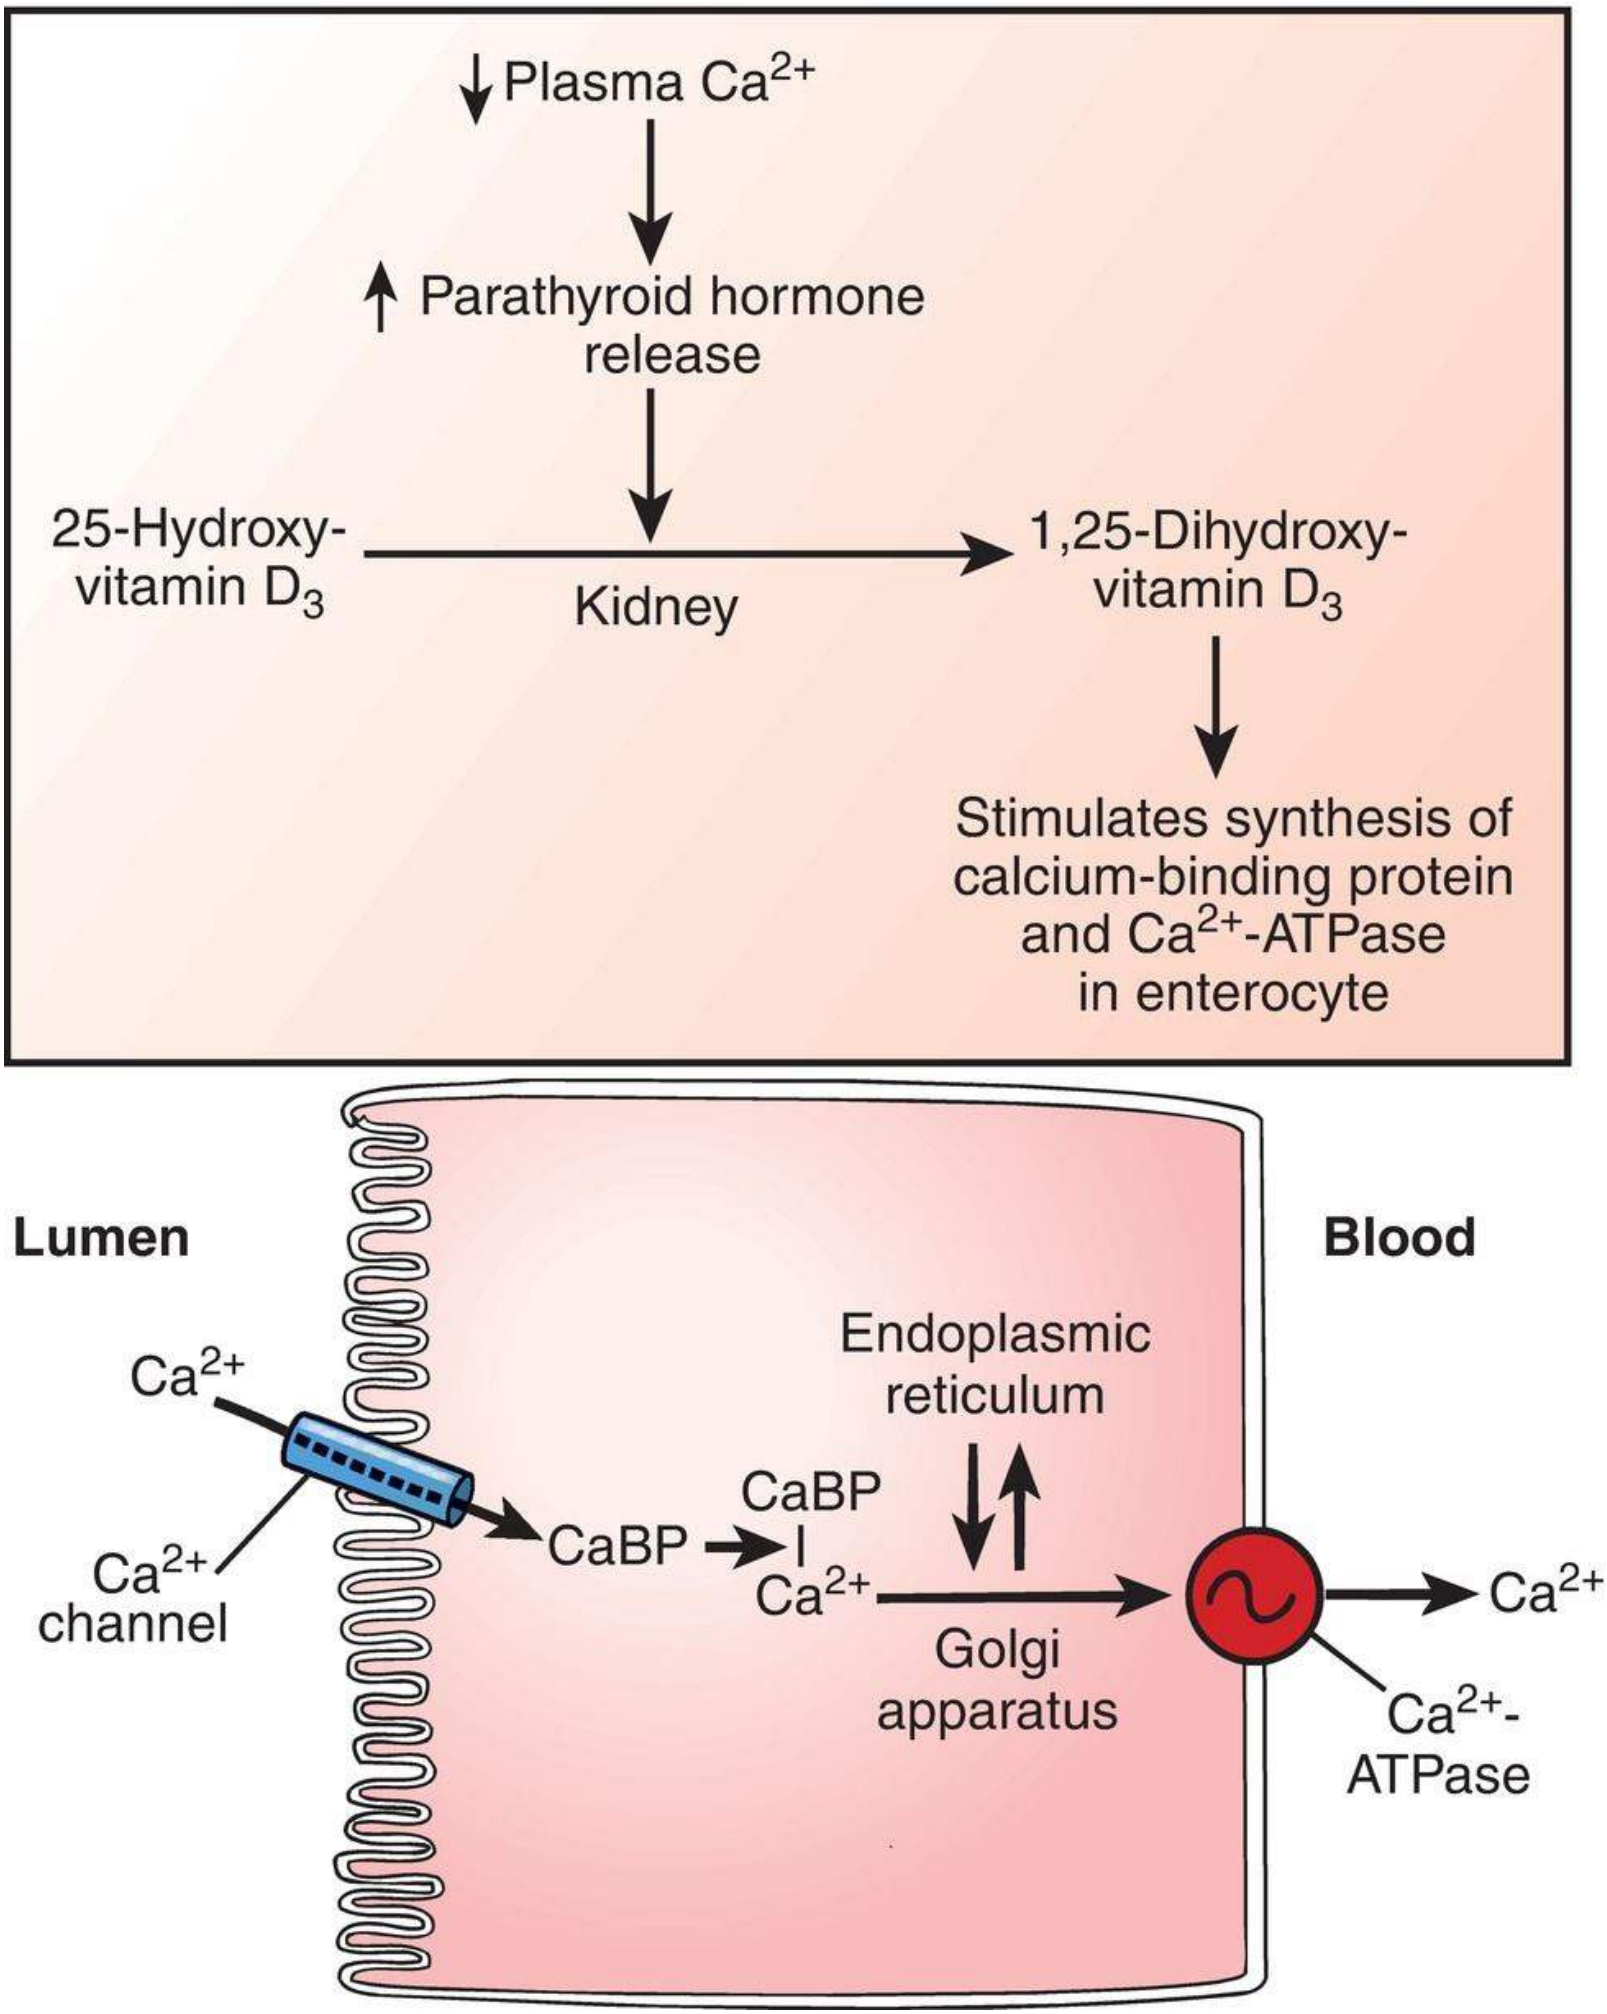

Figure 25.25 Parathyroid hormone and vitamin D are required for calcium absorption by

enterocytes. Parathyroid hormone stimulates the conversion of vitamin D_3 in the kidney to its active metabolite 1,25-dihydroxycholecalciferol (1,25-diOH-vitamin D_3), which stimulates Ca^{2+} uptake via the Ca^{2+} channels. Additionally, it stimulates the synthesis of both Ca^{2+}-binding protein (CaBP) and the Ca^{2+}-ATPase.

In the ileum and colon, HCO_3^- is actively secreted into the lumen in exchange for Cl^-. This secretion of HCO_3^- is important in buffering the decrease in pH resulting from the short-chain fatty acids produced by bacteria in the distal ileum and colon.

Calcium

The amount of Ca^{2+} entering the GI tract is about 1 g/day, approximately half of which is derived from the diet. Most dietary Ca^{2+} is derived from meat and dairy products. Of the Ca^{2+} entering the GI tract, about 40% is absorbed. Several factors affect Ca^{2+} absorption. For instance, the presence of fatty acid can retard Ca^{2+} absorption by the formation of Ca^{2+} soap. In contrast, bile salts form complexes with Ca^{2+} ions, which facilitate Ca^{2+} absorption.

Calcium absorption takes place predominantly in the duodenum and jejunum, is mainly active, and involves three steps: (1) Enterocytes take up Ca^{2+} by passive diffusion through a Ca^{2+} channel, because there is a large Ca^{2+} concentration gradient; the luminal Ca^{2+} is about 5 to 10 mM, whereas free intracellular Ca^{2+} is about 100 nM. (2) Once inside the cell, Ca^{2+} is complexed with **Ca^{2+}-binding protein, calbindin D** (**CaBP**). (3) At the basolateral membrane, Ca^{2+} is extruded from the enterocytes via the Ca^{2+}-ATPase pump. Calcium uptake by enterocytes, the level of CaBP in the cells, and transport by Ca^{2+}-ATPase pumps are increased by 1,25-dihydroxyvitamin D_3. Once inside the cell, the Ca^{2+} ions are sequestered in the ER and Golgi by binding to the CaBP in these organelles.

Calcium absorption by the small intestine is regulated by the circulating plasma Ca^{2+} concentration. Lowering of the Ca^{2+} concentration stimulates the release of parathyroid hormone, which stimulates the conversion of vitamin D to its active metabolite, 1,25-dihydroxyvitamin D_3, in the kidney. This, in turn, stimulates the synthesis of CaBP and the Ca^{2+}-ATPase by the enterocytes (see Fig. 25.25). Because protein synthesis is involved in the stimulation of Ca^{2+} uptake by parathyroid hormone, a lapse of a few hours usually occurs between the release of parathyroid hormone and the increase in Ca^{2+} absorption by the enterocytes.

Magnesium

Humans ingest about 0.4 to 0.5 g/d of Mg^{2+}. The absorption of Mg^{2+} seems to take place along the entire small intestine, and the mechanism involved seems to be passive.

Zinc

The average daily zinc intake is 10 to 15 mg, about half of which is absorbed, primarily in the ileum. A carrier located in the brush border membrane actively transports zinc from the lumen into the cell, where it can be stored or transferred into the bloodstream. Zinc plays an important role in several metabolic activities. For example, a group of metalloenzymes (e.g., alkaline phosphatase, carbonic anhydrase, and lactic dehydrogenase) require zinc to function.

Iron

Iron plays an important role not only as a component of heme but also as a participant in many enzymatic reactions. About 12 to 15 mg/day of iron enters the GI tract and is absorbed mainly in the duodenum and upper jejunum (Fig. 25.26). There are two forms of dietary iron: heme and nonheme. Enterocytes absorb the heme iron intact. Nonheme iron absorption depends on both pH and concentration. Ferric (Fe^{3+}) salts are not soluble at pH 7, whereas ferrous (Fe^{2+}) salts are. Consequently, in the duodenum and upper jejunum, unless Fe^{3+} ion is chelated, it forms a precipitate. Several compounds such as tannic acid in tea and phytates in vegetables form insoluble complexes with iron, preventing absorption. Iron is absorbed by an active process via a carrier(s) located in the brush border membrane. One such transporter, the divalent metal transporter, is expressed abundantly in the duodenum.

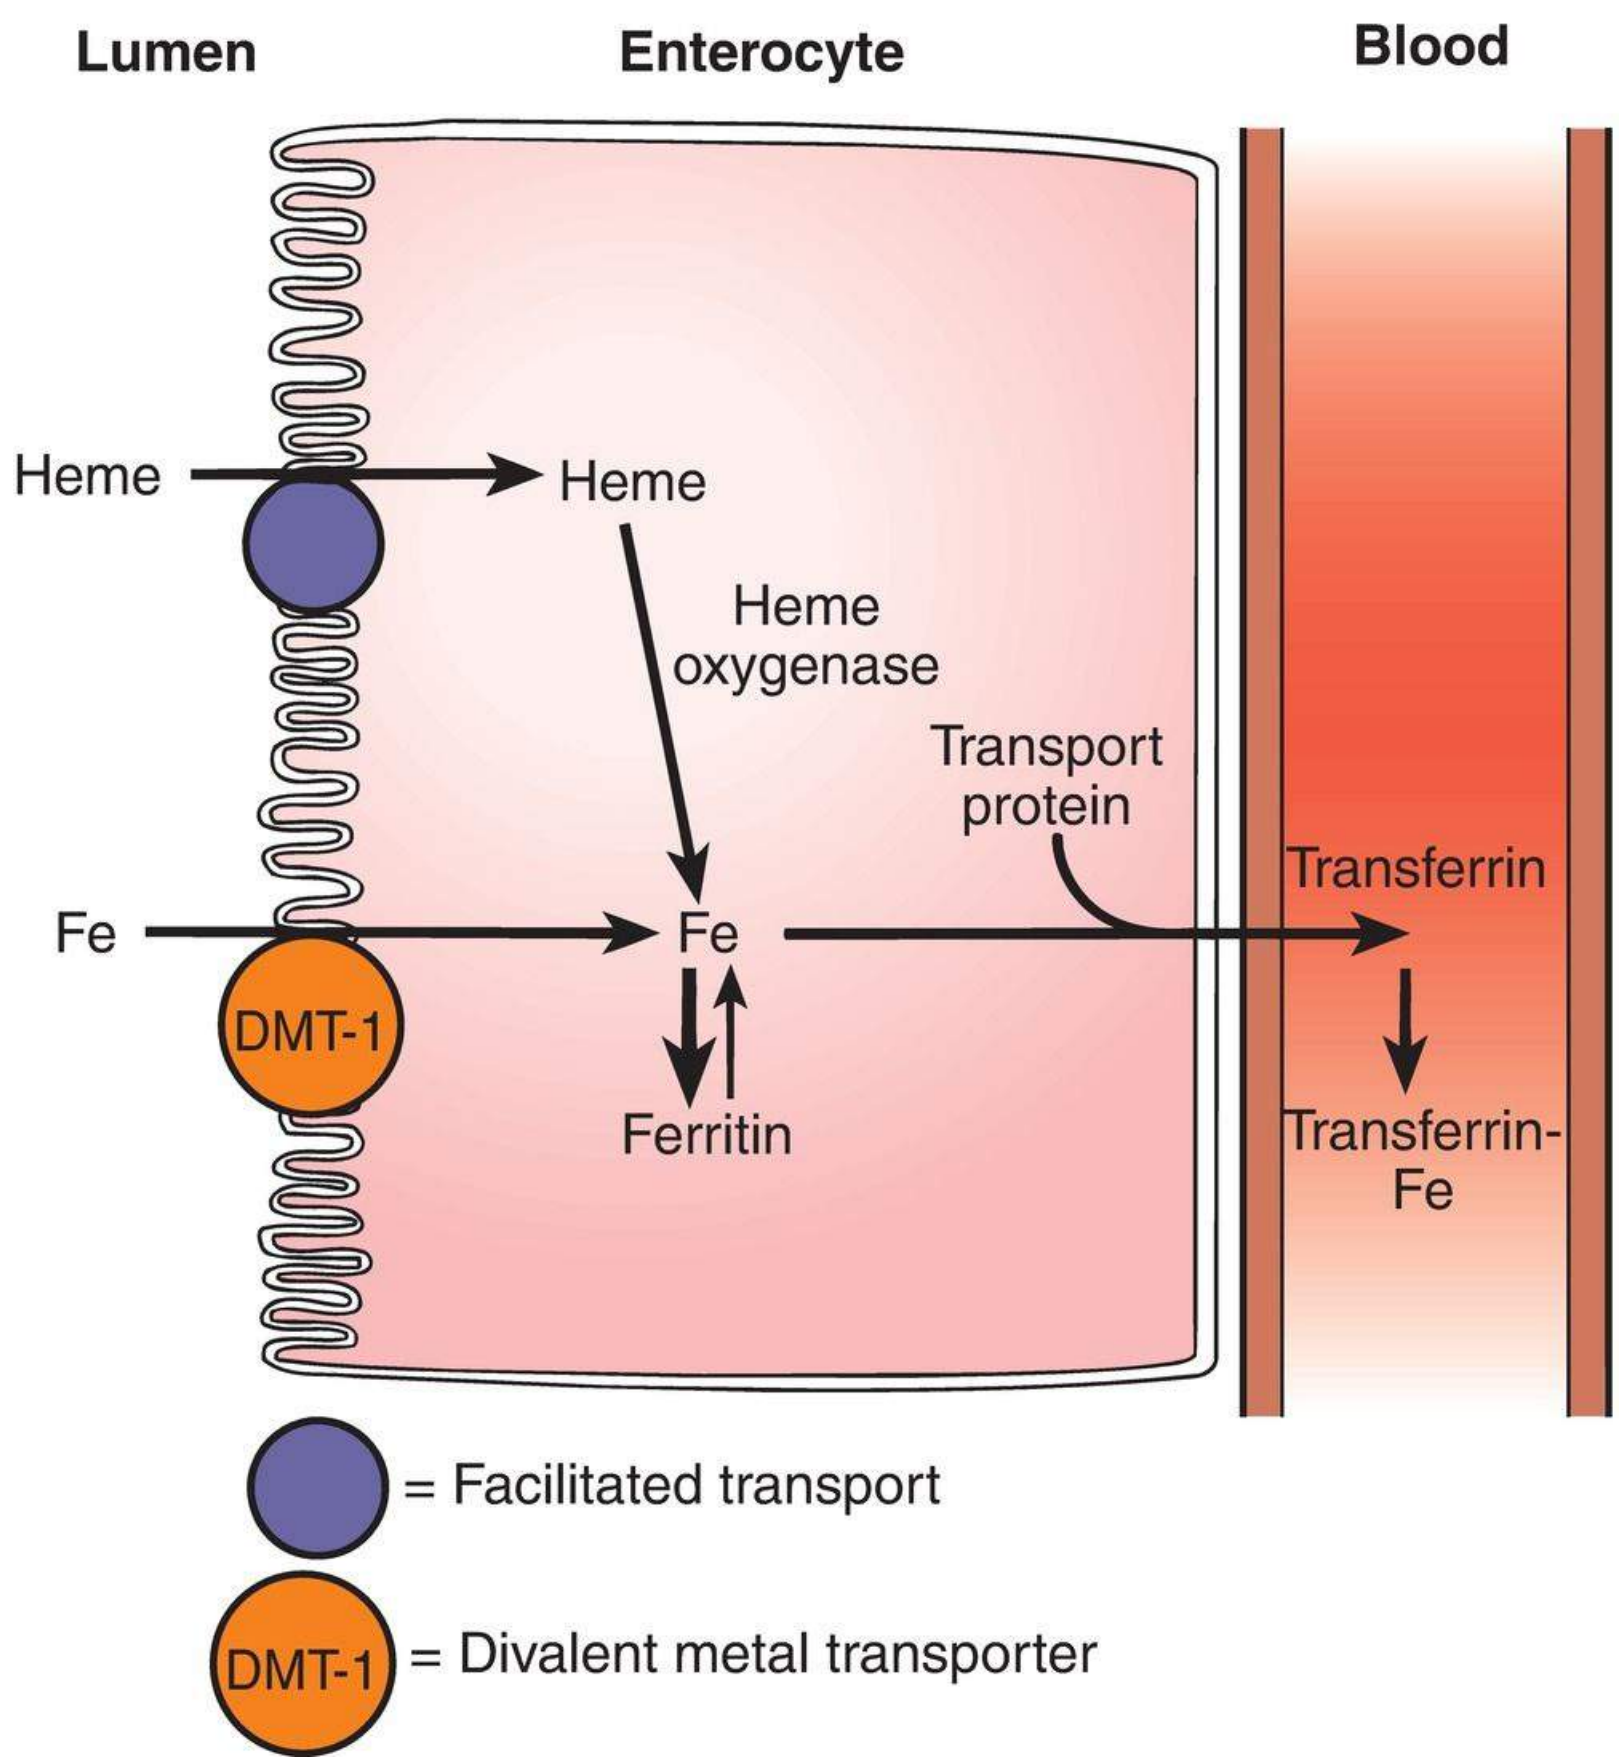

Figure 25.26 Enterocytes absorb iron in the duodenum. Iron must be in ferrous form (Fe^{2+}) to be absorbed. A ferric reductase enzyme on the enterocyte brush border reduces ferric iron Fe^{3+} to Fe^{2+}. A protein metal transporter (DMT-1) transports the iron across the enterocyte's cell membrane and into the cell. DMT-1, divalent metal transporter.

Once inside the cell, heme iron is released by the action of heme oxygenase and mixed with the

intracellular free iron pool. Iron is either stored in the enterocyte cytoplasm bound to the storage protein **apoferritin** to form **ferritin** or transported across the cell bound to transport proteins, which carry the iron across the cytoplasm and release it into the intercellular space. **Transferrin**, a β-globulin synthesized by the liver, binds and transports iron in the blood.

Iron absorption is closely regulated by iron storage in enterocytes and iron concentration in the plasma. Enterocytes are continuously shed into the lumen, and the ferritin contained within is lost. Normally, iron in enterocytes is derived from the lumen and the blood (Fig. 25.27). The amount of iron stored in enterocytes regulates the amount of iron absorbed. In iron deficiency, the circulating plasma iron concentration is low, which stimulates the absorption of iron from the lumen and the transport of iron into the blood. Moreover, in a deficient state, less iron is stored as ferritin in the enterocytes, so the loss of iron through this means is significantly reduced. In iron-loaded patients, there is less absorption of iron because of the large amount of mucosal iron storage, which increases iron loss as a result of enterocyte shedding. Furthermore, because of the high level of circulating plasma iron, the transfer of iron from enterocytes to the blood is reduced. Through a combination of various mechanisms, body iron homeostasis is maintained.

Figure 25.27 Endocyte pathways regulate the body's iron levels. In healthy subjects, the intestinal lining cells can store iron as ferritin (in which case the iron leaves the body when the cell dies and is sloughed off into feces), or the cell can move it into the blood using a protein transporter and carry it as transferrin to the rest of the body. The body regulates iron levels by regulating these pathways. For example, in patients with iron deficiency (middle figure), cells produce more ferrous reductase, DMT-1, and the protein transporter, which results in a net increase in the amount of iron going to transferrin that can be taken up by red cells. In the bottom figure, iron overload results in more iron converted to ferritin and less converted to transferrin.

WATER ABSORPTION

In human adults, the average daily intake of H_2O is about 2 L. As shown in Table **25.7**, secretions from the salivary glands, pancreas, liver, and GI tract make up most of the fluid entering the GI tract (about 7 L). Despite this large volume of fluid, only 100 mL is lost in the feces. Therefore, the GI tract is extremely efficient in absorbing H_2O. Water absorption by the GI tract is passive. The rate of absorption depends on both the region of the intestinal tract and the luminal osmolality. The duodenum, jejunum, and ileum absorb the bulk of the H_2O that enters the GI tract. The colon normally absorbs about 1.4 L of H_2O and excretes about 100 mL. It is capable of absorbing considerably more H_2O (about 4.5 L), however, and watery diarrhea occurs only if this capacity is exceeded.

TABLE 25.7 Water Intake, Absorption, and Excretion by the Gastrointestinal (GI) Tract

Source	Amount (mL)
Water added to GI tract	
Food and beverages	2,000
Salivary secretion	1,000
Biliary secretion	1,000
Gastric secretion	2,000
Pancreatic secretion	1,000
Intestinal mucosal secretion	2,000
Water absorbed in feces	
Duodenum and jejunum	4,000
Ileum	3,500
Colon	1,400
Water lost in feces	100

Water is absorbed in the gut by osmosis.

Because H_2O absorption is determined by the osmolality difference of the lumen and the blood, H_2O can move both ways in the intestinal tract (i.e., secretion and absorption). The osmolality of blood is about 300 mOsm/kg H_2O. The ingestion of a hypertonic meal (e.g., 600 mOsm/kg H_2O) initially leads to net H_2O movement from blood to lumen; however, as the small intestine absorbs the various nutrients and electrolytes, the luminal osmolality falls, resulting in the net H_2O movement from lumen to blood. The water of a hypertonic meal is therefore absorbed mainly in the ileum and colon. In contrast, if a hypotonic meal is ingested (e.g., 200 mOsm/kg H_2O), net H_2O movement is immediately from the lumen to the blood, resulting in the absorption of most of the H_2O in the duodenum and jejunum.

INTEGRATED MEDICAL SCIENCES

Gut Microbiota: A Relationship You Cannot Live Without

A GI tract that is functioning normally has a healthy well-established colonizing microbiota its mucosa and lumen, which is a major contributor to the maintenance of whole body homeostasis. These two communities are not the same and the genera of microbes living in the mucosa vary from those residing in the lumen. Compartmentalization within the GI tract aids in the isolation of genera of microbes to different regions of the tract with the majority of microbes living in the colon. It is well established that the species composition and relative abundance of the gut microbiota are impacted by the diet, lifestyle, and overall health of an individual. Humans, like many other animals, have developed a commensalistic relationship with the gut microbiota. Over time, this relationship has evolved to become a mutualistic and interdependent one, in which the physiological activity of the microbiota has a significant impact on the host and the activity of the host impacts the genera comprising the microbiota. In support of life, gut microbial metabolism supplies the host with short-chain fatty acids, essential vitamins (i.e., vitamins B and K), and contributes to the synthesis and absorption of essential amino acids.

Within the context of this chapter, it is important to note that the digestive, absorptive, and secretory functions of the GI tract are readily affected by the gut's microbiota. The interactions do not end with digestion as microbial chemical signals influence other systems such as the activity of the host's immune cells and immunologic homeostasis. In a normal, healthy individual, the interactions between the host and microbiota are primarily beneficial. However, dysbiosis can lead to, or be a contributing factor in, a number of maladies including inflammatory bowel disease (e.g., Crohn's disease, ulcerative colitis), altered metabolism of bile acids, intestinal malignancy, obesity, and metabolic syndrome.

Clues to the development of the intestinal microbiota have emerged from many different studies. It has long been held that fetuses develop in a sterile environment within the amniotic sac. However, recent studies have shown that certain bacteria are able to cross the placental barrier. When investigators orally administered a genetically labeled species of bacteria to pregnant mice, they

noted the appearance of the bacteria in both the amniotic fluid and the meconium of the pups. Others have shown that the oral microbiota is also capable of reaching, and becoming established at, the level of the placenta. Regardless, as indicated by microbial analysis of meconium, infants are born with relatively few microbes colonizing the intestinal lumen.

All indications are that the major microbial colonization of the gut occurs following birth. These colonizers will generally reflect the microbial diversity present in the environment to which the infant is first exposed. For example, a vaginal birth versus one that occurs by cesarean section exposes the infant to very different microbes. Other factors such as the source of nutrition (i.e., breast milk vs. commercial preparations), gestational age at delivery, and treatment with antibiotics significantly alter the genera of gut microbes. Microbial recovery back to homeostasis after antibiotic treatment may take up to several months. Given the many factors that have an impact on the microbial community, there is a wide range of potential microbiota that can ultimately colonize an infant's gut. This results in much variability between individuals. Immediately after birth, the environment in a newborn's gut is favorable for supporting the growth of facultative anaerobic microbes. Later, the environment favors growth of anaerobes, particularly in the distal regions of the gut with aerobes favoring the more proximal regions. By 5 years of age, the child's gut microbial community has changed to be similar to the adult gut. The gut microbiota does have an influence on the early post birth physical changes that take place in the GI tract including changes in crypt size, mucosal thickness, and surface changes in the intestinal epithelium.

The health of the host and the composition of the gut microbiota are intimately linked through the interactions that occur between the gut microbiome and the host's innate and adaptive immune systems. These interactions have a large impact on the development of the immune system early in life and on the possibility of the host developing certain diseases in later life. Examples include local inflammatory responses in the gut (mentioned previously) and systemic autoimmune disorders such as rheumatoid arthritis, multiple sclerosis, and type 1 diabetes. Beyond the immune system, the intestinal microbiota is felt to play a role in systemic events outside the digestive tract (e.g., cardiovascular disease) because some bacterial species are able to cross the intestinal mucosa and translocate to other regions of the body. Lymphatic tissue (e.g., Peyer patches, lymphoid follicles, immune cells localized to the lamina propria) provides an important line of immunologic defense against such occurrences happening more frequently. Additionally, the mucus secreted onto the luminal surface helps to prevent microbes from breaching the GI tract. Secreted antimicrobial proteins and IgA play a role in maintaining the effectiveness of that barrier.

Microbes have been implicated in other interactions that occur between the body systems. Such interactions generally result in a healthy individual with a normal body mass index. However, it is known that obese individuals do not have the same genera in their gut microbiota as that of more lean individuals. These differences lead to noticeable imbalances in energy metabolism and fat storage along with insulin resistance and have led to such extreme treatments as fecal transplants to treat obesity. However, the cause and effect may be hard to fully ascertain as the composition of the diet also influences the mixture of genera that comprise the gut microbiota. Recent data on patients who have undergone Roux-en-Y gastric bypass surgery indicate that following the procedure, the patient's gut microbiota changed significantly enough that it contributed to the weight loss observed in these patients, most likely by way of altered fatty acid metabolism and fat storage.

This essay has provided only a glimpse into the role and impact that microbes occupying the GI tract can have. Students are encouraged to consult the literature to learn more about other aspects of the host–microbiota interaction in health and disease. ■

Chapter Summary

- Saliva assists in the swallowing of food, carbohydrate digestion, and the transport of immunoglobulins that combat pathogens.
- The major function of the gastrointestinal tract is storage, mixing, digestion, and absorption of nutrients.
- The stomach prepares chyme to aid in the digestion of food in the small intestine.
- Parietal cells secrete hydrochloric acid and intrinsic factor, and chief cells secrete pepsinogen.
- Gastrin plays an important role in stimulating gastric acid secretion.
- The acidity of gastric secretion provides a barrier to microbial invasion of the gastrointestinal tract.
- Gastric secretion is under neural and hormonal control and consists of three phases: cephalic, gastric, and intestinal.
- Gastric inhibitory peptide, secreted by K cells, is a potent inhibitor of gastric acid secretion and enhances insulin release in elevated concentrations of plasma glucose.
- Pancreatic secretion neutralizes the acids in chyme and contains enzymes involved in the digestion of carbohydrates, fat, and protein.
- Secretin stimulates the pancreas to secrete a bicarbonate-rich fluid, thereby neutralizing acidic chyme.
- Cholecystokinin stimulates the pancreas to secrete an enzyme-rich secretion.
- Pancreatic secretion is under neural and hormonal control and consists of three phases: cephalic, gastric, and intestinal.
- Bile salts play an important role in the intestinal absorption of lipids.
- Proteins are digested to form amino acids, dipeptides, and tripeptides before being taken up by enterocytes and transported in the blood.
- The gastrointestinal tract absorbs water-soluble vitamins and ions by different mechanisms.
- Most of the salt and water entering the intestinal tract, whether in the diet or in gastrointestinal secretions, is absorbed in the small intestine.
- Lipids absorbed by enterocytes are packaged and secreted as chylomicrons into the lymph.
- Carbohydrates, when digested, form maltose, maltotriose, and α-limit dextrins, which are cleaved to brush border enzymes to monosaccharides and taken up by enterocytes.
- Calcium-binding protein is involved in calcium absorption.
- Heme and nonheme iron are absorbed in the small intestine by different mechanisms.
- Minerals are classified as bulk minerals and trace minerals.

Chapter Review Questions

1. Parasympathetic stimulation induces salivary acinar cells to release the protease:

A. bradykinin.
B. kallikrein.
C. kininogen.
D. kinin.
E. aminopeptidase.

The correct answer is B. Parasympathetic stimulation induces the release of kallikrein by the salivary acinar cells, which then converts kininogen to form lysyl-bradykinin (a potent vasodilator). Bradykinin is a vasoactive peptide. Kininogen is the precursor for kinin. Kinins are peptides that are related in amino acid sequence and physiological activity to bradykinin. Aminopeptidase releases amino acids from the amino end of peptides and is found in the brush border membrane and cytoplasm of enterocytes.

2. Which of the following best describes enterokinase, an enzyme necessary for protein digestion?

A. It is produced by the pancreas and directly converts ribonuclease into its active form.
B. It is produced by the pancreas and directly converts trypsinogen into trypsin.
C. It is produced by the pancreas and prevents autodigestion of the pancreas by pancreatic enzymes.
D. It is produced by the duodenum and directly inactivates trypsin inhibitor.
E. It is produced by the duodenum and directly converts trypsinogen into trypsin.

The correct answer is E. Enterokinase is an enzyme produced by the cells of the duodenum (crypt of Lieberkühn) that converts trypsinogen to its active form, trypsin.

3. Hartnup disease is an inherited autosomal recessive disorder involving the malabsorption of amino acids, particularly tryptophan by the small intestine. Feeding di- and tripeptides containing tryptophan to patients with this disease improves their clinical condition because:

A. di- and tripeptides, unlike free amino acids, can be taken up passively by enterocytes in the small intestine.
B. peptides, unlike free amino acids, can be taken up by defective amino acid transporters.
C. di- and tripeptides use transporters that are different from the defective amino acid transporters.
D. the presence of di- and tripeptides in the intestinal lumen enhances the uptake of amino acids by the transporters.
E. di- and tripeptides, unlike amino acids, can be taken up passively by the colon.

The correct answer is C. Amino acids as well as di- and tripeptides use different brush border transporters for their uptake. Di- and tripeptides are not taken up passively by any part of the GI tract.

4. Dietary triglyceride is a major source of nutrient for the human body. It is digested mostly in the intestinal lumen by pancreatic lipase to release:

A. lysophosphatidylcholine and fatty acids.
B. glycerol and fatty acids.
C. diglyceride and fatty acids.
D. 2-monoglyceride and fatty acids.
E. lysophosphatidylcholine and diglyceride.

The correct answer is D. Pancreatic lipase hydrolyzes triglyceride to form 2-monoglyceride and fatty acids. Only hydrolysis of phosphatidylcholine results in the formation of lysophosphatidylcholine, so the hydrolysis of triglyceride does not result in the formation of lysophosphatidylcholine. Acid lipase works only in the gastric lumen, not the intestinal lumen. Although diglyceride is an intermediate in the hydrolysis of triglyceride by pancreatic lipase, the hydrolysis continues until 2-monoglyceride and fatty acids are formed. Pancreatic lipase does not hydrolyze triglyceride totally to form glycerol and fatty acids.

Clinical Application Exercises 25.1

LACTOSE INTOLERANCE

A 9-year-old Chinese American boy regularly complains of abdominal cramps, abdominal distention, and diarrhea after drinking milk. A gastroenterologist administers 50 g of lactose by mouth to the child and measures an increase in the boy's expired hydrogen gas.

QUESTIONS

1. Based upon how sugars are normally digested and absorbed by the GI tract, why is this boy suffering from these symptoms?
2. From a physician's standpoint, what recommendations and advice can be given to this patient to address his problem with lactose intolerance?

ANSWERS

1. Lactose is hydrolyzed by a brush border enzyme called lactase to glucose and galactose. The monosaccharides are then absorbed by sodium-dependent secondary active transport. If the lactase enzyme is deficient, lactose will not be broken down and will remain in the intestinal lumen. The osmotic activity of the lactose draws water into the intestinal lumen and results in a watery diarrhea. In the colon, bacteria metabolize the lactose to lactic acid, carbon dioxide, and hydrogen gas. The extra fluid and gas in the intestine result in distention and increased motility (cramps).
2. Avoiding foods that contain lactose (milk, dairy products) is recommended for lactose-intolerant people, but calcium and caloric intake should not be compromised. Milk can be pretreated with an enzyme obtained from bacteria or yeasts that digests lactose, or lactase pills can be taken with meals.

26 Liver Functions and Immune Surveillance

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe how the liver lobule is functionally organized.
- Describe how the architectural arrangement of the hepatocytes allows for the rapid exchange of molecules.
- Describe how the liver is oxygenated.
- Describe the significance of tissue regeneration in the liver.
- Explain the difference between phase I and phase II reactions in drug metabolism of the liver.
- Explain the mechanism by which the liver regulates blood glucose concentration.
- Explain how the liver is involved in the uptake and metabolism of lipids.
- Explain how vitamin A is stored in the liver and transported to other parts of the body when needed.
- Describe the importance and risks of iron storage in the liver.
- Describe how the liver is involved in establishing immunity.

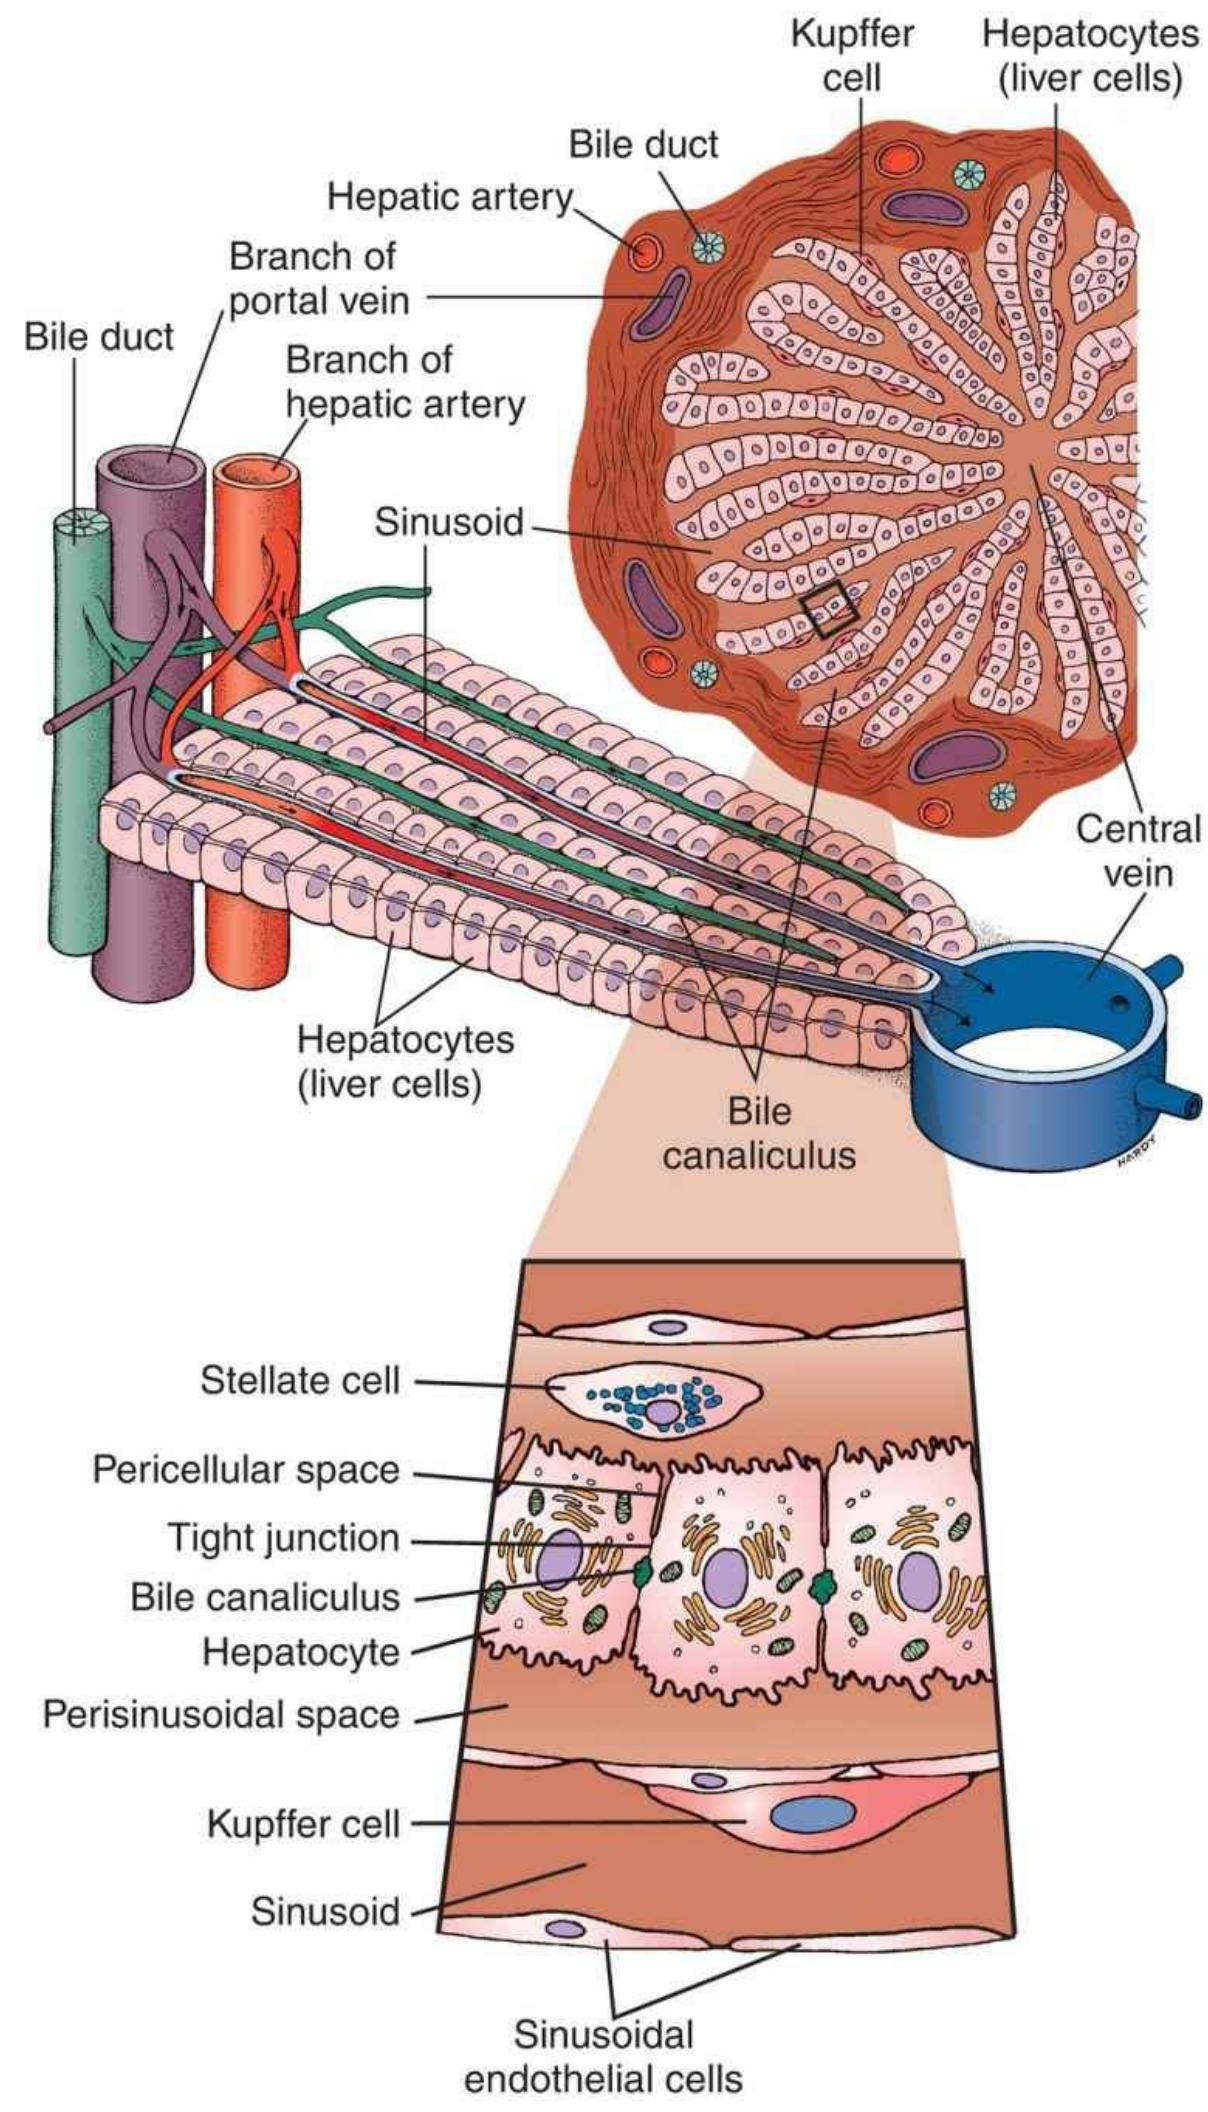
The liver is the largest internal organ in the body, constituting about 2.5% of an adult's body weight. It is composed of several distinct cell types including Kupffer cells, sinusoidal epithelial cells, cholangiocytes, and hepatocytes, but the vast majority, 70% to 80%, is hepatocytes. Given its wide range of functions, the liver is an extremely vital organ for maintaining whole-body homeostasis. Liver functions include glycogen storage, protein synthesis, detoxification, red cell destruction, hormone production, bile production for lipid emulsification, maintenance of blood glucose levels, and regulation of blood lipids by the amount of very-low-density lipoproteins (VLDLs) it secretes. A healthy liver also contributes to both the innate and adaptive immunological defense mechanisms of the body.

The liver is a unique organ because it has a dual blood supply and it is the only internal human organ capable of regenerating lost tissue. With as little as 25% of the liver remaining, it can regenerate into an entire organ, which is possible because hepatocytes are capable of reentering the cell cycle and undergoing mitosis.

This chapter summarizes the liver's many functions including (1) detoxification of hormones, drugs, and waste products; (2) metabolism of carbohydrates, proteins, and fats; (3) storage of iron and vitamins; (4) hormone production; and (5) innate and adaptive immunity.

LIVER STRUCTURE AND FUNCTION

Normal liver function is essential for maintaining the optimal function of other organs. In so doing, the liver interacts with many systems (e.g., cardiovascular, renal, and immune) to maintain homeostasis. Given the liver's wide range of functions, there is surprisingly little specialization among liver cells. The hexagonally shaped lobule is the functional unit of the liver and is built around a central vein (Fig. 26.1). Individual lobules are made up of many cellular plates radiating from the central vein like spokes in a bicycle wheel. Each plate consists of specialized hepatocytes that contain discrete granules and perform a wide variety of metabolic functions and secretory tasks including the manufacture of specific proteins, detoxification of xenobiotics, and the production and secretion of bile.



Kupffer cell
Hepatocytes (liver cells)
Bile duct
Hepatic artery
Branch of portal vein
Bile duct
Branch of hepatic artery
Sinusoid
Central vein
Hepatocytes (liver cells)
Bile canaliculus
Stellate cell
Pericellular space
Tight junction
Bile canaliculus
Hepatocyte
Perisinusoidal space
Kupffer cell
Sinusoid
Sinusoidal endothelial cells

Figure 26.1 Functional anatomy of the liver. The basic unit of the liver is the lobule. The lobule is arranged in a hexagonal fashion and is delineated by vascular and bile channels. The lobule contains specialized cells, such as hepatocytes, sinusoidal cells, and Kupffer cells.

Cell types other than hepatocytes also have specific functions. **Kupffer cells** (**KCs**) play a role in the production of bilirubin and, along with **natural killer cells** (**NKCs**), are involved in innate immunity. **Cholangiocytes** modulate bile flow through the bile ducts. Sinusoidal epithelial cell (SEC) functions are discussed later in this chapter.

Architectural arrangement of hepatocytes in the liver lobule enhances the rapid exchange of material.

One specialized function of hepatocytes is the formation of bile. The bile canaliculus is formed by the intercellular space located between neighboring hepatocytes. Impermeable tight junctions separate the canaliculus from the pericellular space and prevent the mixing of contents between the two regions (see Fig. 26.1). Bile originating in the bile canaliculus drains into a series of ducts that eventually join the pancreatic duct near where it enters the duodenum. The **sphincter of Oddi**, located at the duodenal connection between the bile duct and the pancreatic duct, regulates drainage of bile and pancreatic juice into the duodenum. The pericellular space between two hepatocytes is continuous with the perisinusoidal space (see Fig. 26.1). A layer of SECs separates the **perisinusoidal space** from the sinusoid. Finger-like projections of the hepatocytes extend into the perisinusoidal space, which greatly increases the contact area between hepatocytes and the perisinusoidal fluid.

Liver cells carry out specialized functions.

Liver endothelial cells, unlike those in other parts of the cardiovascular system, lack a basement membrane. Furthermore, they have sievelike plates that permit the ready exchange of materials, even particles, as big as chylomicrons (80 to 500 nm wide), between the perisinusoidal space and the sinusoid. Despite the barrier's permeability, it does have some sieving properties. For example, the protein concentration of hepatic lymph, assumed to derive from the perisinusoidal space, is about 10% lower than that of plasma.

While they do have many functions, hepatocytes are not phagocytic. Phagocytosis is accomplished by resident macrophages (KCs) that line the hepatic sinusoids and are part of the reticuloendothelial system. KCs remove unwanted material (e.g., bacteria, virus particles, fibrin–fibrinogen complexes, damaged erythrocytes, and immune complexes) from the circulation via **endocytosis**.

Perisinusoidal cells called **stellate cells** or **Ito cells** store fat in distinct cytoplasmic lipid droplets that contain vitamin A. Through complex and typically inflammatory processes, stellate cells become transformed to myofibroblasts that are capable of secreting collagen and extracellular matrix into the perisinusoidal space.

Hepatic portal vein is the main blood supply to the liver.

The hepatic portal vein and hepatic arteries supply the liver with blood. During rest, their combined blood flow provides the liver with 25% of the cardiac output. Supplying ~75% of the liver's blood supply, the hepatic portal vein carries venous blood drained from the spleen and the gastrointestinal (GI) tract and its associated organs. Unlike blood flowing in the hepatic artery, hepatic portal vein blood is poorly oxygenated. Despite this difference, the liver's O_2 demand is met almost equally by blood flowing from these vessels. What accounts for the high O_2 uptake from the portal vein in which the O_2 tension is so low? Recall from Chapter 19 that O_2 uptake is highly dependent on blood flow. The large flow in the hepatic portal vein offsets the low O_2 tension and therefore significantly contributes to O_2 taken up by the liver. The portal vein branches repeatedly to form smaller venules, and the hepatic artery branches to form arterioles and then capillaries. These venules and capillaries drain into the liver sinusoids, which are considered to be specialized capillaries. The sinusoids empty into the central veins that join to form the hepatic vein flowing into the inferior vena cava.

Liver as a blood reservoir

The vasculature in the liver is characterized as a high-flow, high-compliance, and low-resistance system. High compliance and low resistance allow large quantities of blood to be stored in the liver's vascular tree. Under normal conditions, it contains about 10% of the body's total blood volume. This storage function is especially important in pathophysiologic situations. For example, during hemorrhaging, the liver is capable of supplying extra blood to help maintain central circulating blood volume.

Hepatic blood volume and flow vary inversely with GI activity. Blood flow increases after eating, whereas blood volume decreases. Conversely, during sleep, flow decreases but blood volume slightly increases. The splanchnic arterioles predominantly regulate blood flow to the intestines and spleen and, in turn, in the portal vein. In this way, eating results in increased blood flow to the intestines followed by increased flow to the liver. Portal vein pressure is normally low. Increased resistance to portal blood flow results in **portal hypertension**, which is the most common complication of chronic liver disease and accounts for a large percentage of the morbidity and mortality associated with this disease (Clinical Focus 26.1).

CLINICAL FOCUS 26.1

Viral Hepatitis

Viral hepatitis refers to the inflammation of the liver caused by the invasion of a number of specific viruses. Many hepatitis viruses have been identified; they are named types A, B, C, D, E, F (not confirmed), and G. Undoubtedly, the known number of viruses that attack the liver will grow as our knowledge of the subject expands. Because of the limitation of space, discussion will focus on the three most common types of hepatitis, A, B, and C.

Viral hepatitis A is a common type of acute liver inflammation caused by the infection of the

hepatitis A virus. It is acute but never becomes chronic. It is highly contagious and can spread from person to person like other viral infections. The spread of viral hepatitis A can be rapid and widespread because it is usually caused by unsanitary conditions that allow water or food to become contaminated by human waste containing the hepatitis A virus. Hepatitis A can also spread from person to person through close contact, such as through the passage of oral secretions via intimate kissing and other sexual practices or contact with feces resulting from improper or poor handwashing. Interestingly, some people can harbor the virus with no apparent symptoms; others, however, exhibit symptoms that mimic severe flu. Patients who are infected with hepatitis A usually recover on their own and do not develop chronic hepatitis or cirrhosis.

Hepatitis B, unlike hepatitis A, is a chronic inflammatory liver disease. It is prevalent in the United States, with 200,000 to 300,000 new cases of viral hepatitis B virus infection reported each year. Hepatitis B is spread through sexual contact and the transfer of blood or serum through shared needles in drug abusers, accidental needle sticks with needles contaminated with infected blood, blood transfusions, hemodialysis and by infected mothers to their newborns. The hepatitis B virus can remain in a person for years without manifesting any symptoms. About 6% to 10% of patients with hepatitis B viruses develop chronic liver inflammation, lasting between 6 months and years or decades. Hepatitis B infections can potentially develop into more advanced stages of liver disease associated with cirrhosis of the liver. Cirrhosis is characterized by abnormal structure and function of the liver. The diseases that lead to cirrhosis do so because they injure and kill liver cells and because the inflammation and repair that are associated with the dying liver cells cause scar tissue to form.

The other common virus that attacks the liver is *hepatitis C*. The spread of hepatic C virus is similar to that of hepatitis B. However, the transmission of the hepatitis C virus through sexual contact is not as prevalent as hepatitis B. Patients with chronic hepatitis C infection can continue to infect others. Patients with chronic hepatitis C infection are at risk for developing cirrhosis, liver failure, and liver cancer. ■

Liver permeability results in large quantities of lymph formation with high-flow rates.

The hepatic sinusoids are very porous and allow a large flux of fluid and protein to move into the perisinusoidal space. Given their high permeability, sinusoidal epithelia form large quantities of lymph, which under resting conditions makes up half of the body's formed lymph. To accommodate both the large quantity and high lymph flow, the hepatic lymphatic system is extensive and is organized around three main areas: adjacent to the central veins, adjacent to the portal veins, and coursing along the hepatic artery. As in other organs, these channels drain fluid and proteins, but the protein concentration is highest in liver lymphatic fluid.

The perisinusoidal space is the largest space drained by the liver's lymphatic system. Disturbances in the balance of filtration and drainage are the primary causes of **ascites**, the accumulation of serous fluid in the peritoneal cavity. Ascites is another common cause of morbidity in patients with chronic liver disease.

Tissue regeneration in the adult liver is a unique feature to maintain optimal metabolic function.

As mentioned previously, of all of the solid organs in the body, the adult liver is the only internal organ capable of regenerating. There appears to be a critical ratio between functioning liver mass and body mass. Deviations in this ratio trigger a modulation of either hepatocyte proliferation (liver growth) or apoptosis (liver cell death) to maintain the liver's optimal size for metabolic function. Peptide growth factors (e.g., transforming growth factor-α, hepatocyte growth factor, and epidermal growth factor) have been the best-studied stimuli of hepatocyte DNA synthesis. After these peptides bind to their receptors on the living hepatocytes and work their way through a myriad of transcription factors, gene transcription is accelerated, resulting in increased cell number and increased liver mass.

Conversely, enhanced hepatocyte apoptosis rates achieve a decrease in liver volume. Apoptosis is inhibited from occurring prematurely by specific molecules, such as growth factors, that act as antiapoptotic molecules. Apoptosis is therefore a carefully programmed process by which cells kill themselves (cell suicide) and ultimately fragment into apoptotic bodies that are phagocytized by macrophages or other phagocytic cells. Apoptosis can occur via factors that stimulate either extrinsic or intrinsic specific pathways leading to mitochondrial permeabilization. Two types of liver cell death have been described. Hepatic apoptosis describes the occurrence of apoptosis involving multiple cell types within the liver. Hepatocyte apoptosis occurs specifically in the liver hepatocytes. In contrast to hepatic apoptosis, cell death that results from necroinflammatory processes is characterized by a loss of cell membrane integrity (plasma membrane becomes permeable) and the activation of inflammatory reactions that occurs following the cell's rupture.

The events associated with apoptosis can actually contribute to the liver's ability to regenerate. Regeneration is actually a "double-edged sword." Under normal circumstances, the liver's ability to rapidly regenerate tissue is beneficial. However, this capability can become a liability with certain diseases. For example, patients diagnosed with primary hepatic carcinoma often undergo a partial hepatectomy to remove malignant tumors. The hepatectomy not only stimulates tissue regeneration but also activates dormant cancer cells, causing the malignancy to further spread in the liver (Clinical Focus 26.2).

CLINICAL FOCUS 26.2

Esophageal Varices, a Common Manifestation of Portal Hypertension

Chronic liver injury can lead to a sequence of changes that terminates with fatal bleeding from esophageal blood vessels. In most forms of chronic liver injury, stellate cells are transformed into collagen-secreting myofibroblasts. These cells are responsible for the deposition of collagen into the sinusoids, thereby interfering with the exchange of compounds between the blood and hepatocytes and increasing resistance to portal venous flow. The resistance appears to be further increased when stellate cells contract. The combination of increased resistance and reduced clearance of

vasoconstrictors that have affected arteriolar beds results in increased portal pressure and decreased liver blood flow. This disorder is seen in ~80% of patients with **cirrhosis**. In a compensatory effort, new channels are formed or dormant venous tributaries are expanded, resulting in the formation of varicose veins in the abdomen. Although varicose veins develop in many areas, portal pressure increases are least opposed in the esophagus because of the limited connective tissue support at the base of the esophagus. This structured condition, along with the negative intrathoracic pressure, favors the formation and rupture of **esophageal varices**. Approximately 30% of those who develop an esophageal variceal hemorrhage die during the episode of bleeding, making it one of the most lethal medical illnesses.

Currently, there are no well-recognized treatments to reverse cirrhosis, but numerous strategies are used to reduce portal hypertension and bleeding. Chief among these is the use of nonselective β-blockers, which have a vasodilator effect. Additionally, bleeding varices are frequently treated by endoscopic ligation of the varices and radiologically or surgically placed portal venous shunts to reduce the portal pressure. ■

DRUG METABOLISM IN THE LIVER

The liver is well suited for its ability to metabolize and detoxify many drugs, including penicillin, ampicillin, erythromycin, and sulfonamides. In a similar manner, many hormones (e.g., thyroxin, aldosterone, estrogen, and cortisol) are either metabolized and/or excreted by the liver. The liver also regulates Ca^{2+} and is the major route of Ca^{2+} secretion via the bile acids that pass into the gut and are excreted in feces.

Hepatocytes are involved in the metabolism of **xenobiotics**, which are compounds not produced by the body and are, therefore, foreign to it. Some xenobiotics (e.g., certain drugs) can be beneficial, but others are toxic. Most environmental xenobiotics are introduced into the body with food, absorbed through the skin, or inhaled during breathing and absorbed into the blood. The kidneys ultimately dispose of these substances, but for effective elimination, they must be rendered hydrophilic (polar and water soluble). Because reabsorption of a substance by the renal tubules depends on its hydrophobicity, the more hydrophobic (nonpolar and lipid soluble) a substance is, the more likely it will be reabsorbed. Many drugs and metabolites are hydrophobic and are converted into hydrophilic compounds by the liver, contributing to their elimination by the kidneys.

Liver metabolism and elimination of drugs and xenobiotics occur in three phases.

Two reactions (phase I and phase II), catalyzed by different enzyme systems, are involved in the metabolism and conversion of xenobiotics and drugs into hydrophilic compounds. In **phase I reactions**, the introduction of one or more polar groups biotransforms the parent compound into a more polar compound. The common polar groups are hydroxyl (OH) and carboxyl (COOH). Most phase I reactions involve oxidation of the parent compound. The majority of the phase I enzymes are located in the smooth endoplasmic reticulum (SER), but some enzymes are cytoplasmic. For example, alcohol dehydrogenase is located in the cytoplasm of hepatocytes and catalyzes the rapid conversion of alcohol to acetaldehyde. It may also play a role in the dehydrogenation of steroids. Metabolites from phase I reactions are often inactive. However, in some instances, their activity is only modified.

The enzymes involved in phase I reactions (i.e., drug biotransformation) are present as an enzyme complex composed of the **NADPH–cytochrome P-450 reductase** and a series of hemoproteins called **cytochrome P-450** (Fig. 26.2). The drug combines with the oxidized cytochrome P-450^{3+} to form the cytochrome P-450^{3+}–drug complex. The enzyme NADPH–cytochrome P-450 reductase catalyzes the reduction of the cytochrome P-450^{3+}–drug complex to the cytochrome P-450^{2+}–drug complex, which then combines with molecular O_2 to form an oxygenated intermediate. One atom of the molecular O_2 combines with two H^+ atoms and an electron to form H_2O. The other O_2 atom remains bound to the cytochrome P-450^{3+}–drug complex and is transferred from the cytochrome P-450^{3+} to the drug molecule. The drug product with an O_2 atom incorporated is released from the complex. The cytochrome P-450^{3+} released can then be recycled for the oxidation of other drug molecules.

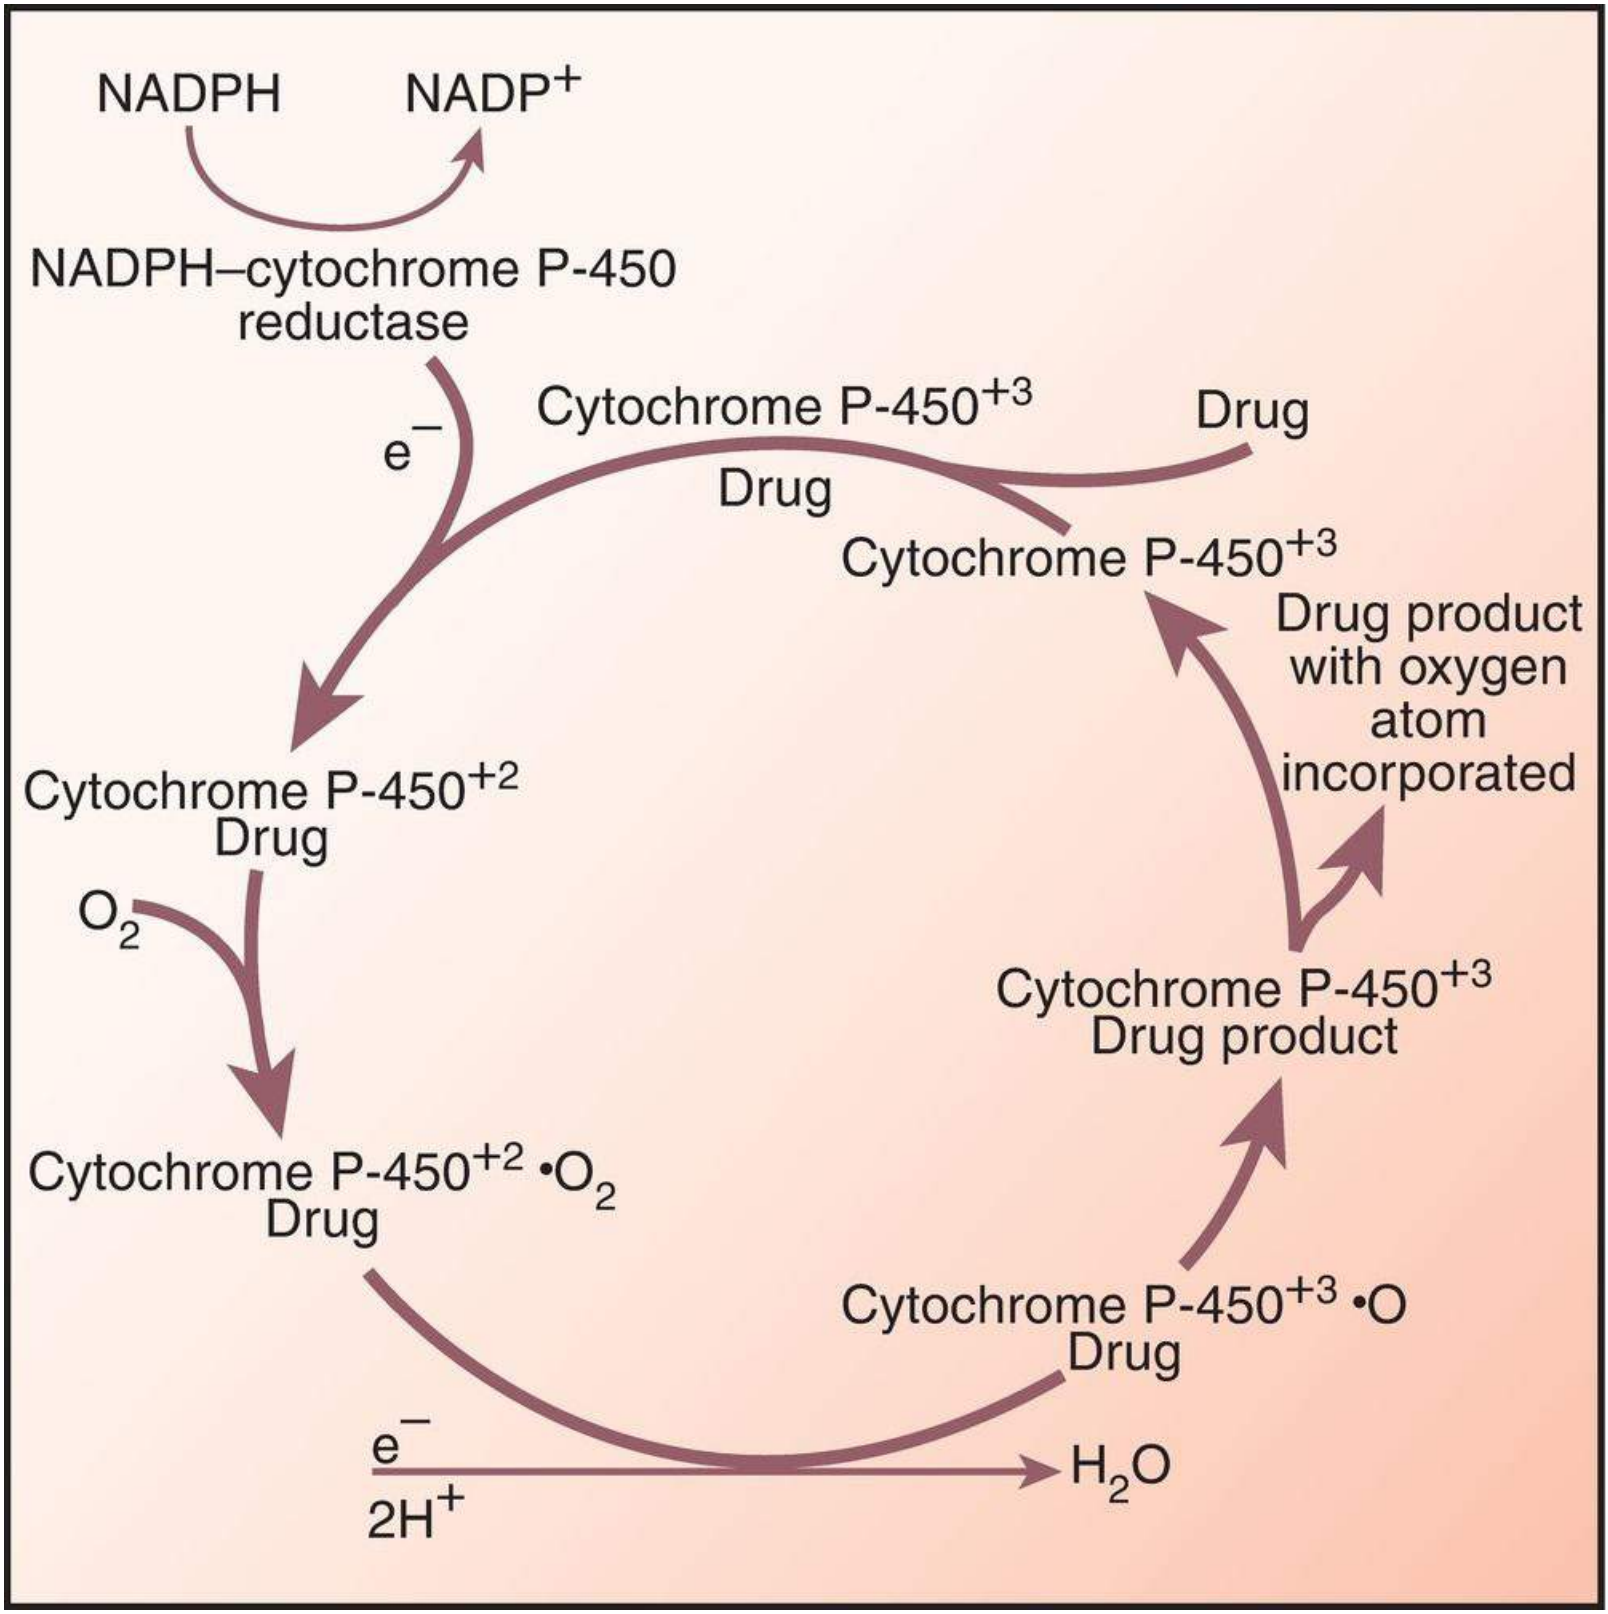


Figure 26.2 Two different enzyme systems catalyze drug metabolism by the liver. The phase I reaction is illustrated here.

In **phase II reactions**, the phase I reaction products undergo conjugation with several compounds (e.g., glucuronic acid, glycine, taurine, and sulphates) rendering them more hydrophilic resulting in enhanced excretion via the urine in particular but also via the bile. Drug conjugation was once believed to represent the terminal inactivation event, thus rendering the drug nontoxic. However, we know that certain conjugation reactions, for example, *N*-acetylation of isoniazid, may lead to the formation of reactive species responsible for the hepatotoxicity of the drug. Isoniazid is used alone or in conjunction with other

drugs to treat tuberculosis.

Phase III reactions involve various transporters (e.g., P-glycoprotein and multidrug resistance–associated protein) that work to eliminate the products of phase II reactions. In doing so, these transporters play a significant role in the absorption, distribution, and excretion of drugs.

Age, nutrition, genetics, sex, and hormones significantly affect drug metabolism and transport in the liver.

The activity of phase I and II enzyme systems is age dependent. These systems are poorly developed in human newborns. It is well known that newborns have a lesser ability to metabolize drugs when compared to adults. At the other end of the spectrum, older adults have a lower capacity than young adults to metabolize drugs. P-450–mediated metabolism may be reduced as much as 35% in older adults, and the clearance of many drugs (e.g., acetaminophen, lidocaine, erythromycin, and triazolam) declines with age. The observed changes in drug metabolism are most likely a reflection of the decrease in liver mass (25% to 35%) and the decrease in blood flow (up to 40%) that accompany aging. The age-related decrease in renal function also impacts drug metabolism.

Nutritional factors can affect the enzymes involved in phase I and II reactions. Insufficient protein intake results in the production of fewer enzyme molecules available to participate in drug metabolism. In fact, low protein intake can result in a decrease of up to 40% in the clearance of certain drugs (i.e., theophylline and phenazone). In some cases, increasing protein intake can return enzyme activity to more normal values.

It is well known that certain factors (e.g., polycyclic aromatic hydrocarbons) can induce drug-metabolizing enzymes. As a result of inhaling polycyclic aromatic hydrocarbons, the metabolism of certain drugs such as caffeine will be increased in cigarette smokers.

The role of genetics in the regulation of hepatic drug metabolism has been investigated to varying degrees in both humans and laboratory animals for at least 60 years, but the impact of genetics on drug metabolisms is still not fully understood. Briefly, some studies have demonstrated loss-of-function polymorphisms and others have shown gain-of-function variants. Both of these changes affect drug clearance and therefore its plasma concentration but in opposite directions. Loss of function results in reduced clearance accompanied by increased plasma concentrations, and gain of function increases clearance and decreases plasma concentrations. Genetic variability combined with the induction or inhibition of P450 enzymes by other drugs or compounds can have a profound effect on what is a safe and effective dose.

Variability in drug metabolism has been observed between individuals and has much to do with the variation in expression and hence the level of activity of the enzymes (e.g., cytochrome P-450s, glutathione transferases, and sulfotransferases) involved in drug metabolism and transport. Studies investigating sex-based differences in drug metabolism have shown that males and females often metabolize the same drug at different rates and that can have a significant impact on the drug’s affect(s). Interestingly, adverse drug reactions tend to occur more frequently in women than men and women account for almost 75% of the drug-induced acute liver failure patients seen in the United States. Differences in the expression of growth hormone and sex hormones between males and females are known to affect the metabolism and clearance of drugs by the liver.

ENERGY METABOLISM IN THE LIVER

The liver is a pivotal organ in regulating the metabolism of carbohydrates, lipids, and proteins. The metabolism and interconversion of these compounds by liver cells is highly impacted by hormones and an individual's nutritional state. One hormone, glucagon has a significant impact on liver cells. Its effect on cells of the liver is especially important in maintaining blood glucose homeostasis by stimulating **glycogenolysis** (conversion of glycogen to glucose) and **gluconeogenesis** (conversion of other substances, such as amino acids, into glucose) during periods of low blood glucose. In contrast, when the circulating level of glucose rises (e.g., after meals), the liver will actively store excess glucose as glycogen by a process called **glycogenesis**.

Hepatic portal vein transports nutrients, water-soluble vitamins, and minerals to the liver.

Most water-soluble nutrients and water-soluble vitamins and minerals absorbed from the small intestine are transported via the portal blood to the liver. The water-soluble nutrients will include amino acids, monosaccharides, and fatty acids that are predominantly of short-chain and medium-chain length. Short-chain fatty acids are largely derived from the fermentation of dietary fibers by bacteria in the colon. Some dietary fibers, such as pectin, are almost completely digested to form short-chain fatty acids (or volatile fatty acids), whereas cellulose is not well digested by the bacteria. The portal blood transports only a small amount of long-chain fatty acids, bound to albumin; most are transported in intestinal lymph as triglyceride-rich lipoproteins (chylomicrons). Chylomicrons serve as a vehicle for delivering fatty acids to muscles and adipose tissue, after which the cholesterol in the chylomicron remnant is transported to and metabolized by the liver.

Liver plays an important role in blood glucose buffering.

The liver is especially important in maintaining normal blood glucose levels. The ability to store glycogen allows the liver to remove excess glucose from the blood and then return it when blood glucose levels begin to fall. The combined result of these pathways is a process called **glucose buffering** (Fig. 26.3) that can be summarized in the following manner. After the ingestion of a meal (usually within 1 to 2 hours), blood glucose concentration increases to a level of 120 to 150 mg/dL (6.6 to 8.3 mmol/L). The hepatocytes remove glucose using a facilitated, carrier-mediated process involving GLUT2. GLUT2 is located in the hepatocyte membrane and its activity is not affected by insulin. Once inside the hepatocytes, glucose is converted to **glucose 6-phosphate** (**G6P**) and subsequently **uridine diphosphate glucose** (**UDP-glucose**). Once phosphorylated, glucose is no longer available and the UDP-glucose is used for glycogenesis. It is generally believed that blood glucose is the major precursor of glycogen. However, recent evidence seems to indicate that the lactate in blood (from the peripheral metabolism of glucose) is also a major precursor of glycogen. Additionally, amino acids (e.g., alanine) can supply pyruvate to synthesize glycogen.

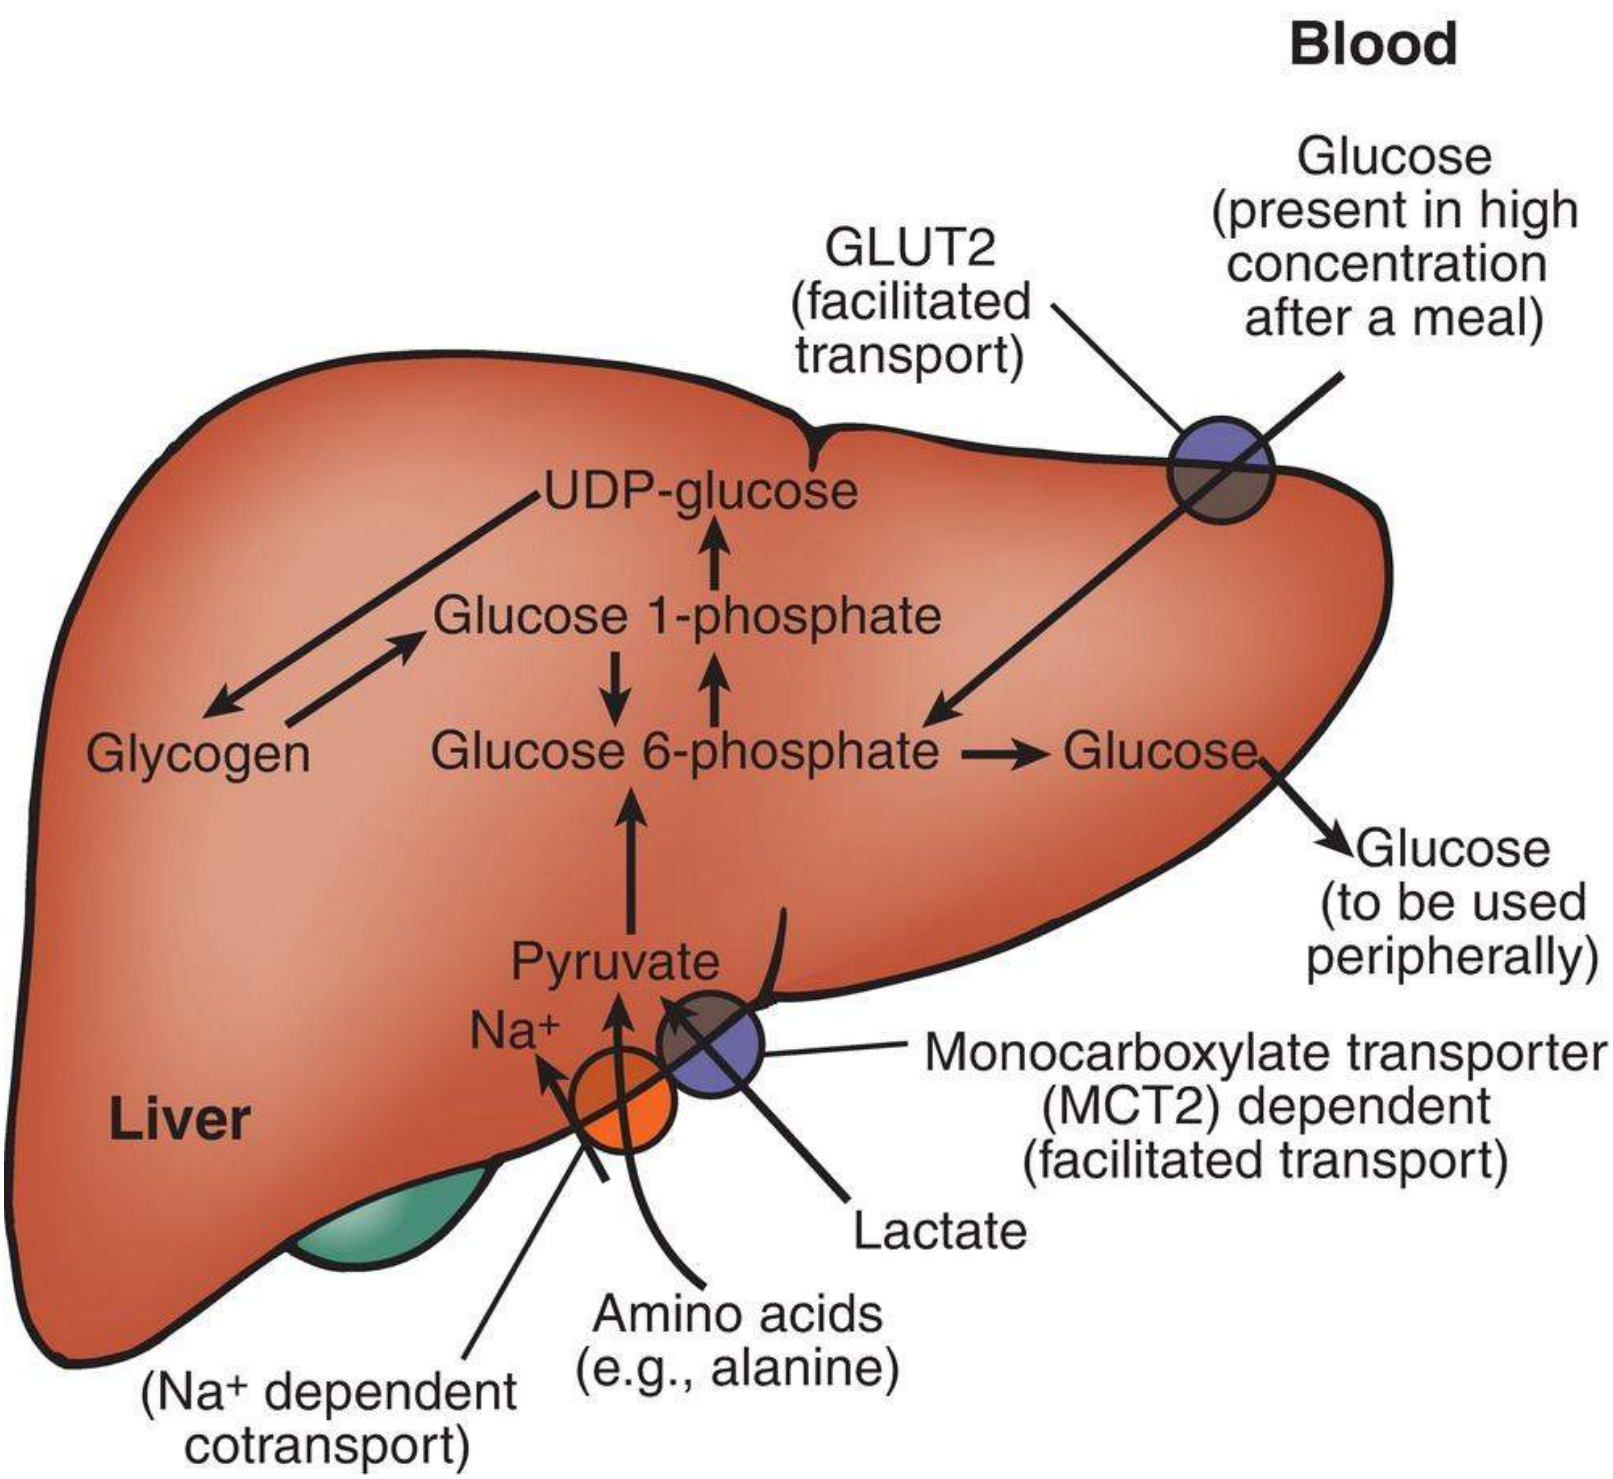

Figure 26.3 The liver is a key organ in regulating carbohydrate metabolism. Glycogen is the main carbohydrate stored by the liver. Uridine diphosphate glucose (UDP-glucose) is a precursor to glycogen.

Glycogen, the main carbohydrate stored in the liver, comprises as much as 7% to 10% of the weight of a normal, healthy liver. During fasting, glycogenolysis breaks down glycogen to yield glucose. The enzyme **glycogen phosphorylase** catalyzes the cleavage of glycogen into glucose 1-phosphate that is then converted to G6P by the enzyme phosphoglucomutase. The enzyme **glucose-6-phosphatase**, present in the liver but not in muscle or the brain, converts G6P to glucose that can then be released into the circulation. G6P is an important intermediate in carbohydrate metabolism because it can be used to provide blood glucose or to form glycogen.

Both glycogenolysis and glycogenesis are hormonally regulated. The pancreas secretes insulin into the portal blood. Therefore, the liver, which is hormone sensitive, is the first organ to respond to changes

in plasma **insulin** levels. Almost half the insulin in portal blood is removed as it passes through the liver. Insulin tends to lower blood glucose by stimulating glycogenesis and suppressing glycogenolysis and gluconeogenesis. A doubling of portal insulin concentration completely shuts down hepatic glucose production. In contrast to insulin, **glucagon** stimulates glycogenolysis and gluconeogenesis, raising blood sugar levels. **Epinephrine** stimulates glycogenolysis. Regardless, the ultimate balance between hepatic glycogenesis and glycogenolysis involves hormonal input as well as input from glucose sensors in the portal vein.

The closely regulated balance between glycogen synthesis and glucose release by the liver is key to maintaining normal glucose concentrations within a narrow limit of 70 to 100 mg/dL. Although patients with liver disease might be expected to have difficulty regulating blood glucose, this is usually not the case due to the relatively large reserve of hepatic function. However, in the case of chronic liver disease, reduced glycogen synthesis and reduced gluconeogenesis may occur. Some patients with advanced liver disease develop portal hypertension, which induces the formation of portosystemic shunting, resulting in elevated arterial blood levels of insulin and glucagon as a result of suppressed liver removal of these hormones.

Kinases in the liver are involved in monosaccharide metabolism.

Kinases are enzymes that add a phosphate group to a substrate. A **hexokinase** specifically phosphorylates a six-carbon sugar. In the liver (but not in the muscle), the isoform **glucokinase** phosphorylates glucose to form G6P. Depending on the energy requirement, G6P is channeled to glycogen synthesis or used for energy production by the glycolytic pathway.

The liver takes up fructose, and fructokinase phosphorylates fructose to form fructose 1-phosphate, which is either isomerized to form G6P or metabolized by the glycolytic pathway. The glycolytic pathway uses fructose 1-phosphate more efficiently than G6P.

Galactose is used to provide energy and in the biosynthesis of glycoproteins and glycolipids. Galactose taken up by the liver is phosphorylated by galactokinase to form galactose 1-phosphate, which then reacts with UDP-glucose to form UDP-galactose and glucose 1-phosphate. UDP-galactose can be used for glycoprotein and glycolipid biosynthesis or converted to UDP-glucose, which can then be recycled.

Gluconeogenesis in the liver helps maintain blood glucose level during fasting.

Gluconeogenesis is the production of glucose from noncarbohydrate sources such as fat, amino acids, and lactate. The required energy is derived predominantly from the β-oxidation of fatty acids. Pyruvate is the initial substrate, and it can be derived from lactate or the metabolism of glucogenic amino acids (amino acids that can contribute to the formation of glucose). Gluconeogenesis occurs predominately in the liver and the kidneys. However, due to its size, the liver contributes much more to the process.

Gluconeogenesis is important in maintaining blood glucose homeostasis, especially during fasting. The red blood cells and renal medulla totally depend on blood glucose for energy, and glucose is the preferred substrate for the brain. Most amino acids can contribute carbon atoms to glucose synthesis, with alanine from muscle being the most important. The rate-limiting factor in gluconeogenesis is the availability of substrate molecules and not the amount of enzyme. Epinephrine and glucagon stimulate gluconeogenesis, but insulin greatly suppresses it. Thus, in type I diabetic patients, gluconeogenesis is greatly stimulated, contributing to the hyperglycemia observed in these patients (see Chapter 15).

Liver plays a vital role in lipid metabolism.

Most cells in the body can metabolize fatty acids to yield energy The majority of fatty acids however are removed from the blood almost immediately and stored as triglycerides by either fat cells or liver cells until they are needed by other cells for energy (Fig. 26.4). As the primary site for metabolism of triglycerides and the synthesis of lipoproteins, cholesterol, and phospholipids, the liver plays a central and vital role in lipid metabolism. Enzymatic pathways in the liver are also able to synthesize fats using proteins and carbohydrates as substrates. Additionally, the body's tissues benefit from the desaturation of fatty acids in the liver, which they then use in the synthesis of membranes and other cellular structures.

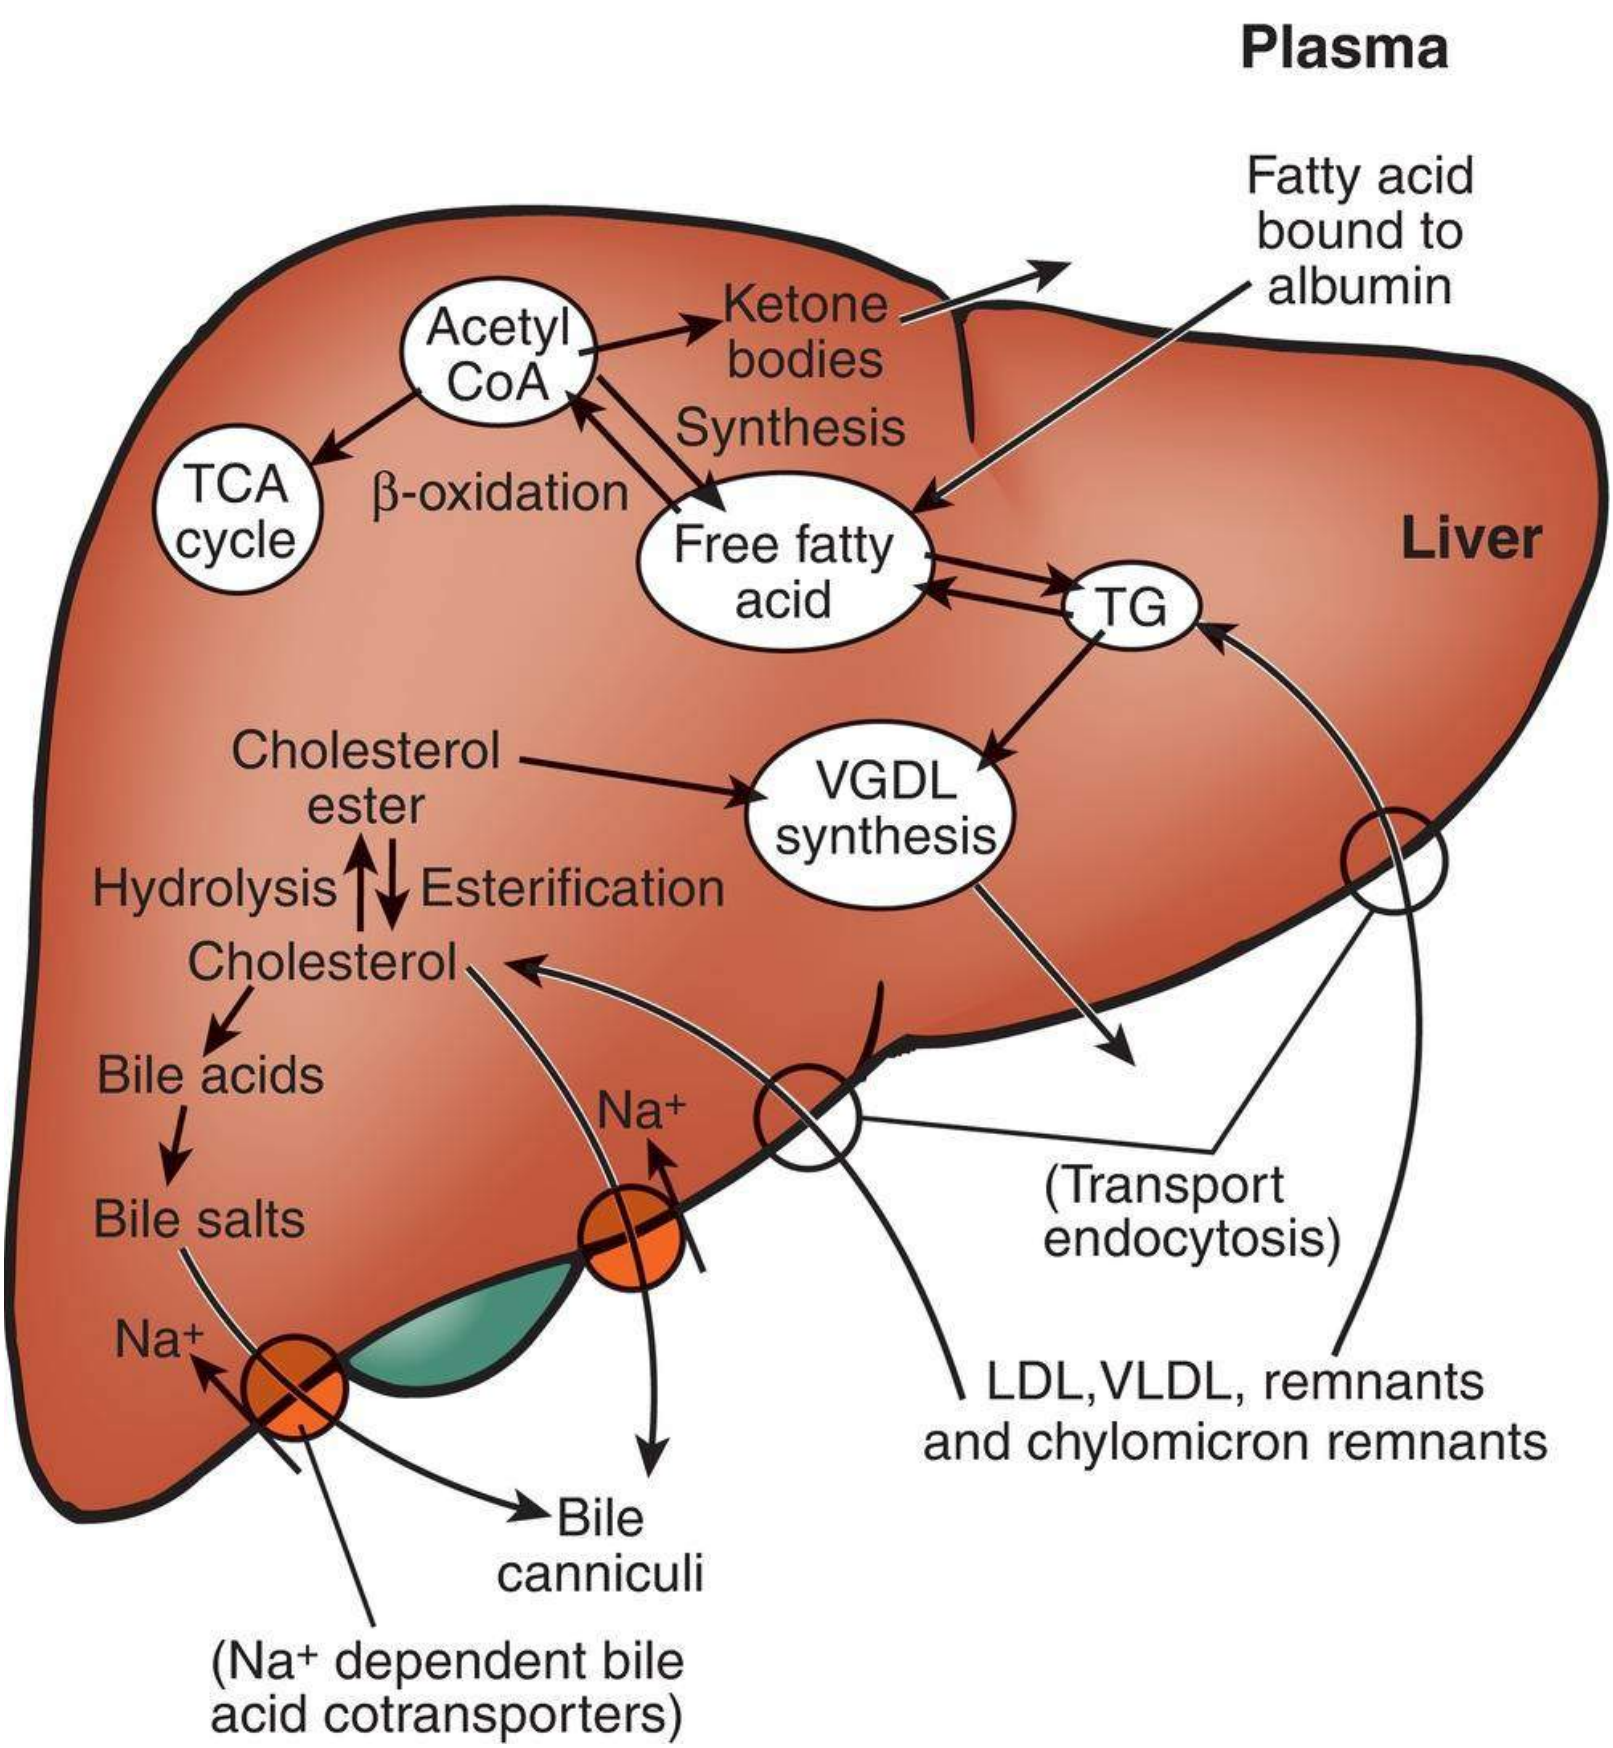

Figure 26.4 The liver plays an important role in lipid metabolism. The liver is involved in the oxidation of fatty acids, the synthesis of very-low-density lipoproteins (VLDLs), and the regulation of blood triglycerides, low-density lipoproteins (LDLs), and circulating high-density lipoproteins (HDLs). Acetyl-CoA, acetyl-coenzyme A; TCA cycle, tricarboxylic acid cycle; TG, triglyceride.

Fatty acid metabolism

After a meal, most of the ingested fat processed by the small intestine is packaged into **chylomicrons** that initially enter the lymph and ultimately the blood. Chylomicrons are comprised almost exclusively of fatty acids (i.e., 80% to 90% of the chylomicron structure), and after they enter the circulation, **lipoprotein lipase** on the endothelial cells of blood vessels hydrolyzes them to liberate fatty acids and glycerol from the triglycerides. Some cells (e.g., heart cells and muscle cells) rely heavily on fatty acids for energy. Adipose cells store them as triglycerides. As metabolism progresses, the chylomicrons shrink and are converted to **chylomicron remnants** that the liver rapidly takes up via chylomicron remnant receptors. The liver then uses the remaining fatty acids to form **very-low-density lipoprotein** (**VLDL**) and for energy production via mitochondrial β-oxidation.

Fatty acids, either absorbed by the digestive tract or released from adipose tissue, are metabolized primarily in the liver. Hepatocytes degrade fatty acids within in the mitochondria yielding acetyl-coenzyme A (acetyl-CoA) in the process. Some acetyl-CoA will enter the citric acid cycle and provide energy to the liver cells. The liver is uniquely able to form acetoacetate, a ketone body, through a condensation reaction between two acetyl-CoAs. Other cells (e.g., muscle, brain, and kidney) absorb the acetoacetate from the blood and convert it back to acetyl-CoA to be used in energy production. In addition to entering the citric acid cycle, acetyl-CoA can be used in the tricarboxylic acid cycle to produce adenosine triphosphate, to synthesize other fatty acids, and to form ketone bodies. Because fatty acids are synthesized from acetyl-CoA, any substances that contribute to the production of acetyl-CoA, such as carbohydrates and proteins, enhance fatty acid synthesis.

The relative amount of fatty acids channeled into the various lipid metabolism pathways of the liver is largely dependent on the person's nutritional and hormonal status. More fatty acid is channeled to ketogenesis or β-oxidation when the supply of carbohydrate is short (during fasting) or under conditions of high circulating glucagon or low circulating insulin (diabetes mellitus). In contrast, more of the fatty acid is used for synthesis of triglyceride for lipoprotein export when the supply of carbohydrate is abundant (during feeding) or under conditions of low circulating glucagon or high circulating insulin.

The liver is one of the main organs involved in fatty acid synthesis. Palmitic acid is synthesized in the hepatocellular cytosol; the other fatty acids synthesized in the body are derived by shortening, elongating, or desaturating the palmitic acid molecule.

Lipoprotein metabolism

A major contribution of the liver to lipid metabolism is the synthesis of lipoproteins, which are the major lipid remaining in the circulation after the metabolism of chylomicrons. The five major classes of circulating plasma lipoproteins are chylomicrons, VLDLs, **low-density lipoproteins** (**LDLs**), **intermediate-density lipoproteins** (**IDLs**), and **high-density lipoproteins** (**HDLs**) (Table 26.1). These lipoproteins differ in chemical composition and are usually isolated from plasma using differential centrifugation. Lipoproteins loose buoyancy as the relative amount of protein in the particle increases. Solubility is maintained because the amphipathic phospholipids and proteins surround the otherwise water-insoluble lipid core. This structural arrangement allows lipoproteins to be transported in an aqueous medium (i.e., plasma).

TABLE 26.1 Plasma Lipoproteins

Lipoprotein	Source	Density (g/mL)	Function
Chylomicron	Intestine	<0.95	Composition: 1% protein and 99% lipid; chylomicron is responsible for transporting lipids from the gut to liver, heart, and skeletal muscle
VLDL	Liver	0.95–1.006	Composition: 7%–10% protein, 90%–93% lipid; VLDL is converted to LDL in the liver and functions as the body's internal transport system for lipids (triglycerides, phospholipids, and cholesterol)
IDL	VLDL	1.006–1.019	Composition: 10%–12% protein, 88%–90% lipid; formed when triglycerides present in VLDLs are hydrolyzed by lipoprotein lipase in the capillary beds
LDL	Chylomicron/VLDL	1.019–1.063	Composition: 20% protein, 80% lipid; transports cholesterol into cells
HDL	Chylomicron/VLDL	1.063–1.21	Composition: 35%–60% protein, 40%–65% lipid; smallest in size of all the lipoproteins and functions in the transport of cholesterol and triglycerides; HDL carries about 30% of blood cholesterol and is able to remove cholesterol from atheroma from blood vessels and carry it back to the liver; sometimes called *good cholesterol*

VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

Chylomicrons have a density <0.95 g/mL, which makes them the lightest of the five lipoprotein classes They are synthesized only by the small intestine and are produced in large quantities following fat ingestion. Chylomicrons are large, lipid-rich particles that cannot enter the intestinal capillary beds, but rather are absorbed into the lymphatic system from which they reach the blood via the subclavian vein connection to the thoracic duct.

VLDLs have a density <1.006 g/mL and are smaller than chylomicrons. The liver synthesizes about 10 times more circulating VLDLs than the small intestine. Like chylomicrons, VLDLs are triglyceride rich and carry most of the triglyceride from the liver to the other organs. VLDLs provide cholesterol to organs that need it for the synthesis of steroid hormones (e.g., the adrenal glands, ovaries, and testes). Lipoprotein lipase (LPL) breaks down the triglyceride of VLDLs to yield fatty acids, which can be metabolized to provide energy. When VLDLs are degraded, IDLs are formed. IDLs have a density ranging from 1.006 to 1.019. Only small amounts of IDLs are present in the blood, and they are often overlooked as a class of lipoproteins.

The human liver normally has a considerable capacity to produce VLDLs, but in acute or chronic liver disorders, this ability is significantly compromised. Liver VLDLs are associated with an important class of proteins, **apo B proteins**. The two forms of circulating apo B are B-48 and B-100. The human liver makes only apo B-100 (M.W. ~500,000), which is important for the hepatic secretion of VLDL. In **abetalipoproteinemia**, apo B synthesis is decreased and the secretion of VLDLs is blocked resulting in the appearance of large lipid droplets in the cytoplasm of the hepatocytes of abetalipoproteinemia patients. This lack of VLDL secretion is not entirely related to the decrease in apo B synthesis. A genetic mutation that affects the gene coding for triglyceride transfer protein is also involved. The other major apolipoproteins associated with VLDLs are apo CI, II, and III and apo E.

Although considerable amounts of LDLs (density range 1.019 to 1.063) and HDLs (density range 1.063 to 1.210) are produced in the plasma, the liver also produces a small amount of these two cholesterol-rich lipoproteins. LDLs transport cholesterol ester from the liver to other organs, and HDLs are believed to remove cholesterol from peripheral tissues and transport it to the liver.

Precursors and hormones, such as estrogen and thyroid hormones, regulate the formation and secretion of lipoproteins. For instance, during fasting, the fatty acids in VLDLs are derived mainly from fatty acids mobilized from adipose tissue. In contrast, during fat feeding, fatty acids in VLDLs produced by the liver

are largely derived from chylomicrons.

Familial hypercholesterolemia, a disorder in which the liver fails to produce the LDL receptor, exemplifies the importance of the liver in lipoprotein metabolism. When LDL binds its receptor, it is internalized and catabolized in the hepatocyte. Consequently, the LDL receptor is crucial for the removal of LDL from the plasma. People suffering from familial hypercholesterolemia usually have high plasma LDLs, predisposing them to early coronary heart disease. Often, the only effective treatment is a liver transplantation.

Ketone body production

The formation of ketone bodies as a product of hepatic fatty acid metabolism is both normal and physiologically important. The human liver can produce half of its equivalent weight in ketone bodies per day, but it lacks ketoacid-CoA transferase the enzyme necessary for the metabolism of ketone bodies. Most other organs can use ketone bodies as an energy source. For example, during prolonged fasting, the brain shifts to use ketone bodies (acetoacetate and β-hydroxybutyrate) for energy, although glucose is the preferred substrate. During fasting, a rapid depletion of the liver's glycogen stores occurs, resulting in a shortage of substrates (e.g., oxaloacetate) for the citric acid cycle, and there is a rapid mobilization of fatty acids from adipose tissues to the liver. Under these circumstances, the acetyl-CoA formed from β-oxidation is channeled to ketone bodies. Ketogenesis is also pronounced in diabetes when insulin levels fall precipitously toward zero.

The level of ketone bodies circulating in the blood is usually low, but during prolonged starvation and in diabetes mellitus, it is highly elevated, a condition known as **ketosis**. In patients with diabetes, large amounts of β-hydroxybutyric acid can make the blood pH acidic, a state called **ketoacidosis**.

Blood cholesterol homeostasis

Cholesterol is essential for life, and the liver plays an important role in cholesterol homeostasis. Liver cholesterol is derived from both *de novo* synthesis and the lipoproteins taken up by the liver. Hepatic cholesterol can be used in the formation of bile acids, biliary cholesterol secretion, the synthesis of VLDLs, and the synthesis of liver membranes. Because the absorption of biliary cholesterol and bile acids by the GI tract is incomplete, this method of eliminating cholesterol from the body is essential and efficient. However, patients with high plasma cholesterol levels might be given additional drugs (e.g., statins) to lower their plasma cholesterol levels. Statins act by inhibiting enzymes that play an essential role in cholesterol synthesis.

PROTEIN AND AMINO ACID METABOLISM IN THE LIVER

The liver is one of the major organs involved in synthesizing nonessential amino acids from the essential amino acids. The body can synthesize all but nine of the amino acids necessary for protein synthesis.

The liver synthesizes important plasma proteins.

Of the many circulating plasma proteins synthesized by the liver, albumin may well be the most important (Fig. 26.5). The liver synthesizes about 3 g of albumin a day. Albumin helps to preserve plasma volume and tissue fluid balance by maintaining the colloid osmotic pressure of plasma. The importance of plasma proteins is illustrated by the fact that both liver disease and long-term starvation result in generalized edema and ascites. Plasma albumin plays a pivotal role in the transport of many substances in blood, such as free fatty acids and certain drugs, including penicillin and salicylate.

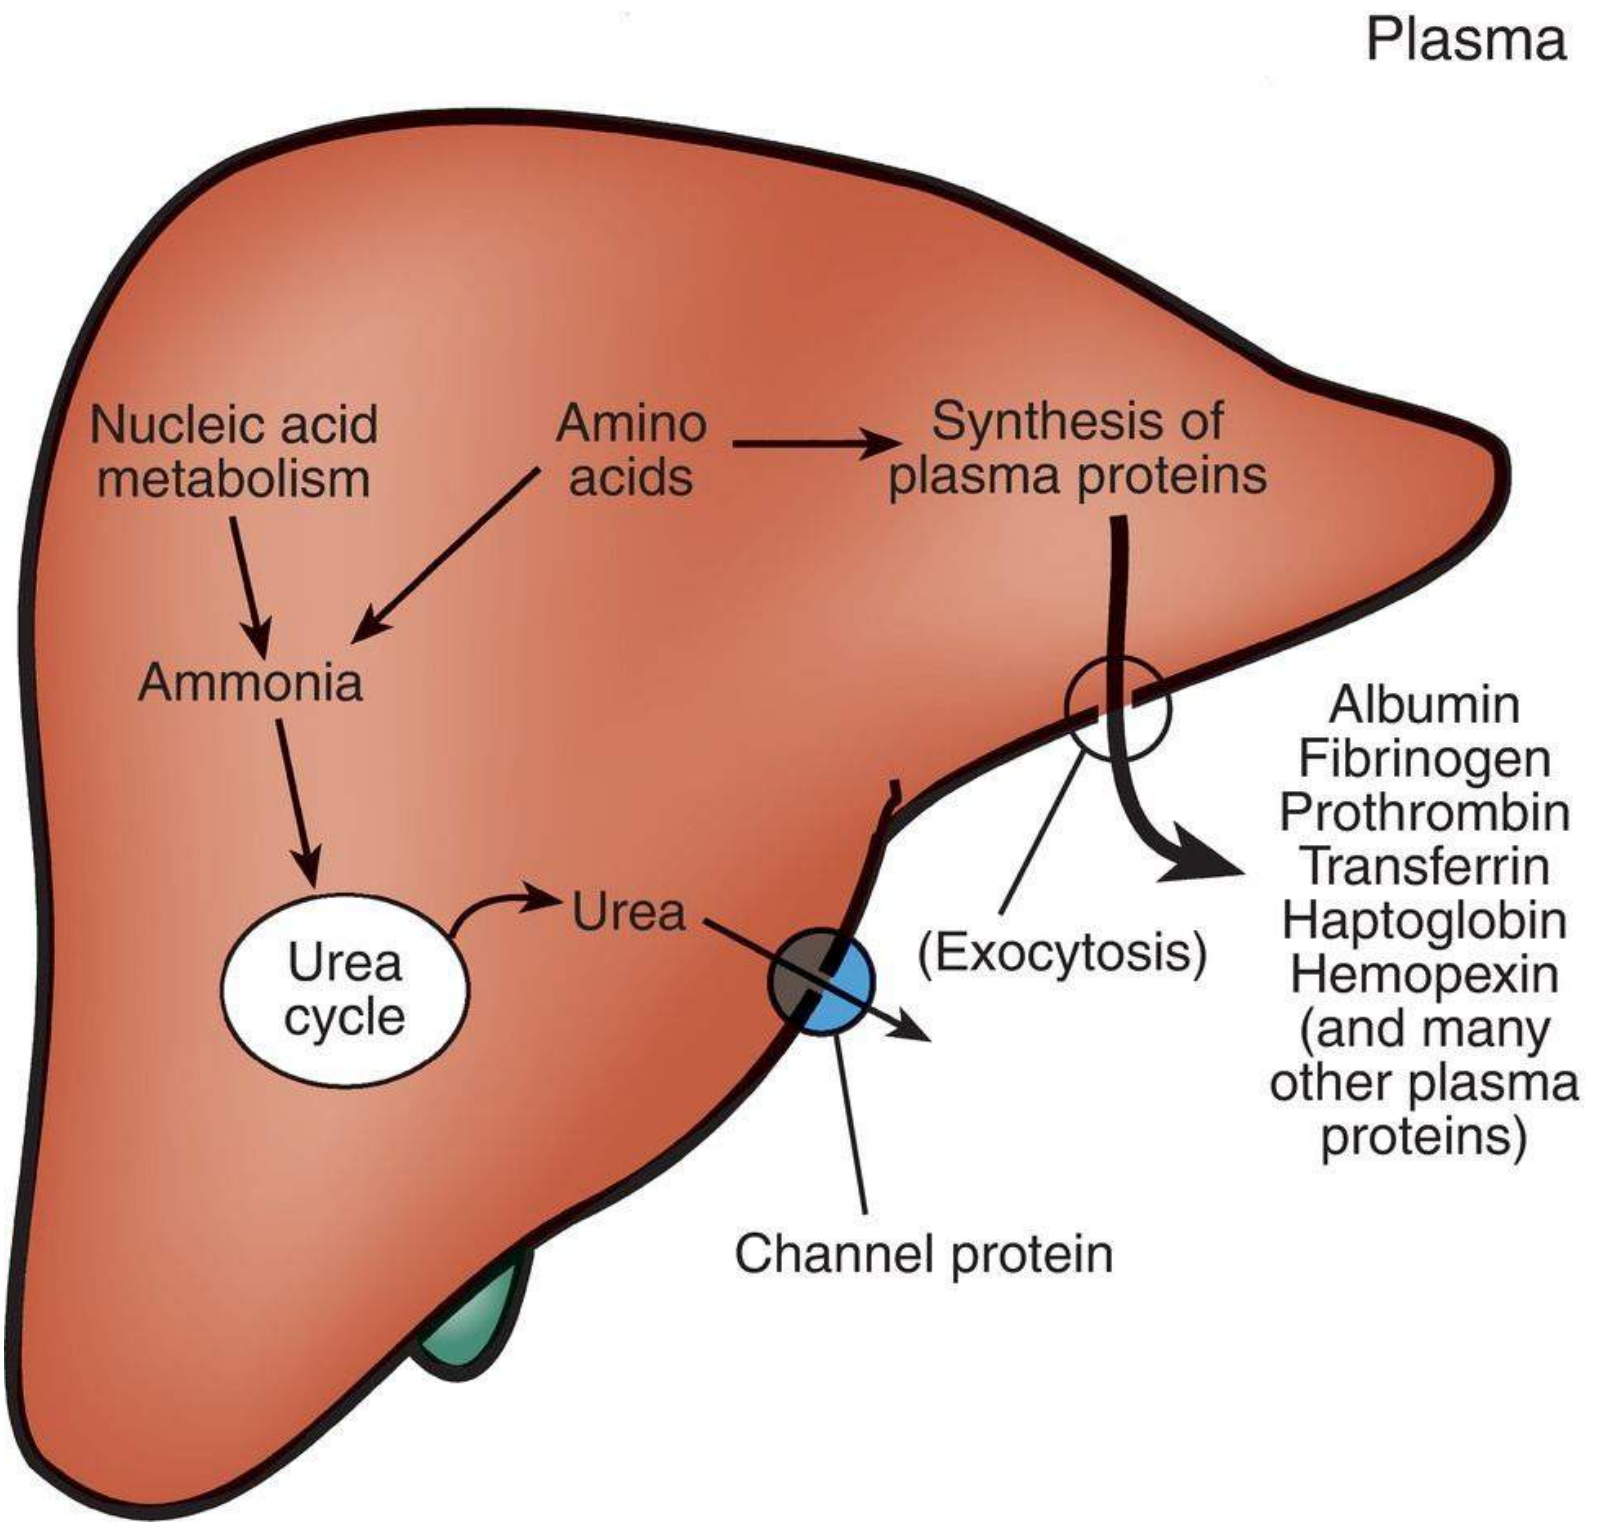

Figure 26.5 The liver synthesizes nonessential amino acids and plasma proteins. The liver is the

body's only source of nonessential amino acids, and it produces most of the circulating plasma proteins.

The other major plasma proteins synthesized by the liver are components of the **complement system**, components of the **coagulation cascade** (i.e., fibrinogen and prothrombin), globulins, and iron transport proteins (i.e., transferrin, haptoglobin, and hemopexin).

Urea production

Ammonia, derived from protein and nucleic acid catabolism, plays a pivotal role in nitrogen metabolism and is needed in the biosynthesis of nonessential amino acids and nucleic acids. The liver metabolizes ammonia and its ammonia level is 10 times higher than plasma. High circulating levels of ammonia are highly neurotoxic, and hyperammonemia causes irritability, vomiting, cerebral edema, and finally coma leading to death.

The liver synthesizes most of the body's urea by way of the ornithine cycle. Protein intake regulates the enzymes involved in the urea cycle. In humans, starvation stimulates these enzymes causing increased urea production and, therefore, an increase in the circulating urea level. The urea produced by the liver is excreted by the kidneys.

Nonessential amino acids

The **essential amino acids** (see Chapter 25) must be supplied in the diet. The liver can form nonessential amino acids from the essential amino acids. For instance, tyrosine can be synthesized from phenylalanine, and cysteine can be synthesized from methionine.

Glutamic acid and glutamine are important in the biosynthesis of certain amino acids in the liver. Glutamic acid is derived from the amination of α-ketoglutarate by ammonia. This reaction is important because ammonia is used directly in the formation of the α-amino group and constitutes a mechanism for shunting nitrogen from wasteful urea-forming products. Glutamic acid can be used in the amination of other α-keto acids to form the corresponding amino acids, and it can be converted to glutamine by coupling with ammonia, a reaction catalyzed by glutamine synthetase. Following urea, glutamine is the second most important metabolite of ammonia in the liver. It plays an important role in the storage and transport of ammonia in the blood. Through the action of various transaminases, glutamine can be used to aminate various keto acids to their corresponding amino acids. It also acts as an important oxidative substrate, and in the small intestine, it is the primary substrate for providing energy.

LIVER AS A NUTRIENT STORAGE ORGAN

The liver stores and metabolizes fat-soluble vitamins and iron as well as some water-soluble vitamins, particularly vitamin B_{12}. These stored vitamins are released into the circulation as needed throughout the body.

Liver is the site for uptake, storage, and release of fat-soluble vitamins.

Vitamin A comprises a family of compounds related to retinol. Vitamin A is important in vision, growth, the maintenance of epithelia, and reproduction. The liver plays a pivotal role in the uptake, storage, and maintenance of circulating plasma vitamin A levels. **Retinol** (alcohol form of vitamin A) is transported in chylomicrons mainly as an ester of long-chain fatty acids. The retinyl ester is not affected by the metabolism of chylomicrons, and the liver eventually takes up and degrades the chylomicron remnants while storing the retinyl ester.

When the vitamin A level in blood falls, the liver hydrolyzes stored retinyl ester releasing retinol that is then bound to **retinol-binding protein** (**RBP**) that has been synthesized by the liver; the RBP–retinol complex is secreted into the blood. The amount of RBP secreted into the blood depends on vitamin A status. Vitamin A deficiency significantly inhibits the release of RBP, whereas vitamin A loading stimulates its release. RBP binds retinol in a 1:1 stoichiometry. The binding results in the solubilization of retinol and protects it from oxidation.

Hypervitaminosis A develops when massive quantities of vitamin A are consumed. Since the liver stores vitamin A, hepatotoxicity is often associated with hypervitaminosis A. The continued ingestion of excessive amounts of vitamin A eventually leads to portal hypertension and cirrhosis. Most cases of vitamin A toxicity and reported overdose were found in arctic explorers who consumed the livers of polar bears and seals, both of which contain high levels of vitamin A. β-Carotene belongs to a family of natural compounds called *carotenes* or *carotenoids*. It is abundant in plants and gives fruits and vegetables their rich orange and yellow colors. The body converts β-carotene to vitamin A (retinol). Although excessive amounts of vitamin A can be toxic, the body converts only as much vitamin A from β-carotene as needed, thereby making β-carotene a safe source of vitamin A.

Vitamin D is thought to be stored mainly in skeletal muscle and adipose tissue. However, the liver activates vitamin D by converting vitamin D_3 to 25-hydroxyvitamin D_3. Additionally, the liver synthesizes vitamin D–binding protein.

Vitamin K is a fat-soluble vitamin important in the hepatic synthesis of prothrombin. Prothrombin is converted to thrombin, an enzyme necessary for the formation of the fibrin clot. Vitamin K deficiency, therefore, leads to impaired blood clotting.

The dietary vitamin K requirement is small and is adequately supplied by the average Western diet. Bacteria in the GI tract also provide vitamin K. This appears to be an important source of vitamin K because prolonged administration of wide-spectrum antibiotics sometimes results in hypoprothrombinemia. Because vitamin K absorption depends on normal fat absorption, any prolonged malabsorption of lipid can result in its deficiency. The vitamin K store in the liver is relatively limited, and therefore, **hypoprothrombinemia** can develop within a few weeks. Administration of vitamin K usually provides a cure. The largest vitamin K store is in skeletal muscle, but the physiologic significance of this and other body stores is unknown.

Liver plays a key role in the transport, storage, and metabolism of iron.

Iron is essential for life, which makes the regulation of iron metabolism an important factor in many aspects of human health and disease. To safely move iron around the body, it must be bound to a protein, because iron-mediated free radical formation can have dire consequences to tissues and organs (e.g., heart and pancreas). The liver synthesizes several proteins involved in iron transport and metabolism. One of these proteins, **transferrin**, plays a critical role in the transport and homeostasis of iron in the blood. The circulating plasma transferrin level is inversely proportional to the iron load of the body. During iron deficiency, liver synthesis of transferrin is significantly stimulated, which enhances the intestinal absorption of iron. When the amount of iron stored in the liver is high, the rate of transferrin synthesis is lower. Iron is stored intracellularly bound to the intracellular-binding protein **ferritin**. This iron–ferritin complex is soluble in the cytoplasm and can functionally act as a buffering mechanism by regulating the amount of iron available for metabolic processes throughout the body. Liver hepatocytes contain the largest amount of ferritin-bound iron, but measurable amounts also exist in the bone marrow and the spleen. The liver synthesizes two transport proteins that play a vital role in iron conservation: **haptoglobin** that binds free hemoglobin and **hemopexin** that binds free heme when they are present in the plasma. The liver then rapidly removes the hemoglobin–haptoglobin and the heme–hemopexin complexes from the blood conserving the iron for later use in the body.

Iron is an essential component of many molecules, and iron-containing proteins, the heme molecules, are involved in an intracellular energy–yielding process that occurs in every cell's mitochondria. Iron is located in the center of heme molecules, and heme-carrier proteins carry out the redox reactions and electron transport required for oxidative phosphorylation related to energy production. Iron–sulfur proteins are another important group of iron-containing proteins, and some are an essential component in oxidative phosphorylation. Iron is at the center of the heme groups that are part of the hemoglobin molecules found in red blood cells and the myoglobin molecules found in cardiac and skeletal muscle. Iron contributes to the ability of these proteins to transport O_2.

Most of the body's iron is contained in red blood cells, and as a result, hemoglobin deficiency anemia and **iron-deficiency anemia** are the two most common types of diseases associated with iron deficiency.

The spleen is the organ that removes red blood cells that are slightly altered. Kupffer cells of the liver also remove damaged red blood cells, especially those that are moderately damaged (Fig. 26.6). Secondary lysosomes rapidly digest the red cells taken up by Kupffer cells to release heme. Microsomal **heme oxygenase** releases iron from the heme, which then enters the free iron pool and is stored as ferritin or released into the bloodstream, where it binds to apotransferrin. Once iron is bound, the molecule is now called ferritin. Some of the ferritin iron may be converted to **hemosiderin granules**. It is unclear whether the iron from the hemosiderin granules is exchangeable with the free iron pool.

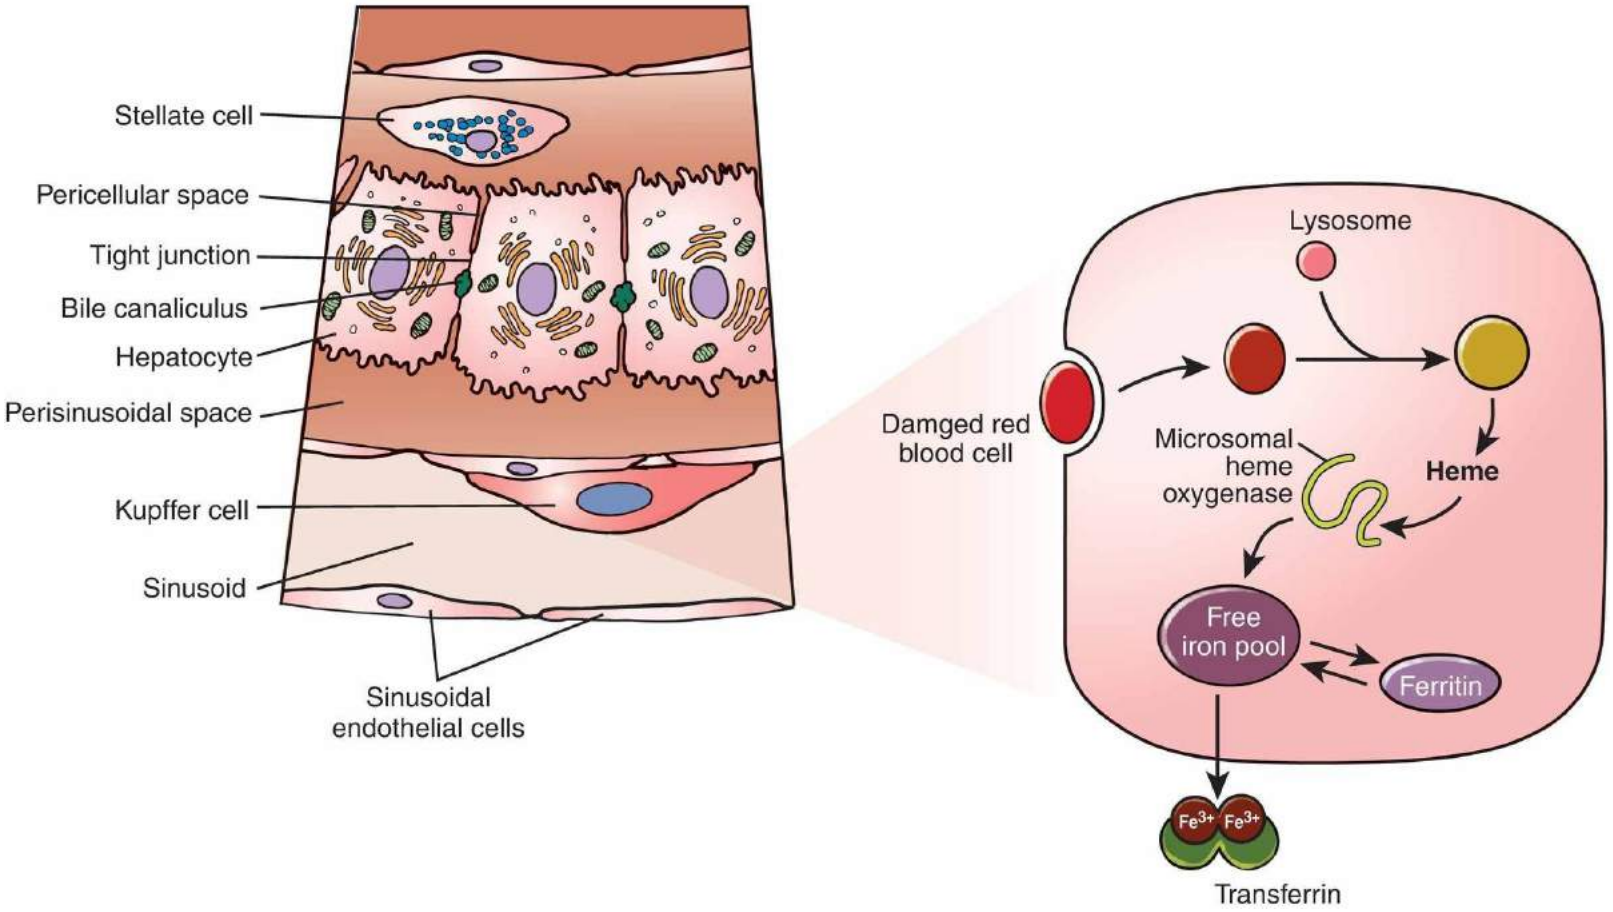

Figure 26.6 Kupffer cells remove damaged red cells from the circulation. Kupffer cells rapidly phagocytize damaged red cells. The iron released from the heme molecule during phagocytosis becomes part of the free iron pool.

It was long believed that Kupffer cells were the only cells involved in iron storage, but recent studies suggest that hepatocytes are the major sites of long-term iron storage. Transferrin binds to receptors on the surface of hepatocytes, and the entire transferrin–receptor complex is internalized and processed (Fig. 26.7). The apotransferrin (not containing iron) is recycled back to the plasma, and the released iron enters a labile iron pool. The iron from transferrin is probably the major source of iron for the hepatocytes, but they also derive iron from haptoglobin–hemoglobin and hemopexin–heme complexes. When hemoglobin is released inside the hepatocytes, it is degraded in the secondary lysosomes releasing the heme. Heme is processed in the SER, and the released free iron enters the labile iron pool. A significant portion of the cytosolic free iron most likely combines rapidly with apoferritin to form ferritin. Like Kupffer cells, hepatocytes may transfer some of the iron in ferritin to hemosiderin.

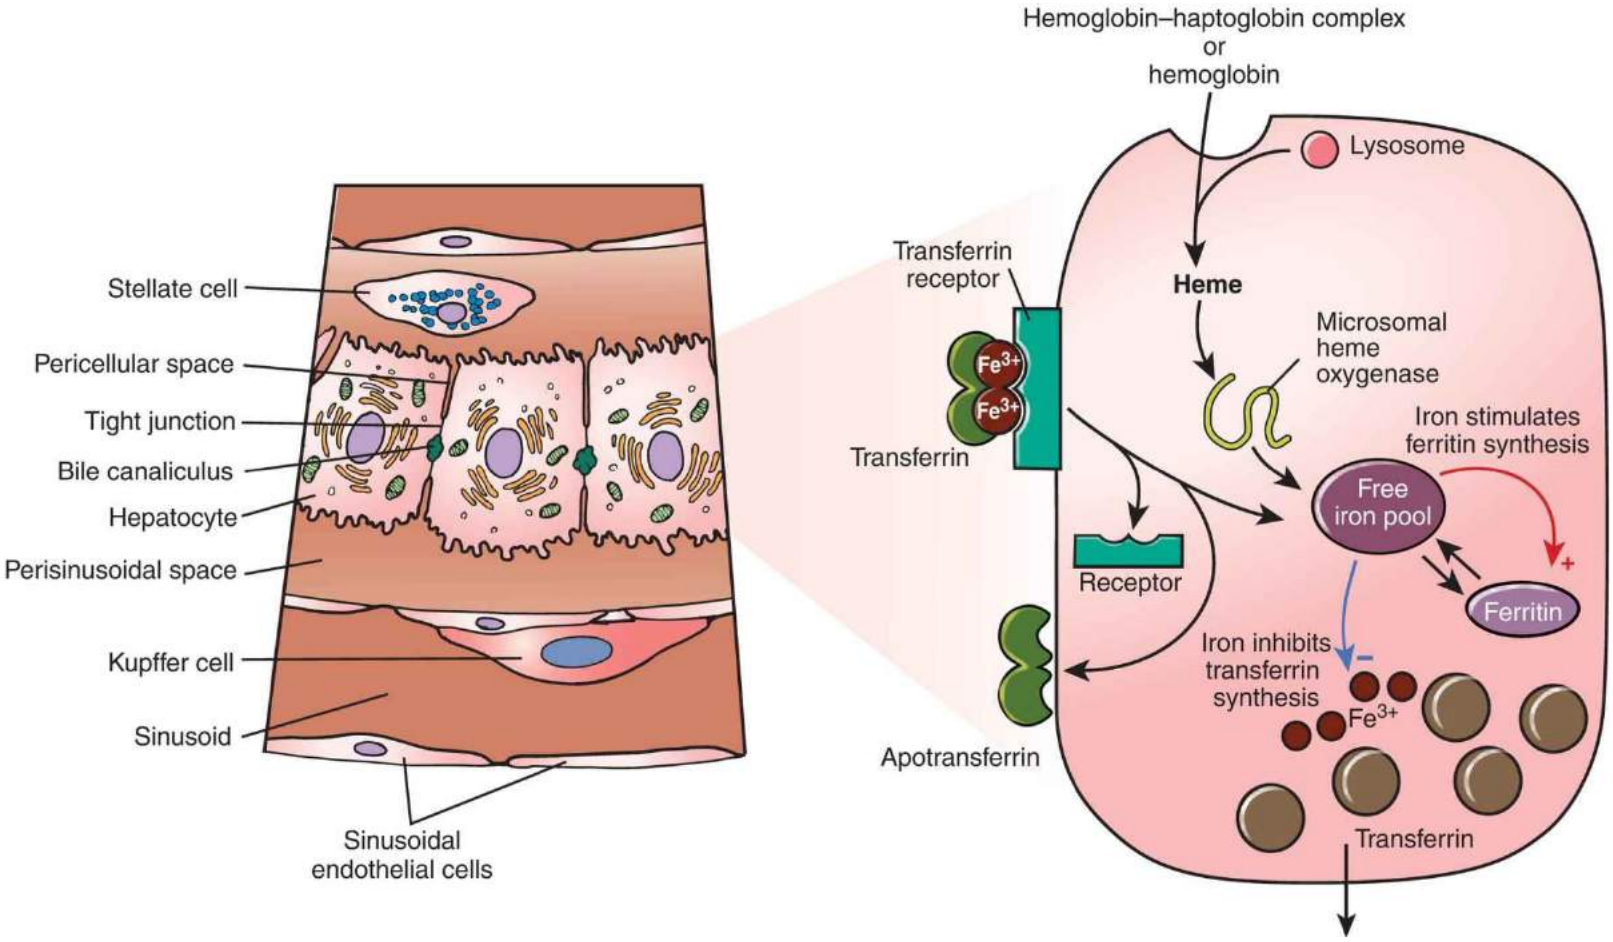

Figure 26.7 The hepatocyte is the major storage site for iron. Transferrin binds to receptors on hepatocytes, and as seen in this figure, the entire transferrin–receptor complex is internalized and processed.

The human body tightly regulates iron absorption and recycling. However, an “iron paradox” exists in physiology; that is, iron is an essential element for life, but the human body has no physiologic regulatory mechanism for excreting iron. Iron overload is prevented solely by the regulation of iron absorption; therefore, those who cannot regulate absorption get disorders of iron overload. With iron overload, iron becomes toxic to cells. Iron toxicity occurs when the amount of circulating iron exceeds the amount of transferrin available to bind it. Toxicity arises when intracellular free iron catalyzes the conversion of hydrogen peroxide into free radicals. These free radicals cause extensive cell damage to the heart, liver, and kidney as well as other metabolic organs. Iron toxicity is usually the result of iron supplement overdose (rare), repeated transfusions, or a genetic disease. A classic example of genetic iron overload is **hereditary hemochromatosis** (**HH**). The defect in HH causes excessive iron absorption from food that in turn causes the hepatocytes to become defective and fail to perform normal functions. The cellular dysfunction is due to free radical damage.

Coagulation proteins are metabolized by the liver.

Liver cells are involved in both the production and the clearance of coagulation proteins. Hepatocytes secrete most of the known clotting factors and inhibitors, some of them exclusively. Additionally, several coagulation and anticoagulation proteins require a vitamin K–dependent modification following synthesis, specifically factors II, VII, IX, and X and proteins C and S, to make them effective.

The monocyte–macrophage system of the liver, predominantly Kupffer cells, is an important system for clearing clotting factors and factor–inhibitor complexes. Disturbances in liver perfusion or a compromise in liver function can result in the ineffective clearance of activated coagulation proteins, so patients with advanced liver failure may be predisposed to developing **disseminated intravascular coagulation** (**DIC**). DIC is the pathologic activation of blood-clotting mechanisms, leading to the formation of small blood clots inside the blood vessels throughout the body, thereby disrupting normal coagulation and causing abnormal bleeding and possible organ malfunction.

ENDOCRINE FUNCTIONS OF THE LIVER

The liver is important in regulating the endocrine functions of hormones. It can amplify the action of some hormones, and it is the major organ involved in the removal of peptide hormones from the circulation.

Liver activates and degrades many hormones.

The liver converts vitamin D_3 to 25-hydroxyvitamin D3, an essential step before conversion to the active hormone 1,25-dihydroxyvitamin D_3 in the kidneys. The liver is also a major site for the conversion of the thyroid hormone thyroxine (T_4) to the biologically more potent hormone triiodothyronine (T_3). The regulation of the hepatic T_4 to T_3 conversion occurs at both uptake and conversion. Given the liver's capacity to convert T_4 to T_3, hypothyroidism is uncommon in patients with liver disease. However, in advanced chronic liver disease, signs of hypothyroidism can be more evident.

The liver modifies the function of growth hormone secreted by the pituitary gland. **Insulin-like growth factors** made by the liver mediate some growth hormone actions (see Chapter 31).

The liver also helps to remove and degrade many circulating hormones. Although insulin is degraded in many organs, the liver and kidneys are by far the most important. The presence of insulin receptors on the surface of hepatocytes suggests that the binding of insulin to these receptors results in degradation of some insulin molecules. In contrast, the degradation of insulin by hepatocyte proteases does not involve an insulin receptor.

Glucagon and growth hormone are degraded mainly by the liver and the kidneys. Consequently, patients with cirrhotic livers often have high circulating levels of hormones such as glucagon. Additionally, the liver degrades various GI hormones (e.g., gastrin), but the kidneys and other organs probably contribute more significantly to inactivating these hormones.

LIVER AND IMMUNE RESPONSES

Like other organs in the body (e.g., kidney and intestine), the liver has multiple roles, with some considered to be primary functions. For example, the liver's role in processing digestive products, the interconversion of nutrients, and the regulation of circulating glucose levels are well known and often discussed, but the liver also carries out other functions. Discussions on the immune system are generally focused on the importance of bone marrow, the thymus, the spleen, and Peyer patches, but the liver is omitted despite the significant contributions it makes to both innate and acquired immune responses by the body.

Liver architecture contributes to its role in immunity.

The liver receives about 30% of the body's blood flow each minute, which makes it an ideal site for the clearance of blood-borne antigens and pathogens. Over 75% of the blood entering the liver arrives from the digestive system via the portal vein. This direct flow from the GI tact to the liver provides a pathway for the liver's immune cells to clear or internalize antigens and pathogens that were able to escape from the intestinal lumen by crossing the protective GI epithelial barrier. A significant role in immunological clearance function is possible due to the liver's unique internal anatomy (e.g., sinusoidal structure) and the cells types located within the organ (e.g., hepatocytes, lymphocytes, Kupffer cells, and hepatic stellate cells). The sinusoidal structure was discussed previously in this chapter. Briefly, the capillary structure (i.e., decrease in diameter) results in a large drop in both blood pressure and blood flow that is unique to the liver. When combined, these changes increase the time period in which the **antigen-presenting cells** are able to come into contact with nearby hepatic lymphocytes. Additionally, other physical features of sinusoids such as the lack of a basement membrane and the cellular extensions from lymphocytes and hepatocytes that enter into the space of Disse also increase the likelihood that blood-borne particles and solutes will come into contact with immune-active cells.

Liver cells have immune functions.

Hepatocytes (parenchymal cells) make up about 80% and nonparenchymal cells about 5% of liver volume. The rest is extracellular space and the cells residing there. The nonparenchymal cells include SECs, KCs, lymphocytes, biliary cells, and hepatic stellate cells. Among the many functions that **hepatocytes** carry out within the liver is the detection of pathogens. It is clear that hepatocytes play a role in innate immunity and specifically in an antiviral response. *In vitro*, they have been shown to present antigens to T cells, but the significance of hepatocytes in this role *in vivo* is not entirely clear. Hepatocytes are the source of acute phase proteins and complement components involved in innate immunity. Hepatocytes, KCs, and SECs are all involved in T-cell apoptosis.

It has been well established that SECs are able to remove and process antigens from the circulation and present them to T cells. Both $CD4^+$ and $CD8^+$ T cells are activated by SEC antigen presentation. This activation contributes to the establishment of immune tolerance. Tolerance is important so that individuals do not regularly mount an immune response to antigens derived from the breakdown and absorption of nutrients from the GI tract or against the naturally occurring gut microbial organisms often present in portal blood.

Kupffer cells are the macrophages of the liver, but they remain stationary and do not move through the vasculature. They are either directly responsible for the phagocytosis of bacteria or the recruitment of immune cells to the liver that will then clear the bacteria from the circulation. KCs are capable of presenting antigen (acquired immunity), and they are a source of cytokines and chemokines involved in innate immunity.

Most of the liver's lymphatic cells are NKCs involved in innate immunity and the destruction of infected liver cells that occurs following the release of perforin and granzyme containing granules from the NKCs. NKCs also defend against tumor cells. Other lymphocytes, NK T cells, circulate in the vasculature and destroy pathogens.

Hepatic stellate cells (Ito cells) are located in the space of Disse. This small group of cells, like others in the liver, plays a role in innate immunity. Ito cells have toll-like receptors on their plasma membrane, and once activated, these cells release interferons in addition to cytokines and chemokines. If liver injury occurs, stellate cells are also capable of transdifferentiating and becoming fibrogenic cells.

INTEGRATED MEDICAL SCIENCES

Hepatotoxicity of Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are taken by millions of individuals every day, and the majority of them purchase NSAIDs as part of a self-directed treatment regimen as opposed to following a physician-directed program. Tracking the hepatotoxicity or other possible negative impacts of these drugs on human health has historically not been easy. However, testing of hepatic enzyme activity has now become more routine and has provided a more direct means of tracking the impact of drugs on liver function. Some NSAIDs have been found to cause significant liver injury

(hepatotoxins) resulting in their withdrawal from the consumer market or an end to their further development (e.g., bromfenac, phenylbutazone, and isoxicam).

Hepatotoxicity does not appear to be related to a patient's age, but certain individual factors do increase a patient's susceptibility to negative effects related to ingesting NSAIDs. A prime example is the association between the development of Reye syndrome in children who have or are recovering from a viral infection and proceed to take aspirin to relieve their symptoms. Investigators have noted that the vast majority of hepatotoxicity is due to idiosyncratic susceptibility (e.g., immunological and genetic idiosyncrasies). Environmental factors cannot be ruled out as contributors or, at the very least, being related to the potential for development of hepatotoxicity.

Certain NSAIDs (e.g., aspirin) can have adverse effects even when taken at normal, therapeutic doses. In contrast, all NSAIDs are going to be toxic at higher exposure levels even though the drug is considered to be safe (i.e., acetaminophen). These situations occur in addition to those that accompany either an unexpected or intentional drug overdose. At least 900 drugs, which include the NSAIDs, have been found to either cause or contribute to hepatotoxicity. The challenge continues to be that drugs like NSAIDs often appear to be safe when first introduced onto the market and any associated hepatotoxicity may take longer to develop and not become apparent until years later. In the last 25 years, however, better testing has led to the detection of hepatic injury much sooner. Regardless, it is believed that liver damage associated with taking NSAIDs is highly underestimated and that the number of cases may be as much as 20 times more frequent in occurrence.

Despite much being known about the action of NSAIDs, the exact causes of hepatotoxicity associated with using these drugs and their specific effect on the liver are not completely understood. This is not surprising given the lipophilic nature of many NSAIDs. However, investigations have provided strong *in vitro* evidence that a common NSAID component, diphenylamine, contributes to the drug-induced damage to liver cells due to an uncoupling of mitochondrial oxidative phosphorylation. As a result of enzymatic bioactivation, acidic NSAIDs are converted to reactive metabolites capable of binding to and altering the activity of liver proteins. This interaction may result in an immune response being mounted against the modified protein. Intrahepatic cholestasis may also be a consequence of drug-induced liver injury that occurs as a result of the NSAID itself or a bioactive drug metabolite. In many situations, a direct correlation between the formation of reactive metabolites and an exact pathway leading to liver injury remains elusive. The ability to fully make a connection and to understand drug–liver interactions is compounded by the fact that a drug can reach the hepatocytes in either the free or protein-bound form, since both can enter the space of Disse. Regardless, NSAID-induced severe or fatal liver injury cases remain rare overall. The majority of cases continue to be either asymptomatic or mild in severity, which is most likely due to the short half-life of many drugs.

Two of the most commonly used NSAIDs are aspirin and Tylenol (acetaminophen or paracetamol). Additionally, Tylenol is often prescribed in combination with or as an active component of other drugs. Both aspirin and Tylenol have clear dose-dependent effects and toxicity. Ingestion of aspirin and Tylenol simultaneously or in combination is extremely dangerous as the negative effects of both are additive. Hepatic injury due to aspirin consumption is generally at the hepatocellular level. While it is difficult to give a precise dosage at which a drug becomes toxic, it has been reported by researchers in London that plasma concentrations in the range of 300 to 500 mg/L produce mild aspirin poisoning, poisoning in the 500 to 700 mg/L range is moderate, and poisoning at levels >750 mg/L was either severe or fatal. These values were determined ~6 hours after ingestion of the drug. Several methods have been reported to treat salicylate poisoning such as

rehydration, gastric lavage, activated charcoal, and urinary alkalization. In cases of mild toxicity, it is typical that an aspirin-induced hepatic injury will self-resolve in about 2 weeks after cessation.

Almost half of the acute liver failure cases in the United States are the result of drug-induced liver injury, and the majority of those cases represent an overdose of acetaminophen. Acetaminophen toxicity has four recognized phases of progressing symptoms. In phase I (the first 24 hours post ingestion), symptoms may include vomiting, nausea, or abdominal pain. Once symptoms have progressed to phase IV (96 hours to 3 weeks post ingestion), the patient may be experiencing hepatic failure, coma, or possibly spontaneous recovery. Acetaminophen toxicity may lead to metabolic acidosis. Given the more general nature of phase I symptoms, acetaminophen poisoning may initially be overlooked. To minimize the potential of drug-induced toxicity, it is generally felt that a daily dose for children should remain under 90 mg/kg and the combined adult daily intake should remain <4 g/d. Fortunately, there is an antidote for acetaminophen toxicity, but it must be given as soon as possible after the drug has been consumed. *N*-acetylcysteine is the treatment of choice, and the treatment protocol is determined by the time of administration post drug ingestion. Unfortunately, it cannot reverse any liver damage that has already occurred.

This essay has provided only a glimpse into the potential hepatotoxicity of NSAIDs. Students are encouraged to consult the literature to learn more about the benefits, possible side effects, and potential physiological, pharmacological, and biochemical impact of this group of drugs on individual organs and systems, as well as how to treat possible overdoses. ■

Chapter Summary

- The basic functional unit of the liver is the liver lobule that contains specialized cells, the hepatocytes.
- The liver plays an important role in maintaining blood glucose levels and in metabolizing drugs and toxic substances.
- The liver is the only organ in the adult that can be regenerated.
- Gluconeogenesis regulates blood glucose during fasting.
- The liver is the first organ to be affected by and respond to changes in plasma insulin levels.
- The liver is one of the main organs involved in fatty acid synthesis.
- The liver aids in the elimination of cholesterol from the body.
- The liver plays an important role in iron metabolism.
- The liver modifies the action of hormones released by other organs.
- The liver plays an important role in establishing immunity.

Chapter Review Questions

1. A 46-year-old patient was not feeling well and was admitted to the emergency department. Upon examination, his liver enzymes were elevated, and he was diagnosed as being jaundiced. Which function would not be affected by his illness?

A. Albumin synthesis
B. Urea production
C. Intestinal glucose absorption
D. VLDL synthesis
E. The conjugation of bilirubin with glucuronic acid

The correct answer is C. Intestinal glucose absorption is not affected by liver dysfunction. All of the other options are correct because they are altered by function of the liver.

2. Both the liver and muscle contain glycogen. However, the liver is the organ capable of contributing glucose to the circulation, because muscle lacks the:

A. glucose-6-phosphatase enzyme.
B. glycogen-converting enzyme.
C. glucose-1-phosphatase enzyme.
D. ability to convert UDP-D-glucose to glucose.
E. ability to carry out gluconeogensis.

The correct answer is A. The liver has the enzyme glucose-6-phosphatase, but muscle does not. Consequently, muscle is incapable of releasing glucose from glucose-6-phosphatase. Option B is incorrect because muscle cannot supply glucose to the circulation. Option C is incorrect because glucose-1-phosphatase is not the right enzyme to hydrolyze glucose-6-phosphatase. Option D is incorrect because UDP-D-glucose is involved in the formation of UDP-galactose, and the enzyme involved is an epimerase. The synthesis of glucose, called gluconeogenesis, is carried out mostly in the liver and to some extent in the kidneys. Option E is incorrect because the synthesis of glucose, called gluconeogenesis, is carried out mostly in the liver and to some extent in the kidneys.

3. The small intestine secretes various triglyceride-rich lipoproteins, but the liver secretes only:

A. chylomicrons.
B. VLDLs.
C. LDLs.
D. HDLs.
E. chylomicron remnants.

The correct answer is B. Although both chylomicrons and VLDLs are triglyceride-rich lipoproteins, the liver, unlike the small intestine, produces only VLDLs. LDLs and HDLs are not triglyceride-rich lipoproteins. Chylomicron remnants are generated in the circulation by the metabolism of chylomicrons.

4. A 55-year-old patient was diagnosed with a portacaval shunt (connection between the portal vein and vena cava). Circulating glucagon level in this individual would be expected to be extremely high because the:

A. pancreas produces more glucagon in these patients.
B. kidney is less efficient in removing the circulating glucagon in these patients.
C. liver normally is the major site for the removal of glucagon.

D. small intestine produces more glucagon in these patients.
E. circulation to the small intestine is compromised.

The correct answer is C. The liver is one of the major sites for the removal of hormones, including glucagon. Consequently, patients with a portacaval shunt have high levels of circulating glucagon and other hormones because portal blood bypasses the liver. Option A is incorrect because the pancreas does not produce more glucagon in portacaval shunt patients. Option B is incorrect because the kidneys are capable of removing glucagon in these patients. However, the kidneys are not nearly as important as the liver in removing glucagon in healthy individuals. Option D is incorrect because the small intestine does not produce glucagon. Option E is incorrect because blood flow to the small intestine is not compromised in portacaval shunt patients.

Clinical Application Exercises 26.1

AUTOIMMUNE HEPATITIS

A 60-year-old male was previously diagnosed as suffering from rheumatoid arthritis and celiac disease. His current complaint is that he has pain over the liver area, has experienced flulike symptoms, is passing a dark yellow stream of urine, and seems to be having more than the usual joint pain. He has had several tattoos over the past 2 years. An office examination discovered leg bruises, which he could not remember receiving, and evidence of bleeding gums. The remainder of the exam was uneventful. It was concluded that the patient had all the classic signs of acute viral hepatitis but an additional workup was needed.

A liver biopsy was taken and blood was drawn. Renal function was also evaluated, but it was normal. The liver biopsy showed evidence of cirrhosis. The blood draw revealed hypergammaglobulinemia along with elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), and autoantibody levels including antinuclear antibodies (ANA), antismooth muscle antibodies (ASMA), and antiliver kidney microsomal antibodies (LKM-1). Alkaline phosphatase levels are normal. He was started on prednisone and azathioprine. He will be closely monitored for signs of pancreatitis, which can lead to diabetes.

QUESTIONS

1. Since the patient is now on a drug regimen, why would it be important to be certain that he is suffering from autoimmune hepatitis and not viral hepatitis?
2. After a month, one more autoantibody test was requested. The results came back positive for pANCA (perinuclear neutrophil antibodies). Why would this additional test have been conducted?

ANSWERS

1. Corticosteroids such as prednisone can actually enhance viral replication perhaps by reducing the normal expression of antiviral genes and interfering with innate immunity pathways. It is also possible that corticosteroids may stimulate viral replication rather than stimulate viral elimination. It if the patient has viral hepatitis the treatment choice would be administration of antivirals and interferon. Autoimmune hepatitis was identified around 1950 and is more common

in females than males. It can occur at any age; younger patients make up the majority of cases. While it may remain patient dependent, history has shown that if the disease has progressed far enough, up to 20% of patients may not respond to drug treatment (i.e., prednisone). Autoimmune hepatitis is an unresolving, chronic inflammatory response in the liver. Some symptoms such as fatigue, joint pain, and itching are not unique to the disease and can even overlap with those of viral hepatitis. A biopsy is often needed to confirm the diagnosis. Viral hepatitis is commonly caused by either the hepatitis A, hepatitis B, or hepatitis C virus, but there are also hepatitis D and E viruses. Hepatitis A, B, and E infections are symptomatic, while hepatitis C–infected individuals may remain asymptomatic. Any of these viral infections can lead to acute hepatitis. The B and C viruses can become chronic hepatitis. Due to the way the viruses replicate, a hepatitis B infection will precede the development of a hepatitis D infection. At this time, hepatitis D is not common in the United States. Symptoms of viral hepatitis can include fatigue, abdominal pain, vomiting, and diarrhea.

2. pANCA autoantibodies are relatively common in autoimmune hepatitis. They are much rarer in viral hepatitis. Both types of hepatitis share many of the same diagnostic abnormalities. Earlier speculation that hepatitis C infection can lead to autoimmune disease has not been definitively proven.

27 Motility and Gastrointestinal Regulation

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Distinguish the differences between electromechanical and pharmacomechanical coupling in initiation of contractions in gastrointestinal muscles.
- Explain the concept of a "functional electrical syncytium," as applied to the gastrointestinal smooth musculature.
- Understand the forms of electrical activity in the gastrointestinal musculature.
- Understand how the sympathetic, parasympathetic, and enteric divisions of the autonomic nervous system innervate the gut and explain why the enteric nervous system is called a "mini-brain."
- Apply the locations of postsynaptic receptors, presynaptic receptors, and presynaptic autoreceptors on enteric neurons to their physiologic significance.
- Distinguish the role of presynaptic inhibition from that of presynaptic facilitation in the function of enteric neural microcircuits.
- Explain why inhibitory musculomotor neurons are necessary for control of contractile behavior of the intestinal musculature by the enteric nervous system.
- Relate the mechanisms involved in the production of physiologic as opposed to pathophysiological ileus in the intestine.
- Explain how inhibitory neuronal motor control of gastrointestinal sphincters differs from inhibitory control of the longitudinal and circular muscle coats of the small and large intestine.
- Explain how function of the gastric reservoir differs from that of the antral pump in the determination of rate of gastric emptying and the role of the vagovagal reflex.
- Describe three types of smooth muscle relaxation responses that occur in the gastric reservoir.
- Explain why symptoms of early satiety, bloating, and vomiting are experienced by patients after disruption of transmission in vagal nerves.
- Explain how the motor behavior of the stomach and small intestine in the interdigestive state differs from that in the digestive state.
- Describe how the mechanisms of neural control of the internal anal sphincter differ from those of the external anal sphincter and puborectalis muscle.
- Explain how neural deficits lead to gastrointestinal problems.

In the last two chapters, we saw that the gastrointestinal (GI) system was responsible for the absorption of ingested nutrients, H_2O, minerals, and vitamins and the removal of toxic materials from the blood. These processes are essential for the cellular and integrative function of the body. This chapter demonstrates how gut motility and its regulation play a central role in these processes. The GI tract or digestive tract is a long, continuous tube with an oral (i.e., mouth) and an anal opening. The digestive system is physically and functionally divided into regions specialized for digestion, secretion, absorption, motility, and compaction. Skeletal and smooth muscle contractions contribute to the physical breakdown of food and the movement of luminal contents toward the anus. The teeth and tongue and secretions from the salivary glands, liver, gallbladder, and pancreas contribute to the physical, chemical, and enzymatic breakdown processes that occur as ingested materials are mixed and move along the GI tract. Sphincter muscles

located at key points along the tube and at critical openings regulate the passage of materials between regions of the tract, the entrance of bile and digestive enzymes into the tract, and the discharge of fecal material from the tract.

Digestive system motility and digestive processes are regulated in a coordinated manner by the sympathetic, parasympathetic, and enteric divisions of the autonomic nervous system, with some conscious control (e.g., the oral and external anal sphincters), along with specific hormones and enzymes. An individual's physiological and psychological state, as well as immune system activity, can have a significant impact on digestive system functions including salivary secretions, processing and absorption disorders, diarrhea, constipation, abdominal pain, the feeling of satiation, and the species of bacteria that colonize the intestines (see Chapter 25).

Gastroenterology focuses on understanding normal and abnormal functions, diseases, and structural problems of the GI tract and the organs and structures connected to it. **Neurogastroenterology** is a subspecialty of clinical gastroenterology and digestive science. As such, it encompasses understanding nervous system regulation and involvement in GI tract functions. This chapter discusses the organization and motility of the GI tract and the role of skeletal and smooth muscle, the nervous system, and hormones in the process.

ORGANIZATION OF THE DIGESTIVE SYSTEM

The digestive system is divided into the **upper GI tract** (i.e., esophagus, stomach, and duodenum) and the **lower GI tract** (i.e., small and large intestine). The system is structurally and functionally organized to efficiently take in and process significant quantities of food in various forms from large pieces of solids to liquids and purees. Striated muscle is present in the mouth, pharynx, upper esophagus, external anal sphincter, and pelvic floor, while visceral-type smooth muscle is found elsewhere. The contraction and relaxation pattern of the smooth musculature is organized to produce the propulsive forces (peristalsis) responsible for the net movement of luminal contents toward the anus, to mix ingested foodstuffs with digestive enzymes, and to bring nutrients into contact with the mucosa for final digestion and absorption. Muscle contraction also contributes to **trituration**, which decreases particle size. This increases the total surface area available for attack by digestive enzymes, particularly in the small intestine (see Chapter 25). The **enteric nervous system** (**ENS**), together with input from the **central nervous system** (**CNS**), organizes motility into patterns of efficient behavior suited to differing digestive states (e.g., fasting and processing of a meal) as well as abnormal patterns (e.g., during emesis). Functionally, the ENS consists of the myenteric plexus and the submucosal plexus. Output from the myenteric complex increases GI peristalsis and submucosal plexus output regulates secretion and absorption.

Gastrointestinal tract wall contains smooth muscle.

The **muscularis externa** is one of four tissue layers making up the wall of the GI tract and is composed of two distinct sheets of smooth muscle—one circular and one longitudinal (Fig. 27.1). Motility in the stomach and intestines is specifically driven by waves of contraction spreading through the surrounding sheets of smooth muscle. One difference is that the stomach's muscularis externa consists of three sheets of smooth muscle with the long axis of the fibers oriented in a longitudinal, circular, or oblique direction.

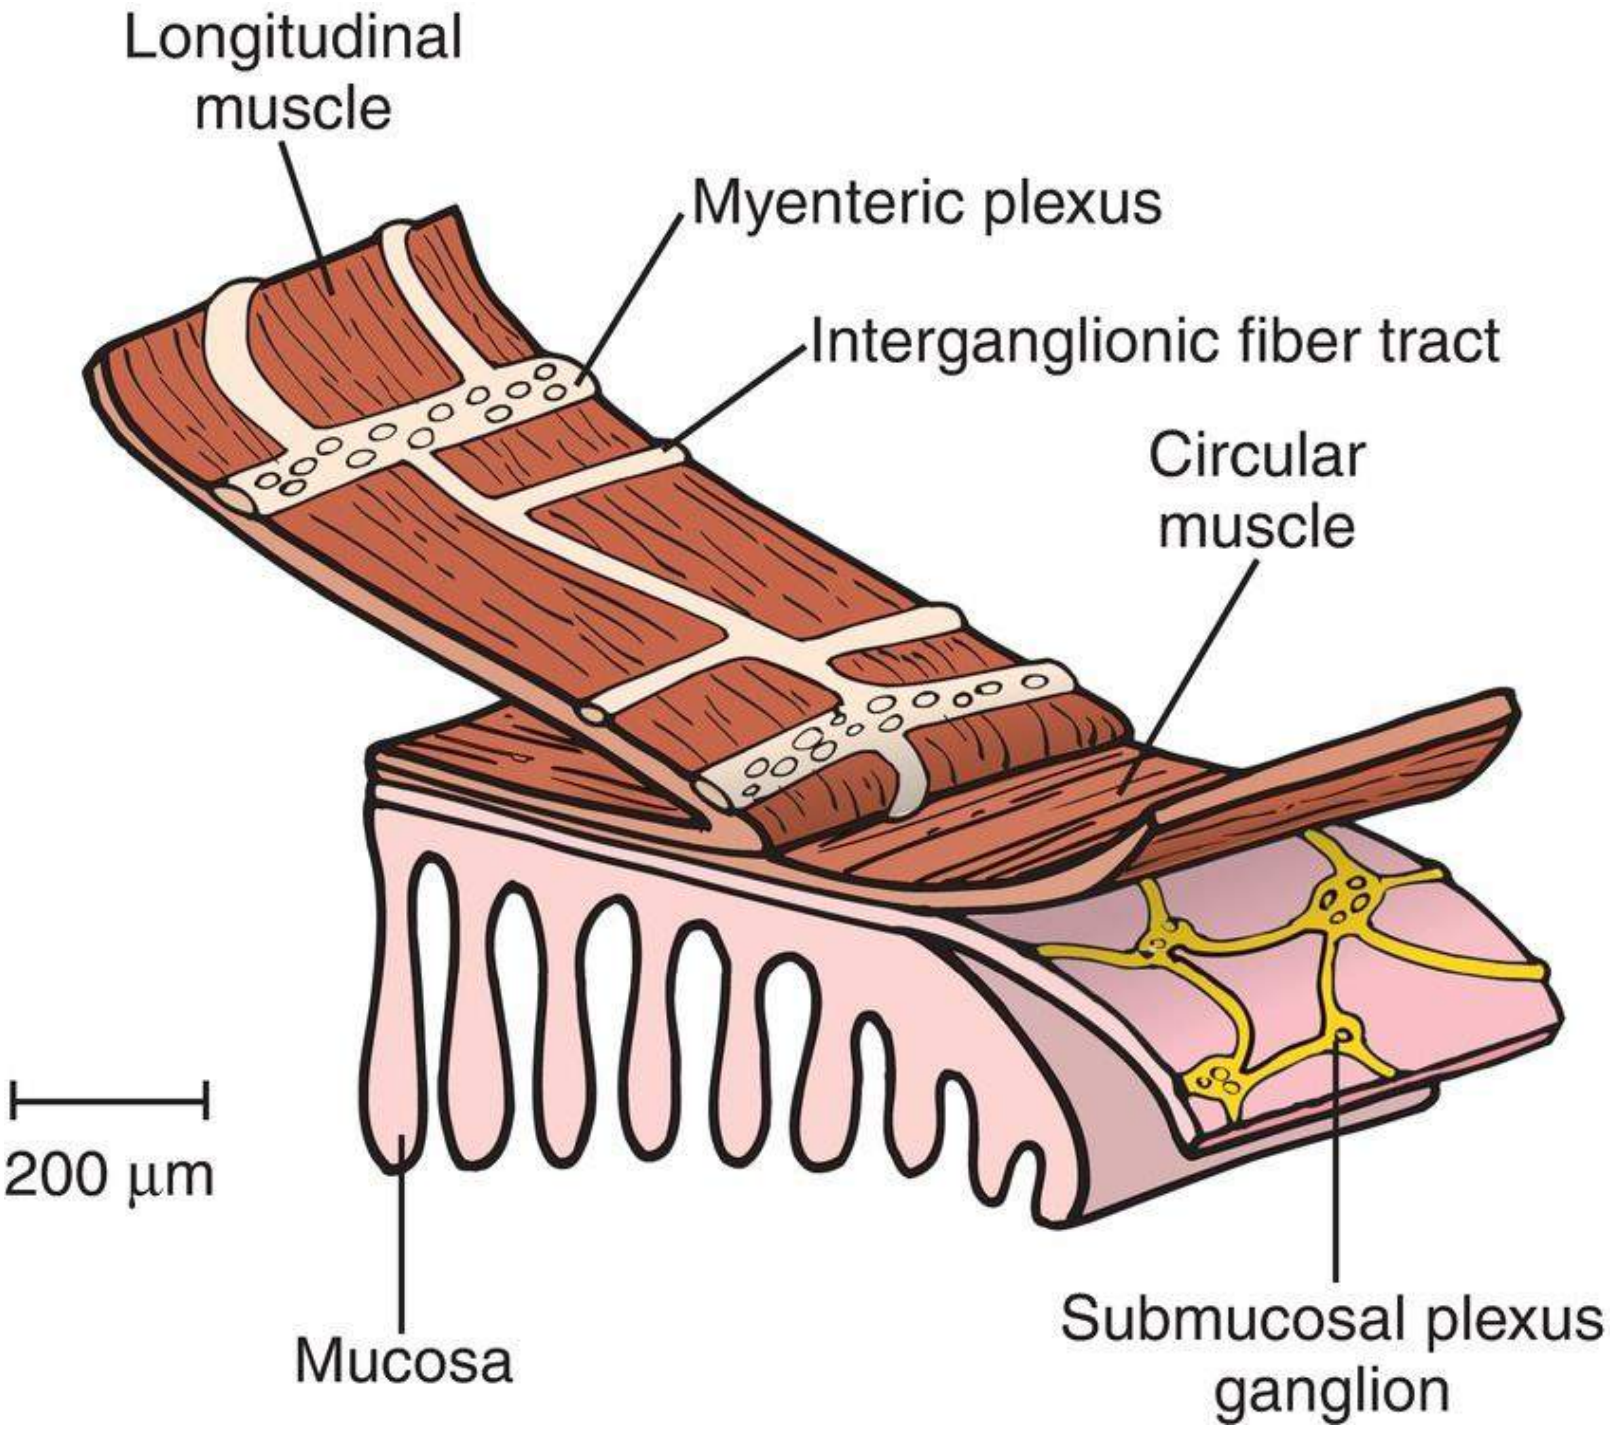

Figure 27.1 Structural relationships of the intestinal musculature and the enteric nervous system. Ganglia and interganglionic fiber tracts form the myenteric plexus between the longitudinal and circular muscle layer and the submucosal plexus between the mucosa and circular muscle layer.

Circular and longitudinal muscle layers of the intestine differ in both structure and function.

The long axis of the intestinal **circular muscle fibers** is oriented in the circumferential direction, and contraction in these fibers results in a reduction in diameter that is accompanied by an increase in length of an intestinal segment. The long axis of the **longitudinal muscle fibers** is oriented along the length of the intestine, and contraction in these fibers produces the reverse effect. These concurrent changes occur because the intestine is a cylinder with a constant surface area, and therefore, a change in diameter must be accompanied by an opposite change in length. The circular muscle layer is thicker than the longitudinal layer and is thus capable of exerting more powerful contractile forces onto the lumen.

Sphincters prevent reflux between specialized compartments of the GI tract.

Six strategically placed sphincters regulate movement between compartments of the GI tract. A seventh is located at the junction of the common bile duct with the duodenum. All but the upper esophageal sphincter consist of rings of smooth muscle that remain in a continuous (tonic) state of contraction (positive resting pressure) that occludes the lumen in the region separating two specialized compartments. With the exception of the internal anal sphincter, sphincters function to prevent the backward reflux of intraluminal contents. In this regard, intraluminal pressure is normally highest on the oral side of the sphincter, which will drive net movement in the aboral direction. If the aboral side develops a higher pressure than the oral side, overall movement will be in a retrograde fashion toward the oral cavity (i.e., emesis).

Myogenic contractile activity (i.e., contractile activity initiated within the muscle that does not require any nervous system input) is responsible for maintaining the tonic state of contraction of the smooth muscle sphincters. Specific signals (e.g., distention, pressure, and nervous input) cause the sphincters to transiently relax and allow movement between neighboring compartments and into reservoirs of the stomach and large intestine. Inhibitory sphincteric motor neurons are normally inactive and are switched on to coordinate the opening of the sphincter with physiologic events in adjacent regions (Fig. 27.2). When this occurs, the released inhibitory neurotransmitter causes relaxation in the sphincteric muscle and prevents excitation and contraction in the adjacent muscle from spreading into and closing the sphincter. **Achalasia** is a pathologic state in which smooth muscle sphincters fail to relax and is most often caused by the loss of the ENS and its complement of inhibitory musculomotor innervation of the sphincters.

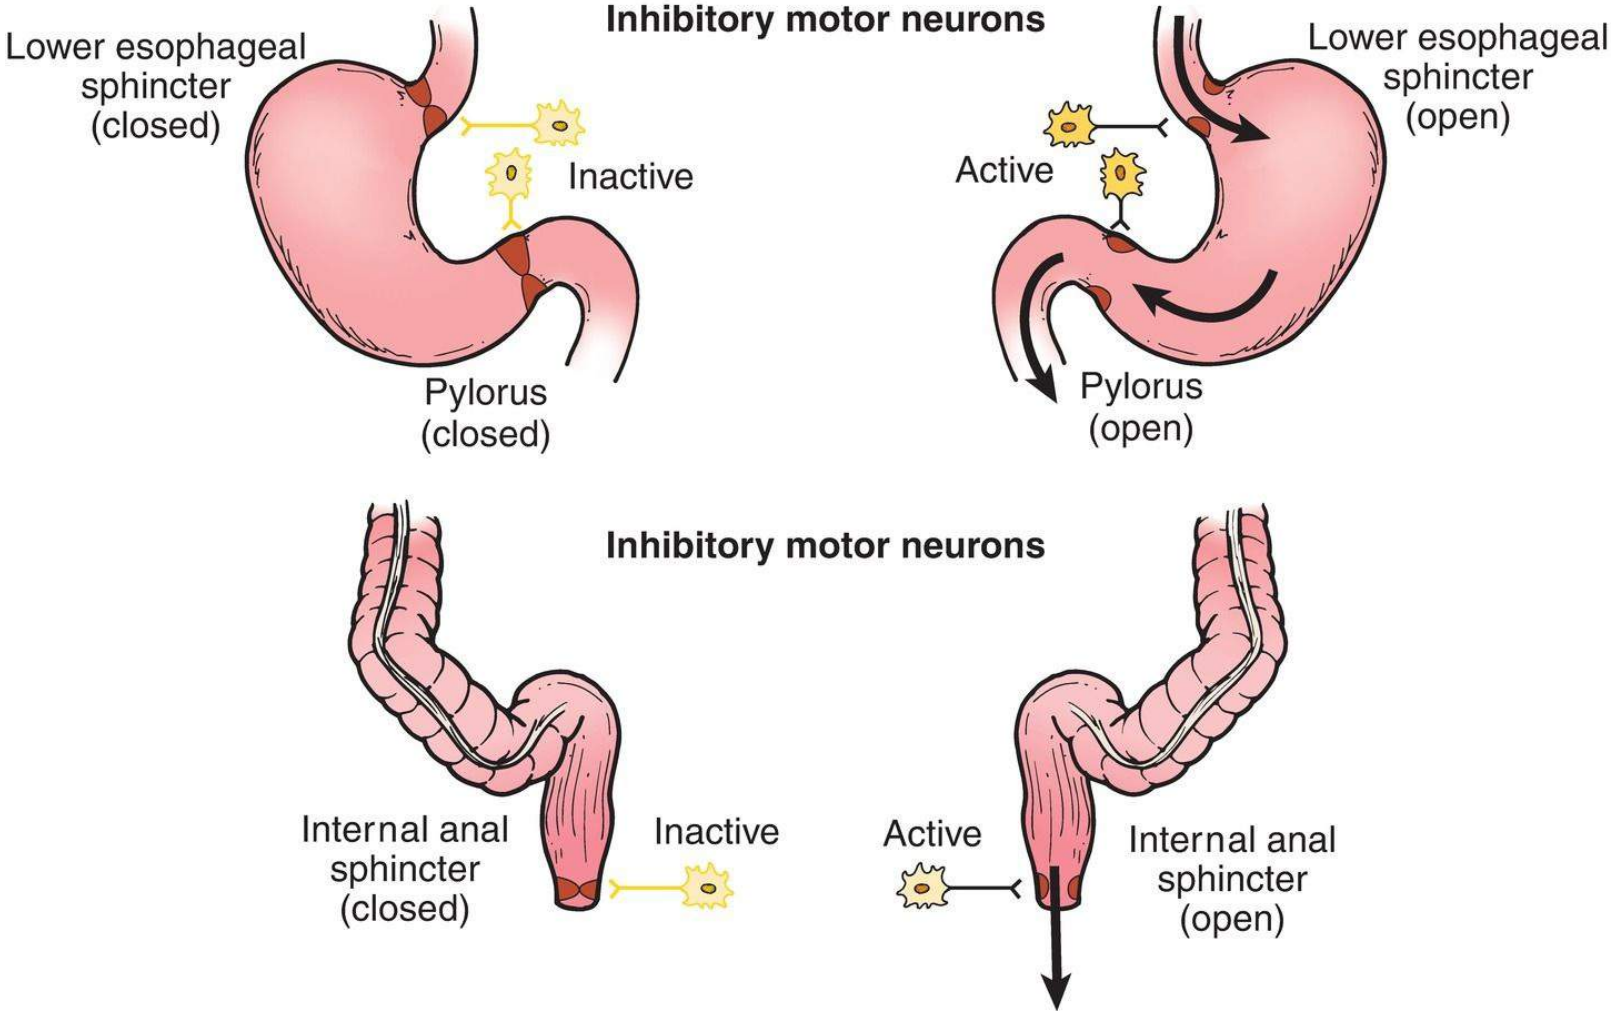

Figure 27.2 Smooth muscle sphincters are closed when their inhibitory innervation is inactive. When inhibitory musculomotor neurons are active, the sphincters are opened.

Upper esophageal sphincter

The **upper esophageal sphincter** (**UES**) is skeletal muscle, and, when compared to the other GI sphincters, it has the highest resting pressure. The UES is located at the junction of the laryngopharynx and esophagus and has two functions. It contracts to close off the esophagus thereby preventing air from entering the digestive tract, and it diverts air into the glottis and trachea during breathing. It relaxes during swallowing to allow food to pass down the esophagus en route to the stomach. During this stage, the epiglottis closes off the glottis. The swallowing center located in the medulla stimulates the UES to relax during swallowing.

Lower esophageal sphincter

The **lower esophageal sphincter** (**LES**) is located at the junction of the esophagus and stomach. It prevents the reflux of gastric contents, including HCl, into the esophagus. Incompetence of the LES permits chronic exposure of the esophageal mucosa to gastric acid, which can lead to heartburn, also known as **pyrosis** or **acid indigestion**. Persistent chronic gastric reflux can lead to inflammation and damage to the esophageal mucosa, a major symptom of **gastroesophageal reflux disease** (**GERD**). GERD patients are at risk for **Barrett esophagus**, a condition in which damaged esophageal cells are transformed into metaplastic cells, which are a precursor to carcinoma. Although the risk of cancer is present, the progression from precancerous metaplasia to dysplasia is <20% in Barrett patients.

Pyloric sphincter

The **pyloric sphincter** (**PS**) is located at the gastroduodenal junction. It prevents reflux of duodenal contents into the stomach. Incompetence of the PS can result in the reflux of bile acids and digestive enzymes from the duodenum into the stomach. Bile acids damage the protective barrier of the gastric mucosa, and prolonged exposure can lead to gastritis, formation of ulcers, and risk of perforation.

Ileocecal sphincter

The **ileocecal** (**ileocolonic**) **sphincter** (**IS**) or **ileocecal valve** is located at the junction of the ileum and cecum. It prevents the reflux of colonic contents into the ileum. Incompetence of the IS can allow bacteria from the colon to enter the ileum, which can result in bacterial overgrowth in the small intestine. Bacterial counts are normally low in the small intestine, and bacterial overgrowth has been associated with symptoms of bloating and abdominal pain in a subgroup of patients diagnosed with the irritable bowel syndrome.

Anal sphincters

The **internal anal sphincter** (**IAS**) and the **external anal sphincter** (**EAS**) surround the anal canal. The IAS regulates passage from the rectum into the anal canal and helps to control the movement of flatus and feces out of the anus. The EAS is located at the distal end of the canal and is the last structure separating the GI tract from the external environment. The IAS is under involuntary control only, but the EAS is controlled both involuntarily (i.e., **rectosphincteric reflex**) and voluntarily. Failure of the IAS to relax underlies the fecal retention that occurs in children with **Hirschsprung disease** and adults with **Ogilvie syndrome**. Fecal incontinence is associated with incompetent anal sphincters.

Sphincter of Oddi

The **sphincter of Oddi** surrounds the opening of the bile duct where it enters the duodenum. It prevents the reflux of intestinal contents into the ducts leading from the liver, gallbladder, and pancreas. Failure of this sphincter to open leads to distention in the biliary tree and the associated biliary tract pain that can be felt in the epigastric region and right upper abdominal quadrant. An incompetent sphincter of Oddi is associated with a risk of reflux-induced pancreatitis.

Enteric nervous system controls activity along the GI tract.

The **enteric nervous system** (**ENS**) is a subdivision of the **autonomic nervous system** (**ANS**) and is embedded in the walls of the GI tract where it serves as a "mini-brain" due to its ability to control GI functions without any direct input from the CNS. However, its activity can be modified by transmissions from either the sympathetic (**SNS**) or parasympathetic (**PNS**) subdivisions of the ANS. This allows the ENS to respond to environmental factors such as stress or time of day. The ENS has as many neurons as the spinal cord and is positioned close to the effector systems it controls within the GI tract (i.e., musculature, secretory glands, and blood vessels) (Fig. 27.3).

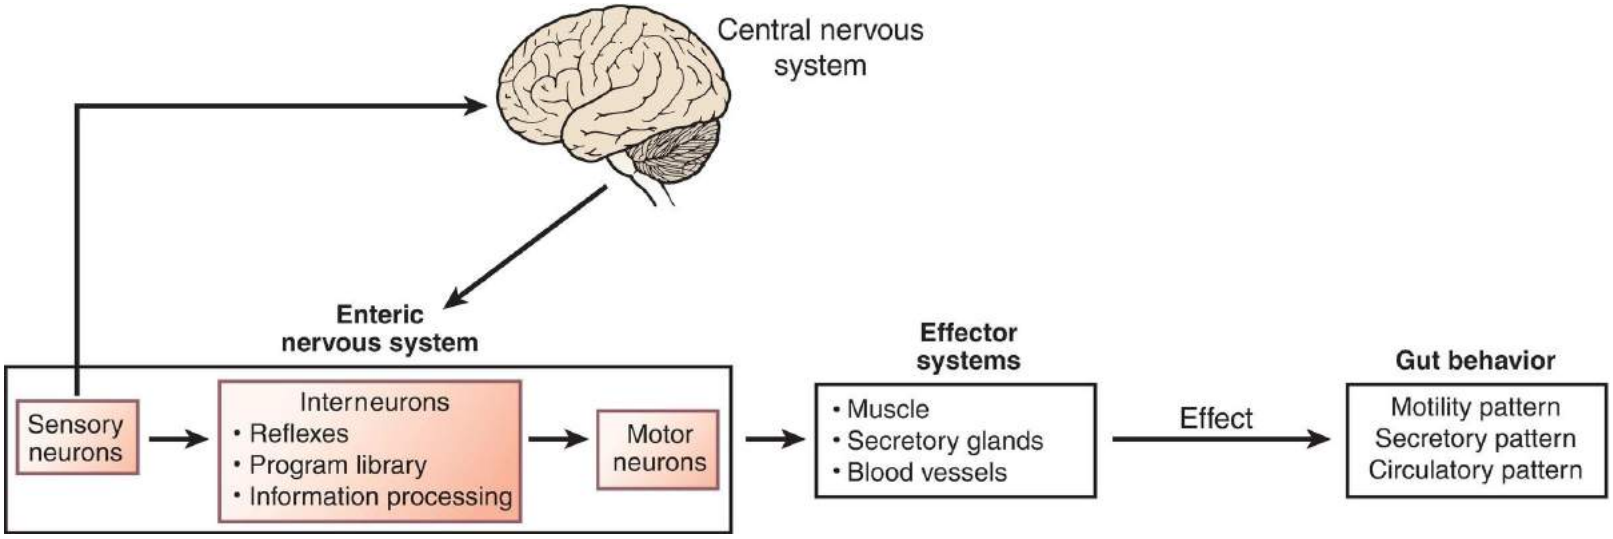

Figure 27.3 The digestive tract is innervated by the enteric division of the autonomic nervous system. Sensory neurons, interneurons, and motor neurons form the microcircuits of the enteric nervous system. As in the central nervous system, information flows from sensory neurons to interneuronal integrative networks to motor neurons to effector systems.

The nerve cell bodies of the ENS are clustered in ganglia that are interconnected by fiber tracts resulting in the formation of two plexuses that play a major role in controlling local blood flow, endocrine cell activity, and gut motility, secretion, and absorption. The **myenteric plexus** or **Auerbach plexus** extends the length of the GI tract and runs between the longitudinal and circular muscle layers (see Fig. 27.1). This arrangement makes it ideal for regulating both the strength and frequency of smooth muscle contraction necessary to move materials along the tract. The plexus also controls sphincter activity. **Interstitial cells of Cajal** (see Chapter 25) are located in the myenteric plexus. The **submucosal plexus** or **Meissner plexus** is situated in the submucosal region between the circular muscle and the mucosa (see Fig. 27.1). This plexus is most prominent as a ganglionated network in the small and large intestine, but it is better developed in the small intestine. It does not exist as a ganglionated plexus in the esophagus and is sparse in the submucosal space of the stomach. The submucosal plexus is involved in regulating secretion (i.e., Brunner glands in the duodenum and the crypts of Lieberkühn in the small and large intestine), absorption, blood flow, and endocrine cell activity in addition to regulating the contraction of the submucosal muscle fibers. Contraction and relaxation of these fibers alters the amount of mucosal folding. Although physically separated, the two plexuses are not functionally isolated from one another. Specific neurons link the two networks into a functionally integrated nervous system.

GASTROINTESTINAL SYSTEM MOTILITY

Digestive system motility relies on the integrated function of multiple muscles, nerves, and sometimes endocrine cells for the generation of various motility patterns that are organized to fulfill the specialized function of individual organs and to move nutrients along the digestive tract.

The ENS, together with input from the CNS, organizes muscular activity and motility into functional patterns of wall behavior needed for normal GI function and differing digestive states (e.g., fasting and processing of a meal) and occasionally into abnormal patterns (e.g., during emesis). Motility patterns differ depending on factors such as awake or sleeping state, time after a meal, and the presence of disease. Nervous system activity is influenced by chemical signals released from **enterochromaffin cells**, **enteroendocrine cells**, and cells associated with the enteric immune system (e.g., **mast cells** and **polymorphonuclear leukocytes**). Specialized pacemaker cells, called **interstitial cells of Cajal** (**ICCs**), are associated with the smooth musculature (see Chapter 25).

Peristalsis and propulsion are the major types of GI motility.

GI motility is divided into two distinct patterns, peristalsis and segmentation. **Peristalsis** (i.e., wavelike contractions in muscle) produces **propulsion**. Propulsion is a basic ENS peristaltic reflex circuit that results in the controlled, progressive, forward movement of food down the esophagus and along the length of the GI tract. It eventually leads to elimination of waste through defecation. **Segmentation** (i.e., the localized division of the intestine into smaller regions lengthwise) occurs when circular muscle contracts. Segmentation aides in the physical breakdown of ingested foods, the mixing of the luminal contents with enzymes for more efficient processing, and the elimination of waste. The **mixing motility pattern** blends pancreatic, biliary, and intestinal secretions with chyme arriving from the stomach and brings digestive products into contact with the absorptive surfaces of the mucosa.

Peristalsis occurs during and shortly after a meal.

Peristalsis is one of the contractions that occur during and shortly after a meal. The contractions occur in wave patterns traveling down short lengths of the GI tract from one section to the next.

The muscle layers of the intestine behave in a characteristic pattern during peristaltic propulsion (Fig. 27.4). Neural networks of the ENS determine this two-component pattern. The contractions occur in waves directly behind a bolus of food, forcing it into the next relaxed section of the GI tract. As part of the first component of peristaltic propulsion, the longitudinal muscle in the segment ahead of the advancing intraluminal contents contracts at the same time the circular muscle layer relaxes, which results in expansion of the lumen and prepares a *receiving segment* for the forward-moving intraluminal contents.

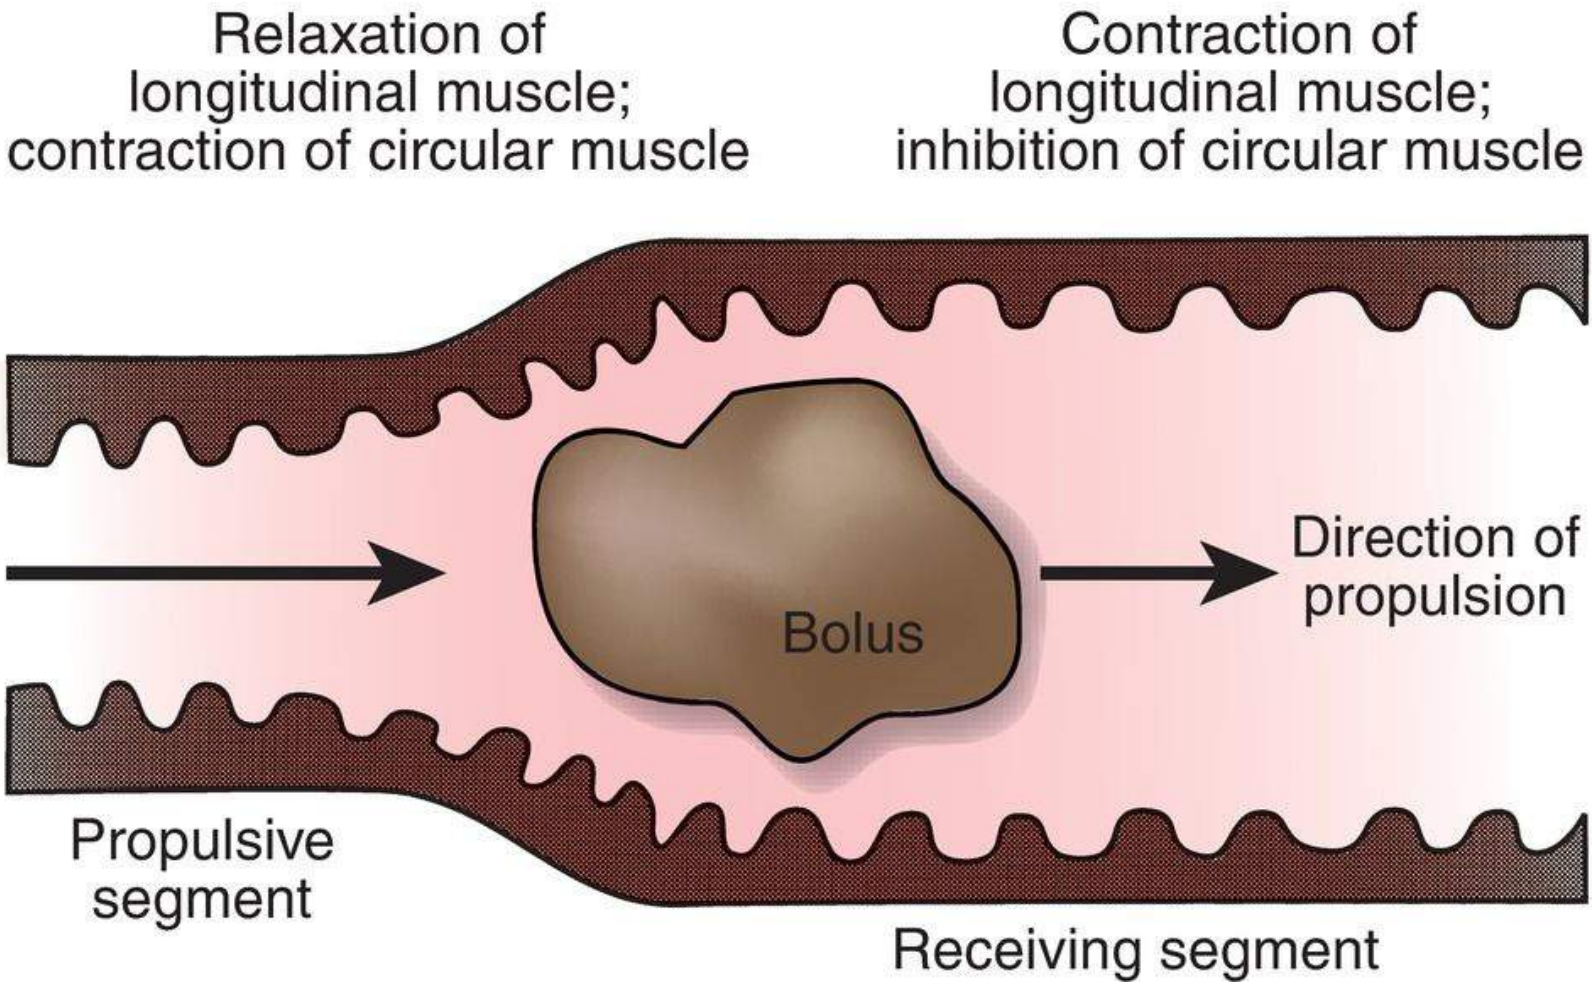

Figure 27.4 Peristaltic propulsion involves the formation of a propulsive and a receiving segment, mediated by reflex control of the intestinal musculature.

The second component is contraction of the circular muscle in the segment behind the advancing intraluminal contents with a simultaneous contraction of the longitudinal muscle layer, which converts this region to a *propulsive segment* that propels the luminal contents forward into the receiving segment. The process of lengthening in the longitudinal axis in the propulsive segment is unclear.

Peristalsis is a polysynaptic neural reflex.

The **peristaltic reflex** (i.e., the formation of propulsive and receiving segments) is organized like somatic nervous system– controlled reflexes in skeletal muscle, where reflex circuits with fixed connections in the spinal cord automatically reproduce a stereotypic pattern of behavior each time the circuit is activated (e.g., Achilles and patellar tendon reflexes; see Chapter 5). Connections for these reflexes remain, irrespective of the destruction of adjacent regions of the spinal cord. The peristaltic reflex circuit is similar, with the exception that the basic circuit is repeated continuously within the ENS along and around the entire length of the intestine. In the same way that the monosynaptic reflex circuit of the spinal cord is the terminal circuit for the production of almost all skeletal muscle movements (see Chapter 5), the basic peristaltic reflex circuit of synaptic connections underlies all patterns of propulsive motility. Blocks of the same basic circuit are connected in series up and down the intestine (Fig. 27.5). Distances over which peristaltic propulsion travels are determined by the number of blocks recruited in sequence along the bowel. Synaptic gates between the blocks determine whether recruitment occurs for the next circuit in the sequence. When the gates are opened, neural signals pass between successive blocks of the basic circuit, resulting in propagation of the peristaltic event over extended distances. Long-distance propulsion is prevented when all gates are closed.

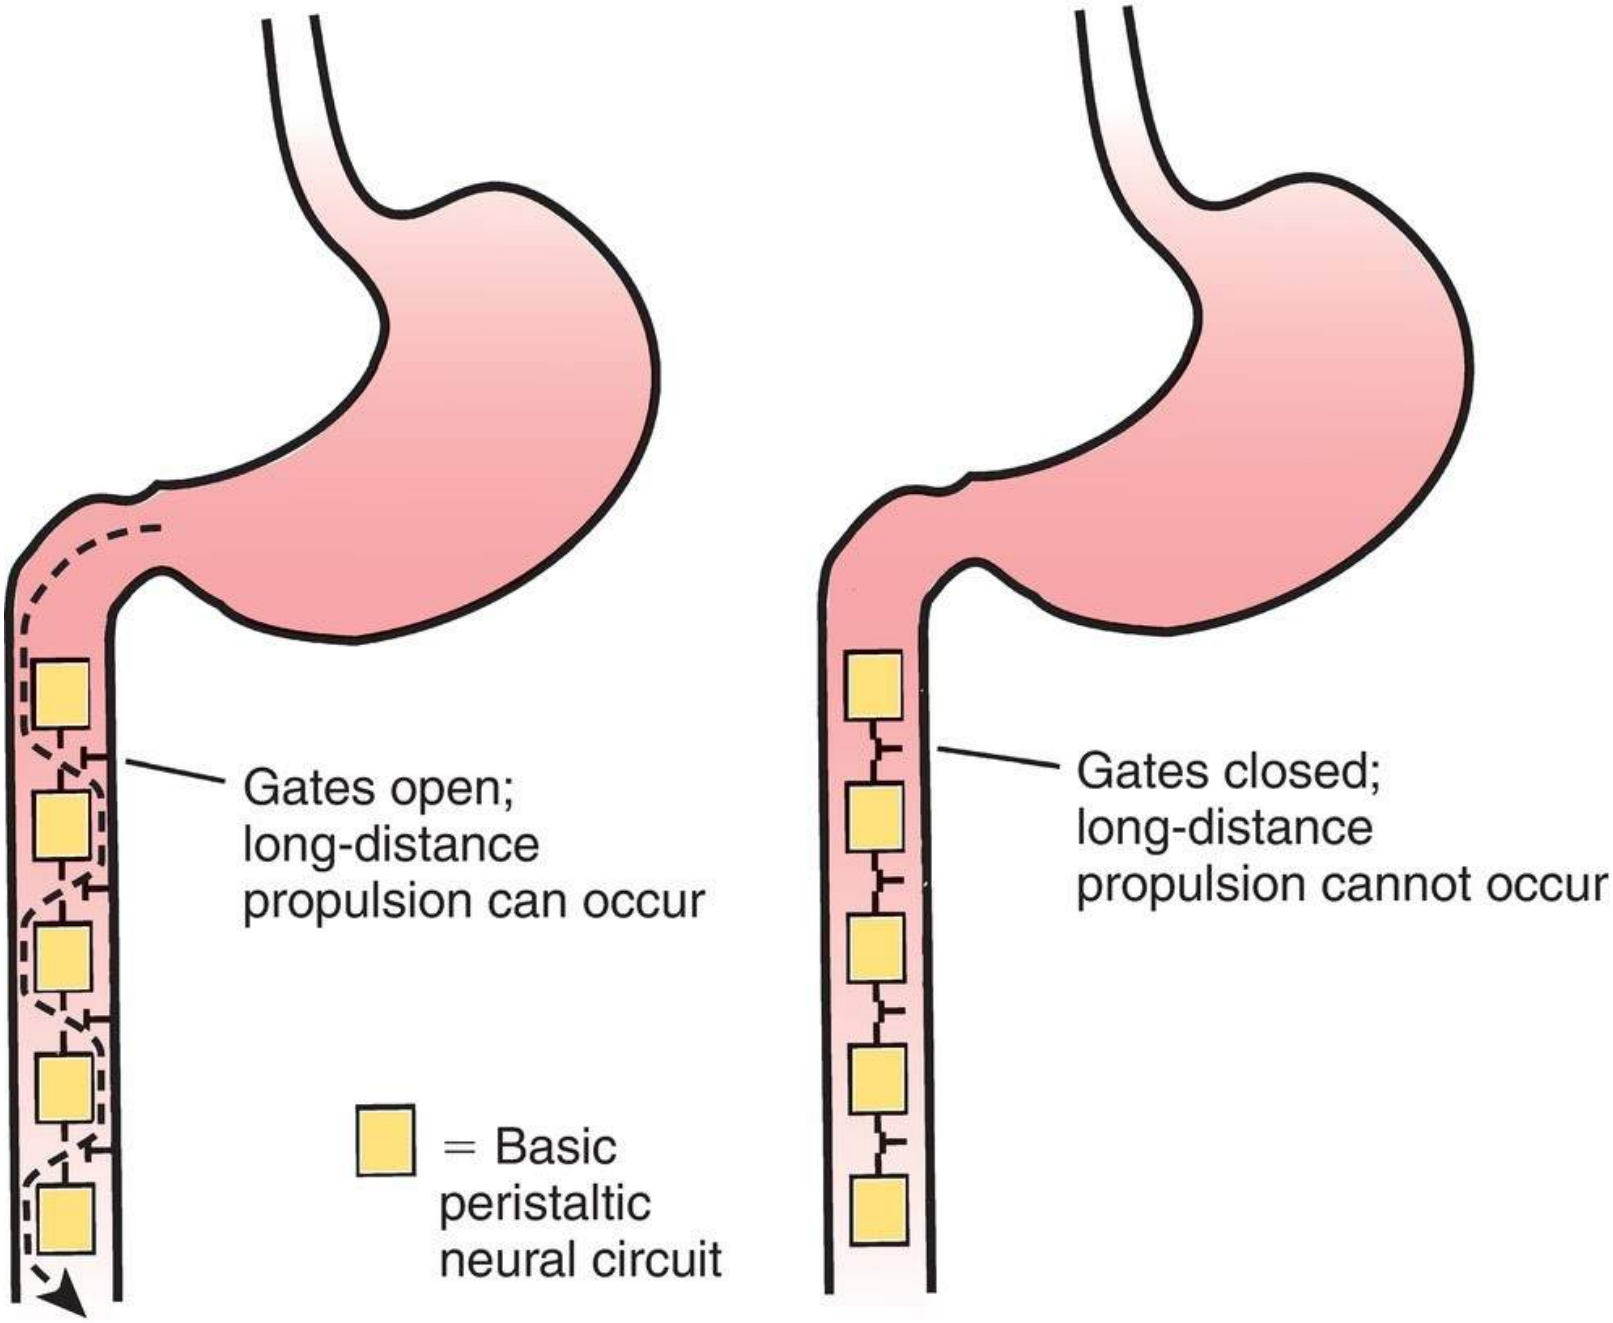

Figure 27.5 Excitatory synapses connect successive blocks of the basic peristaltic reflex circuit and behave like gates between blocks of circuitry. Transmission at the synapses opens the gates between successive blocks of the basic peristaltic reflex circuit and accounts for propagation of peristaltic propulsion over long distances. Long-distance propulsion is prevented when all gates are closed.

Presynaptic inhibition and/or facilitation are involved in gating the transfer of signals between sequential blocks. Synapses between the neurons that carry excitatory signals to the next block are gating points for control of the distance over which peristaltic propulsion travels (Fig. 27.6). Inhibitors of transmitter release at excitatory synapses close the gates to the transfer of information, thereby determining the distance of propagation. Prokinetic drugs that facilitate the release of neurotransmitters at the excitatory synapses (e.g., cisapride and tegaserod) have therapeutic application because they are capable of enhancing propulsive motility.

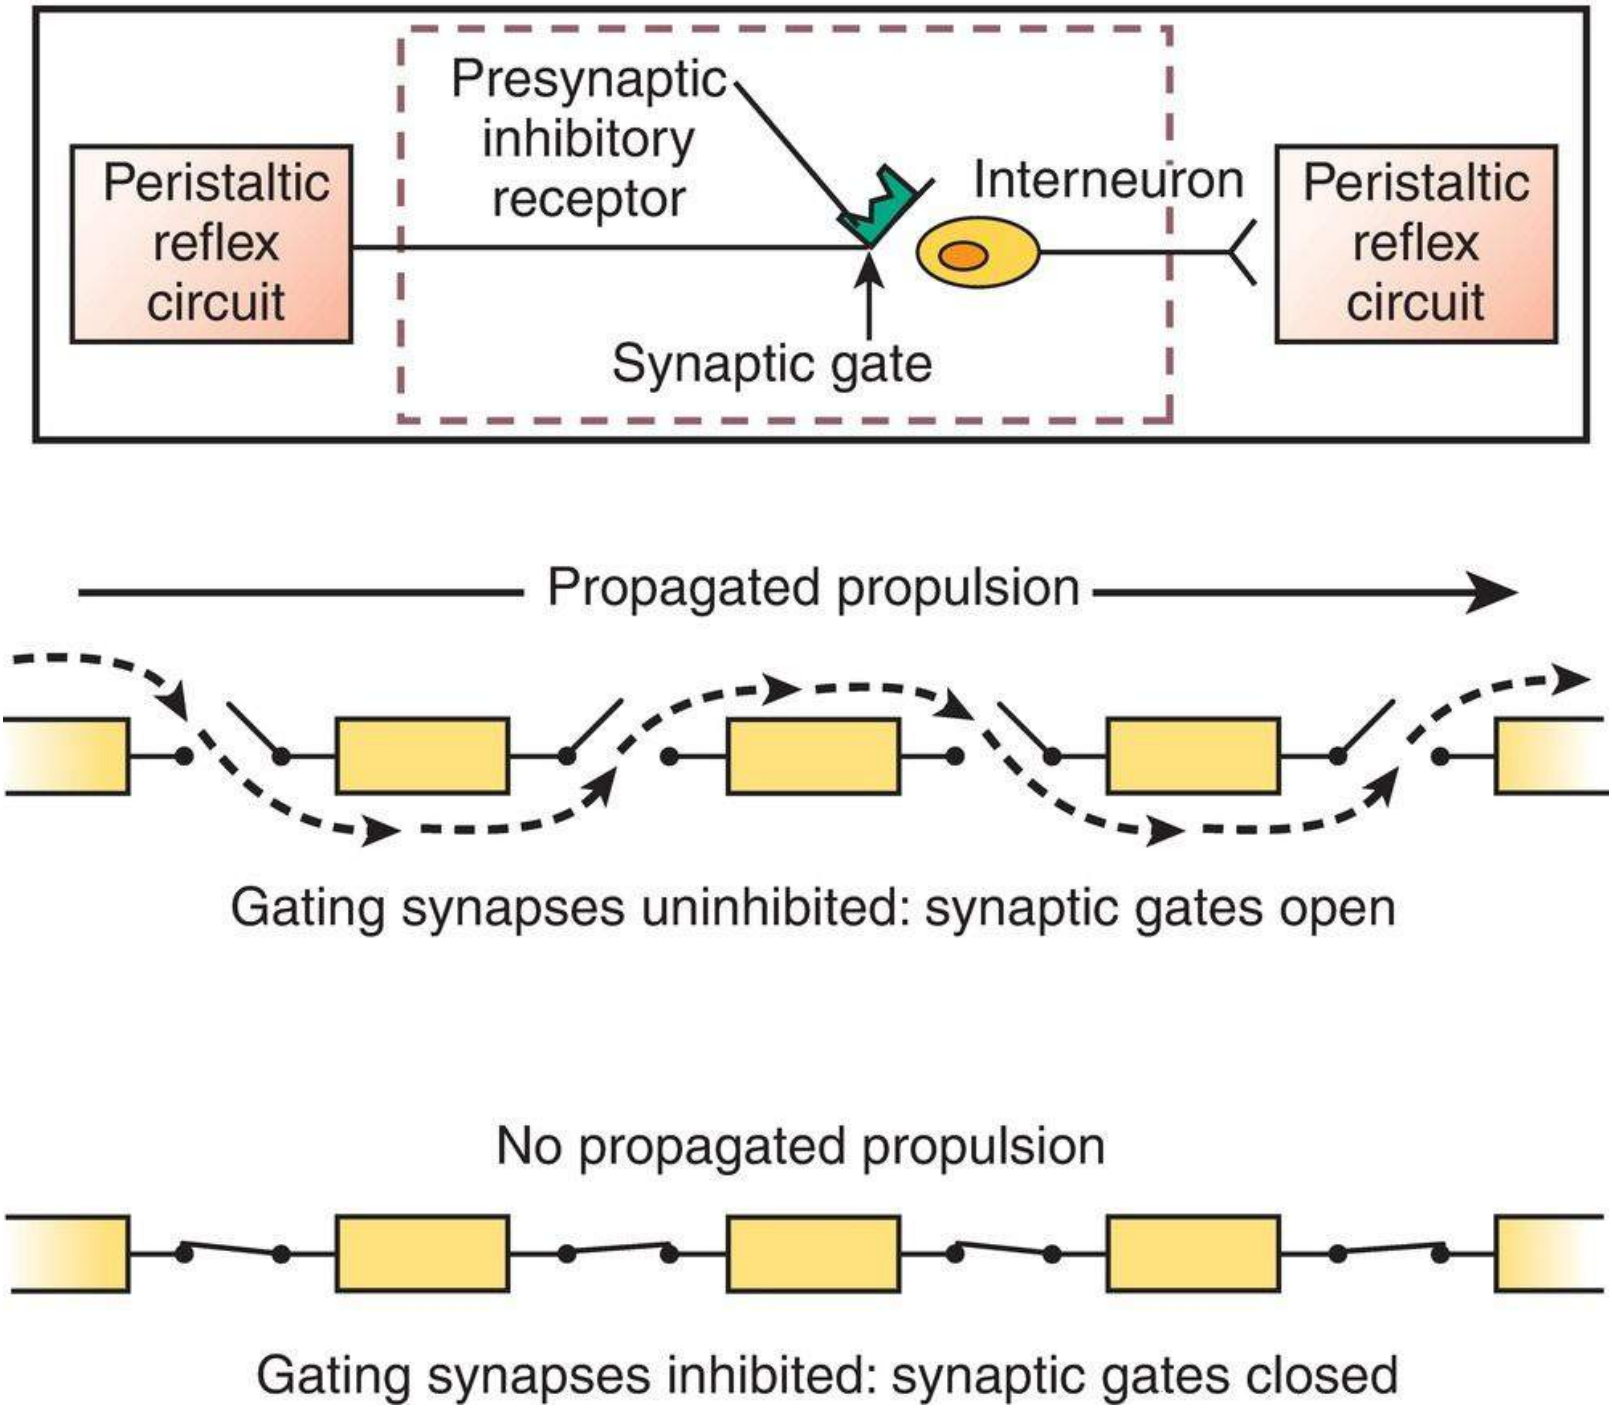

Figure 27.6 Presynaptic inhibitory receptors determine the open and closed states of synaptic gates between blocks of the peristaltic reflex circuit. In the absence of presynaptic inhibition, propagation can proceed in the direction in which the gates are open. Activation of presynaptic inhibitory receptors closes the gates and no propagated propulsion can occur.

Emesis

Vomiting (**emesis**) is the forceful expulsion of the stomach contents out through the mouth and may result from several causes, ranging from gastritis, food poisoning, binge drinking, brain tumors, and brain trauma. Although the terms “vomiting” and “regurgitation” are often used interchangeably, they are different. **Regurgitation** is the return of undigested food back up the esophagus without the forced expulsion associated with vomiting and occurs most commonly in neonates.

Circuits of the ENS are programmed to evoke peristaltic propulsion in either direction along the intestine. If forward passage of the intraluminal contents is impeded in the large intestine, reverse

propulsion propels the bolus over a variable distance away from the obstructed segment. **Retropulsion** then stops and forward propulsion moves the bolus again in the direction of the obstruction. During the act of vomiting, retropulsion occurs in the small intestine. In both cases, the musculature for propulsion is stimulated to contract in the reverse direction.

ESOPHAGEAL AND GASTRIC MOTILITY

The esophagus is divided into three functionally distinct regions: the UES, the esophageal body, and the LES. Esophageal motility involves contraction of striated muscle in the upper esophagus and smooth muscle in the lower third of the esophagus. The esophagus transports ingested solids and liquids downward from the pharynx to the stomach during a swallow and upward during expulsion of gastric contents (i.e., emesis). Swallowing involves voluntary and involuntary muscle contractions. Voluntary muscle contraction in the oral cavity moves the bolus posteriorly and into the pharynx. The swallowing center located in the CNS then initiates involuntary muscle contraction and peristalsis begins. After swallowing, the transit time through the pharynx and esophagus is about 6 to 10 seconds (Clinical Focus 27.1).

CLINICAL FOCUS 27.1

Esophageal Motor Disorders

Dysphagia is defined as difficulty in swallowing. It can result from the failure of mechanisms involving the skeletal muscles of the pharynx, failure of peristalsis in the esophageal body, or failure of the LES to relax. A combination of liquid and solid food dysphagia is a reliable sign of disordered motility in the esophageal body and/or failure of the LES to relax. Dysphagia limited to solid food is most often a symptom of a mechanical obstruction (e.g., malignancies or strictures).

Some dysphagic patients have pressure waves of abnormally high amplitude as peristalsis propagates past the recording ports during diagnostic assessment with manometric catheters. This condition, which is called nutcracker esophagus, is often associated with angina-like chest pain. A manometric diagnosis of nutcracker esophagus is usually made subsequent to confirmation that the patient's chest pain does not reflect blockages in the coronary arteries.

In the absence of chest pain, liquid and solid food dysphagia is likely to be a reflection of LES achalasia. A diagnosis of achalasia is made when manometric recording of esophageal motility fails to show the typical relaxation and reduction of intraluminal pressure in the sphincter coincident with the onset of a swallow (see Fig. 25.24). Successful therapy involves mechanical dilation of the sphincter either by pneumatic inflation of a balloon placed in the sphincter or by passage of a solid bougie dilator. A class of smooth muscle relaxant drugs, known as phosphodiesterase-5 inhibitors (e.g., sildenafil), have been used recently as an alternative treatment for achalasia.

Achalasia, in the majority of cases, reflects the loss of the enteric inhibitory motor innervation of the sphincter. Loss or malfunction of inhibitory motor neurons, which in most cases is an inflammatory ENS neuropathy, is the pathophysiologic starting point for achalasia. Achalasia associated with paraneoplastic syndrome, Chagas disease, and idiopathic ENS degenerative disease are recognizable forms of inflammatory ENS neuropathy. In paraneoplastic syndrome, antigens expressed by a carcinoma (usually small cell carcinoma) in the lung have sufficient similarity to antigenic epitopes expressed by enteric neurons that the immune system simultaneously attacks the tumor and the patient's enteric neurons. Most patients with a diagnosis of achalasia, in combination with small cell lung

carcinoma, have circulating immunoglobulin-G autoantibodies that react with and destroy their enteric neurons. The detection of antienteric neuronal antibodies is a supplemental means to a specific diagnosis of achalasia. The association of enteric neuronal loss and symptoms of achalasia in Chagas disease also reflects autoimmune attack on ENS neurons. *Trypanosoma cruzi*, the blood-borne parasite that causes Chagas disease, has antigenic epitopes similar to enteric neuronal antigens. This antigenic commonality activates the immune system to assault the ENS coincident with its attack on the parasite.

When chest pain is associated with liquid and solid food dysphagia in the absence of nutcracker-like contractions, the problem is most likely a form of failure of peristaltic propulsion, called diffuse esophageal spasm. A diagnosis of diffuse spasm is made when manometric recording of esophageal motility demonstrates that the act of swallowing results in simultaneous contractions all along the length of the smooth muscle region of the esophageal body. A barium study in patients with diffuse spasm shows the morphometric correlate of diffuse spasm to be a contorted esophageal body, which has been described as a "corkscrew esophagus." Diffuse spasm and LES achalasia are often seen as concurrent pathophysiologies, both of which probably reflect a disorder of enteric inhibitory motor neurons. There are no fully satisfactory treatments for diffuse spasm other than attempts to treat with smooth muscle relaxant drugs. ■

Esophageal peristalsis occurs as either a primary or secondary event. **Primary peristalsis** is initiated by the act of swallowing. **Secondary peristalsis** is a subconscious process that is triggered by distention associated with failed downward transport (i.e., food lodging in the esophagus) or by the presence of acid due to gastric reflux. Secondary peristalsis accompanied by the stimulation of salivary secretion is the normal mechanism for "dislodging" the bolus as well as removing acid irritation.

When not involved in swallowing, the muscles of the esophageal body are relaxed and the LES is tonically contracted. In contrast to the intestine, the relaxed state of the esophageal body is not the result of inhibitory motor neuron activity. Rather, the excitability of the muscle is low, and there are no **electrical slow waves** (**ESWs**) to trigger contractions (Fig. 27.7). Activation of excitatory motor neurons, rather than myogenic mechanisms, accounts for the coordinated contractions of the circular and longitudinal muscles during peristaltic propulsion.

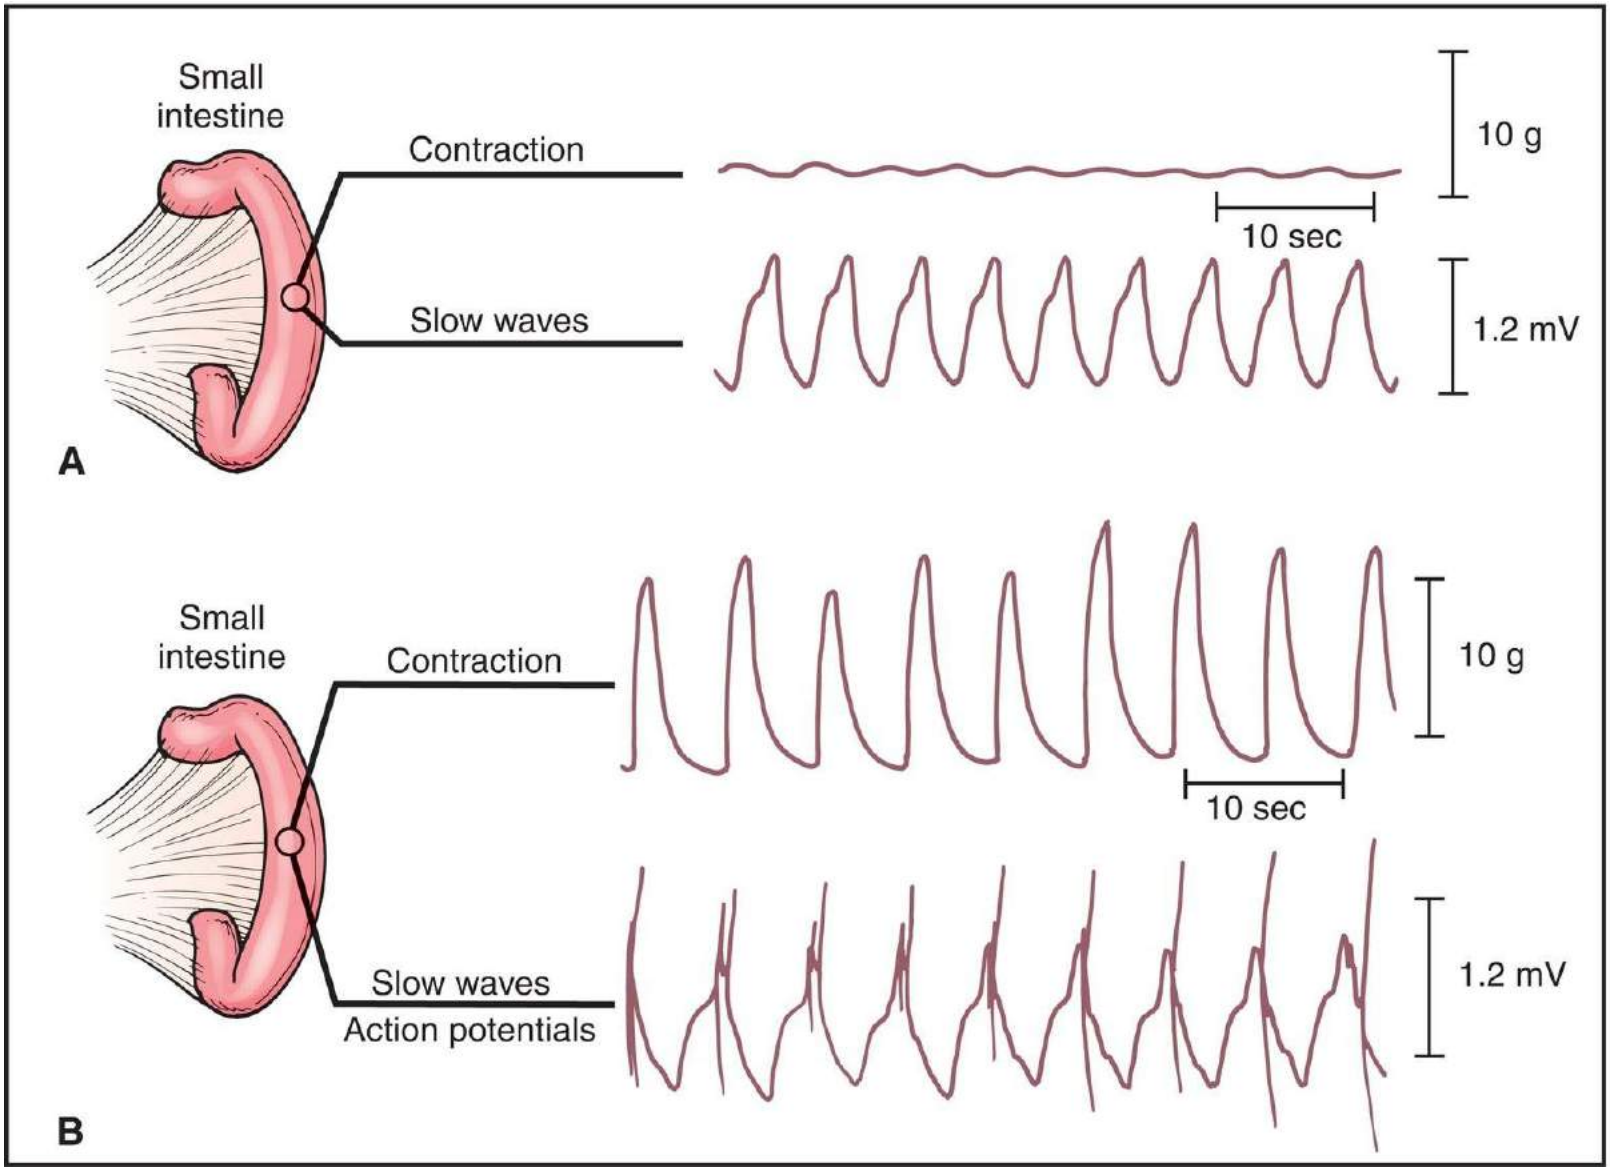

Figure 27.7 Electrical slow waves trigger action potentials and action potentials trigger contractions. Electrical slow waves are always present in the small intestine. However, action potentials are not always associated with a slow wave. **(A)** No action potentials appear at the crests of the slow waves, and the muscle contractions associated with each slow wave are small. **(B)** Muscle action potentials appear as sharp upward–downward deflections at the crests of the slow waves. Large-amplitude muscle contractions are associated with each slow wave when action potentials are present.

Gastric motility is involved in both the filling and emptying of the stomach.

The functions of the stomach include (1) being a reservoir for the storage of ingested food, (2) mixing of food with digestive juices forming chyme, (3) grinding of larger food particles into smaller ones, and (4) emptying. The stomach itself is anatomically divided into four sections, (1) **cardia**, (2) **fundus**, (3) **corpus** (body), and (4) **pylorus** (Fig. 27.8). Each section has different cells and functions. The *cardia* is where the esophageal contents enter the stomach. The *fundus* forms the upper curvature and the *corpus* forms the main or central region of the stomach. The *pylorus* is the lower section of the stomach that facilitates gastric emptying and the passage of chyme into the duodenum of the small intestine.

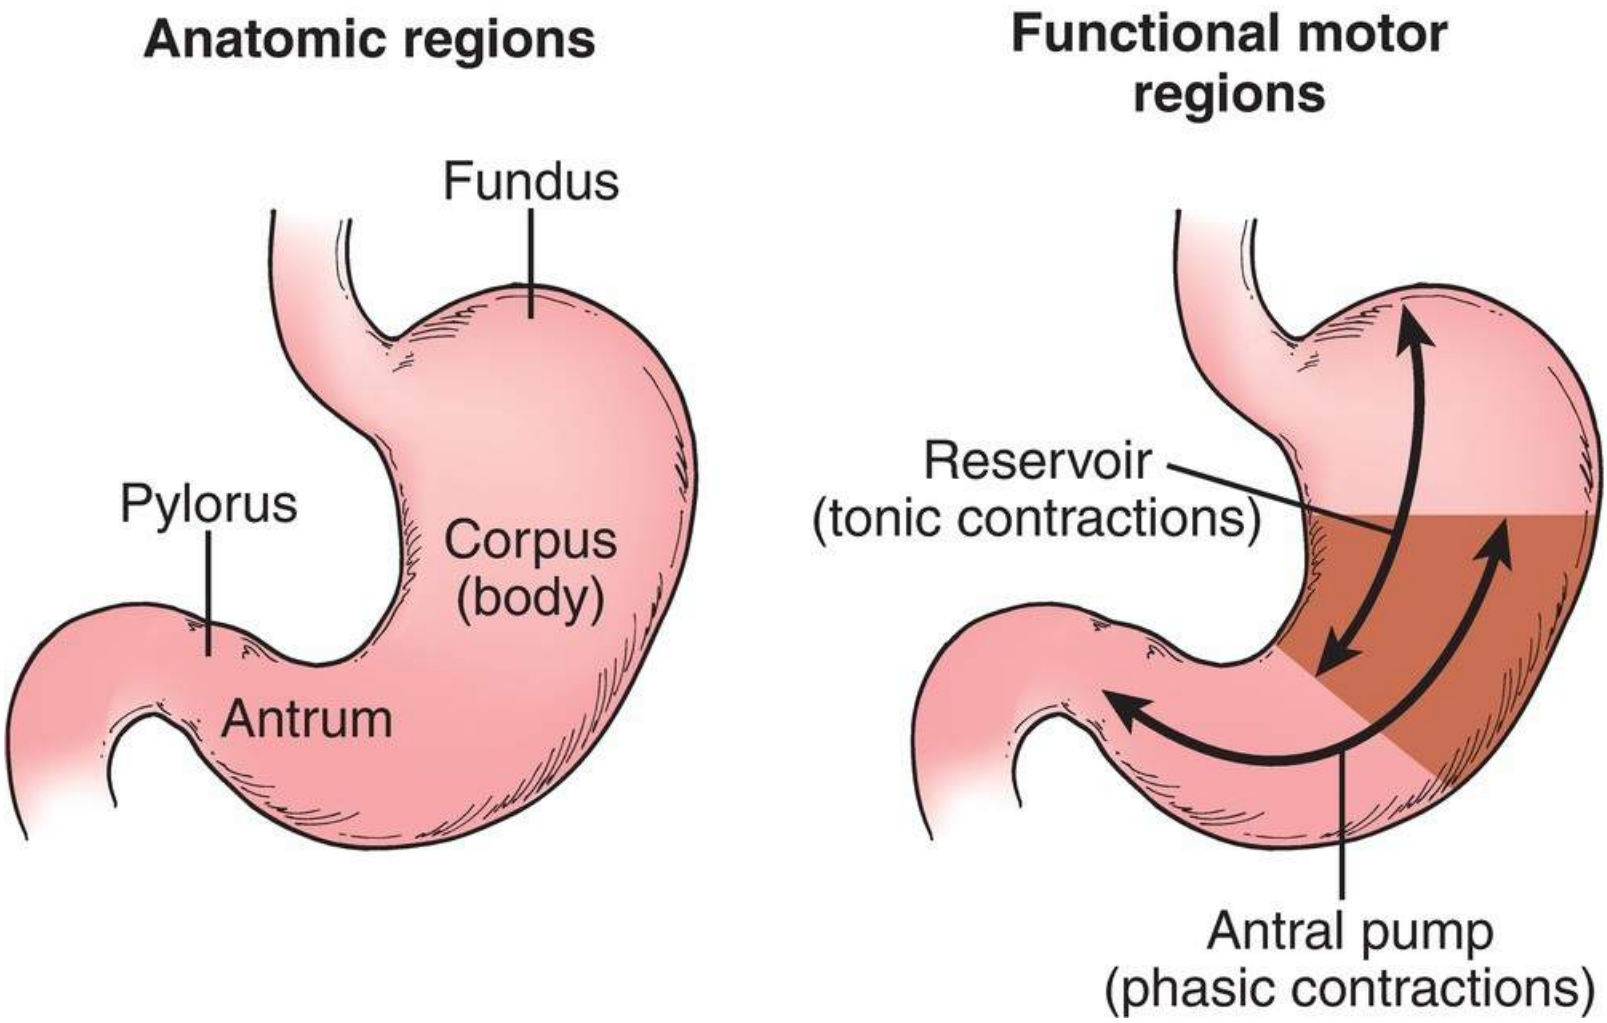

Figure 27.8 The stomach is divided into three anatomical and two functional regions. The gastric reservoir is specialized for receiving and storing a meal. The musculature in the region of the antral pump exhibits phasic contractions that function in the mixing and trituration of the gastric contents. No distinctly identifiable boundary exists between the reservoir and the antral pump.

The stomach is divided functionally into two regions based upon their distinct differences in motility. The proximal **gastric reservoir** consists of the fundus and approximately one third of the corpus. The distal **antral pump** consists of the caudal two thirds of the corpus, the antrum, and the pylorus (see Fig. 27.8).

As food enters the esophagus, the stomach muscles are stimulated to relax, **receptive relaxation**, allowing the stomach to accommodate a change in volume. Muscles in the gastric reservoir maintain a state of tonic contraction and do not contract phasically as does the smooth muscle of the antrum (Fig. 27.9). The transition from tonic to phasic contraction occurs in the body of the stomach. The spread of phasic contractions in the region of the antral pump propels the gastric contents toward the gastroduodenal junction. Strong propulsive waves do not occur in the proximal stomach.

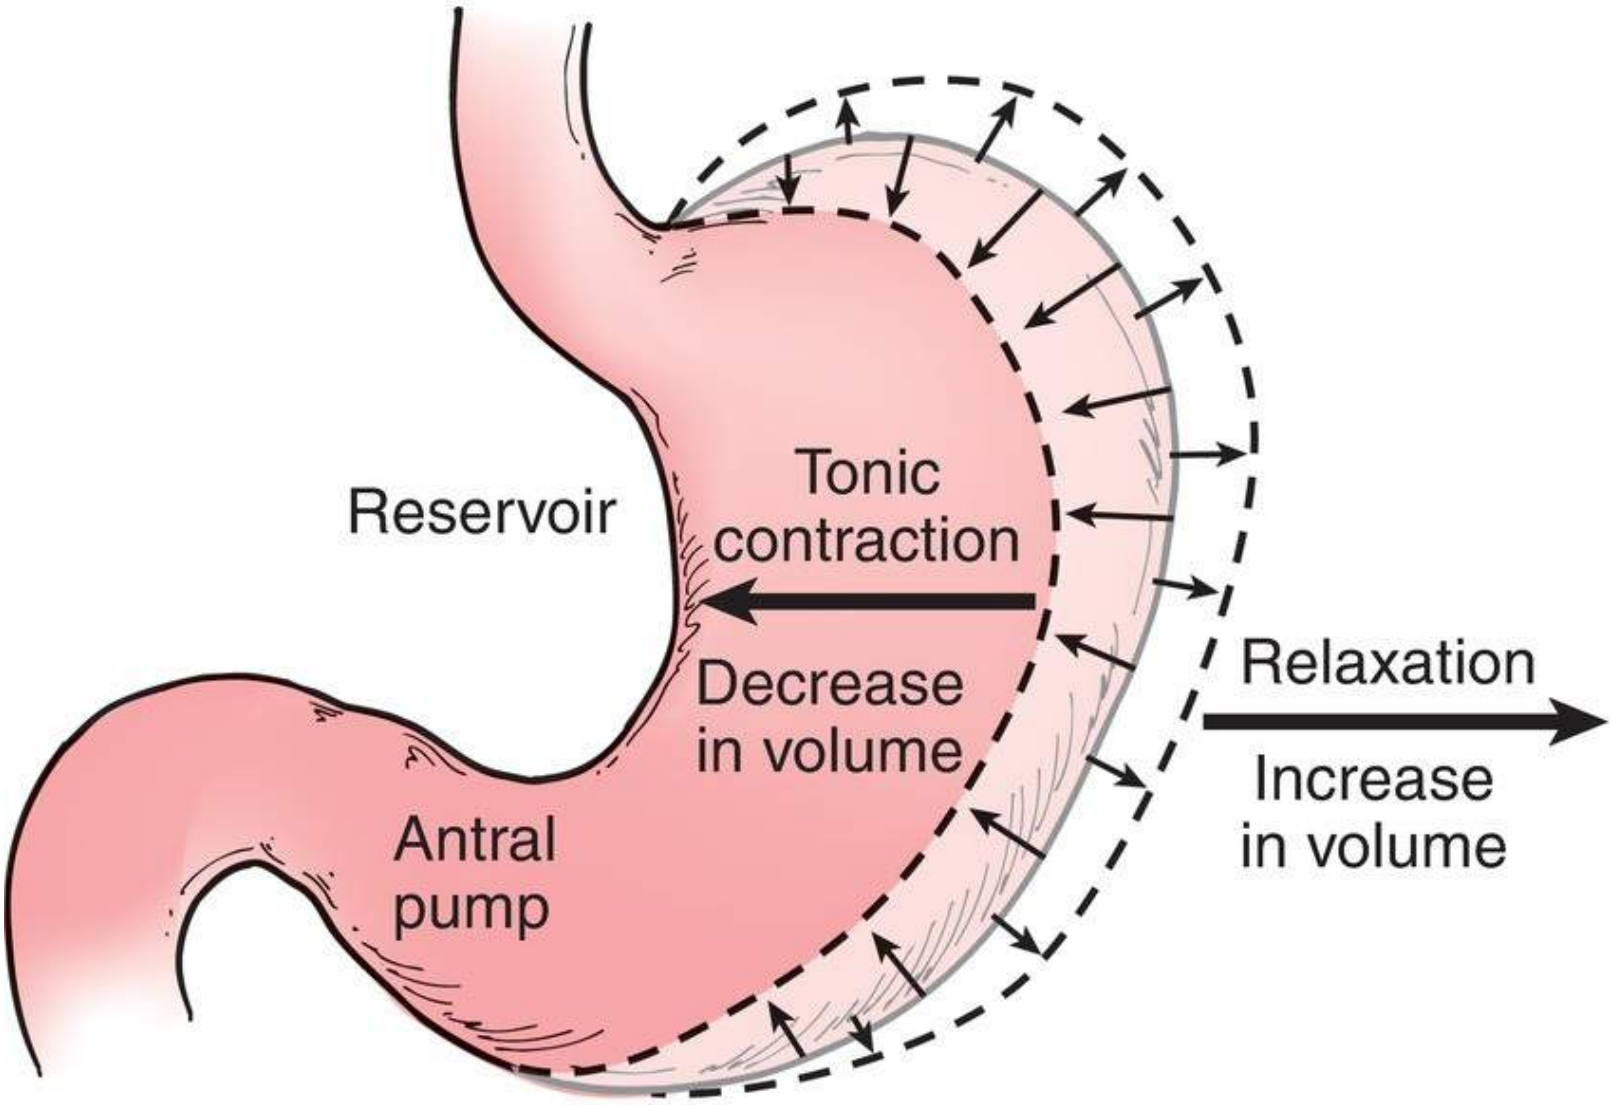

Figure 27.9 Tonic contraction of the musculature of the gastric reservoir decreases the volume and exerts compressive force on the contents. Tonic relaxation of the musculature expands the volume of the gastric reservoir. Neural mechanisms of feedback control determine intramural contractile tone in the reservoir (see Fig. 27.29).

Differences in motility between the reservoir and antral pump reflect adaptations for different functions and different states of satiation (i.e., fasting and after eating). Gastric muscle contractions during the fasting state are known as the **migrating motor complex** or **migrating myoelectric complex** (**MMC**) as opposed to that occurs during the digestive phase that follows food intake.

Rate of gastric emptying is determined primarily by the stomach's volume.

Together with storage in the reservoir and mixing and grinding by the antral pump, another important function of gastric motility is the delivery of gastric chyme to the duodenum at a rate that does not overload the digestive and absorptive functions of the small intestine (Clinical Focus 27.2). Neural control mechanisms adjust the rate of gastric emptying to compensate for variations in the volume, composition, and physical state of the gastric contents.

CLINICAL FOCUS 27.2

Disorders of Gastric Motility

Patients with disordered gastric motility fall either into the category of delayed gastric emptying or into a category in which emptying is too rapid. The symptoms associated with accelerated gastric emptying and delayed emptying overlap.

Delayed Gastric Emptying (Gastric Retention)

Delayed gastric emptying occurs in 20% to 30% of patients with diabetes mellitus and is related to vagal neuropathy as part of a spectrum of diabetic autonomic neuropathy. Conduction in vagal afferent and efferent nerve fibers is impaired in diabetic neuropathy. This compromises the vagovagal reflexes, which underlie receptive, adaptive, and feedback relaxation of the gastric reservoir, during intake of a meal (see Figs. 25.28 and 25.29). Vagal nerves are sometimes damaged during laparoscopic surgery for repair of a hiatal hernia or fundoplication as a treatment for GERD. Iatrogenic vagotomy results in a rapid emptying of liquids and a delayed emptying of solids. Truncal vagotomy impairs adaptive relaxation and results in increased contractile tone in the gastric reservoir (see Fig. 25.29). Elevated contractile tone increases pressure in the gastric reservoir, which ejects liquids more forcefully through the antral pump into the duodenum.

Paralysis with a loss of propulsive motility and, consequently, the trituration of solids by the antral pump occur in diabetic autonomic neuropathy and after a vagotomy. The result is **gastroparesis**, which can account for the delayed emptying of solids after a vagotomy.

Delayed gastric emptying with no demonstrable underlying condition is common. Up to 80% of patients with anorexia nervosa have delayed gastric emptying of solids. Another such condition is idiopathic gastric stasis, in which no evidence of an underlying condition can be found. These kinds of disorders for which no physiologic or biochemical explanation for the patient's symptoms can be found are called **functional gastrointestinal motility disorders.** Motility-stimulating drugs (e.g., cisapride, erythromycin, or domperidone) are used successfully in treating patients for both diabetic gastroparesis and the idiopathic form of gastroparesis.

In children, hypertrophic pyloric stenosis impedes gastric emptying. This is a thickening of the muscles of the pyloric canal, which is associated with a loss of the ENS including inhibitory motor

neurons to the musculature. The absence of inhibitory motor neurons and achalasia of the circular muscle in the pyloric canal are factors that account for the obstructive stenosis.

Rapid Gastric Emptying

Resection of the distal stomach might be done as a treatment for cancer or peptic ulcer disease. Surgical pyloroplasty used to be done together with vagotomy for the treatment of peptic ulcer disease and might still be done at times in patients with idiopathic gastroparesis. Both resection and pyloroplasty compromise mixing and renders the stomach incontinent for solids. Premature and rapid gastric emptying ("dumping") of solids and liquids into the duodenum in these cases causes hyperglycemia. Vagotomy, done at the same time as pyloroplasty, impairs receptive relaxation and accommodation in the gastric reservoir and exacerbates the dumping symptoms of anxiety, sweating, strong hunger, dizziness, weakness, and palpitations. The **dumping syndrome** is managed by restricting the patient to small meals of complex carbohydrates ingested together with small volumes of liquids. ■

The volume of liquid in the stomach is a major determinant of gastric emptying, but the osmolality, acidity, and caloric content of the gastric chyme are also important. The rate of emptying of isotonic, noncaloric liquids (e.g., 0.9% NaCl) is proportional to the initial volume in the reservoir: the larger the initial volume, the more rapid the emptying. Isotonic liquids empty faster than hypotonic and hypertonic liquids. The rate of gastric emptying decreases as the acidity of the gastric contents increases. Meals with a low caloric content empty faster than those with a high caloric content. The neurophysiologic control mechanisms for gastric emptying keep the caloric delivery rate to the small intestine within a narrow range, regardless of the source (i.e., carbohydrate, protein, fat, or a mixed meal). Fat is emptied at the slowest rate and is the most potent inhibitor of gastric emptying. This inhibition involves the enteroendocrine release of **cholecystokinin** in the upper small intestine.

With a meal of mixed composition, liquids empty faster than solids (Fig. 27.10). For digestible particles a **lag phase** is required for the grinding action of the antral pump to reduce the particle size to a sufficiently small size for emptying. However, not all particles are released from the stomach at the same time and the smaller particles are selectively released first (**sieving action** of the stomach). Sieving occurs in the antral region. Eventually, the retained larger particles (generally >7 mm) empty at the start of the first MMC as the digestive tract converts motility from the digestive state to the interdigestive state.

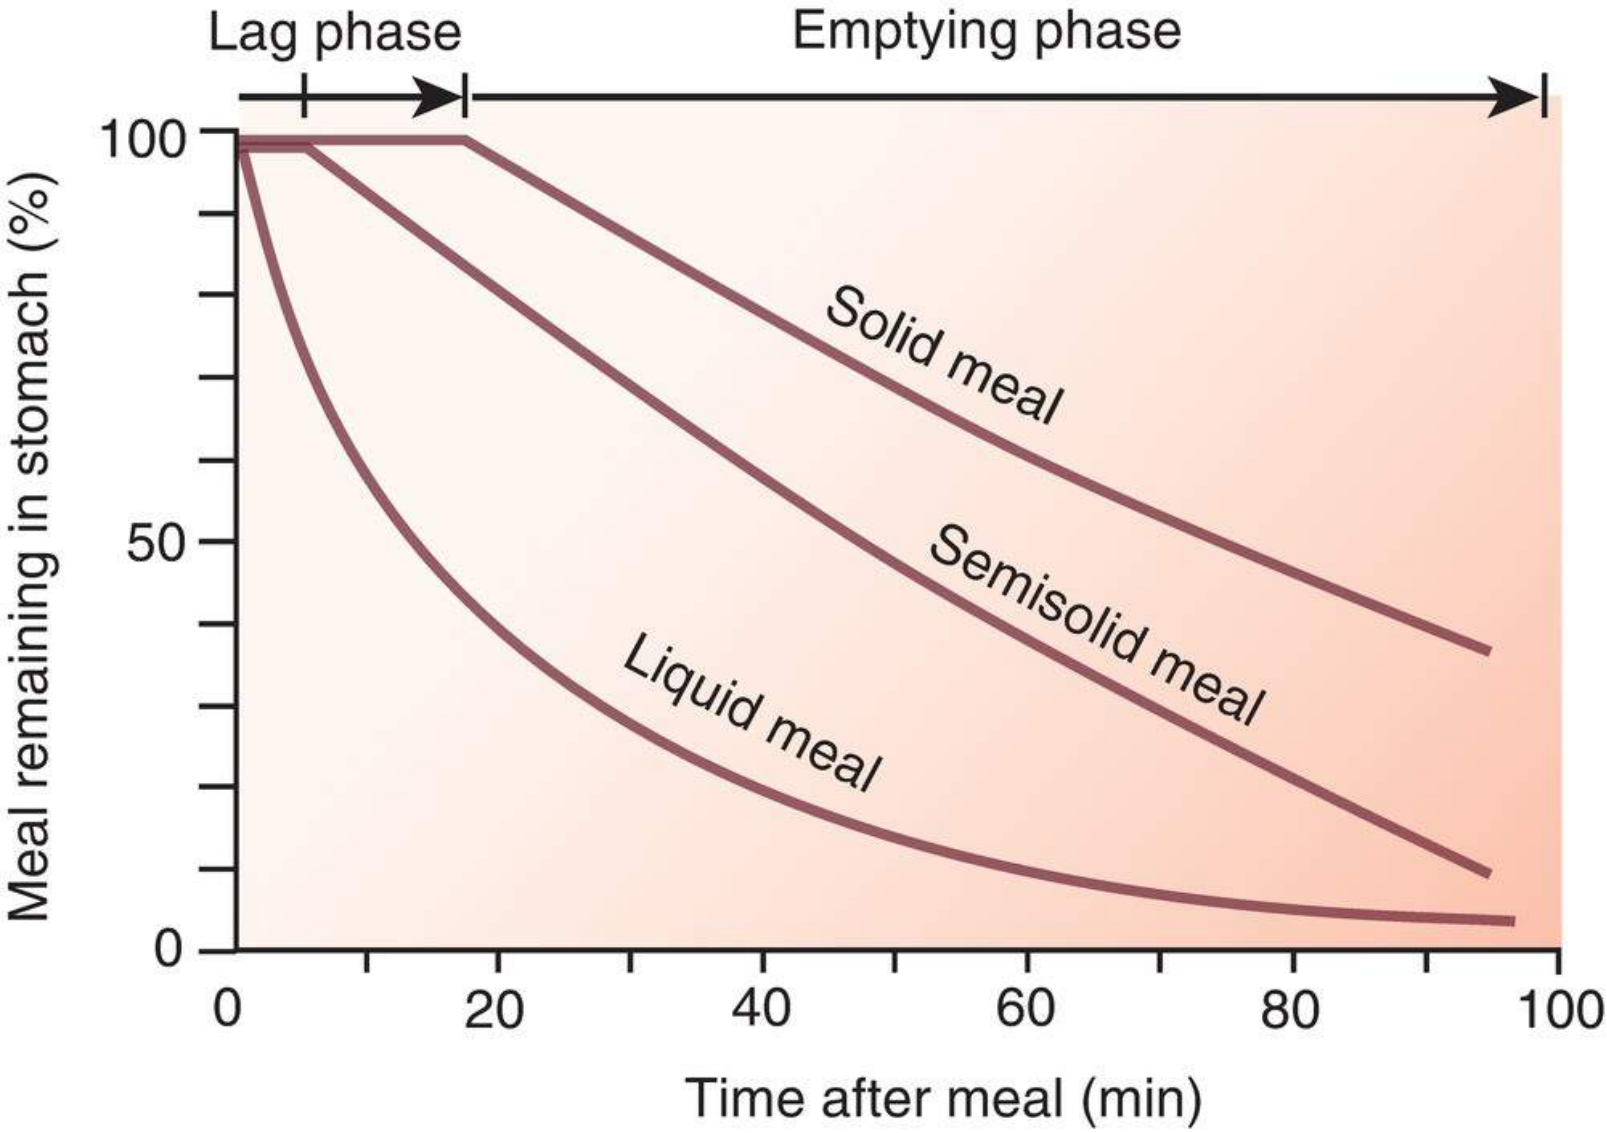

Figure 27.10 The rate of gastric emptying varies with the composition of the meal. Solid meals empty more slowly than semisolid or liquid meals. The emptying of a solid or semisolid meal is preceded by a lag phase, which is the time required for particles to be reduced to a sufficiently small size for emptying.

SMALL INTESTINAL MOTILITY

The small intestine is divided into three functional regions (i.e., duodenum, jejunum, and ileum) and is the site where most food is enzymatically digested and absorbed. Contractions of the duodenum and hormonal signals arising from there significantly influence gastric emptying. Transit of material through the small intestine is influenced by three fundamental patterns of motility: (1) the **interdigestive pattern**, (2) the **digestive pattern**, and (3) **power propulsion**. Motility is one of the gut behaviors controlled by the ENS (see Fig. 27.3).

Gastric contents entering the upper GI tract stimulate the enteric nervous system.

Signals transmitted by vagal efferent nerves to the ENS interrupt the MMC and initiate the mixing pattern of motility during ingestion of a meal. The mixing movements are sometimes called segmenting movements or segmentation. The segmentation appearance is the result of peristaltic contractions, which propagate for only short distances and occur simultaneously at multiple sites along the bowel. Receiving segments with an expanded lumen separate circular muscle contractions that form short propulsive segments on either end of the receiving segment (Fig. 27.11). Each propulsive segment jets the contents in both directions into the opened receiving segments, where stirring and mixing occur. This happens continuously at closely spaced sites along the entire length of the small intestine.

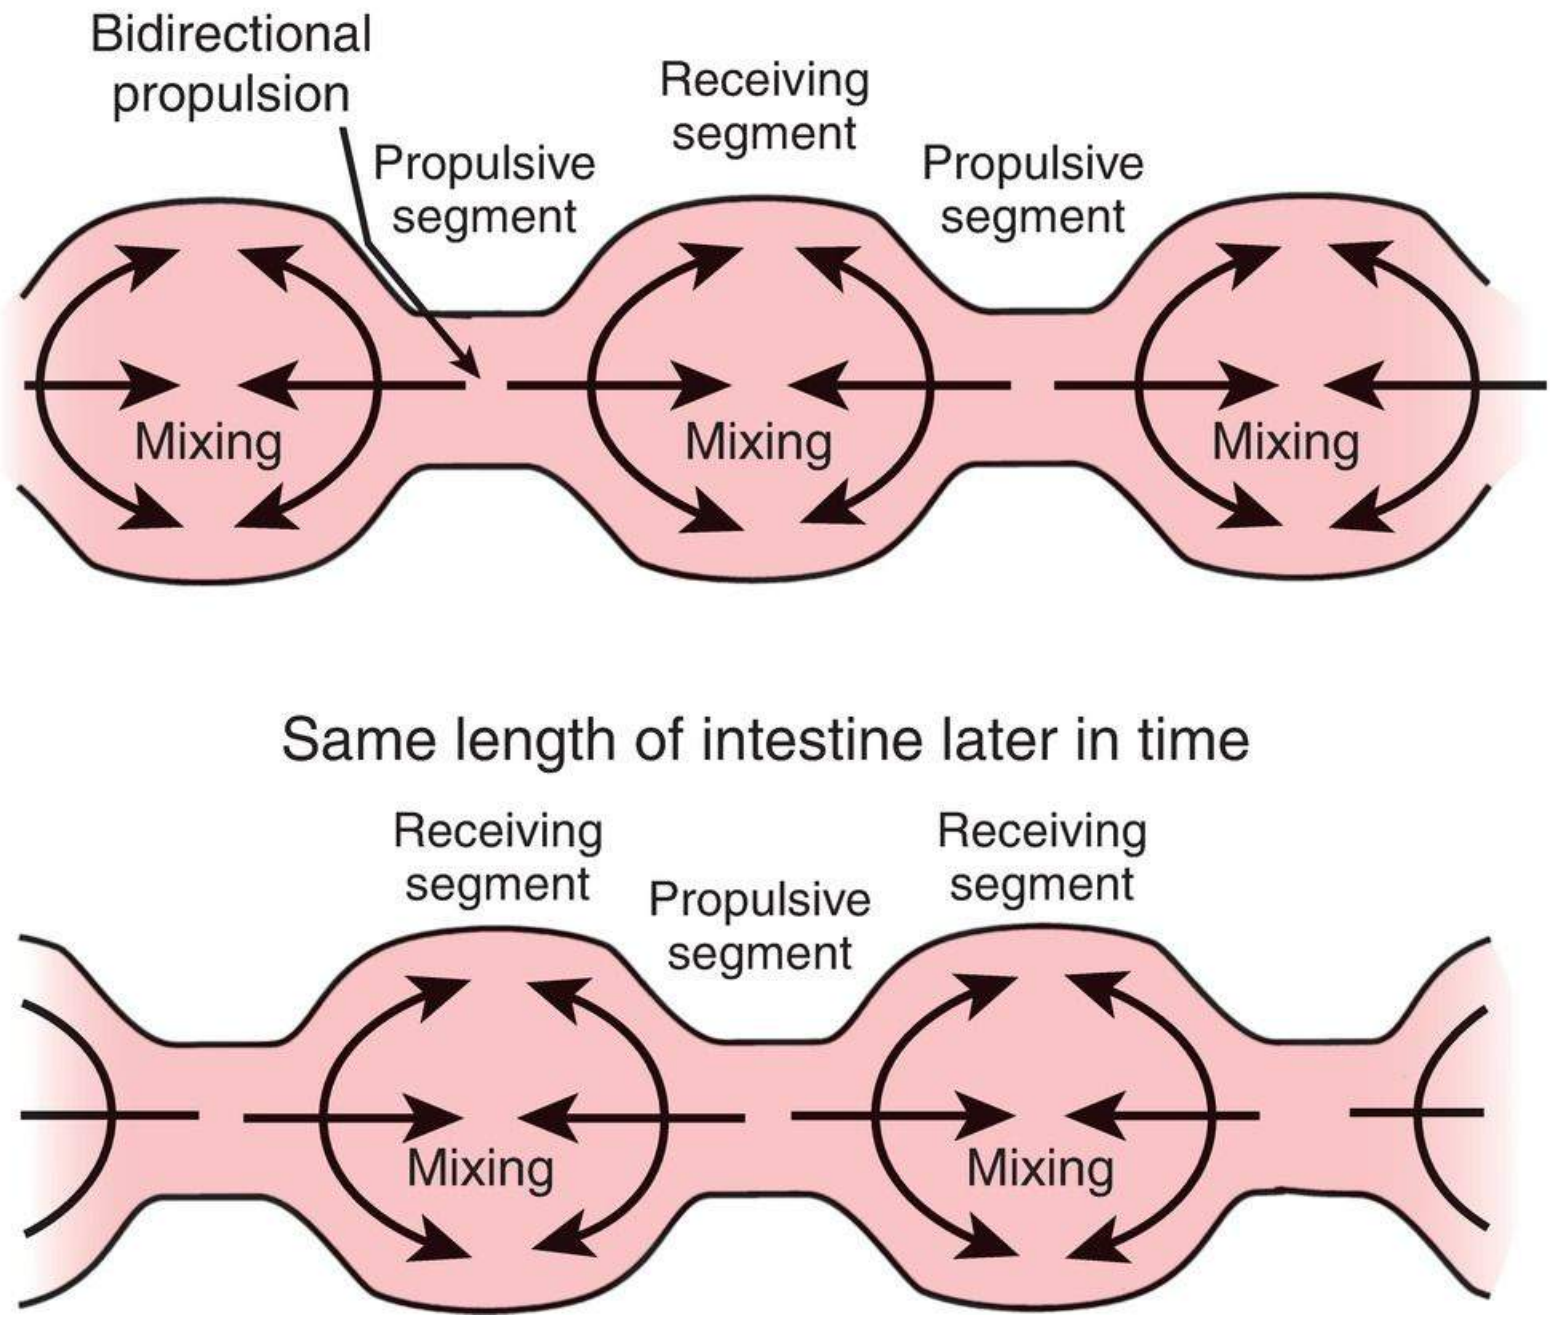

Figure 27.11 The mixing pattern of small intestinal motility is characteristic of the digestive state. Propulsive segments separated by receiving segments occur randomly at multiple sites along the small

intestine. Mixing of the luminal contents occurs in the receiving segments. Receiving segments convert to propulsive segments, whereas propulsive segments become receiving segments.

LARGE INTESTINAL MOTILITY

The large intestine consists of the cecum and the colon. It is divided into functionally distinct compartments, which correspond approximately to the ascending colon, transverse colon, descending colon, rectosigmoid region, and IAS (Fig. 27.12). Digestion of food no longer occurs in the large intestine, but absorption of H_2O, minerals, and vitamins and fecal compaction do occur. Contractile activity occurs continuously in the normally functioning large intestine. Whereas the contents of the small intestine move through sequentially with no mixing of individual meals, the large bowel contains a mixture of the remnants of several meals ingested over 3 to 4 days. The arrival of undigested residue from the ileum does not predict the time of its elimination. Normal transit time through the large intestine is about 36 to 48 hours.

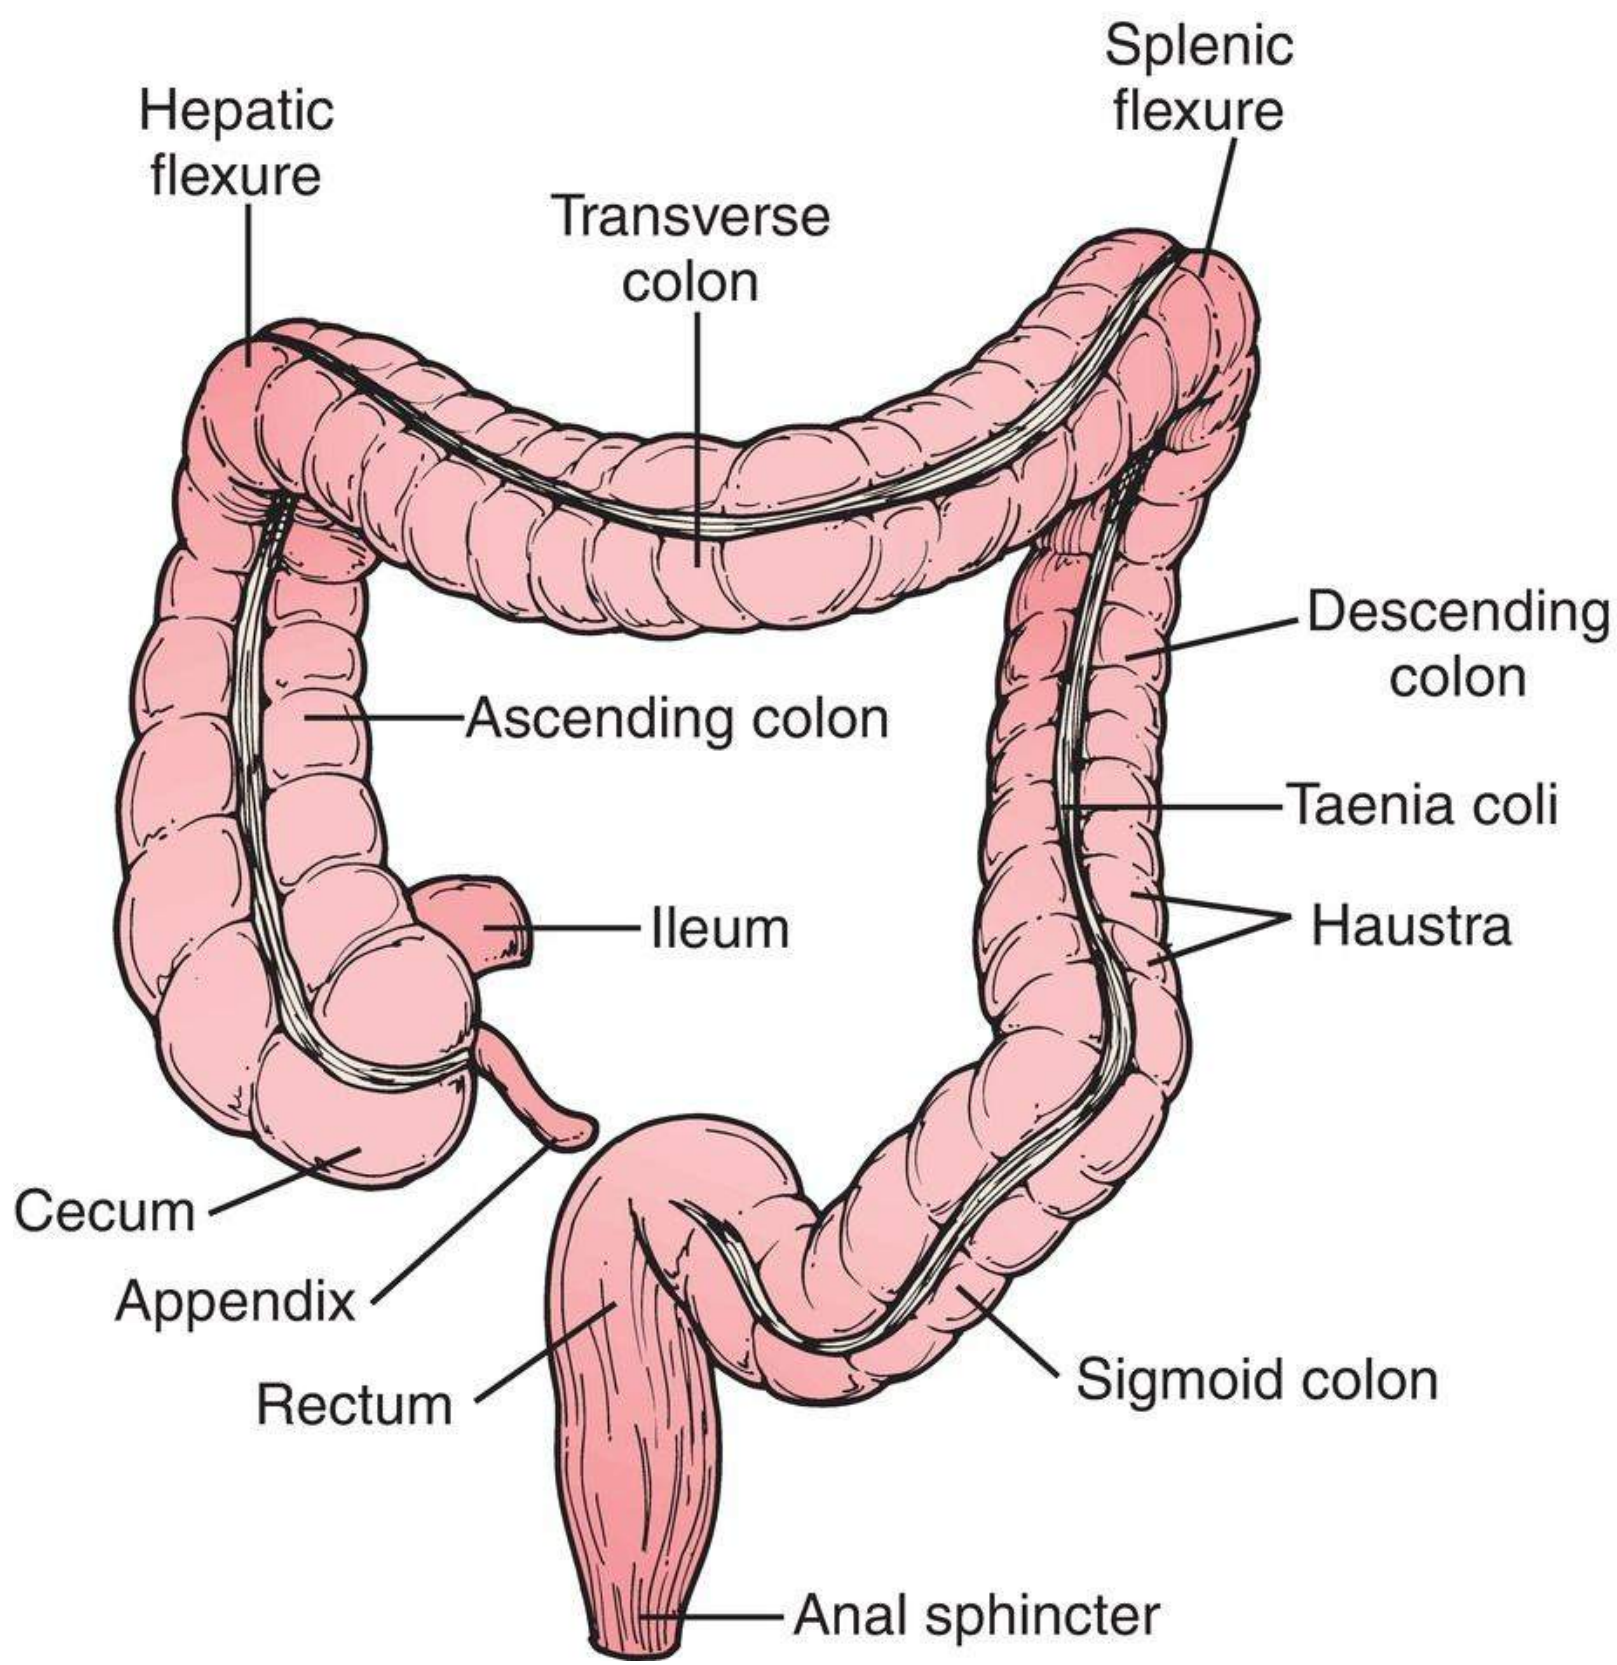

Figure 27.12 The main anatomical regions of the large intestine are the ascending, transverse, descending, and sigmoid colon and the rectum. The hepatic flexure is the boundary between ascending and transverse colon; the splenic flexure between transverse and descending colon. The sigmoid colon is well defined by its shape. The rectum is the most distal region. The cecum is the blind ending of the colon at the ileocecal junction. The appendix is an evolutionary vestige. Internal and external anal sphincters close the terminus of the large intestine. The longitudinal smooth muscle layer in humans is restricted to bundles of fibers called *taeniae coli*.

Power propulsion is unique to the large intestine.

Between meals the colon is generally quiescent. However, following a meal, motility significantly increases due to ENS electrical activity. In humans, the primary stimulus is the presence of fat from the small intestine. Distention of the colon can also act as a strong stimulus.

Power propulsion is controlled by the ENS. Power propulsion occurs in the transverse and descending colon and fits the general pattern of neurally coordinated peristaltic propulsion. It accomplishes the mass movement of feces over long distances. Increased delivery of ileal contents into the ascending colon, as occurs following a meal, often triggers mass movements into the colon. The increased incidence of mass movements and generalized increase in segmental movements following a meal is called the **gastrocolic reflex**. Power propulsion can be initiated by irritant laxatives (e.g., castor oil and senna) and threatening agents, which might be present in the colonic lumen (e.g., parasites, enterotoxins, and food allergens).

Power propulsion in the healthy bowel usually starts in the middle of the transverse colon and is preceded by relaxation of the circular muscle and the downstream disappearance of haustral contractions. An extended length (e.g., 300 cm) of the colon might be emptied as the contents are propelled as far as the rectosigmoid region at rates up to 5 cm/min. Haustration returns after the power contractions pass.

Ascending colon receives intestinal content from the terminal ileum.

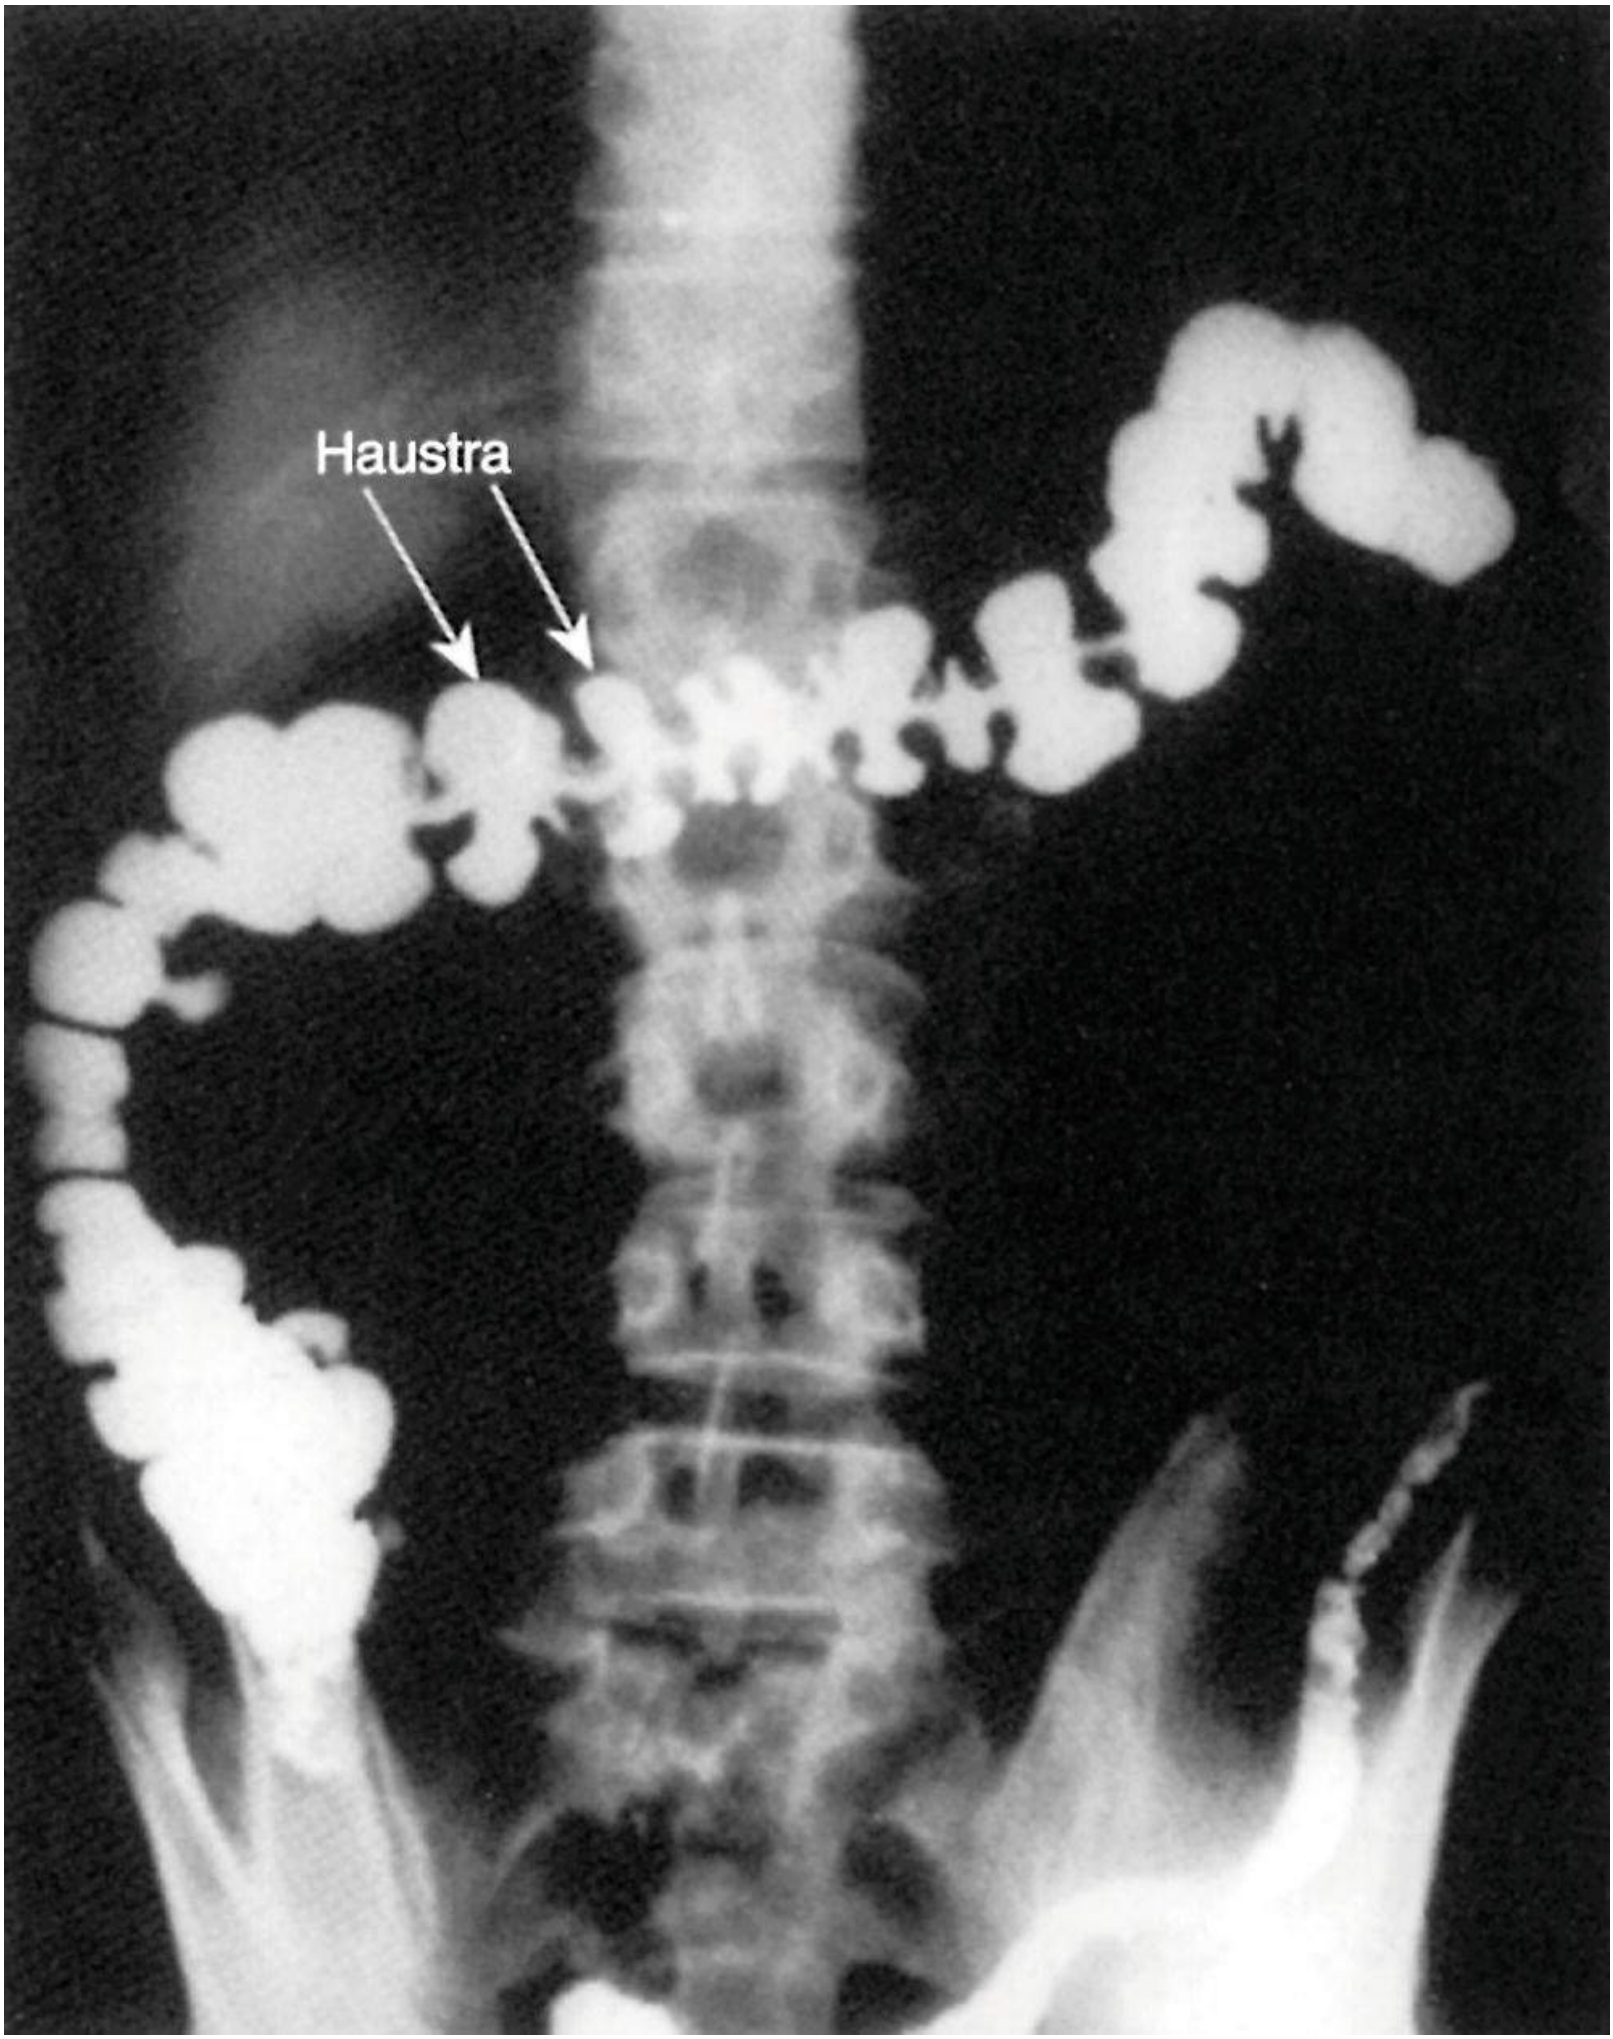
Chemoreceptors and mechanoreceptors in the cecum and ascending colon provide feedback for controlled delivery of the ileum contents into the ascending colon, analogous to gastric emptying into the small intestine. Neuromuscular mechanisms, analogous to adaptive relaxation in the gastric reservoir, permit filling of the ascending colon to occur without large increases in intraluminal pressure.

Dwell time in the ascending colon is long when compared to the small intestine but short when compared to the transverse colon. This suggests that the ascending colon is not the primary site for the storage, mixing, and removal of H_2O from the feces.

The ENS-generated motor patterns of the ascending colon consist of peristaltic propulsion that travels at certain times in the orthograde direction and at others in the retrograde direction. The significance of retrograde propulsion in this region is uncertain; it may be a mechanism for temporary retention of the contents in the ascending colon. Forward propulsion is probably controlled by feedback signals related to the fullness of the transverse colon.

Motility of the transverse colon is specialized for storage and removal of water from the feces.

The contents of the transverse colon are retained for about 24 hours, suggesting that this is the primary location for the removal of H_2O and electrolytes and the storage of solid feces. The ENS-driven segmental pattern of motility is responsible for the ultraslow forward movement and compaction of feces in the transverse colon. In this pattern, ringlike contractions of the circular muscle divide the colon into pockets called **haustra** (Fig. 27.13). **Haustration** is reminiscent of the mixing (segmentation) movements in the small intestine (see Fig. 27.11). Haustral formation differs from small intestinal segmentation in that the contracting and receiving segments on either side remain in their respective states for extended periods of time.



Haustra

Figure 27.13 X-ray shows haustral contractions in the ascending and transverse colon. Between the haustral pockets are segments of contracted circular muscle. Ongoing activity of inhibitory motor neurons maintains the relaxed state of the circular muscle in the pockets. Inactivity of inhibitory motor neurons permits the contractions between the pockets.

Haustrations are dynamic in that they form and reform at different sites. The most common fasting pattern is for the contracting segment to propel the contents in both directions into receiving segments (i.e., haustra). This mechanism mixes and compresses the semiliquid feces in the haustral pockets and probably facilitates the absorption of H_2O without any net forward propulsion as happens when sequential migration of the haustra occurs along the length of the bowel.

Power propulsion in the descending colon is responsible for mass movements of feces into the sigmoid colon and rectum.

The descending colon is a conduit from transverse to sigmoid colon and feces are not retained for very long. Luminal contents begin to accumulate in the sigmoid colon and rectum about 24 hours after entering the cecum. This suggests that the transverse colon is the main fecal storage reservoir, whereas the descending colon serves as a conduit without long-term fecal retention. Power propulsion in the descending colon drives mass movements of feces into the sigmoid colon and rectum.

Rectosigmoid, anal canal, and pelvic floor musculature preserve fecal continence.

The sigmoid colon and rectum are reservoirs with a capacity of up to 500 mL. Distensibility in this region is an adaptation for temporarily accommodating the mass movements of feces downstream. The rectum begins at the level of the third sacral vertebra and follows the curvature of the sacrum and coccyx for its entire length. It connects to the anal canal, which is surrounded by the IAS and EAS. Overlapping sheets of striated muscle called the **levator ani** form the pelvic floor. This muscle group, which includes the **puborectalis** and the EAS, is a functional unit that maintains fecal continence. These skeletal muscles behave in many respects like the somatic muscles that maintain body posture (see Chapter 5).

The pelvic floor musculature can be imagined as an inverted funnel consisting of the levator ani and EAS muscles in a continuous sheet from the bottom margins of the pelvis to the anal verge, which is the transition zone between mucosal epithelium and stratified squamous epithelium of the skin. The pelvic floor descends during defecation. When defecation is complete, the levator ani contracts to restore the perineum to its normal position. Fibers of the puborectalis muscle join behind the anorectum and pass around it on both sides to insert on the pubis. This forms a U-shaped sling that pulls the anorectal tube anteriorly such that the long axis of the anal canal lies at nearly a right angle to the rectum (Fig. 27.14). Tonic contraction of the puborectalis narrows the anorectal tube from side to side at the bend of the angle, resulting in a physiologic valve that is important in preventing leakage of feces and flatus.

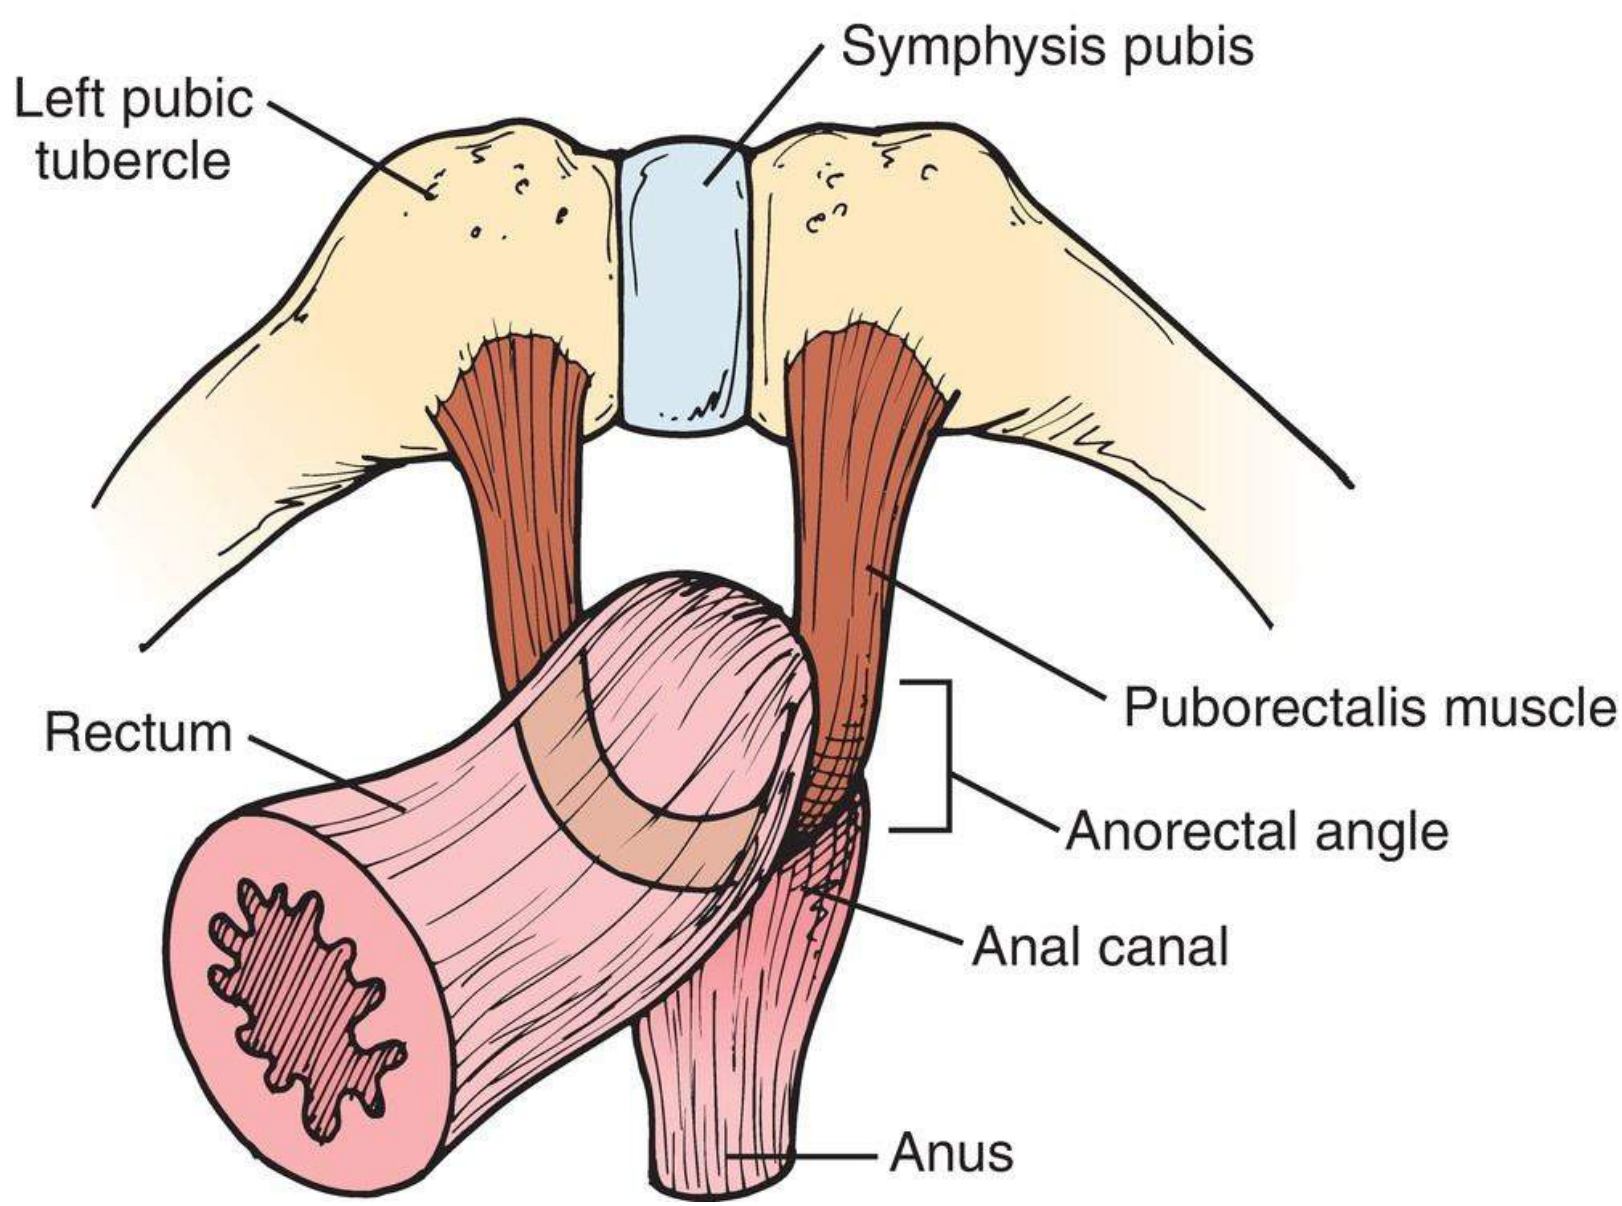


Figure 27.14 The puborectalis muscle contributes to the maintenance of fecal continence. One end of the puborectalis muscle inserts on the left pubic tubercle and the other on the right pubic tubercle, forming a loop around the junction of the rectum and anal canal. Thereby, contraction of the puborectalis muscle forms the anorectal angle, which blocks passage of feces.

The puborectalis sling and the upper margins of the IAS and EAS form the anorectal ring, marking the boundary of the anal canal and rectum. When contracted, the EAS compresses the anus into a slit, thereby closing the orifice. The IAS contracts tonically to sustain closure of the anal canal.

Anal canal is innervated by somatosensory nerves.

Mechanoreceptors in the rectum detect distention and supply the ENS with the sensory information needed for feedback control of this region. Unlike the rectum, the anal canal in the region of skin at the anal verge is innervated by somatosensory nerves that transmit signals to the spinal cord and onto higher processing centers in the brain. This region has sensory receptors that detect and transmit information on touch, pain, and temperature with high sensitivity. Processing of information from these receptors allows the person to discriminate consciously between the presence of gas, liquid, and solids in the anal canal. In addition, stretch receptors in the muscle of the pelvic floor detect changes in the orientation of the anorectum as feces are propelled into the region.

Contraction of the IAS and the puborectalis muscle blocks the passage of feces and maintains continence with small volumes in the rectum. When the rectum is distended, the **rectoanal reflex** pathway is activated to relax contractile tone in the IAS. Rectal distention also results in the sensation of rectal fullness.

IAS relaxation allows the rectal contents to come into contact with the sensory receptors in the lining of the anal canal. Signals from these receptors reach conscious perception and provide the person with an early warning of the possibility of a breakdown of continence. When this occurs, voluntary contraction of the EAS and puborectalis muscle maintains continence. The EAS closes the anal canal and the puborectalis sharpens the anorectal angle (see Fig. 27.14). An increase in the anorectal angle works in concert with increases in intra-abdominal pressure to create a "**flap valve**." This valve is formed by the collapse of the anterior rectal wall onto the upper end of the anal canal, thereby occluding the lumen.

Whereas the ENS mediates the rectoanal reflex, synaptic circuits for the neural reflexes of the EAS and other pelvic floor muscles reside in the sacral portion of the spinal cord. Sensory input from the anorectum and pelvic floor is transmitted over dorsal spinal roots into the sacral cord, and motor outflow to these areas is in ventral sacral root motor nerve fibers. The spinal circuits mediate reflex increases in contraction of the EAS and pelvic floor muscles, which can occur during behaviors that raise intra-abdominal pressure (e.g., coughing, sneezing, lifting weights) and threaten a breakdown in continence.

Neural control of defecation involves the central and enteric nervous systems.

Distention of the rectum evokes an urge to defecate or release flatus. Local processing in the ENS activates the motor program for relaxation of the IAS. At this stage of rectal distention, voluntary contraction of the EAS and the puborectalis muscle prevents leakage and the decision to defecate is voluntary, which results in commands from the brain to the sacral spinal cord to stop excitatory input to the EAS and levator ani muscles. Additional skeletal motor commands contract the abdominal muscles and diaphragm to increase intra-abdominal pressure. Coordination of the skeletal muscle components of defecation results in a straightening of the anorectal angle, descent of the pelvic floor, and opening of the anus.

During defecation, the longitudinal muscle layer in the sigmoid colon and rectum shortens and is followed by strong contraction of the circular muscle layer propelling the luminal contents to the outside (see Fig. 27.4).

A voluntary decision to resist the urge to defecate is eventually accompanied by relaxation of the circular muscle of the rectum, which accommodates the increased volume in the rectum. As wall tension relaxes, the urge to defecate subsides. Receptive relaxation of the rectum is accompanied by a return of contractile tension in the IAS, relaxation in the EAS, and increased pull by the puborectalis muscle sling. When this occurs, the feces remain in the rectum until the next mass movement further increases the rectal volume and again activates mechanoreceptors associated with stimulating defecation.

Motility disorders.

Motility-associated disorders (**dysmotility**) are not uncommon. Without a normal pattern of motility constantly moving along the intestinal tract in an aboral direction, the luminal contents move much slower than normal or they may even stop moving entirely. Motility disorders can occur anywhere along the GI tract from the esophagus through the intestines. The effects of motility disorders will depend upon the region affected. GERD results from a motility problem in the esophagus. Further down in the intestines, problems can range from the less severe (e.g., bloating) to more severe such as nutritional malabsorption leading to malnutrition. The causes of abnormal motility generally fall into two broad categories—myopathy and neuropathy. Chronic intestinal pseudoobstruction can be caused by changes in the regulation of muscle contraction leading to unsynchronized contractions (a **neuropathy**) or contractions may occur but they are weak (a **myopathy**). Irritable bowel syndrome affects large intestine motility.

Physiological ileus is the transient absence of motility (quiescence) in the intestinal tract and is a fundamental behavioral state of the intestine programmed by the ENS. Quiescence of the intestinal circular muscle occurs when inhibitory musculomotor neurons are continuously active and suppress the responsiveness of the circular muscle to the ever-present ESWs. Physiological ileus is a normal state that remains in effect for varying periods of time in different intestinal regions and is affected by factors such as the time after a meal. Ileus disappears after ablation of the ENS. When enteric neural functions are destroyed by pathologic processes, disorganized and nonpropulsive contractile behavior occurs continuously due to myogenic contraction.

The normal state of motor quiescence becomes pathologic when the gates of the peristaltic reflex circuit for the particular motor patterns are rendered inoperative for abnormally long periods. In this state of **pathological ileus** or **paralytic ileus**, the basic circuits are locked in an inoperable state, while unremitting activity of the inhibitory motor neurons continuously suppresses myogenic activity. Paralytic ileus may occur after abdominal surgery.

SMOOTH MUSCLE CONTRACTION

The electrical stimuli for GI smooth muscle contraction may be **myogenic** (signal for contraction originates spontaneously within the smooth muscle itself) or **neurogenic** (contraction is stimulated by the arrival of a nerve impulse). Smooth muscles may also initiate contraction in responses to certain hormones and drugs.

Smooth muscles of the stomach and intestine contract spontaneously in the absence of neural or endocrine influence.

Smooth muscles are classified based on their behavioral properties and associations with nerves. The gastric and intestinal smooth muscle layer behaves like **unitary-type smooth muscle** and contraction is myogenic or a response to stretch. Neuromuscular junctions in the GI tract unitary-type smooth muscle are simpler than the well-structured motor endplates of skeletal muscle (see Chapter 8). Most motor axons in the unitary-type smooth muscle do not release neurotransmitters from terminals as such, but instead, release is from multiple varicosities, which are spaced out along the axon. The neurotransmitter released when an action potential depolarizes the membrane potential of the varicosity diffuses over relatively long distances before reaching the muscle and/or ICCs. This structural organization is an adaptation for the simultaneous application of a neurotransmitter to multiple muscle fibers from a small number of motor axons. Because the muscle fibers are connected by gap junctions, the membrane potential in expanded regions of the musculature can be depolarized to action potential threshold or hyperpolarized below spike threshold by neurotransmitter release from a reduced number of motor axons. The smooth muscle of the esophagus and gallbladder behaves like **multiunit-type smooth muscle**. These muscles contract only in response to nervous input. The nerve runs between the muscle cells and neurotransmitter released from varicosities along the nerve stimulates individual cells. These cells are not connected by gap junctions.

Electromechanical and pharmacomechanical coupling trigger contractions in GI muscles.

GI smooth muscle differs from skeletal muscle in having two mechanisms that initiate the processes leading to contractile shortening and development of tension. In both types of muscle cells, depolarization of the membrane electrical potential leads to the opening of voltage-gated Ca^{2+} channels, followed by the elevation of cytosolic Ca^{2+} and Ca^{2+} activation of contractile proteins. This mechanism is called **electromechanical coupling**. The second mechanism, **pharmacomechanical coupling**, does not occur in skeletal muscle. In this mechanism, the binding of ligands to G protein–coupled receptors on the smooth muscle cell membrane leads to the opening of Ca^{2+} channels and the elevation of cytosolic Ca^{2+} without any change in the membrane electrical potential. The ligands may be chemical substances released from nerves (**neurocrine signaling**), from nonneural cells in close proximity to the muscle (**paracrine signaling**), or from hormones from endocrine cells (see Chapter 1).

GI and esophageal smooth muscles have properties of a functional electrical syncytium.

Neighboring smooth muscle fibers are electrically connected by **gap junctions**, which are permeable to ions and thereby transmit electrical current from one muscle fiber to the next. Ionic connectivity, without cytoplasmic continuity from fiber to fiber, accounts for the **electrical syncytial** properties of smooth muscle just as it does in cardiac muscle (see Chapter 12). Electrical activity and the associated contractions spread from a point of initiation (e.g., a pacemaker region) in three dimensions throughout the bulk of the muscle. The ENS controls the distance and direction the electrical activity spreads in the electrical syncytium. A failure of nervous control can lead to disordered motility that includes spasm and associated cramping abdominal pain.

Inhibitory musculomotor activity determines the distance and direction a contraction travels within the functional electrical syncytium.

Inhibitory musculomotor neurons determine the length of a contracting segment by controlling the distance the action potentials spread within the muscular syncytium (Fig. 27.15). This occurs coincidently with control of contractile force. Contractions can only occur in the circular muscle layer of segments where ongoing inhibition has been inactivated. Contractions are prevented in adjacent segments where the inhibitory innervation is active. The oral and aboral circumferential boundaries of a contracted segment reflect the transition zone from inactive to active inhibitory musculomotor neurons. In this way, the ENS generates short contractile segments during the digestive (mixing) pattern of small intestinal motility and longer contractile segments during propulsive motor patterns, such as power propulsion that travels over extended distances along the intestine.

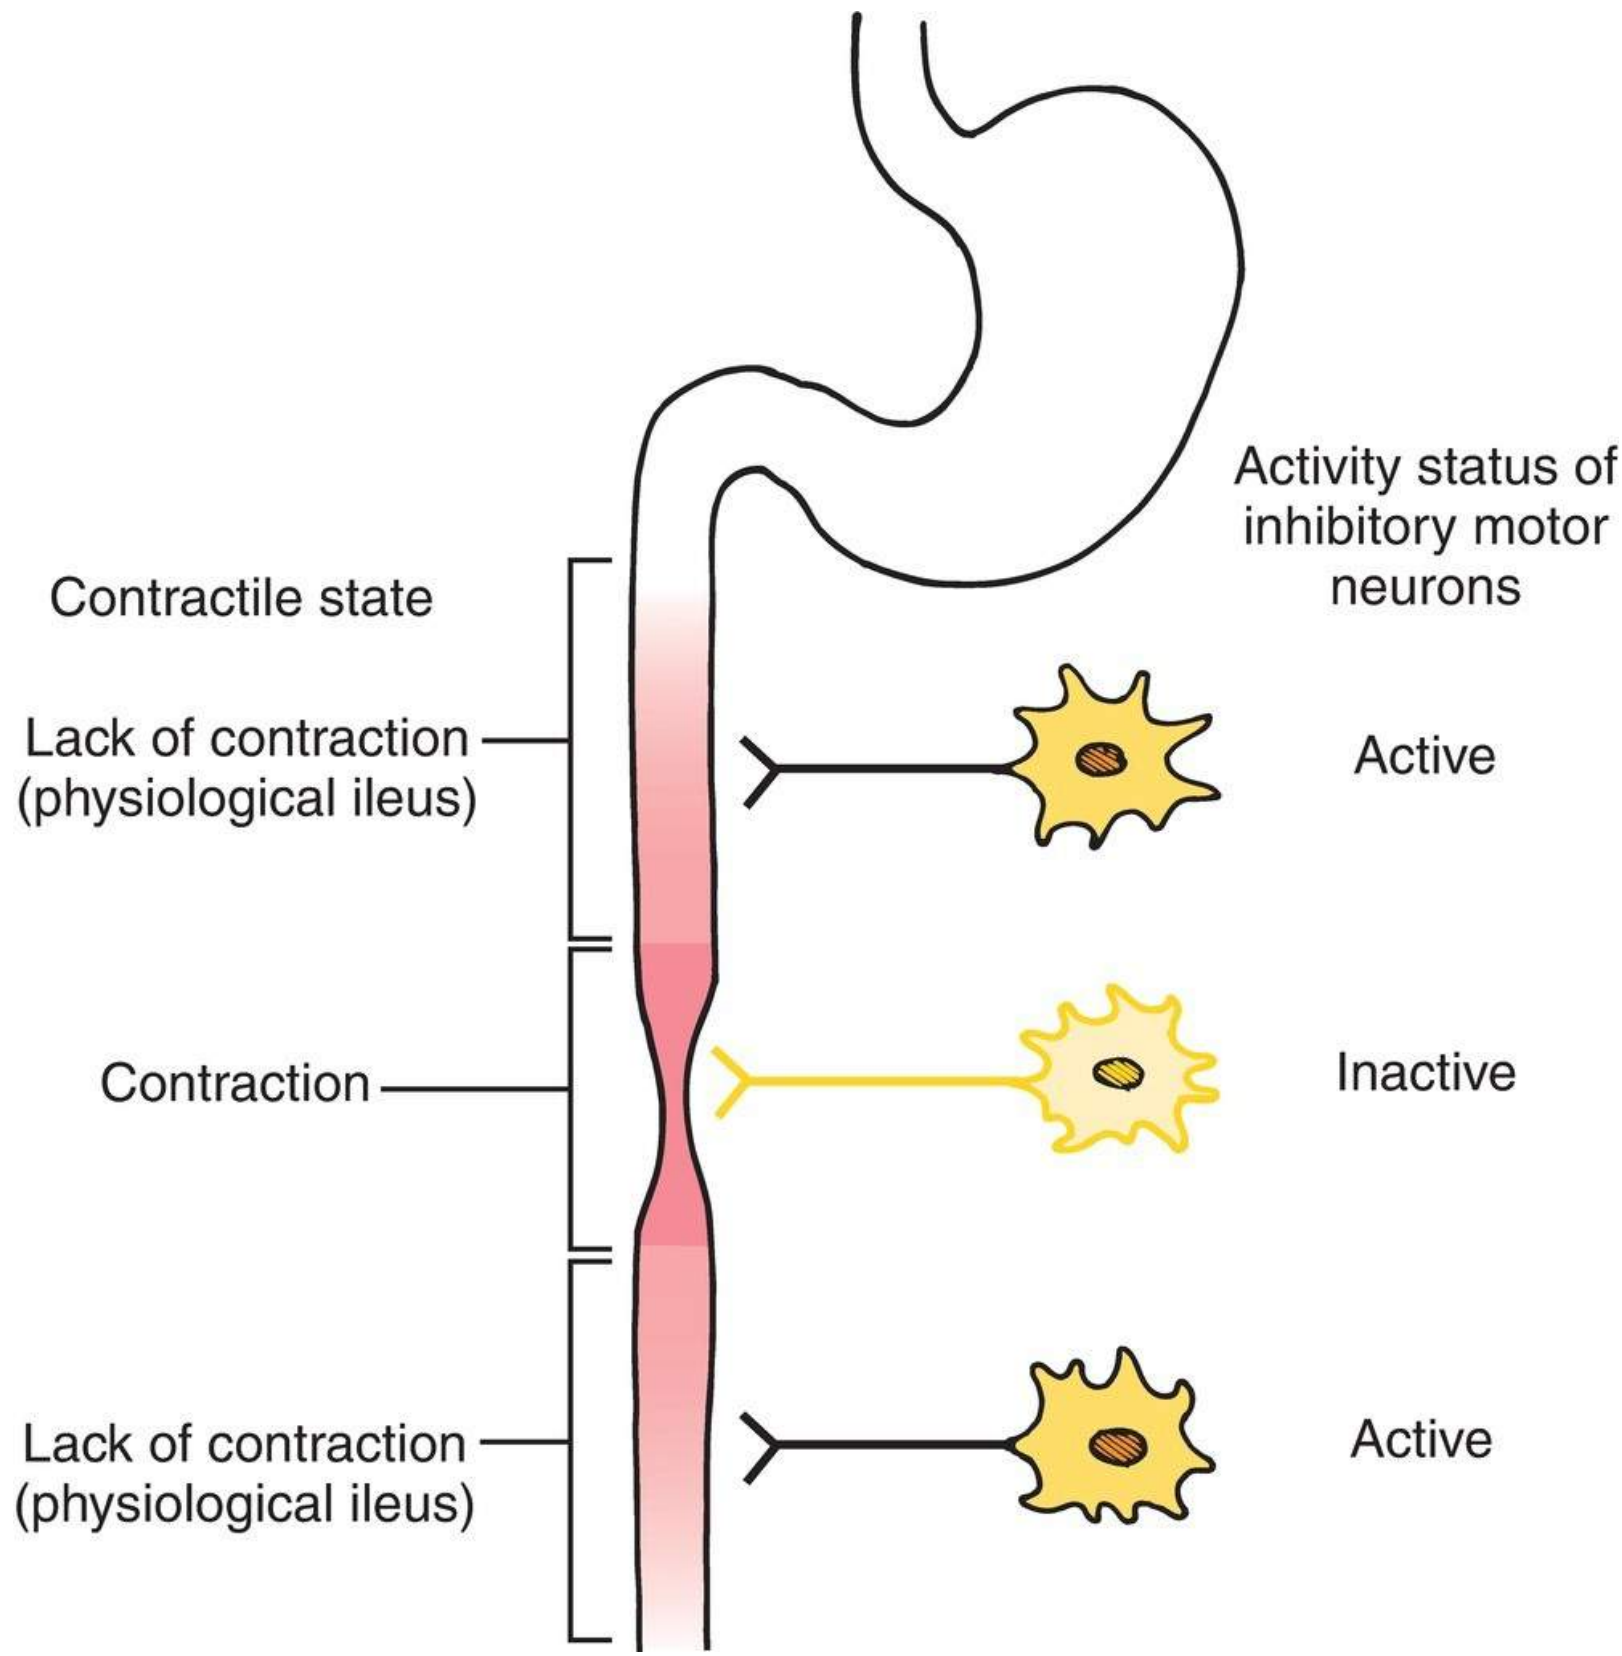

Figure 27.15 Myogenic contractions can occur in segments of intestine where inhibitory musculomotor neurons are inactive. Physiological ileus occurs in segments of intestine where the inhibitory neurons are actively firing.

The directional sequence in which inhibitory musculomotor neurons are inactivated determines whether contractions propagate in the oral or aboral direction (Fig. 27.16). Normally, the neurons are inactivated sequentially in the aboral direction, and thus, contractile activity propagates and moves the intraluminal contents distally. During vomiting, the ENS inactivates inhibitory musculomotor neurons in a reverse sequence, allowing small intestinal propulsion to travel in the oral direction from the midjejunum

and propel the contents toward the stomach.

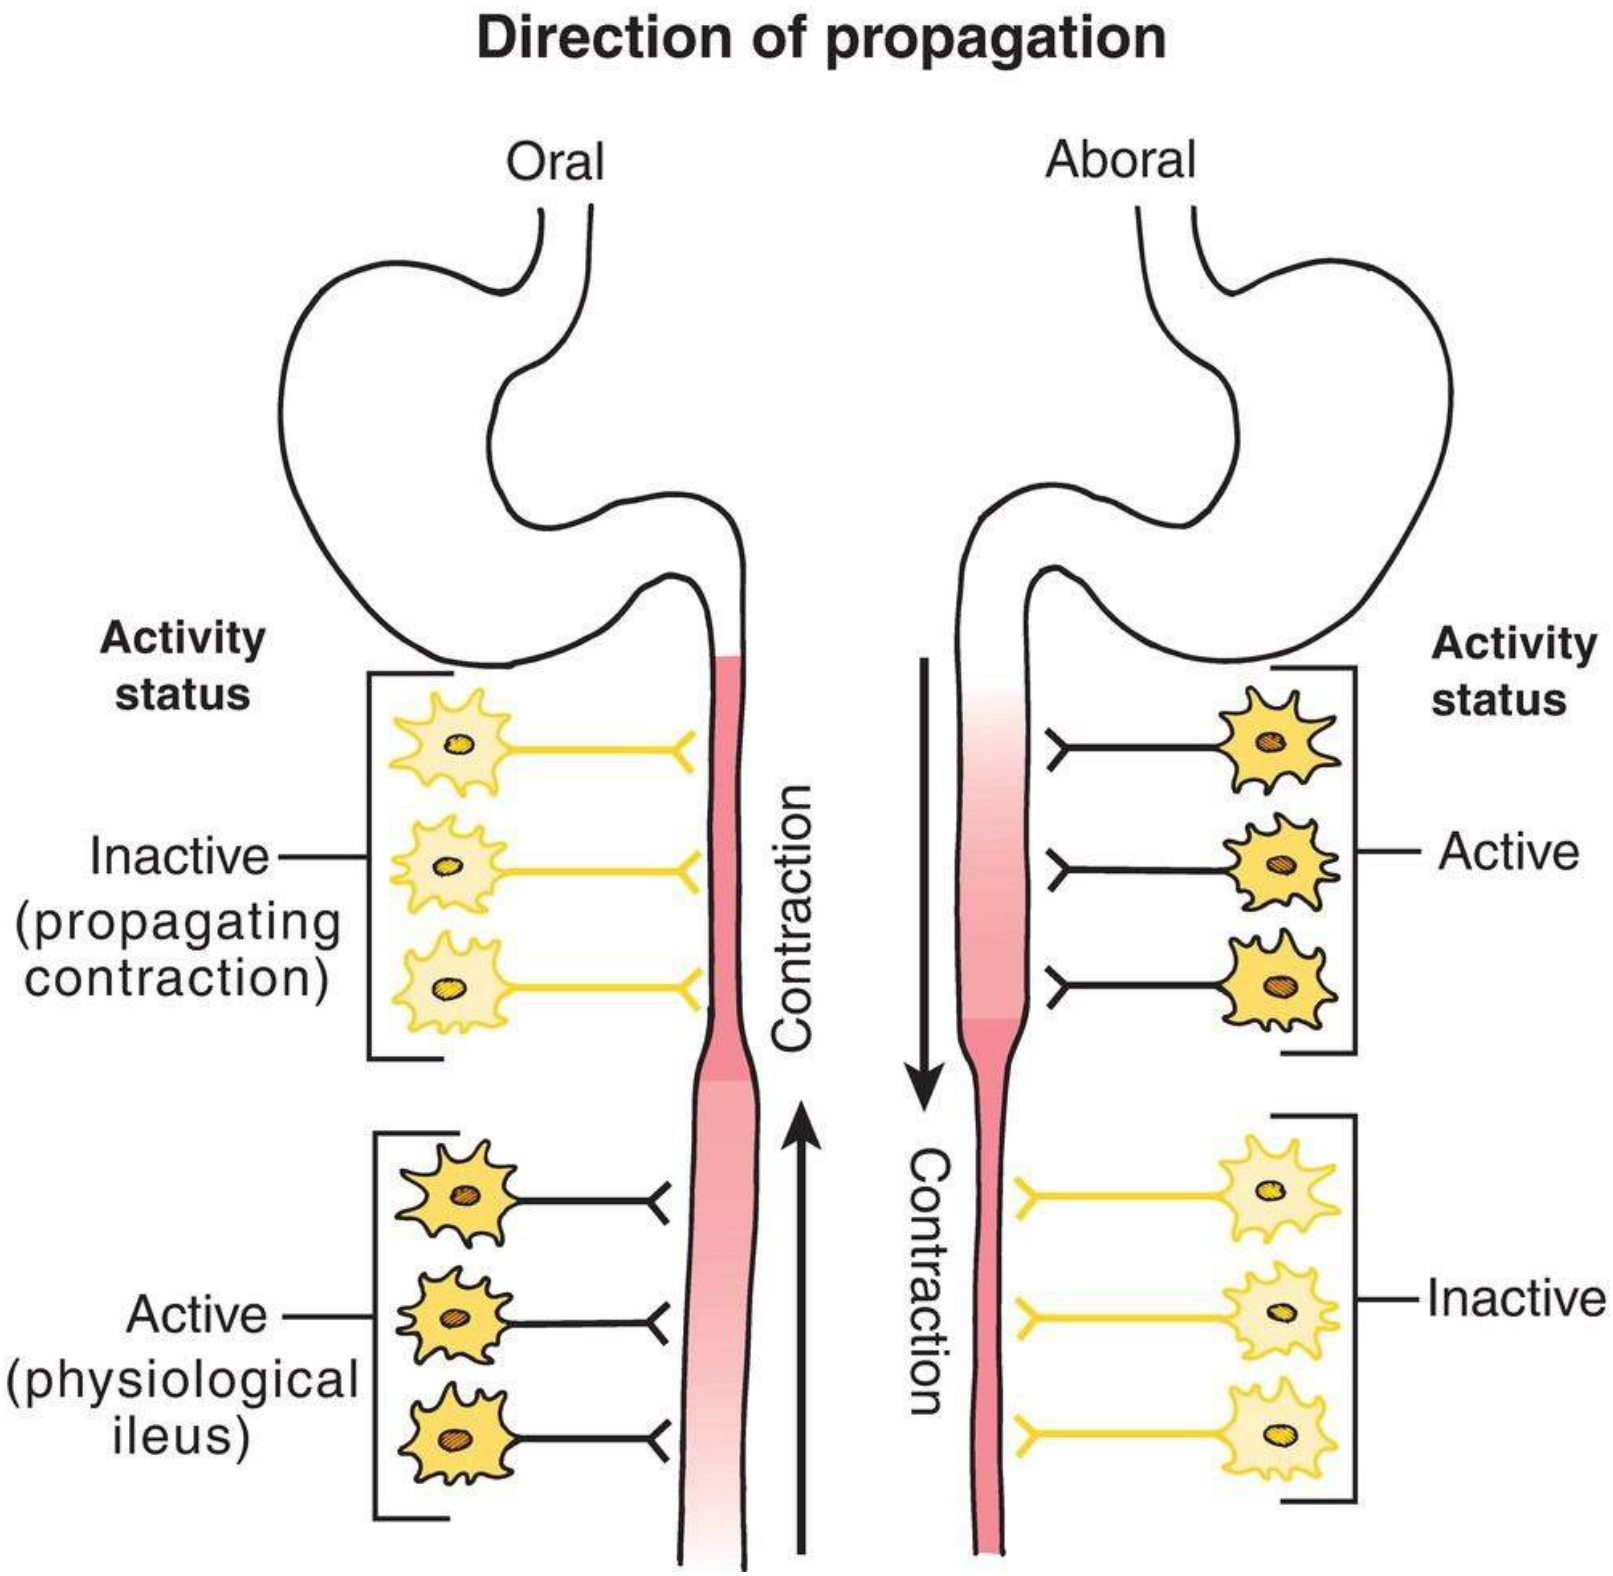

Figure 27.16 Contractions propagate into intestinal segments where inhibitory musculomotor neurons are inactivated. Sequential inactivation in the oral direction permits oral propagation of contractions. Sequential inactivation in the aboral direction permits aboral propagation.

Electrical activity in GI muscles consists of slow waves and action potentials.

ESWs are spontaneous, cyclic changes in the GI smooth muscle membrane potential and are initiated by ICCs. The waves are always present, and if the wave amplitude reaches the electrical threshold of the muscle (this does not occur with every wave), an action potential will be triggered. While ESWs trigger action potentials in some regions, in other regions (e.g., the gastric antrum and large intestinal circular muscle), they represent the only form of electrical activity (Fig. 27.17). In the small intestine, ESWs decrease in frequency along a gradient from the duodenum to the ileum. In the gastric antrum, the terms *slow wave* and *action potential* are used interchangeably for the same electrical event. When action potentials are associated with ESWs, they occur during the plateau phase of the slow wave.

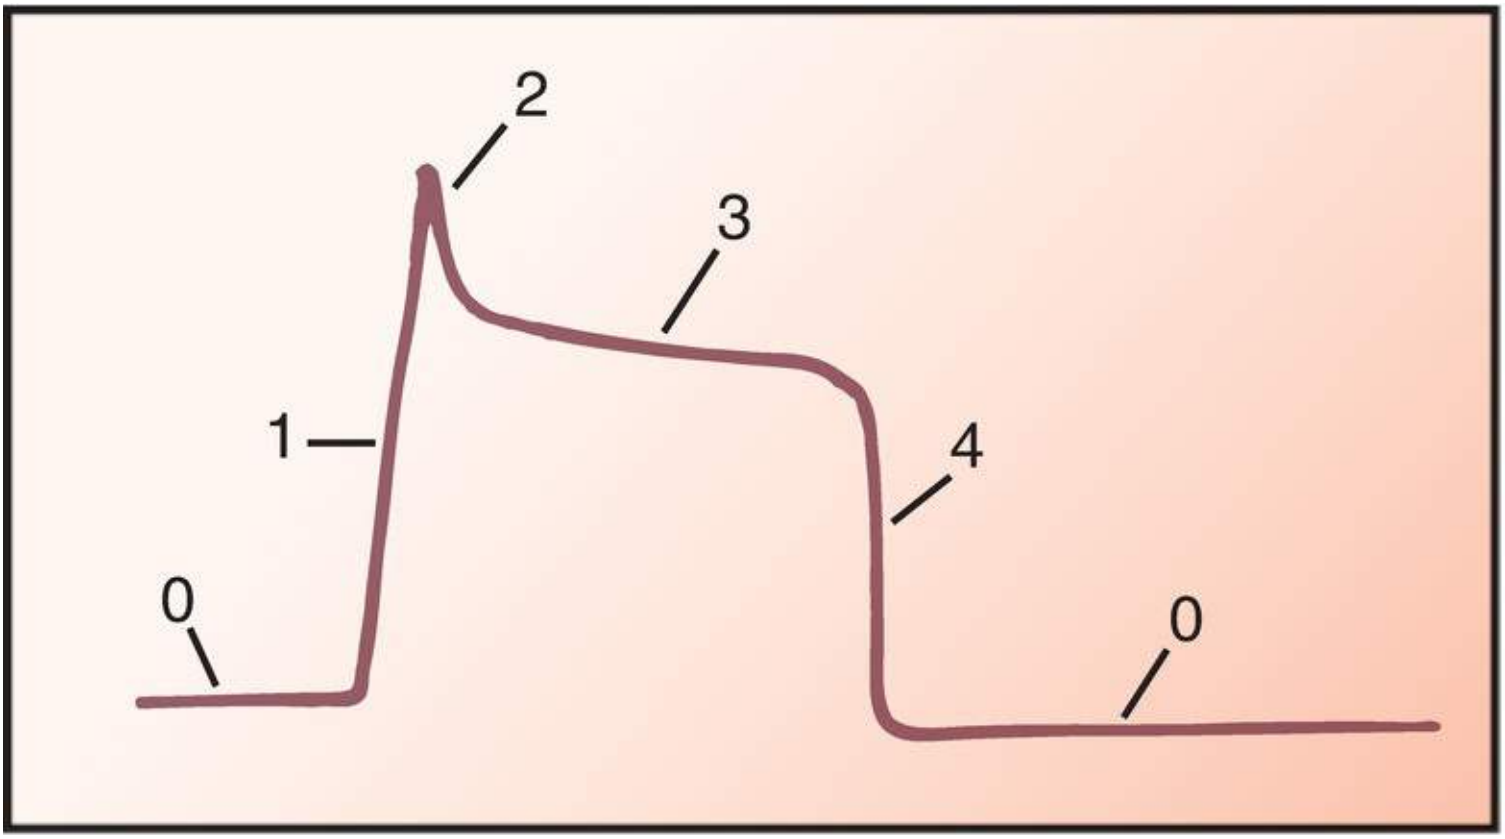

Figure 27.17 Electrical slow waves in gastrointestinal muscles occur in four phases determined by specific ionic mechanisms. Phase 0: Resting membrane potential; outward potassium current. Phase 1: Rising phase (upstroke depolarization); activation of voltage-gated Ca^{2+} channels and activation of voltage-gated K^+ channels. Phase 3: Plateau phase; balance of inward Ca^{2+} current and outward K^+ current. Phase 4: Falling phase (repolarization); inactivation of voltage-gated Ca^{2+} channels and activation of calcium-gated K^+ channels.

Action potentials in GI tract smooth muscle are mediated by changes in conductance in Ca^{2+} and K^{+} channels.

The depolarization phase of the action potential is produced by the inward movement of Ca^{2+} through voltage-gated L-type Ca^{2+} channels also called calcium–sodium channels. Repolarization occurs when K^{+} channels open and K^{+} moves outward as the Ca^{2+} channels are closing at or near the peak of the action potential (see Chapter 3). The L-type Ca^{2+} channels in GI smooth muscle are essentially the same as those found in cardiac and vascular smooth muscle. Therefore, disordered GI motility may be a side effect of treating cardiovascular disease with 1, 4-dihydropyridine drugs that block L-type Ca^{2+} channels.

Electrical slow waves may occur with or without action potentials in the small intestine.

As a general rule, ESWs in the circular muscle of the small intestine trigger action potentials that in turn initiate contractions. However, ESWs are not always accompanied by action potentials, and therefore, contractions will not occur (see Fig. 27.7A). With this method of recording, the size of an action potential appears larger when greater numbers of the total population of muscle fibers are depolarized to action potential threshold by each slow wave. The amplitude of phasic contractions associated with each ESW increases in direct relation to the number of muscle fibers recruited to firing threshold by each slow-wave cycle (see Fig. 27.7B).

Interstitial cells of Cajal generate electrical slow waves.

ICCs are present along the length of the GI tract and generate the ESWs observed in the stomach and intestinal tract. Gap junctions electrically interconnect the ICCs into networks, the ICCs to the circular muscle, and the smooth muscle fibers to one another. Gap junctions allow electrical current to flow from the ICC network to the circular muscle leading to the generation of an action potential followed by a contraction.

Pacemaker networks of ICCs surround the circular muscle of the small intestine at the border with the longitudinal muscle layer (myenteric border) and at the border with the submucosa. Traveling through the gap junctions, ESWs generated by the ICC network at the submucosal border spread passively into the bulk of the circular muscle, and those at the myenteric border spread passively into both longitudinal and circular muscle. The slow-wave electrical current then spreads from muscle fiber to muscle fiber.

Electrical slow-wave frequencies differ in the stomach, small intestine, and colon.

ESWs with similar waveforms occur at a frequency ranging from about 3 waves/min in the antrum, 11 to 12 waves/min in the duodenum, and 2 to 13 waves/min in the colon. Since each slow wave does not result in the generation of an action potential and muscle contraction, the contractile frequency of the muscle may be less than but never greater than the frequency of the ESWs. The ENS determines the nature of the contractile response during each slow wave.

NEURAL CONTROL OF GUT MOTILITY AND DIGESTIVE FUNCTION

The digestive system is under ANS and CNS control. Sensory and motor neuron innervation of the digestive tract control muscle contraction, epithelial secretion and absorption, and blood flow and distribution inside the walls of the esophagus, stomach, intestines, and gallbladder. Sensory nerves transmit information from the gut to the brain accounting for sensations that are localized to the digestive tract (e.g., sensations of discomfort, abdominal pain, and chest pain or heartburn). Motor neurons are able to activate and inhibit muscle contraction. Secretion of H_2O, electrolytes, and mucus into the lumen and absorption from the lumen is affected by **secretomotor neurons** of the ENS.

CNS control of digestive functions involves two way communications with the GI system. Sensory neurons carry information from the gut to the brain and spinal cord and motor neurons carry information from the brain and spinal cord to the gut. Outflow may originate in higher processing centers of the brain (the frontal cortex) and accounts for the projection of an individual's emotional state (psychogenic stress) to the gut. This kind of brain–gut interaction underlies the symptoms of diarrhea and cramping lower abdominal pain sometimes reported by individuals during anticipation of a stressful life event (e.g., a difficult exam or job interview).

Neural integrative centers control the moment-to-moment motor activity of the gut.

The SNS, PNS, and ENS innervate the digestive tract. This comprehensive autonomic innervation of the digestive tract consists of interactive interconnections between the brain, the spinal cord, and the ENS. Sympathetic and parasympathetic pathways carry autonomic signals to the gut from the brain and spinal cord and are the extrinsic component of innervation. Neurons of the ENS provide the intrinsic component of innervation.

Neural control of the gut is hierarchical, with five basic levels of integrative organization (Fig. 27.18). Level 1 is the ENS, which behaves like an independent integrative nervous system (“mini-brain”) inside the walls of the gut. Level 2 consists of the prevertebral ganglia of the sympathetic nervous system. Levels 3, 4, and 5 are within the CNS. Sympathetic and parasympathetic signals to the digestive tract originate at levels 3 and 4 (central sympathetic and parasympathetic centers) in the medulla oblongata and represent the final common pathways for the outflow of information from the brain to the gut. Level 5 includes higher brain centers that provide input for integrative functions at levels 3 and 4.

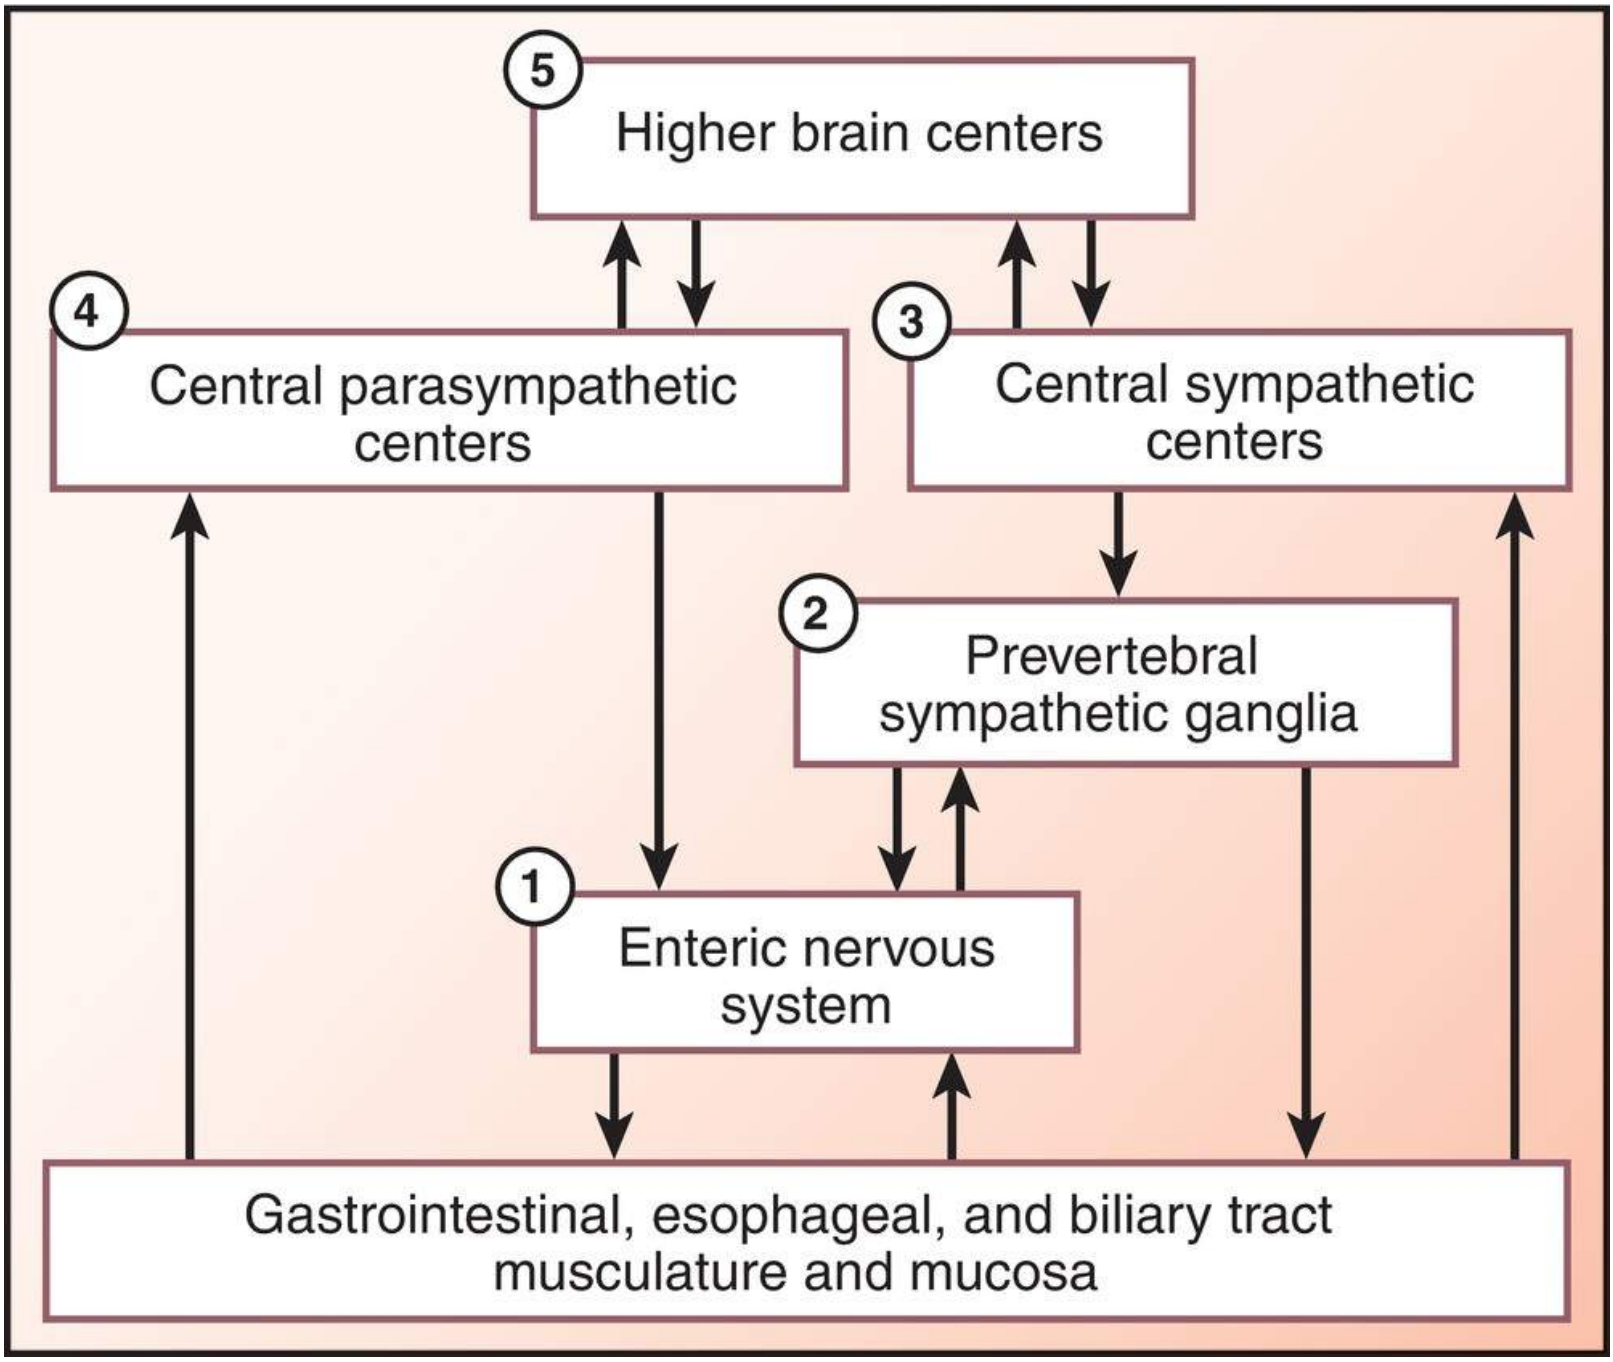

Figure 27.18 A hierarchy of five levels of neural organization determines the moment-to-moment motor behavior of the digestive tract. (See text for details.)

Parasympathetic neurons innervate the gut from the medulla oblongata and sacral spinal cord.

PNS stimulation activates the entire ENS and also increases overall blood flow to the gut and general gut activity including increased secretion. The proximal half of the ENS is innervated from the cranial parasympathetic nerve fibers via the vagal nerve. The distal half is innervated via the sacral parasympathetic nerve fibers. The latter gives rise to a rich nerve supply to the sigmoid colon, rectum, and anus. The sacral parasympathetic pathway plays an important role in defecation. Figure 27.19 shows details of the parasympathetic innervation of the gut.

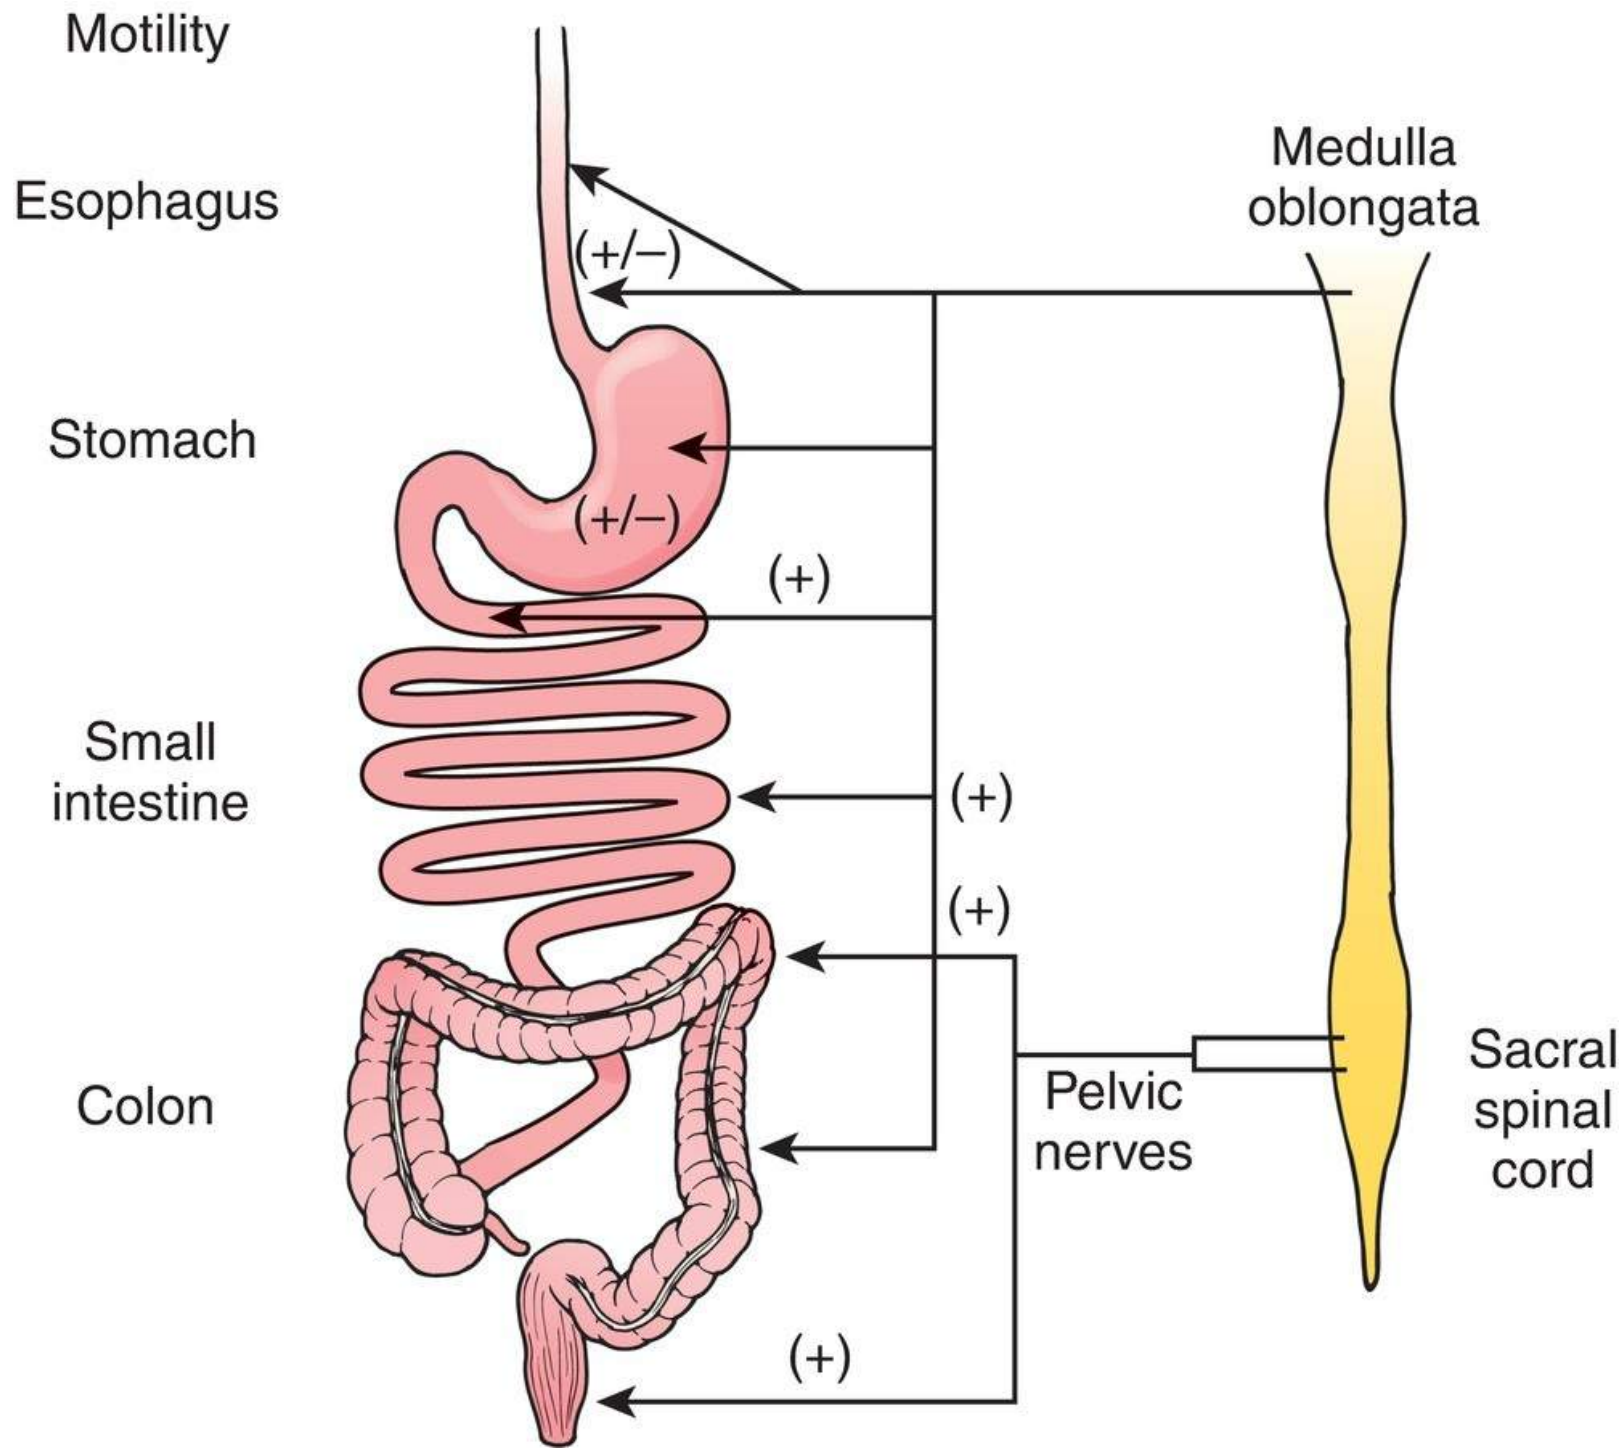

Figure 27.19 The digestive tract is innervated by the parasympathetic division of the autonomic

nervous system. Signals from parasympathetic centers in the central nervous system are transmitted to the enteric nervous system by the vagus and pelvic nerves. These signals result in either contraction (+) or relaxation (−) of the GI tract musculature.

Efferent vagal nerves transmit signals to the ENS to control digestive processes both in anticipation of food intake and following a meal. These ENS circuits regulate gastric smooth muscle contraction and relaxation. Parasympathetic efferents to the wall of the small and large intestine are predominantly stimulatory and they excite musculomotor neurons.

Dorsal vagal complex in the medulla controls the upper GI tract.

The **dorsal vagal complex** (vagal integrative center in the CNS) consists of the **dorsal motor nucleus** of the vagus, **nucleus tractus solitarius**, **area postrema**, and **nucleus ambiguus**. The center is more directly involved in controlling the specialized functions of the esophagus, stomach, duodenum, gallbladder, and pancreas than those of the distal small intestine and large intestine. The neural networks in the dorsal vagal complex and their interactions with higher centers are responsible for the rapid and precise control necessary for adjustments to rapidly changing conditions in the upper GI tract during anticipation, ingestion, and digestion of meals of varied composition.

Vagovagal reflex controls contractions of GI muscle layers in response to food stimuli.

The **vagovagal reflex** is constituted by afferent and efferent fibers of the vagus nerve that coordinate a response to gut stimuli. One function of the vagovagal reflex is to control GI tract smooth muscle contraction in response to distention of the tract by food; the reflex is activated to relax the stomach muscles in response to swallowing food. This reflex also allows for the accommodation of large amounts of food in the GI tract.

The sensory side of the reflex arc consists of vagal afferent neurons connected with a variety of sensory receptors specialized for the detection and signaling of mechanical parameters (e.g., muscle tension and mucosal brushing) or luminal chemical parameters (e.g., pH, osmolality, and glucose concentration). Afferent neural pathways connect the brain to neural networks in the ENS that innervate and control behavior of the musculature and secretory glands. Cell bodies of the vagal afferents are in **nodose ganglia**.

Efferent vagal fibers form synapses with ENS to activate outflow of signals from motor neurons to the effector systems. When the effector system is the musculature, its innervation consists of both inhibitory and excitatory musculomotor neurons that participate in reciprocal control. If the effector systems are gastric or digestive glands, the secretomotor neurons are excitatory and stimulate secretion.

The circuits for CNS control of the upper GI tract are organized much like those that control skeletal muscle movements and involve spinal reflex circuits (see Chapters 5 and 7). Inputs to spinal reflex circuits organize skeletal muscle contractile activity into functional motor behavior. The basic connections of the vagovagal reflex circuit are like somatic motor reflexes, in being “fine-tuned” from moment to moment by input from higher integrative centers in the brain.

Sympathetic nerves innervate gut blood vessels, mucosa, and muscularis and suppress gut activity when stimulated.

Sympathetic fibers exiting from the thoracic and upper lumbar regions of the spinal cord innervate the gut (Fig. 27.20). Efferent sympathetic fibers leave the spinal cord in the ventral roots to make their first synaptic connections with neurons in **prevertebral sympathetic ganglia** located in the abdomen. The prevertebral ganglia are the **celiac, superior mesenteric**, and **inferior mesenteric ganglia**. Cell bodies in the prevertebral ganglia project to the digestive tract, where they synapse with neurons of the ENS in addition to innervating the blood vessels, mucosa, and specialized regions of the musculature. The sympathetic neurons leaving the spinal cord are called **preganglionic sympathetic neurons**; the neurons leaving prevertebral ganglia to the gut are **postganglionic sympathetic neurons**.

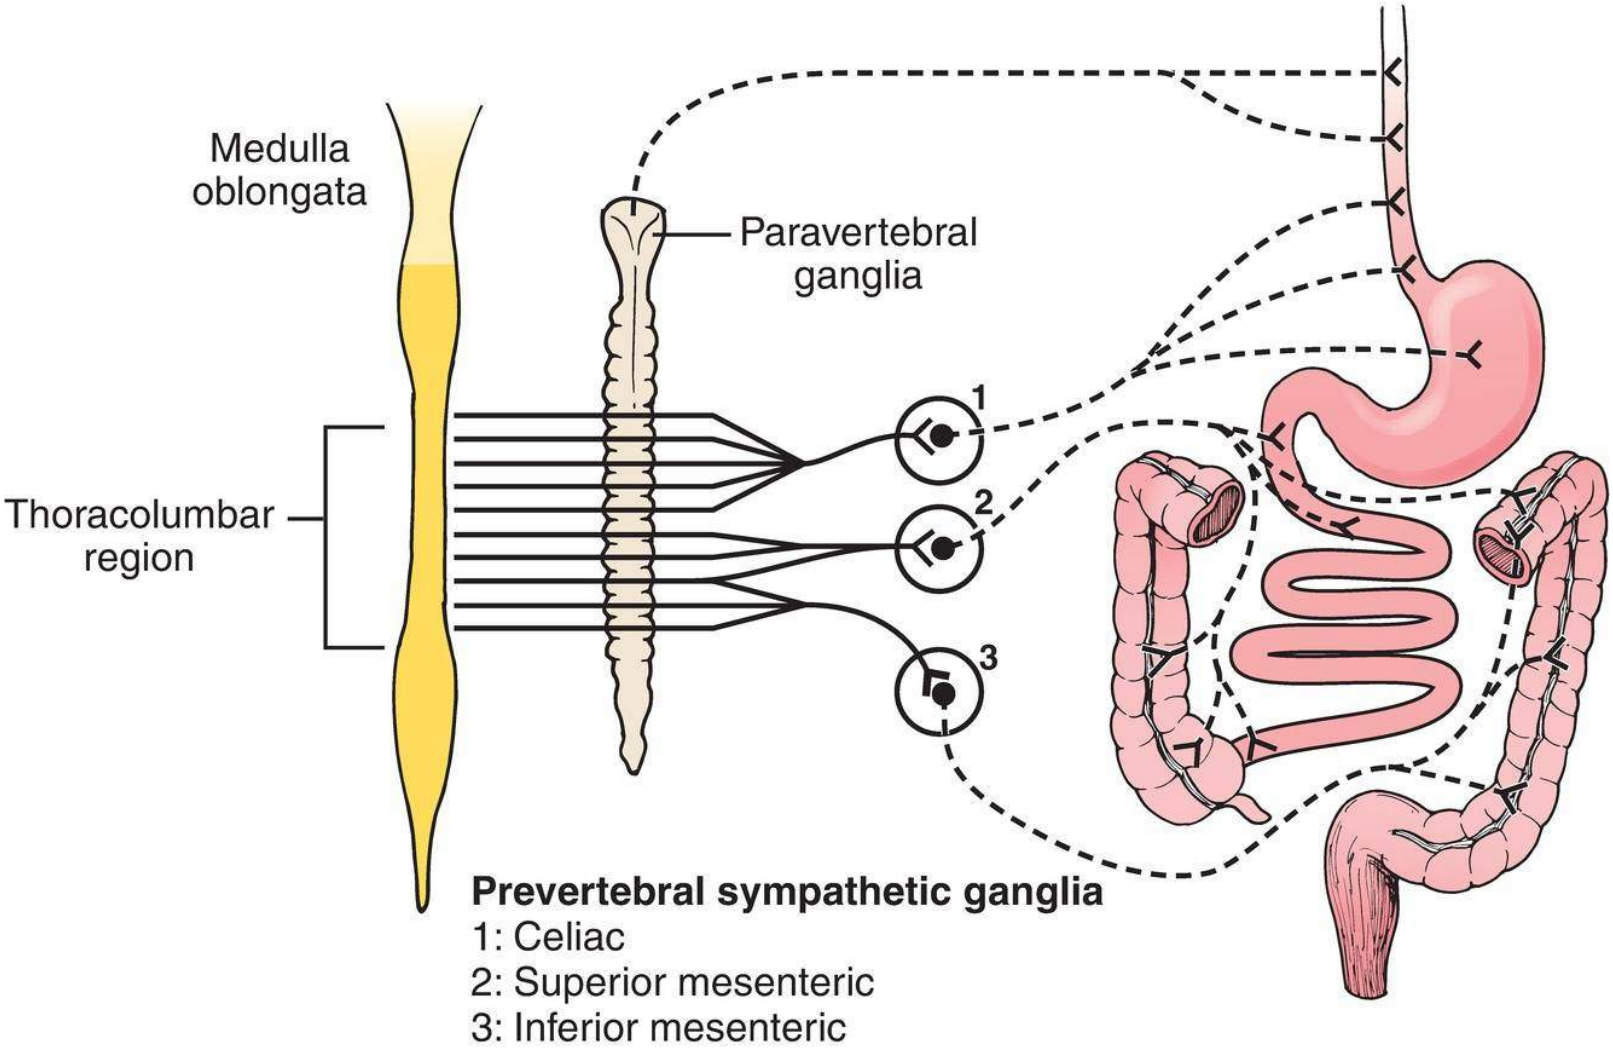

Figure 27.20 The sympathetic division of the autonomic nervous system innervates the digestive tract from the thoracic and lumbar segments of the spinal cord. Preganglionic neurons of the sympathetic division of the autonomic nervous system project to the gut from thoracic and upper lumbar segments of the spinal cord. (See text for details.)

CNS activation of sympathetic input to the GI tract shunts blood from the splanchnic to the systemic circulation during exercise and stressful environmental change. Sympathetic suppression of digestive functions, including motility and secretion, occurs as a coincident adaptation for reduced blood flow.

Norepinephrine (**NE**) released from sympathetic postganglionic neurons is the main mediator of these effects and acts directly on the LES and IAS to increase tension and keep the sphincter closed. Presynaptic inhibitory action of NE at synapses in the ENS suppresses gastric and intestinal motility. Postsynaptic inhibitory action of NE at secretomotor neurons that innervate the intestinal secretory glands prevents secretion (see Fig. 27.3). Aside from smooth muscle sphincters, most sympathetic innervation goes to the ENS, not the musculature.

Paired splanchnic nerves innervate the gut and carry sensory information from and efferent sympathetic signals to the GI tract.

Splanchnic nerves are mixed nerves (i.e., have both sympathetic efferent and sensory afferent fibers) in the mesentery. They are not part of the SNS, and use of the term *sympathetic afferent* is incorrect. The cell bodies of the sympathetic innervation of the GI tract are positioned in the intermediolateral cell columns of the spinal cord descending from the first thoracic to the third lumbar segment. Efferent sympathetic fibers leave the spinal cord in the ventral roots to make synaptic connections with neurons in prevertebral sympathetic ganglia located in the abdomen (see Fig. 27.20).

Sensory afferent fibers in the splanchnic nerves have their cell bodies in dorsal root spinal ganglia (see Chapter 4). They transmit information from the GI tract and gallbladder to the CNS. These fibers bifurcate within the gut wall and transmit information to the ENS. The afferent fibers branch and send collaterals to form synapses with neurons in prevertebral sympathetic ganglia before projecting onto the spinal cord.

The gut sensory receptors include mechanoreceptors, chemoreceptors, thermoreceptors, and most likely nociceptors (pain receptors). Mechanoreceptors sense mechanical events in the mucosa, musculature, serosal surface, and mesentery. They supply both the ENS and the CNS with information on stretch-related tension and muscle length in the wall and on the movement of luminal contents as they come in contact with the mucosal surface. Mesenteric receptors sense gross movements of the organ. Chemoreceptors monitor nutrient concentration, nutrient type (e.g., lipids), osmolality, and luminal pH. Most receptors have been found to be multimodal (i.e., respond to both mechanical and chemical stimuli). Thermoreceptors are located along the GI tract. Gastric reflexes are initiated in response to either warm or cold stimuli and intestinal reflexes have been shown to be stimulated by warm stimuli. The presence of GI nociceptors is likely but not unequivocally confirmed, except in the gallbladder. The sensitivity of splanchnic afferents, including nociceptors, may be elevated in cases of intestinal or gallbladder inflammation.

Sensory neurons, interneurons, and motor neurons form the microcircuits that integrate the ENS.

As they are in the CNS, the sensory neurons, interneurons, and motor neurons in the ENS are connected synaptically for the directed flow of information (see Fig. 27.3). Bidirectional communication occurs between the CNS and ENS, but the ENS organizes and coordinates the activity of each effector system. **Musculomotor neurons** control the musculature, and **secretomotor neurons** control the mucosal secretory glands. Interneurons form information-processing networks.

ENS afterhyperpolarization and synaptic-type neurons are distinguished by their electrophysiologic and synaptic behavior.

Two primary types of ENS neurons (i.e., **afterhyperpolarization** (**AH**)**-type** and **synaptic** (**S**)**-type**) are distinguished by their electrophysiological behavior and morphology.

AH-type neurons

AH-type neurons have multiple long processes, any of which might be an axon or a dendrite, and a long-lasting hyperpolarizing potential (i.e., an AH) that occurs following an action potential (Fig. 27.21). AH-type neurons fulfill the role of interneurons in the ENS. They comprise the largest proportion of myenteric plexus neurons and the smallest proportion of submucosal plexus neurons.

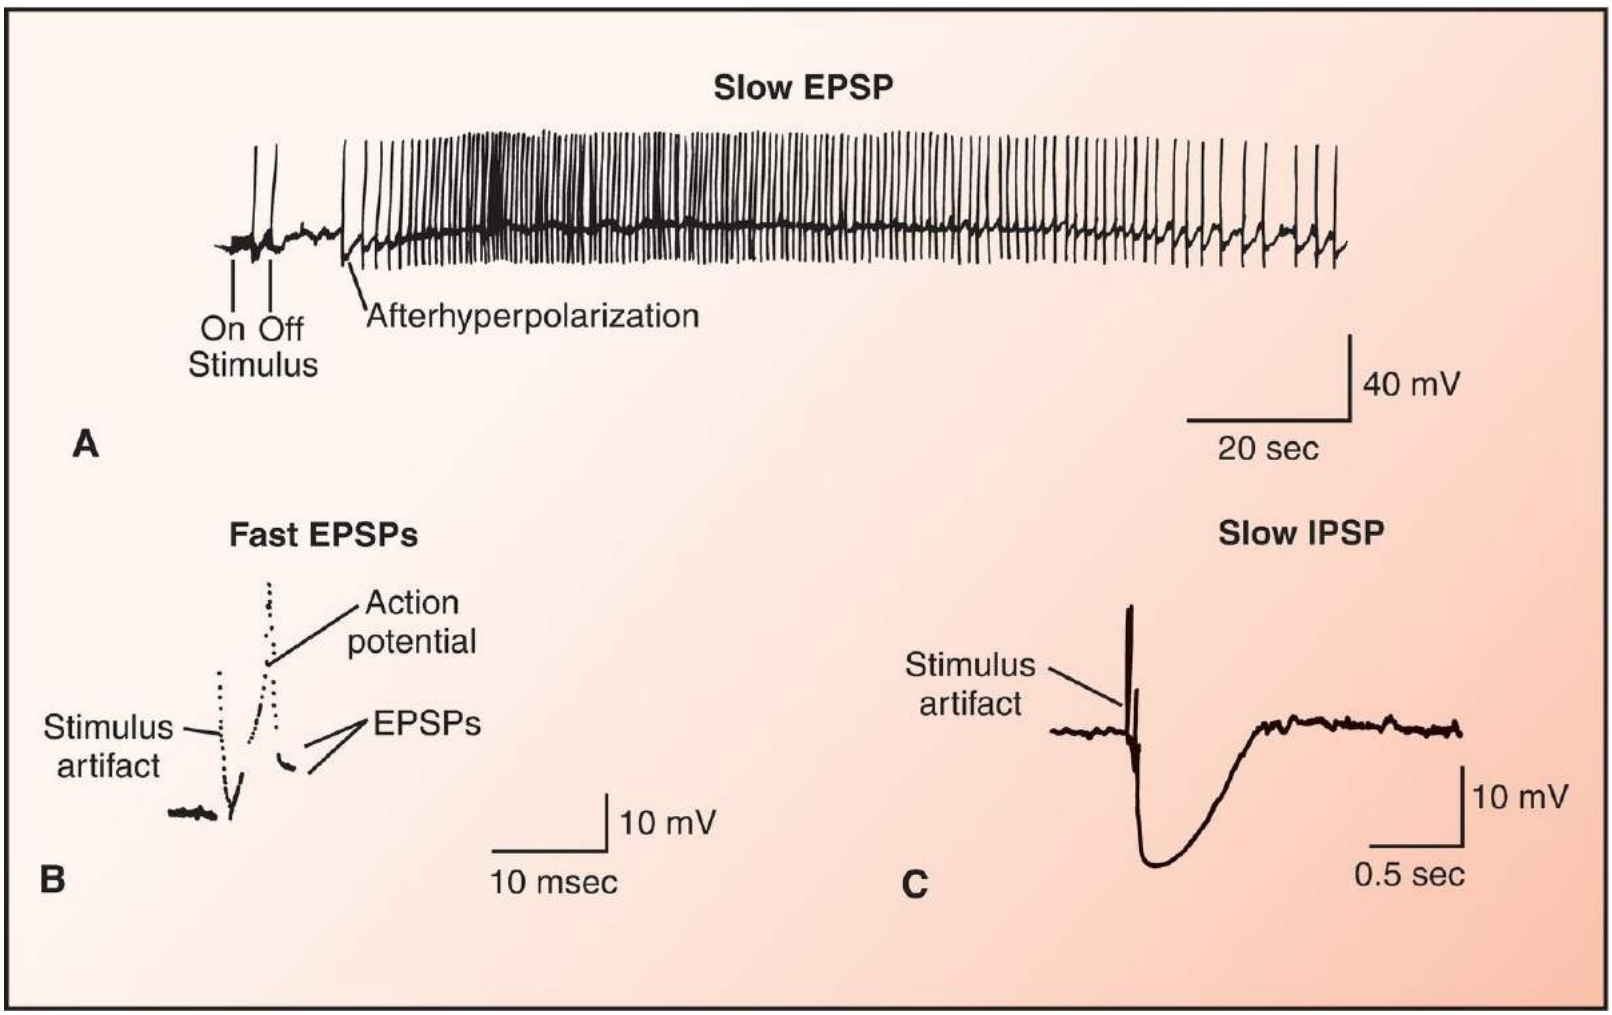

Figure 27.21 Fast excitatory postsynaptic potentials (EPSPs), slow excitatory postsynaptic potentials (EPSPs), and slow inhibitory postsynaptic potentials (IPSPs) are synaptic events in enteric neurons. (A) The slow EPSP was evoked by repetitive electrical stimulation of the synaptic input to the neuron. Slowly activating depolarization of the membrane potential continues for almost 2 minutes after the termination of the stimulus. During the slow EPSP, repetitive discharge of action potentials reflects enhanced neuronal excitability. **(B)** The fast EPSPs were also evoked by single electrical shocks applied to the axon that synapsed with the recorded neuron. Two fast EPSPs were evoked by successive stimuli and are shown as superimposed records. Only one of the EPSPs reached the threshold for the discharge of an action potential. The time course of the EPSPs is in the millisecond range. **(C)** The slow

IPSP was also evoked by the stimulation of an inhibitory input to the neuron. This hyperpolarizing synaptic potential will suppress excitability (i.e., decrease the probability of action potential discharge), compared with enhanced excitability during the slow EPSP.

S-type neurons

S-type neurons have a single long axon with multiple short dendrites. S-type enteric neurons can be distinguished from AH-type neurons by the absence of an AH, lower resting membrane conductance, and greater excitability. Additionally, unlike AH-type neurons, application of the Na^+ channel blocker tetrodotoxin abolishes action potentials in most S-type neurons. S-type neurons are so named because nicotinic fast excitatory postsynaptic potentials (EPSPs) were found in virtually all S-type enteric neurons, whereas only restricted subpopulations of AH-type neurons express nicotinic receptors and fast EPSP-like depolarizing responses to the application of ACh.

All motor neurons in the myenteric and submucosal plexuses (i.e., musculomotor, secretomotor, and vasculomotor) are S-type neurons. Subpopulations of interneurons can also exhibit the properties of S-type neurons. Most neurons in the submucosal plexus are S-type neurons.

SYNAPTIC TRANSMISSION IN THE ENTERIC NERVOUS SYSTEM

Multiple forms of synaptic transmission occur in the ENS, with both “fast” synaptic potentials with durations <50 ms and slow synaptic potentials lasting several seconds occurring. These synaptic events may be EPSPs or inhibitory postsynaptic potentials (IPSPs). Three forms of synaptic transmission can occur in enteric neurons (see Fig. 27.21).

Metabotropic receptors mediate enteric slow excitatory postsynaptic potentials.

Slow EPSPs can last from seconds to minutes. They are mediated by multiple chemical messengers acting at many different G protein–coupled **metabotropic receptors**. Metabotropic receptors characteristically activate a specific intracellular effector (e.g., an enzyme), which in the case of neurons leads to a change in the transmembrane potential. Different kinds of receptors, each of which mediates slow EPSP-like responses, are found in varied combinations on each neuron. Many neurotransmitter-binding metabotropic receptors activate second messenger pathways by activating intracellular cascades. Cyclic AMP (cAMP), diacylglycerol (DAG), inositol triphosphate (IP_3), and Ca^{2+} ions are common second messengers. The most frequent mode of signal transduction for slow EPSPs in AH-type neurons involves receptor activation of the enzyme adenylyl cyclase, the generation of cAMP, and the phosphorylation of protein kinases and/or channel-associated proteins. Postreceptor signal transduction for slow EPSPs in S-type neurons involves activation of the enzyme phospholipase C, synthesis of IP_3 and DAG, and the elevation of free intraneuronal Ca^{2+}. This pathway also leads to the phosphorylation of channel-associated proteins. In some parts of the ENS, G protein–coupled receptors can directly activate ion channels by way of the G protein that dissociates from the receptors following binding of neurotransmitter. Serotonin, substance P, and ACh are examples of enteric neurotransmitters that evoke slow EPSPs.

In **paracrine signaling**, mediators released from nonneural cells evoke slow EPSP-like responses when released in the vicinity of the ENS. Histamine, for example, is released from mast cells during hypersensitivity reactions (e.g., food allergies and parasitic infections) and acts at the histamine H_2 receptor subtype to evoke slow EPSP-like responses in ENS neurons in rodents. Subpopulations of ENS neurons in specialized regions of the gut (e.g., the upper duodenum) have receptors for hormones such as gastrin and cholecystokinin, which also evoke slow EPSP-like responses.

Slow excitatory postsynaptic potentials prolong neural excitation or inhibition of GI effector systems.

The long-lasting discharge of action potentials during the slow EPSP can result in either prolonged excitation or inhibition at neuronal synapses and neuroeffector junctions.

Muscle contractile responses and glandular secretory responses are slow events and take place over several seconds. Figure 27.22 illustrates how the occurrence of slow EPSPs might evoke prolonged muscle contraction or prolonged secretion. Slow EPSPs in inhibitory musculomotor neurons result in prolonged inhibition of contractile force.

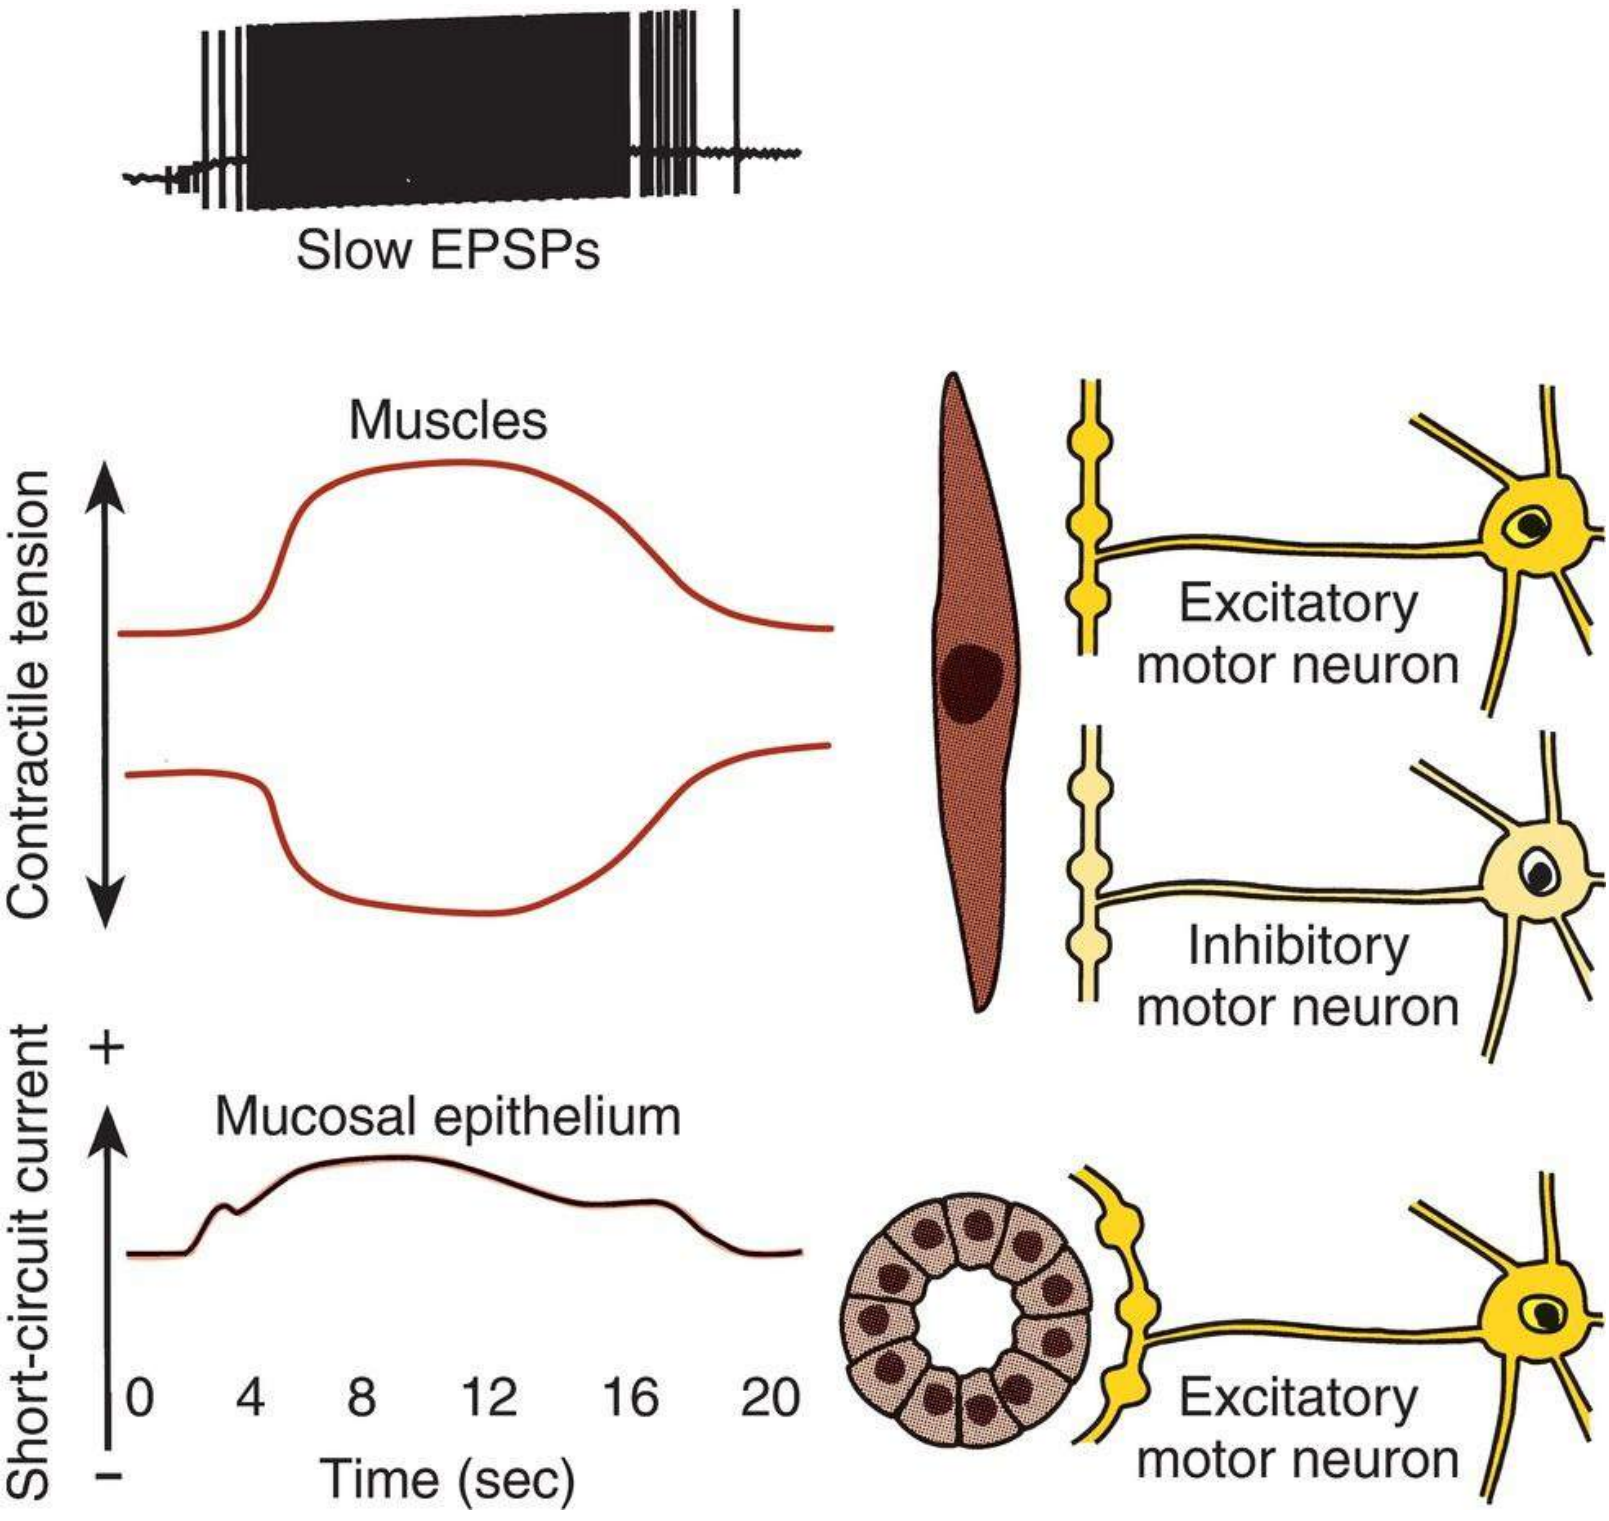

Figure 27.22 Slow excitatory postsynaptic potentials (EPSPS) in excitatory motor neurons result in prolonged muscle contraction or mucosal crypt secretion. Experimental stimulation of secretion is seen as an increase in ion movement (short-circuit current). Slow inhibitory postsynaptic potentials in inhibitory motor neurons result in prolonged inhibition of contractile activity in the muscle, which is observed as decreased contractile tension.

Ionotropic receptors mediate enteric fast excitatory postsynaptic potentials.

Fast EPSPs (see Fig. 27.21) are transient depolarizations of the membrane potential lasting <50 ms. They occur in the ENS throughout the digestive tract. Most fast EPSPs are mediated by ACh acting at **ionotropic receptors**. Ionotropic receptors are coupled directly to ion channels.

Multiple kinds of receptors mediate enteric slow inhibitory postsynaptic potentials.

Peptidergic, purinergic, noradrenergic, somatostatinergic, and cholinergic chemical messengers are examples of substances that evoke slow IPSP-like responses. Adenosine, ATP, or other purinergic analogues experimentally applied to myenteric plexus neurons also mimic slow IPSPs. Opioid peptides and opiate analgesics (morphine) are slow IPSP mimetics. This action is limited to subpopulations of neurons and is blocked by the antagonist naloxone. Addiction to morphine may be seen in enteric neurons, and withdrawal is observed as a high-frequency spike discharge on the addition of naloxone during chronic morphine exposure.

NE released from sympathetic postganglionic neurons acts at α_2-adrenoreceptors to mimic slow IPSPs in S-type neurons in the submucosal plexus and primarily in secretomotor neurons. Slow IPSPs in submucosal neurons reflect a mechanism by which sympathetic innervation suppresses intestinal secretion during physical exercise, when the blood is shunted from the splanchnic to systemic circulation. Somatostatin released from ENS neurons in the submucosal plexus at synapses on secretomotor neurons mimics the inhibitory action of NE.

Presynaptic inhibition acts like a neurocrine transmitter in gut function.

Presynaptic inhibition (Fig. 27.23) plays a significant role at fast nicotinic synapses, at slow excitatory synapses, and at sympathetic inhibitory synapses in the ENS and at excitatory neuromuscular junctions. Presynaptic inhibition functions like a specialized form of neurocrine transmission. Presynaptic inhibition resulting from paracrine or endocrine mediators binding receptors at presynaptic release sites is an alternative to axoaxonal synapses as a mechanism for enhancing or suppressing transmission at a synapse or neuroeffector junction.

Figure 27.23 Presynaptic inhibitory receptors are found on axons at neurotransmitter release sites for both slow and fast excitatory postsynaptic potentials (EPSPs). Different neurotransmitters act at presynaptic inhibitory receptors to suppress release of the transmitters for slow and fast EPSPs. Presynaptic autoreceptors are involved in a special form of presynaptic inhibition whereby the transmitter for slow or fast EPSPs accumulates at the synapse and acts on the autoreceptor to suppress further release of the neurotransmitter. (+), excitatory receptor; (−), inhibitory receptor.

Presynaptic inhibition in the ENS is mediated by multiple chemical mediators and their receptors. Among the known mediators are peptides (cholecystokinin), purinergic substances (ATP), amines (histamine), and ACh. After its release from sympathetic nerve terminals, NE acts at α_2-presynaptic adrenoreceptors to suppress fast EPSPs at nicotinic synapses and slow EPSPs and cholinergic transmission at neuromuscular junctions. A major component of shutdown of gut function by the SNS involves the presynaptic inhibitory action of NE at fast nicotinic synapses. Serotonin suppresses both fast and slow EPSPs in the myenteric plexus. Opiates or opioid peptides suppress some fast EPSPs in the intestinal myenteric plexus.

ACh acts at muscarinic presynaptic receptors to suppress fast EPSPs in the myenteric plexus. ACh released at nicotinic synapses acts in an autoinhibitory way and suppresses ACh release by presynaptic neurons in negative feedback fashion (see Fig. 27.23). Histamine is an example of paracrine-mediated presynaptic suppression in the ENS. After its release from enteric mast cells, histamine acts at histamine H_3 presynaptic receptors to suppress fast EPSPs in the ENS microcircuits of rodents. Presynaptic inhibition mediated by paracrine or endocrine release of mediators is significant in pathophysiologic states (e.g., inflammation).

Presynaptic facilitation enhances the amounts of neurotransmitter released at ENS axon sites.

Presynaptic facilitation refers to an enhancement of synaptic transmission (Fig. 27.24). The phenomenon enhances the amplitude of fast EPSPs in the myenteric plexus of the small intestine and gastric antrum and at noradrenergic inhibitory synapses in the submucosal plexus. Cholecystokinin affects the ENS of the gallbladder in the same way. Presynaptic facilitation is evident experimentally as an increase in amplitude of fast EPSPs at nicotinic synapses and reflects enhanced release of ACh. At noradrenergic inhibitory synapses in the submucosal plexus, the elevation of cAMP in the postganglionic sympathetic fiber appears as an enhancement of slow IPSPs.

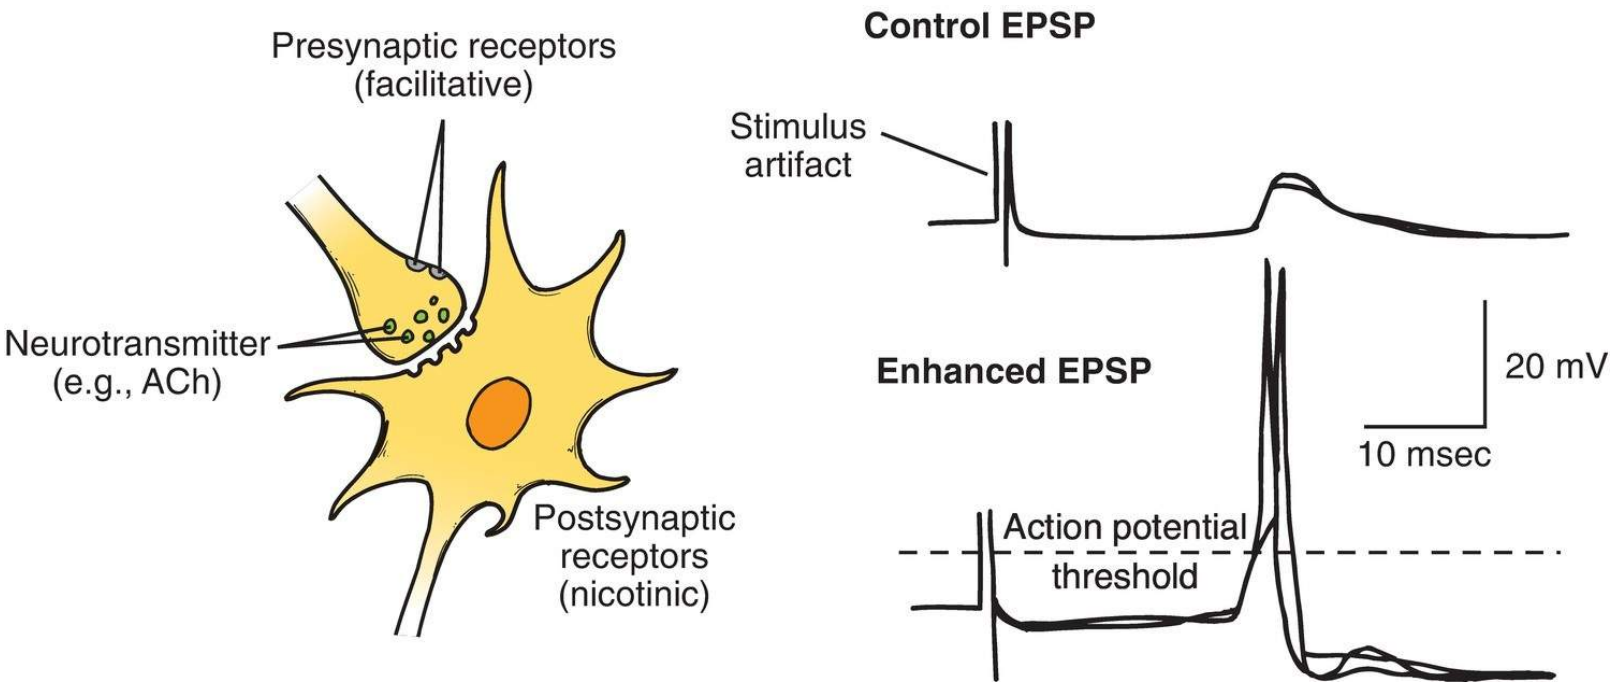

Figure 27.24 Presynaptic facilitation enhances release of acetylcholine (Ach) and increases the amplitude of fast excitatory postsynaptic potentials (EPSPs) at a nicotinic synapse.

Presynaptic facilitation is the mechanism of action of some **prokinetic drugs** (e.g., tegaserod and cisapride), which therapeutically enhance propulsive motility in the GI tract by increasing the amplitude of fast nicotinic EPSPs associated with propulsive motor functions. In the stomach and the intestine, increases in EPSP amplitudes and rates of rise decrease the probability of synaptic transmission failure, thereby increasing the speed of information transfer and enhancing propulsive motility (i.e., gastric emptying and intestinal transit).

ENTERIC MOTOR NEURONS

Both excitatory and inhibitory musculomotor neurons innervate the muscles of the digestive tract and, like spinal motor neurons, are the final pathways for signal transmission from the ENS to the musculature (see Figs. 27.3 and 27.25). Neurotransmitters released from motor neurons act at the neuromuscular junction with smooth muscle fibers and ICCs.

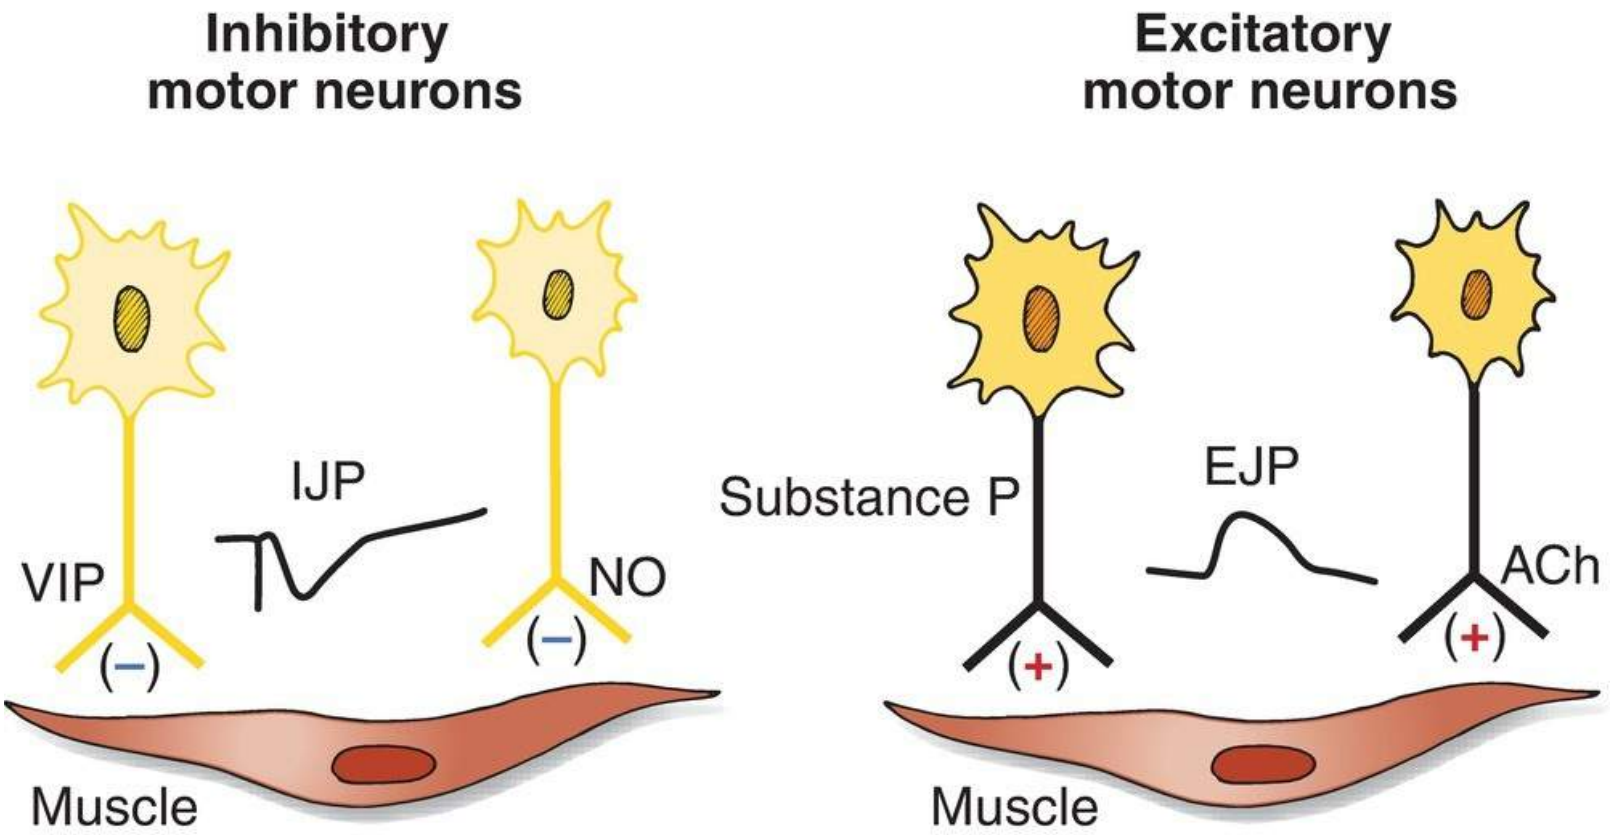

Figure 27.25 Enteric musculomotor neurons are final pathways from the enteric nervous system (ENS) to the gastrointestinal musculature. The motor neuron pool of the ENS consists of both excitatory and inhibitory neurons. Release of vasoactive intestinal peptide (VIP) or nitric oxide (NO) from inhibitory motor neurons evokes inhibitory junction potentials (IJPs). Release of acetylcholine (ACh) or substance P from excitatory motor neurons evokes excitatory junction potentials (EJPs).

Excitatory musculomotor neurons activate smooth muscle contraction in the gut.

Excitatory musculomotor neurons release neurotransmitters that evoke contraction and increased contractile force in GI smooth muscles. ACh and **substance P** are the main excitatory neurotransmitters released from ENS musculomotor neurons.

Two mechanisms of excitation–contraction coupling are involved in the neural initiation of muscle contraction in the GI tract. Transmitters released from excitatory musculomotor axons can trigger muscle contraction by depolarizing the muscle fiber membrane to the threshold for the discharge of action potentials. Neurally evoked depolarizations of the muscle membrane potential, called **excitatory junction potentials** (**EJPs**), can be distinguished from EPSPs and IPSPs (see Fig. 27.25). In the second mechanism, the activation of G protein–coupled receptors is linked to the direct release of Ca^{2+} from stores inside the muscle fiber (i.e., pharmacomechanical coupling) that triggers contractions independent of any changes in membrane electrical activity (i.e., EJPs or action potentials).

The cell bodies of excitatory musculomotor neurons are generally found in the myenteric plexus. In the small and large intestine, they project their axons over relatively short distances to innervate the longitudinal muscle and for longer distances away from the cell body in the oral direction to innervate the circular muscle.

Excitatory motor neurons, also called secretomotor neurons, innervate mucosal secretory glands (i.e., the crypts of Lieberkühn and Brunner glands) and stimulate secretion of NaCl, HCO_3^-, and H_2O in addition to mucus from goblet cells. ACh and vasoactive intestinal peptide (VIP) are the principal excitatory neurotransmitters released by secretomotor neurons. Hyperactivity of these neurons, like that evoked by histamine release from enteric mast cells during allergic responses, can lead to **neurogenic secretory diarrhea**. Suppression of secretomotor neuronal excitability (e.g., by morphine or other opioid analgesics) can result in constipation.

Inhibitory junction potentials diminish gut smooth muscle excitability.

Neurotransmitters released from inhibitory musculomotor neurons activate receptors on the muscle cell membranes to generate **inhibitory junction potentials** (**IJPs**) (see Fig. 27.25). The transmembrane hyperpolarization that occurs during IJPs prevents depolarization to the action potential threshold by the ever-present ESWs and suppresses propagation of action potentials.

Early evidence supported a purine nucleotide, possibly ATP, as the transmitter released by ENS inhibitory musculomotor neurons, which led to the term **purinergic neuron**. Evidence now exists that VIP, pituitary adenylate cyclase–activating peptide, and nitric oxide (NO) also act as ENS inhibitory transmitters. Inhibitory musculomotor neurons that express VIP and/or NO synthase (NOS) innervate the circular muscle of the stomach, intestine, gallbladder, and various sphincters.

The longitudinal muscle layer of the small intestine appears not to have a significant inhibitory musculomotor innervation, but there is significant inhibitory musculomotor innervation of the taeniae coli of the large intestine in humans. In contrast to the longitudinal muscle, inhibitory innervation of intestinal circular muscle is essential for ENS programming of intestinal motility.

An absolute requirement for inhibitory neural control of the circular muscle layer is a demand that emerges from the specialized physiology of the musculature (see earlier discussion on electrical syncytial properties). A nonneural pacemaker system of ESWs (i.e., ICCs) accounts for the self-excitable characteristic of the electrical syncytium and the spontaneous contractile activity that characterizes unitary-type smooth muscle. In the integrated system, the ESWs are a separate extrinsic factor to which the circular muscle responds in addition to its motor innervation.

Why does the circular muscle not always respond with action potentials and contract during every slow-wave cycle? Why do action potentials and contractions not spread in the syncytium throughout the entire length and circumference of the intestine each time they occur? The short answer is that inhibitory neuronal motor activity determines when a slow wave can evoke a contraction and determines the distance and direction over which a contraction spreads within the muscular syncytium.

Inhibitory neurotransmitters block phasic contractions in the gut.

Figure 27.26A shows the spontaneous discharge of action potentials occurring in bursts along a neuron in the myenteric plexus of the small intestine of a cat. This kind of continuous discharge of action potentials by subsets of intestinal inhibitory musculomotor neurons occurs in all mammals. The outcome is continuous inhibition of myogenic activity, because in intestinal segments in which neuronal discharge in the myenteric plexus is prevalent, slow wave–associated muscle action potentials and contractile activity are absent or the contractions occur with reduced force with each ESW. Continuous release of VIP and NO has been shown to occur in these kinds of intestinal states. When the inhibitory neuronal discharge is blocked experimentally with tetrodotoxin, every ESW cycle triggers an intense discharge of muscle action potentials associated with a forceful phasic contraction superimposed on a tonic contracture (i.e., a sustained increase in baseline tension). Figure 27.26B shows how phasic contractions, occurring at slow-wave frequency, progressively increase to maximal amplitude during progressive blockade of inhibitory neural activity after the application of tetrodotoxin in the small intestine. This response coincides with a progressive increase in baseline tension.

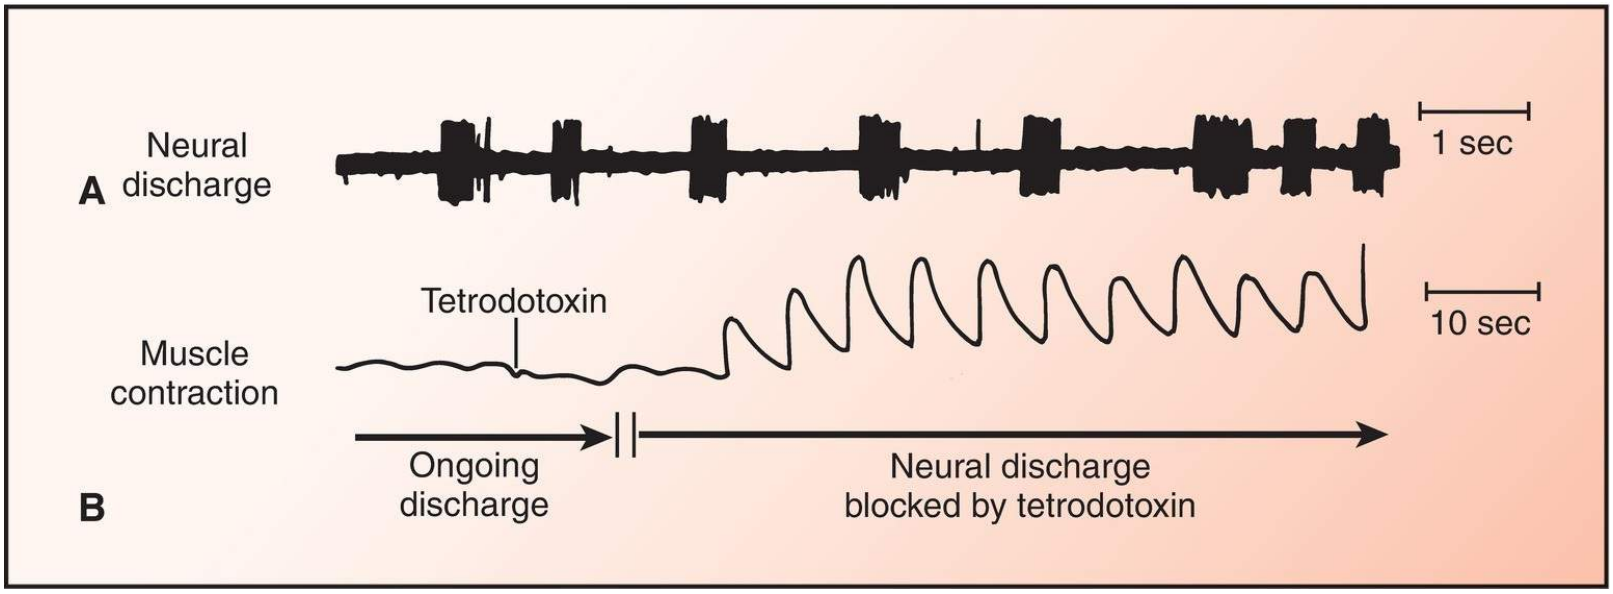

Figure 27.26 Ongoing firing of a subpopulation of inhibitory musculomotor neurons to the intestinal circular muscle prevents electrical slow waves from triggering the action potentials that trigger contractions. When the inhibitory neural discharge is blocked with tetrodotoxin, every cycle of the electrical slow wave triggers discharge of action potentials and large-amplitude contractions. **(A)** Electrical record of ongoing burst-like firing of an inhibitory motor neuron. **(B)** Record of muscle contractile activity before and after application of tetrodotoxin. Application of tetrodotoxin-blocked neuronal firing.

Tetrodotoxin selectively blocks neural activity without affecting the muscle, which makes it a valuable tool for demonstrating ongoing inhibition of contractile activity. Tetrodotoxin acts by selectively blocking neuronal Na^+ channels. The rising phase of circular muscle action potentials reflects opening of Ca^{2+} channels and inward current that is unaffected by tetrodotoxin (see Chapters 3 and 8).

As a general rule, any treatment or condition that removes or inactivates inhibitory musculomotor neurons results in tonic contracture and continuous, uncoordinated contraction of the circular musculature.

Absence of inhibitory musculoneuronal activity is associated with conversion from a hypoirritable to a hyperirritable state of the circular muscle as occurs, for example, following the application of local anesthetics, hypoxia from restricted blood flow to an intestinal segment, an autoimmune attack that destroys enteric neurons, congenital absence in Hirschsprung disease, treatment with opiate drugs, and inhibition of the synthesis of NO.

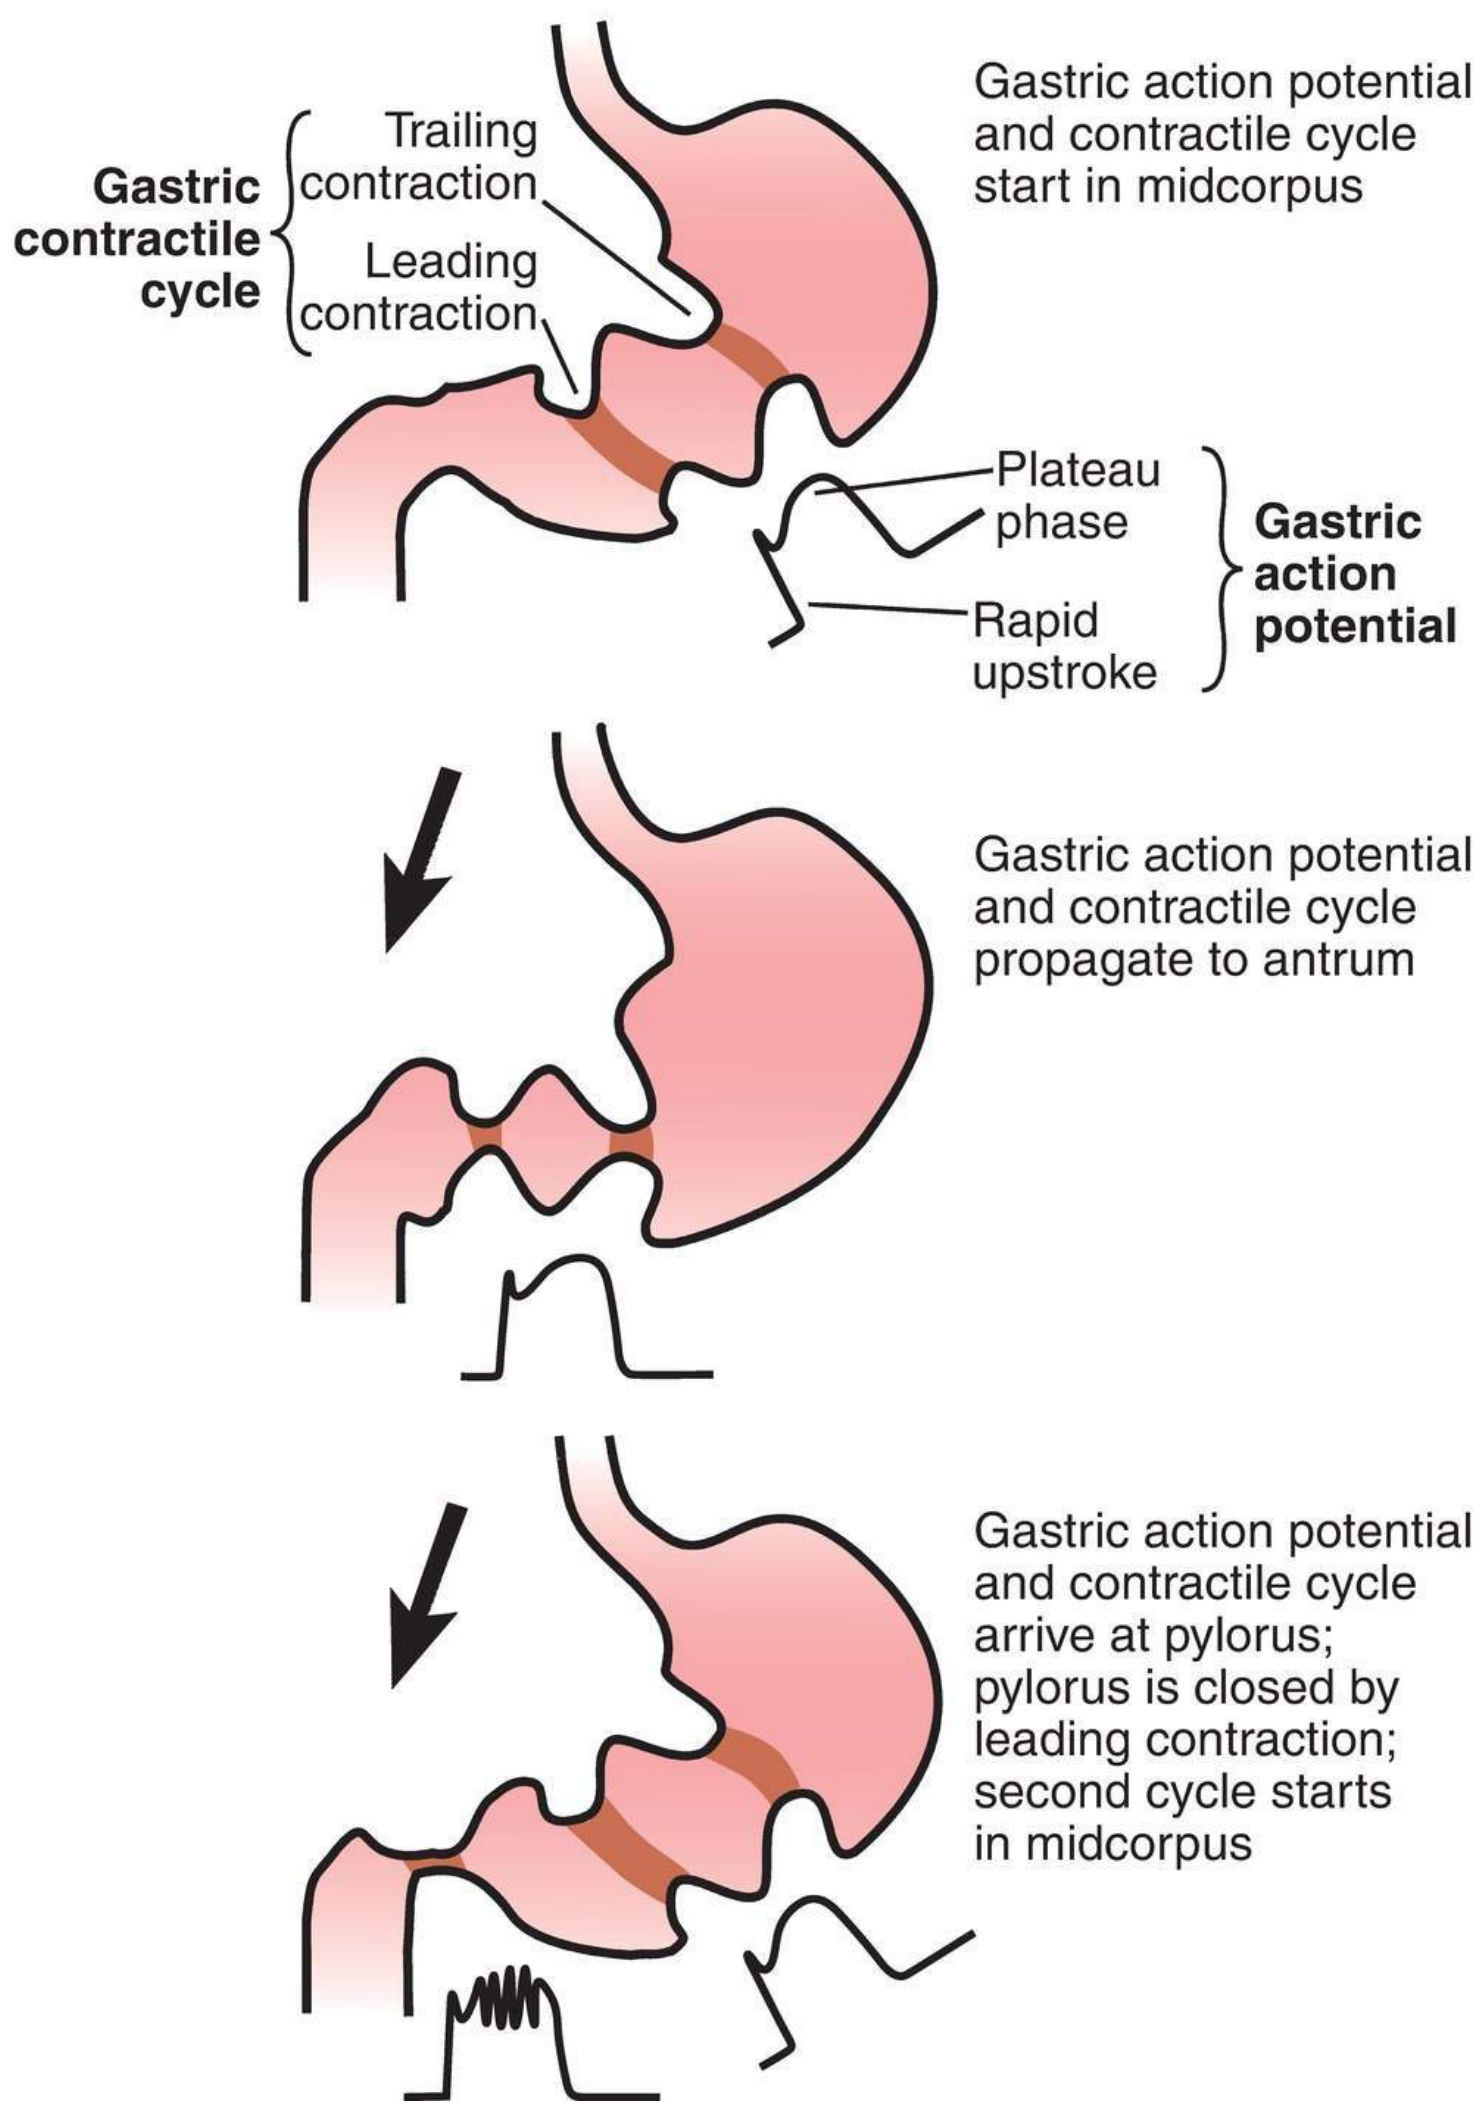
Force of gut smooth muscle contraction is directly related to the activation of the inhibitory neurons.

The force of a circular muscle contraction evoked by a slow-wave cycle is a function of the number of inhibitory musculomotor neurons in an active state. The circular muscle in an intestinal segment can respond to ESWs only when the inhibitory musculomotor neurons are turned off by inhibitory synaptic input from other neurons in the control circuits. This means that inhibitory musculomotor neurons determine when the continuously running slow waves initiate a contraction as well as the force of the contraction, which is determined by the number of muscle fibers responding. With maximum inhibition, no contractions are permitted during a slow-wave cycle (see Fig. 27.7A); with no inhibition, contractions of maximum strength occur since all of the muscle fibers in a segment can be activated (see Fig. 27.7B). Intermediate strength contractions are graded in force according to the number of inhibitory musculomotor neurons that are inactivated during each slow-wave cycle.

Motor behavior of the antral pump consists of leading and trailing contractile components triggered by gastric action potentials.

Gastric action potentials are initiated by a dominant pacemaker (believed to be gastric ICCs) located in the corpus distal to the midregion and determine the duration and strength of the phasic contractions of the antral pump. Once initiated, the action potentials propagate rapidly and spread through the gastric electrical syncytium, traveling around the gastric circumference and triggering a ringlike contraction, which then travels more slowly toward the gastroduodenal junction. The pacemaker region generates action potentials and associated antral contractions at a frequency of 3 contractions/min. The gastric action potential lasts about 5 seconds and has a rising phase (depolarization), a plateau phase, and a falling phase (repolarization) (see Fig. 27.17).

The propulsive contractile behavior in the antral pump has two components; an antral *leading contraction*, of relatively constant amplitude, is associated with the rising phase of the action potential, and an antral *trailing contraction*, of variable amplitude, is associated with the plateau phase (see Fig. 27.27). The gastric pacemaker continuously generates action potentials. Nevertheless, trailing contractions only appear when the plateau phase is at or above threshold, and they increase in strength in direct relation to increases in the amplitude of the plateau potential above threshold.



Gastric contractile cycle
Trailing contraction
Leading contraction
Gastric action potential and contractile cycle start in midcorpus
Plateau phase
Rapid upstroke
Gastric action potential
Gastric action potential and contractile cycle propagate to antrum
Gastric action potential and contractile cycle arrive at pylorus; pylorus is closed by leading contraction; second cycle starts in midcorpus

Figure 27.27 A pacemaker in the antral pump generates gastric action potentials that evoke ringlike contractions as they propagate to the gastroduodenal junction. Gastric action potentials are characterized by an initial rapidly rising upstroke followed by a plateau phase and then a falling phase back to the baseline membrane potential (see Fig. 27.17). The rising phase of the gastric action potential accounts for a leading contraction that propagates toward the pylorus during one propulsive cycle. The plateau phase accounts for the trailing contraction of the cycle. The strength of the leading contraction is relatively constant; the strength of the trailing contraction is variable and increases in direct relation to neurally evoked increases in amplitude of the plateau phase of the action potential.

The leading contractions produced by the rising phase of the gastric action potential have negligible amplitude as they propagate to the pylorus. As the rising phase reaches the terminal antrum and spreads into the pylorus, contraction of the pyloric muscle closes the orifice between the stomach and duodenum. As the trailing contraction, which follows the leading contraction by only a few seconds, approaches the closed pylorus, the gastric contents are forced into an antral compartment of ever-decreasing volume and progressively increasing pressure. This results in jetlike retropulsion through the orifice formed by the trailing contraction (Fig. 27.28). Trituration and reduction in particle size occur as the material is forcibly retropulsed through the advancing orifice and back into the gastric reservoir to wait for the next propulsive cycle. Repetition, at 3 cycles/min, reduces particle size to the 1- to 7-mm range that is necessary before a particle can be emptied into the duodenum during the digestive phase of gastric motility.

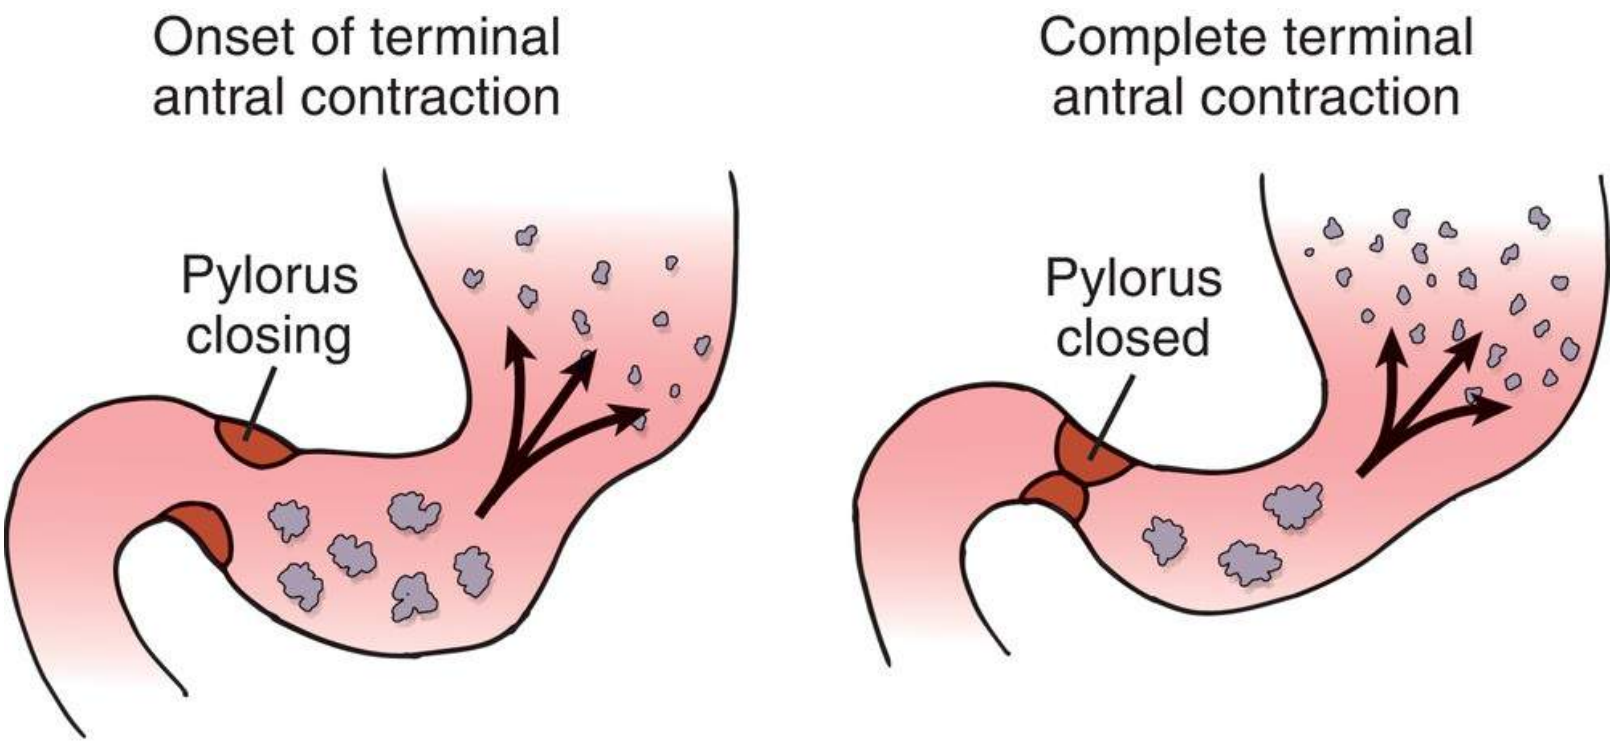


Figure 27.28 Jetlike retropulsion through the orifice of the antral contraction triturates solid particles in the stomach. The force for retropulsion is increased pressure in the terminal antrum as the trailing antral contraction approaches the closed pylorus.

Action potentials in the antral pump are modulated by musculomotor neurons in the gastric ENS.

Action potentials in the antral pump are **myogenic** and modulated by gastric ENS musculomotor neurons. Neurotransmitters, including ACh, released from excitatory musculomotor neurons increase the amplitude of both the plateau phase and the strength of the contraction initiated by the plateau. Inhibitory neurotransmitters including NE and VIP have the opposite effect.

The magnitude of the effects is directly related to the concentration of neurotransmitter present in the neuromuscular junction; an increase in the frequency of action potentials causes a corresponding increase in the amount of neurotransmitter. In this way, the firing of musculomotor neurons determines whether or not a trailing antral contraction occurs. With sufficient release of transmitter, the plateau amplitude grows and starts a contraction as it crosses the depolarization threshold. Beyond threshold, the strength of contraction is determined by the amount of neurotransmitter released and present at receptors on the muscle, which in itself determines the extent of membrane depolarization beyond threshold.

The action potentials in the terminal antrum and pylorus differ somewhat in configuration from those in the more proximal regions. The principal difference is the occurrence of spike potentials on the plateau phase (see Fig. 27.27), which trigger short-duration phasic contractions superimposed on the phasic contraction associated with the plateau. These may contribute to the sphincteric function of the pylorus in preventing the reflux of duodenal contents back into the stomach.

Motor behavior of the gastric reservoir differs from the gastric antrum.

The gastric reservoir has two primary functions. One is to accommodate the arrival of a meal, without a significant increase in intragastric pressure and distention inside the reservoir. Failure of this mechanism leads to the sensations of bloating, epigastric pain, and nausea or *dyspepsia*. The second is to maintain constant compressive forces on the reservoir contents, which act to push the contents into the 3-cycles/min motor activity of the antral pump. Agents that relax the musculature of the gastric reservoir (e.g., insulin) neutralize this function and thereby suppress gastric emptying.

The musculature of the gastric reservoir is innervated by both excitatory and inhibitory musculomotor neurons in the ENS (see Figs. 27.3 and 27.25), and their activity is regulated by efferent vagal nerves. Input from these nerves adjusts the volume and pressure of the reservoir to the amount of solid and/or liquid present while sustaining constant compressive forces on the contents. Continuous adjustments are required during both the ingestion and the emptying of a meal.

An increase in activity of excitatory musculomotor neurons, in concert with decreased activity of inhibitory musculomotor neurons, results in increased contractile tone in the reservoir, a decrease in its volume, and an increase in intraluminal pressure (see Fig. 27.9). An increase in activity of inhibitory musculomotor neurons in concert with decreased activity of excitatory musculomotor neurons produces the opposite set of effects.

Three types of relaxation responses occur in the gastric reservoir.

Neurally mediated decreases in muscle tonic contracture are responsible for initiating gastric reservoir relaxation (i.e., increased volume). The act of swallowing initiates **receptive relaxation**, which is a reflex triggered by stimulation of mechanoreceptors in the pharynx. Distention of the gastric reservoir initiates **adaptive relaxation**, which is a vagovagal reflex that is triggered by stimulation of stretch receptors in the gastric wall (Fig. 27.29). The presence of nutrients in the small intestine initiates **feedback relaxation**. It can involve both local reflex connections between receptors in the small intestine and the gastric ENS or hormones that are released from endocrine cells in the small intestinal mucosa.

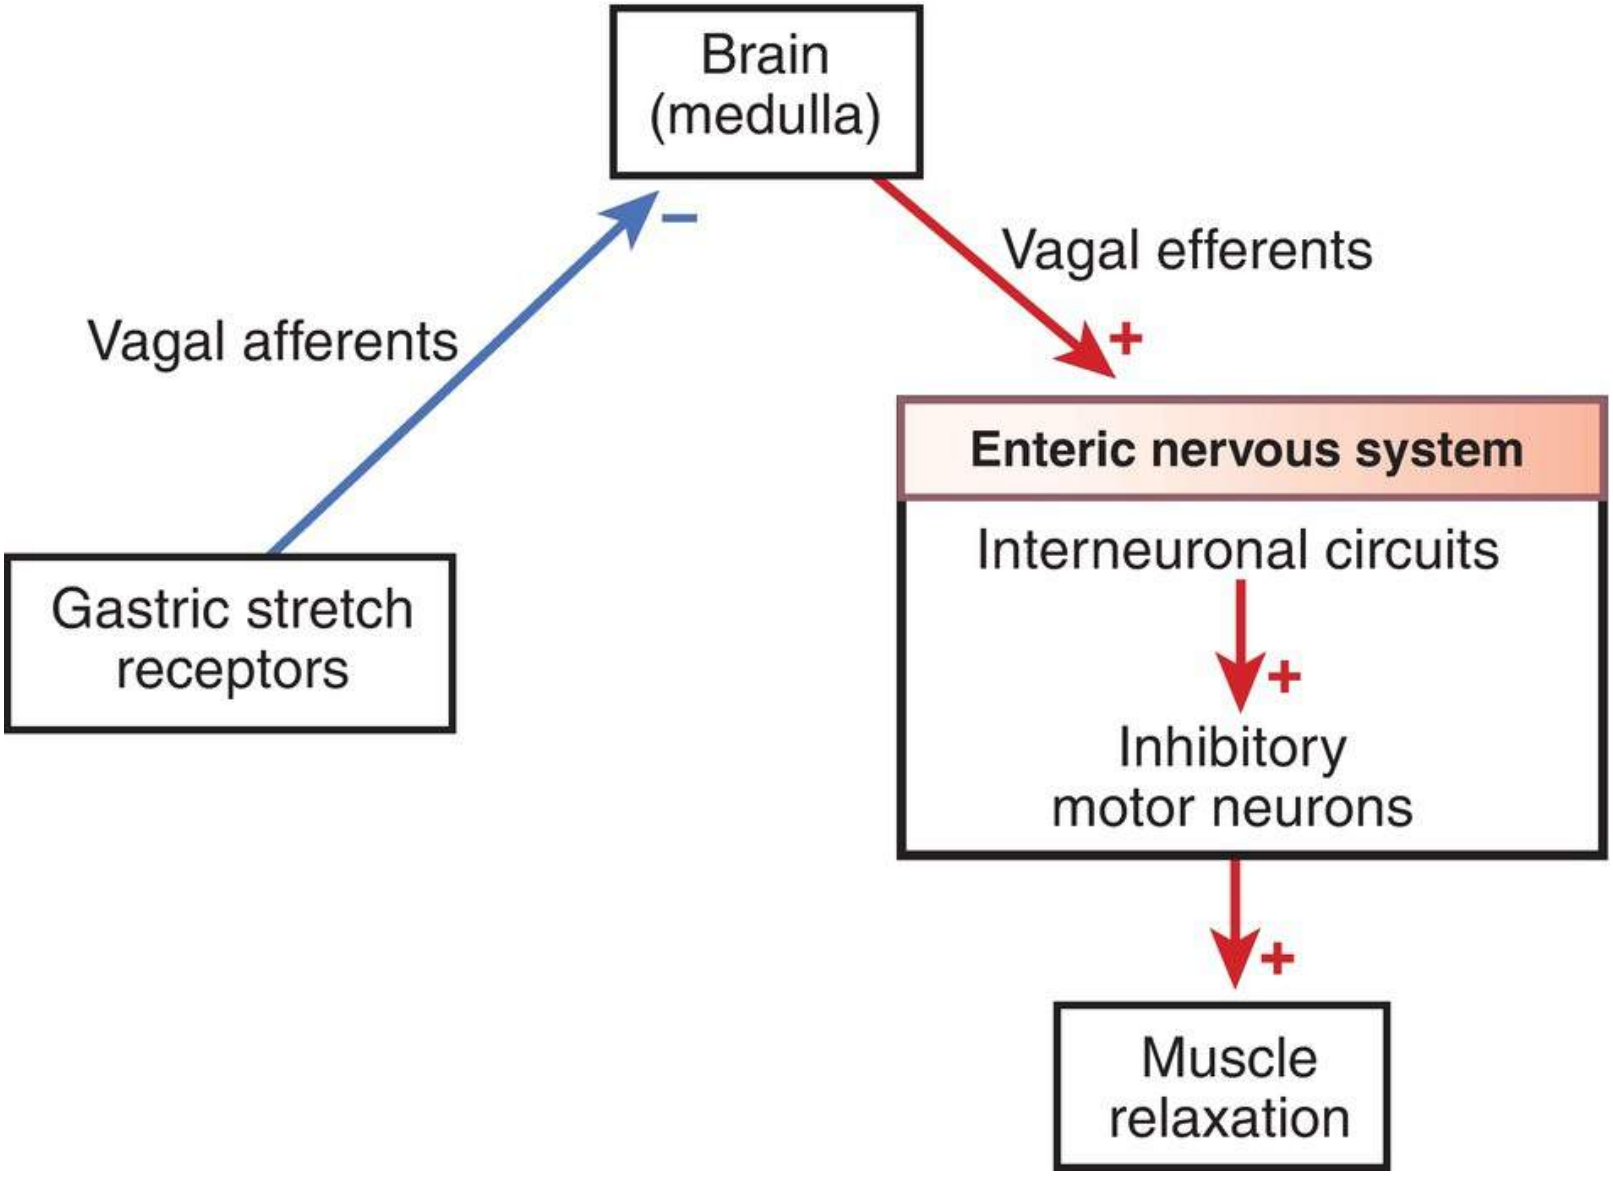

Figure 27.29 Adaptive relaxation in the gastric reservoir is a vagovagal reflex in which information from gastric stretch receptors is the afferent arm of the reflex and outflow from the medullary region of the brain is the efferent component. Vagal efferents transmit to the enteric nervous system, which controls the activity of inhibitory motor neurons that relaxes contractile tone in the reservoir.

Adaptive relaxation is lost in patients who have undergone a vagotomy or it can occur as an iatrogenic result of fundoplication surgery for the treatment of an incompetent LES and acid reflux

disease. Following a vagotomy, increased tone in the reservoir musculature decreases the wall compliance, which in turn changes the response of gastric stretch receptors to distention of the reservoir (Fig. 27.30). The loss of adaptive relaxation after a vagotomy is associated with a lowered threshold for sensations of epigastric fullness and pain. These effects of vagotomy may explain disordered gastric sensations in diseases with a component of vagal nerve pathology (e.g., autonomic neuropathy of diabetes mellitus).

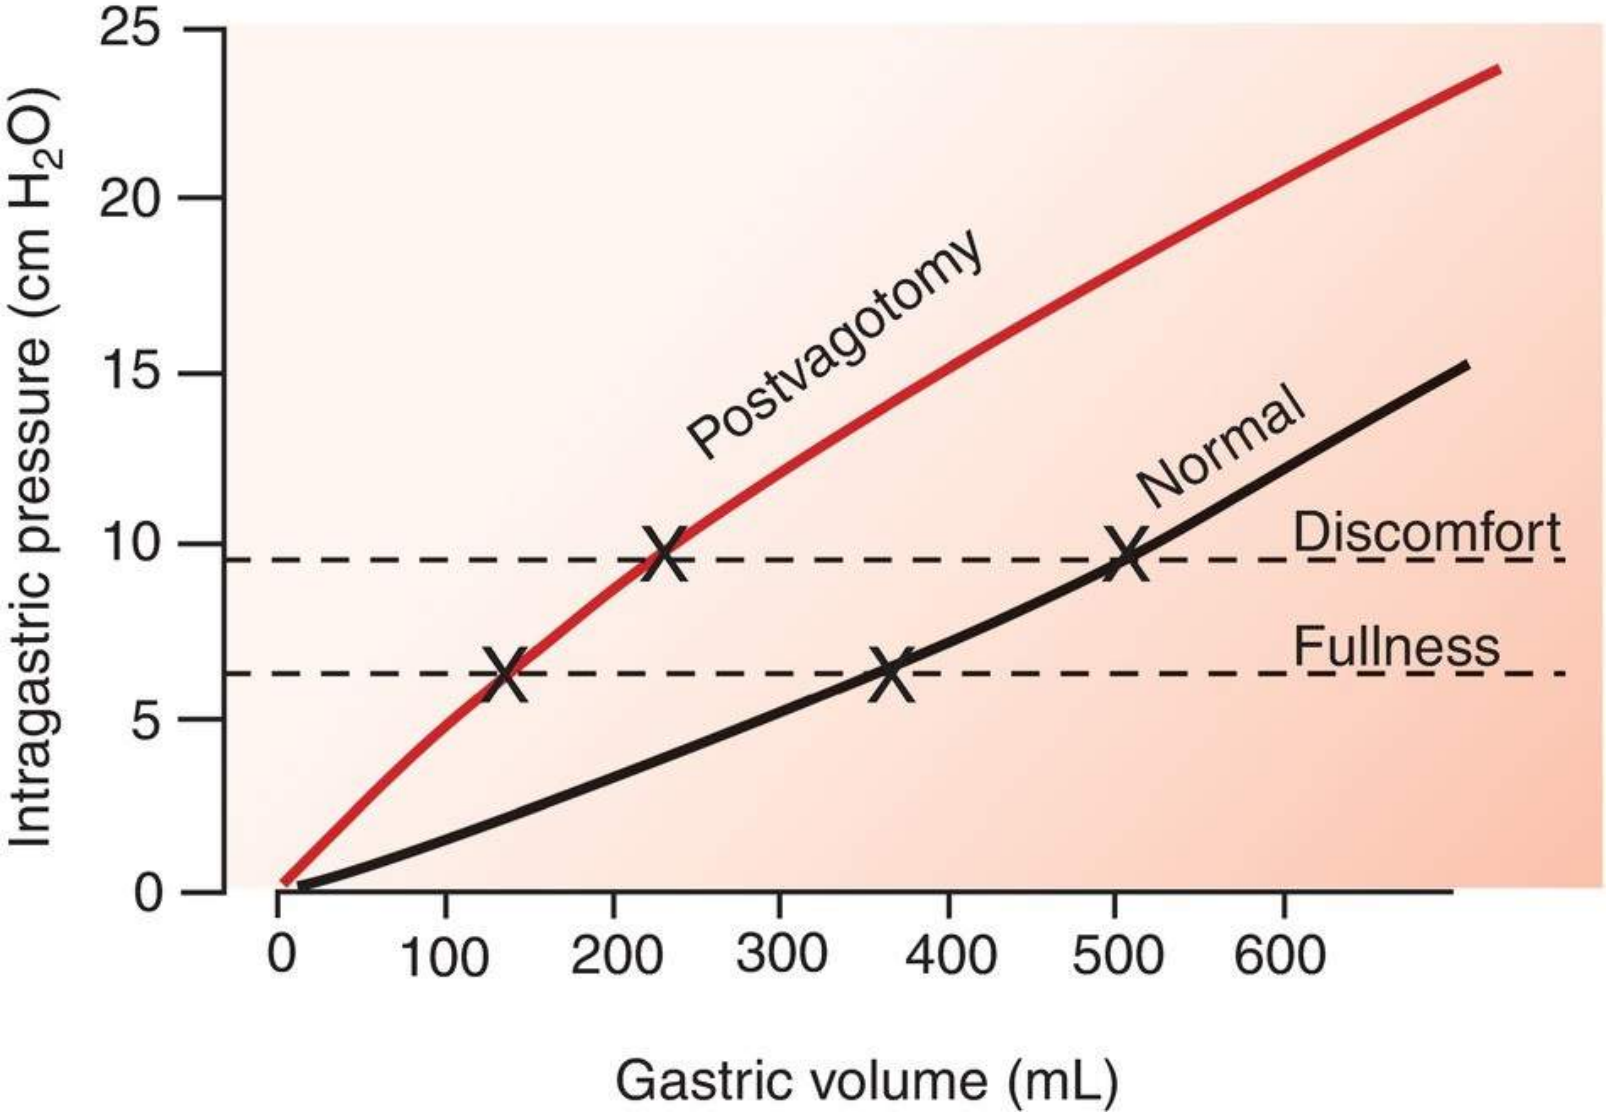

Figure 27.30 Adaptive relaxation of the gastric reservoir is lost following a vagotomy. Loss of adaptive relaxation in the gastric reservoir is associated with a lowered threshold for sensations of fullness and epigastric pain.

Motor patterns in the stomach and small intestine reflect the presence and absence of intraluminal nutrients.

The small intestinal ENS "runs" the **digestive state** motor program when nutrients are present and digestive processes are ongoing. Conversion to the **interdigestive state** motor program starts when digestion and absorption of nutrients are complete, 2 to 3 hours after a meal. The motility pattern of the interdigestive state in the small intestine is called the **migrating motor complex** (**MMC**). The MMC starts as large forceful contractions at 3 contractions/min in the antral pump. Elevated contractile force in the LES coincides with the onset of the MMC in the stomach, which then migrates into the duodenum and down the small intestine to the ileum (Fig. 27.31).

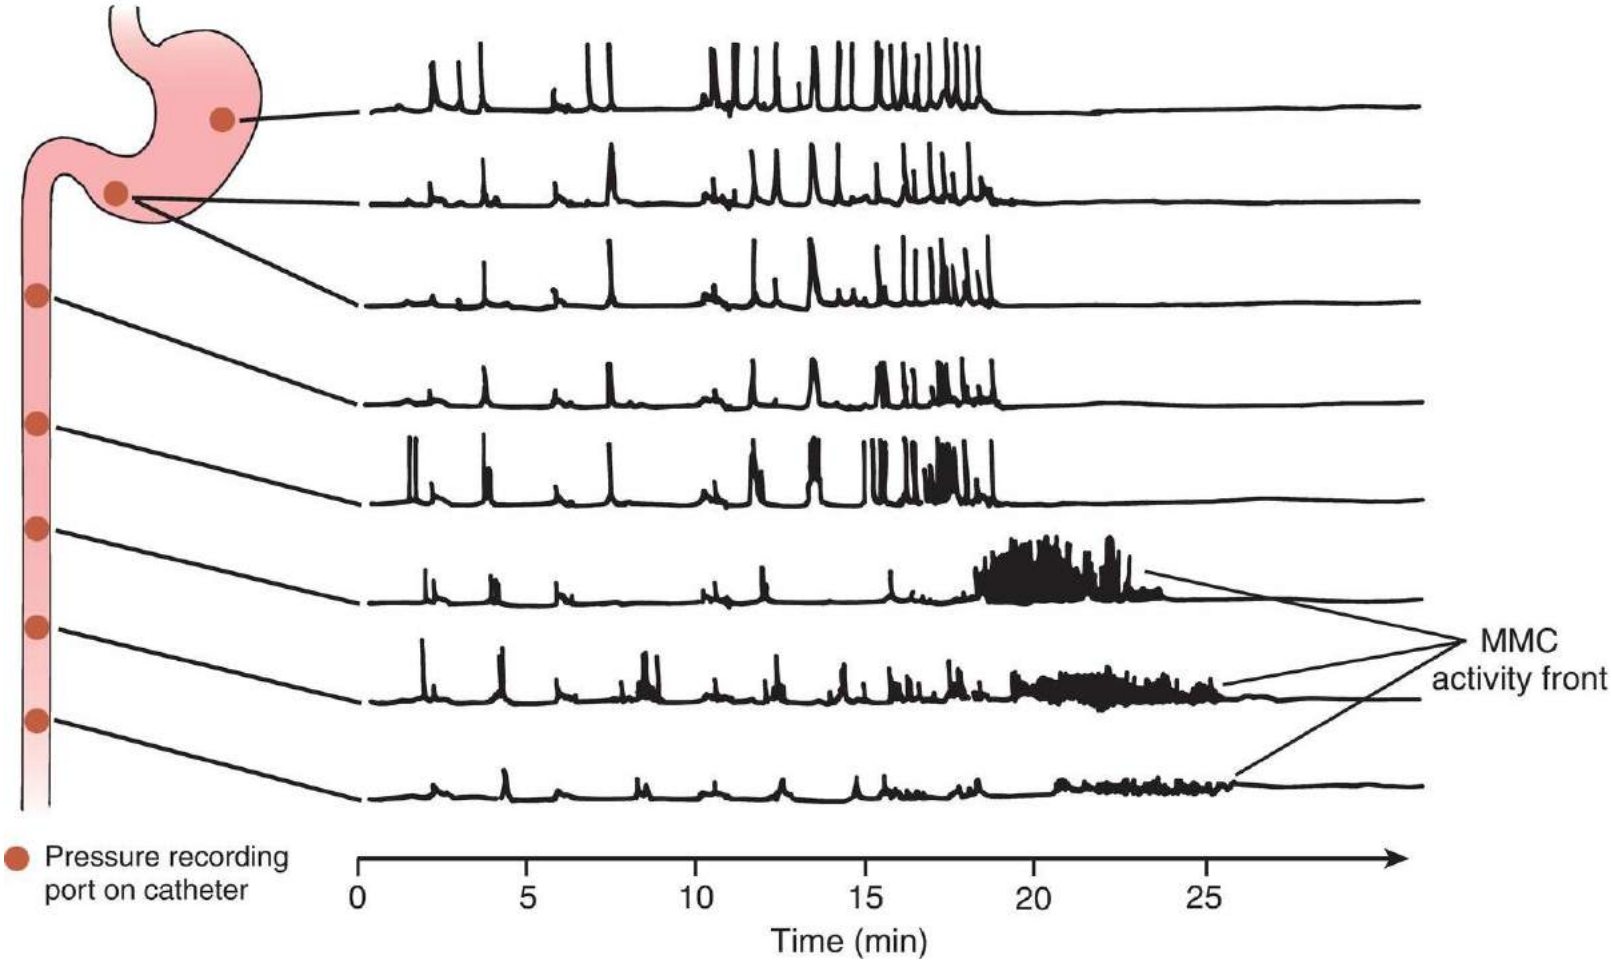

Figure 27.31 The small intestinal migrating motor complex (MMC) consists of an activity front that starts in the gastric antrum and slowly migrates through the small intestine to the ileum. Repetitive contractions, which reflect peristaltic propulsion, occur within the activity front.

At a single recording site in the small intestine, the MMC consists of three consecutive phases:

- Phase I: motor silence without contractile activity; corresponds to physiologic ileus
- Phase II: irregularly occurring contractions
- Phase III: regularly occurring contractions

Phase I returns after phase III, and the cycle repeats at the single recording site after 80 to 120 minutes

(see Fig. 27.31). With multiple sensors positioned along the intestine, slow propagation of the phase II and phase III activity down the intestine becomes evident.

At a given time, the MMC occupies a limited length of intestine called the **activity front**, which has an oral and aboral boundary (Figs. 27.31 and 27.32). The activity front slowly advances along the intestine at a rate that progressively slows as it approaches the ileum. Peristaltic propulsion of luminal contents occurs in the aboral direction between the oral and aboral boundaries of the activity front. The frequency of the peristaltic propulsive waves within the activity front is the same as the frequency of ESWs in that intestinal segment. Each peristaltic wave consists of propulsive and receiving segments, as described earlier (see Fig. 27.4). Successive peristaltic waves start on average slightly farther in the aboral direction and propagate on average slightly beyond the boundary where the previous one stopped. Therefore, the entire activity front slowly advances down the intestine, sweeping the lumen clean as it goes.

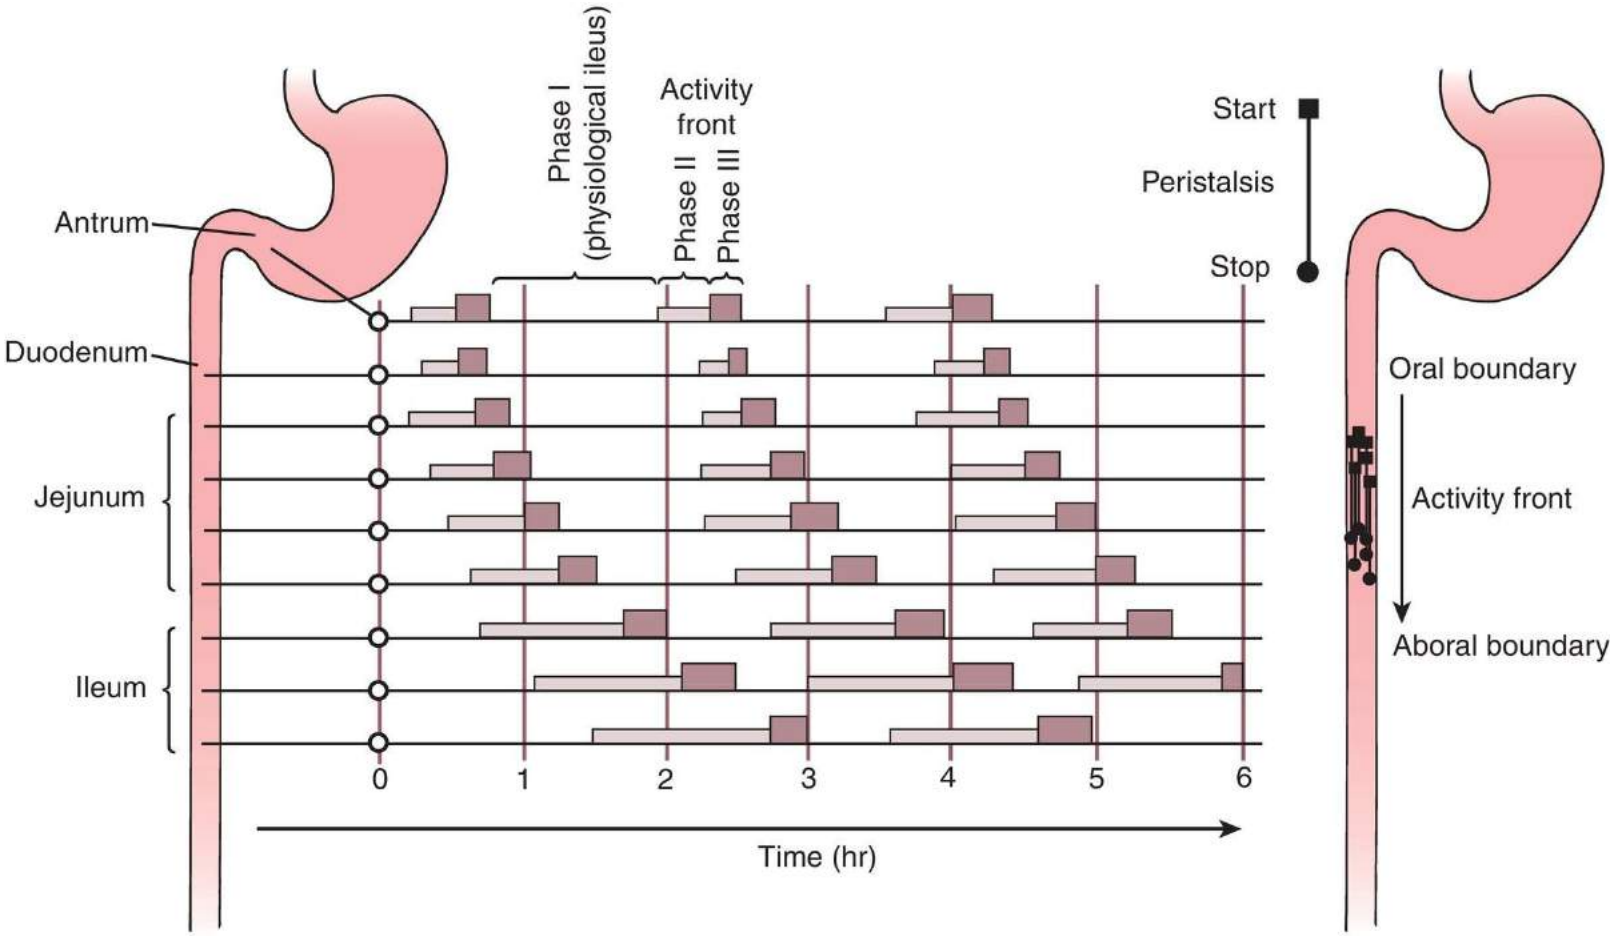

Figure 27.32 The migrating motor complex (MMC) consists of three phases. Phase I of physiological ileus refers to the intestinal region with no activity. Phases II and III reflect the migrating activity front, which has an aboral boundary where propulsive contractions stop and an oral boundary where propulsive contractions start. (See text for details.)

"Phase II" and "phase III" are commonly used terms that have minimal value for understanding the MMC. Contractile activity described as phase II or phase III occurs because of the irregularity of the arrival of peristaltic waves at the aboral boundary of the activity front. On average, each consecutive peristaltic wave within the activity front propagates farther in the aboral direction than the previous wave. Nevertheless, at the lower boundary of the activity front, some waves terminate early and others

travel farther (see Fig. 27.32). Therefore, as the lower boundary of the front passes the recording point, only the waves that reach the sensor are recorded, giving the appearance of irregular contractions. As propagation continues and the midpoint of the activity front reaches the recording point, the propulsive segment of every peristaltic wave is detected. Because the peristaltic waves occur with the same rhythmicity as the ESWs, the contractions are described as being "regular." The regular contractions, which are seen when the central region of the front passes a single recording site, last for 8 to 15 minutes. This time is shortest in the duodenum and progressively increases as the MMC migrates toward the ileum. The MMC occurs in conscious states and during sleep. It starts in the antrum of the stomach as an increase in the strength of the regularly occurring antral contractile complexes and accomplishes the emptying of indigestible particles (e.g., pills and capsules) larger than 7 mm. Eighty to one-hundred and twenty minutes is required for the activity front of the MMC to travel from the antrum to the ileum. As one activity front terminates in the ileum, another begins in the antrum. The time between cycles is longer during the day than that at night. The activity front travels at about 3 to 6 cm/min in the duodenum and progressively slows to about 1 to 2 cm/min in the ileum. It is important not to confuse the speed of travel of the activity front of the MMC with that of the ESWs, action potentials, and peristaltic waves within the activity front. ESWs with associated action potentials and associated contractions of circular muscle travel about 10 times faster.

Cycling of the MMC continues until it is ended by the physical presence of a meal in the upper digestive tract. A sufficient nutrient load terminates the MMC. Intravenous feeding does not stop the MMC. The speed with which the MMC is terminated, wherever it is along the intestine, suggests a neural or hormonal mechanism. Gastrin and cholecystokinin, both of which are released during a meal, terminate the MMC in the stomach and upper small intestine, but not in the ileum, when injected intravenously.

The ENS organizes the MMC (see Fig. 27.3). It continues in the small intestine after a vagotomy or sympathectomy but stops when it encounters a region of the intestine where the ENS has been interrupted. Presumably, command signals to the ENS are necessary for initiating the MMC, but whether the commands are neural, hormonal, or both remains unknown. Although levels of the hormone **motilin** increase in the blood at the onset of the MMC, it is unclear whether motilin is the trigger or is released as a consequence of MMC occurrence.

MMMC acts as “housekeeper” for the small intestine.

Gallbladder contraction and delivery of bile to the duodenum are coordinated with the movement of the MMC into the antroduodenal region. The activity front of the MMC propels the bile from the duodenum through the jejunum to the terminal ileum, where it is reabsorbed into the hepatic portal circulation. This mechanism minimizes the accumulation of concentrated bile in the gallbladder and increases the movement of bile acids in the enterohepatic circulation during the interdigestive state (see Chapter 25).

The MMC also appears to be a mechanism for clearing indigestible debris from the intestinal lumen during the fasting state. Large indigestible particles are emptied from the stomach only during the MMC.

Bacterial overgrowth in the small intestine is associated with an absence of the MMC. This condition suggests that the MMC might play a “housekeeper” role in preventing the overgrowth that would occur if the intestinal contents were allowed to stagnate in the lumen.

INTEGRATED MEDICAL SCIENCES

Opioids Used as Part of Postoperative Pain Management Contribute to Ileus

Intestinal ileus describes the temporary condition in which intestinal peristalsis stops and consequently so does normal propulsion along the intestines. Abdominal distention, vomiting, nausea, gas, and abdominal pain and discomfort are problems that are often associated with opioid-induced bowel dysfunction and postoperative ileus. The occurrence of postoperative ileus does not appear to be specifically linked to the type of surgery. Ileus is a frequent postoperative problem in patients who have had bowel resection or other procedures that involve abdominal surgery, but ileus can also be observed in patients who have undergone nonabdominal surgeries such as cardiac or orthopedic procedures. This indicates that ileus is not linked to the direct manipulation of the intestine. However, surgical patients do share a common thread and that is the pharmacological management of postoperative pain. This management involves the use of opioids such as morphine and codeine. In fact, opium was used to manage pain by the early Greeks and Romans, and its pain-quelling properties were described in a Roman pharmacology textbook, *De Materia Medica*, published in the last part of the first century.

Opioids are considered to be any compound that has the same effects as morphine. In the GI tract, opioids have antisecretory effects and have long been used to treat diarrhea (e.g., paregoric, codeine). Opioid receptors are in a family of G protein–coupled receptors. There are three main types of opioid receptors, mu (μ), delta (κ), and kappa (δ). *In vivo*, these receptors normally bind enkephalins, endorphins, and dynorphins, which are naturally occurring opioid peptides. This is one mechanism for *in vivo* modulation of nociception (i.e., pain pathways). Endogenous opioids suppress intestinal motility in certain situations such as during an inflammatory response and a stress response. Exogenously delivered opioids provide analgesic modulation of pain. The μ receptors are the main group to which postoperative prescribed opioids bind. This binding initiates the pathway leading to

the manifestation of the clinical effects of these drugs. Within the CNS, opioids contribute to analgesia, sedation, and the alteration of mood. In the CNS, opioids affect the sympathetic connections, both excitatory and inhibitory motor pathways, to the ENS. This input from the CNS modifies the normal ENS regulation of GI. In the GI tract, opioids act directly in the ENS, which has μ receptors on cells located in the myenteric and submucosal plexuses. The combined end result of activating nervous system opioid receptors is an inhibition of secretion, a decrease in aboral motility, and an inhibition of peristaltic reflexes. This leads to opioid-induced constipation.

Naloxone acts as a μ receptor antagonist to reverse the effects of opioids by overcoming the blocking action opioids have on the peristaltic reflex. However, the drug does not appear to equally impact transit times along the length of the intestine. While it does accelerate colonic transit time, it has no similar affect in the small intestine. Naloxone does effectively restore peristaltic muscle contraction and thus propulsion along the intestinal tract. A drawback to naloxone administration is that it can decrease the analgesic effects of opioids. In clinical investigations, methylnaltrexone was investigated as a possible alternative to naloxone. Methylnaltrexone helps to return gut function while not blocking the analgesic benefit provided by opioid administration. Another alternative, alvimopan, has been shown to have similar postoperative benefits, particularly in patients who have undergone bowel resection. Alvimopan is administered prior to surgery to block opiate binding. The therapeutic benefits of alvimopan show a dose-dependent response. The use of stool softeners and laxatives is generally ineffective at combating opioid-associated constipation. Mild osmotic agents have also been tried.

Opioid receptors are not limited to the ENS and are also present on the surface of intestinal smooth muscle cells. Opioids can affect motility along the GI tract by stimulating a change in the muscle contraction pattern from the normal electrical slow wave–generated contractions driving movement of the luminal contents aborally to a contraction pattern that results in nonpropulsive motility and stagnation. The absence of peristaltic propulsion increases transit time through the intestine. In addition to effecting longitudinal muscle activity, the drugs also affect circular muscle and intestinal segmentation, overall smooth muscle tone, and therefore contraction in intestinal smooth muscle sphincters. Tonus in the pyloric and anal sphincters is increased and relaxation of the LES is inhibited. While the antegrade movement of the luminal contents is delayed, there is a concurrent dehydration of the lumen as a result of increased fluid absorption that is coupled with decreased secretion of both water and electrolytes.

Postoperative ileus is an example of a condition that has no one specific cause, but rather, it is a physiological condition that occurs when several contributing factors interact. The nervous system and various hormones (e.g., vasoactive intestinal peptide and substance P) as well as localized inflammatory responses and mediators such as prostaglandins are thought to play a role in postoperative ileus. In general, GI function and coordinated electrical activity do not return uniformly to the GI tract following postoperative ileus. Initially, during the recovery period, the sympathetic nervous system is highly active and the electrical activity along the tract is disorganized and erratic. Signals from the sympathetic nervous system inhibit activity in the ENS. In the absence of normal electrical patterns, regular peristalsis and propulsion do not occur. It usually takes 3 to 4 days for stomach and small intestine to return to normal activity. The colon, which is the region of the GI tract most affected by anesthetics due to the absence of gap junctions, is often the last section to return to normal. Total recovery of the GI tract from ileus can take as long as 4 to 5 days. ■

Chapter Summary

- The musculature of the digestive tract is mainly smooth muscle.
- Electrical slow waves and action potentials are the primary forms of electrical activity in the gastrointestinal (GI) musculature.
- GI smooth muscles have properties of a functional electrical syncytium.
- A hierarchy of neural integrative centers in the brain, spinal cord, and periphery determines moment-to-moment behavior of the digestive tract.
- The digestive tract is innervated by the sympathetic, parasympathetic, and enteric divisions of the autonomic nervous system.
- Vagus nerves transmit afferent sensory information to the brain and parasympathetic autonomic efferent signals to the digestive tract.
- Splanchnic nerves transmit sensory information to the spinal cord and sympathetic autonomic efferent signals to the digestive tract.
- The enteric nervous system functions as an independent mini-brain in the gut.
- Fast and slow excitatory postsynaptic potentials, slow inhibitory postsynaptic potentials, presynaptic inhibition, and presynaptic facilitation are key synaptic events in the enteric nervous systems.
- Enteric musculomotor neurons may be excitatory or inhibitory.
- Enteric inhibitory musculomotor neurons to the intestinal circular muscle are continuously active and transiently inactivated to permit muscle contraction.
- Enteric inhibitory musculomotor neurons to the musculature of sphincters are inactive and transiently activated for the timed opening and passage of luminal contents.
- A polysynaptic reflex circuit determines the behavior of the intestinal musculature during peristaltic propulsion.
- Physiological ileus is the normal absence of contractile activity in the intestinal musculature.
- Peristaltic propulsion and relaxation of the lower esophageal sphincter are the main motility events in the esophagus.
- The gastric reservoir and antral pump have different kinds of functional motor behavior.
- Vagovagal reflexes are important in the control of gastric motor functions.
- Feedback signals from the duodenum determine the rate of gastric emptying.
- The migrating motor complex is the small intestinal motility pattern of the interdigestive state.
- Mixing movements are the small intestinal motility pattern of the digestive state.
- Intestinal power propulsion is a protective response to harmful agents.
- Motor functions of the large intestine are specialized for storage and dehydration of feces.
- Physiologic functions of the rectosigmoid region, anal canal, and pelvic floor musculature are responsible preserving fecal continence.

Chapter Review Questions

1. A mouse with a new genetic mutation is discovered not to have electrical slow waves in the small intestine. Identify which of the following cell types was most likely affected by the mutation.

A. Enteric neurons
B. Inhibitory motor neurons
C. Mechanoreceptor
D. Interstitial cells of Cajal
E. Enteroendocrine cells

The correct answer is D. Interstitial cells of Cajal are the pacemaker cells that generate electrical slow waves. Enteric neurons, inhibitory motor neurons, mechanoreceptors, and enteroendocrine cells do not generate electrical slow waves.

2. Examination of the properties of a normal sphincter in the digestive tract will show that:

A. primary flow across the sphincter is unidirectional.
B. the lower esophageal sphincter is relaxed at the onset of a migrating motor complex in the stomach.
C. blockade of the sphincteric innervation by a local anesthetic causes the sphincter to relax.
D. the manometric pressure in the lumen of the sphincter is less than the pressure detected in the lumen on either side of the sphincter.
E. the inhibitory motor neurons to the sphincter muscle stop firing during a swallow.

The correct answer is A. Sphincters function to prevent reflux; therefore, flow across a sphincter is generally unidirectional. Tone in the lower esophageal sphincter is increased during the MMC in the stomach. The sphincter cannot be relaxed after blockade of the inhibitory innervation by a local anesthetic. Pressure in the sphincter is higher than in the two compartments it separates. Inhibitory neurons fire to relax the sphincter during a swallow.

3. An 86-year-old female complains of a compromised lifestyle because of fecal incontinence. Examination of this patient will most likely reveal the underlying cause of the incontinence to be:

A. absence of the rectoanal reflex.
B. elevated sensitivity to the presence of feces in the rectum.
C. loss of the enteric nervous system in the distal large intestine (adult Hirschsprung disease)
D. weakness in the puborectalis and external anal sphincter muscles.
E. a myopathic form of chronic pseudoobstruction in the large intestine.

The correct answer is D. Examination of elderly patients often reveals weakness in the pelvic floor musculature. Weakness in the puborectalis muscle allows the anorectal angle to straighten and lose its barrier function to the passage of feces into the anorectum. The rectoanal reflex (i.e., relaxation of the internal anal sphincter in response to distention of the rectum) does not weaken significantly in the elderly. A deficit in sensory detection, not elevated sensitivity, can be a factor in fecal incontinence. Adult Hirschsprung disease results in constipation, not incontinence. The myopathic form of pseudoobstruction is not associated with fecal incontinence because propulsive motility is absent due to weakening of the intestinal smooth muscle.

4. On a return visit after receiving a diagnosis of functional dyspepsia, a 35-year-old female reports sensations of early satiety and discomfort in the epigastric region after a meal. These symptoms are most likely due to:

A. malfunction of adaptive relaxation in the gastric reservoir.
B. elevated frequency of contractions in the antral pump.
C. an incompetent lower esophageal sphincter.
D. premature onset of the interdigestive phase of gastric motility.
E. bile reflux from the duodenum.

The correct answer is A. As the gastric reservoir fills during ingestion of a meal, mechanoreceptors signal reservoir volume to the brain via vagal afferents. When the limits of adaptive relaxation in the reservoir are reached, signals from the stretch receptors in the reservoir's walls account for the sensations of fullness and satiety. Overdistention is perceived as discomfort. Adaptive relaxation malfunctions in the forms of functional dyspepsia characterized by the symptoms described in this question. When adaptive relaxation is compromised (e.g., by an enteric neuropathy), mechanoreceptors are activated at lower distending volumes and the brain wrongly interprets the signals as if the gastric reservoir were full. Elevated frequency of contractions in the antral pump, an incompetent lower esophageal sphincter, premature onset of the interdigestive phase of gastric motility, or bile reflux from the duodenum would not be expected to activate mechanosensory signaling of the state of fullness of the gastric reservoir.

Clinical Application Exercises 27.1

HEARTBURN

A 67-year-old woman experienced heartburns after eating. The heartburn was most severe after a large meal or eating a meal with a high-fat diet. Recently, she started having heartburns after her morning coffee, after taking her vitamins, or in the evening after drinking a glass of wine. At nights, she would wake up coughing with a burning sensation in her throat. She often experienced wheezing after these episodes. At her next visit with her internist, she mentioned her symptoms. She informed her internist that the burning sensation had been going on for the last 5 years but seemed manageable. She said things improved after she started sleeping on her side instead of her stomach. However, in the last year, the symptoms have gotten worse. After further examination, she was referred to a gastroenterologist for further tests. After a detailed history, a diagnostic endoscopic procedure was performed. The patient was sedated and a thin scope was inserted through the mouth and throat into the esophagus and stomach in order to assess the internal surface of the esophagus, stomach, and duodenum. The endoscopic examination revealed that the patient was suffering from gastroesophageal reflux disease (GERD) with early stages of Barrett esophagus.

QUESTIONS

1. What is the pathophysiology of GERD and what are the contributing factors?
2. What is contributing to the woman's wheezing?
3. What is the relationship between GERD and Barrett esophagus?

ANSWERS

1. Gastroesophageal reflux disease is defined as chronic mucosal damage produced by the abnormal reflux of gastric contents into the esophagus. In healthy patients, the angle of His, the angle at which the esophagus enters the stomach, is intact creating a valve that prevents duodenal bile,

enzymes, and gastric acid from traveling back into the esophagus where it can cause burning and inflammation of the sensitive esophageal tissue. In GERD patients, acid reflux is caused by a failure of the antireflux barrier and its primary component, the gastroesophageal valve.

There are a number of factors that contribute to GERD. Certain type of foods and life styles are considered to promote gastroesophageal reflux. Coffee, alcohol, and large doses of vitamin C supplements are stimulants to gastric acid secretion. Taking these before bedtime compounds the problem of acid reflux. Chocolate and eating spicy foods also contribute to acid reflux. Lifestyles also contribute to gastric acid reflux. Being overweight, eating large meals, foods high in fat, and smoking reduce lower esophageal sphincter competence. Fat also delays the emptying of the stomach. Eating shortly before bedtime also contributes acid reflux.

2. Wheezing usually occurs at night but can occur during the day. Muscles around the esophagus go into spasm with certain postures (slouched or sleeping on ones stomach). As a result, there is no straight path between the stomach and the esophagus. This causes gas and acid to get blocked in the spasm causing coughing and asthma-like symptoms (e.g., wheezing). In severe cases, contents of the acid reflux get into the airway and irritate the lining that induces coughing and wheezing.
3. About 10% of patients who have GERD are diagnosed with Barrett esophagus. Barrett esophagus is a condition in which cells lining the lower esophagus become metastatic. Barrett esophagus is considered to be a premalignant condition and is associated with high risk of esophageal cancer. At present, there is no clinical test to determine which patient with Barrett esophagus become cancerous.

PART VIII TEMPERATURE REGULATION AND EXERCISE PHYSIOLOGY

28 Regulation of Body Temperature

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how the body produces heat and exchanges energy with the environment.
- Explain how sweating, skin blood flow, and metabolic heat production help regulate body temperature.
- Explain how the thermoregulatory set point varies cyclically and is elevated during fever.
- Explain the reflex control of physiologic thermoregulatory responses.
- Explain temperature alterations during exercise in various environments.
- Explain the process of acclimatization to hot and cold environments.
- Explain the adverse effects of excessive heat stress, heat injury, and excessive cold stress.

Humans are warm-blooded animals or **homeotherms**. Like other mammals, humans are able to regulate their internal body temperatures within a narrow range near 37°C, despite wide variations in environmental temperature (Fig. 28.1). In contrast, internal body temperatures of **poikilotherms**, or cold-blooded animals, are governed by environmental temperature. The range of temperatures that living cells and tissues can tolerate without harm extends from just above freezing to nearly 45°C—far wider than the limits within which homeotherms regulate body temperature. What biologic advantage do homeotherms gain by maintaining a stable body temperature? As we shall see, tissue temperature is important for two reasons.

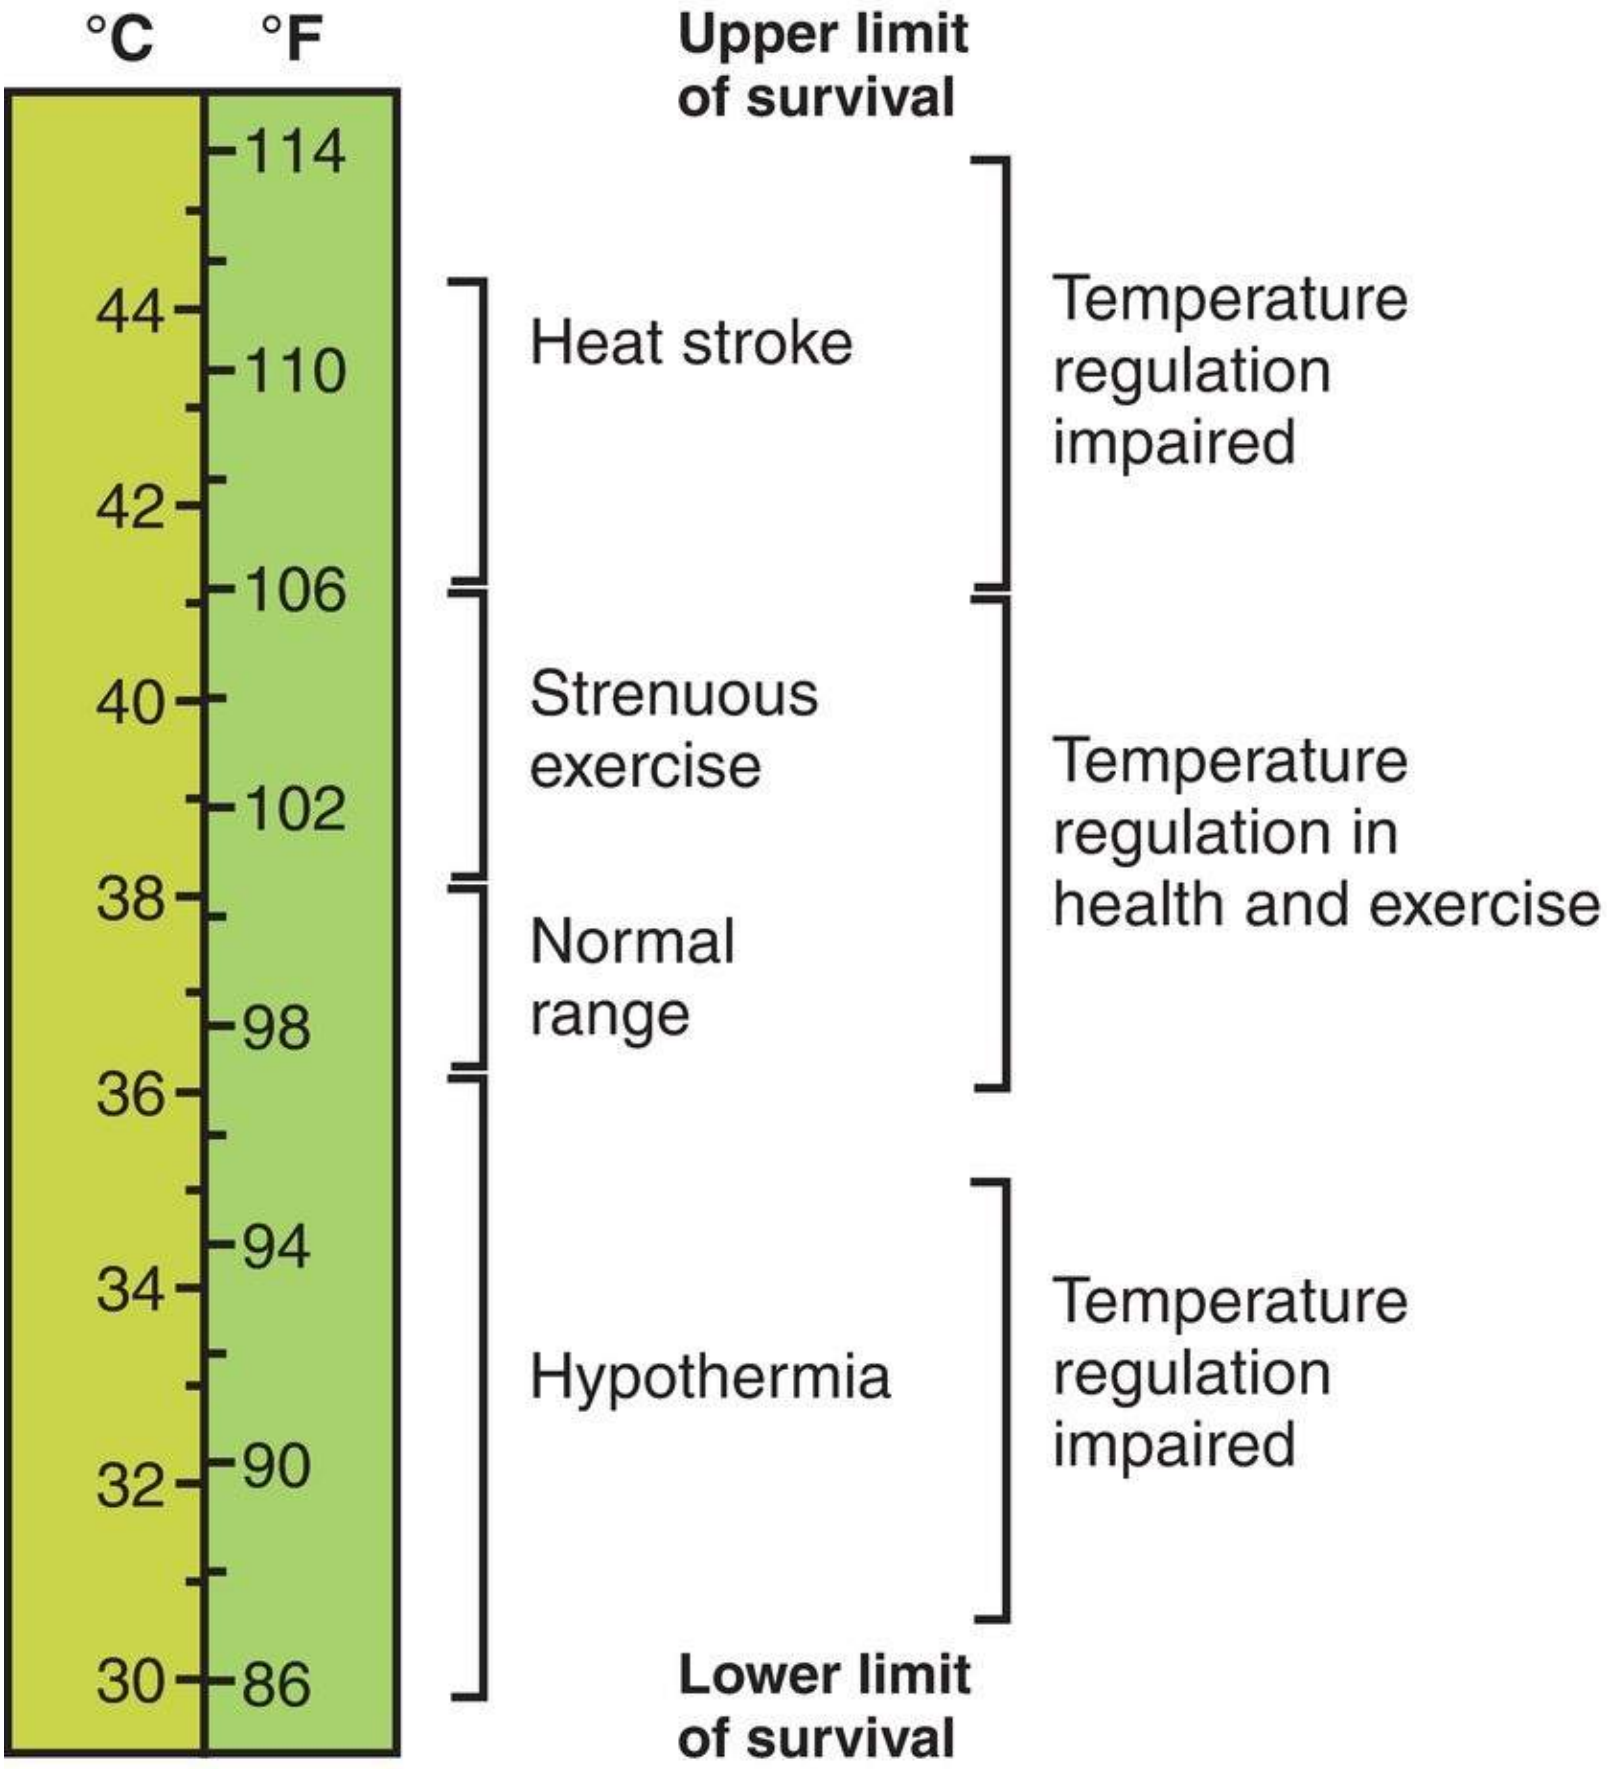

Figure 28.1 Survival ranges of body temperatures in humans.

First, temperature extremes injure tissue directly. High temperatures alter the three-dimensional structure of protein molecules, even though the sequence of amino acids remains unchanged. Such alteration of protein structure is called **denaturation**. Because the biological activity of a protein molecule depends on its configuration and charge distribution, denaturation inactivates a cell's proteins

and injures or kills the cell. Injury occurs at tissue temperatures higher than about 45°C, which is also the point at which heating the skin becomes painful. The severity of injury depends on the temperature to which the tissue is heated and its duration.

Excessive cold can also injure tissues. As a water-based solution freezes, ice crystals consisting of pure water form and all dissolved substances in the solution are left in the unfrozen liquid. Therefore, as more ice forms, the remaining liquid becomes more and more concentrated. Freezing damages cells through two mechanisms. First, ice crystals mechanically injure the cell. The increase in solute concentration of the cytoplasm as ice forms denatures the proteins by removing their water of hydration, increasing the ionic strength of the cytoplasm and causing other changes in the physicochemical environment in the cytoplasm.

Second, temperature changes profoundly alter biologic function through specific effects on such specialized functions as electrochemical properties and fluidity of cell membranes and through a general effect on most chemical reaction rates. In the physiologic temperature range, most reaction rates vary approximately as an exponential function of temperature (T); increasing T by 10°C increases the reaction rate by a factor of two to three. For any particular reaction, the ratio of the rates at two temperatures 10°C apart is called the $\mathbf{Q_{10}}$ for that reaction, and the effect of temperature on reaction rate is called the Q_{10} effect. The notion of Q_{10} may be generalized to apply to a group of reactions that have some measurable overall effect (such as O_2 consumption) in common and, thus, are thought of as comprising a physiologic process. The Q_{10} effect is clinically important in managing patients who have high fevers and are receiving fluid and nutrition intravenously. A commonly used rule is that a patient's fluid and caloric needs are increased 10% to 13% above normal for each 1°C of fever.

The sluggishness of a reptile that comes out of its burrow in the morning chill and becomes active only after being warmed by the sun illustrates the profound effect of temperature on biochemical reaction rates. Homeotherms avoid such a dependence of metabolic rate on environmental temperature by regulating their internal body temperatures within a narrow range. A disadvantage of homeothermy is that, in most homeotherms, certain vital processes cannot function at low levels of body temperature that poikilotherms tolerate easily.

BODY TEMPERATURE AND HEAT TRANSFER

The body is divided into a warm internal core and a cooler outer shell (Fig. 28.2). Because the environment greatly influences the shell temperature, its temperature is not regulated within narrow limits as is the internal core. This is true despite the thermoregulatory responses that strongly affect the shell, especially its outermost layer, the skin. The thickness of the shell depends on the thermal environment and the body's need to conserve heat. In a warm environment, the shell may be <1 cm thick, but in a subject conserving heat in a cold environment, it may extend several centimeters below the skin. The regulated internal body temperature is the temperature of the vital organs inside the head and trunk, which, together with a variable amount of other tissue, comprise the warm internal core.

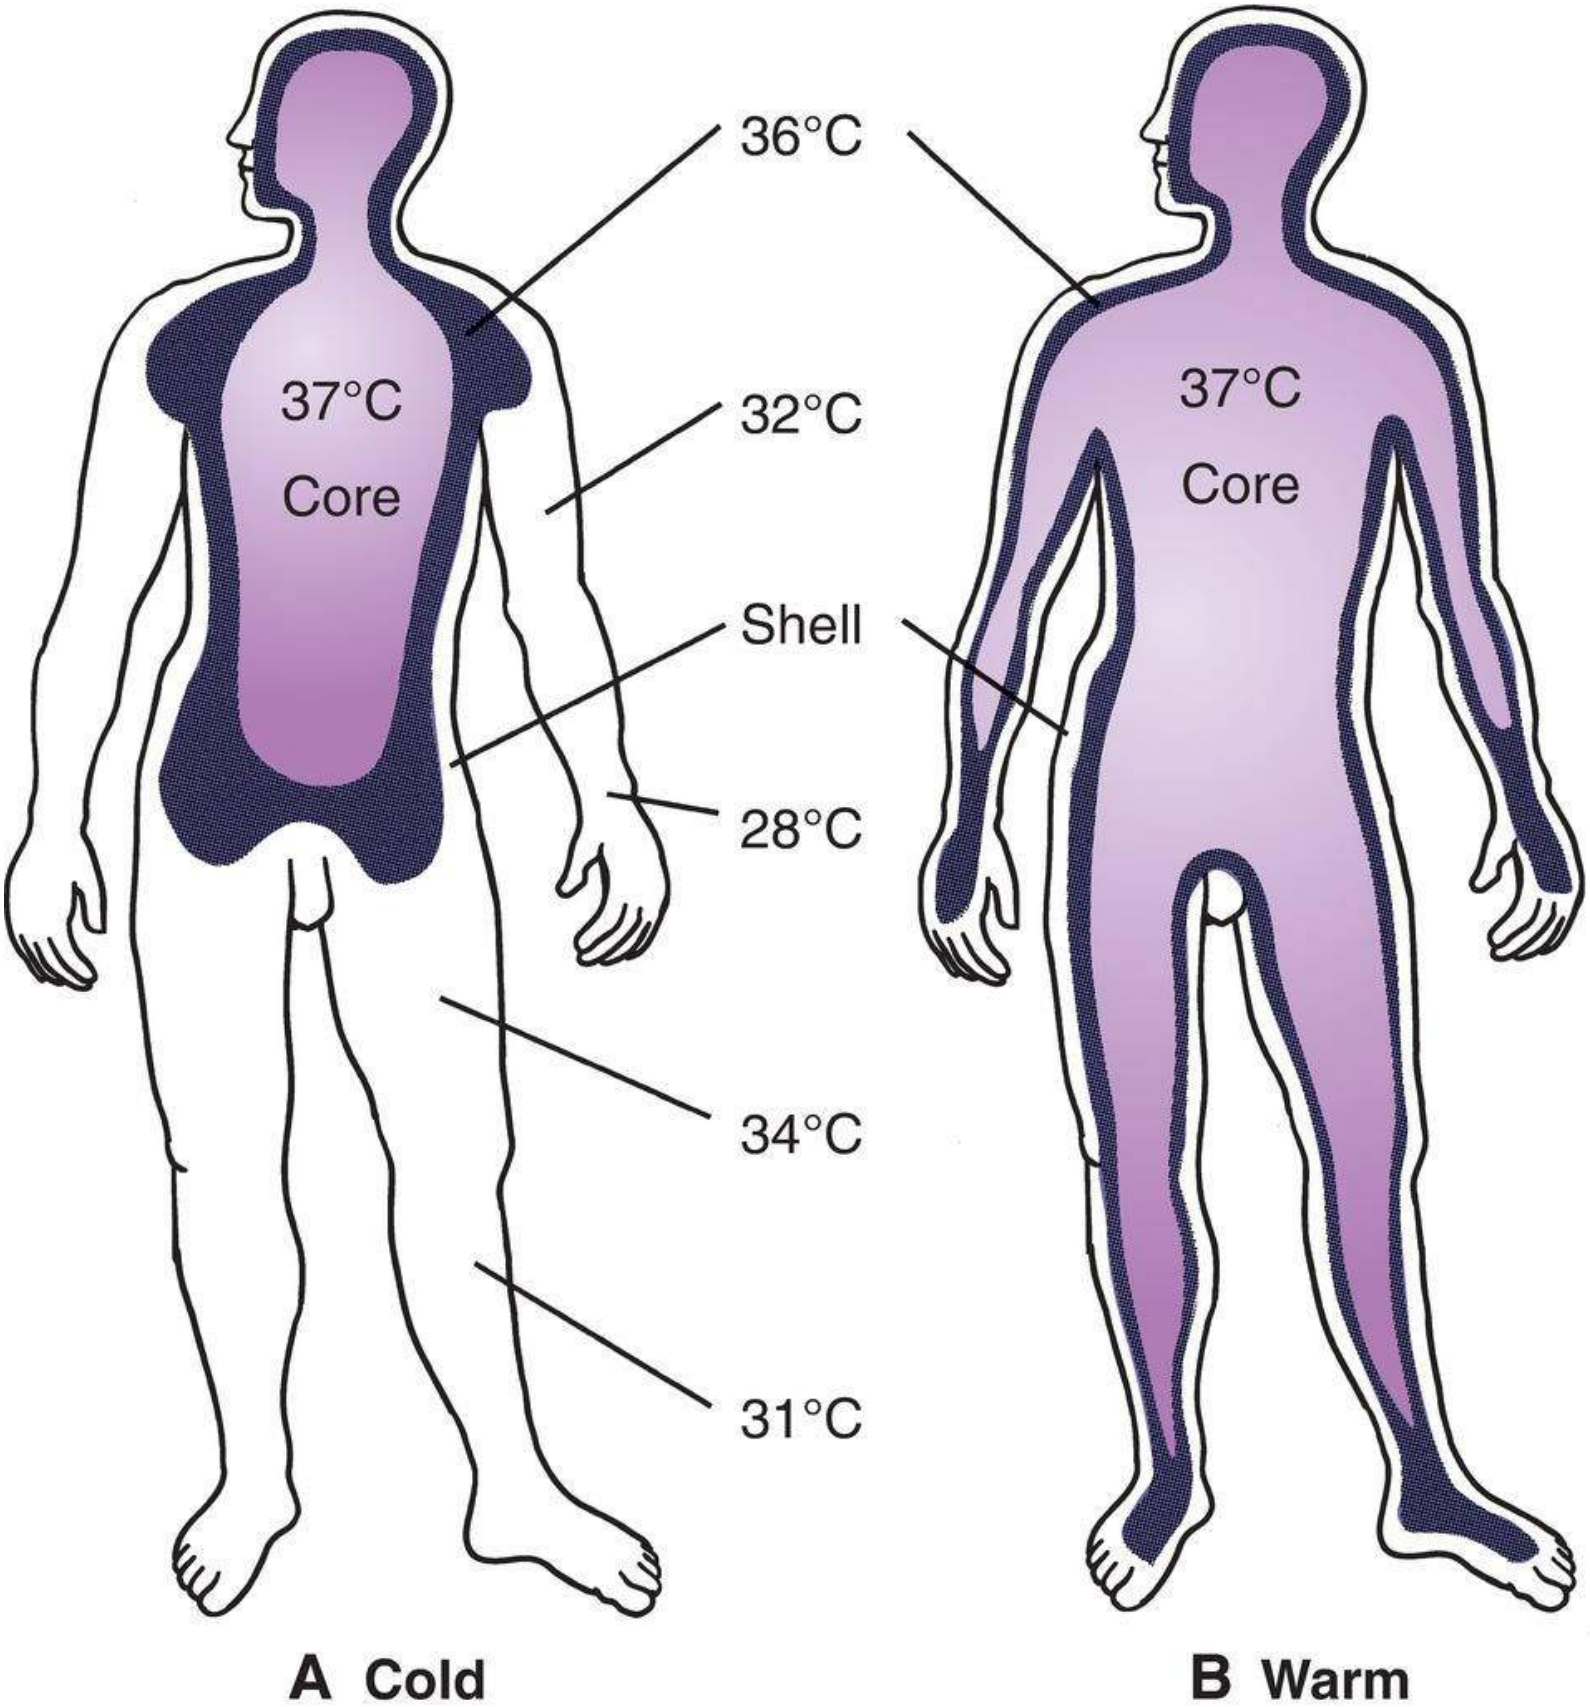

Figure 28.2 Distribution of temperatures in the body's core and shell. (A) During exposure to cold. **(B)** In a warm environment. Because the temperatures of the surface and the thickness of the shell depend on environmental temperature, the shell is thicker in the cold and thinner in the heat.

Heat is produced in all tissues of the body but is lost to the environment only from tissues in contact with the environment—predominantly from the skin and, to a lesser degree, from the respiratory tract. Therefore, we need to consider heat transfer within the body, especially heat transfer (1) from major sites

of heat production to the rest of the body and (2) from the core to the skin. Heat is transported within the body by two means: **conduction** through the tissues and **convection** by the blood, whereby flowing blood carries heat from warmer tissues to cooler tissues.

Heat flow by conduction varies directly with the thermal conductivity of the tissues, the change in temperature over the distance the heat travels, and the area (perpendicular to the direction of heat flow) through which the heat flows. It varies inversely with the distance the heat must travel. As Table 28.1 shows, the tissues are rather poor heat conductors.

TABLE 28.1 Thermal Conductivities and Rates of Heat Flow

Material	Conductivity (kcal/s·m·°C)	Rate of Heat Flow* kcal/h	W
Copper	0.09	33,120	38,474
Epidermis	0.00005	18	21
Dermis	0.00009	32	38
Fat	0.00004	14	17
Muscle	0.0001	40	46
Oak (across grain)	0.00004	14	17
Fiberglass insulation	0.00001	3.6	4.2

*Values are calculated for slabs 1 m^2 in area and 1 cm thick, with a 1°C temperature difference between the two faces of the slab.

Heat flow by convection depends on the rate of blood flow and the temperature difference between the perfused tissue and its blood supply. Because the vessels of the microvasculature have thin walls and, collectively, a large total surface area, the blood temperature equilibrates with that of the surrounding tissue before it reaches the capillaries. Changes in skin blood flow in a cool environment change the thickness of the shell. When skin blood flow is reduced in a cold environment, the affected skin becomes cooler and the underlying tissues—which in the cold may include most of the limbs and the more superficial muscles of the neck and trunk—become cooler as they lose heat by conduction to the cool overlying skin and, ultimately, to the environment. In this way, these underlying tissues, which in a hot environment were part of the body core, now become part of the shell.

Because the shell lies between the core and the environment, all heat leaving the body core, except that which is lost through the respiratory tract, must pass through the shell before being lost to the environment. Thus, the shell insulates the core from the environment. In a cool subject, skin blood flow is low, so conduction dominates core-to-skin heat transfer; the shell is also thicker, providing more insulation to the core, because heat flow by conduction varies inversely with the distance the heat must travel. Changes in skin blood flow, which directly affect core-to-skin heat transfer by convection, also indirectly affect conductive core-to-skin heat transfer by changing the thickness of the shell. In a cool subject, the subcutaneous fat layer contributes to the insulation value of the shell because the fat layer

increases the thickness of the shell and because fat has conductivity about 0.4 times that of dermis or muscle (see Table 28.1). Thus, fat is a correspondingly better insulator. In a warm subject, however, the shell is relatively thin and provides little insulation. Furthermore, a warm subject's skin blood flow is high, and so convection dominates heat flow from the core to the skin. In these circumstances, the subcutaneous fat layer, which affects conduction but not convection, has little effect on heat flow from the core to the skin.

Core temperature approximates central blood temperature.

Core temperature varies slightly from one site to another, depending on such local factors as metabolic rate, blood supply, and the temperatures of adjacent tissues. However, temperatures at different places in the core are all similar to the temperature of the central blood and tend to change together. The notion of a single, uniform core temperature, though not strictly correct, is a useful approximation. The value of 98.6°F, often given as the "normal" body temperature, may give the misleading impression that body temperature is regulated so precisely that it deviates less than a few tenths of a degree. In fact, 98.6°F is simply the Fahrenheit equivalent of 37°C, and body temperature does vary somewhat (see Fig. 28.1). The effects of heavy exercise and fever are familiar; variation among people and such factors as time of day and method of measurement (Fig. 28.3), phase of the menstrual cycle, and acclimatization to heat can also cause differences of up to about 1°C in resting core temperature.

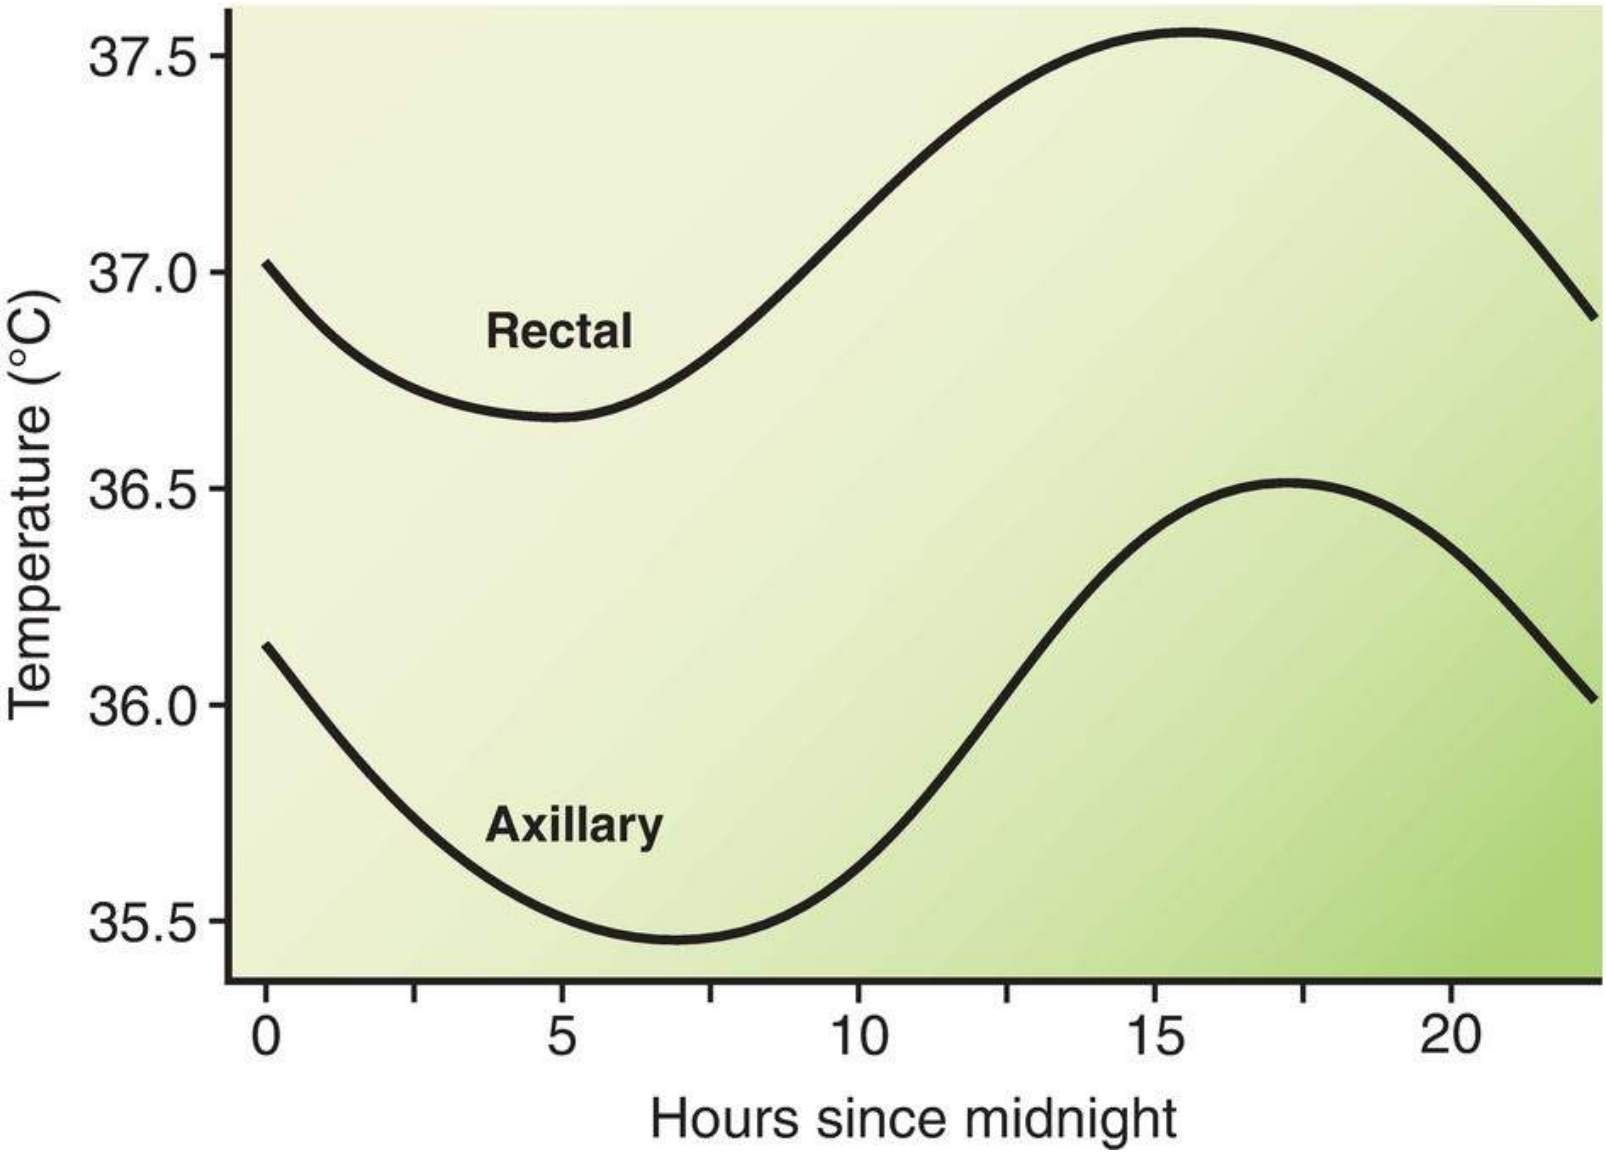

Figure 28.3 Core and axillary temperatures are influenced by circadian rhythm.

To maintain core temperature within a narrow range (36.5°C to 37.5°C), the thermoregulatory system needs continuous information about the level of core temperature. Temperature-sensitive neurons and nerve endings in the abdominal viscera, great veins, spinal cord, and especially, the brain provide this

information. We consider how the thermoregulatory system processes and responds to this information later in the chapter.

Core temperature should be determined at a site where the measurement is not biased by environmental temperature. Clinically used sites include the rectum, the mouth, and, occasionally, the axilla. The rectum is well insulated from the environment; its temperature is independent of environmental temperature and is a few tenths of 1°C warmer than arterial blood and other core sites. The tongue is richly supplied with blood; oral temperature under the tongue is usually close to blood temperature (and 0.4°C to 0.5°C below rectal temperature), but cooling the face, neck, or mouth can make oral temperature misleadingly low. If a patient holds his or her upper arm firmly against the chest to close the axilla, axillary temperature will eventually come reasonably close to core temperature. However, because this may take 30 minutes or more, axillary temperature is used infrequently. Infrared ear (aural) thermometers are convenient and widely used in the clinic, but temperatures of the tympanum and external auditory meatus are loosely related to more accepted indices of core temperature, and ear temperature in collapsed hyperthermic runners may be 3°C to 6°C below rectal temperature.

Skin is an important organ in heat exchange and thermoregulatory control.

Most heat is exchanged between the body and the environment at the skin surface. Consequently, skin temperature is much more variable than core temperature; thermoregulatory responses such as skin blood flow and sweat secretion, the temperatures of underlying tissues, and environmental factors, such as air temperature, air movement, and thermal radiation, affect it. Skin temperature is one of the major factors in heat exchange with the environment. For these reasons, it provides the thermoregulatory system with important information about the need to conserve or dissipate heat.

Because skin temperature usually is not uniform over the body surface, mean skin temperature ($\overline{T}_{sk}$) is frequently calculated from temperatures at several skin sites, weighting each temperature according to the fraction of body surface area it represents. $\overline{T}_{sk}$ is used to summarize the input to the central nervous system (CNS) from temperature-sensitive nerve endings in the skin. $\overline{T}_{sk}$ is also commonly used, along with core temperature, to calculate a mean body temperature and to estimate the quantity of heat stored in the body because the direct measurement of shell temperature would be difficult and invasive.

Peripheral thermoreceptors in the skin code absolute and relative temperatures.

Cutaneous thermosensation is mediated by various primary afferent nerve fibers that transduce, encode, and transmit thermal information. These peripheral **thermoreceptors** are located in the skin and in the oral and urogenital mucosa and include warm-sensitive and cold-sensitive populations. The most numerous and most superficially situated thermosensors are cold-sensitive. Skin cold sensors are located in or immediately beneath the epidermis, and their afferent input is conveyed by thin myelinated Aδ-fibers. The less common warm-sensitive receptors (10-fold fewer than cold sensors) are located slightly deeper in the dermis, and their input travels via unmyelinated C fibers. In contrast to central thermosensitive neurons, peripheral thermosensors are not pacemakers. The mechanisms of peripheral thermosensitivity involve changes in the resting membrane potential. Importantly, the response of most peripheral thermosensors shows a powerful dynamic (phasic) component. These neurons are very active when the temperature changes but quickly adapt when the temperature stabilizes, enabling rapid reaction to thermal environmental changes.

The mechanism of thermal transduction is believed to involve the action of **transient receptor potential** (**TRP**) **ion channels** whose activity depends on the temperature of their environment. Of these, members of three families, the vanilloid TRP channels, the melastatin (or long) TRP channels, and the ankyrin transmembrane protein channels are of particular interest as thermoreceptors. Each of these receptors operates over a specific temperature range, thereby providing a potential molecular basis for peripheral thermosensation. These specialized thermal receptors are embedded in the membranes of afferent fiber terminals as free nerve endings in the skin. Activation of all thermo TRP channels results in an inward, nonselective cationic current and a consequent depolarization of the resting membrane potential. Although individual thermo TRP channels are activated within a relatively narrow temperature range, collectively, their range is quite broad, from noxious cold to noxious heat (see Fig. 28.4).

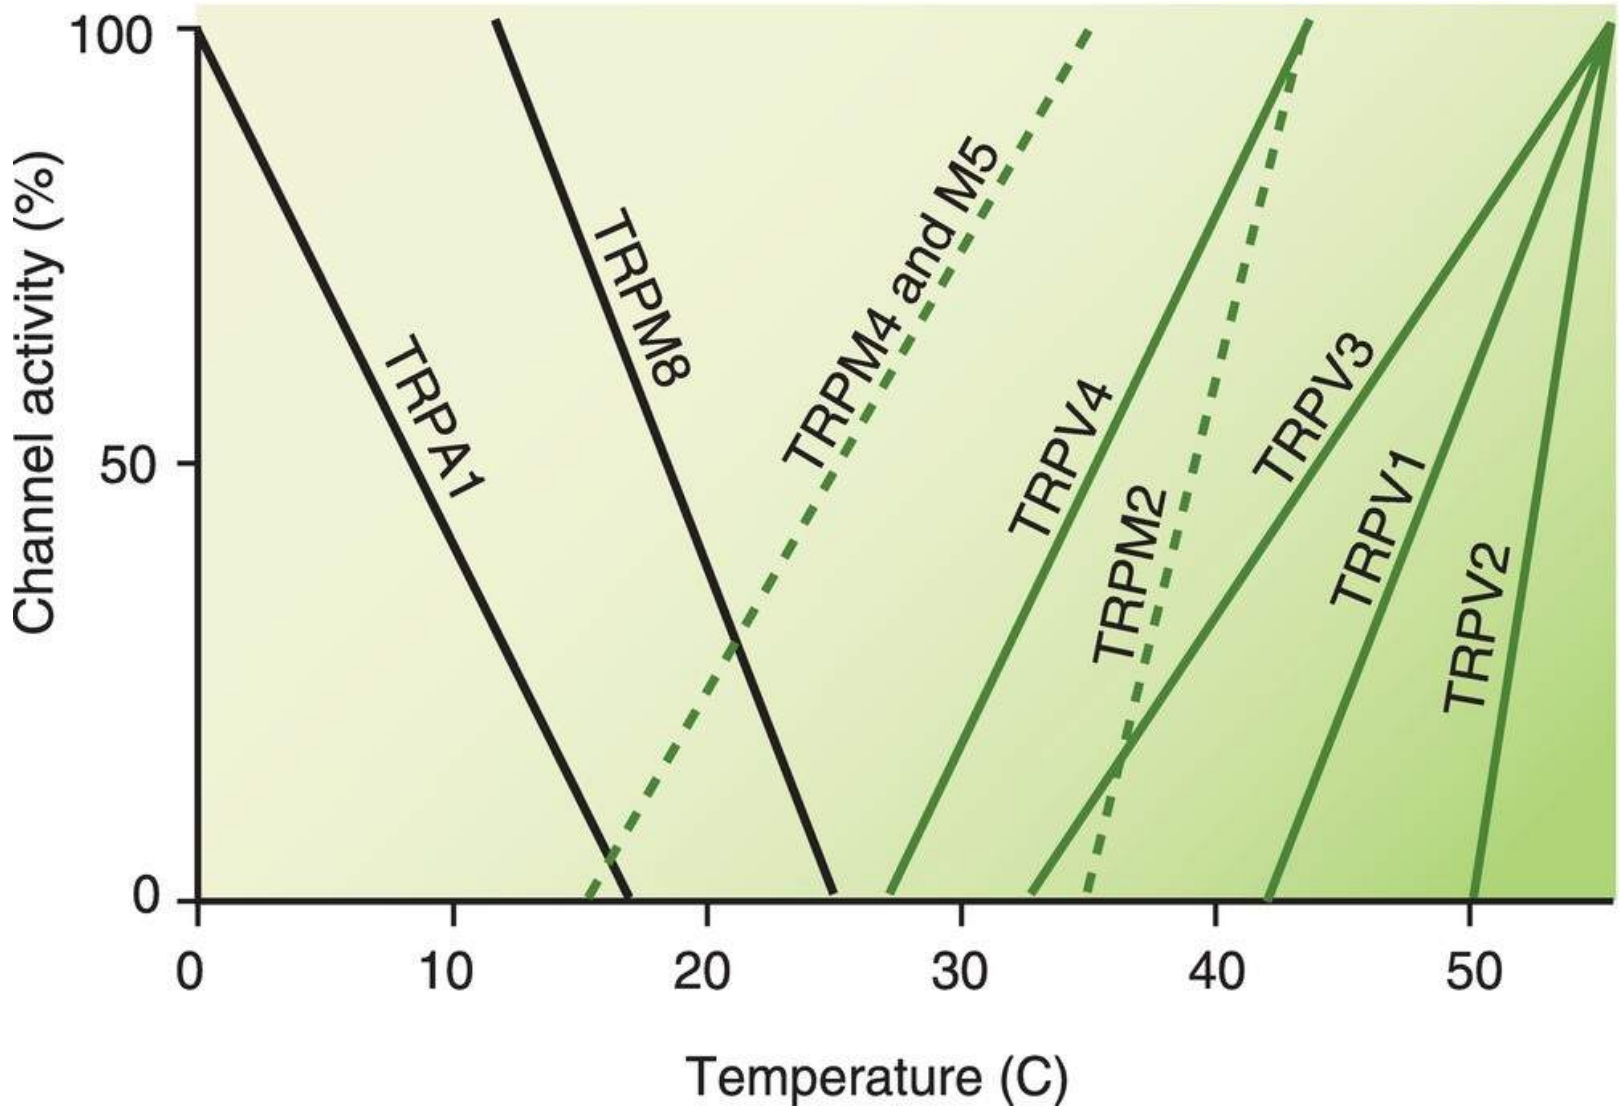

Figure 28.4 Dependence of the activity of cold-activated (*black*) and heat-activated (*green*) thermoTRP channels on temperature. TRP, transient receptor potential.

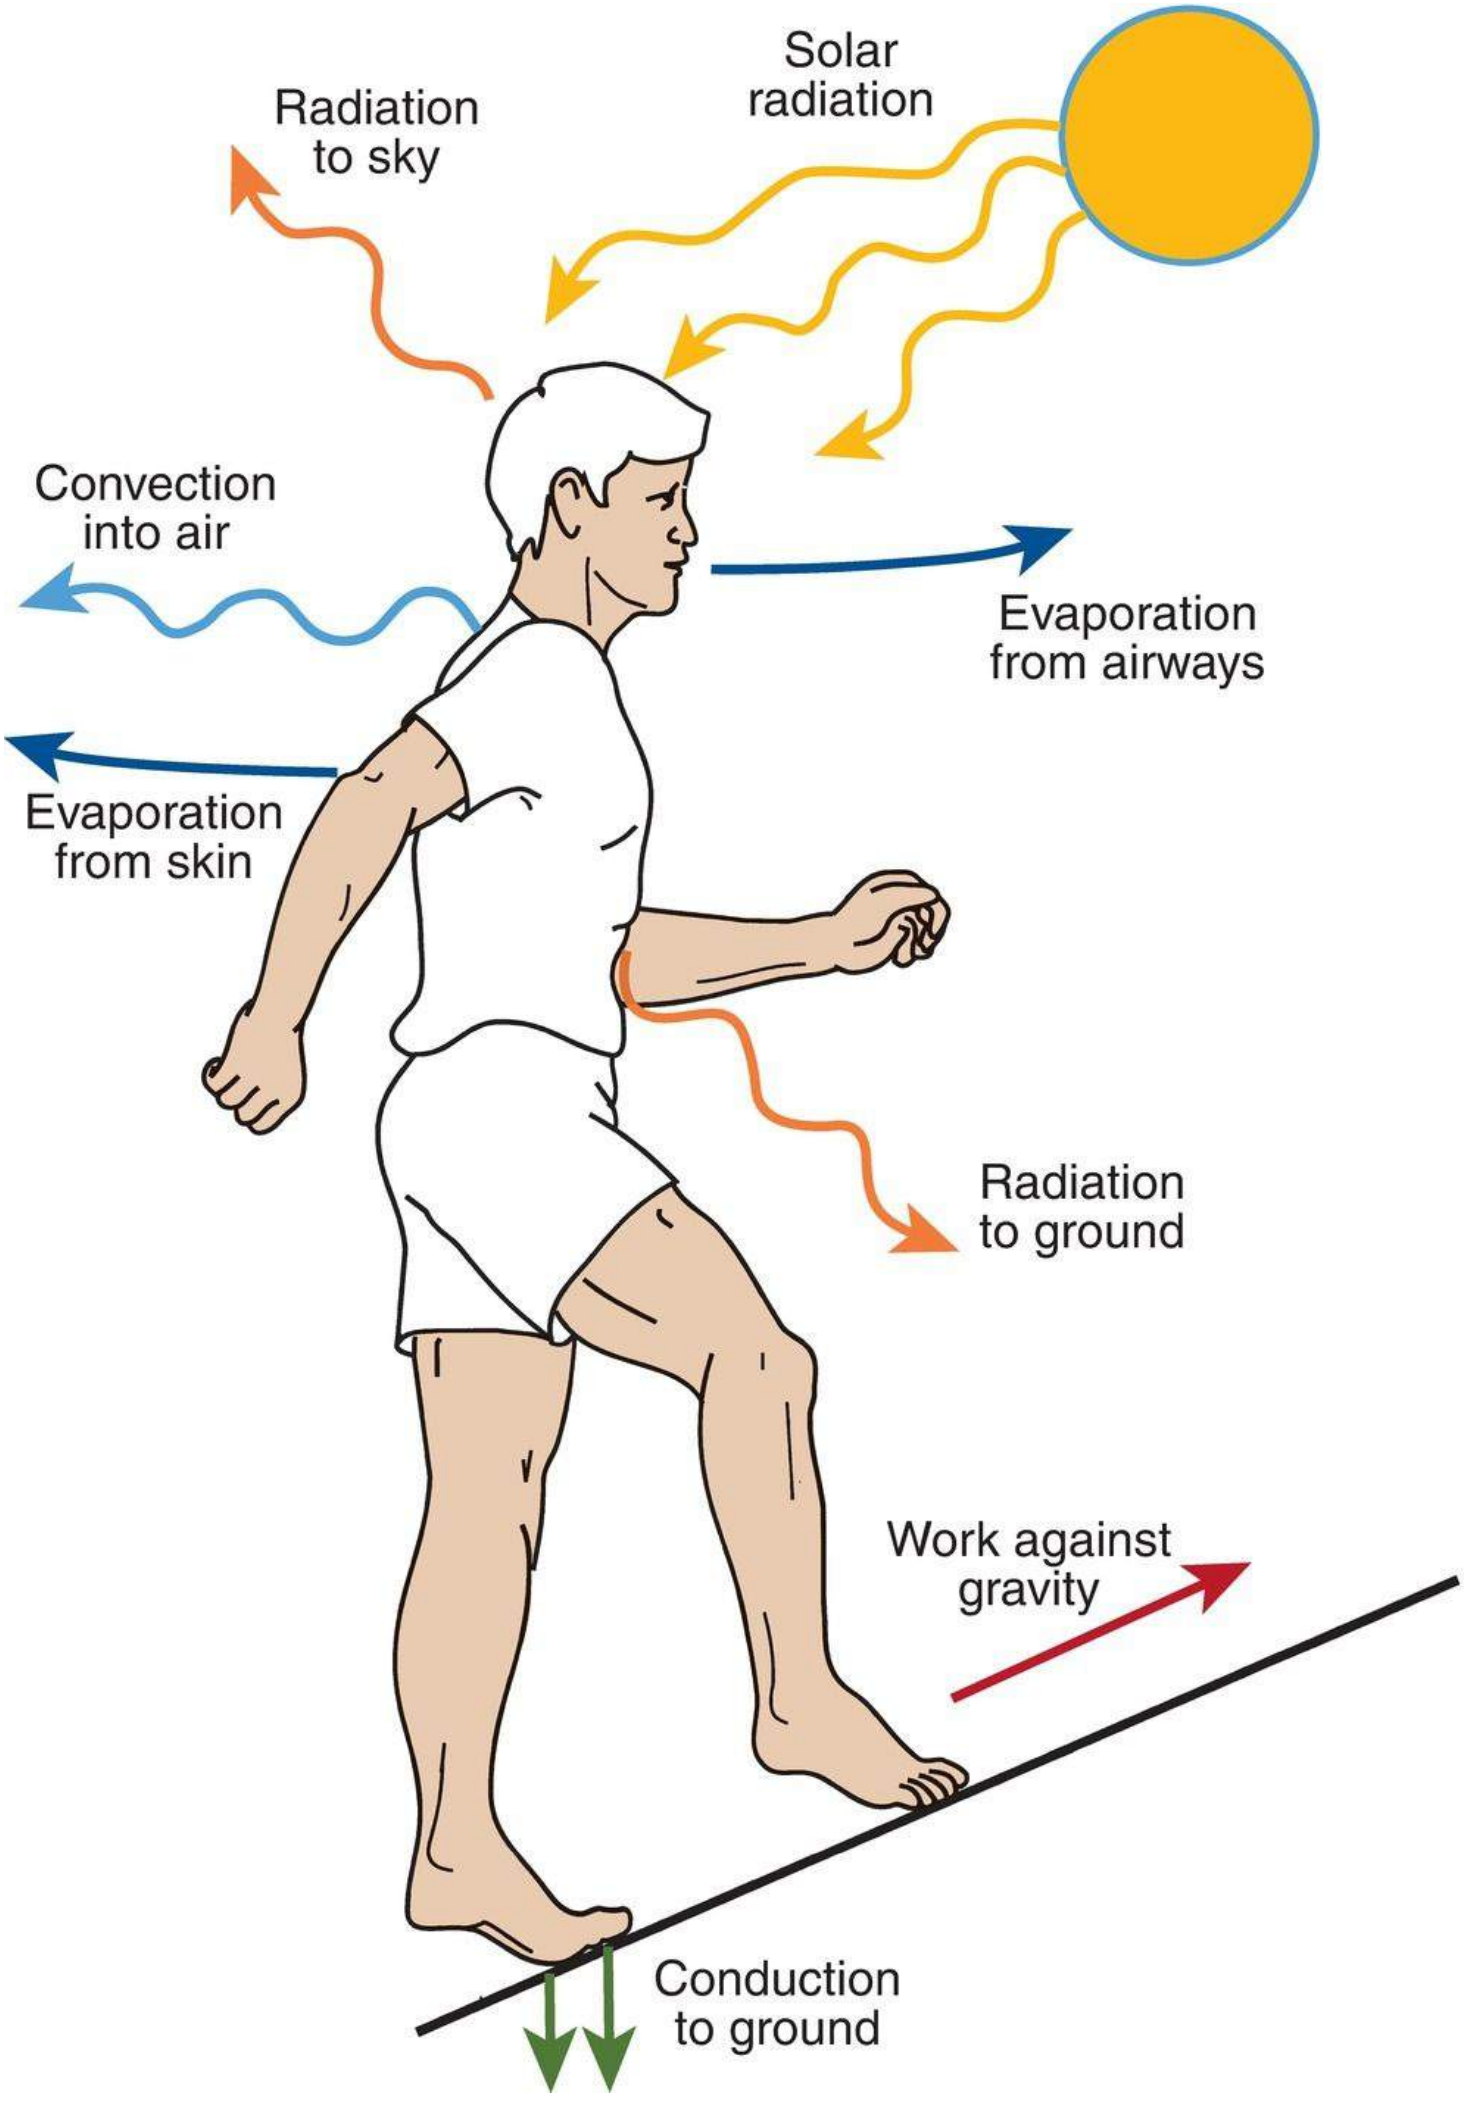
Thermotransduction in these nerve endings by TRP-independent means is also likely. Experimental evidence indicates cold sensing through cold-induced inhibition of K^+ conductances that are normally active at resting membrane potential, leading to membrane depolarization and action potential generation, whereas warm sensing may involve the otherwise mechanosensitive K_2P channels and other nociceptive C fibers.

BALANCE BETWEEN HEAT PRODUCTION AND HEAT LOSS

All animals exchange energy with the environment. Some energy is exchanged as mechanical work, but most is exchanged as heat (Fig. 28.5). Heat is exchanged by conduction, convection, and radiation and as latent heat through evaporation or (rarely) condensation of water. If the sum of energy production and energy gain from the environment does not equal energy loss, the extra heat is “stored” in, or lost from, the body. This relationship is summarized in the following heat balance equation:



Solar radiation
Radiation to sky
Convection into air
Evaporation from airways
Evaporation from skin
Radiation to ground
Work against gravity
Conduction to ground

Figure 28.5 Exchange of energy with the environment. This hiker gains heat from the sun by radiation and loses heat by conduction to the ground through the soles of his feet, convection into the air, radiation to the ground and sky, and evaporation of water from his skin and respiratory passages. In addition, some of the energy released by his metabolic processes is converted into mechanical work, rather than heat, because he is walking uphill.

$$M = E + R + C + K + W + S \quad (1)$$

where M is metabolic rate; E is the rate of heat loss by evaporation; R and C are rates of heat loss by radiation and convection, respectively; K is the rate of heat loss by conduction; W is the rate of energy loss as mechanical work; and S is the rate of heat storage in the body, manifested as changes in tissue temperatures.

M is always positive, but the terms on the right side of equation 1 represent energy exchange with the environment and storage and may be either positive or negative. E, R, C, K, and W are positive if they represent energy losses from the body and negative if they represent energy gains. When S = 0, the body is in heat balance and body temperature neither rises nor falls. When the body is not in heat balance, its mean tissue temperature increases if S is positive and decreases if S is negative. This situation commonly lasts only until the body's responses to the temperature changes are sufficient to restore balance. However, if the thermal stress is too great for the thermoregulatory system to restore balance, the body will continue to gain or lose heat until either the stress diminishes sufficiently or death occurs.

The traditional units for measuring heat are a potential source of confusion because the word calorie refers to two units differing by a 1,000-fold. The *calorie* used in chemistry and physics is the quantity of heat that will raise the temperature of 1 g of pure water by 1°C; it is also called the *small calorie* or *gram calorie*. The *Calorie* (capital C) used in physiology and nutrition is the quantity of heat that will raise the temperature of 1 kg of pure water by 1°C; it is also called the *large calorie*, *kilogram calorie*, or (the usual practice in thermal physiology) the **kilocalorie** (kcal). Because heat is a form of energy, it is now often measured in joules, the unit of work (1 kcal = 4,186 J), and rate of heat production or heat flow in watts, the unit of power (1 W = 1 J/s). This practice avoids confusing calories and Calories. However, kilocalories are still used widely enough that it is necessary to be familiar with them, and there is a certain advantage to a unit based on water because the body itself is mostly water.

METABOLIC RATE AND HEAT PRODUCTION AT REST

Metabolic energy is used for active transport via membrane pumps, for energy-requiring chemical reactions, such as the formation of glycogen from glucose and proteins from amino acids, and for muscular work. Most of the metabolic energy used in these processes is converted into heat within the body. Other energy is converted to heat only after a delay, as when the energy used in forming glycogen or protein is released as heat when the glycogen is converted back into glucose or the protein is converted back into amino acids.

Among subjects of different body sizes, metabolic rate at rest varies approximately in proportion to body surface area. In a resting and fasting young adult man, it is about 45 W/m^2 (81 W or 70 kcal/h for 1.8 m^2 body surface area), corresponding to an O_2 consumption of about 240 mL/min. About 70% of energy production at rest occurs in the body core—trunk viscera and the brain—even though it comprises only about 36% of the body mass (Table 28.2). As a by-product of their metabolic processes, these organs produce most of the heat needed to maintain heat balance at comfortable environmental temperatures; only in the cold must heat produced expressly for thermoregulation supplement such by-product heat.

TABLE 28.2 Relative Masses and Metabolic Heat Production Rates during Rest and Heavy Exercise

Region	Percentage of Body Mass	Percentage of Heat Production	
		Rest	Exercise
Brain	2	16	1
Trunk viscera	34	56	8
Muscle and skin	56	18	90
Other	8	10	1

Factors other than body size that affect metabolism at rest include age, sex (Fig. 28.6), hormones, and digestion. The ratio of metabolic rate to surface area is highest in infancy and declines with age, most rapidly in childhood and adolescence and more slowly thereafter. Children have high metabolic rates in relation to surface area because of the energy used to synthesize the fats, proteins, and other tissue components needed to sustain growth. Similarly, a woman's metabolic rate increases during pregnancy to supply the energy needed for the growth of the fetus. However, a nonpregnant woman's metabolic rate is 5% to 10% lower than that of a man of the same age and surface area probably because a higher proportion of the female body is composed of fat, a tissue with low metabolism.

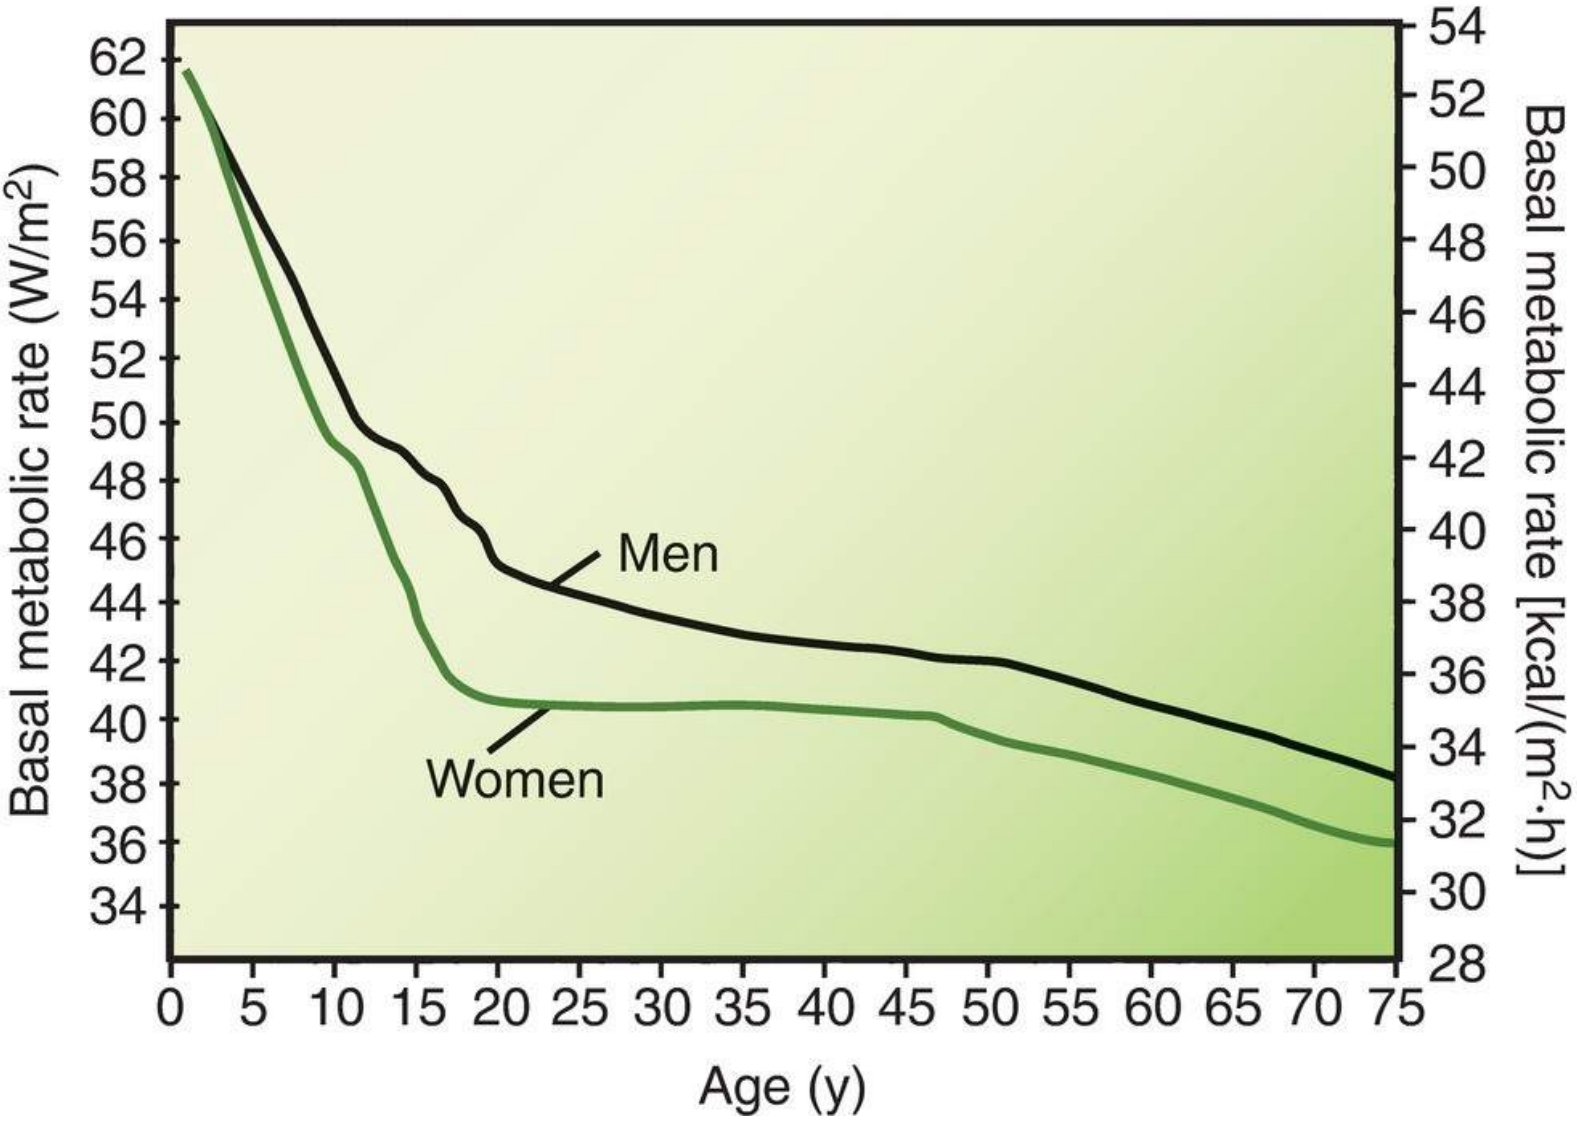


Figure 28.6 Effects of age and sex on the basal metabolic rate of healthy subjects. Metabolic rate here is expressed as the ratio of energy consumption to body surface area.

The catecholamines and thyroxine are the hormones that have the greatest effect on metabolic rate. Catecholamines cause glycogen to break down into glucose and stimulate many enzyme systems, increasing cellular metabolism. Hypermetabolism is a clinical feature of some cases of pheochromocytoma, a catecholamine-secreting tumor of the adrenal medulla. Thyroxine magnifies the metabolic response to catecholamines, increases protein synthesis, and stimulates oxidation by the mitochondria. The metabolic rate is typically 45% above normal in hyperthyroidism (but up to 100% above normal in severe cases) and 25% below normal in hypothyroidism (but 45% below normal with complete lack of thyroid hormone). Other hormones have relatively minor effects on metabolic rate.

A resting person's metabolic rate increases 10% to 20% after a meal. This effect of food, called the **thermic effect of food** (formerly known as *specific dynamic action*), lasts several hours. The effect is greatest after consuming protein and less after consuming carbohydrate and fat; it appears to be associated with processing the products of digestion in the liver.

Metabolic rate is the amount of energy expended under standard conditions.

Because so many factors affect metabolism at rest, metabolic rate is often measured under a set of standard conditions to compare it with established norms. Metabolic rate measured under these conditions is called **basal metabolic rate** (**BMR**). The commonly accepted conditions for measuring BMR are that the person must have fasted for 12 hours; the measurement must be made in the morning after a good night's sleep, beginning after the person has rested quietly for at least 30 minutes; and the air temperature must be comfortable, about 25°C (77°F). BMR is "basal" only during wakefulness because the metabolic rate during sleep is somewhat lower than the BMR.

Heat exchange with the environment can be measured directly by using a human calorimeter. In this insulated chamber, heat can exit either in the air ventilating the chamber or in water flowing through a heat exchanger in the chamber. By measuring the flow of air and water and their temperatures as they enter and leave the chamber, one can determine the subject's heat loss by conduction, convection, and radiation, and by measuring the moisture content of air entering and leaving the chamber, one can determine heat loss by evaporation. This technique is called **direct calorimetry**, and though conceptually simple, it is cumbersome and costly.

Metabolic rate is often estimated by **indirect calorimetry**, which is based on measuring a person's rate of O_2 consumption because virtually all energy available to the body depends ultimately on reactions that consume O_2. Consuming 1 L of O_2 is associated with releasing 21.1 kJ (5.05 kcal) if the fuel is carbohydrate, 19.8 kJ (4.74 kcal) if the fuel is fat, and 18.6 kJ (4.46 kcal) if the fuel is protein. An average value often used for the metabolism of a mixed diet is 20.2 kJ (4.83 kcal) per liter of O_2. The ratio of CO_2 produced to O_2 consumed in the tissues is called the **respiratory quotient** (**RQ**). The RQ is 1.0 for the oxidation of carbohydrate, 0.71 for the oxidation of fat, and 0.80 for the oxidation of protein. In a steady state in which CO_2 is exhaled from the lungs at the same rate it is produced in the tissues, RQ is equal to the respiratory exchange ratio, R (see Chapter 19). One can improve the accuracy of indirect calorimetry by also determining R and either estimating the amount of protein oxidized—which usually is small compared with fat and carbohydrate—or calculating it from urinary nitrogen excretion.

Skeletal muscle is the main source of heat during external work.

Even during mild exercise, the muscles are the principal source of metabolic heat, and during intense exercise, they may account for up to 90%. Moderately intense exercise by a healthy, but sedentary, young man may require a metabolic rate of 600 W (in contrast to about 80 W at rest) and intense activity by a trained athlete 1,400 W or more. Because of their high metabolic rate, exercising muscles may be almost 1°C warmer than the core. The blood perfusing these muscles is warmed and, in turn, warms the rest of the body, raising the core temperature.

Muscles convert most of the energy in the fuels they consume into heat rather than mechanical work. During phosphorylation of **adenosine diphosphate** (**ADP**) to form **adenosine triphosphate** (**ATP**), 58% of the energy released from the fuel is converted into heat, and only about 42% is captured in the ATP that is formed in the process. When a muscle contracts, some of the energy in the ATP that was hydrolyzed is converted into heat rather than mechanical work. The efficiency at this stage varies enormously; it is zero in isometric muscle contraction, in which a muscle's length does not change while it develops tension so that no work is done even though metabolic energy is required. Finally, friction converts some of the mechanical work produced into heat within the body (e.g., the fate of all the mechanical work done by the heart in pumping blood). At best, no more than 25% of the metabolic energy released during exercise is converted into mechanical work outside the body, and the other 75% or more is converted into heat within the body.

Sweating is the primary means of heat loss in humans.

There are four avenues of heat loss: *convection, conduction, radiation,* and *evaporation* (Fig. 28.5). Convection is the transfer of heat resulting from the movement of a fluid, either liquid or gas. In thermal physiology, the fluid is usually air or water in the environment; in the case of heat transfer inside the body, the fluid is blood. To illustrate, consider an object immersed in a fluid that is cooler than the object. Heat passes from the object to the immediately adjacent fluid by conduction. If the fluid is stationary, conduction is the only means by which heat can pass through the fluid, and over time, the rate of heat flow from the body to the fluid will diminish as the fluid nearest the object approaches the temperature of the object. In practice, however, fluids are rarely stationary. If the fluid is moving, heat will still be carried from the object into the fluid by conduction, but once the heat has entered the fluid, the movement of the fluid will carry it—by convection. The same fluid movement that carries heat away from the surface of the object constantly brings fresh cool fluid to the surface, and so the object gives up heat to the fluid much more rapidly than if the fluid were stationary. Although conduction plays a role in this process, convection so dominates the overall heat transfer that we refer to the heat transfer as if it were entirely convection. Therefore, the conduction term (K) in the heat balance equation is restricted to heat flow between the body and other solid objects, and it usually represents only a small part of the total heat exchange with the environment.

When 1 g of water is converted into vapor at 30°C, it absorbs 2,425 J (0.58 kcal), the **latent heat of evaporation**, in the process. Evaporation of water is, thus, an efficient way of losing heat, and it is the body's only means of losing heat when the environment is hotter than the skin, as it usually is when the environment is warmer than 36°C. Evaporation must then dissipate both the heat produced by metabolic processes and any heat gained from the environment by convection and radiation. Most of the water evaporated in hot environments comes from sweat, but even in cold environments, the skin loses some water by the evaporation of **insensible perspiration**, water that diffuses through the skin rather than being secreted. In equation 1, E is nearly always positive, representing heat loss from the body. However, E is negative in the rare circumstances in which water vapor gives up heat to the body by condensing on the skin (as in a wet sauna).

Heat exchange is proportional to surface area and obeys thermodynamic principles.

Heat exchange always occurs from a higher to a cooler temperature and, thus, follows the second law of thermodynamics. Animals exchange heat with their environment through both the skin and the respiratory passages, but only the skin exchanges heat by radiation. In panting animals, respiratory heat loss may be large and may be an important means of achieving heat balance. In humans, however, respiratory heat exchange is usually relatively small and (though hyperthermic subjects may hyperventilate) is not predominantly under thermoregulatory control. Therefore, we do not consider it further here.

Convective heat exchange between the skin and the environment is proportional to the difference between skin and ambient air temperatures, as expressed by the following equation:

$$C = h_c \times A \times (\bar{T}_{sk} - T_a) \quad (2)$$

where A is the body surface area; $\bar{T}_{sk}$ and T_a are mean skin and ambient temperatures, respectively; and h_c is the convective heat transfer coefficient.

The value of h_c includes the effects of the factors other than temperature and surface area that influence convective heat exchange. For the whole body, air movement is the most important of these factors and convective heat exchange (and, thus, h_c) varies approximately as the square root of the air speed, except when air movement is slight (Fig. 28.7). Other factors that affect h_c include the direction of air movement and the curvature of the skin surface. As the radius of curvature decreases, h_c increases, and so the hands and fingers are effective in convective heat exchange disproportionately to their surface area.

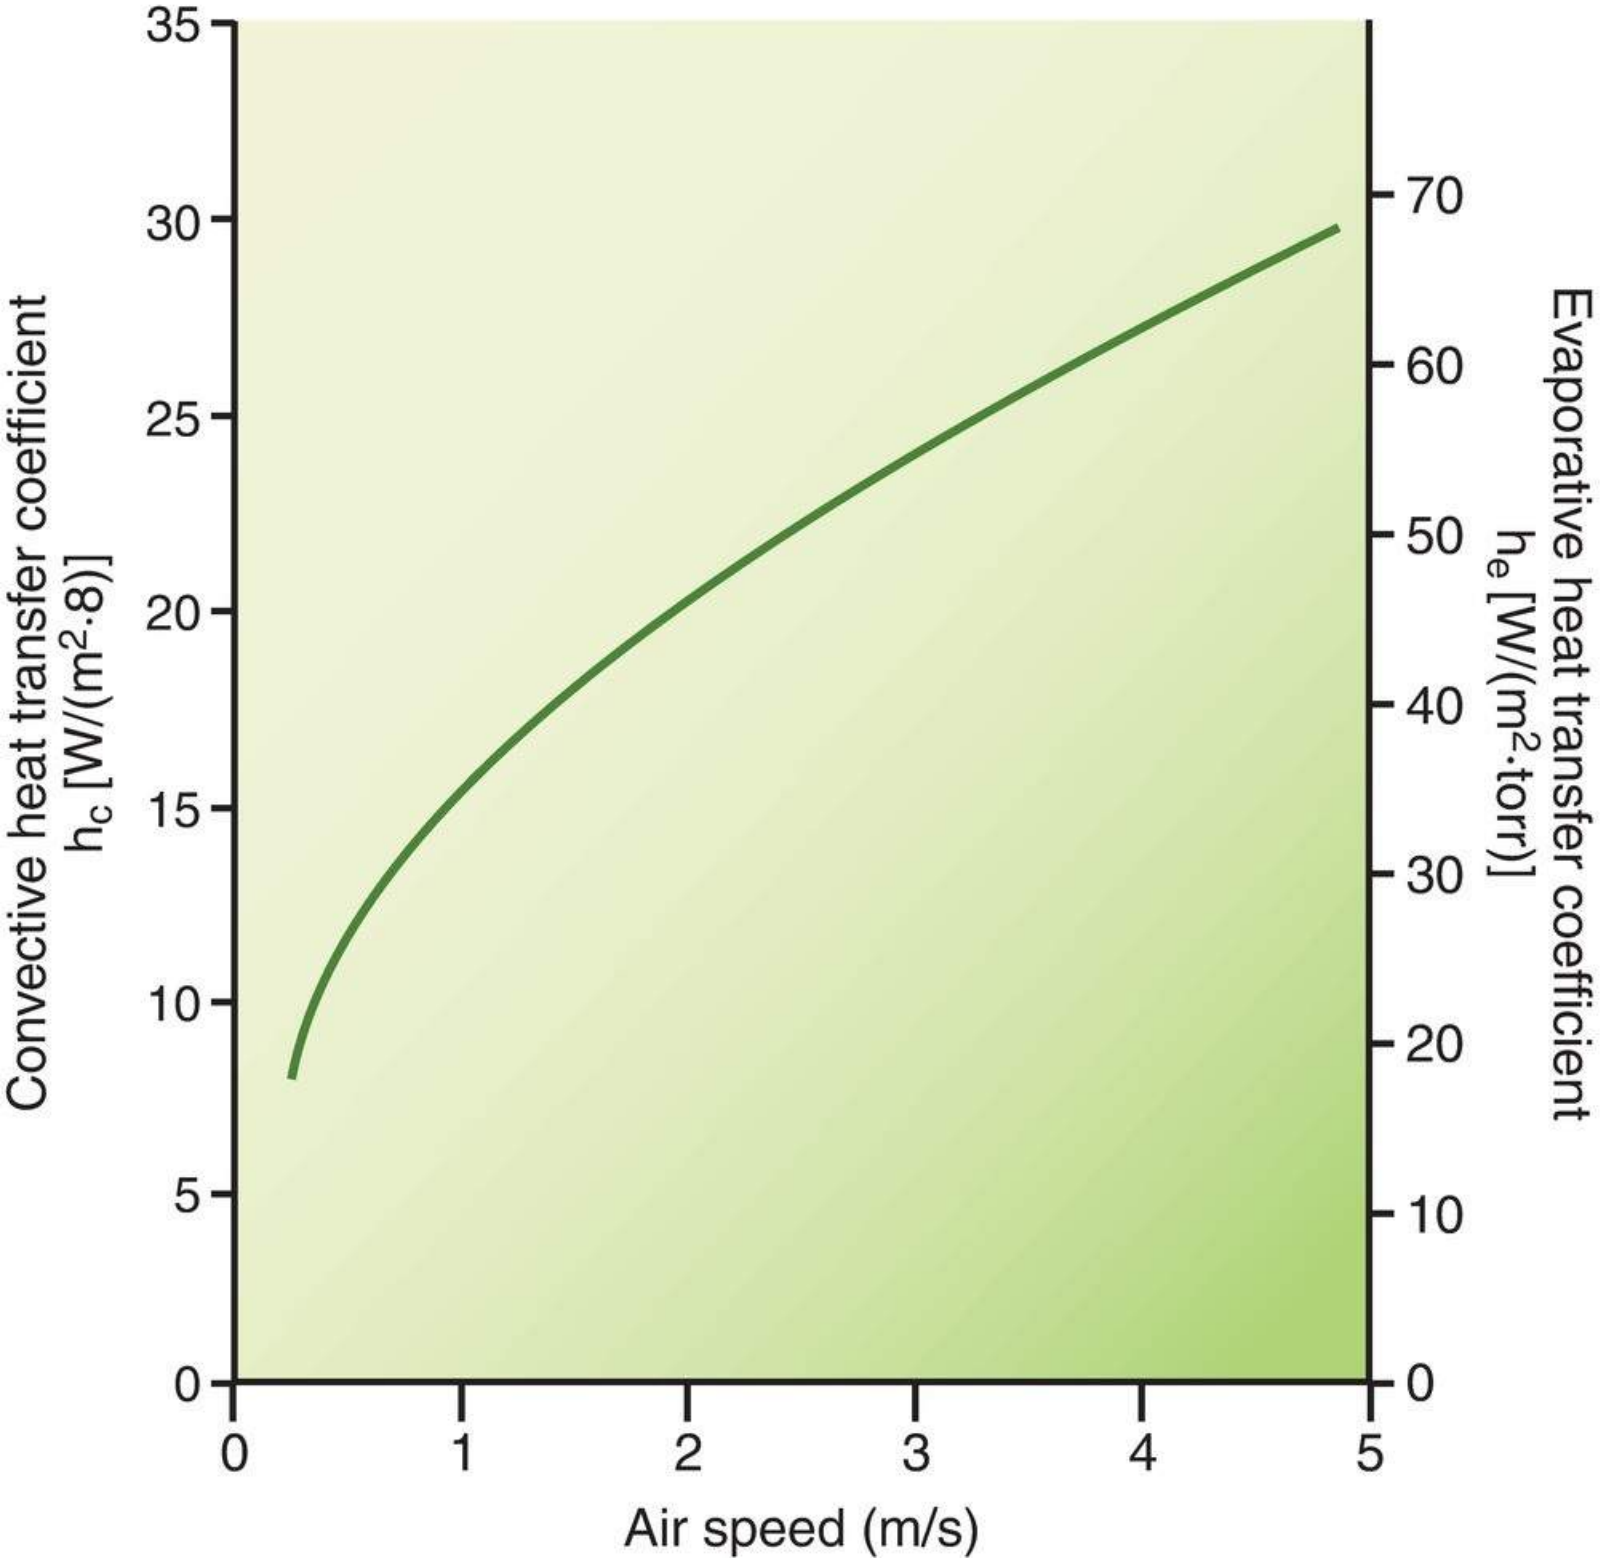

Figure 28.7 Dependence of convection and evaporation on air movement. This figure shows the convective heat transfer coefficient, h_c **(left)**, and the evaporative heat transfer coefficient, h_e **(right)**, for a standing human as a function of air speed. The convective and evaporative heat transfer coefficients are related by the equation $h_e = h_c \times 2.2°C/torr$. The horizontal axis can be converted into English units by using the relation 5 m/s = 16.4 ft/s = 11.2 miles/h.

Radiative heat exchange is proportional to the difference between the fourth powers of the absolute temperatures of the skin and of the radiant environment (T_r) and to the emissivity of the skin

$(e_{sk}): R \propto e_{sk} \times (\bar{T}_{sk}^4 - T_r^4)$

. However, if T_r is close enough to $\bar{T}_{sk}$ that $\bar{T}_k - T_r$ is much smaller than the absolute temperature of the skin, R is nearly proportional to $e_{sk} \times (\bar{T}_{sk} - T_r)$. Some parts of the body surface (e.g., the inner surfaces of the thighs and arms) exchange heat by radiation with other parts of the body surface, and so the body exchanges heat with the environment as if it had an area smaller than its actual surface area. This smaller area, called the effective radiating surface area (A_r), depends on the body's posture and is closest to the actual surface area in a spread-eagle position and least in a curled-up position. Radiative heat exchange can be represented by the following equation:

$$R = h_r \times e_{sk} \times A_r \times (\bar{T}_{sk} - T_r) \quad (3)$$

where h_r is the radiant heat transfer coefficient, 6.43 W/(m^2·°C) at 28°C.

Evaporative heat loss from the skin to the environment is proportional to the difference between the water vapor pressure at the skin surface and the water vapor pressure in the ambient air. These relationships are summarized as follows:

$$E = h_e \times A \times (P_{sk} - P_a) \quad (4)$$

where P_{sk} is the water vapor pressure at the skin surface, P_a is the ambient water vapor pressure, and h_e is the evaporative heat transfer coefficient.

Moving air carries away water vapor, like heat, and so geometric factors and air movement affect E and h_e in the same way that they affect C and h_c. If the skin is completely wet, the water vapor pressure at the skin surface is the saturation water vapor pressure at the temperature of the skin and evaporative heat loss is E_{max}, the maximum possible for the prevailing skin temperature and environmental conditions. This condition is described as follows:

$$E_{max} = h_e \times A \times (P_{sk,sat} - P_a)$$

(5)

where $P_{sk,sat}$ is the saturation water vapor pressure at skin temperature. When the skin is not completely wet, it is impractical to measure P_{sk}, the actual average water vapor pressure at the skin surface. Therefore, a coefficient called skin *wettedness* (w) is defined as the ratio E/E_{max}, with $0 < w < 1$. Skin wettedness depends on the hydration of the epidermis and the fraction of the skin surface that is wet. We can now rewrite equation 4 as follows:

$$E = h_e \times A \times w \times (P_{sk,sat} - P_a)$$

(6)

Wettedness depends on the balance between secretion and evaporation of sweat. If secretion exceeds evaporation, sweat accumulates on the skin and spreads out to wet more of the space between neighboring sweat glands, increasing wettedness and E; if evaporation exceeds secretion, the reverse occurs. If sweat rate exceeds E_{max}, once wettedness becomes 1, the excess sweat drips from the body because it cannot evaporate.

Note that P_a, on which evaporation from the skin directly depends, is proportional to the actual moisture content in the air. In contrast, the more familiar quantity **relative humidity** (rh) is the ratio between the actual moisture content in the air and the maximum moisture content possible at the temperature of the air. It is important to recognize that rh is only indirectly related to evaporation from the skin. For example, in a cold environment, P_a will be low enough that sweat can easily evaporate from the skin even if rh equals 100% because the skin is warm and $P_{sk,sat}$, which depends on the temperature of the skin, will be much greater than P_a.

Heat storage is a balance between net heat production and net heat loss.

The rate of **heat storage** is an indicator of a change in heat content of the body and is the difference between heat production and net heat loss (equation 1). (In unusual circumstances in which there is a net heat gain from the environment, such as during immersion in a hot bath, storage is the sum of heat production and net heat gain.) It can be determined experimentally from simultaneous measurements of metabolism by indirect calorimetry and heat gain or loss by direct calorimetry. Storage of heat in the tissues changes their temperature, and the amount of heat stored is the product of body mass, the body's mean specific heat, and a suitable mean body temperature (T_b). The body's mean specific heat depends on its composition, especially the proportion of fat, and is about 3.55 kJ/(kg·°C) [0.85 kcal/(kg·°C)]. Empirical relations of T_b to core temperature (T_c) and T_{sk}, determined in calorimetric studies, depend on ambient temperature, with T_b varying from $0.65 \times T_c + 0.35 \times T_{sk}$ in the cold to $0.9 \times T_c + 0.1 \times T_{sk}$ in the heat. The shift from cold to heat in the relative weighting of T_c and T_{sk} reflects the accompanying change in the thickness of the shell (see Fig. 28.2).

HEAT DISSIPATION

Figure 28.8 shows rectal and mean skin temperatures, heat losses, and calculated core-to-skin (shell) conductances for nude resting men and women at the end of 2-hour exposures in a calorimeter to ambient temperatures of 23°C to 36°C. Shell conductance represents the sum of heat transfer by two parallel modes: conduction through the tissues of the shell and convection by the blood. It is calculated by dividing heat flow through the skin (HF_{sk}) (i.e., total heat loss from the body minus heat loss through the respiratory tract) by the difference between core and mean skin temperatures:

Figure 28.8 Heat dissipation. These graphs show the average values of rectal and mean skin temperatures, heat loss, and core-to-skin thermal conductance for nude resting men and women near steady state after 2 hours at different environmental temperatures in a calorimeter. (All energy exchange quantities in this figure have been divided by body surface area to remove the effect of individual body size.) Total heat loss is the sum of dry heat loss, by radiation (*R*) and convection (*C*) and evaporative heat loss (*E*). Dry heat loss is proportional to the difference between skin temperature and calorimeter temperature and decreases with increasing calorimeter temperature.

$$C = HF_{sk} / (T_c - \bar{T}_{sk}) \quad (7)$$

where C is shell conductance and T_c and $\bar{T}_{sk}$ are core and mean skin temperatures.

From 23°C to 28°C, conductance is minimal because the skin is vasoconstricted and its blood flow is low. The minimal level of conductance attainable depends largely on the thickness of the subcutaneous fat layer, and women's thicker layer allows them to attain a lower conductance than men. At about 28°C, conductance begins to increase, and above 30°C, conductance continues to increase and sweating begins.

For these subjects, 28°C to 30°C is the zone of **thermoneutrality**, or thermoneutral zone, the range of comfortable environmental temperatures in which thermal balance is maintained without either shivering or sweating. In this zone, controlling conductance and $\bar{T}_{sk}$ and, thus, R and C entirely maintains heat balance. As equations 2 to 4 show, C, R, and E all depend on skin temperature, which, in turn, depends partly on skin blood flow. E depends also, through skin wettedness, on sweat secretion. Therefore, all these modes of heat exchange are partly under physiologic control.

Sweat evaporation can dissipate large amounts of heat.

In Figure 28.8, evaporative heat loss is nearly independent of ambient temperature below 30°C and is 9 to 10 W/m^2, corresponding to evaporation of about 13 to 15 g/(m^2·h), of which about half is moisture lost in breathing and half is insensible perspiration. This evaporation occurs independent of thermoregulatory control. As the ambient temperature increases, the body depends more and more on the evaporation of sweat to achieve heat balance.

The two histologic types of sweat glands are **eccrine** and **apocrine**. Eccrine sweat glands, the dominant type in all human populations, are more important in human thermoregulation and number about 2,500,000. Eccrine secretion is controlled through postganglionic sympathetic C fibers that release acetylcholine (ACh) rather than norepinephrine. Cholinergic stimulation of the sweat gland elicits the secretion of the so-called *precursor fluid*, the composition of which resembles that of plasma, except that it does not contain the plasma proteins. Therefore, sodium and chloride are the primary electrolytes in sweat, with potassium, calcium, and magnesium present in smaller amounts. As the fluid moves through the duct portion of the sweat gland, its composition is modified by active reabsorption of sodium and chloride. As a result, sweat is hyposmotic compared to plasma, and sodium concentration typically ranges from 10 to 70 mmol/L, whereas chloride ranges from 5 to 60 mmol/L, depending on diet, sweat rate, and degree of heat acclimatization. Eccrine sweat also includes lactate, urea, ammonia, serine, ornithine, citrulline, aspartic acid, heavy metals, organic compounds, and proteolytic enzymes. In contrast, apocrine sweat consists mainly of sialomucin. Although initially odorless, as apocrine sweat comes in contact with normal bacterial flora on the surface of the skin, an odor develops. Apocrine sweat is more viscous and produced in much smaller amounts than eccrine sweat. The exact function of apocrine glands is unclear, though they are thought to represent scent glands. During puberty, **apoeccrine** glands appear. These are hybrid sweat glands that are found in the axilla and may play a role in axillary hyperhidrosis. Their secretory structures have both a small-diameter portion similar to those found in eccrine glands and a large-diameter portion that resembles an apocrine gland. Functionally similar to eccrine glands, they respond mainly to cholinergic stimuli, and their ducts are long and open directly onto the skin surface. Interestingly, apoeccrine glands secrete nearly 10 times as much sweat as eccrine glands do.

A healthy man unacclimatized to heat can secrete up to 1.5 L/h of sweat. Although the number of functional sweat glands is fixed before the age of 3, the secretion capacity of the individual glands can change, especially with endurance exercise training and heat acclimatization. Men well acclimatized to heat can attain peak sweat rates of 1.0 to 2.5 L/h, with sweat rates of more than 2.5 L/h possible when the ambient temperature is high. However, such rates cannot be maintained as the maximum daily sweat output is probably about 15 L (Clinical Focus 28.1).

CLINICAL FOCUS 28.1

Water and Salt Depletion as a Result of Sweating

Changes in fluid and electrolyte balance are probably the most frequent physiologic disturbances associated with sustained exercise and heat stress. Water loss via the sweat glands can exceed 1 L/h for

many hours. Salt loss in the sweat is variable; however, because sweat is more dilute than plasma, sweating always results in an increase in the osmolality of the fluid remaining in the body and increased plasma [Na^+] and [Cl^-], as long as the lost water is not replaced. Because people who secrete large volumes of sweat usually replace at least some of their losses by drinking water or electrolyte solutions, the final effect on body fluids may vary. In Table 28.3, the second and third conditions (subject A) represent the effects on body fluids of sweat losses alone and combined with replacement by an equal volume of plain water, respectively, for someone producing sweat, with a [Na^+] and [Cl^-] in the upper part of the normal range. By contrast, the fourth and fifth conditions (subject B) represent the corresponding effects for a heat-acclimatized person secreting dilute sweat. Comparing the effects on these two people, we note (1) the more dilute the sweat that is secreted, the greater the increase in osmolality and plasma [Na^+] if no fluid is replaced; (2) extracellular fluid volume, a major determinant of plasma volume (see Chapter 15), is greater in subject B (secreting dilute sweat) than in subject A (secreting saltier sweat), whether water is replaced; and (3) drinking plain water allowed subject B to maintain plasma sodium and extracellular fluid volume almost unchanged while secreting 5 L of sweat. In subject A, however, drinking the same amount of water reduced plasma [Na^+] by 8 mmol/L and failed to prevent a decrease of almost 10% in extracellular fluid volume. In 5 L of sweat, subject A lost 17.5 g of salt, somewhat more than the daily salt intake in a normal Western diet, and is becoming salt depleted.

Increased osmolality of the extracellular fluid and decreased plasma volume via a reduction in the activity of the cardiovascular stretch receptors stimulate thirst (see Chapter 23). When sweating is profuse, however, thirst usually does not elicit enough drinking to replace fluid as rapidly as it is lost so that people exercising in the heat tend to become progressively dehydrated—in some cases losing as much as 7% to 8% of body weight—and restore normal fluid balance only during long periods of rest or at meals. Depending on how much of his fluid losses he replaces, subject B may either be hypernatremic and dehydrated or be in essentially normal fluid and electrolyte balance. (If he drinks fluid well in excess of his losses, he may become overhydrated and hyponatremic, but this is an unlikely occurrence.) However, subject A, who is somewhat salt depleted, may be dehydrated and hypernatremic, normally hydrated but hyponatremic, or somewhat dehydrated with plasma [Na^+] anywhere in between these two extremes. Once subject A replaces all the water lost as sweat, his extracellular fluid volume will be about 10% below its initial value. If he responds to the accompanying reduction in plasma volume by continuing to drink water, he will become even more hyponatremic than shown in Table 28.3.

The disturbances shown in Table 28.3, although physiologically significant and useful for illustration, are not likely to require clinical attention. Greater disturbances, with correspondingly more severe clinical effects, may occur. The consequences of the various possible disturbances of salt and water balance can be grouped as effects of decreased plasma volume secondary to decreased extracellular fluid volume, effects of hypernatremia, and effects of hyponatremia. The circulatory effects of decreased volume are nearly identical to the effects of peripheral pooling of blood (see Fig. 28.12), and the combined effects of peripheral pooling and decreased volume will be greater than the effects of either alone. These effects include impairment of cardiac filling and cardiac output and compensatory reflex reductions in renal, splanchnic, and skin blood flow. Impaired cardiac output leads to fatigue during exertion and decreased exercise tolerance. If skin blood flow is reduced, heat dissipation will be impaired. Exertional rhabdomyolysis, the injury of skeletal muscle fibers, is a frequent result of unaccustomed intense exercise. Myoglobin released from injured skeletal muscle cells appears in the plasma, rapidly enters the glomerular filtrate, and is excreted in the urine, producing myoglobinuria and staining the urine brown if enough myoglobin is present. This process

may be harmless to the kidneys if urine flow is adequate. However, a reduction in renal blood flow reduces urine flow, increasing the likelihood that the myoglobin will cause renal tubular injury.

Hypernatremic dehydration is believed to predispose to heatstroke. Both hypernatremia and reduced plasma volume often accompany dehydration. Hypernatremia impairs the heat loss responses (sweating and increased skin blood flow) independently of any accompanying reduction in plasma volume and elevates the thermoregulatory set point. Hypernatremic dehydration promotes the development of high core temperature in multiple ways through the combination of hypernatremia and reduced plasma volume.

Even in the absence of sodium loss, overdrinking that exceeds the kidneys' ability to compensate dilutes all the body's fluid compartments, producing dilutional hyponatremia, which is also called water intoxication if it causes symptoms. The development of water intoxication requires either massive overdrinking or a condition, such as the inappropriate secretion of arginine vasopressin, that impairs the excretion of free water by the kidneys. Overdrinking sufficient to cause hyponatremia may occur in patients with psychiatric disorders or disturbance of the thirst mechanism or may be done with a mistaken intention of preventing or treating dehydration. However, people who secrete copious amounts of sweat with a high sodium concentration, such as subject A or people with cystic fibrosis, may easily lose enough salt to become hyponatremic because of sodium loss. Some healthy young adults who come to medical attention for salt depletion after profuse sweating are found to have genetic variants of cystic fibrosis, which cause these people to have salty sweat without producing the characteristic digestive and pulmonary manifestations of cystic fibrosis.

As sodium concentration and osmolality of the extracellular space decrease, water moves from the extracellular space into the cells to maintain osmotic balance across the cell membranes. The resulting swelling of the brain cells causes most of the manifestations of hyponatremia. Mild hyponatremia is characterized by nonspecific symptoms such as fatigue, confusion, nausea, and headache and may be mistaken for heat exhaustion. Severe hyponatremia can be a life-threatening medical emergency and may include seizures, coma, herniation of the brainstem (which occurs if the brain swells enough to exceed the capacity of the cranium), and death. In the setting of prolonged exertion in the heat, symptomatic hyponatremia is far less common than heat exhaustion but potentially far more dangerous. Therefore, it is important not to treat a presumed case of heat exhaustion with large amounts of low-sodium fluids without first ruling out hyponatremia. ■

Increased vasodilation of the skin augments heat loss.

Heat produced in the body must be delivered to the skin surface to be eliminated. When skin blood flow is minimal, shell conductance is typically 5 to 9 W/°C/m^2 of body surface. For a lean resting subject with a surface area of 1.8 m^2, minimal whole body conductance of 16 W/°C (i.e., 8.9 W/[°C·m^2] × 1.8 m^2), and a metabolic heat production of 80 W, the temperature difference between the core and the skin must be 5°C (i.e., 80 W ÷ 16 W/°C) for the heat produced to be conducted to the surface. In a cool environment, $\overline{T}_{sk}$ may easily be low enough for this to occur. However, in an ambient temperature of 33°C, $\overline{T}_{sk}$ is typically about 35°C, and without an increase in conductance, core temperature would have to rise to 40°C—a high, although not yet dangerous, level—for the heat to be conducted to the skin. If the rate of heat production was increased to 480 W by moderate exercise, the temperature difference between core and skin would have to rise to 30°C—and core temperature to well beyond lethal levels—to allow all the heat produced to be conducted to the skin. In the latter circumstances, the conductance of the shell must increase greatly for the body to reestablish thermal balance and continue to regulate its temperature. This is accomplished by increasing the skin blood flow.

Effectiveness of skin blood flow in heat transfer

Assuming that blood on its way to the skin remains at core temperature until it reaches the skin, reaches skin temperature as it passes through the skin, and then stays at skin temperature until it returns to the core, we can compute the rate of heat flow (HF_b) as a result of convection by the blood as follows:

$$HF_b = SkBF \times (T_c - \overline{T}_{sk}) \times 3.85\ kJ/(L \cdot °C) \quad (8)$$

where SkBF is the rate of skin blood flow, expressed in liter per second rather than the usual liter per minute, to simplify computing HF in W (i.e., J/s), and 3.85 kJ/(L·°C) (0.92 kcal/[L·°C]) is the volume-specific heat of blood. Conductance as a result of convection by the blood (C_b) is calculated as follows:

$$C_b = HF_b/(T_c - \overline{T}_{sk}) = SkBF \times 3.85\ kJ/(L \cdot °C) \quad (9)$$

Of course, heat continues to flow by conduction through the tissues of the shell, and so total conductance is the sum of conductance as a result of convection by the blood and that resulting from conduction through the tissues. Total heat flow is given by the following equation:

$$HF = (C_b + C_0) \times (T_c - \bar{T}_{sk}) \quad (10)$$

where C_0 is thermal conductance of the tissues when skin blood flow is minimal and, thus, is predominantly a result of conduction through the tissues.

The assumptions made in deriving equation 8 are somewhat artificial and represent the conditions for maximum efficiency of heat transfer by the blood. In practice, blood exchanges heat also with the tissues through which it passes on its way to and from the skin. Heat exchange with these other tissues is greatest when skin blood flow is low; in such cases, heat flow to the skin may be much less than predicted by equation 8, as discussed further below. However, equation 8 is a reasonable approximation in a warm subject with moderate-to-high skin blood flow. Although measuring whole-body SkBF directly is not possible, it is believed to reach several liters per minute during heavy exercise in the heat. The maximum obtainable is estimated to be nearly 8 L/min. If SkBF = 1.89 L/min (0.0315 L/s), according to equation 9, skin blood flow contributes about 121 W/°C to the conductance of the shell. If conduction through the tissues contributes 16 W/°C, total shell conductance is 137 W/°C, and if T_c = 38.5°C and T_{sk} = 35°C, this will produce a core-to-skin heat transfer of 480 W, the heat production in our earlier example of moderate exercise. Therefore, even a moderate rate of skin blood flow can have a dramatic effect on heat transfer.

When a person is not sweating, raising skin blood flow brings skin temperature nearer to blood temperature, and lowering skin blood flow brings skin temperature nearer to ambient temperature. Under such conditions, the body can control dry (convective and radiative) heat loss by varying skin blood flow and, thus, skin temperature. Once sweating begins, skin blood flow continues to increase as the person becomes warmer. In these conditions, however, the tendency of an increase in sweating to cool the skin approximately balances the tendency of an increase in skin blood flow to warm the skin. Therefore, after sweating has begun, further increases in skin blood flow usually cause little change in skin temperature or dry heat exchange and serve primarily to deliver to the skin the heat that is being removed by the evaporation of sweat. Skin blood flow and sweating work in tandem to dissipate heat under such conditions.

Sympathetic control of skin circulation

Because the nutritional needs of the skin are low, the skin blood flow is controlled mainly by reflexes or changes in temperature. In most of the skin, the vasodilation that occurs during heat exposure depends on sympathetic nerve signals that cause the blood vessels to dilate, and regional nerve block can prevent or reverse this vasodilation. Because it depends on the action of neural signals, such vasodilation is sometimes referred to as *active vasodilation*. Active vasodilation occurs in almost all the skin, except in so-called acral regions—hands, feet, lips, ears, and nose. In skin areas where active vasodilation occurs, vasoconstrictor activity is minimal at thermoneutral temperatures, and active vasodilation during heat exposure does not begin until close to the onset of sweating. Therefore, small temperature changes within the thermoneutral range do not much affect skin blood flow in these areas.

Reflex vasodilation is complex, with potentially many layers of redundancy. With whole-body heating, sympathetic adrenergic tone is withdrawn and a sympathetic active vasodilator system is activated, most likely mediated by a cholinergic neurotransmitter system. Neuronal **nitric oxide** (**NO**) synthase (nNOS)-mediated NO is directly required for 30% to 40% of this response, may also contribute by inhibiting adrenergic function (see below), and appears to have no specific role in response to local

skin warming. Other mediators of this response include **vasoactive intestinal peptide (VIP)**, histamine, prostanoids, endothelial-derived hyperpolarizing factor, and **substance P**.

Increased local skin temperature (T_{loc}) also results in cutaneous vasodilation, although through an independent mechanism. Local vasodilatory mechanisms involved in local skin warming can increase SkBF to maximal levels, a biphasic response involving sensory nerves that mediate an initial transient vasodilatory "peak" followed by a prolonged vasodilatory "plateau" that is mediated primarily by endothelial NOS generation of NO.

Active vasodilation operates in tandem with sweating in the heat and is impaired or absent in **anhidrotic ectodermal dysplasia**, a congenital disorder in which sweat glands are sparse or absent. For these reasons, the existence of a mechanism linking active vasodilation to the sweat glands has long been suspected but never established. Recent studies have demonstrated an attenuated sweat rate after NOS inhibition, suggesting that NO augments sweat secretion. Additionally, NOS inhibition attenuates the sweat response to exercise in a warm environment, suggesting that NO has a role in modifying thermoregulatory sweating, specifically by changing sweat gland output. While the overall importance of NO's role remains unknown, the magnitude of reduction in local sweat rate by NOS inhibition is as large as that induced by dehydration. Accordingly, NO appears to play an important role in thermoregulatory control of sweating during exercise in warm environments.

Reflex vasoconstriction, occurring in response to cold and as part of certain nonthermal reflexes such as baroreflexes, is mediated primarily through adrenergic sympathetic fibers distributed widely over most of the skin. The process is initiated when the mean whole-body skin temperature decreases below thermoneutral levels of around 33°C and is mediated by **norepinephrine** (**NE**) and neuropeptide Y released from vasoconstrictor nerves. Although evidence suggests that endogenous NO can inhibit or modulate this response, these two neurotransmitters appear to be all that is necessary. Accordingly, reducing the flow of impulses in these nerves allows the blood vessels to dilate. In the acral regions and superficial veins (whose role in heat transfer is discussed below), vasoconstrictor fibers are the predominant vasomotor innervation, and the vasodilation that occurs during heat exposure is largely a result of the withdrawal of vasoconstrictor activity. Blood flow in these skin regions is sensitive to small temperature changes even in the thermoneutral range and may be responsible for "fine-tuning" heat loss to maintain heat balance in this range.

There also exists a local vasoconstrictive response to skin cooling that has two components. An adrenergic element includes reduced secretion of norepinephrine that is more than overcome by an increase in α_{2C}-receptor sensitivity via Rho-kinase–mediated signaling. The second element involves a withdrawal of tonic NO production through inhibition of NOS and subsequent steps in the NO system.

THERMOREGULATORY CONTROL

In discussions of control systems, the words “regulation” and “regulate” have meanings distinct from those of the word “control” (see Chapter 1). The variable that a control system acts to maintain within narrow limits (e.g., temperature) is called the *regulated* variable, and the quantities it controls to accomplish this (e.g., sweating rate, skin blood flow, metabolic rate, and thermoregulatory behavior) are called *controlled* variables.

Humans have two distinct subsystems for regulating body temperature: behavioral thermoregulation and physiologic thermoregulation. Behavioral thermoregulation—through the use of shelter, space heating, air conditioning, and clothing—enables humans to live in the most extreme climates in the world, but it does not provide fine control of body heat balance. In contrast, physiologic thermoregulation is capable of fairly precise adjustments of heat balance but is effective only within a relatively narrow range of environmental temperatures.

Temperature is perceived through thermal sensation.

Sensory information about body temperatures is an essential part of both behavioral and physiologic thermoregulation. The distinguishing feature of behavioral thermoregulation is the involvement of consciously directed efforts to regulate body temperature. Thermal discomfort provides the necessary motivation for thermoregulatory behavior, and behavioral thermoregulation acts to reduce both the discomfort and the physiologic strain imposed by a stressful thermal environment. For this reason, both thermal comfort and the absence of shivering and sweating characterize the zone of thermoneutrality.

Warmth and cold on the skin are felt as either comfortable or uncomfortable, depending on whether they decrease or increase the physiologic strain—a shower temperature that feels pleasant after strenuous exercise may be uncomfortably chilly on a cold winter morning. The processing of thermal information in behavioral thermoregulation is not as well understood as it is in physiologic thermoregulation. However, perceptions of thermal sensation and comfort respond much more quickly than core temperature or physiologic thermoregulatory responses to changes in environmental temperature and, thus, appear to anticipate changes in the body's thermal state. Such an anticipatory feature would be advantageous because it would reduce the need for frequent small behavioral adjustments.

Thermal defense mechanisms operate through changes in heat production and heat loss.

Familiar inanimate control systems, such as most refrigerators and heating and air-conditioning systems, operate at only two levels: on and off. In a typical home-heating system, for example, when the indoor temperature falls below the desired level, the thermostat detects the change and turns on the burner and blower in the furnace; when the temperature is restored to the desired level, the thermostat turns the furnace off. Rather than operating at only two levels, most physiologic control systems produce a graded response according to the size of the disturbance in the regulated variable. In many instances, changes in the controlled variables are proportional to displacements of the regulated variable from some threshold value.

The control of heat-dissipating responses is an example of a proportional control system. Figure 28.9 shows how reflex control of two heat-dissipating responses, sweating and skin blood flow, depends on body core temperature and mean skin temperature. Each response has a core temperature threshold—a temperature at which the response starts to increase—and this threshold depends on mean skin temperature. At any given skin temperature, the change in each response is proportional to the change in core temperature, and increasing the skin temperature lowers the threshold level of core temperature and increases the response at any given core temperature. In humans, a change of 1°C in core temperature elicits about nine times as great a thermoregulatory response as a 1°C change in mean skin temperature. (Besides its effect on the reflex signals, skin temperature has a local effect that modifies the response of the blood vessels and sweat glands to the reflex signal, discussed later.)

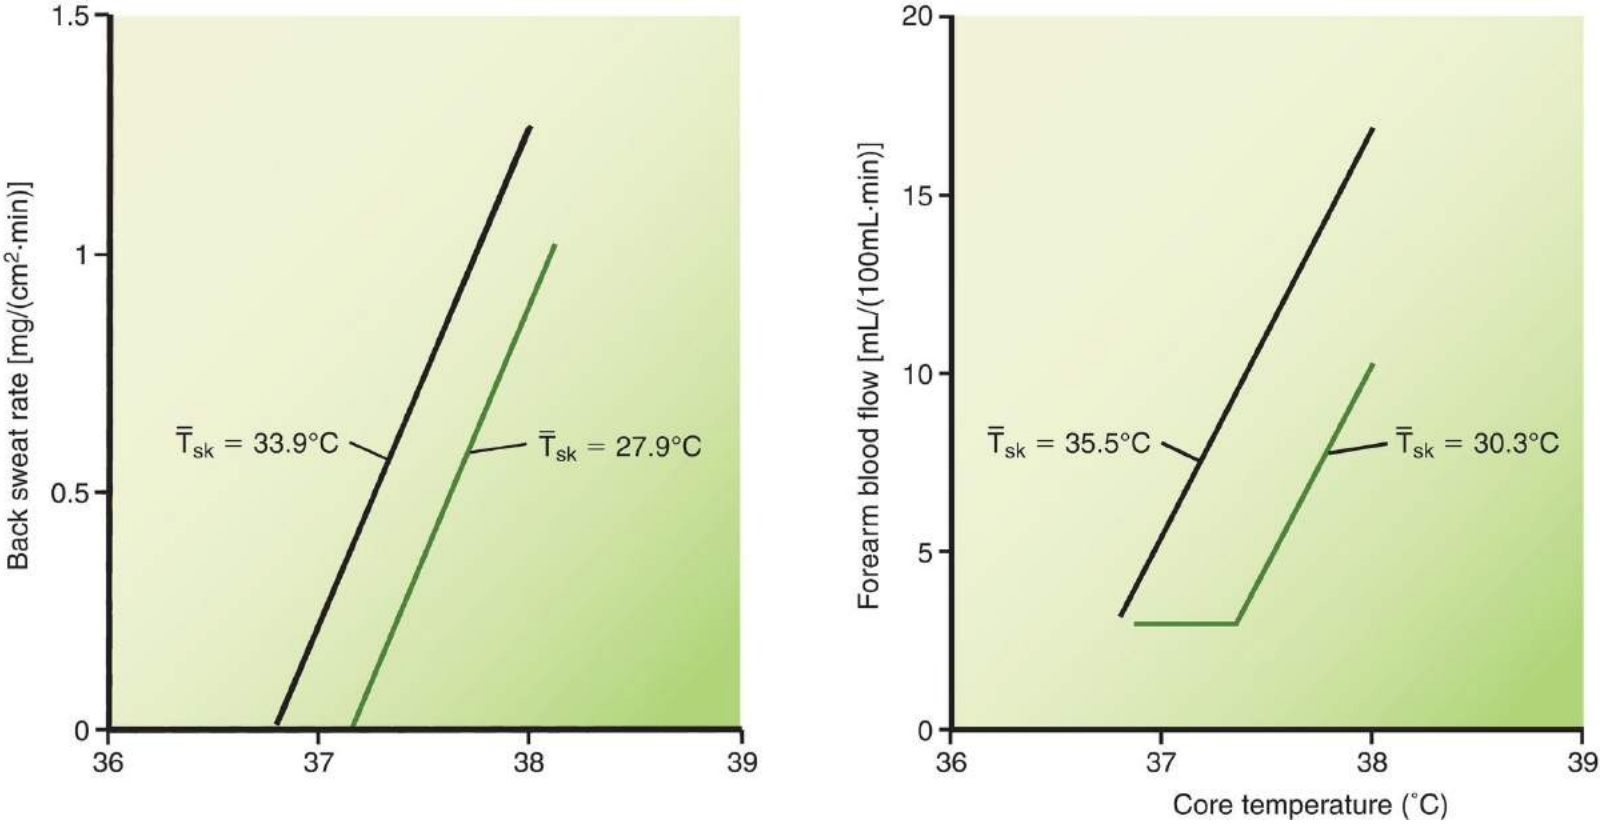

Figure 28.9 Control of heat-dissipating responses. These graphs show the relations of back (scapular) sweat rate **(left)** and forearm blood flow **(right)** to core temperature and mean skin temperatures (

$\overline{T}_{sk}$). In these experiments, exercise increased core temperature.

Cold stress elicits increases in metabolic heat production through shivering and nonshivering thermogenesis. **Shivering** is a rhythmic oscillating tremor of skeletal muscles. On a local level, movement is uncoordinated as reflected by rapid (i.e., 250 Hz) electromyographic activity. However, there is an overall 4 to 8 cycles/min "waxing-and-waning" activity that is clinically apparent during intense shivering. The CNS network generating the cold-evoked bursts of α-motor neuron activity is not well understood, but it includes transmission of cutaneous cold afferent signals through the lateral parabrachial nucleus, integration of thermoregulatory signals in the preoptic area (POA), lifting of its inhibition, and activation of fusimotor neurons (β- and γ-motor neurons), which is dependent on descending neurons in the rostral ventromedial medulla. Although these efferent impulses are not rhythmic, their overall effect is to increase muscle tone, thereby increasing metabolic rate. Once the tone exceeds a critical level, the contraction of one group of muscle fibers stretches the muscle spindles in other fiber groups in series with it, eliciting contractions from those groups of fibers via the stretch reflex, and so on; thus, the rhythmic oscillations that characterize frank shivering begin.

Shivering occurs in bursts, and signals from the cerebral cortex inhibit the "shivering pathway," so that voluntary muscular activity and attention can suppress shivering. Because the limbs are part of the shell in the cold, trunk and neck muscles are preferentially recruited for shivering—the centralization of shivering—to help retain the heat produced during shivering within the body core; and the familiar experience of teeth chattering is one of the earliest signs of shivering. As with heat-dissipating responses, the control of shivering depends on both core and skin temperatures, but the details of its control are not precisely understood.

Hypothalamus integrates thermal information from the core and the skin.

Temperature receptors in the body core and skin transmit information about their temperatures through afferent nerves to the brainstem and, especially, the hypothalamus, where much of the integration of temperature information occurs. The sensitivity of the thermoregulatory system to core temperature enables it to adjust heat production and heat loss to resist disturbances in core temperature. Sensitivity to mean skin temperature lets the system respond appropriately to mild heat or cold exposure with little change in body core temperature, so that changes in body heat as a result of changes in environmental temperature take place almost entirely in the peripheral tissues (see Fig. 28.2). For example, the skin temperature of someone who enters a hot environment may rise and elicit sweating even if there is no change in core temperature. On the other hand, an increase in heat production within the body, as during exercise, elicits the appropriate heat-dissipating responses through a rise in core temperature.

Core temperature receptors involved in controlling thermoregulatory responses are unevenly distributed and are concentrated in the POA of the anterior hypothalamus. Most of these are warm sensitive, meaning they increase their activity with increased brain temperature. In experimental mammals, temperature changes of only a few tenths of 1°C in the hypothalamus elicit changes in the thermoregulatory effector responses. Although much less common, cold-sensitive neurons (i.e., those that increase their activity with a decrease in brain temperature) also exist. However, the cold sensitivity of most of them seems to be due to inhibitory synaptic input from the nearby warm-sensitive neurons. The roles of cold- and warm-sensitive POA neurons are not reciprocal. Studies involving thermal and chemical stimulation of POA cells have shown that both cold-defense and heat-defense autonomic responses are initiated by the corresponding changes in the activity of warm-sensitive neurons; increased activity of warm-sensitive POA neurons triggers heat-defense responses, whereas decreased activity triggers cold-defense responses. Because warm-sensitive POA neurons display spontaneous membrane depolarization, these cells are considered pacemakers; their thermosensitivity is due to currents that determine the rate of spontaneous depolarization between successive action potentials. Furthermore, morphologic identification of thermosensitive neurons in the POA has shown their orientation to be ideally suited to receiving afferent projections from peripheral thermoreceptors via the medial forebrain bundle. In addition to the POA cold- and warm-sensitive neurons, there are peripheral deep-body sensors that respond to changes in core body temperature. They are located in the esophagus, stomach, large intra-abdominal veins, and other organs.

Consider what happens when some disturbance—say, an increase in metabolic heat production resulting from exercise—upsets the thermal balance. Additional heat is stored in the body, and core temperature rises. The central thermoregulatory controller receives information about these changes from the thermal receptors and elicits appropriate heat-dissipating responses. Core temperature continues to rise, and these responses continue to increase until they are sufficient to dissipate heat as fast as it is being produced, restoring heat balance and preventing further increases in body temperatures. In the language of control theory, the rise in core temperature that elicits heat-dissipating responses sufficient to reestablish thermal balance during exercise is an example of a load error. A load error is characteristic of any proportional control system that is resisting the effect of some imposed disturbance or “load.” Although the disturbance in this example is exercise, the same principle applies if the disturbance is a decrease in metabolic rate or a change in the environment. However, if the disturbance is in the environment, most of the temperature change will be in the skin and shell rather than in the core. If the disturbance produces a

net loss of heat, the body will restore heat balance by decreasing heat loss and increasing heat production.

Set point is the body's "thermostat."

The primary autonomic defenses against heat are sweating and active cutaneous vasodilation, whereas the primary autonomic defenses against cold are cutaneous vasoconstriction and shivering. The core temperature, or reference temperature, triggering each response defines its activation threshold. Body temperature is normally maintained between the sweating and vasoconstriction thresholds, temperatures that define the *interthreshold range* (also referred to as the "null zone"). Onset of sweating, thus, usually defines the upper boundary of normal body temperature, and cutaneous vasoconstriction defines the lower boundary. Typically, the interthreshold range is only a few tenths of a degree, and it is thus likely that temperatures within this range are accurately sensed but do not generate an error signal and trigger thermoregulatory responses. Under normal circumstances, thermoregulatory control can thus be roughly modeled as a discrete yet adjustable "**set point**" ($\mathbf{T_{set}}$) (Fig. 28.10). That thermoregulatory responses are likely to have unique thresholds within the thermal integrative network is exemplified by the fact that the threshold for shivering is typically a degree less than the vasoconstriction threshold. Shivering is thus a "last resort" response and appropriately so because it is metabolically inefficient.

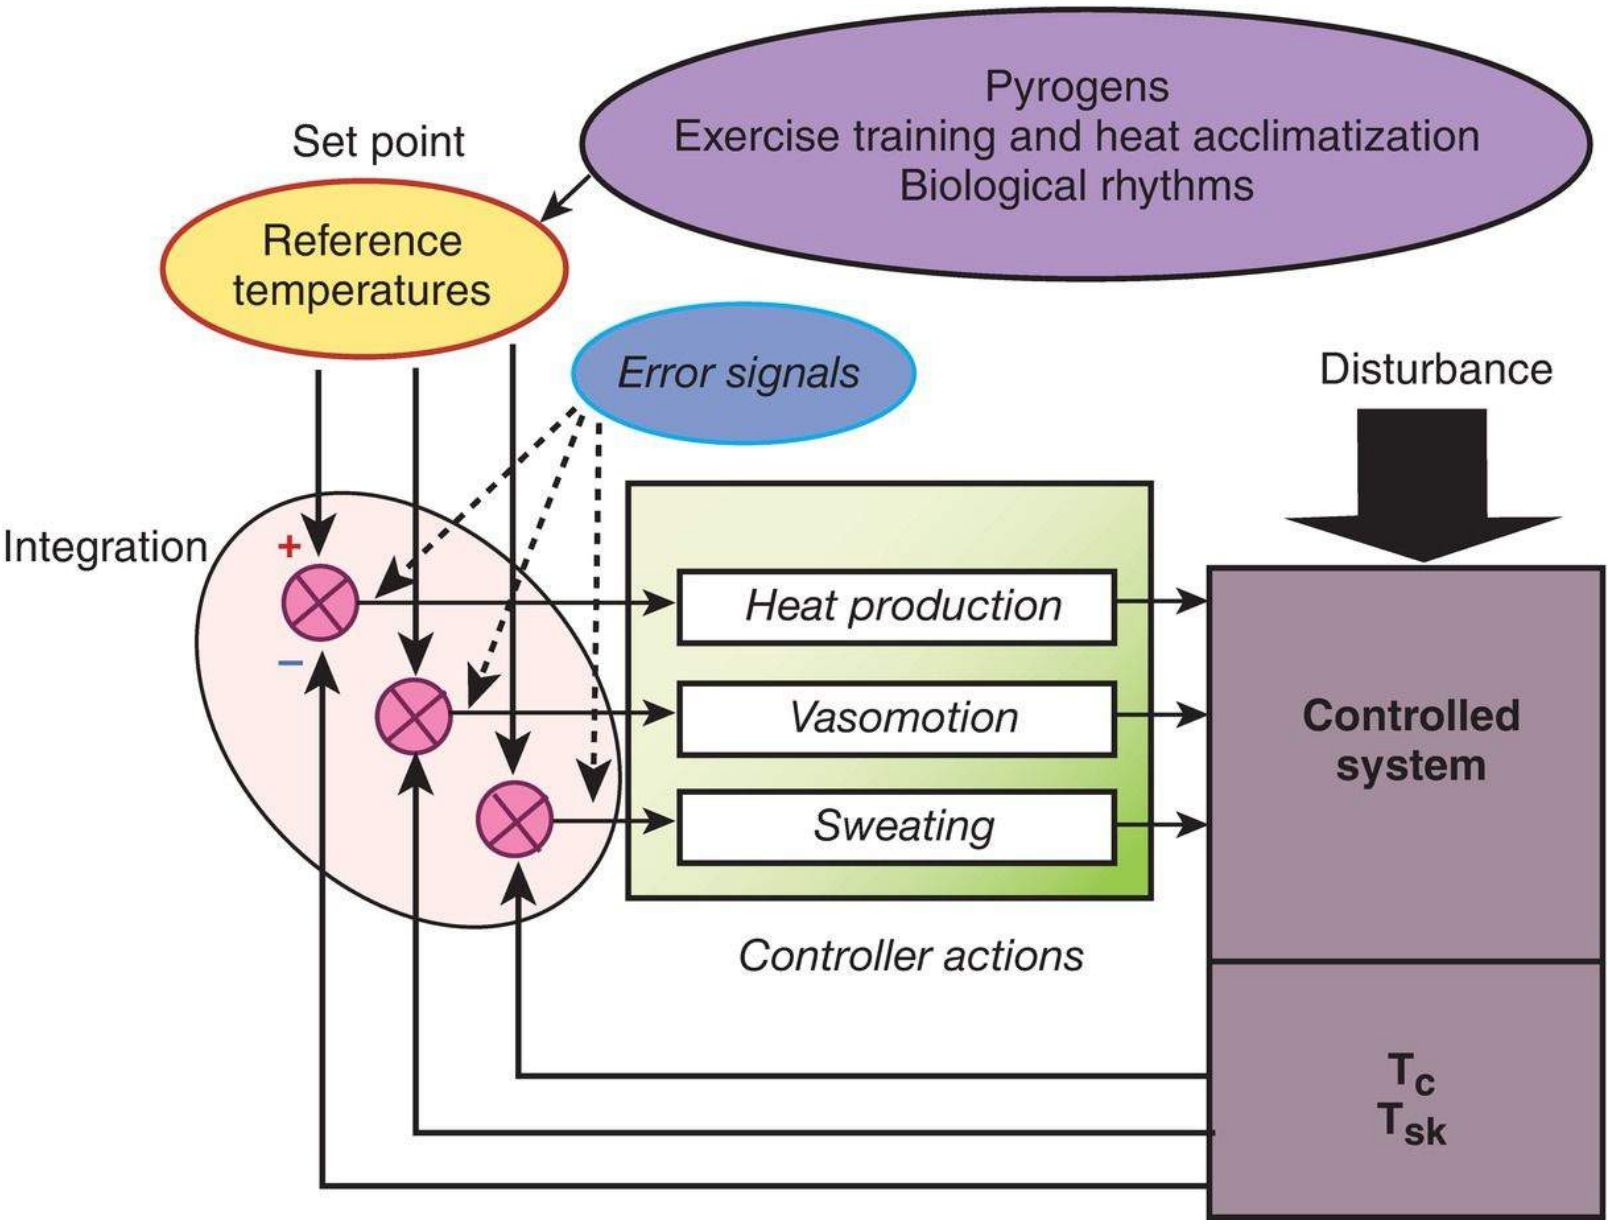

Figure 28.10 A control system model for temperature regulation. Multiple reference temperatures

(one for each thermoeffector) comprise the adjustable set point, and active (controlling system) and passive (controlled system) components are part of the system. A disturbance to the passive system is detected by the sensors and the information from these compare with reference temperatures. The resultant error signal drives the thermoeffectors comprising the controlling system. The aim of such a negative feedback control system is the minimization of the error signal. T_c is core temperature, and T_{sk} is skin temperature.

Effect of nonthermal inputs on thermoregulatory responses

Each thermoregulatory response may be affected by inputs other than body temperatures and factors that influence the set point. We have already noted that voluntary activity affects shivering and certain hormones affect metabolic heat production. In addition, nonthermal factors may produce a burst of sweating at the beginning of exercise, and emotional effects on sweating and skin blood flow are matters of common experience. Skin blood flow is the thermoregulatory response most influenced by nonthermal factors because of its potential involvement in reflexes that function to maintain cardiac output, blood pressure, and tissue O_2 delivery under a variety of disturbances, including heat stress, postural changes, hemorrhage, exercise, hydration state, sleep, and narcosis.

Biologic rhythms and altered physiologic states can change the thermoregulatory set point.

Fever elevates core temperature at rest, heat acclimatization decreases it, and time of day and (in women) the phase of the menstrual cycle change it in a cyclic fashion. Core temperature at rest varies in an approximately sinusoidal fashion with time of day. The minimum temperature occurs at night, several hours before awaking, and the maximum, which is 0.5°C to 1°C higher, occurs in the late afternoon or evening (see Fig. 28.3). This pattern coincides with patterns of activity and eating but does not depend on them, and it occurs even during bed rest in fasting subjects. This pattern is an example of a **circadian rhythm**, a rhythmic pattern in a physiologic function with a period of about 1 day. During the menstrual cycle, core temperature is at its lowest point just before ovulation. During the next few days, it rises from 0.5°C to 1°C to a plateau that persists through most of the luteal phase. Each of these factors—fever, heat acclimatization, the circadian rhythm, and the menstrual cycle—changes the core temperature at rest by changing the thermoregulatory set point, producing corresponding changes in the thresholds for all of the thermoregulatory responses.

Skin temperature alters cutaneous blood flow and sweat gland responses.

The skin is the organ most directly affected by environmental temperature. Skin temperature influences heat loss responses not only through reflex actions (see Fig. 28.10) but also through direct effects on the skin blood vessels and sweat glands.

Local temperature changes act on skin blood vessels in at least two ways. First, local cooling potentiates (and heating weakens) the constriction of blood vessels in response to nerve signals and vasoconstrictor substances. (At low temperatures, however, cold-induced vasodilation [CIVD] increases skin blood flow, as discussed later.) Second, in skin regions where active vasodilation occurs, local heating causes vasodilation (and local cooling causes vasoconstriction) through a direct action on the vessels, independent of nerve signals. The local vasodilator effect of skin temperature is especially strong above 35°C; and, when the skin is warmer than the blood, increased blood flow helps cool the skin and protect it from heat injury, unless this response is impaired by vascular disease. Local thermal effects on sweat glands parallel those on blood vessels, and so local heating potentiates (and local cooling diminishes) the local sweat gland response to reflex stimulation or ACh, and intense local heating elicits sweating directly, even in skin whose sympathetic innervation has been interrupted surgically.

Sweat gland “fatigue” alters thermoregulation.

During prolonged heat exposure (lasting several hours) with high sweat output, sweating rates gradually decline and the response of sweat glands to local cholinergic drugs is reduced. This reduction of sweat gland responsiveness is sometimes called sweat gland “fatigue.” Wetting the skin makes the stratum corneum swell, mechanically obstructing the sweat gland ducts and causing a reduction in sweat secretion, an effect called **hidromeiosis**. The glands’ responsiveness can be at least partly restored if air movement increases or humidity is reduced, allowing some of the sweat on the skin to evaporate. Sweat gland fatigue may involve processes besides hidromeiosis because prolonged sweating also causes histologic changes, including the depletion of glycogen, in the sweat glands.

THERMOREGULATORY RESPONSES DURING EXERCISE

During intense physical exercise, metabolic heat production can increase 10- to 20-fold, with <30% of the heat generated converted into mechanical energy. Consequently, more than 70% of metabolic heat generated must be transported to the skin to be dissipated to the environment. Heat starts to accumulate in the body when the heat-dissipating mechanisms are unable to cope with metabolic heat production, leading to an increase in body temperature. Although hot environments also elicit heat-dissipating responses, exercise ordinarily is responsible for the greatest demands on the thermoregulatory system for heat dissipation. Exercise provides an important example of how the thermoregulatory system responds to a disturbance in heat balance. In addition, exercise and thermoregulation impose competing demands on the circulatory system because exercise requires large increases in blood flow to exercising muscle, whereas the thermoregulatory responses to exercise require increases in skin blood flow. Muscle blood flow during exercise is several times as great as skin blood flow, but the increase in skin blood flow is responsible for disproportionately large demands on the cardiovascular system, as discussed below. Finally, if the water and electrolytes lost through sweating are not replaced, the resulting reduction in plasma volume will eventually create a further challenge to cardiovascular homeostasis.

Core temperature rises during exercise, triggering heat loss responses.

As previously mentioned, the increased metabolic heat production during exercise causes an increase in core temperature, which in turn elicits heat loss responses. Core temperature continues to rise until heat loss has increased enough to match heat production, and core temperature and the heat loss responses reach new steady-state levels. Because the heat loss responses are proportional to the increase in core temperature, the increase in core temperature at steady state is proportional to the rate of heat production and, thus, to the metabolic rate.

A change in ambient temperature causes changes in the levels of sweating and skin blood flow necessary to maintain any given level of heat dissipation. However, the change in ambient temperature also elicits, via direct and reflex effects of the accompanying skin temperature changes, altered responses in the right direction. For any given rate of heat production, there is a certain range of environmental conditions within which an ambient temperature change elicits the necessary changes in heat-dissipating responses almost entirely through the effects of skin temperature changes, with virtually no effect on core temperature. (The limits of this range of environmental conditions depend on the rate of heat production and such individual factors as skin surface area and state of heat acclimatization.) Within this range, the core temperature reached during exercise is nearly independent of ambient temperature. For this reason, it was once believed that the increase in core temperature during exercise is caused by an increase in the thermoregulatory set point, as during fever. As noted, however, the increase in core temperature with exercise is an example of a load error rather than an increase in set point.

This difference between fever and exercise is shown in Figure 28.11. Note that, although heat production may increase substantially (through shivering), when core temperature is rising early during fever, it need not stay high to maintain the fever. In fact, it returns nearly to prefebrile levels once the fever is established. During exercise, however, an increase in heat production not only causes the elevation in core temperature but is necessary to sustain it. Also, although the core temperature is rising during fever, the rate of heat loss is, if anything, lower than it was before the fever began. During exercise, however, the heat-dissipating responses and the rate of heat loss start to increase early and continue to increase as the core temperature rises.

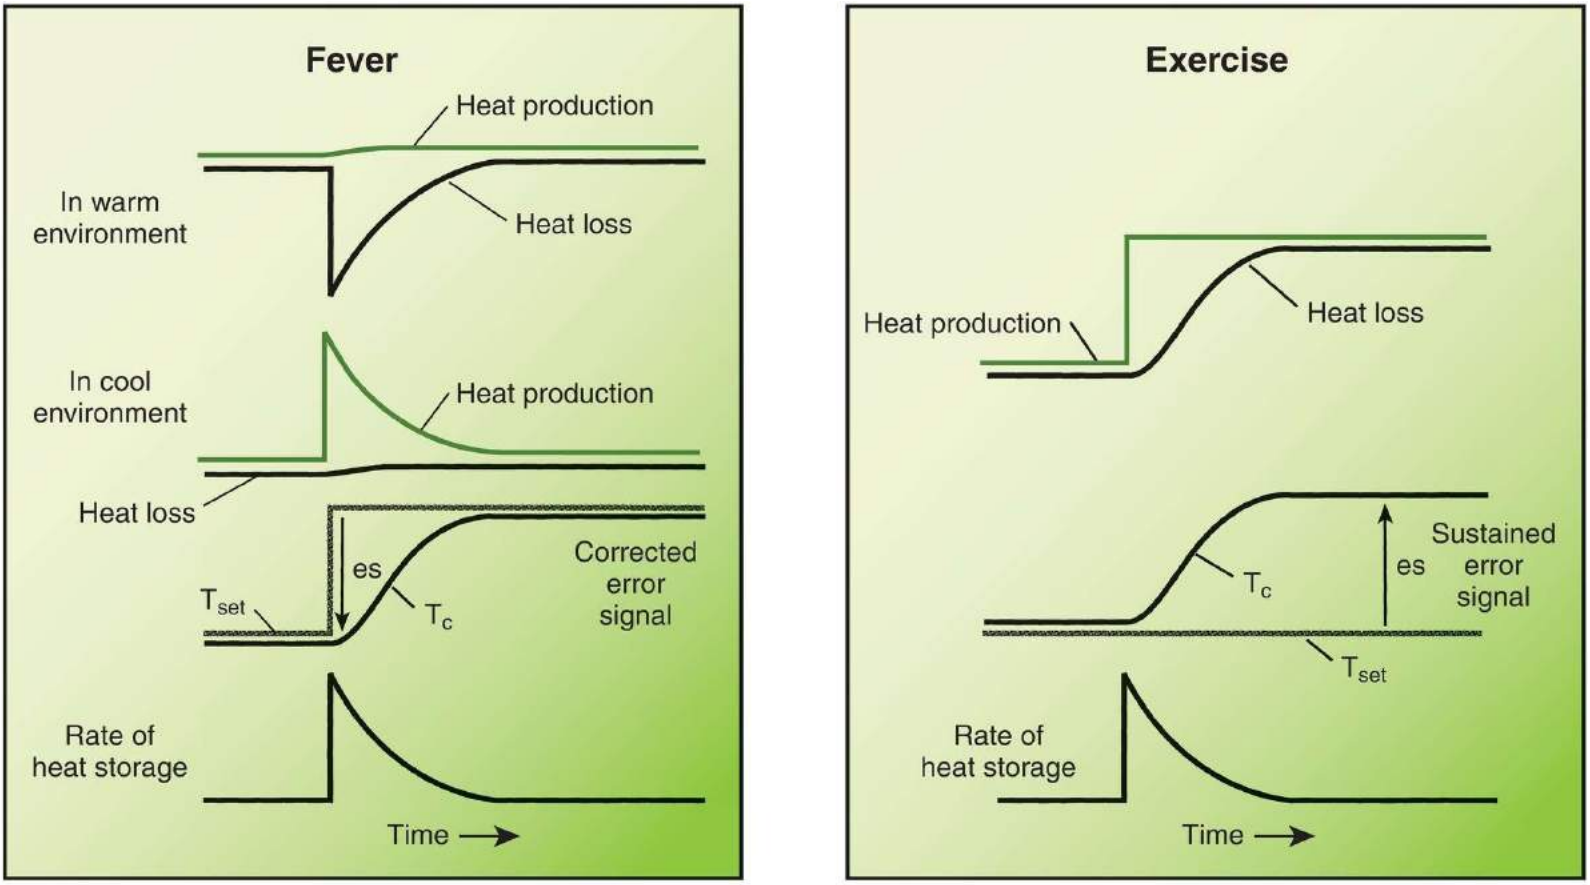

Figure 28.11 Thermal events during fever and exercise. (A) The development of fever. **(B)** The increase in T_c during exercise. The es (error signal or load error) is the difference between the T_c and the T_{set}. At the start of a fever, T_{set} has risen, so that T_{set} is higher than T_c and es is negative. At steady state, T_c has risen to equal the new level of T_{set} and es is corrected (i.e., it returns to zero.) At the start of exercise, $T_c = T_{set}$ so that es = 0. At steady state, T_{set} has not changed but T_c has increased and is greater than T_{set}, producing a sustained es. (es is here represented with an *arrow* pointing downward for $T_c < T_{set}$ and with an *arrow* pointing upward for $T_c > T_{set}$.)

Exercise in the heat can impair cardiac filling.

The rise in core temperature during exercise increases the temperature difference between the core and the skin somewhat but not nearly enough to match the increase in metabolic heat production. Therefore, as we saw earlier, skin blood flow must increase to carry all of the heat that is produced to the skin. In a warm environment, where the temperature difference between core and skin is relatively small, the necessary increase in skin blood flow may be several liters per minute.

The work of providing the skin blood flow required for thermoregulation in the heat may impose a heavy burden on a diseased heart, but in healthy people, the major cardiovascular burden of heat stress results from impaired venous return. As skin blood flow increases, the dilated vascular bed of the skin becomes engorged with large volumes of blood, reducing central blood volume and cardiac filling (Fig. 28.12). Stroke volume is decreased, and a higher heart rate is required to maintain cardiac output. A decrease in plasma volume, if the large amounts of salt and water lost in the sweat are not replaced, aggravates these effects. Because the main cation in sweat is sodium, a disproportionately large amount of the body water lost in sweat is at the expense of extracellular fluid, including plasma, although this effect is mitigated if the sweat is dilute.

Skin

Figure 28.12 Cardiovascular strain and compensatory responses during heat stress. This figure first shows the effects of skin vasodilation on peripheral pooling of blood and the thoracic reservoirs from which the ventricles are filled and, second, the effects of compensatory vasomotor adjustments in the splanchnic circulation. The valves on the *right* represent the resistance vessels that control blood flow through the liver/splanchnic, muscle, and skin vascular beds. *Arrows* show the direction of the changes during heat stress.

Compensatory responses during exercise in the heat

Several reflex adjustments help maintain cardiac filling, cardiac output, and arterial pressure during exercise and heat stress. The most important of these is constriction of the renal and splanchnic vascular beds. A reduction in blood flow through these beds allows a corresponding diversion of cardiac output to the skin and the exercising muscles. In addition, because the splanchnic vascular beds are compliant, a decrease in their blood flow reduces the amount of blood pooled in them (see Fig. 28.12), helping compensate for decreases in central blood volume caused by reduced plasma volume and blood pooling in the skin.

The degree of vasoconstriction is graded according to the levels of heat stress and exercise intensity. During strenuous exercise in the heat, renal and splanchnic blood flows may fall to 20% of their values in a cool resting subject. Such intense splanchnic vasoconstriction may produce mild ischemic injury to the gut, helping explain the intestinal symptoms that some athletes experience after endurance events. The cutaneous veins constrict during exercise; because most of the vascular volume is in the veins, constriction makes the cutaneous vascular bed less easily distensible and reduces peripheral pooling. Because of the essential role of skin blood flow in thermoregulation during exercise and heat stress, the body preferentially compromises splanchnic and renal flow for the sake of cardiovascular homeostasis. Above a certain level of cardiovascular strain, however, skin blood flow, too, is compromised.

HEAT ACCLIMATIZATION

As in other mammals, thermoregulation is an important aspect of human homeostasis. Humans have been able to adapt to a great diversity of climates, including hot humid and hot arid. High temperatures pose serious stresses for the human body, placing it in great danger of injury and even death. For humans, adjusting to varying climatic conditions includes both physiologic mechanisms as a by-product of evolution and the conscious development of cultural adaptations.

Prolonged or repeated exposure to stressful environmental conditions elicits significant physiologic changes, called **acclimatization**, the process of an individual organism adjusting to a change in its environment. Acclimatization occurs in a short time (days or weeks) and can be reversed once removed from the stress, unlike **adaptation**, which is permanent and passed on to the next generation. Some degree of heat *acclimatization* occurs either by heat exposure alone or by regular strenuous exercise, which raises core temperature and provokes heat loss responses. Indeed, the first summer heat wave produces enough heat acclimatization that most people notice an improvement in their level of energy and general feeling of well-being after a few days. However, the acclimatization response is greater if heat exposure and exercise are combined, causing a greater rise of internal temperature and more profuse sweating. Evidence of acclimatization appears in the first few days of combined exercise and heat exposure, and most of the improvement in heat tolerance occurs within 10 days. The effect of heat acclimatization on performance can be dramatic, and acclimatized subjects can easily complete exercise in the heat that earlier was difficult or impossible.

Changes in basal metabolism, heart rate, cutaneous blood flow, and sweat rate occur with heat acclimatization.

Studies of seasonal variation in basal metabolism indicate an inverse relationship between BMR and ambient temperature. A linear correlation between basal metabolism and mean outdoor temperature within a range of 10°C to 25°C exists, so that a rise of 10°C in monthly mean ambient temperature is accompanied by a fall of 2.5 to 3.0 kcal/m^2/h in basal metabolism, a change linked to lower thyroxine levels. During exposure to hot environments, cardiovascular adaptations that reduce the heart rate required to sustain a given level of activity in the heat appear quickly and reach nearly their full development within 1 week. Changes in sweating develop more slowly. After acclimatization, sweating begins earlier and at a lower core temperature (i.e., the core temperature threshold for sweating is reduced). The sweat glands become more sensitive to cholinergic stimulation, and a given elevation in core temperature elicits a higher sweat rate. In addition, the glands become resistant to hidromeiosis and fatigue, and so higher sweat rates can be sustained. These changes reduce the levels of core and skin temperatures reached during a period of exercise in the heat, increase the sweat rate, and enable one to exercise longer. The threshold for cutaneous vasodilation is reduced along with the threshold for sweating, and so the heat transfer from the core to the skin is maintained. The lower heart rate, lower core temperature, and higher sweat rate are the three classic signs of heat acclimatization (Fig. 28.13).

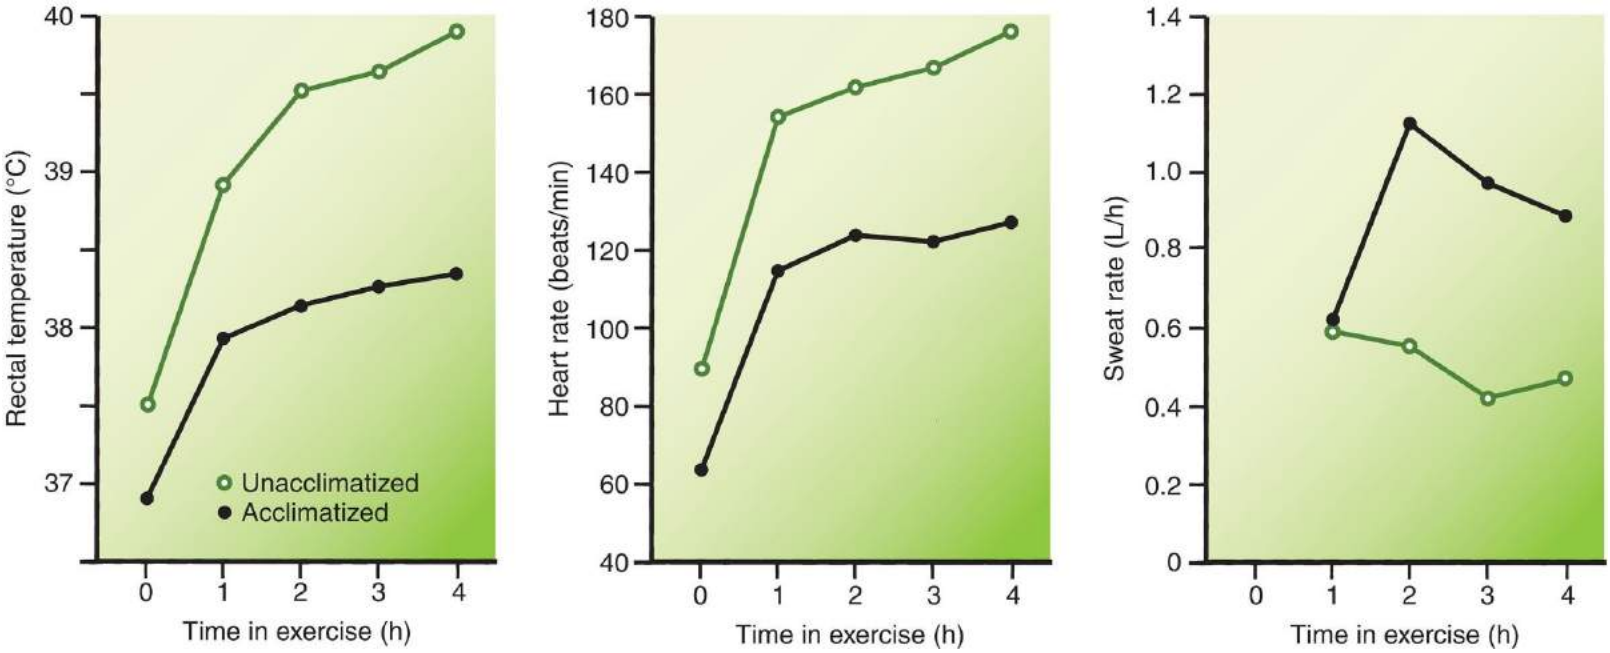

Figure 28.13 Heat acclimatization. These graphs show rectal temperatures, heart rates, and sweat rates during 4-hour exercise (bench stepping, 35 W mechanical power) in humid heat (33.9°C dry bulb, 89% relative humidity, 35 torr ambient vapor pressure) on the first and last days of a 2-week program of acclimatization to humid heat.

Heat acclimatization modifies fluid and electrolyte balance.

During the first week, total body water and, especially, plasma volume increase. These changes likely contribute to the cardiovascular adaptations. Later, the fluid changes seem to diminish or disappear, although the cardiovascular adaptations persist. In an unacclimatized person, sweating occurs mostly on the chest and back, but during acclimatization, especially in humid heat, the fraction of sweat secreted on the limbs increases to make better use of the skin surface for evaporation. An unacclimatized person who is sweating profusely can lose large amounts of sodium. With acclimatization, the sweat glands become able to conserve sodium by secreting sweat with a sodium concentration as low as 5 mmol/L. This effect is mediated through aldosterone, which is secreted in response to sodium depletion and to exercise and heat exposure. The sweat glands respond to aldosterone more slowly than the kidneys, requiring several days. Unlike the kidneys, the sweat glands do not escape the influence of aldosterone when sodium balance has been restored but continue to conserve sodium for as long as acclimatization persists. The cell membranes are freely permeable to water so that the movement of water across the cell membranes rapidly corrects any osmotic imbalance between the intracellular and extracellular compartments (see Chapter 2). One important consequence of the salt-conserving response of the sweat glands is that the loss of a given volume of sweat causes a smaller decrease in the volume of the extracellular space than if the sodium concentration of the sweat is high (Table 28.3).

TABLE 28.3 Effect of Sweat Secretion on Body Fluid Compartments and Plasma Sodium Concentration*

		Extracellular Space		Intracellular Space		Total Body Water			
Subject	Condition	Volume (L)	Osmotic Content (mOsm)	Volume (L)	Osmotic Content (mOsm)	Volume (L)	Osmotic Content (mOsm)	Osmolality (mOsm/kg)	Plasma [Na^+] (mmol/L)
A	Initial	15.0	4,350	25.0	7,250	40	11,600	290	140
	Loss of 5 L of sweat, 120 mOsm/L, 60 mmol Na^+/L	11.9	3,750	23.1	7,250	35	11,000	314	151
	Above condition accompanied by intake of 5 L water	13.6	3,750	26.4	7,250	40	11,000	275	132
B	Loss of 5 L of sweat, 20 mOsm/L, 10 mmol Na^+/L; accompanied by intake of 5 L water	12.9	4,250	22.1	7,250	35	11,500	329	159
	Above condition accompanied by intake of 5 L water	14.8	4,250	25.2	7,250	40	11,500	288	139

*Each subject has total body water of 40 L. The sweat of subject A has a relatively high [Na^+] of 60 mmol/L, whereas that of subject B has a relatively low [Na^+] of 10 mmol/L. Volumes of the extracellular and intracellular spaces are calculated assuming that water moves between the two spaces as needed to maintain osmotic balance.

Heat acclimatization is transient, disappearing in a few weeks if not maintained by repeated heat

exposure. The components of heat acclimatization are lost in the order in which they were acquired. The cardiovascular changes decay more quickly than the reduction in exercise core temperature and sweating changes.

RESPONSES TO COLD

When the body is exposed to cold temperatures, heat loss is minimized in several ways: (1) sweating stops; (2) minute muscles under the skin contract (**piloerection**), causing “gooseflesh” or “goose bumps”; (3) cutaneous arterioles constrict, thereby rerouting the blood away from the skin; (4) shivering, which increases heat production in skeletal muscles; and (5) fat is converted into energy by mitochondria. Brown fat is specialized for this purpose and is most abundant in newborns.

Arteriole vasoconstriction reroutes blood away from the skin to conserve heat.

Reducing **conductance** is the chief physiologic means of heat conservation during cold exposure. The constriction of cutaneous arterioles reduces skin blood flow and shell conductance. However, in extremely cold conditions, excessive vasoconstriction leads to numbness and pale skin. Frostbite only occurs when water within the cells begins to freeze; this destroys the cell, causing the characteristic damage.

Constriction of the superficial limb veins further improves heat conservation by diverting venous blood to the deep limb veins, which lie close to the major arteries of the limbs and do not constrict in the cold. (Many penetrating veins connect the superficial veins to the deep veins so that venous blood from anywhere in the limb potentially can return to the heart via either superficial or deep veins.) In the deep veins, cool venous blood returning to the core can take up heat from the warm blood in the adjacent deep limb arteries. Therefore, some of the heat contained in the arterial blood as it enters the limbs takes a "short circuit" back to the core. When the arterial blood reaches the skin, it is already cooler than the core, and so it loses less heat to the skin than it otherwise would. (When the superficial veins dilate in the heat, most venous blood returns via superficial veins so as to maximize core-to-skin heat flow.) The transfer of heat from arteries to veins by this short circuit is called **countercurrent heat exchange**. This mechanism can cool the blood in the radial artery of a cool but comfortable subject to as low as 30°C by the time it reaches the wrist.

As we saw earlier, the shell's insulating properties increase in the cold as its blood vessels constrict and its thickness increases. Furthermore, the shell includes a fair amount of skeletal muscle in the cold, and although muscle blood flow is believed not to be affected by thermoregulatory reflexes, direct cooling reduces it. In a cool subject, the resulting reduction in muscle blood flow adds to the shell's insulating properties. As the blood vessels in the shell constrict, blood is shifted to the central blood reservoir in the thorax. This shift produces many of the same effects as an increase in blood volume, including the so-called **cold diuresis** as the kidneys respond to the increased central blood volume.

Shivering is a heat-producing mechanism in response to hypothermia.

Shivering is a physiologic response to early hypothermia in mammals. When core body temperature drops, the shivering reflex, mediated through the hypothalamus, is triggered to maintain homeostasis. Muscle groups around vital organs begin to contract in an attempt to generate heat by expending energy. There are two types of shivering: low intensity and high intensity. During *low intensity*, shivering occurs constantly at low levels over long periods during cold conditions. During *high intensity*, shivering occurs violently over a short period. Both processes consume energy. Low intensity burns fat, whereas glucose is burned with high-intensity shivering.

Once skin blood flow is near minimal, metabolic heat production increases—almost entirely through shivering in human adults. Shivering may increase metabolism at rest more than fourfold—that is, to 350 to 400 W. Although it is often stated that shivering diminishes substantially after several hours and is impaired by exhaustive exercise, such effects are not well understood. In most laboratory mammals, chronic cold exposure also causes **nonshivering thermogenesis**, an increase in metabolic rate that is not a result of muscle activity. Nonshivering thermogenesis appears to be elicited through sympathetic stimulation and circulating catecholamines. It occurs in many tissues, especially in the liver and in **brown adipose tissue**, also called *brown fat*, specialized for nonshivering thermogenesis whose color is imparted by high concentrations of iron-containing respiratory enzymes. Brown adipose tissue is found in human infants, and nonshivering thermogenesis is important for their thermoregulation. The existence of brown adipose tissue and nonshivering thermogenesis in human adults is controversial, but recent evidence strongly suggests the presence of functioning brown adipose deposits in a substantial fraction of adult humans. These are located symmetrically in the supraclavicular and the neck regions with some additional paravertebral, mediastinal, para-aortic, and suprarenal (but no interscapular) localizations and respond with increased activity to sympathetic stimulation and exposure to cold.

Cold acclimatization is an important characteristic in thermal regulation and maintaining homeostasis.

The pattern of human cold acclimatization depends on the nature of the cold exposure. It is partly for this reason that the occurrence of cold acclimatization in humans was controversial for a long time. Our knowledge of human cold acclimatization comes from both laboratory studies and studies of populations whose occupation or way of life exposes them repeatedly to cold temperatures.

Metabolic changes in cold acclimatization

At one time, it was believed that humans must acclimatize to cold as laboratory mammals do—by increasing their metabolic rate. There are a few reports of increased BMR and, sometimes, thyroid activity in the winter. More often, however, increased metabolic rate has not been observed in studies of human cold acclimatization. In fact, several reports indicate the opposite response, consisting of a lower core temperature threshold for shivering, with a greater fall in core temperature and a smaller metabolic response during cold exposure. Such a response would spare metabolic energy and might be advantageous in an environment that is not so cold that a blunted metabolic response would allow core temperature to fall to dangerous levels.

Increased tissue insulation in cold acclimatization

A lower core-to-skin conductance (i.e., increased insulation by the shell) has often been reported in studies of cold acclimatization in which a reduction in the metabolic response to cold occurred. This increased insulation is not a result of subcutaneous fat (in fact, it has been observed in lean subjects) but apparently results from lower blood flow in the limbs or improved countercurrent heat exchange in the acclimatized subjects. In general, the cold stresses that elicit a lower shell conductance after acclimatization involve either cold water immersion or exposure to air that is chilly but not so cold as to risk freezing the vasoconstricted extremities.

CLINICAL ASPECTS OF THERMOREGULATION

Temperature is important clinically because of the presence of fever in many diseases, the effects of many factors on tolerance to heat or cold stress, and the effects of heat or cold stress in causing or aggravating certain disorders.

Fever is one of the body's immunologic responses to a bacterial or viral infection.

Fever is due to an increase in the body temperature regulatory set point. This increase in set point increases muscle tone and shivering. Infection or noninfectious conditions (e.g., inflammatory processes such as collagen vascular diseases, trauma, neoplasms, acute hemolysis, and immunologically mediated disorders) may cause fever. **Pyrogens** are substances that cause fever and may be either exogenous or endogenous. *Exogenous pyrogens* are derived from outside the body; most are microbial products, microbial toxins, or whole microorganisms. The best studied of these is the lipopolysaccharide endotoxin of gram-negative bacteria. Exogenous pyrogens stimulate a variety of cells, especially monocytes and macrophages, to release *endogenous pyrogens*, polypeptides that cause the thermoreceptors in the hypothalamus (and perhaps elsewhere in the brain) to alter their firing rate and input to the central thermoregulatory controller, raising the thermoregulatory set point. The local synthesis and release of **prostaglandin E_2** mediate this effect of endogenous pyrogens. Aspirin and other drugs that inhibit the synthesis of prostaglandins also reduce fever.

Fever accompanies disease so frequently and is such a reliable indicator of the presence of disease that body temperature is probably the most commonly measured clinical index. A group of polypeptides called **cytokines** elicits many of the body's defenses against infection and cancer; the endogenous pyrogen is usually a member of this group, **interleukin-1**. However, other cytokines, particularly **tumor necrosis factor**, **interleukin-6**, and the **interferons**, are also pyrogenic in certain circumstances. Elevated body temperature enhances the development of these defenses. How cytokines interact with the hypothalamus remains unclear. However, they are believed to cross the blood–brain barrier by facilitated transport mechanisms, diffuse into areas of the brain where there is no blood–brain barrier, or interact with peripheral neural components of the immune system to signal the hypothalamus to increase the thermal set point. There is evidence to support each mechanism, and it seems likely that each contributes to some extent in various circumstances. If laboratory animals are prevented from developing a fever during experimentally induced infection, survival rates may be dramatically reduced. (Although, in this chapter, fever specifically means an elevation in core temperature resulting from pyrogens, some authors use the term more generally to mean any significant elevation of core temperature.)

Tolerance to heat and cold is dependent on factors affecting thermoregulatory responses.

Regular physical exercise and heat acclimatization increase heat tolerance and the sensitivity of the sweating response. Aging has the opposite effect; in healthy 65-year-old men, the sensitivity of the sweating response is half of that in 25-year-old men. Many drugs inhibit sweating, most obviously those used for their anticholinergic effects, such as atropine and scopolamine. In addition, some drugs used for other purposes, such as glutethimide (a sleep-inducing drug), tricyclic antidepressants, phenothiazines (tranquilizers and antipsychotic drugs), and antihistamines, have some anticholinergic action. All of these and several others have been associated with heatstroke. Congestive heart failure and certain skin diseases (e.g., ichthyosis and anhidrotic ectodermal dysplasia) impair sweating, and in patients with these diseases, heat exposure and especially exercise in the heat may raise body temperature to dangerous levels. Lesions that affect the thermoregulatory structures in the brainstem can also alter thermoregulation. Such lesions can produce **hypothermia** (abnormally low core temperature) if they impair heat-conserving responses. However, **hyperthermia** (abnormally high core temperature) is a more usual result of brainstem lesions and is typically characterized by a loss of both sweating and the circadian rhythm of core temperature.

Certain drugs, such as barbiturates, alcohol, and phenothiazines, and certain diseases, such as hypothyroidism, hypopituitarism, congestive heart failure, and septicemia, may impair the defense against cold. (Hypothermia, instead of the usual febrile response to infection, may accompany septicemia, especially in debilitated patients.) Furthermore, newborns and many healthy older adults are less able than older children and younger adults to maintain adequate body temperature in the cold. This failing appears to be a result of an impaired ability to conserve body heat by reducing heat loss and to increase metabolic heat production in the cold.

Heat stress can lead to pathophysiologic disorders.

The harmful effects of heat stress are exerted through cardiovascular strain, fluid and electrolyte loss, and, especially in heatstroke, tissue injury whose mechanism is uncertain. In a patient suspected of having hyperthermia secondary to heat stress, temperature should be measured in the rectum because hyperventilation may render oral temperature spuriously low.

Heat syncope

Heat syncope is circulatory failure resulting from a pooling of blood in the peripheral veins, with a consequent decrease in venous return and diastolic filling of the heart, resulting in decreased cardiac output and a fall of arterial pressure. Symptoms range from light-headedness and giddiness to loss of consciousness. Thermoregulatory responses are intact, and so core temperature typically is not substantially elevated, and the skin is wet and cool. The large thermoregulatory increase in skin blood flow in the heat is probably the primary cause of the peripheral pooling. Heat syncope affects mostly those who are not acclimatized to heat presumably because the plasma–volume expansion that accompanies acclimatization compensates for the peripheral pooling of blood. Treatment consists in laying the patient down out of the heat to reduce the peripheral pooling of blood and improve the diastolic filling of the heart.

Heat exhaustion

Heat exhaustion, also called *heat collapse*, is probably the most common heat disorder and represents a failure of cardiovascular homeostasis in a hot environment. Collapse may occur either at rest or during exercise and may be preceded by weakness or faintness, confusion, anxiety, ataxia, vertigo, headache, and nausea or vomiting. The patient has dilated pupils and usually sweats profusely. As in heat syncope, reduced diastolic filling of the heart appears to have a primary role in the pathogenesis of heat exhaustion. Although blood pressure may be low during the acute phase of heat exhaustion, the baroreflex responses are usually sufficient to maintain consciousness and may be manifested in nausea, vomiting, pallor, cool or even clammy skin, and rapid pulse. Patients with heat exhaustion usually respond well to rest in a cool environment and oral fluid replacement. In more severe cases, however, intravenous replacement of fluid and salt may be required. Core temperature may be normal or only mildly elevated in heat exhaustion. However, heat exhaustion accompanied by hyperthermia and dehydration may lead to heatstroke. Therefore, patients should be actively cooled if rectal temperature is 40.6°C (105°F) or higher.

The reasons underlying the reduced diastolic filling in heat exhaustion are not fully understood. Hypovolemia contributes if the patient is dehydrated, but heat exhaustion often occurs without significant dehydration. In rats heated to the point of collapse, compensatory splanchnic vasoconstriction develops during the early part of heating but is reversed shortly before the maintenance of blood pressure fails. A similar process may occur in heat exhaustion.

Heatstroke

High core temperature and the development of serious neurologic disturbances with a loss of consciousness and, frequently, convulsions characterize the most severe and dangerous heat disorder. **Heatstroke** occurs in two forms, classical and exertional. In the classical form, the primary factor is environmental heat stress that overwhelms an impaired thermoregulatory system, and most patients have preexisting chronic disease. In exertional heatstroke, the primary factor is high metabolic heat production.

Patients with exertional heatstroke tend to be younger and more physically fit (typically, soldiers and athletes) than patients with the classical form. Rhabdomyolysis, hepatic and renal injury, and disturbances of blood clotting are frequent accompaniments of exertional heatstroke. The traditional diagnostic criteria of heatstroke—coma, hot dry skin, and rectal temperature above 41.3°C (106°F)—are characteristic of the classical form. However, patients with exertional heatstroke may have somewhat lower rectal temperatures and often sweat profusely. Heatstroke is a medical emergency, and prompt appropriate treatment is critically important to reducing morbidity and mortality. The rapid lowering of core temperature is the cornerstone of treatment, and immersion in cold water most effectively accomplishes it. With prompt cooling, vigorous hydration, maintenance of a proper airway, avoidance of aspiration, and appropriate treatment of complications, most patients will survive, especially if they were previously healthy.

The pathogenesis of heatstroke is not well understood, but it seems clear that factors other than hyperthermia are involved, even if the action of these other factors partly depends on the hyperthermia. Exercise may contribute more to the pathogenesis than simply metabolic heat production. Elevated plasma levels of several inflammatory cytokines have been reported in patients presenting with heatstroke, suggesting a systemic inflammatory component. No trigger for such an inflammatory process has been established, although several possible candidates exist. One possible trigger is some product(s) of the bacterial flora in the gut, perhaps including lipopolysaccharide endotoxins. Several lines of evidence suggest that sustained splanchnic vasoconstriction may produce a degree of intestinal ischemia sufficient to allow these products to “leak” into the circulation and activate inflammatory responses. Other causes relate to reticuloendothelial system deactivation and heat-induced changes in proinflammatory and anti-inflammatory cytokines.

The preceding diagnostic categories are traditional. However, they are not entirely satisfactory for heat illness associated with exercise because many patients have laboratory evidence of tissue and cellular injury, but they are classified as having heat exhaustion because they do not have the serious neurologic disturbances that characterize heatstroke. Some more recent literature uses the term **exertional heat injury** for such cases. The boundaries of exertional heat injury, with heat exhaustion on one hand and heatstroke on the other, are not clearly and consistently defined, and these categories probably represent parts of a continuum.

Malignant hyperthermia, a rare process triggered by depolarizing neuromuscular-blocking agents or certain inhalational anesthetics, was once thought to be a form of heatstroke but is now known to be a distinct disorder that occurs in people with a mutation of the ryanodine receptor (type 1) on the sarcoplasmic reticulum. In 90% of susceptible people, biopsied skeletal muscle tissue contracts on exposure to caffeine or halothane in concentrations having little effect on normal muscle. Susceptibility may be associated with any of several myopathies, but most susceptible people have no other clinical manifestations. The control of free (unbound) calcium ion concentration in skeletal muscle cytoplasm is severely impaired in susceptible people, and when an attack is triggered, calcium concentration rises abnormally, activating myosin ATPase and leading to an uncontrolled hypermetabolic process that rapidly increases core temperature. Treatment with dantrolene sodium, which appears to act by reducing the release of calcium ions from the sarcoplasmic reticulum, has dramatically reduced the mortality rate of this disorder.

Aggravation of disease states by heat exposure

Other than producing specific disorders, heat exposure aggravates several other diseases. Epidemiologic studies show that during unusually hot weather, mortality may be two to three times that normally expected

for the months in which heat waves occur. Deaths ascribed to specific heat disorders account for only a small fraction of the excess mortality (i.e., the increase above the expected mortality). Deaths from diabetes, various diseases of the cardiovascular system, and diseases of the blood-forming organs account for most of the excess mortality.

Drop in core temperature results in hypothermia.

Core temperature drops when the body is exposed to cold and the internal thermoregulatory mechanisms are unable to replenish the heat that is being lost. Hypothermia exhibits characteristic symptoms as body temperature decreases, such as shivering and mental confusion.

Much of our knowledge about the physiologic effects of hypothermia comes from observations of surgical patients.

During the initial phases of cooling, stimulation of shivering through thermoregulatory reflexes overwhelms the Q_{10} effect. Metabolic rate, therefore, increases, reaching a peak at a core temperature of 30°C to 33°C. At lower core temperatures, however, the Q_{10} effect dominates metabolic rate, and thermoregulation is lost. A vicious circle develops, wherein a fall in core temperature depresses metabolism and allows core temperature to fall further, so that at 17°C, the O_2 consumption is about 15% and cardiac output 10% of precooling values.

Hypothermia that is not induced for therapeutic purposes is called **accidental hypothermia**. It occurs in people whose defenses are impaired by drugs (especially ethanol, in the United States), disease, or other physical conditions and in healthy people who are immersed in cold water or become exhausted working or playing in the cold.

Hypothermia is also often induced during surgical procedures, based on the idea that hypothermia reduces metabolic rate via the Q_{10} effect and prolongs the time that tissues can safely tolerate a loss of blood flow. Because the brain is damaged by ischemia soon after circulatory arrest, *controlled hypothermia* is often used to protect the brain during surgical procedures in which its circulation is occluded or the heart is stopped (Clinical Focus 28.2).

CLINICAL FOCUS 28.2

Hypothermia

Hypothermia is classified according to the patient's core temperature as mild (32°C to 35°C), moderate (28°C to 32°C), or severe (below 28°C). Shivering is usually prominent in mild hypothermia but diminishes in moderate hypothermia and is absent in severe hypothermia. The pathophysiology is characterized chiefly by the depressant effect of cold (via the Q_{10} effect) on multiple physiologic processes and differences in the degree of depression of each process. Other than shivering, the most prominent features of mild and moderate hypothermia are a result of depression of the central nervous system. Beginning with mood changes (commonly, apathy, withdrawal, and irritability), they progress to confusion and lethargy, followed by ataxia and speech and gait disturbances, which may mimic a cerebrovascular accident (stroke). In severe hypothermia, voluntary movement, reflexes, and consciousness are lost and muscular rigidity appears. Cardiac output and respiration decrease as core temperature falls. Myocardial irritability increases in severe hypothermia, causing a substantial danger of ventricular fibrillation, with the risk increasing as cardiac temperature falls. The primary mechanism presumably is that cold depresses conduction velocity in Purkinje fibers more than in ventricular

muscle, favoring the development of circus-movement propagation of action potentials. Myocardial hypoxia also contributes. In more profound hypothermia, cardiac sounds become inaudible and pulse and blood pressure are unobtainable because of circulatory depression; the electrical activity of the heart and brain becomes unmeasurable; and extensive muscular rigidity may mimic rigor mortis. The patient may appear clinically dead, but patients have been revived from core temperatures as low as 17°C, and so "no one is dead until warm and dead." The usual causes of death during hypothermia are respiratory cessation and the failure of cardiac pumping because of either ventricular fibrillation or direct depression of cardiac contraction.

Depression of renal tubular metabolism by cold impairs the reabsorption of sodium, causing a diuresis and leading to dehydration and hypovolemia. Acid–base disturbances in hypothermia are complex. Respiration and cardiac output typically are depressed more than metabolic rate, and a mixed respiratory and metabolic acidosis results because of CO_2 retention and lactic acid accumulation and the cold-induced shift of the hemoglobin–O_2 dissociation curve to the left. Acidosis aggravates the susceptibility to ventricular fibrillation.

Treatment consists of preventing further cooling and restoring fluid, acid–base, and electrolyte balance. Patients in mild-to-moderate hypothermia may be warmed solely by providing abundant insulation to promote the retention of metabolically produced heat; those who are more severely affected require active rewarming. The most serious complication associated with treating hypothermia is the development of ventricular fibrillation. Vigorous handling of the patient may trigger this process, but an increase in the patient's circulation (e.g., associated with warming or skeletal muscle activity) may itself increase the susceptibility to such an occurrence, as follows. Peripheral tissues of a hypothermic patient are, in general, even cooler than the core, including the heart, and acid products of anaerobic metabolism will have accumulated in underperfused tissues while the circulation was most depressed. As the circulation increases, a large increase in blood flow through cold, acidotic peripheral tissue may return enough cold, acidic blood to the heart to cause a transient drop in the temperature and pH of the heart, increasing its susceptibility to ventricular fibrillation.

The diagnosis of hypothermia is usually straightforward in a patient rescued from the cold but may be far less clear in a patient in whom hypothermia is the result of a serious impairment of physiologic and behavioral defenses against cold. A typical example is the older person, living alone, who is discovered at home cool and obtunded or unconscious. The setting may not particularly suggest hypothermia, and when the patient comes to medical attention, the diagnosis may easily be missed because standard clinical thermometers are not graduated low enough (usually only to 34.4°C) to detect hypothermia and, in any case, do not register temperatures below the level to which the mercury has been shaken. Because of the depressant effect of hypothermia on the brain, the patient's condition may be misdiagnosed as cerebrovascular accident or other primary neurologic disease. Recognition of this condition depends on the physician's considering it when examining a cool patient whose mental status is impaired and obtaining a true core temperature with a low-reading glass thermometer or other device. ■

Therapeutic Hypothermia and Targeted Temperature Management

Cardiac arrest has a grim prognosis with >50% of patients with out-of-hospital cardiac arrest dying at the scene or within a few hours after return of spontaneous circulation (ROSC). The mortality rate after cardiac arrest of patients admitted to the intensive care unit (ICU) is determined largely by (1) their neurological outcomes and (2) the extent of cardiac tissue injury related to an increase in tissue oxidative stress caused by ischemia/reperfusion (I/R) observed within minutes ROSC. In the past decade, this mortality rate has decreased significantly, largely due to increased attention to the post–cardiopulmonary resuscitation (CPR) phase, particularly when therapeutic hypothermia (TH) is included.

Studies have shown that significant levels of oxidative stress in the heart following cardiac arrest stem from the mitochondria within minutes of reperfusion. In isolated cardiomyocytes, simulated I/R induces mitochondrial reactive oxygen species generation, contractile dysfunction, mitochondrial release of cytochrome c, caspase activation, opening of the mitochondrial permeability transition pore, and ultimately cardiomyocyte death. Targeted temperature management (TTM) via TH is the only treatment currently known to improve survival in clinical post–cardiac arrest patients. This type of cooling is now being induced by emergency personnel during CPR, prior to ROSC, in an attempt to improve cardiovascular function and outcome. In some cardiac arrest survivors, cooling is induced after ROSC, while they are transported to a cardiac catheterization laboratory for possible percutaneous coronary intervention of acute myocardial infarction (AMI). Although intraischemic cooling prior to reperfusion may be highly cardioprotective, the general use of cooling for AMI (non–cardiac arrest) patients remains unproven. Recent studies in mouse cardiomyocytes suggest that cardioprotective hypothermia (5°C drop in temperature) does more than simply slow reperfusion ROS generation. Cardiomyocyte cooling increases Akt phosphorylation resulting from relative inhibition of regulatory phosphatases. Akt is a survival kinase that mediates mitochondrial protection by modulating ROS and nitric oxide (NO) generation. In addition, mild cooling can alter the strength of weak bonds that determine the conformation and association of individual proteins/enzymes that increase protein function—temperature-mediated alterations in mRNA translational efficiency have also been observed. Mildly decreased temperature, like that used in TTM, seem to attenuate proapoptotic signals, including cytochrome c release, Fas and Bax up-regulation, and caspase activation and it activates antiapoptotic mechanisms such as the Erk1/2 pathway and the Akt pathway. The expression of p53 is enhanced by hypothermia, promoting repair after focal ischemia. The levels of neuron-specific enolase, a marker of neuron death, are also reduced in patients treated with hypothermia following CPR. Cardioprotection is also associated with several kinase signaling pathways including the G-coupled receptors, the reperfusion injury salvage kinase (RISK), and the JAK STAT pathway. The enhanced Akt-NO signaling with reduction of ROS independent of cGMP suggests that TTM is associated with RISK pathway signaling. This is of particular clinical relevance because it suggests that the beneficial effects of TTM soon may be replaced or enhanced by suitable pharmacological agents that target these protein pathways (Vaity et al. *Critical Care* 2015;19:103).

The most beneficial effect of TTM is a decreased metabolic rate (by 6% to 10% per degree of hypothermia), which leads to reduced oxygen consumption. Additionally, neuronal excitotoxicity—where increased calcium influx in the ischemic neurons and elevated glutamate release combine to induce brain damage—can be prevented or diminished by TTM. Furthermore, activation of the physiological immune response by tissue damage, along with leukocyte and macrophage recruitment and complement activation, provokes additional damage in ischemic conditions through the release of free radicals. TTM modulates these immune-related responses and decreases brain edema. These

destructive cascades that are the consequence of ischemia result in elevated brain temperature. Both global and localized brain edema impede heat dissipation by venous and lymphatic flow, thereby raising the relative ischemic brain tissue temperature up to 2°C, in contrast to core body temperature. This concept, known as cerebral thermo-pooling, is a critical factor directly affected by TTM. ■

Chapter Summary

- Humans are homeotherms and regulate temperature within a narrow range.
- Physiologic and physical processes operate continuously to balance heat production and heat loss and to maintain constant body temperature.
- The body can exchange heat energy with the environment via conduction, convection, radiation, and evaporation.
- Internal conduction and circulatory convection transfer heat from the body's core to the shell.
- Most of the metabolic energy used in cell processes is converted into heat within the body, and metabolic rate is the quantity of food energy converted to heat per unit of time.
- Basal metabolic rate is a measure of the metabolic cost of living measured under standard conditions.
- Metabolic rate is estimated by indirect calorimetry, based on measuring a person's rate of oxygen consumption.
- Heat exchange is proportional to surface area and obeys biophysical principles.
- Sweating is essential for heat loss and involves the glandular secretion of a dilute electrolyte solution onto the skin surface that rapidly evaporates in hot environments, cooling the body.
- Raising skin blood flow brings skin temperature nearer to blood temperature, and lowering skin blood flow brings skin temperature nearer to ambient temperature, enabling convective and radiative heat loss.
- Humans have two distinct subsystems for regulating body temperature: behavioral and physiologic thermoregulation; the latter operates through graded control of heat production and heat loss responses.
- Temperature receptors in the body core and skin transmit information about their temperatures through afferent nerves to the brainstem and, especially, the hypothalamus, where much of the integration of temperature information takes place.
- Signals for both heat-dissipating and heat-generating mechanism recruitment are based on the information about core and skin temperatures as well as nonthermal information received by the central nervous system and on the thermoregulatory set point.
- Fever elevates core temperature at rest, heat acclimatization decreases it, and time of day changes it in a cyclic fashion by changing the thermoregulatory set point.
- Intense exercise may increase heat production within the body 10-fold or more, requiring large increases in skin blood flow and sweating to reestablish the body's heat balance.
- Prolonged or repeated exposure to stressful environmental conditions elicits significant physiologic changes that reduce the resulting strain.
- The body maintains core temperature in the cold by minimizing heat loss and, when this response is insufficient, by increasing heat production.
- Fever enhances defense mechanisms, whereas heat and cold stress can cause significant harm.

Chapter Review Questions

1. An unconscious subject is pulled from an icy river and is found to have a mean skin temperature (T_{sk}) of 8°C. Core temperature (T_c), measured rectally, is 30°C. What is this person's mean body temperature (T_b)?
   A. 37°C
   B. 26.9°C
   C. 21.7°C
   D. 17.8°C
   E. 10.6°C

The correct answer is B. As shown in Figure 28.2, in very cold environments, thickness of the shell depends on the thermal environment and the body's need to conserve heat. In the icy river, the shell expands greatly to keep core temperature as high as possible, thus contributing disproportionately to T_b. Using the formula $T_b = 0.65 \times T_c + 0.35 \times T_{sk}$ (in the cold), 19.5 + 2.8 = 22.3°C.

2. A patient is suspected of suffering from mild hyperthyroidism. Her estimated body surface area is 1.6 m^2, and during a basal metabolic rate test, she consumes 7.5 L of O_2 in 30 minutes. Assuming she is on a mixed diet (energy equivalent of 4.8 Cal/L O_2), what is her metabolic rate?
   A. 18 Cal/m^2/h
   B. 24 Cal/m^2/h
   C. 36 Cal/m^2/h
   D. 45 Cal/m^2/h
   E. 54 Cal/m^2/h

The correct answer is D. Because BMR is indirectly determined by O_2 consumption at near basal conditions and, in this case, the energy equivalent of that consumption is 4.8 Cal/L O_2, the subject consumed 36 L of O_2 during the 30-minute measurement, corresponding to 36 Cal. Correcting for her body surface area, 1.6 m^2, and the half hour duration, her metabolic rate is 45 Cal/m^2/h. Because the typical female BMR is roughly 36 Cal/m^2/h, the suspicion of hyperthyroidism is accurate.

3. What effect on thermoregulatory processes would you expect after infusing N(G)-nitro-L-arginine methyl ester (L-NAME), a competitive inhibitor of nitric oxide synthase (NOS), at 1 mg/kg/h into an exercising subject (treadmill running at room temperature)?
   A. Increased sweating; increased cutaneous vasodilation
   B. Reduced sweating rate; increased cutaneous vasodilation
   C. Reduced sweating rate; decreased cutaneous vasodilation
   D. Increased preoptic area hypothalamic activation
   E. Decreased preoptic area hypothalamic activation

The correct answer is C. As described in the chapter, neuronal nitric oxide (NO) synthase (nNOS)-mediated NO is directly implicated in a significant portion of the withdrawal of sympathetic adrenergic tone and activation of the sympathetic active vasodilator system as well as modifying thermoregulatory sweating, specifically by increasing sweat gland output during whole-body heating. Inhibition of these actions during exercise-induced hyperthermia by the NOS inhibitor L-NAME would be expected to attenuate the response in both thermoregulatory cutaneous vasodilation and sweating.

4. The following are characteristic of which heat stress-related disorder: rapid increase in core temperature due to an uncontrolled hypermetabolic process related to mutation of the ryanodine receptor in susceptible individuals.
   A. Heatstroke
   B. Malignant hyperthermia
   C. Heat exhaustion
   D. Heat syncope
   E. Thermal dystrophy

The correct answer is B. Malignant hyperthermia is a rare process triggered by depolarizing neuromuscular-blocking agents or certain inhalational anesthetics. It was once thought to be a form of heatstroke but is now known to be a distinct disorder that occurs in people with a mutation of the ryanodine receptor (type 1) in the sarcoplasmic reticulum. The other disorders listed are the consequences of either exertional hyperthermia or an inability of thermoregulatory mechanisms to continue to cope with an extremely hot environment.

5. When a subject exercises vigorously in a hot environment, what is the primary thermoregulatory-related cause underlying impaired cardiac filling?
   A. Cutaneous vasodilation
   B. Na^+ loss via sweating
   C. H_2O loss from sweating
   D. Pulmonary hypertension
   E. Reduced ventricular contractility

The correct answer is A. In the heat, skin blood flow increases very significantly (Fig. 28.13) and the dilated vascular bed of the skin becomes engorged with large volumes of blood, reducing central blood volume and venous return. The increased loss of Na^+ and water may aggravate this effect but are secondary. Neither pulmonary hypertension nor reduced ventricular contractility occurs under these conditions. In fact, due to decreased venous return, EDV declines and may thus actually lower contractility.

Clinical Application Exercises 28.1

HEATSTROKE

It was mid-August in San Antonio, another week of consecutive >90°F days with high humidity. Sarah and Katie were using their lunch break to stop by their elderly landlord's house to drop off the rent. When they got there, the landlord was prostrate in his flower garden, semiconscious, his rototiller still idling. While Sarah called 911 on her cell phone, Katie attempted to stir him. He responded weakly, and in a confused state, no sweat evident on his pale dry scalp and arms. EMT personnel advised Sarah to get the victim out of the sun, and, if possible, sprinkle his skin with water, apply a water-soaked cloth to his forehead, and fan him. Arriving within 10 minutes, the EMT techs found the old man conscious, confused, headachy, and nauseous. At the emergency room, Sarah and Katie learned that their landlord had suffered heatstroke. The physician congratulated them on their quick action, saying their intervention probably saved the old man's life. He assured the two that after intravenous fluid and electrolyte administration and an overnight observation in the hospital, Mr. Leslie would fully recover.

QUESTIONS

1. Define heatstroke and explain how it differs from heat exhaustion.
2. Explain why elderly individuals would have a greater risk of suffering or heatstroke.
3. Explain why sprinkling water on the skin with fanning is useful in this case.
4. When attempting to lower body temperature in response to hyperthermia, one should avoid treatments that induce shivering or vasoconstriction. Why?

ANSWERS

1. Dehydration can lead to heat exhaustion, which is characterized by high heart rate, dizziness, headache, loss of endurance/skill/confusion, and nausea. The skin may still be cool/sweating, but there are clear signs of developing vasoconstriction, for example, pale color. Heat-exhausted individuals have little or no urine production, and that which is produced is highly concentrated. Cramps may be associated with dehydration and rectal temperature may be up to 40°C and the victim may collapse on stopping activity. Heatstroke is similar to heat exhaustion, but with a dry skin. Heatstroke may arise in an individual who has not been identified as suffering from heat exhaustion and has persisted in further activity in the heat.
2. Heat tolerance and the sensitivity of the sweating response are significantly reduced in the elderly. Normal mechanisms for temperature regulation function by causing vasodilation of cutaneous blood vessels when the body temperature rises above the thermoregulatory set point. This increases blood flow near the surface of the body and allows the heat from the core of the body that is carried by the blood to leave the body via radiation, convection, and evaporation.
3. Body heat is transferred to the water on the skin by conduction. The air movement that results from the fan increases the rate of evaporation. As the water on the skin evaporates, it removes heat by endothermic process of evaporative heat loss. These are responses no longer at work in the subject, thus impairing his ability to deal with work in the hot environment.
4. Shivering is an effective homeostatic mechanism that generates heat and raises the body temperature. Peripheral vasoconstriction also occurs as a result of this mechanism and functions to decrease heat loss across the skin thereby keeping warm blood in the core of the body. Both of these responses can occur if treatment for hyperthermia is too intense, and both would thwart body temperature reduction.

29 Exercise Physiology

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain the concept of exercise to predict acute or chronic physiologic responses.
- Explain how maximal oxygen uptake predicts work performance.
- Explain the mechanism whereby substantial regional blood flow shifts occur during dynamic and isometric exercise.
- Explain training effects on both myocardial muscle and the coronary circulation.
- Explain how the respiratory system responds predictably to increased O_2 consumption and CO_2 production with exercise.
- Explain how, in healthy people, muscle fatigue during exercise is mediated.
- Explain how chronic physical activity affects insulin sensitivity and glucose entry into cells.
- Explain how exercise affects age-related functional changes.

Exercise is bodily activity that enhances or maintains physical fitness and overall health or wellness. It is performed for various reasons, including strengthening muscles and the cardiovascular system, honing athletic skills, weight loss, and maintenance, and for enjoyment. Frequent and regular physical exercise boosts the immune system and helps prevent the “diseases of affluence,” such as heart disease, cardiovascular disease, type 2 diabetes, and obesity. It also improves mental health, helps prevent depression, helps to promote or maintain positive self-esteem, and can even augment an individual’s sex appeal or body image. Exercise, in its many forms, is so common that true physiologic “rest” is rarely observed. During exercise, defined ultimately in terms of skeletal muscle contraction, the body must initiate rapidly integrated adjustments in every organ system in a coordinated response to increased muscular energy demands. So too must the body adjust integratively by adaptive responses in these same systems to days, weeks, and months of repeated bouts of activity. Exercise physiology is thus the branch of physiology that studies the physical and biochemical events that enable physical movement and underlie cellular and systemic adaptations to repeated or chronic activity.

OXYGEN UPTAKE AND EXERCISE

Exercise physiology is the study of acute and chronic changes in response to a wide range of exercise conditions. In addition, many experiments are carried out to study the effect of exercise on pathophysiology and the mechanisms by which exercise can reduce or reverse disease progression. Oxygen uptake is used to quantitate energy expenditure and exercise intensity during these experiments.

Exercise is as varied as it is ubiquitous. A single episode of exercise, or “acute” exercise, may provoke responses different from the adaptations seen when activity is chronic—that is, during *training*. The forms of exercise vary as well. The amount of muscle mass at work (one finger, one arm, both legs), the intensity of the effort, its duration, and the type of muscle contraction (isometric, rhythmic) all influence the body’s responses and adaptations.

These many aspects of exercise imply that its interaction with disease is multifaceted. There is no simple answer as to whether or how exercise promotes health. In fact, physical activity can be healthful, harmful, or irrelevant, depending on the patient, the disease, and the specific exercise in question.

Maximal oxygen uptake is used to quantitate energy expenditure during dynamic exercise.

Dynamic exercise is defined as skeletal muscle contractions at changing lengths and with rhythmic episodes of relaxation. Fundamental to any discussion of dynamic exercise is a description of its intensity. Because dynamically exercising muscle primarily generates energy from oxidative metabolism, a traditional standard is to measure, by mouth, the oxygen uptake $(\dot{V}O_2)$ of an exercising subject. This measurement is limited to dynamic exercise and usually to the steady state, when exercise intensity and oxygen consumption are stable and no net energy is provided from nonoxidative sources. Three implications of the original oxygen consumption measurements deserve mention. First, the centrality of oxygen usage to work output gave rise to the term “aerobic” exercise. Second, the apparent excess in oxygen consumption during the first minutes of recovery has been termed the **oxygen debt** (Fig. 29.1).

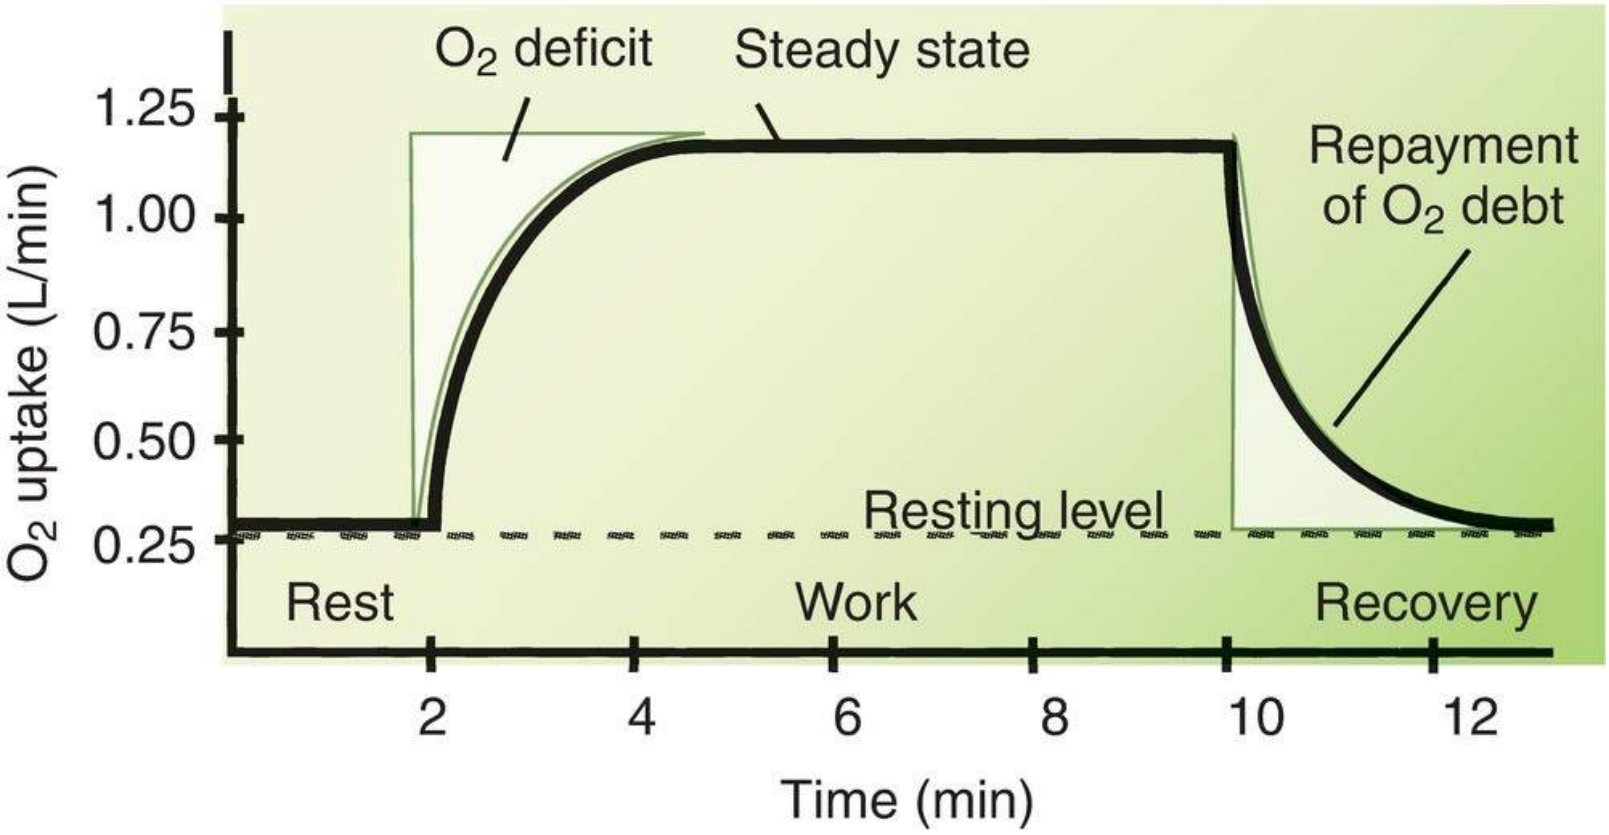

Figure 29.1 Oxygen uptake during rest, exercise, and recovery.

The “excess” oxygen consumption of recovery results from a multitude of physiologic processes, and little usable information is obtained from its measurement. Third, and more useful, during dynamic exercise that uses a large muscle mass, each person has a **maximal oxygen uptake** (

$\dot{V}O_2max$), a ceiling up to 20 times basal consumption that cannot be exceeded, although it can be increased by appropriate training. $\dot{V}O_2max$ is defined as the highest rate at which oxygen can be taken up and used by the body during severe exercise. It is one of the main variables in the field of exercise physiology and is commonly used to indicate cardiorespiratory fitness. $\dot{V}O_2max$ is decreased, all else being equal, by age, bed rest, or increased body fat.

$\dot{V}O_2max$ is also used to express relative work capacity. Obviously, a world-class marathon runner has a greater capacity to consume oxygen than a novice. However, when both are exercising at intensities requiring two thirds of their respective $\dot{V}O_2max$ (the world-class athlete is moving much faster in doing this, as a result of higher capacity), both become exhausted at roughly the same time and for the same physiologic reasons (Fig. 29.2). In the discussion that follows, relative as well as absolute (expressed as L/min of oxygen uptake) work intensities are used to explain physiologic responses. The energy costs and relative demands of some familiar activities are listed in Table 29.1.

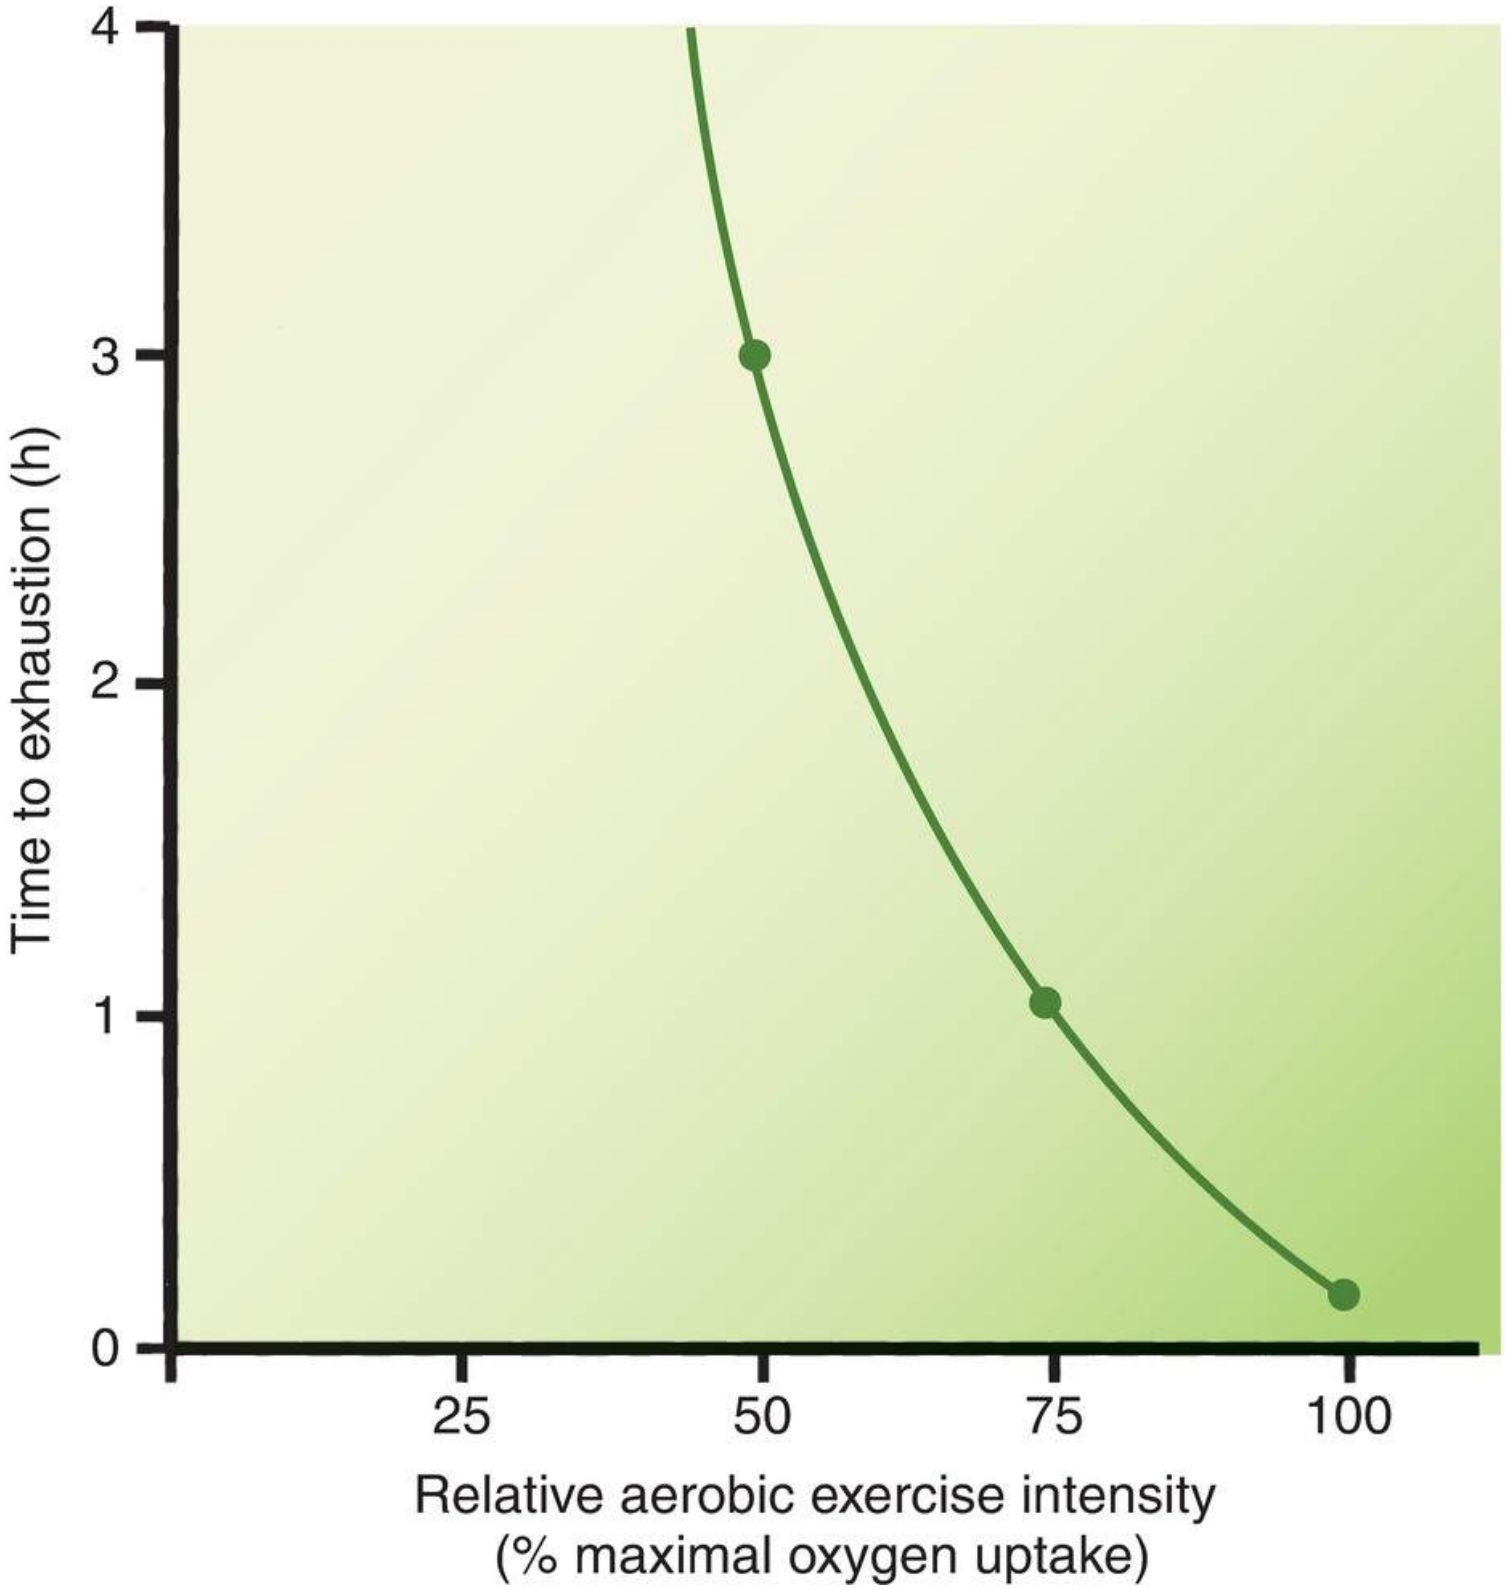

Figure 29.2 Time to exhaustion during dynamic exercise. Exhaustion is predictable on the basis of relative demand on the maximal oxygen uptake.

TABLE 29.1 Absolute and Relative Costs of Daily Activities

		% Maximal Oxygen Uptake	
Activity	**Energy Cost (kcal/min)**	**Sedentary 22-Year-Old**	**Sedentary 70-Year-Old**
Sleeping	1	6	8
Sitting	2	12	17
Standing	3	19	25
Dressing, undressing	3	19	25
Walking (3 mi/h)	4	25	33
Making a bed	5	31	42
Dancing	7	44	58
Gardening/ shoveling	8	50	67
Climbing stairs	11	69	92
Crawl swimming (50 m/min)	16	100	
Running (8 mi/h)	16	100	

What is it that causes oxygen uptake to reach an upper limit? Historically, many arguments claim

primacy for either cardiac output (oxygen delivery) or muscle metabolic capacity (oxygen use) limitations. However, it may be that every link in the chain taking oxygen from the atmosphere to the mitochondrion reaches its capacity at about the same time. In practical terms, this means that any lung, heart, vascular, or musculoskeletal illness that reduces oxygen flow capacity will diminish a patient's functional capacity. It has been shown that in untrained subjects, the oxygen consumption dominates $\dot{V}o_2max$, whereas in endurance-trained athletes, oxygen supply is the main limiting factor.

In **isometric exercise**, force is generated at constant muscle length and without rhythmic episodes of relaxation. Isometric work intensity is usually described as a percentage of the **maximal voluntary contraction (MVC)**, the peak isometric force that can be briefly generated for that specific exercise. Analogous to work levels relative to $\dot{V}o_2max$, the ability to endure isometric effort and many physiologic responses to that effort are predictable when the percentage of MVC among individuals is held constant.

CARDIOVASCULAR RESPONSES TO EXERCISE

Increased energy expenditure with exercise demands more energy production. For prolonged work, the oxidation of foodstuff supplies this energy, with the cardiovascular system carrying the oxygen to working muscles.

Blood flow is preferentially directed to working skeletal muscle during exercise.

Local control of blood flow ensures that only working muscles with increased metabolic demands receive increased blood and oxygen delivery. If the legs alone are active, leg muscle blood flow should increase, whereas arm muscle blood flow remains unchanged or is reduced. At rest, skeletal muscle receives only a small fraction of the cardiac output. In dynamic exercise, both total cardiac output and relative and absolute output directed to working skeletal muscle increase dramatically (Table 29.2).

TABLE 29.2 Blood Flow Distribution during Rest and Heavy Exercise in an Athlete

	Rest		Heavy Exercise	
Area	**mL/min**	**%**	**mL/min**	**%**
Splanchnic	1,400	24	300	1
Renal	1,100	19	900	4
Brain	750	13	750	3
Coronary	250	4	1,000	4
Skeletal muscle	1,200	21	22,000	86
Skin	500	9	600	2
Other	600	10	100	0.5
Total cardiac output	5,800	100	25,650	100

Cardiovascular control during exercise involves systemic regulation (cardiovascular centers in the brain, with their autonomic nervous output to the heart and systemic resistance vessels) in tandem with local control. For millennia, our ancestors successfully used exercise both to escape being eaten and to catch food; therefore, it is no surprise that cardiovascular control in exercise is complex and unique. It is as if a brain software program titled "Exercise" was inserted into the brain as work begins. Initially, the motor cortex is activated; the total neural activity is roughly proportional to the muscle mass and its work intensity. This neural activity communicates with the cardiovascular control centers, reducing vagal tone on the heart (which raises heart rate) and resetting the arterial baroreceptors to a higher level. As work rate is increased further, lactic acid is formed in actively contracting muscles, which stimulates muscle afferent nerves to send information to the cardiovascular center that increases sympathetic outflow to the heart and systemic resistance vessels. However, despite this **muscle chemoreflex** activity, within these same working muscles, low PO_2, increased nitric oxide, vasodilator prostanoids, and associated local vasoactive factors dilate arterioles despite rising sympathetic vasoconstrictor tone. Increased sympathetic drive does elevate heart rate and cardiac contractility, resulting in increased cardiac output; local factors in the coronary vessels mediate coronary vasodilation. Increased sympathetic vasoconstrictor tone in the renal and splanchnic vascular beds and in inactive muscle reduces blood flow to these tissues. Blood flow to these inactive regions can fall 75% if exercise is strenuous. Increased vascular resistance and decreased blood volume in these tissues help maintain blood pressure during dynamic exercise. In contrast to blood flow reductions in the viscera and in inactive muscle, the brain autoregulates blood flow

at constant levels independent of exercise. The skin remains vasoconstricted only if thermoregulatory demands are absent. Table 29.3 shows how a profound fall in systemic vascular resistance matches the enormous rise in cardiac output during dynamic exercise.

TABLE 29.3 Cardiac Output, Mean Arterial Pressure, and Systemic Vascular Resistance Changes with Exercise

Measure	Rest	Strenuous Dynamic Exercise
Cardiac output (L/min)	6	21
Mean arterial pressure (mm Hg)	90	105
Systemic vascular resistance [(mm Hg • min)/L]	15	5

Dynamic exercise, at its most intense level, forces the body to choose between maximum muscle vascular dilation and defense of blood pressure. Blood pressure is, in fact, maintained. During strenuous exercise, sympathetic drive can begin to limit vasodilation in active muscle. When exercise is prolonged in the heat, increased skin blood flow and sweating-induced reduction in plasma volume both contribute to the risk of hyperthermia and hypotension (heat exhaustion). Although chronic exercise provides some heat acclimatization, even highly trained athletes are at risk of hyperthermia and hypotension if work is prolonged and water is withheld in demanding environmental conditions.

Isometric exercise causes a somewhat different cardiovascular response. Muscle blood flow increases relative to the resting condition, as does cardiac output, but the higher mean intramuscular pressure limits these flow increases much more than when exercise is rhythmic. Because the blood flow increase is blunted inside a statically contracting muscle, the consequences of hard work with too little oxygen appear quickly: a shift to anaerobic metabolism, the production of lactic acid, a rise in the **adenosine diphosphate** (**ADP**)/**adenosine triphosphate** (**ATP**) ratio, and fatigue. Maintaining just 50% of the MVC is agonizing after about 1 minute and usually cannot be continued after 2 minutes. A long-term sustainable level is only about 20% of maximum. These percentages are much less than the equivalent for dynamic work, as defined in terms of $\dot{V}O_2max$. Rhythmic exercise

requiring 70% of the $\dot{V}o_2max$ can be maintained in healthy subjects for about an hour, whereas work at 50% of the $\dot{V}o_2max$ may be prolonged for several hours (see Fig. 29.2).

The reliance on anaerobic metabolism in isometric exercise triggers muscle ischemic chemoreflex responses that raise blood pressure more and cardiac output and heart rate less than that in dynamic work. Oddly, for dynamic exercise, the elevation of blood pressure is most pronounced when a medium muscle mass is working. This response results from the combination of a small, dilated active muscle mass with powerful central sympathetic vasoconstrictor drive. Typically, the arms exemplify a medium muscle mass; shoveling snow is a good example of primarily arm and heavily isometric exercise. Shoveling snow can be risky for those in danger of stroke or heart attack because it substantially raises systemic arterial pressure. The elevated pressure places already-compromised cerebral arteries at risk and presents an ischemic or failing heart with a greatly increased afterload.

Cardiovascular responses differ with acute and chronic exercise.

In acute dynamic exercise, vagal withdrawal and increases in sympathetic outflow elevate heart rate and contractility in proportion to exercise intensity (Table 29.4). Factors enhancing venous return also aid cardiac output in dynamic exercise. These include the "muscle pump," which compresses veins as muscles rhythmically contract, and the "respiratory pump," which increases breath-by-breath oscillations in intrathoracic pressure (see Chapter 17). The importance of these factors is clear in patients with heart transplants who lack extrinsic cardiac innervation. Stroke volume rises in cardiac transplant patients with increasing exercise intensity as a result of increased venous return that enhances cardiac preload. In addition, circulating epinephrine and norepinephrine from the adrenal medulla and norepinephrine from sympathetic nerve spillover augment heart rate and contractility.

TABLE 29.4 Acute Cardiac Response to Graded Exercise in a 30-Year-Old Untrained Woman

Exercise Intensity	Oxygen Uptake (L/min)	Heart Rate (beats/min)	Stroke Volume (mL/beat)	Cardiac Output (L/min)
Rest	0.25	72	70	5
Walking	1.0	110	90	10
Jogging	1.8	150	100	15
Running fast	2.5	190	100	19

Maximal dynamic exercise yields a maximal heart rate: further vagal blockade (e.g., via pharmacologic means) cannot elevate heart rate further. Stroke volume, in contrast, reaches a plateau in moderate work and is unchanged as exercise reaches its maximum intensity (see Table 29.4). This plateau occurs in the face of ever-shortening ventricular filling time, testimony to the increasing effectiveness of the mechanisms that enhance venous return and those that promote cardiac contractility. Sympathetic stimulation decreases left ventricular volume and pressure at the onset of cardiac relaxation (as a result of increased ejection fraction), leading to more rapid ventricular filling early in diastole. This helps maintain stroke volume as diastole shortens. Even in untrained subjects, the ejection fraction (stroke volume as a percentage of end-diastolic volume) reaches 80% in strenuous exercise.

The increased blood pressure, heart rate, stroke volume, and cardiac contractility seen in exercise all increase myocardial oxygen demands. A linear increase in coronary blood flow during exercise that can reach a value five times the basal level meets these demands. Local, metabolically linked factors (nitric oxide, adenosine, and the activation of ATP-sensitive K^+ channels) acting on coronary resistance vessels in defiance of sympathetic vasoconstrictor tone drive this increase in flow. Coronary oxygen extraction, high at rest, increases further with exercise (up to 80% of delivered oxygen). In healthy subjects, there is no evidence of myocardial ischemia under any exercise condition, and there may be a coronary vasodilator reserve in even the most intense exercise (Clinical Focus 29.1).

CLINICAL FOCUS 29.1

Stress Testing

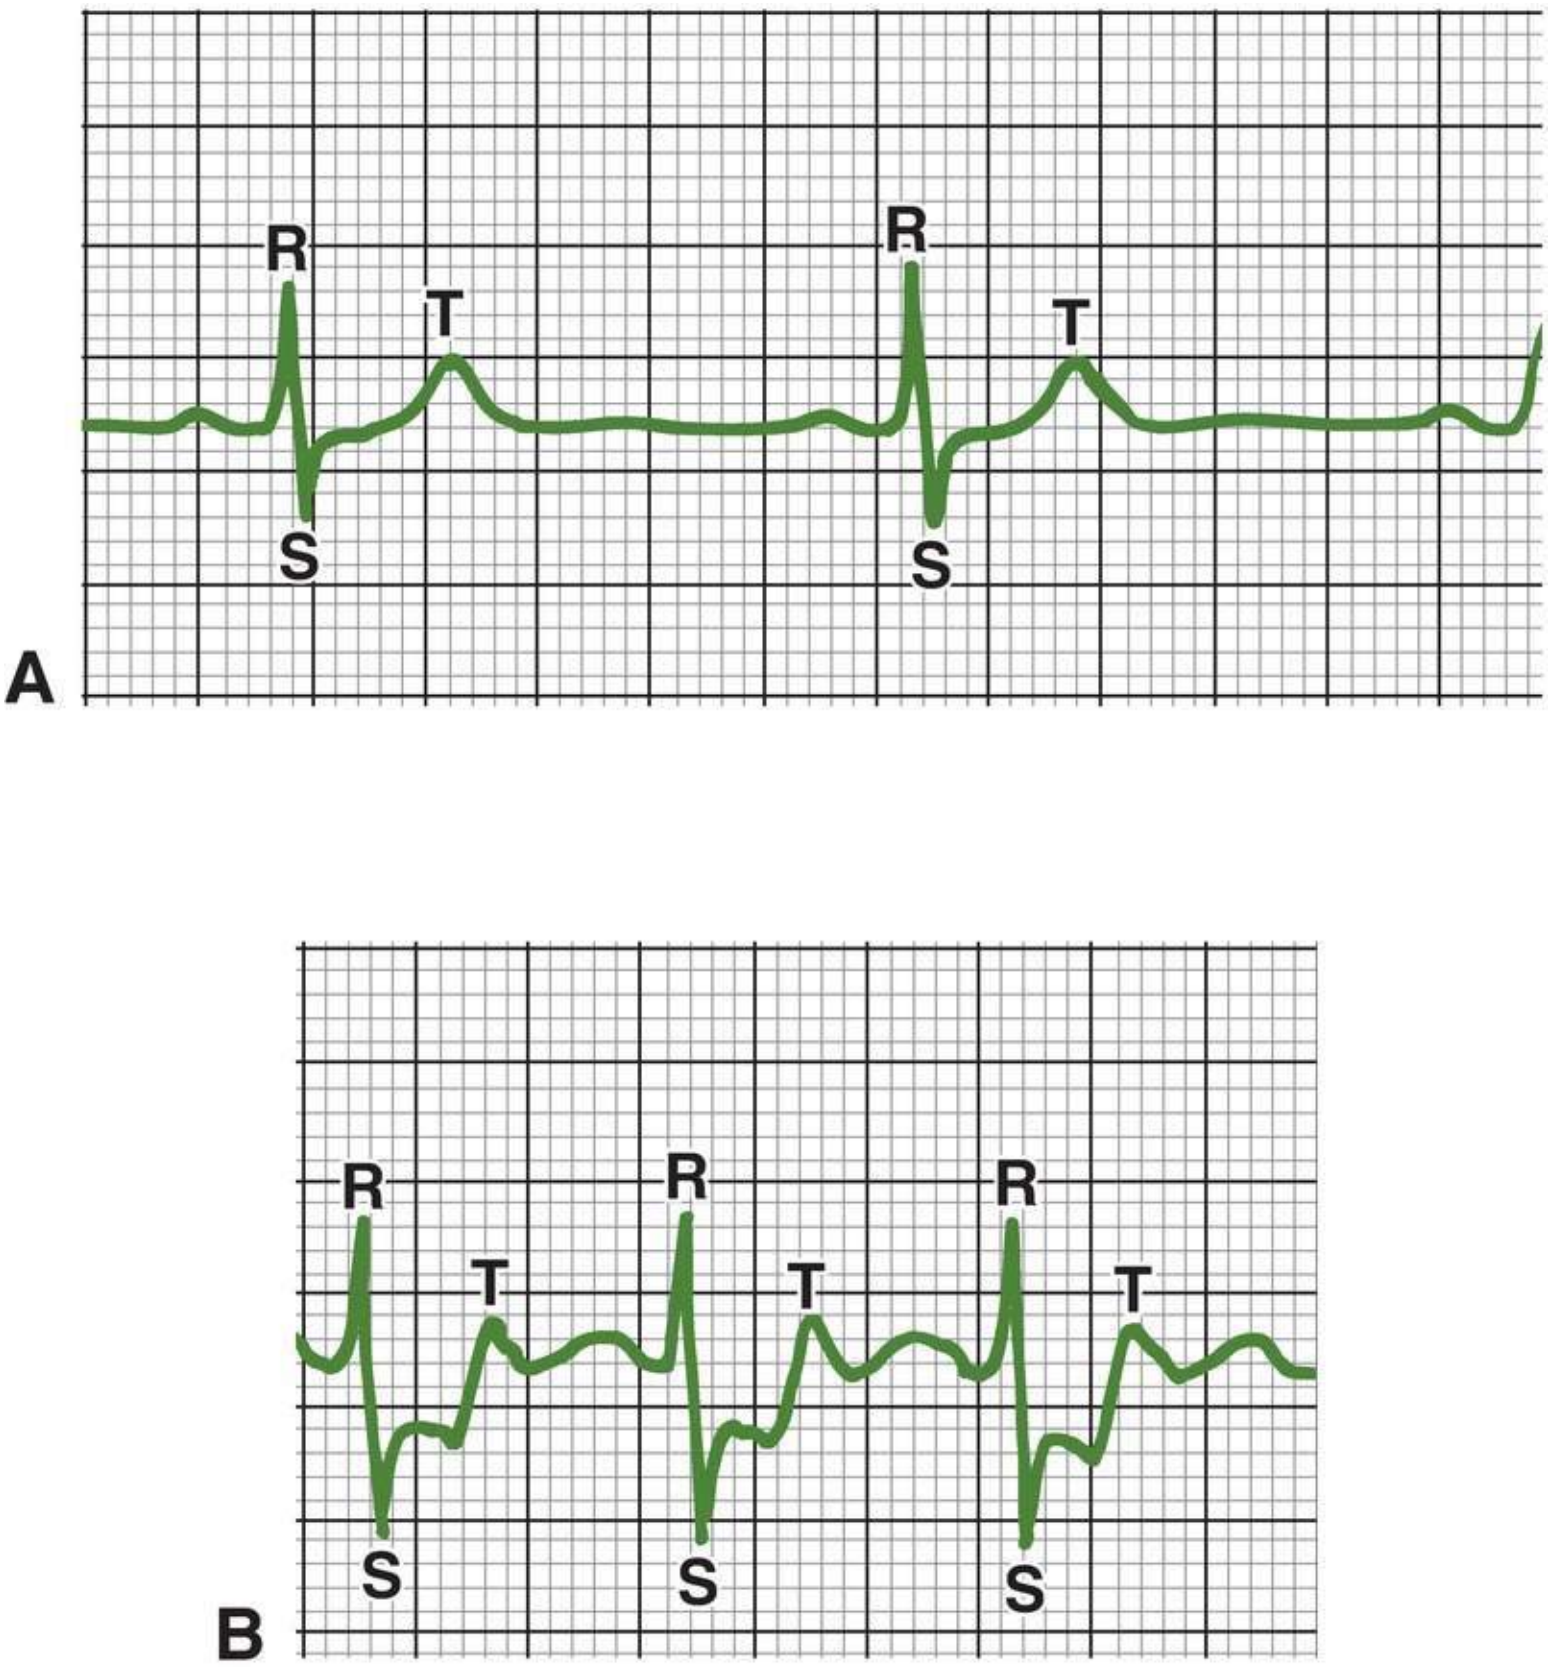
To detect coronary artery disease, physicians often record an electrocardiogram (ECG), but at rest,

many disease sufferers have a normal ECG. To increase demands on the heart and coronary circulation, an ECG is performed while the patient walks on a treadmill or rides a stationary bicycle. It is sometimes called a stress test. Exercise increases the heart rate and the systemic arterial blood pressure. These changes increase cardiac work and the demand for coronary blood flow. In many patients, coronary blood flow is adequate at rest but, because of coronary arterial blockage, cannot rise sufficiently to meet the increased demands of exercise. During a stress test, specific ECG changes can indicate that cardiac muscle is not receiving sufficient blood flow and oxygen delivery.

As heart rate increases during exercise, the length of any portion of the ECG (e.g., the R wave) becomes shorter (see Figure).

In patients suffering from ischemic heart disease, however, other changes occur. Most common is an abnormal depression between the S and T waves, known as *ST-segment depression* (see Figure). Depression of the ST segment arises from changes in cardiac muscle electrical activity secondary to lack of blood flow and oxygen delivery.

During the stress test, the ECG is continuously analyzed for changes while blood pressure and arterial blood oxygen saturation are monitored. At the start of the test, the exercise load is mild. The load is increased at regular intervals, and the test ends when the patient becomes exhausted, the heart rate safely reaches a maximum, significant pain occurs, or abnormal ECG changes are noted. With proper supervision, the stress test is a safe method for detecting coronary artery disease. Because the exercise load is gradually increased, the test can be stopped at the first sign of problems. ■



Effect of exercise on the electrocardiogram (ECG) in a patient with ischemic heart disease. (A) The ECG is normal at rest. **(B)** During exercise, the interval between R waves is reduced, and the ECG segment between the S and T waves is depressed.

The heart adapts to chronic exercise overload much as it does to high-demand pathologic states: by increasing left ventricular volume when exercise requires high blood flow and by left ventricular

hypertrophy when exercise creates high systemic arterial pressure (high afterload). Consequently, the hearts of subjects adapted to prolonged, rhythmic exercise that involves relatively low arterial pressure exhibit large left ventricular volumes with normal wall thickness, whereas wall thickness is increased at normal volume in those adapted to activities involving isometric contraction and greatly elevated arterial pressure such as lifting weights.

The larger left ventricular volume in subjects chronically active in dynamic exercise leads directly to larger resting and exercise stroke volume. A simultaneous increase in vagal tone and decrease in β-adrenergic sensitivity enhance the resting and exercise bradycardia seen after training, so that in effect the trained heart operates further up the ascending limb of its length–tension relationship. Nevertheless, resting bradycardia is a poor indicator of endurance fitness because genetic factors explain a much larger proportion of the individual variation in resting heart rate than does training.

The effects of endurance training on coronary blood flow are partly mediated through changes in myocardial oxygen uptake. Because myocardial oxygen consumption is roughly proportional to the rate–pressure product (heart rate × mean arterial pressure) and because heart rate falls after training at any absolute exercise intensity, coronary flow at a fixed submaximal workload is reduced in parallel. Training, however, increases the peak coronary blood flow, just as it increases cardiac muscle capillary density and peak capillary exchange capacity. Training also improves endothelium-mediated regulation, responsiveness to adenosine, and control of intracellular free calcium ions within coronary vessels. Preserving endothelial vasodilator function may be the primary benefit of chronic physical activity on the coronary circulation.

Exercise increases levels of “good” cholesterol.

Chronic, dynamic exercise is associated with increased circulating levels of **high-density lipoproteins (HDLs)** and reduced **low-density lipoproteins (LDLs)**, such that the ratio of HDL to total cholesterol is increased. These changes in cholesterol fractions occur at any age if exercise is regular. Weight loss and increased insulin sensitivity, which typically accompany increased chronic physical activity in sedentary people, undoubtedly contribute to these changes in plasma lipoproteins. Nonetheless, in subjects with lipoprotein levels that place them at high risk for coronary heart disease, exercise appears to be an essential adjunct to dietary restriction and weight loss for lowering LDL cholesterol levels. Because exercise acutely and chronically enhances fat metabolism and cellular metabolic capacities for β-oxidation of free fatty acids, it is not surprising that regular activity increases both muscle and adipose tissue lipoprotein lipase activity. Changes in lipoprotein lipase activity, in concert with increased lecithin–cholesterol acyltransferase activity and apo A-I synthesis, enhance the levels of circulating HDLs. Evidence from interventional studies repeatedly demonstrates the effectiveness of proper diet and exercise in the prevention of metabolic syndrome and type 2 diabetes in a broad range of subjects.

Exercise prevents cardiovascular diseases and reduces mortality.

There is a direct relationship between physical inactivity and cardiovascular mortality, and physical inactivity is an independent risk factor for the development of coronary artery disease. Changes in the ratio of HDL to total cholesterol that take place with regular physical activity reduce the risk of atherogenesis and coronary artery disease in active people, as compared with those who are sedentary. A lack of exercise is established as a risk factor for coronary heart disease similar in magnitude to hypercholesterolemia, hypertension, and smoking. A reduced risk grows out of the changes in lipid profiles noted above, reduced insulin requirements and increased insulin sensitivity, and reduced cardiac β-adrenergic responsiveness and increased vagal tone. When coronary ischemia does occur, increased vagal tone may reduce the risk of fibrillation.

Regular exercise often, but not always, reduces resting blood pressure. Why some subjects respond to chronic activity with a resting blood pressure decline and others do not remain unknown. Responders typically show diminished resting sympathetic tone, so that systemic vascular resistance falls. In obesity-linked hypertension, declining insulin secretion and increasing insulin sensitivity with exercise may explain the salutary effects of combining training with weight loss. Nonetheless, because some obese people who exercise and lose weight show no blood pressure changes, exercise remains adjunctive therapy for hypertension.

Cardiovascular response to pregnancy is similar to chronic exercise.

The physiologic demands and adaptations of pregnancy in some ways are similar to those of chronic exercise. Both increase blood volume, cardiac output, skin blood flow, and caloric expenditure. Exercise clearly has the potential to be deleterious to the fetus. Acutely, it increases body core temperature, causes splanchnic (hence, uterine and umbilical) vasoconstriction, and alters the endocrinologic milieu; chronically, it increases caloric requirements. This last demand may be devastating if food shortages exist: the superimposed caloric demands of successful pregnancy and lactation are estimated at 80,000 kcal. Given adequate nutritional resources, however, there is little evidence of other damaging effects of maternal exercise on fetal development. The failure of exercise to harm well-nourished pregnant women may relate in part to the increased maternal and fetal mass and blood volume, which reduce specific heat loads, moderate vasoconstriction in the uterine and umbilical circulations, and diminish the maternal exercise capacity.

At least in previously active women, even the most intense concurrent exercise regimen (unless associated with excessive weight loss) does not alter fertility, implantation, or embryogenesis, although the combined effects of exercise on insulin sensitivity and central obesity can restore ovulation in anovulatory obese women suffering from polycystic ovary disease. Regular exercise may reduce the risk of spontaneous abortion of a chromosomally normal fetus. Continued exercise throughout pregnancy characteristically results in normal-term infants after relatively brief labor. These infants are usually normal in length and lean body mass but reduced in fat. Maternal exercise through improved glucose tolerance reduces the risk of large infant size for gestational age, which is increased in diabetic mothers. The incidences of umbilical cord entanglement, abnormal fetal heart rate during labor, stained amniotic fluid, and low fetal responsiveness scores may all be reduced in women who are active throughout pregnancy. Further, when examined 5 days after birth, newborns of exercising women perform better in their ability to orient to environmental stimuli and their ability to quiet themselves after sound and light stimuli than weight-matched children of nonexercising mothers.

RESPIRATORY RESPONSES TO EXERCISE

Increased breathing is perhaps the single most obvious physiologic response to acute dynamic exercise. Figure 29.3 shows that minute ventilation (the product of breathing frequency and tidal volume) initially increases linearly with work intensity and then supralinearly beyond that point. Ventilation of the lungs in exercise is linked to the twin goals of oxygen uptake and carbon dioxide removal.

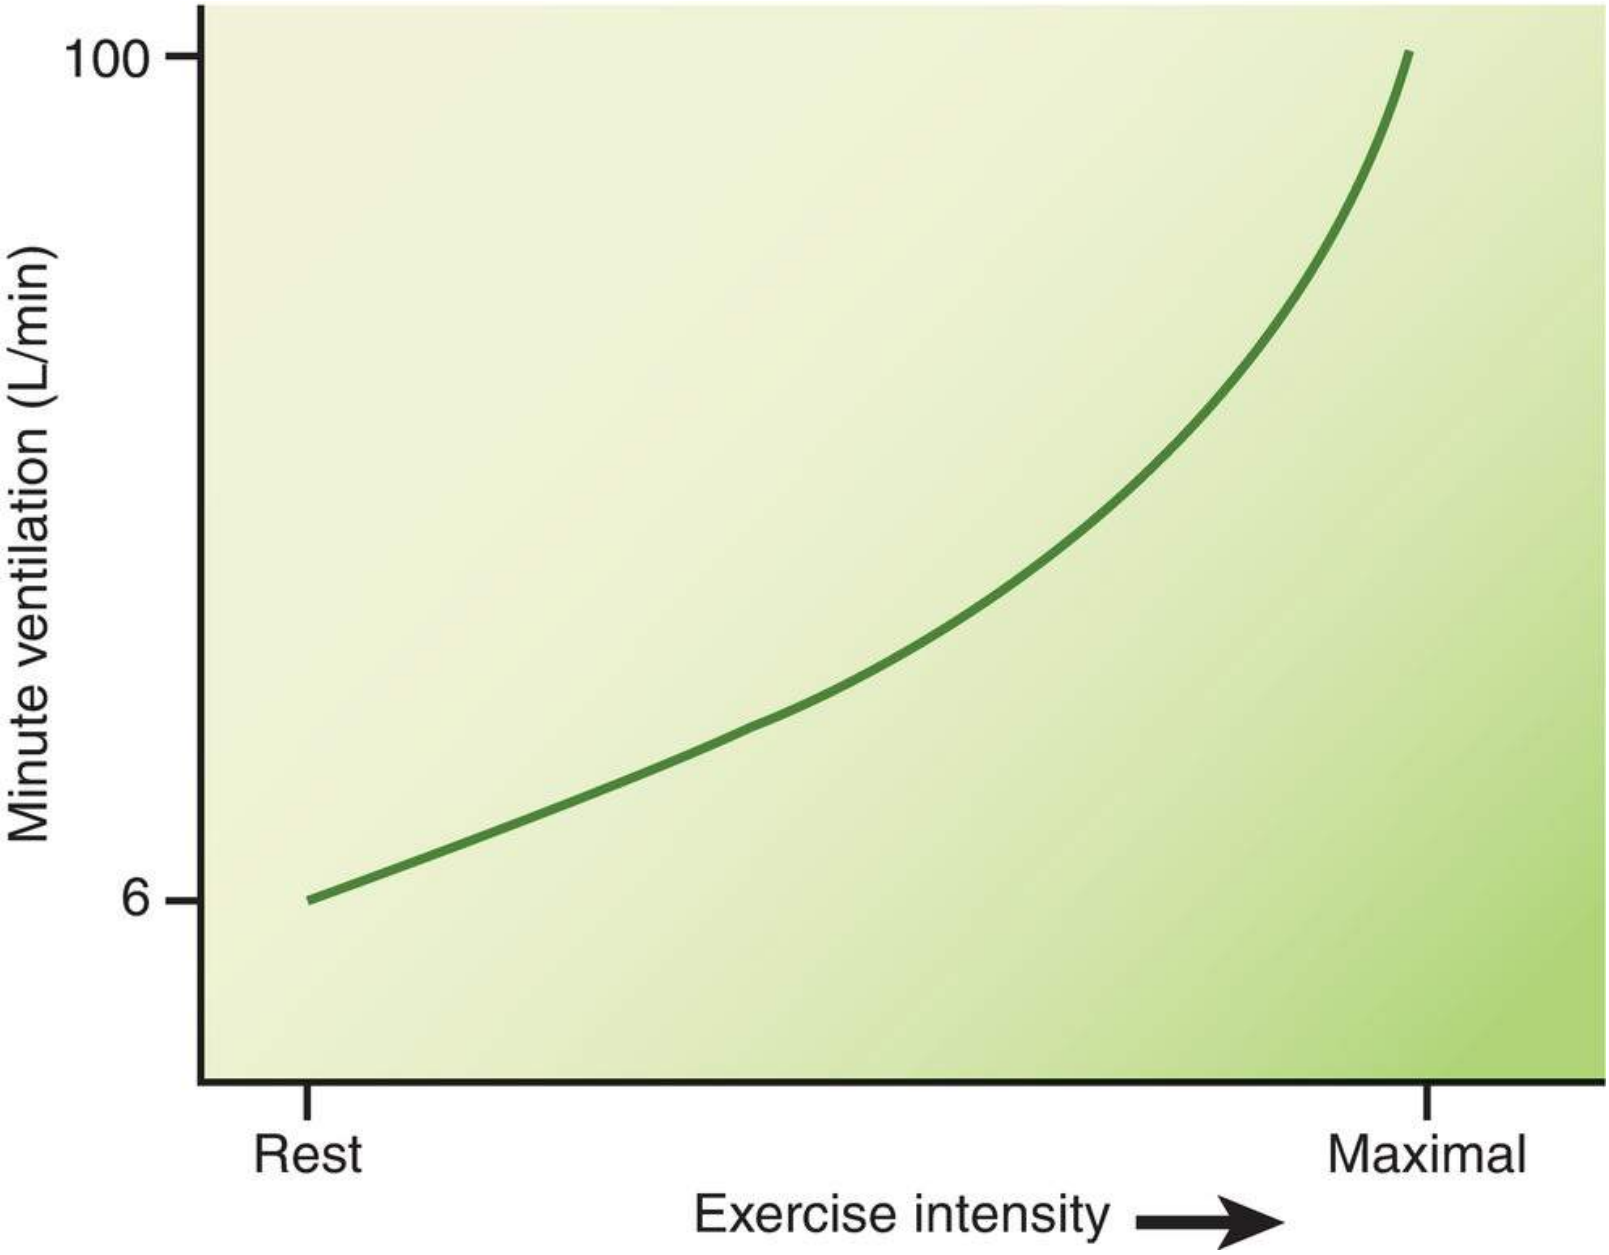


Figure 29.3 Minute ventilation is dependent on the intensity of dynamic exercise. Ventilation rises linearly with intensity until exercise nears maximal levels.

Ventilation matches metabolic demands during a wide range of exercise conditions, but the control mechanisms are poorly understood.

Exercise increases oxygen consumption and carbon dioxide production by working muscles, and the pulmonary response is precisely calibrated to maintain homeostasis of these gases in arterial blood. In mild or moderate work, arterial PO_2 (and, hence, oxygen content), PCO_2, and pH all remain unchanged from resting levels (Table 29.5). The respiratory muscles accomplish this severalfold increase in ventilation primarily by increasing tidal volume, without provoking sensations of dyspnea.

TABLE 29.5 Acute Respiratory Response to Graded Dynamic Exercise in a 30-Year-Old Untrained Woman

Exercise Intensity	Ventilation (L/min)	Ventilation/Perfusion Ratio	Alveolar P_{O_2} (mm Hg)	Arterial P_{O_2} (mm Hg)	Arterial P_{CO_2} (mm Hg)	Arterial pH
Rest	5	1	103	100	40	7.4
Walking	20	2	103	100	40	7.4
Jogging	45	3	106	100	36	7.4
Running fast	75	4	110	100	25	7.3

More intense exercise presents the lungs with tougher challenges. Near the halfway point from rest to maximal dynamic work, lactic acid formed in working muscles begins to appear in the circulation. This occurs when it is produced faster than it can be removed (metabolized). This point, which depends on the type of work involved and the person's training status, is called the **anaerobic threshold** or lactate threshold. Lactate concentration gradually rises with work intensity, as more and more muscle fibers must rely on anaerobic metabolism. Almost fully dissociated, lactic acid causes metabolic acidosis. During exercise, healthy lungs respond to lactic acidosis by further increasing ventilation, lowering the arterial PCO_2, and maintaining arterial blood pH at normal levels. It is the response to acidosis that spurs the supralinear ventilation rise seen in strenuous exercise (see Fig. 29.3). Through a range of exercise levels, the respiratory system fully compensates the pH effects of lactic acid. However, eventually in the hardest work—near exhaustion—ventilatory compensation becomes only partial, and both pH and arterial PCO_2 may fall well below resting values (see Table 29.5). Tidal volume continues to increase until pulmonary stretch receptors limit it, typically at or near half of the vital capacity. Frequency increases at high tidal volume produce the remainder of the ventilatory volume increases.

Hypercapnia relative to carbon dioxide production in heavy exercise helps maintain arterial oxygenation. The blood returned to the lungs during exercise is more thoroughly depleted of oxygen because active muscles with high oxygen extraction receive most of the cardiac output. Because the pulmonary arterial PO_2 is reduced in exercise, blood shunted past ventilated areas can profoundly depress systemic arterial oxygen content. Other than having a diminished oxygen content, pulmonary arterial blood flow (cardiac output) rises during exercise. In compensation, ventilation rises faster than cardiac output: the ventilation/perfusion ratio of the lung rises from near 1 at rest to >4 with strenuous exercise (see Table 29.5). Healthy subjects maintain nearly constant arterial PO_2 with acute exercise,

although the alveolar-to-arterial PO_2 gradient does rise. This increase shows that despite the increase in the ventilation/perfusion ratio, areas of relative pulmonary underventilation and, possibly, some mild diffusion limitation exist even in highly trained, healthy individuals.

The ventilatory control mechanisms in exercise remain undefined. Where there are stimuli—such as in mixed venous blood, which is hypercapnic and hypoxic in proportion to exercise intensity—there are seemingly no receptors. Conversely, where there are receptors—the carotid bodies, the lung parenchyma or airways, the brainstem bathed by cerebrospinal fluid—no stimulus proportional to the exercise demand exists. Paradoxically, the central chemoreceptor is immersed in increasing alkalinity as exercise intensifies a consequence of blood–brain barrier permeability to CO_2 but not hydrogen ions. Perhaps, exercise respiratory control parallels cardiovascular control, with a central command proportional to muscle activity directly stimulating the respiratory center and feedback modulation from the lung, respiratory muscles, chest wall mechanoreceptors, and carotid body chemoreceptors.

Training does not significantly alter the respiratory system.

The effects of training on the healthy pulmonary system are minimal. Lung diffusing capacity, lung mechanics, and even lung volumes change little, if at all, with training. The widespread assumption that training improves vital capacity is false; even exercise designed specifically to increase inspiratory muscle strength elevates vital capacity by only 3%. The demands placed on respiratory muscles increase their endurance, an adaptation that may reduce the sensation of dyspnea in exercise. Nevertheless, the primary respiratory changes with training are secondary to lower lactate production that reduces ventilatory demands at previously heavy absolute work levels. Nonetheless, supervised exercise training that includes whole-body exercise such as cycling and walking is one of the main components of pulmonary rehabilitation in respiratory diseases such as chronic obstructive pulmonary disease (COPD) where training can improve exercise capacity and health-related quality of life (Clinical Focus 29.2).

CLINICAL FOCUS 29.2

Exercise in Patients with Emphysema

Normally, the respiratory system does not limit exercise tolerance. In healthy people, arterial blood saturation with oxygen, which averages 98% at rest, is maintained at or near 98% in even the most strenuous dynamic or isometric exercise. The healthy response includes the ability to augment ventilation more than cardiac output; the resulting rise in the ventilation/perfusion ratio counterbalances the falling oxygen content of mixed venous blood.

In patients with emphysema, ventilatory limitations to exercise occur long before either skeletal muscle oxidative capacity or the ability of the cardiovascular system to deliver oxygen to exercising muscle imposes ceilings. These limitations are manifest during a stress test on the basis of three primary measurements. First, patients with ventilatory limitations typically cease exercise at a relatively low heart rate, indicating that exhaustion is a result of factors unrelated to cardiovascular limitations. Second, their primary complaint is usually shortness of breath or dyspnea. In fact, patients with chronic obstructive pulmonary disease often first seek medical evaluation because of dyspnea experienced during such routine activities as climbing a flight of stairs. In healthy people, exhaustion is rarely associated solely with dyspnea. In emphysematous patients, exercise-induced dyspnea results, in part, from respiratory muscle fatigue exacerbated by diaphragmatic flattening brought on by loss of lung elastic recoil. Third, in emphysematous patients, arterial oxygen saturation characteristically falls steeply and progressively with increasing exercise, sometimes reaching dangerously low levels. In emphysema, the inability to fully oxygenate blood at rest is compounded during exercise by increased pulmonary blood flow and by increased exercise oxygen extraction that more fully desaturates blood returning to the lungs. ■

SKELETAL MUSCLE AND BONE RESPONSES TO EXERCISE

Events within exercising skeletal muscle are a primary factor in fatigue. These same events, when repeated during training, lead to adaptations that increase exercise capacity and retard fatigue during similar work. Skeletal muscle contraction also increases stresses placed on bone, leading to specific bone adaptations.

Muscle fatigue is independent of lactic acid.

Muscle fatigue is defined as a loss of muscle power that results from a decline in both force and velocity. Muscle fatigue differs from *muscle weakness* or *damage* in that the loss of power with fatigue is reversible by rest. Although the exact causes of muscle fatigue and the relative importance of particular factors remain controversial, it is clear that an individual's state of fitness, dietary status, fiber-type composition, and intensity and duration of the exercise all affect the process. Historically, an increase in intracellular H^+ (decrease in cell pH) was thought to contribute to muscle fatigue by direct inhibition of the actin–myosin cross bridge, leading to a reduction in contractile force. Although strenuous exercise can reduce intramuscular pH to values as low as 6.8 (arterial blood pH may fall to 7.2), evidence suggests that elevation in $[H^+]$, although a substantial factor in declining force, is not the sole cause of fatigue. The best correlate of fatigue in healthy subjects is ADP accumulation in the face of normal or slightly reduced ATP, such that the ADP/ATP ratio is high. ADP is implicated in slowing cross-bridge cycling. During periods of high-energy demand, the ATP concentration initially remains almost constant, whereas creatine phosphate (CrP) breaks down to Cr and inorganic phosphate (Pi). Although Cr has little effect on contractile function, Pi may cause a marked decrease of myofibrillar force production and Ca^{2+} sensitivity as well as sarcoplasmic reticular Ca^{2+} release. Accordingly, increased Pi is considered to be a major cause of fatigue. There is widespread use of extra Cr intake among athletes, not only in elite athletes but also among people exercising on a recreational level. Cr enters muscle cells via a Na^+-dependent transporter in the sarcolemma. Inside the cell, Cr is phosphorylated by creatine kinase, and the [PCr]/[Cr] ratio basically depends on the energy state of the cell. Extra Cr intake increases the total muscle Cr content by up to ~20%. Cr supplementation has a modest positive effect on muscle performance during bouts of short-term (~10 seconds), high-power exercise, whereas it does not improve function during more long-lasting types of muscle activity. This corresponds to the fact that PCr breakdown contributes to a relatively large fraction of the ATP supply during the first seconds of high-intensity muscle activity, whereas the PCr contribution is minimal during prolonged exercise. Because the complete oxidation of glucose, glycogen, or free fatty acids to carbon dioxide and water is the major source of energy in prolonged work, patients with defects in glycolysis or electron transport exhibit a reduced ability to sustain exercise.

These metabolic defects are distinct from another group of disorders exemplified by the various muscular dystrophies. In these illnesses, the loss of active muscle mass as a result of fat infiltration, cellular necrosis, or atrophy reduces exercise tolerance despite normal capacities (in healthy fibers) for ATP production. For this reason, Cr supplementation is also used in an attempt to improve muscle function in these diseases. Other potential factors in the etiology of fatigue may occur centrally (pain from fatigued muscle may feed back to the brain to lower motivation and, possibly, to reduce motor cortical output) or at the level of the motor neuron or the neuromuscular junction. Also, skeletal muscles produce ammonia during exercise. This ammonia is taken up by the brain in proportion to its cerebral arterial concentration. Ammonia accumulation is currently thought to be a factor in the sensation of fatigue.

Endurance training enhances muscle oxidative capacity.

Within skeletal muscle, adaptations to training are specific to the form of muscle contraction. Increased activity with low loads results in increased oxidative metabolic capacity without hypertrophy; increased activity with high loads produces muscle hypertrophy. Increased activity without overload increases capillary and mitochondrial density, myoglobin concentration, and virtually the entire enzymatic machinery for energy production from oxygen (Table 29.6). Coordination of energy-producing and energy-using systems in muscle ensures that even after atrophy, the remaining contractile proteins are adequately supported metabolically. In fact, the easy fatigability of atrophied muscle is a result of the requirement that more motor units be recruited for identical external force; the fatigability per unit cross-sectional area is normal. Factors outside the muscle limit the magnitude of the skeletal muscle endurance training response, because cross-innervation or chronic stimulation of muscles in animals can produce adaptations five times larger than those created by the most intense and prolonged exercise.

TABLE 29.6 Effects of Training and Immobilization on the Human Biceps Brachii Muscle in a 22-Year-Old Woman

Measurement	After Strength Training	After 4 Months' Immobilization	Sedentary	After Endurance Training
Total number of cells	300,000	300,000	300,000	300,000
Total cross-sectional area (cm^2)	10	10	13	6
Isometric strength (% control)	100	100	200	60
Fast-twitch fibers (% by number)	50	50	50	50
Fast-twitch fibers, average area ($\mu m^2 \times 10^2$)	67	67	87	40
Capillaries/fiber	0.8	1.3	0.8	0.6
Succinate dehydrogenase activity/unit area (% control)	100	150	77	100

Local adaptations of skeletal muscle to endurance activity reduce reliance on carbohydrate as a fuel and allow more metabolism of fat, prolonging endurance and decreasing lactic acid accumulation. Decreased circulating lactate, in turn, reduces the ventilatory demands of heavier work. Because metabolites accumulate less rapidly inside trained muscle, there is reduced chemosensory feedback to the central nervous system at any absolute workload. This reduces sympathetic outflow to the heart and blood vessels, reducing cardiac oxygen demands at a fixed exercise level.

Isometric contraction stimulates muscle hypertrophy.

It is common knowledge that walking downhill is easier than walking uphill, but the mechanisms underlying this phenomenon are complex. Forces generated by muscles are identical in the two situations. However, moving the body uphill against gravity involves muscle shortening or **concentric contractions**. In contrast, walking downhill primarily involves muscle tension development that resists muscle lengthening or **eccentric contractions**. All routine forms of physical activity, in fact, involve combinations of concentric, eccentric, and isometric contractions. Because less ATP is required for force development during a contraction when external forces lengthen the muscle, the number of active motor units is reduced and energy demands are less for eccentric work. However, perhaps because the force per active motor unit is greater in eccentric exercise, eccentric contractions can readily cause muscle damage. This damage includes weakness (apparent the first day), soreness and edema (delayed 1 to 3 days in peak magnitude), and elevated plasma levels of intramuscular enzymes (delayed 2 to 6 days). Histologic evidence of damage may persist for 2 weeks. Damage is accompanied by an acute-phase reaction that includes complement activation, increases in circulating cytokines, neutrophil mobilization, and increased monocyte cell adhesion capacity. Training adaptation to the eccentric components of exercise is efficient; soreness after a second episode is minimal if it occurs within 2 weeks of a first episode.

Eccentric contraction–induced muscle damage and its subsequent response may be the essential stimulus for muscle hypertrophy. Although standard resistance exercise involves a mixture of contraction types, careful studies show that when one limb works purely concentrically and the other purely eccentrically at equivalent force, only the eccentric limb hypertrophies. The immediate changes in actin and myosin production that lead to hypertrophy are mediated at the posttranslational level; after a week of loading, mRNA for these proteins is altered.

Despite our understanding that feeding and resistance exercise affect muscle protein synthesis and growth, researchers have now begun to study the signaling pathways that are activated with either stimulus in humans. It is known that proteins in the Akt/protein kinase B–rapamycin (mTOR)–S6 kinase pathway are involved in stimulating ribosomal assembly, biogenesis, and global protein synthesis, but the extent of signal to response is far from clear. Upstream of mTOR is the tuberous sclerosis complex (TSC), which is a heterodimeric complex of the TSC1 and TSC2 gene products, hamartin and tuberin, respectively. Studies have shown that the TSC1/TSC2 heterodimer regulates cell growth and cell proliferation as a downstream component of the PI3K (phosphoinositide 3-kinase)–Akt signaling, which modulates signal transduction through mTOR. The cellular mechanisms for hypertrophy are also known to include the induction of insulin-like growth factor-1 and up-regulation of several members of the fibroblast growth factor family, although skeletal muscle hypertrophy can occur in the absence of circulating pituitary hormones, insulin, or local growth factors in response to increased mechanical loading. Although the actual biochemical events that link the mechanical loading of a muscle or muscle fiber to mTOR signaling remain unclear, it is known that mechanical loading or stretch acts independently of amino acids and growth factors to activate mTOR signaling in skeletal muscle. Passive mechanical loading is sufficient to activate mTOR signaling in skeletal muscle, and studies have shown that there is a cytoskeletal requirement for communication of the signaling pathway from mechanical stretch to mTOR. It is likely that this mechanical pathway acts synergistically with changes in amino acid uptake and growth factor availability to contribute to the prolonged activation of mTOR signaling following high-resistance contractions or mechanical overload.

Exercise plays an important role in calcium homeostasis.

Skeletal muscle contraction acts across joints and thus applies force to bone. Because the architecture of bone remodeling involves osteoblast and osteoclast activation in response to loading and unloading, physical activity is a major site-specific influence on bone mineral density and geometry. Repetitive physical activity can create excessive strain, leading to inefficiency in bone remodeling and stress fracture; however, extreme inactivity allows osteoclast dominance and bone loss.

The forces applied to bone during exercise are related both to the weight borne by the bone during activity and to the strength of the involved muscles. Consequently, bone strength and density appear to be closely related to applied gravitational forces and to muscle strength. This suggests that exercise programs to prevent or treat **osteoporosis** should emphasize weight-bearing activities and strength as well as endurance training. Adequate dietary calcium is essential for any exercise effect: weight-bearing activity enhances spinal bone mineral density in postmenopausal women only when calcium intake exceeds 1 g/d. Because exercise may also improve gait, balance, coordination, proprioception, and reaction time, even in older and frail persons, chronic activity reduces the risks of falls and osteoporosis. In fact, the incidence of hip fracture is reduced nearly 50% when older adults are involved in regular physical activity. However, even when activity is optimal, genetic contributions to bone mass are greater than those of exercise. Perhaps, 75% of the population variance is genetic, and 25% is a result of different levels of activity. In addition, the predominant contribution of estrogen to homeostasis of bone in young women is apparent when amenorrhea occurs secondary to chronic heavy exercise. These exceptionally active women are typically thin and exhibit low levels of circulating estrogens, low trabecular bone mass, and a high fracture risk (Fig. 29.4).

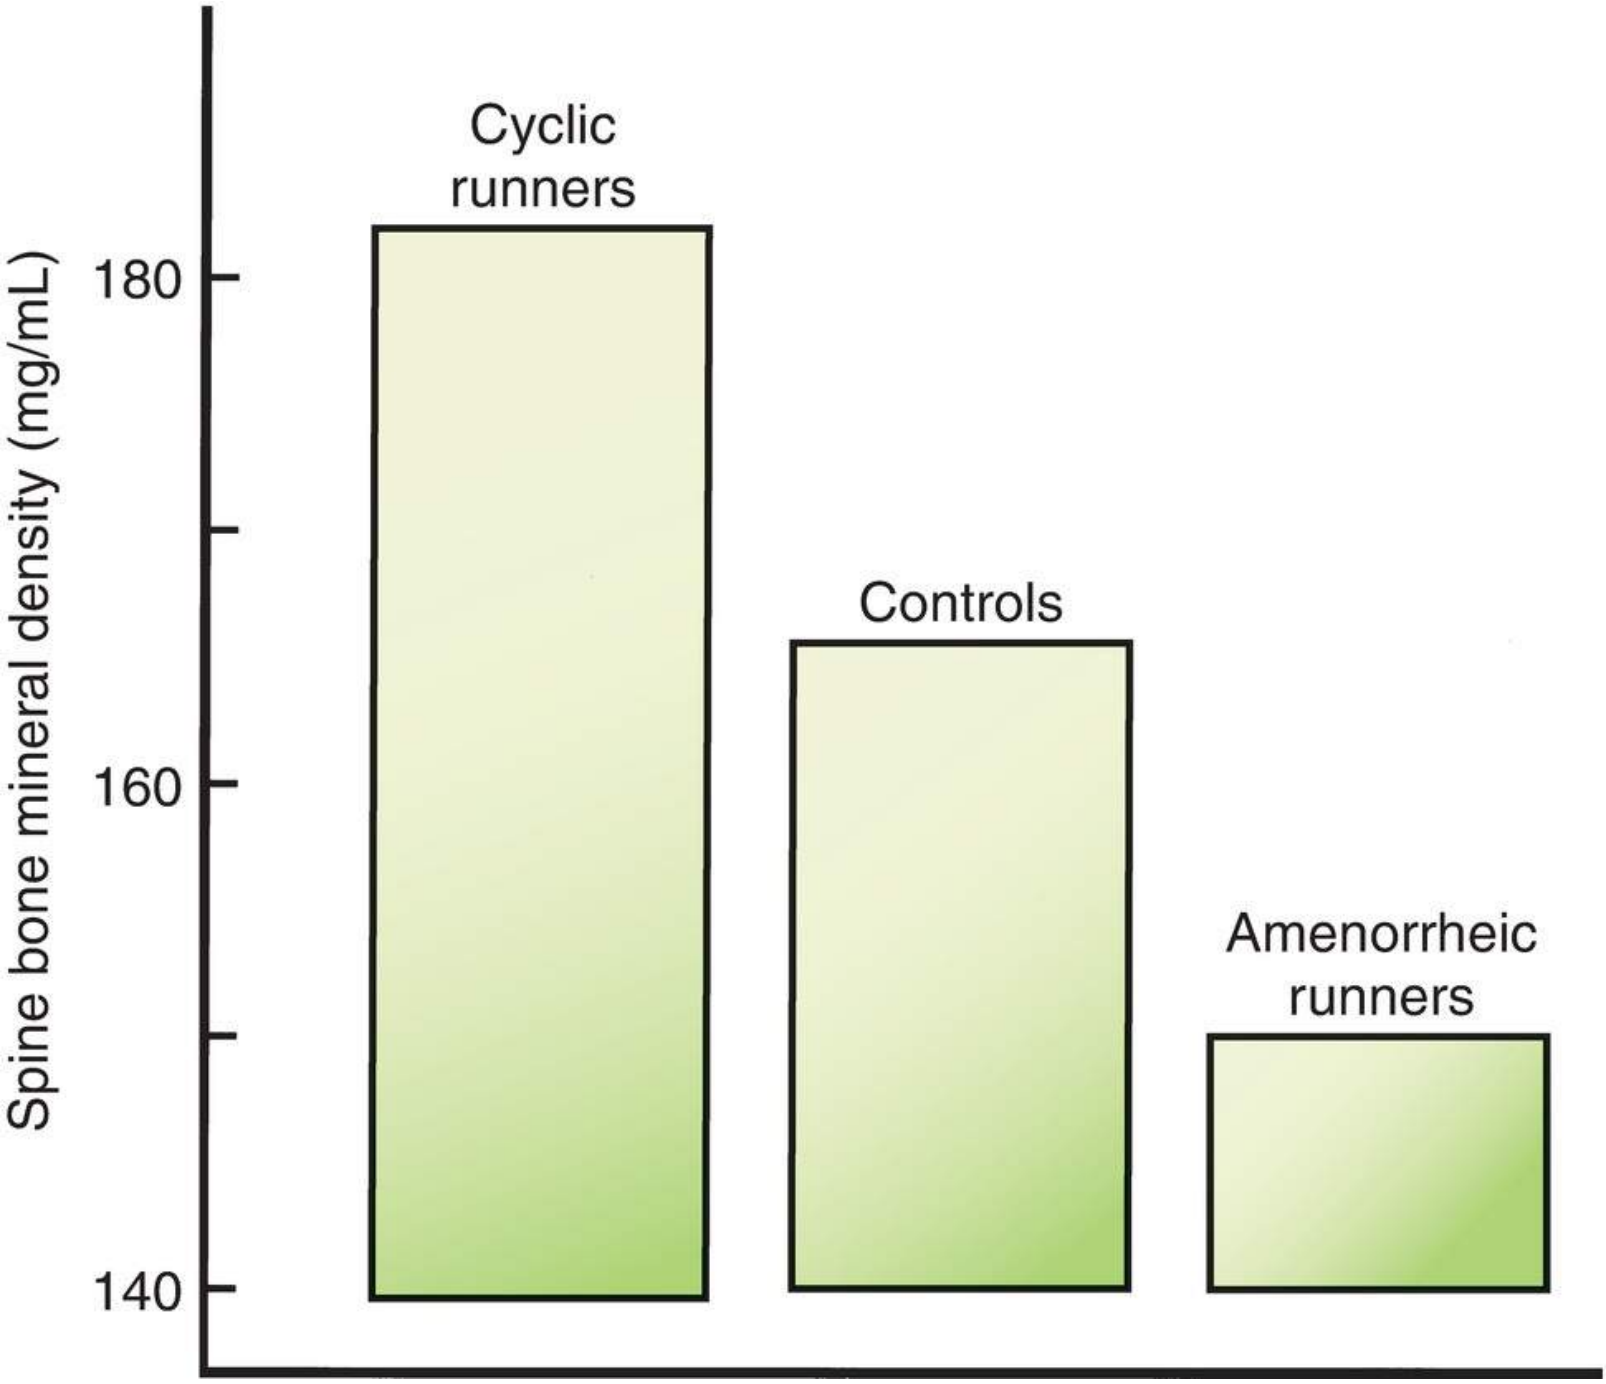

Figure 29.4 Exercise stimulates bone density. This graph shows spine bone density in young adult women who are nonathletes (controls), distance runners with regular menstrual cycles (cyclic runners), and distance runners with amenorrhea (amenorrheic runners). Differences from controls indicate the roles that exercise and estrogen play in determination of bone mineral density.

Exercise also plays a role in the treatment of **osteoarthritis**. Controlled clinical trials find that appropriate, regular exercise decreases joint pain and degree of disability, although it fails to influence the requirement for anti-inflammatory drug treatment. In **rheumatoid arthritis (RA)**, exercise also increases muscle strength and functional capacity without increasing pain or medication requirements. Whether exercise alters disease progression in either RA or osteoarthritis is not known.

OBESITY, AGING, AND IMMUNE RESPONSES TO EXERCISE

In many cases, obesity and type 2 diabetes can be regarded as diseases of physical inactivity. Regular exercise protects against type 2 diabetes through its positive effects on weight management and metabolic pathways involved in glycemic control that are independent of body weight. Increased physical activity is an effective strategy both for the prevention of type 2 diabetes and its management.

It is also well known that aging lowers maximal dynamic and isometric exercise capacities. There is overwhelming evidence, however, that training can substantially mitigate declines in strength and endurance with advancing age. Changes in functional capacity, as well as protection against heart disease and diabetes, do increase longevity in active persons. However, it remains controversial whether chronic exercise enhances lifespan or whether exercise boosts the immune system, prevents insomnia, or enhances mood.

In obese patients, chronic exercise preferentially increases caloric expenditures over increased appetite.

Obesity is common in sedentary societies. Obesity increases the risk for hypertension, heart disease, and diabetes and is characterized, at a descriptive level, as an excess of caloric intake over energy expenditure. Because exercise enhances energy expenditure, increasing physical activity is a mainstay of treatment for obesity.

The metabolic cost of exercise averages 100 kcal/mi. walked. For exceptionally active people, exercise expenditure can exceed 3,000 kcal/d, added to the basal energy expenditure, which for a 55-kg woman averages about 1,400 kcal/d. At high levels of activity, appetite and food intake match caloric expenditure, though the biologic factors that allow this precise balance have never been defined. In obese patients, modest increases in physical activity increase energy expenditure more than food intake, so progressive weight loss can be instituted if exercise can be regularized. This method of weight control is superior to dieting alone, because substantial caloric restriction (>500 kcal/d) results in both a lowered basal metabolic rate and a substantial loss of fat-free body mass.

Exercise has other, more subtle, positive effects on the energy balance equation as well. A single exercise episode may increase basal energy expenditure for several hours and may increase the thermal effect of feeding. The greatest practical problem remains compliance with even the most precise exercise “prescription”; patient dropout rates from even short-term programs typically exceed 50%.

Exercise is a potent tool in regulating blood glucose in diabetic patients.

Although skeletal muscle is omnivorous, its work intensity and duration, training status, inherent metabolic capacities, and substrate availability determine its energy sources. For short-term exercise, stored phosphagens (ATP and CrP) are sufficient for cross-bridge interaction between actin and myosin. Even maximal efforts lasting 5 to 10 seconds require little or no glycolytic or oxidative energy production. When work to exhaustion is paced to be somewhat longer in duration, high intramuscular ADP concentrations drive glycolysis (particularly in fast glycolytic fibers), and this form of anaerobic metabolism, with its by-product lactic acid, is the major energy source. The carbohydrate provided to glycolysis comes from stored, intramuscular glycogen or blood-borne glucose. Exhaustion from work in this intensity range (50% to 90% of the $\dot{V}O_2max$) is associated with carbohydrate depletion. Accordingly, factors that increase carbohydrate availability improve fatigue resistance. These include prior high dietary carbohydrate, cellular training adaptations that increase the enzymatic potential for fatty acid oxidation (thereby sparing carbohydrate stores), and oral carbohydrate intake during exercise. Hypoglycemia rarely occurs during even the most prolonged or intense physical activity. When it does, it is usually in association with the depletion of muscle and hepatic stores and a failure to supplement carbohydrate orally.

Exercise suppresses insulin secretion by increasing sympathetic tone at the pancreatic islets. Despite acutely falling levels of circulating insulin, both non–insulin-dependent and insulin-dependent muscle glucose uptake, increase during exercise. Exercise recruits glucose transporters from their intracellular storage sites to the plasma membrane of active skeletal muscle cells. Because exercise increases insulin sensitivity, patients with **type 1 diabetes** (insulin dependent) require less insulin when activity increases. However, this positive result can be treacherous because exercise can accelerate hypoglycemia and increase the risk of insulin coma. Chronic exercise, through its reduction of insulin requirements, up-regulates insulin receptors. This effect appears to be a result less of training than simply of a repeated acute stimulus. The effect is full-blown after 2 to 3 days of regular physical activity and can be lost as quickly. Consequently, healthy active people show strikingly greater insulin sensitivity than do their sedentary counterparts (Fig. 29.5). In addition, up-regulation of insulin receptors and reduced insulin release after chronic exercise are ideal therapy in **type 2 diabetes** (non–insulin-dependent), a disease characterized by high insulin secretion and low receptor sensitivity. In those with type 2 diabetes, a single episode of exercise results in substantial glucose transporter translocation to the plasma membrane in skeletal muscle.

Figure 29.5 Daily exercise blunts blood glucose and insulin responses to glucose ingestion. Repeated exercise significantly decreases both responses, demonstrating increased insulin sensitivity.

Exercise affects aging more profoundly than longevity.

The influence of exercise on strength and endurance at any age is dramatic. Although the ceiling for oxygen uptake during work gradually falls with age, the ability to train toward an age-appropriate ceiling is as intact at age 70 years as it is at age 20 years (Fig. 29.6). In fact, a highly active 70-year-old person, otherwise healthy, will typically display an absolute exercise capacity greater than that of a sedentary 20-year-old person. Aging affects all the links in the chain of oxygen transport and use, so aging-induced declines in lung elasticity, lung diffusing capacity, cardiac output, and muscle metabolic potential take place in concert. Consequently, the physiologic mechanisms underlying fatigue are similar at all ages.

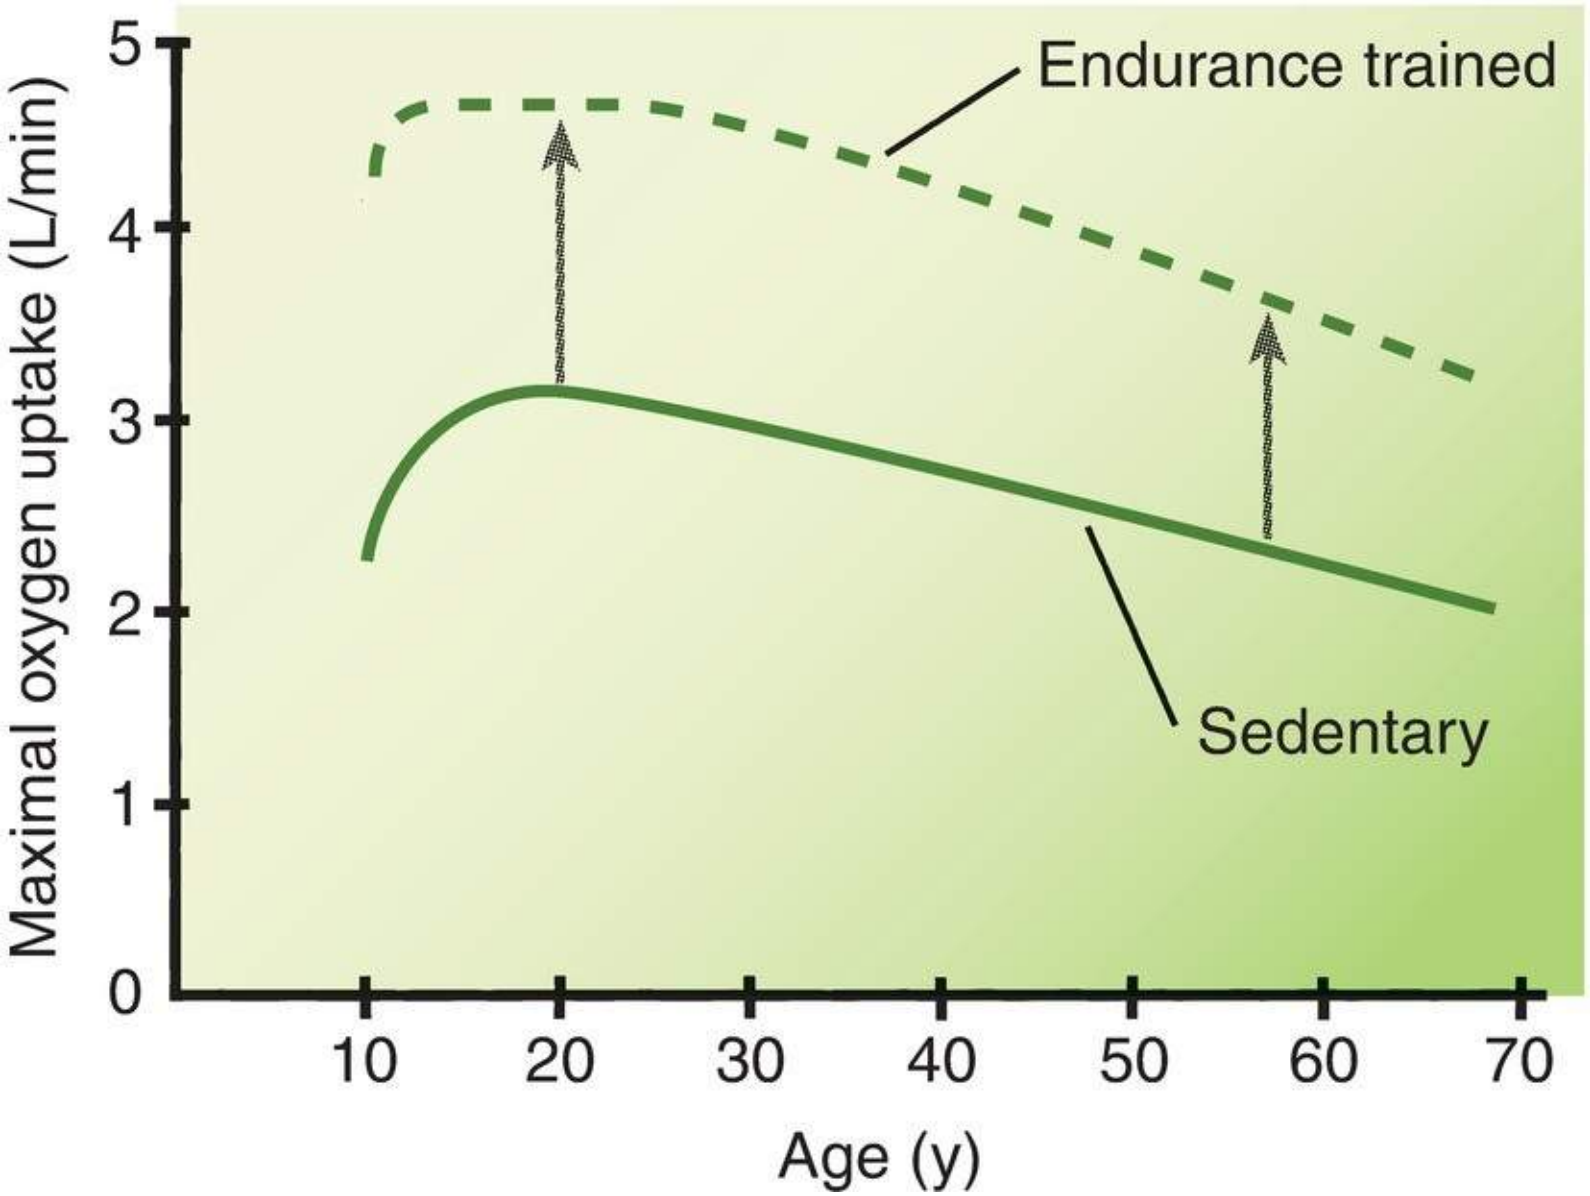

Figure 29.6 Maximal oxygen uptake is enhanced with endurance training. Endurance-trained subjects possess greater maximal oxygen uptake than sedentary subjects, regardless of age.

Regular dynamic exercise, compared with inactivity, increases longevity in rats and humans. In descriptive terms, the effects of exercise are modest; all-cause mortality is reduced but only in amounts sufficient to increase longevity by 1 to 2 years. These facts leave open the possibility that exercise might alter biologic aging. Although physical activity increases cellular oxidative stress, it simultaneously

increases antioxidant capacity. Food-restricted rats experience increased lifespan and exhibit elevated spontaneous activity levels, but the role exercise may play in the apparent delay of aging in these animals remains unclear.

Exercise has modest effect on immune function.

In protein–calorie malnutrition, the catabolism of protein for energy lowers immunoglobulin levels and compromises the body's resistance to infection. Clearly, in this circumstance, exercise merely speeds the starvation process by increasing daily caloric expenditure and would be expected to diminish the immune response further. Nazi labor camps of the early 1940s became death camps, partly by severe food restrictions and incessant demands for physical work—a combination guaranteed to cause starvation.

If nutrition is adequate, it is less clear whether adopting an active versus a sedentary lifestyle alters immune responsivity. In healthy subjects, an acute episode of exercise briefly increases blood leukocyte concentration and transiently enhances neutrophil production of microbicidal reactive oxygen species and natural killer cell activity. However, it remains unproven that regular exercise over time can lower the frequency or reduce the intensity of, for example, upper respiratory tract infections (URTIs). In human immunodeficiency virus (HIV)–positive men and in men with AIDS and advanced muscle wasting, strength training and endurance training yield normal gains. There is also incomplete evidence that training may slow progression to AIDS in HIV-positive men, with a corresponding increase in CD4 lymphocytes. In contrast to moderate or intermittent physical activity, prolonged and very intense exertions are associated with numerous changes in the immune system that reflect physiologic stress and suppression. Athletes subjected to regular strenuous exercise may be at increased risk of URTI during periods of heavy exercise and for a several weeks following race events. It has been suggested that the relationship between exercise and URTIs follows a "J curve," with moderate and regular exercise improving the ability to resist infections and heavy acute or chronic exercise decreasing it. Exercise-induced immunodepression has a multifactorial origin, depending on mechanisms related to neuro–immune–endocrine systems. Prolonged periods of intense training may lead to high numbers of neutrophil and low numbers of lymphocytes, impaired phagocytic and neutrophilic function, and decreases in oxidative burst activity, natural killer cell cytolytic activity, and mucosal immunoglobulin levels. Highly intense training may also enhance release of injury-related proinflammatory cytokines, such as tumor necrosis factor-α, interleukin (IL)-1β, and IL-6. Whether these observations have relevance to clinically immune deficiency remains to be determined.

INTEGRATED MEDICAL SCIENCES

Mobilizing Postoperative Patients: Benefits of Exercise through Early Ambulation

Due to a decline in mortality resulting from critical illness in recent years, a new focus on patient outcomes after hospital discharge has emerged. Notable considerations are (1) enhanced recovery from total hip and knee arthroplasty and (2) lengthy stays in the intensive care unit (ICU). Total hip arthroplasty (THA) and total knee arthroplasty (TKA) elicit physiological stressors accompanied by a proinflammatory cascade that leads to postoperative complications and prolonged rehabilitation and recovery, a multifactorial healing process that includes biological, psychological, and social factors. One simple postoperative intervention that has a positive effect on all these factors and reduces

recovery time is early ambulation. Patient mobilization (within 24 hours) for THA and TKA is a positive predictor for a shorter hospital stay, fewer postoperative complications, and reduced costs and is associated with lower rates of deep vein thrombosis and pulmonary embolism. Additionally, early (postoperative day 1 or 2) progressive strength training is safe and improves knee extension strength and maximal walking speed. It is well known that a single bout of exercise alters the DNA-binding activity of a variety of transcription factors, including MEF2, HDACs, and NRFs, and transient DNA hypomethylation of gene-specific promoter regions precedes increases in mRNA expression in response to acute exercise (Egan, Zierath. *Cell Metabolism* 2013;17:162–184). These immediate adaptations counter atrophic processes that would otherwise ensue and result in muscle wasting and weakness. Prolonged stays in the intensive care unit (ICU) are commonly associated with the development of persistent and often severe neuromuscular weakness. Prominent in the development of ICU-acquired weakness is immobility related to prolonged bed rest. Studies in unrelated, clinically distinct patient populations have demonstrated that moderate exercise is beneficial in counteracting the inflammatory conditions and atrophy that are associated with immobility and in improving muscle strength and physical function. Prolonged bed rest associated with critical illness typically leads to decreased muscle protein synthesis, increased urinary nitrogen excretion (indicating muscle catabolism), and decreased muscle mass, especially in the lower extremities. This type of immobility leads to a proinflammatory state caused by increased systemic inflammation due to proinflammatory cytokines such as IL-1β, IL-2, and interferon-γ proinflammatory cytokines. This potentiates the production of reactive oxygen species (ROS) with a decrease in antioxidative defenses and activation of both nuclear factor-κB and FOXO signaling pathways, resulting in protein loss. Recent studies in the ICU have demonstrated improved clinical outcomes with early mobility that included ambulation and physical therapy. Early mobilization and decreased sedation were found to be synergistically beneficial in mechanically ventilated patients. Their application was associated with decreased lengths of stay in the ICU and hospital, with a trend toward decreased duration of mechanical ventilation, resulting in overall improvements in physical function and quality of life for ICU survivors. Finally, fully sedated patients admitted to the ICU experience the most extensive muscle wasting. Neuromuscular electrical stimulation (NMES) prevents muscle fiber atrophy in these critically ill, comatose patients during lengthy stays and possibly improves survival and subsequent rehabilitation (Dirks, et al. *Clinical Science*. 2015;128:357–365). ■

Chapter Summary

- Exercise is the performance of some activity that involves muscle contraction and joint flexion or extension and places unique stresses on the body's organ systems.
- Measuring maximal oxygen uptake is the most common method of quantifying dynamic exercise.
- Excess in oxygen consumption during the first minutes of recovery is called the oxygen debt.
- Blood flow is preferentially directed to working skeletal muscle during exercise.
- During exercise, blood pressure, heart rate, stroke volume, and cardiac contractility are all increased.
- Hearts of people adapted to prolonged, rhythmic exercise involving low arterial pressure exhibit large left ventricular volumes with normal wall thickness; in those adapted to activities involving isometric contraction and elevated arterial pressure, wall thickness is increased at normal volume.
- Chronic, dynamic exercise is associated with increased circulating levels of high-density lipoproteins (HDLs) and reduced low-density lipoproteins, such that the ratio of HDL to total cholesterol is increased.
- Exercise has a role in preventing and recovering from several cardiovascular diseases.
- Pregnancy shares many cardiovascular characteristics with the trained state.
- Pulmonary ventilation increases during exercise in proportion to O_2 demand and the need for CO_2 removal.
- In lung disease, respiratory limitations appear as shortness of breath or decreased oxygen content of arterial blood and become more apparent during exercise than at rest.
- Muscle fatigue is defined as an exercise-induced reduction in the maximal force capacity of the muscle and is independent of lactic acid.
- Endurance activity at low loads enhances muscle oxidative capacity without hypertrophy, whereas increased activity at high loads produces muscle hypertrophy.
- Although exercise effects on gastrointestinal function remain poorly understood, chronic physical activity plays a major role in the control of obesity and type 2 diabetes.
- As people age, the effects of exercise on functional capacity are more profound than its effect on longevity.

Chapter Review Questions

1. In an effort to strengthen selected muscles after surgery and immobilization has led to muscle atrophy, isometric exercise is recommended. The intensity of isometric exercise is best quantified:
   A. relative to the maximal oxygen uptake.
   B. as mild, moderate, or strenuous.
   C. as a percentage of the maximum voluntary contraction.
   D. in terms of anaerobic metabolism.
   E. on the basis of the total muscle mass involved.

The correct answer is C. A maximal voluntary contraction involving the identical muscles in an identical form of contraction provides the most readily quantified and accurate basis for normalization of isometric exercise intensity. Choice A is incorrect because the basis for comparison involves rhythmic, dynamic exercise. The other choices also contradict the principle that exercise can only be compared with other exercise involving the same muscles and the same types of muscle contraction.

2. Two people, one highly trained and one not, each exercising at 75% of the maximal oxygen uptake, become fatigued:
   A. for similar physiological reasons.
   B. very slowly.
   C. at different times.
   D. while performing equally well for at least a short period of time.
   E. despite much higher circulating lactic acid levels in the trained person.

The correct answer is A. The physiological responses to dynamic exercise are predictable when healthy individuals differing in endurance exercise capacity are compared at matched levels of relative oxygen transport demand. Exercise at 75% of the maximal oxygen uptake will lead to exhaustion in typically 1 to 2 hours, rendering choice B incorrect. The more highly trained person will show increased work output despite fatiguing at about the same time as the person with lower capacity, rendering choices C and D incorrect. Training lowers lactic acid production at any matched fractional use of the maximal oxygen uptake, making choice E incorrect.

3. A patient completes a graded, dynamic exercise test on a treadmill while showing a modest rise (25%) in mean arterial blood pressure. In contrast, during the highest level of exercise at the end of the test, an indirect method shows that cardiac output has risen 300% from rest. These results indicate that during graded, dynamic exercise to exhaustion, systemic vascular resistance:
   A. is constant.
   B. rises slightly.
   C. falls only if work is prolonged.
   D. falls dramatically.
   E. cannot be measured.

The correct answer is A. Active muscle vasodilation during dynamic exercise is quantitatively much greater than the net vasoconstriction in the gut, skin, kidneys, and inactive muscle. Choices B, C, and D contradict this answer. Total systemic vascular resistance can be measured, albeit indirectly, from measurements of systemic arterial pressure and cardiac output.

4. A patient with inflammatory bowel disease and compromised kidney function asks if exercise will alter blood flow to either the gastrointestinal tract or the kidneys. The answer is that

vasoconstriction in both the renal and splanchnic vascular beds during exercise:

A. rarely occurs.
B. occurs only after prolonged training.
C. helps maintain arterial blood pressure.
D. allows renal and splanchnic flows to parallel cerebral blood flow.
E. will be balanced by local dilation in these vascular beds.

The correct answer is C. This answer presumes that vasoconstriction occurs in these vascular beds and that its effect is to help balance vasodilation in active skeletal muscles and prevent exercise-induced systemic hypotension. This effect is ubiquitous across all individuals during all forms of dynamic exercise, making choices B, C, and E incorrect. Cerebral blood flow is held constant during all forms of exercise, unlike renal or splanchnic blood flow.

5. A young, healthy, highly trained individual enters a marathon (40 km) run on a warm, humid day (32°C, 70% humidity). The best medical advice for this individual is to be concerned about the possibility for:

A. heat exhaustion.
B. coronary ischemia.
C. renal ischemia and anoxia.
D. hypertension.
E. gastric mucosal ischemia and increased risk for gastric ulceration.

The correct answer is A. Even highly trained and heat-acclimatized individuals are at risk for heat-related illness if exercise is sufficiently prolonged and if environmental conditions are sufficiently severe. In healthy persons during exercise, coronary vasodilatory capacity is adequate, renal blood flow reductions in health are entirely safe, and gastric mucosal blood flow reductions are easily tolerated. In long-term exercise in a warm environment, hypotension, not hypertension, is the possible cardiovascular risk.

Clinical Application Exercises 29.1

A PATIENT WITH DYSPNEA DURING EXERCISE

A 56-year-old man complained of shortness of breath and chest pain when climbing stairs or mowing the lawn. He is subjected to a stress test, with noninvasive monitoring of heart rate, blood pressure, arterial blood oxygen saturation, and cardiac electrical activity. His resting heart rate is 73 beats/min; blood pressure, 118/75 mm Hg; arterial blood oxygen saturation, 96%; and the ECG, normal. After 3.5 minutes of increasingly intense exercise, the test is terminated because of the subject's severe dyspnea. His heart rate is 119 beats/min (his age and sex-adjusted predicted maximal heart rate is 168 beats/min), blood pressure is 146/76 mm Hg, arterial blood oxygen saturation is 88%, and the ECG is normal.

QUESTIONS

1. What are three lines of evidence for ventilatory limitation to this subject's exercise?
2. Why did arterial blood oxygen saturation fall during exercise?
3. Why did exhaustion occur before maximal heart rate was reached?
4. Why did the pulse pressure rise in exercise?

5. Why would endurance exercise training likely increase this individual's exercise capacity?

ANSWERS

1. Ventilatory limitation is evidenced by severe dyspnea as a primary symptom in exercise, falling arterial blood oxygenation, and exercise termination at relatively low heart rate.
2. Arterial blood oxygen saturation fell during exercise because increased cardiac output (increased pulmonary blood flow) and decreased pulmonary arterial blood oxygen content (a result of increased skeletal muscle oxygen extraction) increase demands for oxygenation in the lungs with inadequate diffusing capacity.
3. Exhaustion occurred before a maximal heart rate was reached because lung disease creates severe dyspnea even in mild exercise.
4. The pulse pressure rose during exercise because sympathetic stimulation and enhanced venous return increase the stroke volume at constant arterial compliance.
5. Endurance exercise training would have little effect on any aspect of lung function. However, training would cause adaptations within exercising muscle that would increase muscle oxidative capacity and reduce lactic acid production. By reducing the ventilatory demands of exercise, these changes would increase exercise capacity in this individual.

PART IX ENDOCRINE PHYSIOLOGY

30 Endocrine Control Mechanisms

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how, in addition to specific endocrine disease states, other prominent diseases, including atherosclerosis, cancer, and even psychiatric disorders, likely have an underlying endocrine component.
- Explain how hormone receptors, restricted distribution of hormones, and hormone activation processes determine target tissues for a specific hormone.
- Explain how normal feedback relationships permit clinical diagnoses of functional and dysfunctional endocrine systems.
- Explain how secretagogues are used clinically to provide meaningful diagnostic information.
- Explain how chemical differences in hormones influence their endocrine functionality.
- Explain how altered target tissue hormonal responses reflected by dose–response curves can provide useful clinical information regarding the underlying cause of a particular disease.

Endocrinology is the branch of physiology concerned with the description and characterization of processes involved in the regulation and integration of cells and organ systems by a group of specialized chemical substances called **hormones**. The diagnosis and treatment of many endocrine disorders are important aspects of any general medical practice. Certain endocrine disease states, such as diabetes mellitus, thyroid disorders, and reproductive disorders, are fairly common in the general population; therefore, it is likely that they will be encountered repeatedly in the practice of medicine.

In addition, because hormones either directly or indirectly affect virtually every cell or tissue in the body, some other prominent diseases not primarily classified as endocrine diseases may have an important endocrine component. Atherosclerosis, certain forms of cancer, and even certain psychiatric disorders are examples of conditions in which an endocrine disturbance may contribute to the progression or severity of disease.

GENERAL ENDOCRINE CONCEPTS

The word “hormone” is derived from the Greek *hormaein*, which means to “excite” or to “stir up.” Glands that comprise the endocrine system produce hormones. The major morphologic feature of endocrine glands is that they are ductless; that is, they release their secretory products directly into the bloodstream and not into a duct system. Figure 30.1 illustrates classical endocrine glands. Many other “nonclassical” hormone-producing glands also exist. These include the central nervous system, kidneys, stomach, small intestine, skin, heart, lung, and placenta. Recent advances in cellular and molecular biology continually broaden our views of the endocrine system. For example, obesity-related research discovered leptin, a hormone formed in adipocytes that signals to the central nervous system to regulate appetite and energy expenditure. Here, general themes and principles that underpin the functionality of the endocrine system as a whole will be presented.

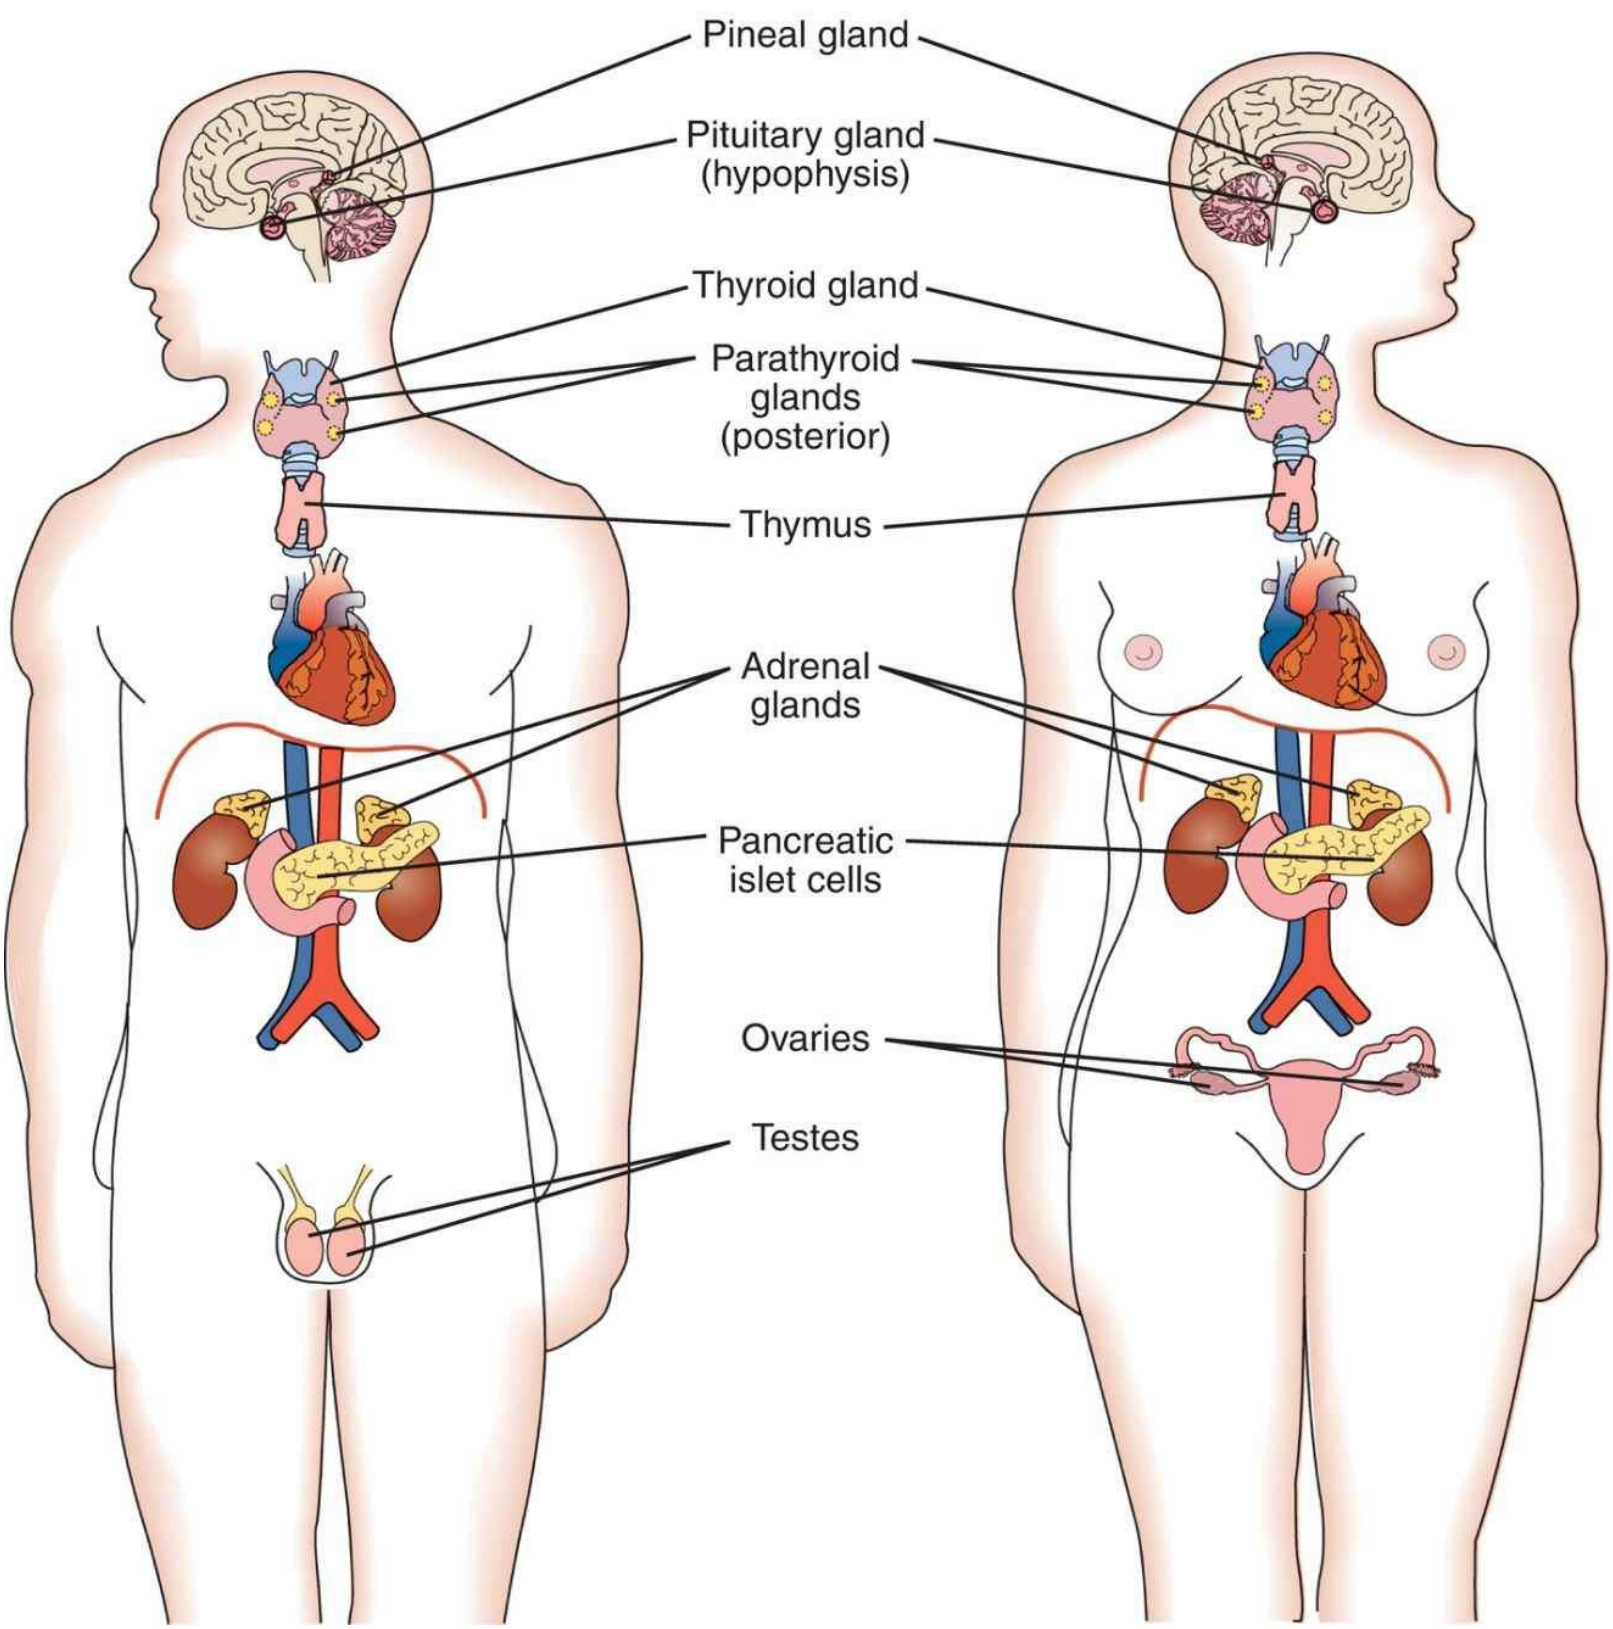

Figure 30.1 Location of many endocrine glands, organs containing endocrine tissue, and associated structures.

Hormones are chemicals released by a cell that regulate many functions.

Hormones function as homeostatic blood-borne chemicals to regulate and coordinate various biologic functions. They are highly potent, specialized, organic molecules produced by endocrine cells in response to specific stimuli and exert their actions on specific target cells. These target cells are equipped with receptors that bind hormones with high affinity and specificity; when bound, they initiate characteristic biologic responses by the target cells.

Although the effects of hormones are many and varied, their actions are involved in (1) regulating ion and water balance; (2) responding to adverse conditions, such as infection, trauma, and emotional stress; (3) sequentially integrating features of growth and development; (4) contributing to basic processes of reproduction, including gamete production, fertilization, nourishment of the embryo and fetus, delivery, and nourishment of the newborn; and (5) digesting, using, and storing nutrients.

In the past, definitions or descriptions of hormones usually included a phrase indicating that these substances were secreted into the bloodstream and carried by the blood to a distant target tissue. Although many hormones travel by this mechanism, we now realize that there are many hormones or hormone-like substances that play important roles in cell-to-cell communication that are not secreted directly into the bloodstream. Instead, these substances reach their target cells by diffusion through the interstitial fluid. Recall the discussion of autocrine and paracrine mechanisms in Chapter 2.

Hormones initiate a cell response by binding to specific receptors.

In the endocrine system, a hormone molecule secreted into the blood is free to circulate and contact almost any cell in the body. However, only **target cells**, those cells that possess specific receptors for the hormone, will respond to that hormone. As presented in Chapter 2, a **hormone receptor** is the molecular entity (usually a protein or glycoprotein) either outside or within a cell that recognizes and binds a particular hormone. When a hormone binds to its receptor, characteristic biologic effects of that hormone are initiated. Therefore, in the endocrine system, the basis for specificity in cell-to-cell communication rests at the level of the receptor. Similar concepts apply to autocrine and paracrine mechanisms of communication.

The restricted distribution of some hormones ensures a certain degree of specificity. For example, several hormones produced by the hypothalamus regulate hormone secretion by the anterior pituitary. These hormones are carried via small blood vessels directly from the hypothalamus to the anterior pituitary, prior to entering the general systemic circulation. The anterior pituitary is, therefore, exposed to considerably higher concentrations of these hypothalamic hormones than the rest of the body; as a result, the actions of these hormones focus on cells of the anterior pituitary.

Another mechanism that restricts the distribution of active hormone is the local transformation of a hormone within its target tissue from a less active to a more active form. An example is the formation of dihydrotestosterone from testosterone, occurring in such androgen target tissues as the prostate gland. Dihydrotestosterone is a much more potent androgen than testosterone. Because the enzyme that catalyzes this conversion is found only in certain locations, its cell or tissue distribution partly localizes the actions of the androgens to these sites. Therefore, although receptor distribution is the primary factor in determining the target tissues for a specific hormone, other factors may also focus the actions of a hormone on a particular tissue.

Hormone regulation occurs through feedback control.

Feedback mechanisms regulate the endocrine system, just as in many other physiologic systems. The mechanism is usually negative feedback, although a few positive feedback mechanisms are known. Both types of feedback control occur because the endocrine cell, in addition to synthesizing and secreting its own hormone product, has the ability to sense the biologic consequences of secretion of that hormone. This enables the endocrine cell to adjust its rate of hormone secretion to produce the desired level of effect, ensuring the maintenance of homeostasis.

In the simplest form, negative feedback is a closed loop in which hormone A stimulates the production of hormone B, which in turn acts on the cells producing A to decrease its rate of secretion (Fig. 30.2A). In the less common positive feedback system, hormone B further stimulates the production of A instead of diminishing it (Fig. 30.2B). Many examples of negative feedback regulation exist and are discussed throughout the endocrine chapters. A typical example of a positive feedback loop is that which exists between luteinizing hormone (LH) and estradiol. As detailed in Chapter 37, positive feedback by estradiol is required to generate an abrupt increase in LH secretion during the menstrual cycle. Endocrine control systems also have feedforward loops, which can be negative or positive and which direct the flow of hormonal information. Unlike negative feedback, which promotes stability, feedforward control anticipates change. Recall discussion of the physiologic regulation in Chapter 2.

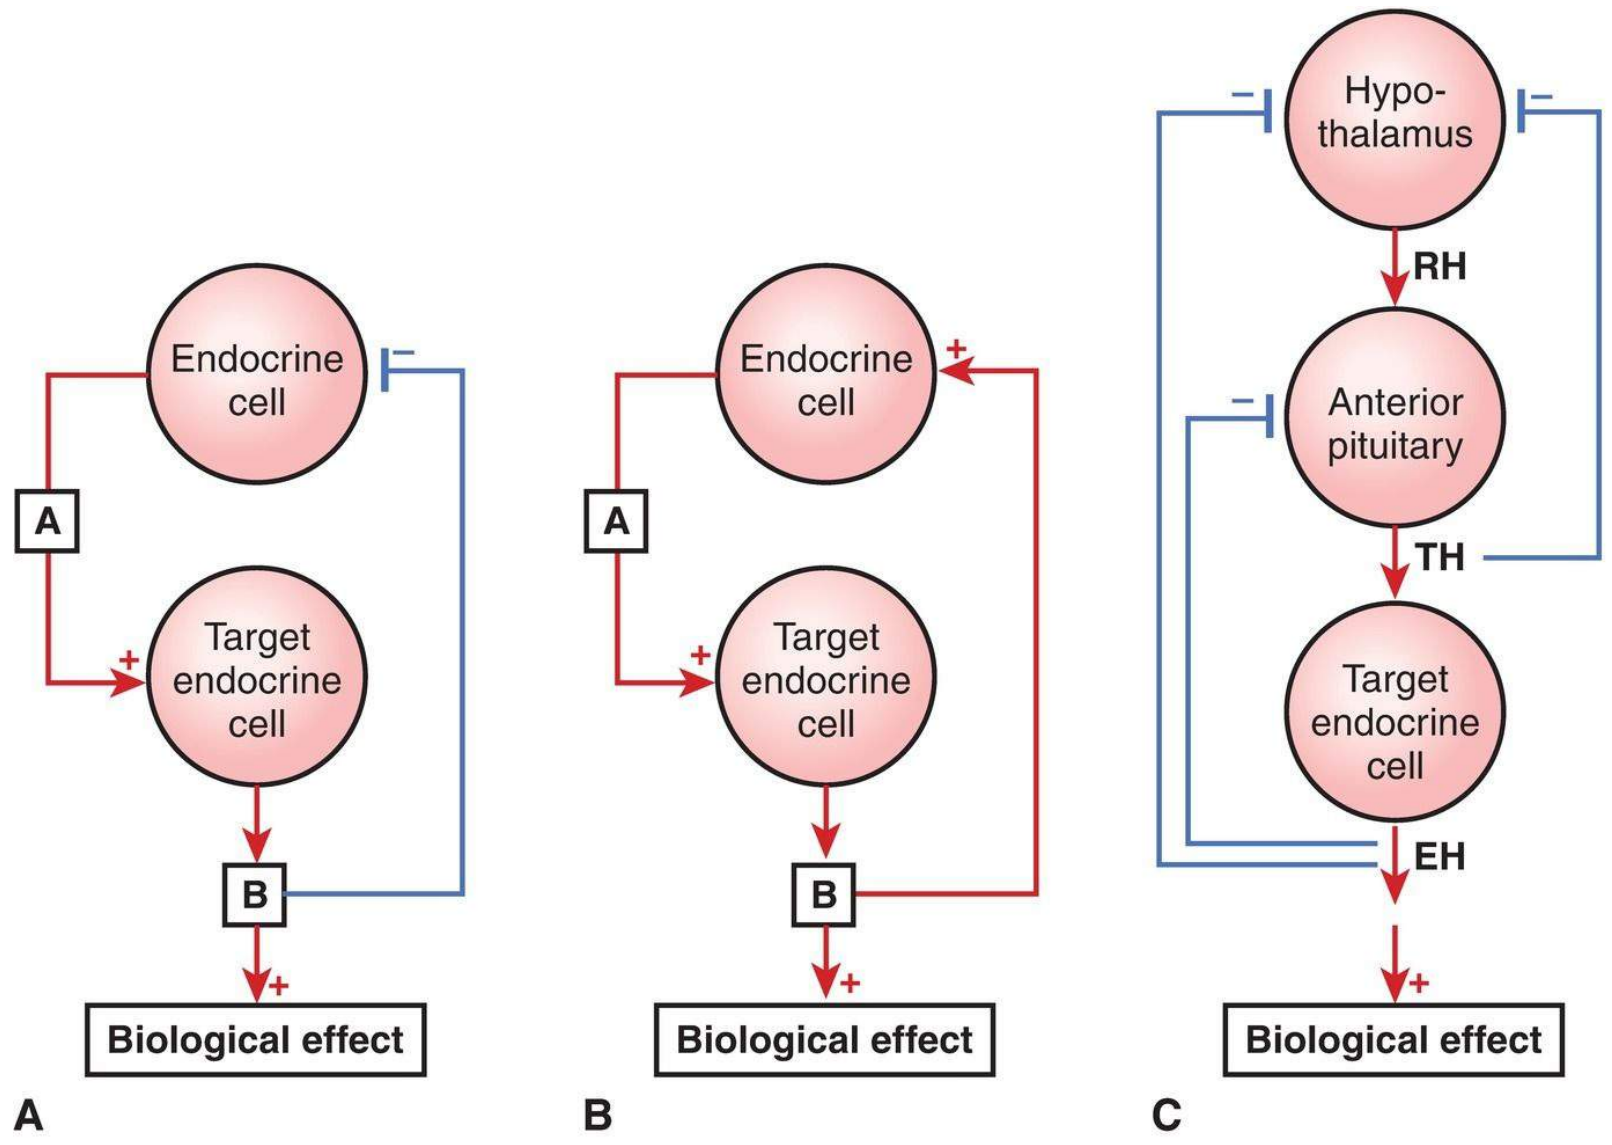

Figure 30.2 Negative, positive, and complex feedback mechanisms in the endocrine system. (A) Negative feedback loop. **(B)** Positive feedback loop. **(C)** A complex, multilevel feedback loop: the hypothalamic–pituitary–target gland axis. Red lines indicate stimulatory effects; blue lines indicate inhibitory, negative feedback effects. EH, endocrine cell hormone; RH, releasing hormone; TH, trophic hormone.

More commonly, feedback regulation in the endocrine system is complex, involving second-order or third-order feedback loops. For example, multiple levels of feedback regulation may be involved in regulating hormone production by various endocrine glands under the control of the anterior pituitary (Fig. 30.2C). The regulation of the secretion of target gland hormones, such as adrenal steroids or thyroid hormones, begins with the production of a **releasing hormone** by the hypothalamus. The releasing hormone stimulates the production of a **trophic hormone** by the anterior pituitary, which in turn stimulates the production of the target endocrine cell hormone by the target gland. As indicated by the blue lines in Figure 30.2C, the target endocrine cell hormone may have negative feedback effects to inhibit secretion of both the trophic hormone from the anterior pituitary and the releasing hormone from the hypothalamus. In addition, the trophic hormone may inhibit releasing hormone secretion from the hypothalamus, and in some cases, the releasing hormone may inhibit its own secretion by the hypothalamus.

The more complex multilevel form of regulation appears to provide certain advantages compared with the simpler system. Theoretically, it permits a greater degree of fine-tuning of hormone secretion, and the multiplicity of regulatory steps minimizes changes in hormone secretion in the event that one component of the system is not functioning normally.

Normal feedback relationships that control the secretion of each individual hormone are discussed in the chapters that follow. Clinical diagnoses are often made based on the evaluation of hormone–effector pairs relative to normal feedback relationships. For example, in the case of anterior pituitary hormones, measuring both the trophic hormone and the target gland hormone concentration provides important information to help determine whether a defect in hormone production exists at the level of the pituitary or at the level of the target gland. Furthermore, most dynamic tests of endocrine function performed clinically are based on our knowledge of these feedback relationships. Dynamic tests involve a prescribed perturbation of the feedback relationship(s). The range of response in a healthy person is well established, whereas a response outside the normal range is indicative of abnormal function at some level and greatly enhances information gained from static measurements of hormone concentrations.

Signal amplification is part of the overall mechanism of hormone action.

Another important feature of the endocrine system is signal amplification, a mechanism that increases the amplitude of the signal. For example, blood concentrations of hormones are exceedingly low, generally 10^{-9} to 10^{-12} mol/L. Even at the higher concentration of 10^{-9} mol/L, only one hormone molecule is present for roughly every 50 billion water molecules. Therefore, for hormones to be effective regulators of biologic processes, amplification must be part of the overall mechanism of hormone action.

As presented in Chapter 2, amplification generally results from the activation of a series of enzymatic steps involved in hormone action. At each step, many times more signal molecules are generated than were present at the prior step, leading to a cascade of ever-increasing numbers of signal molecules. The self-multiplying nature of the hormone action pathways provides the molecular basis for amplification in the endocrine system.

Hormones can have multiple, and share some, actions with other hormones.

Most hormones have multiple actions in their target tissues and are, therefore, said to have **pleiotropic** effects. This phenomenon occurs when a single hormone regulates several functions in a target tissue. For example, in skeletal muscle, insulin stimulates glucose uptake, stimulates glycolysis, stimulates glycogenesis, inhibits glycogenolysis, stimulates amino acid uptake, stimulates protein synthesis, and inhibits protein degradation.

In addition, some hormones are known to have different effects in several different target tissues. For example, testosterone, the male sex steroid, promotes normal sperm formation in the testes, stimulates growth of the accessory sex glands, such as the prostate and seminal vesicles, and promotes the development of several secondary sex characteristics, such as beard growth and deepening of the voice.

The ability of several different hormones to regulate a single biological function is referred to as multiplicity of regulation. The input of information from several sources allows a highly integrated response, which is of ultimate benefit to the whole animal. For example, several different hormones, including insulin, glucagon, epinephrine, thyroxine, and cortisol, regulate liver glycogen metabolism.

Hormones are often secreted in rhythmic patterns.

Many hormones are secreted in a defined, rhythmic pattern. These rhythms can take several forms. For example, they may be pulsatile, episodic spikes in secretion lasting just a few minutes, or they may follow a daily, monthly, or seasonal change in overall pattern. Pulsatile secretion may occur in addition to other longer secretory patterns.

For these reasons, a single randomly drawn blood sample for determining a certain hormone concentration may be of little or no diagnostic value. A dynamic test of endocrine function in which a known agent specifically stimulates hormone secretion often provides much more meaningful information (Clinical Focus 30.1).

CLINICAL FOCUS 30.1

Growth Hormone and Pulsatile Hormone Secretion

Growth hormone (**GH**) is a 191-amino acid protein hormone that is synthesized and secreted by somatotrophs of the anterior lobe of the pituitary gland. As described in Chapter 31, GH plays a role in regulating bone growth and energy metabolism in skeletal muscle and adipose tissue. A deficiency in GH production during adolescence results in dwarfism, and overproduction results in gigantism. Measurements of circulating growth hormone levels are, therefore, desirable in children whose growth rate is not appropriate for their age. However, as with many other hormones, the pulsatile nature of GH secretion needs to be considered.

Most healthy children experience episodes or "bursts" of GH secretion throughout the day, most prominently within the first several hours of sleep. To obtain reliable information about growth hormone secretion, insertion of a continuous withdrawal pump or patent indwelling catheter with unrestricted food intake and physical activity is required. Increasing sampling frequencies from every 20-minute to 5-minute or 30-second sampling intervals enhances the threshold for detecting more pulses per hour. Although cumbersome and expensive, this method eliminates the error of isolated peak or trough measurements that might otherwise be obtained by single or multiple random GH samplings.

A less arduous approach with similar discriminating power in diagnosing GH deficiency entails measuring GH levels in the blood shortly after appropriate pituitary stimulation. Pharmacologic agents that stimulate GH secretion include L-dopa, clonidine, propanolol, glucagon, insulin, and arginine. By perturbing the system in a well-prescribed fashion, the endocrinologist is able to gain important information about growth hormone secretion that would not be possible if a random blood sample were used. As further presented in Clinical Focus 31.2, an alternative means of testing for GH deficiency is to measure the levels of insulin-like growth factor-1 and IGF-binding protein-3 in the blood because both predict the presence of GH. ■

CHEMICAL NATURE OF HORMONES

Hormones can be categorized by several criteria. Grouping them by chemical structure is convenient, because in many cases hormones with similar structures also use similar mechanisms to produce their biologic effects. In addition, tissues with similar embryonic origins usually produce hormones with similar chemical structures. The three chemical classes include (1) amine-derived, (2) polypeptide-derived, and (3) cholesterol-derived hormones.

Amine-derived hormones consist of one or two modified amino acids.

Hormones derived from one or two amino acids are small in size and often hydrophilic. These hormones are formed by conversion from a commonly occurring amino acid; **norepinephrine** and **thyroxine**, for example, are derived from tyrosine (Fig. 30.3A). Each of these hormones is synthesized by a particular sequence of enzymes that are primarily localized in the endocrine gland involved in its production. Many environmental or pharmacologic agents can influence the synthesis of amino acid–derived hormones in a relatively specific fashion. The steps involved in the synthesis of these hormones are discussed in detail in later chapters.

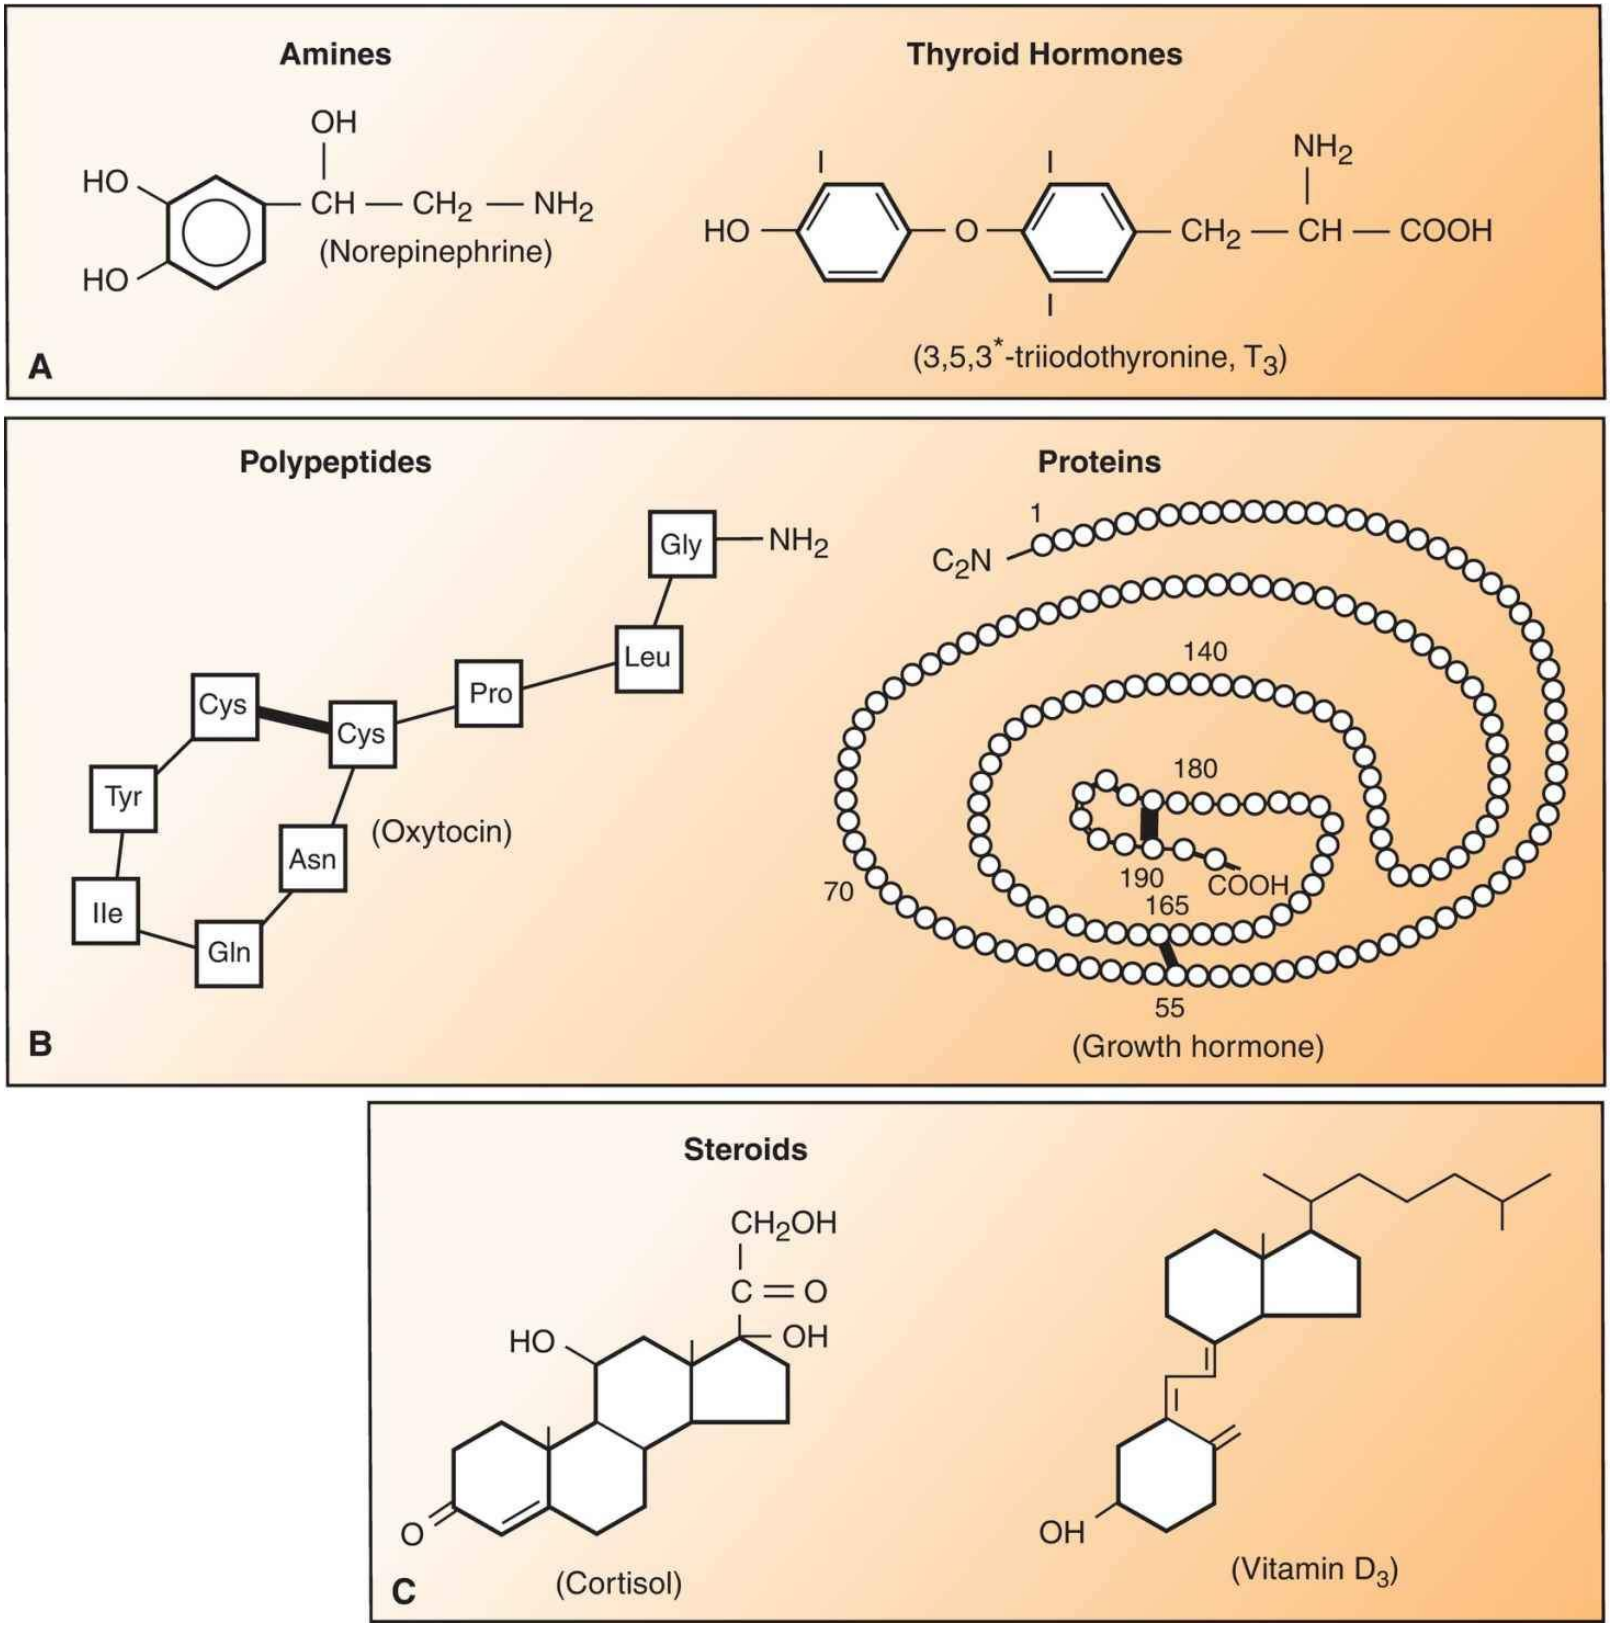

Figure 30.3 Examples of different hormone chemical structures. (A) Amine hormones. **(B)** Peptide hormones. **(C)** Steroid hormones.

Polypeptide-derived hormones are diverse in size and complexity.

Hormones in the polypeptide group may be as small as the tripeptide **thyrotropin-releasing hormone** (**TRH**) or as large as **human chorionic gonadotropin**, which is composed of separate α and β subunits, has a molecular weight of ~34 kDa, and is a glycoprotein consisting of 16% carbohydrate by weight. Figure 30.3B provides examples of this second category of polypeptide and protein hormones.

Within the polypeptide class of hormones are many families of hormones, some of which are listed in Table 30.1. Hormones can be grouped into these families as a result of considerable homology with regard to amino acid sequence and structure. Presumably, the similarity of structure in these families resulted from the evolution of a single ancestral hormone into each of the separate and distinct hormones. In many cases, there is also considerable homology among receptors for the hormones within a family.

TABLE 30.1 Examples of Peptide Hormone Families

Insulin Family	Glycoprotein Family	Growth Hormone Family	Secretin Family
Insulin	Luteinizing hormone	Growth hormone	Secretin
Insulin-like growth factor-1	Follicle-stimulating hormone	Prolactin	Vasoactive intestinal peptide
Insulin-like growth factor-2	Thyroid-stimulating hormone	Human placental lactogen	Glucagon
Relaxin	Human chorionic gonadotropin		Gastric inhibitory peptide

Polypeptide hormones are synthesized and stored in advance of need. Like other proteins destined for secretion, polypeptide hormones are synthesized with a *prepeptide* or *signal* peptide at their amino terminal end that directs the growing peptide chain into the cisternae of the rough endoplasmic reticulum (RER). Moreover, most, if not all, polypeptide hormones are synthesized as part of an even larger precursor or **preprohormone**. The prepeptide is cleaved off on entry of the preprohormone into the RER to form the **prohormone**. Because the prohormone is processed through the Golgi apparatus and packaged into secretory vesicles, it is proteolytically cleaved at one or more sites to yield active hormone. In many cases, preprohormones may contain the sequences for several different biologically active molecules. Inactive spacer segments of peptide, in some cases, may separate these active elements. Specific mechanisms of polypeptide hormone synthesis, storage, and processing are discussed in later chapters.

Steroid hormones are derived from cholesterol.

Steroids are lipid-soluble, hydrophobic molecules synthesized from cholesterol. Examples include **aldosterone**, **cortisol**, and **androgen**, secreted by the cortex (outer zone) of the adrenal glands; **testosterone**, secreted by the testes; and **estrogen** and **progesterone**, secreted by the ovaries. These adrenal and gonadal steroid hormones contain an intact steroid nucleus, as illustrated for cortisol in Figure 30.3C. In contrast, other hormone derivatives of cholesterol, such as vitamin D and its metabolites, have a broken steroid nucleus (the B ring) (see Fig. 30.3C). Steroid hormones are synthesized and secreted on demand (specific mechanisms are discussed in later chapters).

CLINICAL FOCUS 30.2

Pancreatic b-Cell Function and C-Peptide

β cells of the human pancreas produce and secrete **insulin**. The product of the insulin gene is a peptide known as preproinsulin. As with other secretory peptides, the prepeptide or signal peptide is cleaved off early in the biosynthetic process, yielding proinsulin. Proinsulin is an 86-amino acid protein that is subsequently cleaved at two sites to yield insulin and a 31-amino acid peptide known as **C-peptide**. Insulin and C-peptide are, therefore, localized within the same secretory vesicle and are cosecreted into the bloodstream.

For these reasons, measurements of circulating C-peptide levels can provide a valuable indirect assessment of β-cell insulin secretory capacity. In diabetic patients who are receiving exogenous insulin injections, the measurement of circulating insulin levels would not provide any useful information about their own pancreatic function because it would primarily be the injected insulin that would be measured. However, an evaluation of C-peptide levels in such patients would provide an indirect measure of how well the β cells were functioning with regard to insulin production and secretion. ■

MEASUREMENT OF CIRCULATING HORMONES

The amounts of different hormones are regulated by varied mechanisms in the blood and target tissues. For example, in the bloodstream, the binding of a plasma protein to a hormone has many effects including inactivation. In the periphery, some hormones are made more active by various transformations.

Hormones can circulate either free or bound to carrier proteins.

Most amine- and polypeptide-derived hormones dissolve readily in the plasma, and thus, no special mechanisms are required for their transport. Steroid and thyroid hormones are relatively insoluble in plasma. Mechanisms are present to promote their solubility in the aqueous phase of the blood and their ultimate delivery to a target cell.

In most cases, 90% or more of steroid and thyroid hormones in the blood are bound to plasma proteins. Some of the plasma proteins that bind hormones are specialized, in that they have a considerably higher affinity for one hormone over another, whereas others, such as serum albumin, bind many hydrophobic hormones. The extent to which a hormone is protein bound and the extent to which it binds to specific versus nonspecific transport proteins vary from one hormone to another. The principal binding proteins involved in specific and nonspecific transport of steroid and thyroid hormones are listed in Table 30.2. The liver synthesizes and secretes these proteins, and changes in various nutritional and endocrine factors influence their production.

TABLE 30.2 Circulating Transport Proteins

Transport Protein	Principal Hormone(s) Transported
Specific	
Corticosteroid-binding globulin (transcortin)	Cortisol, aldosterone
Thyroxine-binding globulin	Thyroxine, triiodothyronine
Sex hormone–binding globulin	Testosterone, estrogen
Nonspecific	
Serum albumin	Most steroids, thyroxine, triiodothyronine
Transthyretin (prealbumin)	Thyroxine, some steroids

Typically, for hormones that bind to carrier proteins, only 1% to 10% of the total hormone present in the plasma exists free in solution. However, only this free hormone is biologically active. Bound hormone cannot directly interact with its receptor and, thus, is part of a temporarily inactive pool. However, free hormone and carrier-bound hormone are in a dynamic equilibrium with each other (Fig. 30.4). The size of the free hormone pool and, therefore, the amount available to receptors are influenced not only by changes in the rate of secretion of the hormone but also by the amount of carrier protein available for hormone binding and the rate of degradation or removal of the hormone from the plasma.

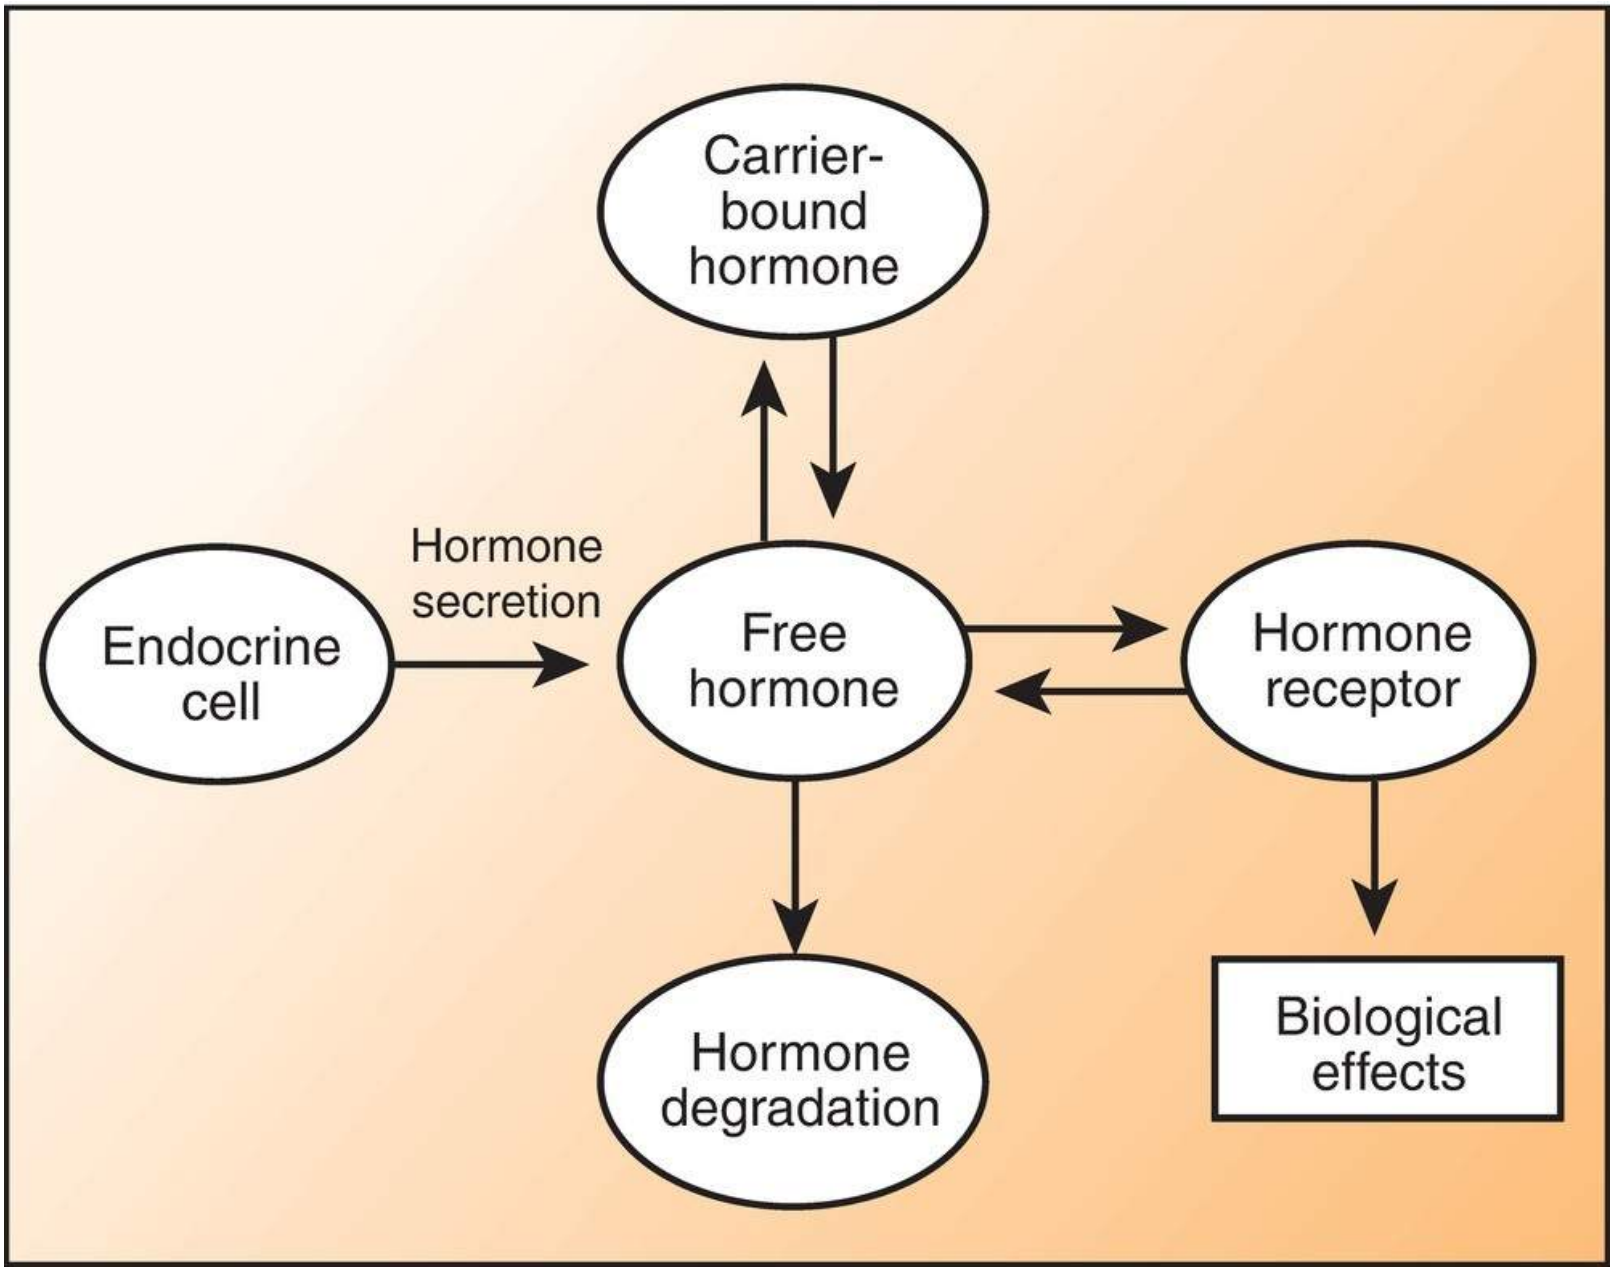

Figure 30.4 The relationship between hormone secretion, carrier protein binding, and hormone degradation. This relationship determines the amount of free hormone available for receptor binding and the production of biologic effects.

In addition to increasing the total amount of hormone that can be carried in plasma, transport proteins also provide a relatively large reservoir of hormone that buffers rapid changes in free hormone concentrations. As unbound hormone leaves the circulation and enters cells, additional hormone dissociates from transport proteins and replaces free hormone that is lost from the free pool. Similarly, following a rapid increase in hormone secretion or the therapeutic administration of a large dose of hormone, most newly appearing hormone is bound to transport proteins because under most conditions these are present in considerable excess. Protein binding greatly slows the rate of clearance of hormones from plasma. It not only slows the entry of hormones into cells, slowing the rate of hormone degradation, but also prevents loss by filtration in the kidneys.

From a diagnostic standpoint, it is important to recognize that most hormone assays are reported in terms of total concentration (i.e., the sum of free and bound hormone), not just free hormone concentration. The amount of transport protein and the total plasma hormone content are known to change under certain physiologic or pathologic conditions, whereas the free hormone concentration may remain relatively

normal. For example, increased concentrations of binding proteins are seen during pregnancy, and decreased concentrations are seen with certain forms of liver or kidney disease. Assays of total hormone concentration might be misleading, because free hormone concentrations may be in the normal range. In such cases, it is helpful to determine the extent of protein binding, so that free hormone concentrations can be estimated.

The proportions of a hormone that are free, bound to a specific transport protein, and bound to albumin vary depending on the hormone's solubility, its relative affinity for the two classes of transport proteins, and the relative abundance of the transport proteins. For example, the affinity of cortisol for **corticosteroid-binding globulin** (**CBG**) is more than 1,000 times greater than its affinity for albumin, but albumin is present in much higher concentrations than CBG. Therefore, about 70% of plasma cortisol is bound to CBG, 20% is bound to albumin, and the remaining 10% is free in solution. Aldosterone also binds to CBG, but with a much lower affinity, such that only 17% is bound to CBG, 47% associates with albumin, and 36% is free in solution.

As this example indicates, more than one hormone may be capable of binding to a specific transport protein. When several such hormones are present simultaneously, they compete for a limited number of binding sites on these transport proteins. For example, cortisol and aldosterone compete for CBG binding sites. Increases in plasma cortisol result in displacement of aldosterone from CBG, raising the unbound (active) concentration of aldosterone in the plasma. Similarly, prednisone, a widely used synthetic corticosteroid, can displace about 35% of the cortisol normally bound to CBG. As a result, with prednisone treatment, the free cortisol concentration is higher than might be predicted from measured concentrations of total cortisol and CBG.

Peripheral tissues transform, degrade, and excrete hormones.

As a general rule, hormones are produced in their active form by their endocrine gland or tissue of origin. However, for a few notable exceptions, hormone activity is enhanced or requires peripheral transformation. Well-known transformations are the conversion of testosterone to dihydrotestosterone, as mentioned above and detailed in Chapter 36, and the conversion of thyroxine to triiodothyronine (see Chapter 32). Other examples are the formation of the octapeptide angiotensin II from its precursor, angiotensinogen (see Chapter 33), and the formation of 1,25-dihydroxycholecalciferol from cholecalciferol (see Chapter 35). Specific hormone transformations may be impaired because of a congenital enzyme deficiency or drug-induced inhibition of enzyme activity, resulting in endocrine abnormalities.

As in any regulatory control system, the hormonal signal must dissipate or disappear once appropriate information has been transferred and the need for further stimulus has ceased. As described earlier, not only the rate of secretion but also the rate of degradation determine steady-state plasma concentrations of hormone. Thus, any factor that significantly alters the degradation of a hormone can potentially alter its circulating concentration. Commonly, however, secretory mechanisms can compensate for altered degradation such that plasma hormone concentrations remain within the normal range. Processes of hormone degradation show little, if any, regulation; alterations in the rates of hormone synthesis or secretion in most cases provide the primary mechanism for altering circulating hormone concentrations.

For most hormones, the liver is quantitatively the most important site of degradation; for a few others, the kidneys play a significant role as well. Diseases of the liver and kidneys may, therefore, indirectly influence endocrine status as a result of altering the rates at which hormones are removed from the circulation. Various drugs also alter normal rates of hormone degradation; thus, the possibility of indirect drug-induced endocrine abnormalities also exists. In addition to the liver and kidneys, target tissues may take up and degrade quantitatively smaller amounts of hormone. In the case of amine and polypeptide hormones, this occurs via receptor-mediated endocytosis.

The nature of specific structural modification(s) involved in hormone inactivation and degradation differs for each hormone class. As a general rule, however, specific enzyme-catalyzed reactions are involved. Inactivation and degradation may involve complete metabolism of the hormone to entirely different products, or it may be limited to a simpler process involving one or two steps, such as a covalent modification to inactivate the hormone. Urine is the primary route of excretion of hormone degradation products, but small amounts of intact hormone may also appear in the urine. In some cases, measuring the urinary content of a hormone or hormone metabolite provides a useful, indirect, noninvasive means of assessing endocrine function.

The degradation of amine and polypeptide hormones has been studied only in a few cases. However, it appears that proteolytic attack inactivates these hormones in many tissues. The first step appears to involve attack by specific peptidases, resulting in the formation of several distinct hormone fragments. Several nonspecific peptidases then metabolize these fragments to yield the constituent amino acids, which can be reused.

The metabolism and degradation of steroid hormones have been studied in much more detail. The primary organ involved is the liver, although some metabolism also takes place in the kidneys. Complete steroid metabolism generally involves a combination of one or more of five general classes of reactions: reduction, hydroxylation, side-chain cleavage, oxidation, and esterification. Reduction reactions are the principal reactions involved in the conversion of biologically active steroids to forms that possess little

or no activity. Esterification (or conjugation) reactions are also particularly important. Groups added in esterification reactions are primarily glucuronate and sulfate. The addition of such charged moieties enhances the water solubility of the metabolites, facilitating their excretion. Steroid metabolites are eliminated from the body primarily via the urine, although smaller amounts also enter the bile and leave the body in the feces.

At times, quantitative information concerning the rate of hormone metabolism is clinically useful. One index of the rate at which a hormone is removed from the blood is the **metabolic clearance rate** (**MCR**). The metabolic clearance of a hormone is analogous to that of renal clearance (see Chapter 22). The MCR is the volume of plasma cleared of the hormone in question per unit time, expressed in milliliter plasma/minute. It is calculated from the equation:

$$\text{MCR} = \frac{\text{Hormone removed per unit time (mg/min)}}{\text{Plasma concentration (mg/mL)}} \quad (1)$$

One approach to measuring MCR involves injecting a small amount of radioactive hormone into the subject and then collecting a series of timed blood samples to determine the amount of radioactive hormone remaining. Based on the rate of disappearance of hormone from the blood, its half-life and MCR can be calculated. The MCR and half-life are inversely related—the shorter the half-life, the greater the MCR. The half-lives of different hormones vary considerably, from 5 minutes or less for some to several hours for others. The circulating concentration of hormones with short half-lives can vary dramatically over a short period of time. This is typical of hormones that regulate processes on an acute minute-to-minute basis, such as many of those involved in regulating blood glucose. Hormones for which rapid changes in concentration are not required, such as those with seasonal variations and those that regulate the menstrual cycle, typically have longer half-lives.

Radioimmunoassays, and several adapted methodologies, are popular tools used to measure hormone concentrations.

The concentration of hormone present in a biologic fluid is often measured to make a clinical diagnosis of a suspected endocrine disease or to study basic endocrine physiology. Most hormones are measured in blood or urine, but alternate testing sources, such as saliva and transdermal membrane monitors, are emerging as new tools in endocrinology. Possibly, the greatest contribution to recent advances in the field of endocrinology has been derived from immunochemical methods.

Even before hormones were chemically characterized, they were quantitated in terms of biologic responses they produced. Thus, early assays for measuring hormones were bioassays that depended on a hormone's ability to produce a characteristic biologic response. As a result, hormones came to be quantitated in terms of units, defined as an amount sufficient to produce a response of specified magnitude under a defined set of conditions. A unit of hormone is, thus, arbitrarily determined. Although bioassays are rarely used today for diagnostic purposes, many hormones are still standardized in terms of **biological activity units**. For example, commercial insulin is still sold and dispensed based on the number of units in a particular preparation, rather than by the weight or the number of moles of insulin.

Bioassays in general suffer from a number of shortcomings, including a relative lack of specificity and a lack of sensitivity. In many cases, they are slow and cumbersome to perform, and often, they are expensive, because biologic variability often requires the inclusion of many animals in the assay.

Development of the **radioimmunoassay** (**RIA**) in the late 1950s and early 1960s was a major step forward in clinical and research endocrinology. Much of our current knowledge of endocrinology is based on this method. An RIA is now available for virtually every known hormone. In addition, RIAs have been developed to measure circulating concentrations of many other biologically relevant proteins, drugs, and vitamins.

The RIA is a prototype for a larger group of assays termed **competitive binding assays**. These are modifications and adaptations of the original RIA, relying to a large degree on the principle of competitive binding on which the RIA is based. It is beyond the scope of this text to describe in detail the competitive binding assays currently used to measure hormone concentrations, but the principles are the same as those for the RIA.

The two key components of an RIA are a specific antibody (Ab) that has been raised against the hormone in question and a radioactively labeled hormone (H*). If the hormone being measured is a peptide or protein, the molecule is commonly labeled with a radioactive iodine atom (^{125}I or ^{131}I) that can be readily attached to tyrosine residues of the peptide chain. For substances lacking tyrosine residues, such as steroids, labeling may be accomplished by incorporating radioactive carbon (^{14}C) or hydrogen (^{3}H). In either case, the use of the radioactive hormone permits detection and quantification of small amounts of the substance.

The RIA is performed *in vitro* using a series of test tubes. Fixed amounts of Ab and H* are added to all tubes (Fig. 30.5A). Samples (plasma, urine, cerebrospinal fluid, etc.) to be measured are added to individual tubes. Varying known concentrations of unlabeled hormone (the standards) are added to a series of identical tubes. The principle of the RIA, as indicated in Figure 30.5B, is that labeled and unlabeled hormones compete for a few antibody-binding sites. The amount of each hormone that is bound to antibody is a proportion of that present in solution. In a sample containing a high concentration of hormone, less radioactive hormone is able to bind to the antibody, and in a sample containing a low

concentration of hormone, more radioactive hormone is able to bind to the antibody. In each case, the amount of radioactivity present as antibody-bound H* is determined. The response produced by the standards is used to generate a **standard curve** (Fig. 30.6). Responses produced by the unknown samples are then compared with the standard curve to determine the amount of hormone present in the unknowns (see *dashed lines* in Fig. 30.6).

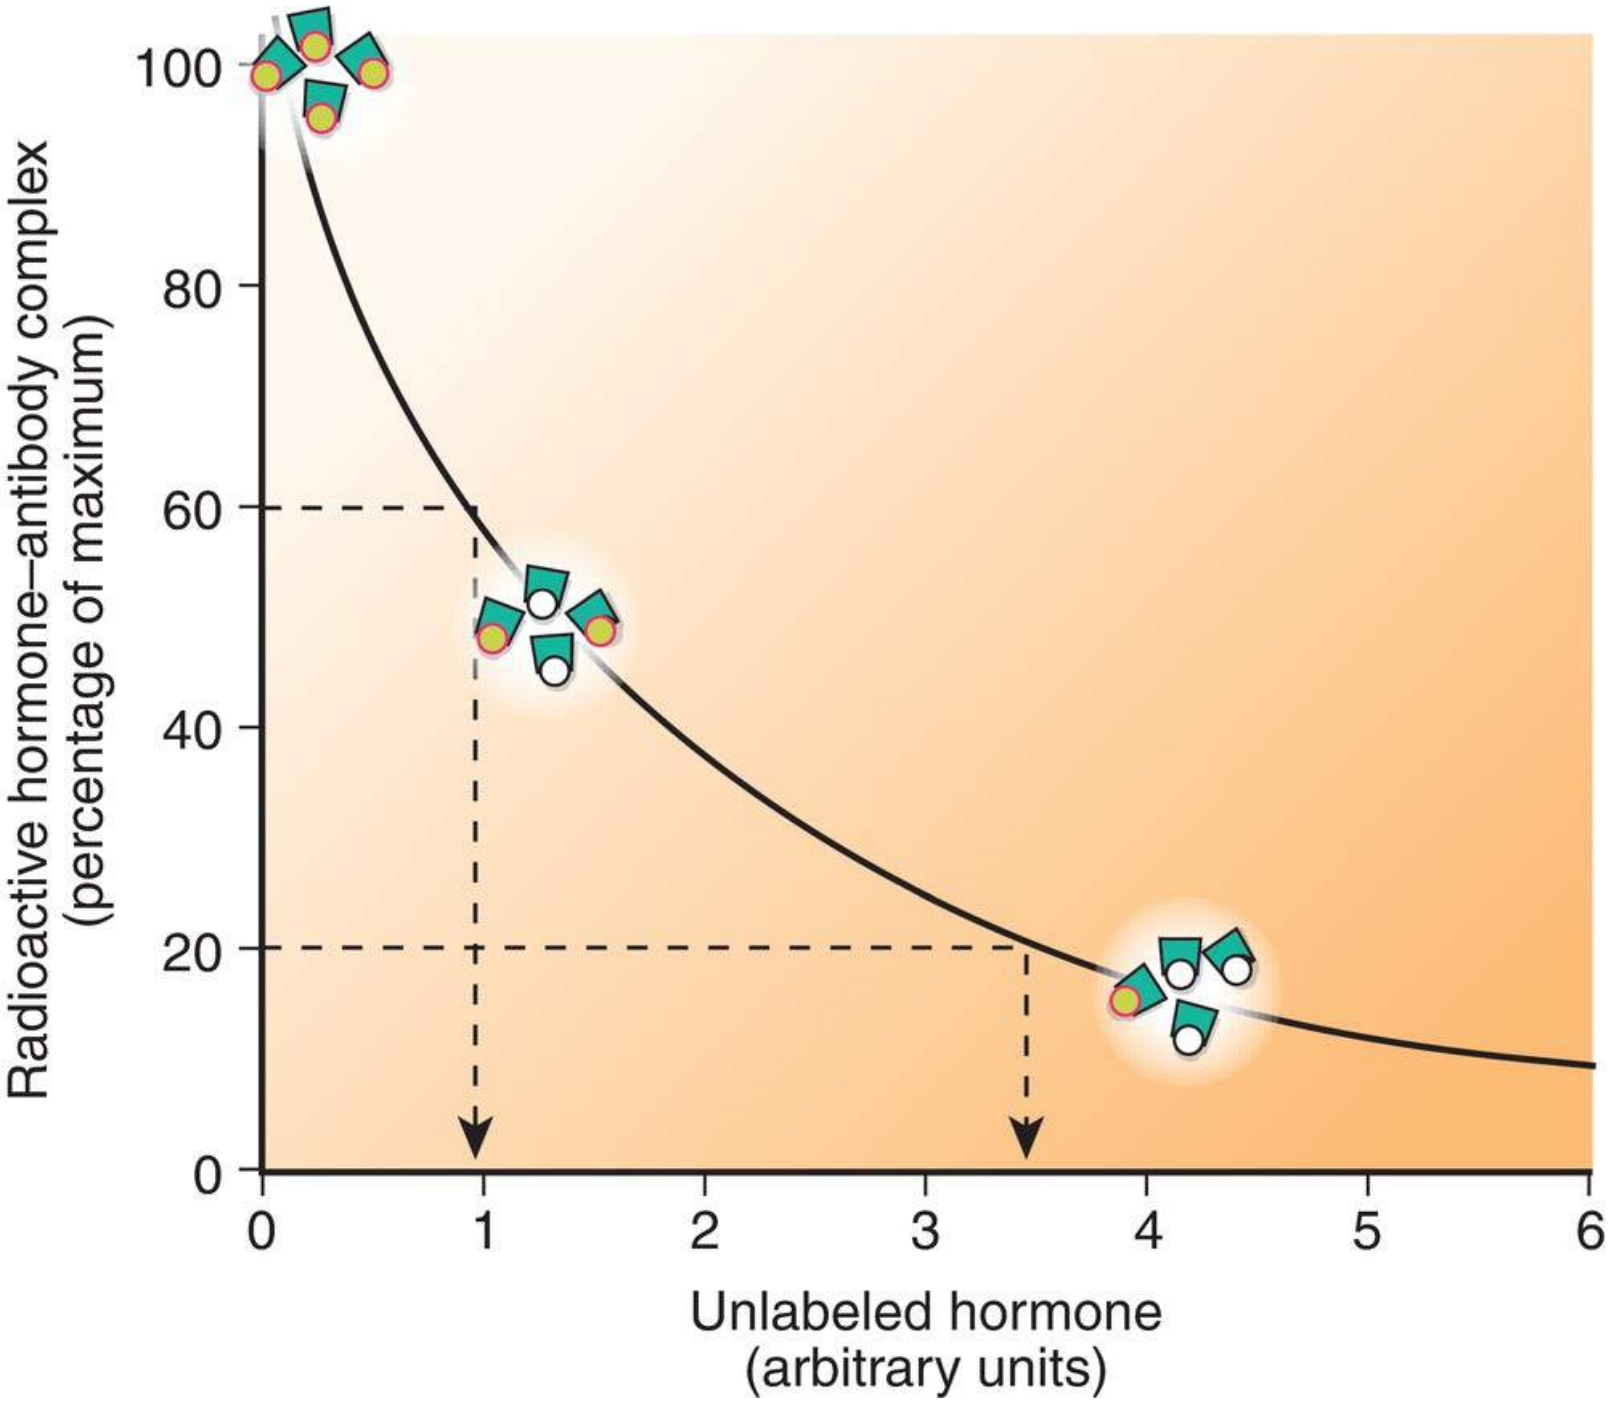

Figure 30.6 A typical radioimmunoassay standard curve. As indicated by the *dashed lines*, the hormone concentration in unknown samples can be deduced from the standard curve.

One major limitation of RIAs is that they measure immunoreactivity rather than biologic activity. The presence of an immunologically related but different hormone or the presence of heterogeneous forms of the same hormone can complicate the interpretation of the results. For example, POMC, the precursor of **adrenocorticotropic hormone** (**ACTH**), is often present in high concentrations in the plasma of patients with bronchogenic carcinoma. Antibodies for ACTH may cross-react with POMC. The results of an RIA

for ACTH in which such an antibody is used may suggest high concentrations of ACTH when actually POMC is being detected. Because POMC has of the biologic potency of ACTH, there may be little clinical evidence of significantly elevated ACTH. If appropriate measures are taken, however, such possible pitfalls can be overcome in most cases and reliable results from the RIA can be obtained.

One important modification of the RIA is the **radioreceptor assay**, which uses specific hormone receptors rather than antibodies as the hormone-binding reagent. In theory, this method measures biologically active hormone because receptor binding rather than antibody recognition is assessed. However, the need to purify hormone receptors and the somewhat more complex nature of this assay limit its usefulness for routine clinical measurements. It is more likely to be used in a research setting.

The **enzyme-linked immunosorbent assay** (**ELISA**) is a solid-phase, enzyme-based assay whose use and application have increased considerably over the past two decades. A typical ELISA is a colorimetric or fluorometric assay, and therefore, the ELISA, unlike the RIA, does not produce radioactive waste, which is an advantage, considering environmental concerns and the rapidly increasing cost of radioactive waste disposal. In addition, because it is a solid-phase assay, the ELISA can be automated to a large degree, which reduces costs. Figure 30.7 shows a relatively simple version of an ELISA. More complex assays using similar principles have been developed to overcome a variety of technical problems, but the basic principle remains the same.

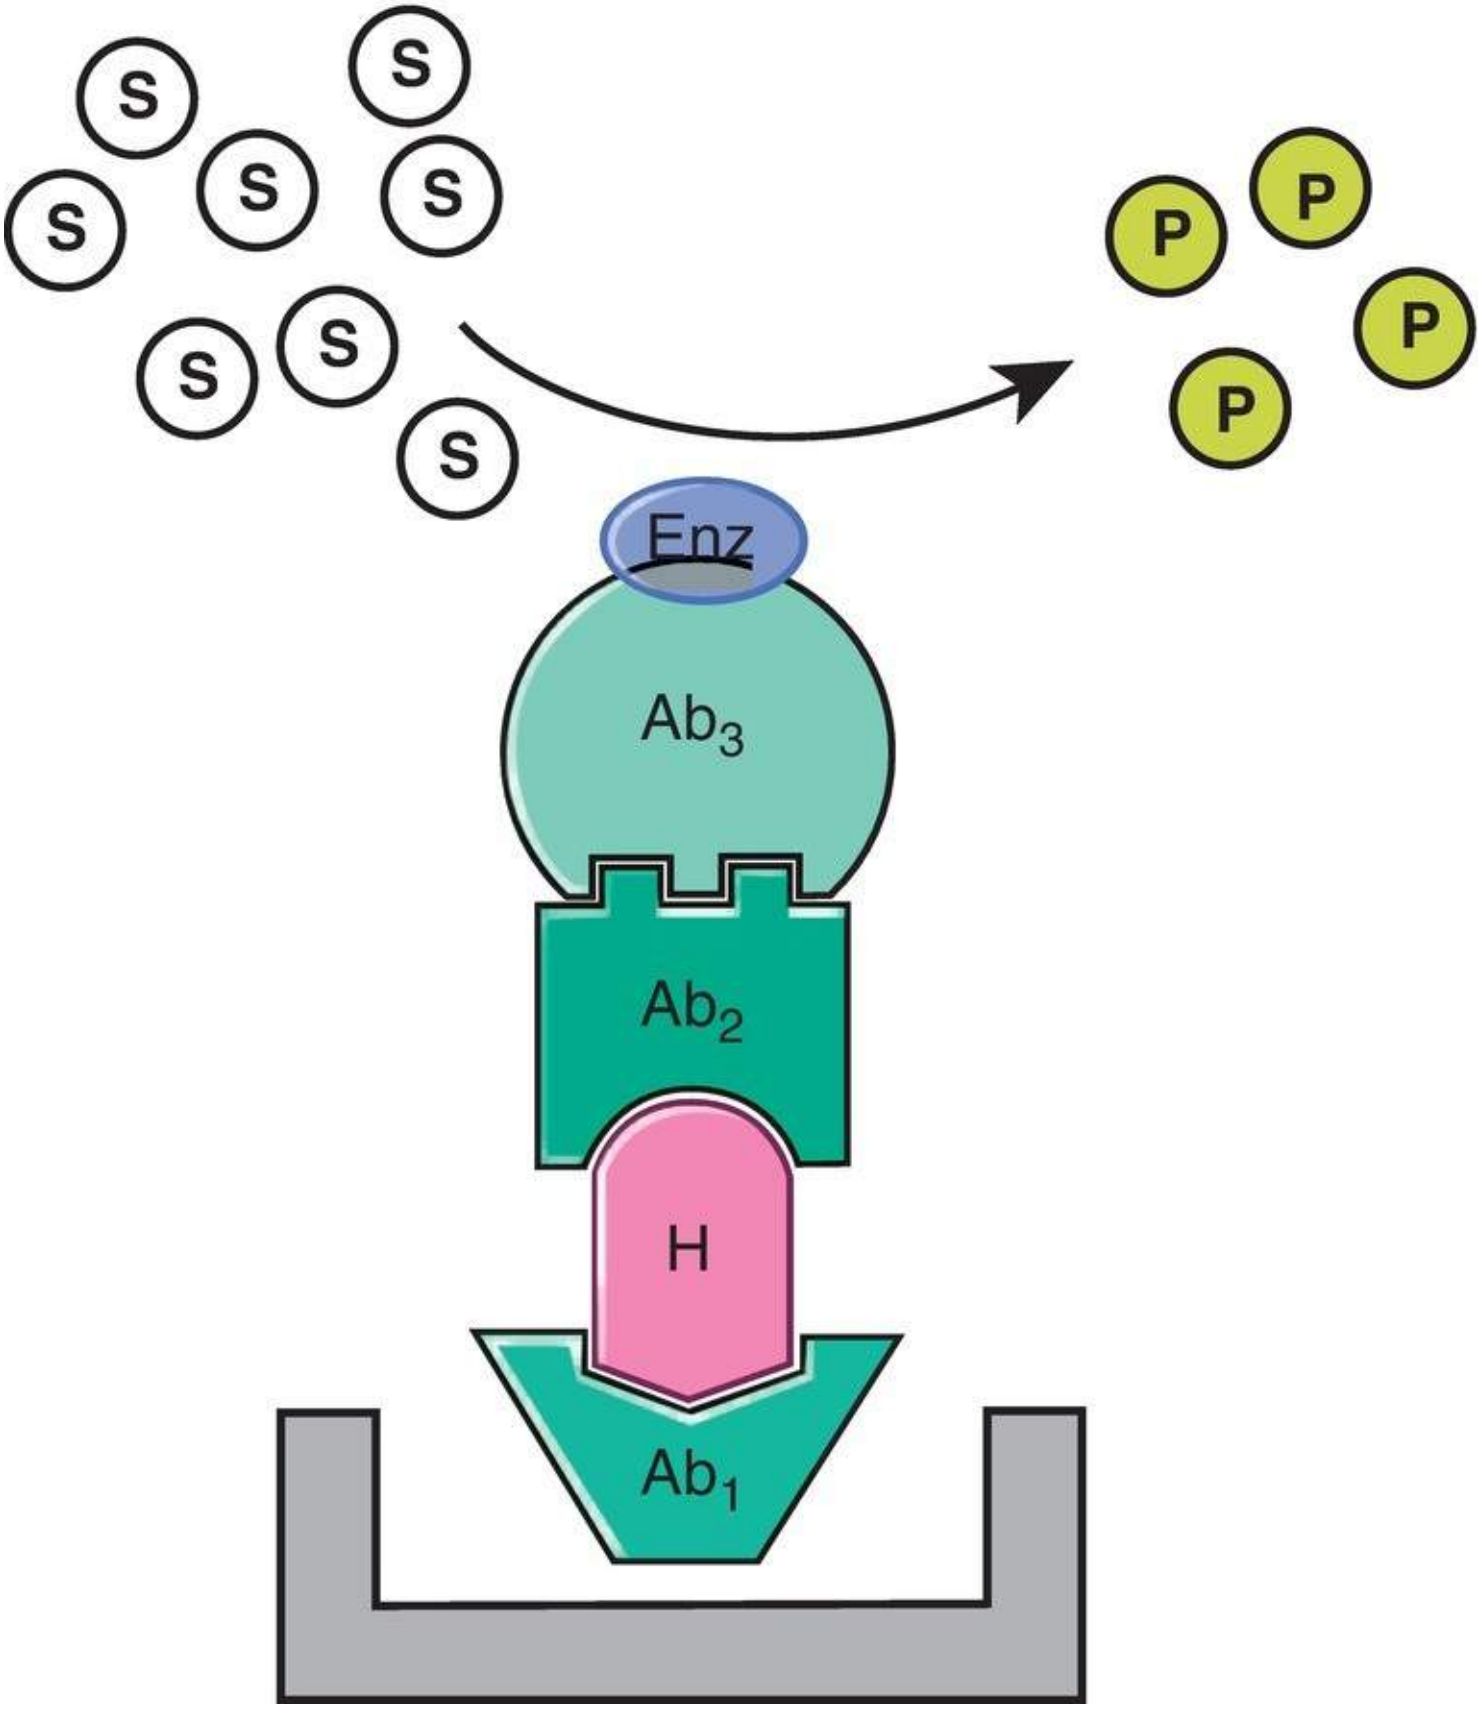

Figure 30.7 The basic components of an enzyme-linked immunosorbent assay (ELISA). A typical ELISA is performed in a 3 × 5-in plastic plate containing 96 small wells. Each well is precoated with an antibody (Ab_1) that is specific for the hormone (H) being measured. Unknown samples or standards are introduced into the wells, followed by a second hormone-specific antibody (Ab_2). A third antibody (Ab_3), which recognizes Ab_2, is then added. Ab_3 is coupled to an enzyme (Enz) that will convert an appropriate substrate (S) into a colored or fluorescent product (P). The amount of product formed can be determined using optical methods. After the addition of each antibody or sample to the wells, the plates are incubated

for an appropriate period of time to allow antibodies and hormones to bind. Any unbound material is washed out of the well before the addition of the next reagent. The amount of colored product formed is directly proportional to the amount of hormone present in the standard or unknown sample. Concentrations are determined using a standard curve. For simplicity, only one Ab_1 molecule is shown in the bottom of the well when, in fact, there is an excess of Ab_1 relative to the amount of hormone to be measured.

MECHANISMS OF HORMONE ACTION

The binding of a hormone to its receptor with subsequent activation of the receptor is the first step in hormone action and also the point at which specificity is determined within the endocrine system. The second step in hormone action entails the receptor-mediated transduction of the extracellular message into an intracellular signal or second messenger. Many intracellular signal cascades exist (recall the discussion of cellular signaling in Chapter 2). Abnormal interactions of hormones with their receptors and/or disturbances in cell signaling are involved in the pathogenesis of many endocrine disease states, and therefore, considerable attention has been paid to these aspects of hormone action. Here, discussion is confined to key principles of hormone–receptor interaction.

Biologic response is partly determined by hormone–receptor binding kinetics.

The probability that a hormone–receptor interaction will occur is related to both the abundance of cellular receptors and the receptor's affinity for the hormone relative to the ambient hormone concentration. The more receptors available to interact with a given amount of hormone, the greater the likelihood there is of a response. Similarly, the higher the affinity of a receptor is for a hormone, the greater the likelihood that a hormone–receptor interaction will occur. The circulating hormone concentration is, of course, a function of the rate of hormone secretion relative to hormone degradation.

The association of a hormone with its receptor generally behaves as if it were a simple, reversible chemical reaction that can be described by the following kinetic equation:

$$[H] + [R] \rightleftharpoons [HR]$$

(2)

where [H] is the free hormone concentration, [R] is the unoccupied receptor concentration, and [HR] is the *hormone–receptor complex* (also referred to as *bound hormone or occupied receptor*). Assuming a simple chemical equilibrium, it follows that:

$$K_a = [HR] / [H] \times [R]$$

(3)

where K_a is the association constant. If R_0 is defined as the total receptor number (i.e., [R] + [HR]), then after substituting and rearranging, we obtain the following relationship:

$$[HR] / [H] = -K_a [HR] + K_a R_0$$

(4)

Literally translated, this equation states that:

$$\frac{\text{Bound hormone}}{\text{Free hormone}} = -K_a \times \text{Bound hormone} + K_a \times \text{Total receptor number}$$

(5)

Notice that equations 4 and 5 have the general form of an equation for a straight line:

$$y = mx + b.$$

To obtain information regarding a particular hormone–receptor system, a fixed number of cells (and, therefore, a fixed number of receptors) are incubated *in vitro* in a series of test tubes with increasing amounts of hormone. At each higher hormone concentration, the amount of receptor-bound hormone is increased until hormone occupies all receptors. Receptor number and affinity can be obtained by using the relationships given in equation 5 above and plotting the results as the ratio of receptor-bound hormone to free hormone ([HR]/[H]) as a function of the amount of bound hormone ([HR]). This type of analysis is known as a **Scatchard plot** (Fig. 30.8). In theory, a Scatchard plot of simple, reversible equilibrium binding is a straight line (see Fig. 30.8A), with the slope of the line being equal to the negative of the association constant ($-K_a$) and the x-intercept being equal to the total receptor number (R_0). Other equally valid mathematical and graphic methods can be used to analyze hormone–receptor interactions, but the Scatchard plot is probably the most widely used.

Figure 30.8 Scatchard plots of hormone–receptor binding data. (A) A straight-line plot typical of hormone binding to a single class of receptors. **(B)** A curvilinear Scatchard plot typical of some hormones. Several models have been proposed to account for nonlinearity of Scatchard plots. K_a, association constant; R_0, total receptor number. (See text for details.)

In practice, Scatchard plots are not always straight lines but instead can be curvilinear (see Fig. 30.8B). Insulin is a classic example of a hormone that gives curved Scatchard plots. One interpretation of this result is that cells contain two separate and distinct classes of receptors, each with a different binding affinity. Typically, one receptor population has a higher affinity but is fewer in number compared with the second population. Therefore, as indicated in Figure 30.8B, $K_{a1} > K_{a2}$ but $R_{02} > K_{01}$. Computer analysis is often required to fit curvilinear Scatchard plots accurately to a two-site model.

Another explanation for curvilinear Scatchard plots is that occupied receptors influence the affinity of adjacent, unoccupied receptors by **negative cooperativity**. According to this theory, when one hormone molecule binds to its receptor, it causes a decrease in the affinity of nearby unoccupied receptors, making it more difficult for additional hormone molecules to bind. The greater the amount of hormone bound, the lower the affinity of unoccupied receptors. Therefore, as shown in Figure 30.8B, as bound hormone increases, the affinity (slope) steadily decreases. Whether curvilinear Scatchard plots in fact result from two-site receptor systems or from negative cooperativity between receptors is unknown.

Dose–response curves determine changes in responsiveness and sensitivity.

Hormone effects are generally not all-or-none phenomena—that is, they generally do not switch from totally off to totally on and then back again. Instead, target cells exhibit graded responses proportional to the concentration of free hormone present.

The dose–response relationship for a hormone generally exhibits a sigmoid shape when plotted as the biologic response on the *y* axis versus the log of the hormone concentration on the *x* axis (Fig. 30.9).

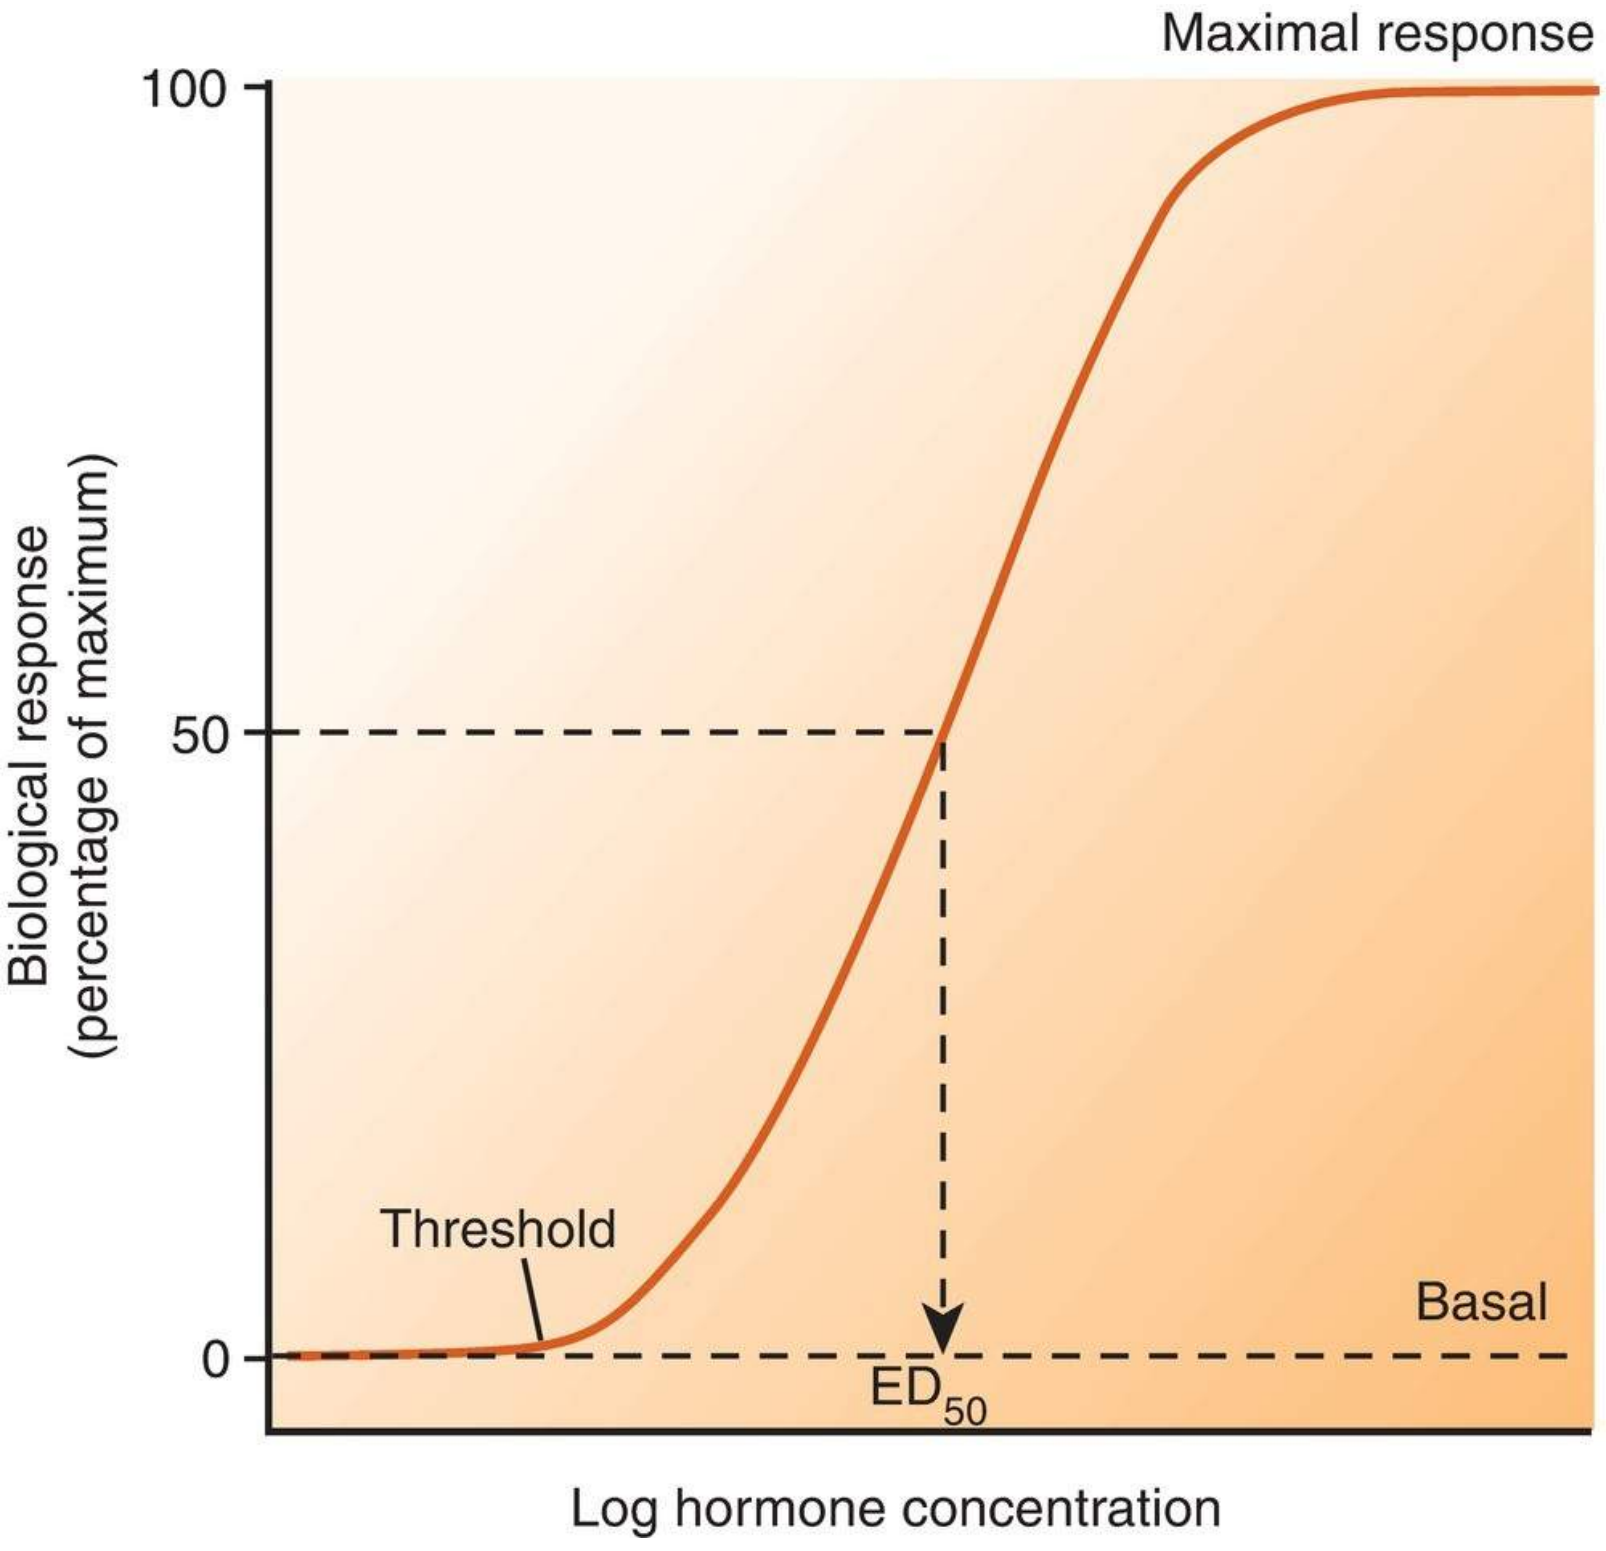

Figure 30.9 A normal dose–response curve of hormone activity. ED_{50}, median effective dose.

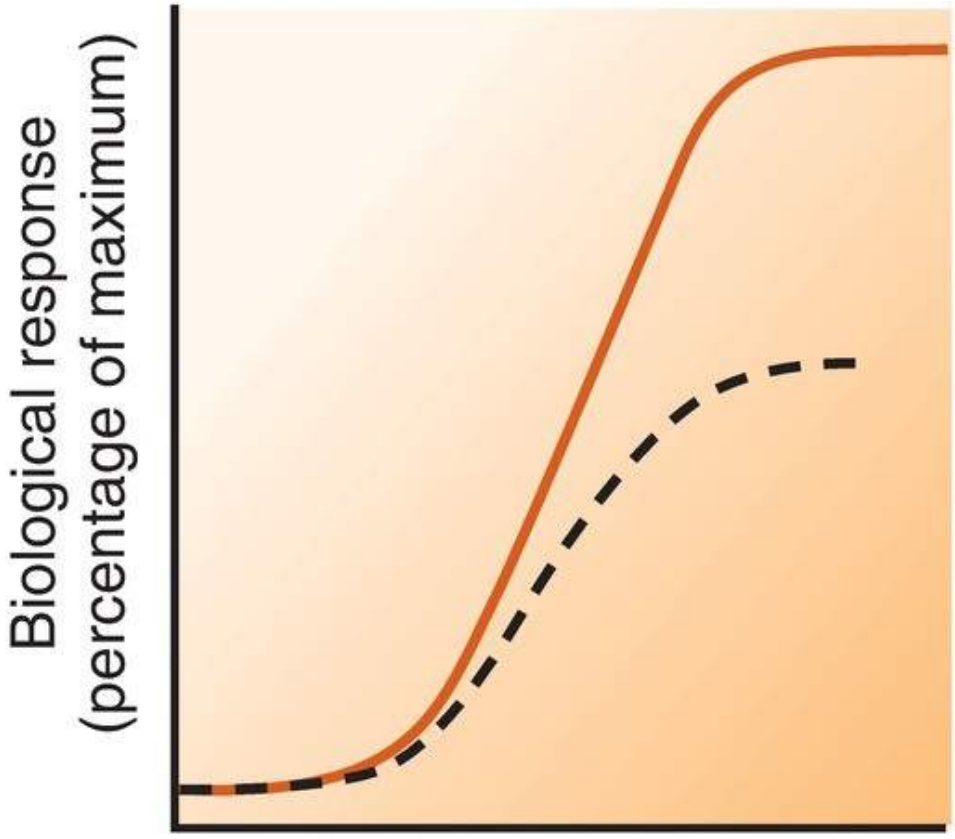
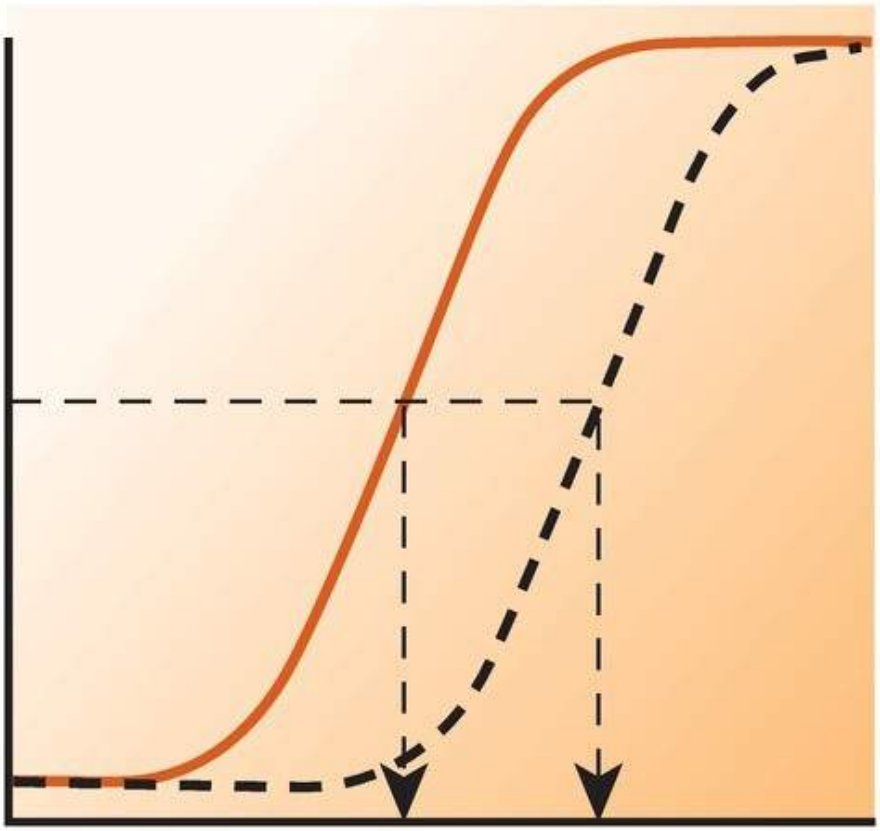
Regardless of the biologic pathway or process being considered, cells typically exhibit an intrinsic *basal level* of activity in the absence of added hormone, even well after any previous exposure to hormone. As the hormone concentration surrounding the cells increases, a minimal **threshold concentration** must be present before any measurable increase in the cellular response can be produced. At higher hormone concentrations, a **maximal response** by the target cell is produced, and increasing the hormone concentration cannot elicit greater response. The concentration of hormone required to produce a response half-way between the maximal and basal responses, the **median effective dose** (**ED_{50}**), is a useful index of the sensitivity of the target cell for that particular hormone (see Fig. 30.9).

For some peptide hormones, the maximal response may occur when only a small percentage (5% to 10%) of the total receptor population is occupied by hormone. The remaining 90% to 95% of the receptors are called spare receptors, because on initial inspection, they do not appear necessary to produce a maximal response. This term is unfortunate, because the receptors are not “spare” in the sense of being unused. Although at any one point in time only 5% to 10% of the receptors may be occupied, hormone–receptor interactions are an equilibrium process and hormones continually dissociate and reassociate with their receptors. Therefore, from one point in time to the next, different subsets of the total population of receptors may be occupied, but presumably all receptors participate equally in producing the biologic response.

Physiologic or pathophysiologic alterations in target tissue responses to hormones can take one of two general forms, as indicated by changes in the hormones’ dose–response curves (Fig. 30.10). Although changes in dose–response curves are not routinely assessed in the clinical setting, they can serve to distinguish between a receptor defect and a postreceptor defect in hormone action, providing useful information regarding the underlying cause of a particular disease state. Changes in responsiveness are indicated by an increase or decrease in the maximal response of the target tissue and may be the result of one or more factors (see Fig. 30.10A). Altered responsiveness can be caused by a change in the number of functional target cells in a tissue, by a change in the number of receptors per cell for the hormone in question, or, if the receptor function itself is not rate limiting for the action of the hormone, by a change in the specific rate-limiting postreceptor step in the hormone action pathway.



A Log hormone concentration



B Log hormone concentration

Figure 30.10 Altered target tissue responses reflected by dose–response curves. (A) Decreased target tissue responsiveness. **(B)** Decreased target tissue sensitivity.

A change in sensitivity is reflected as a right or left shift in the dose–response curve and, thus, a change in the $ED_{50;}$ a right shift indicates decreased sensitivity and a left shift indicates increased sensitivity for that hormone (see Fig. 30.10B). Changes in sensitivity reflect (1) an alteration in receptor affinity or, if submaximal concentrations of hormone are present, (2) a change in receptor number. Dose–response curves may also reflect combinations of changes in responsiveness and sensitivity in which there is both a right or left shift of the curve (a sensitivity change) and a change in maximal biologic response to a lower or higher level (a change in responsiveness).

Cells can regulate their receptor number and/or function in several ways. Exposing cells to an excess of hormone for a sustained period of time typically results in a decreased number of receptors for that hormone per cell. This phenomenon is referred to as **down-regulation**. In the case of peptide hormones, which have receptors on cell surfaces, a redistribution of receptors from the cell surface to intracellular sites usually occurs as part of the process of down-regulation. Therefore, there may be fewer total receptors per cell, and a smaller percentage may be available for hormone binding on the cell surface. Although somewhat less prevalent than down-regulation, **up-regulation** may occur when certain conditions or treatments cause an increase in receptor number compared with normal. Changes in rates of receptor synthesis may also contribute to long-term down-regulation or up-regulation.

In addition to changing receptor number, many target cells can regulate receptor function. Chronic exposure of cells to a hormone may cause the cells to become less responsive to subsequent exposure to the hormone by a process termed **desensitization**. If the exposure of cells to a hormone has a desensitizing effect on further action by that same hormone, the effect is termed **homologous desensitization**. If the exposure of cells to one hormone has a desensitizing effect with regard to the action of a different hormone, the effect is termed **heterologous desensitization**.

INTEGRATED MEDICAL SCIENCES

Artificial Pancreas

Of great importance to the practicing physician is the increased number of patients who have **diabetes mellitus**. As described in Chapter 34, diabetes mellitus is an endocrine disorder of metabolic dysregulation, most notably a dysregulation of glucose metabolism. In patients with type 1 diabetes, control of blood glucose may prevent long-term complications. Unfortunately, achieving near-normal glucose control is difficult, and the incidence of hypoglycemia increases when glucose control approaches normal glucose levels. Over the years, biomedical engineers have been trying to develop an "artificial pancreas." Now, with recent advances in *insulin pump* and *continuous glucose monitoring* technologies, the road has been paved for the development of an artificial pancreas system.

This mechanical closed-loop system would determine glucose levels on a continuous basis, via subcutaneous sensors, and transmit data to an insulin pump. Future artificial pancreas systems may

have physiologic sensors that determine the onset of a meal, determine the level and duration of physical activity, and measure the concentration of insulin in the blood. These additional measures will advance the computer algorithm contained in the pump to provide the appropriate rate of insulin delivery at the right time.

Moreover, new artificial pancreas systems under development include multiple pancreatic peptide hormones, because the healthy endocrine pancreas controls blood glucose through the balanced and coordinated release of insulin, glucagon, amylin, somatostatin, and other pancreatic hormones (see Chapter 34). Along these lines, development of a closed-loop system that delivers both insulin and glucagon as directed by continuous blood glucose readings has been shown to provide a feasible way to control blood glucose and avoid treatment-requiring hypoglycemia. Because amylin is normally cosecreted with insulin and functionally enhances insulin action and continuous delivery of somatostatin lowers the insulin requirement for diabetic subjects, coadministration of amylin and/or somatostatin with reduced insulin dosing might also be used to decrease hypoglycemic risk. ■

Chapter Summary

- The endocrine system integrates organ function via hormones that are secreted from classical endocrine glands and also from organs whose primary function is not endocrine.
- Hormones may signal to the cells that produced them (autocrine) or neighboring cells (paracrine) but are classically defined as blood-borne chemicals that signal to distant target tissues.
- Target cell recognition of hormones depends on specific, high-affinity receptors, which may be located on the cell surface, within the cytoplasm, or in the target cell's nucleus.
- Hormonal signals are organized in a hierarchy of feedback systems, millionfold amplification cascades, and often definable secretion patterns.
- Most hormones display pleiotropic effects and share their ability to control vital physiologic parameters with other hormones.
- Chemically, hormones may be metabolites of single amino acids, peptides, or metabolites of cholesterol and, depending on their solubility, are either transported in the bloodstream free (amine and peptide hormones) or bound to transport proteins (steroid and thyroid hormones).
- Radioimmunoassay and enzyme-linked immunosorbent assay have provided major advancements in the field of endocrinology, but each type of assay has limitations.
- Disturbances in cell signaling and abnormal interactions of hormones with their receptors may lead to endocrine abnormalities.

Chapter Review Questions

1. A shift to the right in the biological activity dose–response curve for a hormone with no accompanying change in the maximal response indicates:
- **A.** decreased responsiveness *and* decreased sensitivity.
- **B.** increased responsiveness.
- **C.** decreased sensitivity.
- **D.** increased sensitivity *and* decreased responsiveness.
- **E.** increased sensitivity.

The correct answer is C. Right or left shifts in dose–response curves indicate changes in sensitivity. Changes in maximal biological response indicate changes in responsiveness. Because there is no change in maximal response, the correct answer must relate to a change in sensitivity only. A right shift indicates decreased sensitivity.

2. Within the endocrine system, specificity of communication is determined by:
- **A.** the chemical nature of the hormone.
- **B.** the distance between the endocrine cell and its target cell(s).
- **C.** the presence of specific receptors on target cells.
- **D.** anatomic connections between the endocrine and target cells.
- **E.** the affinity of binding between the hormone and its receptor.

The correct answer is C. Hormones produce their effects on target cells by interacting with specific receptors. Hormone binding to its receptor generally initiates a cascade of events that lead to biological effects in the target cells.

3. The ability of hormones to be effective regulators of biological function despite circulating at very low concentrations results from:
- **A.** the multiplicity of their effects.
- **B.** transport proteins.
- **C.** pleiotropic effects.
- **D.** signal amplification.
- **E.** competitive binding.

The correct answer is D. Hormones generally circulate at concentrations from 10^{-9} to 10^{-12} M. They produce much larger changes in a variety of biological parameters as a result of signal amplification, in which the rather weak hormonal signal is amplified into a larger biological response.

Clinical Application Exercises 30.1

A study sought to determine the effect of age and sex on GH secretion. A 24-hour secretory profile of GH was generated by 20-minute sampling in 10 young women (age 15 to 30 years) and 10 young men (age 15 to 30 years). The integrated GH concentration was significantly greater in women than in men and greater in the young than in the old. The mean pulse amplitude, duration, and fraction of GH secreted in pulses were each greater in the young, but not significantly different between the sexes. The mean pulse frequency was not affected by sex or age.

QUESTIONS

1. Why was GH secretion measured by a continuous withdrawal pump?
2. What would be a less arduous approach in diagnosing GH deficiency?

ANSWERS

1. Most healthy children experience episodes or "bursts" of GH secretion throughout the day, most prominently within the first several hours of sleep. To obtain reliable information about growth hormone secretion, insertion of a continuous withdrawal pump or patent indwelling catheter with unrestricted food intake and physical activity is required. Increasing sampling frequencies from every 20-minute to 5-minute or 30-second sampling intervals enhances the threshold for detecting more pulses per hour. Although cumbersome and expensive, this method eliminates the error of isolated peak or trough measurements that might otherwise be obtained by single or multiple random GH samplings.
2. A less arduous approach with similar discriminating power in diagnosing GH deficiency entails measuring GH levels in the blood shortly after appropriate pituitary stimulation. Pharmacologic agents that stimulate GH secretion include L-dopa, clonidine, propanolol, glucagon, insulin, and arginine. By perturbing the system in a well-prescribed fashion, the endocrinologist is able to gain important information about growth hormone secretion that would not be possible if a random blood sample were used.

31 Hypothalamus and the Pituitary Gland

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Compare and contrast how the functional anatomy of the hypothalamic–pituitary axis results in different mechanisms of synthesis for posterior pituitary hormones (arginine vasopressin, oxytocin) versus anterior pituitary hormones (adrenocorticotropic hormone, thyroid-stimulating hormone, growth hormone, follicle-stimulating hormone, luteinizing hormone, and prolactin).
- Describe how arginine vasopressin (AVP) acts on water reabsorption in the kidneys and predict the AVP secretory response to a rise and fall in blood osmolality.
- Explain the smooth muscle response to oxytocin in the breast and uterus and predict the effect of suckling or cervical dilation on oxytocin secretion.
- Describe the response of pituitary corticotrophs to corticotropin-releasing hormone and predict the effect of adrenocorticotropic hormone to regulate glucocorticoid release from the adrenal cortex in response to physical or emotional stress, arginine vasopressin, the sleep–wake cycle, and an increase in glucocorticoid in the blood.
- Explain the response of pituitary thyrotrophs to thyrotropin-releasing hormone and predict the effect of thyroid-stimulating hormone to regulate triiodothyronine and thyroxine release from the thyroid follicles in response to cold temperatures, the sleep–wake cycle, and an increase in thyroid hormone in the blood.
- Outline the hypothalamic–pituitary–growth hormone axis, explain the response of pituitary somatotrophs to growth hormone–releasing hormone and somatotropin release–inhibiting factor, and predict the effect of growth hormone (GH), insulin-like growth factor, aging, deep sleep, stress, exercise, and hypoglycemia on GH secretion.
- Outline the hypothalamic–pituitary–gonadal axis and explain the response of pituitary gonadotrophs to luteinizing hormone–releasing hormone.
- Explain the effect of estrogen and dopamine on pituitary lactotrophs and the effect of prolactin on alveolar cells in the mammary gland.

The **pituitary gland** or **hypophysis** is an endocrine gland that protrudes off of the bottom of the hypothalamus at the base of the brain. The pituitary gland is composed of two lobes: the anterior pituitary and the posterior pituitary, with both lobes functionally linked to the hypothalamus by the pituitary stalk. Thus, the hypothalamus controls pituitary gland hormone secretion.

The pituitary gland secretes an array of peptide hormones that regulate almost every aspect of body function. Some pituitary hormones influence key cellular processes to preserve the volume and composition of body fluids. Others bring about changes in body function, which enable the person to grow, reproduce, and respond appropriately to stress and trauma. The pituitary hormones can act directly on their target cells or stimulate other endocrine glands to secrete hormones, which, in turn, bring about changes in body function.

HYPOTHALAMIC–PITUITARY AXIS

The pituitary gland is located at the base of the brain and is connected to the hypothalamus by a stalk. It sits in a depression in the sphenoid bone of the skull called the **sella turcica**. The two morphologically and functionally distinct glands comprising the human pituitary are the adenohypophysis and the neurohypophysis as shown in Figure 31.1. The **adenohypophysis**, or *anterior pituitary*, comprises the **pars tuberalis**, which forms the outer covering of the pituitary stalk, and the **pars distalis** or **anterior lobe**. The **neurohypophysis**, or *posterior pituitary*, comprises the **infundibular stem**, which forms the inner part of the stalk, the **infundibular process** or **posterior lobe**, and the **median eminence** of the hypothalamus (though some do not consider this a part of the pituitary gland). In most vertebrates, the pituitary contains a third anatomically distinct lobe, the **pars intermedia** or **intermediate lobe**. In adult humans, only a vestige of the intermediate lobe is found, consisting of a thin, diffuse region of cells between the anterior and posterior lobes.

Figure 31.1 The human pituitary gland. The magnocellular neuron (large yellow cell body) releases arginine vasopressin or oxytocin at its axon terminals into capillaries that give rise to the venous drainage of the posterior lobe. The neurons with smaller cell bodies are secreting releasing factors into capillary networks that give rise to the long and short hypophyseal portal vessels, respectively. Releasing hormones are shown reaching the hormone-secreting cells of the anterior lobe via the portal vessels.

The adenohypophysis and neurohypophysis have different embryologic origins. The adenohypophysis is formed from an evagination of the oral ectoderm called the **Rathke pouch**. The neurohypophysis forms as an extension of the developing hypothalamus, which fuses with the Rathke pouch as development proceeds. The posterior lobe is, therefore, composed of neural tissue and is a functional part of the hypothalamus.

Hypothalamic neurons whose axons terminate in the posterior lobe synthesize posterior pituitary hormones.

The infundibular stem of the pituitary gland contains bundles of nonmyelinated nerve fibers, which terminate on the capillary bed in the posterior lobe. These fibers are the axons of neurons that originate in the **supraoptic nuclei** and **paraventricular nuclei** of the hypothalamus. The cell bodies of these neurons are large compared with those of other hypothalamic neurons; hence, they are called **magnocellular neurons**. The hormones **arginine vasopressin** (**AVP**) and **oxytocin** are synthesized as parts of larger precursor prohormones in the cell bodies of these neurons, which are then packaged into granules and enzymatically processed to produce AVP and oxytocin. Axoplasmic flow transports the granules down the axons to accumulate at the axon terminals in the posterior lobe.

Events occurring within or outside the body may generate stimuli for the secretion of posterior lobe hormones. The central nervous system (CNS) processes these stimuli, and the signal for secretion of AVP or oxytocin is then transmitted to neurosecretory neurons in the hypothalamus. Secretory granules containing the hormone are then released into the nearby capillary circulation, from which the hormone is carried into the systemic circulation.

Anterior pituitary hormones are synthesized and secreted in response to hypothalamic-releasing hormones carried in the hypophyseal portal circulation.

The anterior lobe contains clusters of histologically distinct types of cells closely associated with blood sinusoids that drain into the venous circulation. These cells produce anterior pituitary hormones and secrete them into the blood sinusoids. Distinctly different types of cells produce the six well-known anterior pituitary hormones. **Adrenocorticotropic hormone** (**ACTH**), also known as **corticotropin**, is secreted by corticotrophs, **thyroid-stimulating hormone** (**TSH**) by **thyrotrophs, growth hormone** (**GH**) by **somatotrophs, prolactin** (**PRL**) by **lactotrophs**, and **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**) by **gonadotrophs**.

The cells that produce anterior pituitary hormones are not innervated and, therefore, are not under direct neural control. Rather, **releasing hormones** called **hypophysiotropic hormones**, synthesized by neural cell bodies in the hypothalamus, regulate their secretory activity. Granules containing releasing hormones are stored in the axon terminals of these neurons, located in capillary networks in the median eminence of the hypothalamus and lower infundibular stem. These capillary networks give rise to the principal blood supply to the anterior lobe of the pituitary.

The blood supply to the anterior pituitary is shown in Figure 31.1. The superior and inferior hypophyseal arteries bring blood to the hypothalamic–pituitary region. The **superior hypophyseal arteries** give rise to a rich capillary network in the median eminence. The capillaries converge into long veins that run down the pituitary stalk and empty into the blood sinusoids in the anterior lobe. They are considered to be portal veins because they deliver blood to the anterior pituitary rather than joining the venous circulation that carries blood back to the heart; therefore, they are called **long hypophyseal portal vessels**. The **inferior hypophyseal arteries** provide arterial blood to the posterior lobe. They also penetrate into the lower infundibular stem, where they form another important capillary network. The capillaries of this network converge into **short hypophyseal portal vessels**, which also deliver blood into the sinusoids of the anterior pituitary. The special blood supply to the anterior lobe of the pituitary gland is known as the **hypophyseal portal circulation**.

When a neurosecretory neuron is stimulated to secrete, the releasing hormone is discharged into the hypophyseal portal circulation (see Fig. 31.1). Releasing hormones travel only a short distance before they come in contact with their target cells in the anterior lobe. Neurosecretory neurons only deliver the amount of releasing hormone needed to control anterior pituitary hormone secretion. Consequently, releasing hormones are almost undetectable in systemic blood.

A releasing hormone either stimulates or inhibits the synthesis and secretion of a particular anterior pituitary hormone. **Corticotropin-releasing hormone** (**CRH**)**, thyrotropin-releasing hormone** (**TRH**), and **GH-releasing hormone** (**GHRH**) stimulate the synthesis and secretion of ACTH, TSH, and GH, respectively (Table 31.1). **LH-releasing hormone** (**LHRH**), also known as **gonadotropin-releasing hormone** (**GnRH**), stimulates the synthesis and release of FSH and LH. In contrast, **somatostatin**, also called **somatotropin release–inhibiting factor** (**SRIF**), inhibits GH secretion. All of the releasing hormones are peptides, with the exception of **dopamine**, which is a catecholamine that inhibits the synthesis and secretion of PRL. Releasing hormones can be produced synthetically and used in the diagnosis and treatment of diseases of the endocrine system. For example, synthetic GnRH is now used for treating infertility in women.

TABLE 31.1 Hypothalamic-Releasing Hormones

Hormone	Chemistry	Actions on Anterior Pituitary
Corticotropin-releasing hormone (CRH)	Single chain of 41 amino acids	Stimulates ACTH secretion by corticotrophs; stimulates expression of POMC gene in corticotrophs
Thyrotropin-releasing hormone (TRH)	Peptide of three amino acids	Stimulates TSH secretion by thyrotrophs; stimulates expression of genes for α and β subunits of TSH in thyrotrophs; stimulates PRL synthesis by lactotrophs
Growth hormone–releasing hormone (GHRH)	Two forms in human: single chain of 44 amino acids and single chain of 40 amino acids	Stimulates GH secretion by somatotrophs; stimulates expression of GH gene in somatotrophs
Luteinizing hormone–releasing hormone (LHRH)	Single chain of 10 amino acids	Stimulates FSH and LH secretion by gonadotropin-releasing hormone (GnRH) gonadotrophs
Somatostatin and somatotropin release–inhibiting factor (SRIF)	Single chain of 14 amino acids	Inhibits GH secretion by somatotrophs; inhibits TSH secretion by thyrotrophs
Dopamine	Catecholamine	Inhibits PRL synthesis and secretion by lactotrophs

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; POMC, proopiomelanocortin; PRL, prolactin; TSH, thyroid-stimulating hormone.

External events or changes occurring within the body itself generate signals within the CNS that result in releasing hormone secretion. For example, sensory nerve excitation, emotional or physical stress, biologic rhythms, changes in sleep patterns or in the sleep–wake cycle, and changes in circulating levels of certain hormones or metabolites all affect the secretion of particular anterior pituitary hormones. Signals generated in the CNS by such events are transmitted to the neurosecretory neurons in the hypothalamus. Depending on the nature of the event and the signal generated, the secretion of a particular releasing hormone may be either stimulated or inhibited. In turn, this response affects the rate of secretion of the appropriate anterior pituitary hormone. The neural pathways involved in transmitting signals to the neurosecretory neurons in the hypothalamus continue to be defined.

POSTERIOR PITUITARY HORMONES

Magnocellular neurons in the supraoptic and paraventricular nuclei of the hypothalamus produce AVP (also known historically as *antidiuretic hormone*) and oxytocin. Individual neurons make either AVP or oxytocin, but not both. The axons of these neurons form the infundibular stem and terminate on the capillary network in the posterior lobe, where they discharge AVP and oxytocin into the systemic circulation.

AVP and oxytocin are closely related small peptides, each consisting of nine amino acid residues. Although AVP and oxytocin differ by only two amino acid residues, the structural differences are sufficient to give these two molecules different hormonal activities. They are similar enough, however, for AVP to have slight oxytocic activity and for oxytocin to have slight antidiuretic activity.

The genes for AVP and oxytocin are located near one another on chromosome 20. They code for much larger prohormones that contain the amino acid sequences for AVP or oxytocin and for a 93 amino acid peptides called **neurophysin**. Mutations in the neurophysin portion of the AVP gene are associated with **hypothalamic** (or **central**) **diabetes insipidus**, a condition in which AVP secretion is impaired. As described earlier, prohormones for AVP and oxytocin are synthesized in the cell bodies of magnocellular neurons and transported in secretory granules to axon terminals in the posterior lobe. During the passage of the granules from the Golgi apparatus to axon terminals, proteolytic enzymes cleave prohormones to produce AVP or oxytocin and their associated neurophysins.

The hypothalamus and posterior pituitary act as a functional unit in the secretion of AVP and oxytocin. When magnocellular neurons receive neural signals for AVP or oxytocin secretion, action potentials are generated in these cells, triggering the release of AVP or oxytocin and neurophysin from the axon terminals. These substances diffuse into nearby capillaries and then enter the systemic circulation.

Arginine vasopressin increases the reabsorption of water by the kidneys.

Two physiologic signals, a rise in the osmolality of the blood and a decrease in blood volume, generate the CNS stimulus for AVP secretion. Chemical mediators of AVP release include catecholamines, angiotensin II, and **atrial natriuretic peptide** (**ANP**). The main physiologic action of AVP is to increase water reabsorption by the collecting ducts of the kidneys. The result is decreased water excretion and the formation of osmotically concentrated urine (see Chapter 22). This action of AVP works to counteract the conditions that stimulate its secretion. For example, reducing water loss in the urine limits a further rise in the osmolality of the blood and conserves blood volume. Low blood AVP levels lead to diabetes insipidus and the excessive production of dilute urine (see Chapter 23).

Oxytocin stimulates the contraction of smooth muscle in the mammary glands and uterus.

Two physiologic signals stimulate the secretion of oxytocin by hypothalamic magnocellular neurons. Breast-feeding stimulates sensory nerves in the nipple. Afferent nerve impulses enter the CNS to stimulate oxytocin-secreting magnocellular neurons. These neurons fire in synchrony and release a bolus of oxytocin into the bloodstream. Oxytocin stimulates the contraction of **myoepithelial cells**, which surround the milk-laden alveoli in the lactating mammary gland, aiding in milk ejection.

Neural input from the female reproductive tract during childbirth also stimulates oxytocin secretion. Cervical dilation before the beginning of labor stimulates stretch receptors in the cervix. Afferent nerve impulses pass through the CNS to oxytocin-secreting neurons. Oxytocin release stimulates the contraction of smooth muscle cells in the uterus during labor, aiding in the delivery of the newborn and placenta. The actions of oxytocin on the mammary glands and the female reproductive tract are discussed further in Chapter 38.

ANTERIOR PITUITARY HORMONES

The anterior lobe contains clusters of histologically distinct types of cells closely associated with blood sinusoids that drain into the venous circulation. These cells produce anterior pituitary hormones and secrete them into the blood sinusoids.

The anterior pituitary secretes six protein hormones, all of which are small, ranging in molecular size from 4.5 to 29 kDa (Table 31.2). Four of the anterior pituitary hormones have effects on the morphology and secretory activity of other endocrine glands; they are called *tropic* (Greek, meaning "to turn to") or *trophic* ("to nourish") hormones. For example, ACTH maintains the size of certain cells in the adrenal cortex and stimulates these cells to synthesize and secrete the **glucocorticoid hormones, cortisol**, and **corticosterone**. Similarly, TSH maintains the size of the cells of the thyroid follicles and stimulates these cells to produce and secrete the thyroid hormones **thyroxine** ($\mathbf{T_4}$) and **triiodothyronine** ($\mathbf{T_3}$). The two other tropic hormones, FSH and LH, are called **gonadotropins** because both act on the ovaries and testes. FSH stimulates the development of follicles in the ovaries and regulates the process of **spermatogenesis** in the testes. LH causes **ovulation** and **luteinization** of the ovulated follicle in the ovary of the human female and stimulates the production of the female sex hormones **estrogen** and **progesterone** by the ovary. In the male, LH stimulates the **Leydig cells** of the testis to produce and secrete the male sex hormone, testosterone.

TABLE 31.2 Hormones of the Anterior Pituitary

Hormone	Chemistry	Physiologic Actions
Adrenocorticotropic hormone (ACTH, corticotropin)	Single chain of 39 amino acids; 4.5 kDa	Stimulates production of glucocorticoids and androgens by adrenal cortex; maintains size of zona fasciculata and zona reticularis of cortex
Thyroid-stimulating hormone (TSH, thyrotropin)	Glycoprotein having two subunits, α and β; 28 kDa	Stimulates production of thyroid hormones, T_4 and T_3, by thyroid follicular cells; maintains size of follicular cells
Growth hormone (GH)	Single chain of 191 amino acids; 22 kDa	Stimulates postnatal body growth; stimulates triglyceride lipolysis; inhibits insulin action on carbohydrate and lipid metabolism
Follicle-stimulating hormone (FSH)	Glycoprotein having two subunits, α and β; 28–29 kDa	Stimulates development of ovarian follicles; regulates spermatogenesis in testes
Luteinizing hormone (LH)	Glycoprotein having two subunits, α and β; 28–29 kDa	Causes ovulation and formation of corpus luteum in ovaries; stimulates production of estrogen and progesterone by ovaries; stimulates testosterone production by testes
Prolactin (PRL)	Single chain of 199 amino acids	Essential for milk production by lactating mammary glands

T_3, triiodothyronine; T_4, thyroxine.

The two remaining anterior pituitary hormones, GH and PRL, are not usually thought of as tropic hormones because their main target organs are not other endocrine glands. However, these two hormones

have certain effects that can be regarded as “tropic.” The main physiologic action of GH is its stimulatory effect on the growth of the body during childhood. In humans, PRL is essential for the synthesis of milk by the mammary glands during **lactation**. Regulation of the secretion of the gonadotropins and PRL and descriptions of their actions are covered in greater detail in Chapters 36 to 38 (Clinical Focus 31.1).

CLINICAL FOCUS 31.1

Pituitary Tumors

Pituitary tumors arise from hormone-secreting adenohypophyseal cells, and the secretory product of the tumor depends on the cell of origin. Generally, tumors of the corticotroph, somatotroph, lactotroph, and thyrotroph hypersecrete their respective hormones. In contrast, gonadotrophic tumors usually do not secrete hormones efficiently. Pituitary adenomas with no clinical symptoms have been reported in about 11% of autopsies. Use of sensitive imaging techniques such as magnetic resonance imaging (MRI) for nonpituitary indications has increased the detection of pituitary abnormalities such that microadenoma is detected in 10% of the normal adult population undergoing MRI of the head. Suspected pituitary tumors are usually examined directly with MRI to assess the effect of tumor mass on surrounding soft tissue structures such as the optic chiasm, which can become compressed by larger tumors, resulting in partial loss of vision.

Testing for aberrant hormone levels in the blood can be used to diagnose the type of pituitary adenoma that is present. For Cushing disease, an elevated 24-hour urinary free cortisol level can be an effective screen for disease. An elevation in insulin-like growth factor 1 (IGF-1) level, compared with age-matched and gender-matched controls, would indicate a growth hormone (GH)–secreting adenoma. Following diagnosis, three modes of therapy are available: surgical, radiotherapeutic, and medical. The goals of therapy are to alleviate compressive mass effects and suppress hormone hypersecretion while maintaining intact function of the unaffected portions of the pituitary.

Pituitary surgery is generally recommended to alleviate pressure effects resulting from tumor mass and to reduce hormone hypersecretion. The transsphenoidal surgical approach is associated with the lowest mortality. Radiotherapy, the delivery of high-energy ionizing radiation, is generally indicated for persistent hormone hypersecretion or residual mass effects after surgery or when surgery is contraindicated. Medical therapy is useful in several cases because pituitary tumors often express receptors for hypothalamic control of hormone secretion. Pharmaceutical ligands that activate the somatotropin release–inhibitory factor (SRIF) receptor on tumors arising from somatotrophs can suppress prolactin (PRL) or GH hypersecretion, block tumor growth, and shrink tumor size. Thus, GH-secreting or PRL-secreting tumors usually respond well to medical therapy. ■

Adrenocorticotropic hormone regulates the function of the adrenal cortex.

The adrenal glands sit on top of the kidneys but do not play a role in renal function. Each adrenal gland is separated into two distinct functional units, the adrenal cortex and medulla. The *adrenal cortex* produces the glucocorticoid hormones, cortisol and corticosterone, in the cells of its two inner zones, the **zona fasciculata** and the **zona reticularis**. These cells also synthesize **androgens**, or male sex hormones. The main androgen synthesized is **dehydroepiandrosterone**.

Glucocorticoids alter gene transcription on many different target cells. Glucocorticoids permit metabolic adaptations during fasting, which prevent the development of **hypoglycemia** or low blood glucose level. They also play an essential role in the response of the body to physical and emotional stress. Other actions of glucocorticoids include inhibition of inflammation, suppression of the immune system, and regulation of vascular responsiveness to norepinephrine.

The cells of the outer zone of the cortex, the **zona glomerulosa**, produce **aldosterone**, the other physiologically important hormone made by the adrenal cortex. It acts to stimulate sodium reabsorption by the kidneys.

ACTH is the physiologic regulator of the synthesis and secretion of glucocorticoids by the zona fasciculata and zona reticularis. The smallest of the six anterior pituitary hormones, ACTH, stimulates the synthesis of these steroid hormones and promotes the expression of the genes for various enzymes involved in steroidogenesis. It also maintains the size and functional integrity of the cells of the zona fasciculata and zona reticularis. ACTH is not an important regulator of aldosterone synthesis and secretion.

The actions of ACTH on glucocorticoid synthesis and secretion and details about the physiologic effects of glucocorticoids are described in Chapter 33.

Adrenocorticotropic hormone synthesis

ACTH is synthesized in corticotrophs as part of a larger 30-kDa prohormone, **proopiomelanocortin** (**POMC**). Enzymatic cleavage of POMC by **prohormone convertase 1** in the anterior pituitary results in ACTH, an amino terminal protein, and β-**lipotropin** (Fig. 31.2). β-Lipotropin has effects on lipid metabolism, but its physiologic function in humans has not been established. Although POMC can be cleaved into other peptides, such as β-endorphin, only ACTH and β-lipotropin are produced from POMC in the human corticotroph. Proteolytic processing of POMC occurs after it is packaged into secretory granules. Therefore, when the corticotroph receives a signal to secrete, ACTH and β-lipotropin are released into the bloodstream in a 1:1 molar ratio.

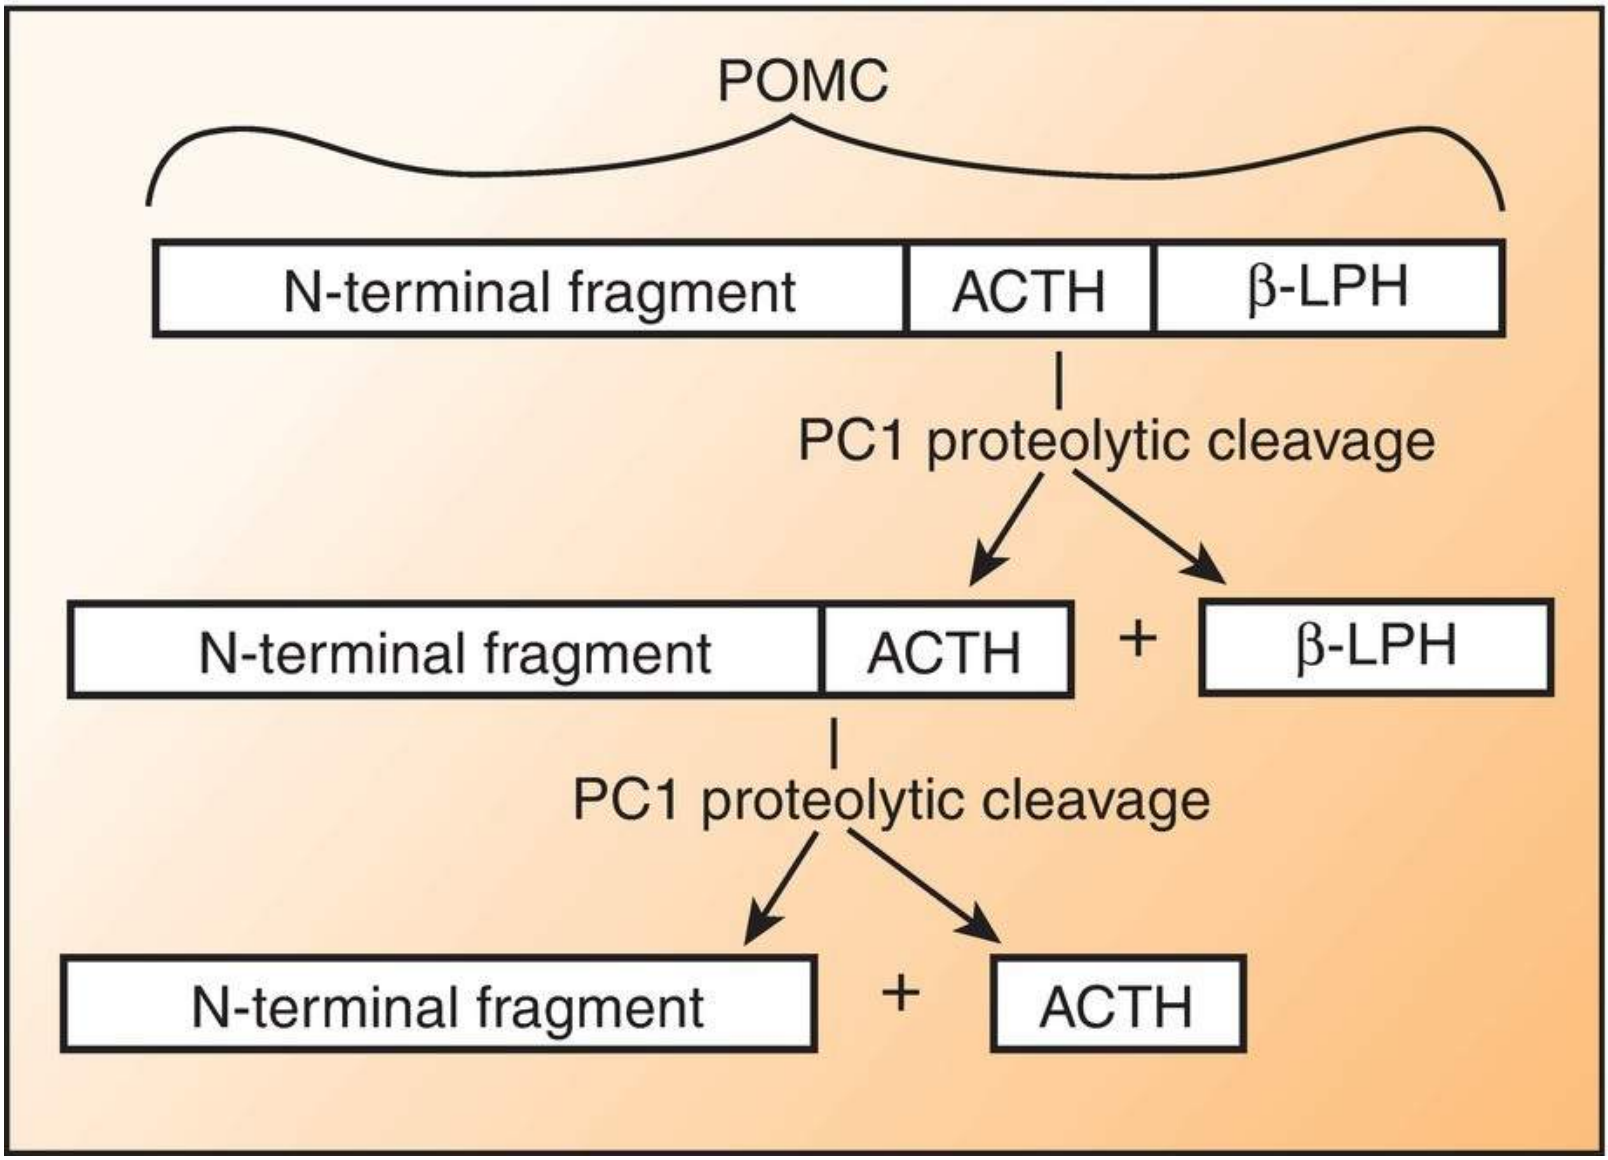

Figure 31.2 The proteolytic processing of adrenocorticotropic hormone (ACTH) from its prohormone proopiomelanocortin (POMC) in the human corticotroph. PC1, prohormone convertase 1; β-LPH, β-lipotropin.

Cells of the intermediate lobe of the pituitary gland and neurons in the hypothalamus also synthesize POMC. In the intermediate lobe, the ACTH sequence of POMC is cleaved by **prohormone convertase 2** to release a small peptide, α-melanocyte–stimulating hormone (α-**MSH**), and, therefore, little ACTH is produced. α-MSH acts in lower vertebrates to produce temporary changes in skin color by causing the dispersion of melanin granules in pigment cells. As noted earlier, the adult human has only a vestigial intermediate lobe and does not produce and secrete significant amounts of α-MSH or other hormones derived from POMC. However, because ACTH contains the α-MSH amino acid sequence at its N-terminal end, it has melanocyte-stimulating activity when present in the blood at high concentrations. Humans who have high blood levels of ACTH, as a result of **Addison disease** or an ACTH-secreting tumor, are often hyperpigmented. In the hypothalamus, α-MSH is important in the regulation of feeding behavior.

A group of neurons with small cell bodies, called **parvicellular neurons**, synthesize CRH in the paraventricular nuclei of the hypothalamus. The axons of parvicellular neurons terminate on capillary networks that give rise to hypophyseal portal vessels. Secretory granules containing CRH are stored in the axon terminals of these cells. On receiving the appropriate stimulus, these cells secrete CRH into the

capillary network; CRH enters the hypophyseal portal circulation and is delivered to the anterior pituitary gland.

CRH binds to receptors on the plasma membranes of corticotrophs, increasing the activity of adenylyl cyclase, which catalyzes the formation of **cyclic adenosine monophosphate** (**cAMP**) from **adenosine triphosphate** (**ATP**) (Fig. 31.3). The rise in cAMP in the corticotroph activates **protein kinase A** (**PKA**), which then phosphorylates cellular proteins. CRH stimulates the secretion of ACTH and β-lipotropin through PKA-mediated phosphorylation of voltage-dependent calcium channels, although the exact mechanism is still not completely understood.

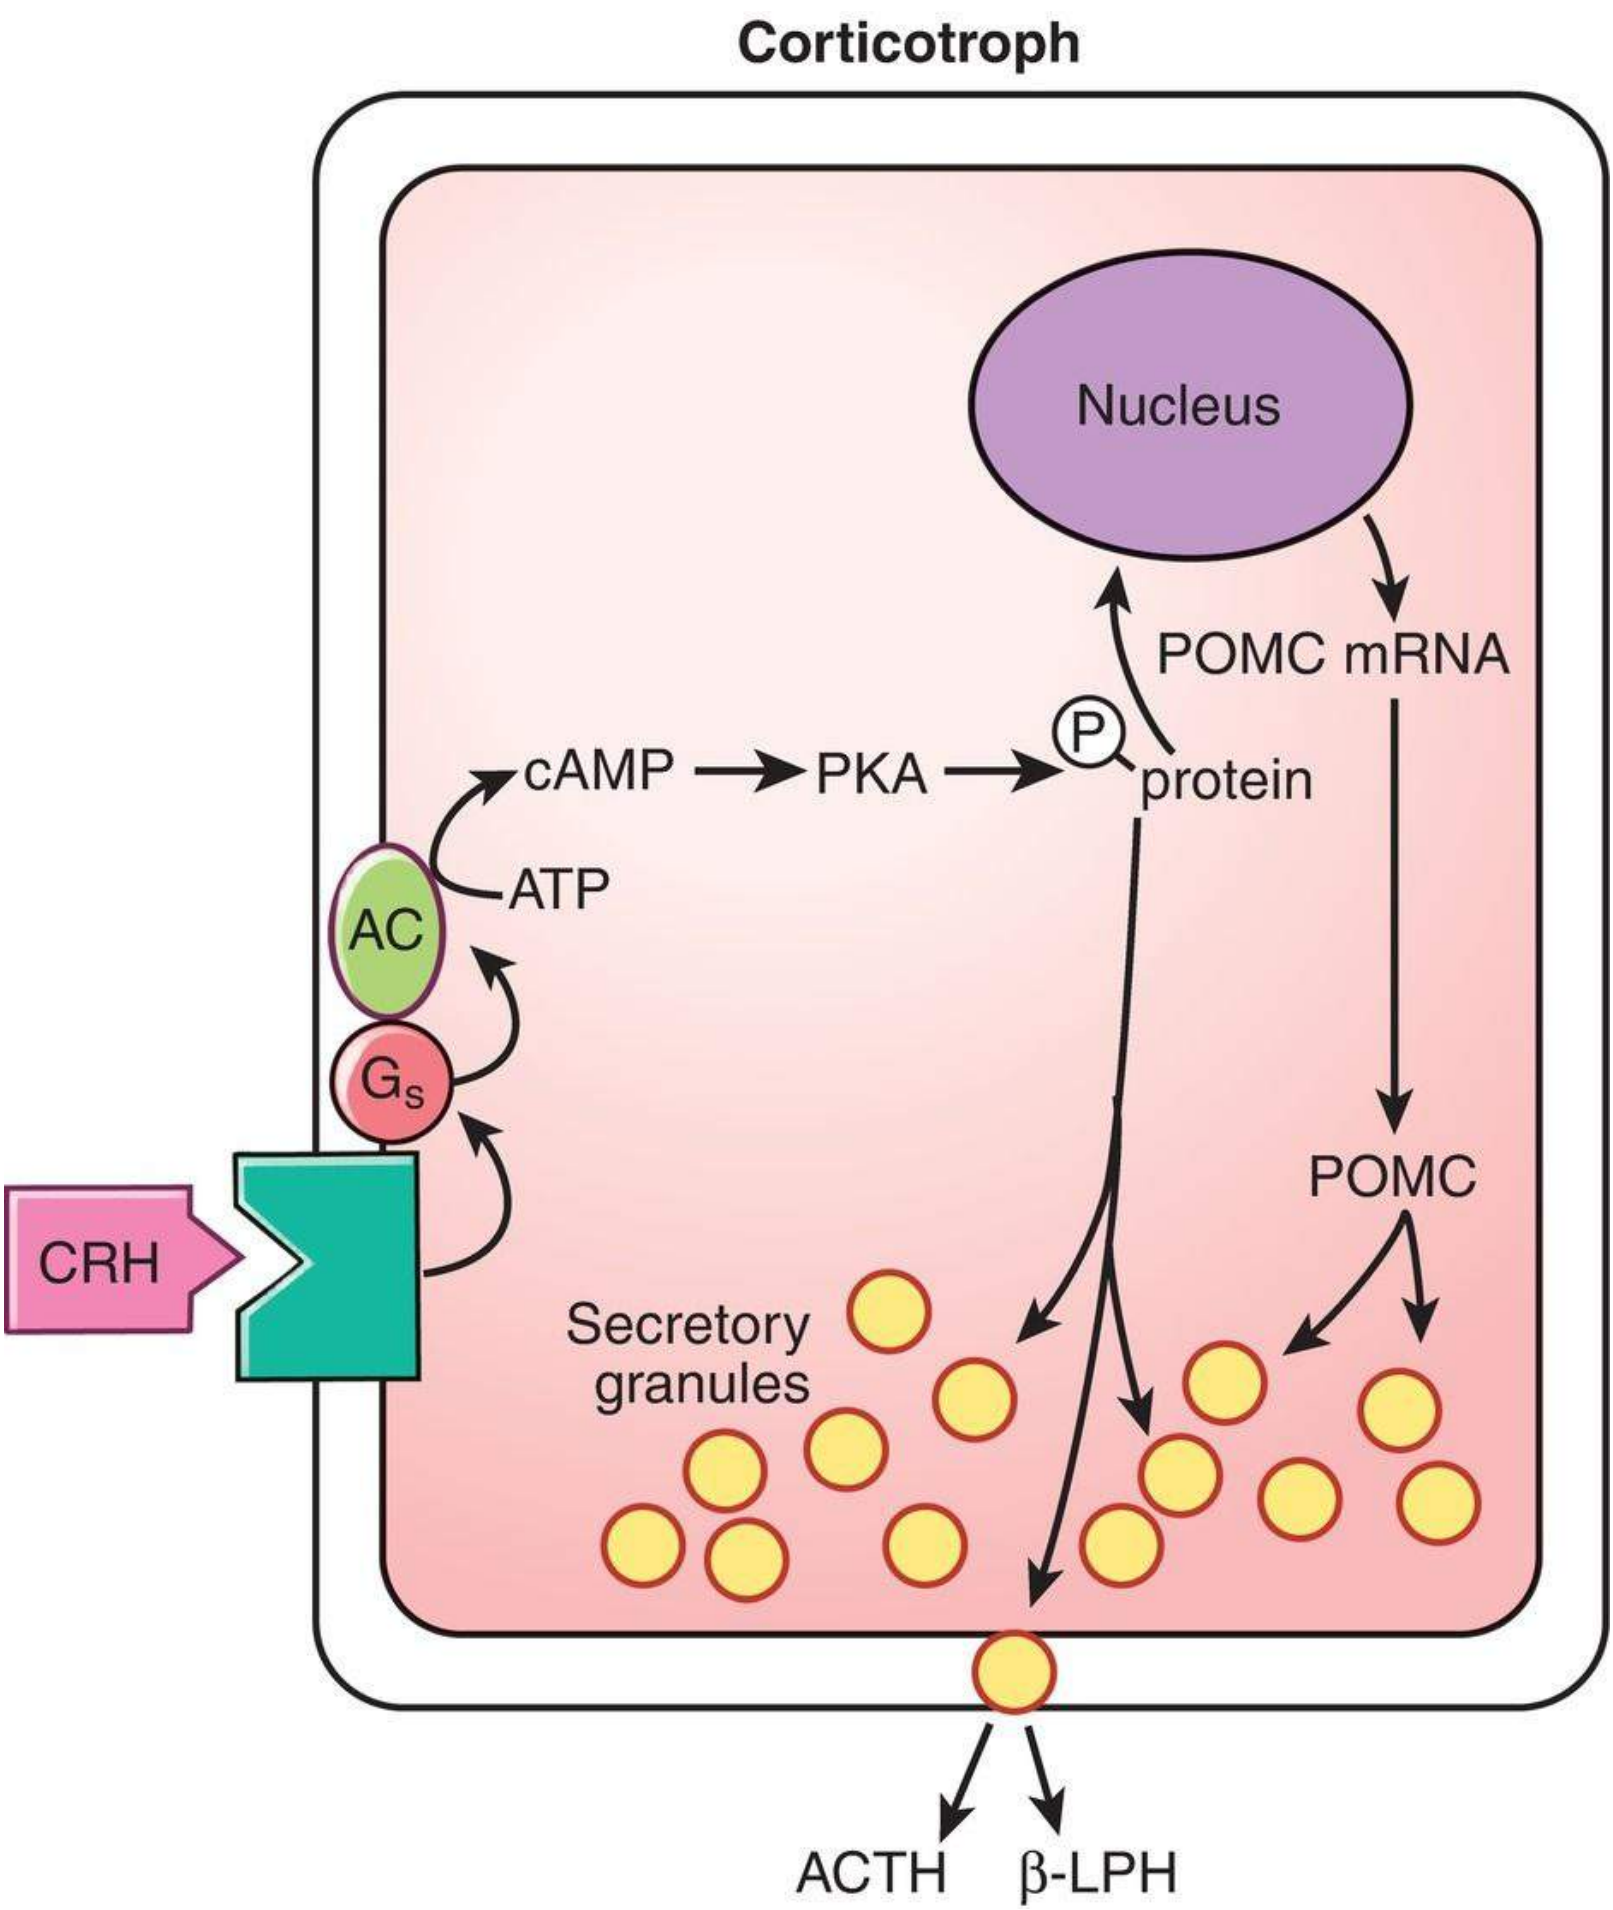

Figure 31.3 The action of corticotropin-releasing hormone (CRH) on a corticotroph. CRH binds to membrane receptors coupled to adenylyl cyclase (AC) by stimulatory G proteins (G_s). Cyclic adenosine monophosphate (cAMP) rises in the cell, activating protein kinase A (PKA), which then phosphorylates

proteins (P-proteins) that stimulate adrenocorticotropic hormone (ACTH) secretion and proopiomelanocortin (POMC) gene expression. β-LPH, β-lipotropin.

CRH-stimulated cAMP production in the corticotroph also increases POMC gene expression in these cells (see Fig. 31.3). Thus, CRH both stimulates ACTH secretion and also maintains the capacity of the corticotroph to synthesize the precursor for ACTH.

Glucocorticoids inhibit ACTH secretion

A rise in glucocorticoid concentration in the blood resulting ACH stimulation of the adrenal cortex inhibits the secretion of ACTH. Thus, glucocorticoids have a negative feedback effect on ACTH secretion, which, in turn, reduces the rate of glucocorticoid secretion by the adrenal cortex. If the blood glucocorticoid level begins to fall for some reason, this negative feedback effect is reduced, stimulating ACTH secretion and restoring the blood glucocorticoid concentration. This interactive relationship is called the **hypothalamic–pituitary–adrenal axis** (Fig. 31.4). This control loop ensures that the level of glucocorticoids in the blood remains relatively stable in the resting state, although there is a diurnal variation in glucocorticoid secretion.

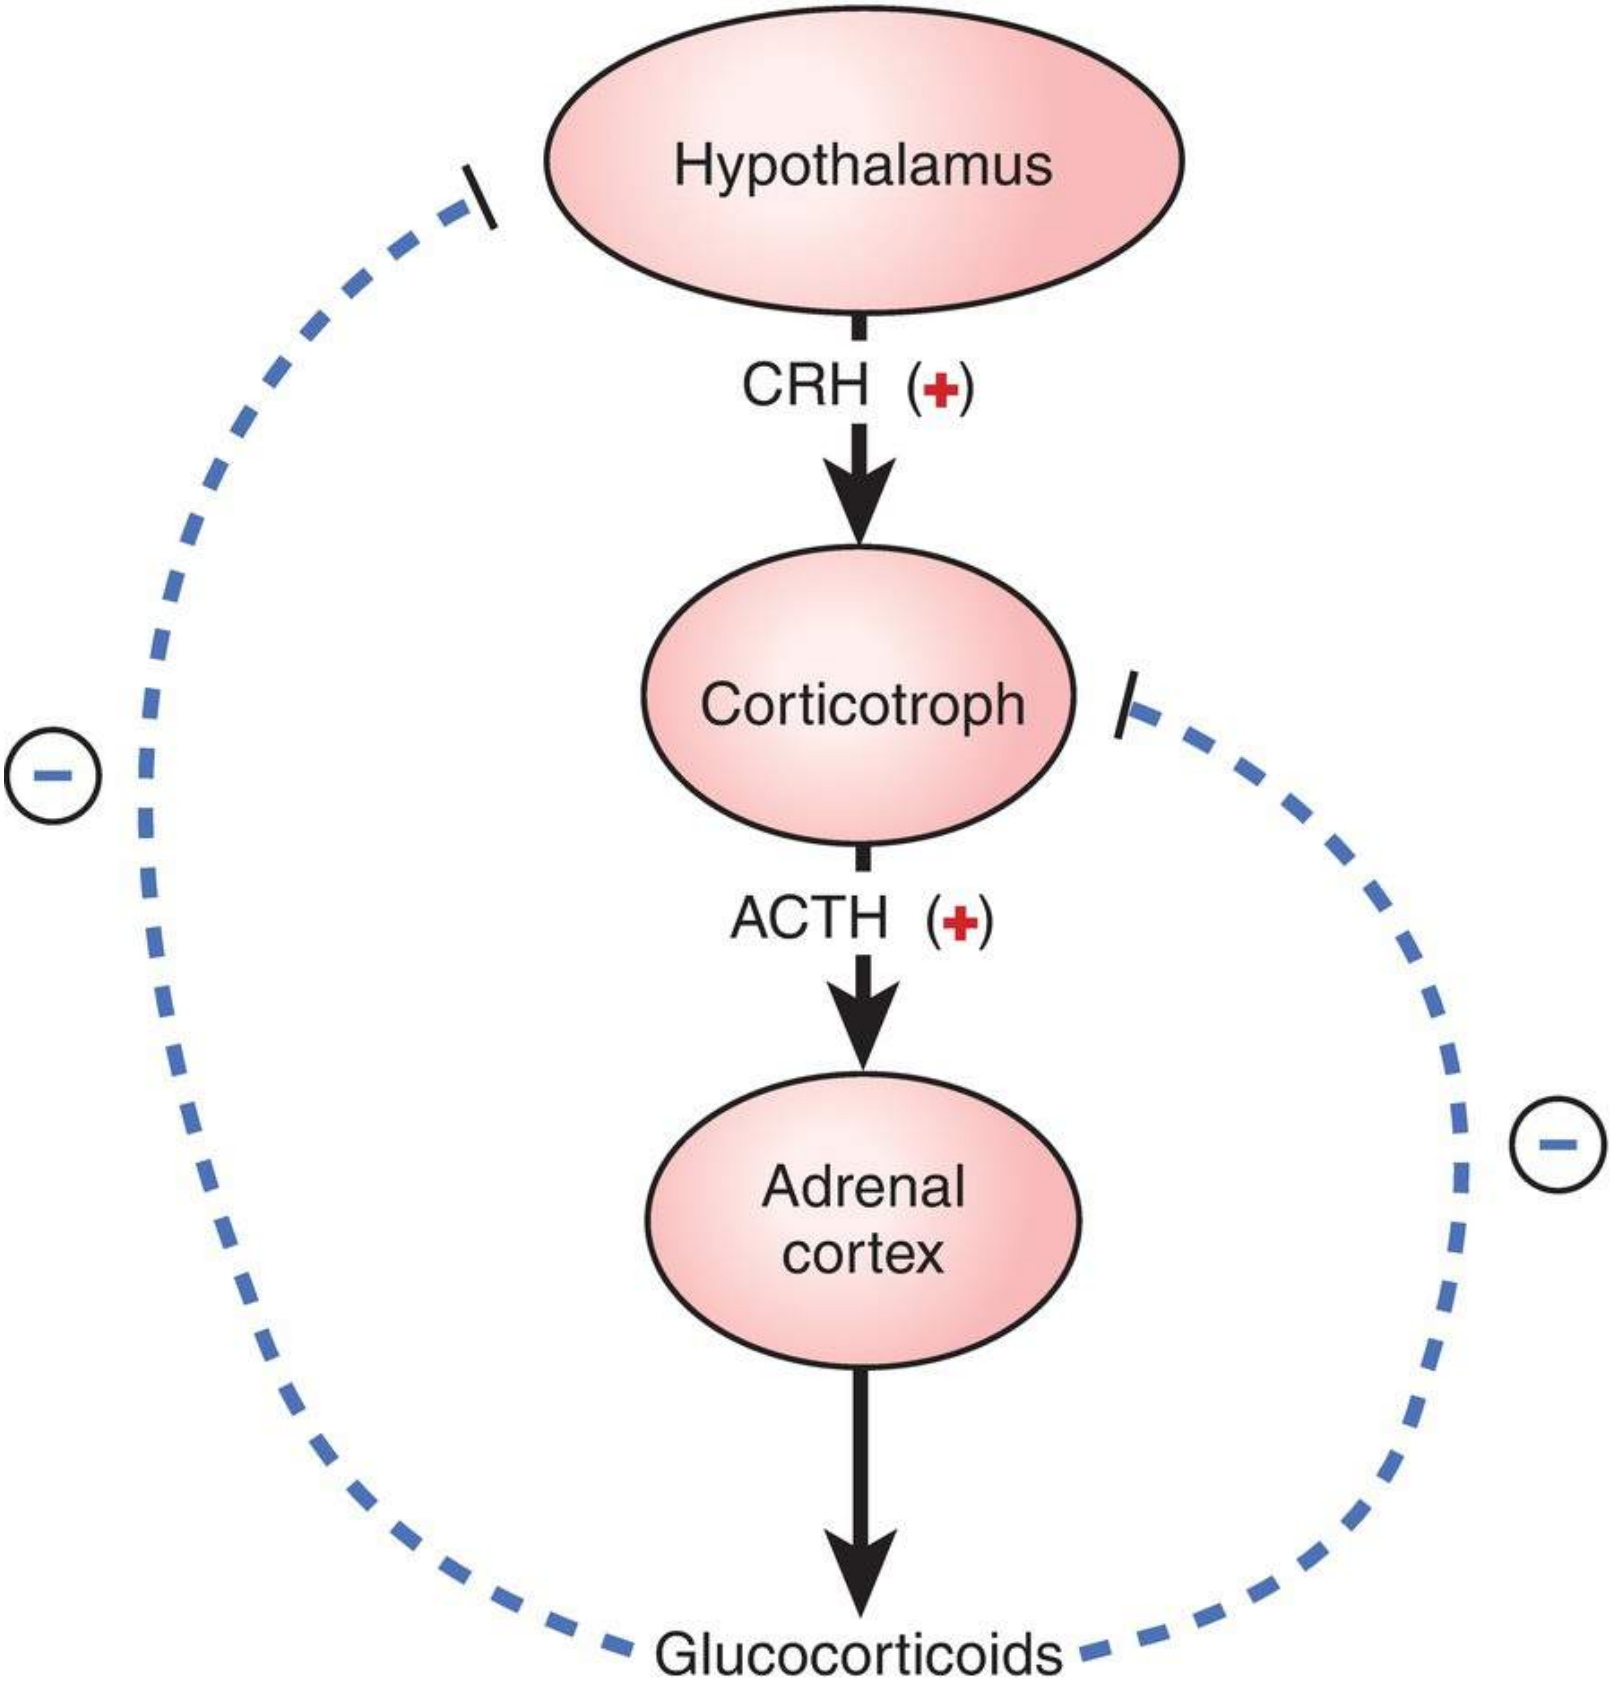

Figure 31.4 The hypothalamic–pituitary–adrenal axis. *Blue dashed lines* indicate the negative feedback actions of glucocorticoids on the corticotroph and the hypothalamus. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

The negative feedback effect of glucocorticoids on ACTH secretion results from actions on both the hypothalamus and the corticotroph (see Fig. 31.4). When the concentration of glucocorticoids rises in the blood, CRH secretion from the hypothalamus is inhibited. As a result, the stimulatory effect of CRH on

the corticotroph is reduced and the rate of ACTH secretion falls. Glucocorticoids act directly on parvicellular neurons to inhibit CRH release, and indirectly through neurons in the hippocampus that project to the hypothalamus, to affect the activity of parvicellular neurons. At the corticotroph, glucocorticoids inhibit the actions of CRH to stimulate ACTH secretion.

If the blood concentration of glucocorticoids remains high for a long period of time, POMC gene expression is inhibited, POMC mRNA in the corticotroph decreases, and the production of ACTH and the other POMC peptides declines. Glucocorticoids inhibit POMC gene expression in part by suppressing CRH secretion and also by acting directly in the corticotroph itself.

The negative feedback actions of glucocorticoids are essential for the normal operation of the hypothalamic–pituitary–adrenal axis. The disturbances that occur when disease or glucocorticoid administration drastically changes blood glucocorticoid levels vividly illustrate this relationship. For example, if a person's adrenal glands have been surgically removed or damaged by disease (e.g., Addison disease), the resulting lack of glucocorticoids allows corticotrophs to secrete large amounts of ACTH. People with glucocorticoid deficiency caused by inherited genetic defects affecting enzymes involved in steroid hormone synthesis by the adrenal cortex also have high blood ACTH levels resulting from the absence of the negative feedback effects of glucocorticoids on ACTH secretion. High blood concentrations of ACTH cause hypertrophy of the adrenal glands; thus, these genetic diseases are collectively called **congenital adrenal hyperplasia** (see Chapter 33). In contrast, the adrenal cortex atrophies in people treated chronically with large doses of glucocorticoids because the high level of glucocorticoids in the blood inhibits ACTH secretion, resulting in the loss of its trophic influence on the adrenal cortex.

Stress-induced ACTH secretion

Stress greatly influences the hypothalamic–pituitary–adrenal axis. When a person experiences physical or emotional stress, ACTH secretion is increased and the blood level of glucocorticoids rises rapidly. Regardless of the blood glucocorticoid concentration, stress stimulates the hypothalamic–pituitary–adrenal axis because stress-induced neural activity generated at higher CNS levels stimulates parvicellular neurons in the paraventricular nuclei to secrete CRH at a greater rate. Thus, stress can override the normal operation of the hypothalamic–pituitary–adrenal axis. If the stress persists, the blood glucocorticoid level remains high because the glucocorticoid negative feedback mechanism functions at a higher set point.

Arginine vasopressin

Glucocorticoid deficiency and certain types of stress increase the concentration of AVP in hypophyseal portal blood. The physiologic significance is that AVP, like CRH, can stimulate corticotrophs to secrete ACTH. Acting along with CRH, AVP amplifies the stimulatory effect of CRH on ACTH secretion.

AVP interacts with a specific receptor on the plasma membrane of the corticotroph that is coupled via G proteins to the enzyme **phospholipase C** (**PLC**). The interaction of AVP with its receptor activates PLC, which hydrolyzes plasma membrane **phosphatidylinositol 4,5-bisphosphate** (**PIP_2**) to generate the intracellular second messengers **inositol trisphosphate** (**IP_3**) and **diacylglycerol** (**DAG**). IP_3 mobilizes intracellular calcium stores, and DAG activates the phospholipid-dependent and calcium-dependent **protein kinase C** (**PKC**) to mediate the stimulatory effect of AVP on ACTH secretion.

As noted earlier, magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus produce AVP and oxytocin. These neurons terminate in the posterior lobe, where they

secrete AVP and oxytocin into capillaries that feed into the systemic circulation. However, parvicellular neurons in the paraventricular nuclei also produce AVP, which they secrete into hypophyseal portal blood. It appears that much of the AVP secreted by parvicellular neurons is made in the same cells that produce CRH. It is assumed that the AVP in hypophyseal portal blood comes from these cells and from a small number of AVP-producing magnocellular neurons whose axons pass through the median eminence of the hypothalamus on their way to the posterior lobe.

Diurnal variation

Under normal circumstances, the hypothalamic–pituitary–adrenal axis in humans functions in a pulsatile manner, resulting in several bursts of secretory activity over a 24-hour period. This pattern is the result of rhythmic activity in the CNS, which causes bursts of CRH secretion and in turn bursts of ACTH and glucocorticoid secretion (Fig. 31.5). The diurnal oscillation in secretory activity of the axis is thought to result from changes in the sensitivity of CRH-producing neurons to the negative feedback action of glucocorticoids, altering their rate of CRH secretion. As a result, there is a diurnal oscillation in the rate of ACTH and glucocorticoid secretion. This **circadian rhythm** is reflected in the daily pattern of glucocorticoid secretion. In people who are awake during the day and sleep at night, the blood glucocorticoid level begins to rise during the early morning hours, reaches a peak sometime before noon, and then falls gradually to a low level around midnight (see Fig. 31.5). This pattern is reversed in people who sleep during the day and are awake at night. This inherent biologic rhythm is superimposed on the normal operation of the hypothalamic–pituitary–adrenal axis.

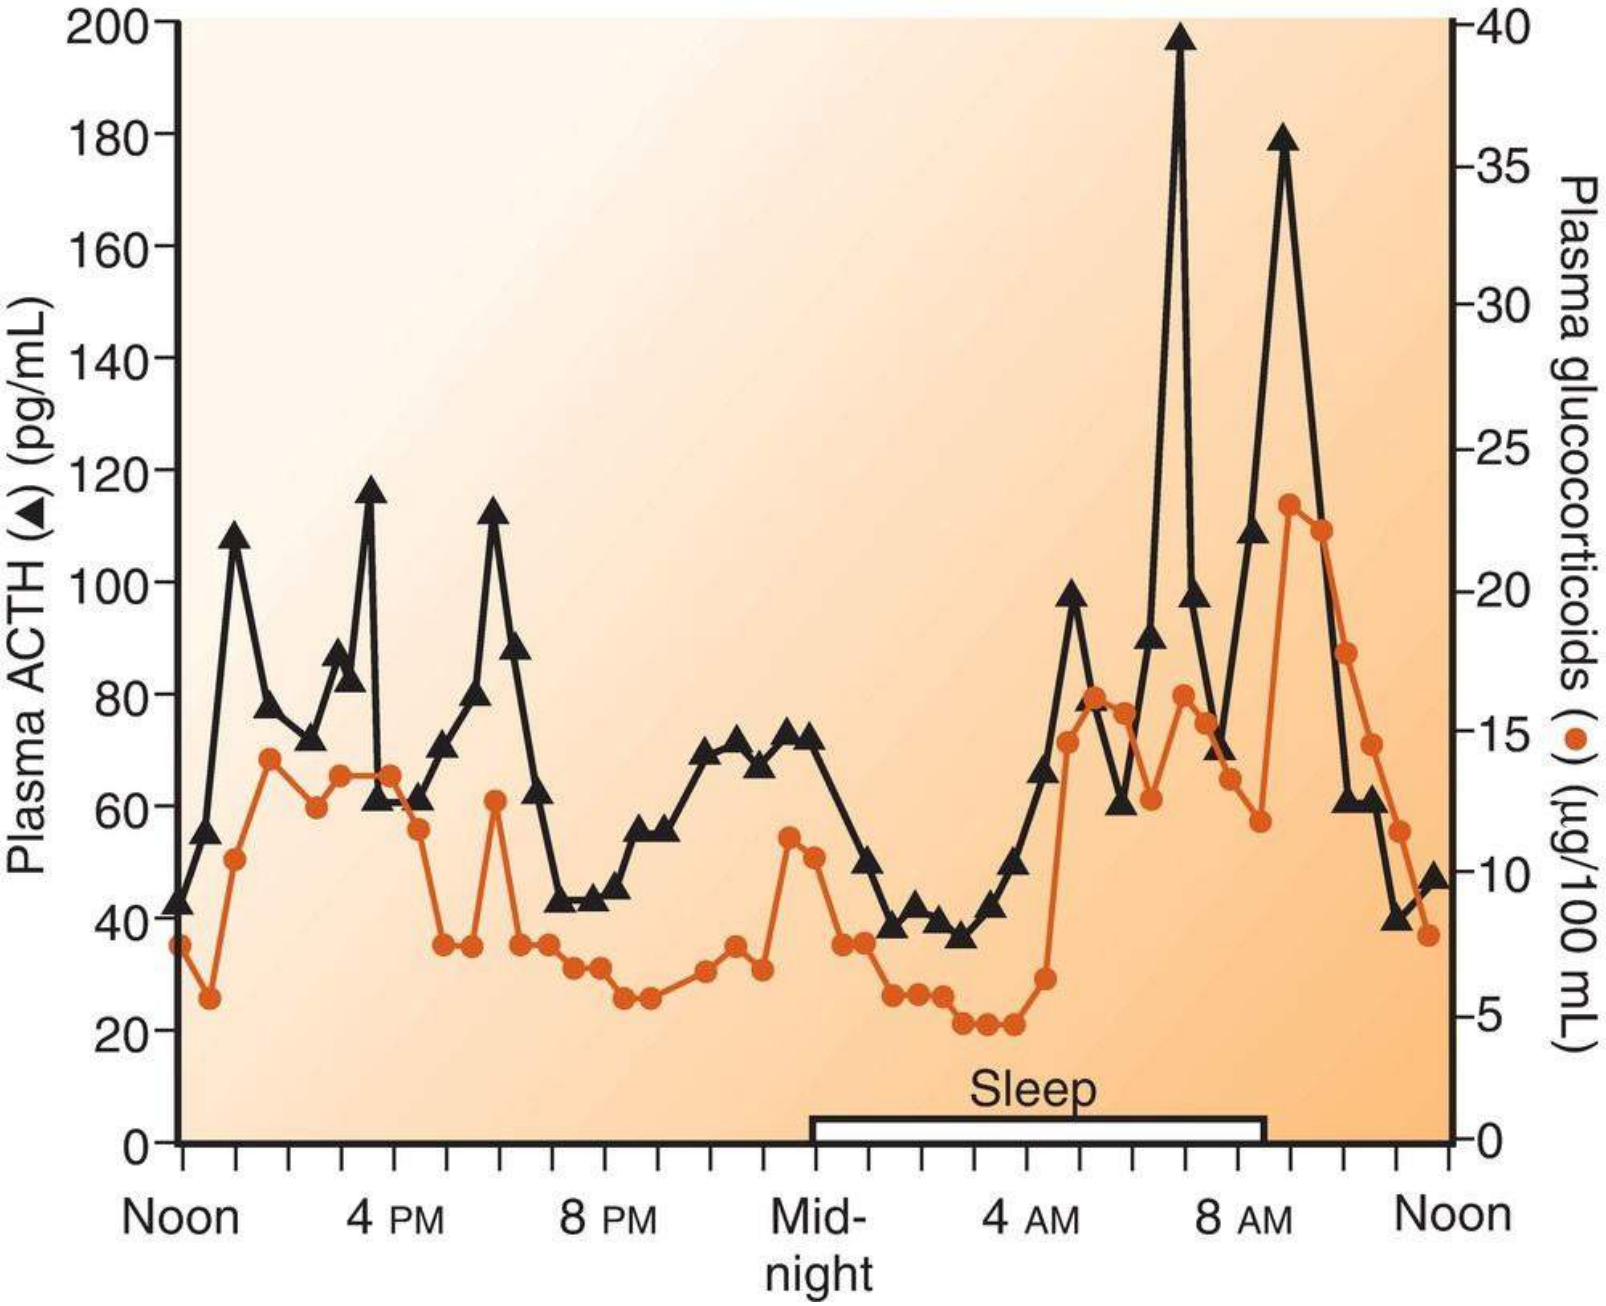

Figure 31.5 Adrenocorticotropic hormone (ACTH) secretion and the sleep–wake cycle. Pulsatile changes in the concentrations of ACTH and glucocorticoids in the blood of a young individual over a 24-hour period. Note that the amplitude of the pulses in ACTH and glucocorticoids is lower during the evening hours and increases greatly during the early morning hours illustrating the diurnal oscillation of the hypothalamic–pituitary–adrenal axis.

Thyroid-stimulating hormone regulates thyroid gland function.

The thyroid gland consists of two lobes and is composed of aggregates of follicle cells, which are formed from a single layer of cells. The follicular cells produce and secrete T_4 and T_3, thyroid hormones that are iodinated derivatives of the amino acid tyrosine. The thyroid hormones control the body's basal metabolic rate, heat production, protein synthesis, growth, and CNS development. They act on many cells, changing gene expression and the production of particular proteins in the cell.

TSH is the physiologic regulator of T_4 and T_3 synthesis and secretion by the thyroid gland. TSH also promotes nucleic acid and protein synthesis in the cells of the thyroid follicles, maintaining their size and functional integrity. The actions of TSH on thyroid hormone synthesis and secretion and the physiologic effects of the thyroid hormones are described in detail in Chapter 32.

Thyroid-stimulating hormone synthesis

The α subunit of TSH is a single peptide chain of 92 amino acid residues with two carbohydrate chains linked to its structure. The β subunit is a single peptide chain of 112 amino acid residues, to which a single carbohydrate chain is linked. Noncovalent bonds hold the α and β subunits together. The two subunits combined give the TSH molecule a molecular weight of about 28,000. Neither subunit has significant TSH activity by itself. The two subunits must be combined in a 1:1 ratio to form an active hormone. The gonadotropins FSH and LH are also composed of two noncovalently combined subunits. The α subunits of TSH, FSH, and LH are derived from the same gene and are identical, but the β subunit gives each hormone its particular set of physiologic activities.

Thyrotrophs synthesize the peptide chains of the α and β subunits of TSH from separate mRNA molecules, which are transcribed from two different genes. The peptide chains of the α and β subunits are combined and undergo glycosylation in the rough endoplasmic reticulum (RER). These processes are completed as TSH molecules pass through the Golgi apparatus and are packaged into secretory granules. Normally, thyrotrophs make more α subunits than β subunits. As a result, secretory granules contain excess α subunits. When a thyrotroph is stimulated to secrete TSH, it releases both TSH and free α subunits into the bloodstream. In contrast, little free TSH β subunit is in the blood.

Thyrotropin-releasing hormone regulation of thyroid-stimulating hormone

TRH is a small peptide consisting of three amino acid residues produced by neurons in the hypothalamus. These neurons terminate on the capillary networks that give rise to the hypophyseal portal vessels and secrete TRH into the hypophyseal portal circulation at a constant or tonic rate. Therefore, the thyrotrophs are continuously exposed to TRH.

TRH binds to receptors on the plasma membranes of thyrotrophs that are coupled via G proteins to PLC (Fig. 31.6). TRH binding with its receptor activates PLC, causing the hydrolysis of membrane PIP_2 and the release of the intracellular messengers IP_3 and DAG. IP_3 increases the concentration of Ca^{2+} in the cytosol, which stimulates the secretion of TSH into the blood. The rise in cytosolic Ca^{2+} and the increase in DAG activate PKC, which phosphorylates proteins to promote TSH secretion. TRH also stimulates the expression of the genes for the α and β subunits of TSH in the thyrotroph to maintain the production of TSH fairly constant (see Fig. 31.6).

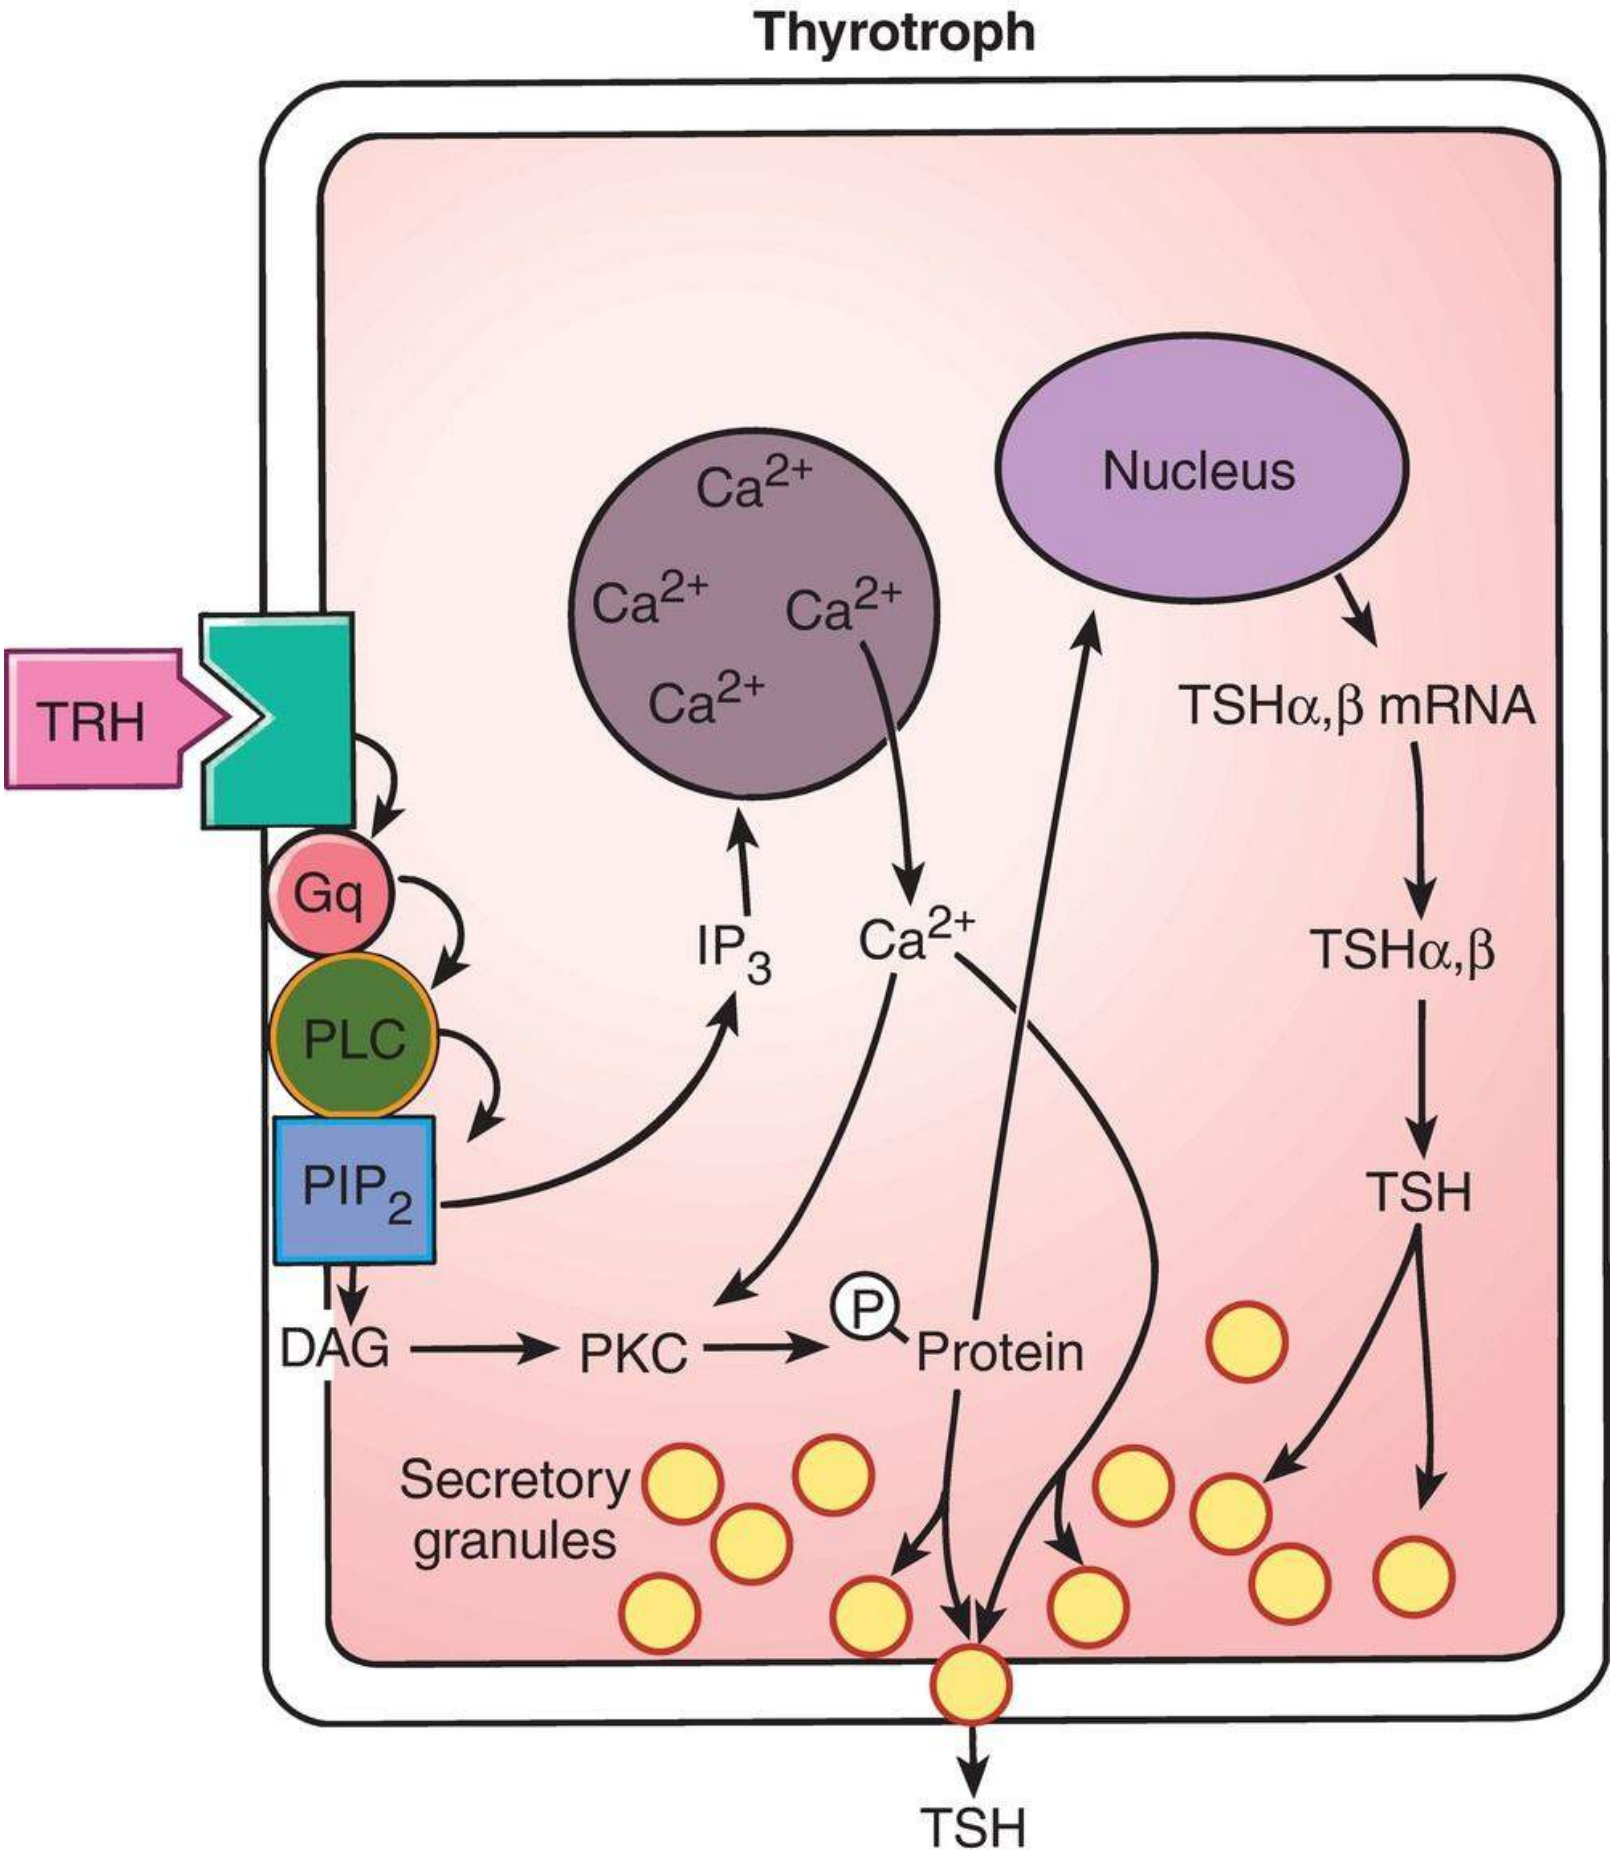

Figure 31.6 The action of thyrotropin-releasing hormone (TRH) on a thyrotroph. TRH binds to membrane receptors coupled to phospholipase C (PLC) by G proteins (G_q). PLC hydrolyzes plasma membrane phosphatidylinositol 4,5-bisphosphate (PIP_2), generating inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 mobilizes intracellular stores of Ca^{2+}. The rise in Ca^{2+} stimulates thyroid-

stimulating hormone (TSH) secretion. Ca^{2+} and DAG activate protein kinase C (PKC), which phosphorylates proteins (P-proteins) that stimulate TSH secretion and gene expression for the α and β subunits of TSH.

The exposure of certain animals to a cold environment stimulates TSH secretion. This makes sense from a physiologic perspective because the thyroid hormones are important in regulating body heat production (see Chapter 32). Brief exposure of experimental animals to a cold environment stimulates the secretion of TSH, presumably a result of enhanced TRH secretion. Newborn humans behave much the same way, in that they respond to brief cold exposure with an increase in TSH secretion. This response to cold does not occur in adult humans.

Thyroid hormone regulation of thyroid-stimulating hormone secretion

The thyroid hormones exert a direct negative feedback effect on TSH secretion. For example, when the blood concentration of thyroid hormones is high, the rate of TSH secretion falls. In turn, the stimulatory effect of TSH on the follicular cells of the thyroid is reduced, resulting in a decrease in T_4 and T_3 secretion. When the circulating levels of T_4 and T_3 are low, their negative feedback effect on TSH release is reduced and more TSH is secreted from thyrotrophs, increasing the rate of thyroid hormone secretion. This control system is part of the hypothalamic–pituitary–thyroid axis (Fig. 31.7).

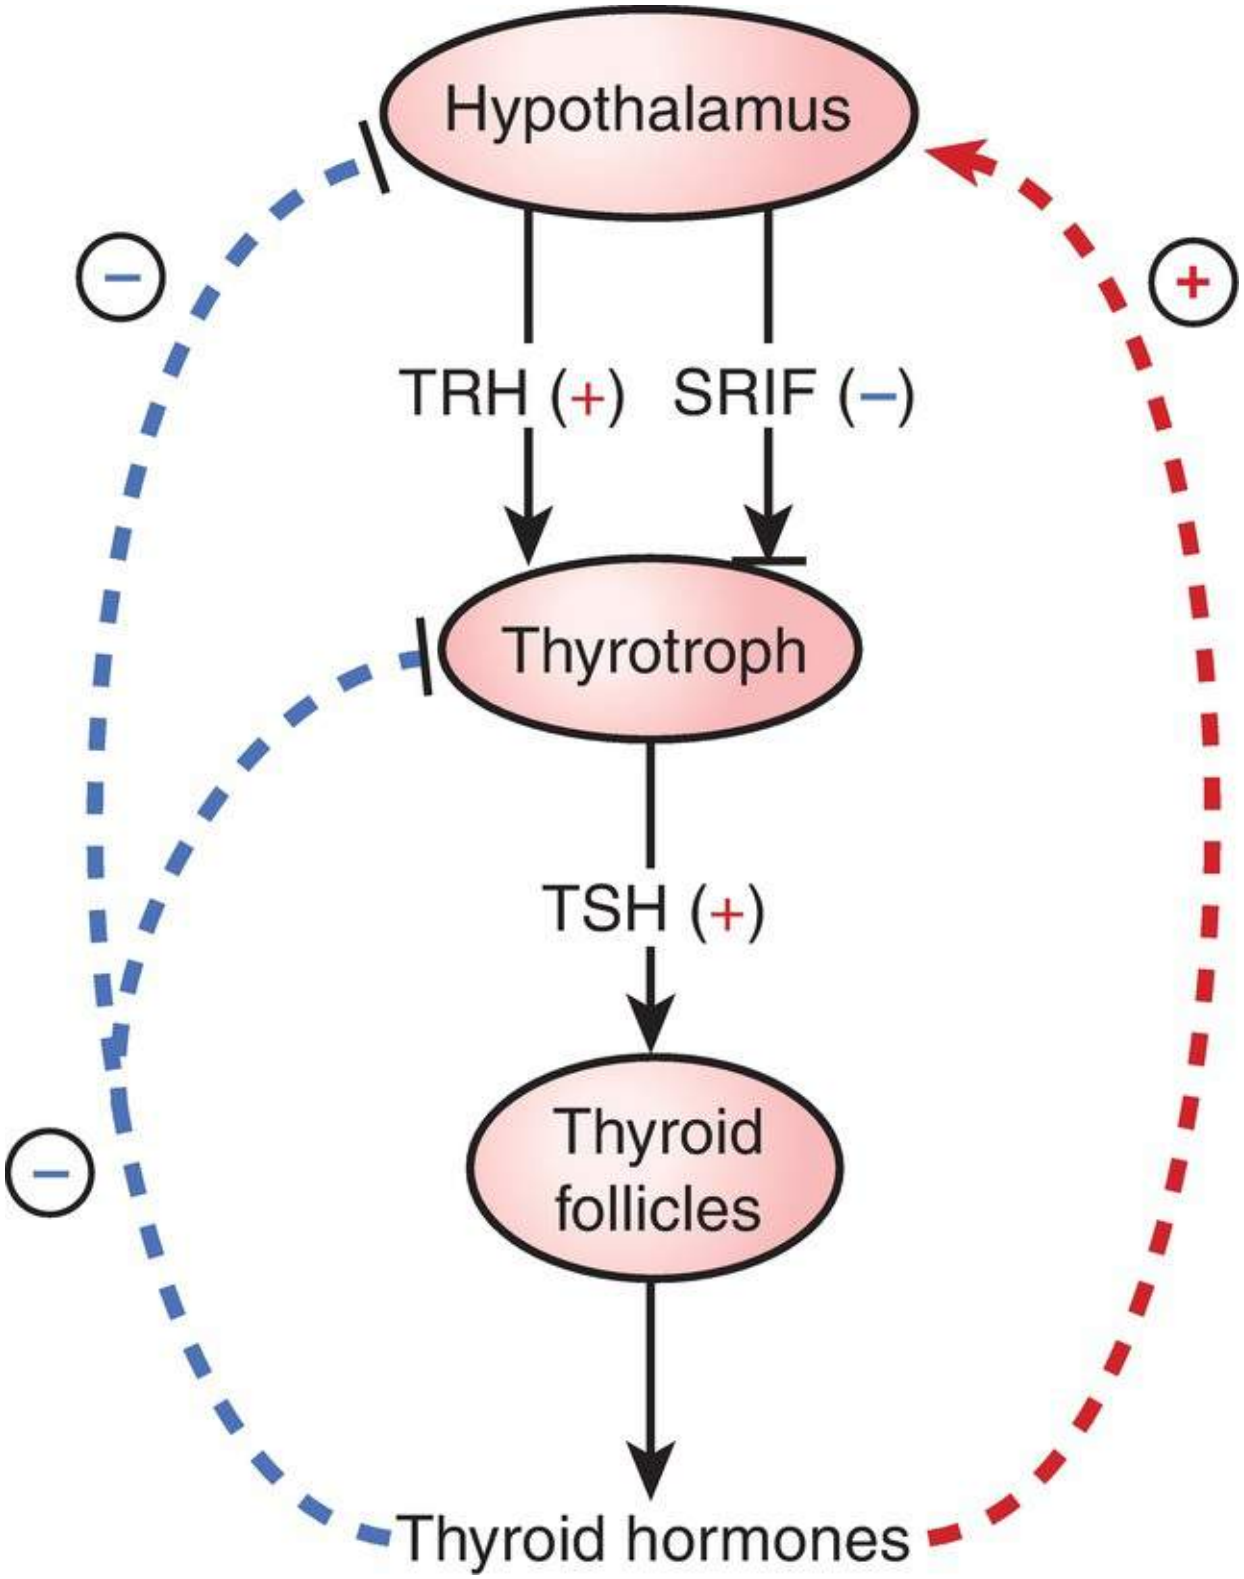

Figure 31.7 The hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) stimulates and somatostatin (SRIF) inhibits thyroid-stimulating hormone (TSH) release by acting directly on the thyrotroph. The negative feedback loops shown in *blue* inhibit TRH secretion and action on the thyrotroph, causing a decrease in TSH secretion. The feedback loops, shown in *red*, stimulate somatostatin secretion, causing a decrease in TRH secretion. SRIF, somatostatin or somatotropin release–inhibiting factor.

The thyroid hormones exert negative feedback effects on both the hypothalamus and the pituitary. In the hypothalamic TRH-secreting neurons, thyroid hormones reduce TRH mRNA and TRH prohormone to decrease TRH release. The thyroid hormones also increase the release of somatostatin from the

hypothalamus. Somatostatin (SRIF) inhibits the release of TSH from the thyrotroph (see Fig. 31.7). In the pituitary, thyroid hormones reduce the sensitivity of the thyrotroph to TRH and inhibit TSH synthesis.

The negative feedback effects of the thyroid hormones on thyrotrophs are produced primarily through the actions of T_3. Both T_4 and T_3 circulate in the blood bound to plasma proteins, with only a small percentage (<1%) unbound or free (see Chapter 32). Thyrotrophs take up the free T_4 and T_3 molecules, and the enzymatic removal of one iodine atom converts T_4 to T_3. The newly formed T_3 molecules and those taken up directly from the blood enter the nucleus, where they bind to thyroid hormone receptors in the chromatin, changing gene expression to decrease the synthesis and secretion of TSH. T_3 also decreases thyrotroph sensitivity to TRH, in part through a reduction in the number of TRH receptors in thyrotroph plasma membrane.

The hypothalamic-pituitary-thyroid axis diurnal rhythm

In humans, peak TSH secretion occurs in the early morning, and a low point is reached in the evening. Physical and emotional stress can alter TSH secretion, but the effects of stress on the hypothalamic–pituitary–thyroid axis are not as pronounced as on the hypothalamic–pituitary–adrenal axis.

Growth hormone promotes growth during childhood and remains important throughout life.

GH is a peptide hormone secreted that promotes the growth of the human body. It does not stimulate fetal growth, and it is not an important growth factor during the first few months after birth. Thereafter, it is essential for the normal rate of body growth during childhood and adolescence.

The anterior pituitary secretes GH throughout life, and GH remains physiologically important even after growth has stopped. In addition to its growth-promoting action, GH has effects on many aspects of carbohydrate, lipid, and protein metabolism. For example, GH is thought to be one of the physiologic factors that counteract and, thus, modulate some of the actions of insulin on the liver and peripheral tissues.

Growth hormone synthesis

GH is a globular 22-kDa protein consisting of a single chain of 191 amino acid residues with two intrachain disulfide bridges, produced in somatotrophs of the anterior pituitary. It is synthesized in the RER as a larger preprohormone that is processed to a prohormone consisting of an N-terminal signal peptide and the 191 amino acid hormones. The signal peptide is then cleaved from the prohormone as it traverses the Golgi apparatus, and the GH is packaged in secretory granules. Human GH has considerable structural similarity to human PRL and placental lactogen.

GHRH regulates the production of GH by stimulating the GH gene expression in somatotrophs. Thyroid hormones also stimulate GH gene expression. As a result, the normal rate of GH production depends on these hormones. For example, a thyroid hormone–deficient person is also GH deficient. This important action of thyroid hormones is discussed further in Chapter 32.

Growth hormone secretion

Two opposing hypothalamic-releasing hormones regulate the secretion of GH. GHRH stimulates GH secretion, and somatostatin inhibits GH secretion by inhibiting the action of GHRH. The net effect of these counteracting hormones on somatotrophs determines the rate of GH secretion. When GHRH predominates, GH secretion is stimulated. When somatostatin predominates, GH secretion is inhibited.

Human GHRH is a single-chain peptide of 44 amino acid residues. A slightly smaller version of GHRH consisting of 40 amino acid residues is also present in humans. The two forms of GH result from posttranslational modification of a larger prohormone. GHRH is synthesized in the cell bodies of neurons in the **arcuate nuclei** and **ventromedial nuclei** of the hypothalamus. The axons of these cells project to the capillary networks giving rise to the portal vessels. When these neurons receive a stimulus for GHRH secretion, they discharge GHRH from their axon terminals into the hypophyseal portal circulation.

GHRH binds to receptors in the plasma membranes of somatotrophs coupled via stimulatory G_s proteins to adenylyl cyclase (Fig. 31.8). GHRH binding its receptor activates adenylyl cyclase to increase cAMP, activating PKA, which, in turn, phosphorylates proteins that stimulate GH secretion and GH gene expression. GHRH binding to its receptor also increases intracellular Ca^{2+}, which stimulates GH secretion. GHRH also stimulates PLC, causing the hydrolysis of membrane PIP_2 in the somatotroph. The importance of this phospholipid pathway for the stimulation of GH secretion by GHRH is not established.

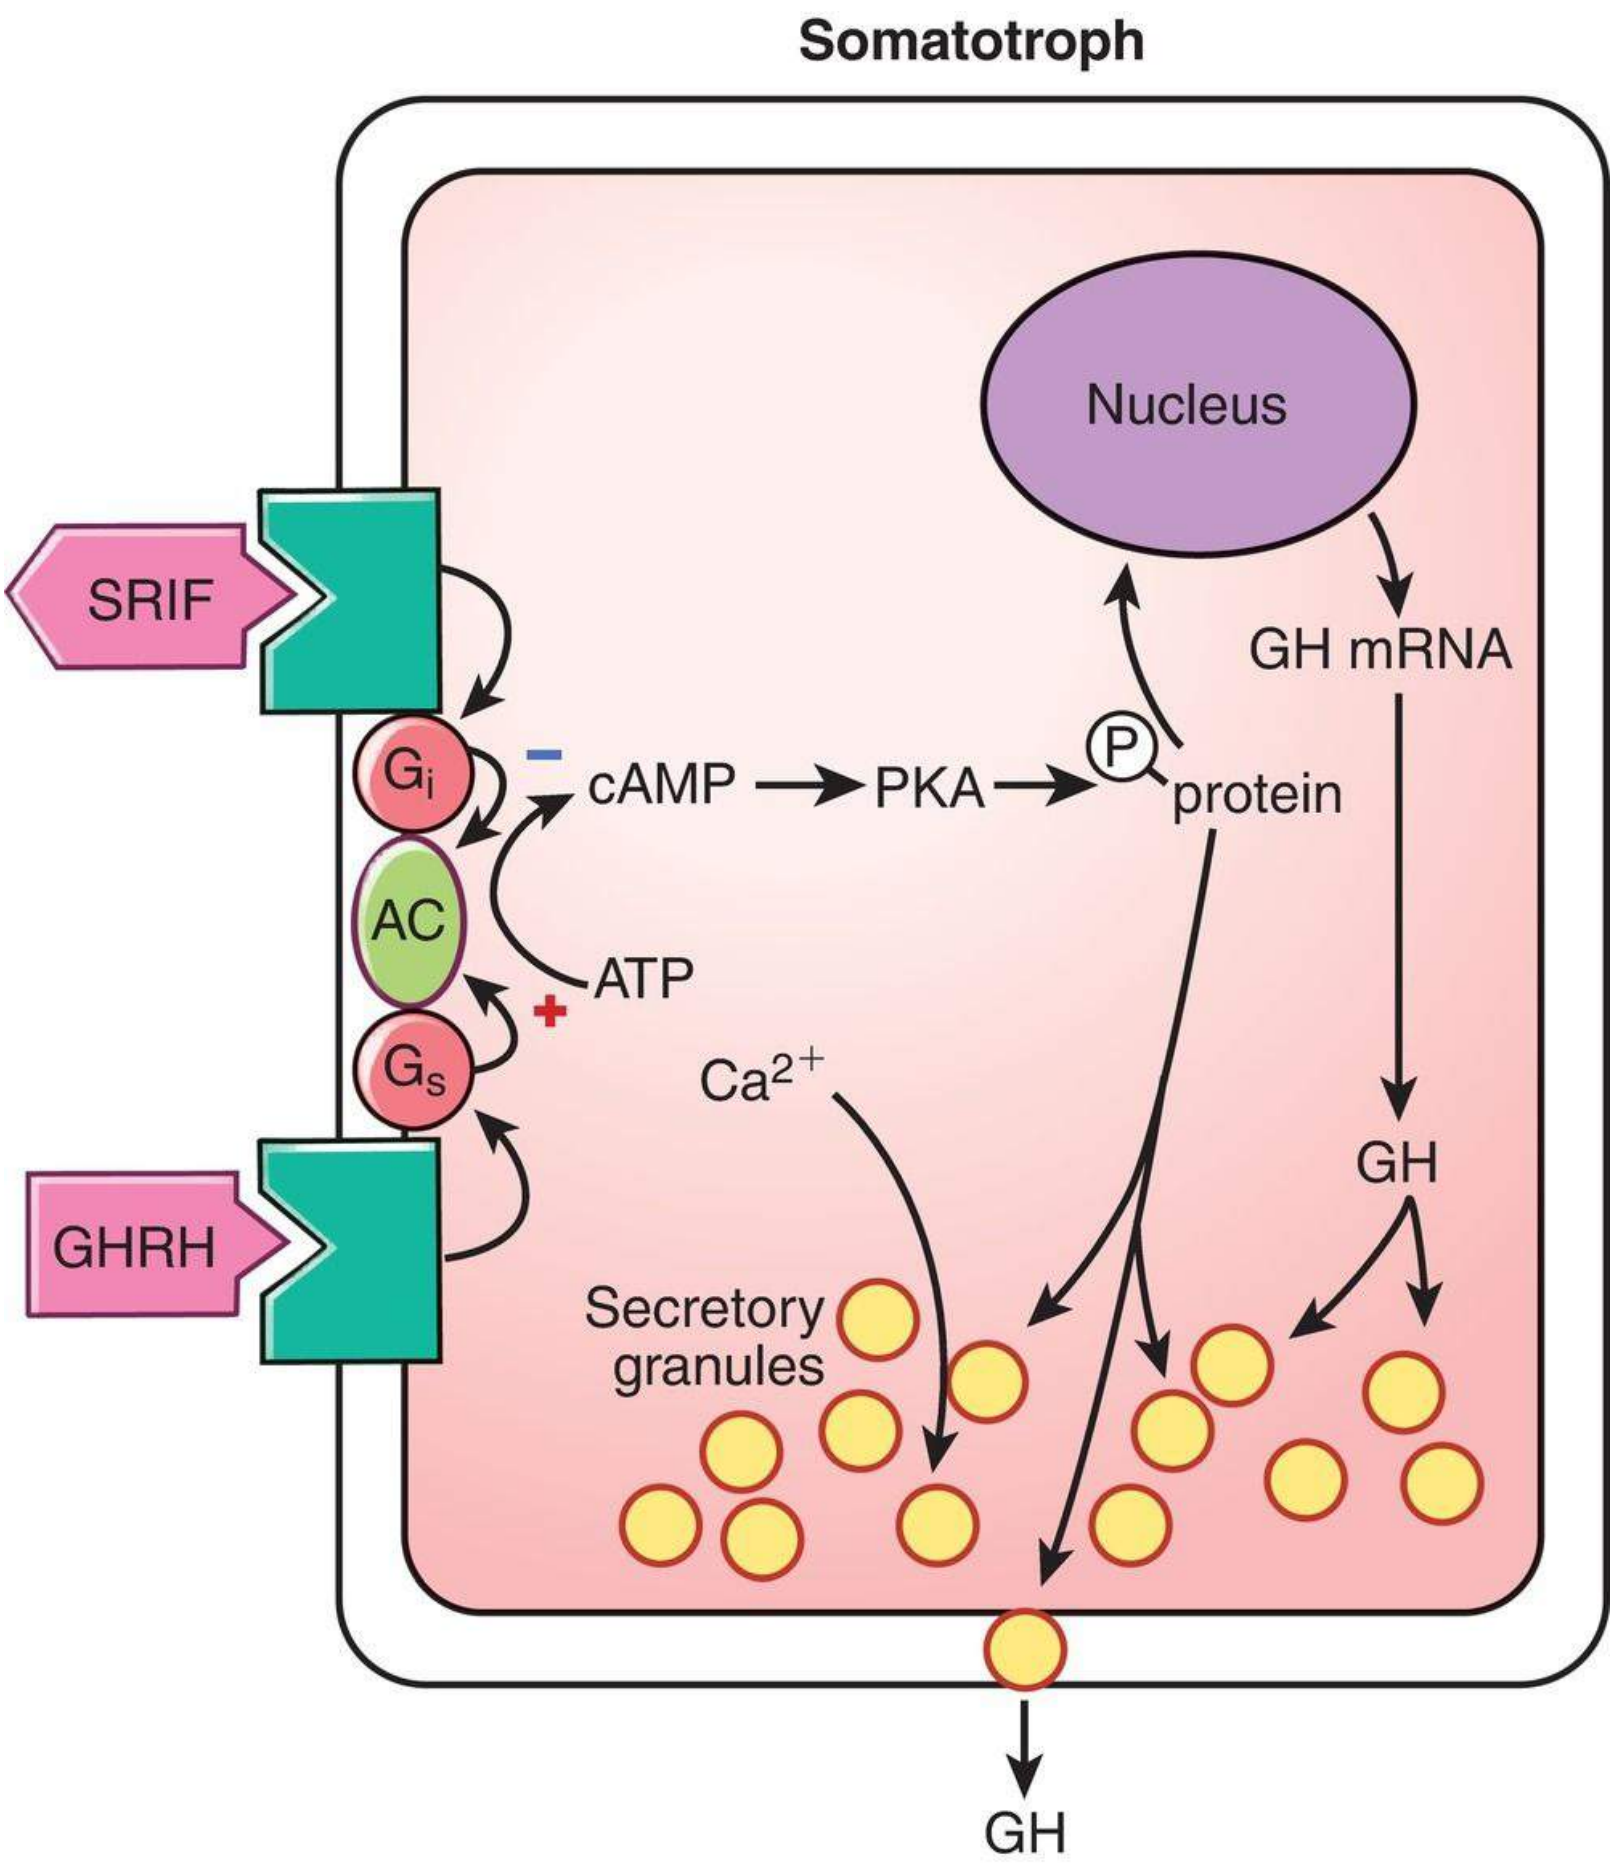

Figure 31.8 The action of growth hormone–releasing hormone (GHRH) and somatostatin (SRIF) on a somatotroph. GHRH binds to membrane receptors coupled by stimulatory G proteins (G_s) to adenylyl cyclase (AC). Cyclic adenosine monophosphate (cAMP) rises in the cell and activates protein kinase A (PKA), which then phosphorylates proteins (P-proteins) that stimulate growth hormone (GH) secretion

and GH gene expression. Ca^{2+} also facilitates GH secretion. The possible involvement of the phosphatidylinositol pathway in GHRH action is not shown. SRIF binds to membrane receptors coupled to adenylyl cyclase by inhibitory G proteins (G_i), which inhibit GHRH stimulation of adenylyl cyclase.

Somatostatin is a small peptide consisting of 14 amino acid residues. Somatostatin neurons are especially abundant in the **anterior periventricular region** (close to the third ventricle), although it is also made by neurons in other parts of the hypothalamus. The axons of these cells terminate on the capillary networks giving rise to the hypophyseal portal circulation, where they release somatostatin into the blood.

Somatostatin binds to receptors in the plasma membranes of somatotrophs that are coupled to adenylyl cyclase by an inhibitory G protein (see Fig. 31.8). Somatostatin binding its receptor decreases adenylyl cyclase activity, reducing intracellular cAMP. Somatostatin binding to its receptor also lowers intracellular Ca^{2+}, reducing GH secretion. When the somatotroph is exposed to both somatostatin and GHRH, the effects of somatostatin are dominant and intracellular cAMP and Ca^{2+} are reduced. Thus, somatostatin has a negative modulating influence on the action of GHRH.

Insulin-like growth factor 1

GH is not a traditional trophic hormone that directly stimulates the growth of its target tissue. Rather, GH stimulates the production of a trophic hormone called **insulin-like growth factor 1** (**IGF-1 or IGF-I**), a potent **mitogenic** agent that mediates the growth-promoting action of GH. IGF-1 was originally called *somatomedin C* or *somatotropin-mediating hormone* because of its role in promoting growth. Somatomedin C was renamed IGF-1 because of its structural similarity to proinsulin. Although most effects of GH are mediated by IGF-1, it is important to note that some effects of GH, such as stimulation of lipolysis in adipose tissue (see below) and stimulation of amino acid transport in muscle, occur independently of IGF-1 action.

Insulin-like growth factor 2 (**IGF-2 or IGF-II**) is structurally similar to IGF-1 and has many of the same metabolic and mitogenic actions. However, the synthesis and release of IGF-2 depends less on GH. Thus, IGF-1 is the more important mediator of GH action.

IGF-1 is a 7.5-kDa protein consisting of a single chain of 70 amino acids. Because of its structural similarity to proinsulin, IGF-1 can produce some of the effects of insulin. Many cells of the body produce IGF-1; however, the liver is the main source of IGF-1 in the blood. Most IGF-I in the blood is bound to specific IGF-1–binding proteins; only a small amount circulates in the free form. The bound form of circulating IGF-1 has little insulin-like activity, so it does not play a physiologic role in the regulation of blood glucose level.

GH increases IGF-1 gene expression in various tissues and organs, such as the liver, and stimulates the production and release of IGF-1. Excessive GH secretion results in a greater-than-normal amount of IGF-1 in the blood. People with GH deficiency have lower-than-normal levels of IGF-1, but there is still some present, because many hormones and factors, in addition to GH, regulate the production of IGF-1 by cells.

Inhibition of growth hormone secretion

An increase in blood GH concentration has direct negative feedback effects on its own secretion, independent of the production of IGF-1. GH inhibits GHRH secretion and stimulates somatostatin

secretion by hypothalamic neurons (Fig. 31.9). GH circulating in the blood can enter the interstitial spaces of the median eminence of the hypothalamus because the blood–brain barrier is porous in this area.

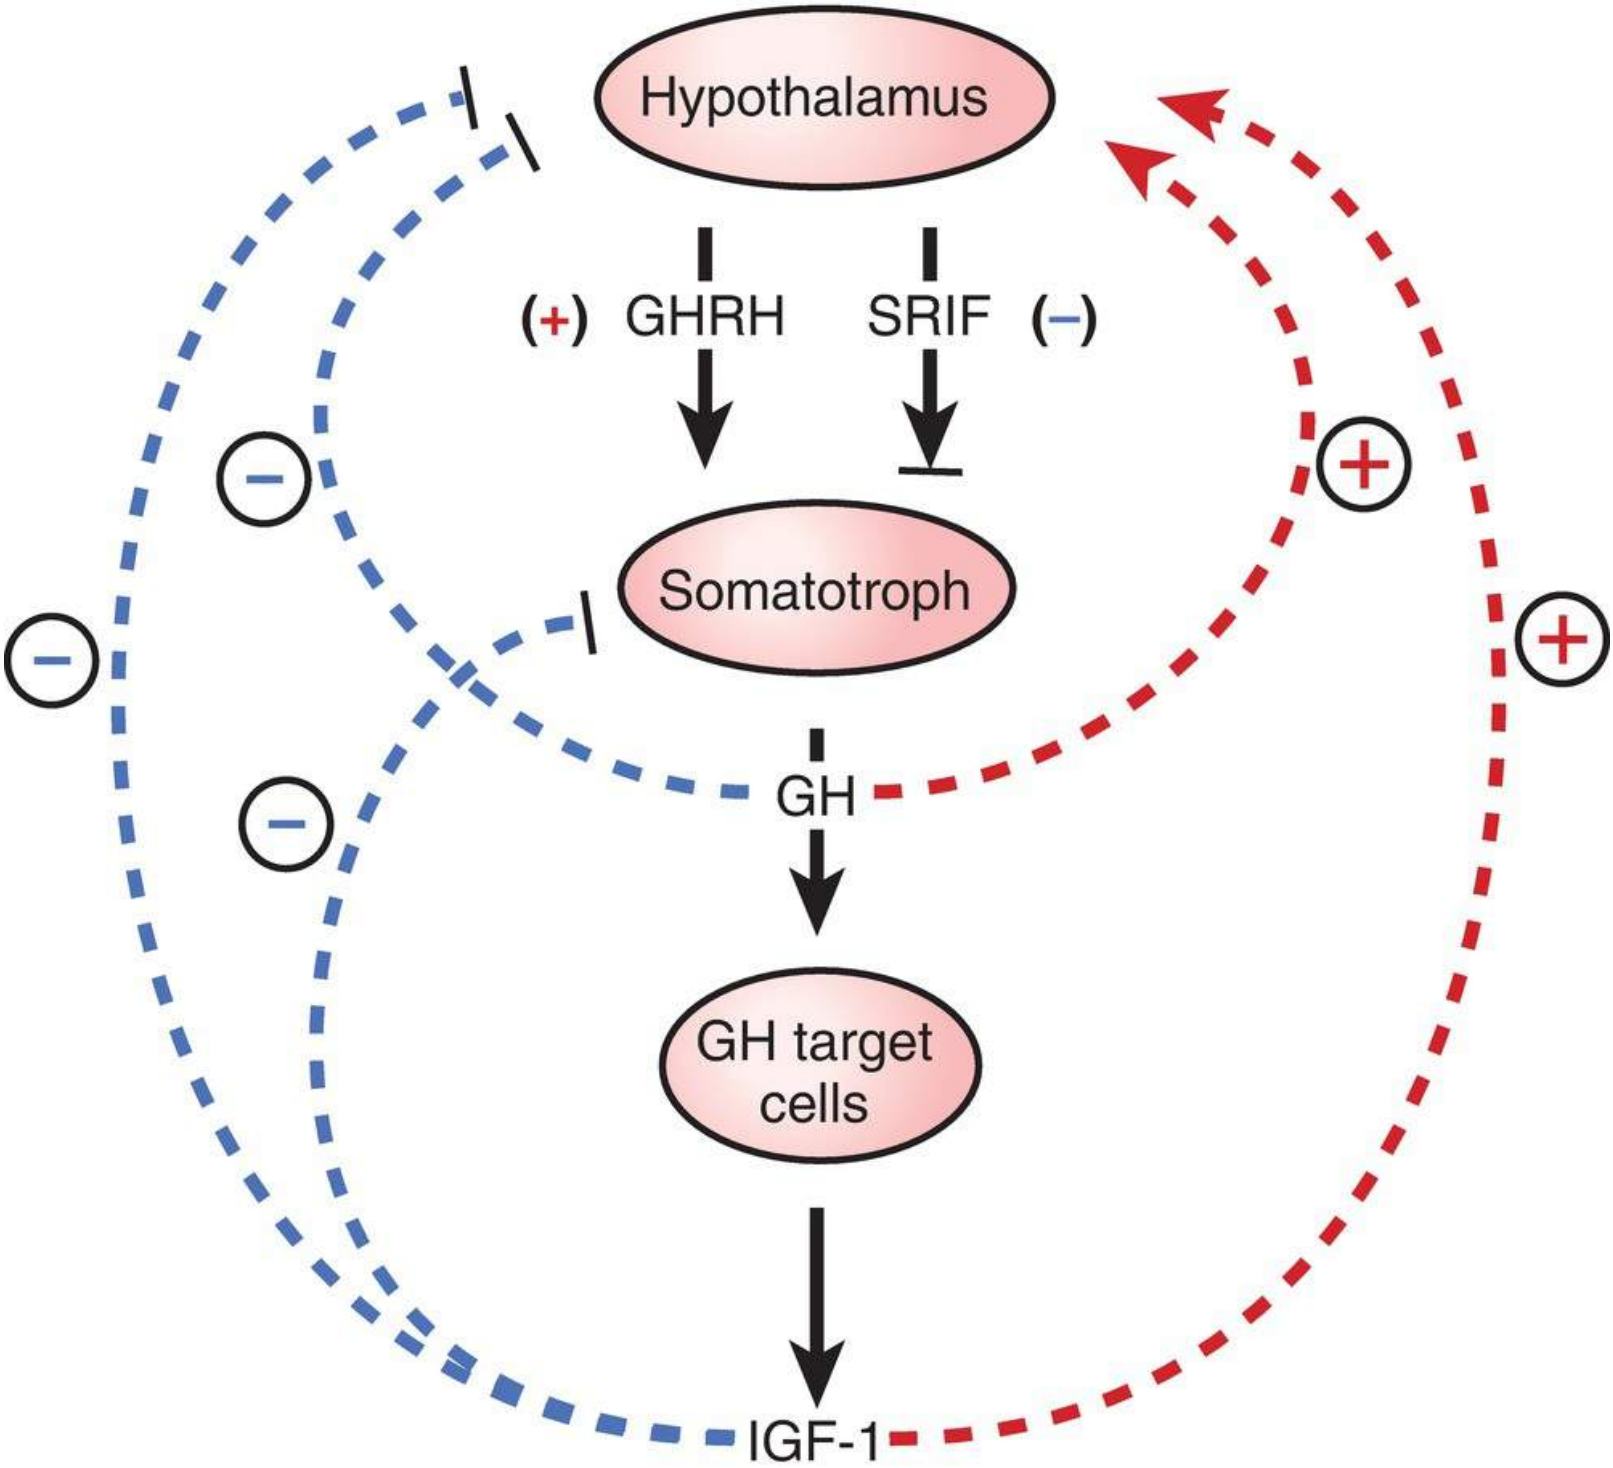

Figure 31.9 The hypothalamic–pituitary–GH axis. Growth hormone–releasing hormone (GHRH) stimulates and somatostatin (SRIF) inhibits growth hormone (GH) secretion by acting directly on the somatotroph. The negative feedback loops shown in *blue* inhibit GHRH secretion and action on the somatotroph, causing a decrease in GH secretion. The positive feedback loops shown in *red* stimulate somatostatin secretion, causing a decrease in GH secretion. IGF-1, insulin-like growth factor 1.

IGF-1 also has a negative feedback effect on the secretion of GH (see Fig. 31.9). It acts directly on the somatotrophs to inhibit the stimulatory action of GHRH on GH secretion. IGF-1 also inhibits GHRH secretion and stimulates the secretion of somatostatin by neurons in the hypothalamus. By stimulating IGF-

1 production, GH inhibits its own secretion. This mechanism is analogous to the way ACTH and TSH regulate their own secretion through the respective negative feedback effects of the glucocorticoid and thyroid hormones. This interactive relationship involving GHRH, somatostatin, GH, and IGF-1 comprises the hypothalamic–pituitary–GH axis.

Growth hormone pulsatile secretory pattern

In humans, GH is secreted in periodic bursts, which produce large but short-lived peaks in GH concentration in the blood. Between these episodes of high GH secretion, somatotrophs release little GH and the blood concentration falls to low levels. It is thought that an increase in the rate of GHRH secretion and a fall in the rate of somatostatin secretion cause these periodic bursts of GH secretion. Increased somatostatin secretion is thought to cause the intervals between bursts, when GH secretion is suppressed. These changes in GHRH and somatostatin secretion result from neural activity generated at higher levels of the CNS, which affects the secretory activity of GHRH and somatostatin-producing neurons in the hypothalamus.

Bursts of GH secretion occur during both the awake and sleep periods of the day; however, GH secretion is maximal at night. The bursts of GH secretion during sleep usually occur within the first hour after the onset of deep sleep (stages 3 and 4 of slow-wave sleep). Mean GH levels in the blood are highest during adolescence (peaking in late puberty) and decline in adults. The reduction in blood GH with aging is mainly a result of a decrease in the size of the GH secretory burst but not the number of pulses (Fig. 31.10).

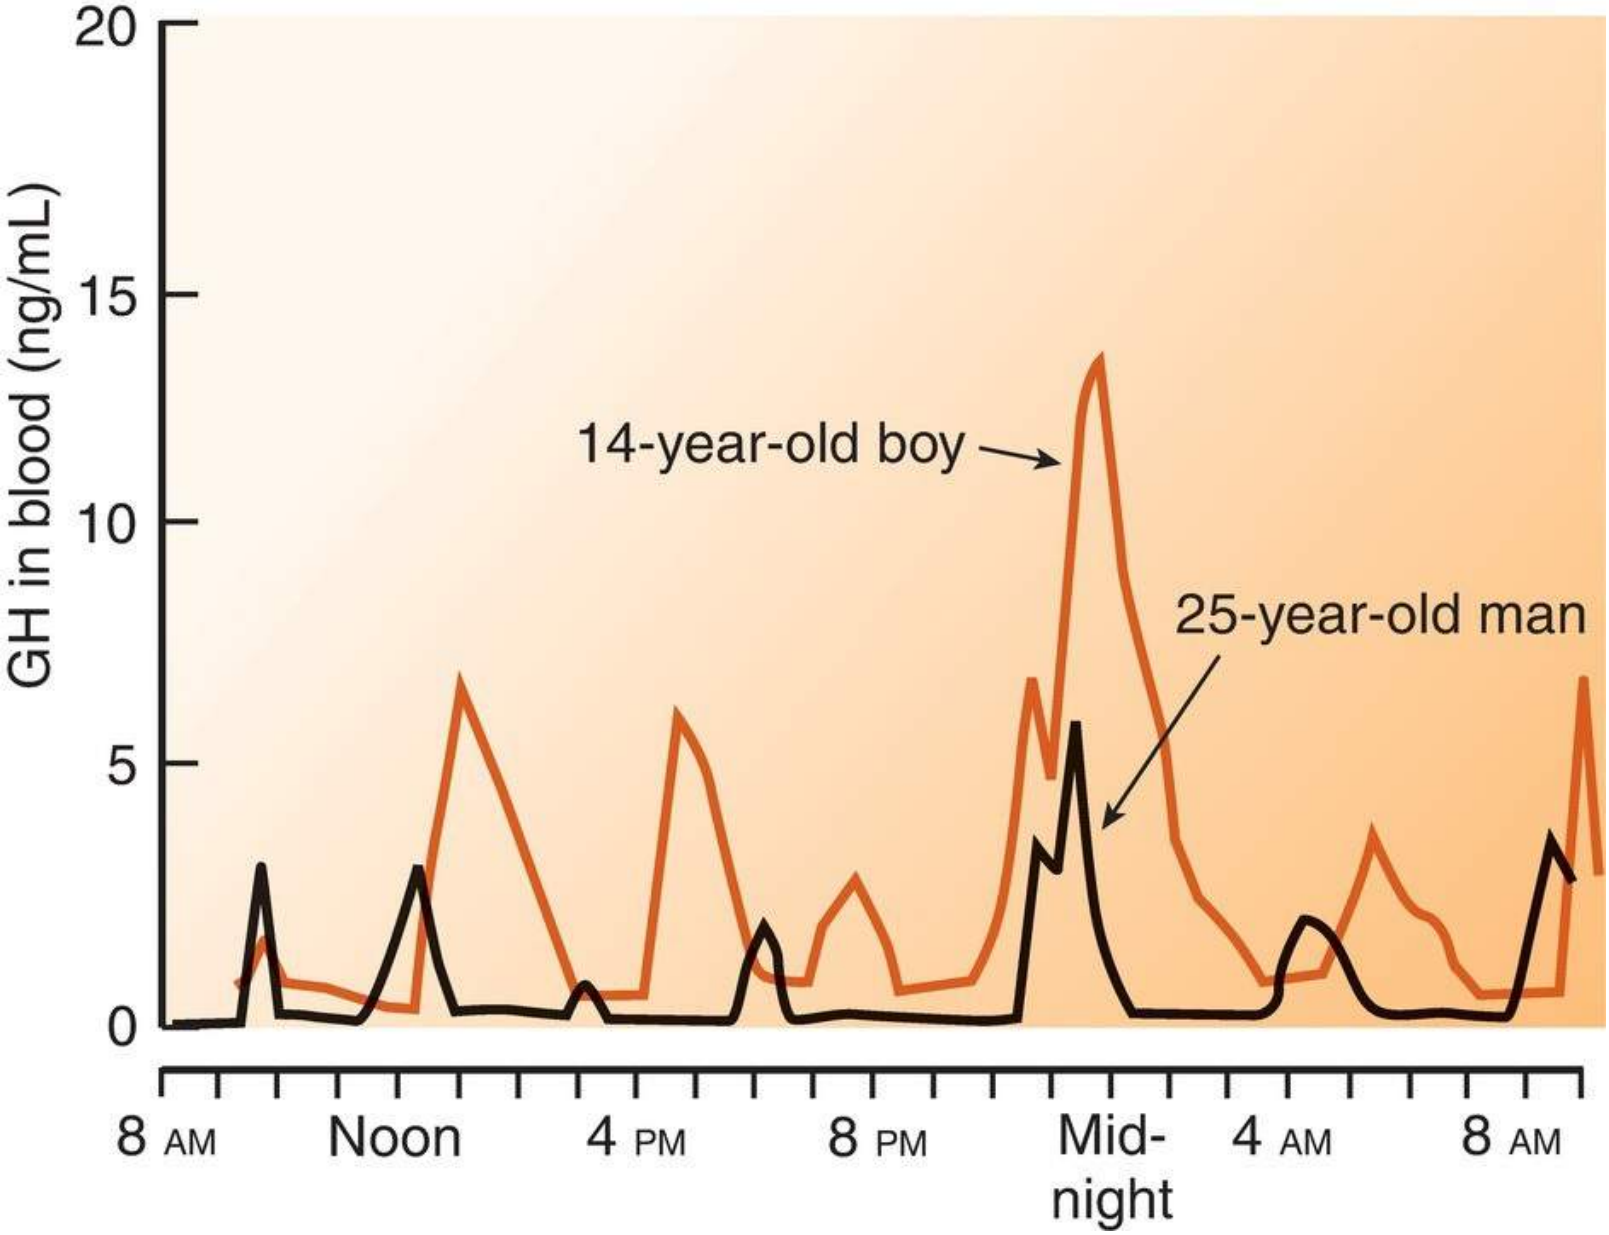

Figure 31.10 Pulsatile growth hormone (GH) secretion in an adolescent boy and in an adult. In the adult, GH levels are reduced as a result of smaller pulse width and amplitude rather than a decrease in the number of pulses.

Many factors affect the rate of GH secretion in humans by changing the hypothalamic neuronal secretion of GHRH and somatostatin. Emotional or physical stress greatly increases the rate of GH secretion, as does vigorous exercise. Obesity results in reduced GH secretion. Changes in the circulating levels of metabolites also affect GH secretion. A decrease in blood glucose stimulates GH secretion, whereas hyperglycemia inhibits it. An increase in the blood concentration of the amino acids arginine and leucine also stimulates GH secretion.

Growth hormone regulation of growth and metabolism

The cells of many tissues and organs of the body have receptors for GH in their plasma membranes through which GH produces its growth-promoting and metabolic effects. The binding of GH to its receptor activates an associated tyrosine kinase (JAK2), which is not an integral part of the GH receptor. Activation of JAK2 initiates changes in the phosphorylation pattern of cytoplasmic and nuclear proteins, ultimately stimulating the transcription of specific genes, including that for IGF-1.

IGF-1 mediates many of the mitogenic effects of GH; however, evidence indicates that GH has direct growth-promoting actions on progenitor or stem cells, such as **prechondrocytes** in the growth plates of bone and **satellite cells** of skeletal muscle. GH stimulates such progenitor cells to differentiate into cells with the capacity to undergo cell division. An important action of GH on the differentiation of progenitor cells is stimulation of IGF-1 gene expression. These cells then produce and release IGF-1, which exerts an autocrine mitogenic action on the cell that produced it or a paracrine action on neighboring cells. In response to IGF-1, these cells undergo division, causing the tissue to grow through cell replication.

GH deficiency in childhood causes a decrease in the rate of body growth. If left untreated, the deficiency results in **pituitary dwarfism**. People with this condition may be deficient in GH only, or they may have multiple anterior pituitary hormone deficiencies. A defect in the mechanisms that control GH secretion or the production of GH by somatotrophs can cause GH deficiency. In some people, the target cells for GH fail to respond normally to the hormone because of several different mutations in the GH receptor.

The excessive secretion of GH during childhood, caused by a defect in the mechanisms regulating GH secretion or a GH-secreting tumor, results in **gigantism**. Affected people may grow to a height of 7 to 8 ft (2.1 to 2.4 m). When excessive GH secretion occurs in an adult, further linear growth does not occur because the growth plates of the long bones have calcified. Instead, it causes the bones of the face, hands, and feet to become thicker and certain organs, such as the liver, to undergo hypertrophy. This condition, known as **acromegaly**, can also result from the chronic administration of excessive amounts of GH to adults.

The main physiologic action of GH is on body growth; however, it also has important effects on certain aspects of fat and carbohydrate metabolism. Its main action on fat metabolism is to stimulate the mobilization of triglycerides from the fat depots of the body. This process, known as **lipolysis**, involves the hydrolysis of triglycerides to fatty acids and glycerol by a number of lipases such as **hormone-sensitive lipase**. The fatty acids and glycerol are released from adipocytes and enter the bloodstream. GH has been shown to directly stimulate lipolysis in some experiments, but most evidence suggests that it causes adipocytes to be more responsive to other lipolytic stimuli, such as fasting and catecholamines.

GH also functions as one of the counterregulatory hormones that limit the actions of insulin on muscle, adipose tissue, and the liver. For example, GH inhibits glucose use by muscle and adipose tissue and increases glucose production by the liver. These effects are opposite those of insulin. GH also makes muscle and fat cells resistant to insulin signaling. Thus, GH normally has a tonic inhibitory effect on insulin action, much like the glucocorticoid hormones (see Chapter 34).

The insulin-opposing actions of GH can produce serious metabolic disturbances in people who secrete excessive amounts of GH (people with acromegaly) or who are given large amounts of GH for an extended time. They may develop insulin resistance and elevated blood insulin levels. They may also exhibit hyperglycemia caused by the inability of insulin to promote glucose utilization by muscle and adipose tissue, coupled with overproduction of glucose by the liver. These disturbances are much like those in people with non–insulin-dependent (type 2) diabetes mellitus. For this reason, this metabolic response to excess GH is called its **diabetogenic action**.

In GH-deficient people, GH has a transitory insulin-like action. For example, intravenous injection of GH in a person who is GH deficient produces hypoglycemia. The hypoglycemia is caused by the ability of GH to stimulate the uptake and use of glucose by muscle and adipose tissue and to inhibit glucose production by the liver. After about 1 hour, the blood glucose level returns to normal. If this person is given a second injection of GH, hypoglycemia does not occur because the person has become insensitive or refractory to the insulin-like action of GH and remains so for some hours. Healthy people do not

respond to the insulin-like action of GH, presumably because they are always refractory from being exposed to their own endogenous GH (Clinical Focus 31.2).

CLINICAL FOCUS 31.2

Growth Hormone Deficiency and Recombinant Human Growth Hormone

Growth hormone (GH) is species specific, and humans do not respond to GH derived from animals. In the past, the only human GH available for treating children who were GH deficient was a limited amount made from human pituitaries obtained at autopsy, but there was never enough to meet the need. Use of pituitary-derived GH was then halted because of concern of a causal relationship between therapy and development of **Creutzfeldt–Jakob disease** (**CJD**), a rare and fatal spongiform encephalopathy. The problems of short supply and potential disease transmission were solved when the gene for human GH was cloned and the production of large amounts of recombinant human GH, with all the activities of the natural substance, became possible. During the 1980s, careful clinical trials established that recombinant human GH was safe to use in GH-deficient children to promote growth. The hormone was approved for clinical use and is now produced and sold worldwide.

Despite the availability of recombinant GH, the diagnosis of GH deficiency has remained controversial. As presented in Figure 31.10, GH release from the pituitary occurs episodically; thus, a random measure of GH in the blood is not useful for diagnosing GH deficiency. However, a random blood sample may be used to detect GH resistance, a syndrome in which the patient exhibits symptoms of GH deficiency but presents with high GH levels in the blood.

Measurement of insulin-like growth factor 1 (IGF-1) and IGF-binding protein 3 (IGFBP3) levels in the blood is a method to assess GH deficiency. IGF-1 mediates many of the mitogenic effects of GH on tissues in the body, and IGF-1 binds to IGFBP3 in the blood. IGFBP3 extends the half-life of the IGF-1, transports it to target cells, and facilitates its interaction with the IGF receptor. GH stimulates the production of IGF-1 and IGFBP3, which are present in the blood at fairly constant, readily detectable levels in healthy people. In children with GH deficiency, the concentrations of IGF-1 and IGFBP3 are low. Treatment with recombinant GH will increase IGF-1 and IGFBP3 in the blood, which will result in increased long bone growth. The epiphyseal growth plate in the bone becomes less responsive to GH and IGF-1 several years after puberty, and long bone growth stops in adulthood (see Chapter 35). GH therapy may be continued after cessation of long bone growth because GH has important metabolic effects, including support of normal gonadal function and attainment of normal adult bone density. ■

Gonadotropins are anterior pituitary hormones that regulate sexual development and reproductive function.

The testes and ovaries have two essential functions in human reproduction. The first is to produce sperm cells and ova (egg cells), respectively. The second is to produce an array of steroid and peptide hormones, which influence virtually every aspect of the reproductive process. The gonadotropic hormones FSH and LH regulate both of these functions. The hypothalamic-releasing hormone LHRH and the hormones produced by the testes and ovaries in response to gonadotropic stimulation, in turn, regulate the production and secretion of the gonadotropins by the anterior pituitary. The regulation of human reproduction by this hypothalamic–pituitary–gonad axis is discussed in Chapters 36 and 37. Here, we describe the chemistry and formation of the gonadotropins.

Like TSH, human FSH and LH are composed of two structurally different glycoprotein subunits, called α and β, which are held together by noncovalent bonds. The β subunit of human FSH consists of a peptide chain of 111 amino acid residues, to which two chains of carbohydrate are attached. The β subunit of human LH is a peptide of 121 amino acid residues. It is also glycosylated with two carbohydrate chains. The combined α and β subunits of FSH and LH give these hormones a molecular size of about 28 to 29 kDa.

As with TSH, the individual subunits of the gonadotropins have no hormonal activity. They must be combined with each other in a 1:1 ratio to have activity. Again, it is the β subunit that gives the gonadotropin molecule either FSH or LH activity because the α subunits are identical.

The same gonadotrophs in the anterior pituitary produce FSH and LH. There are separate genes for the α and β subunits in the gonadotroph; hence, the peptide chains of these subunits are translated from separate mRNA molecules. Glycosylation of these chains begins as they are synthesized and before they are released from the ribosome. The folding of the subunit peptides into their final three-dimensional structure, the combination of an α subunit and a β subunit, and the completion of glycosylation all occur as these molecules pass through the Golgi apparatus and are packaged into secretory granules. As with the thyrotroph, the gonadotroph produces an excess of α subunits over FSH and LH β subunits. Therefore, the rate of β subunit production is considered to be the rate-limiting step in gonadotropin synthesis.

The hormones of the hypothalamic–pituitary–gonad axis regulate the synthesis of FSH and LH. For example, LHRH stimulates gonadotropin production. The steroid and peptide hormones produced by the gonads in response to stimulation by the gonadotropins also affect gonadotropin production. Such hormonally regulated changes in gonadotropin production are caused mainly by changes in the expression of the genes for the gonadotropin subunits. More information about the regulation of gonadotropin synthesis and secretion is found in Chapters 36 and 37.

Prolactin is a peptide hormone that regulates milk secretion from the mammary gland.

Lactation is the final phase of the process of human reproduction. During pregnancy, alveolar cells of the mammary glands develop the capacity to synthesize milk in response to stimulation by many steroid and peptide hormones. Milk synthesis by these cells begins shortly after childbirth. To continue to synthesize milk, PRL must periodically stimulate these cells, and this is thought to be the main physiologic function of PRL in the human female. A role for PRL in the human male is unclear. It is known to have some supportive effect on the action of androgenic hormones on the male reproductive tract, but whether this is an important physiologic function of PRL is not established.

Human PRL is a globular protein consisting of a single peptide chain of 199 amino acid residues with three intrachain disulfide bridges. Its molecular size is about 23 kDa. Human PRL has considerable structural similarity to human GH and to a PRL-like hormone produced by the human placenta called *placental lactogen* (*hPL*). It is thought that these hormones are structurally related because their genes evolved from a common ancestral gene during the course of vertebrate evolution. Because of its structural similarity to human PRL, human GH has substantial PRL-like or lactogenic activity. However, PRL and hPL have little GH-like activity. Human placental lactogen is discussed further in Chapter 38.

PRL is synthesized and secreted by lactotrophs in the anterior pituitary. Synthesized in the RER as a larger peptide, the N-terminal signal peptide sequence of PRL is removed and the 199-amino acid protein passes through the Golgi apparatus and is packaged into secretory granules.

Estrogens and other hormones, such as TRH, increase PRL gene expression and stimulate the synthesis and secretion of PRL. However, dopamine inhibits the synthesis of PRL. Dopamine produced by hypothalamic neurons plays a major role in the regulation of PRL synthesis and secretion by the hypothalamic–pituitary axis. The regulation of the synthesis and secretion of PRL and its physiologic actions are discussed in Chapter 38.

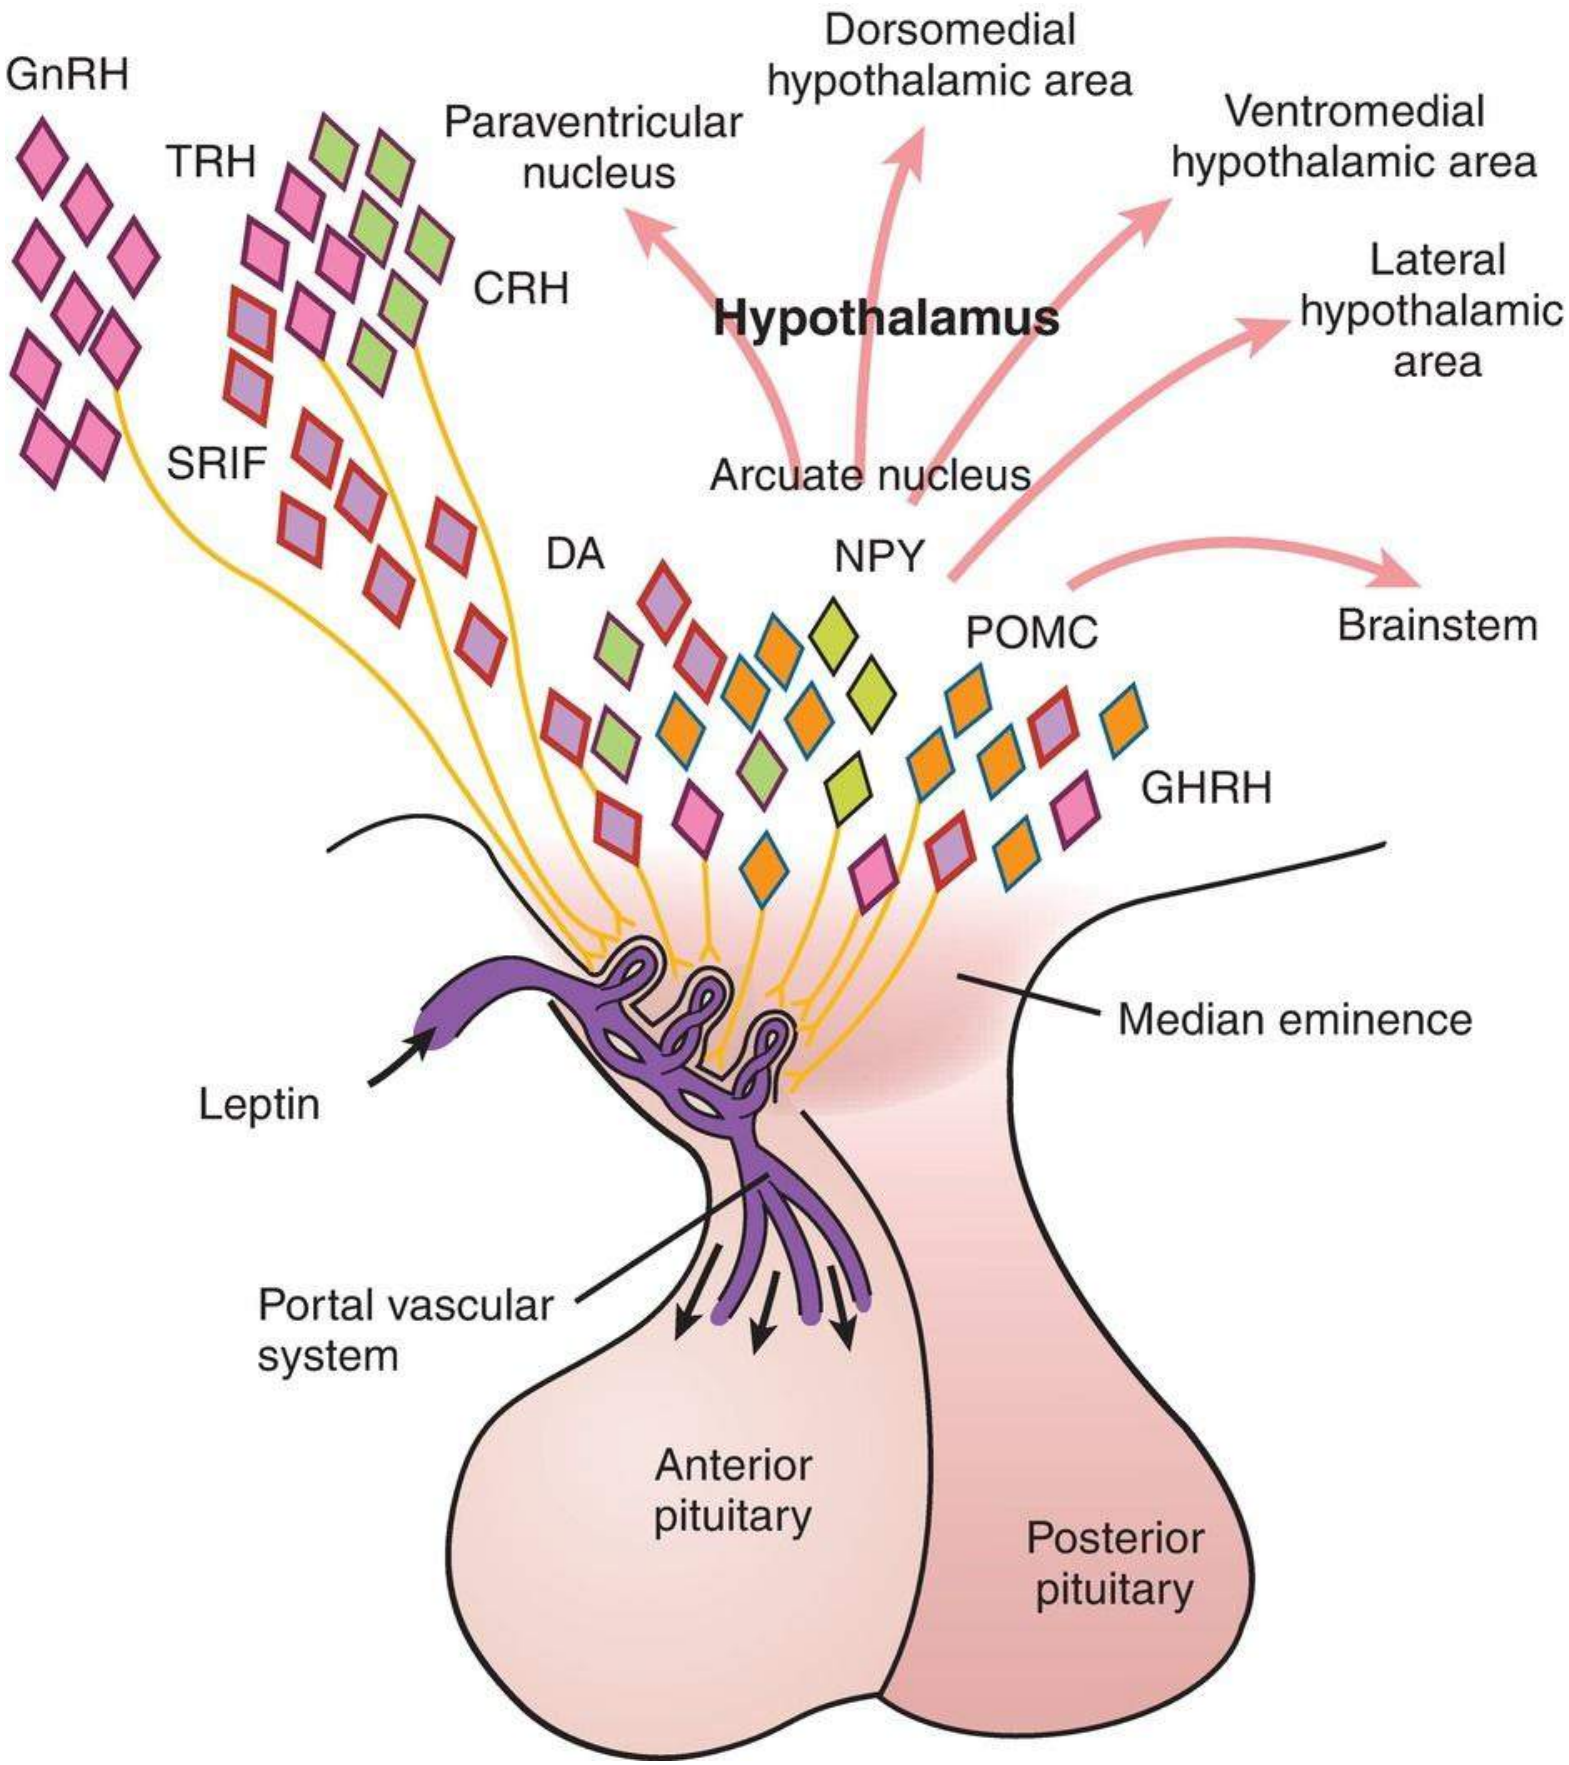
INTEGRATED MEDICAL SCIENCES

Hypothalamic–Pituitary Regulation of Energy Intake and Energy Expenditure

Body weight in adults is fairly stable over many years. This stability in body weight occurs despite large fluctuations in caloric intake, demonstrating that energy intake and energy expenditure are precisely matched. The central nervous system (CNS), primarily the hypothalamus, is responsible for matching energy intake and energy expenditure, receiving information relevant to energy balance through metabolic, neural, and hormonal signals. Some signals regulate energy intake over short time periods, for example, acting to terminate a feeding episode, whereas others are active in the long-term regulation of energy intake, ensuring the maintenance of adequate energy stores. Leptin is a hormone that provides information to the hypothalamus on the amount of energy stored in the body as adipose tissue.

Leptin is a 16-kDa protein product of the *LEP* gene (originally termed *ob* gene), which is most highly expressed in adipose tissue but which is also detectable in other tissues including muscle and placenta. Serum leptin increases as adipose tissue mass increases; thus, leptin is significantly greater in obese subjects than in lean subjects.

The receptor for leptin is detectable in several areas of the CNS but is highly expressed in the arcuate nucleus of the hypothalamus (see Figure). Activation of leptin receptors reduces the expression of neuropeptides that stimulate food intake (neuropeptide Y and agouti-related protein) and increases expression of neuropeptides that reduce feeding (α-melanocyte–stimulating hormone). Administration of exogenous leptin to increase serum levels has been tested as a therapy for weight loss in humans, but leptin treatment had only modest effects on appetite and body weight.



Leptin regulation of hypothalamic–pituitary axis function. TRH, thyrotropin-releasing hormone; GnRH, gonadotropin-releasing hormone; CRH, corticotropin-releasing hormone; SRIF, somatotropin release–inhibitory factor; DA, dopamine; NPY, neuropeptide Y; POMC, proopiomelanocortin; GHRH, growth hormone–releasing hormone.

In addition to regulating food intake, leptin signaling in the hypothalamus also alters anterior

pituitary hormone secretion to influence energy expenditure. Reduced caloric intake and starvation initiate a complex series of biochemical and behavioral adaptations to promote survival, one of which is to reduce whole-body energy expenditure. Thyroid hormones stimulate metabolism and increase energy use (discussed in detail in Chapter 32); thus, it is adaptive to reduce thyroid hormone levels during periods of insufficient food intake. Growth and the ability to reproduce are both energy-intensive processes that are also curtailed during starvation. Although leptin circulates in the blood in proportion to the amount of body fat, serum leptin falls rapidly with restriction of food intake, providing a signal to the hypothalamus to conserve body energy stores. Evidence that leptin coordinates the hypothalamic–pituitary response to starvation was originally derived through replacement experiments in rodents. Preventing the starvation-induced fall in leptin by infusion of recombinant protein blunted the reduction in gonadal, adrenal, and thyroid hormones that would normally occur in starved mice. Similar types of replacement experiments have demonstrated that leptin can regulate anterior pituitary hormone secretion in humans. Thus, leptin may prove useful in treatment of disease resulting from reduced hypothalamic–pituitary function secondary to reductions in adipose tissue mass caused by lipodystrophy or excess energy expenditure such as that in highly trained, female athletes. ■

Chapter Summary

- The hypothalamic–pituitary axis is composed of the hypothalamus, infundibular stalk, posterior pituitary, and anterior pituitary.
- Arginine vasopressin and oxytocin are synthesized in hypothalamic neurons whose axons terminate in the posterior pituitary.
- Arginine vasopressin increases water reabsorption by the kidneys in response to a rise in blood osmolality or a fall in blood volume.
- Oxytocin stimulates milk letdown in the breast in response to suckling and muscle contraction in the uterus in response to cervical dilation during labor.
- Adrenocorticotropic hormone, thyroid-stimulating hormone, growth hormone, follicle-stimulating hormone, luteinizing hormone, and prolactin are synthesized in the anterior pituitary and secreted in response to hypothalamic-releasing hormones carried in the hypophyseal portal circulation.
- Hypothalamic corticotropin-releasing hormone stimulates adrenocorticotropic hormone release from corticotrophs, which, in turn, stimulates glucocorticoid release from the adrenal cortex, to comprise the hypothalamic–pituitary–adrenal axis.
- Glucocorticoids, physical and emotional stress, arginine vasopressin, and the sleep–wake cycle regulate adrenocorticotropic hormone secretion.
- Hypothalamic thyrotropin-releasing hormone stimulates thyroid-stimulating hormone release from thyrotrophs, which, in turn, stimulates triiodothyronine and thyroxine release from the thyroid follicles, to comprise the hypothalamic–pituitary–thyroid axis.
- The thyroid hormones, cold temperatures, and the sleep–wake cycle regulate thyroid-stimulating hormone secretion.
- Hypothalamic growth hormone–releasing hormone increases and hypothalamic somatostatin decreases growth hormone secretion from somatotrophs, which, in turn, stimulate the release of insulin-like growth factor I from liver and other target cells, to comprise the hypothalamic–pituitary–growth hormone axis.
- Growth hormone (GH) itself, insulin-like growth factor I, aging, deep sleep, stress, exercise, and hypoglycemia regulate GH secretion.
- Luteinizing hormone–releasing hormone stimulates the secretion of follicle-stimulating hormone and luteinizing hormone from the anterior pituitary, which, in turn, affects functions of the ovaries and testes, to comprise the hypothalamic–pituitary–reproductive axis.
- Hypothalamic dopamine inhibits prolactin release from lactotrophs in the anterior pituitary.
- Prolactin regulates milk production in the breast.

Chapter Review Questions

1. Which of the following conditions is consistent with a decreased rate of ACTH secretion?

A. Hyperosmolality of the blood
B. Low serum glucocorticoid
C. Loss of hypothalamic neurons
D. Primary adrenal insufficiency
E. Stress as a result of emotional trauma
F. Increased PKA activity in corticotrophs

The correct answer is C. Destruction of the neurons in the paraventricular nuclei of the hypothalamus decreases CRH release, which, in turn, causes decreased synthesis and secretion of ACTH. Hyperosmolality of the blood would lead to an increase in portal blood AVP, which increases ACTH secretion from corticotrophs. Physical or emotional stress increases ACTH release. Glucocorticoids feedback to the hypothalamus and anterior pituitary to decrease ACTH synthesis and secretion. Primary adrenal insufficiency is characterized by a lack of glucocorticoids in the blood, resulting in an increase in ACTH synthesis and secretion. Increased PKA in corticotrophs increases ACTH synthesis and secretion.

2. Which of the following statements most accurately describes the feedback effects of thyroid hormones?

A. They increase the sensitivity of thyrotrophs to TRH.
B. They stimulate transcription of the α and β subunits of TSH in thyrotrophs.
C. They increase the secretion of TSH by thyrotrophs.
D. They stimulate the expression of the GH gene in somatotrophs.
E. They increase IP_3 in thyrotrophs.
F. They increase ACTH release.

The correct answer is D. Thyroid hormones stimulate the expression of the GH gene in somatotrophs. Thyroid hormones exert a negative feedback signal on the hypothalamic–pituitary–thyroid axis to inhibit their own synthesis and secretion. Therefore, thyroid hormones *decrease* the sensitivity of thyrotrophs to TRH, decrease the formation of IP_3 in thyrotrophs, *inhibit* the expression of the genes for the α and β subunits of TSH in thyrotrophs, and *decrease* the secretion of TSH by thyrotrophs. Thyroid hormones have no effect on ACTH release.

3. A 30-year-old woman completed a routine pregnancy with the uncomplicated delivery of a normal-sized baby girl 6 months ago. The woman is currently experiencing galactorrhea (persistent discharge of milklike secretions from the breast) and has not yet resumed regular menstrual periods. The baby had been bottle-fed since birth. What is the most likely explanation of the galactorrhea?

A. Normal postpartum response
B. Excess PRL secretion
C. Insufficient TSH secretion
D. Reduced GH secretion
E. Increased dopamine synthesis in the hypothalamus

The correct answer is C. Galactorrhea is commonly associated with pituitary tumors secreting excess PRL. Prolactin is important in maintaining milk production in the breast after birth. Insufficient LHRH

secretion would result in low levels of PRL, which would not stimulate galactorrhea. Galactorrhea is diagnosed if present longer than 6 months postpartum in a nonnursing mother. The combination of both galactorrhea and amenorrhea is diagnostic of PRL-secreting pituitary tumor. TSH generally has little effect on PRL secretion. GH has lactogenic activity when high not low. Hypothalamic dopamine is an inhibitor of PRL release.

4. A decrease in blood volume would result in an increase in the secretion of:
- **A.** Neurophysin
- **B.** Oxytocin
- **C.** β-lipotropin
- **D.** Somatostatin
- **E.** ACTH
- **F.** POMC

The correct answer is A. Neurophysin is the other product generated when the prohormone for AVP or oxytocin is cleaved. A decrease in blood volume would result in the release of AVP and neurophysin from magnocellular neurons. The hormones oxytocin, β-lipotropin, ACTH, and somatostatin are not involved in the regulation of blood volume.

5. A 50-year-old man complains of decreased muscle strength, libido, and exercise intolerance. Examination reveals a 10% reduction in lean body mass and an increase in body fat, primarily localized to the abdominal region. Thyroid hormone levels are normal. Which diagnosis is most consistent with these symptoms?
- **A.** Glucocorticoid deficiency
- **B.** Addison disease
- **C.** GH deficiency
- **D.** PRL deficiency
- **E.** Acromegaly

The correct answer is C. Growth hormone deficiency in adults is characterized by decreased muscle strength and exercise intolerance, and a reduced sense of well-being (including effects on libido). Lean body mass (muscle) is lost, and excess body fat deposition occurs in the abdominal region. GH replacement can reverse these effects. Thyroid dysfunction is ruled out by the normal thyroid hormone levels. Glucocorticoid deficiency usually results from primary adrenal insufficiency, as in Addison disease. Clinical symptoms include a decreased sense of well-being, gastrointestinal disturbances, and abnormal glucose metabolism. Primary adrenal insufficiency is also characterized by high blood levels of ACTH, which can result in hyperpigmentation due to the melanocyte-stimulating activity of the amino terminal portion of ACTH. Adrenal insufficiency is not usually associated with a redistribution of body fat to central stores. Prolactin does not appear to have a major physiologic effect in human males. Hypoglycemia is a stimulus for GH secretion. Acromegaly results from excessive GH secretion in an adult; the symptoms are not consistent with acromegaly.

Clinical Application Exercises 31.1

GROWTH HORMONE DEFICIENCY

A 6-year-old boy is brought to the endocrine clinic to be evaluated for GH deficiency. The boy's height is between 2 and 3 standard deviations below the average height for his age. Initial physical examination rules out head trauma, chronic illness, and malnutrition. Family history does not suggest

similar short stature in immediate relatives. Thyroid hormones are normal.

QUESTIONS

1. Why would you order a blood test for levels of IGFBP3 and IGF-1?
2. The levels of IGFBP3 and IGF-1 are below the normal range in your patient. What does this finding suggest?
3. What is GH resistance and what test would you order to rule out that the patient does not have this syndrome?
4. Why is it important to treat GH deficiency and short stature prior to the onset of puberty?
5. Why is resistance to insulin action a potential side effect of giving extremely high pharmacologic doses of GH for long periods of time?

ANSWERS

1. GH is released in a pulsatile manner, and between pulses of GH secretion, the concentration in the blood may be undetectable in normal individuals. GH induces the synthesis and secretion of IGF-1 and IGFBP3, both of which are easily detectable in the serum. Low IGF-1 and IGFBP3 would indicate insufficient GH secretion.
2. GH stimulates the synthesis and secretion of IGF-1 and IGFBP3. In most cases, low levels of these molecules in the blood would indicate insufficient GH release. However, low levels of IGF-1 and IGFBP3 could also be due to a defect in the GH receptor resulting in GH resistance.
3. GH resistance is characterized by impaired growth due to very low levels of IGF-1 and IGFBP3 in the blood. However, the concentration of GH in the blood is very high. Defects in the GH receptor, which prevent GH from stimulating the production of IGF-1 and IGFBP3, are a common cause of GH resistance. Measurement of GH in the blood should detect the extremely high levels of the hormone to confirm diagnosis.
4. GH and IGF-1 stimulate the epiphyseal growth plate of the long bones to grow. The epiphyseal plate fuses several years after puberty at which time GH and IGF-1 can no longer stimulate the growth of the bone. Therefore, the earlier GH therapy is initiated, the greater chance of achieving normal adult height before long bone growth stops.
5. GH has diabetogenic actions that oppose the actions of insulin. Thus, chronic, high doses of GH can impair the actions of insulin. Insulin resistance is a condition in which tissues in the body do not respond very well to insulin.

32 Thyroid Gland

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe the function of the thyroid follicles and explain the iodination and coupling reactions catalyzed by the enzyme thyroid peroxidase in the synthesis of the thyroid hormones thyroxine and triiodothyronine.
- Outline how thyroid hormones are released from the thyroid gland.
- Explain the function of thyroid-stimulating hormone in regulating the synthesis and release of thyroid hormones.
- Predict the effect of changes in the concentration of thyroid hormones in the circulation on thyroid-stimulating hormone release from the anterior pituitary.
- Explain the function of the peripheral tissue deiodinases in synthesizing the physiologically active thyroid hormone triiodothyronine.
- Describe how triiodothyronine interacts with its receptor and activates transcription of target genes.
- Outline the effects of thyroid hormones on central nervous system development, growth hormone release, and target tissues such as bone.
- Explain how thyroid hormone regulates basal metabolic rate and intermediary metabolism.
- Predict the effects of excess thyroid hormone and thyroid hormone deficiency on metabolic rate, mental status, and body weight.

At the cellular level, the rate of metabolic processes is tightly regulated. The cell not only meets its basic metabolic “housekeeping” needs but also remains poised to do its own special work in the body, such as conducting nerve impulses and contracting, absorbing, and secreting. During its life span, the cell continues to make the enzymatic and structural proteins that ensure the maintenance of an appropriate rate of metabolism.

The thyroid hormones, **thyroxine (T_4)** and **triiodothyronine (T_3)**, play key roles in the regulation of body development and govern the rate at which metabolism occurs in individual cells. These hormones are not essential for life, but without them, cellular housekeeping moves at a slower pace, eventually influencing the ability of individual cells to carry out their physiologic functions. The thyroid hormones exert their regulatory functions by influencing gene expression and affecting the developmental program and amount of cellular constituents needed for the normal rate of metabolism.

THYROID HORMONE SYNTHESIS, SECRETION, AND METABOLISM

The human thyroid gland consists of two lobes attached to either side of the trachea by connective tissue. A band of thyroid tissue, the isthmus, lies just below the cricoid cartilage and connects the two lobes. The thyroid gland is one of the largest endocrine glands in the body, weighing about 20 g in a healthy adult.

Each lobe of the thyroid receives its arterial blood supply from a superior and an inferior thyroid artery, which arise from the external carotid and subclavian arteries, respectively. Blood leaves the lobes of the thyroid by a series of thyroid veins that drain into the external jugular and innominate veins. This circulation provides a rich blood supply to the thyroid gland, giving it a higher rate of blood flow per gram than even that of the kidneys.

The thyroid gland receives adrenergic innervation from the cervical ganglia and cholinergic innervation from the vagus nerves. This innervation regulates vasomotor function to increase the delivery of **thyroid-stimulating hormone (TSH)**, iodide, and metabolic substrates to the thyroid gland. The adrenergic system can also affect thyroid function by direct effects on the cells.

Follicles within the thyroid gland synthesize and secrete thyroxine and triiodothyronine.

The lobes of the thyroid gland consist of aggregates of many spherical **follicles**, lined by a single layer of epithelial cells (Fig. 32.1). Microvilli cover the apical membranes of the follicular cells, which face the lumen. Pseudopods formed from the apical membrane extend into the lumen. Tight junctions, which provide a seal for the contents of the lumen, connect the lateral membranes of the follicular cells. The basal membranes of the follicular cells are close to the rich capillary network that penetrates the stroma between the follicles.

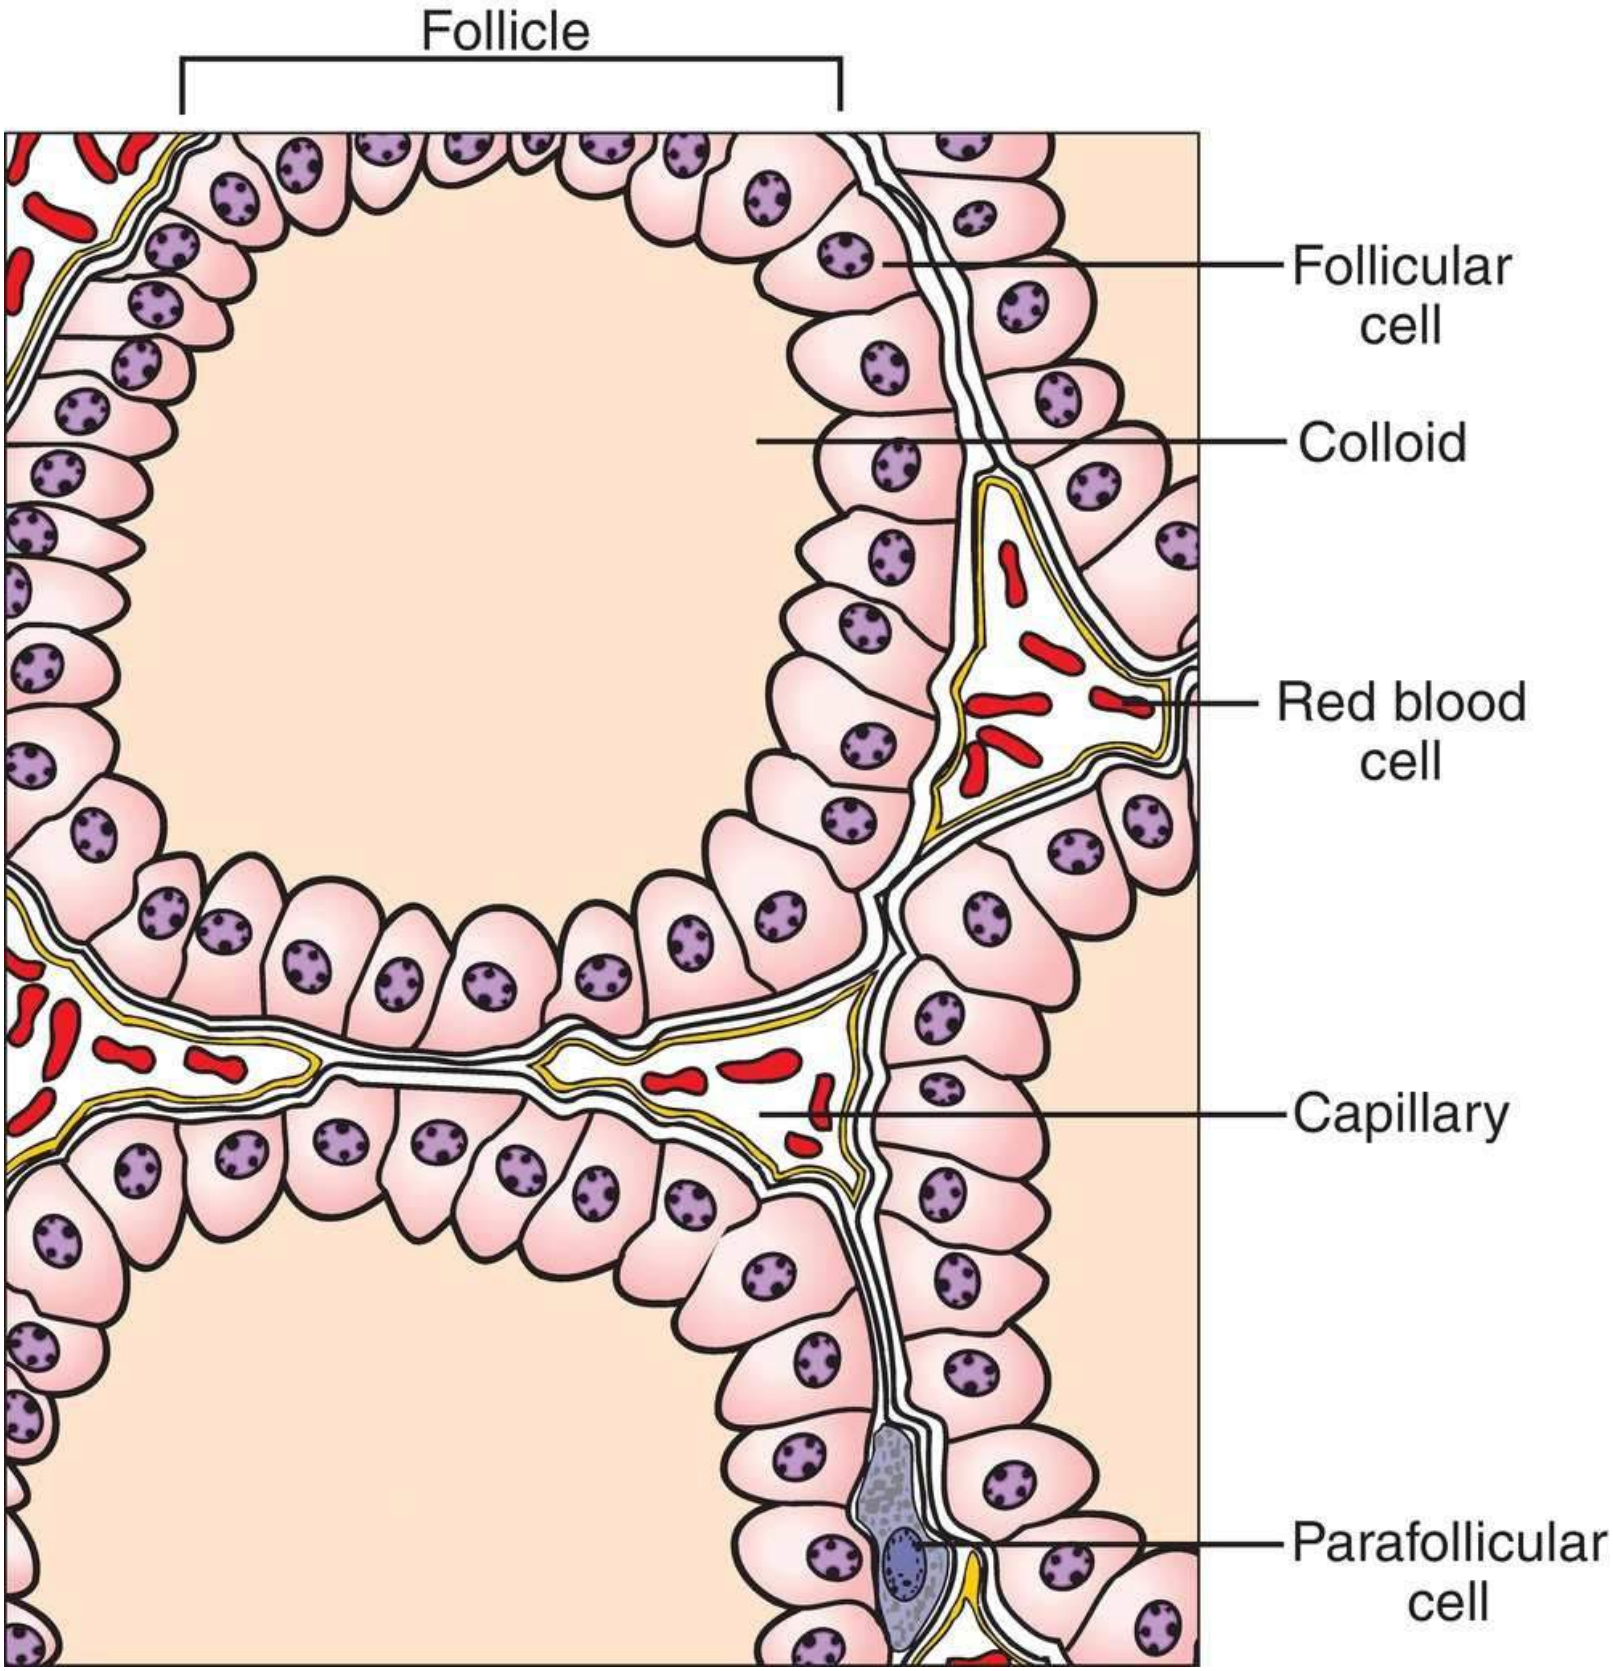

Figure 32.1 A cross-sectional view through a portion of the human thyroid gland. (See text for details.)

The lumen of the follicle contains a high viscosity, proteinaceous gel-like substance called **colloid** (see Fig. 32.1). The colloid is a solution composed primarily of **thyroglobulin (Tg)**, a large protein that is a storage form of the thyroid hormones.

The thyroid follicle produces and secretes two thyroid hormones, T_4 and T_3. The molecular structures of these hormones are shown in Figure 32.3. T_4 and T_3 are iodinated derivatives of the amino acid

tyrosine, formed by an ether linkage between the phenyl rings of two iodinated tyrosine molecules. The resulting structure is called an **iodothyronine**.

T_4 contains four iodine atoms on the 3, 5, 3′, and 5′ positions of the thyronine ring structure, whereas T_3 has only three iodine atoms, at ring positions 3, 5, and 3′ (see Fig. 32.3). Thus, thyroxine is usually abbreviated as T_4 and triiodothyronine as T_3.

Parafollicular cells in the wall of the thyroid follicle synthesize calcitonin.

In addition to the epithelial cells that secrete T_4 and T_3, the wall of the thyroid follicle contains a few **parafollicular cells** (see Fig. 32.1). The parafollicular cell is usually embedded in the wall of the follicle, inside the basal lamina surrounding the follicle, and its plasma membrane does not form part of the wall of the lumen. Parafollicular cells produce and secrete the hormone calcitonin. The effects of calcitonin on calcium metabolism are discussed in Chapter 35.

Follicular cells synthesize and store iodinated thyroglobulin within the follicle.

The thyroid follicle does not directly synthesize T_4 and T_3 in their final form. Rather, T_4 and T_3 are formed by chemical modification of tyrosine residues in the peptide structure of Tg as the follicular cells secrete it into the follicle lumen. Thus, the T_4 and T_3 formed by this chemical modification are actually part of the amino acid sequence of Tg.

The high concentration of Tg in the colloid provides a large reservoir of stored thyroid hormones for later processing and secretion by the follicle. The synthesis of T_4 and T_3 is completed when Tg is retrieved through **pinocytosis** of the colloid by the follicular cells. Lysosomal enzymes then hydrolyze Tg to its constituent amino acids, releasing T_4 and T_3 molecules from their peptide linkage for secretion into the blood.

The steps involved in the synthesis of iodinated Tg are shown in Figure 32.2. This process involves the synthesis of a thyroglobulin precursor, the uptake of iodide, and the formation of iodothyronine residues.

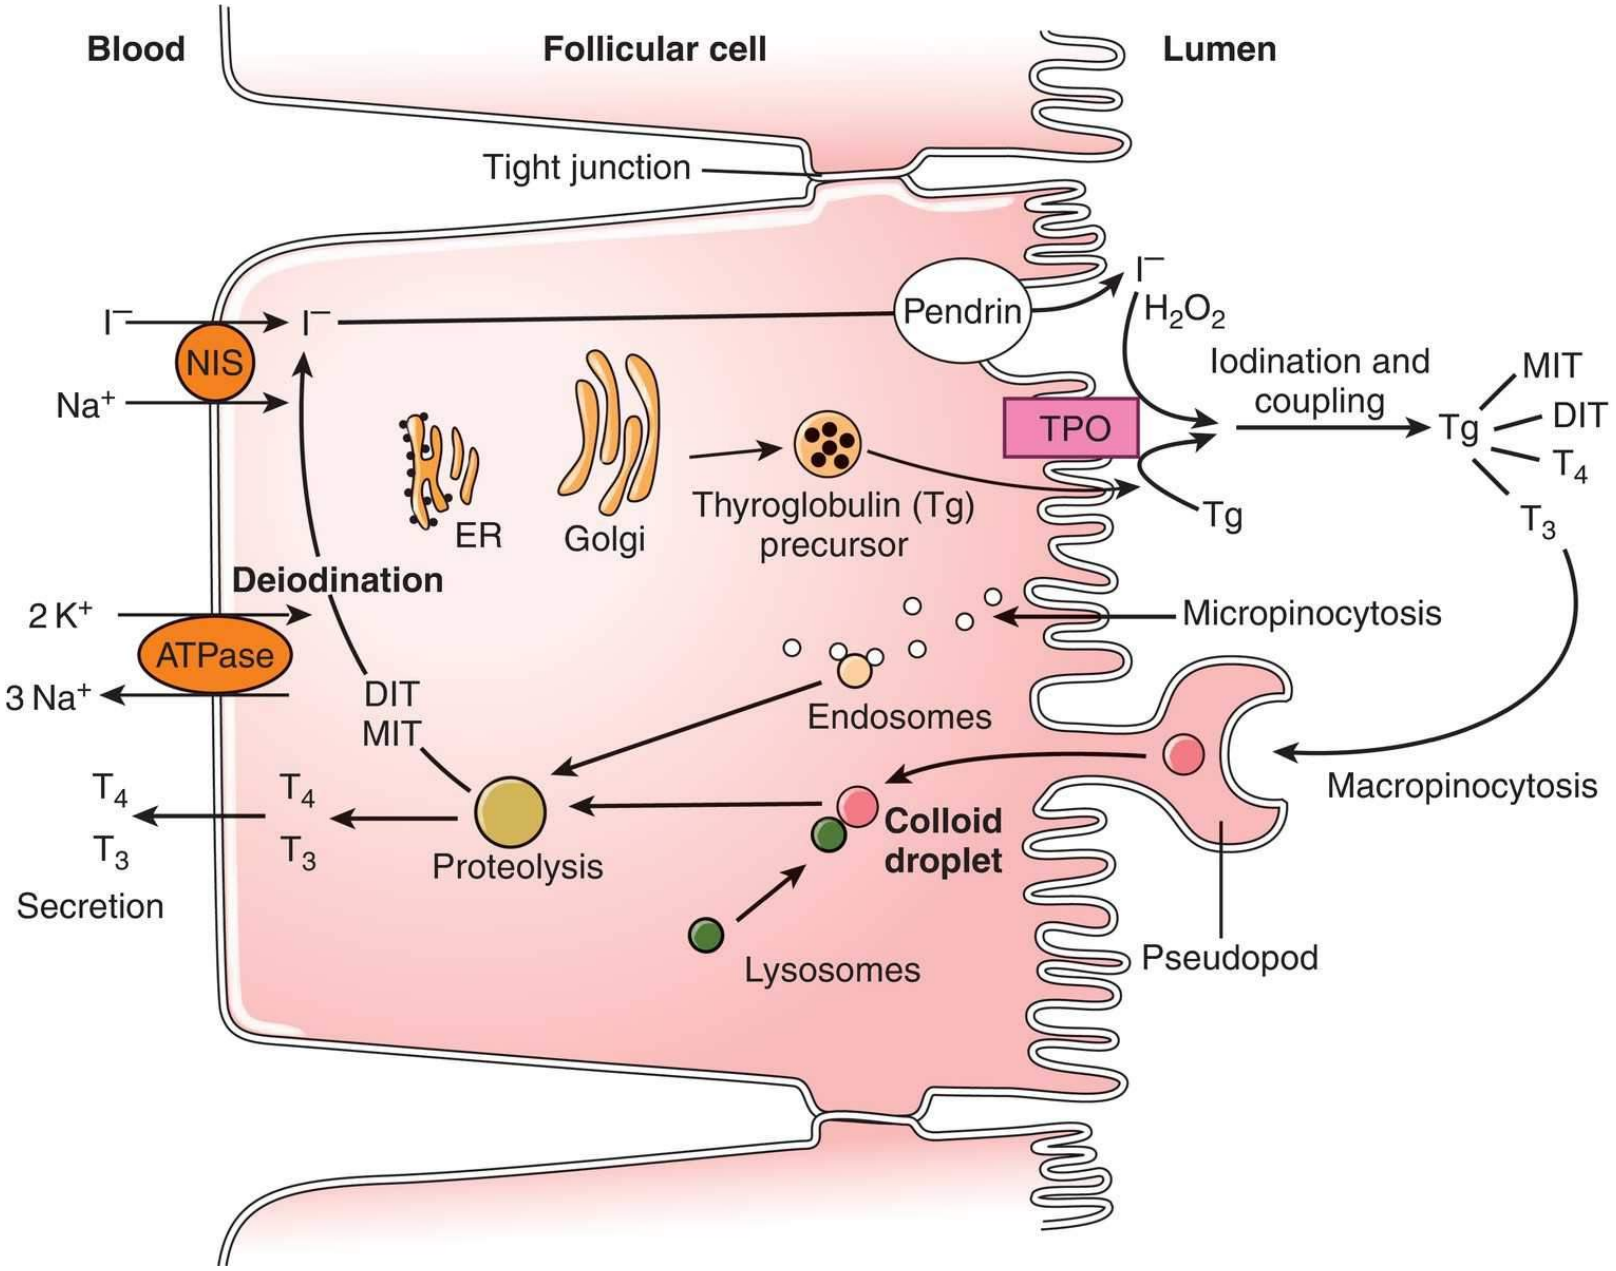

Figure 32.2 Thyroid hormone synthesis and secretion. (See text for details.) ATPase, adenosine triphosphatase; DIT, diiodotyrosine; MIT, monoiodotyrosine; T_3, triiodothyronine; T_4, thyroxine; NIS, sodium–iodide symporter; TPO, thyroid peroxidase.

Thyroglobulin precursor protein

The first step in the formation of T_4 and T_3 is the synthesis of the protein precursor for Tg. This 660-kDa glycoprotein is composed of two similar 330-kDa subunits held together by disulfide bridges. Ribosomes synthesize the subunits on the rough endoplasmic reticulum (ER), which then undergo dimerization and glycosylation in the smooth ER. The Golgi apparatus packages the completed glycoprotein into vesicles. These vesicles migrate to, and fuse with, the apical membrane of the follicular cell. Thyroglobulin precursor protein is then extruded onto the apical surface of the cell, where iodination takes place.

Iodide uptake and release

The iodide used for iodination of the thyroglobulin precursor protein comes from the blood perfusing the thyroid gland. The **sodium–iodide symporter** (**NIS**) is located on the basal plasma membrane of the follicular cell, near the capillaries that supply the follicle (see Fig. 32.2). The NIS uses a sodium gradient

across the basal membrane to transport one iodide atom along with two Na^+ ions into the cytosol of the follicular cell. Although NIS does not require ATP to transport iodide, the Na^+/K^+-ATPase is required to pump Na^+ back out of the cell and to maintain the Na^+ gradient. The NIS also transports other anions, such as bromide, thiocyanate, and perchlorate, across the basal membrane, and these can be used to reduce iodide uptake by the gland. Through the activity of NIS, the follicular cell concentrates iodide many times higher than the concentration of iodide in the blood; thus, follicular cells are efficient extractors of the small amount of iodide circulating in the blood. Once inside follicular cells, the iodide ions diffuse rapidly to the apical membrane, where **pendrin** transports it into the follicle to be used for iodination of the thyroglobulin precursor.

Thyroid peroxidase

The addition of one or two iodine atoms to certain tyrosine residues in the thyroglobulin precursor protein, a process termed **organification**, is the next step in Tg synthesis. The precursor protein contains 134 tyrosine residues, but only a small fraction of these become iodinated. A typical Tg molecule contains only 20 to 30 atoms of iodine.

The enzyme **thyroid peroxidase** (**TPO**), which is bound to the apical membrane of the follicular cells, catalyzes the iodination of Tg. TPO binds an iodide ion and a tyrosine residue in the thyroglobulin precursor, bringing them in close proximity. The enzyme oxidizes the iodide ion and the tyrosine residue to short-lived free radicals, using hydrogen peroxide that has been generated within the mitochondria of follicular cells. The free radicals then undergo addition to form a **monoiodotyrosine** (**MIT**) residue, which remains in peptide linkage in the thyroglobulin structure. This same enzymatic process may add a second iodine atom to a MIT residue, forming a **diiodotyrosine** (**DIT**) residue.

Iodinated tyrosine residues that are close together in the thyroglobulin precursor molecule undergo a **coupling reaction**, which forms the iodothyronine structure. TPO, the same enzyme that initially oxidizes iodine, is believed to catalyze the coupling reaction through the oxidation of neighboring iodinated tyrosine residues to short-lived free radicals. These free radicals undergo addition to produce an iodothyronine residue and a **dehydroalanine residue**, both of which remain in peptide linkage in the Tg structure. For example, when two neighboring DIT residues couple by this mechanism, T_4 is formed. After being iodinated, the Tg molecule is stored as part of the colloid in the lumen of the follicle (see Fig. 32.2).

Only about 20% to 25% of the DIT and MIT residues in Tg become coupled to form iodothyronines. Thus, a typical Tg molecule contains five to six uncoupled residues of DIT and two to three residues of T_4. However, T_3 is formed in only about one of five Tg molecules. As a result, the thyroid secretes substantially more T_4 than T_3.

Follicular cells phagocytose and hydrolyze thyroglobulin to secrete thyroid hormones.

When the thyroid gland is stimulated to secrete thyroid hormones, vigorous pinocytosis occurs at the apical membrane of follicular cells. Pseudopods from the apical membrane reach into the lumen of the follicle, engulfing bits of the colloid (see Fig. 32.2). Endocytotic vesicles formed by this pinocytotic activity migrate toward the basal region of the follicular cell. Lysosomes mainly located in the basal region of resting follicular cells migrate toward the apical region of the stimulated cells. The lysosomes fuse with the Tg-containing droplet and hydrolyze the Tg to its constituent amino acids. As a result, T_4, T_3, and the other iodinated amino acids are released into the cytosol. The T_4 and T_3 formed from the hydrolysis of Tg are released from the follicular cell and enter the nearby capillary circulation. The DIT and MIT generated by the hydrolysis of Tg are rapidly deiodinated, and the released iodide is reused for the continued iodination of Tg (see Fig. 32.2).

Most of the T_4 and T_3 molecules that enter the bloodstream (~70% and 80%, respectively) become noncovalently bound to **thyroxine-binding globulin** (**TBG**), a 54-kDa glycoprotein that is synthesized and secreted by the liver. Each molecule of TBG has a single binding site for a thyroid hormone molecule. The remaining T_4 and T_3 in the blood are bound to **transthyretin** or to albumin. Less than 1% of the blood T_4 and T_3 is in the free form, which is in equilibrium with the large protein-bound fraction. It is this small amount of free thyroid hormone that interacts with target cells.

The protein-bound T_4 and T_3 represent a large reservoir of preformed hormone that can replenish the small amount of circulating free hormone as it is cleared from the blood. This reservoir provides the body with a buffer against drastic changes in circulating thyroid hormone levels as a result of sudden changes in the rate of T_4 and T_3 secretion. The protein-bound T_4 and T_3 molecules are also protected from metabolic inactivation and excretion in the urine; thus, thyroid hormones have long half-lives in the bloodstream. The half-life of T_4 is about 7 days; the half-life of T_3 is about 1 day.

Peripheral tissues metabolize thyroid hormones.

Deiodination reactions in the peripheral tissues both activate and inactivate thyroid hormones. The enzymes that catalyze the various deiodination reactions are regulated, resulting in different thyroid hormone concentrations in various tissues under different physiologic and pathophysiologic conditions.

Thyroxine conversion to triiodothyronine

As noted earlier, T_4 is the major secretory product of the thyroid gland and is the predominant thyroid hormone in the blood. About 40% of the T_4 secreted by the thyroid gland is converted to T_3 by enzymatic removal of the iodine atom at position 5′ of the thyronine ring structure in a reaction termed **outer-ring deiodination** (Fig. 32.3). **Deiodinase type 1** (**D1**) located in the liver, kidneys, and thyroid gland catalyzes this reaction. The T_3 formed by this deiodination and that secreted by the thyroid reacts with **thyroid hormone receptors** (**TRs**) in target cells; therefore, T_3 is the physiologically active form of the thyroid hormones. Skeletal muscle, the central nervous system (CNS), the pituitary gland, and the placenta contain **deiodinase type 2** (**D2**). D2 is believed to function primarily to maintain intracellular T_3 in target tissues, but it may also contribute to the generation of circulating T_3. A third **deiodinase** (**type 3** or **D3**) catalyzes **inner-ring deiodination** reactions during degradation of thyroid hormones as discussed below. All of the deiodinases contain **selenocysteine** in the active center. This rare amino acid has properties that make it ideal for catalysis of oxidoreductive reactions.

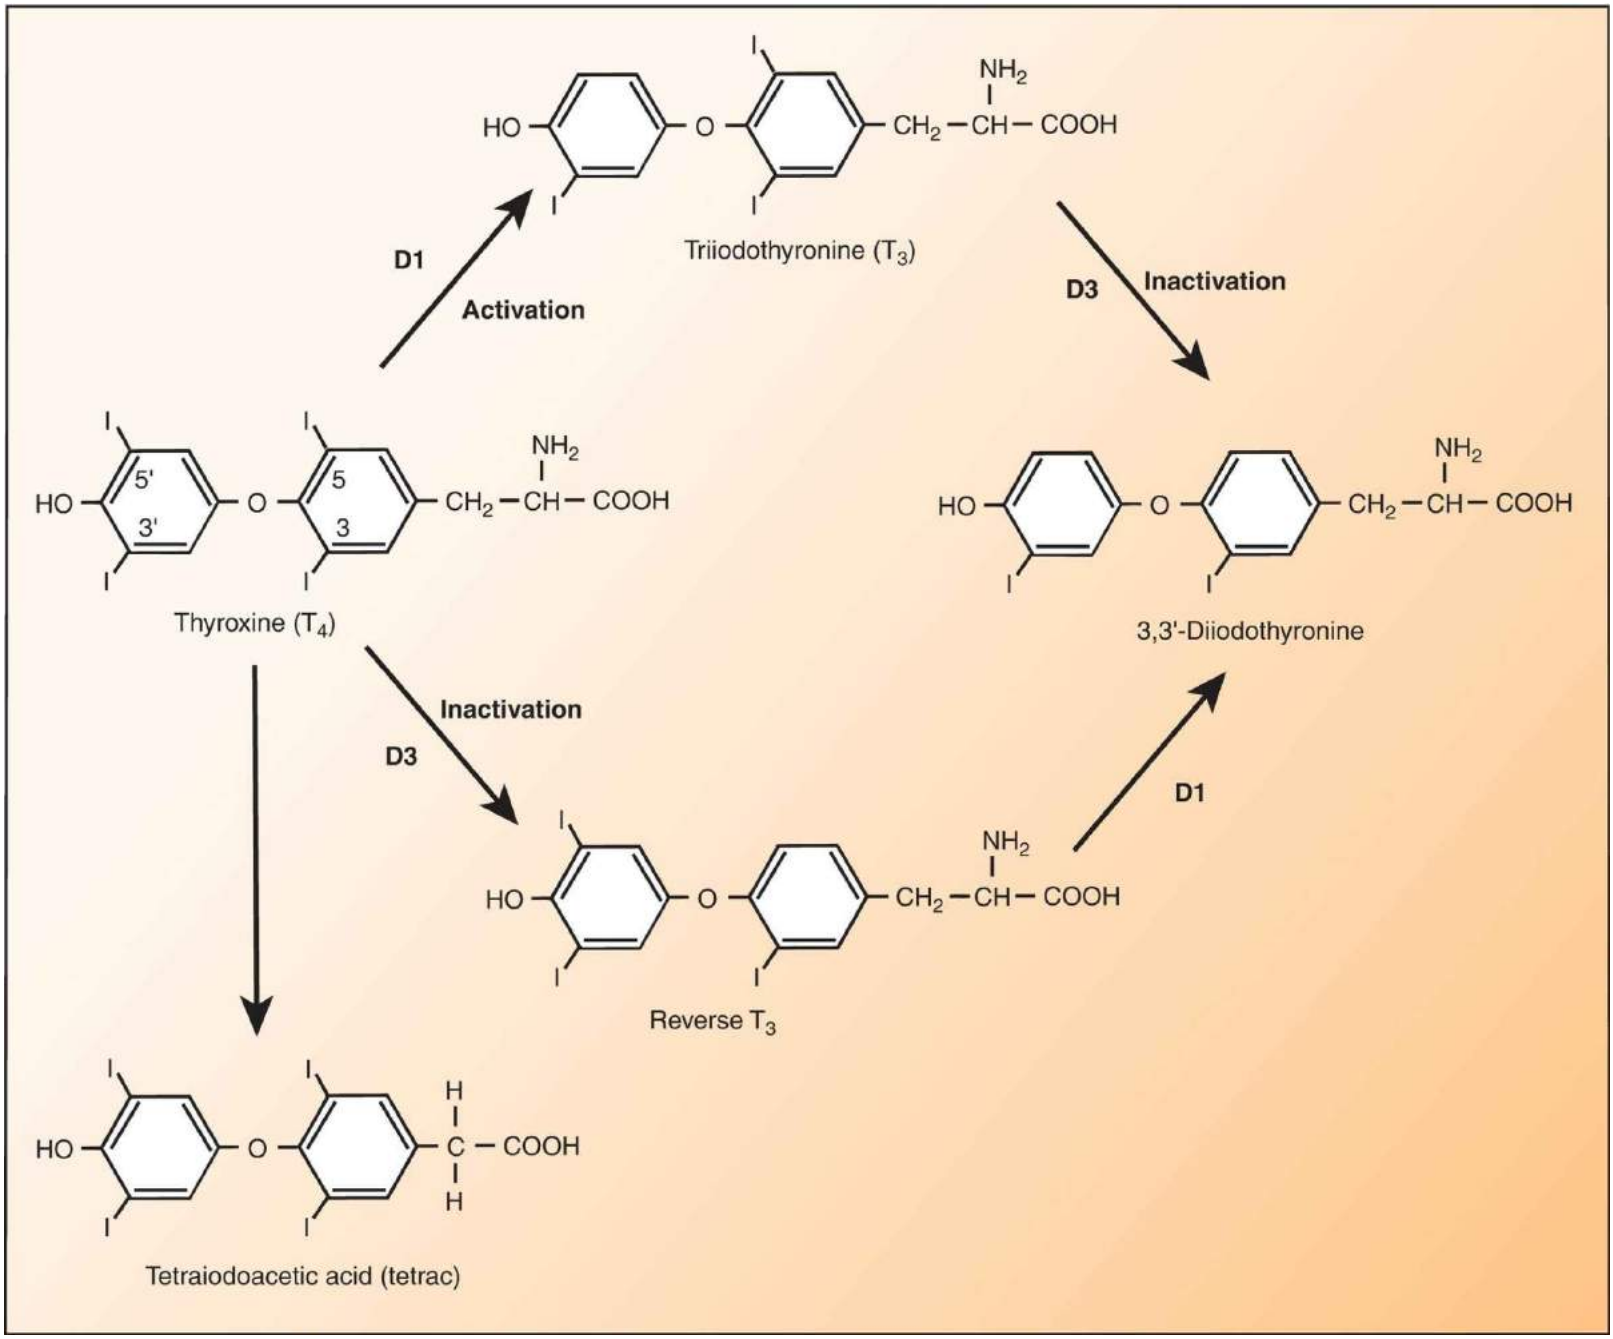

Figure 32.3 The metabolism of thyroxine. Deiodinase type 1 (D1) deiodinates thyroxine (T_4) at the 5′ position to form triiodothyronine (T_3), the physiologically active thyroid hormone. Deiodinase type 3 (D3) also enzymatically deiodinates some T_4 at the 5′ position to form the inactive metabolite, reverse T_3. T_3 and reverse T_3 undergo additional deiodinations to 3,3′-diiodothyronine before being excreted. A small amount of T_4 is also decarboxylated and deaminated to form the metabolite, tetraiodoacetic acid (tetrac), which may then be deiodinated before being excreted.

Thyroxine and triiodothyronine inactivation

Whereas the 5′-deiodination of T_4 to produce T_3 can be viewed as a metabolic activation process, both T_4 and T_3 undergo enzymatic deiodinations, particularly in the liver and kidneys, which inactivate them (see Fig. 32.3). About 40% of the T_4 secreted by the human thyroid gland is deiodinated at the fifth position on the thyronine ring structure by D3 to produce **reverse T_3 (rT_3)**, which has little or no thyroid hormone activity. This deiodination reaction is the major pathway for T_4 metabolic inactivation and disposal. T_3

and rT_3 also undergo deiodination to yield 3,3′-diiodothyronine, which may be further deiodinated before being excreted.

Both physiologic and pathologic factors influence the 5′-deiodination reaction, changing the relative amounts of T_3 and rT_3 produced from T_4. For example, a human fetus produces less T_3 from T_4 than does a child or adult because the 5′-deiodination reaction is less active in the fetus. During fasting, 5′-deiodination is inhibited, particularly in response to carbohydrate restriction, but it is restored to normal when the person is fed again. Trauma and acute and chronic illnesses also suppress the 5′-deiodination reaction. Under all of these circumstances, the amount of T_3 produced from T_4 is reduced and its blood concentration falls. The amount of rT_3 rises in the circulation, not because its conversion from T_4 is increased, as originally believed, but rather because its clearance from the blood is reduced.

Note that during fasting or in the disease states mentioned above, the secretion of T_4 is usually not increased, despite the decrease of T_3 in the circulation. This response is likely a result of the fact that D2 in the CNS and pituitary is not affected under these conditions and continues to produce T_3 in quantities sufficient to maintain relatively normal hypothalamic–pituitary–thyroid axis function.

Thyroxine glucuronidation, decarboxylation, and deamination

T_4 and to a lesser extent T_3 are catabolized by conjugation with glucuronic acid in the liver. The conjugated hormones are secreted into the bile and eliminated in the feces. Many tissues also catabolize thyroid hormones by modifying the three-carbon side chain of the iodothyronine structure via decarboxylation and deamination. The derivatives formed from T_4, such as **tetraiodoacetic acid** (**tetrac**), may also undergo deiodination before being excreted (see Fig. 32.3).

Thyroid hormone synthesis and secretion are controlled by the anterior pituitary.

When the concentrations of free T_4 and T_3 fall in the blood, the anterior pituitary gland is stimulated to secrete TSH, raising the concentration of TSH in the blood. This results in increased binding of TSH to its receptors on thyroid follicular cells.

The TSH receptor is a seven-transmembrane glycoprotein located on the basal plasma membrane of the follicular cell. G_s proteins couple these receptors to the adenylyl cyclase–cyclic adenosine monophosphate (cAMP)–protein kinase A pathway; however, there is also evidence for effects via phospholipase C (PLC), inositol trisphosphate, and diacylglycerol (see Chapter 2). The physiologic importance of TSH-stimulated phospholipid metabolism in human follicular cells is unclear, because high concentrations of TSH are needed to activate PLC.

Thyroid-stimulating hormone promotion of thyroid hormone secretion

By increasing cAMP, TSH stimulates synthesis of NIS and uptake of iodide by follicular cells, the iodination of tyrosine residues in the thyroglobulin precursor, and the coupling of iodinated tyrosines to form iodothyronines. Moreover, TSH promotes the pinocytosis of colloid by the apical membranes, resulting in a large increase in endocytosis and hydrolysis of thyroglobulin. The overall result of these effects of TSH is an increased release of T_4 and T_3 into the blood. In addition, TSH rapidly increases energy metabolism in the thyroid follicular cell.

Thyroid-stimulating hormone regulation of thyroid gland growth

Over the long term, TSH promotes protein synthesis in thyroid follicular cells to maintain their size and structural integrity. Evidence of this trophic effect of TSH is seen in the hypophysectomized patient, in whom the thyroid gland atrophies as a result of a reduction in the height of the follicular cells. In contrast, chronic exposure to excessive amounts of TSH causes an increase in follicular cell height and number, resulting in an enlarged thyroid gland called **goiter**. The trophic and proliferative effects of TSH on the thyroid are mediated by cAMP.

Dietary iodide is essential for the synthesis of thyroid hormones.

A continual supply of iodide is required for the synthesis of T_4 and T_3. If the diet is severely deficient in iodide, as in some parts of the world, the amount of iodide available to the thyroid gland limits T_4 and T_3 synthesis. As a result, the concentrations of T_4 and T_3 in the blood fall, causing a chronic stimulation of TSH secretion, which, in turn, produces a goiter. Enlargement of the thyroid gland increases its capacity to accumulate iodide from the blood and to synthesize T_4 and T_3. However, the degree to which the enlarged gland can produce thyroid hormones to compensate for their deficiency in the blood depends on the severity of the deficiency of iodide in the diet. To prevent iodide deficiency and consequent goiter formation, iodide is added to table salt (iodized salt) in most developed countries. In the United States, iodine intake is decreasing as salt intake is reduced.

THYROID HORMONE EFFECTS ON THE BODY

Most cells of the body are targets for the action of thyroid hormones. The sensitivity or responsiveness of a particular cell to thyroid hormones correlates to some degree with the number of receptors for these hormones. The cells of the CNS appear to be an exception. As is discussed later, the thyroid hormones play an important role in CNS development during fetal and neonatal life, and developing nerve cells in the brain are important targets for thyroid hormones. In the adult, however, brain cells show little responsiveness to the metabolic regulatory action of thyroid hormones, although they have numerous receptors for these hormones. The reason for this discrepancy is unclear.

Triiodothyronine activates a nuclear receptor.

Thyroid hormone receptors (TRs) are located in the nuclei of target cells bound to **thyroid hormone response elements** (**TREs**) in the DNA. TRs are ~50-kDa proteins that are structurally similar to the nuclear receptors for steroid hormones and vitamin D. In humans, two TR genes (a and b) are found on two separate chromosomes and encode several different receptor proteins (TRa1, TRb1, TRb2, and TRb3). The TR receptors are expressed in a tissue-specific manner to impart different effects of thyroid hormone on various tissues. Thyroid receptors bound to the TRE in the absence of T_3 generally act to repress gene expression.

Target cells take up the free forms of T_3 and T_4 from the blood through a carrier-mediated process that requires ATP. Once inside the cell, T_4 is deiodinated to T_3, which enters the nucleus of the cell and binds to its receptor in the chromatin. The TR with bound T_3 forms a complex (called a *heterodimer*) with another nuclear receptor called the **retinoid X receptor** (**RXR**). TR can also complex with other TRs to form homodimers and activate transcription. Transcription coactivators and corepressors also complex with the TR heterodimer or homodimer, resulting in increased or decreased production of certain mRNAs (Fig. 32.4). T_3 can influence cell differentiation by regulating the kinds of proteins produced by its target cells and can influence growth and metabolism by changing the amounts of structural and enzymatic proteins present in the cells (Clinical Focus 32.1).

CLINICAL FOCUS 32.1

Resistance to Thyroid Hormone

Mutations in one allele of the thyroid receptor β (TRb) gene result in **resistance to thyroid hormone (RTH)**. These mutations tend to cluster in areas of the thyroid hormone receptor that have important interactions with the hydrophobic ligand-binding domain; thus, the mutant TRb does not bind T_3 with high affinity. The mutations do not interfere with the DNA-binding domain, the corepressor-binding domain, or the region of the receptor that heterodimerizes with 9-*cis* retinoic acid receptor (RXR).

It is thought that RTH is produced when a mutant TRb heterodimerizes with RXR, a normal TRb, or TRa. Receptor dimers containing mutant TRb compete with wild-type (normal) TRb-containing dimers for binding to thyroid hormone response elements (TREs) of thyroid hormone–regulated genes (see Fig. 32.4). The mutant TRb heterodimers also bind corepressor molecules that cannot be released because of the defect in triiodothyronine (T_3) binding; therefore, genes become more repressed than they normally would be.

Over 400 families with RTH have been identified, and it is expected that many more cases likely exist. The frequency of mutation has been estimated at 1:50,000. The mutation effect is characterized as dominant negative inhibition because TRb interferes with the function of the three normal TR-expressing genes. Patients with RTH may have features of hypothyroidism if the resistance is severe and affects all tissues. Such people are referred to as having *generalized resistance to thyroid hormone*. Alternatively, patients may present with hyperthyroidism if the hypothalamic–pituitary axis is

more severely affected—a condition termed *pituitary resistance to thyroid hormone*. The hypothalamic–pituitary axis is primarily regulated by TRb and thus is more sensitive to mutations in the receptor than tissues such as the heart, in which TRa is the dominant thyroid hormone receptor. Although patients may present with symptoms of hyperthyroidism, thyroid-stimulating hormone (TSH) level is normal or only slightly elevated, a finding important in differentiating between a diagnosis of RTH and TSH-secreting pituitary tumor, which results in high TSH levels.

Many patients may present with a mixture of hypothyroid and hyperthyroid conditions. Treatment of patients with RTH is therefore difficult because thyroid hormone analogs designed to suppress the hypothalamic–pituitary axis and reduce the release of T_4 can worsen effects on the heart, which has functional TRa receptors. β-Blockers may be of use in such situations. Development of thyroid hormone analogs that preferentially bind TRb or TRa may prove useful for treatment of RTH. ■

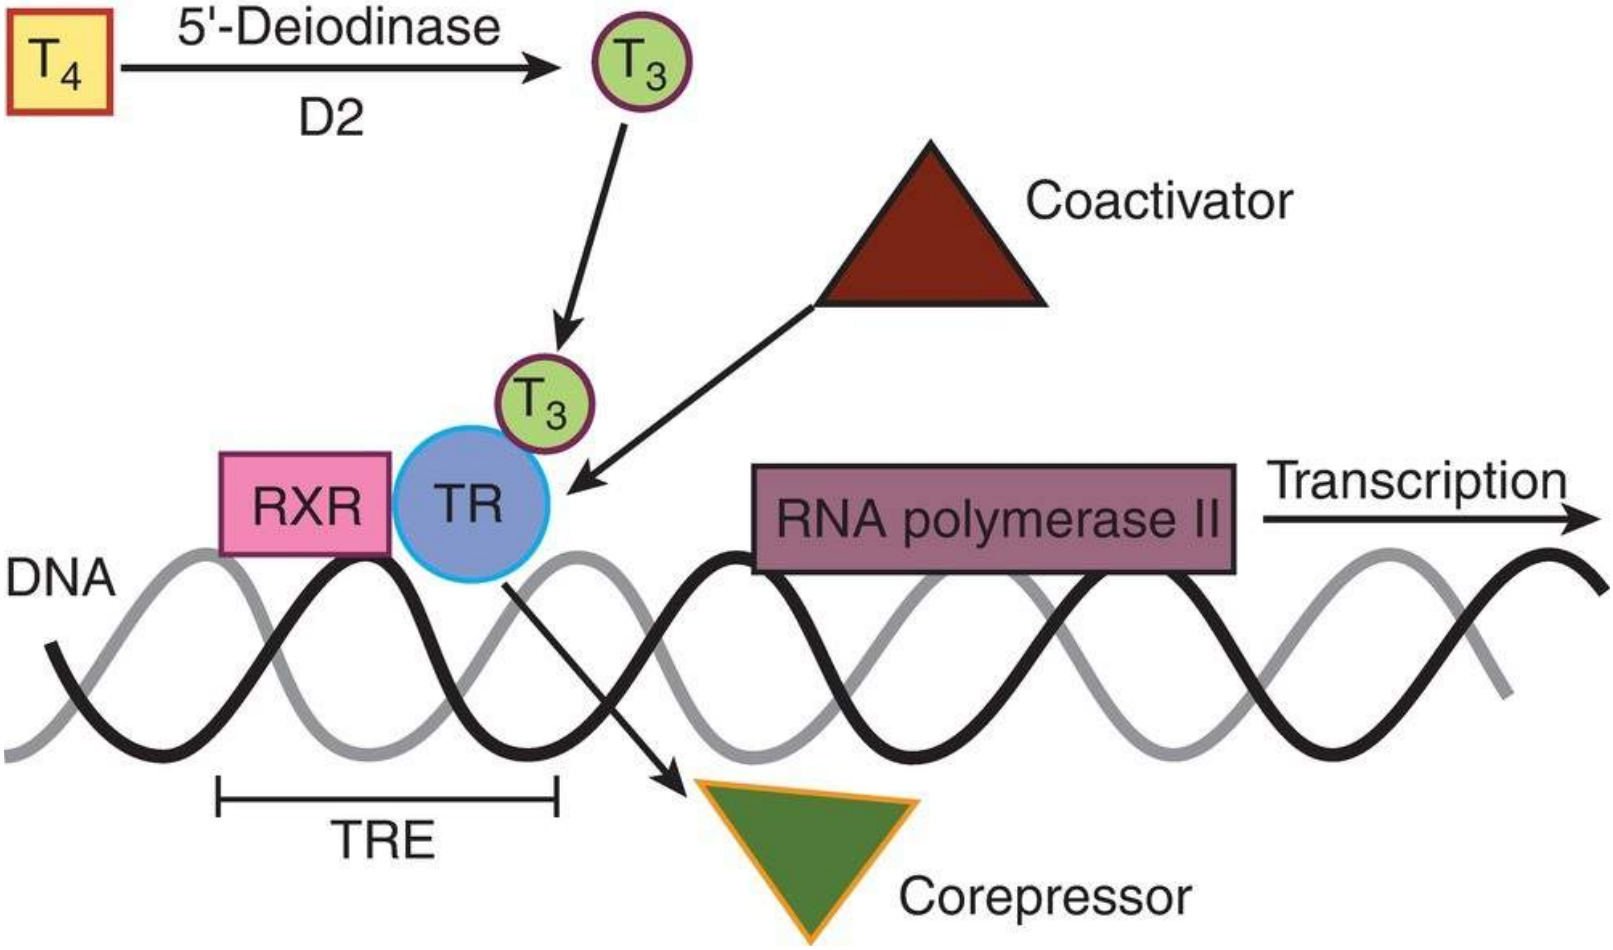

Figure 32.4 The activation of transcription by thyroid hormone. Thyroxine (T_4) is taken up by the cell and deiodinated to triiodothyronine (T_3), which then binds to the thyroid hormone receptor (TR). The activated TR heterodimerizes with a second transcription factor, 9-*cis* retinoic acid receptor (RXR) and binds to the thyroid hormone response element (TRE). The binding of TR/RXR to the TRE displaces repressors of transcription and recruits additional coactivators. The final result is the activation of RNA polymerase II and the transcription of the target gene.

The transcriptional response to T_3 is slow; thus when T_3 is given to an animal or human, several hours elapse before its physiologic effects can be detected. This delayed action reflects the time required

for transcriptional changes and consequent synthesis of key proteins to occur. When T_4 is administered, its course of action is usually slower than that of T_3 because of the additional time required for the body to convert T_4 to T_3.

Thyroid hormones also have effects on cells that occur much faster and do not appear to be mediated by nuclear TR receptors, including effects on signal transduction pathways that alter cellular respiration, cell morphology, vascular tone, and ion homeostasis.

Thyroid hormones are crucial for brain maturation during fetal development.

The human brain undergoes its most active phase of growth during the last 6 months of fetal life and the first 6 months of postnatal life. During the second trimester of pregnancy, the multiplication of neuroblasts in the fetal brain reaches a peak and then declines. As pregnancy progresses and the rate of neuroblast division drops, neuroblasts differentiate into neurons and begin the process of synapse formation that extends into postnatal life.

Thyroid hormones first appear in the fetal blood during the second trimester of pregnancy, and levels continue to rise during the remaining months of fetal life. TRs increase about 10-fold in the fetal brain at about the time the concentrations of T_4 and T_3 begin to rise in the blood. These events are critical for normal brain development because thyroid hormones are essential for timing the decline in nerve cell division and the initiation of differentiation and maturation of these cells.

If thyroid hormones are deficient during these prenatal and postnatal periods of differentiation and maturation of the brain, mental retardation occurs. The cause is thought to be inadequate development of the neuronal circuitry of the CNS. Thyroid hormone therapy must be given to a thyroid hormone–deficient child during the first few months of postnatal life to prevent mental retardation. Starting thyroid hormone therapy after behavioral deficits have occurred cannot reverse the mental retardation (i.e., thyroid hormone must be present when differentiation normally occurs). Thyroid hormone deficiency during infancy causes both mental retardation and growth impairment, as discussed below. Fortunately, this rarely occurs today because thyroid hormone deficiency is usually detected in newborn infants and hormone therapy is given at the proper time.

The exact mechanism by which thyroid hormones influence differentiation of the CNS is unknown. Animal studies have demonstrated that thyroid hormones inhibit nerve cell replication in the brain and stimulate the growth of nerve cell bodies, the branching of dendrites, and the rate of myelinization of axons. These effects of thyroid hormones are presumably a result of their ability to regulate the expression of genes involved in nerve cell replication and differentiation.

Body growth and development require thyroid hormone.

Thyroid hormones are important factors regulating the growth of the entire body. For example, a person who is deficient in thyroid hormones and who does not receive thyroid hormone therapy during childhood will not grow to a normal adult height.

Thyroid hormones promote normal body growth by stimulating growth hormone (GH) gene expression in the somatotrophs of the anterior pituitary gland. In a thyroid hormone–deficient person, GH synthesis by the somatotrophs is greatly reduced, and GH secretion is impaired; thus, a thyroid hormone–deficient person will also be GH deficient. If this condition occurs in a child, it will cause growth retardation (see Chapter 31).

In tissues such as skeletal muscle, heart, and liver, thyroid hormones have direct effects on the synthesis of many structural and enzymatic proteins. For example, they stimulate the synthesis of structural proteins of mitochondria, as well as the formation of many enzymes involved in intermediary metabolism and oxidative phosphorylation.

Thyroid hormones also promote the growth and calcification of bones in the skeleton. Deficiency in the thyroid hormone early in life leads to delayed, abnormal development of bone and can lead to dwarfism. The effect of thyroid hormones to regulate bone growth is, in part, mediated through its effects on GH and insulin-like growth factor 1 (IGF-1) synthesis.

Thyroid hormones are a major determinant of basal metabolic rate.

When the body is at rest, about half of the ATP produced by its cells is used to drive energy-requiring membrane transport processes. The remainder is used in involuntary muscular activity, such as respiratory movements, peristalsis, and contraction of the heart, and in metabolic reactions requiring ATP such as protein synthesis. The energy required to do this work is eventually released as body heat.

Mitochondria produce ATP by the oxidative phosphorylation of **adenosine diphosphate** (**ADP**). The rate of oxidative phosphorylation depends on the supply of ADP for electron transport. The ADP supply is, in turn, a function of the amount of ATP used to do work. For example, when more work is done per unit time, more ATP is used and more ADP is generated, increasing the rate of oxidative phosphorylation. The rate at which oxidative phosphorylation occurs is reflected in the amount of oxygen consumed by the body because oxygen is the final electron acceptor at the end of the electron transport chain.

Activities that occur when the body is not at rest such as voluntary movements use additional ATP for the work involved. The total amount of oxygen consumed and body heat produced over a 24-hour period is the combination of that needed at rest and that needed during activity.

Thyroid hormones regulate the basal rate at which oxidative phosphorylation takes place in cells. As a result, they set the basal rates of body heat production and of oxygen consumed by the body. This is called the **thermogenic action** of thyroid hormones.

Thyroid hormone levels in the blood must be within normal limits for basal metabolism to proceed at the rate needed for a balanced energy economy of the body. If thyroid hormones are present in excess, oxidative phosphorylation is accelerated and body heat production and oxygen consumption are abnormally high. The converse occurs when the blood concentrations of T_4 and T_3 are lower than normal. The fact that thyroid hormones affect the amount of oxygen consumed by the body has been used clinically to assess the status of thyroid function. The amount of oxygen consumed by the body under resting conditions is called the **basal metabolic rate** (**BMR**) and assumes normal thyroid function. A BMR higher than that expected for a person with normal thyroid function would indicate that concentrations of T_4 and T_3 are higher than normal.

Not all tissues are sensitive to the thermogenic action of thyroid hormones. Tissues and organs that do respond include skeletal muscle, heart, liver, and the kidneys, in which TRs are abundant. The adult brain, skin, lymphoid organs, and gonads show little thermogenic response to thyroid hormones, and with the exception of the adult brain, these tissues contain few TRs.

The thermogenic action of the thyroid hormones is poorly understood at the molecular level. The thermogenic effect takes many hours to appear after the administration of thyroid hormones to a human or animal, probably because of the time required for changes in gene expression. T_3 is known to stimulate the synthesis of cytochromes, cytochrome oxidase, and Na^+/K^+-ATPase in certain cells, suggesting that T_3 may regulate the number of respiratory units in these cells and affecting their capacity to carry out oxidative phosphorylation. A greater rate of oxidative phosphorylation results in greater heat production.

Thyroid hormone also stimulates the synthesis of **uncoupling protein 1** (UCP-1) in brown adipose tissue. ATP synthase produces ATP in the mitochondria when protons flow down their electrochemical gradient. UCP-1 acts as a channel in the mitochondrial membrane to dissipate the ion gradient without making ATP. As the protons move down their electrochemical gradient *uncoupled* from ATP synthesis, energy is released as heat. Adult humans do not appear to have enough brown adipose tissue for UCP-1 to

make a significant contribution to nutrient oxidation or body heat production. However, the uncoupling proteins UCP-2 and UCP-3 are found in other tissues, and thyroid hormones regulate their expression. These novel uncoupling proteins may have a role in the thermogenic action of thyroid hormones.

Carbohydrate, fat, and protein metabolism are regulated by thyroid hormone.

In addition to regulating the rate of basal energy metabolism, thyroid hormones influence the rate at which most of the pathways of intermediary metabolism operate in their target cells. When thyroid hormones are deficient, carbohydrate, lipid, and protein metabolism are slowed, and the response of these pathways to other regulatory hormones is decreased. In contrast, these metabolic pathways run at an abnormally high rate when thyroid hormones are present in excess. Thus, thyroid hormones can be viewed as amplifiers of cellular metabolic activity. The amplifying effect of thyroid hormones on intermediary metabolism is mediated through the transcription of gene-encoding enzymes involved in these metabolic pathways.

Thyroid hormones provide negative feedback to control the hypothalamic–pituitary axis.

An important action of the thyroid hormones is the regulation of their own secretion. As discussed in Chapter 31, T_3 inhibits TSH secretion by thyrotrophs in the anterior pituitary gland by decreasing thyrotroph sensitivity to **thyrotropin-releasing hormone (TRH)**. When the circulating concentration of free thyroid hormone is high, thyrotrophs are relatively insensitive to TRH and the rate of TSH secretion decreases. The resulting fall in TSH levels in the blood reduces the rate of thyroid hormone release from the follicular cells in the thyroid. When the free thyroid hormone level falls in the blood, however, the negative feedback effect of T_3 on thyrotrophs is reduced and the rate of TSH secretion increases. The rise in TSH in the blood stimulates the thyroid gland to secrete thyroid hormones at a greater rate. This action of T_3 on thyrotrophs is thought to be a result of changes in gene expression in these cells.

The physiologic actions of the thyroid hormones described above are summarized in Table 32.1.

TABLE 32.1 Physiologic Actions of Thyroid Hormones

Category	Specific Action
Development of central nervous system	Inhibit nerve cell replication
	Stimulate growth of nerve cell bodies
	Stimulate branching of dendrites
	Stimulate rate of axon myelinization
Body growth	Stimulate growth hormone gene expression in somatotrophs
	Stimulate synthesis of many structural and enzymatic proteins
	Promote calcification of bones
Basal energy expenditure	Regulate basal rates of oxidative phosphorylation, body heat production, and oxygen consumption
Intermediary metabolism	Stimulate synthetic and degradative pathways of carbohydrate, lipid, and protein metabolism
Thyroid-stimulating hormone (TSH) secretion	Inhibit TSH secretion by decreasing sensitivity of thyrotrophs to thyrotropin-releasing hormone

ABNORMALITIES OF THYROID FUNCTION IN ADULTS

A deficiency or excess of thyroid hormone produces characteristic changes in the body. These changes result from dysregulation of nervous system function and altered metabolism.

Hyperthyroidism increases energy expenditure and causes weight loss.

The most common cause of excessive thyroid hormone production in humans is **Graves disease**, an autoimmune disorder caused by antibodies directed against the TSH receptor in the plasma membrane of thyroid follicular cells. These antibodies bind to the TSH receptor, increasing adenylyl cyclase activity, raising cAMP levels, and producing effects similar to those of TSH. The thyroid gland enlarges to form a **diffuse toxic goiter**, which synthesizes and secretes thyroid hormones at an accelerated rate, causing thyroid hormones to be chronically elevated in the blood. Feedback inhibition of thyroid hormone production by the thyroid hormones is also lost.

Less common conditions that cause chronic elevations in circulating thyroid hormones include adenomas of the thyroid gland that secrete thyroid hormones and excessive TSH secretion caused by malfunctions of the hypothalamic–pituitary–thyroid axis. Many changes in body function characterize the disease state that develops in response to excessive thyroid hormone secretion, called **hyperthyroidism** or **thyrotoxicosis**.

People with hyperthyroidism are nervous and emotionally irritable, with a compulsion to constant movement. However, they also experience physical weakness and fatigue. BMR is increased resulting in greater body heat production. Vasodilation in the skin and sweating occur as compensatory mechanisms to dissipate excessive body heat. Heart rate and cardiac output are increased. Energy metabolism increases, as does appetite. However, despite the increase in food intake, a net degradation of protein and lipid stores occurs, resulting in weight loss. Reducing the rate of thyroid hormone secretion with drugs or removal of the thyroid gland by radioactive ablation or surgery can reverse all of these changes (Clinical Focus 32.2).

CLINICAL FOCUS 32.2

Autoimmune Thyroid Disease: Postpartum Thyroiditis

Certain diseases affecting the function of the thyroid gland occur when a person's immune system fails to recognize particular thyroid proteins as "self" and reacts to the proteins as if they were foreign. This usually triggers both humoral and cellular immune responses. As a result, antibodies to these proteins are generated, which then alter thyroid function. Two common autoimmune diseases with opposite effects on thyroid function are Hashimoto disease and Graves disease. In Hashimoto disease, the thyroid gland is infiltrated by lymphocytes, and elevated levels of antibodies against several components of thyroid tissue (e.g., antithyroid peroxidase and antithyroglobulin antibodies) are found in the serum. The thyroid gland is destroyed, resulting in hypothyroidism. In Graves disease, stimulatory antibodies to the thyroid-stimulating hormone (TSH) receptor activate thyroid hormone synthesis, resulting in hyperthyroidism.

A third, fairly common autoimmune disease is **postpartum thyroiditis**, which usually occurs within 3 to 12 months after delivery. The disease is characterized by a transient destruction-induced

thyrotoxicosis (hyperthyroidism), often followed by a period of hypothyroidism lasting several months. Many patients eventually return to the euthyroid state. Often, only the hypothyroid phase of the disease may be observed, occurring in more than 30% of women with antibodies to thyroid peroxidase detectable before conception. The disease is also observed in patients known to have Graves disease. The postpartum occurrence of the disorder is likely a result of increased immune system function following the suppression of its activity during pregnancy.

It has been estimated that 5% to 10% of women develop postpartum thyroiditis. The prevalence of the disease has prompted the clinical recommendation that thyroid function (serum thyroxin, triiodothyronine, and TSH levels) be surveyed postpartum at 2, 4, 6, and 12 months in all women with thyroid peroxidase antibodies or symptoms suggestive of thyroid dysfunction. Patients who have experienced one episode of postpartum thyroiditis should also be considered at risk for recurrence after pregnancy.

Treatment for postpartum thyroiditis depends on the time of diagnosis. If symptoms during the period of transient thyrotoxicosis are severe, a β-blocker such as propranolol can be given. Thioamides—drugs that inhibit the oxidation and organic binding of thyroid iodide—are generally not effective for this transient thyrotoxicosis because the release of excess thyroid hormone is not a result of hormone synthesis but rather of destruction of the gland. Thyroid hormone replacement is required to treat the hypothyroidism that occurs later in the progression of the disease. ■

Hypothyroidism decreases metabolism and causes weight gain.

Thyroid hormone deficiency in humans has many causes. For example, iodide deficiency may result in a reduction in thyroid hormone production. Autoimmune diseases such as **Hashimoto disease**, also known as *Hashimoto thyroiditis*, impair thyroid hormone synthesis. Other causes of thyroid hormone deficiency include heritable defects that alter the biosynthesis of thyroid hormones and hypothalamic or pituitary diseases that interfere with TRH or TSH secretion. Obviously, radioiodine ablation or surgical removal of the thyroid gland also causes thyroid hormone deficiency. **Hypothyroidism** is the disease state that results from thyroid hormone deficiency, and the effects on the body are the opposite of those caused by thyroid hormone excess.

Thyroid hormone deficiency impairs the function of most tissues in the body. As described earlier, thyroid hormone deficiency at birth that is not treated during the first few months of postnatal life causes irreversible mental retardation. Thyroid hormone deficiency later in life also influences the function of the nervous system. For example, all cognitive functions, including speech and memory, are slowed and body movements may be clumsy.

Metabolism is also reduced in thyroid hormone–deficient people. BMR is reduced, resulting in impaired body heat production. Vasoconstriction occurs in the skin as a compensatory mechanism to conserve body heat. Heart rate and cardiac output are reduced. The synthetic and degradative processes of intermediary metabolism are slowed and weight gain occurs, despite the fact that food intake is reduced. In severe hypothyroidism, a substance consisting of hyaluronic acid and chondroitin sulfate complexed with protein is deposited in the extracellular spaces of the skin, causing water to accumulate osmotically. This effect gives a puffy appearance to the face, hands, and feet, called **myxedema**. All of the above disorders in adults can be normalized with thyroid hormone therapy. See the Integrated Medical Sciences box for a discussion of euthyroid sick syndrome, in which T_3 levels are reduced to nearly undetectable levels in critically ill patients.

INTEGRATED MEDICAL SCIENCES

Euthyroid Sick Syndrome

Severe caloric restriction and starvation result in reduced T_3 levels, with normal or slightly reduced T_4 and normal TSH levels. This is a result of the decreased release of thyroid hormone and possibly reduced D1 and D2 deiodinase activity in peripheral tissues. Reductions in T_3 result in lower basal oxygen consumption, slower heart rate, and attenuation of nitrogen loss—changes all considered beneficial in adapting to reduced caloric intake. In a patient who is severely ill, T_3 levels can be reduced up to 90% and reverse T_3 (rT_3) increased severalfold, with only slight reductions in T_4. In the most severe cases, the release of TSH and other anterior pituitary hormones is reduced because of the loss of hypothalamic input resulting from endogenous causes and, in some instances, exacerbated by therapy such as glucocorticoids that is given to ill patients. This condition is called **euthyroid sick syndrome** or *low T_3 syndrome*.

The mechanisms resulting in almost undetectable serum T_3 in patients with euthyroid sick syndrome are not entirely clear. It appears that the reduction in serum T_3 is a result of the decreased release of T_3 from the thyroid gland and reduced T_4 outer-ring deiodination. Lower transport of T_4 into tissues such as the liver and kidney, which express D1 deiodinase, and more rapid turnover of D2 deiodinase protein both contribute to reduced T_4 deiodination and lower T_3 levels. The increase in rT_3 in euthyroid sick patients was originally thought to indicate that the specificity of D1 deiodinase was changed from 5′-T_4 to 5-T_4 deiodination, but it has since been shown that increased rT_3 is a result of reduced clearance, not increased synthesis.

Therapy for euthyroid sick syndrome remains controversial. Despite the extremely low T_3 levels, it is still not clear that T_4 or T_3 supplementation should be done because most controlled studies have not shown a beneficial effect of increasing thyroid hormones alone. A promising alternative strategy that is currently under evaluation is the infusion of a combination of growth hormone (GH)-releasing peptides and thyrotropin-releasing hormone. The administration of these factors corrects the impaired pulsatile secretion of GH, thyrotropin, and gonadotropin, resulting in increased circulating concentrations of IGF-1, GH-dependent IGF-binding proteins, T_4, T_3, and testosterone. Although hypothalamic–pituitary function is clearly improved and catabolism in the severely ill patient reversed, a positive effect of this treatment on survival has still not been definitively established. Normalization of glycemia with exogenous insulin has recently been shown to have a positive impact on survival. Thus, studies to understand the neuroendocrine response to critical illness and the interaction of the hypothalamic–pituitary–adrenal axis with peripheral hormonal and metabolic alterations are ongoing in an attempt to improve survival of the critically ill patient. ■

Chapter Summary

- The thyroid gland consists of two lobes attached to either side of the trachea; its primary function is the synthesis and secretion of thyroxine and triiodothyronine.
- The thyroid gland also produces calcitonin, which plays a key role in calcium homeostasis.
- Thyroid hormones are synthesized by iodination and coupling of tyrosines in reactions catalyzed by the enzyme thyroid peroxidase.
- The proteolysis of thyroglobulin within the follicular cells releases thyroid hormones from the thyroid gland.
- Thyroid-stimulating hormone regulates the synthesis and release of thyroid hormones through activation of adenylyl cyclase and generation of cAMP.
- Thyroid hormones circulating in the blood are bound to transport proteins. Only a small fraction of the circulating hormones are free (unbound) and biologically active.
- The concentration of thyroid hormones in the circulation regulates thyroid-stimulating hormone release from the anterior pituitary.
- In peripheral tissues, 5′-deiodinase deiodinates thyroxine to the physiologically active hormone triiodothyronine.
- In target tissues, triiodothyronine binds to the thyroid hormone receptor (TR), which then associates with retinoic acid receptor or a second TR to regulate transcription.
- TR regulates transcription by binding to specific thyroid hormone response elements in target genes and interacting with specific coactivators and corepressors of transcription.
- Brain cells are a major target for triiodothyronine and thyroxine, which play a crucial role in neuronal maturation during fetal development.
- Thyroid hormones stimulate growth by regulating growth hormone release from the pituitary and by direct actions on target tissues such as bone.
- Thyroid hormones regulate basal metabolic rate and intermediary metabolism through effects on mitochondrial ATP synthesis and the expression of genes encoding metabolic enzymes.
- Excess thyroid hormone (hyperthyroidism) results in nervousness, increased metabolic rate, and weight loss.
- Thyroid hormone deficiency (hypothyroidism) results in decreased metabolic rate and weight gain.

Chapter Review Questions

1. The effects of TSH on thyroid follicular cells include:

A. stimulation of endocytosis of thyroglobulin stored in the colloid.

B. release of a large pool of T_4 and T_3 stored in secretory vesicles in the cell.

C. stimulation of the uptake of iodide from the thyroglobulin stored in the colloid.

D. Increase in perfusion by the blood.

E. stimulation of the binding of T_4 and T_3 to thyroxine-binding globulin.

F. increased cAMP hydrolysis.

The correct answer is A. TSH stimulates the endocytosis of colloid by the apical membrane of the follicular cell. Thyroglobulin in the colloid is then hydrolyzed in the lysosomal vesicles to release thyroid hormones. T_3 and T_4 are stored in thyroglobulin in the colloid, not in secretory vesicles in the follicle cell. TSH stimulates the uptake of iodide from the blood, not the colloid. It has no effect on blood flow to the thyroid gland and no direct effect on the binding of T_3 and T_4 to thyroxine-binding globulin. TSH stimulates an increase in cAMP not an increase in the hydrolysis of this second messenger.

2. A child is born with a rare disorder in which the thyroid gland does not respond to TSH. What would be the predicted effects on mental ability, body growth rate, and thyroid gland size when the child reaches 6 years of age?

A. Mental ability would be impaired, body growth rate would be slowed, and thyroid gland size would be larger than normal.

B. Mental ability would be unaffected, body growth rate would be slowed, and thyroid gland size would be smaller than normal.

C. Mental ability would be impaired, body growth rate would be slowed, and thyroid gland size would be smaller than normal.

D. Mental ability would be unaffected, body growth rate would be unaffected, and thyroid gland size would be smaller than normal.

E. Mental ability would be impaired, body growth rate would be slowed, and thyroid gland size would be normal.

F. Mental ability would be unaffected, body growth rate would be unaffected, and thyroid gland size would be unaffected.

The correct answer is C. Thyroid hormones are important for normal development of the CNS and for body growth. TSH stimulates the synthesis and release of thyroid hormones as well as the growth of the thyroid gland. In a disorder in which the thyroid gland does not respond to TSH, thyroid hormone production would be decreased, resulting in poor development of the CNS and poor body growth. TSH would also not be able to stimulate the growth of the thyroid, resulting in a small gland.

3. If the 6-year-old child described in the previous question is now treated with thyroid hormones, how would mental ability, body growth rate, and thyroid gland size be affected?

A. Mental ability would remain impaired, body growth rate would be improved, and thyroid gland size would be smaller than normal.

B. Mental ability would be improved, body growth rate would be improved, and thyroid gland size would be normal.

C. Mental ability would remain impaired, body growth rate would be improved, and thyroid

gland size would be normal.

D. Mental ability would remain impaired, body growth rate would be improved, and thyroid gland size would be larger than normal.

E. Mental ability would be improved, body growth rate would remain slowed, and thyroid gland size would be normal.

F. Mental ability would be improved, body growth rate would remain slowed, and thyroid gland size would be larger than normal.

The correct answer is A. Giving thyroid hormones to the child would improve body growth but not mental ability, because thyroid hormones are most important for CNS development *in utero*. Therefore, giving thyroid hormones after birth would be too late. Thyroid gland size would remain smaller than normal because thyroid hormones have no trophic effect on the gland; only TSH does.

4. Uncoupling proteins:

A. use the proton gradient across the mitochondrial membrane to facilitate ATP synthesis.

B. are decreased by thyroid hormones

C. dissipate the proton gradient across the mitochondrial membrane to generate heat.

D. are present exclusively in brown fat.

E. uncouple fatty acid oxidation from glucose oxidation in mitochondria.

F. are essential for maintaining body temperature in mammals.

The correct answer is C. Uncoupling proteins allow protons to flow down their concentration gradient across the mitochondrial membrane, uncoupled from the synthesis of ATP. The resulting energy generated is released as heat, and ATP is not synthesized. Uncoupling proteins are increased by thyroid hormones. The novel uncoupling proteins are found in many tissues, including muscle and adipose tissue. Fatty acid and glucose oxidation are not coupled in mitochondria, and the uncoupling proteins are not the switch between oxidation of these two substrates. Uncoupling proteins have not been demonstrated to be absolutely essential to the maintenance of body temperature in mammals. However, UCP-1 is important in the ability of small mammals, such as rodents, to tolerate cold temperatures.

5. Triiodothyronine (T_3):

A. is produced in greater amounts by the thyroid gland than T_4.

B. is bound by the thyroid receptor present in the cytosol of target cells.

C. is formed from T_4 through the action of the 5-deiodinase D3.

D. has a half-life of a few minutes in the bloodstream.

E. is released from thyroglobulin through the action of thyroid peroxidase.

F. can be produced by the deiodination of T_4 in pituitary thyrotrophs.

The correct answer is F. T_3 is produced from T_4 by 5′-deiodinase D2 in the anterior pituitary. The major thyroid hormone product of the thyroid gland is T_4. The thyroid hormone receptor (TR) is located in the nucleus. The 5-deiodinase D3 acts on T_4, to make reverse T_3. The half-life of T_3 in the bloodstream is about 1 day because of the protective actions of the thyroid hormone–binding proteins. Thyroid peroxidase catalyzes the iodination of thyroglobulin to form MIT and DIT, the precursor molecules for T_3. Release of T_3 from thyroglobulin is catalyzed by proteases in the lysosomal vesicles.

Clinical Application Exercises 32.1

THYROTOXICOSIS

A 35-year-old woman is seen in the endocrine clinic for evaluation of thyroid disease. The patient complains of weight loss, irritability, and restlessness. Physical examination reveals enlargement of the thyroid gland, weakness in maintaining the leg in an extended position, warm moist skin, and tachycardia. Family history identifies the patient's mother as exhibiting hypothyroidism after the birth of the patient's brother and an aunt with Hashimoto disease.

QUESTIONS

1. Based on the history and physical examination, what would be a reasonable initial diagnosis?
2. From a blood sample what hormone concentrations would you ask the laboratory to measure and what would you expect the results to be?
3. What antibody titers would you request the laboratory to determine? Which antibody titer is the most useful in the diagnosis of Graves disease?
4. What would an increase in antibodies to TPO indicate?
5. The antibody titers indicate that the patient has Graves disease. What treatment would be appropriate for this patient?

ANSWERS

1. The physical findings including the presence of goiter suggest that the patient may be hyperthyroid. However, goiter can also occur in hypothyroidism. As autoimmune thyroid disease "runs in families," the family history of postpartum thyroiditis suggests that the thyroiditis might be due to an autoimmune response. The patient may have Graves disease.
2. The laboratory should determine the levels of thyroid hormone (T_4 and T_3) and TSH. Thyroid hormones should be increased. TSH may be increased if it is early in the progression of Hashimoto disease or decreased if the patient has Graves disease.
3. Antibodies to TSH receptor, thyroid peroxidase, and thyroglobulin can all be elevated in Graves disease. However, the presence of TSH receptor antibodies is diagnostic.
4. Antibodies to thyroid peroxidase (TPO) are elevated to the greatest extent in Hashimoto disease.
5. A thionamide compound should first be used to inhibit thyroid hormone synthesis. This treatment will relieve the symptoms of hyperthyroidism and may result in a reduction in immune response. The drug may be withdrawn after several months of treatment to determine if the disease is in remission. If thyroid hormones increase with cessation of the drug, surgical intervention to remove the thyroid would be indicated.

33 Adrenal Gland

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe the anatomy of the adrenal gland and including which histologically distinct zone synthesizes and secretes glucocorticoids, aldosterone, and adrenal androgens.
- Outline the steps through which cells in the adrenal cortex obtain cholesterol to synthesize steroids, identifying that which is common to steroid synthesis in all three zones of the adrenal cortex.
- Explain the role of the liver in catabolism of adrenal steroids.
- Outline the intracellular signaling steps through which adrenocorticotropic hormone increases glucocorticoid and androgen synthesis in adrenal cortical cells.
- Compare and contrast the mechanism(s) through which angiotensin II and angiotensin III stimulate aldosterone synthesis in the cells of the zona glomerulosa.
- Outline the steps through which glucocorticoids alter gene transcription in target cells and describe the role of glucocorticoids in the adaptation of the body to fasting, injury, and stress.
- Outline the synthesis of epinephrine and norepinephrine and explain how the cellular effects of catecholamines are achieved.
- Compare and contrast how stimuli such as injury, anger, pain, cold, strenuous exercise, and hypoglycemia promote catecholamine release.
- List the effects of catecholamines on liver, muscle, and adipose tissue that regulate blood sugar levels.

To remain alive, the organs and tissues of the human body must have a finely regulated extracellular environment. This environment must contain the correct concentrations of ions to maintain body fluid volume and enable excitable cells to function, as well as an adequate supply of metabolic substrates for cells to generate adenosine triphosphate (ATP). The continual loss of salts, water, and other organic substances from the body through perspiration, respiration, and excretion are normally replenished by the intake of food and liquids. However, a person can survive for weeks on little else but water because the adrenal glands play a key role in adjusting the functions of organs and tissues to preserve body fluid volume and composition. This is readily apparent in an adrenalectomized animal, which cannot survive prolonged fasting. Its blood glucose supply diminishes, ATP generation by the cells becomes inadequate to support life, and the animal eventually dies. Even if fed a normal diet, an adrenalectomized animal typically loses body sodium and water over time and eventually dies of circulatory collapse. Its death is caused by a lack of certain steroid hormones produced by the cortex of the adrenal gland.

▶ ADRENAL CORTEX SYNTHESIZES AND SECRETES STEROID HORMONES

The human adrenal glands are paired, pyramid-shaped organs located on the upper poles of each kidney. The adrenal gland is actually a composite of two separate endocrine organs, one inside the other, each secreting separate hormones and each regulated by different mechanisms. The outer portion or **cortex** of the adrenal gland completely surrounds the inner portion or **medulla** and makes up most of the gland. During embryonic development, the cortex forms from mesoderm; the medulla arises from neural ectoderm.

Adrenal cortex comprises three zones that produce and secrete distinct hormones.

In the adult human, the adrenal cortex consists of three histologically distinct zones or layers (Fig. 33.1). The outer zone, which lies immediately under the capsule of the gland, is called the **zona glomerulosa** and consists of small clumps of cells that produce the mineralocorticoid aldosterone. The **zona fasciculata** is the middle and thickest layer of the cortex and consists of cords of cells oriented radially to the center of the gland. The inner layer, called the **zona reticularis**, is composed of interlaced strands of cells. The zona fasciculata and zona reticularis both produce the physiologically important glucocorticoids cortisol and corticosterone. These layers of the cortex also produce the androgen **dehydroepiandrosterone** (**DHEA**), which is related chemically to the male sex hormone **testosterone**.

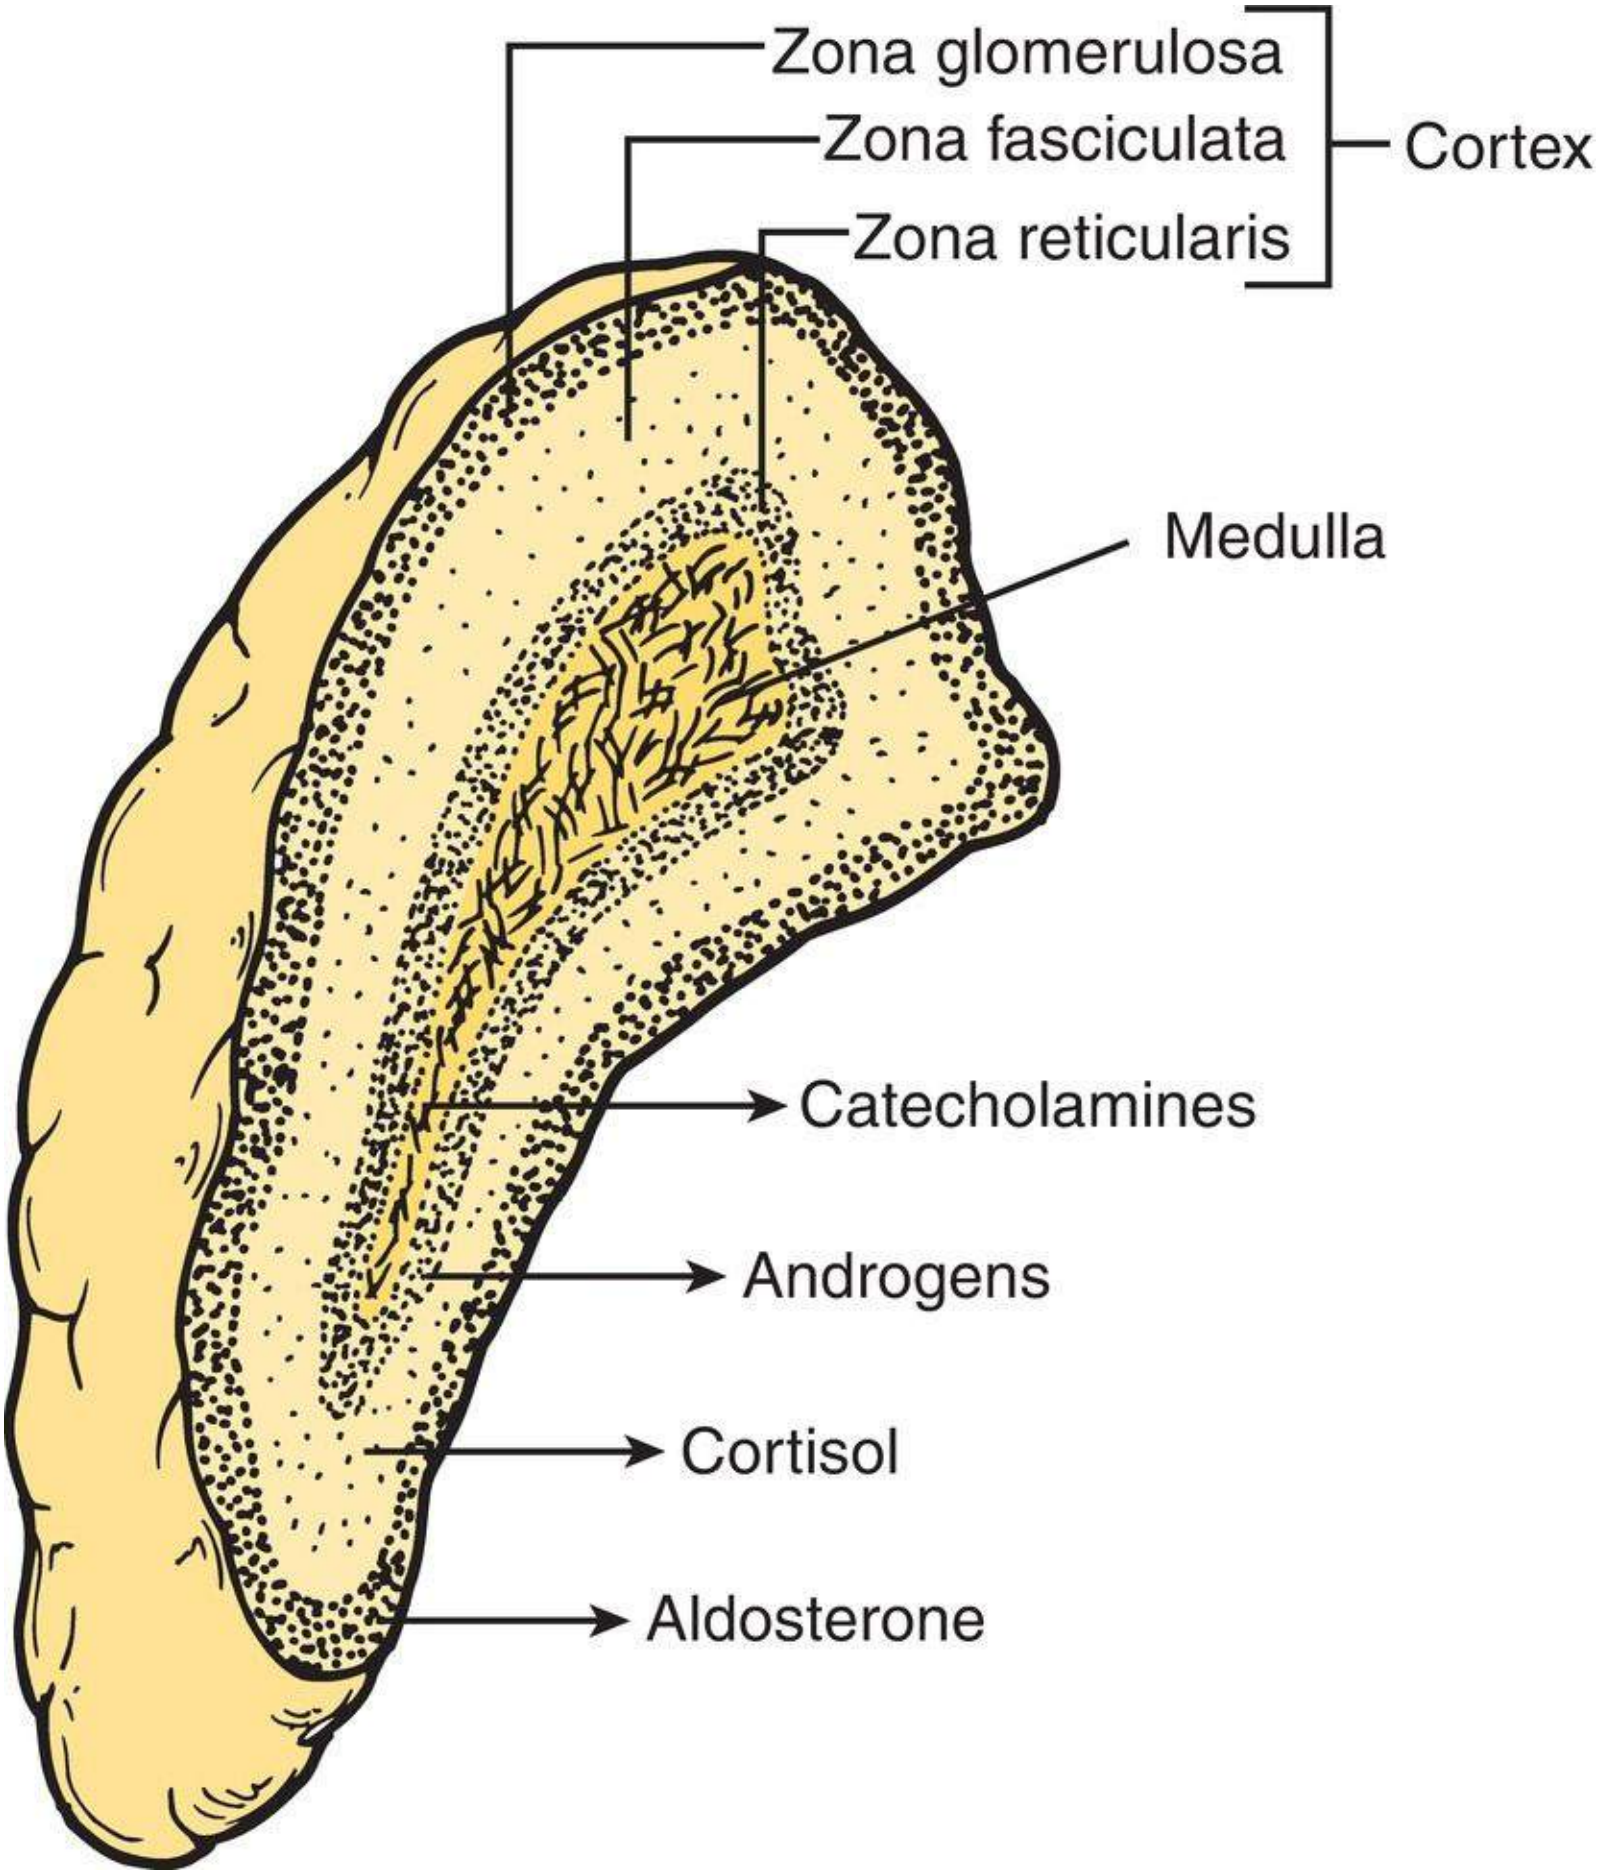

Figure 33.1 The three zones of the adrenal cortex and corresponding hormones secreted. Approximately 80% to 90% of the gland is the cortex, with ~10% to 20% comprising the medulla.

Like all endocrine organs, the adrenal cortex is highly vascularized. Many small arteries branch from the aorta and renal arteries and enter the cortex. These vessels give rise to capillaries that course radially through the cortex and terminate in venous sinuses in the zona reticularis and adrenal medulla; therefore, the hormones produced by the cells of the cortex have ready access to the circulation.

Only small amounts of glucocorticoid, aldosterone, and adrenal androgens are found in adrenal cortical cells at a given time because the cells produce and secrete these hormones on demand, rather than storing them. Humans secrete about 10 times more cortisol than corticosterone during an average day (20 vs. 2 mg); thus, cortisol is considered the physiologically important glucocorticoid in humans. Compared with the glucocorticoids, a much smaller amount of aldosterone (0.1 mg) is secreted each day (Clinical Focus 33.1).

CLINICAL FOCUS 33.1

Glucocorticoid Excess: Cushing Disease

Cushing syndrome is the name given to the signs and symptoms associated with prolonged exposure to inappropriately elevated glucocorticoids. The use of glucocorticoid in the definition covers both endogenous elevations in cortisol and increased glucocorticoid resulting from endogenous sources (e.g., prednisolone or dexamethasone treatment). Endogenous Cushing syndrome may be adrenocorticotropic hormone (ACTH) dependent or ACTH independent. The term *Cushing disease* is reserved for ACTH-dependent conditions, usually caused by a corticotroph adenoma that secretes excessive ACTH and stimulates the adrenal cortex to produce large amounts of cortisol. ACTH-independent Cushing syndrome is generally the result of an adrenocortical adenoma that secretes large amounts of cortisol.

Weight gain and obesity are the most common clinical signs of Cushing syndrome. In adults, weight gain occurs centrally with excess deposition in the visceral adipose depot (deep fat surrounding the organs), and this can be used to initially distinguish Cushing syndrome from generalized obesity. Patients also develop fat depots over the thoracocervical spine (buffalo hump) and over the cheeks, resulting in a moonlike face. Bright red–purple **striae** >1 cm wide are frequently found on the abdomen. In children, glucocorticoid excess often results in a phenotype lacking a central fat deposition but resulting in an overall generalized obesity. Thus, it is necessary to rule out Cushing syndrome in obese children before beginning treatment for general obesity.

Prolonged exposure of the body to large amounts of glucocorticoids causes the breakdown of skeletal muscle protein, increased glucose production by the liver, and mobilization of lipid from the fat depots. The increased mobilization of lipid provides abundant fatty acids for metabolism, and the increased oxidation of fatty acids by tissues reduces their ability to use glucose. The underuse of glucose by skeletal muscle, coupled with increased glucose production by the liver, results in hyperglycemia, which, in turn, stimulates the pancreas to secrete insulin. However, the rise in insulin is not effective in reducing the blood glucose concentration because glucose uptake and use are decreased in the skeletal muscle and adipose tissue. The net result is that the person becomes insensitive or resistant to the action of insulin and little glucose is removed from the blood, despite the high level of circulating insulin. The persisting hyperglycemia continually stimulates the pancreas to secrete insulin,

resulting in a form of “diabetes” similar to type 2 diabetes mellitus (see Chapter 34).

The dexamethasone suppression test is useful for the diagnosis of Cushing syndrome of any cause. In normal subjects, the administration of supraphysiologic doses of glucocorticoid results in the suppression of ACTH and cortisol secretion. There is no suppression of ACTH and cortisol in patients with Cushing syndrome.

Treatment of Cushing syndrome depends on the cause. The removal of adrenal adenomas has a 100% cure rate. Transsphenoidal surgery for pituitary adenoma is also reasonably successful, depending on the type (micro or macro) of adenoma. Features of Cushing syndrome disappear after 2 to 12 months. ■

Glucocorticoids and aldosterone have overlapping actions due to similarities in their structure. For example, cortisol and corticosterone have some mineralocorticoid activity; conversely, aldosterone has some glucocorticoid activity. However, given the amounts of these hormones secreted under normal circumstances and their relative activities, glucocorticoids are not physiologically important mineralocorticoids, nor does aldosterone function physiologically as a glucocorticoid.

The adrenal cortex also synthesizes and secretes substantial amounts of androgenic steroids. DHEA, in both the free and sulfated form (DHEAS), is the main androgen secreted by the adrenal cortex of both men and women, although lesser amounts of other androgens are also produced. The adrenal cortex is the main source of androgens in women. In men, both the testes and adrenal cortex contribute to androgens in the blood. In both girls and boys, adrenal androgens normally have little physiologic effect other than a role in development before the start of puberty, because the male sex hormone activity of the adrenal androgens is weak. Exceptions occur in people who produce inappropriately large amounts of certain adrenal androgens as a result of diseases affecting the pathways of steroid biosynthesis in the adrenal cortex.

Adrenal steroid hormones are synthesized from cholesterol.

Cholesterol, the starting material for the synthesis of steroid hormones, consists of four interconnected rings of carbon atoms (A through D) and a side chain of eight carbon atoms extending from one ring. In all, there are 27 carbon atoms in cholesterol, numbered as shown at the top of Figure 33.3.

The immediate source of cholesterol used in steroid hormone biosynthesis is the abundant lipid droplets within the adrenal cortical cells, which contain cholesterol esters (single molecules of cholesterol esterified to single fatty acid molecules). **Cholesterol esterase** (**cholesterol ester hydrolase** [**CEH**]) hydrolyzes the ester bond, generating free cholesterol for steroid biosynthesis within mitochondria located near the lipid droplet. The process of steroid hormone synthesis from cholesterol is initiated when cholesterol enters the mitochondria.

The cholesterol that has been removed from the lipid droplets for steroid hormone biosynthesis is replenished in two ways; uptake from the blood and *de novo* synthesis from acetate (Fig. 33.2). Most of the cholesterol converted to steroid hormones by the human adrenal gland comes from **low-density lipoprotein** (**LDL**) particles circulating in the blood. LDL particles consist of a core of cholesterol esters surrounded by a coat of cholesterol and phospholipids. **Apolipoprotein B-100** (**ApoB-100**), a 400-kDa protein present on the surface of the LDL particle, is recognized by LDL receptors localized to coated pits on the plasma membrane of adrenal cortical cells. The LDL receptors bind the ApoB-100 and the cell takes up the LDL particle through endocytosis. The endocytic vesicle containing the LDL particles fuses with a lysosome, and the particle is degraded. CEH then hydrolyzes the cholesterol esters in the core of the particle to free cholesterol for steroid synthesis and fatty acid. The enzyme **acyl-CoA: cholesterol acyltransferase** (**ACAT**) converts any cholesterol not immediately used by the cell to cholesterol ester. The esters are then stored in the lipid droplets of the cell to be used later. When steroid biosynthesis is proceeding at a high rate, cholesterol delivered to the adrenal cell may be used directly for steroid production rather than being esterified and stored. There is evidence that **high-density lipoprotein** (**HDL**) cholesterol may also be used as a substrate for adrenal steroidogenesis.

Figure 33.2 Sources of cholesterol for steroid biosynthesis by the adrenal cortex. Most cholesterol comes from low-density lipoprotein (LDL) particles in the blood, which bind to receptors in the plasma membrane and are taken up by endocytosis. The cholesterol in the LDL particle is used directly for steroidogenesis or stored in lipid droplets for later use. Some cholesterol is synthesized directly from acetate. ACAT, acyl-CoA: cholesterol acyltransferase; CEH, cholesterol ester hydrolase; CoA, coenzyme A; HMG, 3-hydroxy-3-methylglutaryl.

In humans, cholesterol that has been synthesized *de novo* from acetate by the adrenal glands is a significant but minor source of cholesterol. The enzyme **3-hydroxy-3-methylglutaryl-CoA reductase** (**HMG-CoA reductase**) catalyzes the rate-limiting step in this process. The newly synthesized cholesterol is then incorporated into cellular structures such as membranes or converted to cholesterol esters through the action of ACAT and stored in lipid droplets (see Fig. 33.2).

Steroid biosynthesis is catalyzed by P450 enzymes in the mitochondria and endoplasmic reticulum.

Cytochrome P450 enzymes (CYPs) are a large family of oxidative enzymes with a 450-nm absorbance maximum when complexed with carbon monoxide. The adrenal CYPs are often referred to by their trivial names, which denote their function in steroid biosynthesis (Table 33.1).

TABLE 33.1 Nomenclature for the Steroidogenic Enzymes

Common Name	Previous Form	Current Form	Gene
Cholesterol side chain cleavage enzyme	$P450_{scc}$	CYP11A1	$CYP_{11}A_1$

11β-Hydroxylase	$P450_{c11}$	CYP11B1	$CYP_{11}B_1$
Aldosterone synthase	$P450_{c11AS}$	CYP11B2	$CYP_{11}B_2$

The conversion of cholesterol into steroid hormones begins with the formation of free cholesterol from the cholesterol esters stored in intracellular lipid droplets. The **steroidogenic acute regulatory protein** (**StAR**) then facilitates the flow of free cholesterol into mitochondria. Once inside a mitochondrion, single cholesterol molecules bind to the **cholesterol side chain cleavage enzyme** (**CYP11A1**) embedded in the inner mitochondrial membrane. This enzyme catalyzes the first and rate-limiting reaction in steroidogenesis remodeling the cholesterol molecule into the 21-carbon steroid intermediate **pregnenolone** and releasing isocaproic acid.

Once formed, pregnenolone molecules dissociate from CYP11A1, leave the mitochondrion, and enter the smooth endoplasmic reticulum (ER). The further remodeling of pregnenolone into steroid hormones, summarized in Figure 33.3, depends on whether the process occurs in the zona fasciculata and zona reticularis or the zona glomerulosa.

Figure 33.3 The synthesis of steroids in the adrenal cortex and catabolism of cortisol in the liver. The enzymes catalyzing each step are shown, and the major steroidogenic products are boxed. Note the chemical structure of cholesterol in the upper left, how the four rings are lettered (*A–D*), and how the carbons are numbered. The hydrogen atoms on the carbons composing the rings are omitted from the figure. *Inset box lower right*: Cortisol is reduced and conjugated to glucuronide in the liver and then is excreted in the urine.

In cells of the zona fasciculata and zona reticularis, most of the pregnenolone is converted to cortisol and the main adrenal androgen, DHEA. Pregnenolone molecules bind to the enzyme **17α-hydroxylase** (**CYP17**), embedded in the ER membrane, which hydroxylates pregnenolone at carbon 17. The product formed by this reaction is **17α-hydroxypregnenolone** (see Fig. 33.3).

The CYP17 has an additional enzymatic action that becomes important at this step in the steroidogenic process. Once the enzyme has hydroxylated carbon 17 of pregnenolone to form 17α-hydroxypregnenolone, it can lyse or cleave the carbon 20–21 side chain from the steroid structure. Some molecules of 17α-hydroxypregnenolone undergo this reaction and are converted to the 19-carbon steroid DHEA. This action of CYP17 is essential for the formation of androgens (19-carbon steroids) and estrogens (18-carbon steroids), which lack the carbon 20–21 side chain. The lyase activity of CYP17 is important in the gonads, where androgens and estrogens are primarily made. CYP17 does not exert significant lyase activity in children before the age of 7 or 8 years. As a result, young boys and girls do not secrete significant amounts of adrenal androgens. The appearance of significant adrenal androgen secretion in children of both sexes is termed **adrenarche**, which normally occurs before the activation of the hypothalamic–pituitary–gonadal axis, which initiates puberty. The adrenal androgens produced as a result of adrenarche stimulate the growth of pubic and axillary hair.

Those molecules of 17α-hydroxypregnenolone that dissociate from CYP17 bind next to another ER enzyme, **3β-hydroxysteroid dehydrogenase** (**3β-HSD II**). This enzyme acts on 17α-hydroxypregnenolone to isomerize the double bond in ring B to ring A and to dehydrogenate the 3β-hydroxy group, forming a 3-keto group. The product formed is **17α-hydroxyprogesterone** (see Fig. 33.3). This intermediate then binds to another enzyme, **21-hydroxylase** (**CYP21A2**), which hydroxylates it at carbon 21. The mechanism of this hydroxylation is similar to that performed by the CYP17. The product formed is **11-deoxycortisol**, which is the immediate precursor for cortisol.

To be converted to cortisol, 11-deoxycortisol molecules must be transferred back into the mitochondrion to be acted on by **11β-hydroxylase** (**CYP11B1**) embedded in the inner mitochondrial membrane. This enzyme hydroxylates 11-deoxycortisol on carbon 11, converting it into cortisol. The 11β-hydroxyl group is the molecular feature that confers glucocorticoid activity on the steroid. Cortisol is then secreted into the bloodstream.

Some of the pregnenolone molecules generated in cells of the zona fasciculata and zona reticularis first bind to 3β-HSD II when they enter the ER. As a result, they are converted to **progesterone**. CYP21A2 hydroxylates some of these progesterone molecules to form the mineralocorticoid **11-deoxycorticosterone** (**DOC**) (see Fig. 33.3). The DOC formed may be either secreted or transferred back into the mitochondrion, where CYP11B1 acts on it to form corticosterone, which is then secreted into the circulation. Progesterone may also undergo 17α-hydroxylation in the zona fasciculata and zona reticularis. It is then converted to either cortisol or the adrenal androgen **androstenedione**.

CYP17 is not present in cells of the zona glomerulosa; therefore, pregnenolone does not undergo 17α-hydroxylation in these cells, and these cells do not form cortisol and adrenal androgens. Instead, the

enzymatic pathway for aldosterone synthesis is followed (see Fig. 33.3). Enzymes in the ER convert pregnenolone to progesterone and DOC. The latter compound then moves into the mitochondrion, where it is converted to aldosterone. This conversion involves three steps: the hydroxylation of carbon 11 to form corticosterone, the hydroxylation of carbon 18 to form 18-hydroxycorticosterone, and the oxidation of the 18-hydroxymethyl group to form aldosterone. In humans, these three reactions are catalyzed by a single enzyme, **aldosterone synthase** (**CYP11B2**), an isozyme of CYP11B1, expressed only in glomerulosa cells. The CYP11B1 enzyme, which is expressed in the zona fasciculata and zona reticularis, although closely related to CYP11B2, cannot catalyze all three reactions involved in the conversion of DOC to aldosterone; therefore, aldosterone is not synthesized in the zona fasciculata and zona reticularis of the adrenal cortex.

Genetic defects in CYP enzymes alter steroidogenesis.

Inherited genetic defects can cause relative or absolute deficiencies in the enzymes involved in steroid hormone biosynthetic pathways. The consequences of such defects are changes in the type and amount of steroid hormones secreted by the adrenal cortex, resulting in disease.

Most of the genetic defects affecting the steroidogenic enzymes impair the formation of cortisol. A drop in cortisol in the blood stimulates the secretion of **adrenocorticotropic hormone** (**ACTH**) by the anterior pituitary (see Chapter 31). The consequent rise in ACTH in the blood exerts a trophic (growth-promoting) effect on the adrenal cortex, resulting in adrenal hypertrophy. People with genetic defects affecting adrenal steroidogenesis usually have hypertrophied adrenal glands. These diseases are collectively called **congenital adrenal hyperplasia**.

In humans, inherited genetic defects occur that affect CYP11A1, CYP17, 3β-HSD II, CYP21A2, CYP11B1, and CYP11B2. The most common defect involves mutations in the gene for CYP21A2 and occurs in 1 of 7,000 people. The gene for CYP21A2 may be deleted entirely, or mutant genes may code for forms of CYP21A2 with impaired enzyme activity. The consequent reduction in the amount of active CYP21A2 blocks the 21-hydroxylation reaction and interferes with the formation of cortisol, corticosterone, and aldosterone. The reduction of cortisol (and corticosterone) secretion in affected individuals promotes ACTH release, which in turn, causes adrenal gland hypertrophy and inappropriate steroidogenesis. With the 21-hydroxylation reaction impaired, pregnenolone is converted to adrenal androgens in inappropriately high amounts. Thus, women afflicted with CYP21A2 deficiency exhibit **virilization** from the masculinizing effects of excessive adrenal androgen secretion. In severe cases, the deficiency in aldosterone production can lead to sodium depletion, dehydration, vascular collapse, and death, if appropriate hormone therapy is not given.

Adrenal steroids are bound to plasma proteins.

Steroid hormones are not stored to any extent by cells of the adrenal cortex but are continually synthesized and secreted. The rate of secretion may change dramatically depending on the stimuli received by the adrenal cortical cells. The accumulation of the final products of the steroidogenic pathways creates a concentration gradient for steroid hormone diffusion through the plasma membranes and into the circulation.

A large fraction of the adrenal steroids entering the bloodstream become noncovalently bound to plasma proteins. **Corticosteroid-binding globulin** (**CBG**), a glycoprotein produced by the liver, binds both glucocorticoids and aldosterone, but has a greater affinity for the glucocorticoids. Serum albumin is a high capacity, weak-binding protein for steroids. The binding of a steroid hormone to a circulating protein molecule prevents it from being taken up by cells or being excreted in the urine.

Circulating steroid hormone molecules not bound to plasma proteins are free to interact with receptors within cells and are therefore cleared from the blood. As this occurs, bound hormone dissociates from its binding protein and replenishes the circulating pool of free hormone. Adrenal steroid hormones have long half-lives in the body, ranging from many minutes to hours, because of binding to plasma proteins.

Adrenal steroids are degraded and eliminated from the body in the urine.

Adrenal steroid hormones are structurally modified to destroy their hormone activity and increase their water solubility, primarily in the liver. The most common structural modifications made to adrenal steroids involve reduction of the double bond in ring A and conjugation of the resultant hydroxyl group formed on carbon 3 with glucuronic acid. Figure 33.3 (lower right) shows cortisol modified in this manner to produce a major excretable metabolite, **tetrahydrocortisol glucuronide**. Cortisol and other 21-carbon steroids with a 17α-hydroxyl group and a 20-keto group may undergo lysis of the carbon 20–21 side chain as well. The resultant metabolite, with a keto group on carbon 17, appears as one of the **17-ketosteroids** in the urine. Adrenal androgens are also 17-ketosteroids. They are usually conjugated with sulfuric acid or glucuronic acid before being excreted and normally comprise the bulk of the 17-ketosteroids in the urine. Before the development of specific methods to measure androgens and 17α-hydroxycorticosteroids in body fluids, the amount of 17-ketosteroids in urine was used clinically as a crude indicator of the production of these substances by the adrenal gland.

Adrenocorticotropic hormone regulates the synthesis of adrenal steroids.

ACTH is the physiologic regulator of the synthesis and secretion of glucocorticoids and androgens by the zona fasciculata and zona reticularis. It has a rapid stimulatory effect on steroidogenesis in these cells, which can raise blood glucocorticoids within seconds. It also exerts several long-term trophic effects on these cells, all directed toward maintaining the cellular machinery necessary to carry out steroidogenesis at a high, sustained rate.

ACTH binds to the melanocortin-2 receptor on the adrenocortical cell, which is coupled by stimulatory guanine nucleotide-binding proteins (G_s proteins) to adenylyl cyclase (Figure 33.4). ACTH increases cAMP and activates protein kinase A (PKA), which then phosphorylates proteins that regulate steroidogenesis. StAR protein that is already present in the cell is phosphorylated, and the rapid synthesis of new StAR protein is initiated. These actions provide abundant cholesterol for side chain cleavage enzyme, which carries out the rate-limiting step in steroidogenesis.

Figure 33.4 The main actions of adrenocorticotropic hormone (ACTH) on steroidogenesis. ACTH binds to the melanocortin-2 receptor, which is coupled to adenylyl cyclase (AC) by stimulatory G proteins (G_s). The intracellular rise in cyclic adenosine monophosphate (cAMP) activates protein kinase A (PKA), which then phosphorylates proteins (P-proteins) that stimulate the expression of genes for steroidogenic enzymes. PKA also phosphorylates steroidogenic acute regulatory (StAR) protein, which mediates the transfer of cholesterol into the mitochondria for steroidogenesis.

Steroidogenic enzyme expression

ACTH regulates transcription of genes for many of the steroidogenic enzymes in the zona fasciculata and zona reticularis. Transcription of the genes for side chain cleavage enzyme, CYP17, CYP21A2, and CYP11B1, is increased several hours after ACTH stimulation of adrenal cortical cells. Healthy people are continually exposed to episodes of ACTH secretion (see Fig. 31.5); thus, mRNA for the steroidogenic enzymes is maintained fairly constant.

The importance of ACTH-induced gene expression is evident in hypophysectomized animals or humans chronically treated with large doses of cortisol or related steroids, which suppress ACTH secretion by the anterior pituitary. The chronic lack of ACTH decreases steroidogenic gene transcription, causing a deficiency in steroidogenic enzymes in the adrenals. As a result, the administration of ACTH to such a person does not cause a marked increase in glucocorticoid secretion. Chronic exposure to ACTH is required to restore mRNA levels for the steroidogenic enzymes and, hence, the enzymes themselves to obtain normal steroidogenic responses to ACTH. A patient receiving long-term treatment with glucocorticoid may suffer serious glucocorticoid deficiency if hormone therapy is halted abruptly; withdrawing glucocorticoid therapy gradually allows time for endogenous ACTH to restore steroidogenic enzyme levels to normal.

Cholesterol availability is increased by ACTH.

There are several long-term effects of ACTH on cholesterol metabolism that support steroidogenesis. ACTH increases the abundance of LDL receptors and the activity of HMG-CoA reductase in cells of the zona fasciculata and zona reticularis, increasing the availability of cholesterol for steroidogenesis. However, it is not clear if ACTH exerts these effects directly. The abundance of LDL receptors in the plasma membrane and the activity of HMG-CoA reductase in most cells are inversely related to the amount of cellular cholesterol. By stimulating steroidogenesis, ACTH reduces the amount of cholesterol in adrenal cells; therefore, the increased abundance of LDL receptors and high HMG-CoA reductase activity in ACTH-stimulated cells may merely result from the normal compensatory mechanisms that function to maintain cell cholesterol levels.

ACTH also stimulates cholesterol esterase activity, promoting hydrolysis of the cholesterol esters stored in lipid droplets within adrenal cells, making free cholesterol available for steroidogenesis. The cholesterol esterase in the adrenal cortex is activated when phosphorylated by PKA.

Maintenance of adrenocortical cell size

Cells in the zona fasciculata and zona reticularis, but not the zona glomerulosa, are dependent on ACTH to maintain their size and structure. The trophic effect of ACTH is clearly evident in states of ACTH deficiency or excess. In hypophysectomized or ACTH-deficient people, the cells of the two inner zones atrophy. Chronic stimulation of these cells with ACTH causes them to hypertrophy.

Aldosterone regulates sodium and potassium to maintain fluid homeostasis.

Aldosterone is synthesized in the cells of the zona glomerulosa. ACTH binds to melanocortin-2 receptors on cells in this region of the adrenal cortex, increasing cAMP to stimulate aldosterone secretion to a small extent. However, angiotensin II is a more important physiologic regulator of aldosterone secretion than ACTH. An increase in serum potassium can also stimulate aldosterone secretion as discussed below.

The principal site of aldosterone action on the kidney is in the distal and collecting tubules, where the hormone promotes Na^+ retention and enhances K^+ elimination during urine formation. A secondary effect of Na^+ retention is the osmotic retention of water in the extracellular fluid compartment. The osmotic effect of aldosterone is important in regulating blood pressure (Clinical Focus 33.2).

CLINICAL FOCUS 33.2

Primary Adrenal Insufficiency: Addison Disease

Adrenal insufficiency may be caused by the destruction of the adrenal cortex (primary adrenal insufficiency), low pituitary adrenocorticotropic hormone secretion (secondary adrenal insufficiency), or deficient hypothalamic release of corticotropin-releasing hormone (tertiary adrenal insufficiency). Addison disease (primary adrenal insufficiency) results from the destruction of the adrenal gland by microorganisms or autoimmune disease. When Addison first described primary adrenal insufficiency in the mid-1800s, bilateral adrenal destruction by tuberculosis was the most common cause of the disease. Today, autoimmune destruction accounts for 70% to 90% of all cases in developed countries, with the remainder resulting from infection, cancer, or adrenal hemorrhage. The prevalence of primary adrenal insufficiency in the developed world is about 40 to 110 cases per 1 million adults.

In primary adrenal insufficiency, all three zones of the adrenal cortex are usually involved. The result is inadequate secretion of glucocorticoids, mineralocorticoids, and androgens. Major symptoms are not usually detected until 90% of the gland has been destroyed. The initial symptoms generally have a gradual onset, with only a partial glucocorticoid deficiency resulting in inadequate cortisol increase in response to stress. Mineralocorticoid deficiency may only appear as a mild postural hypotension. Progression to complete glucocorticoid deficiency results in a decreased sense of well-being and abnormal glucose metabolism. Lack of mineralocorticoid leads to decreased renal potassium secretion and reduced sodium retention, the loss of which results in hypotension and dehydration. The combined lack of glucocorticoid and mineralocorticoid can lead to vascular collapse, shock, and death. Adrenal androgen deficiency is observed in women only (men derive most of their androgen from the testes) as decreased pubic and axillary hair and decreased libido.

Antibodies that react with all three zones of the adrenal cortex have been identified in autoimmune adrenalitis and are more common in women than in men. The presence of antibodies appears to precede the development of adrenal insufficiency by several years. Antiadrenal antibodies are mainly directed to the steroidogenic enzymes: cholesterol side chain cleavage enzyme (CYP11A1), 17α-

hydroxylase (CYP17), and 21-hydroxylase (CYP21A2), although antibodies to other steroidogenic enzymes may also be present. In the initial stages of the disease, the adrenal glands may be enlarged with extensive lymphocyte infiltration. Genetic susceptibility to autoimmune adrenal insufficiency is strongly linked with the HLA-DR3 and HLA-DR4 alleles of human leukocyte antigen.

The onset of adrenal insufficiency is often insidious, and diagnosis is not made until an acute crisis occurs during another illness. Crisis is a medical emergency consisting of hypotension and acute circulatory failure. Treatment for acute adrenal insufficiency should be directed at the reversal of the hypotension and electrolyte abnormalities. Large volumes of 0.9% saline or 5% dextrose in saline should be infused as quickly as possible. Dexamethasone or a soluble form of injectable cortisol should also be given. Daily glucocorticoid and mineralocorticoid replacement allows the patient to lead a normal, active life. ■

Angiotensin II formation

Angiotensin II is a short peptide consisting of eight amino acid residues. It is formed in the bloodstream by the proteolysis of **angiotensinogen**, which is secreted by the liver. The formation of angiotensin II occurs in two stages (Fig. 33.5). First, the circulating protease **renin**, produced by juxtaglomerular cells in the kidney, cleaves angiotensinogen at its amino-terminal end, releasing the inactive decapeptide **angiotensin I**. The protease **angiotensin-converting enzyme**, present on the endothelial cells lining the vasculature, then removes a dipeptide from the carboxy-terminal end of angiotensin I, producing angiotensin II. This step usually occurs as angiotensin I molecules traverse the pulmonary circulation. The rate-limiting factor for the formation of angiotensin II is the renin concentration of the blood.

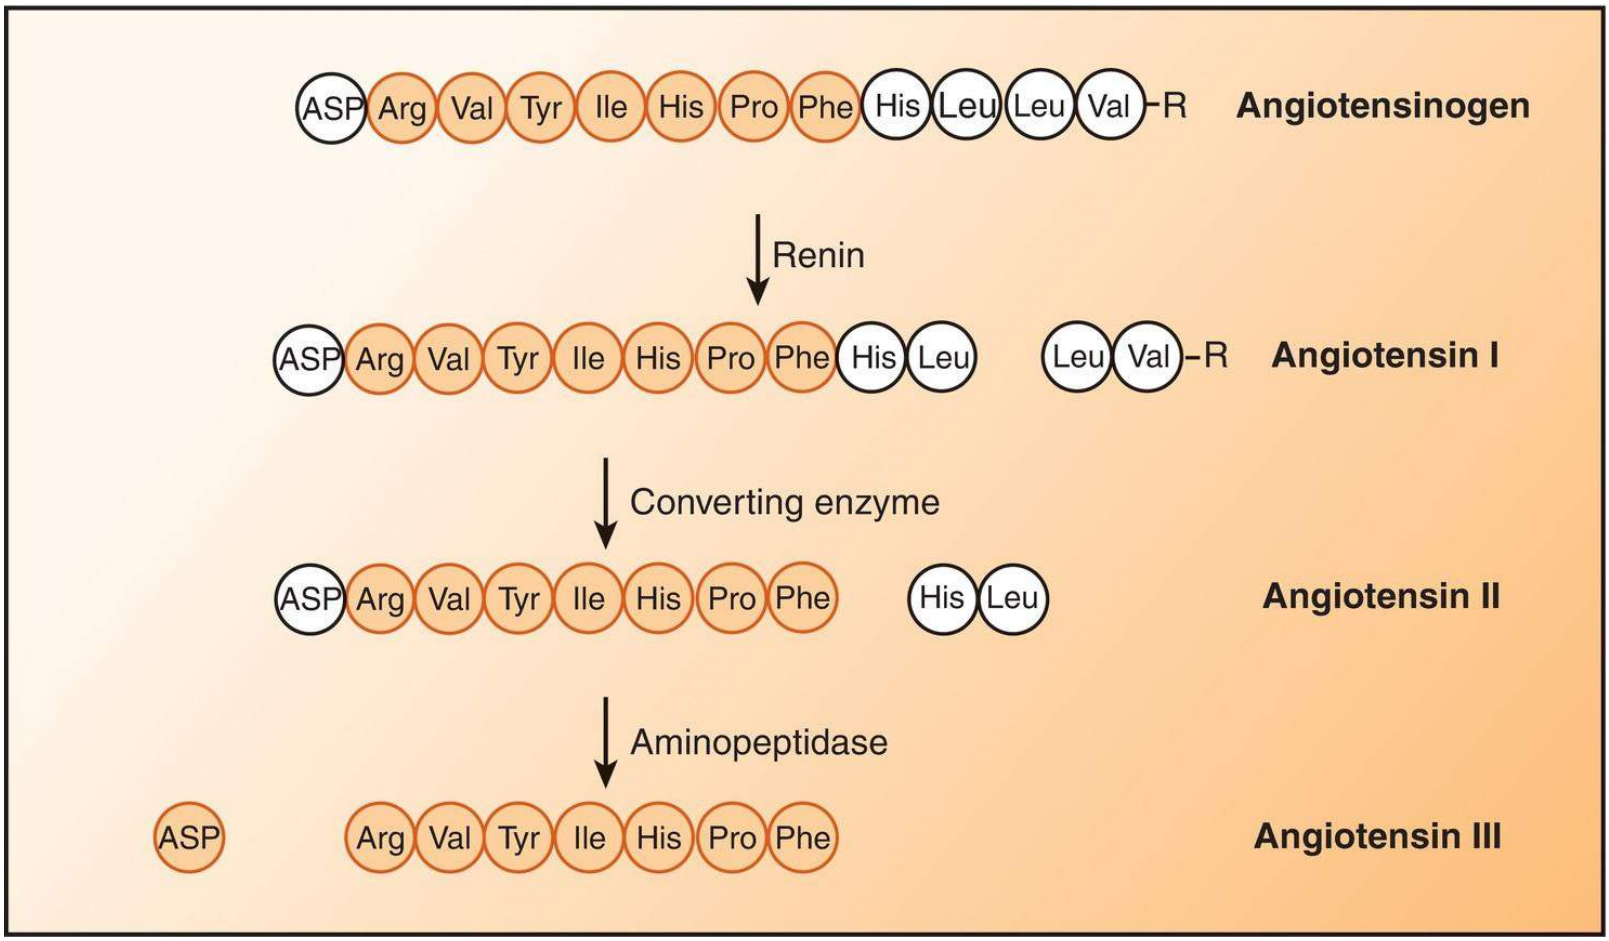

Figure 33.5 The formation of angiotensins I, II, and III from angiotensinogen.

The N-terminal aspartate of angiotensin II is cleaved to form angiotensin III, which circulates at a concentration equivalent to 20% that of angiotensin II. Angiotensin III is as potent a stimulator of aldosterone secretion as angiotensin II.

Angiotensin II action

Angiotensin II stimulates movement of cholesterol into the inner mitochondrial membrane and its conversion to pregnenolone to increase aldosterone synthesis. The primary mechanism is shown in Figure 33.6.

Figure 33.6 The action of angiotensin II on aldosterone synthesis. Angiotensin II binds its receptor on the plasma membrane of zona glomerulosa cells, activating phospholipase C (PLC), which is coupled to the angiotensin II (AII) receptor by G proteins (G_q). PLC hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) in the plasma membrane, producing inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 mobilizes intracellularly bound Ca^{2+}. The rise in Ca^{2+} and DAG activates protein kinase C (PKC) and calmodulin-dependent protein kinase (CMK). These enzymes phosphorylate proteins (P-proteins) that increase the transcription of steroidogenic enzymes and mediate the transfer of cholesterol into the mitochondria (StAR protein). StAR, steroidogenic acute regulatory protein; ER, endoplasmic reticulum.

Aldosterone synthesis is initiated when angiotensin II binds to its receptors on the plasma membranes of zona glomerulosa cells, which are linked by a G protein to phospholipase C (PLC). Activated PLC hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) in the plasma membrane, producing the intracellular second messengers inositol trisphosphate (IP_3) and diacylglycerol (DAG). The IP_3 stimulates calcium release from intracellular structures, increasing the cytosolic calcium concentration. The increase in intracellular calcium and DAG activates protein kinase C (PKC). The rise in intracellular calcium also activates calmodulin-dependent protein kinase (CMK). These enzymes phosphorylate proteins, which initiate steroidogenesis.

Angiotensin II is the final mediator in the physiologic regulation of aldosterone secretion; however, its formation from angiotensinogen depends on the secretion of renin by the kidneys. Thus, the rate of renin secretion ultimately determines the rate of aldosterone secretion. The granular cells in the walls of the afferent arterioles of renal glomeruli secrete renin. These cells are stimulated to secrete renin by three signals that indicate a possible loss of body fluid: a fall in blood pressure in the afferent arterioles of the glomeruli, a drop in sodium chloride concentration in renal tubular fluid at the macula densa, and an increase in renal sympathetic nerve activity (see Chapters 22 and 23). Increased renin secretion results in an increase in angiotensin II formation in the blood, stimulating aldosterone secretion, which conserves body fluid volume because aldosterone stimulates sodium reabsorption by the kidneys.

Aldosterone synthesis

Cells in the zona glomerulosa are sensitive to extracellular potassium concentrations and increase their rate of aldosterone secretion in response to small increases in blood and interstitial fluid potassium concentration. This signal for aldosterone secretion is appropriate from a physiologic point of view because aldosterone promotes the renal excretion of potassium (see Chapter 23).

A rise in extracellular potassium depolarizes glomerulosa cell membranes, activating voltage-dependent calcium channels in the membranes. The consequent rise in cytosolic calcium is thought to stimulate aldosterone synthesis by the same mechanism described above for angiotensin II.

Glucocorticoids regulate many cellular processes through transcription.

Most cells have receptors for glucocorticoids and are potential targets for their actions; thus, glucocorticoids have been used extensively as therapeutic agents, and much is known about their pharmacologic effects.

Unlike many other hormones, glucocorticoids influence physiologic processes slowly, sometimes taking hours to produce their effects. Glucocorticoids that are free in the blood diffuse through the plasma membranes of target cells to bind tightly but noncovalently to receptor proteins present in the cytoplasm, producing an activated glucocorticoid–receptor complex, which translocates into the nucleus. These complexes then bind to specific regions of DNA called **glucocorticoid response elements** (**GREs**) to either stimulate or inhibit transcription of target genes, changing the abundance of proteins in the cell. The apparent slowness of glucocorticoid action is a result of the time required to change the protein composition of a target cell.

Metabolic adaptation to fasting

During the fasting periods between food consumption, metabolic adaptations occur to prevent hypoglycemia and maintain blood glucose for utilization by the brain. Many of the adaptations that prevent hypoglycemia are not fully expressed in the course of daily life because the person eats before they fully develop. Complete expression of these changes is seen only after many days to weeks of fasting.

At the onset of a prolonged fast, there is a gradual decline in the concentration of glucose in the blood. Within 1 to 2 days, the blood glucose level stabilizes at a concentration of 60 to 70 mg/dL, where it remains even if the fast is prolonged for many days (Fig. 33.7). The production of glucose by the body and the restriction of its use by tissues other than the brain stabilize the blood glucose level. A limited supply of glucose is available from glycogen stored in the liver; the more important source of blood glucose during the first days of a fast is gluconeogenesis in the liver and, to some extent, in the kidneys.

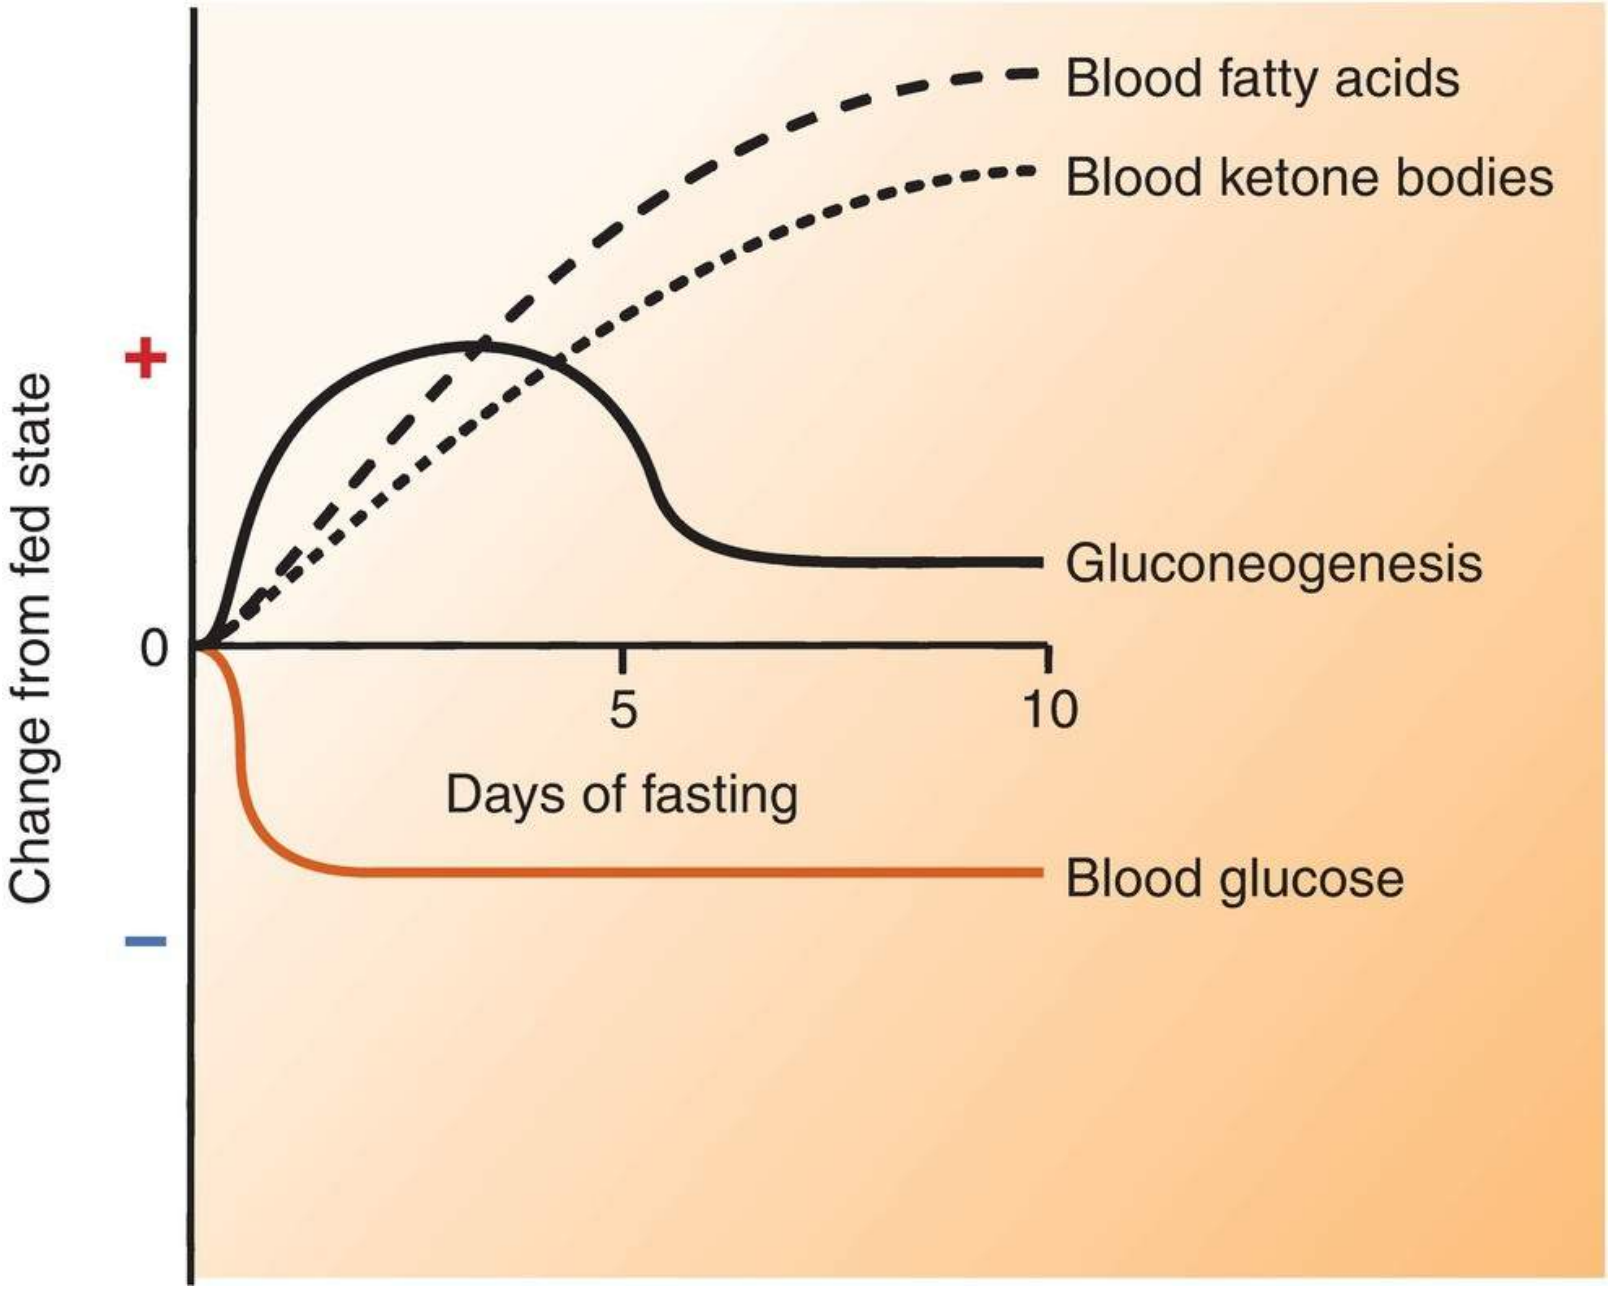

Figure 33.7 Metabolic adaptations during fasting. This graph shows the changes in the concentrations of blood glucose, fatty acids, and ketone bodies, and the rate of gluconeogenesis during the course of a prolonged fast. Only the *direction* of change over time, not the magnitude of change, is indicated: increase (+) or decrease (−).

Gluconeogenesis begins several hours after the start of a fast using amino acids derived from tissue protein are the main substrate. Fasting results in protein breakdown in the skeletal muscle and accelerated release of amino acids into the bloodstream. Insulin and glucocorticoids regulate protein breakdown and protein accretion in adult humans in an opposing fashion. During fasting, insulin secretion is suppressed, and the inhibitory effect of insulin on protein breakdown is lost. As proteins are broken down, glucocorticoids inhibit the reuse of amino acids derived from tissue proteins for new protein synthesis, promoting the release of these amino acids from the muscle. The liver and kidneys extract the amino acids from the blood at an accelerated rate and metabolize them to synthesize glucose, which is then delivered to the bloodstream.

The glucocorticoids are essential for the acceleration of gluconeogenesis during fasting, maintaining gene expression and, therefore, the intracellular concentrations of many gluconeogenic enzymes in the

liver and the kidneys. Glucocorticoids maintain the amounts of transaminases, pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1, 6-diphosphatase, fructose-6-phosphatase, and glucose-6-phosphatase needed to carry out gluconeogenesis at an accelerated rate. In an untreated, glucocorticoid-deficient person, the amounts of these enzymes in the liver are greatly reduced. As a consequence, the person cannot respond to fasting with accelerated gluconeogenesis and will die from hypoglycemia.

The other important metabolic adaptation that occurs during fasting is the mobilization and use of stored fat. Within the first few hours of the start of a fast, the concentration of free fatty acids rises in the blood (see Fig. 33.7) due to lipolysis in the adipose tissue. **Adipose triglyceride lipase** (**ATGL**) and **hormone-sensitive lipase** (**HSL**) hydrolyze the stored triglyceride to free fatty acids and glycerol, which are released into the blood. ATGL catalyzes the removal of the first fatty acid from the triglyceride, and HSL acts on the resulting DAG to cleave the second fatty acid. Monoacylglycerol lipase removes the remaining fatty acid from the glycerol backbone.

ATGL transcription and protein expression are increased by glucocorticoids during fasting. HSL is activated when it is phosphorylated by cAMP-dependent PKA. As the level of insulin falls in the blood during fasting, the inhibitory effect of insulin on cAMP accumulation in the fat cell diminishes, resulting in an increase in intracellular cAMP, activation of PKA and phosphorylation of HSL to activate it. The glucocorticoids are essential for maintaining fat cells in an enzymatic state that permits lipolysis to occur during a fast. Accelerated lipolysis does not occur when a glucocorticoid-deficient person fasts.

Many tissues take up the abundant fatty acids produced by lipolysis. The fatty acids enter mitochondria, undergo β-oxidation to acetyl-CoA, and become a substrate for ATP synthesis. The enhanced use of fatty acids for energy metabolism spares the blood glucose supply. There is also significant hepatic gluconeogenesis from the glycerol released from triglycerides during lipolysis. In prolonged fasting, when the rate of glucose production from body protein has declined, a significant fraction of blood glucose is derived from triglyceride glycerol.

Within a few hours of the start of a fast, the increased delivery and oxidation of fatty acids in the liver results in the production of ketone bodies. A gradual rise in ketone bodies occurs in the blood as a fast continues over many days (see Fig. 33.7). Ketone bodies become the principal energy source used by the central nervous system (CNS) during the later stages of fasting.

The increased use of fatty acids for energy metabolism by skeletal muscle results in less use of glucose in this tissue. Acetyl-CoA and citrate, two products resulting from the breakdown of fatty acids, inhibit glycolysis. As a result, the uptake and use of glucose from the blood are reduced.

In summary, the metabolic adaptation to fasting provides the body with glucose produced primarily from protein until the ketone bodies become abundant enough in the blood to be a principal source of energy for the brain. From that point on, the body uses mainly fat for energy metabolism, and it can survive until the fat depots are exhausted. Glucocorticoids do not trigger the metabolic adaptations to fasting but only provide the metabolic machinery necessary for the adaptations to occur. However, when present in excessive amounts, glucocorticoids can trigger many of the metabolic adaptations to the fasting state, resulting in disease.

Glucocorticoid suppression of inflammation and immune system activity

Tissue injury triggers a complex mechanism called **inflammation**, which precedes the actual repair of damaged tissue. Neighboring cells, adjacent vasculature, and phagocytic cells that migrate to the damaged site release a host of chemical mediators into the damaged area including **prostaglandins**, **leukotrienes**, **kinins**, **histamine**, **serotonin**, and **lymphokines**. These substances exert a multitude of actions at the site

of injury and directly or indirectly promote the local vasodilation, increased capillary permeability, and edema formation that characterize the inflammatory response (see Chapters 9 and 10).

Glucocorticoids inhibit the inflammatory response to injury; thus, they are extensively used therapeutically as anti-inflammatory agents. One mechanism through which glucocorticoids reduce inflammation is by inhibiting the production of prostaglandins and leukotrienes, which play a major role in mediating the inflammatory reaction. Prostaglandins and leukotrienes are synthesized from the unsaturated fatty acid arachidonic acid, which is released from plasma membrane phospholipids by the hydrolytic action of **phospholipase A_2**. Glucocorticoids stimulate the synthesis of a family of proteins called **lipocortins**, which inhibit the activity of phospholipase A_2, reducing the amount of arachidonic acid available for conversion to prostaglandins and leukotrienes.

Glucocorticoids have little influence on the human immune system under normal physiologic conditions. When administered in large doses over a prolonged period, however, they can suppress antibody formation and interfere with cell-mediated immunity. Glucocorticoid therapy is therefore used to suppress the rejection of surgically transplanted organs and tissues.

Exposure to high concentrations of glucocorticoids can kill immature T cells in the thymus and immature B cells and T cells in lymph nodes, decreasing the number of circulating lymphocytes. The destruction of immature T and B cells by glucocorticoids also causes some reduction in the size of the thymus and lymph nodes.

Glucocorticoids and stress

Both physical and psychological stresses stimulate the secretion of ACTH, which increases the secretion of glucocorticoids by the adrenal cortex. Physical stress including fever, surgery, burn injury, hypoglycemia, hypotension, and exercise raise cortisol levels, as does social/emotional stress caused by interpersonal and societal interactions and psychological trauma. The increase in glucocorticoid secretion during stress is a required counterregulatory response. It is well established that glucocorticoid-deficient people require an increase in their replacement therapy to maintain their well-being during periods of stress.

The brain plays a central role in response to both physical and psychological stress. Glucocorticoids along with excitatory neurotransmitters alter neuronal architecture by extending or retracting dendrites and increasing or decreasing synaptic density in different areas of the brain. Chronic stress can lead to epigenetic changes in the brain that can become maladaptive and require therapeutic intervention.

Negative feedback regulation of glucocorticoid release

An important physiologic action of glucocorticoids is the ability to regulate their own secretion. This effect is achieved by a negative feedback mechanism of glucocorticoids on the secretion of **corticotropin-releasing hormone** (**CRH**) and ACTH and on proopiomelanocortin (POMC) gene expression (see Chapter 31).

ADRENAL MEDULLA CATECHOLAMINES

The catecholamines epinephrine and norepinephrine (NE) are the two hormones synthesized by the chromaffin cells of the adrenal medulla. The human adrenal medulla produces and secretes about four times more epinephrine than NE. Postganglionic sympathetic neurons also produce and secrete NE but do not produce epinephrine.

Adrenal medulla is a modified sympathetic ganglion.

The medulla consists of clumps and strands of **chromaffin cells** interspersed with venous sinuses. Chromaffin cells produce epinephrine and NE, which are stored in granules in the chromaffin cells and discharged into then venous sinuses of the medulla when the adrenal branches of splanchnic nerves are stimulated. The catecholamines then diffuse into capillaries and are transported in the bloodstream. Stimuli such as injury, anger, anxiety, pain, cold, strenuous exercise, and hypoglycemia generate impulses in the cholinergic preganglionic fibers, causing a rapid discharge of the catecholamines into the bloodstream.

Catecholamines mediate the “fight-or-flight” response.

Most cells of the body have receptors for, and are responsive to, catecholamines. There are four structurally related forms of catecholamine receptors, all of which are transmembrane proteins: α_1, α_2, β_1, and β_2. All bind epinephrine or NE to varying extents (see Chapter 3).

Epinephrine and NE produce widespread effects on the cardiovascular system, muscular system, and carbohydrate and lipid metabolism in the liver, muscle, and adipose tissues. In response to a sudden rise of catecholamines in the blood, heart rate accelerates, coronary blood vessels dilate, and blood flow to the skeletal muscles is increased as a result of vasodilation, with vasoconstriction occurring in the skin. Smooth muscles in the airways of the lungs, the gastrointestinal tract, and the urinary bladder relax. Muscles in the hair follicles contract, causing piloerection. Blood glucose levels rise. This overall reaction to the sudden release of catecholamines is known as the “fight-or-flight” response (see Chapter 6).

Catecholamine release defends against hypoglycemia.

Catecholamines secreted by the adrenal medulla, and NE released from sympathetic postganglionic nerve terminals, defend the body against hypoglycemia. Catecholamine release generally starts when the blood glucose concentration falls to the low end of the physiologic range (60 to 70 mg/dL), with further declines producing marked catecholamine release. CNS receptors monitoring blood glucose are activated by hypoglycemia, stimulating the neural fibers innervating the chromaffin cells and sympathetic postganglionic nerve terminals.

Hypoglycemia can result from many situations such as insulin overdosing, catecholamine antagonists, or drugs that block fatty acid oxidation. Hypoglycemia is always a dangerous condition because the CNS will die of ATP deprivation in extended cases. The length of time profound hypoglycemia can be tolerated depends on its severity and the person's sensitivity to the hypoglycemia.

Catecholamines stimulate glucose production in the liver through activation of glycogen phosphorylase, resulting in the hydrolysis of stored glycogen, and stimulation of gluconeogenesis from lactate and amino acids. Catecholamines binding to β receptors on skeletal muscle and adipocytes also activate glycogen phosphorylase by stimulating adenylyl cyclase and increasing cAMP. The glucose 6-phosphate generated in these cells is metabolized intracellularly rather than released into the blood, because the cells lack glucose-6-phosphatase. Glycolysis converts the glucose 6-phosphate in muscle to lactate, much of which is released into the blood. The lactate taken up by the liver is then converted to glucose via gluconeogenesis and returned to the blood.

In adipocytes, the rise in cAMP produced by catecholamines activates HSL, increasing the hydrolysis of triglycerides and the release of fatty acids and glycerol into the bloodstream. These fatty acids provide an alternative substrate for energy metabolism in other tissues, primarily skeletal muscle, and block the phosphorylation and metabolism of glucose.

During profound hypoglycemia, the rapid rise in blood catecholamine levels triggers some of the same metabolic adjustments that occur more slowly during fasting. During fasting, these adjustments are initiated primarily in response to the gradual rise in the ratio of glucagon to insulin in the blood. The glucagon-to-insulin ratio also rises during profound hypoglycemia, reinforcing the actions of the catecholamines on glycogenolysis, gluconeogenesis, and lipolysis. The catecholamines released during hypoglycemia are thought to be partly responsible for the rise in the glucagon-to-insulin ratio by directly stimulating the secretion of these hormones by the pancreas. Catecholamines stimulate the secretion of glucagon by the alpha cells and inhibit the secretion of insulin by β cells (see Chapter 34). These catecholamine-mediated responses of the major metabolic tissues to hypoglycemia are summarized in Table 33.2.

TABLE 33.2 Catecholamine-Mediated Responses to Hypoglycemia

Target Tissue	Action
Liver	Stimulation of glycogenolysis
	Stimulation of gluconeogenesis
Skeletal muscle	Stimulation of glycogenolysis
Adipose tissue	Simulation of glycogenolysis
	Stimulation of triglyceride lipolysis
Pancreatic islets	Inhibition of insulin secretion by β cells
	Stimulation of glucagon secretion by α cells

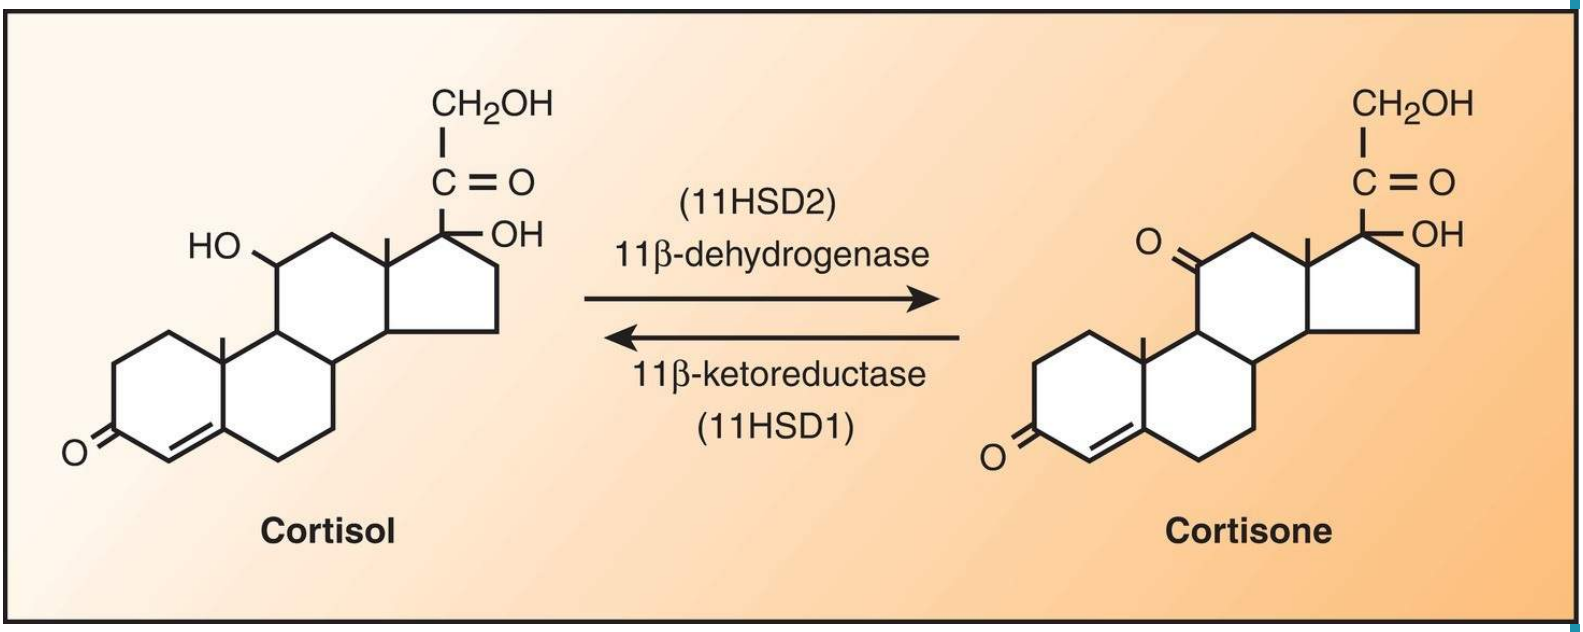
INTEGRATED MEDICAL SCIENCES

Obesity and 11β-Hydroxysteroid Dehydrogenase

Glucocorticoids regulate multiple metabolic processes, including glucose homeostasis, insulin sensitivity, and lipid metabolism. In addition, glucocorticoids are important in the differentiation of preadipocytes to adipocytes, a process termed adipogenesis. In patients with Cushing syndrome, elevated blood glucocorticoid levels cause excess fat deposition in the abdomen surrounding the organs (visceral obesity), insulin resistance, dyslipidemia, and hypertension. A similar collection of metabolic abnormalities is present in obese people, which has prompted investigation into the possibility that general obesity could be attributed to glucocorticoid excess. Although subtle alterations in the hypothalamic–pituitary–adrenal axis have been observed in obesity, no clear role for increased circulating glucocorticoid has been established.

Until recently, tissue glucocorticoid concentrations were thought to be determined by the level of glucocorticoid in the blood and tissue responses controlled by the availability of glucocorticoid receptors. It is now recognized that an enzyme, 11β-hydroxysteroid dehydrogenase (11βHSD), has a central role in regulating the concentration of glucocorticoid in specific tissues. There are two 11βHSD isozymes. The type 2 enzyme is an NAD-dependent dehydrogenase, converting active cortisol to inactive cortisone (see figure on the next page). Its main role is in aldosterone-sensitive

target tissues such as the kidney, colon, salivary glands, and placenta. Cortisol circulates in the blood at concentrations severalfold higher than those of aldosterone, but both hormones have an affinity for the nonselective mineralocorticoid receptor. By inactivating cortisol, 11βHSD2 prevents the flooding of mineralocorticoid receptors by cortisol, leaving free access for aldosterone. The second isozyme, 11βHSD1, is an NADPH-dependent reductase that converts inactive cortisone to active cortisol. 11βHSD1 is expressed primarily in glucocorticoid target tissues, such as the liver, adipose tissue, and the CNS, where it amplifies local glucocorticoid action.



Target tissue cortisol metabolism.

Several lines of evidence point to an important role for 11βHSD1 in the pathogenesis of obesity. The expression and activity of 11βHSD1 are increased in subcutaneous fat of obese humans and in the adipose tissue of obese rodent models. Adipose tissue–specific overexpression of 11βHSD1 in transgenic mice results in a phenotype of central obesity, insulin resistance, and dyslipidemia. Mice with whole-body knockout of the 11βHSD1 allele are protected from the adverse metabolic consequences of obesity such as hyperglycemia that result from high-fat feeding. Furthermore, in mice prone to developing obesity, 11βHSD1 knockout attenuates the effect of a high-fat diet to induce weight gain. Taken together, these observations suggest that 11βHSD1 has a central role in the pathophysiology of obesity and that there could be significant benefit to 11βHSD1 inhibition.

Carbenoxolone, a licorice-based compound previously used as an antiulcer medication, inhibits 11βHSD1 in the liver and has been shown to lower blood glucose in subjects with type 2 diabetes. However, carbenoxolone is poorly selective for the two 11βHSD isoforms, and an effect in adipose tissue has not been demonstrated. A class of selective 11βHSD1 inhibitors called *arylsulfonamidothiazoles* shows promise and is currently in development. Careful evaluation of potential side effects will be necessary during the development of 11βHSD1 inhibitors because the enzyme is found in many tissues. Despite this, 11βHSD1 remains a useful therapeutic target for the treatment of obesity and its associated comorbidities. ■

Chapter Summary

- The adrenal gland comprises an outer cortex surrounding an inner medulla. The cortex contains three histologically distinct zones (from outside to inside): the zona glomerulosa, zona fasciculata, and zona reticularis.
- Hormones secreted by the adrenal cortex include glucocorticoids, aldosterone, and adrenal androgens.
- The glucocorticoids cortisol and corticosterone are synthesized in the zona fasciculata and zona reticularis of the adrenal cortex.
- The mineralocorticoid aldosterone is synthesized in the zona glomerulosa of the adrenal cortex.
- Cholesterol, used in the synthesis of the adrenal cortical hormones, comes from cholesterol esters stored in the cells. Stored cholesterol is derived mainly from low-density lipoprotein particles circulating in the blood, but it can also be synthesized *de novo* from acetate within the adrenal gland.
- The conversion of cholesterol to pregnenolone in mitochondria is the common first step in the synthesis of all adrenal steroids and occurs in all three zones of the cortex.
- The liver is the main site for the metabolism of adrenal steroids, which are conjugated to glucuronic acid and excreted in the urine.
- Adrenocorticotropic hormone (ACTH) increases glucocorticoid and androgen synthesis in adrenal cortical cells in the zona fasciculata and zona reticularis by increasing intracellular cAMP. ACTH also has a trophic effect on these cells.
- Angiotensin II and angiotensin III stimulate aldosterone synthesis in the cells of the zona glomerulosa by increasing cytosolic calcium and activating protein kinase C.
- Glucocorticoids bind to glucocorticoid receptors in the cytosol of target cells. The glucocorticoid-bound receptor translocates to the nucleus and then binds to glucocorticoid response elements in the DNA to increase or decrease the transcription of specific genes.
- Glucocorticoids are essential to the adaptation of the body to fasting, injury, and stress.
- The chromaffin cells of the adrenal medulla synthesize and secrete the catecholamines epinephrine and norepinephrine.
- Catecholamines interact with four adrenergic receptors (α_1, α_2, β_1, and β_2) that mediate the cellular effects of the hormones.
- Stimuli such as injury, anger, pain, cold, strenuous exercise, hypoglycemia, and psychological stress generate impulses in the cholinergic preganglionic fibers innervating the chromaffin cells, resulting in the secretion of catecholamines.
- To counteract hypoglycemia, catecholamines stimulate glucose production in the liver, lactate release from muscle, and lipolysis in adipose tissue.

Chapter Review Questions

1. Which of the following sources of cholesterol is most important for sustaining adrenal steroidogenesis when it occurs at a high rate for a long time?

A. *De novo* synthesis of cholesterol from acetate
B. Cholesterol in LDL particles
C. Cholesterol in the plasma membrane
D. Cholesterol in lipid droplets within adrenal cortical cells
E. Cholesterol from the endoplasmic reticulum
F. Cholesterol in lipid droplets within adrenal medullary cells

The correct answer is B. Cholesterol esters in LDL sources are the most important source of cholesterol for sustaining adrenal steroidogenesis when it occurs at a high rate over a long period of time. This cholesterol can be used directly after release from LDL and not stored. *De novo* synthesis of cholesterol from acetate is a minor source of cholesterol in humans. Cholesterol from the plasma membrane or endoplasmic reticulum is not used for steroidogenesis. Cholesterol esters in lipid droplets within adrenal cortical cells would be used first and depleted during periods of high adrenal steroid hormone synthesis.

2. A 7-year-old boy comes to the pediatric endocrine unit for evaluation of excess body weight. Review of his growth charts indicates substantial weight gain over the previous 3 years but little increase in height. To differentiate between the development of obesity and Cushing syndrome, blood and urine samples are taken. Which of the following would be most diagnostic of Cushing disease?

A. Increased serum ACTH, decreased serum cortisol, and increased urinary free cortisol
B. Decreased serum ACTH, increased serum cortisol, and increased serum insulin
C. Increased serum ACTH, increased serum cortisol, and increased serum insulin
D. Increased serum ACTH, decreased serum cortisol, and decreased serum insulin
E. Increased serum ACTH, decreased serum cortisol, and decreased urinary free cortisol
F. Decreased serum ACTH, decreased serum cortisol, and increased serum insulin

The correct answer is C. The increase in body weight with little linear growth suggests that the patient has Cushing disease rather than general obesity since linear growth usually continues in obesity syndromes. Laboratory findings in Cushing syndrome include elevated ACTH, serum cortisol, urinary cortisol, and serum insulin (due to the cortisol-induced resistance to insulin action in the peripheral tissues).

3. Congenital adrenal hyperplasia is most likely a result of:

A. defects in adrenal steroidogenic enzymes.
B. Addison disease.
C. defects in ACTH secretion.
D. defects in corticosteroid-binding globulin.
E. Cushing disease.
F. defects in aldosterone synthase.

The correct answer is A. Congenital adrenal hyperplasia is the result of genetic defects that affect adrenal steroidogenic enzymes resulting in impaired formation of cortisol. Low serum cortisol is a stimulus for ACTH release from the hypothalamus. The increase in ACTH has a proliferative effect on

the adrenal gland resulting in hyperplasia. Addison disease is the result of pathologic destruction of the adrenal glands by microorganisms or autoimmune disease and would therefore not result in adrenal hyperplasia. ACTH stimulates the growth of the adrenal gland. A reduction in ACTH in the blood would result in atrophy of the adrenal gland. Corticosteroid-binding globulin noncovalently binds steroid hormones in plasma; defects in this protein are not associated with adrenal hyperplasia. Cushing disease results from a pituitary ACTH-secreting tumor; adrenal hyperplasia is secondary, not congenital, in this disease. Aldosterone synthesis is regulated by the renin–angiotensin system. Defective aldosterone synthesis would, therefore, not lead to increased ACTH and adrenal hyperplasia.

4. What is the mechanism through which catecholamines stabilize blood glucose concentration in response to hypoglycemia?

A. Catecholamines stimulate glycogen phosphorylase to release glucose from muscle.
B. Catecholamines inhibit glycogenolysis in the liver.
C. Catecholamines stimulate the release of insulin from the pancreas.
D. Catecholamines inhibit the release of fatty acids from adipose tissue.
E. Catecholamines stimulate gluconeogenesis in the liver.
F. Catecholamines inhibit the release of lactate from muscle.

The correct answer is E. Catecholamines stimulate glycogenolysis and gluconeogenesis in the liver, causing glucose to be synthesized and released into the blood. Catecholamines stimulate glycogen phosphorylase in muscle to free glucose for use by the muscle. Muscle cannot release glucose to the circulation because it lacks glucose-6-phosphatase. However, the muscle can release lactate, which can be used in gluconeogenesis by the liver. Catecholamines inhibit the release of insulin from the pancreas. Insulin would be counterproductive to attempt to increase blood glucose. Catecholamines increase the release of fatty acids from the adipose tissue, to be used in gluconeogenesis by the liver.

5. A patient receiving long-term glucocorticoid therapy plans to undergo hip replacement surgery. What would the physician recommend prior to surgery and why?

A. Glucocorticoids should be decreased to prevent serious hypoglycemia during recovery.
B. Glucocorticoids should be increased to stimulate immune function and prevent possible infection.
C. Glucocorticoids should be decreased to minimize potential interactions with anesthetics.
D. Glucocorticoids should be increased to stimulate ACTH secretion during surgery to promote wound healing.
E. Glucocorticoids should be decreased to prevent inadequate vascular response to catecholamines during recovery.
F. Glucocorticoids should be increased to compensate for the increased stress associated with surgery.

The correct answer is F. Patients on long-term glucocorticoid therapy should have the dose increased prior to undergoing surgery to minimize the effects of surgical stress. These patients cannot mount their own stress response because of the lack of adrenal cortisol release. Glucocorticoid-induced hypoglycemia or interactions with anesthetics are not likely, and these concerns would be secondary to stimulating the response to surgical stress. Glucocorticoids inhibit ACTH release and the immune response. Glucocorticoids increase the response of the vasculature to catecholamines.

Clinical Application Exercises 33.1

CONGENITAL ADRENAL HYPERPLASIA

The pediatric endocrinologist is called in to consult on the case of a 1-week-old female neonate. The baby was born at home and is now being seen in the emergency room because she appears listless and has not nursed at all during the last 24 hours. The parents report that the baby has become increasing listless and less willing to nurse since birth. Upon physical examination, the baby exhibits signs of virilization (growth of pubic hair) and hyponatremia (low plasma sodium), hyperkalemia (high plasma potassium), and volume depletion.

QUESTIONS

1. Based on the physical examination, history, and what you know about adrenal steroidogenesis, what would be a reasonable initial hypothesis?
2. What are the two most likely congenital defects in adrenal steroidogenic enzymes that could explain the findings in this child?
3. From a blood sample, what hormones and metabolites would you ask the laboratory to measure and what would you expect the results to be?
4. From the hormone and metabolite analysis, how would you distinguish between the two most likely causes for this case of congenital adrenal hyperplasia?
5. A genetic screen utilizing DNA from the baby's white cells identifies an inactivating mutation in the gene (*CYP21A2)* for 21-hydroxylase. What would be appropriate hormone replacement for this patient?

ANSWERS

1. A reasonable initial hypothesis is that the baby has a form of congenital adrenal hyperplasia. The virilization (appearance of pubic hair) suggests the presence of excess androgen production by the adrenal gland. The hyponatremia, hyperkalemia, and volume depletion suggest a "salt-wasting" syndrome.
2. Mutations in *CYP21A2*, which encodes 21-hydroxylase, accounts for more than 90% of all cases of adrenal hyperplasia associated with excess androgen production. Mutations in *CYP11B1*, which encodes 11β-hydroxylase, would also result in excess adrenal androgen production.
3. Adrenal androgens would be significantly elevated in patients with virilizing forms of congenital adrenal hyperplasia. Adrenal hyperplasia is usually due to defects in cortisol production. Therefore, the serum concentrations of precursors of cortisol biosynthesis such as progesterone, 17α-hydroxyprogesterone, and 11-deoxycortisol could be elevated. In addition, serum ACTH would be elevated due to the lack of negative feedback from the absent cortisol.
4. Genetic defects in the gene for 11β-hydroxylase resulting in a reduction in the activity of this enzyme would result in increased 11-deoxycortisol. Defects in the gene for 21-hydroxylase, which impair the activity of the enzyme, would not lead to the production of 11-deoxycortisol. Since 11-deoxycortisol has significant mineralocorticoid activity, excess production of this steroid is usually associated with hypertension, rather than volume depletion and hypotension as is observed in this patient.
5. Treatment would be directed toward replacement of glucocorticoids and mineralocorticoids. Glucocorticoids would replace the missing cortisol and also suppress ACTH secretion. With less ACTH stimulation of steroid production from the adrenal gland, the hyperandrogenism should be reduced. Mineralocorticoids are given to treat the "salt wasting" that occurs in the

absence of aldosterone.

34 Endocrine Pancreas

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how cells of the exocrine and endocrine pancreas coordinate to direct many processes related to the digestion, uptake, and use of metabolic fuels.
- Explain how islet cell junctions, vascular supply, and innervation influence islet cell functionality.
- Explain how a key mechanism of insulin secretion led to the development of sulfonylureas.
- Explain how amylin and pancreatic polypeptide work in conjunction with insulin to control fuel metabolism during periods of feeding.
- Explain the molecular aspects of proinsulin biosynthesis that are of clinical significance.
- Explain how mechanistic aspects of the incretin effect have led to a new class of antidiabetic drugs.
- Explain how the etiology of diabetes development is different between types of diabetes.
- Explain how both genetic and nongenetic factors can impair insulin responsiveness.
- Explain how in addition to promoting diabetic complications a series of related variables in metabolic syndrome apparently worsen insulin sensitivity.

The development of mechanisms for the storage of large amounts of metabolic fuel was an important adaptation in the evolution of complex organisms. The processes involved in the digestion, storage, and use of fuels require a high degree of regulation and coordination. Exocrine and endocrine portions of the pancreas play a vital role in these processes. Cells of the **exocrine pancreas** produce and secrete digestive enzymes and fluids into the upper part of the small intestine. Cells of the **endocrine pancreas**, an anatomically small portion of the pancreas (1% to 2% of the total mass), produce hormones involved in regulating fuel storage and use. This chapter focuses primarily on hormones of the endocrine pancreas that coordinate and direct many processes related to the digestion, uptake, and use of metabolic fuels.

ISLETS OF LANGERHANS

The endocrine pancreas consists of numerous discrete clusters of cells, known as the **islets of Langerhans**, which are located throughout the pancreas but are most abundant in the tail region. The human pancreas contains, on average, about 1 million islets, which vary in size from 50 to 300 μm wide. A connective tissue sheath separates each islet from the surrounding acinar tissue. Islets are composed of five major hormone-producing cell types: glucagon-secreting **α cells**, insulin-secreting and amylin-secreting **β cells**, somatostatin-secreting **δ cells**, **pancreatic polypeptide** (**PP**)-secreting **F cells**, and **ghrelin**-secreting **ε cells**.

Cells of the islets of Langerhans display a highly organized arrangement.

In the early 1900s, M. A. Lane established a histochemical method by which two kinds of islet cells could be distinguished. He found that alcohol-based fixatives dissolved the secretory granules in most of the islet cells but preserved them in a few cells. Water-based fixatives had the opposite effect. He named cells containing alcohol-insoluble granules α cells and those containing alcohol-soluble granules β cells. Many years later, immunofluorescence techniques demonstrated that α cells produce glucagon and β cells produce insulin. Moreover, immunofluorescent staining has shown that α-, β-, δ-, F-, and ε-cell types are arranged in each islet in a pattern suggesting a highly organized cellular community, in which paracrine influences may play an important role in determining hormone secretion rates. As illustrated in Figure 34.1, α cells are generally located near the periphery of the islet, where they form a cortex of cells surrounding the more centrally located β cells. The insulin-producing β cells are the most numerous cell type of the islet, comprising 70% to 90% of the islet. The pancreatic islet δ cells that produce somatostatin are typically located in the periphery, often between β cells and the surrounding mantle of α cells. F cells are the least abundant of the hormone-secreting cells of islets, representing only about 1% of the total cell population. The distribution of F cells is generally similar to that of δ cells. Studies performed mainly in rodents suggest that ε cells are a developmentally regulated islet cell with the cells appearing early in development and then dissipating as β cells appear. Interestingly, the number of ε cells is increased in mouse models of β-cell deficiency. In human and rodent pancreases of neonates and adults, a few ε cells remain visible in marginal areas of the islets. Although studies continue to investigate the exact role that ghrelin-secreting ε cells may have in the pancreas, blockade of ghrelin or ghrelin action in pancreatic islets markedly enhances glucose-induced insulin release.

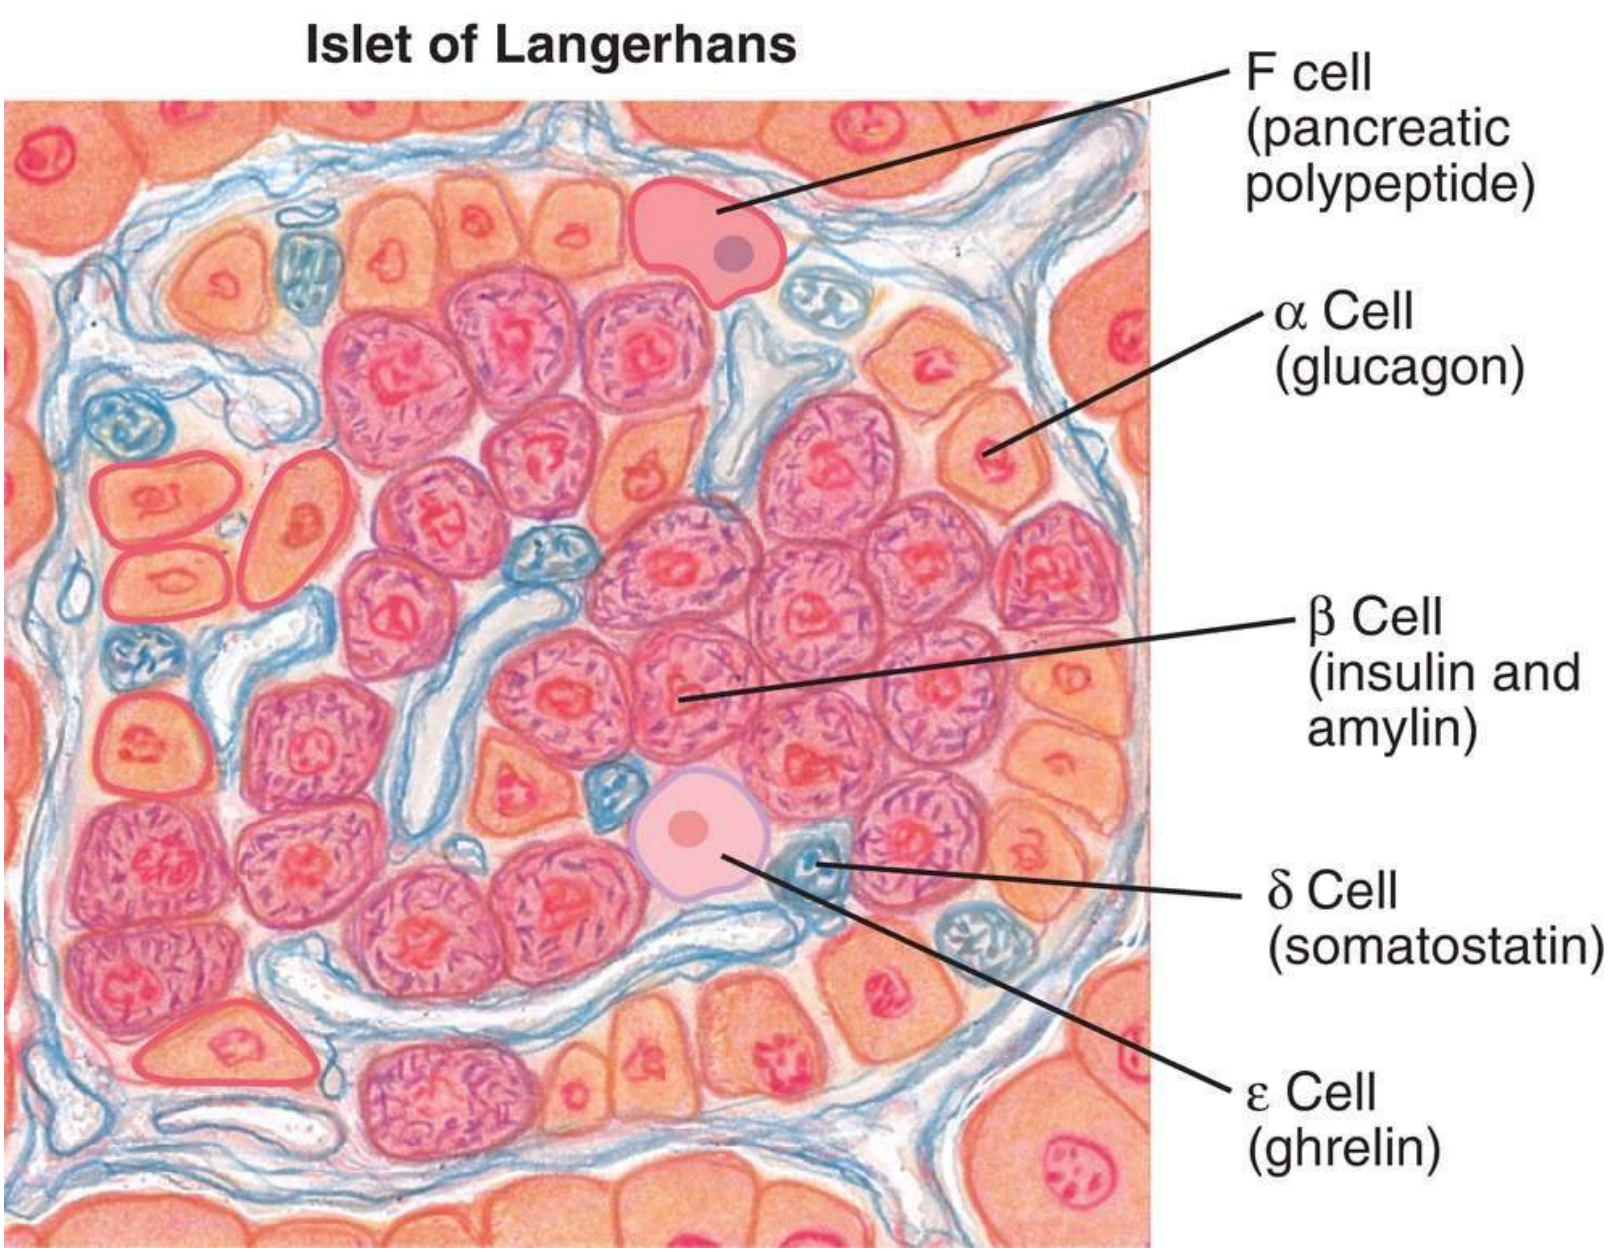

Figure 34.1 Major cell types in a typical islet of Langerhans. Note the distinct anatomic arrangement of the various cell types.

Cell, vascular, and neural connections likely contribute to islet cell functionality.

Islet cells have both gap junctions and tight junctions, suggesting that cell-to-cell communication within the islet may play a role in regulating hormone secretion. Gap junctions link different cell types in the islet and potentially provide a means for the transfer of ions, nucleotides, or electrical current between cells. The presence of tight junctions between outer membrane leaflets of contiguous cells could result in the formation of microdomains in the interstitial space, which may also be important for paracrine communication. Although the existence of gap junctions and tight junctions in pancreatic islets is well documented, their exact function has not been fully defined.

The arrangement of the vascular supply to islets is also consistent with paracrine involvement in regulating islet secretion. Afferent blood vessels penetrate nearly to the center of the islet before branching out and returning to the surface of the islet. The innermost cells of the islet, therefore, receive arterial blood, whereas those cells nearer the surface receive blood containing secretions from inner cells. Because there is a definite anatomic arrangement of cells in the islet (see Fig. 34.1), one cell type could affect the secretion of others. In general, the effluent from smaller islets passes through neighboring pancreatic acinar tissue before entering into the hepatic portal venous system. By contrast, the effluent from larger islets passes directly into the venous system without first perfusing adjacent acinar tissue. Therefore, islet hormones arrive in high concentrations in some areas of the exocrine pancreas before reaching peripheral tissues. However, the exact physiologic significance of these arrangements is unknown.

Neural inputs also influence islet cell hormone secretion. Islet cells receive sympathetic and parasympathetic innervation. Responses to neural input occur as a result of activation of various adrenergic and cholinergic receptors (described below). Neuropeptides released together with the neurotransmitters may also be involved in regulating hormone secretion.

▶ MECHANISMS OF ISLET HORMONE SYNTHESIS AND SECRETION

Understanding the mechanisms by which islet hormones are synthesized and secreted is of fundamental importance and clinical significance for metabolic health.

Glucose is a major physiological factor regulating insulin synthesis and secretion.

Insulin secretion and synthesis are stimulated when islets are exposed to glucose. Apparently, the metabolism of glucose by the β cell triggers both of these events. Whereas molecular steps by which glucose metabolites regulate insulin secretion have been defined, the basis of glucose-regulated insulin synthesis is not entirely clear. However, studies document that within minutes after raising plasma glucose levels, the rate of proinsulin synthesis increases 5- to 10-fold. At the molecular level, an enhanced efficiency of initiation of translation of proinsulin RNA is observed in the β cell following glucose exposure.

The gene for insulin is located on the short arm of chromosome 11 in humans. Like other hormones and secretory proteins, insulin is first synthesized by ribosomes of the rough endoplasmic reticulum (RER) as a larger precursor peptide that is then converted to the mature hormone prior to secretion (see Chapter 30). The insulin gene product is a 110-amino acid peptide, preproinsulin. Proinsulin consists of 86 amino acids (Fig. 34.2); residues 1 to 30 constitute what will form the B chain of insulin, residues 31 to 65 form the connecting peptide, and residues 66 to 86 constitute the A chain. (Note that "connecting peptide" should not be confused with "C-peptide.") In the process of converting proinsulin to insulin, two pairs of basic amino acid residues are clipped out of the proinsulin molecule, resulting in the formation of insulin and **C-peptide**, which are ultimately secreted from the β cell in equimolar amounts. In addition, small amounts of intact proinsulin and proinsulin conversion intermediates are released. Proinsulin and its related conversion intermediates can be detected in the circulation, where they constitute 20% of total circulating insulin-like immunoreactivity. *In vivo*, proinsulin has a biologic potency that is only about 10% of that of insulin, and the potency of split proinsulin intermediates is between those of proinsulin and insulin.

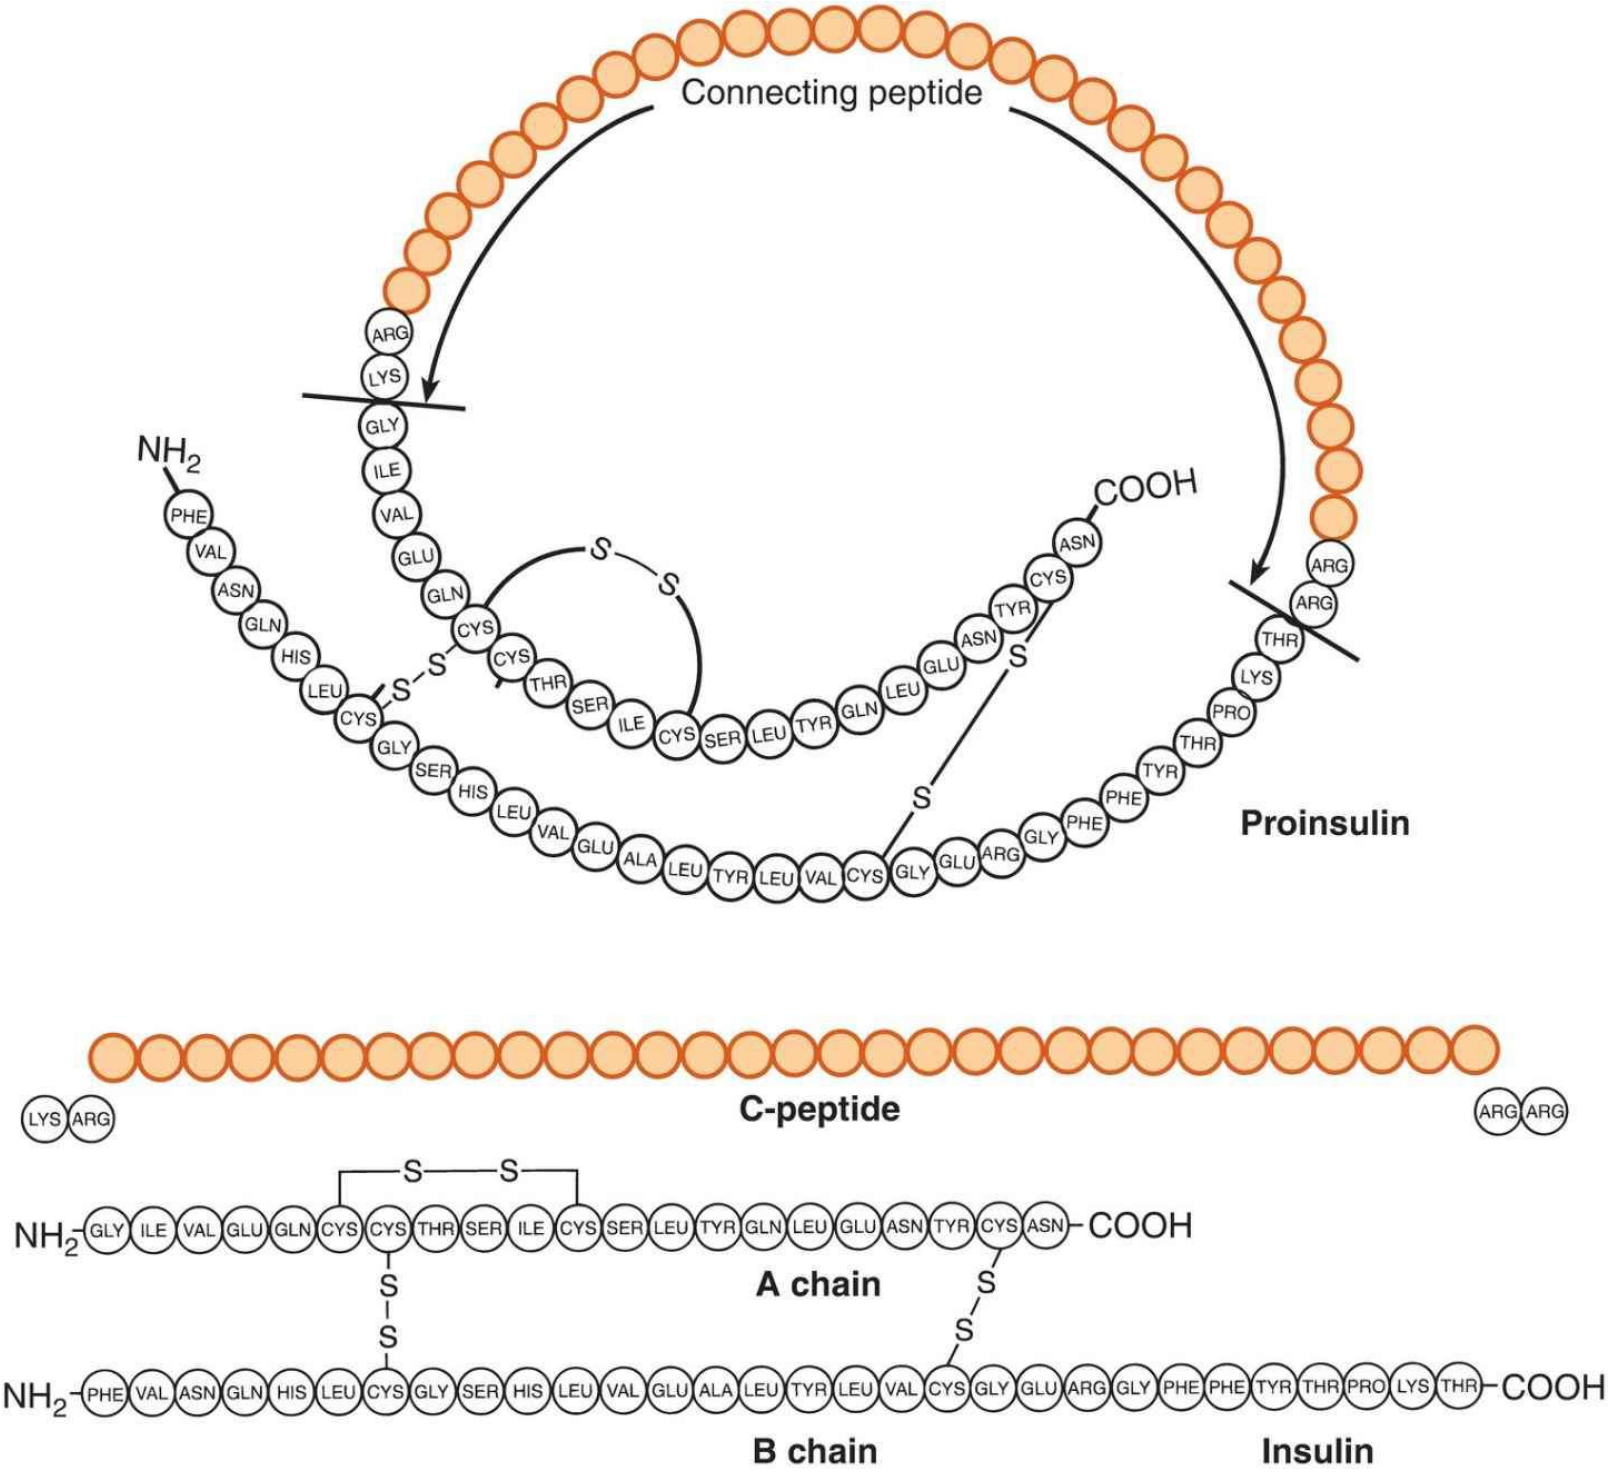

Figure 34.2 The structure of proinsulin, C-peptide, and insulin. Note that with the removal of two pairs of basic amino acids, proinsulin is converted into insulin and C-peptide.

It is of clinical significance that insulin and C-peptide are cosecreted in equal amounts. The measurement of peripheral insulin concentrations by radioimmunoassay is limited by the fact that 50% to 60% of the insulin produced by the pancreas is extracted by the liver without ever reaching the systemic circulation. In contrast, the liver does not extract C-peptide. Because C-peptide is secreted in equimolar concentrations with insulin and is not extracted by the liver, β-cell secretion rates can be calculated. In addition, as discussed in Chapter 30, another advantage of measuring C-peptide is that the standard insulin radioimmunoassay does not distinguish between endogenous and exogenous insulin, making it an ineffective measure of endogenous β-cell function in an insulin-treated diabetic patient (see Clinical Focus 30.2).

Glucose-stimulated insulin secretion is dose related. Dose-dependent increases in insulin release have been observed after oral and intravenous glucose loads. The insulin secretory response is greater after oral than after intravenous glucose administration. Known as the **incretin effect**, this enhanced response to oral glucose has been interpreted as an indication that absorption of glucose by way of the GI tract stimulates the release of hormones and other mechanisms that ultimately enhance the sensitivity of the β cell to glucose (see following discussion). The relationship of glucose concentration to the rate of insulin secretion follows a sigmoidal curve, with a threshold corresponding to the glucose levels normally seen under fasting conditions and with the steep portion of the dose–response curve corresponding to a normal postprandial range of glucose levels (Fig. 34.3A). When glucose is infused intravenously at a constant rate, a biphasic secretory response is observed that consists of a rapid, early insulin peak followed by a second, more slowly rising peak (Fig. 34.3B). In contrast to the slow rise in plasma glucose concentration following an oral glucose challenge, glucose given intravenously promotes a rapid rise in plasma glucose concentration (compare Fig. 34.3A and B). Sensing a rapid rise in plasma glucose concentration, the β cells first secrete their stores of presynthesized insulin. Following this acute phase, the cells begin to secrete newly synthesized insulin in the chronic phase, which lasts as long as the glucose challenge. *In vitro* studies of isolated islet cells and the perfused pancreas have identified a third phase of insulin secretion, commencing 1.5 to 3.0 hours after exposure to glucose and characterized by a spontaneous decline in secretion to 15% to 25% of the amount released during peak secretion: a level maintained for more than 48 hours.

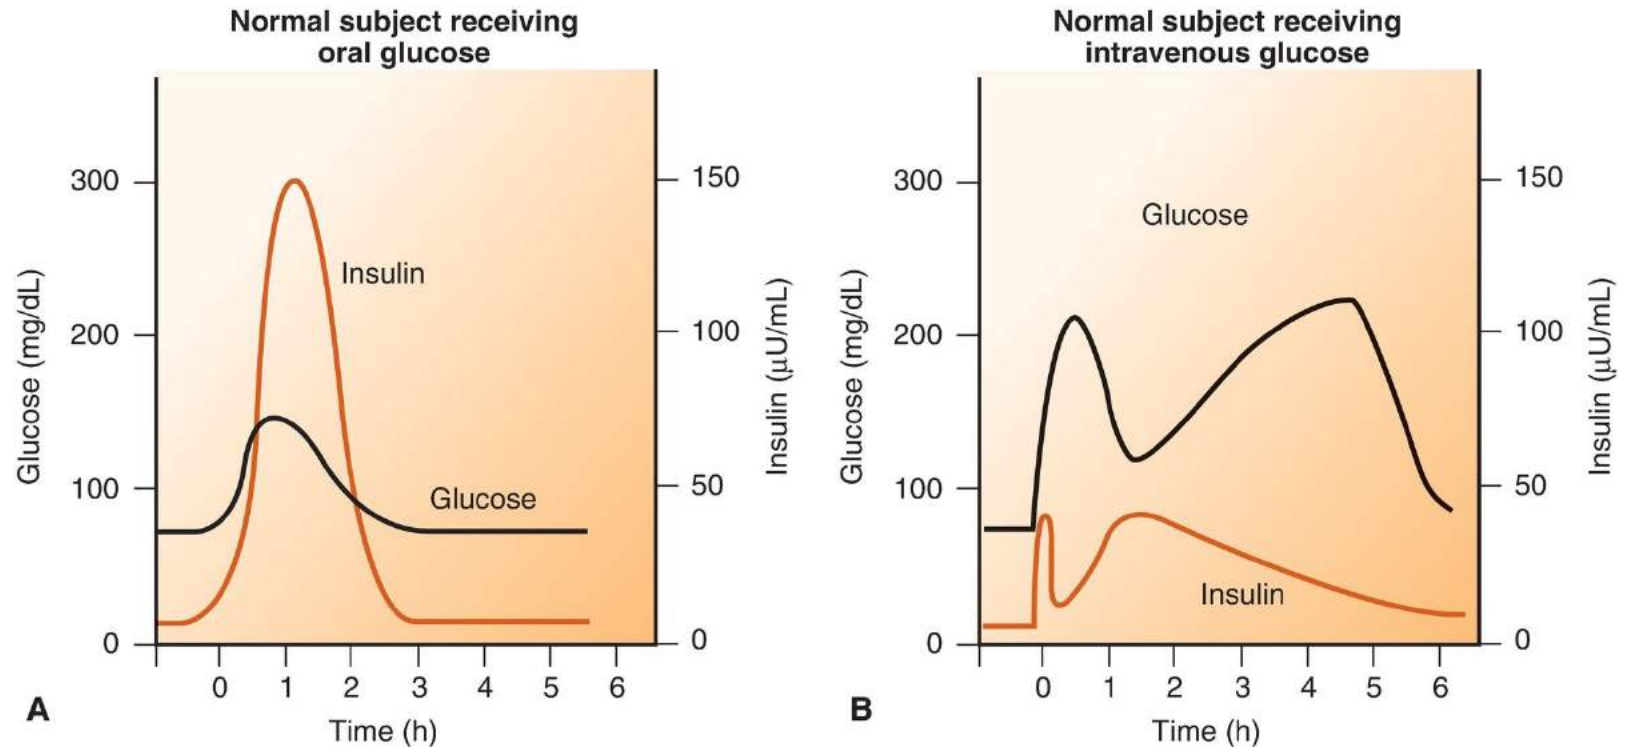

Figure 34.3 Plasma glucose and insulin following an oral (A) or intravenous (B) glucose challenge.

There are several mechanistic steps of glucose-stimulated insulin secretion (Fig. 34.4). Recall from earlier discussion of membrane transport (see Chapter 2) that the movement of glucose into a cell requires a transport system. The glucose transporter **GLUT2** mediates movement of glucose into the β cell. In the cytosol, glycolysis converts glucose to pyruvate in a series of enzymatic steps; the first rate-limiting step in this process is the phosphorylation of glucose to glucose-6-phosphate by the enzyme **glucokinase**. There is considerable evidence that glucokinase, by determining the rate of **glycolysis**, functions as the

glucose sensor of the β cell and that this is the primary mechanism whereby the rate of insulin secretion adapts to changes in blood glucose. **Adenosine triphosphate** (**ATP**) is synthesized during this process, and even more is produced during the subsequent oxidation of pyruvate within the mitochondrion. The increase in cytosolic ATP is a key signal that initiates insulin secretion by causing blockade of the **ATP-dependent K^+ channel** ($\mathbf{K_{ATP}}$) on the β-cell membrane. Blockade of this channel induces membrane depolarization, which activates voltage-gated Ca^{2+} channels. The associated Ca^{2+} influx increases cytosolic Ca^{2+} and additionally boosts cytosolic Ca^{2+} levels via triggering Ca^{2+}-induced Ca^{2+} release. The increase in cytosolic Ca^{2+} is the main spark for exocytosis, the process by which insulin-containing secretory granules fuse with the plasma membrane, leading to the release of insulin into the circulation.

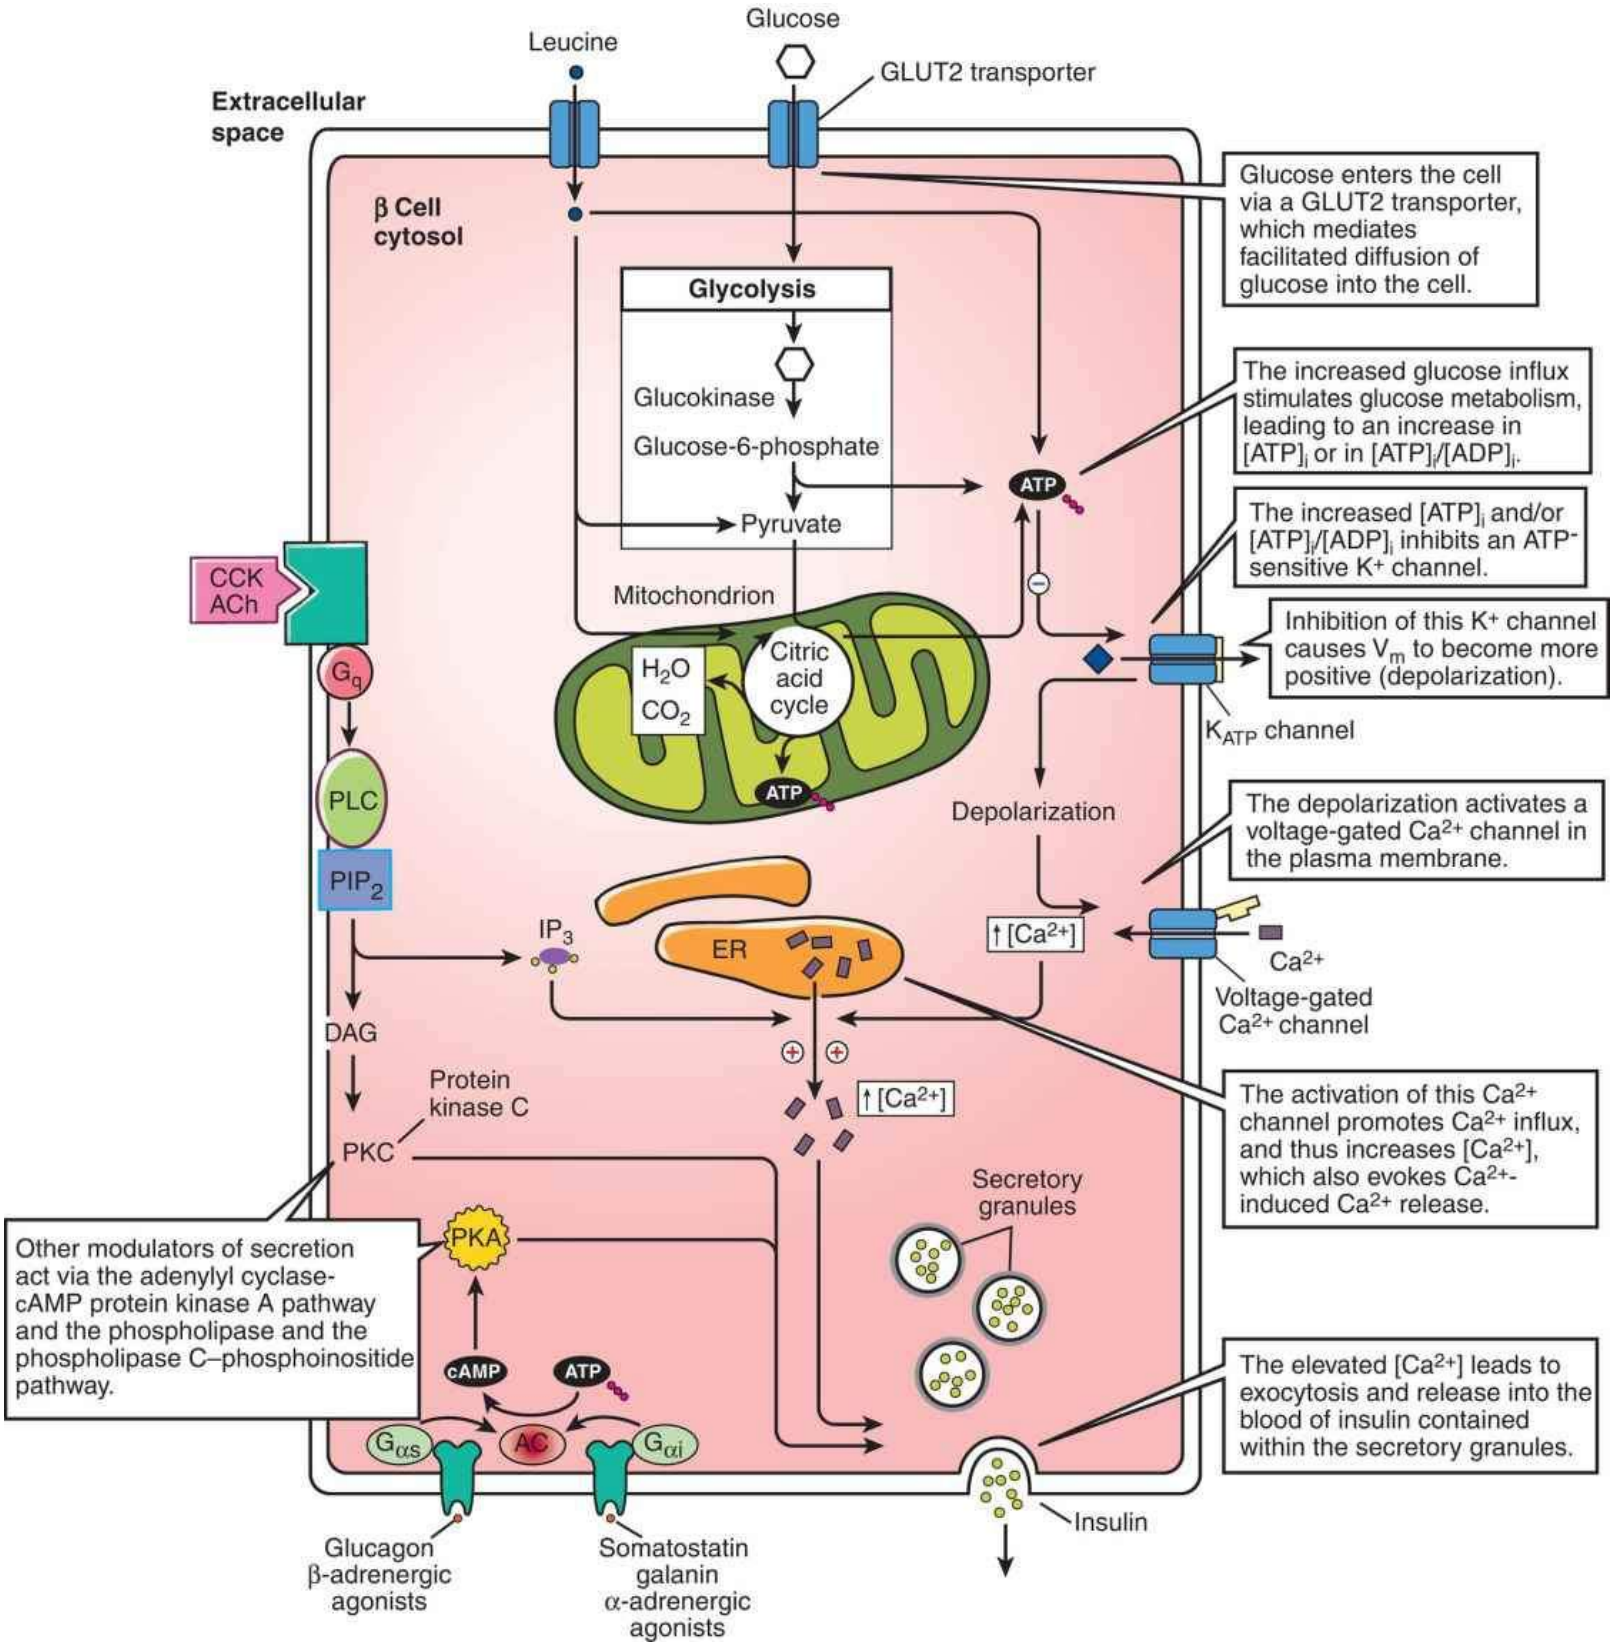

Figure 34.4 Stimuli and signals mediating insulin secretion by the pancreatic β cell. AC, adenylyl cyclase; $[ADP]_i$, intracellular concentration of adenosine diphosphate; ATP, adenosine triphosphate; $[ATP]_i$, intracellular concentration of adenosine triphosphate; cAMP, cyclic adenosine monophosphate; CCK, cholecystokinin; DAG, diacylglycerol; ER, endoplasmic reticulum; $G_{\alpha i}$, guanine nucleotide-binding protein α-inhibitory subclass; $G_{\alpha s}$, guanine nucleotide-binding protein **α**-stimulatory subclass; G_q, G-proteins; GLUT2, glucose transporter; IP_3, inositol trisphosphate; K_{ATP}, ATP-dependent K^+ channel; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; V_m, electrical potential difference across membrane.

Interestingly, in addition to the initial engagement of exocytosis by ATP (i.e., ATP-mediated K_{ATP} closure), ATP also serves as a major permissive factor for movement of insulin granules and for the priming of exocytosis. The essential role of K_{ATP} channels in insulin secretion is the basis for **sulfonylureas**, a class of drugs used orally in the treatment of **type 2 diabetes**. K_{ATP} channels comprise sulfonylurea receptors, and sulfonylureas are a class of drugs used orally as an insulin **secretagogue** in the treatment of T2D.

In addition to glucose, several other factors such as amino acids, hormones, and neural communication serve as important regulators of insulin secretion (Table 34.1). Among the amino acids, leucine, arginine, and lysine are potent secretagogues. The effects of arginine and lysine on the β cell appear to be more potent than that of leucine. Mechanistically, the amino acids appear to trigger insulin secretion via ATP production generated via their metabolism. Various lipids and their metabolites also impact insulin secretion. Acutely, lipids and their metabolites enhance glucose-stimulated insulin secretion. However, long-term exposure of islets to lipid impairs glucose-stimulated insulin secretion and biosynthesis, potentially contributing to β-cell failure.

TABLE 34.1 Factors Regulating Insulin and Glucagon Secretion

	Insulin	Glucagon
Stimulatory agents or conditions	Hyperglycemia	Hypoglycemia
	Amino acids	Amino acids
	Fatty acids (especially long chain)	Acetylcholine
	Gastrointestinal hormones (e.g., GLP1)	Norepinephrine
	Acetylcholine	Epinephrine
	Sulfonylureas	
Inhibitory agents or conditions	Somatostatin	Fatty acids
	Norepinephrine	Somatostatin
	Epinephrine	Insulin

Many GI peptide hormones, including **glucose-dependent insulinotropic peptide, cholecystokinin**, and **glucagon-like peptide 1** (**GLP1**), facilitate the release of insulin from the β cell after a meal. These hormones are released from small intestinal cells following a meal and travel in the blood to reach β cells, where they act through second messengers to increase the sensitivity of these islet cells to glucose. In general, these hormones are not themselves secretagogues, and their effects are evident only in the presence of hyperglycemia. Note that the total amount of insulin that is secreted is greater after oral as opposed to intravenous glucose administration (see Fig. 34.3).

Other intestinal peptide hormones, including VIP, secretin, and gastrin, may also influence the postprandial insulin secretory response, but the exact role of these hormones is currently unclear. The hormones of the neighboring α and δ pancreatic islet cells also modulate β-cell insulin release. Whereas glucagon has a stimulatory effect via a $G_{\alpha s}$-stimulation of adenylyl cyclase, somatostatin suppresses this effect by engaging $G_{\alpha i}$ (see Fig. 34.4). Other hormones reported to exert a stimulatory effect on insulin secretion include growth hormone, glucocorticoids, prolactin, placental lactogen, and the sex steroids.

Sympathetic and parasympathetic divisions of the autonomic nervous system richly innervate islets. Activation of α-adrenoceptors inhibits insulin secretion, whereas β-adrenoceptor stimulation augments insulin secretion. Norepinephrine released by the sympathetic neurons of the pancreas stimulates α-

adrenoceptors more than β-adrenoceptors. This response would appear appropriate because during periods of stress and high catecholamine secretion, the desired response is mobilization of glucose and other nutrient stores. Direct infusion of acetylcholine into the pancreatic circulation stimulates insulin secretion, reflecting the role of parasympathetic innervation in regulating insulin secretion.

Hypoglycemia stimulates glucagon secretion.

Similar to insulin, glucagon is first synthesized as part of a larger precursor protein. Many of the factors that regulate insulin secretion also regulate glucagon secretion. In most cases, however, these factors have the opposite effect on glucagon secretion.

Glucagon is a simple 29-amino acid peptide. The initial gene product for glucagon, preproglucagon, is a much larger peptide. As with other peptide hormones, the “pre” piece is removed in the RER, and the prohormone is converted into a mature hormone as it is packaged and processed in secretory granules. Within α cells of the pancreas, proglucagon is cleaved at two positions to yield three peptides, illustrated in Figure 34.5 (left). In contrast, in other cells of the gastrointestinal tract in which proglucagon is also produced, the molecule is cleaved at three different positions such that **glicentin, glucagon-like peptide 1**, and **glucagon-like peptide 2** are produced (see Fig. 34.5, right).

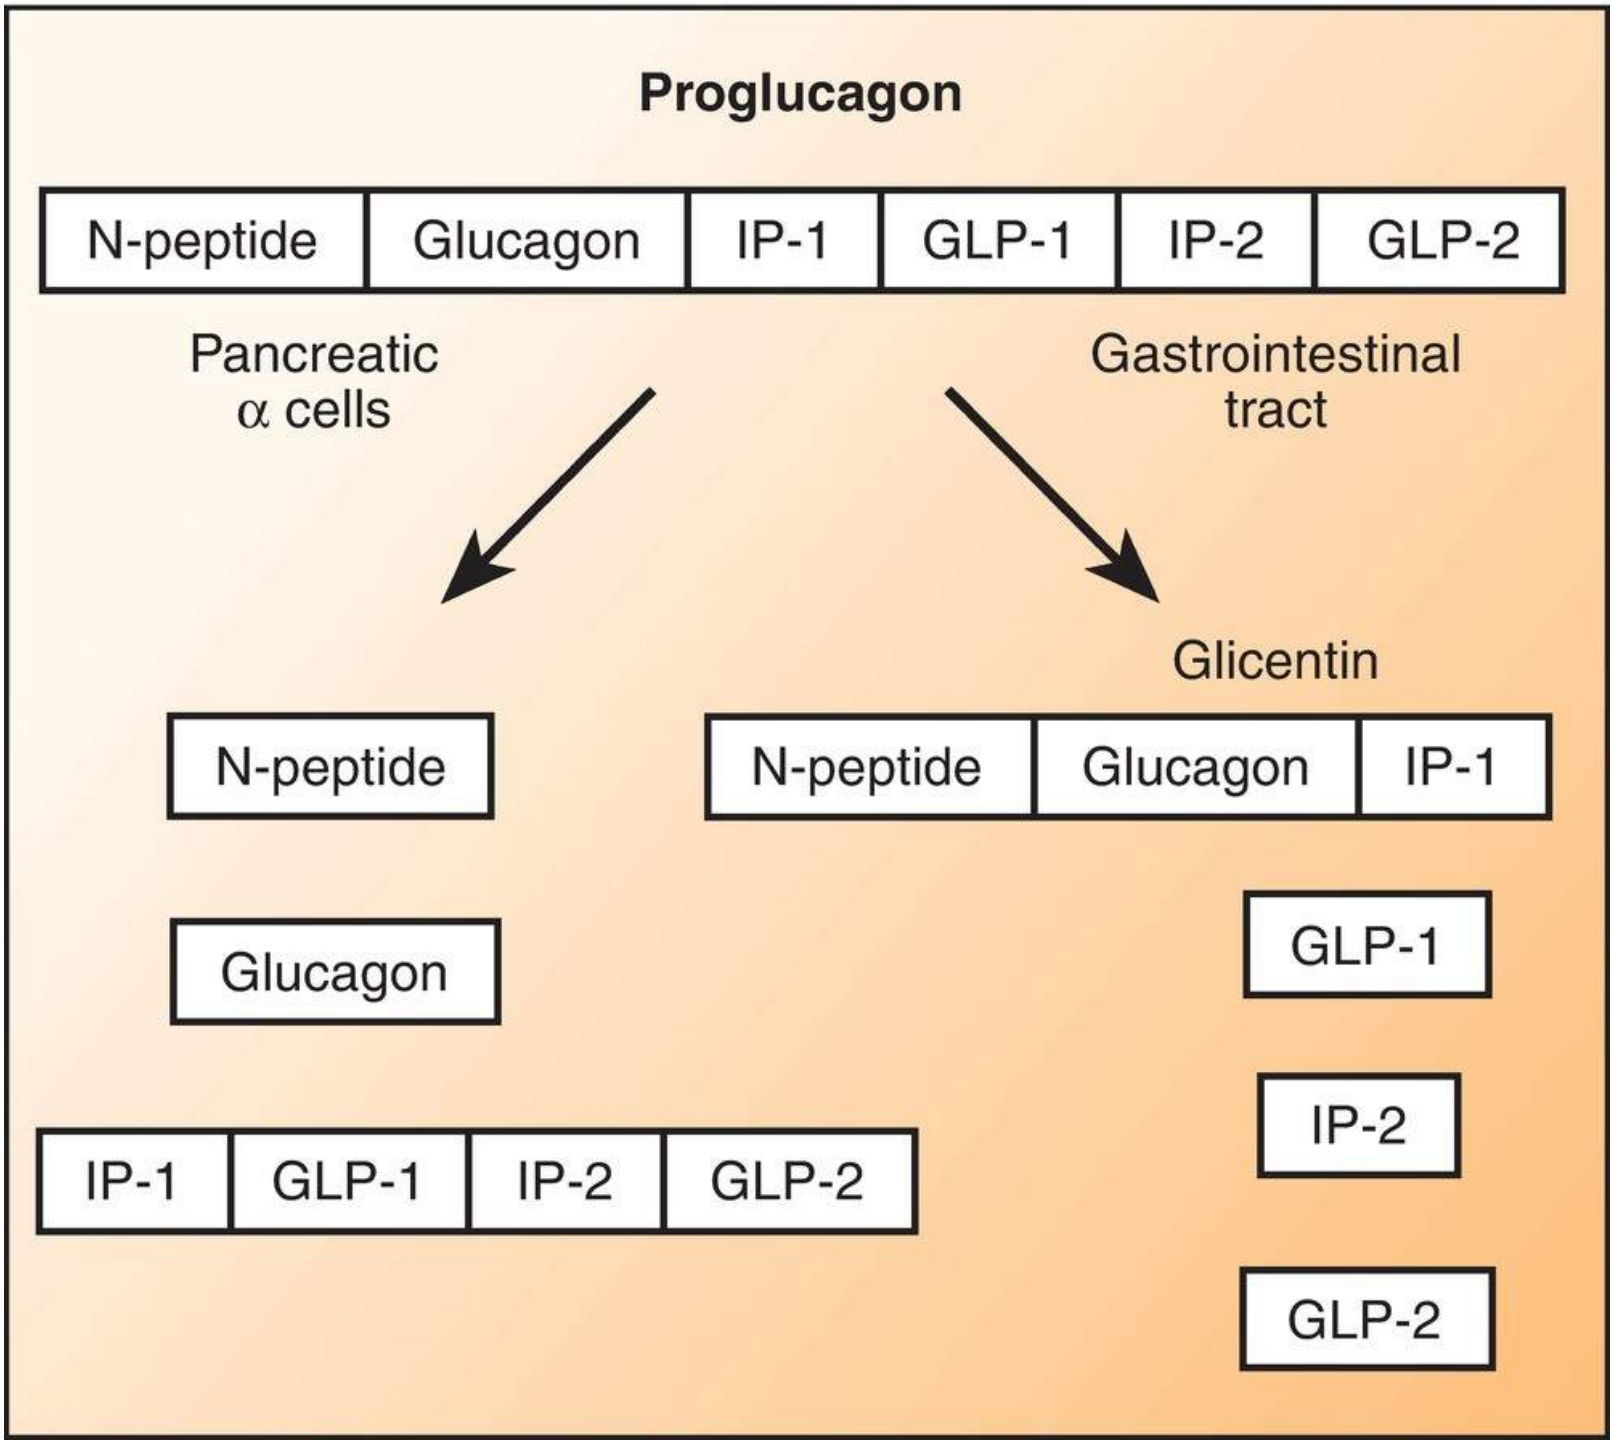

Figure 34.5 The differential processing of proglucagon. In α cells of the pancreas **(left)**, the major bioactive product formed from proglucagon is glucagon itself. It is not currently known whether the other peptides are processed to produce biologically active molecules. In intestinal cells **(right)**, proglucagon is cleaved to produce the four peptides shown. Glicentin is the major glucagon-containing peptide in the intestine. GLP1, glucagon-like peptide 1; GLP2, glucagon-like peptide 2; IP-1, intervening peptide-1; IP-2, intervening peptide-2.

The principal factors that influence glucagon secretion are listed in Table 34.1. The primary regulator of glucagon secretion is blood glucose; specifically, when blood glucose falls below about 72 mg/dL, α cells become active and deliver glucagon to the blood. Amino acids are also major secretagogues; however, the concentrations of amino acids required to provoke secretion of glucagon *in vitro* are higher than those generated *in vivo*. This observation suggests that other neural or humoral factors amplify the response *in vivo*, analogous to the effects of incretins on insulin secretion. Somatostatin inhibits glucagon

secretion, as it does insulin secretion.

Hyperglycemia and glucagon stimulate somatostatin secretion.

As described earlier, somatostatin is first synthesized as a larger peptide precursor, preprosomatostatin. The hypothalamus also produces this protein, but the regulation of somatostatin secretion from the hypothalamus is independent of that from the pancreatic δ cells. On insertion of preprosomatostatin into the RER, it is initially cleaved and converted to prosomatostatin. The prohormone is converted into active hormone during packaging and processing in the Golgi apparatus. Factors that stimulate pancreatic somatostatin secretion include hyperglycemia, glucagon, and amino acids. Glucose and glucagon are generally considered the most important regulators of somatostatin secretion.

The exact role of somatostatin in regulating islet secretions has not been fully established. Somatostatin clearly inhibits both glucagon and insulin secretion from α and β cells of the pancreas, respectively, when it is given exogenously. The anatomic and vascular relationships of δ cells to α and β cells further suggest that somatostatin may play a role in regulating both glucagon and insulin secretion. Although many of these data are circumstantial, it is generally accepted that somatostatin plays a paracrine role in regulating insulin and glucagon secretion from the pancreas.

Pancreatic polypeptide secretion and action are regulated by several factors.

Nutrients, hormones, neurotransmitters, gastric distention, insulin-induced hypoglycemia, and direct vagal nerve stimulation regulate PP secretion, whereas hyperglycemia, bombesin, and somatostatin inhibit PP secretion. Furthermore, we now know that a receptor termed Y4, a G-protein–coupled receptor that inhibits **cyclic adenosine monophosphate** (**cAMP**) accumulation, mediates the actions of PP. The Y4 receptor is expressed in the stomach, small intestine, colon, pancreas, prostate, and enteric nervous system and in select central nervous system neurons. Evidence suggests that PP reduces gastric acid secretion and increases intestinal transit times by reducing gastric emptying and upper intestinal motility. PP also appears to inhibit postprandial exocrine pancreas secretion via a vagal-dependent pathway. Transgenic mice that overexpress PP exhibit reduced weight gain and rate of gastric emptying and decreased fat mass. These findings certainly merit further PP-related research.

INSULIN AND GLUCAGON ACTION

The two main hormones from the endocrine pancreas that direct the storage and use of fuels during times of nutrient abundance (fed state) and nutrient deficiency (fasting) are insulin and glucagon. Insulin is secreted in the fed state and is called the “hormone of nutrient abundance.” By contrast, glucagon is secreted in response to an overall deficit in nutrient supply. It should be noted, as discussed above, that the other islet hormones play very important ancillary roles.

Insulin receptor signaling is complex and controls several biological responses.

The insulin receptor (IR) is a heterotetramer, consisting of a pair of α-/β-subunit complexes held together by disulfide bonds (Fig. 34.6). The IR's α subunits are extracellular and contain several insulin-binding sites. The β subunits of the IR span the plasma membrane and function to couple the extracellular event of insulin binding to its intracellular actions. A key intracellular action stimulated by insulin binding is β-subunit autophosphorylation, involving the phosphorylation of a few selected tyrosine residues in the intracellular portion. This event further activates the tyrosine kinase portion of the β subunit, leading to tyrosine phosphorylation of a host of proteins, including members of the insulin receptor substrate (IRS) family (IRS-1, IRS-2, IRS-3, IRS-4, IRS-5, and IRS-6), Gab-1, Shc, $p62^{dok}$, c-Cbl, SIRP (signal regulatory protein) family members, and APS (adapter protein containing a pleckstrin homology and Src homology 2 domain). A cascade of phosphorylation and dephosphorylation events, second messenger generation, and protein–protein interactions result, leading to several cellular activities, including gene expression and growth, protein synthesis, antiapoptosis, antilipolysis, glycogen synthesis, and glucose transport, to name a few. Note that IR internalization or dephosphorylation by protein tyrosine phosphatases (PTPs) terminates the activity of the IR. Protein tyrosine phosphatase 1B (PTP1B) and leukocyte antigen-related (LAR) phosphatases are two PTPs shown to attenuate IR activity. A later section on diabetes mellitus highlights that several forms of diabetes mellitus (prediabetes, type 2 diabetes, and gestational diabetes) are complicated, multifactorial diseases in which interactions between multiple genes and environmental factors ultimately result in resistance to the action of insulin. In that regard, both PTP1B and LAR have been reported to be elevated in patients displaying **insulin resistance**. In addition to dampening IR function by tyrosine phosphatase activity, serine–threonine phosphorylation of the β subunit of the IR also has been suggested to decrease the ability of the receptor to undergo autophosphorylation. Many protein kinase C isoforms that catalyze the serine or threonine phosphorylation of the IR are elevated in insulin-resistant tissue from animals and humans.

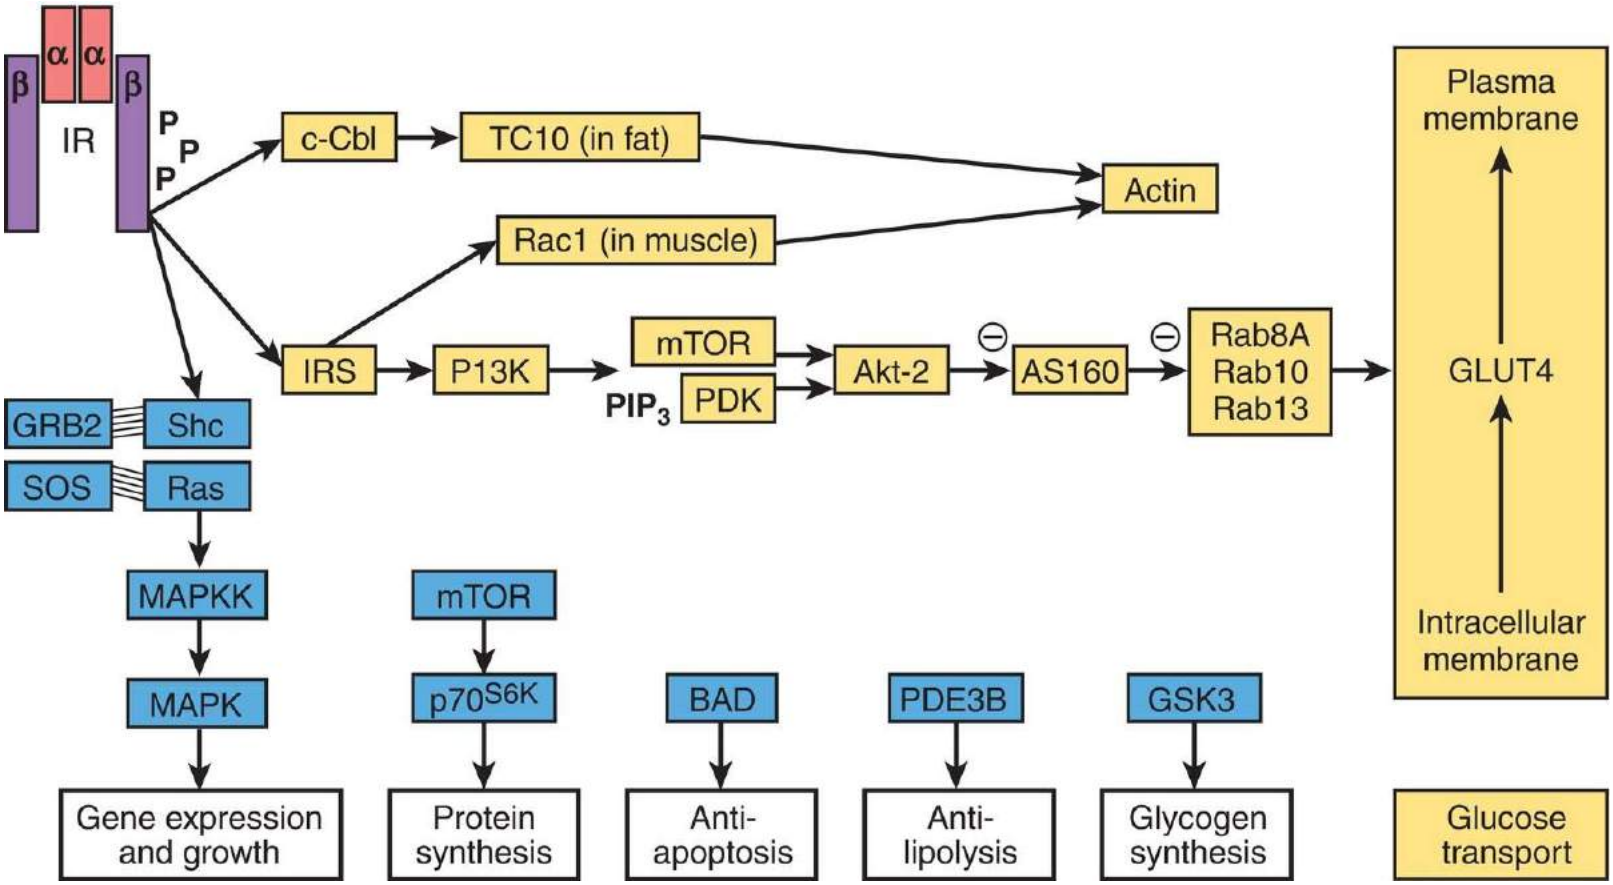

Figure 34.6 Overview of the complexity of the insulin-signaling network and several biologic responses. Shown in *black* and *yellow* are intracellular mediators that are involved in GLUT4-regulated glucose transport in muscle and adipose tissue.

Insulin stimulates the transport, storage, and metabolism of glucose.

In muscle and adipose tissues, insulin promotes the removal of excess circulatory glucose by regulating the subcellular trafficking of the glucose transporter **GLUT4** that resides in intracellular membrane vesicles (see Fig. 34.6). Under normal insulin responsiveness, insulin promotes the removal of excess glucose from the circulation by stimulating the exocytic recruitment of the intracellular vesicles containing GLUT4 to the plasma membrane. This stimulated redistribution of these vesicles results in plasma membrane GLUT4 accumulation that facilitates cellular glucose uptake. Activation of GLUT4 vesicle translocation by insulin requires a phosphatidylinositol 3-kinase (PI3K) signal involving the upstream IR and insulin receptor substrate (IRS) activators and the downstream Akt target enzyme. PI3K generates the phospholipid PI3,4,5-P_3 (PIP_3) that engages both PI-dependent kinase (PDK) and mTORC2 to phosphorylate/activate the serine/threonine kinase Akt (particularly isoform 2). As shown in Figure 34.6, Akt2 has numerous targets, but Akt2-mediated phosphorylation of Akt substrate of 160 kDa (AS160), a GTPase-activating protein (GAP) toward small G-proteins, inhibits the GAP activity allowing the activation of Rab G-proteins. Studies suggest that Rab8A and Rab13 in muscle cells, whereas Rab10 in adipocytes regulates GLUT4 translocation. In parallel, in both muscle and fat cells, insulin triggers distinct signals that regulate the actin cytoskeleton that is essential for GLUT4 translocation (see Fig. 34.6).

Insulin resistance is associated with insufficient recruitment of GLUT4 to the plasma membrane. This finding emphasizes the importance of understanding the molecular mechanisms of insulin-regulated GLUT4 translocation and glucose uptake so that cellular perturbations associated with insulin resistance can be elucidated and effective treatment and preventative strategies can be designed to bypass or ameliorate insulin resistance.

Besides promoting glucose uptake into muscle and fat cells, insulin promotes its storage. Glucose carbon is stored in the body in two primary forms: as **glycogen** and (by metabolic conversion) as triglycerides. Glycogen is a short-term storage form that plays an important role in maintaining normal blood glucose levels. The primary glycogen storage sites are the liver and skeletal muscle; other tissues, such as adipose tissue, also store glycogen but in quantitatively small amounts. Insulin promotes glycogen storage primarily through two enzymes (Fig. 34.7). It activates **glycogen synthase** by promoting its dephosphorylation and concomitantly inactivates **glycogen phosphorylase**, also by promoting its dephosphorylation. The result is that glycogen synthesis is promoted and glycogen breakdown is inhibited.

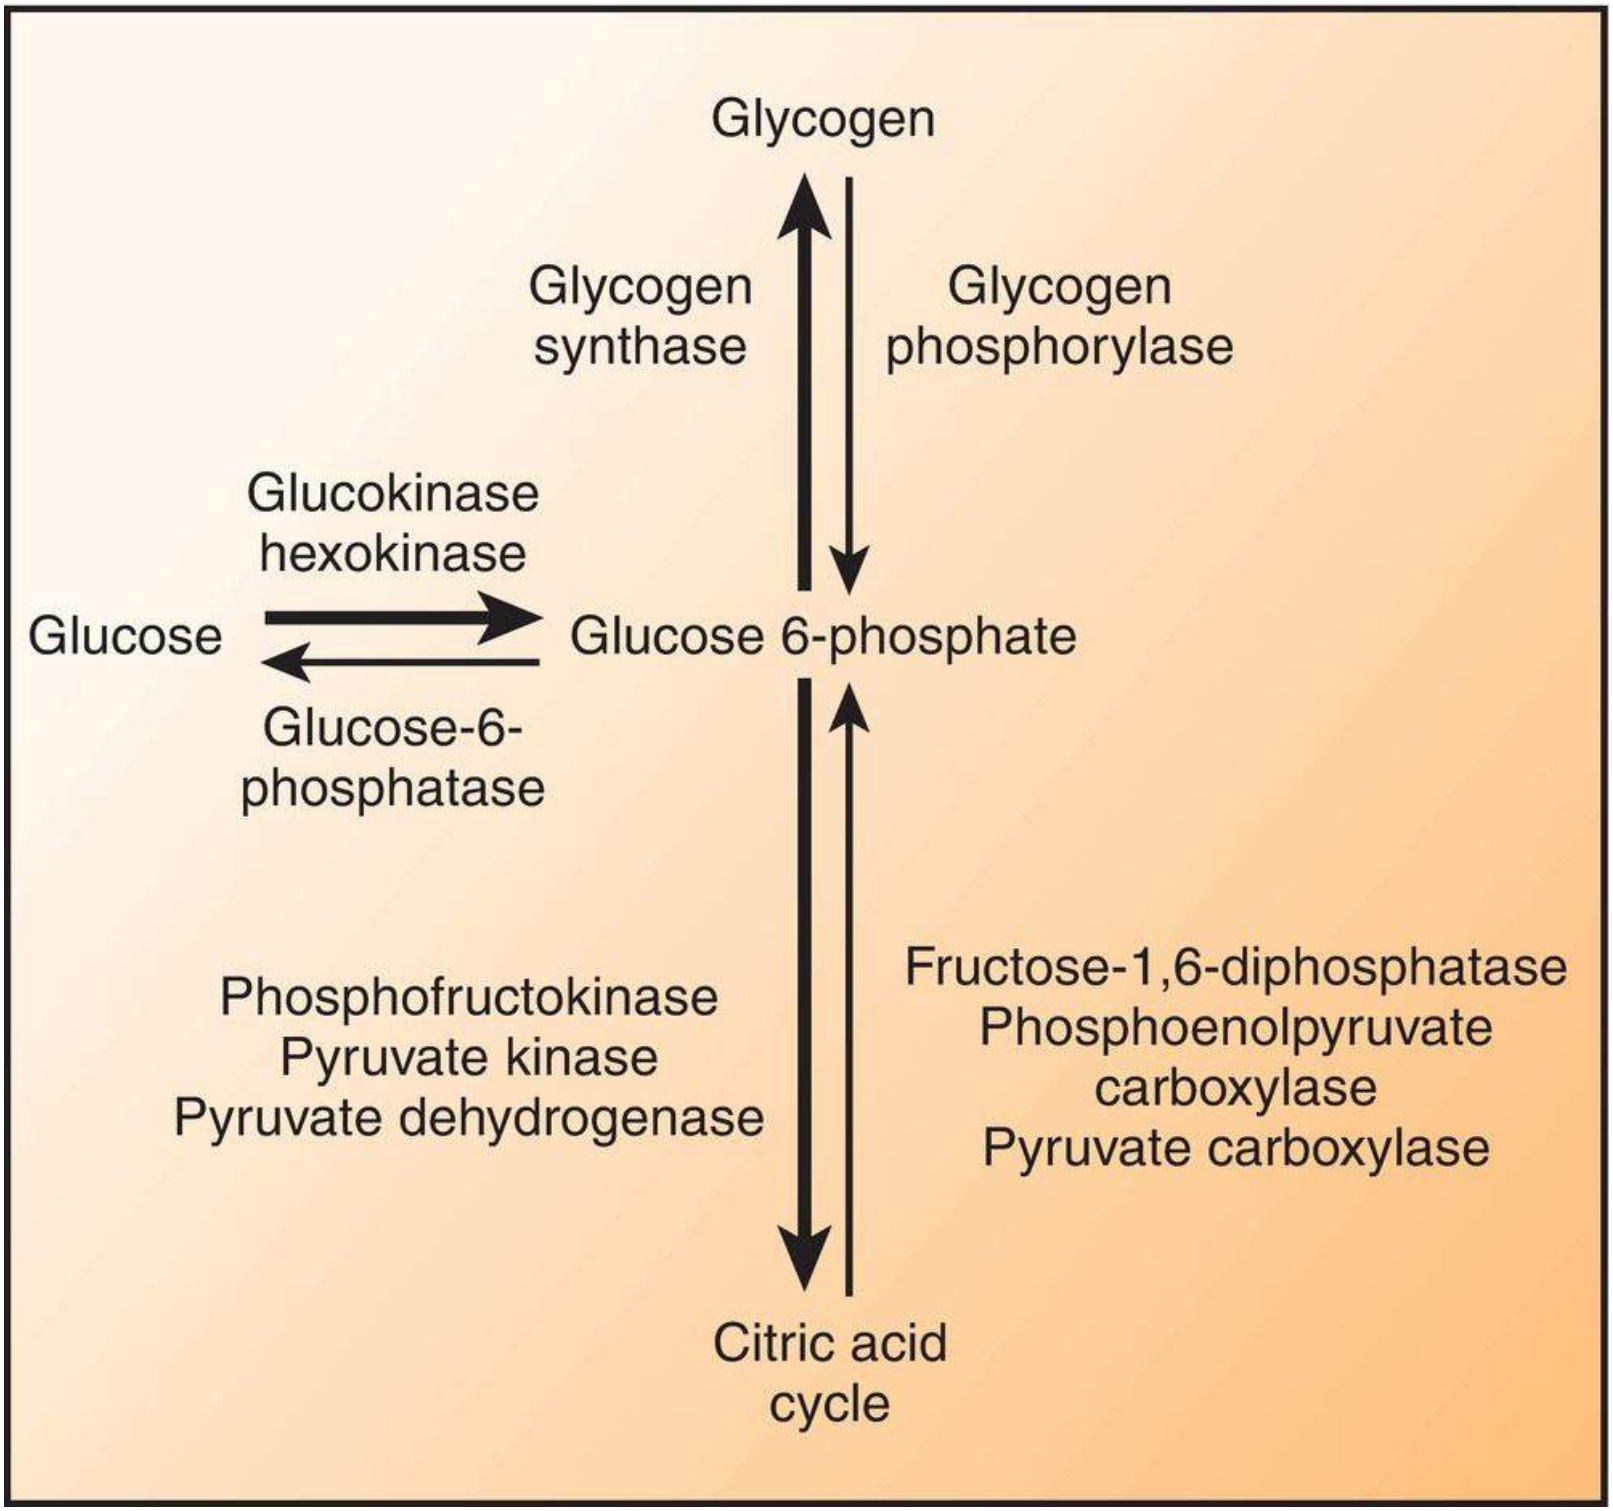

Figure 34.7 Insulin stimulation of glycogen synthesis and glucose metabolism. Insulin promotes glucose uptake into target tissues, stimulates glycogen synthesis, and inhibits glycogenolysis. In addition, it promotes glycolysis in its target tissues. *Bold arrows* indicate processes stimulated by insulin; *light arrows* indicate processes inhibited by insulin.

In addition to increasing glucose uptake and providing a mass action stimulus for glycolysis, insulin activates the enzymes **glucokinase** (liver), **hexokinase** (muscle), **phosphofructokinase, pyruvate kinase**, and **pyruvate dehydrogenase** of the glycolytic pathway (see Fig. 34.7). Also shown is the inhibition of gluconeogenesis by insulin inhibition of **fructose-1,6-diphosphatase, phosphoenolpyruvate carboxylase**, and **pyruvate carboxylase**.

Insulin has important lipogenic and antilipolytic effects.

In adipose tissue and the liver, insulin promotes **lipogenesis** and inhibits **lipolysis** (Fig. 34.8). Insulin has similar actions in muscle, but because muscle is not a major site of lipid storage, the discussion here focuses on actions in adipose tissue and the liver. By promoting the flow of intermediates through glycolysis, insulin promotes the formation of α-glycerol phosphate and fatty acids necessary for triglyceride formation. In addition, it stimulates **fatty acid synthase**, leading directly to increased fatty acid synthesis. Insulin inhibits the breakdown of triglycerides by inhibiting **hormone-sensitive lipase**, which is activated by many counterregulatory hormones, such as epinephrine and adrenal glucocorticoids. By inhibiting this enzyme, insulin promotes the accumulation of triglycerides in adipose tissue.

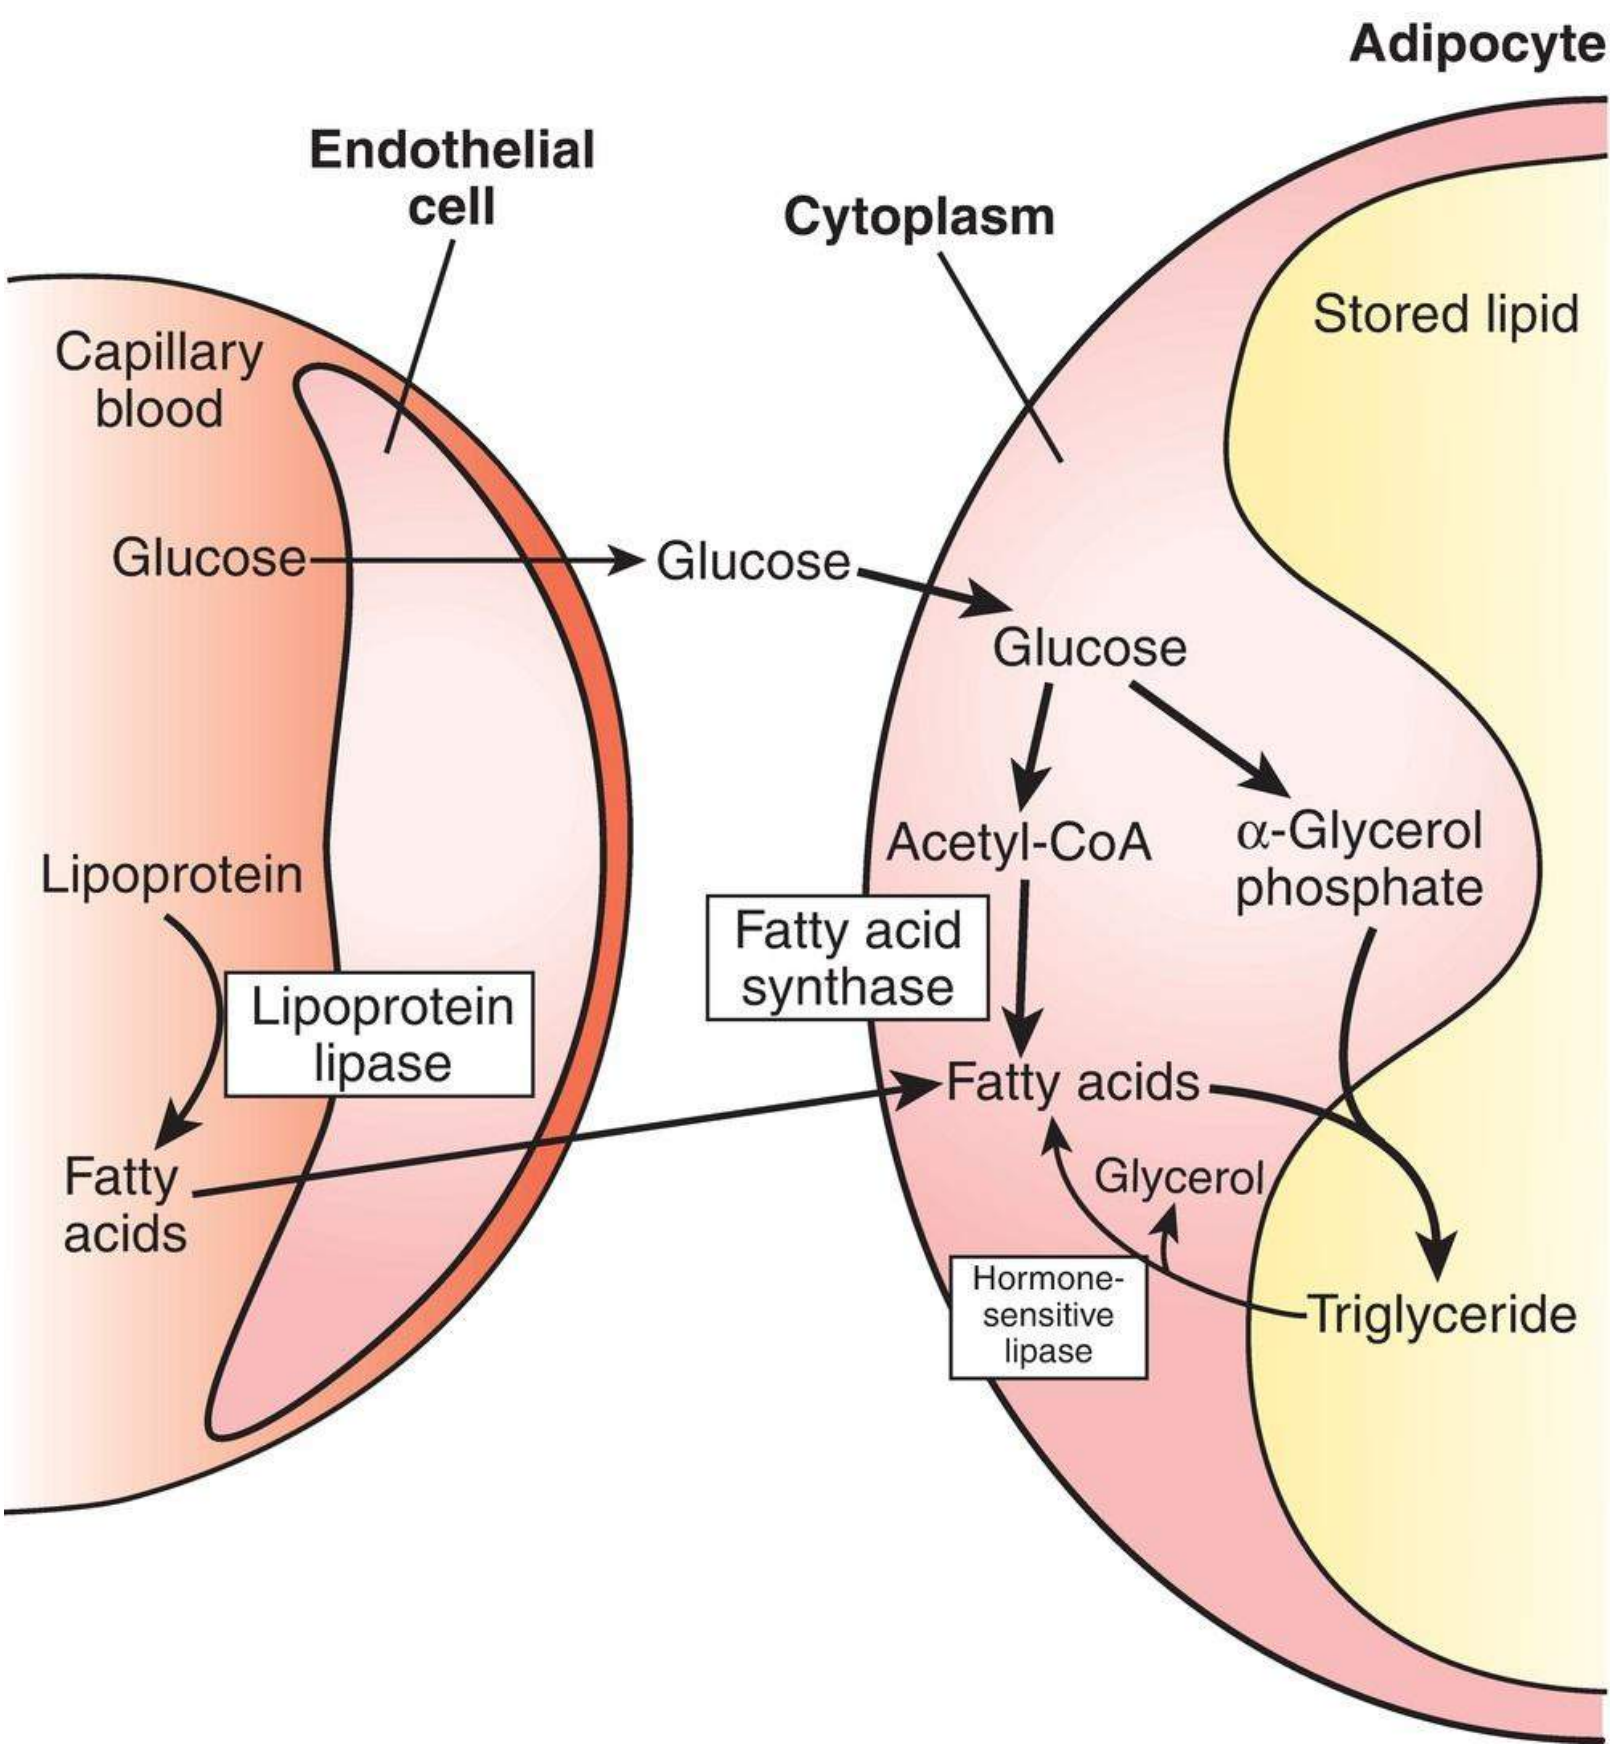

Figure 34.8 Effects of insulin on lipid metabolism in adipocytes. Insulin promotes the accumulation of lipid (triglycerides) in adipocytes by stimulating the processes shown by the *bold arrows* and inhibiting the processes shown by the *light arrows*. Similar stimulatory and inhibitory effects occur in liver cells.

In addition to promoting *de novo* fatty acid synthesis in adipose tissue, insulin increases the activity of **lipoprotein lipase**, which plays a role in the uptake of fatty acids from the blood into adipose tissue. As a

result, adipose tissue takes up lipoproteins synthesized in the liver, and fatty acids are ultimately stored as triglycerides.

Insulin enhances the synthesis and suppresses the degradation of proteins.

Insulin promotes protein accumulation in its primary target tissues—liver, adipose tissue, and muscle—in three specific ways. First, it stimulates amino acid uptake. Second, it increases the activity of several factors involved in protein synthesis. For example, it increases the activity of protein synthesis initiation factors, promoting the start of translation and increasing the efficiency of protein synthesis. Insulin also increases the amount of protein synthesis machinery in cells by promoting ribosome synthesis. Third, insulin inhibits protein degradation by reducing lysosome activity and possibly other mechanisms as well.

Glucagon primarily exerts its metabolic actions, via cAMP signaling, in the liver.

Numerous effects of glucagon have been documented in several tissues, primarily adipose tissue, when the hormone has been added at high, nonphysiologic concentrations in experimental situations. Although these effects may play a role in certain abnormal situations, the normal daily effects of glucagon occur primarily in the liver. Glucagon initiates its biologic effects by interacting with one or more types of cell membrane receptors. Glucagon receptors are coupled to G-proteins and promote increased intracellular cAMP, via the activation of adenylyl cyclase or elevated cytosolic calcium as a result of phospholipid breakdown to form inositol triphosphate.

Glucagon promotes hepatic glucose production, coupled with ammonia disposal.

Glucagon is an important regulator of hepatic glucose production. It produces a net effect of glycogen breakdown (**glycogenolysis**) by increasing intracellular cAMP levels, initiating a cascade of phosphorylation events that ultimately results in the phosphorylation and activation of glycogen phosphorylase (Fig. 34.9). Similarly, glucagon promotes the net breakdown of glycogen by inactivating glycogen synthase. In addition, glucagon stimulates hepatic **gluconeogenesis**. It does this principally by increasing the transcription of messenger RNA coding for **phosphoenolpyruvate carboxykinase** (**PEPCK**), a key rate-limiting enzyme in gluconeogenesis. Glucagon also stimulates amino acid transport into liver cells and the degradation of hepatic proteins, helping provide substrates for gluconeogenesis (see Fig. 34.9). The glucagon-enhanced conversion of amino acids into glucose leads to increased formation of ammonia that glucagon alleviates by increasing the activity of the urea cycle enzymes and **ureagenesis**.

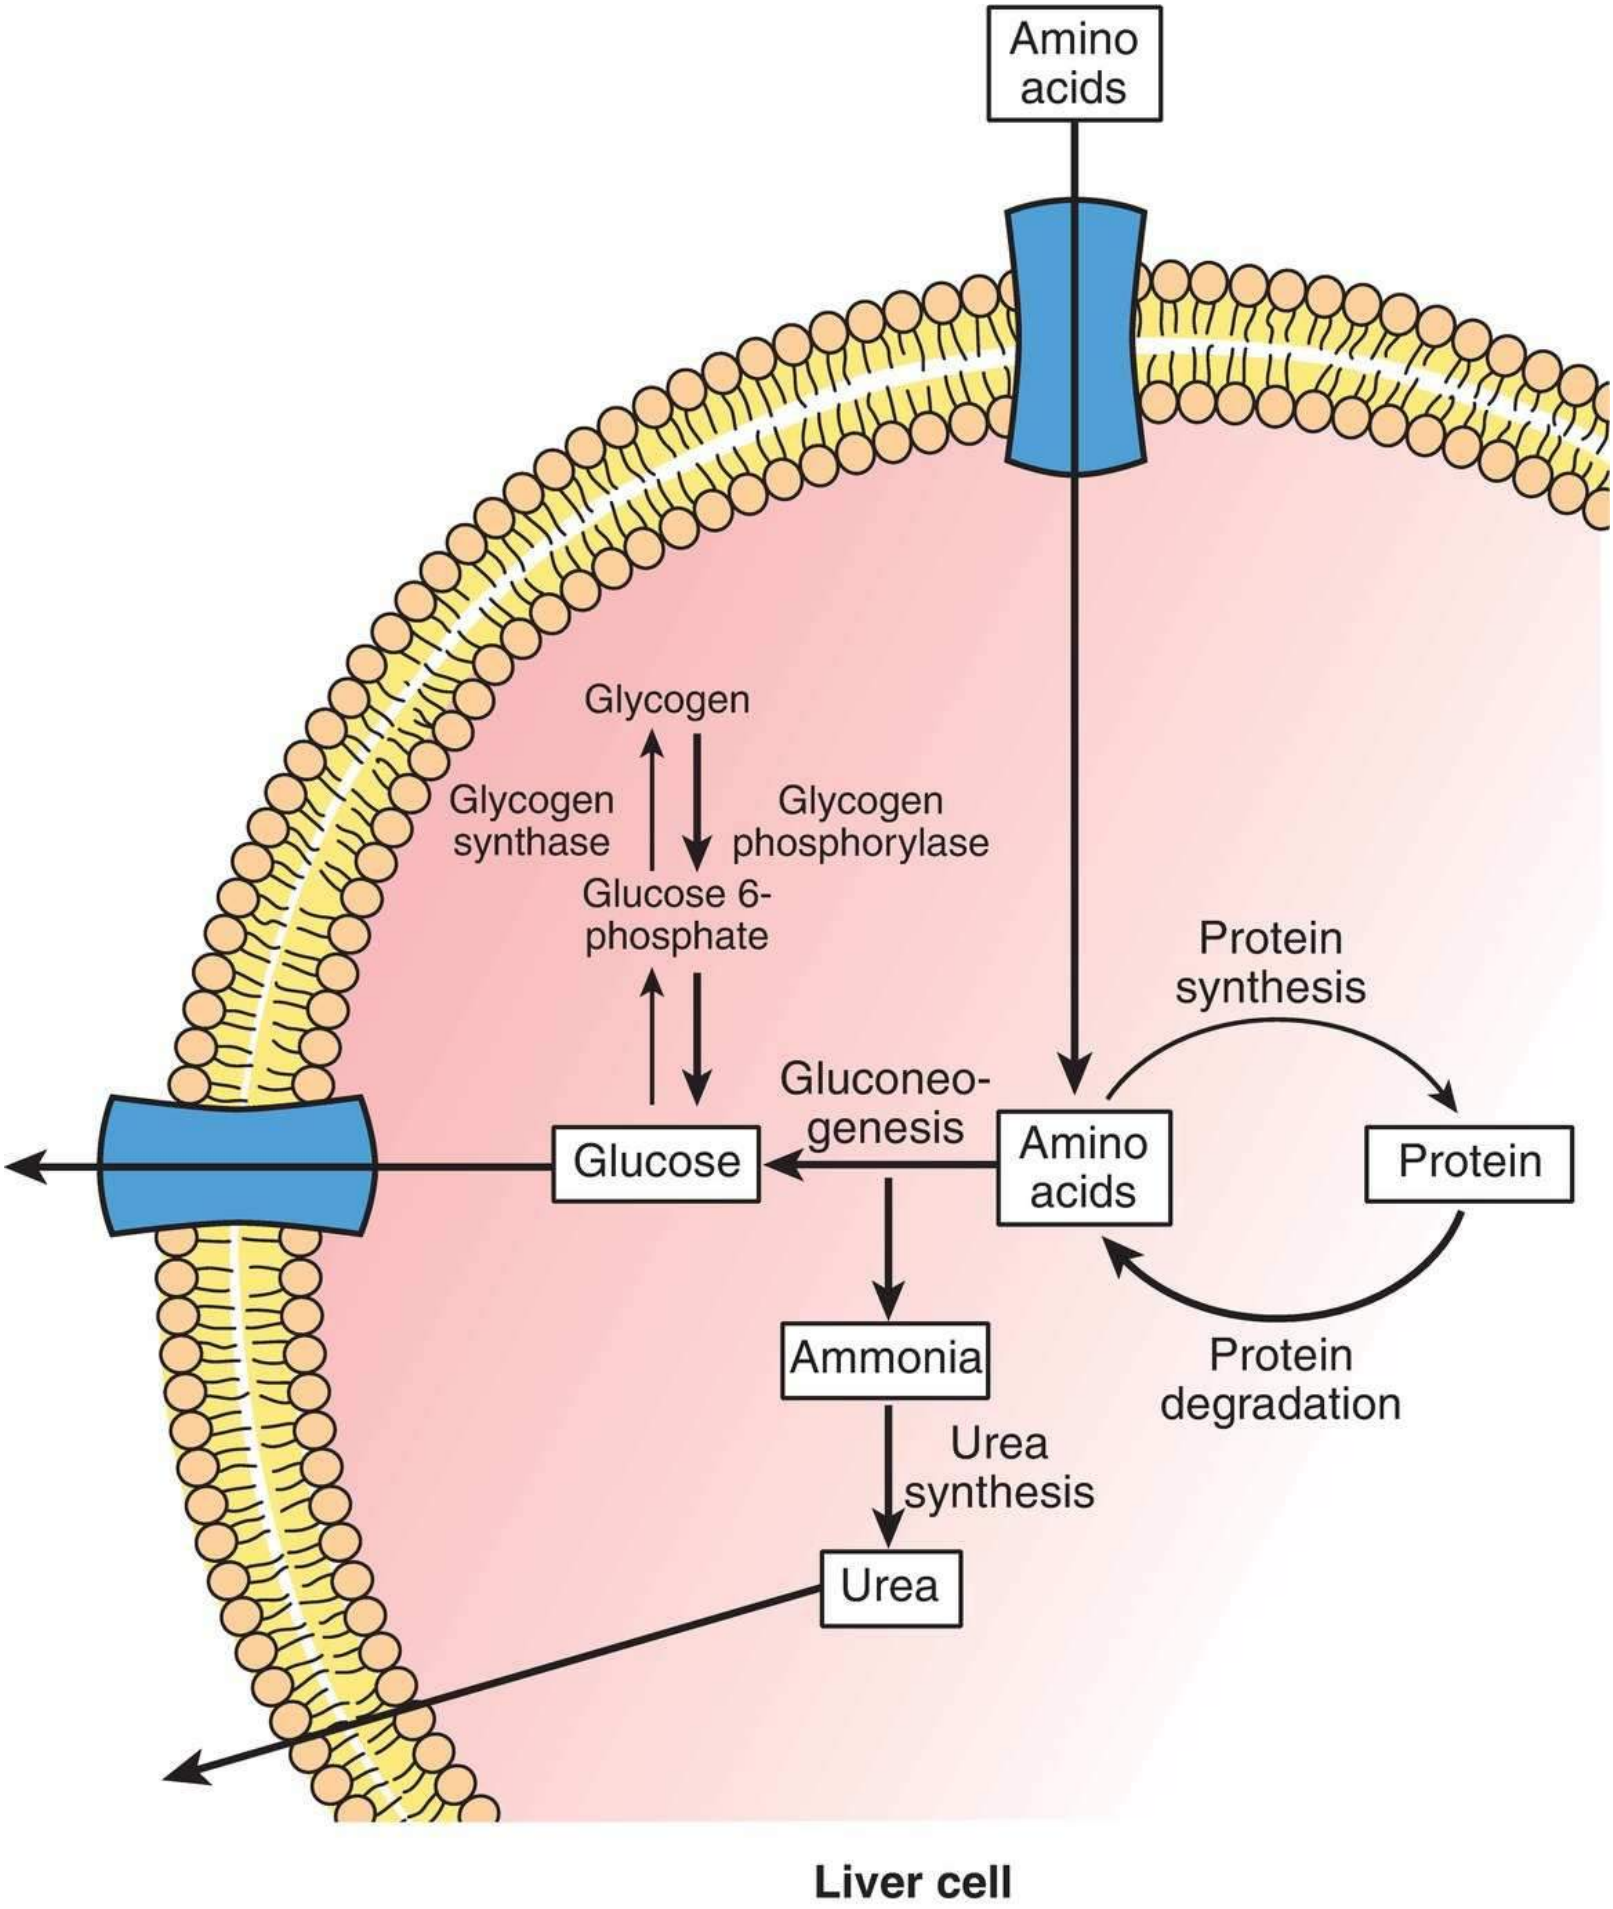

Figure 34.9 The role of glucagon in glucose production liver cells. *Bold arrows* indicate processes stimulated by glucagon; the *light arrows* indicate a process inhibited by glucagon.

Glucagon promotes the oxidation of fats and ketogenesis in the liver.

Glucagon also plays a regulatory role in hepatic lipid metabolism (Fig. 34.10). Mechanistically, glucagon inhibits the activity of acetyl-CoA carboxylase. This inhibition decreases the levels of **malonyl-CoA**, a metabolite that inhibits the activity of the carnitine acyltransferase (CAT) system, which mediates the transfer of fatty acids across the mitochondrial membrane. Therefore, glucagon indirectly increases the delivery of fatty acids into the mitochondria where these become oxidized to produce energy for the liver in the form of ATP. If the rate of fatty acid transport into the mitochondria exceeds the energy needs of the liver, the fatty acids are used in the production of **ketones**. Ketones are an important source of fuel for muscle and heart cells during times of starvation, sparing blood glucose for other tissues that are obligated glucose users, such as the central nervous system. During prolonged starvation, the brain adapts its metabolism to use ketones as a fuel source, lessening the overall need for hepatic glucose production.

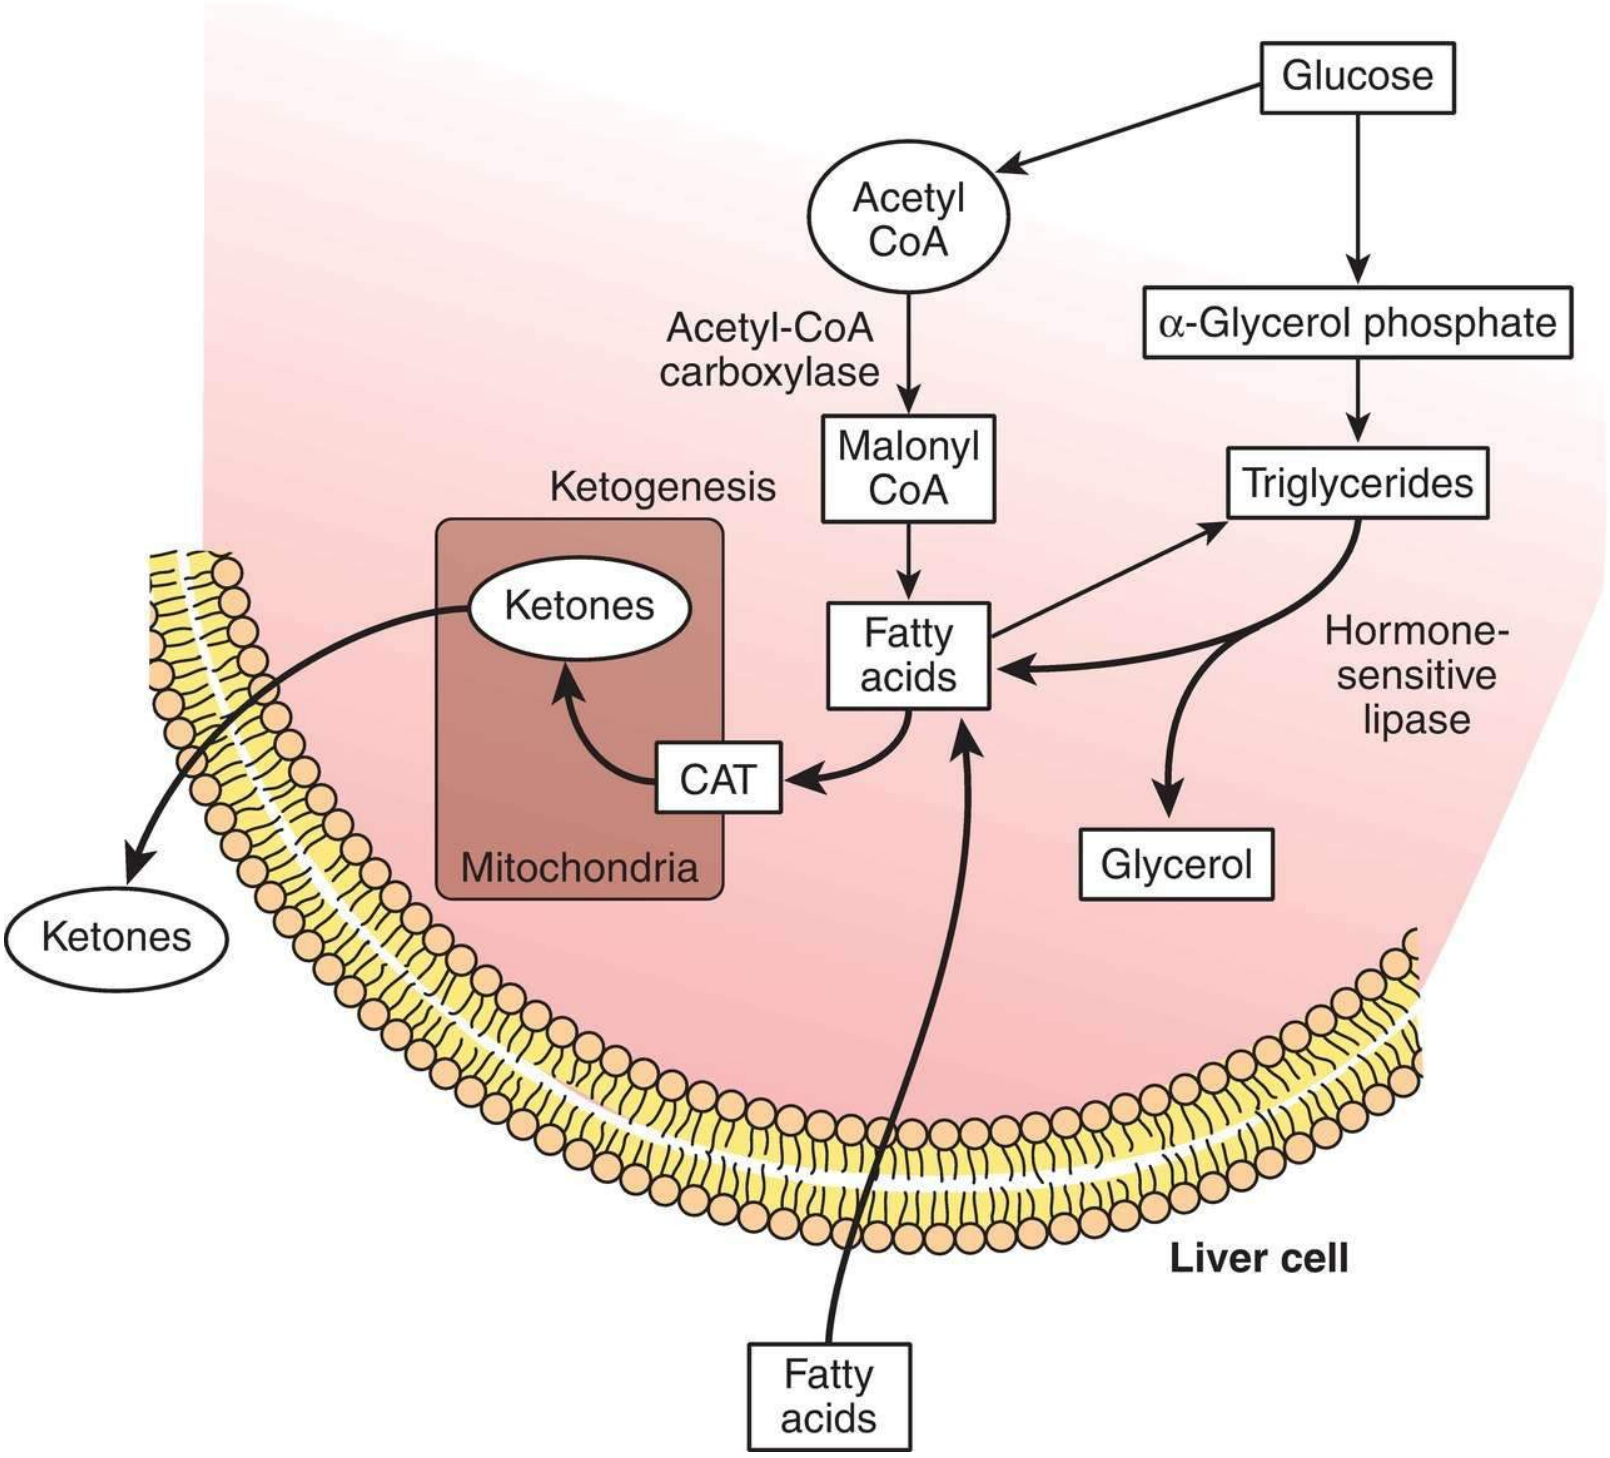

Figure 34.10 The role of glucagon in lipolysis and ketogenesis in liver cells. *Bold arrows* indicate processes stimulated by glucagon; *light arrows* indicate processes inhibited by glucagon.

Insulin/glucagon ratio determines metabolic status.

In most instances, insulin and glucagon produce opposing effects. Therefore, the relative level of both hormones in the blood plasma, the **insulin/glucagon ratio** (**I/G ratio**), determines the net physiologic response. The I/G ratio is highest in the fed state and is the lowest during fasting. The I/G ratio can vary 100-fold or more because the plasma concentration of each hormone can vary considerably in different nutritional states. In the fed state, the molar I/G ratio is ~30. After an overnight fast, it may fall to about two, and with prolonged fasting, it may fall to as low as 0.5.

A good example of the profound influence of the I/G ratio on metabolic status is in T1D (see below). Insulin levels are low, so pathways that insulin stimulates operate at a reduced level. However, insulin is also necessary for α cells to sense blood glucose appropriately; in the absence of insulin, the secretion of glucagon is inappropriately elevated. The result is an imbalance in the I/G ratio and an accentuation of glucagon effects well above what would be seen in normal states of low insulin, such as in fasting.

DIABETES MELLITUS

Diabetes mellitus is a systemic disease in which the body does not produce and/or use insulin and is characterized most notably by **hyperglycemia**. In addition to abnormal glucose metabolism, disorders in the metabolism of lipid and protein intensify the seriousness of the disease. Superimposed on the disorders of carbohydrate, fat, and protein metabolism are diabetic-specific microvascular lesions in the retinas, renal glomeruli, and peripheral nerves. Diabetes, if untreated, leads to renal failure, erectile dysfunction, blindness, coronary arterial disease, and increased risk of cancer. Of these, cardiovascular disease (CVD) is the most prominent. For example, more than 65% of people with diabetes die from heart disease. In fact, adults with diabetes have heart disease death rates about two to four times higher than adults without diabetes. Also, stroke accounts for ~20% of diabetes-related deaths, and the risk for stroke is also two to four times higher among people with diabetes. The cause of diabetes continues to be a mystery, although both genetics and environmental factors such as obesity and lack of exercise appear to play significant roles.

Data from the National Diabetes Statistical Report released in 2014 reported that there are 29.1 million children and adults in the United States, or 9.3% of the population, who have diabetes. Diabetes has several clinical forms, each of which has a distinct etiology, clinical presentation, and course. Diagnosing diabetes mellitus is not difficult to do. Symptoms usually include frequent urination, increased thirst, increased food consumption, and weight loss. Diabetes mellitus is a heterogeneous disorder. The causes, symptoms, and general medical outcomes are variable. There are four main type of diabetes: (1) Type 1 diabetes (T1D) results from the body failure to produce insulin, (2) prediabetes results from insulin resistance, (3) Type 2 diabetes (T2D) results from insulin resistance and β-cell failure, and (4) **gestational diabetes** results from insulin resistance during pregnancy.

Autoimmune disorder underlies type 1 diabetes.

T1D is one of the most intensively studied autoimmune disorders. Although most cases of T1D are a consequence of an inappropriate autoimmune destruction of the β cell, an autoimmune-independent subtype of T1D has recently been described, and recommendations have been put forth to divide T1D into type 1A (immune mediated) and type 1B (other forms of diabetes with severe insulin deficiency). **Type 1B diabetes** appears to be a rare form of T1D in which histologic examination of pancreatic sections demonstrates inflammation but no anti-islet autoantibodies.

Whereas studies to gain deeper insight into type 1B diabetes are currently underway, it is known that **type 1A diabetes** results from a selective destruction of the β cells within the islets. A subtype of type 1A diabetes that has a latent onset in adults also exists, and recent findings suggest that its correct diagnosis and tailored insulin therapy may delay the progression and worsening of the disease (see Clinical Focus 34.1). The development of type 1A diabetes is usually divided into a series of stages, beginning with genetic susceptibility and ending with essentially complete β-cell destruction. Central to the pathology is **insulitis** β-cell injury, involving a lymphocytic attack on β cells.

CLINICAL FOCUS 34.1

Amylin

Amylin is a 37-amino acid peptide that is almost exclusively expressed within pancreatic β cells, where it is copackaged with insulin in secretory granules. Consequently, amylin is normally cosecreted with insulin, and the plasma concentrations of the two hormones display a similar diurnal pattern of low fasting levels and rapid and robust increases in response to meals.

As might be expected, because of the colocalization of both hormones within β cells, patients with T1D have an absolute deficiency of both insulin and amylin, whereas patients with T2D have a relative deficiency of both hormones, including a significantly impaired amylin and insulin response to meals. These findings have led to questions of whether amylin deficiency contributes to the metabolic derangements in diabetic patients and, if so, whether amylin replacement might convey clinical benefit when used in conjunction with insulin replacement.

Extensive studies with amylin and amylin antagonists in rodents and with pramlintide (a synthetic analogue of the human amylin hormone) in diabetic patients have provided an understanding of the role of amylin in glucose homeostasis. Preclinical data indicate that amylin acts as a neuroendocrine hormone that complements the actions of insulin in postprandial glucose homeostasis via several mechanisms. These include a suppression of postprandial glucagon secretion and a slowing of the rate at which nutrients are delivered from the stomach to the small intestine for absorption. The net effect of these actions is to mitigate the influx of endogenous (liver-derived) and exogenous (meal-derived) glucose into the circulation and thus to better match the rate of insulin-mediated glucose clearance from the circulation. ■

Studies of identical twins have provided important information regarding the genetic basis of T1D. If one twin develops T1D, the odds that the second will develop the disease are much higher than for any random person in the population, even when the twins are raised apart under different socioeconomic conditions. In addition, people with certain cell-surface human leukocyte antigens bear a higher risk for the disease than others.

Environmental factors are involved as well because the development of T1D in one twin predicts only a 50% or less chance that the second will develop the disease. The specific environmental factors have not been identified, although much evidence implicates viruses. Therefore, it appears that a combination of genetics and environment is a strong contributing factor to the development of T1D.

Because the primary defect in T1D is the inability of β cells to secrete adequate amounts of insulin, these patients must be treated with injections of insulin. In an attempt to match insulin concentrations in the blood with the metabolic requirements of the person, various formulations of insulin with different durations of action have been developed. Patients inject an appropriate amount of these different insulin forms to match their dietary and lifestyle requirements. New technologies such as insulin pumps and continuous glucose monitors have not only aided treatment but also are paving the road to an artificial pancreas (see Chapter 30 Integrated Medical Sciences Box).

The long-term control of T1D depends on maintaining a balance between several factors including insulin, diet, and exercise, as well as possibly including ancillary hormones such as amylin (see Clinical Focus 34.2). To strictly control their blood glucose, patients are advised to monitor their diet and level of physical activity, as well as their insulin dosage. Exercise *per se*, much like insulin, increases glucose uptake by muscle. Diabetic patients must take this into account and make appropriate adjustments in diet and/or insulin whenever general exercise levels change dramatically.

CLINICAL FOCUS 34.2

Beyond Type 1 and Type 2 Diabetes

It is becoming increasingly apparent that the main forms of diabetes, type 1 diabetes (T1D) and type 2 diabetes (T2D), have subtypes that require the correct diagnosis. A subtype of new concern is termed *latent autoimmune diabetes in adults* ([*LADA*] though some prefer *type 1.5*). This subtype was first revealed in the 1970s while testing a method to identify autoantibodies in the blood of people with T1D. Scientists found that T1D-related autoantibodies were virtually absent in the general population, but they showed up in about 10% of people diagnosed with T2D, which is not an autoimmune disease. Although much debate exists as to whether LADA is distinct from T1D, researchers today are working on a set of criteria for its diagnosis: (1) the presence of autoantibodies in the blood, (2) adult age at onset, and (3) lack of need for insulin treatment in the first 6 months after diagnosis. The first criterion distinguishes LADA from T2D because of autoantibodies in the blood, and the third criterion differs from T1D because T1D patients need to start insulin immediately. We now know that those with T1D have higher levels and more types of autoantibodies than do those with LADA, which may be the reason β cells are destroyed faster in T1D than in LADA.

Importantly, a recent Japanese study found that early insulin treatment in adults with LADA may help them avoid total dependence on insulin. This study also compared the use of insulin to that of

sulfonylurea treatment (a common treatment for people with T2D that enhances β-cell insulin production) and found that, unlike those treated with insulin, patients treated with sulfonylurea lost β-cell function faster and progressed rapidly to insulin dependency. Thus, it is coming to light that a better treatment for this subtype of diabetes may be insulin, not sulfonylureas. ■

Insulin resistance is an underlying aspect of prediabetes, type 2 diabetes, and gestational diabetes.

T2D is the predominant form of diabetes worldwide. An epidemic of T2D is underway in both developed and developing countries. Even more alarmingly, it is estimated that twice as many people have prediabetes, a condition that occurs when a person's blood glucose levels are higher than normal but not high enough for the diagnosis of T2D. Recent research has shown that some long-term damage to the body, especially the heart and circulatory system, may already be occurring during prediabetes. An individual is diagnosed with prediabetes if their fasting plasma glucose (FPG) is 100 to 125 mg/dL, if an oral glucose tolerance test (OGTT), which measures blood glucose levels before and 2 hours after drinking a solution containing 75 to 100 g of glucose, is 140 to 199 mg/dL, or if their A1C (sometimes called hemoglobin A1C, HbA1C, or glycohemoglobin), which measures the percent of glucose attached to hemoglobin, is 5.7% to 6.4%. Because red blood cells are constantly forming and dying, but typically they live for about 3 months, the A1C reflects the average of a person's blood glucose levels over the past 3 months. The higher the A1C percentage, the higher a person's blood glucose levels have been. A normal A1C level is below 5.7%. Individuals with A1Cs >6.5% are diagnosed with T2D, and this equates to an FPG of 126 mg/dL or higher or an OGTT measure that is 200 mg/dL or higher.

Central to prediabetes and T2D is insulin resistance, a term that indicates the presence of an impaired biologic response to either exogenously administered or endogenously secreted insulin. Insulin resistance is manifested by decreased insulin-stimulated glucose transport and metabolism in adipose tissue and skeletal muscle and by impaired suppression of hepatic glucose output.

It is clear that the molecular etiology of insulin resistance involves multiple genetic and nongenetic mechanisms contributing to the final phenotype. Furthermore, the resultant hyperglycemia of the syndrome and the compensatory rise in insulin in turn exacerbate insulin resistance, contributing significantly to the pathogenesis of the disease. Superimposed on that backdrop is the negative contribution of the obese state. New lessons learned from microbiology and immunology suggest an apparent role of intestinal microbiota in the etiology of obesity, insulin resistance, and T2D (see Integrated Medical Science Box). Although pinpointing the site of abnormality induced by these conditions is still an intensive area of current research, evidence strongly suggests that the defects induced by each occur at different loci in the insulin-signaling network.

Mutations in the IR are associated with rare forms of insulin resistance. These mutations affect IR number, splicing, trafficking, binding, and phosphorylation. The affected patients demonstrate severe insulin resistance, including type A syndrome, Donohue syndrome, Rabson–Mendenhall syndrome, and lipoatrophic diabetes.

In some cases, insulin resistance results from the secretion of counterregulatory hormones in a normal (e.g., pregnant) or pathophysiologic (e.g., Cushing syndrome) state. During pregnancy, many women become insulin resistant and develop gestational diabetes that usually disappears after delivery. Women who have had gestational diabetes, however, have an increased risk of developing T2D later in life.

Obesity is closely linked to insulin resistance.

The marked increase in the prevalence of obesity has played an important role in the prevalence of diabetes. According to data from the National Health and Nutrition Examination Survey, two thirds of the adult men and women in the United States with a diagnosis of T2D had a **body mass index** (**BMI**) of 27 kg/m^2 or greater. This index is calculated by dividing weight (in kilograms) by height (in meters squared). There is a strong curvilinear relation between BMI and relative body fat mass. Men and women with a BMI of 25.0 to 29.9 kg/m^2 are considered overweight, and those with a BMI of 30 kg/m^2 or greater are considered obese.

Lifestyle changes and multiple classes of drugs provide therapeutic intervention.

Early on, or in mild cases, diet, weight loss, and exercise can be extremely effective in diabetes therapy and may be the only treatment necessary. Commonly, however, lifestyle intervention is supplemented by treatment with one or more oral agents. Multiple classes of drugs independently address different pathophysiologic features that contribute to the development of T2D. The available oral antidiabetic agents can be divided by mechanism of action into insulin sensitizers with primary action in the liver (e.g., **biguanides**), insulin sensitizers with primary action in peripheral tissues (e.g., **glitazones**), insulin secretagogues (e.g., sulfonylureas), agents that slow the absorption of carbohydrates (e.g., **α-glucosidase inhibitors**), long-acting analogues of incretin hormones (e.g., GLP1 agonists), agents that increase incretin hormone levels (e.g., dipeptidyl peptidase IV inhibitors), and drugs that block the reabsorption glucose in the kidney (e.g., sodium glucose cotransporter inhibitors). In some cases, persons with T2D may be treated with insulin, just like the patient with T1D. Although insulin therapy apparently provides some benefit to type 2 diabetics, this approach is limited in controlling elevated glucose levels or in controlling obesity that predisposes to this disease.

Diabetes mellitus leads to organ dysfunction and tissue damage.

If left untreated or if glycemic control is poor, diabetes leads to acute complications that may prove fatal. However, even with reasonably good control of blood glucose, over a period of years, most diabetics develop secondary complications of the disease that result in tissue damage, primarily involving the cardiovascular and nervous systems.

The nature of acute complications that develop in type 1 and type 2 diabetics differs. Persons with poorly controlled T1D often exhibit hyperglycemia, **glucosuria**, dehydration, and **diabetic ketoacidosis**. As blood glucose becomes elevated above the renal plasma threshold, glucose appears in the urine. As a result of osmotic effects, water follows glucose, leading to **polyuria**, excessive loss of fluid from the body, and dehydration. With fluid loss, the circulating blood volume is reduced, compromising cardiovascular function, which may lead to circulatory failure.

Excessive ketone formation leads to acidosis and electrolyte imbalances in persons with T1D. If uncontrolled, ketones may be elevated in the blood to such an extent that the odor of **acetone** (one of the ketones) is noticeable on the breath. Production of the primary ketones, **β-hydroxybutyric acid** and **acetoacetic acid**, results in the generation of excess hydrogen ions and a metabolic acidosis. Ketones may accumulate in the blood to such a degree that they exceed renal transport capacities and appear in the urine. As a result of osmotic effects, water is also lost in the urine. In addition, the pK of ketones is such that even with the most acidic urine a normal kidney can produce about half of the excreted ketones are in the salt (or base) form. To ensure electrical neutrality, these must be accompanied by a cation, usually either sodium or potassium. The loss of ketones in the urine, therefore, also results in a loss of important electrolytes. Excessive ketone production in T1D results in acidosis, a loss of cations, and a loss of fluids. Emergency department procedures are directed toward immediate correction of these acute problems and usually involve the administration of base, fluids, and insulin.

The complex sequence of events that can result from uncontrolled T1D is shown in Figure 34.11. If left unchecked, many of these complications can have an additive effect to further the severity of the disease state.

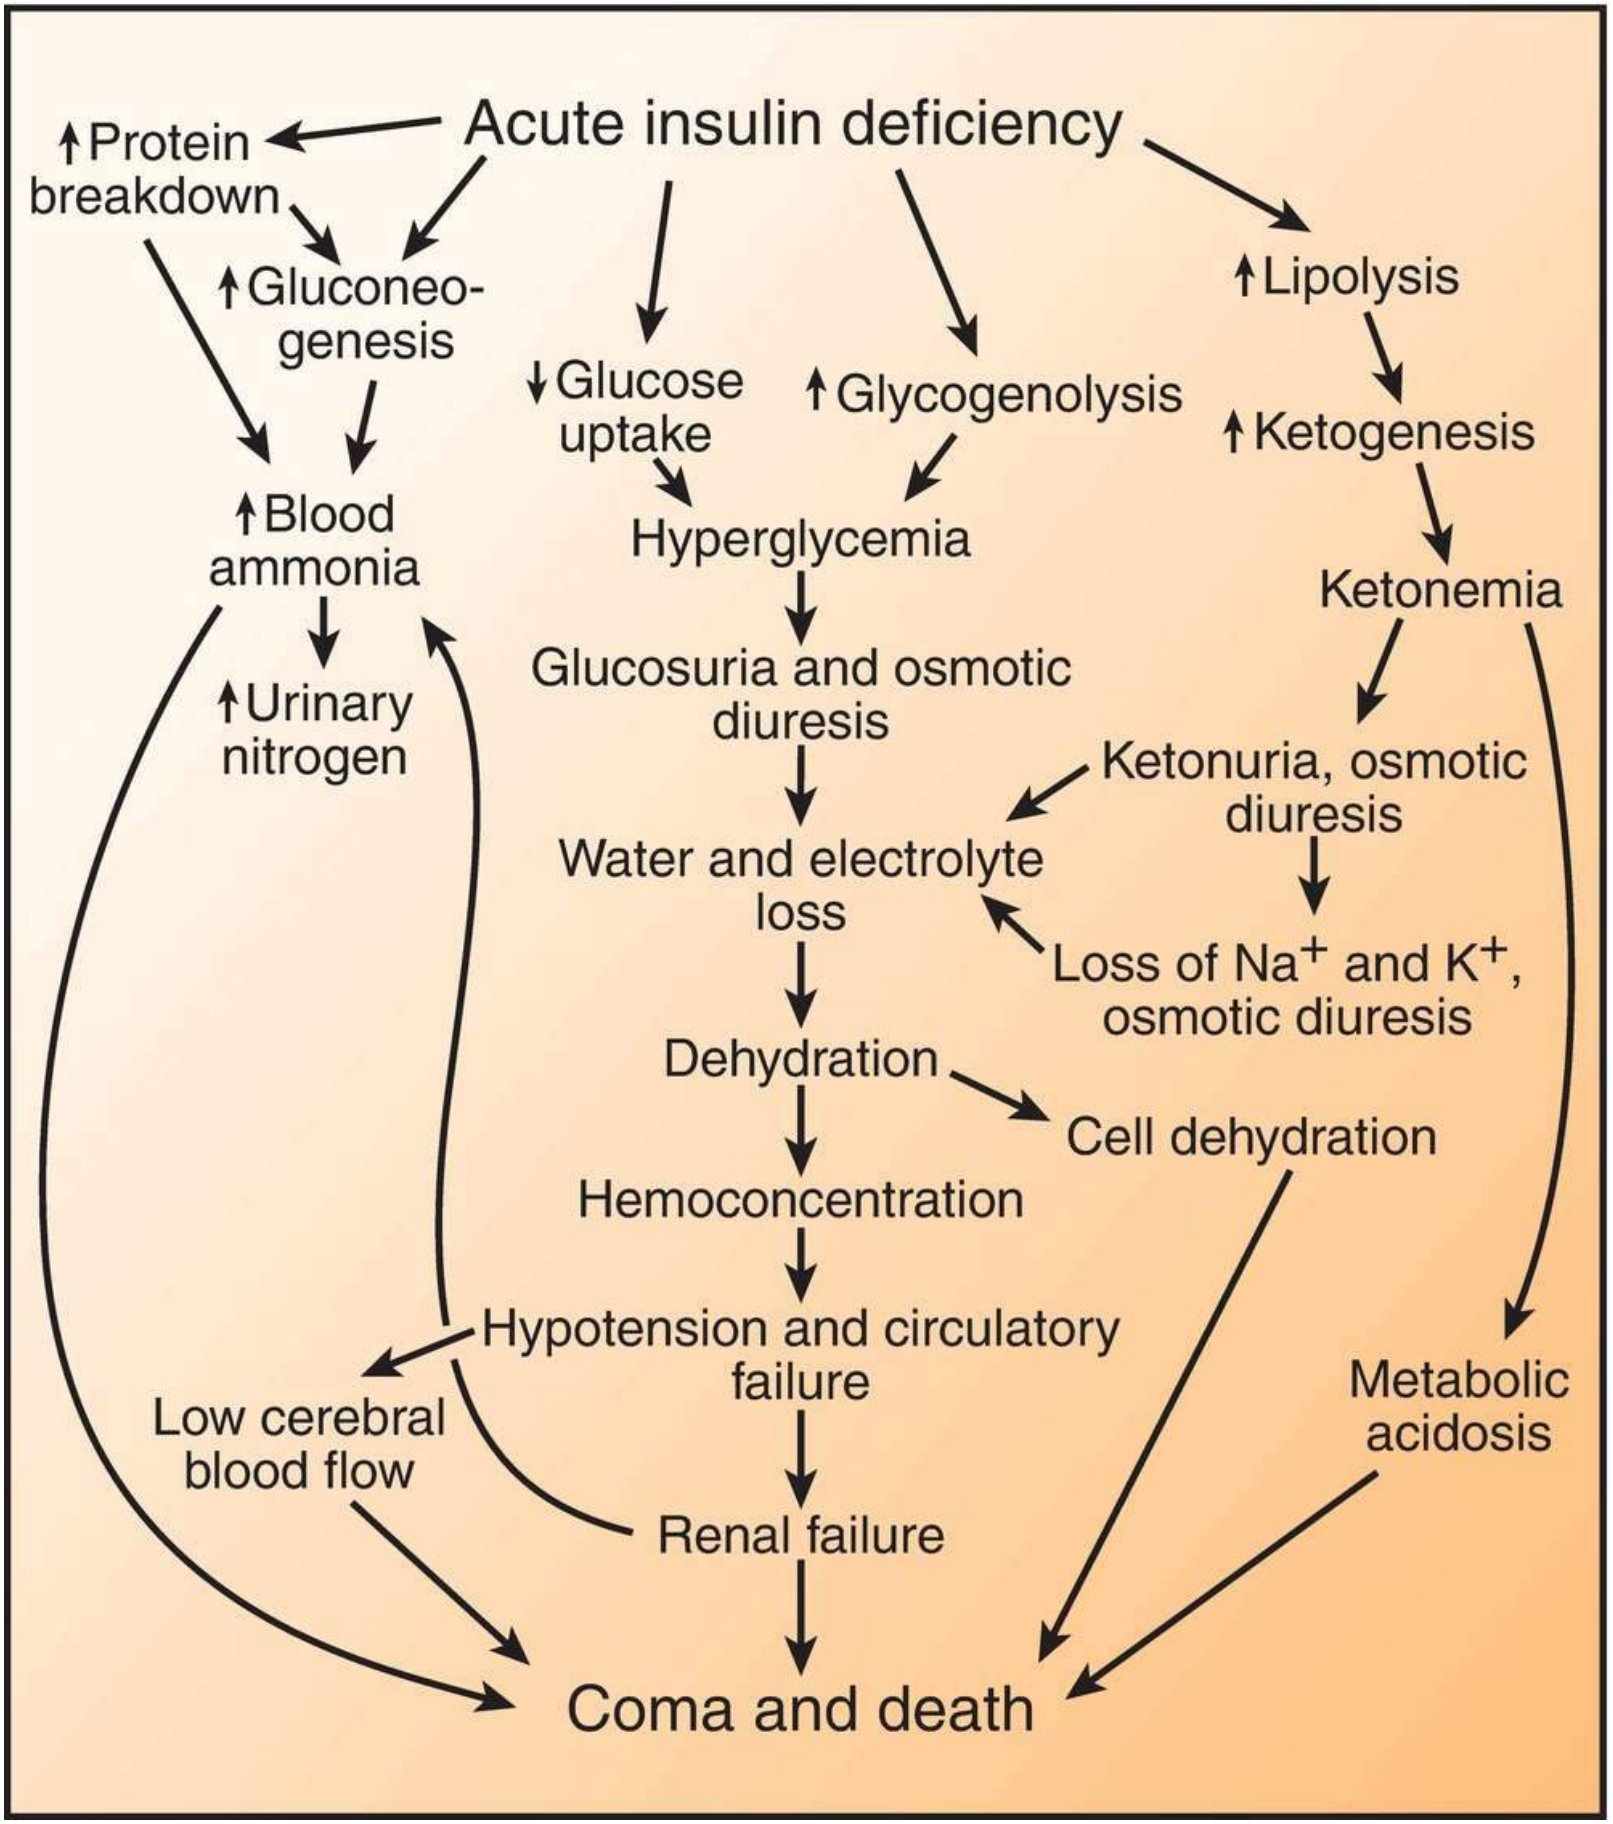

Figure 34.11 Events resulting from acute insulin deficiency in type 1 diabetes mellitus. If left untreated, insulin deficiency may lead to several complications, which may have additive or confounding effects that may ultimately result in death.

Persons with T2D are generally not ketotic and do not develop acidosis or the electrolyte imbalances characteristic of T1D. Hyperglycemia leads to fluid loss and dehydration. Severe cases may result in hyperosmolar coma as a result of excessive fluid loss. The initial objective of treatment in these people is the administration of fluids to restore fluid volumes to normal and eliminate the hyperosmolar state.

With good control of their disease, most persons with diabetes can avoid the acute complications described above; however, it is rare that they will not suffer from some of the chronic secondary complications of the disease. In most instances, such complications will ultimately lead to reduced life expectancy.

Most lesions occur in the circulatory system, although the nervous system is also often affected. Both small and large blood vessels systemic circulation are damaged, producing what are known, respectively, as microvascular and macrovascular complications in both T1D and T2D. The common finding in affected vessels is a thickening of the basement membrane. This condition leads to impaired delivery of nutrients and hormones to the tissues and inadequate removal of waste products, resulting in irreparable tissue damage. Interestingly, micro- and macrovascular complications do not occur in the pulmonary circulation. Although the pulmonary circulation receives all of the cardiac output as well as the same concentration of insulin and glucose as the systemic circulation, it is refractory to diabetes-induced vascular damage.

"Microvascular complications" is a term defining the effects of diabetes on small blood vessels, which include the following: deterioration of blood flow to the retina of the eye, causing **retinopathy** and blindness; deterioration of blood flow to the extremities, causing, in some cases, the need for foot or leg amputation; and deterioration of glomerular filtration in the kidneys, leading to renal failure.

"Macrovascular complications" is a term defining the effect of diabetes on large blood vessels. Diabetes is a major cause of myocardial infarction, stroke, and CVD. Recognized risk factors for CVD (i.e., hypertension, high triglycerides, low high-density lipoprotein cholesterol) are recognized as common in people with diabetes, especially T2D. Patients displaying a constellation of these derangements have been designated as having **metabolic syndrome**.

Another common complication of long-standing diabetes is **diabetic neuropathy**, a disorder affecting the peripheral sensory nerves also known as *peripheral neuropathy*. Diabetic neuropathy is thought to be a microvascular injury involving small blood vessels that supply the nerves. Diabetic neuropathy affects all peripheral nerves (pain fibers and motor neurons) and autonomic nerves.

Many patients with diabetes experience diminished sensation in the extremities, especially in the feet and legs, which compounds the problem of diminished blood flow to these areas. Often, impaired sensory nerve function results in lack of awareness of severe ulcerations of the feet caused by reduced blood flow. Men may develop erectile dysfunction leading to impotence, and both men and women may have impaired bladder and bowel function. Unfortunately, cancer patients (especially colon cancer) suffer from peripheral neuropathy as a side effect of radiation/chemotherapy and manifest the same symptoms.

INTEGRATED MEDICAL SCIENCES

Gut Microbiome

An estimated 100 trillion microbiota colonize the gastrointestinal tract and are considered an essential organ system, with properties that are integrated into the endocrinology, as well as other, systems of the host. Microbiologists refer to these bacteria as the microbiome, which is defined as the genetic material within a microbial community. While the study of the gut microbiome is a relatively new field, evidence suggests that the intestinal microbiota may play an important role in the onset of obesity, insulin resistance, and T2D.

For example, with regard to obesity that sets the stage for insulin resistance and T2D, conventionally raised mice have been reported to have 42% more total body fat than germ-free mice (raised in the absence of any microorganisms), even if their daily caloric intake was 29% less than the germ-free mice. Strikingly, transplanting fecal microbiota from conventionally raised mice into germ-free mice resulted in a 57% increase in the germ-free mice total body fat. Furthermore, germ-free mice transplanted with fecal microbiota from obese donors had a significantly greater increase in total body fat than those colonized with microbiota from lean donors.

Also layered into the integrated science of microbiology and endocrinology is the science of immunology, in that intestinal microbiota are enriched with molecules such as lipopolysaccharide (LPS) and peptidoglycan implicated in the development of inflammation and metabolic diseases. Mice fed a high-fat diet display a significantly altered intestinal microbiota composition and elevated plasma LPS. Normal insulin receptor signaling through IRS-1 is impaired by c-Jun N-terminal kinase (JNK) that is elevated by LPS. This detrimental proinflammatory activity of intestinal microbiota on insulin action is defined as metabolic endotoxemia. In addition to the insulin-signaling dysfunction resulting from increased endotoxemia, metabolic endotoxemia is associated with increased gut permeability. With high-fat feeding, changes in intestinal microbiota reduce tight junction proteins of gut epithelial cells, and the resulting increase in gut permeability sets in motion metabolic endotoxemia and insulin resistance.

Being explored now are therapeutic reversal opportunities to combat the apparent role intestinal microbiota have in the etiology of obesity, insulin resistance, and T2D. Three approaches being investigated are the use of probiotics, antibiotics, and fecal microbiota transplantation. Probiotics are nonpathogenic live microorganisms that have been found to significantly delay the onset of glucose intolerance, hyperglycemia, and hyperinsulinemia in diabetic rats and humans. Antibiotic treatment has also been shown to improve insulin sensitivity with associated lowering of plasma LPS and intestinal expression of inflammatory molecules. Finally, patients with metabolic syndrome who received small intestinal infusions of fecal microbiota from allogenic lean donors for 6 weeks showed an improvement in peripheral and hepatic insulin sensitivity. In closing, this new integrated medical science study of the gut microbiome in metabolic health and disease may be able to boost the development of new effective antidiabetic therapies. ■

Chapter Summary

- The relative distribution of α, β, δ, F, and **ε** cells within each islet of Langerhans shows a distinctive pattern and suggests that there may be some paracrine regulation of secretion.
- Plasma glucose is the primary physiologic regulator of insulin and glucagon secretion, but amino acids, fatty acids, and some gastrointestinal hormones also play a role.
- Insulin has anabolic effects on carbohydrate, lipid, and protein metabolism in its target tissues, where it promotes the storage of nutrients.
- Effects of glucagon on carbohydrate, lipid, and protein metabolism occur primarily in the liver and are catabolic in nature.
- Type 1 diabetes mellitus results from the destruction of β cells, whereas prediabetes, type 2 diabetes, and gestational diabetes result from a lack of responsiveness to circulating insulin.
- Diabetes mellitus may produce both acute complications, such as ketoacidosis, and chronic secondary complications, such as microvascular disease, macrovascular disease, neuropathy, and nephropathy.

Chapter Review Questions

1. Which of the following stimulate the secretion of both insulin and glucagon from the pancreas?
   - **A.** Acetylcholine
   - **B.** Amino acids
   - **C.** Epinephrine
   - **D.** Sulfonylureas
   - **E.** Both acetylcholine and amino acids

The correct answer is E. Acetylcholine and amino acids both stimulate insulin and glucagon secretion. Epinephrine stimulates glucagon secretion but inhibits insulin secretion. Sulfonylureas stimulate insulin secretion.

2. The effects of insulin include:
   - **A.** inhibition of amino acid uptake into skeletal muscle.
   - **B.** stimulation of glucose uptake into all tissues in the body.
   - **C.** inhibition of protein degradation in skeletal muscle.
   - **D.** stimulation of hormone-sensitive lipase in adipose tissue.
   - **E.** stimulation of glycogenolysis.

The correct answer is C. Insulin stimulates amino acid uptake into skeletal muscle, stimulates glucose uptake specifically into adipose tissue and skeletal muscle, inhibits protein degradation, inhibits hormone-sensitive lipase in adipose tissue, and inhibits glycogenolysis.

3. A 55-year-old man was diagnosed with type 1A diabetes at the age of 8. Which would be most characteristic of his form of the disease?
   - **A.** Absence of anti-islet autoantibodies
   - **B.** Insulin resistance
   - **C.** Sulfonylurea treatment
   - **D.** Treatment with exogenous insulin
   - **E.** Virtual absence of secondary complications

The correct answer is D. Persons with type 1A diabetes have islet autoantibodies, whereas persons with type 1B diabetes do not have islet autoantibodies. Both type 1A and type 1B diabetics are insulin deficient, not insulin resistant and are treated with exogenous insulin. Persons with type 2 diabetes are treated with sulfonylureas. Secondary complications are difficult to avoid in any form of diabetes.

Clinical Application Exercises 34.1

TRANSIENT NEONATAL DIABETES

A 21-day-old male infant was referred to a specialized children's hospital for management of hyperglycemia. Hyperglycemia had been noted on day one of life with an initial blood glucose value of 16 mmol/L. At diagnosis, both the plasma immunoreactive insulin (IRI) and immunoreactive glucagon (IRG) were below the reference range for normal neonates. The IRG, but not the IRI, normalized within the first month. A regimen of daily insulin was begun. Interestingly, from day 41 to day 47, the infant did not receive insulin and a crude control of the blood glucose was demonstrated. Peak levels of blood glucose in excess of 20 mmol/L were followed by drops to levels <2 mmol/L

without insulin administration. However, because of unsatisfactory glucose levels, administration of daily insulin was reintroduced. The infant was discharged from the hospital on day 50, and administration of insulin was discontinued uneventfully at 9 months. At 1 year, glycemic control was normal.

QUESTIONS

1. What might be the basis for the infant's reversible bout of hyperglycemia?
2. In addition to hyperglycemia, the patient probably presented with what?
3. Do poorly controlled type 1 diabetic individuals display inappropriate IRG?

ANSWERS

1. The findings indicate an immature function of both beta and alpha cells at the diagnosis with the alpha cells maturing within the first month and the beta-cell recovery later. The exact mechanism to explain this entity is not known, but there are several postulates including transient hypothalamic imbalance, infection, adrenocortical disturbance, insulin resistance, and immaturity of hepatic gluconeogenetic enzymes. However, the most accepted ones are hypoinsulinism with β-cell hypoplasia and temporary delay in β-cell maturity.
2. The infant (even though was full term) might be expected to be small for gestational age with features of dehydration and wasting in presence of normal intake and absence of vomiting and loose motions.
3. Type 1 diabetes is a consequence of an inappropriate autoimmune (type 1A) or, to a lesser extent, nonimmune (type 1B) destruction of the beta cell. As insulin is also necessary for alpha cells to sense blood glucose appropriately; in the absence of insulin or an insufficient insulin therapy regime, the secretion of glucagon is inappropriately elevated. The result is an imbalance in the I/G ratio and an accentuation of glucagon effects well above what would be seen in normal states of low insulin, such as in fasting.

35 Endocrine Regulation of Calcium, Phosphate, and Bone Homeostasis

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how typical daily changes of both calcium and phosphorus between different tissue compartments in a healthy adult are controlled.
- Explain how chondrocytes, osteoblasts, osteocytes, and osteoclasts regulate bone formation and bone reabsorption.
- Explain how parathyroid hormone, calcitonin, and 1,25-dihydroxycholecalciferol affect calcium and phosphate metabolism.
- Explain the underlying mechanisms of osteogenesis imperfecta, osteoporosis, osteomalacia, rickets, and Paget disease.

The plasma calcium concentration is among the most closely regulated of all physiologic parameters in the body. Typically, it varies by only 1% to 2% daily or even weekly. Such stringent regulation in a biologic system usually implies that the parameter plays an important role in one or more critical processes. Phosphate also plays many important roles in the body, although its concentration is not as tightly regulated as that of calcium. Many of the factors involved in regulating calcium also affect phosphate.

OVERVIEW OF CALCIUM AND PHOSPHATE IN THE BODY

Calcium is the most abundant mineral in the body and plays a key role in many physiologically important processes. The average adult contains ~1 kg of calcium in the body, with 99% contained in bone in the form of calcium phosphate. A significant decrease in plasma calcium can rapidly lead to death. A chronic increase in plasma calcium can lead to soft tissue calcification and formation of stones. Phosphate also plays important roles in the body, and because it is a principal component of bone with calcium, phosphate homeostasis is tightly and hormonally coupled to that of calcium.

Calcium and phosphate are major constituents of bone and key cellular functions.

Calcium affects nerve and muscle excitability, neurotransmitter release from axon terminals, and excitation–contraction coupling in muscle cells. It serves as a second or third messenger in several intracellular signal transduction pathways. Some enzymes use calcium as a cofactor, including some in the blood-clotting cascade. Finally, calcium is a major constituent of bone. Of all these roles, the one that demands the most careful regulation of plasma calcium is the effect of calcium on nerve excitability. Calcium affects the sodium permeability of nerve membranes, which influences the ease with which action potentials are triggered. Low plasma calcium (**hypocalcemia**) can lead to the generation of spontaneous action potentials in nerves. When motor neurons are affected, tetany of the muscles of the motor unit may occur; this condition is called **hypocalcemic tetany**. Certain diagnostically important signs may reveal latent tetany. The **Trousseau sign** is a characteristic spasm of the muscles of the forearm that causes flexion of the wrist and thumb and extension of the fingers. It may occur spontaneously or be elicited by inflation of a blood pressure cuff placed on the upper arm. The **Chvostek sign** is a unilateral spasm of the facial muscles that can be elicited by tapping the facial nerve at the point at which it crosses the angle of the jaw. Although rare, hypocalcemia can also influence myocardial function by changing QT intervals or QRS and ST segments. These changes may mimic acute myocardial infarction or conduction abnormalities. A considerable reduction in serum calcium may lead to **grand mal seizures** or **laryngospasm**.

Phosphorus (usually as phosphate) is also a key constituent of bone. In addition, phosphate serves as an important component of intracellular pH buffering and cellular energy metabolism as part of the adenosine triphosphate molecule. Phosphate is a constituent of many other macromolecules, such as phospholipids and phosphoproteins.

Distributions of calcium and phosphorus differ in bone and cells.

Table 35.1 shows the relative distributions of calcium and phosphate in a healthy adult. The average adult body contains ~1 to 2 kg of calcium, roughly 99% of it is in bones. Despite its critical role in excitation–contraction coupling, only about 0.3% of total body calcium is located in muscles. About 0.1% of total calcium is in extracellular fluid. Of the roughly 600 g of phosphorus in the body, most is in bones (86%). Compared with calcium, a much larger percentage of phosphorus is located in cells (14%). The amount of phosphorus in extracellular fluid is low (0.08% of body content).

TABLE 35.1 Body Content and Tissue Distribution of Calcium and Phosphorus in a Healthy Adult

Region	Calcium	Phosphorus
Total body content (g)	1,300	600
Relative tissue distribution (% of total body content)		
Bones and teeth	99	86
Extracellular fluid	0.1	0.08
Intracellular fluid	1.0	14

Bones also contain a relatively high percentage of the total body content of several other inorganic substances (Table 35.2). About 80% of the total carbonate in the body is located in bones. This carbonate can be mobilized into the blood to combat acidosis; thus, bone participates in pH buffering in the body. Long-standing uncorrected acidosis can result in considerable loss of bone mineral. Significant percentages of the body's magnesium and sodium and nearly 10% of its total water content are in bones.

TABLE 35.2 Inorganic Constituents of Bone

Constituent	Percentage of Total Body Content Present in Bone
Calcium	99
Phosphate	86
Carbonate	80
Magnesium	50
Sodium	35
Water	9

Calcium and phosphorus exist in the plasma in several forms.

In humans, the normal plasma calcium concentration is 9.0 to 10.5 mg/dL. Plasma calcium exists in three forms: ionized or free calcium (50% of the total), protein-bound calcium (40%), and calcium bound to small diffusible anions, such as citrate, phosphate, and bicarbonate (10%). The association of calcium with plasma proteins is pH dependent. At an alkaline pH, more calcium is bound; the opposite is true at an acidic pH.

Plasma phosphorus concentrations may fluctuate significantly during the course of a day (±50% of the average value) for any particular person. In adults, the normal range of plasma concentrations is 3.0 to 4.5 mg/dL. Phosphorus circulates in the plasma primarily as inorganic **orthophosphate** (**PO_4**). At a normal blood pH of 7.4, 80% of the phosphate is in the HPO_4^{2-} form and 20% is in the $H_2PO_4^-$ form. Nearly all plasma inorganic phosphate is ultrafilterable. In addition to free orthophosphate, phosphate is present in small amounts in the plasma in organic form, such as in hexose or in lipid phosphates.

Calcium and phosphorous regulation involves the GI tract, kidneys, and bone.

Both calcium and phosphate are obtained from the diet. The approximate tissue distribution and average daily flux of calcium among tissues in a healthy adult are shown in Figure 35.1. Dietary intakes may vary widely, but an “average” diet contains ~1,000 mg/d of calcium. Intakes up to twice that amount are usually well tolerated, but excessive calcium intake can result in soft tissue calcification or kidney stones. Only about one third of ingested calcium is actually absorbed from the GI tract; the remainder is excreted in the feces. The efficiency of calcium uptake from the GI tract varies with the person’s physiologic status. The percentage uptake of calcium may be increased in young growing children and pregnant or nursing women; often, it is reduced in older adults.

Figure 35.1 Typical daily exchanges of calcium between different tissue compartments in a healthy adult. Fluxes of calcium (mg/d) are shown in *bold font*. Total calcium content in each compartment is shown in *regular font*. Note that most ingested calcium is eliminated from the body via the feces.

Figure 35.1 also indicates that ~150 mg/d of calcium actually enters the GI tract from the body. This component of the calcium flux partly results from sloughing of mucosal cells that line the GI tract and also from calcium that accompanies various secretions into the GI tract. This component of calcium metabolism is relatively constant, and so the primary determinant of *net* calcium uptake from the GI tract is calcium absorption. Intestinal absorption is important in regulating calcium homeostasis.

Bone in an average person contains ~1,000 g of calcium. Bone mineral is constantly reabsorbed and deposited in the remodeling process. As much as 500 mg/d of calcium may flow in and out of the bones. Because bone calcium serves as a reservoir, both bone resorption and bone formation are important in regulating plasma calcium concentration.

In overall calcium balance, the net uptake of calcium from the GI tract presents a daily load of calcium that will eventually require elimination. The primary route of elimination is via the urine, and therefore, the kidneys play an important role in regulating calcium homeostasis. The 150 mg/d of calcium excreted in the urine represents only about 1% of the calcium initially filtered by the kidneys; the remaining 99% is reabsorbed and returned to the blood. Therefore, small changes in the amount of calcium reabsorbed by the kidneys can have a dramatic impact on calcium homeostasis.

Figure 35.2 shows the overall daily flux of phosphate in the body. A typical adult ingests ~1,400 mg/d of phosphorus. In marked contrast to calcium, most (1,300 mg/d) of this phosphorus is absorbed from the GI tract, typically as inorganic phosphate. There is an obligatory contribution of phosphorus from the body to the contents of the GI tract (about 200 mg/d), much like that for calcium, resulting in a net uptake of phosphorus of 1,100 mg/d and excretion of 300 mg/d via the feces. Thus, most ingested phosphate is absorbed from the GI tract and little passes through to the feces. Because most ingested phosphate is absorbed and circulating phosphate is readily filtered in the kidneys, tubular phosphate reabsorption is a major process regulating phosphate homeostasis.

CALCIUM AND PHOSPHATE METABOLISM

Homeostatic mechanisms are responsible for bringing calcium and phosphate into the body, maintaining normal blood levels of these minerals, transporting them into the cell, and transporting them out again when needed.

Calcium and phosphate are absorbed primarily by the small intestine.

Calcium absorption in the small intestine occurs by both active transport and diffusion. The relative contribution of each process varies with the region and with total calcium intake. Uptake of calcium by active transport predominates in the duodenum and jejunum; in the ileum, passive diffusion predominates. The relative importance of active transport in the duodenum and jejunum versus passive diffusion in the ileum depends on several factors. At high levels of calcium intake, active transport processes are saturated and most of the uptake occurs in the ileum, partly because of its greater length, compared with other intestinal segments. With moderate or low calcium intake, however, active transport predominates because the gradient for diffusion is low. Active transport is the regulated variable in controlling calcium uptake from the small intestine. Metabolites of vitamin D provide a regulatory signal to increase intestinal calcium absorption. Under the influence of 1,25-dihydroxycholecalciferol, calcium-binding proteins in intestinal mucosal cells increase in number, enhancing the capacity of these cells to transport calcium actively.

The small intestine is also a primary site for phosphate absorption. Uptake occurs by active transport and passive diffusion, but active transport is the primary mechanism. As indicated in Figure 35.2, phosphate is efficiently absorbed from the small intestine; typically, 80% or more of ingested phosphate is absorbed. However, phosphate absorption from the small intestine is regulated to a minor extent. Active transport of phosphate is coupled to calcium transport, and thus, when active transport of calcium is low, as with vitamin D deficiency, phosphate absorption is also low.

Kidneys play an important role in plasma calcium and phosphate regulation.

Filterable calcium comprises about 60% of the total calcium in the plasma. It consists of free calcium ions and calcium bound to small diffusible anions. The remaining 40% of the total calcium is bound to plasma proteins and is not filterable by the glomeruli. Ordinarily, 99% of the filtered calcium is reabsorbed by the kidney tubules and returned to the plasma. Reabsorption occurs both in the proximal and distal tubules and in the loop of Henle. Approximately 60% of filtered calcium is reabsorbed in the proximal tubule, 30% in the loop of Henle, and 9% in the distal tubule; the remaining 1% is excreted in the urine. Renal calcium excretion is controlled primarily in the late distal tubule; parathyroid hormone (PTH) stimulates calcium reabsorption here, promoting calcium retention and lowering urinary calcium. As detailed later, PTH is an important regulator of plasma calcium concentration.

Most ingested phosphate is absorbed from the GI tract, and the primary route of excretion of this phosphate is via the urine. Ordinarily, about 85% of filtered phosphate is reabsorbed and 15% is excreted in the urine. Phosphate reabsorption occurs via active transport, mainly in the proximal tubule, where 65% to 80% of filtered phosphate is reabsorbed. PTH inhibits phosphate reabsorption in the proximal tubule and has a major regulatory effect on phosphate homeostasis. It increases urinary phosphate excretion, leading to the condition of **phosphaturia**, with an accompanying decrease in the plasma phosphate concentration.

Calcium and phosphate in bone are in continuous flux.

Although bone may be considered as being a relatively inert material, it is active metabolically. Considerable amounts of calcium and phosphate enter and exit the bone each day, and these processes are hormonally controlled.

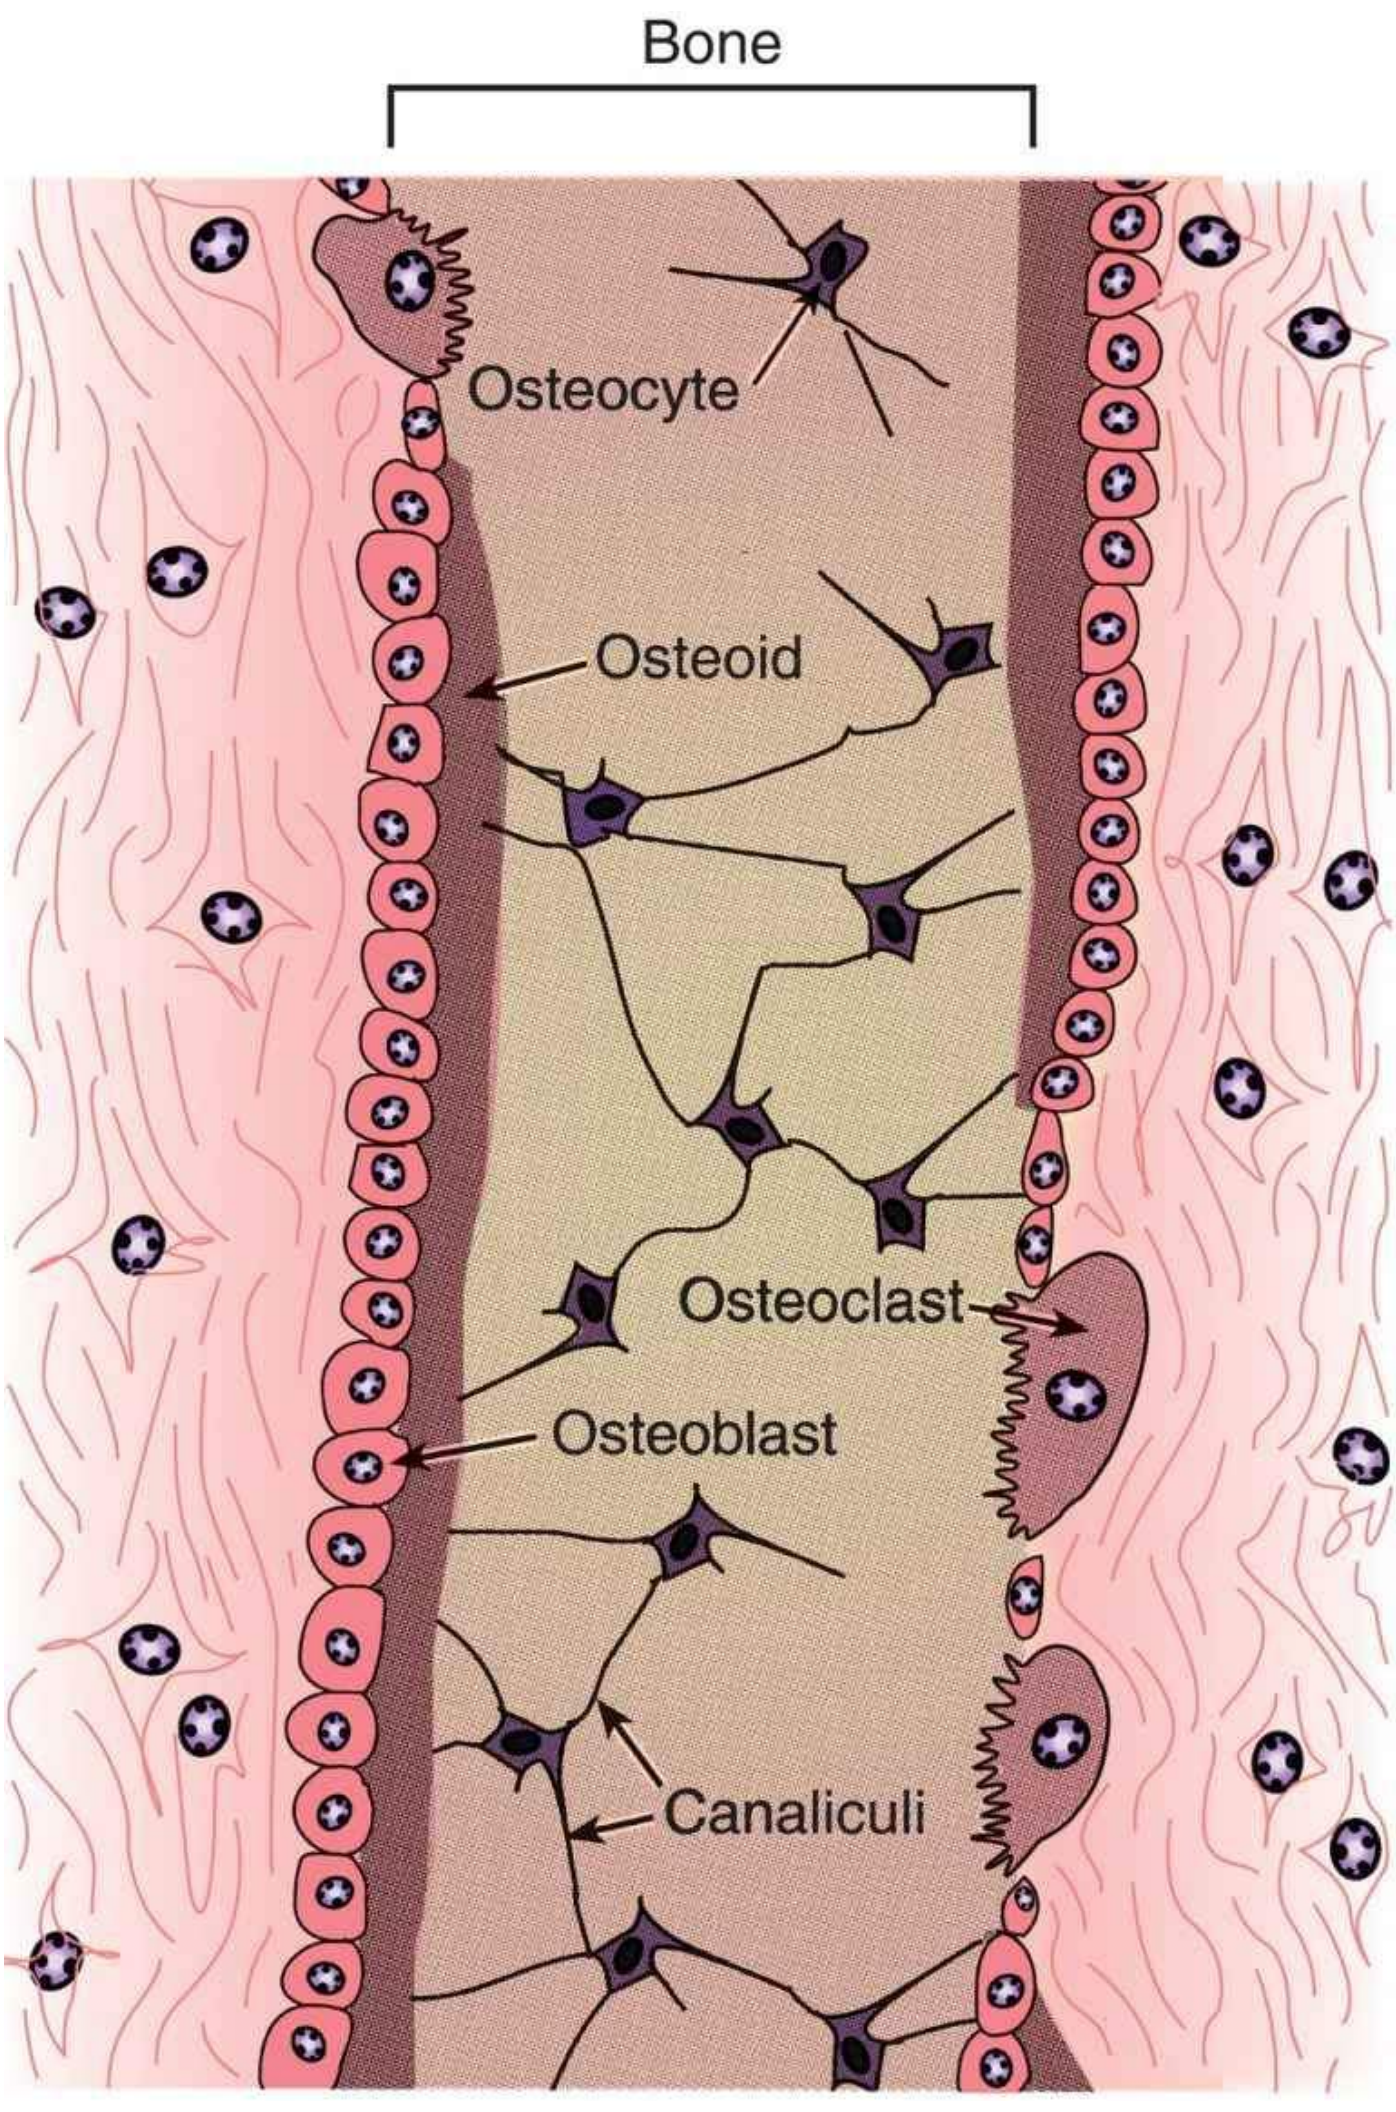
Mature bone can be simply described as inorganic mineral deposited on an organic framework. The mineral portion of bone is composed largely of calcium phosphate in the form of **hydroxyapatite crystals**, which have the general chemical formula Ca_{10} $(PO_4)_6(OH)_2$. The mineral portion of bone typically comprises about 25% of its volume, but because of its high density, the mineral fraction is responsible for approximately half the weight of bone. Bone contains considerable amounts of the body's content of carbonate, magnesium, and sodium, in addition to calcium and phosphate (see Table 35.2).

The organic matrix of bone on which the bone mineral is deposited is called **osteoid. Type I collagen** is the primary constituent of osteoid, comprising 95% or more. Collagen in bone is similar to that of skin and tendons, but bone collagen exhibits some biochemical differences that impart increased mechanical strength. The remaining noncollagen portion (5%) of organic matter is referred to as **ground substance** that consists of various **proteoglycans**. These proteoglycans are high molecular weight compounds consisting of different types of polysaccharides. Typically, they are 95% or more carbohydrate.

Electron microscopic study of bone reveals needle-like hydroxyapatite crystals lying alongside collagen fibers. This orderly association of hydroxyapatite crystals with the collagen fibers is responsible for the strength and hardness characteristic of bone. A loss of either bone mineral or organic matrix greatly affects the mechanical properties of bone. Complete demineralization of bone leaves a flexible collagen framework, and the complete removal of organic matrix leaves a bone with its original shape, but extremely brittle. **Osteogenesis imperfecta**, or brittle bone disease, is a genetic disorder characterized by bones that break easily as a result of defects in the production of the fibrillar collagen matrix.

Osteoblasts, osteocytes, and osteoclasts constitute the major cell types in bone.

Osteoblasts are located on the bone surface and are responsible for osteoid synthesis (Fig. 35.3). Like many cells that actively synthesize proteins for export, osteoblasts have an abundant rough endoplasmic reticulum and Golgi apparatus. Cells actively engaged in osteoid synthesis are cuboidal, whereas those less active are more flattened. Numerous cytoplasmic processes connect adjacent osteoblasts on the bone surface and connect osteoblasts with osteocytes deeper in the bone. Osteoid produced by osteoblasts is secreted into the space adjacent to the bone. Eventually, new osteoid becomes mineralized, and in the process, mineralized bone surrounds osteoblasts.



Bone
Osteocyte
Osteoid
Osteoclast
Osteoblast
Canaliculi

Figure 35.3 The location and relationship of the three primary cell types involved in bone metabolism.

As osteoblasts are progressively incorporated into mineralized bone, they lose much of their bone-forming ability and become quiescent. At this point, they are called **osteocytes**. Many of the cytoplasmic connections in the osteoblast stage are maintained into the osteocyte stage. These connections become visible channels or **canaliculi** that provide direct contact for osteocytes deep in bone with other osteocytes and with the bone surface. It is generally believed that these canaliculi provide a mechanism for the transfer of nutrients, hormones, and waste products between the bone surface and its interior.

Osteoclasts are cells responsible for bone resorption. They are large, multinucleated cells located on bone surfaces. Osteoclasts promote bone resorption by secreting acid and proteolytic enzymes into the space adjacent to the bone surface. Surfaces of osteoclasts facing bone are ruffled to increase their surface area and promote bone resorption. Bone resorption is a two-step process. First, osteoclasts create a local acidic environment that increases the solubility of surface bone mineral. Second, proteolytic enzymes secreted by osteoclasts degrade the organic matrix of bone.

Bone formation starts with neonatal development and continues throughout life.

Early in fetal development, the skeleton consists of little more than a cartilaginous model of what will later form the bony skeleton. The process of replacing this cartilaginous model with mature, mineralized bone begins in the center of the cartilage and progresses toward the two ends of what will later form the bone. As mineralization progresses, the bone increases in thickness and in length.

The **epiphyseal plate** is a region of growing bone of particular interest because it is here that the elongation and growth of bones occur after birth. Histologically, the epiphyseal plate shows considerable differences between its leading and trailing edges. The leading edge consists primarily of **chondrocytes**, which are actively engaged in the synthesis of cartilage of the epiphyseal plate. These cells gradually become engulfed in their own cartilage and are replaced by new cells on the cartilage surface, allowing the process to continue. The cartilage gradually becomes calcified, and the embedded chondrocytes die. The calcified cartilage begins to erode, and osteoblasts migrate into the area. Osteoblasts secrete osteoid, which eventually becomes mineralized, and a new mature bone is formed. In the epiphyseal plate, therefore, the continuing processes of cartilage synthesis, calcification, erosion, and osteoblast invasion result in a zone of active bone formation that moves away from the middle or center of the bone toward its end.

Hormones control chondrocytes of epiphyseal plates. Insulin-like growth factor I, primarily produced by the liver in response to growth hormone, serves as a primary stimulator of chondrocyte activity and, ultimately, of bone growth. Insulin and thyroid hormones provide an additional stimulus for chondrocyte activity.

Beginning a few years after puberty, the epiphyseal plates in long bones (as in the legs and arms) gradually become less responsive to hormonal stimuli and, eventually, are totally unresponsive. This phenomenon is referred to as closure of the epiphyses. In most people, epiphyseal closure is complete by about age 20; adult height is reached at this point, because further linear growth is impossible. Not all bones undergo closure. For example, those in the fingers, feet, skull, and jaw remain responsive, which accounts for the skeletal changes seen in acromegaly, the condition of growth hormone overproduction (see Chapter 31).

The flux of calcium and phosphate into and out of bone each day reflects a turnover of bone mineral and changes in bone structure generally referred to as **bone remodeling**. Bone remodeling occurs along most of the outer surface of the bone, making it either thinner or thicker, as required. In long bones, remodeling can also occur along the inner surface of the bone shaft, next to the marrow cavity. Remodeling is an adaptive process that allows bone to be reshaped to meet changing mechanical demands placed on the skeleton. It also allows the body to store or mobilize calcium rapidly.

PLASMA CALCIUM AND PHOSPHATE REGULATION

Regulatory mechanisms for calcium include rapid nonhormonal mechanisms with limited capacity and somewhat slower hormonally regulated mechanisms with much greater capacity. Similar mechanisms are also involved in regulating phosphate concentrations.

Plasma free calcium can be rapidly buffered by nonhormonal mechanisms.

The calcium bound to plasma proteins and a small fraction of that in bone mineral can help prevent a rapid decrease in the plasma calcium concentration. The association of calcium with proteins is a simple, reversible, chemical equilibrium process. Protein-bound calcium, therefore, has the capacity to serve as a buffer of free plasma calcium concentrations. This effect is rapid and does not require complex signaling pathways; however, the capacity is limited, and the mechanism cannot serve a long-term role in calcium homeostasis.

Recall that ~99% of total body calcium is present in bones, and a healthy adult body has about 1 to 2 kg of calcium. Most of the calcium in bones exists as mature, hardened bone mineral that is not readily exchangeable but can be moved into the plasma via hormonal mechanisms (described below). However, ~1% (or 10 g) of the calcium in bones is in a simple chemical equilibrium with plasma calcium. This readily exchangeable calcium source is primarily located on the surface of newly formed bones. Any change in free calcium in the plasma or extracellular fluid results in a shift of calcium either into or out of the bone mineral until a new equilibrium is reached. Although this mechanism, like that described above, provides for a rapid defense against changes in free calcium concentrations, it is limited in capacity and can provide for only short-term adjustments.

Long-term, hormonal regulation of plasma calcium and phosphate is under the control of parathyroid hormone, calcitonin, and 1,25-dihydroxycholecalciferol.

Hormonal mechanisms have a large capacity and the ability to make long-term adjustments in calcium and phosphate fluxes, but they do not respond instantaneously. It may take several minutes or hours for the response to occur and adjustments to be made. Nevertheless, these are the principal mechanisms that regulate plasma calcium and phosphate concentrations.

One of the primary regulators of plasma calcium concentrations is **parathyroid hormone** (**PTH**). PTH is an 84-amino acid polypeptide produced by the parathyroid glands. Synthetic peptides containing the first 34 amino terminal residues appear to be as active as the native hormone. There are two pairs of parathyroid glands, located on the dorsal surface of the left and right lobes of the thyroid gland. Because of this close proximity, a common cause of chronic hypocalcemia is postsurgical removal of all parathyroid tissue, either during a thyroidectomy and removal of neck-associated malignancies or after inadvertent interruption of blood supply to the parathyroid glands during head and neck surgery. Hypoparathyroidism is a rare complication of radioactive iodine ablation of the thyroid gland in **Graves disease**.

The primary physiologic stimulus for PTH secretion is a decrease in plasma calcium. Figure 35.4 shows the relationship between serum PTH concentration and total plasma calcium concentration. A decrease in the ionized calcium concentration actually triggers an increase in PTH secretion. The net effect of PTH is to increase the flow of calcium into plasma and return the plasma calcium concentration toward normal.

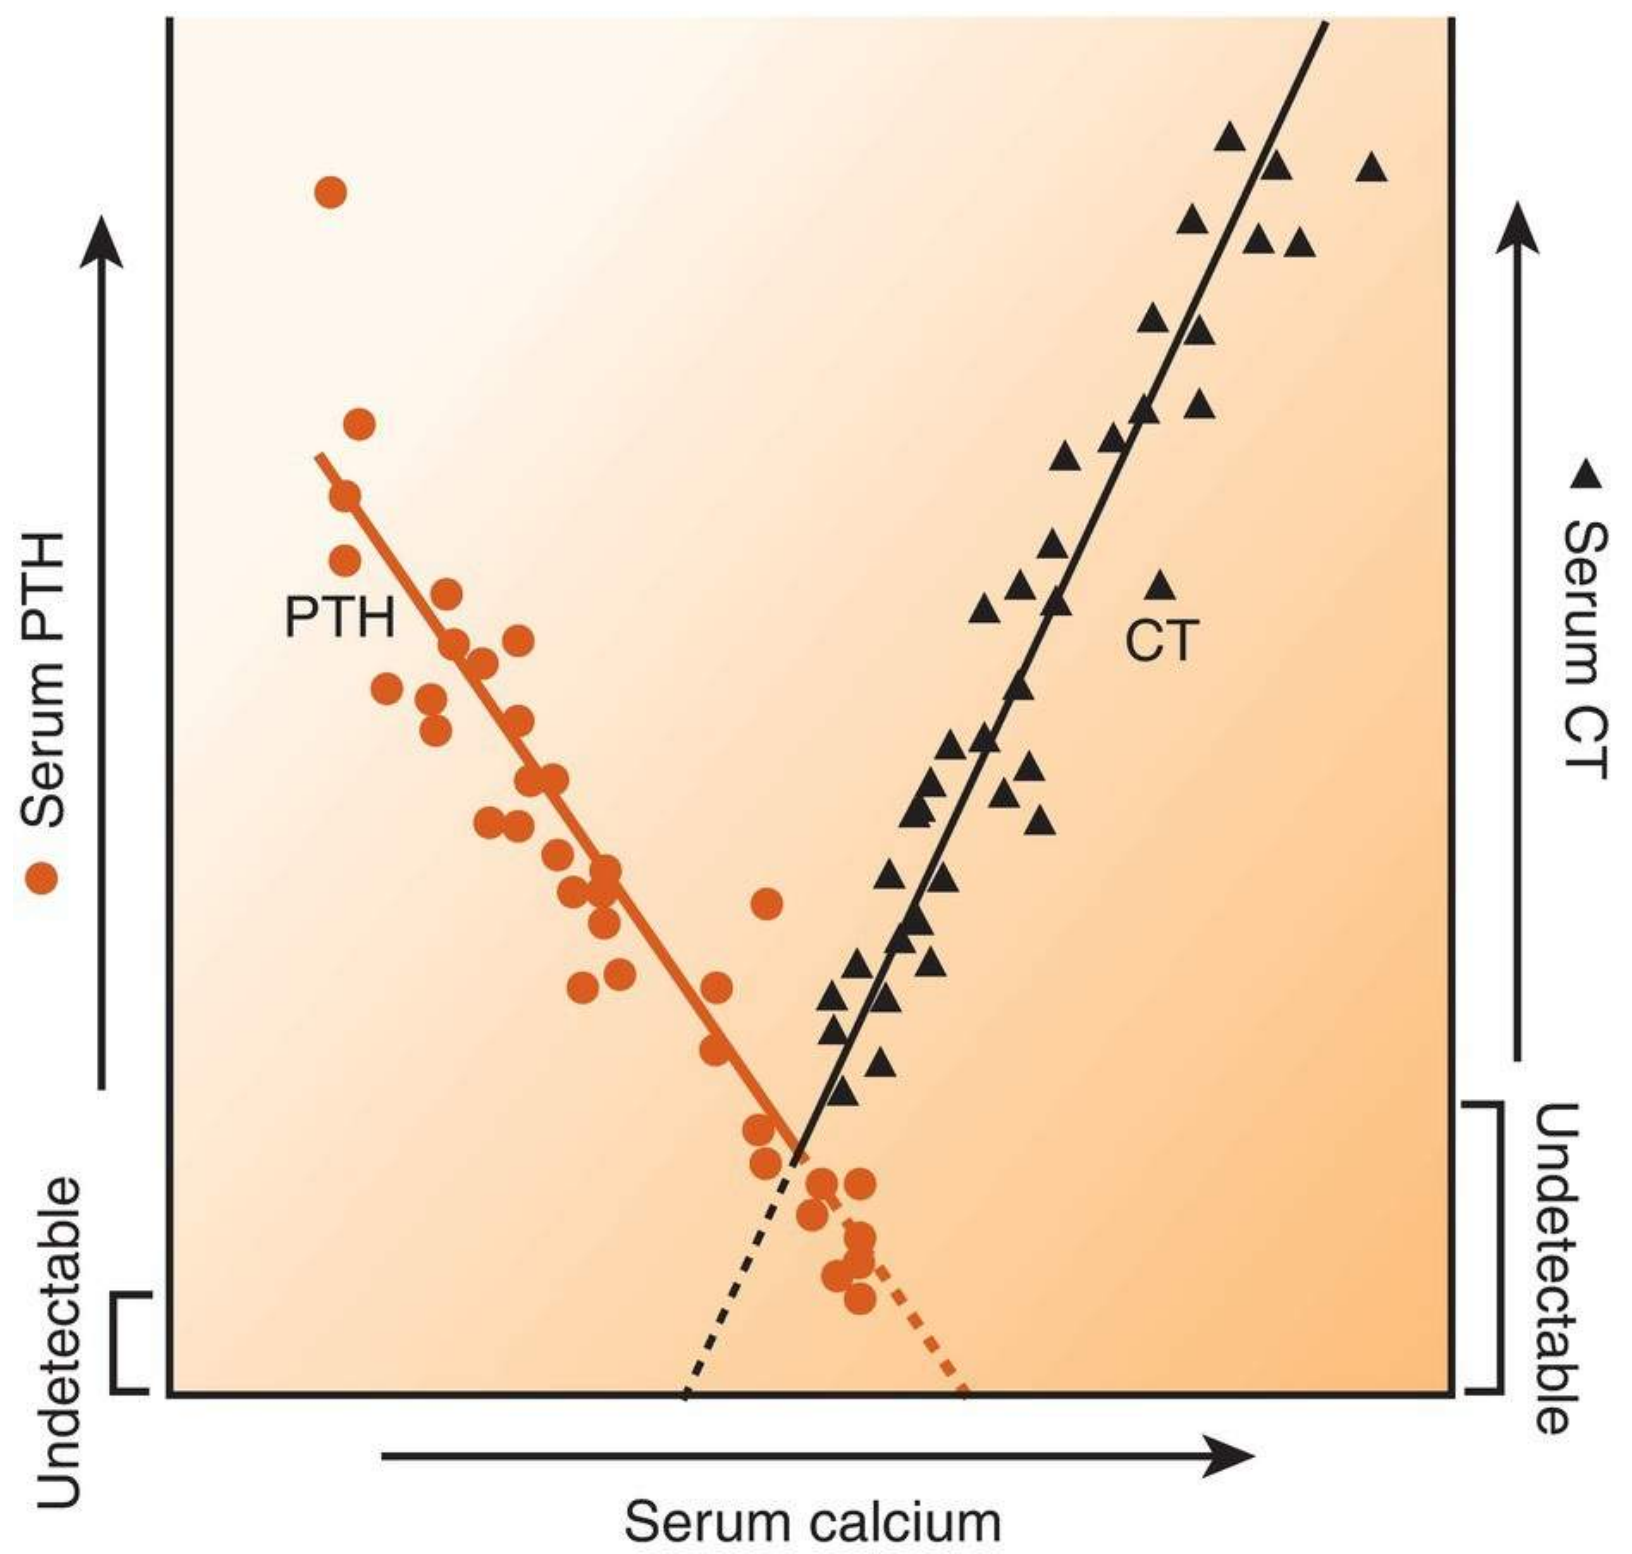


Figure 35.4 Effect of changes in plasma calcium on parathyroid hormone (PTH) and calcitonin (CT) secretion.

Parafollicular cells of the thyroid gland produce a 32-amino acid polypeptide termed **calcitonin** (**CT**), also known as thyrocalcitonin (see Fig. 32.1). Unlike PTH activity, for which only the initial amino terminal segment is required, CT activity requires the full polypeptide. Salmon CT differs from human CT in 9 of the 32 amino acid residues and is 10 times more potent than human CT in its hypocalcemic effect. The higher potency may be a result of a greater affinity for receptors and slower degradation by peripheral tissues. CT is often used clinically as a synthetic peptide matching the sequence of salmon CT.

In contrast to PTH, CT secretion is stimulated by an increase in plasma calcium (see Fig. 35.4).

Hormones of the GI tract, especially gastrin, also promote CT secretion. Because the net effect of CT is to promote calcium deposition in bone, the stimulation of CT secretion by GI hormones provides an additional mechanism for facilitating the uptake of calcium into bone after the ingestion of a meal.

The third key hormone shown in Figure 35.5 involved in regulating plasma calcium is **vitamin D_3** (cholecalciferol). More precisely, a metabolite of vitamin D_3, 1,25-dihydroxycholecalciferol, serves as a hormone in calcium homeostasis. The D vitamins, a group of lipid-soluble compounds derived from cholesterol, have long been known to be effective in the prevention of certain bone diseases such as rickets (discussed below). Research during the past 30 years indicates that vitamin D exerts its effects through a hormonal mechanism. A related compound **vitamin D_2** (also known as ergocalciferol) is the form mainly found in plants and yeasts and is commonly used to supplement human foods because of its relative availability and low cost (see Fig. 35.5). Although it is less potent on a mole-per-mole basis, vitamin D_2 undergoes the same metabolic conversion steps and, ultimately, produces the same biologic effects as vitamin D_3. The physiologic actions of vitamin D_3 also apply to vitamin D_2.

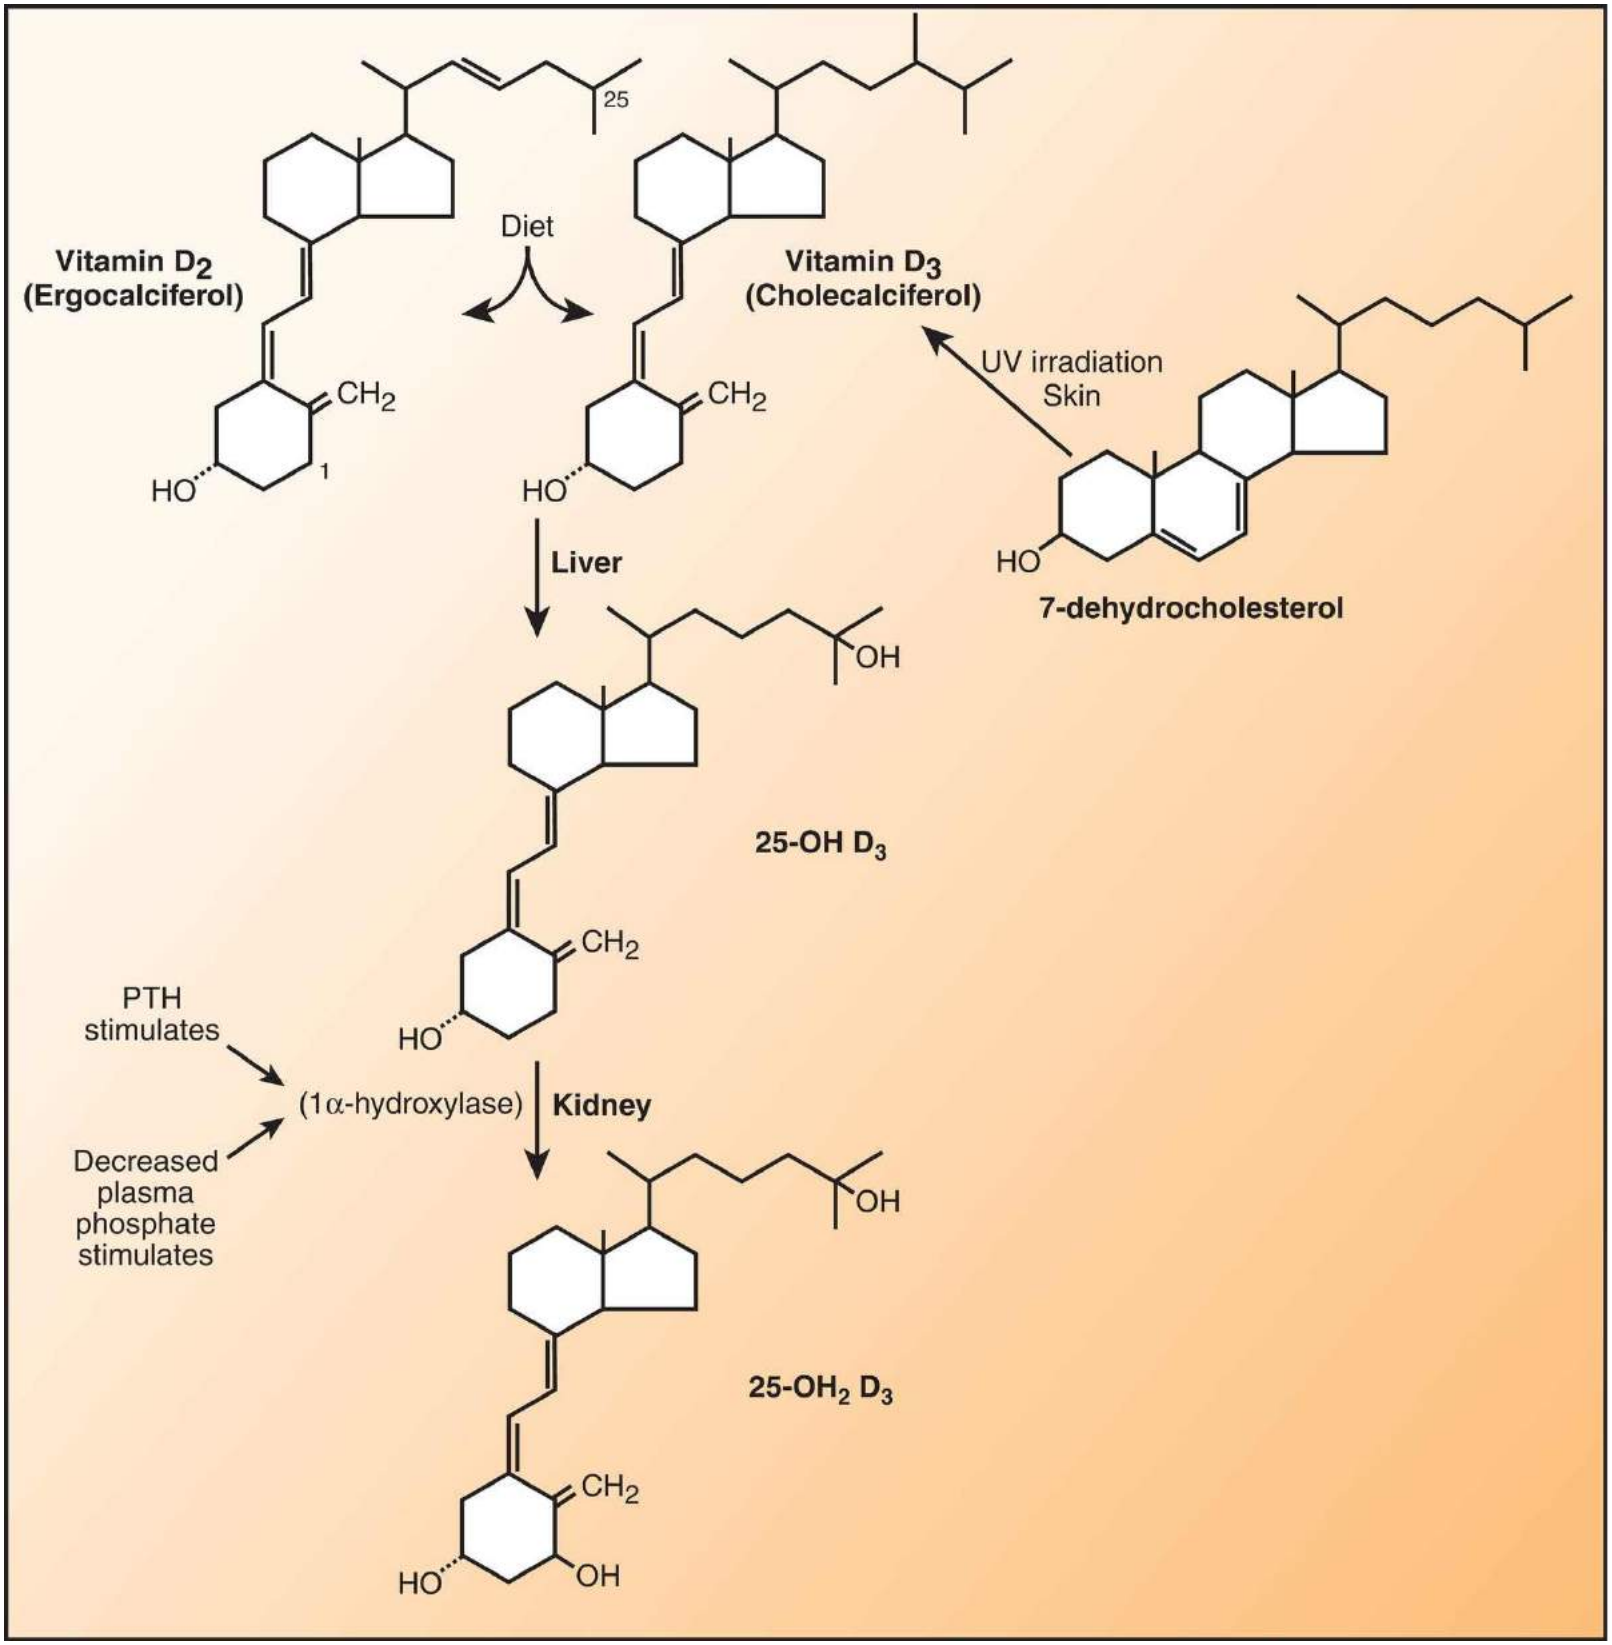

Figure 35.5 The structures of vitamin D_3 and vitamin D_2 and the conversion pathway of vitamin D_3 into 1,25-dihydroxycholecalciferol [1,25-$(OH)_2$ D_3]. Note that they differ only by a double bond between carbons 22 and 23 and a methyl group at position 24. 25-OH D_3, 25-hydroxycholecalciferol; PTH, parathyroid hormone.

Vitamin D_3 can be provided by the diet or formed in the skin by the action of ultraviolet light on a precursor, **7-dehydrocholesterol**, derived from cholesterol (see Fig. 35.5). In many countries where food is not systematically supplemented with vitamin D, this pathway provides the major source of vitamin D.

Because of the number of variables involved, it is difficult to specify a minimum exposure time. However, exposure to moderately bright sunlight for 30 to 120 min/d usually provides enough vitamin D to satisfy the body's needs without any dietary supplementation.

Vitamins D_3 and D_2 are by themselves relatively inactive. However, they undergo a series of transformations in the liver and kidneys that convert them into powerful calcium regulatory hormones (Fig. 35.6). The first step occurs in the liver and involves the addition of a hydroxyl group to carbon 25 to form 25-hydroxycholecalciferol (25-OH D_3). This reaction is largely unregulated, although certain drugs and liver diseases may affect this step. Next, 25-OH D_3 is released into the blood and undergoes a second hydroxylation reaction on carbon 1 in the kidney. The product is **1,25-dihydroxycholecalciferol**, also known as 1,25-dihydroxyvitamin D_3 or calcitriol, the principal hormonally active form of the vitamin. The biologic activity of 1,25-dihydroxycholecalciferol is ~100 to 500 times greater than that of 25-OH D_3. The enzyme 1α-hydroxylase, which is located in tubule cells, catalyzes the reaction in the kidney.

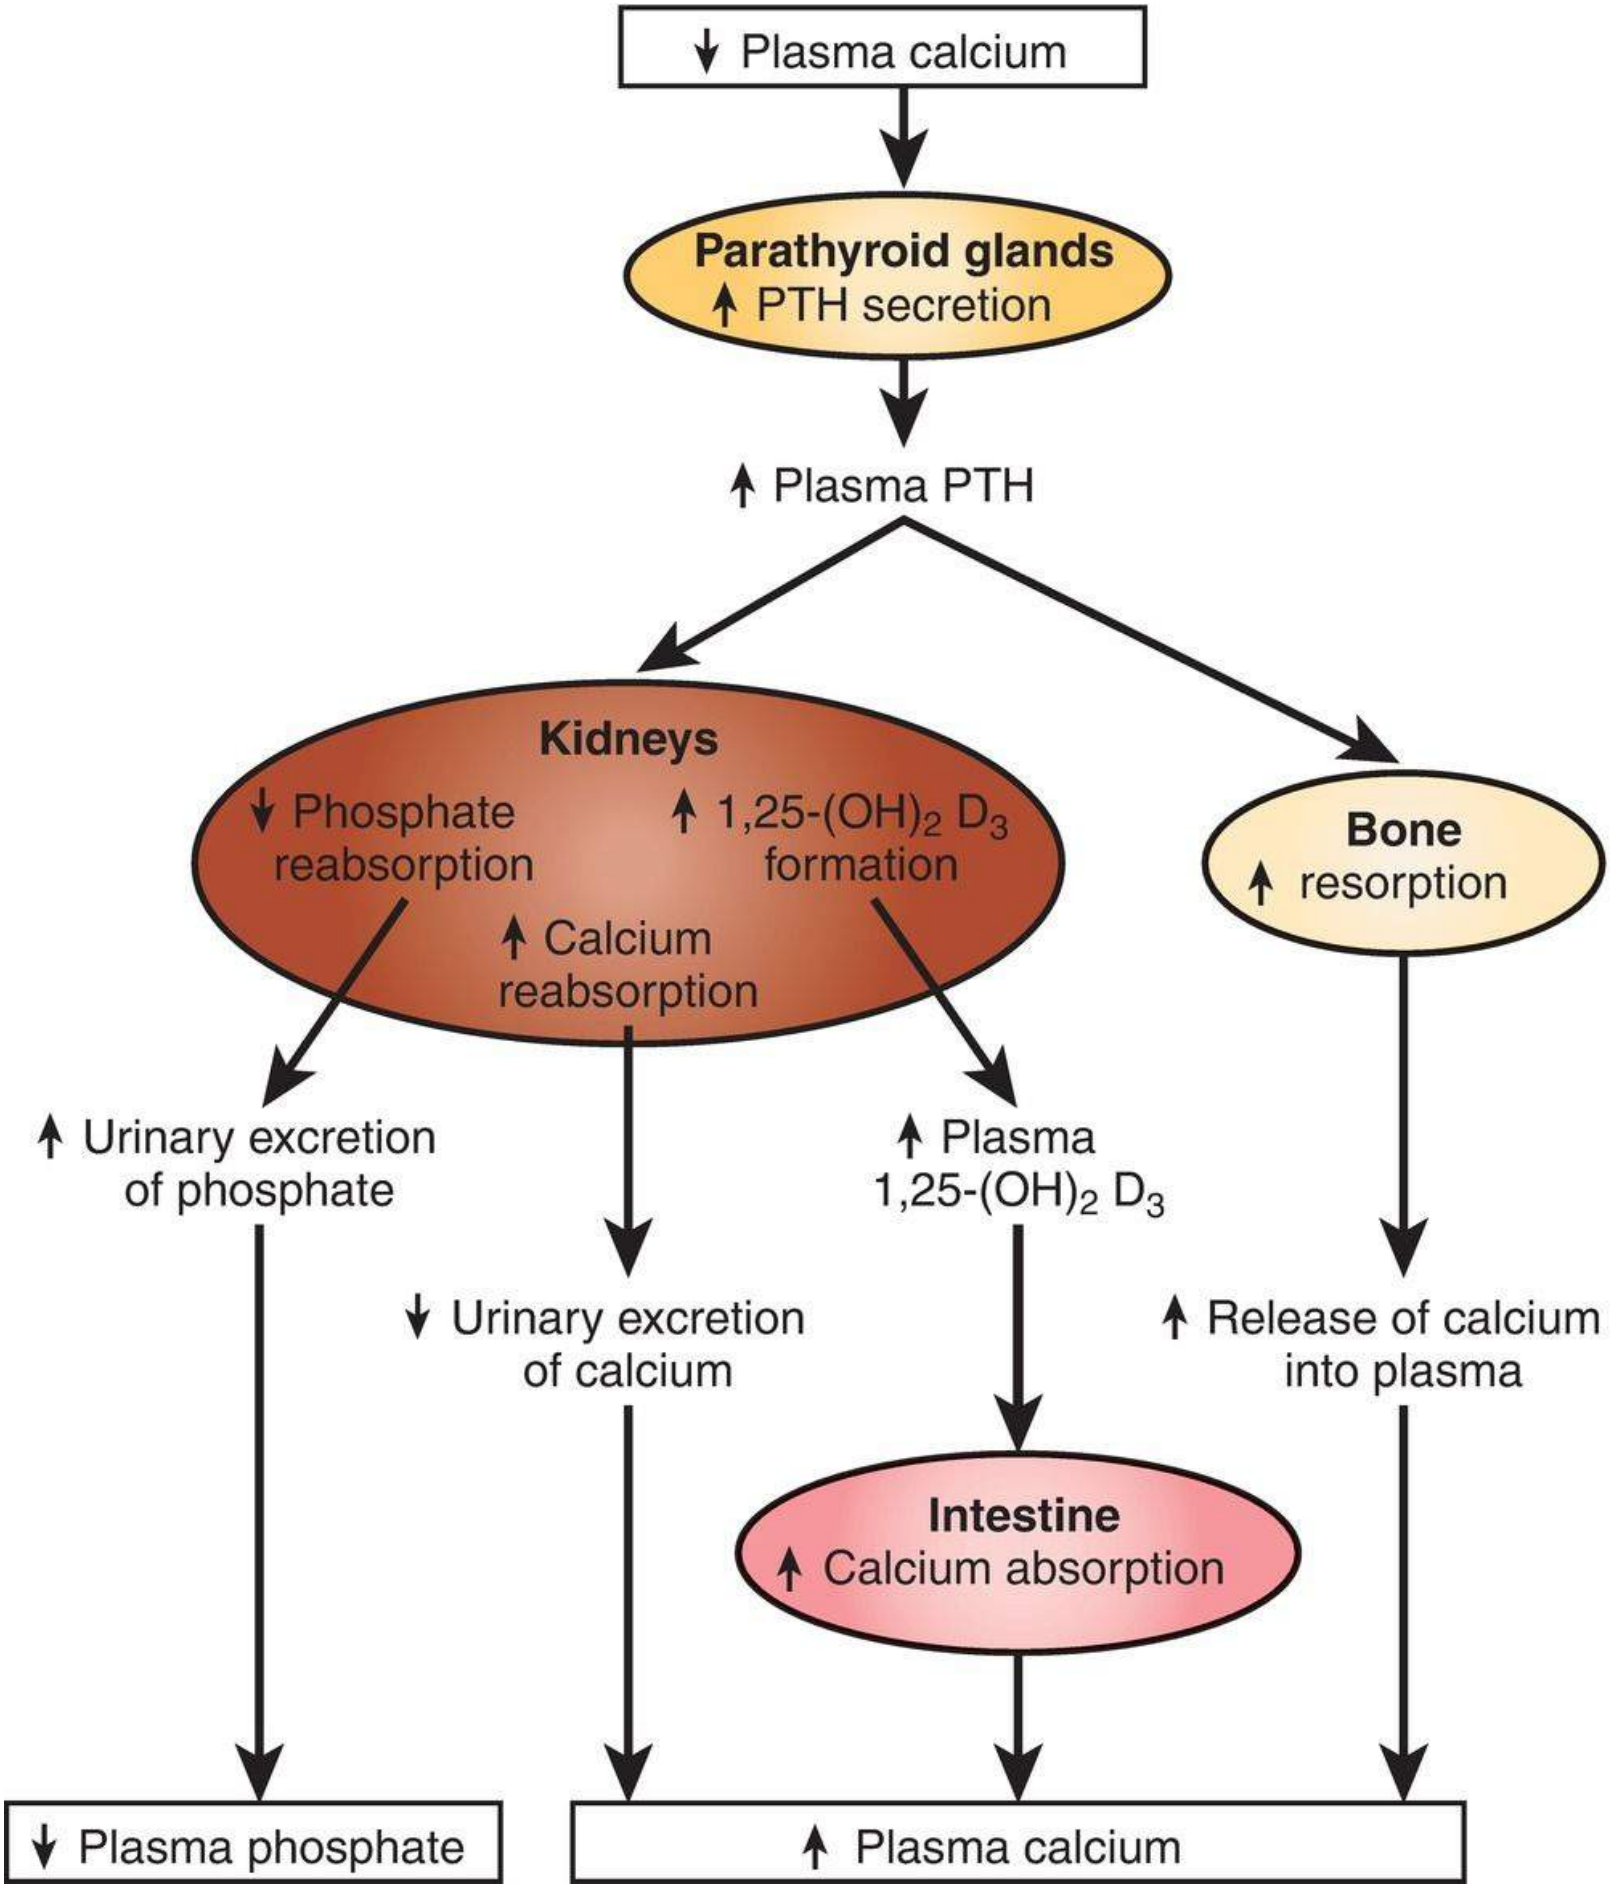

Figure 35.6 Effects of parathyroid hormone (PTH) on calcium and phosphate metabolism. 1,25-$(OH)_2$ D_3, 1,25-dihydroxycholecalciferol.

The final step in 1,25-dihydroxycholecalciferol formation is highly regulated. The activity of 1α-hydroxylase is regulated primarily by PTH, which stimulates its activity. Therefore, if plasma calcium levels fall, PTH secretion increases; in turn, PTH promotes the formation of 1,25-dihydroxycholecalciferol. In addition, enzyme activity increases in response to a decrease in plasma phosphate. This does not appear to involve any intermediate hormonal signals but apparently involves direct activation of either the enzyme or cells in which the enzyme is located. Both a decrease in plasma calcium, which triggers PTH secretion, and a decrease in circulating phosphate result in the activation of 1α-hydroxylase and an increase in 1,25-dihydroxycholecalciferol synthesis.

PTH, CT, and 1,25-$(OH)_2D_3$ together regulate plasma calcium and phosphate.

PTH is essential for life. The complete absence of PTH causes death from hypocalcemic tetany within just a few days. The condition can be avoided with hormone replacement therapy. The net effects of PTH on plasma calcium and phosphate and its sites of action are shown in Figure 35.6. PTH causes an increase in plasma calcium while decreasing plasma phosphate. This decrease in phosphate is important with regard to calcium homeostasis. At normal plasma concentrations, calcium and phosphate are at or near chemical saturation levels. If PTH were to increase both calcium and phosphate levels, these substances would simply crystallize in bone or soft tissues as calcium phosphate, and the necessary increase in plasma calcium would not occur. Thus, the effect of PTH to lower plasma phosphate is an important aspect of its role in regulating plasma calcium.

In the kidneys, PTH stimulates calcium reabsorption in the thick ascending limb and late distal tubule, decreasing urine calcium and increasing plasma calcium (see Fig. 35.6). It also inhibits phosphate reabsorption in the proximal tubule, leading to increased urinary phosphate excretion and a decrease in plasma phosphate. Another important effect of PTH is to increase the activity of 1α-hydroxylase in the kidney, which is involved in forming 1,25-$(OH)_2D_3$.

In bone, PTH activates osteoclasts to increase bone resorption and the delivery of calcium from bone into plasma (see Fig. 35.6). In addition to stimulating active osteoclasts, PTH stimulates the maturation of immature osteoclasts into mature, active osteoclasts. PTH also inhibits collagen synthesis by osteoblasts, resulting in decreased bone matrix formation and decreased flow of calcium from plasma into bone mineral. All of these actions of PTH promoting bone resorption are augmented by 1,25-$(OH)_2D_3$.

PTH does not appear to have any major direct effects on the GI tract. However, because it increases active vitamin D formation, it ultimately increases the absorption of both calcium and phosphate from the GI tract (see Fig. 35.6).

CT is important in several lower vertebrates, but despite its many demonstrated biologic effects in humans, it appears to play only a minor role in calcium homeostasis. This conclusion mostly stems from two lines of evidence. First, CT loss following surgical removal of the thyroid gland (and, therefore, removal of CT-secreting parafollicular cells) does not lead to overt clinical abnormalities of calcium homeostasis. Second, CT hypersecretion such as from thyroid tumors involving parafollicular cells does not cause any overt problems. On a daily basis, CT probably only fine-tunes the calcium regulatory system.

The overall action of CT is to decrease both calcium and phosphate concentrations in plasma (Fig. 35.7). The primary target of CT is bone, although some lesser effects also occur in the kidneys. In the kidneys, CT decreases the tubular reabsorption of calcium and phosphate. This leads to an increase in urinary excretion of both calcium and phosphate and, ultimately, to decreased levels of both ions in the plasma. In bones, CT opposes the action of PTH on osteoclasts by inhibiting their activity. This leads to decreased bone resorption and an overall net transfer of calcium from plasma into bone. CT has little or no direct effect on the GI tract.

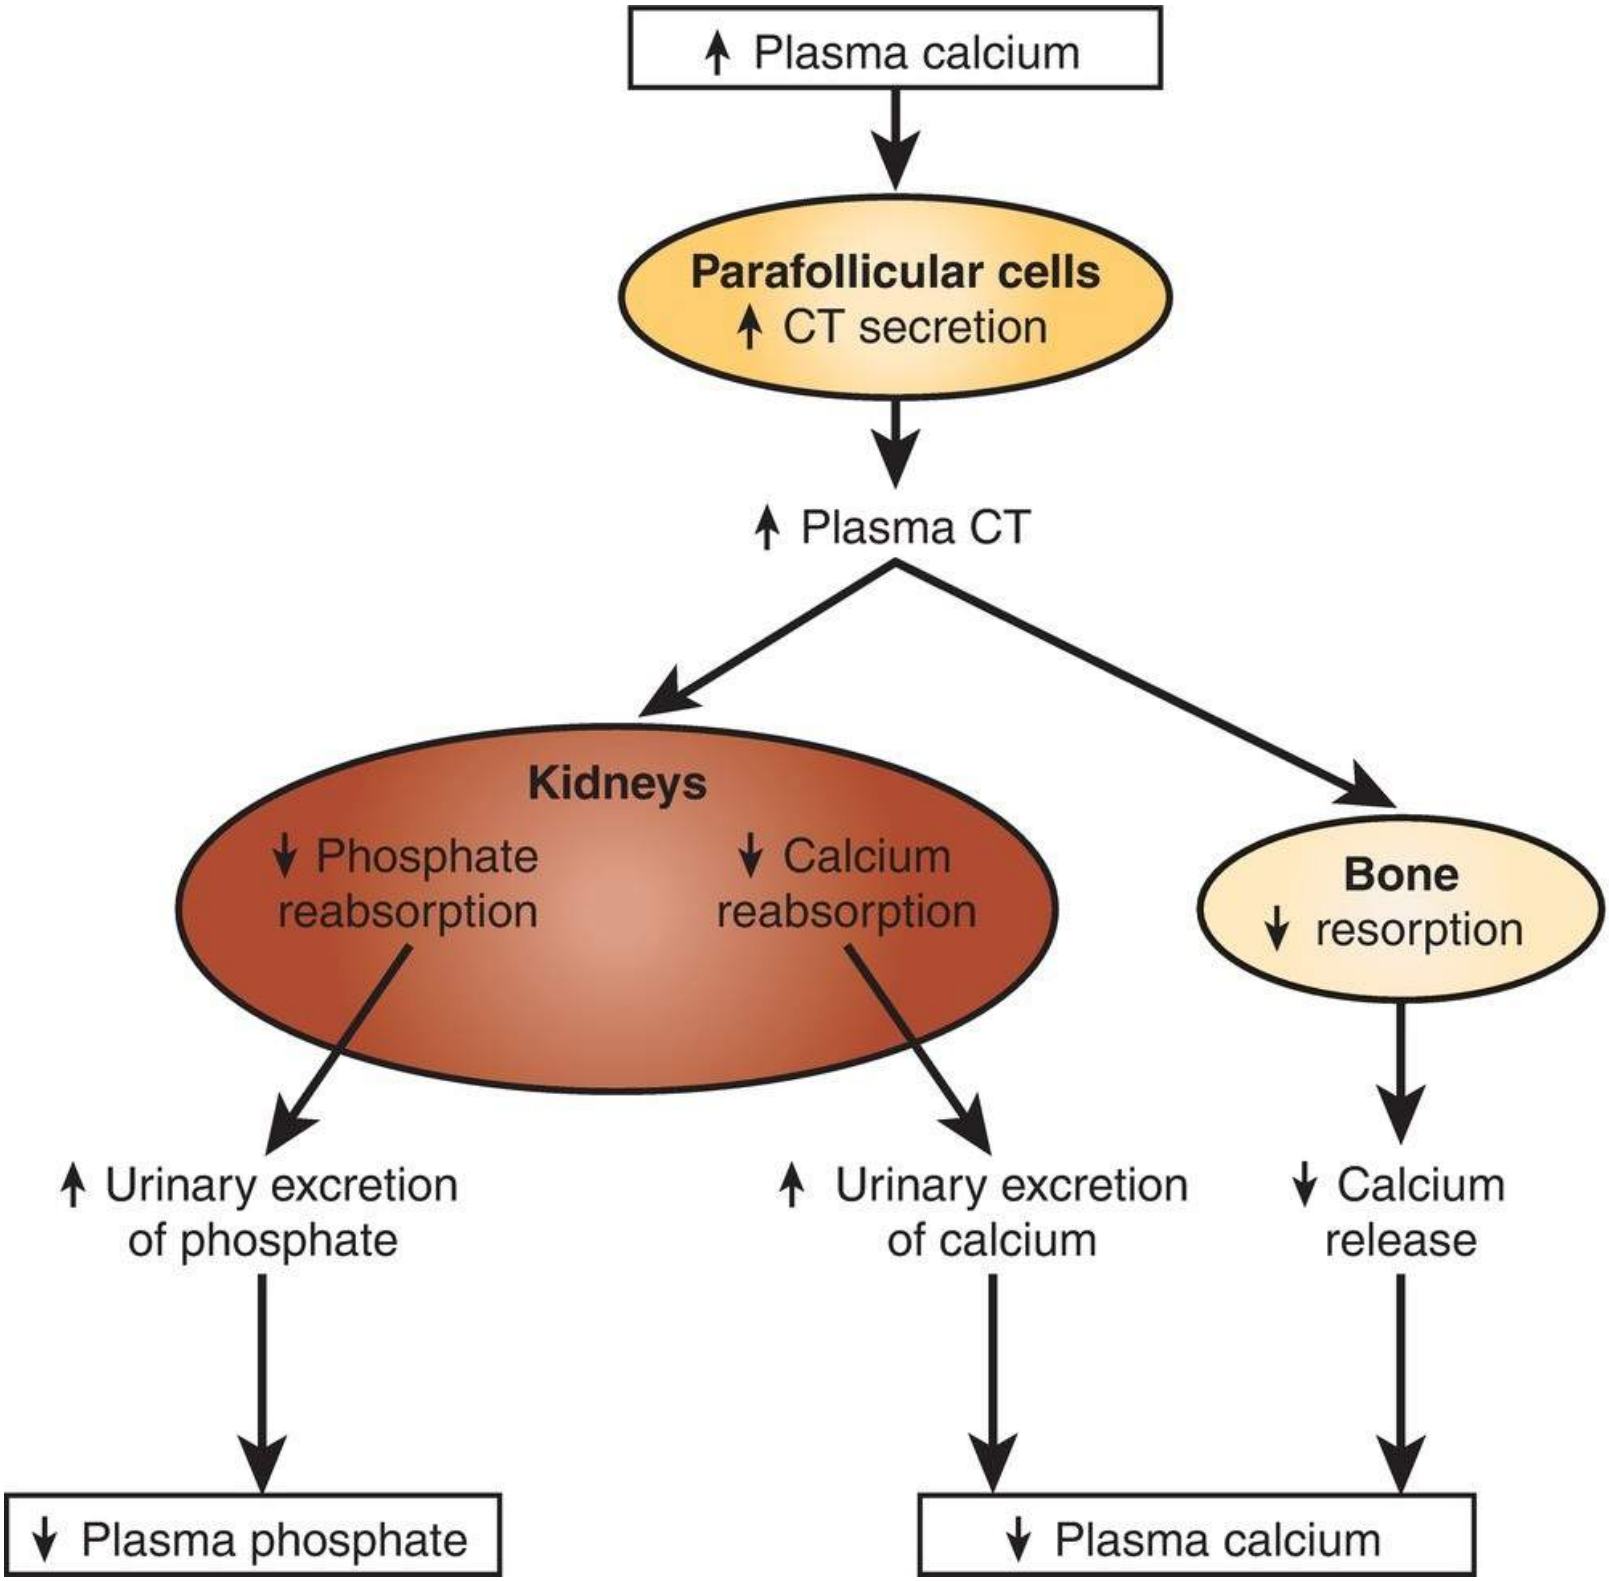

Figure 35.7 Effects of calcitonin (CT) on calcium and phosphate metabolism.

The net effect of 1,25-$(OH)_2D_3$ is to increase both calcium and phosphate concentrations in plasma (Fig. 35.8). The activated form of vitamin D primarily influences the GI tract, although it has actions in the kidneys and bones as well. In the kidneys, 1,25-$(OH)_2D_3$ increases the tubular reabsorption of calcium and phosphate, promoting the retention of both ions in the body. However, this is a weak and probably only minor effect of the hormone. In bones, as mentioned above, 1,25-$(OH)_2D_3$ promotes actions of PTH on osteoclasts, increasing bone resorption (see Fig. 35.8). In the GI tract, 1,25-$(OH)_2D_3$ stimulates calcium and phosphate absorption by the small intestine, increasing plasma concentrations of both ions.

This effect is mediated by increased production of calcium transport proteins resulting from gene transcription events and usually requires several hours to appear.

BONE DYSFUNCTION

There are several **metabolic bone diseases**, all typified by ongoing disruption of the normal processes of either bone formation or bone resorption. There are also genetic bone diseases such as osteogenesis imperfecta (see Clinical Focus 35.1). The conditions most frequently encountered clinically are osteoporosis, osteomalacia, and Paget disease.

CLINICAL FOCUS 35.1

Osteogenesis Imperfecta

Osteogenesis imperfecta is a genetic disorder characterized by bones that break easily, often from little or no apparent cause. Most patients with osteogenesis imperfecta have defects in the genes for type I collagen. Bones, ligaments, skin, sclera, and teeth are affected. Although the number of people affected with osteogenesis imperfecta in the United States is unknown, the best estimate suggests a minimum of 20,000 and possibly as many as 50,000. There are at least four recognized forms of the disorder (types I to IV), representing a range of severities.

Type I osteogenesis imperfecta is the most common and mildest form, resulting from decreased collagen production but normal molecular structure. The more severe forms, *types II* and *III*, involve mutations in the collagen molecule that prevent normal assembly. *Type II* osteogenesis imperfecta is frequently lethal at or shortly after birth, often as a result of respiratory problems. These patients have numerous fractures, severe bone deformity, and small stature. *Type III* patients feature progressively deforming bones, usually with moderate deformity at birth. *Type IV* osteogenesis imperfecta falls between types I and III in severity. Microscopic analyses revealed that some people who are clinically within the type IV group had a distinct pattern to their bones yet did not have evidence of mutations in the type I collagen genes. These people have been designated as *types V* and *VI* osteogenesis imperfecta.

Treatment is directed toward preventing or controlling the symptoms, maximizing independent mobility, and developing optimal bone mass and muscle strength. Care of fractures, extensive surgical and dental procedures, and physical therapy are often recommended for people with osteogenesis imperfecta. Use of wheelchairs, braces, and other mobility aids is common, particularly (although not exclusively) among people with more severe types of osteogenesis imperfecta. A surgical procedure called “rodding” is frequently considered. This treatment involves inserting metal rods through the length of the long bones to strengthen them and prevent and/or correct deformities. Several medications and other treatments are being explored for their potential use to treat osteogenesis imperfecta. For example, antiresorptive therapy with intravenous pamidronate has been shown to decrease fractures in children with severe osteogenesis imperfecta, even before age 3 years. ■

Osteoporosis leads to decreased bone density and increased risk of fracture.

Osteoporosis is a major health problem, particularly because older adults are more prone to this disorder and the average age of the population is increasing (Clinical Focus 35.2). Osteoporosis involves a reduction in total bone mass, with an equal loss of both bone mineral and organic matrix. Several factors are known to contribute directly to osteoporosis. Long-term dietary calcium deficiency can lead to osteoporosis because bone mineral is mobilized to maintain plasma calcium levels. Vitamin C deficiency can also result in a net loss of bone because vitamin C is required for normal collagen synthesis to occur. A defect in matrix production and the inability to produce new bone eventually result in a net loss of bones. For reasons that are not entirely understood, a reduction in the mechanical stress placed on bone can lead to bone loss. Immobilization or disuse of a limb such as with a cast or paralysis can result in localized osteoporosis of the affected limb. Space flight can produce a type of disuse osteoporosis resulting from the condition of weightlessness.

CLINICAL FOCUS 35.2

The Toll of Osteoporosis

Osteoporosis is often called the “silent disease” because bone loss initially occurs without symptoms. People may not know that they have significant bone loss until their bones become so weak that a sudden strain, bump, or fall causes a fracture. Osteoporosis is a major public health threat for an estimated 44 million Americans, including 55% of people 50 years of age and older. In the United States, 10 million people are estimated to have the disease and almost 34 million more are estimated to have low bone mass, placing them at increased risk for osteoporosis. Approximately 80% of those affected by osteoporosis are women. Although osteoporosis is often thought of as an older person’s disease, it can strike at any age. The seeds of osteoporosis are often sown in childhood, and it takes a lifetime of effort to prevent the disease. A frighteningly large number of children do not get sufficient exercise, vitamin D, and calcium to ensure protection from developing the disease later in life.

Osteoporosis is responsible for more than 1.5 million fractures annually, including 300,000 hip fractures, 700,000 vertebral fractures, 250,000 wrist fractures, and 300,000 fractures at other sites. The estimated national direct care expenditures (including hospitals, nursing homes, and outpatient services) for osteoporotic fractures are >18 billion dollars per year. Additional losses in wages and productivity greatly increase this number. Nearly one third of people who have hip fractures end up in nursing homes within a year; nearly 20% die within a year.

What causes osteoporosis, and what can be done to prevent or treat the disease? Although it is known that a diet low in calcium or vitamin D; certain medications, such as glucocorticoids and anticonvulsants; and excessive ingestion of aluminum-containing antacids can cause osteoporosis, in most cases, the exact cause is unknown. However, several identified risk factors associated with the disease include the following: being a woman (especially a postmenopausal woman), being Caucasian or Asian, being of advanced age, having a family history of the disease, having low testosterone levels

(in men), having an inactive lifestyle, cigarette smoking, and an excessive use of alcohol.

A comprehensive program to help prevent osteoporosis includes a balanced diet rich in calcium and vitamin D, regular weight-bearing exercise, a healthy lifestyle with no smoking or excessive alcohol use, and bone density testing and medication when appropriate. Although at present there is no cure for osteoporosis, there are several U.S. Food and Drug Administration (FDA)-approved medications to either prevent or treat the disease in postmenopausal women: estrogens; estrogens and progestins; PTH; alendronate, ibandronate, and risedronate (bisphosphonates); calcitonin; and raloxifene, a selective estrogen receptor modulator. Although 20% of all osteoporosis cases occur in men, only alendronate and risedronate are currently FDA approved for use in men and only for cases of corticosteroid-induced osteoporosis. Also, PTH is approved for the treatment of osteoporosis in men who are at high risk of fracture. Testosterone replacement therapy is often helpful in a man with a low testosterone level. ■

Most commonly, osteoporosis is associated with advancing age in both men and women, and it cannot be assigned to any specific definable cause (see Integrated Medical Sciences Box). For several reasons, postmenopausal women are more prone to develop the disease than are men. Figure 35.9 shows the average bone calcium content for men and women versus age. Until about the time of puberty, males and females have similar bone calcium. However, at puberty, males begin to acquire bone calcium at a greater rate; peak bone mass in men may be ~20% greater than that of women. Maximum bone mass is attained between 30 and 40 years of age and then tends to decrease in both sexes. Initially, this occurs at an approximately equivalent rate, but women begin to experience a more rapid bone calcium loss at the time of menopause (about age 45 to 50 years). This loss appears to result from the decline in estrogen secretion that occurs at menopause. Low-dose estrogen supplementation of postmenopausal women is usually effective in retarding bone loss without causing adverse effects. This condition of increased bone loss in women after menopause is called **postmenopausal osteoporosis**. Along with endocrine mechanisms, it is now appreciated that components of the immune system also have an impact on bone loss in postmenopausal osteoporosis.

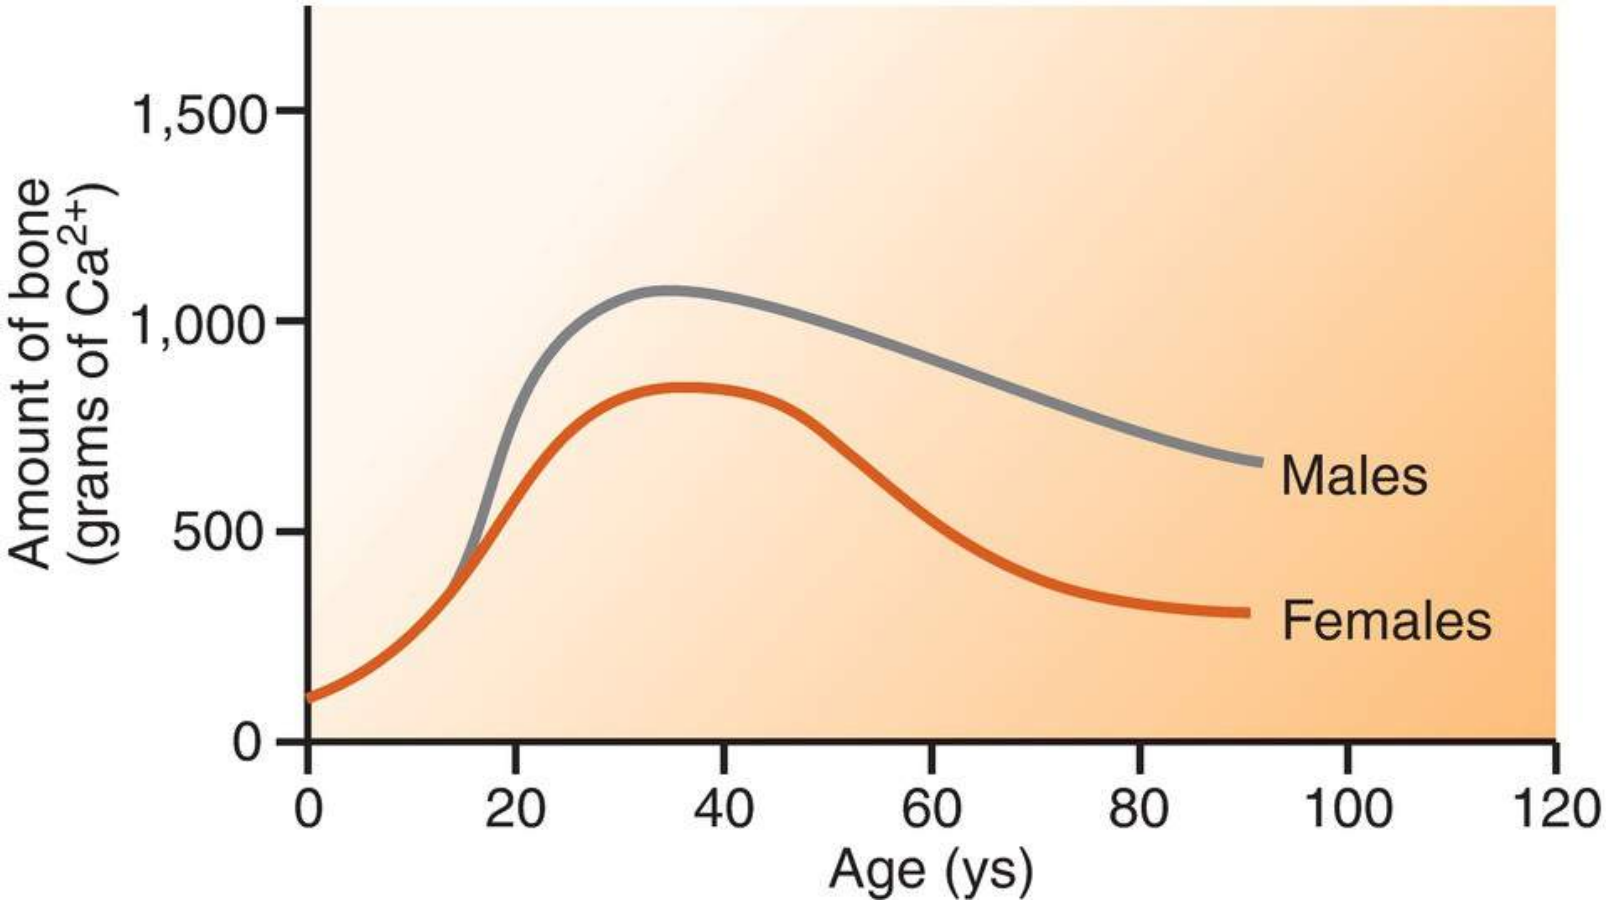

Figure 35.9 Changes in bone calcium content as a function of age in males and females. These changes can be roughly extrapolated into changes in bone mass and bone strength.

Rickets and osteomalacia are disorders of defective bone mineralization.

Rickets is characterized by the inadequate mineralization of new bone matrix, such that the ratio of bone mineral to matrix is reduced. As a result, bones may have reduced strength and are subject to distortion in response to mechanical loads. When the disease occurs in adults, it is called **osteomalacia**; when it occurs in children, it is called rickets. In children, the condition often produces a bowing of the long bones in the legs. In adults, it is often associated with severe bone pain. The primary cause of osteomalacia and rickets is a deficiency in vitamin D activity. Vitamin D may be deficient in the diet; the small intestine may not adequately absorb it; it may not be converted into its hormonally active form; or target tissues may not adequately respond to the active hormone (Table 35.3). Dietary deficiency is generally not a problem in the United States, where vitamin D is added to many foods; however, it is a major health problem in other parts of the world. Because the liver and kidneys are involved in converting vitamin D_3 into 1,25-$(OH)_2D_3$, primary disease of either of these organs may result in vitamin D deficiency. Impaired vitamin D actions are somewhat rare but can be produced by certain drugs. In particular, some anticonvulsants used in the treatment of epilepsy may produce osteomalacia or rickets.

TABLE 35.3 Causes of Osteomalacia and Rickets

Type of Defect	Cause
Inadequate availability of vitamin D	Dietary deficiency or lack of exposure to sunlight
	Fat-soluble vitamin malabsorption
Defects in metabolic activation of vitamin D	25-Hydroxylation (liver)
	Liver disease
	Certain anticonvulsants, such as phenobarbital
	1-Hydroxylation (kidney)
	Renal failure
	Hypoparathyroidism
Impaired action of 1,25-dihydroxycholecalciferol on target tissues	Certain anticonvulsants
	1,25-Dihydroxycholecalciferol receptor defects
	Uremia

Paget disease is a chronic disorder leading to enlarged and deformed bones.

Paget disease is rarely diagnosed in patients younger than 40 years. Men are more commonly affected than women, and prevalence of Paget disease in people older than age 40 years is about 1%. It is typified by disordered bone formation and resorption (remodeling) and may occur at a single local site or at multiple sites in the body. Radiographs of the affected bone often exhibit increased density, but the abnormal structure makes the bone weaker than normal. Often, those with Paget disease experience considerable pain, and in severe cases, crippling deformities may lead to serious neurologic complications. The cause of the disease is not well understood. Both genetic and environmental factors (probably viral) appear to be important. Several therapies are available for treating the disease, including treatment with CT, but these typically offer only temporary relief from pain and complications.

INTEGRATED MEDICAL SCIENCES

New Anabolic Therapies for Osteoporosis

Osteoporosis is a major health problem with a significant consequence being fragility fractures. Mainstay therapies for this disease are agents that reduce *bone resorption*. These antiresorptive agents stabilize bone architecture and the incidence of fractures in osteoporosis. Although antiresorptive therapy has been useful in the management of osteoporosis, this therapy cannot restore the bone structure that has been lost because of increased remodeling. New insight into the mechanisms of bone formation may provide new *anabolic therapies* for osteoporosis. For example, **bone morphogenetic proteins** (**BMPs**) and Wnt have been identified and found to induce the differentiation of mesenchymal cells toward osteoblasts. Also insulin-like growth factor 1 (IGF-1) has been shown to enhance the function of mature osteoblasts. In addition to regulated synthesis and receptor binding, studies have found that the activities of BMPs, Wnt, and IGF-1 are tightly controlled by specific extracellular and intracellular regulatory proteins. Therefore, enhancing the synthesis and/or activity of BMPs, Wnt, or IGF-1 or targeting specific extracellular and intracellular proteins that regulate BMP, Wnt, or IGF-1 may provide a new therapeutic strategy to enhance bone formation in osteoporosis.

One interesting example is a protein named *sclerostin* that has BMP and Wnt antagonistic properties. It is expressed by osteoblasts and osteocytes. Interestingly sclerostin synthesis is suppressed by parathyroid hormone (PTH), and the study suggests that it is the enhanced Wnt signaling that contributes to the anabolic effect of PTH in bone. Along with these observations, clinical findings in *high-bone–mass syndrome* indicate that inactivation or neutralization of sclerostin could be used as an approach to enhance Wnt signaling and obtain an anabolic response in bone. Also, humanized monoclonal antibodies to sclerostin cause enhanced Wnt signaling and an increase in bone mass in animal studies. Of potential therapeutic significance, clinical trials have demonstrated that antisclerostin antibodies can increase bone mass density and biochemical markers of bone formation in humans. With regard to IGF-1, the decline in its secretion with aging may play a role in the

pathogenesis of osteoporosis. New studies suggest that at low doses, IGF-1 increases bone formation without an effect on bone resorption. As the later effect is seen with higher doses of IGF-1, low-dose IGF-1 therapy may provide a means to increase osteoblast function without a concomitant effect on bone resorption. ■

Chapter Summary

- When plasma calcium levels fall below normal, spontaneous action potentials can be generated in nerves, leading to tetany of muscles, which, if severe, can result in death.
- About half of the circulating calcium is in the free or ionized form, about 10% is bound to small anions, and about 40% is bound to plasma proteins. Most of the phosphorus circulates free as orthophosphate.
- Most ingested calcium is not absorbed by the gastrointestinal (GI) tract and leaves the body via the feces; by contrast, phosphate is almost completely absorbed by the GI tract and leaves the body mostly via the urine.
- A decrease in plasma ionized calcium stimulates the secretion of parathyroid hormone (PTH), a polypeptide hormone produced by the parathyroid glands. PTH plays a vital role in calcium and phosphate homeostasis and acts on bones, kidneys, and intestine to raise the plasma calcium concentration and lower the plasma phosphate concentration.
- Sequential hydroxylation reactions in the liver and kidneys convert vitamin D to the active hormone 1,25-dihydroxycholecalciferol. This hormone stimulates intestinal calcium absorption and, thereby, raises the plasma calcium concentration.
- Calcitonin, a polypeptide hormone produced by the thyroid glands, tends to lower plasma calcium, but its physiologic importance in humans has been questioned.
- Osteoporosis, rickets and osteomalacia, and Paget disease are the most common forms of metabolic bone disease.

Chapter Review Questions

1. As part of a routine physical exam, a patient's serum electrolyte levels were measured. Among the measurements, it was determined that total plasma calcium concentration was 10.2 mg/dL. What percentage of total plasma calcium is normally present as the free Ca^{2+} ion?
   A. 25%
   B. 50%
   C. 60%
   D. 75%
   E. 100%

The correct answer is B. Half (50%) of the total plasma calcium is free or ionized.

2. The major route by which ingested phosphate leaves the body is via:
   A. bile.
   B. feces.
   C. sweat.
   D. urine.
   E. both bile and feces.

The correct answer is D. The majority of ingested phosphate is absorbed by the GI tract and leaves the body via the urine.

3. 1,25-Dihydroxycholecalciferol can be formed in the body by metabolism of cholesterol. Which of the following is not either directly or indirectly involved in formation of 1,25-dihydroxycholecalciferol?
   A. Bone
   B. Skin
   C. Kidney
   D. Liver
   E. Both kidney and liver

The correct answer is A. Skin, kidney, and liver can all be involved in forming the active metabolite of vitamin D, 1,25-dihydroxycholecalciferol. Bone does not form this hormone but is a target for its actions.

Clinical Application Exercises 35.1

Two siblings presented with a history of back pain. Radiographs showed decreased lumbar bone density and multiple compression fractures throughout the thoracic and lumbar spines of both patients. One child has moderate short stature and mild neurosensory hearing loss. Protein studies demonstrated electrophoretically abnormal type I collagen in samples from both children. Enzymatic cleavage of RNA:RNA hybrids identified a mismatch in type I collagen alpha2 (COL1A2) mRNA. DNA sequencing of COL1A2 cDNA subclones defined the mismatch as a single-base mutation (1715G → A) in both children. This mutation predicts the substitution of arginine for glycine at position 436 (G436R) in the helical domain of the alpha2(I) chain. Analysis of genomic DNA identified the mutation in the asymptomatic father, who is presumably a germline mosaic carrier.

QUESTIONS

1. What most likely is the disorder?
2. How might these siblings be treated?

ANSWERS

1. Mutations in the type I collagen genes have been identified as the cause of all four types of osteogenesis imperfecta (OI). Type I OI is the most common and mildest form resulting from decreased collagen production but normal molecular structure. The more severe forms, type II and type III, involve mutations in the collagen molecule that prevent normal assembly. Type II OI is frequently lethal at or shortly after birth, often due to respiratory problems. These patients have numerous fractures, severe bone deformity, and small stature. Type III patients feature progressively deforming bones, usually with moderate deformity at birth. Type IV OI falls between type I and type III in severity. Microscopic analyses revealed that some people who are clinically within the type IV group had a distinct pattern to their bone; yet do not have evidence of having mutations in the type I collagen genes. These individuals have been designated as types V and VI OI. Based on the clinical, biochemical, and molecular findings, these siblings might have type III OI or a new variation with only spine manifestations and variable short stature into adolescence.
2. Treatment is directed toward preventing or controlling the symptoms, maximizing independent mobility, and developing optimal bone mass and muscle strength. Care of fractures, extensive surgical and dental procedures, and physical therapy are often recommended for people with OI. Use of wheelchairs, braces, and other mobility aids is common, particularly (although not exclusively) among people with more severe types of OI. A surgical procedure called “rodding” is frequently considered. This treatment involves inserting metal rods through the length of the long bones to strengthen them and prevent and/or correct deformities. Several medications and other treatments are being explored for their potential use to treat OI. For example, antiresorptive therapy with IV pamidronate has been shown to decrease fractures in children with severe OI, even before 3 years of age.

PART X REPRODUCTIVE PHYSIOLOGY

36 Male Reproductive System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how the hypothalamus, anterior pituitary, and testes interactively regulate testicular function.
- Explain how castration causes a large increase in luteinizing hormone levels and why testosterone replacement does not completely correct follicle-stimulating hormone levels.
- Explain how the pampiniform plexus and cremasteric muscle maintain testes at a cooler temperature.
- Explain how mitosis, meiosis, and spermiogenesis mechanistically coordinate the continuous production of fresh spermatozoa.
- Explain how the spermatozoon's head, middle piece, and tail mechanistically function to reach, recognize, and fertilize an egg.
- Explain how testosterone is synthesized and functions.
- Explain how normal spermatogenesis almost never occurs with defective steroidogenesis, but normal steroidogenesis can be present with defective spermatogenesis.

The reproductive system is designed solely for the purpose of survival of the species. Although the reproductive system does not contribute to homeostasis and individual survival, it still plays an important role in physiology and behavior. The reproductive system includes the gonads, reproductive tract, and accessory glands. The overall function of male reproduction is the production of sperm and delivery of the sperm to the female. The testes produce mature male gametes, known as **spermatozoa**, which function to fertilize the female counterpart, the **oocyte**, during conception. This fertilization, in turn, produces a single-celled individual known as a **zygote**. These processes are the cornerstone of sexual reproduction. This chapter focuses on functional aspects of the male reproductive system.

ENDOCRINE GLANDS OF THE MALE REPRODUCTIVE SYSTEM

A diagram of reproduction regulation in the male is presented in Figure 36.1. The system is divided into factors affecting male reproductive function: brain centers, which control pituitary release of hormones and sexual behavior; gonadal structures, which produce sperm and hormones; a ductal system, which stores and transports sperm; and accessory glands, which support sperm viability. The endocrine glands of the male reproductive system include the (1) hypothalamus, (2) anterior pituitary, and (3) testes. The hypothalamus processes information obtained from the external and internal environment, using neurotransmitters that regulate the secretion of **gonadotropin-releasing hormone** (**GnRH**). GnRH moves down the hypothalamic–pituitary portal system and stimulates the secretion of **luteinizing hormone** (**LH**) and **follicle-stimulating hormone** (**FSH**) by the gonadotrophs of the anterior pituitary. In the testes, LH binds to receptors on the **Leydig cells**, and FSH binds to receptors on the **Sertoli cells**. Leydig cells reside in the interstitium of the testes, between seminiferous tubules, and produce **testosterone**. Sertoli cells are located within the seminiferous tubules, support spermatogenesis, contain FSH and testosterone receptors, and produce estradiol, albeit at low levels. Sertoli cells also produce glycoprotein hormones —activin, follistatin, and inhibin—that regulate the secretion of FSH.

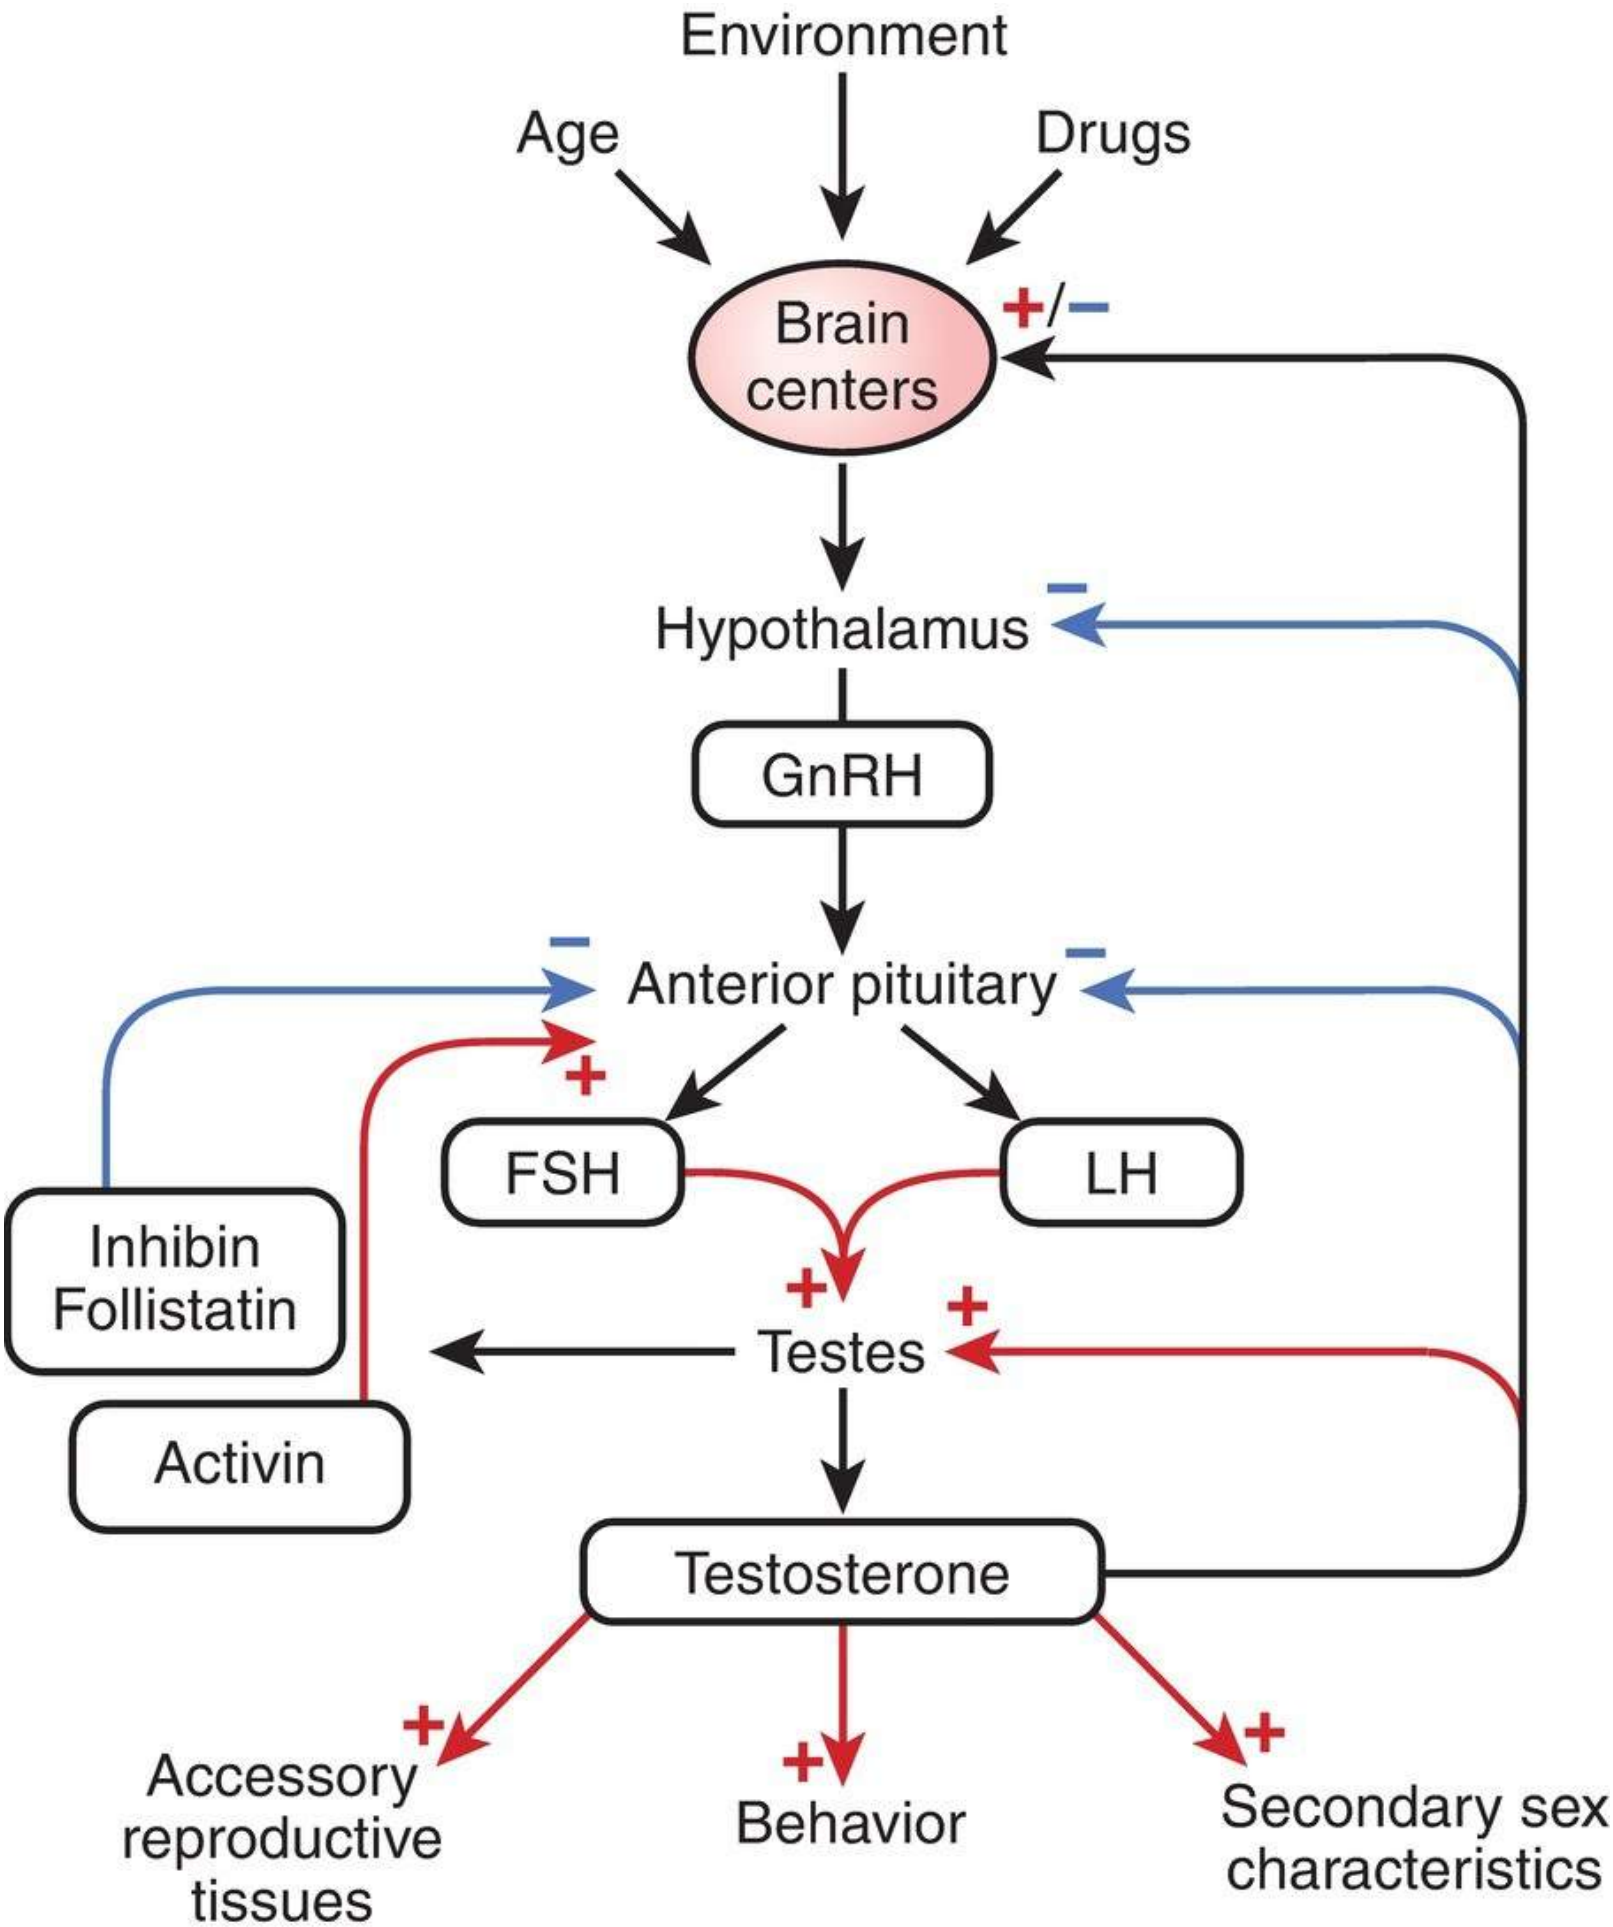

Figure 36.1 Regulation of reproduction in the male. The main reproductive hormones are shown in *boxes*. *Plus* and *minus* signs depict positive and negative regulations, respectively. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

TESTICULAR FUNCTION AND REGULATION

LH and FSH regulate testicular function. LH regulates the secretion of testosterone by the Leydig cells, and FSH, in synergy with testosterone, regulates the production of spermatozoa.

Hypothalamic GnRH regulates both LF and FSH secretion.

Hypothalamic neurons produce GnRH also called LH-releasing hormone [LHRH]), a decapeptide, which regulates the secretion of LH and FSH. GnRH originates from a large precursor molecule called preproGnRH (Fig. 36.2). PreproGnRH consists of a signal peptide, native GnRH, and a GnRH-associated peptide (GAP). The signal peptide (or leader sequence) allows the protein to cross the membrane of the rough endoplasmic reticulum (RER). However, both the signal peptide and GAP are enzymatically cleaved at the RER prior to GnRH secretion. Although neurons that produce GnRH can be located in various areas of the brain, their highest concentration is in the medial basal hypothalamus, in the region of the infundibulum and arcuate nucleus.

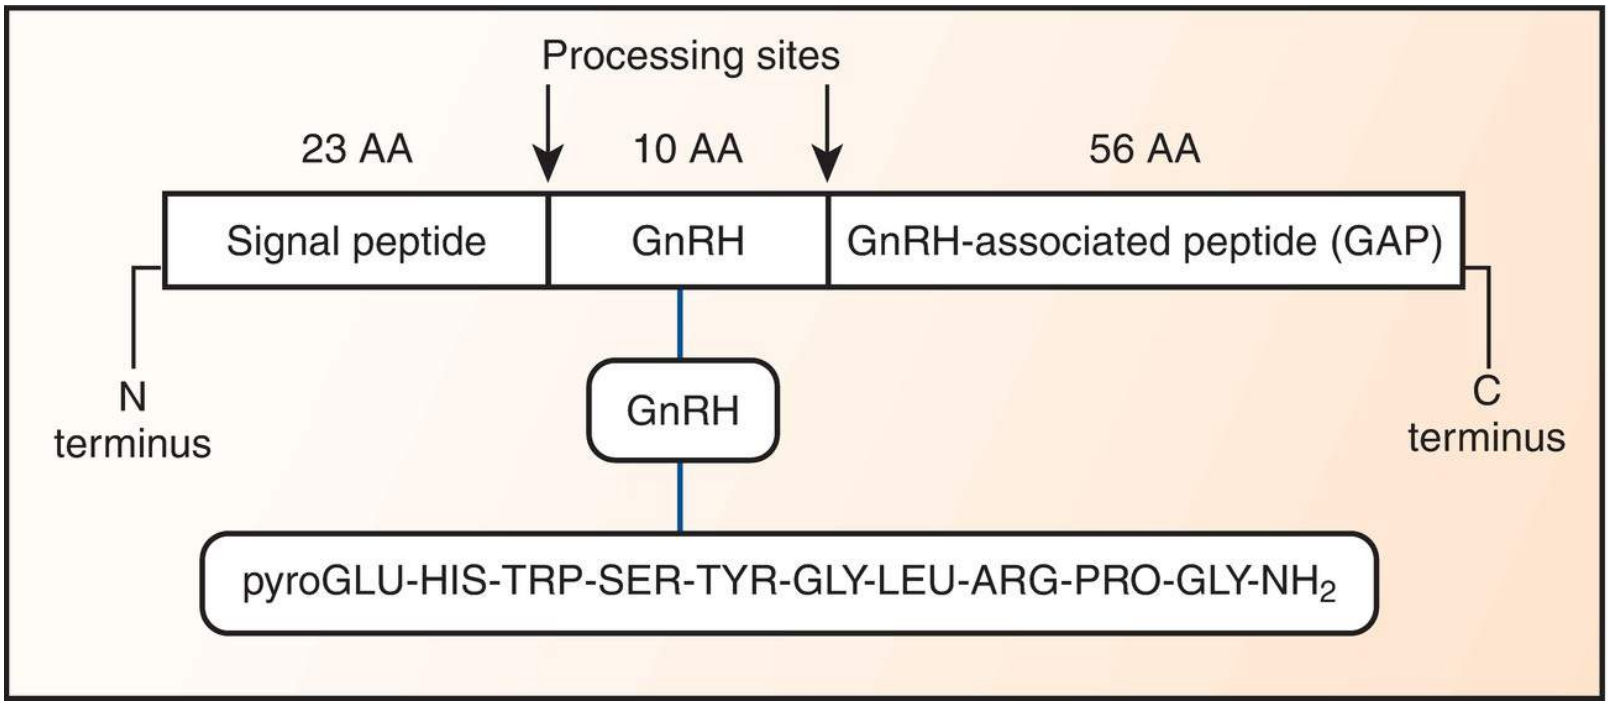

Figure 36.2 The precursor molecule, preproGnRH, that contains gonadotropin-releasing hormone (GnRH). The amino acid sequence of GnRH, a decapeptide, is indicated at the bottom.

GnRH enters the hypothalamic–pituitary portal system and binds to receptors on the plasma membranes of pituitary cells, resulting in the synthesis and release of LH and FSH. Three distinct pituitary LH- and FSH-secreting cells have been identified: (1) LF-secreting **gonadotrophs**, (2) FSH-secreting gonadotrophs, and (3) gonadotrophs that secrete both LH and FSH. GnRH can induce the secretion of both hormones simultaneously because GnRH receptors are present on all of these cell types.

Many external cues and internal signals influence the secretion of GnRH, LH, and FSH. For example, the amounts of GnRH, FSH, and LH secreted change with age, stress levels, and hormonal state. In addition, various disease states lead to hyposecretion of GnRH. Little, if any, secretion of hypothalamic GnRH occurs in patients with prepubertal **hypopituitarism**, resulting in a failure of the development of the testes, primarily a result of a lack of LH, FSH, and testosterone.

Male patients with **Kallmann syndrome** are hypogonadal from a deficiency in LH and FSH secretion because of a failure of GnRH neurons to migrate from the olfactory bulbs, their embryologic site of origin. This failure results in an insufficient hypothalamic source of GnRH to maintain secretion of LH and FSH,

and the testes fail to undergo significant development.

LH and FSH regulate testosterone secretion and sperm production.

LH and FSH each contain two polypeptide subunits, referred to as α and β chains, that are about 15 kDa in size. These hormones contain the same α subunit but different β subunits. Each hormone is glycosylated prior to release into the general circulation. Glycosylation regulates the half-life, protein folding for receptor recognition, and biologic activity.

LH and FSH regulate testicular function. They bind G-protein–coupled receptors on Leydig and Sertoli cells, respectively, that increase cAMP. For the most part, cAMP can account for all of the actions of LH and FSH on testicular cells via PKA-mediated activation of transcription factors such as steroidogenic factor-1 (SF-1) and cAMP response element–binding protein (CREB). These factors activate the promoter region of the genes of steroidogenic enzymes that control testosterone production by Leydig cells. Similar signaling occurs in Sertoli cells that regulate the production of estradiol. The testis converts testosterone and some other androgens to estradiol by the process of aromatization, although estradiol production is low in males.

Another major function of the testis is the production of mature sperm and of several regulatory proteins (activin, androgen-binding protein, follistatin, and inhibin), characteristics of which are detailed in later sections.

Low-frequency GnRH pulses lead to FSH release, whereas high-frequency GnRH pulses stimulate LH release.

GnRH is secreted in a pulsatile manner. GnRH pulsatility is ultimately necessary for proper functioning of the testes because it regulates the secretion of FSH and LH, which are also released in a pulsatile fashion (Fig. 36.3). Continuous exposure of gonadotrophs to GnRH results in desensitization of GnRH receptors, leading to a decrease in LH and FSH release. Therefore, the pulsatile pattern of GnRH release serves an important physiologic function. The administration of GnRH at an improper frequency results in a decrease in circulating concentrations of LH and FSH.

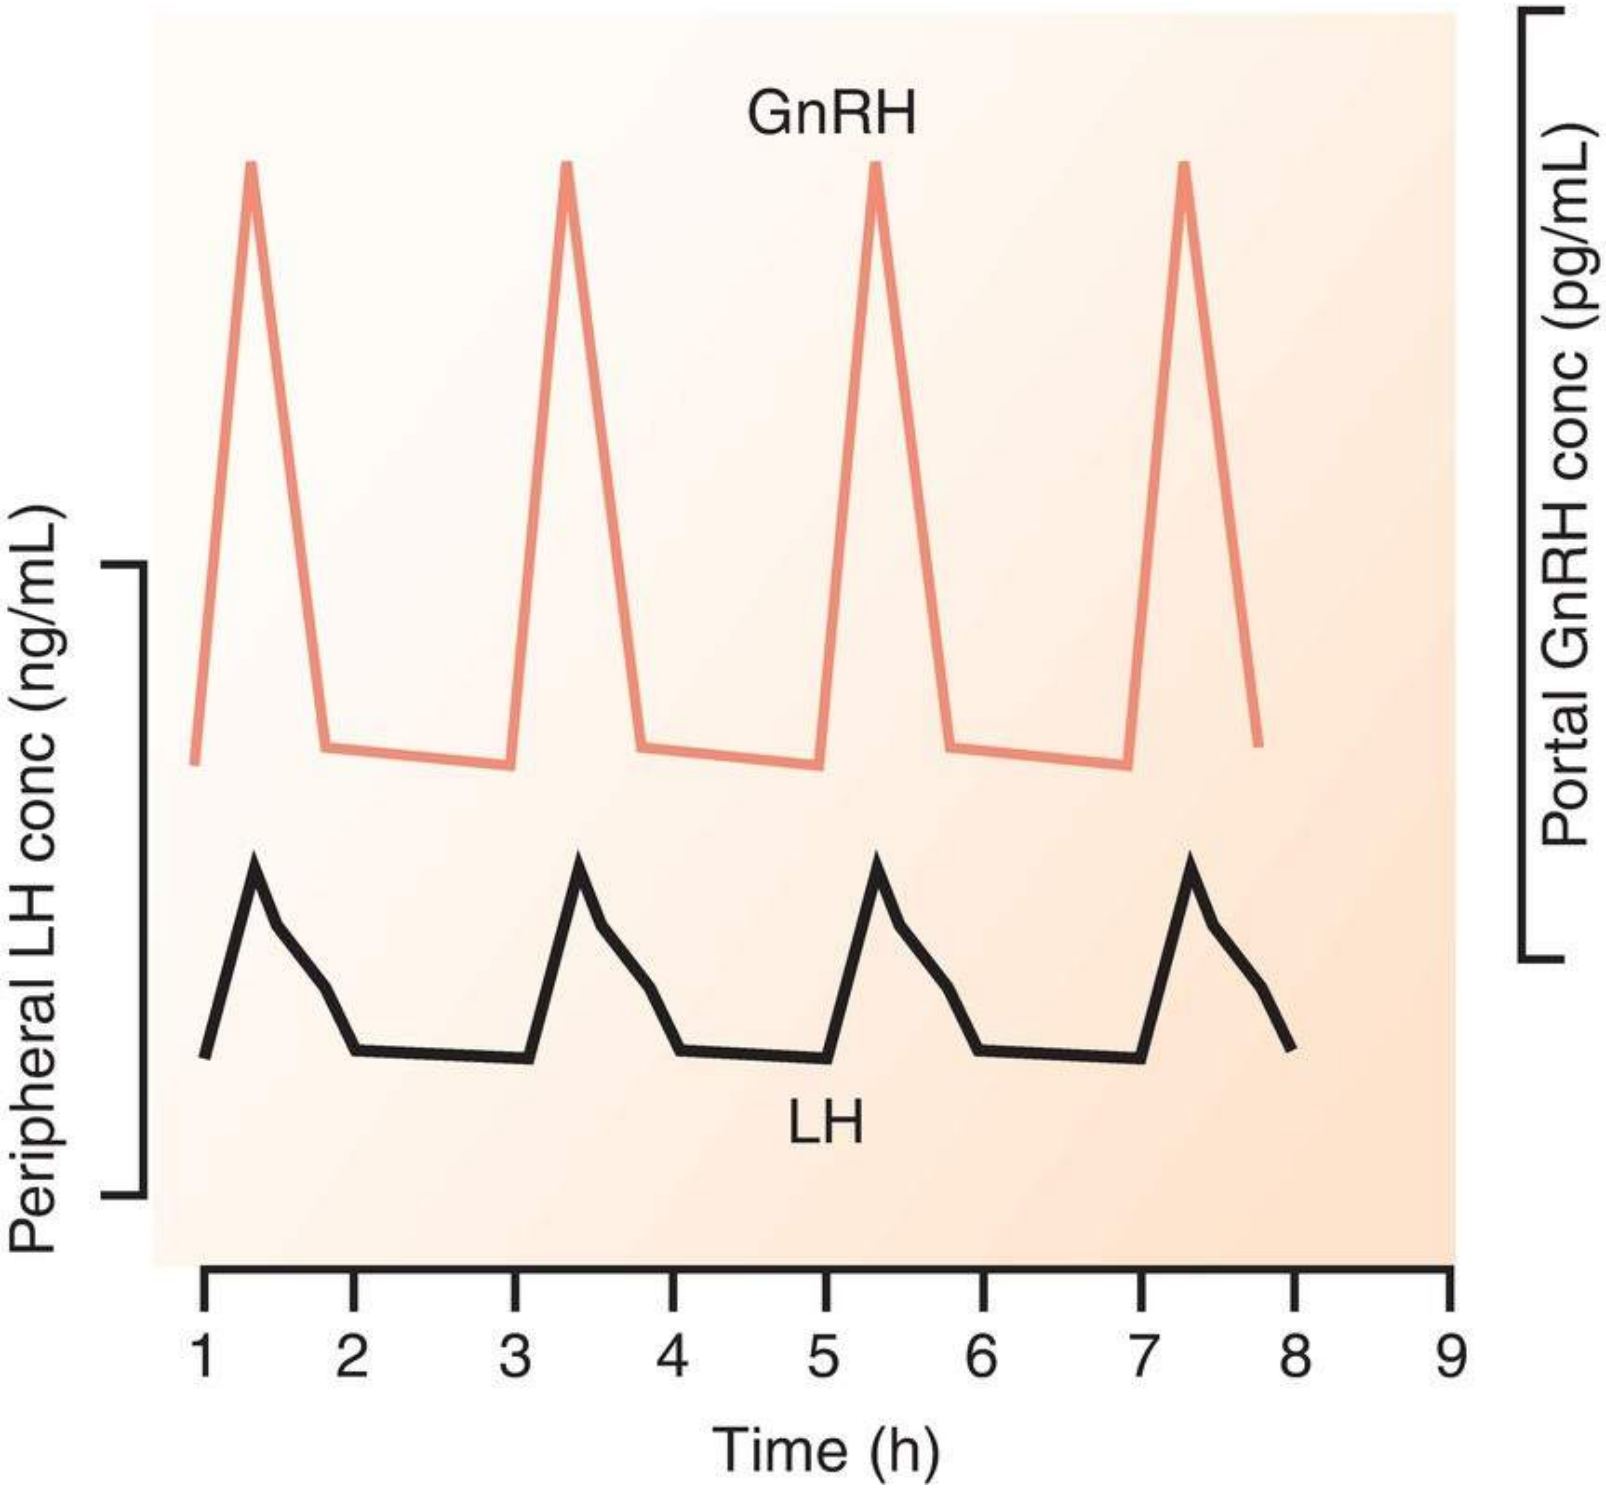

Figure 36.3 A diagram of the pulsatile release of gonadotropin-releasing hormone (GnRH) in portal blood and luteinizing hormone in peripheral blood. conc, concentration.

Most evidence for GnRH pulses has come from animal studies because GnRH must be measured in hypothalamic–hypophyseal portal blood, an extremely difficult area from which to obtain blood samples in humans. Because distinct pulses of LH follow discrete pulses of GnRH, measurements of LH in serum indirectly indicate that GnRH pulses have occurred. Unlike LH secretion, FSH secretion is not always pulsatile, and even when it is pulsatile, there is only partial concordance between LH and FSH pulses. Numerous human studies measuring LH and FSH secretion in peripheral blood at various times have provided much of the information regarding the role of LH and FSH in regulating testicular development and function. However, the exact relationship between endogenous GnRH pulses and LH and FSH secretion in humans is unknown.

Hypogonadal **eunuchoid** men exhibit low levels of LH in serum and do not exhibit pulsatile secretion of LH. Pulsatile injections of GnRH restore LH and FSH secretion and increase sperm counts. FSH pulses tend to be smaller in amplitude than LH pulses, mostly because FSH has a longer half-life than LH in the circulation.

While it remains unclear what generates GnRH pulsatility, the activity of the pulse generator is under negative feedback control by gonadal steroids at the level of the hypothalamus and the pituitary. For example, castration causes a large increase in basal LH levels in serum, as evidenced by an increase in frequency and amplitude of LH pulses, indicating that negative feedback of gonadal steroids controls the GnRH pulse generator. Both testosterone and estradiol provide negative feedback. Studies indicate that the negative feedback of gonadal steroids controls LH at the hypothalamic level. Evidence also supports the concept that testosterone has negative feedback control on LH secretion directly at the pituitary level. In addition to estradiol, dihydrotestosterone, another active metabolite of testosterone, exerts negative feedback control on LH secretion, suggesting that testosterone does not need to be converted to estradiol.

Steroids and polypeptides from the testis inhibit both LH and FSH secretion.

Testosterone, estradiol, inhibin, activin, and follistatin are major testicular hormones that regulate the release of LH and FSH. Testosterone inhibits LH release by decreasing the secretion of GnRH and, to a lesser extent, by reducing gonadotroph sensitivity to GnRH. Estradiol formed from testosterone by aromatase also has an inhibitory effect on GnRH secretion. Acute testosterone treatment does not alter pituitary responsiveness to GnRH, but prolonged exposure significantly reduces the secretory response to GnRH.

Removal of the testes results in increased circulating levels of LH and FSH. Replacement therapy with physiologic doses of testosterone restores LH to precastration levels but does not completely correct FSH levels. This observation led to a search for a gonadal factor that specifically inhibits FSH release. The polypeptide hormone **inhibin** was eventually isolated from seminal fluid. Inhibin is produced by Sertoli cells. Inhibin is composed of two dissimilar subunits, α and β, which are held together by disulfide bonds. There are two β-subunit forms, called A and B. Inhibin B consists of the α subunit bound by a disulfide bridge to the βB subunit and is the physiologically important form of inhibin in the human male. Inhibin acts directly on the anterior pituitary and inhibits the secretion of FSH, but not LH.

Activin is produced by Sertoli cells, stimulates the secretion of FSH, has an approximate molecular weight of 30 kDa, and has multiple forms based on the βA and βB subunits of inhibin. The multiple forms of activin are called activin A (two βA subunits linked by a disulfide bridge), activin B (two βB subunits), and activin AB (one βA subunit and one βB subunit). The major form of activin in the male is currently unknown, although both Sertoli and Leydig cells have been implicated in its secretion.

Follistatin is a single-chain protein hormone, with several isoforms, that binds and deactivates activin. Thus, the deactivation of activin by binding to follistatin reduces FSH secretion. Follistatin is produced by Sertoli cells and acts as a paracrine factor on the developing spermatogenic cells.

Testis is the site of sperm and seminal fluid formation.

During embryonic stages of development, the testes lie attached to the posterior abdominal wall. As the embryo elongates, the testes move to the inguinal ring. Between the seventh month of pregnancy and birth, the testes descend through the inguinal canal into the scrotum. The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C lower than the core body temperature. Two systems help maintain the testes at a cooler temperature. One is the **pampiniform plexus** of blood vessels, which serves as a countercurrent heat exchanger between warm arterial blood reaching the testes and cooler venous blood leaving the testes. The second is the **cremasteric muscle**, which responds to changes in temperature by moving the testes closer or farther away from the body. Prolonged exposure of the testes to elevated temperature, fever, or thermoregulatory dysfunction can lead to temporary or permanent sterility as a result of a failure of spermatogenesis, whereas steroidogenesis is unaltered.

A thick, fibrous connective tissue layer, the tunica albuginea, encapsulates the testes. Each human testis contains hundreds of tightly packed **seminiferous tubules**, ranging from 150 to 250 μm wide and from 30 to 70 cm long. The tubules are arranged in lobules, separated by extensions of the tunica albuginea, and open on both ends into the rete testis. Examination of a cross-section of a testis reveals distinct morphologic compartmentalization. Sperm production is carried out in the avascular seminiferous tubules. Each seminiferous tubule is composed of two somatic cell types (myoid cells and Sertoli cells) and germ cells. A basement membrane (basal lamina) with myoid cells on its perimeter, which define its outer limit, surrounds the seminiferous tubule. On the inside of the basement membrane are large, irregularly shaped Sertoli cells, which extend from the basement membrane to the lumen (Fig. 36.4). Tight junctions attach Sertoli cells to one another near their base (Fig. 36.5). The tight junctions divide each tubule into a basal compartment, whose constituents are exposed to circulating agents, and an adluminal compartment, which is isolated from blood-borne elements. The tight junctions limit the transport of fluid and macromolecules from the interstitial space into the tubular lumen, forming the blood–testis barrier.

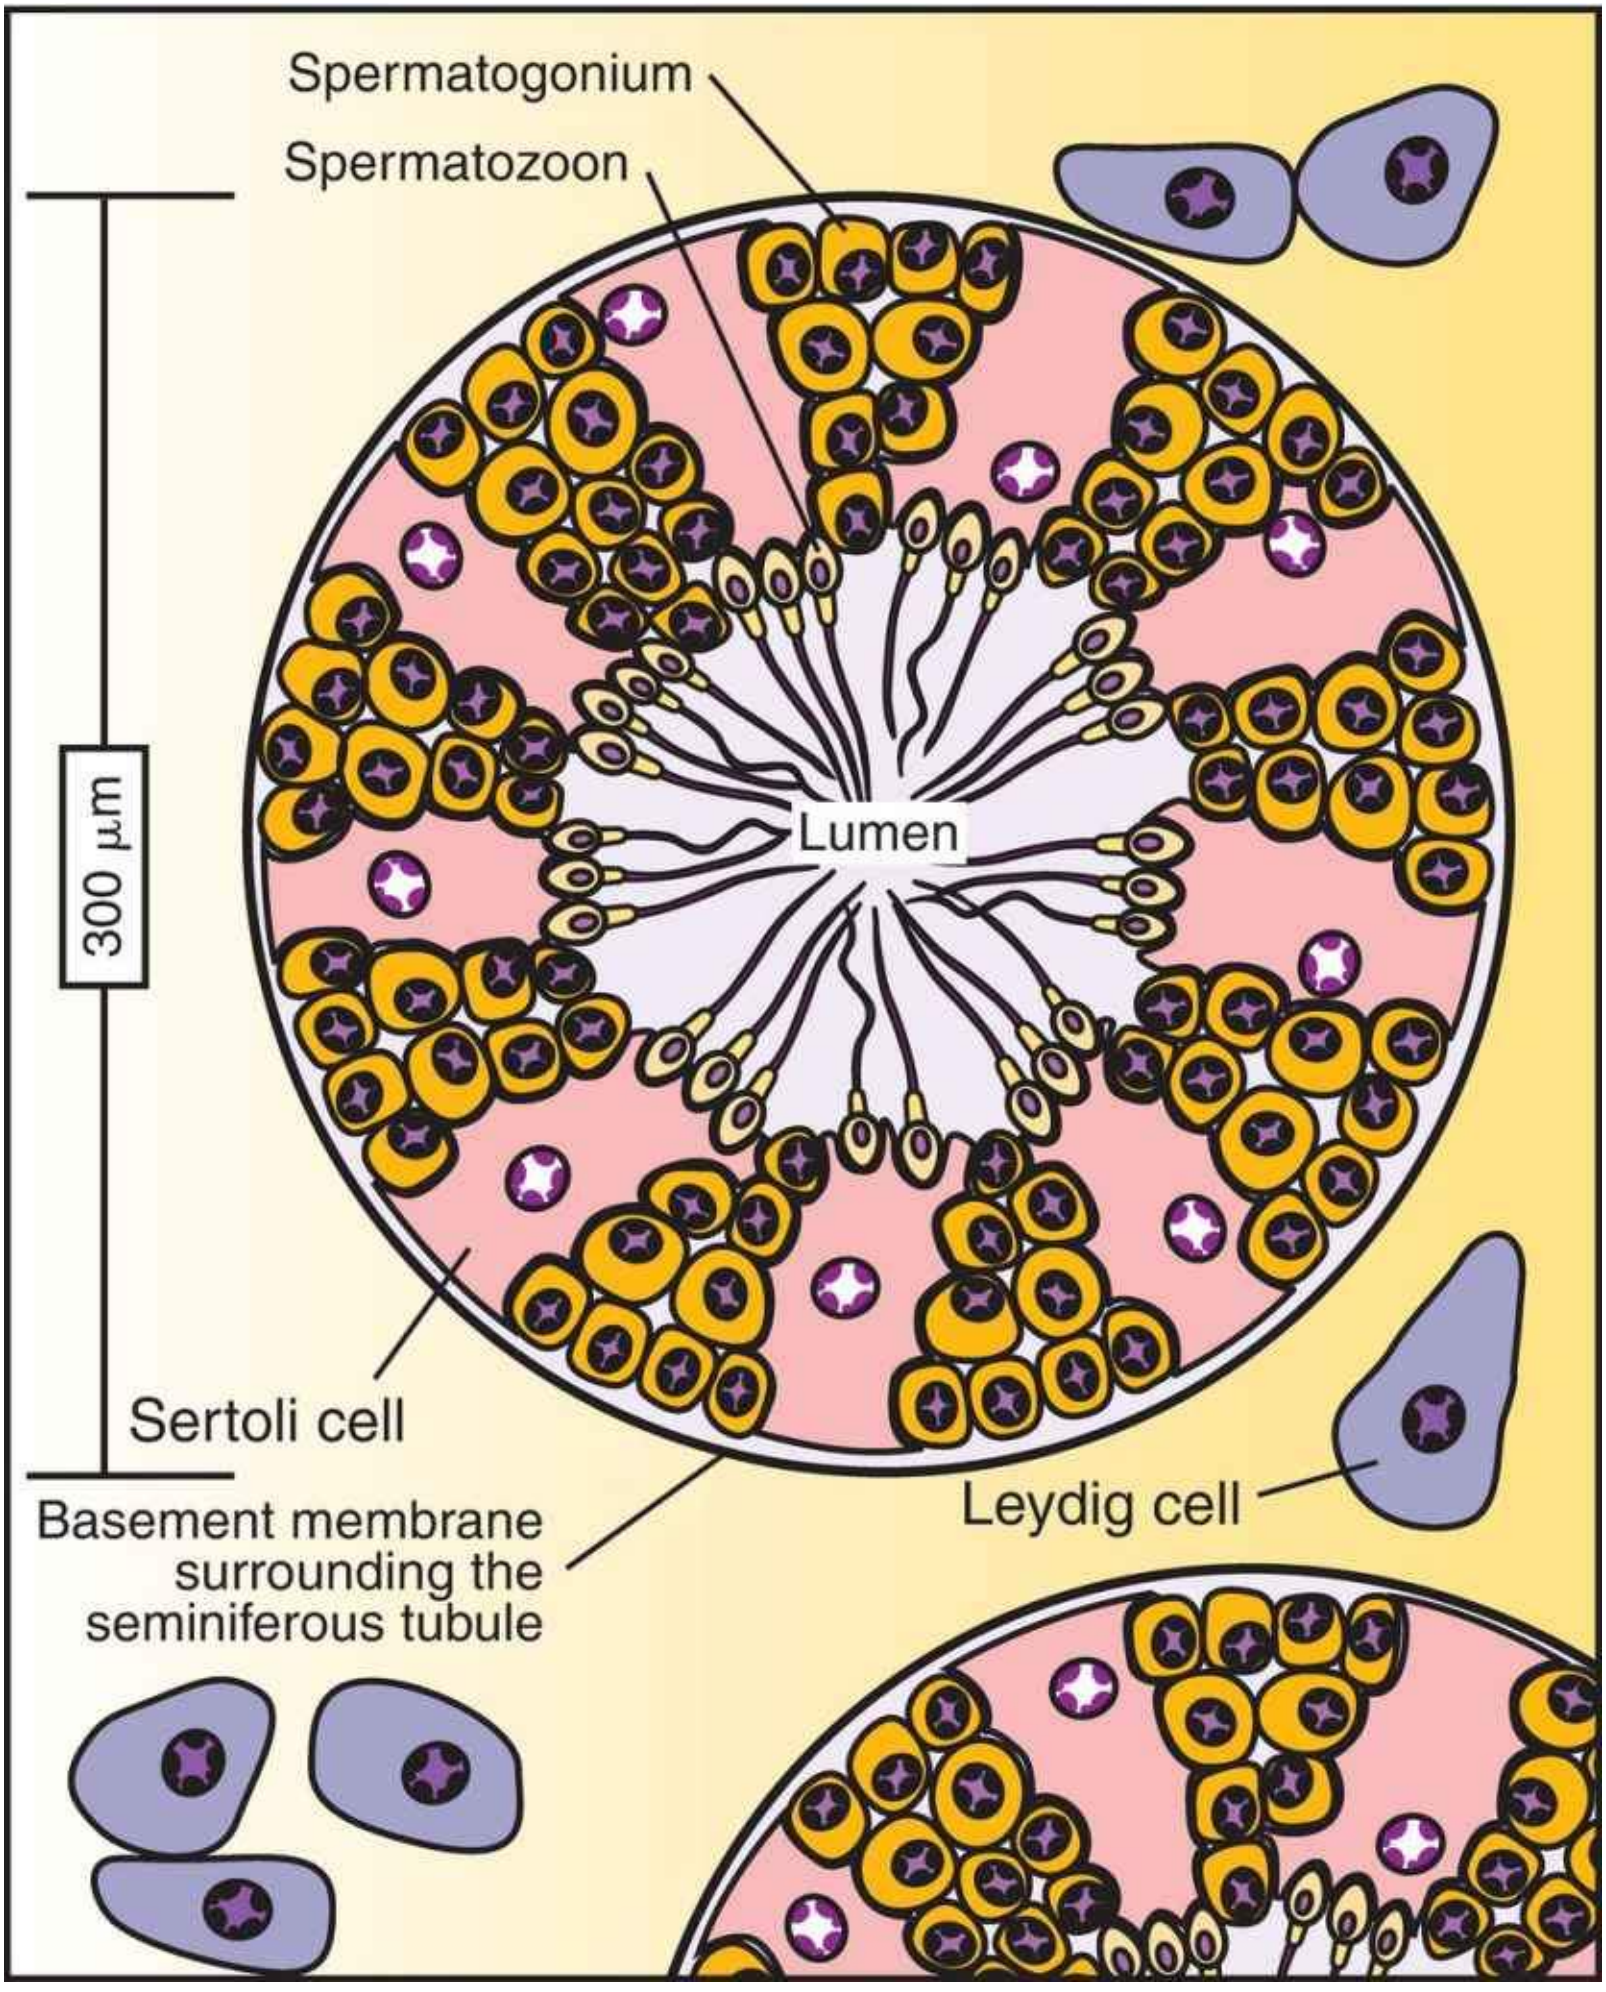

Figure 36.4 The testis. This cross-sectional view shows the anatomic relationship of the Leydig cells, basement membrane, seminiferous tubules, Sertoli cells, spermatogonia, and spermatozoa.

Figure 36.5 Sertoli cells. Sertoli cells are connected by tight junctions, which divide the intercellular space into a basal compartment and an adluminal compartment. Spermatogonia are located in the basal compartment and maturing sperm in the adluminal compartment. Spermatocytes are formed from the spermatogonia and cross the tight junctions into the adluminal compartment; they mature into spermatozoa.

Located between the nonproliferating Sertoli cells are germ cells at various stages of division and differentiation. Mitosis of the **spermatogonia** (diploid progenitors of spermatozoa) occurs in the basal compartment of the seminiferous tubule (see Fig. 36.5). The early meiotic cells (primary spermatocytes) move across the junctional complexes into the adluminal compartment, in which they mature into spermatozoa or **gametes** after meiosis. The adluminal compartment protects spermatozoa from the immune system that does not recognize spermatozoa that develop in the adluminal compartment as "self." If the adluminal compartment is compromised, sperm is allowed to mingle with immune cells from the circulation and males can develop antibodies against their own sperm, resulting in infertility. Sperm antibodies are often present after vasectomy or testicular injury and in some autoimmune diseases in which the adluminal compartment is ruptured.

Sertoli cells nurture the development of sperm cells through spermatogenesis.

Sertoli cells are critical to germ cell development, as indicated by their close contact. As many as 6 to 12 spermatids may be attached to a Sertoli cell. Sertoli cells phagocytose residual bodies (excess cytoplasm resulting from the transformation of spermatids to spermatozoa) and damaged germ cells, provide structural support and nutrition for germ cells, secrete fluids, and assist in **spermiation**—the final detachment of mature spermatozoa from the Sertoli cell into the lumen. Spermiation may involve **plasminogen activator**, which converts plasminogen to plasmin, a proteolytic enzyme that assists in the release of the mature sperm into the lumen. Sertoli cells also synthesize large amounts of transferrin, an iron transport protein important for sperm development.

During the fetal period, Sertoli cells and gonocytes form the seminiferous tubules as Sertoli cells undergo numerous rounds of cell divisions. Shortly after birth, Sertoli cells cease proliferating, and throughout life, the number of sperm produced is directly related to the number of Sertoli cells. At puberty, the capacity of Sertoli cells to bind FSH and testosterone increases. Through cAMP and PKA signaling mechanisms mentioned above, FSH exerts multiple effects on the Sertoli cell (Fig. 36.6). FSH stimulates the production of androgen-binding protein and plasminogen activator, increases secretion of inhibin, and induces aromatase activity for the conversion of androgens to estrogens. The testosterone receptor is within the nucleus of the Sertoli cell.

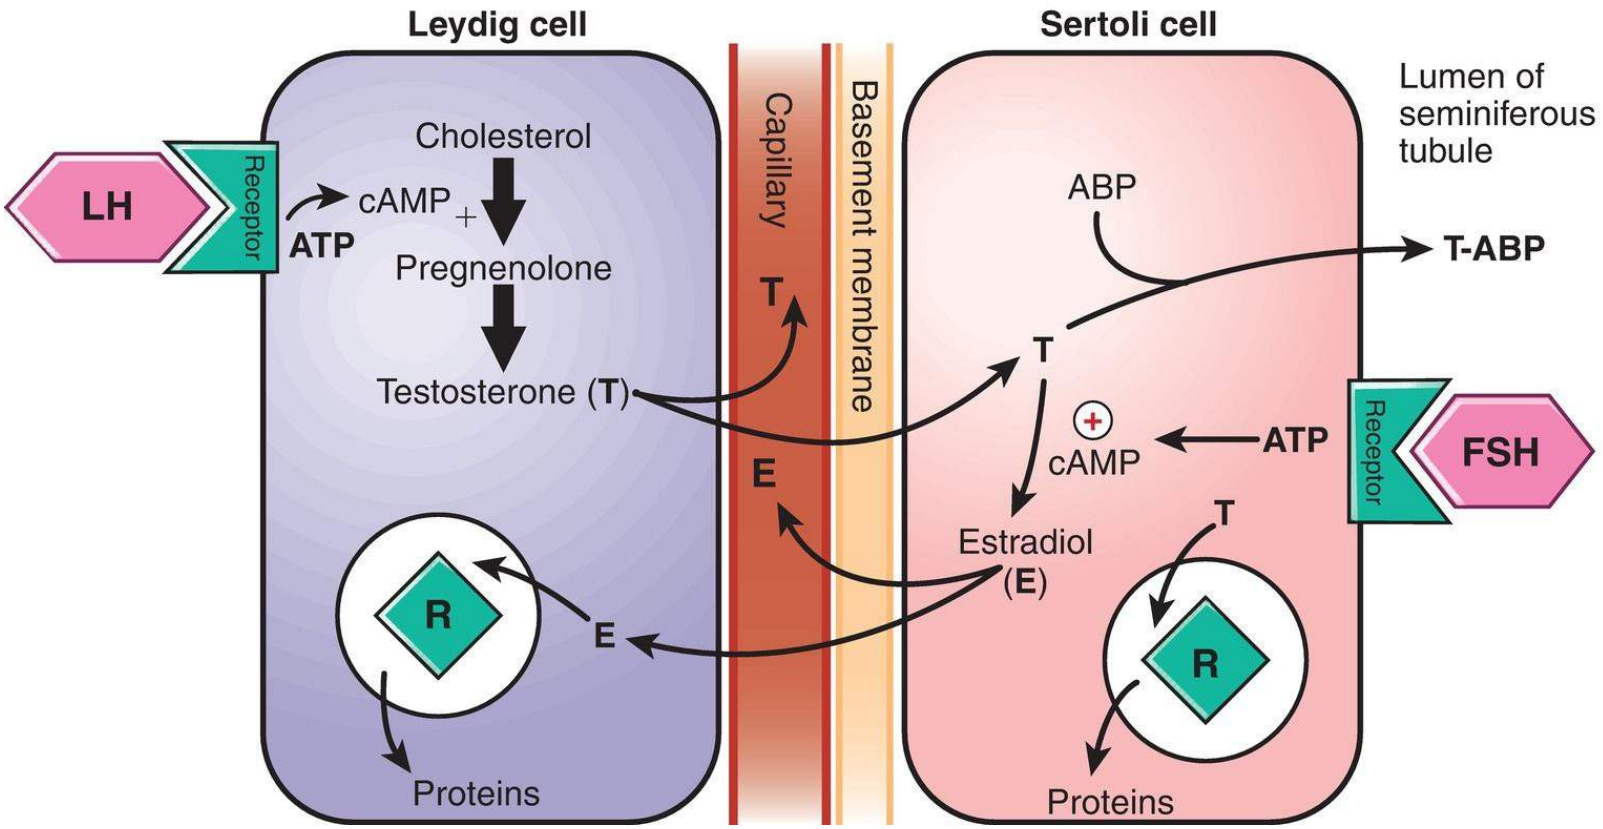

Figure 36.6 Regulation of hormonal products and interactions between Leydig and Sertoli cells. ABP, androgen-binding protein; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; E, estradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; R, receptor; T, testosterone.

Androgen-binding protein (**ABP**) is a 90-kDa protein, made of a heavy and a light chain that has a high binding affinity for dihydrotestosterone and testosterone. It is similar in function, with some homology in structure, to another binding protein, **sex hormone–binding globulin** (**SHBG**), synthesized in the liver. ABP is found at high concentrations in the human testis and epididymis. It serves as a carrier of testosterone in Sertoli cells, as a storage protein for androgens in the seminiferous tubules, and as a carrier of testosterone from the testis to the epididymis. Recall that other products of the Sertoli cell include inhibin, follistatin, and activin. Whereas activin stimulates the secretion of FSH, inhibin and follistatin decrease the levels of FSH by suppressing FSH release from the pituitary gonadotrophs and reducing FSH secretion induced by activin, respectively.

Luteinizing hormone induces Leydig cells to produce testosterone.

Leydig cells are large polyhedral cells that are often found in clusters near blood vessels in the interstitium between seminiferous tubules. They are equipped to produce steroids because they have numerous mitochondria, a prominent smooth endoplasmic reticulum (SER), and conspicuous lipid droplets. Leydig cells undergo significant changes in quantity and activity throughout life. In the human fetus, the period from week 8 to 18 is marked by active steroidogenesis, which is obligatory for differentiation of the male genital ducts. Leydig cells at this time are prominent and active, reaching their maximal steroidogenic activity at about 14 weeks, when they constitute more than 50% of the testicular volume. Because the fetal hypothalamic–pituitary axis is still underdeveloped, **human chorionic gonadotropin** (**hCG**) from the placenta, rather than LH from the fetal pituitary, controls steroidogenesis (see Chapter 38); LH and hCG bind the same receptor. After this period, Leydig cells slowly regress. At about 2 to 3 months of postnatal life, male infants have a significant rise in LH and testosterone production (infantile testosterone surge). The regulation and function of this short-lived surge remain uncertain, yet it is clearly independent of sex steroids. Leydig cells remain quiescent throughout childhood but increase in number and activity at the onset of puberty.

Leydig cells do not have FSH receptors, but FSH can increase the number of developing Leydig cells by stimulating the production of growth stimulators from Sertoli cells, which subsequently enhance the growth of Leydig cells. In addition, androgens stimulate the proliferation of developing Leydig cells. Estrogen receptors are present on Leydig cells and reduce the proliferation and activity of these cells. Leydig cells have LH receptors, and the major effect of LH is to stimulate androgen secretion via a cAMP-dependent mechanism (see Fig. 36.6). The main product of Leydig cells is testosterone, but two other androgens of less biologic activity, dehydroepiandrosterone (DHEA) and androstenedione, are also produced.

There are bidirectional interactions between Sertoli and Leydig cells (see Fig. 36.6). The Sertoli cell is incapable of producing testosterone but contains testosterone receptors as well as FSH-dependent aromatase. The Leydig cell does not produce estradiol but contains receptors for it, and estradiol can suppress the response of the Leydig cell to LH. Testosterone diffuses from the Leydig cells, crosses the basement membrane, enters the Sertoli cell, and binds to ABP. As a result, androgen levels can reach high local concentrations in the seminiferous tubules. Testosterone is obligatory for spermatogenesis and the proper functioning of Sertoli cells. In Sertoli cells, testosterone also serves as a precursor for estradiol production. The daily role of estradiol in the functioning of Leydig cells is unclear, but it may modulate responses to LH. For example, exposure of Leydig cells to LH or hCG leads to an LH or hCG desensitization. Studies show that estradiol is elevated within 30 minutes after hCG administration and that estrogen antagonists can block the hCG-induced down-regulation phenomena.

Duct system functions in sperm maturation, storage, and transport sites.

After formation in the seminiferous tubules, spermatozoa travel to the rete testes and, from there, through the efferent ductules to the **epididymis**. Ciliary movement in the efferent ductules, muscle contraction, and the flow of fluid accomplish this movement of sperm.

Figure 36.7A shows a sagittal section of the male pelvis. The two major elements of the male sexual anatomy are the gonads (i.e., testes) and the sex accessories (i.e., the epididymis, vas deferens, seminal vesicles, ejaculatory duct, prostate, bulbourethral or Cowper glands, urethra, and penis). The epididymis is a single, tightly coiled, 4- to 5-m–long duct. It is composed of a head (caput), a body (corpus), and a tail (cauda) (Fig. 36.7B). The functions of the epididymis are storage, protection, transport, and maturation of sperm cells. Maturation at this point includes a change in functional capacity as sperm make their way through the epididymis. The sperm become capable of forward mobility during migration through the body of the epididymis. A significant portion of sperm maturation is carried out in the caput, whereas the sperm are stored in the cauda.

Figure 36.7 The male reproductive organs. The *top drawing* is a general side view. The *bottom enlargement* shows a sagittal section of the testis, epididymis, and vas deferens.

Frequent ejaculations result in reduced sperm numbers and increased numbers of immotile sperm in the ejaculate. The cauda connects to the vas deferens, which forms a dilated tube, the ampulla, prior to entering the prostate. The ampulla also serves as a storage site for sperm. Vasectomy—the cutting and ligation of the vas deferens—is an effective method of male contraception. Because the sperm are stored in the ampulla, men remain fertile for 4 to 5 weeks after vasectomy.

Erection and ejaculation are under neural control.

Erection is associated with sexual arousal emanating from sexually related psychic and/or physical stimuli. During sexual arousal, impulses from the genitalia, together with nerve signals originating in the limbic system, elicit motor impulses in the spinal cord. The parasympathetic nerves in the sacral region of the spinal cord carry these neuronal impulses via the cavernous nerve branches of the prostatic plexus that enter the penis. Those signals cause smooth muscle vasodilation of the arterioles and corpora cavernosa. An important biochemical regulator of arterial and cavernosal relaxations is **nitric oxide** (**NO**), which is derived from the nerve terminals innervating the corpora cavernosa, the endothelial lining of penile arteries, and cavernosal sinuses. The actions of NO on the cavernosal smooth muscle and arterial blood flow are mediated through the activation of guanyl cyclase and production of **cyclic guanosine monophosphate** (**cGMP**) that causes smooth muscle relaxation by lowering intracellular calcium. The relaxation of the smooth muscles in those structures dilates blood vessels, which then begin to engorge with blood. The swelling of the blood-filled arterioles and corpora cavernosa compresses the thin-walled veins, restricting blood flow. The result is a reduction in the outflow of blood from the penis, and blood is trapped in the surrounding erectile tissue, leading to engorgement, rigidity, and elongation of the penis in an erect position.

Erectile dysfunction (**ED**), formerly called impotence, is the repeated inability to get or keep an erection firm enough for sexual intercourse. The word “impotence” may also be used to describe other problems that interfere with sexual intercourse and reproduction, such as lack of sexual desire and problems with ejaculation or orgasm. Using the term erectile dysfunction makes it clear that those other problems are not involved.

Semen, consisting of sperm and associated fluids, is expelled by a neuromuscular reflex that is divided into two sequential phases: (1) emission and (2) ejaculation. Seminal emission moves the sperm and associated fluids from the cauda epididymis and vas deferens into the urethra. The latter process involves efferent stimuli originating in the lumbar areas (L1 and L2) of the spinal cord and is mediated by adrenergic sympathetic (hypogastric) nerves that induce contraction of smooth muscles of the epididymis and vas deferens. This action propels sperm through the ejaculatory ducts and into the urethra. Sympathetic discharge also closes the internal urethral sphincter, which prevents retrograde ejaculation into the urinary bladder. **Ejaculation** is the expulsion of the semen from the penile urethra; it is initiated after emission. The filling of the urethra with sperm initiates sensory signals via the pudendal nerves that travel to the sacrospinal region of the cord. A spinal reflex mechanism that induces rhythmic contractions of the striated bulbospongiosus muscles surrounding the urethra results in propelling the semen out of the tip of the penis.

The secretions of the accessory glands promote sperm survival and fertility. The accessory glands that contribute to the secretions are the seminal vesicles, prostate gland, and bulbourethral glands. The semen contains only 10% sperm by volume, with the remainder consisting of the combined secretions of the accessory glands. The normal volume of semen is 3 mL, with 20 to 50 million sperm per milliliter; normal is considered more than 20 million sperm per milliliter. The seminal vesicles contribute about 75% of the semen volume. Their secretion contains fructose (the principal substrate for glycolysis of ejaculated sperm), ascorbic acid, and prostaglandins. In fact, prostaglandin concentrations are high and were first discovered in semen but were mistakenly considered to be the product of the prostate. Seminal vesicle secretions are also responsible for coagulation of the semen seconds after ejaculation. Prostate gland secretions (~0.5 mL) include fibrinolysin, which is responsible for liquefaction of the coagulated semen 15 to 30 minutes after ejaculation, releasing sperm.

SPERMATOGENESIS

Spermatogenesis is the process of producing mature male gametes (sperm) and functions to fertilize the female counterpart, the oocyte. In humans, it occurs in the male testes and epididymis in a stepwise fashion in ~64 days. It is a continual process involving mitosis of the male germ cells, which undergo extensive morphologic changes in cell shape and, ultimately, meiosis to produce the haploid spermatozoa.

Spermatogenesis produces an abundance of highly specialized, mobile sperm.

Although sperm production continues throughout life, beginning at puberty, it declines with age. Spermatogenesis is the process of transformation of male germ cells into spermatozoa. This process can be divided into three distinct phases. The phases include cellular proliferation by **mitosis**, two reduction divisions by **meiosis** to produce haploid spermatids, and cell differentiation by a process called **spermiogenesis**, in which the spermatids differentiate into spermatozoa (Fig. 36.8). Spermatogenesis is initiated shortly before puberty, under the influence of the rising levels of gonadotropins and testosterone, and continues throughout life, with a slight decline during old age.

Figure 36.8 The process of spermatogenesis, showing successive cell divisions and remodeling leading to the formation of haploid spermatozoa.

The time required to produce mature spermatozoa from the earliest stage of spermatogonia is 65 to 70 days. Several developmental stages of spermatogenic cells occur during this time frame, and the stages are collectively known as the spermatogenic cycle. There is synchronized development of spermatozoa within the seminiferous tubules, and each stage is morphologically distinct. A spermatogonium becomes a mature spermatozoon after going through several rounds of mitotic divisions, a couple of meiotic divisions, and a few weeks of differentiation. Hormones can alter the number of spermatozoa, but they generally do not affect the cycle duration. Spermatogenesis occurs along the length of each seminiferous tubule in successive cycles. New cycles are initiated at regular time intervals (every 2 to 3 weeks) before the previous ones are completed. As a result, cells at different stages of development are spaced along each tubule in a "spermatogenic wave." This succession ensures continuous production of fresh spermatozoa. Approximately 200 million spermatozoa are produced daily in the adult human testes, which is about the same number of sperm present in a normal ejaculate.

Because sperm cells are rapidly dividing and undergoing meiosis, they are sensitive to external agents that alter cell division. Chemical carcinogens, chemotherapeutic agents, certain drugs, environmental toxins, irradiation, and extreme temperatures are factors that can reduce the number of replicating germ cells or cause chromosomal abnormalities in individual cells. While the immune system normally detects and destroys defective somatic cells, the blood–testis barrier isolates advanced germ cells from immune surveillance.

If physical injury or infection ruptures the blood–testis barrier and sperm cells within the barrier are exposed to circulating immune cells, antibodies can develop to the sperm cells. In the past, it was thought that the development of antisperm antibodies could lead to male infertility. It appears that men with high levels of antisperm antibodies may exhibit some infertility problems. However, men who have developed low or moderate levels of antisperm antibodies after vasectomy and who have had their vas deferens reconnected have normal fertility if the vasectomy was for a relatively short time, according to studies. Vasectomy does not appear to change hormone or sperm production by the testes. Nevertheless, in some cases, a high level of antisperm antibodies in men and women leads to infertility.

Spermatogonia divide mitotically to produce primary spermatocytes, which, in turn, undergo meiosis to become spermatids.

Spermatogonia undergo several rounds of mitotic division prior to entering the meiotic phase (see Fig. 36.8). The spermatogonia remain in contact with the Sertoli cells, migrate away from the basal compartment near the walls of the seminiferous tubules, and cross into the adluminal compartment of the tubule (see Fig. 36.5). After crossing into the adluminal compartment, the cells differentiate into spermatocytes prior to undergoing meiosis. The first meiotic division of **primary spermatocytes** gives rise to diploid (2*n* chromosomes) **secondary spermatocytes**.

The second meiotic division produces haploid (one set of chromosomes) cells called **spermatids**. Of every four spermatids emanating from a primary spermatocyte, two contain X chromosomes and two have Y chromosomes (see Fig. 36.8). Because of the numerous mitotic divisions and two rounds of meiosis, each spermatogonium committed to meiosis should yield 256 spermatids if all cells survive.

There are numerous developmental disorders of spermatogenesis. The most frequent is **Klinefelter syndrome**, which causes hypogonadism and infertility in men. Patients with this disorder have an accessory X chromosome caused by meiotic nondisjunction. The typical karyotype is 47 XXY, but there are other chromosomal mosaics. Testicular volume is reduced >75%, and ejaculates contain few, if any, spermatozoa. Spermatogenic cell differentiation beyond the primary spermatocyte stage is rare.

Formation of a mature spermatozoon requires extensive cell remodeling.

Spermatids are small, round, and nondistinctive cells. During the second half of the spermatogenic cycle, they undergo considerable restructuring to form mature spermatozoa. Notable changes include alterations in the nucleus, the formation of a tail, and a massive loss of cytoplasm. The nucleus becomes eccentric and decreases in size, and the chromatin becomes condensed. The **acrosome**, a lysosome-like structure unique to spermatozoa, buds from the Golgi apparatus, flattens, and covers most of the nucleus. The centrioles, located near the Golgi apparatus, migrate to the caudal pole and form a long axial filament made of nine peripheral doublet microtubules surrounding a central pair (called the "9 + 2 arrangement"). This becomes the **axoneme** or major portion of the tail. Throughout this reshaping process, the cytoplasmic content is redistributed and discarded. During spermiation, most of the remaining cytoplasm is shed in the form of residual bodies.

The reasons for this lengthy and metabolically costly process become apparent when the unique functions of this cell are considered. Unlike other cells, the spermatozoon serves no apparent purpose in the organism. Its only function is to reach, recognize, and fertilize an egg; hence, it must fulfill several prerequisites: it should possess an energy supply and means of locomotion, it should be able to withstand a foreign and even hostile environment, it should be able to recognize and penetrate an egg, and it must carry all the genetic information necessary to create a new person.

The mature spermatozoon exhibits a remarkable degree of structural and functional specialization well adapted to carry out these functions. The cell is small, compact, and streamlined; it is about 1 to 2 µm wide and can exceed 50 µm in length in humans. It is packed with specialized organelles and long axial fibers but contains only a few of the normal cytoplasmic constituents, such as ribosomes, ER, and Golgi apparatus. It has a prominent nucleus, a flexible tail, numerous mitochondria, and an assortment of proteolytic enzymes.

The spermatozoon consists of three main parts: a head, a middle piece, and a tail. The two major components in the head are the condensed chromatin and the acrosome. The haploid chromatin is transcriptionally inactive throughout the life of the sperm until fertilization, when the nucleus decondenses and becomes a pronucleus. The acrosome contains proteolytic enzymes, such as hyaluronidase, acrosin, neuraminidase, phospholipase A, and esterases. They are inactive until the **acrosome reaction** occurs on contact of the sperm head with the egg (see Chapter 38). Their proteolytic action enables the sperm to penetrate through the egg membranes. The middle piece contains spiral sheaths of mitochondria that supply energy for sperm metabolism and locomotion. The tail is composed of a 9 + 2 arrangement of microtubules, which is typical of cilia and flagella, and is surrounded by a fibrous sheath that provides some rigidity. The tail propels the sperm by a twisting motion, involving interactions between tubulin fibers and dynein side arms and requiring ATP and magnesium.

Testosterone is essential for sperm production and maturation.

Spermatogenesis requires high intratesticular levels of testosterone, secreted from the LH-stimulated Leydig cells. The testosterone diffuses across the basement membrane of the seminiferous tubule, crosses the blood–testis barrier, and complexes with ABP. Sertoli cells, but not spermatogenic cells, contain receptors for testosterone. Sertoli cells also contain FSH receptors. FSH function in male subjects is not readily apparent but probably mediates spermatozoa development from spermatids in concert with testosterone, especially as failed spermatogenesis leads to elevated FSH levels.

The actions of FSH and testosterone at each point of sperm cell production are unknown. On entering meiosis, spermatogenesis appears to depend on the availability of FSH and testosterone. In human males, FSH is thought to be required for the initiation of spermatogenesis before puberty. When adequate sperm production has been achieved, LH alone (through stimulation of testosterone production) or testosterone alone is sufficient to maintain spermatogenesis.

ENDOCRINE FUNCTION OF THE TESTIS

A secondary function of the testis is steroidogenesis, the production of the steroid hormones. Testosterone is the main hormone produced by steroidogenesis and is primarily secreted by the testes of males and the ovaries of females. In males, testosterone production is about 10 times greater than that in females and plays a key role in the development of the testes and prostate as well as promoting secondary sexual characteristics, such as increased hair growth, muscle, and bone mass. It is also essential for health and well-being as well as the prevention of osteoporosis. Testosterone is converted to **dihydrotestosterone** (**DHT**), the most biologically active androgen, and to **estradiol**, the most biologically active estrogen.

Testosterone is primarily synthesized in Leydig cells and is derived from cholesterol, involving many enzymatic steps.

The adrenal cortex, ovaries, testes, and placenta produce steroid hormones from cholesterol. Cholesterol, a 27-carbon (C27) steroid, can be obtained from the diet or synthesized within the body from acetate. Each organ uses a similar steroid biosynthetic pathway, but the relative amount of the final products depends on the particular subset of enzymes expressed in that tissue and the trophic hormones (LH, FSH, and adrenocorticotropic hormone) stimulating specific cells within the organ. The major steroid produced by the testis is testosterone, but other androgens, such as androstenediol, androstenedione, and DHEA, as well as a small amount of estradiol, are also produced.

Cholesterol from lipoproteins is released in Leydig cells and transported from the outer mitochondrial membrane to the inner mitochondrial membrane, a process regulated by **steroidogenic acute regulatory protein**. Under the influence of LH, with cAMP as a second messenger, cholesterol side-chain cleavage enzyme (CYP11A1), which removes six carbons attached to the 21 position, converts cholesterol to **pregnenolone** (C21). Pregnenolone is a key intermediate for all steroid hormones in various steroidogenic organs (Fig. 36.9; see also Fig. 33.5). Specific transport proteins transport pregnenolone out of mitochondria. The pregnenolone then moves by diffusion to the SER, where the remainder of sex hormone biosynthesis takes place.

Target Cells

Figure 36.9 Steroidogenesis in Leydig cells and further modifications of androgens in target cells. *Solid arrows* represent the δ5 pathway. *Dashed arrows* represent the δ4 pathway. 3β-HSD, 3β-hydroxysteroid dehydrogenase.

Pregnenolone can be converted to testosterone via two pathways, the δ5 pathway and the δ4 pathway. In the δ5 pathway, the double bond is in ring B; in the δ4 pathway, the double bond is in ring A (see Fig. 36.9). The δ5 intermediates include 17α-hydroxypregnenolone, DHEA, and androstenediol, whereas the δ4 intermediates are progesterone, 17α-hydroxyprogesterone, and androstenedione.

The conversion of C21 steroids (the progestins) to androgens (C19 steroids) proceeds in two steps: first, 17α-hydroxylation of pregnenolone (to form 17α-hydroxypregnenolone) and second, C17,20 cleavage; therefore, two carbons are removed to form DHEA. A single enzyme, 17α-hydroxylase or 17,20-lyase (CYP17), accomplishes this hydroxylation and cleavage. Another two-step enzymatic reaction converts DHEA to androstenedione: dehydrogenation in position 3 (catalyzed by 3β-hydroxysteroid dehydrogenase [3β-HSD]) and shifting of the double bond from ring B to ring A (catalyzed by δ4,5-ketosteroid isomerase); these two may be the same enzyme. 17-Ketosteroid reductase (17β-hydroxysteroid dehydrogenase) carries out the final reaction yielding testosterone by substituting the keto group in position 17 with a hydroxyl group. Unlike all the earlier reactions, this is a reversible step but tends to favor testosterone.

Although estrogens are only minor products of testicular steroidogenesis, they are normally found in low concentrations in men. The action of the enzyme complex aromatase (CYP19) converts androgens (C19) to estrogens (C18). Aromatization involves the removal of the methyl group in position 19 and the rearrangement of ring A into an unsaturated aromatic ring. The products of aromatization of testosterone and androstenedione are estradiol and estrone, respectively (see Fig. 36.9). In the testis, the Sertoli cell is the main site of aromatization, which is stimulated by FSH; however, aromatization may also occur in peripheral tissues that lack FSH receptors (e.g., adipose tissue).

cAMP regulates LH that, in turn, regulates the number of Leydig cells.

The action of LH on Leydig cells is mediated through specific LH receptors on the plasma membrane. A Leydig cell has about 15,000 LH receptors, and occupancy of <5% of these is sufficient for maximal steroidogenesis. This is an example of “spare receptors” (see Chapter 30). Excess receptors increase target cell sensitivity to low circulating hormones by increasing the probability that sufficient receptors will be occupied to induce a response. After exposure to a high LH concentration, the number of LH receptors and testosterone decrease. However, in response to the initial high LH, testosterone will increase and then decrease. Thereafter, subsequent challenges with LH lead to no response or decreased responses. This so-called *desensitization* involves a loss of surface LH receptors as a result of internalization and receptor modification by phosphorylation.

The LH receptor is a single 93-kDa G protein–coupled receptor. LH receptor binding results in the activation of G_s, increased adenylyl cyclase activity, the production of cAMP, and the activation of PKA (Fig. 36.10). Low doses of LH can stimulate testosterone production without detectable changes in total cell cAMP concentration. However, the amount of cAMP bound to the regulatory subunit of PKA increases in response to such low doses of LH. This response emphasizes the importance of compartmentalization for both enzymes and substrates in mediating hormonal action. Other mediators, such as the phosphatidylinositol or calcium, have roles in regulating Leydig cell steroidogenesis, but it appears that the PKA pathway may predominate.

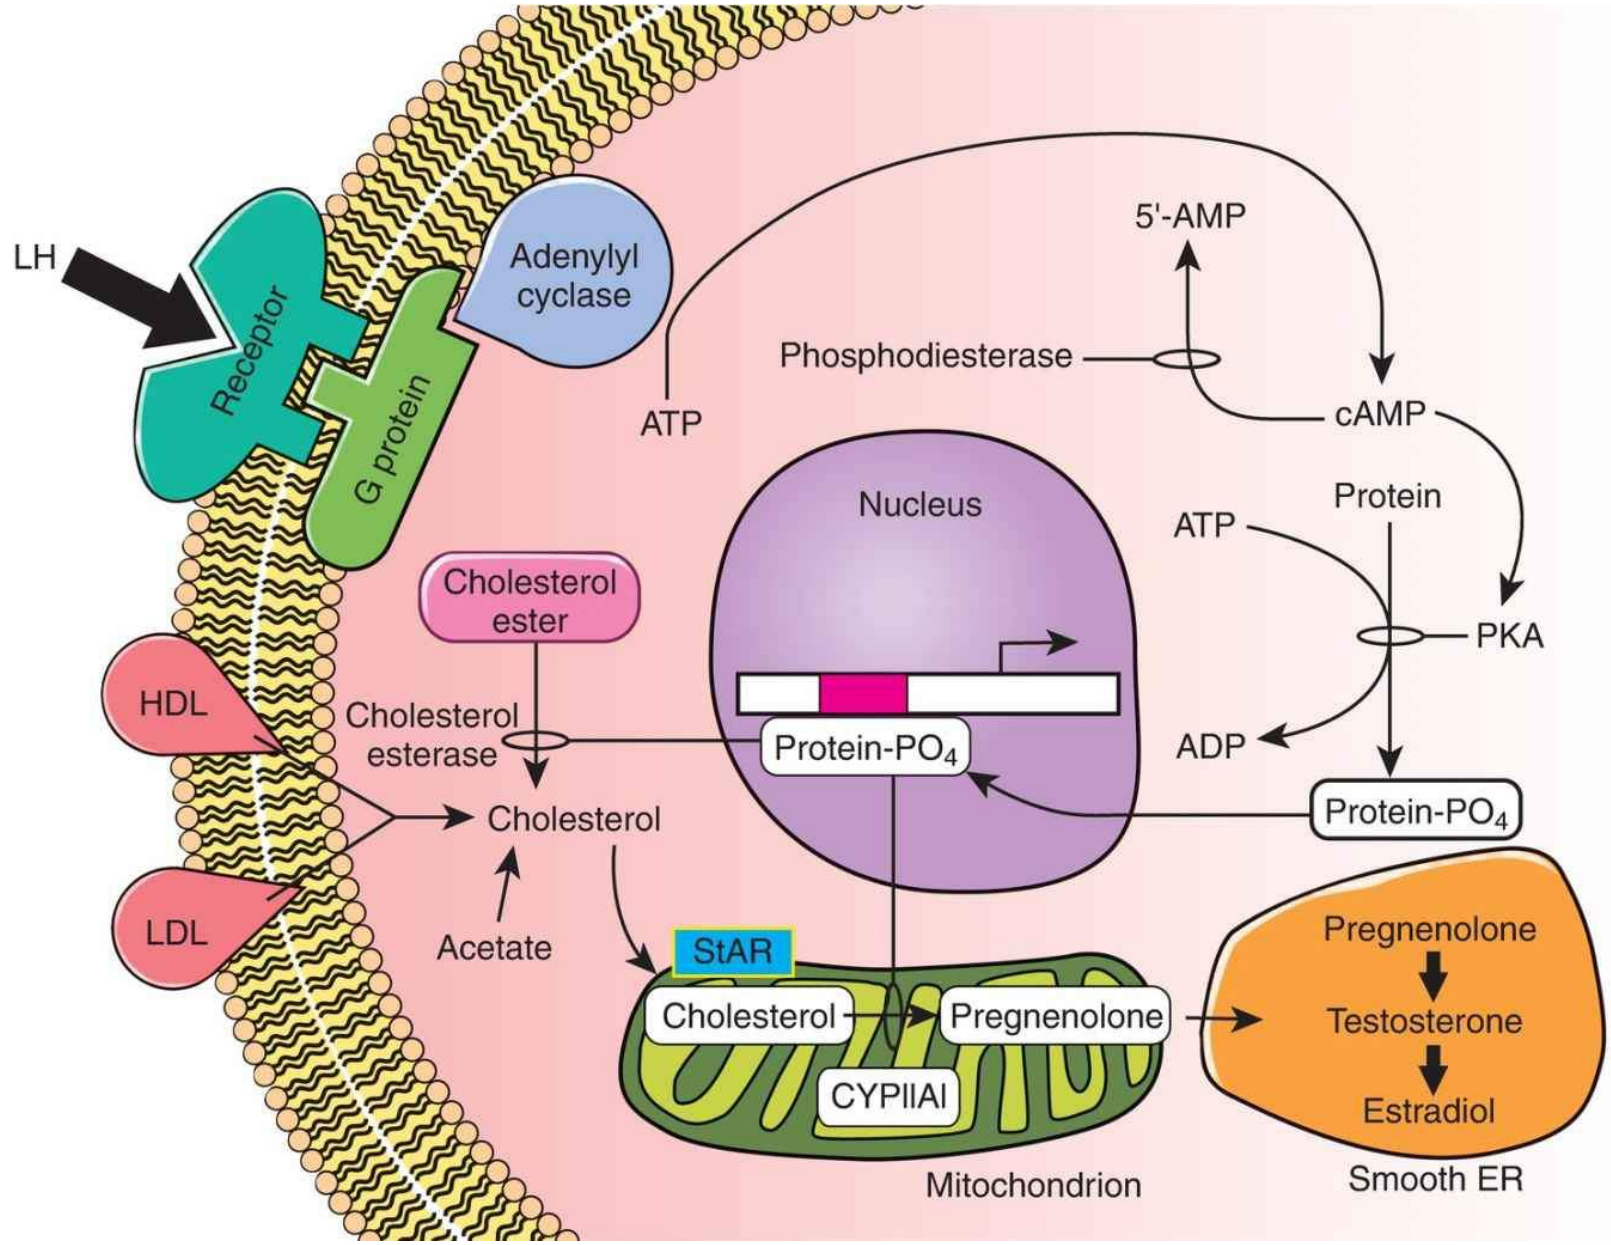

Figure 36.10 A proposed intracellular mechanism by which luteinizing hormone stimulates testosterone synthesis. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; ER, endoplasmic reticulum; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; PKA, protein kinase A; StAR, steroidogenic acute regulatory protein.

The proteins phosphorylated by PKA are specific for each cell type. Some of these, such as CREB, which functions as a DNA-binding protein, regulate the transcription of cholesterol side-chain cleavage enzyme (CYP11A1), the rate-limiting enzyme in the conversion of cholesterol to pregnenolone. **Phosphodiesterase** inactivates cAMP to AMP. This enzyme plays a major role in regulating LH (and, possibly, FSH) responses because gonadotropin stimulation activates phosphodiesterase. The increase in phosphodiesterase reduces the response to LH (and FSH). Certain drugs can inhibit phosphodiesterase; gonadotropin hormone responses will increase dramatically in the presence of those drugs.

LH stimulates steroidogenesis by two principal activations. One is the phosphorylation of cholesterol esterase, which releases cholesterol from its intracellular stores. The other is the activation of CYP11A1.

Leydig cells also contain receptors for **prolactin** (**PRL**). Hyperprolactinemia in men with pituitary tumors, usually microadenomas, is associated with decreased testosterone levels. This condition is a

result of a direct effect of elevated circulating levels of PRL on Leydig cells, reducing the number of LH receptors or inhibiting downstream signaling events. In addition, hyperprolactinemia may decrease LH secretion by reducing the pulsatile nature of its release. Under nonpathologic conditions, however, PRL may synergize with LH to stimulate testosterone production by increasing the number of LH receptors.

ANDROGEN ACTION AND MALE DEVELOPMENT

DHT enhances development of the male reproductive tract, accompanying accessory ducts and glands, and male sex characteristics, including behavior. A lack of androgen secretion or action causes feminization.

Testosterone is not stored but circulated and metabolized by peripheral tissue.

Testosterone diffuses into the blood immediately after being synthesized in Leydig cells. An adult male produces 6 to 7 mg of testosterone per day. This amount slowly declines after age 50 and reaches about 4 mg/d in the seventh decade of life. Therefore, men do not undergo a sudden cessation of sex steroid production on aging as women do during their postmenopausal period when the ova are completely depleted.

Testosterone circulates bound to plasma proteins, with only 2% to 3% present as the free hormone. About 30% to 40% is bound to albumin and the remainder to SHBG that binds both estradiol and testosterone with a higher binding affinity for testosterone. Because its production is increased by estrogens and decreased by androgens, plasma SHBG concentration is higher in women than in men. SHBG serves as a reservoir for testosterone, and therefore, a sudden decline in newly formed testosterone may not be evident because of the large pool bound to proteins. SHBG, in effect, deactivates testosterone because only the unbound hormone can enter the cell. It also prolongs the half-life of circulating testosterone because testosterone is cleared from the circulation much more slowly if bound to a protein. Any type of liver damage or disease will generally reduce SHBG production. The latter can upset the hormonal balance between LH and testosterone. For example, if SHBG declines acutely, then free testosterone may increase, while the total amount of circulating testosterone would decrease. In response to the increase in free testosterone, LH levels would decline in a homeostatic attempt to reduce testosterone production.

Once testosterone is released into the circulation, its fate is variable. In most target tissues, testosterone functions as a prohormone and is converted to the biologically active derivatives DHT by **5α-reductase** or estradiol by aromatase (Fig. 36.11). Skin, hair follicles, and most of the male reproductive tract contain an active 5α-reductase. The enzyme irreversibly catalyzes the reduction of the double bond in ring A and generates DHT (see Fig. 36.9). DHT has a high binding affinity for the androgen receptor and is two to three times more potent than testosterone.

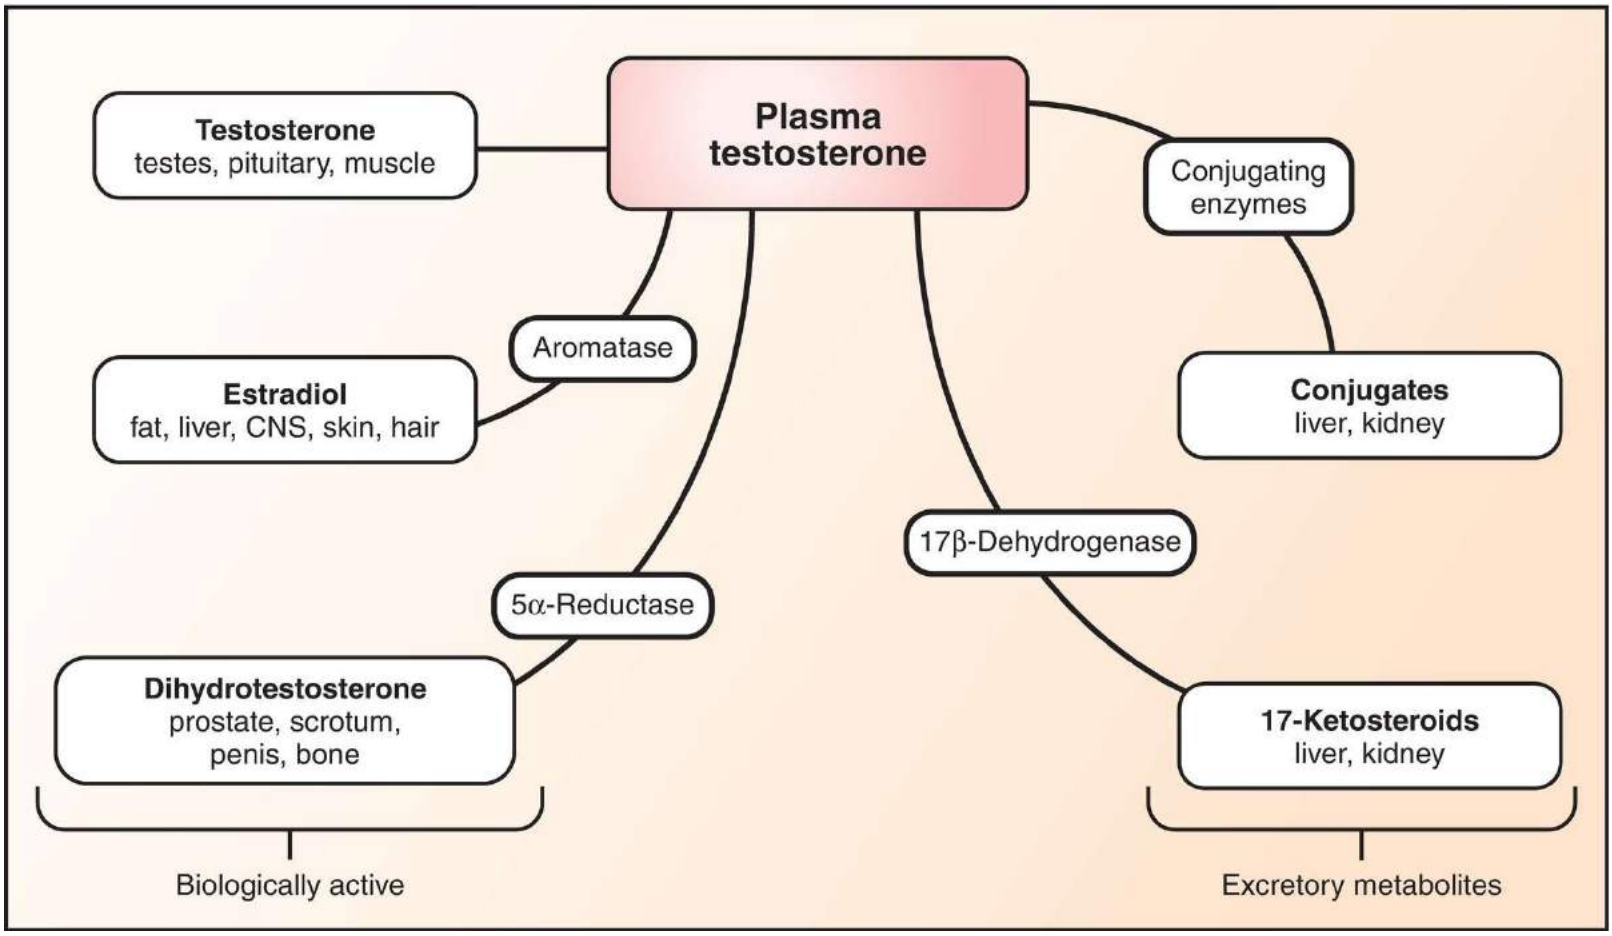

Figure 36.11 Conversion of testosterone to different products in extratesticular sites. CNS, central nervous system.

Congenital deficiency of 5α-reductase in males results in ambiguous genitalia containing female and male characteristics, because DHT is critical for directing the normal development of male external genitalia during embryonic life (see Chapter 38). Without DHT, the female pathway may predominate, even though the genetic sex is male and small, undescended testes are present in the inguinal region. DHT is nonaromatizable and cannot be converted to estrogens.

Drugs that inhibit 5α-reductase are currently used to reduce prostatic hypertrophy because DHT induces hyperplasia of prostatic epithelial cells. In addition, analogs of GnRH, as either agonists or antagonists, can be given to patients to reduce the secretion of androgen in androgen-dependent neoplasia or cancer. In the case of the GnRH antagonist, this analog blocks the secretion of LH. In contrast, GnRH agonists given in large quantities initially induce the secretion of LH (and androgen). However, GnRH receptor down-regulation on the pituitary gonadotrophs ensues, and this results in a decline in circulating LH and androgen.

Aromatization of some androgens to estrogens occurs in fat, liver, skin, and brain cells. Circulating levels of total estrogens (estradiol plus estrone) in men can approach those in women in their early follicular phase. Men are protected from feminization as long as production of and tissue responsiveness to androgens are normal. The treatment of hypogonadal male patients with high doses of aromatizable testosterone analogs (or testosterone), the use of anabolic steroids by athletes, abnormal reductions in testosterone secretion, estrogen-producing testicular tumors, and tissue insensitivity to androgens can lead to **gynecomastia** or breast enlargement. All of these conditions are characterized by a decrease in the testosterone/estradiol ratio.

Androgens are metabolized in the liver to biologically inactive water-soluble derivatives suitable for

excretion by the kidneys. The major products of testosterone metabolism are two 17-ketosteroids, androsterone and etiocholanolone. These, as well as native testosterone, are conjugated in position 3 to form sulfates and glucuronides, which are water soluble, and excreted into the urine (see Fig. 36.11).

Androgens target both reproductive and nonreproductive tissues.

An **androgen** is a substance that stimulates the growth of the male reproductive tract and the development of secondary sex characteristics. Androgens have effects on almost every tissue, including alteration of the primary sex structures (i.e., the testes and genital tract), stimulation of the secondary sex structures (i.e., accessory glands), and development of secondary sex characteristics responsible for masculine phenotypic expression. Androgens also affect both sexual and nonsexual behavior. The relative potency ranking of androgens is as follows: DHT > testosterone > androstenedione > DHEA. The action of sex steroid hormones on somatic tissue, such as muscle, is referred to as "anabolic" because the end result is increased muscle size. The same molecular mechanisms that result in virilization mediate this action.

Between 8 and 18 weeks of fetal life, androgens mediate differentiation of the male genitalia. Testosterone, which reaches these target tissues by diffusion rather than by a systemic route, directly influences the organogenesis of the wolffian (mesonephric) ducts into the epididymis, vas deferens, and seminal vesicles. The differentiation of the urogenital sinus and the genital tubercle into the penis, scrotum, and prostate gland depends on testosterone being converted to DHT. Toward the end of fetal life, testosterone and insulin-like hormones from Leydig cells promote the descent of the testes into the scrotum (see Chapter 38).

Enhanced androgenic activity marks the onset of puberty. Androgens promote the growth of the penis and scrotum, stimulate the growth and secretory activity of the epididymis and accessory glands, and increase the pigmentation of the genitalia. Enlargement of the testes occurs under the influence of LH and FSH. Spermatogenesis depends on adequate amounts of testosterone. Throughout adulthood, androgens are responsible for maintaining the structural and functional integrity of all reproductive tissues. Castration of adult men results in regression of the reproductive tract and involution of the accessory glands (Clinical Focus 36.1).

CLINICAL FOCUS 36.1

Prostate Cancer

Some prostate cancers highly depend on androgens for cellular proliferation; therefore, physicians attempt to totally ablate the secretion of androgens by the testes. Generally, two options for those patients are surgical castration and chemical castration. Surgical castration is irreversible and requires the removal of the testes, whereas chemical castration is reversible.

One option for chemical treatment of these patients is the use of analogs of gonadotropin-releasing hormone (GnRH), the hormone that regulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Long-acting GnRH agonists or antagonists reduce LH and FSH secretion by different mechanisms. GnRH agonists reduce gonadotropin secretion by desensitization of the pituitary gonadotrophs to GnRH, leading to a reduction of LH and FSH secretion. GnRH agonists initially stimulate GnRH receptors on pituitary cells but ultimately reduce their numbers. GnRH antagonists bind to GnRH receptors on the pituitary cells, prevent endogenous GnRH from binding to those receptors, and subsequently reduce LH and FSH secretion. Shortly after treatment, testicular

concentrations of androgens decline because of the low levels of circulating LH and FSH. The expectation is that androgen-dependent cancer cells will cease or slow proliferation and, ultimately, die.

GnRH agonists (leuprolide acetate [trade name, Lupron]) are usually used in combination with other drugs to block most effectively androgenic activity. For example, one of the androgen-blocking drugs includes 5α-reductase inhibitors that prevent the conversion of testosterone to the highly active androgen dihydrotestosterone. In addition, antiandrogens, such as flutamide, bind to the androgen receptor and prevent binding of endogenous androgen. Some prostate cancers are androgen independent, and the treatment requires nonhormonal therapies, including chemotherapy and radiation. ■

Androgens are responsible for secondary sex characteristics and masculinity.

Androgens effect changes in hair distribution, skin texture, pitch of the voice, bone growth, and muscle development. Hair is classified by its sensitivity to androgens into the following: nonsexual (eyebrows and extremities); ambisexual (axilla), which is responsive to low levels of androgens; and sexual (face, chest, and upper pubic triangle), which is responsive only to high androgen levels. Hair follicles metabolize testosterone to DHT or androstenedione. Androgens stimulate the growth of facial, chest, and axillary hair; however, along with genetic factors, they also promote temporal hair recession and loss. Normal axillary and pubic hair growth in women is also under androgenic control, whereas excess androgen production in women causes the excessive growth of sexual hair (**hirsutism**).

The growth and secretory activity of the sebaceous glands on the face, upper back, and chest are stimulated by androgens, primarily DHT, and inhibited by estrogens. Increased sensitivity of target cells to androgenic action, especially during puberty, is the cause of **acne vulgaris** in both males and females. Skin derived from the urogenital ridge (e.g., the prepuce, scrotum, clitoris, and labia majora) remains sensitive to androgens throughout life and contains an active 5α-reductase. Growth of the larynx and thickening of the vocal cords are also androgen dependent. Eunuchs maintain the high-pitched voice typical of prepubertal boys because they were castrated prior to puberty.

A complex interplay between androgens, GH, nutrition, and genetic factors influences the growth spurt of adolescent males. The growth spurt includes growth of the vertebrae, long bones, and shoulders. The mechanism by which androgens (likely DHT) alter bone metabolism is unclear. Androgens accelerate closure of the epiphyses in the long bones, eventually limiting further growth. Because of the latter, precocious puberty is associated with a final short adult stature, whereas delayed puberty or eunuchoidism usually results in tall stature. Androgens have multiple effects on skeletal and cardiac muscle. Because 5α-reductase activity in muscle cells is low, the androgenic action is a result of testosterone. Testosterone stimulates muscle hypertrophy, increasing muscle mass; however, it has minimal or no effect on muscle hyperplasia. Testosterone, in synergy with GH, causes a net increase in muscle protein.

Androgens affect, directly or indirectly, other nonreproductive organs and systems, including the liver, kidneys, adipose tissue, and hematopoietic and immune systems. The kidneys are larger in males, and androgens induce some renal enzymes (e.g., β-glucuronidase and ornithine decarboxylase). HDL levels are lower and triglyceride concentrations higher in men, compared with premenopausal women, a fact that may explain the higher prevalence of atherosclerosis in men. Androgens increase red blood cell mass (and, hence, hemoglobin levels) by stimulating erythropoietin production and by increasing stem cell proliferation in the bone marrow.

Androgen is involved in sexual differentiation of the brain.

Many sites in the brain contain androgen receptors, with the highest density in the hypothalamus, preoptic area, septum, and amygdala. Most of those areas also contain aromatase, and many of the androgenic actions in the brain result from the aromatization of androgens to estrogens. The pituitary also has abundant androgen receptors, but no aromatase. The enzyme 5α-reductase is widely distributed in the brain, but its activity is generally higher during the prenatal period than in adults. Sexual dimorphism in the size, number, and arborization of neurons in the preoptic area, amygdala, and superior cervical ganglia has been recently recognized in humans.

Unlike most species, which mate only to produce offspring, in humans, sexual activity and procreation are not tightly linked. Superimposed on the basic reproductive mechanisms dictated by hormones are numerous psychological and societal factors. In normal men, no correlation is found between circulating testosterone levels and sexual drive, frequency of intercourse, or sexual fantasies. Similarly, there is no correlation between testosterone levels and impotence or homosexuality. Castration of adult men results in a slow decline in, but not a complete elimination of, sexual interest and activity.

MALE REPRODUCTIVE DISORDERS

Male reproductive dysfunctions may be caused by endocrine disruption, morphologic alterations in the reproductive tract, neuropathology, and genetic mutations. Several medical tests, including serum hormone levels, physical examination of the reproductive organs, and sperm count, are important in ascertaining causes of reproductive dysfunctions.

Hypogonadism leads to decreased functional activity of the gonads.

Male **hypogonadism** may result from defects in spermatogenesis, steroidogenesis, or both. It may be a primary defect in the testes or secondary to hypothalamic–pituitary dysfunction. Determining whether the onset of gonadal failure occurred before or after puberty is important in establishing the cause. However, several factors must be considered. First, normal spermatogenesis almost never occurs with defective steroidogenesis, but normal steroidogenesis can be present with defective spermatogenesis. Second, primary testicular failure removes feedback inhibition from the hypothalamic–pituitary axis, resulting in elevated plasma gonadotropins. In contrast, decreased gonadotropin and steroid levels and reduced testicular size almost always accompany hypothalamic and/or pituitary failure. Third, gonadal failure before puberty results in the absence of secondary sex characteristics, creating a distinctive clinical presentation called **eunuchoidism**. In contrast, men with a postpubertal testicular failure retain masculine features but exhibit low sperm counts or a reduced ability to produce functional sperm.

To establish the cause(s) of reproductive dysfunction, physical examination and medical history, semen analysis, hormone determinations, hormone stimulation tests, and genetic analysis are performed. Physical examination should establish whether eunuchoidal features (i.e., infantile appearance of external genitalia and poor or absent development of secondary sex characteristics) are present. In men with adult-onset reproductive dysfunction, physical examination can uncover problems such as *cryptorchidism* (nondescendent testes), testicular injury, *varicocele* (an abnormality of the spermatic vasculature), testicular tumors, prostatic inflammation, or gynecomastia. Medical and family history help determine delayed puberty, anosmia (an inability to smell, often associated with GnRH dysfunction), previous fertility, changes in sexual performance, ejaculatory disturbances, or impotence.

One step in the evaluation of fertility is semen analysis. Semen is analyzed on specimens collected after 3 to 5 days of sexual abstinence, as the number of sperm ejaculated remains low for a couple of days after ejaculation. Initial examination includes determination of viscosity, liquefaction, and semen volume. The sperm are then counted, and the percentage of sperm showing forward motility is scored. The spermatozoa are evaluated morphologically, with attention to abnormal head configuration and defective tails. Chemical analysis can provide information on the secretory activity of the accessory glands, which is considered abnormal if semen volume is too low or sperm motility is impaired. Fructose and prostaglandin levels are determined to assess the function of the seminal vesicles and levels of zinc, magnesium, and acid phosphatase to evaluate the prostate. Terms used in evaluating fertility include aspermia (no semen), hypospermia and hyperspermia (too small or too large semen volume), azoospermia (no spermatozoa), and oligozoospermia (reduced spermatozoa).

Serum testosterone, estradiol, LH, and FSH analyses are performed using radioimmunoassays. Free and total testosterone levels should be measured; because of the pulsatile nature of LH release, several consecutive blood samples are needed. Dynamic hormone stimulation tests are most valuable for establishing the site of abnormality. A failure to increase LH release on treatment with **clomiphene**, an antiestrogen, likely indicates a hypothalamic abnormality. Clomiphene blocks the inhibitory effects of estrogen and testosterone on endogenous GnRH release. An absence of or blunted rise in testosterone after hCG injection suggests a primary testicular defect. Genetic analysis is used when congenital defects are suspected. Karyotyping of cultured peripheral lymphocytes or direct detection of specific Y antigens on cell surfaces can reveal the presence of the Y chromosome.

Hypogonadism or hypergonadism account for most male reproductive disorders.

Endocrine factors are responsible for ~50% of hypogonadal or infertility cases. Those remaining are of unknown etiology or the result of injury, deformities, and environmental factors. Endocrine-related hypogonadism can be classified as hypothalamic–pituitary defects (hypogonadotropic because of the lack of LH and/or FSH), primary gonadal defects (hypergonadotropic because gonadotropins are high as a result of a lack of negative feedback from the testes), and defective androgen action (usually the result of absence of androgen receptors or 5α-reductase). Each of these is further subdivided into several categories, but only a few examples are discussed here.

Hypogonadotropic hypogonadism can be congenital, idiopathic, or acquired. The most common congenital form is Kallmann syndrome, which results from decreased or absent GnRH secretion, as mentioned earlier. It is often associated with anosmia or hyposmia and is transmitted as an autosomal dominant trait. Patients do not undergo pubertal development and have eunuchoidal features. Plasma LH, FSH, and testosterone levels are low, and the testes are immature and have no sperm. There is no response to clomiphene, but intermittent treatment with GnRH can produce sexual maturation and full spermatogenesis.

Another category of hypogonadotropic hypogonadism, **panhypopituitarism** or pituitary failure, can occur before or after puberty and is usually accompanied by a deficiency of other pituitary hormones. **Hyperprolactinemia**, whether from hypothalamic disturbance or pituitary adenoma, often results in decreased GnRH production, hypogonadotropic state, impotence, and decreased libido. It can be treated with dopaminergic agonists (e.g., bromocriptine), which suppress PRL release (see Chapter 37). Excess androgens can also result in suppression of the hypothalamic–pituitary axis, resulting in lower LH levels and impaired testicular function. This condition often results from **congenital adrenal hyperplasia** and increased adrenal androgen production from 21-hydroxylase (CYP21A2) deficiency (see Chapter 33).

Hypergonadotropic hypogonadism usually results from impaired testosterone production, which can be congenital or acquired. The most common disorder is Klinefelter syndrome, as discussed earlier (Clinical Focus 36.2).

CLINICAL FOCUS 36.2

Effects of Testosterone Administration

Although testosterone has a role in stimulating spermatogenesis, infertile men with a low sperm count do not benefit from testosterone treatment. Unless given at supraphysiologic doses, exogenous testosterone cannot achieve the required local high concentration in the testis. One function of androgen-binding protein in the testis is to sequester testosterone, which significantly increases its local concentration.

Exogenous testosterone given to men would normally inhibit endogenous luteinizing hormone (LH) release through a negative feedback effect on the hypothalamic–pituitary axis and lead to a suppression

of testosterone production by Leydig cells and a further decrease in testicular testosterone concentrations. Ultimately, because LH levels decrease when exogenous testosterone is administered, testicular size decreases, as has been reported for men who abuse androgens.

High androgens have an anabolic effect on muscle tissue, leading to increased muscle mass, strength, and performance, a desired result for bodybuilders and athletes. Androgen abuse has been associated with abnormally aggressive behavior and the potential for increased incidence of liver and brain tumors. ■

Pseudohermaphroditism is a reproductive paradox that results from insensitivity to androgens.

Pseudohermaphroditism produces gonads of one sex and the genitalia of the other in the same person. The term male pseudohermaphrodite is used when a testis is present, and the term female pseudohermaphrodite is used when an ovary is present. The term hermaphrodite is reserved for the very rare cases in which both ovarian and testicular tissues are present. One of the most interesting causes of male reproductive abnormalities is the insensitivity of the end organ to androgens. The best characterized syndrome is testicular feminization, an X-linked recessive disorder caused by a defect in the testosterone receptor. In the classical form, patients are male pseudohermaphrodites with a female phenotype and an XY male genotype. They have abdominal testes that secrete testosterone but no other internal genitalia of either sex (see Chapter 38). They commonly have female external genitalia but with a short vagina ending in a blind pouch. Breast development is typical of a female (as a result of peripheral aromatization of testosterone), but axillary and pubic hair, which are androgen dependent, are scarce or absent. Testosterone levels are normal or elevated, estradiol levels are above the normal male range, and circulating gonadotropin levels are high. The inguinally located testes usually have to be removed because of an increased risk of cancer. After orchiectomy, patients are treated with estradiol to maintain a female phenotype.

INTEGRATED MEDICAL SCIENCES

Male Infertility and a Potential Ring of Concern

An active area of bench research is aimed at better understanding the cause of male infertility with an underlying goal of improving semen quality and chances of pregnancy. It is estimated that infertility affects one in every six couples who are trying to conceive, with about half of the cases resulting from the inability of the male to initiate pregnancy. Causes of male infertility include abnormal sperm production or function, impaired delivery of sperm, general health and lifestyle issues, and exposure to certain environmental factors. Of new concern are findings that a modern day environmental factor, the cell phone, commonly carried close to the testicles (i.e., in a trouser pocket or clipped to a waist belt) can reduce a male's fertilizing potential.

Recent studies have highlighted that spermatozoa of infertile men have higher levels of DNA damage, which adversely affects the ability of spermatozoa to reach, recognize, and fertilize an egg. Mechanistically, a key contributing factor of DNA damage in spermatozoa appears to be oxidative stress. Oxidative stress results from an imbalance of **reactive oxygen species** (**ROS**) and antioxidants. Immature spermatozoa with residual cytoplasm produce ROS by having excess nicotinamide adenine diphosphate hydrogen generated via glucose-6-phosphate dehydrogenase. Countering the harmful effect of excess ROS production are antioxidants that are present in normal, healthy seminal ejaculates.

Findings suggesting that electromagnetic waves (EMWs) emitted from cell phones may negatively impact the ROS/antioxidant balance in semen represent a new, modern-day concern. In a large

prospective study, conducted by researchers at the Cleveland Clinic, the effects of EMWs emitted by cell phones (900 to 1,900 MHz) on various markers of sperm quality, such as count, motility, morphology, and viability, were assessed. These studies revealed that exposure of ejaculated semen samples to commercially available cell phones for 1 hour caused a significant decrease in sperm motility and viability, increased ROS levels, and decreased ROS–total antioxidant capacity score when compared with neat semen from a nonexposed group.

As importantly noted by this research team, many men carry their cell phones in a trouser pocket (or clipped to a waist belt) exposing testes to high-power cell phone density. As the effects of frequency, distance of the phone from the source, and the duration of talk time on spermatozoa are not known, current investigations by these researchers are now employing a two-dimensional anatomical model of the tissue to extrapolate the effects seen in *in vitro* condition to real-life conditions. ■

Chapter Summary

- In the testes, LH controls the synthesis of testosterone by Leydig cells, and FSH increases the production of androgen-binding protein, inhibin, and estrogen by Sertoli cells.
- Spermatozoa are produced within the seminiferous tubules of both testes. Sperm develop from spermatogonia through a series of developmental stages that include spermatocytes and spermatids.
- The sperm mature and are stored in the epididymis. At the time of ejaculation, muscular contractions of the epididymis and vas deferens move sperm through the ejaculatory ducts into the prostatic urethra. The sperm are finally moved out of the body through the urethra in the penis.
- GnRH controls LH and FSH secretion by the anterior pituitary.
- Testosterone mainly reduces LH secretion, whereas inhibin reduces the secretion of FSH. The testicular hormones complete a negative feedback loop with the hypothalamic–pituitary axis.
- Androgens have several target organs and have roles in regulating the development of secondary sex characteristics, the libido, and sexual behavior.
- The most potent natural androgen is DHT that 5α-reductase produces from testosterone.
- Male reproductive dysfunction is often a result of a lack of LH and FSH secretion or abnormal testicular morphology.

Chapter Review Questions

1. A major causal factor in some cases of hypogonadism is:
- **A.** reduced secretion of gonadotropin-releasing hormone (GnRH).
- **B.** hypersecretion of pituitary LH and FSH as the result of increased GnRH.
- **C.** excess secretion of testicular activin by Sertoli cells.
- **D.** failure of the hypothalamus to respond to testosterone.
- **E.** increased number of FSH receptors in the testis.

The correct answer is A. Reduced secretion of GnRH will result in extremely low levels of circulating LH and FSH, causing testicular atrophy, as in Kallmann syndrome. Hypersecretion of LH and FSH, increased activin, and an increased number of FSH receptors all lead to hyperfunction of the testis, not hypofunction. A failure of the hypothalamus to respond to testosterone increases LH, leading to increased Leydig cell androgens and testicular hypertrophy.

2. The major function of follistatin is to:
- **A.** bind FSH and increase FSH secretion.
- **B.** inhibit the production of seminal fluid.
- **C.** reduce testosterone secretion by Leydig cells.
- **D.** stimulate the production of spermatogonia.
- **E.** bind activin and thus decrease FSH secretion.

The correct answer is E. Follistatin is a binding protein for activin. Activin cannot increase FSH secretion when follistatin is bound to it, so FSH secretion decreases. Follistatin does not bind FSH, does not inhibit seminal fluid production and Leydig cell testosterone secretion, and does not stimulate the production of spermatogonia.

3. A major function of the epididymis is:
- **A.** storage and transport of mature sperm.
- **B.** initiating the development of spermatozoa.
- **C.** secretion of estrogens.
- **D.** production of inhibin.
- **E.** secretion of fluids that contribute to semen.

The correct answer is A. The epididymis and vas deferens are major storage sites of spermatozoa. Spermatozoa develop in the seminiferous tubules. Sertoli cells, not the epididymis, secrete estrogens and inhibin. The prostate gland, seminal vesicles, and bulbourethral glands secrete the seminal fluids.

Clinical Application Exercises 36.1

SEXUAL DEVELOPMENT

A 20-year-old male patient presented with lack of sexual development. On examination, he was eunuchoidal and hypogonadal, and olfactory function testing showed he was anosmic. Biochemical investigations proved he was hypogonadotropic. His appearance was very different from his alleged identical twin who had undergone a normal puberty and had normal plasma testosterone and gonadotropin levels. However, the twin was hyposmic. Genetic fingerprinting confirmed the twins were identical. Why the syndrome was incompletely expressed in one of them is unexplained. The

parents and a normally menstruating sister had normal olfactory function.

QUESTIONS

1. What is the syndrome afflicting the one twin brother?
2. What is the basis for the low gonadotropin levels?

ANSWERS

1. Kallmann syndrome
2. This syndrome results from decreased or absent GnRH secretion. It is often associated with anosmia or hyposmia and is transmitted as an autosomal dominant trait. Patients do not undergo pubertal development and have eunuchoidal features. Plasma LH, FSH, and testosterone levels are low, and the testes are immature and have no sperm.

37 Female Reproductive System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain the mechanism through which pulses of hypothalamic gonadotropin-releasing hormone regulate secretion of luteinizing hormone and follicle-stimulating hormone and the effect of these two gonadotropins on follicular development, steroidogenesis, ovulation, and formation of the corpus luteum.
- Describe how luteinizing hormone and follicle-stimulating hormone, in coordination with ovarian theca and granulosa cells, regulate the secretion of follicular estradiol.
- Explain how positive feedback of follicular estradiol on the hypothalamic–pituitary axis induces luteinizing hormone and follicle-stimulating hormone surges and causes ovulation.
- Outline the sequence of distinct steps in follicular development including how appropriately timed luteinizing hormone and follicle-stimulating hormone surges, which induce inflammatory reactions in the graafian follicle, lead to follicular rupture and ovulation.
- Predict the effect of gonadotropin suppression on follicular development.
- List the hormones required for the formation of a functional corpus luteum.
- Describe the effects of estradiol and progesterone on the endometrial cycle.
- Describe the changes in hypothalamic secretory function at the onset of puberty that increase luteinizing hormone and follicle-stimulating hormone secretion, enhance ovarian function, and lead to the first ovulation.
- Explain the mechanism that results in menopause and describe the medical complications of this state for older women.

The fertility of a women is cyclic, with the release of a mature ovum approximately once per month. Pulsatile secretion of **luteinizing hormone** (**LH**) and **follicle-stimulating hormone** (**FSH**) from the pituitary gland controls the production of ovarian steroid hormones and the release of an ovum during the menstrual cycle. The cyclic changes in steroid hormone secretion from the ovary cause significant changes in the structure and function of the uterus, preparing it for the reception of a fertilized ovum. At different stages of the menstrual cycle, progesterone and estradiol exert negative and positive feedback effects on the hypothalamus and pituitary gonadotrophs, generating the cyclic pattern of LH and FSH release characteristic of the female reproductive system. Hormonal events during the menstrual cycle are delicately synchronized; thus, stress and environmental, psychologic, and social factors can readily affect the menstrual cycle.

HORMONAL REGULATION OF THE FEMALE REPRODUCTIVE SYSTEM

Unlike for men, in whom there is a continuous production of sperm and a constant secretion of testosterone, women experience cyclic swings in the menstrual cycle, ovulation, and secretion of sex hormones. Under normal conditions, these changes follow a 28-day cycle resulting from the interaction of hormones released by the anterior pituitary and ovary. As shown in Figure 37.1, the hypothalamus produces **gonadotropin-releasing hormone** (**GnRH**; also called **luteinizing hormone–releasing hormone** [**LHRH**]), which stimulates the secretion of LH and FSH from the anterior pituitary. Release of GnRH from the hypothalamus is regulated by brain areas that monitor various internal and external signals. LH and FSH regulate ovarian steroidogenesis, which produces **estradiol**, **progesterone**, and **androgen**. The ovarian steroids have positive effects on the reproductive tract and secondary sex characteristics. Ovarian steroids have a negative feedback effect on the ovary to reduce their synthesis and on the anterior pituitary to inhibit LH and FSH secretion. An important exception to the negative feedback effects of ovarian steroids on the anterior pituitary occurs at midcycle, when estradiol has a positive feedback effect on the hypothalamic–pituitary axis to induce significant increases in the secretion of GnRH, LH, and FSH. The ovary also produces three polypeptide hormones that regulate anterior pituitary hormone release. **Inhibin** and **follistatin** (an activin-binding protein) suppress the secretion of FSH, while **activin** (an inhibin-binding protein) increases the secretion of FSH.

Figure 37.1 Hormonal regulation of reproduction in the female. The main reproductive hormones are shown in boxes. Positive regulation is depicted by a plus sign. Negative regulation is depicted by a minus sign. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PRL, prolactin.

The sex steroids in women, estrogen, progesterone, and androgen, are present in and removed from the plasma through the same mechanisms as other steroid hormones (see Chapter 33). Of the three estrogens, estradiol, **estrone**, and **estriol**, estradiol is the most abundant and is many times more potent than estrone and estriol. Estrogens and androgens in the blood are bound to **sex hormone–binding globulin** (**SHBG**) or with lower affinity to **albumin**. Circulating progesterone binds to the plasma protein **corticosteroid-binding protein** (**transcortin**) and also to albumin. Binding proteins prolong the lifetime of the sex steroids, which are eventually cleared from the circulation by the liver, undergoing conversion to glucuronides or sulfates, and then excreted in the urine.

Neurons in the hypothalamus release GnRH in a pulsatile fashion.

GnRH is a decapeptide, produced by neurons in the hypothalamic arcuate nucleus (and preoptic area under specific conditions), which is released in a pulsatile manner into the hypophyseal portal circulation to regulate the secretion of LH and FSH (see Chapter 31). Bursts of GnRH occur about once per hour, and the half-life of the peptide in blood is 2 to 4 minutes; thus, there are clear oscillations in the portal blood GnRH concentration. Other brain areas regulate the pulsatile release of hypothalamic GnRH. Neurotransmitters such as epinephrine and norepinephrine stimulate the secretion of GnRH, whereas dopamine and serotonin inhibit the secretion of GnRH. Ovarian steroids and peptides also regulate the secretion of GnRH.

GnRH stimulates the pituitary gonadotrophs to secrete LH and FSH in a pulsatile manner by binding to high-affinity receptors on the anterior pituitary gonadotrophs to activate phosphoinositide–protein kinase C intracellular signaling. LH release throughout the female life span is depicted in Figure 37.2. During the neonatal period, LH is released at low and steady rates without pulsatility; this period coincides with lack of mature ovarian follicles and low ovarian estradiol secretion. Pulsatile LH release begins with the onset of puberty in response to the start of pulsatile GnRH release. For several years, pulsatile GnRH and LH secretion occurs only during sleep; this period coincides with increased, but asynchronous, ovarian follicular development and increased secretion of estradiol. Upon the establishment of regular functional menstrual cycles that include ovulation, LH pulses occur throughout the 24-hour period, changing in a monthly cyclic manner. Early in the follicular phase of the menstrual cycle (discussed in detail below), pituitary gonadotrophs are not very sensitive to GnRH; thus, LH pulses are small. At midcycle, gonadotrophs become more responsive to GnRH and LH pulses are much larger. In postmenopausal women whose ovaries lack sustained follicular development and exhibit low ovarian estradiol secretion, mean circulating LH rises to levels higher than that during the midcycle surge.

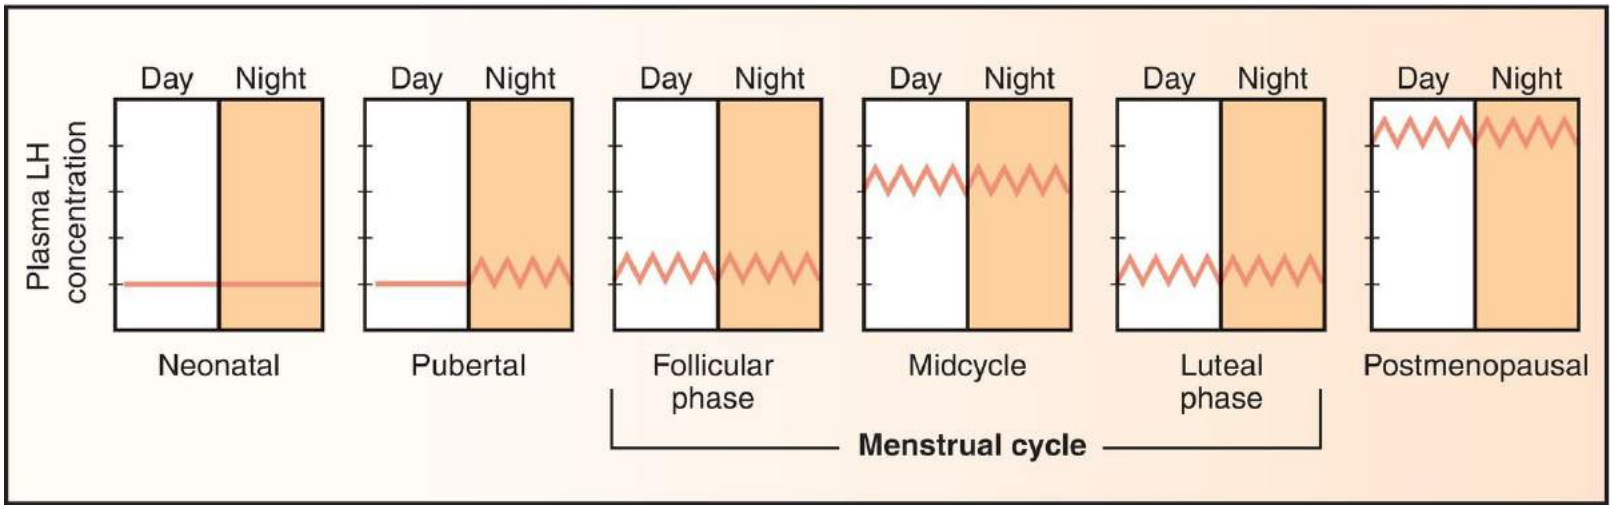

Figure 37.2 Relative levels of luteinizing hormone (LH) release in human females throughout life. Note that pulsatile LH release first begins at night during puberty.

FEMALE REPRODUCTIVE ORGANS

The female reproductive tract has two major components: the ovaries, which produce the mature ovum and secrete progestins, androgens, and estrogens, and the ductal system, which transports the ovum, is the place of the union of the sperm and egg, and maintains the developing conceptus until delivery. The morphology and function of these structures change in a cyclic manner under the influence of the reproductive hormones.

The ovaries are in the pelvic portion of the abdominal cavity on both sides of the uterus and are anchored by ligaments (Fig. 37.3). An adult ovary weighs 8 to 12 g and consists of an outer cortex and an inner medulla, without a sharp demarcation. The cortex contains oocytes enclosed in **follicles** of various sizes, **corpora lutea**, **corpora albicantia**, and stromal cells. The medulla contains stromal cells, connective and interstitial tissues. Blood vessels, lymphatics, and nerves enter the medulla of the ovary through the hilus.

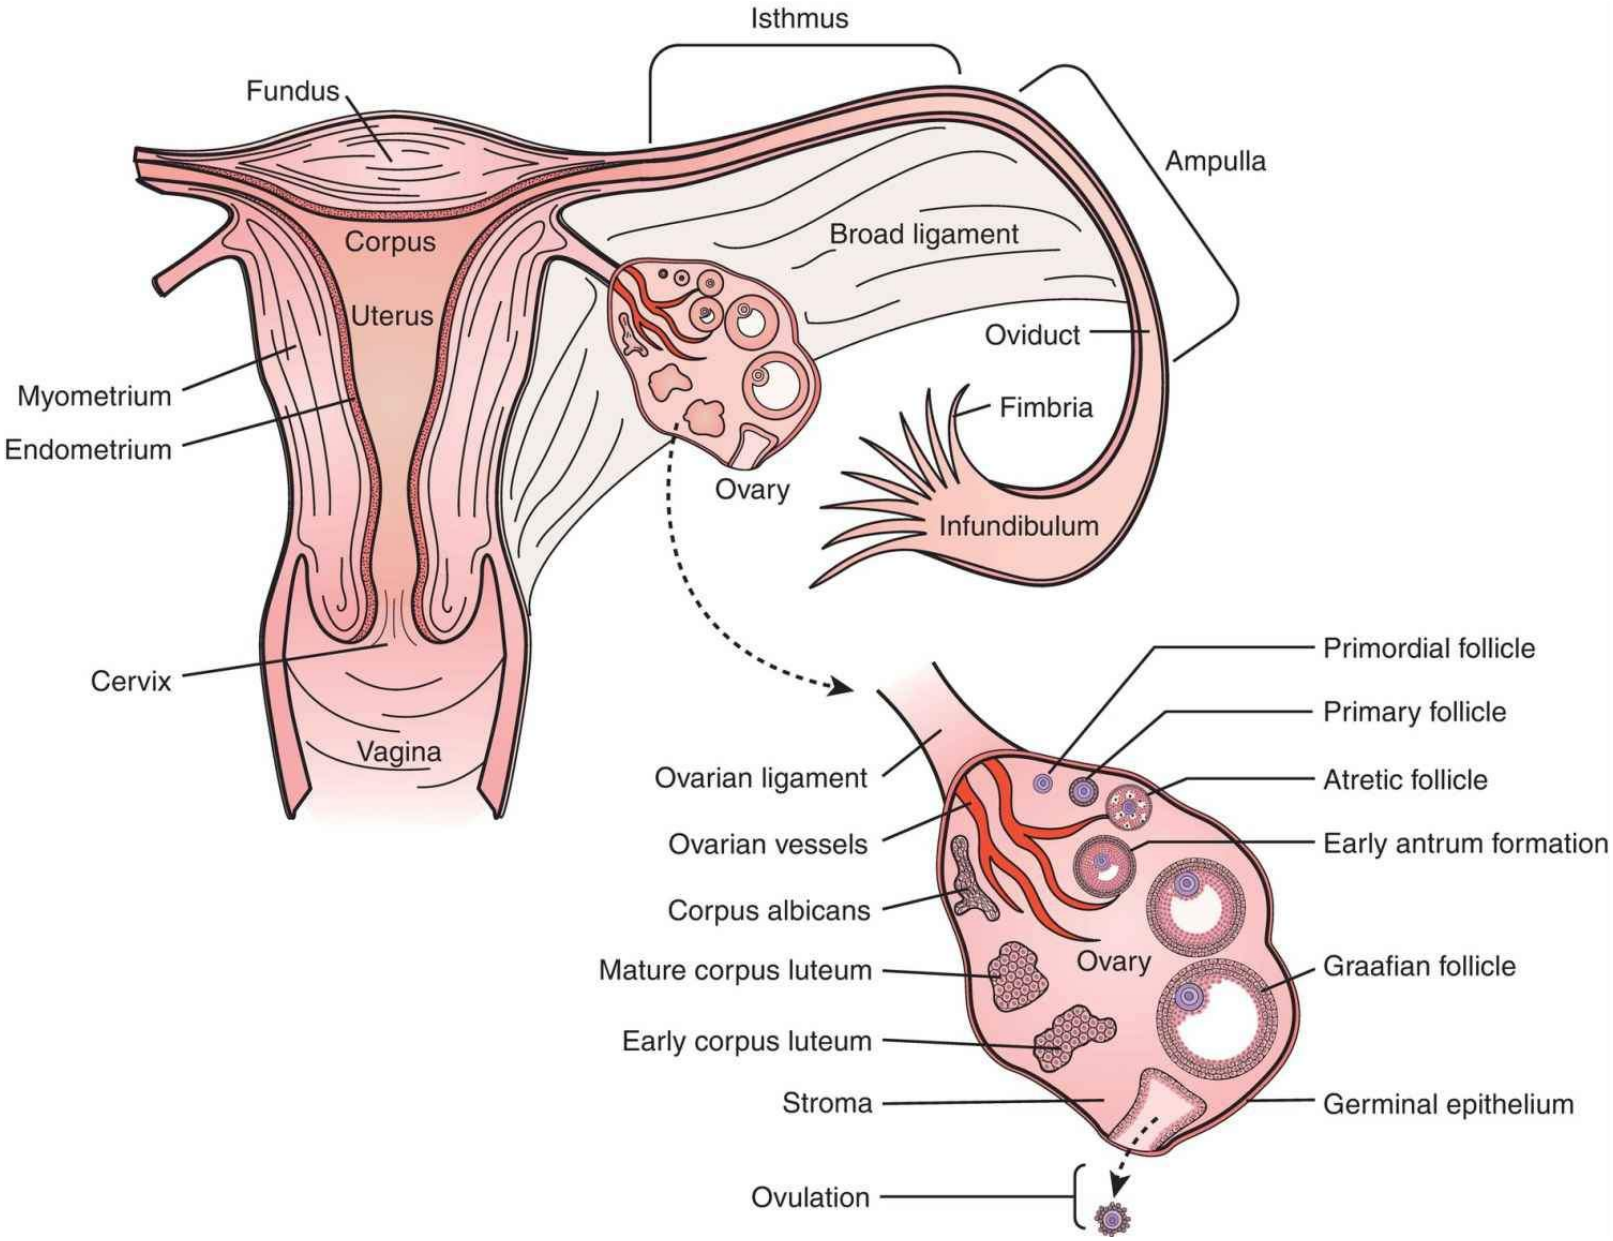

Figure 37.3 Anatomy of the female reproductive organs. (See text for details.)

The **oviduct** (fallopian tube) receives the ovum immediately after ovulation and provides an environment for fertilization and development of the early embryo. The oviducts are 10 to 15 cm long and composed of sequential regions called the **infundibulum**, **ampulla**, and **isthmus**. The infundibulum opens into the peritoneal cavity adjacent to the ovary and with finger-like projections called **fimbria**, grasps the ovum at the time of follicular rupture. Densely ciliated projections cover the walls of infundibulum, which facilitate ovum uptake and movement through this region. Fertilization occurs in the ampulla with its thin musculature and well-developed mucosal surface. The isthmus has a narrow lumen surrounded by smooth muscle that provides sphincter-like properties, which can block the passage of germ cells. The oviducts transport the germ cells in two directions: Sperm ascend toward the ampulla and the zygote descends toward the uterus. This requires coordination between smooth muscle contraction, ciliary movement, and fluid secretion, all of which are under hormonal and neuronal control.

The **uterus** is situated between the urinary bladder and rectum. On each upper side, an oviduct opens into the uterine lumen, and on the lower side, the uterus connects to the vagina. The uterus is composed of two types of tissue: the outer part is the **myometrium**, containing multiple layers of smooth muscle. The inner part lining the lumen of the uterus is the **endometrium**, which contains a deep **stromal layer** next to

the myometrium and a superficial epithelial layer. The stroma is permeated by spiral arteries and contains much connective tissue. Uterine glands present in the stroma and the epithelial layer produce a viscous secretion under the regulation of estrogen and progesterone. The uterus provides an environment for the developing fetus, and eventually, the myometrium will generate rhythmic contractions that assist in expelling the fetus at delivery.

The **cervix** (neck) is a narrow muscular canal that connects the vagina and the body (corpus) of the uterus. It dilates in response to hormones to allow the expulsion of the fetus. The cervix has numerous glands that produce mucus under the control of estradiol. As greater amounts of estradiol are produced during the follicular phase of the cycle, the cervical mucus changes from a scanty viscous material to a profuse, watery, highly elastic substance called **spinnbarkeit**. The viscosity of the spinnbarkeit can be tested by touching it with a piece of paper and lifting vertically. The mucus can form a thread up to 6 cm under the influence of elevated estradiol. If a drop of the cervical mucus is placed on a slide and allowed to dry, it will form a typical **ferning** pattern when under the influence of estradiol.

The **vagina** is well innervated and has a rich blood supply. It is lined by several layers of epithelium that change histologically during the menstrual cycle. When estradiol levels are low, as during the prepubertal and postmenopausal periods, the vaginal epithelium is thin and the secretions are scanty, resulting in a dry and infection-susceptible area. Estradiol induces proliferation and **cornification** (**keratinization**) of the vaginal epithelium, whereas progesterone opposes those actions and induces the influx of polymorphonuclear leukocytes into the vaginal fluids. Estradiol also activates vaginal glands that produce lubricating fluid during coitus.

OVARIAN CYCLE

Each month, a single **oocyte** or mature egg develops and is released from one of a woman's ovaries. A follicle is the functional structure in which this oocyte develops. Most follicles in the ovary undergo atresia; however, some develop into mature follicles, produce steroids, and ovulate. As follicles mature, oocytes also mature by entering meiosis, which produces the proper number of chromosomes in preparation for fertilization. After rupturing, the follicle becomes a **corpus luteum**.

Oogonia produce an oocyte, which is arrested in meiosis.

Female germ cells develop in the embryonic yolk sac and migrate to the genital ridge, where they participate in the development of the ovary. Without germ cells, the ovary does not develop. The germs cells, called **oogonia**, actively divide by mitosis only during the prenatal period (Table 37.1), so that by birth, the ovaries contain a finite number of oocytes, estimated to be about 1 million. Most oocytes degenerate and die, a process called **atresia**. By puberty, only 200,000 oocytes remain; by age 30, only 26,000 remain; and by the time of menopause, the ovaries are essentially devoid of oocytes.

TABLE 37.1 Different Stages in the Development of an Ovum and Follicle

Stage	Process	Ovum	Follicle
Fetal life	Migration	Primordial germ cells	
	Mitosis	Oogonia	Primordial follicle
	First meiotic division begins	Primary oocyte	Primary follicle
Birth	Arrest in prophase		
	Growth of oocyte and follicle		
Puberty	Follicular maturation		Secondary follicle
Cycle			Antral follicle
Ovulation	Resumption of meiosis	Secondary oocyte	Graafian follicle
	Emission of first polar body		
	Arrest in metaphase		
			Corpus luteum
Fertilization	Second meiotic division complete	Zygote	
	Emission of second polar body		
Implantation	Mitotic divisions	Embryo	
	Blastocyst		
Parturition	Body patterning	Fetus	Corpus albicans

When oogonia cease the process of mitosis, they are called oocytes. At that time, they enter the meiotic cycle to prepare for the production of a haploid ovum, become arrested in the prophase of the first meiotic division, and remain arrested in that phase until they either die or grow into mature oocytes at the time of ovulation. The immature oocyte begins development in a **primordial follicle** that is 20 µm wide and which, may or may not be surrounded by a single layer of flattened (squamous) **pregranulosa cells**. When pregranulosa cells eventually grow to surround the oocyte, a basement membrane develops, separating the granulosa cells from the ovarian stroma (see Table 37.1).

Folliculogenesis results in a mature graafian follicle.

The process by which follicles develop and mature is termed **folliculogenesis** (Fig. 37.4). Follicles are in one of the following physiologic states: resting, growing, degenerating, or ready to ovulate. During each menstrual cycle, the ovaries produce a group of growing follicles, most of which fail to grow to maturity and undergo follicular atresia (death) at some stage of development. However, one **dominant follicle** generally emerges from the cohort of developing follicles and ovulates, releasing a mature haploid ovum.

Figure 37.4 Maturation of the ovarian follicle. The progression from primordial to primary follicle is relatively constant and independent of gonadotropins. Growth of the primary follicle to a mature graafian follicle requires LH and FSH.

Primordial follicles are considered the nongrowing resting pool of follicles, which gets progressively depleted such that by the time of menopause, the ovaries are essentially devoid of all follicles. Primordial follicles are located in the ovarian cortex or peripheral regions of the ovary.

Progression from the primordial to the next stage of follicular development, the primary stage, occurs at a relatively constant rate throughout fetal, juvenile, prepubertal, and adult life. Once primary follicles leave the resting pool, they are committed to further development or atresia. Studies in genetically modified mouse models support the concept that the conversion from primordial to primary follicles is independent of pituitary gonadotropins. It is thought that signaling between the oocyte and surrounding granulosa cells, resulting in dramatic oocyte growth, initiates primordial follicle development. There is also evidence that primordial follicles are maintained under a constant inhibitory influence that must be removed for follicle development to occur.

The first sign that a primordial follicle is entering the growth phase is a morphologic change of the flattened pregranulosa cells into cuboidal granulosa cells. The cuboidal granulosa cells proliferate to form a single continuous layer of cells surrounding the oocyte, which has enlarged from 20 μm in the primordial stage to 140 μm wide. At this stage, a glassy membrane, the **zona pellucida**, surrounds the oocyte and serves as the means of attachment through which the granulosa cells communicate with the oocyte. This is the **primary follicular stage** of development, consisting of one layer of cuboidal granulosa cells and a basement membrane (see Fig. 37.4).

The mature graafian follicle contains the oocyte surrounded by granulosa cells and the internal and external theca cell layers.

The follicle continues to grow, mainly through proliferation of its granulosa cells, so that several layers of granulosa cells exist in the **secondary follicular stage** of development (see Fig. 37.4). As the secondary follicle moves deeper into the ovarian cortex, stromal cells near the basement membrane begin to differentiate into cell layers called the **theca interna** and **theca externa**, and a blood supply with lymphatics and nerves forms within the thecal component. The granulosa layer remains avascular.

Theca interna cells eventually become flattened, epithelioid, and steroidogenic. The granulosa cells of secondary follicles acquire receptors for FSH and start producing small amounts of estrogen. The theca externa remains fibroblastic and provides structural support to the developing follicle.

Development beyond the primary follicle is gonadotropin dependent, begins at puberty, and continues in a cyclic manner throughout the reproductive years. As the follicle continues to grow, theca layers expand and **antra** (fluid-filled spaces) begin to develop around the granulosa cells. This early antral stage of follicle development is referred to as the **tertiary follicular stage** (see Fig. 37.4). FSH is the critical hormone responsible for progression from the preantral to the antral stage, stimulating mitosis of the granulosa cells. As the number of granulosa cells increases, the production of estrogens, the binding capacity for FSH, the size of the follicle, and the volume of the follicular fluid all increase significantly.

As the antra increase in size, a single, large, coalesced antrum develops, pushing the oocyte to the periphery of the follicle and forming a large 2- to 2.5-cm-wide **graafian follicle** (also called preovulatory follicle) (see Fig. 37.4). Three distinct granulosa cell compartments are evident in the graafian follicle. **Cumulus granulosa cells** surround the oocyte, with those cells lining the antral cavity termed **antral granulosa cells**. Those cells attached to the basement membrane are called **mural granulosa cells**. Mural and antral granulosa cells produce steroids at a greater rate than cumulus cells.

In addition to exposure to blood-borne hormones, antral follicles have a unique microenvironment in that the follicular fluid contains pituitary hormones, steroids, peptides, and growth factors, some of which are present at a concentration 100 to 1,000 times higher than that in the circulation. As the follicle matures, the intrafollicular concentration of FSH does not change much, whereas that of LH increases and that of PRL declines. The concentrations of estradiol and progesterone increase 20-fold, whereas androgen levels remain unchanged (Table 37.2). The follicular fluid also contains inhibin, activin, GnRH-like peptide, growth factors, opioid peptides, oxytocin, and plasminogen activator.

TABLE 37.2 Different Parameters of Follicles During the First Half of the Menstrual Cycle

Cycle (d)	Diameter (mm)	Volume (mL)	Granulosa Cells ($\times 10^6$)	FSH	LH	PRL	A	E	P
1	4	0.05	2	2.5	—	60	800	100	—

Hormone concentrations in mIU or ng/mL.

FSH, follicle-stimulating hormone; LH, luteinizing hormone; PRL, prolactin; A, androstenedione; E, estradiol; P, progesterone.

Granulosa and theca cells cooperate to synthesize estradiol.

The main physiologically active hormone produced by the follicle is **estradiol**, an 18-carbon steroid. Steroidogenesis depends on the availability of cholesterol, which is the precursor to all steroid synthesis. Low-density lipoprotein (LDL) is the primary source of cholesterol for ovarian steroidogenesis.

The conversion of cholesterol to **pregnenolone** by **cholesterol side-chain cleavage enzyme**, the rate-limiting step in estrogen synthesis, occurs on the inner membrane of mitochondria (Fig. 37.5). LH binds to specific membrane receptors on theca cells, activating adenylyl cyclase through a G protein to increase the production of cyclic adenosine monophosphate (cAMP), which activates protein kinase A (PKA) to phosphorylate intracellular proteins. LH binding increases LDL receptor mRNA expression, LDL cholesterol uptake, and cholesterol transport from the outer to inner mitochondrial membrane, facilitated by the **steroidogenic acute regulatory** (**StAR**) **protein**. Once formed, pregnenolone diffuses out of the mitochondria and enters the endoplasmic reticulum (ER), the site of subsequent steroidogenesis. The initiation of steroidogenesis by LH in the theca cell is similar to that for ACTH-induced steroidogenesis in adrenocortical cells (see Figure 33.4 for a detailed illustration).

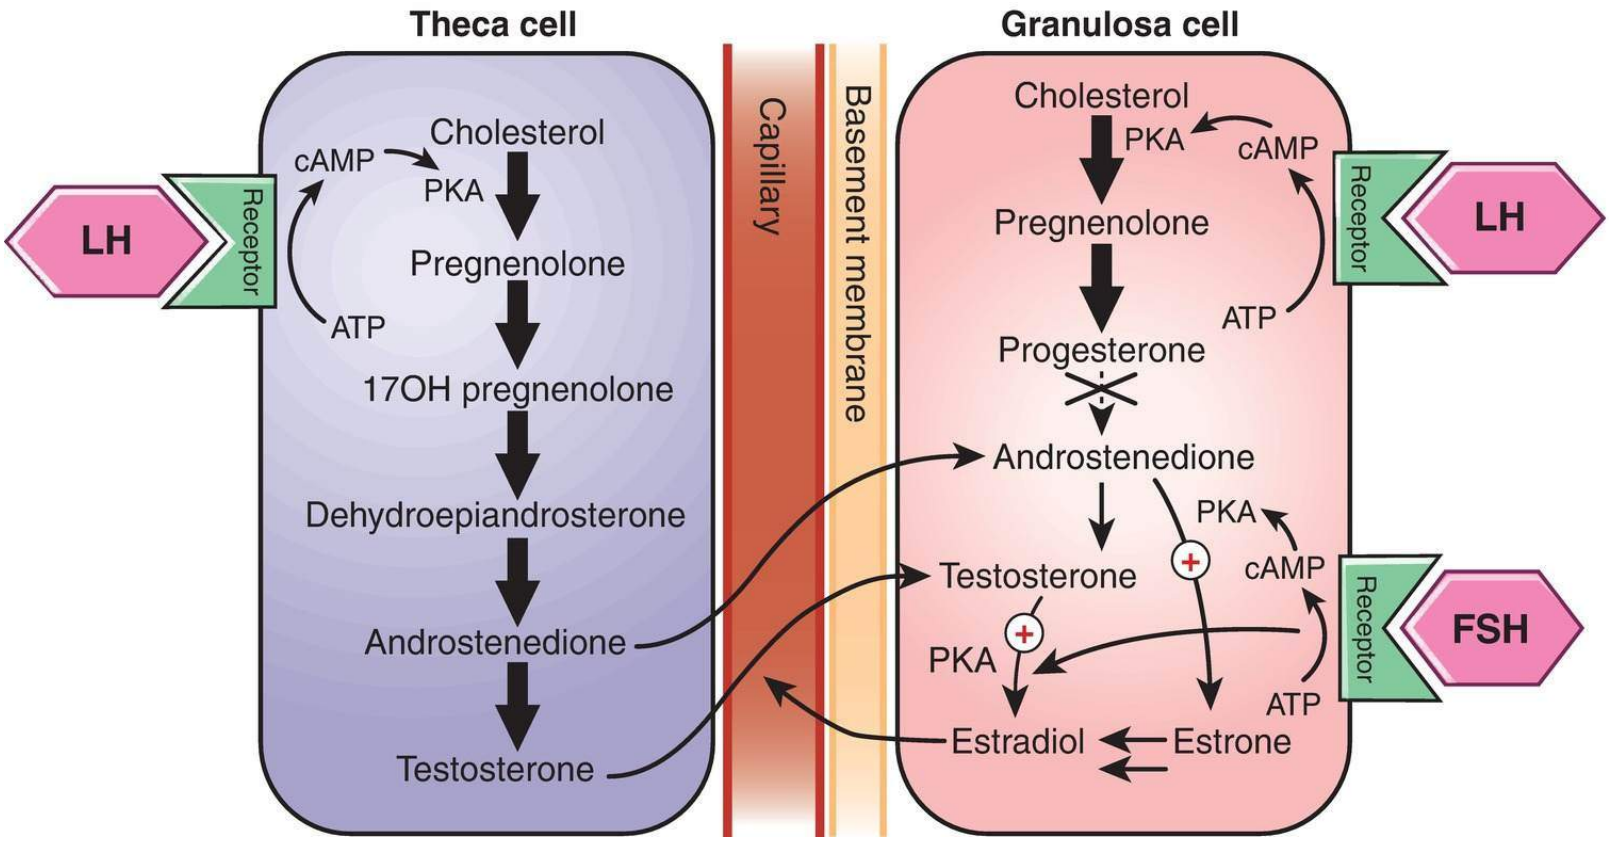

Figure 37.5 The two-cell, two-gonadotropin hypothesis. Follicular theca cells under the control of luteinizing hormone (LH) produce androgens that diffuse to the follicular granulosa cells, where they are converted to estrogens via a follicle-stimulating hormone (FSH)-supported aromatization reaction. Granulosa cells lack of the enzyme 17α-hydroxylase and cannot convert progesterone to androstenedione (indicated by the X).

Two pathways are available for steroidogenesis from pregnenolone (see Fig. 36.9). In theca cells, the **delta 5 pathway** (δ5) is predominant, with the **delta 4 pathway** (δ4) utilized by granulosa cells and the

corpus luteum. In the δ5 pathway, pregnenolone is sequentially converted to **17α-hydroxypregnenolone**, **to dehydroepiandrosterone** (**DHEA**), to **androstenedione**, and finally to **testosterone**. Testosterone and androstenedione are 19-carbon steroids that diffuse from the thecal cell across the basement membrane to enter the granulosa cells.

In the granulosa cell, FSH increases cAMP to activate PKA-induced protein phosphorylation and the expression of **aromatase**, which converts testosterone and androstenedione to estradiol and **estrone**, respectively. A**romatase** modifies the A ring of testosterone and androstenedione to remove one carbon, yielding the 18-carbon estrogen hormones (see Fig. 36.9). Estrone is then converted to estradiol by 17β-hydroxysteroid dehydrogenase present in the granulosa cell.

Estradiol synthesis and secretion from the follicle require cooperation between granulosa and theca cells and coordination between FSH and LH. This **two-cell**, **two-gonadotropin hypothesis** is based on the observation that only granulosa cells possess FSH receptors and respond to the hormone. FSH acts on granulosa cells to produce a broad range of activities including cell proliferation, the induction of aromatase, and increased inhibin and progesterone synthesis. As the follicle matures, FSH stimulates the expression of both LH and FSH receptors on the granulosa cell.

In contrast to the limited expression of FSH receptors, LH receptors are present on theca, granulosa, stromal (interstitial) cells, and the corpus luteum (discussed in detail later). The expression of LH receptors is time dependent as theca cells acquire LH receptors at a relatively early stage, whereas FSH induces LH receptors on granulosa cells in the later stages of the maturing follicle.

In addition to differences in gonadotropin receptor expression, the steroidogenic enzymes are differentially expressed in theca and granulosa cells. Aromatase is expressed only in granulosa cells, and FSH regulates its induction and activation. Granulosa cells are deficient in 17α-hydroxylase and cannot process the C-21 progestins to generate C-19 androgenic compounds (see Fig. 37.5). Consequently, estrogen production by granulosa cells depends on an adequate supply of exogenous aromatizable androgens, provided by theca cells when stimulated by LH.

In the follicle, theca and granulosa cells are exposed to different microenvironments that also influence steroidogenesis. Vascularization is restricted to the theca layer because blood vessels do not penetrate the basement membrane. Thus, theca cells have better access to circulating LDL cholesterol. Granulosa cells must synthesize cholesterol from acetate, a less efficient process.

Androgens are produced by theca and stromal cells as precursors for estrogen synthesis; however, androgens also have a distinct local action at low concentrations to enhance aromatase activity, promoting estrogen production. In contrast, at high concentrations, androgens are converted by 5α-reductase to the more potent androgen dihydrotestosterone. When androgens overwhelm follicles, the intrafollicular androgenic environment antagonizes granulosa cell proliferation and leads to apoptosis of the granulosa cells and subsequent follicular atresia.

Dominant follicle is protected from atresia during FSH suppression.

At the beginning of the menstrual cycle, several follicles begin to grow and develop but only one, the dominant follicle, will go on to ovulate. The remaining follicles will undergo atresia, or destruction of the oocyte and granulosa cells. Atresia is a continuous process and can occur at any stage of follicular development; however, a follicle generally becomes dominant at the preantral stage, with the remaining preantral follicles undergoing atresia. Two main factors contribute to atresia in the nonselected follicles. One is the suppression of plasma FSH by the negative feedback effects of estradiol secreted by the dominant follicle. The decline in FSH support decreases aromatase activity to impair estradiol synthesis and increases production of DHT. Loss of estrogen and expression of the atretogenic DHT interrupts granulosa cell proliferation in the nondominant follicles. The dominant follicle is protected from a fall in circulating FSH levels because it has a healthy blood supply, an accumulation of FSH in the follicular fluid, and an increased density of granulosa cell FSH receptors.

As the dominant follicle grows, vascularization of the theca layer also increases. On day 9 or 10 of the cycle, the vascularity of the dominant follicle is twice that of the other antral follicles, permitting a more efficient delivery of cholesterol to theca cells and better exposure to circulating gonadotropins. At this time, the main source of circulating estradiol in the body is the dominant follicle. Estradiol is the primary regulator of LH and FSH secretion by positive and negative feedback; thus, the dominant follicle ultimately determines its own fate.

Estradiol secretion by the dominant follicle triggers the midcycle LH surge leading to maturation of the oocyte and ovulation.

The midcycle LH surge occurs as a result of rising levels of circulating estradiol that provides a positive feedback effect on the hypothalamic–pituitary axis. Multiple changes in the dominant follicle occur within a relatively short time as a result of the LH surge. These include the resumption of meiosis in the oocyte; granulosa cell differentiation and transformation into luteal cells; the activation of proteolytic enzymes that degrade the follicle wall and surrounding tissues; increased production of prostaglandins, histamine, and other local factors that cause hyperemia; and an increase in progesterone secretion. The midcycle FSH surge is not essential for ovulation; however, only follicles that have been adequately primed with FSH ovulate because they contain sufficient numbers of LH receptors for ovulation and subsequent luteinization.

Periovulatory period

All healthy oocytes in the ovary are arrested in the prophase of the first meiosis, which occurred during fetal life. With the LH surge, the oocyte resumes meiosis and completes its first meiotic division several hours before ovulation (see Table 37.1).

Primary oocytes arrested in meiotic prophase 1 duplicate their centrioles and DNA so that each chromosome has two identical **chromatids**. Crossing over and chromatid exchange occur during this phase to produce genetic diversity. With the resumption of meiosis in metaphase 1, the nuclear membrane disappears, and the chromosomes condense and align at the equator of the spindle. At meiotic anaphase 1, the homologous chromosomes move in opposite directions under the influence of the retracting meiotic spindle at the cellular periphery. At meiotic telophase 1, an unequal division of the cell cytoplasm yields a large **secondary oocyte** and a small, nonfunctional **first polar body**. Both the secondary oocyte and polar body, like secondary spermatocytes (see Fig. 36.8), have a haploid number of duplicated chromosomes (22 somatic and 1 X chromosome). The first polar body degenerates or divides to form nonfunctional cells.

The secondary oocyte begins its second meiotic division and proceeds through a short prophase to become arrested in metaphase, where it remains until fertilization begins with the penetration of a spermatozoon. The second meiotic division resumes and is rapidly completed at the start of fertilization. A second unequal cell division produces a small **second polar body** and a large fertilized egg, the **zygote**, containing a diploid complement of DNA resulting from the haploid contribution of the mother and the father. If fertilization does not occur, the secondary oocyte begins to degenerate within 24 to 48 hours.

Follicle maturation and rupture

The earliest responses of the ovary to the midcycle LH surge are the release of vasodilatory substances including histamine, bradykinin, and prostaglandins, which mediate increased ovarian and follicular blood flow. The highly vascularized dominant follicle becomes hyperemic and edematous, swelling to a size of at least 20 to 25 mm wide. There is also an increased production of follicular fluid, disaggregation of granulosa cells, and detachment of the oocyte–cumulus complex from the follicular wall, moving it to the central portion of the follicle. The basement membrane separating theca cells from granulosa cells begins to disintegrate, granulosa cells begin to undergo luteinization, and blood vessels begin to penetrate the granulosa cell compartment.

At a specific site called the **stigma**, the wall of the follicle thins and bulges due to cellular deterioration; it is at this site on the follicle that rupture will occur. As ovulation approaches, the follicle enlarges and protrudes from the surface of the ovary at the stigma. In response to LH, **plasminogen activator** is produced by theca and granulosa cells, which converts plasminogen to **plasmin**. The proteolytic plasmin enzyme acts directly on the follicular wall to stimulate the production of **collagenase**, an enzyme that digests the connective tissue matrix. The thinning and increased distensibility of the wall facilitate the rupture of the follicle. Smooth muscle contraction extrudes the oocyte–cumulus complex and follicular fluid.

Within a couple of hours after the initiation of the LH surge, the production of progesterone, androgens, and estrogens by the follicle begins to increase. Progesterone, acting through its receptor in granulosa cells, promotes ovulation by releasing mediators that increase the distensibility of the follicular wall and enhance the activity of proteolytic enzymes. As LH levels reach their peak, plasma estradiol levels plunge because of down-regulation of LH and FSH receptors on granulosa cells and the inhibition of granulosa cell aromatase. Eventually, LH receptors on granulosa cells escape the down-regulation, and progesterone production increases.

Corpus luteum forms from the postovulatory follicle.

After ovulation, the wall of the graafian follicle collapses and becomes convoluted, blood vessels course through the granulosa and theca cell layers, and the antral cavity fills with blood. The granulosa cells cease proliferation, undergo hypertrophy, and begin to produce progesterone as their main secretory product. The ruptured follicle forms a solid structure called the **corpus luteum** (Latin for "yellow body"). The numerous biochemical and morphologic changes that result in the corpus luteum occur in response to LH and FSH stimulation and are referred to collectively as **luteinization**. The granulosa cells and theca cells in the corpus luteum are called **granulosa lutein cells** and **theca lutein cells**, respectively.

The corpus luteum is a transient endocrine structure that serves as the main source of circulating steroids during the luteal (postovulatory) phase of the menstrual cycle and is essential for maintaining pregnancy during the first trimester. Continued LH stimulation is needed to ensure healthy luteal cells and progesterone secretion. If pregnancy does not occur, the corpus luteum regresses as luteal cells undergo apoptosis and necrosis, a process termed **luteolysis** or **luteal regression**. Fibrous tissue replaces the luteinized cells, creating a nonfunctional structure called the **corpus albicans**.

Luteinization begins before ovulation occurs. After acquiring a high concentration of LH receptors, granulosa cells enlarge (hypertrophy) and develop smooth ER and lipid inclusions. In contrast to the nonvascular granulosa cells in the follicle, luteal granulosa cells have a rich blood supply. Capillary invasion starts immediately after the LH surge, facilitated by the dissolution of the basement membrane between theca and granulosa cells, and reaches a peak at 7 to 8 days after ovulation. Differentiated theca and stroma cells, as well as granulosa cells, are incorporated into the corpus luteum, and all three classes of steroids, androgens, estrogens, and progestins, are synthesized. Although some progesterone is secreted before ovulation, peak progesterone production is reached 6 to 8 days after the LH surge.

Regression of the corpus luteum occurs about 13 days after ovulation if fertilization does not occur. If fertilization occurs, the embryonic trophoblast produces human chorionic gonadotropin (hCG), an LH-like hormone that rescues the corpus luteum from degeneration (see Chapter 38). hCG binds LH receptors on the corpus luteum to increase cAMP, stimulating progesterone secretion.

Luteal regression in the absence of fertilization and hCG production may occur in two possible ways. The first mechanism is loss of LH stimulation resulting from the fall in circulating LH levels. The second mechanism is inhibition of LH action by locally produced agents such as estrogen, oxytocin, prostaglandins, and GnRH (Clinical Focus 37.1).

CLINICAL FOCUS 37.1

Luteal Insufficiency

Occasionally, the corpus luteum does not produce sufficient progesterone to maintain pregnancy during its early stages. Initial signs of early spontaneous termination of pregnancy include pelvic cramping and vaginal bleeding, similar to indications of menstruation. If the corpus luteum is truly deficient, then fertilization may occur around the idealized day 14 (ovulation), pregnancy terminates during the

deficient luteal phase, and menses will start on schedule. Without measuring levels of human chorionic gonadotropin (hCG), the woman would not know that she is pregnant because of the continuation of regular menstrual cycles.

Analysis of the regulation of progesterone secretion by the corpus luteum provides insights into this clinical problem. There are several reasons for luteal insufficiency. First, the number of luteinized granulosa cells in the corpus luteum may be insufficient because of the ovulation of a small follicle or the premature ovulation of a follicle that was not fully developed. Second, the number of luteinizing hormone (LH) receptors on the luteinized granulosa cells in the graafian follicle and developing corpus luteum may be insufficient. LH receptors mediate the action of LH, which stimulates progesterone secretion. An insufficient number of LH receptors could be a result of insufficient priming of the developing follicle with follicle-stimulating hormone (FSH). It is well known that FSH increases the number of LH receptors in the follicle. Third, the LH surge could have been inadequate in inducing full luteinization of the corpus luteum, yet there was sufficient LH to induce ovulation. It has been estimated that only 10% of the LH surge is required for ovulation, but the amount required for full luteinization and adequate progesterone secretion to maintain pregnancy is not known.

If progesterone values are low in consecutive cycles at the midluteal phase and do not match endometrial biopsies, exogenous progesterone may be administered to prevent early pregnancy termination during a fertile cycle. Other options include the induction of follicular development and ovulation with clomiphene and hCG. This treatment would likely produce a large, healthy, estrogen-secreting graafian follicle with sufficient LH receptors for luteinization. The exogenous hCG is given to supplement the endogenous LH surge and to ensure full stimulation of the graafian follicle, ovulation, adequate progesterone, and luteinization of the developing corpus luteum. ■

MENSTRUAL CYCLE

The **menstrual cycle** describes the coordinated monthly changes in the ovary and endometrial lining of the uterus in women of reproductive age. The cycle is noted to begin with the onset of menstruation, the flow of blood from the uterus through the vagina, when the lining of the uterus is shed. A woman's first menstruation, termed **menarche**, occurs around age 12 years. The end of a woman's reproductive phase, called **menopause**, commonly occurs between ages 45 and 55 years.

The average menstrual cycle length in adult women is 28 days (see Fig. 37.6), with a range of 25 to 35 days. The interval from ovulation to the onset of menstruation is relatively constant, on average 14 days in most women, dictated by the fixed life span of the corpus luteum. In contrast, the interval from the onset of menses to ovulation (the follicular phase) is more variable and accounts for differences in cycle lengths among ovulating women. Sexual intercourse may occur at any time during the cycle, but fertilization occurs only during the postovulatory period. Once pregnancy occurs, ovulation ceases until after parturition. Lactation can provide continued inhibition of ovulation, but this effect is not absolute.

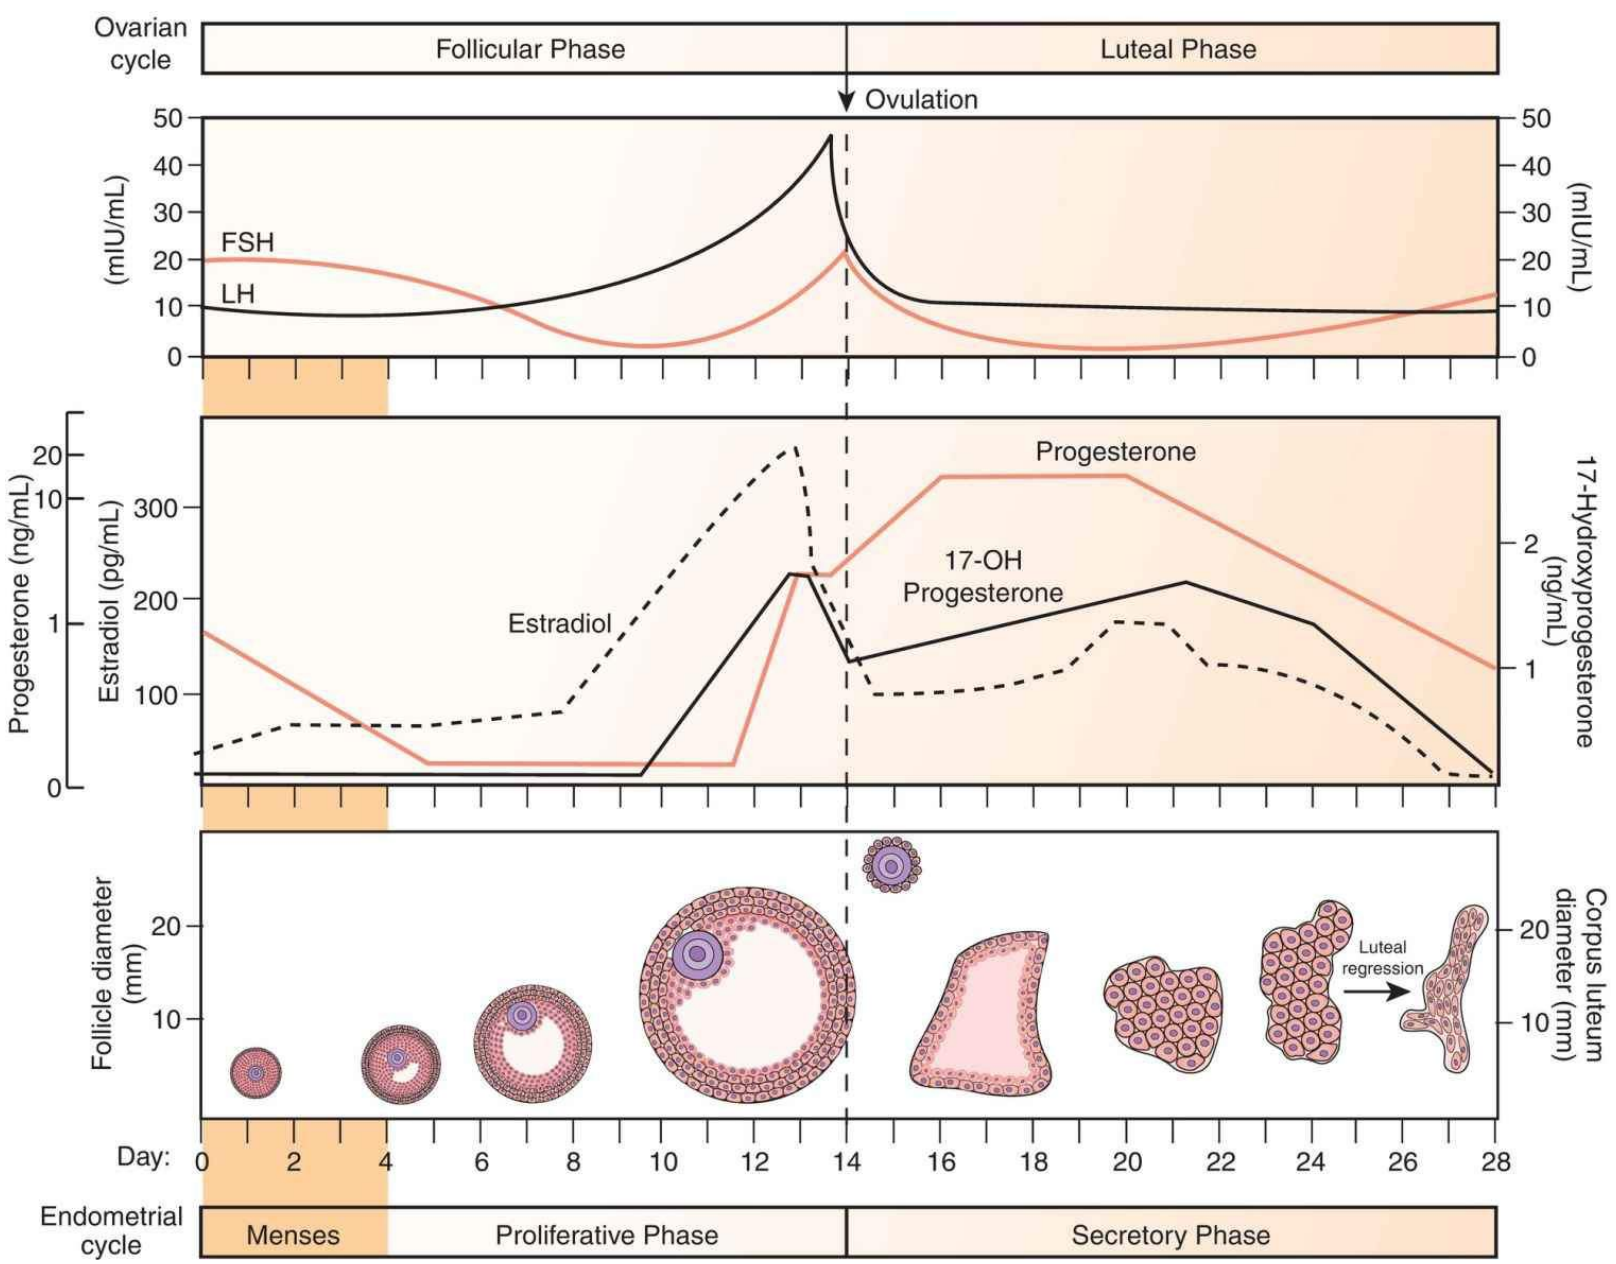

Figure 37.6 Hormonal and ovarian events during the menstrual cycle. LH and FSH release from the anterior pituitary **(top panel)** promotes follicular development **(bottom panel)** and follicle steroidogenesis **(middle panel)**. During the follicular phase, estradiol provides positive feedback to induce the LH surge, which is required for ovulation.

Menstrual cycles become irregular as menopause approaches at around 50 years of age, and cycles cease thereafter. During the reproductive years, the timing of the menstrual cycle is modulated by physiological, psychological, and social factors.

Puberty marks the start of cyclic reproductive function.

During the prepubertal period, the hypothalamic–pituitary–ovarian axis becomes activated, an event termed **gonadarche**, increasing gonadotropins in the circulation that stimulate ovarian estrogen secretion. Pulsatile release of GnRH from the hypothalamus is the initiating event for gonadarche. Factors that stimulate the secretion of GnRH include glutamate, norepinephrine, and neuropeptide Y emanating from synaptic inputs to GnRH-producing neurons. A decrease in γ-aminobutyric acid (GABA) inhibition of GnRH secretion also occurs at this time. At the time of **puberty**, the pituitary also becomes more responsive to GnRH.

The increase in estradiol release from the ovary induces the expression of **secondary sex characteristics**, including breast development and increased fat deposition on the hips and buttocks. The initiation of breast development under the influence of estrogen is known as **thelarche**. Estrogens also regulate the pubertal growth spurt, induce closure of the epiphyses, have a positive effect to maintain bone formation, and can antagonize the degrading actions of parathyroid hormone (PTH) on bone.

The first few menstrual cycles in puberty are usually irregular and anovulatory, due to delayed maturation of the positive feedback by estradiol on a hypothalamus that thus fails to secrete significant GnRH. During puberty, pulsatile LH secretion occurs more during periods of sleep than during periods of wakefulness, resulting in a diurnal cycle.

At puberty, adrenal androgens promote the development of axillary and pubic hair, a process known as **pubarche**. The adrenals begin to produce significant amounts of androgens such as DHEA and androstenedione 4 to 5 years prior to menarche. The start of adrenal androgen production is called **adrenarche**, and this process is independent of gonadarche (see Chapter 38) (Clinical Focus 37.2).

CLINICAL FOCUS 37.2

Precocious Puberty

Signs of secondary sexual maturation at an age 2 standard deviations or more below the mean for pubertal onset is referred to as *precocious puberty*. The average age of pubertal onset has gradually declined as a result in part to better nutrition and general health; thus, present data indicate that the lower limit of puberty in normal boys is age 9 years, but that the lower limit for white girls is age 7 years and for black girls is age 6 years. Thus, signs of secondary sexual maturation earlier than these lower limits should be evaluated.

Two types of sexual precocity are recognized. If there is evidence of premature reactivation of the hypothalamic LHRH pulse generator, the condition is referred to as *complete isosexual precocity*, *true precocious puberty*, or *central precocious puberty*. In this condition, there is pulsatile release of LH that mimics that seen in puberty, and LH increases in response to administration of LHRH. If extrapituitary gonadotropin secretion or gonadal steroid secretion occurs independently of pulsatile LHRH generation, the condition is termed *incomplete isosexual precocity*, *pseudoprecocious puberty*, or *LHRH-independent precocious puberty*. In this condition, there is no pulsatile release of LH as seen

in puberty, and LH does not increase in response to administration of LHRH. In both forms of sexual precocity, increased gonadal steroid secretion results in an increased rate of linear growth, somatic development, and rate of skeletal maturation.

Hamartomas, congenital malformations composed of a heterotropic mass of nerve tissue usually located on the floor of the third ventricle or attached to the tuber cinereum, appear to be a major cause of central precocious puberty. Hamartomas are not neoplastic and do not progress or enlarge. LHRH-releasing cells have been found in hamartomas and appear to release LHRH in a pulsatile manner unrestrained by the central nervous system (CNS) mechanisms that inhibit the normal LHRH pulse generator. It has also been suggested that hamartomas release factors such as transforming growth factor α (TGF-α) that drive LHRH secretion from normal neurons in the hypothalamus. Central precocious puberty can also result from gliomas, CNS infection, CNS radiation, and head trauma.

LHRH agonists are the treatment of choice for central precocious puberty after the possibility of an expanding intracranial lesion has been eliminated. Chronic administration of LHRH analogs results in suppression of pulsatile LH and FSH release, gonadal steroidogenesis, and gametogenesis. This occurs because the constant presence of LHRH results in down-regulation of its receptors and uncoupling of the receptor from the intracellular signal transduction mechanism.

LHRH-independent precocious puberty results from inappropriate gonadal or adrenal steroid secretion. Congenital adrenal hyperplasia (see Chapter 33) leads to elevated androgens and masculinization of boys and girls. McCune-Albright syndrome, resulting from gain of function mutations in activating G proteins coupled to gonadotropin receptors, results in increased ovarian estrogen synthesis in girls and increased testicular testosterone synthesis in boys. In boys, human chorionic gonadotropin (hCG)-secreting tumors can result in precocious puberty because hCG has LH-like activity (serum LH and FSH are not elevated). hCG-secreting tumors do not result in signs of precocity in girls, unless the tumor also secretes estrogen. Estrogen-secreting follicular cysts are the most common ovarian cause of precocity in girls.

Treatment of LHRH-independent precocious puberty centers on inhibition of steroidogenesis. Medroxyprogesterone acetate, which has a direct suppressive effect on gonadal steroidogenesis, is commonly prescribed for both boys and girls. ■

Hormonal regulation of the ovarian cycle requires synchrony between the ovary, brain, and pituitary.

The ovarian cycle includes the follicular (days 0 to 13), ovulatory (days 13 to 14), and luteal phase (days 14 to 28). The ovarian cycle overlaps with the endometrial cycle, which is comprised of the menstrual (days 0 to 4), proliferative (days 4 to 14), and secretory phases (days 14 to 28). The endometrial cycle is discussed in detail in the next section of this chapter.

The menstrual cycle requires several coordinated elements: hypothalamic control of pituitary function, follicular and luteal changes in the ovary, and positive and negative feedback of ovarian hormones at the hypothalamic–pituitary axis. We have discussed separately the mechanisms that regulate the synthesis and release of the reproductive hormones; we now put them together in terms of sequence and interaction.

Follicular phase

The follicular phase begins with the start of menstruation, which is characterized by low estrogen, progesterone, and inhibin levels resulting from the luteal regression that has just occurred, and low estrogen synthesis by immature follicles. Plasma FSH levels are high due to the removal of negative feedback by estrogen, progesterone, and inhibin. The elevated levels of FSH act on a cohort of follicles recruited 20 to 25 days earlier from the resting pool. These 4- to 6-mm-wide follicles are stimulated to grow into the preantral stage between days 3 and 5. FSH promotes granulosa cell proliferation and increased aromatase activity, resulting in plasma estradiol levels rising slightly between days 3 and 7. The designated dominant follicle is selected between days 5 and 7 and increases in size and steroidogenic activity. Between days 8 and 10 plasma estradiol levels rise sharply, reaching peak levels above 200 pg/mL on day 12, 1 day before the LH surge.

During the early follicular phase, LH pulsatility is of low amplitude and frequency coinciding with once per hour pulses of GnRH. As estradiol levels rise, GnRH pulse frequency increases as do LH pulses. The resulting increase in plasma LH further supports follicular steroidogenesis because FSH has increased the number of LH receptors on growing follicles.

During the midfollicular to late follicular phase, rising estradiol and inhibin from the dominant follicle suppress FSH release. The decline in FSH, together with an accumulation of androgens not aromatized to estrogens, induces atresia in the nonselected follicles. The dominant follicle is saved by virtue of its high density of FSH receptors, the accumulation of FSH in its follicular fluid (see Table 37.2), and the acquisition of LH receptors by the granulosa cells.

Ovulatory phase

The midcycle surge of LH is short lived (24 to 36 hours) and results from positive feedback by estradiol. For the LH surge to occur, estradiol must be maintained at a critical concentration (about 200 pg/mL) for a sufficient duration (36 to 48 hours) prior to the surge. A reduction in the critical concentration, or a rise that is too small or too short eliminates, reduces the LH surge.

The mechanism(s) that transforms estradiol from a negative to a positive regulator of LH to induce the LH surge is incompletely understood. It is known that the high estradiol concentrations increase the number of GnRH receptors on the gonadotrophs, making the pituitary more responsive to GnRH. Estradiol may also promote the conversion of a storage pool of LH, perhaps within a subpopulation of

gonadotrophs, to a more readily releasable pool.

There is also evidence that estradiol may induce greater GnRH release to induce the LH surge, an effect on GnRH neurons in the preoptic area of the hypothalamus. It is thought that these neurons do not participate in the daily pulsatile release of GnRH generated by neurons within the arcuate nucleus of the hypothalamus. The high estradiol concentration thus recruits these neurons to secrete additional GnRH to promote the surge. It should be noted, however, that estradiol has been shown to induce an LH surge in monkeys in which an effect to increase GnRH could not occur due to ablation of GnRH neurons in the hypothalamus.

A small but distinct rise in progesterone occurs before the LH surge, which is important for augmenting the LH surge. In contrast, if progesterone levels become too high, it prevents estradiol from inducing the LH surge. The small rise in progesterone together with estradiol promotes a concomitant surge in FSH. There are indications that the midcycle FSH surge is important for inducing enough LH receptors on granulosa cells for luteinization, stimulating plasminogen activator for follicular rupture and oocyte release, and activating a cohort of follicles destined to develop in the next cycle.

The LH surge reduces the concentration of 17α- hydroxylase and subsequently decreases androstenedione production by the dominant follicle. Estradiol levels decline, 17-hydroxyprogesterone increases, and progesterone levels rise. The prolonged exposure to high LH levels during the surge down-regulates the ovarian LH receptors, accounting for the immediate postovulatory suppression of estradiol.

Luteal phase

As the corpus luteum matures, it increases progesterone production and reinitiates estradiol secretion, to achieve high plasma concentrations of these hormones on days 20 to 23, about 1 week after ovulation. The elevated steroids suppress circulating FSH levels. The LH pulse frequency is reduced during the early luteal phase, but the amplitude is higher than that during the follicular phase. LH is important at this time for maintaining corpus luteum function and sustaining steroid production. In the late luteal phase, a progesterone-dependent, opioid-mediated suppression of the GnRH pulse generator reduces both LH pulse frequency and amplitude.

After the demise of the corpus luteum on days 24 to 26, estradiol and progesterone levels plunge, causing the withdrawal of support of the uterine endometrium, culminating within 2 to 3 days in menstruation. The reduction in ovarian steroids acts centrally to remove feedback inhibition. The FSH level begins to rise and a new cycle is initiated.

Ovarian steroids estradiol and progesterone regulate the endometrial cycle.

The endometrial cycle is composed of the menstrual (days 0 to 4), proliferative (days 4 to 14), and secretory phases (days 14 to 28), which are under the influence of ovarian steroids. The endometrium (also called *uterine mucosa*) lining the uterus is composed of a superficial layer of epithelial cells and an underlying stromal layer. The epithelial layer contains glands that penetrate the stromal layer. A secretory columnar epithelium lines the glands. Significant changes in the function and histology of the uterine endometrium, the composition of cervical mucus, and the cytology of the vagina occur across the endometrial cycle (Fig. 37.7).

Figure 37.7 Uterine, cervical, vaginal, and body temperature change in relation to ovarian steroids and ovulation during the menstrual cycle.

Proliferative phase

The **proliferative phase** coincides with the mid to late follicular phase of the ovarian cycle. Under the influence of rising plasma estradiol concentrations, the stromal and epithelial layers of the uterine endometrium undergo hyperplasia and hypertrophy, increasing in size and thickness. The endometrial glands elongate and are lined with columnar epithelium. The endometrium becomes vascularized with more spiral arteries developing to provide a rich blood supply to this region. Estradiol also induces the expression of progesterone receptors and increases myometrial excitability and contractility.

Secretory phase

The **secretory phase** begins on the day of ovulation and coincides with the early to midluteal phase of the ovarian cycle. Under the combined action of progesterone and estrogen, the endometrial glands become coiled, store glycogen, and secrete large amounts of carbohydrate-rich mucus. The stroma increases in vascularity and becomes edematous, and the spiral arteries become tortuous (see Fig. 37.7). Peak secretory activity, edema formation, and overall thickness of the endometrium are reached on days 6 to 8 after ovulation in preparation for implantation of the blastocyst. Progesterone antagonizes the effect of estrogen on the myometrium to reduce spontaneous myometrial contractions.

Menstrual phase

Desquamation and sloughing of the entire functional layer of the endometrium occur during the menstrual phase (*menses*). This process begins with ischemia in the endometrial tissue (sometimes referred to as the ischemic phase), initiated by the declining levels of progesterone and estradiol that result from regression of the corpus luteum. Necrotic changes and abundant apoptosis occur in the secretory epithelium as it collapses. The arteries constrict, reducing the blood supply to the superficial endometrium. Leukocytes and macrophages invade the stroma and begin to phagocytose the ischemic tissue. Leukocytes persist in large numbers throughout menstruation, providing resistance against infection to the denuded endometrial surface.

At the cellular level, the reduction in steroids destabilizes lysosomal membranes in the endometrial cells, resulting in the liberation of proteolytic enzymes and increased production of vasoconstrictor prostaglandins such as prostaglandin F2. The prostaglandins induce vasospasm of the spiral arteries, and the proteolytic enzymes digest the tissue. Eventually, the blood vessels rupture and blood is released, together with cellular debris.

The endometrial tissue is expelled through the cervix and vagina, along with blood from the ruptured arteries. The menstrual flow lasts 4 to 5 days and averages 30 to 50 mL in volume. The menstrual blood flow does not clot due to the presence of fibrinolysin released from the necrotic endometrial tissue.

Estradiol and progesterone prepare the ductal system and signal ovulation.

In addition to regulating the cyclic changes in the endometrium, the ovarian steroids have effects on the ductal system (see Fig. 37.7). Estrogen maintains the ciliated nature of the epithelium and increases the motility of the oviducts. This is important for uptake of the oocyte following ovulation, as well as movement of sperm and the zygote. Lack of estrogen following ovariectomy causes a loss of the cilia from ductal cells. Very high estrogen, as would be achieved with exogenous administration, may increase oviduct contractility to the extent that a fertilized egg becomes trapped, resulting in an ectopic pregnancy. Progesterone opposes the effects of estrogen on smooth muscle contractility of the ductal system.

The cervical mucus undergoes cyclic changes in composition and volume that are important for sperm transport. During the follicular phase, estrogen increases the quantity, alkalinity, viscosity, and elasticity of the cervical mucus. By the time of ovulation, elasticity of the mucus or spinnbarkeit is greatest, and sperm can readily pass through this estrogen-dominated mucus. As progesterone rises after ovulation, during pregnancy, or with low-dose administration of progestogen during the cycle, it opposes these effects of estrogen. Thus, the quantity and elasticity of the cervical mucus declines making it difficult for sperm to pass through, but also providing better protection against infection.

The vaginal epithelium proliferates under the influence of estrogen early in the follicular phase. The columnar epithelium then becomes cornified (keratinized) and reaches its peak in the periovulatory period. During the postovulatory period, progesterone induces the formation of thick mucus, the epithelium becomes infiltrated with leukocytes, and cornification decreases.

At the time of ovulation, there is also a small but detectable rise in basal body temperature, caused by progesterone. The rise in body temperature can be utilized to monitor ovulation in attempts to either maximize or minimize the chances of fertilization and pregnancy.

Menopause is the cessation of ovarian function and reproductive cycles.

A woman is formerly defined to be in menopause 12 months following the completion of her final menstrual period. As a woman approaches her final menses, the cycles and bleeding become irregular, with shorter cycles due to lack of complete follicular development. The ovaries atrophy and are characterized by the presence of few to no healthy follicles.

The decline in ovarian function is associated with a decrease in estrogen secretion and a concomitant increase in LH and FSH, which can be used as a diagnostic tool (Table 37.3). The elevated LH stimulates ovarian stroma cells to continue producing androstenedione. Estrone, derived almost entirely from the peripheral conversion of adrenal and ovarian androstenedione, becomes the dominant estrogen (see Fig. 36.9). As androgens rise, some women exhibit hirsutism. The lack of estrogen causes atrophic changes in the breasts and reproductive tract, accompanied by vaginal dryness, which often causes pain and irritation during intercourse.

TABLE 37.3 Serum Gonadotropin and Steroid Levels in Premenopausal and Postmenopausal Women

		Menstrual Cycle			
Hormone	**Units**	**Follicular**	**Preovulatory**	**Luteal**	**Postmenopausal**
LH	mIU/mL	2.5–15	15–100	2.5–15	20–100
FSH	mIU/mL	2–10	10–30	2–6	20–140
Estradiol	pg/mL	70–200	200–500	75–300	10–60
Progesterone	ng/mL	≤0.5	≤1.5	4–20	≤0.5

LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Hot flashes, resulting from the loss of vasomotor tone, osteoporosis, and an increased risk of cardiovascular disease are important medical conditions for women entering and in menopause. Hot flashes occur primarily during the menopausal transition and are characterized by episodic increases in upper body and skin temperatures, peripheral vasodilation, and sweating. Hot flashes occur concurrently with LH pulses, but are not caused by the gonadotropins because they are evident in hypophysectomized women. It is thought that hot flashes reflect temporary disturbances in the hypothalamic thermoregulatory centers, which are linked to the GnRH pulse generator in some manner.

Osteoporosis increases the risk of hip fractures, and estrogen replacement therapy reduces the risk. Estrogen antagonizes PTH-induced calcium mobilization from bone but enhances PTH-stimulated calcium retention by the kidney. Estrogen also promotes the intestinal absorption of calcium through 1,25-dihydroxyvitamin D_3. See the Integrated Medical Sciences box for a detailed discussion of hormone replacement therapy (HRT) in menopause.

INFERTILITY

Infertility is arbitrarily defined as the inability to conceive within 1 year of unprotected intercourse and should be considered as a medical problem for both partners. We focus here on abnormalities in women that can cause infertility (see Chapter 36 for a discussion of infertility in men). Environmental factors, disorders of the CNS and pituitary, and ovarian abnormalities can interfere with follicular development and/or ovulation. If a normal ovulation occurs, structural, pathologic, and/or endocrine problems associated with the oviduct and/or uterus can prevent fertilization, impede the transport or implantation of the embryo, and, ultimately, interfere with the establishment or maintenance of pregnancy.

Amenorrhea is the most easily recognized and common sign of ovulatory dysfunction and is defined as the absence of menarche by 16 years of age, or no menses for more than three cycles in a woman who previously had cyclic menses. The absence of menses is a result of anovulation, the etiology of which can be broadly characterized as due to hypothalamic dysfunction, hyperprolactinemia, androgen excess or premature ovarian insufficiency.

Hypothalamic amenorrhea encompasses a broad range of conditions, each of which results in insufficient gonadotropin release. In the absence of gonadotropins, follicular development is impaired and downstream estradiol production low. Genetic or anatomic disorders such as tumors or head trauma cause amenorrhea by interfering with GnRH release. However, the most commonly observed causes are emotional distress, excessive exercise, or rapid weight loss, resulting in the condition being termed **functional hypothalamic amenorrhea** because it is assumed that the neuroendocrine pathways are intact. Highly trained athletes and dancers often exhibit energy intakes that are insufficient to match their high energy expenditure. Eating disorders such as **anorexia nervosa** or **bulimia** also result in insufficient energy intake leading to weight loss. In both cases, low levels of the adipose tissue hormone leptin signal the hypothalamus that energy stores are low, resulting in reduced GnRH release. Prolonged daily stress due to work or social issues can also impair GnRH release, resulting in amenorrhea. Therapy can include administration of GnRH or lifestyle modification, depending on the cause of the problem.

Hyperprolactinemia is most commonly due to pituitary prolactinoma and is often associated with galactorrhea, a persistent milklike discharge from the nipple in nonlactating women and men. Other causes of elevated prolactin levels are hypothalamic disorders, trauma to the pituitary stalk, and medications, all of which result in reduced hypothalamic dopamine release. Prolactin suppresses ovarian function by reducing GnRH release. Hyperprolactinemia is treated by surgical removal of the pituitary adenoma or pharmacologic intervention with bromocriptine, a dopaminergic agonist that reduces the size and number of the pituitary lactotrophs.

Polycystic ovarian syndrome is the most common form of androgen excess. This is a heterogeneous disorder associated with elevated LH with normal FSH, polycystic ovaries, hirsutism, insulin resistance, and obesity. Elevated insulin in response to insulin resistance can stimulate LH gene transcription and androgen synthesis. Weight loss and interventions to reduce insulin resistance can be of some therapeutic value.

Premature ovarian insufficiency is defined as the early depletion of follicles prior to 40 years of age and is a state of hypogonadotropic hypogonadism. Patients go through puberty with variable subsequent menstrual cycling. Clinical findings include low estrogen levels and high FSH, with symptoms similar to those of menopause, including hot flashes and an increased risk of osteoporosis. The etiology is variable, including chromosomal abnormalities; lesions resulting from irradiation, chemotherapy, or viral infections; and autoimmune conditions.

INTEGRATED MEDICAL SCIENCES

Hormone Replacement Therapy and the Role of Selective Estrogen Receptor Modulator in Menopause

Clinical features of menopause can be separated into those more closely associated with the transition to menopause, such as hot flashes and night sweats, vaginal dryness, and irritation, versus long-term complications such as bone loss and cardiovascular disease. HRT, consisting of estrogen, or the combination of estrogen plus progestin, has been shown in large clinical trials to reduce hot flashes and vaginal discomfort in most women. Progestin is given with estrogen to protect the endometrium from estrogen-induced hyperplasia or carcinoma. HRT reduces spine and hip fractures resulting from osteoporosis, especially if given during the first 3 years of menopause. Recognized risks of HRT include a small increased incidence of breast cancer, an established greater incidence of endometrial cancer, and a modest increased incidence of deep vein thrombosis.

It has long been thought that estrogen protects against atherosclerosis and cardiovascular disease in women. In premenopausal women, total and LDL cholesterol are lower, HDL cholesterol is higher, and myocardial infarction is six times less common than in men of the same age. During menopause, total and LDL cholesterol levels rise, as does cardiovascular disease risk. Estrogen therapy in postmenopausal women has a favorable impact on lipid profile, lowering total and LDL cholesterol. This finding supported the conclusion that estrogen use in menopause would protect against cardiovascular disease. However, the Women's Health Initiative, a large randomized study of estrogen therapy, was halted early because of a small, but significant, increased incidence of cardiovascular disease and breast cancer. Analyses of data from that trial and others suggest that HRT may increase cardiovascular risk in older women starting therapy many years after menopause, or in women on therapy for many years, but not in women starting therapy to relieve symptoms at the onset of menopause. Thus, current recommendations are that HRT is used for symptoms of menopausal transition but in the long term should be weighed against other therapeutic interventions that are more effective in reducing cardiovascular disease.

Selective estrogen receptor modulators (SERMs) are synthetic nonsteroidal agents with varying estrogen agonist and antagonist activities in different tissues. They are activators of estrogen receptor (ER) in some tissues (bone, liver, and the cardiovascular system), inhibitors in other tissues (brain and breast), and mixed activator/inhibitors in the uterus. The goal of therapy with SERMs is to mimic the beneficial effects of estrogen on the bones and heart, but to inhibit estrogen action in the breast and uterus, minimizing harmful effects in these tissues. FDA approved SERMs include tamoxifen to prevent or treat breast cancer, raloxifene for the treatment of osteoporosis, and ospemifene for postmenopausal vaginal atrophy.

Two distinct ERs exist (ERα and ERβ) that differ in the N-terminal region, which is important in initiation of transcription. The receptors also exhibit different expression patterns, with ERα found predominantly in the breast, uterus, and vagina, and ERβ expressed in tissues of the CNS, cardiovascular system, immune system, gastrointestinal system, kidney, lungs, and bone.

Several mechanisms have been proposed to explain the ability of SERMs to be estrogenic in some

tissues and antiestrogenic in others. SERMs can block estrogen binding to its receptor to inhibit transcription or can promote the interaction of the N-terminal domain of the ER with other coactivators resulting in transcriptional activation. SERMs may also recruit different coactivators and coinhibitors in different tissues than estrogen usually does. Finally, the actions of SERMs can differ depending on which ER isoform they bind. SERMs function as pure antagonists when acting through ERβ on genes containing ER-binding elements, but can function as a partial agonist when acting on them through ERα. Continuing research should lead to a better understanding of the mechanism(s) of action of SERMs and development of new molecules designed for specific and beneficial actions on estrogen-responsive tissues. ■

Chapter Summary

- Pulses of hypothalamic GnRH regulate the secretion of LH and FSH, which regulate follicular development, steroidogenesis, ovulation, and formation of the corpus luteum.
- LH and FSH in coordination with ovarian theca and granulosa cells regulate the secretion of follicular estradiol.
- Ovulation occurs as the result of a positive feedback of follicular estradiol on the hypothalamic–pituitary axis, which induces surges in LH and FSH.
- Follicular development occurs in distinct steps: primordial, primary, secondary, tertiary, and graafian follicle stages.
- Follicular rupture (ovulation) requires the coordination of appropriately timed LH and FSH surges that induce inflammatory reactions in the graafian follicle, leading to dissolution of the follicle wall by ovarian enzymes.
- Follicular atresia results from the withdrawal of gonadotropin support.
- The formation of a functional corpus luteum requires the presence of the LH surge, adequate numbers of LH receptors, sufficient granulosa cells, and significant progesterone secretion.
- Estradiol and progesterone regulate the endometrial cycle, with estradiol inducing proliferation of the endometrium, and progesterone inducing the endometrial glands to secrete carbohydrate-rich mucus.
- During puberty, the hypothalamus begins to secrete increasing quantities of GnRH, which increases LH and FSH secretion, activates ovarian function, and leads to the first ovulation.
- Menopause is characterized by a lack of oocytes in the ovary and the subsequent failure of follicular development and estradiol secretion. LH and FSH levels rise due to the lack of negative feedback by estradiol.

Chapter Review Questions

1. Estradiol synthesis in the graafian follicle involves:
- **A.** activation of LH-stimulated granulosa production of androgen.
- **B.** stimulation of aromatase in the granulosa cell by FSH.
- **C.** decreased secretion of progesterone from the corpus luteum, resulting in increased LH.
- **D.** inhibition of the LH surge during the preovulatory period.
- **E.** synergy between FSH and progesterone.

The correct answer is B. Aromatase is present only in granulosa cells and is regulated mainly by FSH. Although LH may stimulate aromatase in granulosa cells, granulosa cells do not produce androgens. Estradiol synthesis in the graafian follicle is unrelated to progesterone synthesis in the corpus luteum and does not increase LH during this phase. Estradiol increases LH secretion during the LH surge. There is no evidence for synergy between FSH and progesterone in regulating estradiol secretion by the graafian follicle.

2. Granulosa cells do not produce estradiol from cholesterol because they do not have an active:
- **A.** 17α-hydroxylase.
- **B.** aromatase.
- **C.** 5α-reductase.
- **D.** sulfatase.
- **E.** steroidogenic acute regulatory protein.

The correct answer is A. Granulosa cells do not have the enzyme called 17α-hydroxylase, which converts progesterone to 17α-hydroxyprogesterone. Aromatase is the enzyme that converts androgens to estrogens. 5α-Reductase converts testosterone to dihydrotestosterone. Sulfatase is an enzyme that conjugates steroids with sulfate for subsequent excretion in the urine. Steroidogenic acute regulatory protein transports cholesterol from the outer to the inner mitochondrial membrane.

3. A clinical sign indicating the onset of the menopause is:
- **A.** the onset of menses near age 50.
- **B.** an increase in plasma FSH levels.
- **C.** an excessive presence of corpora lutea.
- **D.** an increased number of cornified cells in the vagina.
- **E.** regular menstrual cycles.

The correct answer is B. One of the first clinical measures for menopause is an increase in the serum concentration of FSH (and LH), indicative of the lack of ovarian function. Menses starts at age 12, not age 50, and its onset at this time would not indicate menopause. Excessive corpora lutea would likely indicate multiple ovulations or a failure of luteal regression. Increased vaginal cornification is an indicator of estrogen secretion, which does not occur in menopause. Menstrual cycles become irregular at menopause.

4. Increased progesterone during the postovulatory period is associated with:
- **A.** proliferation of the uterine endometrium.
- **B.** enhanced development of graafian follicles.
- **C.** luteal regression.
- **D.** an increase in basal body temperature by 0.5°C to 1.0°C.
- **E.** increased secretion of FSH.

The correct answer is D. Progesterone has a thermogenic effect on the hypothalamus, increasing the basal body temperature for a few days after ovulation. Women who, because of ovulatory problems, are having trouble getting pregnant are sometimes asked to record their daily oral temperatures and look for the increase in basal body temperature, indicating an increase in progesterone (which indicates ovulation). Progesterone induces a secretory type of endometrium, whereas estrogens induce a proliferative type. During the luteal phase, when progesterone is increasing, graafian follicles are not present. Progesterone levels decrease during luteal regression. FSH decreases when progesterone is rising.

5. The theca interna cells of the graafian follicle are distinguished by:
- **A.** their capacity to produce androgens from cholesterol.
- **B.** the lack of cholesterol side-chain cleavage enzyme.
- **C.** aromatization of testosterone to estradiol.
- **D.** the lack of a blood supply.
- **E.** the production of inhibin.

The correct answer is A. Theca interna cells produce androgens under the influence of LH, whereas granulosa cells do not produce androgens. Theca interna cells do contain cholesterol side-chain cleavage enzyme, which converts cholesterol to pregnenolone. Because theca cells do not express aromatase, they cannot convert testosterone to estradiol. The theca interna has a rich blood supply. Granulosa cells produce inhibin.

Clinical Application Exercises 37.1

EARLY SPONTANEOUS PREGNANCY TERMINATION

A 38-year-old woman visited her obstetrician gynecologist and complained that she was unable to get pregnant. Upon taking a medical history, the physician notes that the patient had regular 28- to 30-day cycles during the past year and engaged in unprotected intercourse. She does not smoke and does not use caffeine, drugs, or alcohol. She appears to be in good health. Her ovaries and uterus appear normal in size for her age. Laboratory tests indicate that her preovulatory (late follicular phase) estradiol is 40 pg/mL (normal, 200 to 500 pg/mL) and midluteal phase progesterone is 3 ng/mL (normal, 4 to 20 ng/mL). Her husband's sperm count is 30 million/mL.

QUESTIONS

1. What are the clinical indications of a fertility problem with this patient?
2. Based on the clinical signs, what basic physiological principles provide insight into the infertility?
3. What are some theoretical treatment options for this patient?

ANSWERS

1. There are two laboratory tests that indicate a problem, the low late follicular phase plasma estradiol concentration and the low midluteal phase plasma progesterone concentration.
2. The low estradiol could be due to the development of a small dominant graafian follicle with insufficient numbers of granulosa cells. The reduced number of granulosa cells would not contain

sufficient aromatase to synthesize the high levels of estradiol required during the late follicular phase. In addition, low estradiol could be due to inadequate FSH receptors on the granulosa cells or inadequate FSH secretion. The low estradiol could also be explained by a lack of LH stimulation of thecal androgen production from the small dominant follicle, possibly the result of inadequate LH receptors on theca cells or low LH levels. The low progesterone during the luteal phase might be due to the ovulation of a small follicle or premature ovulation of a follicle that was not fully developed. The number of LH receptors on the luteinized granulosa cells in the graafian follicle and developing corpus luteum may be insufficient, or LH secretion may be deficient. LH receptors mediate the action of LH, which stimulates progesterone secretion. An insufficient number of LH receptors could be due to insufficient priming of the developing follicle with FSH. Finally, the LH surge may be insufficient for maximal progesterone secretion.

3. Theoretical treatment options for the patient include exogenous progesterone during the luteal phase, which would raise the overall circulating progesterone to levels compatible with maintaining pregnancy, allowing implantation of the embryo. Another option would be to use exogenous FSH to stimulate follicular development to produce larger follicle(s) with sufficient estradiol secretion and LH receptors. Follicles with adequate LH receptors would respond to an LH surge with increased progesterone in the normal range. Another option is the administration of hCG during the periovulatory period for inducing ovulation and full luteinization. The latter would overcome any deficiency in the endogenous LH surge. Finally, the use of clomiphene, an antiestrogen, would increase FSH (and LH) secretion in the follicular phase and, subsequently, induce follicular development with sufficient estradiol to induce a full LH surge. Exogenous hCG could be given during the ovulatory phase to ensure full luteinization of the corpus luteum with sufficient progesterone to maintain pregnancy.

38 Fertilization, Pregnancy, and Fetal Development

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Outline the steps required to unite the sperm and egg to achieve fertilization, and explain the roles of progesterone and estrogen in the preparation of the oviduct and uterus for receiving the developing embryo.
- List the steps and timing of blastocyst implantation into the uterine wall.
- Describe the synthesis of human chorionic gonadotropin and its role in the function of the corpus luteum early during pregnancy.
- Outline the steps required in the development of the placenta and explain the importance of this organ for steroid production during pregnancy.
- List the major hormones produced by the cooperation between the maternal compartment and fetoplacental unit, and explain the role of each during the course of pregnancy.
- Describe the cause, and explain the consequences, of maternal insulin resistance during the latter half of pregnancy.
- Outline the mechanism(s) that result in parturition, including the function of cortisol, oxytocin, estrogen, and prostaglandins.
- Explain the roles of prolactin, insulin, glucocorticoids, and oxytocin in lactogenesis.
- Describe the mechanism through which lactation results in anovulation and suppression of menstrual cycles.
- Explain the processes that activate the hypothalamic–pituitary axis to initiate puberty and the effect of this activation on steroid output by the gonads.
- Outline examples of chromosomal and hormonal alterations that result in disorders of sexual development in males and females.

Fertilization, the successful union of a sperm and an egg, is the start of pregnancy in a female. The fertilized egg, or zygote, begins to divide immediately after fertilization, and a new life begins. Cell division eventually produces a **blastocyst,** which enters the uterus and implants itself into the uterine endometrium. **Implantation** can only occur in a uterus that has been primed by gonadal steroids and is receptive to the blastocyst. At the time of implantation, the trophoblast cells of the early embryonic placenta begin to produce **human chorionic gonadotropin** (**hCG**), a hormone that signals the ovary to continue to produce progesterone, the major hormone required for the maintenance of pregnancy. As a signal from the embryo to the mother to extend the life of the corpus luteum, hCG prevents the onset of the next menstruation and ovulatory cycle. The placenta, an organ produced by the mother and fetus, exists only during pregnancy to regulate the supply of oxygen and energy, and the removal of wastes, for the fetus. The placenta also produces protein and steroid hormones that are important for fetal development and maintenance of pregnancy. The fetal endocrine glands regulate important functions *in utero* including sexual differentiation.

Parturition, the expulsion of the fully formed fetus from the uterus, is the final stage of gestation. The onset of parturition is triggered by signals from both the fetus and the mother and involves biochemical and mechanical changes in the uterine myometrium and cervix. After delivery, the mammary glands of the

mother must be fully developed and secrete milk to provide nutrition to the newborn baby. The act of suckling, through neurohormonal signals, stimulates milk production and prevents new ovulatory cycles. Ovulatory cycles return at the end of the breast-feeding period. Sexual maturity is attained during puberty, which occurs at approximately 11 to 12 years of age. The onset of puberty requires changes in the sensitivity, activity, and function of several endocrine organs, including those of the hypothalamic–pituitary–gonadal axis (Clinical Focus 38.1).

CLINICAL FOCUS 38.1

In Vitro Fertilization

Candidates for *in vitro* fertilization (IVF) are women with disease of the oviducts, unexplained infertility, or endometriosis (occurrence of endometrial tissue outside the endometrial cavity, a condition that reduces fertility) and those whose male partners are infertile (e.g., low sperm count). Follicular development is induced with one or a combination of GnRH analogs, clomiphene, FSH, and menopausal gonadotropins (a combination of LH and FSH). Follicular growth is monitored by measuring serum estradiol concentration and by ultrasound imaging of the developing follicles. When the leading follicle is 16 to 17 mm wide and/or the estradiol level is >300 pg/mL, hCG is injected to mimic an LH surge and induce final follicular maturation, including maturation of the oocyte. Approximately 34 to 36 hours later, oocytes are retrieved from the larger follicles by aspiration using laparoscopy or a transvaginal approach. Oocyte maturity is judged from the morphology of the granulosa cells and the presence of the germinal vesicle and first polar body. The mature oocytes are then placed in culture media.

The donor's sperms are prepared by washing, centrifuging, and collecting those that are most motile. About 100,000 spermatozoa are added for each oocyte. After 24 hours, the eggs are examined for the presence of two pronuclei (male and female). Embryos are grown to the four-cell to eight-cell stage, about 60 to 70 hours after their retrieval from the follicles. Approximately three embryos are often deposited in the uterine lumen to increase the chance for a successful pregnancy. To ensure a receptive endometrium, daily progesterone administrations begin on the day of retrieval. The rate of success for IVF techniques depends on several factors, including the age of the female partner and normal semen analysis. ■

FERTILIZATION AND IMPLANTATION

Fertilization (conception) is the fusion of the male and female gametes (sperm with an ovum), which leads to the formation of an embryo and the development of a new organism. The oviduct facilitates the movement of the gametes toward each other, and after fertilization provides nourishment for the developing embryo while transporting it to the uterus.

Cilia and smooth muscle transport the gametes toward each other within the female genital tract.

During intercourse, a fertile man will deposit 2 to 6 mL of **semen**, the ejaculatory fluid containing 20 to 30 million sperms per milliliter, in the vagina of a woman at the time of ejaculation. Only about 50 to 100 sperms will reach the ampulla of the fallopian tube for fertilization. Major losses of sperm occur in the vagina due to the acidic pH, in the uterus due to phagocytosis by leukocytes, and at the uterotubal junction. Spermatozoa that survive reach the ampulla within 5 to 10 minutes after coitus. Sperm motility; muscular contractions of the vagina, cervix, and uterus; ciliary movement; peristaltic activity; and fluid flow in the oviducts assist transport of the sperms to the ampulla. Sperms remain motile for up to 4 days in the female reproductive tract; however, the capacity for fertilization is limited to 1 to 2 days.

Sperms undergo final maturation within the oviduct in a process called **capacitation**. As sperms develop in the epididymis of a male, surface glycoproteins are acquired that act as stabilizing factors, but which prevent the interaction of sperm and egg. During capacitation, surface glycoproteins are removed, membrane cholesterol is depleted increasing plasma membrane fluidity, and sperm motility increases. Capacitation can occur anywhere in the female reproductive tract where pH is elevated, as shown when sperms are deposited in the intraperitoneal cavity near the fimbria during assisted fertilization procedures. Sperms can also undergo capacitation in chemically defined medium during *in vitro* fertilization.

A secondary oocyte arrested in metaphase of the second meiosis is released from the ovary approximately every 28 days in response to the LH surge (see Table 37.1). Ciliated fingerlike projections of the oviducts, called **fimbria**, grasp the ovum and propel it into the oviduct. The ciliary movement and muscle contractions of the oviduct are stimulated by the estrogen synthesized by the ovary during the periovulatory period. The human ovum is most viable for fertilization for about 24 hours, with fertilization usually occurring within the 2 days following ovulation. There is a space between the fimbria and ovary that is open to the peritoneal cavity (see Fig. 37.3); if the oviducts do not actively pick up the egg when released, it can enter the abdominal cavity. An **ectopic pregnancy** may result if an ovum is fertilized in the abdomen.

The use of chemotaxic signals by sperm to find the egg is well established for marine invertebrates such as sea urchin and starfish. There is suggestive evidence that human spermatozoa are sensitive to progesterone, which is secreted by the cumulus cells surrounding the ovulated oocyte and could thus act as a chemoattractant. However, some sperms that arrive in the ampulla within the vicinity of the egg exit into the abdominal cavity, suggesting that contact between the sperm and egg may be random.

Fertilization begins as the sperm attaches to the zona pellucida and undergoes the acrosomal reaction.

The zona pellucida, or jelly coat, surrounding the ovum contains specific glycoproteins that serve as sperm receptors. When a sperm contacts one of these receptors, an increase in intracellular calcium is triggered, initiating the **acrosomal reaction** in the sperm (Fig. 38.1). The membrane surrounding the acrosome, a large secretory vesicle containing hydrolyzing enzymes, fuses with the plasma membrane of the sperm head. The proteolytic enzymes are then released to dissolve the zona pellucida, and the sperm uses the propulsive force of its tail to move toward the oocyte membrane in a process that may take up to 30 minutes.

Figure 38.1 The process of fertilization. (*1*) The sperm cell weaves past follicular cells to sperm receptors in the zona pellucida. (*2*) Intracellular calcium rises in the sperm initiating the acrosomal reaction. (*3*) Proteolytic enzymes released from the acrosome digest the zona pellucida. (*4*) The sperm penetrates the oolemma, stimulating a rise in intracellular calcium in the egg, which initiates the cortical reaction. (*5*) The rise in intracellular calcium initiates the completion of the second meiotic division and generation of the female pronucleus and second polar body. (*6*) The sperm head enlarges to become the male pronucleus, which fuses with the female pronucleus.

After entering the **perivitelline space**, the sperm head becomes anchored to the **oolemma** (plasma membrane) of the egg through a second set of sperm receptors, with microvilli protruding from the membrane surrounding and eventually engulfing the sperm, incorporating the head and tail into the **ooplasm**.

As the sperm enters the egg, it triggers a rise in intracellular calcium, causing the **cortical reaction.** Lysosome-like organelles located just underneath the oolemma begin to fuse with the membrane, beginning at the point of sperm attachment and propagating over the entire egg surface. The cortical granules contain enzymes that are released into the perivitelline space and diffuse into the zona pellucida. These enzymes act on glycoproteins in the zona pellucida, causing them to harden in a process termed the **zona reaction**. The hardened zona pellucida prevents other sperms from gaining access to the egg, preventing polyspermia (see Fig. 38.1).

The increase in intracellular calcium initiated by entry of the sperm into the ooplasm also triggers completion of the second meiotic division. The chromosomes of the egg separate, and half of the chromatin is extruded as a small second polar body. The remaining haploid nucleus with its 23 chromosomes transforms into the **female pronucleus** (see Fig. 38.1). As the nuclear envelope of the sperm disintegrates, the **male pronucleus** forms and increases four to five times in size. Contractions of microtubules and microfilaments visible 2 to 3 hours after the entry of the sperm into the egg move the two pronuclei to the center of the cell. Replication of the haploid chromosomes begins in both pronuclei. Pores form in the nuclear membranes of the two pronuclei, which then fuse. Successful fertilization thus restores the full complement of 46 chromosomes, initiating the development of an embryo.

The first mitotic division occurs 24 to 36 hours following fertilization and yields two cells called **blastomeres**. Successive divisions produce four- and eight-blastomere structures, at 48 and 72 hours later, respectively. The morula, a solid ball of at least 12 blastomeres, is formed by 96 hours postfertilization. Cell division occurs without growth; thus, cells in the developing embryo become progressively smaller. The developing embryo also remains enclosed in the zona pellucida, which protects it from damage, adhesion to the uterine wall, and immunologic rejection by the mother. Development up to the morula stage occurs within the oviduct because smooth muscle contractions of the isthmus prevent advancement of the conceptus into the uterus while the endometrium is prepared for implantation.

Process of implantation proceeds through stages: apposition, adhesion, and invasion.

The morula enters the uterus 4 to 6 days after fertilization. It remains suspended in the uterine cavity for 2 to 3 days, continuing to undergo cell division, nourished by constituents of the uterine fluid. At the 20- to 30-cell stage, a fluid-filled cavity (blastocoele) appears and enlarges until the embryo becomes a hollow sphere, called a **blastocyst**. The cells of the blastocyst undergo significant differentiation. A single outer layer consists of extraembryonic ectodermal cells called the **trophoblast**, which facilitates implantation, forms the embryonic contribution to the placenta and embryonic membranes, produces hCG, and provides nutrition to the embryo. A cluster of smaller, centrally located cells constitutes the **embryoblast** or inner cell mass and gives rise to the fetus.

As the blastocyst approaches the uterine endometrium, the surrounding zona pellucida is ruptured as the blastocyst expands, aided by proteases released from the endometrium. A loose association of the blastocyst with the endometrial wall, called **apposition**, then occurs (Fig. 38.2). The blastocyst secretes cytokines and hormones including interleukin-1α and interleukin-1β that promote endometrial receptivity. The endometrium responds by secreting leukemia inhibitory factor, colony-stimulating factor-1, and other signals that increase trophoblast protease production. The paracrine interaction between the blastocyst and endometrium results in **adhesion** between the two structures. Cellular adhesion molecules including integrins are expressed by both the trophoblast cells and the endometrium. Expression of the integrins αVβ3 and α4β1 by the endometrium, induced by luteal phase estrogen and progesterone production, is considered a receptivity marker for the blastocyst.

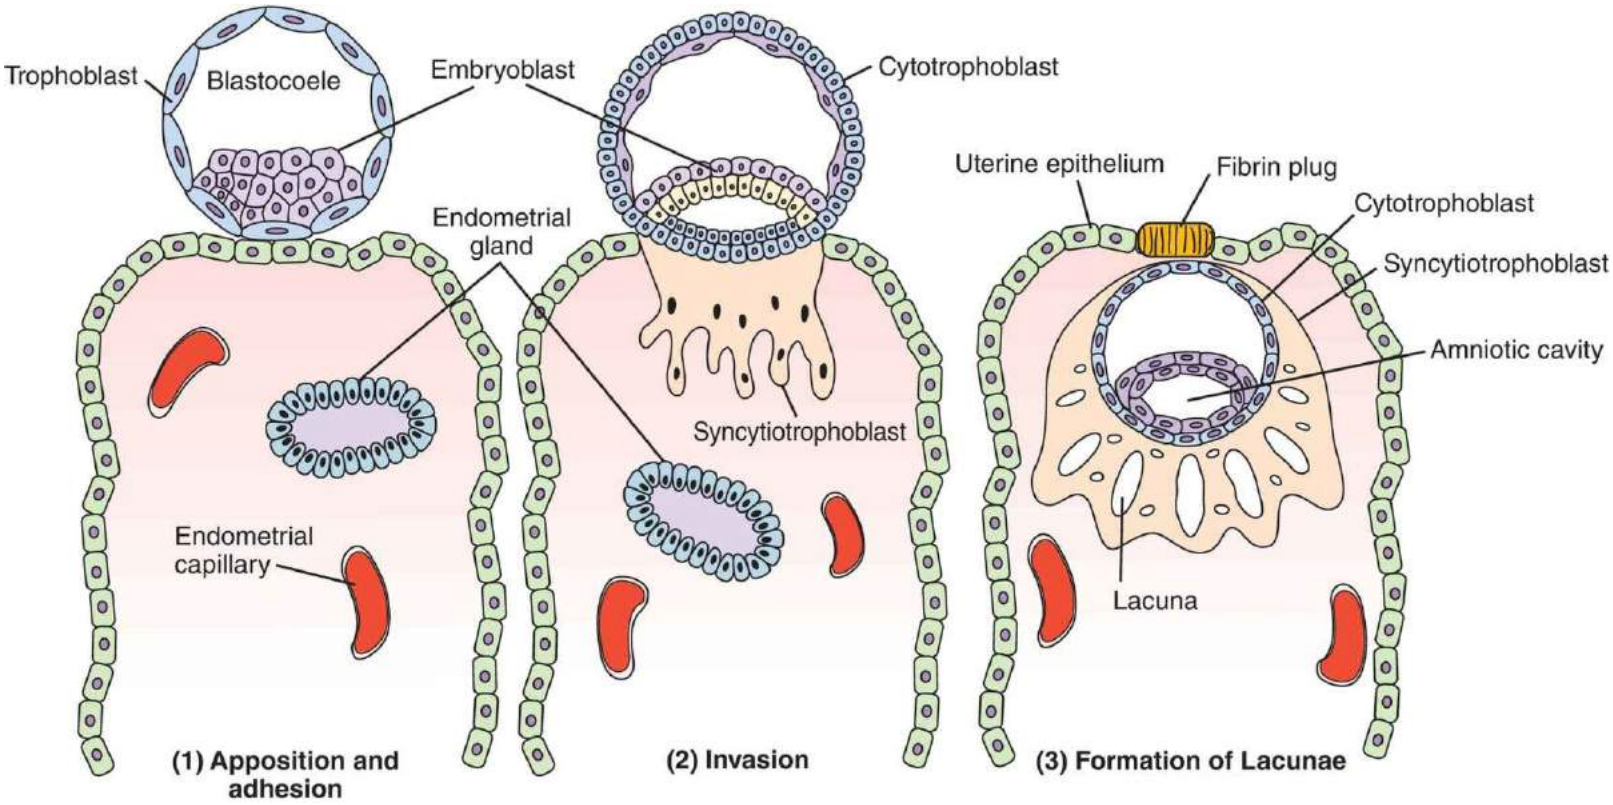

Figure 38.2 Embryo implantation and initiation of placental development. (*1*) The blastocyst loosely adheres to the endometrium (apposition) and then adheres by binding between cellular adhesion molecules. (*2*) The trophoblast differentiates into the syncytiotrophoblast and cytotrophoblast. The syncytiotrophoblast invades the epithelium to reach the uterine stroma. (*3*) The blastocyst is fully

embedded in the uterine wall. Lacunae form within the syncytiotrophoblast and fill with maternal blood. Eventually, the lacunae will coalesce into the intervillous space, and the chorionic villi will form, creating the fully developed placenta.

Differentiation of the trophoblast to syncytiotrophoblasts

Following adhesion, the trophoblast differentiates into large polyhedral **cytotrophoblasts,** with well-defined cell borders that surround the blastocyst, and multinucleated **syncytiotrophoblasts** that lack distinct cell boundaries (see Fig. 38.2). The syncytiotrophoblast extends long protrusions between the uterine epithelial cells, secreting proteases that digest the basement membrane to eventually reach the uterine stroma and initiate the **decidual reaction**, resulting in a highly specialized endometrium of pregnancy. The endometrial stromal cells hypertrophy to contain large amounts of glycogen and lipid and modify their plasma membrane, creating a specialized group of cells called the **decidua**. Decidualization is initiated by estrogen and progesterone, with the cellular transformation completed by factors released by the invading blastocyst. The decidua is classified into three parts based on anatomic location. Decidua directly beneath the implanting embryo, which is modified by the invading syncytiotrophoblast, becomes the **decidua basalis**. The **decidua capsularis** overlies the enlarging blastocyst and separates the conceptus from the rest of the uterine cavity. The **decidua parietalis** covers the remainder of the uterine wall.

As the syncytiotrophoblast continues to invade the endometrium, fluid-filled holes called lacunae begin to form. These lacunae eventually fill with maternal blood as the syncytiotrophoblast permeates first small veins and then small arteries within the endometrium. Mesenchymal cells from the embryonic mesoderm protrude into the lacunae and form fetal blood vessels, establishing a functional communication between the developing embryonic vascular system and the maternal blood (see Fig. 16.6).

Embryoblast differentiation

By day 10 to 12 following ovulation, the blastocyst is totally encased with the endometrium. The inner cell mass differentiates into an ectoderm, endoderm, and mesoderm. The ectoderm will eventually form the epidermis, appendages (nails and hair), and the entire nervous system. The endoderm gives rise to the epithelial lining of the digestive tract and associated structures, and the mesoderm will form the bulk of the body, including connective tissue, muscle, bone, blood, and lymph.

PLACENTAL NUTRIENT UPTAKE, WASTE ELIMINATION, AND GAS EXCHANGE

Chorionic villi are the functional units of the placenta (Fig. 38.3). As mentioned above, these structures begin to form on days 12 to 15, as cytotrophoblast cells extend into the syncytiotrophoblast to the lacunae containing endometrial blood. Mature chorionic villi form when mesenchymal cells from the embryonic mesoderm migrate into the lacunae and form fetal blood vessels. Chorionic villi initially spread over the entire surface of the **chorionic sac**, the outmost membrane surrounding the developing embryo. However, by the third month of development, the chorionic villi are confined to the **chorionic plate**, an area of the chorion directly opposite of the decidua basalis. The chorionic villi aggregate into groups known as **cotyledons** that protrude into the **intervillous space**, a large contiguous area formed as the maternal blood–filled lacunae expand and merge with one another. The decidua basalis and chorionic plate together constitute the placenta proper (see Fig. 38.3).

Figure 38.3 Two stages in the development of the placenta, showing the origin of the membranes around the fetus. Note the three decidual layers and their relationship to the developing fetus. Chorionic villi develop early in placental development.

As the placenta forms, the decidua capsularis surrounding the fetus and the decidua parietalis fuse to occlude the uterine cavity, and the extraembryonic membranes develop. From the fourth month onward, the fetus is fully enclosed within the **amnion** and **chorion**, connected to the placenta by the **umbilical cord**. Two umbilical arteries approach the placenta and branch into capillaries within the chorionic villi. These arteries carry deoxygenated blood to the placenta, which returns to the fetus with oxygen and nutrients through a single umbilical vein. The fetal and maternal circulations remain separated by the chorionic villi, where the maternal blood surrounds the fetal endothelium. Thus, the human placenta is classified as hemochorial, a type of placenta in which maternal blood is in direct contact with chorionic villi.

Oxygen diffuses from maternal to fetal blood down an initial gradient of 60 to 70 mm Hg. **Fetal hemoglobin** has a high affinity for oxygen and enhances the oxygen-transporting capacity of fetal blood. The PCO_2 of fetal arterial blood is 2 to 3 mm Hg higher than that of maternal blood, allowing the diffusion of carbon dioxide toward the maternal compartment. Other compounds, such as glucose, amino acids, free fatty acids, electrolytes, vitamins, and some hormones, are transported by diffusion, facilitated diffusion, or pinocytosis. The lipid-soluble steroid hormones readily pass through the placenta. Some immunoglobulins, viruses, and drugs can also transfer across the blood–placental barrier from the mother to the fetus (Fig. 38.4).

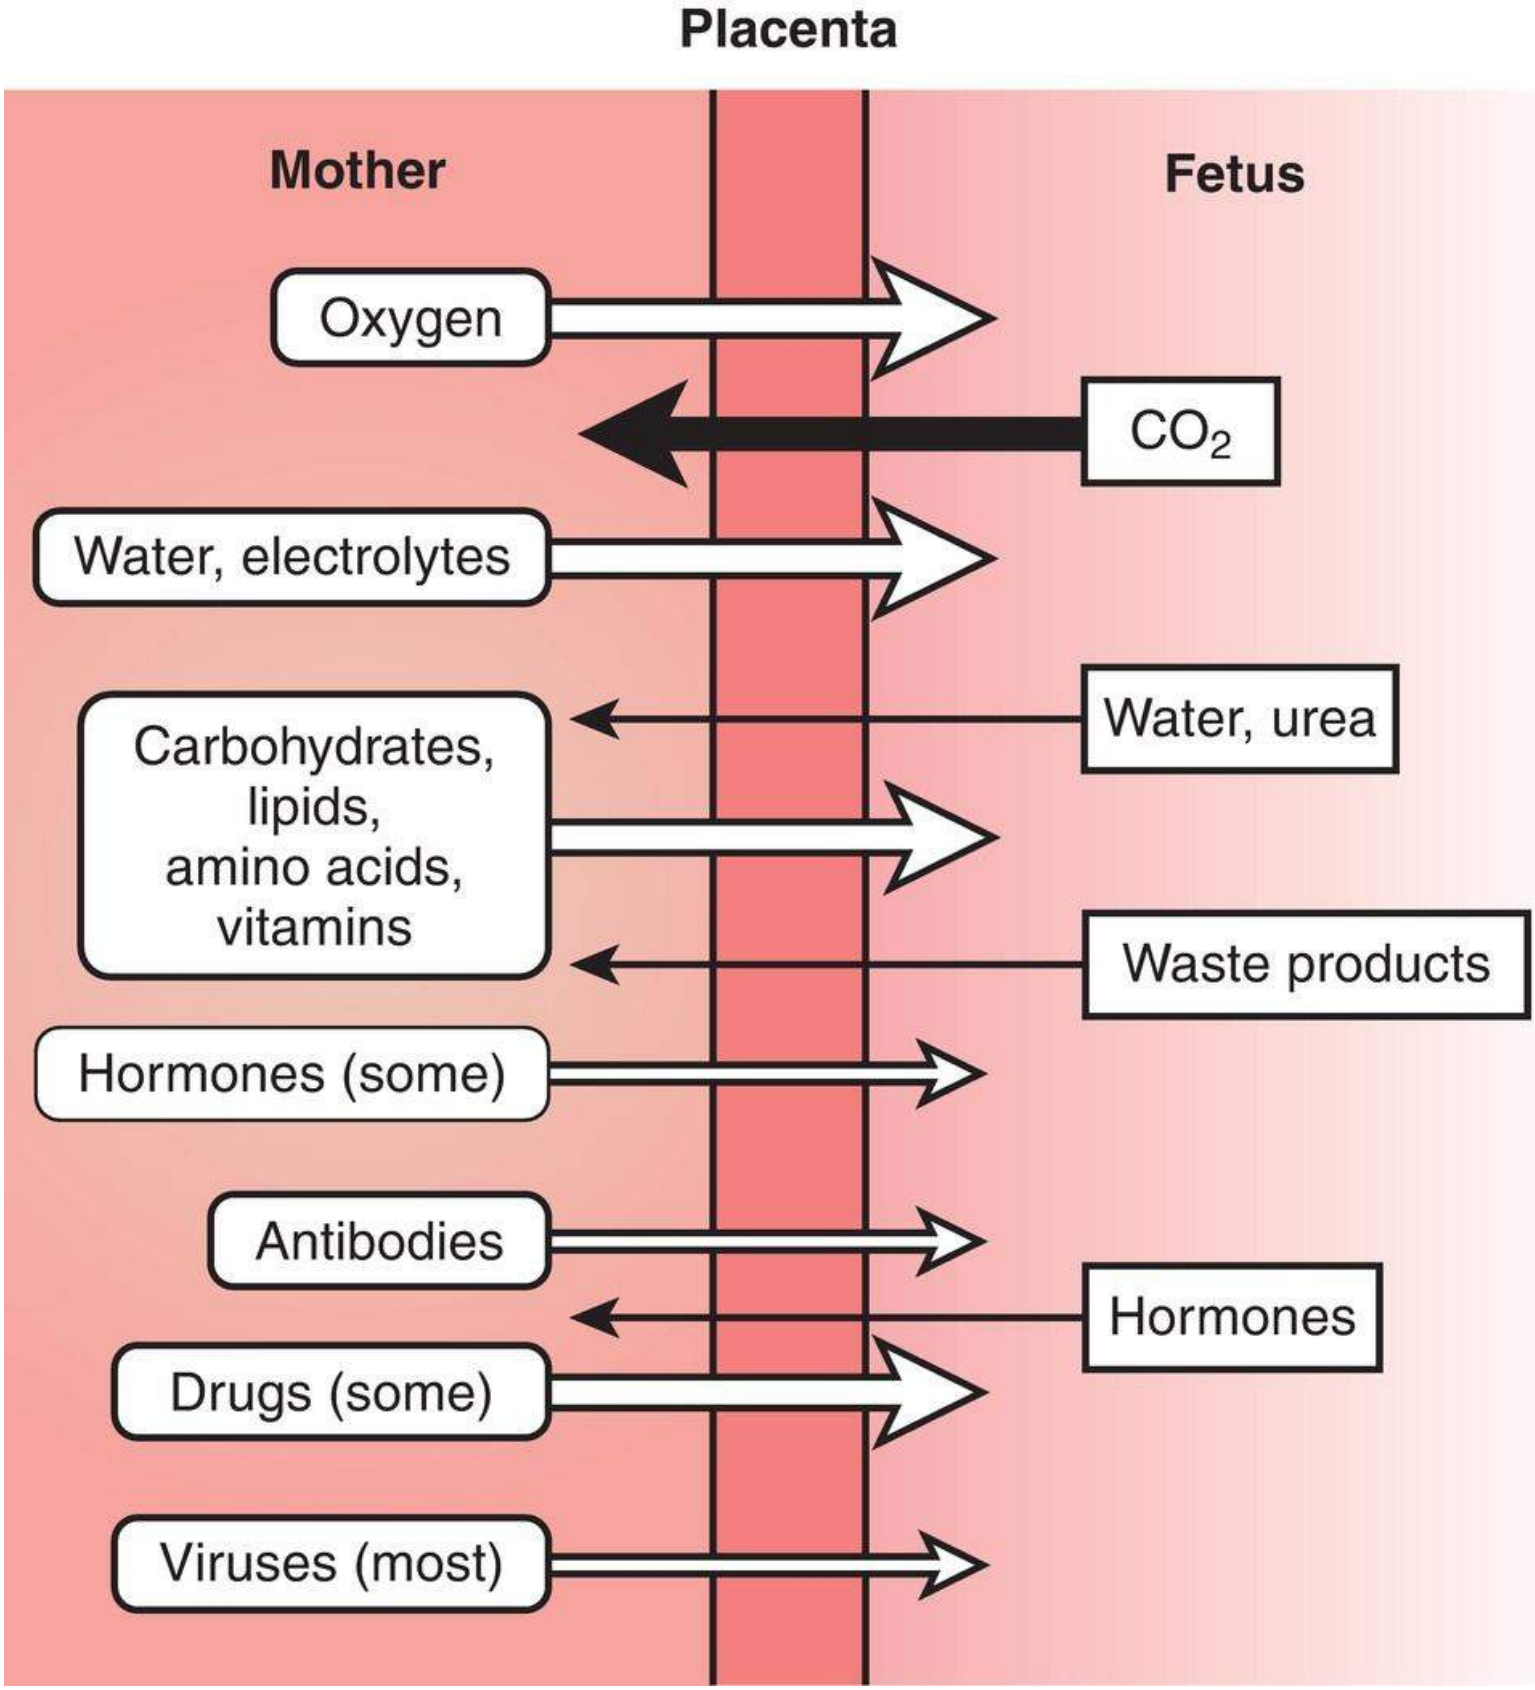

Figure 38.4 Role of the placenta in exchanges between the fetal and maternal compartments. The size of the *arrows* indicates the amount of exchange between the compartments.

Waste products, such as urea and creatinine, diffuse down their concentration gradients from the fetus into the amniotic fluid. The fetal kidneys mature at 10 to 12 weeks, after which they produce 75% of the amniotic fluid. The fetal gastrointestinal tract, amnion, and lungs remove the amniotic fluid, sending the waste products to the material compartment.

HORMONES REQUIRED FOR A SUCCESSFUL PREGNANCY

The placenta produces **progesterone** and **estrogens**, which are essential for the continuance of pregnancy. The placenta also secretes peptide hormones including **human placental lactogen** (**hPL**) and human chorionic gonadotropin (hCG). Corticotropin-releasing hormone (CRH), gonadotropin-releasing hormone (GnRH), and insulin-like growth factors synthesized by the placenta function as paracrine factors.

During a nonconception menstrual cycle, the corpus luteum regresses and circulating progesterone and estrogen decline. With the loss of ovarian steroidal support, the superficial endometrial layer of the uterus degrades, resulting in menstruation. If the egg is fertilized, the developing embryo signals its presence by producing hCG, which extends the life of the corpus luteum, a process called the **maternal recognition of pregnancy**. Syncytiotrophoblast cells produce hCG, which enters the maternal circulation 6 to 8 days after fertilization. hCG can be detected in the urine of a pregnant woman, which is the basis of colorimetric pregnancy tests.

Human chorionic gonadotropin maintains corpus luteum steroidogenesis.

hCG is a glycoprotein structurally similar to LH, FSH, and TSH, with which it shares an identical 92–amino acid α subunit. The β subunit of hCG resembles the β subunit of LH, but with a 24–amino acid extension at the C-terminal end, and includes six N-linked and O-linked oligosaccharide units. Due to this extensive glycosylation, the half-life of hCG in the circulation is longer than that of LH. The major function of hCG in early pregnancy is the stimulation of luteal steroidogenesis. hCG binds to LH receptors on the corpus luteum to activate the rate-limiting step in steroidogenesis, the synthesis of pregnenolone from cholesterol.

Maternal plasma hCG levels double every 2 to 3 days during early pregnancy and reach peak levels at about 10 to 15 weeks of gestation. At week 25, hCG is reduced about 75% from peak and remains at that lower level until term (Fig. 38.5). Fetal concentrations of hCG follow a similar pattern. Maternal plasma hCG levels are higher in pregnancies with multiple fetuses. During the first trimester, GnRH produced by the cytotrophoblasts regulates hCG production through paracrine signaling. The suppression of hCG release during the second half of pregnancy results from negative feedback by placental progesterone and other steroids produced by the fetus. Corpus luteum progesterone secretion is maximal at 4 to 5 weeks after conception but declines despite the rising hCG levels. Corpus luteum refractoriness to hCG results from receptor desensitization and the rising levels of placental estrogens. From weeks 7 to 10 of gestation, steroid production by the placenta gradually replaces steroid production by the corpus luteum. Surgical removal of the corpus luteum after week 10 does not terminate pregnancy. Activin, inhibin, and transforming growth factors α and β are additional placenta-derived growth factors that regulate hCG production.

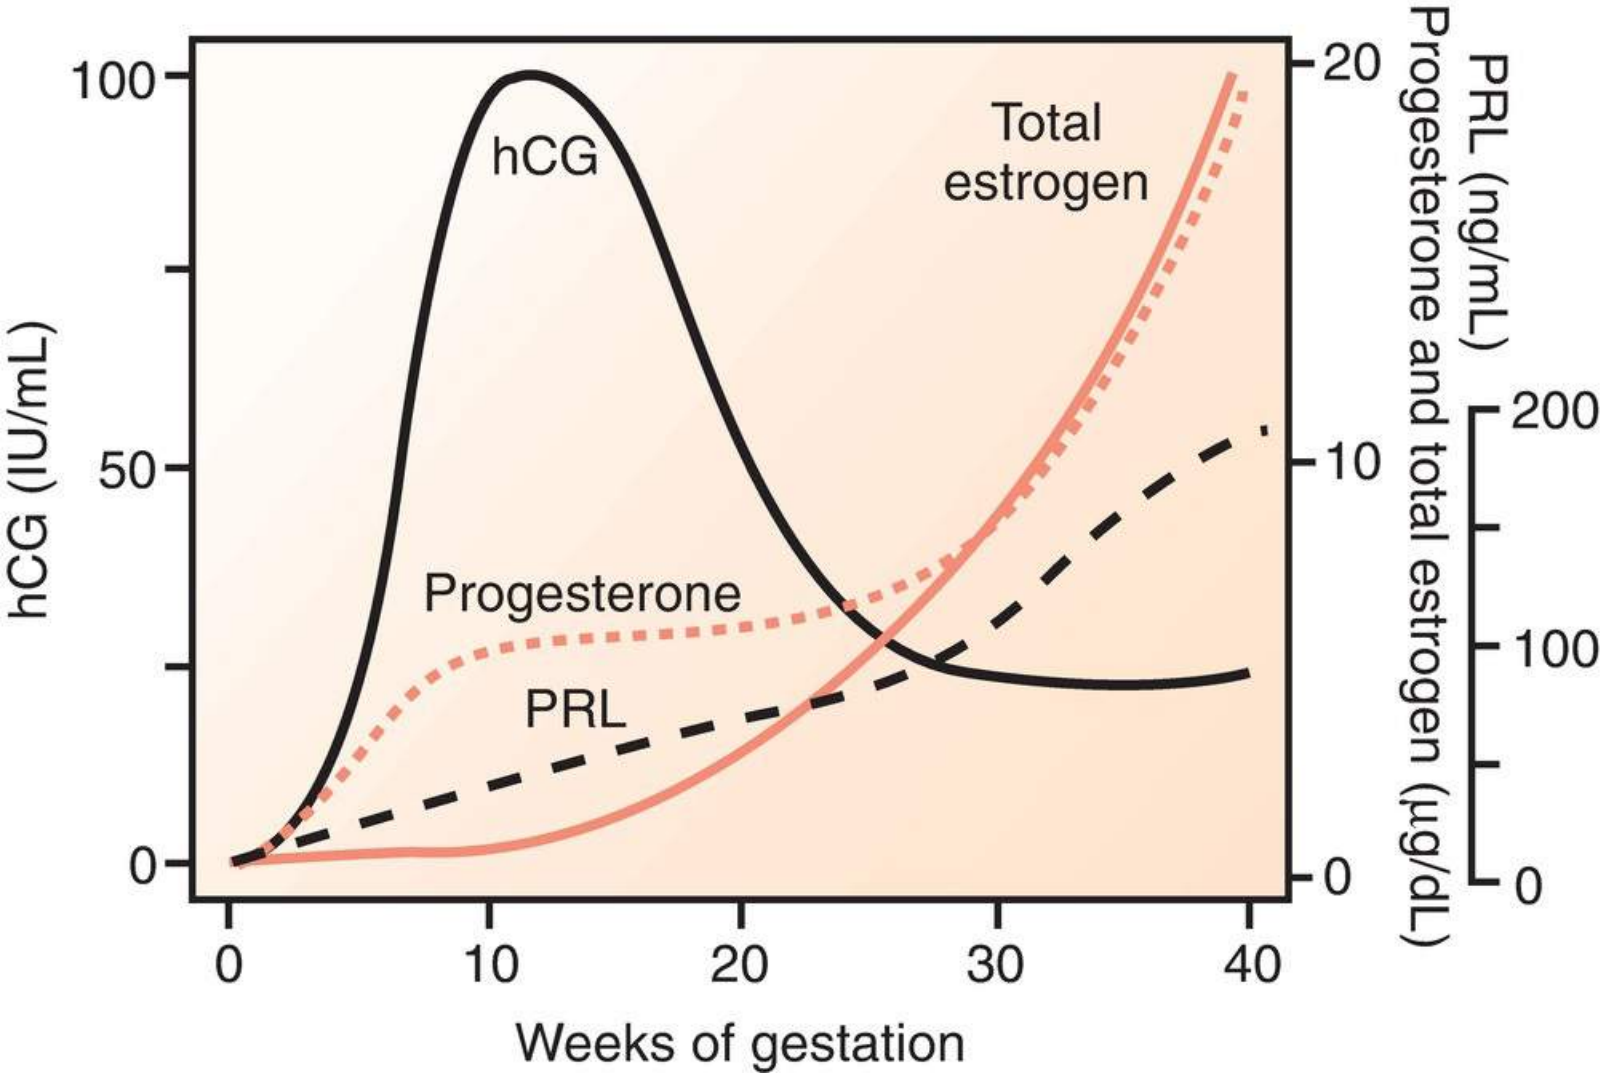

Figure 38.5 Human chorionic gonadotropin (hCG), progesterone, total estrogens, and prolactin (PRL) levels in the maternal blood throughout gestation. Total estrogen represents estradiol and estriol.

Other important targets of hCG are the fetal adrenal gland and testes. hCG is important in the sexual differentiation of the male fetus, which depends on testosterone production by the fetal testes. Peak testosterone production occurs 11 to 17 weeks after conception, coinciding with peak hCG production and predating the functional maturity of the fetal hypothalamic–pituitary axis (thus, fetal LH levels are low). Fetal Leydig cell proliferation and testosterone biosynthesis are regulated by hCG through LH/hCG receptors that appear early in fetal testes development. LH/hCG receptors are not present on fetal ovaries; thus, a role for hCG in fetal ovarian development is less clear.

Human placental lactogen regulates fetal fuel metabolism.

Human placental lactogen (hPL) is a single-chain polypeptide hormone of 191 amino acids with two disulfide bridges. Its structure and function resemble those of prolactin and growth hormone. As a result, it is also called chorionic somatomammotropin and chorionic growth hormone. Three genes encode chorionic somatomammotropin, but only two are transcribed. hPL is synthesized by syncytiotrophoblasts in proportion to placental mass and secreted into the maternal circulation where its levels gradually rise from the third week of pregnancy until term.

The main function of hPL is to regulate fuel availability for the fetus by antagonizing maternal glucose consumption and enhancing maternal fat mobilization. The effects of hPL on carbohydrate, protein, and fat metabolism are similar to those of GH. Despite its important metabolic effects, lack of hPL does not impair pregnancy.

Maternal and fetoplacental units cooperate to produce steroids during pregnancy.

The corpus luteum is the primary source of progesterone and estrogen during the first ~8 weeks of pregnancy. As the placenta develops, the trophoblast cells gradually become the major site of progesterone and estrogen production, although the corpus luteum continues to secrete progesterone. Blood progesterone levels gradually rise during early pregnancy and plateau during the transition period from corpus luteal to placental production (see Fig. 38.5). Thereafter, plasma progesterone levels rise to almost 150 ng/mL near the end of pregnancy. Estradiol and estriol rise gradually during the first half of pregnancy, but increase steeply in the latter half to more than 25 ng/mL near term.

Progesterone and estrogen have numerous functions throughout gestation. Estrogens increase the size of the uterus and uterine blood flow, are critical to the timing of implantation of the embryo into the uterine wall, induce the formation of uterine receptors for progesterone and oxytocin, enhance fetal organ development, stimulate maternal hepatic protein production, and increase the mass of the pregnant woman's breast and adipose tissues. Progesterone is essential for maintaining the uterus and early embryo, inhibits myometrial contractions, and suppresses maternal immunologic responses to fetal antigens. Progesterone also serves as a precursor for steroid production by the fetal adrenal glands and plays a role in the onset of parturition.

The placenta and fetus lack certain steroidogenic enzymes and therefore cannot synthesize all steroids required during pregnancy and fetal development. Thus, the placenta, fetus, and mother share precursors and intermediates to facilitate steroidogenesis.

The placenta obtains cholesterol for steroidogenesis from LDL particles in the maternal blood. The trophoblast cells express **LDL receptors**, which bind and internalize LDL particles, from which cholesterol ester hydrolase produces free cholesterol. The cholesterol side-chain cleavage enzyme then synthesizes pregnenolone from the free cholesterol followed by the conversion of pregnenolone to progesterone by 3β-hydroxysteroid dehydrogenase. Progesterone produced by the placenta then diffuses to the maternal and fetal circulations (Fig. 38.6).

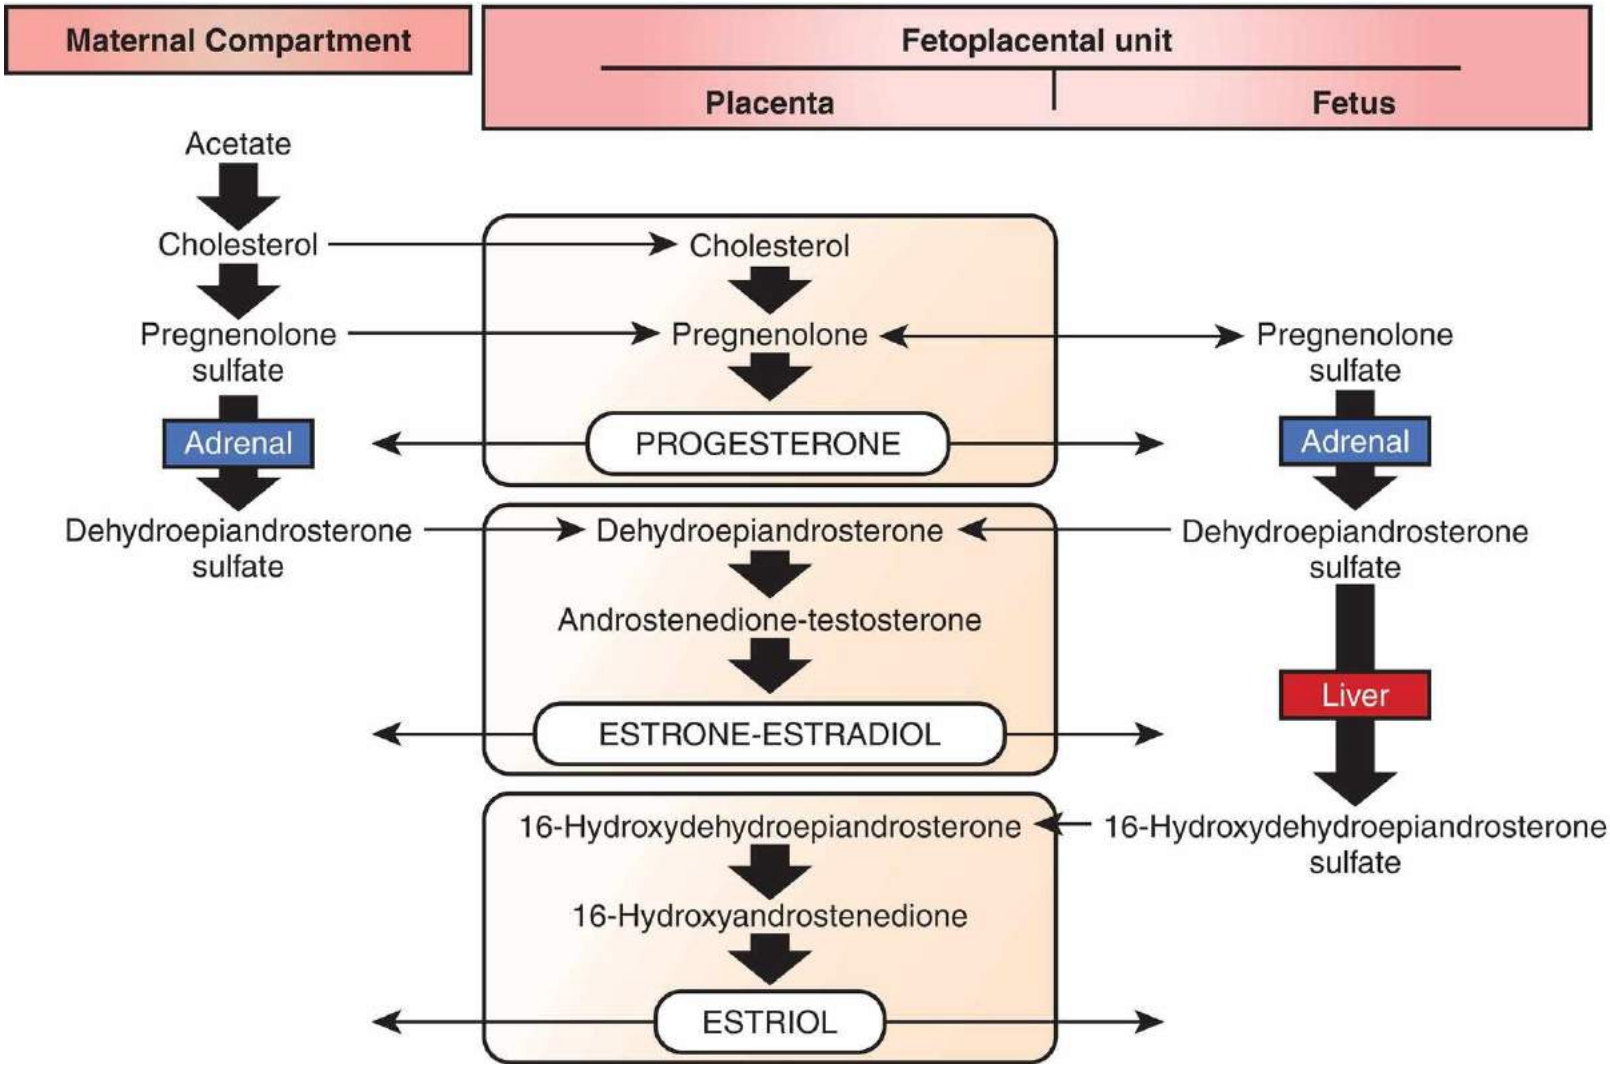

Figure 38.6 The interaction of the maternal compartment and fetoplacental unit in steroidogenesis. Estriol is the major estrogen produced by the placenta and is the product of reactions occurring in the fetal adrenal, fetal liver, and placenta.

The placenta lacks 17α-hydroxylase, which is required to convert progesterone to 17α-progesterone and thus cannot make androgens. Of importance, 17α-hydroxyprogesterone released by the corpus luteum is detectable in maternal blood during the first trimester and serves as a marker of corpus luteum function. To produce estrogens, the placenta uses androgenic substrates derived from both the fetus and the mother (see Fig. 38.6). The primary androgenic precursor is **dehydroepiandrosterone sulfate** (**DHEAS**), which is produced by the maternal and fetal adrenal gland. The fetal adrenal gland is extremely active in the production of steroid hormones, but it lacks 3β-hydroxysteroid dehydrogenase and cannot make progesterone. Therefore, the fetal adrenals use progesterone from the placenta to synthesize and sulfate dehydroepiandrosterone. The conjugation of androgenic precursors to sulfate ensures greater water solubility, aids in transport, and reduces biologic activity while in the fetal circulation. DHEAS diffuses into the placenta and is cleaved by a sulfatase to yield dehydroepiandrosterone, which is converted to androstenedione and then testosterone. The placenta has an active aromatase that converts testosterone to estradiol and estrone, which enter the maternal and fetal circulation.

The main estrogen produced by the placenta is estriol, which has weak estrogenic activity. Estriol is produced by cooperation between the placenta and fetus (see Fig. 38.6). Within the fetal liver, 16α-hydroxylase converts DHEAS produced by the fetal adrenal gland to 16-hydroxydehydroepiandrosterone sulfate (16-OH-DHEAS), which diffuses to the placenta where the sulfate group is removed. Placental

3β-hydroxysteroid dehydrogenase converts 16-OH-DHEAS to 16-hydroxyandrostenedione, which is subsequently aromatized to estriol. The maternal adrenal can synthesize 16-OH-DHEAS from maternal DHEAS but does not do so to any significant extent; thus, it is estimated that 90% of estriol is derived from the fetal 16-OH-DHEAS. The levels of estriol in plasma, amniotic fluid, or urine can be used as an index of fetal well-being. Low levels of estriol would indicate potential fetal distress, although rare inherited sulfatase deficiencies can also lead to low estriol.

Maternal metabolism and endocrine function change to support gestation.

The pregnant woman undergoes significant adjustments in her pulmonary, cardiovascular, renal, metabolic, and endocrine systems to support her growing fetus. Notable changes include hyperventilation, reduced arterial blood PCO_2 and osmolality, increased blood volume and cardiac output, increased renal blood flow and glomerular filtration rate, and substantial weight gain. These changes are brought about by the rising levels of estrogens, progesterone, hPL, and other placental hormones and by mechanical factors such as the expanding size of the uterus and the development of uterine and placental circulations.

There are a number of adaptations in the maternal endocrine system. The high levels of sex steroids suppress the hypothalamic–pituitary–ovarian axis; thus, circulating gonadotropins are low, and ovulation does not occur during pregnancy. In contrast, the rising levels of estrogens stimulate PRL release, which begins to rise during the first trimester, increasing gradually to reach a level 10 times higher near term (see Fig. 38.5). Estrogen stimulates hyperplasia and hypertrophy of the pituitary lactotrophs that synthesize PRL, resulting in enlargement of the pituitary gland. In contrast, the somatotrophs that produce GH are reduced in size, and GH levels are low throughout pregnancy.

The thyroid gland enlarges during pregnancy, but TSH levels remain in the normal range. T_3 and T_4 increase, but estrogen also increases thyroxine-binding globulin synthesis; thus, the pregnant woman remains euthyroid. The parathyroid glands enlarge, and PTH secretion increases during the third trimester. PTH stimulates calcium mobilization from maternal bone stores to meet the growing fetal demand for calcium. Mineralocorticoid and glucocorticoid release from the maternal adrenal increase. Plasma-free cortisol is higher because it is displaced from the cortisol-binding globulin transcortin by the high levels of progesterone, but hypercortisolism does not develop. Maternal ACTH levels rise throughout pregnancy to levels fivefold higher than that prior to pregnancy. ACTH falls 50% just before parturition and then increases 15-fold during the stress of delivery. Both the maternal pituitary and the placenta contribute to the increase in ACTH.

Maternal metabolism also responds to the increasing nutritional demands of the fetus. The major net weight gain of the mother occurs during the first half of gestation, resulting primarily from effects of progesterone to increase appetite and divert glucose into fat synthesis and storage. When the metabolic requirements of the fetus peak later in pregnancy, and also during periods of starvation, the extra fat stores are used as an energy source. Toward the second half of gestation, the mother develops insulin resistance, brought about by the combined effects of GH, PRL, hPL, glucagon, and cortisol, hormones that antagonize insulin action. As a result, maternal glucose usage declines and gluconeogenesis increases, maximizing glucose availability for the fetus.

Fetal endocrine system develops early to regulate fetal homeostasis.

The protective intrauterine environment postpones the initiation of some physiologic functions that are essential for life after birth. For example, the fetal lungs and kidneys do not act as organs of gas exchange and excretion because the placenta carries out these functions. Constant isothermal surroundings alleviate the need to expend calories to maintain body temperature. The gastrointestinal tract does not carry out digestion, and fetal bones and muscles do not support weight or locomotion. Exposure to limited levels of external stimuli results in the slow development of the fetal nervous and immune systems. In contrast, the fetal endocrine system plays a vital role in fetal growth, development, and homeostasis.

The blood–placental barrier excludes most protein and polypeptide hormones from the fetus; thus, the maternal endocrine system has limited direct effects on the fetus. Rather, the fetus is fairly self-sufficient in its hormonal requirements, with the exception of the steroid hormones produced by the fetoplacental unit, which cross easily between the different compartments to carry out integrated functions in both the fetus and the mother. In general, fetal hormones perform the same functions for the fetus as in the adult, but they also subserve unique processes such as sexual differentiation and the initiation of labor.

Hypothalamic–pituitary axis development

The fetal hypothalamic nuclei develop and express releasing hormones such as TRH and GnRH by ~12 weeks of gestation. The anterior pituitary, which forms from the Rathke pouch (an ectodermal evagination of the roof of the fetal mouth) beginning at gestation week 4, is present by gestation week 8, and most anterior pituitary hormones can be identified. The posterior pituitary, which forms by evagination of the floor of the primitive hypothalamus, is present by week 14 and arginine vasopressin (AVP) and oxytocin can be detected. Overall, the hypothalamic–pituitary axis is functional by 12 to 17 weeks of gestation, although the maturation of the portal vascular system continues until 30 to 35 weeks' gestation. The release of pituitary hormones occurs prior to the full maturation of the portal system, suggesting that the hypothalamic-releasing hormones diffuse down to the pituitary from hypothalamic sites of synthesis.

Adrenal gland production of steroidogenic precursors

The fetal adrenal glands are present as distinct organs by 8 weeks' gestation and are composed of three functional zones. The outer definitive zone synthesizes glucocorticoids and mineral corticoids, with the transitional zone producing cortisol. The inner fetal zone, which is much larger than the other two zones, synthesizes significant amounts of androgens such as DHEAS, which are used by the placenta to make estrogens (see Fig. 38.6). The fetal adrenal glands grow rapidly during gestation and at birth are 10- to 20-fold larger than adult adrenals. Postnatally, the adrenal gland undergoes rapid involution due to regression of the inner fetal zone, which is absent by 6 months of age. ACTH is potent stimulus for fetal adrenal steroidogenesis and is required for adrenal growth, as evidenced by the observation that anencephalic fetuses with low ACTH experience fetal zone involution at 15 weeks' gestation. The adrenal medulla develops by about week 10 and is capable of producing epinephrine and norepinephrine. Cortisol has multiple functions in the fetus such as stimulating pancreas and lung maturation, inducing expression of liver enzymes, and promoting intestinal tract cytodifferentiation.

PTH and calcitonin promotion of calcium uptake and bone growth

Calcium is in large demand because of the rapid growth and large amount of bone formation of the fetus. The placenta has a specialized calcium pump that transfers calcium to the fetus, resulting in sustained

increases in calcium and phosphate throughout pregnancy. PTH and calcitonin are evident in the fetus near week 12 of gestation and are important in promoting placental uptake and calcium and bone anabolism, respectively. Fetal PTH also acts on the fetal kidney to promote synthesis of 1,25-dihydroxyvitamin D, which stimulates cartilage and bone growth. At the end of gestation, calcium and phosphate levels in the fetus are higher than those in the mother. However, after delivery, neonatal calcium levels decrease and PTH levels increase to raise serum calcium levels.

Insulin and insulin-like growth factors are required for fetal growth.

The rate of fetal growth increases significantly during the last trimester and includes significant adipose tissue deposition. Surprisingly, GH of maternal, placental, or fetal origin has little effect on fetal growth, as judged by the normal weight of hypopituitary dwarfs or anencephalic fetuses. However, the insulin-like growth factors (IGF-1 and IGF-2) have been shown in mouse studies to be required for placental and fetal growth. Absence of these hormones or their receptors results in significant growth retardation with small placentas. Expression of IGF-1 and IGF-2 is not regulated by GH, which increases in the fetus up to midgestation and then decline when fetal weight is increasing significantly. Rather, nutrition is the major factor modulating IGF production in the fetus.

Insulin is produced by the fetal pancreas by week 10 of gestation at a relatively constant rate, increasing only slightly in response to a rapid rise in blood glucose levels. Glucose is the main metabolic fuel for the fetus, but insulin is not needed for fetal tissue glucose uptake as a relatively constant glucose supply is provided by the mother. However, near-term fetal insulin can increase glucose uptake and lipolysis in fetal tissues. Insulin is considered a fetal growth factor because babies born to women with **diabetes mellitus** and hyperinsulinemia are larger with more adipose tissue deposition. Babies with congenital hyperinsulinemia are also born larger. In contrast, insulin receptor mutations in humans lead to severe intrauterine growth retardation. In women who develop **gestational diabetes**, which results in chronically elevated blood glucose, the fetal pancreas becomes enlarged and fetal insulin levels increase. Consequently, fetal growth is accelerated, and infants of women with uncontrolled diabetes are also born large for gestational age.

There are a large number of additional factors that are involved in fetal growth and development including epidermal growth factor, nerve growth factor, platelet-derived growth factors, fibroblast growth factors, angiogenic growth factors, and members of the transforming growth factor β family. Expression of loss of function and gain of function mutations in these factors in either the fetus or placenta can result in developmental abnormalities.

Placental and fetal factors induce parturition

Parturition is the culmination of a pregnancy, occurring on average 270 ± 14 days from the time of fertilization. Uncoordinated uterine contractions start about 1 month before the end of gestation. Strong rhythmic contractions (*labor*) that may last several hours and eventually generate enough force to expel the fetus terminate the pregnancy. There are a number of mechanisms through which parturition is achieved.

In humans, placental CRH levels in the maternal circulation increase exponentially throughout gestation and may be a coordinating signal for the fetus and uterus to initiate labor. Maturation of the fetal lung is required for survival of the fetus following delivery. Placenta CRH can stimulate fetal pituitary ACTH release and cortisol synthesis, promoting lung maturation. In the mother, placental CRH also increases cortisol levels, which results in maternal androgen synthesis and greater estriol production from the placenta. The rise in estriol acts on the myometrium to induce contractile proteins. Late in pregnancy, CRH also appears to alter the expression of progesterone receptors in the myometrium.

Throughout most of pregnancy, progesterone keeps the uterus quiescent by reducing expression of contractile proteins and hyperpolarizing myometrial cells, a process termed **progesterone block**. It also prevents the release of phospholipase A_2, the rate-limiting enzyme in prostaglandin synthesis (see below). In many species, a sharp decline in progesterone at term induces uterine contractions; however, in humans, progesterone does not significantly fall before parturition. Rather, expression of an alternative progesterone receptor is induced by the elevated CRH, and this receptor functions as an inhibitor of progesterone action on target genes, resulting in withdrawal of the progesterone block.

Prostaglandins produced by uterine decidual cells play a key role in the initiation of labor. Prostaglandin F_{2a} and E_2 stimulate uterine contractions in a paracrine manner and potentiate oxytocin-induced contractions by promoting formation of gap junctions between uterine smooth muscle cells. The prostaglandins also cause softening, thinning, and dilation of the cervix. The myometrium, decidua, and chorion all produce prostaglandins, and shortly before the onset of parturition, the prostaglandin concentration in amniotic fluid rises abruptly. Aspirin and indomethacin block prostaglandin synthesis, inhibiting labor and prolonging gestation.

Cessation of uterine growth toward the end of pregnancy may also contribute to the initiation of parturition. Stretch, which would be induced by the increasing tension on the uterine wall, usually leads to contraction of smooth muscle.

Maternal **oxytocin** is not involved in initiating labor but has an important role in maintaining uterine contractions once labor has been initiated. Rising estrogen levels significantly increase oxytocin receptors on the myometrium and placental decidual tissue during the last few weeks of gestation. **Relaxin**, a large polypeptide hormone produced by the corpus luteum and the decidua, also increases oxytocin receptors. Distension of the cervix initiates bursts of oxytocin release from the maternal posterior pituitary, which stimulates myometrial contractions. Oxytocin is used clinically to facilitate labor and reduce postpartum bleeding after delivery (Clinical Focus 38.2).

CLINICAL FOCUS 38.2

Pharmacologic Induction and Augmentation of Labor

Several drugs are currently used to assist in the therapeutic induction and augmentation of labor. Therapeutic induction implies that the use of a drug initiates labor. Augmentation indicates that labor has started and that a therapeutic agent further stimulates the process.

Oxytocin, the natural hormone produced from the posterior pituitary, is widely used to induce and augment labor. Several synthetic forms of oxytocin can be used by intravenous routes. Prostaglandins (F_{2a} and E_2) have also been used to induce and augment labor and cervical ripening. They promote dilation and effacement of the cervix and can be used intravaginally, intravenously, or intra-amniotically. ■

POSTPARTUM LACTATION

Lactation, the production and removal of milk from the breast, occurs at the final phase of the reproductive process. Prolactin (PRL) promotes mammary growth, initiation of milk secretion, and maintenance of milk production (**galactopoiesis**) once it has been established. Oxytocin activates **milk ejection** or **milk letdown**, the process by which stored milk is released from the mammary glands.

Mammogenesis occurs at three distinct developmental stages.

The growth and differentiation of the mammary glands occur *in utero*, at puberty, and during pregnancy. The **mammary glands** begin to differentiate in the pectoral region as an ectodermal thickening on the epidermal ridge at gestation weeks 7 to 8. The prospective mammary glands lie along bilateral mammary ridges or milk lines extending from the axilla to groin on the ventral side of the fetus. In humans, most of the ridge disintegrates except in the axillary region. Mammary buds derive from the surface epithelium, which invade the underlying mesenchyme. During the fifth gestation month, the buds elongate, branch, and sprout, eventually forming the **lactiferous ducts** (primary milk ducts), which continue to branch and grow throughout life. The ducts unite, grow, and extend to the site of the future nipple. The primary buds give rise to secondary buds, which are separated into lobules by connective tissue and become surrounded by **myoepithelial cells**. The **nipple** and **areola** form during the eighth month of gestation.

The mammary glands of male and female infants are identical and, although underdeveloped, can secrete small amounts of milk ("witch's milk") at birth. Fetal mammary tissue is responsive to the lactogenic hormones of pregnancy and the withdrawal of placental steroids at birth, resulting in milk production in some infants. Sexual dimorphism in breast development begins at the onset of puberty. The male breast is fully developed at about 20 years of age and is similar to the female breast at an early stage of puberty.

Estrogen exerts a major influence on breast growth at puberty in females. The first response is an increase in size and pigmentation of the areola and accelerated deposition of adipose and connective tissues. In association with menstrual cycles, estrogen stimulates the growth and branching of the ducts, whereas progesterone acts primarily on the alveolar components. The action of both hormones, however, requires synergism with PRL, GH, insulin, cortisol, and thyroxine.

The mammary glands undergo significant changes during pregnancy. The ducts become elaborate during the first trimester, and new lobules and alveoli are formed in the second trimester. The alveolar cells differentiate into secretory cells, replacing most of the connective tissue. The development of the secretory capability requires estrogen, progesterone, PRL, and placental lactogen, as well as insulin, cortisol, and several growth factors. Lactogenesis begins during the fifth month of gestation, but only **colostrum** (initial milk) is produced. Elevated progesterone levels antagonize the action of PRL to prevent full lactation during pregnancy. The ovarian steroids synergize with PRL in stimulating mammary growth but antagonize its actions in promoting milk secretion.

Lactogenesis is fully expressed after parturition, on the withdrawal of placental steroids. Lactating women produce up to 600 mL of milk each day, increasing to 800 to 1,100 mL/d by the sixth postpartum month. Milk is isosmotic with plasma, and its main constituents include proteins (casein and lactalbumin), lipids, and lactose. Colostrum, produced in small quantities during the first postpartum days, is higher in protein, sodium, and chloride content and lower in lactose and potassium than normal milk. It also contains immunoglobulin A, macrophages, and lymphocytes, which provide passive immunity to the infant. During the first 2 to 3 weeks, the protein content of milk decreases, whereas that of lipids, lactose, and water-soluble vitamins increases.

Within the mammary gland, the milk-secreting **alveolar cells** form a single layer of epithelial cells around a lumen into which milk components are deposited (Fig. 38.7). The alveolar cells have numerous microvilli on the luminal surface and are surrounded on their basolateral side by contractile myoepithelial cells. Alveolar cells have a well-developed endoplasmic reticulum and Golgi apparatus, numerous mitochondria and lipid droplets, and plasma membrane PRL receptors. In synergism with insulin and

glucocorticoids, PRL is critical for lactogenesis, promoting mammary cell division and differentiation and increasing the synthesis of milk constituents.

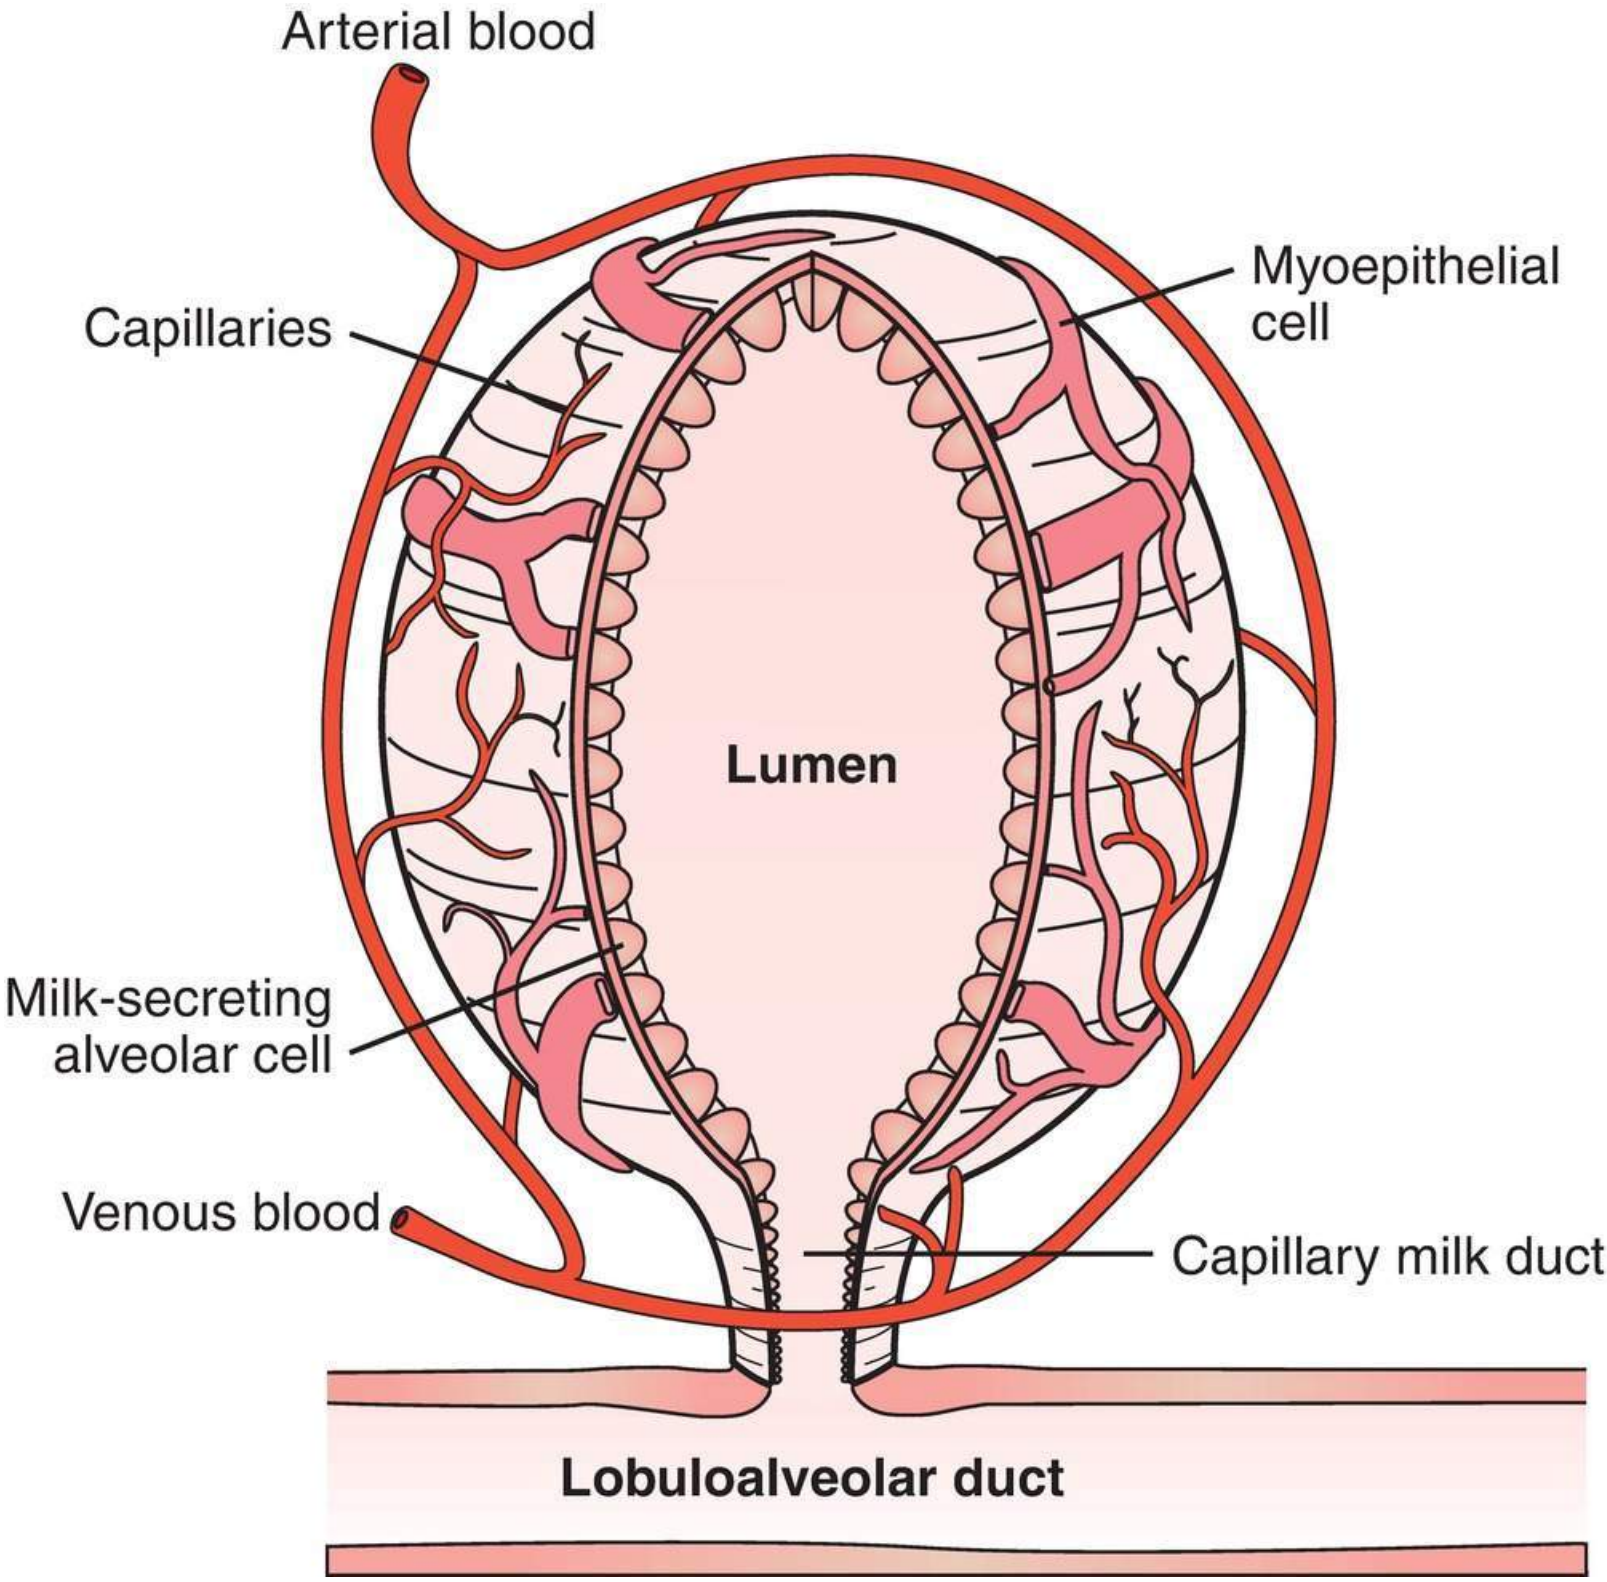

Figure 38.7 The structure of a mammary alveolus. A meshwork of contractile myoepithelial cells surrounds milk-producing cells.

Suckling reflex maintains lactation and inhibits ovulation.

The suckling reflex coordinates the release of PRL and oxytocin to maintain lactation and delay the onset of ovulation. Lactation involves two components: milk secretion, which is a continuous process, and milk removal, which is intermittent. PRL is the major regulator of milk secretion, the process through which alveolar cells synthesize the milk constituents and release the formed milk into the alveolar lumen (see Fig. 38.7). Oxytocin is responsible for milk removal by activating milk ejection.

The stimulation of sensory nerves in the breast by the infant initiates the **suckling reflex**. In contrast to neural–neural reflexes, the afferent arc of the suckling reflex is neural and the efferent arc is hormonal. The suckling reflex increases the release of PRL, oxytocin, and ACTH and inhibits the secretion of gonadotropins (Fig. 38.8). Sensory receptors in the nipple initiate nerve impulses in response to breast stimulation that travel via ascending fibers in the spinal cord to the midbrain. These impulses eventually reach the supraoptic and paraventricular nuclei of the hypothalamus to trigger the release of oxytocin from the posterior pituitary into the general circulation (see Chapter 31). Oxytocin induces the contraction of myoepithelial cells in the mammary gland, increasing intramammary pressure and forcing milk into the main collecting ducts. The milk ejection reflex can be conditioned, occurring in anticipation of nursing or in response to a baby's cry.

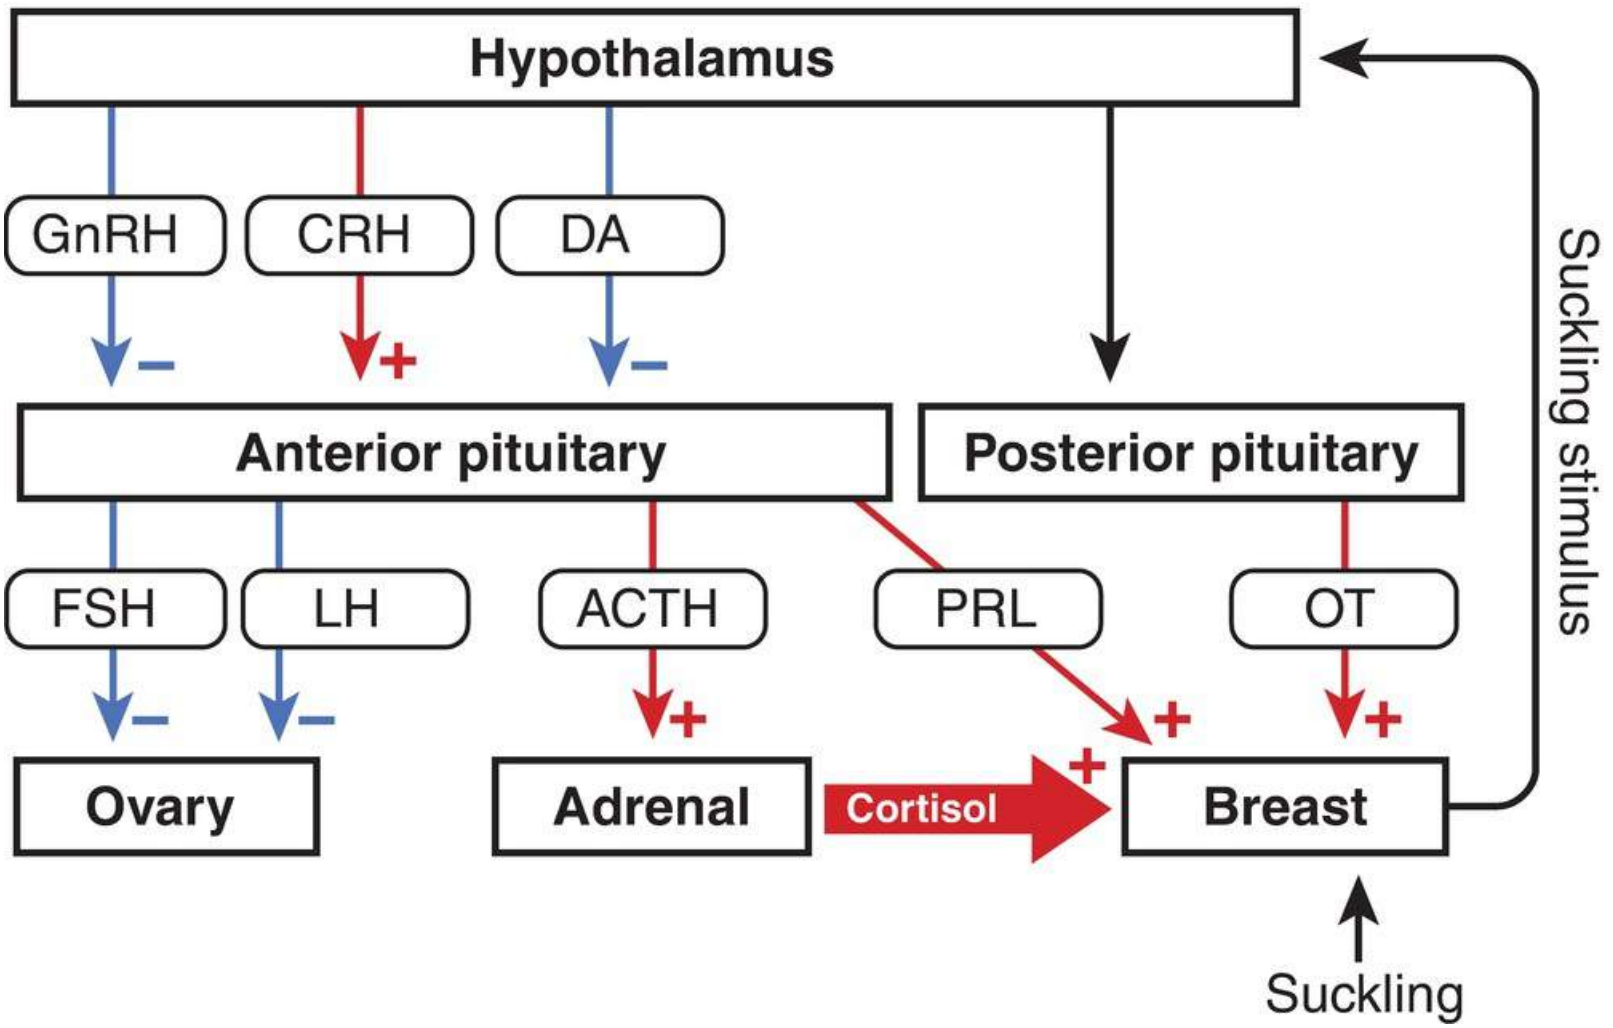

Figure 38.8 Effect of suckling on hypothalamic, pituitary, and adrenal hormones. Neural signals initiated by suckling stimulate hormone release from the anterior pituitary to promote milk secretion and removal. Neural signals also inhibit GnRH release to prevent return of the normal menstrual cycle during

the lactation period.

Blood PRL levels are elevated by the end of gestation and decline by 50% within the first postpartum week, further decreasing to near pregestation levels by 6 months. Suckling elicits a rapid and significant rise in plasma PRL in proportion to the intensity and duration of nipple stimulation. Dopamine release from the hypothalamus into the portal circulation normally inhibits PRL release from lactotrophs in the anterior pituitary. Suckling inhibits dopamine release from the arcuate nucleus, relieving inhibition of the lactotrophs to allow a burst of PRL release. Dopaminergic agonists that reduce PRL or the discontinuation of suckling terminates lactation.

Lactation is associated with the suppression of cyclicity and **anovulation.** The contraceptive effect of lactation is moderate in humans. In non–breast-feeding women, the menstrual cycle may return within 1 month after delivery, whereas lactating women have a period of several months of **lactational amenorrhea**, with the first few menstrual cycles being anovulatory. The cessation of cyclicity results from the combined effects of the act of suckling and elevated PRL levels. Neural signals from suckling directly inhibit pulsatile GnRH release from the hypothalamus (see Fig. 38.8). PRL may also inhibit pulsatile GnRH release and suppress pituitary responsiveness to GnRH. Although lactation reduces fertility, numerous other methods of contraception are more reliable.

PUBERTY ONSET

The onset of puberty depends on a sequence of maturational processes that begin during fetal life. *In utero*, the GnRH pulse generator is operative, and gonadotropins are released in a pulsatile manner, with LH and FSH levels in fetal blood elevated to near-adult values at midgestation. As placental steroids increase, negative feedback reduces GnRH release, slightly lowering LH and FSH levels prior to parturition.

At birth, the newborn is abruptly deprived of maternal and placental steroids, reducing negative feedback on the hypothalamus and pituitary, resulting in increased GnRH, LH, and FSH release. The rise in gonadotropins stimulates the gonads, resulting in increased serum testosterone and estradiol in male and female infants, respectively. At ~3 months of age, the levels of both gonadotropins and gonadal steroids remain in the low-to-normal adult range. Circulating gonadotropins then decline to low levels by 6 to 7 months and remain suppressed until the onset of puberty.

The prepubertal restraint of gonadotropin secretion is the result of two processes. First, the GnRH pulse-generating neurons are extremely sensitive to negative feedback by gonadal steroids. This permits the very low levels of gonadal steroids in the circulation to inhibit GnRH release. The second mechanism is inhibition of the GnRH pulse generator by the central nervous system (CNS). γ-Aminobutyric acid (GABA) and endogenous opioid peptides in the CNS are major inhibitors of the GnRH pulse generator. Thus, the combination of extreme sensitivity to steroid negative feedback and CNS inhibition suppresses the amplitude and frequency of GnRH pulses, resulting in diminished secretion of LH, FSH, and gonadal steroids. Throughout this period of quiescence, the pituitary and the gonads can respond to exogenous GnRH and gonadotropins, but at a relatively low sensitivity.

The hypothalamic–pituitary–gonadal axis becomes reactivated to initiate puberty. This response involves a decrease in hypothalamic sensitivity to sex steroids, so that higher levels are needed to inhibit GnRH release, and a reduction in CNS inhibition of the GnRH pulse generator. The mechanisms underlying the reduction in central inhibition are not fully understood, but involve stimulation of GnRH neurons by kisspeptin, excitatory amino acids, neuropeptide Y, and prostaglandins. The adipose tissue hormone leptin, released in proportion to body energy stores, is also required as a permissive signal that the body has sufficient energy stores for reproduction to take place. As a result of disinhibition, the frequency and amplitude of GnRH pulses increase. Initially, pulsatility is most prominent at night, entrained by deep sleep; later, it becomes established throughout the 24-hour period (see Fig. 37.2). GnRH acts on the gonadotrophs of the anterior pituitary to increase the number of GnRH receptors and augment the synthesis, storage, and secretion of LH and FSH. The increased responsiveness of FSH to GnRH in females occurs earlier than that of LH, accounting for a higher FSH/LH ratio at the onset of puberty than during late puberty and adulthood. A reversal of the ratio is seen again at menopause.

The increased pulsatile release of GnRH and gonadotropins stimulates gonadal steroid synthesis, inducing the progressive development of the secondary sex characteristics and the establishment of the adult pattern of negative feedback on the hypothalamic–pituitary axis. Activation of the positive feedback mechanism in females that results in an estrogen-induced LH surge is a later event that occurs in mid to late puberty.

Genetic, nutritional, climatic, and geographic factors determine the onset of puberty.

The onset of puberty in humans begins on average at age 10 to 12 years (see Clinical Focus Box 37.2). Lasting 3 to 5 years, the process involves the development of secondary sex characteristics, a growth spurt, and the acquisition of fertility. Over the last 150 years, the age of puberty has declined by 2 to 3 months per decade due to improvements in nutrition and general health. Leptin is a hormone produced by adipose tissue that interacts with receptors in the hypothalamus to regulate satiety and energy metabolism. Leptin has a permissive effect on the initiation of puberty, providing a signal to the CNS that there are sufficient energy stores to support reproduction. People with leptin deficiency resulting from mutations in the gene-encoding leptin do not progress through puberty, but will do so if treated with exogenous hormone. See Chapter 31 Integrated Medical Sciences Box for an in-depth discussion of the role of leptin in regulation of the hypothalamic–pituitary axes.

The first physical signs of puberty in girls are breast budding, **thelarche**, and the appearance of pubic hair. Axillary hair growth and peak height spurt occur within 1 to 2 years. **Menarche**, the beginning of menstrual cycles, occurs at a median age of 12.8 years in Caucasian girls in the United States and at 12.2 years in African American girls. The first few cycles are usually anovulatory. The first sign of puberty in boys is enlargement of the testes, followed by the appearance of pubic hair and enlargement of the penis. The peak growth spurt and appearance of axillary hair in boys usually occur 2 years later than in girls. The growth of facial hair, deepening of the voice, and broadening of the shoulders are late events in male pubertal maturation (Fig. 38.9).

Age (years)

Figure 38.9 Pubertal maturation of secondary sex characteristics in girls and boys.

The adrenal androgens DHEA and DHEAS are primarily responsible for the development of pubic and axillary hair. Adrenal maturation (or **adrenarche**) precedes gonadal maturation (or **gonadarche**) by 2 years. The pubertal growth spurt requires the action of sex steroids, GH and IGF-1. Plasma IGF-1 concentrations increase significantly during puberty, with peak levels observed earlier in girls than in boys. The gonadal steroids act primarily by augmenting pituitary GH release, which stimulates the production of IGF-1 in the liver and other tissues.

Defects in hypothalamic–pituitary function can alter the timing of pubertal onset.

P**recocious puberty** has been traditionally defined as physical signs of sexual maturation before the age of 8 years in girls and 9 years in boys. However, given nutritional improvements as discussed above, age alone cannot be used in diagnosis. True precocious puberty results from premature activation of the hypothalamic–pituitary–gonadal axis, leading to the development of secondary sex characteristics as well as gametogenesis. The most frequent causes are CNS lesions or infections, hypothalamic disease, and hypothyroidism. **Pseudoprecocious puberty** is the early development of secondary sex characteristics without gametogenesis. It can result from the abnormal exposure of immature boys to androgens and of immature girls to estrogens. Augmented steroid production can be of gonadal or adrenal origin. See Clinical Focus Box 37.2 for a detailed discussion of precocious puberty.

The definition of **delayed puberty** is the absence of physical signs by age 13 years in girls and 14 years in boys. This condition can result from constitutional delay of growth in which children are below the third percentile for height and have delayed skeletal maturation. It can also result from lack of gonadal development and steroid production. **Hypothalamic–pituitary hypogonadism** refers to conditions where hypothalamic GnRH or pituitary gonadotropins, or both, are deficient or inactive. Single-gene defects have been identified in ~30% of cases. Kallmann syndrome is an example of GnRH deficiency resulting from a defect in the *KAL* gene, which directs GnRH neuronal migration during embryogenesis.

SEXUAL DEVELOPMENT

Normal sexual development consists of three sequential processes. **Chromosomal sex** or **genetic sex** is determined at the time of fertilization by the random unification of an X-bearing egg with either an X-bearing or Y-bearing spermatozoon. The second step takes place during early embryonic life with the development of male or female gonads. Finally, gonadal hormones act at critical times to control the differentiation of the internal and external genitalia. The process of sexual development is incomplete at birth, with the secondary sex characteristics and functional reproductive system fully activated at puberty.

Sex chromosomes dictate the development of the fetal gonads.

Human somatic cells have 44 autosomes and 2 sex chromosomes. The female is **homogametic** (having two X chromosomes) and produces similar X-bearing ova. The male is **heterogametic** (having one X and one Y chromosome) and generates two populations of spermatozoa, one with X chromosomes and the other with Y chromosomes. The X chromosome is large, containing 80 to 90 genes responsible for many vital functions. The Y chromosome is much smaller, carrying only a few genes responsible for testicular development and normal spermatogenesis. Genetic mutations on an X chromosome result in the transmission of X-linked traits, such as hemophilia and color blindness, to male offspring, cannot compensate with an unaffected allele.

Theoretically, by having two X chromosomes, the female has an advantage over the male, who has only one. However, because one of the X chromosomes is inactivated at the morula stage, there is no advantage. Each cell randomly inactivates either the paternally or the maternally derived X chromosome, and this continues throughout the cell's progeny. The inactivated X chromosome is recognized cytologically as the **Barr body**. In males with more than one X chromosome or in females with more than two, extra X chromosomes are inactivated and only one remains functional. This does not apply to the germ cells. The single active X chromosome of the spermatogonium becomes inactivated during meiosis, and a functional X chromosome is not necessary for the formation of fertile sperm. The oogonium, however, reactivates its second X chromosome, and both are functional in oocytes and important for normal oocyte development.

Testicular development requires a Y chromosome and occurs even in the presence of two or more X chromosomes. The testis-determining gene ***SRY*** (sex-determining region, Y chromosome) regulates **gonadal sex** determination. Located on the short arm of the Y chromosome, *SRY* encodes an HMG-box transcription factor. The presence or absence of *SRY* in the genome determines whether male or female gonadal differentiation takes place. Thus, in 46,XX fetuses, ovaries develop.

Whether possessing the 46,XX or 46,XY karyotype, every embryo goes through an initial **ambisexual stage** and has the potential to acquire either masculine or feminine characteristics. A 4- to 6-week-old human embryo possesses indifferent gonads and undifferentiated pituitary, hypothalamus, and higher brain centers. The indifferent gonad consists of a **genital ridge**, derived from coelomic epithelium and underlying mesenchyme, and primordial germ cells, which migrate from the yolk sac to the genital ridges. Depending on genetic programming, the inner **medullary tissue** becomes the testicular component, and the outer **cortical tissue** develops into an ovary. The primordial germ cells become oogonia or spermatogonia. In a 46,XY fetus, the testes differentiate between weeks 6 and 8 of gestation as the cortex regresses, the medulla enlarges, and the seminiferous tubules become distinguishable. Sertoli cells line the basement membrane of the tubules, and Leydig cells undergo rapid proliferation. Development of the ovary does not begin until gestation weeks 9 to 10. Primordial follicles, composed of oocytes surrounded by a single layer of granulosa cells, are discernible in the cortex between weeks 11 and 12 and reach maximal development by weeks 20 to 25.

Hormones from the fetal testes regulate differentiation of the internal and external genitalia.

During the indifferent stage, the primordial genital ducts are the paired **mesonephric** (**wolffian**) **ducts** and the paired **paramesonephric** (**müllerian**) **ducts**. In the genetic male fetus, the wolffian ducts give rise to the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts, whereas the müllerian ducts become vestigial. In the genetic female fetus, the müllerian ducts fuse at the midline and develop into the oviducts, uterus, cervix, and upper portion of the vagina, whereas the wolffian ducts regress (Fig. 38.10). The mesonephros present at the indifferent stage becomes the embryonic kidney.

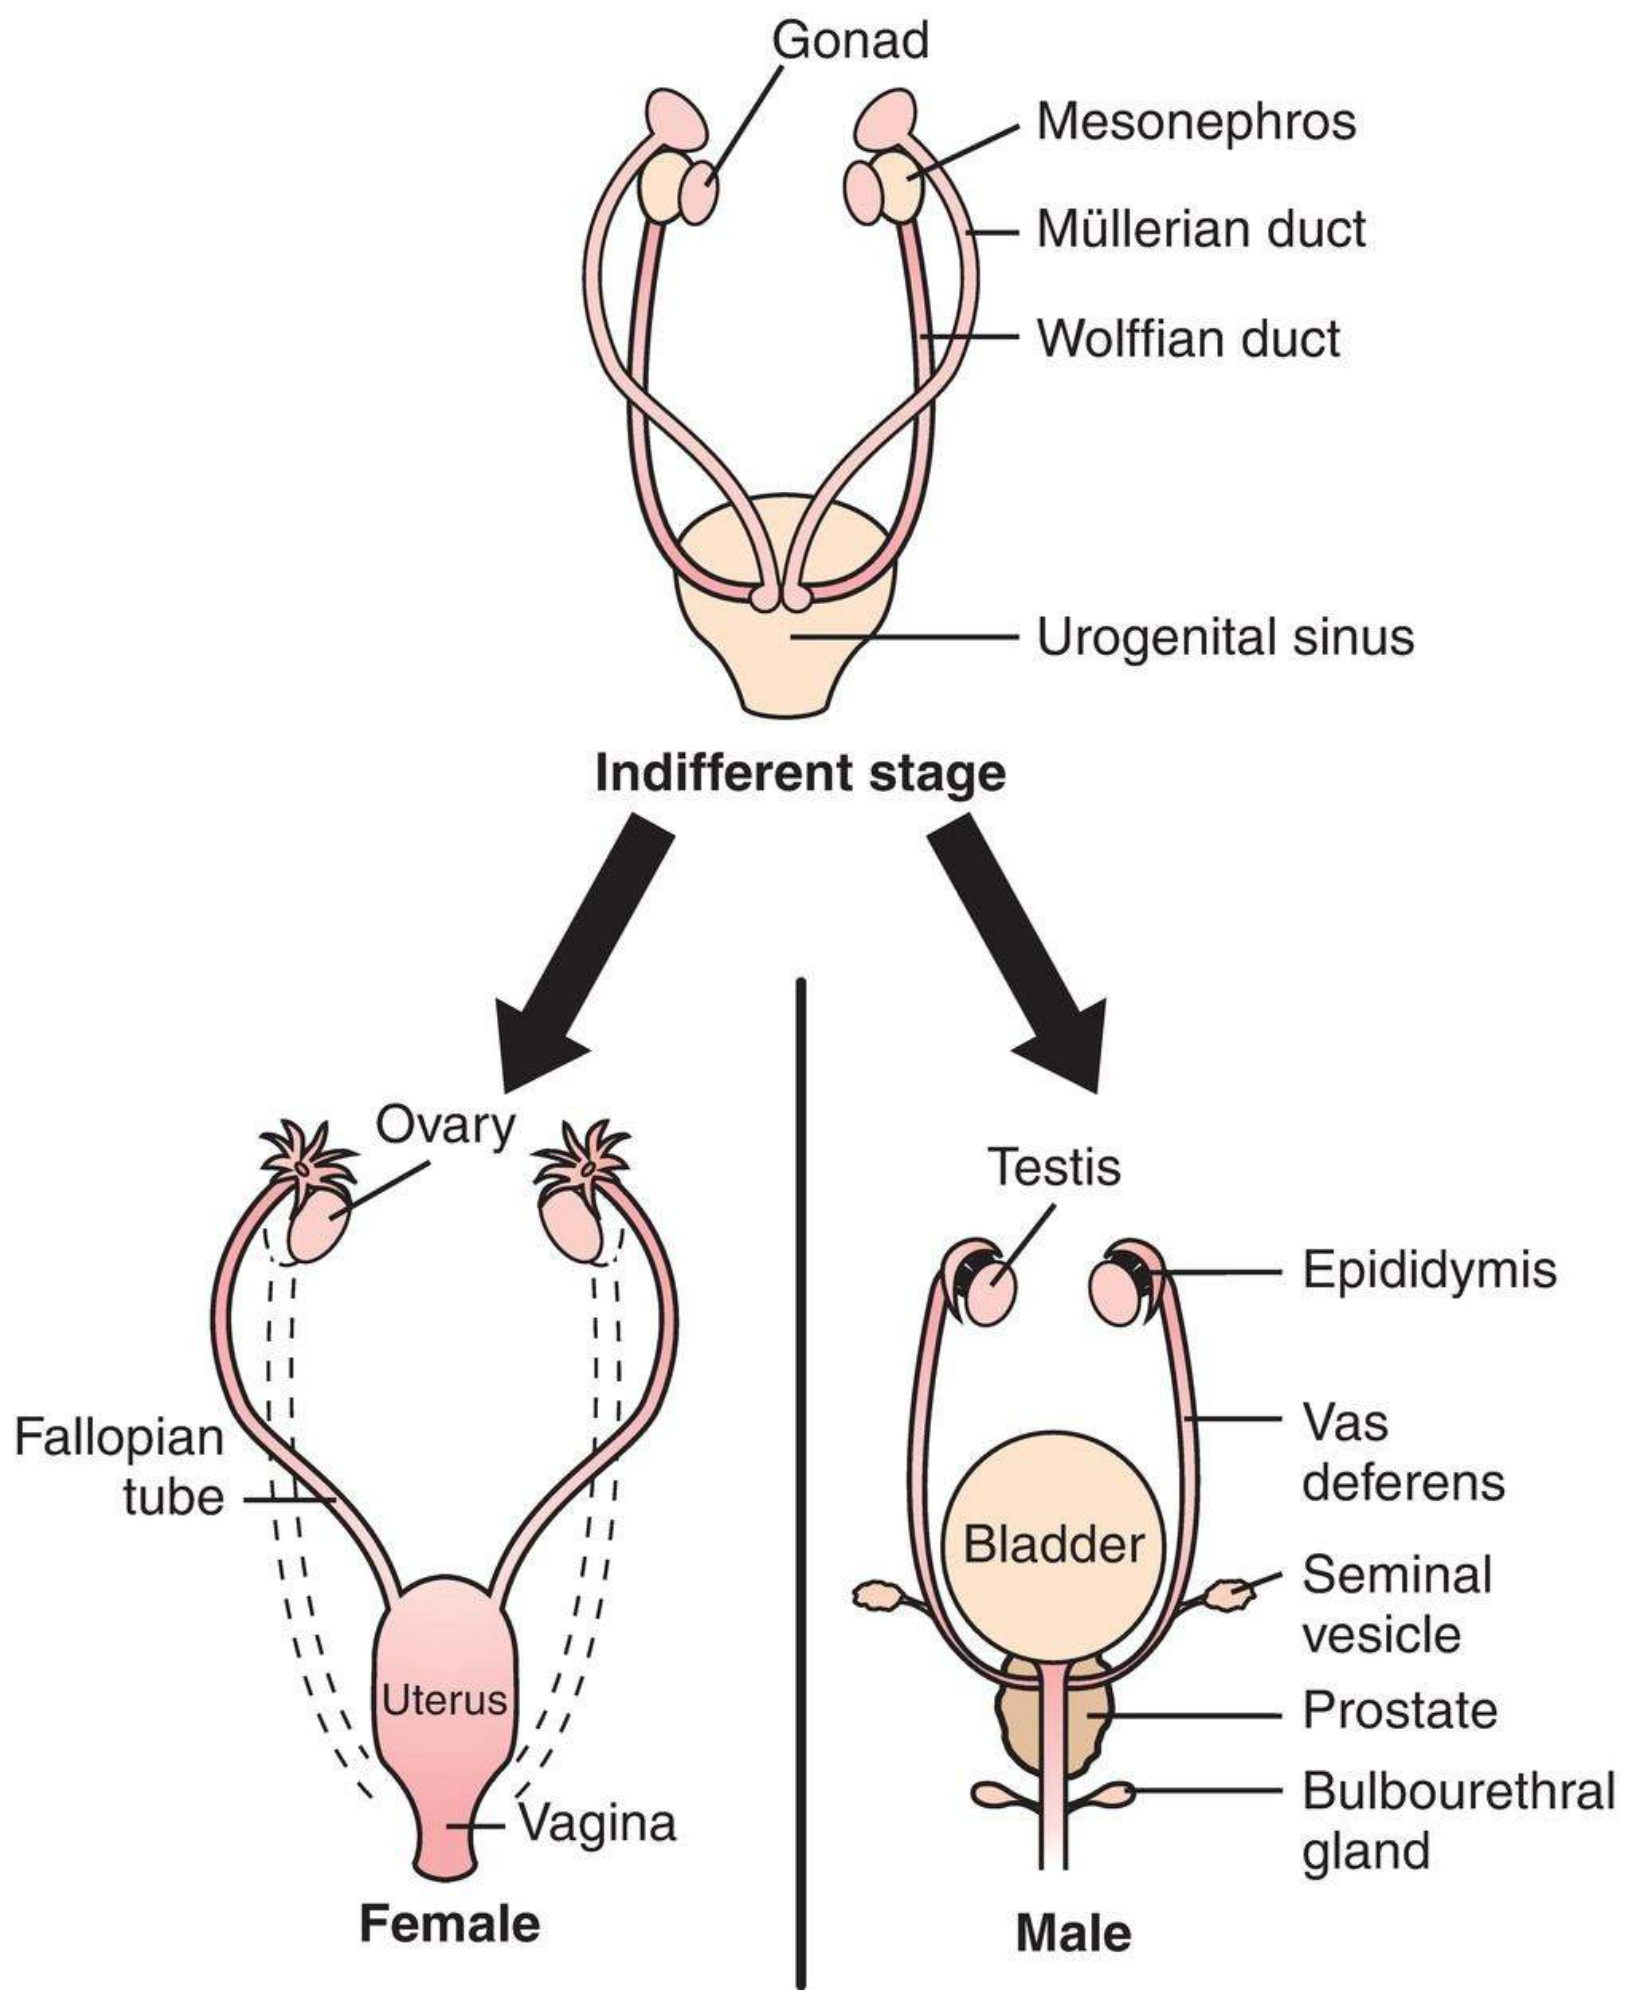

Figure 38.10 Differentiation of the internal genitalia from the sexually indifferent duct system.

Between weeks 6 and 8 of gestation, Leydig cells, either autonomously or under regulation by hCG, start producing testosterone. Sertoli cells also become active and produce two nonsteroidal compounds. One is **anti-müllerian hormone** (AMH), a large glycoprotein with a sequence homologous to inhibin and transforming growth factor β, which inhibits cell division and induces apoptosis, resulting in involution of the müllerian ducts. The second is **androgen-binding protein** (**ABP**), which binds testosterone. Peak production of these compounds occurs between weeks 9 and 12, coinciding with the time of differentiation of the internal genitalia along the male line. The ovary does not produce hormones that regulate differentiation of the internal genitalia.

The primordial external genitalia include the genital tubercle, genital swellings, urethral folds, and urogenital sinus. Differentiation of the external genitalia occurs between gestation weeks 8 and 12, is determined by the presence or absence of male sex hormones, and requires active **5α-reductase**, which converts testosterone to dihydrotestosterone (DHT). Without DHT, regardless of the genetic, gonadal, or hormonal sex, the external genitalia develop along the female pattern. The development of male and female external genitalia from primordial structures is illustrated in Figure 38.11, and a summary of sexual differentiation during fetal life is shown in Figure 38.12. Androgen-dependent differentiation occurs only during fetal life and is thereafter irreversible. However, the exposure of females to high androgens either before or after birth can cause clitoral hypertrophy. Testicular descent into the scrotum, which occurs during the third trimester, is also controlled by androgens.

Disorders of sex development occur when chromosomes, gonads, or development of reproductive anatomy is atypical.

The term **disorders of sex development** (**DSD**) describes congenital conditions in which chromosomal, gonadal, or genital sex is not coincident. Classification of DSD is complex, but these conditions can be broadly defined in three categories: sex chromosome DSD, disorders of testes development and androgenization (46,XY DSD), and disorders of ovary development and androgen excess (46,XX DSD). The nomenclature for DSD was adopted at a consensus conference in 2005, which determined that older terms such as hermaphroditism and intersex were not appropriate given our increasing understanding of the molecular mechanisms regulating sex differentiation.

Sex chromosome DSDs result when the number of sex chromosomes differs from the normal XX or XY distribution, resulting from errors in the first or second meiotic division such as chromosomal nondisjunction, translocation, rearrangement, or deletion. The two most common disorders are Klinefelter syndrome (47,XXY) and Turner syndrome (45,X). Individuals with a 47,XXY karyotype have normal testicular function *in utero* in terms of testosterone and AMH production and no ambiguity of the genitalia at birth. However, the extra X chromosome interferes with the development of the seminiferous tubules and Leydig cell proliferation. Such males have small testes, are azoospermic, and often exhibit some eunuchoidal features. In Turner syndrome (45,X), there is no gonadal development during fetal life, and at birth, the external genitalia present as female. Given the absence of ovarian follicles, such patients have low levels of estrogens and primary amenorrhea and do not undergo normal pubertal development, which is when the syndrome may be diagnosed. The failure of ovarian development highlights the importance of two X chromosomes in this process.

46,XY DSD can result from defects in testes development or disorders of androgen synthesis and action. The external phenotype can range from complete absence of male genitalia to inadequate androgenization of the external genitalia (e.g., a micropenis). Infertility is often also present. There are a number of genetic defects that can impair testes development with subsequent loss of androgen production. Defects anywhere in the androgen synthetic pathway also impair production of the hormone. 5α-reductase deficiency, an autosomal-recessive disorder results in the inability to convert testosterone to DHT. Infants with 5α-reductase deficiency have ambiguous or female external genitalia and normal male internal genitalia. Affected individuals are often raised as females but undergo a complete or partial testosterone-dependent puberty, including enlargement of the clitoris-like small penis, testicular descent, and the development of male psychosexual behavior. Gender role changes may occur at puberty.

Insensitivity to androgens results from defects in the androgen receptor. Complete androgen insensitivity syndrome results in a complete female phenotype in a 46,XY individual with normally formed testes and age-appropriate testosterone production. Partial or minimal androgen insensitivity can result in partial development of the male external genitalia.

46,XX DSD can result from defects in ovarian development, disorders in androgen synthesis, and other conditions that affect sex development. Defects in ovarian development can result from a number of conditions but is most frequently seen in Turner syndrome (46,X) as discussed above. **Congenital adrenal hyperplasia** (**CAH**) is the most common cause of androgen excess in females. This is an inherited abnormality in adrenal steroid biosynthesis resulting most often from 21-hydroxylase (CYP21) deficiency but also from lack of 11β-hydroxylase (see Chapter 33). A female with CAH will have normal ovaries and internal genitalia, but with increasing degrees of androgenization of the external genitalia up to the full male phenotype without palpable testes, resulting from exposure to excessive androgens *in*

utero. In CAH, cortisol production is low, resulting in increased ACTH production by the activated hypothalamic–pituitary axis (Fig. 38.13). The elevated ACTH induces adrenal hyperplasia and an abnormal production of androgens and corticosteroid precursors. When aldosterone levels are also affected, a life-threatening salt-wasting disease results.

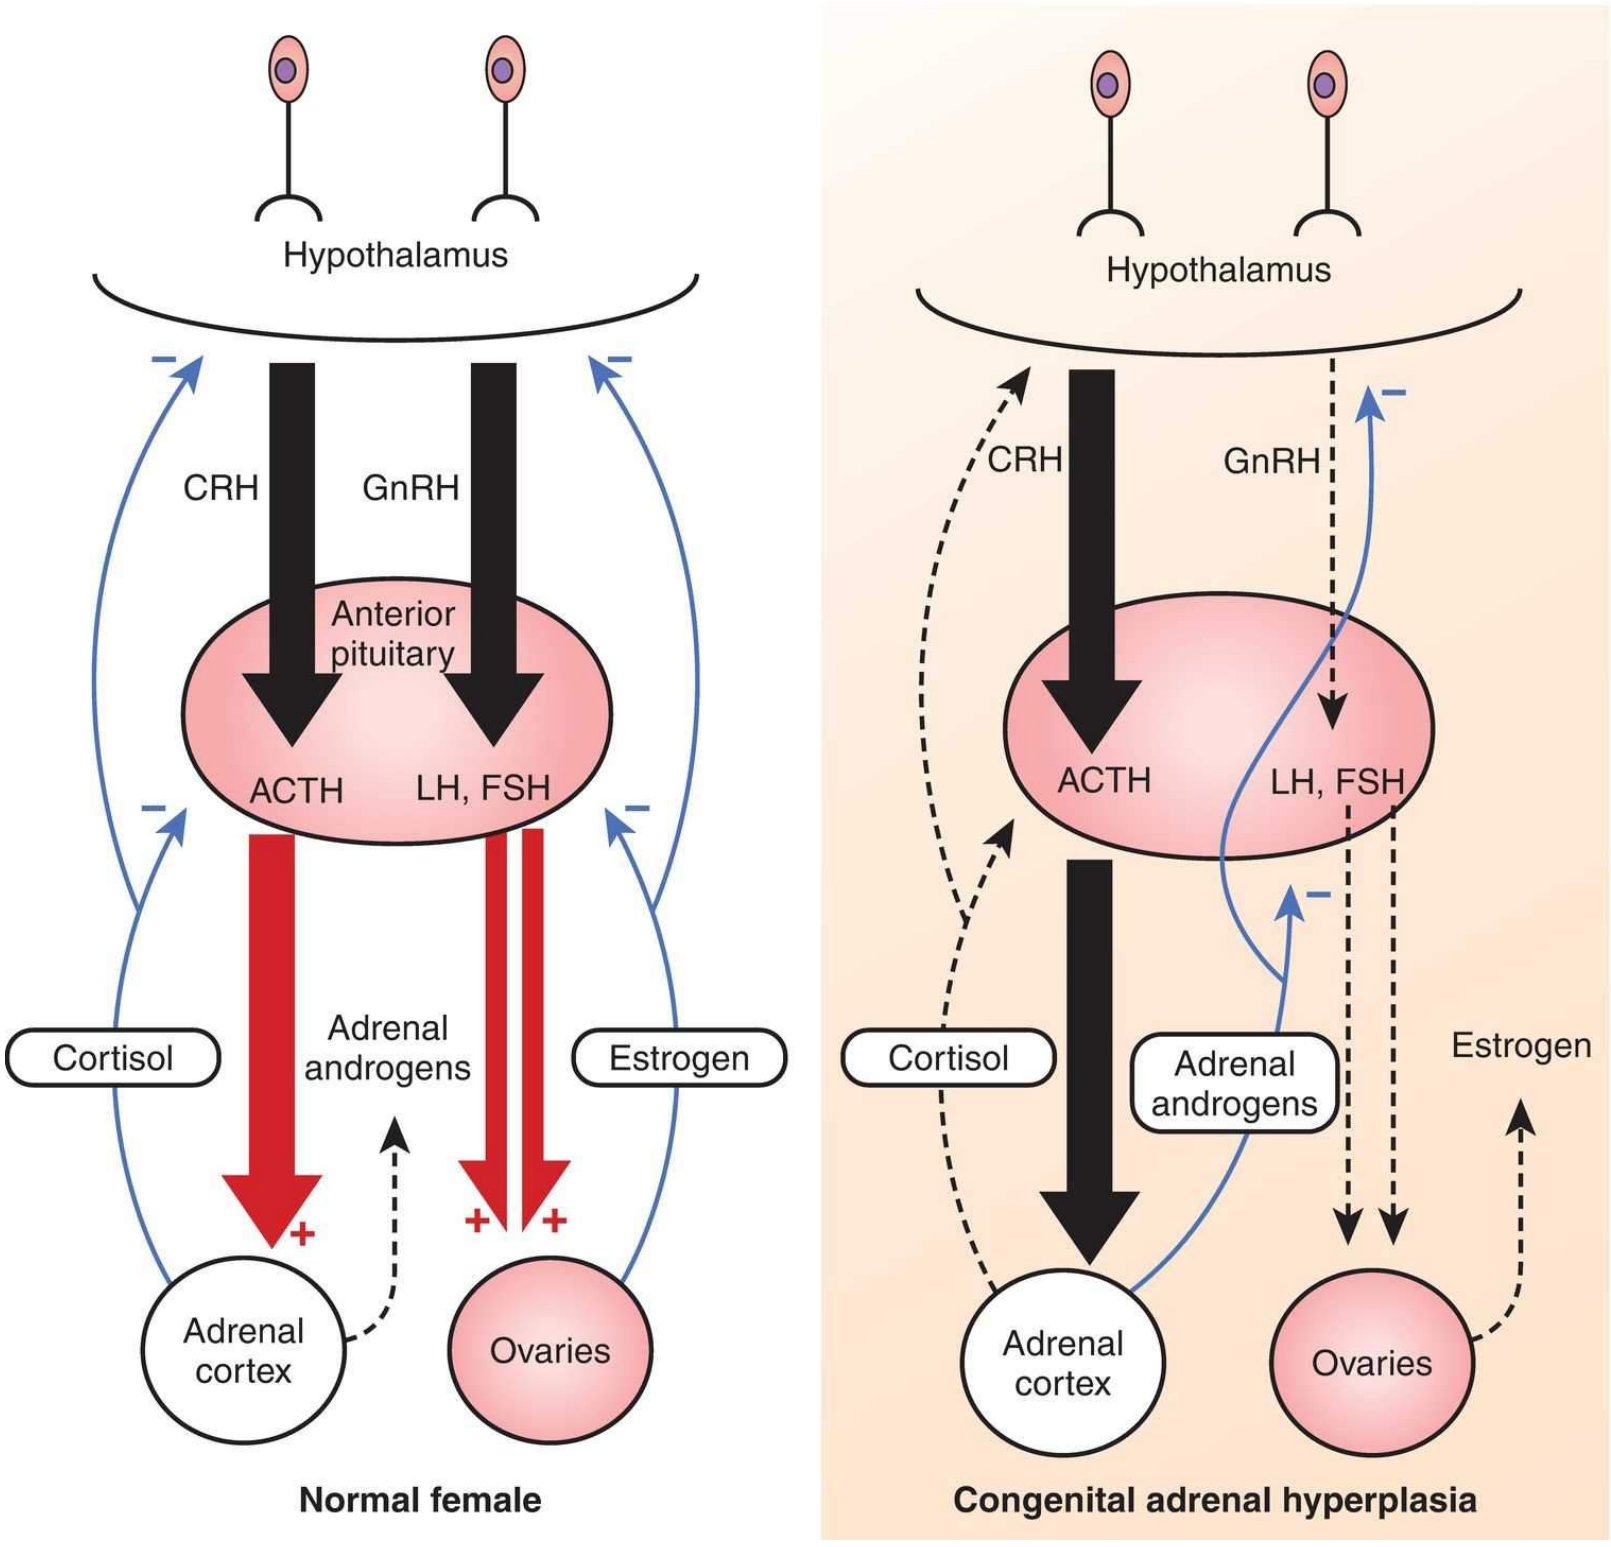

Figure 38.13 The hypothalamic–pituitary–adrenal and hypothalamic–pituitary–ovarian axes in normal female development and with congenital adrenal hyperplasia. *Dashed arrows* indicate low production of the hormone. *Bold arrows* indicate increased hormone production. *Plus* and *minus* signs indicate positive and negative effects.

Contraceptive Methods

Interfering with the association between the sperm and ovum, preventing ovulation or implantation, or terminating an early pregnancy can regulate fertility. Most current methods regulate fertility in women, with only a few contraceptives available for men.

Prevention of Egg and Sperm Contact

Methods to prevent contact between the germ cells include coitus interruptus (withdrawal before ejaculation), the rhythm method (no intercourse at times of the menstrual cycle when an ovum is present in the oviduct), and barriers. Rhythm methods require meticulous monitoring of menstrual cycles and body temperature or cervical mucus characteristics, but can still fail as a result of the unpredictable duration of the follicular phase of the menstrual cycle. Both coitus interruptus and the rhythm method require cooperation and discipline in both partners. Barrier methods include condoms, diaphragms, and intrauterine devices (IUD). The most effective barrier method is the IUD, which reduces the viability of sperm and eggs and creates a local inflammation in the endometrium that prevents implantation. Condoms are the most widely used reversible contraceptives for men but have a high failure rate if not used properly. Condoms also provide protection against the transmission of venereal diseases and AIDS. Diaphragms and cervical caps seal off the opening of the cervix. Postcoital douching with spermicides is not an effective contraceptive method because sperms can rapidly enter the uterus and oviduct.

Surgical methods of contraception are generally considered nonreversible. Vasectomy, cutting of the two vasa deferentia, prevents sperm from passing into the ejaculate. Tubal ligation is the closure or ligation of the oviducts. Surgery for the reversal of a tubal ligation and a vasectomy can be performed; success is variable.

Hormonal Methods (Oral Contraceptives)

Oral contraceptive steroids (birth control pills) prevent ovulation by reducing LH and FSH secretion through negative feedback. The reduction in LH and FSH retards follicular development and prevents ovulation. Birth control pills also adversely affect the environment within the reproductive tract, making it unlikely for pregnancy to result even if fertilization were to occur. Exogenous estrogen and progesterone alter normal endometrial development, and progesterone thickens cervical mucus and reduces oviductal peristalsis, impeding gamete transport.

Noncontraceptive benefits of oral contraception include a reduction in excessive menstrual bleeding, alleviation of premenstrual syndrome, and some protection against pelvic inflammatory disease. In addition, oral contraception results in a significant decrease in incidence of endometrial and ovarian carcinoma. The most commonly reported adverse effects of oral contraception include nausea, headache, breast tenderness, water retention, and weight gain, some of which disappear after prolonged use. Breakthrough bleeding can also be expected in up to 30% of women during the first 3 months of use. Birth control pills are contraindicated in women with a history of thromboembolic disease, atherosclerosis, or breast carcinoma because of the effects of estrogen on these systems.

Emergency Contraception

Women can use emergency contraception to prevent pregnancy after known or suspected failure of birth control or after unprotected intercourse. Two prescription formulations are specifically available for emergency contraception, but over-the-counter preparations are also available. The mechanism of action of emergency contraception is similar to that for standard oral contraceptive use:

prevention of ovulation, insufficient corpus luteum function, and induction of an adverse environment in the female reproductive tract. Emergency contraception is most effective when started within the first 72 hours after unprotected intercourse. Thus, it has been recommended that physicians provide an advance prescription in states where the treatment is not available over the counter. ■

Chapter Summary

- Fertilization of the ovum occurs in the ampulla of the oviduct.
- Sperms undergo capacitation to fully mature and the acrosome reaction to penetrate the zona pellucida surrounding the oocyte.
- The cortical reaction occurs after a sperm penetrates the egg to prevent polyspermy.
- The blastocyst travels the oviduct, enters the uterus, ruptures the zona pellucida, and implants into the uterine wall on about day 7 of gestation. Progesterone and estrogen released from the ovary prepare the uterus to receive the blastocyst.
- Trophoblast cells of the developing placenta produce human chorionic gonadotropin, which stimulates the corpus luteum to continue producing progesterone to maintain pregnancy.
- Following implantation, the placenta develops from embryonic and maternal cells and becomes the major steroid-secreting organ during pregnancy.
- Major hormones produced by the fetoplacental unit are progesterone, estradiol, estrone, estriol, human chorionic gonadotropin, and human placental lactogen. Elevated estriol levels indicate fetal well-being, whereas low levels can indicate fetal stress. Human placental lactogen regulates fetal fuel metabolism.
- Maternal physiology and endocrine function change to support the developing fetus.
- The pregnant woman becomes insulin resistant during the latter half of pregnancy to reduce maternal glucose consumption, making glucose available for the developing fetus.
- The fetal endocrine system develops early in gestation to regulate fetal homeostasis.
- Placental and fetal factors induce parturition.
- Oxytocin maintains strong uterine contractions once initiated. Estrogens, relaxin, and prostaglandins are involved in softening and dilating the uterine cervix so that the fetus may exit.
- Lactogenesis (milk production) requires prolactin (PRL), insulin, and glucocorticoids. Galactopoiesis is the maintenance of an established lactation and requires PRL and other hormones.
- Milk ejection is the process by which stored milk is released. Oxytocin released by the suckling reflex contracts the myoepithelial cells surrounding the milk-producing alveolar cells to eject milk into the alveolar ducts.
- Lactation suppresses the menstrual cycle via a neural signal that reduces GnRH release.
- The GnRH pulse generator in the central nervous system becomes activated at the start of puberty. Increased frequency and amplitude of GnRH pulses initiate increased LH and FSH secretion and increased steroid output by the gonads.
- Sexual development depends on genetic and hormonal factors for differentiation of the internal and external genitalia.
- Disorders of sex development occur when chromosomes, gonads, or development of reproductive anatomy is atypical.

Chapter Review Questions

1. The suckling reflex:

A. has afferent hormonal and efferent neuronal components.
B. increases placental lactogen secretion.
C. increases the release of dopamine from the arcuate nucleus.
D. triggers the release of oxytocin by stimulating the supraoptic nuclei.
E. reduces PRL secretion from the pituitary.

The correct answer is D. Suckling involves hormonal and neuronal components, but the hormonal component is efferent and the neuronal component is afferent. When the baby suckles, neural signals from the nipple travel via nerves to the spinal cord and up to the brain (afferent component), which triggers the release of oxytocin from the supraoptic nuclei (efferent component). Oxytocin enters the circulation, enters the breasts, and causes contraction of the myoepithelial cells. Placental lactogen is no longer present after parturition; it is a placental hormone. Dopamine release is decreased by suckling, and as a result, PRL secretion is increased.

2. Implantation occurs:

A. on day 4 after fertilization.
B. after the endometrium undergoes a decidual reaction.
C. when the embryo is at the morula stage.
D. only after priming of the uterine endometrium by progesterone and estrogen.
E. on the first day after entry of the embryo into the uterus.

The correct answer is D. Under normal circumstances, the uterus must be primed with both progesterone and estrogen for successful implantation. Implantation occurs on day 7 after fertilization. The decidual reaction occurs as the result of the implanting blastocyst. The embryo is in the blastocyst stage of development at the time of implantation. A morula does not implant. The developing embryo enters the uterus on day 3 or 4, it remains suspended in the uterus for 3 or 4 more days, and implantation occurs on day 7.

3. Upon contact between the sperm head and the zona pellucida, penetration of the sperm into the egg is achieved because of:

A. the acrosome reaction.
B. the zona reaction.
C. the perivitelline space.
D. pronuclei formation.
E. cumulus expansion.

The correct answer is A. The acrosome reaction causes a fusion of the plasma membrane and the acrosomal membrane of the sperm, with subsequent release of proteolytic enzymes that help the sperm enter the ovum. The zona reaction and pronuclei formation occur after the sperm has entered the ovum. Sperms enter the perivitelline space after penetration; there is no evidence that this space has any role in penetration. Cumulus expansion assists in movement of the sperm through the mass of granulosa cells for the sperm to get to the surface of the zona pellucida. However, the cumulus cells do not assist in actual penetration of the zona.

4. The next ovulatory cycle after implantation is postponed because of:

A. high levels of PRL.

B. the production of hCG by trophoblast cells.
C. the production of prostaglandins by the corpus luteum.
D. the depletion of oocytes in the ovary.
E. low levels of progesterone.

The correct answer is B. The production of hCG by trophoblast cells stimulates the corpus luteum to continue to produce progesterone so that luteal regression does not occur at the end of the anticipated cycle. Although PRL levels increase throughout pregnancy, PRL is not responsible for maintenance of the corpus luteum of pregnancy. Prostaglandins are generally luteolytic, causing regression of the corpus luteum, termination of the luteal phase, and return to the next cycle; they do not prolong the cycle or postpone it. Oocytes are not depleted after implantation. In fact, pregnancy tends to preserve oocytes, as ovulation ceases during pregnancy. Plasma progesterone levels are high during pregnancy as a result of activation of the corpus luteum and placental production of progesterone. Elevated progesterone blocks follicular development and the ensuing LH surge; low levels of progesterone would permit a return to cyclicity.

5. Polyspermy block occurs as a result of the:
A. cortical reaction.
B. enzyme reaction.
C. acrosome reaction.
D. decidual reaction.
E. inflammatory reaction.

The correct answer is A. Fertilization by more than one sperm is prevented by the cortical reaction. Cortical granules containing proteolytic enzymes fuse just beneath the entire surface of the oolemma. The proteolytic enzymes are released to the perivitelline space, destroy the sperm receptors, and harden the zona, preventing other sperms from penetrating the fertilized ovum. Enzyme reaction is a nonspecific term with little meaning for polyspermy. The acrosome reaction allows the sperm to penetrate the zona. The decidual reaction is an inflammatory-like reaction that occurs simultaneously with implantation of the blastocyst into the uterine endometrium.

Clinical Application Exercises 38.1

FEMALE INFERTILITY

A 25-year-old woman and her 29-year-old husband have been trying to have a baby for 1 year. She has regular menstrual cycles of 24 to 26 days in length. The couple has intercourse three times a week, with no physical problems, and they try to time intercourse around the time of her ovulation. Physical examination and history for the wife are normal. The husband's physical examination is normal. The husband's semen analysis reveals a semen volume of 4 mL, pH 7.5, sperm count of 30 million/mL, and normal morphology and motility of the sperm. Because of the short cycles (24 to 26 days vs. 28 days), the wife's plasma progesterone level during the midluteal phase is assessed and determined to be 10 ng/mL, which is considered normal (4 to 20 ng/mL).

QUESTIONS

1. What hormones can be measured in the blood to determine why the woman is not able to get pregnant?

2. Based on the hormone measurements, what treatment would likely result in a successful pregnancy?

ANSWERS

1. Estradiol should be measured at the end of the anticipated follicular phase. High serum levels of estradiol would indicate that a dominant follicle has been recruited and is active; low levels would indicate a subnormal dominant follicle or lack of a dominant follicle, which could be verified by ultrasound of the ovaries. Serum LH should be measured during the anticipated preovulatory period. High serum levels of LH would indicate that the dominant follicle is receiving the signal to ovulate. Low levels of LH may lead to an unruptured dominant follicle that fails to ovulate but luteinizes, leading to progesterone levels in the normal range for the luteal phase. Plasma concentrations of hCG could be determined during the midluteal to late luteal phase to determine whether she was pregnant.
2. Low estradiol indicates a lack of development of a dominant follicle. Therapies such as gonadotropins and clomiphene would be appropriate to stimulate follicular development, estradiol secretion, and ovulation. If a dominant follicle is present, then hCG can be given to induce follicular rupture. hCG binds to the LH receptor and is preferred over LH and GnRH for induction of ovulation because of its longer half-life.

PAH p-aminohippurate

Pao2 partial pressure of oxygen in arterial blood

Pao2 partial pressure of oxygen in alveoli

Pao2–Pao2 alveolar arterial difference in partial pressure of oxygen

Pc′ pulmonary end-capillary

Pco2 partial pressure of carbon dioxide

PCr phosphocreatine (creatine phosphate)

PDE phosphodiesterase

PEF peak expiratory flow

PG prostaglandin

PI phosphatidylinositol

Pi inorganic phosphate

PIF peak inspiratory flow

PIP2 phosphatidylinositol 4,5-bisphosphate

PKA protein kinase A

PKC protein kinase C

PKG cGMP-dependent protein kinase

pl pleural

PLC phospholipase C

PNS peripheral nervous system

Po2 partial pressure of oxygen

POMC proopiomelanocortin

PRL prolactin

PRU peripheral resistance unit

PT prothrombin time

PTH parathyroid hormone (parathormone)

PTT partial thromboplastin time

PVC premature ventricular complex

Pvco2 partial pressure of carbon dioxide in venous blood

pw pulmonary wedge

generic symbol for flow of any kind

R respiratory exchange ratio; resistance; universal gas constant

R heat loss by radiation

r radius; radiant environment

RAAS renin–angiotensin–aldosterone system

RBF renal blood flow

RBP retinol-binding protein

RDA recommended daily allowance

Re Reynolds number

REM rapid eye movement

rh relative humidity

RIA radioimmunoassay

RISA radioiodinated serum albumin

ROS reactive oxygen species

RPF renal plasma flow

RQ respiratory quotient

RV residual volume

RVD regulatory volume decrease

RVI regulatory volume increase

RV/TLC residual volume to tidal volume ration

S saturation; siemens

S rate of heat storage in the body

s shunt

SA sinoatrial

Sao2 saturation of hemoglobin with oxygen in arterial blood

SF-1 steroidogenic factor 1

SGLT Na+–glucose cotransporter

SH2 src homology domain

SHBG sex hormone–binding globulin

SIADH syndrome of inappropriate ADH

sk skin

SN single nephron

SPCA serum prothrombin conversion accelerator

SRIF somatotropin release–inhibiting factor (somatostatin)

SRY sex-determining region, Y chromosome

SSRI selective serotonin reuptake inhibitor

StAR steroidogenic acute regulatory protein

SV stroke volume

SVR systemic vascular resistance (total peripheral resistance)

SW stroke work

T tension; temperature; time

t tidal

t time

T3 triiodothyronine

T4 thyroxine

ta transairway

TBG thyroxine-binding globulin

TBW total body water

TEA tetraethylammonium

TF tubular fluid

TGF transforming growth factor

TLC total lung capacity

tm transmural

Tm tubular transport maximum

Tn-C calcium-binding troponin

TNF tumor necrosis factor

Tn-I troponin that inhibits actin–myosin interactions

Tn-T tropomyosin-binding troponin

tp transpulmonary

TPA tissue plasminogen activator

TR thyroid hormone receptor

TRE thyroid hormone response element

TRH thyrotropin-releasing hormone

TSC thiazide-sensitive (Na^+–Cl^-) cotransporter

TSH thyroid-stimulating hormone

T tubule transverse tubule

U urine concentration

UCP uncoupling protein

UDP uridine diphosphate

UP ultrafiltration pressure gradient

V volume; volt; vasopressin; vacuolar

v velocity; venous

gas volume per unit time (airflow); minute ventilation; urine flow rate

A alveolar ventilation

A/ alveolar ventilation/perfusion ratio

VC vital capacity

VD dead space volume in the lung (i.e., volume of air that does not participate in gas exchange)

Vd/Vt ratio of dead space volume to tidal volume

E expired minute ventilation (note: minute ventilation and expired minute ventilation are the same)

VEGF vascular endothelial growth factor

VIP vasoactive intestinal peptide

VLDL very-low-density lipoprotein

Vmax maximum theoretical velocity of muscle contraction

o2 oxygen consumption per minute

W heat loss as mechanical work

w wettedness

z valence of an ion

φ osmotic coefficient

η viscosity

λ length (space) constant; wavelength

μ electrochemical potential

π osmotic pressure; 3.14 (pi)

ρ density

σ reflection coefficient

τ time constant

APPENDIX B Normal Blood, Plasma, or Serum Values

Internationale	Fluid*	Reference Range	System Reference Range
Alanine aminotransferase	S	8–20 U/L	0.13–0.33 mkat/L
Aldosterone, with normal sodium intake of 100–200 mEq/d	S	Supine: <16 ng/dL	<444 pmol/L
Aldosterone, with normal sodium intake of 100–200 mEq/d		Upright: 4–31 ng/dL	111–860 pmol/L
Arginine vasopressin	P	1.0–13.3 pg/mL	1.0–13.3 ng/L
Aspartate aminotransferase	S	9–40 U/L	0.15–0.67 mkat/L
Bicarbonate, arterial	P	22–26 mEq/L	22–26 mmol/L
Bilirubin, total	S	0.1–1.0 mg/dL	2–17 µmol/L
Calcium	S	8.4–10.2 mg/dL	2.1–2.6 mmol/L
Carbon dioxide (Pco_2), arterial	B	35–45 mm Hg	4.7–6.0 kPa
Chloride	P, S	95–105 mEq/L	95–105 mmol/L
Cholesterol, recommended	S	<200 mg/dL	<5.2 mmol/L
Cortisol	S	08:00 h: 5–23 µg/dL	138–635 nmol/L
		16:00 h: 3–15 µg/dL	82–413 nmol/L
		20:00 h: <50% of 08:00 h value	<0.50 of 08:00 h value
Creatinine	S	0.6–1.2 mg/dL	53–106 µmol/L
Creatine kinase	S	Female: 10–70 U/L	0.17–1.17 µkat/L
		Male: 25–90 U/L	0.42–1.50 µkat/L
1,25-Dihydroxyvitamin D	S	16–42 pg/mL	38–101 pmol/L
Estradiol	P, S	Female:	
		Prepubertal: <20 pg/mL	<73 pmol/L
		Premenopausal adult: 23–361 pg/mL	84–1,325 pmol/L
		Postmenopausal adult: <30 pg/mL	<110 pmol/L
		Male: <50 pg/mL	<184 pmol/L
Ferritin	S	Male: 15–200 ng/mL	15–200 µg/L
		Female: 12–150 ng/mL	12–150 µg/L
Follicle-stimulating hormone	S	Male: 4–25 mIU/mL	4–25 U/L
		Female:	
		Premenopause: 4–30 mIU/mL	4–30 U/L
		Midcycle peak: 10–90 mIU/mL	10–90 U/L
		Postmenopause: 40–250 mIU/mL	40–250 U/L
Glucagon	P	50–200 pg/mL	50–200 ng/L
Glucose	S	Fasting: 70–110 mg/dL	3.9–6.1 mmol/L
		2-h postprandial: <140 mg/dL	<7.8 mmol/L
Growth hormone	P	2.0–6.0 ng/mL	2.0–6.0 mg/L

Internationale	Fluid*	Reference Range	System Reference Range
HDL cholesterol, as major risk factor	S	<35 mg/dL	<0.91 mmol/L
25-Hydroxyvitamin D	S	8–80 ng/mL	20–200 nmol/L
Insulin	S	0–29 µU/mL	0–208 pmol/L
Iron	S	50–170 µg/dL	9–30 µmol/L
Lactate dehydrogenase	S	100–190 U/L	1.7–3.2 µkat/L
LDL cholesterol, desirable	S	<130 mg/dL	<3.36 mmol/L
Luteinizing hormone	S	Male: 6–23 mIU/mL	6–23 U/L
		Female:	
		Follicular phase: 5–30 mIU/mL	5–30 U/L
		Midcycle: 75–150 mIU/mL	75–150 U/L
		Postmenopause: 30–200 mIU/mL	30–200 U/L
Magnesium	S	1.5–2.0 mEq/L	0.75–1.0 mmol/L
Osmolality	P, S	275–295 mOsm/kg H_2O	275–295 mOsm/kg H_2O
Oxygen content, arterial	B	17–21 mL/dL	0.17–0.21 L/L
Oxygen saturation, arterial	B	96%–100%	0.96–1.00 mol/mol
Oxygen tension (Po_2), arterial	B	75–100 mm Hg	10.0–13.3 kPa
Parathyroid hormone	P	10–60 pg/mL	10–60 ng/L
pH, arterial	B	7.35–7.45 [H^+]	35–45 nmol/L
Phosphatase, alkaline	S	20–70 U/L	0.33–1.17 µkat/L
Phosphorus, inorganic	S	3.0–4.5 mg/dL	1.0–1.5 mmol/L
Potassium	S	3.5–5.0 mEq/L	3.5–5.0 mmol/L
Prolactin	S	Female:	
		Nonpregnant: 3–30 ng/mL	3–30 µg/L
		Pregnant: 10–209 ng/mL	10–209 µg/L
		Postmenopausal: 2–20 ng/mL	2–20 µg/L
		Male: 2–18 ng/mL	2–18 µg/L
Proteins			
Total	S	6.0–7.8 g/dL	60–78 g/L
Albumin	S	3.5–5.5 g/dL	35–55 g/L
Globulin	S	2.3–3.5 g/dL	23–35 g/L
Sodium	S	136–145 mEq/L	136–145 mmol/L
Testosterone, total (morning)	P	Male: 300–1,100 ng/dL	10.4–38.1 nmol/L
		Female: 20–90 ng/dL	0.7–3.1 nmol/L
Thyroid-stimulating hormone	S	0.5–5.0 µU/mL	0.5–5.0 mU/L
Thyroxine (T4), total	S	5–12 µg/dL	64–155 nmol/L
Triglycerides, fasting	S	35–160 mg/dL	0.4–1.8 mmol/L
Triiodothyronine (T3)	S	115–190 ng/dL	1.8–2.9 nmol/L
Urea nitrogen (BUN)	S	7–18 mg/dL	2.5–6.4 mmol urea/L
Uric acid	S	3.0–8.2 mg/dL	0.18–0.49 mmol/L

Internationale	Fluid*	Reference Range	System Reference Range
Hematologic Values			
Blood volume		Male: averages 69 mL/kg body weight	
		Female: averages 65 mL/kg body weight	
Plasma volume		Male: 25–43 mL/kg body weight	0.025–0.043 L/kg body weight
		Female: 28–45 mL/kg body weight	0.028–0.045 L/kg body weight
Erythrocyte count		Male: 4.3–5.9 × 10^6/mm^3	4.3–5.9 × 10^{12}/L
		Female: 3.5–5.5 × 10^6/mm^3	3.5–5.5 × 10^{12}/L
Erythrocyte sedimentation rate		Male: 0–15 mm/h	0–15 mm/h
		Female: 0–20 mm/h	0–20 mm/h
Hematocrit		Male: 41%–53%	0.41–0.53
		Female: 36%–46%	0.36–0.46
Hemoglobin, blood		Male: 13.5%–17.5 g/dL	2.09–2.71 mmol/L
		Female: 12.0–16.0 g/dL	1.86–2.48 mmol/L
Hemoglobin A_{1c}		≤6% of total Hb	≤0.06 of total Hb
Leukocyte count and differential			
Leukocyte count		4,500–11,000/mm^3	4.5–11.0 × 10^9/L
Segmented neutrophils		45%–74%	0.45–0.74
Bands		0%–4%	0.00–0.04
Eosinophils		0%–7%	0.00–0.07
Basophils		0%–2%	0.00–0.02
Lymphocytes		16%–45%	0.16–0.45
Monocytes		4%–10%	0.04–0.10
Mean corpuscular hemoglobin		25.4–34.6 pg/cell	0.39–0.54 fmol/cell
Mean corpuscular hemoglobin concentration		31–36 g/dL	4.81–5.58 mmol Hb/L
Mean corpuscular volume		80–100 mm^3	80–100 fL
Partial thromboplastin time, activated		25–40 s	25–40 s
Platelet count		150,000–400,000/mm^3	150–400 × 10^9/L
Prothrombin time		11–15 s	11–15 s
Red cell distribution width		11.5%–14.5%	0.115–0.145
Reticulocyte count		0.5%–1.5% of red cells	0.005–0.015

*B, blood; P, plasma; S, serum.

Glossary

A band band of muscle myofilament that appears dark under a microscope and contributes to muscles' striated appearance; contains myosin and overlapping projections of actin; anisotropic

ABCA1 ATP-binding cassette transporter member 1 is encoded by the ABCA1 gene. This transporter is a major regulator of cellular cholesterol and phospholipid homeostasis

abdominal wall muscles along the abdomen that are involved in forced expiration

abduction movement away from the midline

abetalipoproteinemia condition in which apo B synthesis cannot occur, thereby blocking production and secretion of very-low-density lipoproteins by the liver; condition is marked by large accumulated lipid droplets in the cytoplasm of hepatocytes

absence seizure characterized by the lack of jerking or twitching movements of the eyes; the person seems to stare off into space; formerly known as petit mal seizures

absolute refractory period window of time following one action potential during which an axon cannot generate an action potential no matter how strong the stimulus

absolute threshold of hearing intensity level below which no sound can be heard; for the human ear, it has a value of 0.0002 dyne/cm2

absorptive hyperemia increase in intestinal blood flow that accompanies digestion; local response to elevated tissue metabolism

absorptivity property of the body surface that depends on the temperature of the body and the wavelength of the incident radiation; dimensionless value measured as the fraction of incident radiation that is absorbed by the body

accessory muscles muscles that are brought into play during forced inspiration and expiration

accessory structures structures that either enhance the specific sensitivity of a sensory receptor or exclude unwanted stimuli such as the lens of the eye

accidental hypothermia drop of central temperature below 35°C not induced for therapeutic purposes; occurs in people impaired by drugs or ethanol, disease, and other physical conditions and in healthy people who are immersed in cold water or become exhausted in the cold

acclimation functional change in response to an environmental stress; changes are not permanent and can be reversed when the environmental stress is removed

acclimatization process of an organism adjusting to changes in its environment, often involving temperature or climate; usually occurs in a short time and within one organism's lifetime

accommodation (1) process of focusing the eye to adjust to varying object distances; (2) decrease in sensory action potential frequency with a constant generator potential

acetoacetic acid unstable acid found in abnormal amounts in the blood and urine in some cases of impaired metabolism (such as diabetes mellitus or starvation)

acetone chemical formed in the blood when the body uses fat instead of glucose (sugar) for energy

acetylcholine (ACh) one of the two major neurotransmitters used by the autonomic nervous system; the transmitter molecule present in cholinergic synapses and the myoneural junction; the neurotransmitter present in cholinergic synapses in the brain; major neurotransmitter in cognitive function, learning, and memory

acetylcholinesterase (AChE) enzyme that hydrolyzes acetylcholine and terminates its action as a transmitter substance

achalasia failure of any sphincter to relax; in clinical practice, achalasia most often refers to a specific condition in which the lower esophageal sphincter fails to relax

acid substance that can release or donate a hydrogen ion

acid dissociation constant (Ka) ionization constant for an acid

acid indigestion indigestion resulting from hypersecretion of acid in the stomach, a synonym for pyrosis

acid tide condition in which the blood from the pancreas is acidic as a result of the bicarbonate secretion in pancreatic juice

acidemia condition in which arterial blood pH is < 7.35

acidosis condition in which blood pH is below 7.35; also known as acidemia

acinar cells major cells found in the exocrine pancreas actively involved in the production of enzymes

acinus blind sac containing mainly pyramidal cells found in the salivary glands of humans and animals that aids in the secretion of saliva

acne vulgaris disease characterized by comedones, pustules, papules, nodules, and cysts; most common in teenagers and young adults

acoustic reflex automatic contractions of the stapedius and tensor tympani muscles that protect the ear from excessively loud noises

acromegaly thickening of the bones of the face, hands, and feet and liver hypertrophy resulting from excess growth hormone in an adult

acrosome caplike structure that surrounds the sperm head and contains enzymes that help penetration of the egg

acrosome reaction fusion of the outer acrosomal membrane of the sperm head with the sperm plasma membrane, forming a composite membrane with openings through which acrosomal enzymes necessary for sperm penetration of the egg pass

actin globular protein that, in its polymeric filamentous form, makes up the bulk of thin myofilaments in muscle and other contractile systems

α-actinin filamentous muscle protein that anchors thin filaments to the structures of Z lines

actin-linked regulation muscle control system based on controlled alteration of the constituents of the actin filaments

action potential short-lasting, all-or-none change in membrane potential of a nerve or muscle cell that arises when a graded membrane depolarization passes a threshold for opening voltage-gated sodium channels; usually becomes a propagated nerve or muscle cell action potential; also known as spike

potential

action tremor tremor present during movement

activated partial thromboplastin time (aPTT) test to monitor the intrinsic and common coagulation pathways

activation gate molecular gate in voltage-gated ion channels that opens in response to a polarization change

active hyperemia blood flow increase in response to increased tissue metabolism or reduced oxygen content in the blood

active immunity immunity resulting from activation of lymphocytes (natural) or vaccination (artificial)

active state the state of the voltage-gated sodium channel in which the channel is open and allowing the flow of sodium ions

active tension component of muscle force that arises from crossbridge interactions

active transport membrane transport of solute or ions against the prevailing chemical and/or electrical gradient and driven by input of metabolic energy usually in the form of adenosine triphosphate (ATP); when solute movement is directly coupled to ATP hydrolysis, the process is termed primary active transport, whereas secondary active transport of solute is driven by an ion gradient (usually Na+) that is maintained by a separate primary active transport process (usually Na+/K+-ATPase)

active zones specialized regions of presynaptic terminals where the synaptic vesicles dock, fuse, and release their transmitter

activin nonsteroidal regulator, composed of two covalently linked β subunits, that is synthesized in the pituitary gland and gonads and stimulates the secretion of follicle-stimulating hormone; the actions of activins are the opposite of those of inhibins

activity front length of the intestine with an oral and aboral boundary occupied by the migrating mot or complex that advances (migrates) along the intestine at a rate that progressively slows as it approaches the ileum

actomyosin ATPase enzymic entity, formed by the interaction of actin and myosin, that hydrolyzes adenosine triphosphate and converts its chemical energy into a mechanical change

acute kidney injury (AKI) serious condition characterized by a rapid decline in glomerular filtration rate, retention of nitrogenous waste products, and disturbances of extracellular fluid volume and electrolyte and acid–base balance; also known as acute renal failure

acute mountain sickness (AMS) pathophysiologic condition caused by acute exposure to high altitude (from hypoxia resulting from a decrease in oxygen tension, not from a decrease in the percentage of oxygen in the inspired air); also known as altitude sickness

acute-phase blood proteins serum proteins elevated during acute inflammation

acute respiratory distress syndrome (ARDS) diffuse lung injury that is characterized by abnormally low compliance, pulmonary edema, and focal atelectasis

acyl-CoA: cholesterol acyltransferase (ACAT) enzyme responsible for the esterification of cholesterol to form cholesterol ester

adaptation genetic change that enhances the ability of the body to adjust to the environment; changes

(e.g., sweat glands) are passed on to the next generation

adaptive immune system antigen-specific interacting components; also called acquired immune system

adaptive relaxation vagovagal reflex triggered by stretch receptors in the gastric wall, transmission over vagal afferents to the dorsal vagal complex, and efferent vagal fibers back to inhibitory musculomotor neurons in the gastric enteric nervous system

Addison disease disorder characterized by hypotension, weight loss, anorexia, weakness, and sometimes a bronze-like melanotic hyperpigmentation of the skin; results from primary deficiency of adrenal cortex function and inadequate secretion of aldosterone and cortisol

adduction movement toward the midline

adenohypophysis anterior pituitary

adenosine inhibitory neurotransmitter believed to play a role in promoting sleep and suppressing arousal, with levels increasing with each hour an organism is awake

adenosine diphosphate (ADP) nucleotide released upon platelet activation, causing platelet aggregation; the product of adenosine triphosphate (ATP) dephosphorylation by ATPases; ADP is converted back to ATP by ATP synthases

adenosine triphosphate (ATP) nucleotide important in transport of energy within cells for metabolism

adenylyl cyclase (AC) enzyme that catalyzes the synthesis of cyclic adenosine monophosphate from adenosine triphosphate

adequate stimulus biologically correct stimulus for a given sensory receptor

adipose triglyceride lipase (ATGL) triglyceride lipase that catalyses the removal of the first fatty acid from the glycerol backbone during triglyceride hydrolysis

adrenal cortex outer portion of the adrenal gland

adrenal medulla inner portion of the adrenal gland

adrenarche adrenal maturation during pubertal development in boys and girls

adrenergic characterized by nerves releasing or tissues responding to the catecholamines norepinephrine or epinephrine

adrenocorticotropic hormone (ACTH) hormone product of corticotrophs located in the anterior pituitary; also known as corticotropin

adventitia outer elastic layer of arteries and veins that gives some structural integrity to blood vessels but more so in arteries than in veins

aerobic pertaining to a biochemical or physiologic process that requires O2 for its function

affect psychological impression of the degree of “pleasantness” of a stimulus

affective disorders illnesses marked by abnormal mood regulation and associated signs and symptoms; also known as mood disorders

afferent carrying toward

afferent nerve (afferents) nerve fiber (usually sensory) carrying impulses from an organ or tissue toward the central nervous system or the information-processing centers of the enteric nervous system;

examples are vagal and spinal afferents

afterhyperpolarization transient period of increased membrane potential that follows the repolarization phase of the action potential

afterload force a muscle experiences (exerts) after it has begun to shorten

aganglionosis congenital absence of ganglion cells in the enteric nervous system in a segment of bowel; peristaltic propulsion is impossible in the absence of the enteric nervous system and is the pathophysiologic basis for Hirschsprung disease

age-related macular degeneration (AMD) decreased sharpness of central vision, especially in bright light; progressive condition whose causes are obscure and for which no cure is available

agonist (1) synthetic drug molecule that selectively binds to a specific receptor and triggers a signaling response in the cells; agonists mimic the action of endogenous biochemical molecules, such as hormones or neurotransmitters that bind to the same receptor; (2) muscle producing the desired movement

agouti-related protein (AgRP) a neuropeptide synthesized in neuropeptide Y containing neurons in the arcuate nucleus of the hypothalamus; increases appetite

agranulocyte mature cell, such as a monocyte or lymphocyte; also known as monomorphonuclear leukocyte

AH-type enteric neuron multipolar neuron with multiple long processes so named because a characteristic long-lasting hyperpolarizing potential (i.e., an afterhyperpolarization or AH) occurs after discharge of an action potential; fulfills the role of interneurons in the enteric neural networks; previously thought to be intrinsic primary afferent neurons

AIDS acquired immunodeficiency syndrome; disease of the human immunodeficiency virus

airway resistance resistance of air movement in airways resulting from turbulent airflow

airway tree airway branching, which occurs in a treelike fashion in the lung

albumin main plasma protein and key regulator of oncotic pressure of blood

albuminuria presence of serum albumin in the urine

aldosterone mineralocorticoid hormone produced by the zona glomerulosa of the adrenal cortex that stimulates tubular reabsorption of sodium and secretion of potassium and hydrogen ions in the kidneys

aldosterone synthase (CYP11B2) substance that synthesizes aldosterone from pregnenolone

alkalemia condition in which arterial blood pH is >7.45

alkaline tide phenomenon that occurs when blood coming from the stomach during active acid secretion contains an overabundance of bicarbonate

alkalosis condition in which blood pH is above 7.45; also known as alkalemia

all-or-none phenomenon once threshold is reached, a full action potential is generated

allergy type I immediate hypersensitivity disorder

allo Greek for “other”

allograft transplantation between genetically different people

alpha cells see α cell

alpha motor neuron see α motor neuron

alpha waves electroencephalogram wave pattern with a rhythm ranging from 8 to 13 Hz, observed when the person is awake but relaxed with the eyes closed

alveolar arterial oxygen gradient pressure difference between the partial pressure of alveolar oxygen and arterial oxygen

alveolar cells milk-secreting cells in the breast

alveolar dead space volume fraction of air in the alveoli that does not participate in gas exchange; occurs because regional blood flow and airflow are not evenly matched (ventilation/perfusion inequalities)

alveolar gas equation formula used to calculate partial pressure of gases in the alveoli

alveolar pressure pressure inside the alveoli

alveolar ventilation amount of fresh air (L/min) brought into the alveoli

alveoli small air sacs in which oxygen and carbon dioxide are exchanged between the atmosphere and the pulmonary capillary blood

Alzheimer's disease (AD) most common form of dementia characterized by plaques and neurofibrillary tangles; symptoms include confusion, long-term memory loss, irritability and aggression, mood swings, language breakdown, and sensory decline; disease is incurable, degenerative, and terminal

amacrine cells interneurons in the retina that are responsible for 70% of input to retinal ganglion cells and that regulate bipolar cells, which are responsible for the other 30% of input to retinal ganglia

ambisexual stage time in development when the embryo has the potential to acquire either masculine or feminine characteristics

amenorrhea absence of menstruation

γ-aminobutyric acid (GABA) inhibitory neurotransmitter

amnion extraembryonic membrane that forms a closed fluid-filled sac around the embryo and fetus

amniotic sac structure that forms the amnion around the developing fetus

amphipathic condition in which both hydrophilic and hydrophobic regions are present in the same molecule, for example, phospholipids

amphoteric capable of acting as either an acid or a base

ampulla woolen end of the oviduct, which receives the egg after it is passed into the duct by the fimbria

amygdala region of the cerebrum involved in visceral components of emotional responses

amylase important digestive enzyme secreted by both the salivary glands and the pancreas that is involved in the digestion of carbohydrates

amylin hormone formed by β cells in the pancreas that regulates the timing of glucose release into the bloodstream after eating by slowing the emptying of the stomach; also known as islet amyloid-associated peptide

anaerobic pertaining to a biochemical or physiologic process that does not require O2 for its function

anaerobic threshold exercise intensity at which lactate (lactic acid) starts to accumulate in the blood,

which happens when lactate is produced faster than it can be removed (metabolized)

anamnestic response increased immune response to repeated antigen exposure

anaphylaxis condition resulting from severe allergic reaction and characterized by intense local and sometimes systemic vasodilation that results in shock; histamine released during the reaction dilates arterioles and increases capillary permeability; fluid loss from transcapillary filtration contributes to plasma volume loss that exacerbates the shock caused by arteriolar dilation

anatomic dead space volume amount of air found in the lungs' airways that does not participle in gas exchange

anatomic shunt blood that bypasses alveoli and does not get oxygenated as a result of a structural defect in the circulation

androgen type of hormone that promotes the development and maintenance of male sex characteristics

androgen-binding protein (ABP) protein produced by Sertoli cells that binds testosterone

androstenedione adrenal androgen made by 17α-hydroxylation of progesterone; serves as a precursor for estrogen synthesis in the ovaries

anemia reduction in erythrocytes, which leads to a decrease in the oxygen-carrying capacity of the blood

anemia of inflammation long-term condition characterized by a lower-than-normal number of healthy red blood cells; also called anemia of chronic disease

aneurysm weakening of the arterial wall that causes it to bulge outward, leak blood, and eventually rupture

angiogenesis formation of new blood vessels

angiotensin I inactive decapeptide formed during the cleavage of angiotensinogen

angiotensin II peptide hormone formed from the proteolysis of angiotensin I by converting enzyme in the lungs; potent vasoconstrictor; enhances the effectiveness of sympathetic nerve stimulation to blood vessels and promotes salt and water retention in the body primarily by stimulating the release of aldosterone from the adrenal cortex

angiotensin-converting enzyme (ACE) enzyme located in the capillary endothelial cells of the lung and kidney that converts angiotensin I to angiotensin II

angiotensinogen α2-globulin produced by the liver that is the substrate for renin

anhidrotic ectodermal dysplasia hereditary condition characterized by abnormal development of the skin, hair, nails, teeth, and sweat glands and in which sweat glands are sparse or absent; affected adults are unable to tolerate a warm environment and require special measures to maintain normal body temperature

anion negatively charged ion, especially the ion that migrates to an anode in electrolysis

anion exchange protein (AE1) transports protein responsible for mediating the electroneutral exchange of chloride (Cl^-) for bicarbonate ($HCO3^-$) across a plasma membrane

anion gap difference (in mEq/L) between plasma [Na^+] and plasma ([Cl^-] + [$HCO3^-$])

anisocytosis large variation in the size of erythrocytes

anorectal angle (approximately) 90° angle between the rectum and the anal canal; becomes more obtuse

during defecation and more acute when holding back stool; formed by the contraction of the puborectalis muscle

anorexia nervosa severe behavioral disorder associated with the lack of food intake, extreme malnutrition, and endocrine changes secondary to psychological and nutritional disturbances

anorexigenic causing a loss of appetite

anovulation period in which no ovulation occurs

antagonist muscle opposing the desired movement

antagonistic pair pair of muscles arranged so that the shortening of one lengthens the other, and vice versa

anterior cavity forward section of the eyeball that contains the iris and the lens

anterior periventricular region portion of the hypothalamus close to the third ventricle

anterograde direction of axonal transport from the cell body toward the axon terminal

anterograde amnesia loss of memory going forward from a trauma

antibody secreted protein that can bind antigen

anterograde transport transport of cellular components from the soma to the nerve process

anticoagulant substance that prevents coagulation

antidiuretic hormone (ADH) peptide hormone synthesized in the anterior hypothalamus and released from the posterior pituitary, whose primary action is to increase the water permeability of the kidney collecting ducts; now known as arginine vasopressin (AVP)

antidromically conduction of nerve action potentials in the direction opposite to that which is usual

antigen substance that binds to antigen receptors and antibody

antigen-presenting cell (APC) cell displaying antigen on its surface together with major histocompatibility complex class II

antigen recognition molecules T-cell receptor, B-cell receptor, and major histocompatibility complex proteins

antioxidant molecule capable of inhibiting the oxidation of another molecule, for example, the enzyme catalase reduces superoxide to oxygen and water

antiport membrane transport process in which the driver ion (usually Na+) and the solute move in opposite directions

antra fluid-filled cavities in a tertiary ovarian follicle

antral dysrhythmia abnormality of electrical rhythm in the gastric antrum (bradygastria/tachygastria) analogous to cardiac arrhythmia

antral granulosa cells cells that line the antral cavity of a graafian follicle

antral pump caudal two thirds of the gastric corpus, the antrum, and the pylorus

aorta largest artery in the body; sole arterial outlet from the left ventricle

aortic bodies specialized innervated nodules located in the aorta that sense low Po2 and pH as well as

high Pco2; send impulses to the medullary area of the brain to elicit reflex activation of the sympathetic nervous system to increase blood pressure and do not respond to low arterial pressure unless the pressure is low enough to affect oxygen delivery to the bodies (<80 mm Hg)

aortic baroreceptors spray nerve endings in the wall of the aortic arch that sense stretch and, therefore, serve as sensory receptors for changes in arterial pressure

aortic valve thin, flexible, trileaflet structure that separates the aorta from the left ventricle; opens into the aorta and closes off the aorta when the left ventricle relaxes

aphasia loss of the ability to use or understand language, usually resulting from injury or stroke

apical that side of a cell or plasma membrane facing the lumen

apical membrane the surface of the plasma membrane of a polarized cell that faces inward to the lumen

aplastic anemia stem cell destruction in the bone marrow that leads to the decreased production of white blood cells, platelets, and red blood cells

apnea temporary cessation of breathing

Apo B proteins class of apolipoproteins that are a component of liver-synthesized very-low-density lipoprotein particles; Apo B48 produced by the small intestine and apo B100 produced exclusively by the liver are the circulating forms of the apo B proteins

apocrine type of exocrine gland from which the apical portion of the secreting cell is released along with the secretory products, for example, sweat glands

apoeccrine hybrid sweat glands found in the axilla with secretory structures similar to those found in both apocrine and eccrine glands but are functionally similar to eccrine glands; they secrete nearly 10 times as much sweat as eccrine glands

apoferritin storage protein found in the enterocyte cytoplasm that binds and stores iron

apoprotein B100 400-kDa protein present on the surface of the low-density lipoprotein (LDL) particle and recognized by LDL receptors

apoproteins major proteins associated with chylomicrons and very-low-density lipoproteins

apoptosis deliberate type of programmed cell death that is mediated by an intracellular signaling pathway; a type of programmed cell death; contrast with necrosis

aquaporin (AQP) small (30-kDa) integral membrane protein that functions as a water channel and explains the rapid movement of polar water molecules across the lipid bilayer of plasma membranes

aqueous humor thin, clear liquid that fills the anterior chamber of the eyeball

arachidonic acid fatty acid released from phospholipids in the membrane when ligand-gated receptors activate phospholipase A2

arcuate nuclei (ARC) hypothalamic nuclei that synthesize growth hormone–releasing hormone and regulate feeding

area postrema area in the lateral wall of the fourth ventricle, which is one of the few locations in the brain where the blood–brain barrier is open; it contains neural networks that trigger vomiting

areflexia absence of muscle stretch reflexes

areola pigmented region of skin surrounding the nipple

arginine vasopressin (AVP) substance produced by magnocellular neurons in the supraoptic and paraventricular nuclei of the hypothalamus that regulates water resorption by the kidneys

aromatase an enzyme that modifies the A ring of testosterone and androstenedione to remove one carbon, yielding the 18-carbon estrogen hormones

arrhythmia abnormality in heart rate; irregularity in the rhythm of the heart or pattern

arterioles small arteries of ~10 to 1,000 μm in diameter that join large arteries to organ capillary networks; they have the same wall structure as larger arteries but generally have thicker walls and smaller lumen diameters and are the primary site of changes in vascular resistance and blood flow distribution within the cardiovascular system; they are also involved with the control of intracapillary hydrostatic pressure

arteriosclerosis a condition of reduced compliance of large arteries, usually caused by breakdown of the organization of elastic fibers in the adventitia as a natural result of the aging process

arteriovenous anastomoses generally, a direct connection between the lumen of an artery and vein that bypasses the capillary bed of an organ; in the skin, arteriovenous anastomoses that are highly innervated by sympathetic nerves link arterioles to subcutaneous venous plexi that serve to conduct heat to or restrict loss of heat from the skin surface; these anastomoses play a key role, therefore, in temperature regulation in the body

artery blood vessel that carries blood away from the heart and composed of three layers: an outermost stiffly elastic adventitia, a middle zone composed of circular layers of smooth muscle, and a single-cell lining of epithelial cells called the endothelium; has structural rigidity in that it retains circular shape even without any positive transmural pressure

ascending reticular activating system system of neurons in the brainstem that project to the thalamus and are involved in arousal and motivation

ascites sites of edema in the organs of the abdominal cavity

aspartate amino acid used as an excitatory neurotransmitter

association cortex cortical region involved in higher-order processing of information

asthma spasmodic contraction of smooth muscle in the bronchi leading to airway obstruction; symptoms include labored breathing accompanied especially by wheezing and coughing and by a sense of constriction in the chest; it is triggered by hyperreactivity to various stimuli (as allergens or rapid change in air temperature)

astigmatism vision defect caused by an eyeball with differing radii of curvature at differing orientations; causes vertical and horizontal lines to have different focal distances

astrocytes glial cells in the CNS that help form the blood–brain barrier and support neuronal functions

ataxia inability to coordinate muscle activity during voluntary movement; most often due to disorders of the cerebellum or the posterior columns of the spinal cord; may involve the limbs, head, or trunk

atelectasis lack of gas exchange in alveoli due to alveolar collapse or fluid consolidation

atherosclerosis thickening of arterial walls from cholesterol plaque buildup, possibly leading to blockage

atopy genetic predisposition to allergens

ATP synthase see F-type ATPase

ATPase enzyme or membrane transport system that hydrolyses adenosine triphosphate (ATP) to adenosine diphosphate and free phosphate; P-type ATPases are ATPases that are phosphorylated during the hydrolysis of ATP and are found on the plasma membrane; V-type ATPases are found on intracellular vacuolar structures; F-type ATPases are located on the inner mitochondrial membrane and synthesize ATP rather than hydrolyze it

ATP-binding cassette (ABC) transporters superfamily of adenosine triphosphate–binding cassette transporters composed of two transmembrane domains and two cytosolic nucleotide-binding domains; the transmembrane domains recognize specific solutes and transport them across the membrane by using a number of different mechanisms, including conformational change

ATP-dependent K+ channel (KATP) class of K channels inhibited by the binding of intracellular adenosine triphosphate

atresia degeneration of follicles in the ovary

atrial fibrillation random, chaotic electrical activation of atrial muscle cells, often resulting in irregular pacing of the ventricles

atrial natriuretic peptide (ANP) peptide hormone that is released from the right atrium when it is stretched, usually from an increased blood volume; promotes the loss of sodium and, indirectly, water from the kidney, thereby helping to restore normal blood volume

atrioventricular (AV) node specialized conduction tissue in the septum of the heart between the atria and ventricles and the only normal path by which electrical activation of the atria spreads into the ventricles; also delays activation of the ventricles during normal cardiac activation, thereby increasing the time the ventricles have to fill with blood during diastole

attention ability to concentrate on a single stimulus

atypical antipsychotics drugs that treat both the positive and negative symptoms of schizophrenia

auditory cortex region of the brain responsible for the higher-level processing of auditory signals

Auerbach plexus ganglionated plexus of the enteric nervous system situated between the longitudinal and circular muscle coats of the muscularis externa of the digestive tract; also known as the myenteric plexus

augmented leads system of three unipolar frontal plane leads in the standard clinical recording of an electrocardiogram (ECG); leads are oriented toward the right shoulder, left shoulder, and feet and are designated aVR, aVL, and aVF, respectively; ECG recordings in these leads are amplified or "augmented" relative to the standard bipolar frontal plane ECG leads

auto Greek for "self"

autocrine signaling form of signaling in which a cell secretes a chemical messenger that signals the same cell

autograft transplanted tissue grafted into a new position on the same person

autoimmunity failure of the body to recognize its own tissue as self, allowing attacks against its own cells and tissues

automaticity property of all cardiac cells in which they have the ability to generate their own action potentials

autonomic nervous system (ANS) part of the nervous system that regulates involuntary functions

autoreceptor receptor found on the presynaptic membrane that responds to the transmitter released by the neuron; usually involved in feedback regulation of transmitter synthesis or release

autoregulation in the cardiovascular system, the ability of an organ to maintain near-normal blood flow in the face of changes in perfusion pressure

A wave venous pulse wave created by backflow into the superior vena cava following contraction of the right atrium; amplified with stenosis of the right atrioventricular valve

axial streaming tendency of blood cells and elements to compact into the center of a blood vessel, where flow velocity is highest, when blood flows through the vessel; results in the phenomenon of plasma skimming, whereby the cellular elements of blood are pushed away from the arterial wall, leaving the wall exposed to essentially cell-free plasma

axon hillock initial segment of an axon adjacent to the neuronal cell body; except in pseudounipolar cells, the region of the axon that initiates the action potential; also known as initial segment or trigger zone

axon terminal region of an axon most distal from the cell body and containing synaptic boutons that signal to the target cell

axoneme main core of a flagellum, consisting of two central microtubules surrounded by nine double microtubules

axons fibers that carry impulses away from the perikaryon of a nerve cell

axoplasmic transport molecular motor-driven mechanism to transport proteins, lipids, synaptic vesicles, and other organelles from the cell body to the axon and its terminals; also used to transport lysosomes and trophic factors from the axon terminal to the cell body

band cell cell undergoing granulopoiesis to become a mature granulocyte

barometric pressure atmospheric pressure that surrounds us; at sea level, the barometric pressure is 760 mm Hg

baroreceptor stretch receptor sensitive to blood pressure and to the rate of change of blood pressure

baroreceptors the name given to neural sensors in the carotid sinus and aortic arch that are activated by stretch and thereby secondarily activated by an increase in arterial pressure. The term is also applied to similar neurosensors in the atria, pulmonary arteries, and atriavenojunction that respond to stretch secondary to a change in blood volume (sometimes called “low-pressure receptors”).

baroreceptor reflex broad term used to describe the marshaling of the autonomic nervous system to the heart, arteries, veins, adrenal medulla, and kidney (renin release) in order to counteract changes in arterial pressure; also sometimes called buffer reflex in that it prevents large deviations in arterial blood pressure brought about by moment-to-moment changes in the internal or external environment of the body

Barr body condensed mass of chromatin in female cells resulting from inactivation of one X chromosome

Barrett esophagus precancerous metaplasia associated with abnormal exposure of the esophageal mucosa to reflux of gastric contents

Bartter syndrome rare, inherited condition of the thick ascending limb of the kidney thought to be caused by a defect in the kidney’s ability to reabsorb sodium, causing a rise in aldosterone and, consequently,

potassium wasting and hypokalemic alkalosis

basal forebrain nuclei subcortical groups of cholinergic neurons located at the base of the forebrain that are involved in cognition

basal ganglia subcortical groups of neurons involved in motor control

basal metabolic rate (BMR) oxygen consumption of the body measured under resting conditions

base substance that can bind or accept a hydrogen ion

basement membrane second layer of the glomerular membrane of the kidney, consisting of a meshwork of fine fibrils embedded in a gellike matrix

basic metabolic panel (BMP) group of blood chemistry tests that includes the analysis of glucose, Ca^{2+}, Na^{+}, K^{+}, CO_2 (or HCO_3^{-}), Cl^{-}, blood urea nitrogen, and creatinine

basilar membrane vibrating membrane in the cochlea along which different frequencies of sound are detected

basolateral that side of a cell or plasma membrane facing the blood supply

basolateral membrane the surface of the plasma membrane of a polarized cell that forms its basal and lateral surfaces, it faces outwards towards the interstitium and away from the lumen

basophil granulocyte of the myeloid series that plays a role in inflammation and immediate allergic reactions

B cell type of lymphocyte with immunoglobulin on the cell membrane surface

B-cell receptor (BCR) antigen recognition molecule of B cells

Becker muscular dystrophy (BMD) inherited disorder that involves slowly worsening muscle weakness of the legs and pelvis; less common than Duchenne muscular dystrophy, affecting 3 to 6 out of every 100,000 males

benign paroxysmal positional vertigo (BPPV) severe vertigo, with incidence increasing with age; thought to be a result of the presence of canaliths, debris in the lumen of one of the semicircular canals

benzodiazepines drugs used to treat anxiety that act at γ-aminobutyric acid receptors

beriberi disorder of the nervous system and heart characterized by anorexia caused by a deficiency in thiamine

Bernoulli principle principle derived from the fact that total energy in a system cannot be created or destroyed but only transferred between different forms. In the cardiovascular system, it is the principle that describes the transfer of energy between kinetic (from flow velocity) and potential (from lateral pressure) energy. The principle predicts that as the velocity of flow in a fluid in a tube increases, the lateral pressure on the wall of the tube decreases

beta cells see β cell

beta waves electroencephalogram wave pattern with a rhythm ranging from 13 to 30 Hz, observed when the person is awake but relaxed with the eyes open

biguanides class of drugs used in the treatment of type 2 diabetes that lower glucose via effects on peripheral tissues, primarily the liver

bile acids one of the major components of bile, they are formed in the liver from cholesterol. There are

two types of bile acid: primary and secondary

bile salts cholesterol derivatives that play an important role in the intestinal absorption of lipids. They are water soluble and are essentially detergents. They are polar molecules that penetrate cell membranes poorly, an important property because it ensures their minimal absorption of fat

bile salt–sodium symport mechanism of bile acid secretion and bile flow that involves hepatocyte uptake of free and conjugated bile salts and is calcium dependent and calcium mediated. Bile salts serve the important function of absorbing fat

bilirubin major pigment present in bile; an orange compound that is an end product of hemoglobin degradation in the monocyte–macrophage system in the spleen, bone marrow, and liver

biliverdin green metabolite product of hemoglobin catabolism

biological activity unit quantitated amount of a hormone defined as an amount sufficient to produce a response of specified magnitude under a defined set of conditions

biologic clock circadian pacemaker located in the hypothalamus that regulates sleep and wakefulness and metabolic pathways

biotin coenzyme for carboxylase, transcarboxylase, and decarboxylase enzymes, which play an important role in the metabolism of lipids, glucose, and amino acids

bipolar cell as part of the retina, these cells exist between photoreceptors (rod cells and cone cells) and ganglion cells and act, directly or indirectly, to transmit signals from the photoreceptors to the ganglion cells

bipolar disorder psychiatric mood disorder in which periods of profound depression are followed by periods of mania, in a cyclic pattern; formerly known as manic–depressive disorder

blastocyst stage in embryonic development after the morula stage that consists of an inner cell mass, an outer trophoblast layer, and a blastocele

blastomeres cells produced by mitotic division of a zygote

bleeding time medical test of hemostasis

bloating sensation of abdominal distention that may or may not be visible

blood indices indices including mean cell (corpuscular) hemoglobin concentration, mean cell (corpuscular) hemoglobin, mean cell (corpuscular) volume, and blood oxygen-carrying capacity

blood lipid profile blood tests including total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), LDL/HDL ratio, and total triglycerides

blood smear spread of a blood drop for microscopic analysis

blood–brain barrier system of anatomical and transport barriers that controls the entry and rates of transport of substances into the brain extracellular space from the capillary blood

blood–gas interface interface between the atmosphere and blood, comprising the alveolar–capillary membrane; the site for gas exchange in the lung

blood–placental barrier barrier that regulates the transmission of substances from the maternal circulation to the fetus

body mass index (BMI) number, derived by using height and weight measurements, that gives a general

indication of whether weight falls within a healthy range

body plethysmograph airtight box in which patient sits to measure the functional residual capacity and total lung capacity of the lungs; also called pulmonary plethysmograph and body box

Bohr effect rightward shift of the oxygen equilibrium curve resulting from a rise in blood carbon dioxide and hydrogen ions

bone conduction means of hearing in which sound vibrations are carried to the inner ear by the bones of the skull

bone morphogenetic proteins (BMPs) growth factors found to induce the differentiation of mesenchymal cells toward osteoblasts as well as orchestrating tissue architecture throughout the body

bone remodeling turnover of bone mineral and changes in bone structure from daily flux of calcium and phosphate into and out of bone; generally occurs along most of the outer surface of the bone, making it either thinner or thicker, as required

botulinum toxin toxin produced by the bacterium Clostridium botulinum, which, in small concentrations, prevents presynaptic transmitter release at the myoneural junction

bouton the specialized axonal nerve ending from which neurotransmitters are released

Boyle law gas law that states that at a constant temperature, the pressure of a gas varies inversely with gas volume

bradykinin nonapeptide hormone that causes a slowly developing contraction of intestinal smooth muscle, vasodilation, and increased renal sodium excretion

brain natriuretic peptide (BNP) peptide hormone produced in the brain and cardiac ventricles that increases renal sodium excretion

brainstem region of the central nervous system between the spinal cord and diencephalon comprising the midbrain, pons, and medulla

brain–gut axis bidirectional nervous connections between the brain (central nervous system [CNS]) and gut that serve various physiologic functions; visceral afferent fibers project to somatotypic, emotional, and cognitive centers of the CNS, producing many interpretations to the stimuli based on prior learning and one's cognitive and emotional state; in turn, the CNS can inhibit or facilitate afferent nociceptive signals, motility, secretory function, or inflammation

breast cancer resistance protein (BRCP) member of the ABC transporter family of multidrug resistance proteins

Broca area area of the frontal lobe of the brain involved in motor control of speech, usually on the left hemisphere

bronchi bifurcation of the airway or the two primary divisions of the trachea that lead respectively into the right and the left lung

bronchial circulation circulation that supplies oxygenated blood to the conducting zone (i.e., the first 17 generations of the lung airways), which originates from the descending aorta and drains into the pulmonary vein

bronchioles small, thin airways that lack cartilage and are subjected to lung pressures; they are branches of the bronchi and terminate by entering the circular sacs called alveoli; also called bronchioli

bronchioli see bronchioles

bronchitis inflammation of the bronchi

brown adipose tissue one of the two types of adipose tissue (the other being white adipose tissue) that are present in many newborn or hibernating mammals; in contrast to white adipocytes (fat cells), which contain a single, large fat vacuole, brown adipocytes contain several smaller vacuoles, a much higher number of mitochondria, and more capillaries because it has a greater need for oxygen than most tissues; also called brown fat

buffer agent that minimizes the change in pH produced when an acid or base is added

buffy coat fraction of an anticoagulated blood sample after centrifugation, containing most of the white blood cells and platelets

bulimia a behavioral disorder involving distortion of body image and an obsessive desire to lose weight, in which bouts of extreme overeating are followed by depression and self-induced vomiting, purging, or fasting

bundle of His specialized conduction tissue that receives impulses from the atrioventricular node. It branches into right and left structures, which in turn give rise to the Purkinje fiber system

C wave venous pulse wave resulting from bulging of the right atrioventricular valve into the superior vena cava during systole followed by descent of the heart. It is amplified when the valve is incompetent (will not close)

Ca2+-binding protein, calbindin D (CaBP) protein that binds with calcium in the duodenum and jejunum that aids in the absorption of calcium

calcitonin (CT) hormone secreted by the thyroid that lowers blood calcium; also known as thyrocalcitonin

calcium pump enzyme that uses the energy generated by the hydrolysis of adenosine triphosphate to move calcium ions out of the cytoplasm or, in the case of muscle cells, from the cytoplasm to the sarcoplasmic reticulum; also known as Ca2+ ATPase

calcium release channel membrane channel in the sarcoplasmic reticulum through which calcium ions exit into the myofilament space or cytoplasm

calcium sparks small localized releases of calcium intracellularly following the activation of one coupled voltage-gated calcium channel:sarcoplasmic reticular–calcium release channel pair

calcium-induced calcium release (CICR) release of calcium from the sarcoplasmic reticulum–calcium release channel in response to a calcium entry signal through the plasma membrane voltage-gated calcium channel

calmodulin (CaM) small calcium-binding protein that confers calcium sensitivity to an enzyme by binding to it and makes its activity subject to calcium control; for example, calmodulin complexed with calcium binds to myosin light-chain kinase to promote its activation

calor heat associated with acute inflammation

cAMP-dependent protein kinase enzyme whose activity (such as regulation of glycogen, sugar, and lipid metabolism) is dependent on cyclic adenosine monophosphate; also known as protein kinase A

canaliculi tiny cytoplasmic connections between osteocytes, where much of calcium homeostasis takes

place

canaliths debris in the lumen of one of the semicircular canals often causing vertigo

cancer immunotherapy therapeutic use of the body's immune system to fight cancer

capacitance two conductors separated by an insulator with the ability to store an electrical charge. The biologic capacitor is the lipid bilayer of the plasma membrane, which separates two conductive regions, the extracellular and intracellular fluids

capacitation maturation of sperm in the female genital tract, which involves a loss of surface glycoprotein, a loss of lipid, and an increase in motility

capillaries smallest elements of the vascular system, composed of a single layer of endothelial cells. They are the primary site of transport between the bloodstream and the extracellular fluid surrounding all tissues. Capillaries can be joined tightly or exist with intermittent openings in their walls, depending on the organ from which they come

capillary distention dilation of a bed of highly compliant small pulmonary arterioles with increased perfusion pressure

capillary filtration coefficient (CFC) constant relating Starling forces to movement of water across the capillaries. It is a measure of how much water can flow per unit of time per net positive pressure moving fluid out of the capillaries

capillary recruitment opening of a bed of pulmonary capillaries with increased perfusion pressure

carbamino proteins proteins that bind with carbon dioxide

carbaminohemoglobin compound of hemoglobin and carbon dioxide, which is one of the forms in which carbon dioxide is transported by the blood

carbon dioxide equilibrium curve curve that reflects the relationship between carbon dioxide content and partial pressure in the blood

carbonic anhydrase (CA) enzyme that catalyzes the reversible reaction $CO2 + H2O \Rightarrow H2CO3$ or, more correctly, $CO2 + OH^- \Rightarrow HCO3^-$

carboxyhemoglobin (Hbco) carbon monoxide bound to hemoglobin

carboxypeptidase A exopeptidase pancreatic protease found in pancreatic juice that is specific in its action to attack polypeptides with a neutral aliphatic or aromatic carboxyl terminal to produce the final products of protein digestion, amino acids, and small peptides

carboxypeptidase B exopeptidase pancreatic protease found in pancreatic juice that is specific in its action to attack polypeptides with a basic carboxyl terminal to produce the final products of protein digestion, amino acids, and small peptides

carboxypolypeptidase pancreatic enzyme that converts peptides into amino acid

cardia one of four stomach sections, where the esophageal contents are emptied

cardiac function curve relationship depicting how cardiac output varies as a function of central venous pressure

cardiac gland one of three main types of glands found in the mucosal lining of the stomach, specifically in a small area adjacent to the esophagus and lined by mucus-producing columnar cells that secrete mucous and bicarbonate ions that protect the stomach from the acid in the lumen

cardiac glycoside drug used in the treatment of congestive heart failure and cardiac arrhythmia; see also digoxin

cardiac index cardiac output normalized for body surface area

cardiac muscle striated muscle tissue that constitutes the contractile pumping elements of the heart in the form of the right and left atria and ventricles. It is an excitable tissue that can contract and generate force when activated intrinsically by an initiating action potential from the SA node or, in abnormal conditions, from any other myocardial cell. It does not require nerves for activation, but its contraction is modified by both branches of the autonomic nervous system. Histologically, it is a functional syncytium whereby all cardiac muscle cells are connected to one another electrically unlike the motor unit construction of skeletal muscle.

cardiac output (CO) total flow output of the heart, often expressed as L/min or mL/min. It is typically between 4 and 5 L/min in healthy adults. It can also be thought of as the sum of all the individual organ blood flows in the body

cardiac tamponade pericardial constriction of the ventricles resulting from bleeding beneath the pericardium. It reduces passive stretch of the ventricle during filling

cardiopulmonary baroreceptors receptors located on the right side of the circulation that sense changes in circulating blood volume or central blood volume through the effects of volume on the stretch of the receptors. They elicit mechanisms to stimulate salt and water loss whenever blood or central volume is too high; also known as “low pressure” or “volume” receptors

carotid bodies specialized innervated nodules located in the bifurcation of the internal and external carotid arteries that sense low Po2 and pH as well as high Pco2. They send impulses to the medullary area of the brain to elicit reflex activation of the sympathetic nervous system to increase blood pressure. They do not respond to low arterial pressure unless the pressure is low enough to affect oxygen delivery to the bodies (<80 mm Hg)

carotid sinus slight dilation of the common carotid artery at its bifurcation into external and internal carotids; it contains baroreceptors that, when stimulated, cause slowing of the heart, vasodilation, and a fall in blood pressure and is innervated primarily by the glossopharyngeal nerve

carotid sinus baroreceptors spray nerve endings in the wall of the carotid sinus that sense stretch, and therefore, serve as sensory receptors for changes in arterial pressure

carrier-mediated diffusion see passive transport

caspases family of cysteine–aspartic proteases involved in apoptosis, cell necrosis, and cell death

catalase enzyme that protects cells by catalyzing hydrogen peroxide

cataract increase in the opacity of the lens of the eye

catechol-O-methyltransferase (COMT) enzyme that degrades the catecholamines by methylating the 3-OH group on the catechol ring

cation ion or group of ions having a positive charge and characteristically moving toward the negative electrode in electrolysis

caudate nucleus one of the basal ganglia; receives input from the cerebral cortex

caveolae microdomain or lipid raft that contains the protein caveolin and forms an invagination of the plasma membrane

caveolin one of a family of integral membrane proteins present in lipid rafts (termed caveolae) and involved in receptor-independent endocytosis

CCK cholecystokinin; satiety signal produced by endocrine cells in the gut wall mediated via the vagus

CD cluster of differentiation; distinct plasma membrane molecules used as cell markers

celiac ganglion prevertebral sympathetic ganglion involved in gastrointestinal control

celiac sprue (gluten-sensitive enteropathy) common disease involving a primary lesion of the intestinal mucosa caused by the sensitivity of the small intestine to gluten that results in the malabsorption of all nutrients as a result of the shortening or a total loss of intestinal villi, which reduces the mucosal enzymes for nutrient digestion and the mucosal surface for absorption

α cell one of five types of cells found in the islets of Langerhans of the endocrine pancreas; this one produces the hormone glucagon

β cell one of five types of cells found in the islets of Langerhans of the endocrine pancreas; this one produces the hormones insulin and amylin

δ cell one of five types of cells found in the islets of Langerhans of the endocrine pancreas; this one produces the hormone somatostatin

ε cell one of five types of cells found in the islets of Langerhans of the endocrine pancreas; this one produces ghrelin

cell adhesion molecules plasma membrane glycoproteins that promote cell adhesion

cellular immunity immunity mediated by activated T cells

cellular respiration final stage of respiration in which food molecules are broken down in the cell, releasing carbon dioxide and oxygen

central autonomic network neurons and axon pathways in the central nervous system that control autonomic function

central blood volume theoretical volume of blood contained in the veins of the thoracic cavity. It is usually measured as pressure in the right atrium

central chemoreceptors chemosensitive neurons located adjacent to the dorsal and ventral respiratory group complex that respond to H+ of the surrounding interstitial fluid

central inspiratory activity (CIA) integrator group of cells in the medulla that activates inspiration

central integrative system brain area involved in the coordinated activities of human behavior

central nervous system (CNS) brain and the spinal cord

central pattern generator (CPG) group of nerve cells producing rhythmic action potentials important in movements

central sulcus a deep fissure on the lateral surface of the cerebral cortex that separates the frontal lobe from the parietal lobe

central venous pressure venous pressure in the right atrium. It is representative of the effect of changes in central blood volume

centroacinar cells cells lining the lumen of the acinus that modify the electrolyte composition of pancreatic secretion

cephalic phase one of three phases that stimulate acid secretion during the ingestion of a meal; involves the central nervous system and is induced by the simple process of smelling, chewing, swallowing, and the thought of food. The cephalic phase accounts for about 40% of total acid secretion

cerebellum brainstem structure important in movement coordination

cerebral cortex (1) sheet of neural tissue outermost to the cerebrum of the mammalian brain that plays a key role in memory, attention, perceptual awareness, thought, language, and consciousness; (2) the outer shell of the brain, containing the cell bodies of neurons

cerebral edema edema formation in the brain. It causes an increase in intracranial pressure that results in restriction of cerebral blood flow

cerebral peduncles pathway in the upper brainstem for corticospinal tract axons

cerebrocerebellum region of the cerebellar cortex that receives input from cerebral cortex, active in control of limb muscles

cervical mucus viscous substance on the surface of the cervix, made up of mucopolysaccharide and water

cervix narrow muscular canal that connects the vagina and the body (corpus) of the uterus

C-fiber endings unmyelinated nerve endings that are located adjacent to alveoli and small bronchioles, that are sensitive to stretch, and that play a protective role in the lung

cGMP-dependent protein kinase enzyme that requires cyclic guanosine monophosphate to phosphorylate potential target substrates, such as calcium pumps in the sarcoplasmic reticulum or sarcolemma, leading to reduced cytoplasmic levels of calcium and, in turn, muscle relaxation; also known as protein kinase G

Chagas disease neuropathic degeneration of autonomic neurons resulting from autoimmune attack in patients infected with the blood-borne parasite Trypanosoma cruzi

channel gating regulation of the opening or closing of ion channels by changes in transmembrane voltage, mechanosensitivity, or ligand binding

channelopathies diseases caused by dysfunction of ion channels

Charcot-Marie-Tooth disease (CMT) group of inherited disorders that affect the peripheral nerves, specifically, involving damage to the covering (myelin sheath) around nerve fibers (either destruction of the myelin sheath or erosion of the central [axon] portion of the nerve cell); nerves that stimulate movement (the motor nerves) are most severely affected, and the nerves in the legs are affected first and most severely

Charles law gas law that states that at a constant pressure, gas volume varies proportionately with temperature

chemical pH buffer mixture of a weak acid and its conjugate base (or a weak base and its conjugate acid)

chemical potential gradient created by different concentrations of an uncharged solute on opposite sides of a membrane

chemical synapse site of communication between a neuron and another neuron or other target cell mediated by the release of a chemical neurotransmitter

chemoattractants cytokines that attract white blood cells

chemokine cytokine that attracts and activates leukocytes

chemoreceptors neurosensitive endings that respond to changes in blood gases (oxygen, carbon dioxide, and pH)

chemosensitive nerve endings efferent arm of the chemoreflex that increases cardiac output and improved blood flow to the ischemic skeletal muscle

chenodeoxycholic acid primary bile acid

Cheyne-Stokes breathing abnormal breathing pattern characterized by periods of breathing with gradually increasing and decreasing tidal volume interspersed with periods of apnea

chief cells cells that reside in the oxyntic glands in the stomach and secrete pepsinogen

chloride bicarbonate exchanger exchange mechanism that allows the red blood cell to maintain electrical neutrality by exchanging Cl^- for HCO_3^- as it diffuses out of the cell

chloride shift movement of chloride ions into the red blood cell coupled with movement of HCO_3^- out to maintain electrical neutrality of the cell

cholangiocytes epithelial cells lining the bile duct

cholecystokinin (CCK) hormone produced by the small intestine that is responsible for gallbladder contraction as well as the secretion of enzyme-rich pancreatic juice

cholesterol sterol derived exclusively from animal fat

cholesterol ester hydrolase (CEH) substance that hydrolyzes the ester bond of esterified cholesterol to generate free cholesterol

cholesterol esterase pancreatic enzyme that hydrolyzes cholesterol ester

cholesterol esters single molecules of cholesterol esterified to single fatty acid molecules

cholesterol side-chain cleavage enzyme (CYP11A1) rate-limiting enzyme in steroidogenesis

cholic acid primary bile acid

choline acetyltransferase enzyme that catalyzes synthesis of acetylcholine from acetyl-CoA and choline

cholinergic neurons releasing acetylcholine as a neurotransmitter

cholinergic receptor receptors with which acetylcholine interacts

chondrocyte nondividing cartilage cell; occupies a lacuna within the cartilage matrix

chorion extraembryonic membrane that forms the fetal portion of the placenta

chorionic plate membrane forming the fetal portion of the placenta

chorionic villi finger-like projections of the chorion that contact maternal blood

choroid plexuses region of the ventricular cavities of the brain that forms the cerebrospinal fluid

choroidal neovascularization (CNV) creation of new blood vessels in the choroid layer of the eye; common symptom of age-related macular degeneration

chromaffin cells cells in the adrenal medulla that synthesize and release epinephrine

chromatid one strand of a chromosome

chromophore part of a molecule responsible for its color

chronic granulomatous disease caused by the lack of phagocytic NADPH oxidase and characterized by recurrent life-threatening bacterial and fungal infections

chronic kidney disease (CKD) slowly progressive disorder that results in an abnormal internal environment, and eventual loss of kidney function is typically a slowly progressive disorder that results in an abnormal internal environment

chronic myeloid leukemia (CML) cancer of the white blood cells characterized by increased and unregulated clonal proliferation of myeloid cells in the bone marrow; results from an inherited chromosomal abnormality that involves a reciprocal translocation or exchange of genetic material between chromosomes 9 and 22 and was the first malignancy to be linked to a genetic abnormality

chronic obstructive pulmonary disease (COPD) classification of lung diseases (e.g., asthma, bronchitis, and emphysema) that obstruct airflow out of the lung

chronotropic related to effects on heart rate

Chvostek sign spasm of the facial muscles elicited by tapping the facial nerve in the region of the parotid gland; seen in tetany

chylomicron remnants remains of chylomicron particles after being broken down during metabolism. These remnants can be rapidly cleared from circulation by the liver via chylomicron remnant receptors

chylomicrons least dense (<0.95 g/mL) of the four lipoprotein classes; produced by the small intestine; their production increases during ingestion of a fat-containing meal. Chylomicrons function in the transport of lipids to the bloodstream

chyme semifluid material produced by the gastric digestion of food that results partly from the conversion of large solid particles into smaller particles via the combined peristaltic movements of the stomach and contraction of the pyloric sphincter

chymotrypsin one of three endopeptidases present in pancreatic juice that attack peptide bonds with an aromatic carboxyl terminal

ciliary ganglion location of synapses between parasympathetic preganglionic and postganglionic neurons of the eye

cingulate gyrus area of the cerebral cortex involved in the limbic system

circadian rhythm roughly 24-hour cycle in organismal physiologic processes. Circadian rhythms are endogenously generated and modulated by external cues such as sunlight and temperature

circumventricular organs regions of the central nervous system that do not have a blood–brain barrier and thus can sense signals in the blood

cirrhosis chronic liver disease characterized by the replacement of normal liver tissue with fibrous tissue as a result of the transformation of stellate cells into collagen-secreting myofibroblasts. Stellate cells deposit collagen into the sinusoids, thereby leading to loss of functional hepatocytes

11-cis-retinal aldehyde form of vitamin A1 (retinal); chromophore that starts the process of photoisomerization of retinal for vision

clearance volume of plasma per unit time from which a substance is completely removed (cleared)

climbing fibers afferent axons from the inferior olive of the medulla to the cerebellum that synapse on Purkinje cells

clomiphene fertility drug that stimulates the production of one or more follicles and, therefore, increases the chances of pregnancy

clonal selection collection of specific lymphocytes grouped by stimulation or inhibition of growth (positive or negative selection)

clonus repetitive, self-sustaining muscle stretch reflexes

closure inability to absorb intact proteins as a result of the maturation of the gut

clot retraction phenomenon that may occur within minutes or hours after clot formation in which the clot draws together, pulling the torn edges of the vessel closer together and reducing residual bleeding and stabilizing the injury site; requires the action of platelets, which contain actin and myosin; reduces the size of the injured area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to start wound healing

coagulation cascade pair of pathways (intrinsic and extrinsic coagulation pathways) in which a series of reactions ultimately result in a stable fibrin clot

coagulation factors series of 13 proteins (I to XIII) synthesized in the liver that circulate in the plasma in an inactive state

coated pit specialized regions of the cell membrane composed of pits made of the protein clathrin

cochlea bony structure of the inner ear, containing the organ of Corti, which is the organized transducer of sound vibrations into nerve impulses

cochlear microphonic generator potential of the inner ear

cognitive science interdisciplinary study of how information (e.g., concerning perception, language, speech, reasoning, and emotion) is represented and transformed in the brain

cold diuresis increased urine production on exposure to cold as a result of peripheral vasoconstriction leading to a transient increase in central blood volume, and consequently, an increase in glomerular filtration rate

cold pressor response reflex increase in heart rate, cardiac output, vascular resistance, and mean arterial pressure following pain associated with sudden exposure, usually of a hand or extremity, to extreme cold. It results from simultaneous activation of the sympathetic nervous system and reduced activity of the parasympathetics to the heart

cold-induced vasodilation (CIVD) acute increase in peripheral blood flow observed during cold exposures

colipase peptide in pancreatic juice necessary for the normal digestion of fat by pancreatic lipase

collagenase enzyme that digests the connective tissue matrix

collateral ganglia collective name for the three prevertebral sympathetic ganglia of the abdominal cavity

collateral vessels vascular connections between adjacent arteries such that when one artery is obstructed, the area it normally supplies with blood is supplied through the collaterals by the neighboring artery

colloid thick, proteinaceous gel-like substance in the thyroid follicle

colloid osmotic pressure osmotic pressure resulting from proteins in water

colostrum thin, yellowish, milky fluid secreted by the mammary glands a few days before or after parturition

commissures bundles of axons that connect neurons in the two sides of the brain

compensated shock stage of shock in which normal mechanisms within the body designed to elevate blood pressure and restore plasma volume correct the shock without the need for external intervention

compensatory pause pause following an extrasystole, when the pause is long enough to compensate for the prematurity of the extrasystole; the short cycle ending with the extrasystole plus the pause following the extrasystole together equal two of the regular cycles

competitive binding assay assay in which a biologically specific binding agent competes for radioactively labeled or unlabeled compounds, used especially to measure the concentration of hormone receptors in a sample by introducing a radioactively labeled hormone

complement serum proteins that can be activated and may lead to cell lysis, formation of opsonins, and regulation of inflammation

complete atrioventricular block any condition in which no action potentials from the atria reach the ventricles. It usually arises from blockage at the level of the atrioventricular node and results in atria and ventricles that are paced at two different rates

complete blood count (CBC) blood tests including white blood cell count, red blood cell count, platelet count, hemoglobin, hematocrit, mean cell (corpuscular) volume, mean cell (corpuscular) hemoglobin, mean cell (corpuscular) hemoglobin concentration, and platelet indices; also known as full blood count (FBC)

complete metabolic panel (CMP) includes the tests of the basic metabolic panel (see also basic metabolic panel) and the following additional tests: albumin, total protein, alkaline phosphatase, alanine transaminase, aspartate transaminase, and bilirubin

complete proteins proteins that supply all of the essential amino acids in amounts sufficient to support normal growth and body maintenance, such as eggs, poultry, and fish

compliance (1) change in volume in a segment of blood vessel or vessels per unit of change in transmural pressure, or $\Delta V/\Delta P$; (2) capability of a region of the gut to adapt to an increased intraluminal volume

compression first step in process of encoding electrical signals to be sent to the central nervous system, involving increasing the density of a medium; opposite of rarefaction

concave lens lens that causes light rays to diverge

concentric contractions muscular contractions that permit the muscle to shorten, because the load on the muscle is less than the maximum tetanic tension the muscle is capable of generating

conductance (1) ease with which ions flow across the membrane through their channels; (2) property of a material that indicates its ability to conduct heat

conducting zone first 16 generations of airways (trachea down to the terminal bronchioles), with its own separate circulation (bronchial circulation). It has a major function of conducting air to the deeper parts of the lung

conduction transfer of energy through matter from particle to particle; the transfer and distribution of heat

energy from atom to atom within a substance

conduction velocity rate of impulse conduction in a peripheral nerve or its various component fibers, generally expressed in meters per second

conductive deafness hearing impairment due to sound vibrations being interrupted in the outer or middle ear and not reaching the inner ear and its nerve endings

cone cell cell in the retina responsible for color (photopic, chromatic) vision. There are separate cone cells for red, blue, and green wavelengths of light

congenital adrenal hyperplasia inherited condition that affects the adrenal glands; these glands are located on top of the kidneys and produce three types of hormones, called cortisol, aldosterone, and androgens; females with classical congenital adrenal hyperplasia are born with masculine-appearing external genitals but with female internal sex organs; males with classical congenital adrenal hyperplasia appear normal at birth; males and females with classical congenital adrenal hyperplasia are likely to have trouble retaining salt, a condition that can be life threatening

congenital nephrotic syndrome rare, inherited condition characterized by excessive filtration of plasma proteins due to a mutation of nephrin

connective tissue matrix complex ground substance between and among cells that provides mechanical integrity to a tissue; also called stroma

connexin four-pass transmembrane proteins that in a group of six form a hemichannel called a connexon

connexon assembly of six proteins called connexins that forms a bridge called a gap junction between the cytoplasms of two adjacent cells

constitutive exocytosis form of exocytosis in which the vesicles are continuously filled and released into the extracellular fluid at a constant rate

continuous ambulatory peritoneal dialysis (CAPD) procedure in which peritoneal membrane, which lines the abdominal cavity, acts as a dialyzing membrane: about 1 to 2 L of a sterile glucose/salt solution are introduced into the abdominal cavity, and small molecules (e.g., K+ and urea) diffuse into the introduced solution, which is then drained and discarded; the procedure is usually done several times every day

contractile activity muscular activity of the gut wall, either of short duration (phasic contractions) or more sustained activity (tonic contractions)

contractility synonym for the inotropic state of the heart

convection transfer of heat by the actual movement of warmed (or cooled) matter. Convection is the transfer of heat energy in a gas or liquid by movement of currents

convex lens converging lens that brings light rays to a focus; it can form a real image

cornea outer, transparent, covering of the front of the eyeball

corneal reflex involuntary blinking of the eye elicited by stimulation of the cornea, bright light, or very loud sounds; also known as the blink reflex

cornification (keratinization) formation of a group of intermediate filaments in epithelial cells

coronary reserve amount of blood flow possible in the coronary circulation above resting values; sometimes used to refer to the dilating capacity of the coronary circulation beyond its resting value

corpora albicantia or corpus albicans connective tissue–filled structure; remnant of the regressed corpus luteum

corpora lutea or corpus luteum yellowish endocrine gland formed from the wall of an ovulated follicle

corpus callosum major axonal fiber bundle in the brain that connects the two hemispheres

corpus of the stomach main or central region of the stomach (body); one of four stomach sections

cortex outer portion of an organ, such as the kidney, as distinguished from the inner, or medullary, portion

cortical granules granules in the cortical vesicles at the edge of the ovum cytoplasm; penetration of sperm causes these granules to release proteases and inhibitors to prevent more sperm from penetrating the egg

cortical tissue part of the indifferent gonad of the embryo; will develop into the ovary

corticospinal tract axons arising from the cortical motor area

corticosteroid-binding globulin (CBG) glycoprotein produced by the liver; binds glucocorticoids and aldosterone in the blood

corticosteroid-binding protein (transcortin) binding protein for progesterone in the blood

corticosterone product of the adrenal cortex; regulates the body's response to fasting, injury, and stress

corticotroph cells located in the anterior pituitary that secrete adrenocorticotropic hormone

corticotropin-releasing hormone (CRH) polypeptide from the hypothalamus; stimulates secretion of adrenocorticotropic hormone

cortisol product of the adrenal cortex; regulates the body's response to fasting, injury, and stress

cotyledons aggregate groups of chorionic villi surrounded by maternal blood

coumarin common oral anticoagulant

countercurrent flowing in an opposite direction

countercurrent exchange passive exchange of solutes, water, or heat between two adjacent streams flowing in opposite directions

countercurrent heat exchange exchange of heat between two separated streams flowing in opposing directions, commonly used to minimize heat loss from the circulatory system by transferring heat from the arteries to the veins

countercurrent multiplication energy-demanding process that sets up a solute (osmotic) gradient along the length of two streams flowing in opposite directions

coupling reaction reaction that forms the iodothyronine structure from iodinated tyrosines

C-peptide peptide made when proinsulin is split into insulin and C-peptide on release from the pancreatic β cell into the blood

cranial nerves 12 pairs of nerves that originate directly from the brain

craniosacral regional locations of the parasympathetic preganglionic neurons

creatine phosphate pool cellular reservoir of high-energy phosphate that can rephosphorylate the

adenosine triphosphate consumed in muscle contraction

creatinine anhydride of creatine, being the end product of creatine metabolism, found in muscle and blood and excreted in the urine

creep slow and time-dependent elongation of a viscoelastic substance subjected to an external force

cremasteric muscle muscle with origin from the internal oblique and inguinal ligament, with insertion into the cremasteric fascia and pubic tubercle, with nerve supply from the genitofemoral nerve, and whose action raises the testicle; in male, the muscle envelops the spermatic cord and the testis; in female, it envelopes the round ligament of the uterus

Creutzfeldt-Jakob disease (CJD) degenerative brain disorder caused by death of nerve cells leading to progressive dementia, speech impairment, ataxia, and seizures; most common form of transmissible spongiform encephalopathy

critical micellar concentration certain point of bile salt concentration in the intestinal lumen at which bile salts aggregate to form micelles

crossbridge transient structure in muscle formed by the myosin heads projecting from thick filaments and attached to binding sites on the thin filament actin

crossbridge cycle series of adenosine triphosphate–consuming and work-producing reactions between actin and myosin that produces muscle contraction

cross-reactivity antibody that reacts with antigen that is similar to the one that induced its formation

crypts of Lieberkühn tubular glands located at the base of intestinal villi in the small intestine. Cells in the crypts of Lieberkühn secrete isotonic alkaline fluid

cumulus granulosa cells granulosa cells surrounding the oocyte in a graafian follicle

curare drug that is a competitive inhibitor of acetylcholine at the myoneural junction

Cushing reflex sympathetic nerve reflex initiated by an increase in intracranial pressure. It significantly elevates arterial pressure by causing severe, sometimes occlusive, constriction of arterioles in systemic organs. It is a defense mechanism that helps maintain cerebral blood flow in the face of elevated intracranial pressure by forcing blood vessels open

Cushing syndrome name given to the signs and symptoms associated with prolonged exposure to inappropriately elevated glucocorticoids; the disease can result from excess adrenocorticotropic hormone secretion from the pituitary (specifically called Cushing disease) stimulating cortisol production from the adrenal gland, or it can result from an adrenocortical adenoma secreting large amounts of cortisol

cyanosis blue coloration of the skin and mucous membranes due to the presence of excess deoxygenated hemoglobin in blood vessels near the skin surface; it is caused by low hemoglobin concentration (>5 g/dL) or from breathing low oxygen (hypoxia)

cyclic adenosine monophosphate (cAMP) second messenger important in many biologic processes; derived from adenosine triphosphate and used for intracellular signal transduction in many different organisms

cyclic guanosine monophosphate (cGMP) intracellular second messenger derived from guanine triphosphate that causes smooth muscle relaxation by lowering intracellular calcium

cyclooxygenase (COX) enzyme that catalyzes the conversion of arachidonic acid to prostaglandins

cystic fibrosis hereditary disease prevalent especially in Caucasian populations that appears usually in early childhood. It is inherited as an autosomal recessive monogenic trait, involves functional disorder of the exocrine glands, and is marked by faulty digestion due to a deficiency of pancreatic enzymes, by difficulty in breathing due to excess mucus secretion and accumulation in airways and by excessive loss of salt in the sweat

cystic fibrosis transmembrane conductance regulator (CFTCR) ion channel belonging to the adenosine triphosphate–binding cassette family of proteins, whose major function is to secrete chloride ions out of the cells, providing chloride in the lumen for the chloride–bicarbonate exchanger to work

cystinuria autosomal recessive disorder associated with a defect in reabsorptive transport of cystine and the dibasic amino acids ornithine, arginine, and lysine by the kidney. Cystinuria also affects the transporter in the small intestine

cytochrome P-450 complex of iron-containing proteins responsible for the oxidation–reduction reactions that transform a nonpolar xenobiotic compound to one that is more polar by introducing one or more polar groups onto the molecule. This particular complex contains the enzyme NADPH–cytochrome P-450 reductase, which is responsible for the reduction of the cytochrome P-450–drug complex being metabolized

cytokines group of protein-signaling compounds that, similar to hormones and neurotransmitters, are used extensively for intercellular communication

cytoskeleton internal meshwork of proteins adjacent and attached to the plasma membrane of the cell that maintains cell shape and other functions

cytosol liquid or matrix found within a living cell

cytotrophoblast cellular component of the trophoblast; gives rise to the chorion

Dalton law gas law that states that total barometric pressure is equal to the sum of the partial pressure of the individual gases

D cells endocrine cells in the antrum that produce somatostatin, a gastrointestinal hormone that inhibits the release of gastrin and, thus, gastric acid secretion

dead space volume air that is inhaled by the lungs but does not take part in gas exchange, because not all the air in each breath is able to be used for the gas exchange and represents the air in the conducting zone; about a third of every resting breath is exhaled exactly as it came into the body (in adults, it is usually in the range of 150 mL)

decerebrate rigidity describes the involuntary extension of the upper extremities in response to external stimuli: the head is arched back, the arms and elbows are extended by the sides, the legs are extended and rotated internally, and the patient is rigid, with the teeth clenched; these signs can be on just one or the other side of the body or on both sides, and it may be just in the arms and may be intermittent

decibel (dB) logarithmic unit that indicates the ratio of a physical quantity relative to a specified or implied reference level; widely known as a measure of sound pressure level

decidua site of implantation and the maternal contribution to the placenta

decidua basalis maternal part of the placenta

decidua capsularis part of the endometrium that grows over and covers the fetus

decidua parietalis pregnant endometrium not contained in the placenta

decidual reaction reaction that occurs in the endometrium and consists of dilation of blood vessels, increasing capillary permeability, edema formation, and increased proliferation of endometrial glandular and epithelial cells

decidualization hypertrophy of endometrial cells that contain large amounts of glycogen and lipid to ready the endometrium for implantation

declarative memory memory of events (episodic) or facts (semantic); also known as explicit memory

defensins antibacterial proteins that can enter phagosomes

degranulation release of granules from cells, such as mast cells and basophils

dehydration removal of water

dehydration reaction chemical reaction in which a hydrogen atom is removed from the end of one molecule that was originally a hydroxyl; the remaining O, from the original OH that only the H was taken from, is then bonded with the other monosaccharide; the H and OH are then released as a molecule of water (H2O)

dehydroalanine residue product of free radical reaction to produce an iodothyronine residue

7-dehydrocholesterol provitamin D; the presence of this compound in human skin enables humans to manufacture vitamin D3 from ultraviolet rays in the sunlight, via an intermediate isomer previtamin D3

dehydroepiandrosterone (DHEA) androgenic precursor for estrogen and testosterone synthesis produced by ovaries and testes

dehydroepiandrosterone sulfate (DHEAS) sulfate salt of dehydroepiandrosterone

deiodinase type 1 (D1) substance located in the liver, kidneys, and thyroid gland; catalyzes outer-ring deiodination

deiodinase type 2 (D2) substance believed to function primarily to maintain intracellular T3 in target tissues

deiodinase type 3 (D3) substance that catalyzes inner-ring deiodination reactions during degradation of thyroid hormones

delayed puberty condition in which physical signs of puberty have not presented by age 13 years in girls and 14 years in boys

delayed afterdepolarizations (DADs) occur late in phase 3 or during phase 4 of the ventricular action potential and are associated with increased intracellular calcium concentration within myocytes, which can thus depolarize the cell membrane to the threshold for an action potential

δ (delta) 4 pathway dominant steroidogenic pathway in granulosa cells and the corpus luteum

δ (delta) 5 pathway dominant steroidogenic pathway in theca cells

delta cells see δ cell

delta waves electroencephalogram wave pattern with a rhythm ranging from 0.5 to 4 Hz, observed when the person is in deepest sleep

delusions fixed false beliefs

dementia progressive loss of brain function, including memory, behavior, and cognition

denaturation structural change in macromolecules caused by extreme conditions, for example, protein denaturation by extreme heat

dendrites fibers that receive synaptic inputs and transmit electrical signals toward the perikaryon of a nerve cell

dendritic cell phagocyte; antigen-presenting cell of epithelia and blood

dendritic spines small membrane protrusions from dendrites that receive synaptic input

denervation hypersensitivity heightened reactivity of an organ to a neurotransmitter following denervation of the organ

dense bodies intracellular protein complexes at the margins of smooth muscle cells that serve as attachment points between intracellular actin and extracellular connective tissue

density mass per unit volume

dentate nucleus largest of the four deep cerebellar nuclei, responsible for the planning, initiation, and control of volitional movements; receives its afferents from the premotor cortex and the supplementary motor cortex, and its efferents project via the superior cerebellar peduncle through the red nucleus to the ventrolateral thalamus

deoxycholic acid secondary bile acid

11-deoxycorticosterone (DOC) mineralocorticoid made from progesterone by 21-hydroxylase

11-deoxycortisol immediate precursor for cortisol synthesis

deoxyhemoglobin hemoglobin that does not bind with oxygen

depolarize when the membrane potential becomes more positive (less negative)

depolarization change in electrical potential in the direction of a more positive potential inside cells; in excitable cells, depolarization to a threshold potential triggers an action potential

depolarizing blockers agents that interfere with neuromuscular transmission by causing the postsynaptic membrane to remain depolarized

desensitization process by which effector cells are rendered less reactive or nonreactive to a given stimulus

diabetes insipidus disorder characterized by excretion of a large volume of osmotically dilute urine, resulting from either deficient production or release of arginine vasopressin

diabetes mellitus disease in which plasma glucose control is defective because of insulin deficiency or decreased target cell response to insulin

diabetic ketoacidosis condition in which extremely high blood glucose levels, along with a severe lack of insulin, result in the breakdown of body fat for energy and an accumulation of ketones in the blood and urine

diabetic neuropathy family of nerve disorders caused by diabetes; also known as peripheral neuropathy

diabetogenic action effect of growth hormone to oppose the actions of insulin

diacylglycerol (DAG) intracellular second messenger generated by hydrolysis of phosphatidylinositol 4,5-bisphosphate

dialysis separation of smaller molecules from larger molecules in solution by diffusion of the small molecules through a selectively permeable membrane; two methods of dialysis are commonly used to treat patients with severe, irreversible ("end-stage") renal failure; see also continuous ambulatory peritoneal dialysis (CAPD) and hemodialysis

diapedesis movement of cells from blood to tissue during acute inflammation

diaphragm dome-shaped sheet of internal skeletal muscle that extends across the bottom of the rib cage and separates the thoracic cavity (heart, lungs, and ribs) from the abdominal cavity; it is the main muscle of breathing and is innervated by the phrenic nerves

diastole period of time in which the heart is in its relaxation phase

diastolic pressure blood pressure in the ventricle or arterial system during the relaxation of the heart, or diastole

diencephalon region of the central nervous system that includes the thalamus and hypothalamus

differential white blood cell count proportions of the different types of circulating white blood cells

diffuse esophageal spasm diagnosis of diffuse spasm is made when manometric recording of esophageal motility demonstrates that the act of swallowing results in simultaneous contractions all along the length of the smooth muscle region of the esophageal body

diffuse toxic goiter enlarged thyroid gland; secretes thyroid hormones at an accelerated rate

diffusion random movement of particles, such as ions and solutes in solution, that leads to mixing and elimination of concentration gradients

diffusion block abnormal increase in the diffusion distance across the alveolar–capillary membrane or to a decrease in the alveolar–capillary permeability leading to decrease in oxygen uptake by the lungs (hypoxemia); pulmonary edema is one of the major causes of a diffusion block and is characterized by a low Pao2, elevated Paco2, and a high A–aO2 gradient

diffusion capacity see lung diffusion capacity

diffusion limited condition in which the uptake of an alveolar gas is limited by the diffusion properties of the alveolar–capillary membrane; see also Fick's law

diffusion-limited transport transport of substances across the capillary in which the rate of diffusion is what limits the rate of transport

diffusive membrane transport see passive transport

digestive state gastrointestinal motor behavior (mixing/segmentation pattern) in effect when nutrients are present in the upper gut

digoxin binds to the extracellular aspect of the a-subunit of the Na+/K+ ATPase and decreases the transport function of the pump; often used to treat atrial fibrillation or atrial flutter; also known as digitalis

dihydropyridine receptors (DHRPs) voltage-sensitive protein molecules that respond to changes in the T-tubule membrane of skeletal muscle as an important step in the excitation–contraction coupling process

dihydrotestosterone (DHT) potent androgen derived from testosterone

1,25-dihydroxycholecalciferol substance that enhances calcium and phosphate absorption by the small intestine and mobilizes calcium and phosphate from bones; the active form of vitamin D; also known as 1,25-dihydroxycholecalciferol or calcitriol

diiodotyrosine (DIT) intermediate in the biosynthesis of thyroid hormone

diopter (D) measure of lens-converging power; the inverse of the focal length in meters

dimer chemical or biologic entity consisting of two structurally similar subunits that are joined by bonds, which can be strong or weak

dimerization (1) aggregation of two monomers of a protein (e.g., receptor), usually mediated by binding of a ligand; (2) chemical reaction in which two monomers combine to form a dimer

dipalmitoylphosphatidylcholine (DPPC) surface-reducing material lining the alveoli that is responsible for reducing surface tension and increasing the distensibility of the lung

diplopia double vision, caused by partial failure of the convergence mechanism driven by the extraocular muscles

dipole difference in the electrical polarity between two physical points

direct calorimetry measurement of the metabolic rate of an organism by measuring the amount of heat energy released as heat over a given period

direct pathway basal ganglia pathway for axons passing from the caudate directly to the globus pallidus internus

discomfort (upper abdomen) subjective, unpleasant sensation or feeling that is not interpreted as pain according to the patient and that, if fully assessed, can include nausea, fullness, bloating, and early satiety

disinhibitory motor disease disordered gastrointestinal motility resulting from neuropathic degeneration of enteric inhibitory motor neurons

disorders of sex development (DSD) congenital conditions in which chromosomal, gonadal, or genital sex is not coincident

disseminated intravascular coagulation (DIC) pathologic activation of blood-clotting mechanisms, leading to the formation of small blood clots inside the blood vessels throughout the body, thereby disrupting normal coagulation and causing abnormal bleeding and possible organ malfunction

distal nephron distal convoluted tubule, connecting tubule, and collecting duct, considered as one functional entity

distending pressure pressure required to stretch material (e.g., the pressure required to inflate the lung)

distensibility measure of the force required to stretch material

diuresis increased urine flow rate

diurnal rhythm 24-hour cycle of activity entrained to the day–night cycle

divergence tendency for spread of sympathetic responses from a lesser number of preganglionic neurons to a greater number of postganglionic ones

diving reflex reflex that occurs when the face is submerged under water, which is found in all mammals (including humans, although less pronounced). The reflex puts the body into an oxygen-saving mode to maximize the time that can be spent underwater. The reflex includes bradycardia, peripheral vasoconstriction, and a decreased metabolic rate

diving response cardiovascular reflex to immersion of the body or even the face underwater. It is characterized by intense slowing of heart rate and sympathetic peripheral vasoconstriction. It is a means

of preserving oxygen to the brain and heart when submerged underwater

D1-like receptor dopamine receptor coupled to stimulatory G proteins, which activate adenylyl cyclase

D2-like receptor dopamine receptor coupled to inhibitory G proteins, which inhibit adenylyl cyclase

DNA vaccine gene that expresses, when incorporated in human cells, immunogenic protein

docosahexaenoic acid omega-3 fatty acid found abundantly in seafood; is present in parts of the brain and the retina and is essential for the normal development of vision in newborns

dolor pain associated with acute inflammation

dominant follicle one follicle from the cohort of developing follicles that will ovulate

dopamine (DA) catecholamine used as a neurotransmitter; important in motor function and limbic pathways; also inhibits the synthesis and secretion of prolactin

dopaminergic neurons relating to nerve cells or fibers that employ dopamine as their neurotransmitter

Doppler ultrasound ultrasound imaging technique that works similar to radar speed detection devices; gives an ultrasound image of the heart but is used primarily for detecting flow velocity abnormalities through the heart valves and in the aorta

dorsal motor nuclei region of the medulla where parasympathetic neurons involved in cardiac, respiratory, and gastrointestinal functions are located

dorsal motor nucleus of vagus location in the medulla oblongata (brainstem) containing cell bodies of vagal efferent (motor) fibers to the digestive tract, excluding parts of the esophagus

dorsal respiratory group (DRG) cluster of neuronal cells located in the dorsal portion of the medulla that is active during inspiration

dorsal vagal complex combined structures of the dorsal vagal motor nucleus, nucleus tractus solitarius, and area postrema in the medulla oblongata (brainstem)

down-regulation process by which a cell decreases the quantity of a cellular component, such as a protein, in response to an external variable

drusen localized deposits of cellular debris whose accumulation distorts the shape of the retina in age-related macular degeneration

Duchenne muscular dystrophy (DMD) rapidly worsening muscle weakness caused by a defective gene for dystrophin (a protein in the muscles); although inherited, it also occurs in those without a family history of the disease

ductus arteriosus fetal blood vessel connection between the pulmonary artery and aorta that shunts blood ejected from the pulmonary artery to the aorta

ductus venosus fetal blood vessel connection between the umbilical veins and the inferior vena cava that shunts oxygenated blood from the veins into the vena cava while bypassing the liver

dumping syndrome syndrome that occurs after a meal due to rapid delivery of gastric chyme into the duodenum, characterized by flushing, sweating, dizziness, weakness, and vasomotor collapse, resulting from rapid passage of large amounts of food into the small intestine, with an osmotic effect removing fluid from plasma and causing hypovolemia

dynamic exercise performance of some activity that involves muscle contraction and joint flexion or

extension; in contrast to static exercise, in which joint movement is absent

dynein microtubule-associated protein involved in retrograde axonal transport of organelles and vesicles (from the plus to the minus ends of the microtubules) via the hydrolysis of adenosine triphosphate

dysphagia difficulty swallowing; sensation of abnormal bolus transit through the esophageal body

dyspnea shortness of breath; a perceived difficulty breathing or pain on breathing

dystrophin filamentous muscle protein that lies just inside the sarcolemma and participates in the transfer of force from the contractile system to the outside of the cells via integrins

early afterdepolarizations (EADs) depolarizations of the muscle cells that occur late in phase 2 or early in phase 3 of the ventricular action potential and are more likely to be induced by factors that prolong the action potential duration, such that slow calcium channels have time to recover and, thus, fire an additional low-amplitude action potential

early satiety feeling that the stomach is overfilled soon after starting to eat; the sensation is out of proportion to the size of the meal being eaten, so that the meal cannot be finished

eccentric contraction contraction characterized by involving the lengthening of muscle fibers while they are maintaining contractile tension; related movements frequently involve deceleration and high passive tension

eccrine ordinary, or simple, sweat gland of the merocrine type. These unbranched, coiled, tubular glands are distributed over almost all of the body surface and promote cooling by evaporation of their secretion

echinocyte spiked erythrocyte; also known as Burr cell

echocardiography general classification of noninvasive techniques by using ultrasound echoes to image the heart wall, its chambers, and movement of the valves during the cardiac cycle

2D echocardiography (1) two-dimensional echocardiography; used to examine ventricular chambers and movement of valves in the beating heart in situ; (2) type of ultrasound cross-sectional image of the heart used to measure ventricular wall thickness, valve motion and abnormalities, and wall motion during the cardiac cycle; it is often used to estimate the ejection fraction of the left ventricle

ectopic foci portion of the myocardial muscle that fires its own action potentials, causing activation of the heart from an area other than the sinoatrial node

ectopic pregnancy implantation of an embryo outside of the uterus

edema clinically apparent increase in interstitial fluid volume

Edinger-Westphal nucleus nucleus region of cranial nerve III where parasympathetic neurons arise

effective arterial blood volume (EABV) degree of fullness of the arterial system, which determines the perfusion of the body's tissues

effector small molecule used to relay signals within a cell. Effectors bind to a protein and alter the activity of that protein

effector cell executing cell of immune responses; in adaptive immunity: plasma cells, T helper cells, and cytotoxic T cells

effector systems musculature, secretory epithelium, and blood–lymphatic vasculature in the digestive tract

efferent carrying away from

efferent nerve (efferents) nerve fibers carrying impulses away from the central nervous system that cause muscles to contract and glands to secrete (inhibitory efferent nerves)

efflux transfer of material from the interior to the exterior of a cell

eicosapentaenoic acid omega-3 fatty acid found in fish, essential for the normal development of vision in newborns

Einthoven triangle theoretical triangle in the frontal plane of the body created from the interconnected electrodes making up the standard bipolar electrocardiogram lead system

ejaculation abrupt discharge of fluid; the expulsion of seminal fluid from the urethra of the penis during orgasm

ejection fraction amount of blood ejected in one systole by the left ventricle expressed as a percentage of the left ventricular residual volume; it is used clinically to detect impaired performance of the left ventricle

elastase one of three endopeptidases present in pancreatic juice that attacks peptide bonds with a neutral aliphatic carboxyl terminal

elastic recoil degree to which stretched material returns to its unstretched position

elastic response proportionate and time-independent force response to the extension of a deformable body such as muscle

elasticity ability of a material when stretched to return to its unstretched position (e.g., a balloon). This property differs from plasticity (the capability of being stretched, but not returning to its unstretched position, e.g., putty)

electrical slow waves omnipresent form of electrical activity (rhythmic depolarization and repolarization) in gastrointestinal muscle cells

electrical synapse site of communication between neurons mediated by movement of ions from one cell to the other via gap junctions

electrical syncytium tissue (e.g., gastrointestinal and cardiac muscle) in which the cells are electrically coupled one to another at cell-to-cell appositions that do not include cytoplasmic continuity; accounts for three-dimensional spread of excitation in excitable tissues

electrochemical potential (gradient) combined effect of electrical and chemical gradients that determines the direction of movement of ions and charged solutes

electroencephalogram (EEG) recording of the electrical activity of the brain

electroencephalography measurement of the electrical activity of the brain

electrogastrography recording of gastric electrical activity from surface electrodes positioned on the abdominal wall

electrogenic system a system in which there is a net movement of charge

electrogenic transport membrane transport system that produces net movement of charge across the membrane, for example, H+ ATPase, Na+/glucose cotransport

electrolyte substance that is ionized in solution and thus becomes capable of conducting electricity

electromechanical coupling in gastrointestinal smooth muscle, depolarization of the membrane electrical potential that leads to the opening of voltage-gated calcium channels, followed by the elevation of cytosolic calcium, which, in turn, activates the contractile proteins

electroneutral system a system in which there is no net movement of charge

electroneutral transport membrane transport system that produces no net movement of charge across the membrane, for example, Na+/H+ exchange

electroneutrality principle that, in an electrolytic solution, the concentrations of all the ionic species are such that the solution as a whole is neutral

electroretinogram generator potential of the retina, recorded extracellularly and at some distance from its source

electrotonic conduction local spread of electrical activity within a group of cells by ionic current flows that do not involve action potential mechanisms; also known as passive conduction

electrotonic potential nonpropagated potential in a nerve or muscle membrane generated by the flow of ions across the membrane

electrotonically way in which electrical activity spreads within a group of cells by ionic current flows that do not involve action potential mechanisms

emboli blood clots that form in the bloodstream

embryoblast cluster of small centrally located cells within the blastocyst that will give rise to the fetus

emesis vomiting

emissivity ratio of energy radiated by a black body at the same temperature. It is a measure of a material's ability to absorb and radiate energy. A true black body would have $\varepsilon = 1$, whereas any real object would have $\varepsilon < 1$

emmetropia normal vision, free from refractive errors

emphysema chronic lung disorder that leads to abnormally high compliance as a result of distention and eventual rupture of the alveoli with progressive loss of pulmonary elasticity; symptoms include shortness of breath with or without cough, which may lead to impaired heart action

end-tidal volume volume of air measured at the end of a tidal volume

end-diastolic volume volume within the ventricle at the end of diastole

endocannabinoids endogenous ligands for the receptors that mediate the effects of the psychoactive component of marijuana, Δ9-tetrahydrocannabinol

endocrine glands glands that secrete their products (hormones) directly into the bloodstream (ductless glands) or release hormones (paracrines) that affect only target cells nearby the release site

endocrine pancreas portion of the pancreas that secretes hormones such as insulin, glucagon, and somatostatin into the bloodstream

endocrinology branch of physiology concerned with the description and characterization of processes involved in the regulation and integration of cells and organ systems by specialized chemical substances called hormones

endocytosis invagination of the plasma membrane to pinch off and internalize substances that are

otherwise unable to cross the plasma membrane. Some endocytic mechanisms involve binding of extracellular solute to a specific membrane receptor protein (receptor-mediated endocytosis)

endogenous originating or produced within the body

endogenous creatinine clearance renal clearance of endogenous (i.e., not administered) creatinine; used to estimate the glomerular filtration rate

endolymph fluid that fills the scala media of the cochlea and the semicircular canals of the vestibular apparatus

endometrial cycle life cycle of the endometrial lining of the uterus; consists of four parts

endometrial veins veins that drain the maternal blood–filled sinus of the placenta

endometrium inner membrane lining the lumen of the uterus

endopeptidases one of two classifications of pancreatic proteases; include trypsin, chymotrypsin, and elastase; are present in pancreatic juice; and hydrolyze certain internal peptide bonds of proteins or polypeptides to release the smaller peptides

endorphins endogenous opioid neurotransmitters that can produce a feeling of well-being

endothelial-derived relaxing factor (EDRF) a compound produced and released by the endothelium to promote smooth muscle relaxation. The best-characterized is nitric oxide. Some sources equate EDRF and nitric oxide.

endothelial growth factor (EGF) cytokine involved in wound healing

endothelial vesicles pinocytotic vesicles used to transport substances that are too large to cross the capillary membrane or pores

endothelin extremely potent vasoconstrictor produced by the endothelium, especially in cardiovascular disease states; the most potent vasoconstrictor yet found

endothelium thin epithelial lining of all blood vessels and the inner surface of the chambers of the heart. It contains anticoagulant factors such as heparin and forms a nonthrombotic surface in arteries. It is also a barrier between the bloodstream and the inner vascular tissue. Endothelium is the prime source of nitric oxide and PGI2, which have vasodilator, antithrombotic, and antiatherogenic properties as well as antimitogenic properties on the underlying vascular smooth muscle. The endothelium also produces growth factors that are thought to be responsible for angiogenesis and intimal repair in blood vessels. The endothelium and its ability to produce nitric oxide are impaired in all known forms of cardiovascular disease, especially those associated with hypertension, atherosclerosis, and diabetes

endothelium-derived relaxing factor (EDRF) original name for endothelial nitric oxide

endotoxin toxins of gram-negative bacteria associated with lipopolysaccharide

endplate current postsynaptic ionic current at the myoneural junction whose local flow excites adjacent areas of muscle membrane to produce action potentials

endplate membrane specialized postsynaptic membrane at the myoneural junction, containing the acetylcholine receptors

endplate potential proportionate depolarization of the endplate membrane caused by the permeability to Na+ and K+ ions that results from the binding of acetylcholine

end-product inhibition end product of a biosynthetic pathway, which inhibits the enzymes that catalyze

the first step in the pathway

end-systolic pressure–volume relationship considered the ideal measure of the inotropic state of the heart, this straight line sets the limit of contraction for the whole heart as it generates pressure and reduces volume during ejection that is formed from all the points of volume and pressure at the end of systole in the whole heart generated from multiple different preloaded and afterloaded contractions of the whole heart. The position, or slope, of this line is independent of the loading conditions on the myocardium but is shifted by positive or negative inotropic influences on the heart

end-systolic volume volume of blood in the ventricle (usually as concerns the left ventricle) and the end of systole; although it is sometimes called the residual volume, it actually best represents the volume in the ventricle at the end of ventricular ejection rather than the start of diastole

enkephalins endogenous ligand that binds to opioid receptors to regulate nociception

enteric mini-brain term used in reference to the brainlike functions of the enteric nervous system

enteric nervous system division of the autonomic nervous system situated within the walls of the digestives tract and involved in independent integrative neural control of digestive functions

enteroceptors sensory receptors classified by "vantage point" in the body; detect stimuli from inside the body

enterochromaffin cells enteroendocrine cells located in the mucosal epithelium of the digestive and respiratory tracts that secrete most of the body's serotonin; cells are stimulated by "brushing" of the mucosa to release 5-hydroxytryptamine as a paracrine signal to neurons in the enteric nervous system

enterochromaffin-like (ECL) cells special neuroendocrine cells located mostly in the acid-secreting regions of the stomach that are believed to be the source of histamine

enterocytes specialized epithelial cells in the small intestine that take up the digested products of nutrients for transport into either the portal circulation or the lymphatic system

enteroendocrine cells cells found throughout the digestive tract that produce hormones and paracrine signals to enteric neurons and sensory neurons

enterogastrone hormone released by the small intestine that inhibits gastric motility and secretion

enterohepatic circulation recycling of bile salts between the small intestine and the liver

entero-oxyntin hormone present in intestinal endocrine cells whose release is stimulated by the distention of the intestine; it stimulates acid secretion

enteropeptidase enzyme found on the luminal surface of enterocytes that converts trypsinogen to trypsin when pancreatic juice enters the duodenum; also known as enterokinase

enzyme-linked immunosorbent assay (ELISA) biochemical technique used mainly in immunology to detect the presence of an antibody or an antigen in a sample. It uses two antibodies, one of which is specific to the antigen and the other of which is coupled to an enzyme. This second antibody gives the assay its "enzyme-linked" name and will cause a chromogenic or fluorogenic substrate to produce a signal

eosin orange dye used in polychrome stains

eosinophil granulocyte of the myeloid series involved in allergic reactions and defense against parasites

ependymal cells glial cells that help form the blood–CSF barrier

epidermal growth factor (EGF) substance in saliva that stimulates gastric mucosal growth and the growth of epithelial cells in the skin and other organs

epididymis tiny tube where sperm collect after leaving the testis

epigenetics a regulatory mechanism in which genes can be switched off and on without altering their genetic code

epigenome the outer structure of the gene that acts as a switch to turn the cell's DNA off and on

epilepsy neurologic disorder of the brain characterized by repeated spontaneous discharges of electrical activity (seizures)

epinephrine (EPI) catecholamine neurotransmitter released by the adrenal medulla

epinephrine reversal phenomenon whereby the vasoconstrictive actions of epinephrine are blocked resulting in its vasodilatory actions being manifested

epineurium the fibrous coat enveloping PNS axons to form nerves

epiphyseal plate cartilage (hyaline) region (between the epiphysis and diaphysis) in bone that allows lengthwise growth of a bone. In puberty, rapid growth in this region leads to height increase, which then ossifies in the adult

episodic memory memory of events

epithelial sodium channel (ENaC) channel through which Na+ enters into the collecting duct cell during K+ regulation

epitope part of the molecule that is recognized by the immune system

epsilon cells see ε cell

equal pressure point (EPP) point in the airway at which the pressure inside equals the pressure outside of the airway

equilibrioception physiologic sense of balance

equilibrium stable situation that occurs when the internal processes of a system are in balance and no overall change in the system occurs

equilibrium potential concentration at which there is a balance between the forces due to the concentration gradient for the ion and the electrical gradient across the membrane

equivalent in chemistry, a unit of measure that contains the Avogadro number (or a mole) of positive or negative charges, each the quantity of electricity possessed by a proton or electron

erectile dysfunction (ED) inability to attain and/or maintain an erection suitable for penetration

erythroblast stem cell committed to differentiate into erythrocytes

erythrocyte see red blood cell

erythrocyte sedimentation rate (ESR) test to measure the settling of erythrocytes per time

erythromelalgia rare neurovascular peripheral pain disorder in which blood vessels, usually in the lower extremities, are episodically blocked and then become hyperemic and inflamed; there is severe burning pain (in the small fiber sensory nerves) and skin redness

erythropoiesis process by which red blood cells are produced in hematopoietic tissues

erythropoietin hormone produced by the kidney that stimulates the bone marrow to produce red blood cells (such as in hypoxia)

esophageal varices varicose veins occurring at the base of the esophagus that form as a compensatory mechanism to the increased resistance to (and, therefore, dramatically decreased) portal venous flow. Conditions at the base of the esophagus (including minimal connective tissue support and the associated negative intrathoracic pressure of the area) together with the increased demand on these vessels to support an increasing load of blood flow lead to a tendency for these varices to rupture, a condition leading to morbidity in 30% of occurrences

essential amino acids amino acids that cannot be synthesized by the liver and, therefore, supplied through dietary consumption. The essential amino acids include histidine, methionine, threonine, tryptophan, isoleucine, leucine, valine, phenylalanine, and lysine

essential fatty acids fatty acids that humans and other animals must ingest for normal cell function, because they cannot be made from other foods; the three essential fatty acids include linolenic acid, linoleic acid, and arachidonic acid

essential light chains small protein constituents of the myosin molecule that are necessary for its function (but not its regulation)

estradiol steroid with 18 carbons

estriol major estrogen produced by the placenta

estrogen steroid that promotes maturation of the female reproductive organs and secondary sexual characteristics

estrone estrogen secreted by the ovaries, placenta, and fat

eunuchoid sexually deficient person; especially one lacking in sexual differentiation and tending toward the intersexual state

eunuchoidism male hypogonadism; the state of being a eunuch (either because of lacking testicles or because they failed to develop)

euthyroid sick syndrome state of adaptation/dysregulation of feedback control with triiodothyronine and/or thyroxine at low levels but normal thyroid-stimulating hormone levels

excitable cells cells such as neurons and muscle with membranes capable of giving rise to action potentials and propagated impulses

excitation–contraction coupling series of steps that begins with the depolarization of a muscle cell membrane and the mechanical events of contraction

excitatory junction potentials (EJPs) neurally evoked depolarizations of the muscle membrane potential

excitatory neurotransmitters neurotransmitters that result in membrane depolarization

excitatory postsynaptic potentials (EPSPs) depolarization of the neuronal membrane at the postsynaptic side of a synapse as a result of ions flowing through channels that open when neurotransmitter released from the presynaptic terminal binds to its receptor

excretion elimination of a substance from the body in the urine or feces

excretory ducts part of the network of ducts in the salivary glands that are lined with columnar cells and

play a role in modifying the ionic composition of saliva

execution orchestration of complex sensorimotor sequences in a seamless path toward a goal

exercise performance of some activity that involves muscle contraction and joint flexion or extension, often to develop or maintain physical fitness and overall health

exertional heat injury syndrome occurring in association with strenuous exercise characterized by hyperthermia with exhaustion or collapse, which is accompanied by evidence of tissue and organ damage

exocrine glands glands that secrete their products (excluding hormones and other chemical messengers) into ducts leading directly into the external environment; contrast with endocrine glands

exocrine pancreas portion of the pancreas that secretes digestive enzymes and HCO_3^- into the intestinal lumen

exocytosis fusion of a secretory vesicle with the plasma membrane and expulsion of the vesicle contents into extracellular fluid

exopeptidases substance present in pancreatic secretion that could be a carboxypeptidase or an aminopeptidase, depending on whether it releases amino acid from the carboxyl end or the amino end of the peptides

expiratory reserve volume (ERV) maximum volume of air exhaled at the end of a tidal volume

expired minute ventilation ($\dot{V}_E$) volume of air expired from the lungs in 1 minute

extension movement that increases the angle between two moving parts of the body

extensors skeletal muscles whose action extends a limb or body part

external anal sphincter ring of skeletal muscle surrounding the anal canal that can be voluntarily contracted to postpone defecation

external intercostal muscles muscles located between the ribs that are involved in forced inspiration

exteroceptors sensory receptors classified by "vantage point" in the body; detect stimuli from outside the body

extra-alveolar vessels small pulmonary vessels that are not part of the blood vessels surrounding the alveoli

extracellular fluid (ECF) fluid outside of cells

extraction (E) or extraction ratio amount of a substance removed from the bloodstream from arterioles to venules by the capillaries

extrafusal muscle fibers population of muscle fibers that produce force during contraction

extramedullary hematopoiesis blood cell formation occurring outside bone medulla

extraocular muscles muscles within the orbit but outside of the eyeball, including the four rectus muscles (superior, inferior, medial, and lateral), two oblique muscles (superior and inferior), and the levator of the superior eyelid (levator palpebrae superioris)

extrathoracic blood volume blood volume in the veins of the systemic circulation

extrinsic coagulation pathway pathway in which blood clots in response to tissue injury

exudate tissue fluid that seeps out of blood vessels into inflammatory tissue

facilitated diffusion see passive transport

factor III see tissue thromboplastin

factor X see prothrombinase

factor XIII see fibrin-stabilizing factor

familial hypercholesterolemia disorder in which the liver fails to produce the low-density lipoprotein (LDL) receptor, which is essential for LDL clearance from plasma. The condition is characterized by elevated levels of plasma LDLs, which typically leads to a predisposition for early coronary heart disease

farad (F) unit of measure of membrane capacitance

fast axoplasmic transport mechanism for transporting proteins, organelles, and other cellular materials needed for the maintenance of the cell along the length of axons

fast synaptic transmission neurotransmission mediated by activation of ligand-gated receptors

fastigial nucleus deals with antigravity muscle groups and other synergies involved with standing and walking; receives afferent input from the vermis, and most efferent connections travel via the inferior cerebellar peduncle to the vestibular nuclei

fast-twitch fibers skeletal muscle fibers specialized for rapid contractions

fatty acid synthase multienzyme complex required to convert carbohydrates to fatty acids

F cells one of five types of cells found in the islets of Langerhans of the endocrine pancreas; this one produces pancreatic polypeptide

feedback relaxation involves both local reflex connections between receptors in the small intestine and the gastric enteric nervous system (ENS) or hormones that are released from endocrine cells in the small intestinal mucosa and transported by the blood to signal the gastric ENS and stimulate firing in vagal afferent terminals in the stomach

feedforward control kind of system that reacts to changes in the environment, usually to maintain some desired state of the system

female athletic triad condition of disordered eating, amenorrhea, and osteoporosis occurring in female athletes and dancers

ferning crystal pattern formed by dried cervical mucus; indicates high estrogen levels

ferritin intracellular protein that binds and stores iron

ferroportin membrane protein for transport of iron from cell cytoplasm into the interstices

fertilization fusion of the male and female gametes (sperm with an ovum), which leads to the formation of an embryo and the development of a new organism; also known as conception

fetal hemoglobin major hemoglobin of the fetus, which exhibits much higher affinity for O2 than does adult hemoglobin

fibrin fibers that form stable blood clots

fibrin-stabilizing factor (factor XIII) clotting factor that catalyzes the formation of covalent bonds between strands of polymerized fibrin, stabilizing and tightening the blood clot

fibrinolysis process by which a fibrin clot is broken down

fibroblast growth factor-23 (FGF-23) protein hormone produced mainly by bone cells that inhibits tubular reabsorption of phosphate and 1α-hydroxylase activity in the kidneys and secretion of PTH; the result of these actions is a lower plasma phosphate concentration

Fick's law gas law that states that the amount of gas that diffuses across a biologic membrane per minute is directly proportional to the membrane surface area (As), the diffusion coefficient of the gas (D), and the partial pressure gradient (ΔP) of the gas and inversely proportional to membrane thickness (T); also known as Fick law

Fick's principle principle based on mass conservation that uses oxygen content of the blood and whole-body oxygen consumption to measure cardiac output

fight-or-flight response cardiovascular response to fear or stress that is similar to the baroreceptor reflex except that vasodilation occurs in the skeletal muscle circulation instead of vasoconstriction on initiation of the reflex

filopodia long, thin, transient actin-containing protrusions from growth cones

filtered load quantity of a substance, per unit time, that is filtered by the glomeruli and is therefore presented to the tubules; for a freely filterable substance, this is equal to the product of the plasma concentration and the glomerular filtration rate

filtration fraction fraction of the plasma flowing through the kidneys that is filtered; the ratio of glomerular filtration rate to renal plasma flow

filtration pressure equilibrium condition in which the pressures favoring fluid movement out of a capillary are exactly balanced by pressures favoring fluid movement into the capillary, so that there is no net fluid movement across the capillary wall

filtration slit space between adjacent glomerular podocytes about 40 nm wide and bridged by a diaphragm composed of nephrin

fimbria finger-like projections on the edge of the infundibulum of each oviduct

final common pathway neurons lower motor neurons and their axons that control skeletal muscles

first-degree atrioventricular block slower-than-normal transmission of action potentials from the atria to the ventricles. It is revealed on an electrocardiogram recording as a PR interval >0.2 seconds but with each P wave being followed by a QRS complex

first heart sound series of low-pitched sounds following the start of ventricular contraction created by vibrations in the chordae tendineae and blood in the ventricles

first messengers the messenger that binds to a receptor to initiate a signaling cascade. Examples are hormones, peptides, gases such as nitric oxide or CO, ions such as Ca2+, and adenosine triphosphate. Note that some first messengers, such as Ca2+, can also be second messengers, depending on whether they initiate or amplify the signaling cascade

first polar body small haploid cell produced by unequal first meiotic division of the oocyte

fixed monocyte–macrophage system cells that remain at a strategic fixed location and when encountering pathogenic material, thus being able to differentiate from monocytes to macrophages to ingest and thereby remove the material from the circulation

flap valve term used to describe the effects of contraction of the puborectalis muscle to interfere with the movement of feces or flatus in the direction of the anus; a component of the mechanisms that sustain fecal continence

flexion movement that decreases the angle between two moving parts of the body

flexor withdrawal reflex complex spinal reflex triggered by cutaneous stimulus resulting in withdrawal of the body part from the stimulus

flexors skeletal muscles whose action retracts a limb or body part

flow-limited transport transport of materials across the capillaries that is limited not by diffusion but instead by the rate at which the materials can be delivered by blood flow into the capillary network of an organ

flow-mediated vasodilation dilation of arteries and arterioles following an increase in blood flow. It is caused by increases in shear stress stimulation of nitric oxide release from the arterial endothelium

flow velocity measure of how fast blood moves from one point to the next downstream in the cardiovascular system. It has units of cm/s and is an important determinant of lateral pressure, intimal shear stress, and flow turbulence when blood flows within blood vessels

flow–volume curve curve that reflects airflow during forced expiration and forced inspiration

fluid mosaic model model conceived by S.J. Singer and G. Nicolson in 1972 to describe the structural features of biologic membranes

fluid-phase endocytosis see exocytosis

flux net transport of ions or solutes in free solution or via membrane transport

focal adhesions dense bodies involved in cell-to-substrate attachment in smooth muscle

focal length (FL) distance behind a positive (converging) lens at which parallel rays from a distant object are brought to a focus

folia folds of the cerebellar cortex

folic acid water-soluble vitamin essential for the formation of nucleic acids, the maturation of red blood cells, and growth

follicles structures containing the oocyte in the ovary

follicle-stimulating hormone (FSH) in women, the pituitary hormone responsible for stimulating follicular cells in the ovary to grow, triggering egg development and production of the female hormone estrogen; in male, the pituitary hormone that travels through the bloodstream to the testes and helps stimulate them to manufacture sperm

follicular phase part of the menstrual cycle during which follicle development occurs

folliculogenesis follicular development

follistatin single-chain protein hormone, with several isoforms, that binds and deactivates activin

foramen ovale opening between the right and left atria of the fetal heart. It shunts oxygenated blood from the right atrium of the fetus into the left atrium

forced expiratory flow (FEF25–75) maximum amount of air (L/s) forced out of the lungs between two given lung volumes (25% and 75%)

forced expiratory volume (FEV1) maximum amount of air (L) forced out of the lungs in 1 second after maximal inhalation

Forced Expiratory Volume in 1 second (FEV1) the volume of air exhaled during the first second of a forced expiratory maneuver started at total lung capacity. FEV1 is the most frequently used test for assessing airway obstruction, bronchoconstriction, or bronchodilation.

forced vital capacity (FVC) maximum volume of air forcibly exhaled after maximal inhalation

force–velocity curve expression of the inverse relationship between muscle force and shortening

fornix fiber bundle in the brain containing axons from hippocampal neurons that project to the hypothalamus and basal forebrain and axons from neurons in those regions that project to the hippocampus

free radical atom and/or molecule with unpaired electrons that is damaging to cell structure and function

fresh frozen plasma (FFP) blood product frozen within 6 hours of collection

frontal lobe region of the brain located most anterior, which controls motor and cognitive functions

fructose 1,6-diphosphatase focal enzyme in gluconeogenesis via its conversion of fructose 1,6-diphosphate (FDP) to fructose 6-phosphate (F-6-P), which permits endogenous glucose production from gluconeogenic amino acids (e.g., alanine and glycine), glycerol, or lactate

F-type ATPase proton pump located in the inner mitochondrial membrane that synthesizes adenosine triphosphate using the energy stored in a gradient of protons that crosses the inner mitochondrial membrane from outside to inside the mitochondria down its electrochemical gradient; also called ATP synthase

functio laesa loss of function associated with acute inflammation

functional gastrointestinal motility disorder disorder for which the physical or biochemical cause of the patient's symptoms cannot be determined

functional residual capacity (FRC) volume of air remaining in the lungs at the end of a normal tidal volume

functional syncytium electrical property of the heart muscle created by gap junction connections between cells that allows all heart muscle to be activated following the generation of an action potential in any myocardial cell

fundus of the stomach upper curvature of the organ; one of four stomach sections

fused tetanus series of skeletal muscle twitches occurring in such rapid succession that there is no intervening relaxation

fusimotor system γ motor neurons and the intrafusal muscle fibers within muscle spindles

G cells neuroendocrine cells present in the stomach and located predominantly in the antrum that produce the hormone gastrin, which stimulates acid secretion by the stomach

G protein–coupled receptors (GPCRs) large protein family of transmembrane receptors that sense molecules outside the cell and activate signal transduction pathways and, ultimately, cellular responses, internally; these cell surface receptors are implicated in many diseases and are the target of about 30% of all drug therapies

GABAergic neurons neurons that use γ-aminobutyric acid (GABA) as their neurotransmitter; in most cases, inhibitory neurons

galactopoiesis maintenance of lactation; regulated by prolactin

galactorrhea persistent milklike discharge from the nipple in nonlactating people

gallstone crystalline concretion formed within the gallbladder by accretion of bile components; these calculi are formed in the gallbladder but may pass distally into other parts of the biliary tract such as the cystic duct, common bile duct, pancreatic duct, or the ampulla of Vater

gamete specialized reproductive cell through which sexually reproducing parents pass chromosomes to their offspring; a sperm or an egg

gamma globulin see γ globulin

gamma motor neuron see γ motor neuron

ganglia grouping of nerve cell bodies situated outside the central nervous system

ganglion cell type of neuron located near the inner surface (the ganglion cell layer) of the retina of the eye that receives visual information from photoreceptors via bipolar and amacrine cells

ganglionated plexus array of ganglia and interganglionic fiber tracts forming parts of the enteric nervous system

gap junction (1) specialized protein channels in the plasma membrane composed of connexins, which form a connexon; allows the flow of ions (electrical current) from cell to cell; (2) membrane-to-membrane apposition in gastrointestinal smooth muscle, which mediates electrotonic coupling and allows electrical (ionic) current to pass from one muscle fiber to another

gas diffusion process in which gas moves across the alveolar–capillary membrane

gas exchange transfer of oxygen and carbon dioxide between the atmosphere and blood via the alveoli

gas tension partial pressure of an individual gas; used interchangeably with partial pressure of oxygen and carbon dioxide (e.g., oxygen tension = Po2; carbon dioxide tension = Pco2)

gastric adaptive relaxation relaxation triggered by distention of the gastric reservoir; a vagovagal reflex triggered by stretch receptors in the gastric wall, transmission over vagal afferents to the dorsal vagal complex, and efferent vagal fibers to inhibitory motor neurons in the gastric enteric nervous system

gastric amylase digests starch that was not digested in the mouth; it is of minor significance in the stomach

gastric feedback relaxation relaxation triggered in the gastric reservoir by the presence of nutrients in the small intestine; it can involve both local reflex connections between receptors in the small intestine and the gastric enteric nervous system or hormones that are released from endocrine cells in the small intestinal mucosa and transported by the blood to signal the gastric enteric nervous system and stimulate firing in vagal afferent terminals in the stomach

gastric glands see oxyntic glands

gastric inhibitory peptide (GIP) enterogastrone produced by the small intestinal endocrine cells that inhibits parietal cell acid secretion by the stomach. Recently, it has been named the glucose-dependent insulinotropic peptide

gastric lipase acidic lipase secreted by the gastric chief cells in the fundic mucosa in the stomach with a pH optimum of 3 to 6; acidic lipases do not require bile acid or colipase for optimal enzymatic activity and make up 30% of lipid hydrolysis occurring during digestion in the human adult, with gastric lipase

contributing the most of the two acidic lipases

gastric mucosa mucous membrane layer of the stomach wall (one of four layers) containing the glands and the gastric pits; it is ~1 mm thick and its surface is smooth, soft, and velvety; it consists of epithelium, lamina propria, and the muscularis mucosae

gastric phase one of three phases that stimulates acid secretion resulting from the ingestion of food. Acid secretion during the gastric phase is mainly a result of gastric distention and the digested peptides in the gastric lumen. The gastric phase accounts for ~50% of total gastric acid secretion

gastric receptive relaxation relaxation initiated in the gastric reservoir by the act of swallowing; a reflex triggered by stimulation of mechanoreceptors in the pharynx followed by transmission over afferents to the dorsal vagal complex and activation of efferent vagal fibers to inhibitory motor neurons in the gastric enteric nervous system

gastric reservoir reservoir consisting of the fundus and approximately one third of the corpus; the muscles of the gastric reservoir are adapted for maintaining continuous contractile tone (tonic contraction) and do not contract phasically

gastrin hormone that stimulates acid secretion by the stomach

gastrin-releasing peptide (GRP) peptide released by the nerves that stimulates G cells to release gastrin, which stimulates parietal cell acid secretion by the stomach. GRP is atropine-resistant, indicating that it works through a noncholinergic pathway

gastrocolic reflex mass movement of feces in the colon that is generally preceded by a similar movement in the small intestine, which often occurs immediately following the intake of a meal

gastroesophageal reflux retrograde flow of gastric contents into the esophagus

gastroesophageal reflux disease (GERD) chronic symptoms or mucosal damage produced by the abnormal reflux of stomach acid to the esophagus, typically accompanied by pyloris (heartburn)

gastrointestinal motility organized application of forces of muscle contraction that results in physiologically significant movement or nonmovement of intraluminal contents

gastroparesis weakness of phasic propulsive contractions in the antral pump, which results in delayed gastric emptying

general gas law gas equation that combines the Charles and Boyle laws

generalized edema widespread accumulation of salt and water in the interstitial spaces of the body

generalized hypoventilation condition in which the entire lung is underventilated, leading to low alveolar ventilation

generalized hypoxia condition in which the entire lung becomes hypoxic, as opposed to only a local region

generalized seizure widespread seizure that involves both cerebral hemispheres simultaneously

generator potential local electrical activity of a sensory receptor that is proportional to the intensity of a stimulus. The magnitude of the generator potential controls the frequency of action potentials along the sensory nerve

genetic sex gender determined by the chromosomes; also known as chromosomal sex

genital ridge embryonic ridge on the dorsal wall of the abdominal cavity; will form the gonads

gestational diabetes form of diabetes that may develop during pregnancy in women who do not otherwise have diabetes

ghrelin signal produced by the epithelia of the stomach and small intestine that stimulates food intake by activating the NPY neurons in the arcuate nucleus of the hypothalamus

gigantism excess growth in height as a result of inappropriately high levels of growth hormone

Gitelman syndrome inherited defect in the distal convoluted tubule of the kidneys, causing the kidneys to pass sodium, magnesium, chloride, and potassium into the urine, rather than allowing them to be reabsorbed into the bloodstream

glandular gastric mucosa stomach's mucosal lining, which contains three main types of glands: cardiac, pyloric, and oxyntic

glaucoma condition that results when drainage of the ocular aqueous humor is impaired, pressure builds up in the anterior chamber, and internal structures are compressed, leading to optical nerve damage that can ultimately cause blindness

glia neuronal support cells

glial cells nonneuronal cells of the nervous system that mediate metabolic functions and myelination

glicentin peptide fragment cleaved from glucagon by prohormone convertase

glitazones antidiabetic sulfonylurea drug that stimulates insulin secretion

γ globulin electrophoretically similar serum proteins, including antibodies

globulins plasma proteins, including antibodies, enzymes, carriers, and transporters

globus pallidus (GP) group of nerve cells in the basal ganglia whose output influences the thalamus and cerebral cortex, divided into an external and internal segment

glomerular filtration process in the kidney glomeruli in which an essentially protein-free filtrate is pushed out of the glomerular capillaries into the urinary space of the Bowman capsule

glomerular filtration barrier structures that separate the blood plasma and the urinary space of the Bowman capsule, namely, capillary endothelium plus glomerular basement membrane plus podocytes

glomerular filtration rate (GFR) rate at which the kidneys filter the plasma

glomerular ultrafiltration coefficient (Kf) product of both the hydraulic conductivity (fluid permeability) and capillary surface area of the glomerular filtration barrier

glomerulonephritis disease characterized by proteinuria and/or hematuria, hypertension, and renal insufficiency that progresses over years

glomerulotubular balance proportionate change in sodium reabsorption by the proximal convoluted tubule and loop of Henle when glomerular filtration rate is changed

glomerulus in the kidney, the tuft of capillaries, surrounded by the Bowman capsule, where the blood is filtered

glucagon hormone produced by the α cells of the pancreas that increases the level of glucose in the blood

glucagon-like peptide-1 (GLP-1) peptide generated from proglucagon that is one of the most potent incretins

glucagon-like peptide-2 (GLP-2) peptide generated from proglucagon that is not an incretin and whose biologic actions are not known

glucocorticoid hormones products of the adrenal cortex

glucocorticoid response elements (GREs) specific regions of DNA that bind glucocorticoid receptor

glucokinase enzyme that facilitates phosphorylation of glucose to glucose 6-phosphate in cells in the liver, pancreas, gut, and brain of humans and most other vertebrates

gluconeogenesis occurring mainly in the liver and kidneys, the energy-dependent production of glucose from noncarbohydrate sources, such as fat, amino acids, and lactate; energy for this process is derived from B oxidation of fatty acids

glucose simple sugar (monosaccharide) and an important carbohydrate used by cells as a source of energy and a metabolic intermediate; one of the main products of photosynthesis that starts cellular respiration

glucose buffering process by which the liver maintains normal blood glucose levels; its ability to store glycogen allows the liver to remove excess glucose from the blood and then return it when blood glucose levels begin to fall

glucose threshold plasma level at which glucose first appears in urine

glucose-6-phosphatase enzyme present exclusively in the liver that catalyzes the breakdown of glycogen to glucose molecules for release into the circulation

glucose 6-phosphate intermediate product in the conversion of glucose to glycogen and in the breakdown of glycogen to glucose

glucose-dependent insulinotropic peptide (GIP) gut hormone secreted by the duodenum that stimulates insulin secretion

glucose–galactose malabsorption (GGM) condition in which the cells lining the intestine cannot transport glucose and galactose, preventing proper absorption of these nutrients

α-glucosidase inhibitors oral medications used to treat type 2 diabetes that decrease the absorption of carbohydrates in the small intestine

glucosuria presence of glucose in the urine

GLUT2 facilitative glucose transporter expressed in the pancreas, liver, intestine, and kidney

GLUT4 insulin-responsive facilitative glucose transporter expressed in muscles and adipose tissues

GLUT5 a fructose transporter expressed on the apical border of enterocytes in the small intestine

glutamate (GLU) amino acid used as an excitatory neurotransmitter

glutamatergic neurons neurons that use glutamate as their neurotransmitter

glutamine precursor for glutamate

glycine (GLY) amino acid used as an inhibitory neurotransmitter

glycinergic neurons neurons that use glycine as their neurotransmitter

glycogen polysaccharide that is the main form of carbohydrate storage in animals and occurs mainly in liver and muscle tissue; readily converted to glucose

glycogen phosphorylase first-acting enzyme in the breakdown of glycogen to glucose, responsible for the production of glucose 1-phosphate from the glycogen substrate, which is subsequently converted to glucose. The enzyme acts on the α-1,4-glycosidic linkage yielding glucose polymers

glycogen synthase enzyme that catalyzes the transfer of glucose from uridine diphosphate–glucose to glycogen

glycogenesis occurring mainly in the liver, the process by which glycogen is synthesized from circulating glucose, lactate, and pyruvate after ingestion of a meal

glycogenolysis process by which glycogen is broken down to glucose 6-phosphate and then to glucose for subsequent release into circulation. The reaction is specific to the liver

glycolipid lipid molecule that contains one or more monosaccharide units

glycolysis adenosine triphosphate–generating metabolic process of most cells in which carbohydrates are converted to pyruvic acid

glycolytic pathway (or glycolysis) series of cytoplasmic chemical reactions that break down glucose molecules and produce adenosine triphosphate for energy-requiring cellular processes

glycoprotein protein that contains one or more monosaccharide units

goblet cells cells that serve to secrete various mucins (mucoproteins) found in intestinal secretions

goiter enlarged thyroid gland

Goldman equation value of the membrane potential when all the permeable ions are accounted for. In its usual form, it shows the relationship between intracellular and extracellular concentrations of Na^+, K^+, and Cl^-, the plasma membrane permeability to these ions, and the membrane potential

Golgi apparatus eukaryotic organelle that processes and packages proteins, lipids, and other molecules after their synthesis

Golgi tendon organs (GTOs) sensory receptors located in tendons that sense the force of muscle contraction

gonadal sex sex of the structures that produce the gametes

gonadarche gonadal maturation during pubertal development in boys and girls

gonadotrophs cells located in the anterior pituitary that secrete luteinizing hormone and follicle-stimulating hormone

gonadotropin-releasing hormone (GnRH) hormone made by the hypothalamus (part of the brain); causes the pituitary gland to make luteinizing hormone and follicle-stimulating hormone, which are involved in reproduction; also known as luteinizing hormone–releasing hormone (LHRH)

gonadotropins products of the gonadotrophs in the anterior pituitary; luteinizing hormone and follicle-stimulating hormone

gout disorder in which plasma uric acid is elevated and urate crystals precipitate in the joints, causing pain and inflammation and swelling of the affected joints (often in the big toe)

graafian follicle mature preovulatory follicle

graded response sensory response in approximate proportion to the intensity of the stimulus

graft tissue or organ transplanted from a donor to a recipient

graft versus host disease (GVHD) disease in which T cells of the graft attack tissue of the recipient as foreign

grand mal seizure see tonic–clonic seizure

granular cells modified pericytes of glomerular arterioles; also known as juxtaglomerular cells

granular layer nuclear layer in the cerebellar cortex rich in interneurons

granulocyte mature cell of the myeloid series, including neutrophils, eosinophils, and basophils; also known as polymorphonuclear leukocyte

granulosa lutein cells cells that are found in the corpus luteum and formed from the granulosa cells

granzyme enzyme family present in the granules of cytotoxic T cells and natural killer cells

Graves disease autoimmune disorder caused by antibodies directed against the thyroid-stimulating hormone receptor

gray matter portions of the CNS that histologically appear gray due to cell bodies and nonmyelinated processes

gray ramus nerve branch that carries postganglionic sympathetic axons back to the spinal nerve

ground substance intercellular material in which the cells and fibers of connective tissue are embedded

growth cone leading edge of a growing axon that samples the environment and makes decisions about the direction of growth

growth factors naturally occurring proteins that are capable of stimulating cellular proliferation, differentiation, or other cellular responses

growth hormone (GH) hormone product of somatotrophs located in the anterior pituitary

growth hormone–releasing hormone (GHRH) polypeptide from hypothalamus; stimulates secretion of growth hormone

guanosine diphosphate (GDP) product of guanosine triphosphate phosphorylation

guanosine triphosphate (GTP) nucleotide that provides source of energy for protein synthesis; essential for G protein signal transduction by converting to guanosine diphosphate via GTPases

guanylin polypeptide hormone produced by the small intestine that increases renal salt excretion

guanylyl cyclase (GC) enzyme that catalyzes the conversion of guanosine triphosphate to 3′,5′-cyclic guanosine monophosphate and pyrophosphate

gustducin G protein associated with tasting bitterness in the gustatory system

gynecomastia excessive development of the male breasts

gyrus convolution on the surface of the brain

H+-ATPases (proton pump) located in the membranes of lysosomes and the Golgi apparatus and pumps protons from the cytosol into the organelles to keep the inside of the organelle more acidic than the cytoplasm; classified as V-type ATPases because they were first discovered in intracellular vacuolar structures; now known to also exist in the plasma membranes

H+/K+-ATPase mechanism present in the apical (luminal) cell membrane of the parietal cell that is involved in the secretion of hydrochloric acid by the stomach

hair cells mechanosensitive cells within the organ of Corti and the vestibular apparatus

Haldane effect effect of oxygen on the carbon dioxide equilibrium curve. Oxygen causes a downward shift of the carbon dioxide equilibrium curve

hallucination perception in the absence of a stimulus

hamartoma nonneoplastic congenital malformation composed of a heterotropic mass of nerve tissue usually located on the floor of the third ventricle or attached to the tuber cinereum

hapten nonimmunogenic antibody-binding molecule, unless linked to a carrier molecule

haptoglobin large glycoprotein (molecular weight of 100,000 Da) that binds free hemoglobin in blood, forming a hemoglobin–haptoglobin complex, which is rapidly removed from circulation by the liver, thereby conserving iron in the body

Hartnup disease extremely rare genetic disorder of amino acid carriers. The membrane carrier for neutral amino acids (e.g., tryptophan) is defective

Hashimoto disease autoimmune disease resulting in impaired thyroid hormone synthesis; also known as Hashimoto thyroiditis

haustration process of formation of a haustrum (haustral sac) in the colon

heart four-chambered, hollow organ composed primarily of striated muscle that is responsible for pumping blood through the lungs and the systemic circulation. It is composed of two upper chambers, a right and left atrium, and two larger, lower chambers called the right and left ventricles. The right atrium receives blood from the peripheral veins and delivers it through the tricuspid valve to the right ventricle. The right ventricle pumps blood through the pulmonic valve into the pulmonary circulation. Blood returning from the pulmonary circulation arrives in the left atrium, where it is pumped through the mitral valve into the left ventricle. This chamber pumps blood through the aortic valve into the aorta and thus into the systemic circulation. In this arrangement, the right and left sides of the heart are actually two pumps arranged in series

heart murmur sound heard over the chest with a stethoscope that results from turbulent flow in the heart, aorta, or pulmonary circulation, usually resulting from stenotic or incompetent heart valves

heart rate number of times the normal heart contracts in 1 minute; in a healthy individual, this rate can range between 50 and 180 contractions per minute

heartburn episodic retrosternal burning

heat exhaustion most common heat-related illness, involving mild to moderate dysfunction of temperature control associated with elevated ambient temperatures and/or strenuous exercise resulting in dehydration and salt depletion. It may rapidly progress to heatstroke when the body's thermoregulatory mechanisms become overwhelmed and fail

heat storage difference between heat production and net heat loss

heat syncope body temperature above 40°C (104°F) with fainting or weakness but without mental confusion; results from circulatory failure as a result of peripheral venous pooling, with a consequent decrease in venous return. Heat syncope is caused by mild overheating with inadequate water or salt

heatstroke extreme hyperthermia, typically above 100.4°F (40°C), associated with a systemic inflammatory response, which leads to end-organ damage with universal involvement of the central nervous system. Heatstroke traditionally is divided into exertional and classic varieties, which are

defined by the underlying etiology but are clinically indistinguishable

heel stick procedure in which a newborn baby's heel is pricked and then a small amount of the blood is collected, usually with a narrow-gauge ("capillary") glass tube or a filter paper

hem(at)/o referring to blood

hematocrit (Hct or Ht) percentage of whole blood that is composed of erythrocytes

hematologist blood specialist

hematopoiesis generation of blood cells

hematopoietins subclass of cytokines regulating hematopoiesis

heme oxygenase microsomal enzyme responsible for the release of iron from heme. Iron then enters the cellular free iron pool and can be stored as ferritin or released into the bloodstream

hemochromatosis condition caused by iron overload that is characterized by excessive amounts of hemosiderin in the hepatocytes, rendering them defective and unable to perform many normal, essential functions. The excess iron is stored in the organs, especially the liver, heart, and pancreas, causing damage to these organs and leading to life-threatening illnesses such as cancer, heart complications, and liver disease

hemocytometer chamber for manual blood cell counts

hemodialysis procedure usually done three times a week (4 to 6 hours per session) in a medical facility or at home in which kidney-failure patient's blood is pumped through an artificial kidney machine; the blood is separated from a balanced salt solution by a cellophane-like membrane, and small molecules can diffuse across this membrane; excess fluid can be removed by applying pressure to the blood and filtering it

hemodynamics study of the physics of the containment and movement of blood in the cardiovascular system

hemoglobin (Hb) oxygen-transporting protein of erythrocytes

hemoglobinopathies diseases caused by mutated hemoglobin

hemolysis bursting (lysis) of red blood cells leading to the release of hemoglobin

hemolytic anemia anemia caused by destruction of erythrocytes that exceeds their generation

hemopexin protein synthesized by the liver that is involved in the transport of free heme in the blood. It forms a complex with free heme, and the liver rapidly removes the complex

hemophilia hereditary bleeding disorders

hemorrhage severe bleeding

hemosiderin iron-storing protein related to ferritin

hemosiderin granules iron stored as ferritin that is sometimes converted to these bodies

hemostasis cessation of bleeding occurring in four steps: (1) compression and vasoconstriction, (2) formation of a temporary loose platelet plug (also called primary hemostasis), (3) formation of stable fibrin clot (also called secondary hemostasis), and (4) clot retraction and dissolution

Henderson-Hasselbalch equation logarithmic form of the acid dissociation equation

Henry law gas law that states that the amount of gas dissolved in a liquid at a given temperature is directly proportional to the solubility and the partial pressure of the dissolved gas

heparin injectable anticoagulant

hepatic arterial buffer response phenomenon in which reduction in portal blood supply to the liver is compensated by an increase in supply from the hepatic artery and vice versa

hepatocytes highly specialized cells arranged along the liver sinusoids that facilitate the rapid exchange of molecules, as they possess numerous finger-like projections that extend into the perisinusoidal space, thereby increasing the surface area over which they are in contact with the perisinusoidal fluid

hepcidin hormone produced by the liver that regulates iron homeostasis by inhibiting ferroportin

hereditary hemochromatosis (HH) inherited disorder that increases the amount of iron that the body absorbs from the gut, causing excess iron to be deposited in multiple organs of the body; excess iron in the liver causes cirrhosis (which may develop into liver cancer); iron deposits in the pancreas can result in diabetes; and excess iron stores can also cause cardiomyopathy, pigmentation of the skin, and arthritis

hereditary spherocytosis genetically transmitted (autosomal dominant) form of spherocytosis characterized by the production of red blood cells that are sphere-shaped and, therefore, more prone to hemolysis

Hering-Breuer reflex reflex that involves the pulmonary stretch receptors and that prevents overinflation of the lungs; also known as lung inflation reflex

heterogametic having one X and one Y chromosome; a male

heterologous desensitization process by which effector cells are rendered less reactive or nonreactive to a given stimulus by a different stimulus

heteroreceptor presynaptic receptor regulating the release of a different neurotransmitter

hexokinase enzyme that facilitates phosphorylation of glucose to glucose 6-phosphate in cells in yeast and muscle

hidromeiosis condition caused by excessive wetting of the skin and subsequent interference with the free flow of eccrine sweat during exercise in humid environments; may be compounded by fatigue of sweat glands as a result of a lack of neurotransmitters

high-altitude cerebral edema swelling in the brain due to cerebral edema and elevated cerebral blood volume. High-altitude cerebral edema is the result of rapid accent to high altitude (5,280 ft above sea level or higher) and is caused by hypoxemia. Initial symptoms include headaches, insomnia, nausea, dizziness, and loss of coordination.

high-altitude pulmonary edema a noncardiogenic form of pulmonary edema resulting from alveolar capillary membrane leakage. The edema is caused by hypoxic-induced pulmonary arterial vasoconstriction and occurs from short-term exposures to altitudes in excess of 2,000 m above sea level (6,560 ft).

high-density lipoprotein (HDL) particles circulating in the blood that contain cholesterol esters; removes cholesterol from cells and transports it back to the liver for excretion or reutilization; also known as good cholesterol

hilum depression or pit at that part of an organ where the blood vessels and nerves enter

hippocampus three-layered cortical structure in the temporal lobe involved in learning and memory

Hirschsprung disease congenital dilation and hypertrophy of the colon resulting from the absence of the enteric nervous system (aganglionosis) of the rectum and a varying but continuous length of gut above the rectum

hirsutism excessive increase of hair growth, sometimes leading to male pattern hair growth in a female

histamine inflammatory mediator, released by mast cells and basophils

HMG-CoA reductase see 3-hydroxy-3-methylglutaryl CoA reductase

homeostasis property of a living organism to regulate its internal environment to maintain a stable, constant condition, by means of multiple dynamic equilibrium adjustments, controlled by interrelated regulation mechanisms

homeotherms warm-blooded animals who keep their core body temperature at a nearly constant level regardless of the temperature of the surrounding environment

homogametic having two X chromosomes; a female

homologous desensitization loss of sensitivity only to the class of agonist used to desensitize the tissue

hopping reaction limb reflex that promotes automatic forward movement of a weight-bearing limb

horizontal cells laterally interconnecting neurons in the outer plexiform layer of the retina of mammalian eyes that help integrate and regulate the input from multiple photoreceptor cells; responsible for allowing eyes to adjust to see well under both bright and dim light conditions as well as other functions

hormone chemical or protein messenger made by one cell that serves as a signal to a target cell

hormone receptor molecular entity (usually a protein or glycoprotein) either outside or within a cell that recognizes and binds a particular hormone

hormone response element (HRE) short DNA sequence that is usually within the promoter or repressor regions of genes and binds a specific hormone/receptor complex to regulate transcription of the gene

hormone-sensitive lipase enzyme that plays an important role in controlling the balance of energy by breaking down fats

Horner syndrome rare condition resulting from damage to the sympathetic nervous system that affects the nerves to the eye and face and causes decreased sweating on the affected side of the face, ptosis, sinking of the eyeball into the face, and a mall (constricted) pupil

host versus graft response condition in which the recipient's immune system attacks transplanted leukocytes

H2 receptors special histamine receptors found in the parietal cells whose stimulation results in increased acid secretion by the stomach

human chorionic gonadotropin (hCG) protein secreted by the blastocyst and placenta; similar in biologic action to luteinizing hormone

human leukocyte antigen (HLA) human mean cell (corpuscular) hemoglobin protein

human placental lactogen (hPL) substance synthesized by the placenta; its structure and function resemble those of prolactin and growth hormone

humoral immunity part of adaptive immunity mediated by soluble factors, especially antibodies

Huntington's disease disease of the basal ganglia producing uncontrollable spontaneous movements

hydration combination with water

hydration reaction chemical reaction, usually happening in a strong acidic solution, in which a hydroxyl group and a hydrogen cation (an acidic proton) are added to two carbon atoms

hydraulic conductivity for water measure of hydraulic resistance across a capillary network; high conductivity means that water passes easily across the network. It is a measure of how much water can be moved in bulk across the capillaries per minute for each 1 mm Hg of driving pressure

hydrochloric acid (HCl) important constituent of gastric acid that aids in the digestion of food; secreted by the parietal cells and responsible for the change in the electrolyte composition of gastric juice

hydrogen peroxide (H_2O_2) reactive oxygen species that is not a free radical and is damaging to cell structure and function

hydrophilic highly soluble in water, for example, ions and polar molecules

hydrophobic having low solubility in water, for example, nonpolar molecules

3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase) substance that catalyzes the rate-limiting step in de novo cholesterol synthesis

hydroxyapatite crystals form of calcium phosphate in the mineral portion of bone

β-hydroxybutyric acid β derivative of hydroxybutyric acid that is found in the blood and urine in some cases of impaired metabolism

hydroxyl radical (•OH) reactive oxygen species that is damaging to cell structure and function

11β-hydroxylase (CYP11B1) substance that hydroxylates 11-deoxycortisol to form cortisol

17α-hydroxylase substance that hydroxylates pregnenolone to form 17α-hydroxypregnenolone

21-hydroxylase (CYP21A2) substance that converts 17α-hydroxyprogesterone to 11-deoxycortisol

17α-hydroxypregnenolone intermediate in steroid synthesis

17α-hydroxyprogesterone intermediate in steroid synthesis

3β-hydroxysteroid dehydrogenase (3β-HSD II) substance that acts on 17α-hydroxypregnenolone to produce 17α-hydroxyprogesterone

5-hydroxytryptamine (5-HT) monoamine neurotransmitter; also known as serotonin

hyperaldosteronism medical condition characterized by too much aldosterone being produced by the adrenal glands, which can lead to lowered levels of potassium in the blood

hypercalciuria excess calcium in the urine

hypercapnia high partial pressure of blood carbon dioxide (>45 mm Hg) resulting from underventilation of the lung

hyperglycemia presence of an abnormally high concentration of glucose in the blood

hypergonadotropic hypogonadism defective development of ovaries or testes; associated with excess pituitary gonadotropin secretion; results in delayed sexual development and growth delay

hyperkalemia condition in which the plasma K^+ level is > 5.0 mEq/L

hyperkinesis excessive movement

hyperopia (farsightedness) condition caused by the eyeball being physically too short to focus on distant objects

hyperosmotic see osmotic pressure

hyperphagia abnormally increased appetite and consumption of food

hyperphosphatemia condition in which plasma phosphate concentration is elevated

hyperpnea increased minute ventilation via increased depth and frequency of breathing (unlike tachypnea, which is rapid, shallow breaths) to meet increased metabolic demand (such as during or following exercise); ventilation increases proportionally to carbon dioxide production, but Paco2 remains the same, which is the hallmark feature of hyperpnea (unlike in hyperventilation, in which Paco2 is significantly lowered, leading to alkalosis)

hyperpolarization change in electrical potential in the direction of a more negative potential inside cells; makes excitable cells less excitable by moving the membrane potential away from the threshold for discharge of an action potential

hyperpolarize when the membrane potential becomes more negative than the resting membrane potential

hyperprolactinemia elevated prolactin secretion from the pituitary causing amenorrhea

hypersensitivity damaging immune responses to allergens, resulting in inflammation and organ dysfunction

hyperthermia acute condition that occurs when the body produces or absorbs more heat than it can dissipate

hyperthyroidism or thyrotoxicosis excessive thyroid hormone secretion

hypertonic see tonicity

hyperventilation state of breathing faster and/or deeper than necessary that causes excess carbon dioxide to be blown off; it can result from a psychological state such as a panic attack, can result from a physiologic condition such as metabolic acidosis, or can be brought about by voluntarily forced ventilation and is characterized by increased minute ventilation with a concomitant decrease in Paco2; also known as overbreathing

hypervitaminosis A condition resulting from consumption of massive quantities of vitamin A that is often associated with hepatotoxicity and that eventually leads to portal hypertension and cirrhosis

hypoaldosteronism condition characterized by decreased levels of aldosterone, which may result in hyperkalemia and urinary sodium wasting, leading to volume depletion and hypotension

hypocalcemia deficiency of calcium in the blood

hypocalcemic tetany condition characterized by low blood calcium levels, resulting in convulsions

hypocapnia condition characterized by low partial pressure of blood carbon dioxide (<35 mm Hg) as a result of overventilation of the lung

hypochromic condition in which there is less hemoglobin per cell than normal

hypocretin/orexin neuropeptide found in neurons in the posterolateral hypothalamus that are sensitive to nutritional status, simulate appetite, and project to arousal areas of the brain; a functional deficit in

hypocretin causes narcolepsy

hypoglycemia condition characterized by low blood sugar level

hypogonadism condition in which sex organs such as the testes or ovaries are underactive

hypogonadotropic hypogonadism absent or decreased function of the gonads, the male testes or the female ovaries, resulting from the absence of the gonadal stimulating pituitary hormones, follicle-stimulating hormone, and luteinizing hormone

hypokalemia condition in which the plasma K+ level is <3.5 mEq/L

hypokinesis condition characterized by less than a normal amount of movement

hyponatremia condition in which the plasma Na+ level is <135 mEq/L

hypophyseal portal circulation special blood supply to the anterior lobe of the pituitary gland

hypophysiotropic hormones releasing hormones synthesized by neural cell bodies in the hypothalamus and that regulate secretion of posterior pituitary hormones

hypopituitarism deficiency of one or more hormones of the pituitary gland

hypoprothrombinemia a deficiency in prothrombin (factor II) resulting in extended blood clotting time

hyposmotic see osmotic pressure

hypotension condition characterized by lower-than-normal arterial pressure

hypothalamic amenorrhea a broad range of conditions, each of which results in insufficient gonadotropin release

hypothalamic amenorrhea, functional amenorrhea resulting from emotional distress, excessive exercise or rapid weight loss, but where the neuroendocrine pathways are intact

hypothalamic diabetes insipidus condition in which arginine vasopressin secretion is impaired

hypothalamic hormones hormones released by the hypothalamus to reach the anterior pituitary lobe by a portal system of capillaries; designated as releasing factors because they regulate the secretion of most hormones of the endocrine system

hypothalamic–pituitary axis functional connection between the brain and the pituitary, in which the hypothalamus plays a central role: the brain links the pituitary gland to events occurring within or outside the body, which call for changes in pituitary hormone secretion

hypothalamic–pituitary–adrenal axis interactive relationship regulating glucocorticoid levels in the blood

hypothalamic–pituitary–gonad axis interactive relationship regulating gonadotropin levels in the blood

hypothalamic–pituitary–growth hormone axis interactive relationship regulating growth hormone levels in the blood

hypothalamic–pituitary–thyroid axis interactive relationship regulating thyroid hormone levels in the blood

hypothalamohypophyseal portal blood vessels system of blood vessels in the pituitary stalk into which neurons within specific nuclei of the hypothalamus secrete releasing factors that are then transported to the anterior pituitary, where they stimulate secretion of hormones

hypothalamohypophyseal tract axons within the pituitary stalk derived from magnocellular neurons whose cell bodies are located in the supraoptic and paraventricular hypothalamic nuclei; represents the efferent limbs of neuroendocrine reflexes that lead to the secretion of the hormones vasopressin and oxytocin into the blood within the posterior pituitary

hypothalamus region of the brain that integrates autonomic responses to temperature and hunger

hypothermia drop of central temperature below 35°C

hypothyroidism condition characterized by inadequate production of the thyroid hormone thyroxine and by low circulating levels of thyroxine and other thyroid hormones

hypotonia reduction in the amount of normal resistance to a muscle undergoing passive stretch

hypotonic see tonicity

hypoventilation decreased alveolar ventilation

hypovolemia condition characterized by an abnormally low circulating blood volume

hypoxemia condition characterized by an abnormally low oxygen content or low Po2 in the arterial blood

hypoxia condition in which the inspired oxygen is below normal leading to abnormal low oxygen tension in the tissues

hypoxia-induced pulmonary vasoconstriction phenomenon in which small pulmonary vessels constrict with low oxygen, which is just the opposite of that which occurs in the systemic circulation

H zone pale region of A band that contributes to striated appearance in muscle

I band band of actin myofilament in muscle that shows low density under a microscope and contributes to muscles' striated appearance; isotropic

I cell type of endocrine cell in the small intestine that releases cholecystokinin

Ig immunoglobulin; a membrane-bound or soluble antigen-binding protein

ileocolonic sphincter prevents reflux of colonic contents into the ileum; incompetence can allow entry of bacteria into the ileum from the colon that may result in bacterial overgrowth

immediate early genes genes that are activated transiently and rapidly in response to a cellular stimuli; the first round of response to stimuli, before any new proteins are synthesized

immune deficiency disease resulting from absent or malfunctioning immune components

immune surveillance theory that the immune system recognizes and destroys tumor cells that are constantly arising during the life of the individual

immune thrombocytopenia purpura (ITP) common autoimmune disorder caused by autoantibodies to platelets formed in the spleen and by the platelet–antibody aggregates being destroyed by the spleen

immune tolerance process by which the immune system does not attack antigens and includes self-tolerance (in which the body does not mount an immune response to self-antigens) and induced tolerance (in which tolerance to external antigens can be created by manipulating the immune system); the three forms are central, peripheral, and acquired tolerance

immunocontraception use of antibodies against the egg, sperm, or zygote or against hormones such as human chorionic gonadotropin or follicle-stimulating hormone to prevent pregnancy (this method of

contraception is still being developed for use in humans)

immunogen substance that provokes the immune system

immunologic synapse complex junction between a T cell and an antigen-presenting cell

immunosenescence gradual deterioration of the immune system because of advancing age

implantation attachment of the blastocyst to the surface endometrial cells of the uterine wall, beginning on days 7 to 8 after fertilization

impulse initiation region region of the receptor membrane that is the location of the formation of action potential in the neuron and constitutes an important link in the sensory process

inactivation voltage-gated sodium channel entering the inactive state

inactivation gate molecular gate in voltage-gated sodium channels that closes after the channel opens and remains closed for a finite period of time and until the membrane is repolarized

inactive state the state of the voltage-gated sodium channel in which it is closed and incapable of being opened

incisura small indentation that appears in the aortic pressure waveform when the aortic valve closes

incomplete proteins proteins that do not provide all of the essential amino acids in amounts sufficient to sustain normal growth and body maintenance, such as those found in most vegetables and grains

incretin effect principle stating that a glycemic stimulus derived from enteral nutrients exerts a greater insulinotropic response than a comparable isoglycemic challenge achieved through parenteral glucose administration

indicator–dilution method technique used to determine cardiac output based on the disappearance of concentration of an indicator over time

indirect calorimetry measure of an organism's metabolic rate by calculating oxygen uptake, assuming that burning 1 cal (kilocalorie) requires 208.06 mL of oxygen

indirect pathway basal ganglia pathway in which axons from the caudate synapse in the globus pallidus externus before reaching the globus pallidus externus

indirect sympathomimetic chemical that produces activation of the sympathetic nervous system by increasing the release of norepinephrine

inferior cervical ganglia lowermost of the sympathetic ganglia located in the neck; also known as stellate ganglion

inferior hypophyseal arteries arteries that provide arterial blood to the posterior lobe

inferior mesenteric ganglion most caudal of the three prevertebral sympathetic ganglia of the abdomen

inferior salivatory nucleus region of the medulla where neurons involved in the control of submandibular, sublingual, and parotid glands are located

inferior vena cava (IVC) single major vein that collects blood from the lower extremities and abdominal organs and that empties into the right atrium

inflammation pathologic process including cytologic changes, cellular infiltration, and mediator release; also known as inflammatory response

influx transfer of material from the exterior to the interior of a cell

infundibular process major portion of the neurohypophysis; also known as posterior lobe

infundibular stem inner part of the pituitary stalk

infundibulum end of the oviduct that receives the ovulated egg from the ovary; has fimbria

inhibin substance secreted by the testes and ovaries that regulates follicle-stimulating hormone levels

inhibitors of apoptosis (IAPs) family of functionally and structurally related proteins that serve as endogenous inhibitors of programmed cell death; there are eight human IAPs

inhibitory junction potential (IJP) membrane hyperpolarization leading to decreased excitability in gastrointestinal muscles; evoked by the release and action of inhibitory neurotransmitters from enteric motor neurons

inhibitory motor neuron neuron that releases neurotransmitter, which suppresses contractile or secretory behavior in the gastrointestinal tract

inhibitory neurotransmitters neurotransmitters that result in membrane hyperpolarization

inhibitory postsynaptic potentials hyperpolarization of neuronal membrane at the postsynaptic side of a synapse resulting from ions flowing through channels that open when neurotransmitter released from the presynaptic terminal binds to its receptor

initial velocity earliest steady velocity of a contracting muscle

innate immune system nonspecific defense mechanisms; also called nonspecific or natural immunity

inner ear portion of the ear containing the cochlea, where the actual sound transduction takes place

inner-ring deiodination enzymatic removal of an iodine atom at the 5 position on the thyronine ring structure

innervated supplied with intact nerves

iNOS inducible nitric oxide synthase; an enzyme that converts l-arginine to l-citrulline and nitric oxide that is not constitutively expressed in tissues. Its appearance in tissues such as vascular smooth muscle and leukocytes occurs after exposure of the tissues to an inducing factor such as endotoxins or lipopolysaccharides

inositol trisphosphate (IP3) intracellular second messenger generated by hydrolysis of phosphatidylinositol 4,5-bisphosphate

inotropic state contractile state of cardiac muscle independent of effects of loading condition; a function of factors that modify the contractile force of cardiac muscle at the level of the cell

insensible perspiration those evaporative losses of water from the moist surfaces of the body (such as the skin and respiratory tree) not resulting from the secretory activity of glands

insensible water loss water loss from the skin and lungs that is not ordinary

insular area region of the temporal cerebral cortex involved in coordination of olfactory and gustatory stimuli for autonomic functions

insulin hormone produced by the β cells of the pancreas that decreases the level of glucose in the blood

insulin resistance inability of a known quantity of exogenous or endogenous insulin to increase glucose

uptake and use in an individual as much as it does in a normal population

insulin/glucagon ratio (I/G ratio) net physiologic response determined by the relative levels of insulin and glucagon in the blood plasma

insulin-like growth factor-1 (IGF-1) potent trophic hormone whose secretion is stimulated by growth hormone; also known as somatomedin C

insulin-like growth factor-2 (IGF-2) trophic hormone

insulin-like growth factors (IGFs) class of small peptides responsible for mediation of some growth hormone actions that increase the rate of cartilage synthesis by promoting the uptake of sulfate and the synthesis of collagen; also known as somatomedins

insulitis penetration by lymphocytes into pancreatic islets of Langerhans that produces an inflammatory or autoimmune response and results in destruction of the β cells of the pancreas

integral (intrinsic) membrane protein protein that is embedded in or completely spans the phospholipid bilayer region of a cell membrane, for example, membrane transport proteins and ion channels

integral proteins a type of membrane protein that is permanently attached to the biological membrane

integration process of assembling parts together to make a whole; a neural network processing resulting in output being a function of input other than one; the organization of behavior of individual digestive effector systems into harmonious function of the whole organ

integrins protein important for platelet adhesion in hemostasis

intention shaping of behavior in accordance with internal motivation and external context

intercalated cells cells in the connecting tubules and collecting ducts of the kidneys that are involved in acid–base transport

intercalated duct one of three ducts that comprise the salivon of the human submandibular gland. The intercalated ducts are connected to the striated duct, which eventually empties into the excretory duct

intercostal muscles muscles between the ribs that are involved in forced expiration

interdigestive state fasting state in the upper gastrointestinal that begins with the absorption of all nutrients, which is characterized by the migrating motor complex behavioral pattern

interferons class of natural proteins produced by the cells of the immune system in response to challenges by foreign agents such as viruses, bacteria, parasites, and tumor cells. Interferons belong to the large class of glycoproteins known as cytokines

interganglionic fiber tracts bundles of nerve fibers connecting adjacent ganglia of the enteric nervous system

interleukin cytokine made by one leukocyte and acting on another

interleukin-1 cytokine secreted by macrophages, monocytes, and dendritic cells as part of the inflammatory response to infection. It enables transmigration of leukocytes to sites of infection and resets the hypothalamic thermoregulatory center, leading to an increased body temperature (fever), thereby acting as an endogenous pyrogen

interleukin-6 proinflammatory cytokine secreted by T cells and macrophages to stimulate immune response to trauma, especially burns or other tissue damage leading to inflammation. IL-6 is one of the most important mediators of fever

intermediate filaments cellular constituents of smooth muscle that form part of the cytoskeleton

intermediate-density lipoprotein (IDL) particles circulating in the blood that contain cholesterol esters; falls between low-density and very-low-density lipoprotein in density

internal anal sphincter smooth muscle sphincter surrounding the anal canal, which provides a passive barrier to the leakage of liquid and gas from the rectum

internal capsule pathway for corticospinal tract neurons within the deep cerebral white matter

international normalized ratio (INR) system established to report the results of blood coagulation (clotting) tests; results are standardized using the international sensitivity index for the particular thromboplastin reagent and instrument combination used to perform the test

interneuron internuncial neuron that is neither sensory nor motor and that connects neurons with neurons

interposed (interpositus) nucleus deep nucleus of the cerebellum composed of the globose nuclei and the emboliform nuclei; receives its afferent supply from the anterior lobe of the cerebellum and sends output via the superior cerebellar peduncle to the red nucleus; modulates muscle stretch reflexes of distal muscle groups

interstitial cells of Cajal (ICCs) specialized cells of mesodermal origin believed to be the pacemaker cells for intestinal electrical slow waves

interstitial fluid fluid outside blood vessels that directly bathes most body cells

intestinal phase one of three phases that stimulate acid secretion resulting from the ingestion of food. During the intestinal phase, protein digestion products in the duodenum stimulate gastric acid secretion through the action of the circulating amino acids on the parietal cells. Distention of the small intestine stimulates acid secretion. The intestinal phase accounts for about 10% of total gastric acid secretion

intracellular fluid (ICF) fluid within cells

intrafusal muscle fibers muscle cells within a muscle spindle whose contraction changes tension on spindle sensory endings

intrinsic coagulation pathway blood-clotting pathway in response to an abnormal vessel wall

intrinsic factor glycoprotein secreted by the parietal cells in the stomach that binds strongly with vitamin B12 to form a complex that is then absorbed in the terminal ileum through a receptor-mediated process

inulin fructose polymer whose renal clearance is used to measure glomerular filtration rate

inulin clearance procedure by which the filtering capacity of the kidney glomeruli is determined by measuring the rate at which inulin, the test substance, is cleared from blood plasma

inverse myotatic reflex type of muscle stretch reflex that helps regulate the tension of contracting muscle

inwardly rectifying K+ channels channels responsible for the hyperpolarizing potassium currents that are the main determinant of the resting membrane potential in myocardial cells. The term “inwardly” is an electrophysiologic convention that refers to the fact that the channels pass potassium currents more readily in the inward than in the outward direction, even though such inward potassium currents never occur in myocardial cells

iodothyronine molecule formed by the coupling of the phenyl rings of two iodinated tyrosine molecules in an ether linkage

ion channel opening through the plasma membrane composed of several polypeptide subunits that span

the membrane and contain a gate that determines whether the channel is open or closed; regulates the flow of ions across the membrane in all cells

ion pump integral membrane protein that uses energy derived from adenosine triphosphate hydrolysis to drive ion movement across the membrane against the electrochemical gradient, for example, Na+/K+-ATPase

ionotropic type of membrane receptor that is a channel that opens (or closes) when the receptor is bound by ligand

ionotropic receptor receptors that are coupled directly to ion channels; fast excitatory postsynaptic potentials in the enteric nervous system are mediated by ionotropic receptors

iron profile blood tests including serum iron, ferritin, total iron-binding capacity, transferrin, and transferrin saturation

iron deficiency anemia condition characterized by decreased healthy red blood cell count because of a dietary iron deficiency and, hence, functioning hemoglobin

irreversible shock stage of shock in which the function of organs needed to maintain cardiac output and blood pressure (heart and brain) is so compromised that the person cannot survive even with prompt and aggressive medical intervention

irritable bowel syndrome (IBS) group of functional bowel disorders in which abdominal discomfort or pain is associated with defecation or a change in bowel habit and with features of disordered defecation

irritant receptors rapidly adapting receptor that is found in the large conducting airways and that is sensitive to irritation by noxious substances

ischemia reperfusion condition in which blood flow is restricted, followed by normal blood flow being reestablished. This condition leads to the formation of reactive oxygen species, which often leads to tissue damage

ischemic phase (of the endometrial cycle) phase in which necrotic changes and abundant apoptosis occur in the secretory epithelium as it collapses

islets of Langerhans cell clusters in the pancreas that form the endocrine part of that organ and that secrete insulin and other hormones

isocaproic acid product of side-chain cleavage of cholesterol

isoelectric in cardiovascular physiology, the portion of the normal electrocardiogram where the tracing is at zero or near-zero potential, which occurs in the PR and ST intervals

isograft transplantation between genetically identical people

isohydric principle idea that all buffer systems in a solution are in equilibrium with the same hydrogen ion concentration

isometric contraction contraction at constant length that produces force but no muscle shortening

isometric exercise form of exercise involving the contraction of a muscle without the shortening of the angle of the joint

isosmotic see osmotic pressure

isotonic denoting a solution having the same osmotic pressure as some other solution, especially one in a cell or a body fluid

isotonic contraction muscle contraction at constant force that produces a change in length

isotonic solution see tonicity

isovolumic contraction portion of systole in which all valves are closed, and therefore, blood does not enter or exit the heart

isovolumic relaxation portion of diastole in which all valves are closed, and therefore, blood does not enter or exit the heart

isthmus portion of the oviduct connecting the ampulla to the uterus

Ito cells perisinusoidal cells that contain lipid droplets in the cytoplasm and that function in the storage of fat. During the inflammatory process, these cells have the ability to transform into myofibroblasts, which secrete collagen into the space of Disse and regulate sinusoidal portal pressure by contracting or relaxing. Ito cells may be involved in the pathologic fibrosis of the liver; also known as stellate cells

J receptors unmyelinated C-fiber nerves that are located adjacent to alveoli that are stimulated by stretch; also referred to as juxtapulmonary capillary receptors or C-fiber endings

junctional complex functional unit in muscle comprising both dihydropyridine and ryanodine receptors

juxtaglomerular apparatus structure in the kidney consisting of macula densa, extraglomerular mesangial cells, and granular cells, located where the end of the thick ascending limb touches afferent and efferent arterioles of its parent glomerulus

juxtamedullary nephron nephron with its glomerulus deep in the cortex, next to the medulla, and having long loops of Henle

juxtapulmonary capillary receptors see J receptors

kallidin see lysyl-bradykinin

kallikrein serine protease released by the acinar cells that acts on endogenous peptides present in body fluid to release lysyl-bradykinin (kallidin), which causes dilation of the blood vessels supplying the salivary glands

Kallmann syndrome syndrome characterized by a congenital absence of gonadotropin-releasing hormone in the hypothalamus (causing, in women, primary amenorrhea and anovulation and, in men, failure of puberty) in combination with a congenitally absent sense of smell

ketoacidosis condition found in diabetics that is characterized by large amounts of β-hydroxybutyric acid in the blood

ketogenesis process by which ketone bodies are produced as a result of fatty acid breakdown

ketones acidic substances produced when the body uses fat, instead of sugar, for energy

ketosis condition observed in diabetic patients and during periods of prolonged starvation that is marked by highly elevated levels of circulating ketone bodies

17-ketosteroids excretable metabolite formed by lysis of the carbon 20 to 21 side chain of 21-carbon steroids

kilocalorie unit of measurement for energy that approximates the heat energy needed to increase the temperature of 1 kg of water by 1°C, equivalent to the dietary “calorie”

kinesin microtubule-associated protein involved in anterograde axonal transport of organelles and

vesicles (from the minus to the plus ends of the microtubules) via the hydrolysis of adenosine triphosphate

kininogen endogenous peptide present in body fluid that releases lysyl-bradykinin (kallidin)

kinins mediator of the inflammatory response

kinocilium nonmotile cilium-like structure on each hair cell of the human ear involved in converting mechanical movement of endolymph into electrical signals

Klinefelter syndrome congenital abnormality of men in which there is one X chromosome too many; men with this condition are usually sterile

Korotkoff sounds sounds made by the first spurts of blood escaping from a compressed artery as the compression is slowly released. They are detected by stethoscope in the measurement of arterial pressure by sphygmomanometer and used as the indicator of peak systolic pressure

Krebs cycle series of mitochondrial chemical reactions that produces adenosine triphosphate in the presence of O2, a process called oxidative phosphorylation

Kupffer cells one of the types of cells lining hepatic sinusoids; resident macrophages of the "fixed monocyte–macrophage system" that act in the removal of unwanted material (bacteria, viral particles, etc.) from the circulation through endocytosis

Kussmaul respiration labored, deep breathing that accompanies severe uncontrolled diabetes

labeled line concept that the central nervous system identifies a particular sensation on the basis of the pathway by which it arrives at the brain

lactation secretion of milk

lactational amenorrhea period of time with no menstrual cycles, resulting from lactation

lactic acid end product of glycolysis that accumulates under anaerobic conditions and is oxidized in the Krebs cycle in muscle

lactiferous ducts primary milk ducts

lactoferrin protein that binds iron

lactogenesis milk production by alveolar cells; also known as lactogenic activity

lactose intolerance condition in which the ingestion of milk products results in severe osmotic diarrhea

lactotrophs cells located in the anterior pituitary that secrete prolactin

lacunae blood-filled spaces formed in the endometrium

lag phase of gastric emptying time required for the grinding action of the antral pump to reduce the size of larger particles to particles of sufficiently small size for emptying (i.e., $< \approx 7$ mm)

Lambert-Eaton myasthenic syndrome (LEMS) rare presynaptic disorder of neuromuscular transmission in which quantal release of acetylcholine is impaired, causing a unique set of clinical characteristics, which include proximal muscle weakness, depressed tendon reflexes, posttetanic potentiation, and autonomic changes

lamellar inclusion bodies electron-dense bodies found in type II epithelial cells of the alveoli that are the storage sites of lung surfactant

laminar flow relative motion of elements of a fluid along smooth parallel paths, which occurs at lower

values of Reynolds number

laminin external filamentous muscle protein that forms a link between integrins and the extracellular matrix

Langerhans cells dendritic epidermal cell present in lymph nodes and other organs

laryngospasm severe constriction of the larynx in response to the introduction of water, allergies, or noxious stimuli

latch state modification of the crossbridge cycle in smooth muscle that results in long contractions with little expenditure of energy

latency period time period between stimulus onset and response occurrence

latent heat of evaporation energy required to overcome the molecular forces of attraction between the particles of a liquid and to bring them to the vapor state, in which such attractions are minimal

lateral inhibition capacity of an excited neuron to reduce the activity of its neighbors

lateral sulcus (sylvian fissure) deep valley that separates the temporal lobe from the frontal and parietal lobes of the brain

LDL receptors low-density lipoprotein receptors; receptors present on the surface of steroid-producing and other cells; bind cholesterol-containing LDL particles in the blood

leak channels channels that are always open, allowing the passage of sodium ions (Na^+) and potassium ions (K^+) across the membrane to maintain the resting membrane potential of −70 mV; also called passive channels

lecithin cholesterol acyltransferase (LCAT) plasma enzyme that is responsible for the esterification of cholesterol in the plasma to form cholesterol ester with the fatty acid derived from the 2 position of lecithin

left atrium left upper muscular chamber of the heart, which receives blood from the pulmonary veins and delivers it through the mitral valve into the left ventricle

left bundle-branch block condition in which transmission of action potentials is blocked in the left branch of the bundle of His

left ventricle left lower muscular chamber of the heart, which receives blood from the left atrium and delivers it through the aortic valve into the aorta

left ventricular end-diastolic pressure (LVEDP) blood pressure within the left ventricle at the end of diastole; function of both the volume contained within the ventricle and ventricular compliance

left ventricular end-diastolic volume (LVEDV) volume of blood in the ventricle at the end of diastole and just before the initiation of ventricular contraction that determines the passive stretch on myocardium before contraction and, therefore, is considered the equivalent of muscle preload in the heart in situ

left ventricular hypertrophy abnormally increased muscle mass in the left ventricle, occurring in response to any factor that chronically increases wall stress on the ventricle, such as systemic arterial hypertension or a stenotic aortic valve

length–tension curve expression of the isometric force a muscle can produce at different fixed lengths

leptin anorexigenic hormone released by white fat cells (adipocytes); levels increase as fat stores increase

leukemia bone marrow cancer resulting in uncontrolled proliferation of leukocytes

leukocyte see white blood cell

leukocytosis condition characterized by a higher-than-normal number of circulating white blood cells

leukopenia condition characterized by a lower-than-normal number of circulating white blood cells

leukotrienes mediator of the inflammatory response

levator ani muscle compound muscle of the pelvic floor formed by pubococcygeus and iliococcygeus muscles that functions to resist prolapsing forces and draws the anus upward following defecation; supports the pelvic viscera

lever system system of bones and joints that confers a mechanical advantage (or disadvantage) on a skeletal muscle

Lewis hunting response response characterized by an intermittent supply of warm blood to cold-exposed extremities via vasodilation that recurs in 5- to 10-minute cycles to provide some protection from the cold

Leydig cells cells within the seminiferous tubules of the testicles that produce testosterone

Liddle syndrome autosomal dominant disorder characterized by hypertension associated with low plasma renin activity, metabolic alkalosis due to hypokalemia, and hypoaldosteronism; one of several conditions with this unusual set of characteristics known collectively as pseudohyperaldosteronism

ligand molecule that binds to another, that is, a hormone or neurotransmitter that binds to a receptor

ligand-gated ion channels channels in membrane receptors that open (or close) when a ligand binds the receptor

limbic system interconnected structures in the central nervous system associated with olfaction, emotion, motivation, and behavior; includes amygdala, cingulate gyrus, hippocampus, hypothalamus, olfactory cortex, and thalamus

lipid bilayer structure formed by spontaneous assembly of amphipathic lipid molecules in an aqueous solution; hydrophobic regions or fatty acids are buried in the interior, and hydrophilic head groups are on the exterior, in contact with the solution

lipid rafts highly organized, free-floating “microdomains” within the plasma membrane that are aggregates of sphingolipids and cholesterol; serve to compartmentalize cellular processes by serving as organizing centers for the assembly of signaling molecules, influencing membrane fluidity and membrane protein trafficking, and regulating neurotransmission and receptor trafficking

lipocortin substance that inhibits the activity of phospholipase A2

lipogenesis conversion of carbohydrates and organic acids to fat

lipolysis mobilization of fatty acids from triglycerides stored in adipose tissue

lipopolysaccharide (LPS) major component of gram-negative bacterial membrane

lipoprotein lipase enzyme responsible for hydrolysis of triacylglycerol molecules packaged and transported in very-low-density lipoprotein particles to fatty acids, which can then in turn be metabolized for energy

lipoproteins complexes or compounds containing lipid and protein. The intestine produces two major

classes of lipoproteins: chylomicrons and very-low-density lipoproteins

β-lipotropin substance derived from proopiomelanocortin that may have effects on lipid metabolism

lithium-induced polyuria excretion of large volumes of dilute urine occurring in patients receiving chronic lithium therapy for psychiatric disorders

lithocholic acid carcinogenic secondary bile acid derived from chenodeoxycholic acid

liver lobule basic functional unit of the liver, which is hexagonal in shape and built around a central vein

loading phase flat portion of the oxygen–equilibrium curve that reflects the loading of oxygen onto blood hemoglobin

local axon reflex pathway for propagation of action potentials within a portion of a neuron; does not pass through the cell body

local excitatory current current through an axon membrane created by the generator potential that provides the link between the formation of the generator potential and the excitation of the nerve fiber membrane

locus caeruleus collection of noradrenergic neurons in the rostral pons that innervate widespread areas of the cerebrum, brainstem, and spinal cord

long hypophyseal portal vessels vessels that deliver blood to the anterior pituitary

long-loop reflexes reflexes that require processing by several spinal or higher levels

long-term memory memory that can last as little as a few days or as long as decades; includes declarative and nondeclarative subtypes

long-term potentiation increased synaptic excitability and altered chemical state on repeated synaptic stimulation with a persistence beyond the cessation of electrical stimulation; thought to underlie learning and memory and be dependent on Ca^{2+} entry through activation of N-methyl-d-aspartate receptors

loop of Henle portion of the nephron leading from the proximal straight tubule to the distal convoluted tubule; main function is to create a concentration gradient in the medulla of the kidney: a countercurrent multiplier system using sodium pumps creates an area of high concentration near the collecting duct; water present in the filtrate in the collecting duct flows through aquaporin channels out of the collecting duct, moving passively down its concentration gradient; this process reabsorbs water and creates a concentrated urine for excretion

low-density lipoprotein (LDL) complex containing a single apolipoprotein B100 molecule, fatty acids, and cholesterol that transports cholesterol and fatty acids to cells; also known as bad cholesterol

lower esophageal sphincter smooth muscle sphincter separating the esophagus from the stomach

L-type Ca^{2+} channels voltage-gated channels that conduct primarily depolarizing Ca^{2+} currents into myocardial cells and nodal tissue during phase 2 of the action potential. The gates are opened and closed by membrane depolarization in a manner analogous to that seen for voltage-gated sodium channels except that their opening and closing kinetics are slower

lung compliance (Cl) measure of lung distensibility; represented by $\Delta volume/\Delta pressure$

lung diffusion capacity amount of oxygen taken up by the lung per minute per mm Hg of oxygen partial pressure

lung inflation reflex see Hering-Breuer reflex

lung lavage medical procedure in which a bronchoscope is passed through the mouth or nose into the lungs and fluid is squirted into a small part of the lung and then recollected for examination; often referred to as bronchoalveolar lavage

luteal insufficiency condition in which the corpus luteum does not produce sufficient progesterone to maintain pregnancy in the early stages

luteal phase part of the menstrual cycle during which progesterone is produced; lasts 14 days

luteinization maturation of the corpus luteum

luteinizing hormone (LH) hormone secreted by the pituitary gland in the brain that stimulates the growth and maturation of eggs in females and sperm in males

luteinizing hormone–releasing hormone (LHRH) polypeptide from the hypothalamus that stimulates secretion of follicle-stimulating hormone and luteinizing hormone; also known as gonadotropin-releasing hormone (GnRH)

luteolysis process of regression of the corpus luteum; also known as luteal regression

lymph transparent, slightly yellow liquid, found in the lymphatic vessels and derived from tissue fluid

lymph node lymphoid organ filled with leukocytes

lymphagogic effect marked increase in lymph flow that plays an important role in the transfer of lipoproteins from the intercellular spaces to the central lacteal vessel

lymphatic bulbs blind lymphatic end tubes that are the origin of lymphatic vessels in the microcirculation

lymphatic vessels flexible, predominantly endothelial vessels that drain the interstitium of plasma filtrate from the capillaries and send the fluid back into the venous side of the circulation at the level of the right atrium. Larger vessels contain one-way valves directed away from the tissues and toward the heart. Muscle cells in the bulb ends of the vessels help with forward flow of fluid into larger lymphatic vessels

lymphoblast stem cell committed to differentiate into lymphocytes

lymphocyte agranular leukocyte: B cell, T cell, or null cell; involved in body defenses against disease

lymphoid organs organs that include bone marrow and thymus (primary) and lymph follicles, lymph nodes, spleen, thymus, and tonsils (secondary)

lymphoid series series of morphologically distinguishable cells once thought to represent stages in lymphocyte development; now known to represent various forms of mature lymphocytes

lymphokine cytokine made by lymphocytes

lymphokine-activated killer cell (LAK) cell derived from natural killer cells

lymphoma cancer of the lymphatic system

lysis decomposition or destruction of cells by antibodies called lysins

lysozyme bacteriolytic enzyme

lysyl-bradykinin potent vasodilator that causes dilation of the blood vessels that supply the salivary glands; also known as kallidin

M line thin line in middle of H zone of muscle

macrocyte larger-than-normal erythrocyte

macrophage phagocytic tissue cell, derived from monocytes

macula sensory structure in each semicircular canal of the vestibular apparatus, used to sense rotation

macula densa closely packed group of densely staining cells in the distal tubular epithelium of a nephron, in direct apposition to the juxtaglomerular cells; they may function either as chemoreceptors or as baroreceptors feeding information to the juxtaglomerular cells

macula lutea area of the retina about 1 mm2 in area, specialized for very sharp color vision

magnocellular neurons hypothalamic neurons with large cell bodies that synthesize arginine vasopressin and oxytocin

major depression one of a class of illnesses marked by abnormal mood regulation and associated signs and symptoms called affective disorders or mood disorders. Major depression can be so profound as to provoke suicide

major histocompatibility complex (MHC) gene-encoding proteins involved in antigen presentation

malignant hyperthermia life-threatening condition resulting from a genetic sensitivity of skeletal muscles to volatile anesthetics and depolarizing neuromuscular-blocking drugs that occurs during or after anesthesia

malonyl-CoA condensation product of malonic acid and coenzyme A and an intermediate in fatty acid synthesis

mammary glands paired structures on the thoracic wall of both sexes; in females, they secrete milk

mammillothalamic tract neuroanatomical tract in the limbic system connecting the neurons in the mammillary bodies of the hypothalamus with the anterior nucleus of the thalamus

mammogenesis differentiation and growth of the mammary glands

manometric related to pressure measurements (in this context, within the gut lumen)

manometric catheter gut manometry is the measurement of intraluminal pressures in a segment of the gut to study its motor function: contractions of muscles within or around the gut wall produce intraluminal pressure waves that are detected by manometry

margination loose adhesion of leukocytes to endothelial cells

marrow stroma bone marrow tissue that is not directly involved in hematopoiesis but provides the necessary microenvironment and factors for it

mast cell connective tissue cell in the intestine that releases paracrine signals, such as histamine, to act at receptors on enteric neurons; functionally resembles basophil

maternal recognition of pregnancy the secretion of human chorionic gonadotropin by a developing embryo to sustain the corpus luteum

maximal oxygen uptake (Vo2 max) highest rate at which oxygen can be taken up and used during exercise. The derivation is V = volume per time, O2 = oxygen, and max = maximum; expressed either as an absolute rate (L/min) or as a relative rate (mL/kg/min), the latter expression is often used to compare the performance of endurance sports athletes

maximal response greatest, most complete, or best response

maximal voluntary contraction (MVC) the peak isometric force that can be briefly generated for a

specific exercise; used as an index of muscle function and, more specifically, isometric work intensity

McCune-Albright syndrome (MAS) rare multisystem disorder characterized by replacement of normal bone tissue with areas of abnormal fibrous growth (fibrous dysplasia), patches of abnormal skin pigmentation (i.e., areas of light-brown skin [café au lait spots] with jagged borders), and abnormalities in the glands that regulate the body's rate of growth, its sexual development, and certain other metabolic functions (multiple endocrine dysfunction)

mean circulatory filling pressure equilibrium pressure throughout all components of the vascular system when cardiac output is zero

mean corpuscular hemoglobin (MCH) index of average hemoglobin per erythrocyte

mean corpuscular hemoglobin concentration (MCHC) index of average hemoglobin in circulating erythrocytes

mean corpuscular volume (MCV) index of average volume of each erythrocyte

mean electrical QRS axis average vector representing the wave of depolarization through the ventricles

mean platelet volume (MPV) evaluates size of platelets

mechanical obstruction any physical obstacle to the caudal movement of intestinal contents, including tumors, scar tissue, or volvulus (twisting); distinguished from a functional obstruction, which is a result of absent or abnormal contractions of the intestine

mechanoreceptors sensory receptors that respond to physical deformations both externally and internally

medial forebrain bundle fiber bundle interconnecting the brainstem (especially the midbrain tegmentum) with the hypothalamus, nucleus accumbens, and basal forebrain

medial prefrontal area region of frontal lobe cerebral cortex involved in coordination of autonomic responses to olfactory and emotional stimuli

median effective dose (ED50) concentration of a substance (e.g., hormone) required to produce a response halfway between the maximal and basal responses

median eminence region in the floor of the hypothalamus that allows release of neurohormones and access to the hypothalamus of blood-borne substances

medulla innermost portion of an organ or structure

medullary reticulospinal tract descending inhibitory brainstem pathway to spinal interneurons that originates in the medulla

medullary tissue part of the indifferent gonad of the embryo, which will become the testicular components

megacolon colon filled with impacted feces above the terminal aganglionic region of large intestine in Hirschsprung disease

megakaryocyte bone marrow precursor cell for platelets

megaloblast nucleated, large, abnormal red blood cell

megaloblastic anemia condition in which red blood cell maturation in the bone marrow is abnormal, possibly resulting from vitamin B12 or folic acid deficiency

meiosis process of two consecutive cell divisions in the diploid progenitors of sex cells, resulting in four rather than two daughter cells, each with a haploid set of chromosomes

Meissner plexus named for Georg Meissner (1829 to 1905), a German histologist; see also submucosal plexus

melanin pigment that in humans is the primary determinant of skin color; in the pigment epithelium of the eye, melanin helps to sharpen an image by preventing the scattering of stray light

α-melanocyte–stimulating hormone (α-MSH) hormone derived from proopiomelanocortin that regulates feeding in humans

melatonin hormone released by the pineal gland in darkness; the mechanism by which the suprachiasmatic nucleus of the hypothalamus regulates diverse functions in a diurnal fashion

membrane lipid bilayer that acts as a boundary to various cellular structures or the environment

membrane attack complex (MAC) complement proteins that form a channel in the target cell membrane

membrane potential difference between voltage measured inside a cell and the value (0) detected by a reference electrode located in the extracellular fluid

membrane-associated dense bodies dense bodies associated with cell margins that serve as anchors for thin filaments and transmit the force of contraction to adjacent cells; also called focal adhesions

memory cell T or B cell that recognizes previously encountered antigens

menaquinones vitamin K derived from bacteria in the small intestine

menarche beginning of menstrual cycles during pubertal development in girls

Ménière disease disorder of the inner ear that can affect hearing and balance to a varying degree and is characterized by episodes of both vertigo and tinnitus and by progressive hearing loss, usually in one ear

menopause final menses at the end of the reproductive cycle in the female

menstrual cycle monthly reproductive cycle in which periodic uterine bleeding occurs

menstrual phase or menses or menstruation bleeding phase of the menstrual cycle or endometrial cycle, which lasts about 5 days

mesangial cell specialized cell found between capillary loops in the glomerulus, which has supportive, phagocytic, and contractile functions

mesolimbic/mesocortical system projection of dopaminergic neurons from the midbrain ventral tegmental area to the limbic system, especially the prefrontal cortex, nucleus accumbens, and hypothalamus

mesonephric (wolffian) ducts ducts that give rise to the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts in male

messenger low molecular weight diffusible molecule used in signal transduction to relay signals within a cell

metabolic acidosis abnormal condition in which the blood becomes too acidic, leading to a decrease in pH. The acidosis is a result of any cause other than elevated carbon dioxide level

metabolic alkalosis abnormal process characterized by a gain of strong base or bicarbonate or a loss of acid (other than carbonic acid), which results in a rise in arterial blood pH

metabolic bone diseases diseases characterized by ongoing disruption of the normal processes of either bone formation or bone resorption

metabolic clearance rate (MCR) volume of plasma cleared of a substance, such as a hormone, in question per unit time

metabolic syndrome cluster of conditions that often occur together, including obesity, high blood glucose, hypertension, and high triglycerides, which can lead to cardiovascular disease

metabotropic characteristic of receptors that do not form an ion channel, instead, causing indirect alterations in current via signal transduction mechanisms or causing only metabolic changes

metabotropic receptor (mGLUR) type of receptor that is linked through G proteins to intracellular production of 1,2-diacylglycerol and inositol 1,4,5-trisphosphate

methemoglobin (metHb) abnormal hemoglobin with oxidized ferric iron

methylene blue component of blood dyes such as Wright stain

MHC class I molecule molecules found in every nucleated cell of the body that bind peptides mainly generated from degradation of cytosolic proteins; see also major histocompatibility complex

MHC class II molecule molecules found only on antigen-presenting cells (macrophages, dendritic cells, and B cells); see also major histocompatibility complex

micellar emulsification process that enhances the delivery of lipid to the brush border membrane by making it water soluble

micelle aggregate of surfactant molecules dispersed in a liquid colloid

microalbuminuria condition characterized by the excretion of 30 to 300 mg of serum albumin in the urine per day, usually a sign of kidney disease

microcirculation region of the circulation involved with the control of blood pressure, blood flow, and transcapillary transport of substances, composed of terminal arterioles, capillaries, and venules

microfilaments elements of the neuronal cytoskeleton that are composed of actin, are 4 to 5 nm wide and about a micrometer in length (except in growth cones, where they can be much longer), and are concentrated in dendritic spines, growth cones, and presynaptic terminals

microglia glial cells in the CNS serving an immune function similar to macrophages

microspherocyte erythrocyte that is smaller than normal

microtubules elements of the neuronal cytoskeleton responsible for the rapid movement of material in axons and dendrites; composed of a core polymer of 50-kDa tubulin subunits that align to form protofilaments, several of which join laterally to form a hollow tube whose diameter is about 23 nm

microtubule-associated proteins (MAPs) accessory proteins associated with microtubules that bind tubulin and, in neurons, are thought to be required for specific sorting of materials to axons or dendrites

microvilli numerous closely packed villi that cover the enterocytes to amplify further the villi that increase the surface area of the small intestine

micturition emptying of the urinary bladder; also known as urination

middle cervical ganglia middle of the three sympathetic ganglia located in the neck

middle ear portion of the ear, containing the ossicles, that couples eardrum movements to the sensory

structures of the inner ear

migrating motor complex (MMC) organized, distinct, cyclically recurring and distally propagating sequence of contractile activity occurring in the small intestine during the fasting state; may be associated with similar activities in the stomach and proximal colon

milk ejection release of stored milk from the mammary glands by the action of oxytocin; also known as milk letdown

milliequivalent (mEq) one-thousandth of an equivalent; calculated from the product of millimoles times valence

mineralocorticoid steroid hormone produced by the adrenal cortex and involved in the regulation of electrolyte and water balance

mineralocorticoid escape limitation of the salt-retaining effects of a mineralocorticoid hormone (such as aldosterone), expressed by increased renal sodium excretion despite the continued presence of high levels of mineralocorticoid

miosis pupillary constriction

mitochondria membrane-bound organelle that supplies energy in the form of adenosine triphosphate to cells

mitochondrial permeability transition pore (MPTP) protein pore that is formed in the membranes of mitochondria under certain pathologic conditions; induction of MPTP can lead to mitochondrial swelling and cell death

mitochondrial voltage-dependent anion channel (VDAC) channel for metabolite diffusion across the mitochondrial outer membrane

mitogen agent that induces proliferation; many growth factors and hormones are mitogens

mitogenic agent agent that stimulates the growth of target tissues

mitosis replication of a cell to form two daughter cells with identical sets of chromosomes

mitral valve thin, flexible, bileaflet structure that separates the left atrium from the left ventricle. It opens into the left ventricle during diastole but closes off the left atrium when the left ventricle contracts

mitral valve prolapse condition whereby either the mitral valve bulges or the leaflets open backward into the pulmonary vein during systole. In the latter case, blood flows back into the pulmonary circulation from the left ventricle during systole

mittelschmerz (German for “middle pain”) lower abdominal and pelvic pain that occurs roughly midway through a woman’s menstrual cycle, associated with ovulation; pain can appear suddenly and usually subsides within hours

mixed acid–base disturbance simultaneous presence of two or more primary acid–base disturbances

mixed contractions skeletal muscle contractions that begin isometrically and become isotonic as force becomes sufficient to lift the afterload

mixed micelles substance that aids in rendering lipid digestion products water soluble. Mixed micelles diffuse across the unstirred water layer and deliver lipid digestion products to the enterocytes for absorption

mixing motility pattern motility pattern of the digestive state

M-mode echocardiography ultrasound image of the heart used to examine motion of the ventricular walls, changes in chamber size, and valve motion during the cardiac cycle

modulator peptide released at a synapse that modifies the response of a coreleased transmitter interacting with its own receptor in the synapse

molecular switch intracellular protein that can transition between "on" and "off" states in response to a cellular stimuli (e.g., G protein)

monoamine oxidase (MAO) a mitochondrial enzyme that degrades catecholamines by removing the amine

monoamine oxidase inhibitors (MAOIs) powerful class of antidepressant drugs

monoaminergic type of neuron that uses a catecholamine or indolamine as a neurotransmitter

monoblast stem cell committed to differentiate into monocytes

monocyte agranular phagocytic white blood cell that is a precursor of macrophages

monocytic series succession of developing cells that ultimately culminates in the monocyte

monoiodotyrosine (MIT) iodinated tyrosine in peptide linkage in the thyroglobulin structure

monokine cytokine made by monocytes

mononuclear leukocyte agranulocyte: either lymphocyte or monocyte

mood sustained emotional state

mood disorders see affective disorders

morula solid ball of cells that develops from a fertilized egg and enters the uterus at day 3 to 4 following fertilization

mossy fibers afferent axons to the cerebellum from pontine nuclei

motilin signal peptide released from enteroendocrine cells and associated with the onset of the migrating motor complex

motility movements within the intestinal tract, encompassing the phenomena of contractile activity, myoelectrical activity, tone, compliance, wall tension, and transit within the gastrointestinal tract

motor endplate see myoneural junction

motor neuron nerve cell that sends an axon to a muscle or, by extension, any effector

α motor neuron innervates the extrafusal muscle fibers, which are responsible for force generation

γ motor neuron controls contraction of the intrafusal muscle cells within a muscle spindle

motor unit alpha motor neuron, its axon, and all the muscle fibers controlled by that motor neuron

motor unit summation see spatial summation

mucin one of two major proteins (a glycoprotein high in carbohydrate) present in saliva that form gels in solution; the most abundant and produced mainly by the sublingual and submandibular salivary glands. Mucins lubricate the mucosal surface and protect it from mechanical damage by solid food particles. Mucins may also provide a physical barrier in the small intestine against the entry of microorganisms into the mucosa

mucous cells cells that line the entire surface of the gastric mucosa and the openings of the cardiac, pyloric, and oxyntic glands; secrete mucus and bicarbonate to protect the gastric surface from the acidic environment of the stomach

mucous gel layer layer covering the surface of the gastric mucosa that traps bicarbonate and neutralizes acid, thus preventing damage to the mucosal cells

mucous neck cells one of several types of cells in the oxyntic glands. The neck region in the gland is where mucous cells are most numerous. Mucous neck cells secrete mucus

müllerian-inhibiting substance (MIS) glycoprotein that inhibits cell division of the müllerian ducts; also known as antimüllerian hormone

multidrug resistance insensitivity of various tumors to a variety of chemically related anticancer drugs; mediated by a process of inactivating the drug or removing it from the target tumor cells

multidrug resistance–associated protein (MRP) transporters class of ABC transporters that interfere with antibiotic therapy and chemotherapy

multiple myeloma typically incurable cancer of plasma cells

multiple sclerosis demyelinating autoimmune disease

multipotent stem cell cell, such as hematopoietic stem cell, that can give rise to different specialized cells

multiunit-type smooth muscle type of smooth muscle that predominates in the pupil of the eye and urinary bladder; it does not contract spontaneously, is not activated by stretch, and expresses structured neuromuscular junctions; contrast with unitary-type smooth muscle

mural granulosa cells cells attached to the basement membrane in a graafian follicle

muramidase lysozyme that can lyse the muramic acid of certain bacteria (e.g., Staphylococcus); present in saliva in small amounts

muscarine compound found in poisonous mushrooms that activates receptors for acetylcholine known as muscarinic receptors

muscarinic receptor metabotropic-type receptor for acetylcholine

muscle chemoreflex reflex initiated by stimulation of the chemosensitive nerve endings as a result of a mismatch between skeletal muscle blood flow and an increase in metabolites that stimulate

muscle fibers contractile cells of a muscle

muscle stretch reflex contraction of a skeletal muscle provoked by a sudden stretch of its tendon

muscularis externa longitudinal and circular muscle coats of the stomach wall (one of four layers); lies over the submucosa and differs from that of other GI organs in that it has three layers of smooth muscle instead of two

musculomotor neuron neuron that innervates the gastrointestinal musculature

myasthenia gravis autoimmune disease that produces weakness by reducing the number of postsynaptic acetylcholine receptors in skeletal muscle

mydriasis pupillary dilation

myelin lipid structure formed by oligodendrocytes in the central nervous system or Schwann cells in the

peripheral nervous system that wraps around neuronal axons and serves to increase the speed with which they conduct action potentials

myelin sheath the lipid surrounding many axonal processes that acts to insulate that portion of the axon

myeloblast stem cell committed to differentiate into cells of the myeloid series

myeloid series various stages of cell development such as those seen in the granulocytic and erythrocytic series

myenteric plexus ganglionated plexus of the enteric nervous system situated between the longitudinal and circular muscle coats of the muscularis externa of the digestive tract; also known as Auerbach plexus

myocardial infarction pathologic condition in which myocardial tissue has died. This usually results from extended exposure of the tissue to ischemic conditions

myocardial ischemia any condition in which the oxygen supply to myocardial tissue cannot meet the oxygen demand of that tissue

myoclonus brief, involuntary muscle twitches that commonly occur during light sleep

myoepithelial cells cells that surround milk-secreting alveolar cells and that contract and expel milk from the lactiferous duct in response to oxytocin

myofibrils longitudinal columns of series-connected sarcomeres in a skeletal muscle

myogenic originating in muscle tissue

myogenic mechanism regulatory mechanism whereby arteries or veins contract in response to an increase in transmural pressure. It is related to activation of stress-operated calcium channels in the smooth muscle itself that open with stretch, thereby increasing calcium entry into the cells and causing contraction of vascular smooth muscle. It is one mechanism responsible for the ability of organs to autoregulate their blood flow in the face of changes in perfusion pressure

myoglobin oxygen-binding protein in skeletal muscle that facilitates oxygen diffusion

myokines are endocrine-like peptides that are released during muscle contraction that exert a local effect on muscle metabolism, repair, tissue regeneration, and immunomodulation

myometrium outer part of the uterus, composed of multiple layers of smooth muscle

myoneural junction see neuromuscular junction

myopathic pseudoobstruction pathologic failure of propulsion in the gastrointestinal tract related to muscular degeneration and weakened contractility

myopia (nearsightedness) condition caused by the eyeball being physically too long to focus on near objects

myosin fibrous protein dimer that makes up both the structural and chemically active portions of the thick filaments in muscle

myosin light-chain kinase (MLCK) calcium/calmodulin-dependent enzyme that phosphorylates the light chains of smooth muscle myosin and initiates contraction. In skeletal muscle, phosphorylation modulates tension during contraction

myosin light-chain phosphatase (MLCP) enzyme that catalyzes the dephosphorylation of the regulatory light chains of muscle, particularly those of smooth muscle myosin

myosin-linked regulation muscle control system that is based on controlled alteration of the constituents of the myosin filaments

myotatic another name for the muscle stretch reflex

myxedema puffy appearance to the face, hands, and feet as a result of hypothyroidism

Na+/K+-ATPase plasma membrane protein that uses the energy of adenosine triphosphate hydrolysis to transport three Na+ ions out of the cell while transporting two K+ ions into the cell; it is a P-type ATPase because the protein is phosphorylated during the transport cycle

NADPH oxidase enzyme-producing superoxide as part of a respiratory burst

NADPH–cytochrome P-450 reductase (NADPH–cytochrome C reductase) the enzyme in the cytochrome P-450 complex that is responsible for the phase I reactions of the drug biotransformation. Specifically, it reduces the drug complexed with cytochrome P-450 so as to make it a more polar compound

narcolepsy neurologic disorder characterized by excessive daytime sleepiness, cataplexy (sudden loss of muscle tone), and vivid hallucinations at sleep onset or on awakening

natriuresis increase in renal sodium excretion

natural killer (NK) cell cytotoxic lymphocyte and major component of the immune system; plays major role in the rejection of tumor and cells infected by virus; kills cells by releasing perforin and granzyme, which cause the target cell to die by apoptosis

nebulin filamentous muscle protein that may play a role in stabilizing thin filament length during muscle development

necrosis unprogrammed cell death, less orderly than apoptosis, results from acute tissue injury; initiates an immune response to remove cell debris (immunogenic)

negative cooperativity cooperativity in which the dissociation constant for each successive ligand bound is higher than for the one preceding it, so that the binding affinity is successively decreased

negative feedback type of feedback in which the system responds in an opposite direction to the perturbation

negative selection process by which T cells that recognize self-MHC (major histocompatibility complex) molecules with high affinity are deleted from the repertoire of cells, producing central tolerance and preventing autoimmunity; occurs after positive selection

neonatal respiratory distress syndrome syndrome of premature infants in which developmental insufficiency of surfactant production and structural immaturity of the lungs cause pulmonary edema and atelectasis; also known as infant respiratory distress syndrome or IRDS

nephrogenic diabetes insipidus condition characterized by lack of response of collecting ducts in the kidney to arginine vasopressin

nephrolithiasis kidney stone disease

nephrin protein necessary for the proper functioning of the renal filtration barrier, which consists of fenestrated endothelial cells, the glomerular basement membrane, and the podocytes of epithelial cells; nephrin is a transmembrane protein involved with the filtration slit diaphragm

nephron basic unit of kidney structure and function, consisting of a renal corpuscle and its attached

tubule

nephrotic syndrome kidney disorder characterized by edema, proteinuria, hypoproteinemia, and, usually, elevated blood lipids

Nernst equation chemical equation that allows calculation of the equilibrium potential for any ion

Nernst equilibrium potential value of the electrical potential difference across the plasma membrane that is necessary for a specific ion to be at equilibrium (no net transport)

nerve growth factor protein molecule that enhances nerve cell development and stimulates the growth of axons

neural networks aggregates of interconnected neurons that produce a range of behaviors associated with the central and enteric nervous systems

neural presbycusis progressive loss of the ability to hear high frequency with increasing age as the hair cells "wear out" over time

neuregulin axonally derived epidermal growth factor–like substance that causes glial cells to myelinate the axon

neuroendocrine both neural and endocrine in structure or function

neuroendocrine system coordinates the interaction of the endocrine and nervous systems to provide dual control in regulating homeostasis and many physiologic processes in the human body

neuroendoimmunology study of the interaction between the nervous, endocrine, and immune systems

neurofilaments cytoskeletal intermediate filaments in neurons that are found in both axons and dendrites and are thought to provide structural rigidity. Neurofilaments are composed of a 70-kDa core protein, are about 10 nm wide, and form ropelike filaments that are several micrometers in length

neurogastroenterology subdiscipline of gastroenterology that encompasses all basic and clinical aspects of nervous system involvement in normal and disordered digestive functions and sensations

neurogenic diabetes insipidus condition characterized by deficient production or release of arginine vasopressin; also called central, hypothalamic, and pituitary diabetes insipidus

neurogenic secretory diarrhea watery diarrhea that reflects stimulated activity of secretomotor neurons in the submucosal plexus

neurohormone neurotransmitters with endocrine effects

neurohypophysis neural portion of the hypophysis; also known as posterior pituitary

neuroleptics class of drugs used to treat schizophrenia and other psychotic disorders; also known as typical antipsychotics

neuromodulator neuropeptides that modulate the postsynaptic actions of a primary neurotransmitter

neuromuscular junction (NMJ) excitatory nicotinic synapse between a motor nerve terminal and a skeletal muscle fiber; also known as motor endplate and myoneural junction

neurons nerve cells

neuropathic pseudoobstruction pathological failure of propulsion in the gastrointestinal tract related to enteric neuropathy and loss of nervous control mechanisms

neuropeptide Y (NPY) neurotransmitter secreted by the hypothalamus associated with a number of physiologic processes in the brain, including the regulation of energy balance, memory and learning, and epilepsy, but its main effect is increased food intake and decreased physical activity

neurophysin part of the arginine vasopressin gene; important in the processing and secretion of arginine vasopressin

neuropil tangle of fine nerve fibers (dendrites and arborizations of axons) and their endings

neurosecretory (neuroendocrine) cells specialized nerve cells that directly convert a neural signal into a hormonal signal

neurotransmitter chemical substance released from nerve cells at synapses that amounts to a signal from one neuron to another or from motor neurons to effectors

neutropenia hematological disorder characterized by an abnormally low number of neutrophils

neutrophil most common type of granulocyte, which destroys pathogens by phagocytosis and respiratory burst

niacin water-soluble vitamin that is absorbed by the small intestine by calcium-dependent, carrier-mediated facilitated transport at low concentrations and by passive diffusion at high concentrations. Niacin plays an important role in coenzymes that participate in many oxidation–reduction reactions involving hydrogen transfer. It has been used to treat hypercholesterolemia for the prevention of coronary artery disease by decreasing plasma total cholesterol and low-density lipoprotein cholesterol and increasing plasma high-density lipoprotein cholesterol

nicotine compound found in tobacco that activates receptors for acetylcholine known as nicotinic receptors

nicotinic acetylcholine (ACh) receptor postsynaptic membrane–based protein assembly in the myoneural junction and at synapses in the central and autonomic nervous systems; its associated channel becomes permeable to Na+ and K+ ions when ACh is bound; stimulated selectively by nicotine and blocked by a specific class of receptor-blocking drugs

nicotinic receptor ionotropic-type receptor for acetylcholine

nigrostriatal system projection of dopaminergic neurons from the midbrain substantia nigra to the striatum (caudate and putamen) in the cerebrum and involved in control of movement; loss of these projections results in parkinsonism

nipple conical structure on the breast that is the external opening to the lactiferous ducts

nitrergic neurons neurons that use nitric oxide as a neurotransmitter

nitric oxide (NO) endothelial autocoid (biological factor that acts like a local hormone) that is a potent relaxer of vascular smooth muscle; it is released from the endothelium in response to calcium activation of the enzyme NO synthase (calcium activation can occur in response to activation of various receptors on the endothelial cell by circulating agonists and by shear forces on the endothelial cells); putative inhibitory neurotransmitter released by enteric motor neurons to gastrointestinal muscles; previously called endothelial-derived relaxing factor (EDRF)

nitric oxide synthase (NOS) enzyme that converts l-arginine to l-citrulline and nitric oxide

NMDA receptor glutamate receptor named for the synthetic analog that specifically activates it, N-methyl-d-aspartate; an ionotropic receptor that is a nonselective cation channel permeable to Na+, K+,

and Ca^{2+}

nociception experience of a stimulus as harmful in contrast to a pleasant sensation

nociceptors receptors that sense unpleasant or harmful stimuli, external and internal

nodes of Ranvier apposition between two internodes of myelin along an axon; a high concentration of voltage-gated Na^+ channels are localized here

nodose ganglion location of cell bodies of vagal afferent neurons

nonadrenergic noncholinergic (NANC) autonomic neurons that release neither norepinephrine nor acetylcholine

nonalcoholic steatohepatitis (NASH) presents as fat in the liver, along with inflammation and fibrosis; patients with NASH often feel healthy and are unaware they have a liver problem, but NASH can be severe and can lead to cirrhosis and consequent failure of the liver

nondeclarative or procedural memory memory for new skills and procedures; sometimes referred to as implicit memory

nonessential amino acids amino acids that are required for normal protein synthesis and that the body synthesizes from other amino acids; comprise 9 of the 20 total common amino acids that form the building blocks for proteins

nongated ion channels pores in the membrane that allow ions to flow across the membrane according to electrochemical parameters

nonrapid eye movement (NREM) sleep see REM sleep

nonshivering thermogenesis mechanism involving the generation of heat in brown adipose tissue as a result of uncoupled mitochondria located there; also known as diet-induced thermogenesis

noradrenergic neuron neuron that uses noradrenaline (norepinephrine) as a neurotransmitter

norepinephrine (NE) catecholamine produced by the adrenal medulla, postganglionic sympathetic axons (in the gut), and central neurons, especially those in the locus caeruleus

normoblast nucleated precursor of mature erythrocytes

normochromic erythrocyte with a normal concentration of hemoglobin

nuclear bag fibers type of intrafusal muscle fiber in muscle spindles

nuclear chain fibers type of intrafusal muscle fiber in muscle spindles

nuclear pore complex opening in membrane surrounding the nucleus, formed by a large assembly of proteins, through which molecules from the cytoplasm travel into the nucleus

nucleus accumbens cholinergic cell group in the base of the forebrain involved in reward pathways; part of the "brain's pleasure center"

nucleus ambiguus column of efferent neurons in the ventrolateral medulla oblongata from which its fibers leave with the vagus and glossopharyngeal nerves and innervate the striated muscle fibers of the pharynx, parts of the esophagus, and the vocal cord muscles of the larynx

nucleus tractus solitarius located in the medulla oblongata, containing cell bodies of second-order neurons in vagal afferent sensory pathways

null cell lymphocyte without T-cell or B-cell markers

nutcracker esophagus condition in which propulsive esophageal contractions are found to have abnormally high amplitudes during manometric testing; can be a source of angina-like chest pain

nystagmus reflexive sideways movement of the eyeballs that allows visual fixation during rotation of the head. It occurs in response to information from the vestibular apparatus

obesity excess of caloric intake over energy expenditure

occipital lobe posterior region of the cerebrum; contains the visual cortex

olfaction process of sensing odors

olfactory bulb complex multilayer neural architecture located in the forebrain that serves as a relay station to transmit information from the nose to the brain

oligodendrocytes glial cells in the CNS that produce a myelin sheath around neuronal axons in the CNS

oligomenorrhea infrequent or irregular menstruation

oncogenes genes that turn immune cells into tumors cells

oncotic pressure osmotic pressure exerted by colloids in a solution; also called colloidal osmotic blood pressure

oocyte immature ovum

oogonia germ cells

oolemma plasma membrane of the egg

ooplasm cytoplasm of an egg

opioids endogenous peptides that bind to opiate receptors

opsonin molecule that coats pathogens to facilitate their phagocytosis

optic chiasma part of the brain where the optic nerves (cranial nerve II) partially cross, located immediately below the hypothalamus

optic disc region of the retina where the optic nerve leaves the eye; the lack of photoreceptors in this region produces a blind spot

optic nerve transmits visual information from the retina to the brain; also called cranial nerve II

optic radiations collections of axons from relay neurons in the lateral geniculate nucleus of the thalamus carrying visual information to the visual cortex along the calcarine fissure; there is one such tract on each side of the brain; also known as geniculostriate pathways

optic tract continuation of the optic nerve that runs from the optic chiasm (where half of the information from each eye crosses sides, and half stays on the same side) to the lateral geniculate nucleus

optimum length (Lo) length corresponding to the maximum isometric force of muscle contraction

orbit bony socket for the eyeball

orexigenic causing stimulation of the appetite

organ of Corti complex organized structure of the inner ear that transforms sound vibrations into nerve impulses

organic anion transporting polypeptides (OATPs) highly expressed in liver, kidney, and brain, OATPs generally transport anionic and cationic chemicals, steroid, and peptide backbones into cells

organification addition of one or two iodine atoms to tyrosine residues in the thyroglobulin precursor protein

orthodromically conduction of nerve action potential in the conventional direction, efferently for motor and afferently for sensory

orthophosphate (PO4) chemistry-based term that refers to an organic phosphate in which the phosphate is attached on the ortho position in a benzene ring

osmolality total solute concentration in a solution expressed as osmoles per kilogram of H2O

osmolarity total solute concentration, expressed as osmoles per liter of solution

osmole Avogadro number (or a mole) of solute particles

osmoreceptor cells neurons in the anterior hypothalamus stimulated by increased extracellular fluid osmolality; they increase the release of arginine vasopressin and thirst

osmoregulation regulation of water potential in an organism by promoting either water retention or secretion, depending on the environmental situation

osmosis passive transport of water across a membrane in response to a gradient of osmotic pressure. Water always moves from the region of low osmotic pressure (low solute concentration) to the region of high osmotic pressure (high solute concentration). Water crosses cell membranes via water channel proteins (aquaporin)

osmotic diuretic solute excreted in the urine that increases urinary excretion of Na+, K+, and water

osmotic pressure property of a solution defined as the pressure necessary to stop the net movement of water across a selectively permeable membrane that separates the solution from pure water: a hyperosmotic solution has a greater solute concentration and exerts a greater pressure than another solution, whereas a hyposmotic solution has a lower solute concentration and exerts a lower pressure than another solution, and an isosmotic solution has the same solute concentration and exerts the same pressure as another solution

osteoarthritis arthritis characterized by erosion of articular cartilage, either primary or secondary to trauma or other conditions, which becomes soft, frayed, and thinned with eburnation of subchondral bone and outgrowths of marginal osteophytes; pain and loss of function result; mainly affects weight-bearing joints; more common in older persons

osteoblast cell that makes bone. It does so by producing a matrix that then becomes mineralized; bone mass is maintained by a balance between the activities of osteoblasts that form bone and other cells called osteoclasts that break it down

osteoclast large multinucleate cell that breaks down bone and is responsible for bone resorption

osteocyte branched cell embedded in the matrix of bone tissue

osteogenesis imperfecta hereditary disease characterized by abnormally brittle, easily fractured bones

osteoid uncalcified bone matrix, the product of osteoblasts

osteomalacia softening of the bones as a result of a deficiency of vitamin D; also known as adult rickets

osteoporosis disease of bone in which the bone mineral density is reduced, bone microarchitecture is

disrupted, and the amount and variety of noncollagenous proteins in bone is changed; osteoporotic bones are more susceptible to fracture

otic ganglion location of pre- to postganglionic synapse of parasympathetic neurons from the inferior salivatory nucleus through cranial nerve IX, which are involved in control of the parotid gland

otolithic organs utricle and saccule in the vestibular apparatus responsible for sensing body position and acceleration

otoliths small particles, composed of a combination of a gelatinous matrix and calcium carbonate, in the viscous fluid of the saccule and utricle of the ear; inertia of these small particles causes them to stimulate hair cells when the head moves

outer-ring deiodination enzymatic removal of the iodine atom at position 5′ of the thyronine ring structure

outwardly rectifying potassium channels myocardial membrane channels that are responsible for carrying hyperpolarizing K+ currents out of myocardial cells, resulting in cell repolarization during phase 3 of the myocardial cell action potential

overshoot part of the action potential in which the inside of the cell becomes positive with respect to the extracellular compartment

oviduct fallopian tube, which receives the ovum immediately after ovulation

ovulation release of an egg from a follicle in the ovary

ovulatory phase part of the menstrual cycle during which an egg is released; lasts 24 hours

oxidative burst cellular generation and release of antimicrobial reactive oxygen species; also known as respiratory burst

oxidative phosphorylation generation of adenosine triphosphate by the reactions of the Krebs cycle in the presence of O2

oxidative stress imbalance between production and degradation of reactive oxygen species

oxidoreductase enzyme that catalyzes the transfer of electrons from one molecule (the reductant, also called the hydrogen or electron donor) to another (the oxidant, also called the hydrogen or electron acceptor)

oxygen-carrying capacity (OCC) total maximum amount of oxygen (mL/dL) carried by 100 mL of blood

oxygen content amount of oxygen (mL/dL) bound to hemoglobin in 100 mL of blood

oxygen debt measurably increased rate of oxygen consumption following strenuous activity. The extra oxygen is used in the processes that restore the body to a resting state and adapt it to the exercise just performed (hormone balancing, replenishment of fuel stores, cellular repair, innervation, and anabolism); also known as excess postexercise oxygen consumption

oxygen diffusion gradient partial pressure difference for oxygen across the alveolar–capillary membrane

oxygen saturation ratio of the amount of oxygen bound to hemoglobin to the carrying capacity of oxygen (O2 content/O2 capacity)

oxygen uptake transfer of oxygen from the alveoli to the pulmonary capillary blood

oxyhemoglobin (Hbo2) oxygen-saturated form of hemoglobin

oxyhemoglobin equilibrium curve curve that reflects the relationship between oxygen saturation and the partial pressure of oxygen

oxyntic glands one of three types of glands found in the fundus and corpus of the stomach that contribute to gastric secretions; they are the most abundant and contain parietal (oxyntic) cells, chief cells, mucous neck cells, and some endocrine cells; also known as gastric glands

oxytocin substance that is produced by magnocellular neurons in the supraoptic and paraventricular nuclei of the hypothalamus and that stimulates smooth muscle contraction in the mammary glands and uterus

Pacinian corpuscle very highly adaptive receptor that is responsible for sensitivity to pressure as well as pain

Paget disease condition in which the existing bone is resorbed, with the simultaneous overgrowth of new, poorly calcified, irregular bone

palmitoyltransferase dimeric complex of the endoplasmic reticulum that catalyzes S-palmitoylation, the addition of palmitate (C16:0), or other long-chain fatty acids to proteins at a cysteine residue

pampiniform plexus venous plexus accompanying the testicular artery up to the superficial inguinal ring and thought thereby to be involved in maintenance of the testicles at some 3°C below body temperature. It forms from veins draining the testis and epididymis at the mediastinum of the testis and unites within the inguinal canal to form the left and right testicular veins

pancreatic amylase substance that continues in the digestion of the remaining carbohydrates at the point at which salivary amylase stops. Pancreatic secretions must first neutralize chyme for pancreatic amylase to work best, at a neutral pH level. The products of pancreatic amylase digestion of polysaccharides are maltose, maltotriose, and α-limit dextrins

pancreatic lipase substance that hydrolyzes lipids, specifically the triglyceride molecule to a 2-monoglyceride and two fatty acids, in the intestinal lumen

pancreatic polypeptide (PP) 36-amino acid peptide secreted by islet cells of the pancreas in response to a meal; of uncertain physiologic function

Paneth cells found in the intestinal tract, these cells contain zinc and lysozyme as well as large eosinophilic refractile granules within their apical cytoplasm; their exact function is unknown but due to the presence of lysozyme, it is likely that Paneth cells contribute to host defense and protection of intestinal stem cells; when exposed to bacteria or bacterial antigens, Paneth cells secrete a number of lysozymes into the lumen of the crypt, thereby contributing to maintenance of the gastrointestinal barrier

panhypopituitarism generalized or particularly severe hypopituitarism, which in its complete form leads to absence of gonadal function and insufficiency of thyroid and adrenal cortical function. Dwarfism, regression of secondary sex characteristics, loss of libido, weight loss, fatigability, bradycardia, hypotension, pallor, depression, and many other manifestations may occur; also known as pituitary failure

papillary light reflex in controlling the diameter of the pupil, this reflex regulates the intensity of light entering the eye

parabrachial nucleus location of neurons in the upper pons that coordinate cardiac and respiratory functions

paracrine signaling signaling in which the signal substance is released into the local environment and moves to receptors on target cells by diffusion in the extracellular milieu

paradoxical sleep stage of sleep, also known as REM (rapid eye movement), in which the electroencephalogram exhibits unsynchronized, high-frequency, low-amplitude waves similar to the awake state, yet the subject is as difficult to arouse as when in stage 4 slow-wave (deep) sleep

parafollicular cells cells that are embedded in the wall of the thyroid follicle and that produce and secrete calcitonin

parallel fibers axons from cerebellar granule cells to the dendrites of the Purkinje cells

paralytic ileus obstruction of the bowel resulting from paralysis of the bowel wall, usually as a result of open abdominal surgery, peritonitis, or shock; sometimes called adynamic ileus

paramesonephric (müllerian) ducts ducts that fuse at the midline and develop into the oviducts, uterus, cervix, and upper portion of the vagina in females

paraneoplastic syndrome neuropathic degeneration of autonomic neurons resulting from autoimmune attack in patients with small cell carcinoma of the lung

paraquat compound found in herbicides that is toxic to lung tissue and skin

parasympathetic division division of the autonomic nervous system, with its outflow from the central nervous system in certain cranial nerves and sacral nerves, respectively, and having its ganglia in or near the innervated viscera

parasympathetic nervous system the division of the autonomic nervous system generally responsible for maintaining normal organ functioning, referred to as the "rest and digest" system

parathyroid hormone (PTH) hormone made by the parathyroid gland that helps the body store and use calcium; also known as parathormone or parathyrin

paraventricular nuclei portion of the hypothalamus in which magnocellular neuron cell bodies are found

paravertebral sympathetic ganglia collections of sympathetic neurons located parallel to the spinal cord; site of most synapses between preganglionic and postganglionic sympathetic neurons

parietal lobe posterolateral region of the cerebrum

parietal (oxyntic) cells one of two primary sources of gastric secretion; secrete hydrochloric acid and intrinsic factor, a peptide that is crucial for the absorption of vitamin B12

parietal–temporal–occipital association cortex interface between the parietal, temporal, and occipital lobes of the cerebrum, which integrates visual, somatosensory, auditory, and cognitive stimuli

Parkinson's disease (PD) neurological disease characterized by hand tremor and slowed body movements as a result of loss of neurons in the substantia nigra

parotid gland largest salivary gland, found wrapped around the mandibular ramus, that secretes saliva into the oral cavity to facilitate mastication and swallowing

pars distalis major part of the adenohypophysis of the pituitary gland; also known as anterior lobe

pars intermedia thin diffuse region of cells between the anterior and posterior lobes of the pituitary in humans; also known as intermediate lobe

pars reticulata (SNr) group of neurons in the substantial nigra producing inhibitory output to eye

movement control regions of the midbrain

pars tuberalis upward extension of the anterior lobe that wraps around the infundibular stalk; its cells, mostly gonadotropic, are arranged in cords and clusters; it is supplied by the superior hypophyseal arteries and contains the first capillary bed and the venules of a portal system that carries neurosecretory factors from the hypothalamus to a second capillary bed in the adenohypophysis where they regulate the release of hormones

partial pressure independent pressure exerted by an individual gas within a mixture of gases

partial seizures seizure preceded by an isolated disturbance of a cerebral function, such as twitching of a limb

partition coefficient measure of a molecule's solubility in oil compared with its solubility in water. The value will be high for a lipid-soluble molecule and low for a water-soluble molecule

parturition birth

parvicellular neurons neurons located in the paraventricular nuclei of the hypothalamus that synthesize corticotropin-releasing hormone

passive conduction passive spread of electrical signal over short segments of the axon

passive force length-dependent component of muscle force that is produced by stretching an inactivated muscle

passive immunity transmission of antibodies from the mother to the fetus via intrauterine transport and to the infant via the mother's colostrum, the thin, yellowish, milky fluid secreted by the mammary glands a few days before or after parturition. The absorption of immunoglobulins (predominantly IgG) plays an important role in the transmission of passive immunity from the mother's milk to the newborn in several animal species

passive transport membrane transport of a solute or ions down the prevailing electrochemical gradient. Solute movement dissipates the gradient and an equilibrium state is eventually reached at which net movement ceases. Passive transport of lipid-soluble solutes can occur without a carrier protein (diffusive membrane transport). Passive transport of ions occurs through ion channel proteins, and polar hydrophilic solutes must use a carrier protein. These are examples of facilitated diffusion

patch clamp sophisticated laboratory technique for studying the behavior of individual ion channels, based on detecting the small current generated when ions flow through an open channel

pathogen agent, primarily an organism, that causes disease

peak expiratory flow (PEF) maximum flow at the outset of forced expiration, which is reduced in proportion to the severity of airway obstruction, as in asthma

pellagra severe niacin deficiency characterized by dermatitis, dementia, and diarrhea

pendrin substance that transports iodide into the follicle to be used for iodination of the thyroglobulin precursor

pepsin endopeptidase in gastric juice that cleaves protein molecules from the inside, resulting in the formation of smaller peptides. Protein digestion starts in the stomach with the action of pepsin, which is secreted as a proenzyme and activated by acid in the stomach

pepsinogen substance secreted by chief cells that is a precursor of the enzyme pepsin and is found in

gastric juice

peptic ulcer disease ulcerative lesions of the gastroduodenal area caused by reduced bicarbonate secretion and, in many circumstances, increased acid secretion resulting from an increased mean number of gastric parietal cells that appear to have increased sensitivity to gastrin. The stomach-emptying rate is greatly increased in patients with duodenal ulcers

peptidase any enzyme capable of hydrolyzing one of the peptide links of a peptide

peptide hormones peptides, such as prolactin, secreted in the bloodstream that serve endocrine functions

perforin protein of natural killer and cytotoxic T cells that forms a pore in target cells

perfusion limited characterized by the limitation of the uptake of an alveolar gas, primarily by pulmonary capillary blood flow

perfusion pressure pressure force driving blood through the circulation of an organ; usually synonymous with the blood pressure in the artery supplying an organ or tissue

periaqueductal gray matter region of the midbrain where integration of afferent and nerve impulses from higher cerebral centers occurs

pericarditis inflammation of the pericardium. It often restricts the ability of the ventricle to fill during diastole

perikaryon cell body of a neuron containing the nucleus; also called soma

perilymph fluid that fills the scala vestibuli and scala tympani and is high in sodium and low in potassium

peripheral chemoreceptors neurosensitive endings that respond to changes in blood chemistry and that are located in the carotid artery and the aorta

peripheral nervous system ganglia and nerves located outside of the CNS; the division of the nervous system localized outside of the brain and spinal cord and composed of nerves and ganglia

peripheral protein protein that is attached to but does not penetrate the phospholipid bilayer region of a cell membrane, for example, spectrin in the red blood cell

perisinusoidal space (space of Disse) space that is continuous with the pericellular space and separated from the sinusoid by a layer of sinusoidal endothelial cells

peristalsis coordinated contraction of inner circular muscle layer and longitudinal layer of the gastrointestinal tract that propel a bolus of food through the tract

perivitelline space region between the zona pellucida and the vitelline membrane of an oocyte

permeability coefficient number expressing the ease with which a solute can cross a plasma membrane. It accounts for factors such as the thickness of the membrane and the lipid solubility of the solute

permeability surface area coefficient coefficient that characterizes how much material per unit of time can pass across the capillaries by diffusion for a given concentration gradient across the capillary membrane. It is a function of the capillary surface area over which diffusion occurs as well as the permeability of the capillary membrane to the diffusing substance in question

pernicious anemia chronic, progressive anemia found in older adults as a result of failure of vitamin B12 absorption, usually resulting from the lack of secretion of intrinsic factor. Pernicious anemia is characterized by numbness and tingling, weakness, diarrhea, loss of weight, and fever

peroxidases enzymes that neutralize peroxynitrites

peroxynitrite free radical formed in the presence of a superoxide ion and nitrous oxide

pH measure of the acidity or alkalinity of a solution. It is equal to the negative logarithm (to the base 10) of the hydrogen ion concentration (the latter is measured in mol/L)

phagocyte cell capable of engulfing particulate material

phagocytosis engulfment of large extracellular particles and microorganisms by expansion of the plasma membrane around the particle to eventually surround it. A typical example is the destruction of invading bacteria by macrophage cells

phagosome phagocytic vacuole for the killing of enclosed pathogens

pharmacomechanical coupling mechanism in gastrointestinal smooth muscles in which the binding of a ligand to its receptor on the muscle membrane leads to the opening of calcium channels and the elevation of cytosolic calcium without any change in the membrane electrical potential; the ligands may be chemical substances released as signals from nerves (neurocrine), from nonneural cells in close proximity to the muscle (paracrine), or from endocrine cells as hormones delivered to the muscle by the blood

phase I reactions reactions in which a parent xenobiotic compound is biotransformed into a more polar compound by the introduction of one or more polar groups, usually hydroxyl (OH) or carboxyl (COOH). Usually, this is accomplished by the oxidation of the parent compound

phase II reactions reactions in which phase I products conjugate to various possible products (i.e., glucuronic acid, catalyzed by glucuronyl transferases), yielding a more hydrophilic end compound

phasic contraction contraction not long maintained (transitory), in contrast to a tonic contraction

phlebotomist technician trained to draw blood

phorbol ester parent alcohol of the cocarcinogens, which are 12,13(9,9a) diesters of phorbol found in croton oil; the hydrocarbon skeleton is a cyclopropabenzazulene; phorbol esters mimic 1,2-diacylglycerol as activators of protein kinase C

phosphatidylinositol 4,5-bisphosphate (PIP2) membrane lipid found in all eukaryotic cells, which regulates many important cellular processes, including ion channel activity

phosphaturia excess of phosphates in the urine

phosphodiesterase (PDE) enzyme that cleaves phosphodiester bonds to yield a phosphomonoester and a free hydroxyl group; for example, cyclic adenosine monophosphate (cAMP) is inactivated by phosphodiesterase action to 5′ AMP; this cleavage is mediated by a cyclic nucleotide phosphodiesterase enzyme

phosphoenolpyruvate carboxykinase (PEPCK) enzyme in the gluconeogenic pathway catalyzing oxaloacetate conversion to phosphoenolpyruvate

phosphoenolpyruvate carboxylase enzyme in the family of carboxy-lyases that catalyzes the addition of bicarbonate to phosphoenolpyruvate to form the four-carbon compound oxaloacetate

phosphofructokinase enzyme that catalyzes the conversion of fructose 6-phosphate to fructose 1,6-diphosphate

phospholamban regulatory protein that inhibits sarcoplasmic reticulum Ca2+ pumps. Its inhibitory effects are removed when it is phosphorylated

phospholipase A2 major pancreatic enzyme for digesting phospholipids, thereby forming lysophospholipids and fatty acids

phospholipase C (PLC) lipase that hydrolyzes phosphatidylinositol 4,5-bisphosphate

phospholipid subclass of lipid molecules based on glycerol 3-phosphate to which are attached two long-chain fatty acids (hydrophobic), for example, palmitic acid, and a specific polar or charged head group (hydrophilic), for example, choline or inositol

phosphorylation transfer of the terminal phosphate of adenosine triphosphate to a protein, under the control of a kinase-type enzyme

photon quantum of the electromagnetic interaction and the basic unit of light and all other forms of electromagnetic radiation

photopic (daytime) vision color vision that is served by the cone cells of the retina

photoreceptors sensory receptors that respond to visual stimuli

phylloquinones vitamin K that is derived from green vegetables

physiological dead space volume total volume of wasted air that does not participate in gas exchange and is the sum of anatomical dead space and alveolar dead space volume

physiological ileus normal absence of motility in a region of the gastrointestinal tract; requires an intact enteric nervous system in the intestine

physiological shunt total amount of venous admixture from anatomical shunts and regions of low ventilation/perfusion ratios

physostigmine (eserine) blocker of the neuromuscular junction that inhibits the action of acetylcholinesterase

piloerection mechanism whereby furred or hairy animals can increase the thickness of their coat and insulating properties by making the hairs stand on end. This response makes a negligible contribution to heat conservation in humans, but manifests itself as gooseflesh

pineal gland gland located superficial to the dorsal midbrain and posterior dorsal thalamus that produces melatonin in response to signals from the suprachiasmatic nucleus of the hypothalamus relayed through the sympathetic nervous system

pinocytosis process by which a cell ingests extracellular fluid and its contents by forming narrow channels through its membrane that pinch off into vesicles and fuse with lysosomes that hydrolyze contents

pituitary dwarfism decrease in the rate of body growth as a result of growth hormone deficiency

pituitary gland gland lying in the sphenoid bone and connected to the hypothalamus; also known as hypophysis

place theory theory of hearing that states that our perception of sound depends on where each component frequency produces vibrations along the basilar membrane, such that the pitch of a musical tone is determined by the places where the membrane vibrates, based on frequencies corresponding to the tonotopic organization of the primary auditory neurons

placenta structure composed of maternal and fetal tissues attached to the inner surface of the uterus

placing reaction cortical reflex producing limb movement, provoked in a dependent limb touching a horizontal surface

plaque the name given to an advanced atherosclerotic lesion in the intima of large arteries consisting of a necrotic, fibrotic core of lipid-laden cells, cholesterol crystals, and calcium deposits covered by an unstable fibrous cap. Plaques can rupture, exposing thrombogenic materials to blood, which then forms a local thrombosis that in turn can occlude the artery.

plasma liquid portion of the blood; an extracellular fluid

plasma cell B-cell–derived cell that secretes antibody

plasma membrane outer surface of the cell, which separates the contents of the cell from the extracellular fluid

plasma membrane calcium ATPase (PMCA) transport protein in the plasma membrane of cells that serves to remove calcium from the cells

plasmapheresis therapeutic plasma exchange

plasmin proteolytic enzyme that acts on the follicular wall during rupture

plasminogen inactive proenzyme that is converted to plasmin by tissue plasminogen activator, which is released by activated endothelial cells

plasminogen activator see tissue plasminogen activator

plateau in cardiovascular physiology, the extended depolarized plateau in phase 2 of the action potential in myocardial cells. It is the basis of the long refractory period seen in ventricular and atria muscle cells and is the reason tetanic contractions cannot be produced in those cells.

platelet anuclear, irregular disklike fragment of megakaryocytes that is important for hemostasis

platelet count (Plt) used as a starting point in the diagnosis of hemostasis

platelet-derived growth factor (PDGF) cytokine involved in wound healing; stimulates the proliferation of vascular smooth muscle and endothelial cells

plegia complete paralysis of a muscle

pleiotropic producing more than one effect

plethysmograph airtight box designed to measure a patient's residual lung volume

pleural pressure (Ppl) pressure between the chest wall and the lungs (i.e., the pleural space)

pleural space fluid-filled space between the chest wall and the lungs

pneumonia disease of the lungs characterized by inflammation and consolidation of lung tissue and accompanied by fever, chills, cough, and difficulty in breathing; it is caused chiefly by infection and is categorized as bronchopneumonia, lobar pneumonia, or primary atypical pneumonia

pneumothorax collapsed lung

podocytes epithelial cells with extensions that terminate in foot processes that rest on the outer layer of the basement membrane of the glomerular membrane of the kidney

poikilocyte irregularly shaped erythrocyte

poikilotherms poikilothermic animal; denoting the so-called cold-blooded animals, such as the reptiles and amphibians

Poiseuille's law law that quantifies the relationship between pressure, flow, and resistance in the

cardiovascular system. It states that blood flow is proportional to the pressure difference across any two points along the vascular system and inversely proportional to the resistance to flow. It can also be used to show that pressure anywhere in the cardiovascular system is the direct product of blood flow and vascular resistance. The work of Poiseuille showed that vascular resistance is proportional to vessel length and blood viscosity but that it is inversely proportional to the fourth power of the internal vessel radius

polyclonal antibody antibodies obtained from different B-cell resources; they are a combination of immunoglobulin molecules secreted against a specific antigen, each identifying a different epitope

polycystic kidney disease (PKD) most common life-threatening inherited disorder in which numerous cysts develop in both kidneys, producing massive enlargement of the kidneys and ultimately complete renal failure

polycystic ovarian syndrome heterogeneous group of disorders characterized by amenorrhea or anovulatory bleeding, an elevated luteinizing hormone/follicle-stimulating hormone ratio, high androgen levels, hirsutism, and obesity

polycythemia proportion of blood volume that is occupied by red blood cells increases abnormally due either to an increase in the mass of red blood cells (absolute polycythemia) or to a decrease in the volume of plasma (relative polycythemia); blood volume proportions can be measured as hematocrit level

polydipsia Extreme thirst in response to excess fluid loss. Common causes of increased fluid loss are from rigorous exercise, diarrhea, vomiting, profuse sweating, hemorrhaging and certain prescription medications. Increase thirst can also occur as a result of high blood sugar and is often one of the first symptoms of both diabetes mellitus and diabetes insipidus.

polymorphonuclear leukocyte granulocyte, with a segmented or lobated nucleus

polyspermy fertilization of an egg by more than one sperm

polyuria condition characterized by excessive excretion of dilute urine, for example, diabetes insipidus

pontine respiratory group group of cells in the medulla responsible for integrating signals and acting as an “off” switch for inspiration and expiration

pontine reticulospinal tract descending brainstem pathway carrying excitatory impulses to spinal interneurons from the pons

pores in the cardiovascular system, the gaps between endothelial cells, which allow the passage of water and solutes between the tissues and capillary blood

portal hypertension high blood pressure in the portal vein and its tributaries; it is often defined as a portal pressure gradient (the difference in pressure between the portal vein and the hepatic veins) of 10 mm Hg or greater

portal vein primary large vein that collects blood exiting the splanchnic organs, such as the stomach, pancreas, small intestine, and portions of the large intestine. It supplies blood into the hepatic circulation, where it is mixed with blood from the hepatic artery

positive feedback feedback that enhances the input and responds in the same direction as the perturbation and that involves the return of some of the output of the system as input, which helps control the process

positive selection process by which cells are recruited with a T-cell receptor able to bind major

histocompatibility (MHC) class I and II molecules with at least a weak affinity, thereby eliminating (in "death by neglect") those T cells that would be nonfunctional due to an inability to bind MHC

postcapillary venules first veins in which blood enters from the capillaries

postganglionic axon axon of the postganglionic autonomic neuron

postganglionic sympathetic neurons neurons leaving prevertebral ganglia to the gut

postjunctional folds invaginations in the endplate membrane that increase its surface area

postmenopausal osteoporosis bone loss resulting from the deficiency of estrogen associated with menopause; also known as type 1 osteoporosis

postpartum thyroiditis usually occurring within 3 to 12 months after delivery, this disease is characterized by a transient destruction-induced thyrotoxicosis (hyperthyroidism), often followed by a period of hypothyroidism lasting several months; many patients eventually return to the euthyroid state

postprandial after meals

postrotatory nystagmus eyeball movements that follow an episode of body or head rotation, resulting from the continued motion of the endolymph in the semicircular canals

poststreptococcal glomerulonephritis nephritic condition that may follow a sore throat caused by certain strains of streptococci; endothelial cell damage, accumulation of leukocytes, and the release of vasoconstrictor substances reduce the glomerular surface area and fluid permeability and lower glomerular blood flow, causing a fall in the glomerular filtration rate

postsynaptic terminal the dendritic nerve ending specialized to receive information

potentiation interaction between two or more drugs or agents, resulting in a pharmacologic response greater than the sum of individual responses to each drug or agent

power output rate at which muscle does work on the environment

power propulsion intestinal motility pattern associated with defense and pathologic conditions; rapid propulsion of luminal contents over extended lengths of intestine

power stroke conformational change in the myosin molecule (crossbridge) that provides the driving force in muscle contraction

PR interval interval of time on the electrocardiogram between the end of the P wave and the start of the QRS complex. It is an estimate of the time it takes for action potentials to proceed from the atria into the ventricles and is a primary reflection of the delay of conduction through the atrioventricular node

prechondrocyte precursor to chondrocyte in the growth plates of bone

precocious puberty physical signs of sexual maturation before the age of 7 years in girls and 9 years in boys

precordial leads set of six unipolar electrocardiogram leads that are oriented in the horizontal plane of the body at the level of the heart. They are designated V1 to V6 and are placed in a semicircle around the left side of the chest, from just right of the sternum to the left midaxial point

prediabetes condition that occurs when a person's blood glucose levels are higher than normal but not high enough for a diagnosis of type 2 diabetes

prefrontal association cortex region of the cerebrum responsible for executive function (making

decisions) and, by virtue of its connections with the limbic system, coordinating emotionally motivated behaviors

prefrontal cortex most anterior region of the cerebrum

preganglionic axon axon of the preganglionic autonomic neuron

preganglionic sympathetic neurons neurons in the intermediolateral cell column of the spinal cord that project axons to make synapse with one of the three prevertebral sympathetic ganglia (celiac, superior mesenteric, and inferior mesenteric ganglia)

pregnenolone precursor for steroid hormone synthesis derived from cholesterol

pregranulosa cells cells that surround the oocyte in a primordial follicle

preload passive stretch placed on a muscle prior to an active contraction; initial passive length to which muscle is stretched prior to the start of a contraction

premature atrial contraction (PAC) premature electrical activation of any portion of the atria outside the sinoatrial node or atrial ectopic foci

premature ovarian insufficiency early depletion of follicles prior to 40 years of age—is a state of hypogonadotropic hypogonadism

premature ventricular atrial contraction (PVC) premature electrical activation of any portion of the ventricles or ventricular ectopic foci

premotor area region of the cerebrum just anterior to the primary motor cortex; serves as the association cortex for the motor system responsible for coordinating movements around a joint

premotor cortex motor-related cortical region located on the lateral surface of the frontal lobe anterior to the primary motor cortex

preprohormone precursor form of a protein hormone extended at the amino termini by a hydrophobic amino acid sequence called leader or signal peptide and in addition containing internal cleavage sites that on enzymatic action yield different bioactive peptides

presbyopia condition characterized by reduced converging power (accommodation) of the eye, caused by increasing stiffness of the crystalline lens resulting from age

pressure technically, the force on a specific surface area and expressed as force per unit area (i.e., pounds per square inch); in physiological systems, it is measured as the force required to raise a column of water or mercury a given distance vertically against gravity and is expressed as mm Hg or cm H_2O

pressure diuresis response of the kidney to increase salt and water excretion whenever arterial pressure is elevated. It has the capacity to continue to increase excretion until blood pressure is returned to a level set by the body for mean arterial pressure. It is believed to be the mechanism whereby the kidney sets the long-term mean arterial pressure set point in the body, around which all cardiovascular reflexes operate

pressure–volume curve curve generated by measuring the amount of pleural pressure required to inflate the lungs to a given volume. The slope of the pressure–volume curve provides a measure of lung compliance

presynaptic facilitation effects of chemical mediators or drugs to increase the release of neurotransmitter at a synapse

presynaptic inhibition receptors on axons suppress the release of neurotransmitters at neural synapses

and neuroeffector junctions

presynaptic inhibitory receptors receptors on axons that suppress the release of neurotransmitters at neural synapses and neuroeffector junctions

presynaptic terminal the axonal nerve ending from which neurotransmitters are released

prevertebral sympathetic ganglia sympathetic ganglia (celiac, aorticorenal, and superior and inferior mesenteric) lying in front of the vertebral column, as distinguished from the ganglia of the sympathetic trunk (paravertebral ganglia); these ganglia occur mostly around the origin of the major branches of the abdominal aorta, and all are in the abdominopelvic cavity; the neurons comprising the ganglia send postsynaptic sympathetic fibers to the gut

primary active transport mechanism see active transport

primary axons (type Ia) largest myelinated afferent axons from the muscle spindle

primary follicular stage ovarian follicle consisting of one layer of cuboidal granulosa cells and a basement membrane surrounding the oocyte

primary lymphoid organs see lymphoid organs

primary motor cortex (M1) region of the cerebral cortex that fits all four parameters of a cortical motor area and is located just anterior to the central sulcus

primary oocyte oocyte in first meiotic arrest

primary peristaltic wave peristaltic propulsion in the esophagus initiated by swallowing

primary somatosensory cortex (S1) region of the cerebral cortex that receives tactile input and is located just posterior to the central sulcus

primary spermatocyte spermatocyte that divides into two secondary spermatocytes

prime mover contracting muscle that contributes most to a movement

primordial follicle ovarian follicle consisting of a primary oocyte surrounded by a layer of pregranulosa cells

progesterone major natural progestogen, promoting the secretory function of the uterus

progesterone block maintenance of uterine quiescence throughout gestation by progesterone to prevent premature delivery

progestin or progestogen substance that promotes secretory function of the uterus

programmed cell death death of a cell mediated by signaling pathways invoked in the cell in response to unhealthy growth conditions (e.g., loss of growth factors, infection by a virus); a deliberate cell suicide; this death is altruistic because the whole organism benefits from the death of a cell, thus it does not initiate an immune response (nonimmunogenic); apoptosis is one type of programmed cell death; contrast with necrosis

progressive shock stage of shock in which the function of organs needed to maintain cardiac output and blood pressure (heart and brain) is compromised but in which the person can survive with prompt and aggressive medical intervention

prohormone precursor form of a protein hormone extended at the amino termini by a hydrophobic amino acid sequence called leader or signal peptide

prohormone convertase 1 (PC1) enzyme encoded by the PCSK1 gene that differentially cleaves proopiomelanocortin to adrenocorticotropic hormone and β-lipotropin

prohormone convertase 2 (PC2) enzyme responsible for the first step in the maturation of many neuroendocrine peptides from their precursors, such as the conversion of proinsulin to insulin intermediates

prokinetic drug agent that acts on enteric nerve endings to enhance propulsion of contents through the gut and that may act by direct muscle stimulation, release of motor neurotransmitters, or blockade of inhibitory neurotransmitters

prolactin (PRL) hormone product of lactotrophs located in the anterior pituitary

proliferative phase phase of the endometrial cycle in which stromal and epithelial layers of the uterine endometrium undergo hyperplasia

pronucleus haploid nucleus with 23 chromosomes. One female pronucleus and one male pronucleus present in an egg 2 to 3 hours after sperm penetration and fuse to form the nucleus of a fertilized egg

proopiomelanocortin (POMC) prohormone from which adrenocorticotropic hormone, β-lipotropin, and α-melanocyte–stimulating hormone are derived

propagated potential the property of action potentials to regenerate and move along a nerve processes

proprioceptors sensory receptors that provide information as to body and limb position, muscle force, and similar properties from within the body

propriospinal cells interneurons that convey action potentials between adjacent spinal segments

propulsion controlled movement of ingested foods, liquids, gastrointestinal secretions, and sloughed cells from the mucosa through the digestive tract

propulsive segment intestinal segment identified by contraction of the circular muscle layer behind a receiving segment in which the circular muscle is inhibited and the longitudinal muscle layer contracted to produce a segment with expanded lumen

prostaglandin derivative of arachidonic acid that usually acts as a local hormone to affect many functions, such as blood flow and inflammation

prostaglandin E2 substance released by blood vessel walls in response to infection or inflammation and acting on the brain to induce fever. The enzyme mPGES-1 is involved in the production of prostaglandin E2 and is an important “switch” for activating the fever response

protein inclusion bodies protein aggregates that typically represent sites of viral multiplication in bacteria; can also signal genetic diseases such as Parkinson’s disease

protein kinase A (PKA) see cAMP-dependent protein kinase

protein kinase C (PKC) phospholipid-dependent and calcium-dependent kinase that, when activated, phosphorylates serine or threonine residues in target proteins to regulate their function

protein kinase G (PKG) see cGMP-dependent protein kinase

protein S deficiency most common inherited thrombotic disorder

proteinuria condition characterized by the presence of proteins in the urine

proteoglycans mortar-like substances made from protein and sugar that are the building blocks of

cartilage

prothrombin time (PT) test to monitor the extrinsic coagulation pathway

prothrombinase (factor X) clotting factor that initiates the common coagulation pathway

protooncogenes normal gene that, when altered by mutation, becomes an oncogene

proton pump see H+-ATPases

pseudohyperkalemia spurious elevation of the serum concentration of potassium occurring when potassium is released in vitro from cells in a blood sample collected for a potassium measurement

pseudohyponatremia artifactual decrease in plasma Na+ resulting from greatly elevated levels of lipids or proteins in plasma

pseudomaturation process in which the oocyte enters meiosis during atresia of the follicle

pseudoobstruction pathological failure of propulsion in the gastrointestinal tract in the absence of mechanical obstruction

pseudoprecocious puberty early development of secondary sex characteristics in the absence of gametogenesis. Results from exposure of immature boys to androgens or immature girls to estrogen

pterygopalatine ganglion location of pre- to postganglionic synapse of parasympathetic neurons from the superior salivatory nucleus through cranial nerve VII, which are involved in control of the lacrimal and nasal glands

ptosis drooping of the eyelid as a result of loss of sympathetic activation of the Müller muscle of the eyelid

P-type ATPase see ATPase

pubarche development of pubic hair during pubertal development in boys and girls

puberty development of physical characteristics of sexual maturation

puborectalis muscle sling muscle that anchors to the symphysis pubis anteriorly and loops around the rectum to form the anorectal angle; this muscle is important to continence for stool

pulmonary artery single artery that transmits all blood pumped from the right ventricle into the lungs. This blood is deoxygenated venous blood from all the peripheral organs

pulmonary circulation lung circulation that perfuses the respiratory zone and participates in alveolar gas exchange

pulmonary edema abnormal collection of fluid in the lung, which can flood the alveoli and impair gas exchange

pulmonary embolism movement of a blood clot or other plug from the systemic veins through the right heart and into the pulmonary circulation, where it lodges in one or more branches of the pulmonary artery; most pulmonary emboli originate from thrombosis in the leg veins but can also originate from the upper extremities; other major sources of pulmonary emboli include air bubbles introduced during intravenous injections, hemodialysis, placement of central catheters, fat emboli (a result of multiple long bone fractures), tumor cells, amniotic fluid (secondary to strong uterine contractions), parasites, and various foreign materials in intravenous drug abusers

pulmonary embolus blood clot that has lodged in the microcirculation or farther upstream in the

pulmonary arterial circulation; large pulmonary emboli can impede filling of the left heart to the extent that death results

pulmonary fibrosis (PF) the most common group of diseases known as interstitial diseases. The term fibrosis means scaring, and interstitial means the condition occurs in the area of the lung between alveoli. It is the scarring of the tissue between the alveoli that interferes with a patient's ability to breathe. In most cases, the cause is unknown, and these cases are diagnosed as idiopathic pulmonary fibrosis (IPF).

pulmonary hypertension potentially severe disease characterized by an increase in blood pressure in the lung vasculature including the pulmonary artery, pulmonary vein, or pulmonary capillaries; symptoms include shortness of breath, dizziness, fainting, and others, all of which are exacerbated by exertion; markedly decreased exercise tolerance and heart failure may result

pulmonary stretch receptors slowly adapting receptors located in the smooth muscle of the conducting airways

pulmonary surfactant a lipoprotein that secreted by alveolar epithelial type II cells that coats the inner lining of the alveoli. The major functions are to reduce surface tension at the alveolar air–liquid interface and to maintain alveolar stability at low lung volumes.

pulmonary wedge pressure pressure measured by wedging a Swan-Ganz catheter–tipped balloon up against small pulmonary vessels

pulmonic valve thin, flexible, trileaflet structure that separates the right ventricle from the pulmonary artery. It opens into the pulmonary artery during systole but closes during diastole

pulse pressure difference in systolic and diastolic arterial pressure. It is the change in pressure associated with each cardiac cycle and is a function of arterial compliance and stroke volume

purinergic neuron enteric neurons that use a purine nucleotide (e.g., adenosine triphosphate or adenosine) as a neurotransmitter

Purkinje cells largest neurons of the cerebellum and the source of efferent cerebellar axons

Purkinje fibers specialized set of modified myocardial fibers that line the endocardium and provide rapid spread of electrical excitation to the ventricles

putamen one of the basal ganglia, receiving input from the cerebral cortex

pyloric glands one of three main types of glands in the stomach's mucosal lining. These glands contain mucous cells that secrete mucus and bicarbonate ions, which protect the stomach from the acid in the stomach lumen. The pyloric glands are located in a larger area adjacent to the duodenum and contain cells similar to mucous neck cells. The pyloric glands consist of many gastrin-producing cells, called G cells

pyloric sphincter sphincter at the boundary of the gastric pylorus and duodenum

pylorus lower section of four stomach sections that facilitates gastric emptying into the small intestine

pyramidal tract major motor control pathway for axons from the cerebral cortex to the spinal cord

pyrogens exogenous and endogenous substances that induce fever, such as the bacterial substance LPS and interleukin-1, which both increase the thermoregulatory set point in the hypothalamus. The endogenous pyrogens may also come directly from tissue necrosis

pyrosis burning sensation in the chest usually associated with gastroesophageal reflux; also called heartburn or acid indigestion

pyruvate carboxylase enzyme of the ligase class that catalyzes the irreversible carboxylation of pyruvate to form oxaloacetate

pyruvate dehydrogenase allosteric enzyme that transforms pyruvate into acetyl-CoA, which is then used in the citric acid cycle

pyruvate kinase enzyme that catalyzes the transfer of a phosphoryl group from phosphoenolpyruvate to adenosine diphosphate, yielding a pyruvate molecule

pyruvic acid end product of the glycolytic pathway

P wave initial, small positive deflection on the electrocardiogram resulting from depolarization of the atria

Q10 phenomenon in which the rate of a biological process increases when the temperature is increased by 10°C; this value is obtained using the following formula: Q10 = rate at (T + 10°C)/rate at T, where T = starting temperature; for biological systems, the Q10 value is generally between 1.5 and 2.5

QRS complex complex, spiked, largely positive deflection on the electrocardiogram resulting from depolarization of the ventricles

QRS interval time interval associated with ventricular depolarization and represented by the time interval of the QRS complex on the electrocardiogram

QT interval interval of time associated with depolarization and repolarization of the ventricles. It measures the interval of time between the initiation of the Q wave and the end of the T wave on the electrocardiogram and is sometimes referred to as electrical systole

quantum number of transmitter molecules released by any one exocytosed synaptic vesicle

quantum content total number of quanta (vesicles filled with a certain number of transmitter molecules) released when the synapse is activated

Q wave first downward (negative) deflection of the electrocardiogram following the isoelectric interval after completion of the P wave

radioimmunoassay (RIA) scientific method used to test antigens (e.g., hormone levels in the blood) without the need to use a bioassay. It involves mixing known quantities of radioactive antigen (frequently labeled with γ-radioactive isotopes of iodine attached to tyrosine) with antibody to that antigen and then adding unlabeled or "cold" antigen and measuring the amount of labeled antigen displaced

radioreceptor assay important modification of the radioimmunoassay that uses specific hormone receptors rather than antibodies as the hormone-binding reagent. In theory, this method measures biologically active hormone, because receptor binding rather than antibody recognition is assessed

rapid adaptation process in phasic sensory receptors in which the output to the central nervous system decreases quickly while the applied stimulus is maintained in intensity

rapid adapting receptors sensory terminals of myelinated afferent fibers found in large conducting airways; also referred to as irritant receptors

rapid ejection phase portion of the cardiac cycle starting immediately after the opening of the aortic valve, in which blood is ejected into the aorta from left ventricular contraction and continuing up to the peak ejection flow rate and peak aortic systolic pressure; it comprises the first third of the ejection phase of ventricular contraction, during which 70% of the stroke volume is ejected

rapid eye movement (REM) sleep see REM sleep

rapid ventricular filling first third of filling of the ventricle during diastole

rarefaction reduction of a medium's density; the opposite of compression

ras (RAt sarcoma) protein subfamily of small GTPases that are generally responsible for signal transduction leading

Rathke pouch evagination of the oral ectoderm from which the adenohypophysis is formed

reactive hyperemia response of a tissue to a period of ischemia or no blood flow in which blood flow exceeds the value seen before the ischemia or flow stoppage once the ischemia or stoppage is removed

reactive oxygen species (ROS) collective term to include free radicals (hydroxyl radical, superoxide ion, and hydrogen peroxide)

receptive relaxation reflex triggered by stimulation of mechanoreceptors in the pharynx followed by transmission over afferents to the dorsal vagal complex and activation of efferent vagal fibers to inhibitory musculomotor neurons in the gastric enteric nervous system

receptor protein molecule on the cell surface or located within the cell that receives and responds to a neurotransmitter, hormone, or other substance

receptors signaling systems that reside either in the plasma membrane or within cells and are activated by a variety of extracellular signals or first messengers, including peptides, protein hormones and growth factors, steroids, ions, metabolic products, gases, and various chemical or physical agents (e.g., light); divided into two categories: cell surface receptors (G protein–coupled receptors, ion channel–linked receptors, and enzyme-linked receptors) and intracellular receptors (steroid and thyroid hormone receptors)

receptor (membrane) membrane surface proteins with unique conformations for specific binding of chemical signal substances and triggering of changes in the cell's behavior

receptor adaptation general loss in the efficacy of a receptor-mediated response after sustained stimulation of the receptor

receptor-mediated endocytosis see exocytosis

receptor potential characteristic electrical record of a sensory receptor; a generator potential specific to a given organ, such as the electroretinogram or the cochlear microphonic

reciprocal inhibition synaptic pattern that causes inhibition of antagonist muscles during contraction of an agonist

rectoanal reflex relaxation of the internal anal sphincter in response to mass movement of feces distention of the rectosigmoid region of the large intestine

red blood cells most common cell in the blood and the principal means of delivering oxygen to cells via the circulatory system; also referred to as erythrocytes

red cell distribution width (RDW) measures the degree of the average size dispersion of erythrocytes and thereby indicates the degree of anisocytosis

red marrow part of bone marrow that forms blood cells

red nucleus group of neurons in the midbrain that receive input from the cerebral cortex and cerebellum and produce output to the spinal cord via the rubrospinal tract

reduced ejection phase ejection phase of the cardiac cycle in which the rate of ventricular outflow starts to diminish. It is the last phase of systole

reduced ventricular filling filling phase of the cardiac cycle in which the rate of ventricular filling begins to diminish. It is the last phase of diastole

5α-reductase steroidogenic enzyme that converts testosterone to dihydrotestosterone

reentry tachycardia type of ventricular tachycardia caused by continual recycling of conducted action potentials through an abnormal pathway in the heart

referred pain pain from deep structures perceived as arising from a surface area remote from its actual origin; the area where the pain is appreciated is innervated by the same spinal segment(s) as the deep structure; also known as reflective pain

reflection coefficient measure of the relative permeability of a particular membrane to a particular solute; calculated as the ratio of observed osmotic pressure to that calculated from van't Hoff law; also equal to 1 minus the ratio of the effective pore areas available to solute and to solvent

reflex neuronal event occurring beyond volition; in neurophysiology, it is a relatively simple behavioral response of an effector produced by influx of sensory afferent impulses to a neural center and its reflection as efferent impulses back to the periphery to the effector (e.g., muscle); the neural center may consist of interneurons; the simplest reflex circuit consists only of sensory and motor neurons

reflex sympathetic dystrophy (RSD) chronic, painful, and progressive neurological condition that affects the skin, muscles, joints, and bones; usually develops in an injured limb, such as a broken leg, or following surgery; however, many cases of RSD involve only a minor injury, such as a sprain, and in some cases, no precipitating event can be identified; also called complex regional pain syndrome

regional compliance pressure–volume relationship at a specific region of the lung (i.e., the apex and base); compliance is the ability of the lungs to stretch during a change in volume relative to an applied change in pressure

regional hypoventilation condition in which a region of the lung is being underventilated with respect to an adjacent region of the lung

regional hypoxia hypoxic condition in a regional part of the lung, as contrasted with generalized hypoxia; see generalized hypoxia

regulated exocytosis form of exocytosis in which vesicles are filled, stored in the cytoplasm, and their contents released only when a specific extracellular stimulus arrives at the cell membrane

regulatory light chains small protein constituents of the myosin molecule that regulate its interaction with actin

regulatory volume decrease mechanism by which solute and water exit the cell to correct a previous increase in volume resulting from the osmotic entry of water

regulatory volume increase (RVI) mechanism by which solute and water enter the cell to correct a previous decrease in volume resulting from the osmotic exit of water

relative humidity quantity of water vapor that exists in a gaseous mixture of air and water

relative pressure pressure relative to atmospheric pressure

relative refractory period window of time following one action potential during which a greater-than-

usual stimulus is required to elicit an action potential

relaxin a polypeptide hormone produced by the corpus luteum and the decidua that assists parturition by softening the cervix and increasing oxytocin receptors

releasing factors see releasing hormones

releasing hormones hypothalamic hormones that reach the anterior pituitary lobe by a portal system of capillaries and regulate the secretion of most hormones of the endocrine system; also known as releasing factors

REM sleep rapid eye movement sleep; a phase of sleep in which the eye movement becomes rapid and the electroencephalograph becomes desynchronized, with a loss of skeletal muscle tone

renal blood flow (RBF) volume of blood delivered to the kidneys per unit time

renal plasma flow (RPF) volume of blood plasma per unit time flowing through the kidneys

renin proteolytic enzyme produced by granular cells in the kidney that catalyzes the formation of angiotensin I from angiotensinogen

renin–angiotensin–aldosterone system salt-conserving system

renin–angiotensin–converting enzyme enzyme in lung endothelium that converts angiotensin I to angiotensin II

repolarization change in membrane potential that returns the membrane potential to a negative value after the depolarization phase of an action potential has just previously changed the membrane potential to a positive value

residual volume (RV) volume remaining in the ventricle at the end of systole

resistance capacity of a membrane that inhibits flow of ions across the membrane

resistance to thyroid hormone (RTH) rare syndrome in which thyroid hormone levels are elevated but thyroid-stimulating hormone level is not suppressed

respiration process of exchanging oxygen and carbon dioxide from the cells

respiratory acidosis abnormal condition caused by an accumulation of carbon dioxide causing the blood to become too acidic, with a concomitant decrease in pH

respiratory alkalosis abnormal process characterized by the loss of too much CO2, which leads to a rise in arterial blood pH

respiratory burst rapid cellular release of reactive oxygen species; also known as oxidative burst

respiratory exchange ratio (R) ratio of the volume of carbon dioxide exhaled to the volume of oxygen taken up

respiratory quotient (RQ) steady-state ratio of carbon dioxide produced by tissue metabolism to oxygen consumed in the same metabolism; for the whole body, normally about 0.82 under basal conditions; in the steady state, the respiratory quotient is equal to the respiratory exchange ratio

respiratory sinus arrhythmia repetitive increase and decrease in heart rate seen on inspiration and expiration of the lungs

resting force force present in a muscle prior to stimulation

resting length length of an unstimulated muscle; its natural length in the body

resting membrane potential membrane potential of an excitable cell in the unstimulated state. It is negative relative to the extracellular fluid and is a steady-state potential defined by the electrochemical gradients for ions that can pass through leakage channels in the membrane and the contribution of an electrogenic pump

resting state the state of the voltage-gated sodium channel in which it is closed but capable of being opened

reticular formation region in the central portion of the brainstem where collections of nerve cells regulate integrative autonomic and spinal reflex functions and coordinate levels of consciousness and attention

reticulocyte young erythrocyte with residual nuclear material

reticuloendothelial system (RES) phagocytic cells in connective tissue responsible for removing old cells, debris, and pathogens from the bloodstream

retinohypothalamic tract projection of axons of retinal ganglion cells in the eye to the suprachiasmatic nucleus of the hypothalamus

retinoid X receptor (RXR) nuclear hormone receptor that binds to other nuclear receptors to form heterodimers that activate transcription

retinol principal form of vitamin A; plays a primary role in vision as well as growth and differentiation. It is derived directly from animal sources or through conversion from beta-carotene (found abundantly in carrots) in the small intestine

retinol-binding protein (RBP) protein synthesized by the liver that binds with retinol in response to falling levels of vitamin A. RBP secretion depends on vitamin A availability

retinopathy deterioration of the blood vessels of the retina, leading to blindness

retinyl ester reesterification of retinol by the enzyme lecithin: retinol acyltransferase. Retinyl ester is incorporated in chylomicrons and taken up by the liver

retrograde direction of movement of material from the tip of an axon toward the cell body of the neuron

retrograde amnesia loss of memory laid down prior to a certain point in time

retrograde transport transport of cellular components from the nerve process to the soma

retropulsion movement of luminal contents in the oral direction

reversal potential voltage across the endplate membrane determined by the Na+ and K+ concentrations inside and out

reverse T3 (rT3) reverse triiodothyronine; a substance generated by inner-ring deiodination of thyroxine

reward system circuit in the brain involved in pleasurable sensation comprising projections from neurons in the midbrain ventral tegmental area to the nucleus accumbens in the cerebrum and other limbic structures

Reynolds number (Re) calculated unit used to predict when turbulence will occur in a fluid flow stream. It takes into account the contribution of fluid flow velocity, fluid viscosity, and the geometry of the tube through which the flow is occurring

rheology study of the fluid properties of blood, which is a suspension and, therefore, a nonhomogeneous fluid

rhesus factor (Rh) protein on the erythrocyte surface of some people

rheumatoid arthritis (RA) traditionally considered a chronic, inflammatory autoimmune disorder that causes the immune system to attack the joints. It is a disabling and painful inflammatory condition, which can lead to substantial loss of mobility as a result of pain and joint destruction

rhodopsin pigment of the retina that is responsible for both the formation of the photoreceptor cells and the first events in the perception of light; also known as visual purple

rhythmicity property of all heart cells by which they can generate their own action potentials in a repetitive, uniform, or rhythmic manner. It naturally occurs in the nodal tissue of the healthy heart and is responsible for setting the intrinsic heart rate but can be manifested in ectopic foci and thus cause cardiac arrhythmias

rib cage 12 pairs of ribs that are hinged to the vertebral column

rickets disorder of normal bone ossification manifested by distorted bone movements during muscular action. Rickets is caused by vitamin D deficiency

right atrium upper chamber of the right heart. It receives the entire venous blood supply returning from all the systemic organs. It empties into the right ventricle through the tricuspid valve

right bundle-branch block condition in which transmission of action potentials is blocked in the right branch of the bundle of His

right ventricle lower chamber of the right heart that receives blood from the right atrium through the tricuspid valve and pumps blood across the pulmonic valve into the pulmonary artery

right ventricular hypertrophy abnormally increased muscle mass in the right ventricle. It occurs in response to any factor that chronically increases wall stress on the right ventricle, such as pulmonary hypertension or a stenotic pulmonic valve

right-to-left shunt anatomical shunt in which blood goes directly from the pulmonary artery to the pulmonary vein and bypasses the alveoli. Shunted blood does not get oxygenated

rigor crossbridge myosin crossbridge strongly attached to actin and lacking adenosine triphosphate

rigor mortis postmortem muscle stiffness resulting from rigor crossbridges in the absence of adenosine triphosphate

rising phase the portion of the action potential in which the membrane potential is approaching 0 mV

rolling slow movement of leukocytes in blood vessels along the endothelium

rough endoplasmic reticulum (RER) eukaryotic organelle that forms an interconnected network of tubules, vesicles, and cisternae within cells; functions to synthesize proteins

rouleaux phenomenon stacking of erythrocytes like coins in blood

rubor redness associated with acute inflammation

rubrospinal tract motor control pathway for axons from the red nucleus to the spinal cord

rugae gastricae longitudinal folds in the corpus of the empty stomach

R wave in the normal heart, it is the highest amplitude, sharp, positive deflection of the QRS complex of

the electrocardiogram (ECG); it is associated with a positive deflection in all frontal ECG leads except aVR and is caused by ventricular depolarization during electrical activation of the heart

ryanodine receptor (RyR) controllable channel in the sarcoplasmic reticulum of muscle that allows calcium release

SA node sinoatrial node; the normal "pacemaker" of the heart. It can generate its own action potentials in a repetitive manner and is responsible for setting the intrinsic heart rate. It is the first area of the heart to display electrical activity during the cardiac cycle

saccades rapid sideways movements of the eyeballs that change the direction of vision

safety factor at the myoneural junction, the amount by which the released transmitter substance exceeds that necessary for effective transmission

salivary glands heterogeneous group of exocrine glands that produces saliva; innervated by both the parasympathetic and sympathetic divisions of the autonomic nervous system. Parasympathetic stimulation of the salivary glands results in increased salivary secretion. The parotid, submandibular (submaxillary), and sublingual glands are the major salivary glands. They are drained by individual ducts into the mouth

salivon basic unit of the human submandibular gland, consisting of the acinus, the intercalated duct, the striated duct, and the excretory (collecting) duct—the network of acini and ducts that comprises the salivary glands

saltatory conduction process in a myelinated nerve whereby action potentials are successively generated at neighboring nodes of Ranvier and thus the action potential appears to jump from one node to the next

sarcolemma plasma membrane of a muscle cell, along with a fine fibrillar connective tissue network

sarcomere fundamental organized contractile unit of a skeletal or cardiac muscle; includes the overlapping myofilaments between two Z lines

sarcoplasmic reticulum elaboration of the endoplasmic reticulum of muscle that contains, releases, and takes up calcium during the control of contraction

satellite cell precursor to a muscle cell

satiety sensation of fullness or being well fed

S cells type of endocrine cell in the intestinal mucosa that releases secretin induced by the entry of acidic chyme from the stomach into the small intestine during the intestinal phase of digestion

scalene muscles three paired accessory skeletal muscles in the lateral neck that elevate the rib cage during forced inspiration

Scatchard plot graph used to find the equilibrium constant for a reaction such as [H] + [R] ⇌ [HR] ([HR]/[H]) versus [HR], or any functions proportional to these quantities; the magnitude of the slope of the graph is the equilibrium constant

schistocyte erythrocyte fragment generated as cell flows through damaged vessels

schizophrenia psychiatric illness marked by disordered thoughts, delusions (fixed false beliefs), inappropriate emotional response, auditory hallucinations, social withdrawal, and lethargy

Schwann cell glial cells in the PNS that produce a myelin sheath around neuronal axons in the periphery

scintigraphic techniques use of radioisotopes, either ingested with food or released from swallowed

capsules (in this case) to measure transit times through different regions of the gastrointestinal tract

scotopic (nighttime) vision noncolor vision that is served by the rod cells of the retina

scotopsin protein moiety in retinal rods that combines with 11-cis-retinal to form rhodopsin

scurvy disorder characterized by weakness, fatigue, anemia, and bleeding gums caused by vitamin C deficiency

second heart sound second normally audible sound of contraction of the heart caused by vibrations set up in the ventricular chamber following abrupt closure of the aortic and pulmonic valves at the onset of ventricular relaxation (diastole); its intensity is proportional to the intensity of valve closure and is increased whenever aortic or pulmonary pressure is abnormally high; thus, it is taken as a clinical indicator of possible systemic or pulmonary hypertension, respectively

second messenger intermediary molecule that is generated as a consequence of the binding of a first messenger to a receptor. These intermediary molecules are generated in large quantities, and this amplifies the signaling initiated by the first messenger. Examples of second messengers are cyclic adenosine monophosphate, cyclic guanosine monophosphate, calcium, inositol 1,4,5-triphosphate, and diacylglycerol

second polar body small haploid cell produced by unequal second meiotic division of an oocyte

secondary active transport mechanisms see active transport

secondary axons (type II) afferent axons from nuclear chair fibers of the muscle spindle, smaller in diameter than primary (type I) endings

secondary follicular stage stage during which several layers of granulosa cells and a single theca surround the oocyte

secondary lymphoid organs see lymphoid organs

secondary oocyte haploid oocyte produced by completion of the first meiotic division

secondary pacemaker ectopic foci that repetitively activates in the myocardium, thereby pacing the heart at a rate other than that set by the sinoatrial node

secondary peristaltic wave peristaltic propulsion in the esophagus initiated by an initial block of forward movement of a swallowed bolus or by the presence of acid in the esophagus

secondary sex characteristics external sex-typical male and female structures

secondary spermatocytes spermatocyte that divides to form the spermatids

second-degree atrioventricular block any condition in which some, but not all, action potentials from the atria reach the ventricles. It usually arises from blockage at the level of the atrioventricular node and results in an irregular heart rate

secretagogue substance stimulating secretion

secretin hormone secreted by the duodenal and jejunal mucosa when exposed to acid chyme that stimulates pancreatic secretion rich in bicarbonate ions. Secretin inhibits gastrin release

secretomotor neuron motor neurons in the submucous plexus, which innervate and evoke secretion from the intestinal glands

secretory phase phase of the endometrial cycle during which the endometrial glands become coiled,

store glycogen, and secrete large amounts of carbohydrate-rich mucus. The stroma increases in vascularity and becomes edematous, and the spiral arteries become tortuous

segmentation specific pattern of small intestinal motility that starts with the ingestion of a meal and accomplishes mixing of the contents in the lumen; also called digestive motility

seizure sudden abnormal synchronized discharge of electrical activity in the brain

selective serotonin reuptake inhibitors (SSRIs) class of compounds typically used as antidepressants to treat depression, anxiety disorders, and some personality disorders

selenocysteine rare amino acid with properties that make it ideal for catalysis of oxidoreductive reactions

self-tolerance see immune tolerance

sella turcica depression in the sphenoid bone of the skull

semantic memory memory of facts

semen combination of sperm, seminal fluid, and other male reproductive secretions

semicircular canals three orthogonally oriented fluid-filled tubes of the vestibular apparatus

seminal emission movement of sperm and associated fluids from the cauda epididymis and vas deferens into the urethra

seminal plasma fluid portion of semen, secreted by the male sex accessory glands

seminiferous tubules tiny tubes in the testes where sperm cells are produced, grow, and mature

sensorineural deafness hearing impairment due to damage of the inner ear nerve endings, the cochlear portion of the eighth cranial nerve, the vestibulocochlear nerve, or the cortical hearing center

sensory modality specific type of sensory activity; the kind of sensation

sensory neuron neuron that conducts impulses arising in a sense organ or at sensory nerve endings

sensory receptor cell or part of a cell specialized and normally functioning to convert environmental stimuli into nerve impulses or some response, which, in turn, evokes nerve impulses; most sensory receptor cells are nerve cells, but some nonnervous cells can be receptors (e.g., intestinal enteroendocrine cells); one method of classifying receptors is by the form of adequate stimulus: chemoreceptors, osmoreceptors, and mechanoreceptors are normally stimulated by chemicals, osmotic pressure differences, and mechanical events, respectively

sensory transduction process whereby environmental signals (radiation, mechanical forces, or chemical quantities) are transformed into trains of nerve impulses

sepsis bloodstream infection causing excessive inflammation

septal nuclei group of cholinergic neurons located in the basal forebrain area with reciprocal connections with the hippocampus

septic shock decrease in blood pressure associated with overproduction of nitric oxide in infected tissue. It is characterized by high, unnecessary blood flow to the affected organs at the expense of flow to other organs in the body

serosa one of four layers of the stomach wall; lies over the muscularis externa, consisting of layers of connective tissue continuous with the peritoneum

serotonergic neuron type of neuron that uses serotonin as a neurotransmitter

serotonin mediator of the inflammatory response and a neurotransmitter used by central and peripheral neurons; also known as 5-hydroxytryptamine or 5-HT

serous cells cells that are found in the salivary glands, contain an abundance of rough endoplasmic reticulum, and secrete digestive enzymes

Sertoli cell cell, found in large numbers lining the semen-producing tubules of the testis, that provides support and nourishment for developing sperm

serum blood plasma without clotting factors

serum iron levels test measuring iron levels in blood as part of the iron profile

serum protein electrophoresis electrophoretic separation test of blood proteins

set point any one of a number of quantities or physiological variables (e.g., body weight, body temperature) that the body tries to keep at a particular value or in a state of dynamic constancy

sex hormone–binding globulin (SHBG) substance that binds sex steroids in the blood

SH2 domain structurally conserved protein domain contained in intracellular signal–transducing proteins that "helps" a protein find its way to another protein by recognizing phosphorylated tyrosine on the other protein

shallow water blackout condition in which a person passes out underwater as a result of hypoxia to the brain

shear stress "rubbing" or frictional effect exerted along the walls of a cylinder as a result of fluid flowing in the cylinder. This force tends to strain or deform the inner portion of the wall in the direction of flow. In arteries, shear stress has an important influence on the function of the endothelium and influences the location of the development of atherosclerotic plaques

shivering bodily function in response to early hypothermia in warm-blooded animals. When the core body temperature drops, the shivering reflex is triggered. Muscle groups around the vital organs begin to shake in small movements in an attempt to create warmth by expending energy. Shivering can also be a response to a fever, as a person may feel cold, although the core temperature is already elevated

short hypophyseal portal vessels vessels that deliver blood into the sinusoids of the anterior pituitary

short-term memory newly acquired information that can be readily recalled for only a few minutes

shunt diversion of blood away from the alveoli

sickle cell anemia hereditary disorder that leads to an abnormal production of erythrocytes

sieving action selective gastric emptying of particles according to the particle size with the smallest particles emptying first

signal cascade series of biochemical reactions in which the products of one reaction are consumed in the next reaction

signal transduction process by which a cell converts one kind of signal or stimulus into another through a series of biochemical reactions that are often linked by second messengers, which serve to amplify the initial stimulus

silent nociceptor unresponsive sensory afferent nerve terminal that becomes responsive to mechanical

stimulation during inflammatory states

simple acid–base disturbance one of the four primary acid–base disturbances

simple micelle micelle in which bile salts alone are present

single breath test test to determine oxygen uptake in a patient, using a single breath of a low concentration of carbon monoxide

single effect establishment of a modest osmotic gradient at any level of the loop of Henle. This gradient is developed into a larger gradient along the axis of the loop by countercurrent multiplication

single nucleotide polymorphism (SNP) DNA sequence variation occurring when a single nucleotide in the genome differs between members of a species or paired chromosomes in an individual

sinus bradycardia decreased heart rate caused by normal physiological effects on the sinoatrial node

sinus tachycardia elevated heart rate caused by normal physiological effects on the sinoatrial node

sinusoidal endothelial cells cells that lack a basement membrane and have sievelike plates, thereby permitting the ready exchange of materials between the perisinusoidal space and the sinusoid

size principle pattern of muscle activation in which the smallest motor neurons and associated motor units are activated first and then, as more power is needed, larger size motor neurons are activated

skeletal muscle striated muscle tissue that is associated with the skeleton as well as the diaphragm, parts of the esophagus, and some voluntary alimentary sphincters (e.g., the external anal sphincter). It is an excitable tissue that can contract and generate force when activated electrically by neurotransmitters released from its associated motor neuron.

sleep apnea a serious sleep disorder that occurs when breathing is interrupted during sleep. There are two types of sleep apnea: (1) obstructive sleep apnea and (2) central sleep apnea. Obstructive sleep apnea is by far the more common of the two forms, and is caused by airway blockage. The blockage usually occurs when soft tissue in the back of the throat collapses during sleep. With central sleep apnea the airways are not blocked, but it is due to a dysfunction in the respiratory control center in the brain that fails to signal the respiratory muscles to contract.

sleep apnea syndrome sleep disorder characterized by abnormal pauses in breathing that last a few seconds to minutes

sliding filament theory schema for muscle contraction involving the relative motion of actin and myosin filaments driven by the action of myosin crossbridges

slow adaptation process in static sensory receptors in which the output to the central nervous system is maintained (or falls slowly) while the applied stimulus is maintained in intensity

slow axoplasmic transport mechanism by which structural proteins, such as actin, neurofilaments, and microtubules, are transported from the cell body to the axon; occurs at 1 to 2 mm/d

slow excitatory postsynaptic potential a postsynaptic potential characterized by membrane depolarization and augmented excitability that lasts for extended periods of seconds or minutes

slow wave membrane electrical potential that waxes and wanes in a rhythmic fashion in the gastrointestinal tract; the slow wave determines the timing of a contraction but is not enough to produce a contraction in the absence of a burst of spike potentials triggered by the release of a neurotransmitter

slow-twitch fibers skeletal muscle fibers specialized for long-duration activity, using aerobic

metabolism

slow-wave sleep (SWS) four stages of progressively deepening sleep during which the electroencephalogram becomes progressively slower in frequency and higher in amplitude

small-molecule transmitters amino acids and monoamines used as neurotransmitters

smooth muscle muscle tissue that lacks the striated microscopic appearance of skeletal and cardiac muscle. It is the most diverse and complex of all the muscle tissues, being able to generate complex contraction patterns to a multitude of physical, chemical, hormonal, paracrine, and neurotransmitter stimuli. Unlike skeletal and cardiac muscle, smooth muscle can be made to relax actively.

SNARES proteins found on both the synaptic vesicle and plasma membrane that cause the synaptic vesicle to dock and bind to the presynaptic terminal membrane

sodium appetite craving for salt

sodium–iodide symporter (NIS) substance located on the basal plasma membrane of the thyroid follicular cell that transports iodide into the cell

solvent drag one mechanism by which sodium is absorbed by the duodenum and jejunum

soma neuronal cell body; also called perikaryon

somatic pain sensation of pain arising from nonvisceral parts of the body

somatomedins class of small peptides responsible for the mediation of some growth hormone actions that increase the rate of cartilage synthesis by promoting the uptake of sulfate and the synthesis of collagen; also known as insulin-like growth factors

somatostatin (1) gastrointestinal hormone secreted by endocrine cells in the antrum of the stomach that inhibits the release of gastrin and consequently gastric acid secretion when the pH of the stomach lumen falls below 3; (2) polypeptide from the hypothalamus that inhibits secretion of growth hormone; also known as somatotropin release–inhibiting factor (SRIF)

somatotopic maps discrete groupings of motor or sensory neurons associated with functions of specific areas of the body

somatotrophs cells located in the anterior pituitary that secrete growth hormone

somatotropin release–inhibiting factor see somatostatin

space constant (λ) length along a membrane required for an electrotonic membrane potential to decay to 37% of its maximal value; also called length constant

spasticity feature of altered skeletal muscle performance occurring in disorders of the central nervous system impacting the upper motor neuron in the form of a lesion; when there is a loss of descending inhibition from the brain to the spinal cord, such that muscles become overactive, this loss of inhibitory control can cause an ongoing level of contraction, with decreased ability for the affected individual to volitionally control the muscle contraction, and increased resistance felt on passive stretch

spatial summation summation of two or more membrane potentials generated at different sites; also called motor unit summation

special senses (i.e., hearing, sight, smell, and taste) senses that have specialized organs devoted to them

specific compliance lung compliance divided by the functional residual capacity; used to correct for lung size

specific gravity measure of blood density

spectrin cytoskeletal protein that lines the intracellular side of the plasma membrane, forming a scaffold important role in maintenance of plasma membrane integrity and cytoskeletal structure

spermatids any of the four haploid cells formed by meiosis in a male organism that develop into spermatozoa without further division

spermatogenesis process of producing sperm, the male reproductive cells

spermatogonia any of the cells of the gonads in male organisms that are the progenitors of spermatocytes

spermatozoa mature sperm cells

spermiation release of mature spermatozoa from the surface of the Sertoli cell into the lumen of the seminiferous tubule

spermiogenesis process by which spermatids mature into sperm cells

spherocyte abnormal, spherical-shaped erythrocyte

sphincter of Oddi ring of smooth muscle surrounding the opening of bile ducts in the duodenum that regulates the flow of bile and pancreatic juice into the duodenum and prevents the reflux of intestinal contents into the pancreatic ducts

sphygmomanometer external, noninvasive device for measuring arterial pressure producing external pressure on a limb that is measured by a column of mercury or calibrated gauge

spinal shock decrease in blood pressure resulting from physical trauma to the spinal cord

spinnbarkeit highly elastic cervical mucus

spinobulbar muscular atrophy neurodegenerative neuromuscular disease associated with mutation of the androgen receptor rarely affecting females; also known as Kennedy disease

spinocerebellar tracts afferent pathways bringing sensory axons from the spinal cord to the cerebellum or associated brainstem nuclei

spinocerebellum portion of the cerebellum concerned with coordination of axial and proximal limb motor function

spiral arteries specialized arteries that supply blood into the maternal placental sinus

spirogram recording from the spirometer, which is an instrument for recording respiratory movements

spirometry measurement of lung volumes by a spirometer

splanchnic nerves mixed nerves in the mesentery that have both sympathetic efferent and sensory afferent fibers

splay renal physiology, the rounding of the corner on the graph relating tubular reabsorption or secretion of a substance to its arterial plasma concentration, resulting in part from the fact that some nephrons reach their tubular maximum before others

splenomegaly enlargement of the spleen usually associated with hyperfunction of the organ SRY sex-determining region gene on the Y chromosome; required to produce male gonadal differentiation

SRY (sex-determining region, Y chromosome) found on the Y chromosome; the gene encodes a transcription factor required for the development of the testes

S-type enteric neurons synaptic-type enteric neurons; neurons with a single long process (axon) and so named because nicotinic fast excitatory postsynaptic potentials occur in virtually all of the S-type enteric neurons

standard curve quantitative research tool and method of plotting assay data that are used to determine the concentration of a substance, particularly proteins and DNA

standard frontal lead system three frontal bipolar lead system developed by Einthoven. It consists of a lead I, in which the right arm has a negative polarity and the left arm is positive; a lead II, in which the right arm has a negative polarity and the left foot is positive; and a lead III, in which the left arm has a negative polarity and the left foot is positive

Starling forces all of the hydrostatic and osmotic forces within the capillary plasma and the interstitium that determine the direction and rate of bulk fluid transfer between the capillary blood and the interstitium

Starling-Landis equation illustrates the role of hydrostatic and oncotic forces in the movement of fluid across capillary membranes, which may occurs from diffusion, filtration, or pinocytosis: $JV = KhA\,[(Pc - Pt) - \sigma(COPp - COPt)]$

Starling's law of the heart law that states that stroke volume increases when ventricular filling increases and decreases when ventricular filling decreases; also known as Starling law of the heart

static compliance compliance curve generated with no airflow

statin drug used to lower plasma cholesterol level; inhibits HMG-CoA reductase, the rate-limiting enzyme of the mevalonate pathway of cholesterol synthesis

steady state state of a system in which the recently observed behavior of the system will continue into the future

steatorrhea excretion of unabsorbed lipids in the feces, caused by a pancreatic deficiency that significantly reduces the ability of the exocrine pancreas to produce digestive enzymes. Normally about 5 g/d of fat are excreted in human stool, but as much as 50 g/d can be excreted in the case of steatorrhea

stereocilia apical modifications of the cell characterized by their length and their lack of motility; found in the inner ear, the ductus deferens, and the epididymis

sternocleidomastoids paired muscles in the superficial layers of the anterior portion of the neck that, in addition to flexing and rotating the head, function as accessory muscles to elevate the rib cage during forced inspiration, along with the scalene muscles of the neck

steroid hormone lipid hormones generally synthesized from cholesterol in the gonads and adrenal glands that can freely traverse the plasma membrane to enter the cytoplasm as well as membranes of other organelles such as the nucleus they are carried in the blood bound to a specific carrier protein

steroidogenesis process of steroid hormone production

steroidogenic acute regulatory (StAR) protein protein that facilitates transport of cholesterol into the mitochondria

stigma specific site where the follicular wall thins by cellular deterioration and bulges for rupture

stimulus input to a sensory receptor that causes it to produce its characteristic output

stellate cells specialized cells that store vitamin A and are located in the space of Disse in the liver

stress relaxation slow and time-dependent fall in force of a viscoelastic substance held at a stretched

length

stretch-activated calcium channels unique calcium channels found in the plasma membrane of vascular smooth muscle cells that open when the cell, or the artery in which it is contained, is stretched. This results in calcium influx and contraction of the smooth muscle cell/artery. This channel is a separate entity from ligand or voltage-gated calcium channels in smooth muscle, and it believed to be responsible for the myogenic contractile response in arteries when they are exposed to an increase in intra-arterial pressure.

stria vascularis pseudostratified columnar vascularized epithelium containing melanocytes, which help maintain the high potassium concentration of the endolymph that is produced here

striae irregular areas of skin that appear as red or purple bands, stripes, or lines

striated duct duct lined with columnar cells that is part of the network of ducts that comprise the salivary glands, whose major function is to modify the ionic composition of the saliva

striatum caudate nucleus and putamen of the basal ganglia

stroke volume volume of blood ejected from the heart in one systole

stromal layer part of endometrium of the uterus; the closest layer to the myometrium

strong acid acid with a high dissociation constant, which consequently is highly ionized in solution

subcortical structures collections of neuronal cell bodies in the cerebrum that are located deep to the cerebral cortex

sublingual glands salivary glands that empty saliva into the mouth; located anterior to the submandibular gland under the tongue, beneath the mucous membrane of the floor of the mouth

submandibular ganglion location of synapse between pre- and postganglionic parasympathetic neurons from the superior salivatory nucleus through cranial nerve VII, which are involved in control of the submandibular glands

submandibular glands (submaxillary glands) paired salivary glands located beneath the floor of the mouth, accounting for 70% of the salivary volume

submucosa layer of dense irregular connective tissue in the stomach wall (one of four layers) or loose connective tissue that supports the mucosa as well as joins the mucosa to the bulk of underlying smooth muscle (fibers running circularly within layer of longitudinal muscle)

submucosal plexus ganglionated plexus of the enteric nervous system situated between the mucosa and circular muscle coat of the small and large intestine; it consists of an inner ganglionated plexus called the Meissner plexus and an outer ganglionated plexus called the Schabadasch plexus

substance P neuropeptide used as a neurotransmitter by small dorsal root ganglion cells that signal pain

substantia nigra group of nerve cells in the upper brainstem, where dopaminergic neurons important in Parkinson's disease are located

subthalamic nucleus group of nerve cells in the basal ganglia that receives input from the other basal ganglia nuclei and provides output to the globus pallidus internus

succinylcholine blocker of the myoneural junction that causes maintained depolarization of the endplate membrane

suckling reflex reflex in which the stimulation of sensory nerves in the breast by the infant initiates a neural signal to the hypothalamus, resulting in release of oxytocin to stimulate milk letdown

sudden infant death syndrome (SIDS) sudden death of an infant that is unexpected by history and cannot be explained following a thorough forensic autopsy; also known as crib death

sulcus valley on the surface of the brain

sulfonylureas any of a group of hypoglycemic drugs that act on the β cells of the pancreas to increase the secretion of insulin

superior cervical ganglion uppermost of the sympathetic ganglia located in the neck. Innervated by the sympathetic nervous system, sympathetic fibers arise in the upper thoracic segments of the spinal cord and synapse in the superior cervical ganglion. Postganglionic fibers leave the superior cervical ganglion and innervate the acini, ducts, and blood vessels, resulting in a short-lived and small increase in salivary secretion

superior colliculus layered structure in which the superficial layers are sensory related and receive input from the eyes as well as other sensory systems; the deep layers are motor related, capable of activating eye movements as well as other responses; and the intermediate layers have multisensory cells and motor properties

superior hypophyseal arteries arteries that give rise to a rich capillary network in the median eminence

superior mesenteric ganglion uppermost of the prevertebral sympathetic ganglia located in the abdomen

superior parietal lobe region of the cerebral cortex that integrates complex sensory information

superior salivatory nucleus region of the pons where parasympathetic preganglionic neurons involved in control of the lacrimal and nasal glands are located

superior vena cava (SVC) single major vein that collects blood from the brain, head, and upper extremities and empties into the right atrium

superoxide dismutase (SOD) antioxidant enzyme that neutralizes superoxide ions in cells by catalyzing the breakdown of superoxide to oxygen and hydrogen peroxide (H2O2)

superoxide ion ($O_2^{\bullet -}$) free radical that is formed during oxygen use in the mitochondria. The free radical is an oxygen molecule with an unpaired electron

supplementary motor area (SMA) cortical region on the medial aspect of the hemispheres that is active in motor control

suprachiasmatic nucleus (SCN) collection of neurons in the hypothalamus responsible for generating the body's circadian rhythms and entraining them to the day–night cycle

supraoptic nuclei portion of the hypothalamus in which magnocellular neuron cells bodies are found

supraventricular tachycardia abnormally high heart rate resulting from an ectopic foci in a region anatomically superior to the ventricles, usually the atria

surfactant surface-reducing material (lipoprotein) lining the alveoli

S wave first downward (negative) deflection of the electrocardiogram following the R wave

sympathetic division division of the autonomic nervous system, with its outflow from the central nervous system in the thoracolumbar segments of the spinal cord and having its ganglia in a pair of chains on either side of the spinal cord and in a grouping of three (celiac and superior and inferior mesenteric) in the abdomen

sympathetic nervous system the division of the autonomic nervous system modulating organ functioning

during times of arousal, stress, and danger, referred to as the “fight-or-flight” system

sympathetic tone concept that some level of neuronal activity is present in the sympathetic neurons, even in an apparent resting state

sympathy coordination of bodily activities by the nervous system

symport membrane transport process in which the driver ion (usually Na+) and the solute move in the same direction

synapse functional (noncytoplasmic) connection between neurons consisting of a presynaptic site of chemical transmitter release and a postsynaptic site of action of the released transmitter

synapsin a class of proteins in the nerve terminal that anchor neurotransmitter-containing vesicles within the cytoplasm

synaptic cleft extracellular space separating the presynaptic and postsynaptic membranes at a chemical synapse

synaptobrevin integral vesicular membrane SNARE protein

synaptotagmin integral vesicular membrane protein that acts as the Ca2+ sensor and binds proteins that cause the vesicles to dock and bind to the presynaptic terminal membrane

syncytiotrophoblast syncytial component of the trophoblast that lacks distinct cell boundaries

syndrome of inappropriate antidiuretic hormone (SIADH) disorder characterized by persistent hyponatremia

synergist muscle that acts in concert with the prime mover muscle

synthase enzyme that catalyzes synthesis of neurotransmitters in the enteric nervous system

systemic circulation circulation outside the thoracic cavity, not including the pulmonary circulation

systole period of time in which the heart is in its contraction phase

systolic hypertension a subclassification of chronic elevated arterial pressure that affects the systolic but not diastolic blood pressure. It is usually seen in the elderly as a result of the general decline of arterial compliance associated with the aging process.

systolic pressure blood pressure in the ventricle or arterial system during the contraction of the heart, or systole

tachyphylaxis rapid decrease in the response to a drug after repeated doses over a short period of time; increasing the dose of the drug will not increase the pharmacological response

tachypnea increased ventilation through rapid shallow breathing (i.e., increased breathing rate)

target cell (1) abnormal erythrocyte with central staining and a pale surrounding area; also known as codocyte or leptocyte; (2) cell that possesses specific receptors for a particular hormone

taste buds organized structures, located on the tongue and pharynx, that serve the gustatory sense

taste pore minute opening of a taste bud on the surface of the oral mucosa through which the gustatory hairs of the specialized neuroepithelial gustatory cells project

T cell type of lymphocyte with specific membrane receptors to recognize peptide antigens

T-cell receptor (TCR) recognition molecule of T cells for antigen–major histocompatibility complex

protein complex

telencephalon region of the central nervous system; also called the cerebrum or brain

temporal lobe inferior and lateral region of the cerebrum

temporal summation time-wise addition of muscle force in response to repeated stimulation; the summation of two or more membrane potentials generated at the same location in quick succession

tension (1) partial pressure of dissolved gas in a liquid; (2) force exerted on the wall of a cylindrical structure that would have the tendency to rip the wall as a result of a positive transmural pressure. It is directly proportional to both the transmural pressure and the radius of the cylinder, such that in two cylinders exposed to the same transmural pressure, the cylinder with the larger internal radius experiences a greater wall tension. This principle is applied to blood vessels and other hollow organs, such as the heart and urinary bladder

terminal arterioles smallest arterioles; they lead directly into capillaries

terminal bronchioles smallest airways in the conducting zone

terminal cisternae lateral regions of the sarcoplasmic reticulum of striated muscle, from which calcium is released and where it is stored at rest; also called lateral sacs

terminal respiratory unit merging of alveolar ducts and their alveoli with adjacent pulmonary capillaries

tertiary follicular stage stage characterized by a large ovarian follicle containing an antral cavity

testosterone main steroid producing the male secondary characteristics

tetanic fusion frequency stimulation rate beyond which individual muscle twitches are no longer discernible

tetanus maintained muscle contraction caused by restimulating a muscle before mechanical relaxation is complete

tetanus/twitch ratio comparison between the maximal tetanic contraction and that of a single twitch

tetrahydrocortisol glucuronide major excretable metabolite of cortisol degradation

tetraiodoacetic acid (tetrac) derivatives formed by degradation of thyroxine

thalamus collection of neuronal cell bodies deep in the cerebrum adjacent to the midline that relays information to and from the cortex

theca externa external dense vascular connective tissue layer of the theca

theca interna internal dense vascular connective tissue layer of the theca

theca lutein cells cells found in the corpus luteum that are formed from the theca cells

thelarche development of breast buds in girls during puberty

The Law of Laplace mathematical relationship relating tension pulling on the wall of a thin-walled vessel to the transmural pressure across the wall. It is given by $T = Pr$, where T is wall tension and r is the internal vessel radius

therapeutic hypothermia (TH) medical treatment that lowers a patient's body temperature order to help reduce the risk of the ischemic injury to tissue that follows a period of insufficient blood flow; also called

controlled hypothermia

thermic effect of food increment in energy expenditure above resting metabolic rate resulting from the cost of processing food for storage and use; one of the components of total metabolism, along with the resting metabolic rate and the exercise component; also known as specific dynamic action

thermodilution in cardiovascular physiology, a technique used to measure cardiac output by the indicator dilution technique in which temperature is used as the indicator

thermogenic action action of thyroid hormones to regulate the basal rate of body heat production and of oxygen consumed

thermoneutrality range of ambient temperatures at which energy expenditure is lowest and no metabolic heat is required to maintain body temperature; thermal balance is maintained with neither shivering nor sweating

thermoreceptors sensory receptors that respond to variation in environmental temperature; separate populations of receptors serve the sensations of warmth and coldness

theta waves electroencephalogram wave pattern with a rhythm ranging from 4 to 7 Hz, observed during sleep

thirst conscious sensation associated with craving for drink, ordinarily interpreted as a desire for water

thirst center located in the anterior hypothalamus, close to the neurons that produce and control arginine vasopressin release; this center relays impulses to the cerebral cortex, so that thirst becomes a conscious sensation

thoracic cavity cavity that houses the lung and is synonymous with the chest cavity

thoracolumbar division division analogous to the sympathetic division of the autonomic system; also called sympathetic division

threshold intensity level below which sensation is not possible. Accessory structures and processes may vary this level

threshold concentration concentration that must be exceeded to begin producing a given effect or result or to elicit a response

threshold potential the membrane potential at which an action potential is generated

thrombi fat globules or air bubbles that form in the bloodstream that act like clots and block vital blood flow

thrombin coagulation protein

thrombocyte cells that play a key role in blood clotting: in mammals, thrombocytes are anucleated cell fragments called platelets; thrombocytes of nonmammalian vertebrates have a nucleus and, thus, resemble B lymphocytes

thrombocytopenia condition characterized by a lower-than-normal number of circulating platelets

thrombopoietin liver/kidney hormone regulating production of thrombocytes

thymus lymphoid organ in which T lymphocytes mature

thyroglobulin (Tg) large protein that is a storage form of the thyroid hormones

thyroid hormone receptor (TR) receptor located in the nuclei of cells that binds thyroid hormones to

facilitate their action on transcription

thyroid hormone response elements (TREs) sequence of DNA in a gene that binds the thyroid hormone receptor

thyroid peroxidase (TPO) substance that catalyzes the iodination of thyroglobulin

thyroid-stimulating hormone (TSH) hormone product of thyrotrophs located in the anterior pituitary

thyrotroph cells located in the anterior pituitary that secrete thyroid-stimulating hormone

thyrotropin-releasing hormone (TRH) polypeptide from the hypothalamus that stimulates secretion of thyroid-stimulating hormone

thyroxine (T4) peptide hormone produced by the thyroid gland that is a precursor to triiodothyronine

thyroxine-binding globulin (TBG) glycoprotein synthesized and secreted by the liver that binds thyroid hormone in the blood

tidal volume volume of air inhaled with each breath

tight junction closely associated areas of two cells whose membranes join together forming a virtually impermeable barrier to fluid

time constant (τ) time required for the membrane potential to decay to 37% of its initial peak value following an influx of ions; a function of membrane resistance and capacitance

tissue growth factors chemical messengers that influence cell division, differentiation, and cell survival; they may exert effects in an autocrine, paracrine, or endocrine fashion

tissue thromboplastin (factor III) factor extrinsic to blood but released from injured tissue during hemostasis; also called tissue factor

tissue plasminogen activator (TPA) substance that has the ability to cleave plasminogen and convert it into plasmin, its active form

titin large filamentous muscle protein that may help prevent overextension of sarcomeres and maintain the central location of A bands

titratable acid acid involved in renal physiology; this term is used to explicitly exclude ammonium (NH_4^+) as a source of acid and is part of the calculation for net acid excretion

toll-like receptor transmembrane protein that recognizes pathogens, activates innate immune responses, and regulates adaptive immune responses

tonic contraction degree of tension, firmness, or maintained contraction in a muscle, in contrast to a phasic contraction

tonic–clonic seizures type of generalized seizure affecting the entire brain; convulsion, characterized by generalized muscle spasms and loss of consciousness, most commonly associated with epilepsy; formerly known as grand mal seizures or grand mal seizures

tonicity quality of a solution related to the concentrations of nonpenetrating solutes, that is, solutes that do not cross the plasma membrane of a cell. Cells placed in a hypotonic solution will accumulate water and their volume will increase. Cells placed in a hypertonic solution will lose water and their volume will decrease. Cell volume will not change in an isotonic solution because there is no net movement of water into or out of the cell

tonotopic organization place-specific frequency discrimination provided over the length of the basilar membrane in the organ of Corti

total bile acid pool total amount of bile acids in the body, primary or secondary, conjugated or free, at any time

total body water volume of water in the body

total iron-binding capacity (TIBC) test analyzing the amount of iron needed to bind to all transferrin

total lung capacity (TLC) total volume of air in the lungs at the end of maximum inspiration

total peripheral vascular resistance (TPR) resistance to flow created by all the systemic vascular segments in the cardiovascular system from the origin of the aorta to the entry of the right atrium. Quantitatively, this value is dominated by the contribution made from the resistance of the arterial side of the circulation, which is much greater than the resistance to flow attributed to the veins. TPR is used in Poiseuille's law to calculate mean arterial pressure or cardiac output in the cardiovascular system as MAP = CO × TPR. MAP, microtubule-associated protein; CO, carbon monoxide

totipotency ability of a cell to divide and produce all the differentiated cells in an organism

toxoid inactivated toxin, used as vaccine against the toxin

trachea main airway of the lung through which respiratory air is brought into the lungs; it is held open by up to 20 C-shaped cartilage rings and prevents airway collapse during forced expiration; commonly known as windpipe

tractus solitarius brainstem structure that carries and receives visceral sensation and taste from the facial (VII), glossopharyngeal (IX), and vagus (X) cranial nerves

transairway pressure pressure difference across the airways (airway pressure–pleural pressure)

transcellular fluid specialized extracellular fluid that is separated from the blood plasma not only by a capillary endothelium but by a continuous layer of epithelial cells. It includes aqueous humor, cerebrospinal fluid, digestive secretions, sweat, synovial fluid, renal tubular fluid, and bladder urine

transcellular transport transport of molecules through an epithelial cell, generally from the apical to basolateral side

transcobalamin protein to which vitamin B12 binds and by which it is transported in the portal blood

transducer any device that changes one form of energy (e.g., from the environment) to a signal for further signal processing (e.g., by the central nervous system)

transducin heterotrimeric G protein naturally expressed in vertebrate retina rods and cones by activation of the effector cGMP phosphodiesterase, which degrades cGMP to 5′GMP

transferrin molecule that functions in the plasma transport of iron and in the maintenance of circulating iron level homeostasis. Plasma transferrin levels are inversely proportional to the iron load of the body

transferrin saturation ratio of iron serum levels and total iron-binding capacity

transient outward K+ channels voltage-gated myocardial cell membrane channels that carry outward, hyperpolarizing K+ current shortly after the initiation of a myocardial cell action potential. They are responsible for phase 1 of the action potential

transient receptor potential (TRP) channels family of loosely related ion channels that are relatively nonselectively permeable to cations, including sodium, calcium, and magnesium

transit time time required for red blood cells to move through alveolar capillaries; under normal resting conditions, the transit time is 0.75 seconds

transmigration see diapedesis

transmitter-specific transporter integral membrane proteins that remove neurotransmitter from the synaptic cleft by high-affinity reuptake into the presynaptic terminal or perisynaptic astrocytes (in the central nervous system)

transmural pressure literally transmural or "across the wall"; the pressure difference between the inside and outside of a hollow structure in the body

transneuronal transport transport of trophic (or other) substances from one cell to another in either the retrograde or anterograde direction

transpulmonary pressure pressure difference across the lung (i.e., alveolar pressure–pleural pressure)

transthyretin binds thyroxine and triiodothyronine in the blood

transverse tubules (T tubules) membrane-bound invaginations of the striated muscle surface membrane that conduct surface electrical activity inward as part of the excitation–contraction coupling process

triacylglycerols see triglycerides

triad structure in skeletal muscles, formed by a transverse (T) tubule surrounded by sarcoplasmic reticulum (including two terminal cisternae)

tricuspid valve a thin, flexible, trileaflet structure that separates the right atrium from the right ventricle. It opens into the right ventricle during diastole but closes off the right atrium when the right ventricle contracts

triglycerides most abundant dietary lipids, consisting of a glycerol backbone esterified in the three positions with fatty acids (more than 90% of the daily dietary lipid intake is in the form of triglycerides); also known as triacylglycerols

triiodothyronine (T3) peptide hormone produced by the thyroid gland that regulates growth, development, and metabolism

trituration process of crushing and grinding ingested food by the gastric pump

trophic hormones hormones produced and secreted by the anterior pituitary that target endocrine glands

trophoblast single outer layer of the blastocyst consisting of extraembryonic ectodermal cells

tropomyosin fibrous protein constituent molecule of the actin filaments that participates in regulating striated muscle contraction

troponin protein complex in striated muscle thin filaments that binds calcium and, acting through tropomyosin, allows interaction between actin and myosin

Trousseau sign indication of latent tetany in which carpal spasm occurs when the upper arm is compressed, as by a tourniquet

trypsin one of three endopeptidases present in pancreatic juice that convert proenzymes to active enzymes. Trypsin splits off basic amino acids from the carboxyl terminal of a protein

tuberoinfundibular system neurons located within the hypothalamus, with cell bodies in the arcuate nucleus and periventricular nuclei and terminals in the median eminence on the ventral surface of the

hypothalamus; responsible for the secretion of hypothalamic-releasing factors into a portal system that carries them through the pituitary stalk into the anterior pituitary lobe

tubular reabsorption transport of materials by the kidney tubule epithelium out of the tubular urine

tubular secretion transport of materials by the kidney tubule epithelium into the tubular urine

tubular transport maximum (Tm) maximum rate at which a particular substance is reabsorbed (e.g., glucose) or secreted (e.g., p-aminohippurate) by the kidney tubules

tubuloglomerular feedback mechanism blood flow control mechanism operating in the kidneys that limits changes in glomerular filtration rate

tubulovesicular membranes extensive smooth endoplasmic reticulum membrane system in the stomach

tumor swelling associated with acute inflammation

tumor necrosis factor (TNF) important cytokine (TNF-α, cachexin, or cachectin) involved in systemic inflammation and the acute-phase response; released by white blood cells, endothelium, and several other tissues in the course of damage, for example, by infection. Its release stimulates fever

tumor-specific antigens molecules present only on tumor cell surfaces to be recognized by cytotoxic T cells or B cells

turbulence chaotic random motion of particles in a flow stream. It results when the kinetic component of flow exceeds the viscous forces holding fluid elements together. In the cardiovascular system, turbulence dissipates more pressure energy than does laminar flow of similar quantitative magnitude

turbulent flow random movement of fluid in a tube (airway or blood vessel)

Turner syndrome congenital abnormality caused by a nondisjunction of one of the X chromosomes, resulting in a 45 X0 chromosomal karyotype

T wave represents repolarization of the ventricles in electrocardiography

twitch single brief contraction of a muscle as the result of a single action potential

two-cell, two-gonadotropin hypothesis steroidogenesis completed by cooperation between granulosa and theca cells

type I collagen type of protein chemical substance that is the main support of skin, tendon, bone, cartilage, and connective tissue

type 1 diabetes (T1D) autoimmune disorder in which the body's immune system attacks the β cells in the islets of Langerhans, resulting in a decreased or complete absence of the production and secretion of insulin; formerly known as childhood or juvenile diabetes or insulin-dependent diabetes

type 1A diabetes subclass of type 1 diabetes characterized as immune-mediated

type 1B diabetes subclass of type 1 diabetes characterized as non–immune-mediated

type 2 diabetes (T2D) metabolic disorder characterized by insulin resistance, relative insulin deficiency, and hyperglycemia; formerly known as diabetes mellitus type II, non–insulin-dependent diabetes (NIDDM), obesity-related diabetes, or adult-onset diabetes

type II pneumocytes granular, cuboidal cells typically found at the alveolar–septal junction that cover a much smaller surface area than type I cells (<5%) but are much more numerous; they are responsible for the production and secretion of surfactant (the majority of which are dipalmitoylphosphatidylcholine), a

group of phospholipids that reduce the alveolar surface tension and are stored in type II pneumocytes in lamellar bodies (specialized vesicles unique to type II cells)

tyrosine hydroxylase rate-limiting enzyme in the synthesis of catecholamines that catalyzes the conversion of l-tyrosine to l-3,4-dihydroxyphenylalanine

tyrosine kinase receptors family of receptors each having a tyrosine kinase domain (which phosphorylates proteins on tyrosine residues), a hormone-binding domain, and a carboxyl terminal segment with multiple tyrosines for autophosphorylation

UDP glucose uridine diphosphate glucose; a molecule involved in the biosynthesis of glycoproteins or glycolipids

ultrafiltrate filtrate formed by ultrafiltration

ultrafiltration filtration through a selectively permeable membrane that allows passage of small molecules but restricts the passage of large molecules, such as proteins

umami one of five main taste sensations referring to that which is “meaty” or savory

umbilical arteries fetal blood vessels that carry blood containing wastes and CO2 from the fetus into the fetal placenta

umbilical cord cord that connects the fetal circulation to the placenta

umbilical veins fetal blood vessels that pick up oxygen from the placental sinus and transport oxygenated blood to the fetus

uncoupling protein-1 mitochondrial protein that uncouples the membrane proton gradient from adenosine triphosphate synthesis

unipolar neuronal cells with only one process emanating from the soma

unitary-type smooth muscle predominant kind of smooth muscle in the gastrointestinal tract; it contracts spontaneously, contracts in response to stretch, and does not have structured neuromuscular junctions; contrast to multiunit-type smooth muscle

universal donor person with type O blood who can, therefore, donate to people with all blood groups

universal recipient person with AB blood group who can, therefore, receive blood from someone with any other blood type

unloading phase steep portion of the oxygen equilibrium curve that reflects the unloading of oxygen from hemoglobin

unsaturated iron–binding capacity (UIBC) calculated amount of transferrin not occupied by iron; UIBC equals total iron-binding capacity minus iron

unstirred water layer layer of poorly stirred fluid that coats the surface of the intestinal villi and that reduces the absorption of lipid digestion products

up-regulation increase in the number of receptors on the surface of target cells, making the cells more sensitive to hormones or other agents

ureagenesis formation of urea, especially the metabolism of amino acids to urea

ureter tube that conducts the urine from the renal pelvis to the bladder; it consists of an abdominal part and a pelvic part, is lined with transitional epithelium surrounded by smooth muscle (both circular and

longitudinal), and is covered externally by a tunica adventitia

urethra tube that carries urine from the urinary bladder to the outside of the body

urine titratable acid amount of acid excreted in the urine combined with buffers such as phosphate, determined by measuring the milliequivalents of strong base (NaOH) needed

urodilatin peptide produced by the kidneys that increases renal sodium excretion

uroguanylin polypeptide hormone produced by the small intestine that increases renal sodium excretion

uterus pear-shaped organ located in the abdomen of a female; the site of pregnancy

Vmax hypothetical maximum velocity of shortening of an isotonic contraction of muscle; also the theoretical velocity obtained by muscle shortening with zero afterload; this value is essentially constant in a given skeletal muscle but can be altered by physiological and pathophysiological influences in cardiac and smooth muscle

vaccine weakened or killed pathogen or piece of pathogen, administered to stimulate immunity

vagina tube extending from the uterine cervix to the vestibule

vagovagal reflexes pertaining to a process that uses both afferent and efferent vagal fibers: during the gastric phase of acid secretion, distention of the stomach stimulates mechanoreceptors, which stimulate the parietal cells directly through short local (enteric) reflexes and long vagovagal reflexes

varicosities specialized regions along postganglionic axons from which neurotransmitter release occurs

vascular capacitance measure of the volume contained in a segment of blood vessel or vessels per unit of transmural pressure, measured in mL/mm Hg

vascular endothelial growth factor (VEGF) factor responsible for the growth of blood vessels (angiogenesis) at many sites in the body

vascular function curve relationship depicting how central venous pressure varies as a function of cardiac output

vascular tree branching of the pulmonary circulation, which parallels airway branching

vasoactive intestinal peptide (VIP) putative inhibitory neurotransmitter released by enteric musculomotor neurons to gastrointestinal muscles; also a putative excitatory neurotransmitter that is a potent stimulator of intestinal secretion by parasympathetic stimulation to increase blood flow to the salivary glands

vasovagal syncope loss of consciousness from profound fear or emotional stress; accompanying cardiovascular events include marked parasympathetic-induced bradycardia and depressed resting sympathetic vasoconstrictor tone, which cause a dramatic drop in heart rate, cardiac output, systemic vascular resistance, and, thus, mean arterial pressure

vein any blood vessel that carries blood toward the heart. It is composed of three layers: an outermost elastic adventitia, a middle zone composed of circular layers of smooth muscle, and a single-cell lining of epithelial cells called the endothelium. Veins are thinner than arteries of similar outer diameter. They do not have structural rigidity and collapse without any positive transmural pressure in them

venipuncture process of obtaining intravenous access for the purpose of intravenous therapy or obtaining a sample of venous blood

venous admixture mixing of venous blood with oxygenated blood

venous–arteriolar response increase in arteriolar constriction in response to an increase in postcapillary venule pressure. It is a mechanism that helps prevent capillary hydrostatic pressure from becoming too high

ventilation movement of air between the mouth and alveoli

ventilation/perfusion ratio ratio of alveolar ventilation to simultaneous alveolar–capillary blood flow in any part of the lung; because both ventilation and perfusion are expressed per unit volume of tissue and per unit time, which cancel, the units become liters of gas per liter of blood

ventral respiratory group (VRG) group of neuronal cells located in the ventral portion of the medulla that is active during inspiration and expiration

ventricular fibrillation random, chaotic electrical activation of all the ventricular muscle cells in which the heart no longer can effectively contract. It results in death of the person if not abolished by some intervention

ventricular tachycardia abnormally high heart rate resulting from an ectopic foci in any area of the ventricles

ventrolateral medullary area region of the medulla where neurons controlling cardiovascular and respiratory functions are located

ventromedial nuclei hypothalamic nuclei, which synthesize growth hormone–releasing hormone

venules small veins ~10 to 1,000 μm wide that drain capillary networks and pass blood to larger veins in the circulation. They are also involved with the control of intracapillary hydrostatic pressure and have some transport function between the bloodstream and the extracellular fluid surrounding all tissues, especially in the presence of histamine

vertigo type of dizziness in which there is a feeling of motion even while stationary due to a dysfunction of the vestibular system in the inner ear; often associated with nausea and vomiting as well as difficulties standing or walking

very-low-density lipoproteins (VLDLs) one of two major classes of lipoproteins produced by the intestine; triglyceride-rich lipoproteins with densities <1.006 g/mL, made continuously by the small intestine during both fasting and feeding

vesicles small membrane-delimited spheres in nerve terminals filled with neurotransmitters whose contents are released into the synaptic cleft on stimulation of the nerve

vestibular apparatus sensory structures of the middle ear that are responsible for sensing body position and acceleration

vestibular nuclear complex groups of neurons in the pons and medulla that receive afferent axons from the vestibular portion of the inner ear

vestibulocerebellum medial portion of the cerebellum that is active in control of eye motions and equilibrium

vestibuloocular reflex (VOR) reflex eye movement that stabilizes images on the retina during head movement by producing an eye movement in the direction opposite to head movement, thus preserving the image on the center of the visual field

vestibulospinal tract axon pathway from the lateral vestibular nucleus to the spinal cord, which influences postural reflexes in the spinal cord

villi finger-like projections of the mucosal surface that increase the surface area of the small intestine by about 30 times

virilization masculinizing effects of excessive adrenal androgen secretion on females

visceral hyperalgesia gut hypersensitivity; the appreciation, or exaggeration, of gut symptoms with stimuli (such as balloon distention of the gut) that would ordinarily not be noticed or considered noxious

visceral pain sensation of pain arising from visceral parts (i.e., internal organs) of the body; often perceived as arising in somatic structures

viscoelastic materials substances whose mechanical reaction to applied forces is time dependent

viscosity measure of the blood property that offers resistance to flow

vital capacity (VC) maximum volume of air that can be exhaled; the sum of expiratory reserve volume, tidal volume, and inspiratory reserve volume (note that this value is the same as forced vital capacity)

vitamin A lipid-soluble vitamin important in vision and in the normal growth of the skin

vitamin B1 (thiamine) water-soluble vitamin that plays an important role in carbohydrate metabolism; absorbed by the jejunum passively and by an active, carrier-mediated process

vitamin B2 (riboflavin) water-soluble vitamin that plays an important role in metabolism. It is absorbed by a specific, saturable, active transport system located in the proximal small intestine

vitamin B6 (pyridoxine) water-soluble vitamin involved in amino acid and carbohydrate metabolism; absorbed throughout the small intestine by simple diffusion

vitamin B12 (cobalamin) water-soluble, cobalt-containing vitamin that plays an important role in the production of red blood cells

vitamin C (ascorbic acid) water-soluble vitamin found in green vegetables and fruits that plays an important role in many oxidative processes by acting as a coenzyme or cofactor; absorbed mainly by active transport through the transporters in the ileum; uptake process is sodium dependent

vitamin D group of fat-soluble compounds collectively known as the calciferols that plays an important indirect role in the absorption of calcium by the gastrointestinal tract and is essential for normal development and the formation of bones and teeth; derived from the skin, which contains a rich source of 7-dehydrocholesterol that is rapidly converted to cholecalciferol when exposed to ultraviolet light and dietary vitamin D3; absorbed by the small intestine passively and incorporated into chylomicrons

vitamin D2 form of vitamin D generated by the irradiation of ergosterol; also known as ergocalciferol

vitamin D3 form of vitamin D normally manufactured in the skin, where ultraviolet light activates the compound 7-dehydrocholesterol

vitamin D–binding protein binding protein in plasma that transfers vitamin D3 during the metabolism of chylomicrons

vitamin E vitamin that is absorbed by the small intestine by passive diffusion and incorporated into chylomicrons and transported in the circulation associated with lipoproteins and erythrocytes and is a potent antioxidant that prevents lipid peroxidation

vitamin K vitamin derived from green vegetables in the diet or the gut flora and incorporated into chylomicrons, where it is rapidly taken up by the liver and secreted together with very-low-density lipoproteins; essential for the synthesis of various clotting factors by the liver

vitreous humor thick clear gel that fills the bulk of the eyeball; provides support for the shape of the eyeball and its retinal structures; also known as vitreous body

voltage-dependent anion channel (VDAC) mitochondrial channel for metabolite diffusion across the mitochondrial outer membrane

voltage-gated ion channels ion-selective pores in the membrane of excitable cells that open (or close) in response to a change in membrane potential

von Willebrand disease most common hereditary bleeding disorder; caused by deficiency of von Willebrand factor

von Willebrand factor a glycoprotein important for coagulation

V-type ATPase see ATPase

V wave venous pressure wave that gradually increases during systole as blood continues to return to the heart while the atrioventricular valves are closed

wall stress force exerted on the wall of a cylindrical structure, as modified by the thickness of the wall of the structure, that would have the tendency to rip the wall apart as a result of a positive transmural pressure. It is directly proportional to both the transmural pressure and the radius of the cylinder but inversely proportional to the wall thickness. Wall stress is less in thick-walled vessels than in thin-walled vessels of the same internal radius when exposed to the same transmural pressure. This principle is applied to blood vessels and other hollow organs, such as the heart and urinary bladder

water diuresis excretion of a large volume of dilute urine

wavelength spatial period of the wave—the distance over which the wave's shape repeats

weak acid acid with a low dissociation constant, which consequently is poorly ionized in solution

Wernicke area area at the junction of the temporal and parietal lobes of the brain involved in sensory perception of language, usually on the left hemisphere

white blood cell (WBC) cell delivered by the blood to sites of infection or tissue disruption, where it defends the body against infecting organisms and foreign agents in conjunction with antibodies and protein cofactors in blood; five main types are neutrophils, eosinophils, basophils, lymphocytes, and monocytes; also known as leukocyte

white blood cell count measures the concentration of leukocytes in blood as an indicator of the body's immunologic stress state

white matter portions of the CNS that histologically appear white due to myelinated processes

white ramus branch of a spinal nerve that carries preganglionic sympathetic axons from the spinal cord to the sympathetic ganglia

whole-gut transit time time required for transit from the mouth to the anus

working memory mechanism whereby new experiences are processed, drawing on skills such as language and mathematical ability, to integrate new inputs in light of previously acquired learning

Wright-Giemsa common dual stain for peripheral blood and bone marrow smears

xanthine oxidase enzyme that catalyzes xanthine to urate. During ischemia–perfusion injury, hypoxanthine builds up and, in the presence of oxygen hypoxanthine, is converted to xanthine. Xanthine oxidase neutralizes xanthine by converting it to urate

xenobiotics hydrophobic compounds foreign to the body, some of which are toxic, that are metabolized by the liver. Xenobiotics are converted into hydrophilic compounds that are then absorbed and excreted by the kidneys

xenograft transplantation in which animal tissue is used to replace human organs

yellow marrow bone marrow of long bones consisting of fat and primitive blood cells

yolk sac extraembryonic membrane that contains a slight amount of yolk

Z line dark structure that crosses the center of the I band in muscle; sometimes termed a Z disk to emphasize its three-dimensional nature

zinc finger small globular protein structures that can coordinate zinc ions with cysteine residues to help stabilize their folds; they can be classified into families and typically function as interaction molecules that bind DNA, RNA, proteins, or small molecules

zona fasciculata inner zone of the adrenal cortex, which produces the glucocorticoid hormones: cortisol and corticosterone

zona glomerulosa outer zone of the adrenal cortex, which produces aldosterone

zona pellucida acellular membrane between the oocyte and membrana granulosa of an ovarian follicle, which surrounds the ovulated egg prior to implantation

zona reaction modification of the zona pellucida that blocks polyspermy; enzymes released by cortical granules digest sperm receptor protein so that they can no longer bind sperm

zona reticularis inner zone of the adrenal cortex, which produces the glucocorticoid hormones: cortisol and corticosterone

zones various regions of the lung (e.g., apex, base) through which blood flows, with respect to pulmonary arterial pressure, pulmonary venous pressure, and alveolar pressure

zygote fertilized egg

zymogen granules granules found in the apical region of acinar cells that store salivary amylase

median effective dose (ED_{50})
median eminence of the hypothalamus
mediastinal membrane
medical pharmacotherapy
medium spiny neuron
medulla
    adrenal
    renal
        inner
        outer
medulla oblongata
    in breathing rhythm
    in respiratory centers
    ventrolateral
medullary pyramid
medullary reticulospinal tract
medullary tissue
megakaryocyte
megaloblast
megaloblastic anemia

meiosis
Meissner corpuscles
Meissner plexus
melanocortin system
melatonin
membrane attack complex (MAC)
membrane-associated dense bodies
membranous labyrinth
memory
    declarative
    long-term
    nondeclarative
    short-term
memory B cells
memory cells, in immune system
memory loss
menaquinones
menarche
menopause
    hormone replacement therapy
    osteoporosis and
    selective estrogen receptor modulators in
menses
menstrual cycle
    estradiol and progesterone
        cervical mucus changes
        ductal system and signal ovulation preparation
        menstrual phase
        proliferative phase
        secretory phase
    menopause,
    ovarian cycle *see* (ovarian cycle)
    puberty
menstrual phase
menstruation
Merkel disks
mesenteric ganglia
    inferior
    superior
mesenteric receptors, in gastrointestinal motility control
mesocortical pathway
mesoderm
mesolimbic pathway

mesolimbic/mesocortical system
mesonephric (wolffian) ducts
metabolic acidosis
anion gap in
diabetes mellitus and
metabolic alkalosis
compensation in
defined
vomiting in
metabolic bone diseases
metabolic clearance rate (MCR)
metabolic condition, electrocardiogram (ECG) in
metabolic energy
metabolic rate
in hypothermia
in response cold
metabolic syndrome
metabolism
of cholesterol
by liver
drugs and xenobiotics
of lipoprotiens
of xenobiotics
methemoglobin (metHb)
methylene blue
MHC class I molecules
MHC class II molecules
micellar emulsification
micelles
microbial infection
microcirculation
arterial microvasculature
capillaries in
anatomic considerations
defined
endothelial vesicles in
pores in
porosity of
defined
diabetes mellitus
lymphatic *see* (lymphatic system)
overview
regulation of

autoregulation
endothelium cells
myogenic
organ blood flow
reactive hyperemia
sympathetic nervous system (SNS)
solute exchange in
capillary filtration coefficient
capillary pressure
colloid osmotic pressure
diffusion
diffusion-limited transport
extraction ratio
filtration
flow-limited transport
hydrostatic pressure
pathological conditions related to
permeability surface area coefficient
Starling-Landis equation
structure and function
vascular resistance and
venules in
microcytes
microfilaments
microglia
microtubules
microvascular disease
microvilli
micturition
defined
urinary incontinence
urine elimination
midbrain extrapyramidal area
migrating motor complex (MMC)
activity front
phase of
milk ejection
milliequivalent
mineral absorption
mineralocorticoid escape
mineralocorticoids. *see also* aldosterone
action of various
excess of

minerals, absorption
minute ventilation
    alveolar ventilation
    dead space volume
    expired
miosis
mitochondria
mitochondrial permeability transition pore
mitochondrial voltage-dependent anion channel (VDAC)
mitogen-activated protein kinase (MAP kinase)
mitogenic agent
mitogens
mitosis
mitral and tufted cells
mitral valve
mitral valve prolapse
mixed acid–base disturbances
mixed contractions
mixed micelles
M-mode echocardiography
monoamine oxidase (MAO)
monoamine oxidase inhibitors (MAOIs)
monoaminergic neurons
monoamines
monoblasts
monochromatic vision
monocyte/macrophage
monocyte-macrophage system, fixed
monocytes
monoiodotyrosine (MIT)
monokines
mononuclear leukocytes
mood
mood disorders
morula
mossy fibers
motion sickness
motivational systems
motor control
    basal ganglia
    brainstem in
    cerebellum
    cerebral cortex role in

Golgi tendon organs in
motor cortex, primary
motor neurons
alpha
gamma
muscle fibers in
muscle spindles in
rubrospinal tract
sensory receptors in
spinal cord in
anatomical consideration
reflexes
motor endplate. *see also* neuromuscular junctions
motor neurons
alpha
gamma
motor reflex
motor unit. *see also* motor neurons
motor unit summation
mucins
mucous cells
mucous gel layer
mucous neck cells
multidrug resistance (MDR)
multiple myeloma
multiple sclerosis
multipolar cells
multipotent stem cells
mural granulosa cells
muramidase
muscarinic receptors
muscle(s)
blood flow during exercise
skeletal *see* (skeletal muscle)
smooth *see* (smooth muscle)
muscle chemoreflex activity
muscle fatigue, defined
muscle fibers
muscle function
muscle plasticity
muscle spindles
muscularis externa
musculomotor neurons

musculoskeletal grafts
myasthenia gravis
mydriasis
myelin sheath
myeloid leukocytes
myenteric plexus
myocardial infarction
myocardial ischemia
    arrhythmias
    defined
    reduced refractory period in
myocarditis
myoclonus
myoepithelial cells
myofibrils
myogenic contraction
myogenic mechanism
myogenic regulation
myoglobin
myokines
myometrium
myoneural junction
myopia
myosin
myosin light-chain kinase (MLCK)
myosin light-chain phosphatase (MLCP)
myosin-linked regulation
myotatic (muscle stretch) reflex
myxedema

N

NADPH oxidase (NOX)
NADPH-cytochrome P-450 reductase
Na^+/K^+-ATPase
narcolepsy
natriuresis
natural immunity
natural killer (NK) cells
necrosis
negative cooperativity
negative feedback
negative selection
nephritis

nephrolithiasis
nephron, acidification
nephrons
nephrotic syndrome
Nernst equation
Nernst equilibrium potential
nerve growth factors
nerve transmission
nervous system
    action potentials
        conduction velocity
        excitatory and inhibitory postsynaptic potentials
        phases
        resting membrane potential
        sodium and potassium channels
        unidirectional propagation
    blood–brain barrier
    central nervous system
    neuronal transport
    peripheral nervous system
    primary cell types
    synaptic transmission
        autoreceptors
        multistep process
        neurohormones
        neurons communication
        presynaptic membrane
        synapsins
neural mediators
neural network layer
neural reflexes
neuroendocrine
neuroendocrine system
neuroendoimmunology
neurofilaments
neurogastroenterology
neurogastroenterology and motility
    enteric nervous system *see* (enteric nervous system)
    gastrointestinal tract
neurogenic secretory diarrhea
neurohormones
neurohypophysis
neuroleptic drugs

neurological disorders
neuromuscular blocking agents
neuromuscular junctions (NMJ)
neuromuscular toxins
neurons
    morphology and function
neuropeptide Y (NPY)
neuropeptides
neurophysin
neurosecretory cells
neurotransmitters
    acetylcholine
    arachidonic acid
    autonomic nervous system
    cannabinoids
    dopamine
    eicosanoids
    endocannabinoids
    epinephrine
    excitatory and inhibitory effect
    G protein–coupled receptors
    GABA
    glutamate
    histamine
    ligand-gated
    monoamines
    neuropeptides
    norepinephrine (NE)
    opioids
    purines
    serotonin
neutralization
neutrophils
niacin
nicotinamide adenine dinucleotide phosphate (NADPH)
nicotinic ACh receptors
nicotinic receptors
nigrostriatal system
nipple
nitric oxide (NO)
nitric oxide synthase (NOS)
nitroglycerin
N-methyl-d-aspartate (NMDA) receptor

NO synthase
nociceptors
nocturnal rhythms
nodes of Ranvier
nodose ganglia
nonadrenergic noncholinergic (NANC) fibers
nondeclarative memory
nonessential amino acids
nongated channels
nonphagocytic leukocytes
non-rapid eye movement (NREM) sleep
nonspecific immunity
nonsteroidal anti-inflammatory drugs
nonvital transplantations
nonvolatile acid-base homeostasis
noradrenaline
noradrenergic neurons
norepinephrine (NE)
    autonomic postganglionic fibers
    sympathetic postganglionic neurons
    synthesis and degradation
norepinephrine transporter (NET)
normoblast
normochromic cells
nuclear bag fibers
nuclear chain fibers
nuclear pore complex
nucleus accumbens
nucleus ambiguus
nucleus tractus solitarius
null cells
nystagmus

O

obesity
occipital lobe
olfactory glomeruli
olfactory system
    mitral cells
    olfactory bulb
    sensory cells
    sneezing
oligodendrocytes

oncogenes
oncotic pressure
oocytes
oogonia
oolemma
ooplasm
open-angle glaucoma
opioid use
opioids
opsonin
opsonization
optic disc
optic nerve
optic radiations
optimum length (L_o)
oral contraceptives
oral contraceptives steroids
oral glucose tolerance test (OGTT)
orexigenic
orexin
organ of Corti
organ systems
organic anion transporting polypeptides (OATPs)
organification
organophosphate poisoning
organophosphates
orthophosphate
osmolality
osmoreceptor cells
osmoregulation
osmotic diuretics
osmotic pressure
osteoarthritis
osteoblasts
osteoclasts
osteocytes
osteogenesis imperfecta
osteoid
osteomalacia
osteoporosis
oval window
ovarian cycle
    corpus luteum

dominant follicle
estradiol synthesis
folliculogenesis
graafian follicle
hormonal regulation of
follicular phase
luteal phase
ovulatory phase
LH surge
follicle maturation and rupture
periovulatory period
oogonia
overshoot phase
oviduct
ovulation
ovulatory phase
oxidative burst
oxidative phosphorylation
oxygen
demands, small intestine
normal range
partial pressure measurement
at sea level
uptake
oxygen carrying capacity (OCC)
oxygen content
oxygen debt
oxygen diffusion gradient
oxygen saturation
oxygen uptake
oxygen-carrying capacity
oxyhemoglobin (HbO_2)
oxyhemoglobin-equilibrium curve
oxyntic glands
oxytocin

P

P wave
pacemaker
for antral pump of stomach
in gastrointestinal motility
pacinian corpuscle
Paget disease

pain
    cold
    deep
    delayed
    initial
    referred
    superficial
    visceral
pain sensory receptor
pampiniform plexus
pancreatic amylase
pancreatic deficiency
pancreatic lipase
pancreatic peptide
    F cell production of
    secreation of
pancreatic proteases
Paneth cells
panhypopituitarism
para-aminohippurate (PAH) clearance
paracrine mediators
paracrine signaling
paradigm shift
paradoxical cold
paradoxical sleep
parafollicular cells
parahippocampal gyrus
parallel fibers
paralytic ileus
paramesonephric (müllerian) ducts
parasympathetic activity
parasympathetic nervous system (PNS)
    autonomic integration
    cholinergic receptors
    cholinergic system
    ganglia
    homeostatic functions
    preganglionic neurons
    salivary secretion of
parathyroid hormone (PTH)
    in calcium regulation
    in phosphate balance
paraventricular nuclei

paravermal zone
parietal (oxyntic) cells
parietal lobe
parietal-temporal-occipital association cortex
Parkinson’s disease (PD)
    basal ganglia in
    deep brain stimulation
    stereotactic neurosurgery
parotid glands, anatomic considerations
pars distalis
pars intermedia
pars reticulata (SNr)
pars tuberalis
partial pressure
    of arterial carbon dioxide
    oxygen
        of gas in liquid
        measurement of
        normal range
        in respiratory gas exchange
        at sea level
    peripheral chemoreceptors
    in respiratory gas exchange
partial pressures
partial seizures
partition coefficient
parturition
parvicellular neurons
passive conduction
passive force
passive immunity
passive length
passive transport
patches
pathogens
    defined
    transmission of
peak expiratory flow, during forced expiration,
pedunculopontine nucleus
pellagra
pendrin
penile erection
pepsin

pepsinogen
peptic ulcers
peptidases
peptide hormones
peptides
    absorption of
    pancreatic
    in protein digestion
    in regulation of insulin
perception
perforin
perfusion pressure
perfusion-limited gas uptake
pericellular space, hepatic
perilymph
peripheral lymphoid organs
peripheral nervous system (PNS)
peripheral neuropathy
peripheral proteins
perisinusoidal space
perivitelline space
permeability coefficient (P)
permeability surface area coefficient
pernicious anemia
petit mal seizures
pH
    buffer
    cerebrospinal fluid in ventilation
    definition
    of saliva
phagocytic leukocytes
phagocytosis
phagosome
pharmacomechanical coupling
phases of digestion
    gastric secretions
phasic receptors
pheochromocytoma
phorbol esters
phosphate
    absorption in small intestine
    in bone, continuous flux
    distribution in bone cells, in healthy adult

inorganic constituents
kidneys, phosphaturia
pH buffering
plasma
regulations in GI tract, kidneys and bone
phosphate buffer, acid-base homeostasis
phosphatidylinositol 4,5-bisphosphate (PIP2)
phosphaturia
phosphodiesterases (PDEs)
phosphoenolpyruvate carboxykinase
phosphoenolpyruvate carboxylase
phosphofructokinase
phospholamban
phospholipase A_2
phospholipase C (PLC)
phospholipids
phosphorus, daily flux of
phosphorus homeostasis
phosphorylation
phosphorylation, oxidative
in skeletal muscle contraction
in smooth muscle contraction
photons
photopic (daytime) vision
photoreceptors
phylloquinones
physiologic regulation
physiology
physostigmine (eserine)
pigment epithelium
pill rolling
piloerection
pineal gland
pinna
pinocytosis
pitch discrimination
pituitary dwarfism
pituitary gland
adenohypophysis
anatomic considerations
anterior hormones
blood supply to
disorders of

congenital adrenal hyperplasia
tumors of
neurohypophysis
posterior hormones
arginine vasopressin
hypothalamic-releasing hormones
oxytocin
pituitary resistance to thyroid hormone
pituitary stalk
pituitary tumors
place theory
placenta
circulation of
development of
vasculature of
placental villus
placing reaction
plasma
electrolyte composition of,
as extracellular fluid (ECF)
fresh frozen
proteins in *see* (plasma proteins)
plasma carbohydrate
plasma cells
plasma lipids
plasma membrane
fluid mosaic model of
memebrane transport
structure
lipid bilayer
lipids
proteins
plasma proteins
in hormone transport
synthesized by liver
plasma volume
in circulatory shock
effects of sweating on,
in heat acclimatization
plasma water
electrolyte composition of,
plasma-derived mediators
plasmapheresis

plasmin
plasminogen
plasminogen activator
plateau region, of action potential
platelet count (Plt)
platelet formation
platelet-derived growth factor (PDGF)
platelets
plegia
pleural pressure
    effect on pulmonary vascular resistance
    in forced expiration
    pneumothorax
pleural space
pneumothorax
podocytes
poikilocytes
poikilotherms, defined
Poiseuille’s law
polyclonal antibody
polycyclic aromatic hydrocarbons
polycystic kidney disease
polycystic ovarian syndrome
polycythemia
polydipsia
polymorphonuclear leukocytes (PMNs)
polyuria
pons, in respiratory centers
pontine respiratory group
pontine reticulospinal tract
pores
porphyrin
portal hypertension
portal vein
positive feedback
positive selection
postcapillary venules
posterior lobe
postganglionic axon
postganglionic fibers
postganglionic neuron
postganglionic sympathetic neurons
postmenopausal osteoporosis

postpartum and prepubertal periods
hypothalamic GnRH
newborn
physical signs, puberty
mammogenesis and lactogenesis
suckling reflex
postpartum thyroiditis
postrema
poststreptococcal glomerulonephritis
postsynaptic terminals
potassium
abnormal levels of
plasma, in pH regulation
acid-base balance
hyperkalemia
hypokalemia
metabolism
potassium channels
inwardly rectifying
outwardly rectifying
transient outward
potentiation
power stroke
PR interval
prechondrocytes
precocious puberty
precordial leads
prefrontal association cortex
prefrontal cortex
preganglionic fiber axon
preganglionic neuron
preganglionic sympathetic axon
preganglionic sympathetic neurons
pregnancy
hormones required for
endocrine function changes
estrogens
fetal endocrine system
hCG
hPL
insulin and insulin-like growth factors
maternal and fetoplacental interactions
parturition

progesterone
postpartum thyroiditis
pregnenolone
in testosterone production
pregranulosa cells
preload
premature atrial contractions (PACs)
premature ovarian insufficiency
premature ventricular contractions (PVCs)
premotor cortex
presbyopia
pressure
pressure diuresis
presynaptic terminal/bouton
pretectal nuclei
prevertebral sympathetic ganglia
primary active transport mechanism
primary adrenal insufficiency. *see also* Addison disease
primary follicular stage
primary (or central) lymphoid organs
primary motor cortex
primary oocytes
primary receptors
primary somatosensory cortex
primary spermatocytes
prime mover
primordial follicle
procedural memory
progesterone
progesterone block
progestin
proglucagon
prohormone
prohormone convertase 1
prohormone convertase 2
prolactin (PRL)
proliferative phase
proopiomelanocortin (POMC)
propagated potential
proprioceptors
propriospinal cells
prostaglandins
prostaglandins E_2

prostate cancer
protein buffer, acid–base homeostasis
protein C
protein inclusion bodies
protein kinase A
protein kinase A (PKA)
protein kinase C (PKC)
protein kinase G (PKG)
protein S deficiency
protein tyrosine phosphatase 1B (PTP1B)
proteins
    absorption
    aminoacids in
    complete
    digestion
    genetic disorders
    incomplete
    metabolism of
proteoglycans
prothrombin
prothrombin time (PT)
prothrombinase (factor X)
proton pumps
protooncogenes
proximal tubule
    cell model for transport
    sodium reabsorption
    Tm for PAH
    toxins and drugs
    water reabsorption
pseudoephedrine
pseudohermaphrodite
pseudohermaphroditism
pseudohyperkalemia
pseudohyponatremia
pseudoprecocious puberty
P-type ATPase
pubarche
puberty
    delayed
    factors
    hypothalamic–pituitary function defects
    precocious

pseudoprecocious
secondary sex characteristics
pulmonary arterial hypertension (PAH)
causes
definition
etiology
molecular mechanism
treatment
pulmonary arteries
pulmonary capillaries
anatomic considerations
fluid exchange
gravity effects on
pulmonary circulation
blood flow in lungs
gravity effects on
hemodynamic features
secondary functions
pulmonary edema
pulmonary embolism
pulmonary embolus
pulmonary hypertension, hypoxia-induced
pulmonary stretch receptors
pulmonary vascular resistance
pulmonary vasoconstriction
hypoxemia
hypoxia-induced
pulmonary wedge pressure
pulmonic valve
pulse pressure
arterial compliance and
defined
interactions of
stroke volume and
systemic vascular resistance and
pupil
pupillary constriction
pupillary light reflex
purinergic neuron
purines
Purkinje cells
Purkinje fibers
putamen

pyloric glands
pyloric sphincter (PS)
pyramidal tract
pyrogens, role in fever
pyruvate carboxylase
pyruvate dehydrogenase
pyruvate kinase
pyruvic acid or pyruvate

Q

Q_{10} effect
Q wave
QRS complex
QT interval
quantum, in synaptic transmission

R

R wave
radial bundles
radiation, in body heat exchange
radioimmunoassay (RIA)
radioreceptor assay
rapid adapting receptors
rapid ejection phase
rapid eye movement (REM)
rapid ventricular filling
ras family
Rathke pouch
reactive hyperemia
reactive oxygen species (ROS)
receptor(s)
    baroreceptors
    in cellular signalling
    chemoreceptors *see* (chemoreceptors)
    for hormones *see* (hormones)
    mechanoreceptors *see* (mechanoreceptors)
    photoreceptors *see* (photoreceptors)
    sensory *see* (sensory receptors)
    thermal
    thyroid hormone
receptor adaptation
receptor potential
receptor-mediated endocytosis
reciprocal inhibition

red blood cells (erythrocytes)
anemia and
destruction of
disorders of
formation of
hematocrit (Hct)
hemoglobin in
iron recycling
life span of
mean corpuscular hemoglobin (MCH)
mean corpuscular hemoglobin concentration (MCHC)
mean corpuscular volume (MCV)
morphology of
normal ranges for
in oxygen transport
structure and functions of
Red blood cells (RBCs)
red cell distribution width (RDW)
red nucleus
red-sensitive pigment
reduced ejection phase
reduced ventricular filling
reentry tachycardia
referred pain
reflection coefficient
reflective pain
reflex(es)
lung
irritant receptors
J receptors
mechanoreceptors
proprioceptors
pulmonary stretch receptors
neural
mechanoreceptors
proprioceptors
regional compliance
regional hypoventilation
regional hypoxia
regulatory light chain
regulatory volume decrease (RVD) mechanisms
regulatory volume increase (RVI) mechanisms
relative refractory period

relative WBC count
relaxin
releasing factors
releasing hormones
renal blood flow (RBF)
    autoregulation
    sympathetic nerve stimulation and hormones
renal clearance
    definition
    glucose reabsorption
    inulin clearance
    net tubular reabsorption
    para-aminohippurate clearance
renal compensation
    metabolic acidosis
    metabolic alkalosis
renal hypoxia
renal response, acid–base homeostasis
renin
renin-angiotensin-aldosterone system
repolarization
residual volume (RV)
resistance
resistance to thyroid hormone (RTH)
respiration
    cellular
    defined
    gas exchange
respiratory acidosis
respiratory acidosis/alkalosis
    altered levels of $PaCO_2$
    cell chemical buffering
    definition
    lungs and kidneys compensate
respiratory alkalosis
respiratory burst
respiratory compensation
    metabolic acidosis
    metabolic alkalosis
respiratory exchange ratio
respiratory quotient (RQ)
respiratory response, acid–base homeostasis
respiratory sinus arrhythmia

respiratory system compensation, metabolic alkalosis
rest-and-digest system
resting force
resting length
resting membrane potential
    cardiac
    electrochemical potential
    Goldman equation
    Nernst equation
    steady state
resting state
reticular formation
reticulocytes
reticuloendothelial system (RES)
reticulospinal tracts
retina
retinohypothalamic tract
retinoid X receptor (RXR)
retinol-binding protein (RBP)
retinopathy
retrograde transport
Reynolds number
rhesus factors (Rh)
rheumatoid arthritis (RA)
rhodopsin
RhoGTP/Rho kinase system
rhythmicity, of cardiac cells
rickets
right atrium
right axis deviation
right bundle branch block
right ventricle
right ventricular hypertrophy
rigor crossbridge
rigor mortis
rising phase
rod cell
rods and cones
rolling
rubrospinal tract
ryanodine receptor (RyR)

S

S cells

    action potential generation in
    adaptation in
    generator potential in
    hearing
    smell sense
    taste sense
    touch sense
sensory signals
sepsis
septal nuclei

septic shock
septicemia
serosa
serotonergic neurons
serotonin
serotonin transporter (SERT)
serous cells
Sertoli cells
    Leydig cells interactions with
    sperm cell development
    spermatogenesis in
serum
serum iron levels
serum protein electrophoresis
set point, in thermoregulation
    defined
    factors influencing
severe combined immunodeficiency (SCID)
sex
    chromosomal
    genetic
    gonadal
    secondary characteristics
        female
        male
    steroids
sex chromosome DSDs
sex hormone–binding globulin (SHBG)
sexual activity
    hypothalamus role in
    limbic system and
sexual arousal
sexual development
    chromosomal sex
    disorders
    fetal gonads
    genetic sex
    internal and external genitalia differentiation
    sexual differentiation
SH2 domain
shallow-water blackout
shear stress
shell conductance

shivering
during cold stress
control of
primary motor center
shock
circulatory
neurogenic
septic
spinal
short hypophyseal portal vessels
short receptors
shortness of breath
short-term memory
shunts
anatomic
vs. dead spaces
hypoxemia related to
right-to-left
sickle cell anemia
side-polar
sieving action, of stomach
sigmoid colon
signal cascade
signal transduction
G protein-coupled receptors (GPCRs)
ion channel-linked receptors
types of
tyrosine kinase receptors
visual
signaling. *see* cellular signaling
signaling cascade
simple acid–base disturbances

        shell conductance
        surface area and

peripheral factors influencing
in response cold
set point and
sympathetic nervous system in
temperature
in heat exchange
in thermoregulation
in thermoregulation
wettedness
sleep
apnea syndrome
arousal from
debt
disorders of
apnea
narcolepsy
non-rapid eye movement (NREM)
rapid eye movement (REM)
REM
slow-wave
sliding filament hypothesis
slit diaphragm
slow excitatory postsynaptic potentials, in gastrointestinal motility
slow inhibitory postsynaptic potentials, in gastrointestinal motility
“slow response” action potentials
slow-twitch fibers
slow-wave sleep (SWS)
small intestinal motility
activity front
digestive state
ENS
interdigestive state
migrating motor
MMC as “housekeeper” for
power propulsion
small intestine
absorption by
anatomic consideration
bile salt recycling in
blood flow
autoregulation
nutrients absorption
sympathetic nerve activity

venous-arteriolar response
during water absorption
digestion and absorption processes
vasculature of
smell sense
smooth muscle
adaptation of
of bladder
of blood vessels
contraction of
calcium
cell-to-cell transmission
control of
latch state
myosin filament proteins, phosphorylation
relaxation
crossbridge cycle
force–velocity curve
mechanical activity in
mechanisms
uterus
smooth muscle contraction
$Ca2^{+}$ and K^{+} channels
electrical slow waves
electrical syncytial properties of
electromechanical and pharmacomechanical coupling
endocrine influence
gap junctions of
SNARES
sodium
appetite
balance
dietary intake
diuretic drugs, effect of
in heat acclimatization
hormonal and neural factors
estrogens hormones, effect of
glomerular filtration rate, effect of
hydrostatic pressure, effect of
natriuretic hormones, effect of
osmotic diuretics, effect of
renin-angiotensin-aldosterone, effect of
sympathetic stimulation, effect of

kidneys excrete
sodium channel antagonists
sodium channel blockers, treatment of cardiac arrhythmias
sodium channels, voltage-gated
sodium glucose cotransporter inhibitors
sodium-dependent glucose transporter-1 (SGLT1)
sodium-iodide symporter (NIS)
solute transport
active
calcium pumps
defined
proton pumps
secondary
sodium-potassium pumps
endocytosis in
exocytosis in
passive
passive diffusion *see* (diffusion)
phagocytosis in
water movement and
cell volume regulation
osmotic pressure
water channels
solvent drag
soma
somatosensory system
nociceptors
skin receptors
thermoreceptors
somatostatin
somatotopic maps
somatotrophs
somatotropin release-inhibiting factor (SRIF)
action of,
structure of,
sound
pressure
transduction of
wavelength
sour receptors
sour taste
spasmodic dysphonia
spasmodic torticollis

spasticity
spatial summation
special senses
spermatogenesis
    meiosis
    mitosis
    phases of
    spermatozoon formation
    testosterone
spermatogenic cycle
spermatogonia
spermatozoa
spermiation
spermiogenesis
spherocytes
sphincter muscles
sphincter of Oddi
sphingolipids
sphygmomanometer
sphygmomanometry
spinal cord motor neuron pools
spinal shock
spinnbarkeit
spinocerebellar tracts
spinocerebellum
spiral arteries
spiral ganglia
spiral ligament
spirogram
spirometry, airflow
splanchnic nerves
splay
spleen, functions of
split brain
SRY (sex-determining region, Y chromosome)
standard curve
standard frontal lead system
stapedius muscle
Starling forces
Starling’s law of the heart
Starling-Landis equation
steady state
steatorrhea

stellate cells
stereocilia
steroid hormones
steroidogenesis
    ACTH action on
    genetic defects in CYP enzymes
steroidogenic acute regulatory protein (StAR)
steroids
    ACTH
    adrenocortical cell size
    cholesterol availability
    steroidogenic enzyme expression
stigma
stimuli
stomach
    anatomic considerations
    functions of
    mucosal lining of
    secretion of
stomatocytes
stress response
stress test
stretch reflex
stretch-activated calcium channels
stria terminalis
stria vascularis
striae
striated duct
striatum
stroke volume
    arterial pressure
    pulse pressure
stroma
stromal layer
strong acid, acid-base homeostasis
subcortical structures
sublingual glands, anatomic considerations
submandibular ganglion
submandibular glands, anatomic considerations
submucosa
substantia nigra
subthalamic nucleus
sudden infant death syndrome (SIDS)

sulcus
sulfonylureas
superior cervical ganglion
superior colliculus
superior hypophyseal arteries
superior mesenteric
superior parietal lobe
superior vena cava (SVC)
superoxide ion
supplementary motor area (SMA)
suprachiasmatic nucleus (SCN)
supraoptic nuclei
supraventricular tachycardia
surface tension
surfactant
sweat glands
    absence of
    apocrine
    eccrine
    evaporative heat loss from
sweating
    evaporation and
    in heat acclimatization
    set point and
    skin temperature and
    skin wettedness and
    in thermoregulation
    water loss and
sweet receptors
sympathetic (SNS)
sympathetic “chain,”
sympathetic nervous system (SNS)
    acetylcholine
    adrenergic receptors
    arousal, stress, and danger
    autonomic integration
    in circulation, skin
    epinephrine
    fight or flight response
    ganglia
    norepinephrine
    organization
    postganglionic axons

postganglionic fibers
preganglionic neurons
sympathetic tone
symport
synapse
synapsins
synaptic cleft
synaptic (S)-type neurons
syncytiotrophoblasts
syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
synergist
systemic circulation
arterial pressures in
blood volume
cardiac function in
systemic inflammatory response syndrome
systemic lupus erythematosus (SLE)
systemic reactions
systemic vascular resistance
arterial pressure and
interaction of
mean artrial pressure
systole, defined
systolic hypertension
systolic pressure

T

T cell–mediated immunity
antigen
clonal selection in
cluster of differentiation in
immunological synapse in
negative selection in
positive selection in
T cells
cytotoxic $CD8^+$
double negative
double positive
effector,
helper $CD4^+$
memory
specific antigen
T helper 1 cells

T helper 2 cells
T regulatory cells
T wave
tachycardia
    reentry
    sinus
    supraventricular
    ventricular
tachyphylaxis
tachypnea
target cells
taste buds
taste pores
taste sense
T-cell receptors (TCRs)
T1D
technetium-99 scans, of heart
tectorial membrane
telencephalic
telescoping system
temperature
    body *see* (body temperature)
    environmental
        during exercise
        in hypothermia
temperature sensory receptors
temporal lobe
temporal summation
tensions
tensor tympani muscle
terminal cisternae
terminal respiratory unit
tertiary follicular stage
testicular feminization
testis
    luteinizing hormone
    steroidogenesis, Leydig cells
testosterone
tetanic fusion frequency
tetanus
tetanus/twitch ratio
tetany, hypocalcemic
tetrahydrocortisol glucuronide

tetraiodoacetic acid
thalamus
theca externa
theca interna
theca lutein cells
thelarche
thermal receptors
thermic effect of food
thermodilution, in cardiac output measurement
thermogenesis
    nonshivering
    thyroid hormone regulation of
thermoneutrality
thermoreceptors
thermoregulation. *see also* body temperature
    behavioral
    body temperature
    central nervous system in
    central thermoregulatory controller
    clinical aspects of
    cold acclimatization
    cold response
    cold stress
    during exercise
        cardiovascular system effects
        compensatory responses
        vs. fever
        in heat
    during fever
    heat acclimatization
    heat stress
        disorders related to
        effects of
    hypothermia
    nonthermal effects on
    physiological
    set point in
        defined
        factors influencing
    skin temperature
    thermal stress
    thermoneutrality
theta waves

thiamine,
thick filaments
    of skeletal muscle
thin filaments
third-degree atrioventricular block
thirst center
thoracic cavity, components of
thoracolumbar region
threshold
threshold concentration
threshold potential
thrombi
thrombin
thrombocytes
thrombocytopenia
thrombomodulin
thrombopoietin
thromboxane A2
thrombus, pulmonary circulation in protection against
thymokine
thymokines
thymus, in immune system
thyroglobulin (Tg)
thyroid gland
    anatomic considerations
    blood supply
    changes during pregnancy
    disorders of
        euthyroid sick syndrome
        excess hormones
        hormone deficiency
        resistance to thyroid hormone
    follicles of
    functions of
    innervation of
    TSH in regulation of
thyroid gland innervation
thyroid hormone receptors
thyroid hormone response elements
thyroid hormones. *see also* thyroxine, triiodothyronine
    calcitonin
    dietary iodide and
    effects on body

in body growth
in bone development
in CNS development
in intermediary metabolism regulation
in metabolism regulation
follicles within
hermogenic action
metabolism of
secretion of
self-regulation of
synthesis of
thermogenic action of
TSH regulation of
thyroid hormones in regulation of
thyroid peroxidase (TPO)
thyroiditis
autoimmune
postpartum
thyroid-stimulating hormone (TSH)
actions of
composition
in regulation of thyroid gland
secretion
synthesis of
in thyroid hormone regulation
TRH regulation
thyrotoxicosis
thyrotrophs
thyrotropin-releasing hormone (TRH)
action of,
structure of,
thyroxine
thyroxine (T_4)
thyroxine, bile acids, and bilirubin
thyroxine, triiodothyronine
metabolism of
secretion of
synthesis of
TSH regulation of
thyroxine-binding globulin (TBG)
tidal volume
tight junctions
time constant

tissue growth factors
tissue plasminogen activator (TPA)
tissue thromboplastin (factor III)
titratable acid, acid-base homeostasis
toll-like receptors
tonic
tonic contraction
tonic phase
tonic-clonic seizures
tonicity
tonotopic map
tonotopic organization
tonus
total bile acid pool
total body water
total iron-binding capacity (TIBC)
total peripheral vascular resistance (TPR)
transairway pressure
transcellular fluids
transcellular transport
transcobalamin
transcriptional–translational feedback loops
transducer
transducin
transferrin
transferrin saturation
transient receptor potential (TRP)
transit time
transmigration
transmission
transmural pressure
transplantation
transpulmonary pressure
transthyretin
transverse tubules (T tubules)
traumatic brain injury (TBI)
triad
tricuspid valve
triglycerides
triiodothyronine (T_3)
    metabolism of
    secretion of
    synthesis of

TSH regulation of
trophoblast
tropomyosin
troponin
Trousseu sign
trypsin
tuberoinfundibular system
tuberomammillary nucleus
tubular reabsorption
collecting duct
diffusion and active transport
distal nephron
sodium
urea reabsorbtion
tubular secretion
potassium secretion
tubular transport maximum (Tm)
tubuloglomerular feedback mechanism
tumor necrosis factor (TNF)
tumor necrosis factor-α
tumor-promoting phorbol esters
tumor-specific antigens
turbulence
Turner syndrome
twitch
two-cell, two-gonadotropin hypothesis
two-neuron efferent pathway
tympanic cavity
tympanic membrane
type 1 and type 2 Diabetes
type 1 diabetes
type 2 diabetes (T2D)
type 1 diabetes mellitus
type 1A diabetes
type 1B diabetes
type I collagen
type II pneumocytes
type III hypersensitivity
type IV hypersensitivity
tyrosine
tyrosine hydroxylase
tyrosine, in thyroid hormone synthesis
tyrosine kinase receptors

U

UDP-glucose
ultrafiltrate
ultrafiltration, of plasma. *see* glomerular filtration
ultrasound, of heart
umami receptors
umbilical arteries
umbilical vein
uncoupling protein-1 (UCP-1)
underwater diving reflex
unipolar cells
unipolar chest leads
unitary-type smooth muscle
universal donor
unsaturated iron-binding capacity (UIBC)
unstirred water layer
uploading phase
upper esophageal sphincter (UES)
up-regulation
ureters
urethra
urinary bladder
urinary concentration mechanism
    adaptation to life
    arginine vasopressin
    countercurrent exchange
    countercurrent multiplication
    hyperosmolarity
    plasma AVP
    urea
urinary incontinence
urinary tract, composition in body fluids
    bladder
    eliminating urine
    micturition
    ureters
    urethra
urine formation
    excretion
    filtered load
    glomerular filtration
    glucose reabsorption

inulin clearance
plasma creatinine
renal blood flow (RBF)
tubular reabsorption
tubular secretion
tubular transport maximum
urobilinogen
urodilatin
uroguanylin
uterus
functions of
smooth muscle of
utricle

V

V wave
vaccinations
vagina
vagovagal reflexes
van’t Hoff equation
variable domain
variable region
varicosities
vascular capacitance
vascular distensibility
vascular function curve
vascular resistance, systemic
arterial pressure and
interaction of
mean artrial pressure
vascular smooth muscle
vasoactive intestinal peptide (VIP)
vasoconstriction
reflex
of skin blood flow
during exercise
in response to clod
in thermoregulation
vasodilation
vasovagal syncope
veins
compliance of
defined

factors that affect muscular contraction
structure of
velocity receptors
venipuncture
venous admixture
abnormal
venous pressure
in blood volume
central
interaction with cardiac output
venous–arteriolar response
ventilation. *see also* airflow; breathing
blood–brain barrier
breathing control
carbon dioxide
cerebrospinal fluid pH
metabolic demands
minute
peripheral chemoreceptors
phasic control
ventilation/perfusion
functional organization
hemodynamic features
ventilation/perfusion ratio
ventral amygdalofugal pathway
ventral respiratory group (VRG), in respiratory centers
ventral tegmental nucleus
ventricle
left
right
ventricular fibrillation
ventricular reentry tachycardia
ventricular tachycardia
ventromedial nuclei
ventromedial nucleus of the hypothalamus (VMH)
venules, defined
vermis
vertical semicircular canals
vertigo
very low-density lipoproteins (VLDLs)
characterisitcs
functions of
synthesis of

vesicle-associated transporter (VAT)
vesicular monoamine transporter (VMAT)
vestibular nerve
vestibular nuclear complex
vestibular system
    dysfunction
    equilibrioception
    otoliths
    semicircular canal
    vestibular apparatus
    vestibulo-ocular reflex (VOR)
vestibule
vestibulocerebellum
vestibulo-ocular reflex (VOR)
vestibulospinal tract
viral hepatitis
virilization
visceral smooth muscle
viscosity
visual cortex
visual signal transduction
visual system
    age-related macular degeneration
    depth perception
    eye layers
    focusing
    ganglion cell layer
    image crossover
    light
    light regulation
    neural network layer
    phototransduction
    visual reflexes
vitamin A (retinol)
vitamin B_1 (thiamine)
vitamin B_2 (riboflavin)
vitamin B_6 (pyridoxine)
vitamin B_{12} (cobalamin)
vitamin C (ascorbic acid)
vitamin D (cholecalciferol)
vitamin D_3 and 1,25-dihydroxycholecalciferol
vitamin D deficiency

vitamin D–binding protein
vitamin E
vitamin K
vitamins
absorption
fat-soluble
functions
water-soluble,
vitreous humor
voltage-gated ion channels
voltage-gated sodium channels, cardiac muscle
von Willebrand factor
V-type ATPases

W

wall stress
water
absorption
plasma
electrolyte composition of,
measurement of
water channels
water diuresis
wavelengths
weak acid, acid–base homeostasis
Wernicke area
wettedness, skin
wheezing
white blood cells (leukocytes)
agranular
basophils
eosinophils
granulocytes
lymphocytes
monocytes
mononuclear
neutrophils
normal ranges for
polymorphonuclear
types of
White blood cells (WBCs)
white matter
withdrawal reflex

working memory
Wright-Giemsa

X

X chromosome
xenobiotics
    defined
    metabolism
xenograft
46,XX DSD
46,XY DSD

Y

Y chromosome
Y4 receptor
yolk sac

Z

Z line
zinc
zinc finger
zona fasciculata
zona glomerulosa
zona pellucida
zona reaction
zona reticularis
zonule fibers
zygote
zymogen granules
