PREFACE

Human physiology is the science that explains how cells, tissues, and organs interact and function as an integrated system. The fifth edition of *Medical Physiology: Principles for Clinical Medicine* provides the latest information of how the body's different systems work to allow it to cope with changes in its internal and external environment. In so doing, it addresses how the body maintains optimal health and ensures survival. Although the emphasis of the fifth edition is on normal physiology, discussion of pathophysiology is also undertaken to show how altered functions are involved in disease processes. We have also created a new type of chapter essay for this edition that highlights how physiology integrates with others medical sciences, such as those involving pharmacology, biochemistry, genetics, and clinical diagnostics. This enrichment of basic physiology reinforces fundamental physiologic principles while also demonstrating how basic concepts in physiology connect to clinical medicine.

Our mission for this edition has developed out of our decades of teaching and mentoring medical students and the feedback we have received from them. We have created a multicomponent learning resource to address three questions that medical students have told us most concern them in their academic training; these are, *"What should I know?"*, *"How do I know that I know it well?"*, and *"How does what I learn fit into medicine?"* Each component of this textbook presents a learning opportunity with these questions in mind. We have attempted to maximize those opportunities to the fullest, while providing a clear, accurate, and up-to-date introduction to medical physiology.

AUDIENCE AND FUNCTION

This book, like the previous edition, is written for medical students but will be useful to dental, graduate nursing, and veterinary students as well. This is neither an encyclopedic textbook nor is it intended to be a condensed, descriptive review. Rather, the fifth edition focuses on the basic key physiologic principles necessary to understand human function and its fundamental context in clinical medicine. An additional important objective for the fifth edition is to demonstrate to the student that physiology is key to understanding other medical sciences such as pharmacology and pathophysiology. Although the book is written primarily with the student in mind, the fifth edition will also be a clear, concise, and helpful reference for physicians and other health care professionals.

All chapters were substantially revised, updated, and edited to achieve unity of voice and to be as concise and lucid as possible. In the fifth edition, each chapter is written to eliminate minutia and minimize the compilation of isolated facts. The chapters are written by medical school faculty members who are experts in their field and who have had decades of experience teaching physiology. They have focused their material on what is important for medical students to know. We have purposefully avoided discussion of research laboratory methods and/or historical material. Although such issues are important in other contexts, most medical students are too busy to be burdened by such information and prefer to focus on the essentials. We have also avoided topics that are as yet unsettled, while recognizing that new research constantly provides fresh insights and sometimes challenges old ideas.

CONTENT AND ORGANIZATION

This book begins with a discussion of basic physiological concepts, such as homeostasis and cell signaling, in Chapter 1. Chapter 2 covers the cell membrane, membrane transport, and the cell membrane potential. Most of the remaining chapters discuss the different organ systems: nervous (Chapters 3–7), muscle (Chapter 8), cardiovascular (Chapters 11–17), respiratory (Chapters 18–21), renal (Chapters 22–23), gastrointestinal (Chapters 25–26), endocrine (Chapters 30–35), and reproductive physiology (Chapters 36–38). Special chapters on the blood (Chapter 9) and immunology (Chapter 10) are included. The immunology chapter emphasizes physiological applications of immunology. Chapters on acid–base regulation (Chapter 24), temperature regulation (Chapter 28), and exercise (Chapter 29) discuss these complex, integrated functions. The order of presentation of topics follows that of most United States medical school courses in physiology. After the first two chapters, the other chapters may be read pretty much as stand-alone units, and some chapters may be skipped if the subjects are taught in other courses (e.g., neurobiology or immunology).

CHANGES FOR THE FIFTH EDITION

For the fifth edition, new expert contributing authors have been brought on board to update and rewrite major sections of the text and their associated ancillary learning tools. The entire Neurophysiology, Gastrointestinal, and Renal physiology sections of the text, as well as the chapters on Blood and Immunology, have been revised by these new authors.

In addition, in response to requests from students and instructors from around the globe, we have moved a portion of our formative assessment tools, formally only available online, into the print copy of the fifth edition of *Medical Physiology: Principles for Clinical Medicine*. Annotated, multiple choice review questions, in which explanations for the right and wrong answers are provided, as well as similar, annotated *Clinical Application Exercises* have been moved into the print copy of the new edition. The print copy, however, also retains links to additional online review questions, clinical application exercises, and advanced clinical problem-solving exercises.

Finally, we have replaced the Bench to Bedside essays found in the previous edition with new *Integrated Medical Sciences* essays. This new feature for the fifth edition is designed to highlight for the novice student the connections between physiology and the other basic medical sciences they are studying, such as pharmacology, pathology, and introductory clinical medicine.

KEY FEATURES AND LEARNING TOOLS

As with previous editions, the fifth edition includes numerous ancillary student-learning tools as complements to the basic text.

Active Learning Objectives

Medical students deal with huge amounts of information from their courses and an ever-expanding electronic medium. This often makes the task of determining what they really need to know difficult for them. Students benefit greatly if they have a set of clear objectives placed in front of them *before* trying to sift through their learning materials. Our active learning objectives direct the student to apply the concepts and processes contained in the chapter, rather than memorize facts. Basic descriptors or table of content-type lists at the start of a chapter do not tell students what they should really know. Simply naming items in a chapter that the student has not yet learned does not help students cope with what they should do with material once it is mastered. *Active Learning Objectives* at the start of each chapter in this text are purposely designed to indicate what a student should be able to do with chapter material once it has been mastered. Medical students need to have understanding of the workings of physiology to become competent problem solvers. Toward that end, our *active learning objectives* direct students to explain, predict, and postulate rather than simply describe, define, and recite.

Annotated Chapter Review Questions, Clinical Application Exercises, and Advanced Clinical Problem-Solving Exercises

Providing students with formative assessment tools is essential if they are to determine what they know, whether they know it well, and what they do not know or do not know well. The fifth edition of *Medical Physiology: Principles for Clinical Medicine* provides the student with a multitiered approach to formative self-assessment. This edition provides student with over 350 USMLE-type multiple choice questions that are organized by chapter content and keyed with explanations for both the right and all the wrong answers. In this manner, students are able to gauge their understanding of the physiology they are learning at the moment. It is very frustrating for students to study hard, get a practice question wrong, and then be clueless as to both why another choice was right and theirs and the remaining choices wrong. We have found that the inability to recognize wrong choices as such is a leading cause of poor student performance. By providing students with explanation for the wrong as well as the right answers with their chapter practice questions, we allow them to identify gaps in their understanding while at the same time avoiding the frustration that arises when they are given review questions without explanations for the answers. Just as important, when given a complete explanation for the choices in a question, students can better determine whether they know material well.

In the fifth edition, we take this type of formative assessment to additional, more complex levels in order to hone student problem-solving skills. We provide two *Clinical Application Exercises* with each of the 38 chapters in the book, with at least one of these placed in the print copy. These exercises are small clinical vignettes purposely circumscribed to the chapter content only. Multiple questions are asked of the student based on the vignette and the chapter content. Explanations are provided for the answers to all the questions. This type of “story problem” method of developing problem-solving skills differs from the typical case study format sometimes used in medical education. In the latter, it is not uncommon to include materials in the case for which the student has not yet learned or to which they have not yet been introduced. This can be counterproductive in that it can confound and misdirect students as they try to focus on the solution to the problem at hand. They can encounter difficulties with solving the case study because they have yet to be taught certain clinical information and complexity, rather than because their understanding of what they are currently learning is lacking. The latter is most important to them when trying to master physiology. Our *Clinical Application Exercises* are focused. They are designed to help students better learn how to apply the physiology they are learning at the moment to real clinically relevant problems. As such, this type of problem-solving exercise further helps the student identify what physiology they understand well and what they do not. In addition, this type of exercise helps students immediately see the clinical relevance of the physiology they are learning; it shows them where the physiology fits into clinical medicine.

Lastly, the online resources that accompany this book contain 38 *Advanced Clinical Problem-Solving Exercises*. These are longer, more involved clinical scenarios, each with multiple questions asked and explanations for the answers provided. These advanced exercises draw on a student’s understanding of multiple disciplines within physiology as well as other biomedical fields. These exercises are more like true clinical case studies. They allow a student to evaluate their ability to integrate multiple disciplines within physiology and apply their collective understanding toward the answers to a multifaceted clinical problem. These advanced exercises elevate a student’s problem-solving skills and further enhance their ability to determine what they do and do not know well. The exercises further illustrate for the student how the study of physiology fits into clinical medicine.

Clinical Focus Essays and Integrated Medical Sciences Essays

For the fifth edition, the *Clinical Focus* boxes of each chapter have again been updated. These short essays deal with pathophysiology, physiopharmacology, and clinical correlates of physiology, including those involved with basic therapeutics and clinical evaluation tools. A new feature, the *Integrated Medical Sciences* essay, has been added to each chapter in the fifth edition. These essays address a growing trend in medical student education of integrating the whole of medical sciences, basic and clinical, within given units of instruction. It is now common for students to be taught pathology, pathophysiology, pharmacology, and introductory medicine simultaneously, so as to create a fuller understanding of a particular disease or medical condition. The *Integrated Medical Sciences Essay* contained in each chapter is directed at connecting the physiology within a chapter to another type of medical science. Together both types of chapter-based essays gives students additional insight into the connection between physiology and the understanding of human disease and its treatment.

ADDITIONAL EDUCATIONAL FEATURES

The fifth edition incorporates many features designed to facilitate learning and guide the student along his or her study of physiology. In-print features included in the fifth edition are as follows.

- **Illustrations and Tables.** The text again contains abundant full-color figures and flow diagrams. Review tables are also provided as useful summaries of material explained in more detail in the text. The illustrations in the text often show interrelationships between different variables or components of a system. These color illustrations are more than just visually appealing. As first employed in the fourth edition, the fifth edition of the text continues the use of color art as an instructive tool. Rather than applying color arbitrarily, color itself is used with purpose and delivers meaning. Graphs, diagrams, and flow charts, for example, incorporate a coordinated scheme; red is used to indicate stimulatory, augmented, or increased effects, whereas blue connotes inhibitory, impaired, or decreased effects.

  A coordinated color scheme is likewise used throughout to depict transport systems. This key, in which membrane pores are blue, primary active transporters are red, facilitated transporters are purple, cell chemical receptors are green, cotransporters are orange, and voltage-gated transporters are yellow, adds a level of instructiveness to the figures not seen in other physiology textbooks. By differentiating these elements integral to the workings of physiology by their function, the fifth edition artwork reinforces their purpose to teach students, rather than merely representing. These beautiful full-color conceptual diagrams guide students to an understanding of the general underpinnings of physiology. Figures work with text to provide meaningful, comprehensible content.
- **Bulleted Chapter Summaries.** These bulleted statements provide a concise summative description of the chapter and provide a good review checklist of the chapter.
- **Key Concept Subheadings.** Secondary chapter subheadings are depicted in bold in the text and written as active concept statements designed to convey the key point(s) of a given section. Unlike typical textbook subheadings that simply title a section, these are given in active full sentence form. For example, instead of heading a section “Edema,” the heading instead becomes “Edema impairs diffusional transport across capillaries.” In this way, the key idea in a section is immediately obvious. When taken together in a chapter, these statement subheadings give the student another means of chapter review.
- **Boldfacing.** Key terms are boldfaced upon their first appearance in a chapter. These terms are explained in the text and defined in the glossary for quick reference.
- **Abbreviations and Normal Values.** An appendix of common abbreviations in physiology and a table of normal blood, plasma, or serum values are included inside the book covers for convenient access. All abbreviations are defined when first used in the text, but the table of abbreviations in the appendix serves as a useful quick access of abbreviations commonly used in physiology and medicine. Normal values for blood are also embedded in the text, but the table on the inside front and back covers provides a more complete and easily accessible reference.
- **Index.** A comprehensive index allows the student to easily look up material in the text.
- **Glossary.** A glossary of all boldfaced terms in the text is included for quick access to definition of terms. Students will appreciate the book’s inclusion of such a helpful and useful tool.

Readability and Design

The text is a pleasure to read, and topics are developed logically. Difficult concepts are explained clearly, in a unified voice, and supported with plentiful illustrations. Minutiae and esoteric topics are avoided. The fifth edition interior design not only makes navigating the text easier but also draws the reader in with immense visual appeal and strategic use of color. Likewise, the design highlights the pedagogical features, making them easier to find and use.

Ancillary Package

Still more features round out the colossal ancillary package online at www.thePoint.com/Rhoades. These bonus offerings provide ample opportunities for self-assessment, additional reading on tangential topics, and animated versions of the artwork to further elucidate the more complex concepts. Look for this icon thePoint® appearing throughout the text indicating associated online features.

- **Additional Formative Assessments.** In addition to the formative assessment tools now placed in the print copy of the textbook, additional chapter review questions and clinical application exercises are available online along with advanced clinical problem solving exercises. As with the print copy of the textbook, all questions are analytical in nature and test the student's ability to apply physiological principles to solving problems rather than test basic fact-based recall. They contain explanations for right and wrong answers. These chapter-based questions were written by the author of the corresponding chapter and not contracted out to a question-writing service.
- **Suggested Reading.** A short list of recent review articles, monographs, book chapters, classic papers, or Web sites where students can obtain additional information associated with each chapter is provided online.
- **Animations.** The fifth edition contains online animations illustrating difficult physiology concepts.
- **Image Bank for Instructors.** An image bank containing all of the figures in the book, in both pdf and jpeg formats, is available for download from our Web site at thePoint®.
- **Instructor Test Bank.** Also, for the fifth edition, the extensive test bank written by subject matter experts has been updated and expanded for instructors using this textbook in their course.

In closing, we would like to add that the discipline of physiology is changing. In the past 20 years, there has been an overemphasis of genetics placed into our understanding of "what makes us tick." This has resulted in the belief that genes control human biology, which has had a major impact on medical physiology and the way diseases are treated. This has recently changed with the emergence of the new science of epigenetics, which means regulation above the gene. Epigenetics can be defined as a mechanism by which genes can be switched off and on, but the genes themselves and their genetic code are not altered. This means protein synthesis and other cellular functions can be controlled above the level of the gene. New research shows that lifestyle and environmental signals can modify and regulate gene activity and shows such things as exercise, nutrition, stress, trauma, emotions, attitude, social engagement, and toxins can modify gene function without altering the genetic code. More striking is that these epigenetic modifications can be passed onto the next generation. Epigenetics is upending our understanding of physiologic regulation and has opened up a new frontier in human physiology and the future of medicine. Physiology is moving from structure–function relationships to epigenetics-induced functional relationships. This has resulted in new research that shows only approximately 15% of chronic diseases (e.g., hypertension, heart disease, asthma, obesity, diabetes, osteoporosis, arthritis, cancer, etc.) are specifically linked to genetics. The remaining 85% are factors due to lifestyle choices (e.g., diet, exercise, physical stress, emotional stress) and to environmental factors (toxins, smoking, pesticides, substance abuse, etc.). The fifth edition of *Medical Physiology: Principles of Clinical Medicine* provides all students with a strong foundation to be built upon by this new and exciting field of epigenetics.

We would like to express our deepest thanks and appreciation to all of the contributing authors.

Without their expertise and cooperation, this fifth edition would have not been possible. We also wish to express our appreciation to all of our students and colleagues who have provided helpful comments and criticisms during the revision of this book. We would also like to give thanks for a job well done to our editorial staff for their guidance and assistance in significantly improving each edition of this book. A very special thanks goes to our Developmental Editor, Kelly Horvath, who was a delight to work with and whose patience and editorial talents were essential to the completion of the fifth edition of this book. We are indebted as well to our artist, Jennifer Clements. Finally, we would like to thank Crystal Taylor, our Acquisitions Editor at Wolters Kluwer, for her support, vision, and commitment to this book. We are indebted to her administrative talents and her managing of the staff and material resources for this project.

Last we would like to thank our wives, Pamela Bell and Judy Rhoades, for their love, patience, support, and understanding of our need to devote a great deal of personal time and energy to the development of this book.

CONTENTS

Preface
Contributors

PART I CELLULAR PHYSIOLOGY

CHAPTER 1 Medical Physiology: An Overview
Scope of Medical Physiology
Future Direction of Medical Physiology

CHAPTER 2 Cell Signaling, Membrane Transport, and Membrane Potential
Basis of Physiologic Regulation
Plasma Membrane Structure
Solute Transport Mechanisms
Water Movement across the Plasma Membrane
Resting Membrane Potential
Communication and Signaling Modes
Molecular Basis of Cellular Signaling
Second Messengers

PART II NEUROMUSCULAR PHYSIOLOGY

CHAPTER 3 Action Potential, Synaptic Transmission, and Nerve Function
The Nervous System
Action Potentials
Synaptic Transmission
Neurotransmission

CHAPTER 4 Sensory Physiology
Sensory Systems
Somatosensory System
Visual System
Auditory System
Vestibular System
Gustatory and Olfactory Systems

CHAPTER 5 Motor System
Skeleton as Framework for Movement
Muscle Function and Body Movement
Nervous System Components for the Control of Movement

Spinal Cord in the Control of Movement
Supraspinal Influences on Motor Control
Cerebral Cortex Role in Motor Control
Basal Ganglia and Motor Control
Cerebellum in the Control of Movement

CHAPTER 6 Autonomic Nervous System

Anatomy of the Autonomic Nervous System
Neurotransmitters of the Autonomic Nervous System
The Parasympathetic Nervous System
Sympathetic Nervous System
Autonomic Integration

CHAPTER 7 Integrative Functions of the Central Nervous System

Hypothalamus
Brain Electrical Activity
Functional Components of the Forebrain
Higher Cognitive Skills

CHAPTER 8 Skeletal and Smooth Muscle

Skeletal Muscle
Motor Neurons and Excitation—Contraction Coupling in Skeletal Muscle
Mechanics of Skeletal Muscle Contraction
Skeletal Muscle Metabolism and Fiber Types
Muscle Plasticity, Epigenetics, and Endocrine Muscle
Smooth Muscle

PART III BLOOD AND IMMUNOLOGY

CHAPTER 9 Blood Composition and Function

Blood Functions
Whole Blood
Soluble Components of Blood and their Tests
Formed Elements of Blood and Common Diagnostic Tests
Red Blood Cells
White Blood Cells
Platelet Formation
Blood Cell Formation
Blood Clotting

CHAPTER 10 Immunology, Organ Interaction, and Homeostasis

Immune System Components
Immune System Activation
Immune Detection System
Immune System Defenses

Cell-Mediated and Humoral Responses
Acute and Chronic Inflammation
Chronic Inflammation
Anti-inflammatory Drugs
Organ Transplantation and Immunology
Immunologic Disorders
Neuroendoimmunology

PART IV CARDIOVASCULAR PHYSIOLOGY

CHAPTER 11 Overview of the Cardiovascular System and Hemodynamics

Functional Organization
Physics of Blood Containment and Movement
Physical Dynamics of Blood Flow
Distribution of Pressure, Flow, Velocity, and Blood Volume

CHAPTER 12 Electrical Activity of the Heart

Electrophysiology of Cardiac Muscle
Pathophysiology of Abnormal Generation of Cardiac Action Potentials
The Electrocardiogram

CHAPTER 13 Cardiac Muscle Mechanics and the Cardiac Pump

Cardiac Excitation–Contraction Coupling
The Cardiac Cycle
Determinants of Myocardial Performance
Determinants of Myocardial Oxygen Demand and Clinical Evaluation of Cardiac Performance
Cardiac Output
The Measurement of Cardiac Output
Imaging Techniques for Measuring Cardiac Structures, Volumes, Blood Flow, and Cardiac Output

CHAPTER 14 The Systemic Circulation

Determinants of Arterial Pressures
Arterial Pressure Measurement
Peripheral and Central Blood Volume
Coupling of Vascular and Cardiac Function

CHAPTER 15 Microcirculation and Lymphatic System

Structure and Function of the Microcirculation
The Lymphatic System
Solute Exchange between the Vasculature and Tissues
Water Exchange between the Vasculature and Interstitium
Regulation of Microvascular Resistance

CHAPTER 16 Special Circulations

Coronary Circulation

Cerebral Circulation
Circulation of the Small Intestine
Hepatic Circulation
Skeletal Muscle Circulation
Cutaneous Circulation
Fetal and Placental Circulations

CHAPTER 17 Control Mechanisms in Cardiovascular Function
Autonomic Neural Control of the Cardiovascular System
Hormonal Control of the Cardiovascular System
Circulatory Shock

PART V RESPIRATORY PHYSIOLOGY

CHAPTER 18 Ventilation and the Mechanics of Breathing
Lung Structural and Functional Relationships
Pulmonary Pressures and Airflow during Breathing
Spirometry and Lung Volumes
Minute Ventilation
Elastic Properties of Lung and Chest Wall
Airway Resistance and the Work of Breathing

CHAPTER 19 Gas Transfer and Transport
Gas Diffusion and Uptake
Diffusing Capacity
Gas Transport by the Blood
Respiratory Causes of Hypoxemia

CHAPTER 20 Pulmonary Circulation and Ventilation/Perfusion
Functional Organization
Hemodynamic Features
Fluid Exchange in Pulmonary Capillaries
Blood Flow Distribution in the Lungs
Shunts and Venous Admixture

CHAPTER 21 Control of Ventilation
Neural and Voluntary Control of Breathing
Neural Reflexes in The Control of Breathing
Physiologic Responses to Altered Oxygen and Carbon Dioxide
Control of Breathing during Sleep
Control of Breathing in Unusual Environments

PART VI RENAL PHYSIOLOGY AND BODY FLUIDS

CHAPTER 22 Kidney Function

Overview of Renal Function
Nephron: Functional Unit of The Kidney
Renal Blood Flow
Glomerular Filtration
Glomerular Hemodynamic Forces
Tubular Reabsorption
Tubule Secretion
Urinary Concentration Mechanisms
Renal Clearance and Assessing Glomerular Function
Micturition

CHAPTER 23 Regulation of Fluid and Electrolyte Balance

Fluid Compartments of the Body
Fluid Balance
Disturbances in Fluid–Electrolyte Balance
Sodium Balance
Potassium Balance
Calcium Balance
Magnesium Balance
Phosphate Balance

CHAPTER 24 Acid–Base Homeostasis

Basic Principles of Acid–Base Interaction
Metabolic Production of Acids
Integration of the Body's Buffering Systems
Regulation of Intracellular pH
Physiologic Disturbances of Acid–Base Balance

PART VII GASTROINTESTINAL PHYSIOLOGY

CHAPTER 25 Gastrointestinal System Functions

Functional Overview of Digestive System
Salivary Secretion
Gastric Secretion
Pancreatic Secretion
Biliary Secretion
Intestinal Secretion
Carbohydrate Digestion and Absorption
Lipid Digestion and Absorption
Protein Digestion and Absorption
Vitamin Absorption
Electrolyte and Mineral Absorption
Water Absorption

CHAPTER 26 Liver Functions and Immune Surveillance

Liver Structure and Function

Drug Metabolism in the Liver
Energy Metabolism in the Liver
Protein and Amino Acid Metabolism in the Liver
Liver as a Nutrient Storage Organ
Endocrine Functions of the Liver
Liver and Immune Responses

CHAPTER 27 Motility and Gastrointestinal Regulation

Organization of the Digestive System
Gastrointestinal System Motility
Esophageal and Gastric Motility
Small Intestinal Motility
Large Intestinal Motility
Smooth Muscle Contraction
Neural Control of Gut Motility and Digestive Function
Synaptic Transmission in the Enteric Nervous System
Enteric Motor Neurons

PART VIII TEMPERATURE REGULATION AND EXERCISE PHYSIOLOGY

CHAPTER 28 Regulation of Body Temperature

Body Temperature and Heat Transfer
Balance between Heat Production and Heat Loss
Metabolic Rate and Heat Production at Rest
Heat Dissipation
Thermoregulatory Control
Thermoregulatory Responses during Exercise
Heat Acclimatization
Responses to Cold
Clinical Aspects of Thermoregulation

CHAPTER 29 Exercise Physiology

Oxygen Uptake and Exercise
Cardiovascular Responses to Exercise
Respiratory Responses to Exercise
Skeletal Muscle and Bone Responses to Exercise
Obesity, Aging, and Immune Responses to Exercise

PART IX ENDOCRINE PHYSIOLOGY

CHAPTER 30 Endocrine Control Mechanisms

General Endocrine Concepts
Chemical Nature of Hormones
Measurement of Circulating Hormones

Mechanisms of Hormone Action

CHAPTER 31 Hypothalamus and the Pituitary Gland

Hypothalamic–Pituitary Axis
Posterior Pituitary Hormones
Anterior Pituitary Hormones

CHAPTER 32 Thyroid Gland

Thyroid Hormone Synthesis, Secretion, and Metabolism
Thyroid Hormone Effects on the Body
Abnormalities of Thyroid Function in Adults

CHAPTER 33 Adrenal Gland

Adrenal Cortex Synthesizes and Secretes Steroid Hormones
Adrenal Medulla Catecholamines

CHAPTER 34 Endocrine Pancreas

Islets of Langerhans
Mechanisms of Islet Hormone Synthesis and Secretion
Insulin and Glucagon Action
Diabetes Mellitus

CHAPTER 35 Endocrine Regulation of Calcium, Phosphate, and Bone Homeostasis

Overview of Calcium and Phosphate in the Body
Calcium and Phosphate Metabolism
Plasma Calcium and Phosphate Regulation
Bone Dysfunction

PART X REPRODUCTIVE PHYSIOLOGY

CHAPTER 36 Male Reproductive System

Endocrine Glands of the Male Reproductive System
Testicular Function and Regulation
Spermatogenesis
Endocrine Function of the Testis
Androgen Action and Male Development
Male Reproductive Disorders

CHAPTER 37 Female Reproductive System

Hormonal Regulation of the Female Reproductive System
Female Reproductive Organs
Ovarian Cycle
Menstrual Cycle

Infertility

CHAPTER 38 Fertilization, Pregnancy, and Fetal Development

Fertilization and Implantation
Placental Nutrient Uptake, Waste Elimination, and Gas Exchange
Hormones Required for a Successful Pregnancy
Postpartum Lactation
Puberty Onset
Sexual Development

Appendix A: Common Abbreviations in Physiology

Appendix B: Normal Blood, Plasma, or Serum Values

Glossary

PART I CELLULAR PHYSIOLOGY

1 Medical Physiology: An Overview

Human physiology is the science that explains how cells, tissues, and organs interact to allow the body to function while coping with changes in the internal and external environment. Accordingly, an important facet of physiology is to examine how the body's different systems are integrated to maintain optimal health and our survival.

SCOPE OF MEDICAL PHYSIOLOGY

This book is designed to examine the connection between the basic sciences, human function, and health. As such, the basic concepts discussed in this book highlight the relationship between physiology and foundational principles for clinical medicine. Often, interns, residents, and practicing physicians become so focused on medical diagnoses, bodily traumas, and the treatment of diseases that they lose sight of the most important part of medicine—that is, *living* and *thriving*. Long before any disease leads to dysfunction and threatens a person's life, the human body is faced with difficulties and constraints to its survival that are dictated by natural chemical, physical, and biological laws. The body expends enormous energy to maintain normal function and to survive. In short, the body encounters many challenges to simply *stay alive*.

Organ systems are designed to regulate the body's internal environment.

The human body is made up of more than 65 trillion cells. That is correct—over 65 *trillion*, not 65 billion—that are organized into specialized tissues and organs that regulate our internal environment in a manner compatible to sustain cell function and survival. Organ systems are responsible for regulating many essential cellular processes to maintain the physical and chemical conditions of the extracellular fluid within a narrow range. These include water volume and osmolality, essential electrolyte concentrations, metabolic substrates, oxygen and carbon dioxide gas concentrations, pH, and temperature, to name a few. The ability to maintain a relative consistency in the chemical and physical environment surrounding the cells of our body, in the face of a variable external environment, is called **homeostasis**.

The ability to control our internal environment against the very intense challenges to our survival is part of the scientific essence of physiology. For example, the human body can be viewed as a warm, wet organism that has to survive in a cool, dry, and harsh world. The energy our body needs to keep all cellular processes running is derived from the oxidation of basic organic molecules. However, this essential metabolic process consumes enormous amounts of oxygen and, in the process, dumps enough carbon dioxide into the extracellular fluid to potentially quickly lower the blood pH from 7.4 to 1. Therefore, the body must contend constantly with the threat of dehydration, hypothermia, and acidosis. The metabolic fuel required for energy-producing oxidation reactions in our body is needed continually by the cells. Some organs, particularly the brain, can only use glucose as a source of energy for this purpose. Moreover, the nutrient sources that originate from the foods in our diet comprise complex polymer molecules of highly different chemical natures. These complex sources require energy and coordinated processing in the body in order to be rendered into monomeric substrates that can be taken up and utilized by the cells. The oxygen needed to combine with these substrates to produce energy for cellular functions moves into cells by simple diffusion, which itself does not require expenditure of energy by the cells. However, considerable effort is required for the lungs to take up enough oxygen to meet the consumption required by the body. Furthermore, the energy-saving process of diffusion will not work unless oxygen is brought to within 100 μM of all cells in the body. Without some sort of mechanism to bring oxygen from the external environment into our body and then transport it to within 100 μM of our cells, we could not survive. Similarly, carbon dioxide cannot simply percolate out of the body from wherever it is produced. It must be neutralized, transported away from cells, and expelled from the body via the lungs. The transport of nutrients, oxygen, carbon dioxide, and waste products to and from cells is carried out by the circulatory system. In tandem with the circulatory system is the respiratory system, also with a mechanical component, that takes oxygen from the atmosphere and transfers it to the circulatory system and expels acid-producing CO_2 as well. It is little wonder that should either our cardiovascular or pulmonary systems become dysfunctional, major complications can occur in a manner of minutes, even death.

Finally, normal function of the body and its survival as a whole require communication between our internal and external environment. Our survival is, therefore, very much dependent on such communication in support of the regulation of basic physiologic conditions within our body.

The neuroendocrine system provides a communication network to tissues and organs.

In the form of a central and peripheral nervous system, we exploit the existence of electrolytes in our body fluids to create voltages and currents that can be used to very rapidly trigger and transmit information about our external and internal environment in the form of electrical signals. These nerve signals, in turn, synthesize and deliver chemical messengers to specialized tissue and different organs. Not only does our body use such a neurological sensing and signaling system to regulate functions throughout our body, but also it exploits the existence of the blood transport system afforded by the cardiovascular system to transmit chemical signal and regulatory molecules from one organ system to another. This type of internal long-distance electrochemical information system dovetails with neurogenic mechanisms in what is collectively called the **neuroendocrine system**.

This system is essential in regulating growth, development, tissue repair, and defense. The neuroendocrine system is also involved in the maintenance of all cellular metabolic pathways, storage of metabolic substrates, electrolyte composition of the extracellular fluid, maintenance of bone structure, sexual maturation, reproduction, and birth.

In addition to long-distance electrochemical transmission, nerve signals are conducted through simple reflex circuits of the nervous system. These simple reflexes send neural signals to various systems that coordinate the activity of the different systems so that the whole body can work efficiently. For example, these simple reflexes are involved in activating muscles in our body to generate the force and motion needed for the survival advantage of physical mobility, the pumping of blood by the heart through our circulatory system, the mechanical movement of air in and out of our lungs, and the processing of complex foods by our digestive tract.

Nerve transmission and simple reflexes that are distributed across the entire system are also important in protective functions. For example, the withdrawal reflex (e.g., withdrawing the hand from a hot stove), cough reflex, stretch reflex, and scratch reflex are all part of the body's protective defense system. These simple reflexes set in motion a process to ensure that the body's tissues and organs are protected from exposure to heat, light, pressure, and toxic chemicals.

Another example of how these simple reflexes act as part of the body's defenses is by turning a contractile skeletal muscle into an endocrine organ. When skeletal muscle contracts, cytokines and peptides, called **myokines**, are released and work in an endocrine-like fashion. The myokines exert a local effect on muscle metabolism and are involved in muscle repair and hypertrophy (increased muscle mass). These myokines are also involved in other tissue regeneration, repair, and immunomodulation. In fact, immunoregulation was the focus of early myokine research. One of the first myokines to be identified and found to be secreted into the bloodstream in response to muscle contractions was **interleukin-6** (**IL-6**). IL-6 is a cytokine that is involved in the body's inflammatory response to fighting infection and repairing wounds. The secretion of IL-6 increases in exponential fashion proportional to the length of exercise and muscle mass. In practical terms, the exercise-induced IL-6 secretion assumes physiological importance in the protection against certain types of chronic diseases.

Another myokine, brain-derived neurotrophic factor (BDNF), is also activated with exercise. Although BDNF is produced by contracting muscle, it is not released into the circulation but rather stays within skeletal tissue to enhance mitochondrial oxidation of fat. Paradoxically, BDNF activation through exercise also increases in the brain. BDNF is structurally related to growth factors and exerts its effects

on neuronal development, growth, maintenance, and repair. BDNF secretion is also involved as a key component in the hypothalamic pathway that controls body mass and energy homeostasis.

To date, exercise-induced BDNF is the only mechanism known to stimulate growth of new nerve tissue. Moreover, long-term aerobic exercise has been shown to improve brain function and causes a significant enlargement in the hippocampus and cortex in the human brain. These exercise-induced changes in neural function have major practical implications in maintaining brain health and the treatment of neurological disorders. For example, dementia is a neurological disorder in which the brain loses its plasticity (i.e., loss of cellular function, circuit repair, and nerve restoration), particularly in the hippocampus.

Another structural component of the body's communication network that is involved in the body's defense system is the **autonomic nervous system**. For example, the vagus nerve, which receives and sends neural reflex signals to many organs, plays an important role in cardiac and gastrointestinal functions as well as inflammation. Stimulation of the vagus nerve inhibits the synthesis of key inflammatory mediators, which are known to exacerbate the conditions of rheumatoid arthritis and other autoimmune diseases. The use of bioelectrical stimulation at specific sites in the autonomic nervous system holds the promise of treating autoimmune diseases physiologically without the use of drugs.

Lastly, the neuroendocrine system as well as other organ systems will not work well, if at all, unless the chemical composition and volume of the aqueous environment surrounding all our cells is well regulated. The renal system has this primary responsibility in the body. Together the renal, neural, endocrine, cardiovascular, and pulmonary systems work in an integrated fashion to make valuable survival functions in our body possible.

FUTURE DIRECTION OF MEDICAL PHYSIOLOGY

Physiology is playing an ever-important role in creating the framework for the maintenance of optimal health and the body's defenses. Moreover, new discoveries in physiology are continuing to provide insight into our understanding of "what makes us tick," as well as charting new directions for future medical therapies and interventions. Many of these discoveries are due to the fact that physiology applies new knowledge from other disciplines (e.g., molecular biology, genetics, immunology, biophysics, and bioengineering) to address important questions about the function and maintenance of human systems and their regulation.

Physiology is the bridge to the new science of epigenetics.

Many of the new discoveries regarding human function and survival are a result of the convergence of several of these disciplines with physiology providing a bridge between molecular/cellular events and organ function. In the past, there has been an overemphasis of genetic determination that has resulted in a scientific belief that the genes control human biology. For a long time, medical scientists thought human function and survival were controlled primarily by the body's DNA blueprint. This belief has had a major impact on the way medical scientists thought about human function. However, DNA is not the real business end of physiology, because it does not carry out many of the activities at the cellular and organ level that are required to keep the body functional and healthy. Those activities are performed mainly by proteins that get expressed by the cell's DNA, and it is these proteins that cause muscles to contract, that power the brain, that turn consumed food into nutrients that can be absorbed, and that transport oxygen throughout the circulatory system. The role of the DNA is to carry the code for all these different proteins. There is no doubt that the genetic code is a starting point and is certainly necessary. But it does not explain many of the functional variations at the tissue and organ levels or the body's ability to survive.

If only the DNA mattered, then identical twins would always be functionally identical, but this is not the case. A number of studies demonstrate that identical twins who are genetically identical show phenotypical and other differences. For instance, in one case of identical twins living together in the same family and being exposed to essentially the same environment, one twin is thin and the other overweight, one tall and the other not, one diabetic and the other not, and one an alcoholic and the other not.

Phenotypical differences between twins become even more striking when they live apart. One could argue that these phenotypic differences seen in identical twins are due to DNA mutation. However, new research shows that this is very seldom the case with twins, yet their lives are different. If nothing happened to the DNA blueprint in these individuals, then the question is, why are the differences occurring? The answer comes from an emerging field in biology called **epigenetics** that is having a major impact on human physiology. Epigenetics involves regulation at a level above the gene and shows that many of the body's functions, capabilities, and personality are not fixed at birth. Epigenetics is upending our understanding of how life is controlled. Epigenetics studies how lifestyle and environmental signals modify and regulate gene activity. The discipline is providing a link between the external environment, genetics, and human function and shows that such things as exercise, nutrition, stress, emotions, trauma, substance abuse, and social engagement can modify gene function without altering the genes themselves or their genetic code. Even more striking is the fact that epigenetic modifications can be passed on to the next generation.

Epigenetics can be defined as a mechanism by which genes can be switched off and on, but the genes themselves and their genetic code are not altered. Epigenetics controls how the genes in the cell's DNA are used. There are regions on the outer structure of the genes, called the *epigenome*, that act like switches that can turn the cell's DNA on and off. Epigenetics is now recognized as the mechanism during development that determines whether cells, which have the same genetic code, become liver, brain, or muscle cells during cell differentiation.

Finally, epigenetics has opened a new frontier in human physiology and medicine. For example, new research shows that ~15% of the chronic diseases (e.g., obesity, diabetes, hypertension, heart attacks, strokes, and certain types of cancer) are specifically linked to genetics. The remaining factors (85%) are due to lifestyle choices (e.g., diet, exercise, emotional stress) and environmental factors (e.g., toxic agents, smoking, and substance abuse).

A paradigm shift is occurring in human physiology.

Physiologists are no longer seeing the body as just a machine in which descriptive biology is attached to structure–function events. In the last 10 years, physiologists have begun identifying specific cellular mechanisms and finding the missing links between nature and nurture. They can connect specific changes in lifestyles that alter whole body function, sometimes forever. Huge areas of physiology are being influenced by epigenetics and are filled with remarkable intrigue and complexity. This has caused a paradigm shift in physiology. Physiology has moved from structure–function relationships to epigenetics-induced functional relationships.

As a result of the shift, important discoveries are being made in neurophysiology and neuroscience, especially in neurological disorders such as dementia and Alzheimer's disease. Epigenetic-induced functional changes are also leading to new discoveries in obesity, an epidemic that has spread worldwide in the last 15 years. In the United States, approximately two out of every three adults are overweight. Obesity is linked to a wide range of health problems, including cardiovascular diseases and type 2 diabetes. In addition to overeating, the two studies cited in *Cell* and *Nature* provides evidence that a parent's diet can directly influence the epigenetic modification that predisposes the offspring to obesity and diabetes.

Another field in which epigenetic-induced functional changes are playing a significant role is in the field of aging. Aging can be defined as "the progressive decline of organ function that eventually results in disease and mortality." Because identical twins with the same genetic makeup can age differently, the questions for future research will be to determine how epigenetics changes with age. Equally important will be to determine how epigenetics can have both a positive and a negative effect on aging. For example, a sedentary lifestyle with poor eating habits, high stress, smoking, and excessive drinking can cause epigenetic-induced effects that accelerate the aging process, whereas a healthy lifestyle that includes daily exercise, good nutrition, smoking avoidance, and less stress can cause epigenetic-induced changes that keep the body younger.

The paradigm shift also has altered our thinking in unexpected frontiers of human function. In the past, medical scientists have been seeing human health and survival from the level of the gene alone. Epigenetic-induced physiologic changes are making it clear that individuals are no longer doomed by their genes. In practical terms, research indicates that about 20% of an individual's health, diseases, and how he or she ages is due to genetics, and the remaining 80% is dependent on epigenetic-induced alterations in human function via changes in lifestyle and environment. For example, many of the diseases that cause early death (high blood pressure, obesity, diabetes, heart attacks, strokes, cancer) are classified as 80/20: 20% due to genetics and 80% related to lifestyle.

In summary, physiology has provided remarkable insight into how cells, tissues, and organs interact and how they are regulated. The interaction between physiology and the new science of epigenetics is showing that human health and survival are no longer determined by the limits set by our genes. Moreover, recent medical advances show the extraordinary influence individuals have over the control of their health, quality of life, and how they age. Lastly, the paradigm shift in epigenetic-induced functional changes is providing new directions for the future treatment of human diseases.

2 Cell Signaling, Membrane Transport, and Membrane Potential

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Compare and contrast negative and positive feedback and explain the importance of these processes to homeostasis.
- Explain the difference between steady state and equilibrium, including the role of energy expenditure in these concepts.
- List the types of molecules that constitute the plasma membrane and explain how they are assembled to form a selectively permeable barrier.
- Describe how the plasma membrane maintains an internal environment that differs significantly from the extracellular fluid.
- Contrast how voltage-gated channels and ligand-gated channels are opened.
- Compare and contrast carrier-mediated transport systems with channels.
- Describe primary active transport and explain how secondary active transport is different.
- Describe the properties of epithelial cells that are necessary to produce directional movement of solutes and water.
- Outline the mechanisms that many cells use to regulate their volume when exposed to osmotic stress.
- List the key components of the Goldman equation and explain why this equation gives the value of the membrane potential.
- Explain why the resting membrane potential of most cells is close to the Nernst potential for K^+.
- Compare and contrast autocrine, paracrine, and endocrine signaling in the control of cell function.
- Describe how second messengers both regulate and amplify signal transduction.
- Explain the major differences between intracellular signal transduction by G-protein–coupled receptors and tyrosine kinase receptors.
- Describe how intracellular calcium concentration is regulated and used in intracellular signal transduction.

The scope of physiology ranges from the functions of individual molecules and cells to the interaction of our bodies with the external world. Understanding how the different cell types that constitute tissues are controlled, how they interact both within and with other tissues, and how they adapt to changing conditions is central to the study of physiology. To maintain health, conditions in the body must be optimized through closely regulated processes that require efficient communication between cells and tissues.

Cells are delineated by their plasma membrane, a barrier that separates the cytosol from the extracellular fluid (ECF). The plasma membrane keeps ions, metabolites, and cell proteins needed for normal cell function from leaking out, allows specific ions and molecules to enter, and blocks entry of factors not needed by the cell. To function in coordination with the rest of the organism, cells send and receive information that is first processed by specific plasma membrane proteins.

This chapter discusses topics related to regulation of cellular homeostasis and communication between cells and tissues. Specific topics include the internal environment, types of membrane transport mechanisms for ions and other solutes, steady state and equilibrium, intercellular and intracellular communication, negative and positive feedback, feedforward control, and intracellular signal transduction cascades.

BASIS OF PHYSIOLOGIC REGULATION

Our bodies are made up of incredibly complex and delicate materials, and we are constantly subjected to all kinds of disturbances, yet we keep going for a lifetime. It is clear that conditions and processes in the body must be closely controlled and regulated—that is, kept within appropriate values. Below, we consider, in broad terms, physiologic regulation in the body.

Stable internal environment is essential for normal cell function.

The 19th-century French physiologist Claude Bernard was the first to formulate the concept of the internal environment (*milieu intérieur*). He pointed out that an external environment surrounds multicellular organisms (air or water) and a liquid internal environment (ECF) surrounds the cells that make up the organism. Cells are not directly exposed to the external world but, rather, interact with it through their surrounding environment, which is continuously renewed by the circulating blood.

For optimal cell, tissue, and organ function in animals, several facets of the internal environment must be maintained within narrow limits. These include but are not limited to (1) oxygen and carbon dioxide tensions; (2) concentrations of glucose and other metabolites; (3) osmotic pressure; (4) concentrations of hydrogen, potassium, calcium, and magnesium ions; and (5) temperature. Departures from optimal conditions may result in dysfunction, disease, or death. Bernard stated, “Stability of the internal environment is the primary condition for a free and independent existence.” He recognized that an animal’s independence from changing external conditions is related to its capacity to maintain a relatively constant internal environment. A good example is the ability of warm-blooded animals to live in different climates. Over a wide range of external temperatures, core temperature in mammals is maintained constant by both physiologic and behavioral mechanisms. This stability offers great flexibility and has an obvious survival value.

Homeostasis is the maintenance of steady states in the body by coordinated physiologic mechanisms.

The key to maintaining the stability of the body's internal environment is the masterful coordination of important regulatory mechanisms in the body. The renowned physiologist Walter B. Cannon captured the spirit of the body's capacity for self-regulation by defining the term **homeostasis** as the maintenance of steady states in the body by coordinated physiologic mechanisms.

Understanding the concept of homeostasis is important for understanding and analyzing normal and pathologic conditions in the body. To function optimally under a variety of conditions, the body must sense departures from normal and then be able to activate mechanisms for restoring physiologic conditions to normal. Deviations from normal conditions may vary between too high and too low, so mechanisms exist for opposing changes in either direction.

Homeostatic regulation of a physiologic variable often involves several cooperating mechanisms activated at the same time or in succession. The more important a variable, the more numerous and complicated are the mechanisms that operate to keep it at the desired value. When the body is unable to restore physiologic variables, then disease or death can result. The ability to maintain homeostatic mechanisms varies over a person's lifetime, with some homeostatic mechanisms not being fully developed at birth and others declining with age. For example, a newborn infant cannot concentrate urine as well as an adult and is, therefore, less able to tolerate water deprivation. Older adults are less able to tolerate stresses, such as exercise or changing weather, than are younger adults.

The term *homeostasis* traditionally refers to the ECF that bathes our tissues—but it can also be applied to conditions within cells. In fact, the ultimate goal of maintaining a constant internal environment is to promote intracellular homeostasis, and toward this end, conditions in the cytosol of cells are closely regulated.

Negative feedback promotes stability, and feedforward control anticipates change.

Feedback is a flow of information along a closed loop. The components of a simple negative-feedback control system include a regulated variable, sensor, controller, and effector (Fig. 2.1). Each component controls the next component. Various disturbances may arise within or outside the system and cause undesired changes in the regulated variable. With **negative feedback**, a regulated variable is sensed, information is fed back to the controller, and the effector acts to oppose change (hence the term *negative*).

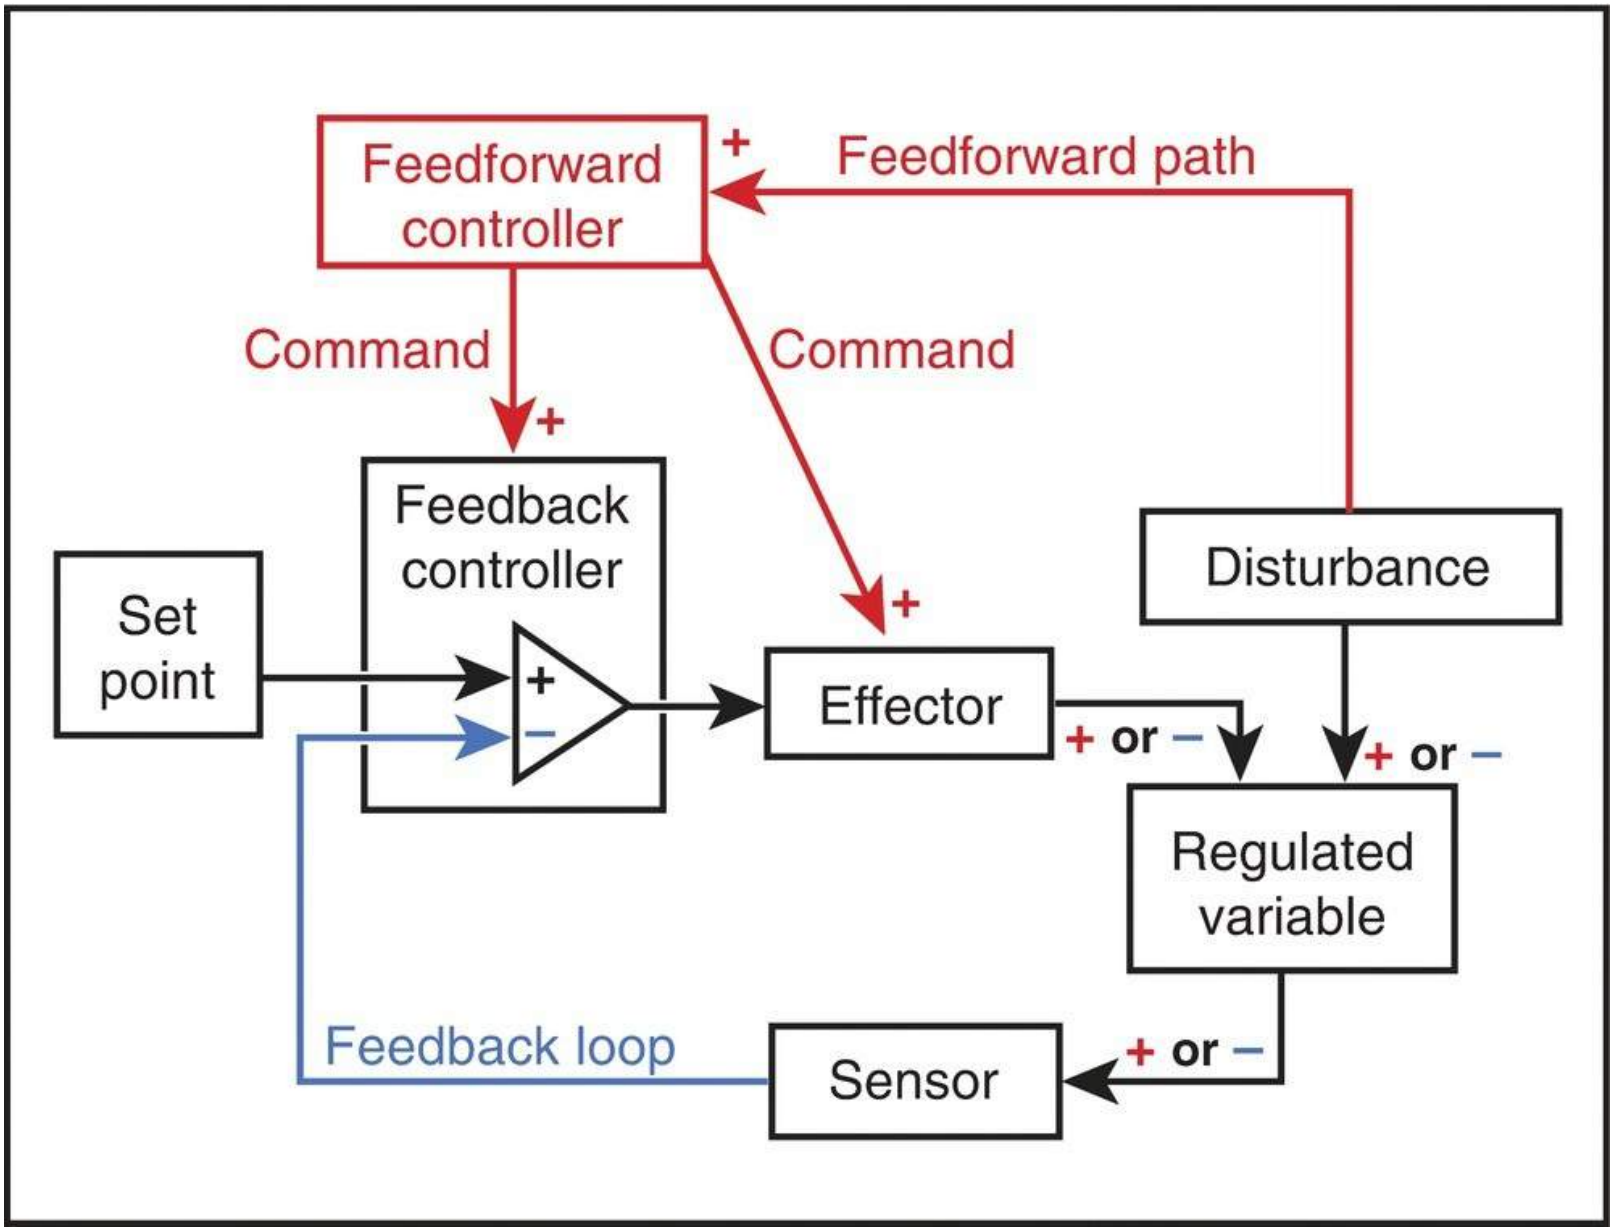

Figure 2.1 Elements of negative-feedback and feedforward control systems. In a negative-feedback control system, information flows along a closed loop. The regulated variable is sensed, and information about its level is provided to a feedback controller, which compares it with a desired value (set point). If there is a difference, an error signal is generated, which drives the effector to bring the regulated variable closer to the desired value. A feedforward controller generates commands without directly sensing the regulated variable, although it may sense a disturbance. Feedforward controllers often operate through feedback controllers.

A familiar example of a negative-feedback control system is the thermostatic control of room temperature. Room temperature (regulated variable) is subjected to disturbances. For example, room temperature falls on a cold day. A thermometer (sensor) in the thermostat (controller) detects the room temperature. The thermostat is set for a certain temperature (set point). The controller compares the actual temperature (feedback signal) with the set point temperature, and an error signal is generated if the room temperature falls below the set temperature. The error signal activates the furnace (effector). The resulting change in room temperature is monitored, and when the temperature rises sufficiently, the furnace is turned off. Such a negative-feedback system allows some fluctuation in room temperature, but the components act together to maintain the set temperature. Effective communication between the sensor and effector is important in keeping these oscillations to a minimum.

Similar negative-feedback systems exist to maintain homeostasis in the body. For example, the maintenance of water and salts in the body is referred to as **osmoregulation** or fluid balance. During exercise, loss of water from sweating results in an increased concentration of salts in the blood and tissue fluids, which is sensed by the cells in the brain (see Chapter 23). The brain responds by telling the kidneys to reduce secretion of water and also by increasing the sensation of thirst. Together, the reduction in water loss in the kidneys and increased water intake return the blood and tissue fluids to the correct osmotic concentration. This negative-feedback system allows for minor fluctuations in water and salt concentrations in the body but rapidly compensates for disturbances to restore acceptable osmotic conditions.

Feedforward control is another strategy for regulating body systems, particularly when a change with time is desired. In this case, a command signal is generated, which specifies the target or goal. The moment-to-moment operation of the controller is “open loop”; that is, the regulated variable itself is not sensed. Feedforward control mechanisms often sense a disturbance and can, therefore, take corrective action that anticipates change. For example, heart rate and breathing increase even before a person has begun to exercise.

Feedforward control usually acts in combination with negative-feedback systems. One example is picking up a pencil. The movements of the arm, hand, and fingers are directed by the cerebral cortex (feedforward controller); the movements are smooth, and forces are appropriate only in part because of the feedback of visual information and sensory information from receptors in the joints and muscles. Another example of this combination occurs during exercise. Respiratory and cardiovascular adjustments closely match muscular activity, so that arterial blood oxygen and carbon dioxide tensions (the partial pressure of a gas in a liquid) hardly change during all but exhausting exercise (see Chapter 21). Importantly, control system function can adapt over time. Past experience and learning can change the control system’s output so that it behaves more efficiently or appropriately.

Although homeostatic control mechanisms usually act for the good of the body, they are sometimes deficient, inappropriate, or excessive. Many diseases, such as cancer, diabetes, and hypertension, develop because of defects in control mechanisms. Formation of a scar is an example of an important homeostatic mechanism for healing wounds, but in many chronic diseases, such as pulmonary fibrosis, hepatic cirrhosis, and renal interstitial disease, scar formation goes awry and becomes excessive.

Positive feedback promotes a change in one direction.

With **positive feedback**, a variable is sensed and action is taken to reinforce a change of the variable. The term positive refers to the response being in the same direction, leading to a cumulative or amplified effect. Positive feedback does not lead to stability or regulation, but to the opposite—a progressive change in one direction. One example of positive feedback is the sensation of needing to urinate. As the bladder fills, mechanosensors in the bladder are stimulated, and the smooth muscle in the bladder wall begins to contract (see Chapter 23). As the bladder continues to fill and become more distended, the contractions increase and the need to urinate becomes more urgent. Responding to the need to urinate results in a sensation of immediate relief upon emptying the bladder, and this is positive feedback. Another example of positive feedback occurs during the follicular phase of the menstrual cycle. The female sex hormone estrogen stimulates the release of luteinizing hormone, which in turn causes further estrogen synthesis by the ovaries. This positive feedback culminates in ovulation (see Chapter 37). Positive feedback, if unchecked, can lead to a vicious cycle and dangerous situations. For example, a heart may be so weakened by disease that it cannot provide adequate blood flow to the muscle tissue of the heart. This leads to a further reduction in cardiac pumping ability, even less coronary blood flow, and further deterioration of cardiac function. The physician's task sometimes is to disrupt detrimental cyclical positive-feedback loops.

Steady state and equilibrium are both stable conditions, but energy is required to maintain a steady state.

Simplistically, the whole body can be divided into two major compartments: intracellular fluid and ECF, which are separated by cell plasma membranes. The fluid component of the body constitutes about 60% of the total body weight. The intracellular fluid compartment constitutes about two thirds of the body's water and contains potassium, other ions, and proteins. The ECF compartment constitutes one third of the body's water (~20% body weight) and consists of all the body fluids outside of cells, including the interstitial fluid that bathes the cells, lymph, blood plasma, and specialized fluids such as cerebrospinal fluid. It is primarily a sodium chloride (NaCl) and sodium carbonate ($NaHCO_3$) solution that can be divided into three subcompartments: the interstitial fluid (lymph and plasma); plasma that circulates as the extracellular component of blood; and transcellular fluid, which is a set of fluids that are outside of normal compartments, such as cerebrospinal fluid, digestive fluids, and mucus.

When two compartments are in **equilibrium**, *opposing forces are balanced*, and there is no net transfer of a particular substance or energy from one compartment to the other. Equilibrium occurs if sufficient time for exchange has been allowed and if no physical or chemical driving force would favor net movement in one direction or the other. For example, osmotic equilibrium between cells and ECF is normally present in the body because of the high water permeability of most cell membranes. An equilibrium condition, if undisturbed, remains stable. No energy expenditure is required to maintain an equilibrium state.

Equilibrium and steady state are sometimes confused with each other. A **steady state** is simply a condition that does not change with time. It indicates that the amount or concentration of a substance in a compartment is constant. In a steady state, there is no net gain or net loss of a substance in a compartment. Steady state and equilibrium both suggest stable conditions, but a steady state does not necessarily indicate an equilibrium condition, and energy expenditure may be required to maintain a steady state. For example, in most body cells, there is a steady state for Na^+ ions; the amounts of Na^+ entering and leaving cells per unit time are equal. But intracellular and extracellular Na^+ ion concentrations are far from equilibrium. Extracellular [Na^+] is much higher than intracellular [Na^+], and Na^+ tends to move into cells down concentration and electrical gradients. The cell continuously uses metabolic energy to pump Na^+ out of the cell to maintain the cell in a steady state with respect to Na^+ ions. In living systems, conditions are often displaced from equilibrium by the constant expenditure of metabolic energy.

Figure 2.2 illustrates the distinctions between steady state and equilibrium. In Figure 2.2A, the fluid level in the sink is constant (a steady state) because the rates of inflow and outflow are equal. If we were to increase the rate of inflow (open the tap), the fluid level would rise, and with time, a new steady state might be established at a higher level. In Figure 2.2B, the fluids in compartments X and Y are not in equilibrium (the fluid levels are different), but the system as a whole and each compartment are in a steady state, because inputs and outputs are equal. In Figure 2.2C, the system is in a steady state and compartments X and Y are in equilibrium. Note that the term *steady state* can apply to a single or several compartments; the term *equilibrium* describes the relation between at least two adjacent compartments that can exchange matter or energy with each other.

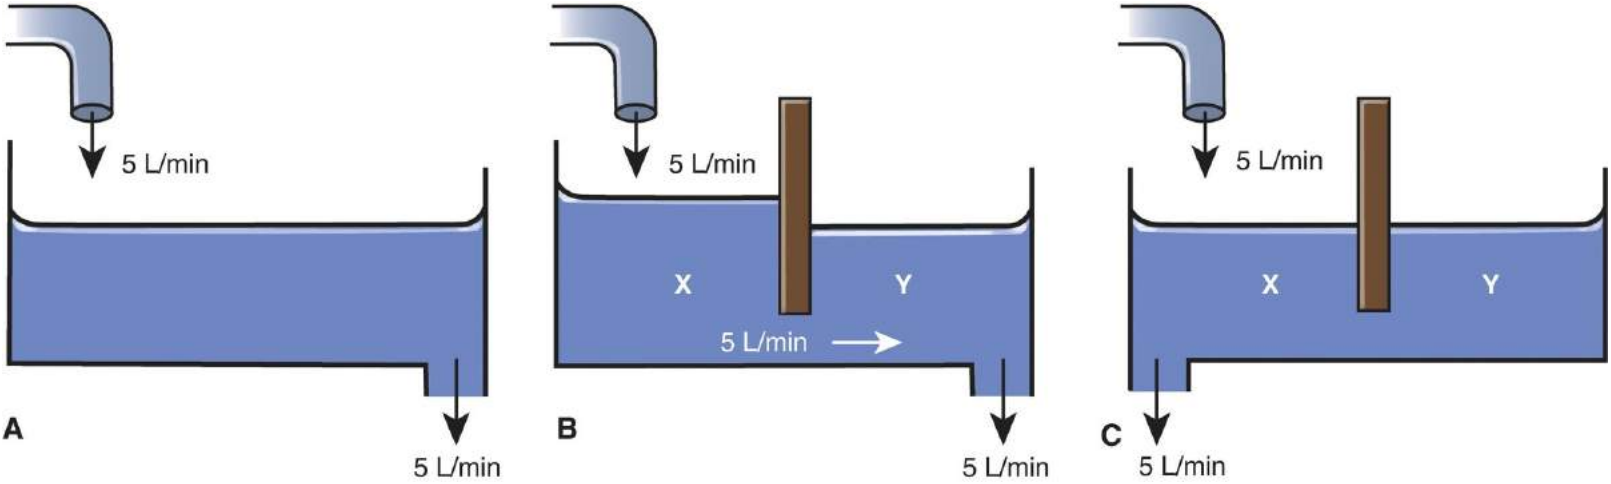

Figure 2.2 Models of the concepts of steady state and equilibrium. Parts **(A–C)** depict a steady state. In **(C)**, compartments X and Y are in equilibrium.

PLASMA MEMBRANE STRUCTURE

The first theory of membrane structure proposed that cells were surrounded by a double layer of lipid molecules, a **lipid bilayer**. However, this theory, based on the knowledge that lipid molecules form bilayers with low permeability to water-soluble molecules, did not explain the selective movement of certain water-soluble compounds, such as glucose and amino acids, across the plasma membrane. In 1972, Singer and Nicolson proposed the **fluid mosaic model** of the plasma membrane, which described the organization and interaction of proteins with the lipid bilayer (Fig. 2.3). With minor modifications, this model is still accepted as the correct picture of the structure of the plasma membrane.

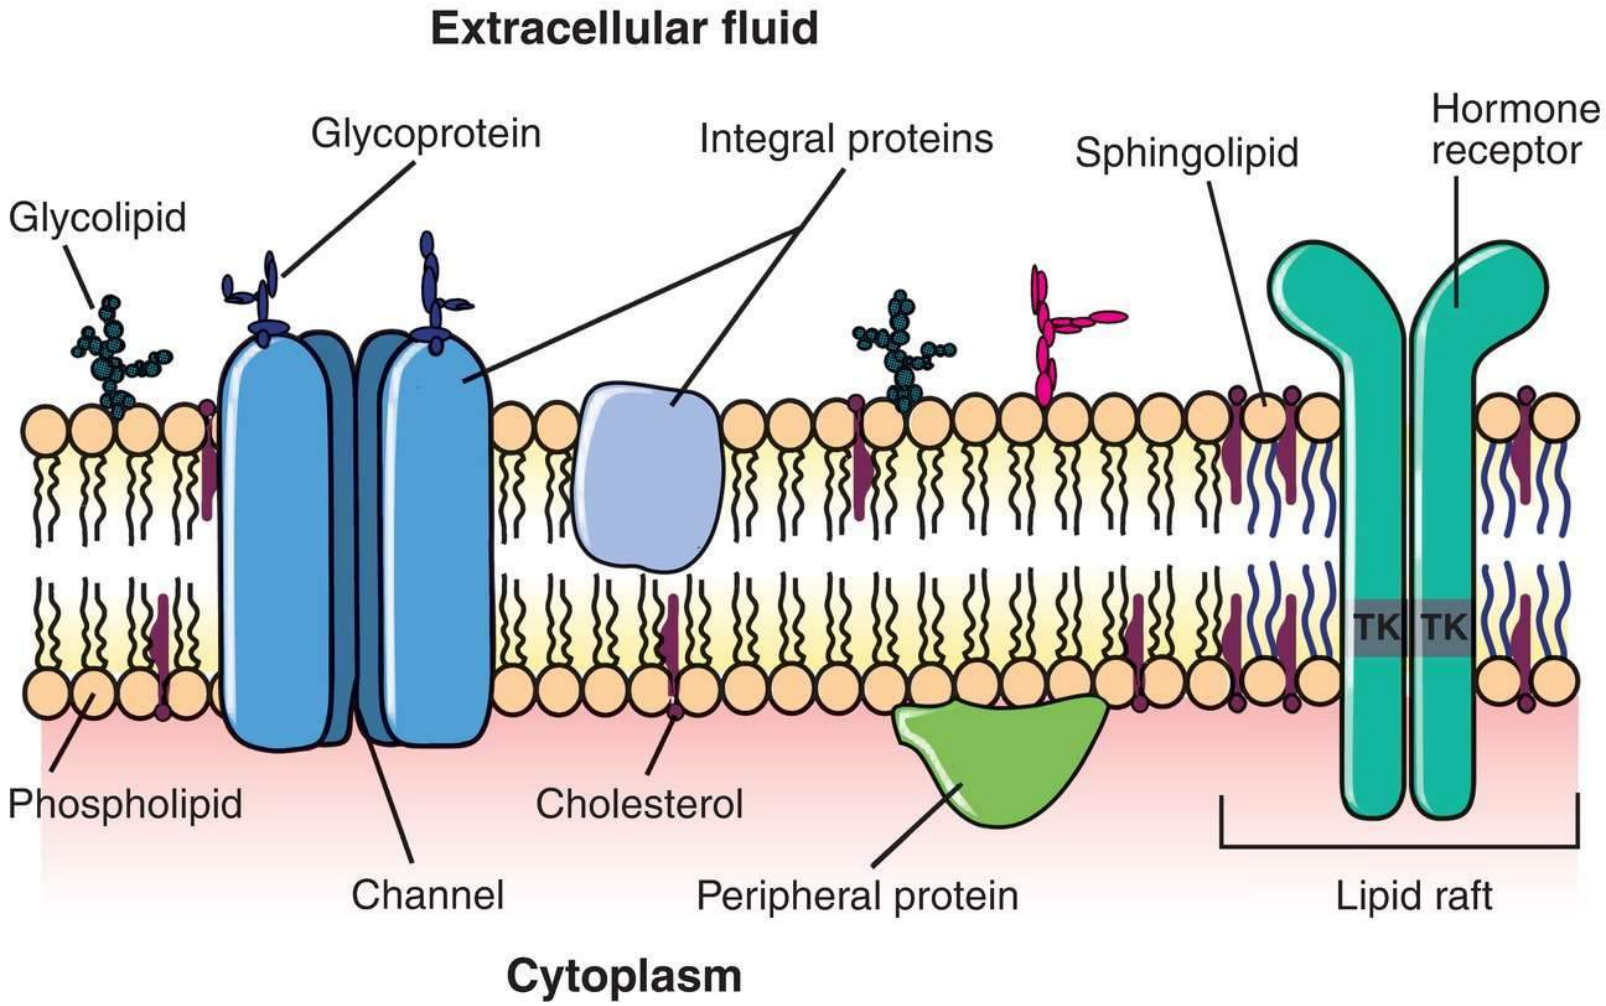

Figure 2.3 The fluid mosaic model of the plasma membrane. Lipids are arranged in a bilayer. Cholesterol provides rigidity to the bilayer. Integral proteins are embedded in the bilayer and often span it. Some membrane-spanning proteins form pores and channels. In some specialized cases, transmembrane pores on adjacent cells fuse together to form gap junctions that facilitate communication between the two cells. Other membrane-spanning proteins are receptors. Peripheral proteins do not penetrate the bilayer. Lipid rafts form stable microdomains composed of sphingolipids and cholesterol.

Plasma membrane consists of different types of membrane lipids with different functions.

Lipids found in cell membranes can be classified into two broad groups: **phospholipids,** which contain fatty acids as part of the molecule and **cholesterol**, which does not have a fatty acid in its structure.

Phospholipids are the most abundant complex lipids found in cell membranes. They are amphipathic molecules formed by two fatty acids (normally, one saturated and one unsaturated) and one phosphoric acid group substituted on the backbone of a glycerol or sphingosine molecule. This arrangement produces a hydrophobic area formed by the two fatty acids and a polar hydrophilic head. When phospholipids are arranged in a bilayer, the polar heads are on the outside and the hydrophobic fatty acids on the inside (see Fig. 2.3). It is difficult for water-soluble molecules and ions to pass directly through the hydrophobic interior of the lipid bilayer.

The phospholipids, with a backbone of sphingosine (a long amino alcohol), are usually called *sphingolipids* and are present in all plasma membranes in small amounts. They are especially abundant in brain and nerve cells. Ceramide is a lipid second messenger that is generated from the sphingolipid sphingomyelin.

Glycolipids are lipid molecules that contain sugars and sugar derivatives (instead of phosphoric acid) in the polar head. They are located mainly in the outer half of the lipid bilayer, with the sugar molecules facing the ECF. Proteins can associate with the plasma membrane by linkage to the extracellular sugar moiety of glycolipids.

Cholesterol is an important component of mammalian plasma membranes. The proportion of cholesterol in plasma membranes varies from 10% to 50% of total lipids. Cholesterol has a rigid structure that stabilizes the cell membrane and reduces the natural mobility of lipids and proteins to move in the membrane. Some cell functions, such as the response of immune system cells to the presence of an antigen, depend on the ability of membrane proteins to move in the plane of the membrane to bind the antigen. A decrease in membrane fluidity resulting from an increase in cholesterol will impair these functions.

Aggregates of sphingolipids and cholesterol can form stable microdomains termed **lipid rafts** that diffuse laterally in the phospholipid bilayer. The protein **caveolin** is present in a subset of lipid rafts (termed **caveolae**), causing the raft to form a cavelike structure. It is believed that one function of both noncaveolar and caveolar lipid rafts is to facilitate interactions between specific proteins by selectively including (or excluding) these proteins from the raft microdomain. For example, lipid rafts can mediate the assembly of membrane receptors and intracellular signaling proteins as well as the sorting of plasma membrane proteins for internalization.

Proteins are integrally and peripherally associated with the plasma membrane.

Proteins are the second major component of the plasma membrane, present in about equal proportion by weight with the lipids. Two different types of proteins are associated with the plasma membrane. **Integral proteins** are embedded in the lipid bilayer, and many span it completely. The polypeptide chain of these proteins may cross the lipid bilayer once or may make multiple passes across it. The membrane-spanning segments usually contain amino acids with nonpolar side chains and are arranged in an ordered α-helical conformation. **Peripheral proteins** do not penetrate the lipid bilayer. They are in contact with the outer side of only one of the lipid layers—either the layer facing the cytoplasm or the layer facing the ECF (see Fig. 2.3). Many membrane proteins have carbohydrate molecules (sugar molecules) attached to the part of the protein that is exposed to the ECF and are termed **glycoproteins**. Some of the integral membrane proteins can move in the plane of the membrane, like small boats floating in the "sea" formed by the lipid bilayer. Other membrane proteins are anchored to the cytoskeleton inside the cell or to proteins of the extracellular matrix.

The proteins in the plasma membrane play a variety of roles. Many peripheral membrane proteins are enzymes, and many membrane-spanning integral proteins are carriers or channels for the movement of water-soluble molecules and ions into and out of the cell. **Gap junctions** are specialized protein channels, made of the protein **connexin**, that facilitate direct cell to cell communication. Six connexins assemble in the plasma membrane of a cell to form a half channel called a **connexon**. Two connexons aligned between two neighboring cells then join end to end to form an intercellular channel between the plasma membranes of adjacent cells. Gap junctions allow the flow of ions and small molecules between the cytosol of neighboring cells, thereby providing rapid transmission of electrical signals between cells in the heart, smooth muscle cells, and some nerve cells. Gap junctions are thought to play a role in the control of cell growth and differentiation by allowing adjacent cells to share a common intracellular environment. Often when a cell is injured, gap junctions close, isolating a damaged cell from its neighbors.

Membrane proteins also have a structural role, for example, maintaining the biconcave shape of the erythrocyte. Finally, some membrane proteins serve as highly specific receptors on the outside of the cell membrane to which extracellular molecules, such as hormones, can bind. If the receptor is a membrane-spanning protein, it provides a mechanism for converting an extracellular signal into an intracellular response.

SOLUTE TRANSPORT MECHANISMS

All cells must import oxygen, sugars, amino acids, and small ions and export carbon dioxide, metabolic wastes, and secretions. At the same time, specialized cells require mechanisms to transport molecules such as enzymes, hormones, and neurotransmitters. The movement of large molecules is carried out by endocytosis and exocytosis: the transfer of substances into or out of the cell by vesicle formation and vesicle fusion with the plasma membrane. Cells also have mechanisms for the rapid movement of ions and solute molecules across the plasma membrane. These mechanisms are of two general types: **passive transport**, which requires no direct expenditure of metabolic energy, and **active transport**, which uses metabolic energy to move solutes across the plasma membrane.

Import of extracellular materials occurs through phagocytosis and endocytosis.

Phagocytosis is the ingestion of large particles or microorganisms, usually occurring only in specialized cells such as macrophages (Fig. 2.4). An important function of macrophages is to remove invading bacteria from the body. The phagocytic vesicle (1 to 2 μm in diameter) is almost as large as the phagocytic cell itself. Phagocytosis requires a specific stimulus. It occurs only after the extracellular particle has bound to the extracellular surface. The particle is then enveloped by expansion of the cell membrane around it.

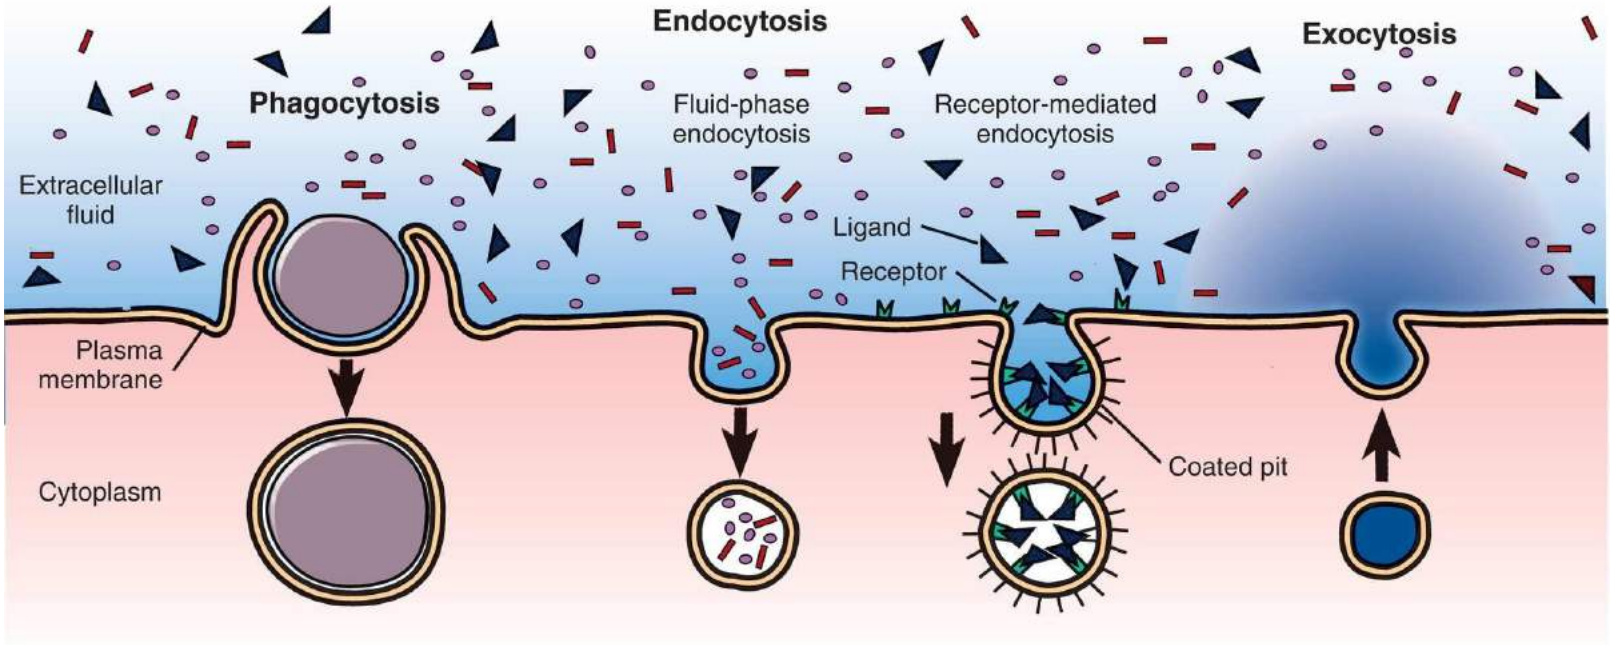

Figure 2.4 The transport of macromolecules across the plasma membrane by the formation of vesicles. Particulate matter in the extracellular fluid (ECF) is engulfed and internalized by phagocytosis. During fluid-phase endocytosis, ECF and dissolved macromolecules enter the cell in endocytic vesicles that pinch off at depressions in the plasma membrane. Receptor-mediated endocytosis uses membrane receptors at coated pits to bind and internalize specific solutes (ligands). Exocytosis is the release of macromolecules destined for export from the cell. These are packed inside secretory vesicles that fuse with the plasma membrane and release their contents outside the cell.

Endocytosis is a general term for the process in which a region of the plasma membrane is pinched off to form an endocytic vesicle inside the cell. During vesicle formation, some fluid, dissolved solutes, and particulate material from the extracellular medium are trapped inside the vesicle and internalized by the cell. Endocytosis produces much smaller endocytic vesicles (0.1 to 0.2 μm in diameter) than phagocytosis. It occurs in almost all cells and is termed a constitutive process, because it occurs continually and specific stimuli are not required. In further contrast to phagocytosis, endocytosis originates with the formation of depressions in the cell membrane. The depressions pinch off within a few minutes after forming and give rise to endocytic vesicles inside the cell.

Two types of endocytosis can be distinguished (see Fig. 2.4). **Fluid-phase endocytosis** is the nonspecific uptake of the ECF and all its dissolved solutes. The material is trapped inside the endocytic

vesicle as it is pinched off inside the cell. The amount of extracellular material internalized by this process is directly proportional to its concentration in the extracellular solution. **Receptor-mediated endocytosis** is a more efficient process, which uses receptors on the cell surface to bind specific molecules. These receptors accumulate at specific depressions known as **coated pits**, so named because the cytosolic surface of the membrane at this site is covered with a coat of several proteins. The coated pits pinch off continually to form endocytic vesicles, providing the cell with a mechanism for rapid internalization of a large amount of a specific molecule without the need to endocytose large volumes of ECF. The receptors also increase the uptake of molecules present at low concentrations outside the cell. Receptor-mediated endocytosis is the mechanism by which cells take up a variety of important molecules, including hormones, growth factors, and serum transport proteins such as the iron carrier **transferrin**. Foreign substances, such as diphtheria toxin and certain viruses, also enter cells by this pathway.

Export of macromolecules occurs through exocytosis.

Many cells synthesize important macromolecules that are destined for **exocytosis** or export from the cell. These molecules are synthesized in the endoplasmic reticulum, modified in the Golgi apparatus, and packed inside transport vesicles. The vesicles move to the cell surface, fuse with the cell membrane, and release their contents outside the cell (see Fig. 2.4).

There are two exocytic pathways—constitutive and regulated. The continuous secretion of mucus by **goblet cells** in the small intestine is an example of the *constitutive pathway* of exocytosis that is present in all cells. In other cells, macromolecules are stored inside the cell in secretory vesicles. These vesicles fuse with the cell membrane and release their contents only when a specific extracellular stimulus arrives at the cell membrane. This process, termed the *regulated pathway*, is responsible for the rapid "on-demand" secretion of many specific hormones, neurotransmitters, and digestive enzymes.

Uncharged solutes cross the plasma membrane by passive diffusion.

Any solute will tend to uniformly occupy the entire space available to it. This movement, known as **diffusion**, is a result of the spontaneous Brownian (random) movement that all molecules experience. A drop of ink placed in a glass of water will diffuse and slowly color all the water. The net result of diffusion is the movement of substances from regions of high concentration to regions of low concentration. Diffusion is an effective way for substances to move short distances.

The speed with which the diffusion of a solute in water occurs depends on the difference of concentration, the size of the molecules, and the possible interactions of the diffusible substance with water. These different factors appear in **Fick's law**, which describes the diffusion of any solute in water. In its simplest formulation, Fick's law can be written as:

$$J = DA(C_1 - C_2)/\Delta X \quad (1)$$

where J is the flow of solute from region 1 to region 2 in the solution; D is the diffusion coefficient of the solute, which is determined by factors such as solute molecular size and interactions of the solute with water; A is the cross-sectional area through which the flow of solute is measured; C is the concentration of the solute at regions 1 and 2; and DX is the distance between regions 1 and 2. Sometimes, J is expressed in units of amount of substance per unit area per unit time, for example, mol/cm^2/h, and is also referred to as the solute **flux**.

The principal force driving the passive diffusion of an uncharged solute across the plasma membrane is the difference of concentration between the inside and the outside of the cell. In the case of an electrically charged solute, such as an ion, diffusion is also driven by the membrane potential, which is the electrical gradient across the membrane. Movement of charged solutes and the membrane potential will be discussed in greater detail later in this chapter.

Diffusion across a membrane has no preferential direction; it can occur from the outside of the cell toward the inside or from the inside of the cell toward the outside. For any substance, it is possible to measure the **permeability coefficient** (**P**), which gives the speed of the diffusion across a unit area of plasma membrane for a defined driving force. Fick's law for the diffusion of an uncharged solute across a membrane can be written as

$$J = PA(C_1 - C_2) \quad (2)$$

which is similar to equation 1. P includes the membrane thickness, the diffusion coefficient of the solute within the membrane, and the solubility of the solute in the membrane. Dissolved gases such as oxygen and carbon dioxide have high permeability coefficients and diffuse rapidly across the plasma membrane. As a result, gas exchange in the lungs is very effective. Diffusion across the plasma membrane implies that the diffusing solute enter the lipid bilayer to cross it; thus, the solute's solubility in a lipid solvent

(e.g., olive oil or chloroform) compared with its solubility in water is important in determining its permeability coefficient.

A substance's solubility in oil compared with its solubility in water is its **partition coefficient**. Lipophilic (lipid-soluble) substances, such as gases, steroid hormones, and anesthetic drugs, which mix well with the lipids in the plasma membrane, have high partition coefficients and, as a result, high permeability coefficients; they tend to cross the plasma membrane easily. Hydrophilic (water-soluble) substances, such as ions and sugars, do not interact well with the lipid component of the membrane, have low partition coefficients and low permeability coefficients, and diffuse across the membrane more slowly.

Solutes such as oxygen readily diffuse across the lipid part of the plasma membrane by simple diffusion. Thus, the relationship between the rate of movement and the difference in concentration between the two sides of the membrane is linear (Fig. 2.5). The larger the difference in concentration ($C_1 - C_2$), the greater the amount of substance crossing the membrane per unit time.

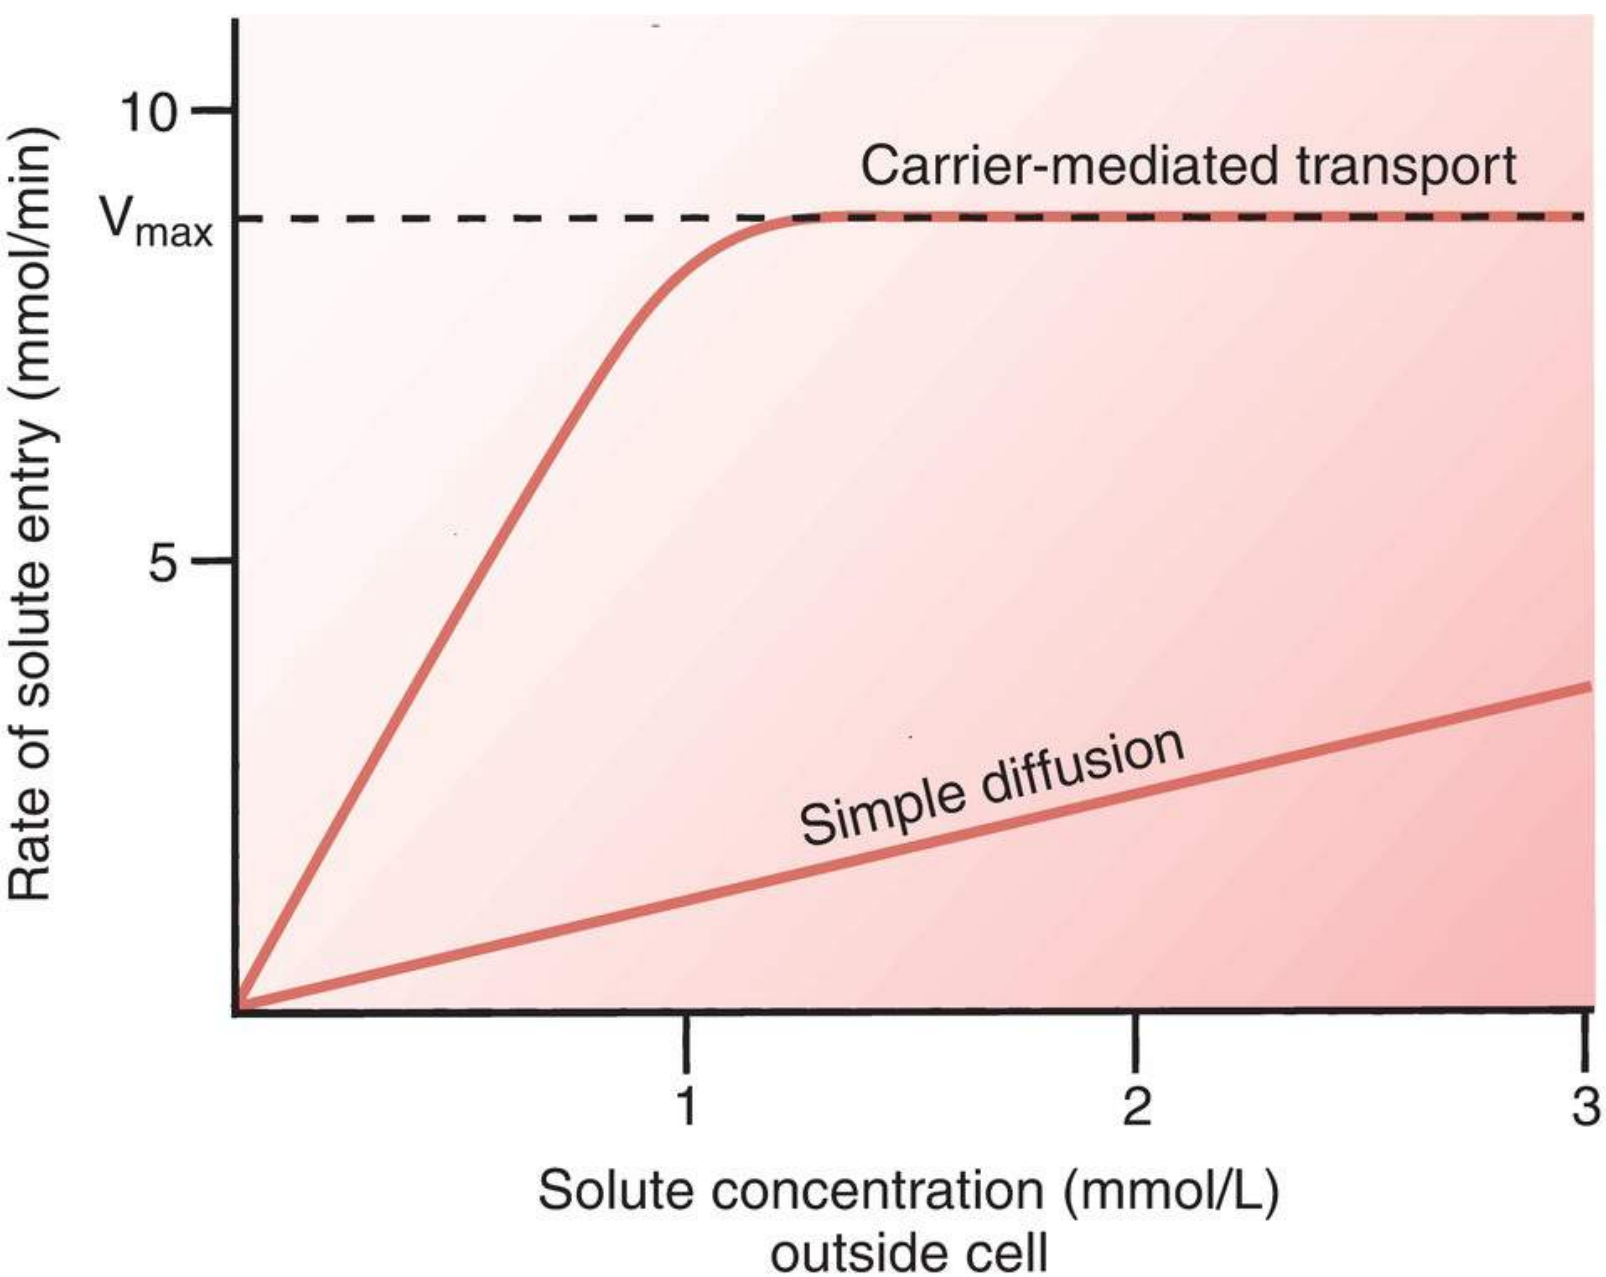

Figure 2.5 Solute transport across a plasma membrane by simple or facilitated diffusion. In simple diffusion, the rate of solute entry increases linearly with extracellular concentration of the solute.

Assuming no change in intracellular concentration, increasing the extracellular concentration increases the gradient that drives solute entry. In facilitated diffusion, the rate of transport is much faster, and increases linearly as the extracellular solute concentration increases. The increase in transport is limited by the availability of channels and carriers. Once all are occupied by solute, further increases in extracellular concentration have no effect on the rate of transport. A maximum rate of transport (V_{max}) is achieved that cannot be exceeded.

Integral membrane proteins facilitate diffusion of solutes across the plasma membrane.

For many solutes of physiologic importance, such as ions, sugars, and amino acids, the rate of transport across the plasma membrane is much faster than expected for simple diffusion through a lipid bilayer. Furthermore, the relationship between transport rate and concentration difference of these hydrophilic substances follows a curve that reaches a plateau (see Fig. 2.5). Membrane transport with these characteristics is often called **facilitated diffusion** or **carrier-mediated diffusion**, because an integral membrane protein facilitates the movement of a solute through the membrane. Integral membrane proteins can form pores, channels, or carriers, each of which facilitates the transport of specific molecules across the membrane.

There are a limited number of pores, channels, and carriers in any cell membrane; thus, increasing the concentration of the solute initially uses the existing "spare" pores, channels, or carriers to transport the solute at a higher rate than by simple diffusion. As the concentration of the solute increases further and more solute molecules associate with the pore, channel, or carrier, the transport system eventually reaches saturation, when all the pores, channels, and carriers are involved in translocating molecules of solute. At this point, additional increases in solute concentration do not increase the rate of solute transport (see Fig. 2.5).

The types of integral membrane protein transport mechanisms considered here can transport a solute along its concentration gradient only, as in simple diffusion. Net movement stops when the concentration of the solute has the same value on both sides of the membrane. At this point, with reference to equation 2, $C_1 = C_2$ and the value of J is 0. The transport systems function until the solute concentrations have equilibrated. However, equilibrium is attained much faster than with simple diffusion.

Membrane pores

A pore provides a conduit through the lipid bilayer that is always open to both sides of the membrane. **Aquaporins** in the plasma membranes of specific kidney and gastrointestinal tract cells permit the rapid movement of water. Within the **nuclear pore complex**, which regulates movement of molecules into and out of the nucleus, is an aqueous pore that only allows the passive movement of molecules smaller than 45 kDa and excludes molecules larger than 62 kDa. The **mitochondrial permeability transition pore** and **mitochondrial voltage-dependent anion channel** (**VDAC**), which cross the inner and outer mitochondrial membranes, promote mitochondrial failure when formed, resulting in the generation of **reactive oxygen species** and cell death.

Gated channels

Small ions, such as Na^+, K^+, Cl^-, and Ca^{2+}, cross the plasma membrane faster than would be expected based on their partition coefficients in the lipid bilayer. The electrical charge of an ion makes it difficult for the ion to move across the lipid bilayer. The excitation of nerves, the contraction of muscle, the beating of the heart, and many other physiologic events are possible because of the ability of small ions to enter or leave the cell rapidly. This movement occurs through selective ion channels.

Ion channels are composed of several polypeptide subunits that span the plasma membrane and contain a gate that determines if the channel is open or closed. Specific stimuli cause a conformational change in the protein subunits to open the gate, creating an aqueous channel through which the ions can

move (Fig. 2.6). In this way, ions do not have to enter the lipid bilayer to cross the membrane; they are always in an aqueous medium. When the channels are open, the ions diffuse rapidly from one side of the membrane to the other down the concentration gradient. Specific interactions between the ions and the sides of the channel produce an extremely rapid rate of ion movement; in fact, ion channels permit a much faster rate of solute transport (about 10^8 ions/s) than the carrier-mediated systems discussed below. Ion channels have a selectivity filter, which regulates the transport of certain classes of ions such as anions or cations or specific ions such as Na^+, K^+, Ca^{2+}, and Cl^- (see Fig. 2.6).

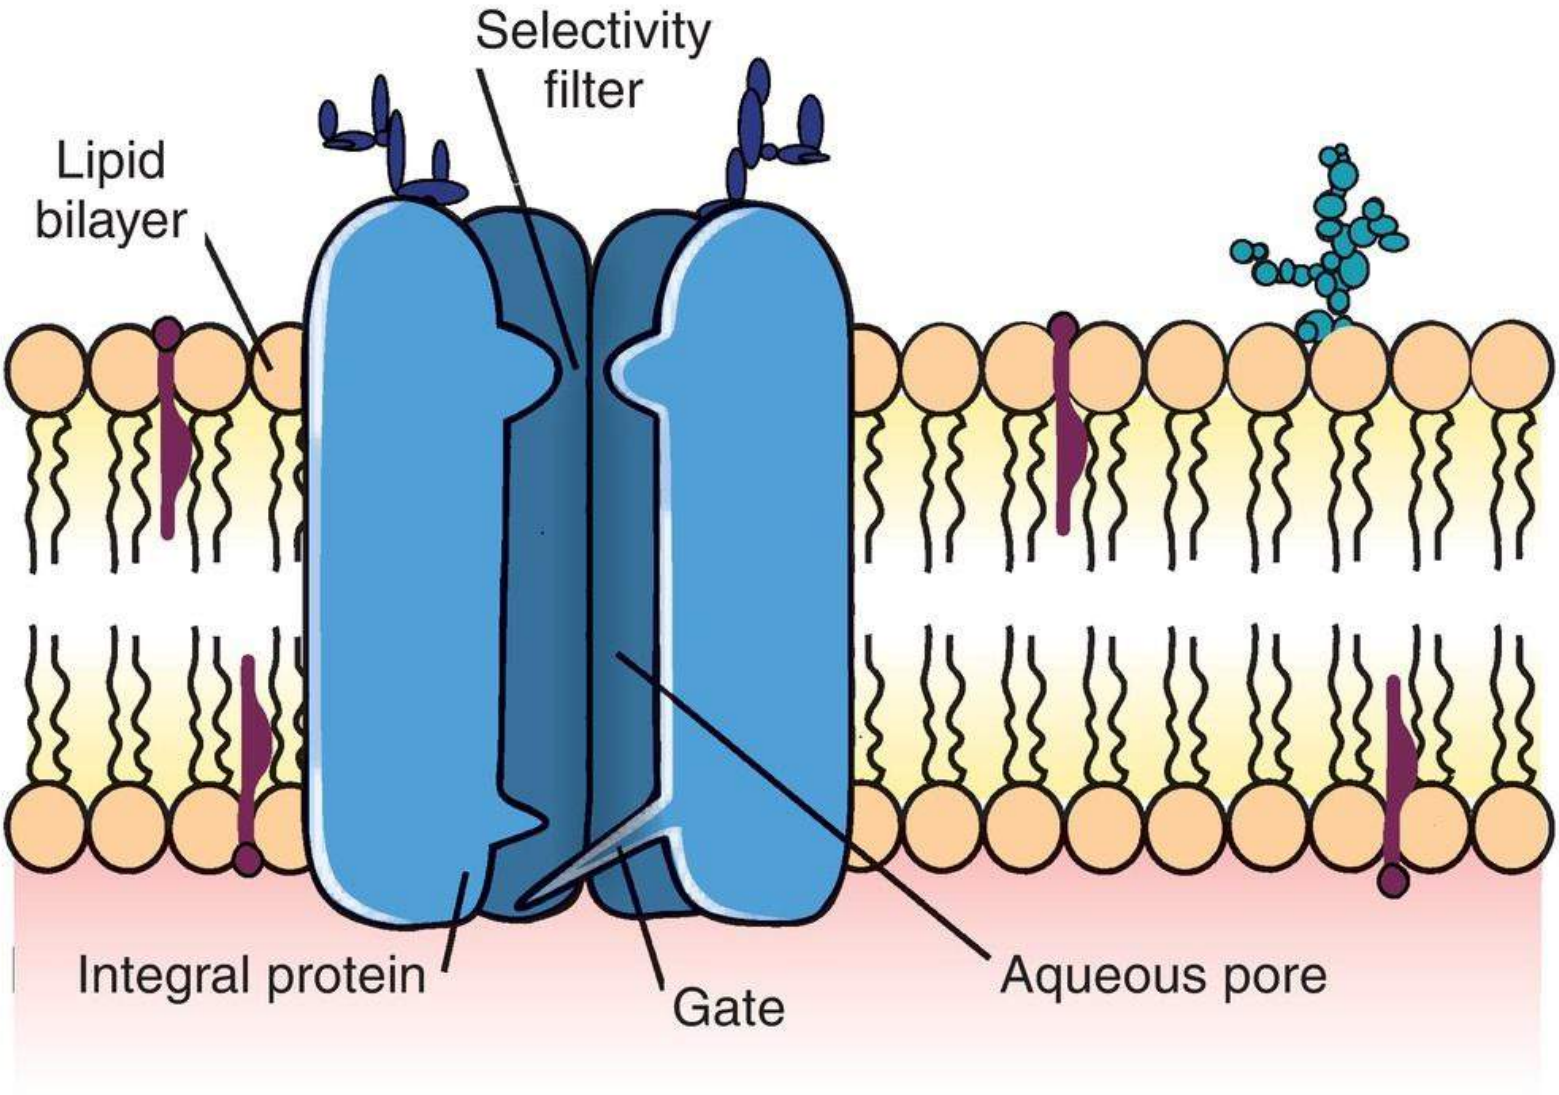

Figure 2.6 An ion channel. The polypeptide subunits of integral proteins that span the plasma membrane provide an aqueous pore through which ions can cross the membrane. Different types of gating mechanisms are used to open and close ion channels that are often selective for a specific ion.

In general, ion channels exist either fully open or completely closed, and they open and close very rapidly. The frequency with which a channel opens is variable, and the time the channel remains open (usually a few milliseconds) is also variable. The overall rate of ion transport across a membrane can be controlled by changing the frequency of a channel opening or by changing the time a channel remains open.

Most ion channels usually open in response to a specific stimulus. Ion channels can be classified

according to their gating mechanisms, the signals that make them open or close. There are voltage-gated channels and ligand-gated channels. Some ion channels are more like membrane pores in that they are always open; these ion transport proteins are referred to as *nongated channels*.

Voltage-gated ion channels open when the membrane potential changes beyond a certain threshold value. Channels of this type are involved in conducting the excitation signal along nerve axons and include sodium and potassium channels (see Chapter 3). Voltage-gated ion channels are found in many cell types. It is thought that some charged amino acids located in a membrane-spanning α-helical segment of the channel protein are sensitive to the transmembrane potential. Changes in the membrane potential cause these amino acids to move and induce a conformational change of the protein that opens the way for the ions.

Ligand-gated ion channels cannot open unless they first bind to a specific agonist. The opening of the gate is produced by a conformational change in the protein induced by the ligand binding. The ligand can be a neurotransmitter arriving from the extracellular medium. It can also be an intracellular second messenger, produced in response to some cell activity or hormone that reaches the ion channel from the inside of the cell. The nicotinic acetylcholine receptor channel found in the postsynaptic neuromuscular junction (see Chapters 3 and 8) is a ligand-gated ion channel that is opened by an extracellular ligand (acetylcholine). Examples of ion channels gated by intracellular messengers also abound in nature. This type of gating mechanism allows the channel to open or close in response to events that occur at other locations in the cell. For example, a sodium channel gated by intracellular cyclic guanosine monophosphate (cGMP) is located in the rod cells of the retina and opens in the presence of cGMP (see Chapter 4). The generalized structure of one subunit of an ion channel gated by cyclic nucleotides is shown in Figure 2.7. There are six membrane-spanning regions, and a cyclic nucleotide-binding site is exposed to the cytosol. The functional protein is a tetramer of four identical subunits. Other cell membranes have potassium channels that open when the intracellular concentration of calcium ions increases. Several known channels respond to inositol 1,4,5-trisphosphate, the activated part of G proteins, or adenosine triphosphate (ATP). The epithelial chloride channel that is mutated in cystic fibrosis is normally gated by ATP.

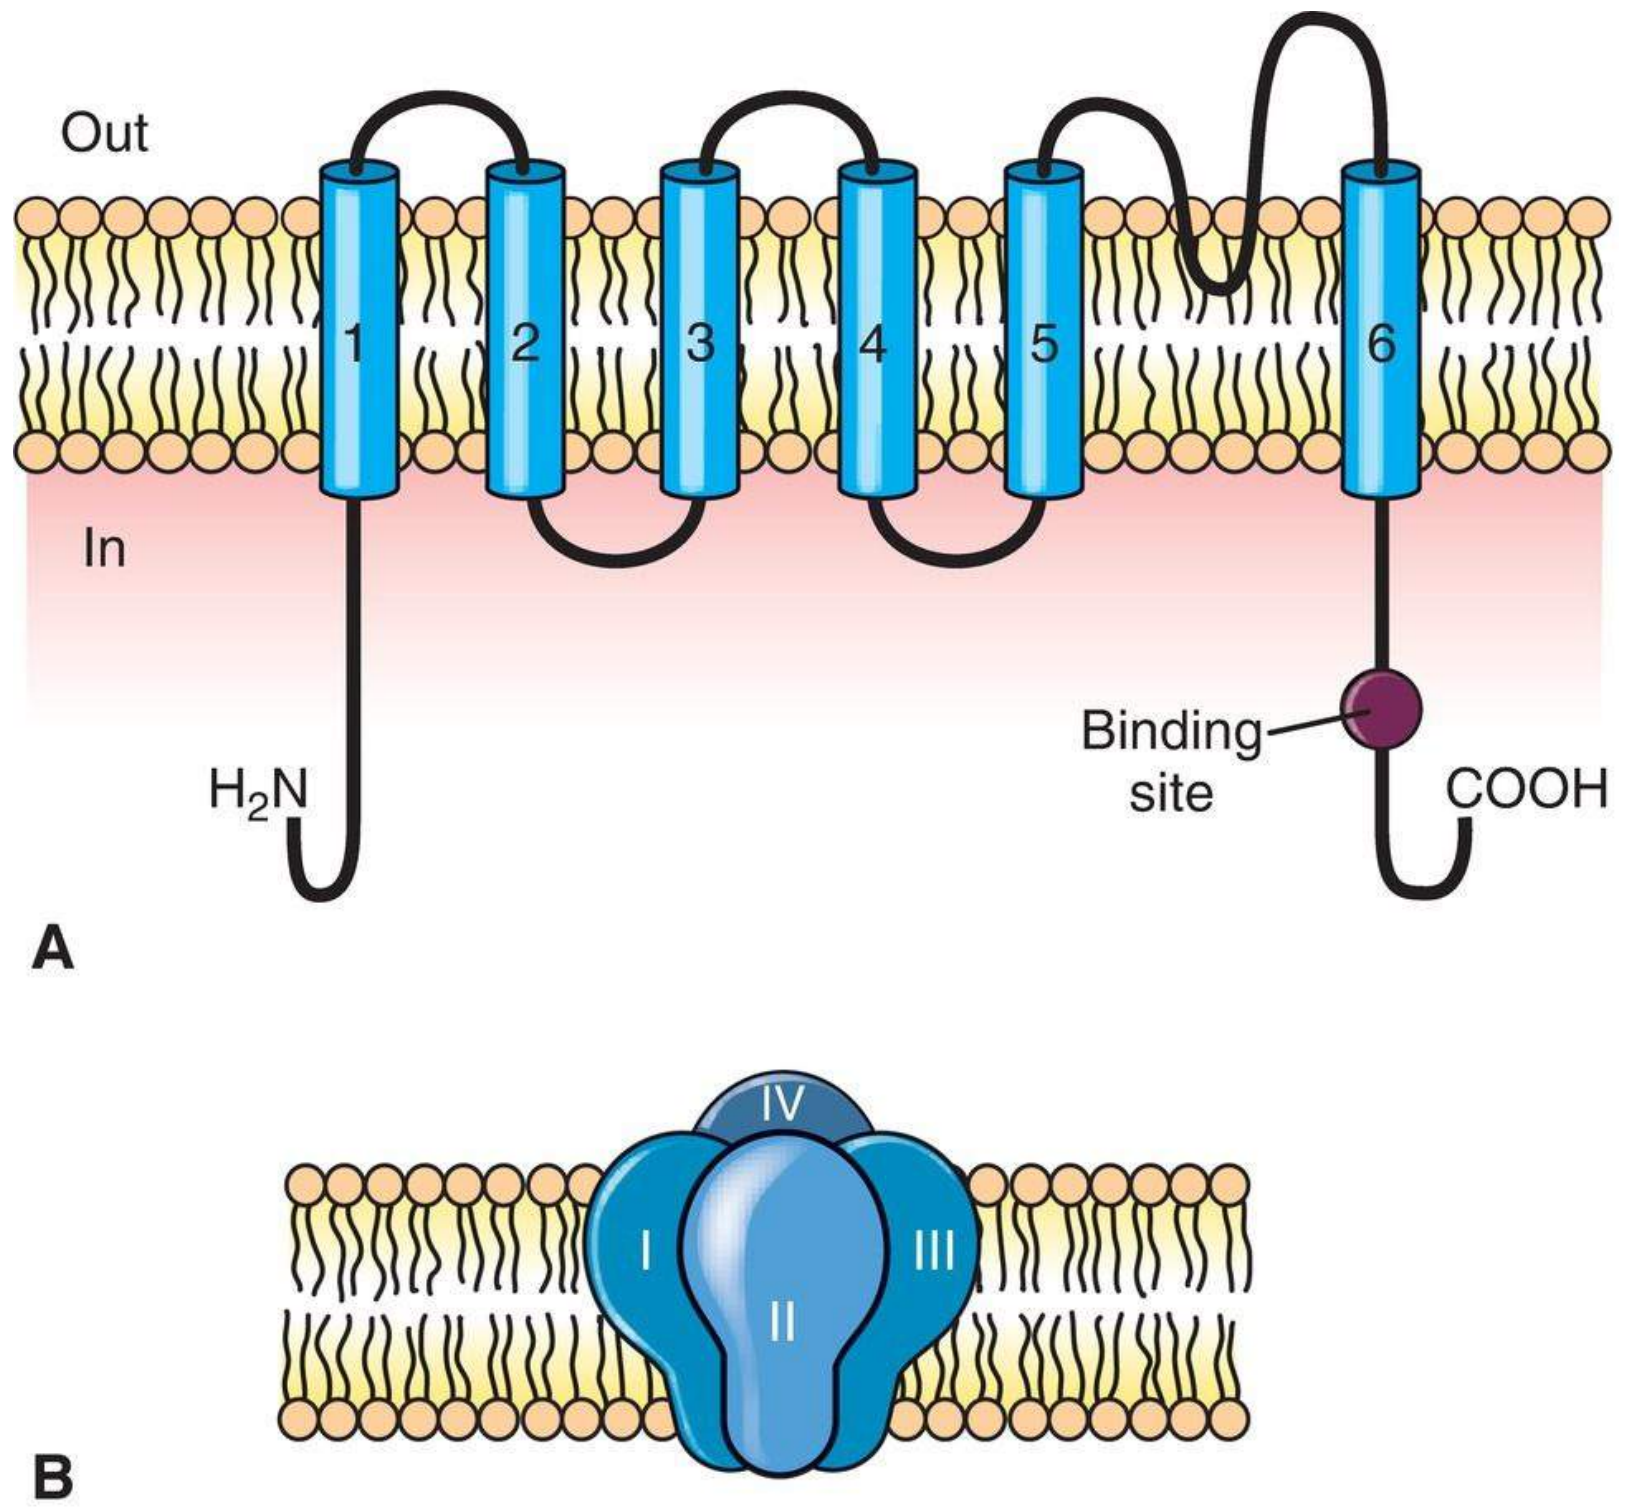

Figure 2.7 Structure of a cyclic nucleotide-gated ion channel. **(A)** The secondary structure of a single subunit has six membrane-spanning regions and a binding site for cyclic nucleotides on the cytosolic side of the membrane. **(B)** Four identical subunits (I–IV) assemble together to form a functional channel that provides a hydrophilic pathway across the plasma membrane.

Carrier-mediated transport moves a range of ions and organic solutes passively across membranes.

In contrast to pores and ion channels, integral membrane proteins that form carriers provide a conduit through the membrane that is never open to both sides of the membrane at the same time. This is due to the presence of two gates (Fig. 2.8). During carrier-mediated transport, binding of the solute to one side of the carrier induces a conformational change in the protein, which closes one gate and opens the second gate, allowing the solute to pass through the membrane. As with pores and channels, carriers function until the solute concentrations have equilibrated.

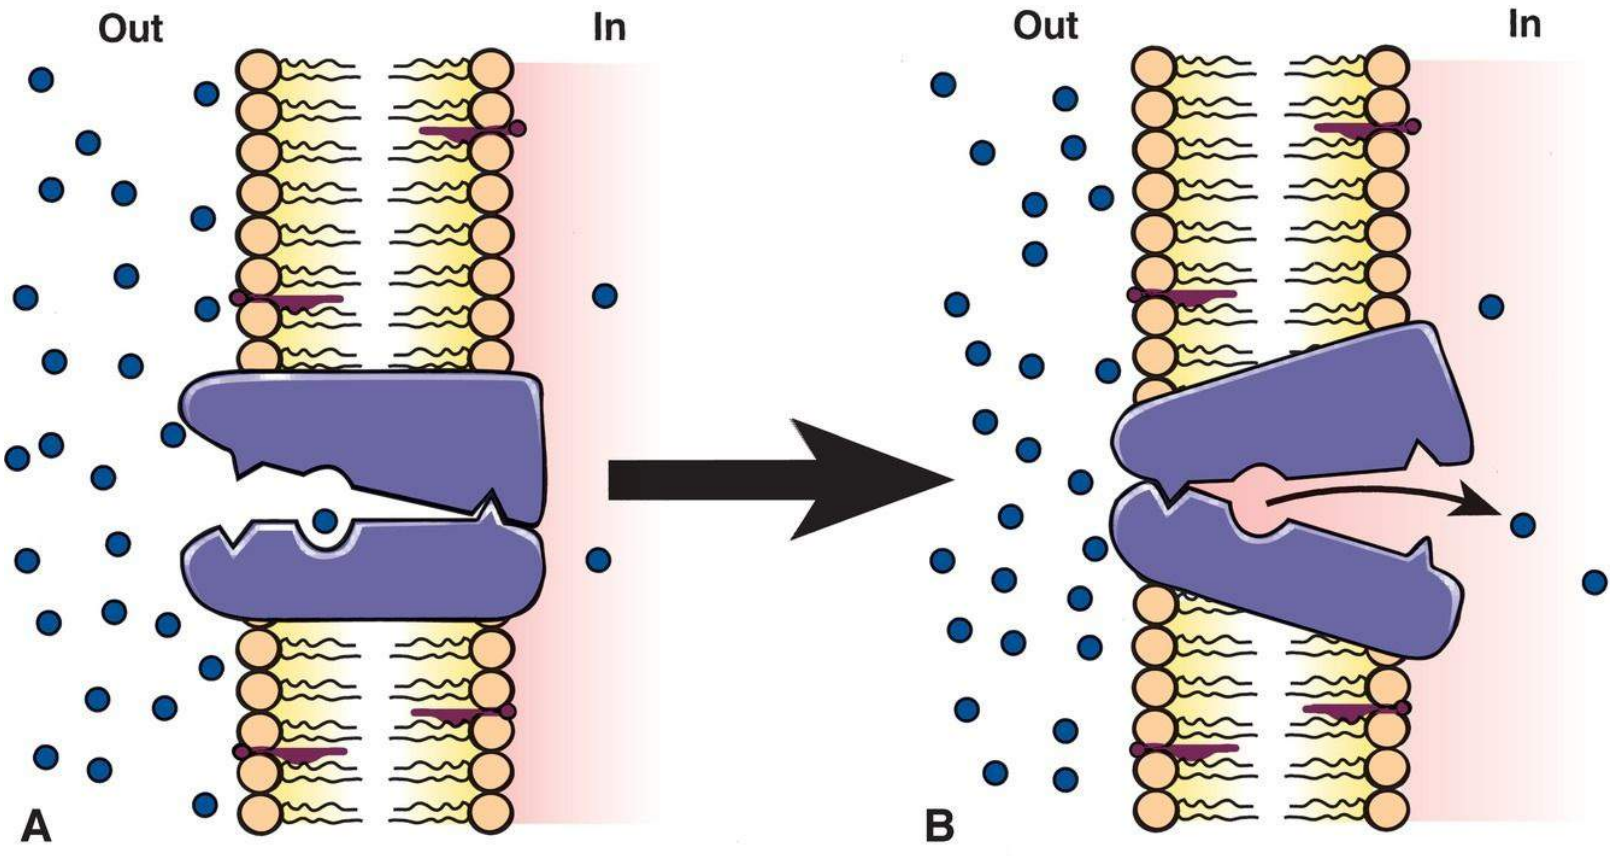

Figure 2.8 The role of a carrier protein in facilitated diffusion of solute molecules across a plasma membrane. In this example, solute transport into the cell is driven by the high solute concentration outside compared with inside. **(A)** Binding of extracellular solute to the membrane-spanning integral protein triggers a change in conformation that exposes the bound solute to the interior of the cell. **(B)** Bound solute readily dissociates from the carrier because of the low intracellular concentration of solute. The release of solute allows the carrier to revert to its original conformation **(A)** to begin the cycle again.

Carrier-mediated transport systems have several characteristics:

- They allow the transport of polar (hydrophilic) molecules at rates much higher than that expected from the partition coefficient of these molecules.
- They eventually reach saturation at high substrate concentration (see Fig. 2.5).
- They have structural specificity, meaning each carrier system recognizes and binds specific chemical structures (a carrier for D-glucose will not bind or transport L-glucose).

- They show competitive inhibition by molecules with similar chemical structure. For example, carrier-mediated transport of D-glucose occurs at a slower rate when molecules of D-galactose are also present. This is because galactose, structurally similar to glucose, competes with glucose for the available glucose carrier proteins.

A specific example of carrier-mediated transport is the movement of glucose from the blood to the interior of cells. Most mammalian cells use blood glucose as a major source of cellular energy, and glucose is transported into cells down its concentration gradient. The transport process in many cells, such as erythrocytes and the cells of fat, liver, and muscle tissues, involves a plasma membrane protein called *GLUT1* (glucose transporter-1). The erythrocyte GLUT1 has an affinity for D-glucose that is about 2,000-fold greater than the affinity for L-glucose. It is an integral membrane protein that contains 12 membrane-spanning α-helical segments.

Carrier-mediated transport, like simple diffusion, does not have a directional preference. It functions equally well bringing its specific solutes into or out of the cell, depending on the concentration gradient. Net movement by carrier-mediated transport ceases once the concentrations inside and outside the cell become equal.

The **anion exchange protein** (**AE1**), the predominant integral protein in the mammalian erythrocyte membrane, provides a good example of the reversibility of transporter action. AE1 is folded into at least 12 transmembrane a helices and normally permits the one-for-one exchange of Cl^- and HCO_3^- ions across the plasma membrane. The direction of ion movement is dependent only on the concentration gradients of the transported ions. AE1 has an important role in transporting CO_2 from the tissues to the lungs. The erythrocytes in systemic capillaries pick up CO_2 from tissues and convert it to HCO_3^-, which exits the cells via AE1. When the erythrocytes enter pulmonary capillaries, the AE1 allows plasma HCO_3^- to enter erythrocytes, where it is converted back to CO_2 for expiration by the lungs (see Chapter 21).

Active transport systems move solutes against gradients.

All the passive transport mechanisms tend to bring the cell into equilibrium with the ECF. Cells must oppose these equilibrating systems and preserve intracellular concentrations of solutes, in particular ions that are compatible with life.

Primary active transport

Integral membrane proteins that directly use metabolic energy to transport ions against a gradient of concentration or electrical potential are known as **ion pumps**. The direct use of metabolic energy to carry out transport defines a **primary active transport mechanism**. The source of metabolic energy is ATP synthesized by mitochondria, and the different ion pumps hydrolyze ATP to ADP using the energy stored in the third phosphate bond to carry out transport. Ion pumps also are called **ATPases**, because of the ability to hydrolyze ATP.

The most abundant ion pump in higher organisms is the sodium–potassium pump or **Na^+/K^+-ATPase**. It is found in the plasma membrane of practically every eukaryotic cell and is responsible for maintaining the low sodium and high potassium concentrations in the cytoplasm by transporting sodium out of the cell and potassium ions in. The sodium–potassium pump is an integral membrane protein consisting of two subunits. The α subunit has 10 transmembrane segments and is the catalytic subunit that mediates active transport. The smaller β subunit has one transmembrane segment and is essential for the proper assembly and membrane targeting of the pump. The Na^+/K^+-ATPase is known as a **P-type ATPase** because the protein is phosphorylated during the transport cycle (Fig. 2.9). The pump counterbalances the tendency of sodium ions to enter the cell passively and the tendency of potassium ions to leave passively. It maintains a high intracellular potassium concentration, which is necessary for protein synthesis. It also plays a role in the resting membrane potential by maintaining ion gradients. The sodium–potassium pump can be inhibited either by metabolic poisons that stop the synthesis and supply of ATP or by specific pump blockers, such as **digoxin**, a **cardiac glycoside** used to treat a variety of cardiac conditions.

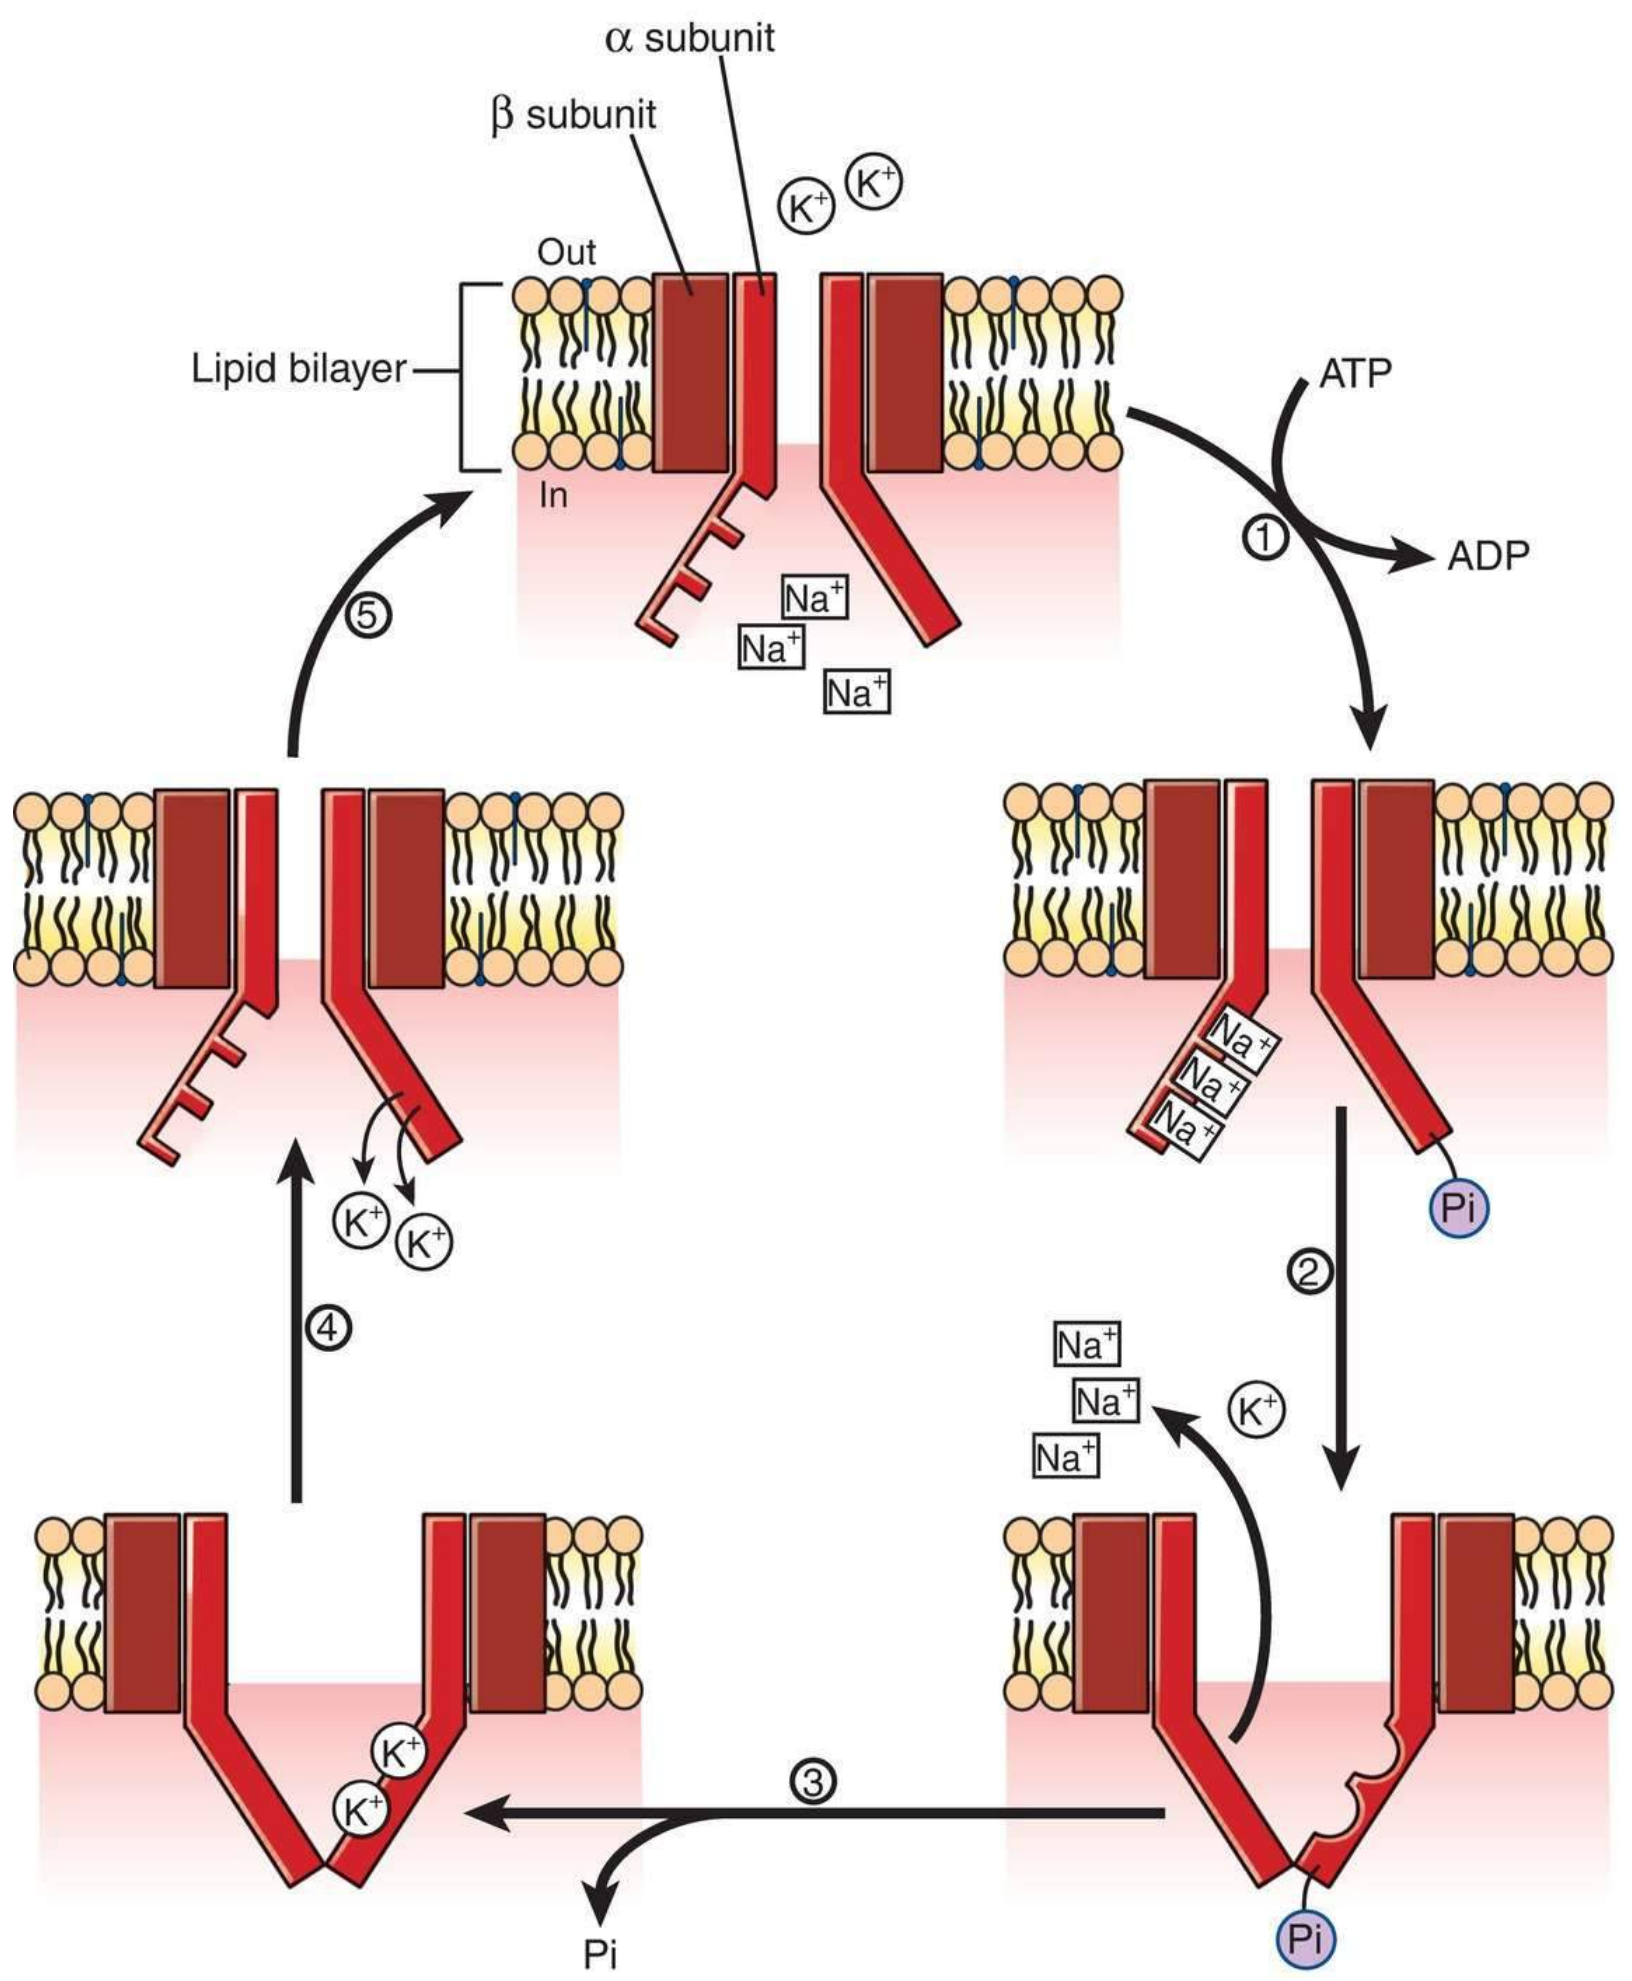

Figure 2.9 Function of the sodium–potassium pump. The pump is composed of two large α subunits that hydrolyze ATP and transport the ions. The two smaller β subunits are molecular chaperones that facilitate

the correct integration of the α subunits into the membrane. In step 1, three intracellular Na^+ bind to the α subunit, and ATP is hydrolyzed to ADP. Phosphorylation (Pi) of the α subunit results in a conformational change, exposing the Na^+ to the extracellular space (step 2). In step 3, the Na^+ diffuses away and two K^+ bind, resulting in dephosphorylation of the α subunit. Dephosphorylation returns the α subunit to an intracellular conformation. The K^+ diffuses away, and ATP is rebound to start the cycle over again (step 6).

As the Na^+/K^+-ATPase specifically moves sodium and potassium ions against their concentration or electrical potential, a number of other pumps move specific substrates across membranes utilizing the energy released by ATP hydrolysis.

- **Calcium pumps** are P-type ATPases located in the plasma membrane and the membrane of intracellular organelles. Plasma membrane Ca^{2+}-ATPases pump calcium out of the cell. Calcium pumps in the membrane of the endoplasmic reticulum and in the sarcoplasmic reticulum membrane within muscle cells (termed *SERCAs* for sarcoplasmic and endoplasmic reticulum calcium ATPases) pump calcium into the lumen of these organelles. The organelles store calcium and, as a result, help maintain a low cytosolic concentration of this ion.
- The **H^+/K^+-ATPase** is a P-type ATPase present in the luminal membrane of the parietal cells in the oxyntic (acid-secreting) glands of the stomach. By pumping protons into the lumen of the stomach in exchange for potassium ions, this pump maintains the low pH in the stomach that is necessary for proper digestion. It is also found in the colon and in the collecting ducts of the kidney. Its role in the kidney is to secrete H^+ ions into the urine, when blood pH falls, and to reabsorb K^+ ions (see Chapter 24).
- **Proton pumps** or **H^+-ATPases** are found in the membranes of the lysosomes and the Golgi apparatus. They pump protons from the cytosol into these organelles, keeping the inside of the organelles more acidic than the rest of the cell. These pumps are classified as **V-type ATPases** because they were first discovered in intracellular vacuolar structures, but are also present in plasma membranes. The secretion of protons by the V-type ATPase in **osteoclasts** helps to solubilize the bone mineral and creates an acidic environment for bone breakdown by enzymes. The proton pump in the kidney is present in the same cells as the H^+/K^+-ATPase and helps to secrete H^+ ions into the urine when blood pH falls.
- **ATP-binding cassette** (**ABC**) **transporters** are a super family of transporters composed of two transmembrane domains and two cytosolic nucleotide-binding domains. The transmembrane domains recognize specific solutes and transport them across the membrane using a number of different mechanisms, including conformational change. The nucleotide-binding domain, or ABC domain, has a highly conserved sequence. ABC transporters are involved in a number of cellular processes, including nutrient uptake, cholesterol and lipid trafficking, resistance to cytotoxic drugs and antibiotics, cellular immune response, and stem cell biology.
- **ABCA1**, a member of the ABC subfamily A, has an important role in effluxing cholesterol, phospholipids, and other metabolites out of cells. ABCA1 transfers lipids and cholesterol to lipid-poor **high-density lipoproteins** (**HDLs**). ABCA1 is a unique ABC transporter because it is also a receptor, binding the lipid-poor HDL to facilitate the loading of the cholesterol that the transporter is moving out of the cell.
- ABC subfamily C transporters play a crucial role in the development of **multidrug resistance** (**MDR**). There are a number of different transporters encoded by multiple MDR genes. The MDR1

transporter is widely distributed in the liver, brain, lung, kidney, pancreas, and small intestine and transports a wide range of antibiotics, antivirals, and chemotherapeutic drugs out of the cell. **MDR-associated protein transporters** are a related class of ABCC transporters that also interfere with antibiotic and chemotherapy. The cystic fibrosis transmembrane conductance regulator (ABCC7) is another member of this family.

- **Organic anion transporting polypeptides** (**OATPs**) are members of the solute carrier family and are highly expressed in the liver, kidney, and brain. OATPs transport anionic and cationic chemicals, steroid, and peptide backbones generally into cells. **Thyroxine**, **bile acids**, and **bilirubin** are important solutes transported by OATPs. These transporters also import agents such 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors (statins), angiotensin-converting enzyme inhibitors, angiotensin receptor II antagonists, and cardiac glycosides into cells.
- **F-type ATPases** are located in the inner mitochondrial membrane. This type of proton pump normally functions in reverse. Instead of using the energy stored in ATP molecules to pump protons, its principal function is to synthesize ATP by using the energy stored in a gradient of protons that is crossing the inner mitochondrial membrane down its concentration gradient. The proton gradient is generated by the respiratory chain.

Secondary active transport

The net effect of ion pumps is maintenance of the various environments needed for the proper functioning of organelles, cells, and organs. Metabolic energy is expended by the pumps to create and maintain the differences in ion concentrations. Besides the importance of local ion concentrations for cell function, differences in concentrations represent stored energy. An ion releases potential energy when it moves down an electrochemical gradient, and this energy can be used to perform work. Cells have developed several carrier mechanisms to transport one solute against its concentration gradient by using the energy stored in the favorable gradient of another solute. In mammals, most of these mechanisms use sodium as the driver solute and use the energy of the sodium gradient to carry out the “uphill” transport of another important solute (Fig. 2.10). Because the sodium gradient is maintained by the action of the Na^+/K^+-ATPase, the function of these transport systems depends on the function of the Na^+/K^+-ATPase. Thus, they are called **secondary active transport mechanisms** because they depend on the supply of energy to the sodium–potassium pump. Disabling the pump with metabolic inhibitors or pharmacologic blockers causes these transport systems to stop when the sodium gradient has been dissipated.

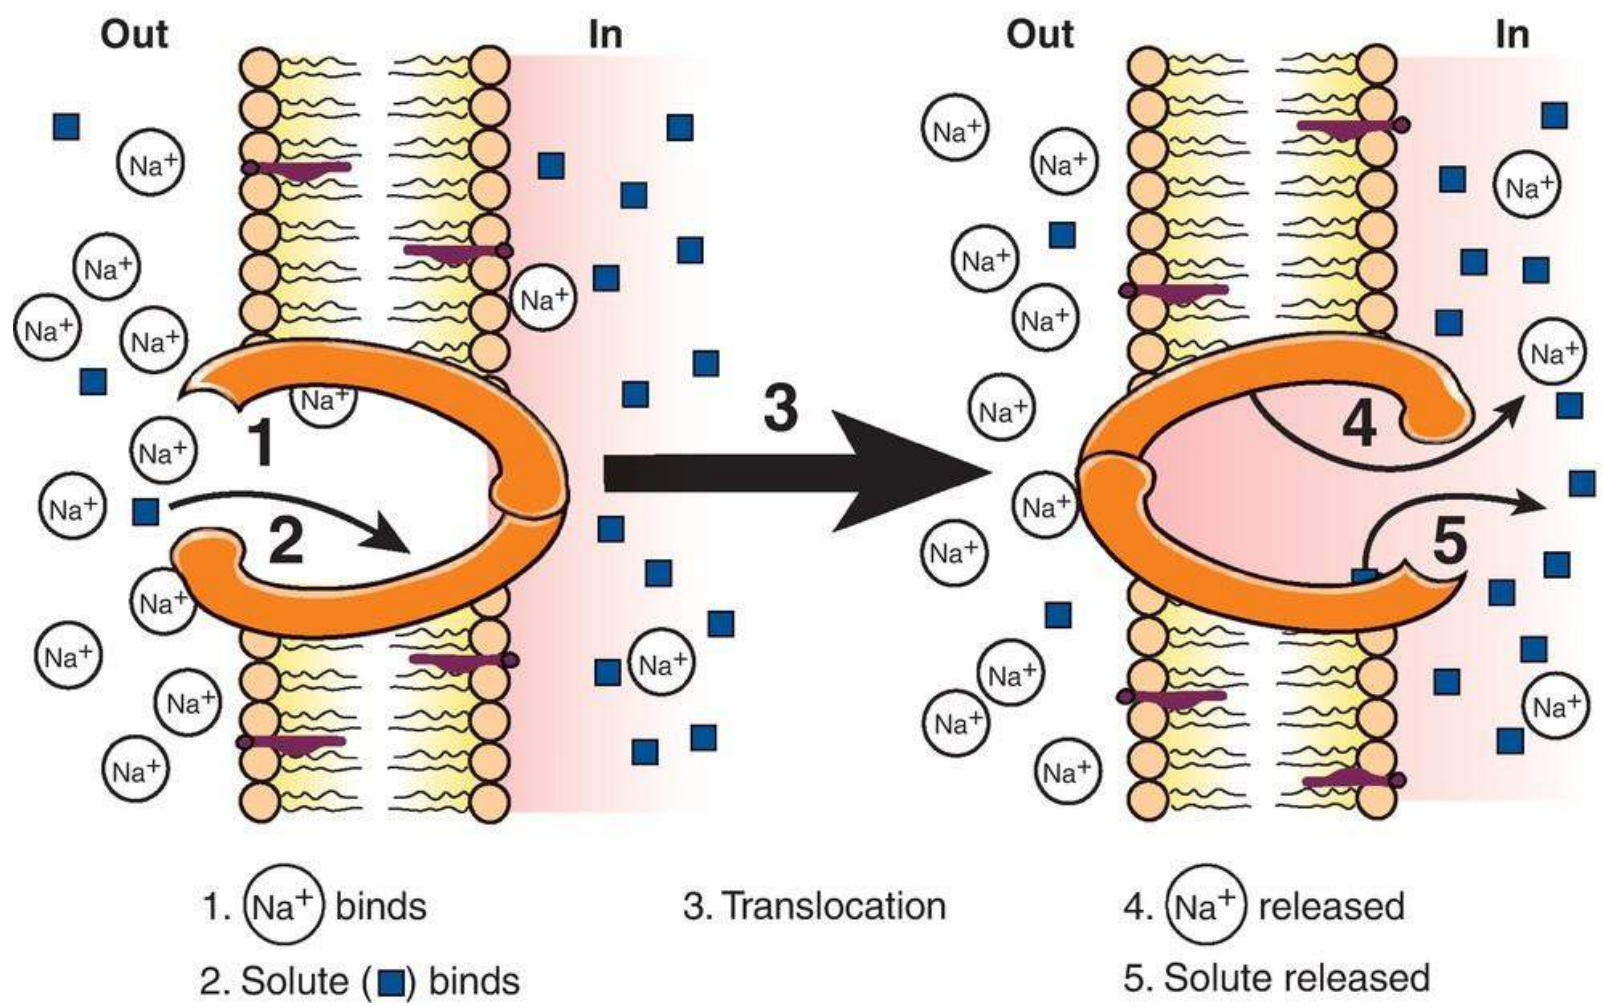

Figure 2.10 Mechanism of secondary active transport. A solute is moved against its concentration gradient by coupling it to Na^+ moving down a favorable gradient. Binding of extracellular Na^+ to the carrier protein (step 1) may increase the affinity of binding sites for solute, so that solute also can bind to the carrier (step 2), even though its extracellular concentration is low. A conformational change in the carrier protein (step 3) exposes the binding sites to the cytosol, where Na^+ readily dissociates because of the low intracellular Na^+ concentration (step 4). The release of Na^+ decreases the affinity of the carrier for solute and forces the release of the solute inside the cell (step 5), where solute concentration is already high. The free carrier then reverts to the conformation required for step 1, and the cycle begins again.

Similar to passive carrier-mediated systems, secondary active transport systems are integral membrane proteins; they have specificity for the solute they transport and show saturation kinetics and competitive inhibition. They differ, however, in two respects. First, they cannot function in the absence of the driver ion, the ion that moves along its electrochemical gradient and supplies energy. Second, they transport the solute against its own concentration or electrochemical gradient. Functionally, the different secondary active transport systems can be classified into two groups: **symport** (cotransport) systems, in which the solute being transported moves in the same direction as the sodium ion, and **antiport** (exchange) systems, in which the sodium ion and the solute move in opposite directions.

Examples of symport mechanisms are the sodium-coupled sugar transport system and the several sodium-coupled amino acid transport systems found in the small intestine and the renal tubule. The symport systems allow efficient absorption of nutrients even when the nutrients are present at low concentrations. The sodium-dependent glucose transporter-1 (SGLT1) in the human intestine contains 664 amino acids in a single polypeptide chain with 14 membrane-spanning segments (Fig. 2.11). One

complete cycle or turnover of a single SGLT1 protein, illustrated in Figure 2.10, can occur 1,000 times/s at 37°C. In reality, this cycle probably involves a coordinated trapping–release cycle and/or tilt of membrane-spanning segments rather than the simplistic view presented in Figure 2.10. Another example of a symport system is the family of sodium-coupled phosphate transporters (termed *NaPi*, types I and II) in the intestine and renal proximal tubule. These transporters have six to eight membrane-spanning segments and contain 460 to 690 amino acids. Sodium-coupled chloride transporters in the kidney are targets for inhibition by specific diuretics. The Na^+–Cl^- cotransporter in the distal tubule, known as *NCC*, is inhibited by thiazide diuretics, and the Na^+–K^+–$2Cl^-$ cotransporter in the ascending limb of the loop of Henle, referred to as *NKCC*, is inhibited by bumetanide.

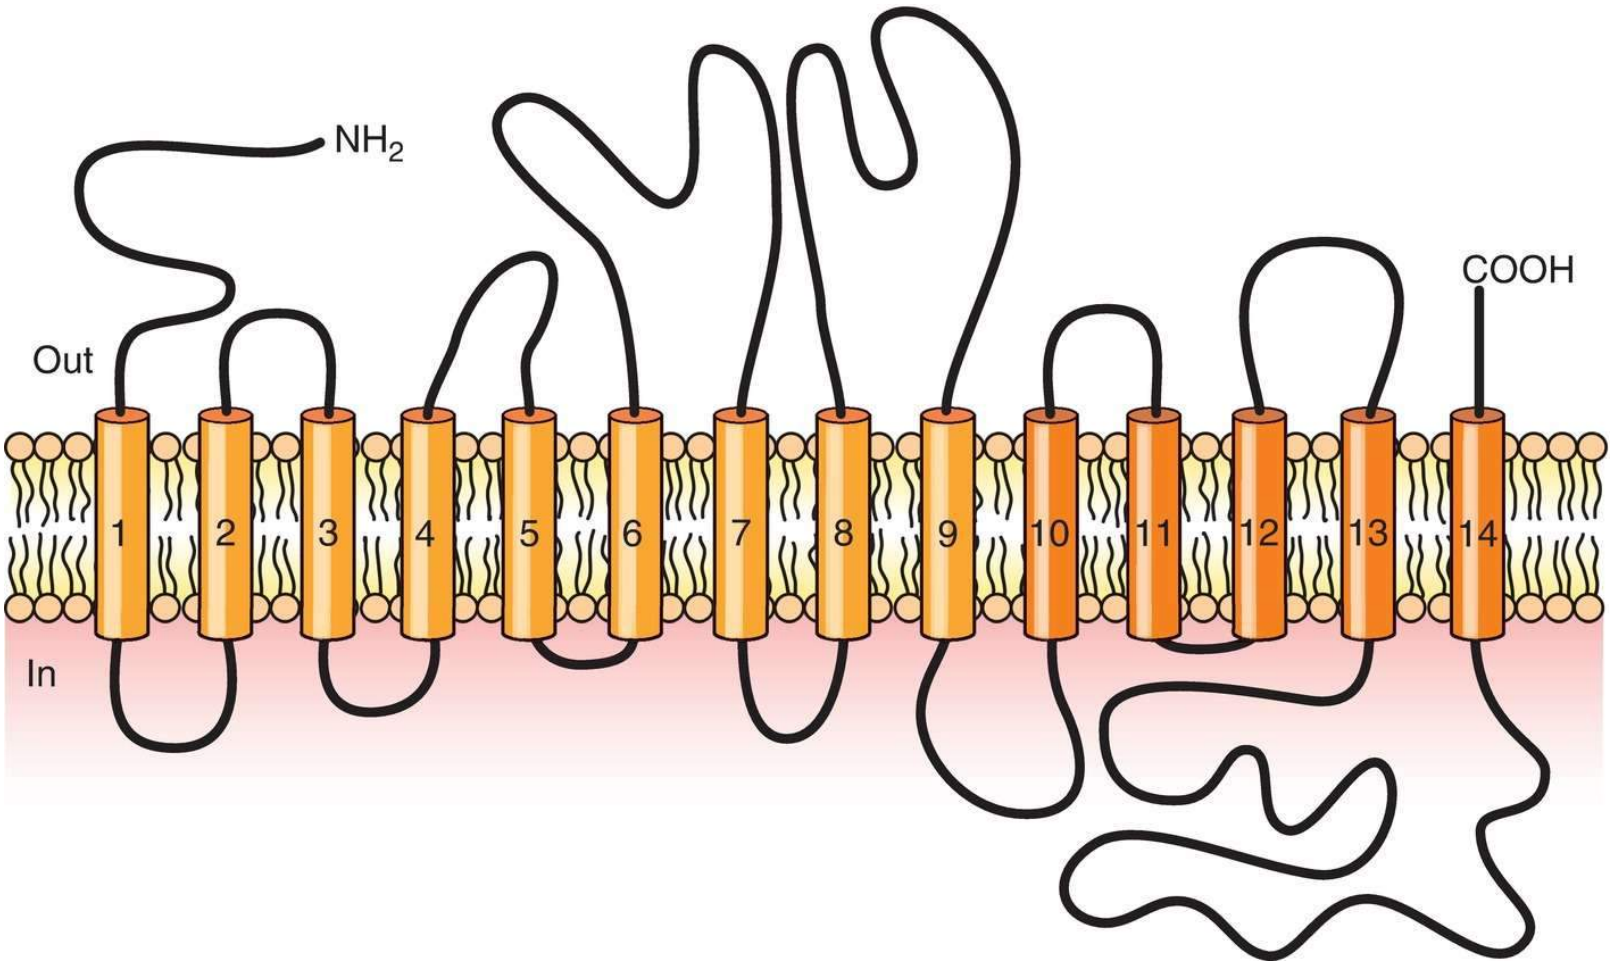

Figure 2.11 A model of the secondary structure of the Na^+–glucose cotransporter protein (SGLT1) in the human intestine. The polypeptide chain of 664 amino acids passes back and forth across the membrane 14 times. Each membrane-spanning segment consists of 21 amino acids arranged in an α-helical conformation. Both the NH_2 and the COOH ends are located on the extracellular side of the plasma membrane. In the functional protein, the membrane-spanning segments are clustered together to provide a hydrophilic pathway across the plasma membrane. The N-terminal portion of the protein, including helices 1 to 9, is required to couple Na^+ binding to glucose transport. The five helices (10–14) at the C terminus form the transport pathway for glucose.

The most important examples of antiporters are the Na^+/H^+ exchange and Na^+/Ca^{2+} exchange systems, found mainly in the plasma membrane of many cells. The first uses the sodium gradient to remove protons from the cell, controlling the intracellular pH and counterbalancing the production of protons in metabolic reactions. It is an **electroneutral system** because there is no net movement of charge. One Na^+ enters the

cell for each H^+ that leaves. The second antiporter removes calcium from the cell and, together with the different calcium pumps, helps maintain a low cytosolic calcium concentration. It is an **electrogenic system** because there is a net movement of charge with three Na^+ entering the cell and one Ca^{2+} ion leaving in each cycle (Clinical Focus 2.1).

The structures of the symport and antiport protein transporters that have been characterized (see Fig. 2.11) share a common property with ion channels (see Fig. 2.8) and equilibrating carriers, namely, the presence of multiple membrane-spanning segments within the polypeptide chain. This supports the concept that, regardless of the mechanism, the membrane-spanning regions of a transport protein form a hydrophilic pathway for rapid transport of ions and solutes across the hydrophobic interior of the membrane lipid bilayer.

CLINICAL FOCUS 2.1

Hexose Malabsorption in the Intestine

Malabsorption of hexoses in the intestine can be the indirect result of a number of circumstances, such as an increase in intestinal motility or defects in digestion because of pancreatic insufficiency. Although less common, malabsorption may be a direct result of a specific defect in hexose transport. Regardless of the cause, the symptoms are common and include diarrhea, abdominal pain, and gas. The challenge is to identify the cause so proper treatment can be applied. Some infants develop a copious watery diarrhea when fed milk that contains glucose or galactose or the disaccharides lactose and sucrose. The latter are degraded to glucose, galactose, and fructose by enzymes in the intestine. The dehydration can begin during the first day of life and can lead to rapid death if not corrected. Fortunately, the symptoms disappear when a carbohydrate-free formula fortified with fructose is used instead of milk. This condition is a rare inherited disease known as **glucose–galactose malabsorption** (**GGM**), and about 200 severe cases have been reported worldwide. At least 10% of the general population has glucose or lactose intolerance, however, and it is possible that these people may have milder forms of the disease. A specific defect in absorption of glucose and galactose can be demonstrated by tolerance tests in which oral administration of these monosaccharides produces little or no increase in plasma glucose or galactose. The primary defect lies in the Na^+–glucose cotransporter protein (SGLT, Fig. 2.11), located in the apical plasma membrane of intestinal epithelial cells (Fig. 2.12). Glucose and galactose have very similar structures, and both are substrates for transport by SGLT. Fructose transport is not affected by a defect in SGLT because a specific fructose transporter named **GLUT5** is present in the apical membrane. Human SGLT was cloned in 1989, and almost 30 different mutations have been identified in GGM patients. Many of the mutations produce premature cessation of SGLT protein synthesis or disrupt the trafficking of mature SGLT to the apical plasma membrane. In a few cases, the SGLT reaches the apical membrane but is no longer capable of glucose transport. The result in all cases is that functional SGLT proteins are not present in the apical membrane so glucose and galactose remain in the lumen of the intestine. As these solutes accumulate in the lumen, the osmolality of the fluids increases and retards absorption of water, leading to diarrhea and severe water loss from the body. Identification of specific changes in defective SGLT proteins in patients has provided clues about the specific amino acids that are essential for the normal function of SGLT. At the same time, advances in molecular biology have

allowed a better understanding of the genetic defect at the cellular level and how this leads to the clinical symptoms. GGM is an example of how information from a disease can further understanding of physiology and vice versa. ■

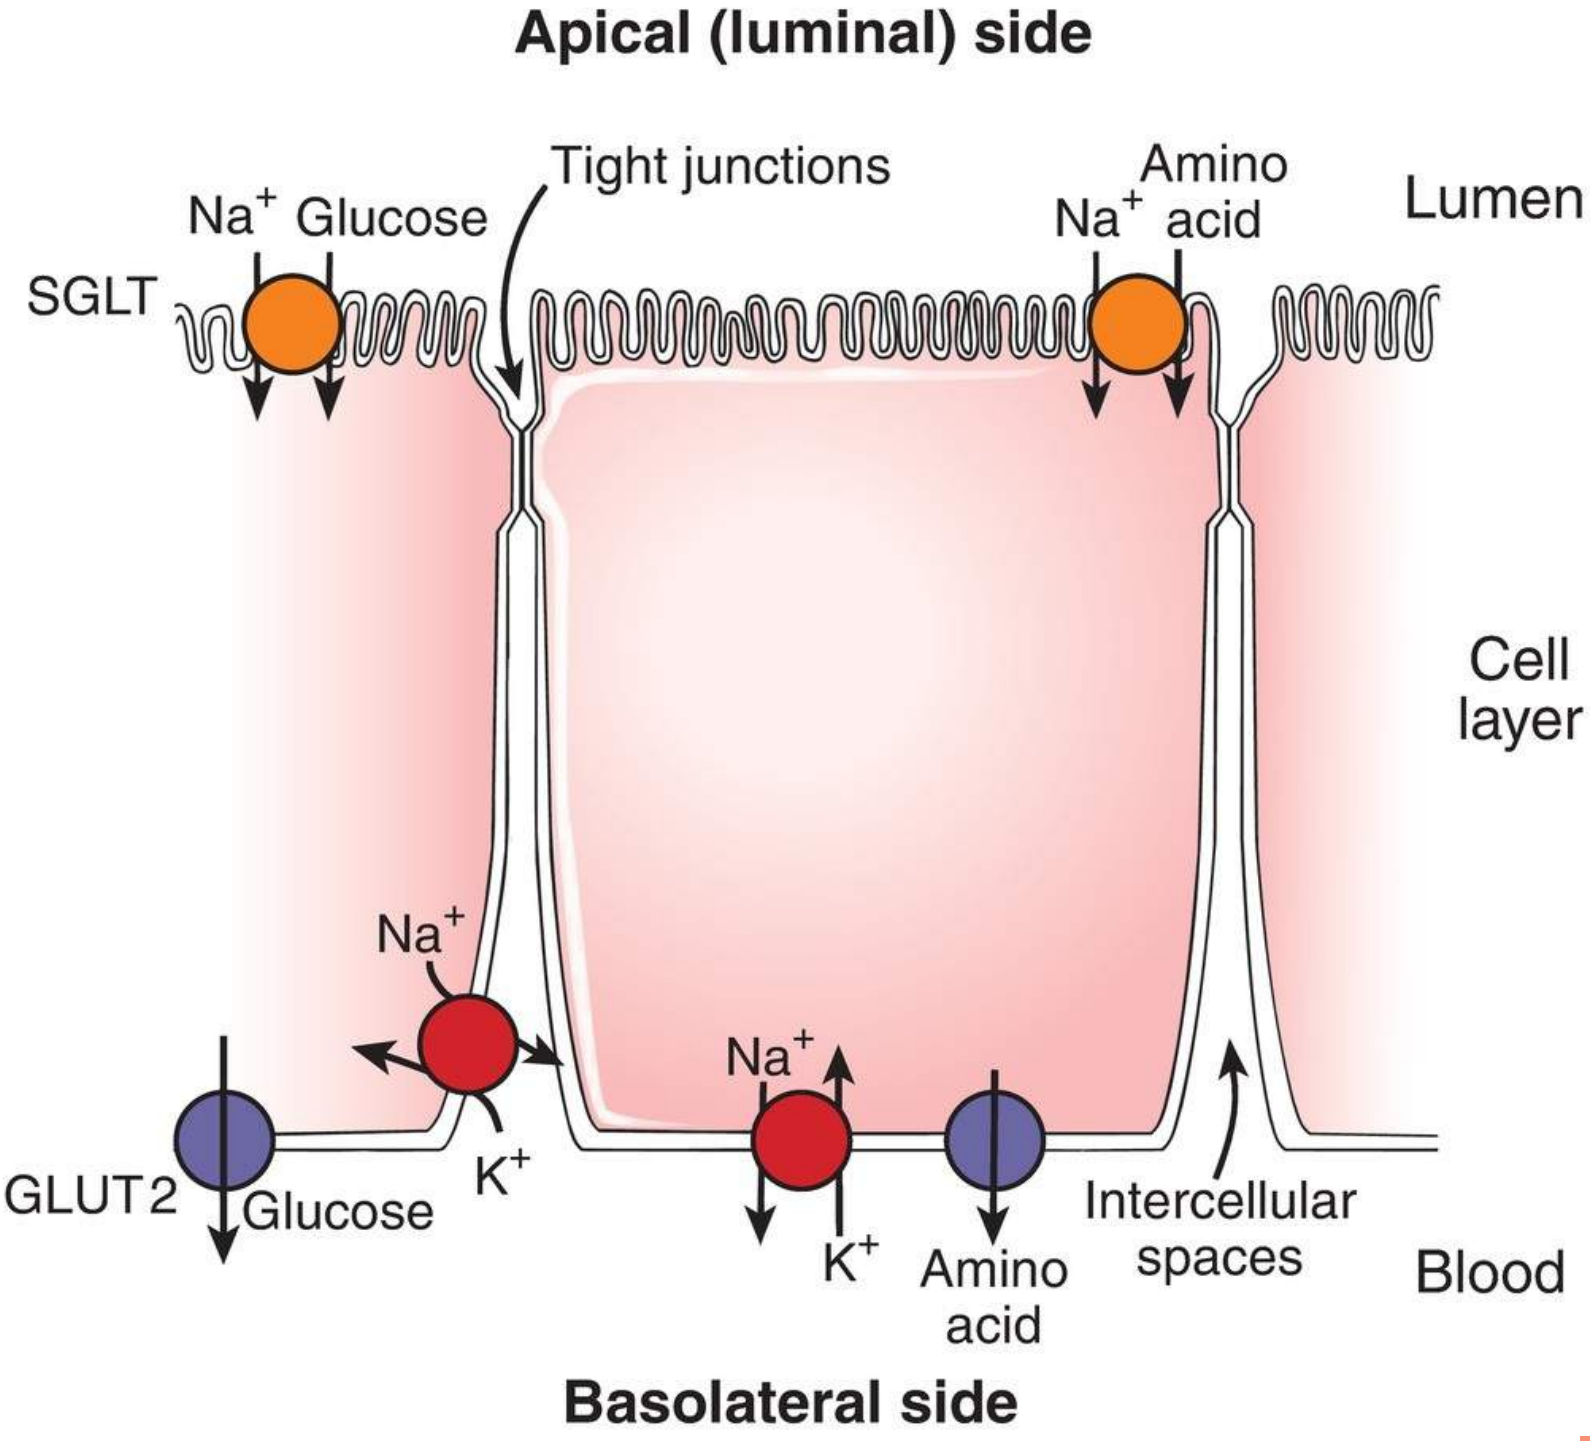

Figure 2.12 The localization of transport systems to different regions of the plasma membrane in epithelial cells of the small intestine. In a polarized cell, the entry and exit of solutes such as glucose, amino acids, and Na^+ occur at opposite sides of the cell. Active entry of glucose and amino acids is restricted to the apical membrane, and exit requires equilibrating carriers located only in the basolateral membrane. For example, glucose enters on sodium-dependent glucose transporter (SGLT) and exits on glucose transporter-2 (GLUT2). Na^+ that enters via the apical symporters is pumped out by the Na^+/K^+-ATPase on the basolateral membrane. The result is a net movement of solutes from the luminal side of the cell to the basolateral side, ensuring efficient absorption of glucose, amino acids, and Na^+ from the intestinal lumen.

Transcellular transport

Epithelial cells occur in layers or sheets that allow the directional movement of solutes not only across the plasma membrane but also from one side of the cell layer to the other. Such regulated movement is achieved because the plasma membranes of epithelial cells have two distinct regions with different morphologies and different transport systems. These regions are the **apical membrane**, facing the lumen, and the **basolateral membrane**, facing the blood supply (Fig. 2.12). The specialized or polarized organization of the cells is maintained by the presence of **tight junctions** at the areas of contact between adjacent cells. Tight junctions prevent proteins on the apical membrane from migrating to the basolateral membrane and those on the basolateral membrane from migrating to the apical membrane. Thus, the entry and exit steps for solutes can be localized to opposite sides of the cell. This is the key to **transcellular transport** across epithelial cells.

An example is the absorption of glucose in the small intestine. Glucose enters the intestinal epithelial cells by active transport using the electrogenic Na^+–glucose cotransporter system (SGLT) in the apical membrane. This increases the intracellular glucose concentration above the blood glucose concentration, and the glucose molecules move passively out of the cell and into the blood via an equilibrating carrier mechanism (GLUT2) in the basolateral membrane (see Fig. 2.12). The intestinal GLUT2, like the erythrocyte GLUT1, is a sodium-independent transporter that moves glucose down its concentration gradient. Unlike GLUT1, the GLUT2 transporter can accept other sugars such as galactose and fructose that are also absorbed in the intestine. The Na^+/K^+-ATPase that is located in the basolateral membrane pumps out the sodium ions that enter the cell with the glucose molecules on SGLT. The polarized organization of the epithelial cells and the integrated functions of the plasma membrane transporters form the basis by which cells accomplish transcellular movement of both glucose and sodium ions.

WATER MOVEMENT ACROSS THE PLASMA MEMBRANE

Water can move rapidly in and out of cells, but the partition coefficient of water into lipids is low; therefore, the permeability of the membrane lipid bilayer for water is also low. Specific membrane proteins that function as water channels explain the rapid movement of water across the plasma membrane. These water channels are small (30 kDa), integral membrane proteins known as **aquaporins**. Of the thirteen known mammalian aquaporins, eight are expressed in the kidney, where water movement across the plasma membrane is particularly rapid.

In the kidney, aquaporin-2 (AQP2) is abundant in the collecting duct and is the target of the hormone **arginine vasopressin**, also known as *antidiuretic hormone*. This hormone increases water transport in the collecting duct in part by stimulating the recruitment of AQP2 proteins into the apical plasma membrane. AQP2 has a critical role in inherited and acquired disorders of water reabsorption by the kidney (see Chapter 22).

Water movement across the plasma membrane is driven by differences in osmotic pressure.

The spontaneous movement of water across a membrane driven by a gradient of water concentration is the process known as **osmosis**. The water moves from an area of high concentration of water to an area of low concentration. Concentration is defined by the number of particles per unit of volume; thus, a solution with a high concentration of solutes has a low concentration of water, and vice versa. Osmosis can be viewed as the movement of water from a solution of high water concentration (low concentration of solute) toward a solution with a lower concentration of water (high solute concentration). Osmosis is a passive transport mechanism that tends to equalize the total solute concentrations of the solutions on both sides of every membrane.

If a cell that is in osmotic equilibrium is transferred to a more dilute solution, water will enter the cell, the cell volume will increase, and the solute concentration of the cytoplasm will be reduced. If the cell is transferred to a more concentrated solution, water will leave the cell, the cell volume will decrease, and the solute concentration of the cytoplasm will increase.

The driving force for the movement of water across the plasma membrane is the difference in water concentration between the two sides of the membrane. For historical reasons, this driving force is not called the chemical gradient of water but the difference in osmotic pressure. The **osmotic pressure** of a solution is defined as the pressure necessary to stop the net movement of water across a selectively permeable membrane that separates the solution from pure water. When a membrane separates two solutions of different osmotic pressure, water will move from the solution with low osmotic pressure (high water and low solute concentrations) to the solution of high osmotic pressure (low water and high solute concentrations). In this context, the term *selectively permeable* means that the membrane is permeable to water but not solutes. In reality, most biologic membranes contain membrane transport proteins that permit solute movement.

The osmotic pressure of a solution depends on the *number* of particles dissolved in it, the total concentration of all solutes, regardless of the type of solutes present. Many solutes, such as salts, acids, and bases, dissociate in water, so the number of particles is greater than the molar concentration. For example, NaCl dissociates in water to give Na^+ and Cl^-, so one molecule of NaCl will produce two osmotically active particles. In the case of $CaCl_2$, there are three particles per molecule. The equation giving the osmotic pressure of a solution is

$$\pi = nRTC \qquad (3)$$

where π is the osmotic pressure of the solution, n is the number of particles produced by the dissociation of one molecule of solute (2 for NaCl, 3 for $CaCl_2$), R is the universal gas constant (0.0821 L·atm/mol·K), T is the absolute temperature, and C is the concentration of the solute in mol/L. Osmotic pressure can be expressed in atmospheres (atm). Solutions with the same osmotic pressure are called **isosmotic**. A solution is **hyperosmotic** with respect to another solution if it has a higher osmotic pressure and **hyposmotic** if it has a lower osmotic pressure.

Equation 3, called the *van't Hoff equation*, is valid only when applied to very dilute solutions, in

which the particles of solutes are so far away from each other that no interactions occur between them. Generally, this is not the case at physiologic concentrations. Interactions between dissolved particles, mainly between ions, cause the solution to behave as if the concentration of particles is less than the theoretical value (nC). A correction coefficient, called the *osmotic coefficient* (Φ) of the solute, needs to be introduced in the equation. Therefore, the osmotic pressure of a solution can be written more accurately as

$$\pi = nRT\Phi C \quad (4)$$

The osmotic coefficient varies with the specific solute and its concentration. It has values between 0 and 1. For example, the osmotic coefficient of NaCl is 1.00 in an infinitely dilute solution but changes to 0.93 at the physiologic concentration of 0.15 mol/L.

At any given T, because R is constant, equation 4 shows that the osmotic pressure of a solution is directly proportional to the term nΦC. This term is known as the **osmolality** or *osmotic concentration* of a solution and is expressed in Osm/kg H_2O. Most physiologic solutions such as blood plasma contain many different solutes, and each contributes to the total osmolality of the solution. The osmolality of a solution containing a complex mixture of solutes is usually measured by freezing point depression. The freezing point of an aqueous solution of solutes is lower than that of pure water and depends on the total number of solute particles. Compared with pure water, which freezes at 0°C, a solution with an osmolality of 1 Osm/kg H_2O will freeze at −1.86°C. The ease with which osmolality can be measured has led to the wide use of this parameter for comparing the osmotic pressure of different solutions. The osmotic pressures of physiologic solutions are not trivial. Consider blood plasma, for example, which usually has an osmolality of 0.28 Osm/kg H_2O, determined by freezing point depression. Equation 4 shows that the osmotic pressure of plasma at 37°C is 7.1 atm, about seven times greater than the atmospheric pressure.

Many cells can regulate their volume.

Cell volume changes can occur in response to changes in the osmolality of ECF in both normal and pathophysiologic situations. Accumulation of solutes can also produce volume changes by increasing the intracellular osmolality. Many cells can correct these volume changes. Volume regulation is particularly important in the brain where cell swelling can have serious consequences because expansion is strictly limited by the rigid skull.

Tonicity

A solution's osmolality is determined by the total concentration of all the solutes present. In contrast, the solution's **tonicity** is determined by the concentrations of only those solutes that do not enter ("penetrate") the cell. Tonicity determines cell volume, as illustrated in the following examples. Na^+ behaves as a nonpenetrating solute because it is pumped out of cells by the Na^+/K^+-ATPase at the same rate that it enters. A solution of NaCl at 0.2 Osm/kg H_2O is hypo-osmotic compared with cell cytosol at 0.3 Osm/kg H_2O. The NaCl solution is also **hypotonic** because cells will accumulate water and swell when placed in this solution. A solution containing a mixture of NaCl (0.3 Osm/kg H_2O) and urea (0.1 Osm/kg H_2O) has a total osmolality of 0.4 Osm/kg H_2O and will be hyperosmotic compared with cell cytosol. The solution is **isotonic**, however, because it produces no permanent change in cell volume. The reason is that cells shrink initially as a result of loss of water, but urea is a penetrating solute that rapidly enters the cells. Urea entry increases the intracellular osmolality, so water also enters and increases the volume. Entry of water ceases when the urea concentration is the same inside and outside the cells. At this point, the total osmolality both inside and outside the cells will be 0.4 Osm/kg H_2O and the cell volume will be restored to normal. By extension, it can be seen that normal blood plasma is an isotonic solution because Na^+ is the predominant plasma solute and is nonpenetrating. This stabilizes cell volume while other plasma solutes (glucose, amino acids, phosphate, urea, etc.) enter and leave the cells as needed.

Volume regulation mechanisms

When cell volume increases because of extracellular hypotonicity, the response of many cells is rapid activation of transport mechanisms that tend to decrease the cell volume. Different cells use different **regulatory volume decrease** (**RVD**) **mechanisms** to move solutes out of the cell and decrease the number of particles in the cytosol, causing water to leave the cell. Because cells have high intracellular concentrations of potassium, many RVD mechanisms involve an increased efflux of K^+, either by stimulating the opening of potassium channels or by activating symport mechanisms for KCl. Other cells activate the efflux of amino acids, such as taurine or proline. The net result is a decrease in intracellular solute content and a reduction of cell volume close to its original value.

When placed in a **hypertonic** solution, cells rapidly lose water and their volume decreases. In many cells, a decreased volume triggers **regulatory volume increase** (**RVI**) **mechanisms**, which increase the number of intracellular particles, bringing water back into the cells. Because Na^+ is the main extracellular ion, many RVI mechanisms involve an influx of sodium into the cell. Na^+–Cl^- symport, Na^+–K^+–$2Cl^-$ symport, and Na^+/H^+ antiport are some of the mechanisms activated to increase the intracellular concentration of Na^+ and increase the cell volume toward its original value.

Mechanisms based on an increased Na^+ influx are effective for only a short time because, eventually,

the sodium pump will increase its activity and reduce intracellular Na^+ to its normal value. Cells that regularly encounter hypertonic ECFs have developed additional mechanisms for maintaining normal volume. These cells can synthesize specific organic solutes, enabling them to increase intracellular osmolality for a long time and avoiding altering the concentrations of ions they must maintain within a narrow range of values. The organic solutes are usually small molecules that do not interfere with normal cell function when they accumulate inside the cell. For example, cells of the medulla of the mammalian kidney can increase the level of the enzyme aldose reductase when subjected to elevated extracellular osmolality. This enzyme converts glucose to an osmotically active solute, sorbitol. Brain cells can synthesize and store inositol. Synthesis of sorbitol and inositol represent different answers to the problem of increasing the total intracellular osmolality, allowing normal cell volume to be maintained in the presence of hypertonic ECF.

Oral rehydration therapy is driven by solute transport.

Oral administration of rehydration solutions has dramatically reduced the mortality resulting from cholera and other diseases that involve excessive losses of water and solutes from the gastrointestinal tract. The main ingredients of rehydration solutions are glucose, NaCl, and water. The glucose and Na^+ ions are reabsorbed by SGLT1 and other transporters in the epithelial cells lining the lumen of the small intestine (see Fig. **2.12**). Deposition of these solutes on the basolateral side of the epithelial cells increases the osmolality in that region compared with the intestinal lumen and drives the osmotic absorption of water. Absorption of glucose, and the obligatory increases in absorption of NaCl and water, helps to compensate for excessive diarrheal losses of salt and water.

RESTING MEMBRANE POTENTIAL

The different passive and active transport systems are coordinated in a living cell to maintain intracellular ions and other solutes at concentrations compatible with life. Consequently, the cell does not equilibrate with the ECF but rather exists in a **steady state** with the extracellular solution. For example, intracellular Na^+ concentration (10 mmol/L in a muscle cell) is much lower than extracellular Na^+ concentration (140 mmol/L), so Na^+ enters the cell by passive transport through nongated (always open) Na^+ channels. The rate of Na^+ entry is matched, however, by the rate of active transport of Na^+ out of the cell via the sodium–potassium pump (Fig. 2.13). The net result is that intracellular Na^+ is maintained constant and at a low level, even though Na^+ continually enters and leaves the cell. The reverse is true for K^+, which is maintained at a high concentration inside the cell relative to the outside. The passive exit of K^+ through nongated K^+ channels is matched by active entry via the pump (see Fig. 2.13). Maintenance of this steady state with ion concentrations inside the cell different from those outside the cell is the basis for the difference in electrical potential across the plasma membrane or the **resting membrane potential**.

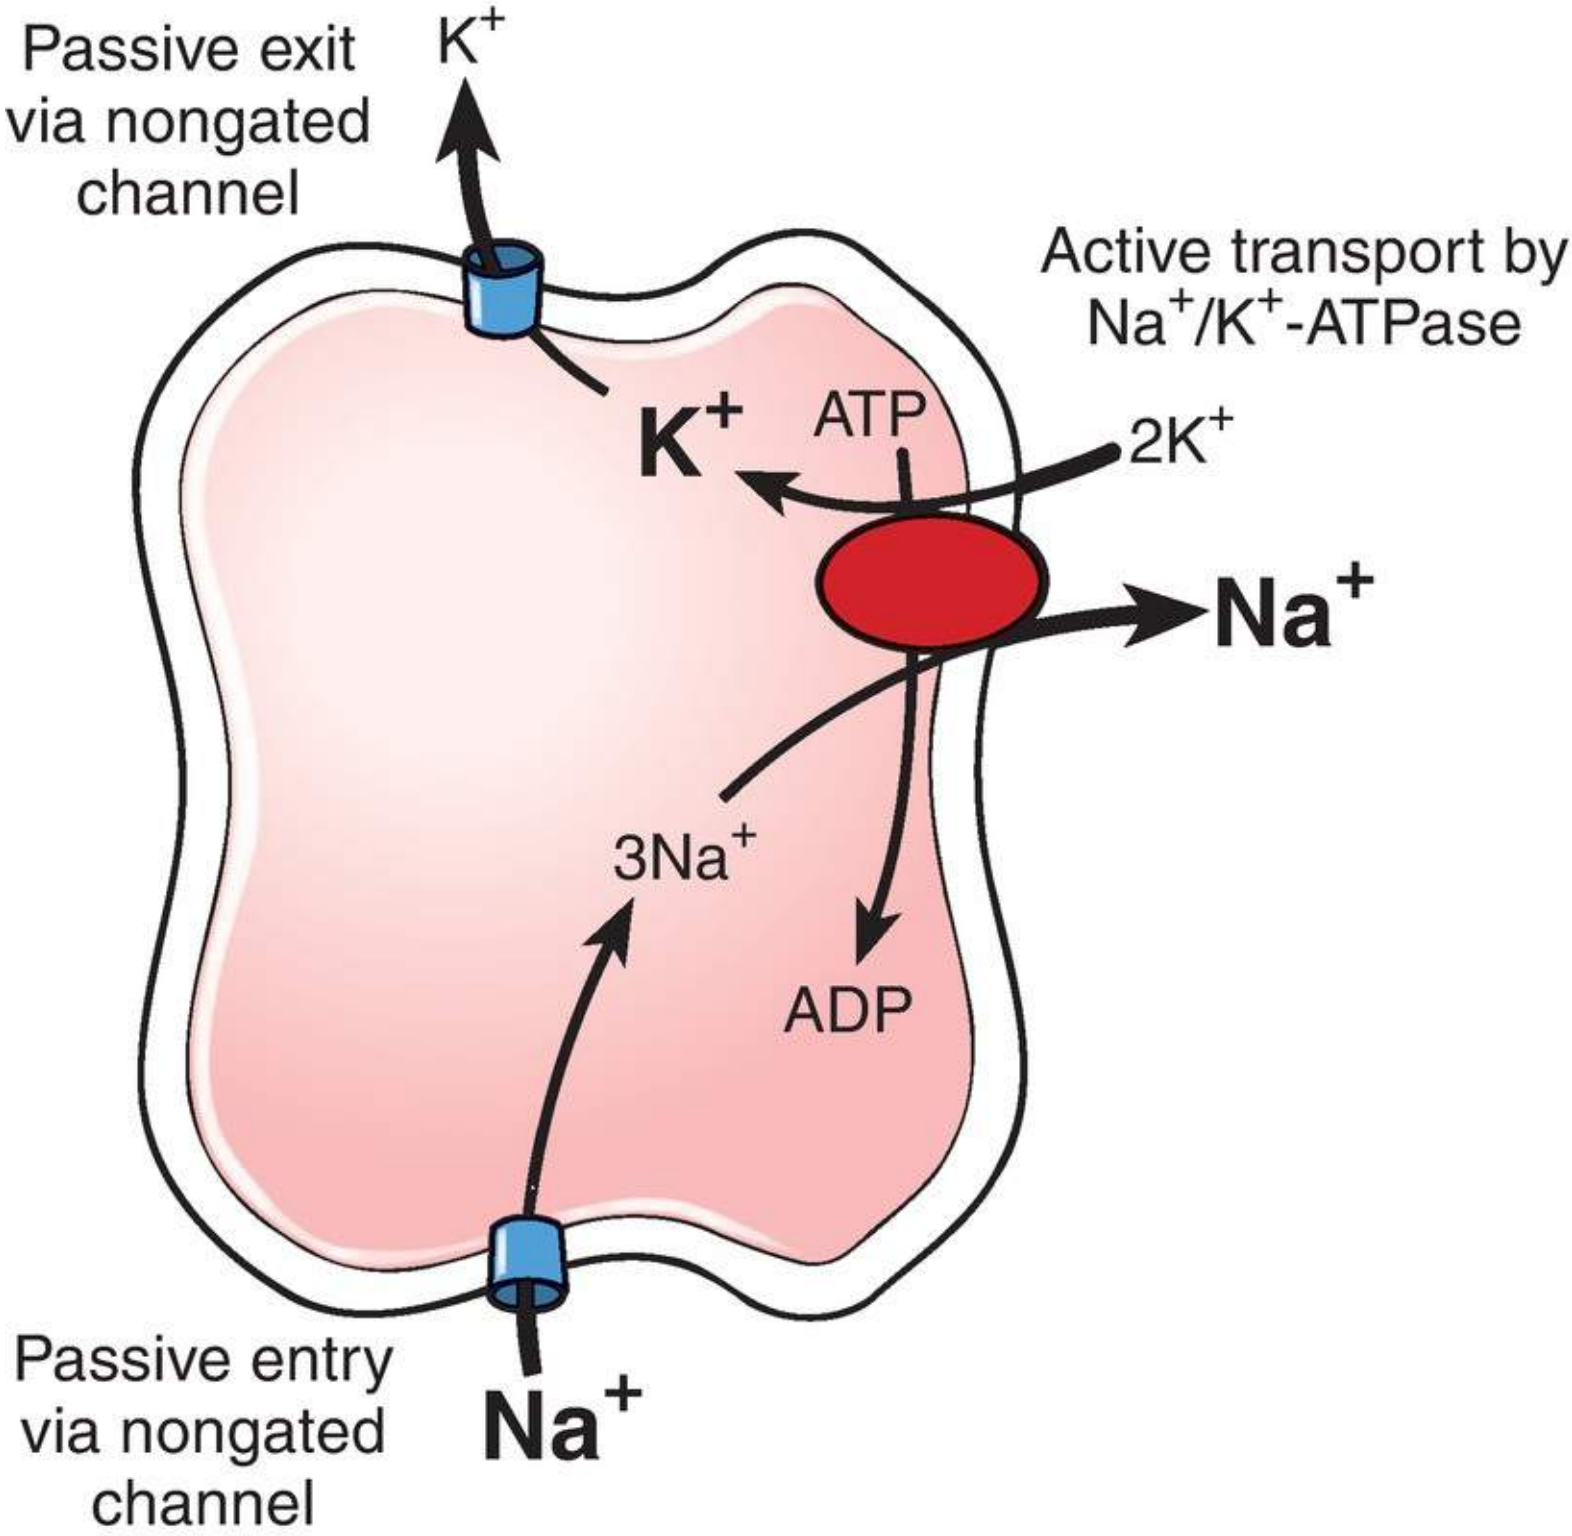

Figure 2.13 The concept of a steady state. Na^+ enters a cell through nongated Na^+ channels, moving passively down the electrochemical gradient. The rate of Na^+ entry is matched by the rate of active transport of Na^+ out of the cell via the Na^+/K^+-ATPase. The intracellular concentration of Na^+ remains low and constant. Similarly, the rate of passive K^+ exit through nongated K^+ channels is matched by the rate of active transport of K^+ into the cell via the pump. The intracellular K^+ concentration remains high and constant. During each cycle of the ATPase, two K^+ are exchanged for three Na^+, and one molecule of adenosine triphosphate (ATP) is hydrolyzed. *Boldfaced* and *lightfaced* fonts indicate high and low ion concentrations, respectively.

Ion movement is driven by the electrochemical potential.

If there are no differences in temperature or hydrostatic pressure between the two sides of a plasma membrane, two forces drive the movement of ions and other solutes across the membrane. One force results from the difference in the concentration of a substance between the inside and the outside of the cell and the tendency of every substance to move from areas of high concentration to areas of low concentration. The other force results from the difference in electrical potential between the two sides of the membrane and applies only to ions and other electrically charged solutes. When a difference in electrical potential exists, positive ions tend to move toward the negative side, whereas negative ions tend to move toward the positive side.

The sum of these two driving forces is called the *gradient* (or difference) of **electrochemical potential** across the membrane for a specific solute. It measures the tendency of that solute to cross the membrane. The expression of this force is given by

$$\Delta\mu = RT \ln C_i/C_o + zF(E_i - E_o) \quad (5)$$

where μ represents the electrochemical potential (Δμ is the difference in electrochemical potential between two sides of the membrane); C_i and C_o are the concentrations of the solute inside and outside the cell, respectively; E_i is the electrical potential inside the cell measured with respect to the electrical potential outside the cell (E_o); R is the universal gas constant (2 cal/mol·K); T is the absolute temperature (K); z is the valence of the ion; and F is the Faraday constant (23 cal/mV·mol). By inserting these units in equation 5 and simplifying, the electrochemical potential will be expressed in cal/mol, which is the unit of energy. If the solute is not an ion and has no electrical charge, then z = 0 and the last term of the equation becomes zero. In this case, the electrochemical potential is defined only by the different concentrations of the uncharged solute, called the **chemical potential**. The driving force for solute transport becomes solely the difference in chemical potential.

Net ion movement is zero at the equilibrium potential.

Net movement of an ion into or out of a cell continues as long as the driving force exists. Net movement stops and equilibrium is reached only when the driving force of electrochemical potential across the membrane becomes zero. The condition of equilibrium for any permeable ion will be $\Delta\mu = 0$. Substituting this condition into equation 5, we obtain

$$0 = RT \ln\left(\frac{C_i}{C_o}\right) + zF(E_i - E_o)$$

$$E_i - E_o = -\frac{RT}{zF} \ln\left(\frac{C_i}{C_o}\right)$$

$$E_i - E_o = -\frac{RT}{zF} \ln\left(\frac{C_o}{C_i}\right)$$

(6)

Equation 6, known as the **Nernst equation**, gives the value of the electrical potential difference ($E_i - E_o$) necessary for a specific ion to be at equilibrium. This value is known as the **Nernst equilibrium potential** for that particular ion, and it is expressed in millivolts (mV). At the equilibrium potential, the tendency of an ion to move in one direction because of the difference in concentrations is exactly balanced by the tendency to move in the opposite direction because of the difference in electrical potential. At this point, the ion will be in equilibrium and there will be no net movement. By converting to $\log_{10}$ and assuming a physiologic temperature of 37°C and a value of +1 for z (for Na^+ or K^+), the Nernst equation can be expressed as

$$E_i - E_o = 61 LOG_{10}(C_o / C_i)$$

(7)

Because Na^+ and K^+ (and other ions) are present at different concentrations inside and outside a cell, it follows from equation 7 that the equilibrium potential will be different for each ion.

Resting membrane potential is determined by the passive movement of several ions.

The resting membrane potential is the electrical potential difference across the plasma membrane of a normal living cell in its unstimulated state. It can be measured directly by the insertion of a microelectrode into the cell with a reference electrode in the ECF. The resting membrane potential is determined by those ions that can cross the membrane and are prevented from attaining equilibrium by active transport systems. Potassium, sodium, and chloride ions can cross the membranes of every living cell, and each of these ions contributes to the resting membrane potential. By contrast, the permeability of the membrane of most cells to divalent ions is so low that it can be ignored in this context.

The **Goldman equation** gives the value of the membrane potential (in mV) when all the permeable ions are accounted for:

$$E_i - E_o = \frac{RT}{F} \ln\left(\frac{P_K[K^+]_o + P_{Na}[Na^+]_o + P_{Cl}[Cl^-]_i}{P_K[K^+]_i + P_{Na}[Na^+]_i + P_{Cl}[Cl^-]_o} \right)$$

(8)

where P_K, P_{Na}, and P_{Cl} represent the permeability of the membrane to potassium, sodium, and chloride ions, respectively, and brackets indicate the concentration of the ion inside (i) and outside (o) the cell. If a specific cell is not permeable to one of these ions, the contribution of the impermeable ion to the membrane potential will be zero. For a cell that is permeable to an ion other than the three considered in the Goldman equation, that ion will contribute to the membrane potential and must be included in equation 8.

It can be seen from equation 8 that the contribution of any ion to the membrane potential is determined by the membrane's permeability to that particular ion. The higher the permeability of the membrane to one ion relative to the others, the more that ion will contribute to the membrane potential. The plasma membranes of most living cells are much more permeable to potassium ions than to any other ion. Making the assumption that P_{Na} and P_{Cl} are zero relative to P_K, equation 8 can be simplified to

$$E_i - E_o = \frac{RT}{F} \ln\left(\frac{P_K[K^+]_o}{P_K[K^+]_i}\right)$$

$$E_i - E_o = \frac{RT}{F} \ln\left(\frac{[K^+]_o}{[K^+]_i}\right)$$

(9)

which is the Nernst equation for the equilibrium potential for K^+ (see equation 6). This illustrates two important points:

- In most cells, the resting membrane potential is close to the equilibrium potential for K^+.
- The resting membrane potential of most cells is dominated by K^+ because the plasma membrane is more permeable to this ion compared with the others.

As a typical example, the K^+ concentrations outside and inside a muscle cell are 3.5 and 155 mmol/L, respectively. Substituting these values in equation 7 gives a calculated equilibrium potential for K^+ of −100 mV, negative inside the cell relative to the outside. Measurement of the resting membrane potential in a muscle cell yields a value of −90 mV (negative inside). This value is close to, although not the same as, the equilibrium potential for K^+.

The reason the resting membrane potential in the muscle cell is less negative than the equilibrium potential for K^+ is as follows. Under physiologic conditions, there is passive entry of Na^+ ions. This entry of positively charged ions has a small but significant effect on the negative potential inside the cell. Assuming intracellular Na^+ to be 10 mmol/L and extracellular Na^+ to be 140 mmol/L, the Nernst equation gives a value of +70 mV for the Na^+ equilibrium potential (positive inside the cell). This is far from the resting membrane potential of −90 mV. Na^+ makes only a small contribution to the resting membrane potential because membrane permeability to Na^+ is low compared with that of K^+.

The contribution of Cl^- ions need not be considered because the resting membrane potential in the muscle cell is the same as the equilibrium potential for Cl^-. Therefore, there is no net movement of chloride ions.

In most cells, as shown above using a muscle cell as an example, the equilibrium potentials of K^+ and Na^+ are different from the resting membrane potential, which indicates that neither K^+ ions nor Na^+ ions

are at equilibrium. Consequently, these ions continue to cross the plasma membrane via specific nongated channels, and these passive ion movements are *directly* responsible for the resting membrane potential.

The Na^+/K^+-ATPase is important *indirectly* for maintaining the resting membrane potential because it sets up the gradients of K^+ and Na^+ that drive passive K^+ exit and Na^+ entry. During each cycle of the pump, two K^+ ions are moved into the cell in exchange for three Na^+, which are moved out (see Fig. 2.13). Because of the unequal exchange mechanism, the pump's activity contributes slightly (about −5 mV) to the negative potential inside the cell.

COMMUNICATION AND SIGNALING MODES

The human body has several means of transmitting information between cells. These mechanisms include direct communication between adjacent cells, autocrine and paracrine signaling, and the release of neurotransmitters and hormones produced by nerves and endocrine cells.

Cells communicate locally by paracrine and autocrine signaling.

Cells may signal to each other via the local release of chemical substances. In **paracrine signaling**, a chemical is liberated from a cell and diffuses a short distance through the ECF to act on nearby cells. Paracrine-signaling factors affect only the immediate environment and bind with high specificity to cell receptors on the plasma membrane of the receiving cell. They are also rapidly destroyed by extracellular enzymes or bound to extracellular matrix, thus preventing their widespread diffusion. **Nitric oxide** (**NO**) is an example of a paracrine-signaling molecule because it has an intrinsically short half-life and thus can affect cells located directly next to the NO-producing cell. NO has major roles in mediating vascular smooth muscle tone, facilitating neurotransmission in the central nervous system (CNS) and modulating immune responses (see Chapters 15 and 25).

In contrast, during **autocrine signaling**, the cell releases a chemical messenger into the ECF that binds to a receptor on the surface of the cell that secreted it. Eicosanoids (e.g., prostaglandins) are examples of signaling molecules that can act in an autocrine manner. These molecules act as local hormones to influence a variety of physiologic processes such as uterine smooth muscle contraction during pregnancy.

Nervous system provides for rapid and targeted communication.

The CNS includes the brain and spinal cord, which links the CNS to the peripheral nervous system (PNS), which is composed of nerves or bundles of neurons. Together, the CNS and the PNS integrate and coordinate a vast number of sensory processes and motor responses. The basic functions of the nervous system are to acquire sensory input from both the internal and external environment, integrate the input, and then activate a response to the stimuli. Sensory input to the nervous system can occur in many forms, such as taste, sound, blood pH, hormones, balance or orientation, pressure, or temperature, and these inputs are converted to signals that are sent to the brain or spinal cord. In the sensory centers of the brain and spinal cord, the input signals are rapidly integrated, and then a response is generated. The response is generally a motor output and is a signal that is transmitted to the organs and tissues, where it is converted into an action such as a change in heart rate, sensation of thirst, release of hormones, or a physical movement. The nervous system is also organized for discrete activities; it has an enormous number of "private lines" for sending messages from one distinct locus to another. The conduction of information along nerves occurs via electrical signals, called *action potentials*, and signal transmission between nerves or between nerves and effector structures takes place at a **synapse**. Synaptic transmission is mediated by the release of specific chemicals or **neurotransmitters** from the nerve terminals. Innervated cells have receptors in their cell membranes that selectively bind neurotransmitters. Chapter 3 discusses the actions of various neurotransmitters and how they are synthesized and degraded. Chapters 4 to 6 discuss the role of the nervous system in coordinating and controlling body functions.

Endocrine system provides for slower and more diffuse communication.

The endocrine system produces hormones in response to a variety of stimuli that are instrumental in establishing and maintaining homeostasis in the body. In contrast to the rapid, directed effects resulting from neuronal stimulation, responses to hormones are much slower (seconds to hours) in onset, and the effects often last longer. Hormones are secreted from endocrine glands and tissues and are broadcast to all parts of the body by the bloodstream. A particular cell can only respond to a hormone if it possesses the appropriate hormone receptor. Hormone effects may be focused. For example, arginine vasopressin specifically increases the water permeability of kidney collecting duct cells but does not alter the water permeability of other cells. Hormone effects can also be diffuse, influencing practically every cell in the body. For example, thyroxine has a general stimulatory effect on metabolism. Hormones play a critical role in controlling such body functions as growth, metabolism, and reproduction.

Cells that are not traditional endocrine cells produce a special category of chemical messengers called **tissue growth factors**. These growth factors are protein molecules that influence cell division, differentiation, and cell survival. They may exert effects in an autocrine, paracrine, or endocrine fashion. Many growth factors have been identified. **Nerve growth factor** enhances nerve cell development and stimulates the growth of axons. **Epidermal growth factor** (**EGF**) stimulates the growth of epithelial cells in the skin and other organs. **Platelet-derived growth factor** stimulates the proliferation of vascular smooth muscle and endothelial cells. **Insulin-like growth factors** stimulate the proliferation of a wide variety of cells and mediate many of the effects of growth hormone. Growth factors appear to be important in the development of multicellular organisms and in the regeneration and repair of damaged tissues.

Nervous and endocrine control systems overlap.

The distinction between nervous and endocrine control systems is not always clear. This is because the nervous system exerts control over endocrine gland function, most if not all endocrine glands are innervated by the PNS, and these nerves can directly control the endocrine function of the gland. In addition, the innervation of endocrine tissues can also regulate blood flow within the gland, which can impact the distribution and thus function of the hormone. On the other hand, hormones can affect the CNS to alter behavior and mood. Adding to this highly integrated relationship is the presence of specialized nerve cells, called **neuroendocrine**, or **neurosecretory cells**, which directly convert a neural signal into a hormonal signal. These cells thus directly convert electrical energy into chemical energy, and activation of a neurosecretory cell results in hormone secretion. Examples are the hypothalamic neurons, which liberate releasing factors that control secretion by the anterior pituitary gland, and the hypothalamic neurons, which secrete arginine vasopressin and oxytocin into the circulation. In addition, many proven or potential neurotransmitters found in nerve terminals are also well-known hormones, including arginine vasopressin, cholecystokinin, enkephalins, norepinephrine, secretin, and vasoactive intestinal peptide. Therefore, it is sometimes difficult to classify a particular molecule as either a hormone or a neurotransmitter.

MOLECULAR BASIS OF CELLULAR SIGNALING

The study of intercellular communication has led to the identification of many complex signaling systems that are used by the body to network and coordinate functions. A general outline for a **signal cascade** is as follows: Signaling is initiated by binding of a first messenger to its appropriate ligand-binding site on the outer surface domain of its relevant membrane receptor. This results in activation of the receptor; the receptor may adopt a new conformation, form aggregates (multimerize), and/or become phosphorylated or dephosphorylated. These changes often result in association of adapter signaling molecules that couple the activated receptor to downstream molecules that transduce and amplify the signal through the cell by activating specific effector molecules and generating a second messenger. The outcome of the signal transduction cascade is a physiologic response, such as secretion, movement, growth, division, or death. It is important to remember these physiologic responses are the collective result of a multitude of signaling messengers that transmit signals to the cells in various tissues.

Plasma membrane receptors activate signal transduction pathways.

Cellular receptors are divided into two general types: *cell-surface receptors* and *intracellular receptors*. Three general classes of cell-surface receptors have been identified: *G protein–coupled receptors* (*GPCRs*), *ion channel–linked receptors*, and *enzyme-linked receptors*. Intracellular receptors include steroid and thyroid hormone receptors and are discussed in a later section in this chapter. Cell-surface receptors are often found in **lipid rafts** that can compartmentalize and organize assembly of signaling complexes.

G protein–coupled receptors transmit signals through trimeric G proteins.

With more than 1,000 members, **G protein–coupled receptors** (**GPCRs**) are the largest family of cell-surface receptors. These receptors regulate their effector targets through the intermediary activity of a separate membrane-bound adapter protein complex called the *trimeric guanosine triphosphate (GTP)-binding regulatory protein* or *trimeric G protein* (Fig. 2.14). GPCRs mediate cellular responses to numerous types of first messenger signaling molecules, and many first messenger ligands can activate several different GPCRs.

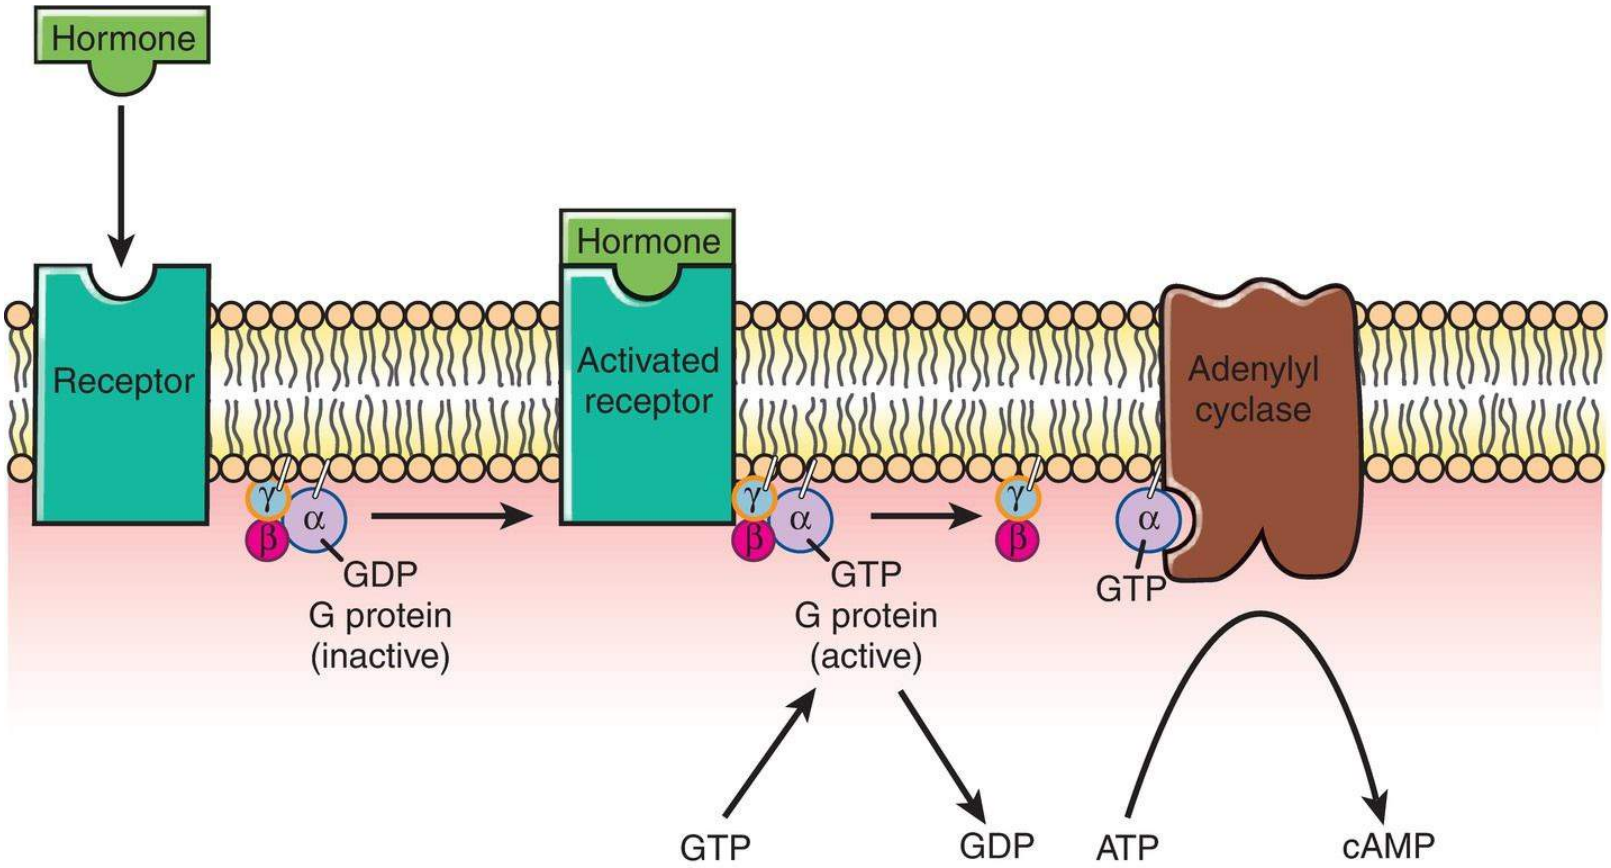

Figure 2.14 Activation of a G protein–coupled receptor and the production of cyclic adenosine monophosphate (cAMP). When bound to guanosine diphosphate (GDP), G proteins are in an inactive state and are not associated with a receptor. Binding of a hormone to the receptor results in association with the inactive, GDP-bound trimeric G protein. The interaction of the GDP-bound trimeric G protein with the activated receptor results in activation of the G protein via the exchange of GDP for guanosine triphosphate (GTP) by the α subunit. The α and βγ subunits of the activated GTP-bound G protein dissociate. The activated, GTP-bound α subunit of the trimeric G protein can then interact with and activate the membrane protein adenylyl cyclase to catalyze the conversion of ATP to cAMP. The intrinsic GTPase activity in the α subunit of the G protein hydrolyzes the bound GTP to GDP. The GDP-bound α subunit reassociates with the βγ subunit to form an inactive, membrane-bound trimeric G-protein complex.

GPCRs have a ligand-binding extracellular domain, separated by a seven-pass transmembrane-spanning region from the cytosolic regulatory domain at the other end of the molecule, where the receptor interacts

with the membrane-bound G protein. Binding of ligand or hormone to the extracellular domain results in a conformational change in the receptor that is transmitted to the cytosolic regulatory domain. This conformational change allows an interaction of the ligand-bound, activated receptor with a trimeric G protein associated with the inner leaflet of the plasma membrane. The interaction between the ligand-bound, activated receptor and the G protein, in turn, activates the G protein, which dissociates from the receptor and transmits the signal to its effector enzyme or ion channel.

The trimeric G proteins are named for their requirement for **guanosine triphosphate** (**GTP**) binding and hydrolysis. Heterotrimeric G proteins are composed of three distinct subunits tethered to the plasma membrane. The G protein subunits are the α subunit, which binds and hydrolyzes GTP, and the β and γ subunits, which form a stable, tight noncovalent-linked βγ dimer. When the α subunit binds **guanosine diphosphate** (**GDP**), it associates with the βγ subunits to form a trimeric complex that can interact with the cytoplasmic domain of the GPCR. The conformational change that occurs upon ligand binding causes the GDP-bound trimeric (αβγ complex) G protein to associate with the ligand-bound receptor. The association of the GDP-bound trimeric complex with the GPCR activates the exchange of GDP for GTP. Displacement of GDP by GTP is favored in cells because GTP is in higher concentration. The displacement of GDP by GTP causes the α subunit to dissociate from the receptor and from the βγ subunits of the G protein. This exposes an effector-binding site on the α subunit, which then associates with an effector enzyme (e.g., AC or phospholipase C [PLC]) to result in the generation of second messengers (e.g., cAMP or IP_3 and DAG). The hydrolysis of GTP to GDP by the α subunit results in the reassociation of the α and βγ subunits, which are then ready to repeat the cycle.

Two major effector molecules regulated by G-protein subunits are **adenylyl cyclase** (**AC**) and PLC. The association of an activated Gα subunit with AC can either stimulate or inhibit the production of cAMP. Association of an α_s subunit (s for stimulatory) promotes the activation of AC and production of cAMP. The association of an α_i (i for inhibitory) subunit promotes the inhibition of AC and a decrease in cAMP. Thus, bidirectional regulation of AC is achieved by coupling different classes of cell-surface receptors to the enzyme by either G_s or G_i (Fig. 2.15).

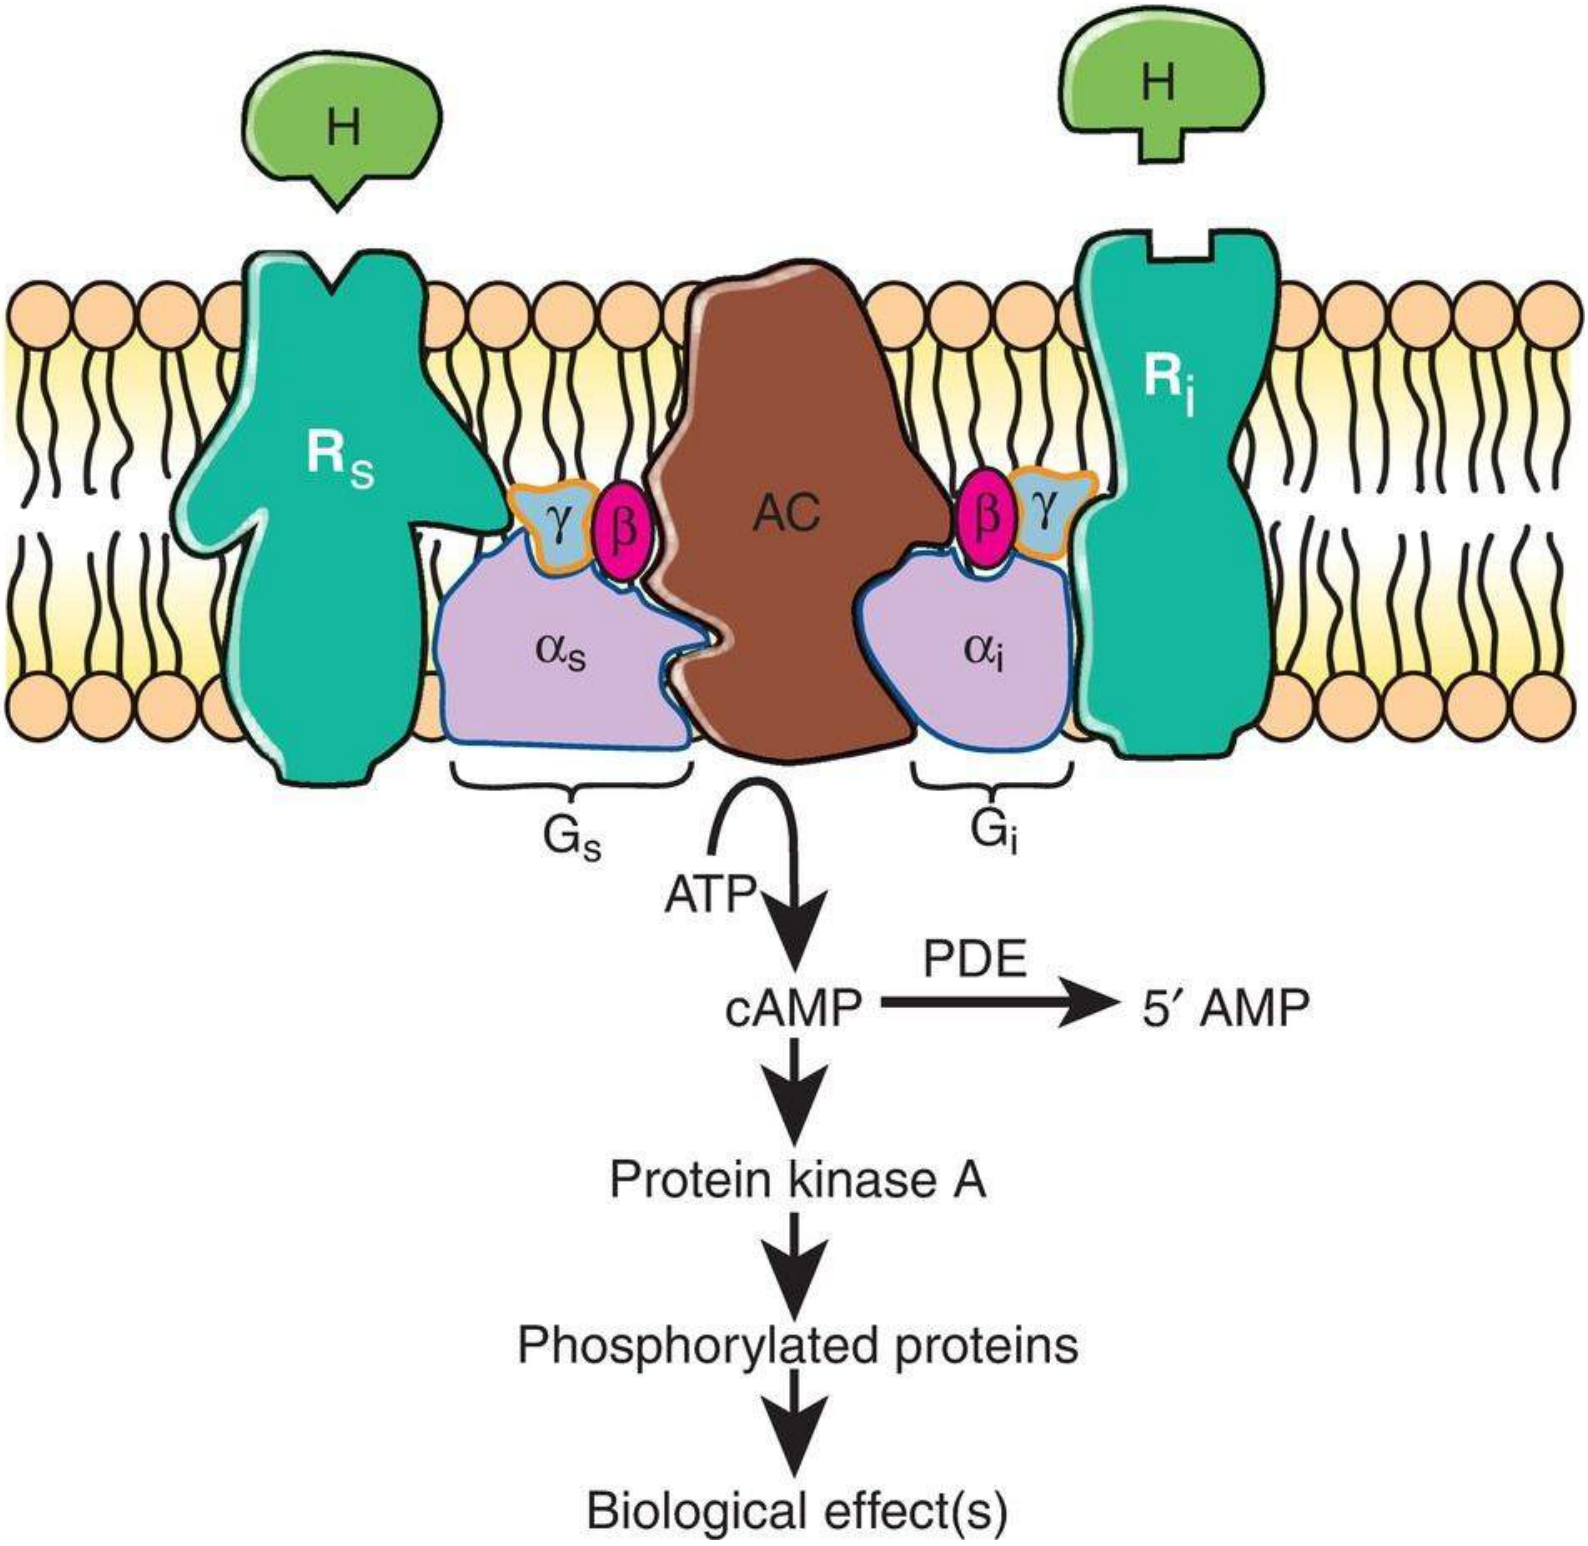

Figure 2.15 Stimulatory and inhibitory coupling of G proteins to adenylyl cyclase. Stimulatory (G_s) and inhibitory (G_i) G proteins couple hormone binding to the receptor with either activation or inhibition of adenylyl cyclase (AC). Each G protein is a trimer consisting of Gα, Gβ, and Gγ subunits. The Gα subunits in G_s and G_i are distinct and provide the specificity for either activation or inhibition of AC. Hormones that bind "stimulatory" receptors (R_s) are coupled to AC through stimulatory G proteins (G_s). Conversely, hormones inhibit AC by binding "inhibitory" receptors (R_i) coupled to AC through inhibitory G proteins (G_i). Intracellular levels of cyclic adenosine monophosphate (cAMP) are modulated by the activity of phosphodiesterase (PDE), which converts cAMP to 5'AMP and turns off the signaling pathway by reducing the level of cAMP.

In addition to α_s and α_i subunits, other isoforms of G-protein subunits have been described. For example, α_q activates PLC, resulting in the production of the second messengers, DAG, and inositol trisphosphate. Another Gα subunit, α_T or **transducin**, is expressed in photoreceptor tissues and has an important role in signaling in light-sensing rod cells in the retina by activation of the effector *cGMP phosphodiesterase* (*PDE*), which degrades cGMP to 5′GMP (see Chapter 4). G-protein subunits are expressed in different combinations in different tissues, which contributes to both the specificity of the transduced signal and the second messenger produced.

Ion channel–linked receptors mediate cell signaling by regulating the intracellular concentration of specific ions.

Ion channels may be opened or closed by changing the membrane potential or by the binding of ligands to membrane receptors. In some cases, the receptor and ion channel are the same molecule such as at the neuromuscular junction, where the neurotransmitter acetylcholine binds to a muscle membrane nicotinic cholinergic receptor. In other cases, the receptor and ion channel are linked via a G protein, second messengers, and other downstream effector molecules, as in the muscarinic cholinergic receptor on cells innervated by parasympathetic postganglionic nerve fibers. Ion channels are also directly activated by cGMP or cAMP produced by receptor activation. This mode of ion channel control is predominantly found in the sensory tissues for sight, smell, and hearing and in the smooth muscle surrounding blood vessels. The opening or closing of ion channels plays a key role in signaling between electrically excitable cells, such as nerve and muscle.

Tyrosine kinase receptors signal through adapter proteins to activate the mitogen-activated protein kinase pathway.

Many hormones and growth factors (**mitogens**) signal their target cells by binding to receptors that have tyrosine kinase activity, resulting in phosphorylation of tyrosine residues in the receptor and other target proteins. Tyrosine kinase receptors either have an intrinsic tyrosine kinase within the cytoplasmic region of the receptor (Fig. 2.16) or, when activated, associate with a cytoplasmic tyrosine kinase.

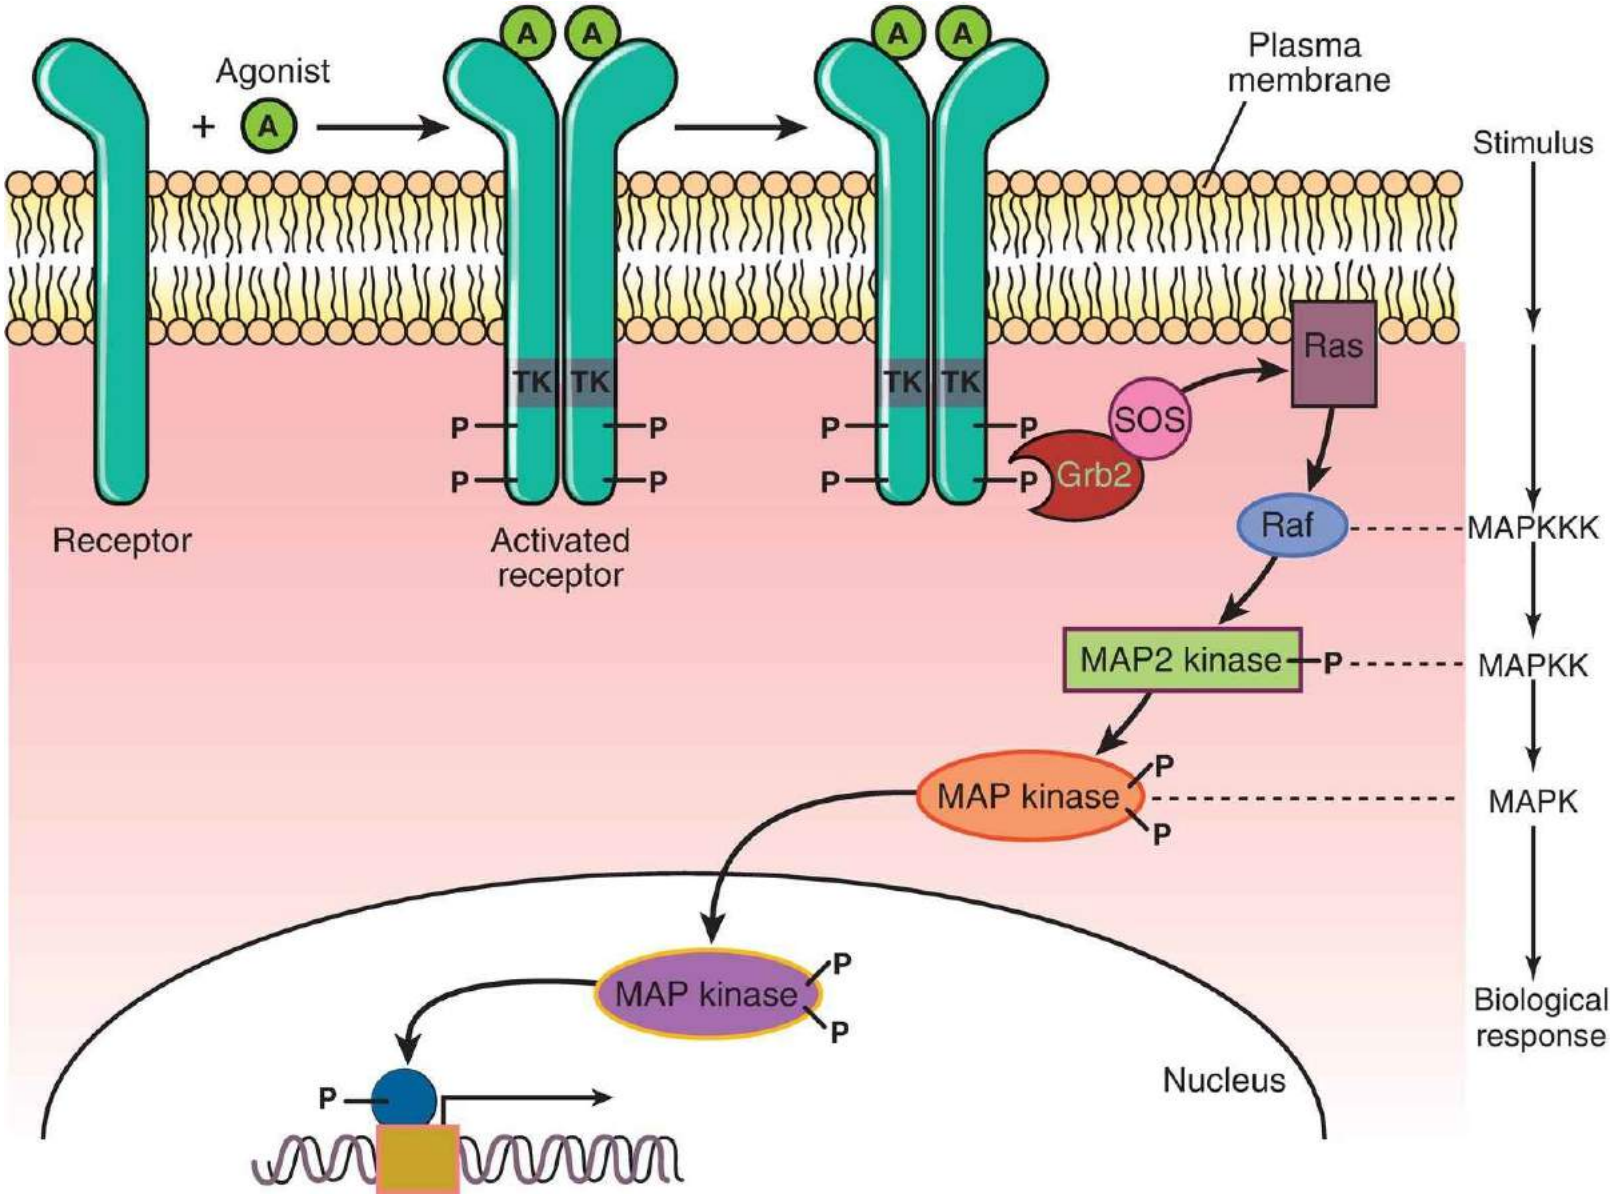

Figure 2.16 A signaling pathway for tyrosine kinase receptors. Binding of agonist to the tyrosine kinase receptor (TK) causes dimerization, activation of the intrinsic tyrosine kinase activity, and phosphorylation of the receptor subunits. The phosphotyrosine residues serve as docking sites for intracellular proteins, such as Grb2, which recruits Son of Sevenless (SOS), a guanine nucleotide exchange factor, to the receptor complex. SOS interacts with and modulates the activity of Ras by promoting the exchange of GDP for GTP. Ras-GTP (active form) activates the serine/threonine kinase Raf, initiating a phosphorylation cascade that results in the activation of mitogen-activated protein kinase (MAPK). MAPK translocates to the nucleus and phosphorylates transcription factors to modulate gene transcription. The right side of the figure illustrates the hierarchical organization of the MAPK signaling cascade. The generic names in this pathway are shown aligned to specific members of a typical tyrosine kinase pathway. Proteins with P attached represent phosphorylation at either tyrosine or serine/threonine residues.

Structurally, **tyrosine kinase receptors** consist of a hormone-binding region that is exposed to the extracellular space, a transmembrane region, and a cytoplasmic tail domain. Examples of **ligands** for these receptors include the hormones insulin or growth factors such as epidermal-, fibroblast-, and platelet-derived growth factors. The signaling cascades generated by the activation of tyrosine kinase receptors can result in the transcription of genes involved in growth, cellular differentiation, and movements (crawling or shape change).

The tyrosine kinase signaling pathway begins with the agonist binding to the extracellular portion of the receptor (see Fig. 2.16), which causes two of the agonist-bound receptors to associate (**dimerization**), and in turn, activating the built-in or associated tyrosine kinase. The activated tyrosine kinase then phosphorylates tyrosine residues in the other subunit (cross-phosphorylation) of the dimer to fully activate the receptor and create docking sites for additional signaling molecules or adapter proteins that have a specific sequence called an **SH2 domain**. The SH2-containing adapter proteins may be serine/threonine protein kinases, phosphatases, or other bridging proteins that transmit the signal from an activated receptor to many signaling pathways, resulting in a cellular response. A notable difference in signaling pathways activated by tyrosine kinase receptors is that they do not generate second messengers such as cAMP or cGMP.

One other signaling pathway associated with activated tyrosine kinase receptors results in activation of monomeric GTPase monomeric. Members of the **ras** family of *monomeric G proteins* are activated by many tyrosine kinase receptor growth factor agonists and, in turn, activate an intracellular signaling cascade that involves the phosphorylation and activation of protein kinases called *mitogen-activated protein kinases* (*MAPKs*). In this pathway, the activated MAPK translocates to the nucleus, where it activates transcription of a cohort of genes needed for proliferation and survival or cell death (Clinical Focus 2.2).

CLINICAL FOCUS 2.2

Tyrosine Kinase Inhibitors for Chronic Myeloid Leukemia

Cancer can result from defects in critical signaling molecules that regulate cell properties such as proliferation, differentiation, and survival. Normal cellular regulatory proteins or **protooncogenes** may become altered by mutation or abnormally expressed during cancer development. **Oncogenes**, the altered proteins that arise from protooncogenes, are in many cases signal transduction proteins that normally function in the regulation of cellular proliferation. Examples of signaling molecules that can become oncogenic span the entire signal transduction pathway and include ligands (e.g., growth factors), receptors, adapter and effector molecules, and transcription factors.

There are many examples of how normal cellular proteins can be converted into oncoproteins. One occurs in **chronic myeloid leukemia** (**CML**). This disease is characterized by increased and unregulated clonal proliferation of myeloid cells in the bone marrow. CML results from an inherited chromosomal abnormality that involves a reciprocal translocation or exchange of genetic material between chromosomes 9 and 22 and was the first malignancy to be linked to a genetic abnormality. The translocation is referred to as the *Philadelphia chromosome* and results in the fusion of the *bcr* gene with part of the cellular *abl* (c-*abl*) gene. The c-*abl* gene encodes a protein tyrosine kinase. This abnormal Bcr–Abl fusion protein has unregulated tyrosine kinase activity, and through SH2 and SH3 binding domains, the mutant protein binds to and phosphorylates the interleukin-3β(c) receptor. This receptor is linked to control of cell proliferation, and the expression of the unregulated Bcr–Abl protein activates signaling pathways that speed up cell division. The BCR–ABL protein also inhibits DNA repair, causing genomic instability and making the cell more susceptible to developing further genetic abnormalities.

The chromosomal translocation that results in the formation of the Bcr–Abl oncoprotein occurs during the development of hematopoietic stem cells, and the observance of a shorter Philadelphia 22 chromosome is diagnostic of this cancer. The translocation results initially in a CML that is characterized by a progressive leukocytosis (increase in number of circulating white blood cells) and the presence of circulating immature blast cells. However, other secondary mutations may spontaneously occur within the mutant stem cell and can lead to acute leukemia, a rapidly progressing disease that is often fatal.

Historically, CML was treated with chemotherapy, interferon administration, and bone marrow transplantation. With the understanding of the molecules and signaling pathways that result in this devastating cancer, targeted therapeutic strategies to attenuate the disease have been developed. Imatinib mesylate was the first tyrosine kinase inhibitor (developed in 2001) that could reduce the signaling activity of Bcr–Abl. Additional, more potent tyrosine kinase inhibitors have since been developed activities has been developed. These drugs can induce complete remission of CML and greatly improve the quality of life and lifespan of the patient. ■

Hormone receptors bind specific hormones to initiate cell signaling in the cells.

Hormone receptors reside either on the cell surface and bind **peptide hormones**, or inside the cell where they bind **steroid hormones**. *Peptide hormone* receptors are usually GPCRs and effect signaling by generation of second messengers such as cAMP and IP_3 and by the release of calcium from its storage compartments. Steroid hormones bind either to soluble receptors located in the cytosol or nucleus or to receptors already bound to the promoter elements of target genes. Cytoplasmic or nuclear steroid hormone receptors include the sex hormone receptors (androgens, estrogen, and progesterone), glucocorticoid receptors (cortisol), and mineralocorticoid receptors (aldosterone). Examples of DNA-bound steroid hormone receptors include vitamin A, vitamin D, retinoid, and thyroid hormone receptors.

Generally, steroid hormone receptors have four recognized domains. The N-terminal *variable domain* is a region with little similarity between receptors. A centrally located *DNA-binding domain* consists of two globular motifs where zinc is coordinated with cysteine residues (**zinc finger**). This domain controls the target gene that will be activated and may also have sites for phosphorylation by protein kinases involved in modifying the transcriptional activity of the receptor. Between the central DNA-binding and the C-terminal hormone-binding domains is located a *hinge domain*, which controls the movement of the receptor to the nucleus. The carboxyl-terminal *hormone-binding and dimerization domain* binds the hormone and then allows the receptor to dimerize, a necessary step for binding to DNA. Steroid hormones bound to their receptor move to the nucleus, where the complex binds to the promoter region of a hormone-responsive gene. The targeted DNA sequence in the promoter is called a **hormone response element** (**HRE**). Binding of the hormone receptor complex to the HRE can either activate or repress transcription, resulting in newly synthesized proteins and/or enzymes that will affect cellular metabolism. Steroid hormone signaling is shown in Figure 2.17. In contrast to steroid hormones, thyroid hormones, retinoic acid, vitamin A, and vitamin D bind to receptors that are already associated with the DNA response elements of target genes. The unoccupied receptors are inactive until the hormone binds, and they serve as repressors in the absence of hormone. Thyroid hormone receptor action is discussed in Chapter 32.

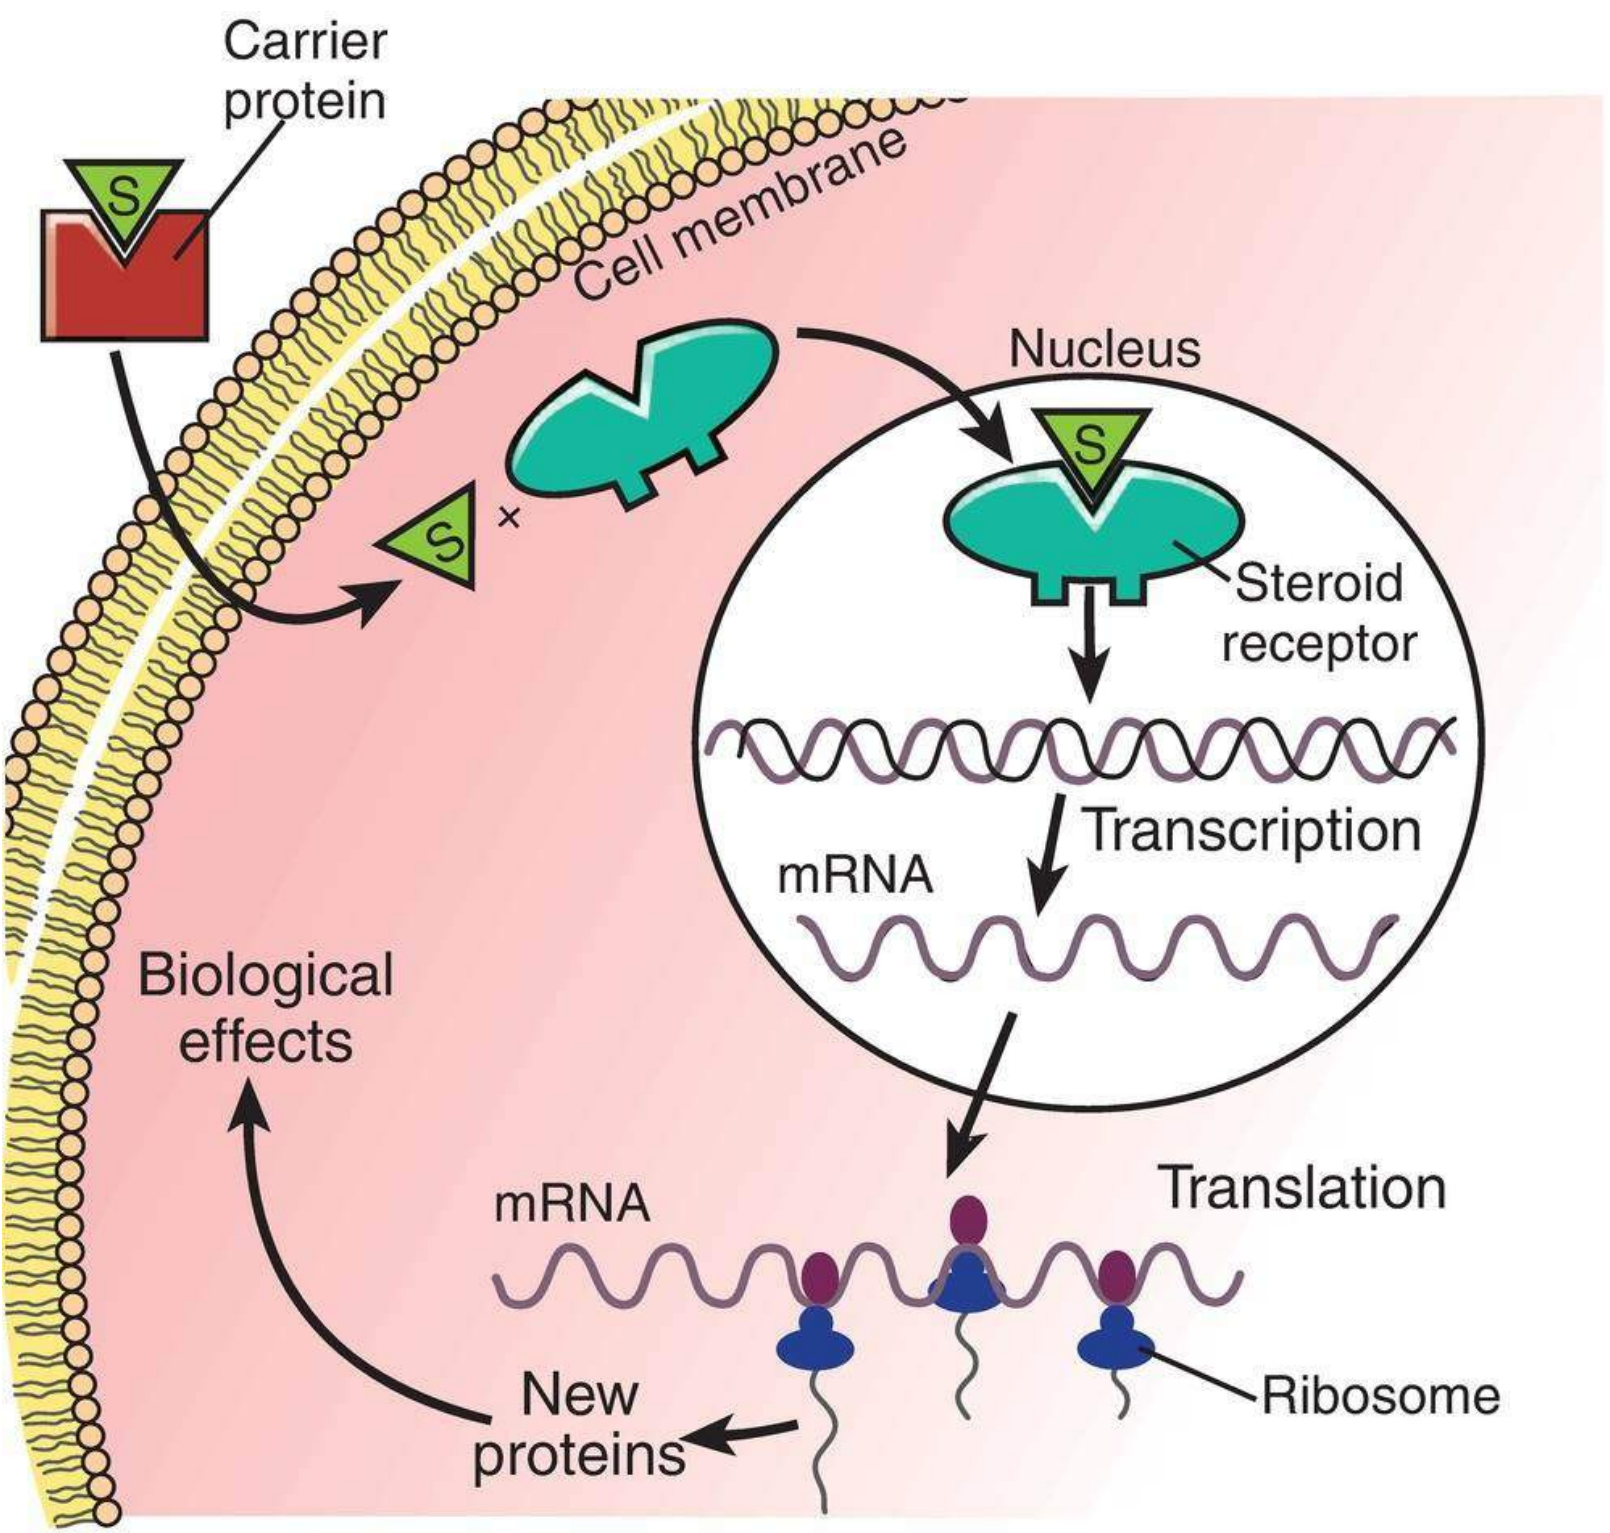

Figure 2.17 The general mechanism of action of steroid hormones. Steroid hormones (S) are lipid soluble and pass through the plasma membrane, where they bind to a cognate receptor in the cytoplasm. The steroid hormone receptor complex then moves to the nucleus and binds to a HRE in the promoter of specific hormone-responsive genes. Binding of the steroid hormone–receptor complex to the response element initiates transcription of the gene to form mRNA. The mRNA moves to the cytoplasm, where it is translated into a protein that participates in a cellular response. Thyroid hormones act by a similar mechanism, although their receptors are already bound to an HRE, repressing gene expression.

SECOND MESSENGERS

The concept of second messengers and their central role in signaling began with Earl Sutherland, Jr., who was awarded the Nobel Prize in 1971 “for his discoveries concerning the mechanisms of action of hormones.” Sutherland discovered cAMP and showed it was a critical intermediate in cellular responses to hormones. **Second messengers** transmit and amplify signals from receptors to downstream target molecules inside the cell. There are three general types of second messengers: hydrophilic, water-soluble messengers, such as IP_3, cAMP, cGMP, or Ca^{2+}; hydrophobic water-insoluble, lipid messengers, which are generally associated with lipid-rich membranes such as DAG and phosphatidylinositols (e.g., PIP_3); and gases, such as NO, CO, and reactive oxygen species (ROS), which can diffuse both through the cytosol as well as across cell membranes. A critical feature of second messengers is that they are able to be *rapidly synthesized and degraded* by cellular enzymes, rapidly sequestered in a membrane-bound organelle or vesicle or have a restricted distribution within the cell. It is the rapid appearance and disappearance that allow second messengers to amplify and then terminate signaling reactions, allowing fine-tuning of the response. For example, when a cell receptor is only briefly stimulated with a ligand, the generation of a second messenger will terminate rapidly. Conversely, when a large amount of ligand persists to stimulate a receptor, the increased levels of second messenger in the cell will be sustained for a longer period of time before termination. Each cell in the body is programmed to respond to specific combinations of first and second messengers, and these messengers elicit distinct physiologic response in different cell types. For example, the neurotransmitter acetylcholine can cause heart muscle to relax, skeletal muscle to contract, and secretory cells to secrete.

cAMP is the predominant second messenger in all cells.

Many peptide hormones and catecholamines bind specific GPCRs to produce an almost immediate increase in the intracellular concentration of cAMP. For these ligands, the receptor is coupled to a stimulatory G protein ($G\alpha_s$), which activates AC, a large transmembrane protein that converts intracellular ATP to cAMP. An increase in cAMP activates **cAMP-dependent protein kinase** (also called **protein kinase A** or **PKA**) and also directly activates some calcium channels.

Some hormones act to decrease cAMP synthesis by binding receptors that are coupled to an inhibitory ($G\alpha_i$) G protein. The intracellular signal provided by cAMP is rapidly terminated by its hydrolysis to 5′AMP by a family of enzymes known as **phosphodiesterases** (**PDEs**), which can be activated by high levels of cyclic nucleotides or by other signal transduction processes.

Protein kinase A mediates the signaling effects of cAMP.

cAMP activates PKA, which, in turn, phosphorylates cellular proteins, ion channels, and transcription factors, altering their activity or function to achieve a cellular response. PKA is a tetramer consisting of two catalytic and two regulatory subunits in the inactive state. When cAMP in the cell increases, two molecules of cAMP bind to each of the regulatory subunits, causing them to dissociate from the catalytic subunits, activating PKA to (Fig. 2.18).

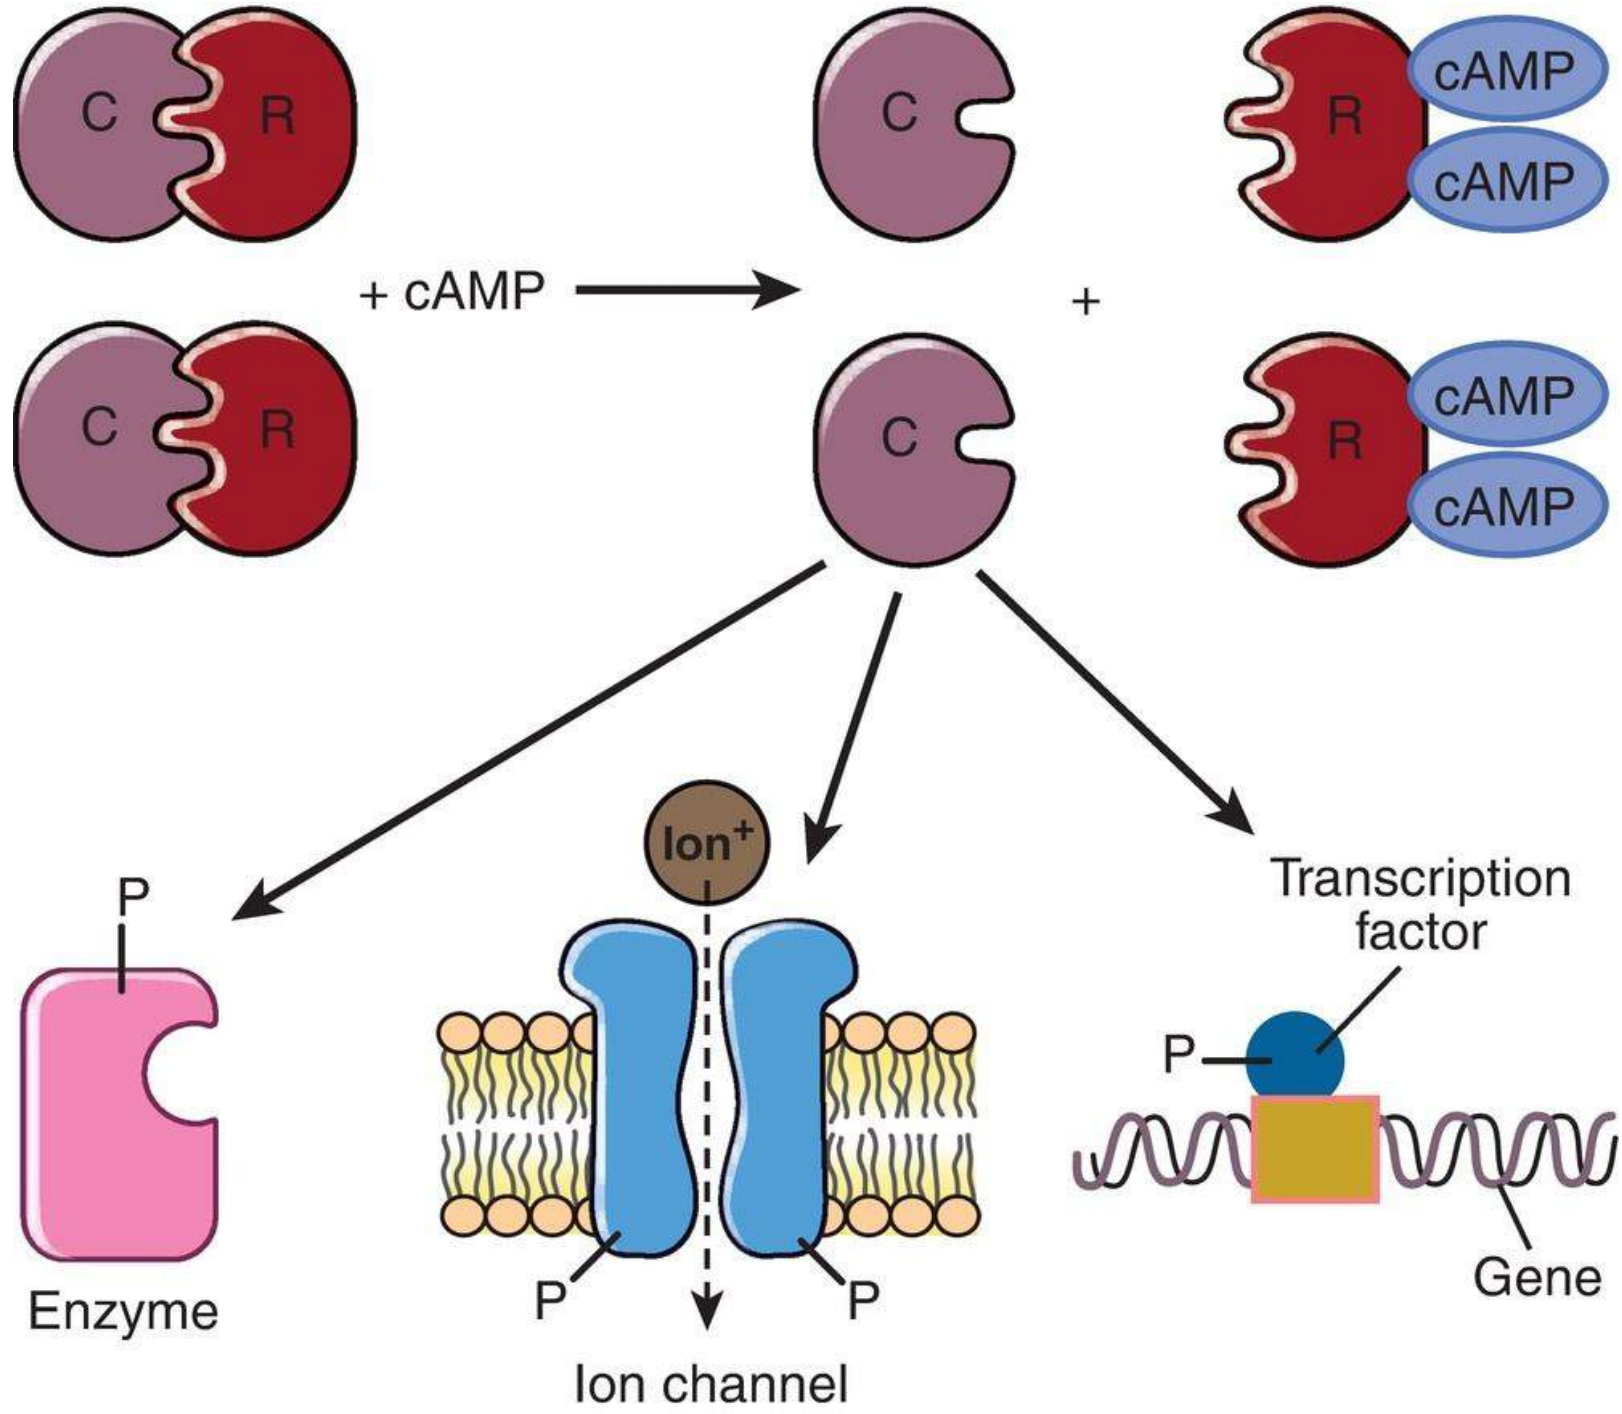

Figure 2.18 Activation and targets of protein kinase A. Inactive protein kinase A consists of two regulatory subunits complexed with two catalytic subunits. Activation of adenylyl cyclase results in increased cytosolic levels of cAMP. Two molecules of cAMP bind to each of the regulatory subunits, leading to the release of the active catalytic subunits. These subunits can then phosphorylate target

enzymes, ion channels, or transcription factors, resulting in a cellular response. R, regulatory subunit; C, catalytic subunit; P, phosphate group.

In some cell types, cAMP can directly bind to and alter the activity of ion channels. Cyclic nucleotide–gated ion channels may be regulated by either cAMP or cGMP and are especially important in the olfactory and visual systems. Odorant receptors are coupled to G proteins and, when stimulated by a specific odorant, activate AC to generate cAMP. The cAMP then binds a cAMP-gated ion channel that opens to allow calcium (Ca^{2+}) into the cell causing membrane “depolarization” (influx of positive ions) as part of the sensing of the odor.

cGMP and NO are important second messengers in smooth muscle and sensory cells.

The second messenger cGMP is generated by the enzyme guanylyl cyclase (GC). Protein kinase G (PKG) is the main target of cGMP, but it can also directly activate ion channels and pumps that modulate cytoplasmic Ca^{2+} levels in smooth muscle (see Chapters 8 and 15) and sensory tissue (see Chapter 6). There are two forms of GC, a soluble, cytoplasmic form and a membrane localized form. Soluble GC is a heterodimeric protein that contains two heme (an organic compound consisting of iron bound to a heterocyclic ring called *porphyrin*) prosthetic groups. Soluble GC is a target for the paracrine-signaling molecule nitric oxide (NO), which binds to the heme prosthetic groups and activates GC leading to the production of cGMP. NO produced by endothelial cells diffuses into smooth muscle cells to increase cGMP, activating PKG and ion channels, which reduce cytoplasmic Ca^{2+} concentrations, resulting in smooth muscle relaxation. Degradation of cGMP is mediated by a PDE activated by high levels of cGMP. The very short half-life of NO also serves to terminate the signaling pathway. NO was initially called **endothelial-derived relaxing factor** (**EDRF**). Research showing that EDRF was actually the gas NO resulted in a Nobel Prize in 1998 awarded to Robert Furchgott, Louis Ignarro, and Ferid Murad. NO is produced by the enzyme nitric oxide synthase (NOS) in a reaction that converts L-arginine to L-citrulline.

The transmembrane form of GC is a receptor for atrial natriuretic (ANP) peptide produced by cardiomyocytes in response to increased blood volume. Binding of ANP to transmembrane GC in the kidney increases cGMP, which stimulates Na^+ excretion to reduce blood volume (see Chapter 23).

Diacylglycerol and inositol trisphosphate are derived from lipid in the plasma membrane

Some GPCRs are coupled to the effector enzyme, **phospholipase C** (**PLC**), which is localized to the inner leaflet of the plasma membrane. Similar to other GPCRs, binding of a ligand or an agonist to the receptor results in activation of the associated G protein, usually $G\alpha_q$ (or G_q). Depending on the isoform of the G protein associated with the receptor, either the α or the βγ subunit may stimulate PLC, resulting in hydrolysis of the membrane phospholipid PIP_2 into **DAG** and **IP_3**. Both DAG and IP_3 serve as second messengers in the cell (Fig. 2.19).

Figure 2.19 The phosphatidylinositol second messenger system. **(A)** The successive phosphorylation of phosphatidylinositol (PI) leads to the generation of phosphatidylinositol 4,5-bisphosphate (PIP_2). Phospholipase C (PLC) catalyzes the breakdown of PIP_2 to inositol trisphosphate (IP_3) and 1,2-DAG, which are used for signaling and can be recycled to generate phosphatidylinositol. **(B)** Binding of hormone (H) to a G protein–coupled receptor (R) releases G_q, a G protein that couples the receptor to PLC. Activated PLC cleaves PIP_2 to IP_3 and DAG. IP_3 interacts with calcium release channels in the endoplasmic reticulum, to release calcium to the cytoplasm. Increased intracellular calcium activates calcium-dependent enzymes. An accumulation of DAG in the plasma membrane activates the calcium- and phospholipid-dependent enzyme protein kinase C and phosphorylation of its downstream targets. Protein-P, phosphorylated protein.

In its second messenger role, DAG accumulates in the plasma membrane and activates the membrane-bound calcium- and lipid-sensitive enzyme **protein kinase C** (**PKC**). When activated, PKC phosphorylates specific proteins in the cell to produce appropriate physiologic effects such as cell proliferation. Tumor-promoting **phorbol esters** that mimic the structure of DAG can bypass receptors to directly activate PKC, resulting in cellular proliferation.

IP_3 promotes the release of calcium ions into the cytoplasm by activation of endoplasmic or sarcoplasmic reticulum IP_3-gated calcium release channels (see Chapter 8). The concentration of free calcium ions in the cytoplasm of most cells is in the range of 10^{-7} M and may abruptly increase 1,000 times or more. The resulting increase in free cytoplasmic calcium synergizes with the action of DAG in the activation of some forms of PKC and may also activate many other calcium-dependent processes.

To terminate DAG and IP_3 signaling, the molecules are rapidly removed from the cytoplasm. IP_3 is dephosphorylated to inositol, which can be reused for phosphoinositide synthesis. DAG is converted to phosphatidic acid by the addition of a phosphate group to carbon number 3. Phosphatidic acid can then be used for the resynthesis of membrane inositol phospholipids (see Fig. 2.19). On removal of the IP_3 signal, calcium is quickly pumped back into its storage sites, restoring cytoplasmic calcium concentrations to low prestimulus levels.

Ceramide, another lipid second messenger, is generated from sphingomyelin through the action of plasma membrane–associated sphingomyelinase. Activation of sphingomyelinase occurs through binding of **cytokines** that mediate immune and inflammatory responses (e.g., **tumor necrosis factor** [**TNF**] and **interleukin-1**) to their receptors. These activated receptors then couple to sphingomyelinase, leading to its activation and generation of ceramide and subsequent activation of the MAPK pathway.

Cells use calcium as a second messenger by keeping resting intracellular calcium levels low.

The level of cytosolic calcium in an unstimulated cell is about 10,000 times lower than in the ECF (10^{-7} M vs. 10^{-3} M). This large calcium gradient is maintained by the limited permeability of the plasma membrane to calcium, by calcium transporters in the plasma membrane that extrude calcium, by calcium pumps in the membranes of intracellular organelles that store calcium, and by cytoplasmic and organellar proteins that bind calcium to buffer its free cytoplasmic concentration. Several plasma membrane ion channels serve to increase cytosolic calcium levels. Either these ion channels are voltage gated and open when the plasma membrane depolarizes or they may be controlled by PKA or PKC phosphorylation.

The endoplasmic reticulum has two other main types of ion channels that release calcium into the cytoplasm when activated. The small water-soluble molecule IP_3 activates the IP_3-gated **calcium release channel** in the membrane of the endoplasmic or sarcoplasmic (a specialized type of endoplasmic reticulum in smooth and striated muscle) reticulum. The activated channel opens to allow calcium to flow down a concentration gradient into the cytoplasm. The **ryanodine receptor** is structurally similar to the IP_3-gated channels and is located in the sarcoplasmic reticulum of muscle cells and neurons. In cardiac and skeletal muscle, ryanodine receptors release calcium to trigger muscle contraction when an action potential invades the transverse tubule system of these cells. Both types of channels are regulated by positive feedback, in which the released cytosolic calcium can bind to the receptor to enhance further calcium release. This form of positive feedback is referred to as **calcium-induced calcium release** and causes the calcium to be released suddenly in a spike, followed by a wavelike flow of the ion throughout the cytoplasm (see Chapters 8 and 13).

Increasing cytosolic free calcium activates many different signaling pathways and leads to numerous physiologic events, such as muscle contraction, neurotransmitter secretion, and cytoskeletal polymerization. Calcium acts as a second messenger in one of two ways:

- It binds directly to an effector target such as PKC to promote in its activation.
- It binds to an intermediary cytosolic calcium-binding protein such as calmodulin.

Calmodulin is a small protein (16 kDa) with four binding sites for calcium. The binding of calcium to calmodulin causes a dramatic conformational change and increases the affinity of the molecule for its effectors (Fig. 2.20). Calcium–calmodulin complexes bind to and activate a variety of cellular proteins, including protein kinases that are important in physiologic processes, such as smooth muscle contraction (myosin light-chain kinase; see Chapter 8) and hormone synthesis (aldosterone synthesis; see Chapter 33).

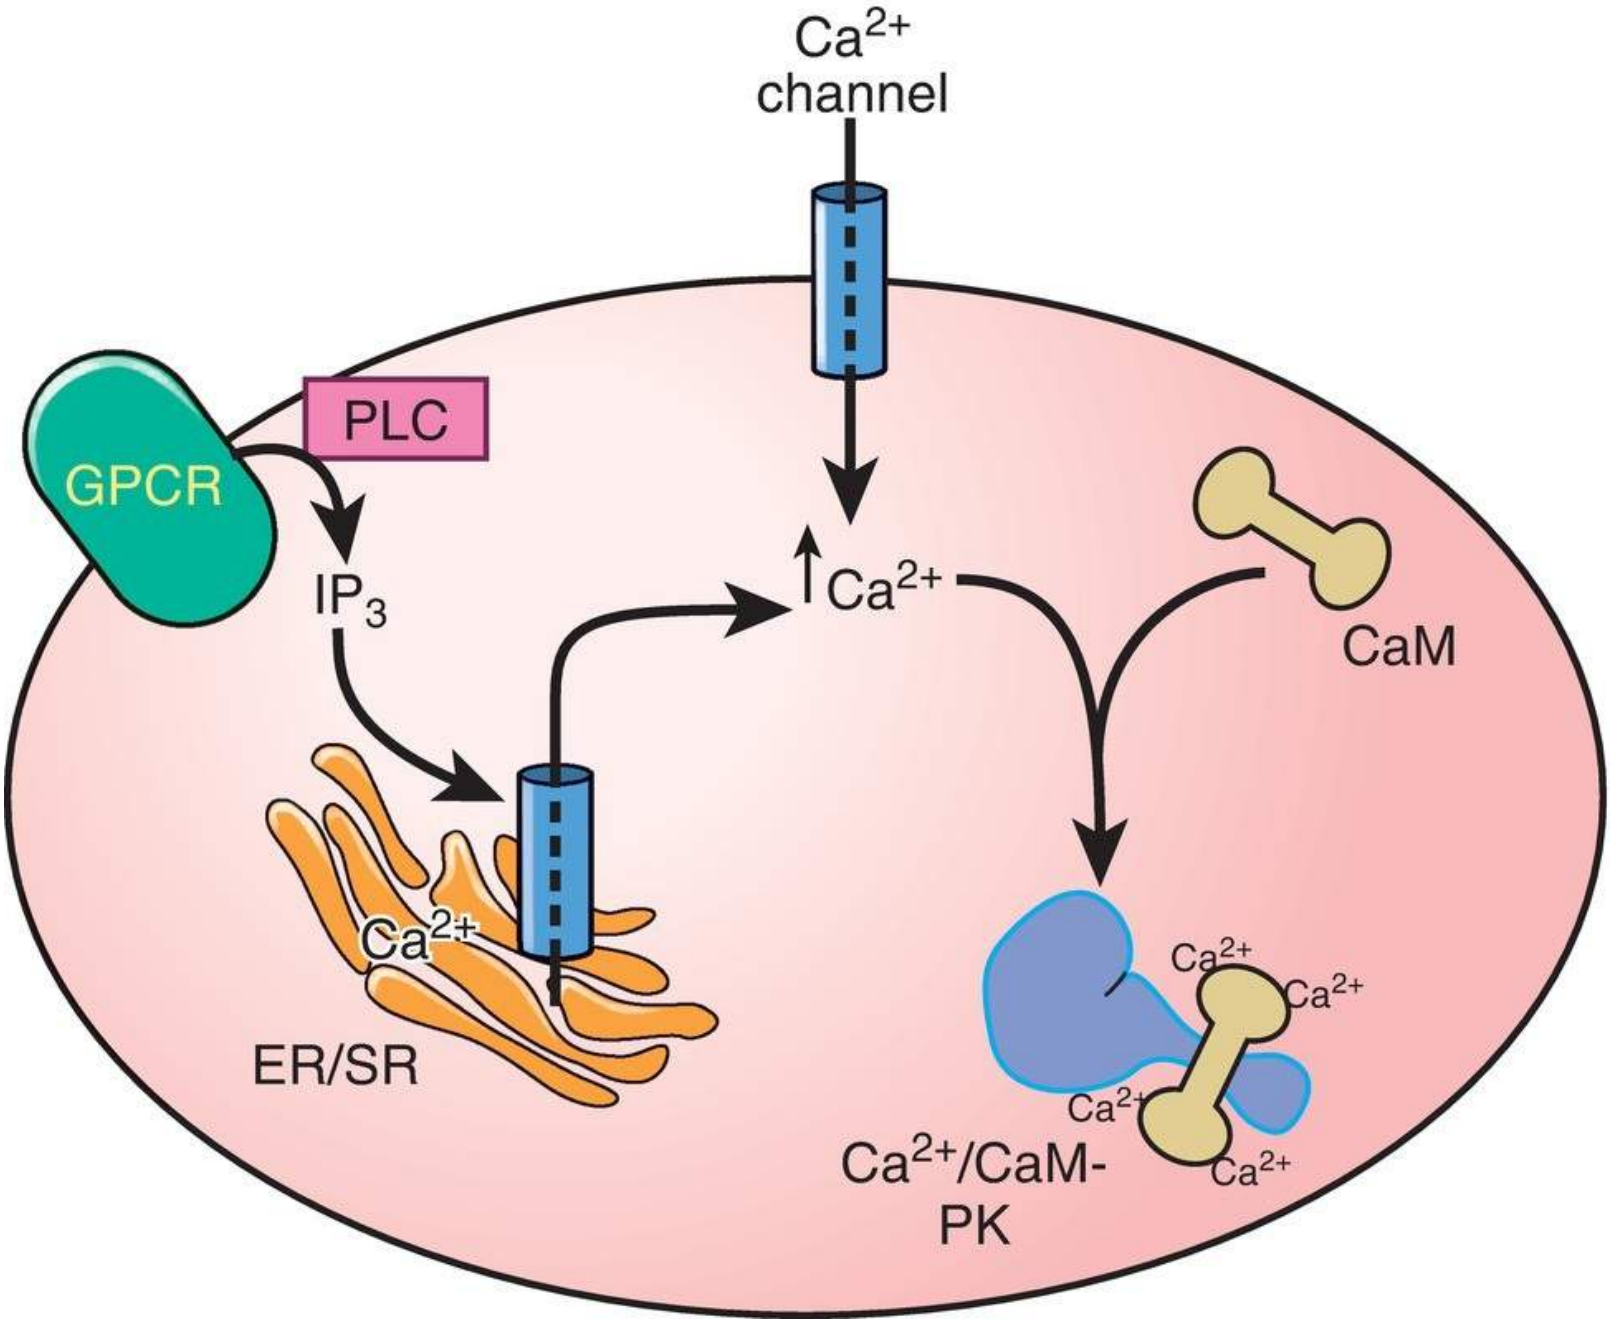

Figure 2.20 The role of calcium in intracellular signaling and activation of calcium–calmodulin-dependent protein kinases. Membrane-bound ion channels allow the entry of calcium from the extracellular space or release from internal stores (e.g., endoplasmic reticulum, sarcoplasmic reticulum in muscle cells, and mitochondria). Calcium can also be released from intracellular stores via the G-protein–mediated activation of phospholipase C (PLC) and the generation of inositol trisphosphate (IP_3). IP_3 releases calcium from the endoplasmic or sarcoplasmic reticulum in muscle cells by activating calcium ion channels. When intracellular calcium rises, four calcium ions complex with calmodulin protein (CaM) to induce a conformational change. Ca^{2+}/CaM can then bind to target proteins including Ca^{2+}/CaM-PKs, which then phosphorylate other substrates.

Two mechanisms operate to terminate calcium action: IP_3 is dephosphorylated by cellular phosphatases to inactivate it. In addition, the plasma membrane, endoplasmic reticulum, sarcoplasmic reticulum, and mitochondrial membranes all have ATP-driven calcium pumps that transport the free calcium out of the cytosol to the extracellular space or into an intracellular organelle. Lowering cytosolic calcium concentrations shifts the equilibrium to release calcium from calmodulin, which then dissociates from the

various proteins that were activated, and the cell returns to its basal state.

INTEGRATED MEDICAL SCIENCES

Phosphodiesterase, Angina, Pulmonary Hypertension, and Erectile Dysfunction—What is the Link?

A phosphodiesterase (PDE) is an enzyme that hydrolyzes a phosphodiester bond. Cyclic nucleotide PDEs are important in the clinical setting as they control the cellular levels of the second messengers, cyclic adenosine and guanosine monophosphate (cAMP and cGMP), and the signal transduction pathways modulated by these molecules. There are many cyclic nucleotide PDEs, which are classified according to sequence, regulation, substrate specificity, and tissue distribution. The tissue-specific expression of PDEs presents an opportunity to target a specific PDE with an inhibitory or activating drug.

Therapeutic agents for angina pectoris (severe chest pain resulting from insufficient blood supply to cardiovascular tissues) include the administration of nitrates, a commonly used agent that reduces myocardial oxygen demand. Nitrates act as an exogenous source of nitric oxide (NO), which stimulates soluble GCs to increase cGMP, transducing a signal that promotes relaxation of vascular smooth muscle in arteries and veins. The salutary effect of nitrates in treating myocardial ischemia is to dilate veins, which allows blood to translocate from inside the ventricles into the peripheral tissues. This reduces stretch and strain on the heart, which reduces myocardial oxygen demand. A common side effect of nitrates is **tachyphylaxis**, or reduced responsiveness to a chronically used drug. The search for new drugs to treat angina pectoris and other similar cardiovascular diseases led to the discovery of sildenafil, which is now marketed under the trade name Viagra. Sildenafil is a fairly selective inhibitor of PDE5, and its administration enhances cGMP levels in vascular smooth muscle cells, leading to vasodilation. Unfortunately, the relatively short half-life thwarted the usefulness of this drug as a practical treatment for chronic angina. In addition, several side effects were noted during clinical trials including the ability of sildenafil to augment the vasodilatory effects of nitrates. One other interesting, common side effect noted was penile erection, and subsequent clinical trials validated the use of this drug as an effective therapeutic agent for **erectile dysfunction** (**ED**).

There are many clinical causes of ED, including psychological conditions such as depression. Common clinical conditions associated with ED include vascular disease; diabetes; neurologic conditions such as spinal cord injury, multiple sclerosis, and Parkinson disease; and numerous inflammatory conditions. During sexual stimulation, the penile cavernosal arteries relax and dilate, allowing increased blood flow. This increase in blood volume and compression of the trabecular muscle result in collapse and obstruction of venous outflow to produce a rigid erection. For an erection to occur, NO activates soluble guanylate cyclase causing increased synthesis of cGMP. Cellular levels of cGMP reflect a balance of activities between NO production by NO synthase and degradation of cGMP by cyclic PDE. Thus, the use of a transient inhibitor of PDE5, the main PDE in the cavernosal arteries and trabecular muscle, provides a rational, temporary vasodilation in those tissues.

Following its wide use as a therapeutic drug for ED, another application for sildenafil was discovered: the treatment of pulmonary hypertension under the trade name Revatio. Pulmonary hypertension results from high blood pressure in the pulmonary circulation. It is a highly progressive disease with a poor prognosis due to the ensuing right heart dysfunction and is often fatal. The usefulness of Revatio is based on the findings that in animal models of pulmonary hypertension, the levels of PDE5 increase in the pulmonary aorta and other arteries of the lung, leading to decreased cGMP and increased tone in this vessel. Thus, administration of sildenafil has a beneficial effect by increasing cGMP and relaxation. As more is learned about PDEs, it is likely that additional uses for sildenafil and other compounds that target cyclic PDEs will be discovered. ■

Chapter Summary

- Homeostasis is the maintenance of steady states in the body by coordinated physiologic mechanisms.
- Negative and positive feedbacks are used to modulate the body's responses to changes in the environment.
- Steady state and equilibrium are distinct conditions. Steady state is a condition that does not change over time, whereas equilibrium represents a balance between opposing forces.
- Macromolecules cross the plasma membrane by endocytosis and exocytosis.
- Passive movement of a solute across a membrane dissipates the gradient (driving force) and reaches an equilibrium at which point there is no net movement of solute.
- Simple diffusion is the passage of lipid-soluble solutes across the plasma membrane by diffusion through the lipid bilayer.
- Facilitated diffusion is the passage of water-soluble solutes and ions through a hydrophilic pathway created by a membrane-spanning integral protein.
- Facilitated diffusion of small ions is mediated by specific pores and ion channel proteins.
- Active transport uses a metabolic energy source to move solutes against gradients, and the process prevents a state of equilibrium.
- Polarized organization of epithelial cells ensures directional movement of solutes and water across the epithelial layer.
- Water crosses plasma membranes rapidly via channel proteins termed aquaporins. Water movement is a passive process driven by differences in osmotic pressure.
- Cells regulate their volume by moving solutes in or out to drive osmotic entry or exit of water, respectively.
- The driving force for ion transport is the sum of the electrical and chemical gradients, known as the gradient of electrochemical potential across the membrane.
- The resting membrane potential is determined by the passive movements of several ions through nongated channels, which are always open. It is described most accurately by the Goldman equation, which takes into account the differences in membrane permeability of different ions. In a muscle cell, for example, the membrane permeability to Na^+ is low compared with K^+ and the resting membrane potential is a result primarily of passive exit of K^+.
- Cellular communication is essential to integrate and coordinate the systems of the body so they can participate in different functions.
- A hallmark of cellular signaling is that it is regulated with a variety of mechanisms to both activate and terminate signal transduction.
- Activators of signal transduction pathways include ions, gases, small peptides, protein hormones, metabolites, and steroids.
- Receptors are the receivers of signaling molecules; they are located either on the plasma membrane or within the cell.
- Second messengers are important for amplification and flow of the signal received by plasma membrane receptors.

Chapter Review Questions

1. If a region or compartment is in a steady state with respect to a particular substance, then:

A. The amount of the substance in the compartment is increasing.
B. The amount of the substance in the compartment is decreasing.
C. The amount of the substance in the compartment does not change with respect to time.
D. There is no movement into or out of the compartment.
E. The compartment must be in equilibrium with its surroundings.

The correct answer is C. In a steady state, the amount or concentration of a substance in a compartment does not change with respect to time. Although there may be considerable movements into and out of the compartment, there is no net gain or loss. Steady states in the body often do not represent an equilibrium condition, but they are displaced from equilibrium by the constant expenditure of metabolic energy.

2. Parathyroid hormone (PTH) acts on osteoblasts in bone and tubular cells in the kidneys. It binds to the PTH receptor to cause the release of calcium from bone to the body, a process called osteolysis. If you treated an animal with PTH, and measure an increase in cAMP levels in bone tissue, what kind of receptor would you predict that PTH binds to?

A. Steroid
B. Tyrosine kinase
C. Nuclear
D. G protein coupled
E. Orphan

The correct answer is D. Generation of cAMP in cells occurs in response to activation of adenylyl cyclase, an effector that is coupled to GPCRs. The other answers represent different intracellular signaling mechanisms that do not require generation of cAMP.

3. A single cell within a culture of freshly isolated cardiac muscle cells is injected with a fluorescent dye that cannot cross cell membranes. Within minutes, several adjacent cells become fluorescent. The most likely explanation for this observation is the presence of:

A. Ryanodine receptors.
B. IP3 receptors.
C. Transverse tubules.
D. Desmosomes.
E. Gap junctions.

The correct answer is E. Cardiac muscle cells have many gap junctions that allow the rapid transmission of electrical activity and the coordination of heart muscle contraction. Gap junctions are pores composed of paired connexons that allow the passage of ions, nucleotides, and other small molecules between cells.

4. Treatment of intestinal epithelial cells with the mitochondrial toxin 2,4 dinitrophenol results in loss of ATP synthesis. Transport of glucose from the apical (luminal) side of the cell to basolateral side of the intestinal cell will be reduced because:

A. GLUT2 will not be able to transport glucose across apical membrane.
B. Na^+ gradient across apical membrane to inside of cell will be dissipated.
C. SLGT on apical membrane will not be able to transport Na^+ out of the cell.
D. Na^+/K^+-ATPase on basolateral membrane will not be able to transport glucose out of cell.
E. K^+ gradient across basolateral membrane to inside of cell will increase.

The correct answer is B. Loss of ATP will stop Na^+/K^+-ATPase on the basolateral membrane from expelling Na^+ out of the cell; thus, the Na^+ gradient across apical membrane will be dissipated and SLGT will not be able to cotransport Na^+ and glucose. GLUT2 transports glucose across the basolateral membrane and SLGT transports Na^+ into the cell, not out of the cell. Na^+/K^+-ATPase does not transport glucose and loss of Na^+/K^+-ATPase will decrease the K^+ gradient across the basolateral membrane.

Clinical Application Exercises 2.1

COLLAPSING FOOTBALL PLAYER

A 16-year-old boy arrives in a Texas hospital emergency room in a semiconscious state. He was transported there after collapsing during football practice. The temperature that August afternoon had reached 102°C and the team had been practicing for nearly 4 hours before the young man collapsed. On the way to the hospital, an IV was inserted, and he received intravenous fluids. He is complaining of dizziness when he sits up, cramping, and nausea and had vomited before being transported to the hospital. Upon examination, the boy is found to be in excellent general physical condition, although his heart rate and temperature are elevated and he is unable to give a urine sample. He claims that he only had a few sips of water during practice and just suddenly blacked out. After oral rehydration for several hours, the young man is released.

QUESTIONS

1. What disorder is consistent with this patient's symptoms?
2. How should this be treated to return the patient to a homeostatic condition?

ANSWERS

1. Symptoms of this patient are consistent with exercise-induced dehydration, a serious and potentially life-threatening condition in which the volume of water within the body compartments is insufficient for normal functions. Many athletes do not adequately maintain hydration during exercise and consequently experience the adverse effects of dehydration, which reduces the ability to tolerate prolonged exercise.
2. Dehydration is a condition that occurs when the loss of body fluids and water is greater than the amount that is taken into the body. The amount of water lost from the body by sweating depends on both the environment and the body fluid composition before exercise. The early effects of dehydration are to increase heart rate, and this impairs heat transfer from muscle contraction to skin where it is dissipated for cooling. Sweating is the body's way of getting rid of heat that is produced by muscle exercise. Sweat glands produce a fluid that is derived from the interstitial spaces and capillaries in the skin and is similar to plasma in that it is composed principally of water and sodium ions. As sweat evaporates, it dissipates the excess heat to cool the body; the dryer the air, the quicker evaporation and cooling occur to help maintain homeostasis. The water lost by sweating comes from the fluid compartments of the body, thus there is a net increase in the concentration of the electrolytes (ions) in the body fluid creating hypertonicity (having a higher concentration of electrolytes inside the fluid compartments than outside). If the water lost due to exercise and sweating is not replaced, dehydration can occur. The solution to the problem is to drink plenty of fluids before and during exercise. Without adequate water replacement, the water

and electrolyte imbalance can lead to heat stroke and even death. Rarely is there a necessity to replace lost sodium, although many sports drinks contain both sodium and potassium. The reason for this is that ingested water, which is rapidly absorbed through the gut, results in adequate salt replacement by absorption from the contents of the digestive tract.

PART **II** NEUROMUSCULAR PHYSIOLOGY

3 Action Potential, Synaptic Transmission, and Nerve Function

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how the organization of the nervous system supports afferent and efferent function.
- Describe how the access of components from the blood to the brain is restricted.
- Explain the specialized functions of the different cell types of the nervous system.
- Explain the mechanism by which components are transported between the soma and neuronal terminals.
- Relate ion channel function to membrane potentials.
- Explain how movement of ions through ion channels can produce an action potential.
- Explain why an action potential is unidirectional and how it propagates without decrement.
- Describe how myelination and diameter can affect axonal conduction velocity.
- Describe how electrical and chemical transmission differ.
- Explain how the specializations of the synapse contribute to synaptic transmission.
- Compare ionotropic and metabotropic receptors in terms of cell signaling.
- Describe different synaptic transmitters in terms of their signaling, function, and role in disease.

THE NERVOUS SYSTEM

The nervous system is comprised of cells in the brain and spinal cord and extends throughout the body via a system of nerves and **ganglia** (clusters of neurons and support cells located outside of the brain and spinal cord). Together the brain and spinal cord are referred to as the **central nervous system** (**CNS**), while the nerves and ganglia throughout the rest of the body comprise the **peripheral nervous system** (**PNS**). The PNS has both **afferent** and **efferent** functions. The afferent function consists of collecting information from sensory and organ systems and transmitting that information to the CNS for processing. The efferent function consists of communicating with organ systems to maintain or adjust function as well as controlling motor function. The PNS also can be divided into the motor system (efferent), sensory systems (afferent), and autonomic nervous system (both efferent and afferent). These will each be covered in subsequent chapters.

Access to the central nervous system is restricted by the blood–brain barrier.

Access of molecules into the CNS from the blood is limited by the **blood–brain barrier** (**BBB**). The BBB is the result of a layer of capillary endothelial cells connected by tight junctions and surrounded by astrocytes cells (Fig. 3.1). Together, these effectively restrict transepithelial permeability and serve to protect the brain from infection and toxins. Molecules such as water, CO_2, O_2, amino acids, and glucose have essentially free access across these cells via carrier-mediated processes and active transport. Lipophilic molecules can also freely cross the BBB. In addition to the BBB, there is also a comparable blood–cerebrospinal fluid (CSF) barrier where the epithelial cells of the choroid plexus form tight junctions and restrict access from the blood into the CSF.

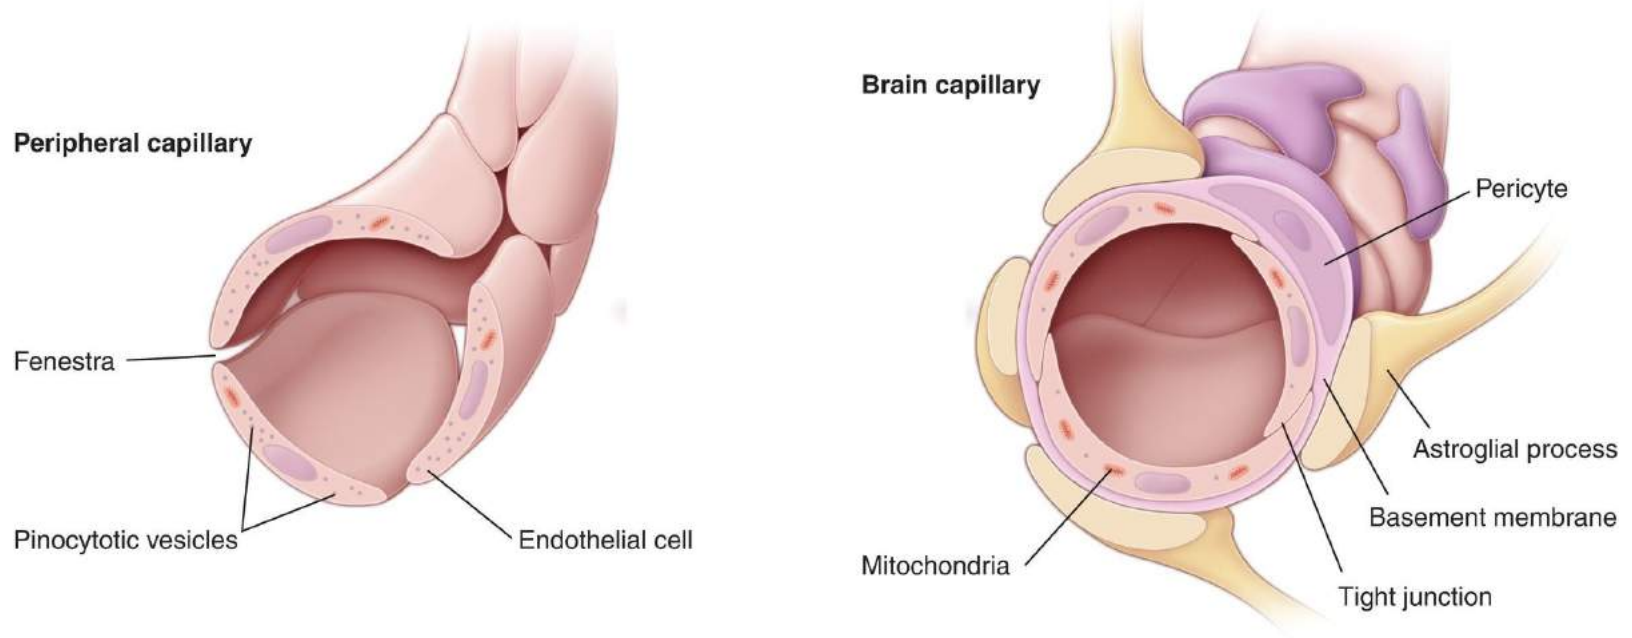

Figure 3.1 The blood–brain barrier restricts access from the capillary into the brain. In the periphery, capillary endothelial cells have gaps (termed *fenestrae*) between them and use intracellular pinocytotic vesicles to facilitate the transcapillary transport of fluid and soluble molecules. In contrast, CNS vessels are sealed by tight junctions between the endothelial cells. The cells have fewer pinocytotic vesicles and are surrounded by pericytes and astroglial processes. In addition, capillary endothelial cells in the CNS have more mitochondria than those in systemic vessels; these mitochondria may reflect the energy requirements necessary for CNS endothelial cells to transport certain molecules into the CNS and transport other molecules out of the CNS.

The primary cell types in the nervous system, neurons and glia, differ in function and morphology.

The primary cell types found in the nervous system are **neurons** and **glia** (Fig. 3.2). Neurons mainly function to store, communicate, and integrate information. Glia support this function and can be divided into multiple cell groups based on morphology and function. **Microglia** are found in the CNS and are related in origin and function to macrophages. They serve an immune function in that they phagocytose damaged cells, invade microorganisms, and secrete immune mediators. **Schwann cells** are found in the PNS and form **myelin**, which wraps around neuronal processes (axons) in a manner that contributes to faster signal conduction along the nerve. **Oligodendrocytes** perform a similar function in the CNS. This myelin sheath can be disrupted, as happens with multiple sclerosis, resulting in abnormalities in signal conduction. The myelin surrounding the axons is responsible for CNS **white matter**: the portions of the CNS that histologically appear white rather than gray. The **gray matter** is composed of cell bodies and nonmyelin surrounded processes. **Astrocytes** are star-shaped cells in the CNS that extend processes to blood vessels and neurons. The processes along blood vessels contribute to the blood–brain barrier. Astrocytic processes along neurons support neuronal function by providing metabolic support, regulating blood flow, helping to maintain appropriate extracellular concentrations of certain ions such as potassium, and recycling signaling molecules such as glutamate and GABA from the extracellular space back to the neuron. **Ependymal cells** line the ventricles of the brain and central canal of the spinal cord and contribute to the blood–CSF barrier. Glial cells are more numerous than neurons and can proliferate particularly in response to injury or infection. This ability to proliferate can also go awry and result in gliomas: tumors derived from glial cells.

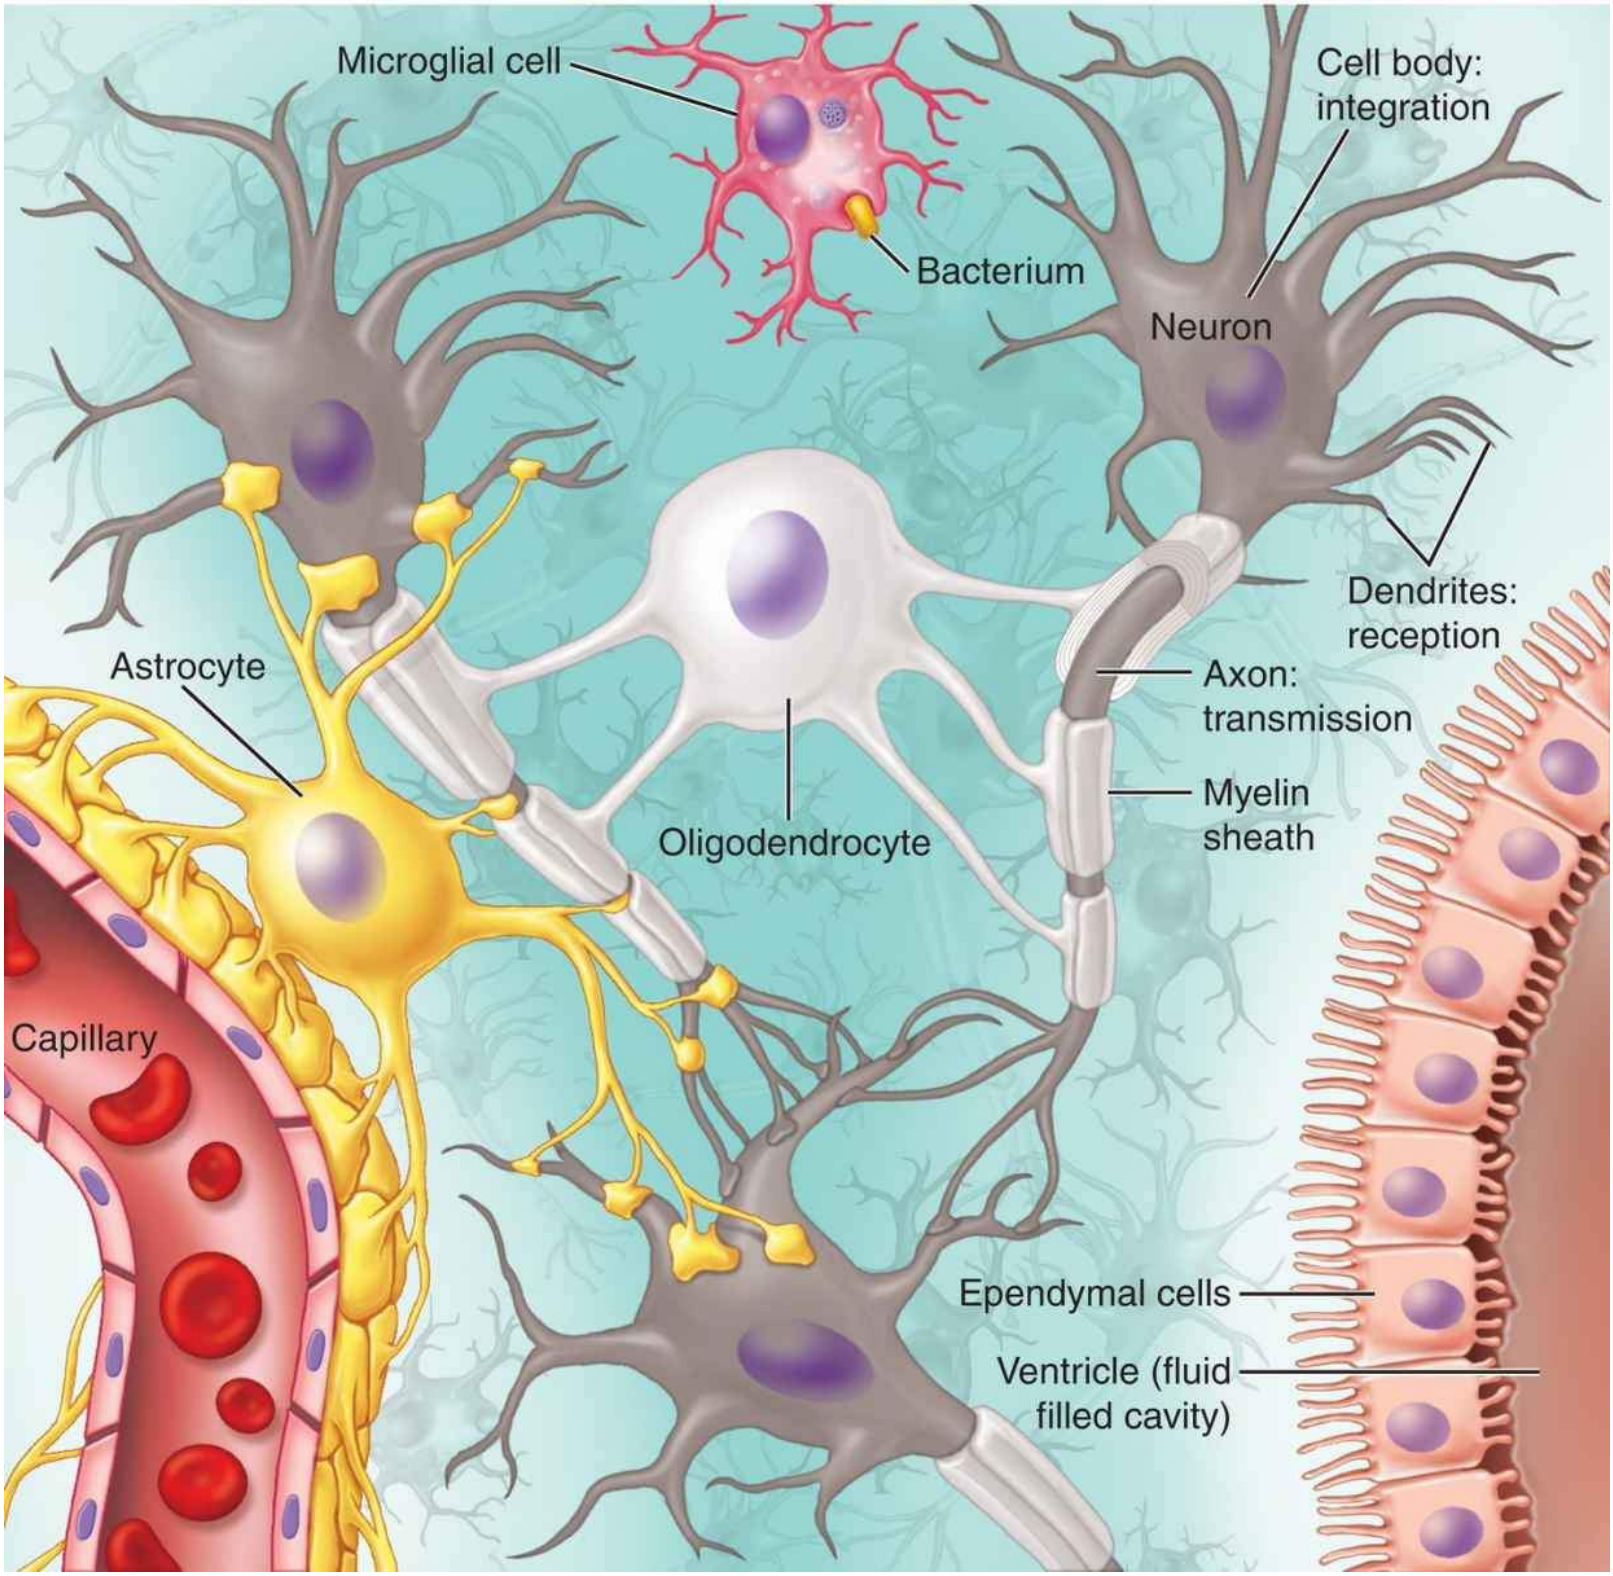

Figure 3.2 Glial cell types in the CNS. Microglia serve an immune function in the CNS similar to that of macrophages in the PNS. Oligodendrocytes sheath central neuronal axons with myelin, which is accomplished by Schwann cells in the PNS. Astrocytes have many functions within the CNS including providing neuronal support and contributing to the blood–brain barrier. Ependymal cells contribute to a blood–CSF barrier.

Neurons are less numerous than glial cells and, like glia, can be classified into different types based on morphology and function (Fig. 3.3). All neurons have a **soma** (cell body) containing the nucleus and primary organelles such as the endoplasmic reticulum and Golgi apparatus. From the soma arise processes. In the case of **unipolar** cells, there is only one process that extends from the soma, whereas

bipolar cells have two processes and **multipolar** cells have multiple processes. In all of these, one process is the **axon**. The portion of the axon that extends from the cell body, the **axon hillock**, is generally a thickened area. This narrows into the initial segment of the axon. Many axons are wrapped in a **myelin sheath** by Schwann cells (PNS) or oligodendrocytes (CNS). These myelin sheaths are made of lipids and proteins and are wound around the axon at regular intervals. In between myelin sheaths are the **nodes of Ranvier**: short segments of the axon that are unmyelinated. The myelin sheath contributes to faster signal conduction along the axon. At the end of the axon is a specialized segment referred to as the **presynaptic terminal** or **bouton**. The axon functions to transmit information in the form of an action potential and to transport materials to the presynaptic terminal. The axon has an efferent function in that it releases signaling molecules to transmit information. The other process that extends from the soma is the **dendrite**. The neuron may have one process sharing dendritic and axonal function (unipolar), one process that is a dendrite (bipolar), or multiple dendritic processes (multipolar). In the case of multipolar neurons, each dendritic branch can have branches off of it producing extensive arborization. Dendrites serve an afferent function in that they gather information and transmit it to the soma. They form **postsynaptic terminals** receiving information released from the axon's presynaptic terminal. Dendrites can also receive information from glia, immune cells, and other cells. The dendrite–soma–axon forms the basic structure of the neuron. The specialized region in which molecules are released from the axon and interact with dendrites is referred to as the **synapse**. A simplified schematic of a synapse consists of a presynaptic terminal at the end of an axon adjacent to a postsynaptic terminal at the end of a dendrite. The 20 nm extracellular space between the terminals is the **synaptic cleft**. The presynaptic terminal contains vesicles that release chemical messengers into the synaptic cleft where they can then interact with receptors that are located on the postsynaptic terminal. Synaptic transmission is discussed below.

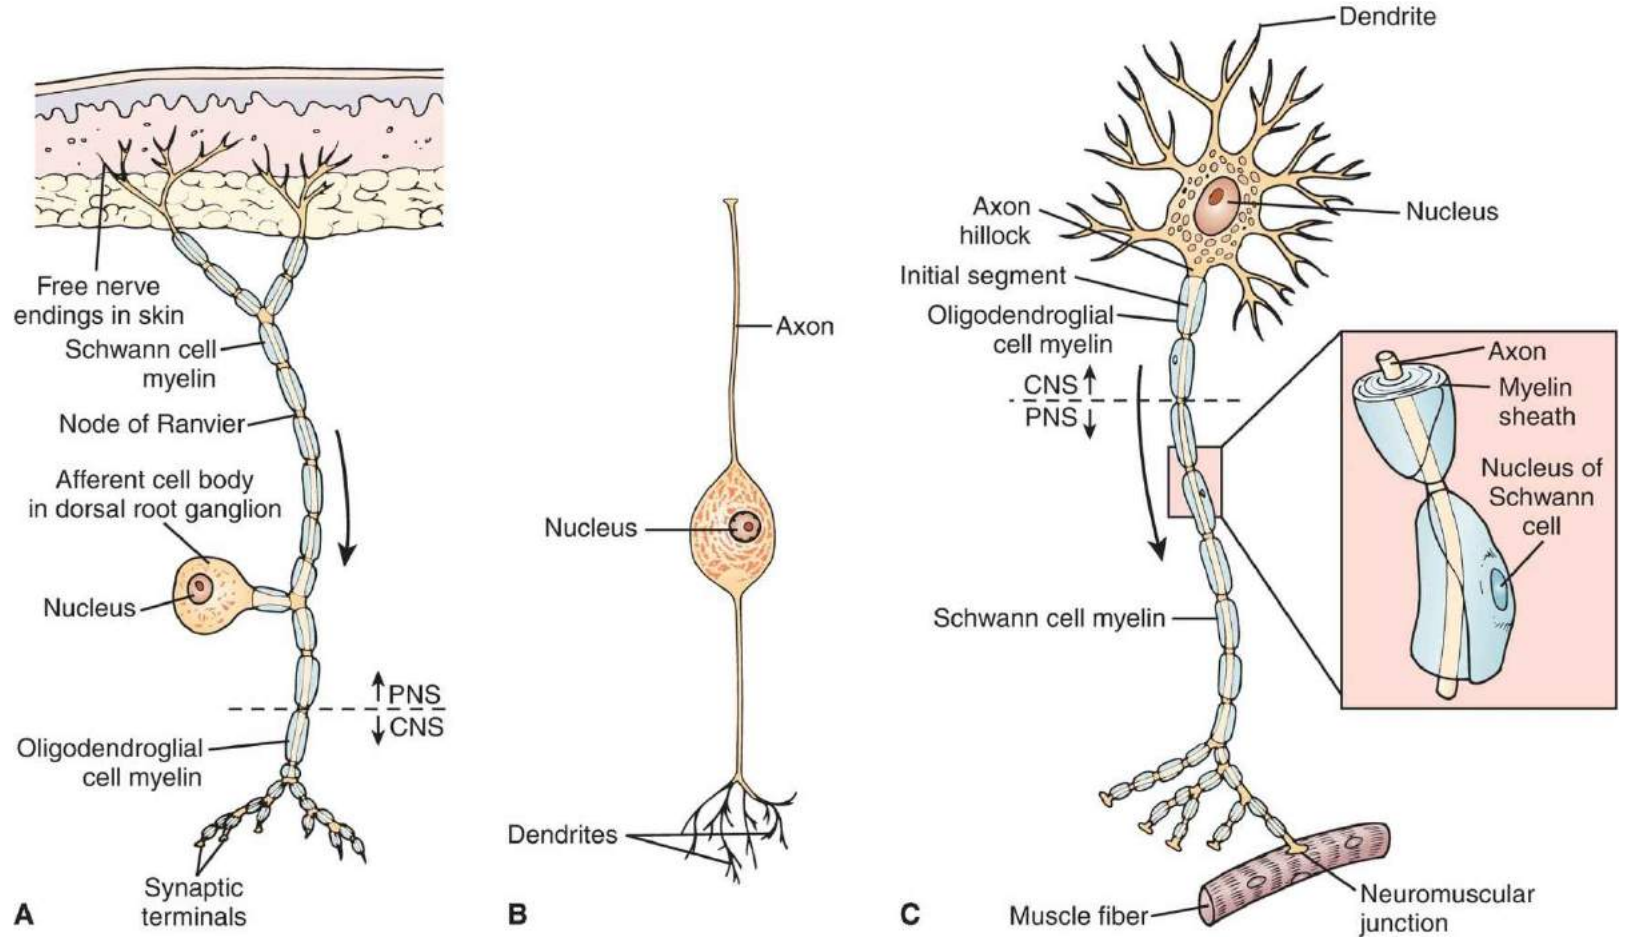

Figure 3.3 Morphological classification of neurons. **(A)** Unipolar and pseudounipolar neurons have a

single process emanating from the soma. Generally, pseudounipolar neurons serve an afferent sensory function: receiving information from the periphery and transmitting that information to the CNS. **(B)** Bipolar neurons have a single axon and a single dendrite emanating from the soma. These are relatively rare but are utilized in some regions such as the retina and other special senses. **(C)** Multipolar neurons have a single axon and many dendrites emanating from the soma. These are the most common neuronal type and are found in the brain, spinal cord, and autonomic ganglia.

CLINICAL FOCUS 3.1

Multiple Sclerosis

Multiple sclerosis (MS) is an autoimmune disease that is characterized by demyelination of axons in the CNS. It affects more women than men with onset in young to middle adulthood. Most cases of MS proceed in a relapsing–remitting pattern where an individual experiences symptoms for a few days followed by a few months that are symptom free. Some individuals do not fully recover between episodes but demonstrate continued deterioration such that progressive attacks are more severe. A small percentage of individuals experience a progressive disease without remission. The etiology of the disease is not well understood but may be influenced by exposure to the Epstein-Barr virus and vitamin D deficiency. Common symptoms experienced in the early phases of the disease include visual disturbances, tingling sensations, and motor disturbances.

The demyelination that occurs during MS is due to production of antibodies that target oligodendroctyes. This leads to their inability to fully myelinate axons and can result in damage to axonal processes. Other immune cells also infiltrate the damaged area along with astrocytes, which can result in scarring around the damaged axon. During the remission phase, remyelination can occur. However, over time the ability to effectively remyelinate the axon decreases.

The decreased myelination impacts the conduction velocity along that axon. Normally the electrical impulse undergoes saltatory conduction (i.e., jumping from one node of Ranvier to the next). This results in fast conduction and a signal that does not undergo diminution as it progresses. Because of disruption to the myelin, the ability of the axon to propagate the electrical signal is disrupted. Either a stronger signal is now needed to reach its destination or the signal simply is not conducted.

The symptoms an individual experiences will depend on the location of the myelin disruption. The disease commonly affects myelination of optic nerves, spinal tracts, and brain regions. Lesions in the optic nerves can result in blurred and double vision. Demyelination of axons forming the motor tracts from the spinal cord to the brain can result in muscle weakness, uncontrolled movement, and eventual paralysis. Other common symptoms include paresthesia (tingling sensation), reduced sensations, impaired bladder function, and cognitive dysfunction such as memory loss and impaired attention.

Diagnosis of MS is based on symptom patterns along with magnetic resonance imaging (MRI) and nerve conduction tests. Using MRI, lesions in the central white matter can be identified. However, it is not uncommon to identify white matter lesions that are not associated with symptoms. Nerve conduction tests are used to determine conduction velocity after stimulation of peripheral nerves. Treatment of MS includes using strong anti-inflammatory medication during acute exacerbations and immunomodulators

to decrease the frequency and progression of future exacerbations. ■

Neuronal transport is mediated by cytoskeletal components and occurs to and from the soma.

Like other cells, the nucleus and protein synthesis machinery is located in the neuronal soma. Because the synapse can be as far as 80 cm from the soma, there must be a mechanism of transport to move proteins to the terminals. As occurs in other cells, proteins are synthesized from mRNA by the ribosomes on the rough endoplasmic reticulum and then packaged into vesicles by the Golgi apparatus (Fig. 3.4). Many proteins are constitutively expressed, whereas the expression of others are induced after the activation of specific transcription factors. Once packaged, the proteins are ready for transport to the terminals via the neuronal cytoskeleton. The neuronal cytoskeleton consists of neurofilaments, microfilaments, and microtubules. **Neurofilaments** are the intermediate-sized component of the cytoskeleton and provide structural rigidity to the axon. **Microfilaments** are smaller in diameter than neurofilaments and are involved in extension of dendrites and axons during development, structural support, and organelle transport. They are composed of actin, which provides a track for its contractile partner myosin and enables cell migration/neuronal process extension. **Microtubules** are the largest in diameter and play a crucial role in transport of organelles and other material from the soma to the processes. This is aided by associated proteins, such as kinesin and dynein, which interact with the microtubule and the organelle to move them in different directions. The transport of cellular materials can occur in an anterograde or retrograde fashion. **Anterograde transport** occurs when organelles and other material are transported from the soma to the neuronal processes. Anterograde transport can be either slow at a rate of ~1 mm/d or fast at a rate of ~400 mm/d. Fast anterograde transport occurs for organelles, vesicles, and membrane glycoproteins. One of the organelles that undergoes transport to the processes is mitochondria. As in other cells, mitochondria are responsible for energy production by providing the cell with ATP. They also serve to maintain calcium homeostasis, can generate reactive oxygen species, and are the site of monoamine oxidase, which is involved in the degradation of monoamine neurotransmitters. In these ways, mitochondria transported to the axon contribute to neuronal signaling. **Retrograde transport**, about 200 mm/d, occurs when material is transported from the process to the soma in order to, for example, interact with nuclear receptors or to be degraded by lysosomes.

Figure 3.4 Axonal transport. The neuronal cytoskeleton provides rigidity to the axon and is involved in the transport of components to and from the soma. Organelles, vesicles, and other material moves along microtubule from the soma to the axonal terminal in an anterograde fashion. Material can also be transported in a retrograde fashion to the soma. ER, endoplasmic reticulum.

ACTION POTENTIALS

Just as there needs to be a mechanism for transporting cellular materials between the soma and neuronal processes, neurons also need a mechanism by which a signal is propagated from the dendritic nerve ending to the presynaptic terminal of the axon where neurotransmitters are stored and from which they are released. This propagation of signal is accomplished electrically through opening of voltage-gated ion channels, depolarization of neuronal membranes, and subsequent production of action potentials.

A neuron's resting membrane potential is heavily influenced by the electrochemical gradient of potassium ions.

As discussed in Chapter 2, channels that are permeable to specific ions reside within the plasma membrane. Some of these channels are sensitive to voltage and open and close at different membrane potentials. The **resting membrane potential** of the neuron is −70 mV (Fig. 3.5). This is heavily influenced by potassium's **equilibrium potential** (i.e., the concentration at which there is a balance between the forces due to the concentration gradient for the ion and the electrical gradient across the membrane), which can be calculated by the **Nernst equation** (see Chapter 2). At rest, there is a higher concentration of potassium ions inside the cell and a higher concentration of sodium ions outside the cell. The potassium concentration is ~140 mM intracellularly compared with 4 mM extracellularly, whereas sodium is 14 mM intracellularly and 140 mM extracellularly. Certain potassium channel subtypes are open at rest allowing potassium to leak out and thus establishing a negative charge differential across the plasma membrane. The **Na^+/K^+-ATPase** continually pumps K^+ back into the cell thus maintaining the high intracellular K^+ concentration and its concentration gradient. The maintenance of the K^+ and Na^+ concentration gradients are critical for the production of action potentials.

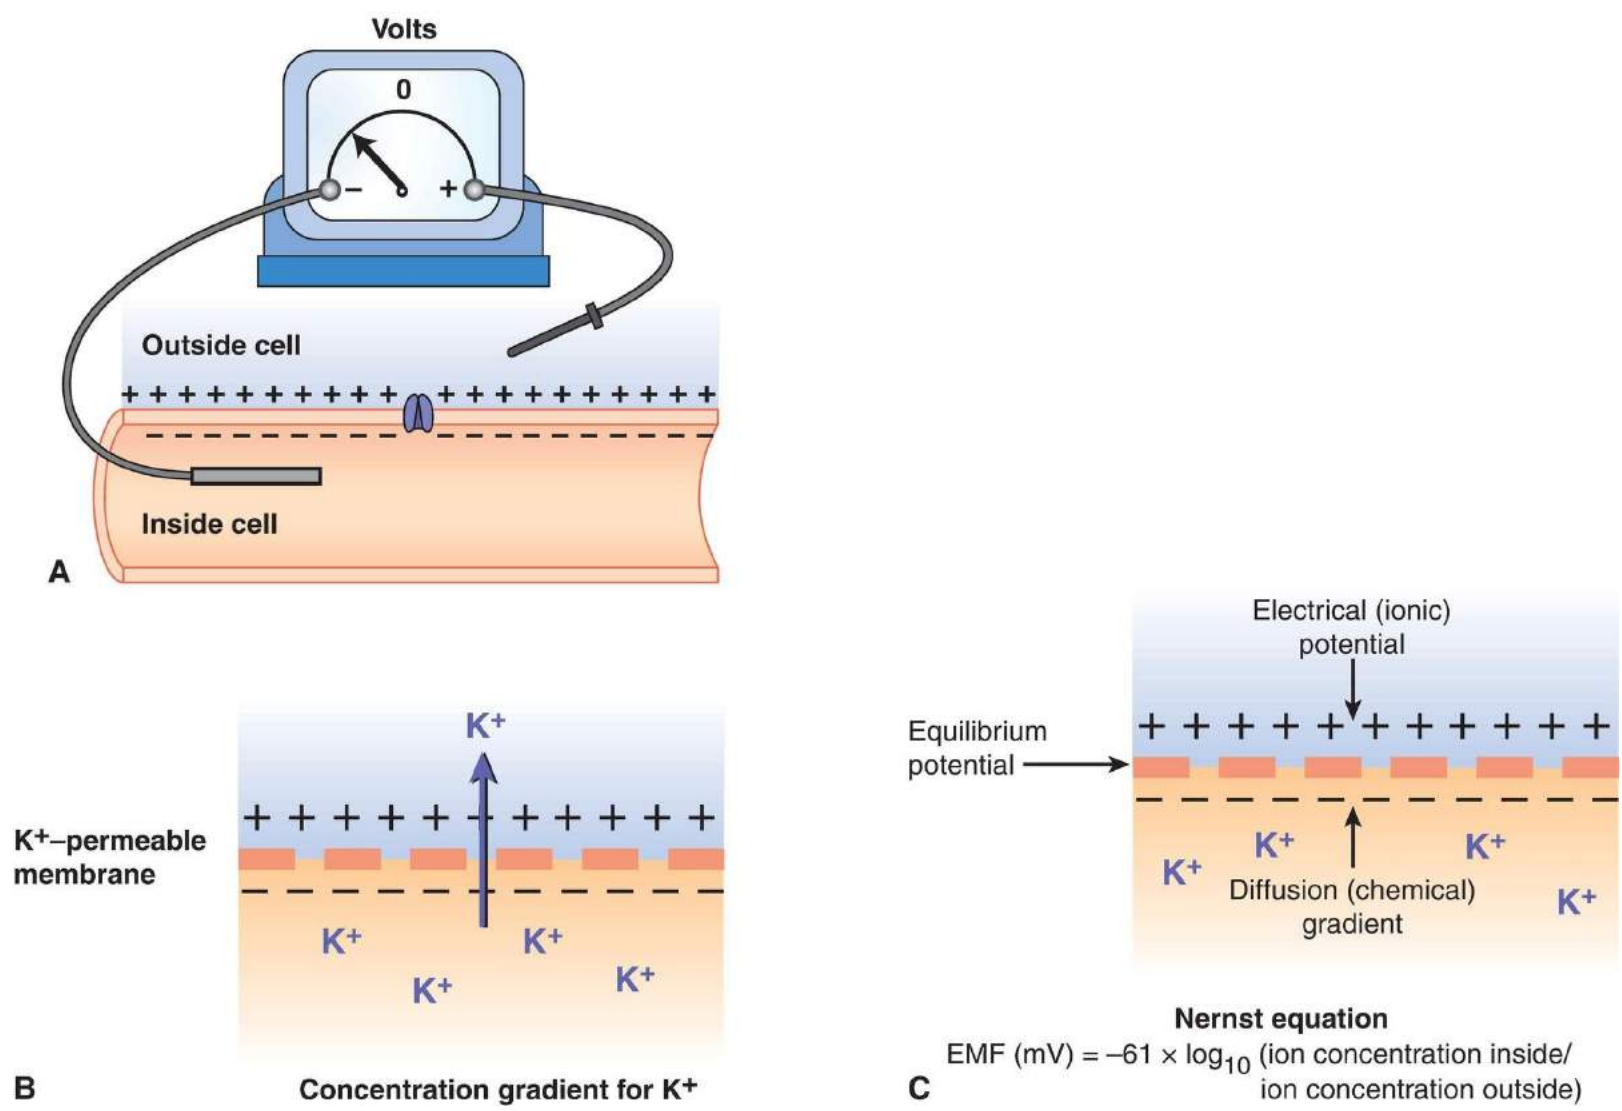

Figure 3.5 Effects of electrochemical forces and membrane permeability on membrane potentials. **(A)** Neurons have electrical potentials that are generated by ions: primarily Na^+, K^+, and Cl^-. Ions cannot freely cross the membrane. This produces differences in the electrical charge within the membrane compared to outside of the cell. This electrical potential difference depends on the charge of the ions on either side of the membrane, their concentration, and the permeability of the membrane to those ions. This voltage across the membrane represents the potential difference and can be measured with a microelectrode. The opening of channels permeable to a particular ion, such as K^+, results in the flow of that ion through the channel and a change in the membrane potential. **(B)** The flow of an ion through an open channel will depend on the concentration and electrical gradients across the membrane. Potassium ions have a higher concentration within the cell, which produces a concentration gradient and leads to the efflux of potassium out of the cell. However, because of the lack of permeability of the membrane to anions, the inside of the membrane is negatively charged, which disfavors the movement of K^+ ions out of the cell. **(C)** The equilibrium potential is the membrane potential at which these two forces are in balance and there is no net movement of the ion through open channels. The equilibrium potential can be calculated using the Nernst equation.

Changes to the permeability of potassium and sodium ions can result in hyperpolarization or depolarization of the membrane.

Although the resting membrane potential for a neuron is −70 mV, this membrane potential can change due to the influx or efflux of ions, particularly sodium and potassium ions. There are a number of subtypes of sodium and potassium channels each with its own set of characteristics. Some of these channels open/close in response to binding of neurotransmitters to receptors, whereas others respond to voltage changes. The subtypes also differ in the length of time they remain open. Additionally, some of the channels inactivate meaning that there is a period of time in which the channel cannot be opened.

When ion channels open such that there is an influx of positive ions resulting in a less negative potential difference across the membrane, the membrane is said to **depolarize**. The primary ion responsible for neuronal depolarization is Na^+ and it can enter the cell through a number of different types of sodium channels. Ligands can bind receptors to open sodium channels such as occurs when acetylcholine binds to nicotinic receptors. Other sodium channels have voltage sensors and open in response to voltage changes. The influx of positive ions leads to an **excitatory postsynaptic potential** (**EPSP**) (Fig. 3.6). The channel remains open for a finite period of time depending on its time constant τ. The increase in the membrane potential is also bounded in space by the space constant λ: when an ion channel opens, the ions enter and distribute along the membrane decreasing in magnitude with increasing distance from the channel. This spread of the signal over short segments of the membrane is known as **electrotonic conduction** or **passive conduction**. If there were only one ion channel subtype on the cell membrane, the membrane potential reached could be determined by the Nernst potential for that ion. Clearly this is not the case and the membrane potential ultimately reached at any portion of the membrane depends on additional factors. Because the opening of ion channels changes the permeability of the membrane to that ion, the number and types of channels open are of critical importance. The **Goldman equation** allows for the calculation of the membrane potential by including the permeability of K^+, Na^+, and Cl^-, the ions that are the major contributors to membrane potential. Additionally, the opening of nearby channels can lead to a **temporal summation** or a **spatial summation** of EPSPs. Once all of the channels return to their unstimulated states, the membrane potential returns to its resting potential.

Figure 3.6 Excitatory and inhibitory postsynaptic potentials. **(A)** Inflow of positive ions at a synapse *(arrow)* makes the postsynaptic membrane potential less negative and increases the likelihood of the postsynaptic cell producing an action potential. This is an excitatory postsynaptic potential (EPSP). **(B)** Inflow of negative ions or outflow of positive ones makes the postsynaptic membrane potential more negative and decreases the likelihood of the cell producing an action potential. This is an inhibitory postsynaptic potential (IPSP). **(C)** If the time constant is long enough, some of the depolarization from the first EPSP is still present when the second occurs, and the individual depolarizations can summate.

Although the opening of sodium channels can produce a more positive membrane potential, the opening of potassium channels will lead to the efflux of potassium ions. Some of the potassium channels respond to the binding of ligands to receptors, such as the binding of opioids to the opioid receptors, while other potassium channels are voltage sensitive. When potassium leaves the cell, the membrane potential **hyperpolarizes** (becomes more negative) thus creating an **inhibitory postsynaptic potential** (**IPSP**). The production of IPSPs serves to dampen a neuron's excitability. The summation of the membrane's EPSPs and IPSPs will determine the final membrane potential.

Action potential has different phases depending on the permeability of the sodium and potassium channels.

If through temporal or spatial summation, the EPSPs reach a particular membrane potential referred to as the **threshold potential** (generally around −55 mV) at the axon hillock, a cascade of opening of voltage-gated sodium channels and subsequent **action potential** can result. Once the threshold potential is reached, enough Na^+ channels open that the membrane potential of the cell approaches the Nernst potential for Na^+, which is typically around +50 mV. Because K^+ channels open to repolarize the cell membrane through the efflux of positive potassium ions, the membrane potential generally peaks around +30 mV.

Action potentials have a characteristic shape that can be divided into specific phases based on the **conductance** of Na^+ and K^+ ions. Conductance is the flow of ions across the membrane and is increased with opening of ion channels. It is the inverse of **resistance**, which is greatest when channels are closed and permeability is decreased. The membrane potential at rest is typically around −70 mV reflecting the permeability of the cell to K^+ and the nearness to its equilibrium potential of −90 mV as calculated by the Nernst equation. As the cell is stimulated, local EPSPs are produced by the opening of channels that allow the influx of Na^+ ions, which results in an increase in the membrane potential to more positive values. If the opening of Na^+ channels is timed appropriately or the Na^+ channels are close to one another, the EPSPs can summate to reach the threshold potential of approximately −55 mV.

If, and only if, the membrane potential reaches the threshold, an action potential will be initiated (Fig. 3.7). In this way, the generation of an action potential is an **all-or-none phenomenon**. Unlike the electrotonic potential, the action potential is a **propagated potential**, which means that it regenerates and is capable of moving long distances along the nerve process. The density and characteristics of voltage-gated sodium channels are responsible for this phenomenon. These are found at high density along the axon hillock near the soma of the cell, which is sometimes referred to as the “trigger zone” because of its ability to generate action potentials. These channels are activated (open) at the threshold potential. Because of the density of the voltage-gated sodium channels along the axon, there is a relatively large influx of sodium across the membrane although the actual quantity of ions moving is very small: <0.01% of the cell’s sodium pool. This leads to the spreading of positive ions to the adjacent membrane and subsequent achievement of its threshold potential leading to opening of voltage-gated sodium channels in these nearby regions and the propagation of the action potential along the axon. As sodium ions enter, the action potential enters the **depolarization** phase, which is composed of a **rising phase**, in which the membrane is approaching a potential of 0 mV, and an **overshoot** phase, in which the membrane potential rises above 0 mV. The membrane potential approaches the equilibrium potential for sodium (+60 mV) but reaches a maximum of only about +30 mV due to inactivation of these channels and opening of potassium channels.

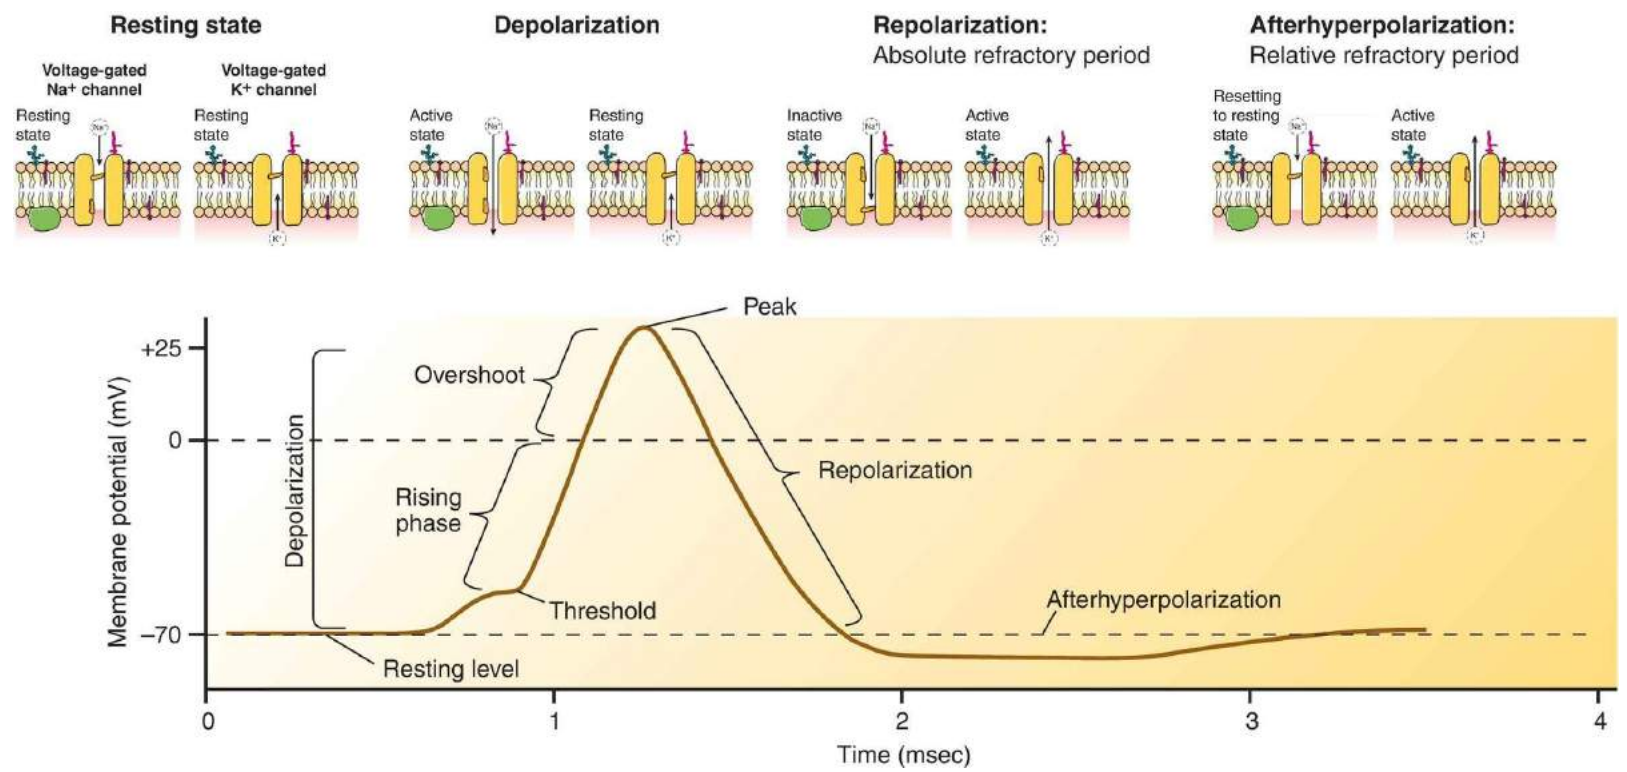

Figure 3.7 Phases of the action potential. **Resting:** When the membrane potential is at its resting level, both Na^+ and K^+ channels are closed. **Depolarized:** During depolarization, Na^+ channels open allowing the influx of Na^+. K^+ channels remain closed. **Repolarization:** As the membrane potential becomes more positive, certain voltage-gated K^+ channels open allowing the efflux of K^+ and returning the membrane potential towards resting levels. After opening, Na^+ channels inactivate. During the period of inactivation of Na^+ channels, another action potential cannot be generated and the membrane is in an absolute refractory period. **Afterhyperpolarization:** As the membrane potential reaches the resting membrane potential, K^+ channels remain open leading to a membrane potential that is more negative than the resting membrane potential. During this time the population of Na^+ channels are returning to their resting closed state. While some of the Na^+ channels remain inactivated, it will take greater stimulation to produce an action potential and the membrane is in a relative refractory period. Once the K^+ channels close, the membrane returns to the resting membrane potential.

The **inactivation** of the sodium channel is phenomenon by which the channel is inaccessible to Na^+ ions even though the membrane potential is such that the channel should be activated. It is accomplished by the closing of a "gate" on the intracellular side of the channel that prevents the passage of ions through the channel. The voltage-gated sodium channel exists in three states: rested, active, and inactivated. In the **resting state** the channel is closed but capable of being opened. In the **active state**, the membrane potential has risen enough such that a conformational change occurs that removes the "gate" on the extracellular side of the channel that was preventing ionic passage. The active state is rapidly followed by the **inactive state** during which time the channel cannot be opened. The inactive state only lasts for a few milliseconds before the channel returns to the resting state. Until this return, another action potential cannot be generated because inactivated sodium channels are impermeable to Na^+ ions. This timeframe is known as the **absolute refractory period**.

At the peak of the action potential, voltage-gated potassium channels open and a relatively large efflux of K^+ occurs. Because the majority of the sodium channels are inactivated and thus there is no movement of Na^+ ions, this results in a rapid **repolarization**: a decrease in the membrane potential

returning towards the resting membrane potential. Certain potassium channels remain open even after the potential returns to resting values. This leads to **afterhyperpolarization**, which is a decrease in the membrane potential past the resting potential. This is short lived since these channels rapidly close leading to a return to the resting membrane potential.

During the repolarization phase, more of the sodium channels are returning to the rested state and are again capable of producing an action potential. However, because there is a proportion of these channels that are still inactivated and due to the open K^+ channels, it would take a stronger-than-normal stimulus to produce another action potential. This timeframe is the **relative refractory period**.

The absolute and relative refractory periods are important in the propagation of action potentials along the axon in a unidirectional manner (Fig. 3.8). As one membrane segment depolarizes to produce an action potential, the entering sodium ions spread to adjacent regions on either side of the depolarized membrane. In the forward direction, this changes the membrane potential of the adjacent segment, which results in the opening of Na^+ channels and production of another action potential. In this manner, there is a sequential depolarization of adjacent segments of the axon producing action potentials down the axon like a wave. Because all action potentials reach the same amplitude, the action potential propagates without decrement. In the adjacent membrane region that has already produced an action potential, many of the Na^+ channels are inactivated and thus in the absolute or relative refractory period, which decreases the opportunity to produce another action potential and propagate the signal backwards.

Figure 3.8 Unidirectional propagation of action potentials. During the action potential, there is spread of sodium to adjacent segments of the depolarized membrane. Sodium channels that have just been involved in an action potential are inactivated for a few milliseconds and cannot be re-opened during that time resulting in the membrane being in a refractory period. Sodium channels on the membrane on the side of the action potential that has not yet generated an action potential, are in the rested state and can open and generate an action potential resulting in an excitable membrane. In this way, the action potential propagates unidirectionally towards the axon.

With all action potentials reaching the same peak, the strength of a signal cannot be encoded by the action potential amplitude. Instead, strong signals increase the frequency of action potentials. This is accomplished by decreasing the time that the membrane is in the resting state.

Conduction velocity is influenced by myelination and fiber diameter.

The speed at which action potentials propagate along the axon is determined by the characteristics of the axon itself specifically the degree of myelination and the axonal diameter. Each axon can be surrounded by many myelin sheaths. The myelin sheaths wrap around an axon at regular intervals and act as insulators. This means that there are few sodium channels and very little current flow across the myelinated membrane. The myelin sheaths are interspersed by unmyelinated regions at the nodes of Ranvier. These unmyelinated regions have a high density of sodium channels. The myelin insulation allows the charge to "jump" from one node to the next by reducing the "leak" of current out of the membrane (Fig. 3.9). This is known as "**saltatory conduction**" and can be up to 50 times faster than propagation without myelination. Importantly, the current does not diminish as it is shunted from one node to the next. The larger the diameter of the axon, the faster the conduction due to decreased internal resistance and greater spread of the sodium ions to the adjacent membrane. Axons can be up to 20 μm in diameter. In contrast, the smallest diameter axons (0.4 μm) are unmyelinated. The speed of conduction is slower in unmyelinated fibers because the action potential is traveling continuously along the axon without jumping over various segments. Unlike the myelinated fibers, sodium channels are distributed evenly along the unmyelinated axon.

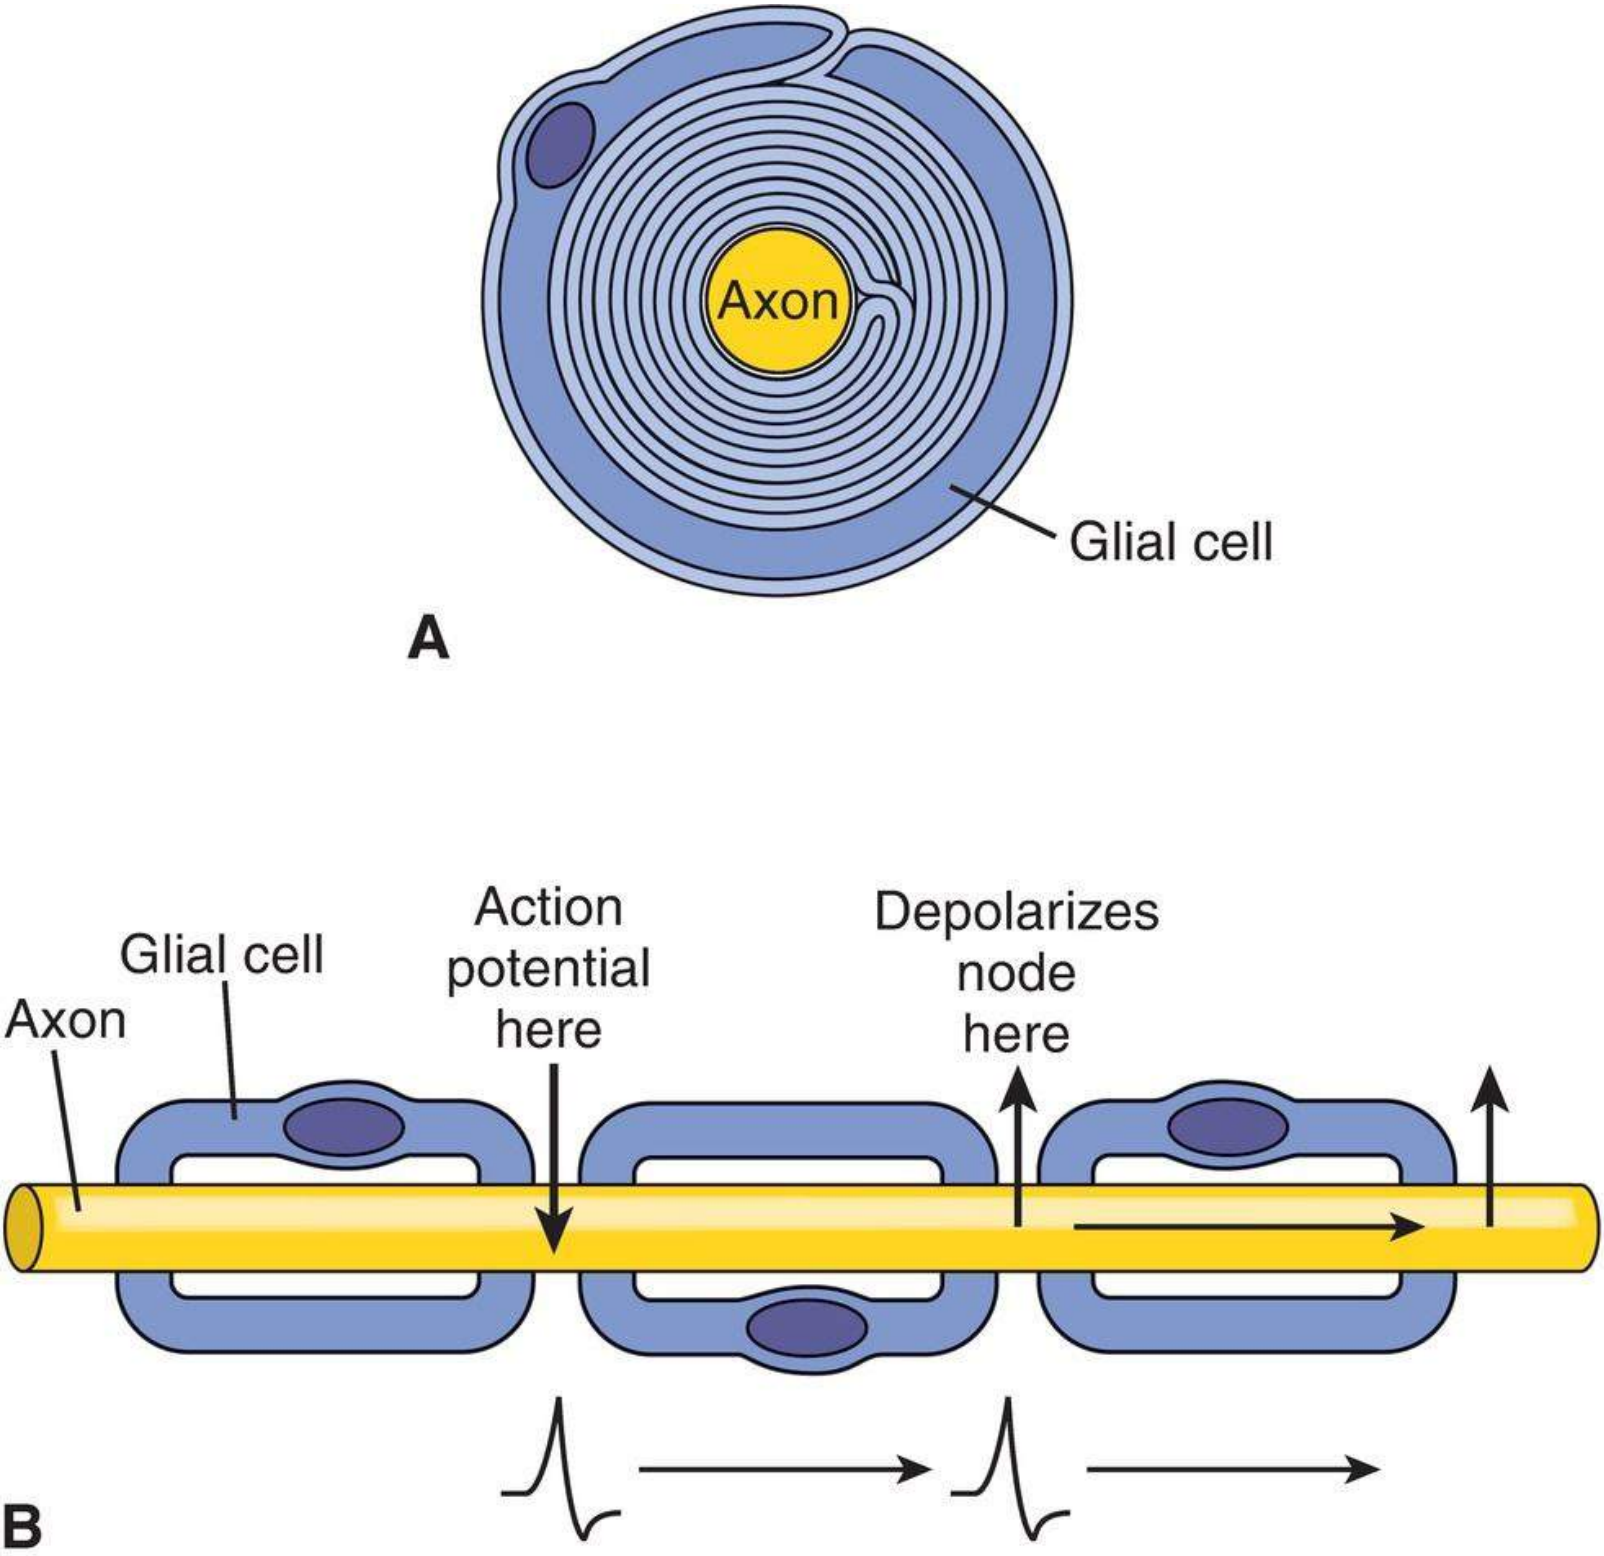

Figure 3.9 Myelination allows for saltatory conduction. **(A)** Glial cells, oligodendrocytes in the CNS and Schwann cells in the PNS, wrap certain axons in overlapping layers of myelin, which serves to insulate the axon and limit ion flow from the underlying membrane. **(B)** Interspersed at regular intervals between myelinated segments are unmyelinated regions, nodes of Ranvier, where action potentials are generated due to the high density of sodium channels. The depolarization spreads through the insulated internodal region to the next node where another action potential is produced. Myelination results in a faster propagation of the action potential along the axon.

Axons in the PNS are bundled together and enveloped by a fibrous coat, known as the **epineurium**, to form nerves. There are three main types of nerve fibers: A, B, and C. These are distinguished based on

myelination, diameter size, and function. The A fibers are large (2 to 20 μm in diameter), myelinated fibers that are involved in touch, proprioception, motor function and some pain transmission. This class is further divided based on the diameter size and function into α, β, γ, and δ subtypes (Table 3.1). The autonomic preganglionic fiber, which is the portion of the autonomic fiber that precedes the soma, is classified as a B fiber and is smaller in diameter than A fibers and only lightly myelinated. The portion of the sympathetic fibers that extends from the soma into the periphery is classified as a C fiber and is small in diameter and unmyelinated. Other C fibers carry information about pain and temperature. Unmyelinated fibers are particularly sensitive to local anesthetics, which block sodium channels. Thus, injection of a local anesthetic is used to block the transmission of information from a painful stimulus. At higher concentrations, local anesthetics can affect myelinated fibers as well. Larger fibers are more sensitive to compression, which can then cause loss of sensitivity to stimuli carried by those fibers.

TABLE 3.1 Nerve Fiber Classification

Fiber Type	Fiber Diameter (μm)	Myelination	Conduction Velocity (m/sec)	Function
Aα	12–20	Yes	80–120	Proprioception, motor
Aβ	5–12	Yes	40–70	Touch, pressure
Aγ	3–6	Yes	15–40	Muscle spindles
Aδ	2–5	Yes	8–30	Pain, temperature
B	<3	Lightly	3–15	Preganglionic, autonomic
C: Dorsal Root	0.4–1.2	No	0.5–2.3	Pain, temperature
C: Sympathetic	0.3–1.3	No	0.7–2.3	Postganglionic

SYNAPTIC TRANSMISSION

The function of action potentials is to communicate information throughout the nervous system by transmitting the information from one portion of the nerve to another. Once the action potential reaches the nerve terminal, the signal can be communicated to another neuron or cell through a process known as synaptic transmission.

Neurons communicate both by electrical and chemical synapses.

Synaptic transmission is accomplished either at **electrical synapses** or chemical synapses. Electrical communication occurs via **gap junctions**, which occur when the terminals from two neurons are in close apposition to one another. Ions can flow directly from one neuron to the other through special channels. In this way, depolarization can spread from one neuron to another without any intermediaries such as neurotransmitters. Gap junctions are found in the embryonic nervous system but rarely occur in adult mammalian neurons (although they are present in adult smooth and cardiac muscle cells).

Chemical synapses consist of the presynaptic terminal, synaptic cleft, and the postsynaptic terminal. The depolarization of the presynaptic terminal results in the release of chemical messengers, **neurotransmitters**, into the synaptic cleft. These communicate the signal to the postsynaptic cell by interacting with specific proteins, **receptors**, on the postsynaptic terminal. The activation of these receptors alters cellular function by opening channels, activating intracellular messengers, and directly or indirectly affecting transcription.

Upon depolarization of the presynaptic membrane, vesicles mobilize to the membrane, dock, and release neurotransmitters.

Neurotransmitters are stored in vesicles. These vesicles contain membrane proteins that are important for anchoring the vesicle within the cytoplasm, releasing the vesicle, and allowing its mobilization and docking at the synaptic terminal where the vesicle can release its contents into the synaptic cleft. Vesicles and associated proteins are synthesized in the soma and transported via axoplasmic transport. Some of the vesicles contain neuropeptides as signaling molecules that are also synthesized in the soma. Others contain neurotransmitters that can be synthesized within the cytosol of the presynaptic terminal or even within the vesicle itself. The neurotransmitter can be recycled and repackaged into the vesicles either by reuptake back into the presynaptic terminal or via degradation in the synaptic cleft and the reuptake of precursors into the presynaptic terminal.

The arrival of the action potential at the nerve terminal leads to a multistep process resulting in the release of neurotransmitters into the synaptic cleft (Fig. 3.10). When the membrane of the presynaptic terminal depolarizes, voltage-gated calcium channels open allowing the influx of calcium. At rest, the intracellular free calcium concentration is around 100 nM, whereas the extracellular calcium concentration is 1.25 mM. Upon depolarization, the intracellular calcium concentration increases to ~1 μM. This increase in intracellular calcium results in activation of various kinases, which phosphorylate a class of proteins called **synapsins**. Synapsins serve to anchor neurotransmitter-containing vesicles within the cytoplasm. Their phosphorylation leads to their release from cytoskeletal proteins and mobilization of vesicles to the **active zone** of the synaptic membrane, which is an area containing calcium channels and proteins, such as syntaxin, which specialize in vesicular release. The proteins on the plasma membrane interact with specific vesicular membrane proteins, such as synaptotagmin and synaptobrevin. These vesicular and axonal membrane proteins are called **SNARES**. The interaction of the vesicular and axonal membrane SNARES enables the vesicle to “dock” (i.e., line up appropriately for the release of its neurotransmitter content into the synaptic cleft). Once docked, the vesicular membrane fuses with the synaptic membrane and releases the vesicular contents into the synaptic cleft.

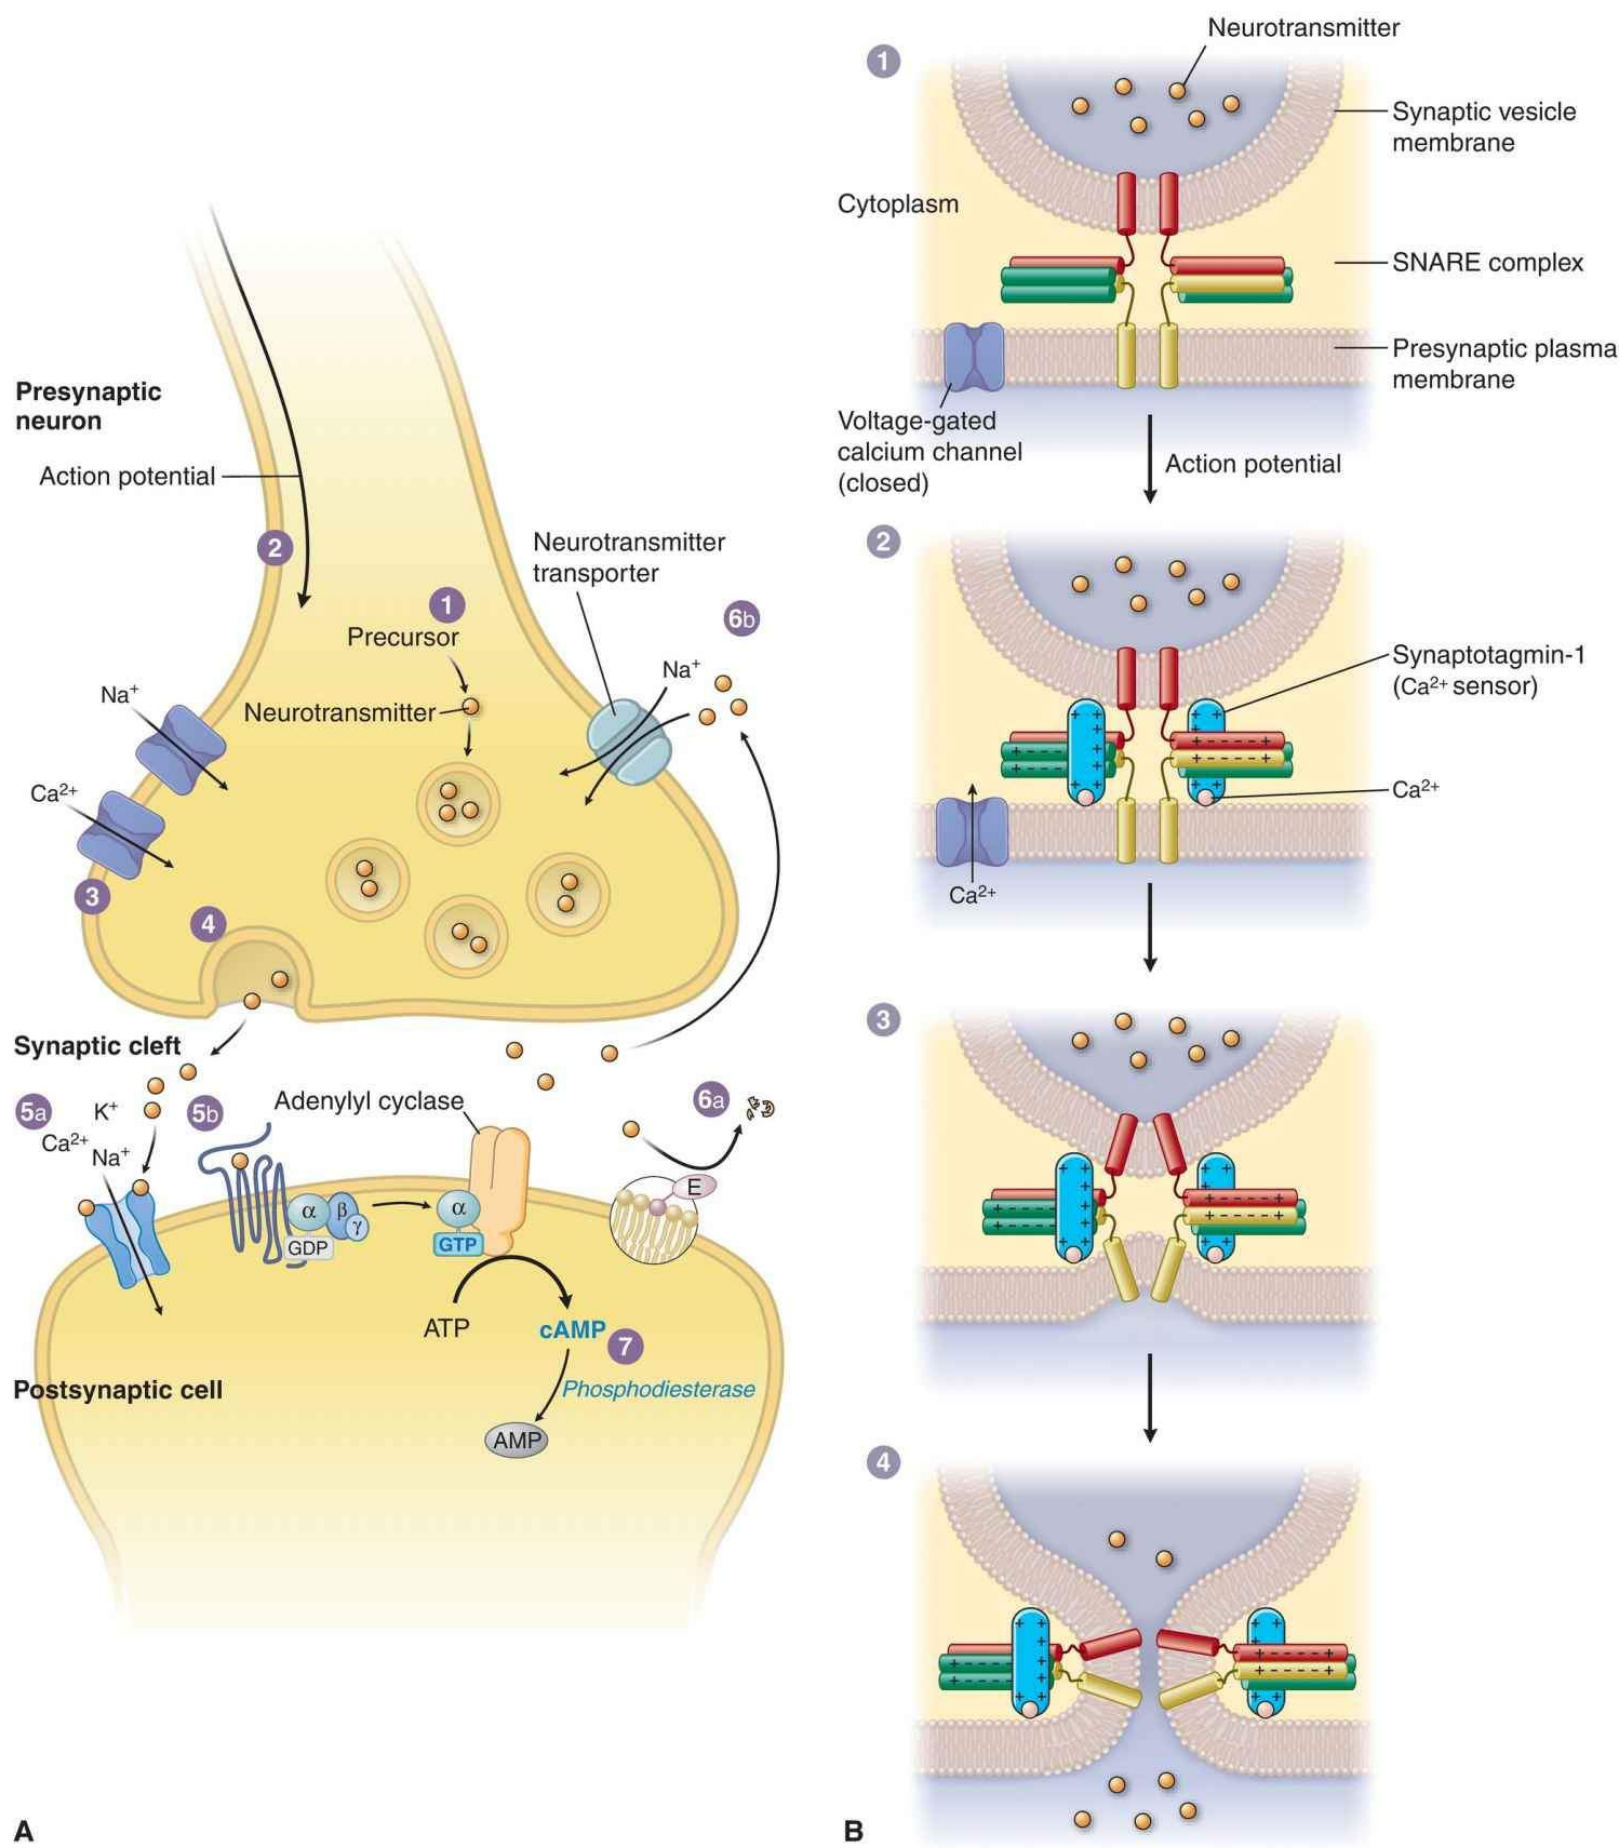

Figure 3.10 Steps in synaptic transmission. **(A)** Synaptic transmission can be divided into a series of steps that couple electrical depolarization of the presynaptic neuron to chemical signaling between the presynaptic and postsynaptic cells. (*1*) A neuron synthesizes neurotransmitters from precursors and stores the transmitter in vesicles. (*2*) An action potential traveling down the neuron depolarizes the presynaptic

nerve terminal. (*3*) Membrane depolarization activates voltage-dependent Ca^{2+} channels, allowing Ca^{2+} entry into the presynaptic nerve terminal. (*4*) The increased cytosolic Ca^{2+} enables vesicle fusion with the plasma membrane of the presynaptic neuron, with subsequent release of neurotransmitter into the synaptic cleft. (*5*) Neurotransmitter diffuses across the synaptic cleft and binds to postsynaptic receptors. (*5a*) Neurotransmitter binding to ionotropic receptors causes channel opening and changes the permeability of the postsynaptic membrane to ions. This may also result in a change in the postsynaptic membrane potential. (*5b*) Neurotransmitter binding to metabotropic receptors on the postsynaptic cell activates intracellular signaling cascades; the example shows G protein activation leading to the formation of cAMP by adenylyl cyclase. In turn, such a signaling cascade can activate other ion-selective channels (not shown). (*6*) Signal termination is accomplished by removal of transmitter from the synaptic cleft. (*6a*) Transmitter can be degraded by enzymes (*E*) in the synaptic cleft. (*6b*) Alternatively, transmitter can be recycled into the presynaptic cell by reuptake transporters. (*7*) Signal termination can also be accomplished by enzymes (such as phosphodiesterase) that degrade postsynaptic intracellular signaling molecules (such as cAMP). **(B)** (*1*) Synaptic vesicles are tethered close to the plasma membrane of the presynaptic neuron by several protein–protein interactions. The most important of these interactions involve SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) proteins present in both the vesicle membrane and the plasma membrane. The SNARE proteins include synaptobrevin (red), syntaxin-1 (yellow), and SNAP-25 (green). Voltage-gated Ca^{2+} channels are located in the plasma membrane in close proximity to these SNARE complexes; this facilitates the sensing of Ca^{2+} entry by Ca^{2+}-binding proteins (synaptotagmin-1, in blue) localized to the presynaptic plasma membrane and/or the synaptic vesicle membrane. (*2–4*) Voltage-gated calcium channels open in response to an action potential, allowing entry of extracellular Ca^{2+} into the cell. The increase in intracellular Ca^{2+} triggers binding of synaptotagmin-1 to the SNARE complex and fusion of the vesicle membrane with the plasma membrane, releasing neurotransmitter molecules into the synaptic cleft. Several additional proteins may also be involved in the regulation of synaptic vesicle fusion (*not shown*).

Presynaptic fibers are generally associated with a predominant neurotransmitter but other chemical messengers can also be present in the presynaptic bouton. Neurotransmitters are small molecules that interact with postsynaptic receptors to produce a fast cellular response. These are generally found in small vesicles that are located near the active zone. Neuropeptides are contained in larger vesicles that are located more diffusely throughout the presynaptic terminal. Rather than producing a fast postsynaptic response, neuropeptides tend to have a modulatory effect on the response to neurotransmitters. In some cases, neuromodulators can be colocalized within the same vesicle as the neurotransmitter. Other signaling molecules can undergo nonvesicular release from the presynaptic terminal. These are generally synthesized “on-demand” in response to the influx of calcium. Some examples of these are prostaglandins, cannabinoids, and nitric oxide. Other molecules signaling through receptors include hormones, such as the steroid hormones, and growth factors, such as neurotrophins.

Once the neurotransmitter has been released into the synaptic cleft, it binds a **receptor**, which is a protein that interacts with ligands to produce a cellular effect without changing the ligand. Receptors can be located on the cell surface or intracellularly. Neurotransmitters can also act at receptors on the presynaptic terminal, sometimes referred to as **autoreceptors**, to modulate further neurotransmitter release. Autoreceptors may act to open certain potassium channels resulting in more positive ions escaping and a hyperpolarization of the membrane and/or to decrease activity of calcium channels resulting in a decrease in vesicular mobilization and neurotransmitter release. In this way, release of neurotransmitter can negatively modulate further release from the same fiber. Receptors will be discussed

in depth below.

Neurotransmitter actions can be terminated via diffusion, degradation, or cellular uptake.

In order to reach receptors, neurotransmitters diffuse away from the release site. They will be at the highest concentration within the synaptic cleft and often interact with receptors located in the postsynaptic density. The distance from which neurotransmitters diffuse away from the presynaptic terminal depends in part on the mechanisms by which that neurotransmitter is removed from the extracellular space, such as degradation or uptake into nearby cells. Some neurotransmitters, such as acetylcholine, are degraded by extracellular enzymes that are abundant in the synaptic cleft. Other neurotransmitters, such as norepinephrine, are taken up into the presynaptic terminal and either degraded by intracellular enzymes or recycled into vesicles for subsequent release. Neurotransmitters can also be taken up into glia or other cells where they undergo degradation or recycling back to neurons. This occurs with the amino acid neurotransmitter glutamate (Fig. 3.11). The further away from the release site the neurotransmitter travels, the lower its concentration will be at subsequent receptors. Some neurotransmitters have endocrine effects (i.e., the concentration can remain high enough as it diffuses from its release site that it can still activate distant receptors). These can be referred to as **neurohormones**.

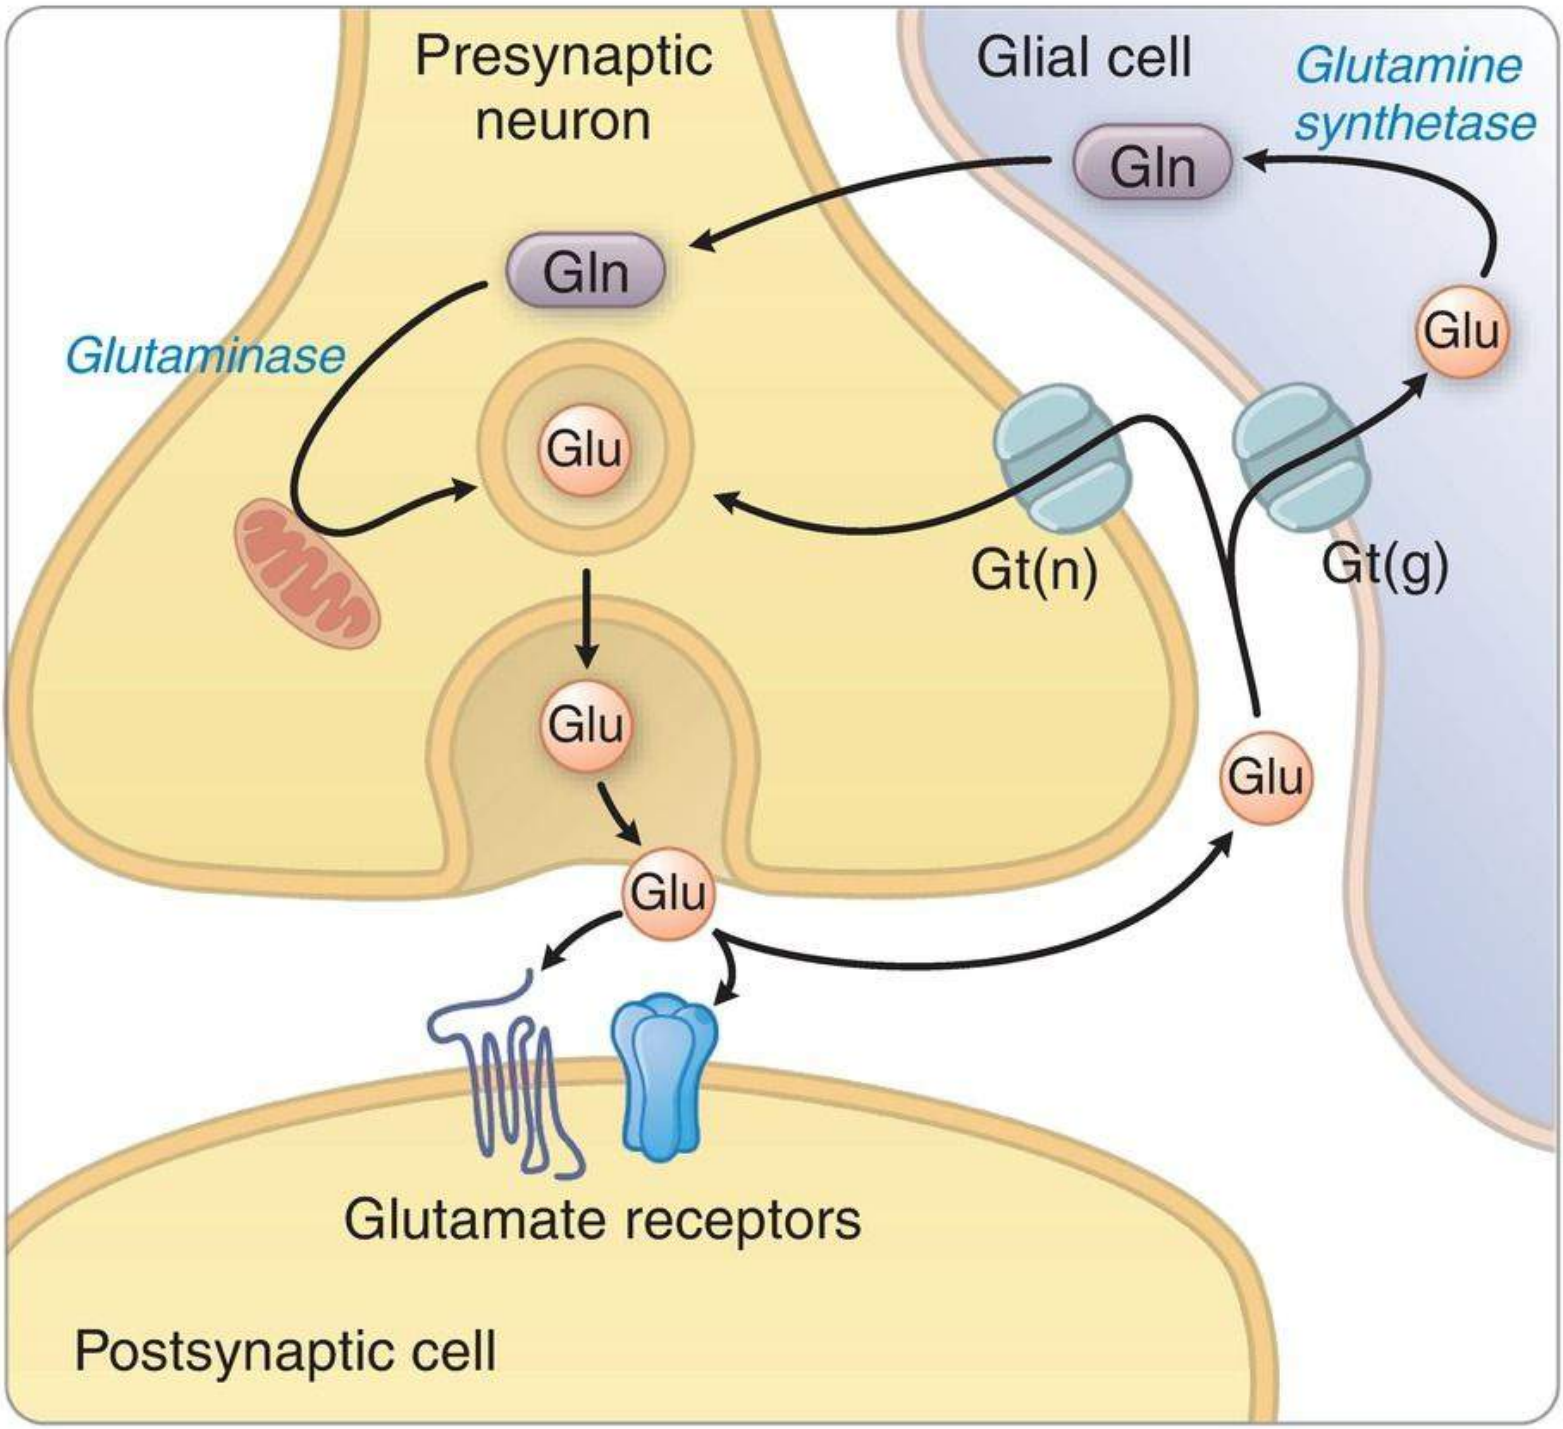

Figure 3.11 Reuptake and recycling of glutamate through glial cells. Glutamate diffuses out of the synaptic cleft where it is transported into the presynaptic terminal by the neuronal glutamate transporter [Gt(n)] or into glial cells by the glial glutamate transporter [Gt(g)]. In the glial cell it can be converted to glutamine (Gln), which is then transferred to the neuron and converted back to glutamate via the mitochondria-associated glutaminase.

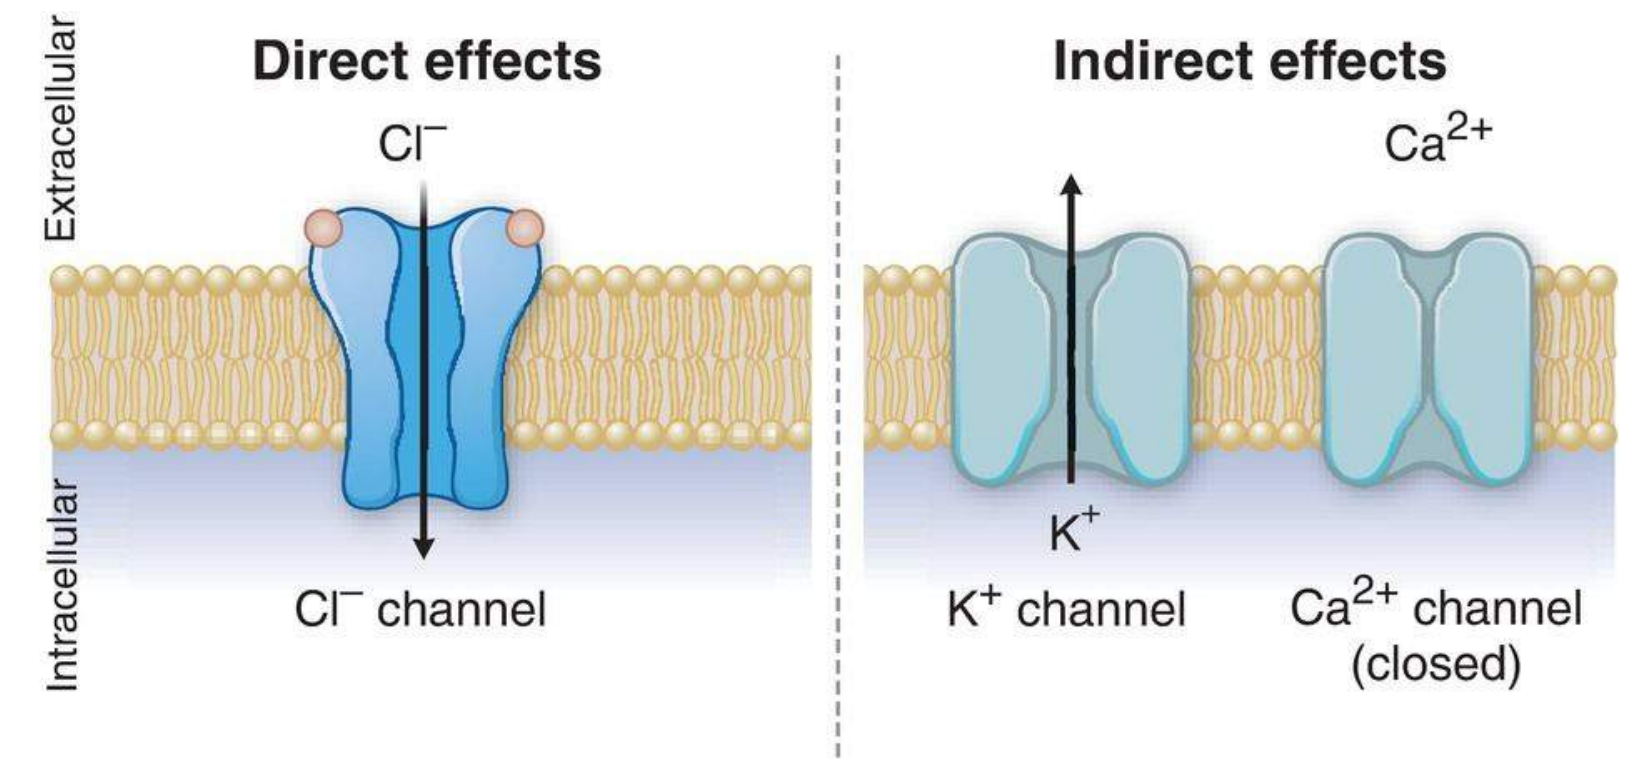
NEUROTRANSMISSION

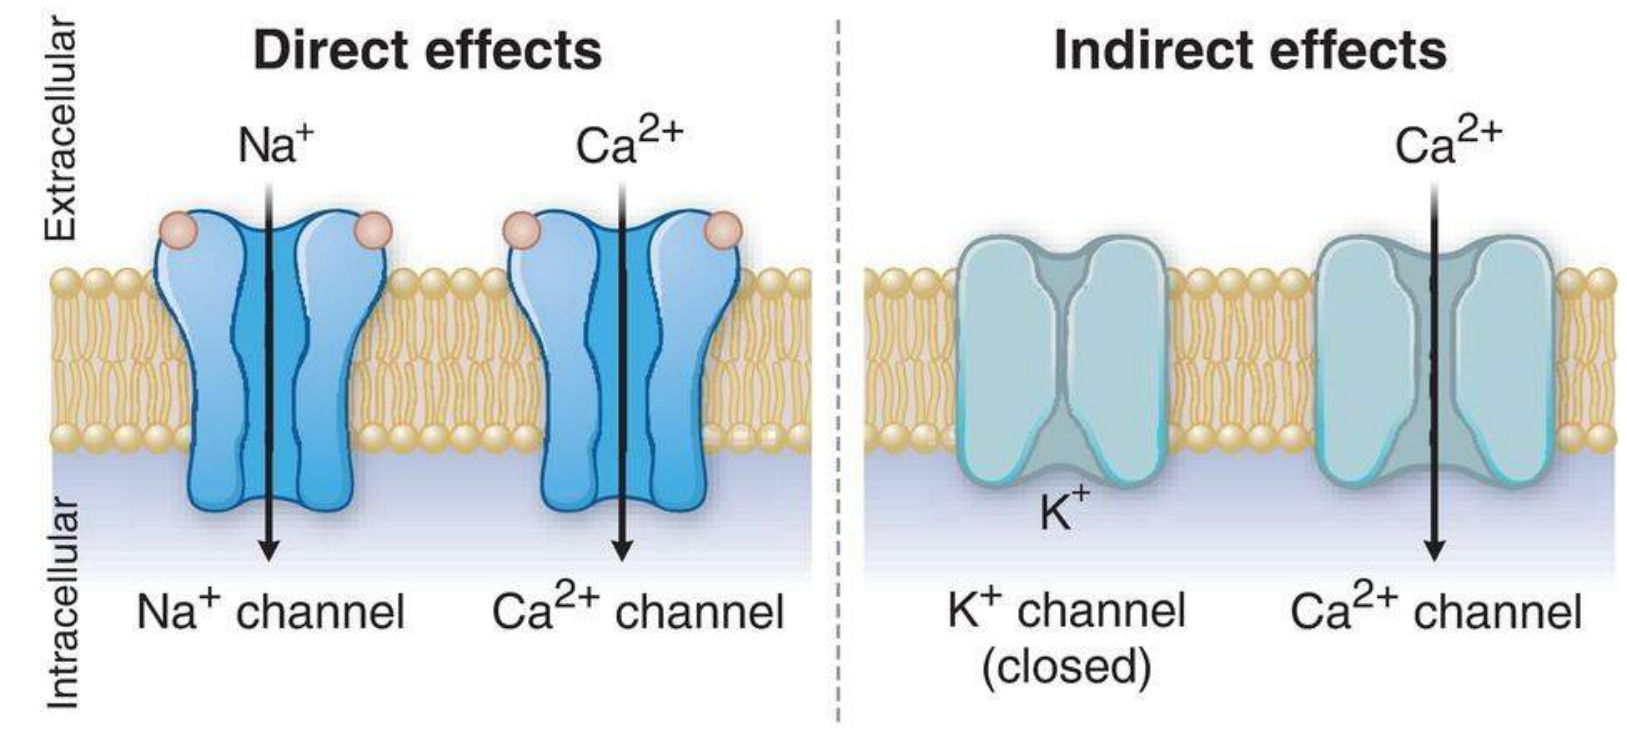
Much of neuronal cellular communication is accomplished by the actions of a handful of small molecule neurotransmitters. These neurotransmitters are stored in vesicles and released in a calcium-dependent fashion from the presynaptic terminal. Once in the synaptic cleft, the neurotransmitters interact with receptors on the postsynaptic terminal and, in certain cases, also with autoreceptors on the presynaptic terminal that function to reduce further neurotransmitter release. The receptors with which the neurotransmitter interacts are specific for that particular neurotransmitter and are generally named for that neurotransmitter (e.g., dopamine interacts with dopamine receptors). There are often many subtypes of receptors with which a particular neurotransmitter can interact.

Neurotransmitters commonly act at ionotropic or metabotropic receptors to produce an effect.

In general, the small molecule neurotransmitters of the central nervous system interact with ligand-gated (**ionotropic**) or G protein–coupled (**metabotropic**) receptors. The ligand-gated receptors possess an internal pore that connects the extracellular and intracellular environments. These receptors respond to binding of the neurotransmitter by assuming a conformation in which the pore is open and permeable to particular ions thus allowing the flow of those ions into or out of the cell. Receptors that form pores that are permeable to sodium, such as certain glutamate receptors, will result in a depolarization of the membrane and an **excitatory** effect. Those that form pores that are permeable to chloride ions, such as certain GABA receptors, will result in hyperpolarization of the membrane and an **inhibitory** effect (Fig. 3.12). The ligand-gated receptor is able to respond quickly, within a few milliseconds, to the binding of the neurotransmitter and thus mediates **fast synaptic transmission**.



A Effects of inhibitory neurotransmitters



B Effects of excitatory neurotransmitters

Figure 3.12 Receptor activation can produce inhibitory or excitatory effects. **(A)** Inhibitory neurotransmitters *hyperpolarize* membranes by inducing a net outward current, by promoting either an influx of anions (e.g., opening a Cl^- channel) or an efflux of cations (e.g., opening a K^+ channel). **(B)** Excitatory neurotransmitters *depolarize* membranes by inducing a net inward current, either by enhancing inward current (e.g., opening a Na^+ or Ca^{2+} channel) or by reducing outward current (e.g., closing a K^+

channel). Potassium channel closure, independent of changes in the resting membrane potential, also increases the resting membrane resistance and renders the cell more responsive to excitatory postsynaptic currents.

G protein–coupled receptors (GPCRs) respond more slowly to interaction with a neurotransmitter because of the initiation of a signaling cascade within the cell. Chapter 2 describes the function of GPCRs in detail. Briefly, once activated by the receptor, the alpha subunit of the G protein will bind to GTP (replacing GDP), which allows the dissociation of the alpha and beta/gamma subunits. The alpha and the beta/gamma subunits can independently interact with various effector molecules. The hydrolysis of GTP to GDP results in the reassociation of the subunits and the termination of their effects. There are three main types of GPCRs categorized by the action of its alpha subunit (Fig. 3.13). The alpha subunit of the G_s type of GPCRs activates adenylyl cyclase to produce cAMP, which can then stimulate protein kinase A and result in protein phosphorylation. The alpha subunit of the G_i type of GPCRs inhibits the activity of adenylyl cyclase thus decreasing intracellular cAMP levels. At the same time, the beta/gamma subunits of G_i can lead to the opening of certain potassium channels, resulting in flow of potassium out of the cell and hyperpolarization of the membrane, and the closing of certain calcium channels, resulting in a reduction of calcium available for the mobilization of neurotransmitter vesicles and a decreased release of neurotransmitters from the presynaptic terminal. The alpha subunit of the G_q type of GPCRs activates phospholipase C, which catalyzes the hydrolysis of phosphatidylinositol 4, 5-bisphophate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). These molecules activate separate signaling pathways. IP_3 diffuses through the cytoplasm to the endoplasmic reticulum where it induces the release of calcium. DAG activates protein kinase C (PKC) leading to phosphorylation of proteins.

Figure 3.13 Activation of adenylyl cyclase (AC) and phospholipase C (PLC) by G proteins. G proteins can interact with several different types of effector molecules. The subtype of Gα protein that is activated often determines which effector the G protein will activate. Two of the most common Gα subunits are $G\alpha_s$ and $G\alpha_q$, which stimulate adenylyl cyclase and phospholipase C, respectively. **(A)** When stimulated by $G\alpha_s$, adenylyl cyclase converts ATP to cyclic AMP (cAMP). cAMP then activates protein kinase A (PKA), which phosphorylates a number of specific cytosolic proteins. **(B)** When stimulate by $G\alpha_q$, phospholipase C (PLC) cleaves the membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2) into diacylglycerol (DAG) and inositol-1, 4, 5-triphosphate (IP_3). DAG diffuses in the membrane to activate protein kinase C (PKC), which then phosphorylates specific cellular proteins. IP_3 stimulates release of Ca^{2+} from the endoplasmic reticulum into the cytosol. Calcium release also stimulates protein phosphorylation events that lead to changes in protein activation. Although not shown, the Bγ subunits of G proteins can also affect certain cellular signal transduction cascades.

It is not uncommon for a particular neurotransmitter to interact with receptors that have both ionotropic and metabotropic subtypes. The exact function of the neurotransmitter will be determined by its site of release as well as the action and distribution of its specific receptors.

CLINICAL FOCUS 3.2

Addiction

Many people have pleasurable experiences associated with food, alcohol, coffee, shopping, etc. and can disengage from these activities when these experiences are having negative consequences on the individual such as causing health or financial issues. Addiction occurs when an individual feels a compulsion to engage in intensely pleasurable behaviors despite negative consequences. These euphoric experiences can result from drugs, alcohol, food, shopping, sex, gambling, etc. The rewarding aspect of these behaviors involve activation of certain brain circuitry. The activation of these pathways produce reinforcing effects and a compulsion for the individual to continue activating these pathways. It is not well understood why one individual is more susceptible to addiction than another but seems to involve genetics, personality, and environmental factors.

Drugs can produce physical dependence and tolerance without producing addiction. Physical dependence is the body's adaptation to continued exposure to the drug. This adaptation can result in tolerance, which is a decreased responsiveness to the same dose of drug. In order to reach the same euphoric experience, the individual must increase the dose of the drug. Because the body has now adapted to the presence of the drug, sudden discontinuation of the drug will lead to a response that is decreased relative to the normal response in the absence of the drug. This can produce withdrawal symptoms. Withdrawal symptoms often are opposite of what is experienced with the drug: if the drug produces a calming effect and slowed heart rate, withdrawal from the drug may produce irritation and an increased heart rate. Many drugs produce physical dependence and in order to avoid withdrawal, patients are tapered off of the drug rather than abruptly discontinuing it.

Addiction is less common than physical dependence. Its development is associated with activation of a dopaminergic brain pathway often referred to as the “reward pathway.” Dopaminergic cells in the ventral tegmental area (VTA) of the brainstem send axonal processes to another brain region, the nucleus accumbens. Dopamine is released in the nucleus accumbens and acts on dopamine receptors. Activation of this pathway is reinforcing in that it motivates behaviors that will lead to further activation of the pathway. Drugs of abuse activate this pathway. Some, such as cocaine, enhance the activation of the pathway by blocking the reuptake of dopamine and thereby increasing its concentration and time in the synaptic cleft to produce greater stimulation of dopamine receptors in the nucleus accumbens. Others, such as amphetamine, stimulate release of dopamine from the presynaptic terminal in addition to blocking the reuptake of dopamine.

Dopaminergic neurons in the VTA are inhibited by GABAergic fibers. These release GABA, which acts to decrease the excitability of the dopaminergic fiber, thus decreasing the release of dopamine into the nucleus accumbens and the activation of dopamine receptors. Some drugs, such as opioids, act at receptors on the GABAergic fibers to remove their inhibition of the dopaminergic fibers. This disinhibition results in the activation of these fibers, the release of dopamine in the nucleus accumbens, and activation of dopamine receptors.

In order to activate the dopamine reward pathway, drugs must cross the BBB and access the CNS. Drugs that are more lipophilic, will more readily cross the BBB and can provide greater stimulation. Thus, the lipophilicity of a drug can impact its abuse potential. Heroin is a more lipophilic form of morphine. It is metabolized in the CNS to morphine where it acts at opioid receptors in the VTA to disinhibit the dopaminergic projections into the nucleus accumbens. It is more addictive than morphine because it is better able to cross the BBB thus providing a faster and greater stimulation of the reward pathway. In general, short-acting lipophilic drugs have a greater addictive potential than longer-acting drugs that are more hydrophilic because they can achieve a greater concentration at the target receptor. ■

Classical neurotransmitters are small molecules.

In general, a given presynaptic terminal will synthesize and store one type of neurotransmitter in its vesicles. Often this presynaptic terminal will also store large molecule **neuromodulators** that have been synthesized in the cell body and transported to the presynaptic terminal. These are usually neuropeptides and serve to modulate the postsynaptic actions of the primary neurotransmitter. Classically, neurotransmitters consist of small molecules including amine molecules and certain amino acids.

Acetylcholine

Acetylcholine (ACh) was one of the first neurotransmitters discovered and played an important role in identifying chemical transmission as a primary means of neuronal communication. In the PNS, acetylcholine is involved in producing muscle contraction as well as mediating the responses of the parasympathetic nervous system, both of which will be discussed in depth in later chapters. Acetylcholine is also a transmitter in the CNS where it is involved in arousal and attention. Acetylcholine is synthesized within the presynaptic terminal from acetyl CoA and choline by the enzyme choline acetyltransferase. Once synthesized in the cytosol, ACh is transported into vesicles via the vesicle-associated transporter (VAT). Upon release into the synaptic cleft, it is degraded by acetylcholinesterase back to choline and acetate. Choline is then recycled back into the presynaptic terminal to be used again in the synthesis of ACh.

The receptors with which ACh interacts are referred to as **cholinergic receptors**. There are two main classes of cholinergic receptors: nicotinic and muscarinic receptors. These are named for substances that selectively activate these receptors. **Nicotinic receptors** have subtypes that are located at the neuromuscular junction, autonomic ganglia, and central nervous system. Nicotinic receptors are ligand-gated ion channels that are permeable to sodium and calcium. The influx of sodium results in local membrane depolarization and can lead to the activation of voltage-gated sodium channels and the production of an action potential. At the neuromuscular junction, this can result in muscle contraction. Excess stimulation of these receptors can also result in a depolarizing blockade in which there is a sustained contraction of the muscle. This will be discussed in depth in Chapter 6.

Muscarinic receptors have multiple subtypes, M_1–M_5, and are all GPCRs. M_1, M_3, and M_5 receptors interact with G_q proteins and thus lead to activation of phospholipase C and the eventual increase in intracellular calcium from intracellular stores along with activation of protein kinase C. M_2 and M_4 receptors interact with G_i proteins leading to decreased protein kinase A activation, hyperpolarization of the membrane due to the activation of certain potassium channels, and reduction in vesicular mobilization due to the closing of certain calcium channels. In addition to actions in the brain, muscarinic receptors are also the primary receptor of the parasympathetic nervous system.

Agents that block cholinergic transmission in the CNS are used clinically in the treatment of motion sickness and in restoring the DA–ACh balance lost in the initial stages of Parkinson's disease. Agents that enhance cholinergic transmission in the brain by inhibiting acetylcholinesterase are currently approved for use in Alzheimer's disease and may delay cognitive impairment in the initial stages of the disease.

Monoamines

The monoamines consist of catecholamines and serotonin. The catecholamines (dopamine, norepinephrine, and epinephrine) are all synthesized from a common precursor, tyrosine, and share a

common synthetic pathway. All of the monoamines are metabolized by monoamine oxidase (MAO), which is located in the mitochondria of both the presynaptic and postsynaptic terminals. Inhibitors of monoamine oxidase can result in elevated levels of the monoamines. When a monoamine oxidase inhibitor is combined with another drug that increases the levels of a particular monoamine, life-threatening situations can result: hypertensive crisis with norepinephrine and serotonin syndrome with serotonin.

Norepinephrine and Epinephrine

Norepinephrine (NE) and epinephrine, sometimes referred to as adrenalin, both act at adrenergic receptors. Norepinephrine is synthesized within the vesicle from dopamine. Dopamine (DA) is transported into the vesicle via the vesicular monoamine transporter (VMAT). If the enzyme dopamine β hydroxylase is present in the vesicle, it will convert DA to NE. Norepinephrine can be further converted to epinephrine if the enzyme phenylethanolamine-*N*-methyltransferase is present. Most epinephrine is secreted from chromaffin cells of the adrenal medulla and circulates peripherally in response to activation of the sympathetic nervous system. Similarly, NE has a primary role in the sympathetic nervous system but it has a larger role in the CNS than does epinephrine. In the CNS, NE is involved in arousal, blood pressure regulation, control of mood, pain modulation, and appetite suppression. Once released, NE can interact with adrenergic receptors located on the postsynaptic and presynaptic terminals. It can then be taken back up into the presynaptic terminal by the norepinephrine transporter. Once in the cytosol, it can be reloaded into the vesicle via VMAT or be metabolized via MAO. It can also be degraded in nonneuronal cells by catechol-*O*-methyltransferase (COMT).

There are two main receptor subtypes with which norepinephrine and epinephrine interact: alpha and beta adrenergic receptors. Alpha adrenergic receptors have two subtypes. The α_1 receptor activates the G_s protein, while the α_2 receptor activates the G_i protein. The α_2 receptor can be found presynaptically where it can function to decrease further release of NE. There are three beta adrenergic receptors (β_1, β_2, and β_3), which all activate G_s proteins.

Adrenergic receptors in the CNS are involved in alertness, pain transmission, and central control of sympathetic tone. Agents that result in the activation of these receptors in the CNS are used clinically in the treatment of attention deficit hyperactivity disorder, narcolepsy, hypertension, depression, pain, and appetite suppression. Certain stimulant drugs, like amphetamine and methamphetamine, also produce effects through activation of adrenergic receptors.

Dopamine

Dopamine was once thought to simply be the precursor for norepinephrine but now it is recognized as a neurotransmitter in its own right. It is involved in control of movement, reward and addiction, and development of schizophrenia. Similar to norepinephrine and epinephrine, DA is released into the synaptic cleft where it can interact with postsynaptic and presynaptic receptors. It is transported back into the presynaptic terminal by the dopamine transporter where it can be re-loaded into vesicles via transport by VMAT. It can also be broken down within the terminal by MAO. Like other catecholamines, it can also be taken up by nonneuronal cells and metabolized by COMT.

Dopamine receptors are classified D_1–D_5 and are all GPCRs. D_1 and D_5 receptors activate the G_s protein, whereas D_2, D_3, and D_4 receptors activate G_i proteins. Activation of dopaminergic receptors is used clinically in the treatment of Parkinson’s disease. Inhibition of these receptors is used clinically in the treatment of schizophrenia and psychosis. Many addictive drugs and behaviors involve activation of the dopaminergic “reward pathway.”

Serotonin

Serotonin, or 5-hydroxytryptamine (5-HT), is a monoamine but not a catecholamine. In the brain, it is involved in mood control, appetite control, and nausea. It is synthesized from tryptophan rather than from tyrosine. Once synthesized in the cytosol, it is transported into the vesicle via VMAT. Upon release into the synaptic cleft, it interacts with postsynaptic and presynaptic receptors. Its action is terminated via reuptake into the presynaptic terminal by the serotonin transporter. Like the other monoamines, serotonin can be degraded within the presynaptic terminal by MAO or recycled into vesicles by VMAT.

Serotonin receptors represent ionotropic and metabotropic receptor classes. The 5-HT_1 receptors are linked to G_i protein, 5-HT_2 receptors are linked to G_q proteins, 5-HT_3 receptors are ligand-gated and permeable to sodium, and 5-$HT_{4–7}$ receptors are linked to G_s proteins. Clinically, serotonin reuptake inhibitors are used to treat depression by enhancing the levels of serotonin in the synaptic cleft. Agents that activate selective serotonin receptors are used clinically to treat migraines and anxiety. Agents that block serotonin receptors in the chemoreceptor trigger zone are used in the treatment of nausea and vomiting. Certain drugs, such as LSD, produce hallucinations through activation of specific 5-HT receptors.

Glutamate

Glutamate is the principle excitatory neurotransmitter of the CNS. It plays a role in learning and memory, pain transmission, epilepsy, and some forms of neurotoxicity. Glutamate in nerve terminals is converted from α-ketoglutarate, from the Krebs cycle, and stored in vesicles. It then undergoes calcium-dependent vesicular release into the synaptic cleft where it can interact pre- and postsynaptically with its receptors. Its action is terminated by uptake via an excitatory amino acid transporter back into the presynaptic terminal or into glial cells where it is converted to glutamine by the enzyme glutamine synthase. Glutamine can then leave the glial cell and enter the presynaptic terminal via the glutamine transporter. It is converted in the presynaptic terminal back to glutamate and then taken up into the vesicle via a vesicular glutamate transporter.

Glutamate receptors are named for particular ligands that activate them. The *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate (KA) receptors are ionotropic receptors. AMPA and KA receptors are permeable to Na^+ and K^+, whereas NMDA receptors are also permeable to Ca^{2+}. The Ca^{2+} permeability is thought to play a role in the toxicity associated with excess glutamate in the synaptic cleft. There are also metabotropic receptors linked to either the G_q or G_i protein.

There are not very many clinical therapies that directly target glutamate receptors. Inhibitors of NMDA receptors may be of some benefit in treating epilepsy and are used to delay cognitive impairment in patients with Alzheimer’s disease. Ketamine inhibits the NMDA receptor by blocking the pore and is used clinically as a general anesthetic and an analgesic. Ketamine is associated with hallucinations. Another blocker of the NMDA receptor pore, the illicit drug PCP, is also a hallucinogen.

GABA

The amino acid γ-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter of the CNS. It functions as a CNS depressant. Disruption of GABA signaling may be involved in anxiety and epilepsy. GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD). It is stored in vesicles and undergoes calcium-dependent vesicular release. GABA is taken into the presynaptic terminal and glial cells by a GABA transporter. It can then be recycled into vesicles or metabolized by GABA transaminase.

GABA interacts with two receptor subtypes. $GABA_A$ receptors are ligand-gated ion channels that are permeable to chloride ions. When the pore opens, these negatively charged ions enter the cell and lead to hyperpolarization thus decreasing the excitability of the cell. $GABA_B$ receptors are G_i proteins that lead to hyperpolarization of cells via the opening of certain potassium channels and decreased vesicular release via inhibition of presynaptic voltage-gated calcium channels.

Activation of GABA receptors has a number of clinical uses. Drugs that activate $GABA_A$ receptors are utilized to treat anxiety, insomnia, and epilepsy and to produce anesthesia. Drugs that activate $GABA_B$ receptors are utilized as muscle relaxants. Alcohol also activates the $GABA_A$ receptor resulting in general CNS depression.

Histamine

Histamine plays a major role in the immune response. It also functions as a minor neurotransmitter in the CNS. There are four identified histamine receptors, H_1–H_4, which are all GPCRs. The H_1 receptors are linked to G_q proteins. Inhibition of these receptors produce drowsiness, which is a side effect of antihistamines that cross the blood–brain barrier. These inhibitors of the H_1 receptors have therapeutic utility in over-the-counter sleep aids. In the periphery, H_1 receptor antagonists ("antihistamines") are mainly used in treating allergic responses and in symptoms of colds and flu. They are also used to reduce itch. H_2 receptor antagonists are used to reduce acid secretions in the gut.

Purines

ATP is another small molecule that can act in a neurotransmitter role. It is stored in vesicles and often found in terminals that also contain norepinephrine. ATP modulates the actions of NE through interacting with P_2 purine receptors. P_{2x} receptors are ionotropic, whereas P_{2Y} receptors are metabotropic. Adenosine is produced from the hydrolysis of ATP and can also act as a neuromodulator. It differs from ATP in that it is not stored in vesicles. It acts at distinct metabotropic receptors: P_1 receptors with subtypes $A_{1–3}$. Effects of caffeine are mediated in part by the inhibition of certain adenosine receptors.

Neuropeptides often serve a neuromodulatory role.

There are a number of neuropeptides that play a role in cellular signaling in the CNS. Many of these are also active in the GI tract and endocrine glands. Neuropeptide precursors are synthesized in the cell body where they are packaged into vesicles by the Golgi apparatus. The precursors are cleaved into smaller peptides by proteases within the vesicle as they are transported to the terminal. Generally, the neuropeptides are co-localized within the same presynaptic terminal with vesicles containing classical neurotransmitters. A strong stimulus can release both the neurotransmitter and neuropeptide into the synaptic cleft. The neuropeptide can modulate the function of the neurotransmitter through activation of its presynaptic and postsynaptic receptors, usually GPCRs. Neuropeptides diffuse out of the synaptic cleft and are degraded by extracellular proteases. Some of the neuropeptide receptors have become primary drug targets.

Opioids

Opioids are a class of compounds that can produce morphine-like effects. These effects are mediated through activation of opioid receptors. The endogenous compounds that activate these receptors are the neuropeptides endorphin, enkephalin, and dynorphin. There are three opioid receptor subtypes: μ, κ, and δ. All three activate G_i proteins resulting in decreased cAMP levels, opening of certain K^+ channels, and closing of certain Ca^{2+} channels. Thus, opioids decrease synaptic transmission by hyperpolarizing the cell and decreasing calcium-mediated vesicular mobilization. This is useful therapeutically in treating pain. However, activation of opioid receptors in other regions of the brain can produce respiratory depression, which is a particular concern with opioid overdose. Opioids can also produce euphoria and addiction through activation of receptors in the “reward pathway” of the brain. The analgesic effects can be separated from the addictive potential through appropriate prescribing practices.

Nonclassical neurotransmitters can be synthesized and released "on demand."

There are a number of other mediators of synaptic transmission that do not undergo classical vesicular storage and release yet are still formed in a calcium-dependent manner. Adenosine, discussed above, is an example of this. Once formed, these nonclassical neurotransmitters diffuse out of the presynaptic terminal to interact with pre- and postsynaptic receptors.

Eicosanoids

There are a number of putative synaptic transmitters that are formed from arachidonic acid. Phospholipase A2 liberates arachidonic acid from the cell membrane. Arachidonic acid can then act as a substrate for a number of enzymes. The presence of the enzyme cyclooxygenase will result in the production of prostaglandins and thromboxane, whereas the presence of the enzyme lipoxygenase will result in the production of leukotrienes. These lipid mediators are not stored in vesicles but will diffuse across the membrane to interact with pre- and postsynaptic receptors. The leukotrienes are implicated in inflammatory responses involved in asthma. The prostanoids play a role in modulating inflammatory responses, pain, and temperature. Certain anti-inflammatory drugs, such as aspirin, act by inhibiting the activation of cyclooxygenase.

Cannabinoids

Endocannabinoids are other lipid mediators derived from arachidonic acid derivatives. These compounds are formed in response to increased intracellular calcium. The fate of arachidonic acid is dependent on the particular enzymes that are present in the cell thus determining which, if any, arachidonic acid derivatives will be formed. Endocannabinoids are not stored in vesicles but instead diffuse across the membrane where they can act pre- or postsynaptically with cannabinoid receptors. These are the same receptors at which delta-9-tetrahydrocannabinol (THC), one of the active constituents of marijuana, acts. There are two receptor subtypes: CB_1 and CB_2. Both are linked to G_i proteins. CB_2 is mostly found in the periphery, whereas CB_1 receptors are located in the CNS. Endocannabinoid signaling may play roles in pain modulation and appetite. Compounds that activate these receptors have been explored therapeutically as analgesics and for the treatment of obesity.

INTEGRATED MEDICAL SCIENCES

Parkinson's Disease

Parkinson's disease is neurodegenerative disease characterized by the loss of dopaminergic neurons in the brain, particularly in the basal ganglia, and subsequent motor deficiencies. Individuals experience slowed movement, rigidity, tremor, and postural instability. Nonmotor symptoms, such as depression and constipation, may also accompany the disease.

Because of the loss of dopamine-synthesizing neurons in the brain, a logical treatment strategy is

to increase dopamine in the brain. However, there are limitations to this approach. If dopamine is administered to a patient by an oral or other systemic route, it will not reach the central nervous system because of two mechanisms. Dopamine, along with other catecholamines, are degraded by COMT and MAO. The liver contains high concentrations of both of these enzymes. As dopamine circulates in the bloodstream and passes through the liver, much of it will be degraded. Any dopamine that remains, will not get into the brain because dopamine does not readily cross the BBB.

In order to increase the concentration of dopamine in the brain, a different strategy is employed. In the body's synthesis of dopamine, tyrosine is converted to dopa, which is then converted to dopamine by the enzyme dopa decarboxylase. One of the stereoisomers of dopa, levodopa or l-dopa, is transported across the BBB and thus has access to the brain where it can be converted to dopamine. Administration of levodopa is a therapeutic strategy in the treatment of Parkinson's disease. In order to prevent levodopa's conversion peripherally, it is administered with carbidopa, an inhibitor of dopa decarboxylase that will not cross the BBB. Another concern with levodopa is that, like dopamine, it is also a substrate for COMT and MAO and is degraded as it passes through the liver. Thus, entacapone, which inhibits COMT, can be administered along with levodopa/carbidopa to prevent the metabolism of levodopa. Inhibitors of monoamine oxidase such as rasagiline can also decrease metabolism of levodopa. With the addition of these drugs, levodopa is able to access the brain where it is then converted to dopamine and serves to increase the low levels of dopamine resulting from loss of dopaminergic neurons. Other strategies in treating Parkinson's disease include using drugs that directly activate dopamine receptors, such as bromocriptine and pramipexole. ■

Chapter Summary

- The nervous system is divided into the central, consisting of the brain and spinal cord, and peripheral, consisting of ganglia and nerves, nervous systems.
- The blood–brain barrier limits access of molecules into the CNS and is formed by a layer of capillary endothelial cells connected by tight junctions and surrounded by astrocytes cells.
- The primary cells in the nervous system are neurons and glia. Glial cells function as neuronal support cells. Schwann cells and oligodendrocytes insulate axons and increase the speed of conduction. Microglia serve an immune function. Astrocytes help form the blood–brain barrier, provide metabolic support to neurons, regulate blood flow, are involved in reuptake and recycling of some synaptic transmitters, and help regulate ionic concentrations in the extracellular fluid.
- Neurons function in storage, communication and integration of information. This is accomplished through dendrites, which receive and transmit information to the soma, and axons, which propagate action potentials and communicate via the release of synaptic transmitters.
- The neuronal cytoskeleton is involved in transporting materials both from the soma to the neuronal processes (anterograde transport) and from the processes to the soma (retrograde transport).
- Ion channels can be ligand-gated or voltage-gated. They are selective for particular ions. Once opened, the flow of ions into or out of the cell is determined by both electrical and concentration gradients for that ion and can be calculated by the Nernst equation.
- When ion channels open and allow the influx or efflux of ions, there is an excitatory or inhibitory postsynaptic potential. These summate both temporally and spatially to influence the net effect on membrane potential.
- Once the membrane potential depolarizes to a threshold potential, a cascade of opening of voltage-gated sodium channels occurs resulting in further depolarization and the production of an action potential.
- The return of the membrane potential to the resting membrane potential is accomplished by the opening of potassium channels and the inactivation of sodium channels.
- Action potentials are self-propagating, unidirectional, and can travel the length of the axon.
- The conduction velocity of action potentials is influenced by the diameter of the nerve fibers and their myelination. Fibers that are unmyelinated and small, C fibers, have the slowest conduction velocity and carry information about pain and temperature. Large myelinated fibers, Aα fibers, have the fastest conduction velocity and carry information about proprioception and motor function.
- The synapse consists of specialized segments of neurons used for chemical communication between cells consisting of the presynaptic terminal, the synaptic cleft, and the postsynaptic terminals of dendrites.
- Most neurotransmitters and neuropeptides are contained in vesicles that are located within the presynaptic terminal.
- The arrival of an action potential at the presynaptic terminal results in the opening of voltage-gated calcium channels, which results in calcium-dependent mobilization of vesicles to the membrane where the synaptic transmitter is released into the synaptic cleft to interact with receptors.
- Some synaptic transmitters are synthesized “on demand” in a calcium-dependent manner but are not stored in vesicles.
- Neurotransmitters can interact with receptors that are located on presynaptic or postsynaptic terminals. Generally, interactions with presynaptic receptors serve as negative modulators of release. Most neuronal receptors can be classified as ionotropic or metabotropic.

Chapter Review Questions

1. How would hypokalemia (low extracellular potassium levels) affect neuronal excitability?
   - **A.** Decreased excitability due to a decreased resting membrane potential
   - **B.** Decreased excitability due to an increased resting membrane potential
   - **C.** Increased excitability due to a decreased resting membrane potential
   - **D.** Increased excitability due to an increased resting membrane potential
   - **E.** It would not affect neuronal excitability

The correct answer is A. Neuronal resting membrane potentials are near the potassium equilibrium potential and there is a much higher concentration of K^+ inside the cell compared with outside the cell. If extracellular K^+ levels decrease, this will result in K^+ leaving the cell to re-establish an equilibrium potential and balance electrochemical forces. When K^+ leaves the cell, the resting membrane potential will decrease making it harder to produce an action potential.

2. Metyrosine is a drug that will inhibit the conversion of tyrosine to dopamine. What other effects will it have?
   - **A.** Activation of the reward pathway
   - **B.** Decreased production of epinephrine
   - **C.** Decreased production of serotonin
   - **D.** Development of schizophrenia
   - **E.** Increased metabolism of norepinephrine

The correct answer is B. Tyrosine is the rate-limiting step in the synthesis of all catecholamines (dopamine, norepinephrine, and epinephrine). Inhibiting the conversion of tyrosine to dopamine will decrease all catecholamines. C is incorrect because, while it is a monoamine, serotonin is not a catecholamine. A and D are incorrect because dopamine is involved in both the reward pathway and schizophrenia. E is incorrect because this will not affect either COMT or MAO, which are the enzymes involved in the degradation of norepinephrine.

3. Activation of opioid receptors leads to the inhibition of voltage-gated calcium channels. What effect will the inhibition of voltage-gated calcium channels have on cellular signaling?
   - **A.** Decrease postsynaptic receptor activation
   - **B.** Decrease the postsynaptic membrane potential
   - **C.** Increase neurotransmitter release
   - **D.** Increase the postsynaptic membrane potential
   - **E.** Inhibit the generation of action potentials

The correct answer is A. Voltage-gated calcium channels are involved in mobilization of vesicles to the plasma membrane enabling them to dock and release neurotransmitters. By inhibiting these calcium channels, there will be less neurotransmitter available to activate postsynaptic receptors.

4. Increasing the refractory period would have what effect on action potentials?
   - **A.** Decrease the amplitude of action potentials
   - **B.** Decrease the frequency of action potentials
   - **C.** Increase the amplitude of action potentials
   - **D.** Increase the frequency of action potentials
   - **E.** Increase Na^+ conductance

The correct answer is B. The refractory period is the time when sodium channels are inactivated

(absolute refractory) or converting back to the rested state (relative refractory). During the absolute refractory period, the sodium channels cannot be activated and an action potential cannot be generated. During the relative refractory period, a larger stimulus is required to generate an action potential. The amplitude of the action potential does not change but there will be a decrease in the frequency of action potential production.

Clinical Application Exercises 3.1

EPISODIC ATAXIA

A previously healthy 30-year-old man notices difficulty completing his usual exercise routine over the last 2 weeks because of excessive fatigue during the workout. He consults his primary physician, and the physical examination reveals lymphadenopathy (enlarged lymph nodes) in the neck, axilla, and groin. Further evaluation by computed tomographic scanning of the chest and abdomen shows enlargement of thoracic and abdominal lymph nodes. He is referred to an oncologist, and a diagnosis of lymphoma is made. He is started on chemotherapy consisting of weekly intravenous infusions of the combination chemotherapy treatment known as *MOPP* (mechlorethamine, Oncovin, procarbazine, and prednisone). He experienced the expected nausea and general fatigue typical of this type treatment but tolerated these side effects relatively well. A few days after the third round of treatment he begins to notice numbness in the toes of both feet. He also notices a burning, stinging sensation in the same areas. These abnormal sensations persist and over the next 2 weeks migrate from the toes up to the level of the ankles. At his next follow-up appointment with the oncologist, the previously enlarged lymph nodes have returned to normal size. Examination of the neurological function of his feet and legs shows that he cannot feel the touch of a ball of cotton or a vibrating tuning fork on his toes. The oncologist tells him that the foot symptoms are due to “transportation troubles in the nerves” from the chemotherapy, and that the symptoms will get better over the next few months.

QUESTIONS

1. Which of the chemotherapy medications is the most likely cause of the abnormal sensations?
2. Why did these abnormal sensations start in the toes?
3. What is the pathogenesis (mechanism) of the nerve dysfunction?
4. Why did the symptoms begin several weeks after the treatment began?

ANSWERS

1. Vincristine (Oncovin) is the medication in the combination of chemotherapy drugs that causes the nerve dysfunction. This medication is in the vinca alkaloids, which are named for the family of plants they are derived from.
2. The patient’s symptoms fit in the category of peripheral neuropathy. This group of disorders can be caused by abnormal function of the nerve cell body, the axon, or the myelin sheath. Abnormalities of axon function are the most common cause of peripheral neuropathy. In this type of nerve disease, the longest axons show the effects of the abnormal function first; therefore, the abnormalities appear first in the toes and distal feet. If the condition worsens, the abnormal sensations spread from the toes to the mid-foot and potentially up to the ankle or mid-shin. The fingers may also show similar abnormalities. Neuropathies like our patient’s are said to be “length dependent,” because the

longest axons show the abnormalities first.

3. Vincristine (Oncovin) impairs transport along the axons by interfering with the assembly of tubulin into microtubules. Microtubules provide the framework for fast axoplasmic transport from the nucleus to the nerve terminal and also for retrograde transport from the nerve terminal back to the nucleus.
4. The nerve dysfunction effects of the vincristine (Oncovin) are cumulative and usually begin only after several cycles of treatment. If the medication is able to be discontinued, nerve function tends to improve over subsequent months as axoplasmic transport is restored and the axons become able to maintain their structure normally.

4 Sensory Physiology

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how the many different forms of environmental energy are transformed by sensory receptors into the same type of electrical signal in sensory nerves.
- Explain why sensory receptors have specificity to sense one type of environmental energy over another.
- Explain why sensory receptors that respond to a selective type of environmental energy can respond to a different type, yet the sensation produced is the same as if the receptor responded to the energy for which it was designed to detect.
- Postulate the value of adaptation of sensory receptors in relation to the selective type of sensation the receptor is designed to detect.
- Explain why action potential frequency is the mode of information transmission in sensory systems and how changes in that frequency are related to graded electrical potential changes in sensory receptors.
- Explain how the processes of adaptation and accommodation permit the processing of a wide-range of stimulus intensities.
- Distinguish between rod and cone vision and point out the special features of each type.
- Describe the organization of the retina, relating each layer to its specific and integrated function in the process of vision.
- Explain, in terms of biochemical events, the process of light and dark adaptation in the retina.
- Describe the processing of sound by different parts of the auditory system, the mechanism of auditory transduction and how the frequency of sound is represented along the basilar membrane.
- Explain the roles of the different components of the vestibular system in detecting rotational and linear acceleration.
- Explain the sensory processes in the related senses of smell and taste and the receptors and mechanisms that underlie chemoreception.

SENSORY SYSTEMS

The survival of any organism depends on having adequate information about the external environment as well as information about the state of internal bodily processes and functions. Information about our external and internal environments is gathered by the sensory branch of the nervous system. This chapter discusses the functions of the sensory receptors, the organs that permit us to gather this information. The discussion emphasizes somatic sensations, that is, those dealing with the external aspect of the body. This chapter does not specifically address the visceral sensations that come from internal organs.

Sensory systems transform physical and chemical signals from the external and internal environments into information in the form of nerve action potentials.

Events in our external and internal worlds must first be translated into signals that our nervous systems can process. Despite the wide range of types of information to be sensed and acted on, a small set of common principles underlies all sensory processes.

Furthermore, although the human body contains a very large number of different sensory receptors, these receptors have many functional features in common. The process of sensation essentially involves sampling small amounts of energy from the environment by sensory receptors and using it to control the generation of trains of action potentials in sensory nerves (Fig. 4.1). The pattern of sensory action potentials, along with the specific nature of the sensory receptor and its neural pathways in the brain, provides an internal representation of a specific component of the external world. The wide variety of specialized sensory functions is a result of structural and physiologic adaptations that fit a particular receptor for its role in the organism. Finally, the process of sensation is a portion of the more complex process of perception, in which sensory information is integrated with previously learned information and other sensory inputs, enabling us to make judgments about the quality, intensity, and relevance of what is being sensed.

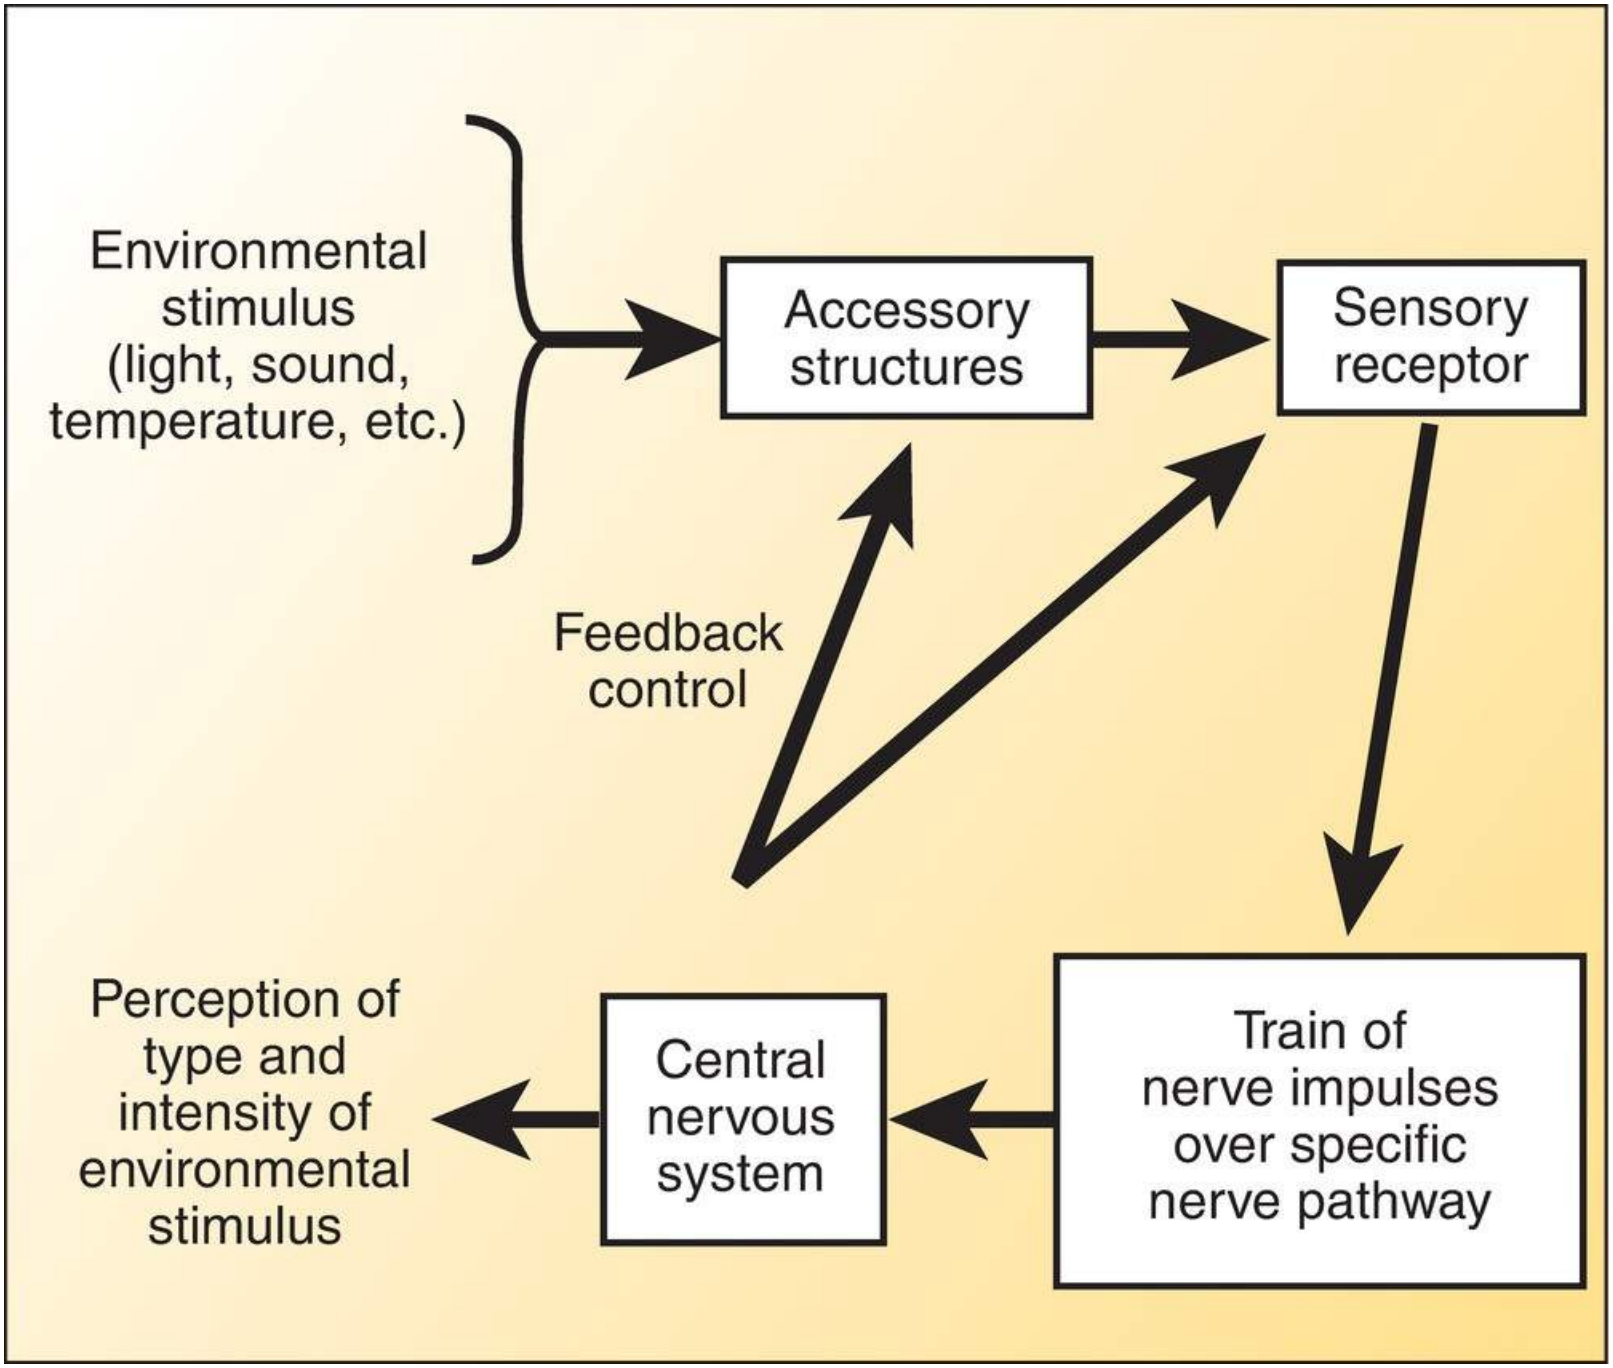

Figure 4.1 A basic model for the translation of an environmental stimulus into a perception. Although the details vary with each type of sensory modality, the overall process is similar.

Sensory Stimuli

A factor in the environment that produces an effective response in a sensory receptor is called a **stimulus**. Typical stimuli include electromagnetic quantities, such as radiant heat or light; mechanical quantities, such as pressure, sound waves, or vibrations; and chemical qualities, such as acidity and molecular shape and size. Regardless of the sensation experienced, all sensory systems transmit information to the brain with the four common attributes of intensity, modality (e.g., temperature, pressure, and vision), location, and duration.

A fundamental property of sensory receptors is their ability to respond to different intensities of stimulation with a representative output. *Intensity* is a measure of the energy content available to interact with a sensory receptor. Most individuals are familiar with sensory intensity in phenomena such as the brightness of light, the “loudness” of sound, or the force of physical contact of an object with the body.

Sensory receptors are capable of detecting the modality of a stimulus. **Sensory modality** is the term used to describe the *kind* of sensation present. Common sensory modalities include taste, smell, touch, sight, and hearing (the traditional five senses) as well as more complex sensations, such as slipperiness or wetness. Sensory modality is often used to classify receptors. For example, **photoreceptors** that serve a visual function sense light. **Chemoreceptors** detect chemical signals and serve the senses of taste and smell. **Mechanoreceptors** sense physical deformation and serve such sensory modalities as touch, hearing, and the amount of stress in a tendon or muscle. Heat, or its relative lack, is detected by **thermoreceptors**. Many sensory modalities are a combination of simpler sensations. For example, the sensation of wetness is actually composed of sensations of pressure and temperature. You can demonstrate this phenomenon yourself by placing your hand in a plastic bag and then immersing it in cold water. Even though your hand will remain dry inside the bag, the perception you sense will be that of wetness.

Although sensory receptors are often classified by the modality to which they respond, other sensory receptors are classified instead by their "vantage point" in the body. For example, exteroceptors detect stimuli from outside the body, interoceptors detect internal stimuli, and proprioceptors (*proprio* is Latin for "one's own") provide information about the positions of joints, muscle activity, and the orientation of the body in space. Nociceptors (pain receptors) detect noxious agents, both internally and externally.

It is often difficult to communicate a precise definition of a sensory modality because of the subjective perception or affect that accompanies it. This property has to do with the psychologic feeling attached to the stimulus. For example, the sensation of cold or touch can be pleasurable at certain intensities but rise to an impression of discomfort or extreme pain at very high intensities. Stimulus affect, however, is more complex than a combination of intensity with modality. Previous experience and learning play a role in determining the affect of a sensory perception. The affect of identical visual stimuli, for example, can provoke pleasure, anger, fear, or terror depending on the experiences of those perceiving the stimulus and the memories associated with it.

Sensory receptors

Most sensory receptors are optimized to respond preferentially to a single kind of environmental stimulus. The usual stimulus for the eye is light and that for the ear is sound. This specificity is a result of several features that match a receptor to its preferred stimulus. The usual and appropriate stimulus for a type of sensory receptor is called its **adequate stimulus**. This is the stimulus for which the receptor has the lowest **threshold**, that is, the lowest stimulus intensity that can be reliably detected. Threshold, however, can be difficult to quantify because it can vary over time, and it can be altered by either the presence of interfering stimuli or the action of accessory structures. These structures are not considered part of the sensory receptor itself. However, in many cases, such as the lens of the eye or the structures of the outer and middle ear, these structures either enhance the specific sensitivity of the receptor or exclude unwanted stimuli. Often these accessory structures are part of a control system that adjusts the sensitivity according to the information being received (see Fig. 4.1).

Most receptors will respond to additional types of stimuli other than the adequate stimulus. However, the threshold for the inappropriate stimuli is much higher. For example, applying pressure to the eye will cause one to "see lights" although light itself is the energy type for which the sensory receptors of the eye have the lowest threshold. Finally, almost all receptors can be stimulated electrically to produce sensations that mimic the one usually associated with that receptor.

Another feature of sensory system specificity resides in the central nervous system (CNS). The CNS pathway over which sensory information travels also plays a role in determining the nature of the

perception. Information arriving by way of the optic nerve, for example, is always perceived as light and never as sound. This is known as the concept of the labeled line. Details of all neural sensory pathways are beyond the scope of this text.

Sensory transduction changes environmental energy into sensory nerve action potentials.

The key physiologic function of a sensory receptor is to translate nonelectrical forms of environmental energy into electrical events that can be transmitted and processed by the nervous system. These electrical events are nerve action potentials, which are the fundamental units of information in the nervous system. A device that translates one form of energy signal into another is called a **transducer**. Sensory receptors in the body, therefore, can be thought of as biologic transducers. A typical sequence of electrical events in the sensory transduction process is shown in Figure 4.2.

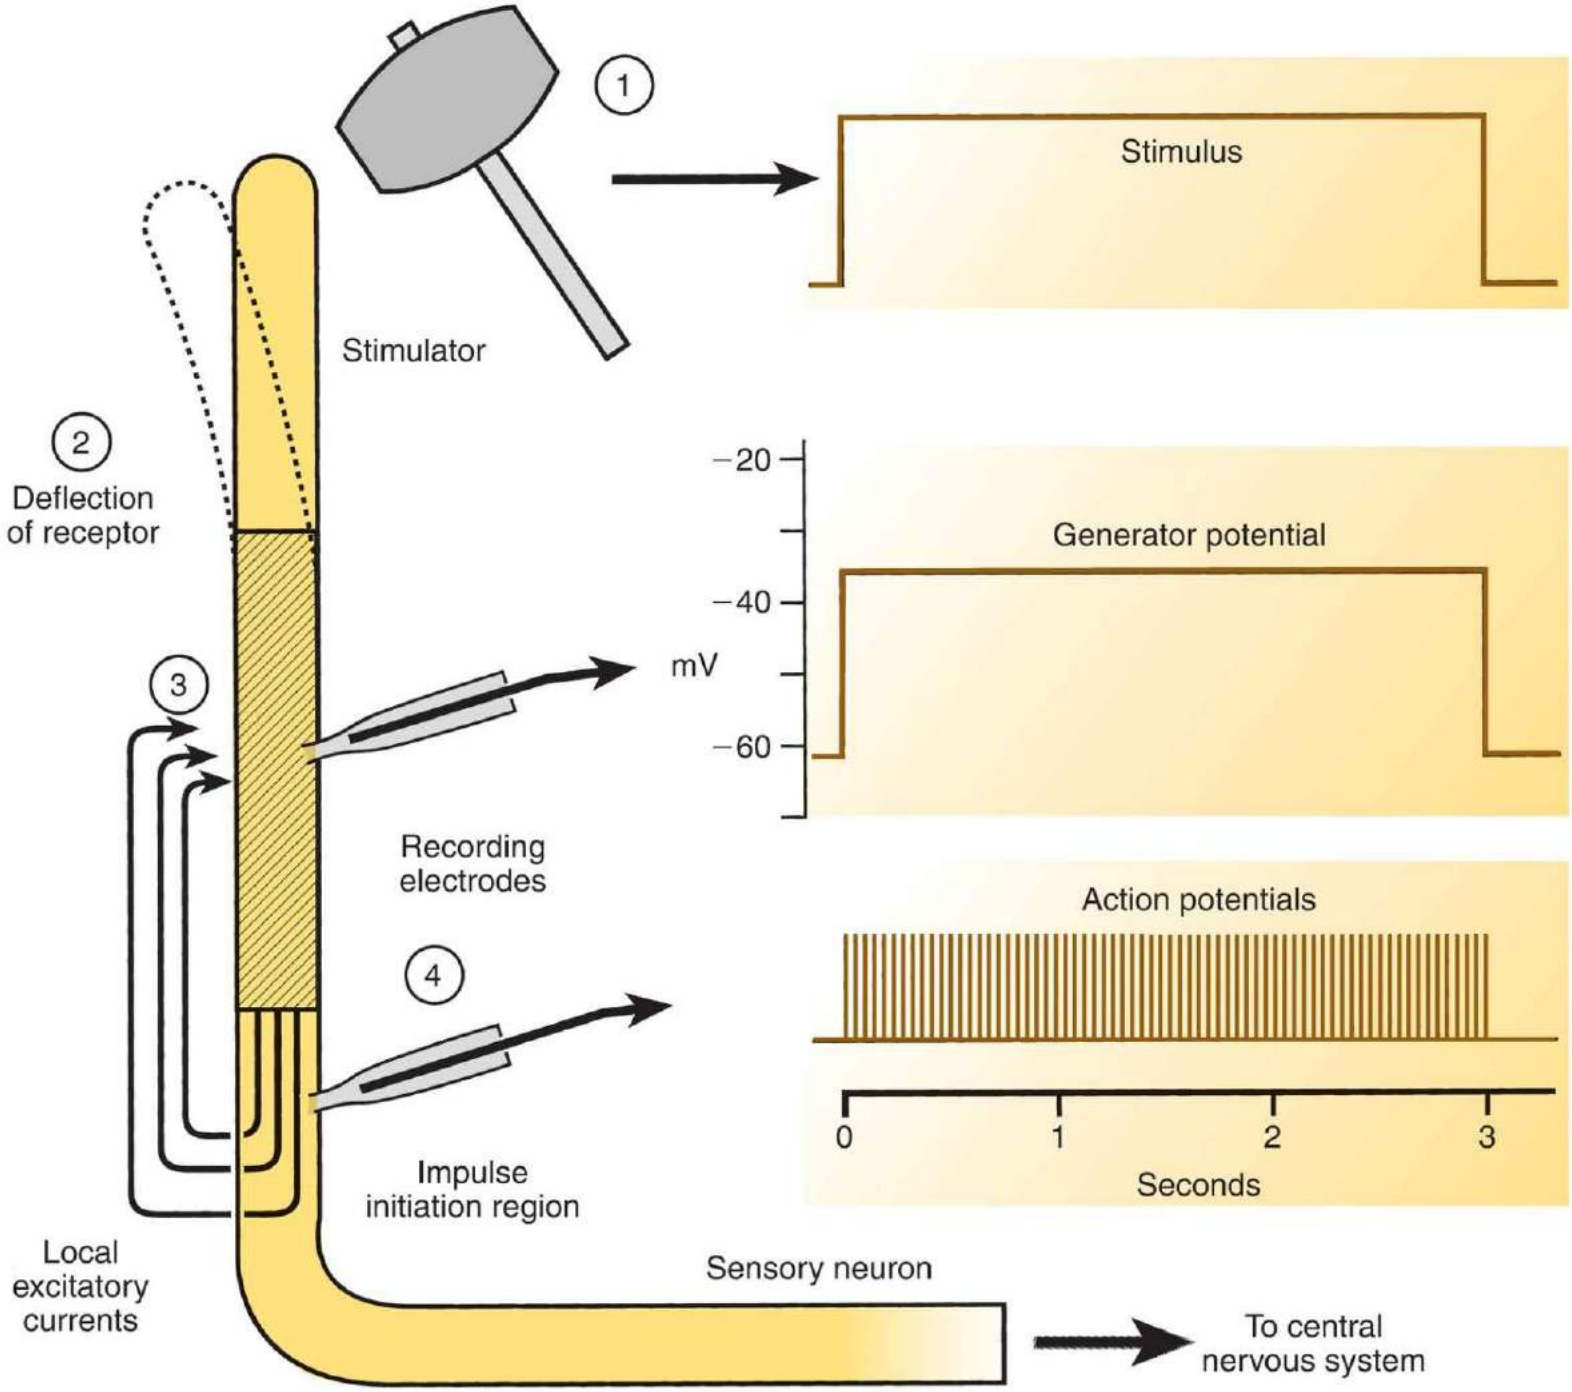

Figure 4.2 The relation between an applied stimulus and the production of sensory nerve action potentials. (See text for details.)

Generator potentials

Figure 4.2 depicts a typical type of sensory receptor system. This example is a representation of a mechanoreceptor, that is, a receptor that translates energy in the form of a physical stress or strain (i.e., pressure, displacement, stretch, etc.) into an electrical signal that will eventually produce action potentials in sensory nerves. In the example in Figure 4.2, the tip of the receptor has been deflected (strained) and held constant (1, 2). This deflection deforms the cell membrane of the receptor, causing a portion of it to become more permeable to positive ions (*shaded region*, 3). The resulting influx of positive charge (mostly from influx of sodium ions) then leads to a localized depolarization, called the **generator potential**. The generator potential creates a current through the axon membrane called a **local excitatory current**. It provides the link between the formation of the generator potential and the

excitation of the nerve fiber membrane.

The production of the generator potential is of critical importance in the transduction process because it is the step in which information related to stimulus intensity and duration is transduced. The strength (intensity) of the stimulus applied (in Fig. 4.2, the amount of deflection) determines the size of the generator potential depolarization. Varying the intensity of the stimulation will correspondingly vary the generator potential, although the changes are not always directly proportional to the intensity. This is called a **graded response**, in contrast to the all-or-none response of an action potential, and causes a similar gradation of the strength of the local excitatory currents.

As generator potential depolarizing currents spread down the neuron, they reach a region of the receptor membrane called the **impulse initiation region** (4). This region is the location of the formation of action potentials in the neuron and constitutes the next important link in the sensory process. In this region, action potentials are produced at a frequency related to the strength of the current caused by the generator potential (and, thus, related to the original stimulus intensity). This region is, therefore, sometimes called the *coding region*, because here the generator potential and flowing current caused by the initial stimulus to the receptor are translated into a train of action potentials of a frequency proportional (but not always in a linear fashion) to the size of the generator potential. The train of action potentials in the sensory nerve fiber is the electrical signal that is sent to the CNS. In complex sensory organs that contain a great many individual receptors, the generator potential may arise from several sources within the organ. Thus, the train of action potentials formed results from multiple inputs to the sensory receptor. In these instances, the generator potential is often called a **receptor potential**.

Sensory receptor subspecialization

The mechanoreceptor depicted in Figure 4.2 is an example of a sensory receptor subtype called a *long receptor*. In such receptors, the formation of the receptor and action potentials occurs in the same cell, the neuron. This type of sensory receptor-to-action potential arrangement is best suited for transmission of sensory information over long distances. In these cases, the initial physical stimulus creates a local receptor potential, which triggers action potentials that are then transmitted all the way to the CNS. The sense of touch and temperature at the tips of our fingers or toes are examples of sensory transduction by long receptors.

In contrast, other types of sensory transduction in the body occur through *short receptors*. Short receptors are highly specialized cells that, like long receptors, also convert a nonelectrical form of energy into a receptor potential within them. However, in short receptors, the receptor generator potential and neuron action potentials occur in two different cells. In short receptors, the local potential event is coupled to the release of neurotransmitter stored in the receptor cell. This transmitter is then released onto synapses of a postsynaptic primary afferent neuron in which it produces another localized generator potential. It is this second generator potential that triggers trains of action potentials in the afferent neuron that are then sent to the CNS. Short receptors produce either depolarizing or hyperpolarizing generator potentials. In some cases, the same receptor can produce depolarizing and hyperpolarizing generator potentials depending on the stimulus they receive. Positive generator potentials increase the rate of transmitter release, whereas negative potentials decrease this rate. The photoreceptors of the eye and the hair receptors of the cochlea of the inner ear are examples of short sensory receptors (see below).

Sensory nerve impulse frequency is modulated by the magnitude and duration of the generator potential.

Figure 4.3 shows how the magnitude and duration of a generator potential affect subsequent action potential formation in a sensory nerve. This example is typical of what might be seen in a long receptor-type sensory nerve. The threshold (*black line* in the figure) is a critical level of depolarization. Membrane potential changes below this level are caused by the local excitatory currents and vary in proportion to them, whereas the membrane activity above the threshold level consists of locally produced **action potentials**. The lower trace shows a series of different stimuli applied to the receptor, and the upper trace shows the resulting electrical events in the impulse initiation region. No stimulus is given at A, and the membrane voltage is at the resting potential. At B, a small stimulus is applied, producing a generator potential too small to bring the impulse initiation region to threshold; no action potential activity results, and the stimulus causing this level of potential generation would, therefore, not be sensed at all. In contrast, at C, a brief stimulus of greater intensity is given, and the resulting generator potential displacement is of sufficient amplitude to trigger a single action potential. As in all excitable and all-or-none nerve membranes, the action potential is immediately followed by repolarization, often to a level that transiently hyperpolarizes the membrane potential because of temporarily high potassium conductance. Because the brief stimulus has been removed by this time, no further action potentials are produced. A longer stimulus of the same intensity (D) produces repetitive action potentials because, as the membrane repolarizes from the action potential, local excitatory currents are still flowing. They bring the repolarized membrane to threshold at a rate proportional to their strength. During this time interval, the fast sodium channels of the membrane are being reset, and another action potential is triggered as soon as the membrane potential reaches threshold. As long as the stimulus is maintained, this process will repeat itself at a rate determined by the stimulus intensity. If the intensity of the stimulus is increased (E), the local excitatory currents will be stronger and the threshold will be reached more rapidly. This will result in a reduction of the time between each action potential and, as a consequence, a higher action potential frequency. This change in action potential frequency is critical in communicating the intensity of the stimulus to the CNS.

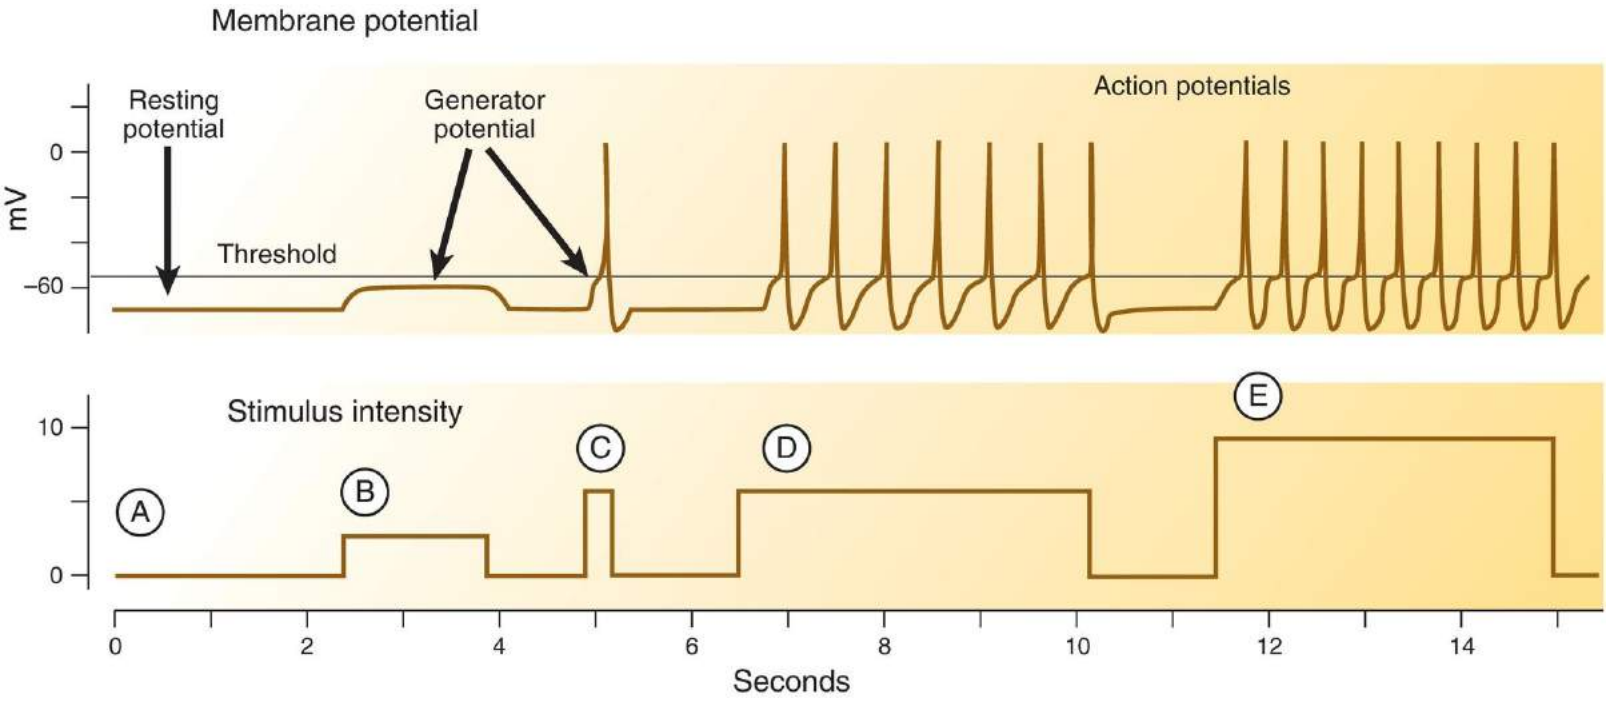

Figure 4.3 Sensory nerve activity with different stimulus intensities and durations. **(A)** With no stimulus, the membrane is at rest. **(B)** A subthreshold stimulus produces a generator potential too small to cause membrane excitation. **(C)** A brief, but intense, stimulus can cause a single action potential. **(D)** Maintaining this stimulus leads to a train of action potentials. **(E)** Increasing the stimulus intensity leads to an increase in the action potential firing rate.

Sustained sensory receptor stimulation can result in diminished action potential generation over time.

In the presence of a constant stimulus, only some sensory receptors maintain the magnitude of their initial generator potential. In most sensory receptors, the magnitude of the generator potential decays over time, even when the original sensory stimulus does not change. This phenomenon is called *adaptation*. Figure 4.4A shows the output from a receptor in which there is no adaptation. As long as the stimulus is maintained, there is a steady rate of action potential firing. Figure 4.4B shows slow adaptation; the generator potential amplitude declines slowly, and the interval between the action potentials increases correspondingly. Figure 4.4C demonstrates rapid adaptation; the action potential frequency falls rapidly and then maintains a constant slow rate that does not show further adaptation. Responses in which there is little or no adaptation are called *tonic*, whereas those in which significant adaptation occurs are called *phasic*. In some cases, tonic receptors may be called *intensity receptors* and phasic receptors may be called *velocity receptors*. Many receptors—*muscle spindles*, for example—show a combination of responses. On application of a stimulus, a rapidly adapting phasic response is followed by a steady tonic response. Both of these responses may be graded by the intensity of the stimulus. As a receptor adapts, the sensory input to the CNS is reduced, and the sensation is perceived as less intense.

Figure 4.4 Adaptation. Adaptation in a sensory receptor is often related to a decline in the generator potential with time. **(A)** The generator potential is maintained without decline, and the action potential frequency remains constant. **(B)** A slow decline in the generator potential is associated with slow adaptation. **(C)** In a rapidly adapting receptor, the generator potential declines rapidly.

The phenomenon of adaptation is important in preventing “sensory overload” and allows less important or unchanging environmental stimuli to be partially ignored. When a change occurs, however, the phasic response will occur again, and the sensory input will become temporarily more noticeable. Rapidly adapting receptors are also important in sensory systems that must sense the rate of change of a stimulus, especially when the intensity of the stimulus can vary over a range that would overload a tonic receptor.

Receptor adaptation can occur at several places in the transduction process. As mentioned above, adaptation of the generator potential itself can produce adaptation of the overall sensory response. In some cases, however, the receptor’s sensitivity is changed by the action of accessory structures, as in the constriction of the pupil of the eye in the presence of bright light (an example of feedback-controlled adaptation). In the sensory cells of the eye, light-controlled changes in the amounts of the visual pigments also can change the basic sensitivity of the receptors and produce adaptation. Finally, the phenomenon of **accommodation** in the impulse initiation region of the sensory nerve fiber can slow the rate of action potential production even though the generator potential may show no change. Accommodation refers to a gradual increase in threshold caused by prolonged nerve depolarization and results from the inactivation of sodium channels.

Perception of sensory information requires encoding and decoding electrical signals sent to the central nervous system.

Environmental stimuli that have been partially processed by a sensory receptor must be conveyed to the CNS in such a way that the complete range of the intensity of the stimulus is preserved. After the acquisition of sensory stimuli, the process of perception involves the subsequent encoding and transmission of the sensory signal to the CNS. Further processing, or decoding, yields biologically useful information.

Compression

The first step in the encoding process is **compression**. Even when the receptor sensitivity is modified by accessory structures and adaptation, the range of input intensities is large, as shown in Figure 4.5. At the left is a 100-fold range in the intensity of a stimulus. At the right is an intensity scale that results from events in the sensory receptor. In most receptors, the magnitude of the generator potential is not exactly proportional to the stimulus intensity; it increases less and less as the stimulus intensity increases. Furthermore, the frequency of the action potentials produced in the impulse initiation region is also not proportional to the strength of the local excitatory currents. Recall from Chapter 3 that there is an upper limit to the number of action potentials that can be generated in a neuron per second because each action potential has a finite refractory period. All these factors are responsible for the process of compression. Because of compression, changes in the intensity of an already large stimulus cause a smaller change in action potential frequency than the same change would cause if the change occurred from an initially small stimulus. As a result, the hundredfold variation in the stimulus is compressed into a threefold range after the receptor has processed the stimulus. Some information is necessarily lost in this process, although integrative processes in the CNS can restore the information or compensate for its absence. Physiologic evidence for compression is based on the observed nonlinear (logarithmic or power function) relation between the actual intensity of a stimulus and its perceived intensity.

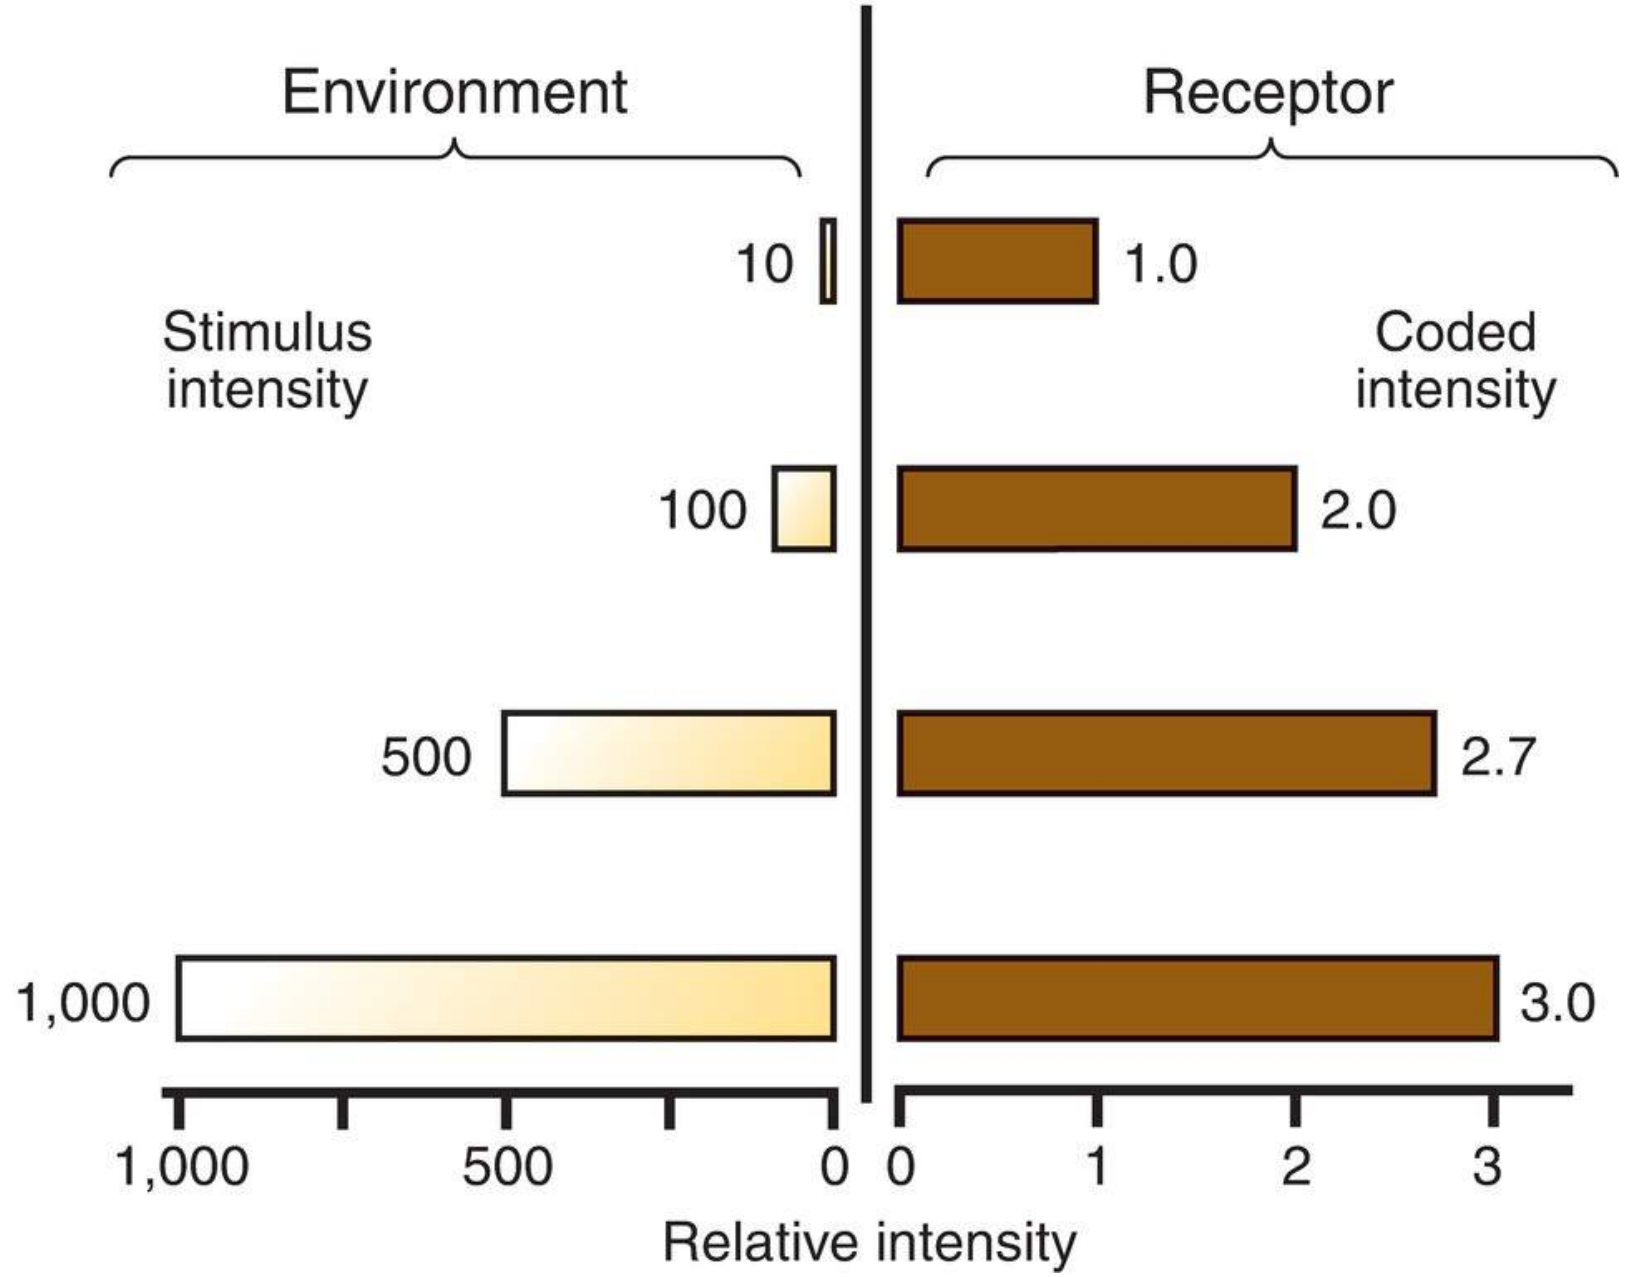

Figure 4.5 Compression in sensory process. By a variety of means, a wide range of input intensities is coded into a much narrower range of responses that can be represented by variations in action potential frequency.

Transmission

Sensory information initiated at the receptor level must be transmitted to the CNS in order to be perceived. The encoding processes in the receptors provide some basis for this transfer by producing a series of action potentials related to the stimulus intensity. A special process is necessary for the complete transfer, however, because of the nature of the conduction of action potentials. Recall that action potentials are transmitted down nerve axons without decrement; their duration and amplitude do not change during conduction and, therefore, the parameters of electrical potential amplitude and duration are lost as a means of transmitting different forms of information to the CNS. It follows, then, that the only information that can be conveyed by a single action potential is its presence or absence.

Relationships between and among action potentials, however, can convey large amounts of information, and this is the system found in the sensory transmission process. To review, in physiologic sensory systems, an input signal provided by some physical quantity is continuously measured and

converted into an electrical signal (the generator potential), whose amplitude is proportional to the input signal. This signal controls the frequency of action potential generation in the impulse initiation region of a sensory nerve fiber. Because action potentials are of a constant height and duration, the amplitude information of the original input signal is now in the form of a frequency of action potential generation. These trains of action potentials are sent along a nerve pathway to some distant point in the CNS, where they produce an electrical voltage in postsynaptic neurons that is proportional to the frequency of the arriving pulses. This voltage is a replica of the original input voltage. Further processing can produce a graphic record of the input data, which is accompanied by processing and interpretation in the CNS.

Perception

The interpretation of encoded and transmitted information into a perception requires several other factors. For instance, the interpretation of sensory input by the CNS depends on the neural pathway it takes to the brain. For this reason, for example, all information arriving on the optic nerves is interpreted as light, even though the signal may have arisen as a result of pressure applied to the eyeball. The localization of a cutaneous sensation to a particular part of the body also depends on the particular pathway it takes to the CNS. Often a sensation (usually pain) arising in a visceral structure (e.g., heart, gallbladder) is perceived as coming from a portion of the body surface, because developmentally related nerve fibers come from these anatomically different regions and converge on the same spinal neurons. Such a sensation is called referred pain.

The remainder of this chapter deals with specific sensory receptors, including those of both the somatosensory system (i.e., touch, temperature, and pain) and the special senses (i.e., sight, hearing, taste, and smell).

SOMATOSENSORY SYSTEM

The somatosensory system is a diverse sensory system comprising receptors and processing centers that produce sensory modalities, such as touch (tactile sensation), proprioception (body position), temperature, and pain (nociception). These sensory receptors cover the skin and epithelia, skeletal muscles, bones and joints, and internal organs. The system responds to a number of diverse stimuli using the following receptors: mechanoreceptors (movement/pressure), chemoreceptors, thermoreceptors, and nociceptors. Signals from these receptors pass via sensory nerves through tracts in the spinal cord and into the brain. Neural information is processed primarily in the somatosensory area in the parietal lobe of the cerebral cortex (see Chapter 7 for details).

Skin receptors provide sensory information from the body surface.

The skin has a rich supply of sensory receptors that provide cutaneous sensations, such as touch (light and deep pressure), temperature (warmth and coldness), and pain. More complicated modalities include itch, tickle, wetness, etc. Cutaneous receptors can be mapped over the skin by using highly localized stimuli of heat, cold, pressure, or vibration. Some areas require a high degree of spatial localization (e.g., fingertips, lips) and, accordingly, have a high density of specific sensory receptors. These areas are correspondingly well represented in the somatosensory area of the cerebral cortex (see Chapter 7).

Touch

Several types of sensory receptors are involved in the sensation of touch (Fig. 4.6). Three of these receptors (Merkel disk, Meissner corpuscles, and Pacinian corpuscles) are distributed on various areas of the skin but are concentrated in regions void of hair (e.g., palm of the hand). The nerve endings of these receptors respond to pressure and texture; therefore, they are classified as **mechanoreceptors**. All mechanoreceptor types are stimulated by deformation of the nerve ending. When these receptors are deformed, either due to pressure or release of pressure, they cause receptor potentials to be generated by opening pressure-sensitive cation ion channels in the axon membrane, which allows an influx of positive ions resulting in the eventual formation of an action potential in the sensory neuron.

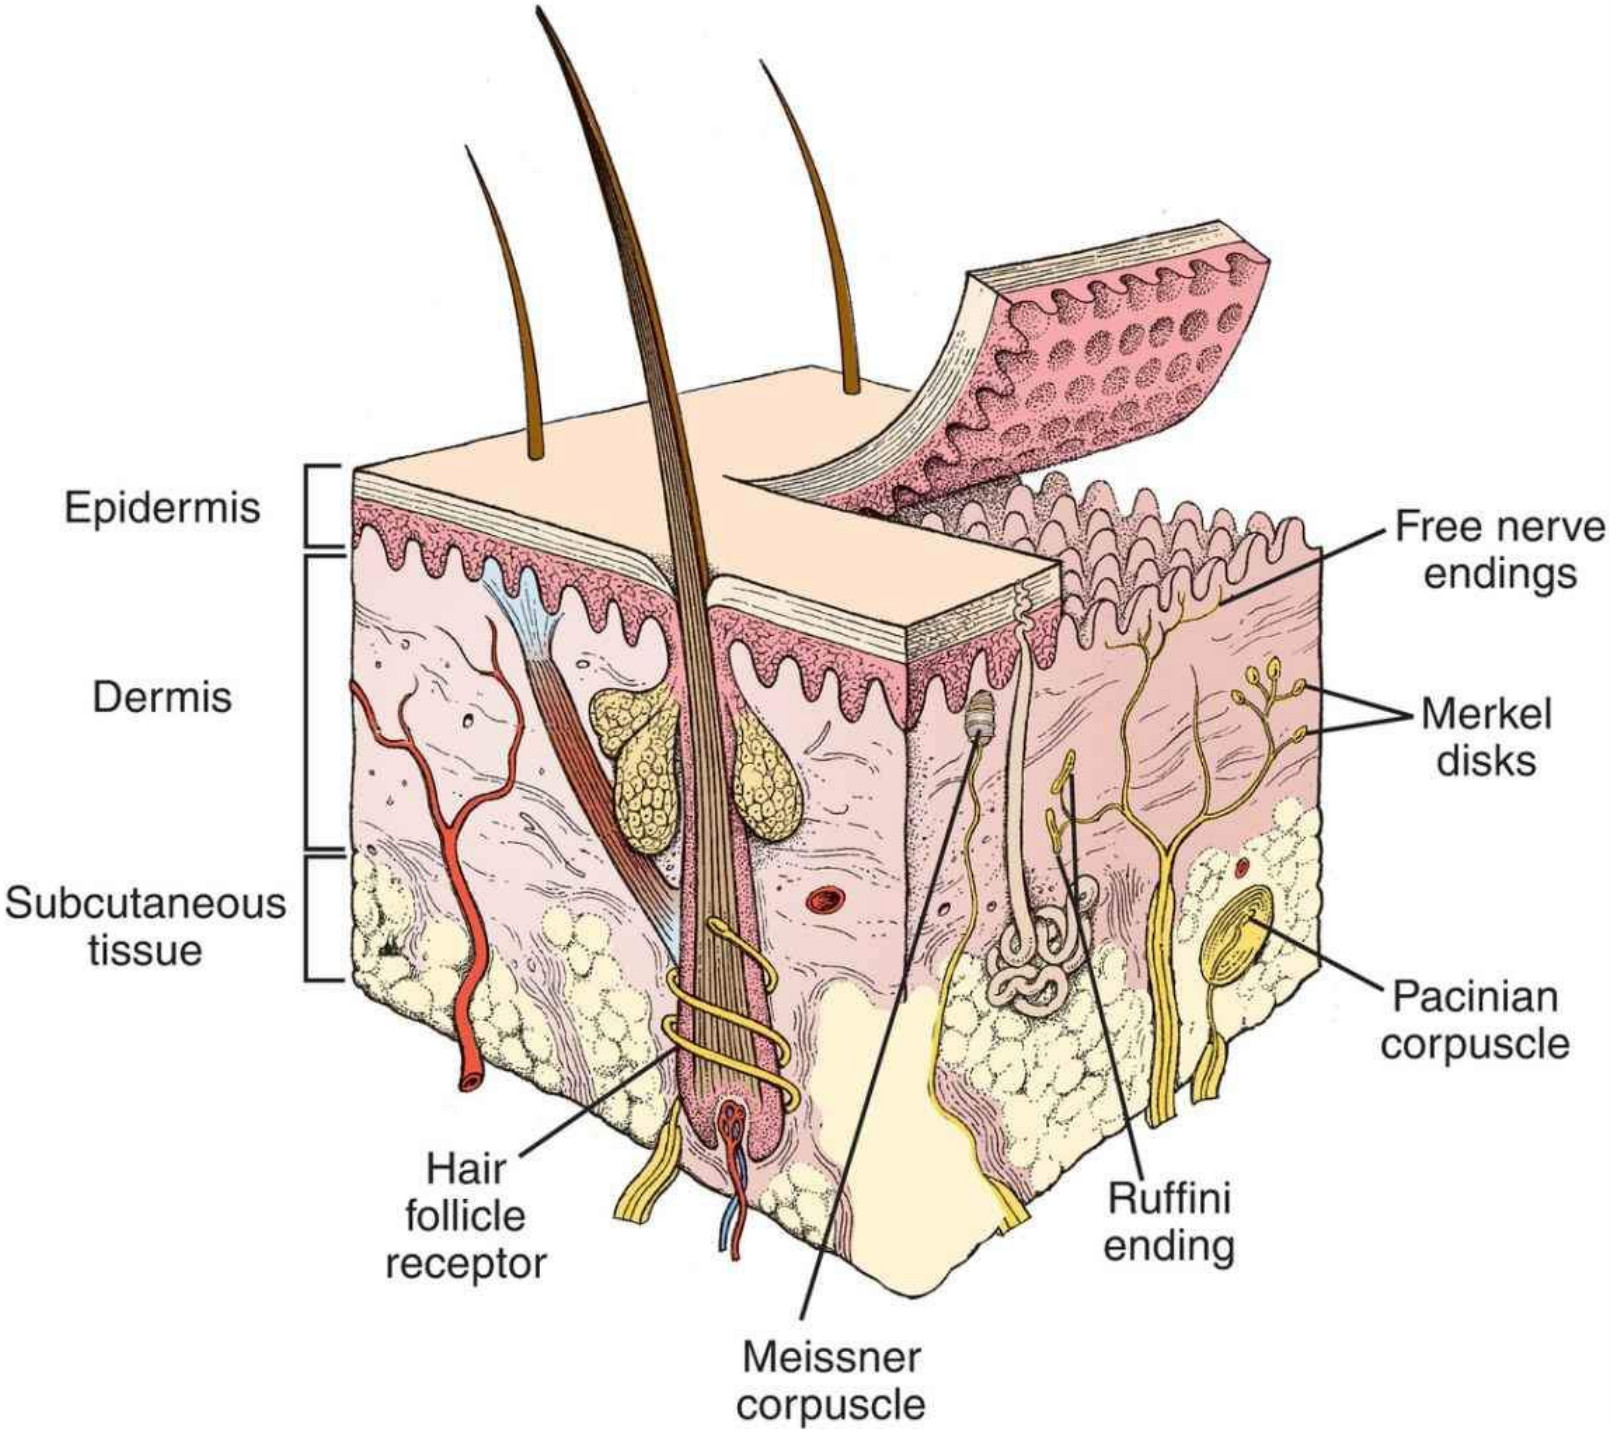

Figure 4.6 Tactile receptors in the skin. Cutaneous receptors providing a sense of touch, pressure, stretch, and vibration are the Merkel disk, Meissner corpuscle, Pacinian corpuscle, Ruffini corpuscle, and the hair follicle receptor.

The *Merkel disks* are receptors (located in the lowest layer of the epidermis) that exhibit slow adaptation and also respond to steady pressure. These receptors provide information about an object's qualities like edges or its curves.

The *Meissner corpuscle* is a cutaneous touch receptor that mediates the sensation of light touch. These receptors are distributed on various areas of the skin but are concentrated in areas sensitive to light touch, such as fingertips, lips, and nipples. The Meissner corpuscle is a capsule surrounding the ending of a sensory nerve (or nerves) that wind between stacks of flattened Schwann cells in the capsule interior. These Schwann "cushions" dissipate deformation of the nerve endings caused by sustained points of

pressure on the skin. This makes these receptors rapidly adaptive.

The *Pacinian corpuscle* is a very highly adaptive receptor that is responsible for sensitivity to pressure. These receptors comprise nerve endings surrounded by multiple gel-like envelopes within capsules that act collectively as a mechanical filter. When the capsule is deformed, for example, by a point of pressure, the underlying nerve ending is deformed and generates an electrical potential. However, the multiple gel envelopes almost immediately equalize pressure surrounding the nerve, thus removing any local deformation. Consequently, the local receptor potential ceases to be generated. The nerve ending only deforms again to generate an electrical potential when the initial deforming pressure is suddenly released. Thus, the Pacinian corpuscle best detects the beginning and ending of a rapidly changing local pressure on the skin. This makes these receptors especially suited for detecting fast-changing stimuli such as vibrations.

Thermoreceptors are sensory nerve endings that code for absolute and relative temperatures.

Humans can discriminate a wide range of innocuous and noxious skin temperatures that are sensed by temperature receptors (thermoreceptors). Thermoreceptors belong to the transient receptor potential (TRP) family of cation channels with each thermally sensitive TRP responsive to a different temperature range. Cooling or warming the skin opens these TRP channels allowing inward flow of cations to depolarize the cell. Information about the thermal stimulus is relayed to the CNS by two groups of low conduction velocity temperature sensitive fibers that are either thinly myelinated fibers (cold) or nonmyelinated (warm). The density of temperature receptors differs at various places on the body surface. They are present in much lower numbers than cutaneous mechanoreceptors, and there are many more cold receptors than warm receptors. The adequate stimulus for a warm thermoreceptor is warming, which results in a concomitant increase in rate of firing of its action potentials. Conversely, cooling results in a decrease in the action potential discharge rate of the warm receptor. Cold-sensitive thermoreceptors give rise to the sensation of cooling or coldness. Their rate of firing increases with cooling and decreases during warming.

The perception of temperature stimuli is closely related to the properties of the receptors. The phasic component of the response is apparent in our adaptation to sudden immersion in, for example, a warm bath. The sensation of warmth, apparent at first, soon fades away, and a less intense impression of the steady temperature may remain. Moving to somewhat cooler water produces an immediate sensation of cold that soon fades away. Over an intermediate temperature range (the “comfort zone”), there is no appreciable temperature sensation. This range is approximately 30°C to 36°C for a small area of skin; the range is narrower when the whole body is exposed. Outside this range, steady temperature sensation depends on the ambient (skin) temperature. Skin temperatures in the range of 20°C up to about 45°C are sensed as innocuous. Skin temperatures >45°C or <17°C elicit warm and cold pain respectively, but this sensation arises from thermosensitive TRP pain receptors, not innocuous thermal receptors. Cold pain can be activated under certain abnormal conditions, such as with peripheral neuropathy or from chemotherapy. Severely diabetic patients who suffer from peripheral neuropathy and patients who undergo chemotherapy can exhibit a cold-induced pain response when they touch a cool object. Both result from damage to the receptors. At very high skin temperatures (>45°C), there is a sensation of *paradoxical cold*, caused by nonspecific activation of a part of the innocuous cold receptor population.

Temperature perception is subject to considerable processing by higher centers. Although the perceived sensations reflect the activity of specific receptors, the phasic component of temperature perception may take several minutes to be completed, whereas the adaptation of the receptors is complete within seconds.

Nociceptors are free nerve endings that trigger the pain sensation in the brain.

Pain is sensed by a population of specific receptors called nociceptors. These receptors can detect mechanical, thermal, or chemical changes and are found in the skin, on internal organ surfaces, and on joint surfaces. The transduction mechanism for nociception is not completely understood, but TRP channels have been implicated for some types of nociception such as temperature-evoked pain responses. Nociceptors typically have a high threshold for mechanical, chemical, and thermal stimuli (or a combination) of intensity sufficient to cause tissue destruction, but these receptors can be sensitized by substances associated with tissue damage and inflammation so that when a previously innocuous stimulus is applied to a damaged area of the skin it is now perceived as painful.

All pain receptors are free nerve endings, and the concentration of these receptors varies throughout the body, mostly on the skin and less so in the internal organs. In the skin, these are the free endings of thin myelinated and nonmyelinated fibers with low conduction velocities. The skin has many more points at which pain can be elicited than it has mechanically or thermally sensitive sites. Because of the high threshold of pain receptors (compared with that of other cutaneous receptors), we are usually unaware of their existence.

Superficial pain may often have two components: an immediate, sharp, and highly localizable *initial pain* and, after a latency of about 1 second, a longer lasting and more diffuse *delayed pain*. These two submodalities appear to be mediated by different nerve fiber endings and are served by unique pathways in the CNS. In addition to their normally high thresholds, both cutaneous and deep pain receptors show little adaptation, a fact that is unpleasant but biologically necessary. Deep and visceral pain appears to be sensed by similar nerve endings, which may also be stimulated by local metabolic conditions such as an electrolyte imbalance leading to muscle cramps. **Referred pain** is a term to describe the pain phenomenon that is perceived at a site adjacent to the site of injury. Sometimes this pain is also referred to as reflective pain. One of the best examples of referred pain is during an episode of ischemia brought on by a myocardial infarction (heart attack) in which pain is frequently experienced in the neck, left arm, shoulders, and back rather than in the chest, the original site of injury.

VISUAL SYSTEM

All sensory systems are important, but, in primates, the visual system is one of the most important. The visual system is the part of the CNS that enables mammals to process visual details. The eyes are organs that detect light and convert it to electrochemical impulses. Complex neural pathways exist that connect the eye, via the **optic nerve**, to the visual cortex and other areas of the brain, which converts these impulses into visual images.

Eyes comprise three layers of specialized tissue.

The eye is a fluid-filled, spherical organ enclosed by a three-layered structure of specialized tissue (Fig. 4.7). The outermost layer consists of a tough layer of connective tissue, called the *sclera*, and accounts for most of the eye's mechanical strength. The **extraocular muscles** are attached to the sclera and control movement of the eye in the socket. The anterior portion of the sclera consists of the transparent cornea through which light rays pass into the interior of the eye. The middle layer of the eye is known as the *choroid layer*, which is highly pigmented and highly vascularized. The *iris* is housed in the middle layer and is a circular smooth muscle structure that forms the *pupil*. The pupil is the neurally controlled aperture that controls the amount of light admitted to the interior of the eye. The iris also gives the eye its characteristic color. The transparent *lens* is located just behind the iris and is suspended from the *ciliary body* by strands of fibers called *zonule fibers*. It is important to note that the lens is not part of any of the three tissue layers. The iris separates the space between the cornea and the lens into *anterior* and *posterior chambers*. The anterior chamber is filled with a clear watery liquid, called aqueous humor. The aqueous humor carries nutrients to the cornea and lens, both of which lack a vascular supply, and is continuously secreted by ciliary epithelial cells located behind the iris. As aqueous fluid accumulates, it is drained through the *canal of Schlemm* and into the venous circulation. If the drainage of aqueous humor is impaired, pressure builds up in the anterior chamber, and internal structures are compressed, leading to optic nerve damage. This condition is known as **glaucoma** and can cause blindness. The posterior chamber lies behind the iris and contains vitreous humor, a clear gelatinous liquid that helps to maintain the spherical shape of the eye.

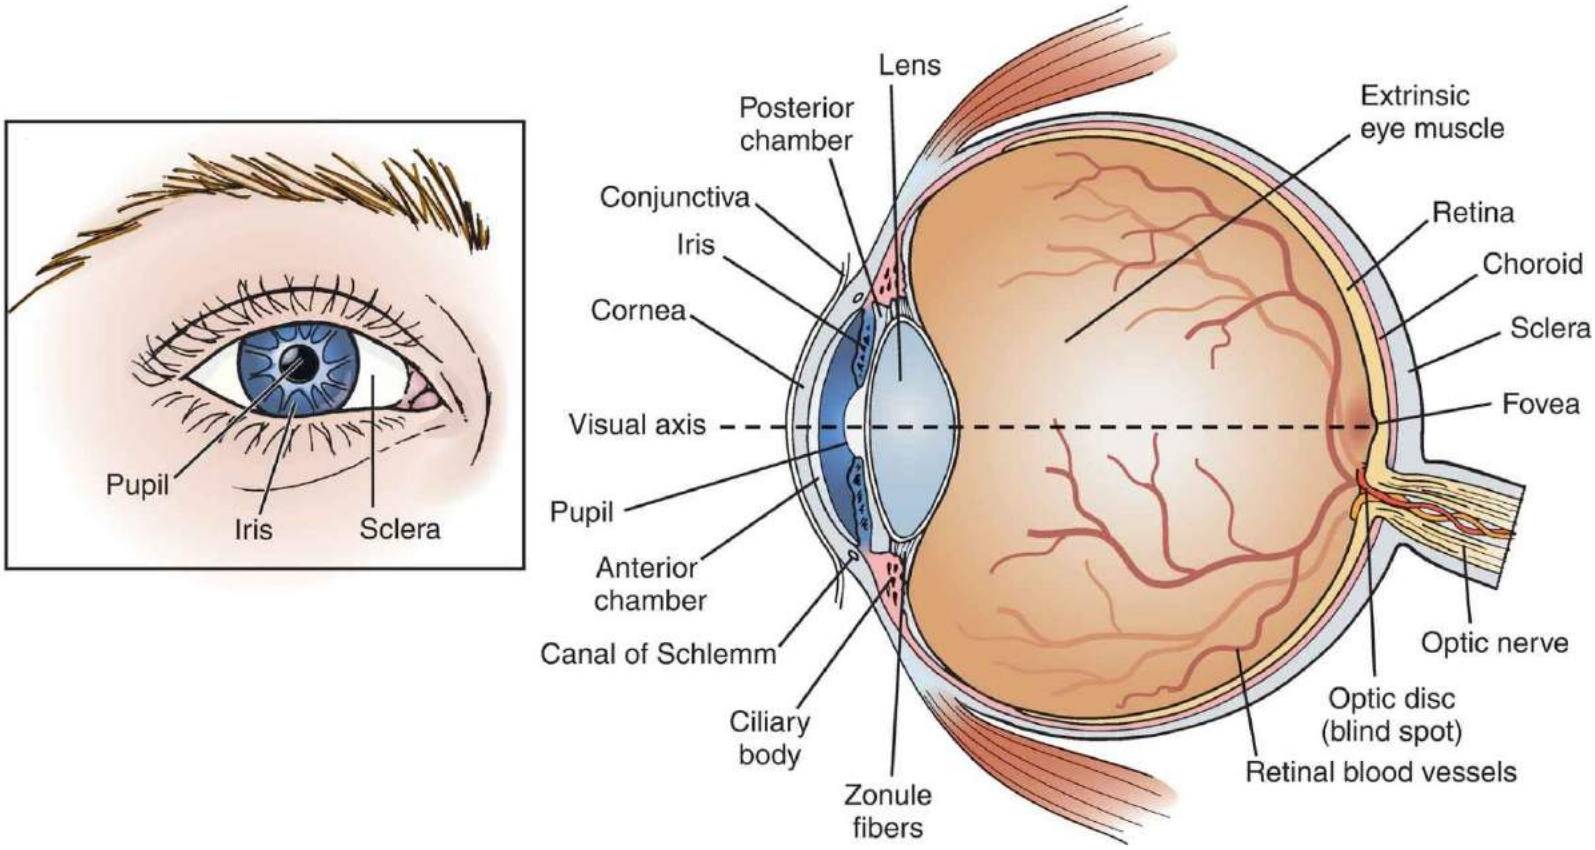

Figure 4.7 The major parts of the human eye. This is a view showing the relative positions of its optical and structural parts.

The innermost layer of the eye is actually a bilayer. The outer of these two layers is a one-cell sheet called the pigment epithelium, which supports and helps maintain the inner *retina*, which extends from the optic disk all the way to the edge of the pupil. The retina contains the photosensitive cells called *rods* and *cones*, and its cells function in the early stage of image processing. Light information from the rods and cones is relayed via the optic nerve to the cerebral cortex and other parts of the brain. Slightly off to the nasal side of the retina is the optic disc, where the optic nerve leaves the retina. There are no photoreceptor cells here, resulting in a *blind spot* in the field of vision.

Eye structures modify incoming light rays to focus an image on the retina.

Light is defined as electromagnetic radiation composed of packets of energy called photons that travel in the form of waves. The distance between two waves is known as wavelengths. Light represents a small part of the electromagnetic spectrum, and the photoreceptors of the eye are sensitive only to wavelengths between 770 nm (red) and 380 nm (violet). The familiar colors of the spectrum all lay between these limits. A wide range of intensities (amplitude or height of the wave), from a single photon to the direct light of the sun, exists in nature. Light rays travel in a straight line in a given medium. Light rays are refracted (bent) as they pass between different media (e.g., air → liquid, or air → glass), and the degree light is bent gives rise to the various refractive indices.

Focusing

Light waves entering the eye must be focused to a common point, called a *focal point*, which in the eye is the *fovea* of the retina. The distance from the lens to the focal point is the *focal length*, which is determined by the length of an individual's eyeball (Fig. 4.8). In the eye, the focal length remains constant so incoming light waves must be refracted by the structures of the eye so they converge onto the fovea. When the refractive power of the eye structures matches the length of the eyeball and the image is focused on the fovea (emmetropia), the image is sharp. Most of the refraction of light waves is accomplished by the eye's convex surfaces the cornea and the lens. The most powerful refractory component of the eye is the curved cornea, which accounts for roughly two-thirds of the eyes refractive power. If the curvature of the cornea is not symmetric, the light waves are scattered with some being focused in front of the fovea and others behind it. This condition is called **astigmatism** and is treated with lens having multiple focal points. The refractive power of the cornea is constant so refraction of light by the lens is important for our ability to adjust our vision between distant and near objects. Light rays from distant objects are relatively parallel when they reach the eye, while lights rays from near objects are more divergent and must undergo greater refraction to focus them on the retina (see Fig. 4.8). The increased refraction needed to focus the near object is supplied by the lens. The muscles of the ciliary body change the refractive strength of the lens by changing the curvature of the lens. For distant objects, the muscles are relaxed, the lens is flat and weakly refractive. For near objects, the ciliary muscles contract and the curvature and thickness of the lens are increased resulting in increased refraction that focuses the near object on the fovea. This ability to adjust the strength of the lens for close vision is called *accommodation*. With age, the lens loses its elasticity, and the point of vision moves farther away. This condition is called *presbyopia*, and supplemental refractive power, in the form of external lenses (reading glasses), is required for distinct near vision. Another problem is the loss of transparency in the lens, a condition known as *cataracts*. Normally, the elastic fibers in the lens are completely transparent to visible light. These fibers occasionally become opaque, and light rays have difficulty passing through the opaque lens. Cataracts can occur at different ages, but their prevalence increases with age. Cataracts are treated by surgical removal of the defective lens. An artificial lens may be implanted in its place, or eyeglasses may be used to replace the refractive power of the lens.

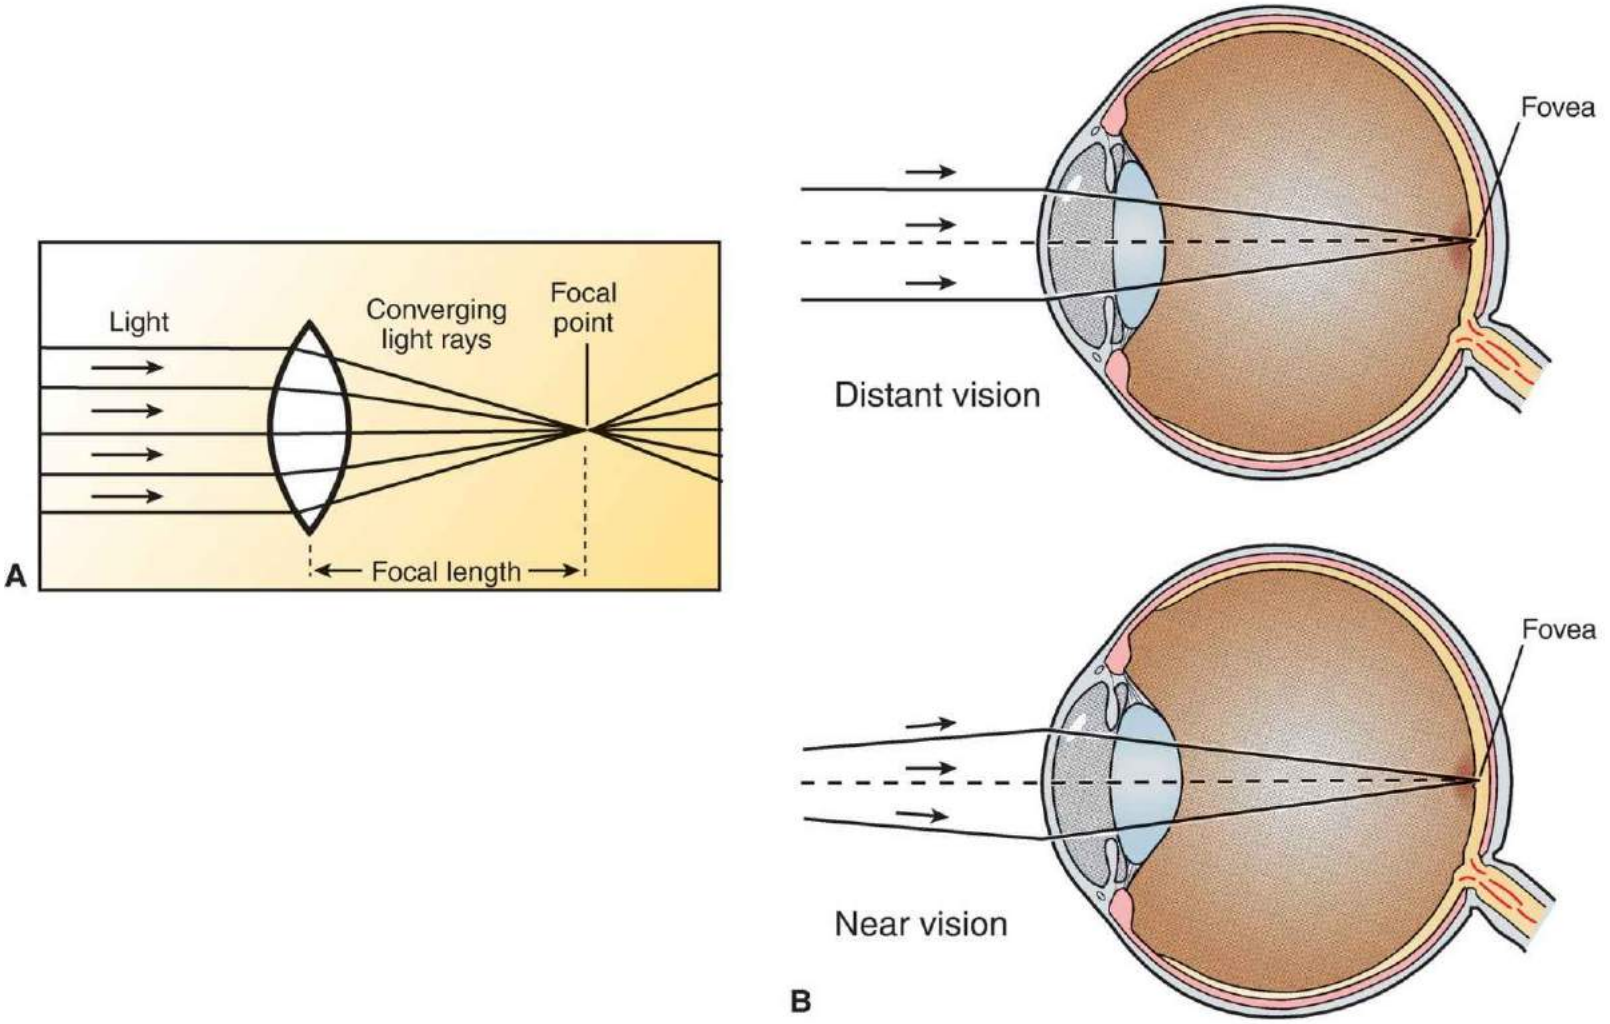

Figure 4.8 The eye as an optical device. **(A)** The eye converges light to a focal point on the retina by a convex lens. **(B)** During fixation, the center of the image falls on the fovea. For distant vision, the lenses are flattened, and rays from a distant object are brought to a sharp focus. For near vision, the lens curvature increases with accommodation, and rays from a nearby object are focused.

Errors of refraction, which are common, lead to blurred images because the images are focused in front of or behind the fovea (Fig. 4.9). They can be corrected with external lenses (eyeglasses or contact lenses). Farsightedness, or *hyperopia*, is caused by the eyeball being physically too short to focus on distant objects. The natural accommodation mechanism may compensate for distance vision, but near objects will be focused behind the retina. The use of a positive (converging) lens corrects this error. If the eyeball is too long, nearsightedness, or *myopia*, results. In effect, the converging power of the eye is too great; close vision is clear, but the eye cannot focus on distant objects. Concave lenses can correct this defect.

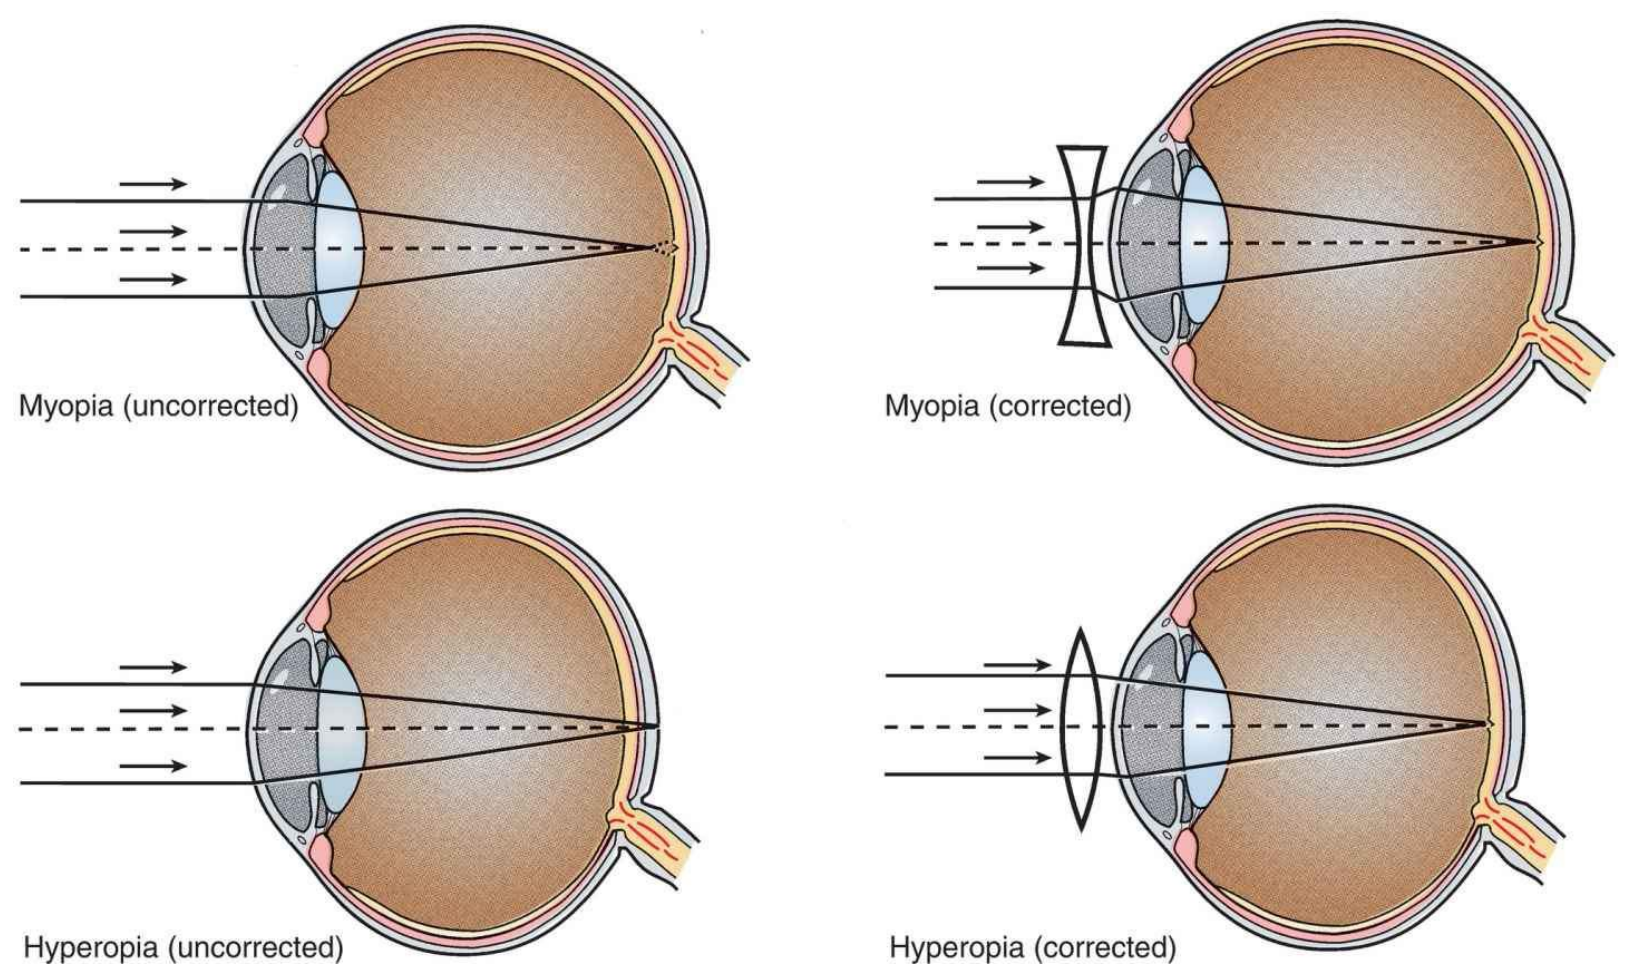

Figure 4.9 The use of external lenses to correct refractive errors. The external optical corrections change the effective focal length of the natural optical components. For myopia (nearsightedness), vision is corrected with concave lenses, which divert light before it reaches the eye. For hyperopia (farsightedness), vision is corrected with convex lenses, which converge light before it reaches the eye.

Light regulation

The iris, which has both sympathetic and parasympathetic innervation, controls the diameter of the pupil (Fig. 4.10). It is capable of a 30-fold change in area and in the amount of light admitted to the eye. This change is under complex reflex control, and bright light entering just one eye will cause the appropriate constriction response in both eyes. As with a camera, when the pupil is constricted, less light enters, but the image is focused more sharply because the more poorly focused peripheral rays are cut off.

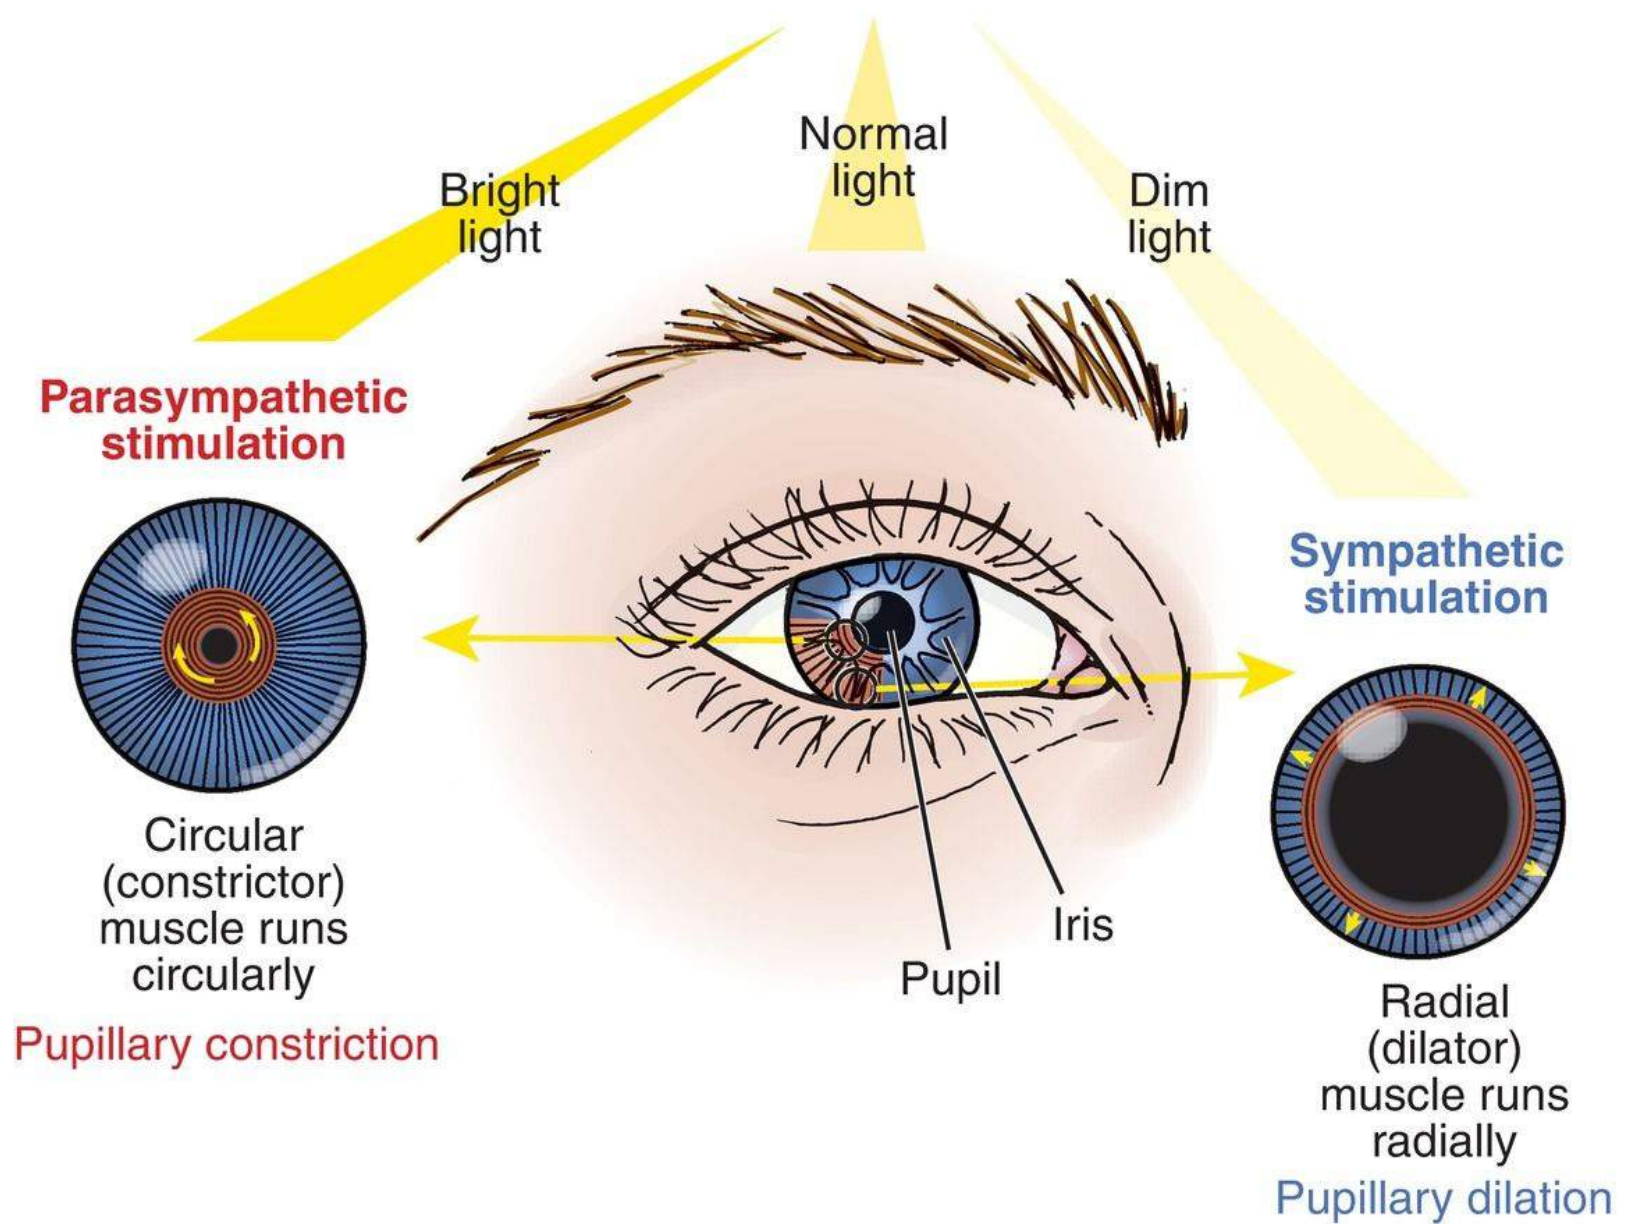

Figure 4.10 Control of pupillary diameter. The pupil controls the amount of light entering the eye by variable contraction of the iris muscles to admit more or less light. The iris muscles run circular (constriction) and radial (dilation).

Phototransduction by retinal cells converts light energy into neural electrical–chemical signals.

The major function of the eye is to focus light waves from the external environment and create an image of the visual world on the retina, which serves much the same function as film in a camera. The retina is an extension of the CNS and is a multilayered structure containing the photoreceptor cells and a complex web of several types of nerve cells (Fig. 4.11). Light striking the photosensitive cells (rods and cons) initiates a cascade of chemical and electrical events that ultimately trigger nerve impulses, which are sent to various visual centers in the brain through the fibers of the optic nerve.

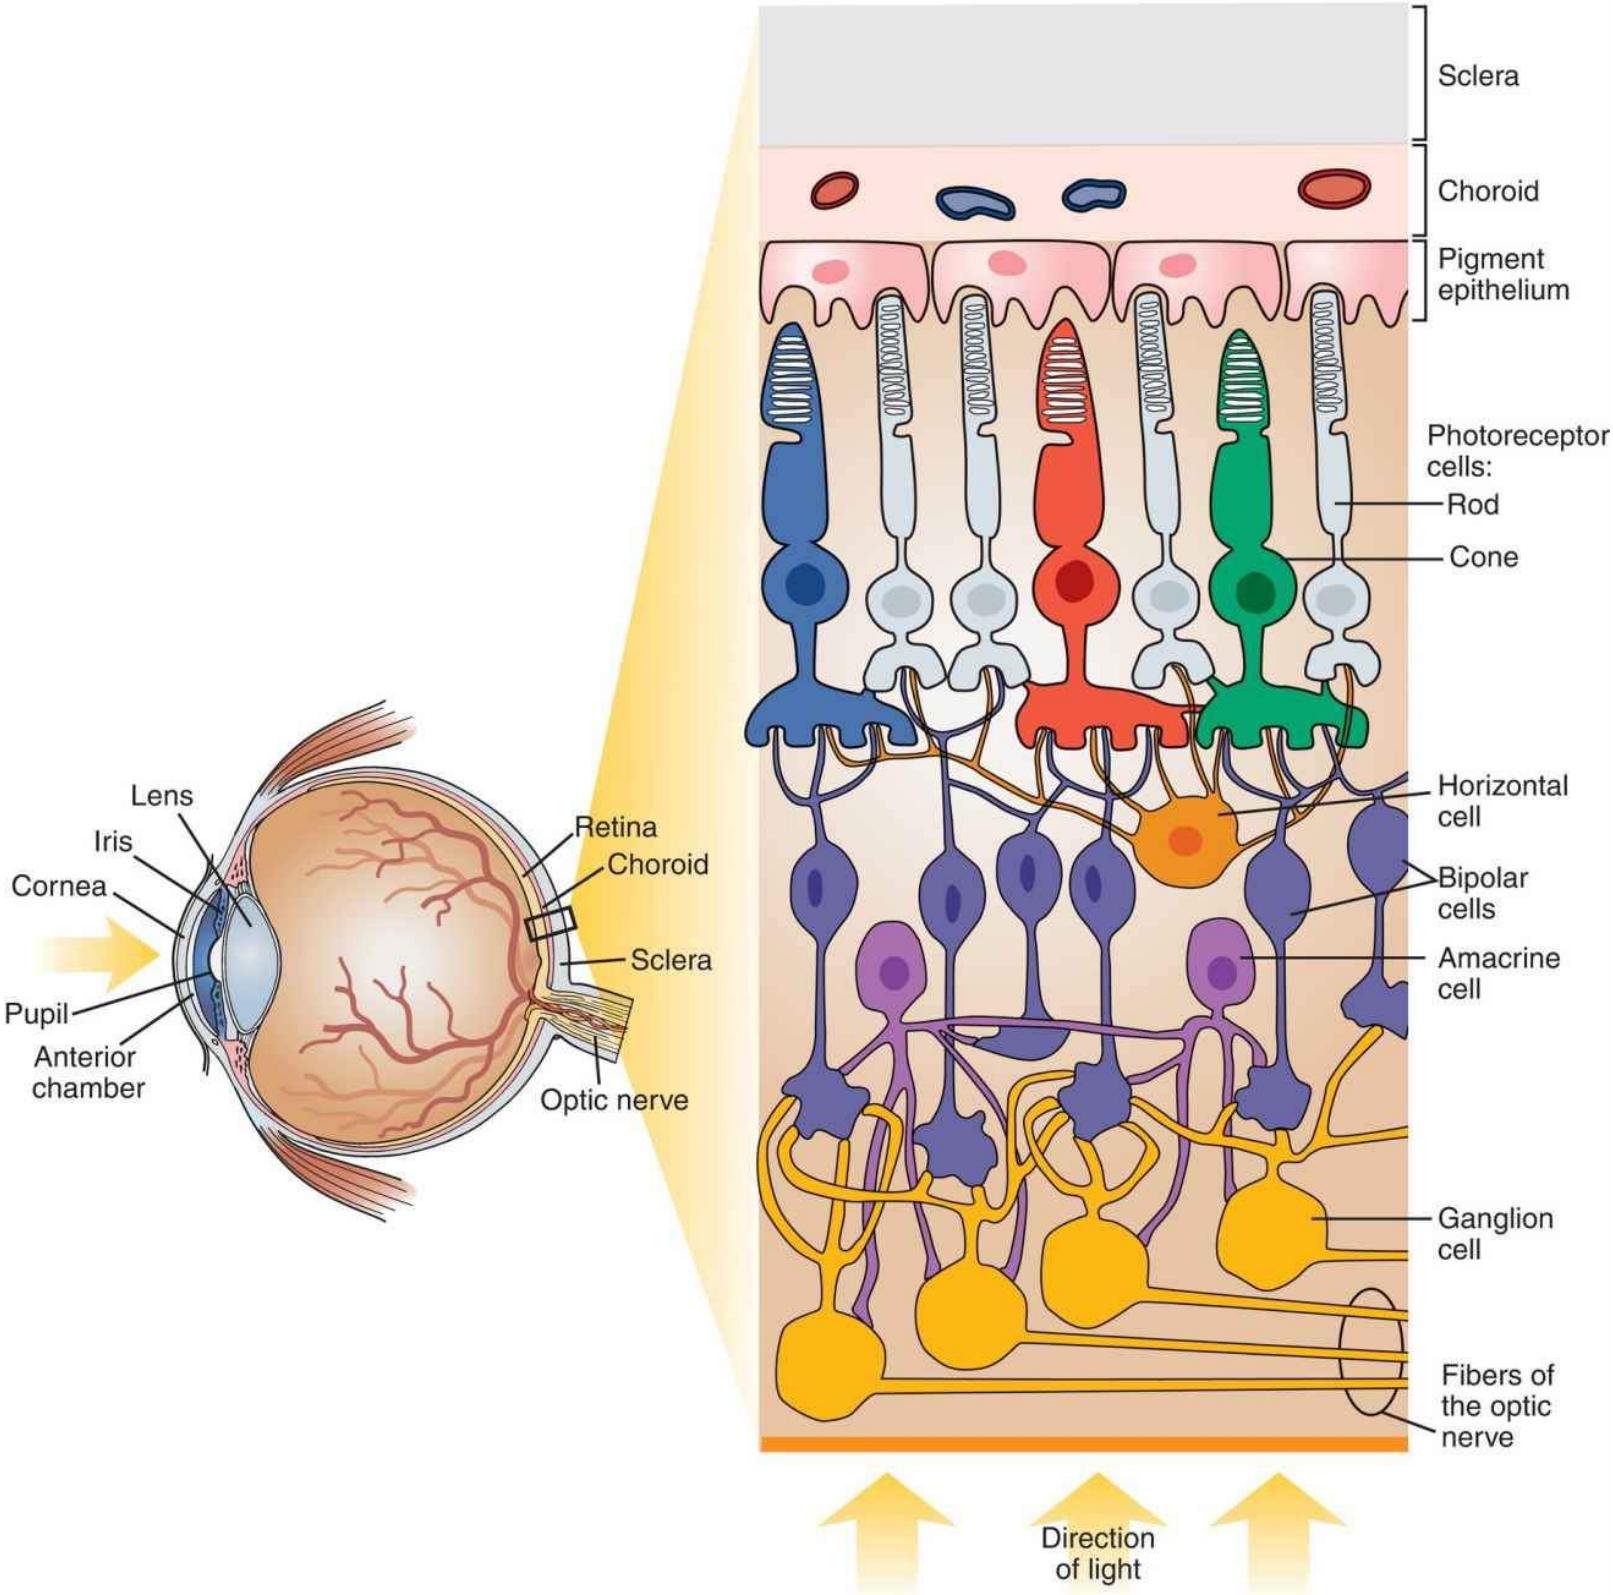

Figure 4.11 Organization of the human retina. The path of the visual retinal layers extends from the rods and cones (photoreceptor cells) to the ganglion cells. The light-sensitive end of the photoreceptor cells faces the choroid layer and away from the incoming light. The amacrine and horizontal cells are involved in retinal processing of visual input.

The retina consists of a stack of four main neuronal layers: pigment epithelium, the photoreceptor layer, the neural network layer, and, finally, the ganglion cell layer. The pigment layer consists of cells with high melanin content and functions to sharpen an image by preventing the scattering of stray light. People with albinism lack this pigment layer and have blurred vision that cannot be corrected effectively with external

glasses.

The photoreceptor layer captures the visual image on the rods and cones. The rods and cones are packed tightly side by side, with a density of many thousand per square millimeter.

The photoreceptors are divided into two classes. The cones are responsible for **photopic** (daytime) vision, which is in color (chromatic), and the rods are responsible for **scotopic** (nighttime) vision, which is not in color. Their functions are basically similar, although they have important structural and biochemical differences.

Cone cells have an *outer segment* that tapers to a point (Fig. 4.12). Three different photopigments are associated with cone cells. The pigments differ in the wavelength of light that optimally excites them. The peak spectral sensitivity for the *red-sensitive pigment* is 560 nm; for the *green-sensitive pigment*, it is about 530 nm; and for the *blue-sensitive pigment*, it is about 420 nm. The corresponding photoreceptors are called *red*, *green*, and *blue cones*, respectively. At wavelengths away from the optimum, the pigments still absorb light but with reduced sensitivity. Because of the interplay between light intensity and wavelength, a retina with only one class of cones would not be able to detect colors unambiguously. The presence of two of the three pigments in each cone removes this uncertainty. Color-blind individuals, who have a genetic lack of one or more of the pigments or who lack an associated transduction mechanism, cannot distinguish between the affected colors. Loss of a single color system produces *dichromatic vision*, and lack of two of the systems causes *monochromatic vision*. If all three are lacking, vision is monochromatic and depends only on the rods.

Figure 4.12 Structure of photoreceptors of the human retina. The rod and cones of the eye's photoreceptors contain three segments. The outer segment contains stacked flattened membrane disks that contain an abundance of light-absorbing photopigments. The inner segment houses the metabolic machinery, and the synaptic terminal stores and releases neurotransmitters.

A **rod cell** is long, slender, and cylindrical, and it is larger than a cone cell (see Fig. 4.12). Its outer segment contains numerous photoreceptor disks composed of cellular membrane in which the molecules of the photopigment **rhodopsin** are embedded. The lamellae near the tip are regularly shed and replaced with new membrane synthesized at the opposite end of the outer segment. The *inner segment*, connected to the *outer segment* by a modified cilium, contains the cell nucleus, many mitochondria that provide energy for the phototransduction process, and other cell organelles. At the base of the cell is a synaptic body that makes contact with one or more bipolar nerve cells and liberates a transmitter substance in response to changing light levels.

The visual pigments of the photoreceptor cells convert light to a nerve signal. This process is best understood in the case of the rod cells. In the dark, the pigment rhodopsin (or *visual purple*) consists of a light-trapping chromophore (the part of a molecule responsible for its color) called **scotopsin**, which is chemically conjugated with **11-cis-retinal**, the aldehyde form of vitamin A1. When struck by light, rhodopsin undergoes a series of rapid chemical transitions, with the final intermediate form metarhodopsin II providing the critical link between this reaction series and the electrical response. The end products of the light-induced transformation are the original scotopsin and an all-*trans* form of retinal, now dissociated from each other. Under conditions of both light and dark, the all-*trans* form of retinal is isomerized back to the 11-*cis* form, and the rhodopsin is reconstituted. All of these reactions take place in the highly folded membranes comprising the outer segment of the rod cell.

The cellular process of visual signal transduction is shown in Figure 4.13. The coupling of the light-induced reactions and the electrical response involves the activation of **transducin**, a G protein; the associated exchange of guanosine triphosphate for guanosine diphosphate activates a phosphodiesterase. This, in turn, catalyzes the breakdown of cyclic guanosine monophosphate (cGMP) to 5′-GMP. When cellular cGMP levels are high (as in the dark), membrane sodium channels are kept open, and the cell is relatively depolarized. Under these conditions, there is a tonic release of neurotransmitter from the synaptic body of the rod cell. A decrease in the level of cGMP as a result of light-induced reactions causes the cell to close its sodium channels and hyperpolarize, thus reducing the release of neurotransmitter.

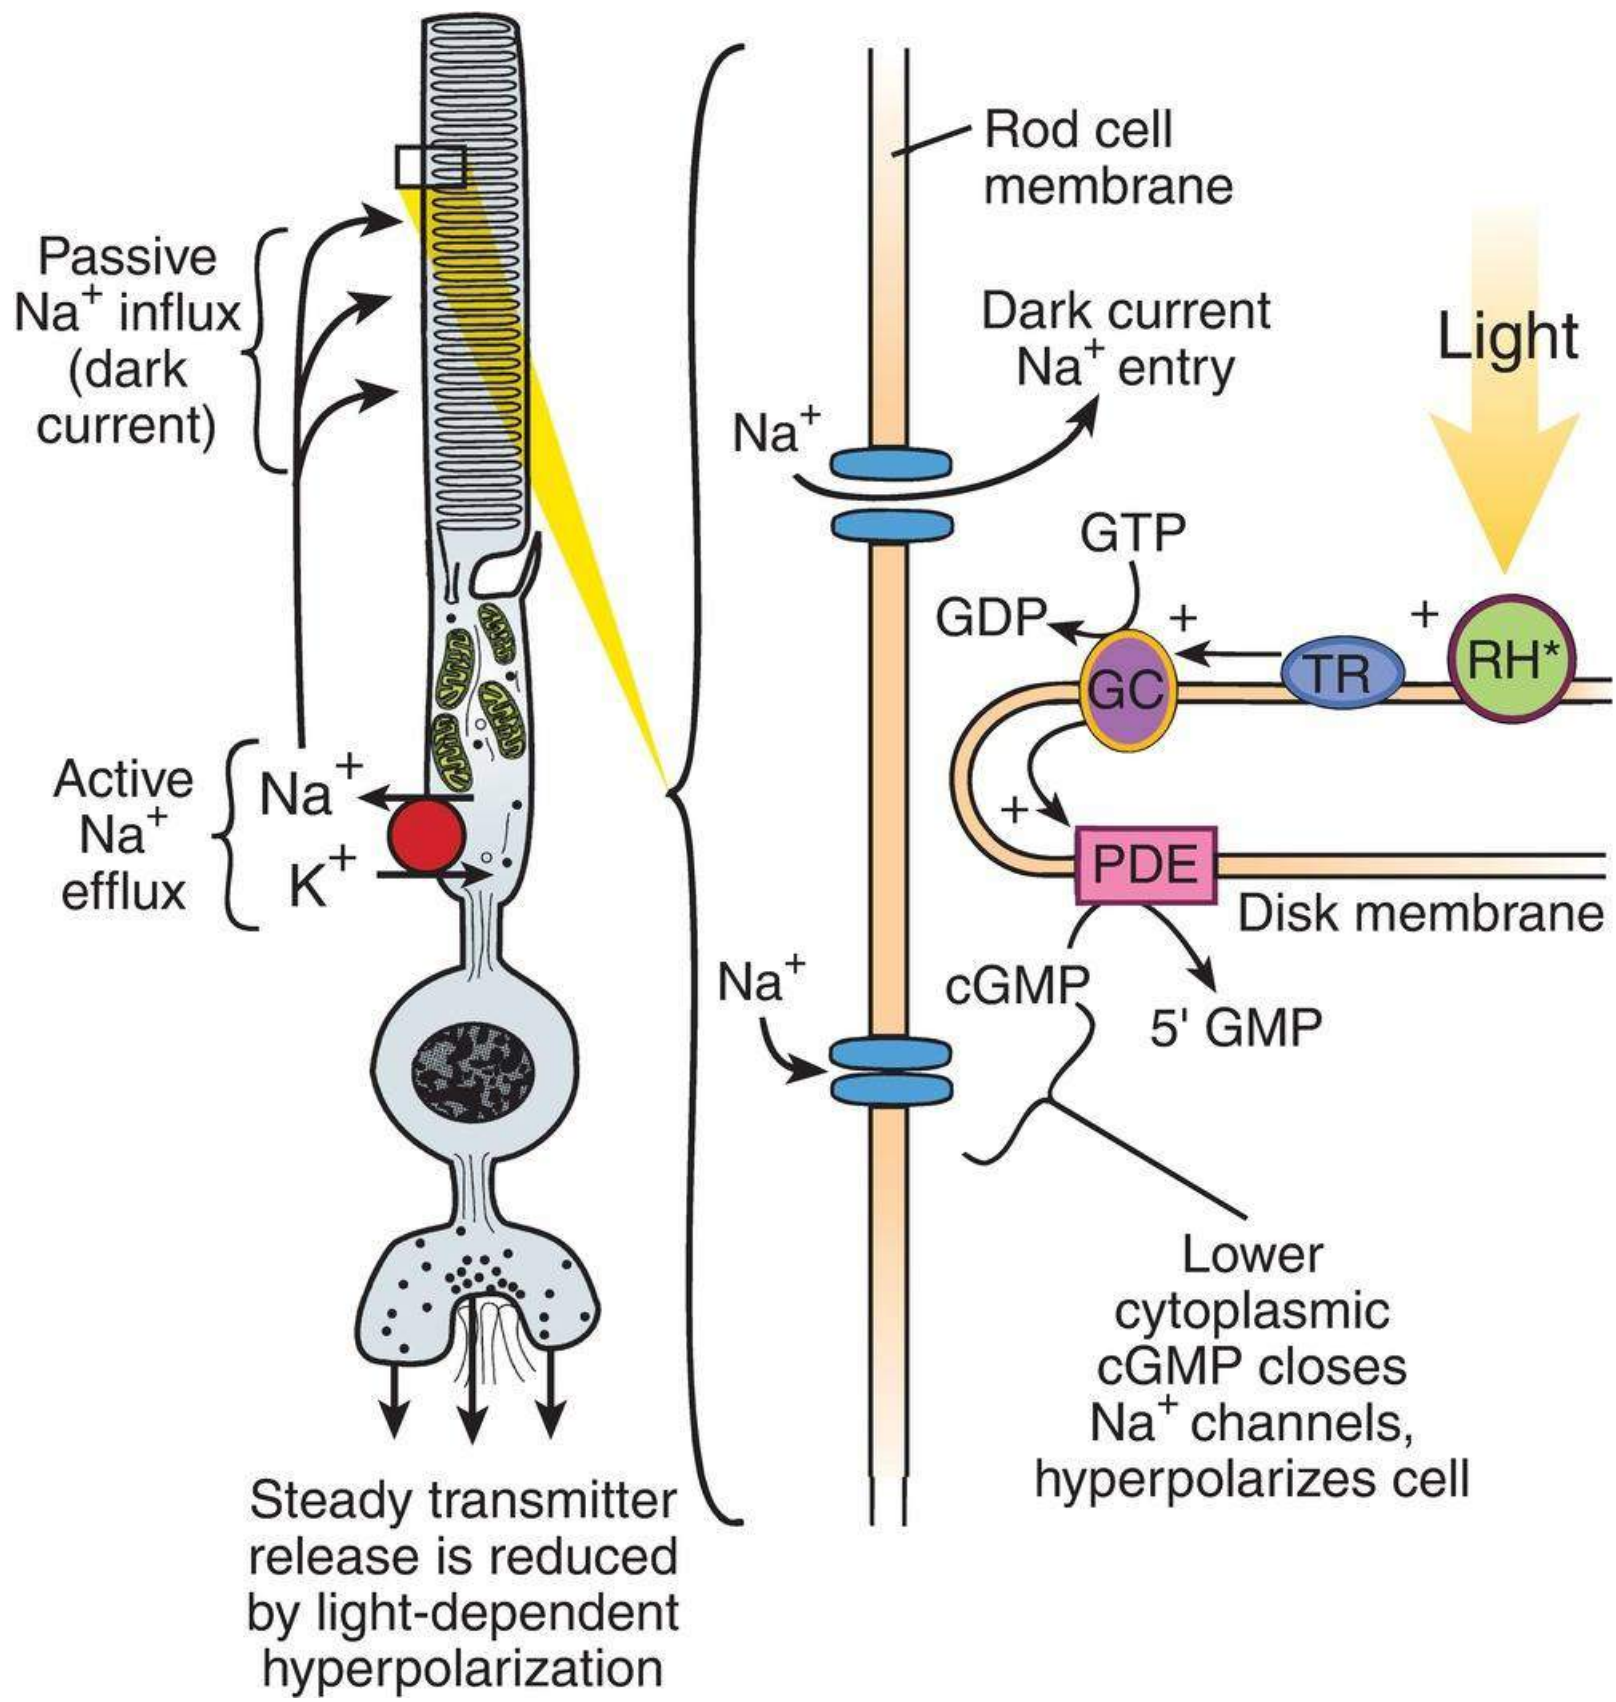

Figure 4.13 Visual signal transduction and photoreceptor activity in the dark and light. **Left:** An active Na^+/K^+ pump maintains the ionic balance of a rod cell, while Na^+ enters passively through channels in the plasma membrane, causing a maintained depolarization and a dark current under conditions of no light. **Right:** The amplifying cascade of reactions (which take place in the disk membrane of a photoreceptor) allows a single activated rhodopsin molecule to control the hydrolysis of 500,000 cyclic guanosine monophosphate (cGMP) molecules. (See text for details of the reaction sequence.) In the presence of light, the reactions lead to a depletion of cGMP, resulting in the closing of cell membrane Na^+ channels and the production of a hyperpolarizing generator potential. The release of neurotransmitter decreases

during stimulation by light. RH^*, activated rhodopsin; TR, transducin; GC, guanylyl cyclase; PDE, phosphodiesterase; GTP, guanosine triphosphate; GDP, guanosine diphosphate.

This change is the signal that is further processed by the nerve cells of the retina to form the final response in the optic nerve. An active sodium pump maintains the cellular concentration at proper levels. A large amplification of the light response takes place during the coupling steps. One activated rhodopsin molecule will activate ~ 500 transducins, each of which activates the hydrolysis of several thousand cGMP molecules. Under proper conditions, a rod cell can respond to a single photon striking the outer segment. The processes in cone cells are similar, although there are three different opsins (with different spectral sensitivities), and the specific transduction mechanism is also different. In addition, the overall sensitivity of the transduction process is lower.

In the light, much rhodopsin is in its unconjugated form, and the sensitivity of the rod cell is relatively low. During the process of *dark adaptation*, which takes about 40 minutes to complete, the stores of rhodopsin are gradually built up, with a consequent increase in sensitivity (by as much as 25,000 times). Cone cells adapt more quickly than rods, but their final sensitivity is much lower. The reverse process, *light adaptation*, takes about 5 minutes.

Neural network layer

Bipolar cells, **horizontal cells**, and **amacrine cells** comprise the *neural network layer* of the eye (see Fig. 4.11). These cells together are responsible for considerable initial processing of visual information. Because the distances between neurons here are so small, most cellular communication involves the electrotonic spread of cell potentials, rather than propagated action potentials. Light stimulation of the photoreceptors produces hyperpolarization that is transmitted to the bipolar cells. Some of these cells respond with a depolarization that is excitatory to the ganglion cells, whereas other cells respond with a hyperpolarization that is inhibitory. The horizontal cells also receive input from rod and cone cells but spread information laterally, causing inhibition of the bipolar cells on which they synapse. Another important aspect of retinal processing is **lateral inhibition**. A strongly stimulated receptor cell can inhibit, via lateral inhibitory pathways, the response of neighboring cells that are less well illuminated. This has the effect of increasing the apparent contrast at the edge of an image. Amacrine cells also send information laterally but synapse on ganglion cells.

Ganglion cell layer

In the *ganglion cell layer* (see Fig. 4.11), the results of retinal processing are finally integrated by the *retinal ganglion cells*, whose axons form the optic nerve. These cells are tonically active, sending action potentials into the optic nerve at an average rate of five per second, even when unstimulated. Input from other cells converging on the ganglion cells modifies this rate up or down.

Many kinds of information regarding color, brightness, contrast, and so on are passed along the optic nerve. The output of individual photoreceptor cells converges on the ganglion cells. In keeping with their role in visual acuity, relatively few cone cells converge on a ganglion cell, especially in the fovea, where the ratio is nearly 1:1. Rod cells, however, are highly convergent, with as many as 300 rods converging on a single ganglion cell. Although this mechanism reduces the sharpness of an image, it allows for a great increase in light sensitivity.

Signals from the retina are modified and separated before reaching the thalamus and visual cortex.

The retina, unlike a camera, does not simply send a picture to the brain. The retina spatially encodes (compresses) the image to fit the limited capacity of the optic nerve. Encoding is necessary because there are 100 times more photoreceptor cells than ganglion cells. The encoding is carried out by bipolar and ganglion cells. Once the image is spatially encoded, the signal is sent out the optic nerve (via the axons of the ganglion cells) through the optic chiasm to the *lateral geniculate nucleus (LGN)*, which is in the thalamus.

Image crossover

Information from the right and left visual fields is transmitted to opposite sides of the brain. The optic nerves, each carrying about 1 million fibers from each retina, enter the rear of the orbit and pass to the underside of the brain to the **optic chiasma** (Fig. 4.14), where about half of the fibers from each eye "cross over" to the other side. Fibers from the temporal side of the retina do not cross the midline but travel in the optic tract on the same side of the brain. Fibers originating from the nasal side of the retina cross the optic chiasma and travel in the optic tract to the opposite side of the brain.

Geniculo-calcarine tract
Visual cortex

Figure 4.14 The central nervous system pathway for visual information. Fibers from the right visual field will stimulate the left half of each retina, and nerve impulses will be transmitted to the left hemisphere.

The first stop in the brain where information is modified from the visual pathways is the LGN, where the divided output information is separated and relayed by fiber bundles known as optic radiations (geniculocalcarine tract) to different zones of the *visual cortex* in the occipital lobe of the brain (see Fig. 4.14). Mechanisms in the visual cortex detect and integrate visual information, such as shape, contrast, line, and intensity, into a coherent visual perception.

Information from the optic nerves is also sent to the **suprachiasmatic nucleus** of the hypothalamus, where it participates in the regulation of circadian rhythms; to the *pretectal nuclei*, which are concerned with the control of visual fixation and pupillary reflexes; and to the **superior colliculus**, which coordinates simultaneous bilateral eye movements, such as tracking and convergence.

Depth perception

Depth perception is the visual ability to see the world in three dimensions (“3D”) and arises from binocular depth cues that require input from both eyes. Depth perception is lost when one eye is damaged. By using two images of the same scene obtained from slightly different angles, it is possible to triangulate the distance to an object. For example, if the object is far away, the disparity of the image falling on both retinas will be small. If the object is closer, the disparity of that image will be large. This binocular oculomotor cue provides a high degree of accuracy for depth/perception.

Visual reflexes are partially under central nervous system control.

Like a modern camera, the eye has an autofocus for light and an autofocus for distance as well as other reflex mechanisms. These reflexes are mediated, in part, by CNS control of the eye, and they help to adapt and protect the eye from injury.

Pupillary reflex

The *pupillary light reflex* controls the diameter of the pupil in response to the intensity of light. Light shone in one eye elicits a pupillary light reflex that causes both pupils to contract. Greater light intensity causes both pupils to become smaller and allow less light in. In contrast, lower intensity causes both pupils to become larger, allowing more light in. The pupillary reflex pathway begins with retinal ganglion cells, which convey information from the photoreceptors via their axons in the optic nerve. The optic nerve is responsible for the afferent limb of the pupillary reflex (i.e., it senses the incoming light). Light level information is processed in the brainstem and adjusting signals are relayed by parasympathetic fibers that travel in the oculomotor nerve, which is the efferent limb of the pupillary reflex (i.e., it causes the muscles to constrict the pupil).

The pupillary light reflex performs several important functions: (1) it regulates the intensity of light that falls on the retina, thereby assisting in adaption to various levels of light and darkness; (2) it aids in retinal sensitivity to light; and (3) it protects the eye from retinal damage from overexposure to light. Aging affects the pupillary light reflex, which becomes most apparent in going from a light to dark room. With aging, it takes longer to adjust to the darkness.

Corneal reflex

The corneal reflex is an involuntary blinking of the eyelids elicited by stimulation of the cornea with a foreign object or bright light. Just touching one cornea causes the reflex blinking of both eyes. The corneal reflex protects the eye from foreign material and bright lights. The reflex is mediated through the ophthalmic branch of the trigeminal nerve (fifth cranial nerve) that senses the stimulus on the cornea. The seventh cranial nerve (facial nerve) initiates the motor response.

This reflex is absent in newborns and is diminished with use of contacts lenses. The corneal reflex is often part of a neurologic examination, especially when a patient is evaluated for a coma.

Accommodation reflex

Accommodation is the process whereby the eye changes its optical power to maintain a clear vision on an object as its distance changes. This reflex action is in response to focusing on a near object and then looking at a distant object (and vice versa). When someone accommodates to a near object, three things happen. First, the eyes converge, which is accomplished by simultaneous activation of extraocular eye muscles (medial recti), to bring the fovea in line with the object. Second, the ciliary muscles contract increasing the curvature of the lenses and producing more refraction. This shortens the focal length so that the image lands on both retinas. Third, the pupil constricts in order to prevent divergent light rays from hitting the periphery of the retina and resulting in blurred vision. Pupillary constriction also improves the depth of vision. All three things happen automatically as part of the accommodation reflex. Accommodation is another visual reflex that diminishes with age. At about 60 years of age, most people will have noticed a decrease in their ability to focus on close objects.

AUDITORY SYSTEM

The sensory systems of primates are astonishing achievements in design and efficiency. In many ways, the ear stands out among the sensory organs. The ear is the organ that not only receives sound but also plays a major role in the sense of balance and body position. The ear is part of the auditory system and consists of three components: the outer, middle, and inner ear (Fig. 4.15). The outer ear collects sound, and the middle ear amplifies the sound pressure before transmitting it to the fluid-filled inner ear. The inner ear houses two separate sensory systems: the auditory system, which contains the **cochlea** whose receptors convert sound waves into nerve impulses, and the vestibular system, which is involved in balance and special position.

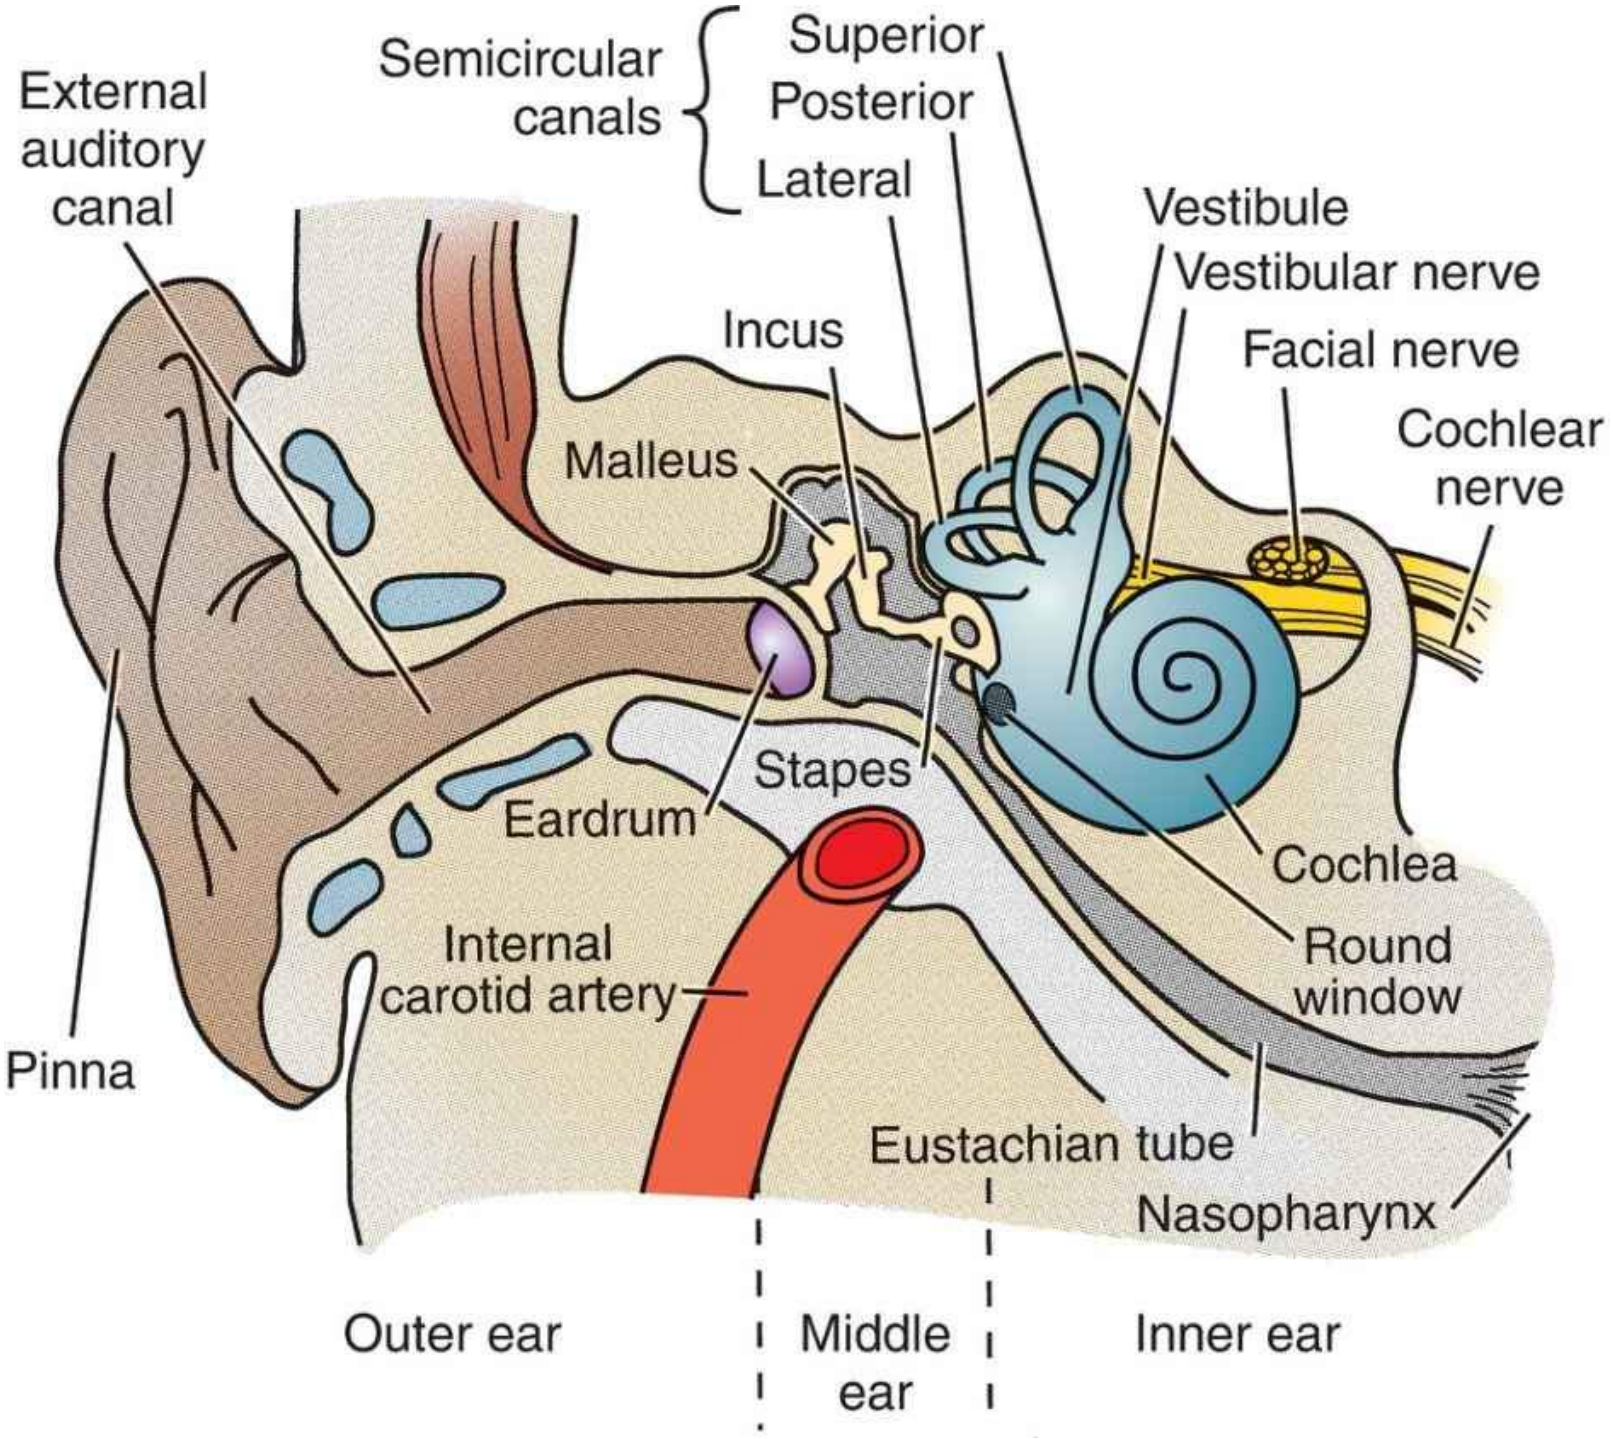

Figure 4.15 Basic structure of the human ear. Each ear consists of three basic parts: the external, middle,

and the inner ear. The structures of the middle and inner ear are encased in the temporal bone of the skull. The external and middle portions of the ear transmit airborne sound waves to the fluid-filled inner ear, amplifying sound waves in the process.

Sound is an oscillating pressure wave composed of frequencies that are transmitted through different media.

Sound is an oscillating pressure wave traveling through a medium (i.e., air, liquid, solid). This process involves both compression and rarefaction (Fig. 4.16). The distance between the compression peaks is called the wavelength of sound and is inversely related to the frequency. Hearing in humans is normally limited to frequencies between 20 and 20,000 Hz (1 Hz = 1 hertz = 1 cycle/s). Bats, however, can perceive a wider range of frequencies (2 to 110 kHz). Pitch or tone of sound is determined by frequency. *Sinusoidal sound waves* (those that have regularly repeating oscillations) contain all of their energy at one frequency and are perceived as pure tones. *Complex sound waves*, such as those in speech or music, consist of the addition of several simpler waveforms of different frequencies and amplitudes. Intensity or loudness depends on the amplitude of the sound wave and is expressed as a decibel (dB) scale:

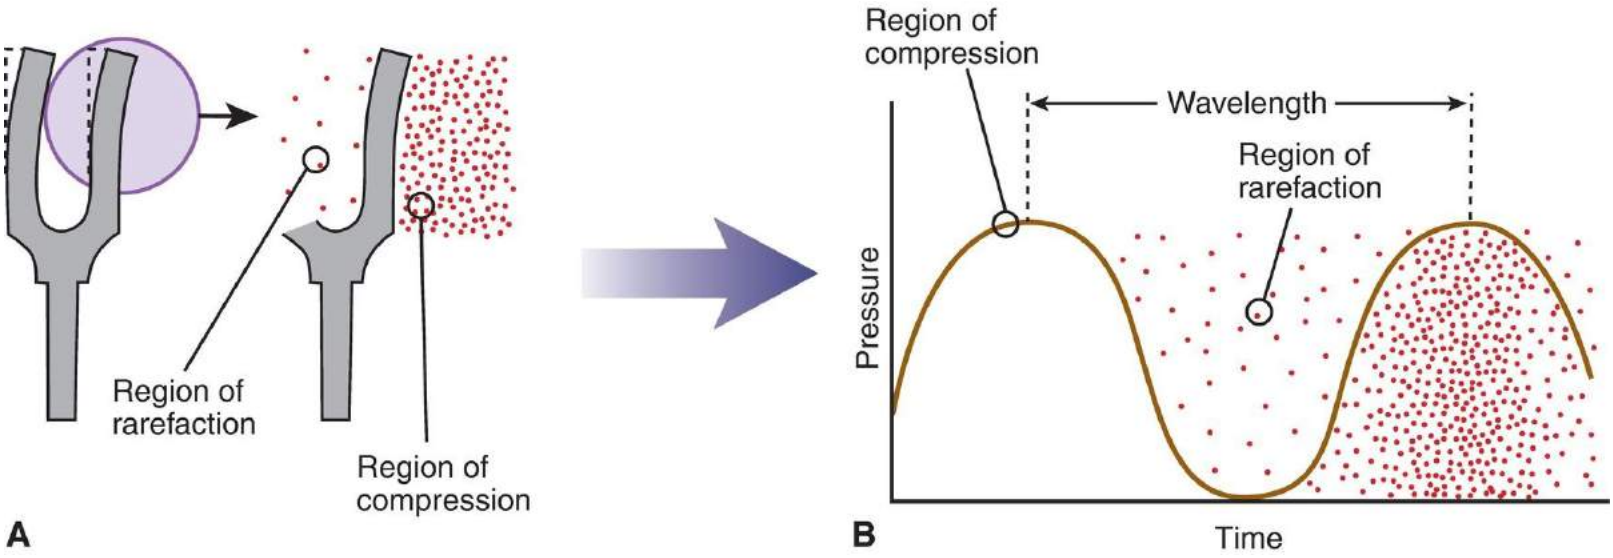

Figure 4.16 Sound wave formations. **(A)** Sound waves generated from a tuning fork cause molecules ahead of the advancing arm to be compressed and the molecules behind the arm to be rarified. **(B)** Sound waves are propagated as sinusoidal, alternating regions of compression and rarefaction of air molecules. The wavelength of a sinusoidal wave is the spatial period between two peak compression waves.

$$\text{Decibels(dB)} = 20 \log P/P_0$$

where P is sound pressure and P_0 is a reference level pressure (i.e., threshold for normal hearing at the best frequency). The threshold stimulus is set at 0 dB ($\log P/P_0 = 0$). For a sound that is 10 times greater than the reference, the expression becomes

$$\text{dB} = 20 \log \left(0.020 / 0.002\right) = 20$$

Thus, any two sounds having a 10-fold difference in intensity have a decibel difference of 20. A 100-fold difference would mean a 40-dB difference, and a 1,000-fold difference would mean a 60-dB difference. Common sounds range from a faint whisper (20 dB) to a jet taking off (140 dB).

External ear captures and amplifies sound.

An overall view of the human ear is shown in Figure 4.15. The auricle or *pinna*, the visible portion of the outer ear, collects sound waves and channels them down the external auditory canal. The external auditory canal extends inward through the temporal bone and its inner end is sealed by the *tympanic membrane* (eardrum), a thin, oval, slightly conical, flexible membrane. An incoming pressure wave traveling down the external auditory canal causes the eardrum to vibrate back and forth in step with the compressions and rarefactions of the sound wave. This is the first mechanical step in the transduction of sound. The overall acoustic effect of the outer ear structures is to produce an amplification of 10 to 15 dB in the frequency range broadly centered around 3,000 Hz.

Middle ear mechanically converts tympanic membrane vibrations to fluid waves in the inner ear.

The middle ear is an air-filled cavity containing three tiny bones that couple vibration of the eardrum into waves in the fluid and membranes of the inner ear. The hollow space of the middle ear is called the *tympanic cavity*. The eustachian tube connects the tympanic cavity to the pharynx, and the tube opens briefly during swallowing, allowing equalization of the pressures on either side of the eardrum. During rapid external pressure changes (such as during takeoff or descent in an airplane), the unequal forces displace the eardrum. Such physical deformation may cause discomfort or pain and, by restricting the motion of the tympanic membrane, may impair hearing. Blockages of the eustachian tube or fluid accumulation in the middle ear (as a result of an infection) can also lead to difficulties with hearing.

Bridging the gap between the tympanic membrane and the inner ear is a chain of three small bones, the ossicles (Fig. 4.17). The *malleus* (Latin for “hammer”) is attached to the eardrum in such a way that the back-and-forth movement of the eardrum causes a rocking movement of the malleus. The *incus* (Latin for “anvil”) connects the head of the malleus to the third bone, the *stapes* (Latin for “stirrup”). This last bone, through its oval footplate, connects to the oval window of the inner ear and is anchored there by an annular ligament.

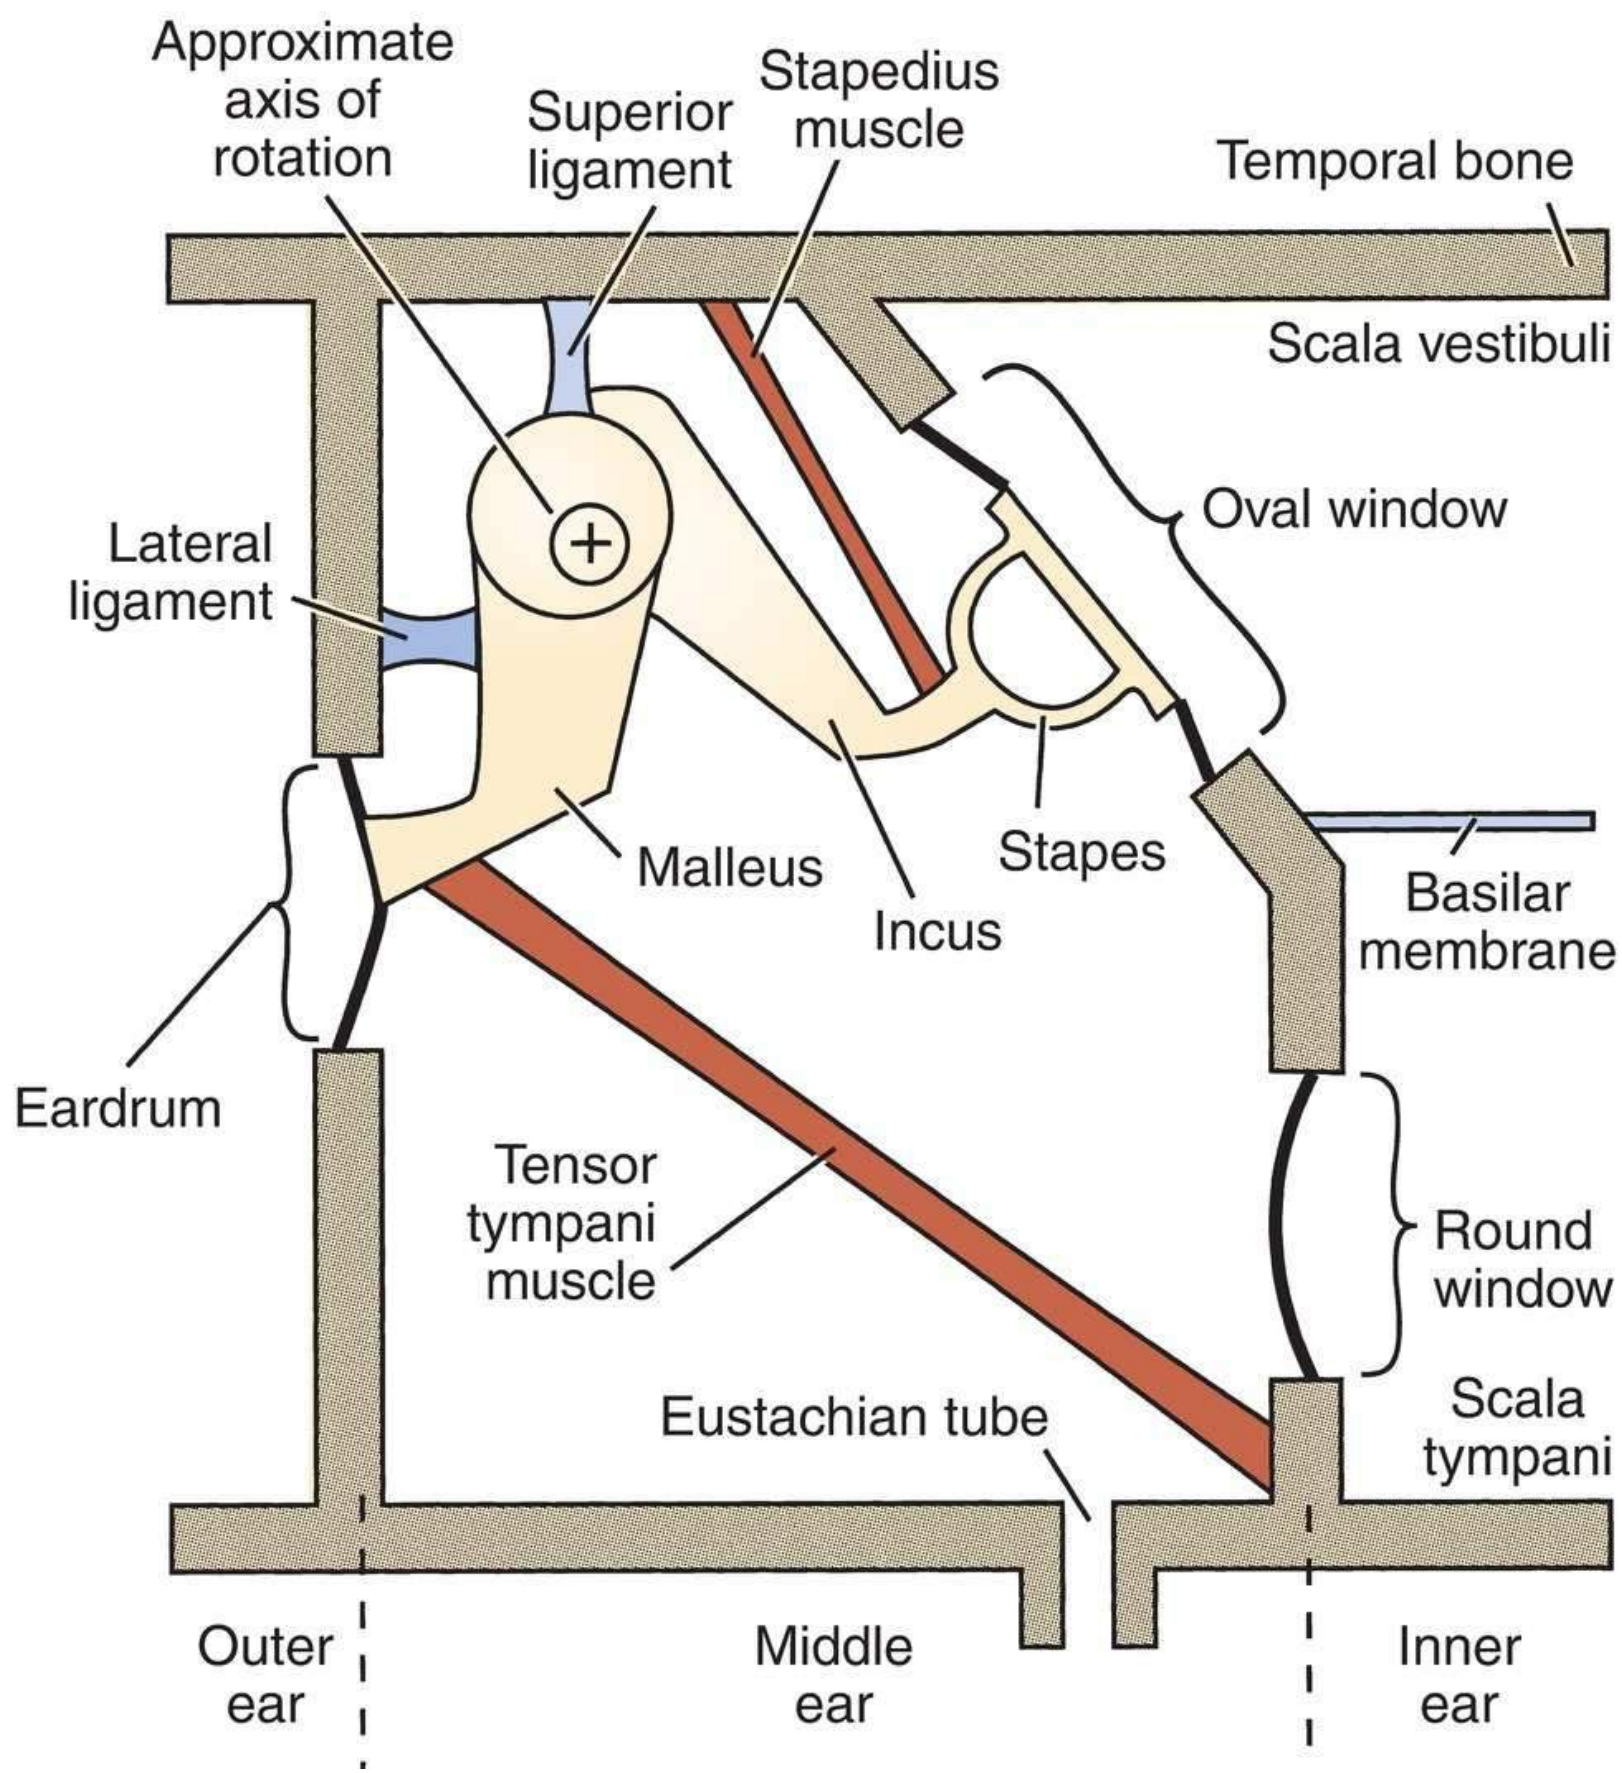

Figure 4.17 Model of the middle ear. Vibrations from the eardrum are transmitted by the lever system formed by the ossicular chain to the oval window of the scala vestibuli. The anterior and posterior ligaments, part of the suspensory system for the ossicles, are not shown. The combination of the four suspensory ligaments produces a virtual pivot point (marked by a *cross*); its position varies with the frequency and intensity of the sound. The stapedius and tensor tympani muscles modify the lever function of the ossicular chain.

Four separate suspensory ligaments hold the ossicles in position in the middle ear cavity. The superior and lateral ligaments lie roughly in the plane of the ossicular chain and anchor the head and shaft of the malleus. The anterior ligament attaches the head of the malleus to the anterior wall of the middle ear cavity, and the posterior ligament runs from the head of the incus to the posterior wall of the cavity. The suspensory ligaments allow the ossicles sufficient freedom to transmit the vibrations of the tympanic membrane to the oval window. This mechanism is especially important because, although the eardrum is suspended in air, the oval window seals off a fluid-filled chamber. When sound waves in air strike liquid, most of the energy (~99%) is reflected off the liquid and lost. The middle ear allows the impedance matching of sound traveling in air to acoustic waves traveling in a system of fluids and membranes in the inner ear. Two principles of mechanical advantage are used in the impedance matching, the hydraulic principle and the lever principle. The shape of the articulated ossicular chain is lever-like and has a lever ratio of about 1.3:1.0, producing a slight gain in force. In addition, the vibrating portion of the tympanic membrane is coupled to the smaller area of the oval window (~a 17:1 ratio). These conditions result in a pressure gain of around 25 dB, largely compensating for the energy loss going from an air to fluid environment. Although the efficiency depends on the frequency, approximately 60% of the sound energy that strikes the eardrum is transmitted to the oval window.

The middle ear is also able to substantially dampen sound conduction when faced with very loud sounds by noise-induced reflex contraction of the middle-ear muscles. These small muscles are attached to the ossicular chain and help hold the bones in position and modify their function (see Fig. 4.17). The *tensor tympani muscle* inserts on the malleus (near the center of the eardrum), passes diagonally through the middle ear cavity, and enters the *tensor canal*, in which it is anchored. Contraction of this muscle limits the vibration amplitude of the eardrum and makes sound transmission less efficient. The *stapedius muscle* attaches to the stapes near its connection to the incus and runs posteriorly to the mastoid bone. Its contraction changes the axis of oscillation of the ossicular chain and causes dissipation of excess movement before it reaches the oval window. These muscles are activated by a reflex (simultaneously in both ears) and contract in response to moderate and loud sounds. They act to reduce the transmission of sound to the inner ear, thereby protecting its delicate structures. This is called the **acoustic reflex**.

Because this reflex requires up to 150 milliseconds to operate (depending on the loudness of the stimulus), it cannot provide protection from sharp or sudden bursts of sound.

The process of sound transmission can bypass the ossicular chain entirely. If a vibrating object, such as a tuning fork, is placed against a bone of the skull (typically the mastoid), the vibrations are transmitted mechanically to the fluid of the inner ear, where the normal processes act to complete the hearing process. Bone conduction is used as a means of diagnosing hearing disorders that may arise because of lesions in the ossicular chain. Some hearing aids employ bone conduction to overcome such deficits.

Inner ear transduces sound.

The inner ear is a tortuous system of fluid-filled channels located in the temporal bone, the cochlea, which contains the receptor cells for the auditory system, and the semicircular canals and otolithic organs, which contain the receptor cells for the vestibular system. The inner ear is where the actual process of sound transduction takes place.

Cochlea

The cochlea defines the overall structure of the auditory transducer. It propagates the mechanical signals as waves in fluid and membranes and transduces them to nerve impulses, which are transmitted to the brain.

The auditory structures are located in the cochlea (Fig. 4.18), part of a cavity in the temporal bone called the *bony labyrinth*. The cochlea (Latin for "snail") is a fluid-filled spiral tube that arises from a cavity called the *vestibule*, with which the organs of balance also communicate. It is partitioned longitudinally into three divisions (canals) called the *scala vestibuli* (into which the oval window opens), the *scala tympani* (sealed off from the middle ear by the *round window*), and the membranous *scala media* (in which the sensory cells are located). Arising from the bony center axis of the spiral (the *modiolus*) is a winding shelf called the osseous spiral lamina. Opposite to it on the outer wall of the spiral is the *spiral ligament*, and connecting these two structures and forming the floor of the scala media is a highly flexible connective tissue sheet, the **basilar membrane**, which runs for almost the entire length of the cochlea. The hair cells, which are the actual sensory receptors, are located on the upper surface of the basilar membrane (see Fig. 4.18B). They are called "hair cells" because each has a bundle of hair-like cilia at the end that project away from the basilar membrane.

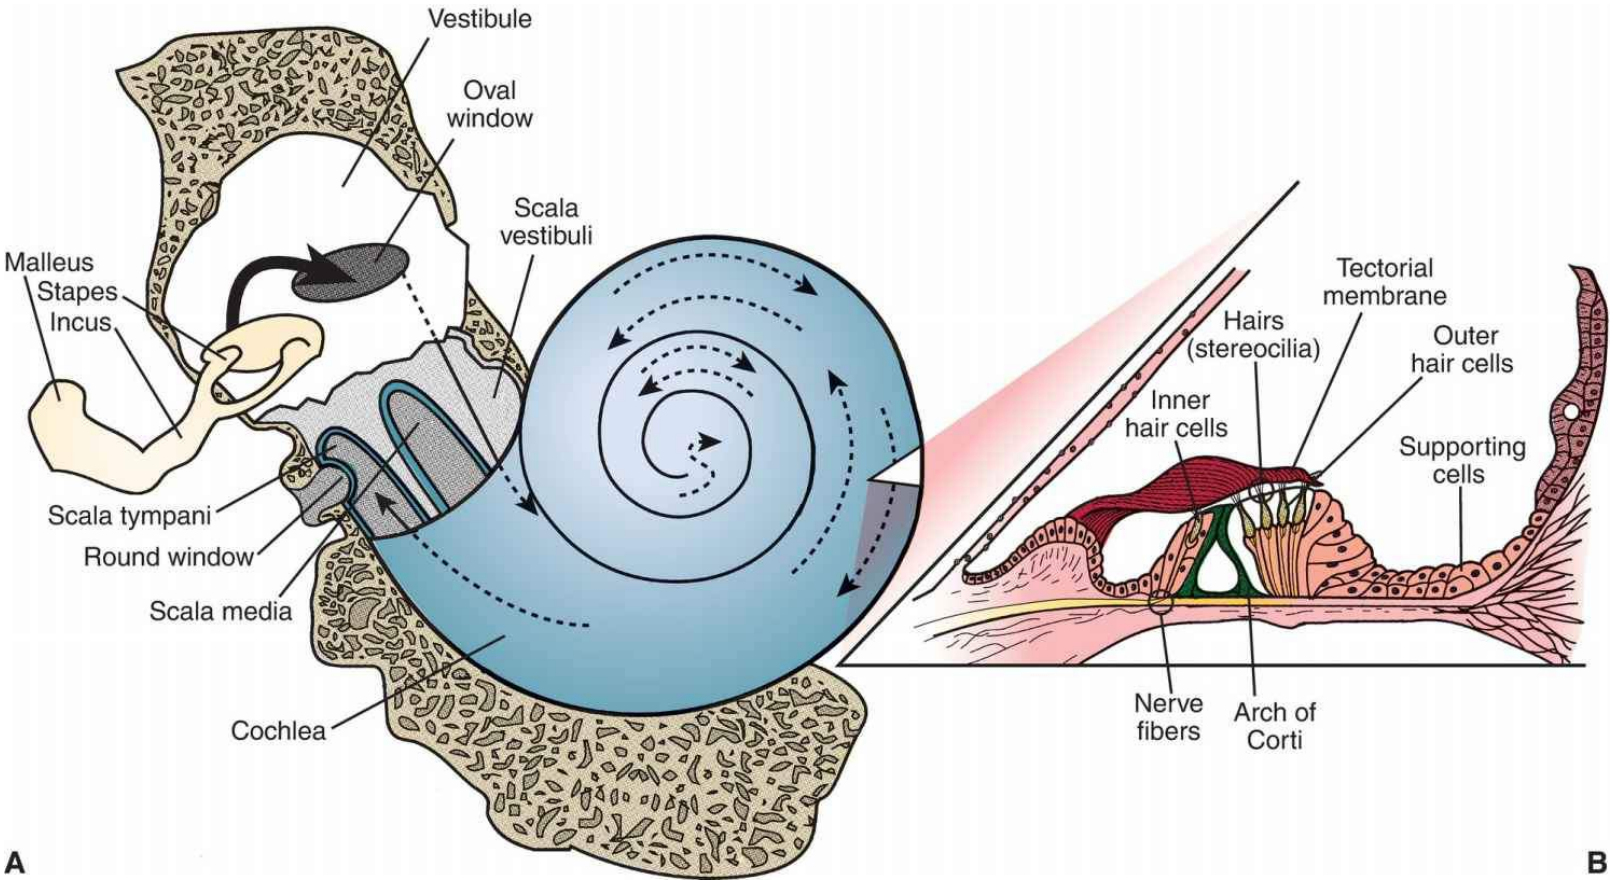

Figure 4.18 The cochlea and the organ of Corti. **(A)** The pea-sized, snail-shaped cochlea is a coiled system and is the hearing portion of the inner ear. **(B)** An enlargement of a cross-section of the organ of Corti, showing the relationships among the hair cells and the membranes. Hair cells in the organ of Corti transduce fluid movement into neural signals.

The Reissner membrane forms the roof of the scala media separating it from the scala vestibuli (see Fig. 4.18). The scala vestibuli communicates with the scala tympani at the apical (distal) end of the cochlea via the helicotrema, a small opening where a portion of the basilar membrane is missing. The scala vestibuli and scala tympani are filled with **perilymph**, a fluid high in sodium and low in potassium. The scala media contains **endolymph**, a fluid high in potassium and low in sodium. The endolymph is secreted by the **stria vascularis**, a layer of fibrous vascular tissue along the outer wall of the scala media. Because the cochlea is filled with incompressible fluid and is encased in hard bone, pressure changes caused by the in-and-out motion at the oval window (driven by the stapes) are relieved by an out-and-in motion of the flexible round window membrane.

Sensory structures

The **organ of Corti** is formed by structures located on the upper surface of the basilar membrane and runs the length of the scala media (see Fig. 4.18B). It contains one row of some 3,000 *inner hair cells*. The arch of Corti and other specialized supporting cells separate the inner hair cells from the three or four rows of *outer hair cells* (about 12,000) located on the stria vascularis side. The rows of inner and outer hair cells are inclined slightly toward each other and are covered by the *tectorial membrane*.

Nerve fibers from cell bodies located in the *spiral ganglia* form radial bundles on their way to synapse with the inner hair cells. Each nerve fiber makes synaptic connection with only one hair cell, but each hair cell is served by 8 to 30 fibers. Although the inner hair cells comprise only 20% of the hair cell population, they receive 95% of the afferent fibers. In contrast, many outer hair cells are each served by a single external spiral ganglion nerve fiber. The collected afferent fibers are bundled in the *cochlear nerve*, which exits the inner ear via the *internal auditory meatus*. Many efferent fibers also innervate the cochlea. They serve to enhance pitch discrimination and the ability to distinguish sounds in the presence of noise. Evidence suggests that efferent fibers to the outer hair cells cause them to shorten (contract), altering the mechanical properties of the cochlea.

Hair Cells

The hair cells of the inner and the outer rows are similar anatomically. Both sets extend upward into the scala media toward the tectorial membrane (see Fig. 4.18B). Extensions of the outer hair cells actually touch the tectorial membrane, whereas those of the inner hair cells appear to stop just short of contact. The hair cells make synaptic contact with afferent neurons using glutamate as their neurotransmitter.

At the apical end of each inner hair cell is a projecting bundle of about 50 **stereocilia**, rod-like structures packed in parallel, slightly curved rows. Minute strands link the free ends of the stereocilia together, so the bundle tends to move as a unit. The height of the individual stereocilia increases toward the outer edge of the cell (toward the stria vascularis), giving a sloping appearance to the bundle. Along the cochlea, the inner hair cells remain constant in size, whereas their stereocilia increase in height from about 4 µm at the basal end to 7 µm at the apical end. The outer hair cells are more elongated than the inner cells, and their size and height of stereocilia increase along the cochlea from base to apex. Each stereocilium contains cross-linked and closely packed actin filaments and, near the tip, a cation-selective transduction channel.

The process of mechanical transduction in hair cells is shown in Figure 4.19. When a hair bundle is deflected slightly (the threshold is <0.5 nm) toward the stria vascularis, minute mechanical forces open the transduction channels, and cations enter the cells. The resulting **depolarization**, roughly proportional to the deflection, causes the opening of voltage-gated calcium channels in the hair cell basolateral membrane. As in other synaptic systems, the entry of calcium ions results in migration and fusion of the synaptic vesicles with the cell membrane and the release of transmitter molecules, which generates action potentials in the afferent nerve. Approximately 15% of the transduction channels are open in the absence of any deflection, and bending in the direction of the modiolus of the cochlea results in hyperpolarization, thereby increasing the range of stereocilia movement that can be sensed.

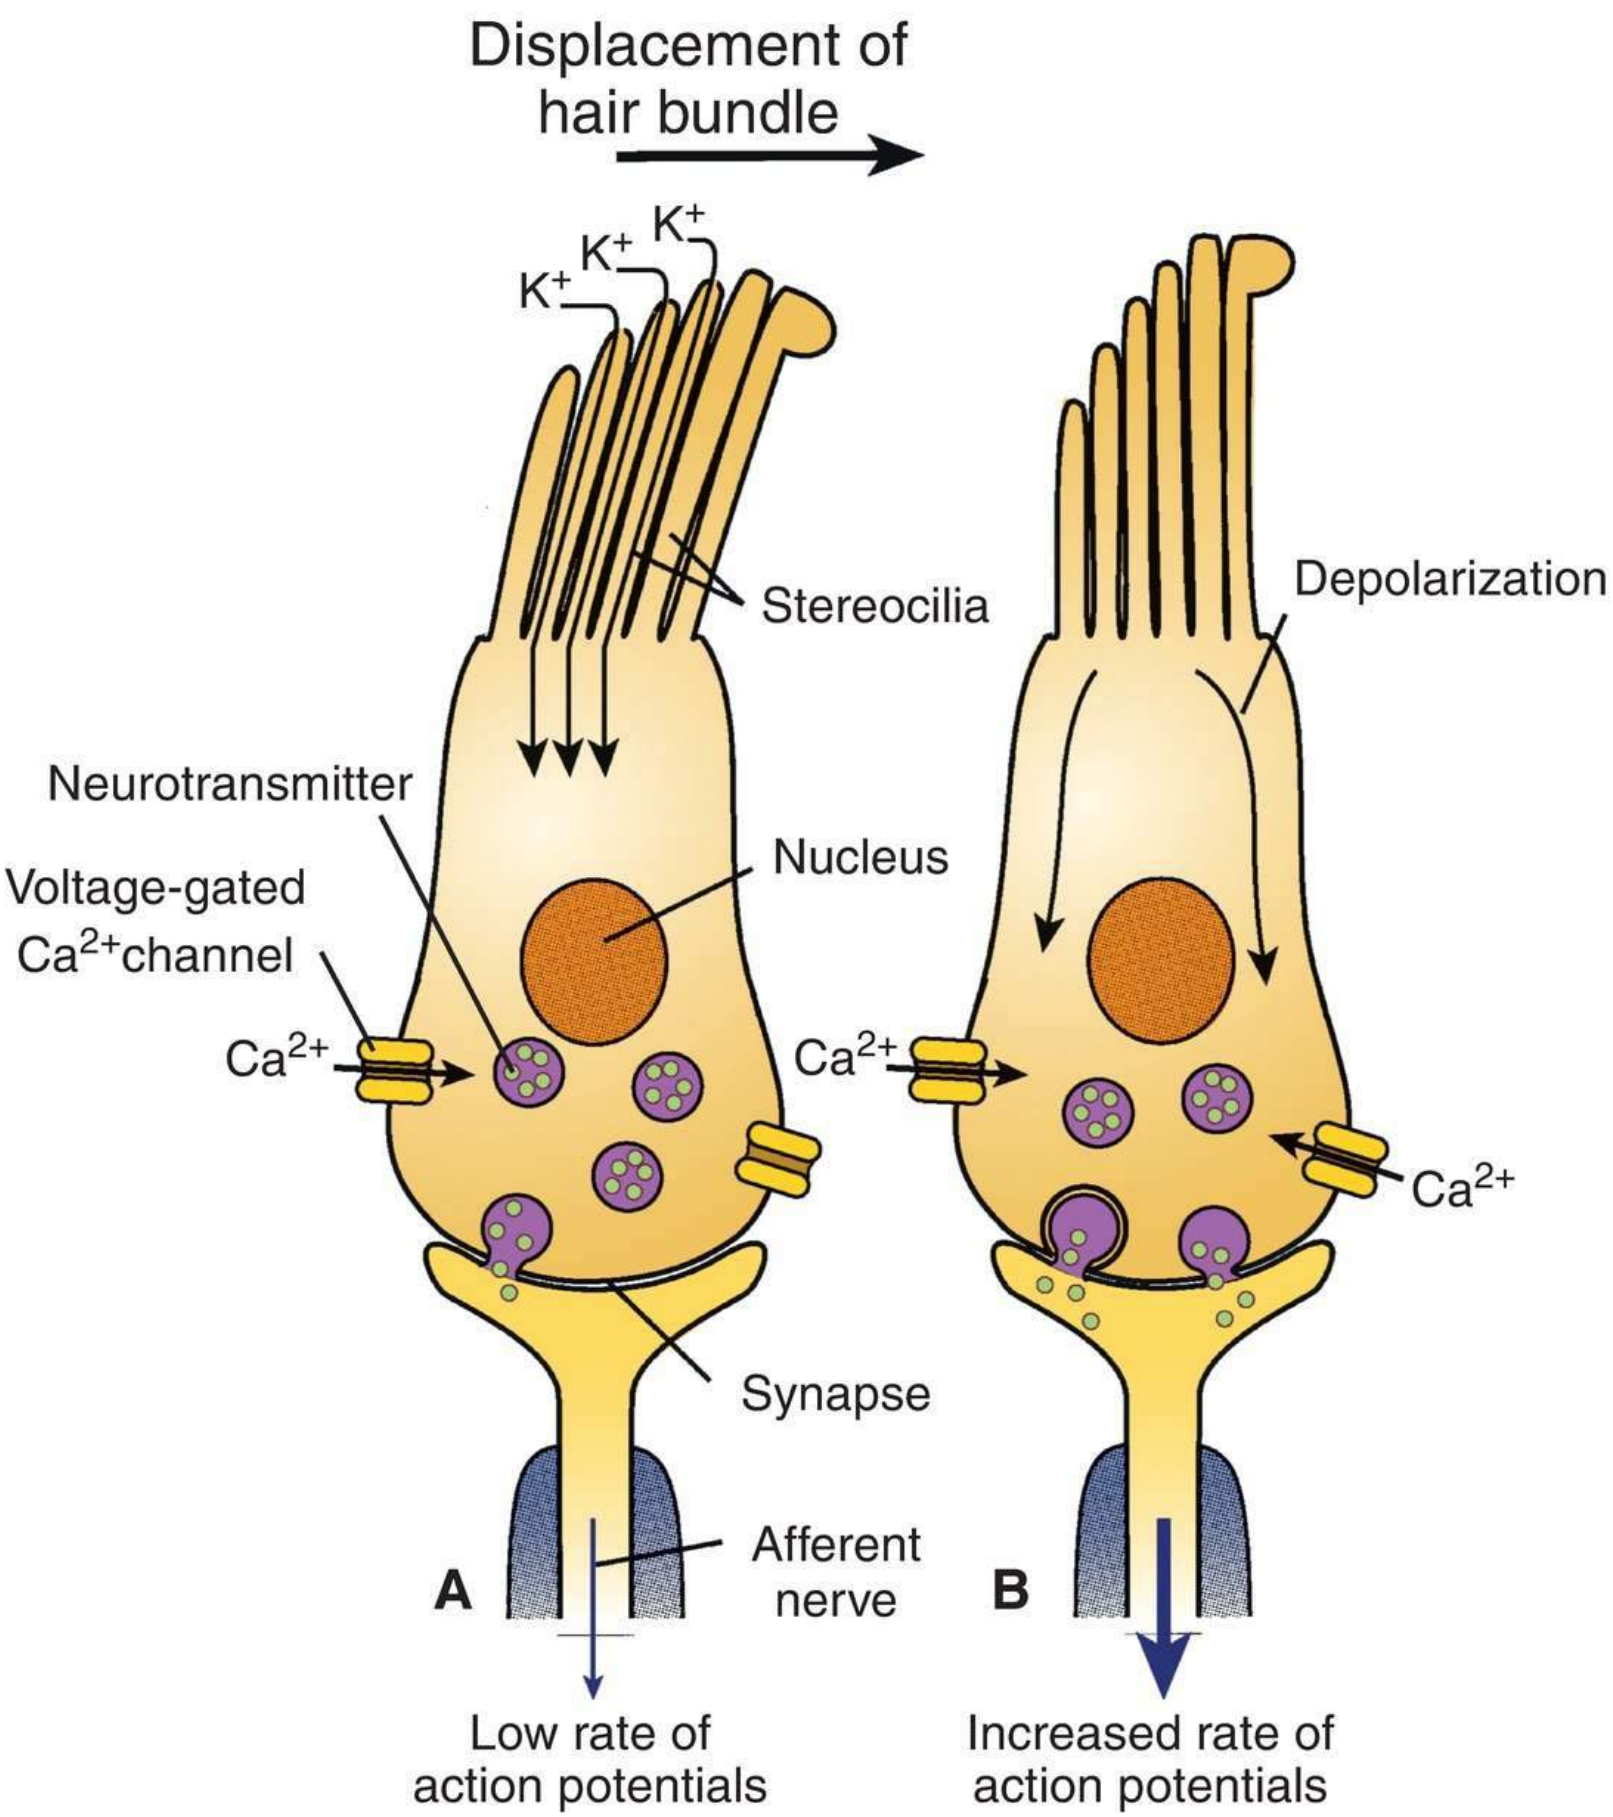

Figure 4.19 Role of stereocilia in sound transduction in the hair cells of the ear. **(A)** Deflection of the stereocilia opens apical K^+ channels. **(B)** K^+ enters the hair cells causing depolarization. The resulting depolarization opens the voltage-gated Ca^{2+} channels at the basal end of the cell. This causes the release of the neurotransmitter, thereby exciting the afferent nerve.

The response time of hair cells is remarkable; they can detect repetitive motions of up to 100,000 times per second. They can, therefore, provide information throughout the course of a single cycle of a sound wave. Such rapid response is also necessary for the accurate localization of sound sources. When a sound comes from directly in front of a listener, the waves arrive simultaneously at both ears. If the sound originates off to one side, it reaches one ear sooner than the other and is slightly more intense at the nearer ear. The difference in arrival time is on the order of tenths of a millisecond, and the rapid response of the hair cells allows them to provide temporal input to the auditory cortex. The timing and intensity information are processed by groups of cells in the central auditory pathways to produce an accurate perception of the location of the sound source.

Organ of Corti

The actual transduction of sound requires an interaction among the tectorial membrane, the hair cells, and the basilar membrane. When a sound wave is transmitted to the oval window by the ossicular chain, a pressure wave travels up the scala vestibuli and down the scala tympani (Fig. 4.20). The canals of the cochlea, being encased in bone, are not deformed, and movements of the round window allow the small volume change needed for the transmission of the pressure wave. Resulting currents in the cochlear fluids produce an undulating distortion in the basilar membrane. Because the stiffness and width of the membrane vary with its length (it is wider and less stiff at the apex than at the base), the membrane deformation takes the form of a “traveling wave,” which has its maximal amplitude at a position along the membrane corresponding to the particular frequency of the sound wave (Fig. 4.21). Low-frequency sounds cause a maximal displacement of the membrane near its apical end (near the helicotrema), whereas high-frequency sounds produce their maximal effect at the basal end (near the oval window). As the basilar membrane moves up, the stereocilia of the hair cells are displaced against the tectorial membrane and subjected to lateral shearing forces that stimulate the cells.

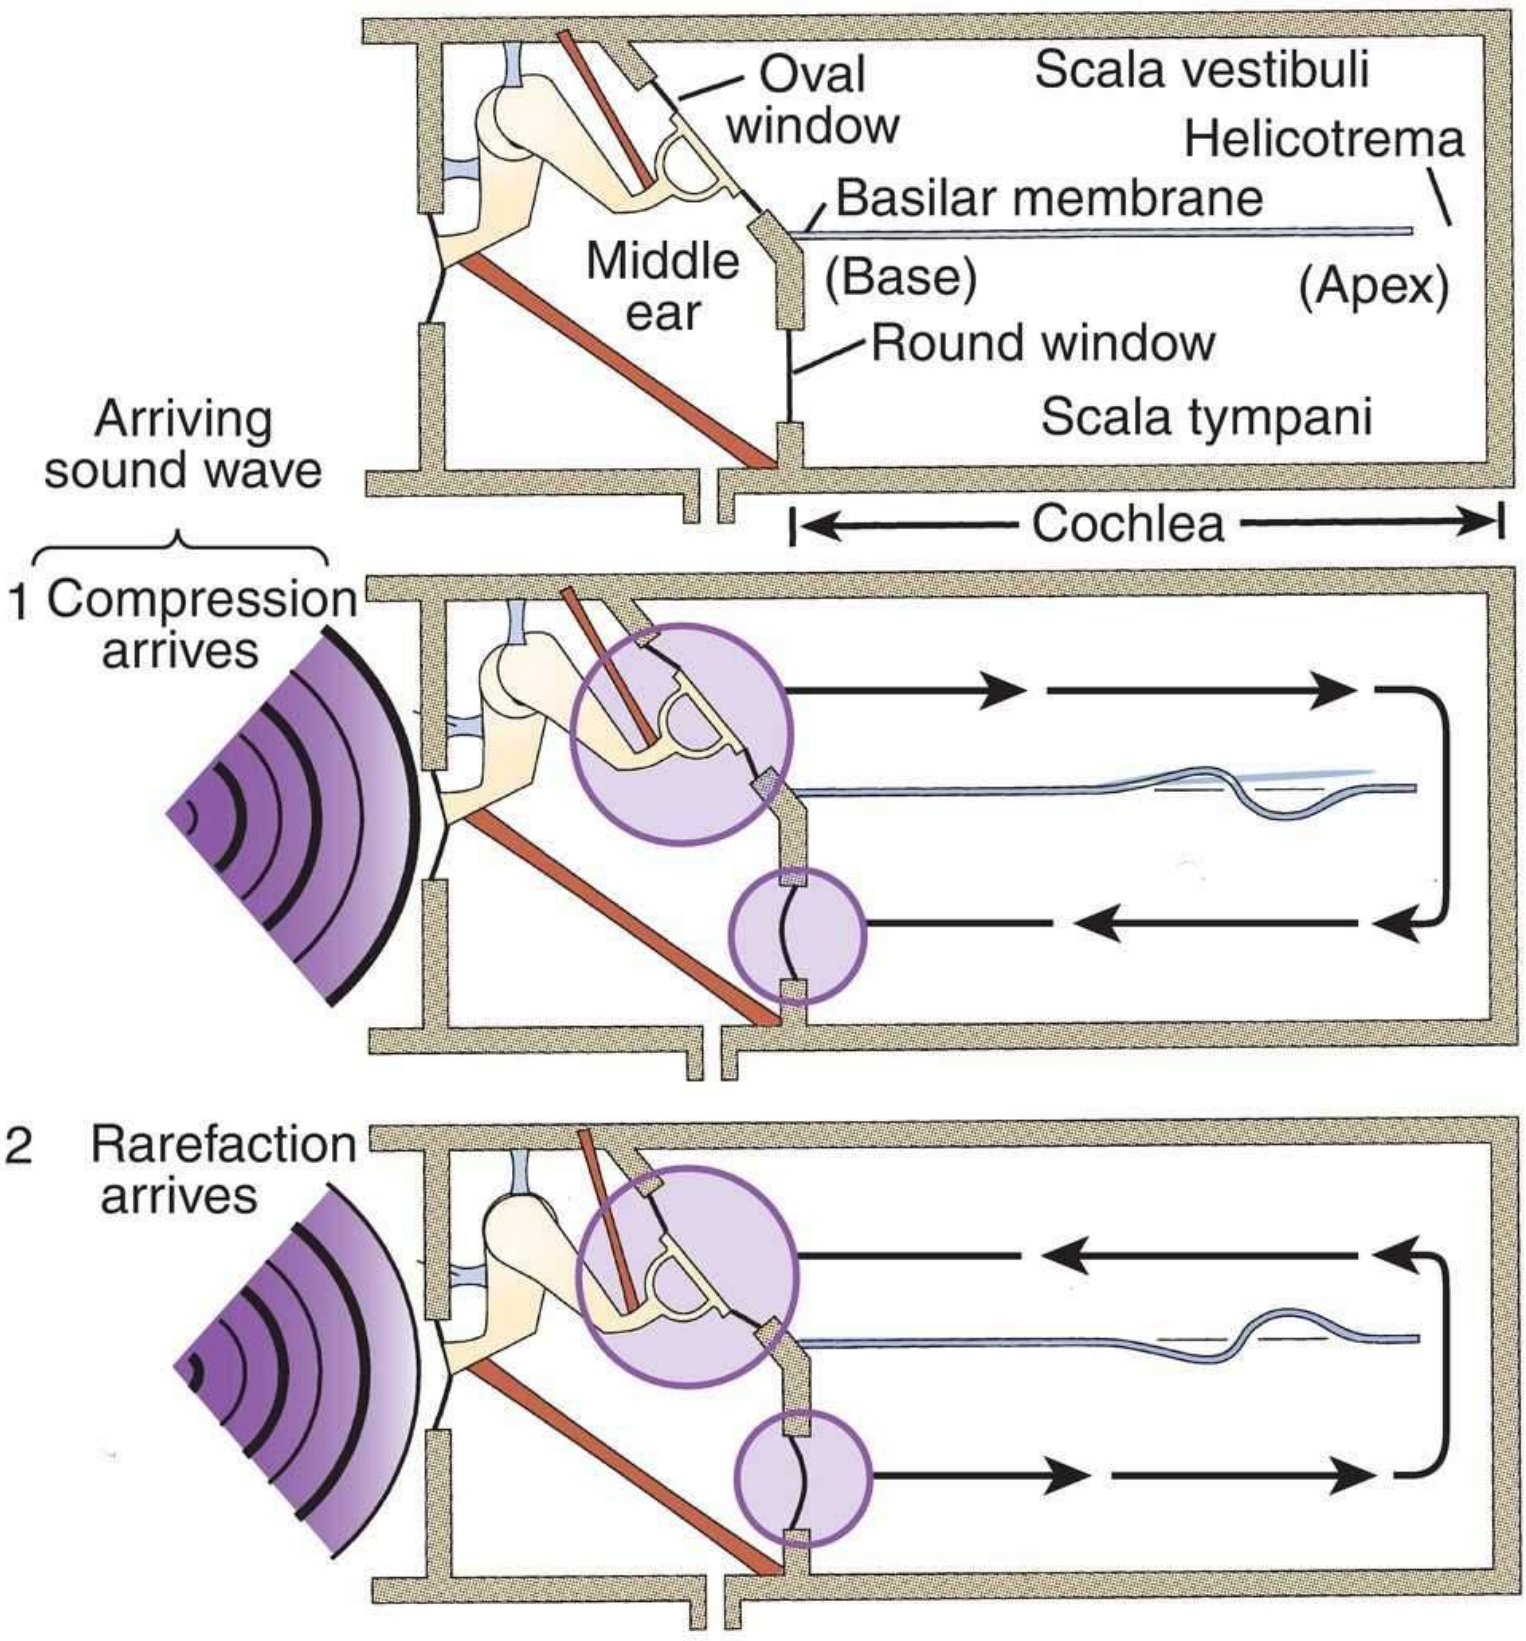

Figure 4.20 The mechanics of the cochlea, showing the action of the structures responsible for pitch discrimination (with only the basilar membrane of the organ of Corti shown). When the compression phase of a sound wave arrives at the eardrum, the ossicles transmit it to the oval window, which is pushed inward. A pressure wave travels up the scala vestibuli and (via the helicotrema) down the scala tympani. To relieve the pressure, the round window membrane bulges outward. Associated with the pressure waves are small eddy currents that cause a traveling wave of displacement to move along the basilar membrane from base to apex. The arrival of the next rarefaction phase reverses these processes. The frequency of the sound wave, interacting with the differences in the mass, width, and stiffness of the

basilar membrane along its length, determines the characteristic position at which the membrane displacement is maximal.

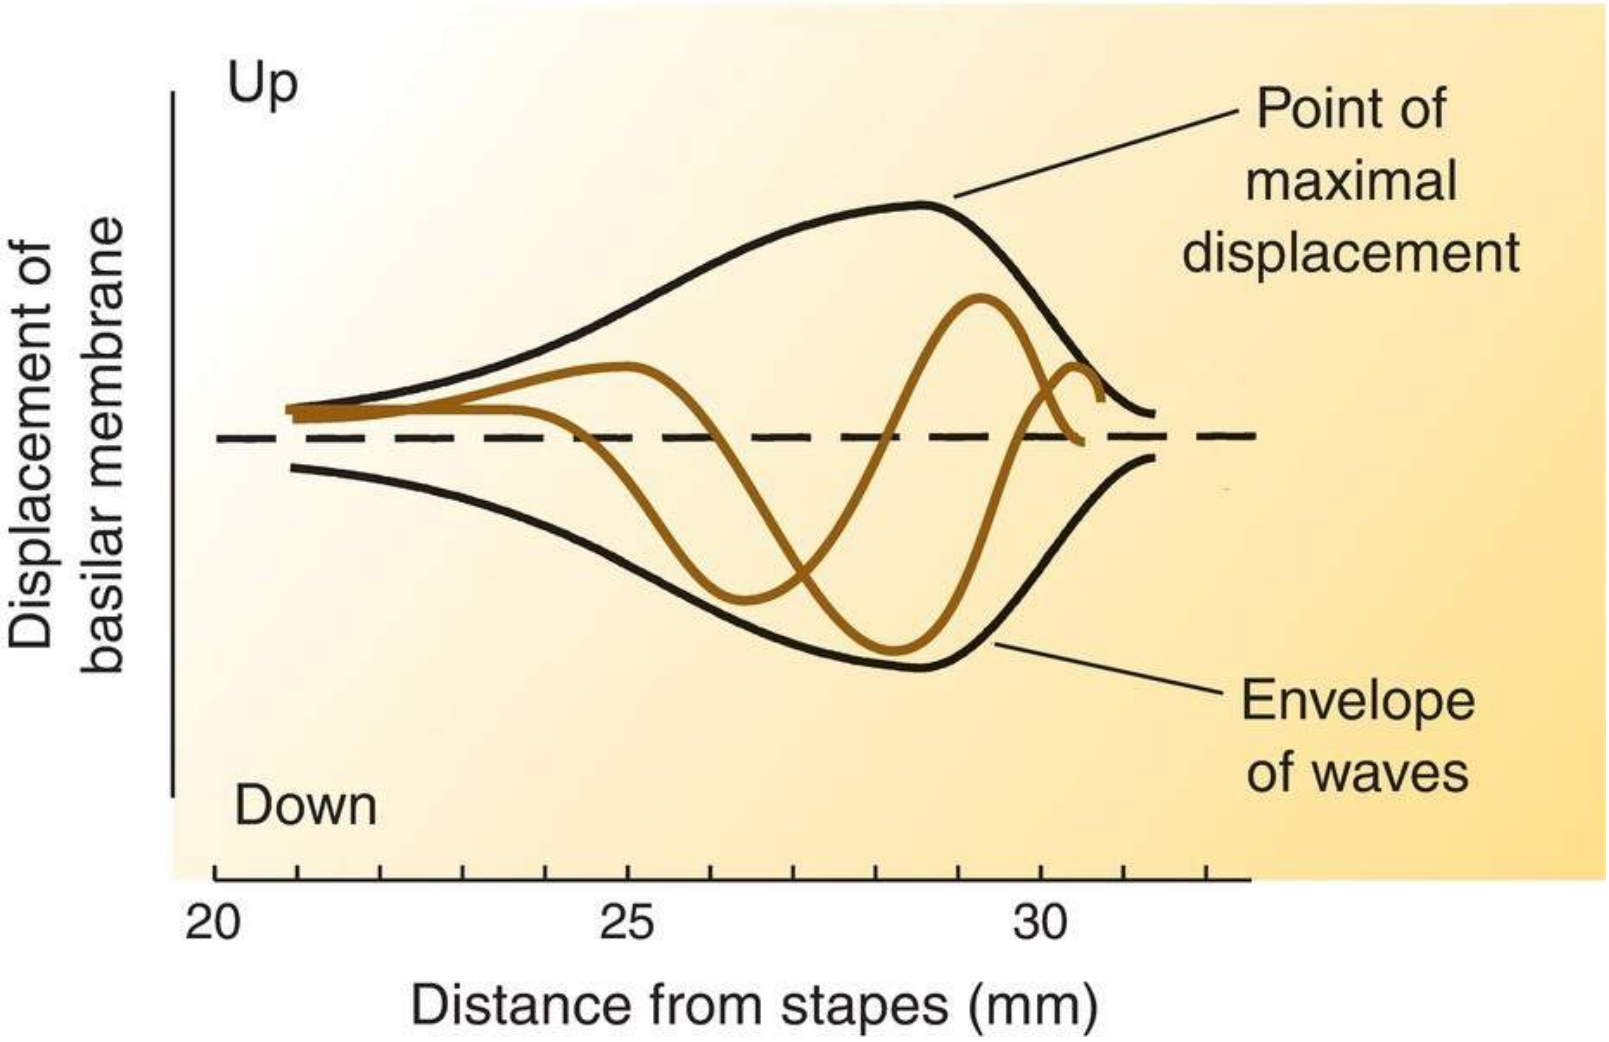

Figure 4.21 Membrane localization of different frequencies. An illustration of a traveling sound wave being displaced along the basilar membrane at two instants. Over time, the peak excursions of many such waves form an envelope of displacement with a maximal value at about 28 mm from the stapes (lower portion). At this position, its stimulating effect on the hair cells will be most intense. Low frequency (<800 Hz) produces maximal effects at the apex of the basilar membrane.

Because of the tuning effect of the basilar membrane, only hair cells located at a particular place along the membrane are maximally stimulated by a given frequency (pitch). This localization is the essence of the **place theory** of pitch discrimination, and the mapping of specific tones (pitches) to specific areas of the basilar membrane is called **tonotopic organization**. As the signals from the cochlea ascend through the complex pathways of the auditory system in the brain, the tonotopic organization of the neural elements is at least partially preserved, and pitch can be spatially localized throughout the system.

The sense of pitch is further sharpened by the resonant characteristics of the different-length stereocilia along the length of the cochlea and by the frequency–response selectivity of neurons in the auditory pathway. The cochlea acts as both a transducer for sound waves and a frequency analyzer that sorts out the different pitches so that they can be separately distinguished. In the midrange of hearing (around 1,000 Hz), the human auditory system can sense a difference in frequency of as little as 3 Hz. The tonotopic organization of the basilar membrane has facilitated the invention of prosthetic devices whose

aim is to provide some replacement of auditory function to people suffering from deafness that arises from severe malfunction of the middle or inner ear.

Central Auditory Pathways

Nerve fibers from the cochlea enter the spiral ganglion. From there, fibers are sent to the *dorsal* and *ventral cochlear nuclei*. The complex pathway that finally ends at the **auditory cortex** in the superior portion of the **temporal lobe** of the brain involves several sets of synapses and considerable crossing over and intermediate processing. As with the eye, there is a spatial correlation between cells in the sensory organ and specific locations in the primary auditory cortex. In this case, the representation is called a *tonotopic map*, with different pitches being represented by different locations, even though the firing rates of the cells no longer correspond to the frequency of sound originally presented to the inner ear.

Pitch discrimination

Pitch represents the perceived frequency of sound and is one of the major auditory attributes to musical tones. Pitch is determined by frequency (cycles per second or hertz) and corresponds closely to the repetition rate of sound waves. Although pitch discrimination (the ability to distinguish between various frequencies) is based on quantified frequencies, it is not an objective physical property but is completely subjective and is based on perceived sound. The basilar membrane is involved in determining pitch. Recall that different regions of the basilar membrane vibrate maximally at different frequencies (i.e., each frequency exhibits a peak vibration at different regions of the membrane). For example, higher frequencies vibrate best at the narrow end nearest the oval window, whereas low frequencies vibrate optimally at the wide end of the membrane. Sound waves themselves do not have pitch; distinguishing the perceived tones requires the work of the human brain. Each region of the basilar membrane is linked to a specific region of the auditory cortex, and tones are perceived in different regions of the primary auditory cortex. Tone deafness is the lack of relative pitch, or the inability to discriminate between musical notes. However, tone-deaf individuals can fully interpret the pitch of human speech.

Loudness

Loudness is another auditory attribute and depends on the amplitude of vibration. Sound waves originating from louder sounds cause the eardrum to vibrate more vigorously. Recall that a greater tympanic membrane deflection is converted into greater amplitude of basilar membrane movement. The CNS interprets this membrane oscillation and hair bending as a louder sound. Although the auditory system is sensitive and can detect very faint sounds, loud sounds can be damaging to the ear. The protective reflexes of the middle ear cannot sufficiently attenuate very loud sounds. Violent vibrations of the basilar membrane that come from sources, such as a jet engine or a siren for example, can permanently damage hair cells leading to noise-induced hearing loss.

Hearing loss results from a mechanical or a neural problem.

Hearing loss or *deafness* refers to conditions in which individuals are unable to detect or perceive some frequencies of sound. Deafness can be temporary or permanent (partial or complete). Hearing loss is the second most common physical disability in North America, affecting approximately 10% of the population. Hearing impairments are categorized by their types—*conductive deafness* and *sensorineural deafness*. A conductive deafness is an impairment resulting from dysfunction in any of the mechanisms that normally conducts sound waves through the outer ear, the eardrum, or the bones of the middle ear. Common causes include the buildup of earwax that blocks the ear canal, a ruptured eardrum, a middle ear infection, and restriction of ossicular movements of bony structures of the middle ear.

A sensorineural hearing impairment occurs as a result of (1) inner ear dysfunction, especially of the cochlea, where sound vibrations are converted into neural signals, or (2) any part of the brain that subsequently processes these signals. The vast majority of sensorineural deafness is associated with damage to the hair cells of the organ of Corti in the cochlea. This dysfunction may be present from birth from genetic or developmental abnormalities or arise through trauma or disease. Diseases causing deafness include measles, meningitis, mumps, and venereal disease. Some medications can also cause irreversible damage to the hair cells. The most important group is the aminoglycosides (primarily gentamicin). Other medications include anti-inflammatory (nonsteroidal) and diuretic drugs. Narcotic painkillers, in particular Vicodin and OxyContin, are another source of medication that causes permanent hearing loss.

One of the most common causes of partial hearing loss is sensory presbycusis, the progressive loss of the ability to hear high-frequency sounds with increasing age as the hair cells near the base of the cochlea “wear out” over time.

VESTIBULAR SYSTEM

Animals need feedback information to keep track of which end is up—that is, how they are oriented to their surrounding environment. The eyes help to keep track of movement with other objects, but the sensory system that also contributes to our balance and sense of spatial orientation is the vestibular system. This system provides dominant input about movement and equilibrioception. The vestibular apparatus sends signals primarily to the neural structures that control the eye movements and keep us upright.

Vestibular system comprises the semicircular canal and the otoliths.

Each ear contains three **semicircular canals** and two **otolithic organs**, the *utricle* and the *saccule* (Fig. 4.22). These structures are located in the bony labyrinth of the temporal bone. As with hearing, the basic sensing elements are hair cells. The semicircular canals are arranged three dimensionally in planes that are at approximately right angles to each other and are called the *horizontal* (lateral), *anterior* (superior), and the *posterior canals* (inferior). The anterior and posterior canals may be collectively called *vertical semicircular canals*. The three pairs of canals work in a push–pull fashion—when one canal is stimulated, its corresponding partner on the other side is inhibited and vice versa. The push–pull systems allow the vestibular apparatus to sense all directions of rotation. For example, the right horizontal canal gets stimulated during head rotations to the right, and the left horizontal canal gets stimulated by head rotations to the left. Vertical canals are coupled in a crossed fashion, which allows for stimulations for the anterior canal to also be inhibitory for the contralateral posterior canal and vice versa.

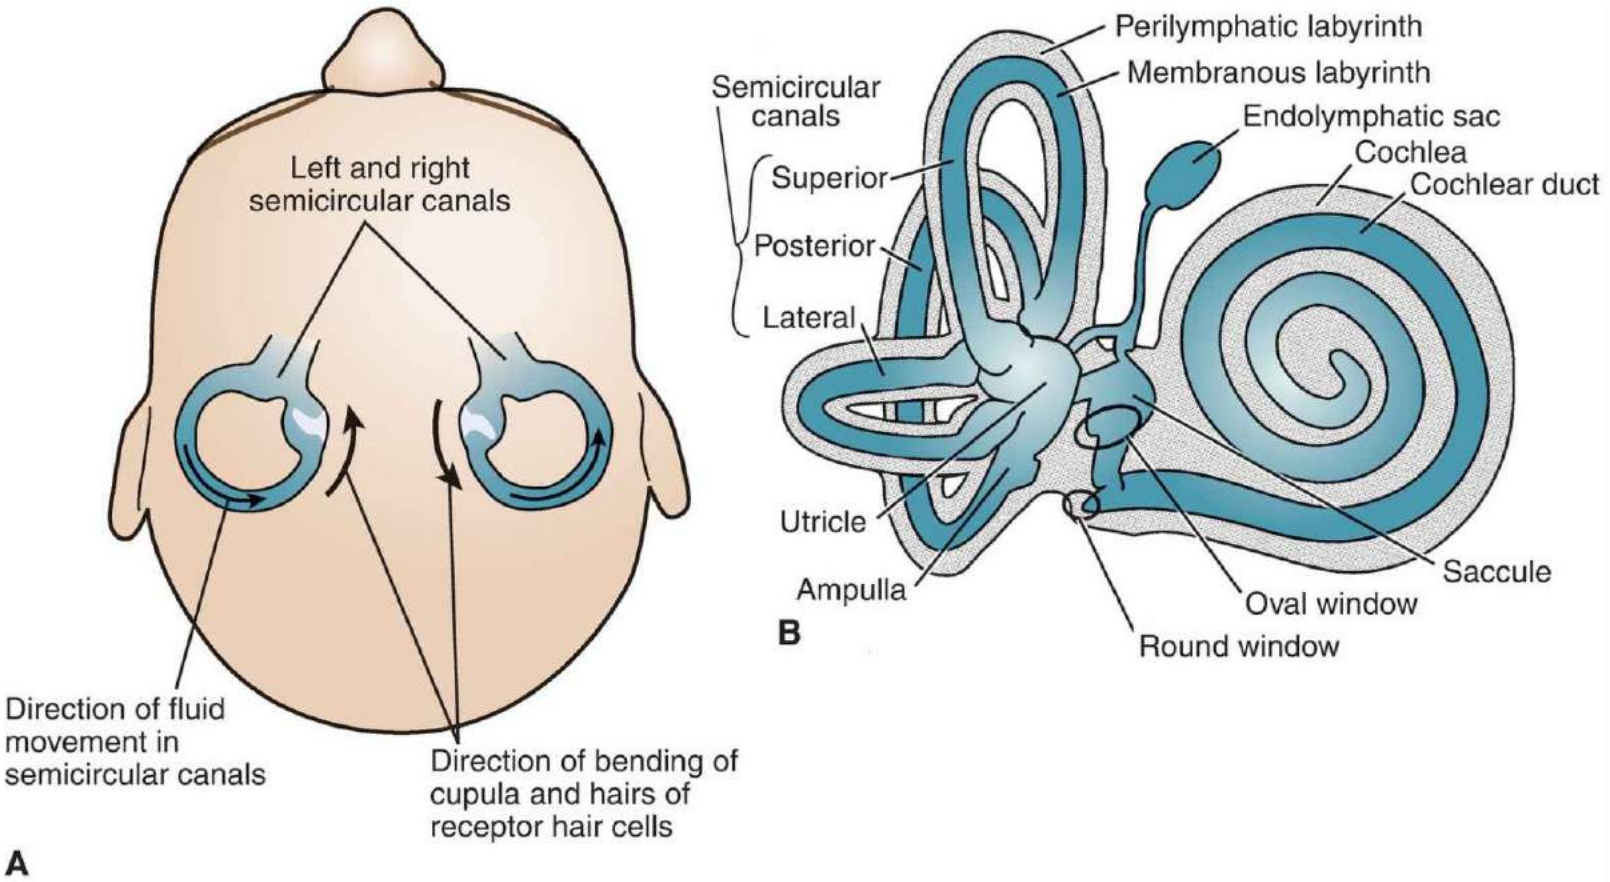

Figure 4.22 The vestibular apparatus in the bony labyrinth of the inner ear. **(A)** Activation of hair cells in the semicircular canals. **(B)** The semicircular canals sense rotary acceleration and motion, whereas the utricle and saccule sense linear acceleration and static position.

Movement of fluid within the horizontal canal corresponds to rotation of the head around a vertical axis (i.e., the neck). The anterior and posterior canals detect rotations of the head in the sagittal plane (i.e., nodding) and in the frontal plane, as when doing a cartwheel. Both anterior and posterior canals are oriented at ~ 45° between the frontal and sagittal planes. Near its junction with the utricle, each canal has a swollen portion called the *ampulla*. Each ampulla contains the sensory structure for that semicircular canal called the *crista ampullaris*. The crista ampullaris contains the vestibular receptor cells, which are

hair cells similar to those in the auditory system, and supporting cells. The crista ampullaris is encapsulated in the *cupula*, a gelatinous mass (Fig. 4.23). Each vestibular hair cell contains up to a 100 stereocilia and a single longer kinocilium. Rotation of the head causes movement of the endolymph fluid in the canals pushing the cupula, which in turn displaces the hair cell stereocilia. Mechanical movement of the vestibular hair cell stereocilia is transduced into an electrical signal in a manner similar to that described above for auditory hair cells. The responses of the stereocilia to movement are polarized with movements of the stereocilia toward the kinocilium depolarizing the hair cell while movement in the opposite direction hyperpolarizes the hair cell. The hair cells synapse with terminal endings of afferent neurons whose axons form the *vestibular nerve*. Depolarization increases the release of neurotransmitters in the hair cells, bringing about a concomitant increased rate of firing in the afferent fibers. Conversely, hyperpolarization inhibits neurotransmitter release from the hair cells and, in turn, decreases the frequency of action potentials in the afferent nerve fibers.

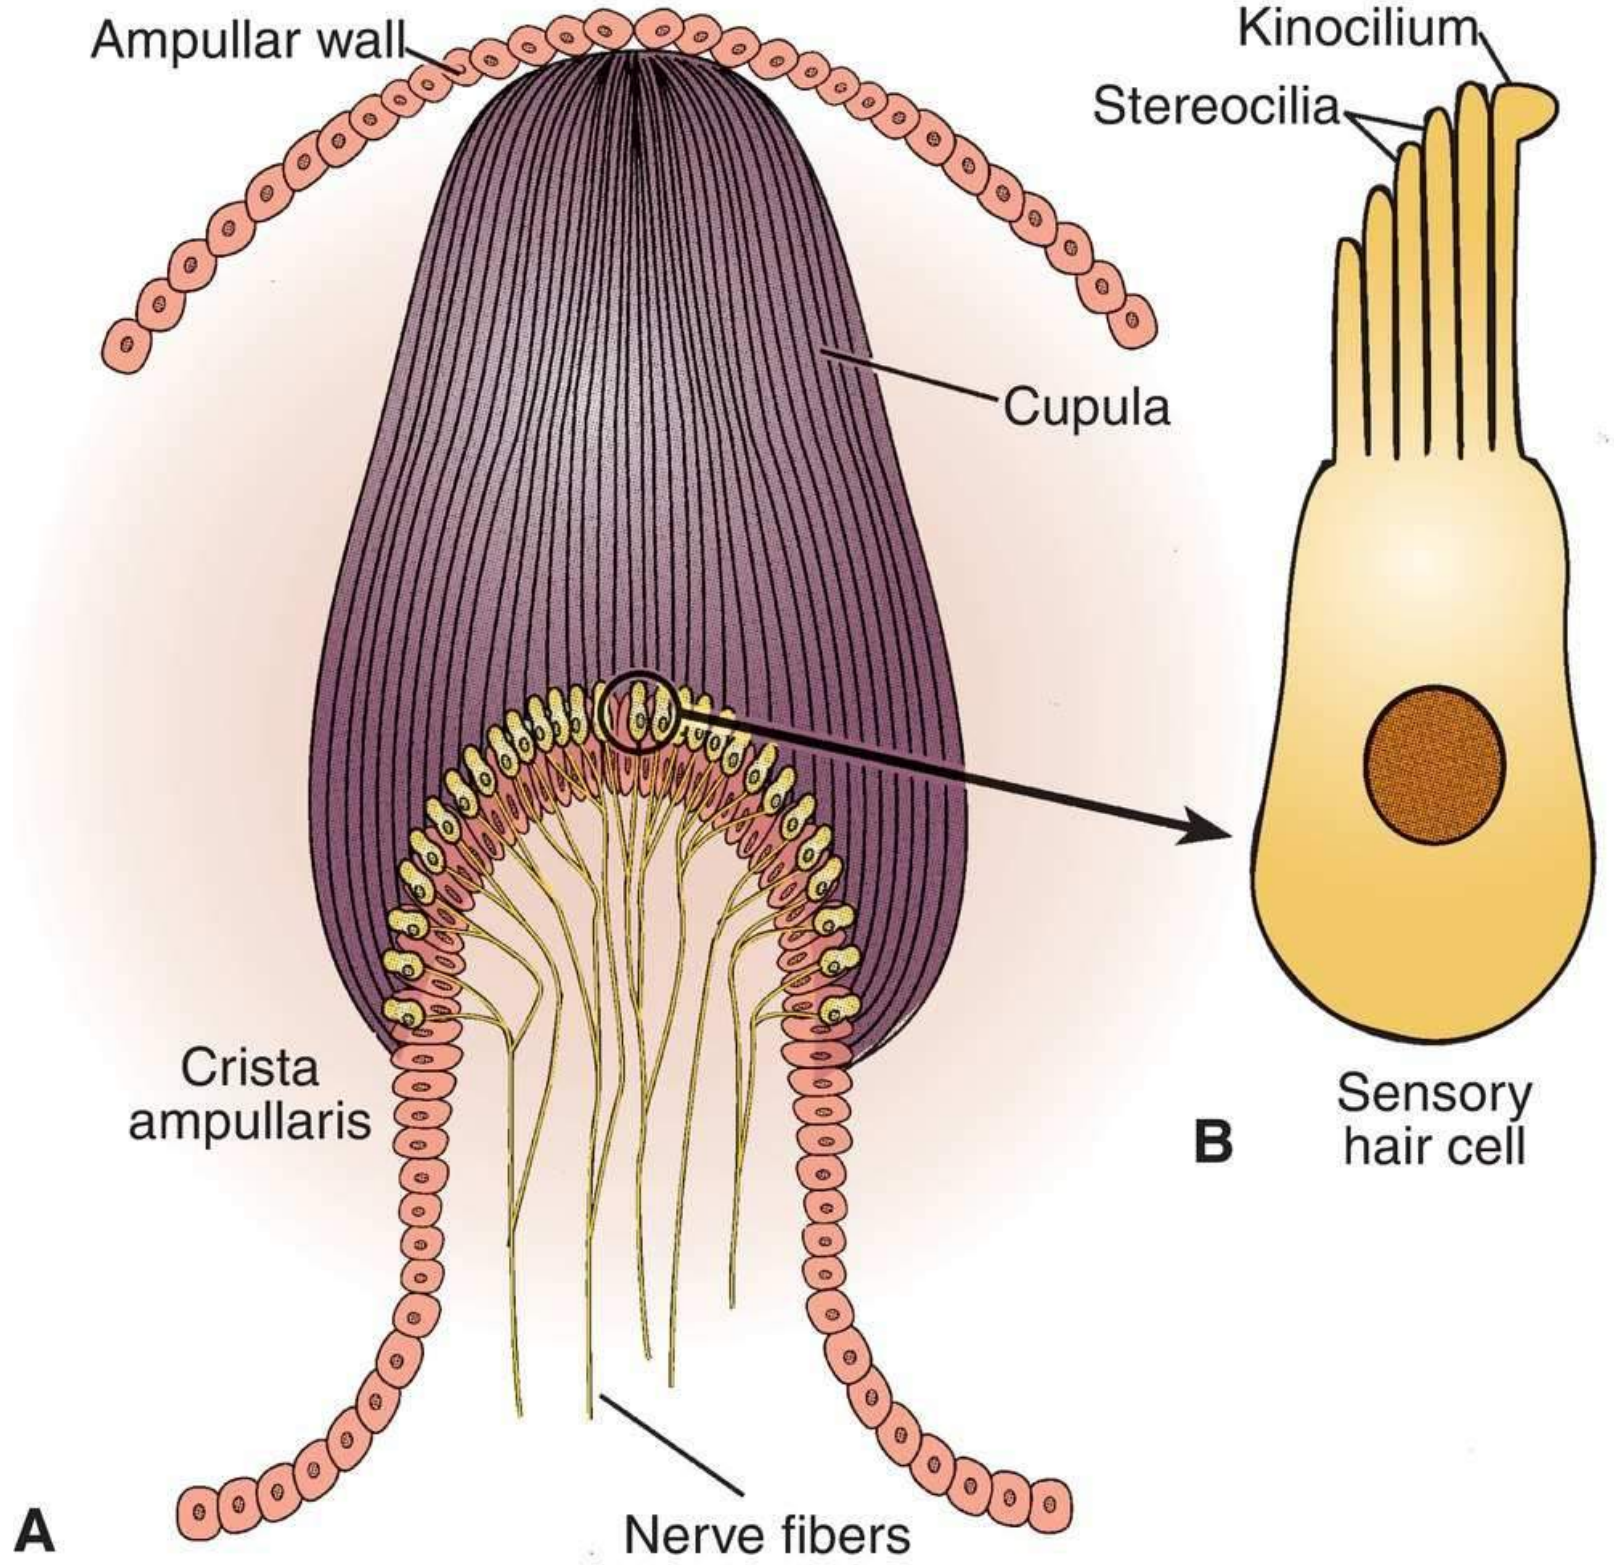

Figure 4.23 The sensory structure of the semicircular canals. **(A)** The crista ampullaris contains the hair (receptor) cells, and the whole structure is deflected by motion of the endolymph. **(B)** An individual hair cell.

Otolithic organs

Whereas the semicircular canals respond to rotation, the otolithic organs sense linear accelerations. The utricle and the saccule, are sac-like structures located in the vestibule, the bony chamber located between the semicircular canals and the cochlea. Calcium carbonate crystals, the **otoliths**, are suspended on a

viscous gel layer over the hair cells and are heavier than their surroundings (Fig. 4.24). During linear acceleration, the otoliths get displaced, which, in turn, deflects the hair cell stereocilia producing a sensory signal. Most of the utricular signals elicit eye movements, whereas most of the saccular signals go to muscles that control our posture.

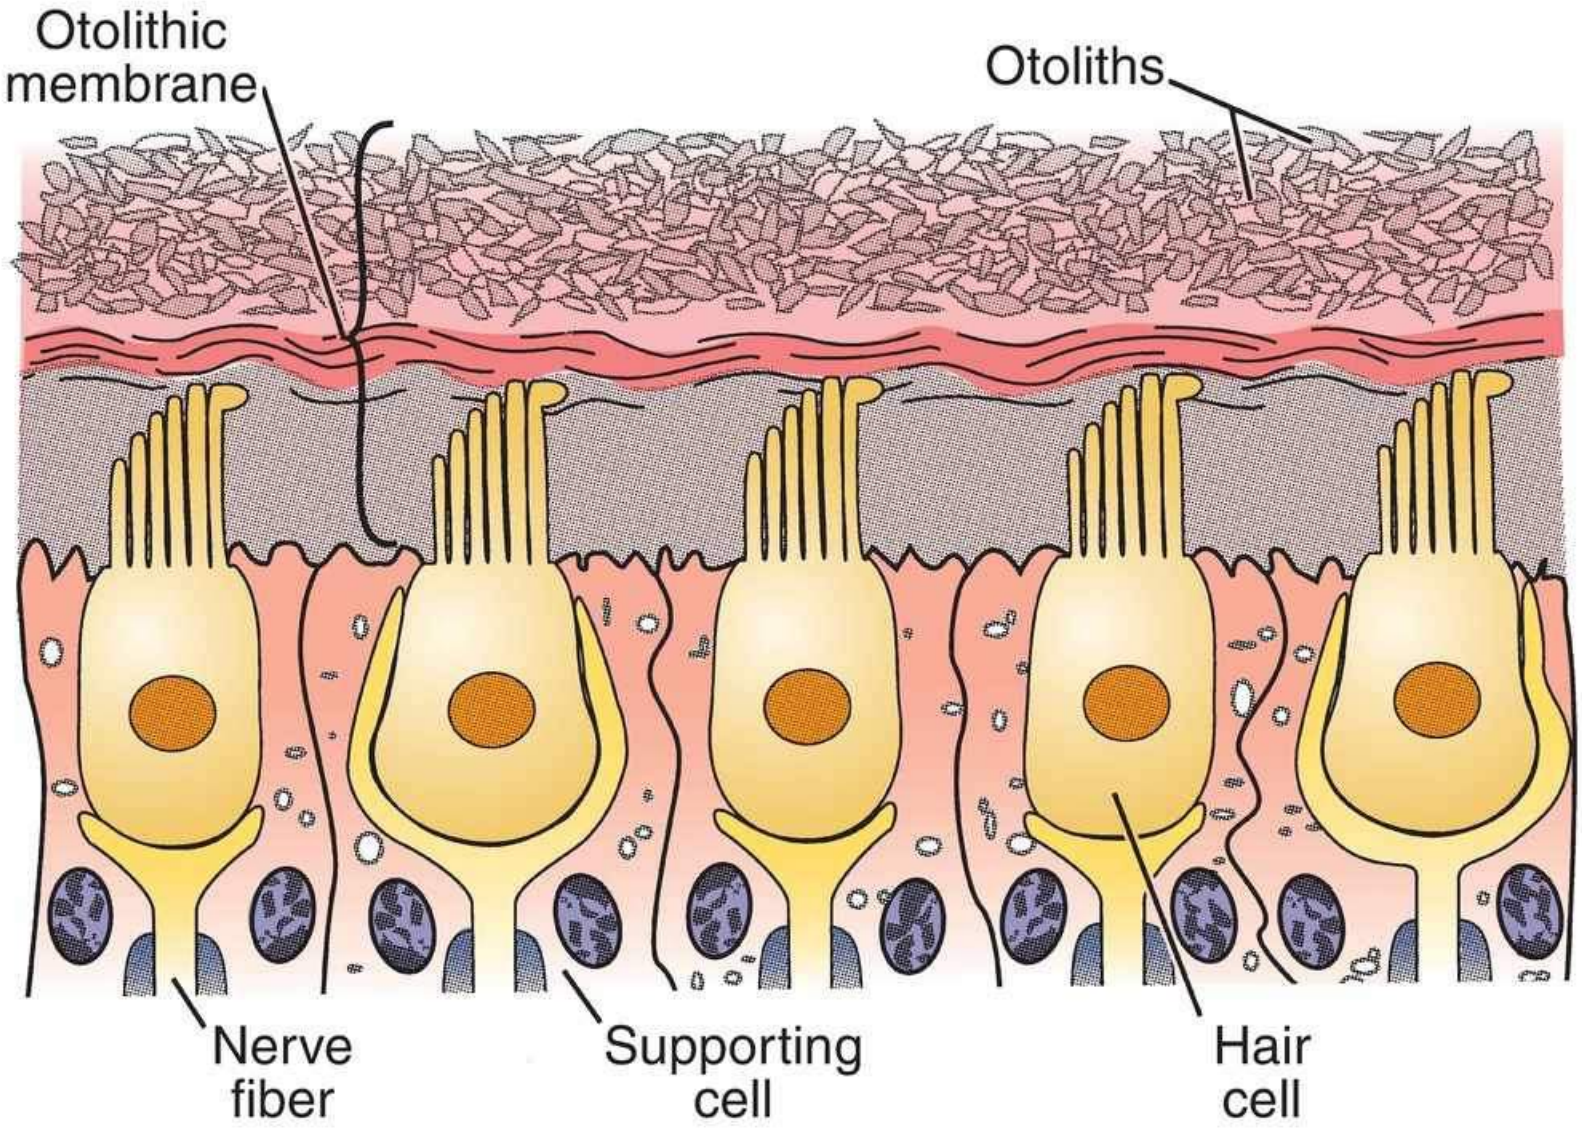

Figure 4.24 The relation of the otoliths to the sensory cells in the macula of the utricle and saccule. The gravity-driven movement of the otoliths stimulates the hair cells.

Vestibulo-ocular reflex

The **vestibulo-ocular reflex** (VOR) is a reflexive eye movement that stabilizes images on the retina during head movement (Fig. 4.25). This reflex produces an eye movement in the direction opposite to the head movement, thus preserving the image on the center of the visual field. The reflex is initiated when the rotation of the head is detected, which, in turn, triggers an inhibitory signal to the extraocular muscles on one side and an excitatory signal to the muscle on the other side. This reflex results in a compensatory movement of the eyes. The VOR has both rotational and translational inputs. When the head rotates about any axis (horizontal, vertical, or torsional), distant images are stabilized by rotating the eyes about the same axis, but in the opposite direction. Because slight head movements are happening all of the time, the

VOR is very important for stabilizing vision. Patients whose VOR is impaired find it extremely difficult to read, because they cannot stabilize the eyes during small head movements. The VOR is driven by signals from the vestibular apparatus in the inner ear. The semicircular canals detect head rotation and drive the rotational VOR. The otoliths detect head translation and drive the translational VOR.

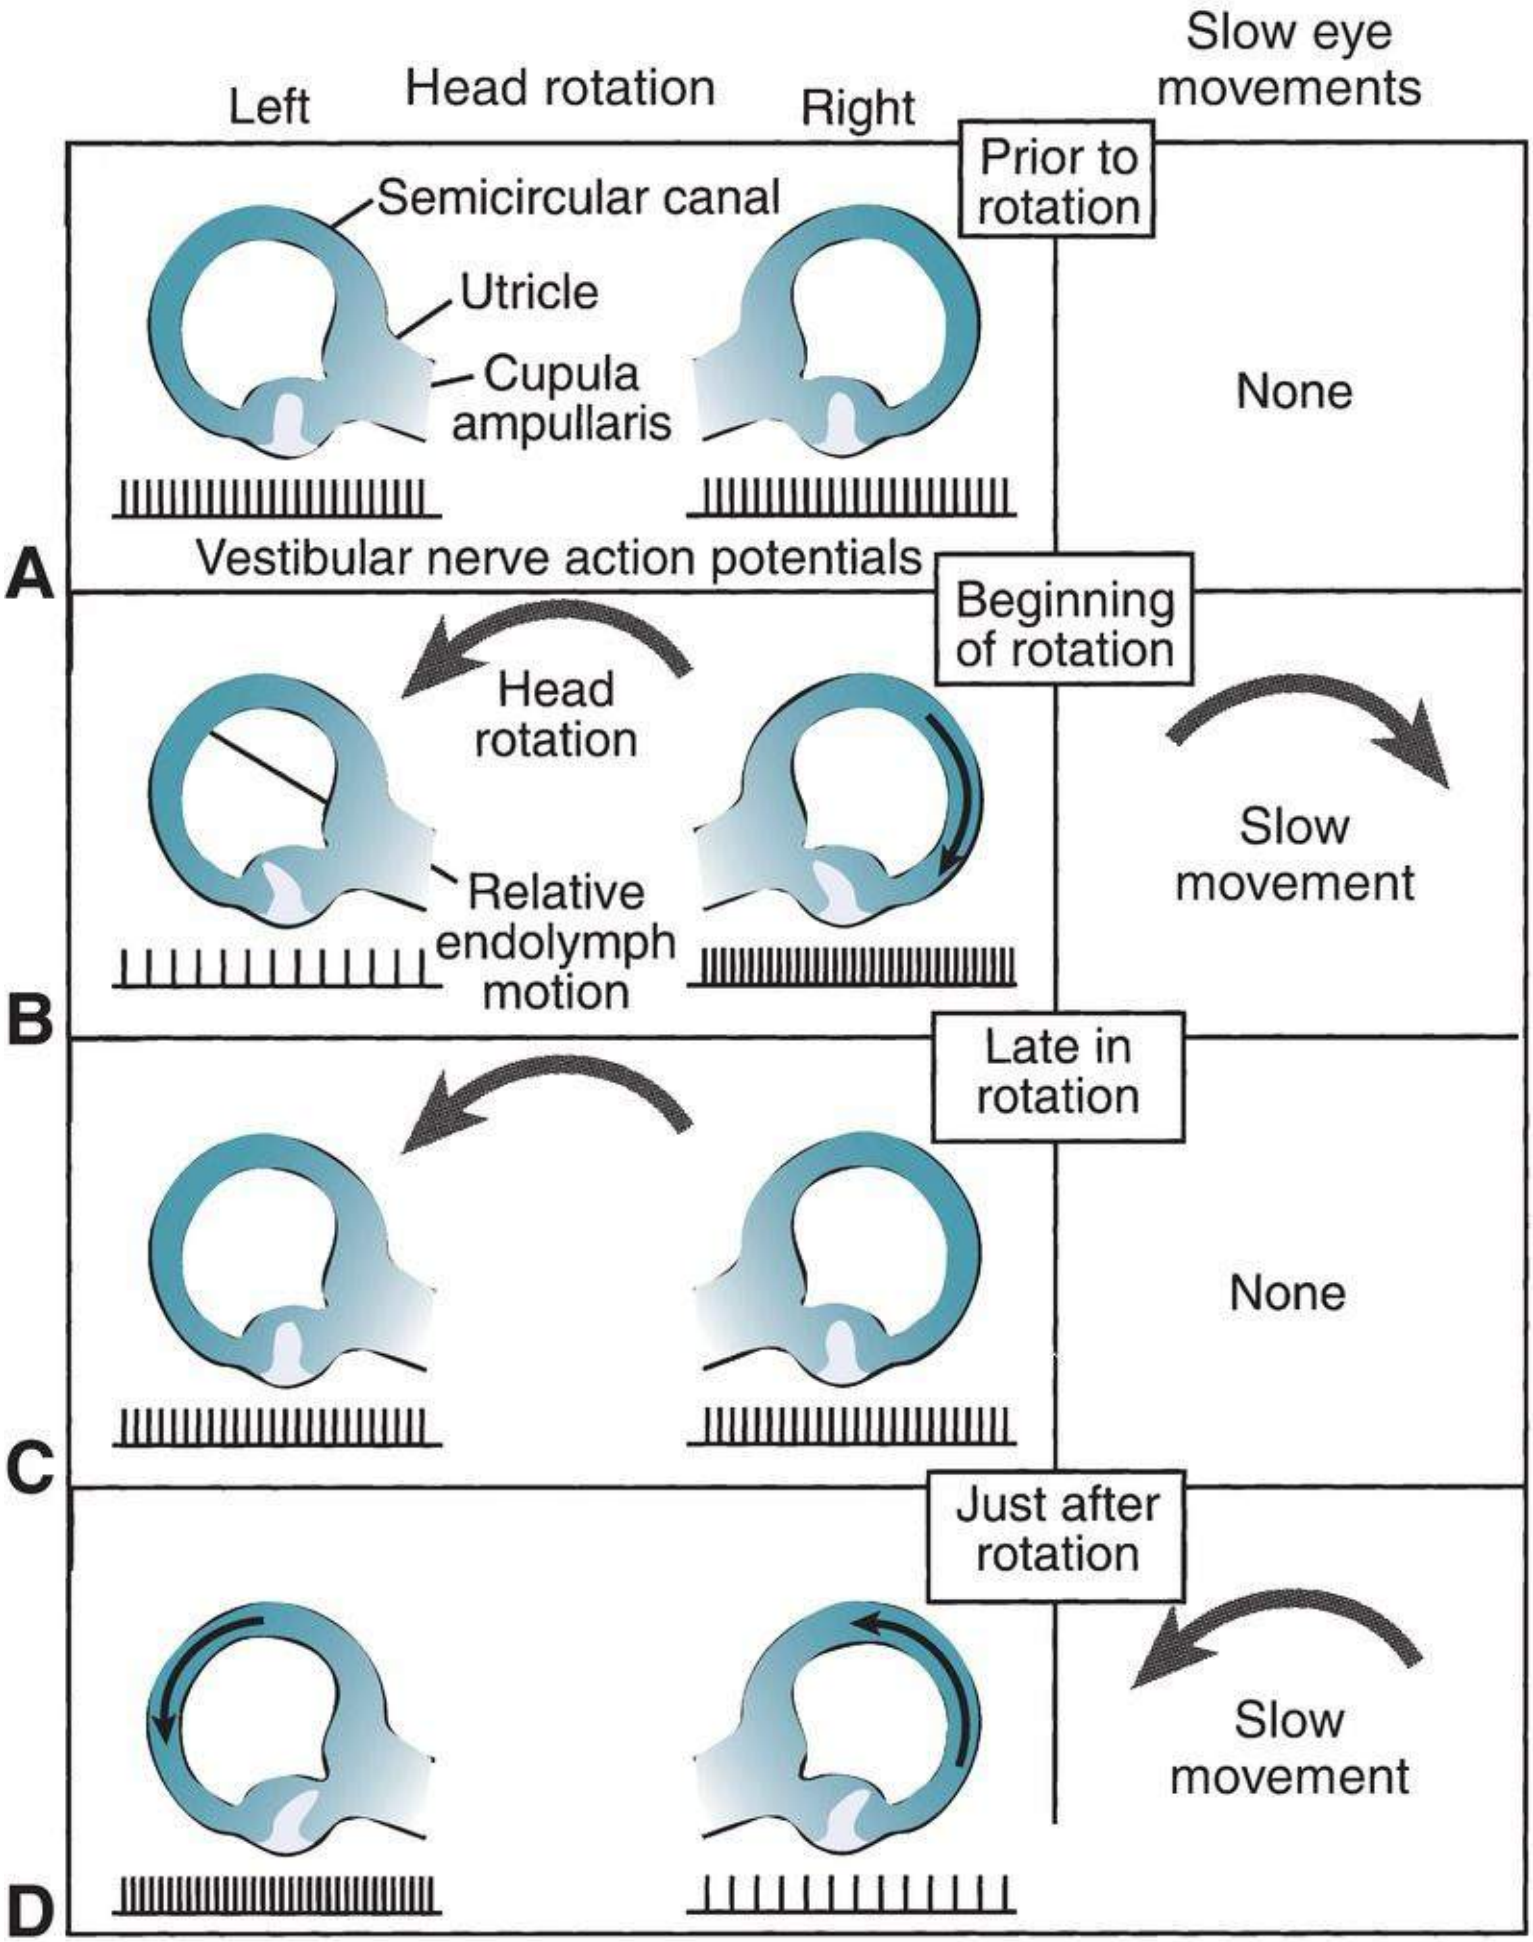

Figure 4.25 The role of the semicircular canals in sensing rotary acceleration. This sensation is linked to compensatory eye movements by the vestibulo-ocular reflex. Only the horizontal canals are considered

here. This pair of canals is shown as if one were looking down through the top of a head looking toward the top of the page. Within the ampulla of each canal is the cupula, an extension of the crista ampullaris, the structure that senses motion in the endolymph fluid in the canal. Below each canal is the action potential train recorded from the vestibular nerve. **(A)** The head is still, and equal nerve activity is seen on both sides. There are no associated eye movements (right column). **(B)** The head has begun to rotate to the left. The inertia of the endolymph causes it to lag behind the movement, producing a fluid current that stimulates the cupulae (*arrows* show the direction of the relative movements). Because the two canals are mirror images, the neural effects are opposite on each side (the cupulae are bent in relatively opposite directions). The reflex action causes the eyes to move slowly to the right, opposite to the direction of rotation (right column). They then snap back and begin the slow movement again as rotation continues. The fast movement is called *rotatory nystagmus*. **(C)** As rotation continues, the endolymph "catches up" with the canal because of fluid friction and viscosity, and there is no relative movement to deflect the cupulae. Equal neural output comes from both sides, and the eye movements cease. **(D)** When the rotation stops, the inertia of the endolymph causes a current in the same direction as the preceding rotation, and the cupulae are again deflected, this time in a manner opposite to that shown in **(B)**. The slow eye movements now occur in the same direction as the former rotation.

CLINICAL FOCUS 4.1

Cochlear Implants

Disorders of hearing are broadly divided into the following categories: conductive hearing loss, related to structures of the outer and middle ear; sensorineural hearing loss ("nerve deafness"), dealing with the mechanisms of the cochlea and peripheral nerves; and central hearing loss, concerning processes that lie in higher portions of the central nervous system. Damage to the cochlea, especially to the hair cells of the organ of Corti, produces sensorineural hearing loss by several means. Prolonged exposure to loud occupational or recreational noises can lead to hair cell damage, including mechanical disruption of the stereocilia. Such damage is localized along the basilar membrane at a position related to the pitch of the sound that produced it. Antibiotics such as streptomycin and certain diuretics can cause rapid and irreversible damage to hair cells similar to that caused by noise, but it occurs over a broad range of frequencies. Diseases such as meningitis, especially in children, can also lead to sensorineural hearing loss. In carefully selected patients, the use of a cochlear implant can restore some function to the profoundly deaf. The device consists of an external microphone, amplifier, and speech processor coupled by a plug-and-socket connection, magnetic induction, or a radiofrequency link to a receiver implanted under the skin over the mastoid bone. Stimulating wires then lead to the cochlea. A multielectrode intracochlear implant (with up to 22 active elements spaced along it) can be inserted into the basal turn of the scala tympani. The linear spatial arrangement of the electrodes takes advantage of the tonotopic organization of the cochlea, and some pitch (frequency) discrimination is possible. The external processor separates the speech signal into several frequency bands that contain the most critical speech information, and the multielectrode assembly presents the separated signals to the appropriate locations along the cochlea. In some devices, the signals are presented in rapid sequence, rather than simultaneously, to minimize interference between adjacent

areas.

When implanted successfully, such a device can restore much of the ability to understand speech. Considerable training of the patient and fine-tuning of the speech processor are necessary. The degree of restoration of function ranges from recognition of critical environmental sounds to the ability to converse over a telephone. Cochlear implants are most successful in adults who became deaf after having learned to speak and hear naturally. Success in children depends critically on their age and linguistic ability; currently, implants are approved for use in children as young as 12 months of age.

Infrequent problems with infection, device failure, and natural growth of the auditory structures may limit the usefulness of cochlear implants for some patients. In certain cases, psychologic and social considerations may discourage the advisability of using auditory prosthetic devices in general. From a technical standpoint, however, continual refinements in the design of implantable devices and the processing circuit are extending the range of subjects who may benefit from cochlear implants. Research directed at external stimulation of higher auditory structures may eventually lead to even more effective treatments of profound hearing loss. ■

Vestibular dysfunction may result in immobilization.

The vestibular system is exquisitely designed to maintain equilibrium. However, there are instances wherein the system malfunctions and patients become immobilized. One such condition is vertigo, which results in dizziness or spinning movement when the patient is stationary. Vertigo is often associated with nausea and vomiting as well as difficulties with standing or walking. If the otolithic organs are stimulated rhythmically, as by the motion of a ship or automobile, distressing symptoms of **motion sickness** (dizziness and nausea) may result. Over time, these symptoms diminish and disappear. The underlying mechanisms causing vertigo and motion sickness are as yet poorly understood.

CLINICAL FOCUS 4.2

Vertigo

A common medical complaint is dizziness. This symptom may be a result of several factors, such as cerebral ischemia (“feeling faint”), reactions to medication, disturbances in gait, or disturbances in the function of the vestibular apparatus and its central nervous system (CNS) connections. Such disturbances can produce the phenomenon of vertigo, which may be defined as the illusion of motion (usually rotation) when no motion is actually occurring. Vertigo is often accompanied by autonomic nervous system symptoms of nausea, vomiting, sweating, and pallor. The body uses three integrated systems to establish its place in space: the vestibular system, which senses position and rotation of the head; the visual system, which provides spatial information about the external environment; and the somatosensory system, which provides information from joint, skin, and muscle receptors about limb position. Several forms of vertigo can arise from disturbances in these systems. Physiologic vertigo can result when there is discordant input from the three systems. Seasickness results from the unaccustomed repetitive motion of a ship (sensed via the vestibular system). Rapidly changing visual fields can cause visually induced motion sickness, and space sickness is associated with multiple-input disturbances. Central positional vertigo can arise from lesions in cranial nerve VIII (as may be associated with multiple sclerosis or some tumors), vertebrovascular insufficiency (especially in older adults), or from the impingement of vascular loops on neural structures. It is commonly present with other CNS symptoms. Peripheral vertigo arises from disturbances in the vestibular apparatus itself. The problem may be either unilateral or bilateral. Causes include trauma, physical defects in the labyrinthine system, and pathologic syndromes such as Ménière disease. As in the cochlea, aging produces considerable hair cell loss in the cristae and maculae of the vestibular system. Rotational or caloric stimulation can be used as an indicator of the degree of vestibular function. The most common form of peripheral vertigo is benign paroxysmal positional vertigo (BPPV). This is a severe vertigo, with incidence increasing with age. Episodes appear rapidly and are limited in duration (from minutes to days). They are usually brought on by assuming a particular position of the head such as one might do when painting a ceiling. BPPV is thought to be a result of the presence of canaliths, debris in the lumen of one of the semicircular canals. The offending particles are usually clumps of otoconia (otoliths) that have been shed from the maculae of the saccule and utricle, whose passages are connected to the semicircular canals. These clumps act as gravity-driven pistons in the canals, and their movement causes the

endolymph to flow, producing the sensation of rotary motion. Because they are in the lowest position, the posterior canals are the most frequently affected. In addition to the rotating sensation, this input gives rise, via the vestibular system, to a pattern of nystagmus (eye movements) appropriate to the spurious input.

The specific site of the problem can be determined by using the *Dix–Hallpike maneuver*, which is a series of physical maneuvers (changes in head and body position). By observing the resulting pattern of nystagmus and reported symptoms, the location of the defect can be deduced. Another set of maneuvers known as the *canalith repositioning procedure of Epley* can cause gravity to collect the loose canaliths and deposit them away from the lumen of the semicircular canal. This procedure is highly effective in cases of true BPPV, with a cure rate of up to 85% on the first attempt and nearly 100% on a subsequent attempt. Patients can be taught to perform the procedure on themselves if the problem returns.

Ménière disease is a syndrome of uncertain (but peripheral) origin associated with vertigo. Its cause(s) and precipitating factors are not well understood. Typical associated findings include fluctuating hearing loss and tinnitus (ringing in the ears). Episodes involve increased fluid pressure in the labyrinthine system, and symptoms may decrease in response to salt restriction and diuretics. Other cases of peripheral vertigo may be caused by trauma (usually unilateral) or by toxins or drugs (such as some antibiotics); this type is often bilateral.

Central and peripheral vertigo often may be differentiated on the basis of their specific symptoms. Peripheral vertigo is more severe, and its nystagmus shows a delay (latency) in appearing after a position change. Its nystagmus fatigues and can be reduced by visual fixation. Position-sensitive and of finite duration, the condition usually involves a horizontal orientation. Central vertigo, usually less severe, shows a vertically oriented nystagmus without latency and fatigability; it is not suppressed by visual fixation and may be of long duration.

Treatment of vertigo, beyond that mentioned above, can involve bed rest and vestibular inhibiting drugs (such as some antihistamines). However, these treatments are not always effective and may delay the natural compensation that can be aided by physical motion such as walking (unpleasant as that may be). In severe cases that require surgical intervention (labyrinthectomy), patients can often achieve a workable position sense via the other sensory inputs involved in maintaining equilibrium. Some activities, such as underwater swimming, must be avoided by those with an impaired sense of orientation, because false cues may lead to moving in inappropriate directions and increase the risk of drowning. ■

GUSTATORY AND OLFACTORY SYSTEMS

Unlike the photoreceptors of the eye and the mechanoreceptors of the ear, the receptors of taste and smell are chemoreceptors. The sensation of taste and smell are two other sensory mechanisms that provide specific information about the external environment. In lower animals, the mechanisms of taste (gustation) and smell (olfaction) play a major role in finding food, seeking prey, finding directions, bonding with offspring and mates, and avoiding danger/predators. In the case of humans, most of these neural signals are associated with food, fragrance, and odors of our surrounding environment. Although our taste and smell are less sensitive than those of other species, millions of dollars are spent on additives to make our food taste better and on deodorants and perfumes to make us more desirable/attractive and sociable. Chemoreceptors are also found in areas of the body not normally associated with taste or smell. For example, cells expressing bitter taste receptors are found in the nose, airway, and digestive tract. When receptors in the nose are stimulated by irritants, protective reflexes like apnea, coughing, and sneezing are elicited to keep the irritant from entering the lungs.

Taste buds house the receptor cells for gustatory sensations.

Taste is important for determining whether food in the mouth is a dangerous substance or safe to consume. The receptors for taste are packaged primarily in **taste buds** that are distributed across the upper alimentary canal with the majority of human taste buds located in the oral cavity (~5,000). The largest numbers are located on the dorsal portion of the tongue with smaller populations found in the epithelium of the soft palate, upper esophagus, epiglottis, and upper larynx. Taste buds are onion-shaped structures containing 50 to 100 elongated cells. Taste receptor cells are modified epithelial cells that extend from the basal lamina to the epithelial surface where their apical microvilli extend into an opening in the epithelium, the **taste pore**, to sample chemical compounds that are dissolved in saliva (Fig. 4.26). Only food that is dissolved in saliva can attach to taste receptor cells and evoke a neural sensation of taste. Taste buds contain four different types of cells. Type I cells act like glial cells providing support and maintaining the extracellular environment within the taste bud. Type I cells do not make synaptic contact with afferent nerve fibers. Type II cells contain, in separate subpopulations, receptors for sweet, bitter, and umami. Although this cell type is in close apposition with numerous afferent fibers, they do not make traditional synaptic contacts with these fibers. Instead, these cells exhibit nonvesicular release of ATP that activates purinergic receptors on afferent nerve fibers and adjacent taste cells. Type III cells contain receptors for sour and form conventional synapses with afferent fibers. This cell type releases several transmitters that interact with sensory nerve endings and other cells in the taste bud. The fourth cell type, the basal cell, acts as a precursor cell able to differentiate into new taste cells. The sensory cells typically have a lifespan of 10 days. They are continually replenished by new sensory cells formed from the basal cells. When a sensory cell is replaced by a maturing basal cell, the old synaptic connections are broken, and new ones must be formed.

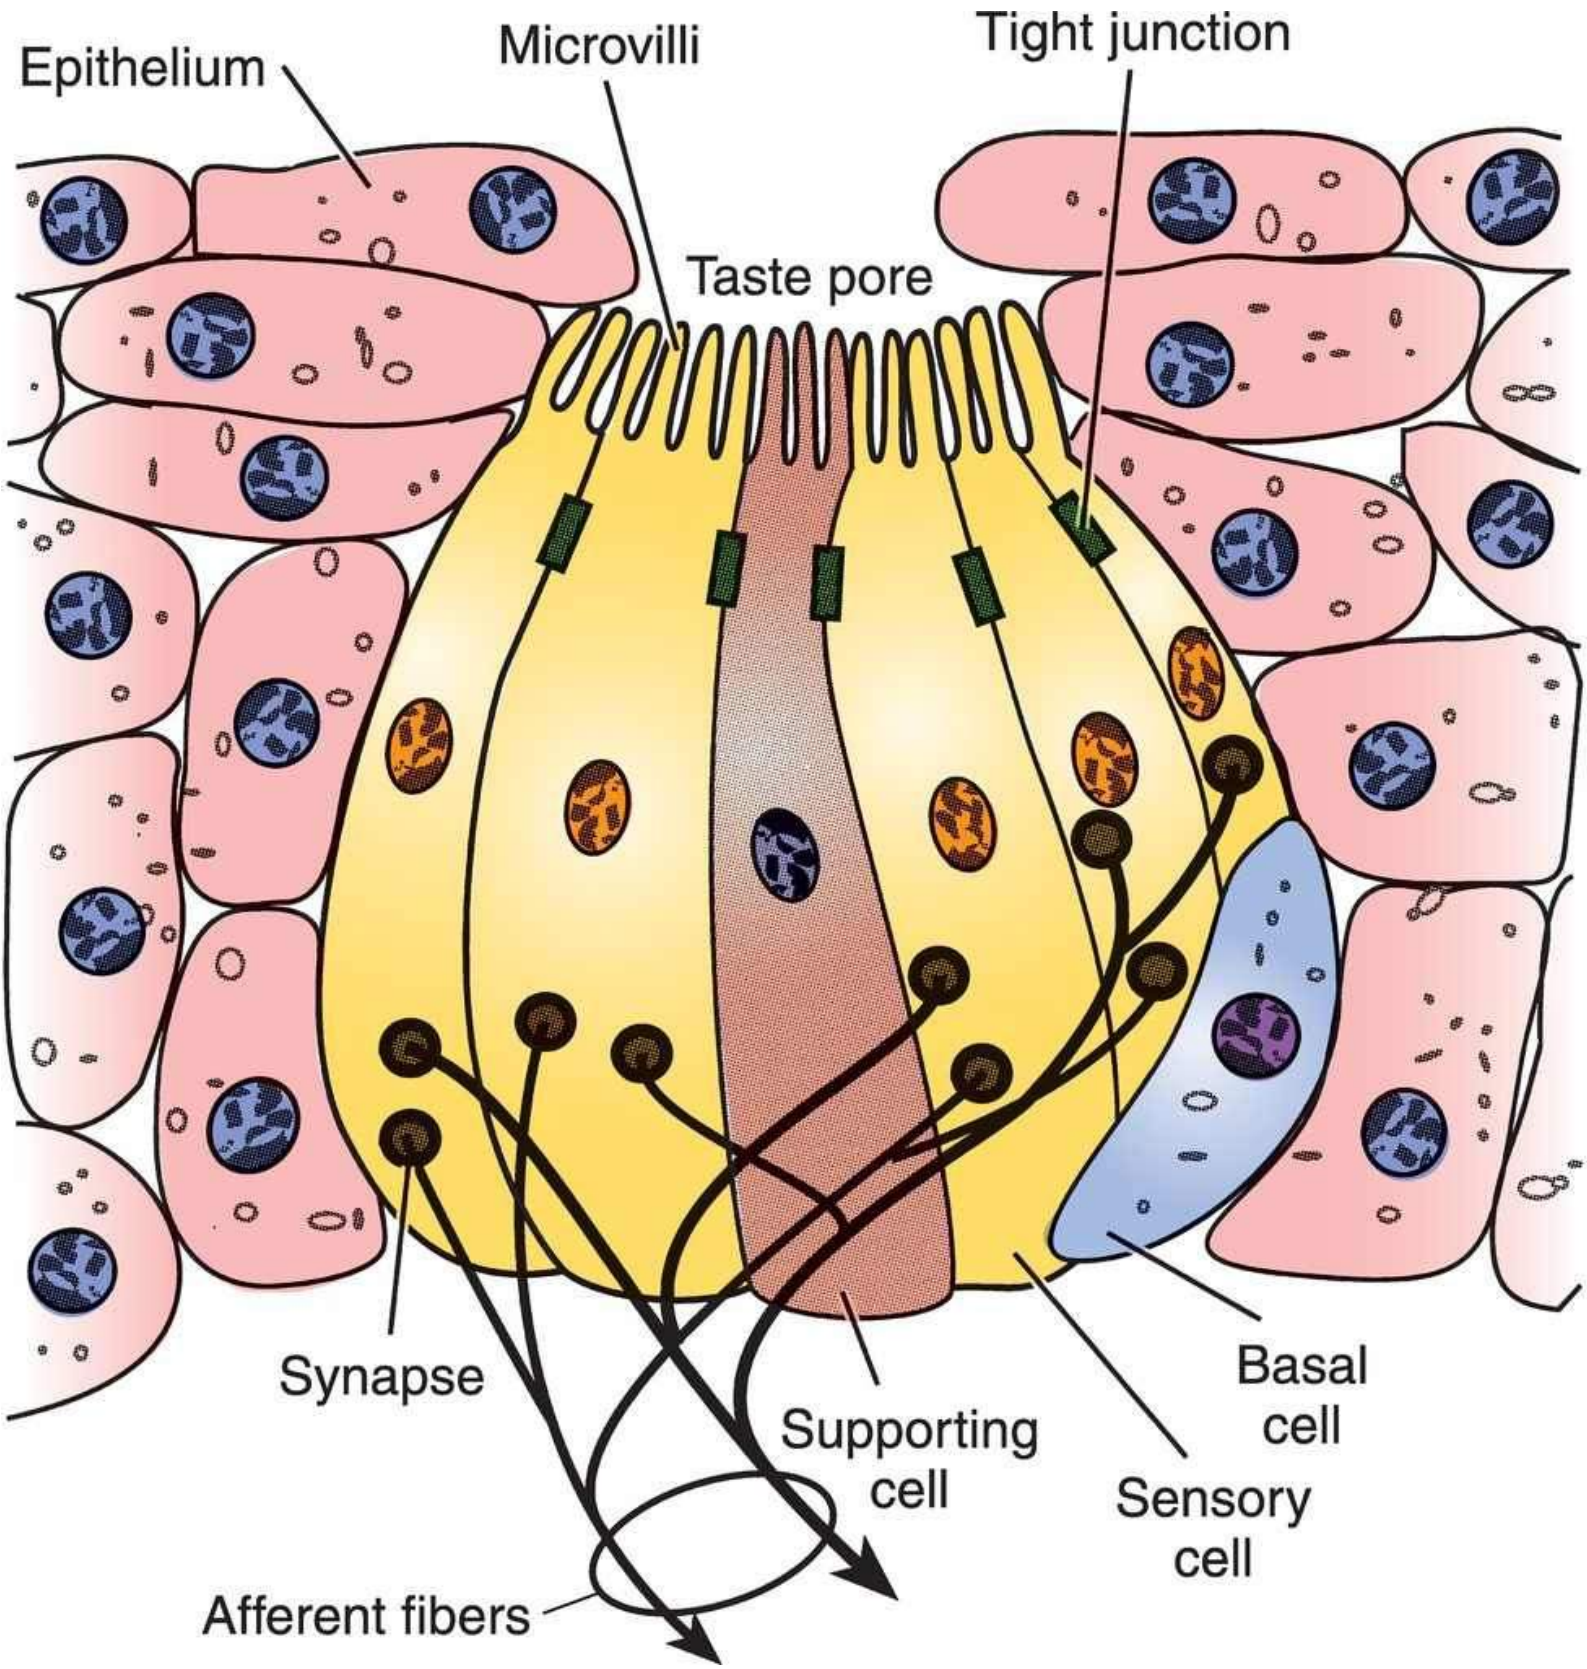

Figure 4.26 The sensory and supporting cells in a taste bud. Taste buds consist of taste cells surrounded by supporting epithelial cells and basal cells. The afferent nerve synapses with the basal areas of the sensory cells.

Stimulating the taste cells alters the cell's ion channels producing a depolarizing potential. Similar to other sensory receptors, a depolarizing potential leads to neurotransmitter release. The neurotransmitter, in turn, triggers action potentials in the afferent nerve fibers that are sent to the solitary nucleus in the brainstem via the seventh, ninth, and tenth cranial nerves. From the solitary nucleus, information is

distributed to cell groups that are involved in feeding and digestive-related functions like salivary and gastrointestinal secretions, and swallowing. Taste information is also relayed, via the thalamus, to cortical structures responsible for the appreciation of taste quality and intensity as well as to cortical areas where multisensory integration of taste, smell, tactile, and temperature cues occurs to produce the experience we call flavor.

Gustatory chemoreception distinguishes five primary taste categories.

Among thousands of different taste sensations, humans can discriminate between five specific tastes received by the gustatory receptors. These are salty, sweet, bitter, sour, and umami, which means “savory” or “meaty” in Japanese. There are also two “accessory qualities” of taste sensation, alkaline (soapy) and metallic. Recently, evidence has accumulated for another taste sensation—fatty. Scientists have identified several potential receptors for free fatty acids. These receptors are located on taste receptor cells and their activation results in an intracellular cascade similar to that observed following receptor activation by sweet, bitter, and umami compounds. Although the reception of different taste qualities has been traditionally represented as occupying specific parts of the tongue (i.e., the receptors for sweetness just behind the tip of the tongue, sour receptors predominately along the sides, salt at the tip, and bitter across the rear), this “tongue map” theory has been refuted. Rather, all areas respond to all five tastes, although there are differences in regional sensitivities to these tastes.

Gustatory transduction is mediated by multiple receptors and intracellular mechanisms.

Multiple receptors and intracellular mechanisms are responsible for converting the chemical compounds in food into the experience we call taste. Some mechanisms involve simple ion channels in the taste receptor membrane, while others activate intracellular second messenger cascades.

Salt receptors

Salt plays a critical role in ion and water homeostasis in animals, especially mammals. NaCl is especially important in the mammalian kidney as an osmotically active molecule that facilitates passive reuptake of water. Because of this, salt elicits a pleasant taste in most mammals, which potentially can lead to excess salt intake in the human diet. The simplest receptor found in the mouth is the NaCl receptor. Na^+ ions enter the taste cell directly through apical cation channels to depolarize the cell. This sodium channel is known as the epithelial sodium channel, or ENaC, and is composed of three subunits. The ENaC channel can be blocked by the drug amiloride in many mammals. However, the action of amiloride is much less pronounced on the salt receptors in humans leading to the speculation that there are additional membrane receptors or ion channels responsible for salt taste.

Sour receptors

Sour taste signals the presence of acidic foods (H^+ ions in solution). The citric taste of lemon is a good example of our experience with the distinctive sour taste. Sour taste can be mildly pleasant in small quantities and is linked to salt flavor. However, in larger quantities, it becomes more of an unpleasant taste. This is a protective mechanism and can signal an overripe fruit, rotten meat, or other spoiled foods that can be toxic to the body because of bacterial contamination. Also, sour taste signals acid (H^+ ions) to the brain, which can warn of serious tissue damage.

Although not completely understood, several mechanisms have been proposed for sour transduction. One mechanism is a simple proton channel that allows hydrogen ions to flow directly into the receptor cell to acidify the cytosol, while another mechanism is the simple diffusion of acids through the plasma membrane into the cell where they dissociate to acidify the cytosol. The acidification of the cytosol opens proton-sensitive sodium channels, the influx of sodium ions producing membrane depolarization, the opening of a voltage-gated Ca^+ channels, and the release of neurotransmitters from the receptor cell.

Receptors for bitter, sweet, and umami

Two families of taste **G protein–coupled receptors** (GPCR) have been identified, type 1 and type 2 taste receptors (T1R and T2R). The T1R family mediates sweet and umami taste, while the T2R mediates bitter taste.

The bitter taste is almost completely unpleasant in humans. This is because many nitrogenous organic compounds that have a pharmacologic effect on humans taste bitter. These include caffeine, the stimulant in coffee, and nicotine, the addictive compound in cigarettes. Almost all poisonous/toxic plants taste bitter; the bitter taste is a protective mechanism, and the reaction is a last-line warning system before the compound is swallowed to cause injury or death. However, humans have evolved a very sophisticated sense for bitter substances and can distinguish between many different compounds. As a result, they have overcome their innate aversion to certain bitter tastes, as evidenced by the wide consumption of

caffeinated drinks enjoyed around the world.

Cells that detect bitter flavors have a large number of receptors, each of which responds to a different bitter flavor. This mechanism allows for many different classes of bitter compounds, which can be chemically very different, to be detected. TheT2R bitter taste receptors are GPCRs that are coupled to the G-protein **gustducin**, a G-protein similar to the visual G-protein, transducin. When a bitter compound binds to a T2R, gustducin is released. Gustducin activates phospholipase C, which stimulates the synthesis of 1,4,5-inositol triphosphate (IP_3) leading to Ca^{2+} release from intracellular stores. The increased intracellular calcium activates monovalent cation channels leading to membrane depolarization, opening of ATP permeable membrane channels and ATP release into the synaptic cleft. ATP in turn activates the afferent nerve endings in the taste bud.

Sweet taste signals the presence of readily usable food. Humans have evolved to seek out the highest caloric intake, because our ancient ancestors were not always sure when the next meal would be available. Carbohydrates have a very high caloric count (therefore, much energy) and, as a result, have been sought out by humans throughout history. Unfortunately, this evolutionary pattern has led to a craving of sweets. Carbohydrates are used as direct energy (sugars) and as stored energy (glycogen).

Like bitter taste T2Rs, the T1Rs for sweet taste transduction involve GPCRs. Three different T1Rs have been identified, T1R1, T1R2, and T1R3. The receptor for sweet compounds is the heterodimer T1R2 + T1R3. Binding of natural sugars, such as cane sugar, to this receptor, activates the GPCR and produces ATP release in manner similar to that described for bitter receptors. Artificial sweeteners, including saccharin, sucralose, and aspartame produce the experience of sweet by binding to the same sweet receptor, but at different binding domains

The umami taste signals the presence of meat, thus encouraging the intake of peptides and proteins. The signal is triggered by amino acids (specifically glutamine), which are used to build such things as muscle, organs, transport molecules (e.g., hemoglobin), and cellular enzymes. Amino acids are critical for the human body to function; therefore, it is important to have a steady supply. Hence, the umami taste signals a pleasurable response to a desirable, nutritionally rich source of protein. The umami receptor is a T1R1 + T1R3 heterodimer GPCR. Glutamate binds to the GPCR and activates the same second-messenger pathways used for transduction of bitter and sweet compounds. Umami receptors also respond to monosodium glutamate (commonly known as *MSG*), which is used as a food additive and is very popular in Asia, especially Japanese dishes.

Taste information is relayed to the brainstem by cranial nerves VII, IX, and X.

These nerves terminate in the solitary nucleus, a nucleus that also processes visceral sensory information and is in involved in visceral-related functions. From the solitary nucleus, information is relayed to cell groups that are involved in feeding and digestive-related functions like salivary and gastrointestinal secretions and swallowing. Taste information is also relayed, via the thalamus, to cortical structures responsible for the appreciation of taste quality and intensity as well as to cortical areas where multisensory integration of taste, smell, tactile, and temperature cues occurs to produce the experience we call flavor.

Olfactory apparatus serves the sense of smell.

The olfactory system has a much broader function than does the gustatory system. It not only participates in the selection and enjoyment of food but also is involved in detecting smell from the surrounding environment (e.g., fragrance of flowers, other people, and dangerous odors that can be harmful to the body). Olfaction compliments the gustatory system and is especially important for the appreciation of flavor. For example, savoring the aroma of a glass of red wine often surpasses the gustatory system. Many patients who complain about the loss of taste often have an olfactory disorder.

Humans, compared with some mammals, have a relative poor sense of smell. However, the human olfactory system is still quite extraordinary insofar as the nose contains >5 million olfactory receptors that can differentiate thousands of different odorants, even some that differ by a single molecular component. The olfactory system detects odorants that are inhaled through the nose, where they contact the olfactory epithelium, which contains various olfactory receptors. The receptor organ for olfaction, the olfactory epithelium, is located in the roof of the nasal cavity. Normally, there is little airflow in this region of the nasal tract, but sniffing serves to direct air upward, increasing the likelihood of an odor being detected. Another route that volatile compounds in food can reach the olfactory epithelium is retronasally from the oral cavity. In contrast to the taste sensory cells, the olfactory receptor cells are bipolar neurons and, as such, are *primary receptors*. These cells are interspersed among supporting cells that bind the cells together at their sensory ends and basal cells (Fig. 4.27). Like taste receptor cells, olfactory receptor neurons continuously turnover with new receptor cells arising from basal cells. The epithelium is covered by a watery mucus through which odors diffuse to reach the olfactory receptors that are located on the cilia of the olfactory receptor neurons. Rather than binding specific ligands like most receptors, olfactory receptors have a binding affinity for a range of odorant molecules. This allows the olfactory system to discriminate among a wide range of different odor molecules. Olfactory thresholds vary widely from substance to substance; the threshold concentration for the detection of ethyl ether (used as a general anesthetic) is around 5.8 mg/L air, whereas that for methyl mercaptan (the odor of garlic) is ~0.5 ng/L. This represents a 10 million–fold difference in sensitivity.

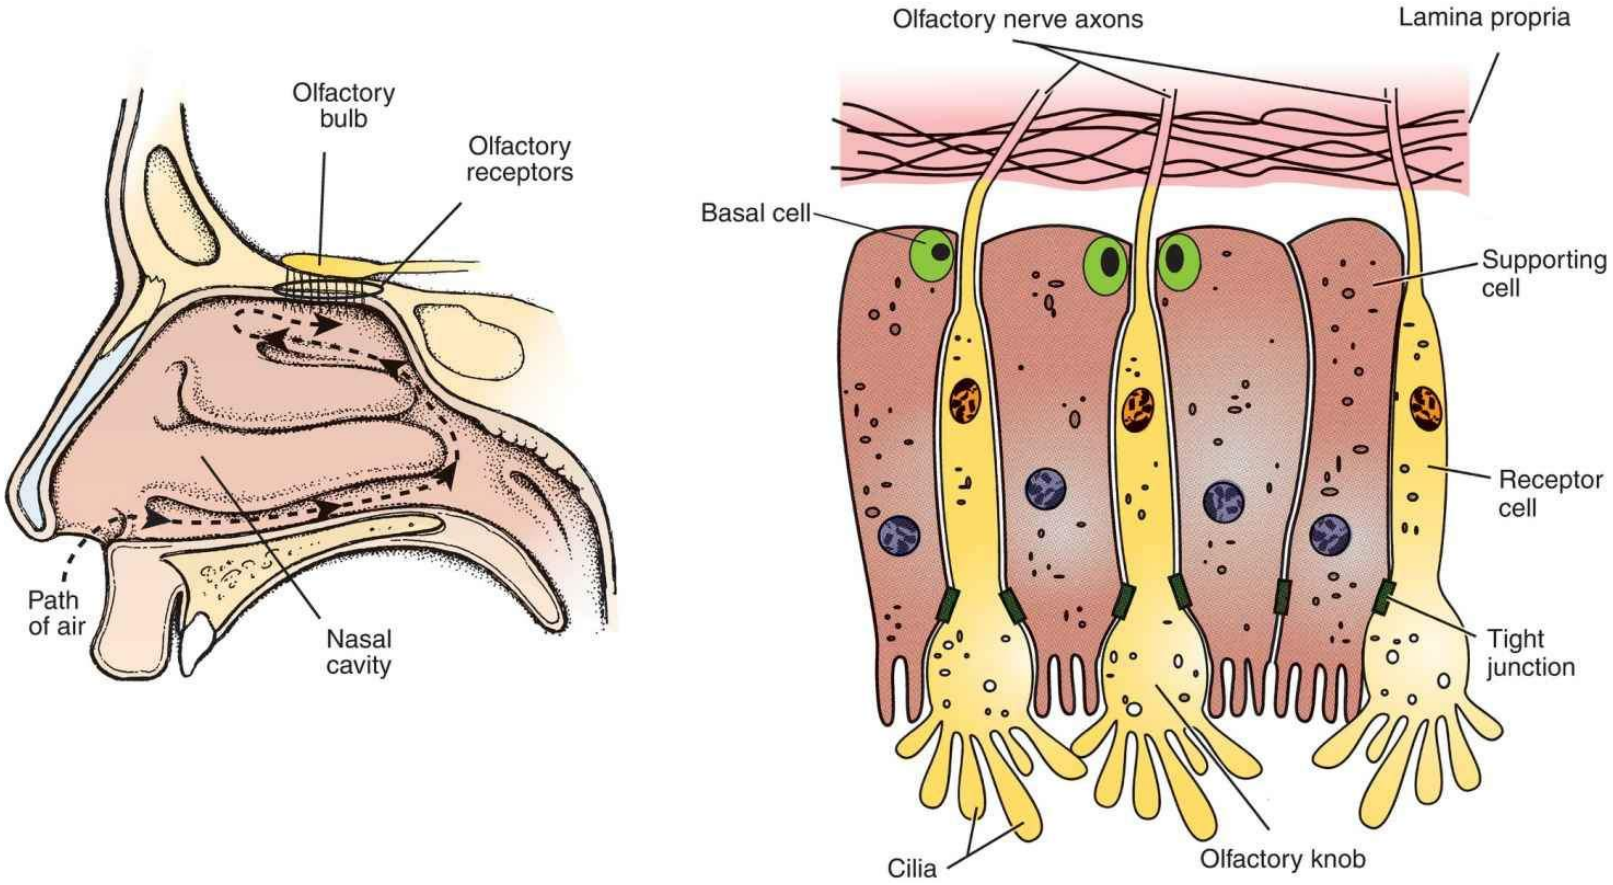

Figure 4.27 The sensory cells in the olfactory mucosa. The olfactory filia, bundles of axons forming the olfactory nerve, represent axons of olfactory receptor cells that terminate in the olfactory bulb.

The detection of an odor occurs when an odor diffuses into the mucus overlying the receptors and is transported to the receptors on the olfactory receptor dendrites by odorant binding proteins. The odors bind to olfactory receptors, which are GPCRs. This binding causes the production of cAMP, which binds to, and opens, cyclic nucleotide gated ion channels in the ciliary membrane allowing sodium and calcium ions to enter the cell. This inward flow depolarizes the olfactory receptor cell to produce a generator potential, which in turn causes action potentials in the afferent fiber. The frequency of the action potentials is dependent on the concentration of the odorant. The action potentials in the axons of the olfactory receptor neurons travel along the olfactory nerves (afferent nerves) through small foramina in the bony cribriform plate above the nose to terminate in the **olfactory bulbs** located at the base of the forebrain. The transiting of the very thin olfactory axons through the cribriform plate makes this region particularly sensitive to traumatic injury that severs the olfactory receptor neuron axons leading to olfactory loss. The olfactory bulbs serve as a relay station that transmits information from the nose to other brain areas and consist of a complex multilayer neural architecture. As they enter the olfactory bulb, the olfactory nerve axon terminals cluster in a ball-like neural junction known as the *olfactory glomeruli*. Complex processing of odor information occurs within the glomerulus with each glomerulus receiving input primarily from olfactory receptor neurons that express similar olfactory receptors. Thus, the glomeruli serve to categorize the sense of smell. Glomeruli are also permeated by dendrites from neurons termed *mitral and tufted cells*, which, in turn, relay information to the olfactory cortex located at the base of the temporal lobe. The primary olfactory cortex further processes olfactory information to determine odor quality and familiarity and is associated with the learning and remembering of odors. Projections from primary olfactory cortex converge on forebrain association cortices associated with the processing of flavor as well limbic areas associated with emotions and memory, which may explain the close association of odors with these functions.

Sneezing

The olfactory mucosa also contains receptors and sensory fibers sensitive to irritants and certain odorous substances, such as peppermint and chlorine, that play a role in the initiation of reflex responses (e.g., sneezing) that result from irritation of the nasal tract. Sneezing typically occurs when an irritant passes through the nasal hairs to reach the nasal mucosa. This triggers the release of histamine, which, in turn, irritates the nerve cells in the nose, resulting in an electrical signal being sent to the brain via the trigeminal nerve to initiate the sneeze reflex. The brain then activates the pharyngeal, tracheal, and chest muscles to expel a large volume of air from the lungs through the nose and mouth. Sneezing is also triggered by sinus infection and allergies.

INTEGRATED MEDICAL SCIENCES

Age-Related Macular Degeneration

The leading cause of impaired vision in older adults is a condition known as age-related macular degeneration (AMD). Approximately 30% of persons older than 75 years have some form of this condition, which leads to decreased sharpness of central vision, especially in bright light. It is a progressive condition whose causes are obscure and for which no cure is available. Despite this, a number of current and emerging treatments can slow the progress of the disease and provide some improvement in function.

Approximately 10% to 15% of AMD cases are of the *exudative*, or "wet" type. It arises from a proliferation of blood vessels in the choroid layer of the retina behind the macula lutea. The macula lutea, which includes the fovea, is a small area of densely packed photoreceptor cells directly at the fixation point of straight-ahead vision. This area is responsible for our sharpest vision, and its mechanical disruption by the proliferating blood vessels leads to distortion of vision and progressive loss of photoreceptors. The process does not affect areas of the retina peripheral to the macula, so some peripheral vision is preserved. The remaining AMD cases are of the "dry" type, with changes in the retinal pigment epithelium and "drusen" (see below). This latter form poses less immediate threat to vision, and high levels of zinc and antioxidants can slow its progress.

The retina of an affected eye is characterized by the presence of drusen, which are localized deposits of cellular debris whose accumulation further distorts the shape of the retina. An important diagnostic tool, and one used by patients to follow the course of the disease, is the *Amsler grid*, a grid of black lines forming a horizontal and vertical meshwork. The lines, when observed by one eye at a time, will appear "wavy" when the retina is distorted. Thus, the patient may detect sudden changes in visual acuity and seek therapy.

The causes of the condition are still obscure. There is a strong suggestion of a hereditary predisposition, and it is most common among white persons from North America and Europe. The primary biologic agent associated with the process of choroidal neovascularization is a molecule known as vascular endothelial growth factor (VEGF). This factor is responsible for the growth of blood vessels (angiogenesis) at many sites in the body. Some evidence also implicates an inflammatory process as an etiologic factor. The disease is also associated with cardiovascular illness and the risk factors that it entails. Smoking also is an aggravating factor. Although there are no

natural animal models for a human-like AMD, several transgenic mouse models can duplicate features of the disease and are being used in its study. It has recently been found that mice with a congenital lack of photoreceptors can be made sensitive to light by the retinal implantation of stem cell–derived embryonic photoreceptor (rod) cells. This appears to be a promising avenue for eventual treatments of a number of types of blindness including AMD.

For the early stages of AMD, there is little specific treatment available. Some help has been obtained by dietary supplementation with high-dose antioxidant vitamins (such as C, E, and β carotene) and zinc. Lutein may provide some benefit, and the effects of corticosteroids are being investigated. For advanced wet AMD, there are several avenues of therapy, and others are being developed. One of the first such approaches was *laser coagulation* of the invading blood vessels. This is a thermal process, and it damages the overlying retinal tissue, producing blind spots. This limits its use to areas outside the macula. A more recent technique is *verteporfin photodynamic laser treatment*; in this method, a dye is injected into the retinal circulation. When a low-intensity laser pulse activates it, the dye releases free radicals that cause occlusion in the target vessel without damage to the retina. Because of the role of VEGF in the neovascularization process, use of an isoform-specific VEGF inhibitor called *pegaptanib sodium* has achieved some success. This drug is well tolerated, and its effectiveness has been established. However, it must be delivered by a long series of intraocular injections. The U.S. Food and Drug Administration has recently approved the drug *ranibizumab*, which is a recombinant humanized monoclonal antibody fragment that targets all of the isoforms of VEGF. In patients with the wet form of AMD, this drug (trade name Lucentis) has been shown to improve vision. Finally, a surgical approach involves the implantation of a miniature telescope in the anterior chamber of the eye in the place of the biologic lens. This optical system spreads the light usually delivered to the fovea (5° of the visual field) to a much larger and usually undamaged surface of the more peripheral retina (a 55° field). Such a device, medically suited to only a subgroup of AMD patients, requires relearning of the visual process but can significantly increase the amount of useful vision.

AMD is a serious detriment to the quality of life in older persons and to those who care for them. Current research is aimed at a better understanding of the cause and progression of the disease and at finding specific therapies that are both effective and practical to apply. ■

Chapter Summary

- Sensory transduction takes place in a series of steps, starting with stimuli from the external or internal environment and ending with neural processing in the central nervous system.
- The structure of sensory organs optimizes their response to the preferred types of stimuli.
- A stimulus gives rise to a generator potential, which, in turn, causes action potentials to be produced in the associated sensory nerve.
- The speeds of adaptation of particular sensory receptors are related to their biologic roles.
- Specific sensory receptors for a variety of types of tactile stimulation are located in the skin.
- Somatic pain is associated with the body surface and the musculature; visceral pain is associated with the internal organs.
- The sensory function of the eyeball is determined by structures that form and adjust images and by structures that transform images into neural signals.
- The retina contains a number of layers and several cell types, each with a specific role in the process of visual transduction.
- The rod cells in the retina have a high sensitivity to light but produce less distinct images without color, whereas the cones provide sharp color vision with less sensitivity to light.
- The visual transduction process requires many steps, beginning with the absorption of light and ending with an electrical response.
- The outer ear receives sound waves and passes them to the middle ear. They are transmitted by the bones of the middle ear and passed to the inner ear, where the process of sound transduction takes place.
- The transmission of sound through the middle ear greatly increases the efficiency of its detection, whereas its protective mechanisms guard the inner ear from damage caused by extremely loud sounds. Disturbances in this transmission process can lead to hearing impairments.
- Sound vibrations enter the cochlea through the oval window and travel along the basilar membrane, where their energy is transformed into neural signals in the organ of Corti.
- Displacements of the basilar membrane cause deformation of the hair cells, the ultimate transducers of sound. Different sites along the basilar membrane are sensitive to different frequencies.
- The vestibular apparatus senses the position of the head and its movements by detecting small deflections of its sensory structures.
- Taste is mediated by sensory epithelial cells in the taste buds. There are five fundamental taste sensations: sweet, sour, salty, bitter, and umami. Several receptors and mechanisms are responsible for taste transduction.
- Smell is detected by nerve cells in the olfactory mucosa. Thousands of different odors can be detected and distinguished.

Chapter Review Questions

1. While recording the responses of a mechanoreceptor to stimulation of the skin, an investigator observes an increase in the number of action potentials. This increase usually signifies

A. increased intensity of a stimulus.
B. cessation of a stimulus.
C. adaptation of the receptor.
D. a constant and maintained stimulus.
E. an increase in the action potential conduction velocity.

The correct answer is A. Receptors code an increase in stimulus intensity by an increase in action potential frequency. A larger stimulus produces a larger depolarization of the receptor membrane (i.e., a larger generator potential), which in turn is translated into a larger number of action potentials at impulse initiation region of the receptor. Cessation of a stimulus would produce a rapid decrease in action potential frequency, and adaptation of the receptor would also decrease action potential frequency. A constant and maintained stimulus would result in a steady response or a decrease due to adaptation. The action potential velocity is determined by the membrane properties of the nerve and would not be affected.

2. The transduction of sweet compounds is the result of:

A. receptor cell intracellular osmotic changes caused by diffusion of sweet molecules into the taste pore.
B. binding of sweet compounds to sweet specific ion channels in the apical membranes of taste receptor cells.
C. sweet compounds binding to T1R G-protein–coupled receptors in the apical membranes of taste receptor cells.
D. sweet molecules binding to T2R G-protein–coupled receptors in the basolateral membrane of taste receptor cells.
E. sweet molecules entering the taste receptor cell through sweet channels in the apical membranes of taste receptor cells.

The correct answer is C. Sweet compounds bind to the T1R family of GPCRs taste receptors that are located on the microvilli of taste bud cells. Diffusion of sweet taste compounds into the mucus-filled taste pore is necessary for sweet taste transduction, but it does not produce significant osmotic changes inside the taste receptor cells. Sweet receptors are not coupled directly to ion channels. The T2R family of taste receptors are responsible for the transduction of bitter compounds and they are located on the microvilli. There are no sweet membrane channels in taste cells, but the entry of H^+ ions through membrane proton channels is a mechanism for sour taste transduction.

3. As a person enters middle age, reading text at distances less than arm's length becomes more difficult. This difficulty is most likely due to:

A. Age-related loss of in the transparency of the lens
B. Age-related distortion of the cornea
C. Age-related loss of receptor cells in the foveal region of the retina
D. Age-related shortening of the eyeball
E. Age-related changes in the elasticity of the lens

The correct answer is E. The person is suffering from presbyopia, the age-related inability to focus on close objects. Due to age-related changes in the elasticity of the lens the ability to accommodate

decreases and the lens shape cannot be sufficiently curved so the near object is focused behind the retina. A loss of lens transparency (cataracts), corneal distortion (astigmatism) or receptor cells in the region of the fovea (age-related macular degeneration) would impair both near and far vision. As a person ages only minor changes occur in the shape of the eyeball.

4. Due to long-term exposure to a loud noise, the hair cells on the basilar membrane in the inner ear were damaged. The site of the damage was in the region of the basilar membrane nearest to the oval window. The damage will result in:

A. diminished sensitivity to all frequencies of sound
B. loss of hearing of high frequencies
C. loss of hearing of low frequencies
D. an exaggerated sensitivity to loud sounds
E. complete deafness in the affected ear

The correct answer is B. The basilar membrane contains a tonotopic map with high frequencies represented at the base of the basilar membrane near the oval window and low frequencies represented at its apex near the helicotrema. Long-term exposure to excessive noise at a particular frequency results in damage to the area of the basilar membrane responsible for coding that frequency.

5. On a moonlit night, human vision is monochromatic and less acute than vision during daytime. This is because:

A. objects are being illuminated by monochromatic light and there is no opportunity for color to be produced.
B. the cone cells of the retina, while more closely packed than rod cell, have lower sensitivity to light of all colors.
C. light rays of low intensity do not carry information as to color.
D. retinal photoreceptor cells that have become dark adapted can no longer respond to carrying wavelengths of light.
E. at low light levels, the lens cannot accommodate to sharpen vision.

Correct answer is B. The cone cells are responsible for color vision and are densely packed in the centrally located fovea, the region of the retina where the image is most focused. However, cone cells cease to function if light levels are too low. In such cases, the single-pigment rod cells that have greater sensitivity, but are located farther away from the fovea and show greater convergence, provide monochromatic but more diffuse vision. The color composition of light does not depend on its intensity, and dark adaptation does not change the spectral sensitivity of the receptors. While focusing mechanisms may be less effective with low light, they still function.

Clinical Application Exercises 4.1

A 43-year-old business executive who recently returned from a flight overseas complains that he had difficulty “popping” his ears as the plane descend and that he experienced significant pain during the episode. After landing, the pain gradually disappeared, but sounds are muffled and he has a sensation of fullness in the ears. His attempts to pop his ears continue to be unsuccessful. Otoscopic examination of his ears reveals tight and slightly distended eardrums with effusion, but no signs of infection, and the patient’s temperature is normal. The patient had a difficult time hearing a finger snap adjacent to either ear. In a Rinne test bone conduction was superior to air conduction in both ears.

1. What does the tight distended ear drum and effusion in this patient suggest?

2. Why did the patient experience a reduction in his ability to hear?
3. What does the inability to “pop” the ears suggest?

ANSWERS

1. The tight distended eardrum suggests that there is an increase in pressure within the middle ear, perhaps due in part to his inability to equalize the external and middle ear pressures (“the pop” during the plane’s descent). The effusion suggests an accumulation of fluid in the normally air-filled cavity is also contributing to the increased pressure.
2. The patient decreased ability to hear a sound reflects a conductive hearing loss that is a result of increased pressure in the middle ear cavity. The increased pressure results in a less flexible tympanic membrane and consequently less energy is transmitted to the ossicles in response to an incoming sound. The increased pressure and fluid can also interfere with the movement of the ossicles further reducing energy transfer through the middle ear. The Rinne test is a relatively simple test that can quickly screen for the presence of conductive hearing loss.
3. The inability to “pop,” or equalize the pressure between the outer and middle ear, indicates that the eustachian tube is blocked. The eustachian tube interconnects the middle ear cavity and the pharynx and is the route by which pressures in the outer and middle ear are equalized.

5 Motor System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

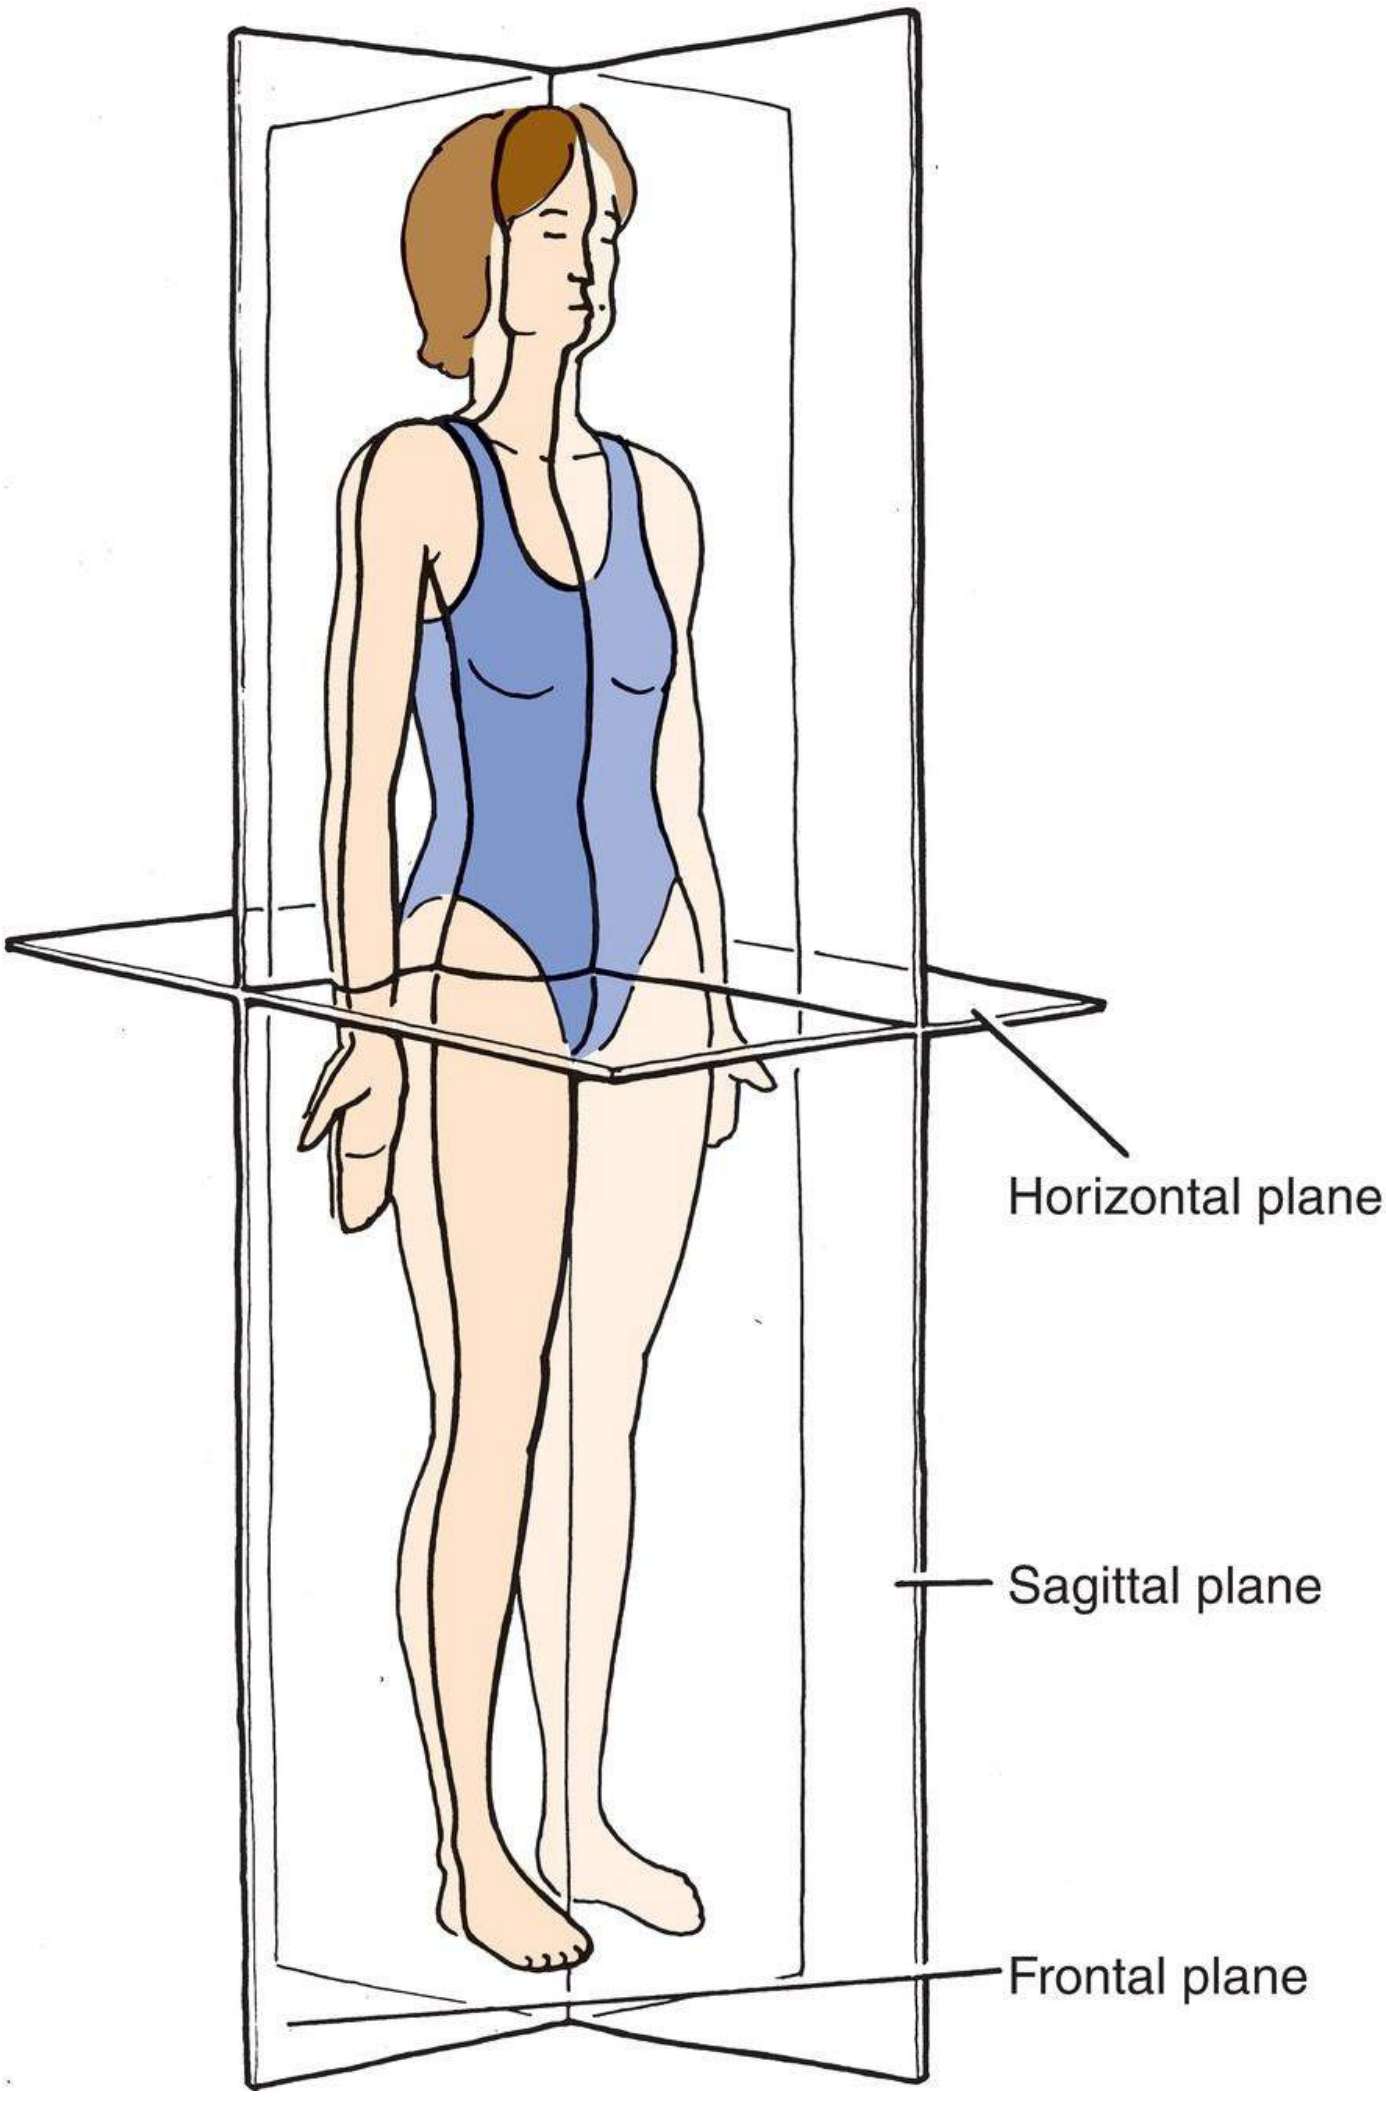
- Explain the role of α motor neurons in skeletal muscle control.
- Explain how the actions of the muscle spindle and Golgi tendon organ regulate muscle action.
- Compare the anatomy of motor neuron subgroups in relation to the muscle groups controlled.
- Explain the three classic spinal reflexes and what they reveal about spinal cord circuitry.
- Explain how the brainstem nuclei and their associated descending spinal cord tracts influence motor neuron function.
- Explain the role of the cerebral cortex, the corticospinal tract, and the basal ganglia in the control of movement.
- Explain the influence of the cerebellum in motor control.

The finger movements of a neurosurgeon manipulating microsurgical instruments while repairing a cerebral aneurysm and the eye–hand–body coordination of a professional basketball player making a rimless three-point shot are two examples of the motor control system operating at high skill levels. The coordinated contraction of the hip flexors and ankle extensors to clear a slight pavement irregularity encountered during walking is a familiar example of the motor control system working at a seemingly automatic level. Conversely, the stiff-legged stride of a patient who experienced a stroke and the swaying walk of an intoxicated person are examples of perturbed motor control.

Although our understanding of the physiology of the motor system is still far from complete, a significant fund of knowledge exists. This chapter proceeds through the major components of the motor system, beginning with the skeleton and ending with the brain.

SKELETON AS FRAMEWORK FOR MOVEMENT

Bones are the body's framework as well as a system of levers. They are the elements that move. The way adjacent bones articulate determines the motion and range of movement at a joint. Ligaments hold the bones together across the joint. Movements are described on the basis of the anatomic planes through which the skeleton moves and the physical structure of the joint. Most joints move in only one plane, but some permit movement in multiple anatomic reference planes (Fig. 5.1).



Horizontal plane
Sagittal plane
Frontal plane

Figure 5.1 Anatomic reference planes. The figure is shown in the standard anatomic position with the associated primary reference planes.

Hinge joints, such as the elbow, are uniaxial, permitting movements in the sagittal plane. The wrist is an example of a biaxial joint. The shoulder is a multiaxial joint; movement can occur in oblique planes as well as the three major planes of that joint. **Flexion** and extension describe movements in the sagittal plane. Flexion movements decrease the angle between the moving body segments. **Extension** describes movement in the opposite direction. **Abduction** moves the body part away from the midline, whereas **adduction** moves the body part toward the midline.

MUSCLE FUNCTION AND BODY MOVEMENT

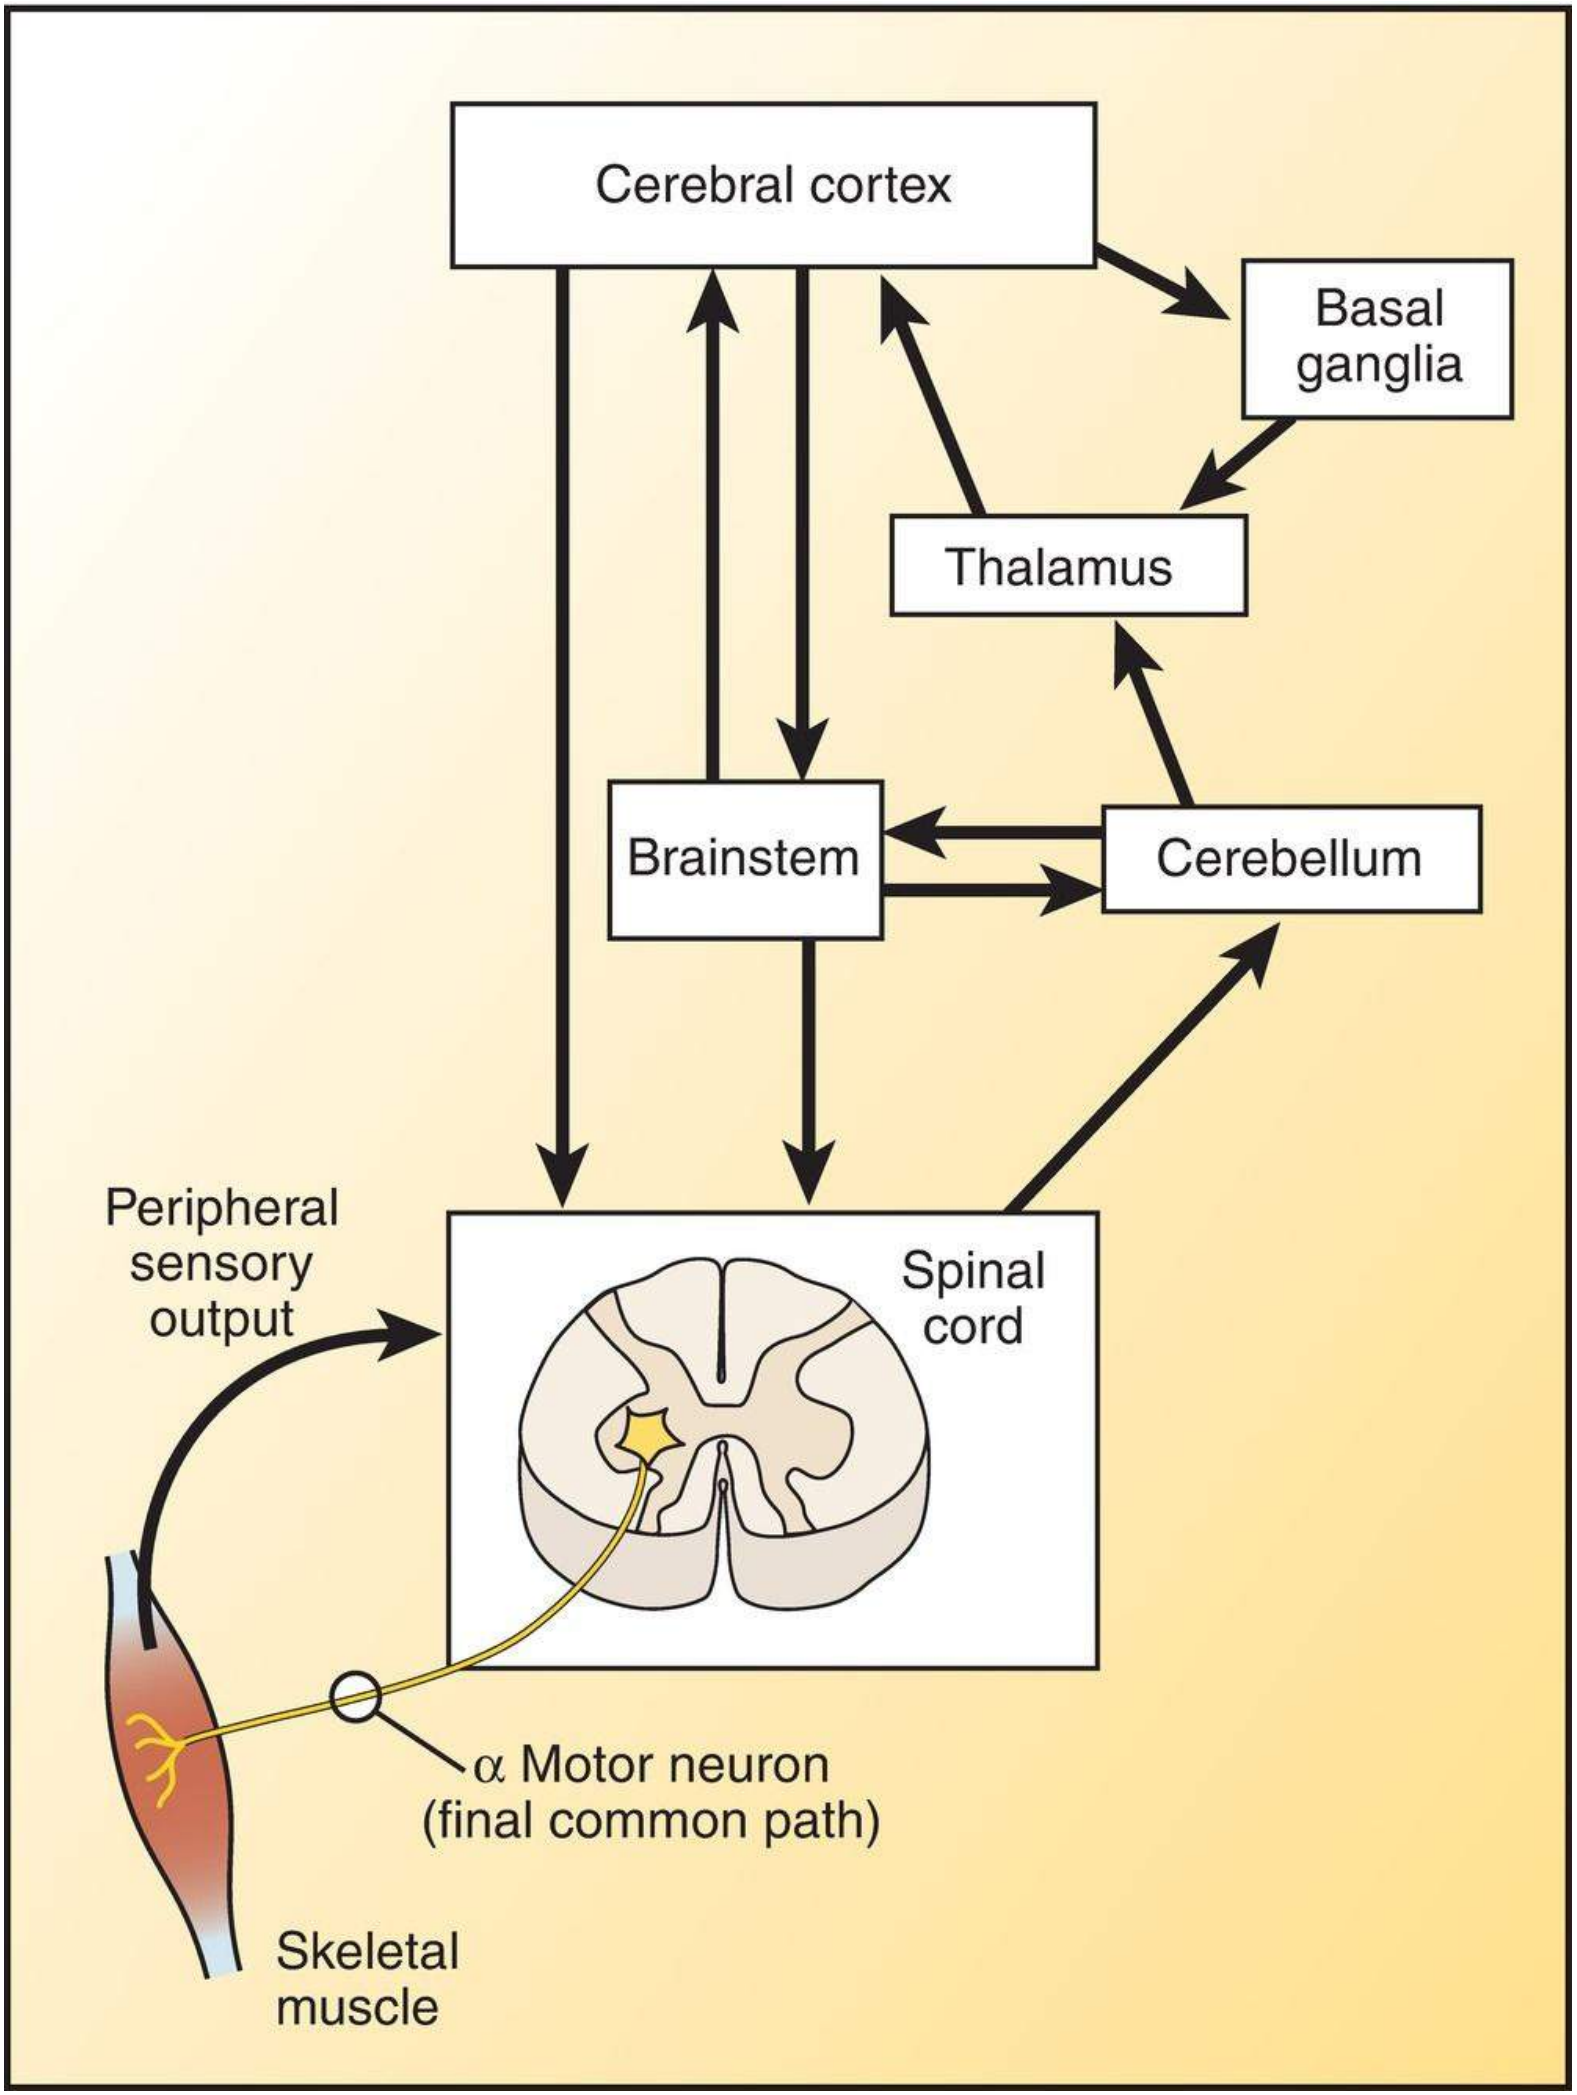
Muscles span joints and are attached at two or more points to the bony levers of the skeleton. The muscles provide the power that moves the body's levers. Muscles are described in terms of their origin and insertion attachment sites. The *origin* tends to be the more fixed, less mobile location, whereas the *insertion* refers to the skeletal site that is more mobile. Movement occurs when a muscle generates force on its attachment sites and undergoes shortening. This type of action is termed an **isotonic** or **concentric contraction**. Another form of muscular action is a controlled lengthening while still generating force. This is an **eccentric contraction**. A muscle may also generate force but hold its attachment sites static, as in **isometric contraction**.

Because muscle contraction can produce movement in only one direction, at least two muscles opposing each other at a joint are needed to achieve motion in more than one direction. When a muscle produces movement by shortening, it is an **agonist**. The prime mover is the muscle that contributes most to the movement. Muscles that oppose the action of the prime mover are **antagonists**. The quadriceps and hamstring muscles are examples of agonist–antagonist pairs in knee extension and flexion. During both simple and light-load skilled movements, the antagonist is relaxed. Contraction of the agonist with concomitant relaxation of the antagonist occurs by the nervous system function of **reciprocal inhibition**. Cocontraction of agonist and antagonist occurs during movements that require precise control.

A muscle functions as a **synergist** if it contracts at the same time as the agonist while cooperating in producing the movement. Synergistic action can aid in the following: producing a movement (e.g., the activity of both the flexor carpi ulnaris and extensor carpi ulnaris is used in producing ulnar deviation of the wrist), eliminating unwanted movements (e.g., the activity of wrist extensors prevents flexion of the wrist when the finger flexors contract in closing the hand), or stabilizing proximal joints (e.g., isometric contractions of muscles of the forearm, upper arm, shoulder, and trunk accompany a forceful grip of the hand).

NERVOUS SYSTEM COMPONENTS FOR THE CONTROL OF MOVEMENT

Here, we identify the components of the nervous system that are predominantly involved in the control of motor function and discuss the probable roles for each of them. It is important to appreciate that even the simplest reflex or voluntary movement requires the interaction of multiple levels of the nervous system (Fig. 5.2).



Cerebral cortex
Basal ganglia
Thalamus
Brainstem
Cerebellum
Peripheral sensory output
Spinal cord
α Motor neuron (final common path)
Skeletal muscle

Figure 5.2 Motor control system. a Motor neurons are the final common path for motor control. Peripheral sensory input and spinal cord tracts that descend from the brainstem and the cerebral cortex influence the motor neurons. The cerebellum and basal ganglia contribute to motor control by modifying the brainstem and the cortical activity.

Motor neurons are the final common path for motor control.

The α motor neurons are referred to as final common pathway neurons because they are the route by which the central nervous system (CNS) controls the skeletal muscles. These motor neurons located in the ventral horns of the spinal gray matter and brainstem cranial nerve nuclei are influenced both by local reflex circuitry and by pathways that descend from the brainstem and cerebral cortex. The brainstem-derived pathways include the rubrospinal, vestibulospinal, and reticulospinal tracts; the cortical pathways are the corticospinal and corticobulbar tracts. Although some of the cortically derived axons terminate directly on motor neurons, most of the axons of the cortical-derived and brainstem-derived tracts terminate on interneurons, which then influence motor neuron function. The outputs of the basal ganglia and cerebellum, two additional motor-related areas, provide fine-tuning of the cortical and brainstem influences on motor neuron functions.

Motor neurons segregate into two major categories, α (alpha) and γ (gamma). **α Motor neurons** innervate the extrafusal muscle fibers, which are responsible for force generation. **γ Motor neurons** innervate the intrafusal muscle fibers, which are components of the muscle spindle. γ Motor neurons are discussed further in the next section. An α motor neuron controls several muscle fibers, 10 to 1,000, depending on the muscle. The term **motor unit** describes an α motor neuron, its axon, the branches of the axon, the neuromuscular junction synapses at the distal end of each axon branch, and all of the extrafusal muscle fibers innervated by that motor neuron (Fig. 5.3). When a motor neuron is activated, all of its muscle fibers are also activated.

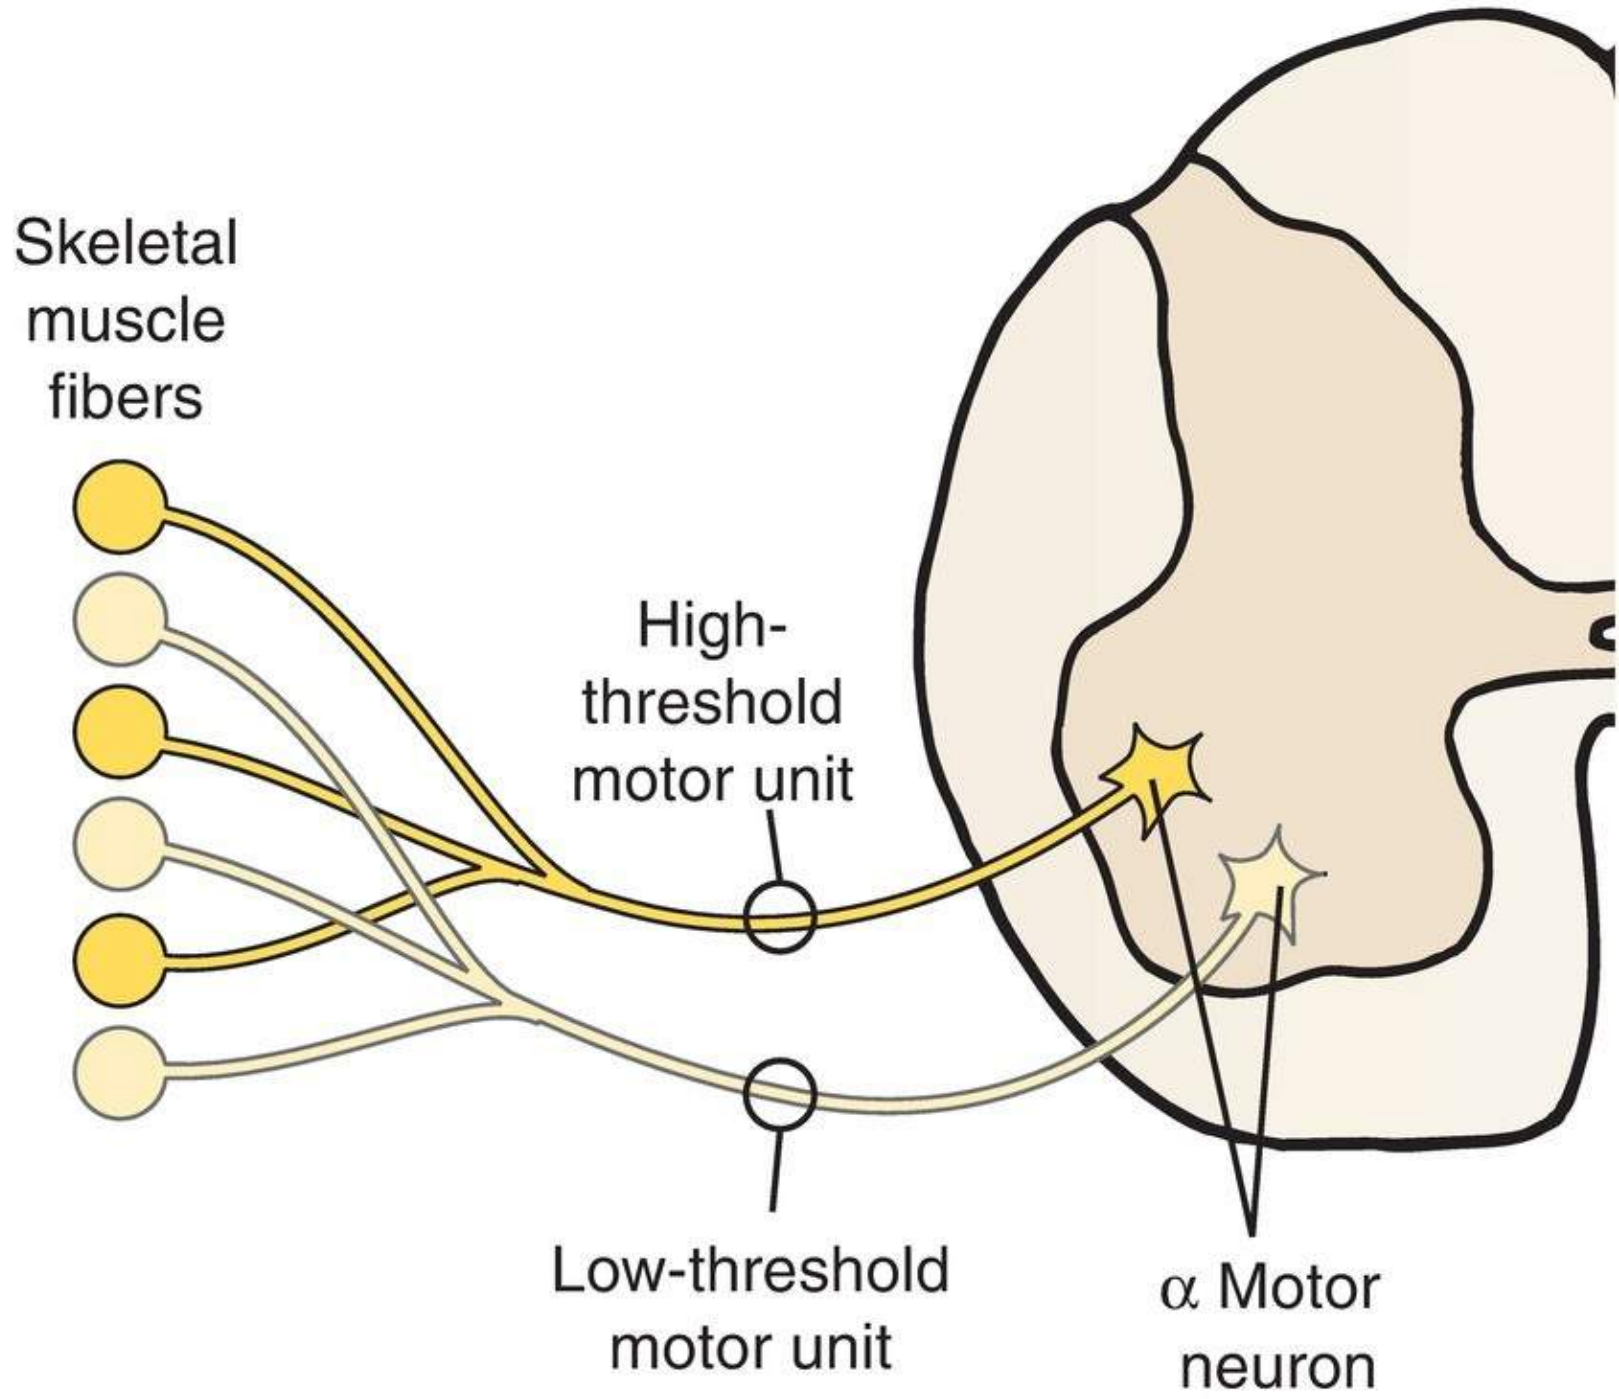


Figure 5.3 Motor unit structure. A motor unit consists of an α motor neuron and a group of extrafusal muscle fibers it innervates. Functional characteristics, such as activation threshold, twitch speed, twitch force, and resistance to fatigue, are determined by the motor neuron. Low-threshold and high-threshold motor units are shown.

α Motor neurons can be separated into two general populations according to their cell body size and axon diameter. The larger cells have a high threshold to synaptic stimulation, have fast action potential conduction velocities, and are active in high-effort force generation. They innervate fast-twitch, high-force but fatigable muscle fibers. The smaller motor neurons have lower thresholds to synaptic stimulation, conduct action potentials at slightly slower velocities, and innervate slow-twitch, low-force, fatigue-resistant muscle fibers (see Chapter 8). The muscle fibers of a motor unit are homogeneous, either fast-twitch or slow-twitch. The twitch property of a muscle fiber is determined by the motor neuron, presumably by trophic substances released at the neuromuscular junction.

The organization into different motor unit types has important functional consequences for the production of smooth, coordinated contractions. The smallest neurons have the lowest threshold and are, therefore, activated first when synaptic activity is low. These motor units produce sustainable, relatively low-force tonic contractions in slow-twitch, fatigue-resistant muscle fibers. If additional force is required, synaptic drive from higher centers increases the action potential firing rate of the initially activated motor neurons and then activates additional motor units of the same type. If yet higher force levels are needed, the larger motor neurons are recruited, but their contribution is less sustained as a result of their tendency for fatigability. This orderly process of motor unit recruitment obeys what is called the **size principle**—the smaller motor neurons are activated first. A logical corollary of this arrangement is that muscles concerned with endurance, such as antigravity muscles, contain predominantly slow-twitch muscle fibers in accordance with their function of continuous postural support. Muscles that contain predominantly fast-twitch fibers, including many physiologic flexors, are capable of producing high-force but less sustainable contractions.

Afferent muscle innervation provides feedback for motor control.

The muscles, joints, and ligaments are innervated with sensory receptors that inform the CNS about body position and muscle activity. Skeletal muscles contain muscle spindles, **Golgi tendon organs** (GTOs), free nerve endings, and some pacinian corpuscles. Joints contain Ruffini endings and pacinian corpuscles, joint capsules contain nerve endings, and ligaments contain Golgi tendon–like organs. Together, these are the proprioceptors, providing sensation from the deep somatic structures. The output of these receptors provides feedback that is necessary for the control of movements.

Muscle spindles provide information about the muscle length and the velocity at which the muscle is being stretched. GTOs provide information about the force being generated. Spindles are located in the mass of the muscle, in parallel with the extrafusal muscle fibers. GTOs are located at the junction of the muscle and its tendons, in series with the muscle fibers (Fig. 5.4).

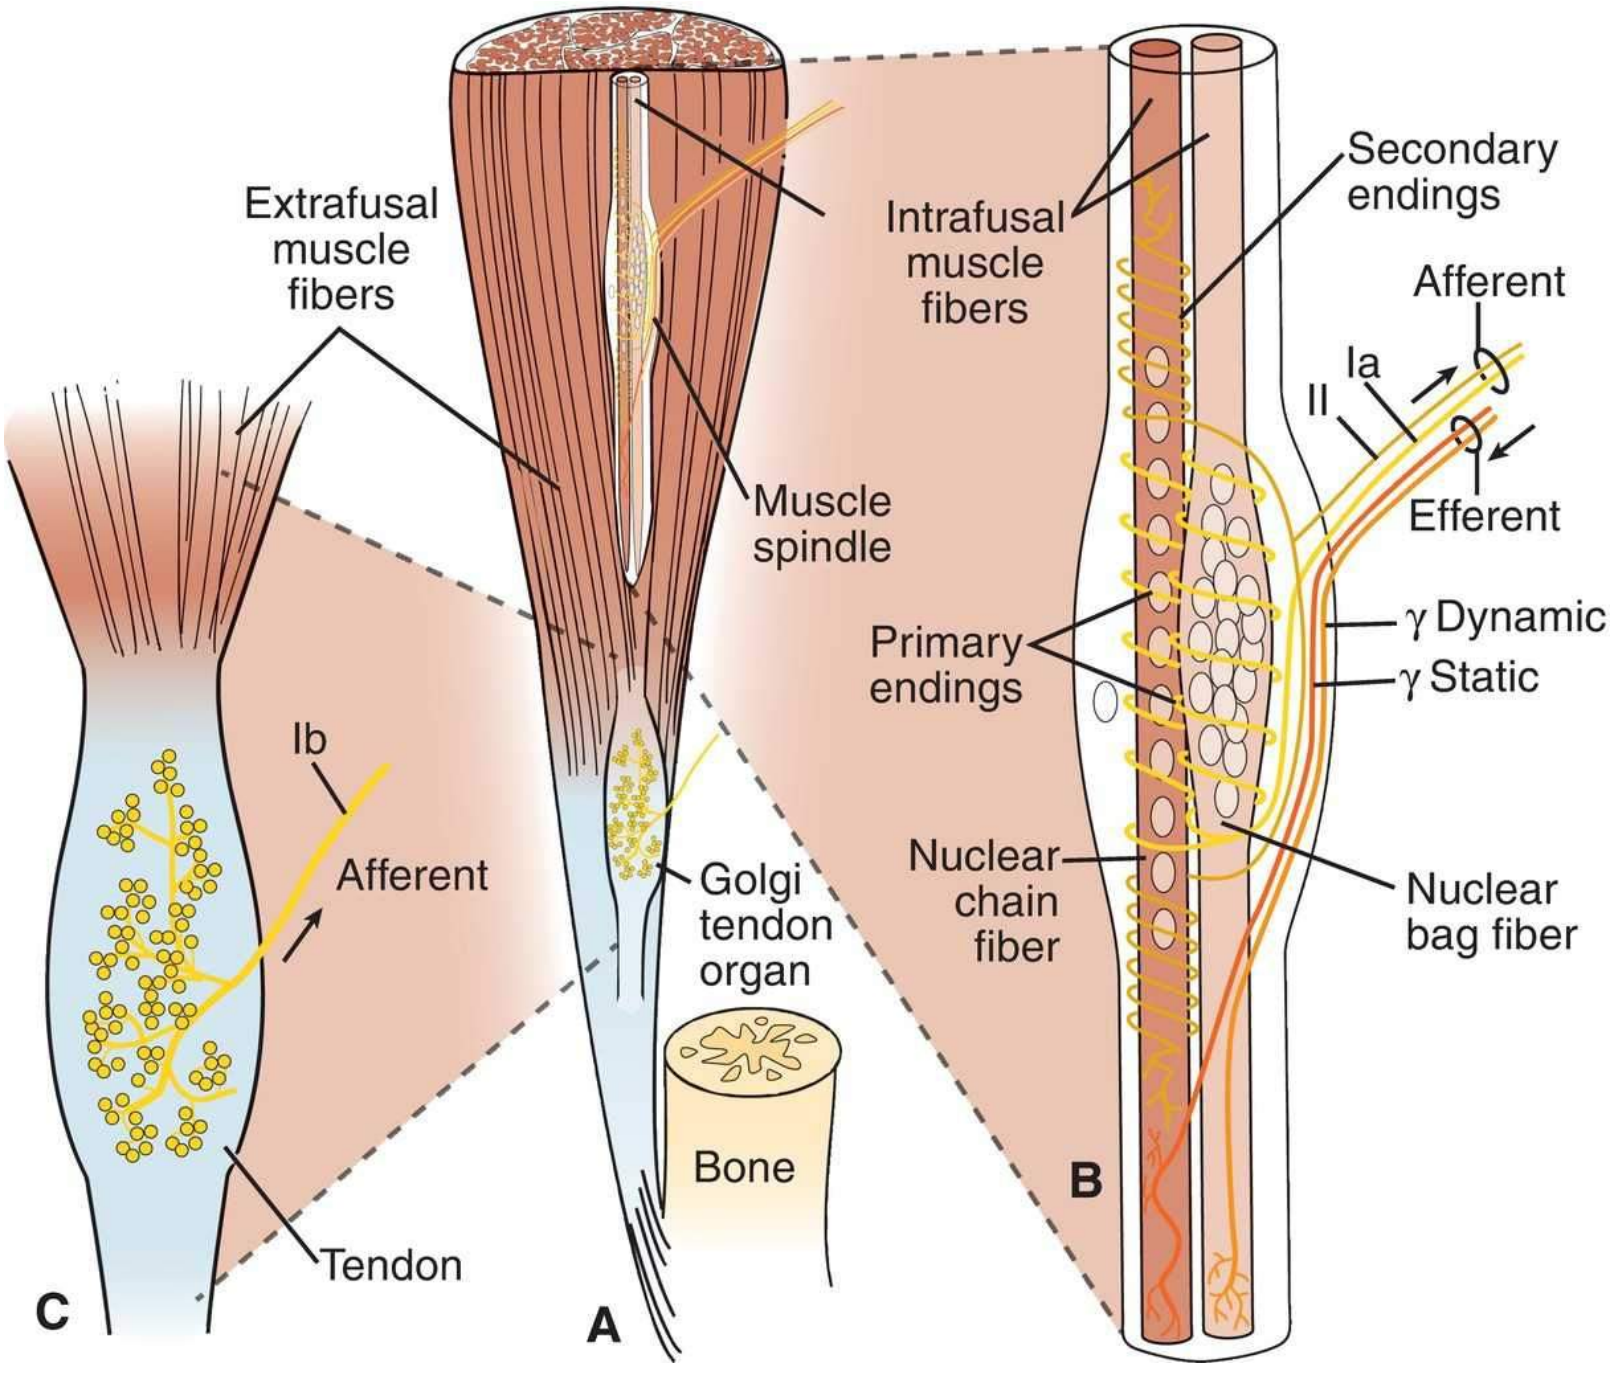

Figure 5.4 Muscle spindle and Golgi tendon organ (GTO) structure. **(A)** Muscle spindles are arranged parallel to extrafusal muscle fibers; GTOs are in series. **(B)** This enlarged spindle shows the following: nuclear bag and nuclear chain types of intrafusal fibers; afferent innervation by Ia axons, which provide primary endings to both types of fibers; type II axons, which have secondary endings mainly on chain fibers; and motor innervation by the two types of γ motor axons: static and dynamic. **(C)** An enlarged GTO. The sensory receptor endings interdigitate with the collagen fibers of the tendon. The axon is type Ib.

Muscle spindles

Muscle spindles are sensory receptors found in almost all of the skeletal muscles. They occur in greatest density in small muscles serving fine movements, such as those of the hand, and in the deep muscles of the neck. Muscle spindles function primarily to detect changes in muscle length and the rate of change in muscle length. They convey this information to the CNS via sensory neurons, and the brain processes this information to help determine position. The response of muscle spindles to changes in length also play a key role in regulating muscle contraction, by activating motor neurons via the stretch reflex to resist muscle stretch.

The muscle spindle, named for its long fusiform shape, is attached at both ends to extrafusal muscle fibers. Within the spindle's expanded middle portion is a fluid-filled capsule containing about seven specialized striated muscle fibers entwined by sensory nerve terminals. These intrafusal muscle fibers have contractile filaments at both ends. The noncontractile midportion contains the cell nuclei (see Fig. 5.4B). γ Motor neurons innervate the contractile elements. There are two types of intrafusal fibers: **nuclear bag fibers**, named for the large number of nuclei packed into the midportion, and **nuclear chain fibers**, in which the nuclei are arranged in a longitudinal row. There are about twice as many nuclear chain fibers as nuclear bag fibers per spindle. The nuclear bag type fibers are further classified as bag_1 and bag_2, based on whether they respond best in the dynamic or static phase of muscle stretch, respectively.

Sensory axons surround both the noncontractile midportion and paracentral region of the contractile ends of the intrafusal fiber. The sensory axons are categorized as primary (type Ia) and secondary (type II). The axons of both types are myelinated. Type Ia axons are larger in diameter (12 to 20 μm) than type II axons (6 to 12 μm) and have faster conduction velocities. Type Ia axons have spiral endings that wrap around the middle of the intrafusal muscle fiber (see Fig. 5.4B). Both nuclear bag and nuclear chain fibers are innervated by type Ia axons. Type II axons innervate mainly nuclear chain fibers and have nerve endings that are located along the contractile components on either side of the type Ia spiral ending. The nerve endings of both primary and secondary sensory axons of the muscle spindles respond to stretch by generating action potentials that convey information to the CNS about changes in the muscle length and the velocity of length change (Fig. 5.5). The primary endings temporarily cease generating action potentials during the release of a muscle stretch (Fig. 5.6).

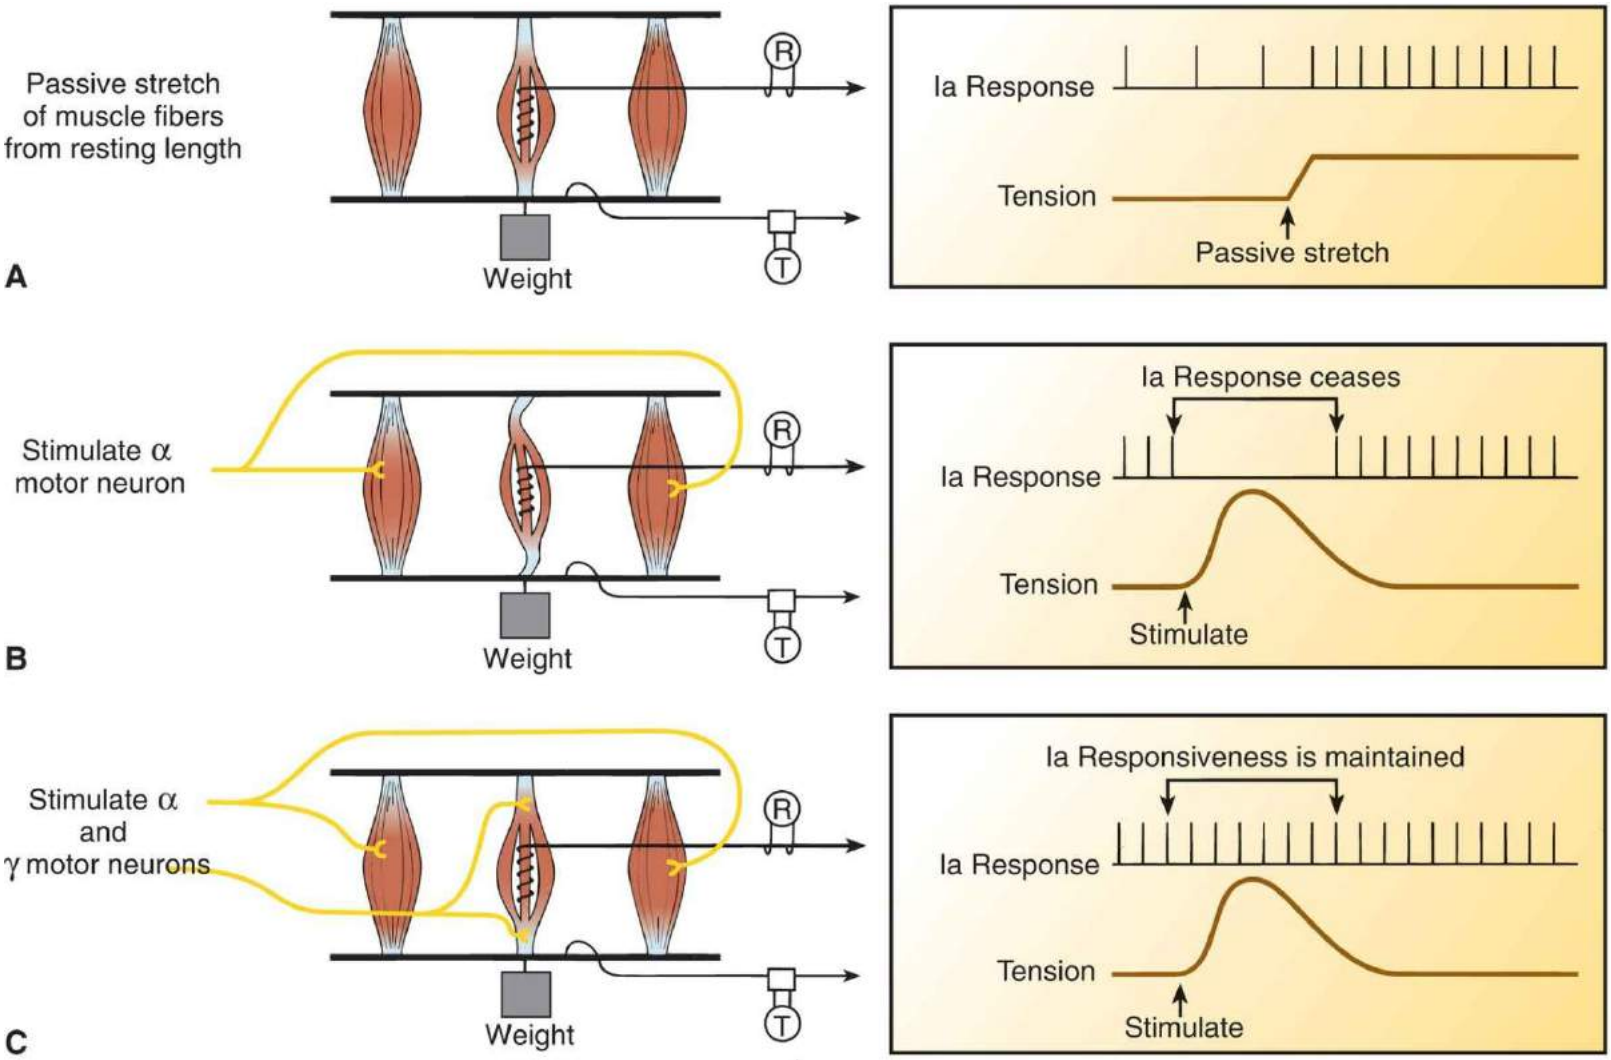

Figure 5.5 Action potentials (R) from type Ia endings versus muscle tension (T). **(A)** The Ia sensory endings from the muscle spindles discharge at a slow rate when the muscle is at its resting length and show an increased firing rate when the muscle is stretched. **(B)**α Motor neuron activation shortens the muscle and releases tension on the muscle spindle. Ia activity ceases temporarily during the tension release. **(C)** Concurrent α and γ motor neuron activation, as occurs in normal, voluntary muscle contraction, shortens the muscle spindle along with the extrafusal fibers, maintaining the spindle's responsiveness to the stretch.

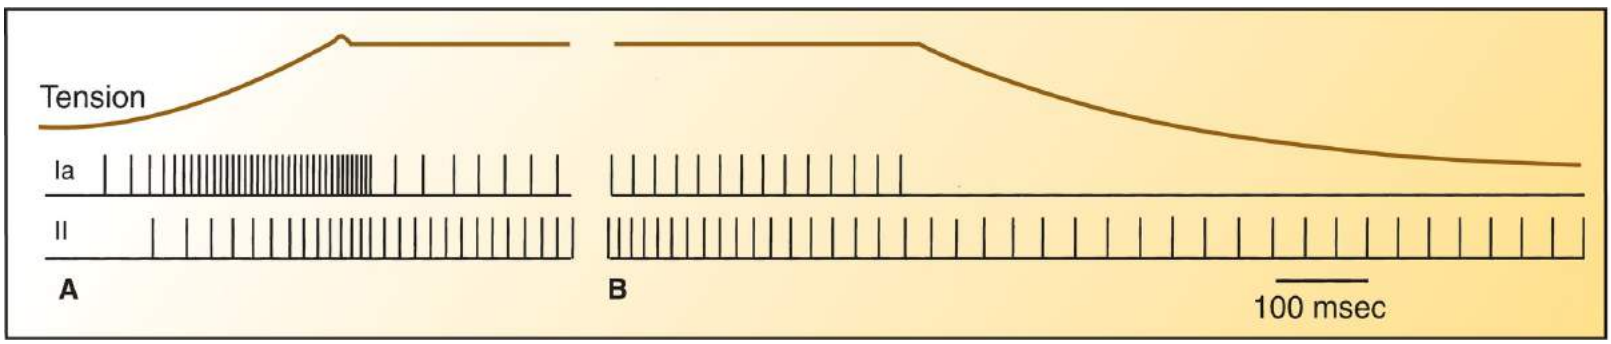

Figure 5.6 Response of types Ia and II sensory endings during muscle stretch. **(A)** During rapid stretch, type Ia endings show a greater firing rate increase, whereas type II endings show only a modest increase. **(B)** With the release of the stretch, Ia endings cease firing, whereas firing of type II endings slows. Ia endings report both the velocity and the length of muscle stretch; type II endings report the length.

Golgi tendon organs

GTOs are 1-mm-long, slender receptors encapsulated within the tendons of the skeletal muscles (see Fig. 5.4A, C). The distal pole of a GTO is anchored in collagen fibers of the tendon. The proximal pole is attached to the ends of the extrafusal muscle fibers. This arrangement places the GTO in series with the extrafusal muscle fibers such that contractions of the muscle stretch the GTO.

A large-diameter, myelinated type Ib afferent axon arises from each GTO. These axons are slightly smaller in diameter than the type Ia variety, which innervate the muscle spindle. Muscle contraction stretches the GTO and generates action potentials in type Ib axons. The GTO output provides information to the CNS about the force of the muscle contraction.

Information entering the spinal cord via type Ia and Ib axons is directed to many targets, including the spinal interneurons that give rise to the **spinocerebellar tracts**. These tracts convey information to the cerebellum about the status of muscle length and tension.

Motor neurons adjust spindle output during muscle contraction.

α Motor neurons innervate the extrafusal muscle fibers, and γ motor neurons innervate the intrafusal fibers. Cells bodies of both α and γ motor neurons reside in the ventral horns of the spinal cord and in nuclei of the cranial motor nerves. Nearly one third of all motor nerve axons are destined for intrafusal muscle fibers. This high number reflects the complex role of the spindles in motor system control. Intrafusal muscle fibers likewise constitute a significant portion of the total number of muscle cells, yet they contribute little or nothing to the total force generated when the muscle contracts. Rather, the contractions of intrafusal fibers play a modulating role in spindle output as they alter the length and, thereby, the sensitivity of the muscle spindles.

Even when the muscle is at rest, the muscle spindles are slightly stretched, and type Ia afferent nerves exhibit a slow discharge of action potentials. Contraction of the muscle increases the firing rate in type Ib axons from GTOs, whereas type Ia axons temporarily cease or reduce firing because the shortening of the surrounding extrafusal fibers unloads the intrafusal muscle fibers. If a load on the spindle were reinstituted, the Ia nerve endings would resume their sensitivity to stretch. The role of the γ motor neurons is to “reload” the spindle during muscle contraction by activating the contractile elements of the intrafusal fibers. This is accomplished by coordinated activation of the α and γ motor neurons during muscle contraction (see Fig. 5.5).

The γ motor neurons and the intrafusal fibers they innervate are traditionally referred to as the **fusimotor system**. Axons of the γ neurons terminate distal to the sensory endings on the striated poles of the spindle’s muscle fibers (see Fig. 5.4B).

γ Motor neurons are designated *dynamic* and *static*. This functional distinction is based on findings that dynamic γ motor neurons are associated with dynamic nuclear bag fibers and stimulation of dynamic γ neurons enhances the response of type Ia sensory axons to stretch but only during the dynamic (muscle length–changing) phase of a muscle stretch. During the static phase of the stretch (muscle length increase maintained), stimulation of the static γ motor neurons, which are associated with static nuclear bag fibers and nuclear chain fibers, enhances the response of type Ia and II sensory axons. These differences allow for largely independent control of the nuclear bag and nuclear chain fibers in the spindle and suggest that the motor system has the ability to monitor muscle length more precisely in some muscles and the speed of contraction in others.

SPINAL CORD IN THE CONTROL OF MOVEMENT

Muscles interact extensively in the maintenance of posture and the production of coordinated movement. The circuitry of the spinal cord automatically controls much of this interaction. Sensory feedback from muscles reaches motor neurons of related muscles and, to a lesser degree, of more distant muscles. In addition to activating local circuits, muscles and joints transmit sensory information up the spinal cord to higher centers. This information is processed and can be relayed back to influence spinal cord circuits.

Spinal motor anatomy correlates with function.

The cell bodies of the spinal motor neurons are grouped into pools in the spinal cord ventral horns. A pool consists of the motor neurons that serve a particular muscle. The number of motor neurons that control a muscle varies in direct proportion to the delicacy of control required. The motor neurons are organized so that those innervating the axial muscles are grouped medially and those innervating the limbs are located laterally in the ventral horn. The lateral limb motor neuron areas are further organized so that neurons innervating flexors are positioned more dorsal and extensors more ventral in the ventral horn. A motor neuron pool may extend over several spinal segments, and the axons then emerge in the ventral nerve roots of two or even three adjacent spinal levels. A physiologic advantage to such an arrangement is that injury to a single nerve root, as might occur by herniation of an intervertebral disk, will not completely paralyze a muscle.

Between the spinal cord's dorsal and ventral horns lies the intermediate zone, which contains an extensive network of interneurons that interconnect motor neuron pools. Some interneurons make connections in their own cord segment; others have longer axon projections that travel in the white matter to terminate in other segments of the spinal cord. These longer interneurons, termed propriospinal cells, carry information that aids coordinated movement. The importance of spinal cord interneurons is clear, insofar as they comprise most of the neurons in the spinal cord as well as being the origin of most of the synapses on motor neurons.

Spinal cord mediates reflex activity.

The spinal cord contains neural circuitry to generate **reflexes**, stereotypical actions produced in response to a stimulus. One function of a reflex is to generate a rapid response. A familiar example is the rapid, involuntary withdrawal of a hand after touching a dangerously hot object well before the heat or pain is perceived. This type of reflex protects the organism before higher CNS levels identify the problem. Some reflexes are simple, whereas others are much more complex. Even the simplest requires coordinated action in which the agonist muscle contracts while the antagonist relaxes. The functional unit of a reflex consists of a sensor, an afferent pathway, an integrating center, an efferent pathway, and an effector. The sensory receptors for spinal reflexes are the proprioceptors and cutaneous receptors. Impulses initiated in these receptors travel along afferent nerves to the spinal cord, where interneurons and motor neurons constitute the integrating center. The motor neurons are the efferent pathway to the effector organs, the skeletal muscles. The responsiveness of such a functional unit can be modulated by higher motor centers acting through descending pathways to facilitate or inhibit its activation.

Study of the three types of spinal reflexes—the myotatic, the inverse myotatic, and the flexor withdrawal—provides a basis for understanding the general mechanism of reflexes.

Myotatic (muscle stretch) reflex

Stretching or elongating a muscle—such as when the patellar tendon is tapped with a reflex hammer or when a quick change in posture is made—causes it to contract within a short duration. The duration between the onset of a stimulus and the response, the **latency period**, is on the order of 30 ms for a knee-jerk reflex in a human. This response, called the **myotatic** or **muscle stretch reflex**, is a result of monosynaptic circuitry, in which an afferent sensory neuron synapses directly on the efferent motor neuron (Fig. 5.7). The stretch activates muscle spindles and type Ia axons from the spindle carry action potentials to the spinal cord, where they synapse directly on motor neurons of the same (homonymous) muscle that was stretched and on motor neurons of synergistic muscles. Activation of these motor neurons causes the muscles to contract.

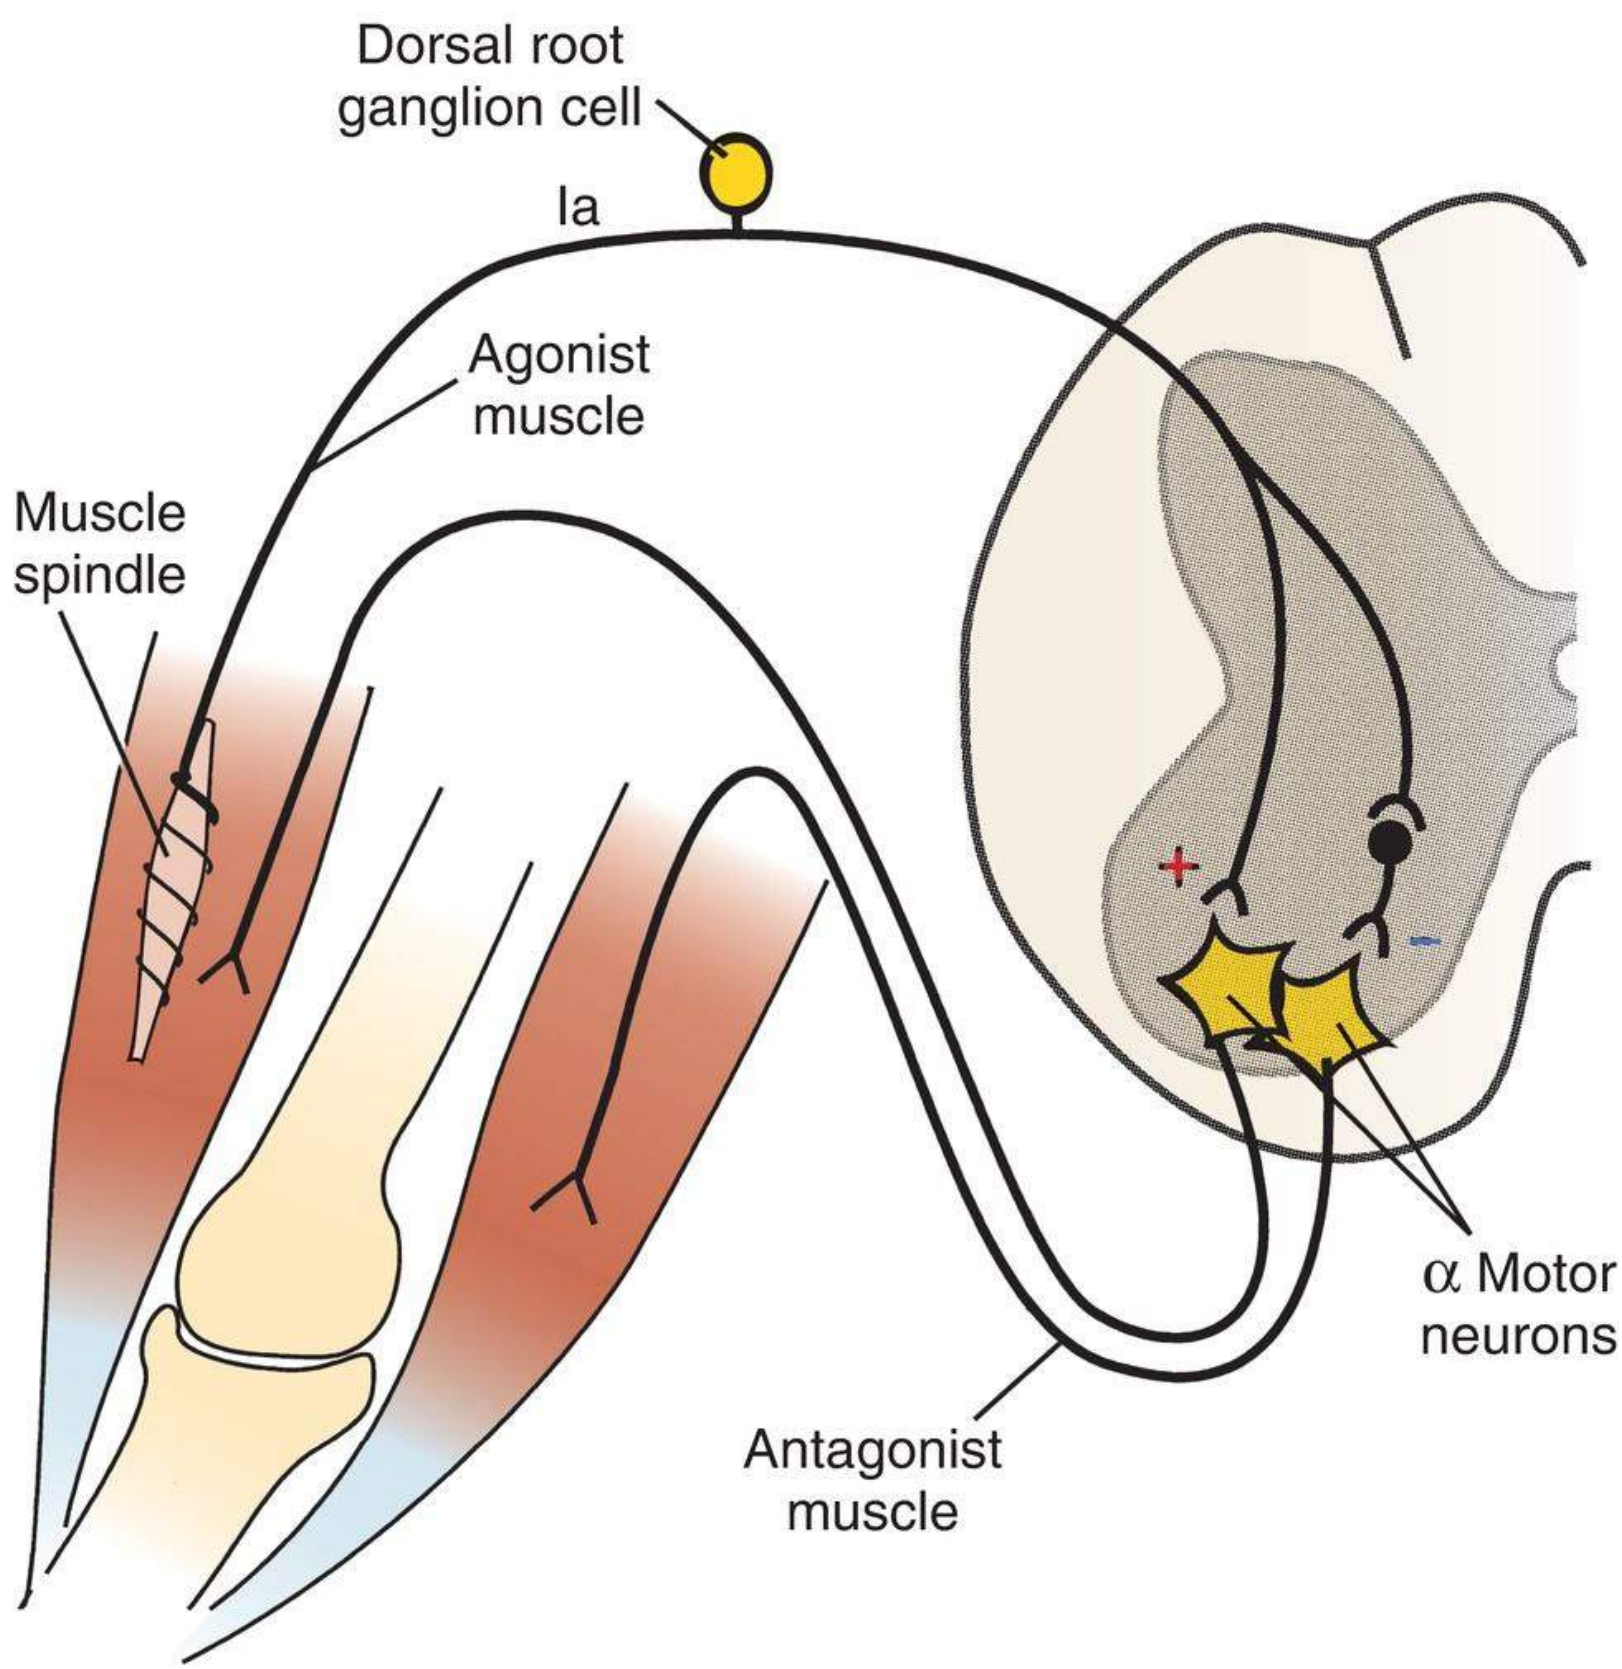

Figure 5.7 Myotatic reflex circuitry. Ia afferent axons from the muscle spindle make excitatory monosynaptic contact with homonymous motor neurons and with inhibitory interneurons that synapse on motor neurons of antagonist muscles. The plus sign indicates excitation; the minus sign indicates inhibition.

Collateral branches of type Ia axons also synapse on interneurons, whose action then inhibits motor neurons of antagonist muscles (see Fig. 5.7). This synaptic pattern, called *reciprocal inhibition*, serves to coordinate muscles of opposing function around a joint. Secondary (type II) spindle afferent fibers also

synapse with homonymous motor neurons, providing excitatory input through both monosynaptic and polysynaptic pathways.

The myotatic reflex has two components: a *phasic part*, exemplified by the quick limb movement after tendon tapping with the reflex hammer, and a more sustained *tonic part*, thought to be important for posture maintenance. These two components blend together, but either one may predominate, depending on whether other synaptic activity, such as from cutaneous afferent neurons or pathways descending from higher centers, influences the motor response. Primary spindle afferent fibers probably mediate the tendon jerk, with secondary afferent fibers contributing mainly to the tonic phase of the reflex. The myotatic reflex performs many functions. At the most general level, it produces rapid corrections of motor output in the moment-to-moment control of movement. It also forms the basis for postural reflexes, which maintain body position despite a varying range of loads on the body.

Inverse myotatic reflex

Active contraction of a muscle also causes reflex inhibition of the contraction. This response is called the **inverse myotatic reflex** because it produces an effect that is opposite to that of the myotatic reflex. Active muscle contraction stimulates GTOs, producing action potentials in the type Ib afferent axons. Those axons synapse on inhibitory interneurons that inhibit motor neurons that innervated the muscles served by the activated GTOs and on excitatory interneurons that excite motor neurons of antagonist muscles (Fig. 5.8). The function of the inverse myotatic reflex appears to be a tension feedback system that can adjust the strength of contraction during sustained activity.

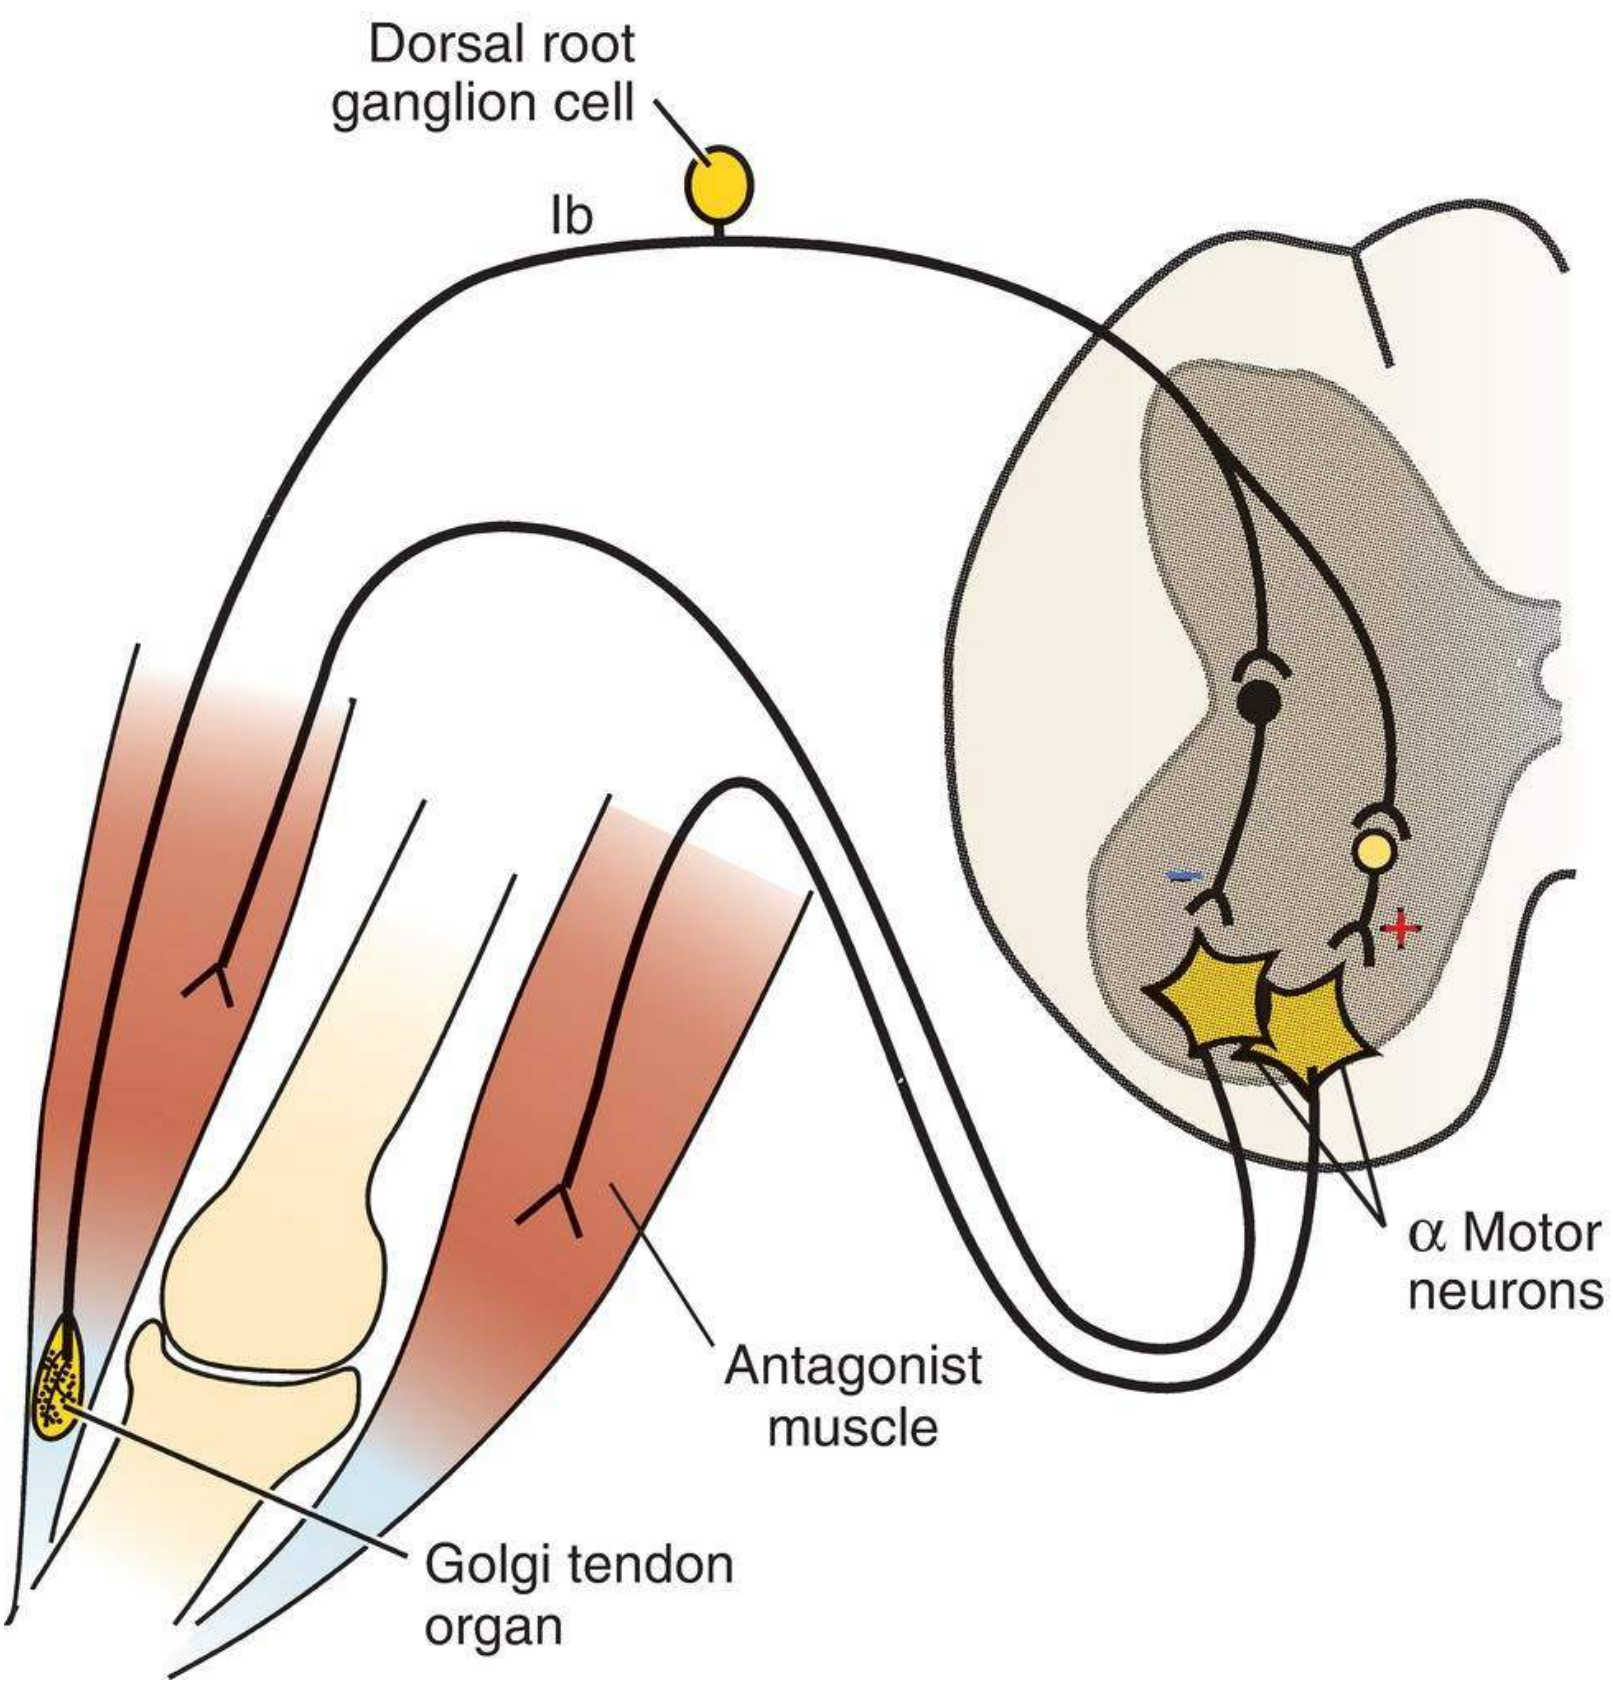

Figure 5.8 Inverse myotatic reflex circuitry. Contraction of the agonist muscle activates the Golgi tendon organ and Ib afferents that synapse on interneurons that inhibit agonist motor neurons and excite the motor neurons of the antagonist muscle.

The inverse myotatic reflex, like the myotatic reflex, has a more potent influence on the physiologic extensor muscles than on the flexor muscles, suggesting that the two reflexes act together to maintain optimal responses in the antigravity muscles during postural adjustments. Another hypothesis about the conjoint function is that both of these reflexes contribute to the smooth generation of tension in muscle by

regulating muscle stiffness.

Flexor withdrawal reflex

Cutaneous stimulation—such as touch, pressure, heat, cold, or tissue damage—can elicit a **flexor withdrawal reflex**. This reflex consists of a contraction of flexors and a relaxation of extensors in the stimulated limb. The action may be accompanied by a contraction of the extensors on the contralateral side. The axons of cutaneous sensory receptors synapse on interneurons in the dorsal horn. Those interneurons act ipsilaterally to excite the motor neurons of flexor muscles and inhibit those of extensor muscles. Collaterals of interneurons cross the midline to excite contralateral extensor motor neurons and inhibit flexors (Fig. 5.9).

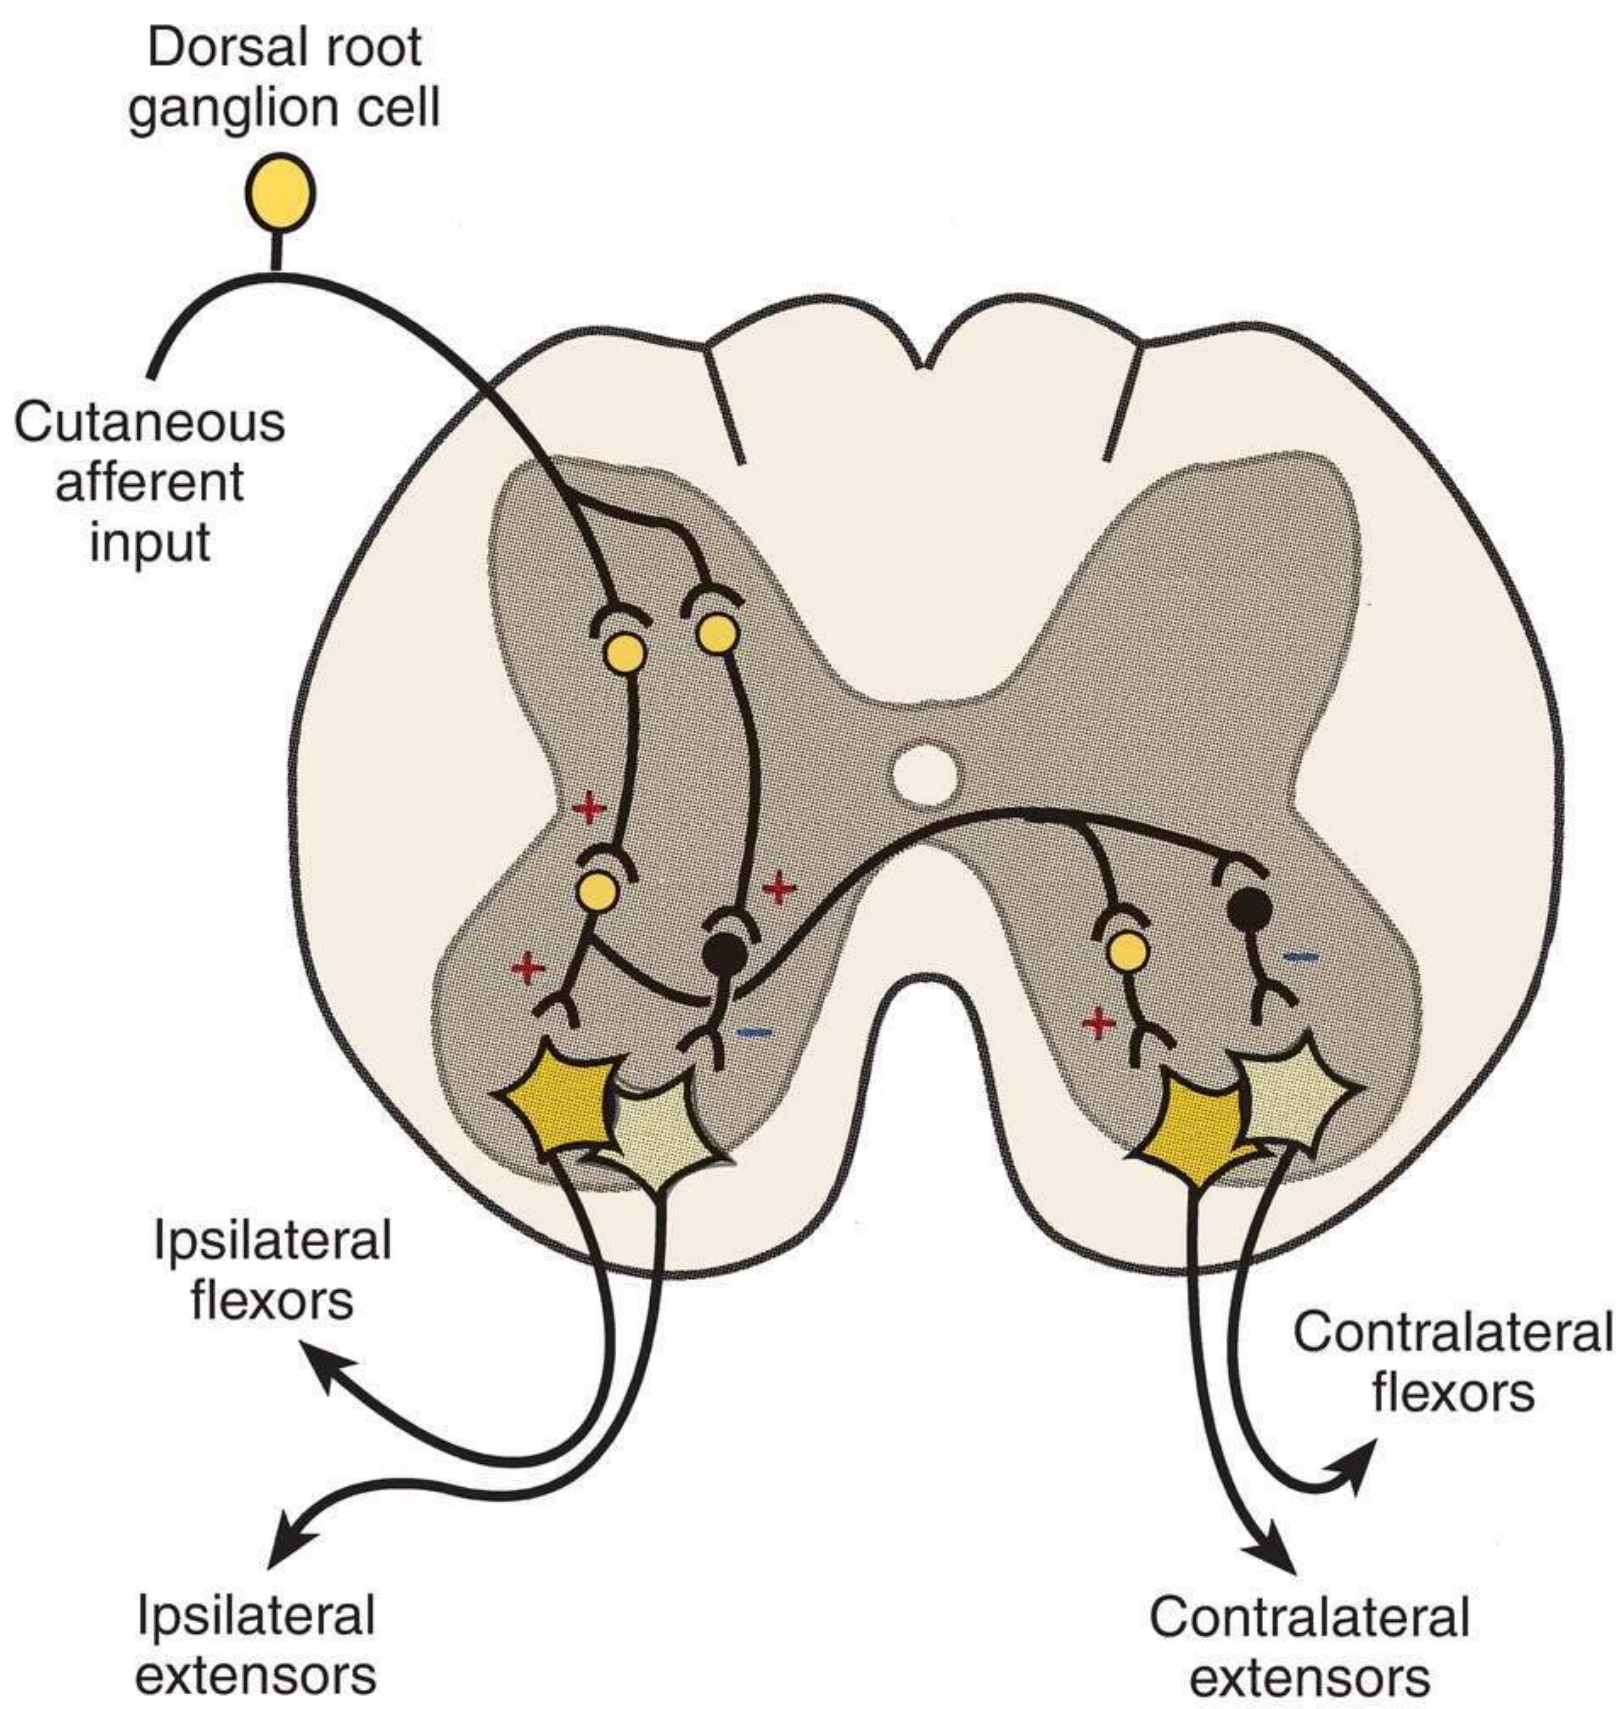

Figure 5.9 Flexor withdrawal reflex circuitry. Stimulation of cutaneous afferents activates ipsilateral flexor muscles via excitatory interneurons. Ipsilateral extensor motor neurons are inhibited. Contralateral extensor motor neuron activation provides postural support for the limb that is flexing.

There are two types of flexor withdrawal reflexes: those that result from innocuous stimuli and those that result from potentially injurious stimulation. The first type produces a localized flexor response accompanied by slight or no limb withdrawal; the second type produces widespread flexor contraction

throughout the limb and abrupt withdrawal. The function of the first type of reflex is less obvious but may be a general mechanism for adjusting the movement of a body part when an obstacle is detected by cutaneous sensory input. The function of the second type is protection of the individual. The endangered part is rapidly removed, and postural support of the opposite side is strengthened to support the body.

Collectively, these reflexes provide for stability and postural support (the myotatic and inverse myotatic) and mobility (flexor withdrawal). The reflexes provide a foundation of automatic responses on which more complicated voluntary movements are built.

Spinal cord injury alters voluntary and reflex motor activity.

When the spinal cord of a human or other mammal is severely injured, voluntary and reflex movements are immediately lost caudal to the level of injury. This acute impairment of function is called **spinal shock**. The loss of voluntary motor control is termed **plegia**, and the loss of reflexes is termed **areflexia**. Spinal shock may last from days to months, depending on the severity of cord injury. Reflexes caudal to the spinal cord damage tend to return, as may some degree of voluntary control depending on the extent of spinal cord damage. As recovery proceeds, myotatic reflexes become hyperactive, as demonstrated by an excessively vigorous response to tapping the muscle tendon with a reflex hammer. A single tap, or limb repositioning that produces a change in the muscle length, may also provoke *clonus*, a condition characterized by repetitive contraction and relaxation of a muscle in an oscillating fashion every second or so. Flexor withdrawal reflexes may also reappear and be provoked by lesser stimuli than normally would be required. The acute loss and eventual overactivity of each of these reflexes results from the lack of influence of the neural tracts that descend from higher motor control centers to the motor neurons and associated interneuron pools.

SUPRASPINAL INFLUENCES ON MOTOR CONTROL

Descending signals from the brainstem and cortex influence the rate of motor neuron firing and the recruitment of additional motor neurons to increase the force of muscle contraction. The brainstem contains the neural circuitry for initiating locomotion and for controlling posture. The maintenance of posture requires coordinated activity of both axial and limb muscles in response to input from proprioceptors and spatial position sensors such as the vestibular apparatus in the inner ear. Cerebral cortex input through the corticospinal system is necessary for the control of fine individual movements of the distal limbs and digits. Each higher level of the nervous system acts on lower levels to produce appropriate, more refined movements.

Brainstem is the origin of descending tracts that influence posture and movement.

Three brainstem nuclear groups give rise to descending motor tracts that influence spinal cord motor neurons and their associated interneurons. These are the **vestibular nuclear complex**, the **reticular formation**, and the **red nucleus** (Fig. 5.10). The other major descending influence on the motor neurons is the corticospinal tract, the only volitional control pathway in the motor system. This tract is discussed later. In most cases, the descending pathways act through synaptic connections on interneurons. The connection is less commonly made directly with motor neurons.

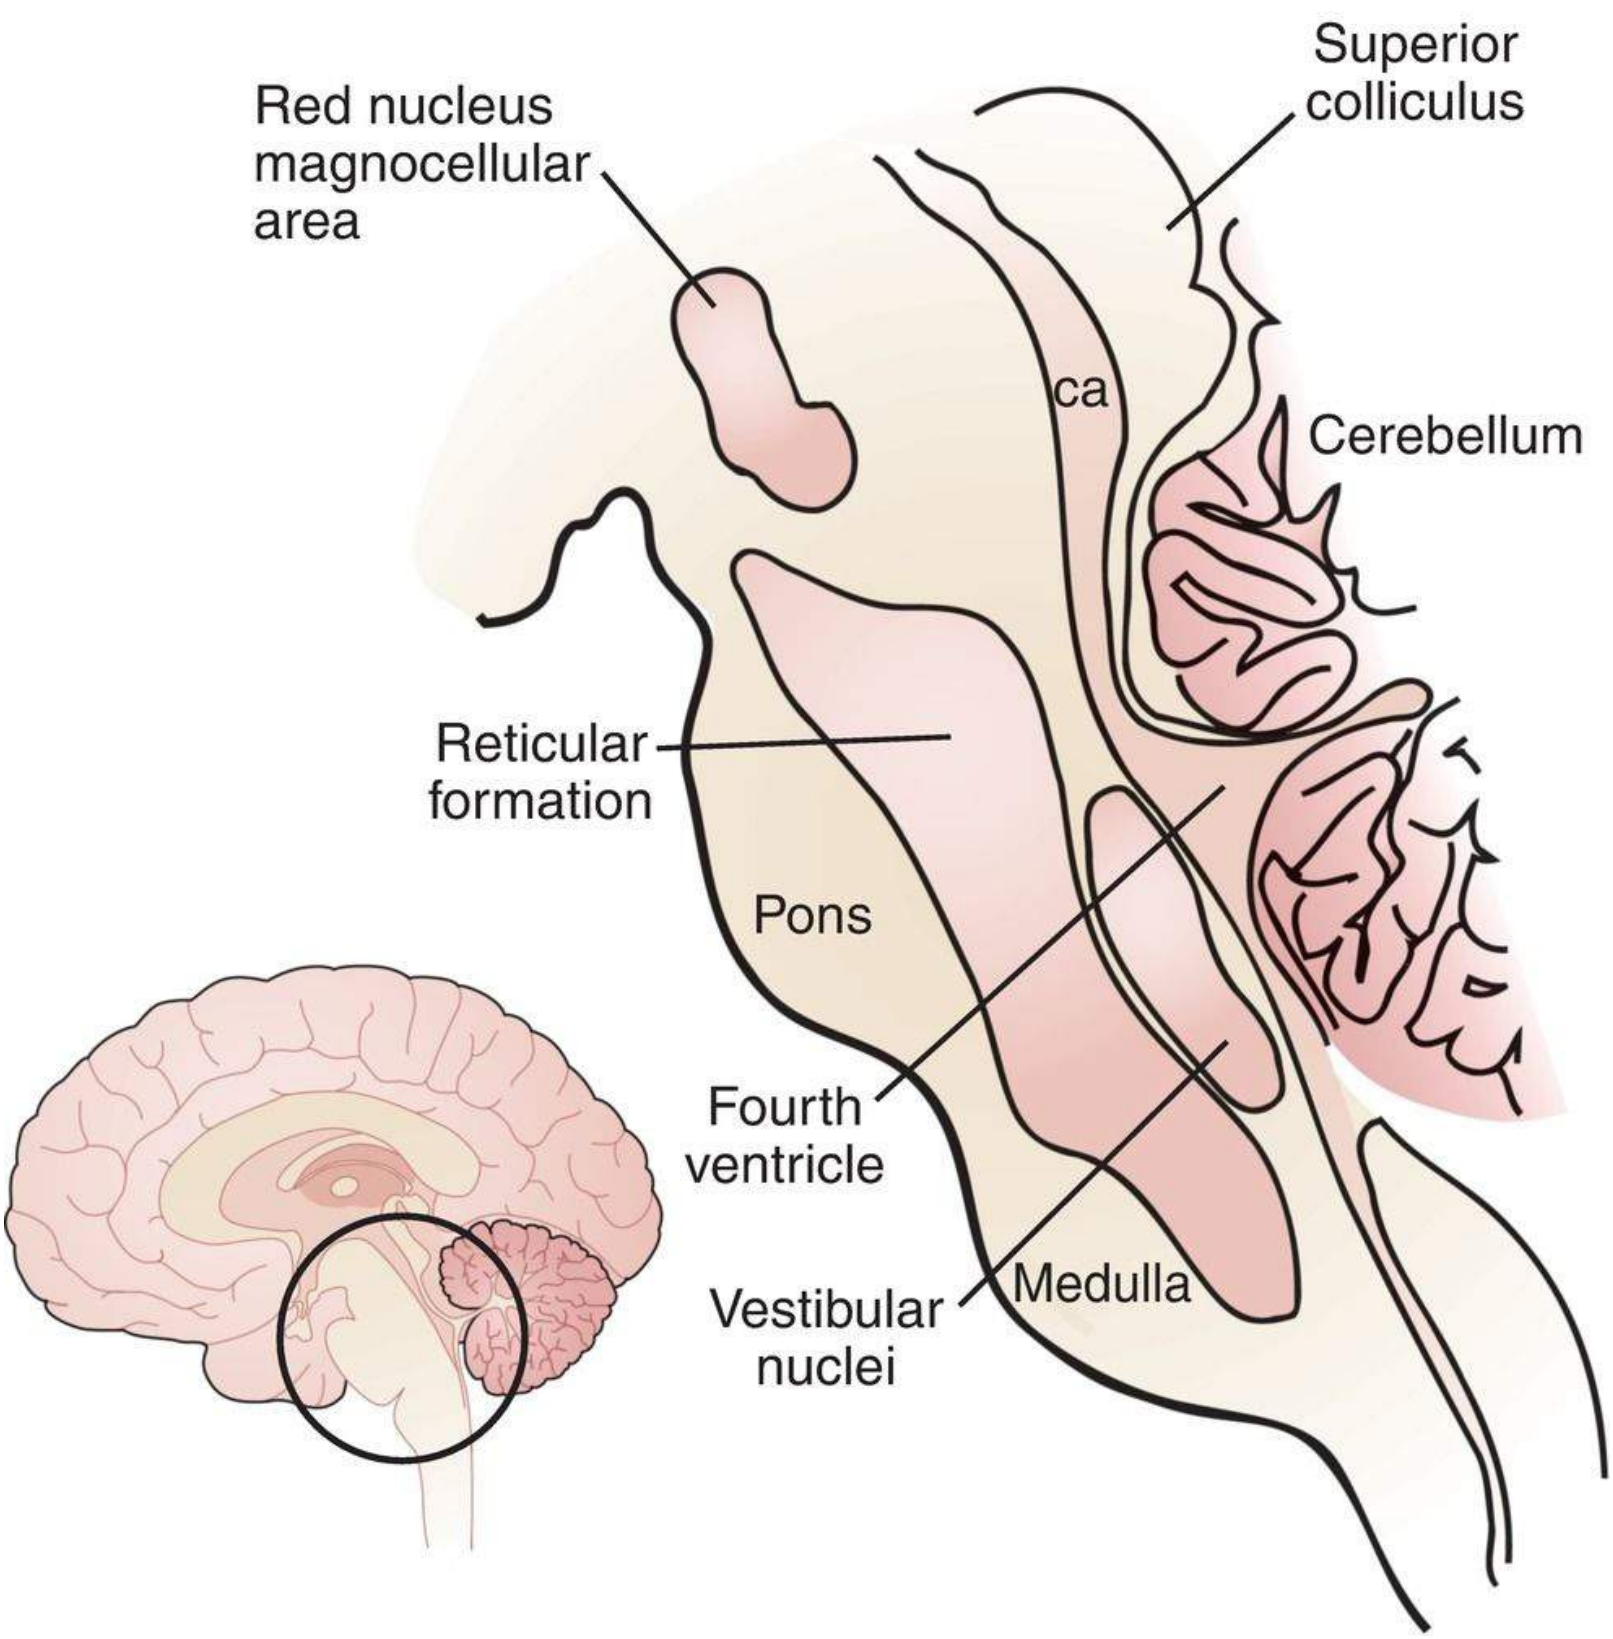

Figure 5.10 Brainstem nuclei of descending motor pathways. The magnocellular portion of the red nucleus is the origin of the rubrospinal tract. The lateral vestibular nucleus is the source of the vestibulospinal tract. The reticular formation is the source of two tracts: one from the pontine portion and one from the medulla. Structures illustrated are from the monkey. ca, cerebral aqueduct.

Rubrospinal tract

The red nucleus of the mesencephalon receives major input from both the cerebellum and the cerebral cortical motor areas. Output via the rubrospinal tract is directed predominantly to contralateral spinal

motor neurons that are involved with movements of the upper limbs. The axons of the rubrospinal tract are located in the lateral spinal white matter. Rubrospinal action enhances the function of motor neurons innervating upper limb flexor muscles while inhibiting extensors. This tract may also influence γ motor neuron function. In higher mammals like humans, the corticospinal tract supersedes most of the function of the rubrospinal tract. However, when lesions of corticospinal tract occur, the rubrospinal tract can partially compensate for the loss of corticospinal tract inputs to upper limb motor neurons.

Vestibulospinal tract

The principal functions of the vestibular system are to activate neck, trunk, and limb muscles to maintain posture in response to movements of the head and to maintain visual fixation of the eyes on a target as the head moves through space. Both of these functions are controlled by pathways that originate from the vestibular complex located in the pons and medulla. The vestibular complex contains four nuclei (*superior*, *lateral*, *medial*, and *inferior vestibular nuclei*) that receive information about the position of the head in space from the vestibular apparatus of the inner ear and proprioceptive information from the spinal cord (see Chapter 4). The vestibular nuclei also are reciprocally connected to the cerebellum and adjacent reticular formation from which it receives sensory- and motor-related inputs. The vestibular nuclei modify both muscle tone and initiate automatic adjustments in posture through two descending pathways, the lateral and medial vestibulospinal tracts.

The *lateral vestibulospinal tract* originates primarily from cells in the lateral vestibular nucleus. The axons from these cells travel in the ipsilateral ventrolateral spinal cord white matter to terminate at all levels of the spinal cord where they excite interneurons and α and γ extensor motor neurons that innervate truncal and proximal limb muscles. These extensor motor neurons and their musculature are important for maintaining posture and modulating posture-related reflexes that help stabilize the body's position against the forces of gravity. As these axons descend, they give off collateral branches at multiple spinal cord levels, which ensure proper coordination of postural reflexes across multiple levels. Lesions in the brainstem secondary to stroke or trauma may abnormally enhance the influence of the vestibulospinal tract and produce dramatic clinical manifestations.

The *medial vestibulospinal tract* arises primarily from the medial vestibulospinal nucleus and descends bilaterally to terminate on motor neuron in the cervical spinal cord that controls neck extensor and flexor muscles. The function of this pathway is to reflexively activate neck muscles in response to changes in head position.

Reticulospinal tracts

The reticular formation is a complicated network of neurons located in the central gray matter core of the brainstem. Many neurons within this network have wide ranging connections that modulate neuronal activity at several CNS levels. Within this network are also discrete circuits that control a diverse set of functions such as sleep, autonomic functions, and eye movements. Within the medial regions of the caudal reticular formation are groups of large neurons that are involved in somatic motor control of both cranial nerve and spinal cord motor neurons. These neurons receive afferent inputs from the many areas including the spinal cord, vestibular nuclei, cerebellum, lateral hypothalamus, **globus pallidus (GP)**, midbrain, and sensorimotor cortex.

Two descending tracts important in the control of spinal lower motor neurons arise from medial reticular formation cells. These pathways mostly influence motor neurons that innervate truncal and limb extensor muscles. Through their influence on gamma motor neurons, these pathways modulate muscle tone and help make anticipatory adjustments in posture during movement. The **medial (pontine) reticulospinal**

tract arises from pontine reticular nuclei and descends bilaterally with an ipsilateral preponderance in the anterior spinal cord white matter. This pathway relays excitatory action potentials to interneurons that influence α and γ motor neuron pools. The **medullary reticulospinal tract** arises from the reticular formation in the medulla and descends ipsilateral in the spinal cord white matter adjacent to the anterior horn. This pathway has an inhibitory influence on interneurons that modulate extensor motor neurons.

Terminations of the brainstem motor tracts correlate with their functions.

The rubrospinal tract terminates mostly on interneurons in the lateral spinal intermediate zone, but it also has some monosynaptic connections directly on motor neurons to muscles of the extremities. This tract supplements the corticospinal tract for independent movements of the upper extremities.

The vestibulospinal and reticulospinal tracts terminate in the ventromedial part of the intermediate zone, an area in the gray matter containing propriospinal interneurons (Fig. 5.11). There are also some direct connections with motor neurons of the neck and back muscles and the proximal limb muscles. These tracts are the main CNS pathways for maintaining posture and head position during movement.

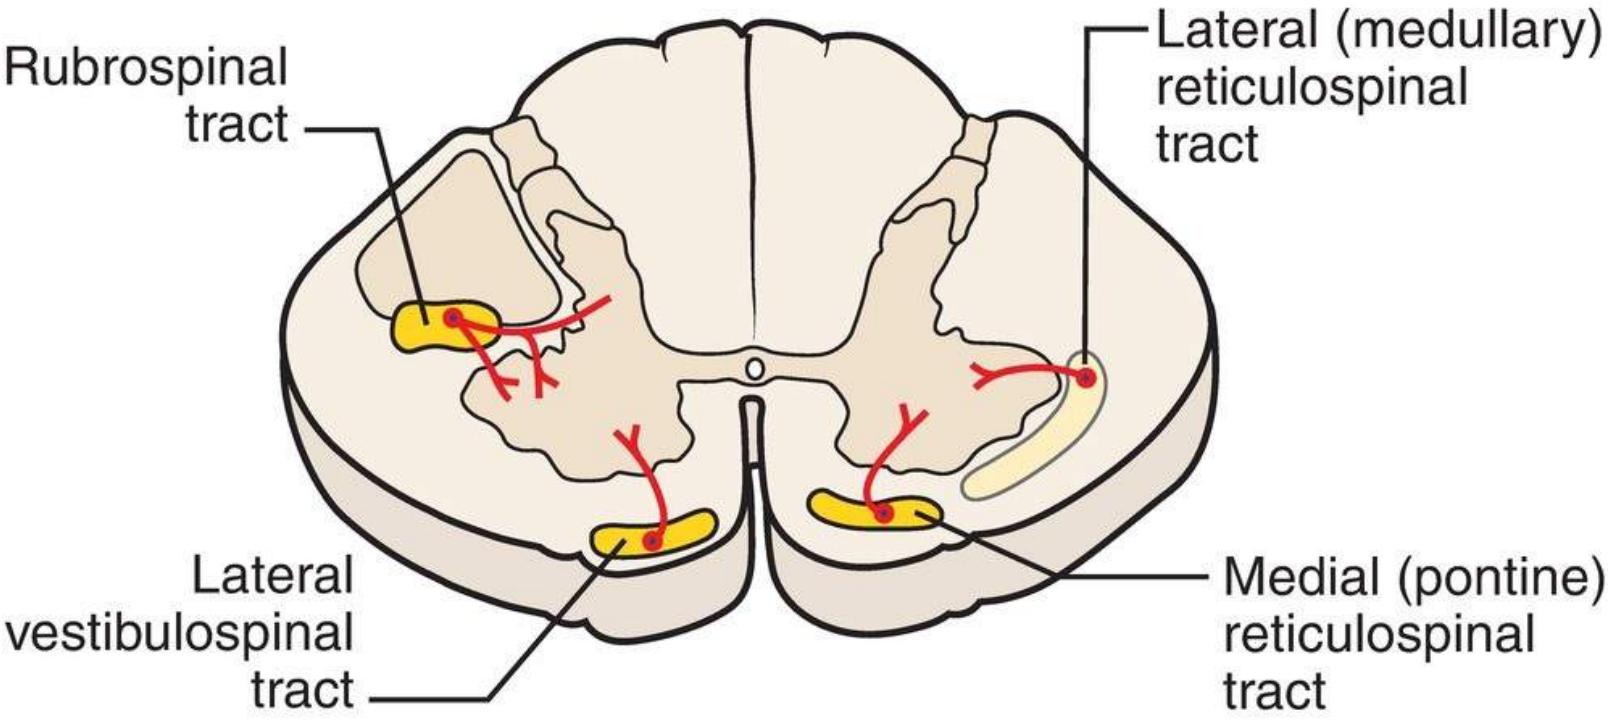

Figure 5.11 Brainstem motor control tracts. The vestibulospinal and reticulospinal tracts influence motor neurons that control axial and proximal limb muscles. The rubrospinal tract influences motor neurons controlling distal limb muscles.

In accordance with their medial or lateral distributions to spinal motor neurons, the reticulospinal and vestibulospinal tracts are thought to be most important for the control of axial and proximal limb muscles, whereas the rubrospinal (and corticospinal) tracts are most important for the control of distal limb muscles, particularly the flexors

Sensory and motor systems work together to control posture.

The maintenance of an upright posture in humans requires active muscular resistance against gravity. For movement to occur, the initial posture must be altered by flexing some body parts against gravity. Balance must be maintained during movement, which is achieved by postural reflexes initiated by several key sensory systems. Vision, the vestibular system, and the somatosensory system are important for postural reflexes.

Somatosensory input provides information about the position and movement of one part of the body with respect to others. The vestibular system provides information about the position and movement of the head and neck with respect to the external world. Vision provides both types of information as well as information about objects in the external world. Visual and vestibular reflexes interact to produce coordinated head and eye movements associated with a shift in gaze. Vestibular reflexes and somatosensory neck reflexes interact to produce reflex changes in limb muscle activity. The quickest of these compensations occurs at about twice the latency of the monosynaptic myotatic reflex. These response types are termed **long-loop reflexes**. The extra time reflects the action of other neurons at different anatomic levels of the nervous system.

CEREBRAL CORTEX ROLE IN MOTOR CONTROL

The cerebral cortical areas concerned with motor function exert the highest level of motor control with influence exerted over both involuntary and voluntary movements. The cortex modifies sensory-evoked involuntary movements like brainstem- and spinal cord–related postural adjustments by continuous modulation of brainstem descending motor pathways and spinal cord reflex pathways. The role of this modulation is readily apparent when it is damaged (see Clinical Focus 5.1). Cortical control of skilled voluntary movements, most of which involve the distal extremities, is accomplished through connections with cranial nerve motor nuclei and spinal cord interneurons and motor neurons that control skilled movement. In addition, these skilled movements are performed on a background of ongoing postural adjustments, which the cortex accomplishes by simultaneously activating brainstem descending motor pathways.

CLINICAL FOCUS 5.1

Decerebrate Rigidity

A patient with a history of poorly controlled hypertension is brought to the emergency department because of sudden collapse and subsequent unresponsiveness. A neurologic examination performed about 30 minutes after onset shows no response to verbal stimuli. Spontaneous movements of the limbs are absent. A painful stimulus, compression of the soft tissue of the supraorbital ridge, causes immediate extension of the neck and all of the limbs. This posture relaxes within a few seconds after the stimulation is stopped. After the patient is stabilized medically, he undergoes a magnetic resonance imaging (MRI) study of the brain. The study demonstrates a large area of hemorrhage bilaterally in the upper portion of the brainstem.

The posture this patient demonstrated in response to the noxious stimulus is termed **decerebrate rigidity**. Its occurrence is associated with lesions of the mesencephalon that eliminate the influence of higher brainstem and cortical centers. The abnormal posture is a result of extreme antigravity extensor muscle activation by the unopposed action of the reticulospinal and vestibulospinal tracts. A model of this condition can be produced in experimental animals by a surgical lesion located between the mesencephalon and pons. ■

Several distinct cortical areas participate in voluntary movement.

Cortical areas associated with voluntary motor control are located in the frontal lobe rostral to the central sulcus and include **primary motor cortex (M1)**, Brodmann area 4 (Fig. 5.12), Brodmann area 6, which lies just rostral to M1, and the frontal eye fields, Brodmann area 8, which control conjugate horizontal movements of the eyes. Brodmann area 6 contains the *supplementary motor area (SMA)* located on the medial surface of the frontal lobe and *premotor area* located on the lateral surface. Other cortical areas that contribute to descending control of voluntary movements are the postcentral gyrus, areas 1, 2, and 3 and areas 5 and 7 of the parietal lobe. Each of these motor areas contributes fibers to the corticospinal tract, the principal efferent motor pathway from the cortex. Motor-related cortex receives information from cortical and subcortical areas that process sensory information, from cortical areas that underlie the motivation to move, and from subcortical structures that modulate motor activity like the cerebellum and basal ganglia.

Figure 5.12 Brodmann cytoarchitectural map of the human cerebral cortex. Area *4* is the primary motor cortex; area *6* is the premotor cortex on the lateral and supplementary motor area on the medial aspect of the hemisphere. Area *8* influences voluntary conjugate eye movements. Areas *1*, *2*, *3*, *5*, and *7* have sensory functions but also contribute axons to the corticospinal tract. The central sulcus divides areas *4* and *3*.

Primary motor cortex

The primary motor cortex, Brodmann area 4, is located in the precentral gyrus laterally and anterior paracentral lobule medially. Like the organization of primary somatosensory cortex, the body is represented as somatotopic maps (Fig. 5.13). Those parts of the body that perform fine movements, such as the digits and the facial muscles, are controlled by a greater number of neurons that occupy more cortical territory than the neurons for the body parts only capable of gross movements. However, studies have shown that the somatotopic map, especially in areas representing the distal extremities, is not just a simple one-to-one representation. Stimulation at a specific location often activates multiple muscles over several spinal segments and muscles are often represented at more than one cortical location.

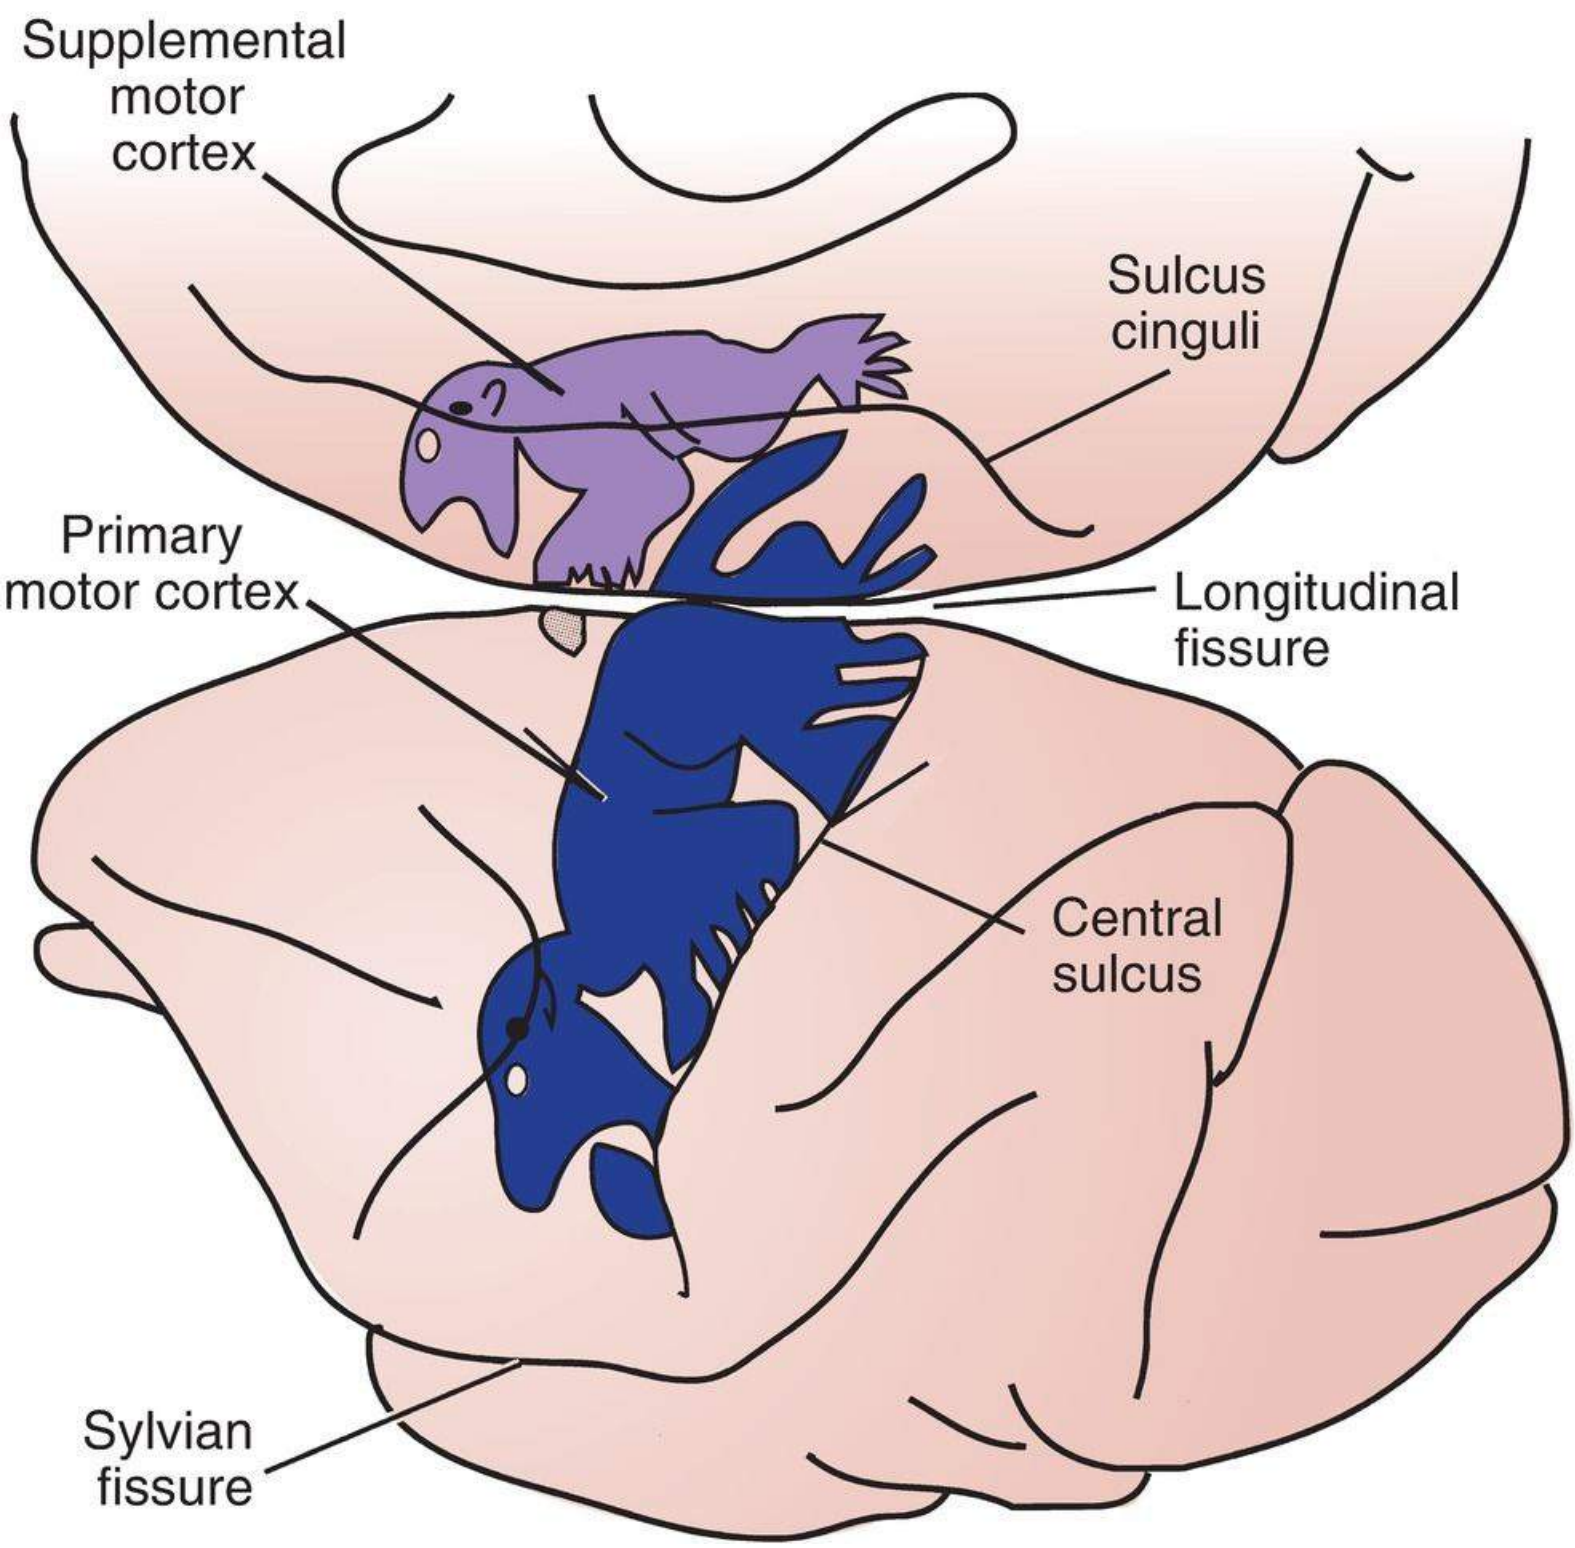

Figure 5.13 A cortical map of motor functions. Primary motor cortex and supplementary motor cortex (SMA) areas in the monkey brain. SMA is on the medial aspect of the hemisphere.

Neurons in M1 have the capability to encode the control of muscle force, muscle length, joint movement, and position. Low-level electrical stimulation of surgically exposed M1 produces twitch-like contraction of a few muscles or, less commonly, a single muscle. Movements elicited from M1 have the lowest stimulation thresholds and are the most discrete of any movements elicited by stimulation of motor cortical areas. Studies have shown that stronger stimulation of greater duration can elicit coordinated movements of multiple muscle groups indicating that M1 is important for controlling the number of muscles activated for a particular movement as well the trajectory and force of movements.

Stimulation of M1 body areas produces contralateral movement, whereas stimulation of cortical areas

where the head is represented may produce bilateral motor responses. Destruction of any part of the primary motor cortex leads to immediate paralysis of the muscles controlled by that area. In humans, some function may return days to months later, but the movements lack the fine degree of muscle control of the normal state. For example, after a lesion in the arm area of M1, the use of the hand recovers, but the capacity for discrete finger movements does not.

M1 receives somatosensory input, both cutaneous and proprioceptive, as well as motor-related inputs from the cerebellum and basal ganglia via the thalamus. Other afferent projections come from the contralateral motor cortex and many other ipsilateral cortical areas. There are many axons between the precentral (motor) and postcentral (somatosensory) gyri and many connections with visual cortical areas. Because M1 receives continuous sensory feedback regarding the performance of a movement, the cortical motor neurons can alter ongoing motor activity in response to peripheral sensory feedback. For example, cells innervating a particular muscle may respond to cutaneous stimuli originating in the area of skin that moves when that muscle is active, and they may respond to proprioceptive stimulation from the muscle to which they are related. The primary motor cortex also has the capability to control the flow of somatosensory information to motor control centers by way of efferent fibers from the primary motor cortex that terminate in brain areas that contribute to ascending somatic sensory pathways.

The importance of close coupling of sensory and motor functions is demonstrated by two cortically controlled reflexes that were originally described in experimental animals as being important for maintaining normal body support during locomotion—the placing and hopping reactions. The **placing reaction** can be demonstrated in a cat by holding it so that its limbs hang freely. Contact of any part of the animal's foot with the edge of a table provokes immediate placement of the foot on the table surface. The **hopping reaction** is demonstrated by holding an animal so that it stands on one leg. If the body is moved forward, backward, or to the side, the leg hops in the direction of the movement so that the foot is kept directly under the shoulder or hip, stabilizing the body position. Lesions of the contralateral precentral or postcentral gyrus abolish placing. Hopping is abolished by a contralateral lesion of the precentral gyrus.

Supplementary motor area

The SMA **(supplementary motor area)** portion of Brodmann area 6 is located on the medial surface of the hemispheres, above the cingulate sulcus and rostral to the leg area of the primary motor cortex (see Fig. 5.13). SMA receives input from other motor cortical areas and the prefrontal cortex, is reciprocally connected with M1, and projects directly to the reticular formation and spinal cord. Experimental lesions in M1 eliminate the ability of SMA stimulation to produce movements. SMA contains a somatotopic map of the body although it is less precisely organized than that of M1. Electrical stimulation of SMA produces movements, but a higher stimulus strength is required than for M1 and the movements produced are more complex and frequently bilateral. Evidence suggests that SMA is important for the movements we decide to make volitionally. The importance of SMA for this type of motor programming was demonstrated in a series of experiments that examined functional activation of motor cortical activities using functional magnetic resonance. When a subject makes a series of random finger movements, activity is localized to the hand area of M1. When the subject plans and makes a movement of the fingers, activity is observed in both M1 and SMA, and when finger movements are mentally planned, but not undertaken, activity is only observed in SMA. Additionally, lesions in SMA reduce the number of self-initiated movements but have little effect on movements evoked by external sensory cues.

Premotor cortex

The premotor cortex occupies an area on the lateral surface of the frontal lobe rostral to M1. Like SMA,

there is a somatotopic representation of the body and higher stimulus intensities are required to elicit movements. Premotor cortex receives inputs from somatosensory areas of the parietal cortex and projects to M1, reticular formation motor-related nuclei, and spinal cord areas associated with control of proximal limb and axial muscles. The significant sensory input from cortical areas associated with somatosensory and visual movement processing and outputs to motor groups associated with postural adjustments suggests that premotor cortex is important for guiding movements in response to sensory stimuli. Studies have shown that premotor cortex neurons play an important role in conditional motor tasks where a particular movement, like reaching in a particular direction, is made in response to a learned cue such as a visual stimulus. In these cases, premotor neurons are active following the presentation of the visual cue and before the movement is made. Lesions in this area impair the ability to carry out conditional motor tasks. This and other evidence suggests that the premotor cortex is important for encoding movement intention and the selection of movements based on environmental sensory inputs.

Primary somatosensory cortex

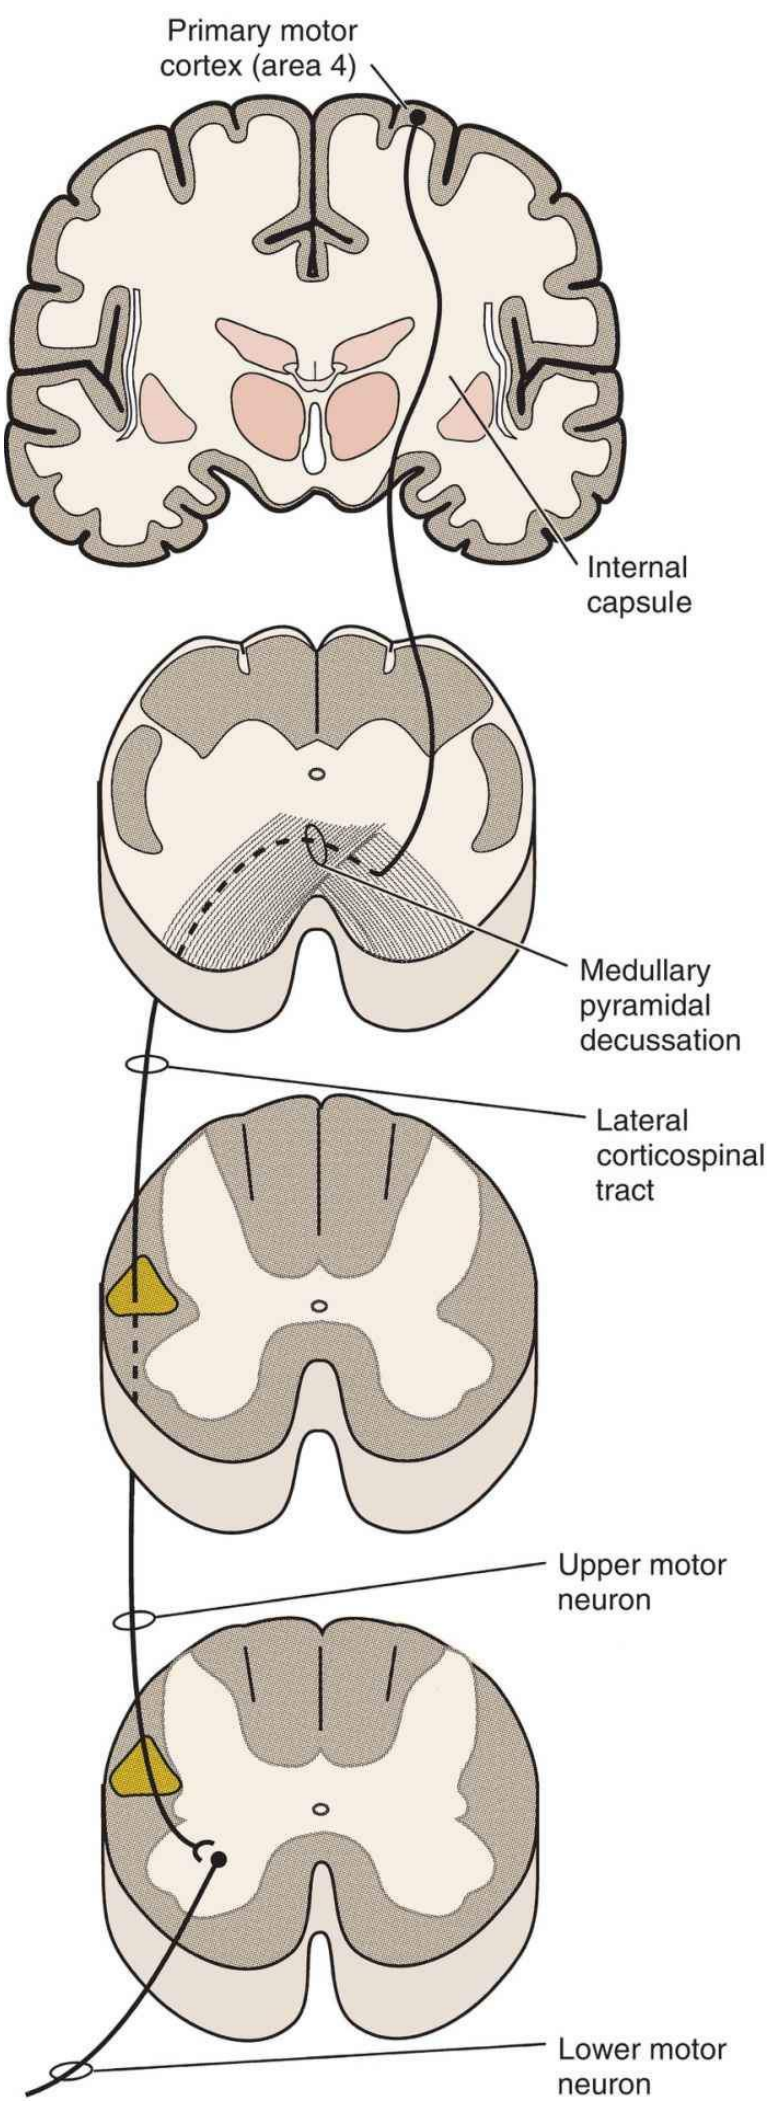
The primary somatosensory cortex (S1) (Brodmann areas 1, 2, and 3) lies on the postcentral gyrus (see Fig. 5.13) and has a role in movement. Electrical stimulation here can produce movement, but thresholds are two to three times higher than in M1. S1 is reciprocally interconnected with M1 in a somatotopic pattern—for example, arm areas of sensory cortex project to arm areas of motor cortex. S1 Efferent fibers travel in the corticospinal tract and terminate in the dorsal horn areas of the spinal cord. These terminations are thought for modifying sensory inputs related to movements.

Superior parietal lobe

The superior parietal lobe (Brodmann areas 5 and 7) also has important motor functions. This area processes somatosensory and visual information related to the location of objects in the visual field. In addition to contributing a small number of fibers to the corticospinal tract, the superior parietal lobe is well connected to the motor areas in the frontal lobe, especially SMA and the frontal eye field Brodmann area 8. Studies in animals and humans suggest this area is important for the use of complex sensory information in the production of movement and for relaying visual information related to conjugate eye movements.

Corticospinal tract is the primary efferent path from the cortex.

The corticospinal tract originates from motor areas of the cerebral cortex with the largest contribution from M1 (about one third of the fibers). The corticospinal tract is also referred to as the **pyramidal tract** because it traverses the medullary pyramids on its way to the spinal cord (Fig. 5.14). All other descending motor tracts emanating from the brainstem are generally grouped together as the extrapyramidal system. In primates, 10% to 20% of corticospinal fibers end directly on motor neurons; the others end on interneurons associated with motor neurons.



Primary motor cortex (area 4)
Internal capsule
Medullary pyramidal decussation
Lateral corticospinal tract
Upper motor neuron
Lower motor neuron

Figure 5.14 The corticospinal tract. Axons arising from cortical motor areas descend through the internal capsule, decussate in the medulla, descend in the lateral funiculus of the spinal cord as the lateral corticospinal tract, and terminate on motor neurons and interneurons in the ventral horn areas of the spinal cord. Note the designations of upper and lower motor neurons.

From the cerebral cortex, the corticospinal tract axons descend through the brain along a path located between the basal ganglia and the thalamus, known as the **internal capsule**. They then continue along the ventral brainstem as the **cerebral peduncles** and through the pyramids of the medulla. Most of the corticospinal axons cross the midline in the medullary pyramids and descend in the contralateral spinal cord. Thus, the motor cortex in each hemisphere controls the muscles on the contralateral side of the body. After crossing in the medulla, the corticospinal axons descend in the dorsal lateral white matter of the spinal cord as the *lateral corticospinal tract* and terminate in lateral motor pools that control distal muscles of the limbs. A smaller group of axons does not cross in the medulla and descends as the *ventral (anterior) corticospinal tract* in the anterior spinal white matter. These axons terminate in the motor neuron pools and adjacent intermediate zone interneurons that control the axial and proximal musculature. Damage to the corticospinal tract above the level of the decussation or lateral corticospinal tract at the level of the spinal cord produces a characteristic type of impairment in motor control. Initially, muscles are weak and flaccid, but following a period of recovery, spastic paralysis, hypertonia, hyperreflexia, and pathologic reflexes (Babinski sign) are observed.

In addition to the direct corticospinal tract, there are other indirect pathways by which cortical fibers influence motor function. Some cortical efferent fibers project to the reticular formation and then to the spinal cord via the reticulospinal tract; others project to the red nucleus and then to the spinal cord via the rubrospinal tract. A third group of axons, termed corticonuclear or corticobulbar, terminate on brainstem interneurons and cranial nerve motor neurons for control of head musculature.

INTEGRATED MEDICAL SCIENCES

Spasticity

Patients who develop lesions, such as an infarction in the internal capsule of the cerebrum or spinal cord trauma affecting the anterior two thirds of the cord, develop a disorder of motor control that is termed **spasticity**. Clinically, this is characterized by (1) weakness, slowness, and clumsiness of movement in body parts below the level of the lesion; (2) abnormally increased muscle stiffness to passive lengthening; and (3) abnormally overactive muscle stretch reflexes in those limbs. The neurophysiology of spasticity is not fully understood, but the spinal interneurons involved with motor control become disinhibited and overactive as a result of impaired inhibitory influence from the upper brainstem and cortex. Although the increased muscle tone is partly compensatory for the impaired corticospinal tract input, it may become so exaggerated that the affected limbs become even less functional as a result of the exaggerated muscle stiffness.

Several medications are available to treat spasticity. These medications target either the CNS pathways associated with motor control or peripherally on muscles themselves. Dantrolene is a

medication that directly targets the skeletal muscle dissociating the excitation–contraction coupling by interfering with Ca^{++} release from the sarcoplasmic reticulum (see Chapter 8). Baclofen is a medication that is an analog of the CNS inhibitory neurotransmitter γ-aminobutyric acid (GABA). When given orally or intrathecally using an implanted baclofen pump, it binds to the GABAB receptor and inhibits motor activity at the spinal cord level. Injection of precisely diluted amounts of the toxin produced by the anaerobic bacteria *Clostridium botulinum* into the abnormal muscles is another method to reduce their overactivity. The toxin impairs release of the neurotransmitter acetylcholine from the motor neuron at the synapse with muscle cells. Proper dosing partially weakens the muscle and reduces the abnormally increased muscle stiffness. Gaining an understanding of the physiology of synaptic vesicle release and discovering the role of the botulinum toxins in disturbing this process have allowed treatment with these agents to be made available to patients with conditions that formerly were difficult to treat. ■

BASAL GANGLIA AND MOTOR CONTROL

The **basal ganglia** are a group of subcortical nuclei located primarily in the base of the forebrain, with some in the diencephalon and upper brainstem. The striatum, globus pallidus, subthalamic nucleus, and substantia nigra comprise the basal ganglia. Input is derived primarily from motor areas of the cerebral cortex, and output is directed back, via a relay in the thalamus, to cortical areas concerned with movement. Basal ganglia action influences the entire motor system and plays a role in the preparation and execution of coordinated movements.

The forebrain (telencephalic) components of the basal ganglia consist of the **striatum**, which is made up of the **caudate nucleus** and the **putamen**, and the **globus pallidus (GP)**. The GP has two subdivisions: the *external segment (GPe)*, adjacent to the medial aspect of the putamen, and the *internal segment (GPi)*, medial to the GPe. The other main nuclei of the basal ganglia are the **subthalamic nucleus** in the diencephalon and the **substantia nigra** in the mesencephalon.

Basal ganglia are extensively interconnected.

Although the circuitry of the basal ganglia appears complex at first glance, it can be simplified into input, output, and internal pathways (Fig. 5.15). Input from the cerebral cortex is directed to the striatum and the subthalamic nucleus. The predominant nerve cell type in the striatum is termed the medium spiny neuron, based on its cell body size and dendritic structure. This type of neuron receives input from all of the cerebral cortex except for the primary visual and auditory areas. The input is roughly somatotopic and is excitatory via glutamate-containing neurons. The caudate receives most of its input from prefrontal, premotor, and supplementary motor cortex, whereas the putamen receives most of the cortical input from primary sensorimotor cortical areas. The subthalamus receives excitatory glutaminergic input from cortical areas concerned with motor function, including eye movement.

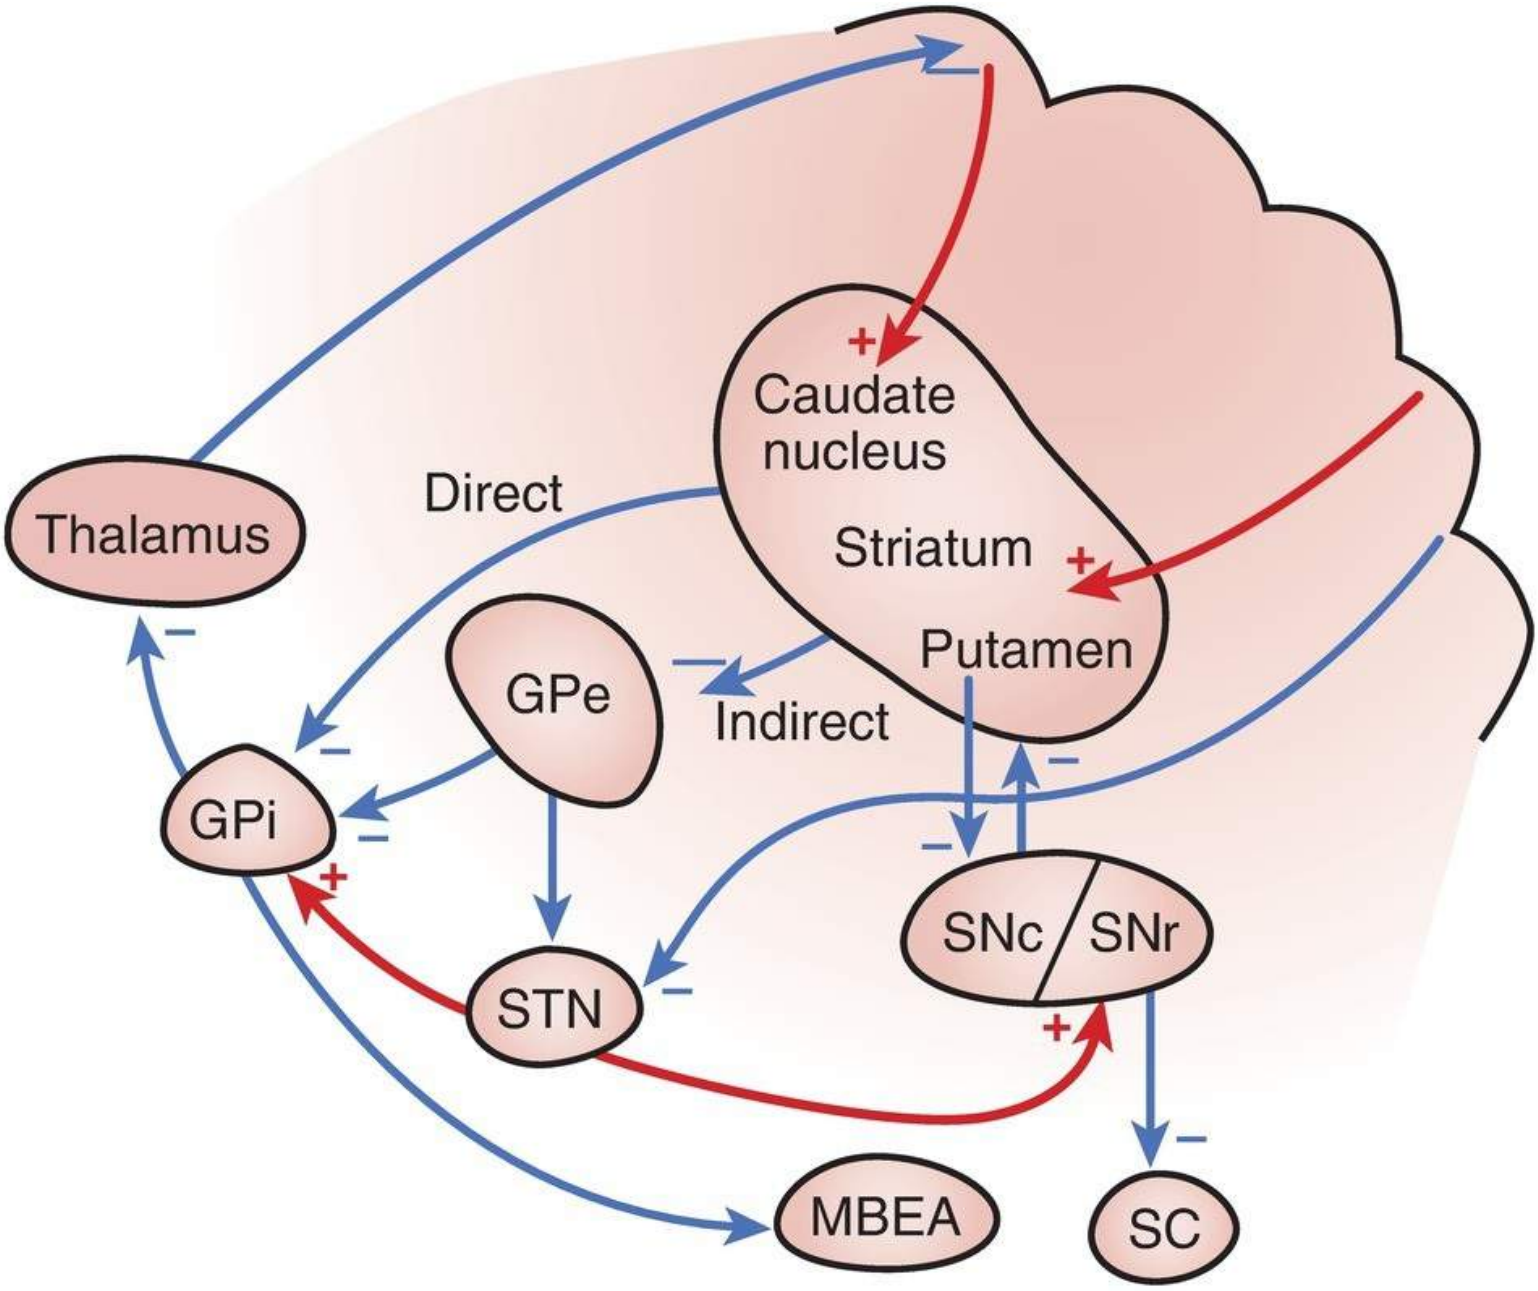


Figure 5.15 Basal ganglia nuclei and circuitry. The neuronal circuit of cerebral cortex to striatum to globus pallidus interna (GPi) to thalamus and back to the cortex is the main pathway for basal ganglia influence on motor control. Note the direct and indirect pathways of the striatum, GPi, globus pallidus externa (GPe), and subthalamic nucleus (SNT). GPi output also flows to the midbrain extrapyramidal area (MBEA). The substantia nigra pars reticulata (SNr) to superior colliculus (SC) pathway is important in eye movements. Excitatory pathways are shown in *red*, and inhibitory pathways are shown in *blue*. SNc, substantia nigra pars compacta.

Basal ganglia output is from the GPi and a segment of the substantia nigra. This output is inhibitory using γ-aminobutyric acid (GABA) as the neurotransmitter. The GPi output is directed to ventrolateral and ventral anterior nuclei of the thalamus, which feed back to the cortical motor areas. Output from the GPi is also directed to a region in the upper brainstem termed the midbrain extrapyramidal area. This area then projects to the neurons of the reticulospinal tract. The substantia nigra output arises from the **pars reticulata (SNr)**, which is histologically similar to the GPi. The output is directed to the same areas that receive GPi terminations as well as to the superior colliculus of the mesencephalon, which is involved in eye movement control.

The GPe, the subthalamic nucleus, and the pars compacta region of the substantia nigra (SNc) form important internal pathways within the basal ganglia. The GPe receives GABAergic inhibitory inputs from the striatum. The output of the GPe is inhibitory via GABA release and is directed to both the GPi and the subthalamic nucleus. The subthalamic nucleus output is excitatory and is directed to the GPi and the SNr. The striatum–GPe–subthalamic nucleus–GPi circuit has been termed the **indirect pathway**. Activation of this pathway inhibits the excitatory drive of the thalamus on cortical motor neurons resulting in decreased motor activity. In contrast, activation of the **direct pathway**, in which output from the striatum directly inhibits GPi, increases thalamic excitatory outputs and increases motor activity (see Fig. 5.15). The SNc output modulates cortical influence on the striatum via dopamine-releasing neurons, which are excitatory to the direct pathway and inhibitory to the indirect pathway.

Functions of the basal ganglia are partially revealed by disease.

Basal ganglia diseases produce profound motor dysfunction in humans. The disorders can result in reduced motor activity, **hypokinesis**, or abnormally enhanced activity, **hyperkinesis**. Two well-known neurologic conditions that show histologic abnormality in basal ganglia structures, **Parkinson's disease (PD)** and **Huntington's disease**, illustrate the effects of basal ganglia dysfunction. Patients with PD show a general slowness of initiation of movement and paucity of movement when in motion. The latter takes the form of reduced arm swing and lack of truncal swagger when walking. These patients also have a resting tremor of the hands, described as "pill rolling." The tremor stops when the hand goes into active motion. At autopsy, patients with PD show a severe loss of dopamine-containing neurons in the SNc region. Patients with Huntington's disease have uncontrollable, quick, brief movements of individual limbs. These movements are similar to what a normal individual might show when flicking a fly off a hand or when quickly reaching up to scratch an itchy nose. At autopsy, a severe loss of inhibitory striatal neurons is found.

The function of the basal ganglia in normal individuals appears to be modulation of cortical output. One theory is that the primary action is to allow desired motions to proceed and to inhibit undesirable movements. Neuronal activity is increased in the appropriate areas of the basal ganglia prior to the actual execution of movement. The basal ganglia act as a brake on undesirable motion by inhibitory output from the GPi back to the thalamus and, ultimately, to the motor cortex. The loss of dopamine-releasing neurons in PD is thought to enhance this braking effect by increasing the activity of the indirect basal ganglia pathway. This effect ultimately increases the inhibitory output of the GPi because the subthalamus is disinhibited. Decreased motor action is the final result. Hyperkinetic disorders such as Huntington's disease are thought to result from decreased GPi output resulting from loss of inhibitory influence of the direct pathway.

In addition to the basal ganglia motor loops described above, the basal ganglia also have circuits that are involved in modulating emotional and intellectual activities of the cortex and disorders in these functions frequently accompany the motor signs observed in basal ganglia disorders (Clinical Focus 5.2).

CLINICAL FOCUS 5.2

Stereotactic Neurosurgery and Deep Brain Stimulation for Parkinson's Disease

Parkinson's disease (PD) is a degenerative central nervous system disorder producing a generalized slowness of movement and resting tremor of the hands. Loss of dopamine-producing neurons in the substantia nigra pars compacta is the underlying pathology of the condition. Treatment with medications that stimulate an increased production of dopamine by the surviving substantia nigra neurons has revolutionized the management of Parkinson's disease. Unfortunately, the benefit of the medications tends to lessen after 5 to 10 years of treatment. After prolonged treatment, patients develop medication-related motor complications and motor fluctuations characterized by dyskinesias and the sudden loss of medication effectiveness producing significant decreases in mobility. Improved knowledge of basal

ganglia circuitry has enabled neurosurgeons to develop surgical procedures to ameliorate some of the effects of the advancing disease.

Degeneration of the dopamine-releasing cells of the substantia nigra decreases inhibitory output of the striatum. The effect of this decreased inhibition on the direct pathway is less inhibition of GPi. The effect of decreased inhibitory drive on the indirect pathway results is increased activity in GPi. Enhanced activity of the GPi increases its inhibitory influence on the thalamus and results in decreased excitatory drive back to the cerebral cortex and hence decreased muscle activity.

The use of stereotactic neurosurgery to treat Parkinson's disease is generally employed after a patient no longer shows good symptomatic control with medications. Stereotactic neurosurgery is a technique in which a small probe is precisely placed into a target within the brain. Magnetic resonance imaging (MRI) of the brain defines the three-dimensional location of the desired target. The surgical probe is introduced into the brain through a small hole made in the skull and is guided to the target by the surgeon by using the MRI coordinates.

In the past, stereotactic surgery was directed at the GPi, which was destroyed by heating or passing direct electrical current through the probe. This destruction of GPi reduces the inhibitory outflow of the GPi and movement improves.

More recently, GPi lesioning has been replaced by the implantation of neurostimulators whose electrodes are implanted in either the GPi or a second target, the subthalamic nucleus. Although the exact mechanism involved is not known, high-frequency electrical stimulation of the GPi or subthalamic nucleus paradoxically reduces their output and, thereby, improves function of the thalamocortical pathway for motor control. Although DBS has proven to be an effective treatment for PD, like medical management of this disorder, it is only a symptomatic treatment and does not slow disease progression. ■

CEREBELLUM IN THE CONTROL OF MOVEMENT

The **cerebellum**, or "little brain," lies caudal to the occipital lobe and is attached to the posterior aspect of the brainstem through three-paired fiber tracts: *inferior*, *middle*, and *superior* **cerebellar peduncles**. The cerebellum receives motor, sensory, and cognitive information from peripheral sensory receptors, the brainstem, and the cerebral cortex. Most of this information reaches the cerebellum through the inferior and middle cerebellar peduncles. The efferent projections of the cerebellum arise from three pairs of intrinsic nuclei located deep inside the cerebellum: the **fastigial**, interposed (or **interpositus**), and **dentate**. In some classification schemes, the interposed nucleus is further divided into the *emboliform* and *globose* nuclei. Cerebellar efferents are directed mainly to other motor control areas of the CNS and mostly exit the cerebellum in the superior cerebellar peduncle.

Structural divisions of the cerebellum correlate with function.

The cerebellar surface is arranged in multiple, parallel, longitudinal folds termed folia. Two deep transverse fissures divide the cerebellum into three main morphologic components—*anterior*, *posterior*, and *flocculonodular lobes* (Fig. 5.16). The cerebellum can also be divided in the sagittal plane into three functional subdivisions—the *vestibulocerebellum*, *spinocerebellum*, and *cerebrocerebellum*. These divisions appear in sequence during evolution. The lateral cerebellar hemispheres increase in size along with expansion of the cerebral cortex. The three divisions have similar intrinsic circuitry; thus, the function of each depends on the nature of the inputs it receives and output nucleus to which it projects.

V

Figure 5.16 The structure of the cerebellum. The three lobes are shown: anterior, posterior, and flocculonodular. The functional divisions are demarcated by color. The vestibulocerebellum (*white*) is the flocculonodular lobe, which projects to the vestibular (V) nuclei. The spinocerebellum includes the vermis (*green*) and the intermediate zone (*violet*), which project to the fastigial (F) and interposed (IP) nuclei, respectively. The cerebrocerebellum (*pink*) projects to the dentate nuclei (D).

The **vestibulocerebellum** is composed of the flocculonodular lobe. It receives input from the vestibular system about the position of the head in space and information concerning eye movements and visual processing from brainstem nuclei. Output goes either directly or indirectly, through a relay in the fastigial nucleus, back to vestibular and reticular formation nuclei in the brainstem The vestibulocerebellum functions to control equilibrium by influencing brainstem descending motor pathways associated with axial and proximal musculature and eye movements through actions on brainstem cranial nerve nuclei. Damage to the vestibulocerebellum is associated with falling, gait problems, tremor of the head or trunk, and deficiencies in pursuit eye movements.

The medially placed **spinocerebellum** consists of the midline vermis plus the medial portion of the lateral hemispheres, called the intermediate or paravermal zone (see Fig. 5.16). There is a somatotopic representation of the body in the spinocerebellum with the legs represented anteriorly and the head posteriorly. The trunk is mapped to the vermis and the limbs more laterally in the intermediate zone. Spinocerebellar pathways carrying somatosensory information terminate in the vermis and intermediate zones in somatotopic arrangements. The auditory, visual, and vestibular systems, and sensorimotor cortex, through a relay in the pons, also project to this portion of the cerebellum. Output from the vermis is directed to the fastigial nuclei, which project through the inferior cerebellar peduncle to the vestibular nuclei, reticular formation of the pons and medulla, and upper levels of the spinal cord. Output from the intermediate zones goes to the interposed nuclei and then to the red nucleus, and ventrolateral nucleus of the thalamus, which is connected motor cortical areas. The vermal component of the spinocerebellum mainly controls axial musculature important for posture and locomotion. The intermediate zone of the spinocerebellum is thought to be important for controlling ongoing limb movements. The intermediate zone receives information regarding an intended movement from cortical motor areas and sensory feedback information about the actual movements from ascending spinocerebellar pathways. It then compares intention to actual movements and sends correcting signals back to motor cortex.

The **cerebrocerebellum** occupies the lateral aspects of the cerebellar hemispheres. Input comes exclusively from the cerebral cortex, relayed through the middle cerebellar peduncles from nuclei in the pons. The cortical areas that are prominent in motor control are the sources for most of this input. Output is directed to the dentate nuclei and, ultimately, to the motor and premotor areas of the cerebral cortex via the ventrolateral thalamus. The cerebrocerebellum is thought to participate in the planning, control, and timing of learned skilled movements, especially those that involve the distal extremities.

Intrinsic circuitry of the cerebellum is regulated by Purkinje cells.

The cerebellar cortex is composed of five types of neurons arranged into three layers (Fig. 5.17). The *molecular layer* is the outermost and consists mostly of axons and dendrites plus two types of interneurons: stellate cells and basket cells. The *Purkinje cell layer* contains the Purkinje cells, whose dendrites reach upward into the molecular layer in a fanlike array. The Purkinje cells are the efferent neurons of the cerebellar cortex. Their action is inhibitory, with GABA being the neurotransmitter. Deep to the Purkinje cells is the granular layer, containing Golgi cells and small local circuit neurons, the granule cells. The granule cells are numerous; there are more granule cells in the cerebellum than neurons in the entire cerebral cortex!

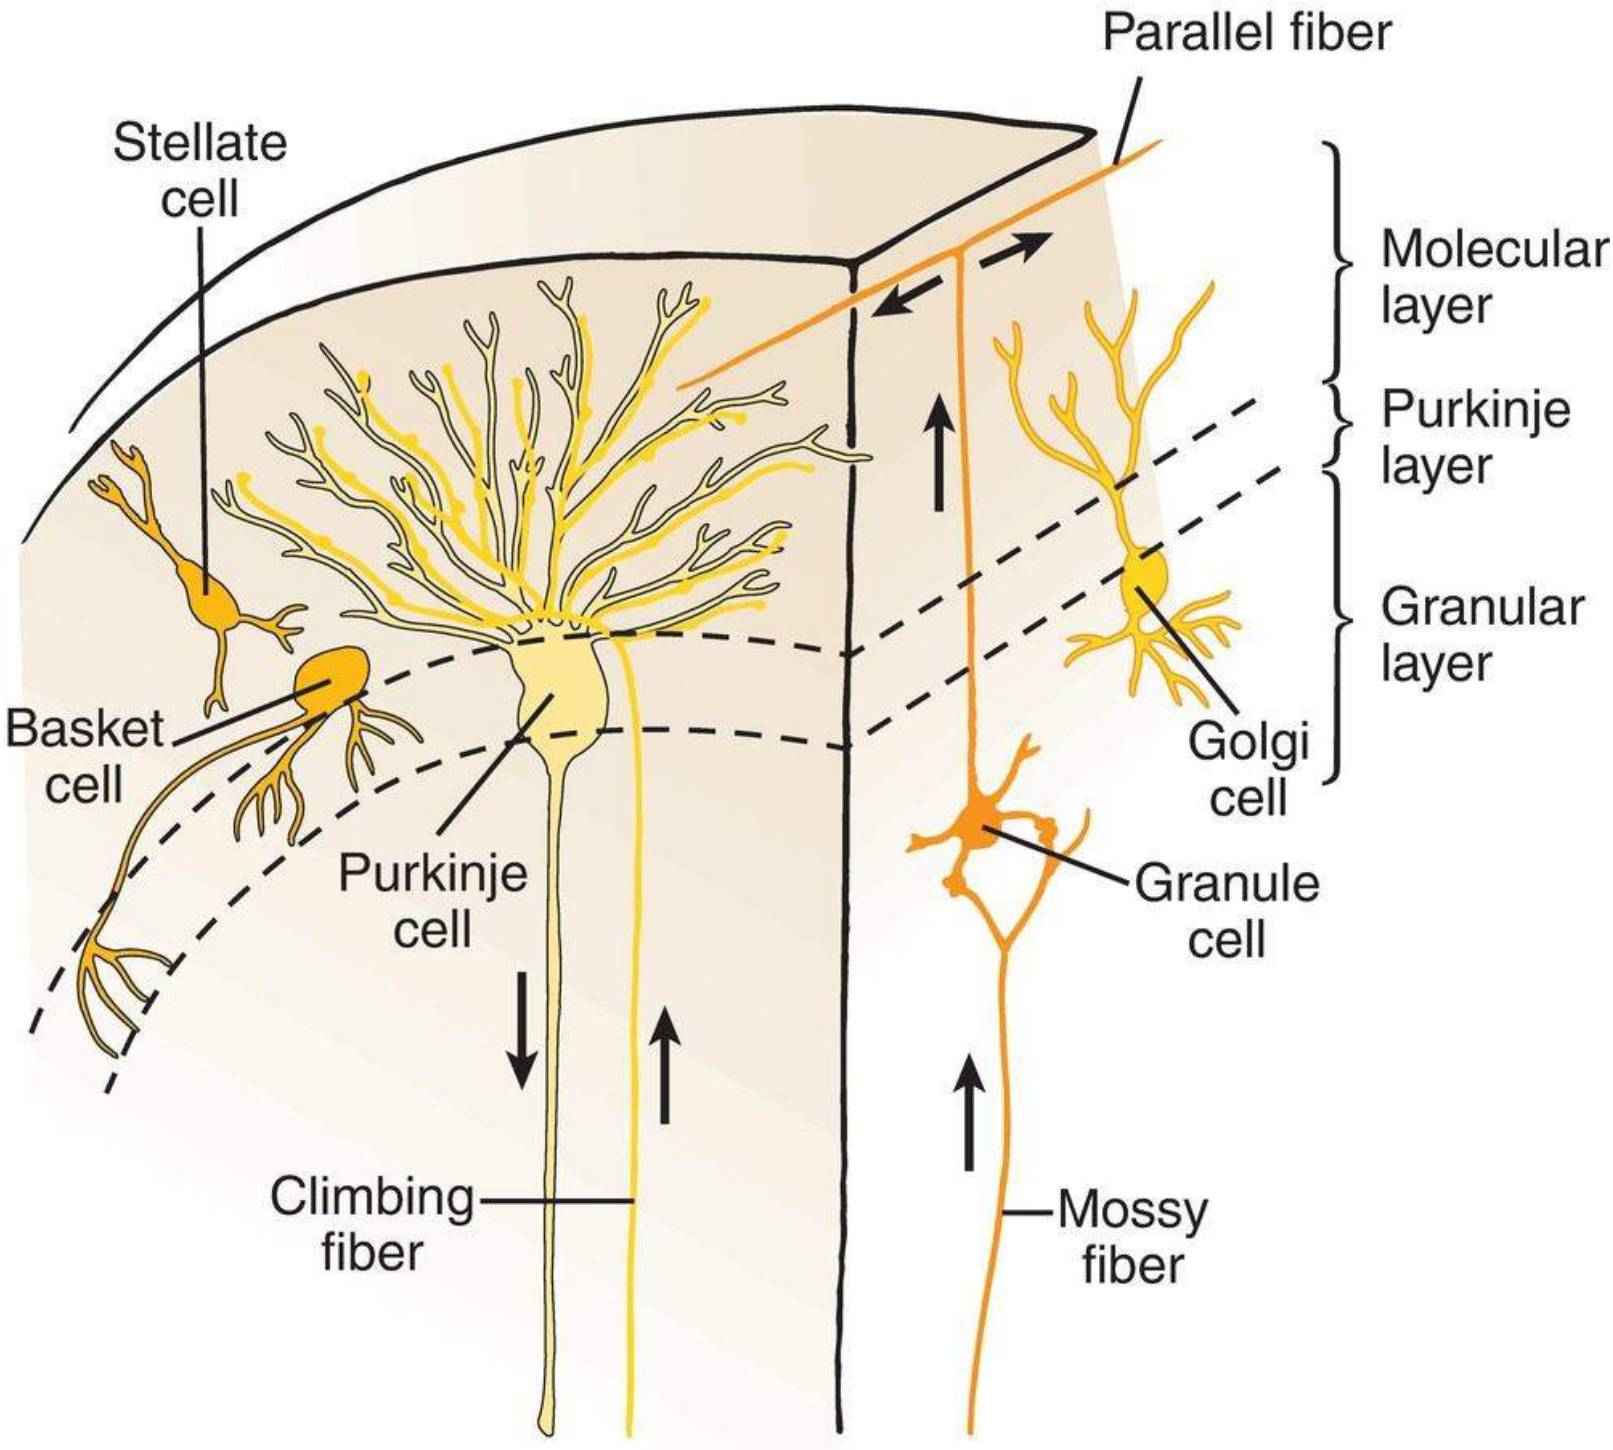

Figure 5.17 Cerebellar circuitry. The cell types and action potential pathways are shown. Mossy fibers

are afferent from the spinal cord and the cerebral cortex. Climbing fibers are afferent from the inferior olive nucleus in the medulla and synapse directly on the Purkinje cells. The Purkinje cells are the efferent pathways of the cerebellum.

Afferent axons to the cerebellar cortex are of two types: **mossy fibers** and **climbing fibers**. Mossy fibers arise from spinal cord and brainstem neurons, including those of the pons that receive input from the cerebral cortex. Mossy fibers make multicontact excitatory glutaminergic synapses on granule cells. The axons of the granule cells then ascend to the molecular layer and bifurcate, forming the parallel fibers that travel perpendicular to and synapse with the dendrites of hundreds of Purkinje cells. Mossy fibers discharge at high tonic rates, 50 to 100 Hz, which increase further during voluntary movement. When mossy fiber input is of sufficient strength to bring a Purkinje cell to threshold, a single action potential results.

Climbing fibers arise from the inferior olive, a nucleus in the medulla. Each climbing fiber synapses directly on the dendrites of a Purkinje cell and exerts a strong excitatory influence. One action potential in a climbing fiber produces a burst of action potentials in the Purkinje cell, called a *complex spike*. Climbing fibers also synapse with basket, Golgi, and stellate interneurons, which then make inhibitory contact with adjacent Purkinje cells. This circuitry allows a climbing fiber to produce excitation in one Purkinje cell and inhibition in adjacent ones.

Mossy and climbing fibers also give off excitatory collateral axons to the deep cerebellar nuclei before reaching the cerebellar cortex. The cerebellar cortical output (Purkinje cell efferents) is inhibitory to the cerebellar and vestibular nuclei, but the final output of the cerebellum by those nuclei is predominantly excitatory.

Cerebellar lesions reveal functions of the cerebellum.

Lesions of the cerebellum produce impairment in the coordinated action of agonists, antagonists, and synergists. This impairment is clinically known as **ataxia**. The control of limb, axial, and cranial muscles may be impaired depending on the site of the cerebellar lesion. As noted above, lesions of the vestibulocerebellum or medial aspects of the spinocerebellum are manifest as problems with balance, truncal ataxia, and eye movements. The swaying, legs spaced far apart, walk of an intoxicated individual is a vivid example of truncal ataxia. More laterally placed cerebellar lesions produce limb ataxias that manifest as lower limb ataxia or the coarse jerking motions of an arm and hand during reaching for an object instead of the expected, smooth actions. This jerking-type motion is referred to as **action tremor**.

Cerebellar lesions can also produce a reduction in muscle tone, called **hypotonia**, which manifests as a decrease in the level of resistance to passive joint movement present in a normal relaxed person. Myotatic reflexes produced by tapping a tendon with a reflex hammer reverberate for several cycles (pendular reflexes) because of impaired damping from the reduced muscle tone. The hypotonia is likely a result of impaired processing of cerebellar afferent action potentials from the muscle spindles and GTOs.

Other common deficits associated with lateral lesions are the inability to perform rapid alternating movements, garbled speech, and a decrease in motor learning. In addition to its participation in controlling posture and movements, research has suggested that the cerebellum has a role in many other cognitive and affective behaviors and is associated with deficits in language.

Chapter Summary

- The contraction of skeletal muscle produces movement by acting on the skeleton.
- Motor neurons activate the skeletal muscles.
- Sensory feedback from muscles is important for precise control of contraction.
- The output of sensory receptors, such as the muscle spindle, can be adjusted.
- The spinal cord is the source of reflexes that are important in the initiation and control of movement.
- Spinal cord function is influenced by higher centers in the brainstem.
- The highest level of motor control comes from the cerebral cortex and this control is exerted via the corticospinal tract.
- The basal ganglia and the cerebellum provide feedback to the motor control areas of the cerebral cortex and brainstem.

Chapter Review Questions

1. Which type of motor unit is of prime importance in generating the muscle power necessary for the maintenance of posture?
   A. Low threshold, fatigue resistant
   B. High threshold, fatigable
   C. Intrafusal, gamma controlled
   D. High threshold, high force
   E. Extrafusal, gamma controlled

The correct answer is A.

The maintenance of posture requires continuous muscle action. The low-threshold, for activation, fatigue-resistant motor units are the type active in postural control. Intrafusal muscle fibers do not contribute to force generation.

2. An elderly man suffers a stroke that damages the vestibulocerebellum. What type of deficit in motor function would you expect to see?
   A. Paralysis accompanied by spasticity
   B. Falling and gait problems
   C. Hyperreflexia
   D. Muscle rigidity
   E. Difficulty learning new skilled movements

The correct answer is B.

The vestibulocerebellum works with the vestibular system to help control equilibrium. Damage to the vestibulocerebellum may also produce a truncal tremor and problems with smooth pursuit eye movements. Paralysis accompanied by spasticity is associated with damage to the corticospinal tract. Muscle rigidity and hyperreflexia are most frequently observed following damage to upper motor neurons. Muscle rigidity is also seen in some diseases of the basal ganglia. Difficulty learning new skilled movements is associated with damage to the more laterally located cerebrocerebellum.

3. A disease that produces decreased inhibitory input to the internal segment of globus pallidus should have what effect on the motor areas of the cerebral cortex?
   A. Increased excitatory feedback directly to the cortex
   B. No effect
   C. Decreased excitatory output from the thalamus to the cortex
   D. Increased excitatory output from the putamen to the cortex
   E. Increased excitatory output from the thalamus to the cortex

The correct answer is C.

Decreased inhibitory input to the GPi from the putamen would enhance inhibitory output from the GPi to the thalamus. Thalamic output excites the cortex hence increased inhibition by GPI would decrease excitatory output from the thalamus back to the cortex and decreased motor cortical activity. There is no direct projection to the cortex from GPi or the putamen so there could be no direct effects.

4. A patient suffers a stroke that damages the primary motor cortex. An MRI would reveal damage in what part of the brain?
   A. Superior parietal lobe

B. Superior temporal lobe
C. Precentral gyrus
D. Postcentral gyrus
E. Medial hemisphere rostral to the paracentral lobule

The correct answer is C.

The primary motor cortex is located along the precentral gyrus. The superior parietal lobe is association cortex responsible for processing somatosensory information and integrating visual and spatial inputs. The superior temporal lobe is associated with language reception. The postcentral gyrus is the location of primary somatosensory cortex. The medial hemisphere rostral to the paracentral lobule is the location of supplementary motor cortex.

Clinical Application Exercises 5.1

UNSTEADY CARPENTER

A 55-year-old carpenter presents for evaluation of unsteadiness of stance and difficulty walking. The problem began about 1 year ago when he noted a feeling of imbalance when attempting to put his trousers on while standing. He had to start doing this sitting on the side of the bed instead. A few months later, he also noted an unsteady feeling when standing or maneuvering in tight crowds. Over the past year, the difficulties have mildly worsened. His health has been good otherwise. There is no family history of similar problems.

Examination shows normal strength of lower extremity muscles. Muscle stretch reflexes (myotatic) are normal, as is sensory functions of the legs. When the patient is asked to perform a coordination test in which he has to run the heel of one foot down the shin of the opposite leg, he has difficulty keeping either heel accurately tracking along the shin and tends to lose his balance. During standing, he places his feet wider apart than normal, and when asked to move the feet closer together, he becomes notably unsteady. He cannot satisfactorily perform a “walk the line” test like administered by police to check for intoxication. Upper extremity coordination as assessed by having him touch the end of either index finger to the tip of his nose is normal. The patient denies drinking alcohol prior to the appointment today.

QUESTIONS

1. A lesion in which portion of the nervous system would best account for the pattern of dysfunction demonstrated on the neurological examination.
2. What does the fact that the patient’s problems involve lower extremity coordination but spare coordination in the upper limbs say about the location of the lesion?

ANSWERS

1. The most likely site of damage in this patient is the cerebellum. Problems in coordination are often due to dysfunction of the cerebellum, particularly when the neurological examination does not show abnormalities in sensation or muscle strength in the involved limbs.
2. The patient demonstrates coordination deficits in the lower extremities in the form of problems smoothly running the heel of one foot along the shin of the opposite leg, so-called heel-to-shin dystaxia. The difficulty he demonstrates when attempting the “walking the line” test is also a

manifestation of the type of neurological dysfunction found in this type of patient. Selective atrophy of the anterior midline components of the spinocerebellum is observed at autopsy in patients with predominantly lower extremity coordination deficits like these. Magnetic resonance imaging of the brain can also demonstrate this selective atrophy. Remember that there is a somatotopic map of the body on the surface of the cerebellum and the legs are represented anteriorly. The term “anterior cerebellar syndrome” is used to define the combination of clinical and anatomical deficits observed in this patient.

6 Autonomic Nervous System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe the autonomic nervous system efferent pathways from the CNS to effector organs and explain how these differ from the pathway of a motor neuron to the neuromuscular junction.
- Explain the difference between the parasympathetic and sympathetic nervous systems in terms of preganglionic neuronal location, ganglia location, and primary neurotransmitters utilized.
- Describe what is meant by cotransmitters in the autonomic nervous system.
- Explain nonadrenergic, noncholinergic transmission and give an example.
- Describe the function of the parasympathetic and sympathetic nervous systems.
- Explain the role of cholinergic and adrenergic receptors in autonomic function.
- Explain the importance of tonic activation of the parasympathetic and sympathetic nervous systems.
- Explain how presynaptic inhibition influences autonomic function.
- Describe autonomic integration in the eye.
- Explain what is meant by epinephrine reversal.
- Explain the mechanism of organophosphate poisoning and its physiological consequences and treatment.
- Describe how stimulants can produce life-threatening effects.
- Explain the “cheese syndrome” associated with monoamine oxidase.
- Describe the physiological impact and treatment of pheochromocytoma.

The nervous system can be divided into the **central nervous system** (**CNS**) composed of the brain and spinal cord and the **peripheral nervous system** (**PNS**) composed of nerves and ganglia localized outside of the CNS. The **autonomic nervous system** (**ANS**) is one of the components of the PNS and functions as a conduit between the CNS and peripheral organs. Information regarding the subconscious functioning of peripheral organs is transmitted to homeostatic control centers in the hypothalamus and brainstem. Autonomic regulation of these organs is modulated by input from the hypothalamus and brainstem based on these internal stimuli as well as external stimuli that are interpreted by other regions of the brain such as the limbic system and cerebral cortex. In this way, the ANS maintains homeostasis and stimulates necessary alterations in organ function in response to stimuli.

ANATOMY OF THE AUTONOMIC NERVOUS SYSTEM

The two main divisions of the ANS are the **parasympathetic nervous system** (**PSNS**) and the **sympathetic nervous system** (**SNS**). The PSNS can be thought of as the "rest and digest" system that is active in controlling normal organ functioning. The SNS, on the other hand, is the "fight-or-flight" system that modulates organ functioning during times of arousal, stress, and danger. The **enteric nervous system** in the gut is often considered a third division of the ANS. The enteric nervous system regulates the functioning of the gastrointestinal system. It will be discussed separately from the PSNS and SNS in Chapter 27. The PSNS and SNS are both two-neuron pathways, but they differ in the location of these neurons.

Autonomic nervous system consists of a two-neuron efferent pathway.

The CNS communicates with muscles via the somatic motor system, which consists of a cell body in the spinal cord with an axon terminating on muscles at a specialized ending called the **neuromuscular junction** (Fig. 6.1). Unlike this one-neuron pathway, the ANS consists of a two-neuron efferent pathway. The first neuron is located in the brainstem, regions of the sacral spinal cord, or the intermediolateral gray area of the spinal cord. Its axon projects to a second neuron located outside of the CNS. The cell bodies of these second neurons are clustered together with supporting cells in a **ganglion**. The axon from the second neuron projects to the effector organ. The ANS is oriented from the ganglia such that the first neuron is called the **preganglionic neuron**, its axon is the **preganglionic fiber** or **preganglionic axon**, the second neuron is the ganglionic cell or **postganglionic neuron**, and its axon is the **postganglionic fiber** or **postganglionic axon**. The preganglionic axon is a lightly myelinated, slow conducting B fiber, whereas the postganglionic axon is an unmyelinated C fiber that is of smaller diameter and is slower conducting than the preganglionic axon. Unlike an axon from a motor neuron that terminates in a synaptic bouton at the muscle, the postganglionic axons consist of multiple regions specialized for neurotransmitter release, called **varicosities**, that are aligned along the axon in a manner similar to beads on a string. Rather than releasing neurotransmitter from a presynaptic terminal juxtaposed to receptors on postsynaptic neuronal dendrites as occurs in the CNS, neurotransmitters from varicosities are released into extracellular fluid where they diffuse short distances to effector cells and receptors. In some organs, these effector cells can then transmit this information electrically to another cell via gap junctions. The varicosities enable a stimulated fiber to simultaneously release neurotransmitter in multiple areas of the effector organ resulting in a greater coordinated impact on the organ.

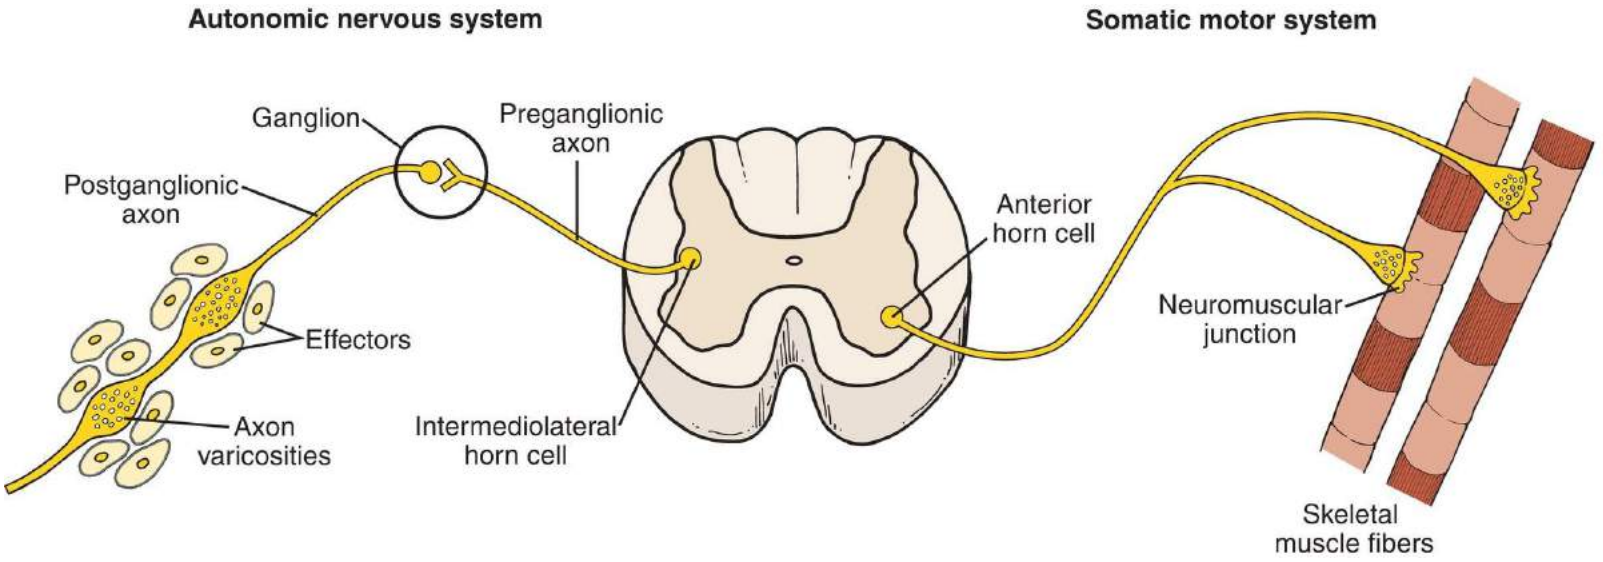

Figure 6.1 Comparison of the autonomic nervous system (ANS) with somatic motor system. The ANS utilizes a two-neuron pathway and releases neurotransmitters at varicosities. The somatic motor system utilizes a one-neuron pathway and releases neurotransmitters from localized nerve endings.

PSNS and SNS differ in the location of their preganglionic neurons and ganglia.

There are differences in the location of the preganglionic and postganglionic neurons for the PSNS and SNS (Fig. 6.2). The preganglionic neurons of the PSNS are located in the brainstem and the sacral (lowest) portion of the spinal cord. Together, these regions are referred to as the **craniosacral** regions. The PSNS ganglia are located in or near the effector organs. This results in a long preganglionic fiber and a short postganglionic fiber. The brainstem PSNS preganglionic fibers are associated with a number of **cranial nerves** ([CN] Table 6.1).

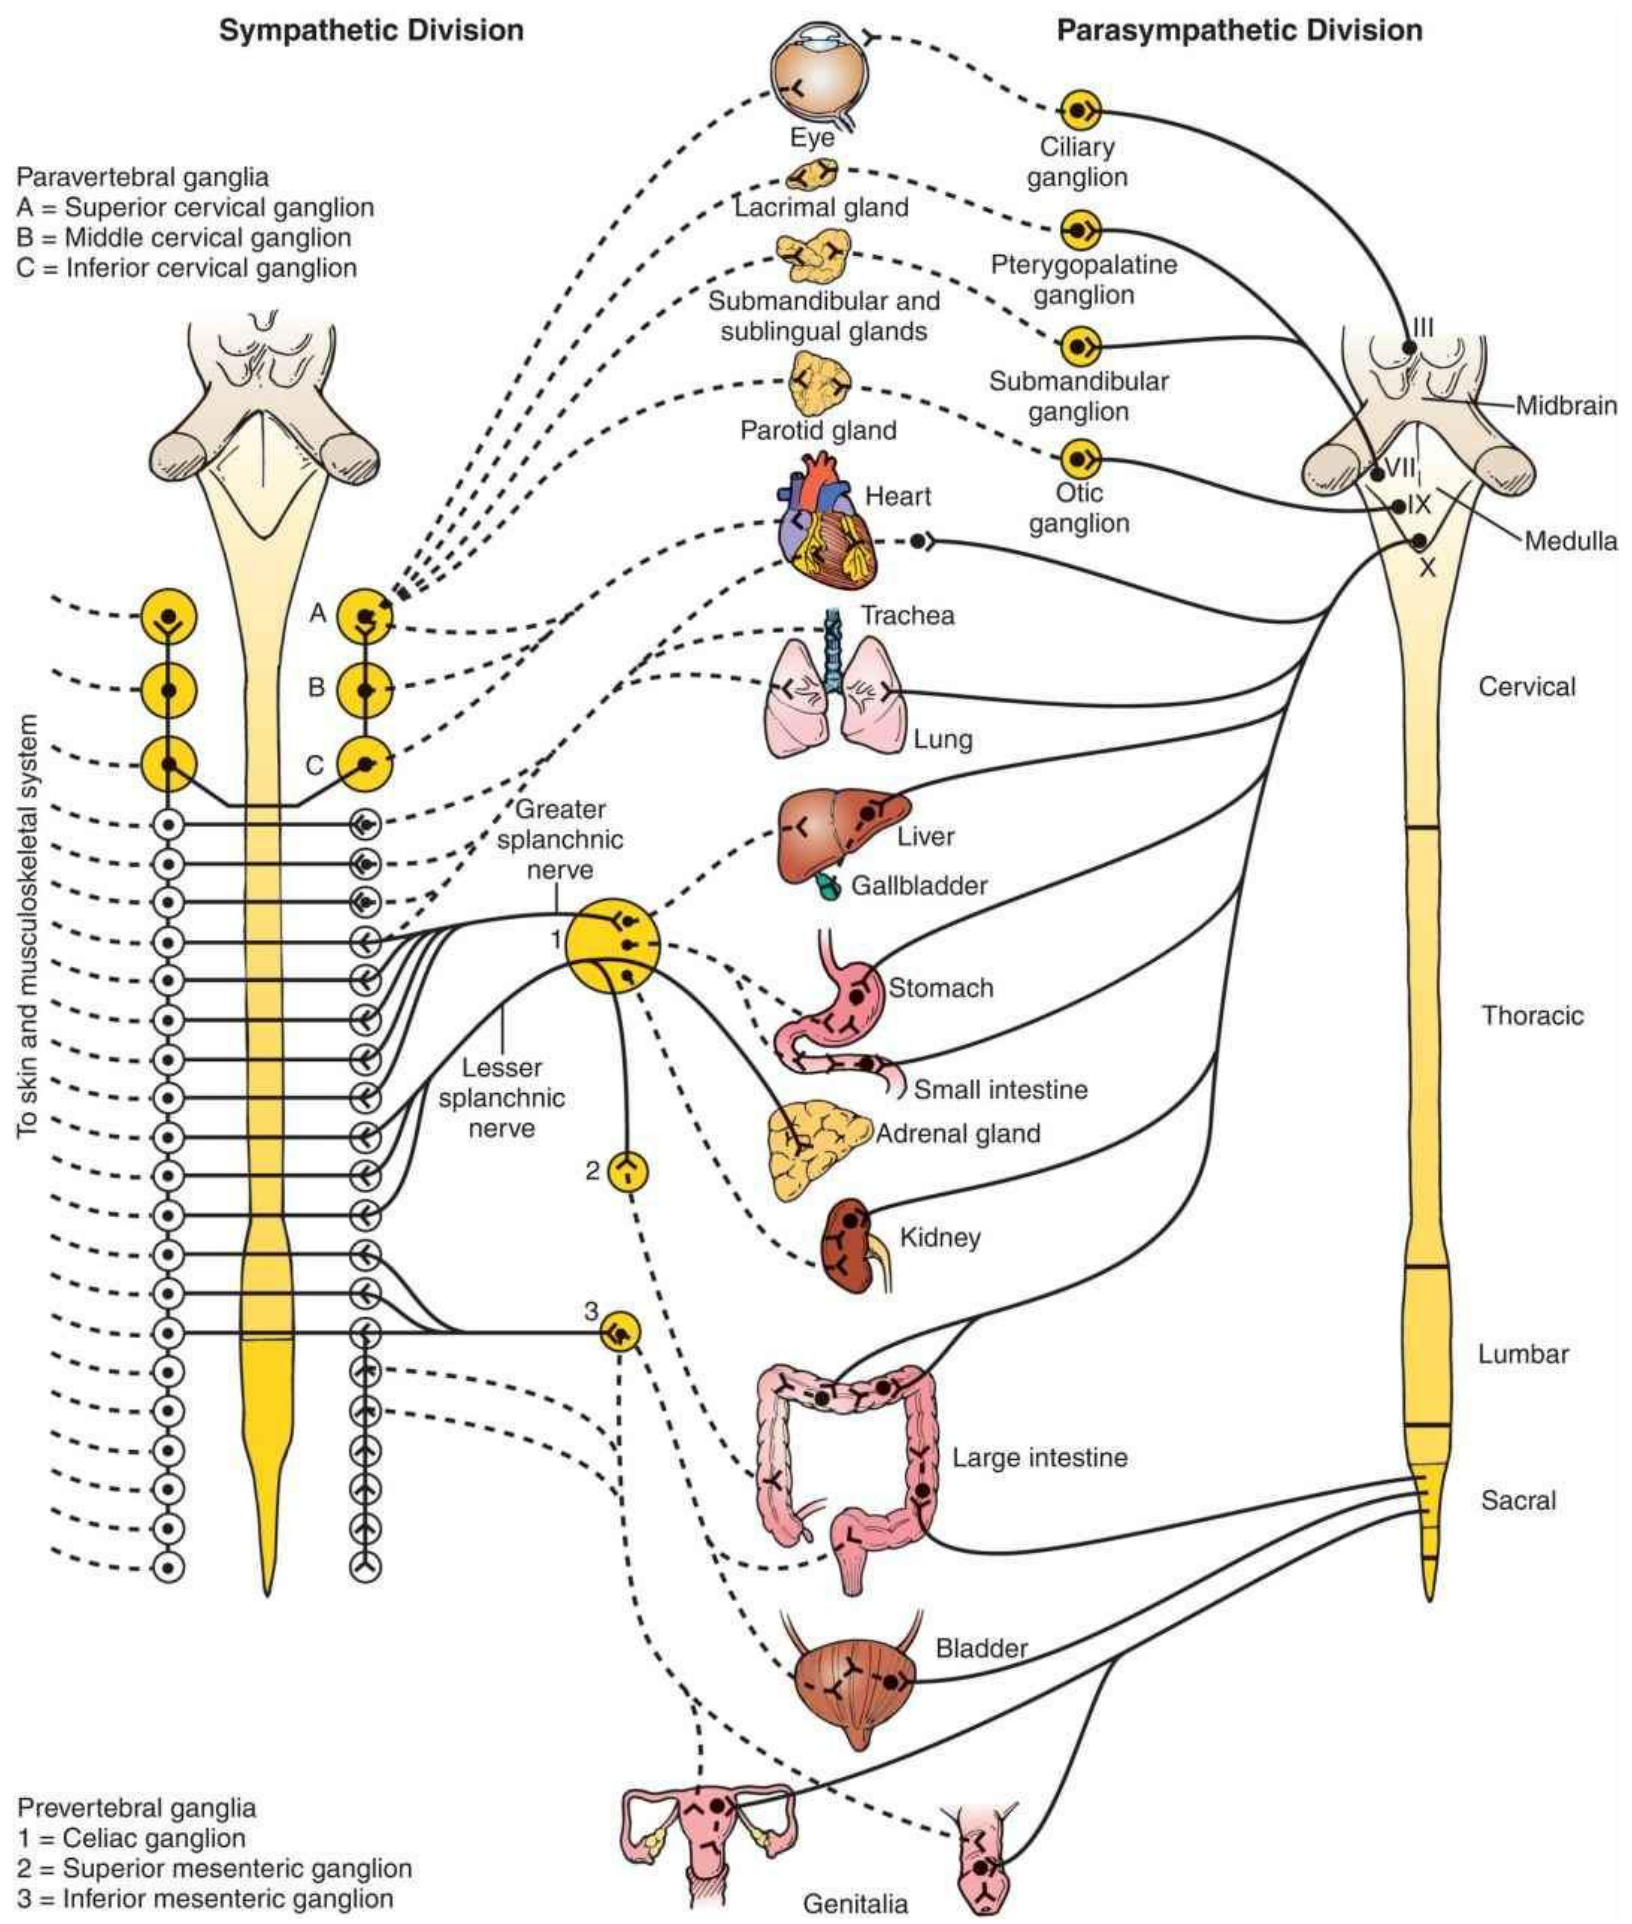

Figure 6.2 The organ-specific arrangement of the autonomic nervous system. Preganglionic axons are indicated by *solid lines* and postganglionic axons by *dashed lines*. Sympathetic axons destined for the skin and musculoskeletal system are shown on the left side of the spinal cord. Note the named

paravertebral and prevertebral ganglia.

TABLE 6.1 Origins and Innervations of PSNS Fibers

Location of Preganglionic Neuron	Preganglionic Axons Location	Preganglionic Axon Termination	Postganglionic Effector Organ	Major Effects
Edinger-Westphal nucleus	Oculomotor (CN III)	Ciliary ganglion	Eye	Miosis (pupillary constriction) Accommodation
Superior salivatory nuclei	Facial (CN VII)	Pterygopalatine ganglion	Lacrimal gland	Tearing
			Nasal and palatal mucosa	Increased secretions
		Submandibular ganglion	Submandibular and sublingual glands	Salivation
Inferior salivatory nuclei	Glossopharyngeal (CN IX)	Otic ganglion	Parotid gland	Salivation
Nucleus ambiguus Dorsal motor nuclei	Vagus (CN X)	Cardiac plexus	Heart	Decreased heart rate, Decreased contraction force
		Pulmonary plexus	Lungs	Bronchoconstriction
				Increased secretions in lungs
		Myenteric plexus	GI tract	Increased motility of stomach
		Submucosal plexus		Increased secretions in stomach
Sacral spinal cord (S2, S3, S4)	Pelvic nerves	Myenteric plexus	Lower large intestine	Increased motility
		Submucosal plexus		Increased secretions
		Hypogastric plexus	Bladder	Urination
			Reproductive organs	Erection

The preganglionic neurons of the SNS are located in the middle regions of the spinal cord: the thoracic and lumbar portions (see Fig. 6.2). Together, these are referred to as the **thoracolumbar** region. Most SNS ganglia are **paravertebral**, located alongside the spinal cord in a **sympathetic "chain."** Because of the proximity to the spinal cord, the SNS preganglionic fibers are short and the postganglionic fibers are long. There are, however, a few exceptions to this generality in which the SNS preganglionic fiber is much longer. The celiac, super mesenteric, and inferior mesenteric ganglia are **collateral (prevertebral) ganglia** located beyond the paravertebral ganglia in the abdomen and pelvis. Another exception is the adrenal medulla, which is an end organ directly innervated by sympathetic *preganglionic* axons in a manner analogous to sympathetic ganglia but lacking postganglionic neurons. Thus, the preganglionic axons projecting to the adrenal medulla and collateral ganglia are longer than the typically short SNS preganglionic axons.

NEUROTRANSMITTERS OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system consists primarily of cholinergic and adrenergic fibers. The PSNS is fully a cholinergic system, whereas the SNS utilizes acetylcholine, norepinephrine, and epinephrine. The primary neurotransmitter of the postganglionic SNS fiber depends on the target organ.

All preganglionic axons release acetylcholine.

All neurons sending projections outside of the CNS (motor, PSNS, and SNS) are cholinergic neurons that release acetylcholine (ACh) from their axons (Fig. 6.3). Acetylcholine released from motor neurons interacts with nicotinic receptors at the neuromuscular junction (NMJ), whereas ACh from preganglionic fibers interacts with nicotinic receptors on the postsynaptic membrane of the sympathetic and parasympathetic postganglionic neurons. The nicotinic receptors at the NMJ are a different subtype (N_m) than those at the ganglia (N_n), but both open cation-selective ion channels when activated by ACh or another agonist. This allows the influx of sodium ions (Na^+) and the depolarization of the membrane, which can ultimately result in a muscle contraction at the NMJ or depolarization of postganglionic fibers. This depolarization can generate an action potential that is conducted by nerve fibers and can result in neurotransmitter release.

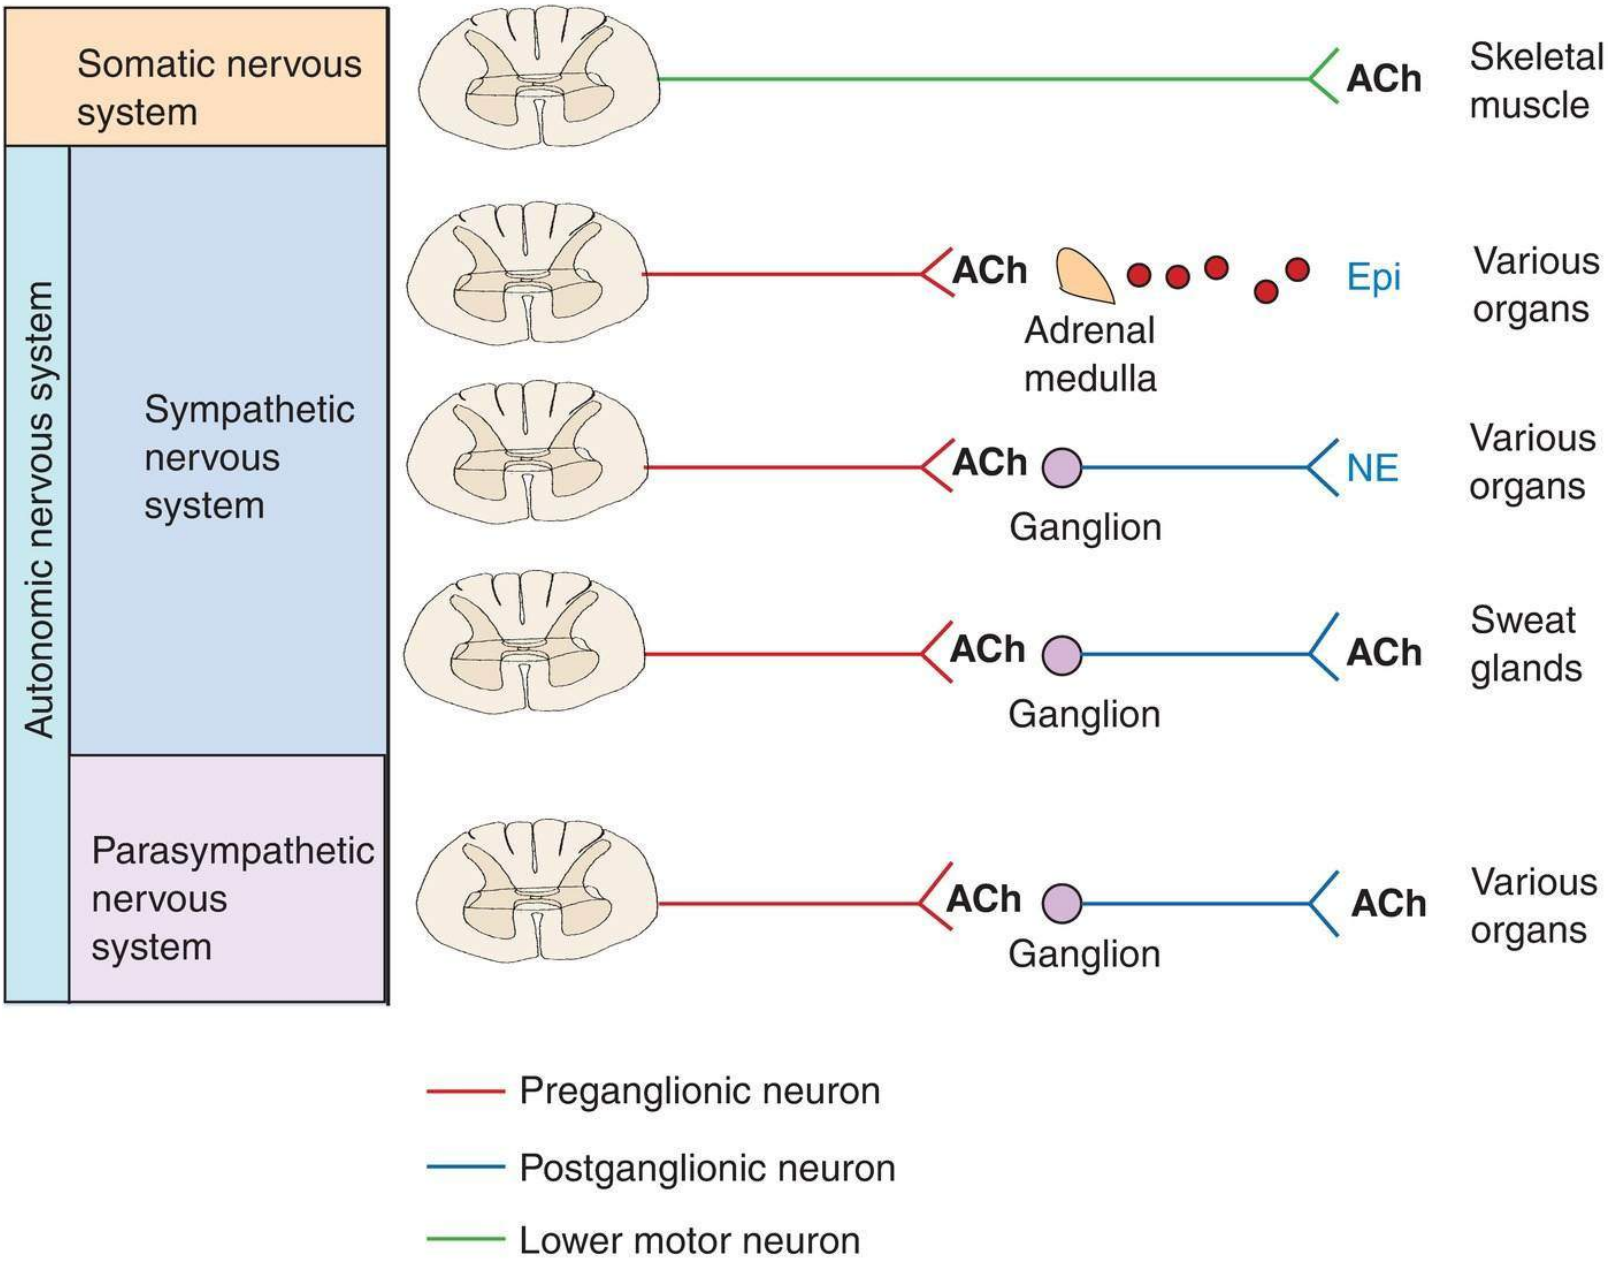

Figure 6.3 Neurotransmitters synthesized and released from somatic and autonomic nervous systems. Acetylcholine (ACh) is released from all axons exiting the spinal cord. Postganglionic axons of the parasympathetic nervous system also release ACh. Postganglionic axons of the sympathetic nervous system primarily release NE except for those innervating sweat glands, which release ACh. Sympathetic activation of the adrenal medulla by preganglionic fibers releases epinephrine directly into the bloodstream.

Parasympathetic postganglionic neurons release acetylcholine, whereas sympathetic postganglionic neurons primarily release norepinephrine.

In the PSNS, all postganglionic neurons are cholinergic synthesizing and releasing ACh from the postganglionic axon onto the effector organ where it can interact with muscarinic receptors. Acetylcholine is synthesized from choline, which is transported into the presynaptic terminal, and acetyl CoA, from mitochondria (Fig. 6.4). Acetylcholine is synthesized in the cytosol and then transported into the synaptic vesicle via the vesicle-associated transporter (VAT). Upon depolarization of the membrane from an action potential and opening of voltage-gated calcium channels, the synaptic vesicles are released from cytosolic anchor proteins, migrate to fuse with the plasma membrane, and release ACh where it can then act on pre- and postsynaptic cholinergic receptors. After release, ACh is rapidly hydrolyzed to choline and acetate by the enzyme acetylcholinesterase located on the postsynaptic membrane. Choline can then be transported back into the presynaptic terminal where it can be recycled to produce more ACh.

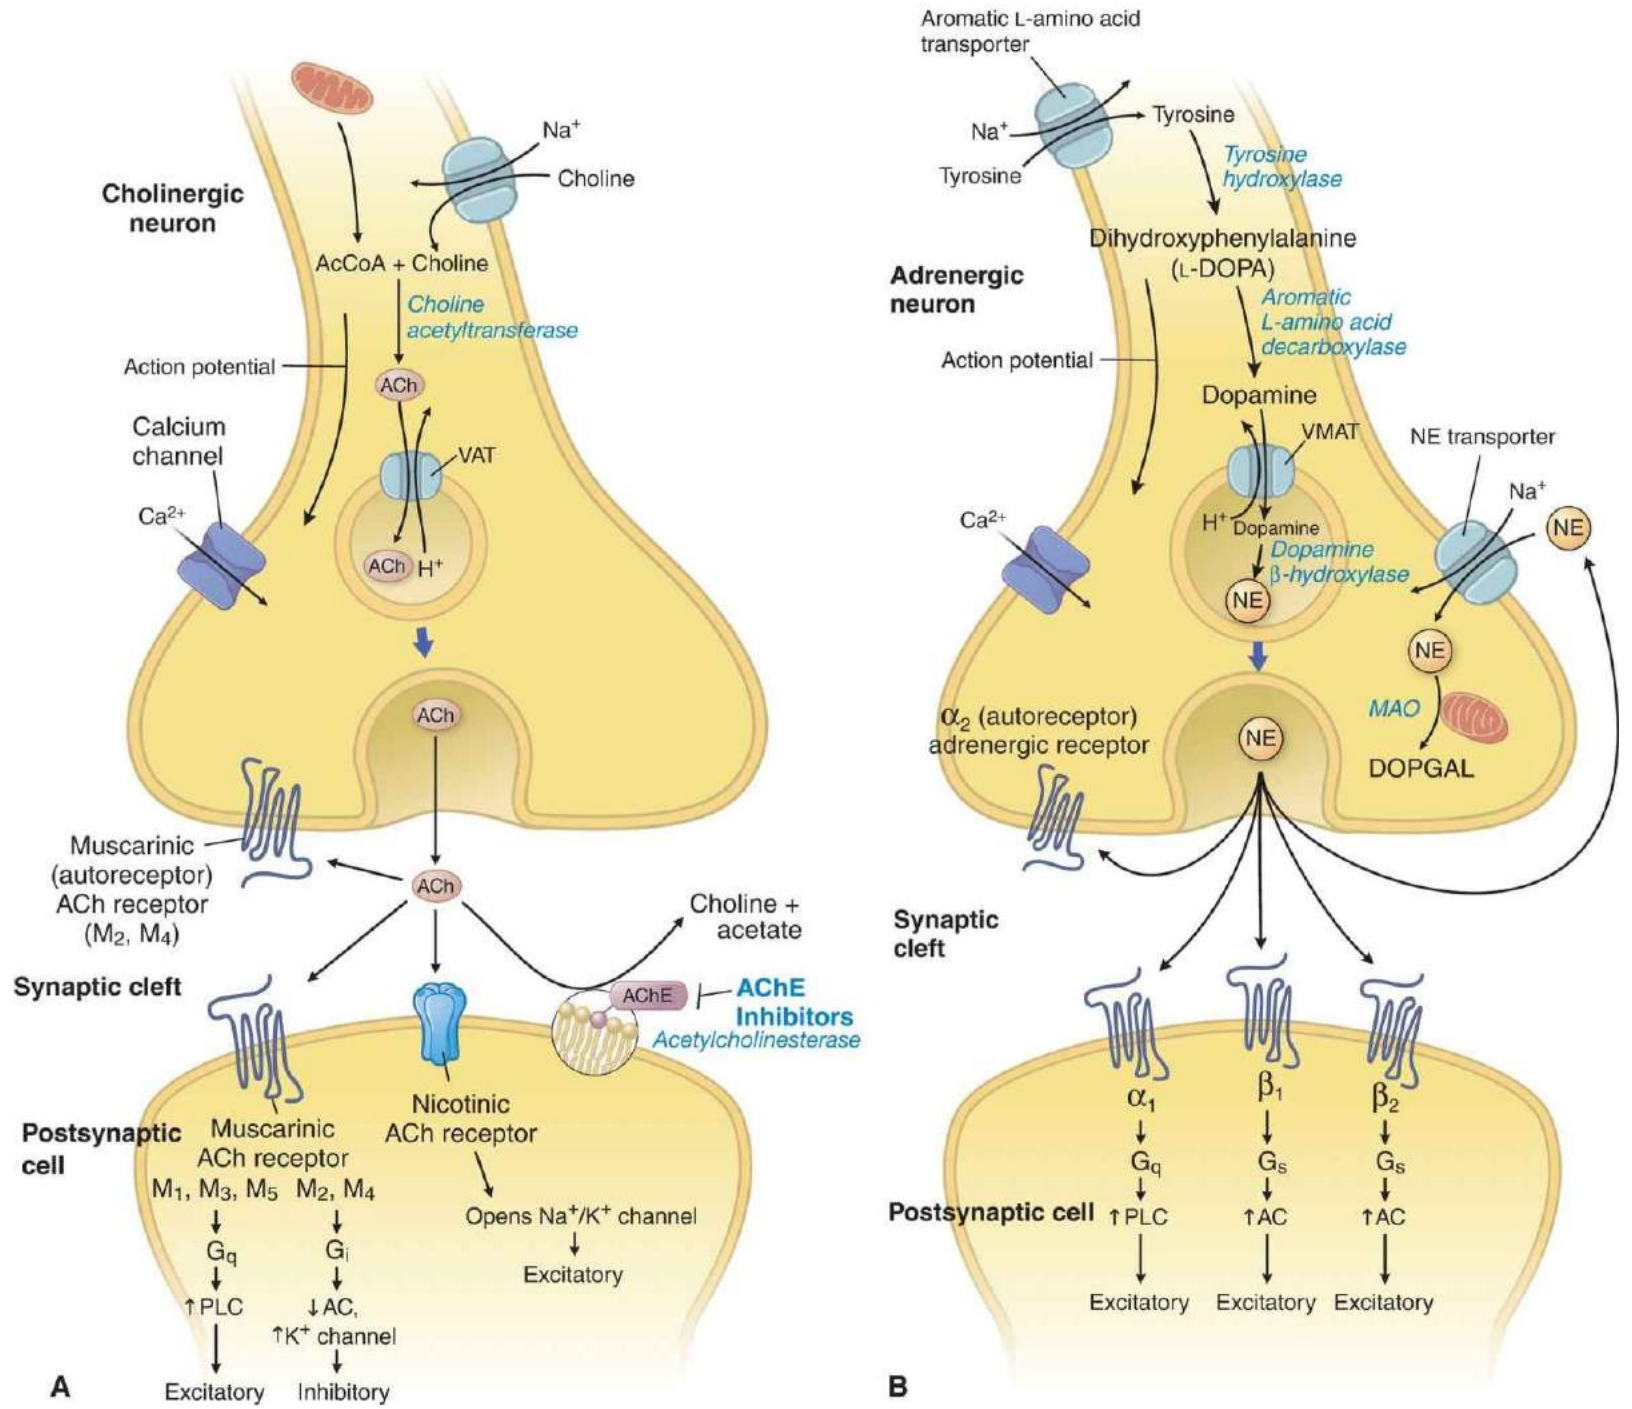

Figure 6.4 Synthesis and degradation of acetylcholine (ACh) and norepinephrine (NE). **(A)** Acetylcholine is synthesized from choline and acetyl CoA, transported into vesicles, released in a calcium-dependent manner, and degraded in the synaptic cleft by acetylcholinesterase. It can interact with muscarinic or nicotinic receptors (shown in the figure on the same membrane but generally located on different postsynaptic cells). **(B)** Tyramine is the precursor for all catecholamines. It is converted to dopamine in the cytosol, which is then transported into vesicles. Once there, it can be converted to NE if the enzyme dopamine-β-hydroxylase is present. Norepinephrine is released in a calcium-dependent manner. It is removed via uptake by the norepinephrine transporter, or it can diffuse away, be taken up by other cell types, and degraded by catechol-O-methyltransferase (not shown). In the cytosol, it can be recycled into the vesicle or degraded by monoamine oxidase. After release, NE can interact with α or β adrenergic receptors (shown in the figure on the same membrane but generally located on different postsynaptic cells).

The SNS primarily utilizes norepinephrine (NE), sometimes referred to as noradrenaline, as the signaling molecule released from postganglionic axons. Norepinephrine is a catecholamine that is synthesized from the common catecholamine precursor tyrosine (see Fig. 6.4). Tyrosine is transported into the presynaptic terminal and converted to L-dopa and then dopamine. Dopamine is transported into synaptic vesicles by the vesicular monoamine transporter (VMAT). If the vesicle contains the enzyme dopamine-β-hydroxylase, dopamine will be converted to NE. Excess dopamine in the cytosol can be metabolized by monoamine oxidase (MAO), an enzyme located on the outer membrane of mitochondria. Upon release, NE interacts with presynaptic and postsynaptic adrenergic receptors. Unlike ACh, which is degraded in the extracellular fluid, NE either diffuses away where it can then be degraded by catechol-*O*-methyltransferase (COMT) or is taken back into the presynaptic terminal by the norepinephrine transporter where it can either be degraded by MAO or recycled to the vesicle by VMAT.

There are two instances in which neurotransmitters other than NE are utilized by the SNS at effector organs (see Fig. 6.3). The first is the sweat glands where sympathetic postganglionic axons synthesize and release ACh, which then interacts with muscarinic receptors to increase sweating. The second involves the adrenal medulla. The adrenal medulla receives input from the *preganglionic* sympathetic axon and acts as the sympathetic ganglion. Instead of a postganglionic axon, the chromaffin cells of adrenal medulla directly secrete epinephrine (Epi), sometimes referred to as adrenalin, which then circulates peripherally as a hormone (Fig. 6.5). Epinephrine is synthesized from NE by the enzyme phenylethanolamine *N*-methyltransferase. Approximately 20% of the neurotransmitter released by the adrenal medulla is NE with Epi accounting for the other 80%.

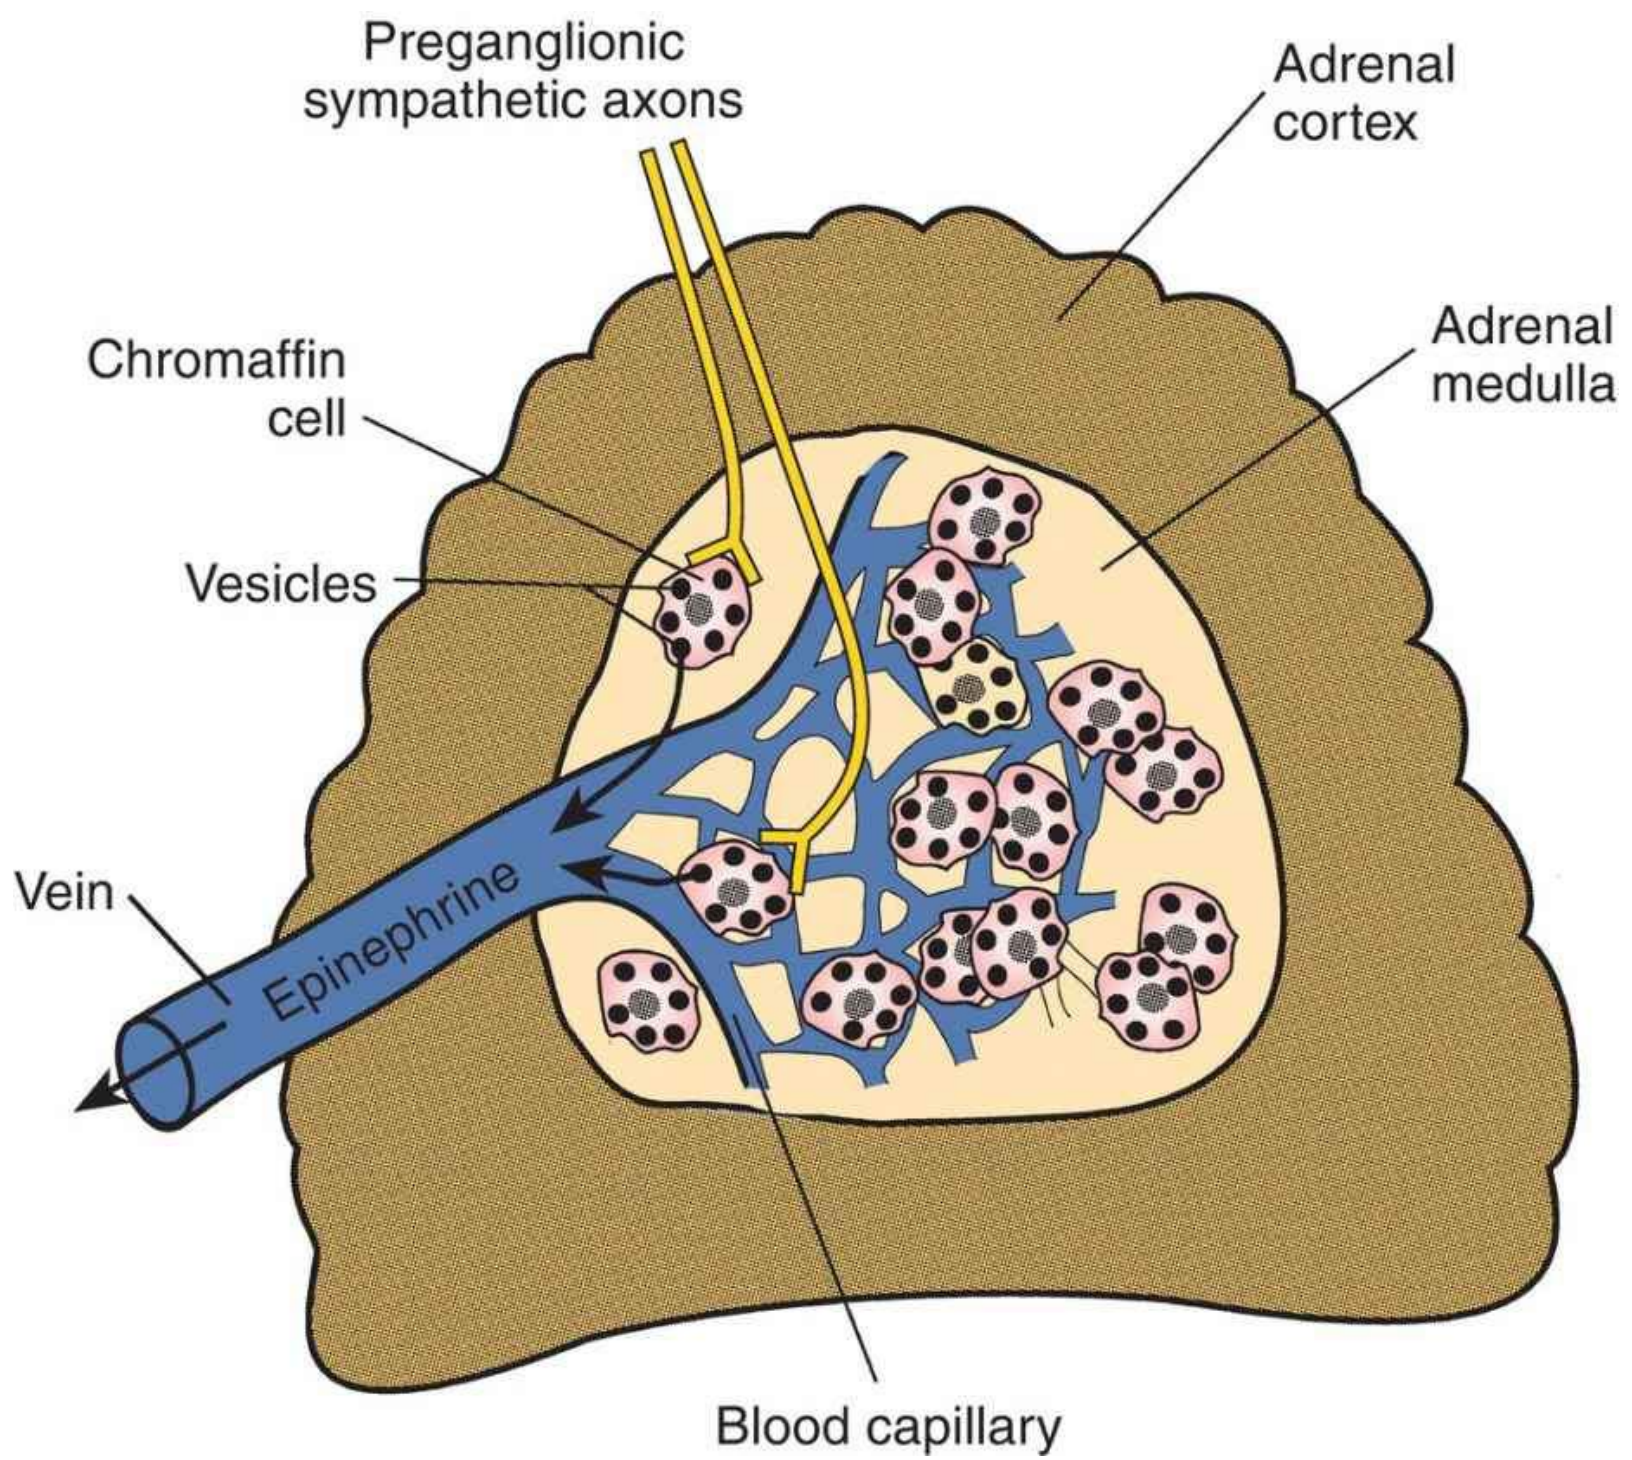

Figure 6.5 Sympathetic innervation of the adrenal medulla. Preganglionic sympathetic axons terminate on the chromaffin cells. When stimulated, the chromaffin cells release epinephrine into the circulation.

Many autonomic postganglionic fibers contain cotransmitters along with acetylcholine and norepinephrine.

In addition to the primary neurotransmitter in the autonomic fibers, autonomic postganglionic fibers can contain cotransmitters that modulate the function of the primary neurotransmitter. Often these cotransmitters are packaged into large dense core vesicles in the cell body and transported inside the vesicle to the synapse. There are also instances of the cotransmitters colocalizing with the primary neurotransmitter in the smaller clear vesicles that are located closer to the synaptic membrane. The vesicles that are further from the membrane require more stimulation to produce vesicular mobilization and neurotransmitter release. In this way, the action of a primary neurotransmitter can be modulated during times of greater activity and thus affect the duration or extent of the postsynaptic response. There are a number of cotransmitters that have been identified including ATP, adenosine, neuropeptide Y, vasoactive intestinal peptide, calcitonin gene-related peptide, and substance P.

Some autonomic fibers contain neither acetylcholine nor norepinephrine but instead undergo nonadrenergic noncholinergic (NANC) transmission.

Although most ANS fibers are associated with acetylcholine, norepinephrine, or epinephrine, there are ANS fibers that communicate using other signaling molecules such as nitric oxide. Nitric oxide is found in certain nonadrenergic noncholinergic (NANC) fibers of the parasympathetic nervous system such as those that innervate the corpus cavernosum of the penis. Nitric oxide is a gas that is formed presynaptically from arginine by the enzyme nitric oxide synthase in response to increased cytosolic calcium. Once synthesized, it diffuses out of the presynaptic terminal and into the postsynaptic terminal where it activates guanylyl cyclase to produce cyclic GMP (cGMP). Cyclic GMP activates protein kinase G, which phosphorylates certain proteins resulting in smooth muscle relaxation and vasodilation. In the corpus cavernosum, the vasodilation leads to penile engorgement and produces an erection (Fig. 6.6). The action of cGMP is terminated when it is degraded by phosphodiesterases. Certain types of phosphodiesterase inhibitors are used to prolong the action of cGMP and thus can treat disorders such as erectile dysfunction. Examples of these medications include sildenafil (brand name Viagra), tadalafil (Cialis), and vardenafil (Levitra). The enteric nervous system also utilizes nitric oxide as well as other compounds such as vasointestinal peptide and substance P in NANC fibers.

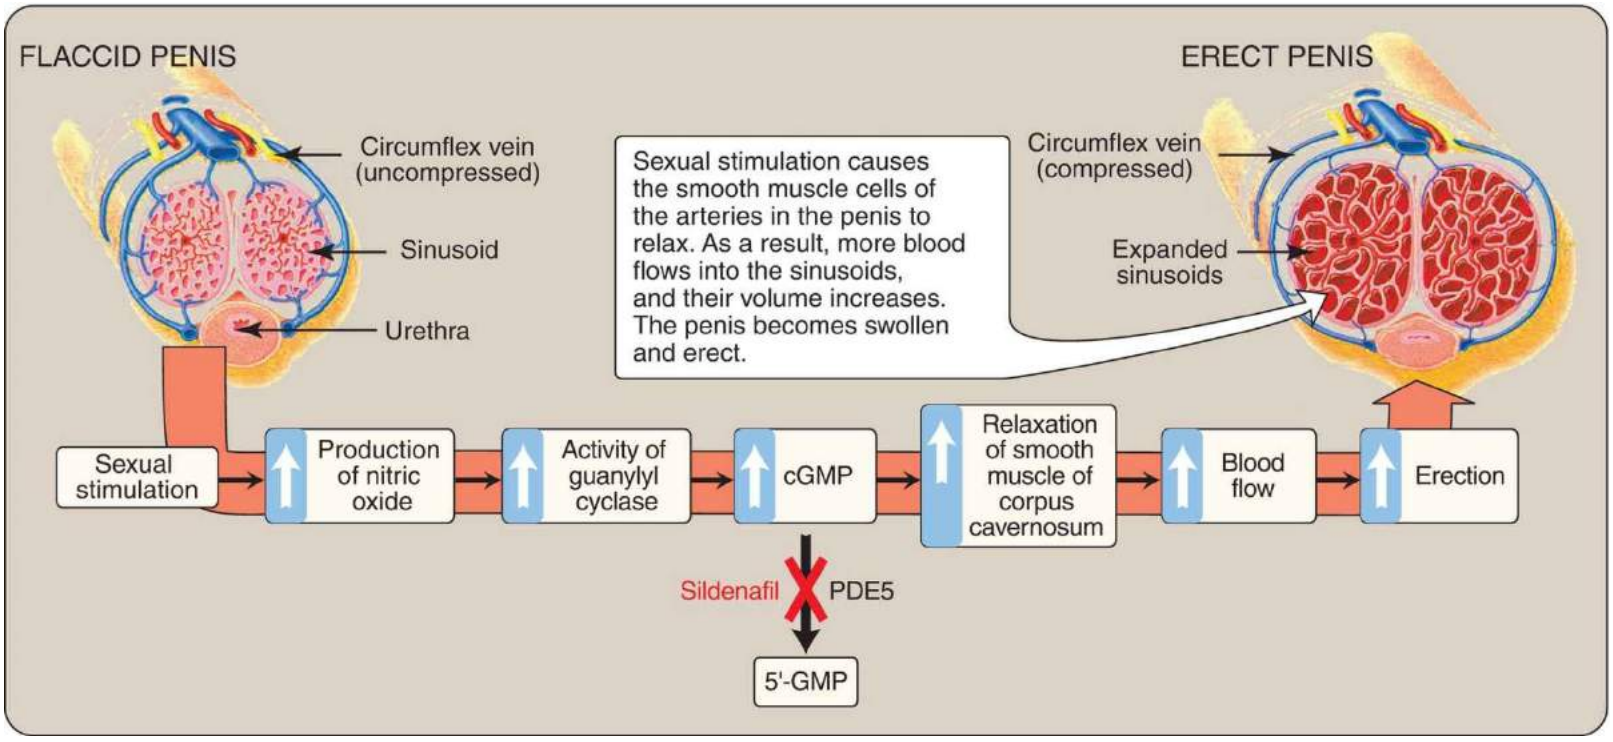

Figure 6.6 Nonadrenergic noncholinergic (NANC) parasympathetic nervous system (PSNS) mediation of penile erection. Release of nitric oxide from NANC PSNS postganglionic fibers acts in the corpus cavernosum to produce smooth muscle relaxation allowing engorgement from increased blood flow and subsequent erection. Phosphodiesterase type 5 (PDE5) converts cGMP to 5'-GMP. This can be inhibited with selective PDE5 inhibitors such as sildenafil.

THE PARASYMPATHETIC NERVOUS SYSTEM

The PSNS preganglionic neurons are located in specific cranial nerve nuclei (collection of neurons) in the brainstem (see Table 6.1 and Fig. 6.2). The preganglionic axons travel along that cranial nerve to terminate at parasympathetic ganglia. These may be true ganglia (i.e., a collection of cells), located a short distance from the organ that the postganglionic axon innervates as is seen with CN III, CN VII, and CN IX. The “ganglia” of CN X (vagus nerve) and pelvic nerves, however, are not true ganglia but are rather nerve plexuses, branching networks of intersecting nerves and blood vessels, located in or very near the effector organ itself.

PSNS is involved in normal homeostatic functions.

Many organs receive moderate PSNS input under normal conditions when an individual is in a nonstressed and safe environment. This regulation can be modulated by either increasing or decreasing the PSNS input. As much as 75% of parasympathetic activity may be mediated through the vagus nerve. Activation of the PSNS will result in miosis (pupillary contraction), accommodation of the lens, lacrimation (tearing), salivation, bradycardia, decreased force of myocardial contraction, bronchoconstriction and increased bronchial secretions, increased digestive secretions and GI motility, and urination (Table 6.2).

TABLE 6.2 Responses of Effectors to Parasympathetic and Sympathetic Stimulation

Region	Effector	Parasympathetic (Muscarinic Receptors)	Sympathetic (Adrenergic Receptors)
Eye and face	Pupil	Constriction: via circular muscle contraction (miosis)	Dilation (α_1): via radial muscle contraction (mydriasis)
	Ciliary muscle	Contraction	Relaxation (β_2)
	Müller muscle	None	Contraction (α_1)
	Lacrimal gland	Secretion	None
	Nasal glands	Secretion	Inhibition (α_1)
	Salivary glands	Secretion	Amylase secretion (β)
Skin	Sweat glands	None	Secretion (cholinergic muscarinic receptors)
	Piloerector muscles	None	Contraction (α_1)
Blood vessels	Skin (general)	None	Constriction (α)
	Facial and neck muscles	Dilation (?)*	Constriction (α)
			Dilation (?)*
	Skeletal muscle	None	Dilation (β_2)
			Constriction (α)
	Viscera	None	Constriction (α_1)
Heart	SA Node	Decrease heart rate	Increase heart rate ($\beta_1 > \beta_2$)
	AV Node	Decrease conduction velocity	Increase conduction velocity ($\beta_1 > \beta_2$)
	Atria	Decrease contractility	Increase contractility ($\beta_1 > \beta_2$)
	Ventricle	Little effect	Increase contractility ($\beta_1 > \beta_2$)

ACh, acetylcholine; NO, nitric oxide.

*The status of vasodilator activity to the face (as shown in blushing and/or response to cold exposure) is still controversial.

†The contribution of β_2 vs. β_3 to detrusor relaxation is controversial.

PSNS effects are mediated by cholinergic receptors.

For many organs, there is a 1:1 relationship between the PSNS preganglionic axon and postganglionic axon such that the effect of preganglionic activation is very discrete at the effector organ. Upon activation, the postganglionic axons of the PSNS release ACh, which activates muscarinic receptors in the effector organ. The muscarinic receptor family consists of five subtypes linked to two different signaling pathways. As Figure 3.13 shows, the M_1, M_3, and M_5 receptors activate the G_q G protein. This results in the hydrolysis of phosphatidylinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol triphosphate (IP_3). Diacylglycerol can activate protein kinase C resulting in phosphorylation of numerous proteins. Inositol triphosphate can release calcium from the endoplasmic reticulum, which can result in cellular contraction. Other cellular signaling molecules are also activated and ultimately modulate cellular function. The M_2 and M_4 muscarinic subtypes activate the G_i G protein. This results in decreased adenylyl cyclase activity and subsequent decreased cAMP levels. Additionally, activation of the G_i G protein can open certain potassium channels leading to membrane hyperpolarization and close certain presynaptic calcium channels ultimately decreasing vesicular release. Some M_2 receptors are located presynaptically and serve as autoreceptors producing negative feedback to decrease further release of ACh. The primary muscarinic receptors in autonomic effector organs are M_2 in the heart, which can result in *decreased* heart rate and force of contraction, and M_3 in smooth muscle and glands, which can result in *increased* secretions and muscle contraction.

SYMPATHETIC NERVOUS SYSTEM

The SNS preganglionic axons exit the spinal cord along with axons from motor neurons via the ventral root (Fig. 6.7). These myelinated fibers separate from the motor neuron axons to form the white rami communicantes of the thoracic and lumbar nerves and terminate on the corresponding sympathetic ganglion. These SNS preganglionic axons can send additional projections to nearby ganglia along the sympathetic trunk. This results in a broader, more divergent effect of SNS preganglionic neuronal activation in contrast to the more discrete and direct effect of PSNS preganglionic neuronal activation. Also in contrast to the PSNS, it is the SNS *postganglionic* fibers that travel in nerve bundles to the effector organ.

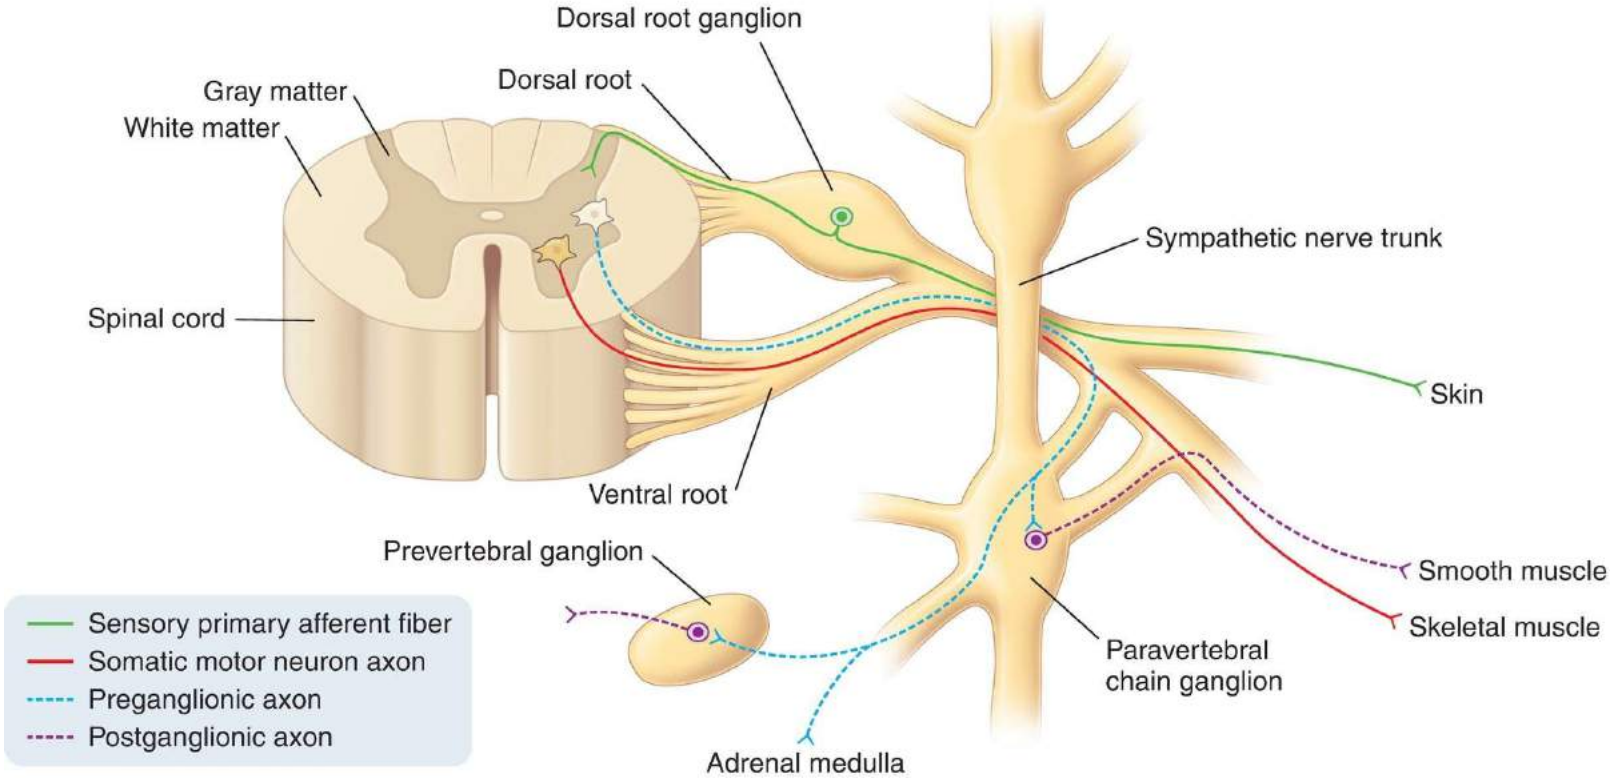

Figure 6.7 Organization of the sympathetic nervous system. Sympathetic preganglionic axons (*dashed blue line*) exit the spinal thoracic and lumbar segments of the spinal cord together with somatic motor neuron axon (*red line*) via the ventral root and project to paravertebral and prevertebral ganglia. Sympathetic postganglionic axons (*dashed purple line*) exit the ganglia and project to effector organs. The adrenal medulla receives preganglionic input and has no postganglionic axons. Sensory information is received by neurons with cell bodies in the dorsal root ganglion and axons projecting to both the periphery and spinal cord (*solid green line*).

SNS mediates responses in times of arousal, stress, and danger.

Like the PSNS, some organs receive tonic activation through the SNS allowing mediation by either increasing or decreasing the level of SNS activity. Activation of the SNS prepares a person to fight or flee through an increase in oxygen and energy delivery to key organs (Table 6.3).

TABLE 6.3 Effects of Sympathetic Activation on the Fight or Flight Response

Organ Effect	Utility for the Fight or Flight Response
Increased heart rate and force of contraction	Increase oxygen delivery to key organs and muscles
Bronchodilation	Increase oxygen supply
Mydriasis (pupillary dilation)	Increase light entering eye
Vasoconstriction	Decreases blood flow if injured Redistribute blood flow to key organs
Vasodilation in skeletal muscle	Increase energy delivery for increased energy consumption
Relaxation of the gut and bladder	Decrease energy delivery to organs not utilized during the danger
Sweating	Dissipation of heat generated from increased muscle activity
Increased gluconeogenesis and glycogenolysis in liver	Increase energy supplies for delivery to key organs
Decreased insulin secretion	Maintain energy supplies for delivery to key organs
Lipolysis in adipose tissue	Use fatty acids to provide energy for skeletal muscles

SNS effects are mediated mostly by adrenergic receptors.

Upon activation of the SNS, many organs receive input from preganglionic neurons at multiple levels of the spinal cord due to the divergence of preganglionic axons along the sympathetic chain. It has been estimated that one sympathetic preganglionic neuron affects twenty postganglionic neurons. The effects of NE at the effector organs are relatively short lived due to the reuptake of NE by the NET and diffusion from the synapse. The effects of epinephrine, however, persist much longer. Epinephrine is released from the adrenal medulla after activation by SNS preganglionic axons and acts as a hormone circulating peripherally and activating multiple organs.

With the exception of the sweat glands, which utilize muscarinic cholinergic receptors, stimulation of the SNS results in activation of adrenergic receptors at effector organs. The primary adrenergic subtypes are α_1, α_2 and β_1, β_2, and β_3. The α_1 receptors interact with G_q G proteins to ultimately increase protein kinase C activity and intracellular calcium levels (see Fig. 3.13). The α_1 receptors on vascular smooth muscle mediate vasoconstriction and maintenance of adequate blood pressure. The α_2 receptors interact with G_i G proteins and function presynaptically to inhibit further sympathetic output. The α_2 receptors also act postsynaptically to inhibit insulin output. The β_1, β_2, and β_3 receptors all interact with the G_s G protein. The β_1 receptors function in the heart to increase heart rate, the force of contraction, and conduction velocity. Activation of β_2 receptors produce bronchodilation, vasodilation in skeletal muscle, and increased plasma glucose levels through actions in the liver. The β_3 receptors are involved in relaxation of the bladder and lipolysis in adipose tissue (Clinical Focus 6.1).

AUTONOMIC INTEGRATION

The autonomic nervous system is always active. As the “rest-and-digest” system, many organs receive input from the PSNS during “normal” activity. These include the eyes, heart, lungs, gut, and bladder. Parasympathetic activity can be increased when needed or decreased during times of increased SNS activation. Some organs are maintained by SNS basal activity. The blood vessels do not receive innervation from the PSNS, and thus, systemic vascular resistance is maintained by SNS input.

Presynaptic inhibition can modulate functioning of the ANS.

In addition to acting as autoreceptors to decrease further release of its own neurotransmitter, the M_2 and α_2 receptors can also function as ***heteroreceptors*** decreasing the release of other neurotransmitters. Input from the PSNS or SNS can be decreased through actions of one system on the presynaptic terminals of the other system's postganglionic axons. Release of ACh, for example, at postganglionic PSNS varicosities can activate M_2 receptors on SNS postganglionic fibers and *decrease* the release of NE from these fibers. Conversely, activation of the SNS can result in the release of NE from postganglionic varicosities and the activation of α_2 receptors on PSNS postganglionic fibers resulting in *decreased* ACh release from these fibers. In this way, an increase in the activity of one system can directly decrease the activity of the other system.

Eye receiving input from the PSNS and SNS is an example of autonomic integration.

In most organs, modulation of function occurs by integration of signals from the PSNS and SNS. The eye is an example of such integration. Pupillary constriction and dilation occur through the contraction of two different types of muscles. The circular muscles, also known as sphincter or constrictor muscles, form concentric rings around the pupil (Fig. 6.8). Activation of the PSNS results in the contraction of these muscles and pupillary constriction (**miosis**). The radial muscles radiate out perpendicularly from the circular muscles. Contraction of the radial muscles in response to SNS activation results in pupillary dilation (**mydriasis**). Certain drugs of abuse affect these systems. One of the signs of opioid use is pinpoint pupils. This occurs due to opioids relieving inhibition on parasympathetic fibers innervating the iris thus producing release of ACh, activation of muscarinic receptors, and contraction of circular muscles. Conversely, amphetamine and cocaine increase the activation of adrenergic receptors in the iris resulting in contraction of radial muscles and pupillary dilation.

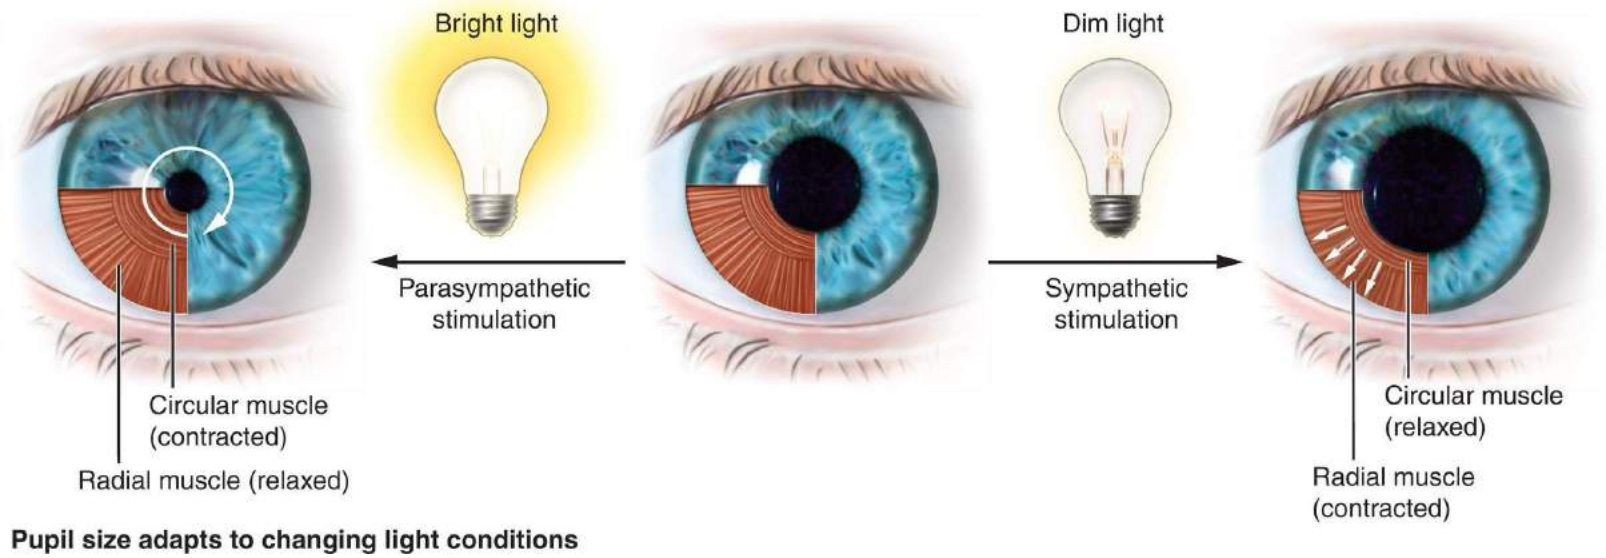

Figure 6.8 Autonomic regulation of pupil light adaptation. The iris contains two muscles that are involved in modulation of pupillary diameter. The circular muscles surround the pupil in concentric rings, whereas the radial muscles are perpendicular to the circular muscles. Activation of the parasympathetic nervous system in response to bright light results in contraction of the circular muscles and pupillary constriction. Activation of the sympathetic nervous system in response to dim light results in contraction of the radial muscles and pupillary dilation.

Both the PSNS and the SNS also contribute to intraocular pressure. Activation of adrenergic receptors increases the secretion of aqueous humor from the ciliary body epithelium into the anterior chamber of the eye (Fig. 6.9). The aqueous humor exits the anterior chamber through the canal of Schlemm after flowing through the trabecular meshwork. Contraction of the ciliary muscle by muscarinic receptor activation opens the trabecular meshwork and allows more aqueous humor to flow out thus decreasing intraocular pressure. Elevated intraocular pressure can lead to glaucoma with damage to the optic nerve and potential vision loss. Open-angle glaucoma is associated with increased secretion of aqueous humor and/or decreased draining. Treatment is aimed at decreasing secretion of aqueous humor through targeting

adrenergic receptors and increasing outflow by targeting muscarinic receptors or other receptors involved in contracting the ciliary muscle to open the trabecular meshwork.

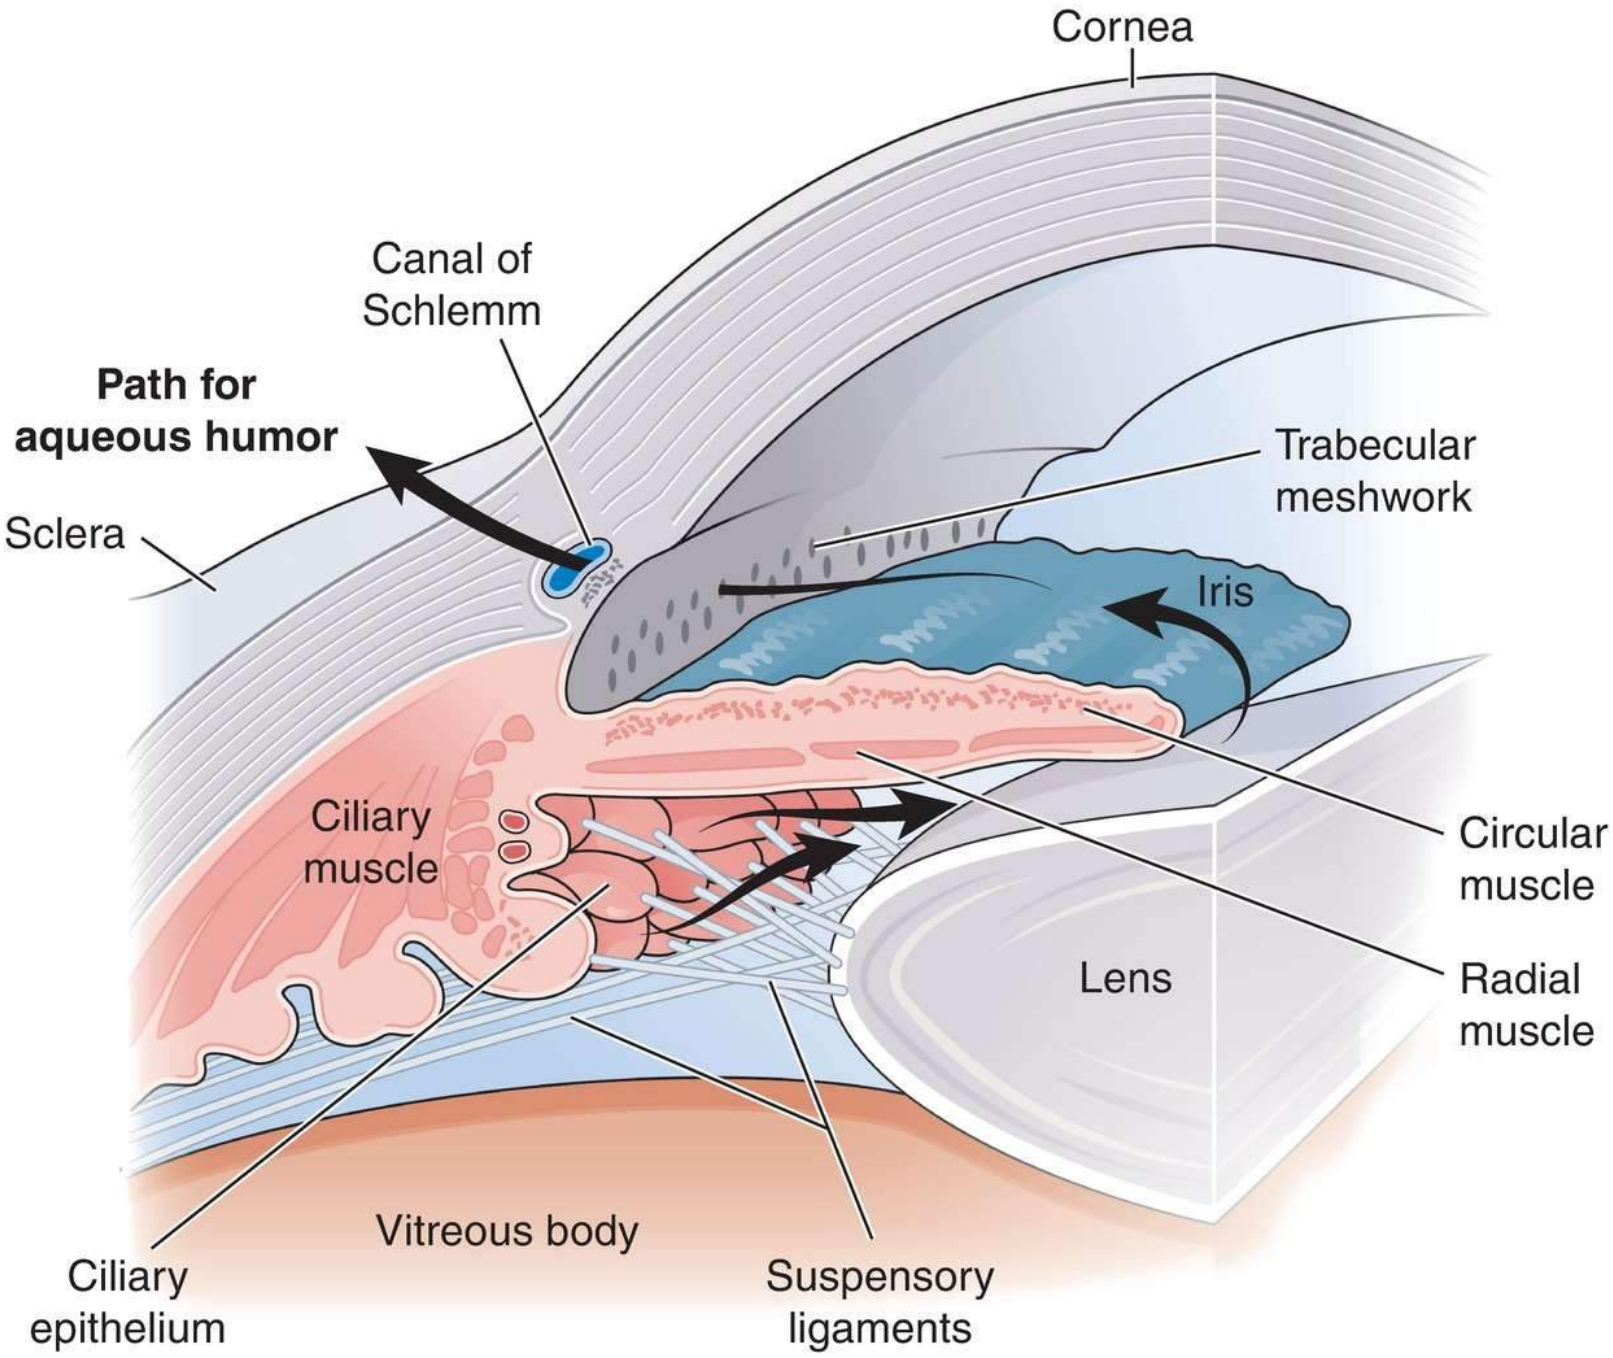

Figure 6.9 Autonomic regulation of aqueous humor and intraocular pressure. Aqueous humor is produced by the ciliary body epithelium in response to sympathetic nervous system activation and secreted into the anterior chamber of the eye. Activation of the parasympathetic nervous system results in the contraction of ciliary muscle and opening of the canal of Schlemm, which allows the outflow of the aqueous humor from the anterior chamber and the lowering of intraocular pressure. Activation of the SNS will relax the ciliary muscle decreasing outflow through the canal of Schlemm.

Vasculature receives input only from the SNS, which contributes to the maintenance of appropriate blood pressure.

Unlike the eye, the vasculature receives input only from the SNS: there are no PSNS fibers that terminate on the vasculature. Thus, the SNS is responsible for maintaining systemic vascular resistance, which, along with cardiac output, determines blood pressure. Blood pressure can be influenced by many factors, and the SNS must respond quickly and appropriately. When a person stands up, gravitational force leads to pooling of blood at the feet due to increased venous volume. In order to counteract this and continue systemic blood flow to all organs, there must be a concomitant increase in blood pressure. This increase is critical in maintaining adequate blood supply to the brain and is accomplished primarily through activation of SNS fibers that terminate on vascular smooth muscle cells and release norepinephrine to interact with α_1 adrenergic receptors. This activates the G_q G protein leading to increased intracellular calcium levels enabling the interaction of actin and myosin and vasoconstriction of the blood vessel thus counteracting the venous dilation. The lack of appropriate blood pressure modulation can result in orthostatic hypotension.

While there is no PSNS innervation of the vasculature, there are muscarinic receptors on endothelial cells that can be activated by ACh released by other cells, such as platelets and macrophages. Activation of these muscarinic receptors leads to the synthesis of nitric oxide (Fig. 6.10). Nitric oxide diffuses into the smooth muscle cell where it activates guanylyl cyclase and ultimately results in vasodilation. These muscarinic receptors can also be activated by exogenous compounds such as those found in certain mushrooms like those of the *Clitocyb*e species. This can lead to "fast" mushroom poisoning characterized by activation of muscarinic receptors on endothelial cells and in the sweat glands and other organs resulting in hypotension, sweating, diarrhea, vomiting, bradycardia, bronchoconstriction, salivation, and visual disturbances.

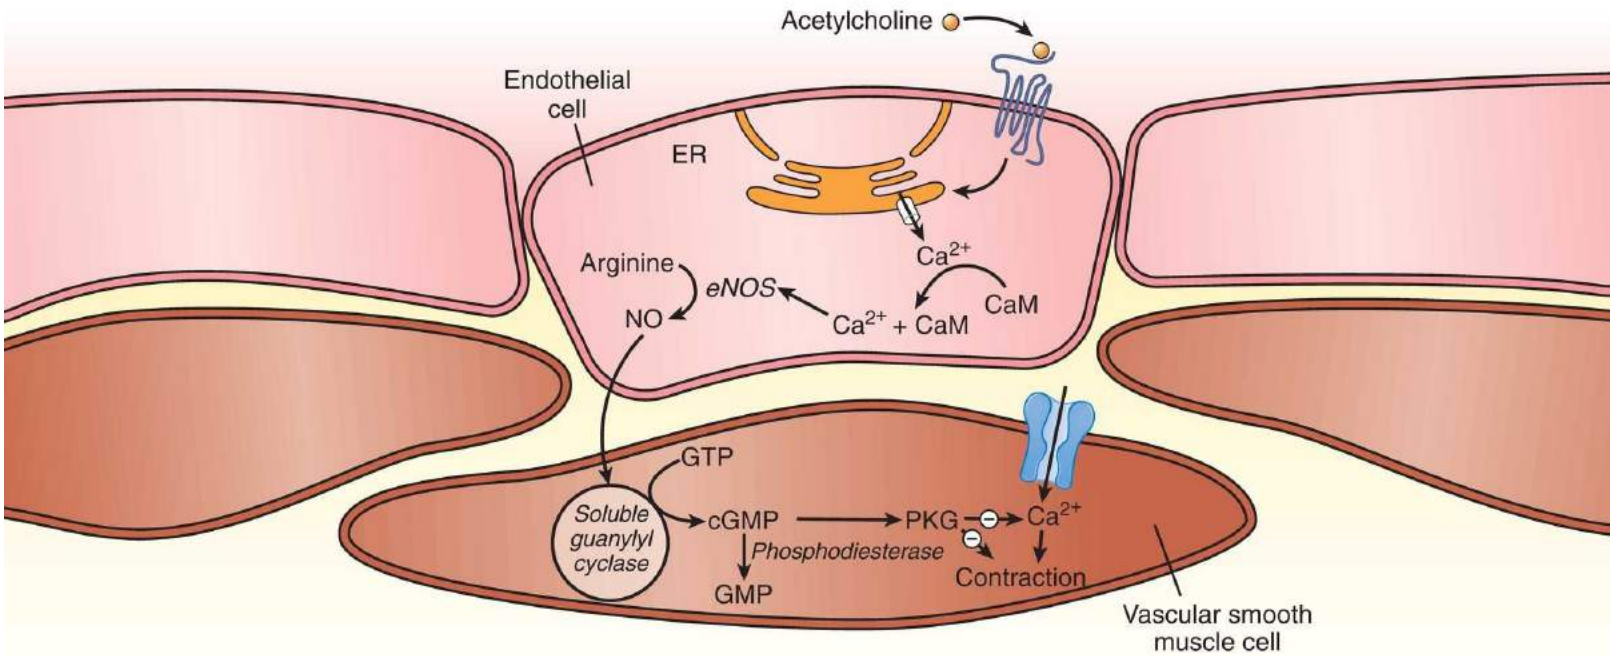

Figure 6.10 Nitric oxide-induced vascular smooth muscle relaxation. Acetylcholine can interact with receptors on endothelial cells to stimulate the synthesis of nitric oxide (NO). Nitric oxide diffuses into the vascular smooth muscle cell where it activates guanylyl cyclase to produce cGMP, which increases

activity of protein kinase G (PKG). Protein kinase G phosphorylates calcium channels and actin/myosin proteins to decrease contraction, which results in vasodilation.

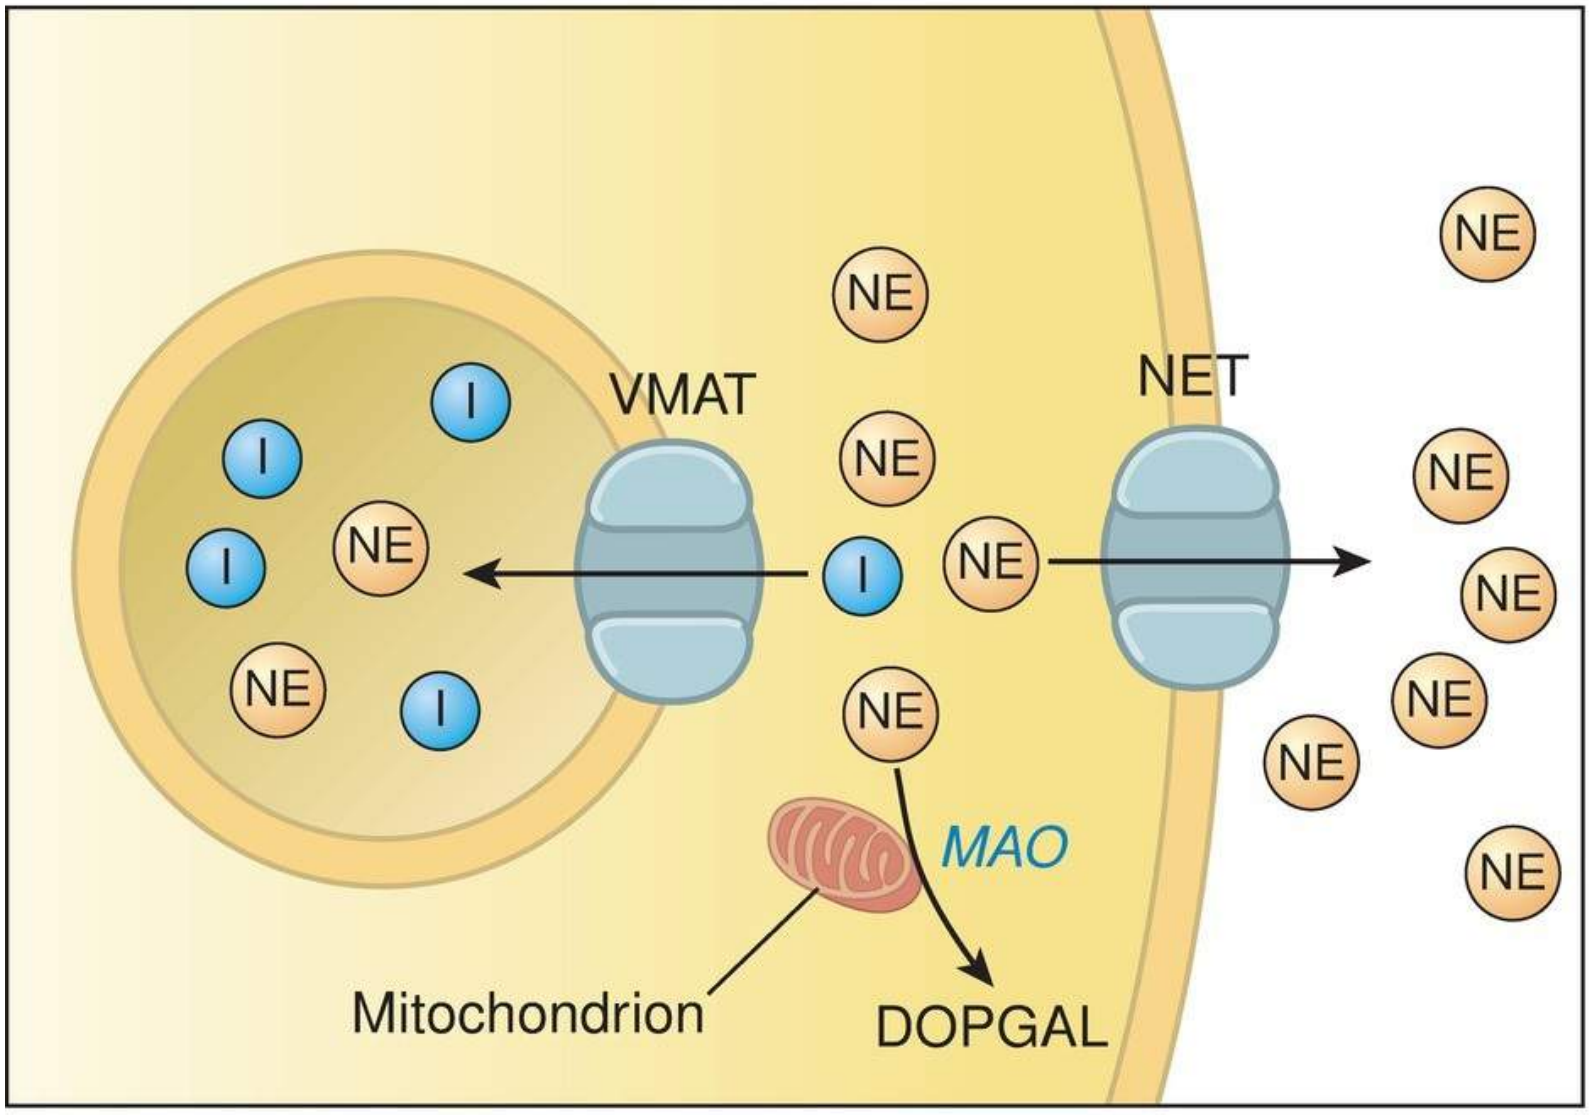
CLINICAL FOCUS 6.1

Indirect Sympathomimetics

An **indirect sympathomimetic** is a compound that is transported into the cell via the NET, via the DAT, and sometimes by SERT. It is then transported into the synaptic vesicle via the vesicular monoamine transporter (VMAT), as shown in the figure. Once in the vesicle, the indirect sympathomimetic displaces NE or DA from the vesicle. This increases NE or DA in the cytosol where it can be metabolized by monoamine oxidase. Because of the large cytosolic concentration, the NET or DAT will operate in reverse transporting the monoamine *into* the synaptic cleft thus producing a calcium-independent neurotransmitter release.

Methamphetamine is a stimulant drug of abuse that is an example of an indirect sympathomimetic. In addition to its indirect sympathomimetic activity, it has other actions such as inhibition of MAO, which can also increase adrenergic or dopaminergic activation. Increased release of NE in the periphery mimics certain functions of the SNS. Increased release of DA can activate the dopamine "reward" pathway between the ventral tegmental area and nucleus accumbens in the brain that is involved in the development of addiction. The activation of peripheral and central adrenergic receptors by methamphetamine can result in cardiac arrhythmias, myocardial infarction, stroke, and seizures, whereas activation of the reward pathway contributes to the addictive potential of methamphetamine.

Cocaine is another stimulant drug that activates both the dopamine reward pathway and adrenergic receptors, but it does so through a different mechanism. Cocaine inhibits reuptake of the monoamines at their individual transporters: the norepinephrine transporter (NET), dopamine transporter (DAT), and serotonin transporter (SERT). It also acts as a local anesthetic through inhibition of voltage-gated sodium channels. Similar to methamphetamine, elevated NE by cocaine can produce cardiac arrhythmias, myocardial infarction, stroke, and seizures. Overdoses of stimulants can be treated with benzodiazepines, which act at the $GABA_A$ receptor to produce CNS depression and counteract the CNS effects of stimulants.



Indirect sympathomimetics act to increase release of norepinephrine. Indirect sympathomimetics (I) gain access to the cytosol via transport by the norepinephrine transporter (NET). They are then transported into vesicles via the vesicular monoamine transporter (VMAT). Inside the vesicle, these displace the stored NE resulting in an increase in cytosolic NE. Some of the NE is degraded by monoamine oxidase (MAO) and some is transported out of the cell via the reversal of the NET. Thus, NE is released independent of an action potential.

Pseudoephedrine, brand name Sudafed, is also an indirect sympathomimetic. It produces decongestion through the vasoconstriction of the nasal mucosa by increasing the release of NE and subsequent activation of the α_1 adrenergic receptor. At therapeutic doses, pseudoephedrine produces less cardiac and abuse concerns than accompany methamphetamine. Pseudoephedrine can be chemically converted to methamphetamine and for this reason is an over-the-counter drug that is highly regulated.

Pseudoephedrine contains a warning that it should not be taken by a person who has recently received a monoamine oxidase inhibitor (MAOI). The MAOIs are antidepressant drugs that are primarily used to treat depression that is refractory to other treatments. By inhibiting MAO, these drugs increase the concentration of norepinephrine, dopamine, and serotonin in the presynaptic terminal. This becomes dangerous in the presence of indirect sympathomimetics. Normally, a portion of the NE that pseudoephedrine displaced from the vesicle into the cytosol is metabolized by MAO resulting in a smaller concentration of NE that is released into the synaptic cleft. When MAO is inhibited, there is a

larger concentration of NE released and the subsequent activation of α_1 receptors on the vasculature and β_1 receptors in the heart can result in a life-threatening increase in blood pressure.

This dangerously high concentration of NE and hypertensive crisis can also occur when foods containing tyramine are ingested when MAO is inhibited. Tyramine is another indirect sympathomimetic that is normally degraded by intestinal and hepatic MAO. When MAO is inhibited, tyramine is able to enter the circulation and affect sympathetic nerve terminals and lead to increased NE release and potential hypertensive crisis. Tyramine is found in aged cheese, smoked fish, cured meats, and some beers. Because of this, the tyramine–MAOI effect is sometimes referred to as the "cheese effect." ■

Epinephrine can produce both vasoconstriction and vasodilation.

Another role of the SNS is providing appropriate blood supply to skeletal muscle. This is particularly important during the "fight-or-flight" response. Unlike norepinephrine, which mostly acts locally in the area in which it was released from the postganglionic fiber, epinephrine circulates throughout the periphery as a peripheral hormone. As such, it interacts with α_1 receptors on vascular smooth muscle cells to produce vasoconstriction. This is part of the rationale for the use of "EpiPens" to counteract anaphylactic shock. During anaphylaxis, histamine produces vasodilation and bronchoconstriction through the activation of histamine receptors. Epinephrine counters this through actions on α_1 receptors to produce vasoconstriction and on β_2 receptors to produce bronchodilation.

Epinephrine also interacts with β_2 receptors on blood vessels in skeletal muscle to produce *vasodilation* thus facilitating the delivery of oxygen, glucose, and nutrients to meet increased metabolic demands. Despite this vasodilation, the net effect observed with systemic epinephrine is an *increase* in blood pressure because the β_2 vasodilation in skeletal muscle is masked by the much greater α_1 vasoconstriction. However, if the α_1 receptors are blocked, a decrease in blood pressure can be measured. This phenomenon is referred to as "**epinephrine reversal**" because initially an increase in blood pressure is observed but this increase can be "reversed" by blocking α_1 receptors resulting in a decrease in blood pressure. This reversal does not occur with norepinephrine because it has little effect on β_2 receptors (Clinical Focus 6.2).

CLINICAL FOCUS 6.2

Pheochromocytoma

Pheochromocytoma is a rare tumor of the chromaffin cells of the adrenal medulla. These are the same cells that receive preganglionic sympathetic input and release epinephrine, along with some NE, in the systemic circulation. In a person with pheochromocytoma, there is an overproduction of epinephrine and NE leading to high concentrations of catecholamines in the blood. This results in increased blood pressure, increased heart rate, and generalized sweating. Additionally, headaches are common possibly due to effects on the vasculature. Most tumors are removed surgically; however, drugs can be used to manage symptoms prior to surgery.

One approach to reduce symptoms is to block adrenergic receptors. Phenoxybenzamine irreversibly blocks both α_1 and α_2 receptors. Blocking α_1 receptors will decrease vasoconstriction and relieve the hypertension. However, the drop in blood pressure can activate the baroreceptor reflex (see Chapter 17) leading to *increased* NE release into the heart and *increases* in heart rate due to activation of the β_1 receptor. Once phenoxybenzamine begins lowering the blood pressure, a β-adrenergic receptor blocker can be added to block the baroreceptor-induced adrenergic stimulation of the heart. If the β-blocker is started before phenoxybenzamine, blood pressure can *increase* due to blockade of β_2 receptors in skeletal muscle: activation of β_2 receptors by epinephrine normally results in vasodilation

but this effect is masked by the interaction of epinephrine with α_1 receptors and the overwhelming vasoconstriction that ensues. Because the β_2 receptor–induced vasodilation acts to mitigate the α_1 receptors, removal of β_2 vasodilation by the β-blocker can further *increase* blood pressure. A second approach to reduce symptoms of pheochromocytoma is the use of calcium channel blockers, which produce vasodilation and also decrease the stimulation of the heart. A third approach is the use of metyrosine. Metyrosine blocks the enzyme tyrosine hydroxylase, which converts tyrosine to L-dopa. This is the rate-limiting step in the synthesis of catecholamines. This results in the reduction of catecholamines throughout the body, which also produces a number of adverse effects including sedation, depression, and movement dysfunction. While not ideal, these approaches can provide short-term management of symptoms until the tumor can be removed. ■

Receptors and pathways of the autonomic nervous system provide targets for therapeutics.

Because of the breadth of functions of the ANS, there are many medications that target the different receptors of the autonomic nervous system. In some cases, **agonists** are utilized to mimic the action of ACh or NE at its receptors. At other times, **antagonists** are utilized to block the function of ACh or NE at its receptor and decrease overall activity. Common medical conditions involving the ANS and their treatments are listed in Table 6.4. It is also important to remember that while activating or blocking part of the autonomic nervous system can produce therapeutically beneficial effects, it can also result in predictable adverse effects. In fact, many drugs for which "dry mouth" is an associated adverse effect produce some degree of muscarinic receptor blockade. Overall, drugs targeting functions modulated by the autonomic nervous system are highly effective and useful.

TABLE 6.4 Common Treatments for Disorders Involving the ANS

		Indication	Example Generic	Example Brand Name
ACh Receptor Agonists:	Muscarinic Receptor	Glaucoma	Pilocarpine	Salagen
		Sjögren's syndrome		
		Urinary retention	Bethanechol	Urecholine
		Bronchoprovocation testing	Methacholine	Provocholine
	Nicotinic Receptor	Smoking cessation	Varenicline (partial agonist)	Chantix
ACh Receptor Antagonists:	Muscarinic Receptor	COPD	Ipratropium	Atrovent
		Motion sickness	Scopolamine	Transderm-Scop
		Overactive bladder	Tolterodine	Detrol
			Darifenacin	Enablex
		Parkinson's disease	Trihexyphenidyl	Artane
	Nicotinic Receptor: (Depolarizing)	Surgical paralysis	Succinylcholine	Anectine
	Nicotinic Receptor: (Nondepolarizing)	Surgical paralysis	Rocuronium	Zemuron

INTEGRATED MEDICAL SCIENCES

Organophosphate Poisoning

Acetylcholinesterase (AChE), the enzyme that hydrolyzes ACh, can be inhibited by different types of compounds. Some of these, such as the therapeutic drugs pyridostigmine (Mestinon) and donepezil (Aricept), inhibit the enzyme *reversibly*. This will allow the buildup of ACh in the synaptic cleft or at

the neuromuscular junction (NMJ), thus increasing the signaling by ACh. However, when the ACh reaches high enough concentrations, it will outcompete the AChE inhibitor preventing toxic levels of ACh from accumulating. In this manner, these compounds are useful in the treatment of myasthenia gravis (pyridostigmine) and some cognitive symptoms of Alzheimer's disease (donepezil).

Other inhibitors of AChE interact with the enzyme *irreversibly*. This results in ACh accumulating and reaching toxic concentrations. At the NMJ, this can produce a **depolarizing blockade** of the nicotinic receptor. A depolarizing blockade occurs initially when the nicotinic receptor, a ligand-gated ion channel allowing the influx of sodium ions, remains open due to the continued binding of ACh and later due to the desensitization of the nicotinic receptor such that it can no longer be activated. The open channel of the nicotinic receptor prevents the repolarization of the membrane, which is critical for the reactivation of voltage-gated sodium channels that are involved in propagating action potentials necessary for muscle contraction. Thus, the muscle cannot undergo the normal contraction–relaxation cycle and is paralyzed. Irreversible inhibitors of AChE are often organophosphates. One use of organophosphates is as pesticides. In the United States, the pesticides used are selective for insects but will affect humans at very high doses. Thus, organophosphate poisoning has been reported in farm workers or others who experience accidental high exposure to these pesticides. Another use of organophosphates is in chemical weapons such as the nerve gas sarin. Many of these compounds are deadly in very small amounts and act very quickly. Exposure to such compounds was a concern during the Gulf Wars.

Upon exposure to organophosphates, a person can experience stimulation of muscarinic receptors throughout the body due to the accumulation of ACh along with muscle weakness and paralysis due to the depolarizing blockade at the NMJ. Peripheral activation of muscarinic receptors will mimic parasympathetic nervous system activity along with activation of the sympathetic muscarinic receptors at the sweat glands. Thus, one experiences symptoms represented by the mnemonic DUMBBELSS: diarrhea, urination, meiosis, bradycardia, bronchoconstriction, emesis (vomiting), lacrimation (tearing), salivation, and sweating. In the CNS, activation of muscarinic receptors can lead to generalized seizures along with decreased respiratory drive through inhibition in the respiratory center in the brainstem.

Organophosphate poisoning can be treated with two drugs. One of these, pralidoxime, is a strong nucleophile that can remove the organophosphate from the AChE. This allows for the regeneration of the enzyme such that it can begin metabolizing the toxic levels of ACh. Pralidoxime cannot cross the blood–brain barrier. Because of this, it is effective at treating the paralysis and the stimulation of PSNS effector organs but it is ineffective in treating the CNS toxicity. For this, another drug is necessary. Atropine is an antagonist at muscarinic receptors and will block the access of ACh to muscarinic receptors. It is effective both peripherally and centrally and thus will block the overstimulation of all muscarinic receptors; however, it does not interact with nicotinic receptors and will not reverse the paralysis. Thus, both pralidoxime and atropine are necessary for the treatment of organophosphate poisoning. Autoinjectors containing both of these compounds are used by the military to protect against chemical weapon attacks. However, organophosphate poisoning must be treated quickly due to "aging" in which stronger bonds are formed between the organophosphate and AChE that are essentially unbreakable by pralidoxime. Aging occurs at different rates depending on the organophosphate but can occur in as little as 10 minutes. ■

Chapter Summary

- The autonomic nervous system consists of a two-neuron efferent pathway.
- The preganglionic neurons of the parasympathetic nervous system are located in the craniosacral regions of the spinal cord/brainstem and project to ganglia that are located in or near the effector organ.
- The preganglionic neurons of the sympathetic nervous system are located in the thoracolumbar region of the spinal cord and mostly project to ganglia that are located near the spinal cord in the sympathetic chain.
- The adrenal medulla is innervated by a sympathetic preganglionic axon and secretes epinephrine into the peripheral circulation.
- All preganglionic axons release acetylcholine.
- Parasympathetic postganglionic neurons release acetylcholine, whereas sympathetic postganglionic neurons primarily release norepinephrine with acetylcholine release from sweat glands.
- Many autonomic postganglionic fibers contain cotransmitters along with acetylcholine and norepinephrine.
- Some autonomic fibers contain neither acetylcholine nor norepinephrine but instead undergo nonadrenergic noncholinergic (NANC) transmission.
- The parasympathetic nervous system mediates normal functioning under nonstressed conditions, whereas the sympathetic nervous system mediates functioning during arousal, stress, and danger.
- The PSNS effects are mediated by cholinergic receptors, whereas the SNS effects are mostly mediated by adrenergic receptors.
- Both the PSNS and SNS exhibit tonic activity at different organs.
- Presynaptic inhibition can modulate functioning of the ANS by decreasing further output.
- The eye receives input from the PSNS and SNS and is an example of autonomic integration.
- The vasculature receives input only from the SNS, which is responsible for maintaining appropriate blood pressure.
- Epinephrine can produce vasoconstriction through actions at the α_1 receptor and vasodilation through actions at the β_2 receptor.
- There are many therapeutic drugs that target receptors involved in autonomic function.
- Stimulant drugs of abuse produce dangerous stimulation of peripheral adrenergic receptors.
- The combination of an indirect sympathomimetic and monoamine oxidase inhibitor can result in a hypertensive crisis.
- Pheochromocytoma is a tumor resulting in overproduction of catecholamines and can be treated by blocking their receptors or synthesis.
- Organophosphate poisoning can occur from exposure to pesticides or certain chemical weapons and will irreversibly block the breakdown of acetylcholine.

Chapter Review Questions

1. A 6-year-old boy is brought to the emergency department by his mother. The boy was playing in the yard while she was gardening and ingested some berries. He presents with dilated pupils, dry skin, elevated temperature, and apparent disorientation. His symptoms are a result of a chemical in the berries interfering with the normal functioning of the autonomic nervous system. Inhibition of which receptor or enzyme is consistent with the boy's presentation?

A. Acetylcholinesterase
B. α-Adrenergic receptor
C. β-Adrenergic receptor
D. Muscarinic cholinergic receptor
E. Nicotinic cholinergic receptor

The correct answer is D. The muscarinic receptor antagonist, atropine, is found in the plant *Atropa belladonna*, also known as "deadly nightshade." This can produce symptoms described as "hot as a hare, blind as a bat, dry as a bone, red as a beet, and mad as a wet hen." The boy is dry due to the lack of sweating and salivating. The lack of sweating also contributes to an increased temperature. The blockade of muscarinic receptors in the eye results in pupillary dilation and blurred vision. Blocking muscarinic receptors in the CNS can result in confusion and delirium.

2. A 65-year-old male patient is being treated for erectile dysfunction with a drug that prolongs the actions of nitric oxide. Which of the following would be a predictable adverse effect?

A. Constipation
B. Sweating
C. Muscle paralysis
D. Pupillary dilation
E. Vasodilation

The correct answer is E. Nitric oxide relaxes smooth muscle in the corpus cavernosum of the penis allowing an increased blood flow and subsequent erection. Phosphodiesterase inhibitors are used in the treatment of erectile dysfunction to decrease the breakdown of nitric oxide increasing the smooth muscle relaxation and erection. Nitric oxide also produces vasodilation. By decreasing the breakdown of nitric oxide, the phosphodiesterase inhibitors can lead to hypotension particularly in individuals taking nitrates for treatment of the cardiovascular disorder angina pectoris.

3. A 65-year-old male has been using propranolol, a nonselective β-adrenergic receptor antagonist, for the treatment of hypertension. Today he experienced an allergic reaction and visited the emergency department since he was having trouble breathing. He was administered epinephrine. Which of the following would be a predictable effect of epinephrine administration in this patient?

A. Bronchodilation
B. Shock (resulting from low blood pressure)
C. Stroke (resulting from high blood pressure)
D. Tachycardia (increased heart rate)
E. Dry mouth

The correct answer is C. Epinephrine usually produces bronchodilation through activation of β_2 receptors, increased heart rate through activation of β_1 receptors, and vasoconstriction through the activation of α_1 receptors. However, the current patient is receiving propranolol, which will block the

access of epinephrine to β receptors, which could prevent epinephrine from producing bronchodilation and increasing heart rate. Thus, answers A and D are incorrect.

The allergic reaction experienced by this patient is mediated by histamine release, which produces bronchoconstriction and vasodilation leading to a decrease in blood pressure, which can result in shock. Epinephrine is usually an effective treatment since it will produce bronchodilation, through activation of β_2 receptors, and vasoconstriction, through activation of α_1 receptors, resulting in a normalization of blood pressure. The α_1-mediated vasoconstriction is usually mitigated through activation of β_2 receptors, which produce vasodilation and thus prevent dangerously high blood pressures from occurring. In the absence of β_2 receptor stimulation, which can occur due to blocking of the receptors by a β receptor antagonist such as propranolol, there can be a large increase in blood pressure resulting in a hypertensive crisis, which can produce a stroke.

Clinical Application Exercises 6.1

A 13-year-old boy is staying a few days with his grandparents for a summer visit. His grandparents promise him a banana split if he will clean and straighten their garden workshed. During the cleanup, the boy accidentally knocked over a half-filled glass bottle of liquid, which falls and breaks on the cement floor of the shed. Thinking of being responsible, he calmly goes into the house for some paper towels and proceeds to clean up the spill in the workshed. He does not wear gloves or any kind of eye and face protection during the cleanup because the need for such protection does not cross his mind.

Within minutes after finishing the cleanup, the boy starts to salivate uncontrollably, and his eyes burn and tear up. His lower bowel churns, and he feels nauseated and dizzy. His muscles start to twitch. It is difficult for him to inhale, and he wheezes with each breath. He tries to walk to the house to get his grandparents, but he has great difficulty walking, and, along the way, he starts to urinate involuntarily. He collapses at the doorstep of his grandparents' home, where they immediately discover him and, realizing he is in severe physical distress, decide to immediately drive him to their local hospital emergency department, where he is immediately admitted and attended. Upon brief questioning by the attending ED physician, it is discovered that the shed the boy was cleaning contained fertilizers and a few herbicides and pesticides. The grandparents could not remember exactly which chemicals were present in the shed, but they do recall that a neighbor once said that one of the bottles contained the same chemical they heard was used to treat head lice.

QUESTIONS

1. Is there a single internal physiological factor that could account for the 13-year-old patient's presentation of both skeletal muscle and systemic autonomic effects following his exposure to the chemical he was trying to clean up? If so, what would cause exposure of the boy to that factor?
2. What chemical is used to treat head lice that would also create the symptoms exhibited by the patient in this case? To what class of chemical does this agent belong and what is its mechanism of action? Since the subject in this case did not ingest the liquid in the bottle he broke, how did the chemical(s) in the bottle enter his body?
3. How does exposure to excessive acetylcholine cause skeletal muscle twitching followed by muscle weakness?
4. Based on what you know thus far from this case presentation, how should the organophosphate poisoning in this boy be managed?

ANSWERS

1. The skeletal muscle twitching, followed by muscle weaknesses, including difficulty inhaling, is characteristic of overexposure of striated muscle to acetylcholine. Acetylcholine is also the parasympathetic neurotransmitter responsible for lacrimation, salivation, and bronchiole constriction. Acetylcholine stimulates GI acid secretion and intestinal motility and causes contraction of the urinary bladder, resulting in micturition. The boy's symptoms in this case could all be caused by excessive amounts of acetylcholine in the region of nicotinic receptors (primarily motor endplates) and autonomic muscarinic receptors (primarily parasympathetic postganglionic fiber receptors). Excessive concentrations of acetylcholine at synapses can result from excessive release from appropriate nerve endings or impaired chemical inactivation of acetylcholine by acetylcholinesterases in the synapses.
2. Malathion is a common pesticide used as a garden or agricultural insecticide to control mosquito populations or plant pests. It is also found in some treatments of head lice. Malathion belongs to a class of drugs called organophosphates, which are acetylcholinesterase inhibitors. Therefore, exposure to this agent mimics the effects of excess acetylcholine at end organs including striated muscle and several end organs whose function is modulated by the parasympathetic nervous system. Malathion is highly lipid soluble, and individuals can receive toxic concentrations of this agent by absorption through the skin, inhalation, or absorption through mucous membranes including the mouth and eyes. Malathion belongs to a subclass of organophosphates called irreversible cholinesterase inhibitors. Once bound to the cholinesterase, they become inactivated only extremely slowly. This factor enhances the potential toxicity of these agents.
3. Acetylcholine activates nicotinic receptors in skeletal muscle cells, which are ligand-gated sodium channels. Activation of these channels leads to a local depolarization of the membrane, which spreads electrotonically until they activate fast voltage-gated sodium channels in the vicinity. Activation of these channels causes the formation of action potentials in the muscle fiber and muscle contraction. Inhibition of acetylcholinesterases causes random activation of muscle fibers throughout the body, resulting in muscle twitching and fasciculations. However, continual activation of nicotinic receptors results in general muscle fiber depolarization and a shift in the resting membrane potential of the muscle fiber to more positive values. In many cases, this partial depolarization at rest locks the fast sodium channels in their inactive state, rendering them unable to trigger an action potential. A muscle fiber in this condition cannot contract, and, when this effect is spread to large groups of fibers, an overall muscle weakness ensues.
4. There are three primary goals to treatment of a patient poisoned by organophosphate exposure—decontaminate the patient, support cardiovascular and respiratory function, and restore normal acetylcholine balance. Skin of an exposed patient should be washed and the eyes flushed. The patient should be intubated and mechanically ventilated if unconscious. Atropine, a muscarinic-receptor antagonist, should be used to counteract all the parasympathomimetic actions of the organophosphate. In addition, pralidoxime should be used immediately in order to break the binding of the organophosphate with the cholinesterase. This is especially important with malathion because the bond of this agent with the enzyme "ages" over time, making it more and more difficult to dislodge the organophosphate from the enzyme.

7 Integrative Functions of the Central Nervous System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how the hypothalamus interfaces among the endocrine, autonomic, and limbic systems.
- Explain the difference between a biologic rhythm and a cycle.
- Explain the role of the brainstem reticular formation in consciousness and arousal.
- Describe the stages of sleep.
- Describe the functional organization of the forebrain.
- Describe the functional components of the limbic system.
- Explain the brain's reward system.
- Explain the components of the limbic system involved in mood disorders and schizophrenia.
- Explain the concept of long-term potentiation and how it relates to learning.
- Describe the areas of the brain that involve memory and learning.
- Describe how the Broca and Wernicke areas serve as functional components of language.

The **central nervous system (CNS)** detects and processes sensory information from both the internal and external environment. The motor system directs information to skeletal muscle for locomotion and fine movement. Both sensory and motor functions do not occur in isolation but are highly coordinated. The CNS can be grouped according to integrative function and comprises the following:

I. Brainstem
    A. Medulla
    B. Pons
    C. Midbrain
II. Cerebellum
III. Forebrain
    A. Diencephalon
    B. Hypothalamus
    C. Thalamus
    D. Cerebrum
        1. Basal nuclei
        2. Cerebral cortex

The brain areas involved in the coordinated activities of human behavior is part of the central integrative system. An overview of these components is shown in Figure 7.1 with their respective integrative functions shown in Table 7.1. Functional components of the central integrative system can be classified into several broad categories. *Motivational systems*, for example, are those responsible for the human drive to satisfy basic needs such as hunger and thirst. Another is the group of systems that carry out functions such as *learning* and *memory*. These systems endow us with the ability to acquire and store new

information. Still another category involves systems responsible for *communication*, specifically the form of the written and spoken language. Many of these functions depend on input from the **brainstem** regarding both internal and external environmental stimuli; the brainstem is also critical to the efferent control mediated by higher centers.

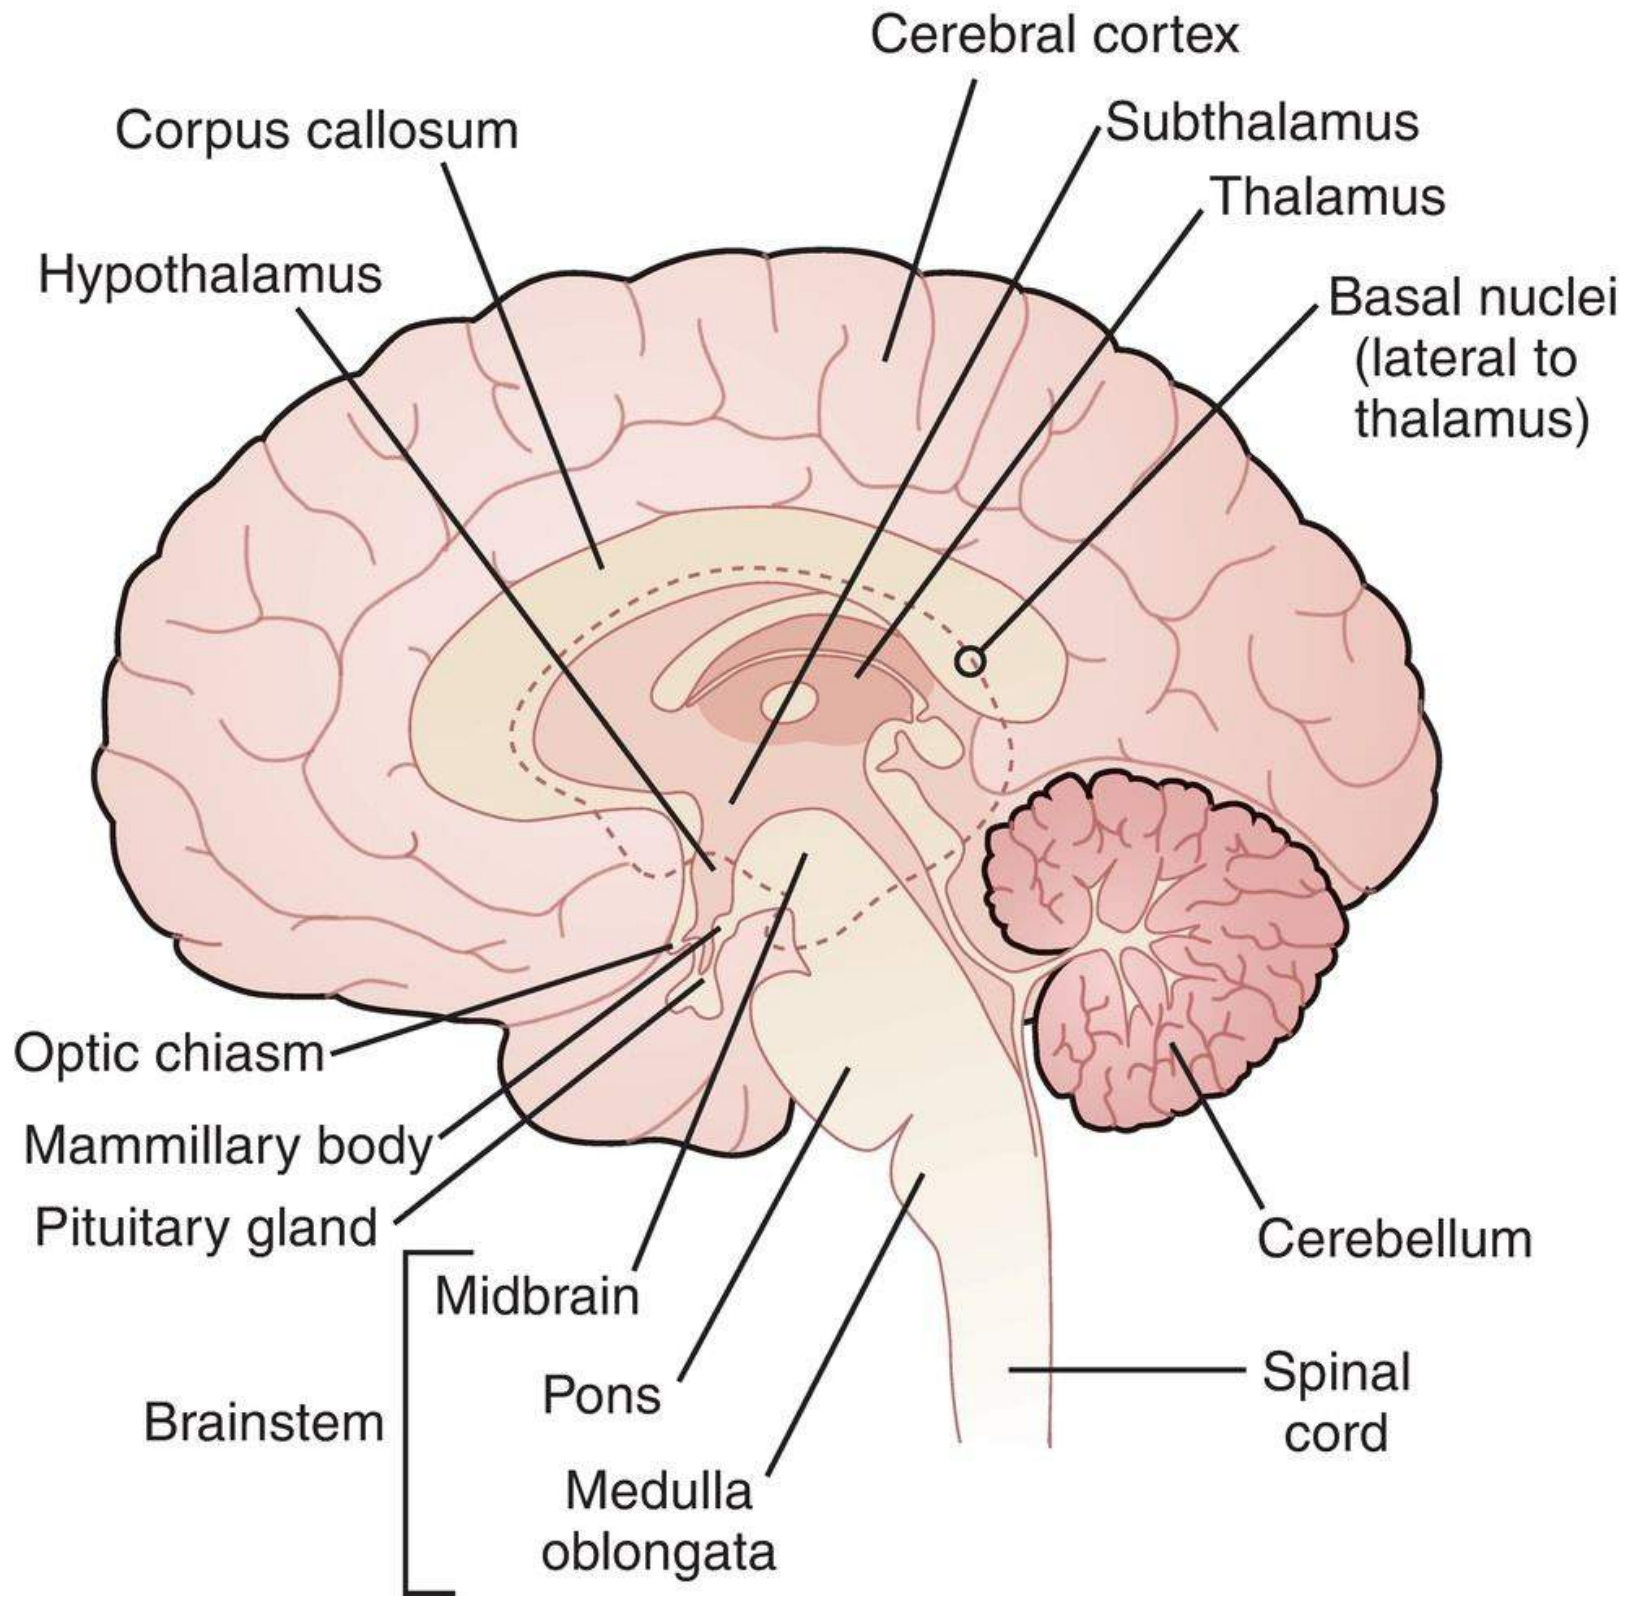

Figure 7.1 A midsagittal section through the brain showing the most prominent components. The cerebrum (*dotted line*) is the largest portion of the human brain.

TABLE 7.1 Major Integrative Functions of the Brain

Component	Major Functions
Cerebral cortex	Sensory perception
	Voluntary movement
	Language
	Personality
	Memory/decision making
Basal nuclei	Muscle tone
	Coordination of slow/sustained movements
	Inhibition of random movement
Thalamus	Relay station for all synaptic input
	Awareness of sensations
	Motor control
Hypothalamus	Homeostatic regulation for temperature, thirst, food intake, fluid balance, and biological rhythms
	Relay station between nervous and endocrine systems
	Sex drive and sexual behavior
	Emotions and behavior patterns
	Sleep–wake cycle
Cerebellum	Balance
	Muscle tone
	Coordination of voluntary muscle activity
Brainstem	Origin of most peripheral cranial nerves
	Control centers for cardiovascular, respiratory, and digestive regulation
	Regulation of muscle reflexes for posture and equilibrium
	Some control of sleep–wake cycle
	Integration of all synaptic input from spinal cord
	Activation of cerebral cortex

This chapter describes the brain areas responsible for these integrated functions and also examines how the brain collects and integrates information from its two hemispheres, specifically how similar functions are located on one side of the brain.

HYPOTHALAMUS

The **hypothalamus** is a portion of the brain that contains a number of small nuclei with a variety of functions. The hypothalamus is located just below the thalamus and just above the brainstem. It forms the inferior part of the **diencephalon**. The diencephalon includes the hypothalamus, thalamus, and subthalamus (see Fig. 7.1). The rostral border of the hypothalamus is at the optic chiasm, and its caudal border is at the mammillary body. The hypothalamus is connected to the endocrine system via the pituitary and serves as the major regulator of endocrine function. On the basal surface of the hypothalamus, exiting the median eminence, the pituitary stalk contains the **hypothalamohypophyseal portal blood vessels** (Fig. 7.2). Parvocellular neurons within specific nuclei of the hypothalamus secrete *hypothalamic-releasing hormones*, also designated as **releasing factors**, into the portal vessels. Releasing factors then regulate the secretion of most hormones of the endocrine system. The releasing factors are transported to the anterior pituitary, where they stimulate secretion of trophic hormones to other glands of the endocrine system (see Chapter 31). The pituitary stalk also contains the axons of magnocellular neurons whose cell bodies are located in the supraoptic and paraventricular hypothalamic nuclei. These axons form the **hypothalamohypophyseal tract** within the pituitary stalk and represent the efferent limbs of neuroendocrine reflexes that lead to the secretion of the hormones **arginine vasopressin** and **oxytocin** into the blood. These hormones are made in the magnocellular neurons and released by their axon terminals next to the blood vessels within the posterior pituitary.

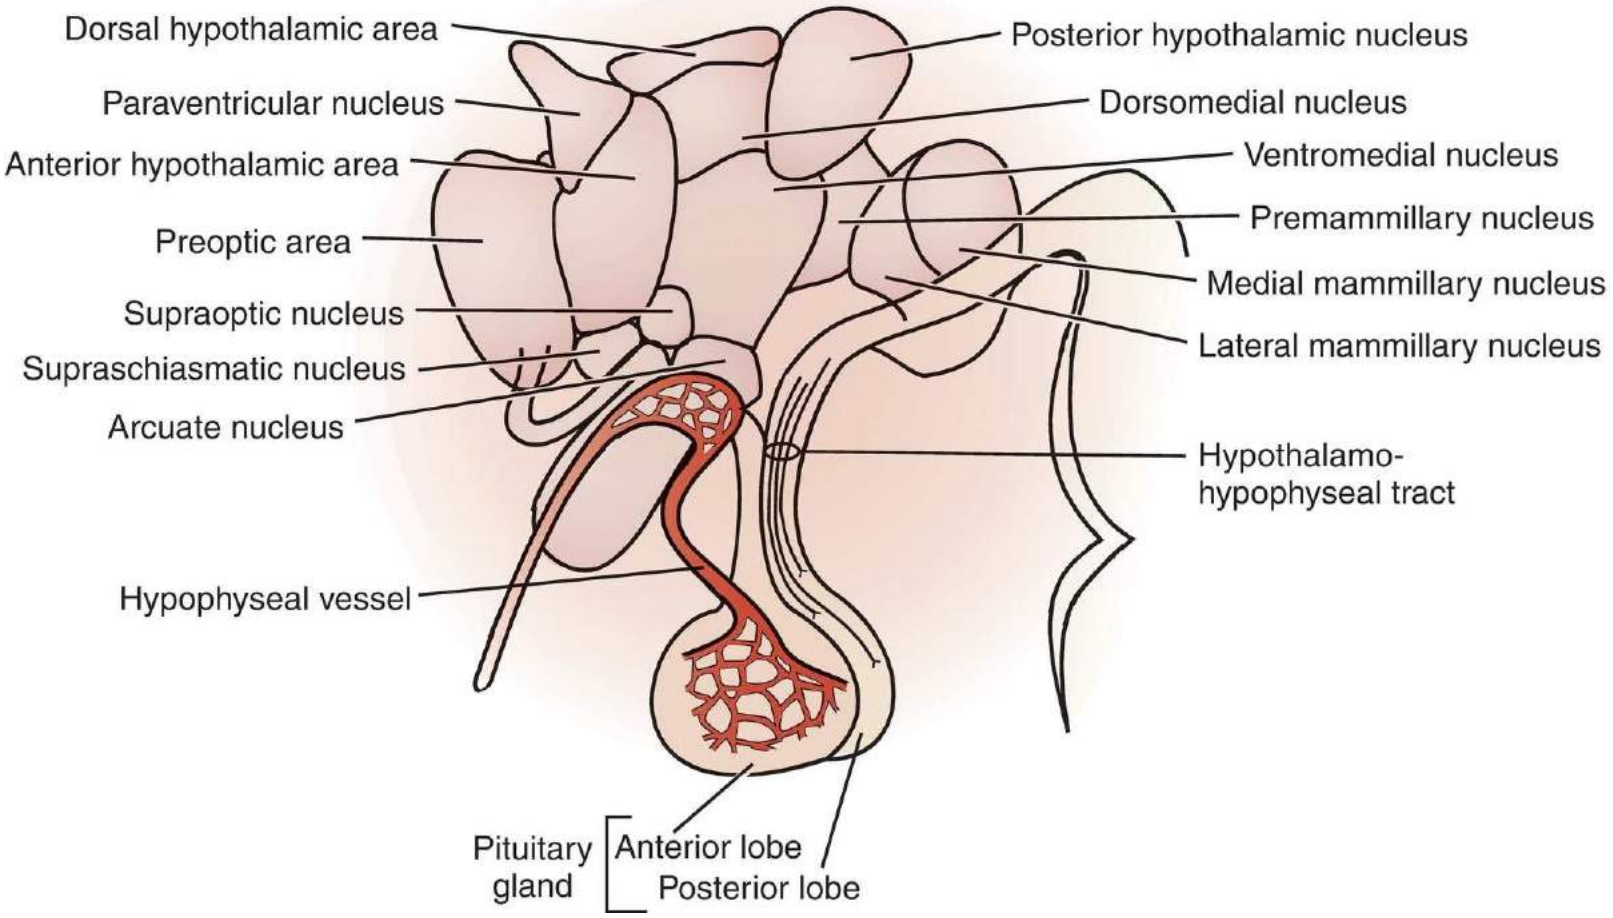

Figure 7.2 The hypothalamus and its nuclei. The hypothalamus comprises several different clusters of cell nuclei that are involved in many of its integrative functions. The connections between the hypothalamus and the pituitary gland are also shown.

In the adult human, the hypothalamus is approximately the size of an almond. Despite its small size, it serves as the major headquarters for coordinating many functions. The hypothalamus is responsible for coordinating autonomic reflexes of the brainstem and the spinal cord. It also activates the endocrine and somatic motor systems when responding to signals generated either within the hypothalamus or brainstem or in higher centers, such as the **limbic system**, where emotion and motivation are generated. The hypothalamus accomplishes this integration by virtue of its unique location at the interface between the limbic system and the endocrine and autonomic nervous systems.

As a major regulator of homeostasis, the hypothalamus receives input about the internal environment of the body via signals in the blood and from visceral afferents relaying through the brainstem. In most of the brain, capillary endothelial cells are connected by tight junctions that prevent substances in the blood from entering the brain. These tight junctions are part of the blood–brain barrier. The **blood–brain barrier** is missing in several small regions of the brain, called **circumventricular organs**, which are adjacent to the fluid-filled ventricular spaces. Important circumventricular organs are in and near the hypothalamus. Capillaries in these regions, similar to those in other organs, are fenestrated (“leaky”), allowing the cells of hypothalamic nuclei to sample the composition of the blood. Neurons in the hypothalamus then initiate the mechanisms necessary to maintain levels of constituents at a given set point, fixed within narrow limits by specific hypothalamic nuclei. Homeostatic functions regulated by the hypothalamus include body temperature, water and electrolyte balance, blood glucose levels, and energy balance.

Hypothalamus consists of distinct nuclei that interface between the endocrine, autonomic, and limbic systems.

The nuclei of the hypothalamus have ill-defined boundaries, despite their customary depiction (see Fig. 7.2). Many are named according to their anatomic location (e.g., anterior hypothalamic nuclei, ventromedial nucleus) or for the structures they lay next to (e.g., the periventricular nucleus surrounds the third ventricle, the **suprachiasmatic nucleus** [**SCN**] lies above the optic chiasm).

The hypothalamus receives afferent inputs from all levels of the CNS and makes reciprocal connections with the limbic system via fiber tracts in the **fornix**, stria terminalis, and ventral amygdalofugal pathway. The hypothalamus also makes extensive reciprocal connections with the brainstem, including the reticular formation and the medullary centers of cardiovascular, respiratory, and gastrointestinal regulation. Many of these connections travel within the **medial forebrain bundle**, which also connects the brainstem with the cerebral cortex.

Several major connections of the hypothalamus are one-way rather than reciprocal. One of these, the **mammillothalamic tract**, carries information from the mammillary bodies of the hypothalamus to the anterior nucleus of the **thalamus**, from where information is relayed to limbic regions of the cerebral cortex. A second one-way pathway carries visual information from the retina to the SCN of the hypothalamus via the optic nerve. Through this retinal input, the light cues of the day–night cycle entrain or synchronize the “biologic clock” of the brain to the external clock. The hypothalamus also projects directly to the spinal cord to activate sympathetic and parasympathetic preganglionic neurons (see Chapter 6).

Hypothalamus regulates energy balance by integrating metabolism and eating behavior.

Energy balance is the homeostasis of energy in living systems. It is measured by the following equation: energy intake = energy expenditure + storage. *Energy intake* is dependent on diet, which is mainly regulated by hunger and calories consumed. *Energy expenditure* is the sum of internal heat production and external work produced. Internal heat production is, in turn, the **basal metabolic rate** (**BMR**) and the thermal effect of food. External work is determined by physical activity. The hypothalamus plays a key role in regulating the homeostatic energy balance by controlling both energy intake and energy expenditure.

The regulation of eating behavior by the hypothalamus is part of a complex pathway that regulates food intake and energy expenditure in the face of changes in nutritional state. In general, the hypothalamus regulates caloric intake, use, and storage in a manner that tends to maintain the body weight in adulthood. The presumptive set point around which it attempts to stabilize body weight is remarkably constant but can be altered by changes in physical activity, composition of the diet, emotional states, stress, aging, pregnancy, and pharmacologic agents such as atypical antipsychotics.

The melanocortin system in the **arcuate nucleus** (ARC) of the hypothalamus is a critical CNS component in the regulation of energy homeostasis (Fig. 7.3). Within ARC, **proopiomelanocortin (POMC)** neurons act as **anorexigenic** (causing loss of appetite) neurons, their stimulation leading to decreased food intake and increased energy expenditure. The decrease in feeding by POMC is mediated by alpha-melanocyte–stimulating hormone, a cleaved product of POMC, which simulates melanocortin receptors. Studies have shown that mutations in melanocortin receptor 4 are associated with early-onset obesity and mutations of this receptor occur in some patients with severe obesity. A second group of neurons in the ARC are **orexigenic** (stimulating appetite) and contain **neuropeptide Y** (**NPY**) and **agouti-related protein** (**AgRP**). Stimulation of NPY/AgRP neurons causes increased food intake, decreased energy expenditure, and inhibition of POMC neurons.

POMC
Ghrelin from stomach
Insulin from pancreas
Leptin from adipocytes

Figure 7.3 Control of energy expenditure and feeding behavior. Cell groups within the arcuate nucleus (ARC) integrate peripheral orexigenic and anorexigenic signals. Activation of neuropeptide Y (NPY)/agouti-related protein (AgRP) neurons within the ARC leads to a decrease in energy expenditure acting via the paraventricular nucleus of the hypothalamus (PVH), the pituitary, and the autonomic nervous system and an increase in feeding behavior acting via the lateral hypothalamic area (LH) and several other central nervous system (CNS) sites. Activation of proopiomelanocortin (POMC) neurons within the ARC increases energy expenditure and decreases feeding behavior acting via the same areas. Additional peripheral signals activate the brainstem via the vagus nerve; the brainstem then bypasses the ARC to act directly on the PVH and LH. Many central pathways (*not shown*) involved in feeding behavior and/or energy expenditure also project to the ARC, PVH, and LH.

Both POMC and NPY/AgRP neurons express receptors for a wide variety of energy-related hormones and sample levels of these peptides through nearby circumventricular organs. Some, such as **leptin** and **insulin**, act on a longtime course to maintain body weight and blood glucose levels, and others, such as **cholecystokinin (CCK)** and ghrelin, act on a shorter time course to regulate initiation or cessation of a meal. Additionally, these neurons receive feeding-related sensory signals from the external environment as well as from the viscera, the latter being relayed via the vagus nerve and brainstem nuclei.

Outputs from ARC that mediate alterations in feeding or energy expenditure include projections to the lateral hypothalamus, dorsomedial nucleus, ventromedial nucleus, and paraventricular nucleus, as well as a variety of structures in the brainstem and forebrain cortical and limbic systems involved with feeding and motivated behaviors. Direct output to parasympathetic and sympathetic preganglionic neurons in the brainstem and spinal cord derives from the paraventricular nucleus and the ARC. The paraventricular nucleus engages the endocrine system through its regulation of the pituitary gland.

A key player in the regulation of body weight is the hormone leptin, which is released by white fat cells (adipocytes). As fat stores increase, plasma leptin levels increase; conversely, as fat stores are depleted, leptin levels decrease. Leptin inhibits the NPY/AgRP cells and stimulates the POMC cells in the ARC (see Fig. 7.3). Physiologic responses to low leptin levels (starvation) are initiated by the hypothalamus to increase food intake, decrease energy expenditure, decrease reproductive function, decrease body temperature, and increase parasympathetic activity. Physiologic responses to high leptin levels (obesity) are initiated by the hypothalamus to decrease food intake, increase energy expenditure, and increase sympathetic activity.

In addition to long-term regulation of body weight, the hypothalamus also regulates eating behavior more acutely. Factors that limit the amount of food ingested during a single feeding episode originate in the gastrointestinal tract and influence the hypothalamic regulatory centers. These include the following: sensory signals carried by the vagus nerve that signify stomach filling; chemical signals giving rise to the sensation of satiety, including absorbed nutrients (glucose, certain amino acids, and fatty acids); and gastrointestinal hormones, especially CCK, produced by endocrine cells in the gut wall, and ghrelin, produced by the epithelia of the stomach and small intestine. CCK is a satiety signal mediated via the vagus, whereas ghrelin stimulates food intake by activating the NPY/AgRP neurons in the ARC. The success of bariatric gastric bypass surgery as a treatment for morbid obesity is thought in part to be a result of the decreased secretion of ghrelin.

The complex regulation of energy balance and the evolutionary pressure to conserve energy conspire to make weight loss a difficult proposition. The ready availability of highly palatable foods and the decrease in exercise levels required to procure them are thought to underlie the increased incidence of

obesity in the population. Drugs that target increasing energy expenditure by activating the sympathetic nervous system have unacceptable side effects. Drug development has focused on blocking components of the central modulatory system that influences appetite (see Integrated Medical Sciences). One target has been the **endocannabinoids**. These compounds are the endogenous ligands for the cannabinoid receptors that mediate the effects of the psychoactive component of marijuana. Endocannabinoid receptors play an important role in energy homeostasis and are expressed in brain areas like the ARC, in several forebrain regions associated with motivated behavior, and in peripheral tissues associated with energy regulation like the liver and pancreas. Although the role of endocannabinoids in energy homeostasis is not completely understood, studies suggest that they modulate neuronal and tissue responses at multiple sites associated with energy homeostasis.

Integrated Medical Sciences

Central Nervous System: Therapeutic Targets for Antiobesity Medications

Marijuana (*Cannabis sativa*) has been a cultivated crop with known psychoactive properties for more than 4,000 years, but its active constituent, Δ-9 tetrahydrocannabinol, was not isolated until 1964. A high-affinity binding site in the brain was discovered in 1988, and the first cannabinoid receptor (CB_1) was cloned in 1991. Soon thereafter, the first endogenous cannabinoid, anandamide, was discovered. These findings set the stage for intensive efforts to develop pharmacological agonists and antagonists that target the endogenous pathways. A major motivation for this effort was the hyperphagia and carbohydrate craving associated with marijuana intoxication, with the implication that the endocannabinoids are involved in the regulation of feeding behavior. Researchers hoped that by targeting this system, they could increase appetite in cancer patients and to decrease appetite in obese patients.

Early studies of the selective CB_1 receptor blocker, rimonabant, found peripheral and central effects that influenced metabolism, decreased food intake, weight, triglyceride levels, low-density lipoprotein levels, C-reactive protein levels, and insulin resistance while increasing high-density lipoprotein levels. Despite early success and approval as a weight loss drug in Europe, rimonabant had to be withdrawn from the market because of a serious gastrointestinal and adverse psychiatric side effects.

Another target for antiobesity drugs is the brain's serotonin system, which plays a role in energy and glucose homeostasis. Hypothalamic anorexigenic POMC neurons express serotonergic receptors and treatments that reduce central serotonergic signaling can produce weight gain. Lorcaserin, a centrally acting serotonin 5-HT_{2c} receptor agonist, reduces body weight primarily by reducing food intake. Animal evidence suggests that lorcaserin works by activating anorexigenic POMC neurons.

Melanocortin receptors are also being investigated as potential targets for treating obesity. Melanocortin receptor 4 (Mc4) is expressed on neurons in the feeding pathways and defects in Mc4 cause of a form autosomal dominant obesity. Mc4 receptor agonists have been shown to induce weight loss in animal studies and early-phase clinical trials, but the agents have yet to make it to market. ■

Sexual drive and sexual behavior are controlled by the hypothalamus.

The anterior and preoptic hypothalamic areas are sites for regulating gonadotropic hormone secretion and sexual behavior. Neurons in the medial preoptic area (MPOA) secrete **gonadotropin-releasing hormone (GnRH)**, beginning at puberty, in response to signals that are not understood. These neurons contain receptors for gonadal steroid hormones, testosterone, and/or estradiol, which regulate GnRH secretion in either a cyclic (female) or a continual (male) pattern following the onset of puberty.

At a critical period in fetal development, circulating testosterone secreted by the testes of a male fetus changes the characteristics of cells in the MPOA that are destined later in life to secrete GnRH. These cells, which would secrete GnRH cyclically at puberty had they not been exposed to androgens prenatally, are transformed into cells that secrete GnRH continually at a homeostatically regulated level. As a result, males exhibit a steady-state secretion rate for gonadotropic hormones and, consequently, for testosterone (see Chapter 36).

In the absence of androgens in fetal blood during development, the MPOA remains unchanged, so that at puberty, the GnRH-secreting cells begin to secrete in a cyclic pattern. This pattern is reinforced and synchronized throughout female reproductive life by the cyclic feedback of ovarian steroids, estradiol and progesterone, on secretion of GnRH by the hypothalamus during the menstrual cycle (see Chapter 37).

Steroid levels during prenatal and postnatal development are known to mediate differentiation of sexually dimorphic regions of the brain of most vertebrate species. Sexually dimorphic brain anatomy, behavior, and susceptibility to neurologic and psychiatric illness are evident in humans. However, with the exception of the GnRH-secreting cells, it has been difficult to definitively show a steroid dependency for sexually dimorphic differentiation in the human brain.

In addition to secretion of GnRH, the MPOA has other roles in male sexual behavior. The MPOA is indirectly connected with all sensory systems and through reciprocal connections can modify sensory processing biasing it to prefer sexually relevant sensory cues. Outputs from the MPOA terminate in hypothalamic and brainstem nuclei that regulate autonomic and somatic behaviors related to male sexual responses. The paraventricular nucleus also contributes to male sexual behavior and its cells release oxytocin during sexual arousal, which has a powerful proerectile effect.

The ventromedial nucleus of the hypothalamus (VMH) has been implicated in the central neural control of female sexual behavior regulating fertility and sexual receptivity. Neurons in the VMH express high levels of estrogen receptors and injections of estrogen into the VMH in ovariectomized animals restore sexual receptivity.

Hypothalamus contains the “master biological clock” that controls rhythms and cycles.

Many physiologic events or processes repeat themselves with periodicity. When an event is repeated daily in the body, it is *rhythmic*, and if the event follows a monthly pattern, it is *cyclic*. Daily rhythms are referred to as **circadian rhythms**. Circadian rhythms are linked to the light–dark cycle. If the activity occurs during the day, the circadian rhythm is referred to as a **diurnal rhythm**. *Nocturnal* is another type of daily rhythm, and the behavior is characterized by activity during the night. Nocturnal rhythms are most prevalent in other vertebrates. An example of a diurnal rhythm is body temperature, which peaks during the day and falls at night. An example of the monthly cycle is the female menstrual cycle, in which a series of physiologic events is repeated every 28 days.

Circadian rhythms are endogenous (within the body) because they persist even in the absence of time cues, such as day–night cycles for light and dark periods, lunar cycles for monthly rhythms, or changes in temperature and day length for seasonal change. Accordingly, most organisms, including humans, are said to possess an endogenous timekeeper, a so-called **biologic clock** that times the body’s regulated functions.

The machinery of the biological clock resides within the cell. Nearly every mammalian tissue examined has been shown to have an intrinsic molecular circadian clock that utilizes transcriptional–translational feedback loops involving several genes termed *clock genes*. Some examples of clock genes are *CLOCK* and *BMAL1*, which encode proteins in the positive arm of the loop, and the *PERIOD* (*PER*) and *CRYTOCHROME* (*CRY*) families that are part of the negative arm.

Most homeostatically regulated functions exhibit peaks and valleys of activity that recur approximately daily. The hypothalamus plays a critical role in regulating all of these biologic rhythms serving as the “master clock” for synchronization of these daily rhythms. Within the hypothalamus, the SCN has a special role. Its cells have the properties of an oscillator whose spontaneous firing patterns change dramatically during a day–night cycle. This diurnal cycle of activity is maintained *in vitro* and is an internal property of SCN cells that employ the same molecular clocks seen in other tissues. The SCN has multiple cellular clocks that interact with other hypothalamic and nonhypothalamic nuclei to produce a functional network that controls the circadian rhythms of the body. The SCN is also key to entrainment of the body’s endogenous circadian rhythms to the world’s external day–night clock. The SCN receives light information from special nonimage forming photoreceptors containing melanopsin located in the ganglion cell layer of the retina. This information travels to the SCN in the **retinohypothalamic tract** of the optic nerve and is important for resetting the brain’s internal biological clock to match the external clock.

Figure 7.4 illustrates some of the circadian rhythms of the body. One of the most vivid is alertness, which peaks in the afternoon and is lowest in the hours preceding and following sleep. Another, body temperature, ranges ~1°C (~2°F) throughout the day, with the low point occurring during sleep. Plasma levels of growth hormone increase greatly during sleep, in keeping with this hormone’s metabolic role as a glucose-sparing agent during the nocturnal fast. Cortisol, on the other hand, has its highest daily plasma level prior to arising in the morning. The mechanism by which the SCN can regulate diverse functions is partly related to its control of the production of melatonin by the pineal gland. Melatonin levels increase with decreasing light as night ensues.

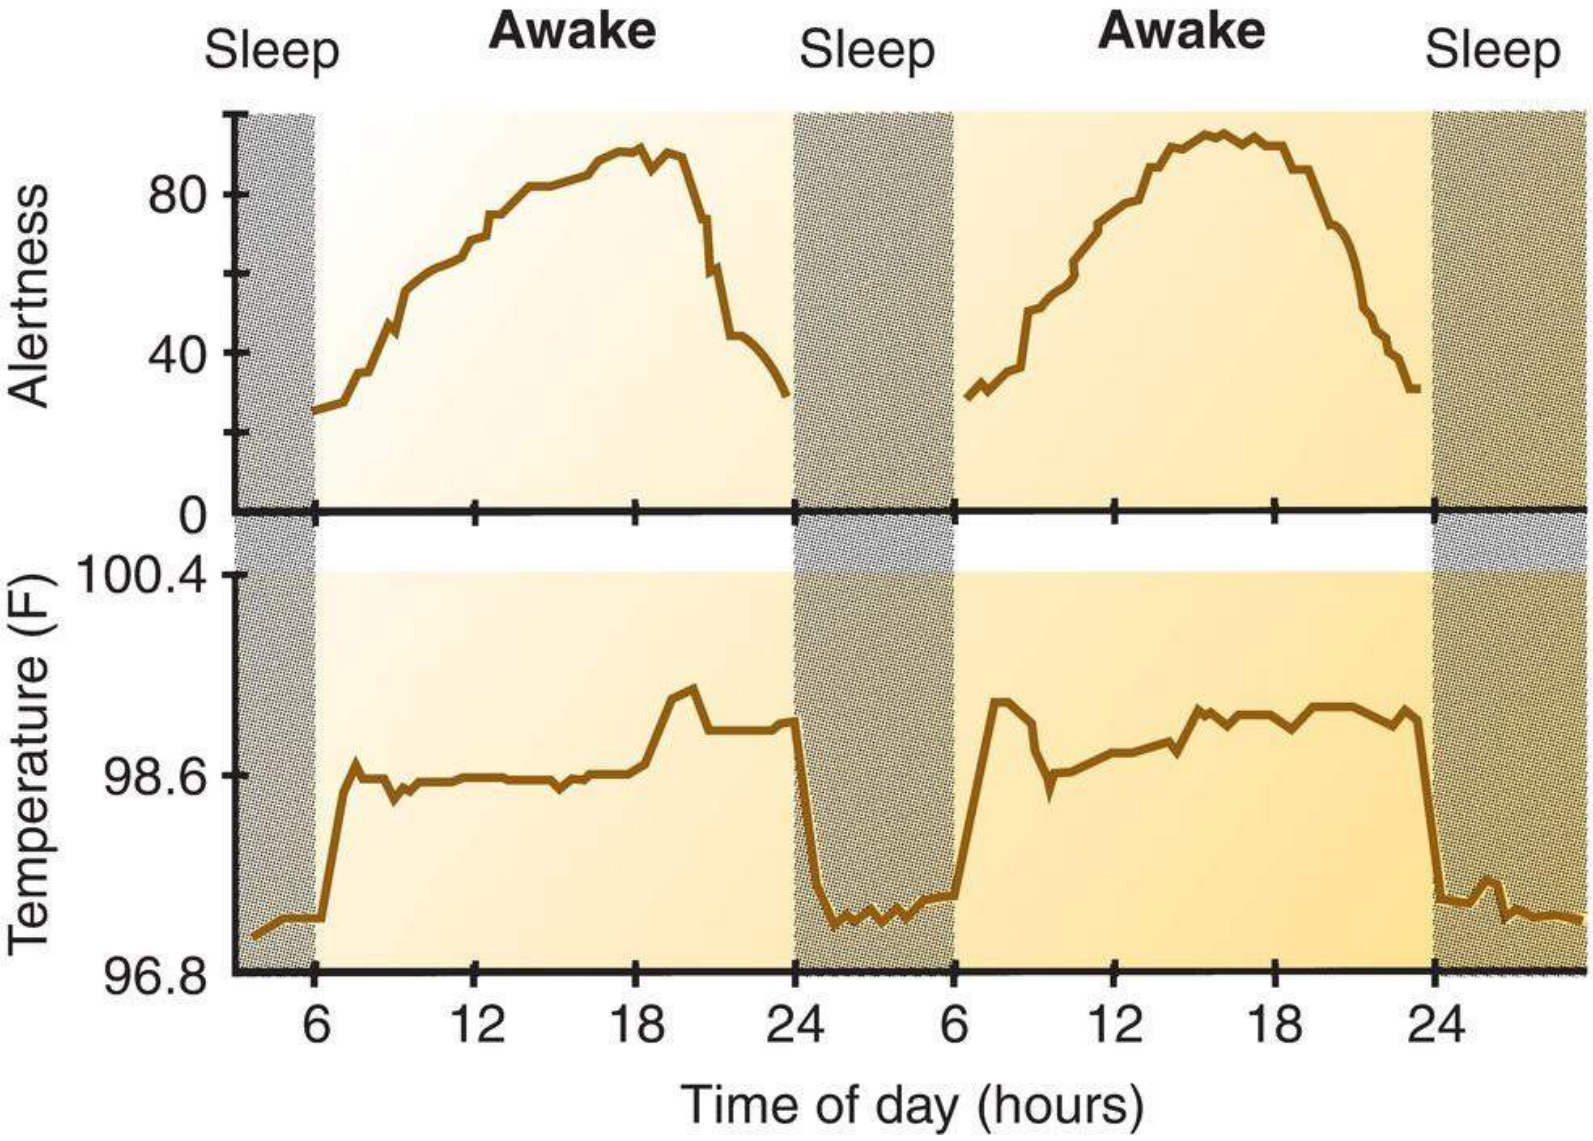

Figure 7.4 Circadian rhythms in some homeostatically regulated functions during two 24-hour periods. Alertness is measured on an arbitrary scale between sleep and most alert. Note that alertness and body temperature parallel each other.

Other homeostatically regulated functions exhibit diurnal patterns as well. When they are all in synchrony, they function harmoniously and impart a feeling of well-being. When there is a disruption in rhythmic pattern, such as by sleep deprivation or when passing too rapidly through several time zones, the period required for reentrainment of the SCN to the new day–night pattern is characterized by a feeling of malaise and physiologic distress. This is commonly experienced as "jet lag" in travelers crossing several time zones or by workers changing from day shift to night shift or from night shift to day shift. In such cases, the hypothalamus requires time to "reset its clock" before the regular rhythms are restored and a feeling of well-being ensues. The SCN uses the new pattern of light–darkness, as perceived in the retina, to entrain its firing rate to a pattern consistent with the external world. Resetting the clock may be facilitated by the judicious use of exogenous melatonin and by altering exposure to light.

In addition to entrainment of the biologic clock by light cycles, recent evidence suggests that the homeostatic mechanisms related to energy balance are intimately associated with the sleep–wake cycle. The link is a set of neurons in the posterolateral hypothalamus that express **hypocretin** (also known as *orexin*). These neurons are sensitive to nutritional status, stimulate appetite, and project to arousal areas of the brain. The SCN projects to the hypocretin-containing neurons and also receives input from the ARC. A functional deficit in hypocretin was found to be the cause of **narcolepsy** in animal models of this

disease. Narcolepsy is characterized by sudden short episodes of sleep, cataplexy (a sudden episode of muscle weakness leading to collapse), excessive daytime sleepiness, vivid dreams, and sleep paralysis during sleep onset or upon waking.

Reticular formation governs the regulation of muscle tone, pain, and the sleep–awake pattern.

The brainstem contains anatomic groupings of cell bodies clearly identified as the nuclei of cranial sensory and motor nerves or as relay cells of ascending sensory or descending motor systems. The remaining cell groups of the brainstem, located in the central core, constitute a diffuse-appearing system of neurons with widely branching axons, known as the **reticular formation**. The reticular formation constitutes the core of the brainstem and runs through the midbrain, pons, and medulla. A unique characteristic of neurons of the reticular formation is their widespread system of axon collaterals, which make extensive synaptic contacts and, in some cases, travel over long distances terminating in multiple areas of the CNS. The reticular formation contains small neural networks with varied functions including the regulation of arousal, the sleep–wake cycle, modulation of pain, regulation of muscle tone, and control of autonomic functions like heart rate and respiration.

Ascending reticular activating system mediates consciousness and arousal.

The ascending reticular activating system connects to areas in the cortex, thalamus, and hypothalamus and is important for cortical arousal and the maintenance of consciousness. Sensory neurons bring peripheral sensory information such as touch, hearing, or vision to the CNS via specific pathways that ascend and synapse with specific nuclei of the thalamus, which, in turn, innervate primary sensory areas of the cerebral cortex. Each modality has, in addition, a nonspecific form of sensory transmission in that axons of the ascending fibers send collateral branches to cells of the reticular formation (Fig. 7.5). The latter, in turn, send their axons to the cerebral cortex or to the intralaminar nuclei of the thalamus, which innervate wide areas of the cerebral cortex and limbic system. In the cerebral cortex and limbic system, the influence of the nonspecific projections from the reticular formation is arousal of the organism. This series of connections modulates forebrain neurons and is termed the **ascending reticular activating system**. So important is the ascending reticular activating system to the state of arousal that a malfunction in the reticular formation, particularly the rostral portion, can lead to a loss of consciousness and coma.

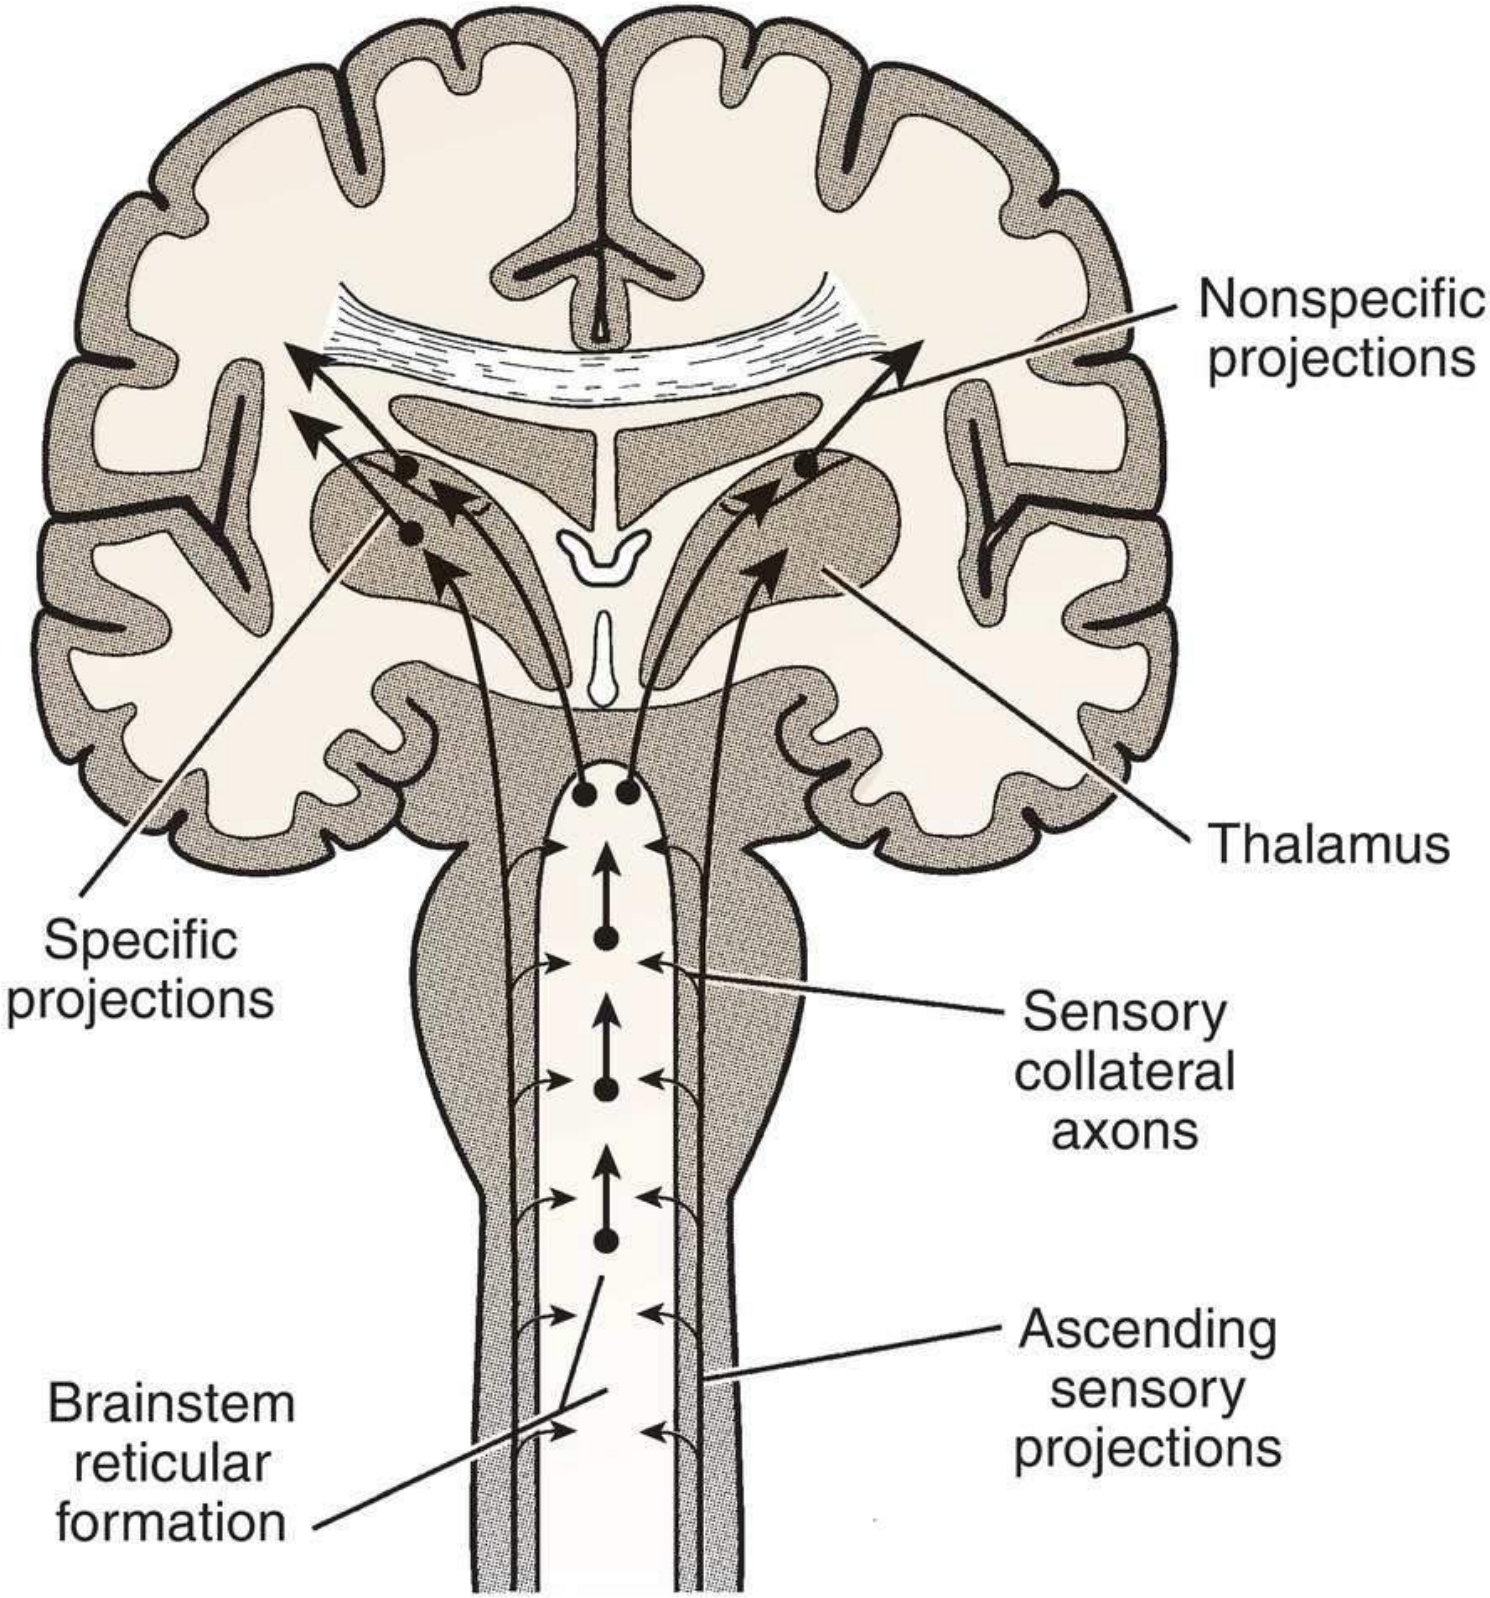

Figure 7.5 The brainstem reticular formation and reticular activating system. Ascending sensory tracts send axon collateral fibers to the reticular formation. Neurons in the reticular formation give rise to fibers that synapse in the intralaminar nuclei of the thalamus and the cerebral cortex. From the intralaminar nuclei, thalamic projections influence widespread areas of the cerebral cortex and limbic system.

Monoaminergic reticular formation cell groups

Monoaminergic neurons release monoamine neurotransmitters derived from aromatic amino acids (e.g., tryptophan, tyrosine, and phenylalanine). Monoamine neurotransmitters include *histamine*,

catecholamines (e.g., dopamine, norepinephrine [NE], and epinephrine), and *tryptamines* (melatonin and serotonin). Most monoaminergic cells are located in the reticular formation and axons arising from these cell groups innervate all parts of the CNS via widespread, divergent pathways. The cortex, limbic system, and basal ganglia are richly innervated by catecholaminergic (noradrenergic and dopaminergic) and serotonergic nerve terminals emanating from brainstem nuclei that contain relatively few cell bodies compared with their extensive terminal projections. From neurochemical manipulation of monoaminergic neurons in the limbic system, it is apparent that they play a major role in determining emotional state.

Dopamine pathways

Dopaminergic neurons are located in three major pathways originating from cell groups in either the midbrain (the substantia nigra and ventral tegmental area) or the hypothalamus (Fig. 7.6). The **nigrostriatal system** consists of neurons with cell bodies in the substantia nigra (pars compacta) and terminals in the striatum (caudate and putamen) located in the basal ganglia. This dopaminergic pathway is essential for maintaining normal muscle tone and modulating voluntary movements (see Chapter 5). The **tuberoinfundibular system** of dopaminergic neurons is located entirely within the hypothalamus, with cell bodies in the arcuate nucleus and periventricular nuclei and terminals in the median eminence on the ventral surface of the hypothalamus. The tuberoinfundibular system is responsible for the secretion of hypothalamic releasing factors into a portal system that carries them through the pituitary stalk into the anterior pituitary lobe (see Chapter 31). The dopaminergic neurons inhibit prolactin release from the pituitary.

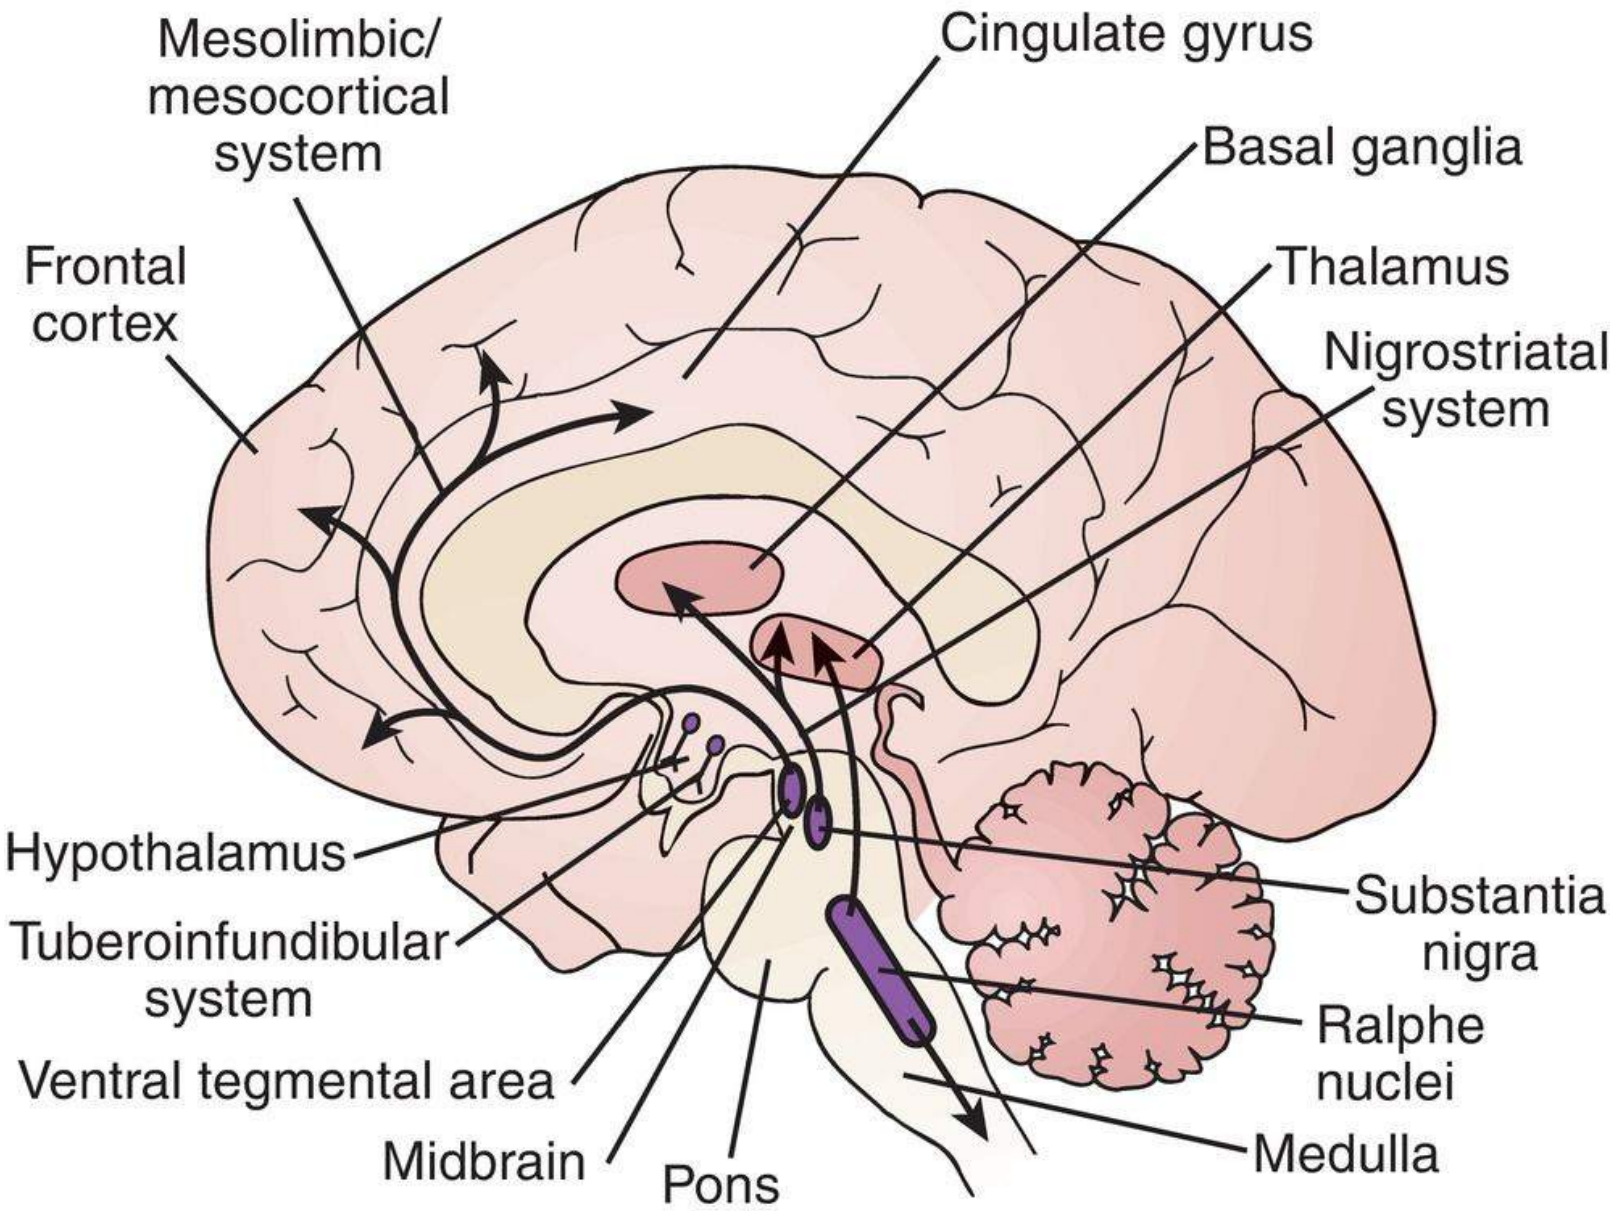

Figure 7.6 The origins and projections of the three major dopaminergic systems and the origins and projections of the serotonergic system.

A major dopaminergic pathway in the brain is the *mesolimbic pathway*, part of the **mesolimbic/mesocortical system**. This pathway begins in the ventral tegmental area of the midbrain of the brainstem and innervates the limbic system, hippocampus, and the medial prefrontal cortex. It functions in modulating behavioral responses, especially motivation and drive, to stimuli through the neurotransmitter dopamine (see Fig. 7.6). The ventral tegmental nucleus is also part of the brain's reward system. Drugs that increase dopaminergic transmission, such as cocaine, which inhibits dopamine reuptake, and amphetamine, which promotes dopamine release and inhibits its reuptake, lead to repeated administration and abuse in part because they stimulate dopamine transmission in the brain's reward system. The mesolimbic dopaminergic system is also one site of action of **neuroleptic** drugs, which are used to treat schizophrenia (discussed later) and other psychotic conditions.

The *mesocortical pathway* is another dopaminergic pathway of the mesolimbic/mesocortical system that connects the ventral tegmentum to the cerebral cortex, particularly the frontal lobes. This pathway is essential to the normal cognitive function of the prefrontal cortex. It is thought to be involved in motivation and emotional response and, like the mesolimbic system, its dysfunction has been implicated in schizophrenia

Noradrenaline pathways

Noradrenergic neurons (containing NE) are located in cell groups in the medulla and pons (Fig. 7.7). The medullary cell groups project to the spinal cord where they influence cardiovascular regulation and other autonomic functions. Cell groups in the pons include the lateral system, which innervates the basal forebrain and hypothalamus, and the locus ceruleus, which sends efferent fibers to nearly all parts of the CNS.

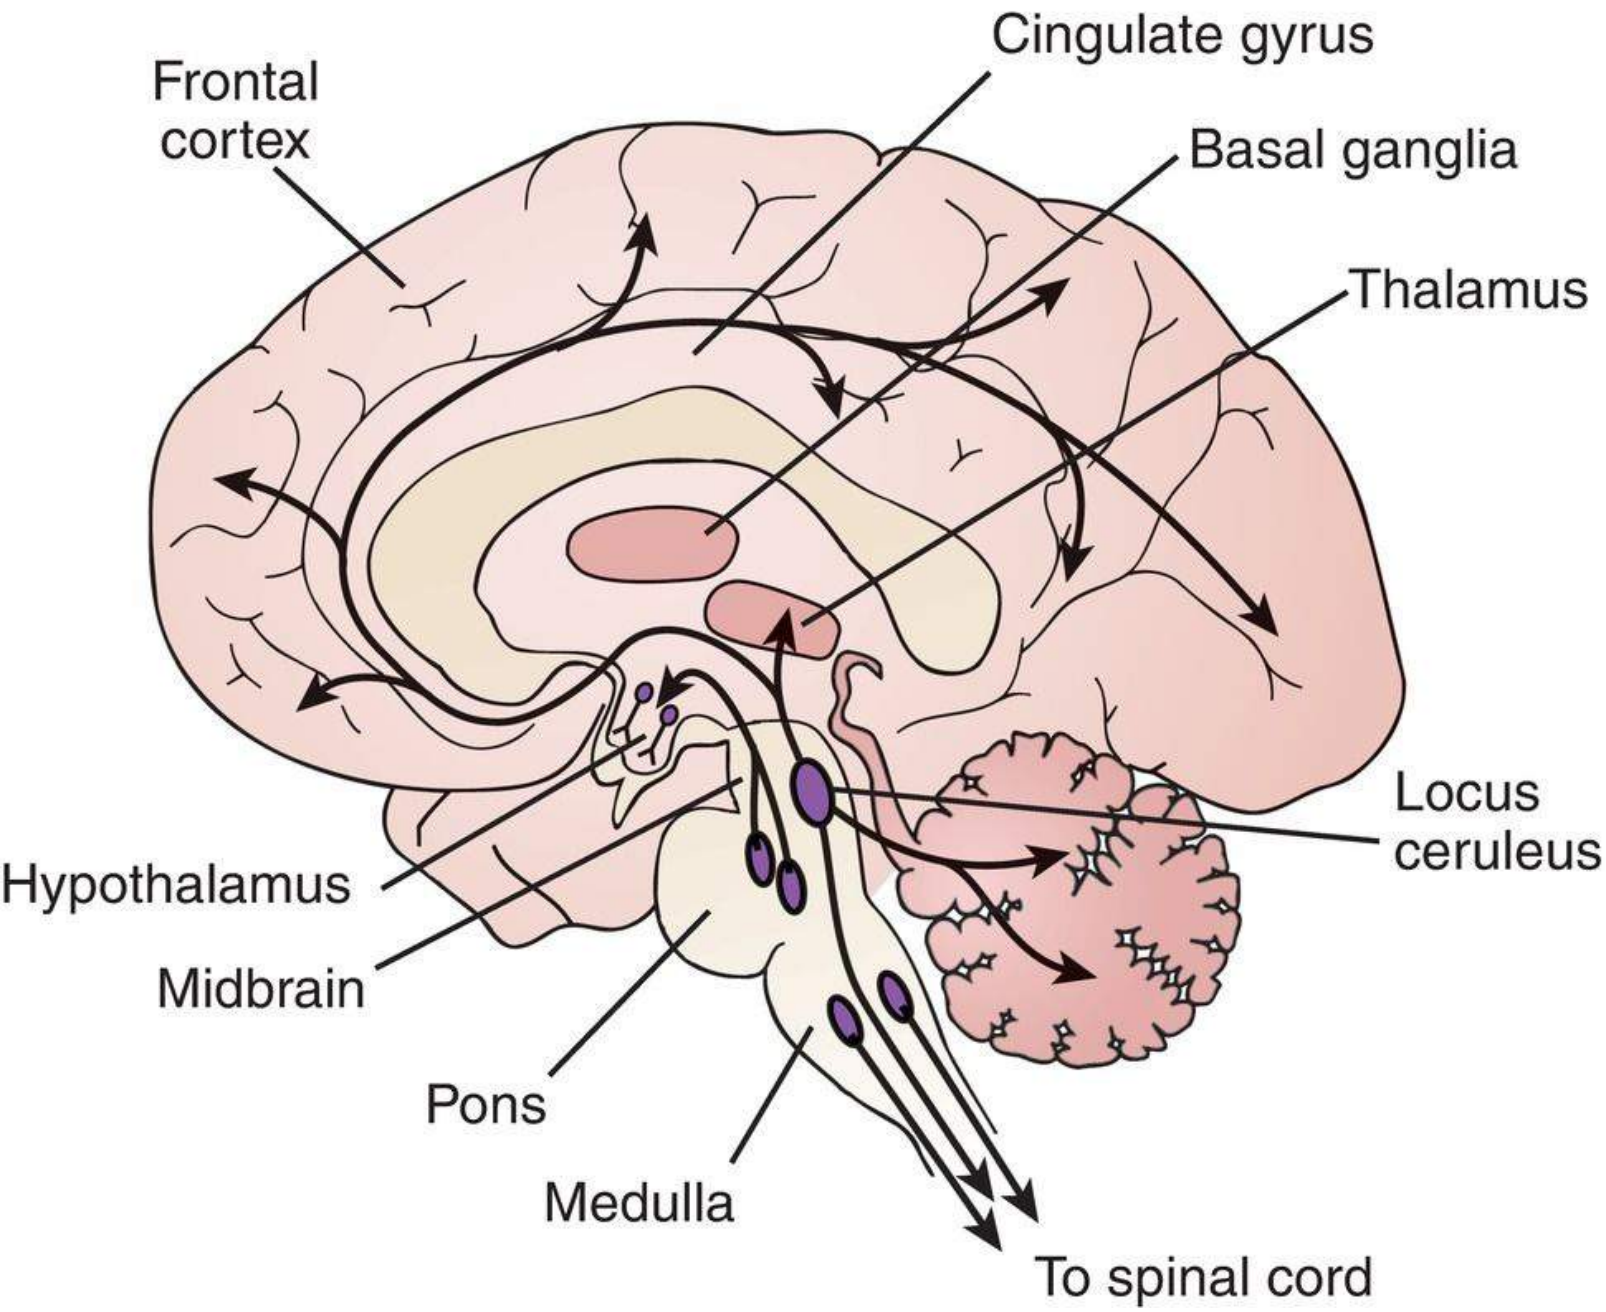

Figure 7.7 The origins and projections of five of seven cell groups of noradrenergic neurons of the brain. The depicted groups originate in the medulla and pons. Among the latter, the locus coeruleus in the dorsal pons innervates most parts of the central nervous system.

Noradrenergic neurons innervate all parts of the limbic system and the cerebral cortex, where they play a major role in setting **mood** (sustained emotional state) and **affect** (the emotion itself; e.g., euphoria, depression, anxiety). Drugs that alter noradrenergic transmission have profound effects on mood and affect. For example, reserpine, which depletes brain NE, induces a state of depression. Drugs that

enhance NE availability, such as monoamine oxidase inhibitors (MAOIs) and inhibitors of reuptake, reverse this depression. Amphetamines and cocaine have effects on boosting noradrenergic transmission similar to those described for dopaminergic transmission; they inhibit reuptake and/or promote the release of NE. Increased noradrenergic transmission results in an elevation of mood, which further contributes to the potential for abusing such drugs, despite the depression that follows when drug levels fall. Some of the unwanted consequences of cocaine or amphetamine-like drugs reflect the increased noradrenergic transmission, in both the periphery and the CNS. This can result in a hypertensive crisis, myocardial infarction, or stroke, in addition to marked swings in affect, starting with euphoria and ending with profound depression.

Serotonin pathways

Serotonergic neurons (neurons containing serotonin) also innervate most parts of the CNS. Most serotonergic neurons are located in the *raphe nuclei*, groups of cells located adjacent to the midline of the brainstem (see Fig. 7.6). Serotonin functions in mood, feeding, memory, sleep, and cognitive skills and decreased serotonin levels are linked to affective disorders like depression (discussed later). Drugs that increase serotonin transmission are effective antidepressant agents. Serotonin also regulates heart rate and breathing, and low levels of serotonin have been linked to **sudden infant death syndrome (SIDS)** or *crib death*. SIDS is marked by the sudden death of an infant that is unexpected by history and cannot be explained following a thorough forensic autopsy. An abnormality in serotonin signaling is not the only link; the frequency of SIDS appears to be a strong function of the infant's sex, age, birth weight, sleeping position, and ethnicity as well as the education and socioeconomic status of the parents.

Consciousness and arousal neurochemical systems

Reticular formation monoaminergic cell groups are not the only neurochemical systems that modulate cortical activity. The *tuberomammillary* nucleus of the lateral hypothalamus contains *histaminergic* neurons (cells using histamine as a neurotransmitter). The histaminergic projections from the tuberomammillary nucleus to the cerebral cortex increase cortical activation and alertness. These neurons fire at a high level during wakefulness and are important in the maintenance of wakefulness. Oral antihistamines, which reduce allergy symptoms through their peripheral action, also block central histamine activity resulting in a common side effect of these drugs, drowsiness.

The *cholinergic system* (cells containing acetylcholine) is a nonmonoaminergic system that modulates cortical activity. Concentrations of cholinergic neurons in the brainstem reticular formation *pedunculopontine nucleus* project to the thalamus, spinal cord, and other regions of the brainstem (Fig. 7.8). These cholinergic neurons influence the state of arousal by activating thalamocortical neurons involved in wakefulness and altering the activity of thalamic nuclei that are part of the sleep system.

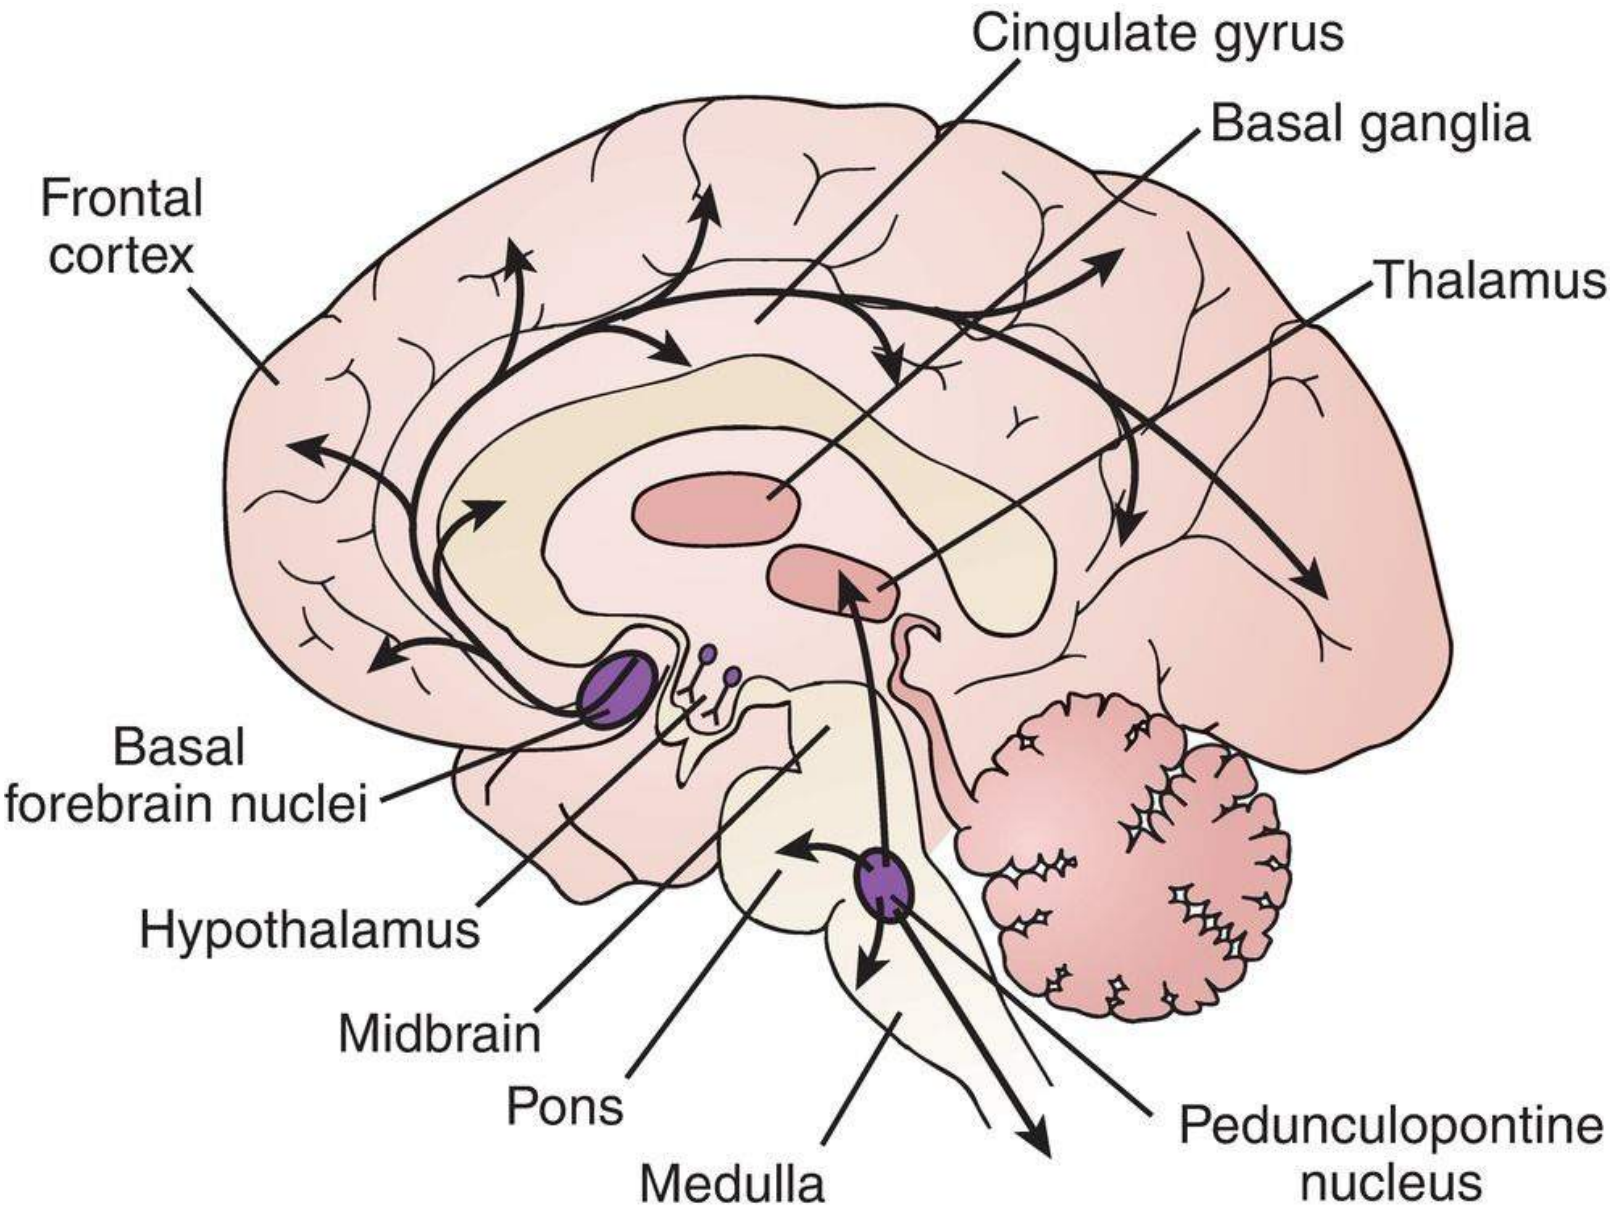

Figure 7.8 The origins and projections of major cholinergic neurons. Cholinergic neurons in the basal forebrain nuclei innervate all regions of the cerebral cortex. Cholinergic neurons in the brainstem's pedunculopontine nucleus provide a major input to the thalamus and also innervate the brainstem and spinal cord. Cholinergic interneurons are found in the basal ganglia. Not shown are peripherally projecting neurons, the somatic motor neurons, and autonomic preganglionic neurons, which also are cholinergic.

The basal forebrain region contains prominent populations of cholinergic neurons that project to the hippocampus and to all regions of the cerebral cortex (see Fig. 7.8). These cholinergic neurons are known generically as **basal forebrain nuclei** and include the septal nuclei, the nucleus basalis, and the nucleus accumbens. Cholinergic projections from the nucleus basalis terminate throughout the cerebral cortex and contribute to wakefulness as well as REM sleep. Cortical cholinergic connections are also thought to be important for selective attention and projections to the hippocampus are involved in memory.

BRAIN ELECTRICAL ACTIVITY

The influence of the ascending reticular activating system on the brain's activity can be monitored via **electroencephalography** (**EEG**). EEG is a sensitive recording device for picking up the electrical activity of the brain's surface through electrodes placed on designated sites on the scalp. This noninvasive tool measures simultaneously, via multiple leads, the electrical activity of the major areas of the cerebral cortex. It is also the best diagnostic tool available for detecting abnormalities in electrical activity, such as in epilepsy, and for diagnosing sleep disorders.

The detected electrical activity reflects the extracellular recording of the myriad postsynaptic potentials in cortical neurons underlying the electrode. The summated electrical potentials recorded from moment to moment in each lead are influenced greatly by the input of sensory information from the thalamus via specific and nonspecific projections to the cortical cells, as well as inputs that course laterally between different regions of the cortex.

EEG waves have characteristic patterns corresponding to state of arousal.

EEG frequency usually ranges from <1 to about 30 Hz, and amplitude, or height of the wave, usually ranges from 20 to 100 μV. Because the waves are a summation of activity in a complex network of neuronal processes, they are highly variable. However, during various states of consciousness, EEG waves have certain characteristic patterns. At the highest state of alertness, when sensory input is greatest, the waves are of high frequency and low amplitude, as many units discharge asynchronously. At the opposite end of the alertness scale, when sensory input is at its lowest in deep sleep, a synchronized EEG has the characteristics of low frequency and high amplitude. An absence of EEG activity is indicative of brain death.

EEG wave patterns are classified according to their frequency (Fig. 7.9). **Alpha waves**, a rhythm ranging from 8 to 13 Hz, are observed when the person is awake but relaxed with the eyes closed. When the eyes are open, the added visual input to the cortex imparts a faster rhythm to the EEG, ranging from 13 to 30 Hz and designated **beta waves**. The slowest waves recorded occur during sleep: **theta waves** at 4 to 7 Hz and **delta waves** at 0.5 to 4 Hz, in deepest sleep.

Figure 7.9 Patterns of brain waves recorded on an electroencephalogram. Wave patterns are designated alpha, beta, theta, or delta waves, based on frequency and relative amplitude. In epilepsy, abnormal spikes and large summated waves appear, as many neurons are activated simultaneously.

Abnormal wave patterns are seen in **epilepsy**, a neurologic disorder of the brain characterized by spontaneous discharges of highly synchronized electrical activity, resulting in abnormalities ranging from momentary lapses of attention, to seizures of varying severity, to loss of consciousness. The characteristic waveform signifying seizure activity is the appearance of spikes or sharp peaks, as abnormally large numbers of units fire simultaneously. Examples of spike activity occurring singly and in a spike-and-wave pattern are shown in Figure 7.9.

Sleep stages are defined by the EEG.

Sleep follows a circadian rhythm and is a naturally recurring altered state of consciousness, in which sensory and motor activity are suspended, as well as nearly all voluntary muscle activity. During sleep, a heightened anabolic state exists, accentuating growth and rejuvenating the immune, nervous, and muscular systems. Sleep is regulated by the body's biologic clock. The biologic clock for sleep works in tandem with adenosine, a neurotransmitter that inhibits most of the functional processes associated with wakefulness. Adenosine rises over the course of the day, and high levels induce drowsiness. The hormone melatonin is released during drowsy sleep and causes a concomitant gradual decrease in core temperature.

Electrical activity associated with sleep was first discovered in 1937 using EEG. The EEG recorded during sleep reveals a persistently changing pattern of wave amplitudes and frequencies, indicating that the brain remains continually active even in the deepest stages of sleep. The EEG pattern recorded during sleep varies in a cyclic fashion that repeats approximately every 90 minutes, starting from the time of falling asleep to awakening 7 to 8 hours later. Sleep stages and other characteristics of sleep are assessed in a specialized sleep laboratory. Measurements include EEG of brain waves, *electrooculography* of eye movements, and *electromyography* of skeletal muscle activity. Sleep is divided into two broad categories: **rapid eye movement** (**REM**) and **nonrapid eye movement** (**NREM**) **sleep**. Each type has a distinct set of functional, neurologic, and physiologic features. NREM is further divided into three substages: N1, N2, and N3. N3 is also called *delta sleep* or slow-wave sleep (SWS). Sleep proceeds in cycles of REM and NREM, the order normally being awake → N1 → N2 → N3 → N2 → REM. There is a greater amount of deep sleep early in the night, whereas the proportion of REM sleep increases later in the night and just before natural awakening. In humans, each cycle lasts on the average 90 to 110 minutes. NREM sleep stages are characterized as follows:

- Stage N1 is referred to as *somnolence* or *drowsy sleep stage*. Brain waves in stage N1 transition from the beta waves of wakefulness to alpha waves then theta waves (Fig. 7.10). During this transition, sudden twitches, also known as myoclonus, are often observed. Also, muscle tone and most conscious awareness are lost during N1.
- During stage N2, muscular activity decreases and conscious awareness of the external environment completely disappears. The brain waves continue to slow and sleep spindles and K-complexes characteristic of this stage appear (Fig. 7.10). This stage occupies 45% to 55% of total sleep in adults.
- Stage N3 is characterized as *deep* or SWS with the presence of delta waves ranging from 0.4 to 4 Hz. During this stage physiological indicators such as breathing rate, heart rate, and blood pressure are all at their lowest levels. This is the stage in which night terrors, bed wetting (nocturnal enuresis), sleepwalking, and sleeptalking (somniloquy) most frequently occur.

Figure 7.10 The brain wave patterns during a normal sleep cycle. Sleep cycles are divided into REM (rapid eye movement) and NREM (nonrapid eye movement) sleep. NREM is further divided into three stages: N1, N2, and N3.

REM sleep

REM sleep is characterized by REM as well as rapid, low-voltage EEG and accounts for 20% to 25% of total sleep time in most adults. This is the stage in which most memorable dreaming occurs. REM sleep is also known as paradoxical sleep, because of the seeming contradictions in its characteristics. First, the EEG exhibits unsynchronized, high-frequency, low-amplitude waves (i.e., a beta rhythm), which is more typical of the awake state than sleep (see Fig. 7.10), yet the subject is difficult to arouse. Second, the autonomic nervous system is in a state of excitation; blood pressure and heart rate are increased and breathing is irregular. In males, autonomic excitation in REM sleep includes penile erection. This reflex is used in diagnosing impotence, to determine whether erectile failure is based on a neurologic or a vascular defect (in which case, erection does not accompany REM sleep). When subjects are awakened during an REM period, they usually report dreaming. Accordingly, it is customary to consider REM sleep as dream sleep. Another curious characteristic of REM sleep is that most voluntary muscles are temporarily paralyzed. Two exceptions, in addition to the muscles of respiration, include the extraocular muscles, which contract rhythmically to produce the REMs, and the muscles of the middle ear, which protect the inner ear (see Chapter 4). Muscle paralysis is caused by an active inhibition of motor neurons mediated by a group of neurons located close to the locus coeruleus in the brainstem. Many of us have experienced this muscle paralysis on waking from a bad dream, feeling momentarily incapable of running from danger. In certain sleep disorders in which skeletal muscle contraction is not temporarily paralyzed in REM sleep, subjects act out dream sequences with disturbing results, with no conscious awareness of this happening.

Sleep in humans varies with developmental stage. Newborns sleep ~16 hours per day, of which about 50% is spent in REM sleep. Normal adults sleep 7 to 8 hours per day, of which about 25% is spent in REM sleep. The percentage of REM sleep declines further with age, together with a loss of the ability to achieve stage 3. Sleep debt is not getting enough sleep. Sleep deprivation can lead to a large sleep debt, which can cause emotional, mental, and physical problems. Sleep deprivation leads to increased irritability, cognitive impairment, memory loss, muscle tremors, and daytime yawning. Sleep deprivation has been shown to be a risk factor for weight gain, hypertension, type 2 diabetes, and impaired immune system. There are many reasons for poor sleep that lead to sleep deprivation. Pain, drugs, and stress can be the culprit. Sleep apnea, narcolepsy, insomnia, restless leg syndrome, and peripheral neuropathy are also causes of poor sleep.

Abnormal brain waves indicate epilepsy.

Seizure is defined as a transient symptom of abnormal excessive electrical activity in the brain. This abnormal activity is readily apparent in the EEG and different types of seizures have characteristic patterns that can aid in seizure classification. Several different etiologies can cause seizures including metabolic imbalances, high fever, drug abuse, genetic abnormalities, and brain infections or injury. **Epilepsy** is a chronic condition where an individual has recurrent seizures. The abnormal electrical activity of a seizure results from abnormal neuronal physiology that produces neuronal hyperexcitabilty and hypersynchrony. This abnormal pathology occurs in groups of neurons and represents an imbalance between excitatory and inhibitory ionic currents in the neuronal networks of the brain. Many of the drugs used to treat epilepsy target the neuronal ion channels responsible for these currents in an attempt to bring the networks back into balance. Although these drugs may control the seizures of epilepsy, they do not cure the disease and patients must often take these drugs their entire lives.

The outward effect of epileptic seizures is manifested in three different ways: (1) dramatic wild thrashing movements (tonic–clonic seizure), (2) mild loss of awareness, or (3) convulsions. Seizure is not always accompanied by convulsions. Sometimes, a patient may lose consciousness and "slump" to the ground or they may only temporarily stare into space. After a seizure, while the brain is recovering, there is often a transient loss of memory.

Generalized and partial seizures

Epilepsy is not a single disease having many clinical manifestations and underlying pathologies. Seizures are generally divided into two major types, *generalized* and *partial*, based on where the seizures start and how they then spread.

Generalized seizures usually start in both hemispheres or at a subcortical location like the thalamus. The tonic–clonic seizure (formerly known as *grand mal seizures*) is an example of a generalized seizure that affects the entire brain. In the *tonic phase,* the person quickly loses consciousness and the skeletal muscles suddenly become tense, causing extremities to be pulled inward toward the body.

During the *clonic phase*, muscles contract and relax rapidly, causing convulsions. The convulsions can range from exaggerated twitches to violent shaking. The eyes typically roll back or close, and the tongue often suffers bruises sustained from jaw contractions. Incontinence sometimes occurs. Confusion and complete amnesia are usually experienced upon regaining consciousness. Due to physical and nervous exhaustion, a long sleep period usually follows a tonic–clonic seizure.

Absence seizures (formerly known as *petit mal seizures*) are another type of generalized seizure. In this seizure, the person appears to stare into space with episodes lasting up to 10 seconds. Partial seizures (formerly known as *focal seizures*) begin in a localized area of the brain and the disturbances produced reflect the function of that brain area. For example, a disturbance may include a twitching of part of the body, such as a limb, or a deceptive or illusory sensation. Partial seizures are further classified as (1) simple partial (with no interruption to consciousness) and (2) complex partial (interrupts consciousness). Most often, partial seizures result from a localized lesion or functional abnormality. Examples include scar tissue that adheres to adjacent brain tissue, a brain tumor that compresses a discrete area of the brain, or dysfunctional local circuitry. Although starting at a specific locality, in some cases, partial seizures can spread to encompass larger brain areas.

FUNCTIONAL COMPONENTS OF THE FOREBRAIN

The forebrain is the rostral most portion of the brain consisting of diencephalon and cerebrum. The forebrain is responsible for controlling body temperature, reproductive functions, eating, sleeping, emotional affect, and cognitive functions.

The cerebrum consists of the **cerebral cortex** and the subcortical structures rostral to the diencephalon. The cortex, a few-millimeters thick outer shell of the cerebrum, has a rich, multilayered array of neurons and their processes form columns perpendicular to the surface. The axons of cortical neurons give rise to descending fiber tracts and intrahemispheric and interhemispheric fiber tracts, which, together with ascending axons coursing toward the cortex, make up the prominent white matter underlying the outer cortical gray matter. A deep sagittal fissure divides the cortex into a right and left hemisphere, each of which receives sensory input from and sends its motor output to the opposite side of the body. A set of **commissures** containing axonal fibers interconnects the two hemispheres, so that processed neural information from one side of the forebrain is transmitted to the opposite hemisphere. The largest of these commissures is the **corpus callosum**, which interconnects a major portion of the cerebral hemispheres (Fig. 7.11). Among the subcortical structures located in the cerebrum are the amygdala and hippocampus, components of the limbic system, which regulates emotional response, and the basal ganglia (caudate, putamen, and globus pallidus), which are essential for coordinating motor activity (see Chapter 5) and thought processes.

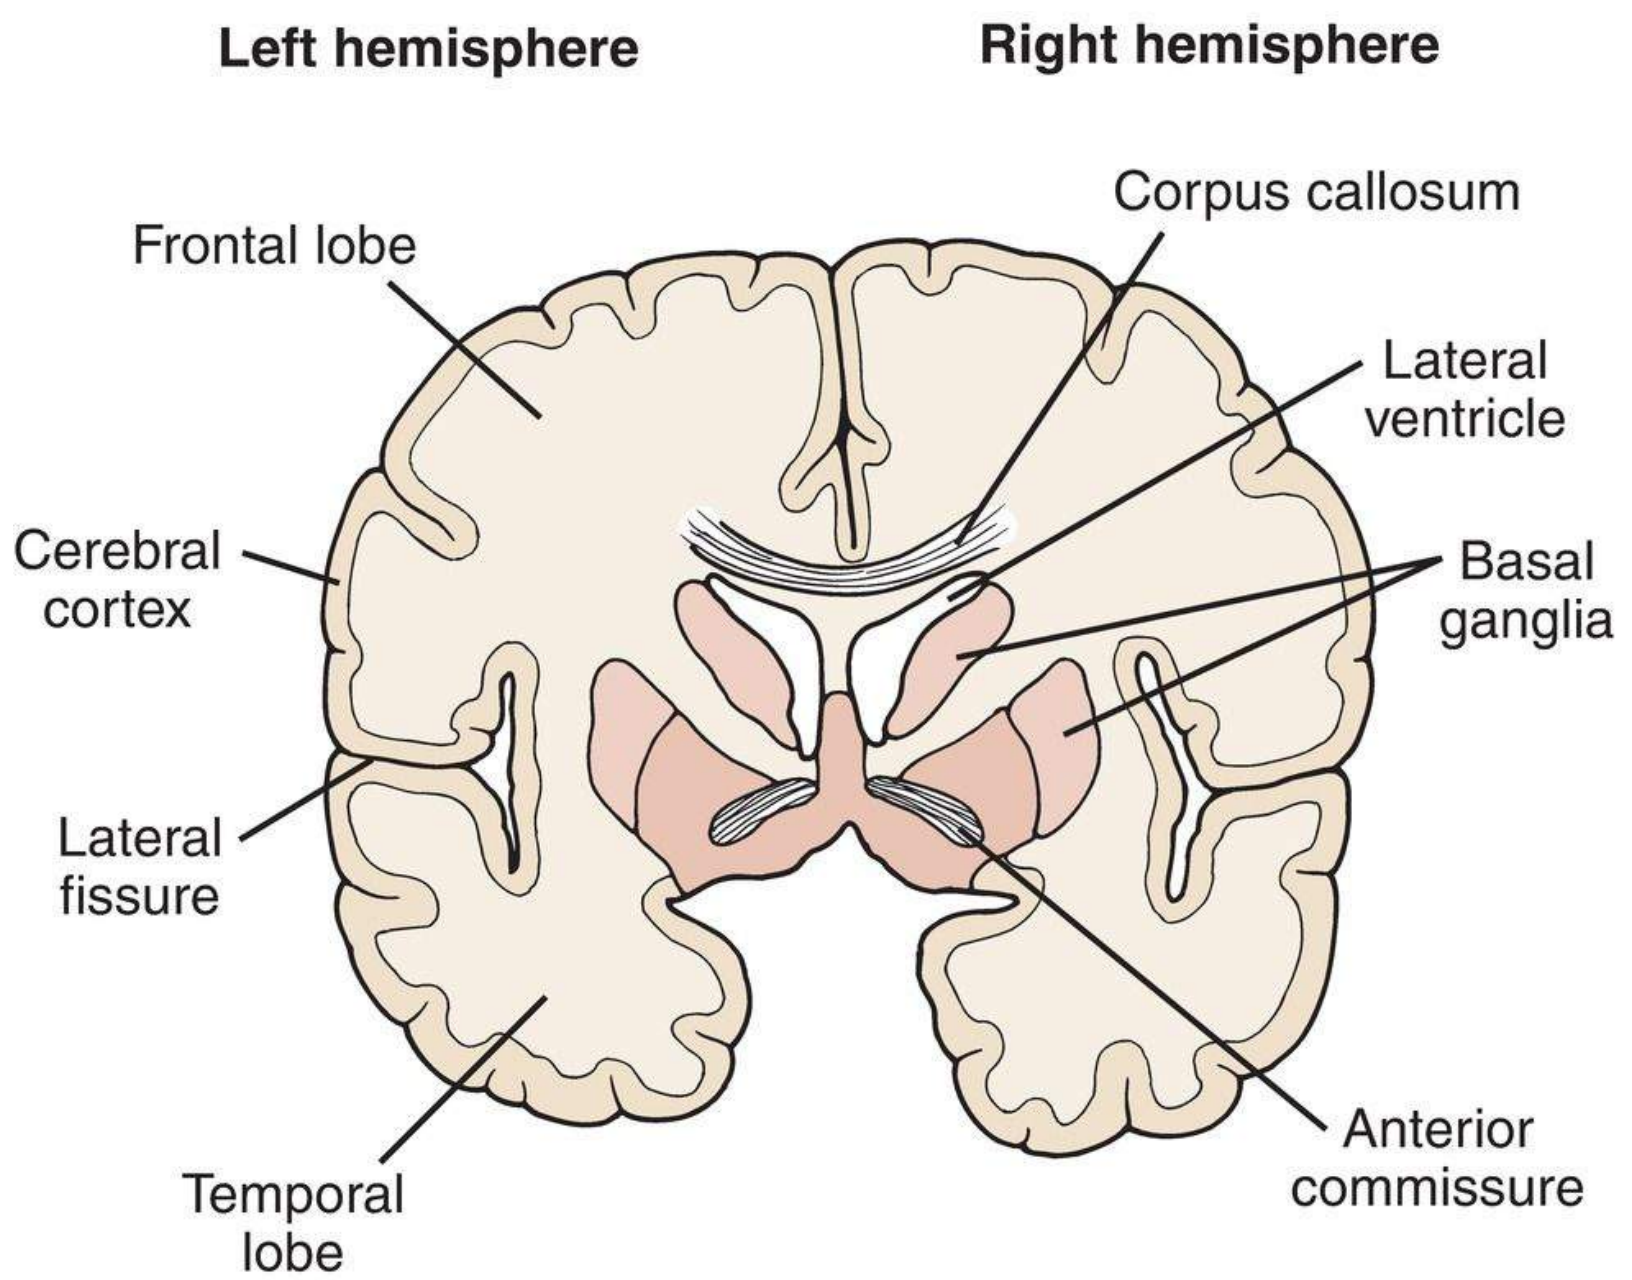

Figure 7.11 The cerebral hemispheres and some deep structures in a coronal section through the rostral forebrain. The corpus callosum is the major commissure that interconnects the right and left hemispheres. The anterior commissure connects rostral components of the right and left temporal lobes. The cortex is an outer rim of gray matter (neuronal cell bodies and dendrites); deep to the cortex is white matter (axonal projections) and then subcortical gray matter.

Cerebral cortex comprises three functional areas: sensory, motor, and association areas.

In the human brain, the surface of the cerebral cortex is highly convoluted, with gyri (singular, **gyrus**) and sulci (singular, **sulcus**), which are akin to hills and valleys, respectively. Deep sulci are also called *fissures*. Two deep fissures form prominent landmarks on the surface of the cortex. The **central sulcus** divides the **frontal lobe** from the **parietal lobe**, and the **lateral sulcus** (sylvian fissure) divides the **parietal lobe** from the **temporal lobe** (Fig. 7.12). The **occipital lobe** has less prominent sulci separating it from the parietal and temporal lobes.

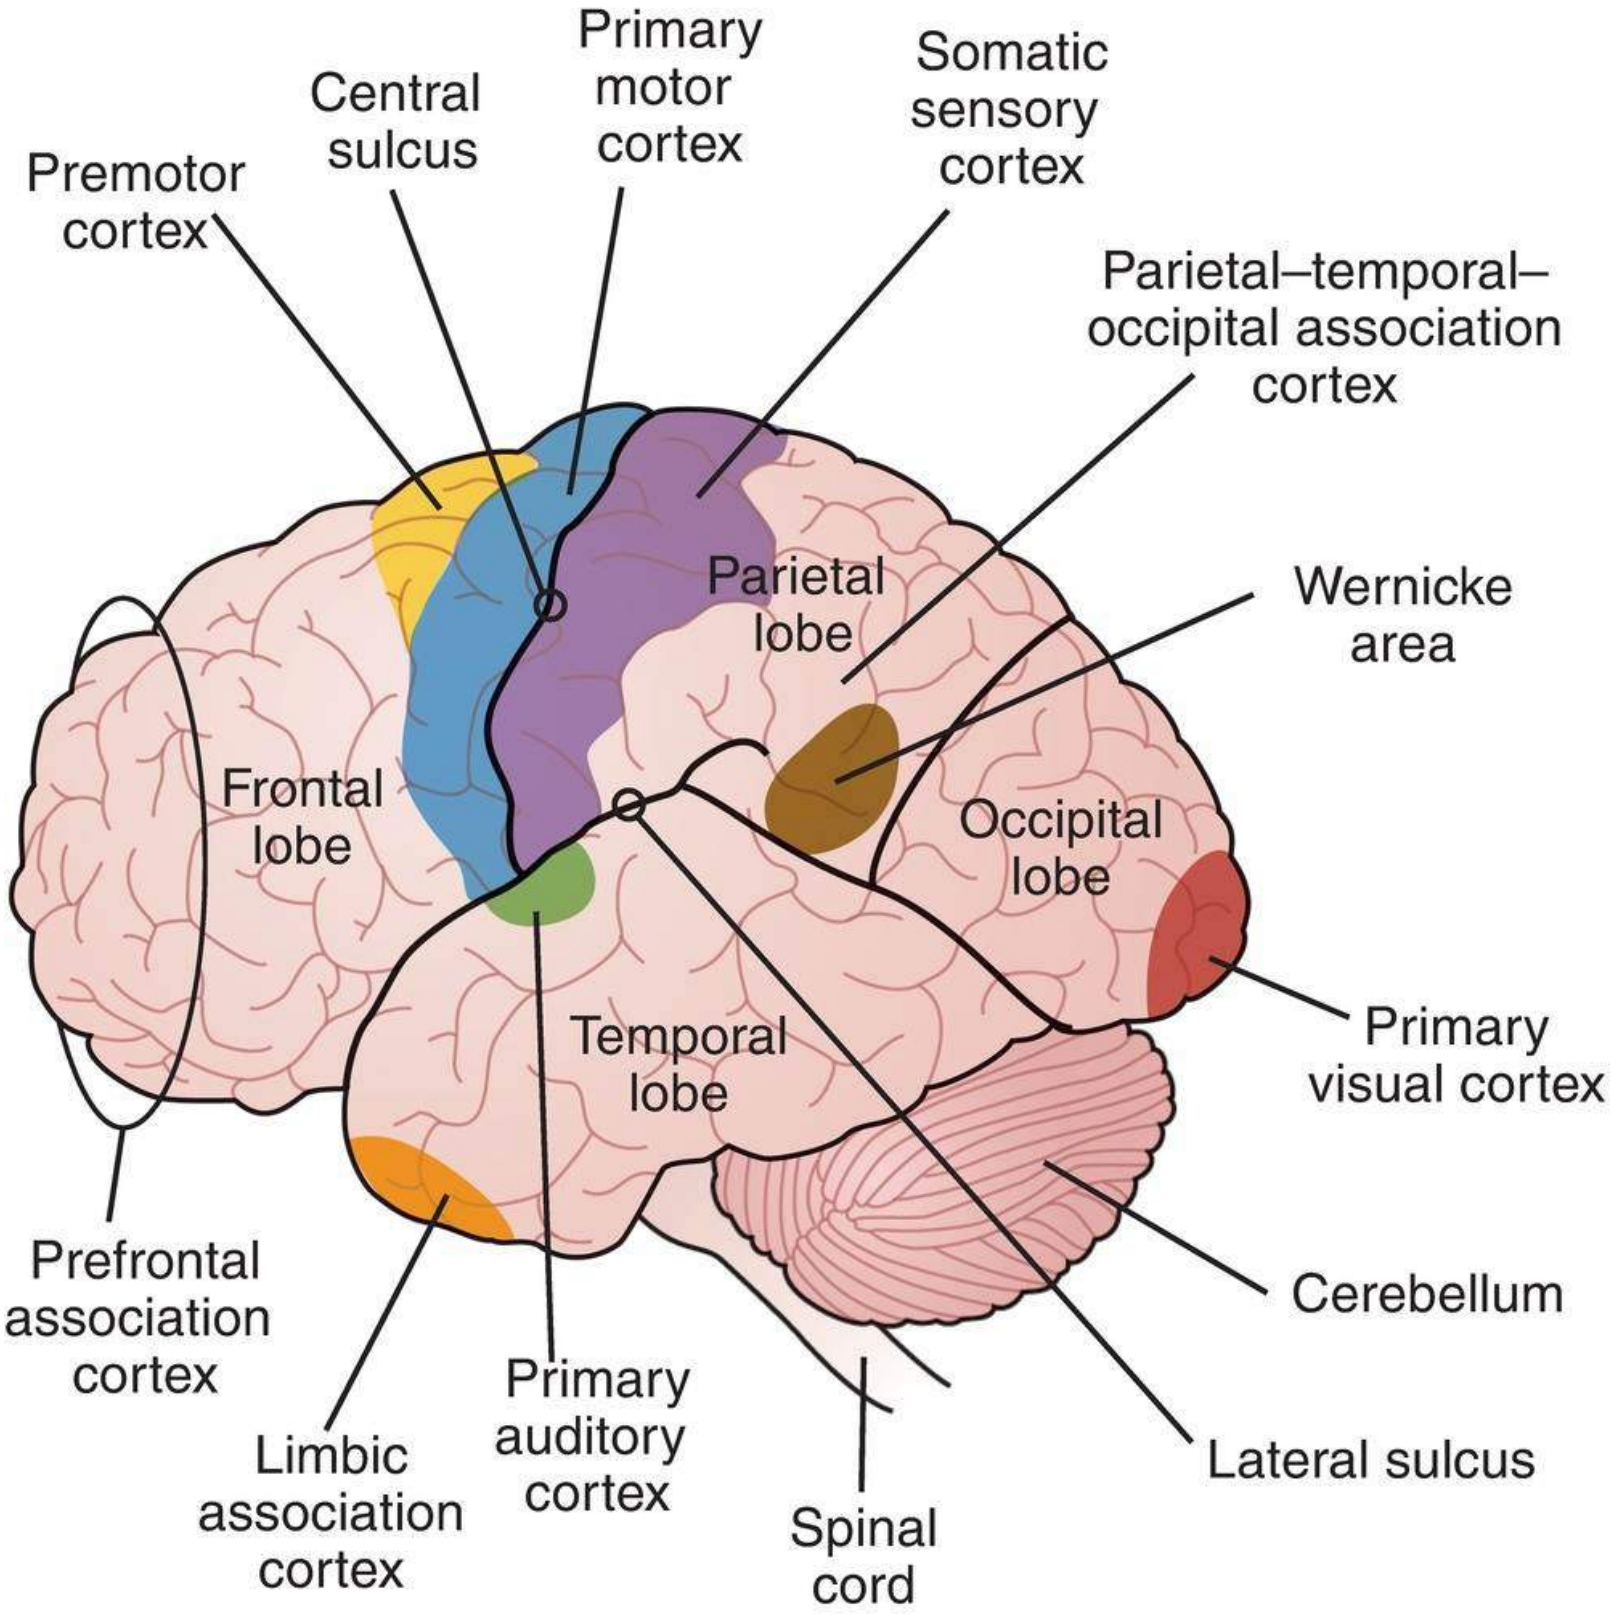

Figure 7.12 The four lobes of the cerebral cortex and their respective functional areas. The central sulcus and lateral sulcus (sylvian fissure) are prominent landmarks used in defining the cortical lobes. The primary auditory cortex is responsible for hearing. The limbic association cortex is the region for motivation, emotions, and memory. The prefrontal association cortex is responsible for voluntary activity, decision making, and personality traits. The premotor cortex is responsible for coordinating complex motor movements. The primary motor cortex is responsible for voluntary movements. The somatosensory cortex is responsible for sensation and proprioception. The parietal–temporal–occipital association cortex integrates all sensory input and is important in language. The Wernicke area is responsible for speech comprehension.

Topographically, the cerebral cortex is divided into areas of specialized functions, including the primary sensory areas for vision (occipital cortex), hearing (temporal cortex), somatic sensation (postcentral gyrus), and motor functions (precentral gyrus) (see Chapters 4 and 5). Sensory and motor functions are controlled by cortical structures in the contralateral hemisphere (see Chapters 4 and 5). Particular cognitive functions or components of these functions may also be lateralized to one side of the brain.

As shown in Figure 7.12, these well-defined areas comprise only a small fraction of the surface of the cerebral cortex. The majority of the remaining cortical area is known as **association cortex**, where the processing of neural information is performed at the highest levels of which the organism is capable. Among vertebrates, the human cortex contains the most extensive association areas. The association areas are also sites of long-term memory, and they control such human functions as language acquisition, speech, musical ability, mathematical ability, complex motor skills, abstract thought, symbolic thought, and other cognitive functions.

Association areas interconnect and integrate information from the primary sensory and motor areas via intrahemispheric connections. The **parietal–temporal–occipital association cortex** integrates neural information contributed by visual, auditory, and somatic sensory experiences. The **prefrontal association cortex** is that part of the frontal lobe other than the specific motor and speech regions. The prefrontal area governs the following: **attention**, the monitoring of the external and internal milieu; **intention**, the shaping of behavior in accordance with internal motivation and external context; and **execution**, the orchestration of complex sensorimotor sequences in a seamless path toward a goal. The selection and execution of cognitively driven sensorimotor sequences depend on integration with the basal ganglia in the same way that motor sequences do (see Chapter 5). The prefrontal cortex is responsible for executive function (making decisions) and, by virtue of its connections with the limbic system, coordinates emotionally motivated behaviors. The prefrontal cortex receives neural input from the other association areas and regulates motivated behaviors by direct input to the premotor cortex, which serves as the association area of the motor cortex.

CLINICAL FOCUS 7.1

Alzheimer’s Disease

Alzheimer’s disease (AD) is the most common cause of dementia in older adults. The cause of the disease still is unknown, and there is no cure. In 2016, an estimated 5.4 million people in the United States suffered from AD. Although the disease usually begins after the age of 65 years and the risk of AD goes up with age, it is important to note that AD is not a normal part of aging. The aging of the baby boom generation has made AD one of the fastest growing diseases. Estimates indicate that by the year 2050, more than 13 million people in the United States will suffer from AD.

Cognitive deficits are the primary symptoms of AD. Early on, there is mild memory impairment that is most notable in the patient’s inability to consolidate short-term memories to long-term memories. As the disease progresses, memory problems increase with long-term memories now involved, and difficulties with language are generally observed, including word-finding problems and decreased verbal fluency. Many patients also exhibit difficulty with visuospatial tasks. Personality changes are common, and patients become disoriented as the memory problems worsen. A progressive

deterioration of function follows and, at late stages, the patient is bedridden, nearly mute, unresponsive, and incontinent. A definitive diagnosis of AD is not possible until autopsy, but the constellation of symptoms and disease progression allow a reasonably certain diagnosis.

Gross pathology consistent with AD is mild-to-severe cortical atrophy (depending on the age of onset and the age at death). Microscopic pathology indicates two classic signs of the disease even at the earliest stages: the presence of senile plaques (SPs) and neurofibrillary tangles (NFTs). As the disease progresses, synaptic and neuronal loss or atrophy and an increase in SPs and NFTs occur.

Although many neurotransmitter systems are implicated in AD, the most consistent pathology is the loss or atrophy of cholinergic neurons in the basal forebrain. Medications that ameliorate the cognitive symptoms of AD are cholinergic function enhancers. These observations emphasize the importance of cholinergic systems in cognitive function. ■

Cortical and subcortical structures are part of the architectural design of the limbic system.

The limbic system comprises specific areas of the cortex and subcortical structures interconnected via circuitous pathways (Fig. 7.13). Originally, the limbic system was considered to be restricted to a ring of cortical structures surrounding the corpus callosum, including the **cingulate gyrus**, parahippocampal gyrus, and **hippocampus**, together with the fiber tracts that interconnect them with the diencephalic components of the limbic system, the hypothalamus, and the anterior thalamus. Current descriptions of the limbic system also include the **amygdala** (deep in the temporal lobe); the **nucleus accumbens** (the limbic portion of the basal ganglia), a region of the brain involved in pleasure and reward; the **septal nuclei** (at the base of the forebrain); the **prefrontal cortex** (anterior and inferior components of the frontal lobe); and the habenula (in the diencephalon).

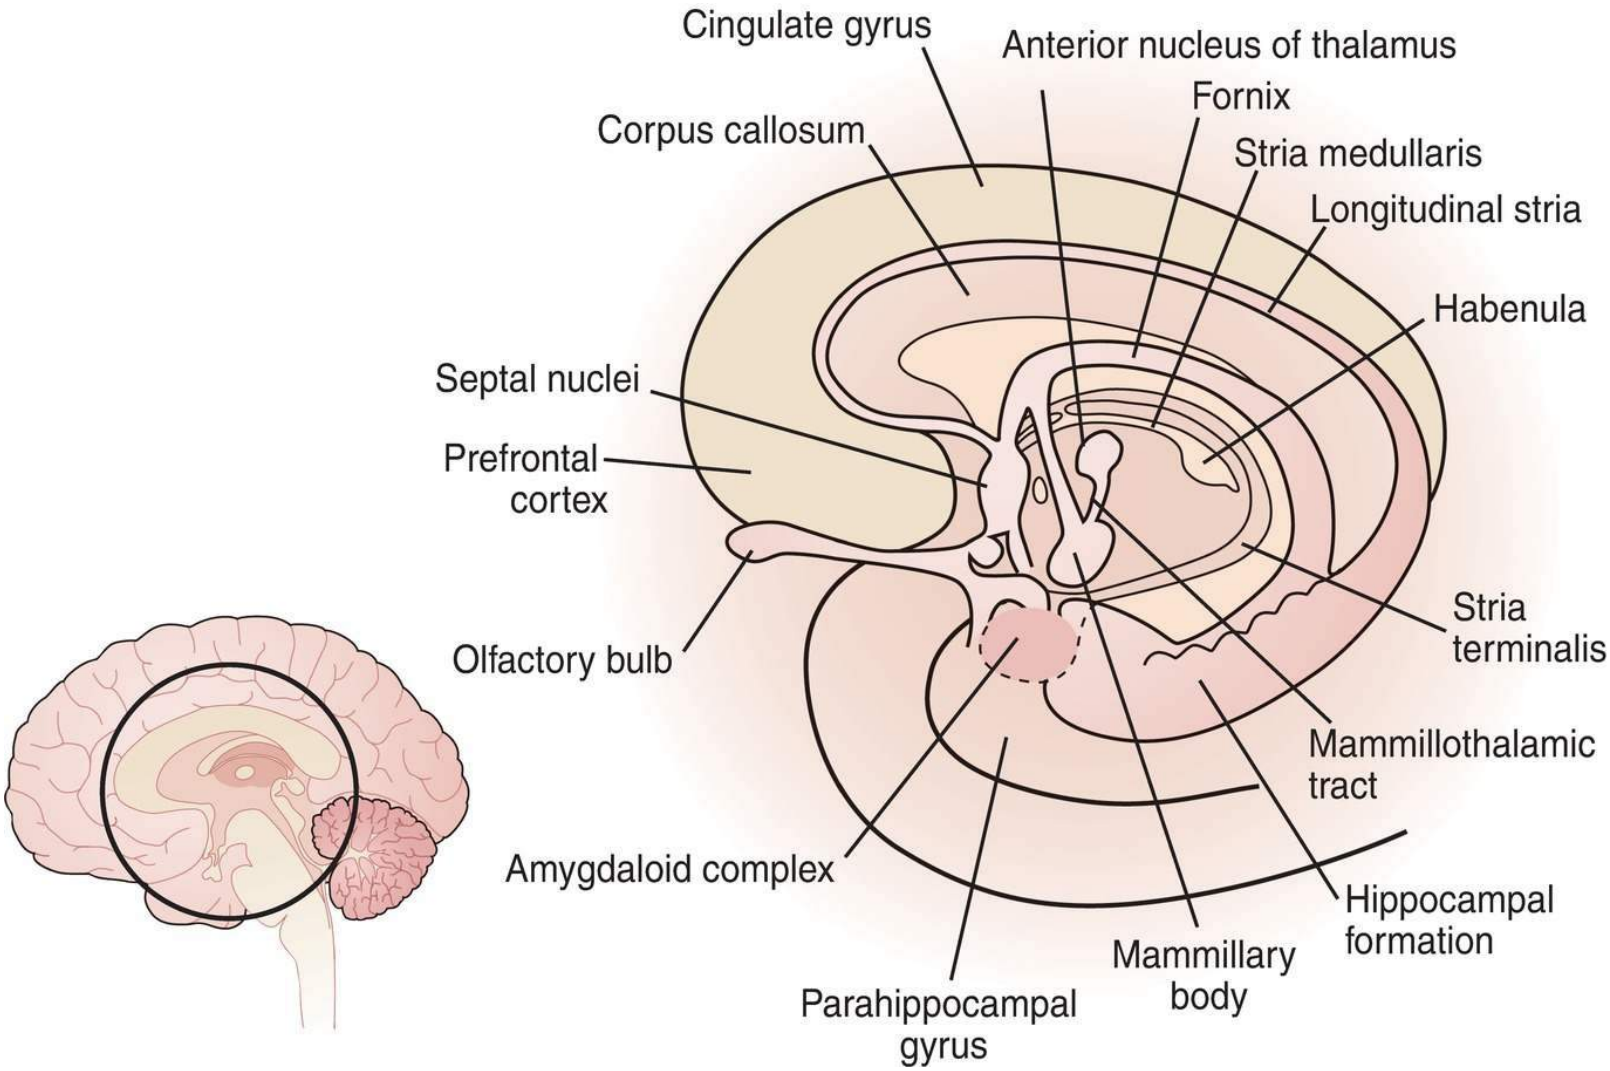

Figure 7.13 The cortical and subcortical structures of the limbic system extending from the cerebral cortex to the diencephalon. Some of the fiber tracts that interconnect the structures of the limbic system are also shown.

The limbic system supports a variety of functions, including memory, behavior, emotions, and olfaction. The limbic system operates by influencing the automatic nervous system and the endocrine system. It plays

a role in sexual arousal and the emotional "high" derived from recreational drugs. Many of the psychiatric disorders, including bipolar disorder, depression, schizophrenia, and dementia, involve malfunctions in the limbic system.

Circuitous loops of fiber tracts interconnect the limbic structures. The main circuit links the hippocampus to the mammillary body of the hypothalamus by way of the fornix, the hypothalamus to the anterior thalamic nuclei via the mammillothalamic tract, and the anterior thalamus to the cingulate gyrus by widespread, anterior thalamic projections. To complete the circuit, the cingulate gyrus connects with the hippocampus. Other structures of the limbic system form smaller loops within this major circuit, forming the basis for a wide range of emotional behaviors. Of particular importance is the amygdala, which interconnects with the hypothalamus, thalamus, and basal forebrain region via the stria terminalis and ventral amygdalofugal pathway and is responsible for fear conditioning and vigilance in learning and memory paradigms.

The fornix also connects the hippocampus to the base of the forebrain, where the septal nuclei and nucleus accumbens reside. The prefrontal cortex and other areas of association cortex provide the limbic system with information based on previous learning and currently perceived needs. Inputs from the brainstem provide visceral and somatic sensory signals, including tactile, pressure, pain, and temperature information from the skin and sexual organs and pain information from the visceral organs.

Brain's reward system

Experimental studies beginning early in the last century demonstrated that stimulating the limbic system or creating lesions in various parts of the limbic system can alter emotional states. Most of our knowledge comes from animal studies, but emotional feelings are reported by humans when limbic structures are stimulated during brain surgery or when limbic structures are activated during epileptic seizures.

Electrical stimulation of various sites in the limbic system produces either pleasurable (rewarding) or unpleasant (aversive) feelings. To study these findings, researchers use electrodes implanted in the brains of animals. When electrodes are implanted in structures presumed to generate rewarding feelings and the animals are allowed to deliver current to the electrodes by pressing a bar, repeated and prolonged self-stimulation is seen. Other needs—such as food, water, and sleep—are neglected. The sites that provoke the highest rates of electrical self-stimulation are in the ventral limbic areas, including the septal nuclei and nucleus accumbens.

The limbic system is one component of an extensive brain reward system. The reward system is responsible for increasing the likelihood of behaviors that have a positive outcome (positive reinforcement) and are pleasurable. Extensive studies have shown that activation of the mesolimbic dopamine system involving connections between the ventral tegmental nucleus, nucleus accumbens, and prefrontal cortex plays a major role in mediating reward. The nucleus accumbens is thought to be one site of action of addictive drugs, including opiates, alcohol, nicotine, cocaine, and amphetamine.

Aggressive behavior

A fight or flight response, including the autonomic components (see Chapter 6) and postures of rage and aggression characteristic of fighting behavior, can be elicited by electrical stimulation of sites in the hypothalamus and amygdala. If the frontal cortical connections to the limbic system are severed, rage postures and aggressiveness become permanent, illustrating the importance of the higher centers in restraining aggression and, presumably, in invoking it at appropriate times. By contrast, bilateral removal of the amygdala results in a placid animal that cannot be provoked.

Sexual arousal

The biologic basis of human sexual activity is poorly understood because of its complexity and because findings derived from nonhuman animal studies cannot be extrapolated. The major reason for this limitation is that the cerebral cortex, uniquely developed in the human brain, plays a more important role in governing human sexual activity than the instinctive or olfactory-driven behaviors in nonhuman primates and lower mammalian species. Nevertheless, several parallels in human and nonhuman sexual activities exist, indicating that hormones and the limbic system, in general, coordinate sex drive and mating behavior, with higher centers exerting more or less overriding influences.

Copulation in mammals is under parasympathetic control and is coordinated by reflexes of the sacral spinal cord, including male penile erection and ejaculation reflexes and engorgement of female erectile tissues as well as the muscular spasms of the orgasmic response. Copulatory behaviors and postures can be elicited in animals by stimulating parts of the hypothalamus, olfactory system, and limbic areas.

Human sexual desire and arousal are largely mediated through the limbic system. The amygdala contributes to the emotional aspects of sex and stimulation produces sexual feelings. The ventral striatum and septal nuclei are involved in the pleasure and rewarding aspects of sex. The orbitofrontal cortex, located at the base of the frontal lobe, has been implicated in mate selection, and frontal and parietal cortical areas play a role in sexual excitement. Ablation studies have shown that sexual behavior requires an intact connection of the limbic system with the frontal cortex. Additional important determinants of human sexual activity are the higher cortical functions of learning and memory, which serve to either reinforce or suppress the signals that initiate sexual responding, including the sexual reflexes coordinated by the sacral spinal cord.

Limbic system malfunction leads to psychiatric disorders.

The major psychiatric disorders, including affective disorders and schizophrenia, are disabling diseases with a genetic predisposition and no known cure. The functional basis for these disorders remains obscure. In particular, the role that environmental influences play on individuals with a genetic predisposition to developing a disorder is also unclear. Altered states of the brain's monoaminergic systems have been a major focus as possible underlying factors, based on extensive human studies in which neurochemical imbalances in catecholamines, acetylcholine (ACh), and serotonin have been observed. Another reason for focusing on the monoaminergic systems is that the most effective drugs used in treating psychiatric disorders are agents that alter monoaminergic transmission.

Affective disorders

Illnesses marked by abnormal mood regulation and associated signs and symptoms are called **affective disorders** or **mood disorders**. The word "mood" describes an overall emotional tone that provides the background to one's internal life. Mood disorders are broadly classified as **major depression**, which can be so profound as to provoke suicide, and **bipolar disorders** (formerly known as *manic–depressive disorder*), in which periods of profound depression are followed by periods of mania, in a cyclic pattern. Neurophysiologic studies indicate that depressed patients show decreased use of brain NE. In manic periods, NE transmission increases. Whether in depression or in mania, all patients seem to have decreased brain serotonergic transmission, suggesting that serotonin may exert an underlying permissive role in abnormal mood swings, in contrast with NE, whose transmission, in a sense, titrates the mood from highest to lowest extremes. The most effective treatments for depression are antidepressant drugs such as monoamine oxidase inhibitors (MAOIs), tricyclics, and **selective serotonin reuptake inhibitors (SSRIs)** that inhibit monoamine reuptake or increase levels of monoamines in the synaptic cleft. A therapeutic response to monoamine-based treatments ensues only after treatment is repeated over time. Similarly, when treatment stops, symptoms may not reappear for several weeks. This time lag in treatment response is presumably a result of alterations in the long-term regulation of receptor and second messenger systems in relevant regions of the brain. With electroconvulsive therapy, these pharmacological treatments have in common the ability to alter noradrenergic and serotonergic transmission serving the limbic system. These observations led to the most common theory of depression, the monoamine deficiency hypothesis.

The potential to understand depression—and other complex mental illness—has dramatically increased with the advent of both molecular genetics and imaging technologies. An important finding was that a genetic variation in the serotonin reuptake transporter predicts susceptibility to depression subsequent to a number of stressors. Functional imaging studies have suggested the possible involvement of several brain structures in depression. A meta-analysis suggests that the volume of anterior cingulate cortex and adjacent medial prefrontal cortex is reduced in individuals at risk of familial major depression and deep brain stimulation in this region has produced clinical benefits.

The need for new technologies to explain disease mechanisms is highlighted by the other side of the affective spectrum. The most effective long-term treatment for mania is lithium, although antipsychotic (neuroleptic) drugs, which block dopamine receptors, are effective in the acute treatment of mania. The therapeutic actions of lithium remain unknown, but the drug has an important action on a receptor-mediated second messenger system. Lithium interferes with regeneration of phosphatidylinositol in neuronal membranes by blocking the hydrolysis of inositol-1-phosphate. Depletion of

phosphatidylinositol in the membrane renders it incapable of responding to receptors that use this second messenger system. Without knowing the specific neuroanatomic underpinnings of the disease, it is difficult to ascertain how these mechanisms might relate to amelioration of symptoms.

Schizophrenia: uncoupling of thought and emotional processes

Schizophrenia is the collective name for a group of psychotic disorders that vary greatly in symptoms among individuals. It most commonly manifests as delusions (fixed false beliefs) or hallucinations (perceptions in the absence of a stimulus) that are coupled to disorganized thinking and speech. Delusions are usually persecutory in nature and tend to follow themes of being harassed, cheated on, conspired against, drugged, or poisoned. Hallucination (most commonly hearing voices) is often paranoid in nature and frequently tied to social dysfunctions. The onset of symptoms typically occurs in young adulthood with ~2% reporting lifetime prevalence. No neurologic tests for schizophrenia currently exist, and the diagnosis is based exclusively on the patient's self-reporting experiences and observed behavior.

Although the exact cause of schizophrenia is not known, increased dopamine activity in the mesolimbic pathway of the brain (see Fig. 7.6) is commonly found in patients with schizophrenia. The mainstay of treatment is antipsychotic medication that primarily works on suppressing dopamine activity. Older antipsychotic drugs (**neuroleptics** or typical antipsychotics) achieve their therapeutic effect by blocking dopamine D_2 receptors. Current research is focused on finding a subtype of dopamine receptor that mediates mesocortical/mesolimbic dopaminergic transmission but does not affect the nigrostriatal system, which controls motor function (see Fig. 7.6). So far, neuroleptic drugs that block one pathway almost always block the other as well, leading to unwanted neurologic side effects, including abnormal involuntary movements after long-term treatment or Parkinsonism in the short term. Similarly, some patients with Parkinson's disease who receive L-DOPA to augment dopaminergic transmission in the nigrostriatal pathway must be taken off the medication because they develop hallucinations.

Newer, so-called **atypical antipsychotics** have relatively low affinity for dopamine receptors and their clinical effectiveness as a schizophrenia treatment does not correlate with D_2 antagonism. Instead, this class of drug antagonizes serotonin receptors suggesting that dopamine may not be the primary culprit in the disease. Evidence is accumulating that hypofunctioning of glutamate signaling through the *N*-methyl-D-aspartate (NMDA) receptor (see Chapter 3) may also contribute to schizophrenia. The idea is that glutamate may normally activate pathways that inhibit dopaminergic pathways; and therefore, hypofunction of NMDA receptor signaling would increase dopamine signaling.

HIGHER COGNITIVE SKILLS

Cognitive science is the interdisciplinary study of how information (e.g., concerning perception, language, speech, reasoning, and emotion) is represented and transformed in the brain. Multiple research disciplines (neuroscience, psychology, artificial intelligence, and learning science) are brought together to investigate neural circuitry and modular brain organization in an effort to analyze information from low-level learning and decision-making mechanisms to high-level logic and planning.

Cerebral cortex and the limbic system provide the architectural components for learning and memory systems.

Learning involves synthesizing different types of information in order to acquire (1) new knowledge, (2) behavior, (3) skills, (4) values, and (5) preferences. Memory allows the brain to store information for later retrieval and consists of both long-term (i.e., days, months, years) and short-term (i.e., minutes, hours) storage. Memory and learning are inextricably linked because part of the learning process involves the assimilation of new information and its commitment to memory. The most likely sites of learning in the human brain are the large association areas of the cerebral cortex, in coordination with subcortical structures deep in the temporal lobe, including the hippocampus and amygdala. The association areas draw on sensory information from sensory areas of the cortex and on emotional feelings transmitted via the limbic system. This information is integrated with previously learned skills and stored memory, which presumably also reside in the association areas.

The learning process itself is poorly understood, but it can be studied experimentally at the synaptic level in isolated slices of mammalian brain or in more simple invertebrate nervous systems. Synapses subjected to repeated presynaptic neuronal stimulation show changes in the excitability of postsynaptic neurons. These changes include the facilitation of neuronal firing, altered patterns of neurotransmitter release, second messenger formation, and, in intact organisms, evidence that learning occurred. The phenomenon of increased excitability and altered chemical state on repeated synaptic stimulation is known as **long-term potentiation**, a persistence beyond the cessation of electrical stimulation, as is expected of learning and memory. Ca^{2+} entry through activation of NMDA receptors is critical to the development of long-term potentiation. An early event in long-term potentiation is a series of protein phosphorylations induced by receptor-activated second messengers leading to activation of a host of intracellular proteins and altered excitability. In addition to biochemical changes in synaptic efficacy associated with learning at the cellular level, structural alterations occur. The number of connections between sets of neurons increases as a result of experience. The cellular and structural changes that accompany the formation of long-term memories reflect changes in gene expression within the neuron. Inhibition of transcription or translation blocks the formation of long-term, but not short-term, memories in model systems.

Much of our knowledge about human memory formation and retrieval is based on studies of patients in whom stroke, brain injury, or surgery resulted in memory disorders. Such knowledge is then examined in more rigorous experiments in nonhuman primates capable of cognitive functions or using brain imaging such as functional MRI. From these combined approaches, we know that memories are not stored in a single place in the brain but are distributed across many areas. The prefrontal cortex is essential for coordinating the formation of memory, starting from a learning experience in the cerebral cortex, then processing the information, and communicating it to the subcortical limbic structures. The prefrontal cortex receives sensory input from the parietal, occipital, and temporal lobes and emotional input from the limbic system. Drawing on skills such as language and mathematical ability, the prefrontal cortex integrates these inputs in light of previously acquired learning. The prefrontal cortex can thus be considered the site of working memory, where new experiences are processed, as opposed to sites that consolidate the memory and store it. The processed information is then transmitted to the hippocampus, where it is consolidated over several hours into a more permanent form that is stored in, and can be retrieved from, the association cortices.

Long-term and short-term memory comprise the brain's memory system.

Memory can be divided into that which can be recalled for only a brief period (seconds to minutes) and that which can be recalled for weeks to years. Newly acquired learning experiences can be readily recalled for only a few minutes or more using **short-term memory**. An example of short-term memory is looking up a telephone number, repeating it mentally until you finish dialing the number, then promptly forgetting it as you focus your attention on starting the conversation. Short-term memory is a product of working memory; the decision to process information further for permanent storage is based on judgment as to its importance or on whether it is associated with a significant event or emotional state. An active process involving the hippocampus must be employed to make a memory more permanent.

The conversion of short-term to **long-term memory** is facilitated by repetition, by adding more than one sensory modality to learn the new experience (e.g., writing down a newly acquired fact at the same time one hears it spoken) and, even more effective, by tying the experience (through the limbic system) to a strong, meaningful emotional context. The role of the hippocampus in consolidating the memory is reinforced by its participation in generating the emotional state with which the new experience is associated.

Declarative memory (sometimes referred to as *explicit memory*) is one of the two subtypes of long-term memory systems. Declarative memory refers to the memory system that consciously recalls facts and events (e.g., birthdays, state capitals, musical event, and personal events). The counterpart to declarative memory is known **nondeclarative** or **procedural memory** (sometimes referred to as *implicit memory*) and refers to unconscious memories of how to do things (e.g., from tying shoes to driving a car). These memories are automatically retrieved and occur without the need for conscious control.

Memory loss

Memory loss can be partial or total. Unfortunately, memory loss is considered normal when it comes with aging. Sudden memory loss can result from brain trauma, strokes, cardiac arrest, meningitis, and epilepsy. Trauma to the brain is not the only cause of sudden memory loss. It may appear as a side effect from chemotherapy in which cytotoxic drugs are used to treat cancer or from drugs that are prescribed for lowering blood cholesterol. Sudden memory loss can be permanent or temporary. When it is caused by other medical conditions, such as Alzheimer's disease or Parkinson's disease, memory loss is gradual and tends to be permanent.

Cholinergic innervations play an important role in memory, with ACh as the major neurotransmitter in cognitive function, learning, and memory. Loss of cholinergic function is associated with **dementia**, an impairment of memory, memory loss, abstract thinking, and judgment (see Clinical Focus Box 7.1).

CLINICAL FOCUS 7.2

The Split Brain

Patients with life-threatening, intractable epileptic seizures were treated in the past by surgical commissurotomy or cutting of the corpus callosum (see Fig. 7.11). This procedure effectively cut off most of the neuronal communication between the left and right hemispheres and vastly improved patient status because seizure activity no longer spread back and forth between the hemispheres.

There was a remarkable absence of overt signs of disability following commissurotomy; patients retained their original motor and sensory functions, learning and memory, personality, talents, emotional responding, and so on. This outcome was not unexpected because each hemisphere has bilateral representation of most known functions; moreover, those ascending (sensory) and descending (motor) neuronal systems that crossed to the opposite side were known to do so at levels lower than the corpus callosum.

Notwithstanding this appearance of normalcy, following commissurotomy, patients were shown to be impaired to the extent that one hemisphere literally did not know what the other was doing. It was further shown that each hemisphere processes neuronal information differently from the other and that some cerebral functions are confined exclusively to one hemisphere.

In an interesting series of studies by Nobel laureate Roger Sperry and colleagues, these patients with a so-called split brain were subjected to psychophysiological testing in which each disconnected hemisphere was examined independently. Their findings confirmed what was already known: sensory and motor functions are controlled by cortical structures in the contralateral hemisphere. For example, visual signals from the left visual field were perceived in the right occipital lobe, and there were contralateral controls for auditory, somatic sensory, and motor functions. (Note that the olfactory system is an exception, as odorant chemicals applied to one nostril are perceived in the olfactory lobe on the same side.) However, the scientists were surprised to find that language ability was controlled almost exclusively by the left hemisphere. Thus, if an object was presented to the left brain via any of the sensory systems, the subject could readily identify it by the spoken word. However, if the object was presented to the right hemisphere, the subject could not find words to identify it. This was not due to an inability of the right hemisphere to perceive the object, as the subject could easily identify it among other choices by nonverbal means, such as feeling it while blindfolded. From these and other tests, it became clear that the right hemisphere was mute; it could not produce language.

In accordance with these findings, anatomic studies show that areas in the temporal lobe concerned with language ability, including the Wernicke area, are anatomically larger in the left hemisphere than in the right in a majority of humans, and this is seen even prenatally. Corroborative evidence of language ability in the left hemisphere is shown in persons who have had a stroke, where aphasias are most severe if the damage is on the left side of the brain. Analysis of people who are deaf who communicated by sign language prior to a stroke has shown that sign language is also a left-hemisphere function. These patients show the same kinds of grammatical and syntactical errors in their signing following a left-hemisphere stroke as do speakers.

In addition to language ability, the left hemisphere excels in mathematical ability, symbolic thinking, and sequential logic. The right hemisphere, on the other hand, excels in visuospatial ability, such as three-dimensional constructions with blocks and drawing maps, and in musical sense, artistic sense, and other higher functions that computers seem less capable of emulating. The right brain exhibits some ability in language and calculation, but at the level of children aged 5 to 7. It has been postulated that both sides of the brain are capable of all of these functions in early childhood, but the larger size of the language area in the left temporal lobe favors development of that side during language acquisition, resulting in nearly total specialization for language on the left side for the rest of one’s life. ■

Language and speech are coordinated in specific areas within the association cortex.

The ability to communicate by language, verbally and in writing, is one of the most difficult cognitive functions to study because only humans are capable of these skills. Thus, much of our knowledge of language processing in the brain has been inferred from clinical data by studying patients with aphasias—disturbances in producing or understanding the meaning of words—following brain injury, surgery, or other damage to the cerebral cortex.

Two areas appear to play an important role in language and speech: the **Wernicke area**, in the upper temporal lobe, and the **Broca area**, in the frontal lobe (Fig. 7.14). Both of these areas are located in the association cortex, adjacent to cortical areas that are essential in language communication. The Wernicke area is in the parietal–temporal–occipital association cortex, a major association area for processing sensory information from the somatic sensory, visual, and auditory cortices. The Broca area is in the prefrontal association cortex, adjacent to the portion of the motor cortex that regulates movement of the muscles of the mouth, tongue, and throat (i.e., the structures used in the mechanical production of speech). A fiber tract, the arcuate fasciculus, connects the Wernicke area with the Broca area to coordinate aspects of understanding and executing speech and language skills.

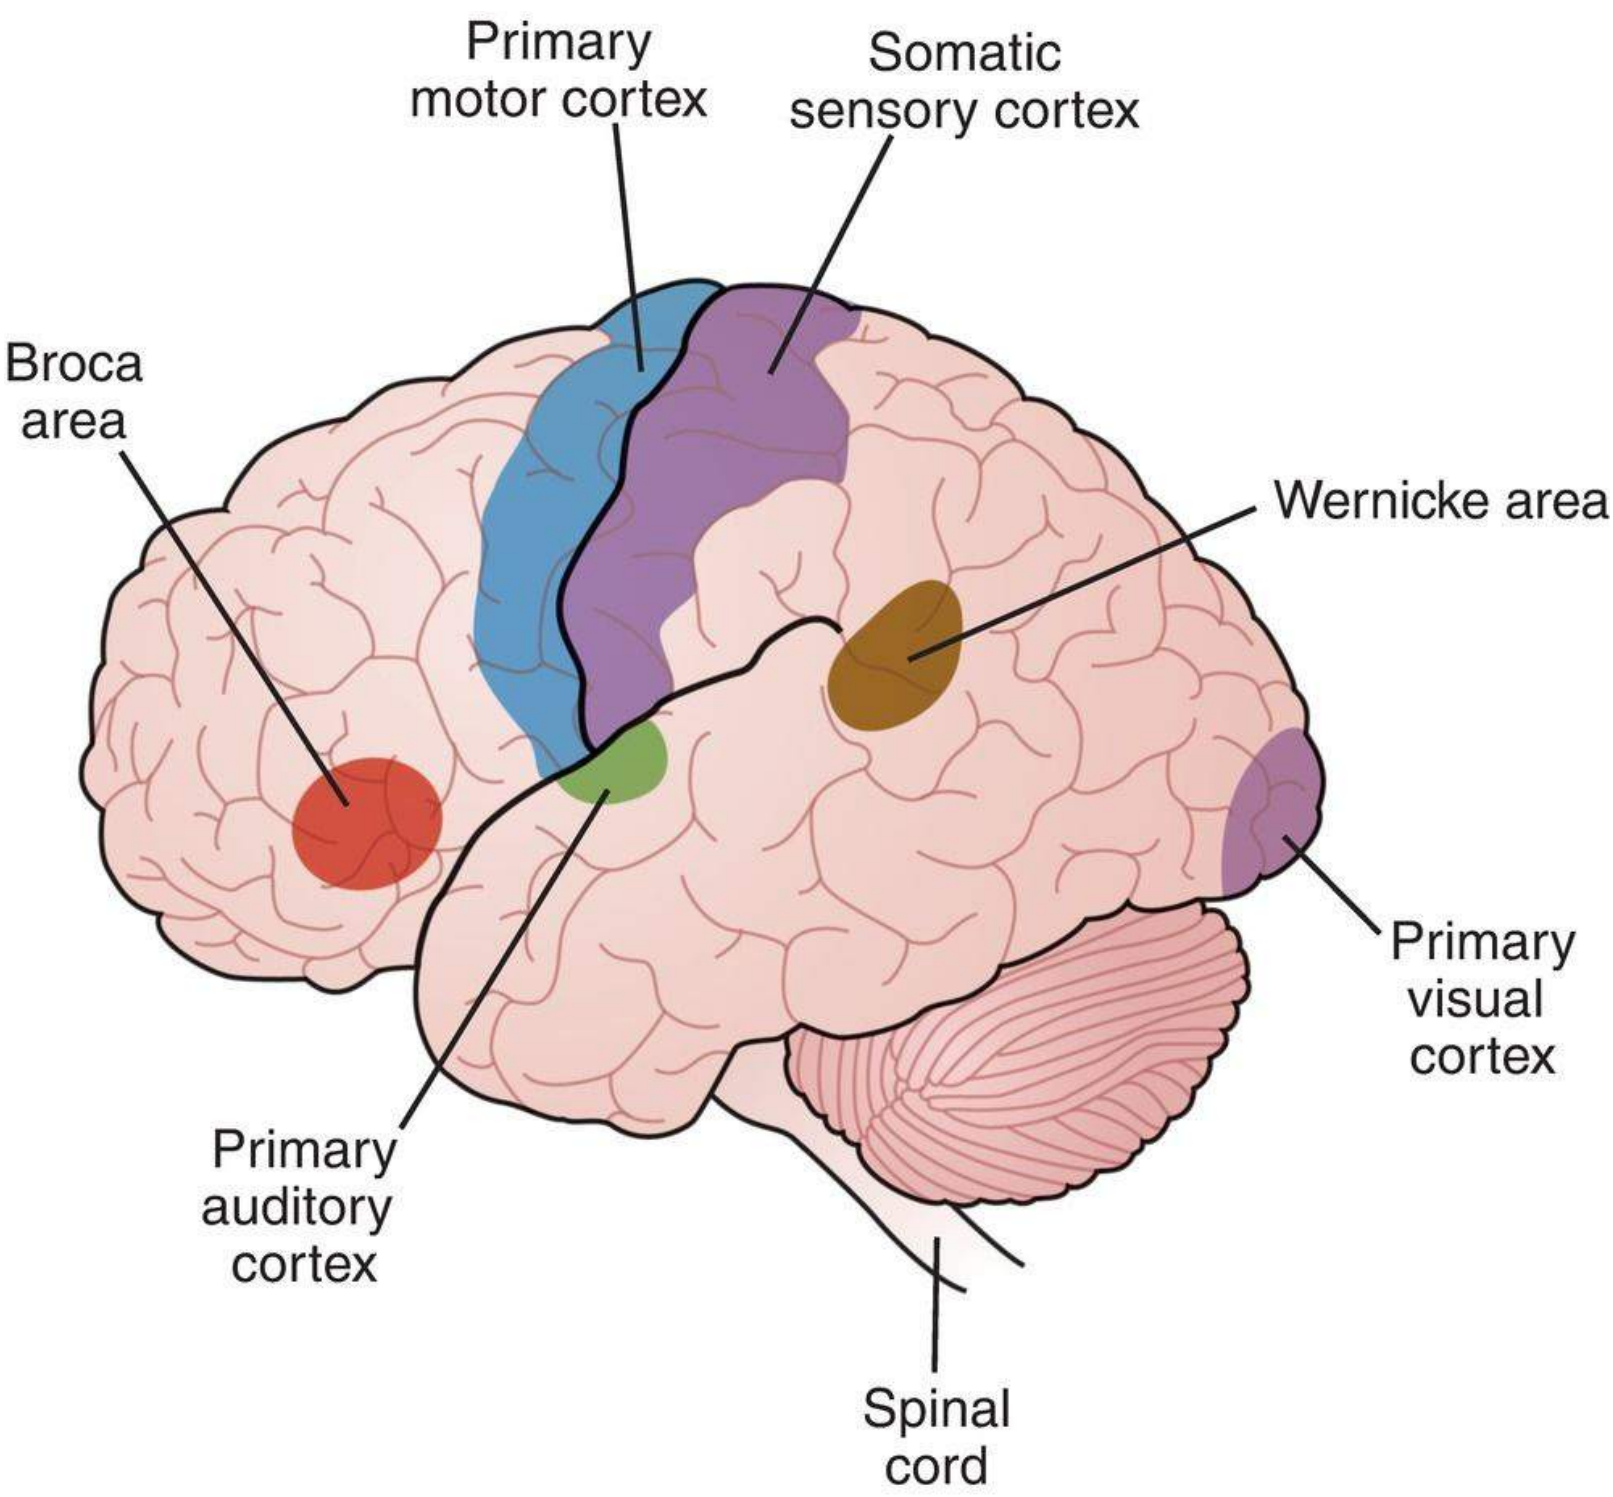

Figure 7.14 Wernicke and Broca areas and the primary motor, visual, auditory, and somatic sensory cortices.

Clinical evidence indicates that the Wernicke area is essential for the comprehension, recognition, and construction of words and language, whereas the Broca area is essential for the mechanical production of speech. Patients with a defect in the Broca area show evidence of comprehending a spoken or written word but are not able to say the word. In contrast, patients with damage in the Wernicke area can produce speech, but the words they put together have little meaning.

Language is a highly lateralized function of the brain residing in the left hemisphere (see Clinical Focus Box 7.2). This dominance is observed in left-handed as well as right-handed people. Moreover, it is language that is lateralized, not the reception or production of speech. Thus, native signers (people who use sign language) who have been deaf since birth still show left-hemisphere language function.

Chapter Summary

- The central nervous system receives, integrates, and acts on sensory stimuli from the internal and external environment.
- The hypothalamus is the interface between the endocrine, autonomic, and limbic systems.
- The hypothalamus regulates energy balance by integrating metabolism and eating behavior, it controls the gonads and sexual activity, and it contains the biological clock.
- The brainstem reticular formation is critical for arousal and sleep and contains several monoaminergic systems that innervate the forebrain.
- The ascending reticular activating system mediates consciousness and arousal.
- An electroencephalogram records electrical activity at the brain's surface in waves that have characteristic patterns depending on the state of arousal.
- The forebrain contains the thalamus, hypothalamus, and the cerebrum and processes sensory information, executes behavior, makes decisions, and is capable of learning.
- The cerebral cortex comprises three parts: sensory, motor, and association areas.
- The limbic system contains cortical and subcortical structures and is the seat of emotions, containing a reward system, mediating aggression, and coordinating sexual activity as well as being implicated in psychiatric disorders.
- Affective disorders are marked by abnormal mood regulation.
- Schizophrenia involves disordered thought processes, delusions, and hallucinations.
- Memory and learning require the cerebral cortex and limbic system.
- Declarative and nondeclarative memory involve different central nervous system structures.
- Cholinergic innervation is associated with cognitive function.
- Language and speech are coordinated in specific areas of the association cortex.

Chapter Review Questions

1. A patient's wife complains that several times during the last few weeks, her husband struck her as he flailed around violently during sleep. The husband indicates that when he wakes up during one of these sessions, he has been dreaming. What is the likely cause of his problem?
   A. Increased muscle tone during stage N3 sleep
   B. Increased drive to the motor cortex during REM sleep
   C. Lack of behavioral inhibition by the prefrontal cortex during sleep
   D. Lack of abolished muscle tone during REM sleep
   E. Abnormal functioning of the amygdala during paradoxical sleep

The correct answer is D. Dreams are associated with REM sleep. Normally, a person does not "act out" his or her dream because all of the motor neurons to muscles other than those for respiration, the middle ear, and the extraocular eye muscles are inhibited, abolishing muscle tone. If this inhibition does not occur, a person exhibits marked and often dangerous movement during dreaming. Muscle tone is reduced but not abolished during N3 stage sleep; however, movements are not an issue, presumably because dreaming does not occur. (Note, however, that sleepwalking occurs in slow-wave sleep.) Increased activity in motor areas of the cortex (or other areas) during REM sleep normally would not cause movement because motor neurons are inhibited.

2. A scientist develops a reagent that allows identification of leptin-sensing neurons in the CNS. The reagent is a fluorescent compound that binds to the plasma membrane of cells that sense leptin. Where would application of this reagent to sections of the brain result in fluorescent staining?
   A. Arcuate nucleus of the hypothalamus
   B. Mammillary nuclei of the hypothalamus
   C. Paraventricular nucleus of the hypothalamus
   D. Preoptic nucleus of the hypothalamus
   E. Ventromedial nucleus of the thalamus

The correct answer is A. Leptin is released into the blood from the body's adipocytes. Circulating leptin levels are sensed by neurons in the arcuate nucleus, which are located in an area that does not possess a blood–brain barrier. While other regions of the hypothalamus also lack a blood–brain barrier, the other hypothalamic nuclei listed do not contain leptin-sensing cells.

3. Classical language disorders include Broca aphasia, where people can understand language but cannot produce it, and Wernicke aphasia, where a person cannot understand language and produces only nonsensical language. However, damage to regions of the left frontal and parietal lobes outside Broca and Wernicke areas also produce language deficits. Where would an individual who presents poststroke with an ability to understand language but is able to produce only nonsensical language most likely have suffered damage?
   A. Thalamocortical tract
   B. Reticular activating system
   C. Prefrontal lobe
   D. Fornix
   E. Arcuate fasciculus

The correct answer is E. The arcuate fasciculus is the fiber bundle connecting the Broca and Wernicke areas. Damage to the arcuate fasciculus disconnects the Wernicke area, which is responsible for recognition and construction of words and language, from Broca area, which is responsible for language

production. The fornix connects the hippocampus with the hypothalamus and basal forebrain. The thalamocortical tract connects the thalamus with the cortex and the reticular activating system connects the brainstem with the thalamus and cortex. Although both are important for modulating cortical activity, damage does not produce the deficit seen in this individual. The prefrontal lobe is not a fiber bundle.

4. A blindfolded subject is asked to verbally identify a common object presented to her left hand. She is not allowed to touch the object with her right hand. Which of the following structures must be intact for her to complete the task?

A. Primary somatic cortex on the left side of her brain
B. Primary visual cortex on the right side of her brain
C. Fornix
D. Corpus callosum
E. Hippocampus

The correct answer is D. Somatic sensory information from the left hand would be perceived in the right cortex, which does not generate language. To verbally explain what the object is, the information must cross to the left hemisphere. This crossing occurs through the corpus callosum. The fornix and hippocampus would be involved in storing memories about particular items, not retrieving the memory. Neither the primary somatic sensory cortex on the left side nor the visual cortex on either side plays a role in identifying an object placed in the left hand by tactile cues.

5. Which region of the central nervous system is thought to be the "master clock" for controlling various biological rhythms?

A. Pineal body
B. Reticular formation
C. Forebrain
D. Hypothalamus
E. Pituitary gland

The correct answer is D. Biological rhythms (monthly, circadian) are controlled by the suprachiasmatic nucleus in the hypothalamus. The pituitary is sometimes referred to as the "master" endocrine gland. It secretes nine hormones that regulate homeostasis. The pineal gland secretes serotonin and melatonin, two hormones that affect wake–sleep patterns. However, they are not the master clock for the control of the body's biological rhythms. The reticular formation modulates alertness and sleep but does not control biological rhythms. The forebrain controls body temperature, reproductive functions, eating, sleeping, and some emotions.

Clinical Application Exercises 7.1

STROKE

A 67-year-old man was taken to see his physician by his wife. For the preceding 2 days, the patient's wife had noticed that he did not seem to make sense when he spoke. She also indicated that he seemed a little disoriented and did not respond appropriately to her questions. He has no obvious motor or somatic sensory deficits. On examination, the physician concludes that the man had a stroke in a region of one of his cerebral hemispheres. As part of the diagnosis, the physician tests the man's visual fields and notices a decreased awareness of stimuli presented to one visual field.

QUESTIONS

1. Which side of the brain most likely suffered the stroke?
2. Which regions of the hemisphere suffered the stroke?
3. What information from the case history gives the answers to Questions 1 and 2?
4. Which visual field is affected by the stroke?

ANSWERS

1. The stroke occurred on the left side of the brain.
2. The stroke involved the superior posterior temporal lobe encompassing the Wernicke area and the occipital lobe encompassing the primary visual cortex.
3. Language deficits indicate involvement of the left hemisphere. The fluent but nonsensical speech indicates involvement of the Wernicke area. The visual field deficit indicates a loss in the visual cortex. The lack of motor or somatic sensory deficits excludes the posterior frontal and anterior parietal lobes.
4. The right visual field would be affected, because visual fields are represented in the contralateral hemispheres.

8 Skeletal and Smooth Muscle

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain why impulses from motor neurons are required for contraction of skeletal muscle and how these impulses are linked to the generation of a muscle contraction.
- For each specific step in excitation–contraction coupling, explain how failure of that step prevents skeletal muscle contraction.
- Explain why skeletal muscle contraction is either “full on” or “full off.”
- Explain how force generation in muscle is enhanced by rapid repeated stimulation of the muscle and describe the value of this mechanism in terms of specific mechanical task muscles perform.
- Explain how lack of oxygen to skeletal muscle locks it into a rigor state.
- Distinguish between isotonic and isometric conditions and contractions and give examples of each.
- Explain the molecular basis of why the production of isometric force depends on the length to which muscle is stretched prior to its activation.
- Show how the isometric length–tension curve sets the limit for all isotonic contractions in skeletal muscle.
- Contrast the important steps in the regulation of smooth versus skeletal muscle contraction by calcium.
- Explain why the contraction of a smooth muscle cell can be graded, whereas that of a skeletal muscle fiber cannot.
- Explain the mechanism by which smooth muscle reduces its energy requirements during long-duration, sustained contractions.

Muscles are organs composed of cells that possess the ability to contract and thus generate force and movement. Muscle is commonly classified into subtypes based on anatomical location and appearance; the muscle associated primarily with the bones of the skeleton is designated **skeletal muscle**; that comprising the heart is called **cardiac muscle** and that found in the alimentary tract, the genitourinary system, blood vessels, bronchi, and the eye is called ***smooth muscle*** because of its unremarkable or “smooth” appearance when viewed microscopically. These anatomical classifications, however, are of little use for distinguishing the physiology of these structural subtypes of muscle. The mechanics of muscle contraction and relaxation as well as the regulation of the proteins that produce contraction are markedly different among the three histologic muscle types. This chapter explains the cellular physiology and mechanics of skeletal and smooth muscle. The physiology and mechanics of cardiac muscle are discussed in Chapters 12 and 13.

SKELETAL MUSCLE

Skeletal muscle is primarily associated with the bones of the skeleton. However, this type of muscle also makes up the muscles of the diaphragm, parts of the esophagus, and the muscles that move the eye. Muscles of the skeleton are responsible for the large and forceful movements involved in walking, running, and lifting heavy objects. Large skeletal muscle groups, such as those in the lower back, buttocks, and thigh, are also responsible for stabilizing the body's position against gravity, which prevents teetering. Smaller skeletal muscle groups are used for the fine, delicate movements of the hands, such as those used in writing, playing the violin, and manipulating tiny objects. Finally, a secondary function of skeletal muscle is the production of heat. Heat given off in shivering or during general exercise is an important source of heat generation in the body (see Chapters 28 and 29).

Protein filaments provide the architecture and contractile machinery of skeletal muscle.

All skeletal muscles have a striated (striped) appearance when viewed with a light or an electron microscope. This appearance comes from the highly organized arrangement of protein filaments within each muscle cell. These filaments make up the structure of the contractile mechanism and participate in the chemical processes that are responsible for converting chemical energy into mechanical energy and thus mechanical function of muscle.

A whole skeletal muscle is composed of numerous muscle cells, also called **muscle fibers**, which can measure to 100 μm in diameter and many centimeters long. Most skeletal muscle generates the ATP needed to supply energy for contraction through oxidative metabolism and therefore have an abundant supply of **mitochondria**.

Thick and thin filaments

The process of muscle contraction requires an elaborate subcellular structure of contractile proteins that couple cyclic biochemical interactions into physical movements. These contractile proteins are polymers that are described generically as thick filaments and thin filaments. The fundamental unit of a thick filament is **myosin** (molecular weight, ~500,000), a complex protein molecule with several distinct regions (Fig. 8.1).

Figure 8.1 Myofilament components of skeletal muscle fibers. The myosin molecular structure is assembled into thick filaments. The S2 region of the molecule is flexible, whereas the tail region is stiff. Actin-binding sites are located on the globular myosin heads, which also contain light chains with ATPase activity. Thin (actin) filaments of skeletal muscle are formed from actin monomers (G-actin) into helical F-actin strands, which associate with a troponin–tropomyosin complex to form the functional actin filament. ATP, adenosine triphosphate; Tn-C, troponin-C; Tn-T, troponin-T; Tn-I, troponin-I; G-actin, globular actin; F-actin, filamentous actin.

The molecule consists of a long, straight portion (the "tail" portion) composed of light meromyosin. The remainder of the molecule, heavy meromyosin (HMM), consists of a protein chain, the *S2 region* (or *subfragment 2*), that serves as a flexible link between the tail and a globular head portion, called the *S1 region* (or *subfragment 1*). This region contains a binding site for another protein filament with the muscle cell called **actin** (which comprises the bulk of the thin filament; see Fig. 8.1) and an ATP-binding site that is involved in the supply of energy for the actual process of contraction. The S1 region is responsible for the enzymatic and chemical activity that results in actin and myosin interaction that generates muscle contraction. Two low molecular weight peptide chains, called "light chains," are loosely attached to the S1 region; one called the essential light chain stabilizes myosin, whereas the other, called the **regulatory light chain**, is phosphorylated during muscle activity and serves to modulate muscle function. Functional myosin molecules are paired; their tail and S2 regions are wound about each other along their lengths and the two heads lie adjacent to each other. The tail regions, formed from close packing of the individual myosin dimers into thick filaments, are aligned so that they are tail to tail in the center of the thick filament and extend outward from the center in both directions, creating a bare zone (i.e., no heads protruding) in the middle of the filament (see Fig. 8.1).

Each actin filament (thin filament) is composed of two helically entwined strands, or chains, of repeating subunits of the globular protein, G-actin (molecular weight, 41,700). This chain is called *F-actin* (or *filamentous actin*; see Fig. 8.1). In the groove formed down the length of the helix, there is an end-to-end series of fibrous protein molecules (molecular weight, 50,000) called **tropomyosin**. Near one end of each tropomyosin molecule is a protein complex called **troponin**, composed of troponin-C (Tn-C), troponin-T (Tn-T), and troponin-I (Tn-I). The tropomyosin: troponin complexes are involved in regulating the interaction of actin with myosin heads that are responsible for muscle contraction and relaxation as described later in this chapter.

Interdigitating regions of thick and thin filaments in structural units called sarcomeres form the contractile unit of a muscle fiber.

A single muscle fiber (cell) is divided lengthwise into several hundred to several thousand parallel tubular structures called **myofibrils**. Each myofibril has alternating light and dark bands that repeat at regular intervals down the length of their long axis. These bands arise from the way actin and myosin interdigitate within the myofibril and give the fiber as a whole a striated (striped) appearance (Fig. 8.2). For ultrastructural identification, the bands are named as follows: **A band**—bounded by dark bands of the myofibril due to overlap of actin and myosin; **H zone**—a narrow, lighter-colored region in the center of the A band; **M line**—a prominent feature found at the center of the H zone in many skeletal muscles; **I band**—a low-density region between the A bands; and the **Z line**—a dark structure (also called a Z disk because the myofibril is a three-dimensional structure) that crosses the I band. The filaments of the I band attach to the Z line and extend in both directions into the adjacent A bands. The I band contains only thin (actin) filaments, whereas the A bands contain the thick (myosin) filaments and the overlapping projections of the thin filaments from the I band. The fundamental repeating unit of the myofibril bands is called a **sarcomere** and is defined as the space between (and including) two successive Z lines. Every myofibril contains numerous sarcomeres arranged in series along its long axis.

CLINICAL FOCUS 8.1

Neuromuscular Toxins in Nature: From Physiological Exploration to Clinical Pharmacology

The ability of skeletal muscle to provide force and movement to an organism has obvious survival value in the animal kingdom. Many animals and even plants have evolved the ability to manufacture toxins that can inactivate skeletal muscle as a means of warding off predation by another species or immobilizing a species as prey. Discovery of natural compounds that alter key physiological processes in the human body often leads to their use as tools to reveal the cellular mechanisms of those processes. It is not uncommon to then take this one step further and combine an understanding of the toxin's structure and its physiological actions to create related compounds that can be used clinically to manipulate physiological phenomena for a medicinal benefit to a human patient.

The legendary arrow poisons, collectively called *curare*, used by indigenous peoples of South and Central America to paralyze and kill animals for food, are an example of the transition in medicine of natural discovery, to revealed physiology, to clinical pharmacotherapeutics. First brought to Europe near the end of the 16th century, curare is a collection of alkaloids collected and prepared from plants of the *Strychnos* genus native to South and Central America. In the middle of the 19th century, experiments on the actions of curare preparations on animals revealed that the agents induced flaccid paralysis of skeletal muscle, including the diaphragm needed for pulmonary ventilation, while not affecting other life processes like the pumping of the heart. Claude Bernard demonstrated that the mechanism of action involved interference of the action of the motor neurons to activate the muscle rather than affecting the muscle itself thus demonstrating the principle of neuromuscular transmission in the genesis of muscle contraction. Over the next century, many investigations revealed that the curare alkaloids acted on the motor endplate, not the nerve itself, by competitively binding to the acetylcholine-binding sites of the nicotinic receptor/depolarizing ion channel of the skeletal muscle cell membrane. When bound by the alkaloids, acetylcholine released from the muscle's motor nerve terminals cannot open the nicotinic channels. This then renders the muscle incapable of generating depolarizing endplate potentials large enough to trigger action potentials, which are responsible for initiating skeletal muscle contraction. This accounts for the observation of induction of flaccid paralysis in animals exposed to curare. From the 1930s on, this collective knowledge was used to develop semisynthetic and synthetic substitutes for curare that could be used medically as a means to induce muscle relaxation in patients. Today, a handful of such competitive agents are available for therapeutic applications and are collectively called neuromuscular blocking agents. These agents are widely used to induce temporary flaccid paralysis in patients as a means of facilitating extensive surgical procedures and reducing the level of general anesthesia that would otherwise be needed to induce muscle relaxation during surgery. In this manner, levels of anesthesia that might otherwise

suppress cardiopulmonary function can be avoided. ■

MOTOR NEURONS AND EXCITATION–CONTRACTION COUPLING IN SKELETAL MUSCLE

Chemically, actin and myosin have a natural affinity for one another, and when added together in solution, the myosin head will bind tightly to sites on the G-actin monomer subunits of F-actin. The binding link between these two filaments is called a **crossbridge**. This binding is prevented from occurring spontaneously in the myofilaments of skeletal muscle by the presence of tropomyosin on the thin filament, which sterically interferes with the ability of myosin to access its actin-binding site. This is the state of skeletal muscle at rest (i.e., when it is not contracting) and is what is responsible for the flaccid property of resting skeletal muscle.

As described above, actin and myosin are arranged in a highly organized, interdigitating, structure within the sarcomere. In this arrangement, it is easy to see that it is possible for actin filaments to slide longitudinally between the myosin filaments (see Fig. 8.2). Consequently, if actin and myosin were allowed to temporarily bind to one another and the actin then somehow pulled into the A band of the sarcomere, then released at its new position and allowed to reattach to another myosin-binding site, and subsequently allowed to repeat the entire cycle in a "hand-over-hand"–like manner, the entire sarcomere would generate force and shorten. Extrapolated to all the sarcomeres in all the muscle fibers within a muscle, the muscle itself would then generate force and shorten as well, that is, it would contract.

The postulate that actin and myosin can interact in a controlled manner as just described is called the sliding filament hypothesis and it has long since been established as the molecular mechanism of muscle contraction. The activation and cycling of actin and myosin crossbridge formation during a muscle contraction is called the **crossbridge cycle**.

If skeletal muscle as a tissue is to be able to generate force and movement in any structure in the body, the crossbridge cycle must be activated and deactivated in a controlled manner. As it turns out, skeletal muscle cells cannot be activated on their own. All such cells require activation by neurotransmitters released from motor neuron axons that terminate at specialized regions of the skeletal muscle cell membrane. This process of activation of the skeletal muscle crossbridge cycle is called **excitation–contraction coupling**.

Skeletal muscle is considered an "excitable" tissue, which means that its membrane potential is linked to activation of that cell's function (i.e., contraction). Depolarization of the skeletal muscle cell membrane of sufficient magnitude can lead to the generation of muscle cell action potentials. These action potentials trigger an increase in intracellular Ca^{2+} concentration within the muscle fiber, which activates the crossbridge cycle (see below for details). *Skeletal muscle cells, however, cannot generate these action potentials by themselves*. Instead, they must receive a depolarizing signal from motor neurons that innervate the cell. Consequently, all skeletal muscles are externally controlled; they cannot contract without a signal from the somatic nervous system. This system is analogous to the light in a table lamp. The light cannot be turned on unless an electric cord connects the lamp to a source of electrical current. Similarly, skeletal muscle cells cannot contract if the motor neurons innervating them are severed or transmission of the chemical signal to the underlying fiber is blocked. In such situations, the muscle group innervated by the motor neuron is flaccidly paralyzed.

Electrochemical events at the neuromuscular junction link synaptic transmission to muscle contraction.

The sequence of events that leads to contraction of skeletal muscle starts with action potentials that travel down somatic motor nerves originating in the central nervous system (CNS). Upon reaching a muscle cell, the axon of a motor neuron typically branches into several terminals, each of which constitutes the *presynaptic* portion of a special synapse called the **neuromuscular junction** (**NMJ**), also called the **myoneural junction** or **motor endplate** (Fig. 8.3). The terminals, which are all covered by a Schwann cell, lie in grooves or "gullies" in the surface of the muscle cell membrane. The signal from motor neuron to muscle cell is transmitted in the form of a chemical transmitter (neurotransmitter) released from nerve to muscle across the NMJ. This type of synapse has a close association between the membranes of the nerve and muscle. It possesses many of the features of a nerve–nerve synapse in the CNS. It is somewhat simpler, however, because it is only excitatory and accepts no feedback from the postsynaptic cell.

B

Figure 8.3 Structural features and electrical activity of the neuromuscular junction. Acetylcholine released from membrane vesicles is released from the axon terminal and diffuses to the underlying membrane where it binds with nicotinic receptors concentrated in invaginations of the sarcolemma. **(A)** An action potential from a motor neuron releases a small amount of acetylcholine into the myoneural junction. This causes a small depolarization in the motor endplate that is transmitted electrotonically with decrement through the myoplasm. In this instance, the amount of depolarization reaching the first available voltage-gated sodium channel in the cell membrane is below threshold for opening the channel, and no muscle action potential is formed. **(B)** With greater frequency of action potentials reaching the motor axon terminal, acetylcholine reaches a higher concentration in the myoneural junction. This creates a larger endplate potential than that seen with lesser motor neuron activation. Although this potential proceeds down the muscle fiber with decrement, the depolarization reaching the first sodium channels is greater than its threshold, and the muscle fiber is able to fire an action potential. Action potentials are self-reinforcing and travel down the muscle fiber without decrement in a manner similar to that seen in unmyelinated nerve fibers.

Within the axoplasm of the motor nerve terminals are located numerous membrane-enclosed vesicles containing **acetylcholine** (**ACh**). The postsynaptic portion of the NMJ or **endplate membrane** is formed into postjunctional folds that contain **nicotinic ACh receptors** (see Chapter 3). When action potentials reach the terminal of a motor axon, the resulting depolarization of the terminal causes membrane channels to open, allowing external calcium ions to enter the axon. This causes the axoplasmic vesicles of ACh to migrate to the inner surface of the axon membrane, where they fuse with the membrane and release their contents. The vesicles are all approximately the same size and all release about the same amount, or **quantum**, of neurotransmitter. ACh released from the motor neuron terminal then diffuses across the NMJ and binds to the ACh receptors in the motor endplate. When two ACh molecules are bound to a receptor, it undergoes a conformational change, opening a channel in the receptor that allows the relatively free passage of sodium and potassium ions down their respective electrochemical gradients. The opening of the channels depends only on the presence of neurotransmitter and not on membrane voltage. Sodium and potassium permeability changes occur simultaneously, and both ions share the same membrane channels, but the change in electrochemical gradient for sodium into the cell is much greater than that for potassium out of the cell. The result is a net inward positive current that depolarizes the postsynaptic membrane. This positive voltage change is called the **endplate potential** (see Fig. 8.3).

Endplate depolarization is *graded*, that is, its amplitude will vary with the number of receptors bound with ACh. The number of receptors bound is proportional to the local concentration of ACh in the NMJ, which, in turn, is a function both of the ACh released by the motor neuron and the amount of ACh degraded by **acetylcholinesterase** (**AChE**) in the NMJ. ACh binds loosely to its receptor. It can detach and diffuse away and become hydrolyzed into choline and acetate by AChE thus terminating its function as a transmitter molecule. At low action potential frequencies of the motor neuron, the amount of ACh entering the synaptic cleft will be low (see Fig. 8.3A) and reduced even further by the action of AChE. Consequently, the concentration of ACh receptors occupied will be very low and result in a small amplitude endplate depolarization. Endplate potentials are simple local depolarizations that are transmitted outward (leak) from underneath the motor endplate. They diffuse from their initial location with decrement, that is, their amplitude decays as they travel through the myoplasm.

The motor endplate does not contain voltage-gated sodium channels and cannot produce self-propagating action potentials. However, regions of the sarcolemma away from the motor endplates do contain voltage-gated sodium channels. If these channels can be brought to threshold, the muscle fiber can

form self-propagating action potentials in a manner analogous to that in unmyelinated neurons. However, because endplate potentials move down the muscle fiber with decrement, an initial small endplate potential may be of insufficient amplitude by the time it reaches a sodium channel to bring that channel to its threshold for firing an action potential (see Fig. 8.3A). In contrast, large amounts of ACh released into the NMJ will cause a proportionally larger endplate depolarization (see Fig. 8.3B). Although this endplate potential will also spread out across the muscle membrane with decrement, enough depolarization will reach the region of voltage-gated sodium channels in the muscle membrane to cause them to open and fire an action potential. Once formed, the muscle action potential will then be self-propagating along the muscle cell membrane as with a nonmyelinated nerve fiber.

Neuromuscular transmission can be altered by toxins, drugs, and trauma.

Under normal circumstances, the endplate potential is much more than sufficient to produce a muscle action potential; this reserve, or safety factor, can help preserve function under abnormal conditions. However, neuromuscular transmission is subject to interference at several steps. Presynaptic blockade can occur if calcium does not enter the presynaptic terminal. Inhibition of choline uptake by the presynaptic terminal, such as that caused by the drug hemicholinium, results in the depletion of ACh in the neuron. **Botulinum toxin** interferes with SNARE proteins responsible for vesicular ACh release and results in flaccid paralysis of muscle exposed to the toxin, including the diaphragm, resulting in death.

Postsynaptic blockade can result from drugs that can bind to nicotinic receptors in the muscle membrane. Derivatives of **curare**, originally used as arrow poison in South America, bind tightly to ACh receptors without opening it thus reducing the endplate potential, which can result in flaccid muscle paralysis. Several classes of agents, such as **physostigmine** (**eserine**) and organophosphates (malathion and sarin gas), are potent inhibitors of AChE. At sufficient strength, they can result in excessive concentration of ACh at the NMJ, which forces the muscle cell to remain depolarized and unable to return from the inactive state to form additional action potentials. This is called depolarization blockade and can result in death. However, in carefully controlled doses, AChE inhibitors can temporarily alleviate symptoms of **myasthenia gravis**, an autoimmune condition that results in a loss of postsynaptic ACh receptors with resultant small endplate potentials and muscular weakness. Partial inhibition of the enzymatic degradation of ACh allows it to remain in higher concentration in the NMJ and, thus, to compensate for the loss of receptor molecules.

CLINICAL FOCUS 8.2

Treatment of Focal Dystonias with Botulinum Toxin

Focal dystonias are neuromuscular disorders characterized by involuntary and repetitive or sustained skeletal muscle contractions that cause twisting, turning, or squeezing movements in a body part. Abnormal postures and considerable pain, as well as physical impairment, often result. Usually, the abnormal contraction is limited to a small and specific region of muscles, hence the term focal (by itself). *Dystonia* means "faulty contraction." *Spasmodic torticollis* and *cervical dystonia* (involving neck and shoulder muscles), *blepharospasm* (eyelid muscles), *strabismus* and **nystagmus** (extraocular muscles), *spasmodic dysphonia* (vocal muscles), *hemifacial spasm* (facial muscles), *writer's cramp* (finger muscles in the forearm), achalasia (failure of the lower esophageal sphincter to open), and other esophageal dysmotilities are common dystonias. Such problems are neurologic, not psychiatric, in origin, and sufferers can have severe impairment of daily social and occupational activities.

Although the specific cause is located somewhere in the central nervous system, the exact nature of dystonia is unknown. A genetic predisposition to the disorder may exist in some cases. Centrally acting drugs are of limited effectiveness, and surgical denervation, which carries a significant risk of permanent and irreversible paralysis, may provide only temporary relief.

Botulinum toxin, which produces chemical denervation of motor neurons resulting in flaccid muscle paralysis, has shown potential benefit in the treatment of dystonias. Botulinum toxin is produced from the bacterium *Clostridium botulinum* and is one of the most potent natural toxins known; a lethal dose for a human adult is about 2 to 3 µg. Type A toxin, the complex form most often used therapeutically, is sold under the trade names Botox and Oculinum.

The toxin first binds to the cell membrane of presynaptic nerve terminals in skeletal muscles. The initial binding does not appear to produce flaccid paralysis until the toxin is actively transported into the cell, a process requiring more than an hour. Once inside the cell, the toxin disrupts calcium-mediated acetylcholine release by binding to docking proteins that link synaptic vesicles containing neurotransmitter to the nerve terminal membrane. This prevents action potentials from being able to release neurotransmitter into the neuromuscular junction. The transmission block at the neuromuscular junction of the affected neuron is irreversible. The nerve terminals begin to degenerate, and the denervated muscle fibers atrophy. Eventually, new nerve terminals sprout from the axons of affected nerves and make new synaptic contact with the chemically denervated muscle fibers. During the period of denervation, which may be several months, the patient usually experiences considerable relief of symptoms. The relief is temporary, however, and the treatment must be repeated when reinnervation has occurred.

Clinically, highly diluted toxin is injected into the individual muscles involved in the dystonia. Recently, Botox has been used to treat retractable esophageal dysmotility disorders that are refractory to other forms of treatment. In dystonias involving muscles in the extremities, injections of toxin are done in conjunction with electrical measurements of muscle activity (electromyography) to pinpoint the muscles involved. Patients typically begin to experience relief in a few days to a week. Depending on the specific disorder, relief may be dramatic and may last for several months or more. The abnormal contractions and associated pain are greatly reduced, speech can become clear again, eyes reopen and cease uncontrolled movements, and, often, normal activities can be resumed.

The principal adverse effect is a temporary weakness of the injected muscles. However, this property has been exploited for the cosmetic use of Botox for releasing muscle tension in the face and forehead, which then reduces the formation of wrinkles in the skin. Studies have shown that the toxin's activity is confined to the injected muscles, with no toxic effects noted elsewhere. Long-term effects of the treatment, if any, are unknown. ■

Muscle action potentials release calcium from the sarcoplasmic reticulum to activate the crossbridge cycle.

The outer surface of a skeletal muscle fiber is surrounded by an electrically excitable cell membrane supported by an external meshwork of fine fibrous material. Together, these layers form the cell's surface coat, the **sarcolemma**. The sarcolemma generates and conducts action potentials much like those of nerve cells. Contained wholly within a skeletal muscle cell is another set of membranes called the **sarcoplasmic reticulum** (**SR**), which is a specialization of the endoplasmic reticulum (Fig. 8.4). The SR is specially adapted for the uptake, storage, and release of calcium ions. Calcium ATPase pumps in the SR allow it to concentrate calcium within the SR to concentrations more than a million times that in the cytoplasm of the myofiber at rest. This organelle plays a key role in controlling muscle contraction because the free calcium ion concentration within the muscle fiber is critical in controlling the processes of contraction and relaxation (see details below). Within each sarcomere, the SR consists of two distinct portions. The longitudinal element forms a system of hollow sheets and tubes that are closely associated with the myofibrils. The ends of the longitudinal elements terminate in a system of **terminal cisternae** (or *lateral sacs*). These contain a protein, calsequestrin, that weakly binds calcium, and most of the stored calcium is located in this region.

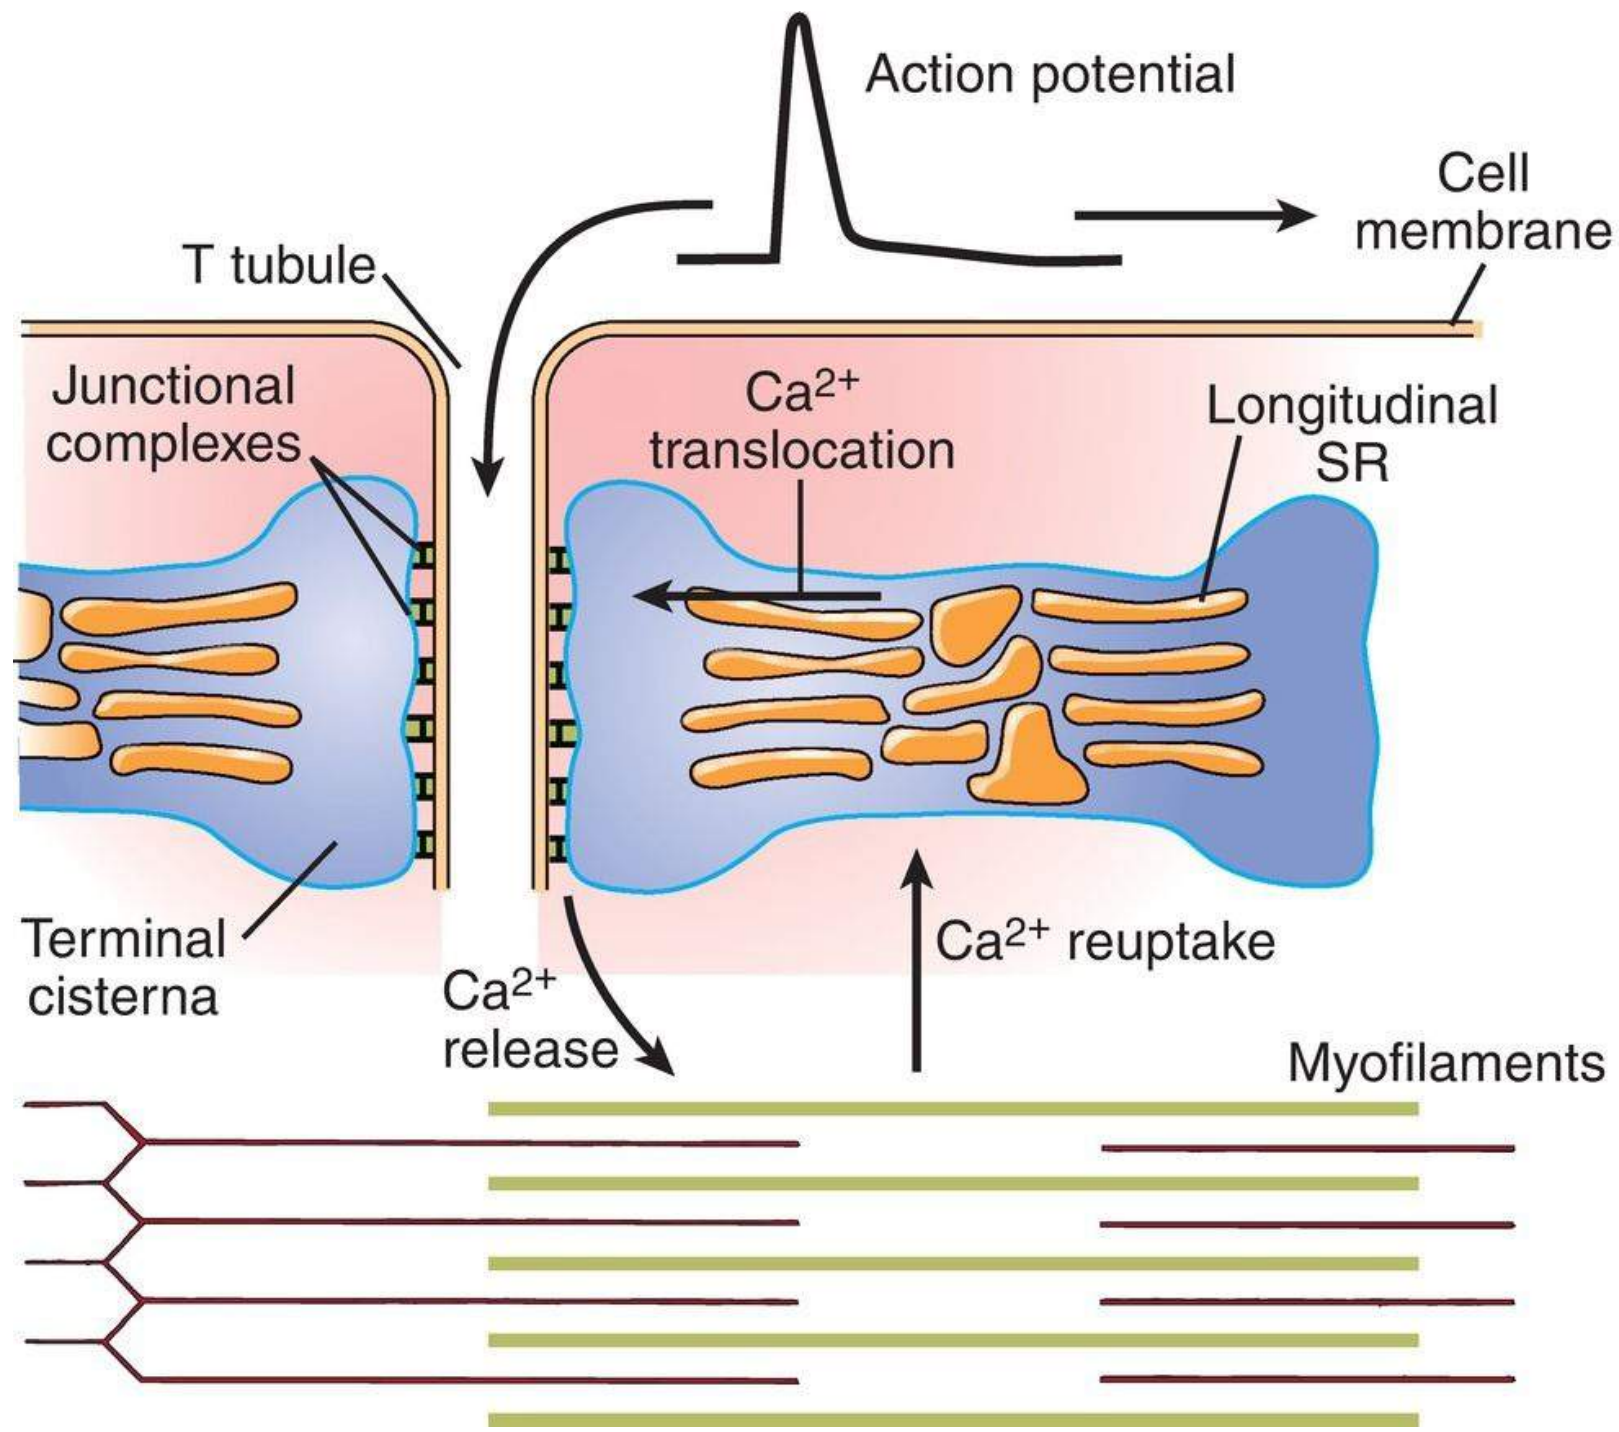

Figure 8.4 Release of activator calcium from the SR by a muscle action potential. Excitation–contraction coupling involves opening of ryanodine receptors by action potentials in the T-tube membrane with subsequence release of calcium stored in the SR into the sarcoplasm. This activates actin–myosin crossbridge cycling. The SR is replenished with calcium from the sarcoplasm by Ca^{2+} ATPase pumps in the SR membrane. (See text for details of the process.) T tubule, transverse tubule; SR, sarcoplasmic reticulum.

Closely associated with both the terminal cisternae and the sarcolemma are the **transverse tubules** (**T tubules**), which are inward extensions of the cell membrane whose interior is continuous with the extracellular space. Although they traverse the muscle fiber, T tubules do not open into its interior. The association of a T tubule and the two terminal cisternae at its sides is called a **triad**, a structure important in excitation–contraction coupling.

The large diameter of skeletal muscle cells places interior myofilaments out of range of the immediate

influence of events at the cell surface, but the T tubules, SR, and their associated structures act as a specialized internal communication system that allows the surface action potential signal to penetrate to interior parts of the cell. This process begins in skeletal muscle with the electrical excitation of the surface membrane (see Fig. 8.4). An action potential sweeps rapidly down the length of the fiber and propagates down the T-tubule membrane. This propagation results in numerous action potentials traveling toward the center of the fiber, one in each T tubule.

At some point along the T tubule, the action potential reaches the region of a triad where the presence of the action potential is communicated to the terminal cisternae of the SR. Here, the T-tubule action potential affects specific protein molecules called **dihydropyridine receptors** (**DHPRs**). These molecules, which are embedded in the T-tubule membrane in clusters of four, serve as voltage sensors that respond to the T-tubule action potential. They are located in the region of the triad where the T-tubule and SR membranes are the closest together. Each cluster is located in close proximity to a specific channel protein called a **ryanodine receptor** (**RyR**), which is embedded in the SR membrane. The RyR serves as a controllable channel through which calcium ions can move readily when it is in the open state. These are therefore sometimes termed **calcium release channels**. DHPR and RyR form a functional unit called a **junctional complex** (see Fig. 8.4).

When the muscle is at rest, the RyR is closed; when T-tubule depolarization reaches the DHPR, it causes the RyR to open and release calcium from the SR. This leads to rapid release of calcium ions from the terminal cisternae into the intracellular space surrounding the myofilaments.

State of total relaxation to maximum contraction in skeletal muscle is tightly linked to its intracellular calcium concentration.

In resting skeletal muscle, the free calcium ion concentration in the region of the myofilaments is low ($<10^{-7}$ M), and crossbridge formation is prevented by the troponin–tropomyosin complex of the thin myofilaments (Fig. 8.5). In this state, the muscle is thus relaxed. The trigger for activating the skeletal muscle crossbridge cycle is the rapid release of calcium from the SR, down its huge electrochemical gradient, upon stimulation by action potentials entering the triad. When RyR open in the SR in response to action potentials, intracellular calcium ion concentrations increase above resting levels and these ions begin to bind to the Tn-C subunit associated with each tropomyosin molecule. Through the action of Tn-I and Tn-T, calcium binding causes the tropomyosin molecule to change its position slightly, uncovering the myosin-binding sites on the actin filaments (see Fig. 8.5). The myosin is thus allowed to interact with actin, and the events of the crossbridge cycle begin. As long as calcium ions are bound to the Tn-C subunit, the crossbridge cycle can occur. The switching action of the calcium–troponin–tropomyosin complex in skeletal muscle is extended by the structure of the thin filaments, which allows one troponin molecule, via its tropomyosin connection, to control seven actin monomers. Because the calcium control in striated muscle is exercised through the thin filaments, it is termed **actin-linked regulation**.

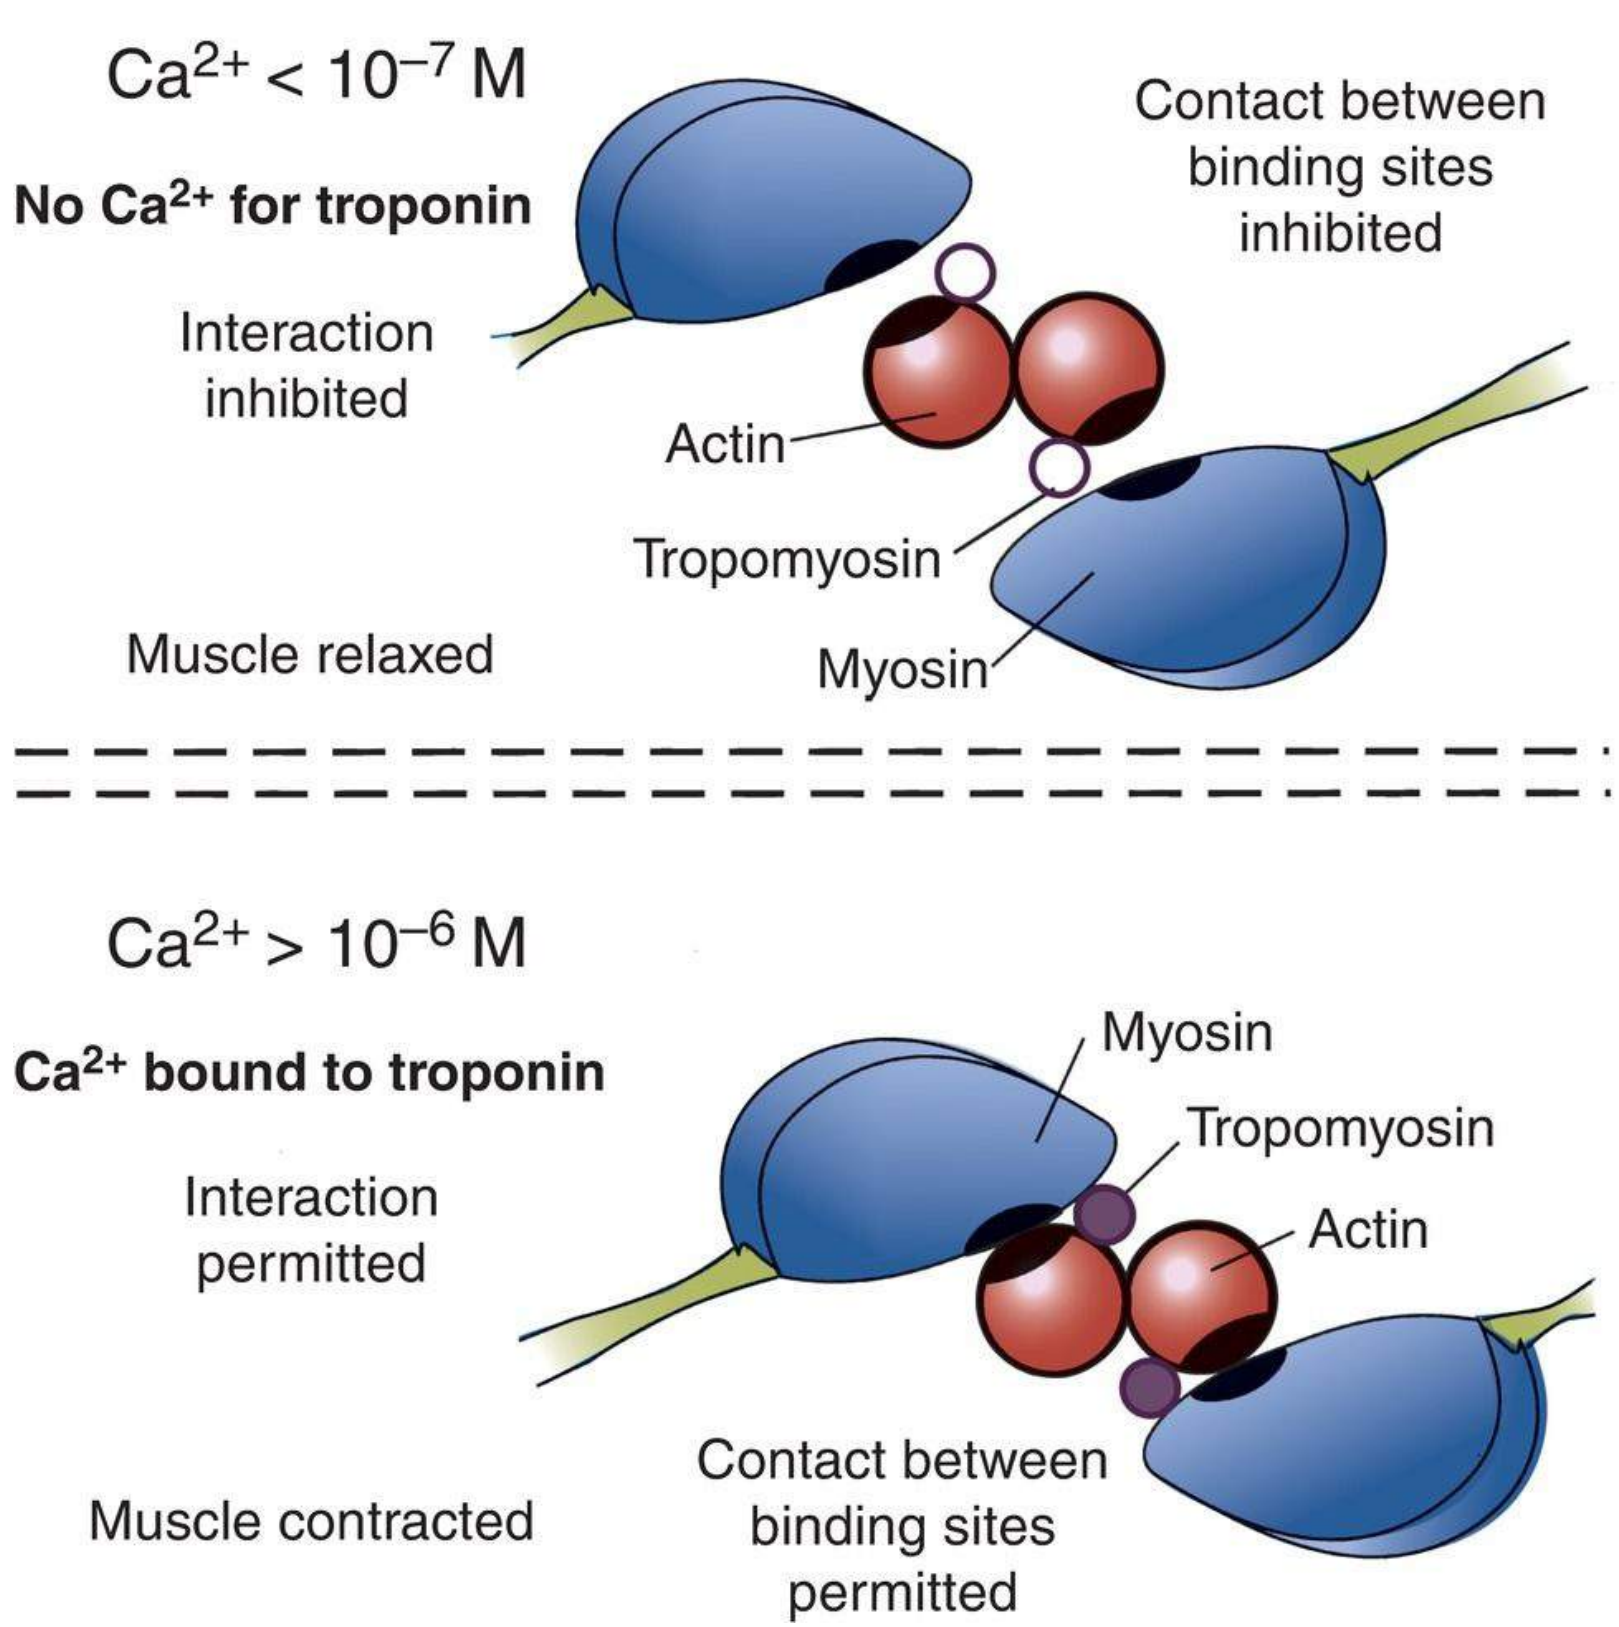

Figure 8.5 The calcium switch for controlling skeletal muscle contraction. Calcium ions, via the troponin–tropomyosin complex, control the blocking of the interaction between the myosin heads (the crossbridges) and the active site on the thin filaments. The thin filaments are seen in cross section.

The relationship between the relative force developed by actin–myosin binding and the calcium concentration in the region of the myofilaments is steep. At a calcium concentration of $<1 \times 10^{-7}$ M, the interaction between actin and myosin is negligible, whereas an increase in the calcium concentration to 1×10^{-5} M produces essentially full-force development. This process is saturable, so that further increases in calcium concentration lead to little increase in force. In skeletal muscle, an excess of calcium ions is

usually present during activation, and the contractile system is nearly saturated. There is only one burst of calcium ion release for each action potential. If action potential generation in the muscle ceases, intracellular calcium concentration in the myofibrils rapidly decreases and the fiber returns to the relaxed state. This is because Ca^{2+} ATPases or "**calcium pumps**" in the SR membranes continuously take up free calcium ions from the myofilament space and actively pump them into the interior of the SR. In the absence of a stimulus for calcium release from the SR, the continuous activity of the calcium pumps reduces calcium in the region of the myofilaments to a low level ($<1 \times 10^{-7}$ M). Once returned into the SR, the resequestered calcium ions are moved along the longitudinal elements to storage sites in the terminal cisternae, and the system is ready to be activated again. This entire process takes place in a few tenths of a millisecond and may be repeated many times each second.

Cyclic interaction of actin and myosin is the molecular engine driving muscle contraction.

The process of contraction of a muscle cell involves a controlled cyclic interaction between the actin and myosin in a sequence of events called the **crossbridge cycle**. This cycle is shown in Figure 8.6. Briefly, this cycle involves attachment of thick-filament myosin heads to binding sites on actin monomers to form a crossbridge, incremental movement of the filaments to produce sarcomere shortening, detachment of the filaments, and then reattachment of myosin heads along the thin filaments and the repeat of the incremental movement, etc. This cycling of crossbridges results both in force generation and movement through the whole muscle fiber.

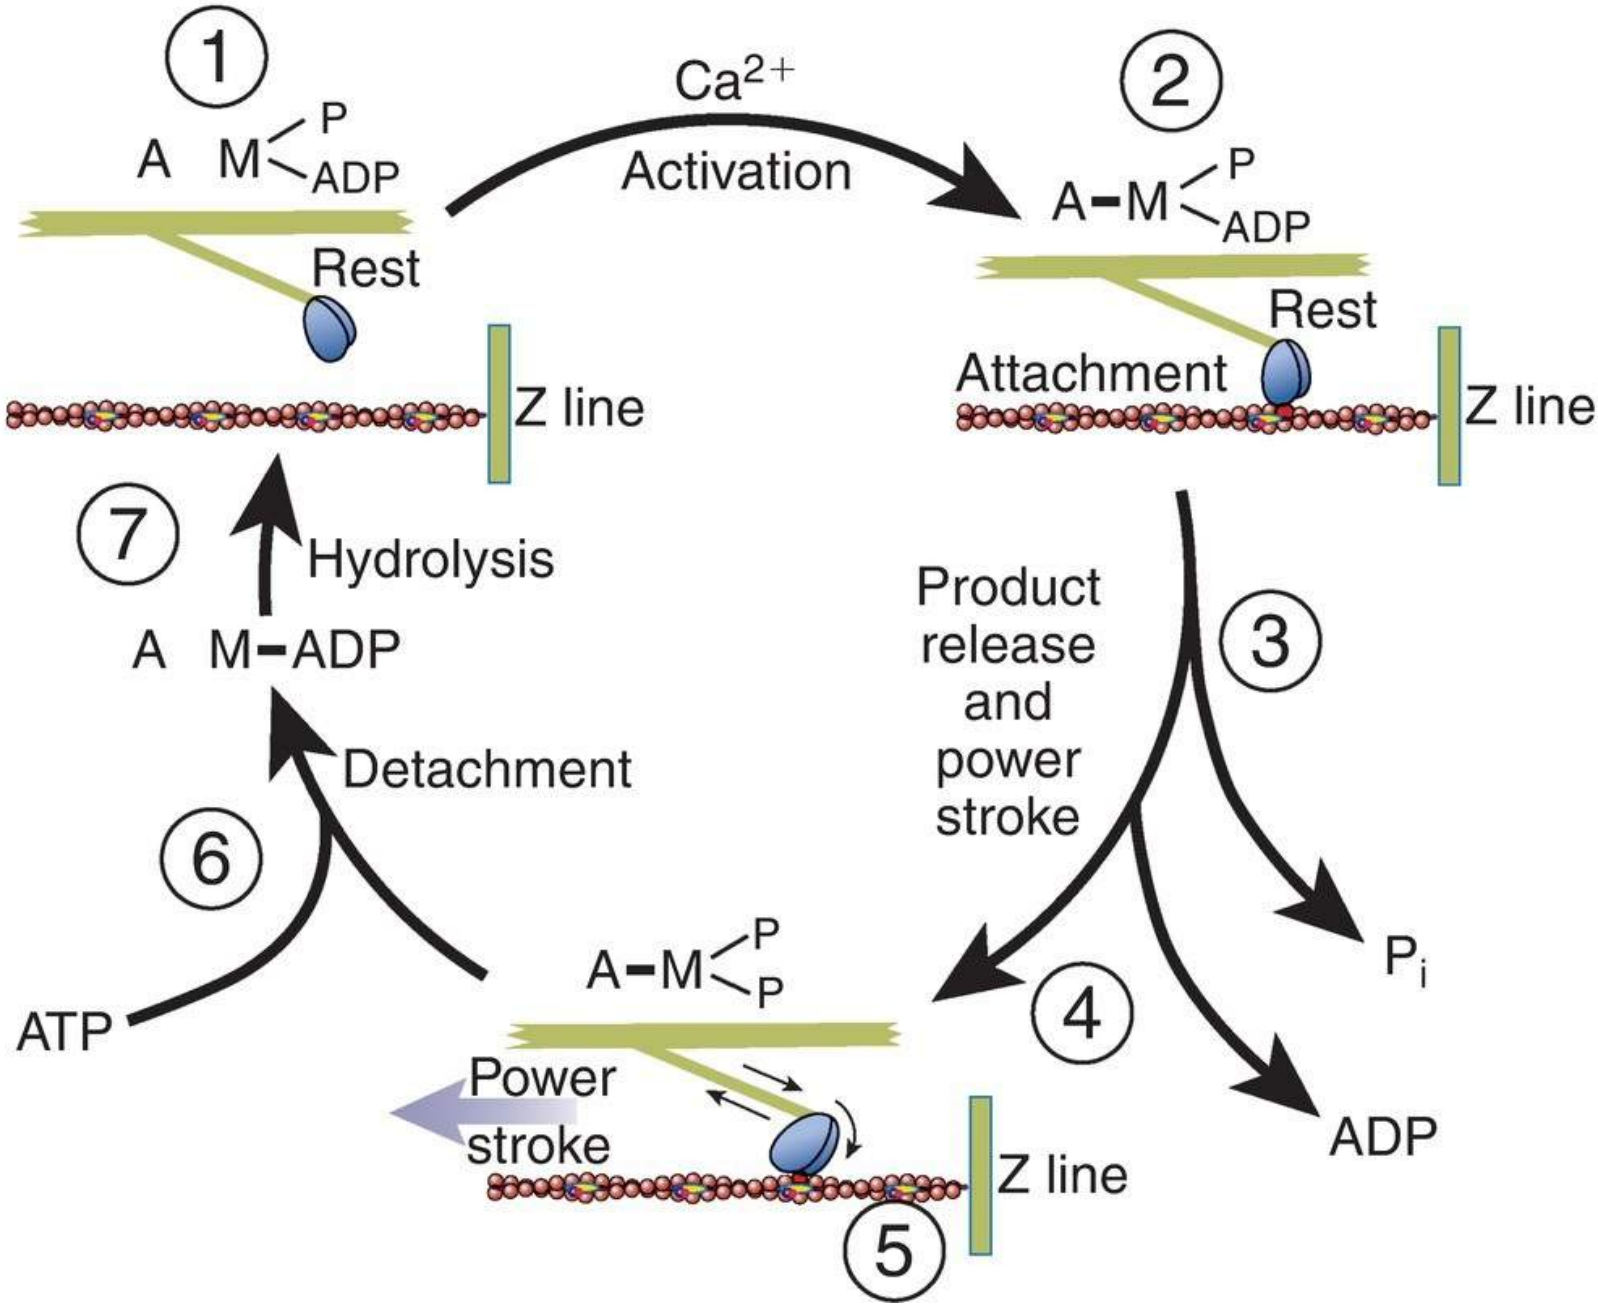

Figure 8.6 Events of the crossbridge cycle in skeletal muscle. (*1*) At rest, adenosine diphosphate (ADP) and inorganic phosphate are bound to the myosin head, which is in position to interact with actin. The interaction, however, is blocked allosterically by tropomyosin. (*2*) Inhibition of actin–myosin interaction

is removed by binding of calcium to troponin-C; the myosin head binds to actin. The release of ADP and phosphate (*3*) changes the conformation of the myosin head from 90° to 45°, stretching the myosin S2 region (*4*). Recoil of the S2 region creates the power stroke (*5*). The still-attached crossbridge is now in the rigor state. Detachment (*6*) is possible when a new adenosine triphosphate (ATP) molecule binds to the myosin head and is subsequently hydrolyzed. Energy from ATP hydrolysis resets the myosin head from a 45° conformation back to its original 90° conformation (*7*), thereby returning the myosin and actin positions to their original resting state. These cyclic reactions can continue as long as the ATP supply remains and activation via Ca^{2+} maintained. (See text for further details.) A, actin; M, myosin; P_i, inorganic phosphate ion; –, chemical bond.

At rest, the myosin heads in the thick filaments are bound with **adenosine diphosphate** (**ADP**) and inorganic phosphate (P_i) and situated 90° to the axis of the thin filaments. Myosin does not bind to actin in this state because of the inhibitory action of tropomyosin on crossbridge attachments (see Fig. 8.6, step 1). When the inhibition of tropomyosin on crossbridge attachments is removed by calcium released from the SR, actin and myosin bind strongly, and the crossbridges become firmly attached (see Fig. 8.6, step 2). When myosin is attached to actin, it loses its affinity for ADP and P_i, which then fall free into the cytoplasm (see Fig. 8.6, step 3). The release of ADP and P_i from myosin causes it to undergo a conformational change while the tip of the myosin head is still attached to actin so that the portion of the head attached to the flexible S2 region pitches outward by 45°, thereby stretching this flexible chain region in a manner similar to stretching a spring (see Fig. 8.6, step 4). This “spring,” however, snaps back as soon as it is stretched, and because myosin is still attached to actin, the snapping back pulls the actin filaments past the myosin filaments in a movement called the **power stroke** (see Fig. 8.6, step 5).

Following this movement (which results in a relative filament displacement of around 10 nm) the actin–myosin binding is still strong and the crossbridge cannot detach. At this point in the cycle, the state of actin–myosin binding is termed a **rigor crossbridge** (see Fig. 8.6, step 5). If ATP is present, it binds to the rigor crossbridge at the myosin head, resulting in detachment of myosin from actin (see Fig. 8.6, step 6). The ATPase property of myosin then partially hydrolyzes ATP to ADP and P_i, which remain bound to the myosin head. The energy released from this hydrolysis is used to reset the conformation of the myosin head to its original 90° orientation (see Fig. 8.6, step 7) and the newly recharged myosin head can begin the cycle of attachment, power stroke, and detachment again (see Fig. 8.6, step 1). This cycle can repeat as long as the muscle is activated, a sufficient supply of ATP is available, and the physical limit to shortening has not been reached. If cellular energy stores are depleted, as happens after death, the crossbridges cannot detach because of the lack of ATP, and the cycle stops in an attached state (see Fig. 8.6, step 5). This produces an overall stiffness of the muscle, which is observed as the **rigor mortis** that sets in shortly after death.

Cellular structure of skeletal muscle transforms crossbridge cycling into mechanical motion.

The amounts of movement (~10 nM) and force (~4 pN) produced by a single crossbridge interaction are exceedingly small, and it is the organization of the myofilaments into sarcomeres that both allows useful work to be done and creates the chemically and mechanically cyclic nature of the crossbridge reactions. In a shortening muscle, the power stroke moves the two sets of filaments past one another, and the crossbridge that is formed following one “turn” of the cycle involves myosin attaching to a new actin monomer further down the thin filament.

The width of the A bands (thick-filament areas) in striated muscle remains constant, regardless of the length of the entire muscle fiber, whereas the width of the I bands (thin-filament–only areas) varies directly with the length of the fiber. The spacing between Z lines also depends directly on the length of the fiber. The lengths of the thin and thick myofilaments themselves remain constant despite changes in fiber length. The sliding filament theory proposes that changes in overall fiber length are directly associated with changes in the overlap between the thick and thin filaments. During contraction, this is accomplished by the interaction of the globular heads of the myosin molecules with binding sites on the actin filaments.

A muscle contains many thousands of sarcomeres placed end to end (in series). This arrangement has the effect of adding up all the small sarcomere length changes into a large overall shortening of the muscle. Similarly, the amount of force exerted by a single sarcomere is small (a few hundred micronewtons), but, again, there are thousands of sarcomeres side by side (in parallel), resulting in the production of considerable force.

MECHANICS OF SKELETAL MUSCLE CONTRACTION

Muscle is a biologic motor; it produces physical work by transforming chemical energy into the generation of mechanical force and movement. In spite of the remarkable variety of controlled muscular movements that humans can make, the fundamental mechanical events of the contraction process can be described by a relatively small set of specially defined functions that result from particular muscle capabilities.

Contraction of large muscle groups results from temporal and spatial summation of single contractions in muscle units.

A single muscle action potential leads to a single brief contraction of the muscle called a **twitch** (Fig. 8.7). Though the contractile machinery (i.e., the crossbridge cycle mechanism) may be fully activated (or nearly so) during a twitch, some of this active contraction must be used first to stretch a series of elastic elements in the muscle fibers before full contractile force can be transmitted to the muscle fiber. Thus, the amount of force produced by a single twitch is relatively low. The duration of the action potential in a skeletal muscle fiber, however, is shorter (~5 ms) than the duration of a twitch (tens or hundreds of milliseconds). For this reason, the muscle fiber could be activated again long before the muscle has relaxed. Figure 8.7 also shows the result of stimulating a muscle that has not yet fully relaxed from a prior stimulus at a time well outside its electrical refractory period from that prior stimulus. In this situation, the force of the second stimulus is added to the remaining force from the first stimulus, and significant additional force is developed. These are called partially fused twitches. It is possible to fuse twitches so closely together that the force of the second stimulus is added to the first even before the first force has begun to decline. This results in even greater force enhancement in the muscle beyond that of a single twitch. Thus, in skeletal muscle, the interplay of the electrical refractory period and the duration of mechanical contraction allow individual twitch contractions to be summed *temporally* to enhance the contractile force generated by a muscle fiber.

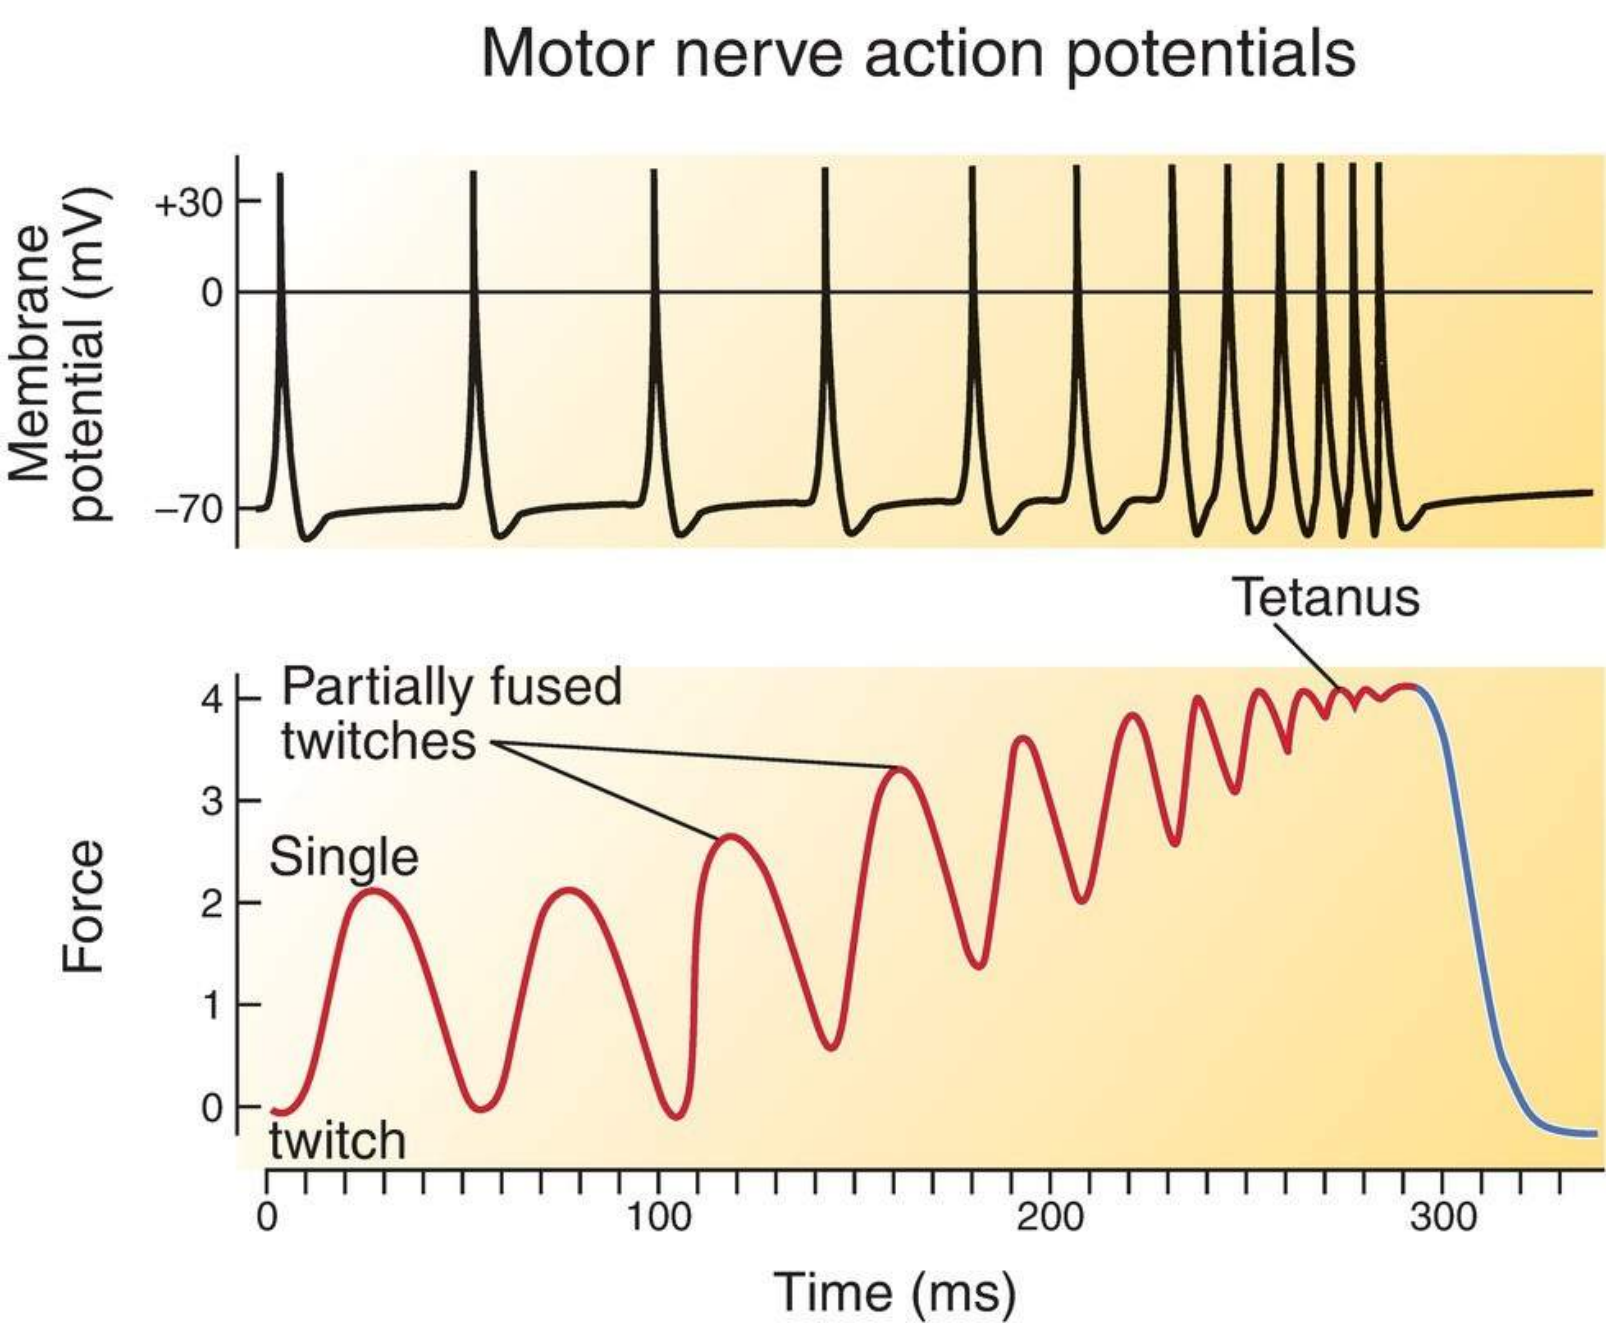

Figure 8.7 Twitch contraction, temporal summation, and fused tetanus. The first two contractions on the left are in response to a single action potential and are examples of a muscle twitch. When the interval between successive activations allows twitches to partially relax in between contractions, peak tension increases but oscillates. This is called *partial tetanus*. As the interval between successive stimuli steadily decreases, twitches fuse on top of one another, and a sustained, smooth higher force is created. This is called *tetanus*.

As an extension of this phenomenon, if many stimuli are given repeatedly and rapidly to the muscle fiber, the result is an amplified, *sustained* contraction called tetanus (see Fig. 8.7). When the contractions occur so close together that no fluctuations in force are observed, a **fused tetanus** is said to result. The repetition rate at which this occurs is the **tetanic fusion frequency**, typically 20 to 60 stimuli per second (which is considered beyond normal physiological stimuli), with the higher rates found in muscles that contract and relax rapidly. The amount of force produced in tetanus is typically several times that of a twitch, and the disparity between the two is expressed as the **tetanus/twitch ratio**. Figure 8.7 shows these effects in a special situation, in which the interval between successive stimuli is steadily reduced. Because it involves events that occur close together in time, a tetanus is a form of temporal summation.

Intracellular Ca^{2+} levels are different in muscle cells during fused tetanus than during partially fused twitches (partial tetanus). Action potentials do not vary significantly in muscle cells, and each action potential releases essentially the same amount of Ca^{2+} from the SR. This amount of calcium is sufficient to cause a twitch. During partial tetanus, the calcium increase with each action potential is very transient because SR Ca^{2+} ATPases rapidly pump the calcium back into the SR. Calcium levels peak and return to control levels repeatedly in this situation, and any increase, or summation, of twitch force is due to incomplete mechanical relaxation of a twitch before the muscle fiber is activated again. During complete, or fused, tetanus, the muscle fiber is activated at a frequency that adds calcium into the intracellular space faster than it can be pumped into the SR. In this case, total tension and intracellular calcium concentration are maximized, with the high calcium levels continually activating muscle contraction as long as the muscle is stimulated at a high enough rate. Although tetanic contractions can greatly increase force generation in skeletal muscle, this type of stimulation is poorly tolerated by the tissue and can damage the muscle cells. Therefore, full fused tetanus is rarely seen in skeletal muscle.

Muscles are organized into functional neuromuscular units that allow partial activation of a whole muscle.

Skeletal muscles are made up of many muscle fibers. These fibers require innervation from a motor neuron in order to be functional, but each fiber is not innervated by its own single neuron. Instead, a typical motor axon branches as it courses through the muscle, with each of its terminal branches innervating a single muscle fiber. In this manner, one neuron can innervate many muscle fibers. In some cases, a neuron may innervate just a few fibers, whereas in other cases, a single neuron, through its branching, can innervate tens of thousands of muscle fibers. A group of muscle fibers innervated by branches of the same motor neuron is called a **motor unit** (Fig. 8.8). Any large muscle group (e.g., the biceps, quadriceps, and gastrocnemius) contains many motor units. This arrangement allows for activation of only a portion of the muscle at any one time and represents a *spatial* control of muscle contraction. The pattern of activation is determined by the CNS and distribution of the motor axons among the muscle fibers.

Figure 8.8 Motor unit summation. Two motor units, *A* and *B*, are shown above with their motor nerve action potentials and muscle twitches below. The summed force represents the total force generated in the whole muscle due to activation of both motor units. In the first example, fibers from motor units *A* and *B* are activated in close succession. Total force is the simple spatial summation of twitches from the two motor units; in the second, a brief tetanus in motor unit *A* (temporal summation) is spatially added to a twitch from motor unit *B* to create an even larger generation of force by the whole muscle.

A motor unit functions as a single mechanical entity; all the fibers in the unit will contract together when an action potential travels from the CNS through the motor neuron to the muscle fibers contained within the unit. Independent contraction of only some of the fibers in a motor unit is impossible. Therefore, the motor unit is normally the smallest functional unit of a muscle. In muscles adapted for fine and precise control, only a few muscle fibers are associated with a given motor axon. In muscles in which high force is more important, a single motor axon controls many thousands of muscle fibers.

The number of motor units active at any one time determines the total force produced by a muscle; as more motor units are brought into play, the force increases. This is called **motor unit summation** or **spatial summation** and is illustrated in the lower tracing of Figure 8.8. This type of modulation of muscle function endows a large muscle group with the ability to deal with light loads with an economy of function. When light loads need to be moved or supported with the muscles of an arm, for example, the CNS activates only enough motor units to accomplish the task of moving such a load rather than modulating the contractile force of all the muscle fibers in all the muscle groups in the arm. This becomes particularly valuable for conservation of energy when a limb needs to support a weight that is far less than the maximum weight that could be supported by all the muscle groups in the limb. If the CNS were to simply stimulate all the muscle fibers in the arm (and, thus, all the motor units) to just hold pieces of paper, it would be expending far more energy than necessary to accomplish the task. Furthermore, there is no value in the CNS simply reducing the frequency of motor neuron action potential generation to all the arm muscles in order to reduce the total force generated by those muscles. Such a temporal reduction will only reduce the peak force generated by the muscle while producing oscillations in muscle contraction and relaxation. Instead of using either of these modes of muscle activation, the CNS causes fused contractions in reduced numbers of muscle fibers to produce a submaximal sustained contraction. It should be noted that holding objects against gravity is not quite this simple. A balance of activation of opposing muscle groups in a limb is primarily used to hold limbs steady against any opposing force, as sustained tetany is not tolerated well by muscle. During a sustained contraction involved with more complex movements, the CNS continually changes the pattern of activity, and the burden of contraction is shared among the motor units. This results in smooth contractions, with the force precisely controlled to either stabilize parts of the body or produce desired movements.

The mechanical environment of skeletal muscle modifies its contractile activity.

Mechanical factors external to the muscle influence the force, speed, and extent of shortening of contraction. These factors include the position to which a muscle is stretched prior to contracting and the load the muscle tries to move once contraction has begun. These relationships have been revealed by experiments in which mechanical conditions can be controlled to aid in the analysis of muscle contraction. Generally, these experimental arrangements represent “artificial” conditions that are better controlled and less complex than those encountered in real daily activities. Nevertheless, these types of analyses demonstrate how certain mechanical variables alter the contractile performance of muscle. Such relationships are not only applicable to understanding skeletal muscle as a mechanical engine but also represent critical components that control the mechanical performance of the heart as well. An understanding of such mechanical relationships is critical to understanding the function of the heart in health and disease in the clinical setting (see Chapter 13).

Isometric muscle contraction occurs when muscle contracts against a load that is too heavy to move.

If a muscle is attached on its ends to a permanent fixture so that it cannot move when activated, the muscle will express its contractile activity by developing force without shortening. This simplest type of contraction is termed an **isometric contraction** (meaning “same length”) and is demonstrated when we try to push or pull an immovable object or an object whose mass is beyond our ability to move. In such situations, we feel our muscles contract, tense, and “harden,” although our muscles do not actually shorten and no object is moved.

A representation of an isometric muscle contraction is shown in Figure 8.9 in which a dissected muscle group was fixed at a given length to a recording apparatus such that it could not shorten when stimulated. In this example, the muscle is stimulated only once but with sufficient strength to activate all its motor units. This produces a single twitch in which isometric force develops relatively rapidly followed by a subsequent slower isometric relaxation. The durations of both contraction time and relaxation time are related to the rate at which calcium ions can be delivered to and removed from the region of the crossbridges, the actual sites of force development. During an isometric contraction, the muscle consumes energy to fuel the processes that generate and maintain force, though no actual physical work is done on the external environment because no movement takes place.

Figure 8.9 An isometric twitch contraction in skeletal muscle. In an experimental setting, the length of a muscle segment (preload) is fixed by attaching it to an immovable support and is thus held constant when the muscle is stimulated to contract. Upon delivery of a single maximum stimulus to the muscle, the muscle develops force over time and then relaxes. The muscle develops force but does not shorten. Therefore, the contraction is, by definition, isometric. (Force, length, and time units in the figure are arbitrary.)

Isotonic contractions in muscle result in movement of a load because the muscle generates a force greater than the load.

When conditions are arranged so that a muscle can generate a force larger than the load (weight) to which it is attached, the muscle will have the ability to shorten and thus move the mass. To accomplish load movement, the muscle first develops force enough to equal the weight of that mass to which it is attempting to move then begins to move the mass with whatever force-generating capability remains for that muscle contraction. This type of contraction is called **isotonic contraction** (meaning "same force"). In the simplest conditions, this constant force is the load a muscle moves. This load is also called an **afterload**, because its magnitude and presence are not apparent to the muscle until *after* it has begun to shorten.

An example of an isotonic contraction is shown in Figure 8.10, which shows the result of an experiment where a dissected muscle group is attached to a recording device on one end whereas a weight attached at the opposite end is less than the peak force capability of the muscle. When the muscle is stimulated, it will begin to develop force without shortening because it takes some time to build force and, initially, this force is less than that needed to lift the weight. This phase of the contraction is thus isometric (see Fig. 8.10, phase 1). After sufficient force has been generated, the muscle will begin to shorten and lift the load (see Fig. 8.10, phase 2). The contraction is now isotonic because the force exerted by the muscle is sufficient to match the weight the muscle is contracting against (Fig. 8.10, flat portion of the solid red line in the upper tracing). Beyond this point, developed force in the muscle needed to hold the weight is translated into muscle shortening (Fig. 8.10, solid line, lower tracing). As relaxation begins (phase 3, Fig. 8.10), the muscle lengthens at constant force because it is still supporting the load. This phase of relaxation is isotonic, and the muscle is re-extended by the weight. When the muscle has been extended sufficiently to return to its original length, conditions again become isometric (phase 4, Fig. 8.10), and the remaining force in the muscle declines as it would in a purely isometric twitch. In almost all situations encountered in daily life, isotonic contraction is preceded by isometric force development; such contractions are called **mixed contractions** (isometric–isotonic–isometric).

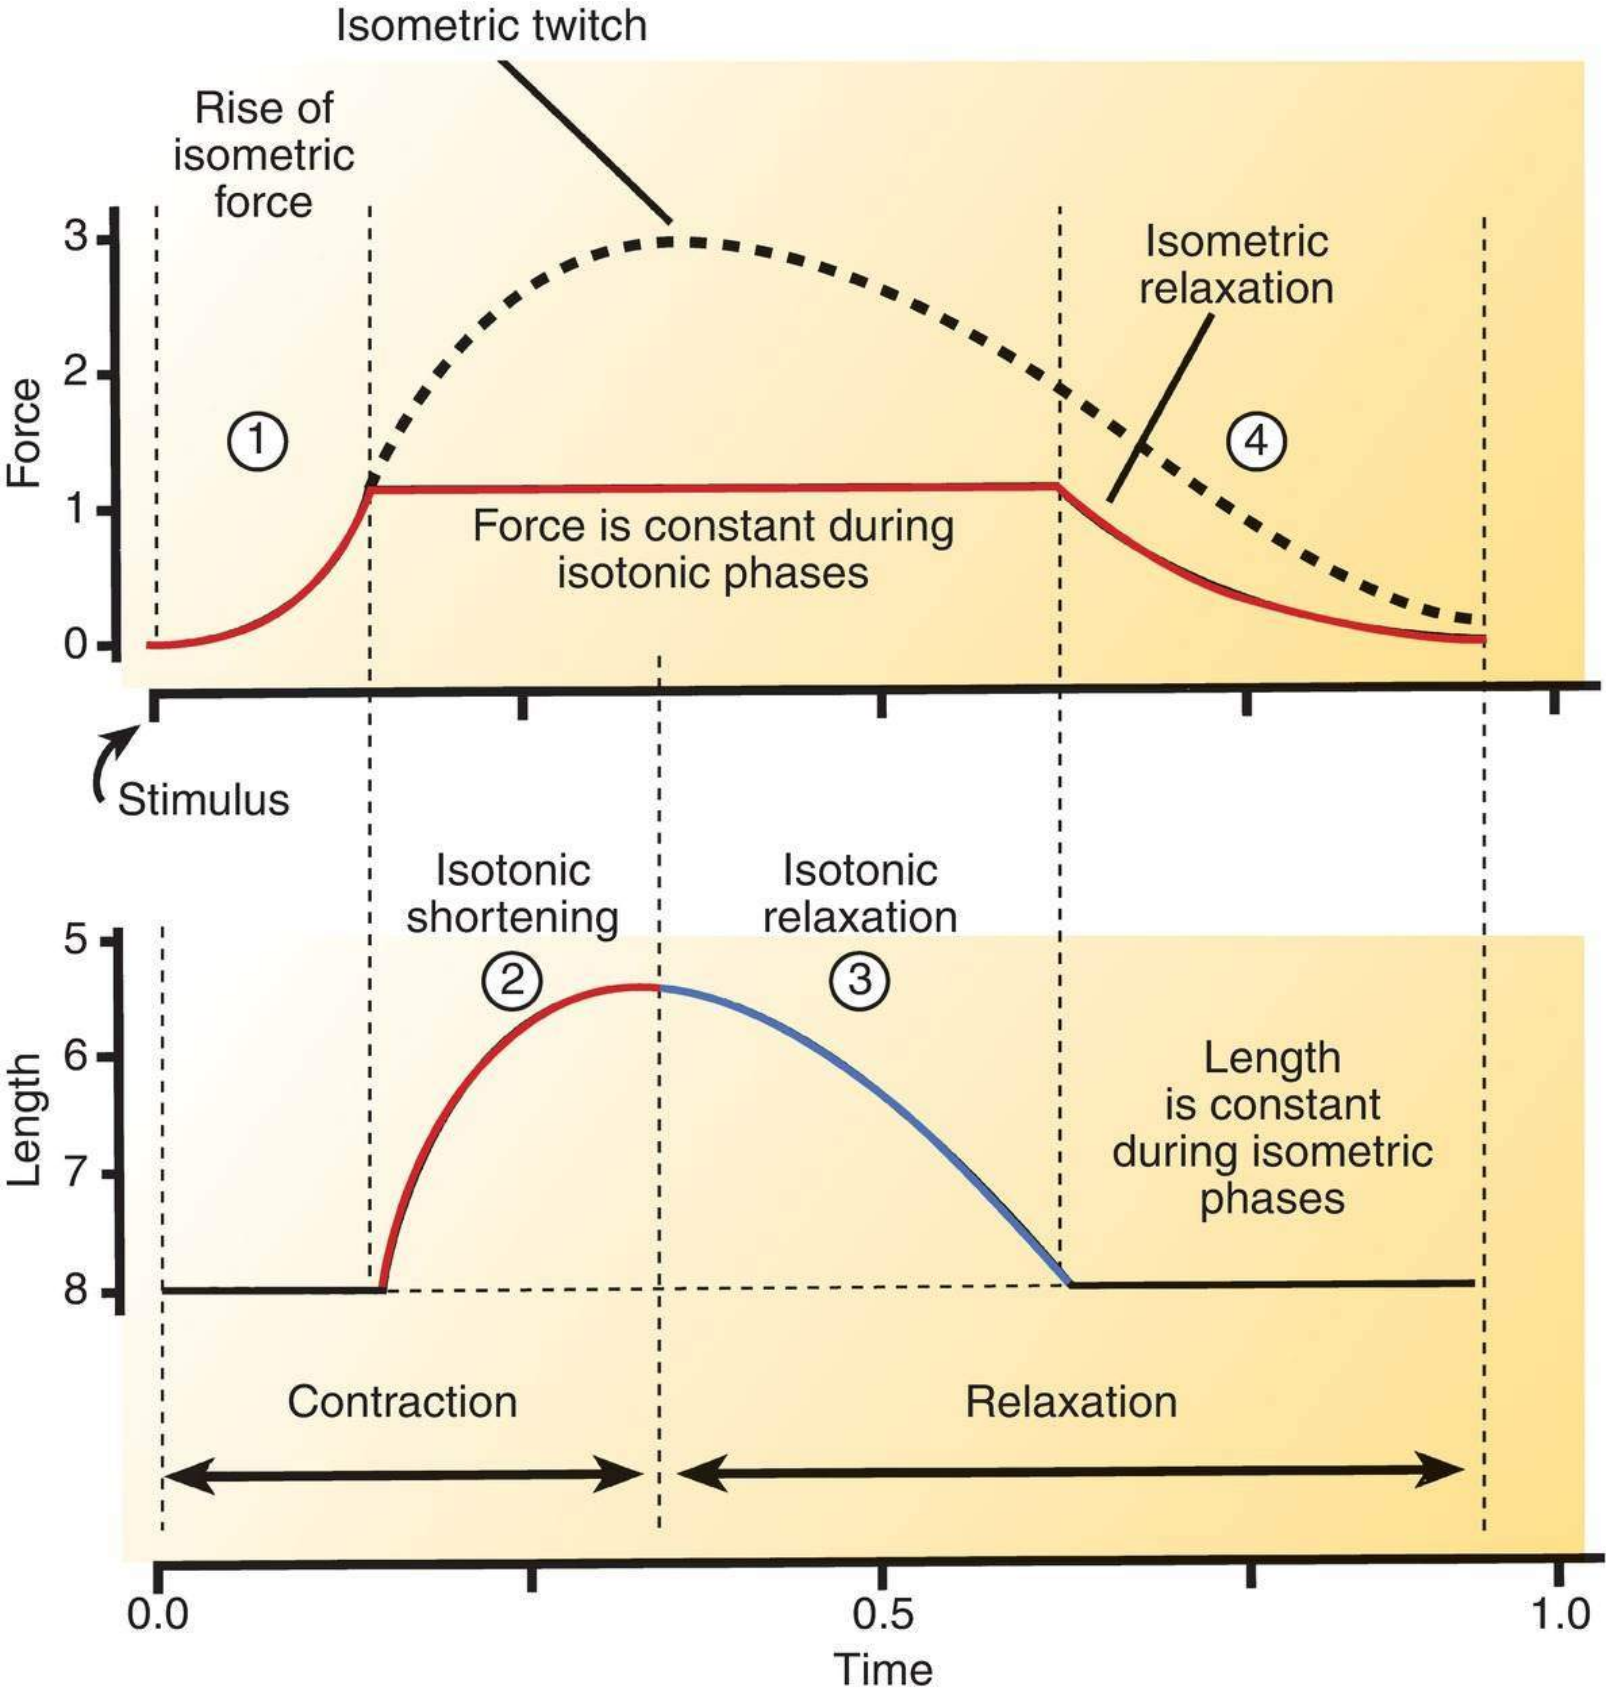

Figure 8.10 A single isotonic contraction of skeletal muscle. In an experimental setting, a segment of skeletal muscle is stretched to a given length and attached to a supported weight that can be moved. When this muscle segment is stimulated, the first part of the contraction will be isometric until sufficient force has developed to lift the weight. Once enough force has developed to support the weight, the contracting muscle can then move the weight by shortening. During shortening and isotonic relaxation, the force is constant (isotonic conditions), and during the final relaxation, conditions are again isometric because the muscle no longer lifts the weight. The *dotted line* in the force trace show the isometric twitch that would have resulted if the force had been too large (greater than three units) for the muscle to lift.

The extent and velocity of shortening of a mixed contraction depend on the afterload the muscle moves. Figure 8.11 presents a series of three muscle contractions. In the figure, contraction A has the lowest afterload, the afterload in contraction B is twice that of A, and the afterload for contraction C is too heavy for the muscle to move at all. Note from this figure that the isotonic contraction with a heavy afterload cannot move that load as fast or as far as it can a lighter afterload. This unique relationship between afterload and the extent and velocity of shortening of isotonic contraction are described in detail below.

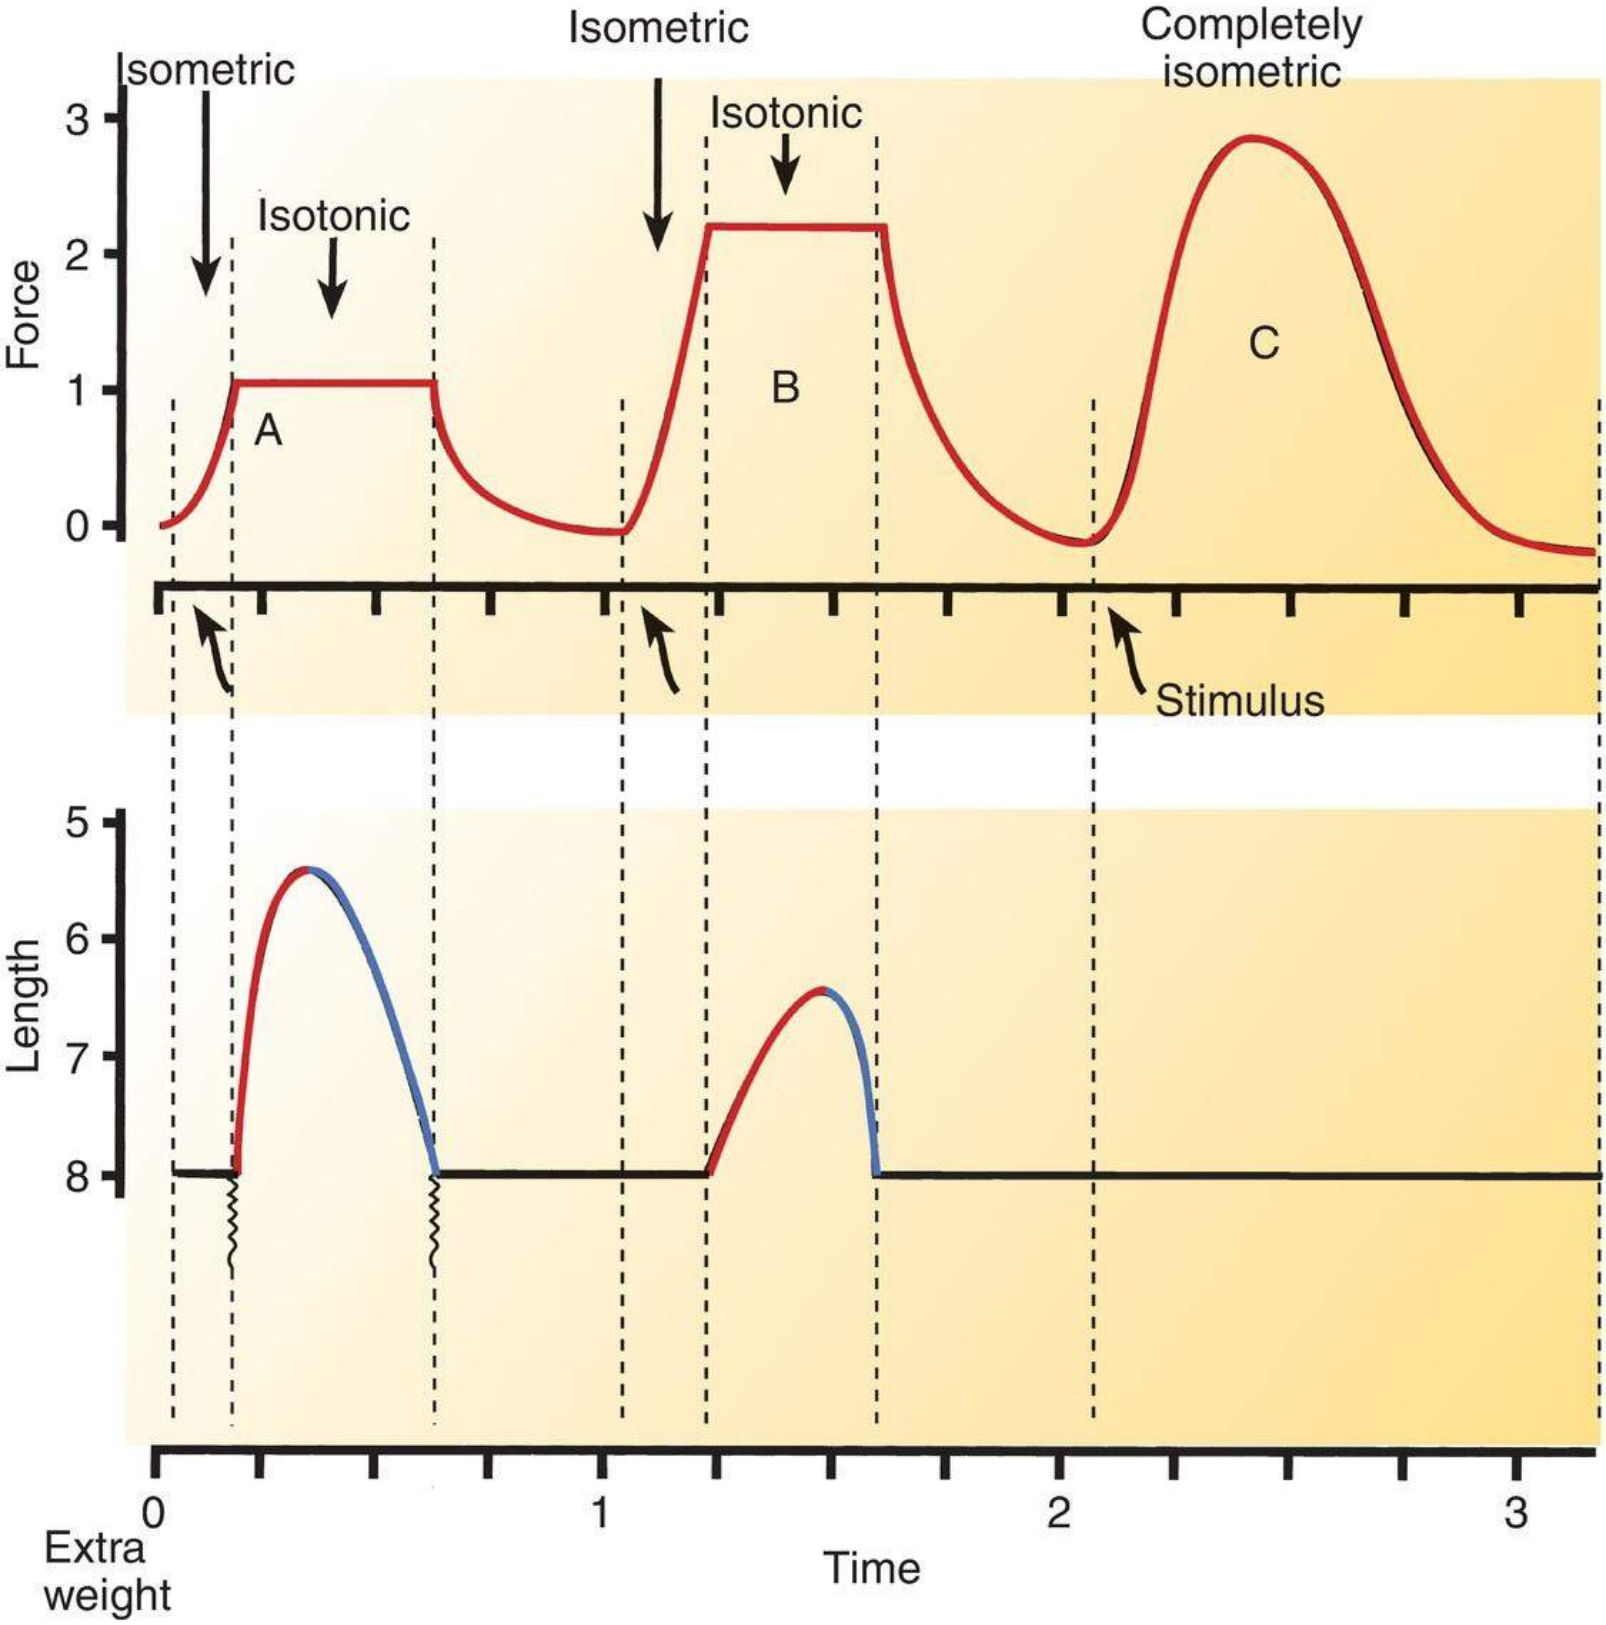

Figure 8.11 A series of afterloaded isotonic contractions. The curves are labeled *A* and *B* and correspond to the force and shortening records during the lifting of successively heavier weights (afterloads) by an isolated segment of skeletal muscle. All contractions started from the same muscle length, or preload. Note the lower force and greater shortening with the lower weight (*A*) than that seen when the muscle lifted the heavier weight (*B*). Because weight *C* is heavier than the force-generating capacity of the muscle segment that contraction remains isometric.

The mechanics of muscle contraction are altered by its initial passive stretch and its afterload.

Two important relationships describe the mechanics of muscle contraction:

- The length–tension relationship—This represents the effect of changing the length to which resting muscle is stretched prior to contraction on the force generated by an *isometric* contraction. This passive precontraction or **resting length** is often called the **preload**.
- The force–velocity relationship—This represents the effect of *afterload* on the initial velocity of shortening of an isotonic contraction of muscle. Importantly, the curve defining this relationship is itself variable in that its position is altered by muscle preload.

The isometric length–tension relationship

Resting, noncontracting, skeletal muscle has nonlinear elastic properties when stretched to different lengths. When it is short, it is slack and will not resist passive extension. As it is made longer and longer, however, its resisting force increases more and more (Fig. 8.12, lower black line). This is analogous to the increasing stiffness, or resistance to stretch, felt when a rubber band is stretched to longer and longer lengths. This resisting force is called **passive force**, passive length, or **resting force** and is related to the preload on the muscle.

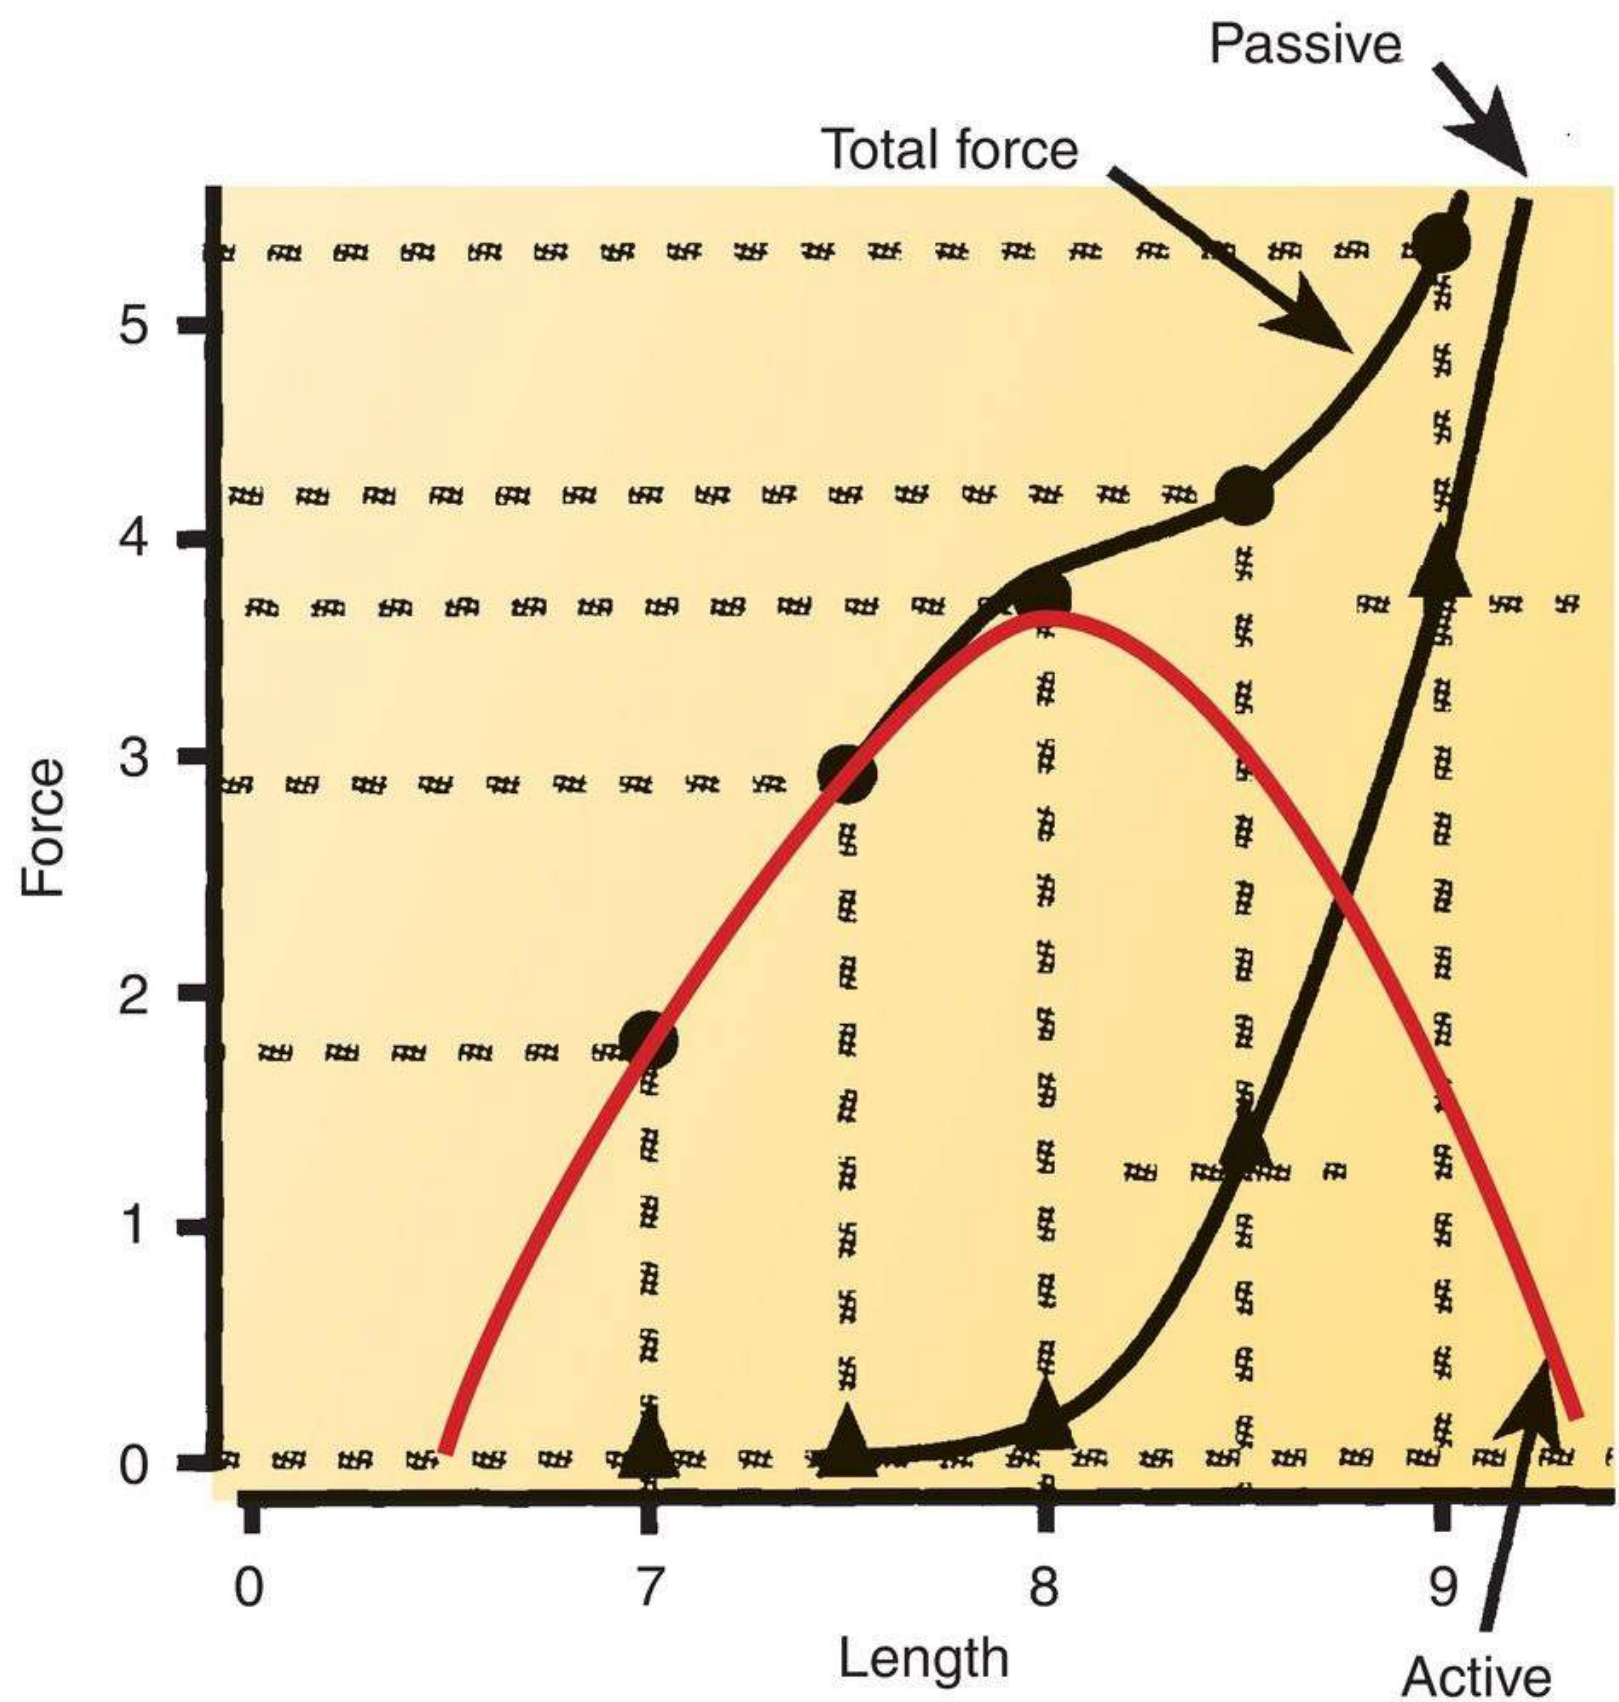

Figure 8.12 A length–tension curve for skeletal muscle. Contractions are made at several resting lengths, and the resting (passive) and peak (total) forces for each twitch are plotted on a graph depicting force versus the length to which muscle was stretched prior to stimulation of contraction (preload). Total force in activated muscle is a sum of passive stretch (resistive) force plus the active force generated by activation of muscle crossbridges. Subtraction of the passive curve from the total force curve yields the active force curve (*red*). Note that the parabolic relationship between isometric force generation and initial stretch indicates that there is an optimum length (L_O) to which muscle can be stretched prior to contraction that will yield maximum isometric force generation in activated muscle. (Force and length are

listed in arbitrary units.)

In an *isometric* muscle contraction, the relationship between *active* force and passive length is much different. Figure 8.12 also shows a graph of the force produced by a series of isometric twitches made over a range of initial passive muscle lengths (upper black line). The resulting tension (passive tension plus active isometric force) at each muscle length is plotted with the total peak force from each twitch related to its initial passive length (top black line in the figure). The difference between the total force and the passive force at any length is the active force (red line in the figure). *Note that the active length–tension curve is parabolic*. Consequently, isometric force has a maximum in relation to its preload, or initial resting length. The length corresponding to this maximum isometric force is called the optimum length (L_O). If the muscle is set to a shorter or longer length than L_O and then stimulated, it produces less force. At extremely short or long lengths, it produces no force at all.

The parabolic length–tension relationship for isometric contraction in the whole muscle results from changes in actin and myosin overlap within the sarcomere as the muscle is stretched prior to contraction. The effect of actual sarcomere length on force generation is summarized in Figure 8.13. At lengths near L_O, where the isometric force that the muscle can generate is maximum, the number of actin-binding sites opposite the number of myosin heads available for contraction are also at a maximum. (Note in Fig. 8.13 that "maximum" isometric force is not a true "peak"; force does not vary with the degree of overlap between 1.95 and 2.25 µm. This occurs because further overlap of the bare zone along the thick filaments at the center of the A band, where no myosin heads are present, does not lead to an increase in the number of attached crossbridges.)

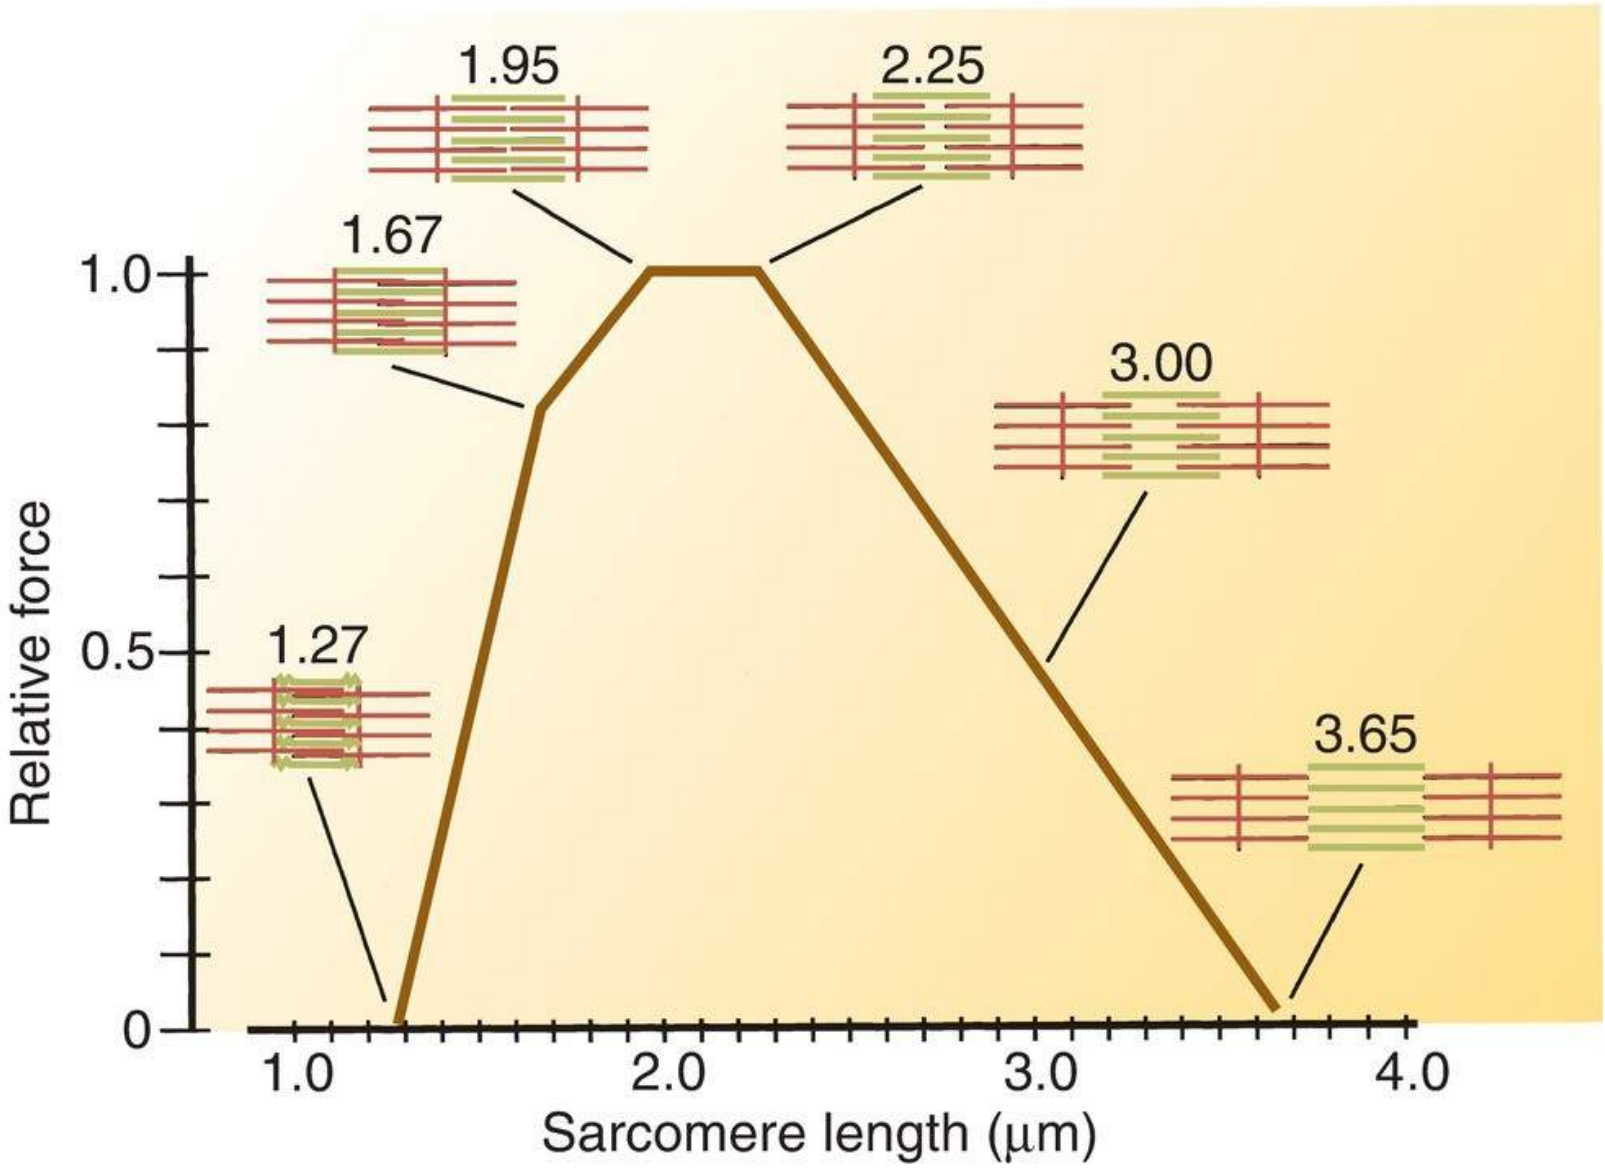

Figure 8.13 Effect of filament overlap on force generation. The force a muscle can produce depends on the amount of overlap between the thick and thin filaments, because this determines how many crossbridges can interact effectively. (See text for details.)

When the muscle is stretched beyond its normal resting length, decreased filament overlap occurs with increasing stretch. This reduces the amount of force that can be produced because less length of the thin filaments interdigitates with A-band thick filaments and fewer crossbridges are available for any subsequent contraction. At passive resting lengths shorter than L_O, additional geometric and physical factors play a role in myofilament interactions. Because muscle is a "telescoping" system, there is a physical limit to the degree to which resting muscle length can decrease. As thin myofilaments penetrate the A band from opposite sides, they begin to meet in the middle and interfere with each other (1.67 μm). At the extreme, further reduction in resting lengths are limited by the thick filaments of the A band being forced against the structure of the Z lines (1.27 μm). Note, however, if one were to start at this extreme short length and then stretch the muscle to various passive lengths up to and including L_O, any resulting isometric contraction would increase as the passive initial length of the muscle increases. This region of the isometric length–tension curve is sometimes called the *ascending limb* of the length–tension curve. In this region, isometric force is positively proportional to initial resting length (preload).

It should be noted that, in the body, many skeletal muscles are confined by their attachments to a

relatively short region of the isometric length–tension curve near L_O. Although this positions preload on the muscle to an area that can produce the best possible force generation in the muscle, it also means that skeletal muscle is essentially incapable of adjusting its force-generating capacity by repositioning itself at different locations on the length–tension curve prior to initiating contractions. However, the isometric length–tension relationships points to a potentially exploitable property of the sliding filament property of any muscle type. Modulation of active contraction is possible in muscle, hollow, organs like the heart (cardiac muscle) and blood vessels, bronchi, the alimentary tract, and reproductive organs (smooth muscle).

The isotonic force–velocity relationship

When all the motor units in the muscle are stimulated (i.e., no motor units left to recruit), a muscle's performance can still be affected by loading conditions. The extent and velocity of shortening of skeletal muscle during an isotonic contraction are negatively related to afterload but positively related to preload. Everyday experience shows that light loads can be lifted faster than heavy ones. A detailed analysis of this observation can be performed experimentally by arranging a muscle so that it can be presented with a series of afterloads (Fig. 8.14; also see Fig. 8.11). Measuring the **initial velocity**—the velocity during the earliest part of the shortening—at various afterloads shows that lighter loads are lifted more quickly and heavier loads more slowly. (Initial velocity is measured because the muscle soon begins to slow down upon moving the load.) When all the initial velocity measurements are related to each corresponding afterload lifted, an inverse relationship known as the *force–velocity curve* is obtained (see Fig. 8.14). This relationship shows that as the afterload is decreased, the velocity of shortening increases in a hyperbolic manner; that is, velocity increases more and more as the load is reduced. It also shows that if the applied load is greater than the maximal force capability of the muscle, no shortening will result, and the contraction will be isometric. This point is known as F_{max}.

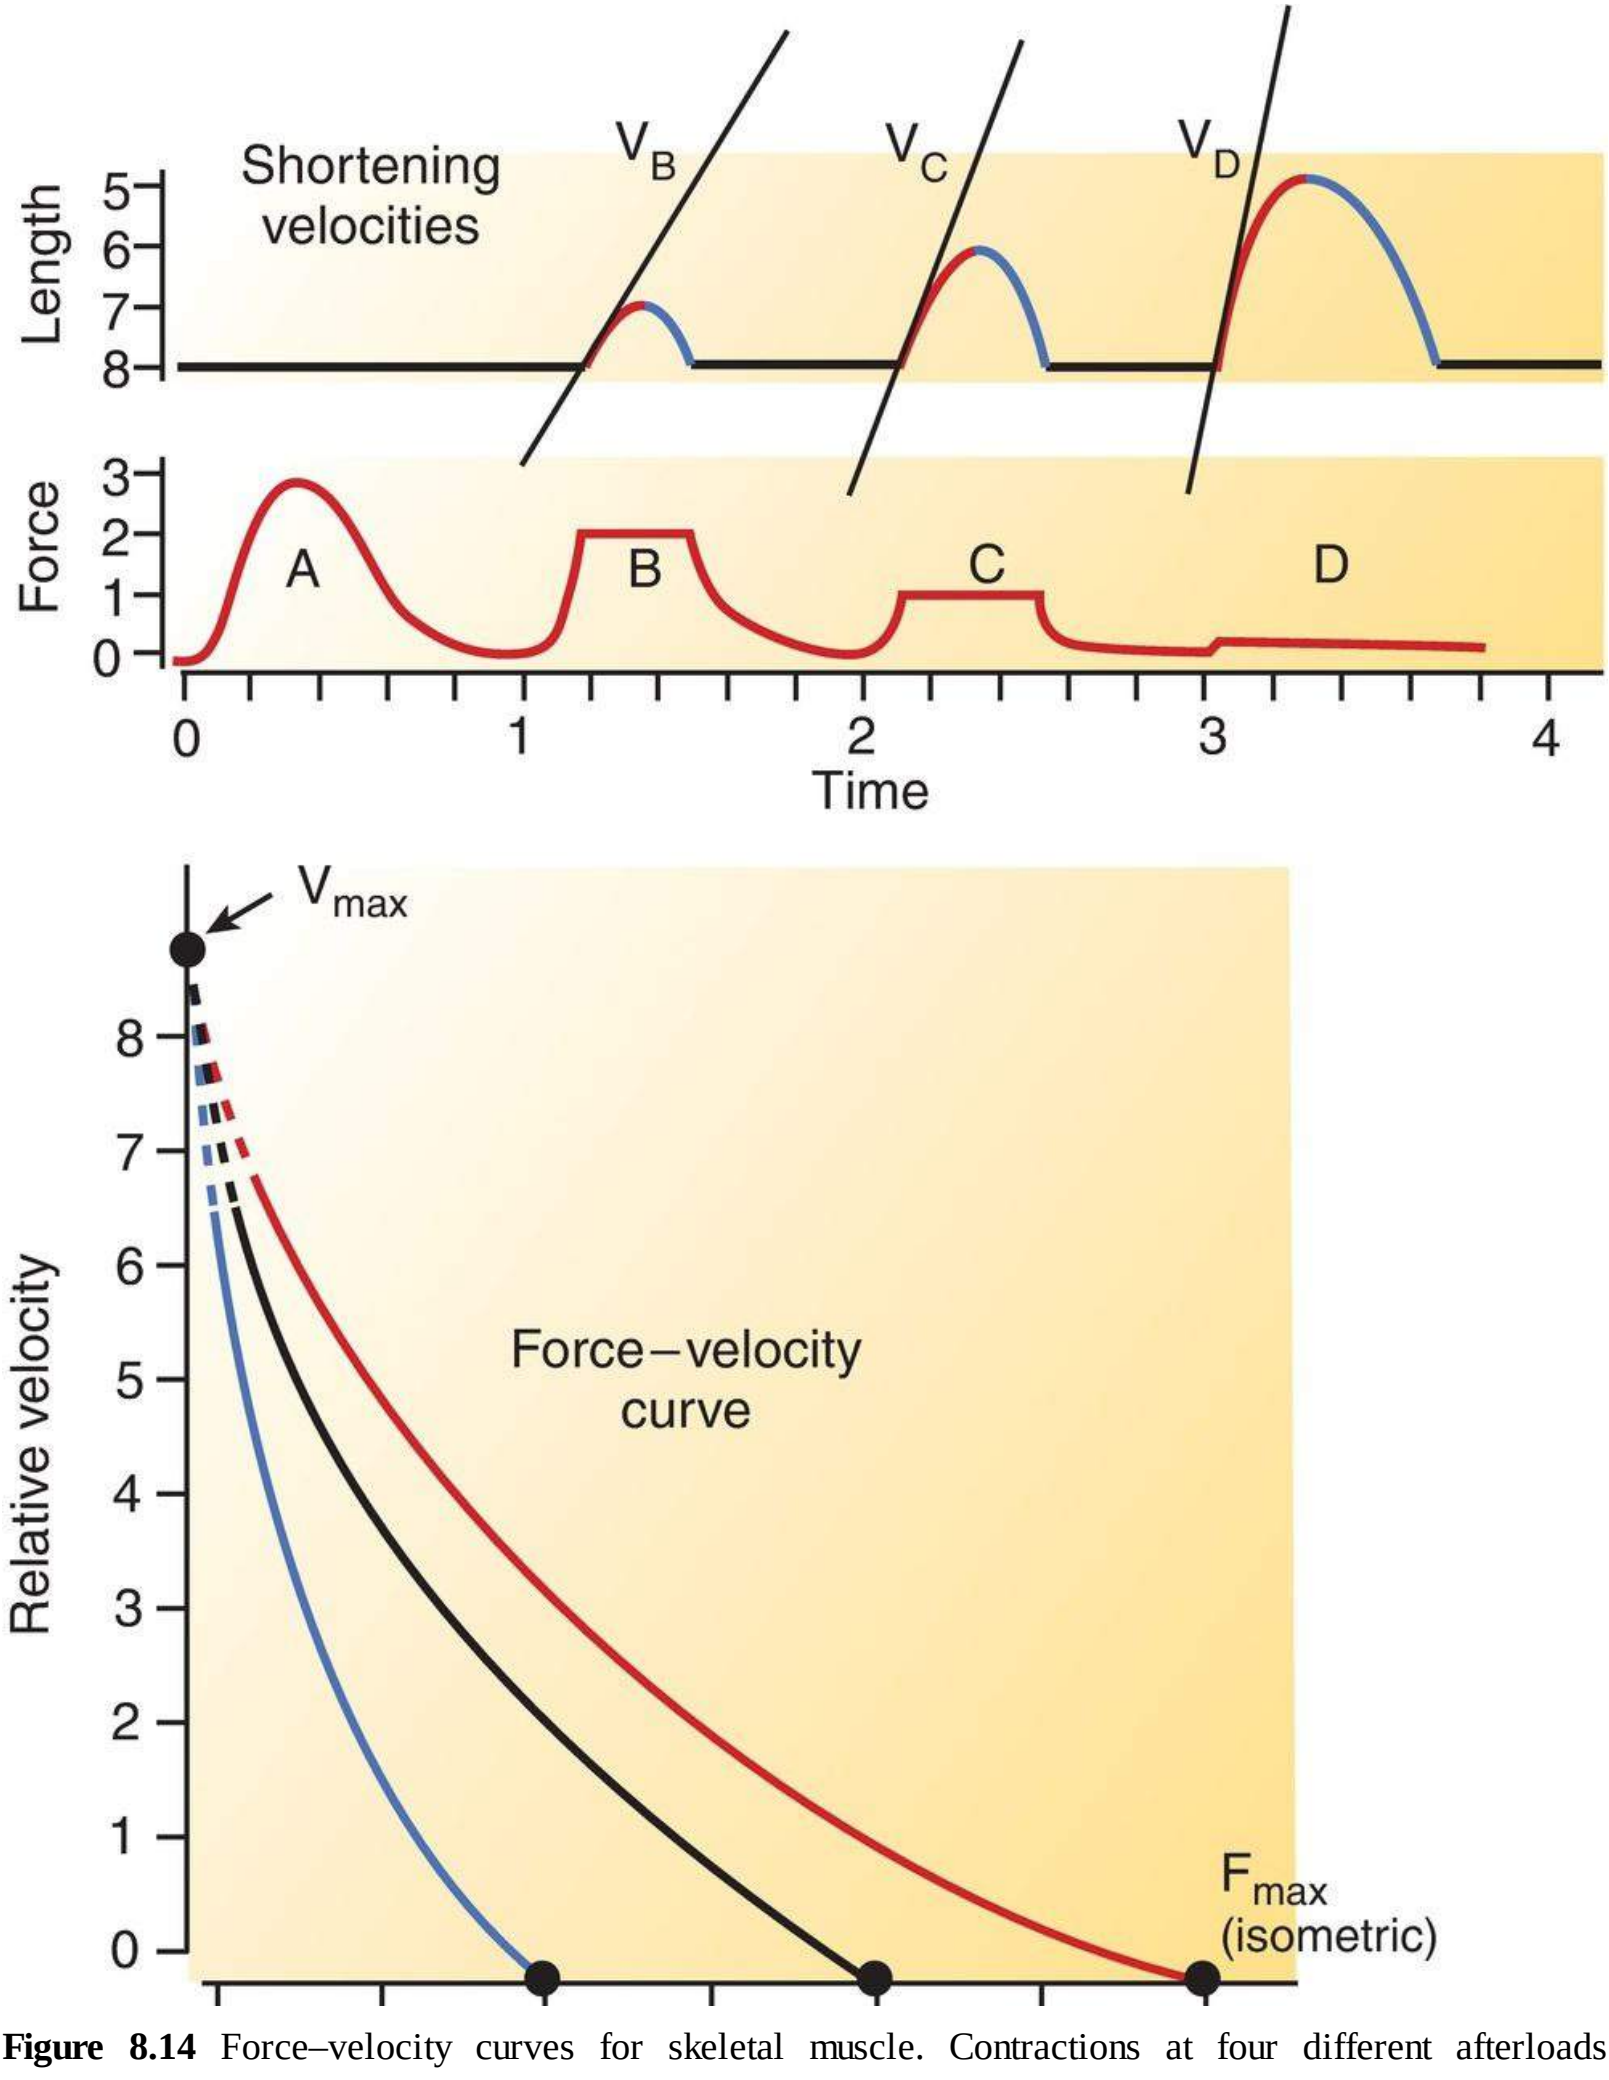

Figure 8.14 Force–velocity curves for skeletal muscle. Contractions at four different afterloads

(decreasing left to right) are shown in the **top figure**. The initial shortening velocity (slope) is measured (V_B, V_C, V_D) and the corresponding force and velocity points plotted on the axes in the **bottom** graph (*black line*). Note that the initial velocity of shortening increases when afterload is decreased. The *black line* represents the force–velocity curve of a muscle starting at a less than maximum preload. The *red line* represents the relationship with the muscle starting at its optimum preload, and the *blue line* shows the relationship at the lowest preload in this example. Notice how preload affects the velocity of shortening of any isotonic contraction and F_{max}, but neither it nor afterload affects V_{max} (maximal velocity of shortening).

Note from the force–velocity relationship that there is a theoretical velocity that the muscle could obtain if it does not have to move any afterload. This represents the *maximum velocity* of shortening capability of that muscle and is, therefore, known as V_{max}. In practice, a completely unloaded contraction is very difficult to arrange. Instead, V_{max} is obtained by mathematical extrapolation of the force–velocity curve. The value of V_{max} represents the maximal rate of crossbridge cycling for that muscle; it is directly related to the biochemistry of the actin–myosin ATPase activity in a particular muscle type and can be used to compare the properties of different muscles. Figure 8.14 shows force–velocity curves for a fully activated muscle. When measurements are made on a fully activated muscle, a force–velocity curve defines the upper limits of the muscle's isotonic capability. Factors that modify muscle performance, such as fatigue or incomplete stimulation (e.g., fewer motor units activated), result in operation *below* the limits defined by this force–velocity curve.

Importantly, the force–velocity relationship is also affected by the preload on the muscle prior to contraction (see red and blue relationships in Fig. 8.14). The curve is shifted to the right with increasing preload and to the left with decreased preload, providing the muscle is not operating at lengths longer than L_O. As revealed by crossbridge overlap on the ascending limb of the length–tension relationship, the effect of preload on the force–velocity relationship must reflect the number of crossbridges available for an isotonic contraction as well. Examination of Figure 8.14 reveals that with increasing preload, a given afterload can be moved faster than those starting at a lesser preload. The figure also shows that at any given velocity, a larger afterload can be moved if started at a higher preload (providing it does not exceed L_O) than that which can be moved with a lesser preload. In short, muscle performance is enhanced by bringing more crossbridges into play at the start of a contraction. Although this feature of muscle behavior does not have direct physiologic application to skeletal muscle *in situ*, which has a fixed initial length through attachment to the skeleton, this relationship becomes important in muscles in hollow organs were preload may be altered prior to a contraction (e.g., the heart and blood vessels).

Figure 8.14 also reveals an important feature of the physiology of skeletal muscle with regard to crossbridge cycling. Note that although preload alters the force–velocity position for isotonic contractions, the V_{max} is not altered by preload or any afterloads moved; force–velocity relationships starting at low preloads end up at the same V_{max} as those starting with many more crossbridges available. Consequently, V_{max} is said to be totally load independent in skeletal muscle. This is because V_{max} reflects the intrinsic biochemical interaction of actin and myosin during crossbridge cycling, and this interaction for skeletal muscle actin and myosin cannot be altered by any normal physiologic mechanism in the body; modification of muscle performance at this cellular level is not possible in skeletal muscle. However, as discussed later in this chapter and in Chapter 13, such cell-based performance modification is available physiologically in cardiac and smooth muscle.

Loading conditions affect the extent of skeletal muscle shortening.

The length–tension curve represents the effect of initial resting length, or preload, on the isometric contraction of skeletal muscle. At initial lengths less than and up to L_O, such a curve represents the maximum force that can be generated at any given preload. No shortening occurs in these situations, and the curve depicts muscle contraction as if all its energy was channeled into the development of force only. Points A, B, C, and D in Figure 8.15, for example, are the maximum force generation capability of a muscle at initial lengths (arbitrary units) of 8, 6.6, 5.6, and 5, respectively, with point A in this diagram being representative of the isometric force-generating capacity of the muscle at L_O.

Figure 8.15 The relationship between isotonic and isometric contractions. The **top** graphs show the contractions from Figure 8.14, with different amounts of shortening. The **bottom** graph shows that, for contractions *B*, *C*, and *D*, the initial portion is isometric (the line moves upward at constant length) until the afterload force is reached. The muscle then shortens at the afterload force (the line moves to the left) until its length reaches a limit determined (at least approximately) by the isometric length–tension curve. The *dotted lines* show that the same final force/length point can be reached by several different approaches. Relaxation data, not shown on the graph, would trace out the same pathways in reverse.

Although the length–tension curve depicts isometric contraction of muscle, it also represents the limit of shortening of any isotonic contraction of that muscle. Isotonic contractions involve an initial isometric phase during which force is generated up to the point it equals the load the muscle is trying to move (i.e., the afterload). Once that point is reached, the muscle then shortens while moving that load (the isotonic phase). Such contractions are depicted in Figure 8.15 by the solid red arrows that end at B, C, and D in the diagram. Note that during an isotonic contraction, the muscle will eventually reach a length where the maximum isometric force capable by the muscle matches the afterload the muscle is trying to move (see *dashed lines* in Fig. 8.15 that converge on point C). At this point, the muscle cannot shorten anymore; to do so would place the muscle at a length where its maximum isometric force-generating capability was less than the load it was trying to move—an impossibility. In other words, isotonic contractions of a muscle moving any afterload cannot move past a limit defined by the isometric length–tension curve for that muscle.

As Figure 8.15 shows, a lightly afterloaded muscle will shorten farther than one starting from the same initial length, or preload, but bearing a heavier load. Also note that if the muscle begins its shortening from a reduced initial length, its subsequent extent, or amount, of shortening will be reduced because the muscle starts closer to the limit imposed by the isometric–length tension curve. The following constraints apply to the extent of shortening of an isotonic contraction of skeletal muscle: (1) increasing preload up to L_o increases the extent of shortening (the distance the afterload is moved); (2) at any given preload, increasing the afterload decreases the extent of shortening; (3) at any given preload, the final length of the muscle at the end of an isometric contraction is proportional to the afterload; and (4) the isometric length–tension curve sets the limit to the extent of shortening of any isotonic contraction of skeletal muscle.

The example above demonstrates that the distance a muscle can move an object is progressively reduced as the muscle tries to move increasingly heavy loads. One might postulate that skeletal muscle could move a heavy load as far as it could a light load if there was some way to change (enhance) the intrinsic contractile ability of the muscle cell itself. Such intrinsic enhancement would reveal itself as a shift of the ascending limb of the length–tension curve upward and to the left relative to its original position. Such a shift would move the limit to extent of shortening to the left, thereby letting the muscle move the heavy load as far as it could move the light load in its original state. Unfortunately, such intrinsic or cellular/molecular enhancement of the contractile mechanism is not possible under any normal physiologic conditions for skeletal muscle fibers. In essence, skeletal muscle shortening is constrained by its loading conditions; it *cannot* modify its cellular contractile capabilities independently of preload and afterload. Such is not the case with cardiac muscle, however, which can shift its length–tension relationship (see Chapter 13).

Skeletal attachments create lever systems that modify muscle action.

Anatomic location also places restrictions on muscle function by limiting the amount of shortening or determining the kinds of loads encountered. Skeletal muscle is generally attached to bone, and bones are attached to each other. The bones and muscles together constitute a **lever system** (Fig. 8.16). In most cases, the system works at a mechanical disadvantage with respect to the force exerted. For example, curling the forearm requires muscles that are attached near the fulcrum of the arm "lever" rather than at the more mechanically advantageous position near the hand. This means that in order to pull the forearm toward the upper arm while holding a weight in the hand, the muscle must exert a much greater force than the actual weight of the load being lifted (the muscle force is increased by the same ratio that the length change at the end of the extremity is increased). In the case of the human forearm, the biceps brachii, when moving a force applied to the hand, must exert a force at its insertion on the radius that is approximately seven times as great. However, the shortening capability of skeletal muscle by itself is rather limited. The benefit of the skeletal lever system is that it multiplies the distance over which an extremity can be moved. Consequently, it is possible to create large distances moved by the end of the limb with only small actual shortening of the muscle responsible for moving the limb. In this forearm example, the resulting movement of the hand is approximately seven times as far and seven times as rapid as the shortening of the muscle itself.

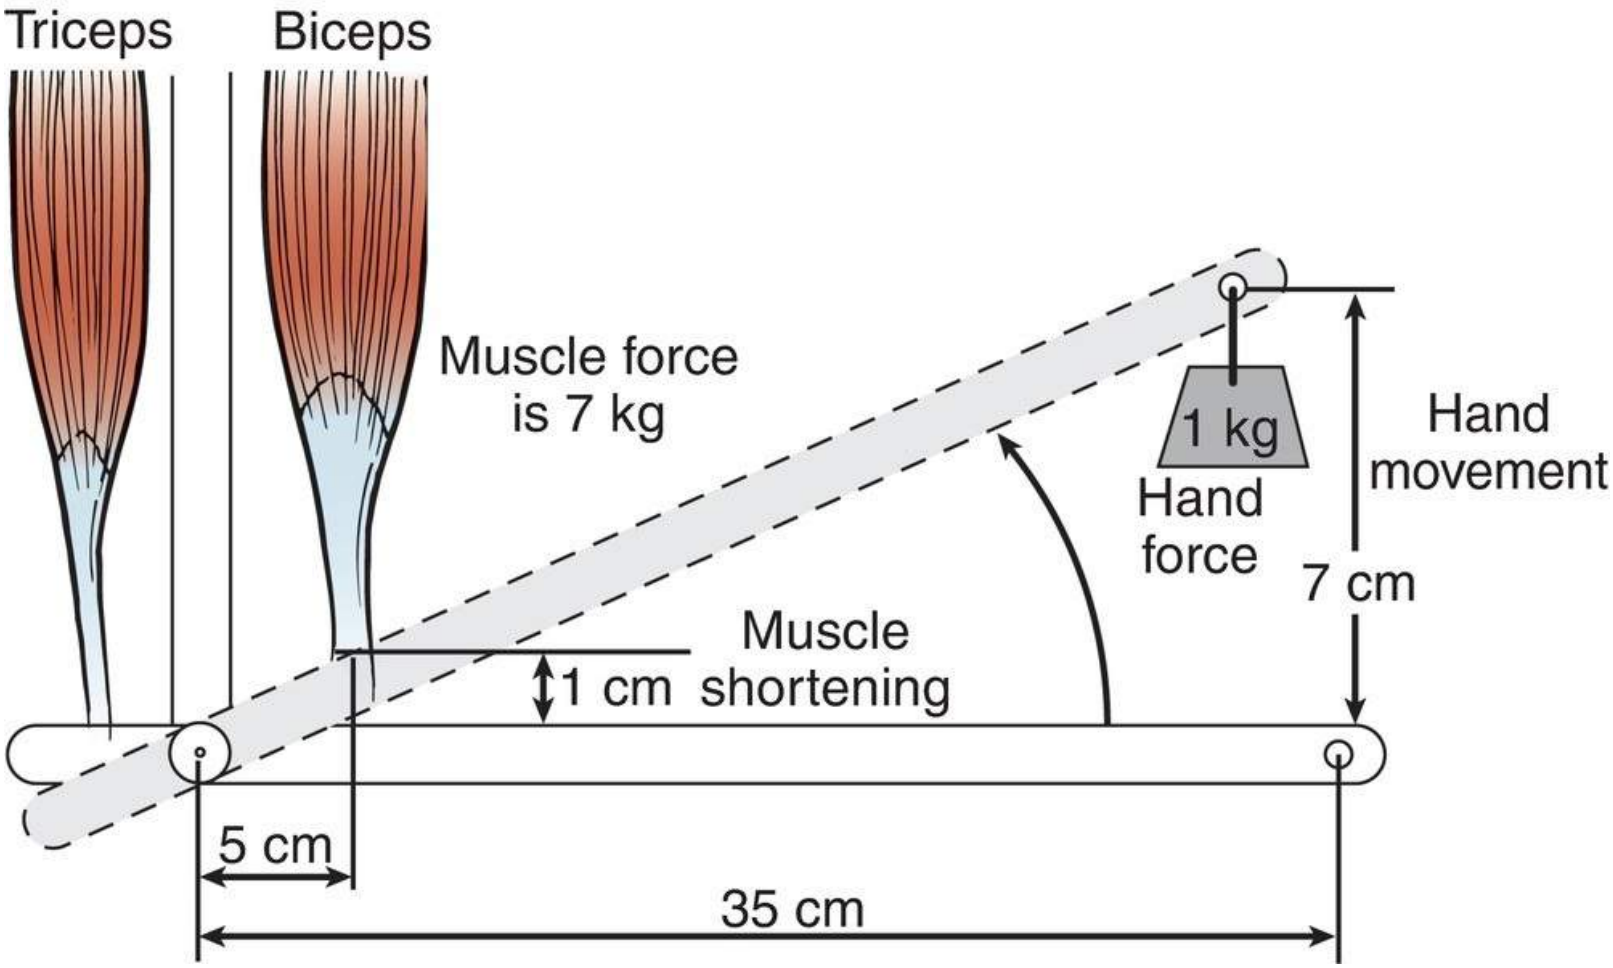

Figure 8.16 Antagonistic pairs and the lever system of skeletal muscle. Contraction of the biceps muscle lifts the lower arm (flexion) and elongates the triceps, whereas contraction of the triceps lowers the arm and hand (extension) and elongates the biceps. The bones of the lower arm are pivoted at the elbow joint (the fulcrum of the lever). The force of the biceps is applied through its tendon close to the fulcrum. The

hand is seven times as far away from the elbow joint. Thus, the hand will move seven times as far (and fast) as the biceps shortens (lever ratio, 7:1), but the biceps will have to exert seven times as much force as the hand is supporting.

Finally, acting independently, a muscle can only shorten. Force must be used to relengthen the muscle, and this force must be provided externally. In some cases, gravity provides the external restoring force. However, in the body, muscles are often arranged in **antagonistic pairs** of **flexors** and **extensors**. In this manner, for example, a shortened biceps can be relengthened by the action of the triceps; the triceps, in turn, is relengthened by contraction of the biceps.

SKELETAL MUSCLE METABOLISM AND FIBER TYPES

ATP derived from glucose metabolism is the primary energy-supplying mechanism for skeletal muscle contraction.

Cellular processes within skeletal muscle cells must supply biochemical energy to the contractile mechanism because contracting muscles perform work. Additional energy is required to pump the calcium ions involved in the control of contraction and for other cellular functions as well. In muscle cells, as in other cells, this energy ultimately comes from the universal high-energy compound, ATP, which is predominantly derived from oxidative metabolism. Although ATP is the immediate fuel for the contraction process, its concentration in the muscle cell is never high enough to sustain a long series of contractions. Most of the immediate energy supply is held in an "energy pool" of the compound creatine phosphate or phosphocreatine (PCr), which is in chemical equilibrium with ATP. After a molecule of ATP has been split and yielded its energy, the resulting ADP molecule is readily rephosphorylated to ATP by the high-energy phosphate group from a creatine phosphate molecule. The creatine phosphate pool is restored by ATP from the various cellular metabolic pathways. These reactions (of which the last two are the reverse of each other) can be summarized as follows:

$$ATP \rightarrow ADP + P_i + \text{Energy for contraction and other cell systems}$$

$$ADP + PCr \rightarrow ATP + \text{Creatine (i.e., rephosphorylation of ATP)}$$

$$ATP + Cr \rightarrow ADP + PCr \text{ (restoration of PCr)}$$

Because of the chemical equilibria involved, the concentration of PCr can fall to low levels before the ATP concentration shows a significant decline. It has been shown experimentally that when 90% of PCr has been used, the ATP concentration has fallen by only 10%. This situation results in a steady source of ATP for contraction that is maintained despite variations in energy supply and demand. Creatine phosphate is the most important storage form of high-energy phosphate; together with some other smaller sources, this energy reserve is sometimes called the **creatine phosphate pool**.

Glycolysis, an **anaerobic** pathway, and **oxidative phosphorylation**, an aerobic pathway, are the two major metabolic paths that supply energy to the energy-requiring reactions in the cell and to the mechanisms that replenish the creatine phosphate pool. Glucose for the glycolytic pathway may be derived from circulating blood glucose or from **glycogen**, which is the polymer storage form of glucose in skeletal muscle and liver cells. Glycolysis is rapid but extracts only a small fraction of the energy contained in the glucose molecule (2 ATPs per glucose molecule). The end product of anaerobic glycolysis is **lactic acid** or lactate. Under conditions of sufficient oxygen, this is converted to **pyruvic acid** or pyruvate, which enters the **Krebs cycle** where substrates are made available for oxidative phosphorylation (36 ATPs per glucose). **Glucose** is the preferred fuel for skeletal muscle contraction at higher levels of exercise. At maximal work levels, almost all the energy used is derived from glucose produced by glycogen breakdown in muscle tissue and from blood-borne glucose from dietary sources. Muscle has performance limitations based on its structure and energy-conversion processes; as such, its efficiency is much <100%, and it produces relatively large quantities of heat, which must be dealt with by the organism that it is serving (see Chapter 28).

Metabolic differences among muscle fibers affect their ability to sustain contraction.

Although the basic structural features of the sarcomeres and the thick–thin-filament interactions are essentially the same among skeletal muscles, the chemical reactions that supply the contractile system with energy vary. The enzymatic properties (i.e., the rate of ATP hydrolysis) of actomyosin ATPase also vary. A typical skeletal muscle usually contains a mixture of fiber types with different metabolic properties. However, in most muscles, a particular type predominates.

Muscle fibers are sometimes classified as oxidative (types I and IIA, or red fibers) or glycolytic (type IIB, or white fibers). Red fibers utilize oxidative metabolism for contraction and owe their color to the presence of **myoglobin**, which is a hemoglobin-like molecule that can bind, store, and release oxygen. It is abundant in muscle fibers that depend heavily on aerobic metabolism for their ATP supply, where it facilitates oxygen diffusion (and serves as a minor auxiliary oxygen source) in times of heavy demand. Such muscles generally perform heavy sustained tasks. The quadriceps and gluteal muscles that continually maintain posture while standing are examples of this type of muscle. Red muscle fibers are divided into **slow-twitch fibers** and **fast-twitch fibers** on the basis of their contraction speed. The differences in rates of contraction (shortening velocity or force development) arise from differences in actomyosin ATPase activity (i.e., in the basic crossbridge cycling rate).

White muscle fibers, which contain little myoglobin, are fast-twitch fibers that rely primarily on glycolytic metabolism. They contain significant amounts of stored glycogen, which can be broken down rapidly to provide a quick source of energy. They are responsible for quick, short muscle movements such as those involved with movement and blinking of the eyes. Although they contract rapidly and powerfully, they fatigue easily (i.e., their endurance is limited).

Fast muscles, both white and red, not only contract rapidly but also relax rapidly. Rapid relaxation requires a high rate of calcium pumping by the SR, which is abundant in these muscles. In such muscles, the energy used for calcium pumping can be as much as 30% of the total consumed. Fast muscles are supplied by large motor axons with high conduction velocities; this correlates with their ability to make quick and rapidly repeated contractions.

MUSCLE PLASTICITY, EPIGENETICS, AND ENDOCRINE MUSCLE

Skeletal muscle structure and metabolism are not immutable, as has long been evidenced by the differing effects of aerobic exercise, isometric load exercise (e.g., weight lifting) and immobility on muscle mass, velocity of shortening, and metabolism (see Chapter 29 for details). The emerging science of epigenetics is revealing potential mechanisms by which external conditions from the environment, such as exercise, inactivity, proper nutrition, malnutrition, and exposures to medication or even environmental toxins, cannot just influence the body acutely but affect the genome through epigenetic mechanisms. Epigenetics is an evolving science that seeks to describe and explain how gene expression is changed independent of genotype yet can be heritable by subsequent generations. This provides a mechanism, for example, as to how environmental/nutritional conditions to which parents are exposed can be passed on to not just their immediate offspring, in the form of altered suppression or activation of their genes, but also possibly onto the next several generations as well. Insights into epigenetic effects on muscle cell growth, differentiation, and regeneration have beneficial potential for rehabilitative medicine and perhaps even set the stage for the ability to grow and replace muscle cells lost from trauma or disease.

Recent experimental studies have provided evidence for epigenetic modification of muscle type. For example, although muscle fiber phenotype (fast vs. slow) is determined during development by interactions with other elements in the developing body, such as motor neuron innervation type and thyroid hormone, it has been shown in cell culture that slow fibers only grow into slow fibers and fast fibers only into fast fibers. This cannot occur unless epigenetic changes occurred in the muscle precursor cells (i.e., stable and heritable changes in the muscle DNA of each type).

Other factors have been revealed recently to affect the epigenome of muscle. Obesity has been shown to induce epigenetic changes in a lipogenic muscle gene that alters the muscle cell to be smaller and thus better able to store fat. This muscle feature is a hallmark of type 2 diabetes, which has been correlated with obesity. Acetylation and deacetylation of histones are considered epigenetic modes of altering gene expression. Recently, HDAC inhibitors have been shown to promote regeneration of muscle cells while inhibiting fibrosis and fat deposition in dystrophic muscle. Finally, numerous recent studies have shown that the epigenetic marks of DNA methylation, histone acetylation, and miRNA are all altered by aerobic and isometric exercise, not just in skeletal muscle but also in other cell types such as leukocytes, brain cells, and adipose tissue.

Exercise is known to have beneficial effects on several tissues in the body besides skeletal muscle. Recent evidence that exercise creates epigenetic marks in tissues beyond just skeletal muscle suggests that muscle may not only be an epigenetic target, but that itself may send signals to other tissues to induce epigenetic changes in them as well. As introduced in Chapter 1, muscle cells are now believed to have an endocrine function via secretion of myokines. Myokines released from skeletal muscle have been shown to “cross-talk” with adipocytes and have been suggested to attenuate the insulin resistance and low-grade inflammation associated with type 2 diabetes (such attenuation is a known beneficial effect of regular exercise). In contrast, a lack of beneficial myokine secretion with aging of muscle has been suggested to link deterioration of that tissue to increased incidence of age-related neuromotor, neurocognitive, metabolic, and oncologic disorders, although evidence in support of this postulate is more correlative than causative at this time.

SMOOTH MUSCLE

Smooth muscle is by far the most physiologically complicated and versatile muscle tissue in the body. Recall that skeletal muscle can only be activated intermittently and requires a signal from a neuron innervating it to do so. Furthermore, its relaxation is not active but rather the absence of contraction. In contrast, smooth muscle can both contract and relax actively on its own, as well as in response to neural signals, hormonal signals, chemical signals, or physical signals. Smooth muscle can exhibit twitch contraction, summed twitch contraction, or graded contractions, that is, smooth increments in contraction or relaxation rather than the "all-on-all-off" characteristic of skeletal muscle. In blood vessels, for example, vascular smooth muscle must be partially tonically active at all times (i.e., it must remain partially contracted continuously). This seemingly energy-intensive process is mitigated by the fact that smooth muscle, unlike skeletal muscle, contains special crossbridge cycling switching mechanisms that allow it to sustain high force at low levels of energy expenditure.

Smooth muscle outside the cardiovascular system is often labeled *visceral smooth muscle*. This muscle plays a key role in the functions of the digestive system, where it physically manipulates gut contents in complex ways during digestion and moves materials and fluids along the alimentary tract. Visceral smooth muscle in the gut, therefore, must be able to contract or relax phasicly in response to the many different types of neural, chemical, and physical signals involved in digestion. Some smooth muscles such as that in sphincters (circular bands of muscle that can stop flow in tubular organs) can remain contracted and closed for long periods but then relax and open transiently before contracting and closing again. Sphincters at the ends of the esophagus, the stomach, and rectum operate in this fashion (see Chapter 25). Smooth muscle in still other visceral organs remains relaxed most of the time but then can contract strongly in response to physiologic stimuli. Smooth muscles in the esophagus, urinary bladder, and gall bladder behave in this manner. As an ultimate case of this type of behavior, the smooth muscle of the uterus is relatively inactive during most of a woman's life but contracts and relaxes rapidly and powerfully over several hours during parturition.

Multiple smooth muscle contraction and relaxation patterns can be produced by neural, humoral, chemical, physical, and intrinsic stimuli.

Contractile activity in smooth muscle is initiated in markedly different ways compared to that for skeletal muscle. In the previous section, it was shown that skeletal muscle cannot contract without neural input to the muscle cells. Furthermore, the neural inputs to skeletal muscle fibers (via motor neurons) are often initiated from conscious thought and are, therefore, voluntary. Although smooth muscle is indeed innervated (predominantly by postganglionic sympathetic fibers), innervation is not necessary for smooth muscle contraction and modulation of smooth muscle contraction is totally involuntary. Rather than being the sole means of muscle activation, neurotransmitters from autonomic neurons are but one of many factors that modulate smooth muscle contraction. Contractile activity in smooth muscle is also modulated by numerous receptor-dependent and receptor-independent (direct-acting) contractile and relaxing agents.

Smooth muscle does have excitable tissue properties and can form action potential–driven contractions in response to signals from the ANS or other contractile agents. Smooth muscle can also summate contractions in response to a train or small burst of ANS-driven action potentials in a manner similar to temporal summation and tetanus in skeletal muscle. However, there are many other contractile agents that can mobilize calcium in smooth muscle and cause contraction without the formation of any action potentials. Furthermore, calcium levels and associated contraction of smooth muscle can be *graded* in response to changes in its *resting* membrane potential. For example, stepwise incremental depolarizations of the resting membrane potential in smooth muscle cause proportional incremental increases in smooth muscle tone (contractile force); the contractions are graded and not linked to the formation of action potentials. Similar graded contraction or relaxation responses can be elicited in smooth muscle without any change in membrane potential at all. This can occur in response to changes in the concentration of many different constrictor and relaxing agents that act on smooth muscle directly or act via membrane receptors. Thus, whereas skeletal muscle is like a lamp with an on-and-off switch that will not work unless it is linked to a source of electricity, smooth muscle is like a light with a dimmer switch and its own source of excitation.

Altering smooth muscle contraction changes the internal dimensions of hollow organs.

Just a few basic tissue types accomplish a wide variety of smooth muscle tasks. The simplest smooth muscle arrangement is found in the arteries and veins of the circulatory system. Smooth muscle cells are oriented in the circumference of a vessel so that their shortening results in reducing the vessel's diameter. This reduction may range from a slight narrowing to a complete obstruction of the vessel lumen, depending on the physiologic needs of the body or organ. Tonic contraction there helps the vessels counteract the expanding force on the arteries due to exposure to high internal blood pressure. The blood pressure provides a force that would otherwise relengthen the cells in the vessel walls. In the smallest arterioles, the muscle layer may consist of single cells wrapped around the vessel, where it functions as an on/off spigot to control blood flow to very precise regions within an organ.

The circular arrangement of smooth muscle is also prominent in the airways of the lungs, where it regulates the resistance to airflow entering and exiting that organ. The circular smooth muscles making up sphincters, such as those in the gastrointestinal and urogenital tracts, have a special nerve supply and participate in complex reflex behavior. The intestinal tracts (small and large) contain two regions of smooth muscle cells within their walls. The outermost muscle layer, which is relatively thin, runs along the length of the intestine. The inner muscle layer, thicker and more powerful, has a circular arrangement. Coordinated alternating contractions and relaxations of these two layers mix and propel the contents of the intestine, although most of the motive power is provided by circular muscle. Control of the motility of the intestine through these smooth muscle layers is very complex and discussed in more detail in Chapter 25.

The most complex arrangement of smooth muscle is found in organs such as the urinary bladder and uterus. Numerous layers and orientations of muscle fibers are present, and the effect of their contraction is an overall reduction of the volume of these organs. The relengthening force, in the case of these hollow organs, is provided by the gradual accumulation of contents. In the urinary bladder, for example, the muscle is gradually stretched as the emptied organ fills again with urine from the kidneys.

Smooth muscle cells lack the ultrastructural organization of skeletal muscle fibers.

In contrast to skeletal muscle fibers, smooth muscle cells are small relative to the tissue they make up. Individual smooth muscle cells are 100 to 300 μm long and 5 to 10 μm in diameter. When isolated from the tissue, the cells are roughly cylindrical along most of their length and taper at the ends. Electron microscopy reveals that the cell margins contain many areas of small membrane invaginations, called **caveolae**, which are sites of specialized cell functions. There is no organized T-tubular system in smooth muscle, and its SR is not as abundant as that of skeletal muscle. The bulk of the cell interior is occupied by three types of myofilaments: thick, thin, and intermediate (Fig. 8.17). The *thin filaments* are similar to those of skeletal muscle but lack the troponin protein complex. The *thick filaments* are composed of myosin molecules, as in skeletal muscle, but the arrangement of the individual molecules into filaments is different; the filaments are called *side-polar*, with one crossbridge orientation on one side of the filament and the opposite orientation on the other. There is no central bare region without crossbridges. The **intermediate filaments** are so named because their diameter of 10 nm is between that of the thick and thin filaments. Intermediate filaments appear to have a cytoskeletal, rather than a contractile, function. Prominent throughout the cytoplasm are small, dark-staining areas called **dense bodies**. They are associated with the thin and intermediate filaments and are considered analogous to the Z lines of skeletal muscle. Dense bodies associated with the cell margins are often called **membrane-associated dense bodies** (or patches) or **focal adhesions**. They appear to serve as anchors for thin filaments and transmit the force of contraction to adjacent cells.

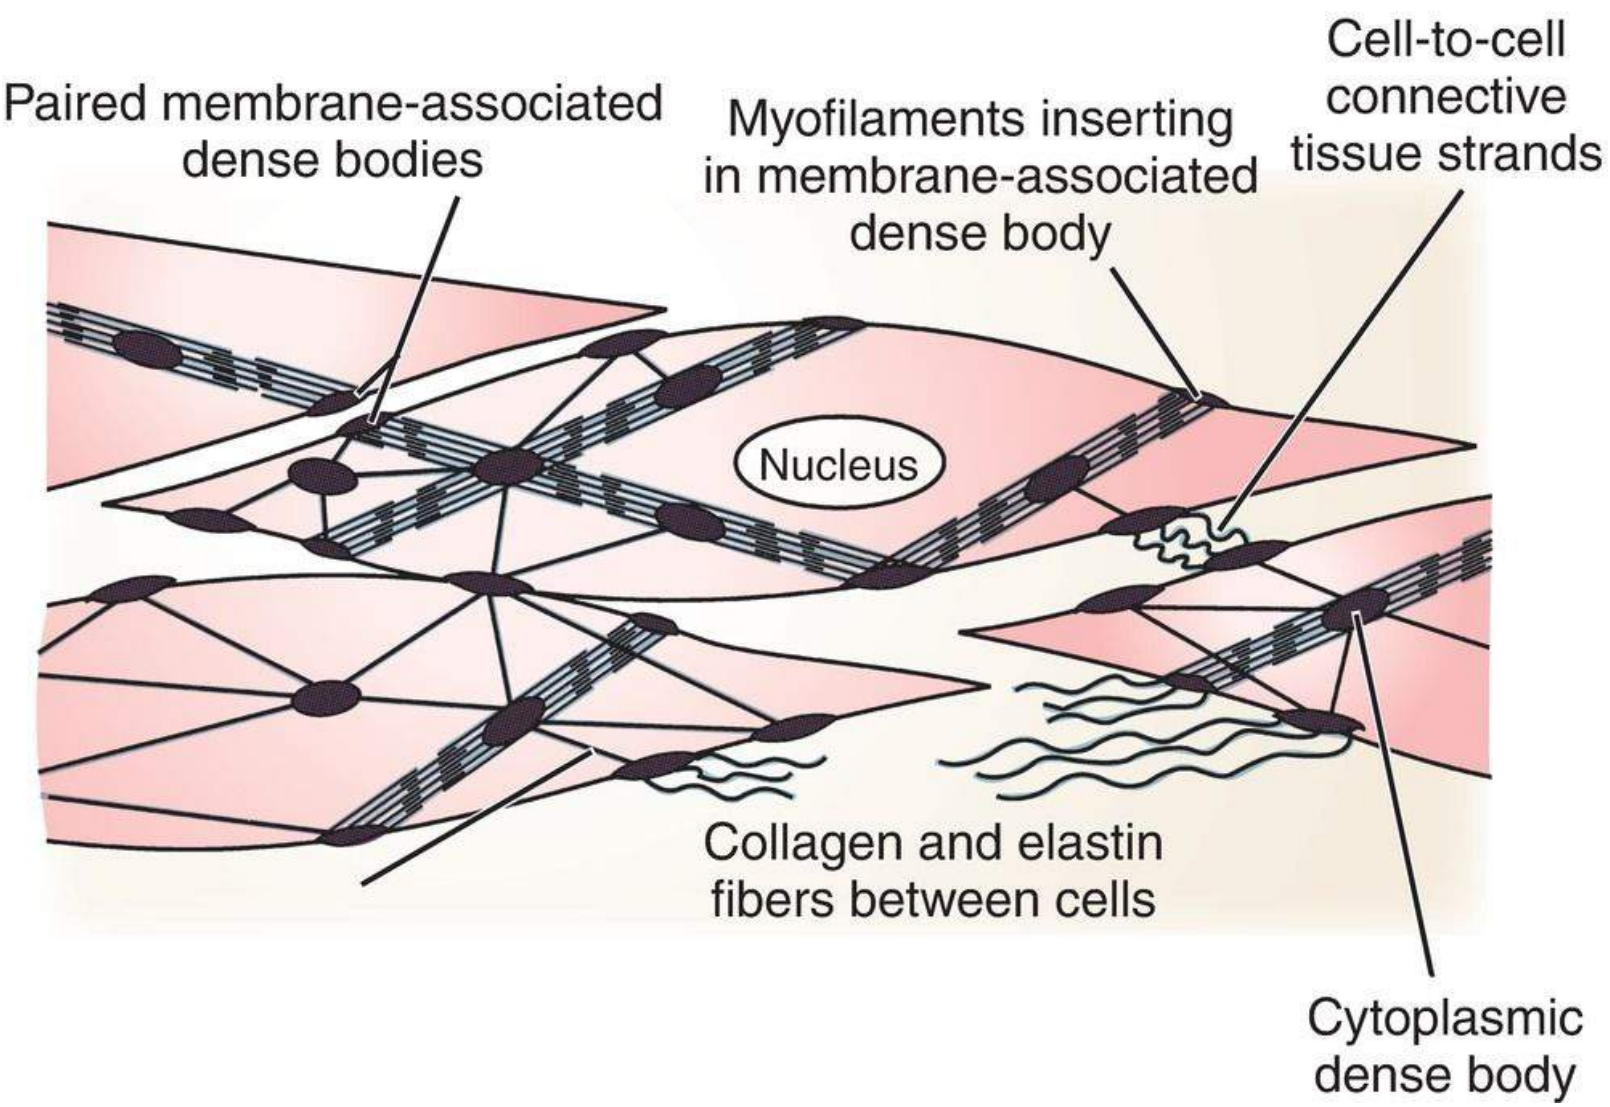

Figure 8.17 A schematic representation of the contractile system and cell-to-cell connections in smooth muscle. Note regions of association between thick and thin filaments that are anchored by the cytoplasmic and membrane-associated dense bodies. A network of intermediate filaments provides some spatial organization (see, especially, the *left side*). Several types of cell-to-cell mechanical connections are shown, including direct connections and connections to the extracellular connective tissue matrix. (Structures are not necessarily drawn to scale.)

Smooth muscle lacks the regular sarcomere structure of skeletal muscle. There is some association among dense bodies down the length of a cell and a tendency of thick filaments to show a degree of lateral grouping. However, it appears that the lack of a strongly periodic arrangement of the contractile apparatus is an adaptation of smooth muscle associated with its ability to function over a wide range of lengths in its host organ and to develop high forces.

Cell-to-cell transmission of force and electrical activity

A proposed arrangement of the smooth muscle contractile and force transmission system is also shown in simple terms in Figure 8.17. Assemblies of myofilaments are anchored within the cell by the dense bodies and at the cell margins by the membrane-associated dense bodies. The contractile apparatus lies oblique to the long axis of the cell. Many of the membrane-associated dense bodies are opposite on one another in adjacent cells and may provide continuity of force transmission between the contractile apparatus in each cell. Collagen and elastin fibers run throughout the tissue. These fibers, along with reticular connective tissue, comprise the **connective tissue matrix** or stroma found in all smooth muscle tissues. It connects

the cells and gives integrity to the whole tissue.

Smooth muscle cells are also coupled electrically, although this functional connectivity predominates in visceral, rather than vascular, smooth muscle. The structure most responsible for this coupling is the **gap junction**, which allows a low-resistance pathway for electrical currents to flow between cells. This facilitates the propagation of changes in membrane potential throughout tissue containing many smooth muscle cells.

Calcium required to contract smooth muscle is obtained from both extracellular and intracellular sources.

An elevation of intracellular calcium concentration to about 1 μM is an absolute requirement for smooth muscle contraction, and a reduction in smooth muscle calcium concentration below this level is considered a primary mechanism of smooth muscle relaxation. Figure 8.18 gives an overall picture of calcium regulation in smooth muscle. These processes may be grouped into those modulating *calcium entry*, intracellular *calcium liberation*, and *calcium exit* from the cell. Calcium enters the cell through several pathways, including voltage-gated 1,4 dihydropyridine calcium channels, numerous different ligand-gated channels, stretch-activated calcium channels, and a relatively small number of unregulated **"leak" channels**. Calcium leaks can permit the continual passive entry of small amounts of extracellular calcium in the cell, though this entry is negligible under normal conditions. Such leaks can affect cell calcium entry in pathological conditions such as that seen contributing to excessive smooth muscle contraction in arterial hypertension.

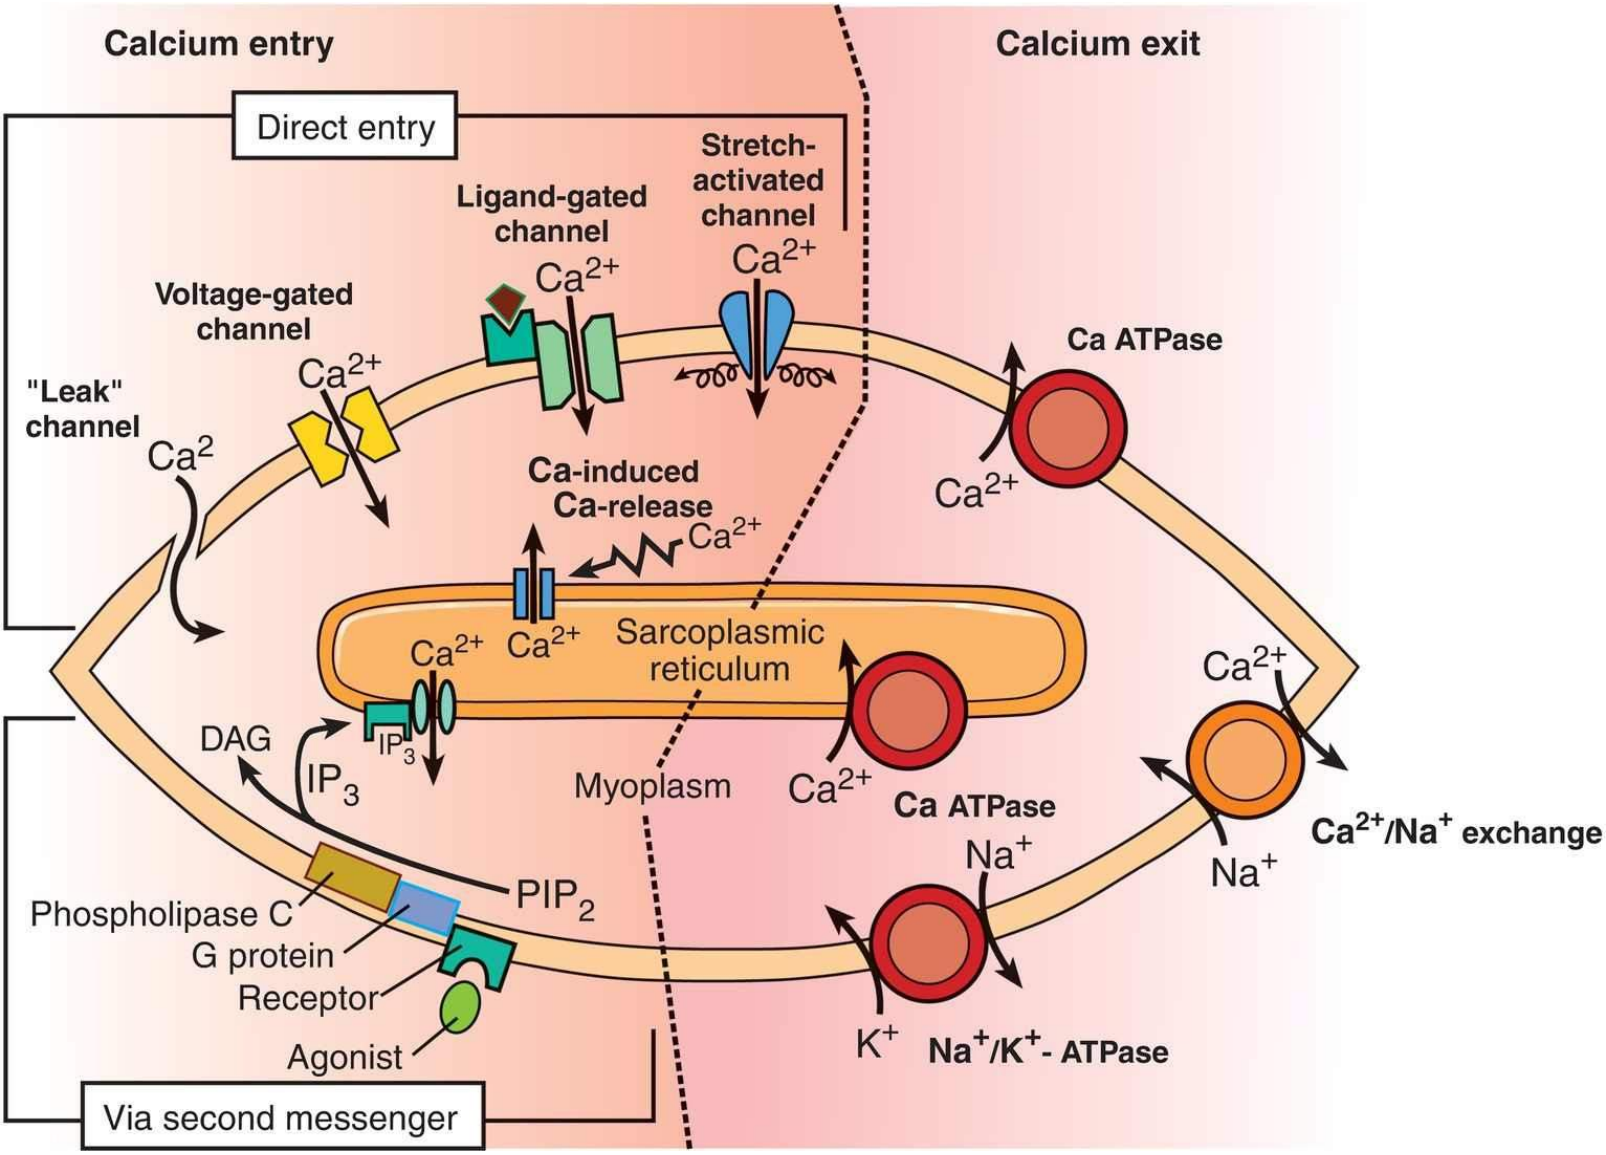

Figure 8.18 Major routes of calcium entry and exit from the cytoplasm of smooth muscle. Calcium enters the smooth muscle cell through voltage-gated, ligand-gated, stretch-activated, and "leak" calcium channels. Calcium can also be released into the cell from the sarcoplasmic reticulum (SR) by inositol 1,4,5-trisphosphate (IP_3) and Ca^{2+}-stimulated calcium release. The processes on the *left side* increase cytoplasmic calcium and promote contraction; those on the *right side* decrease internal calcium and promote relaxation. DAG, diacylglycerol; IP_3, inositol 1,4,5-trisphosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate.

Membrane depolarization opens voltage-gated calcium channels in smooth muscle that operate in a similar fashion to the voltage-gated sodium channels in nerves and skeletal muscle. These channels have an activation gate that opens during membrane depolarization starting at approximately −55 to −40 mV, along with an inactivation gate that closes with membrane depolarization several milliseconds after opening of the activation gate. The opening and closing kinetics of these types of calcium channels are much slower compared to that seen in voltage-gated sodium channels. The kinetics of voltage-gated calcium channels provides a short window of opportunity through which calcium can enter the cell from the extracellular fluid through the channel, down an enormous electrochemical gradient. This calcium influx is a significant source of activator calcium for smooth muscle contraction and the rapid influx of positive charge from the calcium can also create an action potential. This action potential, however, is of smaller amplitude and has a slower upstroke than those caused by voltage-gated sodium channels in nerve

and skeletal muscles.

Literally dozens of different ligand-gated calcium channels exist among the smooth muscles in the body, with each type designed to be activated by a specific agonist, or ligand. Many of these channels open to allow calcium entry into the cell and initiate contraction when a specific agonist binds to a specific receptor on the channel. Many hormones and neurotransmitters contract smooth muscle through this mechanism. Activation of ligand-gated calcium channels generally does not generate action potentials in smooth muscle except at very high agonist concentrations. Contraction of smooth muscle via ligand-gated calcium channels without the generation of an action potential is called **pharmacomechanical coupling**. Some ligands for ligand-gated calcium channels operate by decreasing the open time of the channel or decreasing the amount of time the channel is open. These ligand channels decrease intracellular calcium concentration and cause the muscle to relax.

Within the cell, the major storage site of calcium is the SR. In some types of smooth muscles, its capacity is quite small and these tissues are strongly dependent on extracellular calcium for their function. Nevertheless, calcium from the SR can contribute to smooth muscle contraction. Calcium is released from the SR by at least two mechanisms, including inositol 1,4,5-trisphosphate (IP_3)-induced release and a **calcium-induced calcium release**. IP_3 formation is caused by activation of phospholipase C (PLC), by ligand-activated membrane receptors, which forms IP_3 and diacylglycerol (DAG) from phosphatidylinositol 4,5-bisphosphate (PIP_2) in the cell. In this latter mechanism, calcium that has entered the cell via a membrane channel causes additional calcium release from the SR, amplifying its activating effect.

Smooth muscle cells also have calcium channels that open whenever the smooth muscle cell is stretched. These channels are distinct entities and not simply voltage-gated or ligand-gated calcium channels that are opened by stretch (although there is some evidence to suggest that voltage-gated channels can be affected this way in some circumstances). Stretch-activated calcium channels play a key role in the regulation of vascular smooth muscle contraction because they are linked to the control of organ blood flow (see Chapter 15).

During a contraction, the cytoplasmic calcium level is significantly elevated. Following contraction, calcium leaves the myoplasm in two directions: a portion of it is returned to storage in the SR by a Ca^{2+}-ATPase pump in the SR membrane and the rest is ejected from the cell by two mechanisms. The more important of these is via a membrane Ca^{2+} ATPase pump located in the cell membrane. The second mechanism, also located in the plasma membrane, is sodium–calcium exchange, which exchanges the entry of three sodium ions to the extrusion of one calcium ion. This mechanism derives its energy from the large sodium gradient across the plasma membrane of the cell; thus, it depends critically on the operation of the cell membrane Na^+/K^+- ATPase.

Phosphorylation of myosin filament proteins is necessary for smooth muscle contraction.

Calcium ions are central to the control of contraction in smooth muscle, where they modulate the crossbridge cycle. However, the thin filaments of smooth muscle lack troponin, and the actin-linked regulation of skeletal muscle is not present in smooth muscle. Control of smooth muscle contraction relies instead on the thick filaments and is, therefore, called **myosin-linked regulation**. In actin-linked regulation, the contractile system is in a constant state of "inhibited readiness" and calcium ions remove the inhibition. In the case of smooth muscle myosin-linked regulation, the role of calcium is to cause *activation from* a resting state of the contractile system. This general scheme is shown in Figure 8.19. At rest, there is little cyclic interaction between the myosin and actin filaments because of a special feature of its myosin molecules. The S2 portion of each myosin molecule (the paired "head" portion) contains four protein *light chains*. Two are necessary for actin–myosin interaction (essential light chains, M.W. 16,000) and two others are critical requirements for smooth muscle contraction (regulatory light chains, M.W. 20,000) Regulatory light chains contain specific amino acid residues that can be phosphorylated by ATP. The enzyme responsible for this **phosphorylation** is **myosin light-chain kinase** (**MLCK**). When the regulatory light chains are phosphorylated, the myosin heads can interact in a cyclic fashion with actin in the crossbridge cycle much as in skeletal muscle. The cycle will not initiate if myosin is not phosphorylated. It is important to note that the ATP molecule that phosphorylates a myosin light chain is separate and distinct from the one consumed as an energy source by the mechanochemical reactions of the crossbridge cycle.

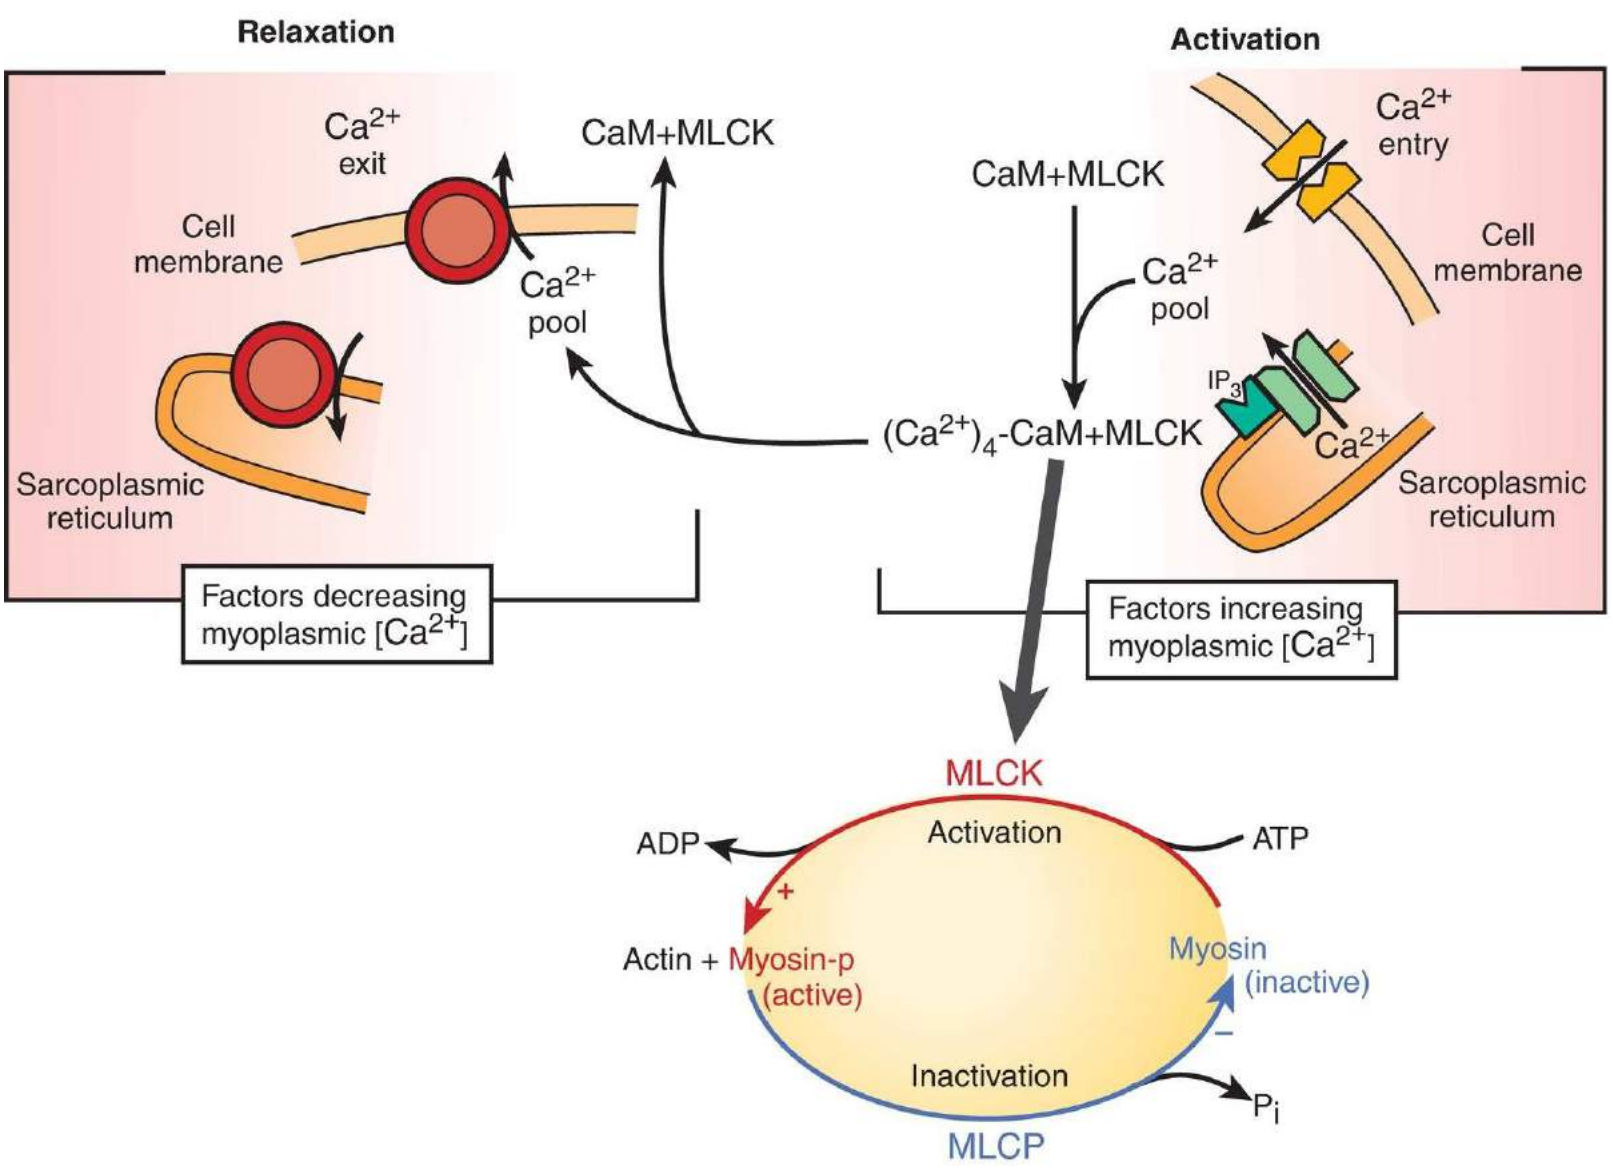

Figure 8.19 Reaction pathways involved in the regulation of the crossbridge cycle in smooth muscle. Activation (*upper right*) begins when cytoplasmic calcium levels are increased and calcium binds to calmodulin (CaM), activating the myosin light-chain kinase (MLCK). The kinase (*lower right*) catalyzes the phosphorylation of myosin, changing it to an active form (myosin-P, or Mp). The phosphorylated myosin can then participate in a mechanical crossbridge cycle much like that in skeletal muscle, although much slower. When calcium levels are reduced, calcium leaves CaM, the kinase is inactivated, and the myosin light-chain phosphatase (MLCP) dephosphorylates the myosin, making it inactive. The crossbridge cycle stops, and the muscle relaxes. A, actin; ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate ion.

For myosin phosphorylation to occur, the MLCK must be activated. This activation is subject to control. Closely associated with the MLCK is **calmodulin** (**CaM**), a smaller protein that binds calcium ions. When four calcium ions are bound, the CaM protein activates its associated MLCK and light-chain phosphorylation can proceed (see Fig. 8.19). It is this MLCK-activating step that is sensitive to the cytoplasmic calcium concentration. At levels below 10^{-7} M Ca^{2+}, no calcium is bound to CaM and no contraction can take place. When cytoplasmic calcium concentration is $>10^{-5}$ M, the binding sites on CaM are fully occupied, light-chain phosphorylation proceeds at maximal rate, and contraction occurs. Between these extreme limits, variations in the internal calcium concentration can cause corresponding gradations in the contractile force. This, then, is the biochemical mechanism responsible for the fact that

smooth muscle contraction can be graded between total relaxation and total contraction in contrast to the all-or-none–type limitation to the activation of skeletal muscle contraction. The phosphorylation of myosin can be reversed by the enzyme **myosin light-chain phosphatase** (**MLCP**). The activity of this phosphatase appears to be only partially regulated; that is, there is always some enzymatic activity, even while the muscle is contracting. During contraction, however, MLCK-catalyzed phosphorylation proceeds at a significantly higher rate, and phosphorylated myosin predominates. There is some evidence that during ligand-gated contraction, a DAG-PKC (protein kinase C)–dependent pathway results in the formation of the protein CPI-17, which inhibits MLCP, thereby favoring the phosphorylated myosin state (Fig. 8.20). This ligand-gated pathway also activates the RhoGTP/Rho kinase system, which activates CPI-17 and inhibits MLCP by phosphorylation of those proteins.

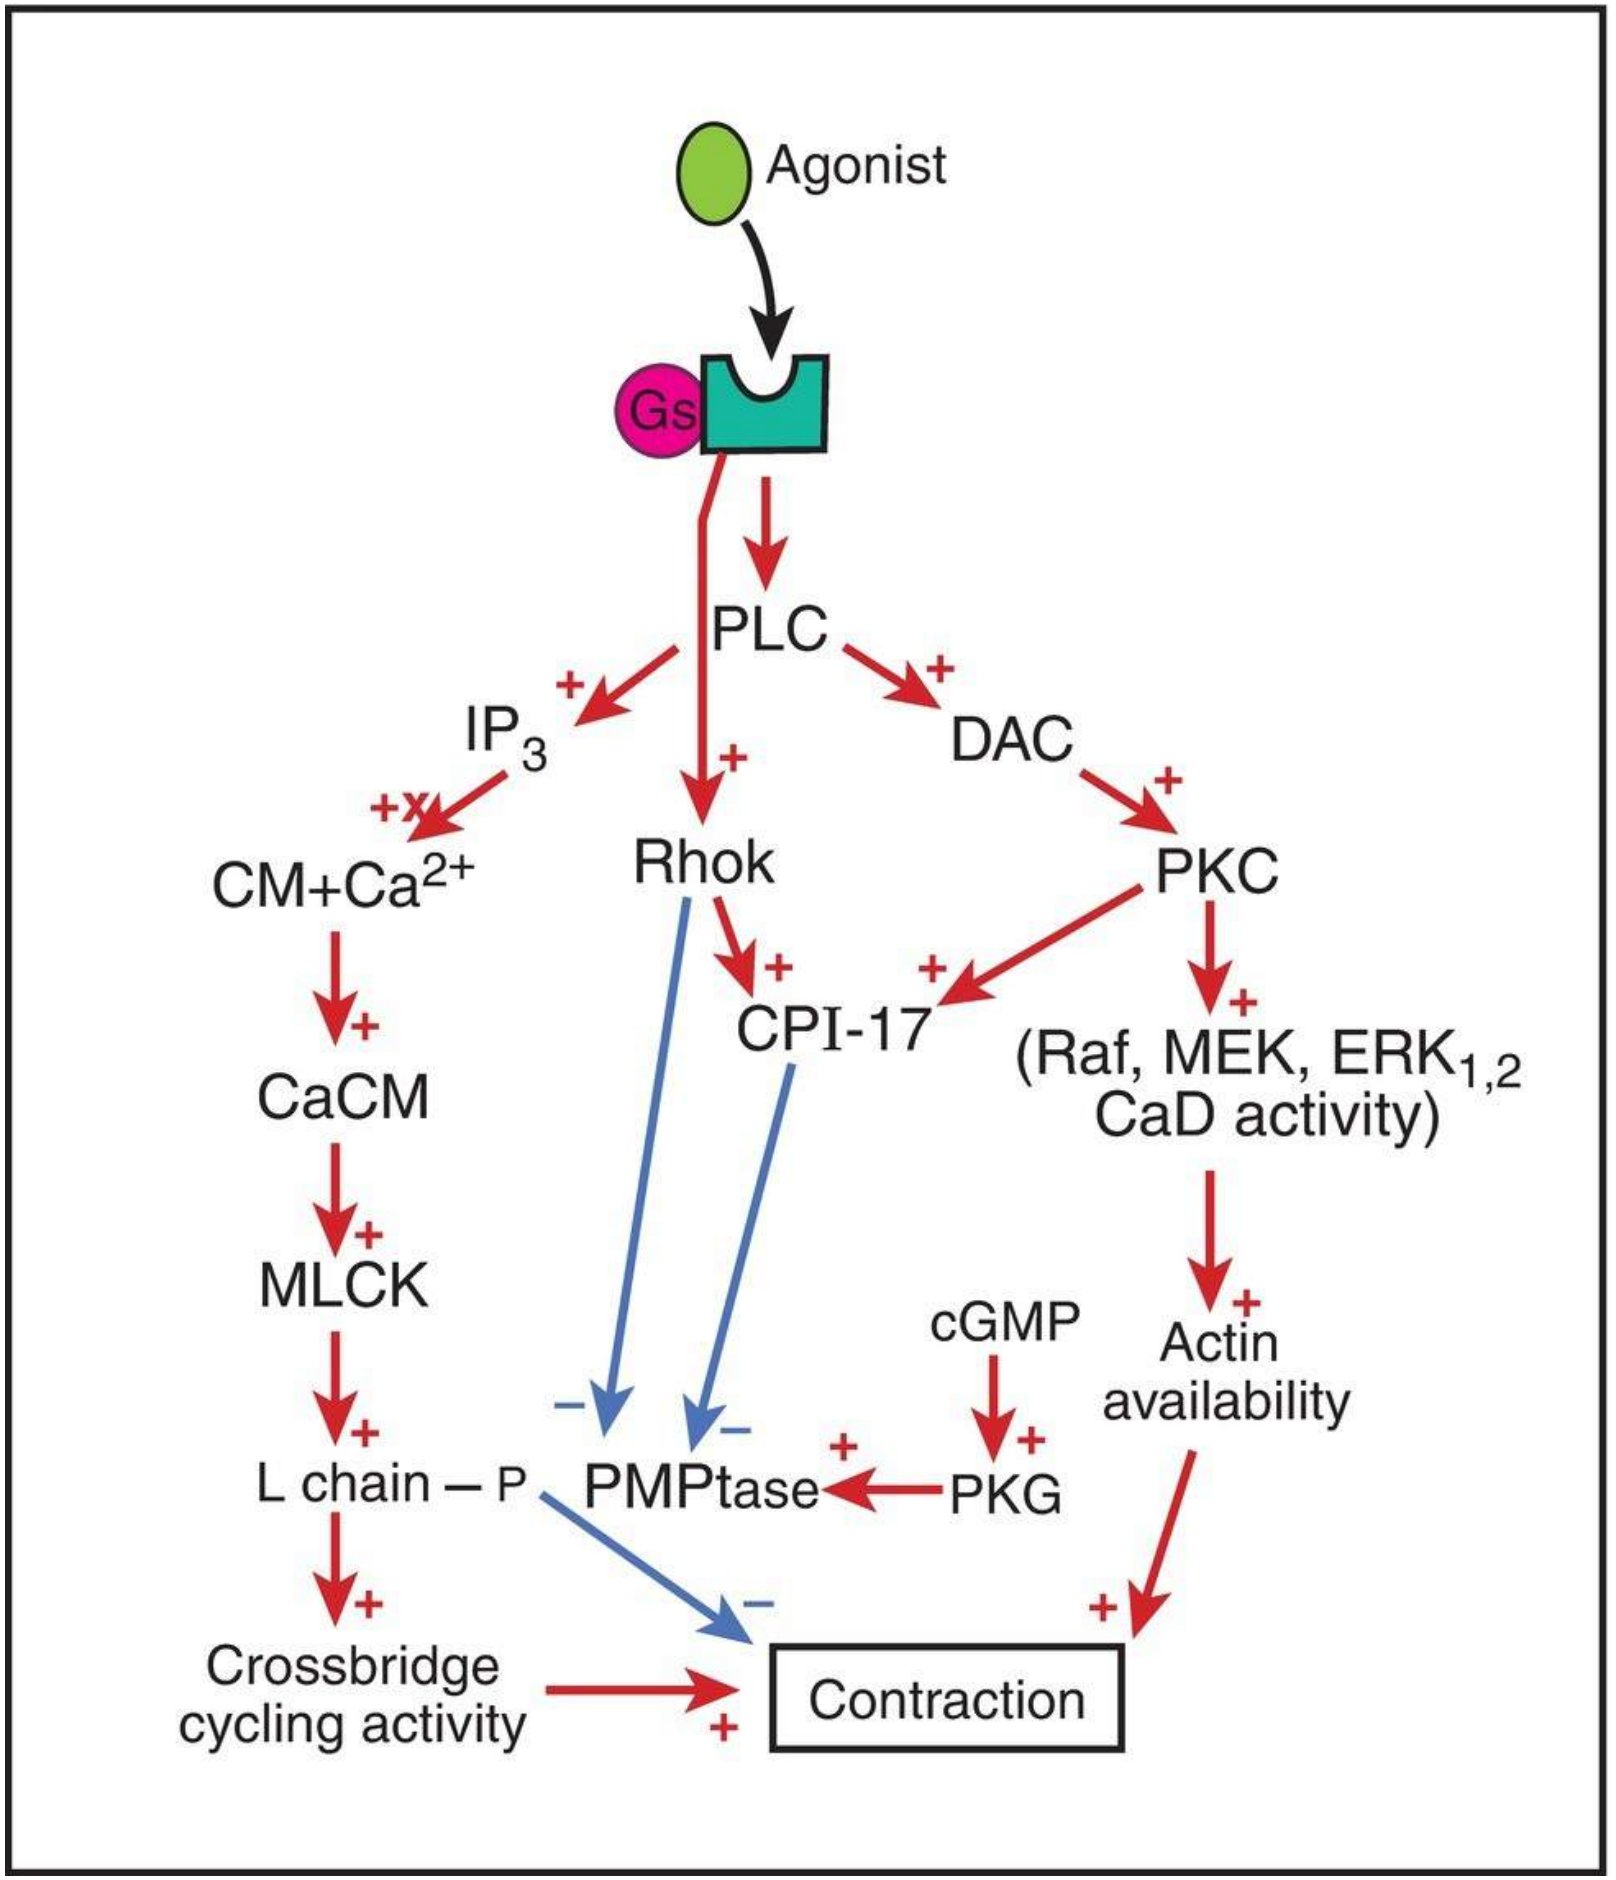

Figure 8.20 Regulation of contraction and relaxation in vascular smooth muscle. Myosin must be phosphorylated in vascular smooth muscle in order for crossbridge cycling to occur. The extent of myosin phosphorylation is believed to result from the net effect of phosphorylation by myosin light-chain kinase (MLCK) and dephosphorylation by myosin light-chain phosphatase (MPtase). Contraction of vascular

smooth muscle occurs through activation of MLCK and inactivation of MPtase. Other proteins also regulate contraction/relaxation by making actin more or less available to participate in crossbridge cycling with phosphorylated myosin.

When the cytoplasmic calcium concentration falls, MLCK activity is reduced because the calcium dissociates from the CaM, and myosin dephosphorylation (catalyzed by the phosphatase) predominates. Because dephosphorylated myosin has a low affinity for actin, the reactions of the crossbridge cycle can no longer take place. Relaxation is, thus, brought about by mechanisms that lower cytoplasmic calcium concentrations, decrease MLCK activity, or increase MLCP activity. It also appears that actin itself can be made more or less available to interact with phosphorylated myosin and, thereby, control the extent of contraction of vascular smooth muscle. PKC, in particular, appears to activate a cascade of signal proteins within the smooth muscle cell to increase the availability of actin to then interact with phosphorylated myosin and promote vascular smooth muscle contraction.

Latch state is a mechanism that reduces the energy cost of continual smooth muscle contraction.

Smooth muscle contractile activity cannot be divided clearly into twitch and tetanus, as in skeletal muscle. In some cases, smooth muscle makes rapid phasic contractions, followed by complete relaxation. In other cases, smooth muscle can maintain a low level of active tension for long periods without cyclic contraction and relaxation. This type of long-maintained contraction is called *tonus* (rather than tetanus) or a *tonic contraction*. This is typical of smooth muscle activated by ligand-gated calcium channels (hormonal, pharmacologic, or metabolic factors), whereas phasic activity is more closely associated with activation of voltage-gated calcium channels (i.e., by membrane depolarization). This extended maintenance of force capability is called the **latch state** (Fig. 8.21). The latch state is not a rigor state but rather a state of reduced rate of crossbridge cycling so that each remains in the attached state for a longer portion of its total cycle. This condition is characterized by low levels of ATP utilization and has a lower calcium concentration requirement. Thus, the latch state can be thought of as a means of reducing the energy requirements of long, sustained contractions over what might be expected based on energy usage in short-duration contractions. Current understanding of the latch state suggests that it may occur when myosin is dephosphorylated while still attached to actin during the crossbridge cycle. In this sense, this dephosphorylation of myosin is different than that which appears to be involved in smooth muscle relaxation.

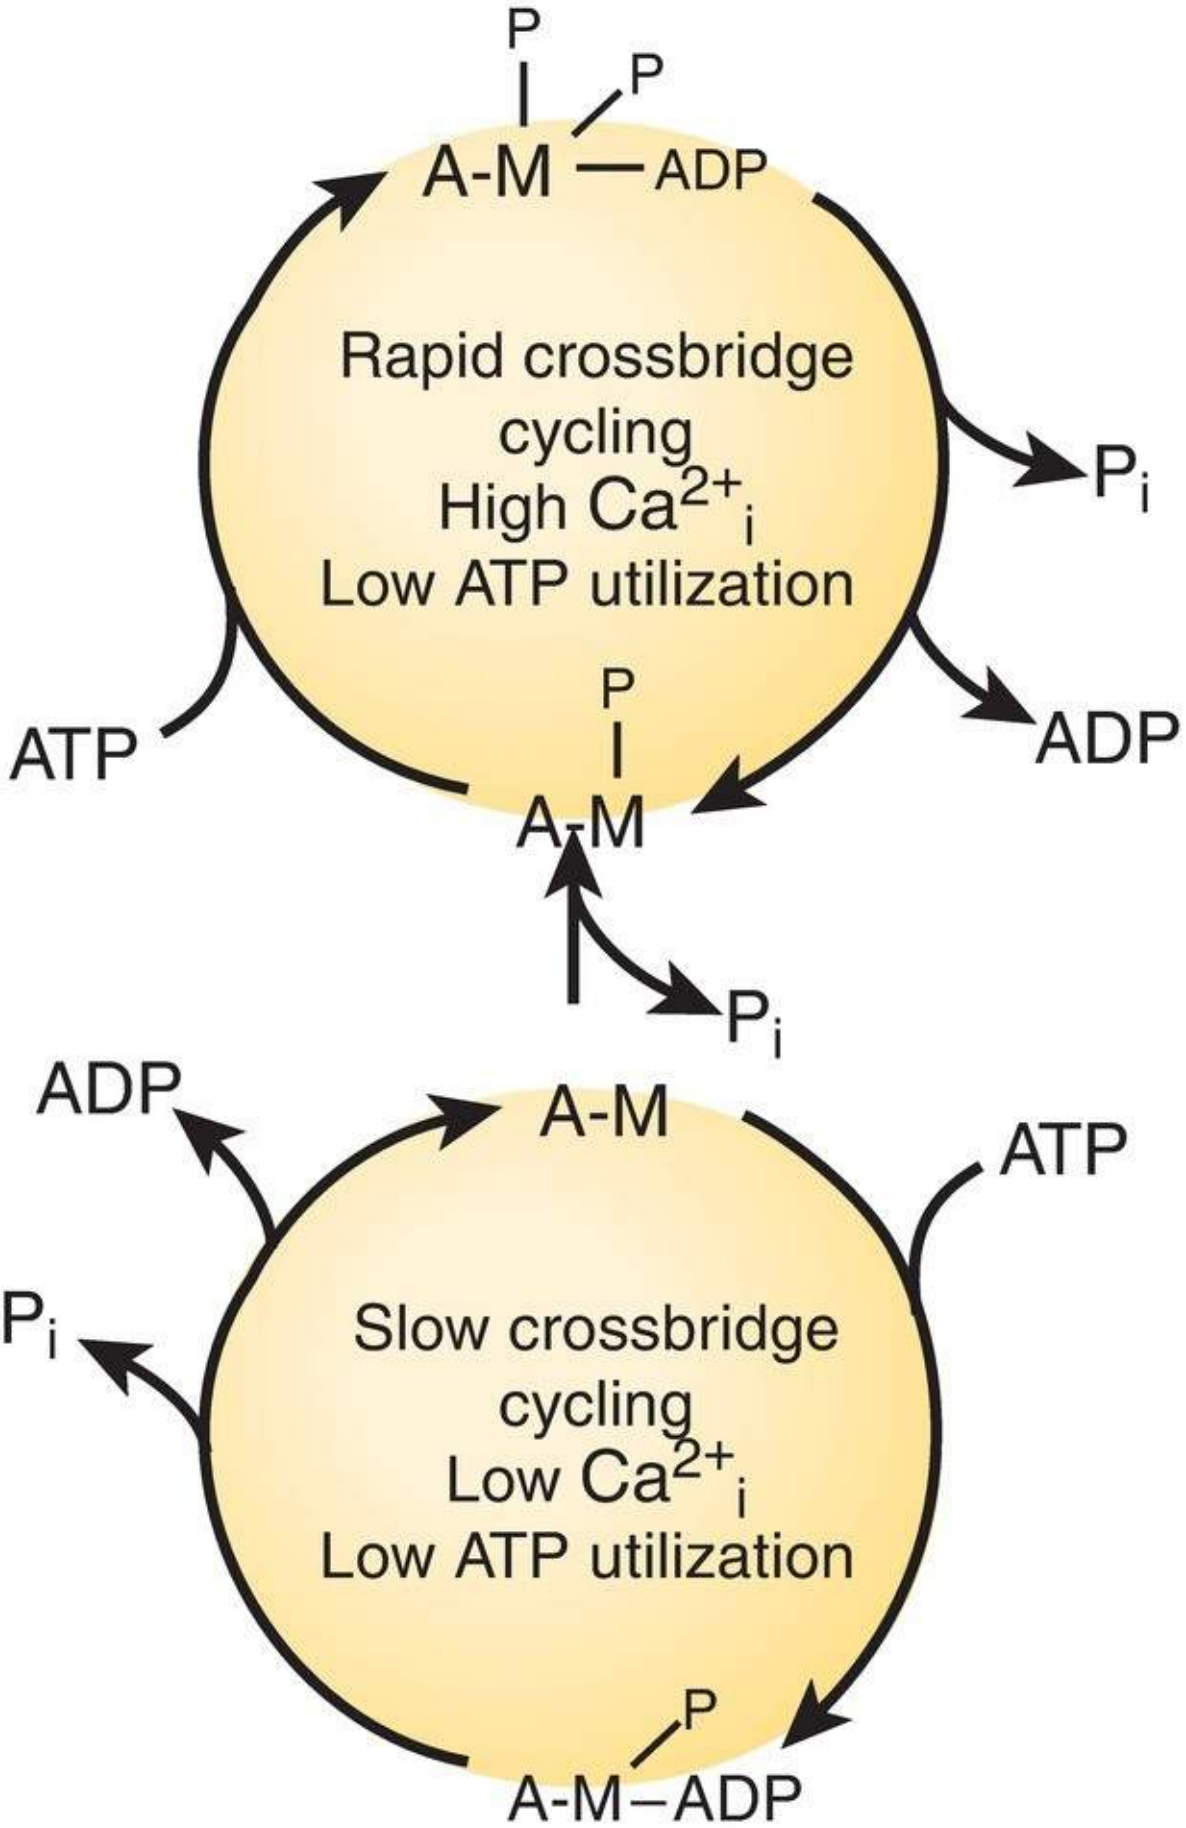

Figure 8.21 Representation of the latch state of the crossbridge cycle. When myosin is dephosphorylated while attached to actin, the crossbridge cycling slows because actin and myosin remain attached for longer durations than normal. This allows the muscle to maintain tonic contractions for long periods of time with a reduced energy requirement for adenosine triphosphate (ATP) and at a reduced intracellular calcium concentration. P, protein; P_i, inorganic phosphate; ADP, adenosine diphosphate; A-M, actin bound

to myosin.

Mechanical activity in smooth muscle is adapted for its specialized physiologic roles.

The isometric length–tension relationship in smooth muscle is generally much broader than that for skeletal muscle with a less defined L_O. This allows smooth muscle to function at higher capacities over a significantly greater range of lengths. This is a beneficial property in that smooth muscle is not constrained by skeletal attachments but is instead often found lining hollow organs whose dimensions, and thus the stretch placed on the muscle therein, can vary over a large range.

Smooth muscle exhibits more resistance to stretch on the ascending limb of this relationship (Fig. 8.22A), which is mostly a result of the network of connective tissue that supports the smooth muscle cells and resists overextension.

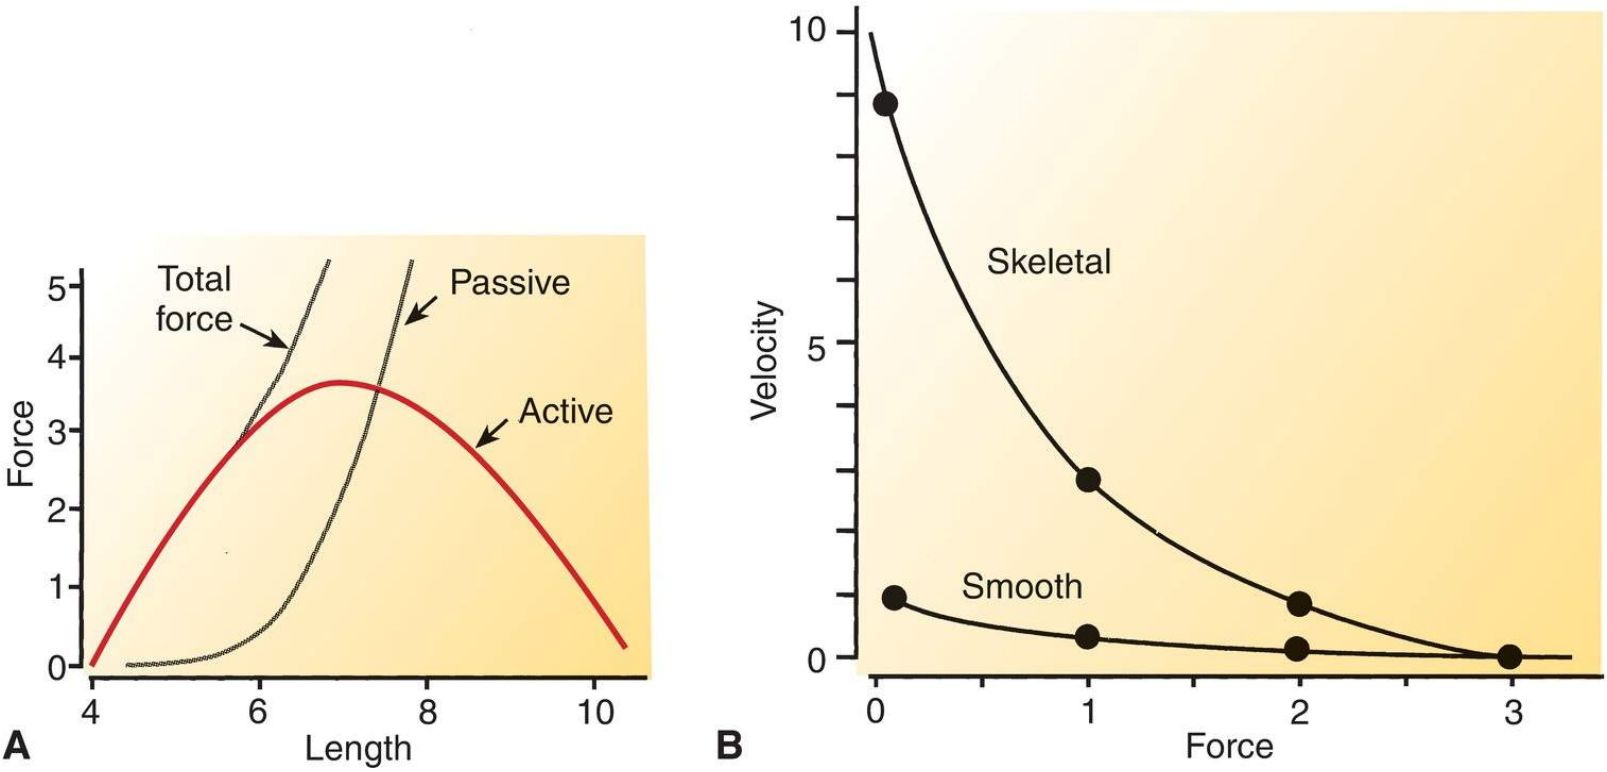

Figure 8.22 Smooth muscle mechanical characteristics. **(A)** Typical length–tension curves from skeletal and smooth muscle. Note the greater range of operating lengths for smooth muscle and the leftward shift of the passive (resting) tension curve compared to that seen in skeletal muscle. **(B)** Skeletal and smooth muscle force–velocity curves. Although the peak forces may be similar, the maximum shortening velocity of smooth muscle is typically 100 times lower than that of skeletal muscle. (Force and length units are arbitrary.)

The contraction and relaxation of smooth muscle is much slower than that of skeletal or cardiac muscle though it can maintain contraction far longer. The source of these differences lies largely in the chemistry of the interaction between the actin and myosin of smooth muscle. The inherent rate of the actomyosin ATPase correlates strongly with the velocity of shortening of the intact muscle. Most smooth muscles require several seconds (or even minutes) to develop maximal isometric force. A smooth muscle that contracts 100 times more slowly than a skeletal muscle will have an actomyosin ATPase that is 100 times

as slow. The major source of this difference in rates is the myosin molecules; the actin found in smooth and skeletal muscles is rather similar. There is also a close association in smooth muscle between maximal shortening velocity and degree of myosin light-chain phosphorylation. The high economy of tension maintenance, typically 300 to 500 times greater than that in skeletal muscle of similar size, is vital to the physiologic function of smooth muscle. Compared with that in skeletal muscle, the crossbridge cycle in smooth muscle is hundreds of times slower, and, therefore, much more time is spent with the crossbridges in the attached phase of the cycle.

The force–velocity curve for smooth muscle (Fig. 8.22B) reflects the differences in crossbridge functions described previously. Although smooth muscle contains one third to one fifth as much myosin as skeletal muscle, the longer smooth muscle myofilaments and the slower crossbridge cycling rate allow it to produce as much force per unit of cross-sectional area as does skeletal muscle. Thus, the maximum values for smooth muscle on the force axis would be similar, whereas the maximum (and intermediate) velocity values are different. Furthermore, smooth muscle can have a set of force–velocity curves, each corresponding to a different level of myosin light-chain phosphorylation. This is often revealed by the particular maximum contractions and contraction velocities produced by different receptor-mediated contractile agonists in smooth muscle. That is, three different contractile agonists of the same concentration on the same smooth muscle can produce three different levels of maximum force generation and contraction velocities in that smooth muscle.

Smooth muscle has several modes of relaxation.

The central cause of smooth muscle relaxation is a reduction in the internal (cytoplasmic) calcium concentration, a process that is itself the result of several mechanisms. Electrical repolarization of the plasma membrane leads to a decrease in the influx of calcium ions, whereas the plasma membrane calcium pump and the sodium–calcium exchange mechanism (to a lesser extent) actively promote calcium efflux. Most important quantitatively is the uptake of calcium back into the SR. The net result of lowering the calcium concentration is a reduction in MLCK activity so that dephosphorylation of myosin can predominate over phosphorylation.

The cyclic nucleotides cAMP and cGMP are second messenger links between smooth muscle relaxation and activation of specific smooth muscle membrane receptors by chemical ligands that mediate relaxation of smooth muscle. For example, binding of catecholamines to beta-adrenergic receptors in vascular and bronchial smooth muscle activates **adenylyl cyclase**, which results in the formation of **cyclic adenosine monophosphate** (**cAMP**). Cyclic AMP triggers a cascade of events within the smooth muscle that lead to relaxation. These include enhanced calcium uptake by the SR and decrease myosin light-chain phosphorylation.

Nitric oxide and nitrodilators such as nitroglycerin relax smooth muscle by activating guanyl cyclase and producing the second messenger **cGMP**. This leads to the activation of **cGMP-dependent protein kinase** (**PKG**), which promotes the opening of calcium-activated potassium ion channels in the cell membrane, leading to hyperpolarization and subsequent relaxation. PKG also activates MLCP and blocks the activity of agonist-evoked **phospholipase C** (**PLC**). This action reduces the liberation of stored calcium ions by IP_3.

INTEGRATED MEDICAL SCIENCES

Smooth Muscle: A Target for Medical Pharmaceutical Therapies

The highly diverse mechanisms used by smooth muscle to initiate contraction and relaxation allow it to perform very diverse tasks in the body. A lot of these tasks revolve around the location of smooth muscle in what can be called hollow organs (e.g., blood vessels, airways, the GI, and genitourinary systems and bladders). Smooth muscle can maintain constant tone, stay relaxed until needed to contract, and stay contracted until needing to relax and can both contract and relax in coordinated fashion to provide directional movement. In this manner, smooth muscle is employed to alter air flow in the lungs, blood flow to tissues as well as blood distribution and blood pressure in the body, and to function as sphincters and movement mechanisms to produce swallowing, movement, and evacuation in the GI tract as well as contraction of the bladder. These widespread organ-specific locations and functions, coupled with the multiple intracellular mechanisms and membrane receptors regulating contraction of smooth muscle, make this tissue a rich target for medical pharmacotherapy. For example, nitroglycerin is used in patients suffering an ischemic attack of the heart, which occurs when the heart's demand for oxygen exceeds its supply. Nitroglycerin produces NO in blood vessels, which directly relaxes its smooth muscle through intracellular activation of guanylate cyclase and production

of cGMP. This highly lipid-soluble and rapidly absorbed agent is taken to produce acute, significant dilation of arteries and veins, which causes redistribution of blood out of the pulmonary and cardiac area and into the periphery. This redistribution reduces and relieves stress on the heart and its need for oxygen thereby relieving the ischemic attack. Drugs that block the 1,4 DHP or L-type calcium channel have similar smooth muscle uses. These channels are predominantly found in the cardiovascular system. Like NO, they are a non–receptor-acting agent that binds to and inhibits the ability of the channel to allow calcium into smooth muscle. This causes a graded reduction in smooth muscle tone that then dilates arteries, reducing blood pressure and stress on the heart. These vascular actions of these agents are used to treat hypertension (high blood pressure) and to prevent myocardial ischemia. α1-Adrenergic receptor blockers are a class of membrane receptor selective agents that block the action of catecholamines, usually released from vascular sympathetic nerve endings, on vascular smooth muscle. They are used to dilate arteries, primarily to reduce arterial blood pressure, and have wide use in the treatment of hypertension and myocardial ischemia. Cholinergic mimics and anticholinergic agents (blockers) have been used as pharmacotherapy for many GI and urinary bladder disorders. They can be used to decrease or increase motility in the GI tract, aid swallowing, and either reduce urinary retention or calm overactive bladder muscle.

As the student will start to surmise while progressing through this book, smooth muscle is an inviting target for pharmacological intervention in the treatment of organ system diseases and malfunctions. It will become equally apparent however that actual successful development of such therapies must be complicated by the fact that an agent used to ameliorate one malfunction in one organ system could spill its effects to another system at the same time and thus may cause serious undesired side effects. There are too many agonists and receptors in common with too many systems innervated by the ANS for this not to be a real possibility. Such ANS receptor elements are also found in the CNS and skeletal muscle system further enhancing the possibility of complex side effects. Pharmaceuticals for bladder or GI issues can spill over to other cholinergic processes such as tear formation and salivation. Even more complexity arises if these drugs have spillover effects on skeletal muscle and the CNS as well. Sometimes, route of administration of a drug used for smooth muscle effect can mitigate spill over side effects in organs. For example, β-adrenergic agonists (stimulators) relax bronchiole smooth muscle but also stimulate the heart, which could prove dangerous. However, when inhaled, these drugs dilate bronchiole smooth muscle without spilling into the general circulation. In this manner, they can be used to counteract dangerous bronchospasm in asthma without affecting the CV system. Considerations such as those mentioned above are the driving force for the need of much training of physicians so that they can properly utilize and understand the full medical consequences of using smooth muscle drugs. ■

Chapter Summary

- The contractile apparatus of skeletal muscle is made up of thick (myosin-containing) and thin (actin-containing) myofilaments arranged in interdigitating arrays called *sarcomeres*.
- Contraction is brought about by a cyclic enzymatic interaction between the myofilaments. The biochemical reactions of the crossbridge cycle require adenosine triphosphate (ATP) as a metabolic fuel and a ligand to detach myofilament attachments during the cycle. The power stroke of the myosin head provides the force to cause relative myofilament sliding and sarcomere shortening.
- The neuromuscular junction is a specialized chemical synapse that links motor nerve impulses to skeletal muscle activation.
- In skeletal muscle, membrane excitation is coupled to contraction by the action of calcium on the troponin regulatory complex on the thin filaments.
- Calcium ions are stored in the sarcoplasmic reticulum (SR) and released to the myofilaments upon depolarization of the T-tubule membranes. Binding of calcium ions to troponin allows the interaction of actin and myosin filaments in the crossbridge cycle. Relaxation occurs when calcium is pumped back into the SR.
- Muscle contraction is fueled by ATP derived primarily from the metabolism of carbohydrates and also by metabolism of amino acids and fatty acids.
- Contractile force in whole muscle is adjusted by varying the number of motor units stimulated and by the temporal pattern of stimulation. Brief, single contractions are twitches; summed contractions are tetanies.
- The length–tension curve relates initial, passive muscle length to isometric tension, and the force–velocity curve relates speed of shortening to the force exerted by the muscle while moving a load in an isotonic contraction.
- Skeletal attachments act as a lever system, increasing the effective range of muscle shortening while reducing the amount of force a limb can exert. These attachments also confine the muscle operation to near the optimal length on its length– tension curve.
- Metabolic and structure adaptations fit skeletal muscle for a variety of roles. Red muscle fibers are associated with aerobic metabolism, whereas white muscles operate anaerobically.
- Muscle metabolism and structure are plastic and may be altered epigenetically while also acting as an endocrine organ to affect other tissues in the body through epigenetic mechanisms.
- Smooth muscle is specialized for a wide range of tonic- and phasic-type contractions. It has an actin–myosin contractile system, although it lacks the regular ultrastructure of skeletal muscle.
- Regulation of smooth muscle contraction is under the control of calcium ions, which promote, via the enzyme myosin light-chain kinase, phosphorylation of the light chains on the myosin molecule. This enables it to interact with actin and participate in the crossbridge cycle.
- Smooth muscle cells are electrically coupled, and activation spreads from cell to cell throughout the tissue. Nerves may initiate contraction or modify its duration and extent.
- The latch state of smooth muscle is a condition of slow crossbridge cycling that conserves energy during tonic contractions.
- Relaxation in smooth muscle is associated with a lowering of cytoplasmic calcium and dephosphorylation of the myosin through the action of a phosphatase enzyme.

Chapter Review Questions

1. Anticholinesterases are a class of drug that inhibits the enzyme (acetylcholinesterases) that breaks down acetylcholine after its release into the neuromuscular junction. What would happen in a skeletal muscle motor unit in response to a train of motor nerve impulses if the muscle was exposed to an anticholinesterase?

A. Acetylcholine concentration would be higher in motor endplate synapse compared to normal.

B. Endplate potentials would be diminished compared to normal.

C. It would require that the motor neuron be stimulated at a higher frequency than normal to produce normal amounts of acetylcholine at the motor endplate.

D. The skeletal muscle fiber could not form action potentials.

E. Release of acetylcholine from the motor neuron would be impaired compared to normal.

The correct answer is A. The concentration of acetylcholine in the myoneural junction is the net effect of acetylcholine being released into the junction from the motor neuron and decomposition of the acetylcholine by acetylcholinesterase in the junction. Anticholinesterases would block acetylcholine breakdown and, thus, increase the concentration of acetylcholine in the junction. The endplate potential is proportional to the number of nicotinic receptors occupied by acetylcholine and would likely be increased in the presence of an anticholinesterase. This would make it more likely that muscle action potentials could be formed. In the presence of anticholinesterases, less motor neuron stimulation (and, thus, less acetylcholine release) would be needed to maintain normal concentrations of acetylcholine in the vicinity of the motor endplate. Finally, anticholinesterases have no effect on the release of acetylcholine from the motor neuron terminal; these enzymes affect acetylcholine after it is released.

2. At L_0, a muscle group produces a maximum isometric twitch force of 10 g, whereas it produces a maximum isometric force of 7 g at 0.5 L_0. If the muscle length at L_0 is 5 cm, which of the following is true?

A. Starting a 0.5 L_0, the muscle cannot produce an isotonic contraction with a 6 g afterload.

B. Starting a 0.5 L_0, the muscle can move an 8 g load to 0.4 L_0.

C. An isotonic contraction of 10 g load can occur at 0.8 L_0.

D. Starting at L_0, the muscle can move a 9 g load to 2.5 cm.

E. Starting at L_0, the muscle can move a 7 g load to 2.5 cm.

The correct answer is E. Starting at an optimum preload, the muscle will shorten if it moves a load less than the maximum isometric force possible at its optimum preload until it reaches a length whose maximum isometric force-generating capacity is the same as the load being moved. The muscle cannot move beyond this point because, at shorter lengths, there will not be enough crossbridges to support the load being moved.

3. Blockade of calcium release from the SR of smooth muscle will:

A. Prevent contraction of the muscle following activation of ligand-gated calcium channels

B. Prevent action potential generation in the smooth muscle cells

C. Not affect tonic contraction of the muscle stimulated by activation of ligand-gated membrane channels

D. Not affect the contribution to contraction of the muscle as stimulated by IP_3

E. Result in total relaxation of the smooth muscle

The correct answer is C. Activator calcium for contraction of smooth muscle is obtained from both the release of calcium from the SR and the entry of calcium from the extracellular fluid through one or more of the types of calcium channels in the muscle cell membrane. Opening of ligand-gated channels will contract the muscle tonically, first due to the influx of calcium through the channel and second by activating the latch state mechanism in the cell. Action potential generation in smooth muscle occurs primarily from calcium influx through membrane channels and not from release of calcium from the SR. IP_3 is a trigger for the release of calcium from the SR and contributes to smooth muscle contraction when it is produced in response to activation of membrane receptors by the appropriate ligand. Blockade of calcium release from the SR would not relax smooth muscle because of the availability of activator calcium from the extracellular fluid via membrane calcium channels.

Clinical Application Exercises 8.1

For the past month, a 48-year-old male office manager has noticed increasing muscle weakness about his shoulders, neck, and arms along with occasional trouble getting both eyes to focus on single objects (diplopia). While cleaning out his garage of garden fertilizers, malathion insecticide, and herbicides, he becomes easily fatigued, especially while reaching up and outward to clean shelving. He decides to get examined by his family physician. During his history and physical examination 2 weeks later, the patient reveals he's had no sudden falls or injuries at any time prior to appearance of his symptoms nor did he experience symptoms solely while cleaning his garage. He does complain that he is becoming more short of breath while doing physical activity. His physical revealed that he had normal reflexes but had trouble abducting or holding out his arms for any length of time. When he tries to keep his eyelids open for extended time, his left lid starts to droop. When the patient tries to smile, his smile resembles a grimace though the patient is not in any pain. Based on this history and examination, the patient's physician orders an electromyogram study of the patient's proximal arm muscles along with an acetylcholine receptor (AChR) antibody test. The myogram shows marked diminution of compound muscle action potentials within 12 minutes of stimulated electroshocks to the muscle of four stimuli per second (normal equals about 30 minutes). The anti-AChR antibody test indicates the presence of acetylcholine receptor antibodies in the patient's plasma. Based on the patient's physical and test results, the patient's physician concludes that the patient has myasthenia gravis and decides to forego an IV edrophonium test on the patient to further verify the diagnosis. He instead immediately prescribes therapy that includes intermittent use of pyridostigmine for the patient's symptoms.

QUESTIONS

1. Based on the patient's history and physical examination, postulate what type of potential causes were eliminated by the patient's physician and why.
2. Postulate what connection might exist between the patient's physical and clinical test results and his symptoms.
3. The physician determines that the patient has myasthenia gravis. What findings are consistent with this result?

ANSWERS

1. Skeletal muscle contraction requires motor nerve stimulation, release of acetylcholine transmitter at the NM junction, and excitation contraction coupling of muscle. There is no indication of traumatic

injury to the CNS or peripheral nerves in this patient that would indicate a neurogenic cause of his symptoms. Similarly, this is not indicated by intact muscle reflexes as well as the fact that his symptoms are bilateral and involve more central muscles (eyelids, shoulders, neck). That is not consistent with a specific anatomical injury. Malathion is an organophosphate anticholinesterase that can amplify acetylcholine effects at the NM junction rather than reduce them. Although in severe cases this can cause depolarization paralysis by locking the muscle sodium channel in the inactive state, this is an acute response that can result in death from paralysis of the diaphragm as well as widespread acute ANS effects. Thus, it is unlikely that the patient was exposed to toxic concentrations of malathion while cleaning his garage.

2. ACh receptor antibodies occur when acetylcholine receptors are attacked by the body's immune system. If such an attack should damage or destroy the nicotinic acetylcholine receptors in the NM junction, this would account for muscle weakness. This would also account for the patient's fatigue, inability to sustain muscle contractions (arm abduction, eye lid lift), and the fact that his muscles weaken when stimulated repetitively. When stimulated repetitively (as in the EMG test), the acetylcholine released from motor neurons diminishes over time in a process called presynaptic rundown with the effect of diminished activation of underlying skeletal muscle. However, in a normal patient, stimuli of two to four cycles per second produce a 10% to 15% reduction in muscle activation after about 30 minutes of stimulation. When this rundown phenomenon is coupled with lots of ACh receptors on the NM junction, rundown occurs much more rapidly.
3. Myasthenia gravis is a prototypical autoimmune disease that destroys nicotinic ACh receptors (via compliment fixation), stimulates internalization of the receptors, and otherwise destroys and reduces the NM surface folds. The result is markedly reduced ACh receptors available for any quanta of ACh released by motor neurons at the NM junction. Because muscle contraction depends on the number of nicotinic receptors bound to ACh, MG results in weak muscle contractions in response to normal motor neuron stimulation and exacerbates synaptic rundown. The patient's history, physical, and test results are consistent with the onset of myasthenia gravis, which generally appears suddenly without notable cause and affects muscle of the face and upper extremities and bulbar muscles.

PART **III** BLOOD AND IMMUNOLOGY

9 Blood Composition and Function

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Understand the four major functions of blood: transport, hemostasis, regulation of temperature and pH, and immunity.
- Describe the components of plasma and understand the main functions of each.
- Understand the types of formed elements and their unique roles in homeostasis.
- Explain how the blood lipid profile can be applied to assess cardiovascular health.
- Discuss the clinical usefulness of blood tests including the basic metabolic panel, complete metabolic panel, hematocrit, and complete blood cell count.
- Understand how the composition of red blood cells contributes to their function.
- Distinguish the different types of anemia and understand how these differences dictate the type of treatment protocols that would be used.
- Explain the function and clinical significance of erythropoietin as well as its involvement in blood doping.
- Understand how white blood cells form an integrated response to prevent and fight infections.
- Track the roles and components of the blood clotting phases, from immediate actions to wound healing.
- Explain the relevance of blood type in blood transfusions.

The viability and metabolism of the body's cells are dependent on adequate perfusion by the blood. In the systemic circulation, arterial blood transports components necessary for maintaining a relatively stable and constant cellular environment (e.g., osmolytes, nutrients, and O_2) and blood flowing through the veins transports CO_2 and other metabolic waste products to the lungs, kidneys, and liver for disposal. Because the heart is a dual pump, the blood flowing in the pulmonary arteries carries O_2-poor blood to the lungs for oxygenation, and the aorta carries the oxygenated blood to the systemic circulation (see Chapter 11). The components carried by the blood are delivered to individual cells as it passes through an extensive network of thin-walled capillaries. Blood also plays a role in maintaining body temperature and in fighting infection (see Chapter 10). Blood tests are common diagnostic tools to detect a wide variety of homeostatic imbalances.

BLOOD FUNCTIONS

Blood is a dynamic and complex living connective tissue. The cellular and plasma components of blood work in concert to perform four major roles: transport substances, regulate hemostasis, maintain a stable internal environment by regulation of temperature and pH, and aid in resisting infection or disease via the immune system.

Transport

As the primary means of long-distance transport in the body, blood carries an abundance of important substances including electrolytes, amino acids, sugar, proteins, lipids, minerals, hormones, and waste products. Depending upon the solubility of an individual substance, it can be transported as freely dissolved in solution (plasma), bound to a specific carrier protein (e.g., iron bound to transferrin), bound to a nonspecific carrier protein (e.g., hormones bound to albumin), or within blood cells. Control of the transport modality can be physiologically regulated. For example, about half of circulating calcium is in its free form (Ca^{2+}), whereas the other half is complexed to albumin or anions. In contrast, O_2 is preferentially transported within **red blood cells** (**RBCs**) bound to **hemoglobin** (**Hgb** or **Hb**)**,** and <1% is freely dissolved in the plasma.

Hemostasis

Complex and efficient mechanisms have evolved to prevent blood loss from a damaged vessel. The arrest of bleeding is called **hemostasis**. The failure to stop bleed after injury is called **hemorrhage** and can result in life-threatening blood loss if not controlled by the physiological mechanisms that constitute normal hemostasis.

Homeostasis

Homeostasis, as a physiological term, means maintaining a relatively steady state to create an optimal internal environment. The blood system plays a pivotal role in preserving homeostasis by maintaining pH and temperature. Plasma proteins form an immediately available buffer system to modulate the acid equivalents produced by most metabolic reactions. In addition, blood carries excess acid and base equivalents to organs such as the kidney and lungs for elimination. The rapidly circulating blood is an excellent conduit for transporting the heat generated by metabolic reactions and, therefore, plays a major role in thermoregulation by sequestering blood in the core as a result of vasoconstriction when ambient temperature is low or by dissipating heat by peripheral vasodilation when the environment is hot or the body has generated internal heat (e.g., during exercise).

Immunity

White blood cells (**WBCs**) are involved in the body's defense against infection and disease caused by pathogens and in the clearance of foreign antigens (see Chapter 10). Although the unbroken skin and mucous membranes act as barriers to the entry of infectious agents into the body, microbes can penetrate or bypass these frontline defenses. WBCs, working in conjunction with various proteins, monitor the blood to detect the presence of microorganisms and other foreign substances. In most cases, the blood's defense system is efficient enough to eliminate the pathogens or to prevent their spreading before they can cause substantial bodily harm.

WHOLE BLOOD

The average adult has about 5 L (5.3 quarts) of whole blood; men have 5.0 to 6.0 L and women have 4.5 to 5.5 L. Approximately 55% of the total blood volume is liquid (**plasma**), and about 45% is formed elements (i.e., RBCs, WBCs, and **platelets**). Blood accounts for 6% to 8% of the body weight of a healthy adult.

Blood is a specialized connective tissue.

Blood is considered a type of connective tissue because the cells that give rise to the formed elements are derived from the same lineage as the cells that form bone, cartilage and the dermal layer of skin. Connective tissues are made of cells surrounded by matrix. In the case of blood, the matrix is the plasma, whereas the formed elements are RBCs, WBCs, and platelets. These are called the *formed elements* because only the WBCs are truly cells containing a nucleus. RBCs contain a nucleus during development in the red bone marrow but lose this when fully mature. Platelets are pieces of cells derived during the controlled breakage of a large cell called a **megakaryocyte**.

When fully oxygenated, whole blood is bright red, which results from the oxygenated iron in Hgb. Oxygen-poor blood (deoxygenated blood) has a lower level of oxygenated Hbg and is darker red. Oxygen-poor blood is carried by veins in the systemic circulation and by arteries in the pulmonary circulation. Systemic veins, when viewed through the skin, typically appear blue in color from the deflection of light when it penetrates the skin.

Medical terms related to whole blood often begin with **hem/o-** or **hemat/o-** from the Greek word *haima* for blood. For instance, ***hemo*lysis** is the premature destruction of **erythrocytes**, and a ***hemato*logist** is a blood specialist.

To obtain whole blood for laboratory analysis, an **anticoagulant** must be added to keep the blood from clotting. Clinically, there are not many assays in which whole blood is used; whole blood is so viscous (normal viscosity values are 3.5 to 5.5) and cloudy that it interferes with the chemical reactions in the test solutions. However, there is a continual effort to develop assays that overcome these problems, which would allow the use of whole blood for fast diagnosis in emergency situations.

SOLUBLE COMPONENTS OF BLOOD AND THEIR TESTS

Because blood is the transport medium for many organic and inorganic substances in the body, analysis of the components of the plasma is important for detecting normal as well as pathological processes. Reference values such as those in Table 9.1 are well documented and can be useful in detecting diseases or other physiological changes that disrupt homeostasis.

TABLE 9.1 Basic Components of Plasma

Class	Substance	Reference Range
Cations	Sodium (Na^+)	136–145 mEq/L
	Potassium (K^+)	3.5–5.0 mEq/L
	Calcium (Ca^{2+})	4.2–5.2 mEq/L
	Magnesium (Mg^{2+})	1.5–2.0 mEq/L
	Iron (Fe^{3+})	50–170 µg/dL
	Copper (Cu^{2+})	70–155 µg/dL
	Hydrogen (H^+)	35–45 nmol/L
Anions	Chloride (Cl^-)	95–105 mEq/L
	Bicarbonate (HCO_3^-)	22–26 mEq/L
	Lactate$^-$	0.67–1.8 mEq/L
	Sulfate (SO_4^{2-})	0.9–1.1 mEq/L
	Phosphate (HPO_4^{2-}/ $H_2PO_4^-$)	3.0–4.5 mg/dL
Proteins	Total	6–8 g/dL
	Albumin	3.5–5.5 g/dL
	Globulin	2.3–3.5 g/dL
Fats	Cholesterol	150–200 mg/dL
	Phospholipids	150–220 mg/dL
	Triglycerides	35–160 mg/dL
Carbohydrates	Glucose	70–110 mg/dL
Other examples	Alkaline phosphatase	20–140 U/L
	Alanine transaminase	8–20 U/L
	Aspartate transaminase	9–40 U/mL
	Bilirubin (total)	0.1–1.0 mg/dL
	Blood urea nitrogen	7–18 mg/dL
	Creatinine	0.6–1.2 mg/dL
	Ketones	0.2–2.0 mg/dL
	Vitamin A	0.15–0.6 µg/mL
	Vitamin B_{12}	200–800 pg/mL
	Vitamin C	0.4–1.5 mg/dL

Plasma becomes serum after the removal of clotting factors.

Plasma is about 93% H_2O, with the remaining 7% composed of dissolved or suspended solutes (6% organic substances and 1% inorganic substances). Plasma is obtained by collecting whole blood in a tube containing an anticoagulant that prevents blood clotting, such as ethylenediaminetetraacetic acid (EDTA), citrate, or heparin. Centrifugation is used to separate the blood into an upper plasma layer; a lower RBC layer; and a thin interface, the **buffy coat** that contains WBCs and platelets. When blood is allowed to clot or coagulate before centrifugation, the liquid remaining at the top of the tube is **serum**, which is now devoid of the soluble clotting factors that precipitated with the clot.

Plasma from a patient who has fasted overnight is a cloudy, pale, or grayish yellow liquid. If the blood is drawn shortly after a meal, it may appear milky, due to a high lipid or chylomicron content. Reddish samples are generally due to the presence of Hgb due to hemolysis of RBCs.

For many biochemical tests, plasma and serum can be used interchangeably. For some tests, only serum can be used because the clotting factors in plasma interfere with the assay. For coagulation tests, only plasma can be used because all clotting factors need to be present.

Plasma can be stored frozen below −20°C for future analysis, but it must be frozen within 6 to 8 hours after donation to preserve clotting factors. **Fresh frozen plasma** (**FFP**) can be stored in a blood bank for 1 to 7 years and can be used for therapeutic plasma exchange called **plasmapheresis**. FFP that is frozen after 6 and 24 hours of whole blood collection has a lower level of labile coagulation factors, such as factors V and VIII.

Analyzing blood samples reveals a patient's health status.

For most analyses, blood samples are drawn from a patient's arm vein (**venipuncture**). In newborns, blood is collected by a **heel stick**. Blood from an artery is collected mainly to measure arterial blood gases (i.e., O_2 and CO_2) and HCO_3^- to determine their levels related to lung function. Systemic arterial blood will be highest in the blood gases because it has not moved through the tissues where extraction of these gases takes place. For the same reason, arterial concentrations of drugs are higher than venous concentrations. For most other analyses, values from the arterial and venous sides are equal.

Blood is collected into evacuated collection tubes, designed to fill with a predetermined volume (typically 7 mL) of blood. The rubber stoppers are color-coded according to the additive present in the tube. Lavender-top tubes contain EDTA to bind Ca^{2+}, a critical component for blood clotting, and are used to produce plasma for hematology tests such as **complete blood counts** (**CBCs**) and blood typing. Light-blue tubes contain sodium citrate, an alternative anticoagulant, and are used for coagulation tests. Green tubes contain the anticoagulant heparin and are used to obtain plasma for a variety of clinical chemistry tests. Red tubes (serum separator tubes) contain clot activators and are used to produce serum.

Plasma contains ions, carbohydrates, lipid, and proteins.

Electrolytes are salts found in their dissociated form (ions) in the blood and are either negatively (**anions**) or positively (**cations**) charged. Ions are important for maintaining a normal osmotic balance in the plasma. In general, when the body needs to move water from one compartment to another, an electrolyte is transported under controlled conditions (often hormonally regulated) and water follows passively.

In plasma, Na^+ is the most abundant cation and Cl^- and HCO_3^- are the major anions. These three ions are the main osmotically active solutes in the extracellular fluid. Because electrolytes are the most easily transported substances between cellular compartments, their movement will directly impact osmotic water gain or loss. For example, a gain or loss of Na^+ will cause blood volume expansion or contraction, respectively, and can contribute to blood pressure. Other functions of electrolytes include their role in membrane excitability and pH regulation.

Like electrolytes, proteins also contain a net charge that is usually negative at physiological pH. Because of the principle of **electroneutrality** in blood plasma, the sum of positive charges equals the sum of negative charges.

Proteins are the most abundant organic components in the plasma. Almost 1,400 different *plasma proteins* accounting for 6 to 8 g of protein/dL of blood have been identified. The proteins function as enzymes, hormones, antibodies, and transporters as well as contribute to plasma osmolality and acid–base balance. Proteins in the blood form the **oncotic pressure**, also known as **colloidal osmotic pressure**. Because proteins do not diffuse across cell membranes, this component of the total osmotic pressure is relatively stable, whereas the osmotic pressure due to electrolytes is more changeable due to the ease of transport of these ions across cell membrane.

Albumins account for about 60% of the total plasma protein concentration, which makes these proteins a significant contributor the oncotic pressure. Albumin also serves as a nonspecific transport protein that noncovalently binds a variety of molecules including fatty acids, hormones, drugs, and other substances. Albumins are produced by the liver, and a low concentration in serum might indicate liver disease and/or malnutrition.

Globulins constitute about 36% of the total plasma proteins and are often subdivided into categories called **alpha** (**α**), **beta** (**β**), and **gamma** (**γ**) **globulins**. These designations are historical and arise from a now outdated technique of column chromatography, which separated the plasma membrane proteins by molecular weights. Because the categories separate proteins by size, each of the subdivisions represents multiple types of proteins. In general, the α and β globulins are proteins produced in the liver, whereas γ globulins are produced by cells of the immune system. The α and β globulin fractions contain specific transport proteins (e.g., metal-binding proteins, hormone-binding proteins, and lipid-binding proteins) and proteins involved in clot retraction. γ-Globulins are predominately antibodies produced by B lymphocytes (see Chapter 10).

Fibrinogens are large proteins synthesized in the liver that account for about 4% of the total plasma proteins. Fibrinogen is enzymatically cleaved by thrombin to yield the insoluble protein **fibrin**, which forms the fibrous, meshlike structure of a blood clot. *In vitro*, plasma depleted of fibrinogen will not coagulate. Higher fibrinogen levels are correlated with an increased risk of stroke.

The main **plasma lipids** are cholesterol, phospholipids, and triglycerides. Cholesterol is an important component of cell membranes as well as a precursor for steroid hormone synthesis. Phospholipids are used for building plasma membranes. Triglycerides are important for the transfer of food-derived energy

into cells. Because of their hydrophobic nature, plasma lipids are transported together with proteins.

Dietary triglycerides and dietary cholesterol are assembled into chylomicrons by the intestinal mucosa before they are released into the lymph and ultimately into the circulation (see Chapter 25). Triglycerides and cholesterol from the liver are packaged as **very-low-density lipoproteins** (**VLDLs**) and **intermediate-density** or **low-density** (**LDL**) **lipoproteins** that are released into the plasma for the delivery of lipids including cholesterol to other tissues. LDLs are absorbed by peripheral cells in which the cholesterol content of the lipoproteins is removed and used by the cells. The liver and small intestine also form and release **high-density lipoprotein** (**HDL**), which binds serum cholesterol and delivers it back to the liver, where it is passed from the body via bile (see Chapter 26).

The major **plasma carbohydrate** is glucose. Glucose is a primary energy source for all the body's cells and the sole source of energy for cells such as nerves and cardiac muscle cells. Serum glucose level is tightly regulated within 70 to 110 mg/dL (4 to 8 mmol/L), except for the time immediately following a meal. Hence, blood glucose tests are standardized in regard to food intake (e.g., fasting test and 2-hour postprandial test). When quantifying blood glucose, the serum must be promptly separated from the RBCs because they can utilize glucose in the absence of insulin.

Blood lipid profile helps determine a patient's cardiovascular disease risk.

A standard **blood lipid profile** includes values for total cholesterol, LDL, HDL, and total triglycerides. These profiles give important information about a patient's risk of developing heart-related conditions, with high LDL, low HDL, and/or high triglycerides being positive indicators of health risk. With high LDL (the form that takes cholesterol to tissues), the risk of cholesterol plaque buildup in arterial walls (**atherosclerosis**) is increased. Low HDL levels indicate decreased ability to remove excess cholesterol. Many people with obesity, heart disease, and/or diabetes also have high triglyceride levels. Several ratios, such as the LDL/HDL ratio and the total cholesterol/HDL ratio, are also used as risk predictors.

Basic and complete metabolic panels are indicators of metabolic health.

The **basic metabolic panel** (**BMP**) includes the analysis of glucose, Ca^{2+}, Na^{+}, K^{+}, CO_2 (or HCO_3^{-}), Cl^{-}, blood urea nitrogen (**BUN**), and creatinine. The latter two are metabolites that are filtered out of plasma by the kidneys, so their increase in plasma might indicate kidney dysfunction. Abnormalities in an **electrolyte panel** (i.e., electrolytes and HCO_3^{-}) commonly portend problems with fluid balance, such as edema or hypertension.

The **complete metabolic panel** (**CMP)** includes the tests of the BMP and the following components: albumin; total protein; bilirubin; and the liver enzymes alkaline phosphatase (ALP), alanine transaminase (ALT), and aspartate transaminase (AST). The latter four components are used to assess liver health and function. For instance, ALP is elevated in hepatitis, ALT is commonly increased with bile duct obstruction, and AST levels are used to monitor general liver damage. Bilirubin is a waste product of the liver, produced from RBC breakdown and recycling. Depending on its form (conjugated or unconjugated), bilirubin levels can be used to identify a problem that occurs before the liver (e.g., hemolytic anemia), a problem within the liver (e.g., cirrhosis), or a problem after the liver (e.g., bile duct blockage).

Abnormal serum protein patterns in electrophoresis reveal health problems.

Serum protein electrophoresis is a common method for separating blood proteins in a solid matrix (mostly cellular acetate) according to their size and charge (Fig. 9.1). Globular blood proteins (albumin, and α, β, and γ globulins) normally form five main peaks, or zones, on the matrix: albumin (59%), α_1-zone (4%), α_2-zone (7.5%), β-zone (12%), and γ-zone (17.5%). These zones might differ in size and/or pattern in a patient with certain types of anemias, during acute inflammation, or in the presence of an autoimmune disease. For instance, an increased β_1 peak is typical of iron deficiency anemia due to an increased level of the iron-binding protein transferrin. Another example is a largely increased γ-globulin peak observed in most patients with multiple myeloma due to the presence of proteins produced by abnormal plasma cells.

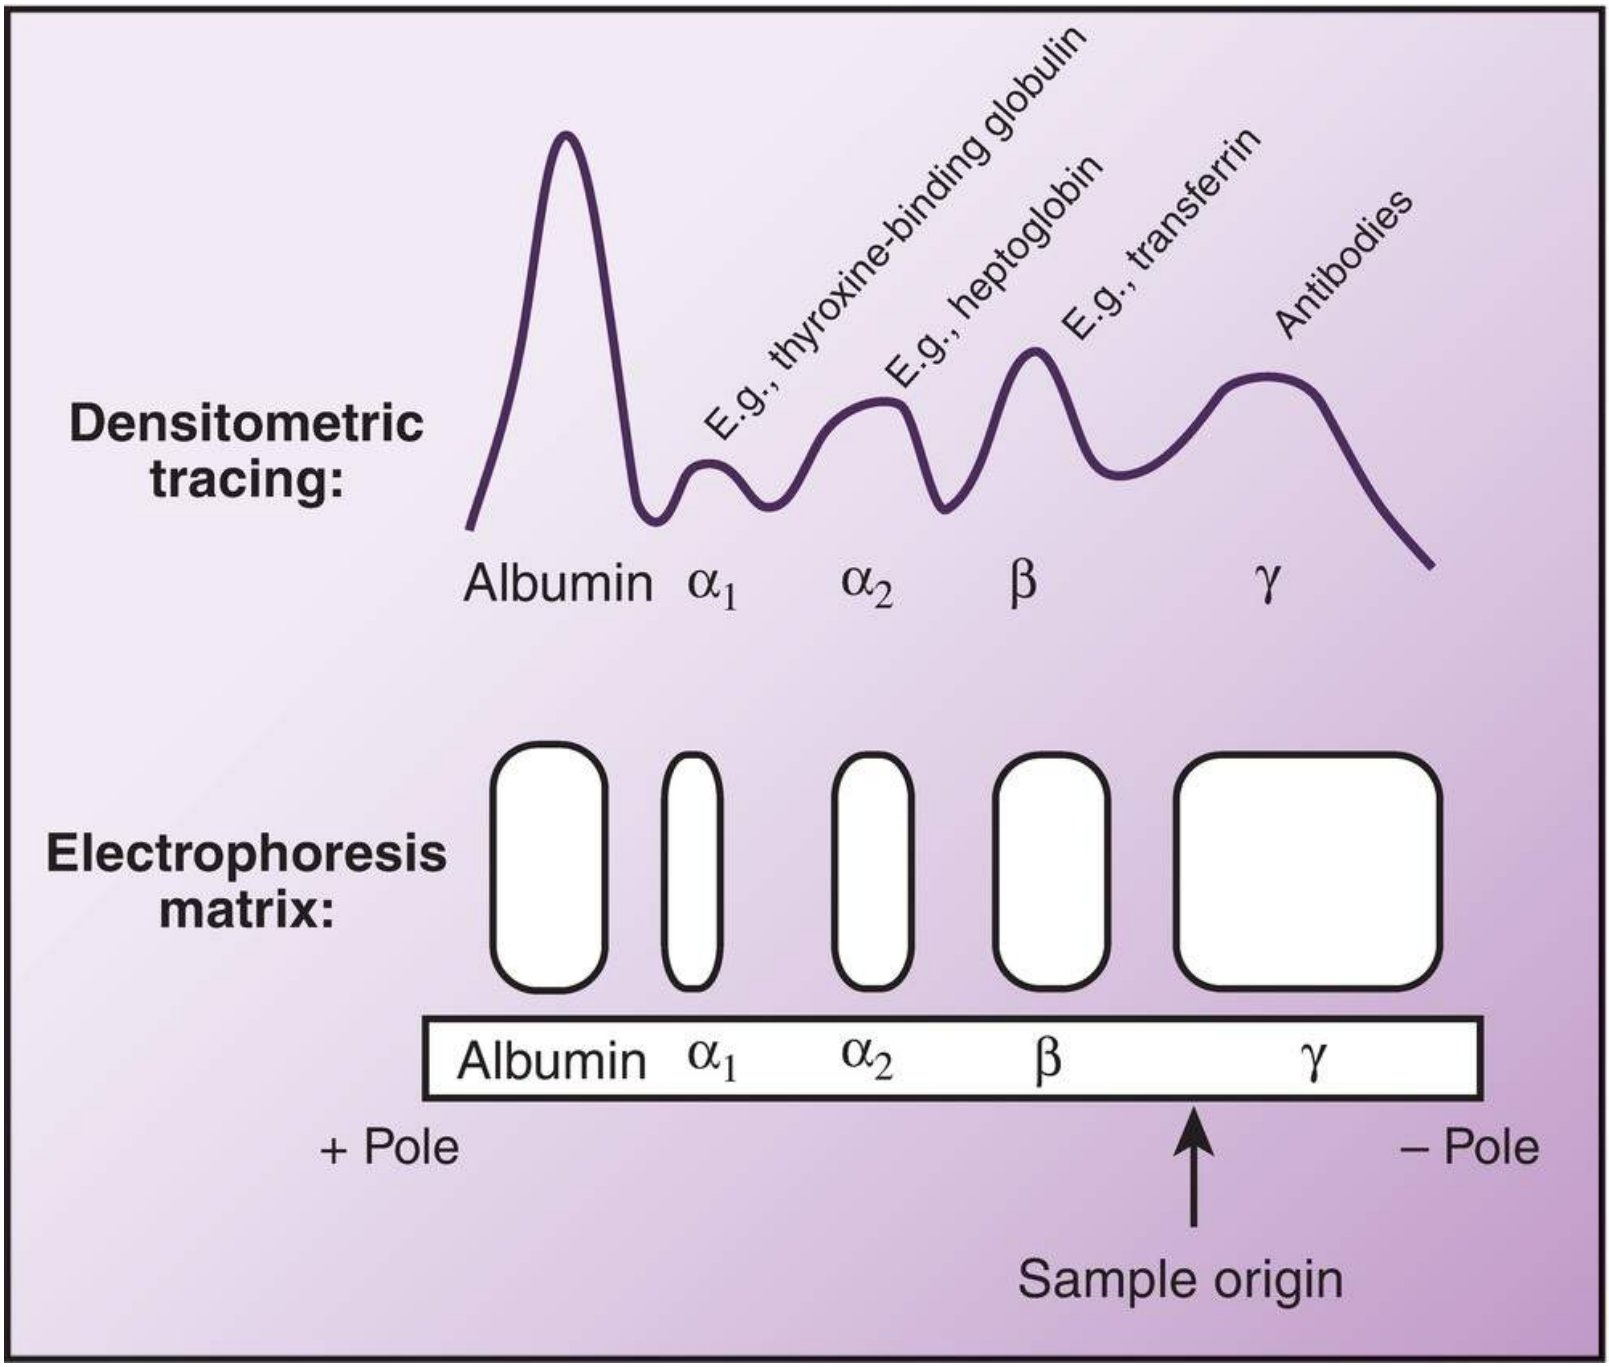

Figure 9.1 Serum protein electrophoresis. Globular serum proteins are electrophoretically separated on a matrix and stained. The intensity of the dye can be densitometrically quantified, and changes to the normal pattern are clinically relevant.

Immunologic assays detect and measure serum antigens and antibodies.

A wide variety of serum immunoassays are available in which a precipitation reaction occurs as a result of antibodies combining with a specific antigen. The detection and quantification of either antibodies or antigens are diagnostically valuable. For example, elevation of smooth muscle cell antibodies and antinuclear antibodies points toward autoimmune hepatitis. Elevation of gluten or antigliadin antibodies can be used to diagnose celiac disease. Abnormal antigens found on microorganisms can be detected by immunoassay and can often identify infected people before symptoms appear; alternatively, the presence of circulating antibodies to particular antigens can be used to determine if a recovered patient was infected with a particular microorganism.

In some cases, antigens interact with antibodies to produce large aggregates visible to the naked eye, for example, the instantaneously readable ABO-Rh blood typing test kits, in which the antigens on the surface of RBCs agglutinate with added antibodies. In most cases, however, the antigen–antibody complexes must be labeled for detection (e.g., dyes, fluorescent reagents, or radioactive isotopes).

The blood tests that are cited are meant to be neither an exclusive nor an exhaustive list. However, it is useful to remember that the blood is the conduit for moving both nutrients and waste products and is, therefore, where many of the aberrations of homeostasis will be expressed.

FORMED ELEMENTS OF BLOOD AND COMMON DIAGNOSTIC TESTS

As noted above, the formed elements of blood are RBCs (**erythrocytes**), WBCs (**leukocytes**), and platelets (**thrombocytes**) (Fig. 9.2). The term **formed elements** is used instead of cells because only the WBCs are truly cells. Each microliter of blood contains 4 to 6 million RBCs, 4,500 to 10,000 WBCs, and 150,000 to 400,000 thrombocytes.

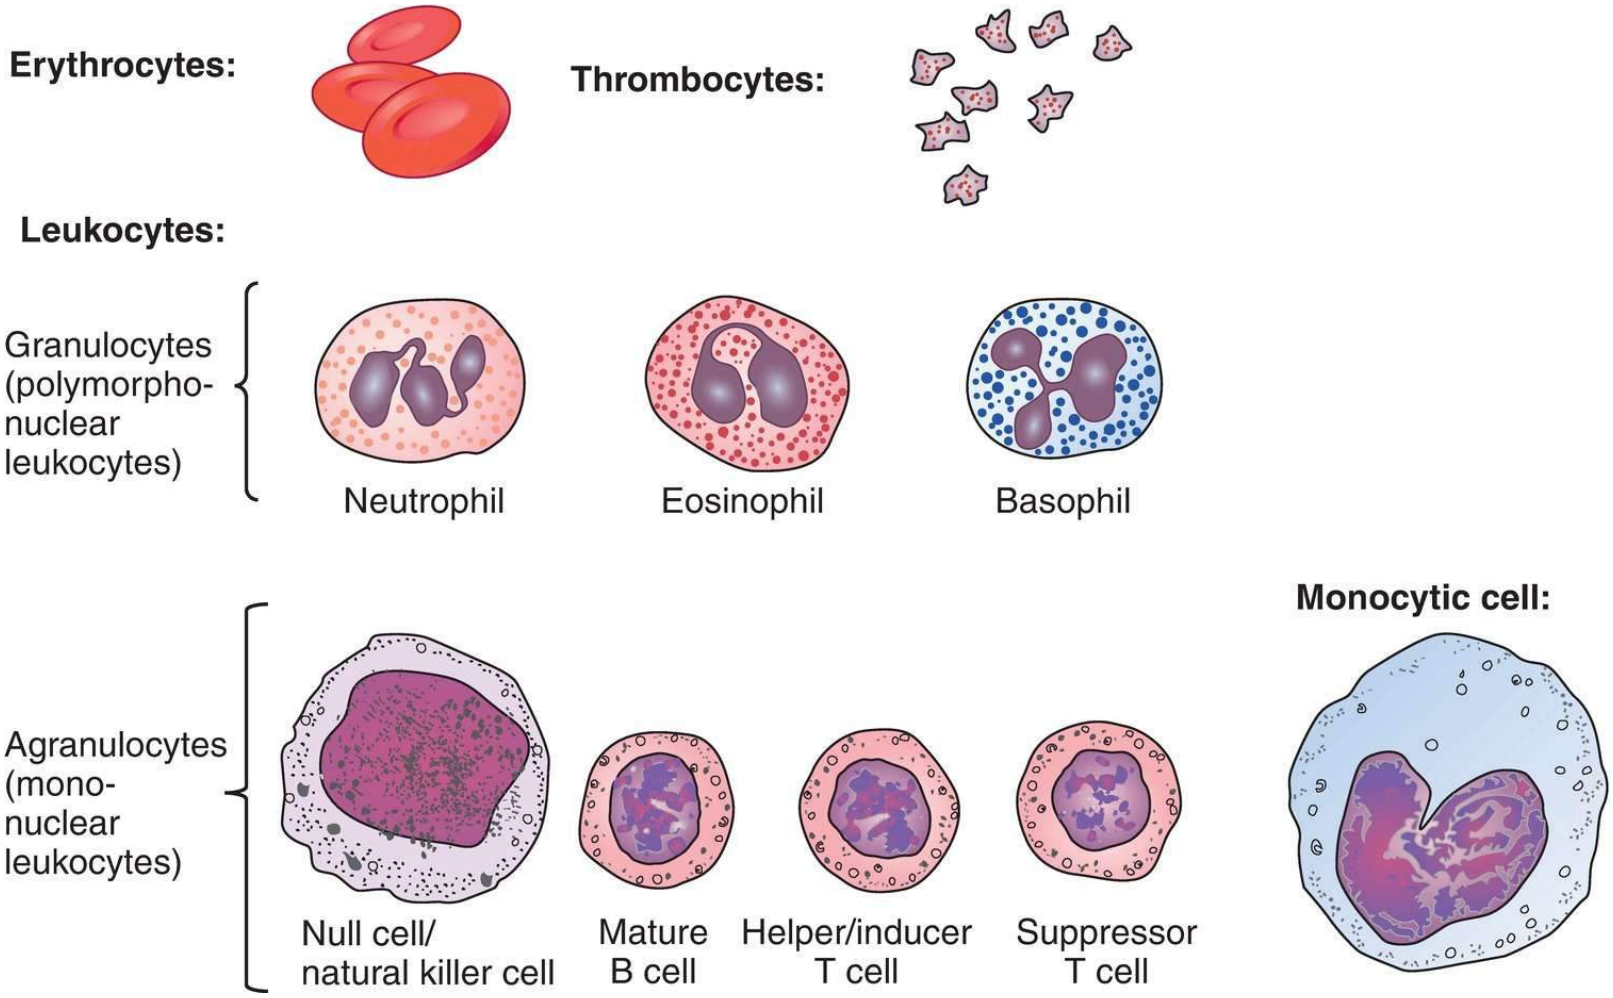

Figure 9.2 Formed elements of blood. This figure shows the size and appearance of cells and cell fragments (thrombocytes) found in the circulation.

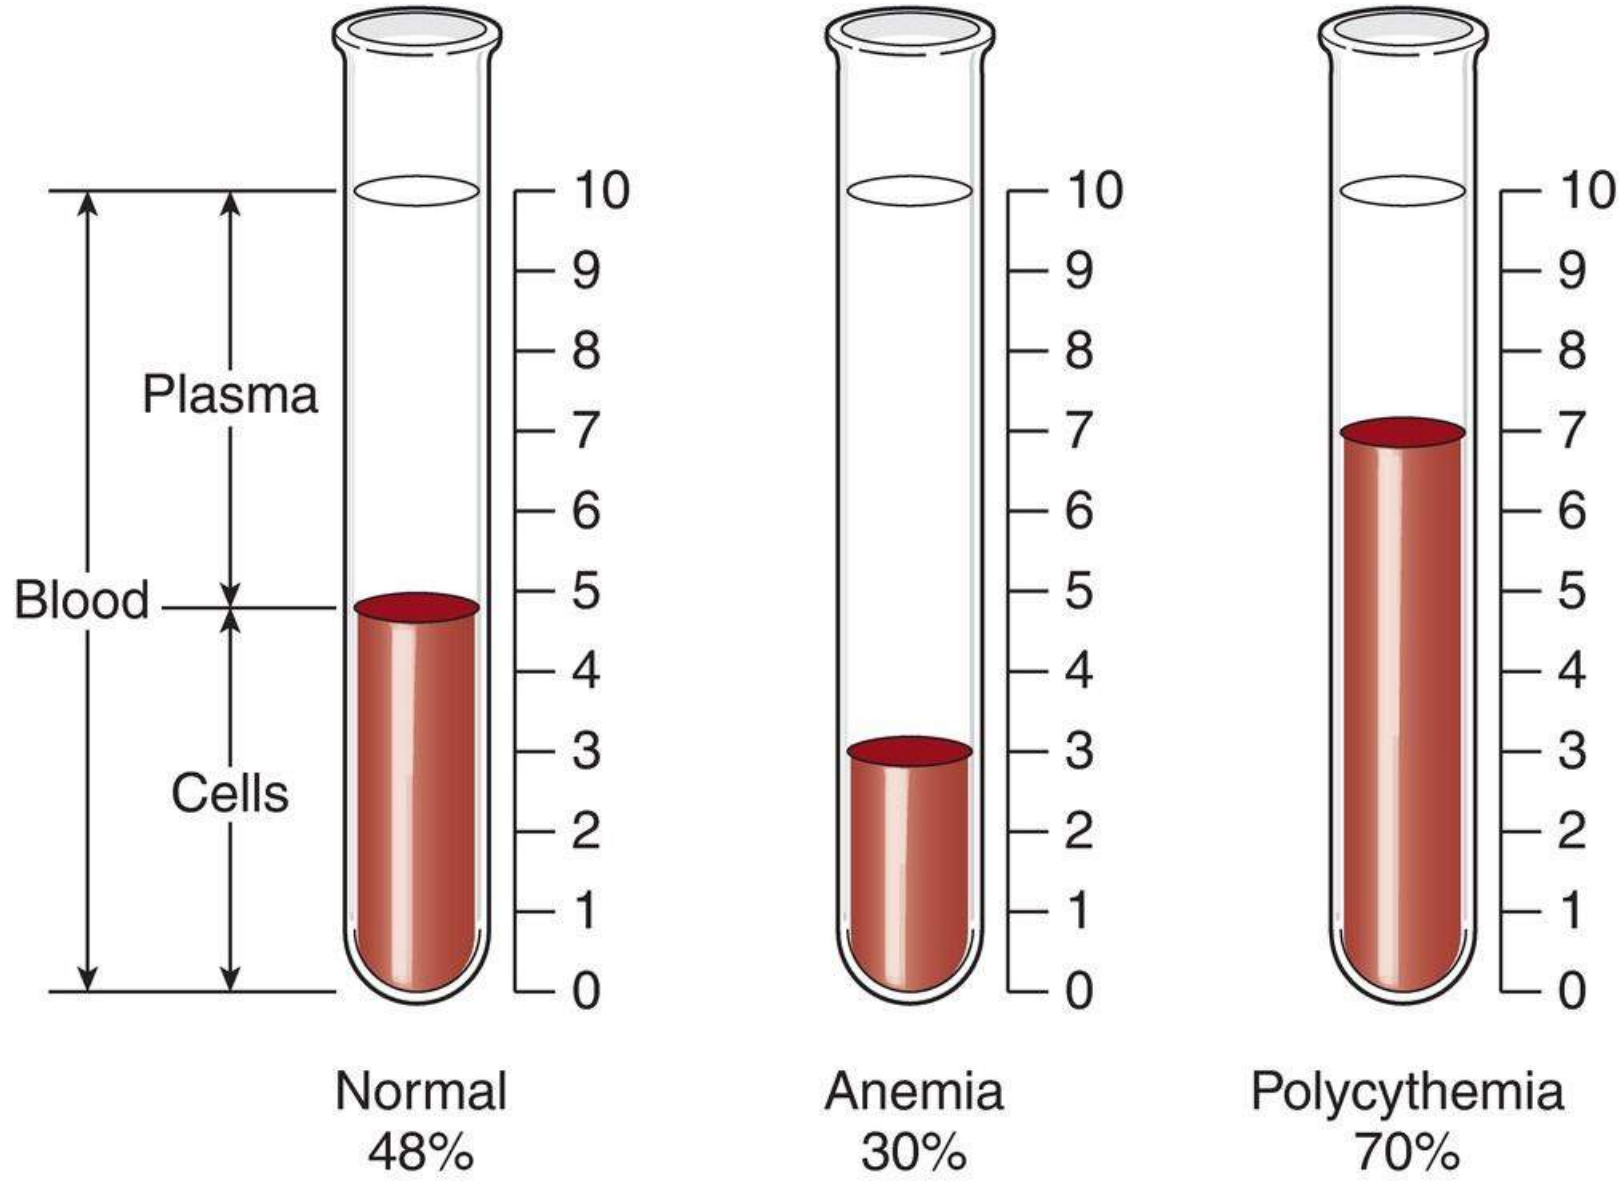
Blood is a viscous liquid.

The **viscosity** of blood, a measure of resistance to flow, is 3.5 to 5.5 times that of H_2O. The plasma viscosity is about 1.5 to 1.8 times that of H_2O. Blood viscosity increases or decreases as the total number of formed elements or plasma proteins changes. Pumping high-viscosity blood puts strain on the heart because a higher pressure is required to achieve tissue perfusion. High-viscosity blood also tends to coagulate more easily. In healthy people, a slight increase in the relative blood cell concentration and, hence, blood viscosity can occur (for instance, due to dehydration), but this is easily tolerated. However, in those with more viscous blood, such as the substantial increase in RBCs seen in patients with lung disease, the increase may lead to cardiovascular problems. Decreased blood viscosity is usually indicative of other serious health problems that cause a decrease in plasma proteins or formed elements. Because RBCs are the most abundant of the formed elements, a decrease in viscosity is often associated with anemias.

Hematocrits determine the amount of red blood cells.

The **hematocrit** (**Hct**) is the fraction of the total blood volume composed of RBCs and is a simple and important screening diagnostic procedure in the evaluation of hematologic disease. Hct can be determined by centrifugation of anticoagulated blood within small capillary tubes to separate blood cells from the plasma. A simple measurement of the RBC volume (length of RBCs in capillary tube) divided by the total length of the RBCs plus the plasma provides the percentage of RBCs (Fig. 9.3). Hct values have a relatively large normal range and vary somewhat between men and women (Table 9.2).



$$\text{Hematocrit \%} = \frac{\text{Red cell volume}}{\text{Whole blood volume}} \times 100$$

Normal hematocrit ratios	
Adult female	37%–47%
Adult male	42%–52%

Figure 9.3 The hematocrit. After centrifugation of whole blood, the relative amount of RBCs as a function of total blood volume is calculated as shown in the figure. Normal values differ slightly according to gender. Anemia that results from a loss of RBCs will result in a low hematocrit; various physiological or pathophysiological states that result in high RBC production will result in a high hematocrit (polycythemia).

TABLE 9.2 Complete Blood Count

Abbreviation	Test	Reference Range	Standardized International Reference	Significance (Examples)
RBC	Red blood cells			
	Men	4.3–5.9 × 10^6/μL	4.3–5.9 × 10^{12}/L	
	Women	3.5–5.5 × 10^6/μL	3.5–5.5 × 10^{12}/L	
Hgb or Hb	Hemoglobin			↓: anemia, severe bleeding
	Men	13.5–17.5 g/dL	2.09–2.71 mmol/L	↑: too many made, fluid loss, polycythemia
	Women	12–16 g/dL	1.86–2.48 mmol/L	
Hct or Ht	Hematocrit			
	Men	41%–53%	0.41–0.53	
	Women	36%–46%	0.36–0.46	
MCV	Mean cell volume	80–100 μm^3	80–100 fL	↓: iron deficiency, thalassemia
MCH	Mean cell hemoglobin	25.4–34.6 pg/cell	0.39–0.54 fmol/cell	↑: B12 and folate deficiency (MCH variable)
MCHC	Mean cell hemoglobin concentration	31%–36% Hb/cell	4.81–5.58 mmol Hb/L	↓: deficient Hgb synthesis
				↑: spherocytosis

A decreased Hct indicates **anemia** that can arise from deficiencies in RBC production or premature RBC lysis. Immediately after hemorrhage, the Hct does not change because cells and plasma are lost in equal proportions.

Increased Hct values indicate **polycythemia** and may result from either an increase in the rate of production or a decrease in the rate of destruction of RBCs. For example, respiratory disease can cause polycythemia because the lack of O_2 due to the compromised gas exchange signals the synthesis of additional RBCs. Dehydration, which decreases the H_2O content and thus the volume of plasma, also results in an increased Hct.

Complete blood counts determine the number and type of cells in the blood.

The complete blood count (CBC) includes the following tests, which are summarized in Table 9.2: RBC count, Hgb, Hct, and RBC indices; total WBC count and differential WBC count; and platelet count and mean platelet volume. The cell counts can be given as absolute values or as percentages. In Table 9.2, the reference values of a healthy adult are given both in commonly used and in standardized international (SI) units. The values vary slightly with age, sex, and physiologic condition (e.g., pregnancy and elevation above sea level).

In evaluating patients for hematologic diseases, it is important to determine the total number of circulating RBCs and the Hgb concentration in the blood. This information is used to determine whether the patient is anemic. The Hct can only be used to determine anemia when fluid status is taken into account. With a given RBC count, Hgb, and Hct, several other important **blood indices** can be derived.

CLINICAL FOCUS 9.1

Blood Group Systems

The blood types A, B, AB, and O are based on the presence or absence of distinct antigens A or B on red blood cells. People with red blood cells that are covered with A or B molecules are said to have *type A* blood or *type B* blood, respectively. If both molecules, A and B, are present, the blood is *type AB*; if neither is present, it is called *type O*.

Knowing about a person's blood type is important for blood transfusions. Inappropriate combinations between the blood groups of the recipient and the donor can lead to potentially fatal agglutination, because the recipient's immune system will have antibodies against the donor's red blood cells. Agglutination of red blood cells may lead to improper blood circulation, release of hemoglobin (Hgb) that crystallizes, and eventually, kidney failure.

People have antibodies of the immunoglobulin (Ig) M class directed against the antigens that are not on their red blood cells. Therefore, someone with an A blood type will have anti-B antibodies; someone with B blood type will have anti-A antibodies and someone with O blood type will have antibodies to both A and B. Consequently, a person with type A blood can receive type A or O, not type B or AB blood. Correspondingly, a person with type B can receive type B or O blood. Those with AB blood can receive blood from anyone and are, therefore, **universal recipients**. Type O persons can receive blood from a type O person only but can donate to all groups and are, thus, called **universal donors**.

Blood type can further be useful for a person's identification, such as in forensic medicine and for the identification of family relationships in disputed parentage. The latter is possible because the blood type of the child is related to that of the parents. For instance, if the mother and the child have type O blood, the father's blood type must be A, B, or O. If the mother has type O blood, but the child presents with type B blood, the father's blood type must be B or AB.

In the United States, type O blood is most common, followed by types A, B, and AB, in this order. Because blood groups are genetically determined, the frequency of the ABO blood groups varies in populations throughout the world, even in different groups within a given country. Most likely, these differences will gradually disappear because of increased mobility and a greater societal acceptance of interracial marriages. In the United States, whites are currently characterized by a higher frequency of type A and a lower frequency of type B in comparison with African and Asian Americans, whereas Indians have a low frequency of both A and B types.

The blood type of a person is unrelated to his or her Hgb type because blood antigens are membrane factors, whereas Hgb is dissolved within the cell cytoplasm.

The other blood group system that is often grouped with the ABO system involves **Rhesus factors** (**Rh**), which are unique cell surface proteins. The Rh system is complex, involving three genes producing Rh antigens C, D, and E. Rh D, the most important, is found in the blood of 85% of people, who are classified as Rh^+ (Rhesus positive). The remaining 15% are said to be Rh^- (Rhesus negative).

Knowing about the Rh factor is important in pregnant women because a baby's life can be endangered if it inherits Rh^+ blood from its father but the mother is Rh^-. Late in pregnancy, or at parturition, the baby's blood may cross to the mother's system, where the erythrocytes are recognized as foreign and antibodies are formed against them. These antibodies pose a serious threat to any future Rh^+ babies of hers in following pregnancies. To prevent this, the mother receives anti-Rhesus D immunoglobulin around the 28th week of pregnancy and right after delivery. The Ig attaches to Rh^+ cells from the baby in the mother's bloodstream and destroys them, preventing the triggers for the mother's immune system to produce its own anti-D antibody.

Similar problems of incompatibility between mother and child generally do not exist for the ABO blood groups because the antibodies formed belong to the IgM class and cannot cross the placenta. In rare cases, however, a type O mother with a fetus that is A, B, or AB can deliver a newborn with signs of immunologic defense reactions such as jaundice, anemia, and elevated bilirubin levels. Because of these complications, all pregnant women are advised to determine their ABO/Rh blood type during their first prenatal visit. ■

The **mean corpuscular** (or **cell**) **volume** (**MCV**) is the index most often used, because it reflects the average volume of each RBC. It is calculated as follows:

$$\text{MCV} = \frac{\text{Hematocrit}}{\text{RBC (cells/L)}} \quad (1)$$

Cells of normal size are described as **normocytic**, cells with a low MCV are **microcytic**, and those with a high MCV are **macrocytic**.

The **mean corpuscular** (or **cell**) **hemoglobin** (**MCH**) value is an estimate of the average Hgb content of each RBC. It is derived as follows:

$$MCH = \frac{\text{Blood hemoglobin (g/L)}}{\text{RBC (cells/L)}} \quad (2)$$

MCH values usually rise or fall as the MCV is increased or decreased. The MCH is also often related to the **mean corpuscular** (or **cell**) **hemoglobin concentration** (**MCHC**) because the RBC count is usually related to the Hct. Exceptions to this rule yield important diagnostic clues.

The MCHC provides an index of the average Hgb content in the mass of circulating RBCs. It is calculated as follows:

$$MCHC = \frac{\text{Blood hemoglobin (g/L)}}{\text{Hematocrit}} = \frac{MCH}{MCV} \quad (3)$$

Low MCHC indicates deficient Hgb synthesis, and the cells are described as **hypochromic**. High MCHC values are rare because, normally, the Hgb concentration is close to the saturation point in RBCs.

The **red cell distribution width** (**RDW**) measures the degree of the average size dispersion of RBCs, thereby indicating the degree of **anisocytosis** (variation in RBC size).

The **oxygen-carrying capacity** (**OCC**) is the maximum amount of O_2 that can be carried by the Hgb contained in 1 dL (100 mL) of blood. Each gram of Hgb can combine with and transport 1.34 mL of O_2, which is equal to 20 ml of O_2 per dL under ideal conditions. The actual measured value will vary with the total Hgb, which is why anemia can lead to severe hypoxemia.

The **white blood cell count** (**WBCC**) measures the concentration of leukocytes in blood. A high WBCC is called **leukocytosis** and occurs in infection, allergy, systemic illness, inflammation, tissue injury, and leukemia. A low WBCC is called **leukopenia** and can be present in some viral infections, immunodeficiency states, and bone marrow failures. The WBCC is often used to monitor a patient's recovery from illness.

For diagnostic purposes, a **differential white blood count** (**diff**) will determine which type of WBC is affected. This information provides invaluable clues to the type of illness but also requires careful analysis. Unlike for RBCs, there are various storage pools for WBCs outside of blood, such as the spleen, lymph nodes, and lymphoid tissues. Therefore, changes in blood concentrations indicate changes in the storage pool equilibrium. Second, the number and percentage of WBCs vary somewhat with age. Newborns have a high WBCC for the first weeks after birth with a high percentage of **neutrophils**. In childhood, **lymphocytes** are predominant, whereas, at senescence, total WBCC might be decreased. Last, the CBC provides a **platelet count** (**PltC**), which is used as a starting point in the diagnosis of disorders of hemostasis. Decreased PltsC may be the result of bone marrow failure or of peripheral platelet

destruction.

Blood smears detect blood parasites and other hematologic disorders.

A visual analysis of the blood cells in a **blood smear** can validate any cellular abnormalities or determine the presence of certain microorganisms. Light microscopic analysis allows the differentiation of WBCs according to their morphologic appearance and staining characteristics and the identification of immature cells, so-called **band cells**. A blood smear analysis will reveal the characteristic “sickle” shapes of RBCs, which occur in sickle cell anemia and changes in the appearance of the cytoplasm of RBCs infected with parasites such as those that cause malaria.

Blood smears are commonly stained with a polychrome stain such as **Wright-Giemsa** after fixing the cells with methanol. The orange **eosin** dye stains the basic components of the cell, such as the granules of eosinophils and the Hgb of RBCs. The **methylene blue** dye stains the acid components of the cell, such as the DNA and RNA. Many other stains are available.

A **relative WBC count** indicates which individual cell type is expanded relative to the other types of cells and aids in disease diagnosis. The numbers of particular types of WBCs will change in response to infection, allergic reactions, inflammation, and certain cancers such as leukemia. **Leukopenia** indicates an inadequate number of WBCs, whereas **leukocytosis** refers to high numbers of WBCs.

RED BLOOD CELLS

RBCs are the most abundant of the formed elements and are the principle means of delivering O_2 to cells via the circulatory system. The cell's cytoplasm is rich in Hgb, an iron-containing biomolecule that readily binds with O_2. Mammalian mature RBCs are unique among those of vertebrates because they lack a nucleus and most organelles. RBCs are produced in the red bone marrow and circulate for about 100 to 120 days before being recycled by macrophages.

Erythrocytes consist mainly of hemoglobin, a unique pigment containing heme groups in which iron atoms bind to oxygen.

Mature RBCs have the shape of flexible biconcave disks, with a diameter of about 7 μm and a maximum thickness of 2.5 μm (Fig. 9.4). This form maximizes the amount of surface area available for gas exchange. Hgb within the RBCs is responsible for binding and transporting 99% of the O_2 need by the tissues. The other 1% is dissolved in the plasma.

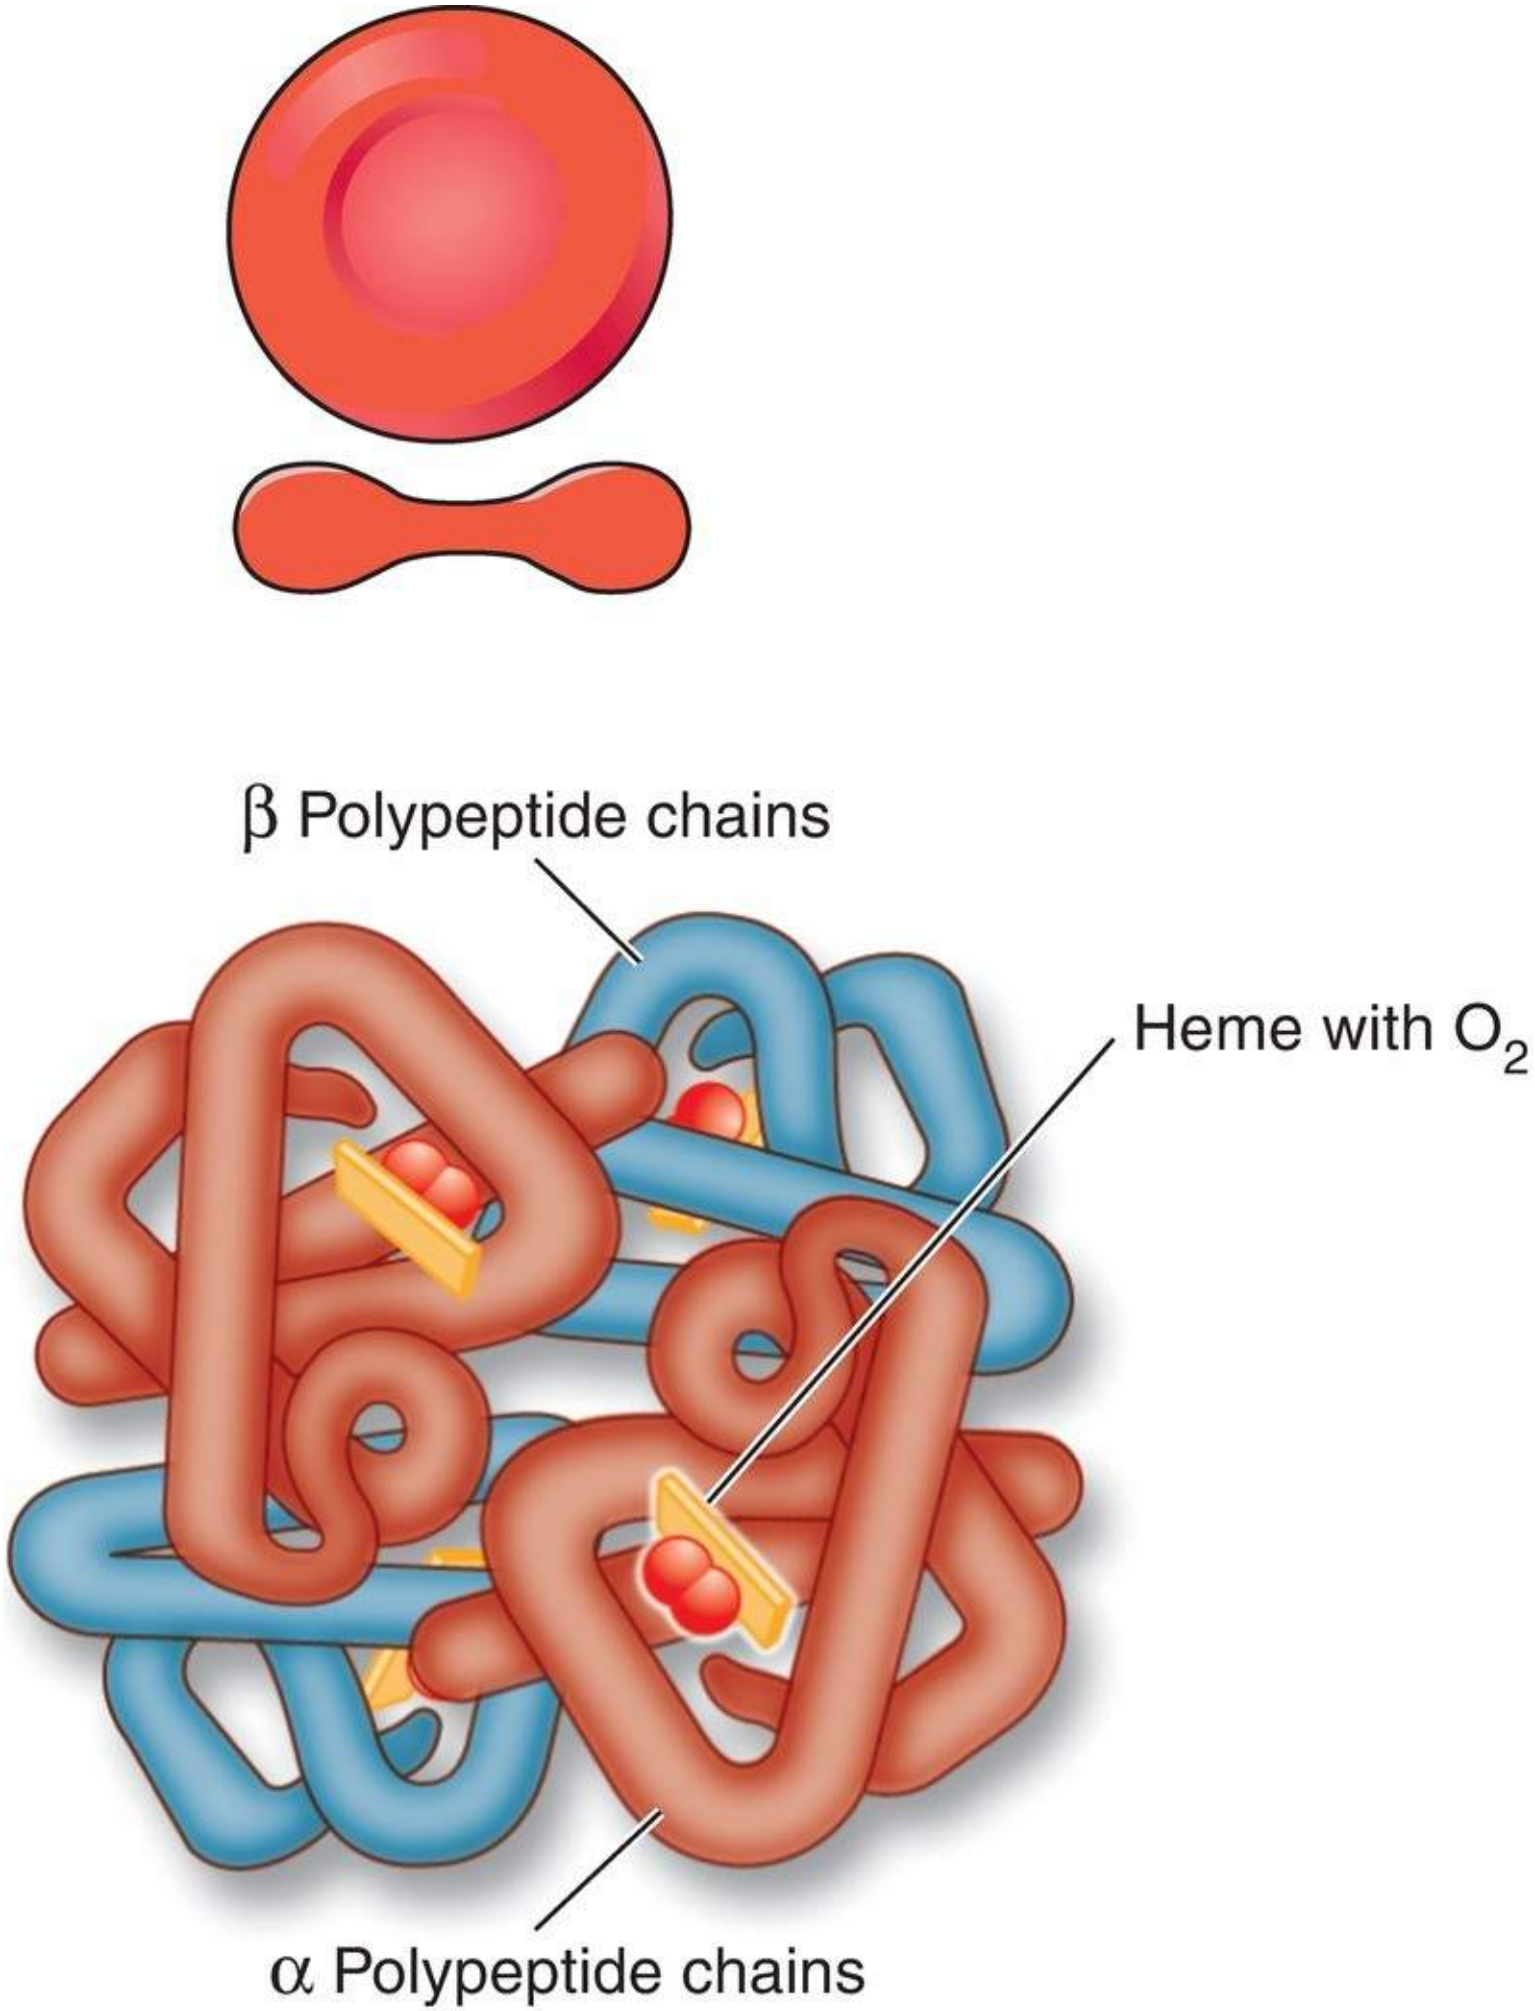


Figure 9.4 Structure of hemoglobin A. Erythrocytes have the shape of biconcave disks, with a diameter of

about 7 μm and a maximum thickness of 2.5 μm. They contain several hundreds of hemoglobin molecules, each consisting of four polypeptide chains (two α and two β), with each chain containing iron bound to its heme group.

(Modified from McArdle WD, Katch FI, Katch VL. *Essentials of Exercise Physiology*. Baltimore, MA: Lippincott Williams & Wilkins, 2005.)

Each RBC contains several hundred Hgb molecules of about 64,500 daltons consisting of four globin polypeptides and four heme groups, the iron-carrying portion. These polypeptide chains contain two α-globin molecules and two molecules of another type of globin chain (β, γ, δ, or ε). Four types of mature Hgb molecules, designated by their polypeptide composition, can be found in human RBCs. The most prevalent in adults is HbA (see Fig. 9.4) consisting of two α and two β polypeptide chains ($\alpha_2\beta_2$). HbA_2, which makes up about 1.5% to 3% of total adult Hgb, has the subunit formula $\alpha_2\delta_2$. **Embryonic hemoglobin** (**EH**) is present in RBCs during early human development. It consists of two α chains and two ε chains ($\alpha_{2\varepsilon 2}$). The production of ε chains ceases at about the 3rd month of fetal development. **Fetal hemoglobin** (**FH**) (also known as **hemoglobin F** or $\boldsymbol{\alpha_2\gamma_2}$) replaces EH and is the major Hgb component during intrauterine life. Both EH and FH have higher O_2-binding affinity to assure proper O_2 levels for the fetus within the uterine environment. FH levels in circulating RBCs decrease rapidly during infancy but are maintained at a concentration of ~0.5% in adults.

The production of each type of globin chain is controlled by individual structural genes with five different loci. Mutations can occur anywhere in the five gene loci resulting in the production of abnormal Hgb molecules leading to **hemoglobinopathies**. The most common of this spectrum of diseases is sickle cell anemia, which is caused by a point mutation (single amino acid substitution) in the β-globin chain. Another relatively well-known type of hemoglobinopathies is the thalassemias. These fall into two types, the α and β thalassemias named for the globin chain containing the mutation.

Each globin chain is bound to a heme group, which is a complex porphyrin ring containing a central iron atom (see Fig. 9.4). O_2 binds to the iron forming **oxyhemoglobin** (**HbO_2**), the O_2-saturated form of Hgb, which transports O_2 from the lungs to tissues. When the O_2 is released to the tissues, HbO_2 becomes reduced hemoglobin (**deoxyhemoglobin**).

The reduced hemoglobin has an increased affinity for carbon dioxide, which reversibly binds the α and β chains to remove this waste product of metabolism from the tissues. However, only a minor portion of the CO_2 is removed in this way. In the tissues, the removal of CO_2 takes place via three mechanisms. Approximately 5% to 7% is bound to plasma proteins, 10% to 15% binds to Hgb, and the remainder is converted into H_2CO_3. CO_2 diffuses into RBCs and is converted to H_2CO_3 by carbonic anhydrase. It then freely dissociates into HCO_3^- and H^+. The H^+ ions are buffered by Hgb, and, in this way, erythrocytes also play a major role in maintaining blood pH. Hgb also acts as a buffer by ionizing the imidazole ring of histidines in the protein.

Carbon monoxide (**CO**) can rapidly replace O_2 in HbO_2, forming the almost irreversible binding, which accounts for the asphyxiating properties of CO. Nitrates and certain other chemicals oxidize the iron in Hgb from the ferrous (Fe^{+2}) to the ferric state (Fe^{+3}), resulting in the formation of **methemoglobin** (**metHb**). The O_2 carried by MetHb is so tightly bound to ferric iron that it is not released to the tissues and is, therefore, useless in respiration.

Cyanosis, the dark-blue coloration of skin associated with **anoxia**, becomes evident when the

concentration of reduced hemoglobin exceeds 5 g/dL. If the condition is caused only by a diminished O_2 supply it is reversible by the administration of O_2, but if it is caused by the accumulation of stabilized metHb, then administration of O_2 alone will not be effective.

Changes in erythrocyte morphology provide insights into specific blood disorders.

The RBC membrane is attached to a complex skeleton of fibrous intracellular proteins. This structural arrangement gives the cell stability and its unique shape, while providing the flexibility necessary to move through small, curved vessels such as capillary beds. Changes in RBC composition may lead to morphologic changes, which can provide valuable clinical information regarding the nature of the pathology (Fig. 9.5).

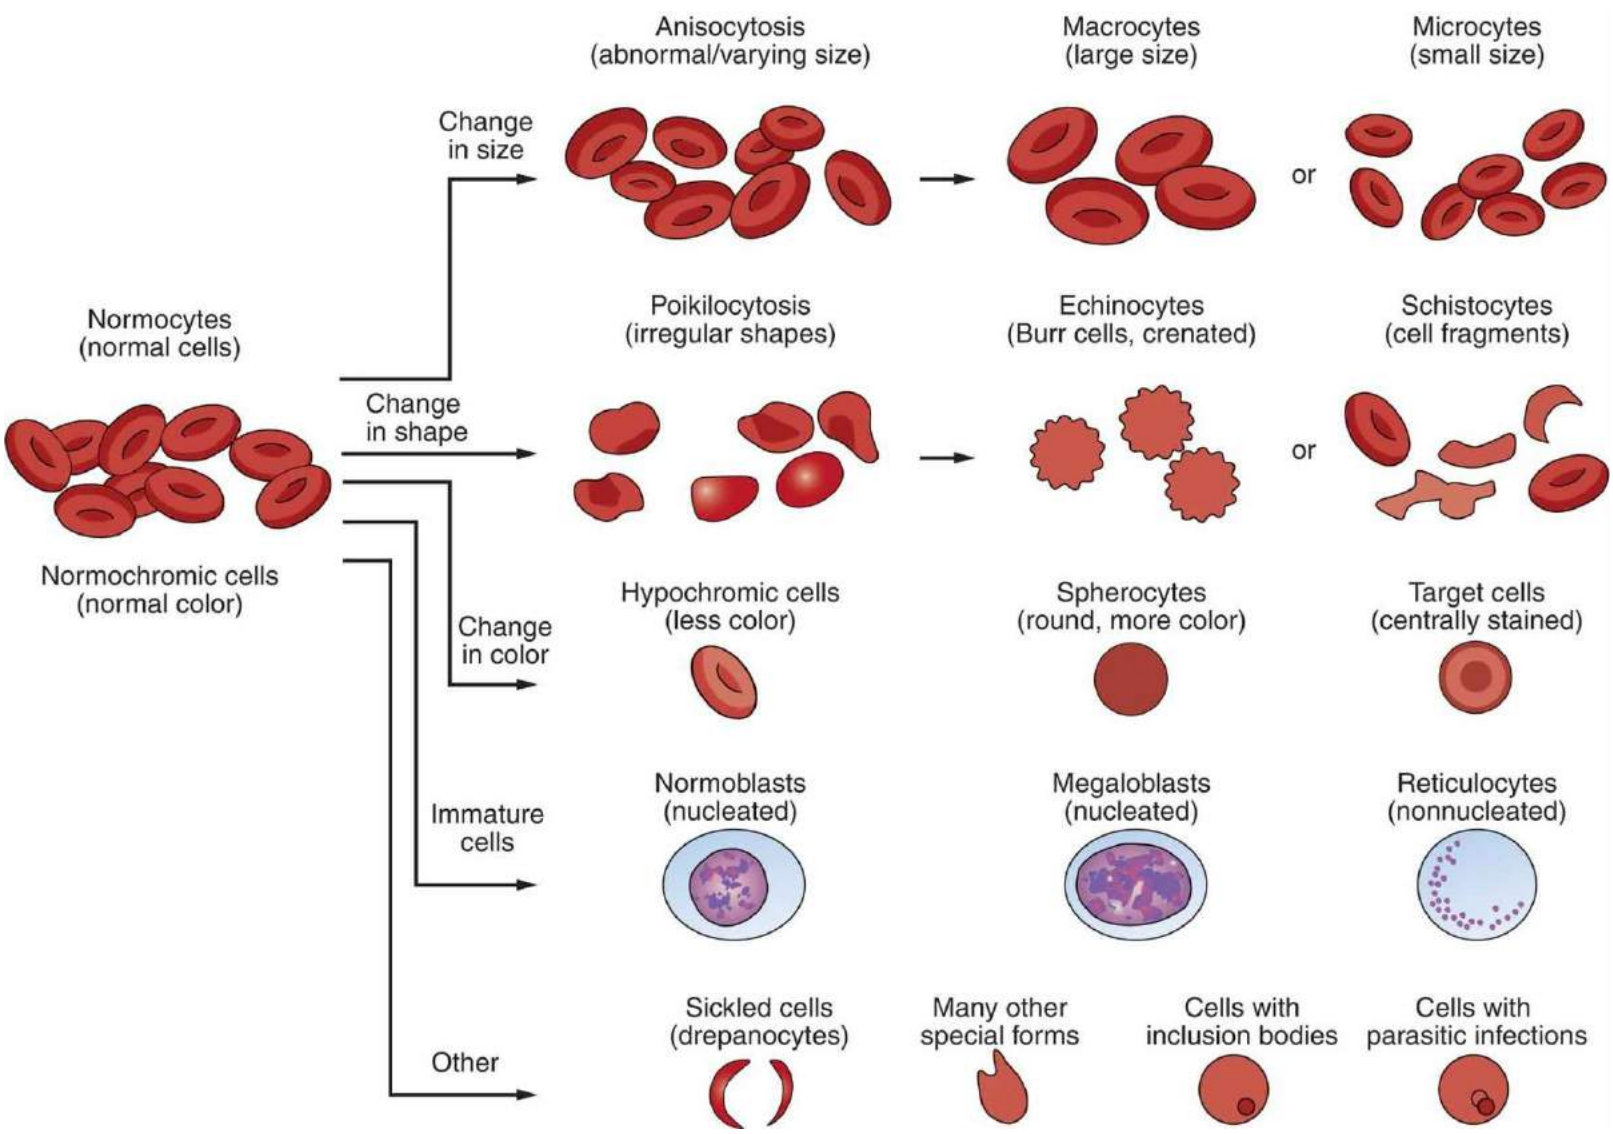

Figure 9.5 Pathological changes in erythrocyte morphology. This synopsis of erythrocyte abnormalities presents a variety of possible deviations that are helpful for the diagnosis of anemias and other diseases.

Changes in size and shape

Large variation in the size of RBCs is referred to as **anisocytosis**. Larger-than-normal RBCs are termed **macrocytes**; smaller-than-normal RBCs are referred to as **microcytes**. Irregularly shaped RBCs are referred to as **poikilocytes**. **Echinocytes**, or **Burr cells**, are spiked RBCs generated by alterations in the plasma environment. **Schistocytes** are fragments of RBCs damaged during blood flow through abnormal blood vessels or cardiac prostheses.

Changes in color

Abnormal Hgb content of RBCs may lead to changes in the staining pattern of cells observed on stained, dried films. Normal cells appear red-orange throughout, with a slight central pallor as a result of the cell shape (**normochromic**). **Hypochromic** cells appear pale with only a ring of deeply colored Hgb on the periphery. Other pathologic variations in RBC appearance include **spherocytes**, small, densely staining cells with a loss of biconcavity due to membrane abnormalities, and **target cells** (also known as *codocytes* or *leptocytes*), which are cells with a densely staining central area and a pale surrounding area. Target cells are observed in liver disease and after splenectomy.

Immaturity

Normal mature RBCs do not have cell nuclei, and, therefore, the presence of nucleated RBCs in peripheral blood is of diagnostic significance. An immature form of RBCs that still has its nucleus, the **normoblast**, is found predominately in the red bone marrow (see Fig. 9.8) but is seen in the blood in several types of anemias, especially when the marrow is actively responding to a demand for new RBCs. In seriously ill patients, the appearance of normoblasts in peripheral blood is a grave prognostic sign preceding death, often by several hours. Another nucleated RBC, the **megaloblast**, is unusually large due to delayed nuclear maturation and cell division. Megaloblasts are seen in peripheral blood in pernicious anemia and folic acid deficiency. **Reticulocytes** are immature cells that have shed their nucleus but still retain residual nuclear material that can be made visible with a specific vital stain. A small amount of these normal RBC precursors is found in the blood. However, an increase in the percentage of reticulocytes is an indicator that the level of **erythropoiesis** (RBC formation) in bone marrow has increased. For instance, if a patient is anemic or has had a recent hemorrhage and the bone marrow is functioning properly, the reticulocyte count will be elevated.

Other changes

There is an abundance of other RBC abnormalities, which may result from hemoglobinopathies (e.g., **drepanocytes**, or sickled cells), liver diseases (e.g., **stomatocytes**, or mouth cells), and hematopoiesis outside the bone marrow cavity (e.g., **dacryocytes**, or teardrop cells). Cells may contain **protein inclusion bodies** from abnormal Hgb precipitation, lead poisoning, or abnormal erythropoiesis. Four species of the protist genus *Plasmodium* are able to infect human RBCs and cause malaria. Another protist genus, *Babesia*, causes malaria-like symptoms. Both *Plasmodium* and *Babesia* infections can be diagnosed by observing the characteristic appearance of the cytoplasm of RBCs from infected individuals.

Red blood cell components are recycled.

Following their release from the bone marrow, RBCs circulate in the blood for about 120 days before they become senescent and die. To maintain homeostasis under normal conditions, about 200 billion replacement RBCs are made daily, and this can be increased several-fold under conditions of RBC loss. Some of the old cells break up in the bloodstream, causing **hemolysis**, but the majority are engulfed by macrophages of the liver, spleen, and bone marrow. This phagocytic process initiates the recycling of important components of the RBCs including iron and protein.

Hgb released from hemolyzed RBCs binds to proteins such as **haptoglobin** or **hemopexin**, which are cleared from the circulation by macrophages in the liver. Hgb from RBCs that are engulfed by macrophages is broken down into globin and heme within the phagocytic cells. The globin portion is catabolized by proteases into constituent amino acids that are reused for protein synthesis. Heme is broken down into free iron, and the components of the **porphyrin** ring surrounding the iron are first metabolized to **biliverdin**, a green substance that is further reduced to **bilirubin**. Bilirubin is then carried by albumin to the liver, where it is chemically conjugated to glucuronide before it is excreted in the bile.

Unconjugated and conjugated bilirubin is measured clinically to detect and monitor liver or gallbladder dysfunction. Blood samples with high bilirubin are said to be **icteric**, which is evident as a yellow-green tint and increased stickiness. Those with icteric blood develop jaundice. The yellow coloration that is characteristic of jaundice can be seen in the skin, particularly under the fingernails. The increase in bilirubin to a level that can be visually detected is a serious situation because a high level of bilirubin that is not bound to plasma proteins is neurotoxic.

Most of the iron in the body is involved in RBC production, so it is carefully reclaimed during RBC turnover. Free iron is toxic, so, in the blood, iron is transported bound to the protein **transferrin**. Cells that need iron possess membrane receptors to which transferrin binds and is then internalized. Inside the cell, the ferric iron is released and either incorporated into new heme or stored, predominately in the liver, bound to **ferritin**. Although iron recycling is efficient, small amounts are continuously lost and must be replenished by dietary intake. In women, iron loss is increased during menstrual bleeding. The majority of iron in the diet is derived from heme in meat (*organic iron*), but iron can also be provided by the absorption of *inorganic iron* (mainly Fe^{2+}, some Fe^{3+}) by intestinal epithelial cells.

Iron profile evaluates iron stores of the body.

To sufficiently differentiate between iron deficiency anemias and the anemia of inflammation as well as to diagnose iron overload, an **iron profile** is analyzed (Table 9.3). **Serum iron levels** ("iron" for short) are measured with a simple colorimetric method. However, the body's iron stores are better represented by *ferritin* levels, which are measured by radioimmunoassays or enzyme immunoassays. **Total iron-binding capacity** (**TIBC**) is the amount of iron needed to bind to all iron-binding proteins. Because *transferrin* represents the largest quantity of iron-binding proteins, TIBC is an indirect assessment of the amount of transferrin present. The **unsaturated iron-binding capacity** (**UIBC**) is the calculated amount of transferrin that is not occupied by iron. UIBC equals TIBC minus iron. Last, the **transferrin saturation** is calculated as the ratio of serum iron and TIBC values and is expressed as a percentage. Thus, it indicates the percentage of transferrin with iron bound to it, which is 20% to 40% in healthy people. In addition to serum analyses, bone marrow aspiration and biopsies are helpful to determine total body iron stores.

TABLE 9.3 Iron Profile

Name	Reference Range	Standardized International Reference	Description
Iron	50–170 µg/dL	9–30 µmol/L	Amount of iron bound to transferrin in blood
Ferritin	150–200 ng/mL	15–200 µg/L	Storage form of excess iron
Total iron-binding capacity (TIBC)	252–479 µg/dL	45–86 µmol/L	Amount of iron needed to bind to all transferrin
Unsaturated iron-binding capacity ([UIBC] TIBC—iron)	202–309 µg/dL	36–56 µmol/L	Transferrin not bound to iron
Transferrin (measured)	200–380 mg/dL	2–3.8 g/L	Transferrin not bound to iron
Transferrin saturation (iron/TIBC)	20%–50%	0.2–0.5	Percentage of transferrin with iron bound to it

In iron deficiency, the iron level is low, but the TIBC is increased so that transferrin saturation becomes low. TIBC is also increased in pregnancy. In iron excess, the iron level will be high and the TIBC will be low or normal, resulting in an increase of transferrin saturation. To evaluate a patient's nutritional status or liver function, typically the protein transferrin will be monitored because it is produced in the liver. Anemias often present with characteristic changes in iron profiles.

WHITE BLOOD CELLS

WBCs, or leukocytes, are delivered by the blood to sites of infection or tissue disruption, where they defend the body against infecting organisms, foreign compounds, and damaged tissue.

Leukocytes contain five diverse cell types and constitute part of the immune system.

The five main types of WBCs are **neutrophils**, **eosinophils**, **basophils**, **lymphocytes**, and **monocytes** (see Figs. 9.2 and 9.7). These cells are further divided into two classifications, **granulocytes** and **agranulocytes**, based on the presence and absence of intracellular granules that can be visualized with a light microscope. The neutrophils, eosinophils, and basophils are granular leukocytes, whereas the lymphocytes (i.e., B cells and T cells) and monocytes are agranular. Although monocytes and lymphocytes may also possess cytoplasmic granules, they are not as numerous or as distinct on a regularly stained blood smear. The nuclei of mature granular cells are multilobed, and these cell types are often called **polymorphonuclear leukocytes** (**PMNs**) as opposed to the monocytes and lymphocytes, which are termed **mononuclear leukocytes**.

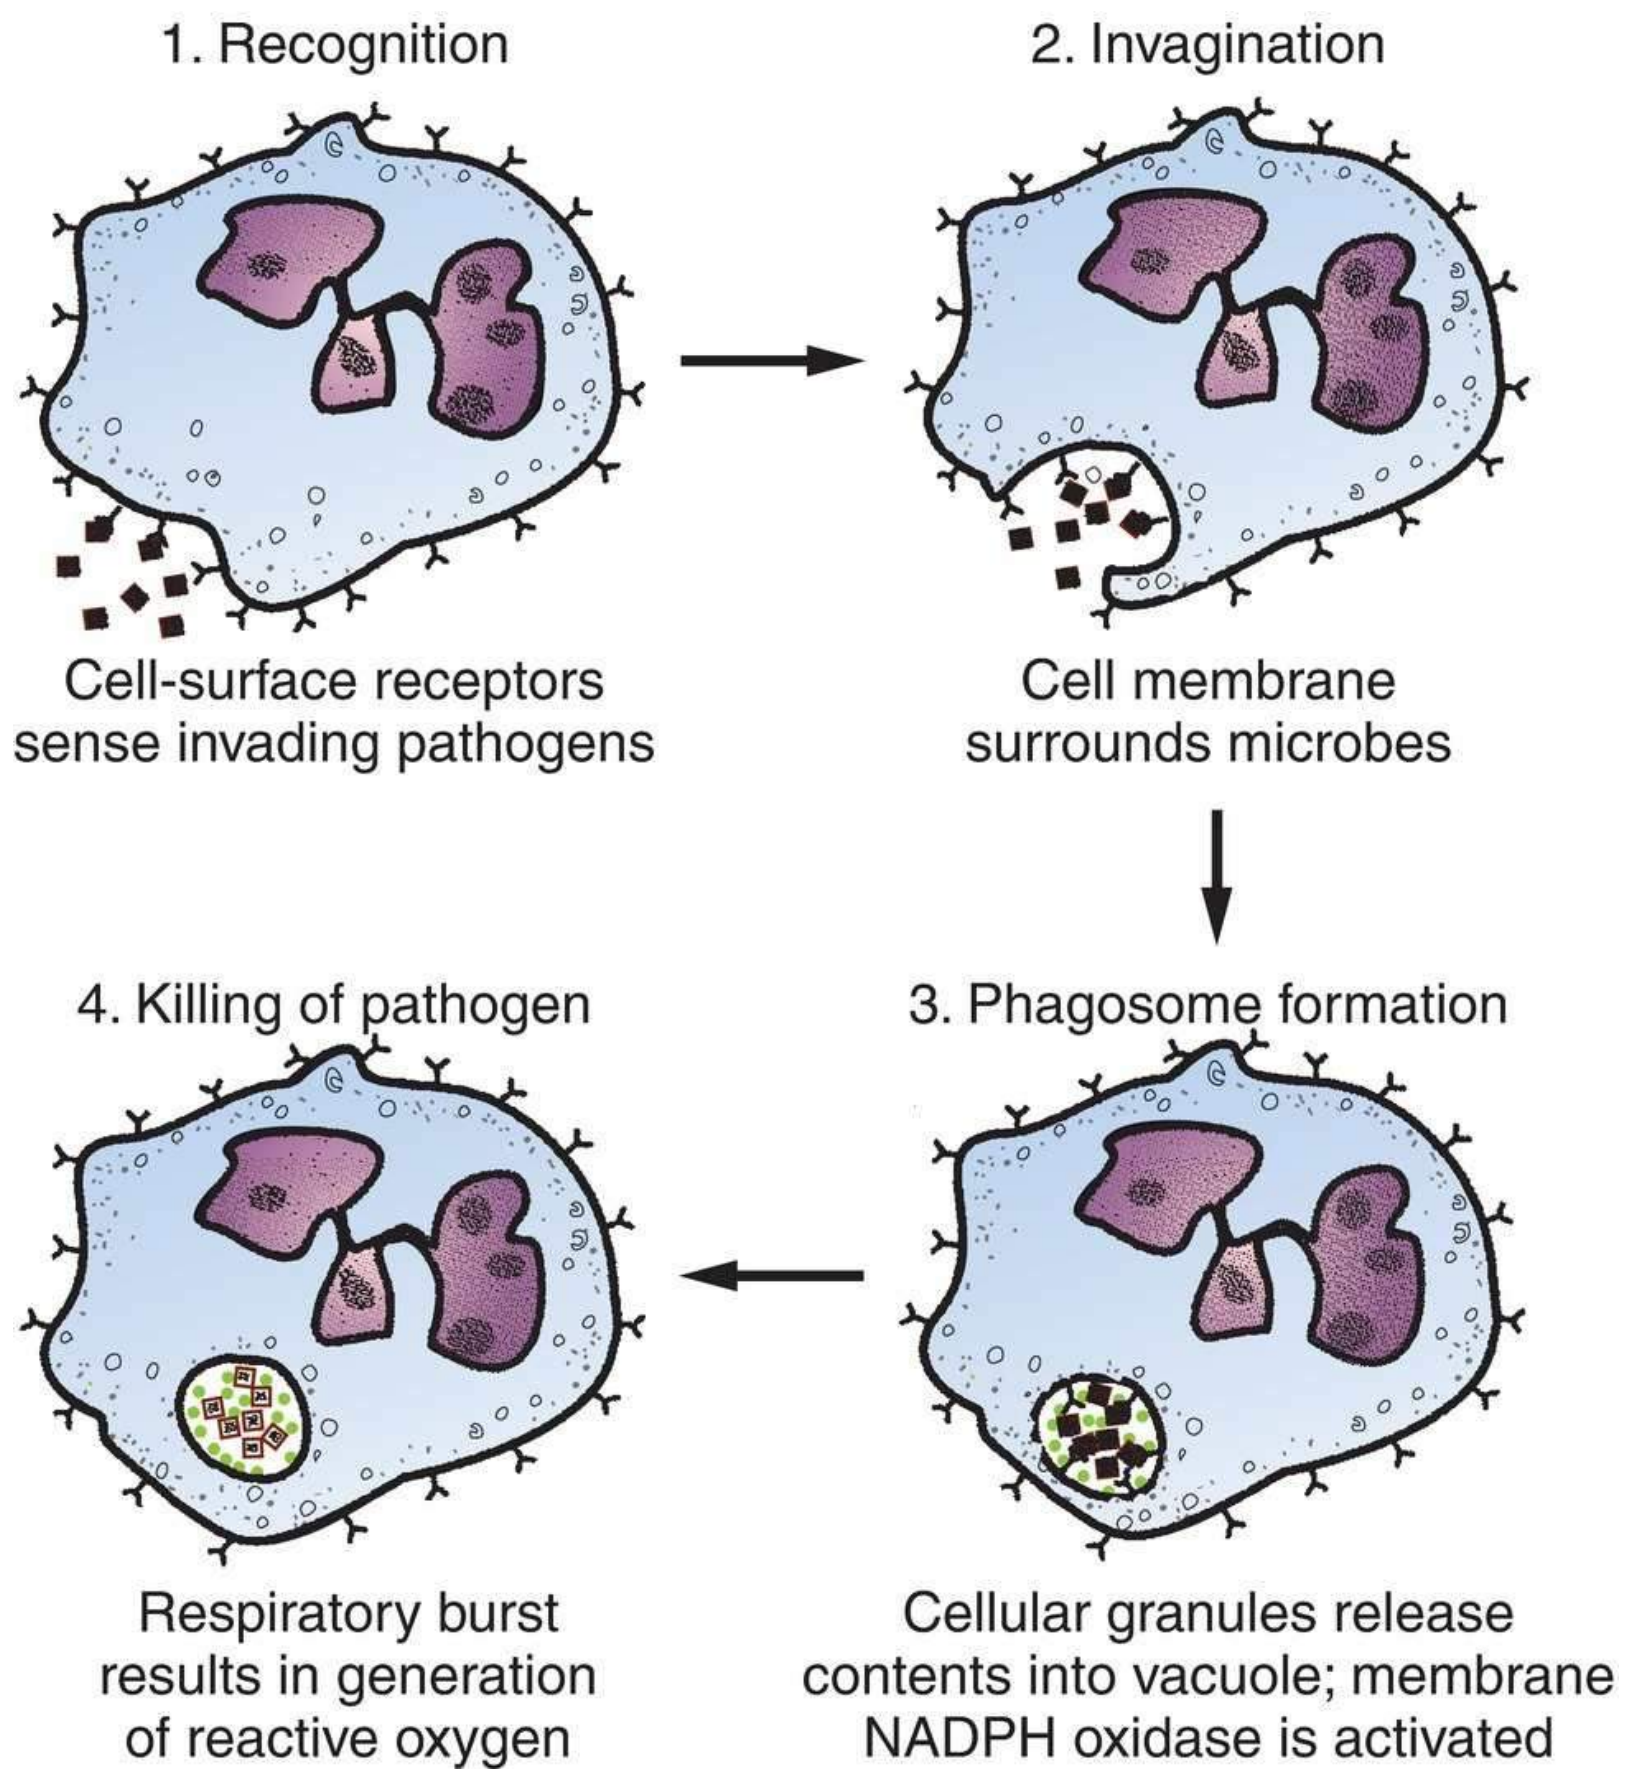

Figure 9.7 Hematopoiesis. All circulating blood cells are believed to be derived from a common bone marrow progenitor—the hematopoietic stem cell. Its differentiation along different lineages via increasingly more committed stem cells toward the final blood cells depends on the encountered conditions and hematopoietins.

Hematopoietic stem cells reside predominately in the red bone marrow and can be further differentiated

into various lineages by a group of cytokines that are collectively called **colony-stimulating factors**. The first stage of differentiation is into two lineages giving rise to myeloid and lymphoid progenitor cells. Myeloid progenitor cells give rise to RBCs and all WBCs except the lymphocytes, which are part of the lymphoid lineage (Fig. 9.7).

Neutrophils defend against bacterial and fungal infection through phagocytosis.

Neutrophils are the most prevalent leukocyte in the peripheral blood of a healthy person (50% to 70% of all leukocytes). They are highly motile phagocytic cells and are the first defensive cell type to be recruited to a site of inflammation. The primary mission of neutrophils is to find bacteria or fungi and neutralize them by **phagocytosis**. This process can be described in four steps (Fig. 9.6**)**. Defects in neutrophil function quickly lead to massive infection and, quite often, death.

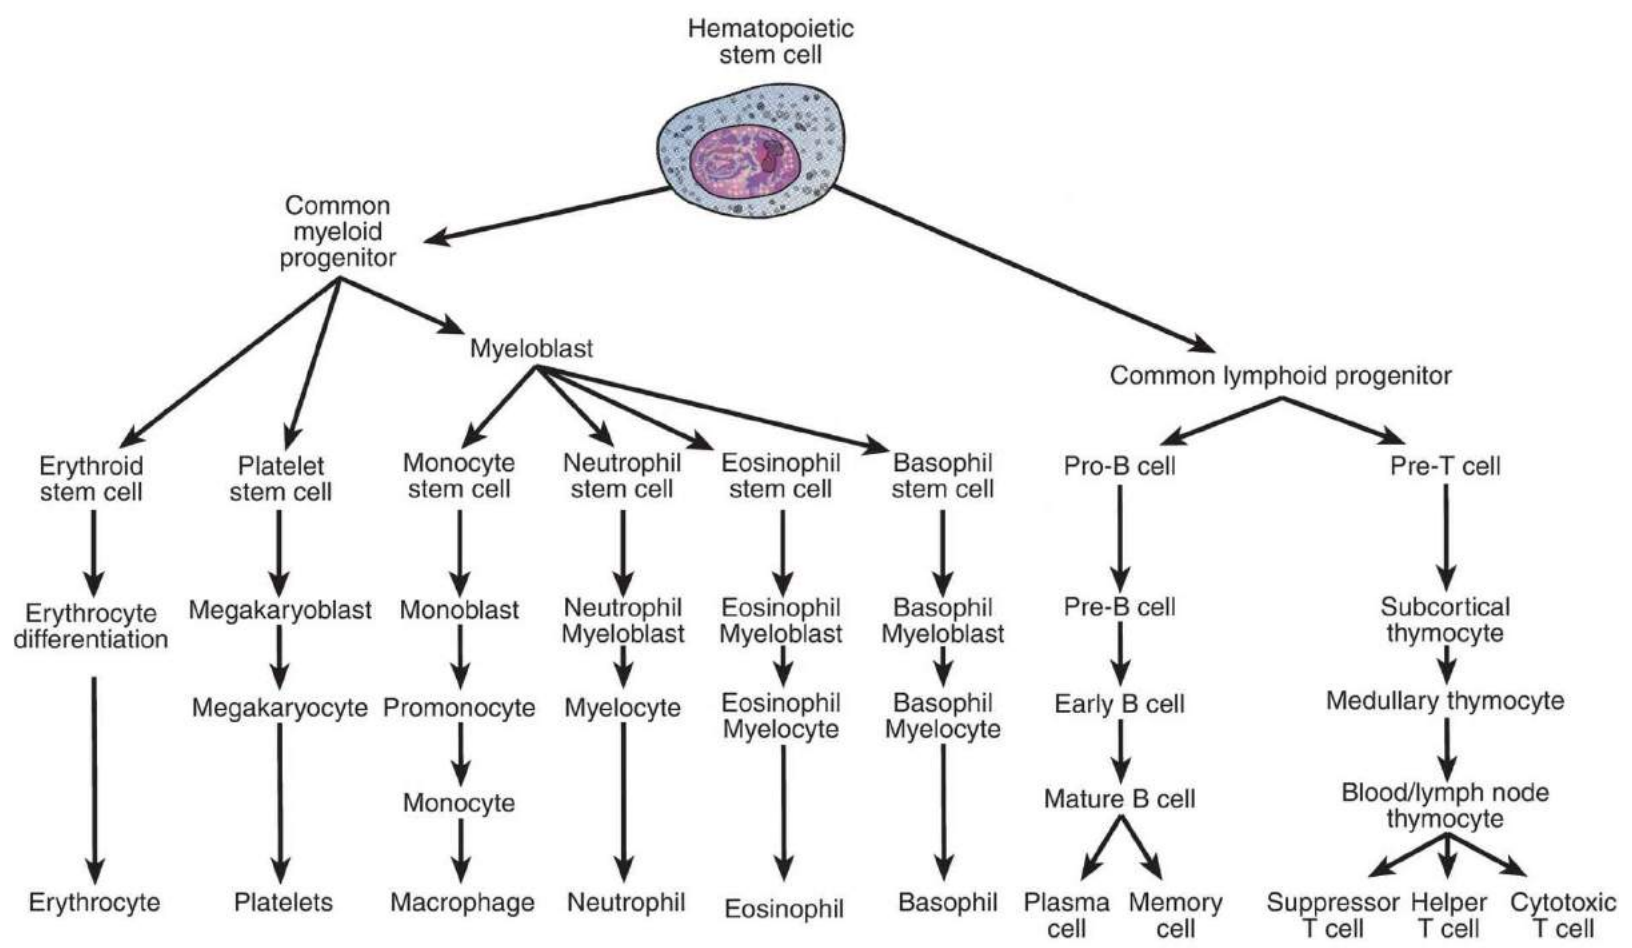

Figure 9.6 Steps in phagocytosis and intracellular killing by neutrophils. Neutrophils are the first defensive cells to be recruited to a site of inflammation. NADPH, nicotinamide adenine dinucleotide phosphate.

Step 1: Recognition of foreign invader

When bacteria or their products are recognized and bound by circulating antibodies, the bacteria release chemotactic factors that attract neutrophils. Neutrophils recognize the bacteria as foreign by binding to the antibodies via Fc receptors. Bacteria can also interact with tissue cells, lymphocytes, or platelets that then release factors that attract and activate neutrophils.

Step 2: Invagination of cell membrane

At the site of infection, neutrophils engulf the invading pathogen by phagocytosis. Phagocytosis is facilitated when the bacteria are coated with host defense proteins known as **opsonins** (for details see Chapter 10).

Step 3: Phagosome formation

The generated phagocytic vacuole, or **phagosome**, fuses with intracellular granules containing digestive enzymes and **defensins**. The defensins are cationic proteins that kill the microorganisms by creating holes in their plasma membranes. Agents stored in neutrophil granules include lysozyme, a bacteriolytic enzyme, and myeloperoxidase, which reacts with hydrogen peroxide to generate potent, bacteria-killing oxidants. One of these oxidants is hypochlorous acid (HOCl), a chemical typically found in household bleach. Granules also contain proteases (e.g., collagenase).

Step 4: Killing of pathogens

An important step for the effective destruction of pathogens is the activation of the enzyme **nicotinamide adenine dinucleotide phosphate** (**NADPH**) oxidase. The oxidase is dormant in resting cells but activated by its interaction with a G protein and cytosolic molecules generated during phagocytosis. Enzyme activation leads to the catalytic production of **superoxide ion**, a toxic free radical, within the phagosome. The generation of superoxide and other potent reactive agents is collectively termed the **respiratory burst** or **oxidative burst**. The reactive agents kill bacteria directly or participate in secondary free radical reactions to generate other potent antimicrobial agents such as **hydrogen peroxide**.

The important role of the **NADPH oxidase** (**NOX**) for efficient host protection against invading pathogens becomes evident in **chronic granulomatous disease**, which is caused by the lack of phagocytic NADPH oxidase and is characterized by recurrent life-threatening bacterial and fungal infections.

Eosinophils are inflammatory cells that defend against parasitic infections.

In a healthy person, eosinophils are 2% to 4% of circulating WBCs and are readily identified by their characteristic appearance and the staining of their cytoplasm. As the name implies, *eosin*ophils take on a deep orange-red color during staining with eosin or other acidic dyes. Like neutrophils, eosinophils migrate in response to chemotactic signals and exhibit a metabolic burst when activated. Eosinophils participate in the defense against parasites such as roundworms. They are effective against these large invading organisms by releasing their granular contents that contain nitric oxide and cytotoxic enzymes. These WBCs increase several-fold in number in response to parasitic infections. Eosinophils are involved in allergic reactions because they are also activated by allergens. They also play a role in wound healing by releasing growth factors and chemicals that neutralize inflammatory mediators.

Basophils release histamine, causing the inflammation of allergic and antigen reactions.

The number of basophils in the blood smear of a healthy individual ranges from 0% to 2% of the WBCs. This makes basophils even rarer than eosinophils, and many differential counts show none. Basophils have multiple pleomorphic, deep-staining granules throughout their cytoplasm and are readily stained with basic dyes. Basophils are recruited to sites of cellular injury or inflammation. The granules contain **heparin** and **histamine**, which have anticoagulant and vasodilating properties, respectively. When stimulated, the granular contents are released from the cells and mediate increases in regional blood flow and the attraction of other WBCs, including eosinophils.

Mast cells are capable of synthesizing many of the same mediators as basophils. However, the two cell types appear to be distinct despite their close similarities. Basophils and mast cells must be activated to release their inflammatory mediators in a process called **degranulation**. In an allergic response, activation and degranulation occurs when antigens that are already tightly bound to basophils and mast cells bind to immunoglobulin E (IgE). Other direct or supportive stimuli for degranulation include mechanical injury, activated complement proteins, and drugs. When antigens are allergens such as pollen, the release of histamine and heparin can cause the characteristic symptoms of allergy.

Monocytes migrate from the blood stream and become macrophages.

Monocytes, together with lymphocytes, belong to the category of mononuclear leukocytes. Monocytes constitute about 2% to 8% of total WBCs and can be distinguished from lymphocytes based on their pale-blue or blue-gray cytoplasm when stained with a Wright stain. On activation, monocytes leave blood vessels, migrate into tissue, and fully differentiate into macrophages, which are large phagocytic cells. Macrophages contain granules with lytic enzymes and chemicals that are used to destroy ingested microbes, antigens, and other foreign substances. In addition to their role as phagocytes, macrophages secrete chemotactic signals for other WBCs and fibroblasts. Macrophages are considered an integral part of the immune system because they serve as antigen-presenting cells to B cells and T cells (see Chapter 10).

Lymphocytes contain three cell types that participate in the immune system.

About 16% to 45% of leukocytes are lymphocytes composed of **B cells** and **T cells** and **natural killer** (**NK**) cells. In a stained light microscopic slide, the different types of lymphocytes cannot be distinguished from each other. Circulating lymphocytes possess a deeply stained nucleus that is large in relation to the remainder of the cell so that often only a small rim of cytoplasm appears around the nucleus (see Fig. 9.2). Some lymphocytes such as NK cells have a broader band of cytoplasm, closely resembling monocytes. Most of the lymphocytes are found outside the blood in lymphoid organs or connective tissue.

Most circulating lymphocytes are T cells or T lymphocytes (for *thymus-dependent lymphocytes*). They participate in cell-mediated immune defenses and are divided into several subtypes (e.g., helper T cells, cytotoxic T cells, and NK cells) (see Chapter 10). Some 20% to 30% of circulating lymphocytes are B cells. B cells are bone marrow–derived lymphocytes. When a B cell encounters its specific antigen (**clonal selection**), it becomes activated and proceeds to replicate itself (**clonal expansion**). Many of these clonal B cells will mature into **plasma cells**. Plasma cells are highly specialized cells with the ability to produce large amounts of target-specific antibody. They are larger and stain darker than naive B cells because of the large amount of protein being synthesized within.

PLATELET FORMATION

Platelets are irregularly shaped, disklike fragments of their precursor cell, the megakaryocyte. They are one fourth to one third the size of erythrocytes (1.5 to 3.0 μm). As megakaryocytes develop, they undergo a process of controlled fragmentation that results in the release of over 1,000 platelets per cell. Several factors stimulate megakaryocytes to release platelets within the bone marrow sinusoids. This includes the hormone thrombopoietin, which is mainly generated by the liver and the kidneys and released in response to low numbers of circulating platelets. Platelets have no nucleus but possess important proteins, nucleotide, and other factors, which are stored in intracellular granules and secreted when platelets are activated during platelet aggregation in response to vascular injury.

BLOOD CELL FORMATION

Blood cells must be continuously replenished. As already stated, RBCs survive in the circulation for about 120 days. Platelets have an average lifespan of 15 to 45 days, but many of them are immediately consumed as they participate in day-to-day hemostasis. Leukocytes have a variable lifespan. Some lymphocytes circulate for 1 year or longer after production. Neutrophils, constantly guarding body fluids and tissues against infection, have a circulating half-life of hours to days.

Hematopoiesis takes place in bone marrow and lymphatic tissue.

Hematopoiesis, the process of blood cell generation, occurs in healthy adults in the red bone marrow and lymphatic tissues, such as the spleen, thymus, and lymph nodes (Fig. 9.7). During fetal development, hematopoietic cells are present in high levels in the liver, spleen, and blood. Shortly before birth, blood cell production gradually begins to shift to the marrow. By age 20 years, the marrow in the cavities of many long bones becomes inactive, and blood cell production mainly occurs in the marrow of iliac crest, sternum, pelvis, and ribs. In some disease states such as leukemia, liver and lymphatic tissue can resume their hematopoietic function in adulthood, which is called **extramedullary hematopoiesis**.

Mature blood cells originate from a multipotent stem cell.

Blood cell production begins with the proliferation of **multipotent stem cells** called **hematopoietic stem cells**. Depending on the stimulating factors, the progeny of hematopoietic stem cells can form any of the WBCs, RBCs and platelets. Colony-stimulating factors are cytokines or hormones that control the lineage fate of cells as well as the speed of cellular production. This large family of factors can be released by various tissues in response to a variety of stimuli. Examples of the hematopoietic factors include **erythropoietin** (RBC production), **M-CSF** (monocyte production), **G-CSF** (granulocyte production), and **multi-CSF** (granulocyte, monocyte, and platelet production).

Erythropoiesis is regulated by the renal hormone erythropoietin.

Erythropoiesis is the process by which RBCs are produced. A major factor controlling RBC production is erythropoietin. This hormone is released by the kidneys in response to decreased O_2 delivery. The decreased O_2 can come from a variety of causes including hemorrhage; anemia; respiratory problems, such as **emphysema** or **chronic obstructive pulmonary disease** (**COPD**); or a sudden change in altitude (lower O_2 pressure). Erythropoietin regulates the differentiation of the uncommitted stem cells to enter the erythrocyte lineage, forming, in order, normoblasts (also called *erythroblasts*); reticulocytes; and, finally, mature erythrocytes, which enter the bloodstream (Fig. 9.8). A common symptom of patients with chronic kidney disease is anemia from the lack of erythropoietin. Genetically engineered human erythropoietin and some longer lasting analogs are used for the treatment of anemia due to chemotherapy or chronic kidney failure. The availability of the recombinant form combined with the extra O_2 carrying capacity of increased numbers of RBCs has made this a drug of abuse for endurance athletics. The risks for excessive erythropoietin are discussed in Clinical Focus 9.2.

CLINICAL FOCUS 9.2

Blood Doping and Erythropoietin

Charging an athlete with "blood doping" is unfortunately a common newspaper headline during world-class endurance sports events. It refers to methods of enhancing an athlete's red blood cell count in advance of a competition to increase oxygen delivery capacity and to reduce muscle fatigue.

One blood doping method is autologous blood transfusion, in which the athlete's own red blood cells are stored and then transfused back in, a week or less before competition. This technique is not only illegal but also dangerous. An increase in hematocrit (Hct) results in increased blood viscosity, which is a major contributor for developing heart disease.

Another way to increase Hct is by increasing the concentration, production, or activity of the hormone erythropoietin. Erythropoietin is a glycoprotein produced primarily by peritubular cells in adult kidneys in response to low blood O_2. It promotes the proliferation and differentiation of erythrocyte precursors,

The human gene for erythropoietin was cloned in 1985, leading to the production of recombinant human erythropoietin (rhEPO) and genetically engineered darbepoetin, which has an increased lifetime compared to the recombinant hormone form. The large-scale production of synthetic erythropoietin made it available for the treatment of anemias. Currently, rhEPO and darbepoetin are approved in the United States to treat patients with severe anemias associated with chronic renal failure, AIDS, and chemotherapy. Usage in the treatment of severe anemias is limited in order to balance the benefits of increased red cell production with the health risks associated with an elevated Hct, especially for those who are ill.

Within the first 4 years after the synthetic versions of erythropoietin became available, more than 17 high-performance athletes died from the consequences of drug-induced blood clots. The fatal dangers of excess erythropoietin include sudden death from stroke or heart failure or the development of antierythropoietin antibodies, which, ironically, cause the destruction of red blood cells.

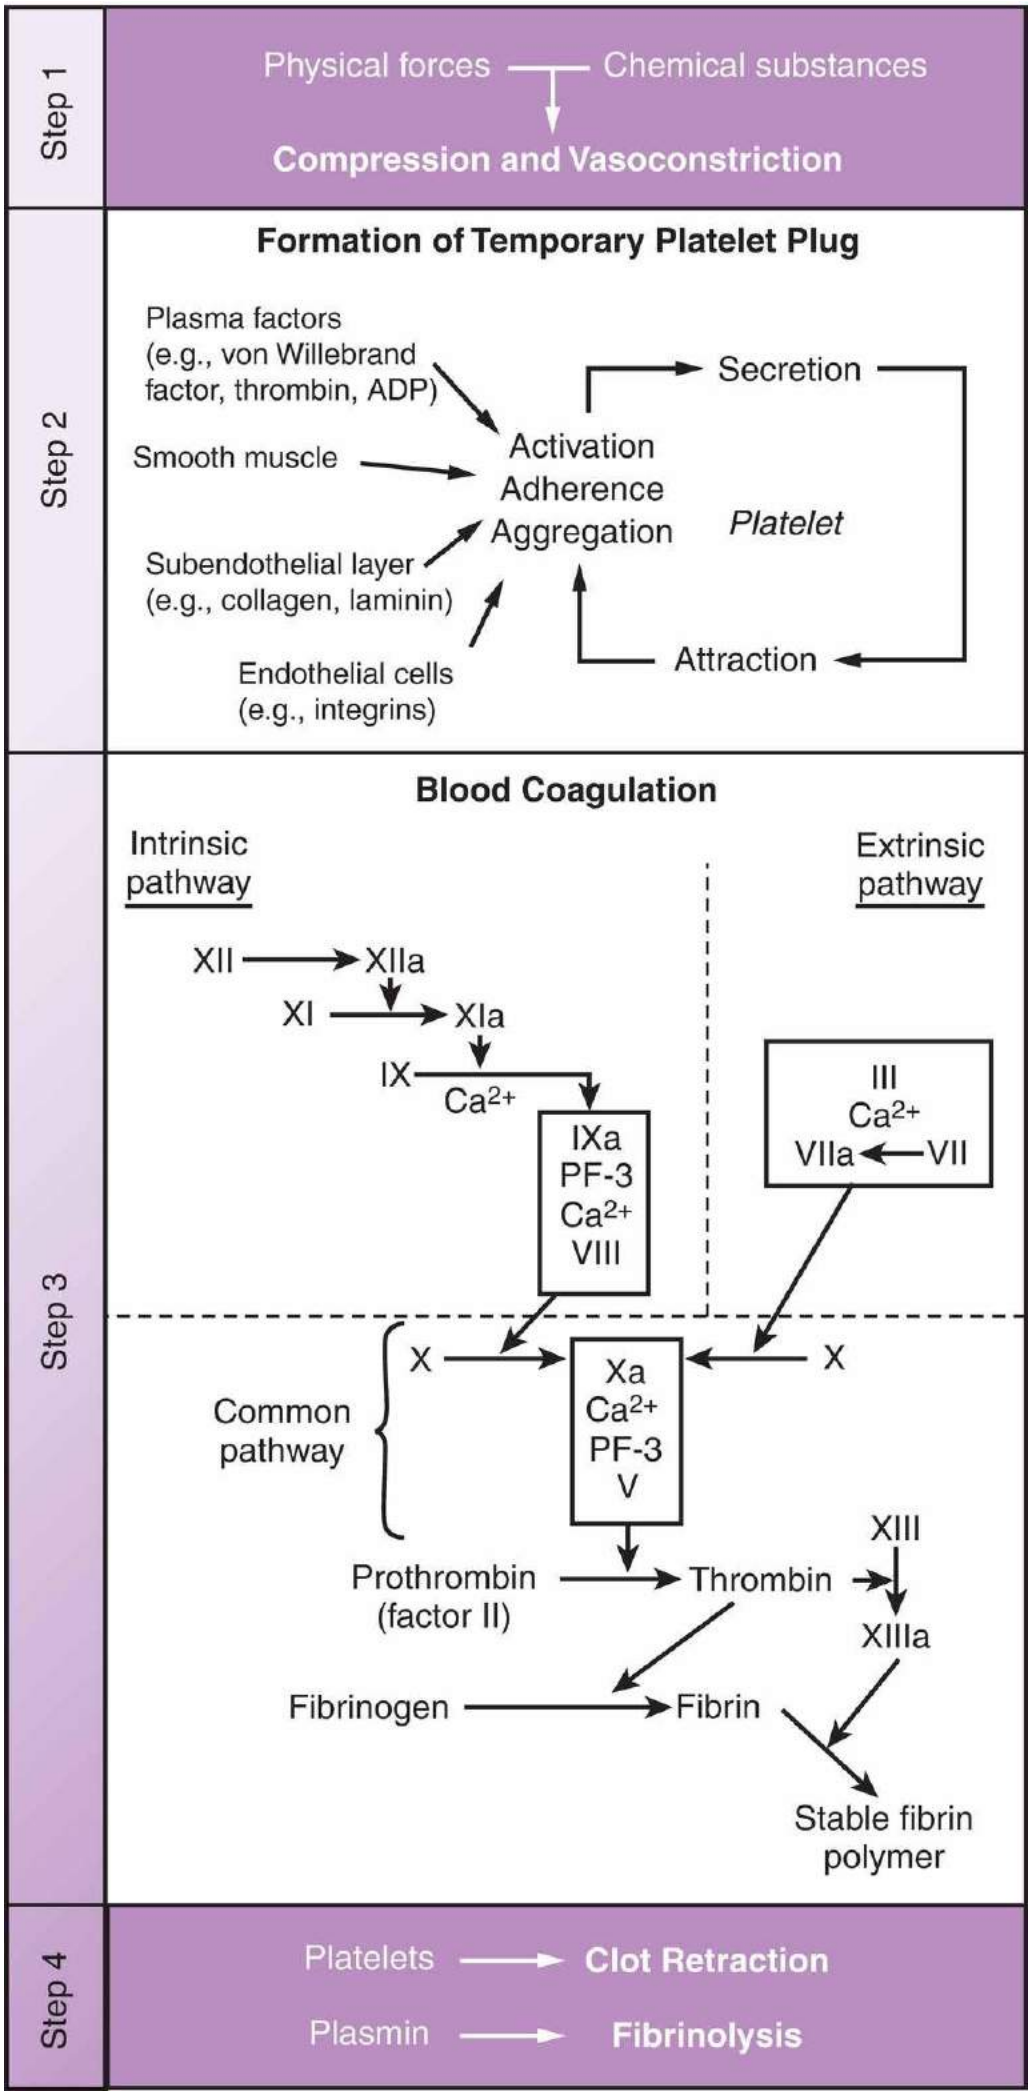
During drug screening, increased Hct and elevated reticulocyte blood count indicate potential erythropoietin abuse. In this case, urine and blood tests will be done. Erythropoietin in urine can only be detected for a few days after injection. Erythropoietin in blood has a half-life of about 2 weeks. In addition, normal Hct levels show a wide range and can be substantially altered by dehydration or training at high altitudes. This creates a challenge for the correct testing time because the drug-induced increase in red cell mass can last up to a few months.

Currently, exogenous hormone can be distinguished from the body's normal hormone by electrophoresis, but this is valid only while the exogenous hormone is in the bloodstream. Because repeated pre-event testing for every athlete is not realistic, exposing illegal blood doping will remain a

challenge. Additionally, drug advancements will require concomitant advancements in drug-detection procedures. ■

BLOOD CLOTTING

Damage to the vasculature, if unrepaired, could lead to extreme blood loss and consequent organ failure. Hemostasis (the cessation of blood loss from a damaged vessel) can be organized into four separate but interrelated events: vasoconstriction, the formation of a temporary platelet plug, formation of the more stable fibrin clot, and finally, clot retraction and dissolution (Fig. 9.9). The four steps are explained in more detail in the following sections.



Step 1

Figure 9.9 Hemostasis. The blood's response to blood vessel injury can be viewed as four interrelated steps. Roman numerals refer to coagulation factors. ADP, adenosine diphosphate; PF-3, platelet factor 3.

Hemostasis step 1: Vascular phase begins.

At the site of blood vessel trauma, the first reaction is a constriction of the vessel via the contraction of circular smooth muscles surrounding the vasculature. This reaction is known as a **myogenic contraction**. At the site of injured tissue, there is also the release of potent chemical substances such as ADP, tissue factor, and prostacyclin that play roles in subsequent phases. The injured endothelial cells also release factors such as **endothelins** that, in addition to stimulating smooth muscle contraction, act as growth factors in the stimulation of endothelial, muscle, and fibroblast proliferation. The endothelial cells at the site of injury become “sticky,” enhancing the platelet reaction in the second phase.

Hemostasis step 2: Platelet plug forms.

The immediate goal of hemostasis is the fast production of a physical barrier that covers the opening in the blood vessel. The initial plug is composed of platelets (thrombocytes). The exposure of collagen from the injured vascular wall, as well as the sticky surface formed by the endothelial cell reaction, cause the platelets to adhere to the vessels and become activated. Platelet activation causes a shape change and aggregation of the platelet to each other and the exposed collagen. The platelets contract and release their vesicle contents (**degranulation**) initiating both acute and long-term effects. ADP and the prostanoid **thromboxane A2**, released by the platelets together with the exposed collagen on the vessel wall stimulate further platelet aggregation and degranulation, ultimately forming the platelet plug. Other granule contents have additional roles. Serotonin and thromboxane A2 stimulate vascular contraction, released clotting factors and Ca^{2+} play roles in the subsequent clotting cascade, and **platelet-derived growth factor** (**PDGF**) promotes vessel repair. The positive feedback loop that promotes further platelet aggregation and degranulation is tempered by **prostacyclin**, a prostaglandin that is released from the damaged endothelial cells and inhibits platelet activation, and by circulating enzymes in the blood that break down ADP.

Importance of the platelet count for hemostasis

As in many cases, disease states can illustrate the importance of a physiological process. **Thrombocytopenia**, a low number of platelets, can be due to decreased production of platelets (e.g., in patients with serious bone marrow disease or undergoing chemotherapy), unavailability of platelets (e.g., platelets can be sequestered in an enlarged spleen), or accelerated destruction of platelets (e.g., coating of platelets with IgG and removal by phagocytes). **Immune thrombocytopenia purpura** is a common autoimmune disorder caused by autoantibodies to platelets. Purpura (meaning *bruising*) and multiple bruises all over the body as a result of minor bumps are one of the first characteristics of thromobocytopenia. This serves to illustrate that, under normal physiological conditions, the platelets plug the minor breaks in the vessels, particularly the small vessels, that are a part of daily life.

Hemostasis step 3: Thrombin catalyzes the conversion of fibrinogen into fibrin to form a stable clot.

The first two phases are not sufficient to close large breaks in blood vessels. A **blood clot** that can form on the top of a platelet plug is a network composed of the insoluble protein **fibrin**, which traps blood cells, platelets, and fluid. The fibrin is formed from the proteolytic degradation of fibrinogen, a normal blood protein, by the enzyme **thrombin**. The activation of thrombin and blood clot formation takes place according to a carefully orchestrated signal transduction cascade called **coagulation**.

The coagulation cascade is mediated by the sequential activation of a series of **coagulation factors**, proteins synthesized in the liver that circulate in the plasma in an inactive state. The coagulation factors are referred to by Roman numerals in a sequence based on the order in which they were discovered, not the order in which they occur in the cascade. The plasma coagulation factors and their common names are listed in Table 9.4.

TABLE 9.4 Factors of the Coagulation Cascade

Scientific Name	Common Names	Pathway
Factor I	Fibrinogen	Both
Factor II	Prothrombin	Both
Factor III	Tissue factor; tissue thromboplastin	Extrinsic
Factor IV	Calcium	Both
Factor V	Proaccelerin; labile factor; accelerator (Ac–) globulin	Both
Factor VI (Va)	Accelerin	
Factor VII	Proconvertin; serum prothrombin conversion accelerator (SPCA); cothromboplastin	Extrinsic
Factor VIII	Antihemophilic factor A; platelet cofactor 1; antihemophilic globulin (AHG)	Intrinsic
Factor IX	Christmas factor; platelet thromboplastin component (PTC); antihemophilic factor B	Intrinsic
Factor X	Prothrombinase; Stuart–Prower factor	Both
Factor XI	Plasma thromboplastin antecedent (PTA)	Intrinsic
Factor XII	Hageman factor; contact factor	Intrinsic
Factor XIII	Fibrin-stabilizing factor (FSF); protransglutaminase; fibrinoligase	Both

Two separate coagulation cascades, the **intrinsic coagulation pathway** and the **extrinsic coagulation pathway**, result in blood clotting in response to different initiation signals (see Fig. 9.9). The final steps in fibrin formation are common to both pathways. Many of the steps in all parts of the cascade require both phospholipids and Ca^{2+} as cofactors. Hence, sequestering Ca^{2+} by Ca^{2+} chelators such as EDTA is used as a means to inhibit blood coagulation.

The intrinsic pathway is so named because the necessary factors are contained within the blood. Exposed collagen from the vessel activates factor XII, which then activates factor XI, which, in turn, activates factor IX. Activated factor IX binds factor VII in the presence of Ca^{2+} to activate factor X, which is the beginning of the common pathway.

For the initiation of the extrinsic pathway, a factor extrinsic to blood but released from injured tissue, called **tissue thromboplastin** (**factor III**) or *tissue factor*, is required. Factor III, in the presence of Ca^{2+}, forms a complex with factor VII, and this enzyme complex activates factor X.

Any attempt to describe a distinct division of coagulation into the two separate pathways is an oversimplification. For instance, the factor VII/III complex of the extrinsic pathway can stimulate the formation of activated factor IX in the intrinsic pathway. Although the concept of independently acting intrinsic versus extrinsic coagulation pathways is incorrect, the pathways are still important to understand because they are monitored individually in the clinical coagulation tests: The activated partial thromboplastin time monitors the intrinsic pathway, and prothrombin time monitors the extrinsic pathway, as outlined below.

Common coagulation pathway

The final events leading to fibrin formation by either pathway result from the activation of the common pathway. Activated factor X, in the presence of platelet phospholipids and Ca^{2+}, activates the conversion of proenzyme prothrombin to thrombin. Thrombin is a proteolytic enzyme that catalyses the cleavage of fibrinogen to fibrin. A plasma enzyme, fibrin-stabilizing factor (factor XIII), catalyses the formation of covalent bonds between strands of polymerized fibrin, stabilizing and tightening the blood clot.

Thrombin is also a potent platelet and endothelial cell stimulus and enhances the participation of these cells in coagulation during hemostasis step 2. To a large extent, the interaction of coagulation factors occurs on the surfaces of platelets and endothelial cells. Although plasma can eventually clot in the absence of surface contact, localization and assembly of coagulation factors on cell surfaces amplifies reaction rates by several orders of magnitude.

Prothrombin time

The extrinsic system is evaluated by determination of the **prothrombin time** (**PT**). The PT, reported as time in seconds, represents how long a plasma sample takes to clot after a mixture of thromboplastin (factor III) and calcium chloride are added. A time longer than 11 to 13 seconds indicates a deficiency in prothrombin or other clotting factors that affect prothrombin.

PT is commonly used to measure the effectiveness of **coumarin**-type anticoagulant drugs. If a patient with a prolonged PT must have surgery, it is important that the PT be brought within a normal range before surgery.

Activated partial thromboplastin time

The test used to monitor the activity of the intrinsic system is the **activated partial thromboplastin time** (**aPTT**). The aPTT measures the clotting time of plasma, from the activation of factor XII by a commercial biologic aPTT reagent through the formation of a fibrin clot. If a patient's value does not fall into the reference range of 25 to 38 seconds, additional tests are necessary to determine the exact cause of the coagulation problem.

The aPTT is used to monitor **heparin** therapy. Heparin is an injectable anticoagulant that prevents the formation and growth of clots and may be advised for patients with severe heart disease. All anticlotting therapies carry the risk of bleeding, and so appropriate heparin or coumarin dosing is critical.

The deficiency or deletion of any one factor of the cascade can lead to **hemophilia**. For instance, individuals deficient in factor VIII (antihemophilic factor) have hemophilia A, a severe X chromosome–linked condition with prolonged bleeding time on tissue injury as a result of delayed clotting. Hemophilia B is the result of factor IX deficiency.

Hemostasis step 4: Plasmin mediates fibrinolysis.

Clot retraction is a phenomenon that may occur within minutes or hours after clot formation. The clot draws together, which pulls the torn edges of the vessel closer together, reducing residual bleeding and stabilizing the injury site. The retraction requires the action of platelets, which contain actin and myosin. Clot retraction reduces the size of the injured area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to start wound healing.

Fibrinolysis is the process of breaking down the product of coagulation, a fibrin clot. The main enzyme in fibrinolysis is **plasmin**, which cleaves the fibrin mesh at various places, leading to the formation of circulating fragments that are cleared by other proteases or by the kidney and liver. Plasmin is a serine protease that circulates as the inactive proenzyme **plasminogen**. Plasminogen is converted to plasmin by a **tissue plasminogen activator** (**TPA**), which is released by activated endothelial cells.

Control of the clotting cascade

A number of endogenous anticoagulants exert control over the clotting cascade. Platelet function is strongly inhibited, for example, by the endothelial cell metabolite prostacyclin, which is generated from arachidonic acid during cellular activation. Thrombin bound to **thrombomodulin** on the surface of endothelial cells converts **protein C** to an active protease. Activated protein C and its cofactor, protein S, restrain further coagulation by proteolysis of factors Va and VIIIa. Furthermore, activated protein C augments fibrinolysis by blocking an inhibitor of TPA. Finally, antithrombin III is a potent inhibitor of proteases involved in the coagulation cascade such as thrombin. The activity of antithrombin III is accelerated by small amounts of heparin, a mucopolysaccharide released by both basophils and endothelial cells.

Chemoattractants, mitogens, and growth factors

While the blood clot resolves, multiple factors participate in wound healing. Optimal wound healing requires the generation of new tissue cells as well as the recruitment of new blood vessels to nourish the repairing tissue. **Chemoattractants** attract smooth muscle cells, inflammatory cells, and fibroblasts to the wound, and **mitogens** induce them to proliferate. **Growth factors**, a subclass of cytokines, induce stem cells to differentiate. There are many different growth factors involved in this proliferative phase of wound repair, including **platelet-derived growth factor** (**PDGF**) and **epidermal growth factor** (**EGF**). They control the wound contraction and continuous remodeling of tissue and collagen over an extended period for ultimate healing.

An important event during wound healing is **angiogenesis**, the formation of new blood vessels. Platelets play an important role because they secrete factors that induce proliferation, migration, and differentiation of two of the major components of blood vessels: endothelial cells and smooth muscle cells. There are at least 20 angiogenic growth factors and 30 angiogenesis inhibitors found naturally in the body. These keep most blood vessels in a quiescent state but shift the balance toward formation of new vessels after injury.

A detailed understanding of the events that regulate angiogenesis has profound therapeutic potential. For example, exogenously applied *angiogenesis-inducing agents* may prove useful in accelerating the repair of tissue damaged by thrombi in the pulmonary, cerebral, or cardiac circulation. In addition, angiogenic factors may assist in the repair of lesions that normally repair slowly—or not at all—such as skin ulcers in patients who are bedridden or diabetic. On the other hand, *inhibition of angiogenesis* may

prove particularly useful in the treatment of patients with cancer, because growing tumors require the recruitment of blood vessels to survive.

INTEGRATED MEDICAL SCIENCES

Anemias: Understanding the Physiology and the Importance of an Accurate Diagnosis

Anemia is a spectrum of diseases that are characterized by low O_2-carrying capacity of blood. The lack of O_2 delivery to tissues for ATP and energy production accounts for the common symptoms, which include weakness, shortness of breath, inability to maintain temperature, and chronic mental and physical fatigue.

The first line of treatment for anemia is often a transfusion of packed red cells. However, because the disease has multiple causes, effective and safe long-term treatment requires that the underlying pathology be diagnosed. Anemias can be divided into three general classifications with multiple subtypes within each classification. The three general causes of anemia are (1) insufficient RBCs, (2) decreases in hemoglobin production, and (3) abnormal hemoglobin.

Insufficient RBCs

Insufficient RBCs can arise from hemorrhage, hemolysis, or a decrease in RBC production. Hemorrhagic anemia can result from an acute blood loss or a more chronic loss such as a bleeding ulcer. This would be considered a secondary consequence of the injury or disease that causes the blood loss. In an otherwise healthy individual, curing the source of the blood loss will rapidly attenuate the anemia.

Hemolytic anemia means that the RBCs are breaking down prematurely. There are rare genetic defects that can result in red cell lysis. One of these is glucose-6-phosphate deficiency (G6PD), an X-linked recessive disorder, and another is sickle cell disease. Sickle cell disease is also classified as a hemoglobinopathy and will be considered as such in the third classification.

Certain infectious agents can also cause red blood cell lysis. These agents include many gram-positive bacteria (e.g., *Streptococcus*, *Enterococcus*, and *Staphylococcus*) and some parasites (e.g., *Plasmodium*, the malaria parasite). Hemolytic anemia can also be caused by autoimmune disorders due to autoantibodies or complement fragments deposited on red blood cells.

Finally, hemolytic anemia is a consequence of transfusion with mistyped blood during which the naturally occurring antibodies in the recipient's body recognize the transfused blood as having foreign antigens and mount an effective immune response to destroy the foreign RBCs.

A decrease in the production of RBCs produces aplastic anemia. This form of the disease can also have multiple causes including radiation, cytotoxic drugs (e.g., drugs used in cancer chemotherapy), environmental pollutants (e.g., benzene), or autoimmune disease. The cells that are most vulnerable to these insults are hematopoietic stem cells, so aplastic anemia will usually result in a decrease of not only RBCs but also WBCs and platelets.

Decreased Hemoglobin Production

The second major category of anemias comprises those that arise from decreases in hemoglobin production. The two most common subtypes are iron deficiency anemia and pernicious anemia. Iron is required for the production of mature, O_2-binding hemoglobin, and most of the iron in the body is contained in hemoglobin. Iron deficiency anemia can arise from a lack of dietary iron. Alternatively, and more difficult to treat, are the iron deficiencies that arise from an inadequate absorption of iron or the loss of iron stores. The inadequate absorption of iron can be due to intestinal diseases such as celiac disease or Crohn's disease. With the increasing prevalence of gastric bypass surgery and the accompanying malabsorptive syndrome, the risk of iron deficiency anemia is likely to increase in this patient population. Liver is the main storage organ for iron and, therefore, severe liver disease can cause iron deficiency. Iron deficiency anemia is considered the main global form of anemia.

Pernicious anemia is a deficiency in vitamin B_{12}, which is necessary to form erythrocyte maturation factor. A glycoprotein called *intrinsic factor* is produced by the stomach and aids in the uptake of vitamin B_{12}. Once absorbed, the vitamin B_{12} complexes with the intrinsic factor to form erythrocyte maturation factor, which is necessary for normal RBC production. Pernicious anemia can be caused by a dietary deficiency of vitamin B_{12} or by a defect in the intestinal transport process.

Abnormal Hemoglobins

The final major category of anemias includes the genetic diseases that result in the formation of abnormal hemoglobin, notably sickle cell disease and thalassemia. Sickle cell disease is caused by a two–amino acid mutation in the globin protein. Due to the conformational change induced by this mutation, deoxygenation causes a change in cellular morphology leading to stiff, crescent-shaped cells that can get trapped in small capillaries blocking blood flow and causing tissue anoxia, swelling, and pain. The sickled cells also lyse more easily. Interestingly, this was one of the first genetic diseases in which the actual mutation was discovered. Despite decades of research, there is still no cure and only moderately effective treatment.

There are two types of thalassemia, α and β, which have mutations in the α- and β-globin chains respectively. The mutations in thalassemia result in a decrease in the synthesis of the pertinent globin protein resulting in lowered levels of hemoglobin production.

Importance of Accurate Diagnosis

An elucidation of the pathophysiology is crucial for appropriate treatment of anemia. Perhaps the best illustration of this principle is provided by the example of the importance of distinguishing iron deficiency anemia from hemolytic anemia—both of which can occur in developing countries where a simple hematocrit would be the most available diagnostic test.

In hemolytic anemia, the RBCs are being lysed prematurely and, hence, the body is attempting to recycle the important components of the RBC breakdown including the iron of the heme moiety. Because iron is toxic, the liberated ion is bound to the protein transferrin for transport to the storage sites and is bound to ferritin during storage. During a hemolytic event, both of those proteins are likely to be saturated with iron.

Iron deficiency anemia is effectively treated with increases in dietary iron or iron supplementation. Misdiagnosis of hemolytic anemia as iron deficiency anemia could lead to treatment that would increase toxic (ionic) form of iron in the body because of a lack of iron-binding proteins. ■

Chapter Summary

- Blood is a dynamic connective tissue with four major functions: to transport substances throughout the body; to protect the body from losing blood due to an injury; to maintain body homeostasis in regard to pH, water, heat, osmolality, and other factors; and to circulate cells and chemicals that defend the body against disease.
- Adult humans have ~5 L of whole blood, with about 45% of formed elements suspended in 55% plasma and solutes.
- Plasma is the liquid portion of blood. It contains 93% water and 7% of molecules such as proteins (e.g., albumin, globulins, fibrinogen, enzymes, and hormones), lipids (e.g., cholesterol and triglycerides), carbohydrates (glucose), electrolytes (e.g., Na^+, Cl^-, and HCO_3^-), and cellular waste (e.g., bilirubin, urea, and creatinine).
- Serum contains all components of plasma except for substances involved in blood clotting.
- Erythrocytes are anuclear, disk-shaped cells that deliver oxygen throughout the body via hemoglobin (Hgb). Adult Hgb is made of an α and β globin and a heme group containing an iron surrounded by a porphyrin ring that binds the O_2. Although changes in Hgb are rare, several hundred abnormal variants exist, producing clinical disorders such as sickle cell disease.
- Erythrocytes are characterized by number, shape, size, color, and maturity, providing valuable indicators for the diagnosis of anemias, hemoglobinopathies, infections, and other illnesses.
- Anemias can be caused by decreased red blood cells, decreased hemoglobin production, or abnormal hemoglobin. Treatment is dependent on the type of anemia.
- At the end of about a 4-month lifetime, old erythrocytes are engulfed by macrophages. Their hemoglobin, including iron, is recycled while generating the diagnostic waste product bilirubin. Excess bilirubin or an inability to process the bilirubin due to liver or gallbladder disease causes jaundice.
- Leukocytes are classified morphologically as granulocytes (eosinophils, basophils, and neutrophils) and agranulocytes (monocytes and lymphocytes).
- Leukocytes defend the body against infection using phagocytosis and various antimicrobial weapons, release mediators to control inflammation, and contribute to wound healing.
- Neutrophils are early inflammatory mediators, killing and engulfing microbes. Eosinophils support neutrophils and can also attack multicellular parasites. Basophils support eosinophils and are also associated with asthma and allergies. T lymphocytes are the key players for cell-mediated immunity. B lymphocytes make antibodies that attack bacteria and toxins.
- Hematopoiesis is the development of circulating blood cells from the uncommitted hematopoietic stem cell of bone marrow. Immature cells differentiate along cell lineages into mature cells promoted by hematopoietins and other cytokines.
- Erythropoietin is a hormone produced by the kidney and in response to low blood O_2 and promotes erythropoiesis in bone marrow. Patients on dialysis often require erythropoietin intake to maintain a normal hematocrit (Hct). Some aerobic athletes abuse erythropoietin to illegally increase their Hct.
- Thrombocytes (platelets) are irregularly shaped, small, anuclear, cell-derived structures that, together with plasma proteins, control blood clotting and promote wound healing.
- Blood coagulation involves the fast formation of a weak platelet plug of aggregated platelets, which is expanded and stabilized into a more robust plug made of cells, platelets, and insoluble fibrin molecules. Endothelial cells, blood coagulation factors, Ca^{2+}, and mediators released by platelets,

control the coagulation cascade. Thrombin is necessary for fibrin clot formation and plasmin for its dissolution.

- The basic metabolic panel reveals blood values for glucose, electrolytes, BUN, and creatinine; the CMP additionally gives values for albumin, total protein, ALP, ALT, AST, and bilirubin.
- The complete blood count includes WBC counts, red blood cell counts, platelet counts, hemoglobin (Hgb), hematocrit, red blood cell indices (mean cell volume, mean cell Hgb, and mean cell Hgb concentration), and mean platelet volume.
- Other routinely performed blood tests include blood viscosity, specific gravity, serum protein electrophoresis, erythrocyte sedimentation rate, coagulation tests (e.g., bleeding time, platelet count, prothrombin time, and activated partial prothrombin time), and iron profile (serum iron, ferritin, total iron-binding capacity, UIBC, transferrin, and transferrin saturation).
- For blood transfusions, donor and recipient blood must be compatible to avoid agglutination between erythrocyte-associated A, B, and Rh antigens and anti-A, anti-B, and anti-Rh antibodies.

Chapter Review Questions

1. Which of the following would be expected to contain relatively high numbers of functional hematopoietic progenitor cells?
   A. Adult circulating blood
   B. Adult spleen
   C. Adult thymus
   D. Circulating blood in children
   E. Umbilical cord blood

The correct answer is E. Umbilical cord blood, derived from the circulating blood of newborn infants, possesses high levels of hematopoietic progenitors. Levels of circulating progenitors rapidly decrease after birth. The spleens of adult humans function as a hematopoietic organ only in certain disease states, such as leukemia. The thymus is only involved in hematopoiesis prior to birth. Circulating blood cells in the adult or child are mature cells.

2. The clinician in charge hands you a patient's chart that contains results from about 50 blood tests. He asks you to have a look at the patient's granulocyte count. From the following list of cells, to which cells does the clinician refer?
   A. B cells
   B. Macrophages
   C. Monocytes
   D. Neutrophils
   E. T cells

The correct answer is D. The granulocyte group consists of neutrophils, eosinophils, and basophils, while monocytes/macrophages and lymphocytes (B cells and T cells) belong to the category of agranulocytes.

3. Polycythemia vera is a hereditary neoplastic bone marrow disorder characterized by abnormally high red blood cell production. The steady state concentration of a substance in serum can provide additional information to confirm the diagnosis of the patient with polycythemia vera. Its level is typically low. This is in contrast to patients with secondary polycythemia, which is caused by respiratory conditions like emphysema that stimulate erythrocyte production. Which of the following substances is most likely tested?
   A. Albumin
   B. Bilirubin
   C. Erythropoietin
   D. Haptoglobin
   E. Plasmin

The correct answer is C. Erythropoietin (EPO) is a hormone that stimulates bone marrow to produce erythrocytes. Its steady state condition in serum can provide useful information in the assessment of various anemic and polycythemic conditions. In polycythemia vera, EPO is low in response to the constant overproduction of erythrocytes due to mutated myeloblasts. On the other hand, any condition that leads to increased production of EPO (physiologically from hypoxia) will cause overproduction of erythrocytes and is defined as secondary polycythemia.

4. Which of the following patients is most likely to have a low total iron-binding capacity (TIBC) and normal transferrin saturation?

A. A heavily menstruating woman
B. A patient with chronic colon cancer leading to colonic bleeding
C. A person with severe hookworm infestation
D. A trauma victim, hematocrit 18, after being given large amounts of saline IV in the ER
E. A woman nursing twins recently born by a complicated caesarian section

The correct answer is D. The low hematocrit of 18 (normal 36 to 50 depending on age and gender) indicates acute severe blood loss and concomitant loss of transferrin (low TIBC). To avoid hemorrhagic shock, the victim is treated with saline, which equally diluted all blood components. Since he probably lost both transferrin and serum iron, he might have a normal transferrin saturation, the ratio of serum iron and TIBC. On the other hand, all other patients are likely to suffer from iron deficiency anemia due to chronic blood loss or increased iron demand. Iron deficiency anemia presents with low serum iron and elevated transferrin (high TIBC), which increases when iron stores are low. Percent transferrin saturation is typically low due to the insufficient iron. Typical causes for iron deficiency anemia are blood loss due to heavy menstruation and chronic occult bleeding, often from the GI tract, such as present in the patient with colon cancer and the patient with parasites. Blood loss during a complicated caesarian section and increased iron requirement for lactation might cause anemia for the woman with the twins.

Clinical Application Exercises 9.1

ANEMIC BABY

A 24-year-old woman delivered her first child, a baby girl, in mid December. She felt well prepared by the nurse to take care of the baby at home, and breast-feeding was less of a problem than anticipated. The new family had a wonderful traditional Christmas at the farm where they live. In mid January, she visited her family doctor. He noted that the baby looked pale. He determined the blood type of the baby as AB+ and the blood type of the mother as A+. The hemoglobin (Hgb) content of the baby's blood sample was 11.1 mg/dL, and the mother's blood sample revealed Hgb content of 11.8 mg/dL. A follow-up visit was scheduled in early February.

At the February meeting, the baby looked very pale and bluish; the mother looked very tired and said that the baby cries a lot. The Hgb of the baby was now 9 mg/dL, and the mother's 12 mg/dL. A smear of the baby's blood revealed severe hypochromic microcytic erythrocytes with marked anisocytosis and poikilocytosis. The sample contained target cells and schistocytes. The pediatrician became concerned and was suspicious about the presence of a blood disorder, possibly thalassemia, a condition in which insufficient Hgb is formed. The result of a genetic analysis confirmed the diagnosis of beta-thalassemia major.

QUESTIONS

1. What can be concluded from the January Hgb values of the baby and the mother?
2. Explain the baby's red blood cell (RBC) values and morphology at the February visit.
3. The automated blood analysis performed in February resulted in an elevated white blood cell (WBC) count of the baby. Can you explain why?

ANSWERS

1. The baby's Hgb value of 11.1 mg/dL is at the low end of the normal range of a 1-month-old baby (11 to 15 mg/dL); the mother's Hgb value of 11.8 mg/dL is slightly low (12 to 16 mg/dL), but not unusual for a new mother. No interventions are necessary at this point. Since low iron is the most common reason for anemia of babies, it is necessary to closely monitor Hgb values in the near future. Blood type incompatibility between the mother and the child, which can lead to mild anemia in newborns, is unlikely since it occurs when the mother is type O and her baby is type A, B, or AB. Rhesus incompatibility is excluded.
2. The major form of beta-thalassemia leads to a significant deficiency in the beta chain production of Hgb so that there is little or no Hgb A present. As a consequence, Hgb A2 and Hgb F are elevated and for a short time substitute for the Hgb A loss. However, with decreasing Hgb F, starting soon after birth, the baby becomes hypoxic (pale), which stimulates erythropoietin production. Erythropoietin stimulates intramedullary, and eventually extramedullary, hematopoiesis.
   Newly produced blood cells are small (microcytic) and contain only alpha chains (hypochromic), which may precipitate in the developing red blood cells (RBCs). This leads to target cells with dense center and pale rim, and generally to a cell population of unequal size (anisocytosis), abnormal shape (poikilocytosis), and cell breakage (schistocytes). Small-size cells lead to low hematocrit and low mean corpuscular volume (MCV). Inadequate Hgb production leads to decreased MCH, MCHC, and oxygen carrying capacity. Anisocytosis leads to increased RDW.
4. The initial automated blood cell count after the disease manifests often erroneously reveals an elevated WBC. This is due to the presence of nucleated RBCs (regenerative response by bone marrow), which are indistinguishable from leukocytes in hematology analyzers, regardless of technique. For this reason, the WBC count needs to be corrected for the number of nucleated RBCs, which is typically done when a differential blood cell count reveals more than 10 nucleated red cells per 100 white cells. After the correction, the WBC should be within the normal range in the baby.

10 Immunology, Organ Interaction, and Homeostasis

Active Learning Objectives

Upon mastering the material in this chapter you should be able to:

- Explain immune system triggers and self-tolerance.
- Apply the roles of both noncellular and cellular components of innate immunity in maintaining body homeostasis.
- Explain how the adaptive immune system achieves its three main features: specificity, diversity, and memory.
- Describe the mechanisms for both exogenous and endogenous antigen presentation in cell-mediated immunity.
- Explain the roles of T-cell subtypes in adaptive immunity.
- Apply the clinical relevance of both innate and adaptive immunity.
- Identify three ways that the five classes of antibodies work to eliminate antigens.
- Recognize the signs and functions of both acute and chronic inflammation.
- Explain the clinical roles of pro- and anti-inflammatory cytokines.
- Explain the influences of the immune system upon organ transplantation.
- Recognize immune system disorders by immune system reactions.
- Apply the principle of immune surveillance in hematologic malignancies.
- Describe the interaction among the immune, neuronal, and hormonal systems in maintaining homeostasis.

You have learned about the neuromuscular system in the previous section. In later chapters, you will learn about other systems, such as the cardiovascular, respiratory, renal, and endocrine systems. By contrast, you will see in this chapter that the immune system is made up of a wide variety of disease-fighting cells found throughout the body in the plasma, lymph, tissues, and the various organs. The immune system is essential in our survival and the maintenance of optimal health. The immune system protects the body with a set of remarkable molecules called **antibodies** that can recognize an infinite range of foreign invaders known as **pathogens** (e.g., viruses, bacteria, parasites, toxins) and tags them for destruction by the other components of the immune system.

Immunology is the study of the functional process in which foreign matter (living and nonliving) is either destroyed or rendered harmless by the body's defense system. The functional role of the immune defense system is to (1) protect the body against infection and pathogens (bacteria, fungi, viruses, parasites, and other microbes), (2) neutralize and/or destroy foreign matter, and (3) function as an immune surveillance system (screening and neutralizing malignant cells).

Immunologic disorders (autoimmune diseases, hypersensitivities, and immune deficiency) result from malfunctions or inappropriate responses of the immune system. Immunology has contributed to great advances in medicine following Louis Pasteur's theory that microorganisms are the cause of infection and his role in the understanding that vaccination prevents infectious disease. The aim of this chapter is to

present basic components of the immune system and their roles in organ function and homeostasis.

IMMUNE SYSTEM COMPONENTS

The immune system defends the body from disease by identifying and killing pathogens, cells infected with a pathogen, and tumor cells. The immune system detects a wide variety of pathogenic agents, from bacteria to viruses to parasitic worms. In addition to identifying pathogens, it must also distinguish them from the body's own healthy cells and tissues. Detection is a complex, ongoing process because pathogens evolve rapidly, producing adaptations that help them avoid detection by the immune system and allow successful infection.

The defense system consists of layered specificity and sophistication.

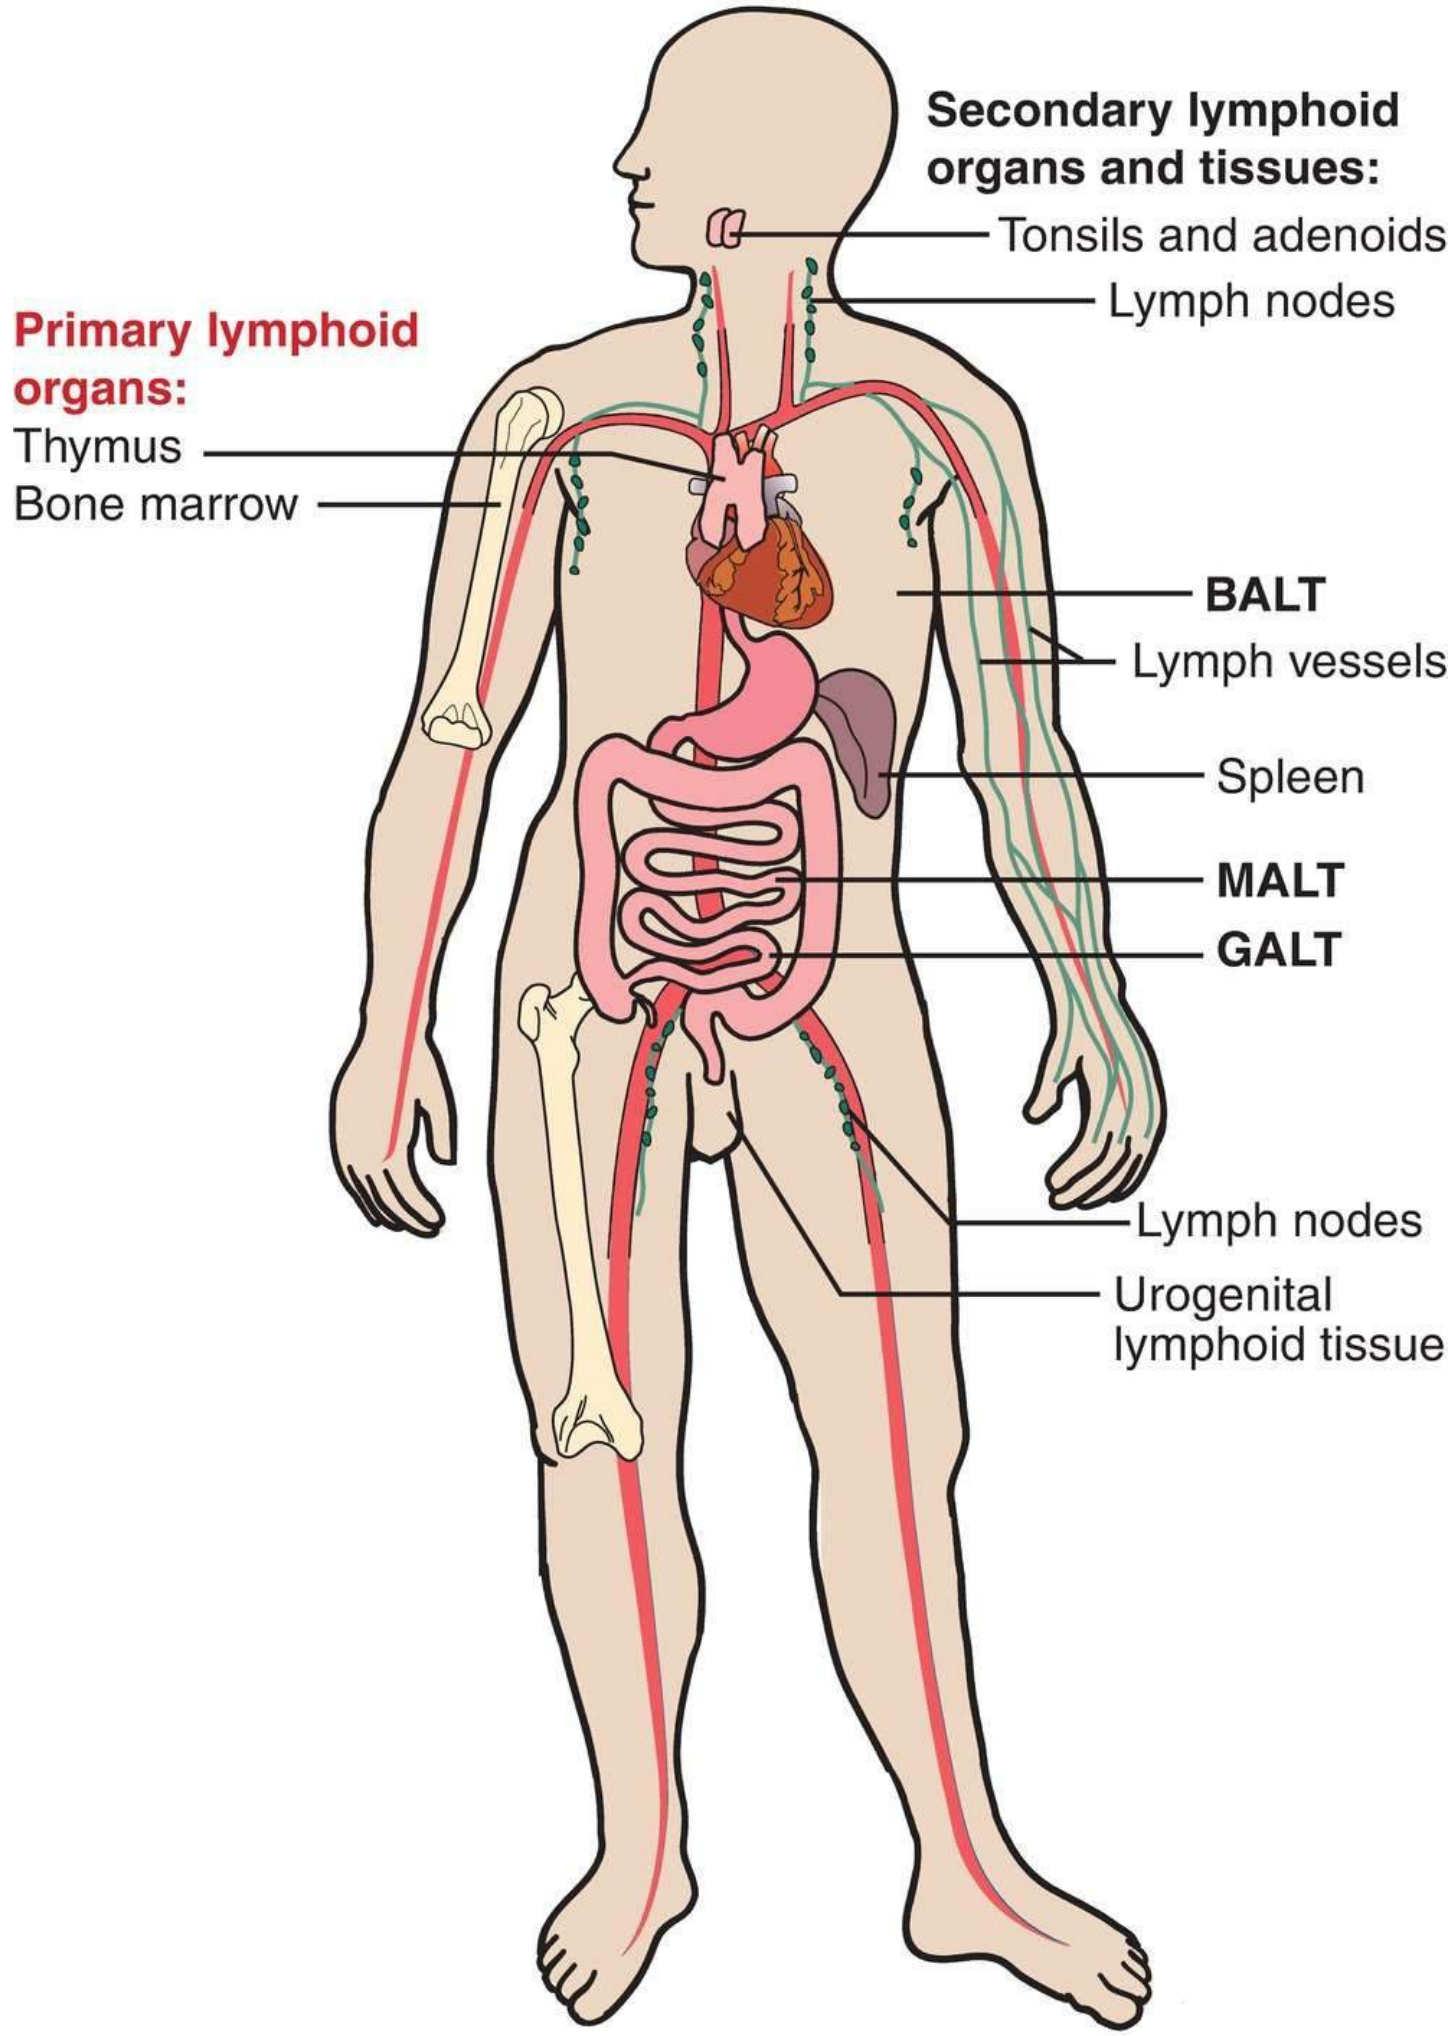
The immune system protects the body against infection with layered defenses of increasing specificity. The surface barriers (e.g., skin and membrane secretions) are the first line of defense to prevent pathogens such as bacteria and viruses from entering the body. The skin and respiratory tract provide an important chemical barrier by secreting antimicrobial agents. Within the genitourinary and gastrointestinal tracts, commensal floras serve as biological barriers by competing with pathogenic bacteria for food and in some conditions changing their environment such as pH or available iron. The biologic barrier reduces the probability that pathogens will reach a critical mass to cause an illness.

If pathogens breach these barriers, the **innate immune system** provides an immediate nonspecific response. The innate response is triggered when specific molecules on the microbes are identified by pattern recognition receptors on immune cells. If pathogens successfully evade the innate response, the body engages a third layer of protection, the **adaptive immune system**, which is activated by the innate response. The cells of the adaptive response are specifically recruited to participate in the reactions, and this is why this immunity is also called *acquired immunity*. The adaptive system can change its response during an infection to improve recognition of the pathogen.

Thymus and bone marrow are linked to the adaptive immune system.

The thymus and bone marrow are called **primary** (or **central**) **lymphoid organs**. Lymphocytes, the specialized leukocytes involved in adaptive immunity, mature and become *immunocompetent* in the primary lymphoid organs. All lymphoid cells originate, and some complete the maturation process within the bone marrow, while others move to secondary lymphoid organs to complete the process (e.g., the eosinophil moves to the spleen to complete maturation). The exception is the pre-T cell, which leaves the bone marrow and undergoes complete maturation in the thymus before it is released into the body.

Lymph nodes, tonsils, mucosa-associated lymphoid tissues (MALT), and the spleen are considered **secondary** (or **peripheral**) **lymphoid organs**. These are the organs where mature immune cells participate in specific immune reactions. Figure 10.1 shows the primary and secondary lymphatic tissues.



Secondary lymphoid organs and tissues:
Tonsils and adenoids
Lymph nodes
Primary lymphoid organs:
Thymus
Bone marrow
BALT
Lymph vessels
Spleen
MALT
GALT
Lymph nodes
Urogenital lymphoid tissue

Figure 10.1 Leukocytes are special cells of the adaptive immune system called lymphocytes. The thymus and bone marrow are primary sites of lymphocyte maturation. Lymph nodes, tonsils, the spleen, and lymphoid tissues of the lung, gut, and urogenital tract are secondary lymphoid organs. BALT, bronchus-associated lymphoid tissue; MALT, mucosa-associated lymphoid tissue; GALT, gut-associated lymphoid tissue.

Lymph nodes are the sites through which blood, lymph, and immune cells are filtered. These encapsulated organs are located throughout the body at junctions of **lymphatic vessels** and are optimized for interaction between professional **antigen-presenting cells** (**APCs**) and T and B lymphocytes. The movement of lymph through lymph vessels and lymph nodes is supported by skeletal muscle movement but is otherwise passive. There is no organ similar to the heart to pressurize the lymph flow.

During a bacterial infection, lymph nodes swell as a result of proliferation of immune cells. Palpation of lymph nodes is part of most orderly clinical examinations and gives an indication of the activity level of the immune system.

There is an abundance *of noncellular immune elements* in blood and lymph. They include, but are not limited to, antibodies, communication molecules (e.g., cytokines and chemokines), and complement and are presented later in the chapter. Additionally, the innate immune system encompasses a variety of fluids and other noncellular components with antimicrobial characteristics.

IMMUNE SYSTEM ACTIVATION

The paramount function of the immune system is to recognize and destroy pathogens that enter the body. Pathogens contain **antigens**; some are surface antigens and some are antigens found within the pathogen. **Immunogens** are antigens that activate the immune system, whereas **haptens** are antigens that do not activate the immune system. However, haptens do become immunogenic when linked to a carrier molecule. Infection activates the immune system. More specifically, infection activates B and T lymphocytes through receptor recognition of immunogens.

Pathogens may enter the body through a cut in the skin (as in the case of the hepatitis B virus), through membranes of the respiratory tract (as in the case of the measles virus), or through membranes of the digestive tract (as in the case of *Salmonella* bacteria). Pathogens may also be transmitted by insect bites (as in the case of malaria) or by sexual encounter (as in the case of the human immunodeficiency virus).

In addition to pathogens, other organic and nonorganic foreign substances can be antigenic. Pesticides, cosmetics, and exhaust particles are examples of such substances that can activate the immune system.

Large complex molecules and proteins are the best activators of the immune system.

Proteins are by far the best immunogens. Their complex three-dimensional conformation, their electrical charges, and their ability to aggregate make them good candidates to be recognized by immune defenses. Polysaccharides, lipids, and nucleic acids by themselves induce either weak or no immune responses. But, similar to proteins, their immunogenicity increases with increasing complexity. For instance, polymers made of only one type of nucleic acid are poor immunogens, whereas polymers made of more than one base are usually well recognized. Lastly, size matters. Typically, only molecules with a molecular weight of 4,000 Da or above elicit an immune response.

Because proteins are immunologically the best recognized, they are used for many vaccines to improve the immunogenicity. For instance, the vaccine targeting the carbohydrate capsule of *Streptococcus pneumoniae* is conjugated to protein carriers to enhance its effectiveness.

The immune system is highly selective: Severe injury and necrosis activate immune defenses, whereas mild injury and apoptosis do not.

Immune activation is selective. For example, injury and necrosis will activate the immune system, but mild injury and apoptosis will not. The activation is coupled with other body defenses and reactions. When the body sustains injury, whether from physical force, cellular breakdown, or biologic infection, the decision for immune activation depends on the severity and type of the injury.

If the cells are not too severely injured, the injured and surrounding cells may adapt to the event by changing their size, number, and functions, without activating immune responses. For instance, if skeletal muscle cells are stressed within tolerable limits, they become larger and improve their functions. This is the principle for strength exercise. On the other hand, severe cellular stress can activate the immune system, for instance, in the case of airway cells that respond strongly to irritating smoke particles with inflammation.

If the damage to a cell is too great, the cell will die by **necrosis**. The immune system is activated when the cells collapse and their cellular contents, including lysosomal enzymes, leak into the surrounding tissue, causing further damage and starting an intense inflammatory response. As a result, chemokines (chemicals leaked from the damaged cells) attract various types of immune cells to the injury site, which further activate the immune response. An example is Duchenne muscular dystrophy. In this case, severe muscle fiber stress and necrosis as a result of genetically induced muscle weakness lead to immune responses that further promote the death of dystrophic muscle. Necrosis pulls the body away from homeostasis.

In contrast to necrotic cell death, cell death by **apoptosis** will not cause immune activation. Apoptotic cells die without bursting apart, and as a result, no damaging substances are released from the cells and an inflammatory response is avoided. Apoptosis is the body's nonpathologic process of removing cells. This is especially important for the role of the immune system in maintaining homeostasis and regulating tolerance. Every day, several million B and T lymphocytes are generated, and most are removed, apoptotically, by negative selection (or activation-induced cell death).

Complementary processes are involved in the activation of innate and adaptive immunity.

Exogenous pathogens, such as extracellular bacteria and intracellular bacteria, that are still identifiable from outside the cell are first attacked by the **innate immunity** response (Fig. 10.2). Phagocytic cells, such as neutrophils, eosinophils (in some cases), macrophages, and dendritic cells, might engulf the antigen or destroy it with enzymes and nitrogen and oxygen reactive species. The pathogen might directly activate **complement** proteins, another important component of the innate immune system. This activation can result in **lysis** of the organism and promote activation of the *inflammatory response*, or **inflammation**.

Innate Immunity

Figure 10.2 Overview of the immune system. As part of the innate immunity, the human body has natural measures to prevent entry of microbes. When these barriers are overcome, a foreign invader first encounters phagocytes. Complement may bind to the invader and facilitate its phagocytosis or lysis. Inflammation may develop. If the innate immune system cannot destroy the invader, the adaptive immune system is activated with T and B lymphocytes as its effectors. Although the innate and adaptive immune systems are characterized by contrasting functions and timing, they work closely together and rely on each other to succeed in removing invading pathogens.

If some antigenic (immunogenic) parts of the microorganism are present on the plasma membrane of the host cell, antibodies can bind directly to the infected cell and activate complement (discussed later in detail).

If the pathogen evades the innate immune system and no antibodies are present, then the **adaptive immune system** response is triggered. Adaptive immunity is also activated by viruses, protozoan parasites, and intracellular bacteria that cannot be recognized from outside the cell (endogenous antigens). In this case, the antigen is degraded intracellularly into smaller pieces. The pieces are then incorporated into the host cells' plasma membranes and, together with **major histocompatibility complex** (**MHC**) **proteins**, are presented to T cells (discussed later in detail). These microorganisms are ultimately eliminated together with the infected host cell.

Although innate and adaptive immune systems are characterized by contrasting functions and timing, they work together in ways that obscure their differences. For instance, the initiation and adequate functioning of the innate system often depend on the presence of elements of the adaptive immune system such as small amounts of specific antibody in blood plasma. The reverse is true as well. Antibodies and other mediators of the adaptive immune system depend on elements that are typically associated with the innate immune system such as phagocytic macrophages and dendritic cells.

Only when working together can the innate and adaptive immune systems prevent the establishment and long-term survival of infectious agents. For this reason, Figure 10.2 is presented as an analogy of the Chinese yin and yang symbol, in which opposites intertwine and complement each other toward a greater whole.

IMMUNE DETECTION SYSTEM

The task of the immune system is to screen millions of molecules and eliminate them when recognized as not being a normal part of the body. For that, it has to discriminate *self* from *nonself*. To destroy only pathogens while leaving the body's own healthy cells intact requires a complex system because microorganisms and human tissue are made of closely related material.

Self-tolerance, the action of the immune system to forgo attacking the body's own cells and proteins, is a multistep process that begins in the thymus during T-lymphocyte development. This process, called *central tolerance*, is discussed later in this chapter. Self-tolerance then continues with additional mechanisms outside of the thymus (called *peripheral tolerance*).

Tolerance.

In addition to self-antigen, a few important foreign antigens also do not activate the immune system (called *acquired* or *induced tolerance*). We generally tolerate food-derived foreign particles (although foods can induce allergic reactions). A mother does not reject the fetal molecules that are derived from both maternal and paternal genes. We also do not destroy the nonpathogenic microbiota in our gastrointestinal tract, even though they are foreign to the human body.

Any mistake in the process of self/nonself discrimination can have devastating consequences to the organism. When a body erroneously mounts an immune response against its own tissues, it can lead to an *autoimmune disease*.

IMMUNE SYSTEM DEFENSES

The immune system employs three mechanisms to mount its defense against invaders: physical barriers, innate immunity, and adaptive immunity.

Surface barriers are the immune system's first line of defense.

As mentioned earlier, our immune system protects against infection with layered defenses of increasing specificity. The physical barrier (e.g., skin and membrane secretions) is the first line of defense to prevent pathogens, such as bacteria and viruses, from entering the body. Our skin is an effective anatomical and physiologic barrier against microorganisms. First, the cells of the epidermal layers are dry and densely packed, making them an inhospitable environment to many bacteria. Furthermore, salty secretions from sweat glands and oily secretions from the sebaceous glands associated with hair follicles create a hyperosmotic and slightly acidic skin environment, which dehydrates bacteria and discourages those that prefer a neutral pH for colonization. Additionally, the continuous desquamation of skin cells eliminates bacteria adhering to epithelial cells. Lastly, many noninvasive, nonpathogenic commensal (part of normal microbiota) microorganisms on the skin prevent growth of harmful microorganisms in a process called *competitive exclusion*.

Acidity is also used in other places of the body as an antimicrobial tool. For example, natural microbiota alters the fluids of the vaginal and urinary tracts to an acidic pH below 4.5 so that yeast and other microorganisms cannot grow. Likewise, parietal cells of the stomach create highly acidic gastric juice below pH 3 to hinder microbial growth.

Other factors such as low oxygen tension and fever are said to contribute to the barrier defenses, but their physiologic impact is still under discussion. The role of fever is thought to have a direct negative effect on certain microorganisms and may also enhance the efficiency of **phagocytosis**.

Cellular secretions

Various types of cellular secretions destroy and eliminate pathogens. *Mucus* prevents microorganisms from adhering to epithelial cells and contains antibacterial components. The mucus of the gut blocks, inactivates, or destroys pathogens associated with food before they can enter the body. A thin layer of mucus covering the airway from the nose to the bronchioles traps inhaled viruses, bacteria, pollens, and other particles and facilitates their removal before they can damage the airway lining cells. The flow of *saliva* helps to wash away bacteria attached to food particles while attacking them with thiocyanates and lysozymes. Saliva can also contain antibodies that destroy oral bacteria. *Tears* and *nasal secretions* contain similar antibacterial components.

The list of chemical factors with antimicrobial characteristics is long. It includes **pepsin** in the stomach, **defensins** produced by immunologic cells, and **surfactant** of the lung, to name a few. **Interferons** are a group of proteins that are produced by cells following viral infection. Complement is a group of serum proteins that circulate in an inactive state and can be activated by a variety of specific and nonspecific immunologic mechanisms. Their actions, sometimes called the *humoral component* of the innate immune system, are discussed in more detail below. An important role of these chemical factors is to connect the three lines of immune system defenses.

Innate immunity is the second line of defense.

The ability of cells and tissues to respond to and to get rid of environmental challenges is an ancient evolutionary development that has persisted through vertebrate development as innate immunity. The zoologist Metchnikoff discovered that cells of a starfish could phagocytose invaders, which means that this 600-million-year-old invertebrate possesses an innate immune system. Innate immunity is also called *nonspecific* or *natural immunity*. Table 10.1 contrasts its basic characteristics in humans with the characteristics of the adaptive immune system (also called the *acquired immune system*). The innate immune system:

TABLE 10.1 Characteristics of the Innate and Adaptive Immune Systems

	Innate	Adaptive
System	Primitive, found in invertebrates	Evolved in early vertebrates
	Present at birth	Develops and changes throughout life
	Responses do not change over time	
Stimulation	Not required	Required
Specificity	Minimal	Highly specific
	Fixed	Self vs. nonself discrimination
	Microbial pattern recognition	Diverse antigen receptors mediate responses.
Response	Within minutes	Develops over days
	No change in quality and quantity over time	Improved by previous exposure
Memory	No	Yes
Soluble factors	Lysozyme, complement, acute-phase proteins, interferon, cytokines	Antibodies, cytokines (interleukins), interferon
Cells	Phagocytic leukocytes, natural killer cells	T cells, B cells

- Is present at birth
- Persists throughout life
- Can be mobilized rapidly and acts quickly
- Attacks all antigens fairly equally because it recognizes patterns on pathogens
- Maintains the quantity and quality of the response (the response does not change over time)

Phagocytic leukocytes

As mentioned in Chapter 9, the leukocytes commonly found in the blood are neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Most of these leukocytes participate in innate immune mechanisms, while lymphocytes are involved with the adaptive immune response. Innate leukocytes include phagocytes (neutrophils, macrophages, eosinophils, and dendritic cells) and nonphagocytic cells as outlined in Table 10.2. Phagocytic cells identify and eliminate pathogens, either by attacking larger pathogens through contact or by engulfing them. They can be activated by T-cell contact (e.g., neutrophils), by T-cell cytokines (e.g., macrophages), or by contact with pathogens. For the latter, phagocytes can directly sense the pathogens through a group of transmembrane receptors, the so-called **toll-like receptors.**

TABLE 10.2 Cellular Elements of the Innate Immune System

Cells	Main Function	Phagocytosis
Neutrophils	Kill microorganisms intracellularly and extracellularly	+
Macrophages	Kill microorganisms intracellularly and extracellularly Present antigen	+
Dendritic cells	Phagocytose pathogens Present antigen	+
NK and LAK cells	Destroy virus-infected and tumor cells	–
Eosinophils	Secrete factors that kill certain parasites and worms	+
Mast cells	Release factors that increase blood flow and vascular permeability	–

NK, natural killer; LAK, lymphokine-activated killer.

On activation, phagocytes engulf the microorganism, particle, or cell debris. The engulfed matter is enclosed within vacuoles and enzymatically digested, after fusion with lysosomes. Some pathogens have been coated with **opsonins** in a process called opsonization to render them more attractive to phagocytosis. Examples of opsonins are immunoglobulin G (IgG) antibody and the C3b molecule of the complement system.

Neutrophils (one of the *polymorphonuclear leukocytes*) recognize chemicals produced by bacteria in a cut or scratch and migrate toward them. Once arrived, they ingest the bacteria and kill them. For killing,

neutrophils use proteolytic enzymes and reactive oxygen and nitrogen species produced as part of the respiratory burst (see Chapter 9).

Macrophages are derived from circulating monocytes. Once monocytes migrate into tissue, they differentiate and become the larger, more powerful, phagocytic macrophages. Macrophages kill, like neutrophils, by using the respiratory burst and proteolytic enzymes. Macrophages secrete various cytokines that attract other leukocytes to the infection site and initiate the acute-phase inflammatory response. Finally, macrophages act as professional APCs to T cells and are hence an important bridge to the T-cell–mediated immunity of the adaptive immune response.

Macrophages can circulate in lymph vessels (*wandering, nonfixed macrophages)*, or they can reside in connective tissue, in lymph nodules, along the digestive tract, in the lungs, in the spleen, and in other places (*mature, fixed macrophages)*. Fixed macrophages are part of the **reticuloendothelial system** (**RES**), which, in addition to removing pathogens, also removes old cells and cellular debris from the bloodstream. Some of these macrophages have their own names. For instance, the macrophages along certain blood vessels in the liver are called **Kupffer cells**, whereas the macrophages of the joints are called *synovial A cells*. *Microglial cells* are macrophages located in the brain.

Eosinophils are best known as participants in allergic reactions, where they might detoxify some of the inflammation-inducing substances. But they are also primarily evolved to secrete factors that punch small holes in worms and other parasites, causing them to die. However, they can also be phagocytic when the situation permits.

Dendritic cells are, like macrophages, a critical link between the innate and adaptive immune systems. They exist in an immature form throughout the epithelium of the skin (e.g., **Langerhans cells**), the respiratory tract, and the gastrointestinal tract. After phagocytosis of pathogens, the cells mature and travel to regional lymph nodes, where they activate T cells, which then activate B cells to produce antibodies against the pathogen.

Nonphagocytic leukocytes

In addition to phagocytic cells, innate leukocytes also comprise nonphagocytic cells (NK and LAK cells and mast cells) as shown in Table 10.2. NK cells attack aberrant body cells such as virus-infected cells and malignant cells. They release the cytolytic protein **perforin**, which forms a pore in the plasma membrane of the target cell. Proteolytic enzymes, such as **granzyme**, are also part of the NK's cytoplasmic granules. When released, it enters the target cell and induces apoptosis. On exposure to lymphocyte secretions, such as interleukin-2 and interferon-γ, NK cells become **lymphokine-activated killer** (**LAK**) **cells**, which are even more efficient in killing than NK cells.

Mast cells are present in most tissues in the vicinity of blood vessels and contain many granules rich in **histamine** and **heparin**. They are especially prominent under coverings lining the body surfaces such as the skin, mouth, nose, lung mucosa, and digestive tract. Although best known for their roles in allergy and anaphylaxis of the adaptive immune system (see next section), mast cells play an important role in the innate system as well. Additionally, they are intimately involved in wound healing. They release factors that increase blood flow and vascular permeability, bringing components of immunity to the site of infection. In combination with IgE antibody from B cells, mast cells can also target parasites that are too large to be phagocytosed, such as intestinal worms.

Adaptive immunity is the third line of defense.

Adaptive immunity uses three important features in its method of attack: specificity, diversity, and memory. Microbes that escape the onslaught of cells and molecules of the innate immune system face attack by T cells, B cells, and B-cell products of the adaptive immune system, also called the *acquired immune system*. Table 10.1 lists its basic characteristics in comparison to those of the innate immune system. The adaptive immune system:

- Is a relatively recent evolutionary development and characteristic of jawed vertebrates
- Is activated by thousands of diverse antigens, which are presented as glycoproteins on the surface of bacteria, as coat proteins of viruses, as microbial toxins, or as membranes of infected cells
- Responds with the proliferation of cells and the generation of antibodies that specifically assault the invading pathogens
- Responds slowly, being fully activated about 4 days after the immunologic threat
- Is capable of immunologic memory, so that repeated exposure to the same infectious agent results in improved resistance against it

Specificity

The *specificity* of the adaptive immune system is created by **antigen recognition molecules**, which are synthesized prior to the exposure to antigen and, in B lymphocytes, can be modified during the immune response to make them even more specific to the antigen.

Several different types of recognition molecules participate in this anticipatory defense system: (1) specific receptors on T and B lymphocytes; (2) major histocompatibility complex (MHC) proteins (recognition molecules on cell surfaces); and (3) antibodies, which are the secreted form of B-cell receptors (BCRs). Though the general structure for the types of molecules is very similar (e.g., every antibody has a typical Y-shaped form), a small region of each individual molecule is different (e.g., for antibodies, the hypervariable region) and allows only the binding of a specific antigen. There are five major classes of antibodies: IgG, IgM, IgA, IgE, and IgD. Each class of antibody plays a unique role in immune defense and will be discussed later in the chapter.

An antigen might be recognized by several recognition molecules. To stay with the example of antibodies, most protein antigens have several **epitopes** (the part of the antigen that binds the antibody) and, hence, are recognized by different B cells, which release different antibodies to mount a **polyclonal antibody** response.

On the other hand, closely related antigens may share epitopes (**cross-reactivity**). For instance, antibodies that are induced by some microbial antigens cross-react with polysaccharide antigens found on red blood cells and are the basis for the ABO blood type system (see Chapter 9).

Diversity

The *diversity* of adaptive immune responses is based on a huge variety of antigen receptor configurations, essentially one receptor for each different antigen that might be encountered.

In a person, there are about 10^{18} different possible **T-cell receptors** (**TCRs**), with each T cell expressing one type of receptor. The **B-cell receptor** (**BCR**) is a membrane-bound form of immunoglobulin. There are about 10^{14} possible BCRs, again one type of immunoglobulin per B cell. The

molecule diversity is mainly achieved by variable recombination of gene segments prior to exposure to antigen and, in the case of immunoglobulins, additionally by mutation of the molecules after exposure to antigen.

The recognition of an antigen by the lymphocyte with the best-fitting receptor occurs mainly in the local lymph node and induces the activation, proliferation, and differentiation of the responsive cell, a process known as **clonal selection**. Figure 10.3 shows the process for four B cells with different BCRs and one recognizing the antigen. Not evident in the figure is that optimal activation and proliferation of B cells (and, equally, T cells) occur only when costimulatory signals, secondary to TCR and BCR bindings, are present.

Plasma cells
Memory cells

Figure 10.3 Clonal selection of lymphocytes. Only the clone of the lymphocyte that has the unique ability to recognize the antigen of interest proliferates and generates progenitor cells. These cells are specific to the inducing antigen but may have different functions. In the case of B cells, plasma cell clones produce antibodies, and memory cell clones enhance subsequent immune responses to the specific antigen. In the case of T cells, the clones become either effector cells or memory cells. Clonal selection occurs in secondary lymph organs such as the local lymph nodes.

Clonal selection amplifies the number of T or B lymphocytes that are programmed to specifically respond to the inciting stimulus. In Figure 10.3, this means all resulting cells from proliferation have the same BCRs, ready to bind more of the specific antigen. However, not all cells possess the exact identical functional characteristics. For instance, antigen binding to the BCRs induces their development into memory cells and into **plasma cells.** Plasma cells are much larger and are capable of producing and secreting antibodies. Initially, the plasma cells produce IgM antibodies and later can switch to produce IgG, IgA, or IgE antibodies when antibodies with different functional capabilities are needed. This maturation process is called *Ig isotype switching*.

Similarly, clonal proliferation of T cells can lead to the generation of more *antigen-specific T cells* and to the production of **effector T cells**, such as T helper and cytotoxic T cells, and memory T cells.

Memory

The *memory* of the adaptive immune system is based on the fact that some descendants in the expanded B-cell and T-cell clones function as **memory cells** (see Fig. 10.3). These cells mimic the reactive specificity of the original lymphocytes that responded to the antigen and accelerate the responsiveness of the immune system when the antigen is encountered again (**anamnestic response**) and are the basis for immunization via vaccinations.

CELL-MEDIATED AND HUMORAL RESPONSES

The adaptive immune system has two major branches, cell-mediated and humoral immunity. As mentioned previously, though presented as distinct systems, no part of the immune system works separately. Rather, they all work in a cooperative fashion using cytokines and other means as a communication system.

B cells mediate the humoral immune response, whereas T cells regulate the cell-mediated immune response. The CD4 and CD8 ("CD" for cluster differentiation) T-cell subgroups of the cellular immunity branch of the adaptive immune system have different functions and are divided into additional subtypes according to their molecular appearance, cytokine sensitivity and production, and specific functions. These cells form, with each other and with other immune cells, a complex network of communication and immune response that is the basis for the efficiency, flexibility, and longevity of the adaptive immune system.

Figure 10.4 graphically summarizes important interactions between cells. The figure is organized according to the type of encountered antigen (exogenous or endogenous, left), to the sensing and responding processes (antigen recognition and presentation and immune response, top), and to the involvement of T cells and B cells (cellular and humoral immune responses, right).

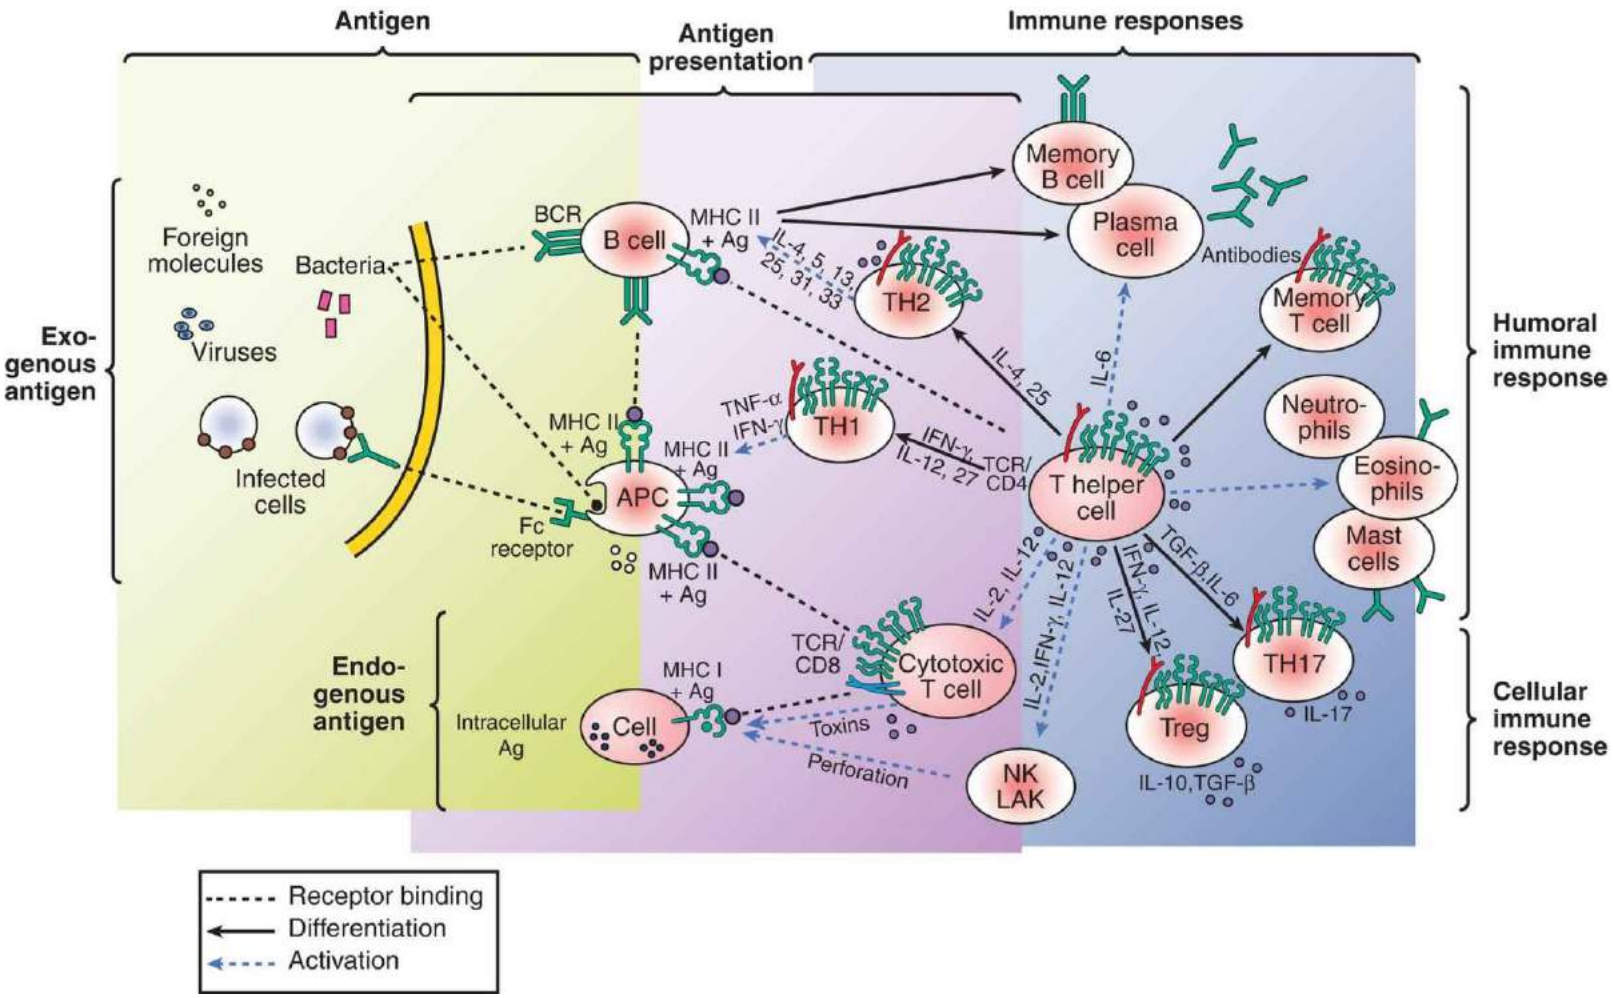

Figure 10.4 Cellular and humoral immune responses of the adaptive immune system. Activated T cells accomplish cellular immune responses, and B cells and antibodies mediate humoral immune responses. Exogenous antigen activates B cells by binding to the B-cell receptor (BCR) and T cells by binding to the T-cell receptor (TCR). However, TCR binding only occurs when antigen peptide is presented by antigen-presenting cells in association with major histocompatibility complex (MHC)

proteins. The TCR is either associated with CD4 or CD8, depending on the T-cell type. Endogenous antigens are presented via MHC class I proteins to cytotoxic T cells, which destroy the host cell together with the intracellular pathogen. The immune response involves two paths, one using B cells (humoral immune response) and one using cytotoxic T cells (cellular immune response). Millions of different B and T cell types exist to recognize millions of different antigens. Ag, antigen; CD, cluster of differentiation; IFN, interferon; IL, interleukin; LAK, lymphokine-activated killer cell; NK, natural killer cell; TH, T helper cell; TNF, tumor necrosis factor; Treg, T regulatory cell.

Cell-mediated response involves activation of T cells and release of cytokines.

Cell-mediated responses in adaptive immunity do not involve antibodies or complement but, rather, activation of macrophages, NK cells, T lymphocytes, and the release of various cytokines in response to an antigen.

T cells continuously patrol the body and check the foreignness of antigen. T cells become activated when antigen binds to the specific TCR plus a costimulatory element. Antigen can only bind to the TCR when presented by APCs in combination with MHC proteins. The complex interaction between the T cell and the APC is called **immunologic synapse**. Figure 10.5 and Table 10.3 summarize the events at the synapse.

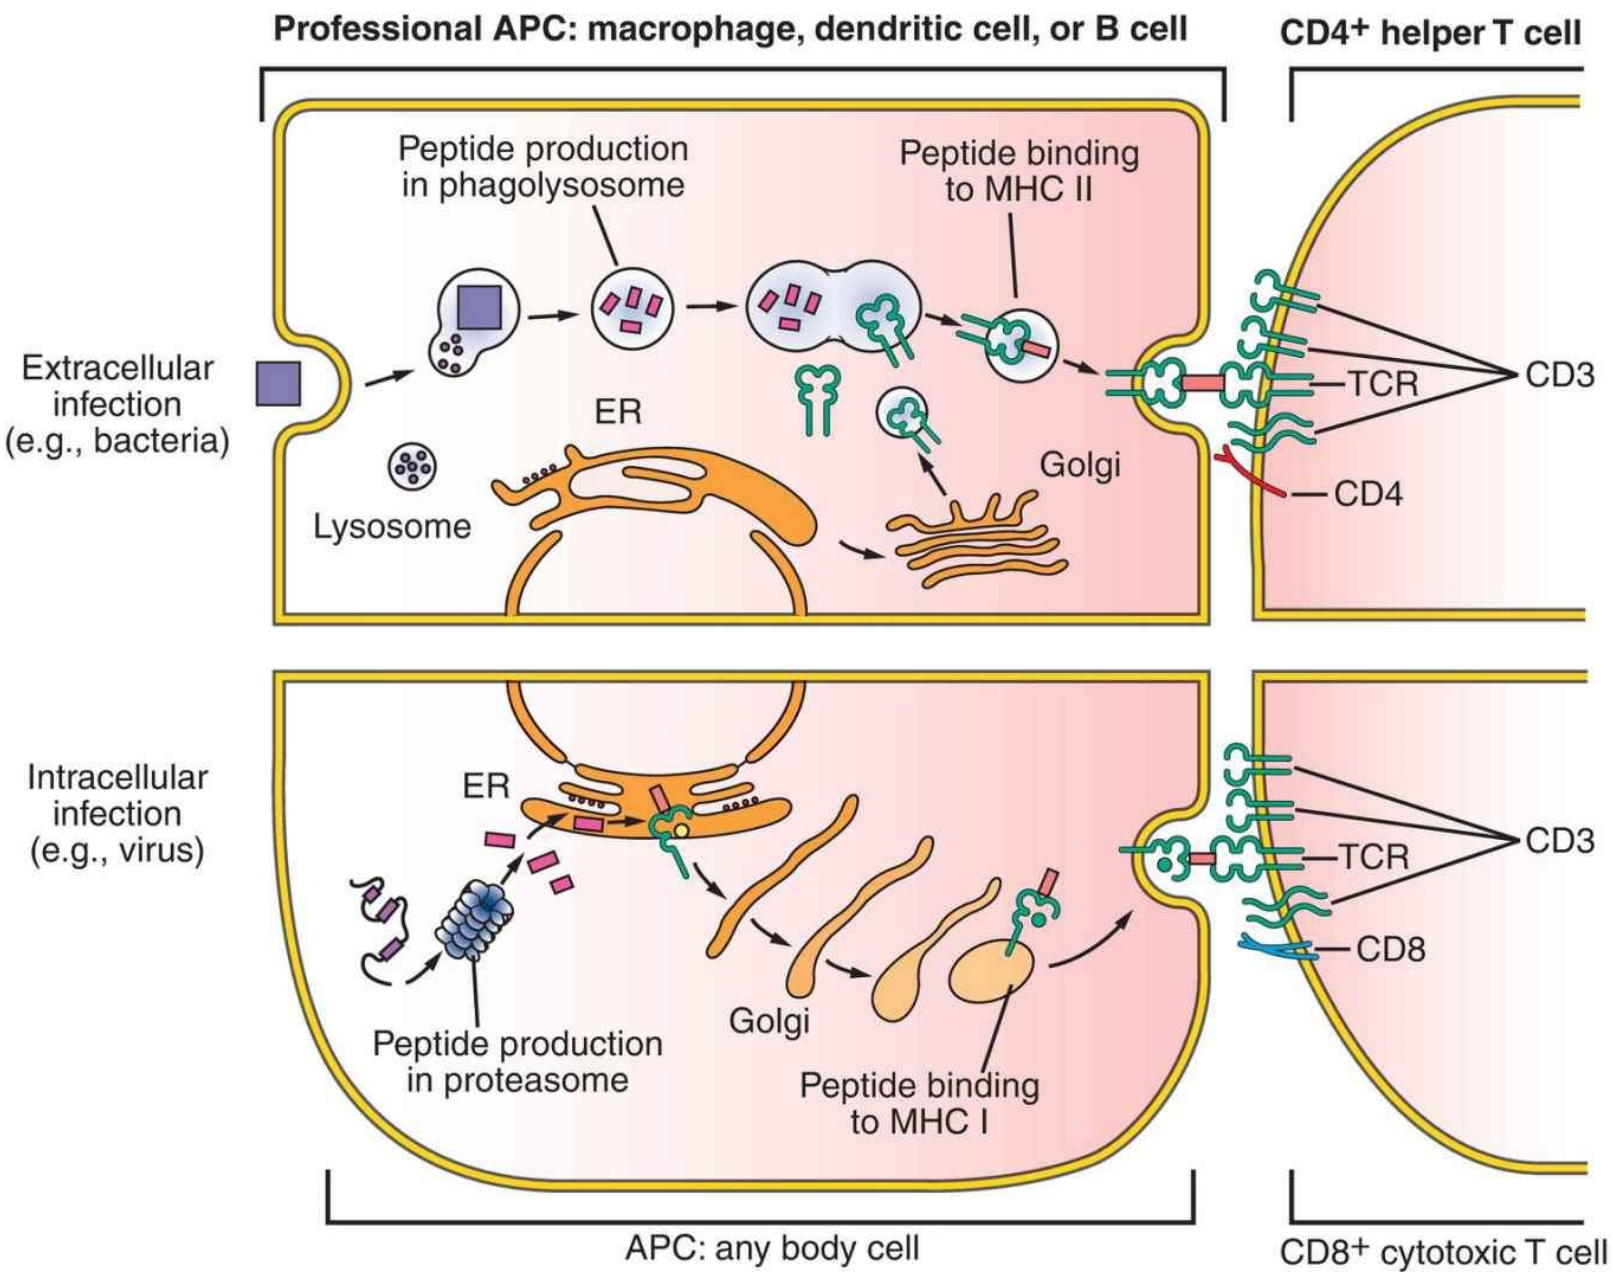

Figure 10.5 Antigens bind to antigen-specific receptors. An antigen cannot induce an immune response by itself. They first have to bind to an antigen-specific receptor to trigger a response. Extracellular antigens are phagocytosed, degraded within the phagolysosome, and associated with MHC class II

molecules. The antigen is then presented on the surface of the professional antigen-presenting cell, where it binds to the T-cell receptor (TCR) of $CD4^+$ T helper cells. Macrophages, dendritic cells, and B cells are such antigen-presenting cells. Intracellular antigen is digested within the proteasome, associated with MHC class I molecules, and presented on the surface of the cell to the TCR of $CD8^+$ cytotoxic T cells. Almost every cell in the body can present antigen in this latter way. CD, cluster of differentiation; ER, endoplasmic reticulum; MHC, major histocompatibility complex.

TABLE 10.3 T-cell–Mediated Immunity Response According to the Source of Antigen

	Intracellular Infection (Viruses, Some Bacteria)	Extracellular Infection (Bacteria)	Extracellular Proteins: Antigen surfaces, Vaccines, and Toxins
Location of antigen	Cytosol	Phagosomes	Endosomes
Antigen-presenting cell (APC)	Any cell	Professional: macrophages, dendritic cells, B cells	B cells
Location of APC	Anywhere	Lymphoid and connective tissue, body cavities, epithelium	Lymphoid tissues, blood
Molecules of display	MHC class I	MHC class II	MHC class II
Antigen recognition cells	$CD8^+$ CTL cells	$CD4^+$ T_H1 and $CD4^+$ T_H2 cells	$CD4^+$ T_H2 cells
Response	Release of cytotoxic effector molecules	Release of macrophage-activating effector molecules and molecules that support B-cell activation and differentiation	B-cell activation and $CD4^+$ T_H cell activation
Effect	Death of infected cell	Killing of bacteria and parasites; supported activation of B cells	Secretion of antibody to eliminate bacteria and toxins

MHC, major histocompatibility complex; CD, cluster of differentiation; CTL, cytotoxic T cells; T_H1, T helper 1 cell; T_H2, T helper 2 cell.

Major histocompatibility complex

The **major histocompatibility complex** (**MHC**) is a large genomic region or gene family found in most vertebrates. When activated, MHC genes produce MHC molecules that play an important role in the immune system.

In the case that the antigen stems from extracellular proteins or phagocytosed bacteria, the antigen is digested intracellularly within phagolysosomes and associated with **MHC class II molecules** on the surface of professional APCs, which then present the antigen to the TCR of $CD4^+$ T helper cells (see Fig. 10.4, upper part). Only macrophages, dendritic cells, and B cells can do so; hence, they are professional APCs.

Macrophages become APCs when they upregulate their MHC II molecules in response to infection and appropriate stimuli such as **lipopolysaccharide** (**LPS**) from gram-negative bacteria. *Dendritic cells* are mostly found in peripheral tissue, where they ingest, accumulate, and process antigens. *B cells* become activated by ligand binding to the BCR. Hence, they present the particular antigen to which the antibody that they express is directed. For other antigens, B cells are not very efficient APCs.

Almost every nucleated cell in the body can present antigen to the TCR of $CD8^+$ cytotoxic T cells. In this case, the antigen is an intracellular pathogen, which is degraded in the cytosol and associated with

MHC class I molecules (see Fig. 10.5, lower part).

Similarly, exposure to foreign antigen from a tissue graft triggers an immune reaction in the body. This occurs when the tissues of the donor and the recipient are not *histocompatible*, which explains the origin for the name "major histocompatibility complex."

T-Cell differentiation

T cells, or *T lymphocytes*, play a central role in cell-mediated immunity. They are distinguished from other lymphocytes, such as B cells and NK cells, by the presence of a special receptor on their cell membrane called T-cell receptors (TCRs). "T" stands for *thymus*, the principal organ responsible for the T cell's maturation.

There are more than 160 known clusters that coat the surface of leukocytes and many other cells. CD3 is found on the surface of all T cells as the signal transduction portion of the TCR. CD3 is made up of three dimers: two zeta proteins, a gamma and an epsilon protein, and an epsilon and a delta protein. CD4 and CD8 are two that are used to identify functionally critical T-cell subsets. To give two other examples, CD14 is an LPS-binding protein receptor on monocytes and macrophages, and CD69 is used as a marker of cell activation for T, B, NK cells, and macrophages.

When the cells coming from the bone marrow reach the thymus, T cells have neither CD4 nor CD8 (*double-negative T cells*), but they then start expressing both markers (*double-positive T cells*) while undergoing maturation in the thymus. During development in the thymus, double-positive cells differentiate into cells with either CD4 or CD8 receptors (single positives). This is a critical step because during this time they develop their ability to distinguish self from nonself peptides.

First, cells that do not bind MHC/antigen complexes within 3 to 4 days will die. The rest of the cells undergo **positive selection**. This means that T cells that proliferate bind antigen (self- or nonself) complexed with class I or II MHC proteins. This happens in the *cortex of the thymus*. At this time, cells that are specific to MHC II protein retain CD4, lose CD8, and become T helper cells. T cells that are specific to MHC I protein retain CD8, lose CD4, and become cytotoxic T cells.

After positive selection, cells undergo **negative selection** in the *medulla of the thymus*. During this process, cells that bind with *high affinity* to MHC/self-antigen complexes die by apoptosis. This is important because these cells would have later reacted with self-peptides and caused autoimmune diseases. Cells that bind with low affinity to MHC/self-antigen are allowed to leave the thymus. They will later only be activated by high-affinity binding to MHC/*foreign* antigen complex, the adequate signal for immune activation.

Killer, helper, and memory T cells

Killer T cells, helper T cells, and memory T cells can be distinguished based on their immunologic function. *Killer T cells*, or cytotoxic T cells ($CD8^+$), are lymphocytes that release lymphotoxins and are designed to kill cells that are infected with viruses or other pathogens.

Helper T cells ($CD4^+$) help determine which types of immune response the body will take to attack a particular pathogen. These cells have no cytotoxic activity and do not directly kill infected cells or clear pathogens. Instead, helper T cells control the immune response by directing other cells to perform these tasks. They function to regulate both the innate and adaptive immune responses. Helper T cells direct the immune response by secreting lymphokines. They stimulate proliferation of B cells and cytotoxic T cells, attract neutrophils, and activate macrophages. The differentiation of $CD4^+$ T helper cells into best-known subtypes T helper 1 and T helper 2 cells occurs after activation in the peripheral lymphoid system. Each

subtype produces a distinct set of effector molecules.

For instance, *T helper 1 cells* release the macrophage-activating effector molecules interferon-γ and tumor necrosis factor-α (TNF-α). The resultant actions, called T helper 1 response, or *type 1 response*, support activities of macrophages and cytotoxic T cells of the cellular immune system.

On the other hand, *T helper 2 cells* produce effector molecules, such as interleukin-4, interleukin-5, interleukin-13, interleukin-25, interleukin-31, and interleukin-33, among numerous other cytokines. This T helper 2 response, or *type 2 response*, promotes the actions of B cells and hence the humoral immune system.

Research shows that the dual T helper cell model is far too simple. For instance, many helper T cells express cytokines from both profiles. They are often named *T helper zero* cells. Additionally, other immune cells express many of the specific T-cell cytokines as well. Several new models have been proposed that include T helper 17 cells, but as of today, there is no unanimously accepted approach.

About 10% of $CD4^+$ T cells are *T regulatory cells* (previously known as *suppressor T cells*). Several subtypes have been named (e.g., Treg, Tr1, and Th3 cells). All have in common the ability to suppress immune responses and, hence, are important in maintaining immune homeostasis. For instance, they are known to inhibit the production of cytotoxic T cells when they are no longer needed. On the other hand, it has been shown that T helper cells are also capable of "regulating" their own responses. Regulatory T cells are thought to be associated with induction of tolerance to microbiota at mucosal surfaces.

Lastly, *memory T cells* are lymphocytes that become "experienced" by having encountered an antigen during a prior infection or a previous vaccination, or a cancer cell. Memory T cells, when encountering an invader (pathogen) for the second time, mount a faster and stronger immune response than they did the first time. These cells are critical for the longevity of specific immunity. T helper cells are absolutely required for B-cell memory cells to develop and antibody class-switching events to occur.

Time delay in cell-mediated immunity

T cells and their products may exert their effects in concert with other effector cells, such as neutrophils, eosinophils, and mast cells. The secretion of T-cell factors that recruit and activate other cells takes time, and thus, the consequences of T-cell activation are not noticeable until 24 to 48 hours after antigen challenge.

An example illustrating this time delay is the *delayed-type hypersensitivity reaction* (see Immunologic Disorders) to purified protein derivative (PPD), a response used to assess prior exposure to the bacteria that cause tuberculosis. Injected under the skin, PPD elicits the familiar inflammatory reaction characterized by local erythema and edema 1 to 2 days post injection.

Cell-mediated immune responses, although slow to develop, are potent and versatile. They provide the main defense against many pathogens. T cells are also responsible for the rejection of transplanted tissue grafts (see Organ Transplantation and Immunology) and the containment of the growth of neoplastic cells (see Immunologic Disorders). A deficiency in T-cell immunity, such as that associated with AIDS, predisposes the affected patient to a wide array of serious, life-threatening infections.

Humoral immunity is mediated by secreting antibodies.

Binding of antigen to the BCR activates B lymphocytes, which then start proliferating. Activated B cells can differentiate into plasma cells that secrete antibodies. If the activated B cell is in the presence of an activated T helper cell, the T helper cell releases cytokines that support B-cell activation (see Fig. 10.4). In the classical, somewhat outdated model, B-cell–activating cytokines, such as IL-4, are part of the T helper 2 response. Most new cells become plasma cells, which produce antibodies for 4 to 5 days, resulting in a high level of antibodies in plasma and other body fluids. These antibodies can bind specifically to the antigenic determinant that induced their secretion. When T helper cells are involved with the activation, other B-cell clones become long-lived *memory B cells* (see Figs. 10.3 and 10.4).

In contrast to the time-delayed response of cell-mediated immunity, antibodies can induce immediate responses to antigens and, thereby, provoke *immediate hypersensitivity reactions* (see Immunologic Disorders).

Antibody structure

Antibodies are also called **immunoglobulins**. The primary structure of an antibody is illustrated in Figure 10.6. Each antibody molecule consists of four polypeptide chains (two *heavy chains* and two *light chains*) held together as a Y-shaped molecule by one or more disulfide bridges.

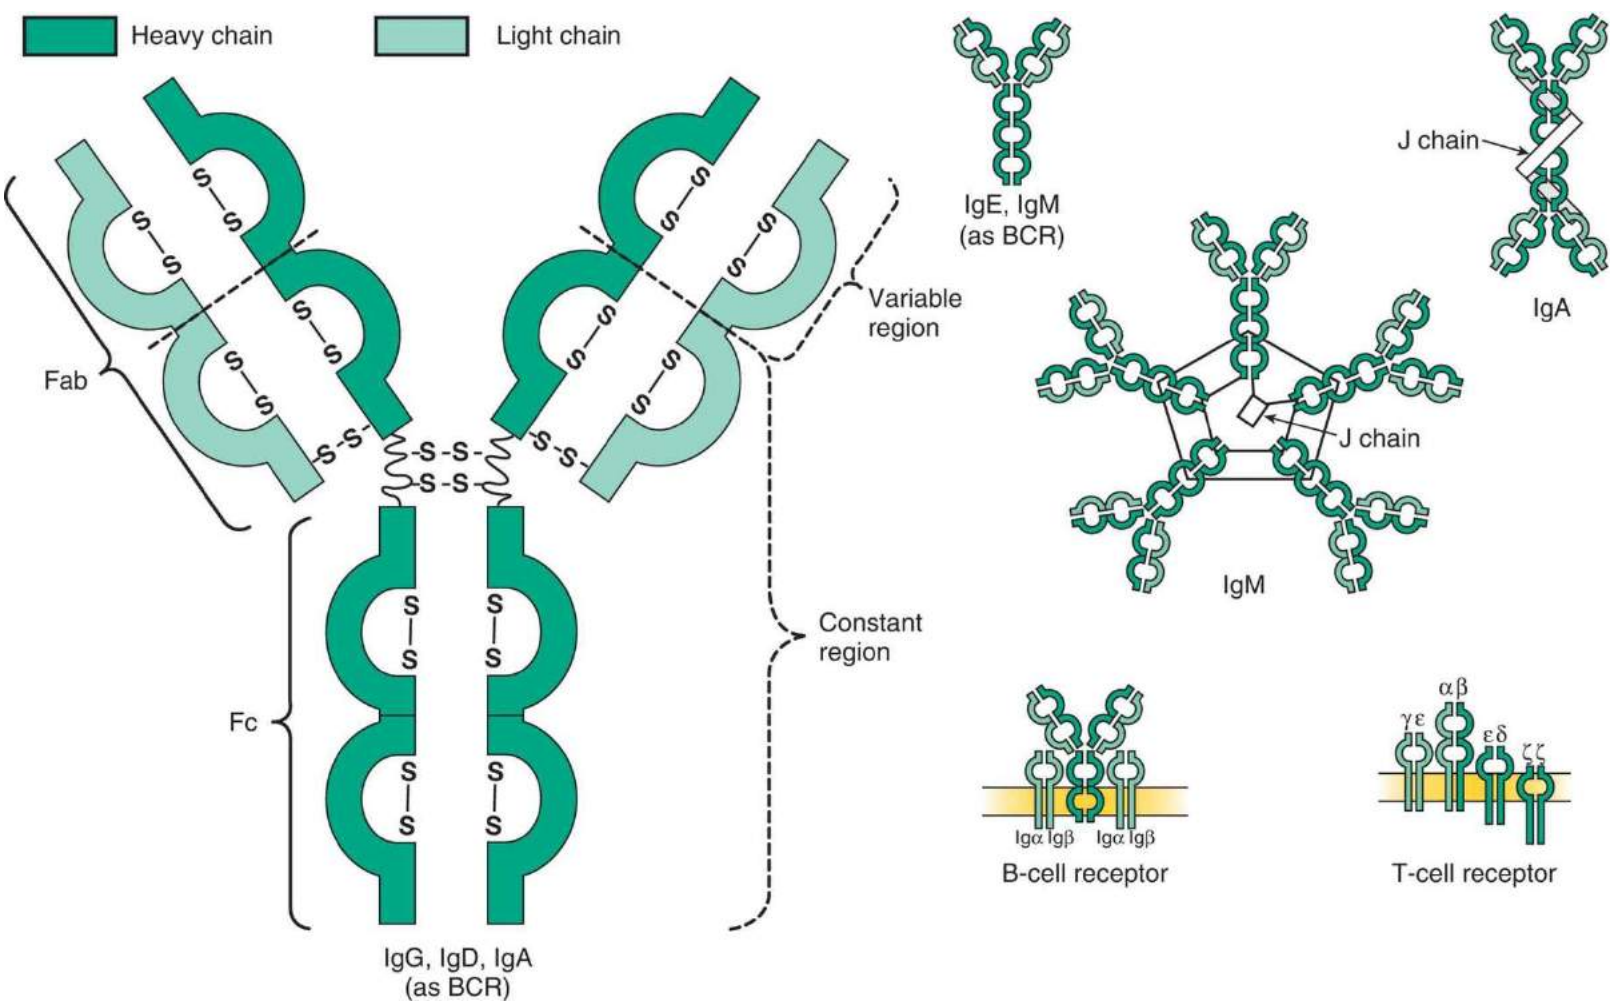

Figure 10.6 Antibodies and antigen receptors. Antibodies are immunoglobulins (Ig) with five isotypes (IgA, IgD, IgE, IgG, IgM). Not shown are the four IgG and two IgA subtypes. The basic unit of each isotype is a monomer that consists of two heavy chains and two light chains held together in a Y-configuration by disulfide bonds. The heavy chains are different for the various isotypes. Each end portion of the "Y" is called *Fab* because it is the *fragment* that contains the *antigen-binding* site. A second, *crystallizable fragment* is called *Fc*. When secreted from plasma cells, IgG, IgD, and IgE consist of one monomer, IgA of two (dimer), and IgM of five (pentamer). The B-cell receptor resembles a membrane-associated Ig monomer. The T-cell receptor contains a Fab-like structure.

There are two isotypes of the light chain, κ and λ. Heavy chains have five different isotypes (α, δ, ε, γ, and μ), which constitute five different classes of antibody, each with different effector functions (see below). Each polypeptide chain possesses both a *constant region*, where the protein structure is highly conserved, and a *variable region*, where considerable amino acid sequence heterogeneity is found.

The amino terminal domains at each end of the forked portion of the "Y" of both the heavy and light chains are known as the *Fab regions* ("Fab" for fragment, antigen binding), which contain the antigen-binding regions. Antibodies are flexible in that the Fab arm can wave, bend, and rotate. This freedom of movement allows it to more easily conform to the shape of the antigen.

The carboxy terminal end of the heavy chain is termed the *Fc region* ("Fc" for fragment, crystallizable). Neutrophils, monocytes, and mast cells can recognize Fc regions via their Fc receptors, which facilitate effector mechanisms such as phagocytosis.

Classes of antibodies

The BCR is on the surface of a B cell and is comprised of an antibody coupled with a dimer (an Igα protein and Igβ protein). The Igα and Igβ dimer is associated with signal transduction, whereas the antibody is focused upon antigen binding. There are five classes (isotypes) of antibodies (IgA, IgD, IgE, IgG, and IgM), each class has specific biologic properties that deal with particular antigens. Figure 10.6 and Table 10.4 summarize the shape and functions of the five major classes of antibodies. Figure 10.6 additionally shows the similarities of the TCR and the BCR to immunoglobulin.

TABLE 10.4 Characteristics of Different Antibody Classes

Characteristic	IgG	IgA	IgM	IgD	IgE
Molecular weight ($\times 10^{-3}$ Da)	150	150, 400	900	180	190
Serum concentration (mg/dL)	600–1,500	85–300	50–400	<15	0.01–0.03
Serum concentration (% of Ig)	~76	~15	8	1	0.002
Half-life (days)	~23	~6	~5	~3	~3
Crosses placenta	+ (not IgG4)	–	–	–	–
Enters secretions	+	+ +	–	–	–
Agglutinates particles	+	+	+ + +	–	–
Allergic reactions	+	–	–	–	+ + + +
Complement fixation	+ (not IgG4)	–	+ +	–	–
Fc receptor binding to monocytes and neutrophils	+ +	–	+	–	–

Ig, immunoglobulin.

IgM is the dominant class of antibody secreted during a primary immune response (first encounter with the antigen). It has a half-life of about 5 days. The BCR on a naïve B cell (B cells that have not yet been activated by antigen) express IgM is a monomer. However, IgM, when secreted by plasma cells, consists of five "Y" units, held together by a *joining chain (J chain)*. The size of secretory IgM and its many antigen-binding sites provide the molecule with an excellent capacity for agglutination of bacteria and blood cells. Although it has the potential to bind 10 antigens, in reality, it usually only binds five. Fixed macrophages of the RES system efficiently and quickly remove such agglutinated antigens.

IgD is found in plasma (in very small amounts) and on the surface of naïve B cells. It has a half-life of 3 days. An exact function is not known, but its ubiquitous presence in the animal kingdom suggests an important role. It has been postulated to be involved in the induction of immune tolerance. IgD was also found to activate basophils and mast cells. IgD serum concentration does increase during chronic infection but is not associated with any particular disease.

IgG is the major antibody produced in response to secondary and higher-order antigen encounters (subsequent encounters with antigens from which memory cells were created). Secondary immune responses are turned on faster and produce more antibodies that have a higher affinity to the antigen compared with primary responses. Hence, IgG is the most prevalent antibody in serum and is responsible for adaptive immunity to bacteria and other microorganisms. IgG exists in serum as a monomer. There are four IgG subclasses in humans (IgG1, IgG2, IgG3, and IgG4). IgG has a half-life of 23 days, the longest among the antibody classes. When bound to antigen, IgG can activate serum complement and cause opsonization. It can cross the placenta and is secreted into colostrum, protecting the fetus as well as the

newborn from infection.

IgA usually exists as a polymer, when secreted from plasma cells, of the fundamental Y-shaped antibody unit. In most IgA molecules, a *joining chain* (*J chain*) holds together two antibody units (dimeric form). As the IgA passes through epithelial cells, an additional antigenic fragment, the *secretory piece,* is added. In this conformation, IgA is actively secreted into saliva, tears, colostrum, and mucus and hence is known as secretory immunoglobulin (sIgA). IgA is also found in serum, mainly as IgA1 isotype produced by bone marrow B cells, while IgA2 subtype is present in secretions. As part of the BCR, IgA is found in the monomeric form. IgA has a half-life of about 6 days.

IgE is a monomeric antibody that is slightly larger than IgG but has a relatively short half-life of about 3 days. IgE avidly binds via its Fc region to cells, such as mast cells, basophils and eosinophils, which are involved in allergic reactions and antiparasitic immunity.

Antibody action

Antibodies act against antigens in three ways: they neutralize the antigen, opsonize the antigen, or stimulate complement fixation to assist phagocytes.

1. **Neutralization.** Antibodies can bind to antigens, forming easily recognizable antibody–antigen complexes, which are removed by phagocytosis. Antibodies can also immobilize and agglutinate infectious agents so that a virus cannot penetrate the host cell or a microbe cannot colonize mucosal tissue.
2. **Opsonization.** IgG antibodies bind to bacteria or virus-infected cells at the Fab region. That way, the pathogen is “tagged” or “opsonized” for destruction by free radicals and enzymes or phagocytosis. For phagocytosis, the Fc portion of the antibody binds to Fc receptors on phagocytes. Some complement components (e.g., C3b and C4b) can also act as opsonins.
3. **Complement fixation.** Complement is a group of at least nine distinct proteins that circulate in plasma in an inactive form, but involves about 25 proteins and protein fragments (Fig. 10.7). When the inactive proteins hydrolyze, they become activated. A cascade of events occurs when the first protein, C1, recognizes preformed IgM or IgG antibody–antigen complexes (*classical pathway*). A side entry to this pathway exists, in which complexes between bacterial mannose residues and the plasma protein mannose-binding lectin start the cascade (*lectin pathway*). C-reactive protein (CRP) can also provide a side entry into this pathway by directly activating C1. The cascade leads to the formation of C3 convertase through the activation of C4 and C2, and so the convertase has the form C4b2a.

Figure 10.7 The complement system attacks the surface of foreign cells. Over 20 different complement (C) proteins supplement antibody activity in a cascade of events to eliminate pathogens. The goal is to produce opsonin C3b, anaphylatoxins, chemoattractants C4a, C3a and C5a, and the membrane attack complex (MAC). The MAC inserts into membranes of cells and causes their lysis. Antigen–antibody (Ag–Ab) complexes and other (e.g., C-reactive protein and lectin pathway components) activate the classical pathway. Spontaneously hydrolyzed C3 and pathogen surface molecules (e.g., lipopolysaccharides) activate the alternative pathway and other (e.g., lectin pathway components). The lectin pathway is initiated in response to microbial surfaces (mannose). The classical and alternative pathways use structurally different but functionally identical enzymes C3 convertase and C5 convertase.

A homologous variant of C3 convertase (C3bBb) is also formed in an *alternative pathway*, which is activated by small amounts of C3b that spontaneously hydrolyzed from C3. When C3b binds to human cells, it is quickly inactivated. However, C3b becomes protected when it binds to microbial cell surfaces and forms C3 convertase through factors D and B. The complex is stabilized by properdin (factor P). A side entry to this pathway exists, in which complexes between bacterial mannose residues and the plasma protein mannose-binding lectin start the cascade (*lectin pathway*). Compared to the classical pathway, the alternative pathway is faster, but requires specific microbial antigens for activation.

The C3 convertases of both pathways lead to the formation of complement C3b that activates C5 convertase, another critical enzyme in the cascade that forms C5b. In the classical pathway, C5 convertase is created when C3b joins C4b2a (C4b2a3b) and in the alternative pathway when C3b joins C3bBb (C3bBbC3b). C5b and the four complement proteins, C6, C7, C8, and C9, form the **membrane attack complex** (**MAC**). The tubular MAC inserts into the membrane of the target cell because of its hydrophobic nature. This allows free passage of small molecules, ions, and water, resulting in the target cell’s death.

Serum levels of C3 and CRP can be used to assess inflammation in a patient. Low serum levels of C3 indicate that C3 is being consumed (activated) in complement activation pathways, whereas an elevated level of CRP correlates with increased inflammation.

ACUTE AND CHRONIC INFLAMMATION

Inflammation is the initial response of the body to infection or trauma. Although *microbial infection* is probably the most common cause of inflammation, many types of *tissue injury* can also evoke inflammatory reactions. These include mechanical injury, radiation, burns, frostbites, chemical irritants, and tissue necrosis resulting from lack of oxygen or nutrients. The body instigates a nonspecific cascade of physiologic processes in vascularized tissues involving elements of the innate immune system, with the goal of repairing cellular damage and restoring the tissue to its normal function.

- In a normal response, inflammation is self-initiating, temporally self-propagating, and self-terminating.
- Inflammation is a necessary response to tissue injury, and human life without inflammation is unthinkable.
- On the other hand, inflammation often overshoots in its reactions, which leads to a vicious circle of repeated injury and persistent inflammation.
- Inflammation is closely connected with all kinds of illnesses, so that anti-inflammatory therapy is at the heart of many treatments.

Acute inflammation is a short-term process and is characterized by five cardinal signs.

Inflammation is a protective mechanism that involves immune cells, blood vessels, and cellular mediators. Inflammation is a general response and therefore is part of the innate mechanism of immunity, as compared to adaptive immunity, which is specific for each pathogen. The purpose of inflammation is to (1) eliminate the initial cause of tissue injury, (2) clear out necrotic cells and remove damaged tissue caused from the initial insult, and (3) initiate tissue repair. The classical signs of acute inflammation follow a common pattern with the first sign consisting of redness, followed by heat, swelling, and pain.

With increasing knowledge of the complexity of inflammation, many models have been put forward to expand on these four signs to categorize the great variety of inflammatory responses. However, they are not yet commonly applied in clinics beyond the addition of a fifth sign, **functio laesa** (the loss of function), which is a consequence of tissue operating at conditions out of homeostasis and spending energy on repair processes.

Acute inflammation is a three-step process involving vasodilation and cell migration from blood to tissue.

Inflammation can be classified as either acute or chronic. *Acute inflammation* is the body's initial response and involves the movement of leukocytes, especially granulocytes from the blood into the damaged tissue. Prolonged inflammation is known as *chronic inflammation* and involves a shift in the type of cells present at the injured site. The progressive shift in cells types triggers the destruction and healing process.

At the onset of infection, burn, or other injuries, acute inflammation is initiated by cells already present in the injured tissue—mainly, resident macrophages, dendritic cells, Kupffer cells, and mast cells. These cells release inflammatory mediators that bring about functional changes to tissues. One of the immediate changes observed in acute inflammation is vasodilation and, therefore, increased permeability. Vasodilation increases blood flow to the injured area, sometimes up to 10-fold. Additionally, the vessel walls become leaky, on the one hand, as a result of the injury-related necrosis of endothelial cells and, on the other hand, as a result of chemically directed retraction of endothelial cells. Histamine, which is released by mast cells, basophils, eosinophils, and platelets, is a major chemical mediator of this process.

Water, salts, and small proteins, such as fibrinogen, exit from the plasma into the damaged area. Fibrinogen forms fibrin networks to trap microorganisms. The leaking fluid is called **exudate**, or *pus* in the case of an infected wound. If an infected area is further liquefied and shielded from surrounding tissue, it is called an *abscess*. *Blisters*, pools of lymph fluid, may form in response to burns, infections, or irritating agents.

Blood leukocytes are attracted and migrate into the inflamed tissue in a regulated process that evolves three steps: in the first step, called **margination**, neutrophils are recruited and form bridges with endothelial cells at the inflamed sites. These bridges are made of *selectins*, P-selectins and E-selectins on endothelial cells and L-selectins on neutrophils.

In the second step, called **rolling**, the neutrophils move along the endothelium like tumbleweed since the bridges are initially loose and form and detach continuously. Eventually, a more firm connection is built between *integrins* on neutrophils and *intracellular* and *vascular adhesion molecules* on the endothelial side.

In the third step, leukocyte extravasation, commonly called **diapedesis** or *transmigration*, neutrophils actively migrate through the blood vessel basement membrane into the tissue, with the aid of the firm connection but without damaging the endothelial cells. After neutrophils, *monocytes* are attracted and differentiate into *macrophages* when leaving the blood. Later, *lymphocytes* follow as well. The appearance and increase of the nongranular cells, monocytes, and lymphocytes mark the transition into chronic inflammation.

Inflammatory mediators develop and maintain the inflammatory response.

Inflammatory mediators are soluble molecules that act locally at the site of damage and coordinate the inflammatory responses.

Exogenous mediators (produced outside of the body) include **endotoxin**, which is a family of bacterial toxins associated with the LPS complex of gram-negative bacteria. Endotoxin is released from lysed bacteria and binds to receptors on monocytes and macrophages, thus activating them.

Endogenous mediators (produced within the body) are released from injured or activated cells at the inflammation site. Numerous substances are known to regulate inflammation, many of them with seemingly redundant functions. Table 10.5 lists a few of them. Some have previously been mentioned as part of the innate immune system, demonstrating the tight interplay between the two immune responses.

TABLE 10.5 Endogenous Inflammatory Mediators

Type	Name	Released by	Some Actions
Chemical mediators	Histamine	Mast cells, basophils, eosinophils, leukocytes, platelets	Vasodilation, vascular permeability
	Lysosomal compounds	Neutrophils, macrophages	Vascular permeability, complement activation
	Eicosanoids:	Many cells, neutrophils	Vasoactive properties, platelet aggregation, prolongation of edema
	Prostaglandins		
	Thromboxanes		
	Leukotrienes		
	Platelet-activating factor	Neutrophils, monocytes, mast cells, eosinophils	Vascular permeability, neutrophil migration, bronchoconstriction
	Serotonin	Mast cells, platelets	Vasoconstriction
	Cytokines	Lymphocytes, monocytes	Vasoactive and chemotactic properties
	Chemokines	Tissue cells, endothelial cells, leukocytes	Chemotaxis of inflammatory effector cells
Gases	Nitric oxide	Endothelial cells, macrophages	Vascular smooth muscle relaxation and vasodilation, microbe killing, inhibitor of platelet actions
Neuropeptides	Tachykinins, kinins	Mainly sensory neurons	Vasodilation, vascular permeability, smooth muscle contraction, mucus secretion, pain
Plasma factors	Complement (C5a, C3a, and others)	Enzymes from dying cells; antigen–antibody complexes; endotoxins; products of kinin, coagulation, and fibrinolytic system	Chemotaxis, degranulation of phagocytes, mast cells and platelets, cytolytic activity, opsonization of bacteria
	Kinins	Coagulation factor XII	Vascular permeability, mediators of pain, nonvascular smooth muscle contraction
	Coagulation factors	Coagulation factor XII	Conversion of fibrinogen to fibrin
	Fibrinolytic system		Plasmin lyses fibrin

Many mediators can interact with multiple receptors, often exerting diverse functions. For instance, histamine interacts with three receptors. The H_1 receptors mediate acute proinflammatory vascular effects, whereas activation of H_2 receptors results in anti-inflammatory actions. H_3 receptors are involved in the control of histamine release.

From a structural standpoint, inflammatory mediators belong to many different categories, such as proteins (e.g., complement, antibodies, and acute-phase reactants), lipids (e.g., prostaglandins and platelet-activating factor), amines (e.g., histamine), gases (e.g., nitric oxide), kinins (e.g., bradykinin), and neuropeptides (e.g., substance P).

Many *plasma-derived mediators* are present as precursors and need enzymatic cleavage to become active. For example, thrombin is necessary to transform soluble fibrinogen into insoluble fibrin for blood clots. *Cell-derived mediators* can be preformed (e.g., histamine) or synthesized as needed (e.g., prostaglandin).

Inflammatory cytokine profiles provide a biomarker for the severity of inflammation.

An important class of mediators is **cytokines**, which are cell products synthesized de novo in response to immune stimuli. They generally act over short distances and short time spans. They comprise **lymphokines** (cytokines made by lymphocytes), **monokines** (made by monocytes), **chemokines** (chemoattractants made by various cells), and **interleukins** ([ILs] made by one leukocyte and acting on other leukocytes).

Certain inflammatory diseases present with characteristic cytokine profiles; therefore, inhibition of proinflammatory cytokines may aid in the treatment of the diseases. The classical proinflammatory cytokine triad contains IL-1, IL-6, and TNF-α. The following presents the sources, major targets, and principal activities along with those of IL-8 and INF-γ, two additional clinically relevant factors.

Interleukin-1: IL-1 is produced by phagocytes, lymphocytes, endothelial cells, and others. It targets lymphocytes, macrophages, and endothelial cells. It activates cells, increases adhesion molecule expression, and induces fever and the release of acute-phase proteins.

Interleukin-6: IL-6 is produced by lymphocytes, macrophages, fibroblasts, and endothelial cells. It targets B cells and hepatocytes. In addition to B-cell differentiation, it promotes the production of acute-phase proteins and fever.

Tumor necrosis factor-a: TNF-α derives from macrophages, mast cells, lymphocytes, and endothelial cells. Its targets and effects are similar to those of IL-1. It additionally stimulates angiogenesis and has other functions outside of inflammation.

Interleukin-8: IL-8 has been renamed *CXCL8*, because it is a chemokine produced by macrophages, endothelial cells, and fibroblasts. It targets neutrophils, basophils, and T cells. Its major actions are chemotactic and angiogenic.

Interferon-g: IFN-γ is produced by T cells and NK cells. It targets leukocytes, tissue cells, and T helper cells. In inflammation, it activates phagocytes and enhances leukocyte–endothelial adherence.

In response to IL-1, IL-6, and others, the liver produces **acute-phase blood proteins**. An important member is *C-reactive protein*, which is used to monitor the severity and progression of some cardiovascular diseases. Another example is *acute-phase serum amyloid A* (*A-SAA*) *proteins*. One of their functions is to recruit immune cells to the inflammation site. Blood concentration of A-SAA might rise up to 1,000-fold during inflammation; therefore, A-SAAs are used as markers in some autoimmune diseases.

Acute inflammation is a stereotypic, highly complex process that self-terminates.

Modern molecular biology superimposes many additional layers of complexity onto the presented model of acute inflammation as a stereotypic process of the vascular system. For instance, it has been shown that factors independent of the vasculature can trigger and modulate aspects of both inflammation and repair. *Vibration* and *hypoxia* can lead to histamine release of mast cells (degranulation), hence initiating inflammatory events. *Mechanical load* on tendon fibroblasts can modulate their response during inflammation, promoting their destruction at high loads and protecting them from inflammatory apoptosis at low loads. Furthermore, proinflammatory molecules can be upregulated without any concomitant invasion and stimulation of inflammatory cells.

Under normal circumstances, acute inflammation terminates itself. Chemical mediators disappear either because of their short half-life or because they are enzymatically inactivated (e.g., kininases inactivate kinins). Substrates are consumed, and the lymph flow carries the mediators away faster than they can be produced. *Anti-inflammatory cytokines* such as IL-4, IL-10, and transforming growth factor-β (TGF-β) induce repair of damaged tissue. Following inflammation, tissue that is capable of regeneration will be almost completely restored; otherwise, *scar formation* occurs.

CHRONIC INFLAMMATION

Chronic inflammation is the failure to resolve inflammation and usually causes serious bodily harm. Chronic inflammation develops when neither agent nor host is strong enough to overwhelm the other (e.g., in the case of osteomyelitis, the infection of bone), when there is prolonged exposure to the toxic agent (e.g., silicosis from inhalation of crystalline silica dust), or as part of autoimmune disease processes (e.g., rheumatoid arthritis [RA]). It can also develop without being preceded by acute inflammation (e.g., in tuberculosis).

Chronic inflammation may last weeks, months, or years and leads to *chronic wounds*, which are composed of loosely arranged connective tissue (*granulation tissue*), infiltrated fibroblasts, and inflammatory cells. The vastly dominant inflammatory cell type is the *monocyte/macrophage*. It is the only cell type present in the case of chronic inflammation resulting from a nonantigenic agent such as a suture thread. In the case that the injurious agents are also antigenic, other cell types appear, such as lymphocytes, plasma cells, and eosinophils.

Chronic inflammation is characterized by ongoing tissue damage from reactive oxygen and nitrogen species and proteases that are secreted by inflammatory cells. Other products, such as arachidonic acid and proinflammatory cytokines, amplify as well as propagate the damage. This weakens the body and makes it even more susceptible to infection and further inflammation. It is a vicious cycle that leads to clinical symptoms typical of chronic inflammatory diseases, such as RA, atherosclerosis, or psoriasis.

Overwhelming inflammation combined with immune suppression can lead to *systemic inflammatory response syndrome*, which is called **sepsis**, or *septicemia*, when the inflammation is a result of infection. In severe cases, it might lead to organ failure and death.

Chronic inflammatory diseases can affect every body part and are usually indicated by adding the suffix “itis.” For instance, *myocarditis* is inflammation of the heart, and *nephritis* is inflammation of the kidney. Some inflammatory conditions do not follow the conventional terminology. The most common one is *asthma*. Another example is *pneumonia*, which is more commonly used than “pneumonitis” to name the chronic inflammatory infection of the lung.

Chronic inflammation is both a symptom and a cause of disease.

The role of inflammation in diseases that were not traditionally categorized as inflammatory diseases has been viewed with considerable interest. In fact, inflammation is now recognized to be a critical pathologic component underlying many illnesses, ranging from Alzheimer's and Parkinson's diseases to diabetes and certain types of cancer (e.g., colon cancer).

Although the association between inflammation and disease has been recognized for a long time, inflammation was mainly considered a result, rather than a cause, of the illness. Studies clearly show that the destructive, self-promoting cycle between oxidative stress and resulting inflammation causes more oxidative stress and contributes to the development of chronic illnesses. This chain of events may initially occur at a low, asymptomatic level, which leads to the speculation that *subacute chronic inflammation* might be the cause of a number of illnesses.

ANTI-INFLAMMATORY DRUGS

Corticosteroids are the most powerful anti-inflammatory drugs currently available. They inhibit the accumulation of neutrophils at sites of inflammation (see Neuroendoimmunology) but also have widespread effects on other inflammatory cells and processes. This is the reason for abundant side effects ranging from osteoporosis to disruption of the hypothalamic–hypophyseal axis.

Nonsteroidal anti-inflammatory drugs inhibit **cyclooxygenase** (**COX**), which is involved in prostaglandin production. There are at least two isoforms of this enzyme. *COX-1* is found in platelets and catalyzes the production of thromboxane A2. COX-1 inhibition leads to diminished blood clotting, so COX-1 inhibitors are used as blood thinners. *COX-2* is expressed in blood vessels and macrophages in response to inflammation and leads to production of prostaglandin I2. Drugs that specifically block COX-2 can decrease inflammatory pain. However, both COX-1 and COX-2 are present at many more sites, which is a reason for the abundant pharmacologic side effects of COX inhibitors.

Alternative therapies include a wide variety of natural substances that have antioxidative and anti-inflammatory features but often have poorly understood mechanisms of action. These include nutrients such as vitamin E, herbs such as chamomile, and supplements such as glucosamines, to name a few.

Because the side effects or uncertainties associated with many existing anti-inflammatory drugs often outweigh their benefits, a main focus of twenty-first century medical research is to develop novel anti-inflammatory strategies. Novel drugs generally aim to target specific pathways instead of general inflammatory processes. For instance, leukotriene modifiers, a relatively new class of anti-inflammatory medications for asthma patients, specifically block the products of arachidonic acid metabolism and can prevent an asthma episode before it even starts (Clinical Focus 10.1).

CLINICAL FOCUS 10.1

Allergies and Asthma

Epidemiologic data confirm what many parents suspect. Their children are more susceptible to allergies than they were when they were children. In the past 30 years, the prevalence of allergies has been greatly increasing in the United States and in the world, proportionally more so in more developed countries compared with developing countries and more so in urban areas compared with rural areas.

One hypothesis, often referred to as the hygiene model, proposes that the children who are not exposed to enough antigens or innocuous microorganisms from soil or water early in their childhood do not adequately develop their T helper 1 cell response. This leads to an imbalance toward T helper 2 cell responses, which are present from birth. Even though this hypothesis is disputed as being grossly oversimplified, it is undisputed that the various manifestations of allergic inflammation are the result of wrongly activated T helper 2 cells.

Asthma is one common allergic disorder. About 23 million people, including almost 7 million children, have asthma. It belongs to type I hypersensitivity disorders and is characterized by airways

that narrow excessively in response to many provoking stimuli.

Typical allergens causing atopic (also called extrinsic or allergic) asthma are animal dander, dust mite excrement, grass pollen, and cockroach antigen. Strenuous exercise or worry might trigger nonatopic asthma.

The symptoms of both asthma types are similar and include wheezing, breathlessness, chest tightness, and coughing. They are caused by chronic inflammation of the airways, which leads to their swelling. Bronchoconstriction, excess production of mucus, and increased collagen deposition further exacerbate the restriction of the airflow to and from the lungs.

The development of asthmatic symptoms ultimately depends on the presence of T helper 2 cells, which secrete a characteristic cytokine repertoire. Of these, interleukin-4 activates B cells to produce IgE antibodies, which bind to mast cells, eosinophils, and other airway cells via receptors that are specific for the Fc portions of the antibodies. On subsequent encounters with the antigen, IgE cross-linking on mast cells and eosinophils occurs and leads to the cells' activation and their release of histamine and leukotrienes. These and other inflammatory factors recruit inflammatory cells including additional T helper 2 cells to the lung, resulting in a damaging immunologic positive feedback cycle. IL-4, together with IL-9, is also necessary for mast cell maturation, and along with IL-5, for eosinophil recruitment.

Several treatments are available that interfere with the different allergic processes. Antihistamine drugs for treatment of atopic asthma target H1 receptors or prevent the release of histamine from mast cells. Epinephrine and β2-selective agonists for treatment of systemic anaphylaxis modulate the sympathetic nervous system (see Neuroendoimmunology). Corticosteroids and leukotriene receptor antagonists aim at suppression of inflammation. Immunotherapy (also called hyposensitization or desensitization) involves subcutaneous injections that contain gradually increasing doses of an allergen extract. The immune system responds with gradually increasing levels of IgG antibodies, making fewer IgE antibodies, which seems to help a patient avoid dramatic reactions when the allergen is then encountered naturally. Patients of allergen immunotherapy are at risk of developing systemic anaphylaxis. Antibody titers should be monitored throughout the hyposensitization process to insure the patient is making fewer IgE antibodies and that the therapy is not increasing the levels of IgE. ■

ORGAN TRANSPLANTATION AND IMMUNOLOGY

Both organs and tissues can be transplanted. Transplanted organs include heart, liver, lungs, pancreas, intestines, and thymus. Transplanted tissues include cornea, skin, heart valves, veins, bones, and tendons. The latter two are both referred to as *musculoskeletal grafts*. Worldwide, the kidney is the most common organ transplant, although musculoskeletal transplants (tissue) outnumber the kidney more than 10-fold.

Organ transplantation is indicated when irreversible damage has occurred and alternative treatments are not applicable. In the early 1950s, the first human kidney was transplanted to the donor's identical twin brother. Such transplantation is called an **isograft** because the donor and recipient are genetically identical. In 2014, ~17,000 kidneys were transplanted in the United States, most often as **allografts** between genetically different people.

Kidneys, lungs, and livers can come from living donors, because a person can live with one kidney or one lung and because liver tissue regenerates. Transplantations of heart, whole lung, pancreas, and cornea come from deceased donors. So-called nonvital transplantations refer to the replacement of body parts such as the hands, knees, uterus, trachea, and larynx.

Tissue that is transplanted in the same person from one place to another place is called an **autograft**. Skin and blood vessels are common tissues for such transplantation.

Although, technologically, transplantation is a viable therapeutic option, it is mainly limited by the immensely larger demand for transplantation organs compared with their availability. An attempt to overcome the donor organ shortage is **xenograft** transplantation, in which animal tissue is used to replace human organs.

Two other avenues for replacement of tissue are the development of *artificial organs* and the transplantation of *stem cells*, which may be able to regenerate full-functioning organs. The latter is the "holy grail" of organ replacement because the new tissue would not be recognized as foreign if the stem cells came from the recipient. However, as of today, these alternatives do not work nearly as well as allografted organs.

There are many issues to consider and challenges to overcome, involving ethical, social, and legal problems. To name just a few, xenotransplantation may introduce new diseases to humans and lead to disrespectful treatment of animals. The use of animal and artificial organs may raise problems of self-esteem as a result of the presence of nonhuman tissue in the body, and stem cell therapy may confer the risk of developing cancer (Clinical Focus 10.2).

CLINICAL FOCUS 10.2

Bone Marrow Transplantation

When a patient has a terminal bone marrow disease, such as leukemia or aplastic anemia, often the only possibility for a cure is bone marrow transplantation. In this procedure, healthy bone marrow cells are used to replace the patient's diseased hematopoietic system.

To identify a suitable donor, blood leukocytes of prospective donors, usually close relatives, are

screened to determine whether their antigenic patterns match those of the patient. A transplant is successful only if the donor's human leukocyte antigens closely match those of the recipient. Because there are several antigenic determinants and each can be occupied by any one of several genes, there are thousands of possible combinations of leukocyte antigens. The odds that any person's cells will randomly match those of another are less than one in a million.

The antigenic composition of leukocytes in bone marrow and peripheral blood are identical, so analysis of blood leukocytes usually provides enough information to determine whether the transplanted cells will engraft successfully. Peripheral blood stem cells are currently being tested to see whether they can be used as effectively as bone marrow blood stem cells. This would minimize the pain and risks undertaken by donors.

If significantly different from the recipient's tissue type, transplanted leukocytes may be recognized as foreign by the patient's immune system and, therefore, be rejected, a phenomenon called host-versus-graft response. However, this often plays a minor role because the patient's immune system is immunocompromised and not able to react strongly.

The major problem of bone marrow transplantations is the fact that functional T cells in the graft recognize the host's tissue as foreign and mount an immune response. This is called **graft-versus-host disease** (**GVHD**). The disease often begins with a skin rash, as transplanted lymphocytes invade the dermis, and may end in death as lymphocytes destroy every organ system in the marrow recipient.

There are several methods to decrease the morbidity of marrow transplantations. Immunosuppressive agents, including steroids, cyclosporine, and anti–T-cell antiserum, effectively decrease the immune function of the transplanted lymphocytes. Another useful approach involves the physical removal of T cells from bone marrow prior to transplantation.

T-cell–depleted bone marrow is much less capable than untreated marrow of causing acute GVHD. These techniques have substantially increased the potential pool of bone marrow donors for a given patient. ■

Histocompatibility is the most important criterion for a match in organ donation.

The major reason for the donor organ shortage is that the blood and tissue of the donor and the blood and tissue of the recipient need to have similar immunogenic markers in order to avoid rejection. For instance, virtually all kidneys with unmatched *ABO blood group* between donor and recipient will be rejected within minutes.

For successful transplantation, it is critical that the recipient does not have, or develop, antibodies against the donor's **human leukocyte antigen** (**HLA**). HLAs are the human antigens of the MHC complex, MHC classes I and II proteins. The MHC class I antigens are present on the surface of most body cells but were first discovered on leukocytes. HLA-A, HLA-B, and HLA-C are MHC class I antigens, and HLA-DP, HLA-DQ, and HLA-DR are MHC class II antigens, present on professional APCs. There are numerous alleles for each of the HLA antigens. For minimum requirements, transplantation doctors look at only six of the many HLA antigens (two A, two B, and two DRB1 antigens) for matching donors to patients. However, research has shown that a match in more HLA antigens and additional factors such as race, age, and sex improves the patient's chances for successful transplantation.

Although tissue typing decreases the risk of transplant rejection, the match between donor and recipient is never perfect (except for identical twins), and the reality of clinical practice requires organ transfer between less well-matched pairs. So, clinical symptoms resulting from immune attacks on the transplant are fairly common. Table 10.6 summarizes the three different types of graft rejections according to time elapsed after transplantation.

TABLE 10.6 Types of Graft Rejection

Type	Time	Reasons
Hyperacute	Minutes–hours	Preformed antidonor antibodies trigger type II hypersensitivity reactions (antibody-mediated destruction of cells).
Acute	Days–weeks	HLA incompatibility or inappropriate connection to blood supply triggers T-cell activation and type IV hypersensitivity reactions ($CD4^+$ T_H1 cells and activated macrophages); complicated by antibody-mediated rejection.
Chronic	Months–years	Unclear; cellular and humoral mechanisms involved; mediated by growth factors and repair mechanisms; recurrence of disease possible

HLA, human leukocyte antigen; $CD4^+$ T_H1, $CD4^+$ T helper type 1 cell.

Immunosuppressive drugs greatly decrease the risk of rejection. There are numerous drugs available that inhibit different immune processes. Many of them downregulate the unwanted T-cell responses. Total destruction of T cells and other leukocytes by whole-body irradiation is used before bone marrow transplantation (see Chapter 9). However, the compromised immune system of a bone marrow transplant patient predisposes them to develop graft-versus-host disease (GVHD).

IMMUNOLOGIC DISORDERS

Table 10.7 presents a list of immune disorders, which is not intended to be comprehensive but to provide a framework that can be expanded in pathology courses. It is organized into hypersensitivity, immunodeficiency, and autoimmune disorders.

TABLE 10.7 Immune Disorders

Names	Mechanisms	Examples (Common Names)
Hypersensitivity disorders: Damaging immune responses elicited by allergens		
Immediate hypersensitivity		
Type I (immediate hypersensitivity)	Allergens cause cross-linking of IgE bound to mast cells, basophils, and eosinophils, which release vasoactive mediators (e.g., histamine); symptoms within minutes.	• Atopic diseases: hives, asthma, hay fever • Food allergy • Systemic anaphylaxis
Type II (Ag–Ab cytotoxicity)	Cytotoxicity is mediated by antibody (primarily IgG) directed against epitopes on surface membrane of host cells; symptoms within hours.	• Newborn hemolytic anemia • Autoimmune hemolytic anemia • Blood transfusion reactions
Type III (Ag–Ab immune complex disease)	Circulating immune complexes (primarily IgG) escape phagocytosis and cause deposits in tissues or blood vessels leading to inflammation; symptoms within hours.	• Serum sickness • Glomerulonephritis • Farmer's lung
Delayed-type hypersensitivity		
Type IV (cell-mediated hypersensitivity)	Memory TH_1 cells cause cell-mediated immunity resulting in tissue damage by macrophages; symptoms within day(s).	• Contact dermatitis • Photoallergic dermatitis • Celiac disease
Immunodeficiency disorders: Caused by deficiencies (primary) or by illness in previously healthy person (secondary)		
B cell	Deficiency in antibody-mediated immunity	• Bruton agammaglobulinemia • IgA deficiency
T cell	Deficiency in cell-mediated immunity	• DiGeorge syndrome
Combined	Combined deficiency of cellular and humoral immunity	• SCIDs
Nonspecific	Mediated by deficient phagocytic and/or natural killer cells	• Leukocyte adhesion deficiency • Chronic granulomatous disease
Complement	Defects of individual components or control proteins	• C1, C4, C2, C3, C5–C9 deficiencies • Hereditary angioedema with lack of C1 inhibitor
Acquired	Human immunodeficiency virus (HIV) infects and kills CD_4^+ T helper cells, which leads to massive immunosuppression and increased risk of cancer.	• AIDS • Prolonged serious disorders such as cancers, kidney failure, and diabetes
Autoimmune disorders: Immune responses against the body's own tissue		
Antibody mediated	A specific antibody targets a particular antigen, which leads to its destruction and the signs of the disease.	• Autoimmune hemolytic anemia • Myasthenia gravis • Graves disease
Immune complex mediated	Antibodies complex with autoantigen into large molecules, which circulate around the body and cause destruction.	• Systemic lupus erythematosus • Rheumatoid arthritis
T cell mediated	T cells recognize autoantigen, which leads to tissue destruction without requiring the production of autoantibody.	• Multiple sclerosis • Type 1 diabetes • Hashimoto thyroiditis
Mediated by complement deficiency	Deficiencies in complement components often lead to or predispose to the development of autoimmunity.	• Systemic lupus erythematosus

Ag–Ab, antigen–antibody; CD, cluster of differentiation; Ig, immunoglobulin; SCIDs, severe combined immunodeficiencies; AIDS, acquired immunodeficiency syndrome; T_H1, T helper 1 cell.

Many diseases involve mechanisms that fit into several of the categories presented in the table. One

such example is **rheumatoid arthritis** (**RA**). An unknown antigen that stimulates antibody formation, characteristic of *type III hypersensitivity*, is thought to initiate RA. This leads to joint damage, and as a result, autoantigens are released, which perpetuate the disease in the typical fashion of an *autoimmune disease*. T cells are recruited and activate macrophages, which leads to *chronic inflammation*. Immune responses dominated by T helper 1 cells, characteristic of *type IV hypersensitivity* reactions, maintain the disease.

Immunological dysfunction is due to overreaction, failure to respond, and incorrect response.

As mentioned previously, under normal conditions, when infection resolves, the inflammatory response is actively terminated to prevent unnecessary damage to tissue. Failure to do so results in chronic inflammation and tissue damage. Accordingly, the immune system must be sensitive to pathogens and use sufficient power to defeat the pathogen, because even small numbers of residual microorganisms might soon endanger the body again. But this principle comes at the risk of overdoing it. Asthma, familial Mediterranean fever (recurrent episodes of peritonitis, pleuritis, and arthritis), and Crohn's disease (an inflammatory bowel disease) are examples in which chronic inflammation leads to immunologic disorders and tissue damage.

Overreaction

The most common immunologic disorders due to immune system overreaction are known as **allergies**, or **anaphylaxis** in the case of severe forms. Allergies are categorized into four types, hypersensitivity disorder type I to type IV (see Table 10.7). Depending on the sensitivity of the affected person, allergies can cause localized or systemic symptoms. *Localized reactions* are usually biphasic, with an immediate response mainly resulting from histamine (erythema, wheal, and flare) and a delayed response that may last several hours. *Systemic reactions* might be life threatening because of the sudden loss of blood pressure as a result of general vasodilation and due to airway obstruction as a result of smooth muscle contraction.

Immunodeficiency

Immunodeficiency (or **immune deficiency**) is a condition in which the immune system's ability to fight infections is compromised or absent. Many disorders fall into this category, although the number of patients with congenital immunodeficiency diseases is low.

The study of these diseases reveals important insights into cellular and molecular immunology. For instance, *severe combined immunodeficiency (SCID)*, commonly known as "bubble-boy disease," represents a group of congenital disorders characterized by little or no immune response. Research showed that in the X-linked form of SCID, T cells are dysfunctional as a result of a mutation of the IL-2 receptor gamma chain. The immunologic consequences of missing IL-2 signaling are severe and may lead to the patient's death within the first year of life.

Autoimmunity

Autoimmunity is the failure of the body to recognize its own tissue as self, which allows an attack against its own cells and tissues. Diseases that result from such aberrant immune response are termed *autoimmune disease*. Examples of autoimmune diseases include type 1 diabetes mellitus, systemic lupus erythematosus (SLE), Graves disease, and RA. Genetic and environmental factors as well as gender contribute to the development of many of the autoimmune diseases. For example, ~75% of the 24 million Americans who suffer from autoimmune disease are women.

Although many contributing factors are involved, the trigger mechanism(s) for most autoimmune diseases is still poorly understood. For example, SLE is a chronic autoimmune disease that affects multiple organs. Its etiology is largely unknown, although it is clear that a genetic predisposition to its

development exists, because an identical twin has 3 to 10 times increased risk for developing SLE. Hormones most likely play a role because 90% of patients with SLE are women. Lastly, it seems that environmental factors such as certain medications, stress, and other diseases can also lead to SLE.

Immune cells may become carcinogenic, leading to hematologic malignancies.

Not represented in Table 10.7 are *hematologic malignancies* because they typically form a separate category. Like any cell, cells of the immune system can grow out of control. **Multiple myeloma** is a typically incurable cancer of plasma cells. **Leukemia**, the abnormal proliferation of leukocytes, is the most common childhood cancer. **Lymphomas** encompass a diverse group of cancers that present as solid masses specific to the lymphatic system.

Immune **oncogenes**, genes that turn immune cells into tumor cells, can be induced spontaneously, but their persistence is increased in the presence of carcinogens or viruses. For example, the human T-cell leukemia virus type 1 can cause acute T-cell leukemia and lymphoma, and the Epstein-Barr virus of the herpes family is linked to Burkitt lymphoma and, possibly, Hodgkin lymphoma.

Tumor antigens can identify tumor cells and serve as potential candidates for cancer immunotherapy.

Some leukemias and lymphomas are easy to differentiate histologically from healthy tissue, whereas others are not. For instance, lymphoblasts in acute lymphoblastic leukemia look different than normal lymphocytes. However, the cells in chronic lymphocytic leukemia are hard to distinguish from normal cells, and the disease might resemble a physiologically high lymphocyte count. In this case, identification of specific cell markers, which are not present in healthy cells, aids the diagnosis. Hence, tumor immunology identifies **tumor-specific antigens**.

Some tumor antigens, such as overexpressed normal antigen, mutated proteins, or viral antigens, can be recognized by the immune system, in a process called **immune surveillance**, to develop antitumor immunity. This is one reason why people immunocompromised as a result of previous infections, other diseases, or age are more likely to develop cancers. For instance, although most people with Burkitt lymphoma remain healthy when infected, it is the most common childhood cancer in central Africa, where malaria and malnutrition contribute to immune weakness.

Nevertheless, most cancers occur in people with a normal immune system. The reason is that tumor cells develop mechanisms to evade or disturb appropriate immune responses. These include the loss or reduced expression of MHC proteins and the secretion of immunosuppressive cytokines such as TGF-β, to name two mechanisms.

In the rapidly advancing field of **cancer immunotherapy**, which aims to enhance the body's natural defenses against malignant tumors, we can utilize components of the anticancer immune response that have already developed in that patient. Active immunization with tumor antigens and cytokine or antitumor antibody therapies are examples of this type of treatment.

NEUROENDOIMMUNOLOGY

Neuroendoimmunology is the study of the interaction between the nervous, endocrine, and immune systems. These systems exchange an extensive amount of information between the three systems. For example, they share a number of the same receptors and synthesize and secrete some of the same molecules, such as peptide hormones, neurotransmitters, and cytokines. Accordingly, it is not surprising that the strength of a person's immune response depends not only on the type of antigen or the person's age and genetic makeup but also on the person's lifestyle choices, emotional character, and ability to cope with stress.

Immune system is downregulated by neuronal and hormonal stress signals.

It is well known that the physiologic stress response downregulates the immune system. As a consequence, people who are stressed, for instance, from losing a relative or facing examinations, become sick more easily.

During an immune response, cytokines such as IL-1 stimulate the activity of paraventricular hypothalamic neurons to release corticotropin-releasing factor (CRF), which starts the physiologic *stress response* aimed at bringing a person back to physiologic homeostasis. In the pituitary gland, CRF stimulates the expression of pro-opiomelanocortin, which is converted to β-endorphin and adrenocorticotrophic hormone (ACTH). ACTH stimulates the release of corticosteroids from the adrenal gland. All these molecules can also bind directly to receptors on immune cells. The resulting actions are generally inhibitory to the immune system but can also be immunosupportive, especially during acute stress.

Activating the stress response via CRF also leads to activation of the *sympathetic nervous system* and the release of its neurotransmitter norepinephrine. Cytokines that are released by immune cells or by cells of the central nervous system (CNS), such as microglia and astrocytes, can also activate this autonomic path of the stress response.

A network of autonomic nerve fibers sends information from the CNS to the spleen and lymph nodes, where the fibers end in close proximity to T lymphocytes and macrophages. These immune cells, as well as B cells, express β-adrenergic receptors of the β-2 subtype, and their activation generally leads to inhibition of cell function. For instance, adrenergic activation of T cells decreases their expression of integrins, so that they cannot migrate out of the blood vessel into the tissue. This explains the high T-cell counts seen soon after a stressful event.

Furthermore, sympathetic nerve endings and the adrenal medulla release **endorphins** and **enkephalins**. These opioid peptides oppose the body's stress response and help maintain homeostasis during times of physical and psychological stress. The immune responses to opioids vary, depending on the subtype and concentration of the neuropeptide.

Melatonin, a hormone of the pineal gland, seems to regulate the opioid network and consequently the immune system. Melatonin therapy is under consideration to support the immune system of older people to avoid **immunosenescence**.

Neural mediators

Immune cells that are present in neuronal and other tissue produce mediators that can act on the brain.

Lymphokines and *thymokines* (produced by the thymus) carry the information flow from the peripheral immune system to the CNS. For instance, IL-1 is a potent mitogen for astroglial cells. In addition, it acts at hypothalamic cells causing fever. IL-2 promotes the division and maturation of oligodendrocytes, and IL-3 supports the survival of cholinergic neurons.

$CD4^+$ T cells and macrophages manufacture *neuropeptides*, such as vasoactive intestinal peptide and pituitary adenylate cyclase–activating polypeptide, which were previously thought to be products solely of nonimmune cells.

Until recently, it was also believed that the brain was devoid of peripheral immune cells. It is now

known that immune cells can pass the blood–brain barrier and enter the CNS. It seems that they are present to regulate physiologic neuronal events and potentially contribute to maintaining the brain's ability for cognitive functions. On the other hand, neuronal immune cells may trigger autoimmune disorders. For instance, autoimmune T cells that recognize myelin basic protein of myelin sheaths can be associated with the development of the demyelinating disease **multiple sclerosis**.

Hormonal mediators

The endocrine system and immune system work in concert to maintain homeostasis. Many hormones have been linked to immune functions. For instance, cells of the immune system also produce (e.g., monocytes and lymphocytes) and use (e.g., lymphocytes, monocytes, and NK cells) **thyroid-stimulating hormone**, best known as a regulator of metabolic functions. *Growth hormone*, *prolactin*, female and male *sex hormones*, and *leptin* are additional examples of hormones that unequivocally modulate the immune system.

In the typical fashion of hormones, they exert multiple actions in many target cells, depending on the hormone concentration, the target tissue, and the environment. This makes hormones optimal regulators of the body's homeostasis but usually causes unwanted side effects when used clinically.

Unpredictable side effects are one reason why use of *immune therapies* using hormones or neuropeptides is still limited. For example, the adrenal hormone epinephrine is given to reverse some effects of allergy. The field of psychoneuroimmunology builds on the fact that positive experiences and behavior may also boost the immune system. Thus, immunocompromised people are counseled to find ways for dealing with stress. However, many new applications are being developed, and targeted enhancement or suppression of immune cell functions will play a more important role in our approaches to help the body to maintain homeostasis.

INTEGRATED MEDICAL SCIENCES

Vitamin D Deficiency

Vitamin D is a fat-soluble vitamin that is best associated with the ultraviolet (UV) rays of the sun and calcium absorption. It has been suggested that exposure of the face, arms, legs, and back to the UV rays from the sun for, 5 to 30 minutes any time from 10 AM until 3 PM, at least twice each week would promote adequate vitamin D synthesis and maintain the protective properties of endogenous vitamin D. However, this exposure to UV rays comes with the potential health risk of developing melanoma. Individuals who do not get the adequate exposure to the UV rays of the sun, must consume exogenous vitamin D found in foods or taken as dietary supplements. Vitamin D is found naturally in foods such as milk, egg yolks, salmon, trout, and cod liver oil. Vitamin D is also available as a dietary supplement and is often added to foods in which it does not naturally occur. The vitamin D obtained from the diet is absorbed by the small intestine and is transported to the liver by vitamin D–binding protein (VDBP). Our body activates vitamin D in both the liver and the kidneys. It first becomes 25-hydroxyvitamin D (calcidiol) in the liver and later is converted to 1,25-dihydroxyvitamin D (calcitriol) in the kidneys. Vitamin D promotes absorption of calcium in the gastrointestinal tract and is best associated with bone growth and strength.

Vitamin D deficiency has long been associated with rickets in children, when bones become brittle and soft due to the lack of calcium, and osteoporosis in the elderly. There is, however, increasing evidence that suggests that vitamin D plays a significant role in immune function, both in regulating immune responses to infectious diseases and regulating the immune cells' interactions with the commensal, nonpathogenic microbiota of the digestive tract. It has been suggested that numerous cell types, including the majority of immune cells, can express the vitamin D receptor (VDR) and that vitamin D can influence the activation or differentiation of these cells *in vitro*. If this modulation is also found during immune responses in vivo, the presence of vitamin D could influence both the innate and adaptive immune systems. Dysregulation of immune responses can result in the susceptibility to infectious diseases and the development of various autoimmune conditions such as Crohn disease (CD), multiple sclerosis (MS), and systemic lupus erythematosus (SLE).

Crohn disease is an inflammatory bowel disease, typically affecting the ileum and/or the colon. The inflammation in the lining of the intestines obstructs normal functioning of the digestive system and leads to altered flow of digested foods and decreased absorption of nutrients and interferes with the body's first line of defense at the mucosa. The inflammatory response leads to collateral damage of healthy cells that compromises the integrity of the mucosa, and the cells that secrete antimicrobial peptides are damaged or lost. Symptoms usually develop over time and can be cyclic, coming with periods of disease exacerbations and remissions. There is no clear evidence that a specific type of food is a trigger or aggravator of the disease; however, some patients find that consuming a low-fat diet with limited dairy products and limited fiber helps control symptoms. It has also been suggested that patients with a low plasma vitamin D level may have an increased risk of developing CD; experiencing an exacerbation of CD symptoms; developing cancers, in particular colorectal cancer; and developing *Clostridium difficile* infection.

Vitamin D deficiency has also been associated with MS. MS is characterized by the demyelination of the neurons of the central nervous system (CNS). The demyelination presents early in the disease as weakness or tingling in arms and legs, loss of coordination, loss of mental focus, and/or loss of balance. MS is, typically, a disease with relapses and periods of remissions. It has long been reported that individuals who grow up in higher latitudes are more likely to develop MS than those who grow up in the tropics. Individuals living in the tropics have increased exposure to the ultraviolet light from sunshine and subsequent production of vitamin D compared to those living at higher latitudes. Recent evidence suggests that vitamin D deficiency is a risk factor for both the development of and progression of MS.

Systemic lupus erythematosus is a chronic inflammatory disease that can affect various organs of the body such as joints, the skin, lungs, blood vessels, kidneys, and the heart. SLE patients also may experience relapses and remissions. SLE patients, typically, have low serum levels of vitamin D. This vitamin D insufficiency could be correlated with the photosensitivity associated with SLE, limiting SLE patients' exposure to the sun. Another contributing factor could be that many of the drugs used to treat SLE interfere with vitamin D metabolism and could also contribute to this deficiency. Some studies have suggested that vitamin D deficiency may be a risk factor for SLE or contribute to the progression of SLE, but the data are controversial at this point. These discrepancies could be due to polymorphisms in the VDR gene; however, this has not yet been clearly demonstrated. Also, yet to be determined is whether vitamin D insufficiency changes the course and prognosis of SLE. Correlating a specific environmental agent to the development and/or progression of SLE is difficult as there are genetic, hormonal, environmental, and immunological contributions to this autoimmune disease. Other complications associated with SLE studies are that patients may experience a mixture of symptoms and the comorbidity of SLE with other autoimmune diseases.

Chronic inflammation in response to infectious agents or due to autoimmune disease can also be associated with the development of cancer. At this time, current data suggest that vitamin D can be considered as a potential anti-inflammatory agent and an immunosuppressant and could be used to treat autoimmune diseases such as CD, MS, and SLE. It is also likely that vitamin D plays a role supporting the regulatory efforts at the mucosa, helping immune cells determine what microbes are commensal microbiota and what microbes are pathogenic and require removal. ■

Chapter Summary

- The immune system encompasses the thymus, spleen, bone marrow, and lymph system. It additionally includes cells such as macrophages, dendritic cells, mast cells, and blood leukocytes (neutrophils, lymphocytes, monocytes, eosinophils, basophils) as well as noncellular elements that are part of every tissue throughout the body.
- Antigens are substances that bind to T- and B-cell receptors or antibodies. Haptens and immunogens are antigens, but only immunogens elicit an immune response. Proteins are by far the best immunogens.
- The immune system operates by distinguishing between self and foreign molecules inside our body and then tolerating normal body substances (including nonpathogenic microbiota) and eliminating any invasion by foreign substances causing harm.
- Immune system defenses include physical, chemical, and mechanical barriers to entry of pathogens.
- The immune system is divided into two systems: the innate system as the immediate response to common immunogens and the adaptive system, which changes throughout life and which has memory to respond to an encounter more strongly the second time compared with the first time.
- Innate and adaptive systems work together so that the immune response is adjusted to the type and severity of the threat.
- The innate leukocytes include phagocytes that encompass neutrophils, macrophages, and dendritic cells. They have receptors for pathogens and for complement-coated and antibody-coated antigens. They can engulf and destroy pathogens while influencing immune responses via immune mediators. Macrophages and dendritic cells can act as professional antigen-presenting cells to T cells. Even though eosinophils are involved in allergy and other immune responses, such as antiparasitic immunity, they can also be phagocytic.
- The innate leukocytes further include nonphagocytic cells such as natural killer cells that attack aberrant body cells, and mast cells that participate in the defense against pathogens and wound healing.
- Acute inflammation is the body’s initial response to infectious microorganisms and injuries. It is characterized by the dilation and leaking of blood vessels and subsequent attraction of circulating leukocytes to the inflammatory site, where innate immune responses occur.
- Adaptive immunity is a delayed, but highly effective immune response against specific antigens. The adaptive immune system is divided into cell-mediated immunity, which targets infected cells and is managed by T cells, and humoral immunity, which deals with infectious agents in blood and tissues and is mediated by B cells and their antibodies.
- B cells and T cells have antigen-specific receptors, which bind directly to antigen in the case of B cells or antigen presented on major histocompatibility complex (MHC) proteins in the case of T cells.
- Stimulation by antigen plus other signals causes T lymphocytes to proliferate into clones of effector cells and memory cells.
- Cytotoxic $CD8^+$ T cells recognize and kill cells that are infected with intracellular pathogen presented on class I MHC protein. $CD4^+$ T helper 1 cells activate macrophages that present antigen on class II major histocompatibility complex (MHC) protein. $CD4^+$ T helper 2 cells activate B cells that present antigen on class II MHC protein.

- Activated B cells become antibody-producing plasma cells and can become memory cells, with the help of $CD4^+$T helper cells.
- Antibodies are antigen-specific binding proteins that neutralize and opsonize antigen and activate complement to promote various immune reactions. Antibodies occur in five isotypes with special functions, IgM, IgD, IgG, IgA, and IgE.
- Graft rejection is the major complication of organ transplantation and depends mainly on the allogeneic differences in the human leukocyte antigens between organ donor and recipient.
- Graft-versus-host disease is a complication of bone marrow transplants. Newly engrafted T cells can begin attacking the host cells when the patient is immunocompromised.
- Every acute illness evokes an immunologic response, and nearly every prolonged serious illness interferes with the immune system.
- Chronic inflammation leads to tissue damage and clinical symptoms. It is associated with the predisposition to a multitude of diseases.
- Immune system diseases are caused by abnormal or absent immunologic mechanisms, whether humoral, cell-mediated, or both.
- The actions of the immune system are closely interrelated with the actions of the endocrine and the neuronal systems to keep body homeostasis. Forthcoming information on these interactions will lead to novel treatments.

Chapter Review Questions

1. Penicillin is a small antibiotic molecule with a molecular weight of 300 Da. It binds to an enzyme in the wall of many bacteria, which leads to the weakening of the cell wall. As an unwanted side effect, penicillin can also bind to serum or tissue proteins, and the resulting complexes can cause allergic reactions. Which of the following describes the role of penicillin in the immune response?

A. Antigen
B. Hapten
C. Immunogen
D. Opsonin
E. Pathogen

The correct answer is B. Penicillin is a hapten. Haptens are too small to be immunogenic on their own, but when attached to a macromolecule, usually a protein, they become quite immunogenic. Penicillin, alone, is not immunogenic. Penicillin is not acting as an opsonin, as opsonins attach to pathogens and facilitate phagocytosis. The pathogen is the disease-causing agent.

2. Herpes simplex viruses tend to infect cells of the skin or mucous membranes. Which of the following are the correct types of host cells, antigen-presenting molecules, and target cells that are involved in the immune response against the infection?

Host Cells Type of Antigen-Presenting Molecules Target Cells

A. Any cell MHC class I Cytotoxic T cell
B. Any cell MHC class II T helper cell
C. Any cell MHC class I T helper cell
D. B cell MHC class II Cytotoxic T cell
E. Dendritic cell MHC class II Cytotoxic T cell

The correct answer is A. Endogenous antigens, such as viruses replicating within a host cell, are digested by enzymes of the host cell and presented, coupled to MHC class I molecules, to activated $CD8^+$ cytotoxic T cells, which destroy the infected cell. Class I MHC molecules are expressed by almost all host cells with a nucleus. In the case that the antigen stems from extracellular proteins or phagocytosed bacteria, the antigen is digested intracellularly within phagolysosomes and associated with MHC class II molecules, which then present the antigen to the TCR of $CD4^+$ T helper cells. Macrophages, dendritic cells, and B cells are professional antigen-presenting cells and present to $CD4^+$ T cells.

3. On a train ride, a 2nd-year medical student overhears part of the conversation between a couple who are sitting next to her. The man says “The bad news is that I need an allogeneic graft, but the good news is that I do not need to take immunosuppressive drugs.” Which of the following transplant types are they discussing?

A. Bone marrow
B. Cartilage
C. Heart
D. Kidney
E. Liver

The correct answer is B. An allogeneic graft is a transplant between genetically different people. The immune system of the recipient will recognize the slightly different antigen on the surface of the donor

cells (human leukocyte antigens) as foreign and start an immune attack, leading to graft rejection. Immunosuppressive drugs minimize the rejection by suppressing both cell-mediated and antibody-mediated immunity. Hence, tissue rejection and immunosuppressive therapy rely on tissue vascularization. The only avascular tissue in the list of answers is cartilage. Unlike other connective tissues, cartilage does not contain blood vessels. Since there is no risk of an immune reaction, chondrocytes from cadaver cartilage can be allografted.

4. A 34-year-old male complains about recurring infections that truly bother him since he is preparing for the iron man triathlon. Blood is drawn for extensive analysis of the patient's health. It might also include a test for which of the following hormones that, when increased, might explain the increased susceptibility to infection?

A. Adrenaline
B. Cortisol
C. Estrogen
D. Growth hormone
E. Insulin

The correct answer is B. Severe exercise induces stress to which the body responds with increased cortisol levels. Cortisol depresses a variety of immune responses. Although severe exercise induces the synthesis of adrenaline, there is no known correlation to increased susceptibility to infection. Estrogens tend to stimulate immune responses. Moreover, there is no indication why estrogen levels should be increased in this patient. Growth hormone does not depress immune responses. While stress alters insulin needs, stress does not raise insulin levels. In fact, insulin secretion is reduced during exercise, partly through the suppressive actions of cortisol.

5. A newborn has signs of birth defects including hearing loss and cardiovascular abnormalities that could be attributed to congenital rubella syndrome. A rubella antibody test is ordered and the results reveal the presence of specific IgM and IgG antibodies against the rubella virus in the newborn's cord blood. Which of the following can be concluded?

A. The mother has passed IgM antibodies in utero to the child.
B. The mother has passed both IgM and IgG in utero to the child.
C. The newborn has no evidence of infection with rubella virus.
D. The newborn was infected with rubella virus during pregnancy.
E. This is a false-positive result since a newborn cannot have antibodies.

The correct answer is D. The presence of IgM antibodies against the rubella virus in a newborn indicates that the newborn was infected during pregnancy since the mother's IgM antibodies cannot pass to the baby through the umbilical cord and the present IgM has to be fetal antibody. Since congenital rubella syndrome occurs because of infection during the first trimester, or to a lesser extent the second trimester, the mother's system has most likely developed both IgM and IgG antibodies by week 24. IgG antibodies can be passed from the mother to the child in utero, so that the IgG of the newborn could be a mixture of both the maternal and the fetal IgG.

If the baby's blood would only contain IgG but no IgM, it would indicate that the mother has passed IgG, obtained by immunization, to the child, which may protect the child from rubella infection during the initial months of life. However, the presence of IgM antibodies in the baby indicates a recent infection with, not immunity to, the rubella virus. Although false-positive results are possible due to some cross-reactivity of test components, the reasoning that a newborn cannot have antibodies is a false statement.

Clinical Application Exercises 10.1

A MYSTERIOUS AUTOIMMUNE DISEASE

A Japanese male, age 31, was treated by his family practitioner for bacterial tonsillitis. His tonsils had been removed at age 11. Two weeks later, the patient complained of blood in his urine and some flank pain. A low-grade fever was present. A urine dipstick analysis showed mild proteinuria. Urine analysis revealed some casts and dysmorphic erythrocytes. The patient was treated for urinary tract infection but the symptoms remained. Based on elevated creatinine concentration, the decision for a kidney biopsy was made. Immunofluorescence microscopy revealed prominent globular deposits of IgA in the mesangium of the glomeruli. The complement components C3, C5b-9, properdin, and various lectins were found. The diagnosis of IgA nephropathy was made. IgA nephropathy is a rare disorder of the immune system in which IgA is deposited in the kidney mesangium, slowly destroying it in about 50% of the cases.

QUESTIONS

1. What is the role of IgA in the immune system?
2. Discuss the rationale for immunosuppressants, dietary changes, and antihypertensive and diuretic medication as part of the treatment of a patient with IgA nephropathy.
3. To which complement pathways do the glomerular deposits C3, C5b-9, properdin, and lectins point?

ANSWERS

1. IgA is known as the secretory immunoglobulin and can make up 10% to 15% of the antibody found in a healthy person. It is secreted as dimers into fluids that have access to the body surfaces such as saliva, tears, and mucus of the gut and the lungs. IgA can directly bind pathogens preventing their colonization of mucosal tissues. It seems that the antibody in IgA nephropathy is derived from the mucosal immune system of the respiratory or gastrointestinal tract. The IgA deposited within the glomerular mesangium is predominantly J chain containing polymeric IgA1.
2. The treatments for a patient with IgA nephropathy depend very much on the severity of the disease symptoms that range from asymptomatic to severe kidney impairment. The risk/benefit ratio of the treatments has to be carefully considered. *Immunosuppressants* such as steroids address the aberration of the immune system in producing excess IgA and the inflammation of the kidney caused by irritating casts. Fish oil capsules, rich in omega-3-polyunsaturated fatty acids, have been prescribed to produce altered, less effective proinflammatory eicosanoids. Food and vitamins with antioxidant capabilities reduce inflammation as well.

   Recommendations for additional *dietary changes* include a low-salt and low-potassium diet to control the high blood pressure that can occur as a consequence of kidney failure. Low-protein diets have been recommended to slow the progression of kidney damage.

   To minimize any additional stress on the kidneys, *high blood pressure medication* and *diuretic therapy* might be warranted. If there is a risk for end-stage renal failure, dialysis and kidney transplantation need to be considered.
3. The presence of C3 together with C5b-9 and properdin in the glomerular casts points toward the activation of the complement cascade via the alternative pathway. Recent evidence indicates that

deposits of mannose-binding protein and other lectins point toward the involvement of the lectin pathway in a significant number of cases.

PART IV CARDIOVASCULAR PHYSIOLOGY

11 Overview of the Cardiovascular System and Hemodynamics

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain why the outputs of the left and right ventricle are interdependent.
- Explain how the parallel arrangement of arteries supplying systemic organs allows independent control of each organ's blood flow.
- Explain the mechanisms by which major physiological vasoconstrictors and vasodilators contract or relax arteries and veins.
- Explain how vascular compliance is altered by transmural pressure, vascular smooth muscle contraction, and aging.
- Explain why changes in blood volume alter volume in the venous side of the circulation more than on the arterial side of the circulation.
- Explain why standing causes blood to drain from regions above the heart and pool in the lower extremities.
- Predict the consequences of a distended vessel on vascular wall stress, the probability of vessel dissection and rupture, as well as the ability of a blood vessel to contract.
- Explain how changes in arterial pressure and vascular resistance alter blood flow and how blood flow and vascular resistance affect arterial pressure.
- Predict how a vasoactive agent will directly affect blood pressure or organ blood flow.
- Explain the hemodynamic consequences of polycythemia and dehydration on the ability of the heart to supply adequate blood flow to systemic organs.
- Predict and explain how pathological changes in cardiovascular anatomy and the physical composition of blood can create flow murmurs.

The cardiovascular system is commonly described as a fluid transport system that delivers substances to the tissues of the body while removing the by-products of tissue metabolism. This definition is technically correct. However, lost in such a bland, generic, definition is a sense of how absolutely essential the cardiovascular system is for *human survival*. Chemical energy that supports cell functions in the body is generated predominantly by oxidative metabolism. Transport of oxygen across the cell membrane to support this metabolism occurs by simple passive diffusion. Although this process has the advantage of saving the cell from expending energy to transport oxygen into it, transport by passive diffusion has significant limitations. Transporting anything by simple diffusion encounters the problem of being able to get the substance from one point to another "on time." The consumption of oxygen by any cell requires that oxygen must be transported across the cell membrane at a rate (flux) that is sufficient to match the rate at which it is consumed. Failure to do so will eventually stop oxidative metabolism and result in cell death. The key problem of transport by passive diffusion is that the time required for any molecule to diffuse from one point to another is markedly affected by the distance to be traveled between the points. For example, it takes ~5 seconds for an O_2 molecule to diffuse 100 μm. (This distance happens to be compatible with the size of our cells, their nearest source of O_2, and the rate of O_2 usage by cellular

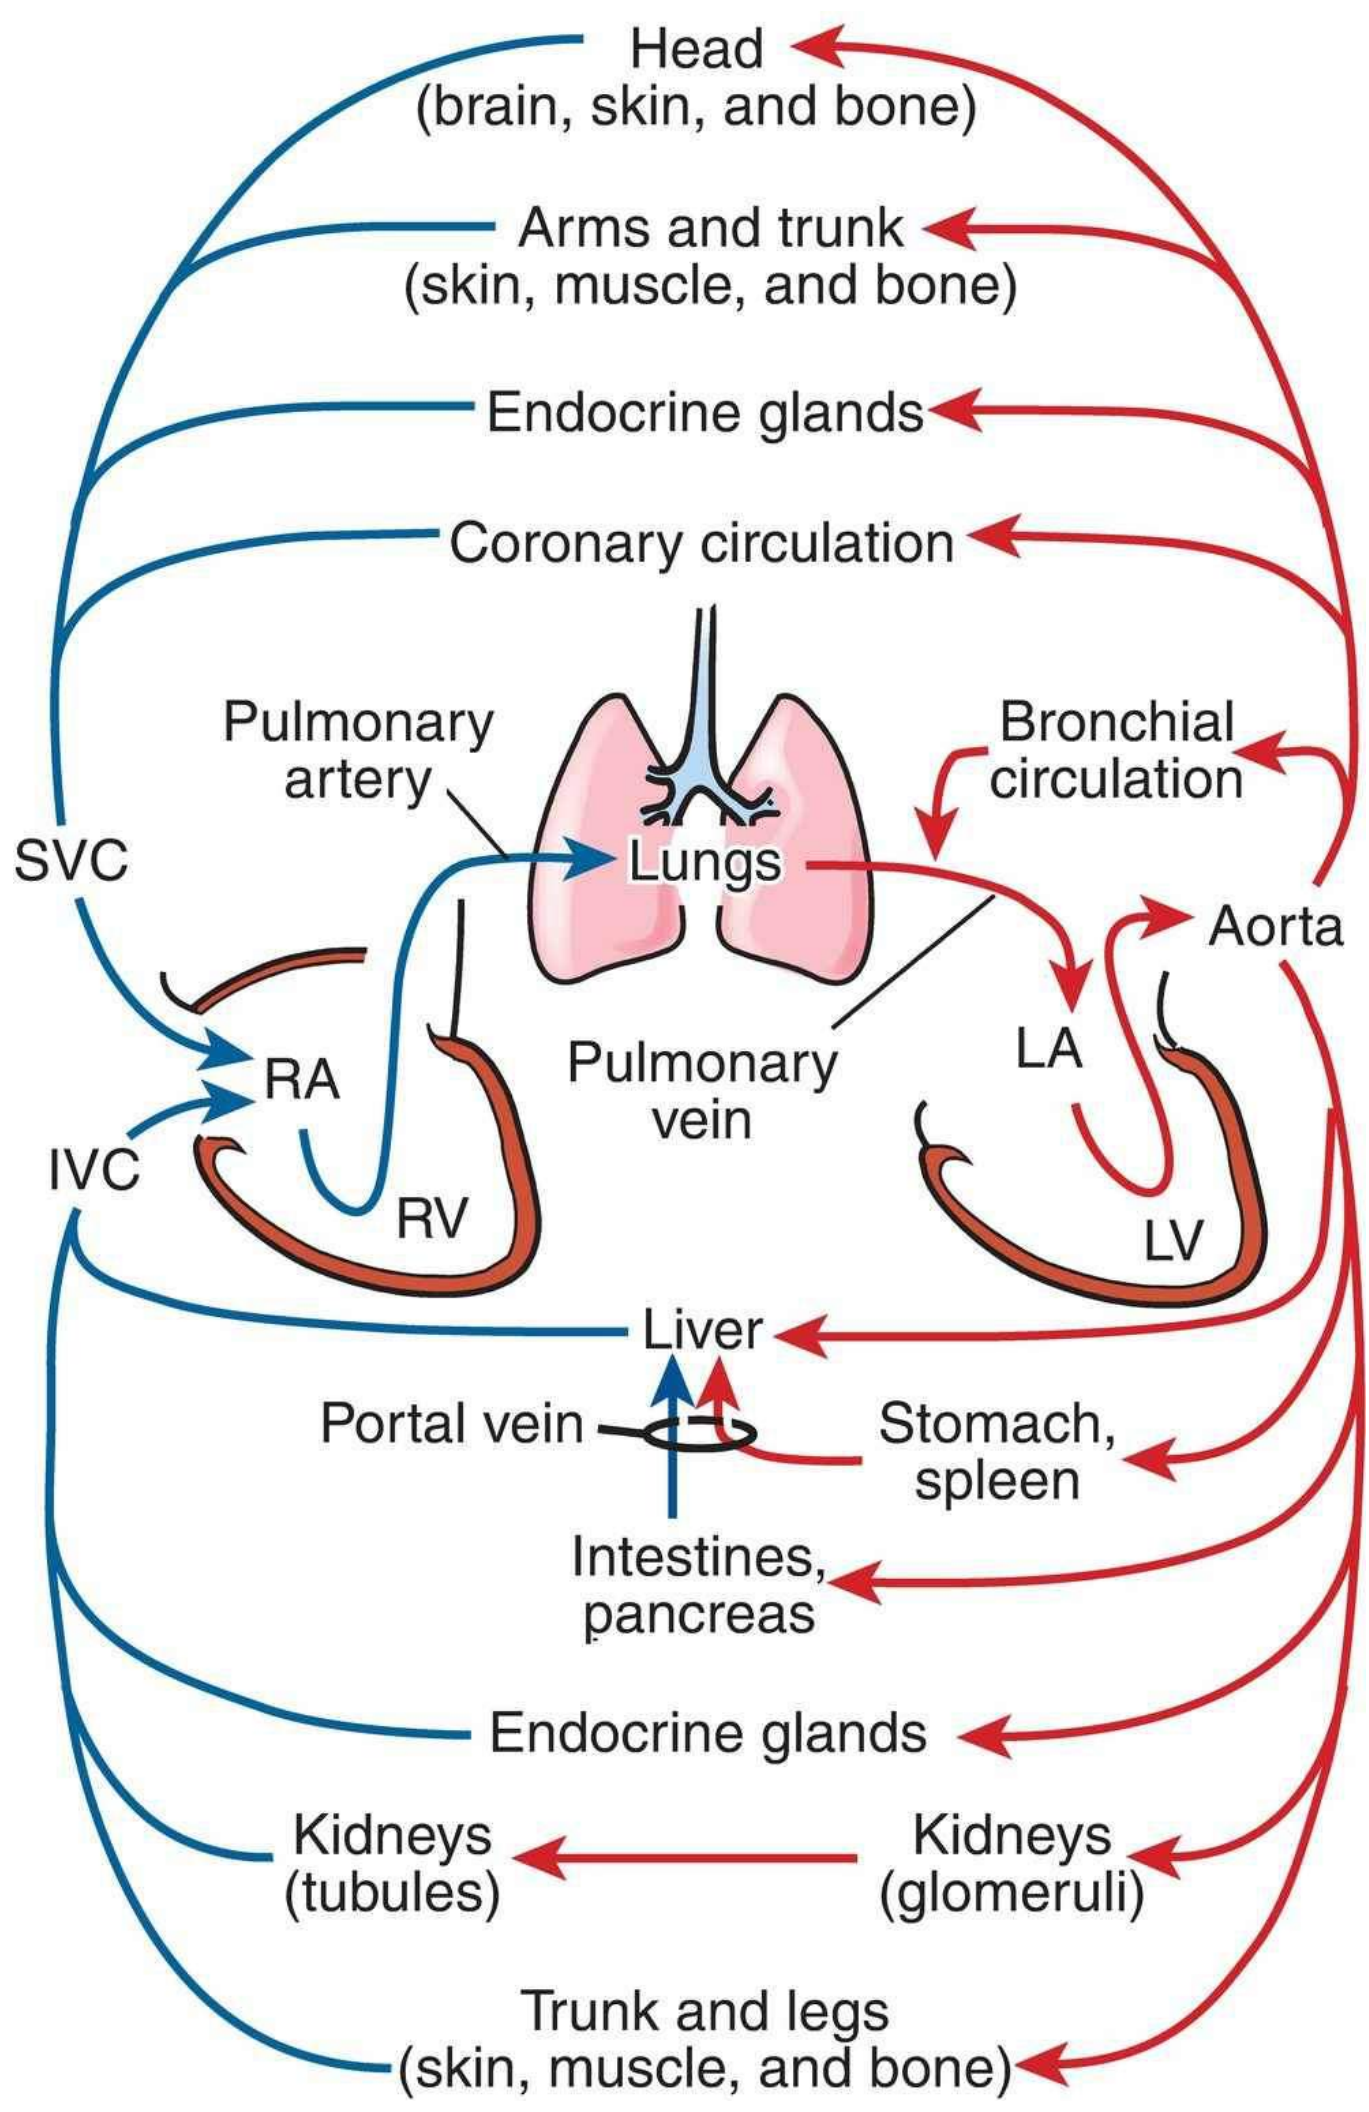
metabolism.) However, the physics of random molecular motion, which drives passive diffusion, is such that each 10-fold increase in the distance that must be traveled increases the average time required to traverse that distance by a factor of 100. Therefore, should the diffusion distance in the example above increase from 100 to 1,000 μm (1 mm), the average time a molecule would take to traverse that distance would increase to 500 seconds. A further increase from 1 mm to 1 cm would increase the average time to 50,000 seconds, or almost 14 hours!

The time factor limitation associated with passive diffusion has important consequences for us as a living organism. First, the dependency of our cells to get oxygen by passive diffusion necessitates that we have some sort of transport system that can bring oxygen to within 100 μm of every cell. Although our pulmonary system gets oxygen from the atmosphere into our body, it is the ultimate function of a circulatory system to get that oxygen close enough to every cell so that it can enter by diffusion. Because of dependency on oxygen diffusion the survival of even the tiniest oxygen-consuming multicellular organisms requires the existence of a circulatory, or transport system, for oxygen. It is not surprising that when our cardiovascular system malfunctions, we as a whole malfunction, and if this system fails, our body "fails." The physics of passive diffusion places another constraint on our body. If for any reason a cell becomes separated by more than 100 μm from its nearest source of oxygen, as arranged by the existing cardiovascular system, that cell will receive insufficient O_2 to meet its metabolic needs. In such a state, the cell will malfunction and likely die. As shall be seen later in this text, tissue ischemia is a major clinical problem in the cardiovascular and other organ systems in the body.

Although the oxygen problem is reason enough for a large organism like ourselves to have an absolute requirement for a cardiovascular system, our oxidative metabolism creates another problem that this same system helps resolve. Carbon dioxide produced by oxidative metabolism can rapidly acidify the cell and its surroundings if it is not removed. Fortunately, CO_2 transport out of our cells can also utilize simple diffusion because a circulatory system to transport it away and carry it to the lungs is already in place. In addition to its essential role in delivering oxygen and removing carbon dioxide, the cardiovascular system is also exploited for other tasks in the body. For example, the body uses hormones for the control of important physiologic functions, and these hormones are transported from the site of their production to their target organs in the bloodstream by the cardiovascular system. In addition, blood serves as a reservoir for heat. The cardiovascular system plays an important role in the control of heat exchange between the body and external environment by controlling the amount of blood flowing through the skin, which is the site of heat transfer between our body and the external environment.

FUNCTIONAL ORGANIZATION

Students in medical physiology should be familiar with the anatomic organization of the heart and blood vessels from their courses in gross anatomy and histology. A brief overview is contained in this section. The cardiovascular system is a fluid transport system for the movement of blood throughout the body. This is represented in simplistic form in Figure 11.1. Blood is driven through the cardiovascular system through the actions of a hollow muscular pump called the **heart**. The heart is a four-chambered muscular organ that contracts and relaxes in a regular repeating cycle to pump blood.



Head
(brain, skin, and bone)
Arms and trunk
(skin, muscle, and bone)
Endocrine glands
Coronary circulation
Pulmonary
artery
Bronchial
circulation
SVC
Lungs
Aorta
RA
Pulmonary
vein
LA
IVC
RV
LV
Liver
Portal vein
Stomach,
spleen
Intestines,
pancreas
Endocrine glands
Kidneys
(tubules)
Kidneys
(glomeruli)
Trunk and legs
(skin, muscle, and bone)

Figure 11.1 A model of the cardiovascular system. The right and left sides of the heart are aligned in series, as are the systemic circulation and the pulmonary circulation. In contrast, the circulations of the organs other than the lungs are in parallel. Each organ receives blood from the aorta and returns it to the vena cava. Exceptions to the series arrangements exist between the splanchnic veins and portal circulation of the liver as well as the glomerular and tubular capillary networks of the kidney. SVC, superior vena cava; IVC, inferior vena cava; RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

The heart is really two pumps connected in series. The left heart is composed of the **left atrium** and **left ventricle**, separated by the **mitral valve**. Contraction of the left ventricle is responsible for pumping blood to all systemic organs except the lungs. During contraction of the ventricles, blood exits the left ventricle through the **aortic valve** into a single tubular conduit called the **aorta**. The aorta is an **artery**, which, by definition, is any blood vessel that carries blood away from the heart and to the tissues of the body. The aorta branches into successively smaller arteries, many of which are given anatomic names. These arteries, in turn, branch into millions of smaller vessels of ~10 to 1,000 μm in external diameter, called **arterioles**. Arterioles, in turn, terminate into billions of **capillaries**, which are the main site of transport of water, gases, electrolytes, substrates, and waste products between the bloodstream and the extracellular fluid. Blood from the capillaries of all the systemic organs coalesces into thin-walled **venules**, which merge into **veins**. By definition, a vein is any blood vessel that returns blood from the tissues back into the heart. Small veins eventually merge to form two large single veins called the **superior vena cava** (**SVC**) and the **inferior vena cava** (**IVC**). The SVC collects blood from the brain, head, and upper extremities above the level of the heart, whereas the IVC collects blood from all regions below the level of the heart. Both of these large veins empty into the **right atrium**. The right atrium is the upper chamber of the right heart. It is separated from the **right ventricle** by the **tricuspid valve**. The right ventricle pumps blood through the **pulmonic valve** into the **pulmonary artery** and thence into the lungs. Blood exiting the lungs is returned to the **left atrium** where it passes through the **mitral valve** and into the left ventricle, completing the circulatory loop. As a whole, the period of time the heart spends in contraction and pumping blood out of the ventricles is called **systole**, and the time it spends in relaxation when these chamber fill with blood is called **diastole**.

The outputs of the right and left heart are interdependent because they are connected in series.

The right and left heart are said to be arranged *in series*, or in line, one after the other, right to left. For this simple reason, it cannot be possible for the flow output of the right and left heart to differ for anything more than a few seconds. To see how this must be, imagine a bucket of water interposed between two pumps. One pump removes water from the bucket and pumps it into the inflow of the second pump. The second pump takes this inflow and returns it into the bucket for the first pump to remove again. It is obvious that if the outputs of the two pumps are not matched identically, the level of water in the bucket will change; the bucket could be drained dry or could overflow. This is analogous to the situation in the pulmonary circulation that is interposed between the right and left heart. Because of the series arrangement between the right and left heart, an output of the left heart that exceeds that of the right by as little as 2% will drain the pulmonary circulation dry within minutes. Conversely, if the right heart output exceeded the left by a similar amount, the pulmonary circulation would overflow and the person would drown in his or her own body fluids. Clearly, neither of these situations arises in a healthy person. The implication of this is that some mechanism must function to closely match the outputs of the right and left heart. Such a mechanism exists at the level of the muscle cell and is based on the same principles of skeletal muscle cell mechanics you have read about in earlier chapters. Details of these principles as they apply to the heart are discussed in Chapter 13.

The series arrangement of the right and left heart also implies that malfunctions in the left heart will be transmitted back into the pulmonary circulation and the right heart. This in turn can cause the respiratory system to malfunction. Indeed, one of the first clinical signs of left heart failure is respiratory distress. Conversely, problems originating on the right side of the circulation affect the output of the left heart and imperil the blood supply to all systemic organs. For example, large blood clots, which can form in the major veins of the leg and abdomen following surgery can break away and slip through the right heart chambers and into the pulmonary artery where they eventually lodge, to form a **pulmonary embolus**. If such emboli block enough of the pulmonary circulation, the left heart may not be able to pump enough blood for the individual to survive.

Parallel arrangement of organ circulations permits independent control of blood flow in individual organs.

The metabolic demands of our muscles, digestive system, brain, and so on are different relative to one another and relative to their own resting values, depending on the activity in the organ at a given time. The arterial system delivers blood to organ systems that are arranged in a *parallel*, or side-by-side, network. Therefore, in most cases, blood flow into one organ system is not dependent on blood flow through another organ upstream. The parallel arterial distribution system of organ blood supply allows the adjustment of blood flow to an individual organ to meet its own needs without creating major disturbances in the blood supply to other organs. A notable exception to this arrangement, however, is seen in the portal circulation. Venous outflow from the intestines and other splanchnic organs drains into the liver through the **portal vein** before being emptied into the IVC. The liver obtains blood from the portal vein as well as its own arterial supply (see Fig. 11.1) and can be considered to be arranged in series with much of the splanchnic circulation.

Vascular smooth muscle actively controls the diameter of arteries and veins.

All blood vessels, except capillaries, have a similar basic structure. They are both lined with a single layer of epithelial cells called the **endothelium**. The media of these vessels contain circular layers of smooth muscle cells, whereas the outermost layer, called the **adventitia**, is composed of collagen and elastin fibers that add flexible structural integrity to arteries and veins. Because the smooth muscle within blood vessels is arranged in circular layers, contraction or relaxation of these muscles will reduce or widen, respectively, the lumen diameter of arteries and veins. Altering blood vessel caliber has a profound effect on organ blood flow and blood volume distribution in the cardiovascular system. These effects are discussed later in this chapter.

There are literally scores of normal physiologic, pathologic, and clinical pharmacologic agents that can alter the contraction and relaxation of arterial and venous smooth muscle. These take the form of direct physical forces and chemical agents, hormones, paracrine substances, and receptor-mediated hormonal and neurotransmitter agonists. For example, the contraction of arteries and veins is modified by transmitters released from sympathetic nerve endings that enter these vessels through their adventitial layer and act on specific receptors on the smooth muscle membrane. The endothelium, which stands at the interface between blood plasma and the rest of the vessel wall, is the source of important paracrine agents that have major, receptor-independent, direct effects on blood vessel contraction. A simplified, partial list of factors that contract or relax vascular smooth muscle is provided in Table 11.1.

TABLE 11.1 A Simplified List of Direct (Non–Receptor-Mediated) and Smooth Muscle Membrane Receptor–Mediated Factors that Contract or Relax Vascular Smooth Muscle

Vasoconstrictor/Vasodilator	Mechanism of Action
	Vasoconstrictors: Nonreceptor mediated
Ca^{2+}	Enters cells through membrane channels or is released from the SR by IP_3; binds to calmodulin, which activates myosin light chain kinase to initiate crossbridge attachment and cycling
K^+	Membrane depolarization resulting in activation of L-type Ca^{2+} channels
O_2 (normoxia)	Maintenance of contraction
Membrane depolarization	Activation of L-type Ca^{2+} channels
Increased transmural pressure	Activation of stretch-activated plasma membrane calcium channels
Action potentials	Membrane depolarization resulting in the activation of L-type calcium channels
	Vasoconstrictors: Receptor mediated
Norepinephrine	Activation of α adrenoceptors to open receptor-operated plasma membrane calcium channels, activation of phospholipase C, formation of IP_3 and DAG, and release of calcium from the SR
Epinephrine	Same as norepinephrine
Acetylcholine	Activation of muscarinic M_2 receptors to open receptor-operated plasma membrane calcium channels, activation of phospholipase C, formation of IP_3 and DAG, and release of calcium from the SR; inhibits cAMP formation
Serotonin	Activation of 5-HT_2 receptors to open receptor-operated plasma membrane calcium channels
Vasopressin	Activation of V receptors to open receptor-operated plasma membrane calcium channels
Angiotensin II	Activation of angiotensin II receptors to open receptor-operated plasma membrane channels and activate IP_3/DAG pathways
Endothelin	Activation of ET_A receptors with stimulation of phospholipase C, formation of IP_3, and release of calcium from the SR
ATP	Activation of P_{2x} receptor to open receptor-operated plasma membrane channels
	Vasodilators: Direct
Nitric oxide	Activation of guanylate cyclase, formation of cGMP, and calcium removal
Hyperpolarization	Inhibition of voltage-gated Ca^{2+} channels
Decreased transmural pressure	Inhibition of stretch-operated Ca^{2+} channels
Hypoxia	Decreased ATP supply and formation of adenosine. H_2S and/or CO formation
Hypercapnia	Likely from acidosis
Acidosis	Unknown
Hyperosmolarity	Unknown
CO	Stimulation of calcium activated K^+ channels
cAMP	Activation of cAMP-dependent kinase resulting in a phosphorylation cascade that reduces intracellular calcium concentration
cGMP	Activation of cGMP-dependent kinase resulting in a phosphorylation cascade that reduces intracellular calcium concentration
Hyperkalemia (low levels)	Membrane hyperpolarization resulting from activation of the Na^+/K^+ pump

Vasodilators: Receptor mediated	
Epinephrine	β_2 receptor–mediated activation of adenyl cyclase resulting in the formation of cAMP
Adenosine	A_1, A_{2A}, and A_{2B} receptor activation of ATP-dependent K^+ channels leading to membrane hyperpolarization and closure of voltage-gated calcium channels
Histamine	H_2 receptor activation of adenyl cyclase with formation of cAMP
PGI_2	Activation of adenyl cyclase with formation of cAMP

5-HT, 5-hydroxytryptamine; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; DAG, diacylglycerol; IP_3, inositol 1,4,5-triphosphate; PGI_2, prostacyclin; SR, sarcoplasmic reticulum.

PHYSICS OF BLOOD CONTAINMENT AND MOVEMENT

The study of the physical variables related to the containment and movement of blood in the cardiovascular system is called **hemodynamics**. From an engineering standpoint, an accurate description of all the hemodynamic phenomena in the cardiovascular system is complex. Fortunately, the human body deals with these phenomena and their control in a considerably simplified manner. The cardiovascular system behaves much as if the heart were producing an average steady flow through a series of solid pipes, similar to the flow of water through a city's water distribution system. Thus, basic principles of fluid dynamics can be applied to the understanding of cardiovascular phenomena.

Fluid cannot move through a system unless some energy is applied to it. In fluid dynamics, this energy is in the form of a difference in **pressure**, or pressure gradient, between two points in the system. Pressure is expressed as units of force, or weight, per unit area. A familiar example of this is in the pounds per square inch (psi) recommendation stamped on the side of tires. The psi indicates the pressure to which a tire should be inflated with air above atmospheric pressure. Inflating a tire to 32 psi signifies that 32 more pounds press against every square inch of the inner tire surface than against the outside of the tire.

The pressure exerted at any level within a column of fluid reflects the collective weight of all the fluid above that level as it is pulled down by the acceleration of gravity. It is defined as

$$P = \rho g h \quad (1)$$

where P = pressure, ρ = the density of the fluid, g = the acceleration of gravity, and h = the height of the column of fluid above the layer where pressure is being measured. The force represented by pressure in a fluid system is often described as the force that is able to push a column of fluid in a tube straight up against gravity. In this way, the magnitude of the force resulting from fluid pressure can be measured by how high the column of fluid rises in the tube (Fig. 11.2A). In physiologic systems, pressure is expressed in this manner as centimeters H_2O, or the more practical mm Hg. Because mercury is much denser than water, it will not be pushed as far upward by typical pressures seen within the cardiovascular system and thus devices containing columns of mercury (or based on them) can be easily used to measure physiological pressures in the body.

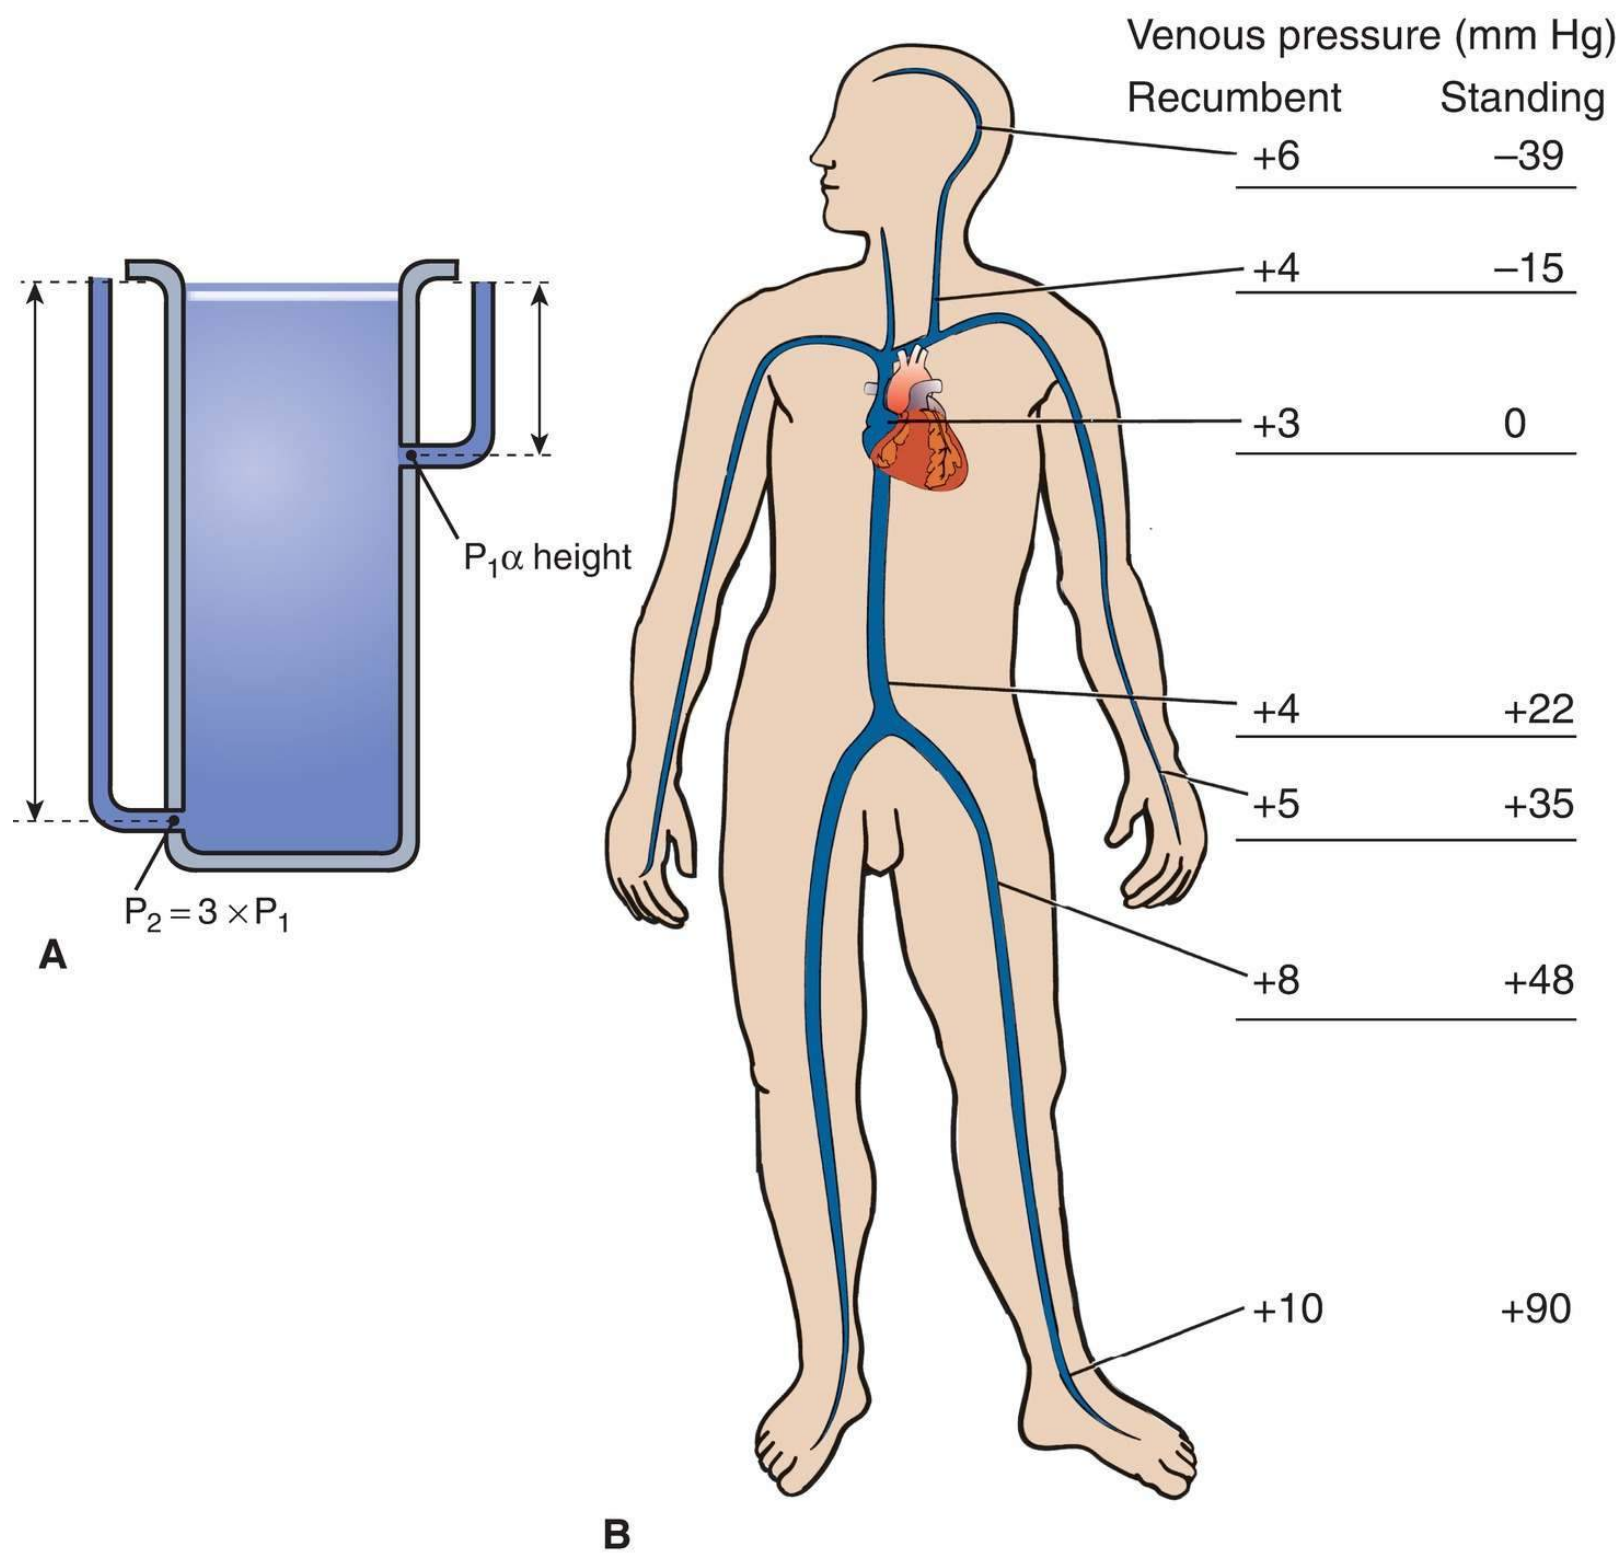


Figure 11.2 The effect of height on pressure at different levels within a column of fluid. (A) Fluid pressure is proportional to the height of the column of fluid above the point of measurement. Pressure in the cardiovascular system is commonly reported in units of mm Hg. **(B)** The effect of gravity on pressure within veins. Blood is pulled down by the effect of gravity, subtracting pressure from veins in the head and adding pressure to veins in the lower extremities.

In the human cardiovascular system, aortic pressure peaks during contraction of the heart to about 120 mm Hg and drops to about 80 mm Hg when the heart relaxes. The peak pressure is called the **systolic pressure,** whereas the minimum arterial pressure value during relaxation of the heart is called the **diastolic pressure**. Thus, if one end of a tube were to be inserted into the aorta with the other end connected to a column of mercury sitting perpendicular to the ground at the level of the heart, that column

of mercury would rise 120 mm during systole and fall to 80 mm during diastole. In clinical practice, human arterial pressure is reported as systolic over diastolic pressure or, in this example, 120/80 mm Hg. (Our mean arterial pressure is not the arithmetic mean of systolic and diastolic pressure but is instead about 93 mm Hg, because the time the heart spends relaxing is longer than the time it spends contracting and ejecting blood into the aorta.)

The pressure outside the body or on the outside of any hollow structure within the body other than the intrapleural space is about the same as atmospheric pressure. Atmospheric pressure at sea level is usually about 760 mm Hg. In reality, therefore, our average blood pressure is 93 + 760 mm Hg, or 863 mm Hg. However, pressures within our body are never expressed in this technically exact manner. Instead, the effect of atmospheric pressure is simply ignored and taken as a *zero reference point*. The pressure reported in our systems then is really the difference of pressure within that system relative to atmospheric pressure.

The effect of gravity on pressure within blood vessels in our body is significant when we are standing, as shown in Figure 11.2B for veins. In a recumbent position, pressure in the veins is between 2 and 10 mm Hg. However, when one stands, the influence of gravity subtracts ~40 mm Hg of pressure from the vessels in the head and adds about 90 mm Hg of pressure to those in the feet. If human veins were rigid tubes, this would not have a profound effect on the circulation or on distribution of blood within sections of the cardiovascular system. However, veins are flexible structures. Therefore, when one stands, blood tends to pool in the veins of the lower extremities. This is responsible in part for the swelling and aching of the feet after standing for long periods of time. Standing in this manner can even result in such extensive pooling that fainting will occur from an inability of enough blood to return to the heart to be pumped to the brain.

Blood vessel volume is a function of vessel flexibility and the pressure difference across the vessel wall.

The volume of fluid within a container made of inflexible walls, such as a glass bottle, is the same no matter what the pressure difference is between the inside and the outside of the bottle. In such a container, the walls cannot move when any difference in pressure is applied across them. In contrast, the walls of arteries and especially veins are flexible. Consequently, the volume contained within them is a function of both the pressure difference across their wall, called the **transmural pressure**, and the degree of flexibility within the vascular wall. Transmural pressure, or P_T, is always defined as the difference in pressure *inside versus outside* a hollow structure. Large transmural pressures within flexible vessels create large intravascular volumes; small transmural pressures in stiff-walled vessels produce small intravascular volumes.

There are a couple of ways of depicting pressure/volume interrelationships in blood vessels. The volume of blood contained in the vessel for a given transmural pressure is called the **vascular capacitance** and is calculated as

$$\text{Capacitance} = \text{Volume}/P_T \quad (2)$$

where volume and transmural pressure are generally given the units of mL and mm Hg, respectively. However, physiologists are interested in how volume changes in a distensible blood vessel for a given change in pressure. The change in volume for a given change in transmural pressure is called the **compliance** and is given by the equation

$$C = \Delta V / \Delta P \quad (3)$$

where the Δ signifies the before/after change of volume or pressure. (Note that although pressure outside the vessel is taken to be atmospheric pressure, or zero baseline, this pressure can become positive in certain pathologic conditions and thus reduce the distending effect of pressure within the blood vessel.) The compliance equation can be rearranged to yield two useful relationships relating changes in either volume or pressure as a function of the other in a blood vessel. For example, one can write $\Delta V = C \times \Delta P_T$. This equation indicates that the change in volume contained within a vascular segment will be great in a vessel with high compliance and a large change in intravascular pressure. One can also write $\Delta P_T = \Delta V/C$, which indicates that adding volume into a vascular segment will produce a large increase in pressure within the vessel if the volume added is large and the vascular compliance is low.

Both capacitance and compliance can be used as measures of the distensibility, or flexibility, of a blood vessel; highly distensible vessels have a higher capacitance and compliance than vessels with stiff walls, *if the vessels have the same initial dimensions*. For this reason, veins have a higher capacitance and compliance than arteries of similar size. However, the use of these variables to measure vessel flexibility fails when vessels of significantly different sizes are compared. For example, a large stiff-

walled vessel may have a higher capacitance value than a tiny flexible vessel. For this reason, one should use the *percentage* increase in volume for a given increase in pressure as a means of comparing distensibility between vessels and segments of the vasculature of different sizes. This value is sometimes called *vascular distensibility*. As explained in later chapters, vascular capacitance, compliance, and distensibility are critical determinants of the performance of the heart, the stress and workload placed on the heart, and the amount of oxygen the heart must receive to function properly. All of these factors are important parameters in understanding the consequences of heart diseases and their treatments.

Even within a given artery or vein, capacitance, distensibility, and compliance are not constants in the cardiovascular system. For example, as transmural pressure increases, compliance decreases (Fig. 11.3). In addition, arterial compliance decreases with age at any given transmural pressure and is reduced by contraction of the smooth muscle within either arteries or veins. This active control over pressure/volume interrelationships in the vascular tree is an important component of the moment-to-moment control of blood volume distribution in the body and cardiac performance.

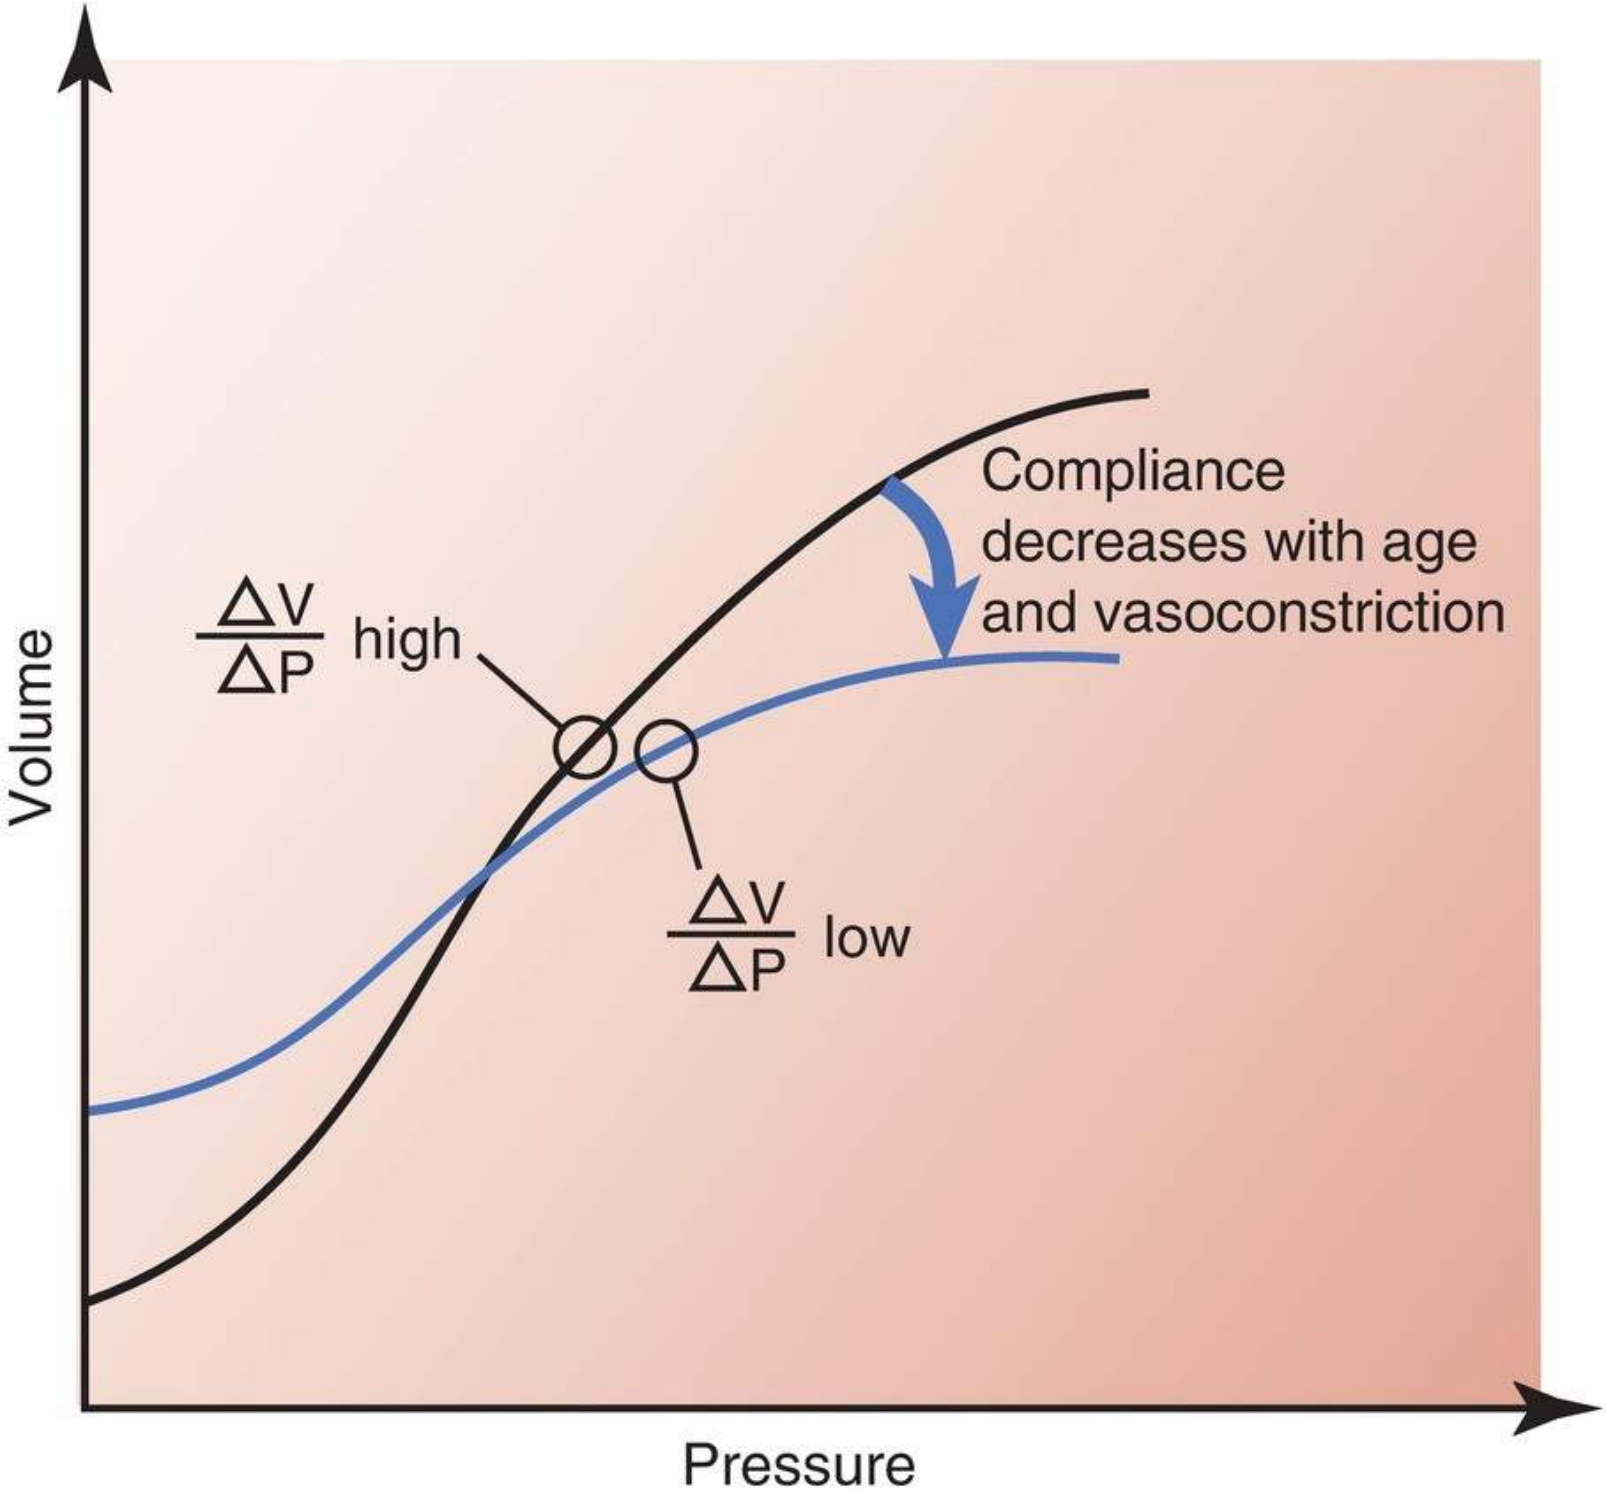

Figure 11.3 The relationship between volume and transmural pressure in arteries. Volume within an artery increases with an increase in transmural pressure because the arterial wall is flexible. An artery is stiffest at low and high transmural pressure, respectively. The slope of this arterial volume–pressure relationship at any point is a measure of arterial compliance. Arterial compliance also decreases with aging and with the level of active smooth muscle contraction in the artery.

Blood vessels must overcome wall stress to be able to contract.

Any transmural pressure within an artery or a vein exerts a force on the vessel wall that would tend to rip the wall apart were it not for the opposing forces supplied by the muscle and connective tissue of the vessel wall, as shown in Figure 11.4. This force is called **tension** and is equal to the product of the transmural pressure and the vessel radius. This relationship is called the **law of Laplace**. However, this relationship applies directly only to cylinders with thin walls. Blood vessel walls are sufficiently thick, so that in reality, this force is equal to a **wall stress** (the product of pressure [P] and the radius [r] divided by the wall thickness [w], or $S = P \times r/w$). There are many consequences of this relationship in distensible tubes. First, because tension and stress are related to vessel radius, small vessels are able to withstand higher pressures than vessels of larger diameters. For this reason, capillaries (inner diameter ~10 μm) can withstand relatively high intravascular pressure even though they are composed only of a single cell layer of endothelial cells. In arteries and veins, vessels with thick walls relative to their radius are able to withstand higher pressure than vessels with large r/w ratios because wall stress is lower in the former. Finally, tension and stress, not simply pressure, are the true forces that must be overcome to contract any hollow organ, such as a blood vessel or the heart. As is discussed later in the text, tension and stress are important determinants of energy requirements for the contraction of hollow organs.

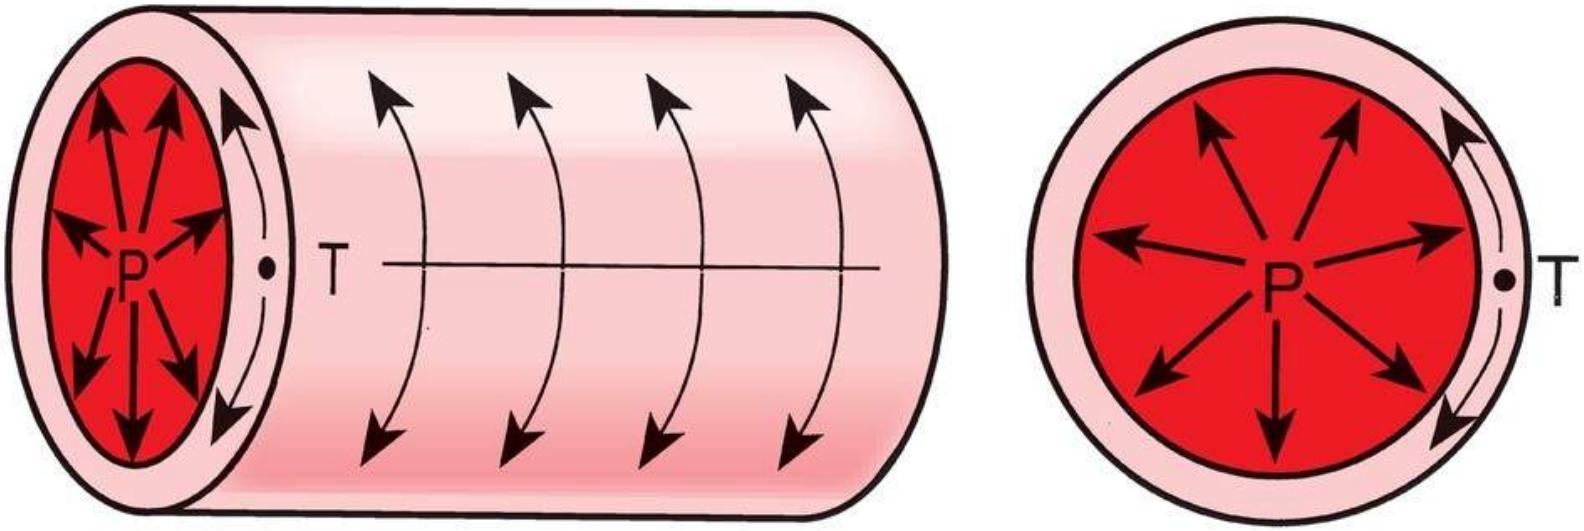

Figure 11.4 Pressure and tension in a cylindrical blood vessel. The tension is the force that would pull the vessel apart along an imaginary line along the length of the vessel. Tension in the vessel wall is related by the law of Laplace, as described in the text. P, pressure; T, tension.

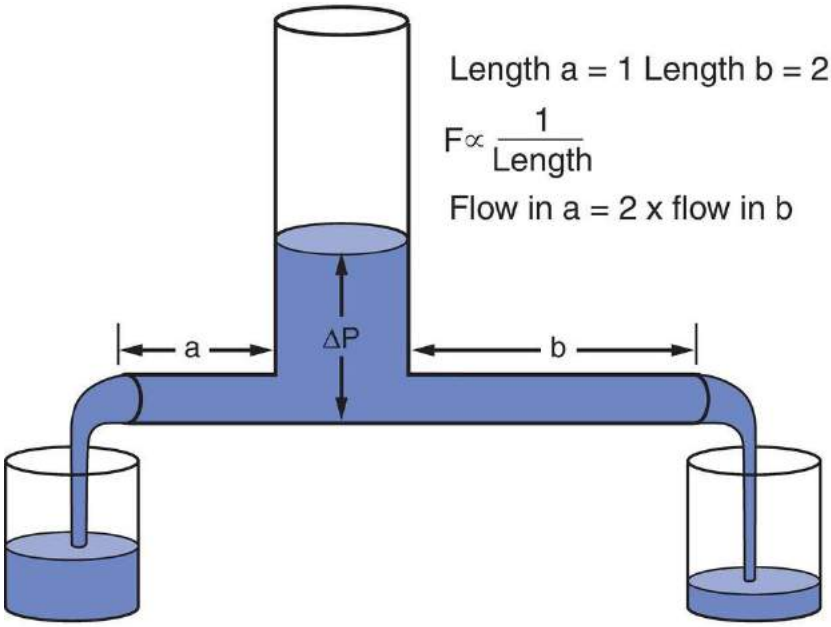
PHYSICAL DYNAMICS OF BLOOD FLOW

An understanding of the physical factors and laws that govern the movement of blood in the cardiovascular system is critically important to the overall understanding of cardiovascular functions. The amount of blood that flows through any segment of the cardiovascular system is a function of blood pressure, vascular geometry, and the dynamic fluid characteristics of blood. In any tube of a given diameter, the amount of flow through the tube is proportional to the *difference* in pressure between one end of the tube and the other (Fig. 11.5); doubling the pressure difference doubles the flow, whereas halving the difference halves the flow. Flow through a cylindrical tube is related to the length of the tube in an inverse proportion, for example, keeping all other determinants of flow unchanged, doubling only the length of a cylindrical tube reduces flow through the tube by half; tripling the length reduces flow to 1/3 that of the shorter tube and so forth. However, as shown in Figure 11.5, flow through a tube is profoundly affected by the tube radius in that flow is proportional to the radius^4. Consequently, doubling the tube radius results in a 16-fold increase in flow. This radius effect has a profound influence therefore on blood flow through any tubular system.



Length a = 1 Length b = 2

Radius a = 2 Radius b = 1
F∝ r4
Flow in a = 16 x flow in b
ΔP
a
b

Figure 11.5 The influence of pressure difference, tube length, and tube radius on flow. The pressure difference driving flow (ΔP) is the result of the height of the column of fluid above the openings of tubes a and b. Increasing the pressure *difference* increases flow; if pressure was the same at the entrance and exit of the tubes, there would be no flow. Flow is reduced in direct proportion to the length of the tube through which it flows. Because flow is also a function of the fourth power of the tube radius, small changes in radius have a marked effect on flow. F, flow; P, pressure.

Finally, fluid flow through a tube is affected by the viscosity, or the "thickness and stickiness," of the fluid. Thick, sticky fluids will not flow as easily as thinner, watery fluid. The units of viscosity are given in poise, named after Louis Poiseuille. Water has a viscosity of ~0.01 Poise or 1 centipoise (cP). Blood is a suspension of proteins and cells in a salt solution. As such, it is more viscous than water. Blood plasma has a viscosity of 1.7 cP whereas whole blood, which contains plasma and blood cells, has a viscosity of ~4 cP.

Relationships between pressure, fluid flow, and resistance are quantified by Poiseuille's law.

In the 1840s, Louis Poiseuille conducted experiments that resulted in a mathematical relationship to describe flow in a cylindrical tube. This has become known as **Poiseuille's law**. This law states that:

$$Q = \left(P_1 - P_2\right)\pi r^4 / 8\eta l$$

(4)

where Q = flow, $(P_1 - P_2)$ = the pressure difference between the beginning and the end of the tube, r = the tube radius, l = the tube length, η = viscosity, and π and 8 are constants of proportionality. This relationship can also be written as $(P_1 - P_2) = Q\ 8\eta l/\pi r^4$. In this form, the term $8\eta l/\pi r^4$ is the resistance to blood flow and is sometimes simply designated as R. Flow resistance is a measure of how easily the fluid can pass through a tube for any given pressure difference. In physiology, it is easier to calculate resistance as $(P_1 - P_2)/Q$ and to express it in units of mm Hg/mL/min. This value is then called a peripheral resistance unit (PRU).

Poiseuille's law gives two of the most fundamentally important relationships used to describe flow and pressure in the cardiovascular system, which are

$$Q = \left(P_1 - P_2\right)/R \text{ and } \left(P_1 - P_2\right) = Q \times R$$

(5)

These equations indicate that flow is proportional to the pressure difference between the entrance and exit points of the tube and inversely proportional to the resistance (i.e., as resistance increases, flow decreases). It also tells us that at any given flow, the pressure drop along any two points down the length of the tube is proportional to resistance. In the cardiovascular system, the final "end of the tube" is considered the right atrium. Pressure in the right atrium is about 2 mm Hg but considered sufficiently close to zero to be ignored. Therefore, $(P_1 - P_2)$ becomes simply P. Furthermore, for the purpose of understanding basic hemodynamics, P is usually taken as the mean pressure within an artery or vein. Consequently, Poiseuille's law reduces to

$$Q = P/R \text{ or } P = Q \times R$$

(6)

Applied to the whole cardiovascular system, this law indicates that arterial pressure is the product of the flow output of the heart, called the **cardiac output**, and the resistance to flow provided by all the blood vessels in the circulation. This resistance is termed the **total peripheral vascular resistance**

(**TPR**) or less correctly just vascular resistance.

Strictly speaking, Poiseuille's law applies only to nonpulsatile flow of a homogenous fluid in uniform, rigid, nonbranching cylindrical tubes. Because none of these characteristics is met in the cardiovascular system, one might imagine that Poiseuille's law cannot be applied to blood flow. However, this law can be and is applied to the cardiovascular system. Note that this application is not used as a simplified expedient that ignores some of the complex realities of the physics of blood flow. Rather, it is used in the manner expressed in equation 6 because the cardiovascular system truly does behave as if the heart pumped blood at a steady flow, producing a mean arterial pressure as the result of a single TPR. Thus, equation 6 predicts that mean arterial pressure will increase if the cardiac output, TPR, or both increase. It also predicts that at a constant mean arterial pressure, blood flow through any portion of the vascular tree will increase if TPR decreases. These simple cause-and-effect relationships are the critical determinants of arterial pressure and organ blood flow in the cardiovascular system and will be described more fully in the context of cardiovascular control mechanisms in Chapter 17.

The series and parallel arrangement of blood vessels within an organ affects vascular resistance in the organ.

The cardiovascular system is composed of millions of vessels of different sizes. There are two simple rules used to determine how many vessels of different sizes combine to give a single resistance to flow. In a system composed of different-sized tubes arranged in series (i.e., sequentially, or end to end), the total resistance of that system is simply the sum of the individual resistances. Or

$$R_{total} = \Sigma R_{individual} \quad (7)$$

For example, if one were to examine the resistance of a segment of a tapering artery where the proximal 1 cm of length had an R = 1 PRU, the next 1 cm had an R = 2 PRUs, and the 1 cm after that an R = 5 PRUs, the resistance across the entire 3-cm length of that artery would be 1 + 2 + 5 = 8 PRUs. Nevertheless, the arterial portion of the cardiovascular system is not a single long blood vessel; the aorta branches into parallel vessels that reach the billions once at the level of capillaries. The total resistance in a system of parallel tubes is given by

$$1/R_{total} = \Sigma\left(1/R_{individual}\right) \quad (8)$$

That is, the reciprocal of the total resistance in vessels arranged in parallel is the sum of the reciprocals of the individual resistances. Using the arterial segments mentioned above but arranged in parallel, one would arrive at $1/R_{total} = 1/1 + 1/2 + 1/8 = 13/8$ and $R_{total} = 8/13$, or ~0.62 PRUs. In this case, the total resistance of the system of the three arteries arranged in parallel is not only less than it would have been if they were arranged in series but is actually less than the resistance of any one segment in the circuit. In most cases, this is a *general* rule of thumb; adding similar-sized arteries in parallel reduces resistance, whereas losing similar-sized arteries in parallel raises vascular resistance. The first case is seen following long-term aerobic training such as distance running, in which the arteriolar and capillary network increase their numbers in parallel, thereby reducing resistance to blood flow.

The effect of summed series and parallel elements in the cardiovascular system is a bit more complicated than can be described solely by equations 7 and 8. In the cardiovascular system, vessels get smaller as they proceed from arteries down to arterioles and capillaries, which tends to increase resistance to flow. However, the number of vessels arranged in parallel also increases dramatically in this direction, which tends to decrease resistance. The effect of these two phenomena on the relative resistances of individual sections of the vasculature depends on whether the number of vessels added in parallel can compensate for the resistance effects of adding vessels that individually have a high resistance. This interplay between series and parallel elements is a primary factor in creating the form of the pressure profile, or ΔP, along the arterial side of the circulation, as will be explained later in this

chapter.

CLINICAL FOCUS 11.1

Vascular Abnormalities Associated with Chronic Primary Arterial Hypertension

Chronic arterial hypertension is a cardiovascular disease in which the main manifestation is a consistent elevation of arterial pressure ≥140/90 mm Hg. Diagnosis of chronic arterial hypertension in a patient is established following documentation of elevated pressure in a clinical setting at several time points over a period of many weeks or months. It is now estimated that up to 1/3 of the population of the United States suffers from chronic arterial hypertension. Such a high prevalence of hypertension represents a serious national health issue as this condition is the leading risk factor in stroke and a major contributor to morbidity and mortality associated with heart failure, coronary artery disease, atherosclerosis, and renal insufficiency.

Arterial hypertension is largely asymptomatic until it results in end-stage organ disease, which is a major reason it often goes unrecognized and untreated by the patient. Left untreated, arterial hypertension becomes more severe over time, as the result of progressive arterial and renal abnormalities resulting from exposure to high arterial pressure. People with untreated arterial hypertension do not get better on their own and must stay on medication throughout their lives to keep their arterial pressure down. Keeping pressure down in hypertension has been clinically established to provide definitive benefits to the patient, whereas failure to control hypertension results in definitive harm.

Chronic arterial hypertension is classified broadly as either *primary* or *secondary hypertension*. Secondary hypertension indicates that the elevated blood pressure is a secondary result of some other primary disease. Hypertension is a secondary consequence of renal artery stenosis, renal parenchymal disease, primary aldosteronism, pheochromocytoma, aortic coarctation, and thyrotoxicosis. Although there are several mechanisms known to cause secondary hypertension, only 5% to 15% of all cases of chronic arterial hypertension fall into that category. The remaining individuals with hypertension have what is called *primary hypertension* (formerly called essential hypertension). The primary classification indicates that the hypertension is a primary condition in its own right of unknown cause. Currently, the etiology of primary hypertension is believed to be the result of a mosaic of initiating factors and regulatory dysfunctions with strong genetic predispositions involving both. Many of these appear to involve the kidney and salt balance.

Regardless of the mechanisms creating hypertension, chronic arterial hypertension is the result of elevated peripheral vascular resistance. For this reason, hypertension is considered a *vascular* disease involving the arterioles because these vessels are the major contributor to total peripheral vascular resistance. Arteries are not static vessels; they enlarge when chronically exposed to high blood flow, regress when flow is chronically low and importantly increase in thickness when exposed to high internal stress. In chronic hypertension, arteries have thickened vascular walls and narrowed lumens. This thickening is due to vascular smooth muscle cell hypertrophy and hyperplasia as well as increased water content and accumulation of fibrotic material in the arterial wall. These factors increase the

resistance of arteries, even in the absence of all vascular smooth muscle contraction, and acts as a structural, geometric amplifier of any vasoconstrictor stimuli. As a result, all arterial smooth muscle contraction, from maximum dilation to maximum contraction, results in exaggerated increases in arterial resistance in arteries from hypertensive, compared with normotensive, patients. In addition, the arterial smooth muscle cells in hypertensive patients are hypersensitive to vasoconstrictor stimuli and hyposensitive to vasodilators. This too results in an exaggerated increase in vascular resistance with any vasoconstrictor stimuli and a reduced capacity of the arteries to counteract this exaggeration with any vasodilator stimuli. Lost production and bioavailability of arterial endothelial nitric oxide, which is a potent vasodilator and antimitogenic agent for smooth muscle, is also a consequence of hypertension and may be a contributing factor in the maintenance and inevitable progression of that disease. ■

High blood flow velocity decreases lateral pressure while increasing shear stress on the arterial wall.

In addition to arterial blood flow, physiologists are often interested in how fast the bloodstream is flowing within the artery. This variable is called **flow velocity** and is usually expressed in cm/s. Fluid flow velocity is given simply by the volume of flow per second (cm^3/s) divided by the cross-sectional area of the system through which the fluid is flowing (Fig. 11.6A). If a flow of 200 mL/s in a tube is forced through another narrower tube, the flow must go through that smaller opening faster to maintain a volume flow at 200 mL/s. Conversely, if this fluid is allowed to expand into a much larger cross-sectional area, it can move slower and still deliver 200 mL/s. This relationship holds whether applied to a single tube or a composite cross-sectional area of many tubes arranged in parallel such as a cross-section through a portion of the vascular system. Thus, at a constant flow, a decrease in the cross-sectional area through which the flow is moving increases flow velocity, and an increase in area decreases flow velocity.

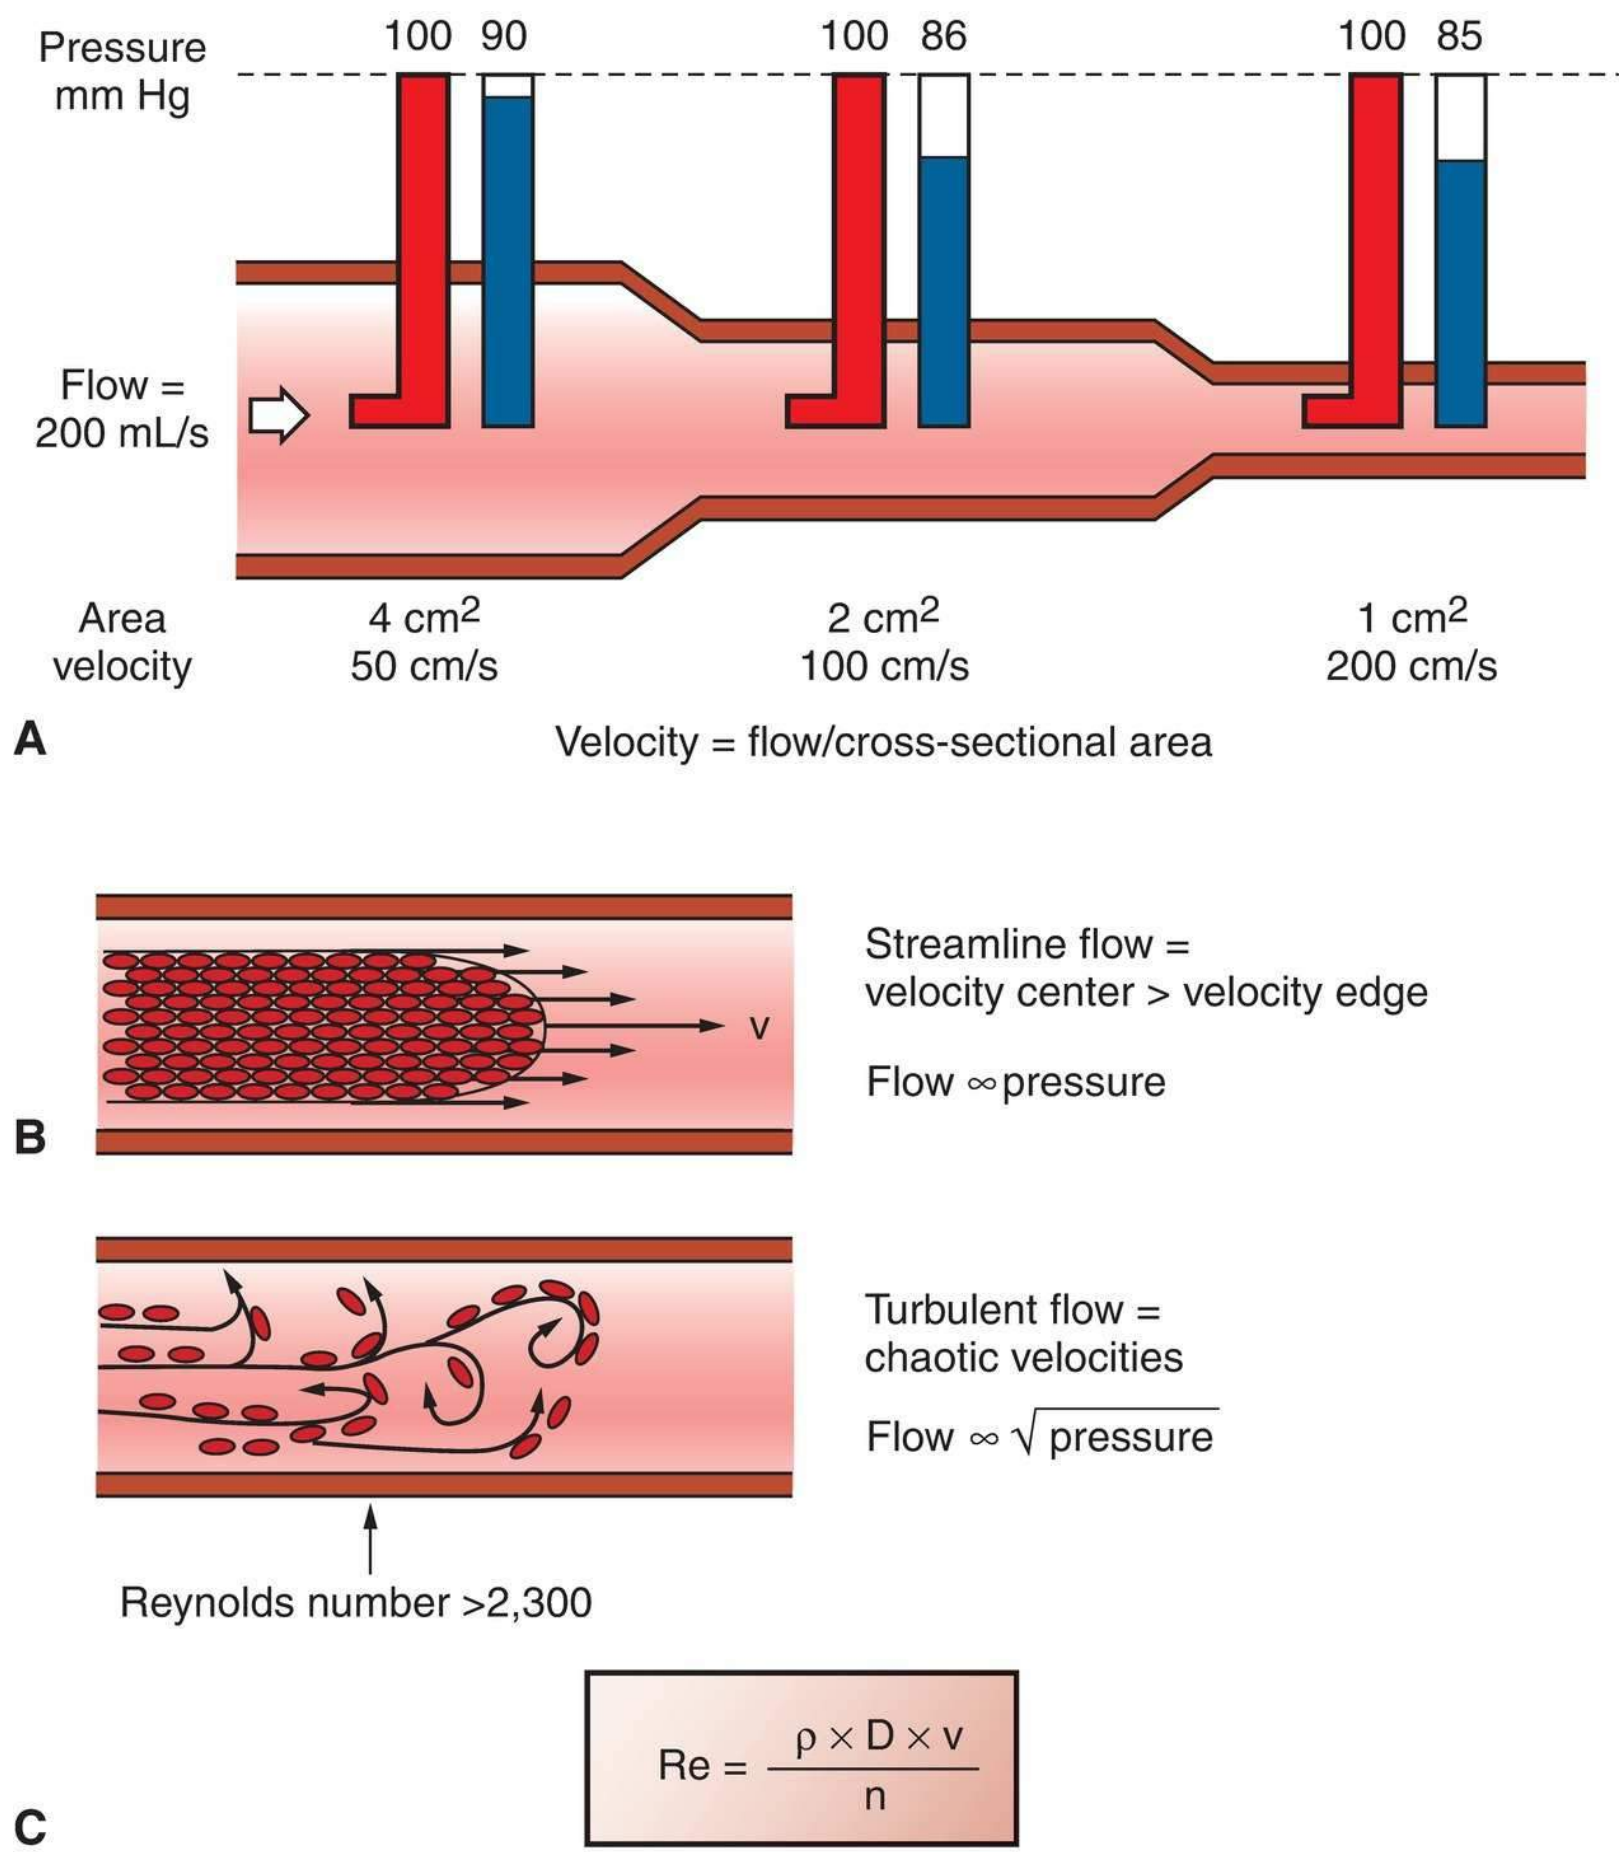

Figure 11.6 Effect of flow velocity on lateral intravascular pressure, axial streaming, and turbulent flow. (A) If any given flow of blood is forced through progressively smaller cross-sectional areas, the velocity of blood flow must increase. The Bernoulli principle states that increased flow velocity reduces the lateral pressure of the flow stream exerted against the wall of the vessel. **(B)** The distribution of red blood cells in a blood vessel depends on flow velocity. As flow velocity increases, red blood cells move

toward the center of the blood vessel (axial streaming), where velocity is highest. Axial streaming of red blood cells creates a cell-free layer of plasma along the inner vessel wall. **(C)**At high flow velocity, the kinetic forces of flowing fluid overcome the viscous forces holding layers of fluid together, resulting in turbulent flow.

The blood pressure exerted against the walls of an artery and the energy required to move blood at a certain velocity are interrelated by the **Bernoulli principle**. The total energy of blood flow in a blood vessel is the sum of its potential energy (represented as pressure against the vascular wall) and its kinetic energy resulting from its velocity (kinetic energy = ½ mv^2, where m = mass and v = velocity). Because energy is conserved, the total of potential and kinetic energy at any given point in a system is constant. Consequently, any increase in one form of the energy has to come at the expense of the other. For example, as flow velocity increases, lateral pressure must decrease to keep the total energy of the system constant (see Fig. 11.6A). This principle is seen with flow in the aorta, where high velocity reduces lateral pressure relative to that measured directly facing the flow stream, which equals the total energy in the system. This phenomenon is exploited clinically to evaluate the severity of the hemodynamic consequences of a stenotic (narrowed) aortic valve. A catheter with two pressure sensors is placed in the heart such that one lies within the ventricle and the other just across the narrowed aortic valve. A high-velocity jet of blood moving through the narrowed valve causes a significant drop in lateral pressure detected by the aortic sensor compared with the ventricular sensor; the hemodynamic severity of the stenosis is proportional to this pressure difference.

All flowing fluids exert a “rubbing” force against the inner wall of the cylinder in which they flow. This force is analogous to what one feels by rubbing the palms of the hands together and is called **shear stress**. Shear stress on the inner walls of arteries increases proportionally as the velocity of flow near the wall increases. This has several medical implications. The release of paracrine substances from the endothelium as well as other transport phenomena is stimulated by increased shear stress on the endothelial cells that line the arteries. These factors are instrumental in stimulating capillary growth and endothelial repair and may be the link between the growth of new blood vessels in skeletal muscle and periodic increases in muscle blood flow during aerobic exercise training. In atherosclerosis, plaque formation is reduced in areas of high shear but increased in low shear areas of arteries (see Clinical Focus 11.2).

CLINICAL FOCUS 11.2

Hemodynamic Localization of Atherosclerosis

Atherosclerosis is a chronic inflammatory response of the walls of large arteries that is initiated by injury to the endothelium. The exact cause of this injury is unknown. However, exposure to high serum lipid levels in the form of low-density lipoprotein (LDL) cholesterol and triglycerides is considered a prime factor, with contributions from hypertension, the chemicals in cigarette smoke, viruses, toxins, and homocysteinemia. With injury, the normal endothelium barrier becomes compromised. Leukocytes, primarily monocytes, adhere and infiltrate the arterial intima. These cells and the intima itself accumulate large quantities of lipoproteins, mainly LDL, which, when oxidized, further damages the

artery, stimulates the production of damaging reactive oxygen species, and sets up a more aggressive local arterial inflammatory response. This results in mitotic activation of arterial smooth muscle cells, which migrate into the intima, as well as the activation of monocytes, which transform into macrophages that engulf lipid to become foam cells. These factors stimulate intimal thickening and smooth muscle cell growth with infiltrates the intima. These processes create an inwardly directed growth of the arterial wall, which encroaches on the arterial lumen and creates the appearance of fatty streaks on the inner arterial wall. Over time, this streak grows with the accumulation of extracellular matrix proteins, the development of a fibrous cap over the atheroma, and the development of a lipid-laden necrotic core-containing debris, foam cells, crystallized cholesterol, and calcium deposits. This creates what is often called an *atherosclerotic plaque*.

Atherosclerotic plaques usually only develop in a portion of the circumference of the arterial wall. The wall opposite the plaque can actively contract in response to vasoconstrictor stimuli, whereas the wall beneath the plaque becomes weakened, creating an arterial aneurysm that can rupture. Atherosclerotic plaques stimulate platelet aggregation and blood clot formation that can totally occlude an artery. Furthermore, the plaque is friable and can rupture, spilling debris into the arterial lumen, which further stimulate clot formation. Plaque rupture in the arteries of the heart is a primary cause of death from heart attack.

Branch points and curvatures alter flow velocity and shear stress at the arterial wall; these are decreased along the inner curvature of a flow stream and at the upstream edge of branch points. It is well known that plaque formation in the vascular system does not occur either uniformly or totally randomly in the vascular tree. Instead, it develops at branch points and bifurcations and along the inner curvature of arteries. All these areas contain regions of low flow velocity and low shear stress. The anatomic characteristics of the coronary arteries, the bifurcation of the common carotid arteries, and the entry to the renal arteries make these regions especially susceptible to the accumulation of atherosclerotic plaques and thus place the blood supply to the heart, the brain, and the kidneys at risk. ■

High blood flow velocity can create turbulent flow in arteries.

Flow velocity also affects the organization of fluid layers of blood in arteries. Normally, blood cells flow in a streamlined or bullet-shaped profile with the concentric layers of fluid flow in arteries as illustrated in Figure 11.6B. In three dimensions, this can be envisioned as a set of thin telescoping cylindrical layers projecting from the inner arterial wall out uniformly to the center of the vessel. Flow velocity is highest in the center of a streamline blood flow and lowest adjacent to the inner arterial wall. However, if total flow velocity becomes too high in an artery, the kinetic energy of the flow streams overcomes the tendency of the fluid layers to stick together from viscous forces. When this happens, the fluid layers break apart and become random and chaotic. This is a condition called **turbulence** (see Fig. 11.6C). Turbulence is a wasteful process that dissipates pressure energy in the cardiovascular system, which could otherwise be used to produce flow. The tendency to produce turbulent flow is expressed in a mathematical term called the **Reynolds number, Re**. The Reynolds number is a measure of the ratio of kinetic energy in the system (which will pull fluid layers apart) and the viscous component of the system (which holds the fluid layers together). It is represented by

$$Re = \rho D v / \eta \quad (9)$$

where ρ = fluid density, D = inner vessel diameter, v = flow velocity, and η = blood viscosity. Generally, a Re ≥ 2,300 indicates that turbulence will occur in the fluid stream. Clearly, large-diameter vessels, high flow velocity, and low blood viscosity favor turbulence in the cardiovascular system.

Whereas laminar flow in arteries is silent, turbulent flow creates sounds. These sounds are clinically known as **murmurs** or **bruits**. Certain diseases, such as atherosclerosis and rheumatic fever, can scar the aortic or pulmonic valves, creating narrow openings and high flow velocities when blood is forced through them. A clinician can detect this problem by listening to the noise created by the resultant turbulence.

Blood viscosity is increased by red blood cells and low flow velocity.

The fluid dynamic properties of blood are more complicated than they are for a simple homogenous fluid such as water because blood is a suspension of proteins and cells in an aqueous medium. The study of the fluid dynamic properties of blood is called **rheology**. The presence of proteins and cells in blood has two important hemodynamic consequences. First, blood viscosity increases exponentially as the blood hematocrit increases (Fig. 11.7A). Thus, as the hematocrit increases, the flow resistance against which the heart must pump increases, which substantially increases the cardiac workload. Although there are some pathologic instances in which a patient's hematocrit can increase because of overproduction of red blood cells (e.g., polycythemia vera), an abnormally increased hematocrit can come from the loss of blood plasma without a proportional loss of red blood cells. This can occur in severe dehydration, loss of plasma from severe burns, or inappropriate loss of water through the renal system as a consequence of kidney disease. Secondly, red blood cells tend to clump if blood flow velocity is sluggish (see Fig. 11.7B). This clumping raises blood viscosity, which can be a negative complicating factor in any condition that adversely diminishes the overall flow output of the heart, such as circulatory shock or heart failure.

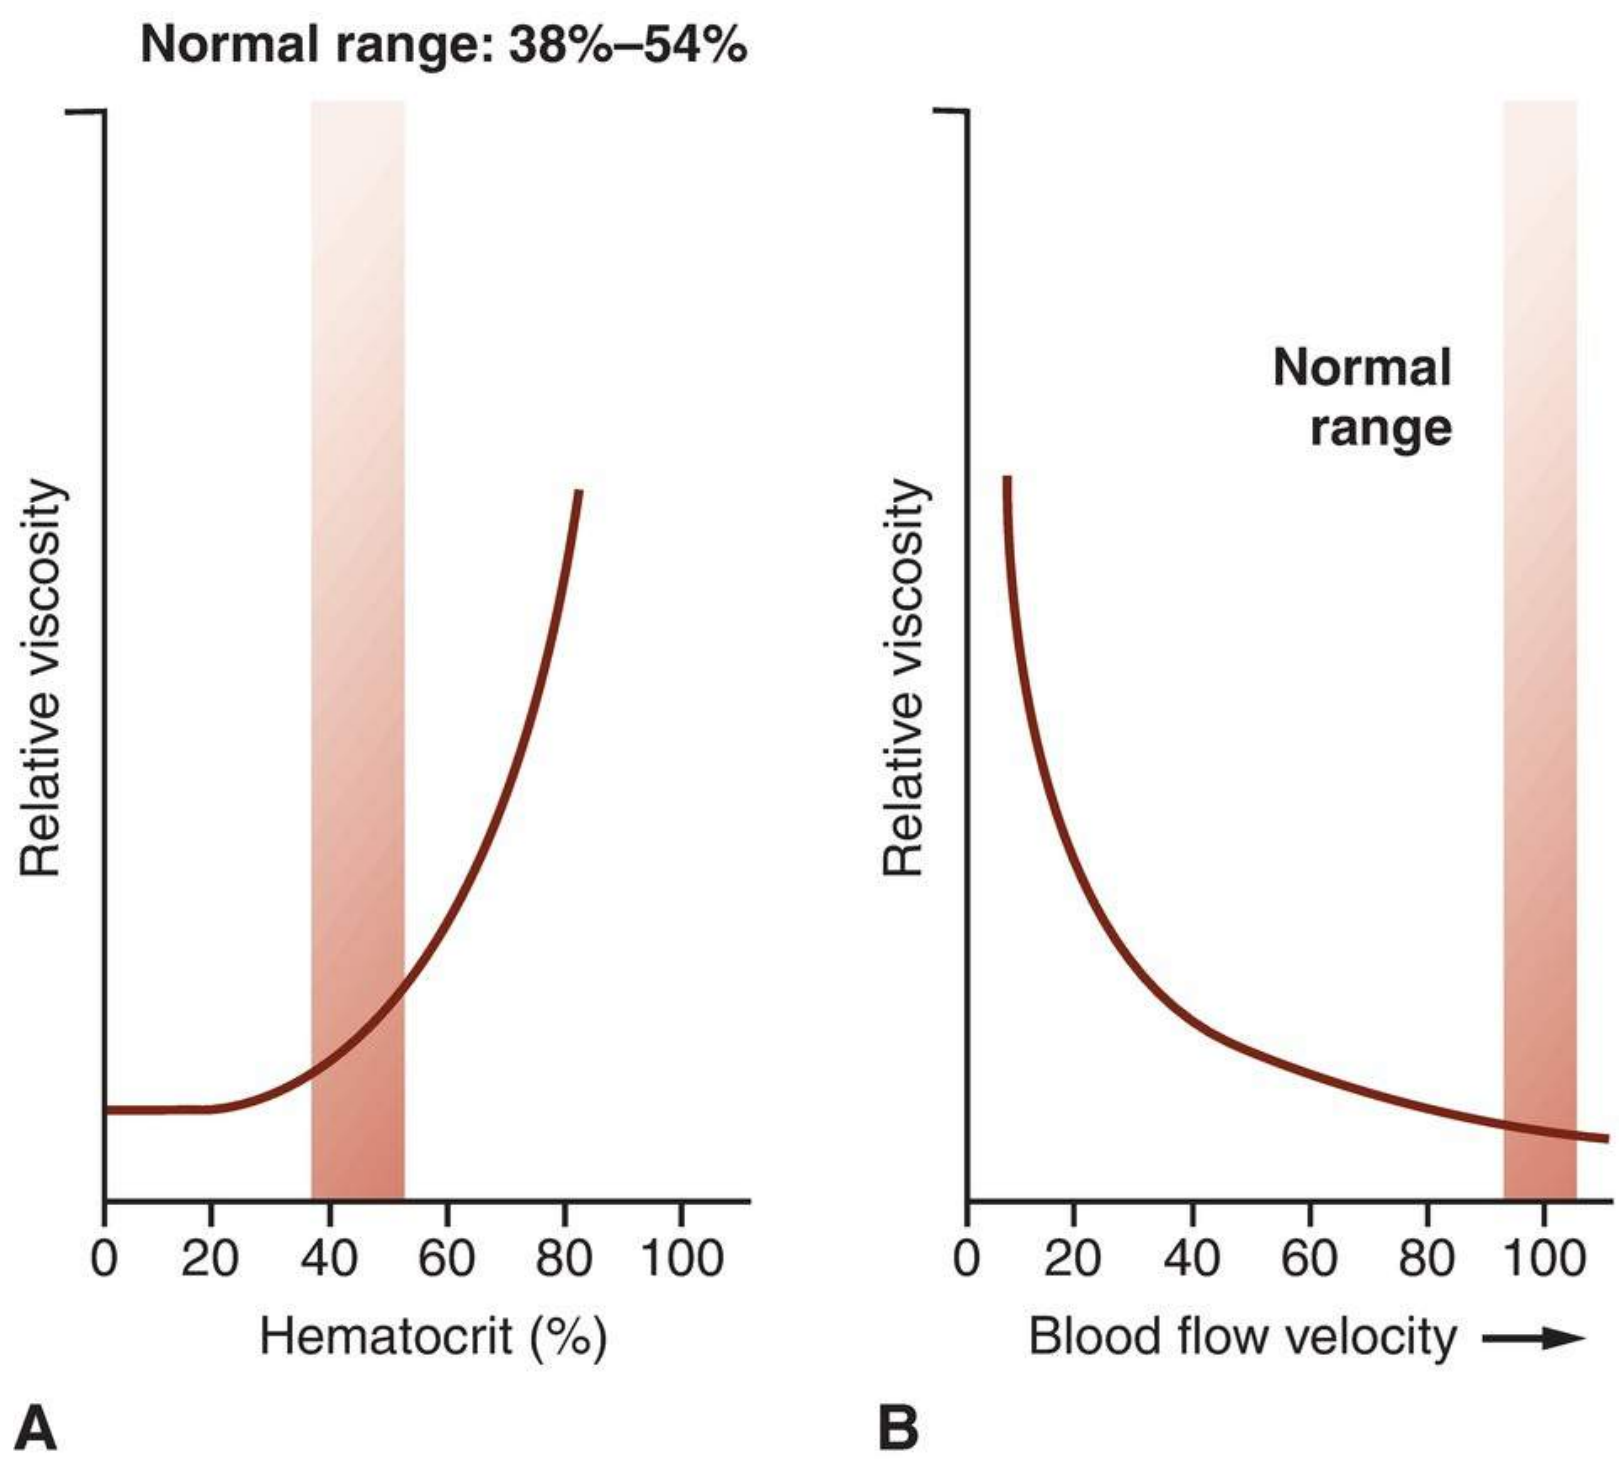

Figure 11.7 Effect of hematocrit and flow velocity on blood viscosity. (A) Increases in hematocrit above normal values produce a sharp increase in viscosity, causing marked increase in resistance to flow. **(B)**Blood viscosity in arteries increases dramatically whenever flow velocity slows to low levels. Thus, the resistance to flow is higher in a slow-moving arterial stream than in one that moves with high velocity.

Axial streaming of cells in flowing blood

Application of Poiseuille's law to fluid dynamics assumes that the fluid is homogeneous, that is, it is made of one element of uniform composition, such as water. Although all suspensions are nonhomogeneous fluids, the properties of blood cells flowing in arteries are such that blood behaves hemodynamically as if it were a homogeneous fluid. Blood cells tend to compact densely in the center of the flow stream, leaving a thin layer of cell-free plasma against the vascular wall. This is called **axial streaming**. As such, blood flows more as a compact bulk fluid than as a mixed conglomeration of

particles in suspension. For this reason, Poiseuille's law can be applied to the cardiovascular system as it was written. However, axial streaming of blood does tend to separate this bulk flow into two components of different viscosities. The fluid near the vessel wall is essentially cell-free plasma and has a viscosity of only 1.7 cP, as opposed to 4 cP for whole blood. In large vessels such as the aorta, this low-viscosity layer is only a small percentage of the average viscosity of the flow stream. Thus, for all practical purposes, the viscosity of the blood flowing through the entire aortic cross-section can be considered to be 4 cP. However, in small arterioles (<300 μm interior diameter) and capillaries, this thin layer becomes a greater percentage of the total volume contained within the vessel and thus contributes a greater percentage to the total viscosity of the blood traveling through those vessels. When fluid flows through these smaller vessels, fluid viscosity, as a whole, decreases. This is called the *Fahraeus-Lindqvist effect*, and it is responsible for reducing blood viscosity, and therefore, flow resistance when blood flows through extremely small vessels such as capillaries. This makes it easier for blood to flow through vessels that otherwise have extremely high resistances.

DISTRIBUTION OF PRESSURE, FLOW, VELOCITY, AND BLOOD VOLUME

Meaningful insights into characteristics of the cardiovascular system can be obtained by examination of the distribution of flow, velocity, pressure, and volume within the system. For example, because veins are more compliant than arteries, one would expect that more of the total volume of blood in the cardiovascular system would reside in the venous rather than the arterial side of the circulation. This is precisely the case; about 2/3 of total blood volume is contained in veins relative to arteries and about 80% of that is contained in small veins. Less than 20% of total blood volume is contained in arteries and capillaries with the rest of the volume contained in the pulmonary circulation and chambers of the heart. Also, because cross-sectional area increases greatly from arteries to the arterioles and to the capillaries, the lowest blood flow velocity occurs through the capillary network (Fig. 11.8). This slow velocity through this exchange segment of the vascular system has the beneficial effect of allowing more time for the exchange of material between the cardiovascular system and the extracellular fluid.

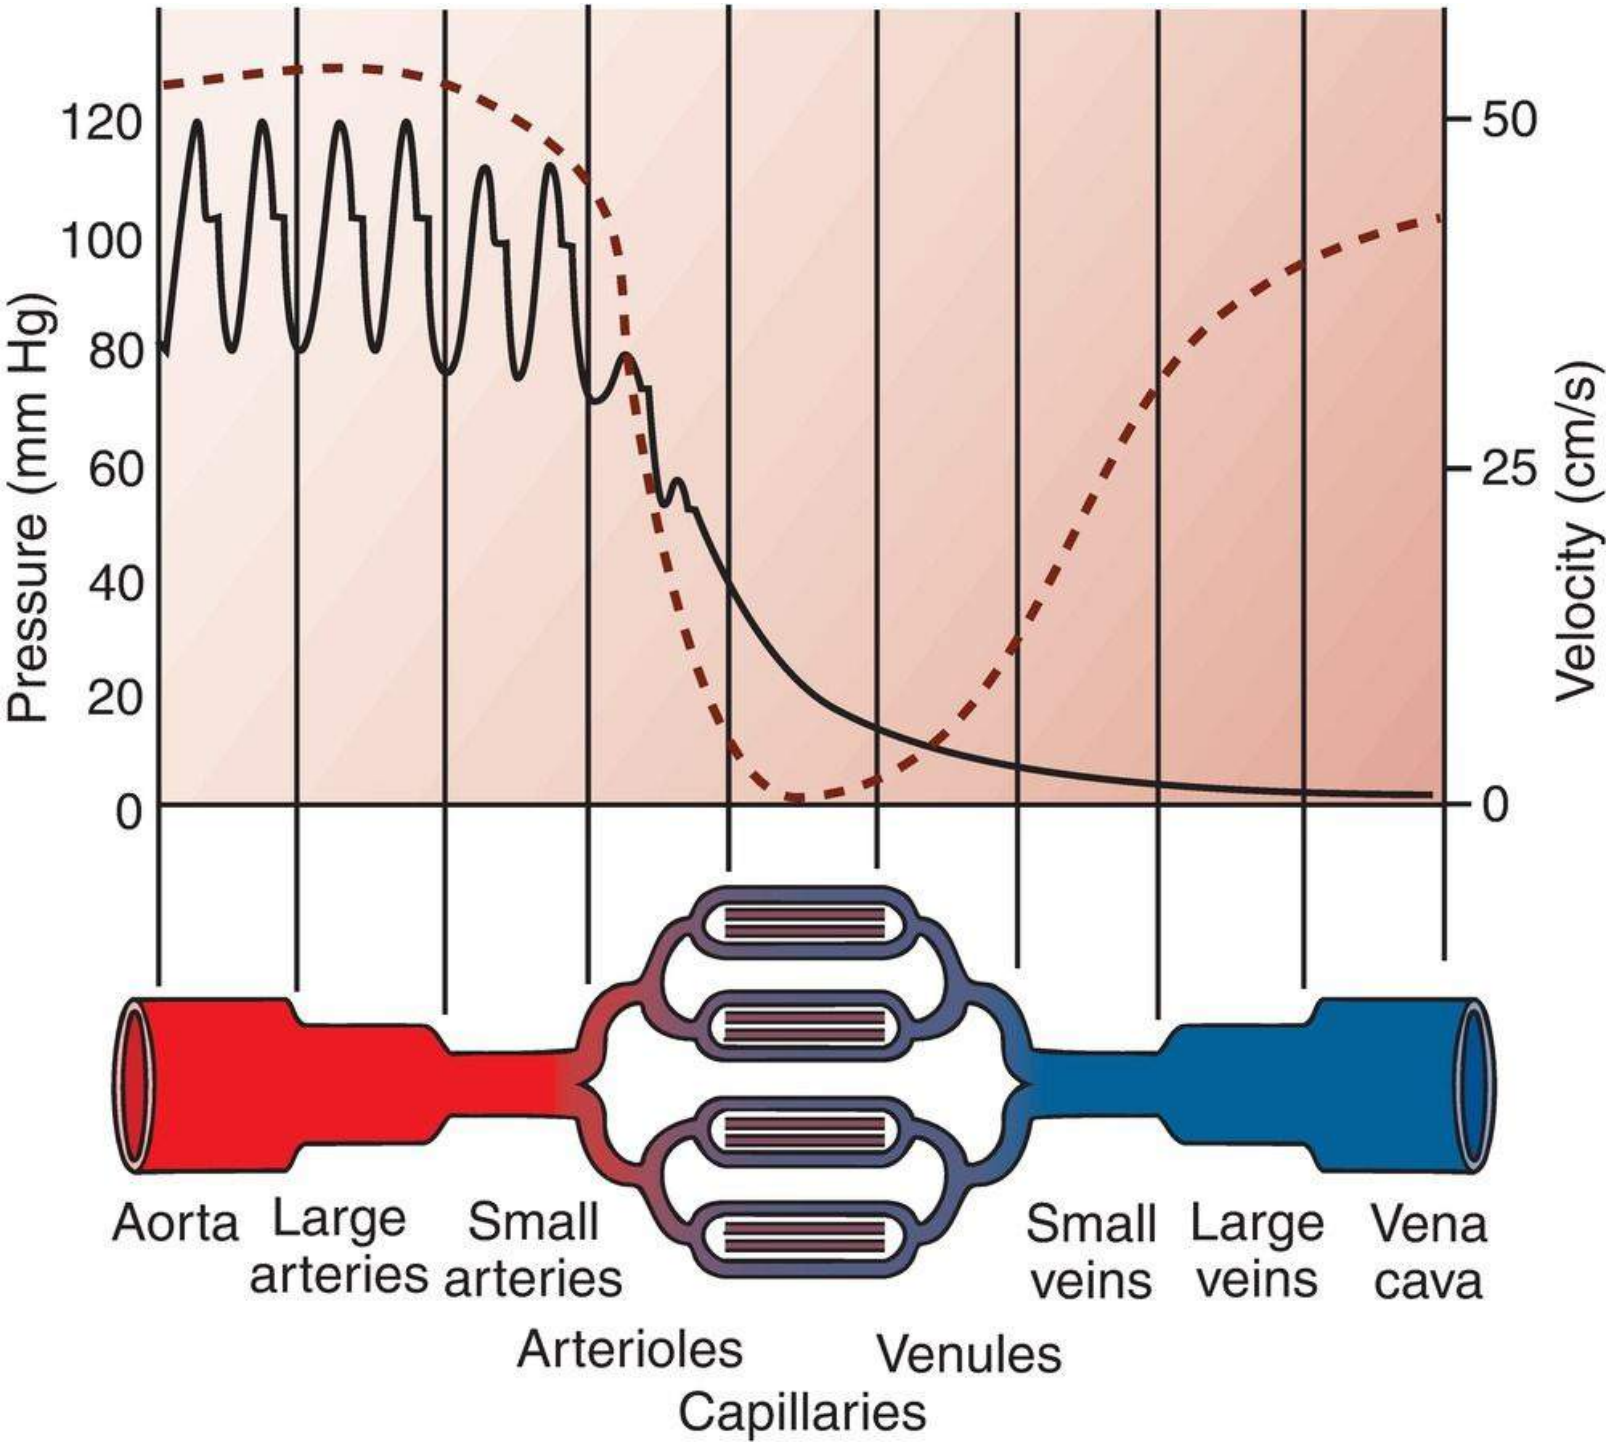

Figure 11.8 Pressure and flow velocity profile in the systemic circulation. The arterial portion of the circulation is characterized by high, pulsatile pressure and high flow velocity. This profile changes to one of low pressure and velocity without pulsatile character in the veins. The largest drop in mean arterial pressure occurs across the arteriolar segment of the circulation, indicating that this is the sight of highest vascular resistance in the cardiovascular system.

The heart is an intermittent pump; it generates high pressure within the ventricles when it contracts during systole, which then drops to near zero during diastole. However, because arteries are compliant, some of the ejected blood into the arteries distends these vessels. During diastole, recoil of the arteries pushes blood forward against the downstream vascular resistance, generating a significant diastolic pressure. For this reason, diastolic pressure drops to only about 80 mm Hg in the aorta as compared with near zero in the ventricles.

Examination of the pressure profile across the cardiovascular system (see Fig. 11.8) shows that the

largest drop of pressure occurs across the arterioles, indicating that this is the site of the greatest vascular resistance in the cardiovascular system. Although there are many more arterioles than arteries in the cardiovascular system (resistances in parallel), this large pressure drop indicates that their reduction in individual size dominates over the addition of parallel vessels. Similarly, although individual capillaries are very small (~10 μm), so many of these lie in parallel that resistance across the capillaries is actually lower than that across the arterioles; hence, the pressure drop across the capillary segment of the circulation is less than that across the arterioles.

Pressures within the arteries of the pulmonary circulation are not the same as those in the systemic circulation. Pulmonary arterial pressure is about 25/8 mm Hg. Because the outputs of the right and left heart are the same, the low pressure in the pulmonary circulation must indicate, according to Poiseuille's law, that vascular resistance is much lower in the pulmonary circulation than in all the organs combined that make up the systemic circulation.

INTEGRATED MEDICAL SCIENCES

Arteriogenesis

The growth of the human body from birth through puberty and to adulthood requires that the circulatory system needed to support the body as a whole grows with it. There are two ways in which the arterial system grows normally as the body grows. Arteries must grow larger and new arteries formed (**arteriogenesis**) and new capillaries must increase in numbers as well (**angiogenesis**). The process of arteriogenesis is currently the subject of intense multidisciplinary research. Insight into the mechanisms for stimulation of vascular growth hold the promise of development of methods of a circumventing damage to tissue below an occluded artery by stimulation of new collateral arterial growth through and around tissue downstream from the occlusion. Such new methods could circumvent current medical treatments (e.g., surgery) that are at best palliative by nature, as well as be a means to counteract abnormal growth of vessels that support tumor growth and create stenosis of arteries in disease states. Currently, the term angiogenesis is mainly applied to the development of collateral circulation around subacute, or slowly developing, arterial occlusions. In occlusive disease, only angiogenesis provides the means to fix flow deficits caused by an arterial occlusion. Angiogenesis requires both the enlargement of small, preexisting collateral arterial vessels and an increase in their length. Such a process must involve stimulation of arterial wall cell proliferation. Consequently, arteriogenesis is a process of active growth not passive distention of existing vessels.

Unlike angiogenesis, arteriogenesis is not initially stimulated by hypoxia. Instead, it is initiated by alterations in collateral vessel fluid dynamics. The pressure gradient between the upstream high pressure origin of the collateral above the occlusion and the downstream low pressure postocclusion zone initiates a marked increase in blood flow through the collateral vessel. It is now well established that the initiating stimulant for angiogenesis is the increased fluid shear stress on arterial endothelial cells that accompanies the increased blood flow. Because there is no direct cell-to-cell contact between the endothelial and smooth muscle layers in arteries, the signal from this mechanical force on the intima to underlying cells in the arterial wall has to be through a diffusible molecule. The current most likely candidate for this transmitter is NO through shear stress stimulation of endothelial NO

synthase. Blockade of the NO pathway totally blocks angiogenesis. Sheer stress stimulates the endothelial calcium channel, TRPV4 (transient receptor potential cation channel) and because NO synthase is a calcium activated enzyme, it is likely this channel serves as the means by which shear stress activates NO production in the endothelium.

Although NO appears to be intimately responsible for the initiation of arteriogenesis, endothelium NO synthase is noted as primarily being involved in inducing arterial dilation rather than arterial wall proliferation. Therefore, other proliferative pathways must be involved in arteriogenesis. Arteriogenesis is known to be stimulated by inflammation. Circulating monocytes, either directly or by activating arterial wall macrophages, are known to stimulate arterial wall secretion of chemokines, growth factors, and proteases that can be involved in arterial wall growth and remodeling. Sheer stress stimulates monocyte chemoattractant protein (MCP-1) secretion by arterial smooth muscle cells and this factor seems to be involved in stimulation of cell growth in angiogenesis though its exact mechanism of action is not known. MCP-1 attracts monocytes in adventitia and activates indwelling macrophages. These in turn are thought to increase inflammatory factors such as TNFα and inducible NO synthase (iNOS, see Chapter 16). These findings indicate that the immune system in the body could play a key role in arteriogenesis. Recent studies have indicated that, in addition to macrophages, immune cells such as natural killer (NK) cells, T helper cells, and regulatory T lymphocytes all may have roles in arteriogenesis though their exact roles in this type of vascular growth remain to be fully elucidated. ■

Chapter Summary

- The cardiovascular system is a fluid transport system that delivers substances to the tissues of the body while removing the by-products of metabolism.
- The heart is composed of two pumps connected in series. The right heart pumps blood into the lungs. The left heart pumps blood through the rest of the body.
- Pressure is created within the atria and ventricles of the heart by contraction of the cardiac muscle. The directional opening of valves, which prevent back flow between chambers, ensures forward movement of blood through the heart.
- Arteries transport blood from the heart to the organs. Veins transport blood from the organs to the heart.
- Capillaries are the primary site of transport between blood and the extracellular fluid.
- Altering vascular smooth muscle contraction changes blood vessel radius and hemodynamic properties.
- Vascular resistance is inversely proportional to the internal radius of the blood vessel.
- The volume contained within any vascular segment is a function of transmural pressure and the compliance of the vascular wall.
- Transmural pressure in blood vessels produces wall tension and stress that must be overcome for the vessel to contract.
- Blood flow and pressure throughout the vascular system is created in accordance with the principles of Poiseuille’s law; flow is proportional to the pressure gradient between points in the circulation but inversely proportional to vascular resistance.
- The velocity of blood flow in an artery affects lateral pressure and inner wall shear stress in arteries as well as transport across the capillary wall. It is also a factor in the creation of turbulence in the arterial flow stream.
- Flow resistance in arteries is influenced by hematocrit and blood flow velocity.
- The hemodynamic profile in the cardiovascular system is the result of the combined effects of all the relationships and laws governing the containment and movement of blood in the cardiovascular system.

Chapter Review Questions

1. Which of the following will exacerbate the pooling of blood that occurs in veins in the lower extremities of a patient when he or she assumes an upright position?

A. Activation of α-adrenergic receptors on veins by the sympathetic nervous system

B. Administration of the antianginal drug, nitroglycerin, which directly dilates veins more than arteries

C. Administration of the emergency antihypertensive agent sodium nitroprusside, which directly dilates arteries more than veins

D. Applying external compression to the lower extremities

E. Placing the patient in supine position with his or her legs up

The correct answer is B. Blood preferentially pools in the veins versus the arteries under the influence of gravity because veins are more compliant than arteries. Contraction of vascular smooth muscle reduces vascular compliance, whereas relaxation of vascular smooth muscle increases compliance. For this reason, nitroglycerin will increase the amount of blood pooling in veins in a patient when he or she stands upright. This is a contributing factor in postural hypotension that often occurs in patients taking nitroglycerin for angina or heart failure. The enhancement of pooling temporarily causes a reduction in cardiac output severe enough to reduce arterial pressure and cause fainting. Drugs that predominantly relax arteries over veins do not cause much blood pooling upon standing and are generally not associated with postural hypotension. Anything that contracts or compresses veins helps prevent venous pooling. Indeed, contraction of veins by activation of the sympathetic nervous system is the body's natural mechanism for preventing postural hypotension. Support stockings, mechanical compression devices used on the legs after surgery, and the lower body compression suits worn by jet fighter pilots are ways in which application of external compression on the veins counteracts venous pooling in the lower extremities. Laying a patient horizontally with his or her legs up does take advantage of the effects of gravity on blood volume in the veins, except in this case gravity helps drain blood from the legs and send it to the heart.

2. A patient has a significantly reduced blood hematocrit as the result of a chronic bleeding ulcer. A heart murmur during systole can be heard with a stethoscope over the patient's chest. The likely cause of this murmur is:

A. increased aortic turbulence due to decreased blood viscosity.

B. creation of streamline flow in the aorta during systole.

C. reduced resistance to blood flow in the arterioles.

D. increased aortic turbulence due to increased blood viscosity.

E. reduced flow velocity in the aorta during systole.

The correct answer is A. Blood viscosity is significantly related to blood hematocrit; blood with a low hematocrit has low viscosity. As reflected in the Reynolds number, turbulence is most likely to occur with low viscosity fluid at high flow velocity in vessels with large internal diameters. This corresponds to the situation in the aorta during systole in a patient with an abnormally low hematocrit. Streamline flow is silent and does not cause murmurs. Although the decreased hematocrit decreases resistance to flow through any segment of the arterial system, this effect in arterioles is unrelated to any murmur heard from the heart.

3. Which of the following describes the properties of an aortic segment exposed to a transmural pressure of 200 mm Hg compared to the same segment exposed to a transmural pressure of 100

mm Hg?

A. Compliance will be reduced, and wall tension will be increased.
B. Compliance will be increased, and wall tension will be reduced.
C. Compliance and wall tension will be reduced.
D. Compliance and wall tension will be increased.
E. Neither compliance nor wall tension will change.

The correct answer is A. Re: Arteries are stiffer (reduced compliance) at very low and very high pressures. An aortic segment exposed to an internal net pressure of 200 mm Hg is distended to a place on its volume versus pressure curve where the aorta is stiffer, or less compliant. Tension = P × r is higher in cylindrical tubes like the aorta at high transmural pressures and large radii. In the segment exposed to 200 mm Hg versus 100 mm Hg not only is distending pressure higher but the aorta will be distended to a slightly larger radius and therefore that will also increase wall tension. None of the other choices to the question correctly state that an aorta under high pressure is both in a region of low compliance and exposed to high wall tension.

Clinical Application Exercises 11.1

A 15-year-old girl sees her family physician for a routine school athletic physical. Upon routine examination, her physician detects a reasonably loud systolic murmur when placing her stethoscope parasternally around the second and third intercostal spaces, but her physical exam is otherwise unremarkable. The patient mentions that she has no trouble with her endurance and does not feel her physical activities are limited. Her doctor orders a chest x-ray and an echocardiogram to investigate possible sources of the murmur. The echocardiogram reveals a small to moderate, irregular atrial septal defect (openings in the atrial septum between the left and the right atrium) with turbulent left-to-right shunting of blood through the septal defect, and a somewhat enlarged right atrium. This enlargement is consistent with findings from her chest x-ray, which also indicates slight dilation of the pulmonary arteries.

QUESTIONS

1. What is the source of the systolic murmur in this patient?
2. Why is this patient largely asymptomatic with respect to her physical endurance?
3. What is the cause of the patients enlarged right atrium and dilated pulmonary artery?

ANSWERS

1. Heart murmurs are indicative of turbulent flow conditions in the heart. The likely source of this murmur, therefore, is flow from the left to right atrium through the irregular septal defect that occurs because left atrial pressure is higher than right atrial pressure in the cardiovascular system.
2. Because left atrial pressure is higher than right atrial pressure, blood flows from left to right through the septal defect. Thus, there is a tendency for oxygenated blood to leak into the pulmonary circulation rather than deoxygenated blood mixing with the systemic blood supply. In this patient, the oxygen output to her systemic circulation is not significantly affected unless there is marked reduction in left ventricular output due to the shunt. This is unlikely given her physical presentation and the modest size of her septal defect.

3. Increased flow through the atrial septal defect increases volume on the right side of the heart, starting at the right atrium. This results in dilation of these structures and eventual hypertrophy as the atrial muscle and arterial tree respond to increased stress caused by chronic exposure to increased volume loading.

12 Electrical Activity of the Heart

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Contrast electromechanical coupling in cardiac muscle versus skeletal muscle and explain how this dictates differences in mechanical mechanisms of contraction in the two muscles.
- Explain how changes in membrane voltage-gated channels for sodium, potassium, and calcium create the five phases of atrial and ventricular muscle action potentials.
- Explain why it is not possible to create tetanic contraction in cardiac muscle.
- Predict how changes in ventricular conductances or plasma concentrations of sodium, calcium, and potassium will change the amplitude, duration, and refractory period of action potentials in ventricular muscle cells.
- Predict how changes in ion conductances or plasma concentration of electrolytes could enhance or inhibit the formation of ectopic foci in the myocardium.
- Explain how changes in plasma potassium concentration can lead to ventricular arrhythmias and cardiac arrest.
- Relate the changes in membrane conductances for sodium, calcium, and potassium in cardiac nodal tissue to their automaticity.
- Predict and explain how the intrinsic firing rate of the SA node is altered by (a) a change in the resting membrane potential and (b) the rate of decay of K^+ conductance in phase 4 of the nodal potential.
- Explain the mechanism for the effects of acetylcholine and norepinephrine on sinoatrial node rhythmicity and how that relates to the effect of these neurotransmitters on heart rate.
- Predict ways in which the conduction of action potentials can be slowed through the myocardium.
- Explain how the normal ECG waveform is created by electrical events in the myocardium.
- Describe how the frontal and horizontal electrocardiogram lead systems can be used to determine the orientation of the heart, the direction of electrical activation of the heart, and changes in the muscle mass of atria and ventricles.
- Use electrocardiogram recordings to identify atrial and ventricular tachycardias, fibrillation, premature atrial contractions, premature ventricular contractions, and heart blocks.
- Use QRS vector analysis of electrocardiogram recordings to identify atrial and ventricular hypertrophy as well as abnormal myocardial conduction pathways.
- Identify myocardial ischemia, injury, infarction, and plasma electrolyte disturbances from electrocardiogram recordings.
- Predict changes in electrocardiograms caused by various cardiac drugs on the basis of their effect on ion conductances in the myocardium.

Although the heart is composed of striated muscle, it only shares a few functional similarities with skeletal muscle tissue. The basic mechanical–molecular cyclic interaction of actin and myosin is similar in cardiac and skeletal muscle. The links between action potential generation, calcium, and the initiation of contraction are similar on a general level, as are principles of muscle mechanics related to the effects of preload and afterload. However, beyond these few shared characteristics, the physiology of cardiac

muscle is very different from that of skeletal muscle.

Skeletal muscle cannot contract without being connected to a motor neuron, which is analogous to a lamp that cannot be turned on if its cord is unplugged. Also, like the light bulb in the lamp, skeletal muscle fibers are either switched on (activated) or off (not activated). Finally, at any given preload and afterload, the force-generating capacity of skeletal muscle cannot be altered by any normal physiological mechanism. In contrast, cardiac muscle does not require innervation to be activated, and the intrinsic force generation capacity of each cardiac cell can be enhanced or depressed, much like a light on a dimmer switch. In this and the following chapter, the unique electrical and mechanical properties of cardiac muscle are addressed. This chapter focuses on the electrophysiology of cardiac muscle, whereas the mechanical properties of this muscle tissue are examined in Chapter 13.

ELECTROPHYSIOLOGY OF CARDIAC MUSCLE

The heart is composed of muscle whose contraction is coupled to the generation of action potentials within its cells. However, cardiac muscle does not require action potentials from nerves to activate its own electrical activity (a fact that makes heart transplantation operations possible). Although both branches of the autonomic nervous system (ANS) innervate the heart, the ANS modulates cardiac function rather than initiates it. Furthermore, there are no anatomic or functional correlates of neuromuscular motor units in the heart. Therefore, the heart cannot recruit neuromuscular units to enhance its force-generating capacity.

Cardiac cells are electrically connected and can generate their own action potentials.

All myocardial cells are coupled electrically through gap junctions at points called *nexi* (Fig. 12.1). This allows the generation of an action potential in one myocardial cell to spread rapidly to all cells in the heart. Thus, electrically, the heart behaves as a **functional syncytium**, as if it was activated totally as one large cell. The advantage of this electrical connectivity between all cells is that it helps the heart contract as a large, coordinated mechanical unit for the purpose of pumping blood. The heart could not function as a pump if its millions of cells activated randomly. However, the syncytial character of the myocardium also means that the contractile force of the whole heart, unlike that of skeletal muscle groups, cannot be modulated by the recruitment of motor units. During systole, all cardiac cells are activated; there are no cells left to recruit. Although the syncytial character of the heart enables it to function better as a muscular pump, it also means that the activation of any cell in the heart can inadvertently activate the heart as a whole. This can have detrimental effects on the ability of the heart to pump blood, as is discussed later in this chapter.

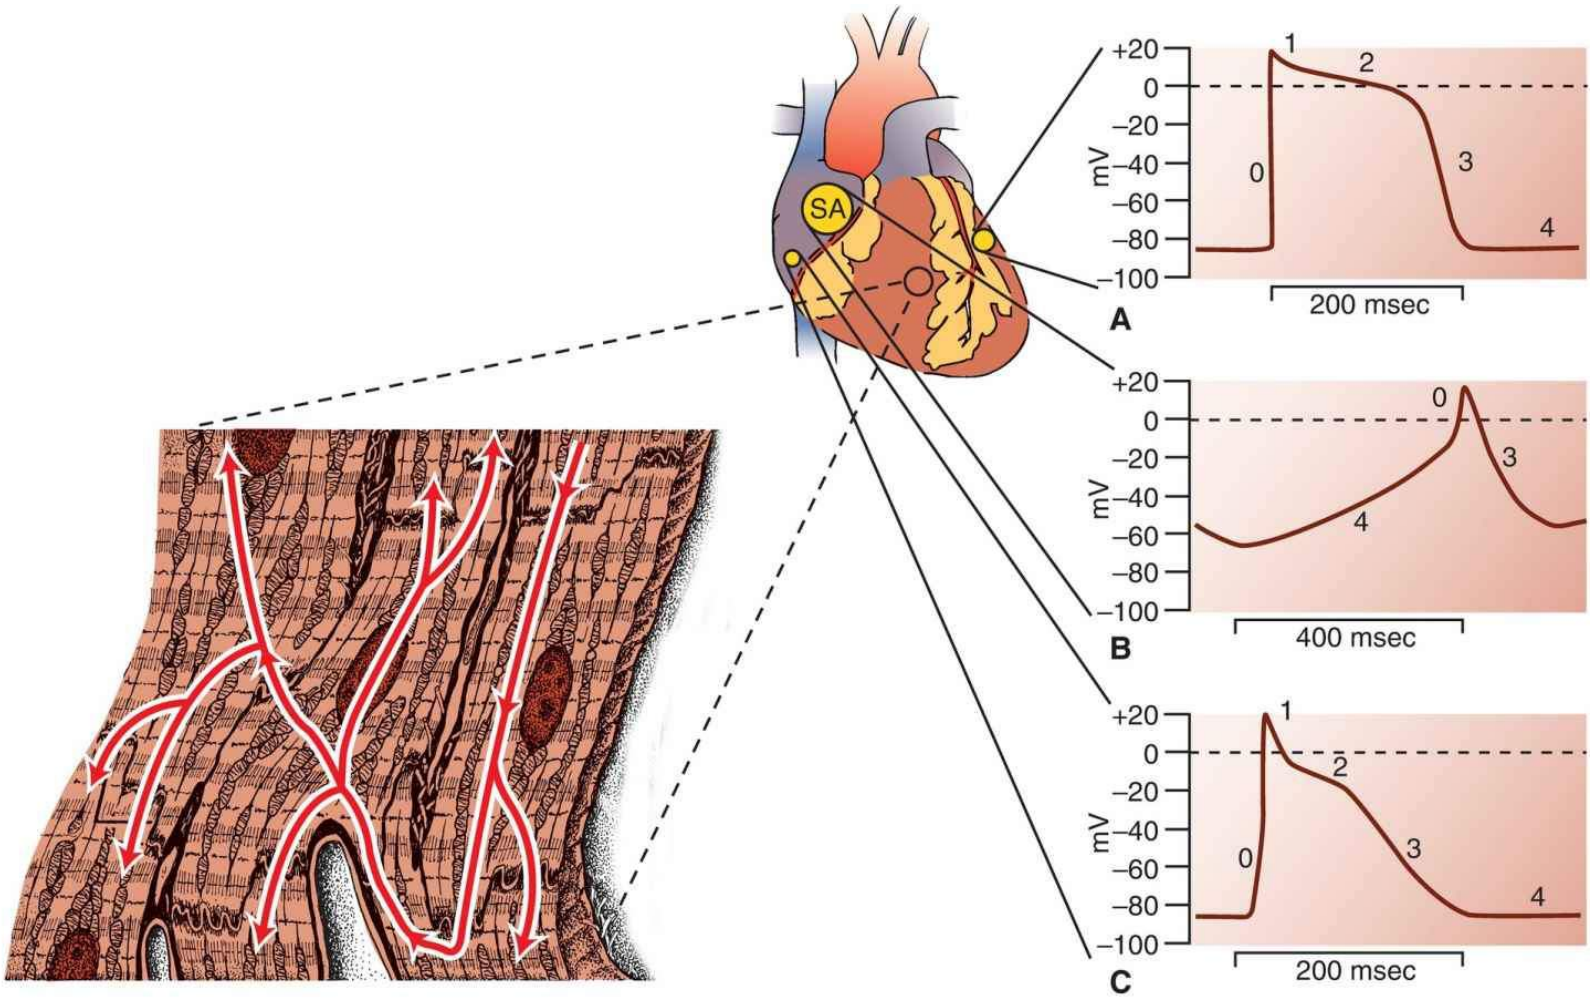

Figure 12.1 Cardiac action potentials (mV) recorded from ventricular (A), sinoatrial node (B), and atrial cells (C). Note the difference in the time scale of the sinoatrial cell. Numbers 0 to 4 refer to the phases of the action potential (see text). **Inset:** Diagrammatic representation of the nature of the functional syncytium in the myocardium. The colored line represents the path of excitation through the myocardium as it passes from cell to cell through gap junctions at cardiac nexi. SA, sinoatrial.

Cardiac cells possess the unique property of **automaticity**; that is, they have the ability to generate their own action potentials without the need for chemical or electrical stimuli from other sources. Furthermore, some specialized cardiac cells display the property of **rhythmicity** or the ability to generate these potentials in a regular, repetitive manner. Unfortunately, however, in pathologic conditions, automaticity can occur in any myocardial cell as well as in the **Purkinje fibers**. This results in abnormal activation of the heart and its pumping mechanism.

Two major types of unique action potentials characterize electrical excitation of the heart.

The appearance of cardiac action potential is significantly different from the rapid spike characteristics seen in neurons or skeletal muscle fibers. There are two broad types of cardiac action potentials. Those characteristics of ventricular and atrial muscle, as well as of Purkinje fibers, are called “fast response” action potentials, whereas those observed in the sinoatrial (SA) node and atrioventricular (AV) node are called “slow response” action potentials (see Fig. 12.1). The fast response is divided into five phases (Fig. 12.2). The initial rapid depolarization of the cell membrane is designated phase 0. Phase 1 represents the subsequent partial repolarization of the membrane, which is followed by phase 2. Phase 2 is unique to cardiac muscle and is often called the plateau region of the action potential. Phase 3 is the rapid repolarization phase of the action potential, and phase 4 is the resting membrane potential.

Figure 12.2 Changes in cationic currents responsible for the formation of the fast response action potential in ventricular muscle cells. I = current flow; downward deflections indicate current flow into the cell, whereas upward deflections indicate current flow out of the cell. The rise in action potential (phase 0) is caused by rapidly increasing Na^+ current carried by voltage-gated Na^+ channels. Na^+ current falls rapidly because voltage-gated Na^+ channels are self-inactivating by depolarization. K^+ current rises briefly, causing phase 1 ($i_{to,f}$ and $i_{to,s}$) and then falls precipitously as transient outward currents cease and I_{K1} channels close. Ca^{2+} channels are opened by depolarization and are responsible, along with closed I_{K1} channels, for phase 2. K^+ current begins to increase because of the delayed opening of I_{Kr} and I_{Ks} channels by depolarization and an increase in intracellular calcium concentration. These currents are responsible for rapid repolarization in phase 3. Once repolarization occurs, Na^+ and Ca^{2+} channels are returned to their resting state. Repolarization reopens I_{K1} channels and re-establishes phase 4.

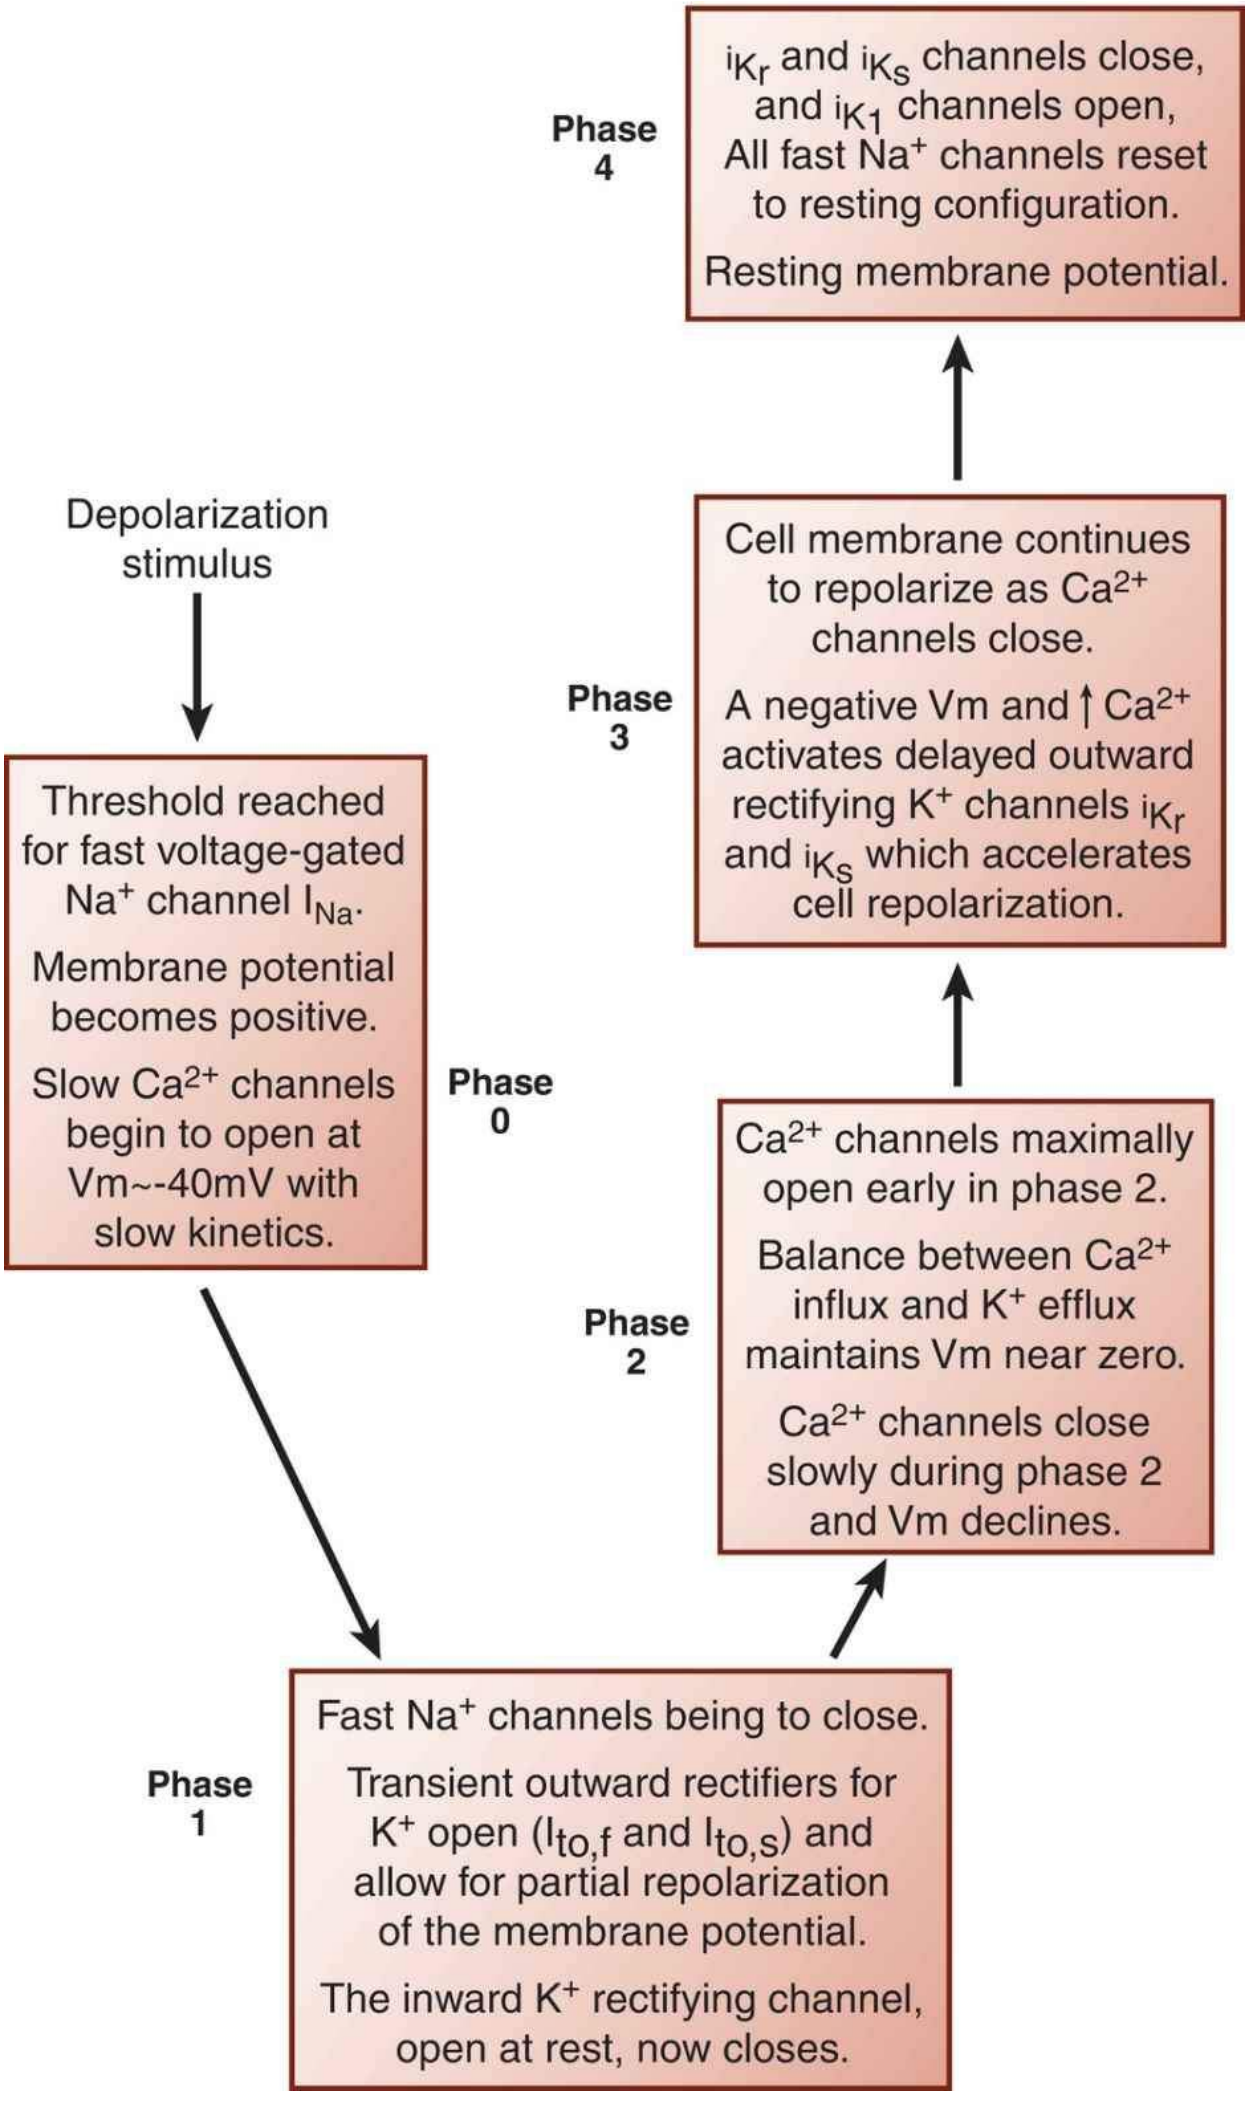
Changes in plasma potassium concentration markedly alter the myocardial resting membrane potential.

Many ion channels contribute to the creation of the fast response (see Fig. 12.2). The resting membrane potential (phase 4) is primarily a K^+ diffusion potential, and thus, it is sensitive to changes in external K^+ concentration. High plasma K^+ concentrations (hyperkalemia) depolarize cardiac cells, whereas hypokalemia hyperpolarizes the tissue. Both of these conditions can adversely affect cardiac function, and for this reason, plasma K^+ levels are monitored carefully in a clinical setting. There is a small component of Na^+ influx to the cardiac resting membrane potential, making the resting membrane potential slightly more positive than the K^+ Nernst potential.

Cardiac cells have an intrinsic resting membrane potential buffer system that attenuates changes in membrane potential caused by changes in external K^+ concentration in the range of the normal plasma concentration of about 4.4 mM. Potassium conductance in myocardial cells is altered by the extracellular concentration of potassium surrounding the cells. Over the physiologic extremes of 2 to 7 mM, K^+ conductance increases when external K^+ concentration increases and decreases when external K^+ concentration decreases. Thus, the depolarizing effect of elevated external K^+ concentration is somewhat buffered by an increased K^+ efflux caused by a modest increase in K^+ conductance. However, this system cannot totally counteract the effect of external potassium on cardiac resting membrane potential. Hyperkalemia will always depolarize the cell at rest; it is simply that the magnitude of this depolarization is less than that predicted by the Nernst equation because of the effect of external K^+ on potassium conductance in cardiac myocytes.

Voltage-gated sodium and potassium channels initiate and terminate phase 0 of the fast response.

The five phases of the ventricular action potential results from overlapping time-dependent activation and inactivation of membrane channels for Na^+, K^+, and Ca^{2+} (Fig. 12.3; also see Fig. 12.2). The rapid upstroke in phase 0 occurs by a mechanism similar to that seen in nerve or skeletal muscle. Membrane depolarization up to and more positive than ~ −55 mV opens "activation, or m, gates" on voltage-sensitive Na^+ channels, allowing a rapid influx of Na^+ through the now open channel pore down its steep electrochemical gradient. This influx further depolarizes the membrane, opening more Na^+ channels, and so on, which causes a rapid, self-reinforcing increase in the depolarization of the cell. Opening of the cardiac Na^+ channel is self-limiting, however, in that the same depolarization that causes conformational changes in the channel protein to open the channel also triggers a conformation change in a second gate in the channel that closes it several milliseconds later (the h or "inactivation gate"). Past the peak of the cardiac action potential, more than 99% of the sodium channels are in the inactivated state. The inactivation gate will remain closed unless the cell membrane potential drops below about −50 mV. Like nerve and skeletal muscle cells, ventricular (and atrial) cells cannot fire a second action potential until the sodium channel is reset to its resting state by the cell returning to its normal resting membrane potential.



Depolarization stimulus
Threshold reached for fast voltage-gated Na^+ channel I_{Na}.
Membrane potential becomes positive.
Slow Ca^{2+} channels begin to open at Vm~-40mV with slow kinetics.
Phase 0
Fast Na^+ channels being to close.
Transient outward rectifiers for K^+ open ($I_{to,f}$ and $I_{to,s}$) and allow for partial repolarization of the membrane potential.
The inward K^+ rectifying channel, open at rest, now closes.
Phase 1
Ca^{2+} channels maximally open early in phase 2.
Balance between Ca^{2+} influx and K^+ efflux maintains Vm near zero.
Ca^{2+} channels close slowly during phase 2 and Vm declines.
Phase 2
Cell membrane continues to repolarize as Ca^{2+} channels close.

Phase 4

Figure 12.3 A flow chart of the events associated with the ventricular action potential. (See text for details.)

In nerve and skeletal muscle, a K^+ channel opens soon after the initial Na^+ event and the resulting facilitation of K^+ efflux through this channel rapidly repolarizes those cells. This does not occur in cardiac cells. In cardiac cells, the K^+ conductance (I_{K1}) largely responsible for the resting membrane potential is actually suppressed during depolarization, thus impairing any potential rapid repolarization of the tissue. There is some enhanced K^+ conductance at this time point in the cardiac action potential, but it is short lived, owing to the opening and then closing of two potassium channels that allow only K^+ to exit the cell. These channels are called **transient outward (to) K^+ channels** and are designated $I_{to,fast}$ and $I_{to,slow}$, owing to slightly different channel time kinetics. Coupled with the inactivation of the sodium channels in the membrane, the opening of these transient potassium channels causes the small, temporary repolarization of the cardiac cell that is designated as phase 1.

Cardiac cell refractory period is prolonged by opening of slow voltage-gated Ca^{2+} channels.

All cardiac cells contain **L-type Ca^{2+} channels** (also called 1,4 dihydropyridine calcium channels). These channels open and close with depolarization in a manner analogous to that seen for the Na^+ channel, except their opening and closing kinetics are much slower. They also open at slightly less negative potentials than do the fast sodium channels (~ −40 to −50 mV). The electrochemical gradient for Ca^{2+} is enormous in cardiac cells, and the conductance of these channels for calcium is high. Once the calcium channels open, positive charge from Ca^{2+} rushes into the cell. During this phase of the action potential, hyperpolarizing effects of potassium efflux are diminished because of the inactivation of I_{K1} channels by membrane depolarization. In phase 2, the influx of positive current from calcium approximately matches the remaining positive efflux carried by K^+ exiting through a few open K^+ channels in the membrane. This balance causes the membrane potential to remain relatively constant at a positive value and helps create phase 2 of the action potential. Eventually, the Ca^+ channels close, preventing further depolarizing currents from entering the cell, which aids in the eventual repolarization of the cell membrane.

The plateau phase of the ventricular action potential has a significant functional effect on cardiac muscle activation. Because of the plateau phase of the cardiac action potential, cardiac cells have a long refractory period, and a single contraction of cardiac muscle (twitch contraction) is completed before a second action potential can be generated. Thus, *cardiac cells cannot be tetanized*. This is a fortunate consequence in that tetany of cardiac muscle would obviously not be compatible with the function of the heart as a blood pump.

Repolarization of cardiac muscle cells involves activation of K^+ channels.

Outwardly rectifying potassium channels open later during phase 2 and during phase 3 of the cardiac muscle action potential. I_{Ks} and I_{Kr}, which stand for slow and rapid outwardly rectifying potassium currents carried by these channels, intensify during phase 3 and bring about a rapid repolarization of the cell membrane. I_{Ks} and I_{Kr} channels are opened by depolarization and closed by membrane hyperpolarization starting at about −55 mV. The activation, or reopening, of I_{K1} late in phase 3 is responsible for finishing the repolarization of the cell membrane and the reestablishment of the resting membrane potential. The increased intracellular calcium concentration from calcium influx during phase 2 appears to reactivate I_{K1}.

The sinoatrial node initiates and maintains the rhythm of electrical activation in the heart.

For the heart to function as an efficient pump, action potentials and subsequent myocardial contraction must be generated and spread through the myocardium in a regular, repetitive and organized manner. This will not occur if cardiac cells express their automaticity in a random, unpredictable fashion. Normally, prior to each contraction of the heart, cardiac electrical activity is initiated by a modified set of muscle cells on the posterior aspect of the right atrium at the junction of the superior and inferior vena cava, called the sinoatrial or SA node (Fig. 12.4). Once the SA node initiates an action potential, it travels through both atria at a rate of 0.1 to 1.0 m/s and coalesces at a second area of specialized conduction tissue called the atrioventricular or AV node. This node lies at the junction between the atria and ventricles in the ventricular septum. Conduction through the AV node is slow (~0.05 m/s), which delays the movement of the cardiac action potential into the ventricles. This delay has the important effect of allowing more time for the ventricles to fill during diastole. The conduction of action potentials through the AV node shows directional preference; that is, action potentials travel more easily from the atria through the AV node toward the ventricles than in the opposite direction. The AV node is the only normal pathway by which action potentials from the atria travel into the ventricles because the connective tissue between the atria and ventricles and encircling the heart valves acts as an electrical insulator. Once the action potential emerges from the AV node, it enters the **bundle of His**, which splits into left and right bundle branches; these branches, in turn, give rise to Purkinje fibers, which line the entire endocardial surface of both ventricles. The ventricle itself is then activated in sequence from the septum/papillary muscle and endocardium to the epicardium and from the apex to the base of the heart. Action potentials travel so fast through Purkinje fibers (~4 m/s) that the underlying ventricular muscle is activated almost essentially simultaneously. Coupled with the syncytial nature of ventricular muscle cells, this ensures that the ventricular cells contract essentially *en masse* once activated, which allows for the effective pumping of blood out of the ventricles.

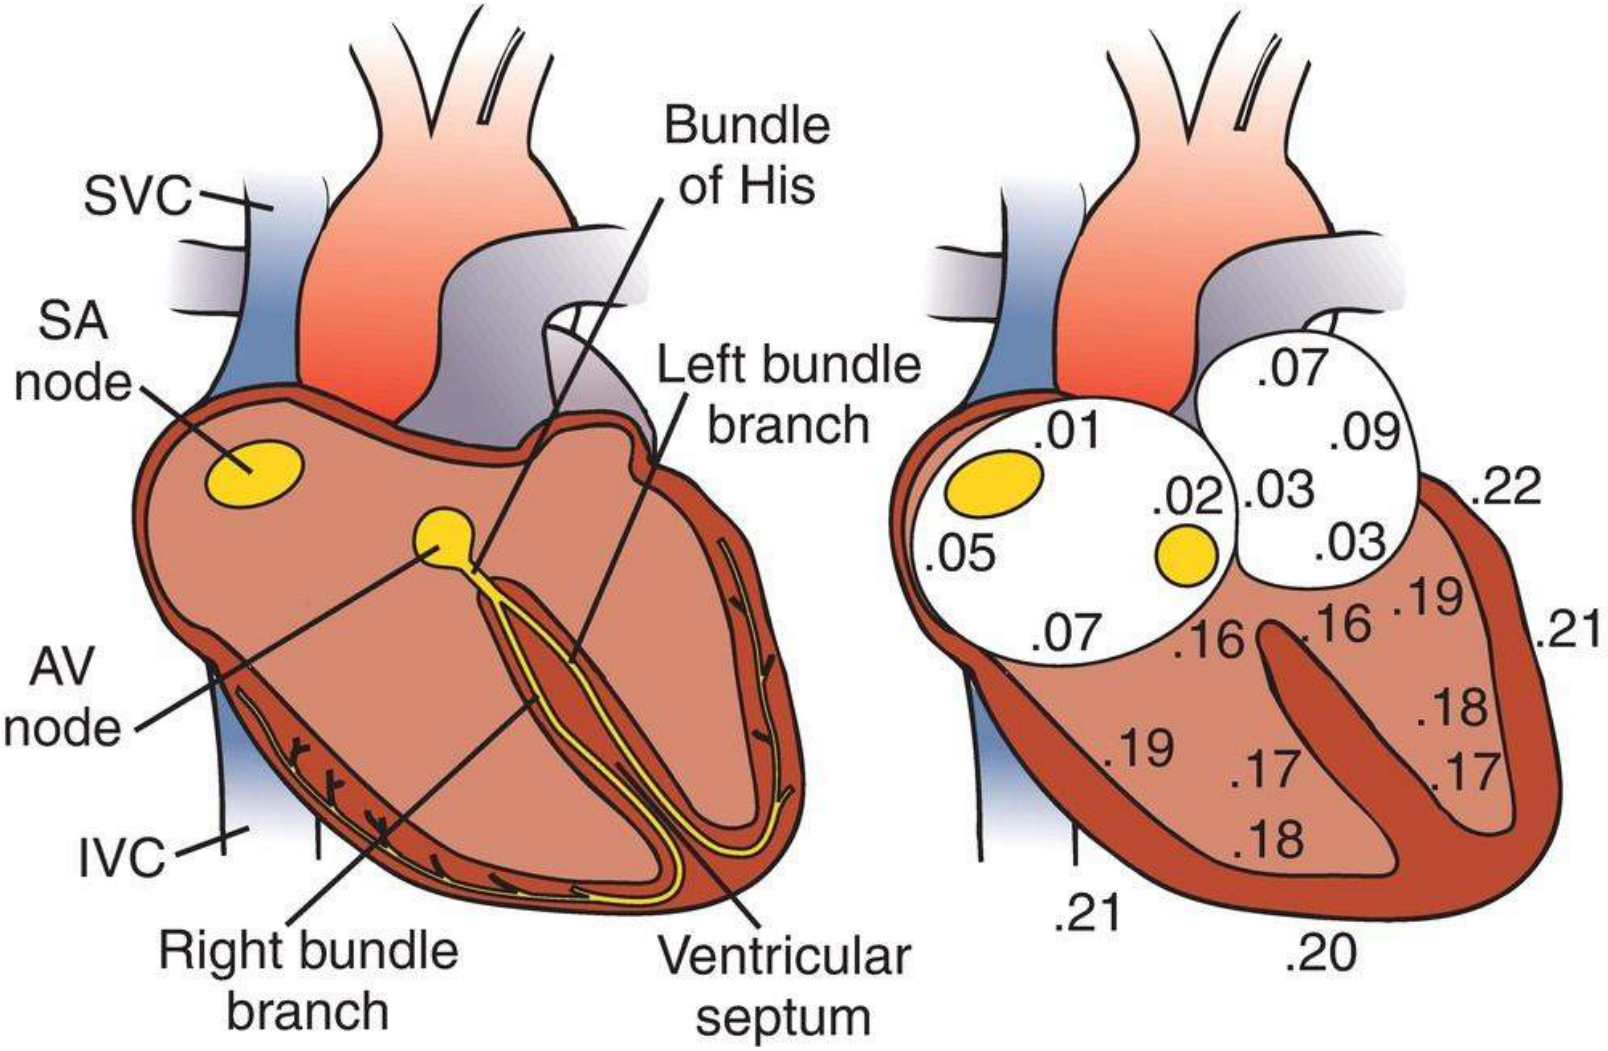

Figure 12.4 The timing of the excitation of various areas of the heart (in seconds). AV, atrioventricular; SA, sinoatrial; SVC, superior vena cava; IVC, inferior vena cava.

Unique recycling changes of ion conductances create automaticity and rhythmicity in cardiac nodal tissue.

Action potentials generated in the SA and AV nodes are smaller than those seen in cardiac muscle (Fig. 12.5). Nodal tissue does not contain fast voltage-gated Na^+ channels. The action potential is carried entirely by slow, L-type voltage-gated Ca^{2+} channels. Although these channels can carry small amounts of sodium current, the channel is conductive predominantly for calcium. The slow opening and closing of these channels with membrane depolarization create a phase 0 that is slower compared with that in ventricular cells. In addition, nodal action potentials start from more positive resting membrane potential (~ −65 mV), show no plateau, and exhibit a slow phase 3 as compared with that in cardiac muscle cells.

Figure 12.5 Sinoatrial (SA) nodal potential as a function of time. (*b*) Representation of a normal pacemaker potential. (*a*) Effect of norepinephrine. (*c*) Effect of acetylcholine. The light horizontal *dashed line* indicates threshold potential, which is set at about −48 mV in this example. The more rapidly rising phase 4 in the presence of norepinephrine (*a*) results from enhanced Na^+ permeability. The hyperpolarization and slower rise in phase 4 in the presence of acetylcholine (ACh) result from decreased Na^+ permeability and increased K^+ permeability, as a result of the opening of ACh-activated K^+ channels. For the purpose of illustration only, the cationic current changes responsible for the formation of the SA nodal potential are aligned temporally with the normal pacemaker potential in the figure. The pacemaker potential reaches threshold primarily through a slow decay of potassium conductance (gK^+) in the SA node. g, ionic conductance.

The most unique characteristic of action potentials in the SA and AV nodes is the spontaneous, progressive, and recycling depolarization that occurs in phase 4. This forms the basis for automaticity and rhythmicity in the SA node and cannot be considered a true "resting" potential. Shortly after phase 3, these cells experience a slight increase in Na^+ conductance (gNa^+_i), which results in a small inward depolarizing sodium current called $I_{Na,f}$, or "funny" sodium current. The depolarizing effects of this current tend to halt and reverse further hyperpolarization of the cell membrane (see Fig. 12.5). The sodium channel mediating this effect belongs to a class of cyclic nucleotide–gated channels called *hyperpolarization-activated cyclic nucleotide–gated* (more commonly known as *HCN*) *channels*. Defects in this channel have been associated with abnormal hyperpolarization of nodal tissue, which results in an abnormally slow or irregular heart rate. The $I_{Na,f}$ current, however, is not responsible by itself for the automaticity of nodal tissue. Throughout phase 4 of nodal action potentials, there is a progressive reduction in K^+ conductance. This tends to progressively reduce K^+ efflux from the cell, allowing it to slowly depolarize over time. This depolarization eventually begins to activate slow Ca^+ channels, and the membrane becomes depolarized in a reinforcing manner that commonly results in an action potential. Depolarization later inactivates the Ca^{2+} channels, and the cell repolarizes as a result of K^+ efflux. The decay of gK^+ in phase 4 then occurs again, thus repeating the action potential cycle. The cycling decay of gK^+ during phase 4 of the nodal action potential is the primary source of the automaticity of the SA node and its resulting rhythm.

The SA node possesses the highest intrinsic rate of spontaneous action potential generation of the specialized conduction tissues. The true intrinsic rate of the SA node is about100 impulses/minute. However, the node rate is modified by innervation from the ANS. With a normal, intact ANS, the node's intrinsic rate is suppressed to about 70 to 80 impulses/min (see Chapter 17). This physiological resting rate is still greater than the intrinsic rates of the AV node (~50 impulses/min) or the Purkinje fibers (<20 impulses/min). Consequently, the SA node continually activates the heart before any other cardiac tissue can generate its own action potential. For this reason, the SA node is often called the heart's "pacemaker," because its rate of firing determines the **heart rate** or number of contractions per minute of the heart as a whole.

Both branches of the ANS affect phase 4 of the action potentials in the nodal tissue. ACh from the vagus nerve, which innervates the SA node, slows the heart rate. ACh enhances K^+ conductance in nodal tissue and hyperpolarizes the resting membrane potential while also decreasing the slope in phase 4. Consequently, it takes longer for the cells to spontaneously reach a threshold and fewer action potentials are generated in a given period of time. Conversely, norepinephrine or activation of the sympathetic

nervous system increases cation conductance in nodal tissue (primarily sodium) and increases the slope in phase 4 of the SA node thereby increasing the heart rate (see Fig. 12.5).

Although the AV node can generate its own repetitive action potentials, it does not do so unless the intrinsic activity of the SA node is severely suppressed. This can happen with excess activation of the vagus nerve to the SA node, administration of drugs that increase ACh at the SA node, or in certain disease states. When this occurs, the heart does not stop but instead becomes paced by the AV node. In this situation, the AV node is considered to be a **secondary pacemaker**. Although the heart beats rhythmically when paced by the AV node, it does so at a substantially reduced rate compared with that seen with the SA node as the heart's pacemaker. In extreme conditions, when both the SA and AV nodes are not functional, the Purkinje fibers will pace the heart. However, the intrinsic Purkinje pacing is so slow that the flow output of the heart is insufficient for little more than keeping a person alive; normal activity is not possible. Patients in such conditions require pacing of the heart at a higher, controlled, rate by an implantable artificial pacemaker device.

Action potential conduction velocity through the myocardium is proportional to the amplitude and phase 0 upstroke of the cardiac action potential.

The conduction of action potentials through myocardial cells is affected by the characteristics of the action potentials themselves. Conduction velocity is increased when the amplitude of the action potential is increased. This increase in amplitude may occur as a result of factors that enhance Na^+ and Ca^{2+} influx into the cell. Alternately, it can also occur by hyperpolarization of the resting membrane potential, which results in a larger amplitude action potential once the cell is activated. Hypokalemia and increased K^+ conductance are two such mechanisms that can lead to hyperpolarization of myocardial muscle cells. Conduction of action potentials through the myocardium is also increased whenever the rate of depolarization in phase 0 is increased (increased dV/dt). This increase in depolarization amplitude and rate of rise will happen with any factor that increases the electrochemical gradient for Na^+ in phase 0, such as cell membrane hyperpolarization or an increase in the ratio of extracellular to intracellular Na^+ concentration. Conversely, partial depolarization of the cell membrane at rest will reduce the size and rate of rise of subsequent cardiac muscle action potentials, which in turn will slow the conduction of these action potentials from cell to cell through the myocardium. If myocardial cells become depolarized to the extent that their fast sodium channels cannot reset from the inactive state, then these cells will generate action potentials from the activation of the slow Ca^{2+} channels in the membrane instead. However, these action potentials will exhibit a slow rate of depolarization in phase 0 and small amplitude. As such, they will be conducted slowly through the myocardial muscle tissue.

Conduction specifically through the AV node is affected by normal physiologic phenomena. ACh from the vagus nerve decreases, whereas norepinephrine from sympathetic nerves enhances conduction velocity through the AV node. This helps the activation of the ventricles to match the pace set by the rate in the SA node. In addition, conduction through the AV node is sensitive to repetitive stimulation. Continuous stimulation at high rates results in an increased refractoriness of the nodal tissue. This helps prevent the ventricles from being driven at abnormally high rates, which can impinge on ventricular diastolic filling and hence the output of the whole heart.

PATHOPHYSIOLOGY OF ABNORMAL GENERATION OF CARDIAC ACTION POTENTIALS

The efficient function of the heart as a blood pump capable of meeting any metabolic need of the body is totally dependent on generation of an appropriate, regular frequency of activation (i.e., beats per minute) and proper conduction of each individual impulse in normal sequence through the myocardium. Any deviation in the origin of an action potential from a site other than the SA node and any abnormal deviation in heart rate, its regularity, or its conduction path can result in poor mechanical performance of the heart as a blood pump. Some such deviations can be life threatening. In the following section, we will examine some of the electrophysiological mechanisms responsible for the generation of abnormal action potentials in the myocardium. Abnormal rhythm mechanisms will be included in the section of this chapter devoted to the electrocardiogram (ECG).

CLINICAL FOCUS 12.1

Mechanism of Ventricular Reentry Tachycardias

Abnormal rhythms of the heart are characteristic of many pathologic conditions in the heart and by themselves can pose serious health risks to a patient. However, cardiac arrhythmias can be especially problematic when they cause the ventricles to be paced at extremely high rates. Starting at heart rates of about 180 beats/min and above, the time available for the filling of the heart during diastole becomes so compromised that even though the heart is beating many times per minute, its output is reduced as a result of decreased filling time. At this level, the faster the heart rate is, the lower is the output of the heart. It is not uncommon for individuals with ventricular tachycardia to have heart rates in excess of 250 beats/min.

In some cases, myocardial ischemia and injury can induce severe ventricular arrhythmias, called **reentry tachycardias**. Following myocardial infarction, dead zones of myocardium exist within the heart. These zones cannot conduct electrical impulses. However, because of the syncytial nature of the myocardium, electrical impulses simply flow around the dead zone and activate the remaining healthy myocardium. However, during conditions of ischemia and ischemic injury, ischemic portions of the myocardium will allow action potentials to proceed through them in one direction but not in the opposite direction. This is called *unidirectional blockade*. If action potentials are able to leak through this damaged area and emerge in the healthy myocardium after that area is past its refractory period, this “reentry” action potential will reactivate the healthy myocardium, sending another action potential generation through the injured tissue path. This process will then repeat again and again in an endless circle. This condition is called a *circus rhythm* and, as impulses generated from this circus cycle radiate outward through the syncytium, they activate the heart as a whole, at the rate set by the circus rhythm. Such circuits thus become secondary pacemakers. They may involve a few myocardial cells or large portions of the myocardium and often end up pacing the heart at an abnormally high rate (>250 beats/min). The AV node, because it is naturally predisposed to unidirectional conduction, is a common site of such reentry problems.

Although the presence of a unidirectional conduction block in the myocardium is necessary for the creation of reentry tachycardias, it is not, by itself, sufficient to set up a circus rhythm. The area of myocardium that receives action potentials from the reentry circuit as they emerge from the injured tissue zone must be over their refractory period for the cycle to be initiated anew. Consequently, *any* condition that slows but does not block the conduction of action potentials through the myocardium or shortens the refractory period of healthy cardiac cells will increase the probability of creating ventricular reentry tachycardias. Furthermore, should these factors enhance automaticity in cardiac cells, there is a good chance that such tachycardias will be initiated. Unfortunately, myocardial ischemia, by causing partial membrane depolarization, brings cells closer to their activation threshold and creates action potentials of small amplitude, which are conducted slowly through the myocardium, thus enhancing the probability of creating reentry tachycardias. ■

Abnormal pacemaker sites can appear anywhere in the heart in response to factors that cause partial depolarization or shortened refractory periods in cardiac cells.

Certain pathologic conditions, such as myocardial ischemia, scar tissue formation after myocardial infarction, or alterations of myocardial electrolyte handling, can result in action potentials being generated in areas of the myocardium other than the SA node. These areas are called **ectopic foci**. Because cardiac muscle is an electrical syncytium, any cell or group of cells that act as ectopic foci can activate the rest of the myocardium. This in turn will result in extra, abnormal, activations of myocardial contraction. In some cases, these ectopic foci fire only occasionally, but they can fire repetitively and at high intrinsic rhythms in a manner that impairs the performance of the heart as a pump. Problems occur when such action potentials are generated in the myocardium in a random fashion or when the myocardium becomes paced by the ectopic foci at rates too high to allow proper filling of the ventricular chambers with blood (**ventricular tachycardias**).

Ischemic conditions predispose the heart to the formation of ectopic foci. Ischemia inhibits Na^+/K^+ pump activity, resulting in intracellular accumulation of Na^+ and Ca^{2+} and partial membrane depolarization. This places the resting membrane potential in the affected cells closer to their threshold for the activation of action potentials. In this state, small additional depolarizing stimuli, which would be insufficient to push normal cells to their threshold, will push the membrane potential of affected cells beyond their threshold, causing them to fire and activate the rest of the heart. Hyperkalemia, hypercalcemia, distention of the heart chambers (as occurs in congestive heart failure and hypertension), clinical treatment of chronic heart failure with cardiac glycosides (which partially inhibits the Na^+/K^+ pump), all can partially depolarize the resting membrane potential and predisposes affected cells to become ectopic foci. Any factor that reduces potassium conductance at rest or increases intracellular calcium concentration can also partially depolarize cardiac cells (e.g., catecholamines, see Chapter 13). Fatigue and emotional or physical stress predispose a person to the formation of ectopic foci because such states activate the sympathetic nervous system and release catecholamines onto the heart. The probability of the formation of ectopic foci in the heart is also increased by an individual's use of caffeine or nicotine, the former which increases intracellular calcium concentration in myocardial cells through multiple mechanisms. Besides partial depolarizing factors, agents that shorten the refractory period of cardiac cells allows affected cells increased time to be reactivated by any depolarizing stimulus and thus increase the probability of ectopic foci occurring in the heart. Catecholamines, which increase gK^+ in phase 3 of the action potential, and a class of drugs called calcium channel blockers, used to treat angina and hypertension, are examples of agents shortening the refractory period of myocardial cells.

In addition to the ion channels responsible for myocardial and nodal action potentials, heart muscle cells also contain a group of non–voltage-gated K^+ channels called inwardly rectifying (IR) K^+ channels, because they pass the inward current of K^+ more easily than the outward currents. However, this is simply an electrophysiologic classification in that there are never any inwardly directed potassium currents during the cardiac action potential (the cell membrane never reaches the potassium reversal potential of −90 to −100 mV). It is the outward current through these channels that is physiologically important. $I_{K,\ ATP}$ potassium channels are inactivated by intracellular adenosine triphosphate (ATP) and activated by adenosine diphosphate. They are thought to be one link between cardiac metabolism and membrane potential. These channels may be responsible for the reduced refractory period seen during myocardial

ischemia. Other IR channels, such as I_K, ACh, and $I_{K,\ ado}$ (ACh, acetylcholine; ado, adenosine), are ligand-gated potassium channels that hyperpolarize the ventricular muscle cell. These channels may mediate cholinergic-mediated atrial arrhythmias (abnormally slow heart rates) as well as certain antiarrhythmic effects of adenosine, which is used to treat certain arrhythmic conditions.

Triggered activity

Triggered activity is a type of ventricular arrhythmia in which the abnormal beats are not generated *de novo* from ectopic foci. Instead, such activity follows a previous action potential or action potentials, which "triggers" an abnormal depolarization of ventricular muscle before the prior action potential is complete. This type of arrhythmia is most likely to occur in ventricular muscle cells and can result in individual **premature ventricular contractions** (**PVCs**) or, when repeated, more detrimental sustained tachycardias. Such conditions in the heart are difficult to terminate as one abnormal action potential triggers another and another, etc. Triggered activity is not self-activating, but it is thus considered self-sustaining.

Triggered activity is classified by the timing of the appearance of the abnormal depolarization. **Early afterdepolarizations** (**EADs**) are depolarizations of the muscle cells that occur late in phase 2 or early in phase 3 of the ventricular action potential. They are more likely to be induced by factors that prolong the action potential duration, such that slow calcium channels have time to recover and, thus, fire an additional low-amplitude action potential. Consequently, bradycardias favor the formation of EADs as do factors that impair outward potassium current in phase 3 of the ventricular action potential. EADs are also more likely to occur with excessive stretch of the ventricular chambers, such as that which occurs with congestive heart failure.

Delayed afterdepolarizations (**DADs**) occur late in phase 3 or during phase 4 of the ventricular action potential. DADs are associated with increased intracellular calcium accumulation and concentration within the myocytes, which can thus depolarize the cell membrane to the threshold for an action potential. DAD formation is favored by tachycardias. Tachycardias increase the number of times per minute calcium channels open during phase 2 and thus can bring calcium into the cell faster than it can be removed, allowing its concentration to rise over time. Agents such as norepinephrine, which enhances calcium entry into myocardial cells, as well as cardiac glycosides, which reduce intracellular calcium removal, favor DAD formation.

THE ELECTROCARDIOGRAM

When activated, the heart is a concentrated locus of time-varying electrical potentials in the body. When a portion of the myocardium becomes depolarized from an action potential, its polarity is temporarily reversed, becoming positive on the inside and negative on the outside relative to the neighboring inactivated tissue. When this reversal occurs, it temporarily creates two neighboring regions of opposite charge, or polarity, within the myocardium (Fig. 12.6). This difference in polarity between two locations is called a **dipole**. Electrical currents readily flow from one pole of a dipole to the other through any media between the poles that can conduct them. The intracellular and extracellular fluids in the body are largely composed of electrolyte solution, which is a good conductor of electricity. Thus, any dipole, formed at any time and in any direction within the myocardium, is transmitted through the body as a current between the ends of the dipole. This current then radiates outward through the body to the surface of the skin where it can be detected.

Figure 12.6 Example of a cardiac dipole. Partially depolarized myocardium creates a dipole. *Arrows* show the direction of the net dipole caused by depolarization of a portion of the myocardium. Dipoles are present only when a portion of the myocardium is in the process of depolarization or repolarization while other portions are not. They are not formed when the entire myocardium is depolarized or repolarized.

An electrocardiogram (ECG) is an amplified, timed recording of the electrical activity of the heart, as detected on the surface of the body. The recording gives a plot of voltage as a function of time. It results from the composite effect of all the different types of action potentials generated in the myocardium during activation and the resulting magnitude and orientation of the dipoles created by them. Although it is correct to say that the electrical activity in the heart is responsible for creating the ECG, the physician looks at this process in reverse; that is, the physician examines the ECG to create a picture of the electrical activity in the heart.

The ECG is one of the most useful diagnostic tools available in medicine. However, it is important to understand what information can and cannot be gained from the analysis of an ECG. The ECG can be used to detect abnormalities in heart rhythm and conduction, myocardial ischemia and infarction, plasma electrolyte imbalances, and effects of numerous drugs. One can also gain information from the ECG about the anatomic orientation of the heart, the size of the atria and ventricles, and the path taken by action potentials through the heart during normal or abnormal activation (e.g., the average direction of activation of the ventricles). The ECG, however, cannot give *direct* information about the contractile performance of the heart, which is equally important in the evaluation of myocardial status in a clinical setting. Other tools must be used for such an evaluation, and these will be discussed in later chapters.

The normal ECG depicts cyclic electrical activity and conduction in the atria and ventricles.

It is useful to recognize that certain well-known elements of the ECG represent key events in the electrical activation of the heart even though a detailed explanation of how all the myocardial action potentials during activation of the heart end up creating the common ECG is complex. The basic normal ECG is represented in Figure 12.7. Standard ECGs are run at a recording speed of 25 mm/s with 10 mm of vertical amplitude set to equal 10 mV. The first sign of electrical activity in the heart as revealed by the ECG is a small, rounded, upward (positive) deflection called a **P wave**. The P wave is caused by depolarization of the atria (not just the SA node). After a short interval, a complex, short-duration, high-amplitude, spike-like potential is observed. This potential is called the **QRS complex** and is caused by depolarization of the ventricles. By definition, within this complex, the first downward deflection after the P wave is called a **Q wave**, the next upward deflection is called an **R wave**, and the next subsequent downward deflection is called an **S wave**. However, depending on the location of the ECG recording on the body, the Q and S deflections may not be seen, and ventricular depolarization may appear only as an R wave on the ECG. Nevertheless, such a wave is still often called the QRS complex. Following the QRS complex, the entire ventricular mass is depolarized and thus there are no potential differences (dipoles) between areas of the myocardium. For this reason, no deflections are registered on the ECG, and the ECG is said to be **isoelectric** or at zero potential. Next, ventricular repolarization produces a broad wave of modest upward amplitude called a **T wave**. Repolarization of the atria is not seen in a typical ECG because it occurs during the same interval as the QRS complex and is lost in that signal.

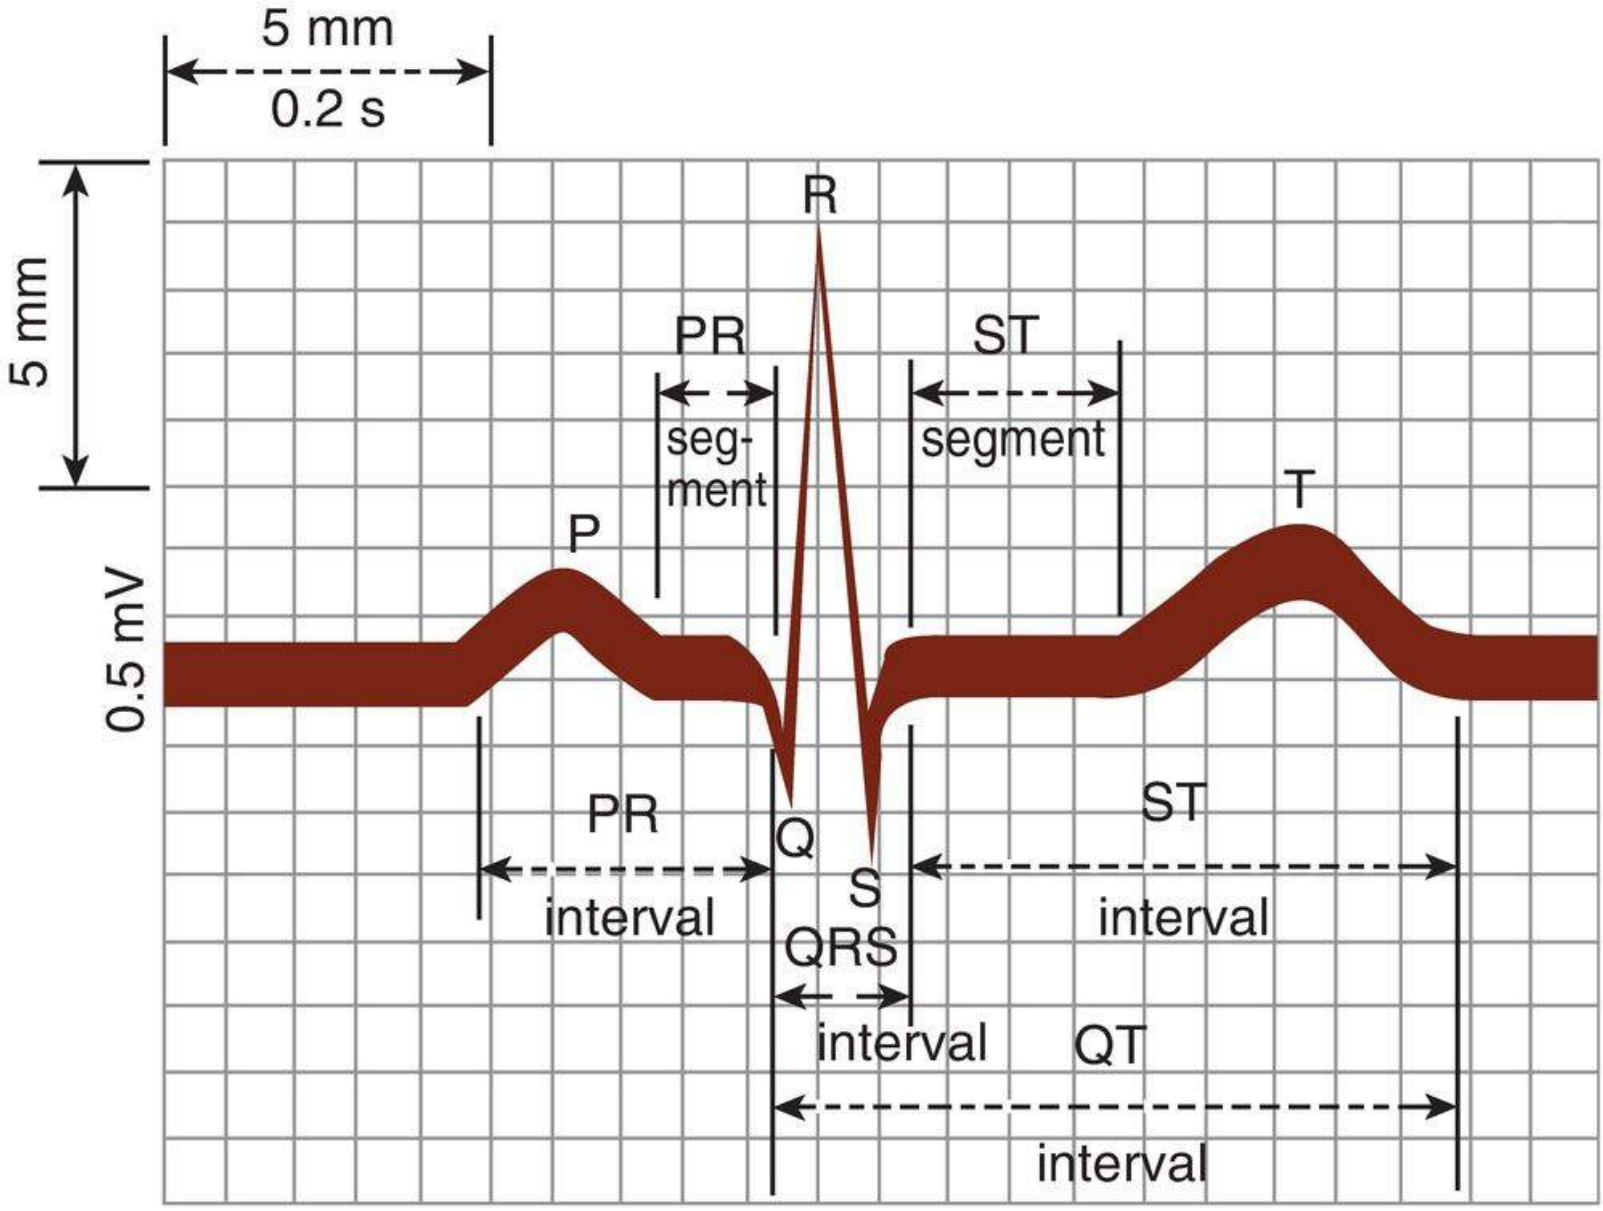

Figure 12.7 The major waveforms and intervals associated with the normal electrocardiogram (ECG). P, P wave; Q, Q wave. R, R wave; S, S wave; T, T wave.

Intervals between waves in the ECG are of physiologic and clinical importance. The **PR interval** is the time from the beginning of the P wave to the start of the QRS complex and represents the amount of time the action potential takes to travel from the SA node through the AV node. The PR interval typically lasts 0.12 to 0.20 seconds. Because most of this time represents the delay of the action potential conduction through the AV node, clinically significant inhibition of conduction through the AV node is often reflected as a lengthening of the PR interval. The **QRS interval** represents the interval of time that the action potential takes to travel from the end of the AV node through the ventricles (normally 0.06 to 0.1 seconds). The duration of the QRS complex is roughly equivalent to the duration of the P wave, despite the much greater muscle mass of the ventricles, because of the very rapid, synchronous excitation of the ventricles. The normal conduction pathway through the bundle branches, Purkinje fibers, and ventricular muscle is the most efficient and rapid mode of action potential travel. Therefore, any pathway other than this, which would thus be considered abnormal, will take longer and be reflected on the ECG as an abnormally long QRS interval.

The time between the initiation of the QRS complex and the end of the T wave is called the **QT interval**. If the ventricular action potential and QT interval are compared, the QRS complex corresponds

to initial ventricular depolarization, the ST segment corresponds to the plateau phase, and the T wave corresponds to repolarization. The relationship between a single ventricular action potential and the events of the QT interval is approximate because the events of the QT interval represent the combined influence of all of the ventricular action potentials. Regardless, the QT interval measures the total duration of ventricular activation. The QT interval is altered by drugs or conditions that alter the rate of myocardial repolarization in phase 3 (e.g., altered K^+ conductance), but it is also naturally inversely proportional to the heart rate. When corrected for existing heart rate, abnormal QT intervals indicate problems with repolarization of the ventricles. For example, if ventricular repolarization is delayed, the QT interval is prolonged. Delayed repolarization is associated with the genesis of ventricular arrhythmias. Therefore, when corrected for the existing heart rate, the presence of a prolonged QT interval on the ECG is considered an ominous sign requiring medical attention.

Moment-to-moment orientation and magnitude of net dipoles in the heart determine the formation of the ECG.

The formation of the standard waveforms within the ECG can be explained as arising from the orientation and magnitude of the net, or collective average, of all the dipoles that are created throughout the heart during the electrical activation of the myocardium. To explain further, consider the voltage changes produced in which the body serves as a volume conductor and the heart generates a collection of changing dipoles (Fig. 12.8). In this example, an electrocardiographic recorder is connected between points A and B such that point A is positive relative to point B. In this alignment, when the positive pole of a dipole is directed primarily more toward point A than point B, the ECG is deflected upward, and when it is primarily pointed toward point B, it is deflected downward.

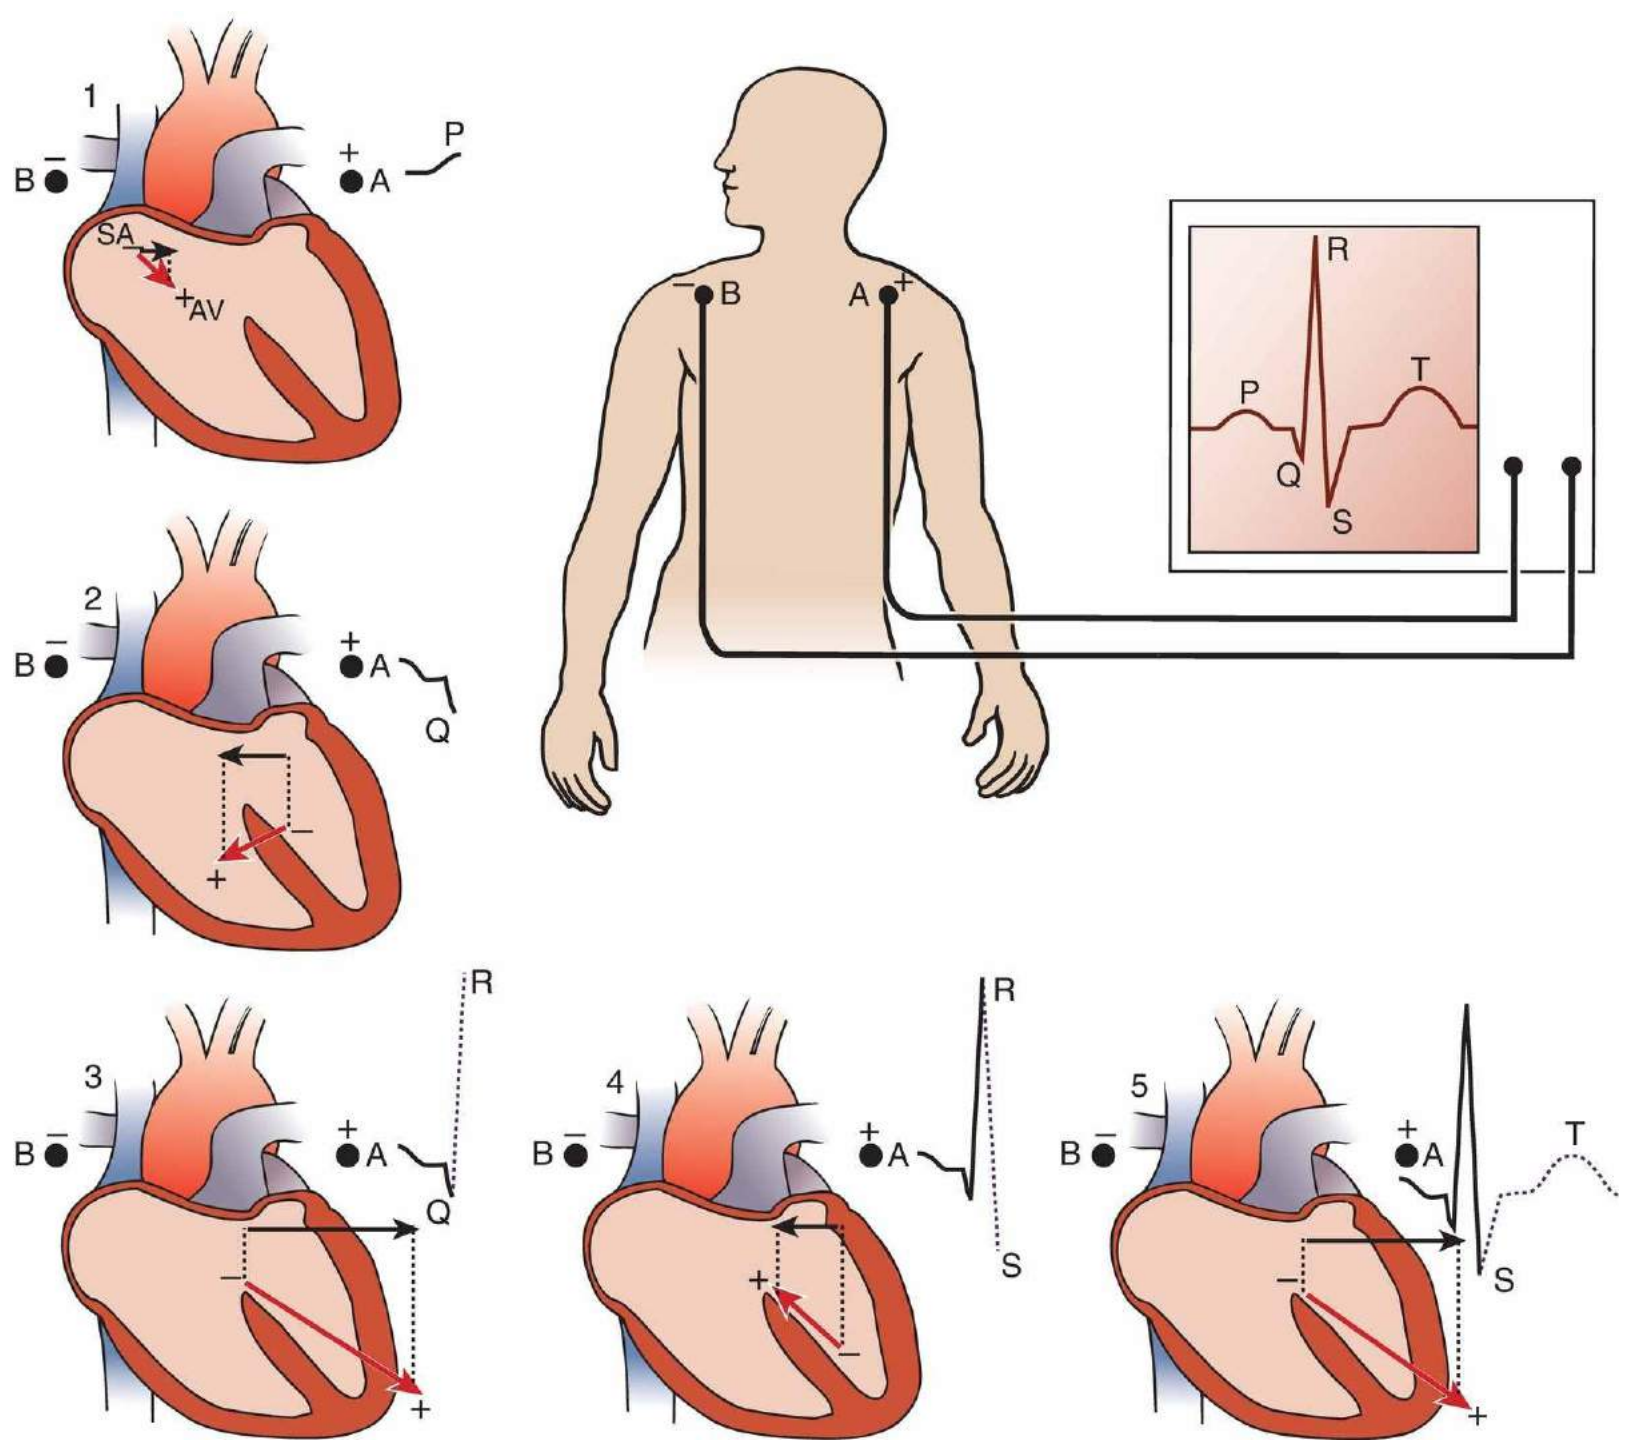

Figure 12.8 The sequence of major dipoles giving rise to electrocardiogram (ECG) waveforms. The *black arrows* are projected vectors that represent the magnitude and direction of a major dipole in the myocardium, which is depicted as a *red arrow* in the diagram. The magnitude is proportional to the mass of myocardium involved. The direction is determined by the orientation of depolarized and polarized regions of the myocardium. The vertical dashed lines project the vector onto the *A–B* coordinate (analogous to lead I); it is this component of the vector (represented here by the *black arrow*) that is sensed and recorded on the ECG. In panel 5, the last areas of the ventricles to depolarize are the first to repolarize (i.e., repolarization proceeds in a direction opposite to that of depolarization). The projection of the vector (*black arrow*) for repolarization points to the more positive electrode (*A*) as opposed to the less positive electrode (*B*) and so an upward deflection is recorded on this lead. AV, atrioventricular; SA, sinoatrial.

In Figure 12.8, the red arrows show (in two dimensions, projected onto the frontal plane of the body)

the direction of the *net* dipole resulting from the many individual dipoles present at that interval of time. The length of the red arrow is proportional to the magnitude (voltage) of the net dipole, which is related to the mass of myocardium from which it is generated. The black arrows show the magnitude of the dipole component that is projected onto or "parallel" to the imaginary line between points A and B (the points of recording electrodes). Importantly, it is this projected component that determines the amplitude and polarity of voltage that will be recorded on the ECG. As indicated in panel 1 of Figure 12.8, atrial excitation results from a wave of depolarization that originates in the SA node and spreads over the atria. The net dipole generated by this excitation has a magnitude proportional to the mass of the atrial muscle involved and a direction indicated by the red arrow. The head of the arrow points toward the positive end of the dipole, where the atrial muscle is not yet depolarized. The negative end of the dipole is located at the tail of the arrow, where depolarization has already occurred. Because point A is positive relative to point B on the recording electrodes, there will be an upward deflection of the ECG. The magnitude of this upward deflection depends on two factors: (1) the amount of tissue generating the dipole (with amplitude being proportional to the tissue mass involved) and (2) the orientation of the dipole relative to a parallel line connecting points A and B (i.e., black arrow projected in parallel onto the imaginary line connecting A and B. This latter relationship is demonstrated in Figure 12.9.

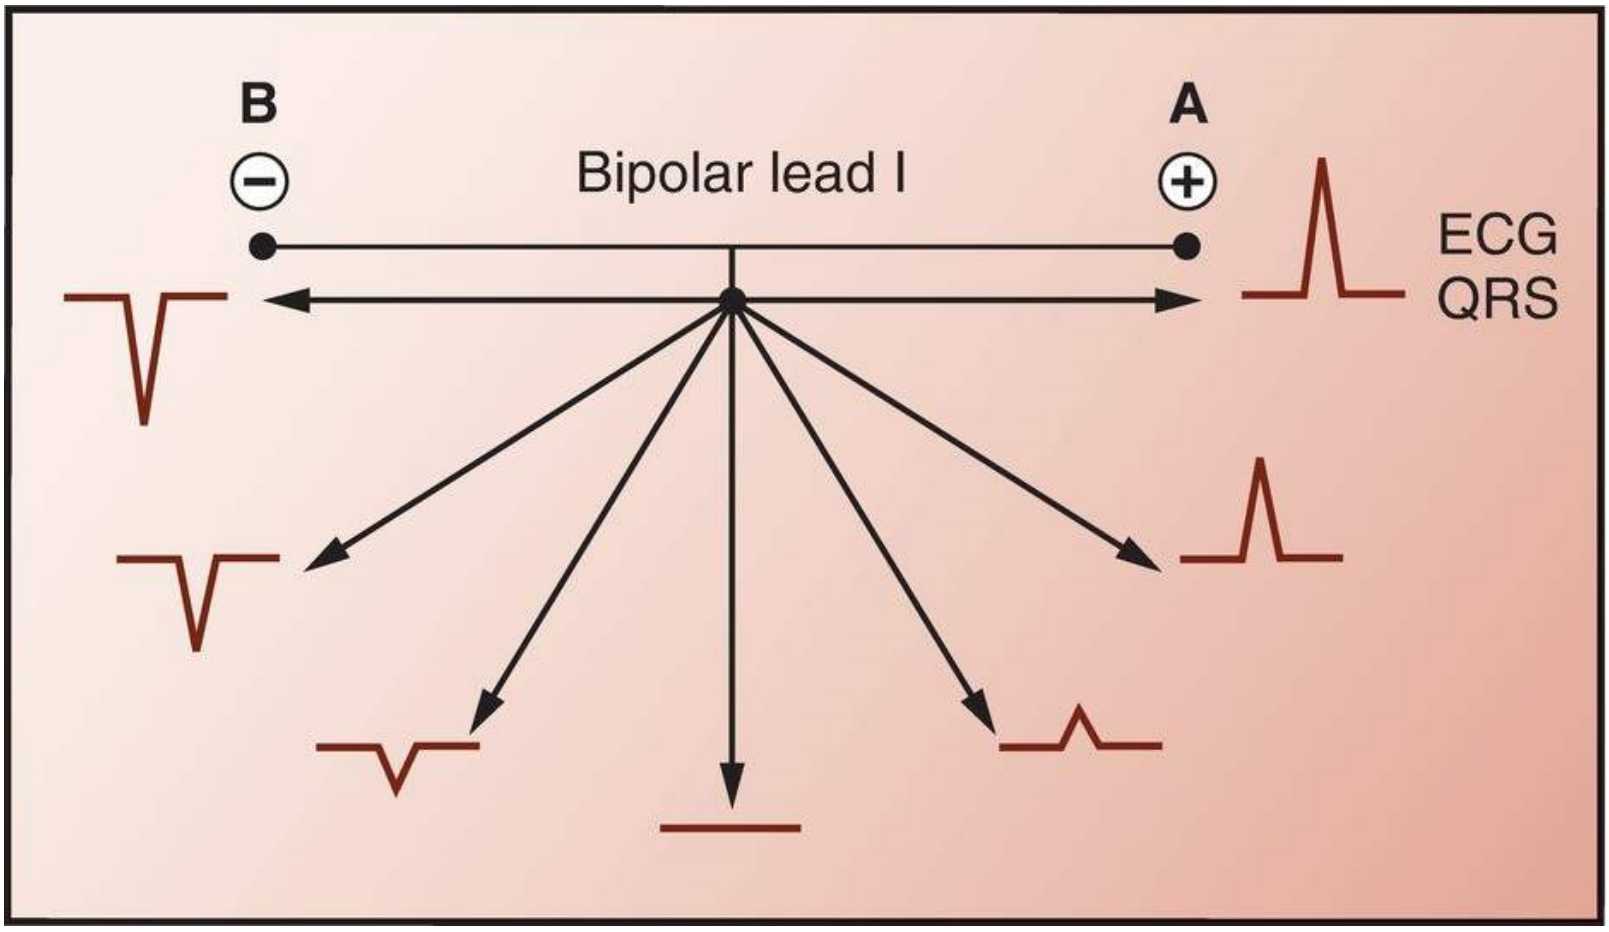

Figure 12.9 A representation of how the orientation of a dipole in the ventricle relative to a bipolar lead affects the magnitude and polarity of a hypothetical deflection on the electrocardiogram (ECG). Positive ends of the dipole pointed to the positive pole of the lead create positive deflections in the complex. Dipoles pointed directly to the positive pole, parallel to the lead, create the most positive deflection waves. Those pointed directly to the negative pole create the most negative deflection. Dipoles oriented perpendicularly to the lead have no component pointed to either pole of the lead and thus register no deflection of the ECG. QRS, QRS complex and interval.

Imagine a net dipole in the atria muscle pointing directly along the line connecting point B to point A with its positive end pointing directly at point A. This depolarization will then create a positive deflection as described above. For the sake of example only, we shall assign this deflection an amplitude of +4 mm on the ECG recorder. Should this same depolarization, however, proceed directly from point A toward point B, with the positive end pointing directly at point B, a downward deflection of the same amplitude would result (i.e., a 4-mm deflection, but in the negative direction or, −4 mm). The amplitude of the deflection will thus vary in this example between −4 mm and +4 mm, depending on the angle of the net dipole relative to the line connecting A and B. Should, instead, the net dipole point toward A at a 45° angle, the deflection would be a positive 2 mm; if it points at 90° (perpendicular) to the line connecting A and B, it would not be pointing at either pole and no deflection would be recorded on the ECG. (Note, this is not the only way, however, in which the deflection will register zero. Once the atria are completely depolarized, no voltage difference, or dipole, will exist between A and B and thus the ECG would record zero deflection during that time).

Although the preceding discussion is an oversimplification, it presents the basic principles that create the pattern of the common ECG. For example, after the P wave, the ECG returns to its baseline or isoelectric level. During this time, the wave of depolarization moves through the AV node, the AV bundle, the bundle branches, and the Purkinje system. The dipoles created by the depolarization of these structures are too small to produce a deflection on the ECG. However, the depolarization of ventricular structures does create deflections on the ECG. The net dipole that results from the initial depolarization of the septum is shown in panel 2 of Figure 12.8. This depolarization is pointed toward point B and away from point A because the left side of the septum depolarizes before the right side. This orientation creates a small downward deflection produced on the ECG, called the Q wave although in many instances, the normal Q wave is so small that it is not apparent. Next, the wave of depolarization spreads via the Purkinje system across the inside surface of the free walls of the ventricles. Depolarization of free-wall ventricular muscle proceeds from the innermost layers of muscle (subendocardium) to the outermost layers (subepicardium). Because the muscle mass of the left ventricle is much greater than that of the right ventricle, the net dipole during this phase has the direction indicated in panel 3. The deflection of the ECG is upward because the dipole is directed at point A and it is large because of the great mass of tissue involved. This upward deflection is the R wave. The last portions of the ventricle to depolarize generate a net dipole with the direction shown in panel 4, and thus, the deflection on the ECG is downward. This final deflection is the S wave. The ECG tracing returns to baseline when all of the ventricular muscle becomes depolarized and all dipoles associated with ventricular depolarization disappear. The ST segment, or the period between the end of the S wave and the beginning of the T wave, is generally isoelectric. This indicates that no dipoles large enough to influence the ECG exist because all ventricular muscle is depolarized (the action potentials of all ventricular cells are in phase 2).

Repolarization, like depolarization, generates a dipole because the voltage of the depolarized area is different from that of the repolarized areas. The dipole associated with atrial repolarization does not appear as a separate deflection on the ECG because it generates a low voltage and because it is masked by the much larger QRS complex, which is present at the same time. Ventricular repolarization is not as orderly as ventricular depolarization. The duration of ventricular action potentials is longer in subendocardial myocardium than in subepicardial myocardium. The longer duration of subendocardial action potentials means that even though subendocardial cells were the first to depolarize, they are the last to repolarize. Because subepicardial cells repolarize first, the subepicardium is positive (outside) relative to the subendocardium; that is, the polarity of the net dipole of repolarization is the same as the polarity of the dipole of depolarization. This results in an upward deflection because, as in depolarization, point A is positive with respect to point B. This deflection is the T wave (see panel 5,

Fig. 12.8). The T wave has a longer duration than the QRS complex because repolarization does not proceed as a synchronized, propagated wave. Instead, the timing of repolarization is a function of the properties of individual cells, such as the number of particular K^+ channels.

ECG evaluation is standardized by the use of a designated 12-lead system.

There are two broad classes of evaluations performed using the ECG. One of these involves the evaluation of abnormalities in the basic ECG form. Arrhythmias, conduction abnormalities, electrolyte disturbances, drug effects, and myocardial metabolic disorders such as ischemia can be detected as abnormal patterns from a single ECG electrode placed at most any location on the surface of the body. However, as explained in the previous section, the amplitude and, in some cases, the polarity of various waveforms within the ECG depend in part on the orientation of the net dipoles generated in the heart relative to the position of the electrode system measuring the ECG. Clearly then, the same electrical event in the heart will appear differently if it is viewed by two different electrode systems with different orientations relative to the event. For this reason, a standard system consisting of 12 specifically located “leads” or electrode connections is used in the clinical application of ECG recordings in patients. This system provides two benefits. First, it provides a standard framework for identifying patterns in the ECG, thus making the recognition of abnormalities easier and more consistent. Second, it enables an investigator to see the electrical activity in the heart from many different “views and angles” at any given point in time. Analysis of these different “views” is used to gain information about the orientation of the heart, the size of its chambers, and the general direction of activation in the myocardium during any interval.

Imaging cardiac electrical activity in the frontal plane uses six standardized frontal limb leads.

The first ECG lead system was developed by Willem Einthoven and was based on the idea that the heart sits at the center of a triangle in the frontal plane of the body, with vertices at the right shoulder, left shoulder, and pubic region (Fig. 12.10A). This triangle is called the **Einthoven triangle**, and it is the simplest geometry in which straight lines can completely encircle the heart in the frontal plane (i.e., 360°). In this system, the arms and the legs are considered extensions of the vertices, and ECG electrodes are placed on the right arm, left arm, and left leg, with the right leg serving as an electrical ground. This creates a series of connections, or leads, between each pair of electrodes. These leads are bipolar, meaning each has a positive and a negative pole. In lead I, the right arm is negative and the left arm is positive. In lead II, the right arm is negative and the left leg is positive. Finally, in lead III, the left arm is negative and the left leg positive. If one imagines the frontal plane of a person as being represented by a 360° circle, lead I has its positive pole placed at "3 o'clock" on the circle and is designated by convention as 0°. The positive pole of lead II is at 60°, and that for lead III is at 120°, as shown in Figure 12.10B. This lead system is often called the **standard frontal lead system**.

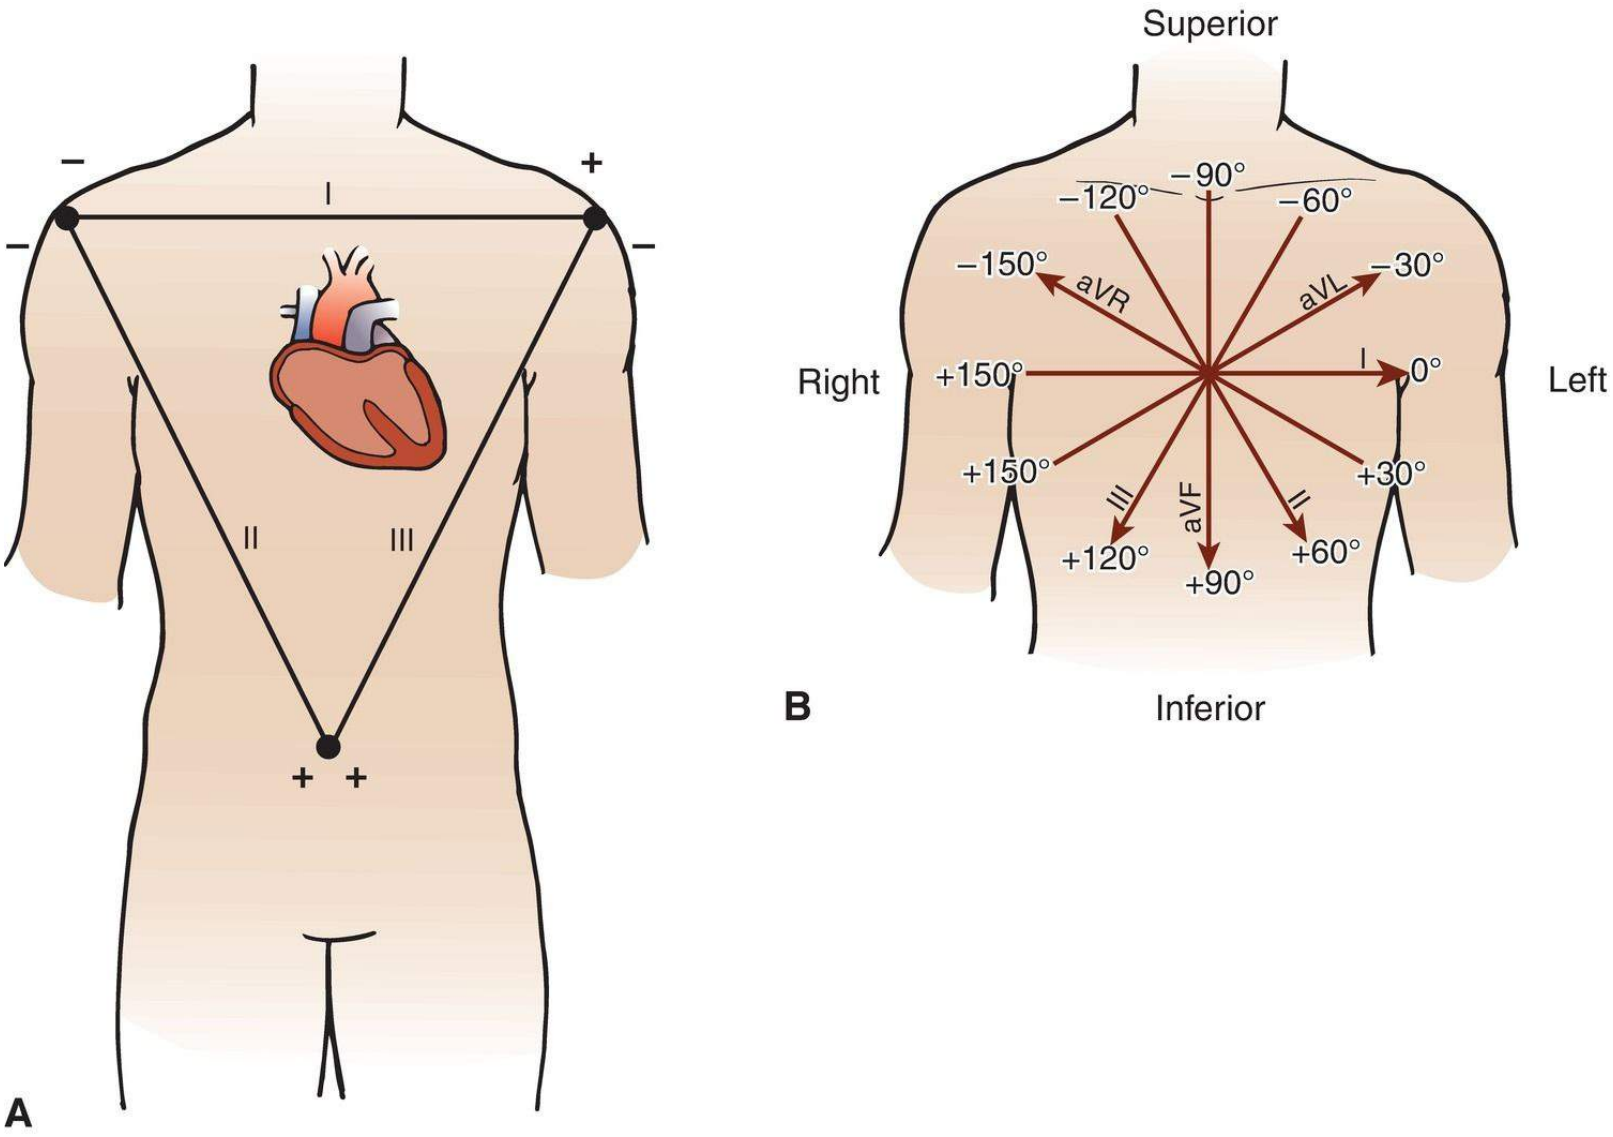

Figure 12.10 The Einthoven triangle. (A) The heart is considered to be at the center of a triangle, each

corner of which serves as the location for electrodes that send signals as a positive and negative pole pair to the electrocardiogram recorder. The three resulting bipolar leads are designated I, II, and III. By convention, positive dipoles generated within the myocardium that are pointed in the direction of the positive pole of any of the leads create a positive deflection that is recorded from that lead; when pointed at the negative pole, a negative deflection is recorded. **(B)**The hexaxial reference system for the standard bipolar and augmented unipolar chest leads. The limb leads give information on cardiac dipole vectors in the frontal plane and are referenced by the angle, in degrees, in which the vector points as if viewed in two dimensions in the frontal plane. aVF, augmented foot lead; aVL, augmented left lead; aVR, augmented right lead.

Another lead system is arranged in the frontal plane of the body and consists of three unipolar leads created by special connections between the same electrodes placed on the arms and legs for the creation of the standard frontal lead system. These leads are single positive poles relative to the center of the chest, which is considered zero potential. These leads are often called **augmented leads** because the ECG recording device amplifies the signal from these leads relative to those obtained in the bipolar leads (see Fig. 12.10B). The pole of one lead sits at the right shoulder at 210° and is called the *augmented right*, or *aVR*, lead; another sits at the left shoulder at 330° and is called *augmented left* or *aVL*. The final augmented lead is oriented at 90° in the frontal plane and is called the *augmented foot* or *aVF lead*. The augmented and standard limb leads give a two-dimensional picture of the electrical activity of the heart as it would be viewed, or projected, onto the frontal plane of the body.

Imaging cardiac electrical activity in the horizontal plane uses six standardized chest leads.

In a typical 12-lead ECG system, a series of six unipolar leads is arranged in a horizontal plane around the chest as shown in Figure 12.11. These are sometimes called **precordial or chest leads** and are designated V_1 to V_6, from just to the right of the sternum in the 4th intercostal space to the axial line in the 5th intercostal space. These leads give a two-dimensional picture of the electrical activity in the heart as it would be viewed from above or below a horizontal plane bisecting the heart. In addition, because these leads lie so close to the surface of the heart, individual precordial leads give detailed information about the electrical activity in the small, specific portions of the heart that lie beneath each electrode.

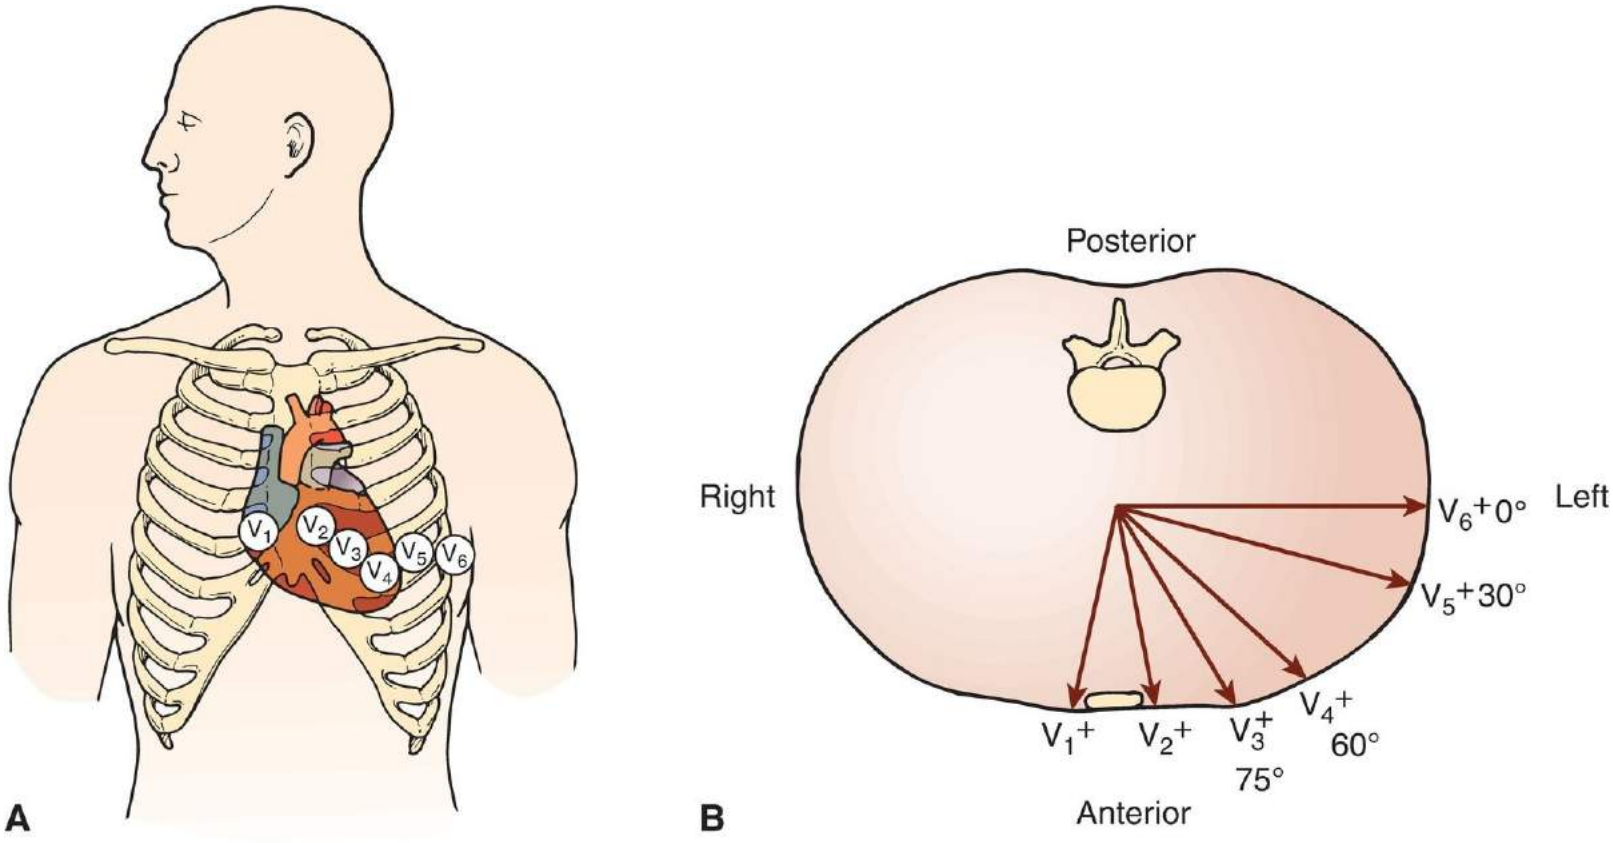

Figure 12.11 Unipolar chest leads. (A) V_1 is just to the right of the sternum in the 4th intercostal space. V_2 is just to the left of the sternum in the 4th intercostal space. V_4 is in the 5th interspace in the midclavicular line. V_3 is positioned midway between V_2 and V_4. V_5 is in the 5th intercostal space in the anterior axillary line. V_6 is in the 5th intercostal space in the midaxillary line. The reference, or zero, voltage for the unipolar chest leads is electronically combined out of the three limb leads. **(B)**The orientation of the unipolar chest leads in the horizontal plane. The chest leads give information on cardiac dipole vectors as if viewed in two dimensions in the horizontal plane.

Typical tracings from the six frontal and six horizontal lead systems are shown in Figure 12.12. In general, clinical practice, all 12 leads are recorded in a patient at the same time. Because the chart speed for all ECG recordings is standardized at 25 mm/s, this affords an easy means of converting intervals between two points on the ECG into an estimate of heart rate in beats/minute (bpm). For example, R

waves that are uniformly separated by 25 mm indicate that the heart is beating at 60 (bpm), 20 mm = 75 bpm, 15 mm = 100 bpm, 10 mm = 150 bpm, and 5 mm = 300 bpm.

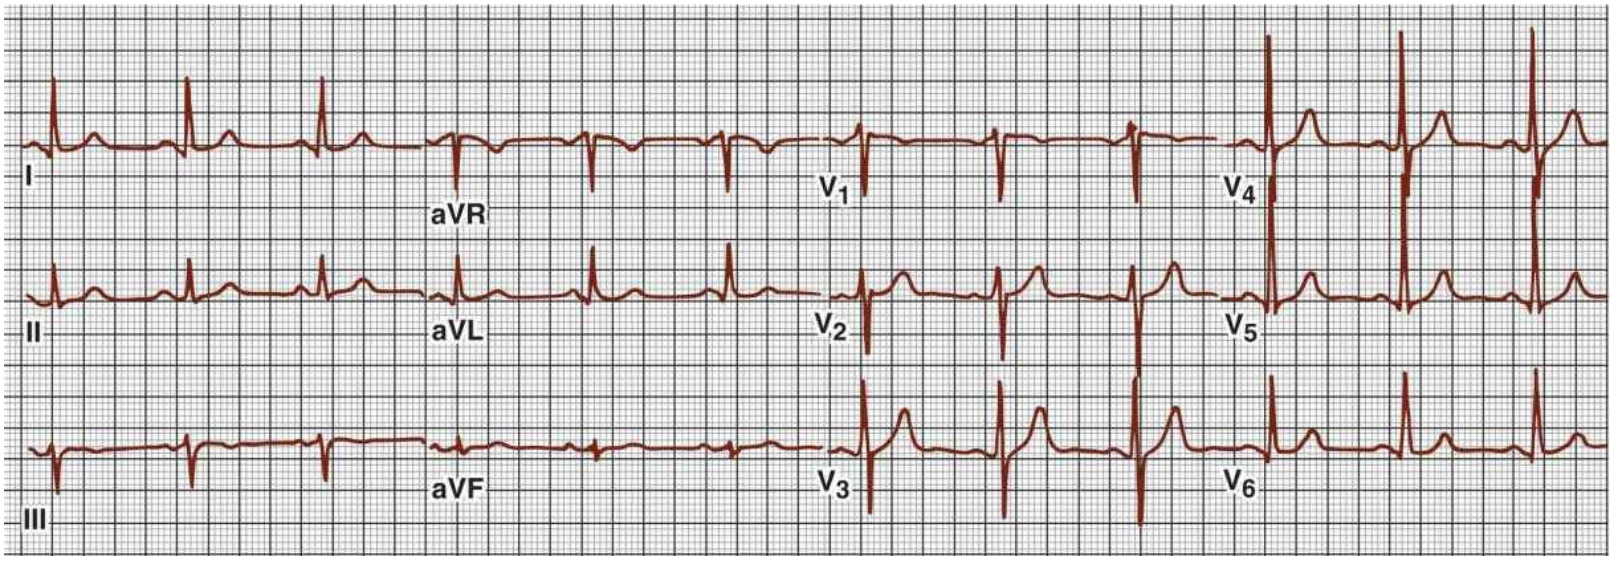

Figure 12.12 The clinical standard 12-lead electrocardiogram. Six limb leads and six chest leads are shown. Two dark horizontal lines (10 mm) are calibrated to be 1 mV. Dark vertical lines represent 0.2 seconds. aVF, augmented foot lead; aVL, augmented left lead; aVR, augmented right lead.

Figure 12.12 shows that a P wave is always followed by a QRS complex of uniform shape and size. The PR interval is 0.16 seconds (normal 0.10 to 0.20 seconds). This measurement indicates that the conduction velocity of the action potential from the SA node to the ventricular muscle is normal. The average time between R waves (successive heart beats) is about 0.84 seconds, making the heart rate ~71 beats/min.

Information about the orientation of the heart, ventricular size, and conduction pathways can be obtained through the frontal QRS vector.

As explained above, changes in the magnitude and direction of any momentary cardiac dipole will cause changes in a given ECG lead, as determined by the orientation of the dipole relative to the orientation of the specific lead. Theoretically, by comparing the magnitude of any portion of an ECG simultaneously in several leads, one could work backward and determine what the orientation of the net dipole was in the heart at that moment that gave rise to those magnitudes in the different leads. In other words, by comparing, for example, the magnitude of positive deflections at one point of the ECG in leads I, II, and III at the same time, one could "triangulate in" and get an estimate of the direction of the net dipole in the heart at that precise moment. That direction could then be represented by a vector on the hexaxial reference system shown in Figure 12.10B.

Hypothetically, one could construct a set of vectors resulting from the net dipoles produced in the myocardium during every millisecond of cardiac activation. However, this is impractical and is not necessary to glean important clinical information from the ECG. Instead, what is done is to focus on a major cardiac event that is represented within the ECG, construct a general average vector for that event, and then plot its vector in the frontal or horizontal plane as desired. The most common event that is analyzed this way from the ECG is ventricular depolarization and its associated ECG QRS complex. In broad terms, the overall direction of depolarization through the myocardium is from the right atrium to the left atrium, down through the AV node, and on into the ventricles. The heart in most people sits in the chest at an angle with the apex pointing toward the lower left portions of the lungs. Thus, the long axis of the ventricles from base to apex is roughly a line pointed downward from the area of the right shoulder to the lower left side of the chest. Therefore, if one could "see" the *average* grand trek of depolarization through the ventricles projected in two dimensions onto a flat screen in the frontal plane of the body, it would appear as a vector proceeding from the upper right of the ventricles down toward the heart apex at an angle of ~ +60° on the hexaxial reference system. This average vector is called the **mean electrical QRS axis**, or mean QRS vector. Using the standard bipolar limb leads, the Einthoven triangle, and the hexaxial reference system for orientation, the *average* deflections of the QRS complexes giving rise to this mean vector would be most positive in lead II and least positive in lead III and in between these two magnitudes in lead I. (In fact, the axiom that I + III = II for average QRS amplitudes always applies and can be used as a handy check for proper connection of the frontal ECG leads.)

Calculating the average deflection for the mean QRS vector is simplified for the purpose of clinical analysis. Basically, a line along the isoelectric line of the ECG from a given lead (e.g., lead I) is drawn through the QRS complex, and the amplitude of the peak of the R wave is measured. The peak of any negative deflections in the QRS complex below the isoelectric line (usually the sum of the negative peaks of the Q and S waves) is subtracted from the R wave peak to give the average QRS amplitude in that lead. This value is then plotted in the appropriate polarity direction along the line on a hexaxial plot system that corresponds to the lead from which the ECG was measured (see Fig. 12.10). A perpendicular line is then dropped from that point. This same procedure is repeated for at least one other lead in the same plane (e.g., either lead II or lead III in this example). A line drawn from the center of the hexaxial system to the point of intersection of the perpendiculars represents the mean QRS vector in the heart at that moment in time.

An example of the application of mean QRS vector determination is shown in Figure 12.13, which

uses the ECG tracings in Figure 12.12. For this example, the Einthoven triangle is used to calculate the vector. The net magnitude of the QRS complex in leads I, II, and III is measured and plotted on the appropriate axis. A perpendicular line is dropped from each of the plotted points and a vector drawn between the center of the triangle and the intersection of the perpendicular lines. This gives a mean QRS axis of +3°. Another simple way of estimating the mean QRS vector in this example is to simply examine the QRS complex in the six frontal limb leads and select the lead in which the average QRS complex deflection is closest to zero. As discussed earlier, when the cardiac dipole is perpendicular to a particular lead, the net deflection is zero. Once the net QRS deflection closest to zero is identified, it follows that the mean electrical axis is perpendicular to that lead, and the hexaxial reference system can be used to determine the angle of that axis. In Figure 12.12, the lead in which the net QRS deflection is closest to zero is lead aVF (enlarged in Fig. 12.13). Lead I is perpendicular to the axis of lead aVF, and because the QRS complex is upward in lead I, the mean electrical axis points to the left arm. Thus, the mean QRS vector is estimated to be about 0°, which is not far from the +3° of the actual calculated vector from the frontal bipolar leads.

Figure 12.13 An example of the determination of the mean QRS axis. This axis can be estimated by using the Einthoven triangle and the net voltage of the QRS complex in any two of the bipolar limb leads. It can also be estimated by inspection of the six limb leads and select the lead most closely yielding a net voltage of zero (see text for details). Electrocardiogram tracings are from Figure 12.12 and are enlarged to facilitate viewing. aVF, augmented foot; LA, left arm; LL, left leg; RA, right arm.

The mean QRS vector is influenced by the position of the heart in the chest, the properties of the cardiac conduction system, the excitation and repolarization properties of the ventricular myocardium, and the size of the ventricles. Because the last three of these influences are most significant, the mean QRS electrical axis can provide valuable information about a variety of cardiac diseases. In healthy people, the mean QRS vector is oriented within the range of −10° to +110° on the hexaxial system. Sometimes, a rough measure is used to determine whether the QRS vector is normal in an individual by simply determining whether the amplitude of the QRS vector is positive in both lead I and lead II; if they both are, then the patient is considered to have an essentially normal QRS vector and no further vector analysis is required. A mean QRS vector outside these limits however indicates serious changes in either the path of depolarization in the ventricles or abnormal ventricular muscle mass, such as **left ventricular hypertrophy** (**LVH**) **or right ventricular hypertrophy** (RVH). Ventricular hypertrophy is a serious condition resulting from either ventricle being exposed chronically to high arterial pressure or outflow obstruction (e.g., valve stenosis). In LVH, the mean QRS vector shows what is called **left axis deviation**. In this situation, the mean QRS points to the upper left quadrant of the hexaxial projection between –30° and –90°. RVH is the approximate mirror image of this abnormal orientation with the mean QRS vector pointing between +110° and +150°.

Any ECG can detect abnormalities in the electrical activation and conduction in the heart.

Several types of ECG recordings are listed in Figure 12.14. Unless stated otherwise, one may assume these ECGs are from lead II. The ECG in Figure 12.14A shows **respiratory sinus arrhythmia**, which is an increase in the heart rate with inspiration and a decrease with expiration. The presence of a P wave before each QRS complex indicates that these beats originate in the SA node. Intervals between successive R waves of 1.08, 0.88, 0.88, 0.80, 0.66, and 0.66 seconds correspond to heart rates of 56, 68, 68, 75, 91, and 91 beats/min. The interval between the beginning of the P wave and the end of the T wave is uniform, and the change in the interval between beats is primarily accounted for by the variation in time between the end of the T wave and the beginning of the P wave. Although the heart rate changes, the interval during which electrical activation of the atria and ventricles occurs does not change nearly as much as the interval between beats, indicating that it is variations in the activation of the heart at the SA node that is altering rhythm and not variation in conduction through the heart. Respiratory sinus arrhythmia is caused by cyclic changes in sympathetic and parasympathetic neural activity to the SA node that accompanies respiration. It is observed in people with healthy hearts, although this particular example is somewhat dramatic. Respiratory sinus arrhythmia is usually accentuated in patients under anesthesia.

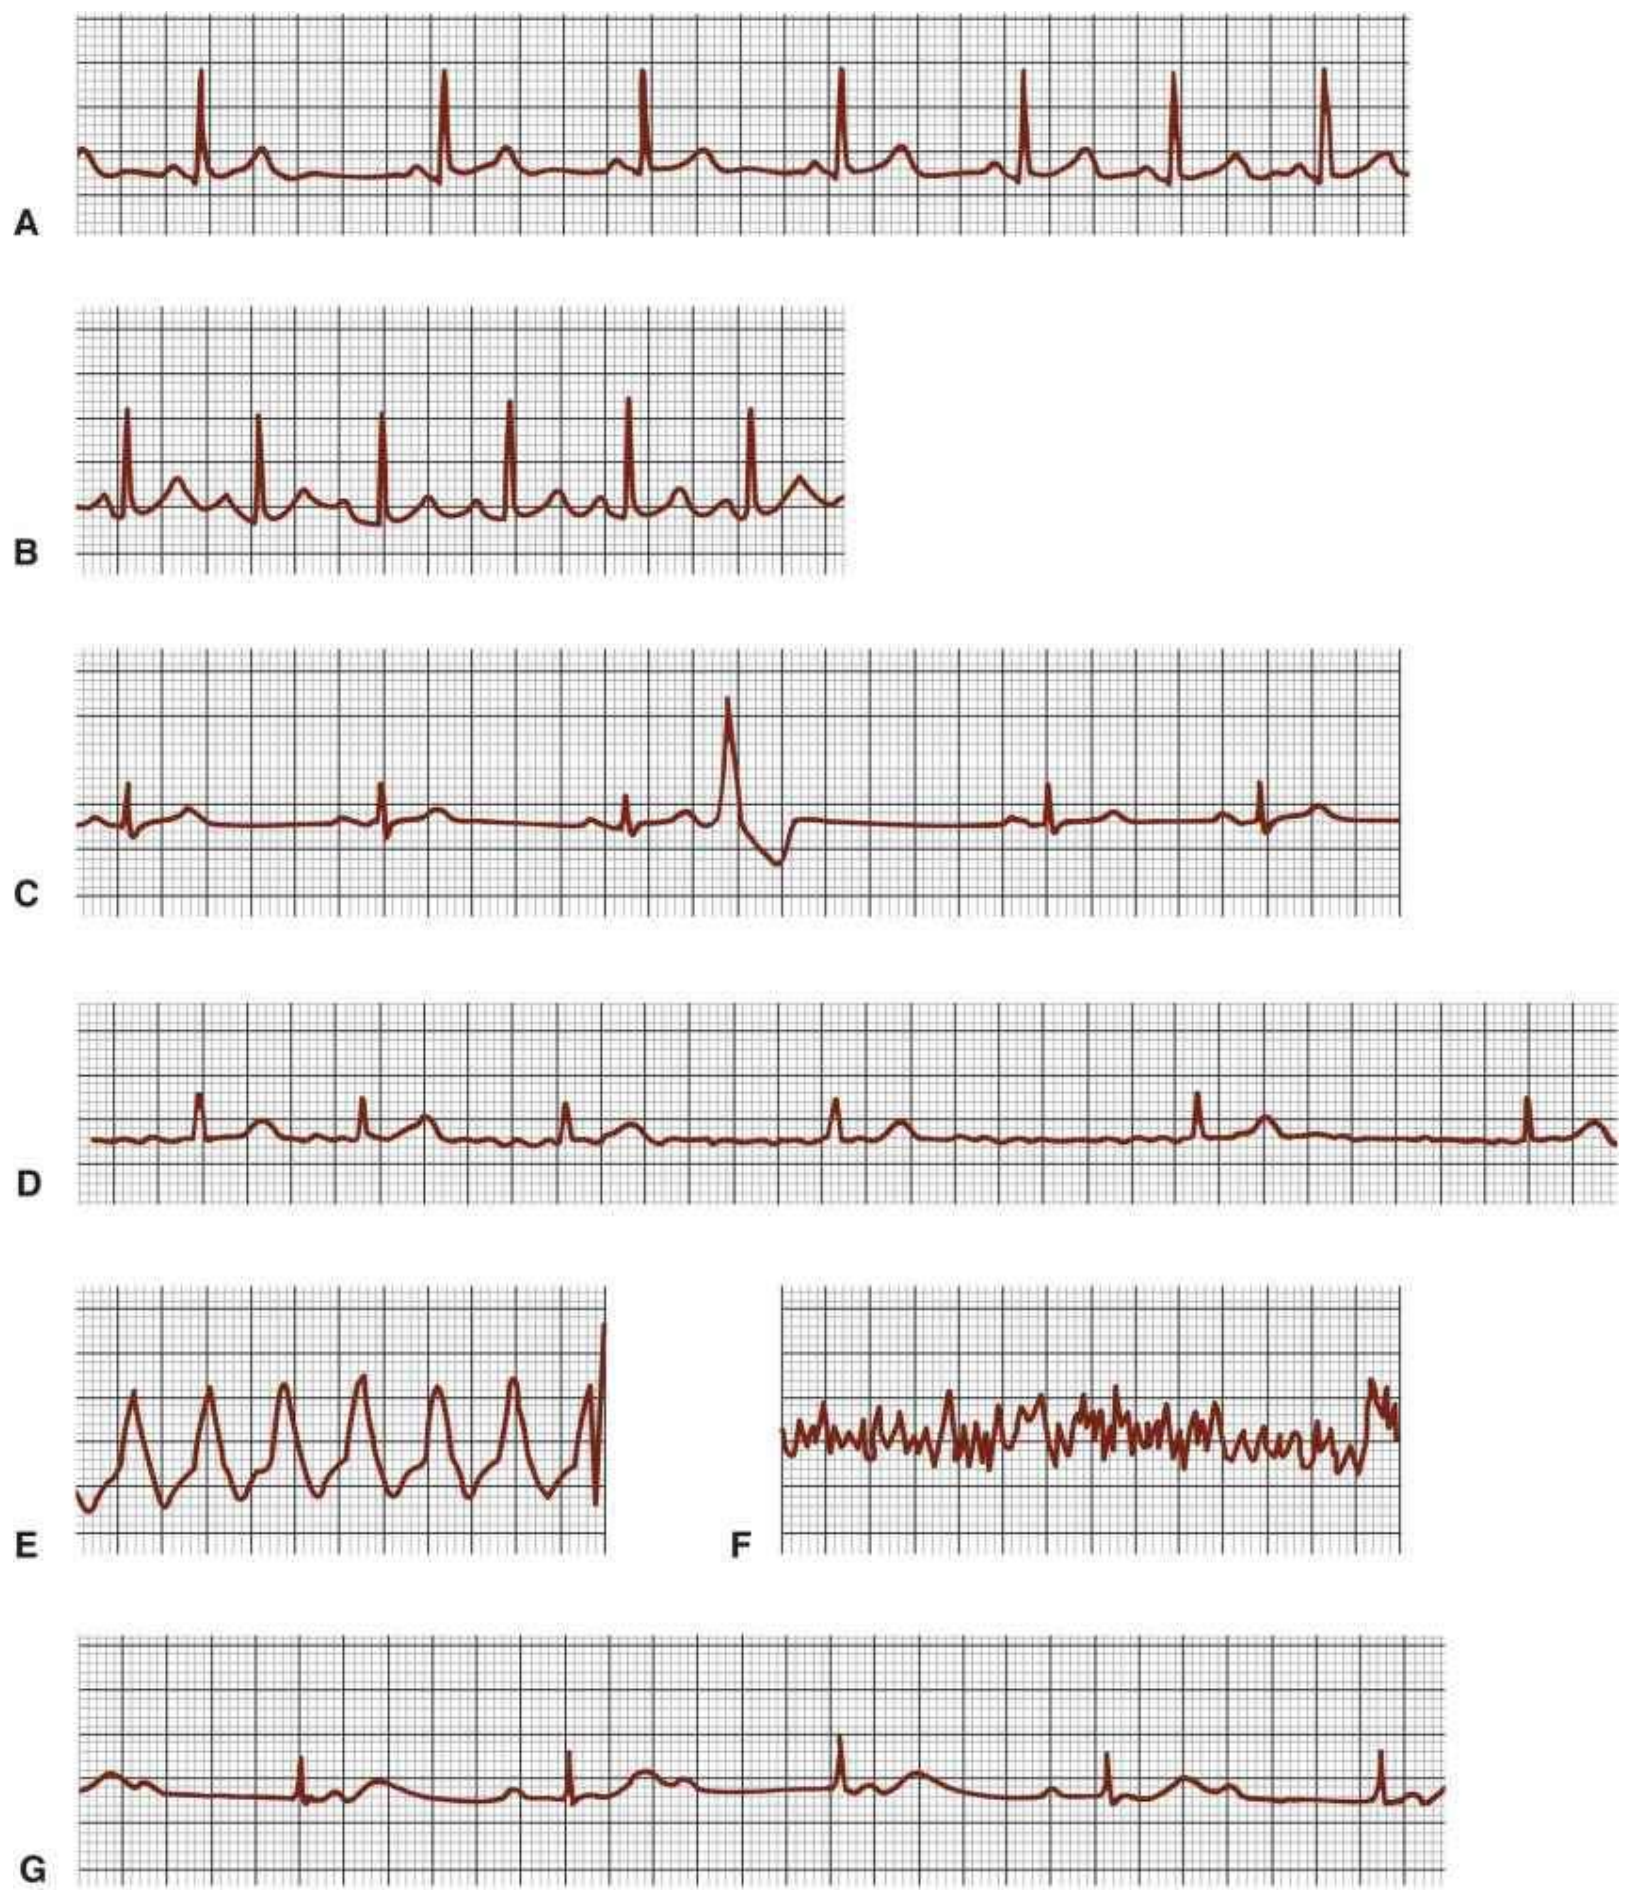

Figure 12.14 Electrocardiograms (lead II) showing abnormal and normal variations in heart rhythms. (**A**) Respiratory sinus arrhythmia. **(B)** Sinus tachycardia. **(C)** Premature ventricular complex. **(D)** Atrial fibrillation. **(E)** Ventricular tachycardia. **(F)** Ventricular fibrillation. **(G)** Complete atrioventricular block.

In the tracing in Figure 12.14B, the pattern of P, QRS, and T waves is normal but the interval between successive P, QRS, or T waves is much shorter than normal. This represents an SA node–driven increase in heart rate and is called a **sinus tachycardia**. Conversely, a slow SA node–driven heart rate is called a **sinus bradycardia** (image not shown). These patterns would be seen in a healthy person during acute exercise or in a well-conditioned athlete during rest, respectively.

Occasionally, the heart will be activated by the spontaneous generation of an action potential in one of the ventricular cells. Such an ectopic foci and its effect on the ECG are shown in Figure 12.14C. The first three QRS complexes in this panel are preceded by P waves; then, after the T wave of the third QRS complex, a QRS complex of increased voltage and longer duration occurs. This complex will result in a PVC, or premature ventricular contraction. The term PVC is used to designate the appearance of the firing of the ventricular ectopic foci on the ECG even though the ECG is the electrical, not mechanical, representation of the event. The premature complex in this example is not preceded by a P wave and is followed by a pause before the next normal P wave and QRS complex. In panel C, the ectopic focus is probably in the Purkinje system or ventricular muscle, where an aberrant pacemaker reached threshold before being depolarized by the normal wave of excitation. Once the ectopic focus triggers an action potential, the excitation is propagated over the ventricles. The abnormal pattern of excitation accounts for the greater voltage, change of mean electrical axis, and longer duration (inefficient conduction) of the QRS complex. Although the abnormal wave of excitation reached the AV node, retrograde conduction usually dies out in the AV node because the node preferentially conducts in the antegrade direction. The next normal atrial excitation (P wave) occurs but is hidden by the inverted T wave associated with the abnormal QRS complex. This normal wave of atrial excitation does not result in ventricular excitation because, when the impulse arrives at the AV node, a portion of the node is still refractory from excitation by the PVC. As a consequence, the next “scheduled” ventricular beat is missed. A prolonged interval following a premature ventricular beat is called a **compensatory pause**.

Ectopic pacemakers can also occur in the atria, where they are called **premature atrial contractions** (**PACs**). Occasional PVCs or PACs are not uncommon in healthy people. However, the probability of their occurrence is increased by cigarette smoking, nicotine in any form, physical or emotional stress, caffeine, and fatigue. In some circumstances, atrial ectopic foci fire in a random, or chaotic, manner. This is shown in Figure 12.14D, which is an ECG from a patient with **atrial fibrillation**. In this condition, many small, random waves of depolarization occur in the atria such that actual, concentrated atrial contraction does not occur. In a patient with atrial fibrillation, the AV node conducts action potentials whenever a wave of atrial excitation happens to reach it and it is not refractory to activation. Thus, the ventricles are activated in a “hit or miss” fashion. The resulting ventricular rate is consequently highly irregular and can be detected in the patient as a highly irregular arterial pulse. Unless there are other abnormalities, conduction through the AV node and ventricles is normal, and the resulting QRS complex is normal. However, without a concentrated area of depolarization in the atria, the ECG shows QRS complexes that are not preceded by P waves. Atrial fibrillation is associated with numerous disease states, such as cardiomyopathy, pericarditis, hypertension, and hyperthyroidism, but it sometimes occurs in otherwise healthy people.

Sometimes, specific atrial ectopic foci can fire repetitively at a high rate, serving as an ectopic pacemaker that drives the ventricles. Such atrial ectopic foci can fire regularly at a rate of >200 times/min. This high rate of atrial activation can get through the AV node and activate the ventricles at the same rate. This is called **supraventricular tachycardia**. Such a condition may pace the heart at a rate too fast to allow adequate ventricular filling during diastole. Because pacing of the heart in this condition results from an ectopic focus in the atria, the resulting ECG may look similar to that of a person with sinus tachycardia.

An abnormally high rate of ventricular activation generated from ventricular ectopic foci is called **ventricular tachycardia** (Fig. 12.14E). Ventricular tachycardia results in a bizarre inefficient activation of the ventricles and extremely high heart rates that limit the period of ventricular filling. When filling is compromised, the flow output of the heart falls. This can result in syncope (dizziness/fainting) and can even lead to sudden death. Ventricular tachycardia is often a prelude to the life-threatening event of **ventricular fibrillation** (Fig. 12.14F). Ventricular fibrillation is characterized by the random, uncoordinated activation of millions of ventricular cells and results in no pumping of blood by the heart. Unless the heart can be converted through intervention to a regular rhythm, ventricular fibrillation will result in death.

In some situations, there is a disconnect between the electrical activation of the atria and the ventricles. This results from an impairment of the conduction of action potentials from the atria through the AV node and can result in a dissociation of P waves and QRS complexes in the ECG. In Figure 12.14G, both P waves and QRS complexes are present, but the timing of each is independent of the others. This situation is called **complete atrioventricular block** (sometimes called *third-degree block* or *complete heart block*) because the AV node fails to conduct impulses from the atria to the ventricles. Because the AV node is the only electrical connection between these areas, the pacemaker activities of the two muscles become entirely independent. In addition, a secondary pacemaker must take over the regular pacing of the heart. Because this usually involves the AV node or Purkinje systems that have low intrinsic rhythmicity, the heart will be paced at a lower-than-normal rate. In this example, the distance between P waves is about 0.8 seconds, giving an atrial rate of 75 beats/min. However, the distance between R waves averages 1.2 seconds, giving a ventricular rate of 50 beats/min. It is this rate that is responsible for pumping blood from the heart. In this example, the atrial pacemaker is probably in the SA node, and the ventricular pacemaker is probably in a lower portion of the AV node or bundle of His. Patients with complete atrioventricular block cannot resume normal activity without having an electronic pacemaker device permanently implanted in their chest to pace the heart at a faster rate.

AV block is not always complete. Sometimes, the PR interval is lengthened beyond normal limits (e.g., >0.2 seconds), but all atrial excitations are eventually conducted to the ventricles. This is **first-degree atrioventricular block**. When some, but not all, of the atrial excitations are conducted by the AV node, the block is called **second-degree atrioventricular block**. Second-degree heart block is often divided into two subtypes; type I (or Wenckebach) and type II (or Mobitz). In type I 2nd-degree heart block, the P–R interval gets successively longer with each heart beat until a P wave fails to be conducted to the ventricles, resulting in a pause of the heart. In this case, the R–R interval after the pause is less than the preceding R–R waves and more than the R–R interval after the pause. In type I 2nd-degree block, P–R intervals are normal, but occasionally, a P wave appears and is not conducted to the ventricles.

In some disease states, either the left or right branch of the bundle of His cannot transmit excitation. Depending on the branch affected, this type of heart block is called **right bundle branch block** or **left bundle branch block**. In these conditions, the portion of the heart with the blocked branch receives delayed activation from the unblocked side of the ventricles because the route of activation is less efficient. The resulting QRS complex becomes widened and will sometimes display a characteristic split in the R wave, creating a double-positive spiked appearance of the QRS complex. These twin spikes are designated as R and R^1.

Changes in electrically active ventricular mass are obtained by contrasting the ECGs from multiple leads.

In the healthy heart, the left ventricle is larger than the right and dominates the resulting QRS complex. Leads with positive poles most closely aligned on the left side of the body yield the most positive average QRS deflections (e.g., leads I, II, V_5, and V_6). Indeed, the only ECG lead that shows an average negative QRS deflection in a healthy person is aVR because the normal wave of activation of the ventricles proceeds away from this positive electrode. In addition, the ECGs from a healthy heart recorded from the precordial leads create a pattern of progressively greater average positive deflections from V_1 to V_6.

Chronic pulmonary hypertension or pulmonary emboli increase stress on the right ventricle each time it contracts. Over time, this creates **right ventricular hypertrophy**, or a larger than normal mass of the right ventricle. This mass pulls the net dipoles during ventricular activation to the right and can create mirror image deflections of the QRS complex in all the leads compared with that seen in the healthy heart. For example, lead aVR becomes positively deflected, V_6 downwardly deflected, V_1 net positively deflected, and so on. The recording in Figure 12.15 shows some effects of right ventricular enlargement on the ECG. The increased mass of right ventricular muscle results in R waves greater than S waves in lead V_1, which is the opposite of the pattern seen in the normal heart. This increased right ventricular mass also creates a large S waves in lead I and a larger than normal R waves in lead aVF. Finally, right ventricular hypertrophy causes a shift in the dipole of ventricular depolarization to the right (i.e., **right axis deviation**, QRS vector at +120° to +180°).

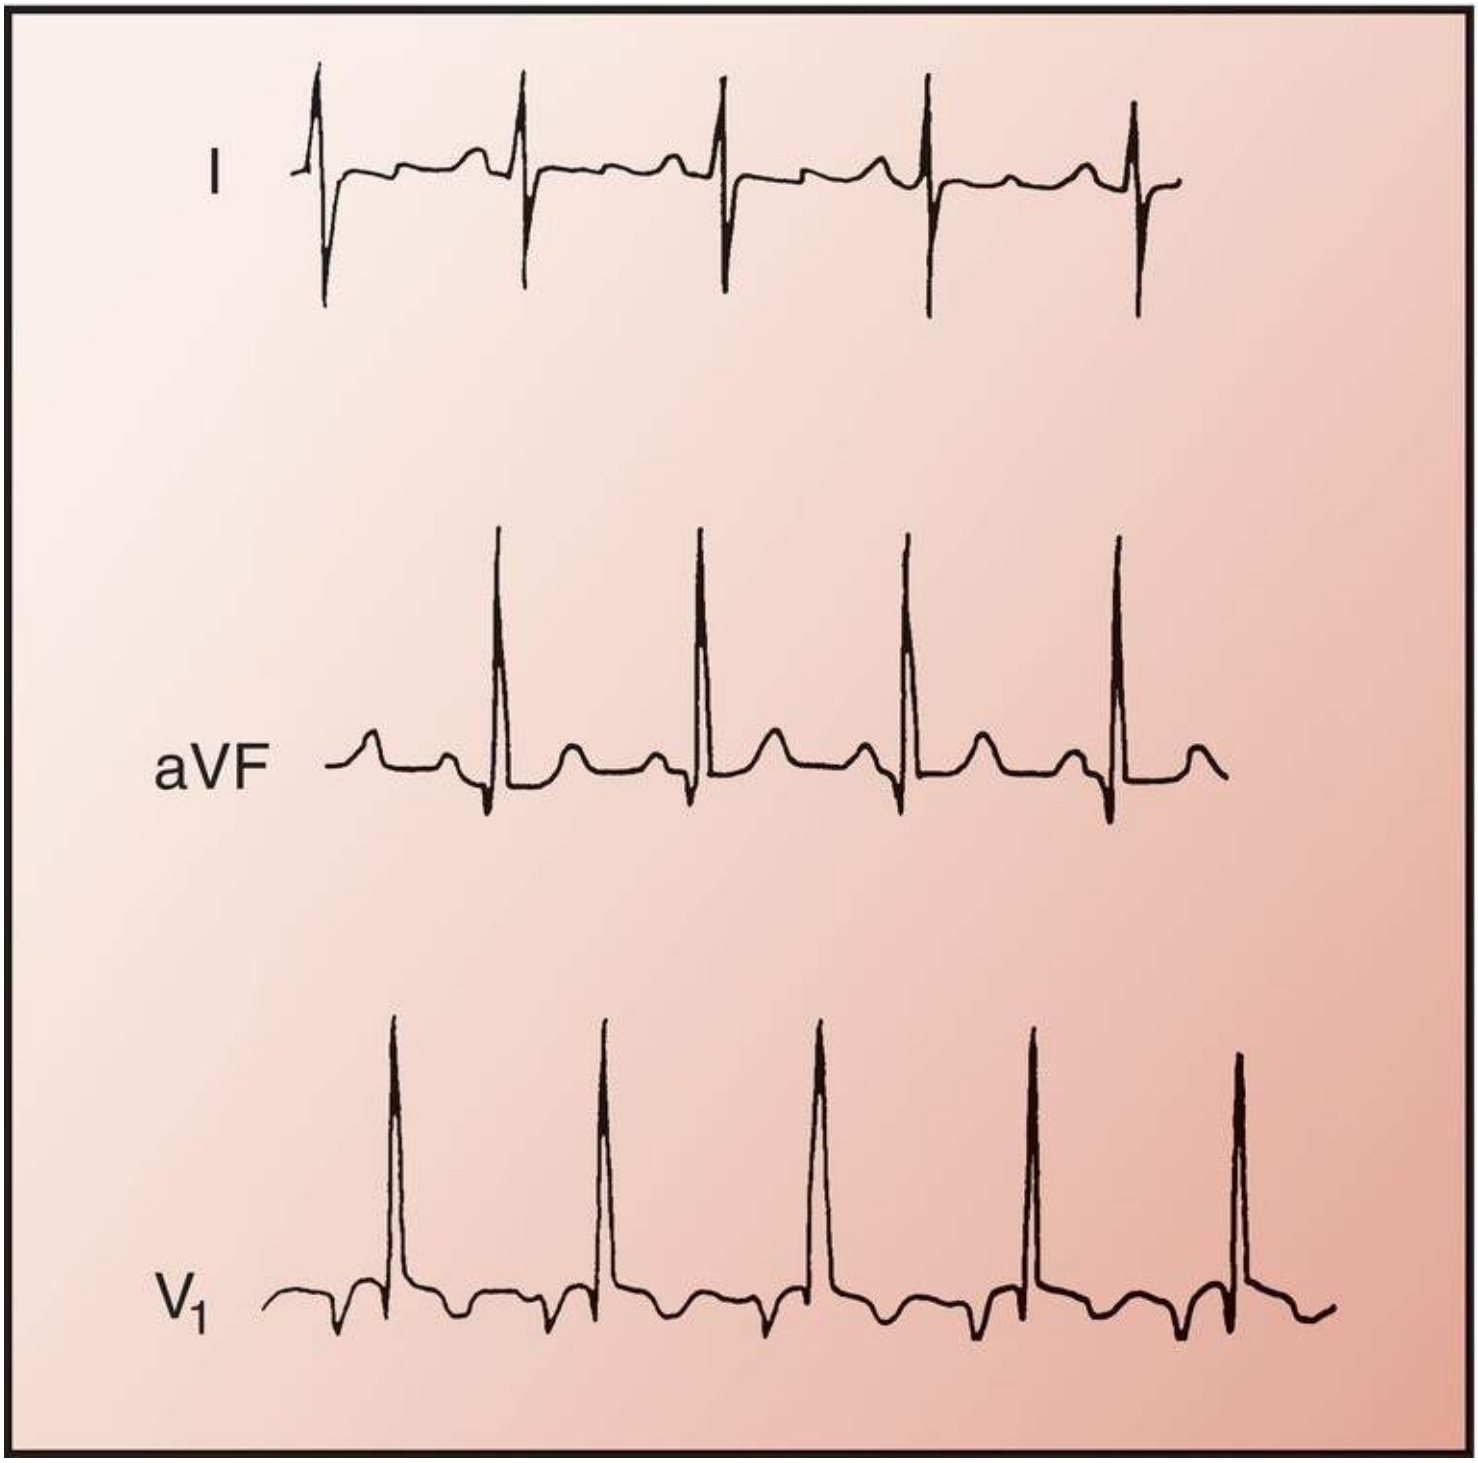

Figure 12.15 Effects of right ventricular hypertrophy on electrocardiogram recordings. Leads I, aVF, and V_1 of a patient are shown.

Other types of cardiac hypertrophy can be detected through the examination of simultaneous waveforms from different ECG leads. For example, Figure 12.16A shows an ECG from a patient with atrial hypertrophy. This is reflected by the P waves of lead III, which have a higher amplitude than normal because of the enlarged muscle mass of the atria. Figure 12.16B represents an ECG characteristic of left ventricular hypertrophy. In contrast to the ECG from a normal heart, there is a prominent S wave in V_1 and V_5 and the R waves are > +35 mm, which together are considered indicative of left ventricular hypertrophy. R waves > 11 mm in aVL or 15 mm in lead I are also indicative of left ventricular hypertrophy. Left ventricular hypertrophy rotates the direction of the major dipole associated with ventricular depolarization more to the left than usual (i.e., **left axis deviation**, a negative QRS vector >

−30°).

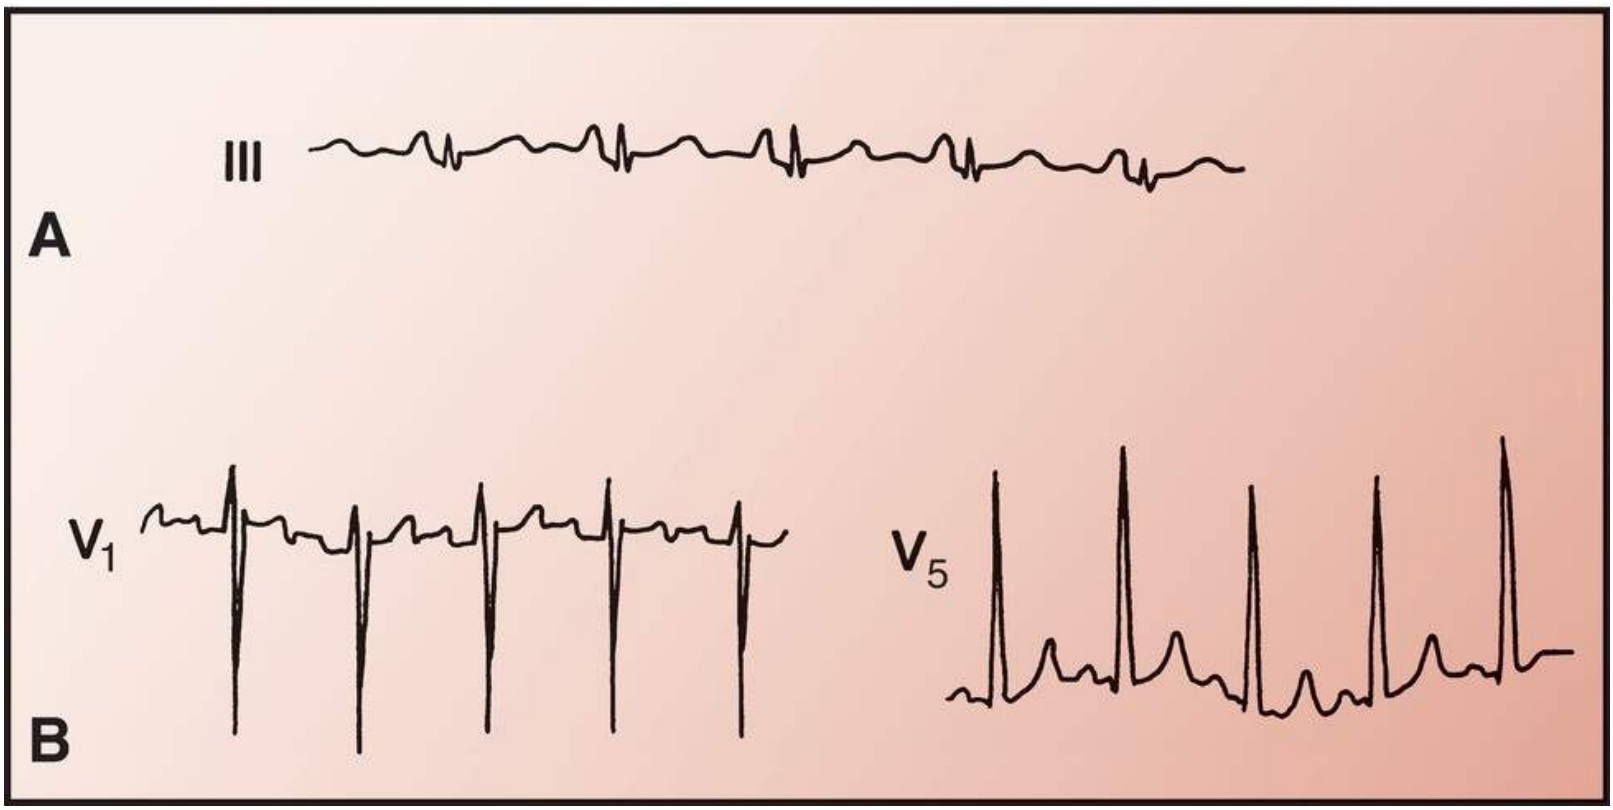

Figure 12.16 Effects of atrial and left ventricular hypertrophy on electrocardiogram recordings. (A) Large P waves (lead III) caused by atrial hypertrophy. **(B)** Altered QRS complex (leads V_1 and V_5) produced by left ventricular hypertrophy.

Metabolic conditions, drug effects, and myocardial injury can be detected by unique features of individual ECG waveforms.

Individual ECGs often contain tell-tale indicators of certain abnormal conditions. For example, plasma electrolyte disturbances create signature abnormalities in the ECG. Hyperkalemia alters potassium conductance in phase 3 of the cardiac action potential and thus affects repolarization patterns in the ventricles, resulting in a characteristic spiking or “mountain” characteristic of the T wave (Fig. 12.17). Hypokalemia also affects the myocardium in phase 3 and produces a characteristic flattened T wave followed by a secondary repolarization ECG wave, designated by the letter U. Both of these unique ECG waveforms are valuable indicators to clinicians because high plasma K^+ levels can induce fibrillation in the heart, whereas low K^+ can seriously suppress cardiac excitability and prevent cardiac activation.

CLINICAL FOCUS 12.2

Electrocardiogram Exercise Testing

Myocardial ischemia is one of the most dangerous cardiac conditions existing in patients with common forms of coronary artery disease, hypertension, heart failure, and arrhythmias. The electrocardiogram (ECG) can easily detect ischemia in a patient but only while the patient is connected to the ECG recorder. In the case of patients with coronary artery disease, the oxygen demand of the heart at rest may be within the ability of the compromised coronary artery system to deliver oxygen to the tissues (see Chapters 15 and 16 for more details). Thus, when the patient is at rest (e.g., at the doctor's office), evidence of myocardial ischemia may not appear on the ECG. However, should the oxygen demands of the heart increase from increased physical activity or emotional stress in the patient, the heart's diseased arterial system may not be able to meet the new, higher oxygen demand and the heart will become ischemic. This condition can result in heart attack and death.

Cardiac stress testing uses the ECG coupled with exercise as a means to examine the limits of oxygen delivery in the heart of patients with coronary artery disease. This testing has many clinical modalities but all basically create increased oxygen demand in the heart through exercise while the patient's ECG and/or hemodynamic indicators are measured. Isometric stress (handgrip), dynamic (aerobic) stress (such as bicycle or treadmill ergometry), or combinations of the two are used to increase oxygen demand in the heart and in the body as a whole. The response of the patient as well as the response of the heart to this increased demand is monitored and analyzed. Extensive clinical guidelines for using and interpreting exercise stress testing have been developed and are continually updated by the American Heart Association and other professional cardiopulmonary or sports medicine groups.

Exercise testing has long been used for the diagnosis of the hemodynamic consequences, or severity, of obstructive coronary artery disease. Such obstructions do not often manifest themselves at rest but can be revealed by evidence of myocardial ischemia on the ECG and by other means during exercise stress testing. The use of exercise stress testing to reveal this "silent coronary artery disease" is invaluable to the clinician. ■

Calcium is one of the triggers for increasing potassium conductance during phase 3. Abnormally low serum Ca^{2+} levels can thus delay the repolarization of the ventricles, and this is revealed on the ECG as an abnormally long QT interval, which can predispose the heart to EADs. Similarly, many antiarrhythmic drugs exert their effects by either increasing or decreasing the electrical refractory period in the ventricles. The toxic effects of such drugs can be detected by their effect on the QT interval of the ECG.

Finally, the clinically useful indication of myocardial ischemia, injury, and infarction (tissue death)

can be detected by the ECG. One of the first signs of ischemia in the heart is an inversion of the T wave, as shown in Figure 12.18. Acute injury to the myocardium resulting from progressive ischemia results in an easily detected elevation of the ST segment. Infarction, or death of myocardial tissue, is recognized by the development of Q waves in front of these elevated ST segments. Old infarctions also present with abnormal Q waves in patients but without the elevated ST segment associate with acute ischemia. With myocardial ischemia, the cells in the ischemic region partially depolarize to a lower resting membrane potential because of a lowering of the potassium ion concentration gradient, although they are still capable of firing action potentials. As a consequence, a dipole is present during the TP interval in injured hearts because of the voltage difference between normal (polarized) and abnormal (partially polarized) tissue. However, no dipole is present during the ST interval because depolarization is uniform and complete in both injured and normal tissue (this is the plateau period of ventricular action potentials). Because the ECG is designed so that the TP interval is recorded as zero voltage, the true zero during the ST interval is recorded as a positive or negative deflection.

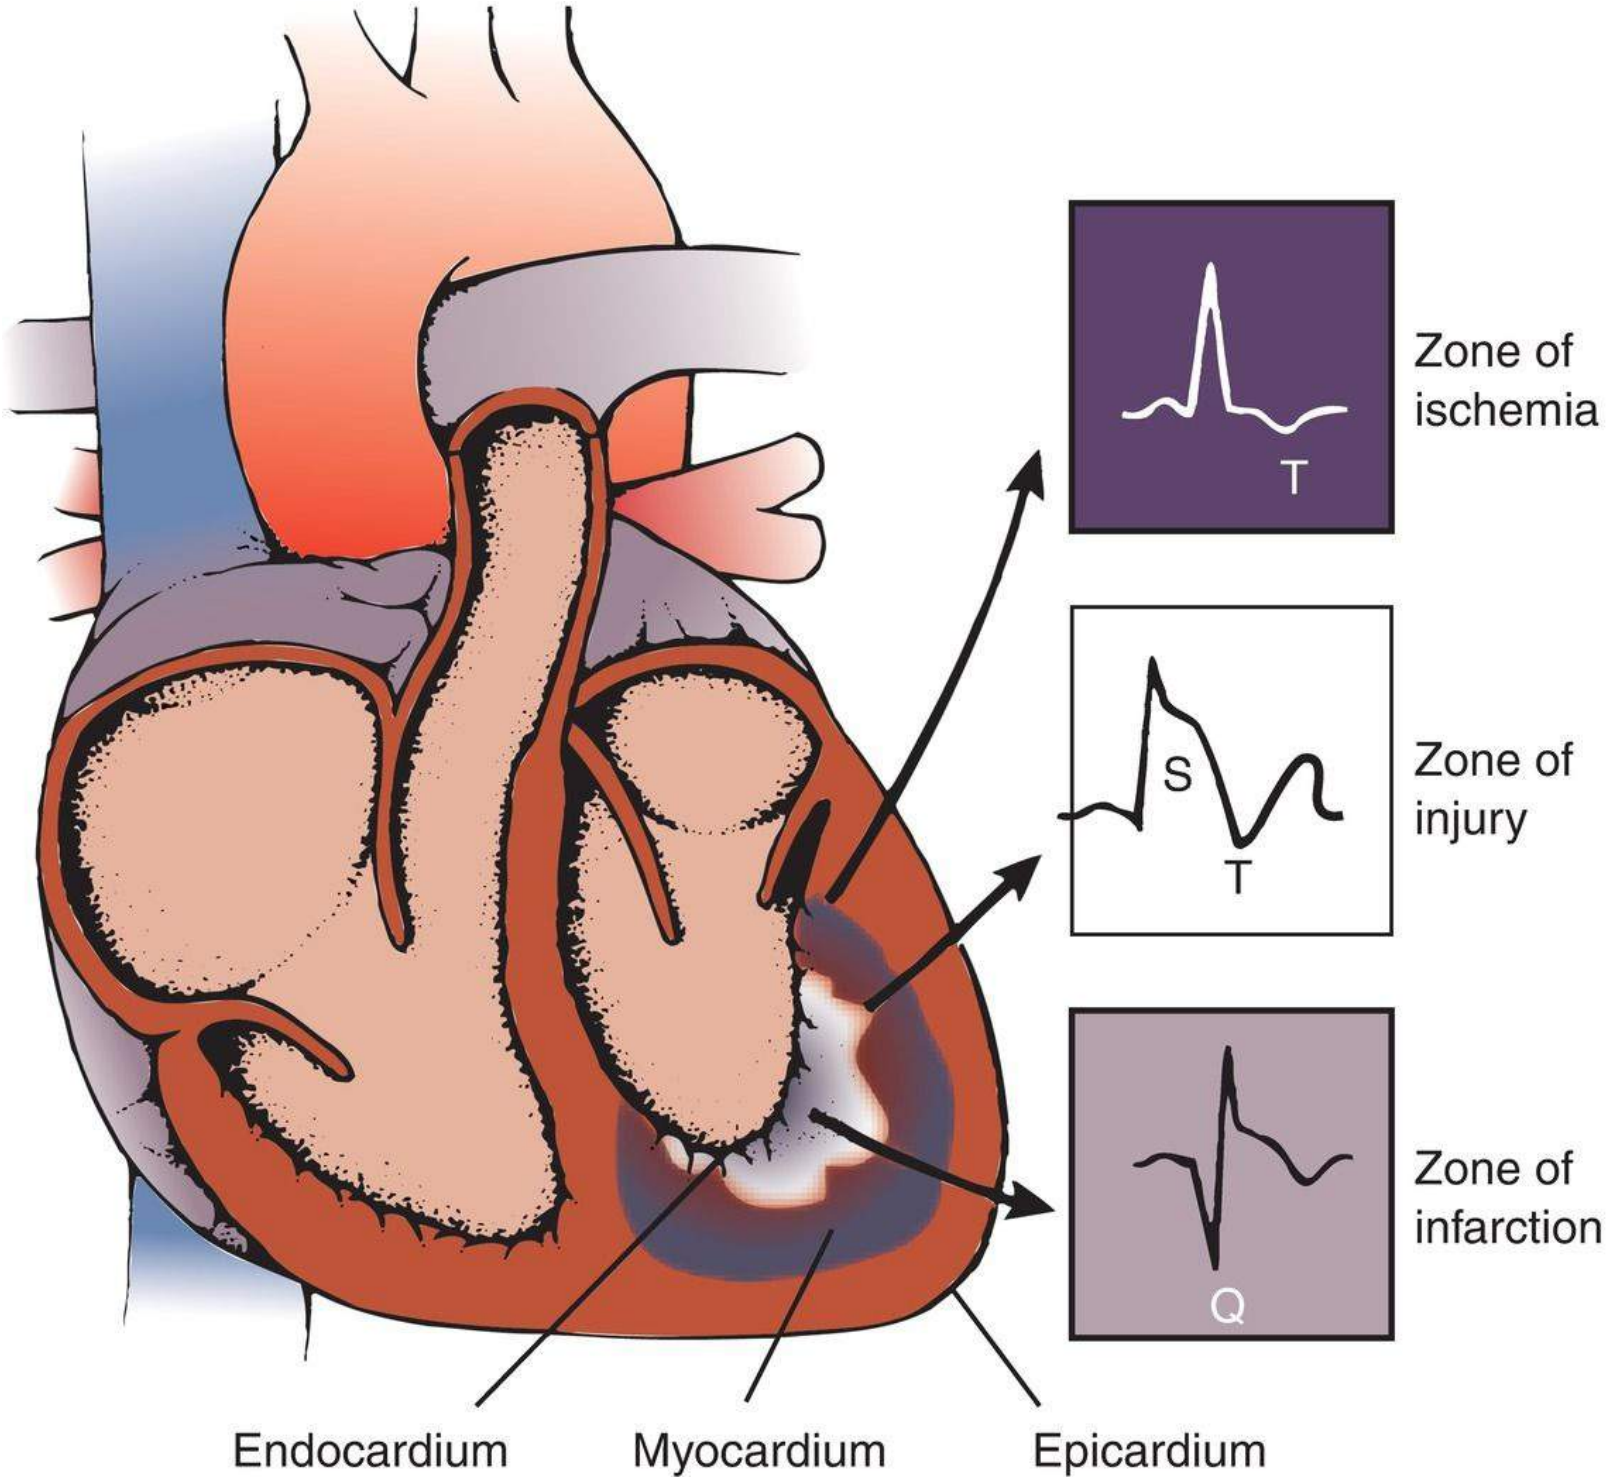

Figure 12.18 Electrocardiogram (ECG) changes associated with myocardial ischemia. The initial effects of ischemia create an inverted T wave in the ECG. The distinctive ST segment elevation in ischemic myocardium is associated with myocardial injury. The apparent zero baseline of the ECG before depolarization is below zero because of partial depolarization of the injured area. After depolarization (during the action potential plateau), all areas are depolarized and true zero is recorded. Because zero baseline is set arbitrarily (on the ECG recorder), a depressed diastolic baseline (TP segment) and an elevated ST segment cannot be distinguished. Regardless of the mechanism, this is referred to as an elevated ST segment. The ECG of a patient with acute myocardial infarction produces a Q wave in association with ST segment elevation. An abnormal Q wave without ST segment elevation (not shown) is indicative of an old myocardial infarction.

INTEGRATED MEDICAL SCIENCES

Sodium Channel Blockers for the Treatment of Cardiac Arrhythmias

Cardiac arrhythmias refer to any deviation from normal in the origin, conduction, or rhythm of the electrical activation of the heart. Such deviations in activation can result in erratic and insufficient mechanical activation of the heart such that blood flow output to peripheral organs is compromised. Some such arrhythmias can cause a patient to collapse and even die. The diagnosis of cardiac arrhythmias is aided greatly by detailed analyses using the electrocardiogram. However, management of many arrhythmias in patients is exceptionally challenging. Many drugs that modify cardiac electrical processes have been employed for the control and management of arrhythmias. Although these drugs can often be proarrhythmic and come with many other side effects, they are still used extensively as pharmacotherapy for many types of arrhythmias. These drugs have different, diverse, effects on electrical properties of cardiac cells. As an aid to organizing antiarrhythmic agents, these drugs have been collated into four categories (I, II, III, and IV) based on key electrophysiological properties common to the drugs in each category. Type I agents are called sodium channel antagonists because they impair the fast sodium channel kinetics in myocardial cells. Beta-adrenergic receptor antagonists (inhibitors) comprise the type II antiarrhythmics. Type III agents are primarily potassium channel inhibitors that extend the myocardial cell refractory period. And type IV agents are comprised of the calcium channel blockers, verapamil and diltiazem as well as adenosine.

Type I agents slow phase 0 of the myocardial action potential and thereby slow conduction of action potentials through the myocardium. There are actually three subclasses of type I agents. Type I_A drugs show moderate phase 0 inhibition though they also tend to block K^+ channels and therefore extend cell refractory period. By impairing sodium channel operation, they tend to raise the effective action potential threshold in atrial and ventricular cells and thereby reduce cell excitability. These agents are most effective in ischemic tissue. Their salutatory effect is to convert unidirectional conduction blocks in damaged myocardium into bidirectional blocks thereby quashing reentry arrhythmias. Quinidine (a derivative of quinine), procainamide, and disopyramide belong to this subclass. Although these agents can be used to treat various atrial and ventricular arrhythmias as well as reentry tachycardias, they are so fraught with undesirable autonomic and other side effects that they are generally reserved for acute treatment of life-threatening arrhythmias. Quinidine, in particular, is so cardiotoxic that it has to be discontinued in roughly 50% of patients after just a single use. Class I_B agents have the smallest phase 0 sodium channel effect of the type I agents. Their primary beneficial effect is that they enhance K^+ conductance in Purkinje fibers without altering the resting membrane potential. This enables these cells, which are often prone to form ectopic foci, to more easily counteract depolarizing stimuli that could otherwise create an ectopic foci. These agents gain access to the fast sodium channel in the active and inactive state so they are especially effective in rapidly cycling or partially depolarized tissue. For this reason, they reduce conduction velocity in ischemic tissue but not normal myocardium and are especially effective in reducing ectopic-based tachycardias. Lidocaine is the prototypical drug in this class, which are the agents of choice in the acute treatment of sustained ventricular tachycardia and the prevention of ventricular fibrillation. Agents in this class

have anesthetic properties and cause CNS disturbances, which make them unsuitable for anything other than very short-term control of arrhythmias. Class I_c agents produce the most marked phase 0 depression in myocardial cells. Flecainide was one of the early drugs developed in this category, which also includes the agent propafenone. These agents however tend to be actually proarrhythmic in many instances and are therefore rarely used. Flecainide has actually been shown to increase mortality in arrhythmic patients.

The complex effects and side effects of Class I agents make them difficult to use in the long-term management of arrhythmias. Similar problems are associated with Class III agents as well. For this reason, current clinical management utilizes surgical and medical device modalities for the long-term treatment of arrhythmias. Fluoroscopic cardiac catheterization procedures and sophisticated electrophysiological recording analyses are now used to pinpoint areas of ectopic foci, which can then be physically destroyed by cryo- and radio ablation catheters, which can be inserted into the CV system and guided to the area of ectopy. Implantable, programmable, cardiac pacemaker/defibrillator units are now being used as a surgical solution to both abnormal bradyarrhythmias (pacemaker capability) as well as sudden emergent ventricular tachycardia or fibrillation (automatic fibrillation detection and electrical defibrillation). ■

Chapter Summary

- Cardiac cells do not require signals from nerve fibers to generate action potentials.
- Specialized nodal tissue cells exhibit the properties of automaticity and rhythmicity.
- Gap junctions at nexus between adjacent cells allow the heart to behave as a functional syncytium.
- Opening of voltage-gated sodium and calcium channels and the closing of voltage-gated potassium channels initiate action potentials in cardiac muscle cells.
- Action potentials in atrial and ventricular muscle cells have an extended depolarization plateau that creates an extended refractory period in the cardiac muscle cell.
- Cardiac muscle cells are repolarized following the depolarization phase by the closing of voltage-gated calcium channels and the opening of voltage-gated and ligand-gated potassium channels.
- A recycling decay and resetting of potassium conductance in the nodal cell membrane create recycling pacemaker potentials in the sinoatrial node.
- The sinoatrial node initiates electrical activity in the normal heart.
- Norepinephrine increases pacemaker activity and the speed of action potential conduction, whereas acetylcholine decreases pacemaker activity and the speed of action potential conduction.
- Electrical activity initiated at the sinoatrial node spreads preferentially in sequence across the atria, through the atrioventricular node, through the Purkinje system, and to ventricular muscle.
- The atrioventricular node delays the entry of action potentials into the ventricular system.
- Purkinje fibers transmit electrical activity rapidly into the inner layers of the ventricular myocardium.
- The conduction of electrical activity through the myocardium is a function of the amplitude of action potentials and the rate of rise of depolarization of action potentials in phase 0.
- An electrocardiogram is a recording of the time-varying voltage differences between repolarized and depolarized regions of the heart.
- The electrocardiogram provides clinically useful information about the rate, rhythm, pattern of depolarization, and mass of electrically active cardiac muscle.
- Changes in cardiac metabolism and plasma electrolytes as well as the effects of medicinal drugs on the electrical activity of the heart can be detected by an electrocardiogram.

Chapter Review Questions

1. The cardiac glycoside, digitalis, is a common agent used for the treatment of heart failure. This agent inhibits the Na^+/K^+ ATPase in all heart cells. Its therapeutic benefit arises from its effect in ventricular tissue where it causes intracellular calcium concentration to rise and enhances the contractile force that can be generated by the failing heart. However, the electrophysiological effects of a therapeutic concentration of this drug also alter Purkinje fibers in a manner that make them prone to the creation of ectopic foci and ventricular arrhythmias. The mechanism for these electrophysiological effects of a therapeutic level of digitalis most likely is because this drug will:

A. Bring Purkinje fibers cells closer to their action potential threshold and reduce the action potential refractory period

B. Bring Purkinje fibers closer to their action potential threshold and increase the action potential refractory period

C. Bring Purkinje fibers farther from their action potential threshold and increase the action potential refractory period

D. Block activation of sodium and calcium channels in Purkinje fibers

E. Inactivate outwardly rectifying K^+ channels in Purkinje fibers

The correct answer is A. Inhibition of the Na^+/K^+ ATPase results in partial depolarization of the cell membrane thus bringing the myocardial cells closer to their threshold. Increases in intracellular calcium activate outwardly rectifying potassium channels in myocardial cells that terminate the depolarization phase of the action potential. This, therefore, shortens the cell refractory period. The effects of digitalis then on both the resting membrane potential and action potential refractory period increase the probability that Purkinje fibers can fire their own action potentials and do so at a high repetitive rate. Total blockade of sodium and calcium ion channels responsible for action potential formation would stop the heart. Therefore, this could not be a therapeutic effect of digitalis. Inhibiting outward rectifying potassium channels would extend, not shorten the refractory period of Purkinje fibers.

2. In a patient with left ventricular hypertrophy, which of the following ECG leads would register the most negative mean amplitude in the QRS complex?

A. Lead I

B. V_5

C. Lead III

D. Lead aVR

E. aVF

The correct answer is C. In left ventricular hypertrophy, the increased left-sided muscle mass swings the mean QRS axis strongly to the left beyond the normal limit of –30°. At this angle, the mean QRS amplitude would be strongly positive in lead I. Mean QRS amplitude in aVR is negative in the normal heart; in left ventricular hypertrophy, it would be positive. Similarly, V_5 is in the area of the hypertrophy and would register a positive deflection during ventricular activation. Both leads III and aVF would show negative mean amplitudes in the QRS complex, but the angle relative to lead III would be greater away from the positive pole of that lead compared to the aVF positive poll. Therefore, lead III would show the greater negative mean amplitude.

3. Which of the following would be an indicator of an abnormal electrical condition in the heart?
   A. A mean frontal QRS vector at 67°
   B. PR interval of 180 msec
   C. A negative QRS deflection in lead III
   D. Presence of a T wave in lead II
   E. A positive average QRS deflection in lead aVR

The correct answer is E. A positive mean QRS deflection in lead aVR would imply that action potentials originated near the apex of the heart with the ventricles then being activated from the apex to the base, or in a retrograde fashion. This is the opposite of the typical path of activation. A mean QRS vector of + 67° and a PR interval of 180 msec are normal, and T waves are not abnormal occurrences in ECG leads. A normal heart could have a mean QRS vector between – 10° and + 30°. Such normal vectors would nevertheless produce a negative mean amplitude of the QRS complex in lead III.

4. Several antiarrhythmic drugs prolong phase 3 of the ventricular action potential. The clinical electrophysiological presentation of a patient on this drug would most likely resemble one with:
   A. High-amplitude spiked T waves on the ECG and hyperkalemia
   B. Prolonged QT intervals on the ECG and increased probability of forming early afterdepolarizations (EADs)
   C. Shortened PR intervals on the ECG and increased probability of forming early afterdepolarizations
   D. Split R waves on the ECG (i.e., an R followed by an R′ wave)
   E. Prolonged QRS intervals and second-degree heart block

The correct answer is B. Early afterdepolarizations (EADs) are action potentials that fire in cardiac cells (usually Purkinje fibers) during phase 3 of the action potential. Any factor that prolongs phase 3 of action potentials in cardiac cells makes those cells prone to the formation of EADs. Phase 3 of the cardiac action potentials represents the rapid repolarization phase of the action potential, which is determined, in part, by the duration of the QT interval on the ECG. Therefore, patients on drugs that prolong phase 3 of the cardiac action potential will often have prolonged QT intervals and an increased probability of forming EADs. Such drugs would not be expected to have any effect on plasma potassium concentration and would, therefore, create neither hyperkalemia in the patient nor its associated characteristic spiked T wave on the ECG. PR intervals occur before activation of the ventricular myocardium and reflect conduction time between activation of the atria and the start of activation of the ventricles; they are not indicative of any phase 3 phenomena in the ventricular myocardium. Split R waves are characteristic of bundle branch block and are a phenomenon distinct from EADs. Prolonged QRS intervals reflect the duration of conduction of action potentials through the ventricular myocardium and not the repolarization phase of the ventricular muscle cells.

Clinical Application Exercises 12.1

A 58-year-old woman arrived in the emergency department complaining of sudden onset of palpitations, light-headedness, and shortness of breath. These symptoms began ~2 hours previously. On examination, her blood pressure is 95/70 mm Hg, and her heart rate is essentially regular but averages 170 beats/min. An ECG demonstrates an abnormally shaped P wave, but the P–R interval is within normal limits. Her physical examination is otherwise unremarkable.

QUESTIONS

1. What is the likely cause of the patient's high heart rate?
2. Postulate why the patient was lighted, dizzy, and short of breath.
3. If you were to use a drug to manage this patient's electrophysiological situation, what cardiac action of that drug would be beneficial in alleviating the symptoms the patient is experiencing?

ANSWERS

1. The abnormal P wave on the ECG indicates that the atria are being activated from a location other than the SA node. For this site to be able to override the automaticity of the SA node, it must have an intrinsic rate higher than that of the SA node. The essentially normal P–R interval suggests that these ectopic foci are located near the AV node, which is allowing action potentials from these foci to reach the ventricles through this normal pathway. However, because the ectopic foci have a high intrinsic rate, the ventricular rate matches that of the ectopic foci. This type of arrhythmia is called supraventricular (i.e., above the ventricles) tachycardia.
2. When the ventricular rate is extremely rapid, there is little opportunity for ventricular filling to occur; despite the high heart rate, cardiac output falls in this setting (see Chapter 13 for more detailed explanation). This leads to hypotension and associated symptoms such as light-headedness and shortness of breath.
3. Drugs that can slow conduction through the AV node are useful in treating atrial fibrillation. These include beta-blockers and L-type calcium channel blockers. By slowing AV nodal conduction, these drugs reduce the rate of excitation of the ventricles or prevent all atrial activation from activating the ventricles as well. This will result in a slowing of the ventricular rate even though the atria may be tachycardic due to the ectopic foci there. At a slower ventricular rate, there is more time for filling, and the output of the heart is increased.

13 Cardiac Muscle Mechanics and the Cardiac Pump

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how altering calcium regulatory mechanism in myocardial cells can alter the inotropic state of the heart.
- Identify the correct chronological sequence of any set of hemodynamic variables associated with the cardiac cycle.
- Identify the mechanisms responsible for the four primary heart sounds and correctly relate abnormalities in these sounds to valve defects, changes in aortic pressure, or changes in ventricular filling.
- Explain how changes in myocardial contractility can counteract inhibitory effects of reduced preload or increased afterload on cardiac muscle contraction.
- Explain how changes in preload or afterload can counteract the inhibitory effects of reduced contractility on cardiac muscle contraction.
- Use left ventricular pressure volume loops to demonstrate how changes in left ventricular end-diastolic volume, aortic pressure, and contractility affect stroke volume.
- Explain the relationship of Starling's law of the heart to the mechanisms that match the output of the right and left ventricles.
- Explain how Starling's law of the heart helps maintain cardiac output when either afterload or heart rate is increased.
- Predict how changes in heart rate, aortic pressure, stroke volume, and contractility, either alone or in combination, alter myocardial oxygen demand.
- Identify physiologic and pathologic factors that alter cardiac output through changes in ventricular filling and explain the mechanisms responsible for this alteration.
- Identify pathologic factors that are associated with a negative inotropic state in the heart and explain known mechanisms for their effect.
- Explain how the reciprocal relationship between heart rate and stroke volume helps maintain cardiac output at high heart rates and at low heart rates.
- Explain the principles of the thermodilution technique for measurement of cardiac output.
- Explain the benefits and limitations associated with modern imaging techniques for determining ventricular volumes and cardiac output.

Clinical interest in cardiac electrophysiology stems from the fact that this activity is coupled to the contraction of the heart and movement of blood through the cardiovascular system. The metabolic demands of different organs of the body and the body as a whole vary widely in an individual, and the output of blood pumped by the heart must match those demands. Clearly, the output of the heart must be able to be increased when tissue metabolic demands increase. The heart can do so by changing its rate of activation (heart rate, or beats per minute) and by changing the contractile force it generates with each beat.

The heart is made of striated muscle and shares several contractile properties with that tissue. However, two modes of enhancing contractile force in skeletal muscle, tetanic contraction and motor unit recruitment, are unavailable to cardiac muscle and therefore cannot be used to enhance contractile performance of the heart. Cardiac muscle cannot form tetanic contractions because the extended action potential refractory period of atrial and ventricular muscle fibers is too long to allow for the force of individual twitch contractions to be summated (Fig. 13.1). Furthermore, because the heart is an electromechanical syncytium, it does not possess motor units that could otherwise be recruited to enhance force generation of the heart as a whole. As discussed in the previous chapter, all healthy cells of the heart are activated with each heart beat; there are no spare units to recruit.

Figure 13.1 A representation of a cardiac muscle action potential and isometric twitch. The duration of the mechanical twitch in the muscle is completed before the muscle is over its refractory period to normal stimuli. Therefore, twitch contractions cannot be summed on one another and the muscle cannot be tetanized. ARP, absolute refractory period; RRP, relative refractory period; SNP, period of supranormal excitability.

In spite of its syncytial properties, cardiac muscle has the ability to enhance its force-generation capacity via two mechanisms that are not available to skeletal muscle. Recall that skeletal muscle exhibits an active isometric length–tension relationship whereby increases in passive length, up to an optimum length, generate more isometric force. However, because skeletal muscles are attached to fixed points on the skeleton, moving passively along the ascending limb of the length–tension curve is not done by that tissue to adjust contractile force. The heart, in contrast, is a hollow, compliant, organ. It can, and does, have its force generation modified by moving along the ascending limb of the length–tension relationship. Finally, skeletal muscle fibers do not contain mechanisms whereby the intrinsic force-generation capacity of individual cells can be enhanced by normal physiological means. In contrast, the force-generation capacity of the heart muscle can be altered at the level of the individual cell.

CARDIAC EXCITATION–CONTRACTION COUPLING

Coupling of electrical activity in the heart to myocardial contraction uses mechanisms similar to those previously discussed for skeletal muscle. Cardiac cells contain an extensive network of T tubules that extend longitudinally along myocardial fibers (in contrast to the radial arrangement in skeletal muscle). As in skeletal muscle, these carry action potentials deep into the cell, where they open dihydropyridine (DHP) calcium channels that are coupled to ryanodine-sensitive calcium release channels in the sarcoplasmic reticulum (SR). The actin–myosin crossbridge cycling and its control through Ca^{2+}/troponin/tropomyosin interactions are essentially the same in both forms of striated muscle. Finally, both muscles use Ca^{2+} adenosine triphosphatase (ATPase) pumps in the SR to remove Ca^{2+} from the intracellular fluid while accumulating it into the SR against a concentration gradient. Ca^{2+} ATPase pumps and Na^{+}/Ca^{2+} in the cell membrane also reduce intracellular calcium levels and terminate contraction.

Force of contraction in cardiac muscle can be altered by changes in intracellular calcium concentration.

In contrast to skeletal muscle fibers, intracellular Ca^{2+} levels and force generation can be altered in individual myocardial cells by normal physiologic as well as abnormal conditions (Fig. 13.2). Physiologically, myocardial contraction is modified by altering the gating of the DHP Ca^{2+} channels in the cell membrane that are activated during phase 2 of the action potential. Calcium entering the cell through this channel, however, is not itself used to directly cause contraction. Only about 10% of this Ca^{2+} contributes to contraction of the muscle. Instead, increased intracellular Ca^{2+} through the channel serves as a trigger to release substantial stores of Ca^{2+} from within the SR (**calcium-induced calcium release**). In cardiac muscle, the DHP channel is linked to the ryanodine-sensitive calcium release channel in the SR membrane such that each quantum of calcium admitted through the DHP channel causes a small, localized release of calcium from one ryanodine receptor channel in the SR. These localized intracellular bursts of calcium are called **calcium sparks**. The localized high concentration caused by a single calcium spark does not diffuse within the intracellular fluid to neighboring receptors in the SR at a high enough concentration to cause them to open. Instead, multiple calcium sparks are summated temporally and spatially within the myocardial cell to produce overall increases in intracellular Ca^{2+} concentration. In addition, high intracellular calcium concentrations stimulate the pumping of Ca^{2+} into the SR by the Ca^{2+} ATPase. This creates a larger pool of calcium within the SR that can be released with the next opening of the SR calcium release channels.

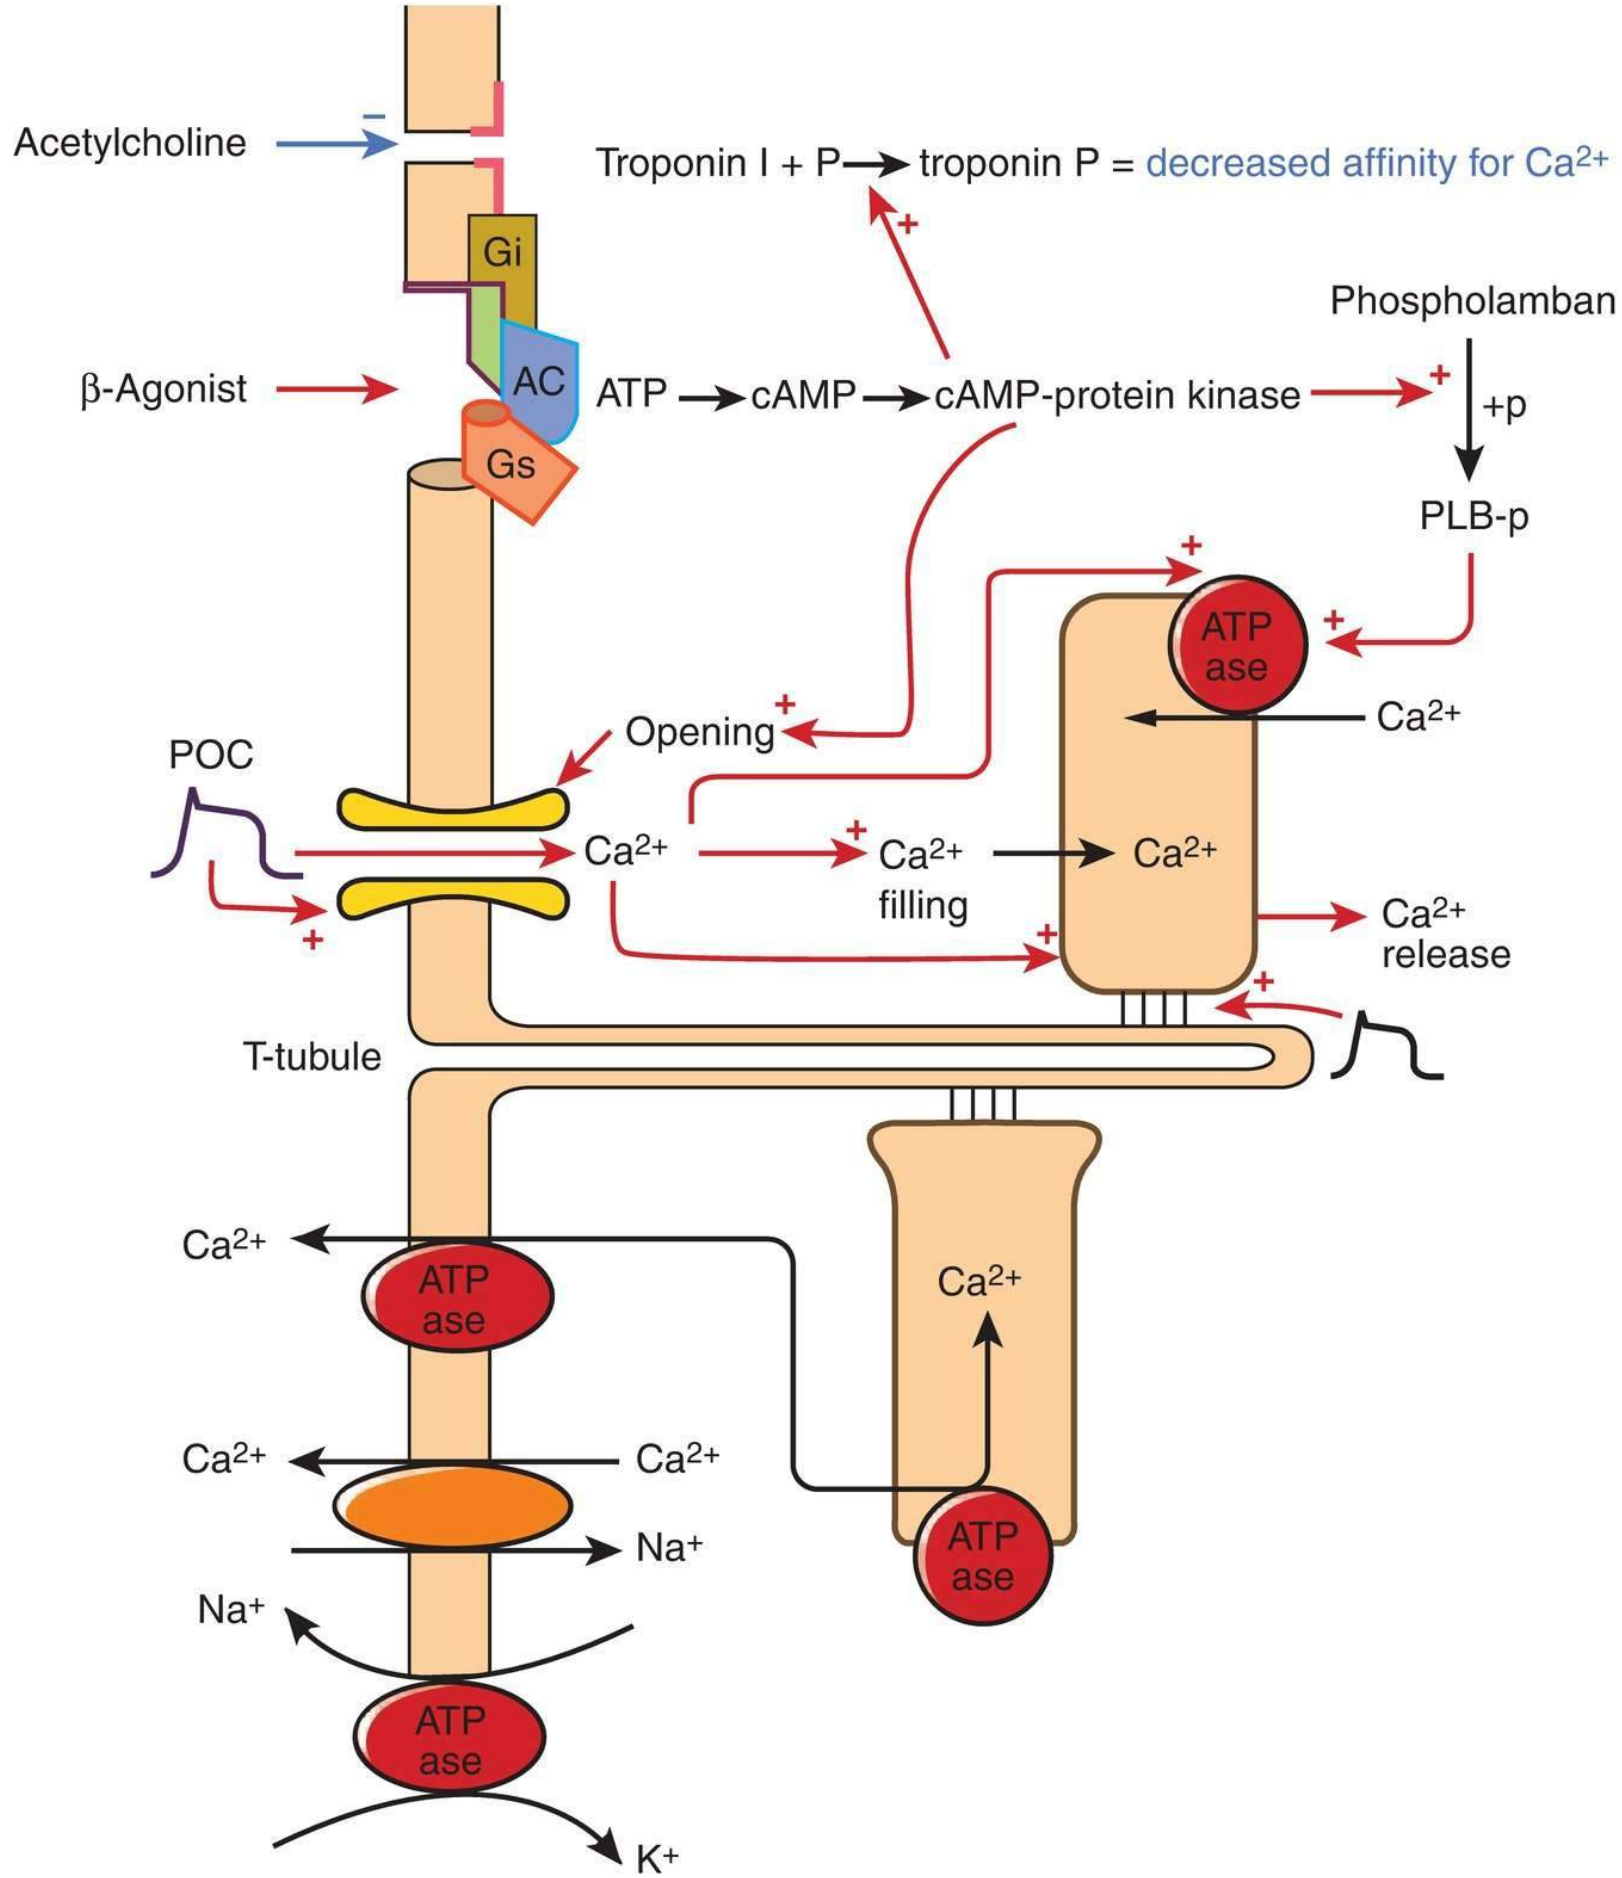

Figure 13.2 Handling of calcium in a cardiac muscle cell. Action potentials cause an influx of calcium through voltage-gated L-type 1,4 dihydropyridine (1,4 DHP) Ca^{2+} channels. Influx through one channel is closely linked to the release of calcium from one calcium-release channel in the sarcoplasmic reticulum (SR) (calcium-induced calcium release), causing a "calcium spark." Modulation of the influx of calcium

through DHP channels through G protein–linked receptor and non–receptor-mediated events gives rise to the capability of modulation of the inotropic state of a single myocardial cell. Cyclic adenosine monophosphate (cAmp)-mediated mechanisms also speed relaxation during β-adrenergic receptor–mediated increases in cell contractility. Calcium pumps in the plasma and SR membranes as well as secondary active transport mechanisms for calcium in the plasma membrane return intracellular calcium concentration to low levels between action potential activations of the cell. AC, adenylate cyclase; ATPase, adenosine triphosphatase; Gi, inhibitory G protein; Gs, stimulatory G protein; P, phosphate; PLB-p, phosphorylated phospholamban; POC, potential-operated Ca^{2+} channel.

In general, anything that enhances calcium influx during the action potential in a cardiac myocyte results in a greater intracellular release of Ca^{2+} and thus a stronger subsequent contraction. This is the basis of the ability of cardiac muscle cells to alter their strength of contraction at the level of the cell. Furthermore, Ca^{2+} influx through the voltage-dependent channels in cardiac muscle cells can be modified by cellular regulatory mechanisms. For example, catecholamines (e.g., norepinephrine released from sympathetic nerve endings, or circulating epinephrine) activate β_1-adrenergic receptors on the myocardial cell membrane. These receptors are linked to adenylate cyclase within the myocardial cell by a stimulatory G protein (G_S). When catecholamine binds to the β_1 receptor, the adenylate cyclase is activated and converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). In myocardial cells, cAMP binds to a cAMP-dependent protein kinase that phosphorylates the voltage-dependent Ca^{2+} channel. This phosphorylation increases the channel's probability of opening and increases the average time the channel remains open once activated. This enhances Ca^{2+} influx with every action potential, resulting in more intracellular calcium release and a stronger contraction in each myocardial cell. Extended to the whole heart, this increases the force-generating capacity of that organ and increases the output of blood with each contraction.

Modification of force generation in individual myocardial cells is independent of loading conditions on cardiac muscle.

The ability of myocardial cells to change the strength of contraction at the level of the cell represents a key additional mechanism by which the heart as a whole can adjust its contractile ability. Importantly, this modification of force-generating capacity can occur *independently* of any changes in force caused by alterations in preload or afterload on the heart. In cardiac muscle, this additional cellular factor is superimposed on any effects of preload or afterload on the heart. Thus, at *any* given loading condition, the heart exposed to an agent that enhances its ability to contract at the level of each cell can potentially generate more isometric force and move a greater load faster and farther compared with a heart not exposed to that agent. A modification of the contractile ability of muscle at the cellular level, independent of loading conditions, is said to be a modification of the **inotropic state** or **contractility** of the muscle. The ability to modify muscle performance by changing the inotropic state of individual cells is a hallmark of the physiologic control of myocardial contraction. (Note that the term "contractility" is often applied loosely in clinical settings to any factor that alters the contraction of the heart. This is a misapplication of the term. It is important for both physiologists and clinicians to distinguish alterations in the performance of the heart resulting from changes in inotropic state from those changes caused by alterations in loading conditions. In this text, the term "contractility" will be used to refer to the inotropic state of the heart.)

Factors that alter myocardial contractility

Many agents and conditions can alter the contractility, or inotropic state, of the heart (see Fig. 13.2 for reference). For example, β-receptor agonists are positive inotropic agents, whereas β-receptor antagonists are negative inotropic agents. Agents that block 1,4 DHP Ca^{2+} channels reduce myocardial contractility and thus exert a negative inotropic effect on the heart. Acetylcholine, released from parasympathetic nerve endings in the heart, is a negative inotropic agent. It inhibits adenyl cyclase through an inhibitory G protein and stimulates guanylate cyclase to produce cyclic guanosine monophosphate, which inhibits the opening of the Ca^{2+} channel.

The DHP channels require ATP for normal functioning. Therefore, myocardial ischemia, or lack of oxygen to the heart, results in an inhibition of the Ca^{2+} channel and is considered a negative inotropic condition. Also, acidosis (increased plasma H^+), which often occurs in ischemic conditions, inhibits myocardial contractility by interfering with the DHP channel.

Other non–receptor-mediated factors can alter intracellular calcium concentration and thus alter myocardial contractility. For example, Na^+/Ca^{2+} exchangers in the myocardial cell membrane remove Ca^{2+} from the interior of the cell through a secondary active transport mechanism linked to the influx of sodium moving down its electrochemical gradient. The reduction of the sodium gradient by the inhibition of Na^+/K^+ ATPase results in Ca^{2+} accumulation within the cell and a positive inotropic effect. This mechanism is responsible for the positive inotropic effects of cardiac glycosides such as digitalis and is the basis of their use to augment myocardial performance in heart failure. Methylxanthines, such as caffeine and theophylline (an asthma medication and component of tea), inhibit cAMP phosphodiesterase. These compounds therefore increase cAMP accumulation and induce a positive inotropic effect.

Activation of the sympathetic nervous system increases heart rate (a positive chronotropic effect) at the same time as it enhances myocardial contractility through β_1-receptor activation. Rapid heart rates require the rapid removal of calcium and inactivation of actin/myosin interactions so that relaxation can

be accelerated and diastole shortened to accommodate the high heart rate. Generation of cAMP and protein kinase A by norepinephrine phosphorylates a regulatory protein in the SR called **phospholamban**. This protein normally inhibits the Ca^{2+} ATPase pumps in the SR. However, when it is phosphorylated, its inhibitory effects are removed and the pumping activity of the Ca^{2+} ATPase increases, thus removing calcium from the intracellular fluid. In addition, phosphorylation of troponin 1 by protein kinase A decreases its affinity for calcium, allowing the cellular actin–myosin crossbridges to break their attachments. The effects on calcium pumping in the SR and on calcium affinity accelerate the relaxation of myocardial cells.

THE CARDIAC CYCLE

The cyclic contraction and relaxation of the myocardium sets into motion a sequence of events resulting in time-dependent changes in ventricular and aortic pressure, ventricular volumes, and flow into and out of the heart. A graphical representation of the variations in hemodynamic variables associated with the cardiac cycle is depicted in Figure 13.3. Such representations usually depict hemodynamic variables in the left heart and systemic circulation along with a tracing of the electrocardiogram (ECG) and heart sounds.

Time (s)

Figure 13.3 The timing of various hemodynamic and related events during the cardiac cycle. (See text for details.)

Ventricular systole consists of isovolumic contraction followed by a rapid, then reduced, blood ejection phase.

The peak of the R wave on the ECG is used to signify the start of systole, or the contraction phase of the cardiac cycle. This contraction increases intraventricular pressure above end-diastolic levels, which are about 0 to 5 mm Hg in healthy adults. As soon as left ventricular pressure during systole exceeds that in the left atrium, the mitral valve closes. This closure is associated with a series of broad low-pitched sounds that are a result of the vibrations of blood and the chordae tendineae in the ventricles. This is called the **first heart sound**. (These sounds are not made by valve leaflets "slapping against one another.") The intensity of the first heart sound is proportional to the strength of myocardial contraction, and its evaluation is useful in clinical diagnosis.

As the ventricle contracts, there is a period of time when intraventricular pressure exceeds that in the left atrium but is still less than that in the aorta. In this state, all cardiac valves remain closed and the ventricle builds pressure without moving blood. This phase of systole is called **isovolumic contraction**. Once the left ventricular pressure exceeds that in the aorta, the aortic valve opens and blood leaves the ventricle, initiating the ejection phase of the cardiac cycle. During systole, a healthy heart ejects from 45% to about 67% of the volume of blood that was in the ventricles at the end of the previous diastole. Initially, with the opening of the aortic valve, ventricular volume decreases rapidly; about 70% of the volume to be ejected exits the ventricle during the first third of the ejection phase. This period is thus called the **rapid ejection phase**. During this phase, blood enters the vascular system faster than it can drain into the veins. Consequently, aortic pressure as well as intraventricular pressure rise during this phase. This causes a temporary increase in aortic blood volume, which distends the aortic wall and increases lateral aortic pressure. This pressure may actually slightly exceed left ventricular pressure, but the combined potential and kinetic energy during ejection is still greater in the ventricle than in the aorta, so flow proceeds outward. However, as some of the kinetic energy of outflow is converted into the potential energy that distends the aorta walls, the rate at which blood exits the ventricle begins to decline. This is called the **reduced ejection phase**.

During the reduced ejection phase, the T wave of the ECG begins and the aortic and ventricular pressures start to decline. When ventricular pressure eventually declines below total aortic pressure (lateral and kinetic components), the aortic valve closes. The sudden cessation of ventricular outflow caused by valve closure creates a **second heart sound**, whose intensity is proportional to the intensity of the valve closure. Intensity is increased whenever aortic or pulmonary arterial pressure is abnormally high and is taken as a clinical indicator of possible systemic or pulmonary hypertension, respectively. The closure of the aortic valve also causes a transient, sharp, small drop in aortic pressure, creating a notch in the aortic pressure profile, called the **incisura**. This event is used sometimes to demarcate the transition from systole to diastole in the cardiac cycle. However, systole is more correctly considered to be concluded when the T wave ends on the ECG.

The difference in the volume of blood in the ventricle at the end of diastole, or the **end-diastolic volume**, and the volume of blood in the ventricle at the end of systole, or the **end-systolic volume**, is called the **stroke volume**. Stroke volume represents the volume of blood ejected with each contraction of the ventricles (see Fig. 13.3). Note that the ventricles do not empty completely with each contraction. At the end of systole, a significant volume of blood remains in the ventricles and is called the **residual volume**. Residual volume is decreased by increases in myocardial contractility and heart rate and increased whenever the heart is weakened (e.g., heart failure) or when faced with increased outflow

resistance (e.g., aortic valve stenosis). Thus, examination of end-systolic volume is useful clinically as an indicator of potential abnormal conditions affecting the heart.

Ventricular diastole consists of isovolumic relaxation followed by a rapid, then reduced, filling phase.

During the relaxation, or diastolic, phase of the cardiac cycle, volume and pressure changes proceed in the reverse of that seen for systole. Early in left ventricular relaxation, the aortic and mitral valves are closed, and the ventricle relaxes isovolumetrically. Thus, this phase of the cardiac cycle is called **isovolumic relaxation**. Once ventricular pressure falls below that of the left atrium, the mitral valve opens and the filling of the ventricle begins. Just prior to this occurrence, abrupt cessation of ventricular distention and the deceleration of blood create a faint third heart sound not normally heard in healthy people. However, the third heart sound is amplified in abnormally stiff or distended ventricles, such as that associated with heart failure, and its presence is therefore considered a serious sign of underlying cardiac abnormalities.

During diastole, the ventricles fill in a rapid filling phase, followed by a reduced filling phase (**rapid ventricular filling** and **reduced ventricular filling** phases). During rapid ventricular filling, ventricular pressure actually continues to decline because ventricular relaxation occurs more rapidly than does the filling of the ventricle. During the reduced filling phase, sometimes called diastasis, ventricular pressure starts to increase. The appearance of the P wave on the ECG and atrial contraction begin at the end of the reduced filling phase of the cardiac cycle. Atrial contraction produces a faint fourth heart sound that is amplified with A–V valve stenosis or with stiff ventricles. Diastole is considered to be concluded with the appearance of the next R wave on the ECG.

Abnormal conditions in heart valves are revealed by changes in venous pressure waveforms.

Occasionally, pressure waveforms in the jugular vein are depicted on cardiac cycle diagrams. When the right atrium contracts, a retrograde pressure pulse wave is sent backward into the jugular vein. This is called the **A wave**. Factors that impede the flow of blood from the atria to the ventricles, such as tricuspid valve stenosis, increase the amplitude of the A wave. A second venous pulse wave, called the **C wave**, is seen as an increase followed by a decrease in venous pulse pressure during the early phase of systole. The upslope of this wave is created by the bulging of the tricuspid valve into the right atrium during ventricular contraction, which sends a wave into the jugular vein. This wave is combined with a lateral transmission of the carotid systolic arterial pulse to the adjacent jugular vein. The subsequent decrease in pressure in the C wave is caused by the descent of the base of the heart and atrial stretch. Failure of the tricuspid valve to completely close during ventricular systole results in the propulsion of blood back into the atrium and vena cava and results in a high-amplitude C wave. The **V wave** of the venous pulse is seen as a gradual pressure increase during reduced ejection and isovolumic relaxation followed by a pressure decrease during the rapid-filling phase of the cycle. This wave is created first by continual peripheral venous return of blood to the atrium against a closed tricuspid valve followed by the sudden decrease in atrial distention caused by rapid ventricular filling. Tricuspid valve stenosis increases resistance to the filling of the right ventricle, which is indicated by an attenuation of the descending phase of the V wave.

Analysis of venous waveforms along with skilled attention to analysis of heart sounds was once used to provide clinical insights into cardiovascular disease involving cardiac valves. Such physical examination diagnosis is still valuable today in that, in the hands of a skilled physician, it provides a quick, inexpensive analysis of important aspects of the patient’s heart that can signal dangerous conditions and their severity without having to wait for time-consuming technical instrument analyses to be scheduled, completed, and analyzed. Nevertheless, this type of indirect diagnosis is difficult and often benefits from additional high-tech analyses provided by several modern imaging techniques used to reveal valve condition and motion in the heart (as discussed later in this chapter).

DETERMINANTS OF MYOCARDIAL PERFORMANCE

Evaluation of the mechanical properties of the heart as they relate to its function as a pump is important to physiologists and physicians. Myocardial performance is hindered in pathologic conditions such as ischemia and heart failure and evaluation of such conditions as they affect the heart as a pump are clinically important. In the previous section, it was shown that alteration of the inotropic state of individual myocardial cells is one means by which the contractile performance of the heart can be altered. However, as is the case with skeletal muscle, preload and afterload effects are also important determinants of the performance of cardiac muscle. These factors interact collectively with inotropic conditions to modify the overall contractile performance of the heart.

Preload, afterload, and inotropic state interact to alter contractile performance of cardiac muscle.

Four factors influence the contractile strength of cardiac muscle: (1) preload, or the initial length to which the muscle is stretched prior to contraction; (2) afterload, or all the forces against which cardiac muscle must contract to generate pressure and shorten; (3) contractility (inotropic state); and (4) the indirect inotropic effect of increased heart rate. This last effect is caused by the fact that high heart rates bring Ca^{2+} into the cell faster than it can be removed thereby increasing intracellular Ca^{2+} concentration and contractility. This helps the heart eject more blood with each contraction, thereby compensating for reduced filling time associated with high rates.

Cardiac muscle exhibits an active length–tension relationship similar to that of skeletal muscle (Fig. 13.4, red tracing). However, because the heart is a distensible hollow organ, its preload, or stretch just prior to contraction, could theoretically be altered by the degree to which it is filled at the end of diastole. Although cardiac muscle is not anchored to a fixed object in the body, it is intrinsically stiffer than skeletal muscle and exhibits significant passive resistance to stretch at a length corresponding to L_O (Fig. 13.4, lower black tracing). The functional consequence of this structural property is that cardiac muscle is *constrained to contract from lengths* $\leq L_O$; it does not get stretched past that length even with extreme filling. In practical terms, the heart is therefore constrained to operate on the ascending limb of the active length–tension curve. As a consequence, in the whole heart increased filling during diastole increases end-diastolic stretch (preload) and thus the potential isometric contractile force that can be generated in the heart once it begins to contract.

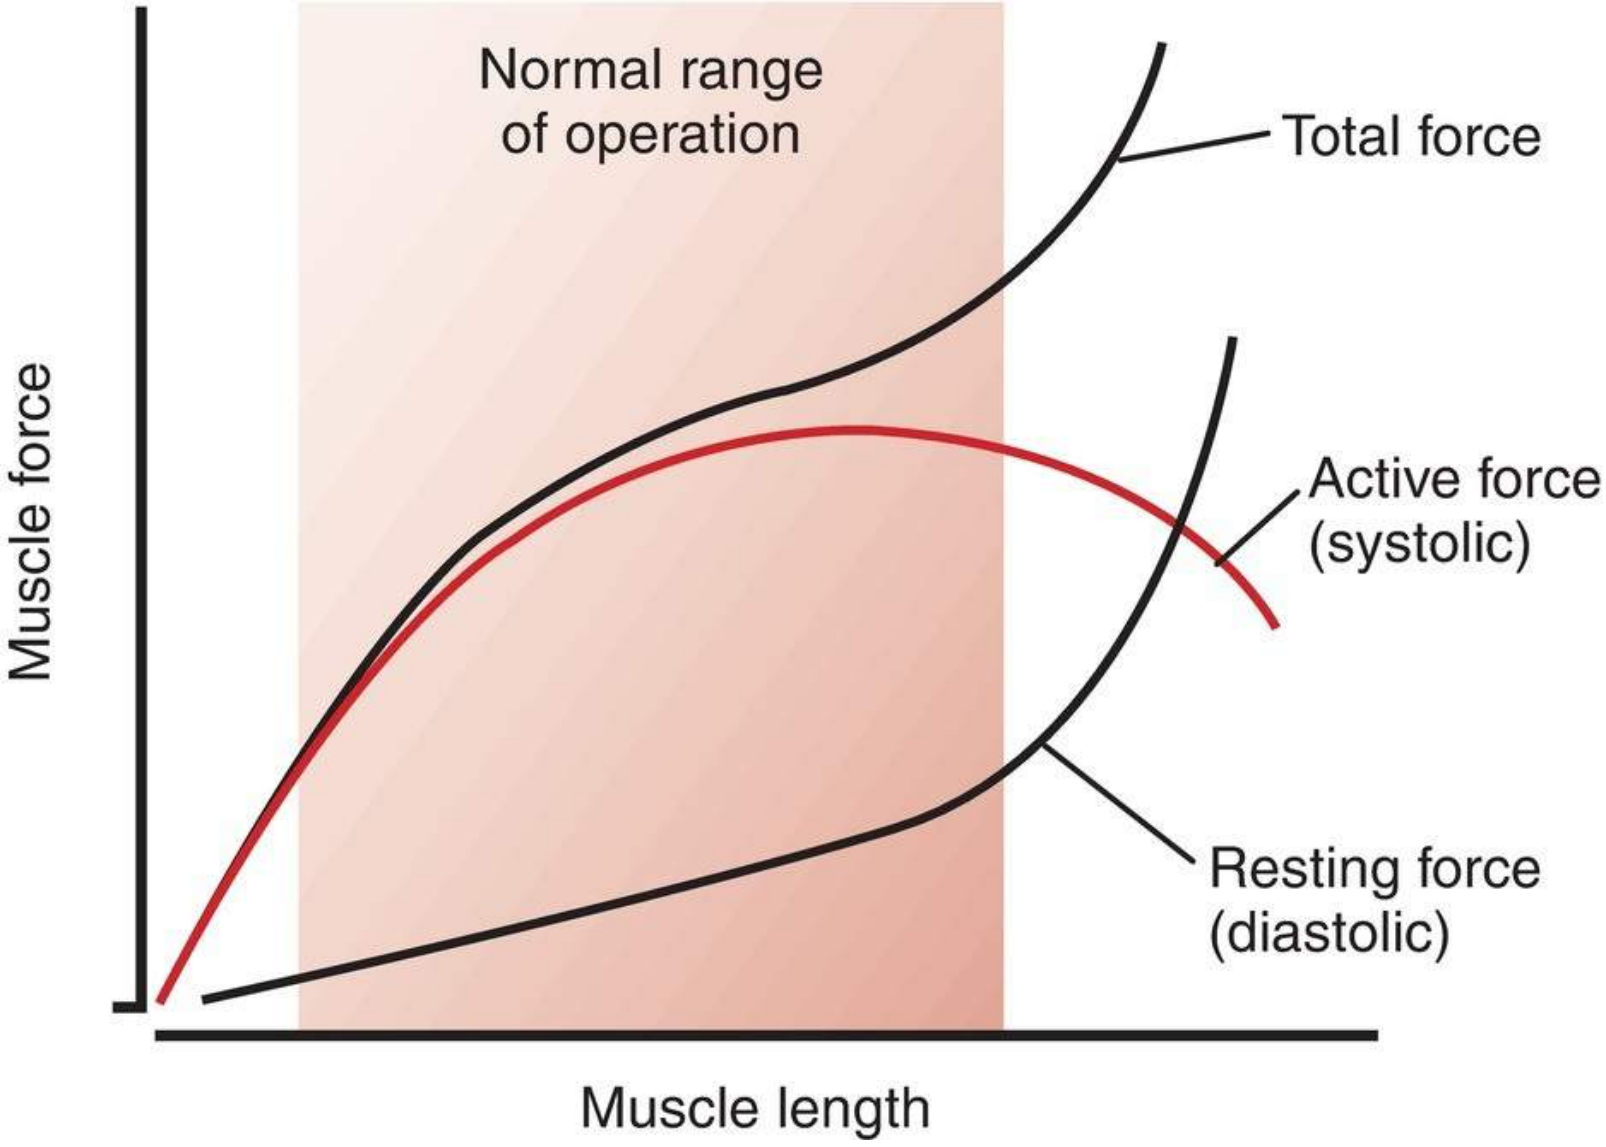

Figure 13.4 The isometric length–tension curve for isolated cardiac muscle. Cardiac muscle displays a parabolic active length–tension relationship similar to that of skeletal muscle but shows considerably more passive resistance to stretch at L_o. Functionally, this passive property constrains the heart to contraction along the ascending limb of the length–tension curve.

CLINICAL FOCUS 13.1

Cardiomyopathies: Abnormalities of Heart Muscle

Heart disease takes many forms. Although some of these are related to problems with the valves or the electrical conduction system, many are a result of malfunctions of the cardiac muscle itself. These conditions, called *cardiomyopathies*, result in impaired heart function that may range from asymptomatic conditions to malfunctions causing sudden death.

There are several types of cardiomyopathy, and they have several causes. In *hypertrophic cardiomyopathy*, an enlargement of the ventricular muscle fibers occurs because of a chronic overload, such as that caused by systemic arterial hypertension or a stenotic aortic valve. Such muscle may fail

because its high metabolic demands cannot be met, ischemia results, or fatal electrical arrhythmias develop. *Congestive* or *dilated cardiomyopathy* refers to cardiac muscle so weakened that it cannot pump strongly enough to empty the heart properly with each beat. This condition is common in patients with chronic congestive heart failure. In *restrictive cardiomyopathy*, the muscle becomes so stiffened and inextensible that the heart cannot fill properly between beats. Chronic poisoning with heavy metals, such as cobalt or lead, can produce *toxic cardiomyopathy*, and the skeletal muscle degeneration associated with muscular dystrophy is often accompanied by cardiomyopathy.

Cardiomyopathy arising from *viral myocarditis* is difficult to diagnose and may show no symptoms until death occurs. The action of some enteroviruses (e.g., coxsackievirus B) may cause an autoimmune response that does the actual damage to the muscle. This damage may occur at the subcellular level by interfering with energy metabolism while producing little apparent structural disruption. Such conditions, which can usually only be diagnosed by direct muscle biopsy, are difficult to treat effectively, although spontaneous recovery can occur. In tropical regions, infection with a trypanosome (Chagas disease) can produce chronic cardiomyopathy. The tick-borne spirochete infection called Lyme disease can cause heart muscle damage and lead to heart block. Excessive and chronic consumption of alcohol can also cause cardiomyopathy that is often reversible if total abstinence is maintained.

Another important kind of cardiomyopathy arises from ischemia. An acute ischemic episode may be followed by a *stunned myocardium*, with reduced mechanical performance, whereas chronic ischemia can further reduce mechanical performance. Ischemic tissue has impaired calcium handling, which can lead to destructively high levels of internal calcium. These conditions can be improved by reestablishing an adequate oxygen supply (e.g., following clot dissolution or coronary bypass surgery), but even this treatment is risky because rapidly restoring the blood flow to ischemic tissue can lead to the production of oxygen radicals that cause significant cellular damage. ■

Effects of preload and afterload on cardiac contraction are enhanced or depressed by changes in cardiac inotropic state.

A key to understanding the contraction of cardiac muscle is to understand that *the effect of any given loading condition on the contractile force generated by the heart can be altered by the inotropic state of the heart*. At any given preload, isometric force generation of cardiac muscle is increased by positive inotropic stimuli and decreased by negative inotropic stimuli (Fig. 13.5). In other words, the ascending limb of the isometric length–tension relationship is shifted upward and to the left by a positive inotrope and downward and to the right by a negative inotrope.

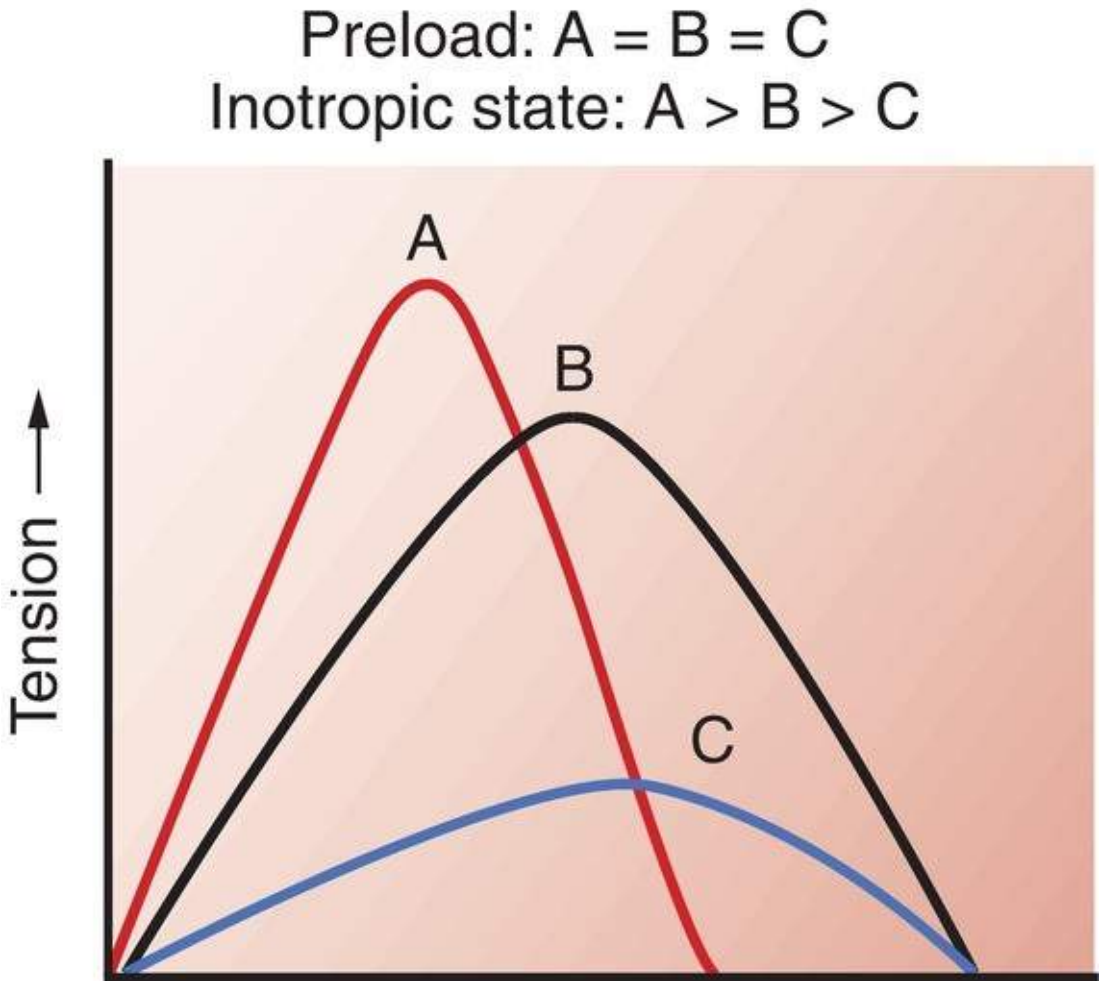

Figure 13.5 Three isometric twitch contractions of isolated cardiac muscle from identical preloads. A = effect of a positive inotropic agent. Note the increased peak, and rate of tension development compared to a normal contraction (B). C = effect of a negative inotropic agent.

In cardiac muscle, the isotonic force–velocity relationship is similar to that seen in skeletal muscle (Fig. 13.6A, black tracing); contractions with lighter loads proceed with greater velocity than those with heavier loads. Also, changes in preload have effects on the position of the isotonic force–velocity relationship that are similar to those seen in skeletal muscle. Decreasing preload reduces the velocity of shortening obtainable at any given afterload as well as the magnitude of the afterload the cardiac muscle can move at any given velocity (Fig. 13.6A, blue tracing vs. black tracing). Increasing preload, naturally, has the opposite effect on afterloaded contraction (Fig. 13.6A, red tracing vs. black tracing). However,

the entire force–velocity relationship for any given preload can be shifted by the inotropic state of the heart. Positive inotropic influences shift the force–velocity curve at any given preload upward and to the right. In this manner, a positive inotropic agent allows cardiac muscle, at any given preload, to move a heavier load faster than that possible with normal myocardium at the same preload (Fig. 13.6B). Negative inotropic agents obviously have the opposite effect.

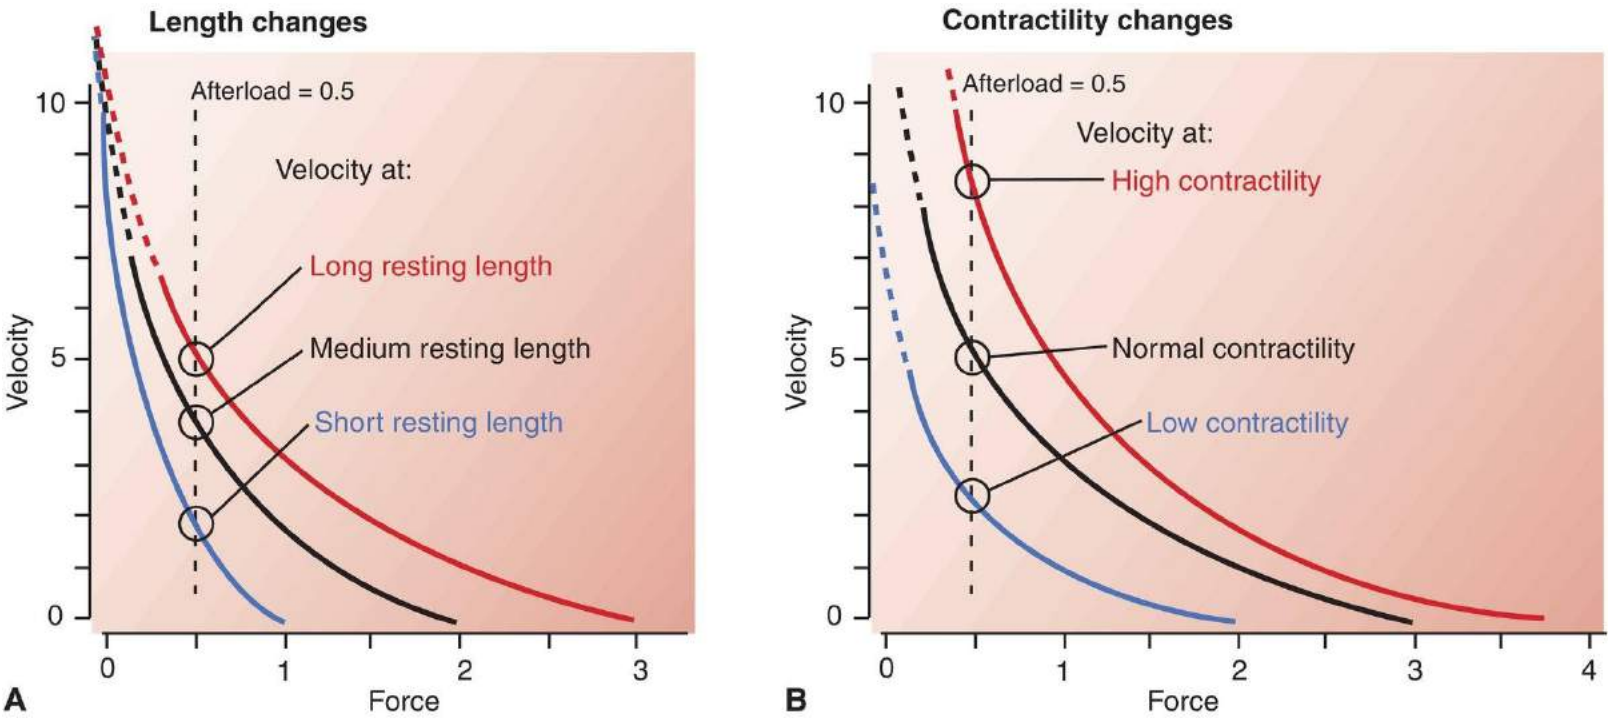

Figure 13.6 Effect of length and contractility changes on the force–velocity curves of cardiac muscle. (A) Decreased starting length (with constant contractility) produces lower velocities of shortening at a given afterload but does not affect the theoretical maximum velocity of shortening (V_{max}). Because of the presence of resting force (characteristic of heart muscle), it is impossible to make a direct measure of a zero-force contraction at each length. **(B)**Increased contractility produces increased velocity of shortening at a constant muscle length; V_{max} is proportional to the inotropic state.

Unlike skeletal muscle, the theoretical maximum rate of crossbridge cycling, or $\mathbf{V_{max}}$, in cardiac muscle is not constant. It is enhanced by positive inotropic stimuli and depressed by negative inotropic influences (note dashed extension of the tracings in Fig. 13.6B). Furthermore, V_{max} is not appreciably affected by loading conditions in cardiac muscle. Therefore, V_{max} can be thought of as a reflection of the inotropic state of the heart and indices that are related to V_{max} can be used to estimate the state of myocardial contractility (see below).

Figure 13.7 demonstrates how preload, afterload, and inotropic state interact to define myocardial contraction. As stated previously, positive inotropic stimuli shift the ascending limb of the isometric length–tension relationship upward and to the left, enabling cardiac muscle to generate more isometric force at any preload, whereas negative inotropic stimuli have the opposite effect. However, recall that the isometric length–tension relationship also represents the limit of how far muscle can shorten during an isotonic contraction against an afterload. Therefore, at any given combination of preload and afterload, a positive inotropic stimulus allows cardiac muscle to shorten farther, and/or shorten a given distance against a greater afterload, compared to that obtained by cardiac muscle in the normal inotropic state

(note the extent of the horizontal blue, black, and red arrows in Fig. 13.7). Unfortunately, this effect of inotropic state can be detrimental to the heart as well. As can be seen in Figure 13.7, any negative inotropic stimuli will reduce the ability of the heart to shorten with any given preload and afterload combination and/or reduce the load the heart can contract against for any specified amount of shortening.

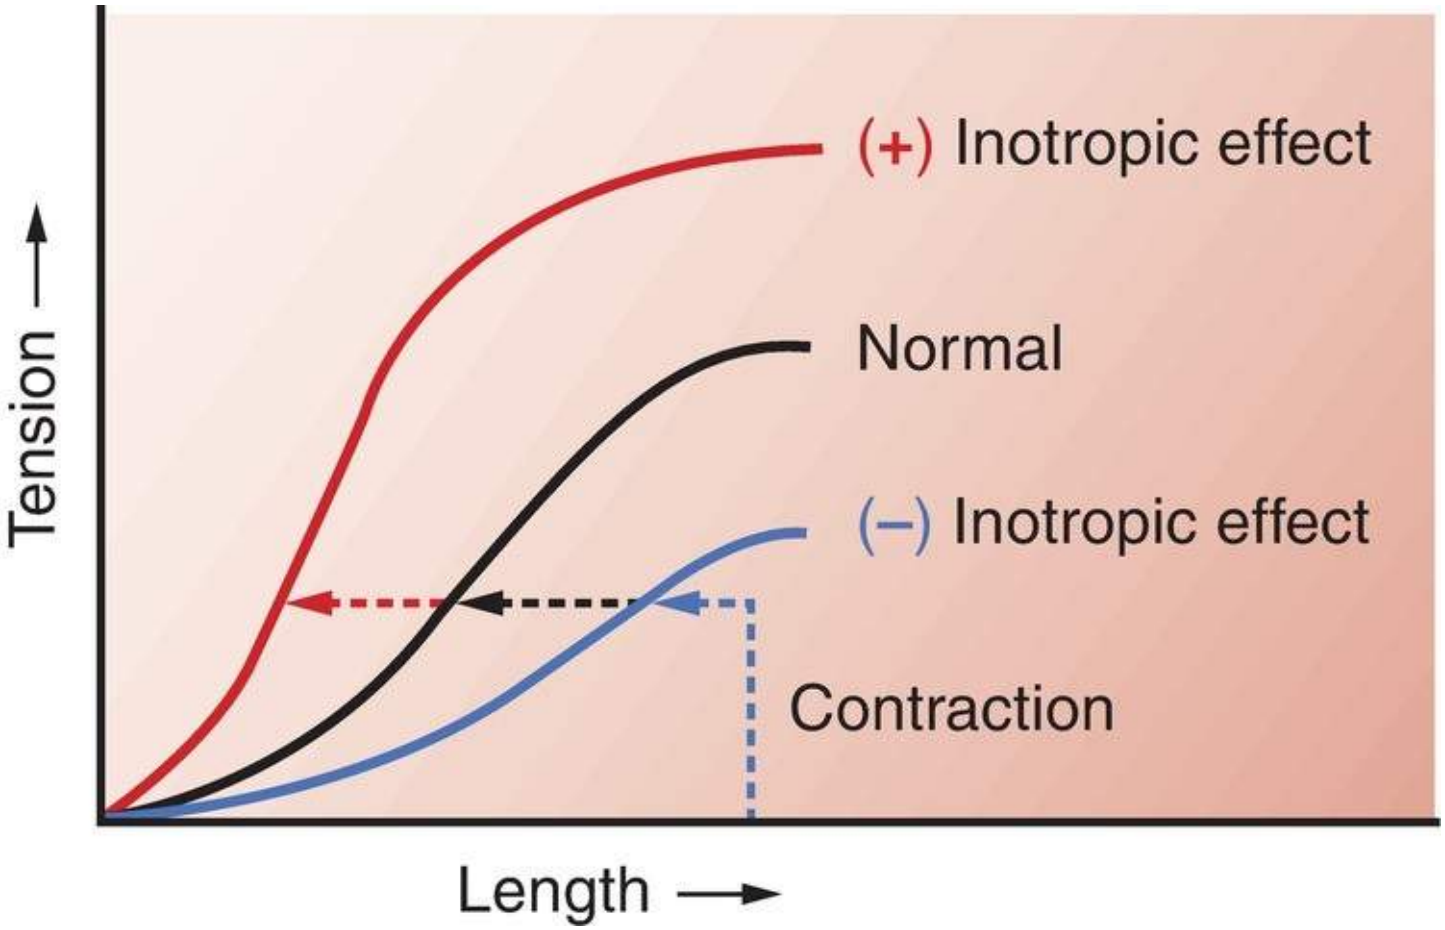

Figure 13.7 The effects of changes in inotropic state on isotonic contractions in the heart. Positive inotropic stimuli shift the isometric length–tension curve to the left, which demarks the limit of any isotonic shortening. Consequently, positive inotropic stimuli increase the extent of shortening of muscle at any given combination of preload and afterload on the heart (*red extension*); negative inotropic stimuli have the opposite effect (*blue tracing*).

Variables associated with contractile performance of the heart *in situ* are analogous to afterload, preload, and muscle shortening.

The relationships among preload, afterload, shortening, and contractility elucidated from studies of isolated cardiac muscle determine the output characteristics of the whole heart. To understand how loading conditions and contractility affect myocardial shortening and flow output, one needs to identify variables in the whole heart that are analogous to those in isolated muscle. For example, stroke volume, or the amount of blood ejected with each contraction of the heart, is analogous to muscle shortening. Similar analogs are used for preload and afterload. As the left ventricle fills with blood during diastole, it becomes stretched. The magnitude of this stretch is related to the blood volume in the heart at the end of diastole (**left ventricular end-diastolic volume,** or **LVEDV**). Therefore, LVEDV can be used as an indirect estimate of the preload in the left ventricle in the heart *in situ*. Because changes in end-diastolic volume result in changes in end-diastolic pressure, left ventricular end-diastolic pressure (LVEDP) is sometimes used as an indicator of preload on the heart. However, caution must be used in applying LVEDP as a measure of preload. Myocardial compliance can be reduced by myocardial ischemia, infarction, or hypertrophy. All of these will result in an increased end-diastolic pressure at any given LVEDV. Consequently, a person recording an increased LVEDP in this situation could assume, erroneously, that preload in the heart was increased when in fact it was not.

Pulmonary Wedge Pressure

Another hemodynamic measure of preload on the heart is the **pulmonary wedge pressure**. For this determination, a catheter with an inflatable balloon on its tip is inserted through a large systemic vein, through the right atria and ventricle and into the pulmonary artery until it encounters an artery smaller than the catheter. At this point, the balloon is inflated. The catheter now forms a quasi-lateral conduit between the pulmonary vessels downstream that empty into the left atrium and a pressure transducer on its other end outside the body. This pressure reflects changes in left atrial pressure, which is a determinant of left ventricular filling and thus preload. However, often, the pulmonary wedge pressure itself is used as a marker of impaired ventricular performance, such as in heart failure. In a failing heart, blood backs up into the pulmonary circulation to the extent it can markedly elevate the wedge pressure. Normal pulmonary wedge pressure is about 6 to 12 mm Hg with 18 mm Hg or above considered indicative of heart failure. The pulmonary wedge pressure is also elevated in pulmonary hypertension and is used to help determine the hemodynamic severity of mitral valve stenosis as well as a means of monitoring the effects of IV fluid infusions into a patient. In the latter case the infusion is adjusted to keep the wedge pressure between 12 and 14 mm Hg to prevent inducing pulmonary edema with the infusion.

Aortic pressure and wall stress are major determinants of afterload on the heart *in situ*.

In the left ventricle as a whole, afterload is equal to all the forces the muscle must overcome to eject a given volume of blood. The major contributor to afterload in the heart is ventricular or aortic pressure. However, it is more difficult to contract a distended heart against a given pressure than a normal heart, because cardiac wall tension and stress increase at any pressure when the average radius of the ventricular chamber increases. Therefore, tension (T = pressure × chamber radius) and wall stress (S = pressure × chamber radius/chamber thickness) are considered more accurate estimators of cardiac afterload. Other forces, such as those needed to overcome blood inertia, accelerate blood, or overcome the resistance of the valves, also contribute to afterload, especially in pathologic conditions.

The use of technologies to give better determinations of ventricular volumes, preload, and afterload in the heart encompasses a large portion of clinical cardiology. These techniques are not used in common physical examination but instead are used by qualified specialists in cardiology for the evaluation of myocardial performance as well as for the diagnosis and treatment of patients with serious heart conditions. A full description of these technologies is beyond the scope of this book.

Pressure–volume loops can be used to reveal the effects of loading conditions and inotropic state on the performance of the whole heart.

The effects of preload, afterload, and contractility on the stroke volume of the heart can be easily seen with a tracing of the changes in intraventricular pressure and volume during the cardiac cycle, called a **pressure–volume loop**, as shown in Figure 13.8. In this depiction of the cardiac cycle, the time for each portion of the cycle is, by convention, not indicated on the loop. The cardiac cycle starts at point A with the beginning of diastole. Filling of the ventricle proceeds along the line connecting point A to point B, where B represents LVEDV, which can be considered a measure of the preload on the heart. Isovolumic contraction proceeds from this point to point C, where ventricular pressure equals that in the aorta. At this point, the aortic valve opens and blood is then ejected from the ventricle against aortic pressure, which is the prime determinant of afterload in the normal heart. The volume in the ventricle during ejection proceeds from point C to point D, which represents the pressure and volume in the heart at the end of systole (LVESV). The volume change between LVEDV and LVESV is the stroke volume. At a given inotropic state, point D falls on a line that represents the most pressure the ventricle can generate at a given preload. This line is analogous to the isometric length–tension curve for isolated muscle, which sets the mechanical barrier for how far isotonic shortening in muscle can proceed. Finally, the heart undergoes isovolumic relaxation from point D back to point A where the diastole begins the cycle again.

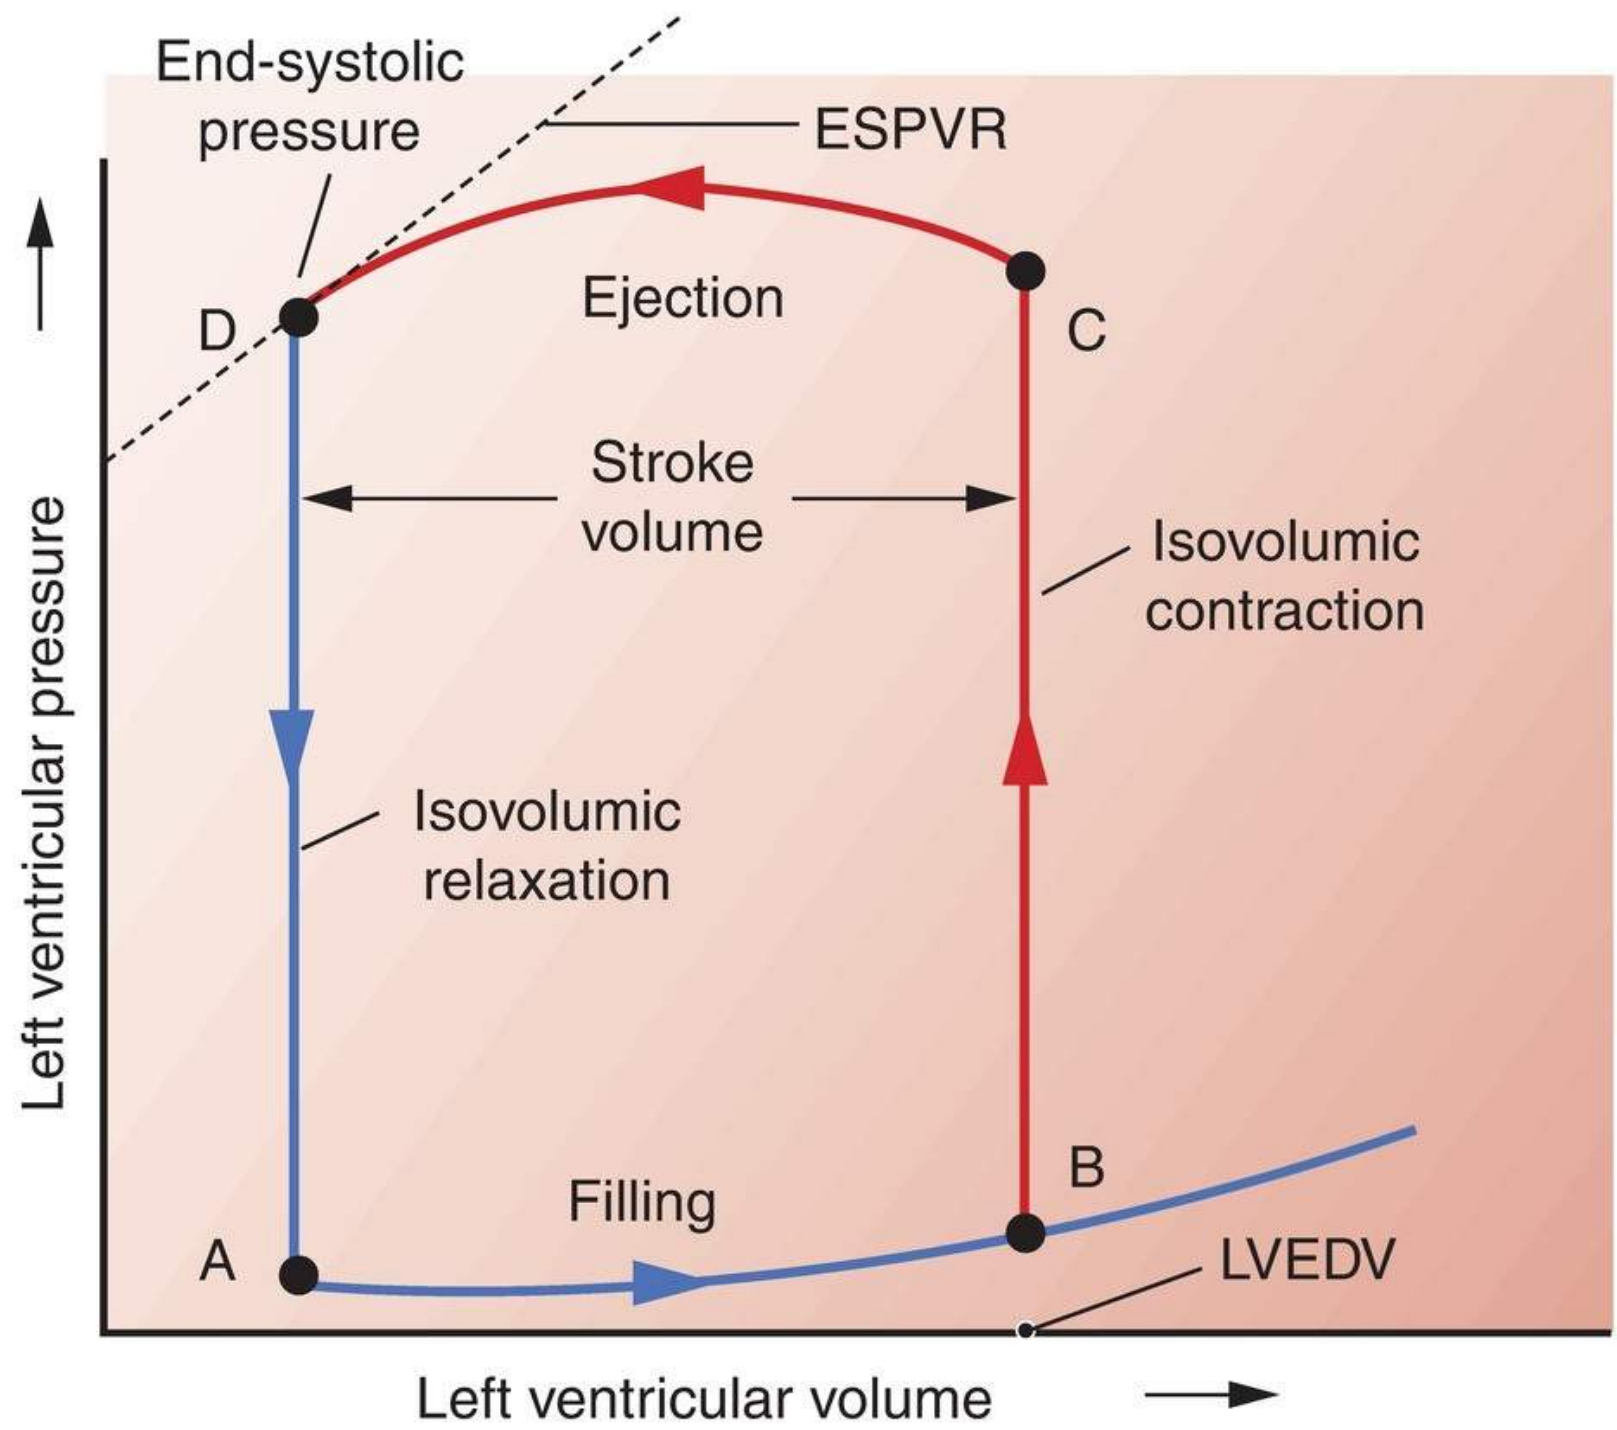

Figure 13.8 A pressure–volume loop representation of the cardiac cycle. (See text for details.) LVEDV, left ventricular end-diastolic volume; ESPVR, end-systolic pressure–volume relationship.

Stroke volume is positively related to the level of the inotropic state of the heart.

The pressure and volume in the heart at the end of systole represent the point to which the heart has shortened such that the maximum force it can develop at that length just equals aortic afterload. The heart cannot shorten beyond this point because, at shorter circumferences, the number of crossbridges available would not enable the heart to generate enough force to move blood against existing ventricular stress. If one were to examine several cardiac cycles starting at various LVEDV (preloads) and proceeding against several different aortic pressures (afterloads), a linear plot of ventricular end-systolic pressure versus left ventricular end-systolic volume would emerge. This line is called the **end-systolic pressure–volume relationship** (**ESPVR**), and at a given inotropic state, it sets the limit to the extent of shortening cardiac muscle can produce against a given afterload. The position of this line is independent of loading conditions on the heart. *The ESPVR can only be changed by a change in the inotropic state of the heart;* it does not matter which combination of afterloaded and preloaded contractions was used to create the line. As a result, the ESPVR is considered to be an ideal indicator of the inotropic state of the heart.

Relative to a normal heart, a positive inotropic influence will rotate the ESPVR upward and to the left, whereas a negative inotropic influence will rotate it downward and to the right. The consequence of such a shift for the whole heart is that, *at any given afterload and preload, stroke volume is increased by a positive inotropic influence and decreased by a negative inotropic influence* (Fig. 13.9A, tracings 3 and 1, respectively).

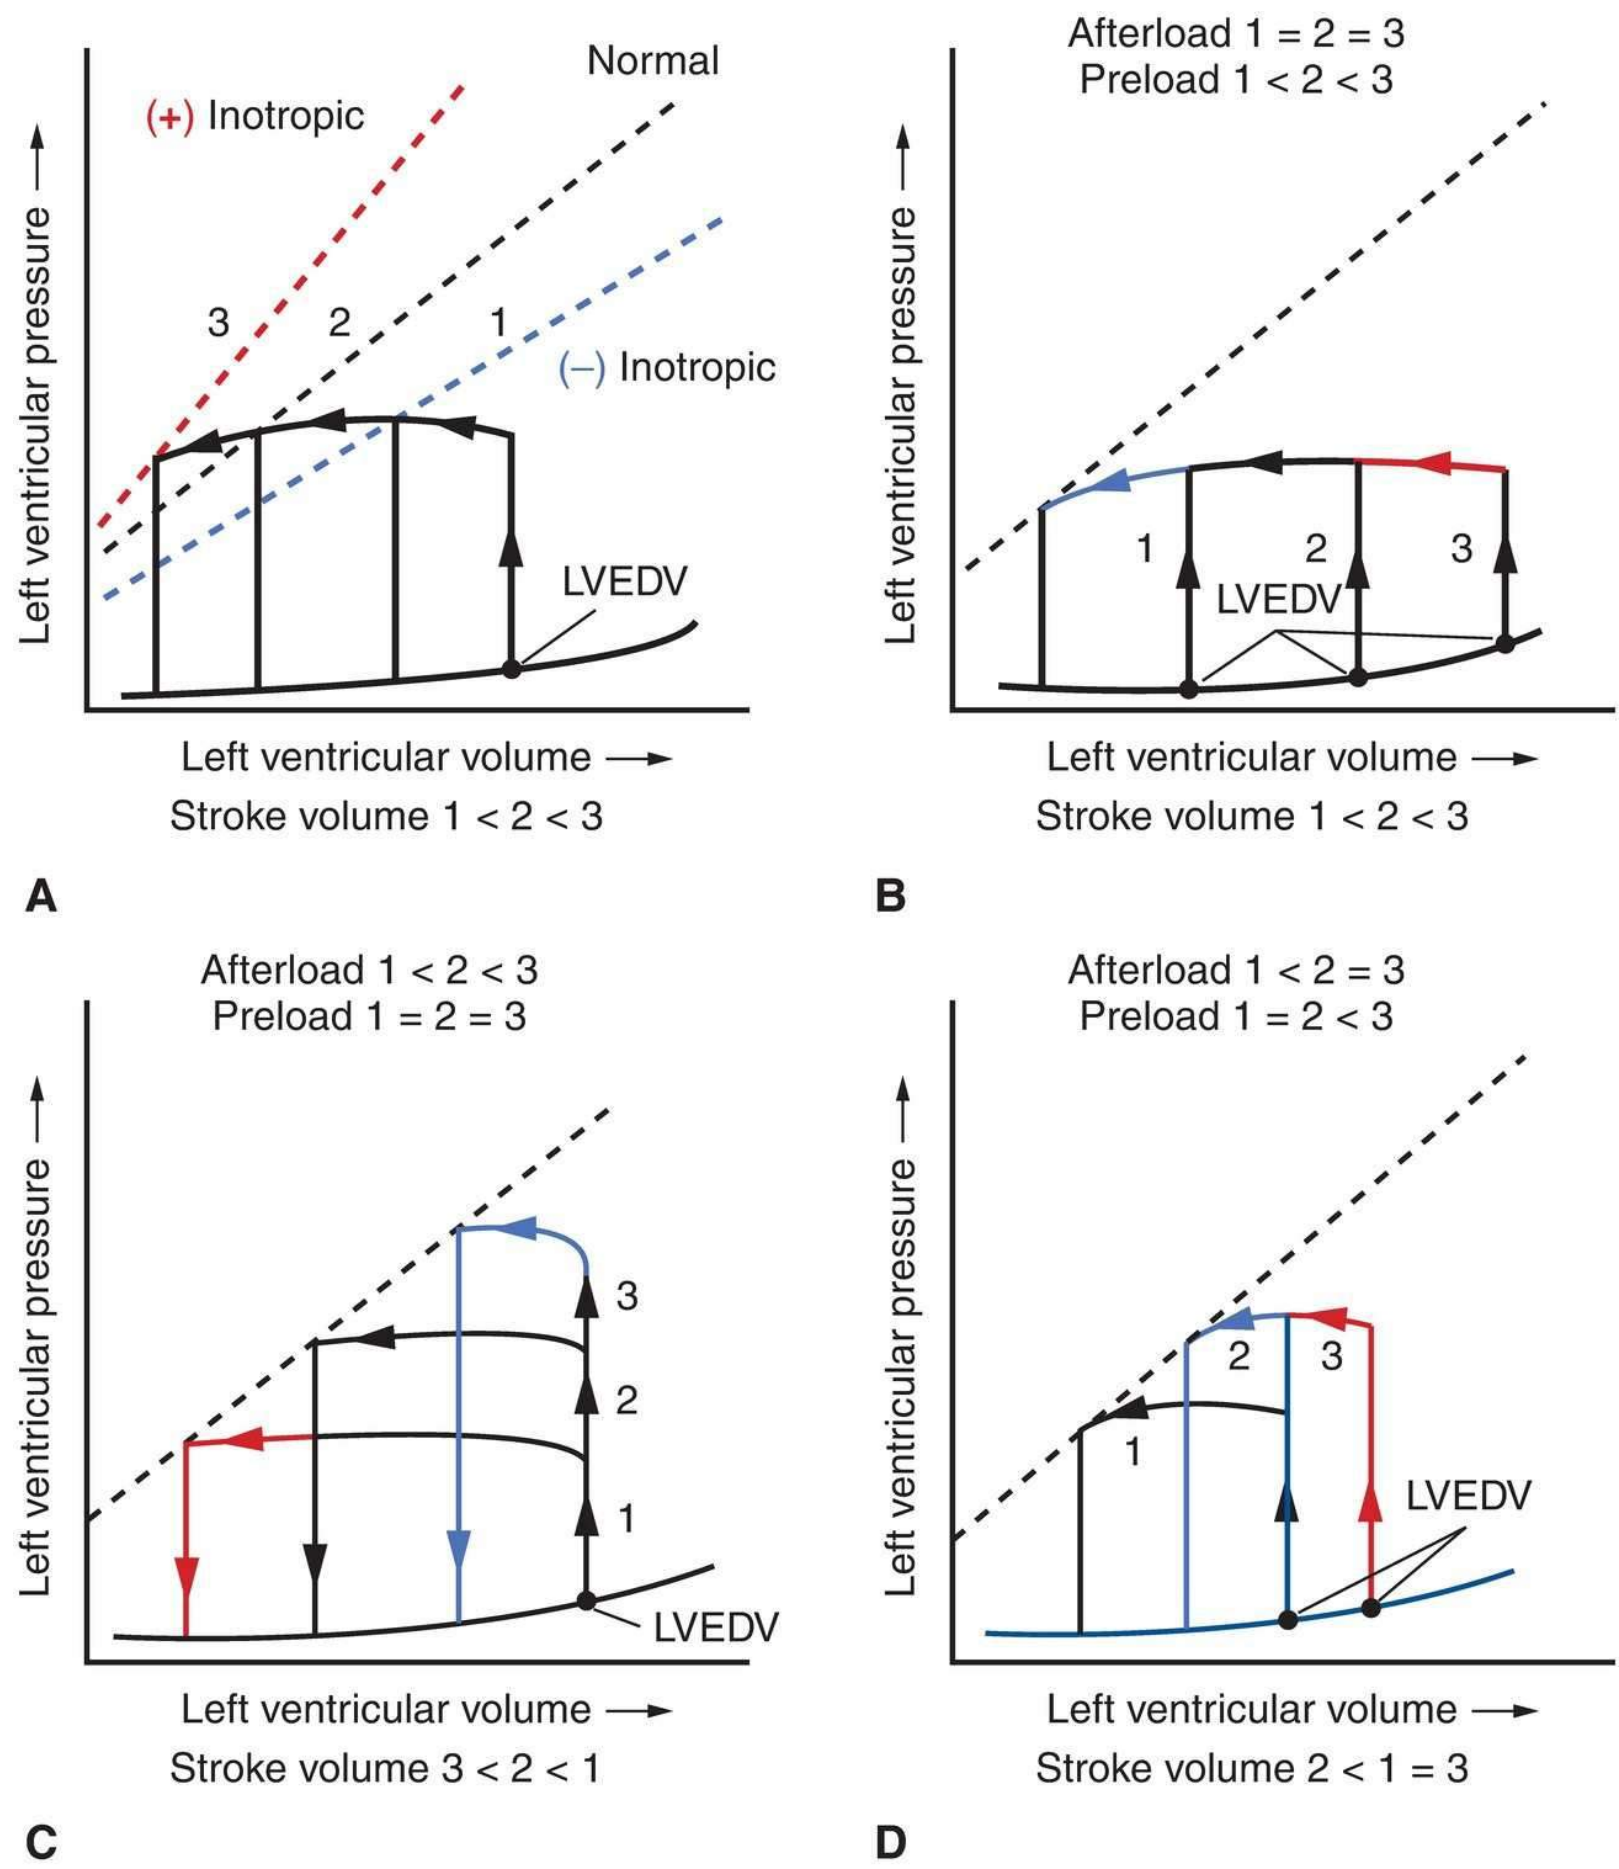

Figure 13.9 Determinants of stroke volume as revealed by pressure–volume loop representations of the cardiac cycle. (A) Effect of inotropic state on stroke volume at a given left ventricular end-diastolic volume (LVEDV) and arterial pressure. **(B)** Effect of changes in LVEDV on stroke volume at constant arterial pressure and inotropic state (the Frank-Starling relationship). **(C)** Immediate effect of changes in

afterload on ventricular stroke volume at constant LVEDV. **(D)** Changes in LVEDV following an initial increase in afterload and during the next cycle. *Red, increased effect; Blue, decreased effect*.

Stroke volume is increased by an increase in preload or a decrease in afterload.

By themselves, loading conditions also affect the output of the heart. In Figure 13.9B, cardiac cycles 1, 2, and 3 occur with the same afterload and inotropic state but at different LVEDVs and thus preloads. As LVEDV increases, the initial muscle length from which myocardial contraction proceeds increases as well. Once contraction is initiated, the heart ejects blood until the pressure and volume remaining in the ventricle meets the ESPVR. As can be seen in the figure, greater initial LVEDV results in a greater stroke volume. This relationship was elucidated by Ernest Starling in the early 1900s and is known now as **Starling's law of the heart** (also known as *Starling law of the heart*, or heterometric regulation of stroke volume). Put simply, this law states, "*the more the heart fills, the more it pumps*." The relationship between ventricular filling and the stroke output of the heart is important in relation to the performance of the heart as a pump. As will be seen in subsequent sections, this relationship is involved in both physiologic and pathologic conditions affecting **cardiac output** (**CO**), which is the total flow output of the heart per minute.

Afterload, by itself, has a negative impact on stroke volume in the heart (see Fig. 13.9C). Each of the three cardiac cycles in this figure start from the same LVEDV and inotropic state but proceed against three different afterloads. Blood cannot be ejected from the heart until left ventricular pressure meets aortic pressure. When the ventricle contracts at higher afterloads (pressure), it will not shorten much before encountering the ESPVR. This results in a lower stroke volume compared with contractions proceeding against lower afterloads. It also indicates that pumping against elevated arterial pressure will have a detrimental effect on the output of the heart unless certain compensatory mechanisms are brought into play. One such mechanism is shown in Figure 13.9D. Cardiac cycle 1 in this figure represents a contraction at normal LVEDV against a normal arterial pressure. Loop 2 (blue tracing) represents the first contraction against an elevated arterial pressure from the same LVEDV and results in a reduced stroke volume. However, this reduced stroke volume means that the heart did not empty to its normal residual volume at the end of systole. In other words, the volume in the heart prior to its next filling is larger than normal. Thus, when the normal diastolic inflow in the next cardiac cycle is added to this increased residual volume, an increased LVEDV will be created for the next contraction (contraction 3 on the figure, red tracing). By Starling's law, an augmented stroke volume will result. Heterometric regulation is thus a mechanism that enables the heart, within certain limits, to maintain a normal stroke volume against elevated arterial pressure.

Starling's law of the heart is also responsible for the remarkable balancing of the output of the right and left ventricles. For example, if the output of the right heart should suddenly exceed that of the left, inflow into the left ventricle would also increase, increasing LVEDV and thus subsequent output of the left ventricle; the same balance would occur if output from the right heart were suddenly decreased. In this manner, Starling's law automatically ensures that outputs of the right and left ventricle will always match.

In heart failure, the inability of individual cardiac cells to contract normally (a negative inotropic effect) can be somewhat compensated for by the fact that reduced ejection allows blood to pool in the left ventricle, increasing LVEDV and subsequently enhancing stroke volume. In fact, in heart failure, additional compensatory mechanisms in the body increase salt and water retention in the body as a whole in an effort to increase venous pressure and thus filling of the heart in diastole. This then increases stroke volume via Starling's law. Similarly, when the heart is paced at a slow rate, such as from the atrioventricular node or Purkinje fibers, the detrimental effect of this low rate on the cardiac output is

somewhat attenuated by the fact that the ventricles have more time to fill and thus augment the stoke volume with each contraction according to Starling's law of the heart.

Although Starling's law applies qualitatively to the heart in any condition, the quantitative effect of this law is attenuated whenever compliance of the myocardium is decreased. This is because when the heart is stiff, little stretch of the myocardium is produced with a normal amount of ventricular filling. Consequently, subsequent stroke volumes become compromised. For example, myocardial hypertrophy, from chronic ventricular overload (common with chronic aortic valve stenosis or systemic hypertension) reduces ventricular compliance. Reduced ventricular compliance is especially problematic when it results from scar tissue formed in the heart following myocardial infarction, chronic inflammation, or infiltrative processes from infections.

Sometimes bleeding may occur between the ventricles and the pericardium, such as if a coronary artery is punctured during a cardiac catheterization procedure. This bleeding, called **cardiac tamponade**, compresses the ventricles, making it difficult for them to expand during diastole, thus reducing diastolic filling and subsequent stroke volumes. A similar situation can arise from scar tissue following **pericarditis**, in which inflamed pericardium eventually adheres to the epicardial tissue. This condition essentially wraps the heart in stiff tissue, which then impedes stretch of the heart chamber with ventricular filling.

DETERMINANTS OF MYOCARDIAL OXYGEN DEMAND AND CLINICAL EVALUATION OF CARDIAC PERFORMANCE

The heart is only 0.3% of adult body weight, yet at rest, it uses ~7% of the body's total O_2 consumption. Due to the high O_2 requirements of the heart, this organ uses a wide variety of metabolic substrates. Two thirds of myocardial energy needs are derived from the metabolism of fatty acids because, on a molar basis, these compounds generate more ATP than sugars or amino acids. However, the metabolism of glucose supplies about 20% of the heart's energy needs, with the remaining needs supplied by the metabolism of lactate, pyruvate, amino acids, and certain ketones.

Any index that could predict cardiac O_2 demand under a variety of hemodynamic conditions would be invaluable to clinical medicine. Myocardial oxygen demand is one half of the important relationship between supply and demand of oxygen to the heart. Myocardial ischemia results whenever demand exceeds supply (see Chapters 15 and 16 for more details). For this reason alone, determination of oxygen demand by the heart is clinically valuable. However, a single index for determination of myocardial oxygen demand has yet to be found that is both clinically practical and universally applicable to all conditions that alter cardiac O_2 demands. Nevertheless, in an effort to develop such an index, much has been learned about determinants of oxygen consumption by the heart. This information has proved invaluable to the management of cardiovascular disease and acute cardiovascular crises in the clinical setting.

Increased afterload increases myocardial oxygen demand more than does increased preload, shortening, or inotropic state.

The energy output of a system is classically defined as the sum of heat production and work. Work, in turn, is defined as a force acting through a distance, or work = force × distance. As applied to work done by the left ventricle, work is given as the product of stroke volume and either arterial pressure, ventricular pressure, or wall stress during systole. It can also be determined by the area circumscribed by the pressure–volume loop depiction of the cardiac cycle.

In the heart, energy and, thus, oxygen must be used both to generate pressure and to pump blood (i.e., generate force and movement). In would seem that determination of cardiac work would be one way in which the oxygen demand of the heart could be determined. To the contrary, work alone is a poor indicator of the magnitude of oxygen demand by the heart. Consider that in relation to the mathematics of basic physics, there is no distinction between whether a given quantity of cardiac work results from a large stroke volume ejected against a low pressure or a small stroke volume ejected against a high pressure; the same quantitative value of work would emerge. However, in the heart, much more O_2 is required to generate force than to shorten. *Thus, more oxygen is needed to meet increased work resulting from an increase in cardiac stress than from an increase in stroke volume*. In other words, pumping against a high pressure is more oxygen costly, than pumping a high flow output, even if the total work is the same in both situations. Consequently, changes in cardiac work are poor quantitative indicators of myocardial oxygen demand.

Beyond the basal O_2 consumption needed to run membrane pumps and basic cellular activity, four major determinants of increased O_2 demand in the heart have been identified; these are (1) increased systolic pressure (or, more accurately, ventricular wall stress), (2) increased extent of muscle shortening (or stroke volume), (3) increased heart rate, and (4) positive inotropic stimuli.

Combinations of hemodynamic variables have been used as estimators of O_2 demand in the heart. The double product or systolic pressure × heart rate and the tension–time index (the area under the left ventricular systolic pressure curve) have been used as predictors of cardiac O_2 demand. Changes in these indices reflect changes in the oxygen needs of the heart caused by changes in heart rate and force generation, but they often fail in instances in which certain drugs, such as β-adrenergic agonists, produce positive inotropic and chronotropic (heart rate) effects on the heart at the same time that their vasodilator effects cause a drop in blood pressure. Indices based on the ESPVR can give accurate estimates of cardiac O_2 demand, but the determination of such relationships is currently impractical in a clinical setting.

Even without a good index available as a predictor of cardiac oxygen demand, it is useful to simply recognize factors proven to alter myocardial O_2 demand. For example, hypertension, or high blood pressure, greatly increases the stress load on the heart and thus increases O_2 demand. Similarly, exercise increases heart rate, myocardial contractility, and, in unconditioned people, blood pressure as well, all of which synergize to create greatly increase myocardial O_2 demand. In patients who have compromised coronary circulations resulting from atherosclerosis, it is thus helpful to realize that decreasing blood pressure and heart rate will lessen the possibility that cardiac oxygen demand will exceed cardiac oxygen supply.

Ejection fraction and hemodynamic evaluations are used as simple clinical indices of myocardial performance.

Clinical evaluation of the condition of the heart in patients is technologically demanding. Although many technologies and devices are available to evaluate the heart, their implementation requires specialized skills in cardiology. Nevertheless, there are some relatively simple means of estimating cardiac performance available to the clinician.

Clinicians can obtain a two-dimensional view of changes in the size of the ventricular chambers during the cardiac cycle through the use of ultrasound images employed in echocardiography. Ventricular chamber cross-sectional area during systole and diastole can be estimated from these real-time images and used to estimate stroke volume in the heart. The change in areas between diastole and systole is expressed as a percentage of the area during diastole and is called the **ejection fraction**. In normal hearts, the ejection fraction is 45% to 67%; values ≤40% indicate impaired performance.

Variables that reflect changes in the inotropic state of the heart have proven difficult to develop and are often used on the basis of what works reasonably well in the clinic. For example, the peak rate of rise of pressure in the left ventricle during isovolumic contraction (peak dP/dt) has been shown to reflect alterations in myocardial contractility and to be affected little by changes in preload or afterload. A peak dP/dt < 1,200 mm Hg/s indicates abnormally low myocardial contractility. Under certain conditions, inferences about the inotropic state of the heart can be made from the inspection of plots of stroke volume, CO, or stroke work versus LVEDV, LVEDP, or pulmonary wedge pressure. For example, the only way a patient's stroke volume can decrease or remain unchanged in the face of an increased ventricular preload is if the patient's heart is experiencing a negative inotropic influence. Conversely, increased stroke volume in the face of an unchanged or decreased preload indicates that the heart is under a positive inotropic influence.

There are certain physiologic and pathologic conditions that are known to change loading conditions and the inotropic state of the heart. For example, drugs that relax venous smooth muscle lower central venous and ultimately right atrial pressure, thereby reducing the filling of the heart and ventricular preload. Standing causes pooling of blood in the lower extremities and also decreases pressure in the right atrium with a similar effect unless the body corrects for this by activation of sympathetic nerves to veins (see Chapter 17). This occurs in normal healthy individuals. However, drugs used to treat certain cardiovascular diseases such as hypertension and myocardial ischemia can counteract this corrective reflex by directly relaxing vascular smooth muscle. Such an effect in veins causes a drop in preload when the patient taking such medications rises from a supine to standing position. Nitroglycerin in particular, which is used to treat angina, preferentially dilates veins over arteries. People taking these medications are susceptible to fainting on standing as a result of excess pooling of blood in the veins. This pooling causes a precipitous drop in right atrial pressure, reduced output of the heart, and transient low blood pressure (postural hypotension). Conversely, lying down and raising the feet increases right atrial pressure and stroke output of the heart by Starling mechanism.

Contraction of skeletal muscle squeezes muscle veins, increasing venous pressure and forcing blood back to the heart. This factor augments ventricular output during exercise by increasing preload. The lack of contraction, such as in someone standing at attention for exceeding long times, prevents this skeletal "squeezing" action and can thus lead to pooling of blood in the lower extremities and result in fainting.

Certain hormones, neurotransmitters, and drugs are known to affect the contractility of the heart. For

example, any condition that activates the sympathetic nervous system will enhance myocardial contractility. Conditions that activate the vagus nerve to the heart or inhibit sympathetic activity can have a negative inotropic effect. Such conditions are discussed in later chapters. Myocarditis and myocardial ischemia can be assumed to be negative inotropic influences. Certain anesthetics, such as barbiturates, antiarrhythmic drugs, and Ca^{2+} antagonists, are known negative inotropic agents.

CLINICAL FOCUS 13.2

Heart Failure and Muscle Mechanics

Heart failure is a condition where the heart is unable to maintain sufficient output to meet the body's normal metabolic needs. In its mildest forms, it can be seen as an abnormally low ejection fraction without causing outward symptoms in the patient. In its most severe form, it relegates an individual unable to do the simplest physical activities with physical distress even present at rest. Once begun, heart failure usually becomes more severe over a period of months to years as the result of a progressive deterioration of ventricular muscle, remodeling of the ventricular walls and chambers, and sometimes ventricular wall stiffening with impairment of diastolic filling. The progression of pathologic factors that impair heart output, such as chronic hypertension, recurring myocardial ischemia or infarction, diabetes mellitus, etc., also contributes to the progression of heart failure. The term *congestive heart failure* refers to fluid congestion in the lungs that often accompanies heart failure. However, a person can have impaired ventricular performance without pulmonary congestion or fluid congestion independent of a malfunctioning heart. Although the pathogenic mechanisms that can lead to heart failure are many, complex, and incompletely understood at this time, the mechanical consequences of heart failure are more clearly understood and will be the focus of this discussion.

The most typical forms of heart failure involve impairment of systolic function, which can be seen graphically by a downward and rightward rotation of the ESPVR on a pressure volume loop diagram (see Fig. 13.9A). In congestive heart failure, retention of salt and water by the body and the reduced contractility of the heart failure combine to increase LVEDV. Although this helps increase stroke volume in the otherwise failing heart, the weakened heart cannot shorten as far and with normal velocity at normal afterloads. This negative effect is much greater than any benefit imparted by a higher than normal LVEDV. Consequently, stroke output is diminished in the failing heart. However, the decreased slope of the ESPVR and the rather flattened Starling relationship (SV as a function of LVEDV; see Fig. 13.7) change the response of a failing heart to *changes* in afterload and preload in important ways compared to a normal heart. A simple comparison of pressure–volume loops in a failing heart versus a normal heart shows that a reduction in afterload produces a much greater increase in stroke volume in the failing heart than in the normal heart (see Fig. 13.9). Furthermore, the more flattened Starling relationship in the failing heart indicates that a reduction in LVEDV and/or LVEDP will have a smaller effect on reducing stroke volume in the failing heart than the normal heart (see Fig. 13.7). In short, the output of a failing heart is more sensitive to changes in afterload and less sensitive to changes in preload than a normal heart. This property is both a benefit and hindrance to the management of heart failure. It means that vasodilators will have an especially good benefit in patients in heart failure in that a reduction in arterial pressure will greatly augment stroke volume, whereas any venodilation effect to reduce stroke volume will be muted. The latter allows the clinician to reduce

fluid volume in the patient, to relieve pulmonary and systemic congestion, without having a major impact on stroke output via Starling mechanism. However, it also means that a patient in heart failure is exquisitely sensitive to the negative effects of any increase in systemic arterial pressure and cannot get the benefit of increasing output by increasing preload without resulting in pulmonary and systemic congestion. This emphasizes the importance of the need to avoid factors that increase blood pressure and/or salt and water retention in the clinical management of patients with congestive heart failure. ■

CARDIAC OUTPUT

Cardiac output (**CO**) is defined as the volume of blood ejected from the heart per unit time. The usual resting values for adults are 5 to 6 L/min, but this can rise to >25 L/min during heavy exercise. CO divided by body surface area is called the **cardiac index**. When it is necessary to normalize CO to compare outputs among people of different sizes, either cardiac index or CO divided by body weight can be used. CO is the product of heart rate (HR) and stroke volume (SV):

$$CO = SV \times HR \quad (1)$$

Previously discussed factors that alter stroke volume as well as factors that alter HR combine to produce an overall effect on CO. These are outlined in Table 13.1. If HR remains constant, CO increases in proportion to stroke volume, and therefore, factors that increase stroke volume are also considered factors that can increase CO. If stroke volume remains constant, CO increases in proportion to an HR up to about 180 beats/min. Therefore, within this limit, factors that increase HR also increase CO.

TABLE 13.1 Factors Influencing Cardiac Output

Positive Effects
Increased end-diastolic fiber length (Starling's law, preload)
Increased ventricular end-diastolic volume or pressure
Decreased afterload (decrease aortic pressure or LV wall stress)
Increased contractility
Sympathetic stimulation via norepinephrine acting on β_1 receptors
Circulating epinephrine acting on β_1 receptors (minor)
Intrinsic changes in contractility in response to changes in heart rate
Positive inotropic drugs, for example, digitalis, β-receptor agonists, and phosphodiesterase inhibitors
Hypertrophy (i.e., from aerobic exercise training if filling is not impaired due to decreased compliance)
Negative Effects
Decreased end-diastolic fiber length
Decreased ventricular end-diastolic volume or pressure
Decreased ventricular compliance; hypertrophy, cardiac tamponade, scar tissue
Increased afterload (increased aortic pressure, ventricular systolic pressure, or LV wall stress)
Increased ventricular radius
Negative inotropic drugs; calcium-channel blockers, general anesthetics, β-blockers
Disease (coronary artery disease, myocarditis, cardiomyopathy, etc.)
Myocardial ischemia
Ventricular and supraventricular tachycardias
Irregular heart rate
Atrial fibrillation
Aortic valve stenosis
Mitral valve stenosis

Cardiac output is maintained over a large range of heart rates through a reciprocal interaction between heart rate and stroke volume.

Heart rate can vary from <50 beats/min in a resting, physically fit person to >180 beats/min during maximal exercise. Changes in HR, however, do not necessarily cause proportional changes in CO because HR inversely affects stroke volume. As the HR increases, the duration of the cardiac cycle and diastole decreases thus reducing the time available for ventricular filling. This causes end-diastolic volume and thus stroke volume to fall. Events in the myocardium compensate to some degree for the decreased time available for filling. First, increases in HR reduce the duration of the action potential and, thus, the duration of systole, so the time available for diastolic filling decreases less than it would if the rate was changed through a change in the duration of diastole alone. Second, as discussed earlier, faster HRs are accompanied by an increase in the force of contraction, which tends to augment stroke volume. The increased contractility is sometimes called *treppe* or the *staircase phenomenon*. In reality, CO is not adversely affected by the decreased filling time during high HRs unless the rate exceeds ~180 beats/min. A person with abnormal tachycardia, however, (e.g., 250 to 300 beats/min caused by an ectopic ventricular pacemaker) has such reduced filling time that the patient usually has a reduction in CO despite the very high HR.

The reciprocal relationship between HR and the duration of diastole can also have a positive effect when HR is low. As the HR falls, the duration of ventricular diastole increases, and the longer duration of diastole results in greater ventricular filling, increased end-diastolic fiber length, and thus an increased stroke volume. This somewhat compensates for the decreased HR. This balance works until the HR is <20 beats/min. At this point, additional increases in end-diastolic fiber length cannot augment stroke volume further because the maximum of the ventricular function curve has been reached. At HRs < 20 beats/min, CO falls in proportion to decreases in HR.

Changes in heart rate occur through the reciprocal activation of parasympathetic and sympathetic nerves to the heart.

Normal physiologic changes in HR are brought about by reciprocal changes in the activity of the parasympathetic (vagus) and sympathetic nerves to the sinoatrial (SA) node. Vagal effects predominate with regard to HR such that the HR is actually held down from what it would be if paced by the SA node without any autonomic influences present. Nevertheless, decreasing vagal activity and increasing sympathetic nerve activity to the heart bring about increases in HR. A decreased HR results from opposite changes in both branches of the autonomic nervous system.

The release of norepinephrine by sympathetic nerves not only increases the HR (see Chapter 12) but also dramatically increases the force of contraction through its positive inotropic effect. Furthermore, norepinephrine increases conduction velocity in the heart, resulting in a more efficient and rapid ejection of blood from the ventricles. These effects, summarized in Figure 13.10, maintain the stroke volume as the HR increases when the sympathetic nervous system is activated. The effect of HR on CO depends on the extent of concomitant changes in ventricular filling and contractility. CO increases proportionately over a broad range, when the HR increases physiologically as a result of an increase in sympathetic nervous system activity (as during exercise).

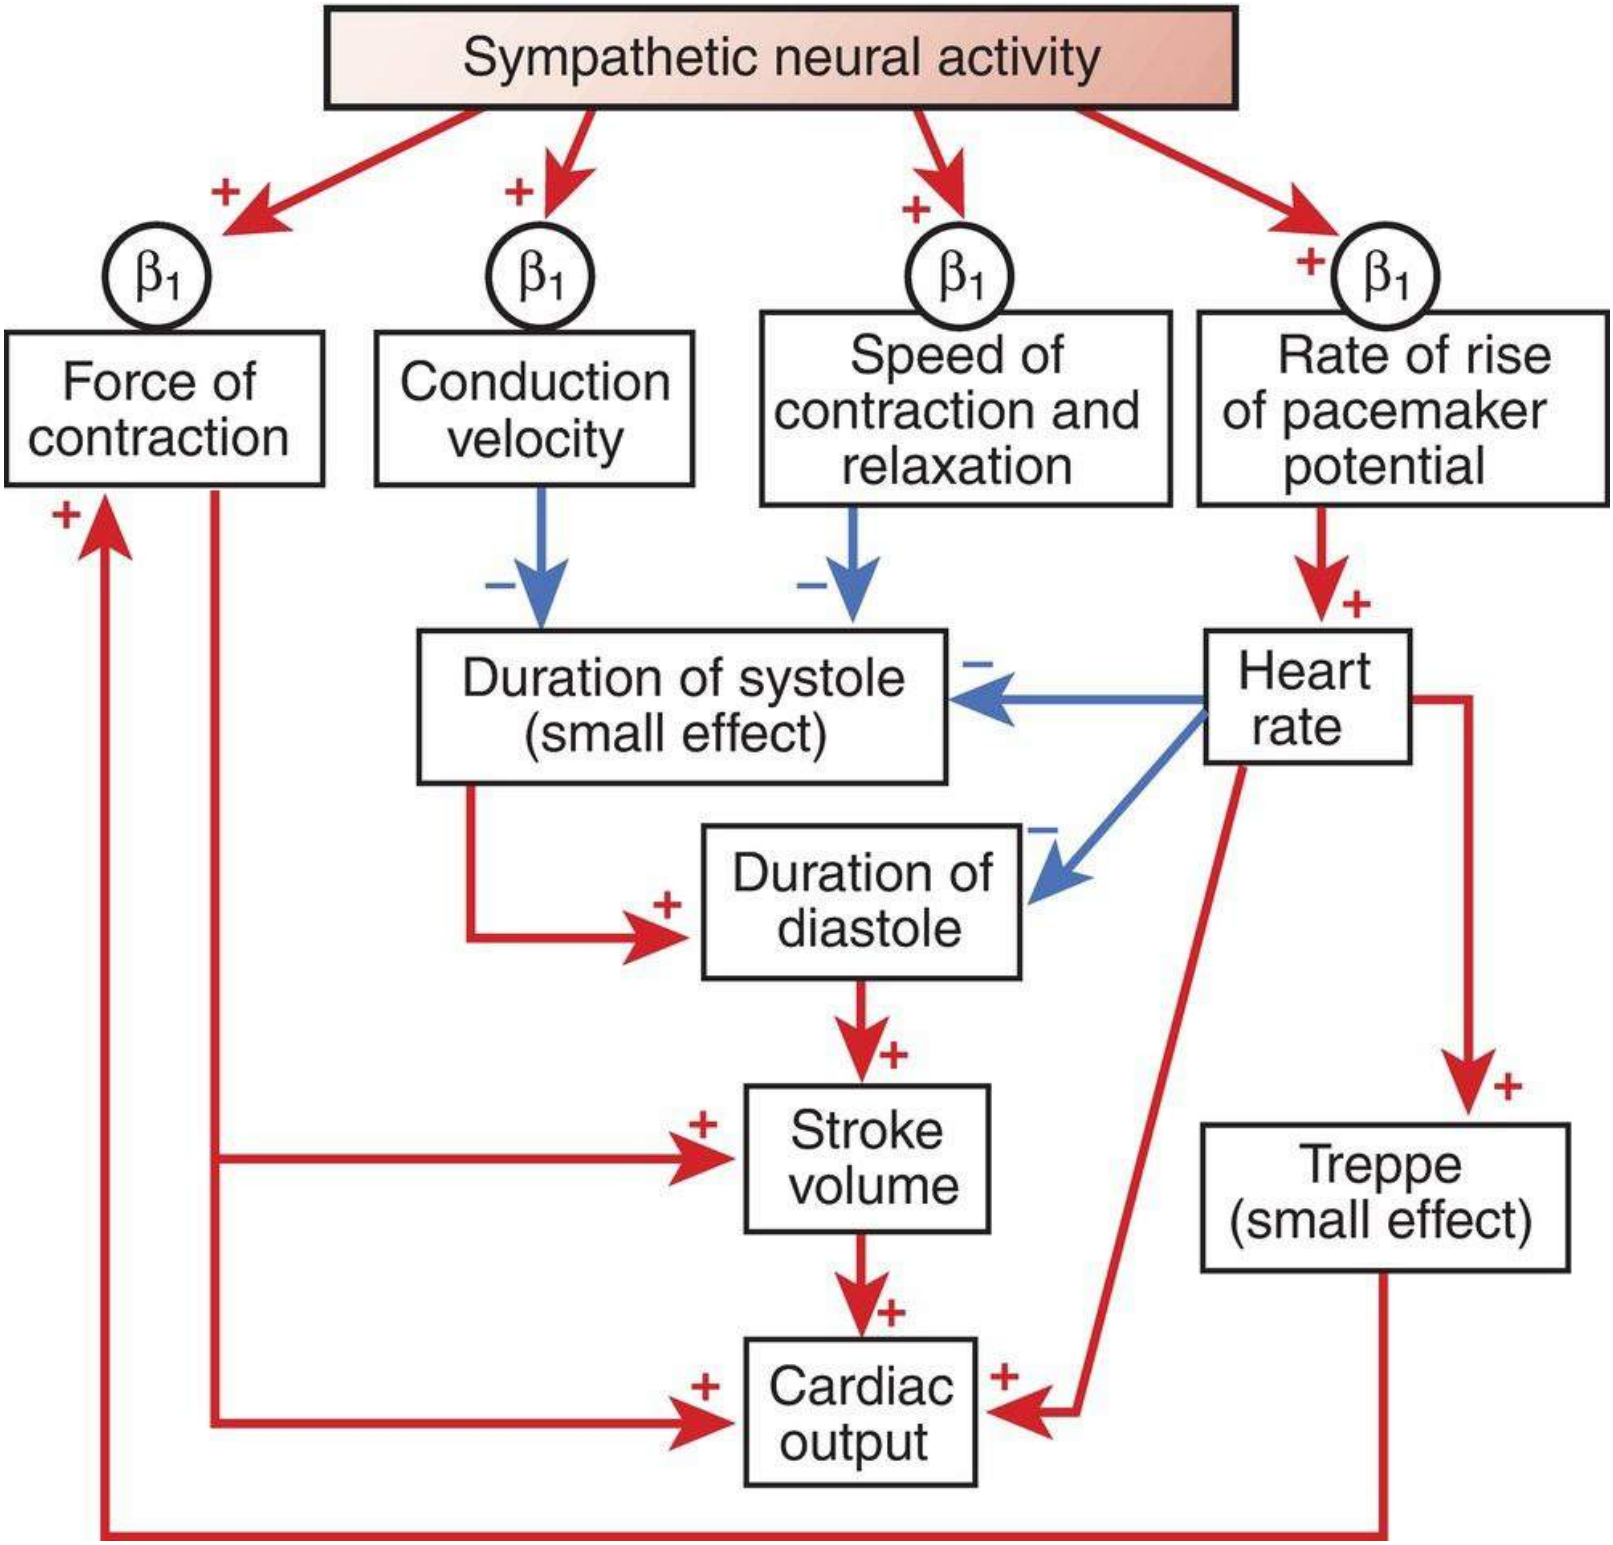

Figure 13.10 Effects of increased sympathetic neural activity on heart rate, stroke volume, and cardiac output (CO). Various effects of norepinephrine on the heart compensate for the decreased duration of diastole and hold stroke volume relatively constant, so that CO increases with increasing heart rate. *Red lines indicate stimulatory influences. Blue lines indicate inhibitory influences.*

In summary, changing stroke volume and HR regulate CO. Stroke volume is influenced by the contractile force of the ventricular myocardium and by the force opposing ejection (the aortic pressure or afterload). Myocardial contractile force depends on ventricular end-diastolic fiber length (Starling's law) and myocardial contractility. Contractility is influenced by four major factors:

1. Norepinephrine released from cardiac sympathetic nerves and, to a much lesser extent, circulating

norepinephrine and epinephrine released from the adrenal medulla
2. Certain hormones and drugs, including glucagon, isoproterenol, and digitalis (which increase contractility), and anesthetics (which decrease contractility)
3. Disease states, such as coronary artery disease, myocarditis, bacterial toxemia, and alterations in plasma electrolytes and acid–base balance
4. Intrinsic changes in contractility with changes in HR

THE MEASUREMENT OF CARDIAC OUTPUT

The ability to measure CO is important for performing physiologic studies involving the heart and managing clinical problems in patients with heart disease or heart failure. In current clinical practice, CO in an individual is most often estimated as the product of HR, obtained by an ECG, and stroke volume, obtained by echocardiography. Alternatively, CO can be measured by measuring flow velocity and aortic cross-sectional area with Doppler ultrasound techniques. However, older techniques that were used to measure CO did so accurately by applying the principles of mass balance with indicator dilution techniques. This technique, in a slightly different iteration, is still employed today in experimental settings as a means for measuring oxygen consumption in an organ. An overview of the basic principles involved in determining CO and organ oxygen consumption by mass balance and indicator dilution techniques is summarized below.

Indicator–dilution techniques are applications of the principle of mass balance to determine cardiac output.

The use of mass balance to measure CO is best understood by considering the measurement of an unknown volume of liquid in a beaker. Dispersing a known quantity of dye throughout the liquid and then measuring the concentration of dye in a sample of liquid can determine the volume. Because mass is conserved, the quantity of dye (A) in the liquid is equal to the concentration of dye in the liquid (C) times the volume of liquid (V), $A = C \times V$. Because A is known and C can be measured, V can be calculated as $V = A/C$.

When the principle of mass balance is applied to CO, the goal is to measure the volume of blood flowing through the heart per unit of time. A known amount of dye or other indicator is injected, and the concentration of the dye or indicator is measured over time. This method for determining CO is called the **indicator dilution technique**. In this application, a known amount of indicator (A) is injected into the circulation, and the blood downstream is serially sampled after the indicator has had a chance to mix (Fig. 13.11). The indicator is usually injected on the venous side of the circulation (often into the right ventricle or pulmonary artery but, occasionally, directly into the left ventricle), and sampling is performed from a distal artery. The resulting concentration of indicator in the distal arterial blood (C) changes with time. First, the concentration rises as the portion of the indicator carried by the fastest-moving blood reaches the arterial sampling point. Concentration rises to a peak as the majority of indicator arrives and falls off as the indicator carried by the slower moving blood arrives. Before the last of the indicator arrives, the indicator carried by the blood flowing through the shortest pathways comes around again (recirculation). To correct for this recirculation, the downslope of the curve is assumed to be semilogarithmic, and the arterial value is extrapolated to zero indicator concentration. The average concentration of indicator can be determined by measuring the indicator concentration continuously from its first appearance (t_1) until its disappearance (t_2). The average concentration during that period (C_{ave}) is determined, and CO is calculated as

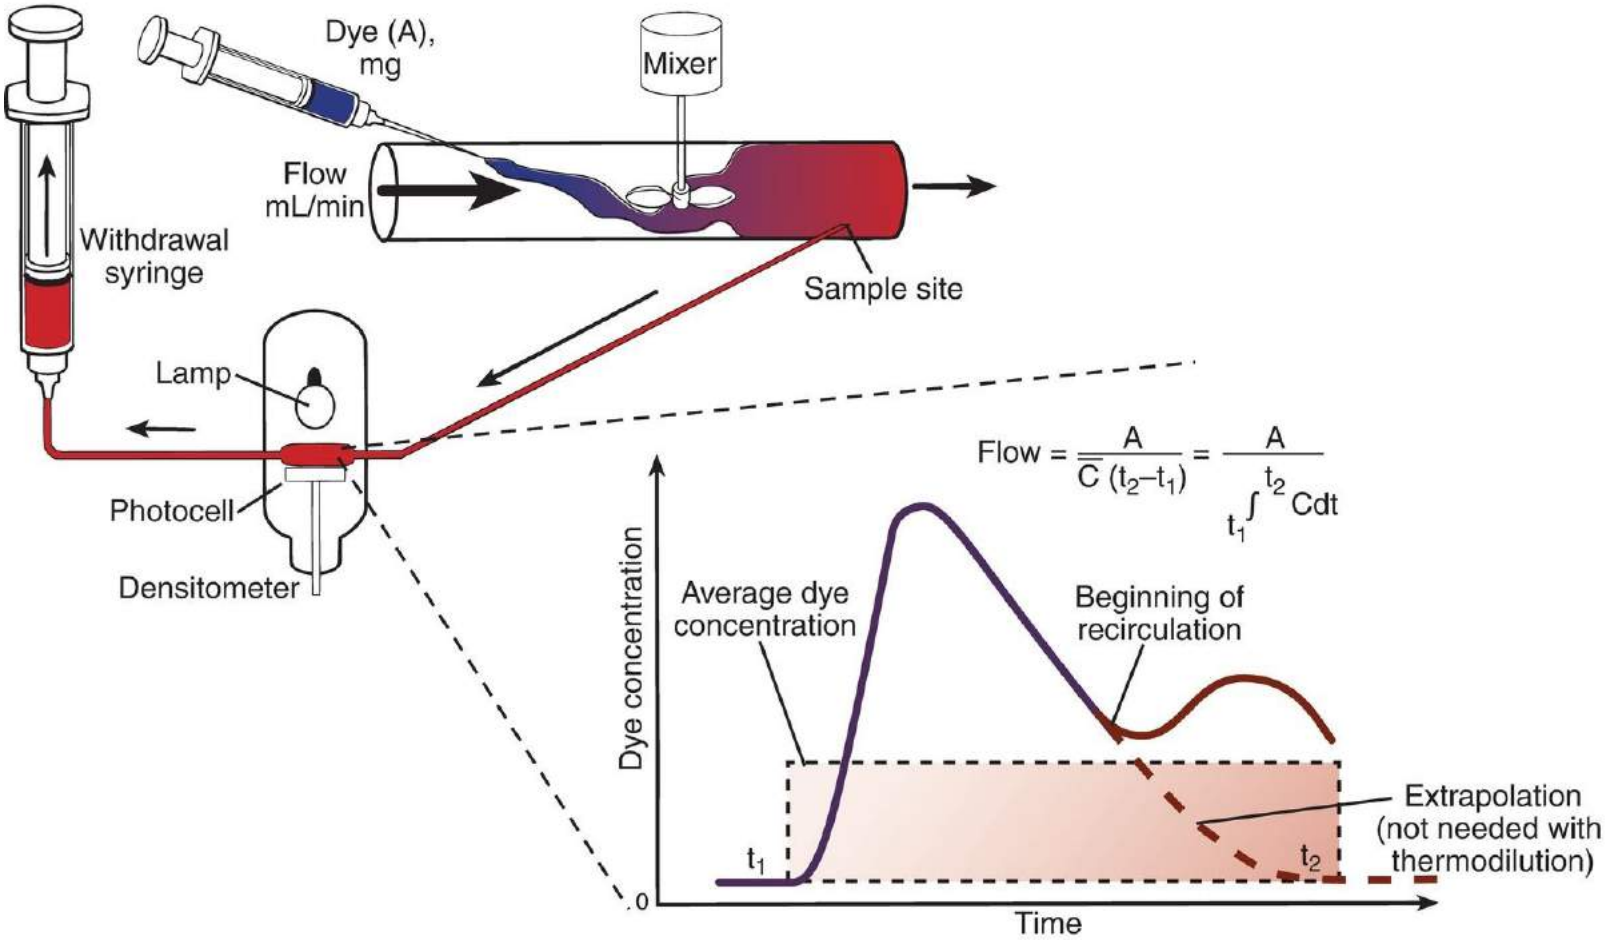

Figure 13.11 Illustration of the indicator dilution method for determining flow. The volume per minute flowing in the tube equals the quantity of indicator (in this example, an injected dye (A) divided by the average dye concentration (C) at the sample site, multiplied by the time between the appearance (t_1) and disappearance (t_2) of the dye). The downslope of the dye concentration curve shows the effects of recirculation of the dye (*solid line*) and the semilogarithmic extrapolation of the downslope (*dashed line*) used to correct for recirculation.

$$CO = A / [C_{ave} (t_1 - t_2)]$$

(2)

Note the similarity between this equation and the one for calculating volume in a beaker. On the left is volume per minute (rather than volume, as in the beaker example). In the numerator on the right is the amount of indicator (A) and in the denominator is the average concentration over time (rather than absolute concentration, as in the beaker example). Concentration, volume, and amount appear in both examples, but time is present in the denominator on both sides in equation 2.

A better means of determining CO by the indicator dilution method involves the process of **thermodilution**. A Swan-Ganz catheter (a soft, flow-directed catheter with a balloon at the tip) is placed into a large vein and threaded through the right atrium and ventricle so that its tip lies in the pulmonary artery. The catheter is designed to allow a known amount of ice-cold saline solution to be injected into the right side of the heart via a side port in the catheter. This solution decreases the temperature of the surrounding blood. The magnitude of the decrease in temperature depends on the volume of blood that

mixes with the solution, which depends on CO. A thermistor on the catheter tip (located downstream in the pulmonary artery) measures the fall in blood temperature. The CO can be determined using calculations similar to those described for the indicator dilution method. The advantage to this method is that there is no recirculation of the "indicator" and thus more accurate measurements of CO can be determined and done repeatedly over any interval of time. The thermodilution measure of cardiac output is considered the current gold standard for CO determination clinically; all other techniques are measured against it.

Another way in which the principle of mass balance is used to calculate CO takes advantage of the continuous entry of oxygen into the blood via the lungs. This measurement is based on **Fick's principle** and is the oldest means of accurately measuring CO. Although very accurate, measurement of CO by Fick's principle is very cumbersome and impractical for modern day clinical use. However, the principles espoused by this technique have instructional value to medical students.

To explain, in a steady state, the oxygen leaving the lungs (per unit time) via the pulmonary veins must equal the oxygen entering the lungs via the mixed venous blood returning from systemic organs plus that added into that blood at the pulmonary capillaries from air taken into the lungs during ventilation. When the body is at rest and in a steady state, without having recently been exposed to exercise or a meal, the amount of oxygen entering the blood through the lungs per minute is equal to the amount consumed by body metabolism per minute ($\dot{V}O_2$). Therefore, O_2 in blood leaving the lungs equals O_2 input via the pulmonary artery plus O_2 added by respiration.

The O_2 output via the pulmonary veins, in mL of O_2 per minute, is equal to the pulmonary vein O_2 content (vO_2, in mL of O_2 per mL of whole blood) multiplied by the CO (in this case, mL of whole blood per minute). Because O_2 is neither added nor subtracted from the blood as it passes from the pulmonary veins through the left heart to the systemic arteries, the arterial O_2 content (aO_2) multiplied by the CO is a reasonable measure of the O_2 output via pulmonary veins. Similarly, O_2 input via the pulmonary artery is equal to mixed venous blood oxygen input to the right heart and is given as mixed venous blood O_2 content (vO_2) multiplied by the CO. As indicated above, in the steady state, O_2 added by respiration is equal to oxygen consumption. Thus,

$$CO \times aO_2 = CO \times vO_2 + \dot{V}o_2 \quad (3)$$

which rearranges to

$$CO = \dot{V}o_2 / (aO_2 - vO_2) \quad (4)$$

Thus, CO can be calculated with measurement of systemic arterial blood oxygen content, pulmonary arterial (mixed venous) blood oxygen content, and total body oxygen consumption. This method measures CO accurately. However, the needed elements to the equation require cardiac catheterization and measurement of whole body oxygen consumption, which are impractical to use in the clinical setting. The relationship above, however, can be rearranged to yield a way to determine O_2 consumption in an organ or region of tissue ($\dot{V}O_2$) if total blood flow into the region can be measured along with the difference between the arterial oxygen content entering the region and that exiting it in its venous effluent (tissue $aO_2 - vO_2$, also called *oxygen extraction*). This determination is a more common application of Fick's principle in cardiovascular physiology.

IMAGING TECHNIQUES FOR MEASURING CARDIAC STRUCTURES, VOLUMES, BLOOD FLOW, AND CARDIAC OUTPUT

A variety of clinical techniques employ imaging modalities as a means of measuring/estimating ventricular wall and chamber dimensions, the motion of the ventricles during the cardiac cycle and CO. Those that use time-dependent images of the heart to estimate the difference between end-diastolic and end-systolic volumes, which gives stroke volume, can be combined with HR to estimate CO.

Technetium-99 scans use tagging of radioactive technetium-99 to red blood cells or albumin as a means of measuring blood distribution. The radiation (gamma rays) emitted by the large pool(s) of blood in the cardiac chambers is measured using a specially designed gamma camera. The emitted radiation is proportional to the amount of technetium bound to the blood (easily determined by sampling the tagged blood) and the volume of blood in the heart. Using computerized analysis, the amount of radiation emitted by the left (or right) ventricle during various portions of the cardiac cycle can be determined (Fig. 13.12). Stroke volume is determined by measuring the difference in the amount of radiation measured at the end of diastole with that at the end of systole and multiplying this number by the HR to yield the CO.

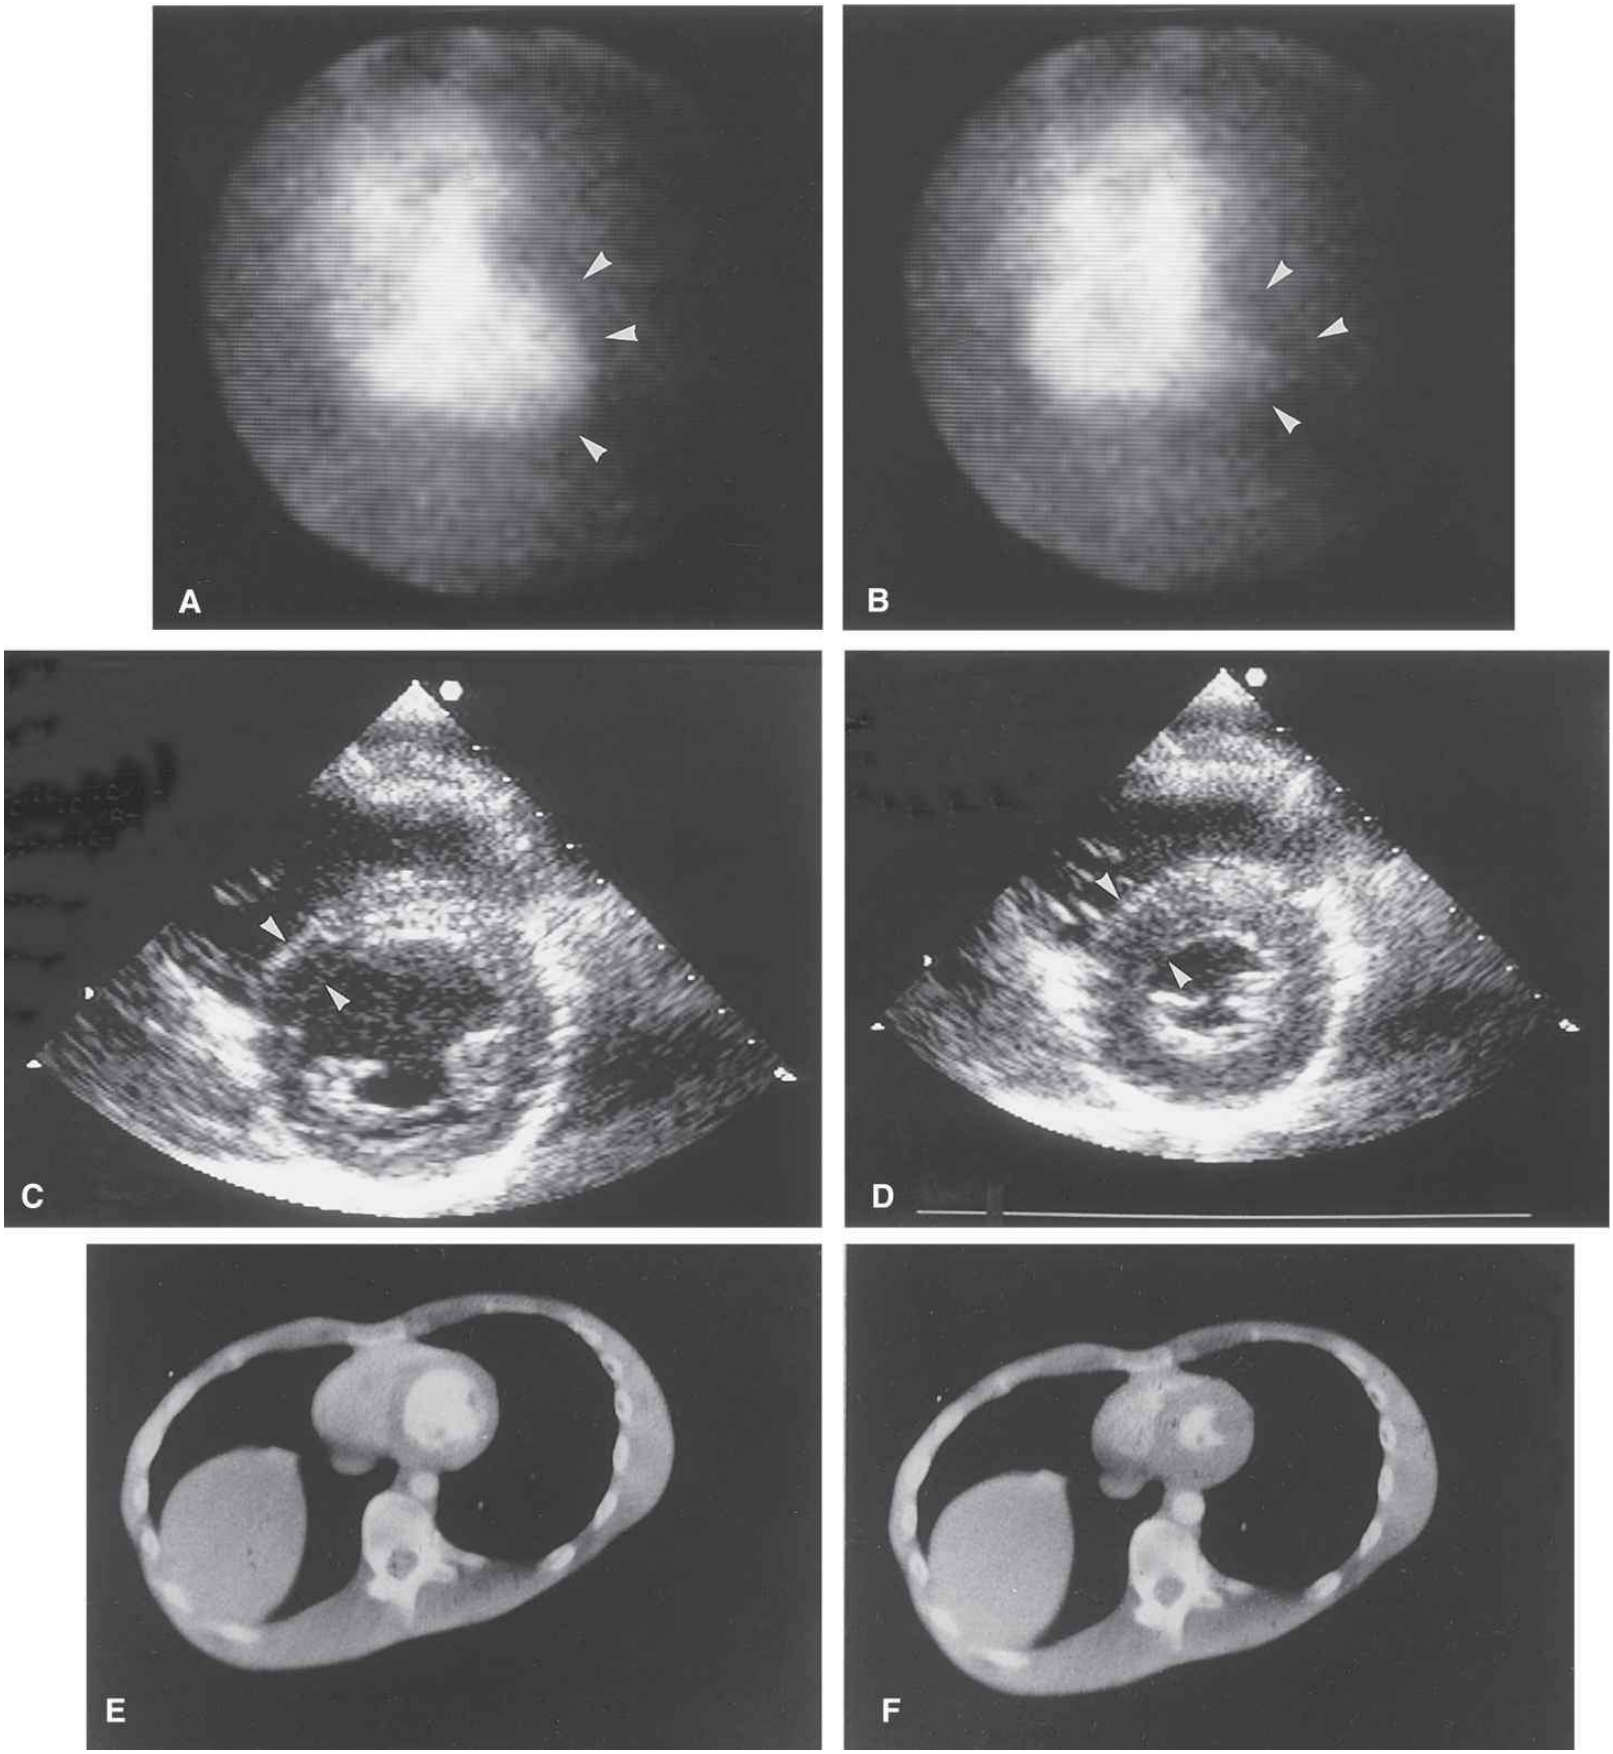

Figure 13.12 Imaging techniques for measuring cardiac output (CO). (A and B) Radionuclide angiograms. The *white arrowheads* in **(A)** show the boot-shaped left ventricle during cardiac diastole when it is maximally filled with radionuclide-labeled blood. In **(B)**, much of the apex appears to be missing (*white arrowheads*) because cardiac systole has caused the blood to be ejected as the intraventricular volume decreases. **(C and D)** Two-dimensional echocardiograms. In this cross-sectional view, the left ventricle appears as a ring. *White arrowheads* indicate wall thickness. In diastole **(C)**, the ventricle is large and the wall is thinned; during systole **(D)**, the wall thickens and the ventricular size

decreases. **(E and F)** Ultrafast (cine) computed tomography. The ventricular size and the wall thickness can be assessed during diastole and systole, and the change in ventricular size can be used to calculate CO.

Echocardiography is a noninvasive technique that uses ultrasound waves to produce one-dimensional and two-dimensional, real-time images of the heart. This is the same technology that is used to image the fetus during pregnancy. The one-dimensional mode of this technique, called **M-mode echocardiography** (where M stands for motion), sends a single beam of ultrasound across a single position to reveal a reflection of the thickness of ventricular walls and the chambers of the heart as well as the motion of the walls and valves during the cardiac cycle. The dimensions of the great vessels can also be imaged with this technique. Detection of abnormalities in ventricular wall motion is an important clinical sign of underlying muscle disease. For example, ischemic myocardium does not contract, and infarcted areas of the heart weaken and actually bulge outward, rather than contract inward, during systole. Such abnormalities are also imaged with two-dimensional echocardiography (**2D echocardiography**). In 2D echocardiography, the ultrasound probe rapidly scans back and forth to give a two-dimensional cross-sectional image of the heart. Simply changing the position of the probe can change the plane of this cross section and the resulting image. This method is used as a noninvasive means of estimating stroke volume and ejection fraction in the heart of a patient.

Doppler ultrasound is also used to detect blood flow across the valves of the heart and in blood vessels. The velocity of blood flow can be determined by measuring the Doppler shift (change in sound frequency) that occurs when the ultrasound wave is reflected off moving blood, much the same way a radar device measures the speed of a moving object. In cardiac evaluation, the velocity of blood flow is color-coded by computer. Turbulence and unusually high flow velocities, such as that which occurs when blood is ejected through a stenotic aortic valve, can be detected. The direction of flow can also be color-coded. This is useful in detecting regurgitation through valves such as in **mitral valve prolapse**.

In sum, echocardiography can be used to measure changes in ventricular chamber size (see Fig. 13.12C, D), aortic diameter, and aortic blood flow velocity occurring throughout the cardiac cycle. CO can also be estimated with this information in one of two ways. First, the change in ventricular volume occurring with each beat (stroke volume) can be determined and multiplied by the HR. Second, the average aortic blood flow velocity can be measured (just above or below the aortic valve) and multiplied by the measured aortic cross-sectional area to give aortic blood flow (which is nearly identical to CO). Ultrafast (cine) computed tomography and magnetic resonance imaging provide cross-sectional views of the heart during different phases of the cardiac cycle (see Fig. 13.12E, F). Stroke volume (and CO) can be calculated using the same principles described for radionuclide techniques or echocardiography. However, when ventricular volume changes are estimated from simply cross-sectional data, assumptions are made about ventricular geometry. The heart is not a sphere, and therefore, its volume cannot be estimated from a single dimension. Estimates using two or three axis approximations of an ellipse can be used with imaging techniques to give a better estimate of volume changes, but these assumptions can lead to errors in calculating CO. Nevertheless, such estimates of ventricular volumes and CO from imaging ventricular dimensions have proven useful in clinical applications.

Current Pharmacotherapy for the Management of Chronic Congestive Heart Failure

Although there are many factors that can lead to chronic congestive heart failure (CHF), the goals of any therapy for the condition are essentially the same: to (1) improve organ perfusion and (2) relieve pulmonary and systemic congestion caused by fluid accumulation in the patient. In Clinical Focus 13.2, it was shown that both these factors can be improved by exposing the patient to generalized vasodilation. Although this was part of early treatment strategies for CHF decades ago, it is now relegated primarily for short-term benefit in acute heart failure emergencies. Newer pharmacotherapies, based on better understanding of cellular malfunctions in heart failure, are now part of modern management of the syndrome. CHF can be thought of as a slow "shock" syndrome in which mechanisms the body normally uses acutely to support blood pressure and cardiac output, when those variable are impaired acutely, instead become activated chronically (see Chapter 17). These compensations include support of blood pressure by activation of the sympathetic nervous system and the formation of a peptide, angiotensin II, which is a vasoconstrictor that also promotes salt and water retention by the kidneys. This latter factor supports cardiac output acutely through Starling mechanism. However, the cardiovascular system does not respond well to continual activation of these systems over months, which is what occurs in chronic heart failure. Chronic exposure to angiotensin II results in overproduction of oxygen radicals in the heart as well as blood vessels and is also mitogenic. Long-term exposure to catecholamines is especially damaging to the heart as well. In chronic heart failure, continual exposure to these agents results in accelerated apoptosis in the heart and malignant myocardial remodeling in which the heart, already weakened, becomes dilated and thus under even more stress. For this reason, current therapeutic recommendations are that patients be given drugs that block the actions of catecholamines and reduce angiotensin II in the circulation at the very first sign of heart failure (i.e., reduced ejection fraction) even if the patient has yet to show any symptoms of that cardiac impairment. Current recommendations are to place patients on β-adrenergic receptor blockers and a class of drugs called angiotensin-converting enzyme inhibitors (ACE inhibitors) to blunt the formation of angiotensin II in the body. The benefit of the latter is easy to visualize in that not only does this agent block the long-term pathological effects of sustained angiotensin II exposure but it also benefits the CHF patient by lowering vascular resistance and reducing water retention. The beneficial effects of a β-receptor antagonist (or "beta-blocker") are not apparent at first glance and were actually an unexpected finding during clinical trials examining the use of such agents for other purposes. Acutely, inhibition of cardiac beta receptors produces negative inotropic and chronotropic effects on the heart; these obviously, at first, would appear to be detrimental to patients with CHF. Indeed, within the first month of treatment with a beta-blocker, CHF patients may actually present with a slightly even more reduced ejection fraction. However, with sustained treatment over several months, their ejection fraction improves to a level higher than that seen when they first showed signs of failure. Current theory proposes that beta-blockers provide an "antiremodeling" effect on the failing heart, thus preventing and even reversing the malignant cardiac dilation seen with the disease. Beta-blockers and ACE inhibitors have been proven to improve exercise tolerance and endurance and extend the lives of patients with CHF.

In spite of recent evidence of the benefit beta-blockers and ACE inhibitors in patients with CHF, it is generally difficult to manage the patient with more severe forms of CHF without the use of drugs to help remove water and salt from the body. Diuretics are a class of drugs that help the kidney excrete sodium and water (see Chapter 23) and are used extensively to aid patients with CHF, especially in terms of alleviating pulmonary and systemic edema. Finally, it would seem that finding a means to stimulate the failing heart might help patients with CHF by directly increasing its output in spite of its weakened or damaged tissue. To date however, there is only one agent used for this purpose, that being the cardiac glycoside digitalis. Digitalis has been used to treat "heart ailments" in medicine for over 200 years. It partially inhibits the Na^+/K^+ ATPase in myocardial cells, which secondarily impairs calcium extrusion from the cells by the Na^+/Ca^{2+} exchanger in the plasma membrane. This results in a positive inotropic effect on the heart and an improvement in its stroke output. However, digitalis also has detrimental electrophysiological properties on the heart and is a difficult drug to manage in the patient with CHF. Digitalis partially depolarizes the resting cell membrane potential, reduces the amplitude of myocardial action potentials and dV/dt, shortens the cell refractory period, and causes phase 4 in Purkinje fibers to drift toward threshold for firing an action potential. All of these factors taken together are a recipe for stimulating the formation of ectopic foci in the heart and creating favorable conditions for the creation of re-entry tachycardias and DADs. ■

Chapter Summary

- Tetanic contraction is prevented in cardiac muscle because the cardiac muscle action potential is longer than the duration of the contraction.
- Cardiac muscle operates at lengths along the ascending limb of the isometric length–tension curve.
- The velocity of shortening of cardiac muscle is inversely related to the force being exerted.
- Cardiac muscle contraction can be regulated by changes in contractility.
- The contractility of cardiac muscle is changed by inotropic interventions that include changes in the heart rate, the presence of circulating catecholamines, or sympathetic nerve stimulations.
- Calcium enters a cardiac muscle cell during the plateau of the action potential and promotes the release of internal calcium stores in the sarcoplasmic reticulum.
- Changes in cardiac muscle contractility are associated with changes in the amount of calcium released by calcium-induced calcium release mechanisms.
- Ventricular ejection is divided into rapid and reduced ejection phases.
- Stroke volume is the amount of blood ejected from the ventricles during one systole; it is the difference between ventricular end-diastolic and end-systolic volumes.
- The ventricles do not empty completely during systole, leaving a residual volume in the ventricle for the next filling cycle.
- Ventricular filling is divided into rapid and reduced filling phases.
- Heart sounds during the cardiac cycle are related to the opening and closing of valves in the heart.
- Venous pressure waves can detect abnormalities in atrioventricular valves.
- Cardiac output is the total flow output of the heart per minute and is the product of stroke volume times heart rate.
- Stroke volume is determined by end-diastolic fiber length, afterload, and contractility. Heart rate influences ventricular filling time and stroke volume so that changes in cardiac output caused by changes in heart rate are attenuated.
- The influence of the heart rate on cardiac output depends on simultaneous effects that enhance ventricular contractility at high rates.
- Cardiac energy demands are determined by collective contributions from ventricular wall stress, heart rate, stroke volume, and contractility.
- The energy cost of work in the heart is greater for work done to generate pressure than for work done to eject blood.
- Cardiac output can be measured by methods that rely on mass balance or cardiac imaging.

Chapter Review Questions

1. Which of the following pathological conditions would be most likely to create a prominent third heart sound during normal auscultation of the heart with a stethoscope?
   A. Congestive heart failure
   B. Systemic arterial hypertension
   C. Increased heart rate by 20 beats/min
   D. Decreased heart rate by 20 beats/min
   E. Arterial hypotension (i.e., lower-than-normal blood pressure)

The correct answer is A. The third heart sound is not normally heard, and its presence is a sign of underlying pathology. Its intensity is increased whenever the heart fills into a distended chamber or stiff ventricle. Ventricular distention is common in heart failure as blood backs up into the failing heart. High arterial pressure would increase the intensity of the second heart sound. Hypotension would not be expected to affect the third heart sound because the third sound occurs during diastole. Modest changes in heart rates are normal physiological adjustments and would not create an abnormal heart sound.

2. If a normal heart has a left ventricular end-diastolic volume (LVEDV) of 140 mL, a stroke volume of 70 mL, and a cardiac output of 4.9 L/min and pumps against a systolic arterial pressure of 120 mm Hg, which would be true of this same heart if its LVEDV became 160 mL and its stroke volume 70 mL without a change in its cardiac output or mean systolic arterial pressure?
   A. Myocardial oxygen consumption would be increased because heart rate increased.
   B. Myocardial oxygen consumption would be decreased due to an increase in extent of shortening of the heart muscle.
   C. Myocardial oxygen consumption would be increased because the heart is now under a positive inotropic influence.
   D. Myocardial oxygen consumption would be increased due to an increase in systolic wall stress.
   E. Myocardial oxygen consumption would be decreased because passive diastolic stretch on the ventricle is decreased.

The correct answer is D. An increase in LVEDV without a change in stroke volume means the radius of the ventricular chamber is greater than normal throughout systole. Without any change in mean systolic pressure, the increased chamber radius increases ventricular wall stress. Wall stress is a major determinant of myocardial oxygen consumption. Filling did not increase in the ventricle, but rather just the volume about which filling occurred. Heart rate did not change in this example because CO = SV × HR and SV and CO did not change. A heart with increased LVEDV should increase SV if nothing else changed in the myocardium. The only way stroke volume could not change in this example when preload is increased is if the heart was under a negative inotropic influence. A negative inotropic condition would tend to reduce myocardial oxygen consumption, but this effect would likely be negated by the increased wall stress, which is the most significant variable in determining myocardial oxygen consumption in this instance.

3. Which of the following will promote an increase in the stroke volume of the heart?
   A. A reduction in venous tone
   B. A pneumothorax
   C. Dehydration
   D. General anesthetics

E. Skeletal muscle contraction

The correct answer is E. Contraction of the skeletal muscle, such as that which occurs during walking or running, compresses veins and increases their intravascular pressure. This increased pressure translocates blood to the thoracic cavity (central circulation), increasing right atrial pressure, which, in turn, increases ventricular diastolic filling and preload. This increased preload results in an increased stroke volume by Starling mechanism. A reduction in venous tone (smooth muscle contraction in the veins) would have the opposite effect on right atrial pressure and filling and, thus, reduce stroke volume. Dehydration will reduce all body water volume, including that in the intravascular compartment. However, the primary effect of a loss of volume in the body on the vascular compartment is in the venous side of the circulation. Therefore, dehydration reduces venous and right atrial pressure. General anesthetics are negative inotropes and, by reducing myocardial contractility, will reduce stroke volume at any given preload or afterload.

4. Caffeine inhibits cyclic adenosine monophosphate phosphodiesterase and stimulates the release of calcium from the sarcoplasmic reticulum. The effect of caffeine on the heart through this effect would most likely be:

A. an increase in myocardial contractility.
B. a decrease in the rate of ventricular relaxation.
C. a decrease in calcium influx into myocardial cells during systole.
D. a reduction in the amount of calcium pumped into the sarcoplasmic reticulum during diastole.
E. a decrease in myocardial contractility.

The correct answer is A. Both effects of calcium would increase the intracellular calcium concentration in the heart, thereby augmenting myocardial contractility. Cyclic adenosine monophosphate (cAMP) phosphodiesterase increases intracellular cAMP concentration by inhibiting its breakdown. cAMP increases the open time of L-type calcium channels and indirectly stimulates pumping of calcium into the sarcoplasmic reticulum by calcium ATPases. The latter effect helps speed myocardial relaxation during diastole.

5. All of the following would be consistent with the finding of heart failure in a patient except:

A. elevated pulmonary wedge pressure (a measure of pressure in the left atrium).
B. decreased stroke volume at normal arterial pressure.
C. a left ventricular ejection fraction under 30%.
D. an increased left ventricular max dP/dt (the maximum rate of change in ventricular pressure during systole).
E. a left ventricular Starling relationship that is shifted downward and to the right compared to a normal heart.

The correct answer is D. A heart that is failing exhibits the characteristics of a heart under the influence of negative inotropic effects. The heart pumps either a normal stroke volume, but at a higher than normal filling pressure, or a reduced stroke volume in spite of a normal or even increased filling pressure. The latter is most common in heart failure beyond its earliest manifestations and is reflected in an abnormally high pulmonary wedge pressure. Another way of viewing this pressure is to consider that because the heart cannot produce a normal output, blood backs up into the pulmonary circuit, thereby raising pressure there. The ejection fraction of a normal heart is above 45% and up to 67%. A heart in failure has a flattened Starling relationship of stroke volume to preload; compared to a normal heart, a failing heart produces very little augmentation of stroke volume for a given increase in preload (ventricular filling).

Clinical Application Exercises 13.1

POSTINFARCTION LEFT VENTRICULAR FAILURE

A 44-year-old female patient with a 2-pack-a-day cigarette habit since age 18 suffers a major myocardial infarction in the anterior wall of her left ventricle from a blood clot in the proximal portion of her left anterior descending artery. The clot is removed through intracoronary administration of tPA during an emergency cardiac catheterization procedure, but the removal does not occur until 4 hours after the onset of the infarction. Twenty-four hours later, the patient is conscious with a heart rate of 100, BP of 110/85, occasional PVCs, dyspnea, tachypnea, and pulmonary rales. An echocardiogram of the patient reveals an abnormally large residual volume, increased left ventricular diastolic and systolic dimensions, an ejection fraction of 29%, and reduced peak systolic aortic flow velocity. During systole, there is asymmetric contraction of the left ventricle with bulging of the anterior wall. Chest x-ray evaluation reveals pulmonary congestion and edema formation.

QUESTIONS

1. What general diagnosis would you give this patient 24 hours after her myocardial infarction and what is its primary cause?
2. What explains the patient's echocardiographic findings?
3. What is the likely systolic left ventricular wall stress in this patient during the cardiac cycle as compared to someone without this magnitude of myocardial infarction?
4. General vasodilator therapy, which dilates both arteries and veins, will enhance stroke volume and relieve pulmonary congestion in this patient. What is the mechanical mechanism of this generalized vasodilator effect on the heart such that it can both increase stroke volume and reduce pulmonary congestion? How does this effect differ from that which would be seen in a normal healthy patient given this same therapy?

ANSWERS

1. The patient has all the symptoms of left ventricular congestive heart failure resulting from loss of a large amount of left ventricular contractile mass due to cell death and injury from the myocardial infarction. The infarction was likely exacerbated by the extended time the myocardium was ischemic followed by ischemia reperfusion injury during restoration of LAD patency by tPA.
2. Ischemic or infarcted myocardium is acontractile and cannot generate force during systole. The magnitude of this patient's infarction has obviously impaired myocardial contractile performance as evidenced by the low EF and low peak aortic flow velocity. As such, residual volume rises in this patient, and the diastolic volume of the heart increases. However, in spite of the increased preload, the heart is unable to sustain a normal stroke volume. This conclusion is consistent with the observation of a larger than normal end-systolic volume, abnormally low ejection fraction, reduced peak aortic flow velocity, and small pulse pressure. Infarcted myocardium is stiffer than normal myocardium but retains some compliance although it cannot contract. Therefore, the increase in ventricular pressure during systole causes the infracted portion of the myocardium to bulge during myocardial contraction.
3. Although the patient's blood pressure is slightly lower than average, the increased ventricular

chamber size throughout the cardiac cycle places this heart in a condition of increased wall stress. This stress is especially high in the infracted, bulging region of the myocardium where the radius of curvature of the ventricular wall is greatly increased.

4. Stroke volume in the heart is determined by preload, afterload, and the position or slope of the left ventricular end-systolic pressure volume relationship (ESPVR). Preload, in part, is a function of venous filling pressure, and afterload is largely determined by peripheral vascular resistance and systolic arterial pressure. The ESPVR determines the final point to which the heart can contract at any given set of loading conditions and has a positive slope on a plot of left ventricular pressure versus volume. Contraction proceeds from any given afterload and preload until the PV point intersects the ESPVR. This determines the extent of shortening and the resulting stroke volume. Decreasing afterload positions any contraction at a level where the ESPVR is farther away from the start of contraction. Thus, extent of shortening can increase when afterload is decreased, and stroke volume will thus increase when afterload is decreased. As can be seen with any plot of the ESPVR in conjunction with a left ventricular pressure–volume loop, this enhancement of stroke volume is small in a heart with a steep ESPVR, such as a normal healthy heart. However, a heart in failure has an ESPVR with a decreased slope resulting from that heart's depressed contractile state. The result of this decreased slope is that the left end of the ESPVR is tilted up and to the left on the left ventricular pressure–volume relationship. When contractions from any loading condition proceed with this ESPVR in place, the contraction is able to proceed farther than that seen for the same loading conditions in a normal healthy heart. Thus, augmentation of stroke volume by decreasing afterload with an arterial dilator is greater in a failing heart than in a normal heart.

Venodilation decreases venous filling pressure and tends to reduce stroke volume. However, venodilation allows for fluid to exit the central circulatory blood volume compartment thus reducing blood volume in the pulmonary circulation and in the heart. This helps reduce pulmonary congestion and ventricular wall stress, respectively. A normal heart has a steep Frank-Starling relationship, which means that small changes in preload have marked effects on stroke volume. Thus, venodilation in a healthy heart will likely cause a precipitous drop in cardiac output owing to this steep relationship. However, the Frank-Starling curve in a failing heart is very flat; rather large decreases in venous filling pressure (preload) can occur with minimal negative effect on stroke volume. This small effect to reduce stroke volume is offset by the concurrent arterial dilation afterload effect. Thus, implementation of generalized vasodilator therapy in a patient in heart failure augments stroke volume while at the same time reducing pulmonary congestion and myocardial wall stress.

14 The Systemic Circulation

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Predict how changes in arterial compliance and stroke volume will change pulse pressure.
- Use analysis of the arterial pressure waveform to determine what changes in heart rate, stroke volume, and vascular resistance created the waveform.
- Explain how shifts between central and systemic venous volumes affect cardiac output.
- Explain how changes in central venous pressure cause changes in cardiac output and how changes in cardiac output cause changes in central venous pressure.
- Given the interdependence between cardiac output and central venous pressure, explain how equilibrium between the two variables arises in the cardiovascular system.
- Explain how and why the equilibrium point between cardiac output and central venous pressure is shifted by changes in blood volume, venous tone, arteriolar resistance, and the inotropic state of the heart both individually and collectively.

The aorta and other large-diameter arteries do not contribute significantly to total vascular resistance and therefore do not play a role in the regulation of organ blood flow or systemic arterial pressure. However, their elastic characteristics influence a variety of important cardiovascular variables. These include the arterial pressure waveform, cardiac work, and the effects of changes in vascular characteristics on cardiac output (CO).

DETERMINANTS OF ARTERIAL PRESSURES

Four principal pressures of physiologic interest are contained within the arterial pressure waveform. These are the mean, systolic, diastolic, and pulse pressure. Clinically, arterial pressure is often reported as the ratio of systolic (peak) over diastolic pressure (lowest pressure), for example, as 120/80 or 110/75 mm Hg. Arterial pressure varies between these two values from heart beat to heart beat.

Mean arterial pressure is determined by cardiac output and systemic vascular resistance.

$\overline{P}_a$

Mean arterial pressure, $\overline{P}_a$, is the integrated average arterial pressure determined from the arterial pressure waveform (Fig. 14.1). However, it is often approximated from the equation

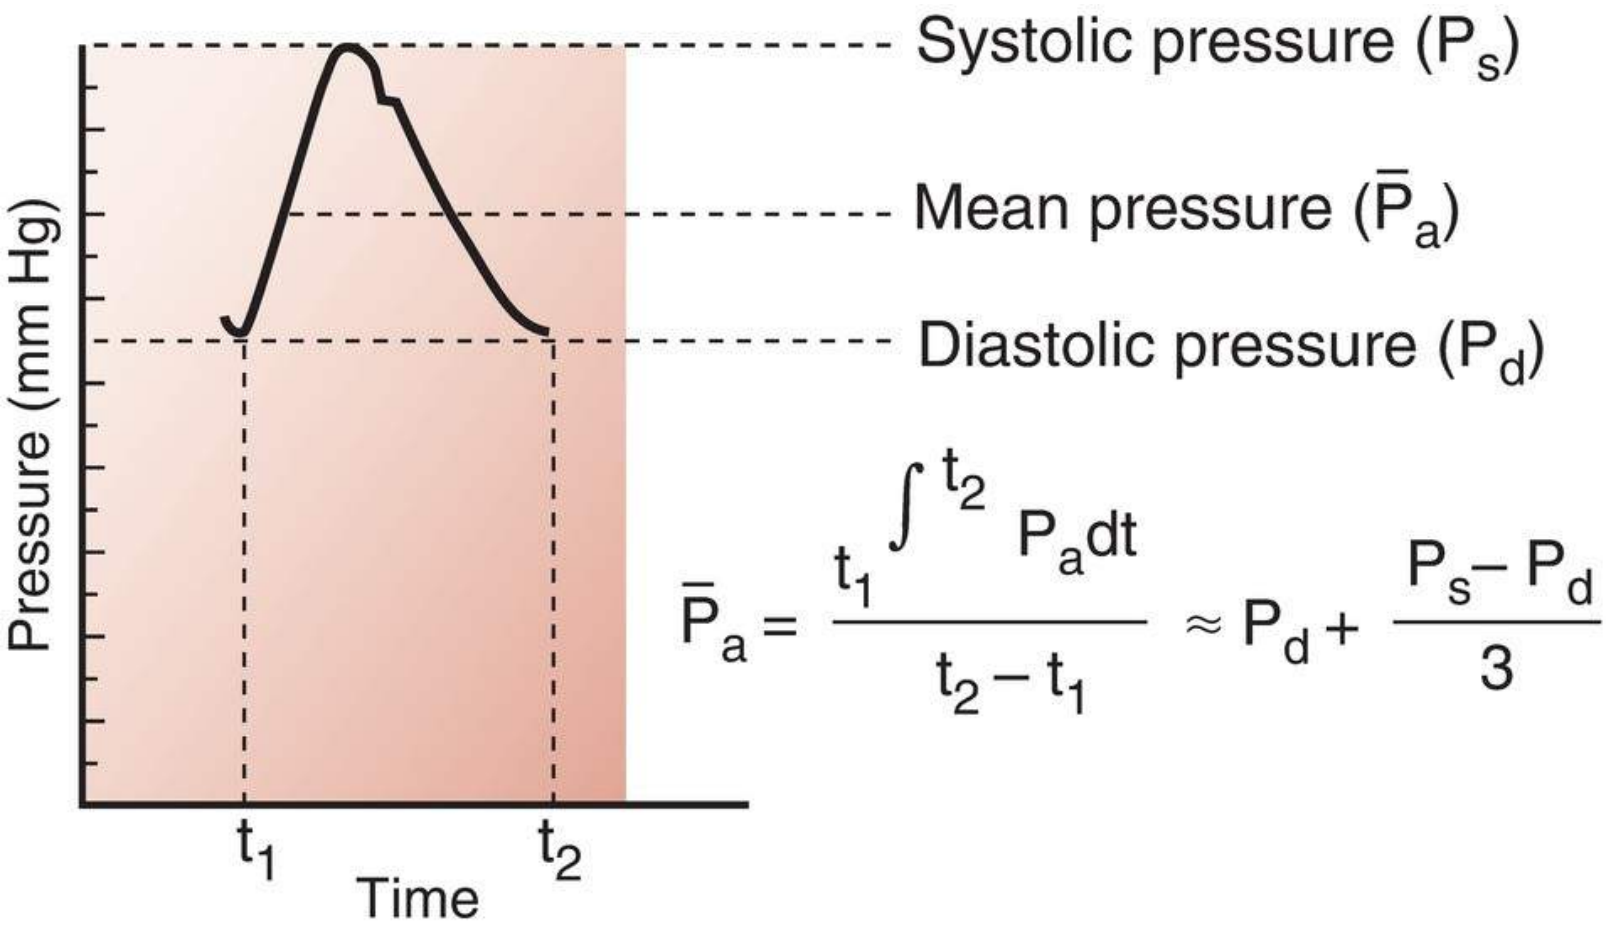

Figure 14.1 Definition of mean arterial pressure. Mean pressure is the area under the pressure curve divided by the time interval. This can be approximated as the diastolic pressure plus one third the pulse pressure.

$$\overline{P}_a = P_d + 1/3(P_s - P_d) \quad (1)$$

where P_d is the diastolic pressure, P_s is the systolic pressure, and $P_s - P_d$ is the **pulse pressure**. Mean

arterial pressure is closer to P_d, instead of the arithmetic average of P_s and P_d, because the duration of diastole is about twice as long as that of systole. In addition, because right atrial pressure is small and near zero (~2 mm Hg), mean arterial pressure can be approximated as equal to the product of cardiac output and total systemic vascular resistance (CO × SVR).

Changes in stroke volume and arterial compliance alter pulse pressure.

Pulse pressure is a function of stroke volume and arterial compliance. Figure 14.2A shows how aortic pressures change in response to a simple chance in aortic volume alone (i.e., when there is no concurrent change in aortic compliance, SVR, and heart rate). During rapid ejection, blood enters the aorta faster than it can run off, thus increasing aortic volume. This increased volume increases pressure in the aorta to a peak value in accordance with the interrelationship between aortic compliance, volume, and pressure in a hollow, flexible structure ($\Delta P = \Delta V/C$). During the reduced ejection phase of the cardiac cycle and diastole, blood exits the arteries faster than it enters. Volume in the aorta thus declines as does the pressure associated with it. If the amount of blood ejected into the aorta doubled, without a change in heart rate or SVR, this would double CO and, from Poiseuille's law, double mean arterial pressure. Changes in pressure resulting from increases and decreases in arterial blood volume would oscillate about this new mean. In the example in which ejection doubles, most of this volume would be ejected in the rapid ejection phase. Therefore, the amount ejected that exceeds runoff would also approximately double, and this would be reflected by a larger increase in the systolic pressure. Runoff would be little affected by this increased ejection, so diastolic pressure would fall at about the same *rate* as before but from this new, higher systolic pressure. Therefore, pressure would drop to a diastolic pressure that is considerably higher than before. Thus, an increase in mean aortic, systolic, diastolic, and pulse pressure results when stroke volume increases without any concurrent change in SVR, arterial compliance, and heart rate.

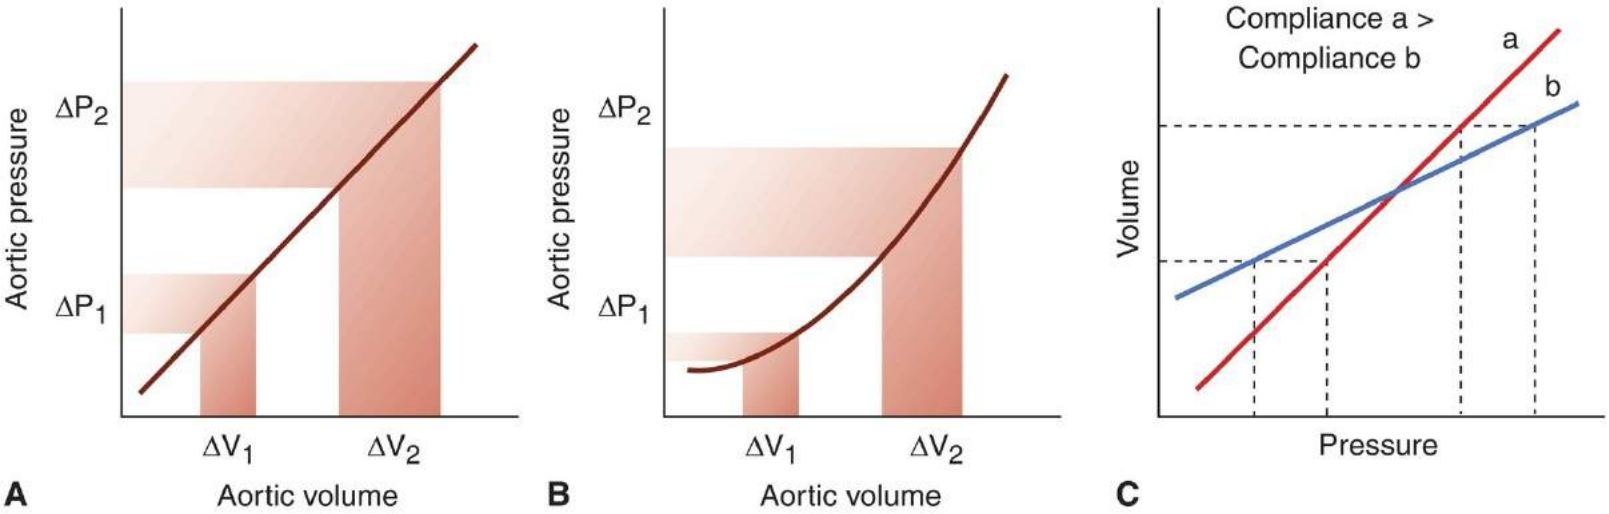

Figure 14.2 Relationship between aortic volume and pressure. (A) Theoretical condition where aortic compliance is independent of aortic volume. The change in volume (ΔV_1) causes the change in pressure (ΔP_1). A larger volume increment (ΔV_2), without changing heart rate or arterial compliance, produces a larger mean pressure and larger change in pressure (ΔP_2). **(B)** In the cardiovascular system, aortic compliance decreases as aortic volume and pressure increase. A change in volume (ΔV_1) is associated with a change in pressure (ΔP_1). The same change in volume at a higher initial volume (ΔV_2) causes a much larger change in pressure (ΔP_2) because of reduced compliance at the higher mean pressure. **(C)** With the same ΔV, ΔP increases with a decrease in compliance.

As explained in Chapter 11, arterial compliance is not constant but rather, in part, a function of transmural pressure in the arterial system; arterial compliance decreases as transmural pressure is increased (Fig. 14.2B). Because of this, a given change in aortic volume at a low initial volume, and thus transmural pressure, causes a relatively small change in arterial pressure with ejection. However, at a high initial transmural pressure, that same change in volume causes much larger changes in arterial pressure.

The general effect of a change in arterial compliance on arterial pressures is shown in Figure 14.2C. When arteries are stiff, they flex less during systole and recoil less during diastole. Therefore, for a given change in volume, decreased arterial compliance causes an increase in systolic pressure and a *decrease* in diastolic pressure. Note, if there is no change in arterial resistance or heart rate, mean arterial pressure will *not* change with a change in arterial compliance alone.

Interactions among stroke volume, heart rate, and systemic vascular resistance alter arterial pressures.

When CO changes in the face of a constant vascular resistance, mean arterial pressure is influenced according to the formula $\overline{P}_a = CO \times SVR$. The influence of a change in CO on mean arterial pressure is independent of the cause of the change, whether it comes from heart rate or stroke volume. In contrast, the effect of a change in CO on pulse pressure greatly depends on whether and how stroke volume or heart rate change.

If an increase in heart rate is balanced by a proportional and opposite change in stroke volume, *mean* arterial pressure does not change because CO remains constant. However, the decrease in stroke volume that occurs in this situation results in a diminished pulse pressure. The reduced volume ejected during systole reduces systolic blood pressure, while the increased heart rate provides less time for pressure to diminish during diastole. Consequently, diastolic pressure increases. An increase in stroke volume accompanied by a decreased heart rate such that there is no change in CO likewise causes no change in mean arterial pressure. The increased stroke volume, however, produces a rise in pulse pressure. The increased volume ejected with each contraction causes a greater rise in systolic pressure. However, because heart rate is reduced, there is more time available for blood to run out of the arteries during diastole. Arterial volume, therefore, drops to a lower value than before, and diastolic pressure decreases as a result.

Another way to think about these events is depicted in Figure 14.3A. The first two pressure waves have systolic pressure of 120 mm Hg, a diastolic pressure of 80 mm Hg, and a mean arterial pressure of 93 mm Hg. Heart rate in this example is72 beats/min. After the second beat, the heart rate is slowed to 60 beats/min, but stroke volume is increased sufficiently to maintain the same CO. The longer time interval between beats allows the diastolic pressure to fall to a new (lower) value of 70 mm Hg. The next systole, however, produces an increase in pulse pressure because of the ejection of a greater stroke volume, so systolic pressure rises to 130 mm Hg. The pressure then falls to the new (lower) diastolic pressure, and the cycle is repeated. Mean arterial pressure does not change because CO and SVR are constant, and the increased pulse pressure is distributed around the same mean arterial pressure as before. In some instances, mean arterial pressure may remain constant despite a change in CO because of an alteration in SVR. A good example of this is **dynamic exercise** (e.g., running or swimming). Dynamic exercise often produces little change in mean arterial pressure because the increase in CO is balanced by a decrease in SVR. The increase in CO is caused by increases in both heart rate and stroke volume. The elevated stroke volume results in a higher systolic pressure, whereas diastolic pressure is lower because the fall in SVR allows greater runoff from the aorta during diastole (Fig. 14.3B).

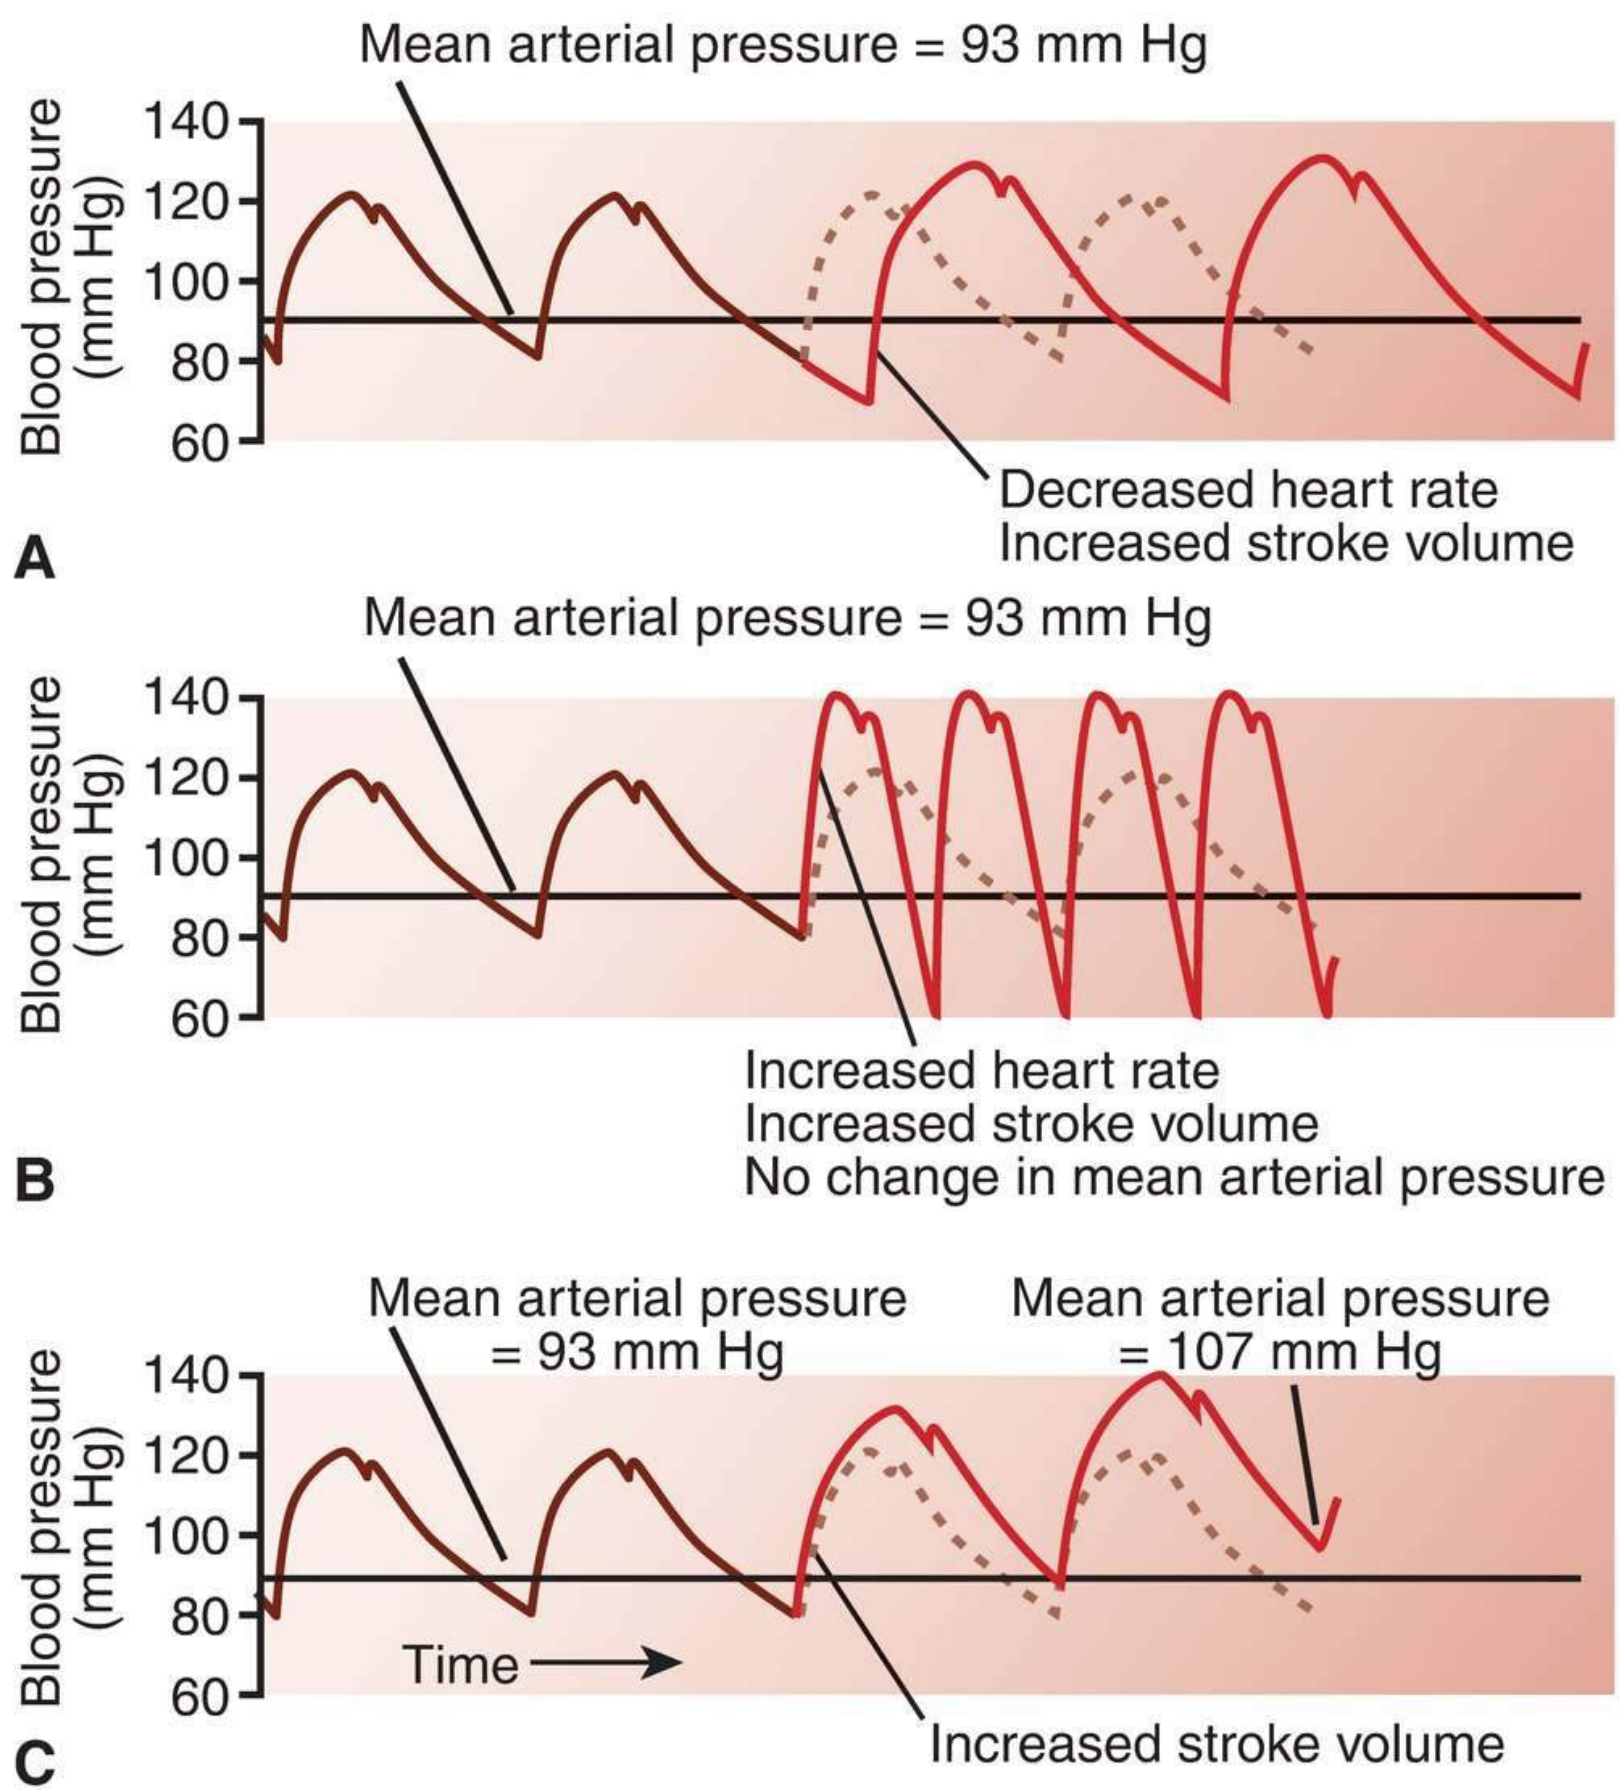

Figure 14.3 Effects of changes in heart rate (HR), stroke volume, and systemic vascular resistance (SVR) on arterial pressure. (A) Effect of increased stroke volume on arterial pressure with constant cardiac output (CO) and SVR. When cardiac output is held constant by lowering HR, there is no change in mean arterial pressure (93 mm Hg), but systolic pressure increases while diastolic pressure decreases. **(B)** Effect of increased HR *and* stroke volume with no change in mean arterial pressure because of decreased SVR. After the first two beats, stroke volume and HR are increased. Pulse pressure increases

around an unchanged mean arterial pressure. Systolic pressure is higher due to higher ejection associated with the increased stroke volume, and diastolic pressure is lower than the control because the lower SVR allows more rapid runoff of blood out of the arterial system during diastole. **(C)** Effect of increased stroke volume, with constant HR and SVR. CO, mean arterial pressure, systolic pressure, diastolic pressure, and pulse pressure are all increased.

Figure 14.3C shows what happens if CO is increased by increasing stroke volume with no change in heart rate or SVR. The increased stroke volume occurs at the time of the next expected beat, and the diastolic pressure is as it was for previous beats, or 80 mm Hg. After a transition beat, the increased stroke volume results in an elevation in systolic pressure to 140 mm Hg. The decline of blood pressure during reduced ejection and diastole is not affected by the increased stroke volume alone, and thus, pressure falls normally during this phase, but from the higher systolic pressure caused by the increased stroke volume. This results in an increased final diastolic pressure (~90 mm Hg). Thus, in this new steady state, systolic, diastolic, and mean arterial pressures are all higher, the latter because CO increased while SVR remained unchanged. Also, in this instance, a further change in pulse pressure is created because the increase in mean arterial pressure (to 107 mm Hg) pushes oscillations in pressure to a less compliant region of the arterial system (see Fig. 14.2). Consequently, the increase in pulse pressure seen results from both higher stroke volume and decreased arterial compliance.

ARTERIAL PRESSURE MEASUREMENT

Arterial blood pressure can be measured by direct or indirect (noninvasive) methods. In the laboratory and sometimes in clinical research or diagnostic settings, a cannula or pressure transducer-tipped catheter can be placed in an artery to measure pressure directly. During simple physical exams in clinical practice, however, blood pressure is usually measured indirectly.

Sphygmomanometry is a noninvasive measurement of blood pressure in humans.

Clinical measurement of blood pressure is almost always determined noninvasively by sphygmomanometry. In this method, a **sphygmomanometer** that registers pressure is connected to an inflatable cuff that is wrapped around the patient's arm and inflated so that the external pressure on the arm exceeds systolic blood pressure. When this occurs, blood flow into the arm is cut off, and no pulses can be detected distal to the cuff (Fig. 14.4). The external pressure in the cuff is measured by the height of a column of mercury in the manometer connected to the cuff or by means of a mechanical or digital electronic manometer that has been calibrated to a column of mercury. To measure blood pressure, the air in the cuff is first slowly released until blood can leak past the occlusion at the peak of systole. At this point, blood spurts past the point of partial occlusion at high velocity, resulting in turbulence. The vibrations associated with the turbulence are in the audible range and can be heard with a stethoscope placed over the brachial artery. These noises are known as **Korotkoff sounds**. The pressure corresponding to the first Korotkoff sound is the systolic pressure. As pressure in the cuff continues to fall, the brachial artery returns toward its normal shape and both the turbulence and Korotkoff sounds cease. The pressure at which the Korotkoff sounds cease is the diastolic pressure.

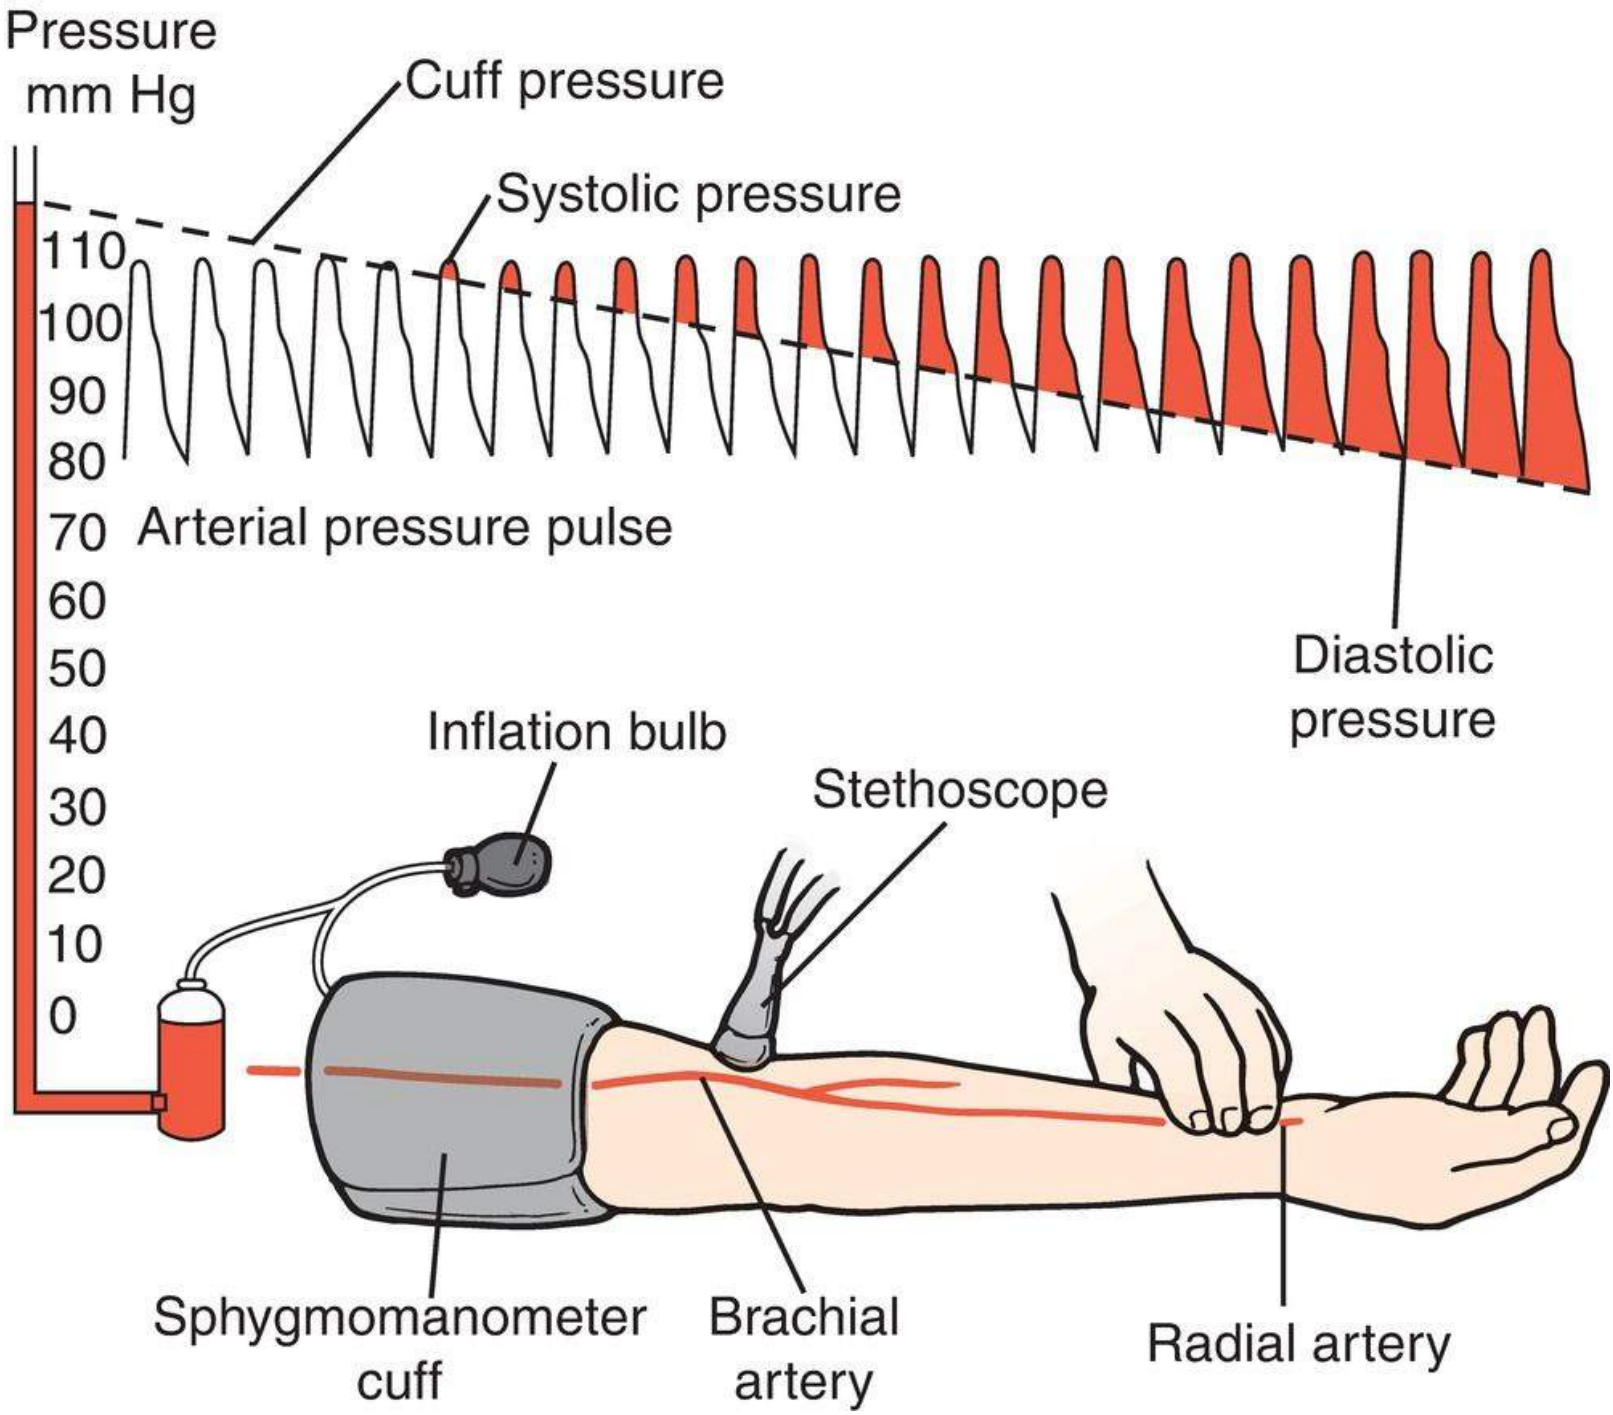

Figure 14.4 Indirect measurement of arterial blood pressure by sphygmomanometry and radial artery auscultation. To measure arterial blood pressure, an inflatable cuff connected to a pressure gauge calibrated against a mercury manometer is placed around the upper arm above the brachial artery. The cuff is initially inflated to a pressure ~20 mm Hg above the expected systolic pressure for the patient, and a stethoscope is placed lightly over the brachial region. Initially, there is no audible sound from the region. The cuff is deflated at a rate of 2 to 3 mm Hg/s, while the clinician listens for sounds created by pulsatile squirting of blood past the partially occluded artery. These sounds are called *Korotkoff sounds* and are characterized by five phases: Phase I is the level at which the first appearance of clear, repetitive, tapping sounds occur. This coincides approximately with the resumption of a palpable pulse. The pressure at which the first two tapping sounds occur is considered to be the peak systolic pressure. Phase II is the interval in which a swishing murmur is added to the initial tapping as the cuff is deflated. Phase III is characterized by distinct, crisp, and louder sounds as the artery opens more with cuff deflation. Phase IV is the start of a distinct muffled sound with a soft, blowing quality. Phase V is the final silence due to the resumption of full laminar flow in the brachial artery. The last sound heard before the onset of

Phase V is considered to represent diastolic arterial pressure. If sounds persist from Phase IV to zero pressure, then the pressure recorded at the start of Phase IV is considered the diastolic blood pressure.

Although the cuff method has become a standard means of evaluating blood pressure in clinical settings, it is not without artifact errors. A cuff that is too narrow will give a falsely high pressure because the pressure in the cuff is not fully transmitted to the underlying artery. Ideally, cuff width should be ~1.5 times the diameter of the limb at the measurement site. Obesity may contribute to an inaccurate assessment if the cuff used is too small. In older adults (or those who have "stiff" or hard-to-compress blood vessels from other causes, such as arteriosclerosis), additional external pressure may be required to compress the blood vessels and stop the flow. This extra pressure can give a falsely high estimate of blood pressure.

CLINICAL FOCUS 14.1

Arteriosclerosis and Systolic Hypertension in Older Adults

Arteriosclerosis is broadly defined as any disease leading to the general hardening of the arteries. This includes reduced arterial compliance associated with the aging process, restenosis phenomena, hardening following transplantations of vascular segments, and even atherosclerosis. However, these conditions all differ significantly with respect to key immune, mitogenic, and lipid components to their pathology. Typically, the term arteriosclerosis is used to describe the general progressive decrease in arterial compliance that accompanies the aging process (see Chapter 11). Even in the absence of true systemic arterial hypertension and atherosclerosis, people in their 70s have considerably stiffer arterial walls than those in their 20s. The process that leads to this arterial stiffening is thought to be related to the continual, day-to-day exposure of arteries to oxygen radicals produced in the arterial wall as the by-product of natural metabolism. However, it likely also results from accumulated insults to the arteries from lifestyles, dietary factors, and pathological conditions known to stimulate excess radical production such as tobacco use, hypertension, and diabetes mellitus.

Arteries in young people owe their suppleness to the orderly arrangement of elastin and collagen in the arterial wall. Oxygen radicals attack the collagen and elastin matrix within the arteries, causing both strand breaks and rearrangement of elastic fibers into a more random configuration. This random configuration results in a stiffer artery. In the absence of any other pathologic factors, an older person with this type of arteriosclerosis exhibits an increased pulse pressure associated with an increased systolic pressure, lower diastolic pressure, and normal mean arterial pressure compared with a healthy younger person (healthy meaning with a blood pressure of 120/80 mm Hg). People with this condition have what is called **systolic hypertension** because only their systolic pressure is elevated.

Until somewhat recently, older patients with systolic hypertension were not treated with typical antihypertensive drug therapies for their condition. These people did not have the underlying vascular abnormalities associated with the increased arterial resistance of essential hypertension because their mean arterial pressure was not changed. Furthermore, their age led some to believe that there may be no long-term benefit to drug treatments, especially when such treatments were associated with serious side effects. However, systolic hypertension is no longer neglected in older adults and is instead treated with therapies designed to reduce arterial pressure. The reason for this is that systolic pressure

is a key component of the wall stress that must be overcome for the heart to effectively contract. High systolic pressure leads to high stress that in turn increases oxygen demand by the heart. This places the heart at risk for ischemia and arrhythmias, whose incidence can be reduced if the systolic pressure is decreased. In addition, clinical trials have shown that the morbidity and mortality of older patients with systolic hypertension are improved with treatment to lower the systolic pressure, thus providing evidence-based support for antihypertensive therapies in older adults with systolic hypertension. ■

Age, race, gender, diet, and body weight affect the range of arterial pressure seen in humans.

Although the range of blood pressures in the population as a whole is rather broad, changes in a given patient are of diagnostic importance. Normal arterial blood pressure in adults is often stated to be 120/80 mm Hg. However, these values were originally derived from insurance actuary data in acculturated Western societies after World War II. A more extensive examination of arterial pressures in the human population suggests that true normal human systolic pressure may be 100 to 110 mm Hg, with a corresponding diastolic pressure of 60 to 70 mm Hg.

In Western societies, arterial pressure is dependent on age. Systolic blood pressure rises throughout life, whereas diastolic blood pressure rises until the sixth decade of life, after which it stays relatively constant. Blood pressure is higher among African Americans than among Caucasian Americans, but it is lower in aboriginal Negroid populations than in Western Caucasian populations. Blood pressure is higher among men than among premenopausal women of similar age. Dietary fat and salt intake, as well as obesity, is associated with higher blood pressure. Other factors that affect blood pressure are excessive alcohol intake and psychosocial stress (which elevates pressure) as well as potassium and calcium intake and physical activity (which are associated with reductions in arterial pressure).

CLINICAL FOCUS 14.2

Effects of Age, Race, and Diet on Arterial Pressure

The common assignment of normal arterial pressure as 120/80 mm Hg is a convenient benchmark that does not reveal that arterial pressure varies within populations as a result of a variety of genetic and environmental factors. Human blood pressure values are a continuum. There is no clear dividing point within the human population that separates subpopulations with normal distributions around a “normal” mean arterial pressure from a different subpopulation distributed around a distinctly elevated arterial pressure. As stated in this chapter, the 120/80 mm Hg dividing point for normalcy has more to do with data sampling than with what is intrinsically supposed to be normal arterial pressure in healthy human beings.

In Western societies, mean arterial pressure and pulse pressure drift upward with age, even if the patient does not have clinically established classic arterial hypertension. However, members of primitive societies do not show this increase in pressure with age, have lower systolic and diastolic pressures as a group compared with members of Western societies, do not develop standard arteriosclerosis, and actually exhibit a slow decline in blood pressure with aging. An interesting observation in members of these primitive groups is that they consume potash as a seasoning, which contains high amounts of potassium. There is laboratory evidence that potassium may reduce wall stiffening although it has been speculated that chronic high NaCl consumption may lead to decreased compliance and impaired passive relaxation of arteries.

African Americans have a higher incidence and severity of arterial hypertension than do

Caucasians of the same gender and similar age. In particular, their arterial pressure seems to be sensitive to salt in the diet. However, Negroid groups in primitive societies do not show this propensity to hypertension at all. An interesting hypothesis proposed to explain these dual effects in the same racial profile has pointed out that human populations that evolved in hot, dry environments have restricted access to water and salt. Those living in such environments possess traits that better enable them to aggressively extract and conserve salt and water from their diet and have a survival advantage over those who cannot conserve salt as well. However, placing such people in a Western society, where salt is a ubiquitous component of canned and processed foods, restaurant meals, etc., has been proposed to create a situation whereby too much salt is added into a body that is predisposed to conserve it aggressively. This then is thought to result in hypertension. It is believed also that such salt loading leads to a stiffening of the arterial walls as well as hypervolemia in the circulation. The influence of diet, rather than race, on hypertension is further supported by the observation that populations such as native Asians that consume a largely vegetarian diet have lower arterial pressures than the same populations raised and living in Western cultures, whereas native Japanese, who consume large amounts of salt in their diet (soy sauces, salted fish, etc.), have a high incidence of arterial hypertension and hypertension-related stroke. ■

PERIPHERAL AND CENTRAL BLOOD VOLUME

As discussed in Chapter 11, blood volume is distributed among the various segments of the circulatory system according to their basic geometry and compliance. Total blood volume in a 70-kg adult is 5.0 to 5.6 L. Approximately 80% of the total blood volume is located in the **systemic circulation** (i.e., the total volume minus the volume in the heart and lungs), and about 60% of the total blood volume (or 75% of the systemic blood volume) is located on the venous side of the circulation. The blood present in the small arteries and capillaries is only about 20% of the total blood volume. Because most of the systemic blood volume is in the veins, it is not surprising that changes in systemic blood volume primarily create changes in venous volume.

Large compliance in the veins allows them to accommodate high volumes with little change in pressure.

Systemic veins are ~20 times more compliant than systemic arteries; small changes in venous pressure are, therefore, associated with large changes in venous volume. If 500 mL of blood is infused into the circulation, about 80% (400 mL) locates in the systemic circulation. This increase in systemic blood volume raises what is termed the **mean circulatory filling pressure** (**MCP**) by a few mm Hg. MCP is the pressure that equilibrates into all segments of the vascular system when the heart is stopped. It is normally about 7 mm Hg and is a measure of how "full" the vascular system is or how "tightly" blood is contained within the vasculature as a result of vascular tone. A small rise in filling pressure, distributed throughout the systemic circulation, has a much larger effect on the volume of systemic veins than systemic arteries. Because of the much higher compliance of veins than arteries, 95% of the 400 mL from the example above (or 380 mL) will be distributed into the veins whereas only 5% (20 mL) will be found in arteries.

Central blood volume is useful for evaluating the effects of changes in blood volume on cardiac output.

Because of Starling's law of the heart, the filling of the heart is one of the key determinants of CO. In considering the role of distribution of blood volume in filling the heart, it is useful to divide the blood volume into central (or intrathoracic) and systemic (or extrathoracic) portions. The **central blood volume** includes the blood in the superior vena cava and the intrathoracic portions of the inferior vena cava, right atrium and ventricle, pulmonary circulation, and left atrium; this constitutes ~25% of the total blood volume. The central blood volume can be decreased or increased by shifts in blood to and from the extrathoracic blood volume. From a functional standpoint, the most important components of the **extrathoracic blood volume** are the *veins of the extremities and abdominal cavity*. Blood shifts readily between these veins and the vessels of the central blood volume. Blood in the central and extrathoracic arteries can be ignored in these shifts because of their low compliance. Furthermore, the extrathoracic blood volume in the neck and head is of little importance because there is far less blood in these regions and blood volume inside the cranium cannot change much because the skull is rigid. The volume of blood in the veins of the abdomen and extremities is about equal to the central blood volume; therefore, about half of the total blood volume is involved in shifts in distribution that affect the filling of the heart.

Central venous pressure is a qualitative measure of central blood volume.

Under normal conditions, changes in **central venous pressure** are a good reflection of central blood volume because the compliance of the intrathoracic vessels tends to be constant. Central venous pressure can be measured by placing the tip of a catheter in the right atrium. In general, the use of central venous pressure to assess changes in central blood volume depends on the assumption that the right heart is capable of pumping normally. In certain situations, however, the physiologic meaning of central venous pressure is changed. For example, if the tricuspid valve is incompetent (i.e., cannot close completely), right ventricular pressure is transmitted to the right atrium during ventricular systole, creating an abnormally high central venous pressure that is not primarily a result of increased central venous volume. Also, central venous pressure does not necessarily reflect left atrial or left ventricular filling pressure. Abnormalities in right or left heart function or in pulmonary vascular resistance can make it difficult to predict left atrial pressure from central venous pressure.

Unfortunately, measurements of the peripheral venous pressure, such as the pressure in an arm or leg vein, are subject to too many influences to be helpful in most clinical situations (e.g., partial occlusion caused by positioning or venous valves).

Cardiac output is sensitive to changes in central blood volume.

Consider what happens if blood is steadily infused into the inferior vena cava of a healthy person. As this occurs, the volume of blood returning to the chest—the venous return—is transiently greater than the volume leaving it, that is, the CO. This difference between the input and output of blood produces an increase in central blood volume. It will occur first in the right atrium, where the accompanying increase in pressure enhances right ventricular filling, end-diastolic fiber length (preload), and stroke volume. Increased flow into the lungs increases pulmonary blood volume and filling of the left atrium. The output of the left ventricle will increase according to Starling's law of the heart so that the output of the two ventricles exactly matches. CO will increase until it equals the sum of the previous venous return to the heart plus the infusion of new blood.

It can be surmised from the discussion above that central blood volume is altered by two events: changes in total blood volume and changes in the distribution of total blood volume between central and extrathoracic regions. An increase in total blood volume can occur as a result of an infusion of fluid, the retention of salt and water by the kidneys, or a shift in fluid from the interstitial space to plasma (see Chapter 15). A decrease in blood volume can occur as a result of hemorrhage; fluid losses through sweat, vomiting, or diarrhea; or the transfer of fluid from plasma into the interstitial space. In the absence of compensatory events, changes in total blood volume result in proportional changes in both central and extrathoracic blood volume. For example, a moderate hemorrhage (10% of blood volume) with no distribution shift would cause a 10% decrease in central blood volume. The reduced central blood volume would, in the absence of compensatory events, lead to decreased filling of the ventricles and diminished stroke volume and CO.

Central blood volume can be altered by a shift in blood volume to or away from the extrathoracic circulation. Shifts in the distribution of blood volume occur for two reasons: a change in transmural pressure or a change in venous compliance. Changes in the transmural pressure of vessels in the chest or periphery can either enlarge (increased P_T) or diminish (decreased P_T) their size. Because total blood volume is finite, volume shifts in response to changes in transmural pressure in one region affect the volume of the other region. Imagine a long balloon filled with water. If it is slowly turned vertically on its long axis, the lower end of the balloon has the greatest transmural pressure because of the weight of the water pressing from above. Consequently, the lower end of the balloon will bulge and the upper end will shrink; volume increases in the lower end at the expense of a loss at the upper end.

The best physiologic example of a change in regional transmural pressure occurs when a person stands up. Standing increases the transmural pressure in the blood vessels of the legs because it creates a vertical column of blood between the heart and those vessels. The arterial and venous pressures at the ankles during standing can easily be increased almost 100 mm Hg higher than those in the individual in the recumbent position. The increased transmural pressure (outside pressure is still atmospheric) results in little distention of arteries because of their low compliance but results in considerable distention of veins because of their high compliance. In fact, ~550 mL of blood is needed to fill the stretched veins of the legs and feet when an average person stands up. Filling of the veins of the buttocks and pelvis also increases but to a lesser extent than the lower extremities, because the increase in transmural pressure is less. When a person stands, blood continues to be pumped by the heart at the same rate and stroke volume for one or two beats. However, much of the blood reaching the legs remains in the veins as they become passively stretched to their new size by the increased venous transmural pressure. This decreases the return of blood to the chest. Since CO exceeds venous return for a few beats, the central blood volume falls (as

does the end-diastolic fiber length, stroke volume, and CO). Once the veins of the legs reach their new steady-state volume, the venous return again equals CO. Thus, the equality between venous return and CO is re-established even though the central blood volume is reduced by 550 mL. However, the new CO and venous return are decreased (relative to what they were before standing) because of the reduction in central blood volume. Without compensation, the decrease in systemic arterial pressure resulting from this decreased CO could cause a drop in brain blood flow and loss of consciousness. Compensatory mechanisms are then obviously required to maintain arterial pressure in the face of decreased CO (as well as blood flow to the brain). For example, upon standing, sympathetic nerves to peripheral veins are activated causing them to contract. The resulting decrease in venous compliance results in a redistribution of blood volume toward the central blood volume. The redistribution of blood toward the central blood volume helps to maintain ventricular filling and CO during standing. Therefore, it is not surprising that venoconstriction is one important compensatory mechanism for supporting CO following a drop in this output due to hemorrhage. Such compensatory mechanisms are discussed in detail in Chapters 16 and 17.

COUPLING OF VASCULAR AND CARDIAC FUNCTION

Vascular volume, pressure, and resistance alter the output performance of the heart. However, because the cardiovascular system is a true “circulatory” system, it is equally true that the output of the heart alters vascular volumes and pressures. Therefore, equilibrium must exist between these two functional relationships. This section will explain how interactions between the cardiac and vascular systems combine to affect CO and cardiac work.

Compliant arteries reduce cardiac work.

One of the more important consequences of the elastic nature of large arteries is that it reduces cardiac work and myocardial oxygen demand. Consider the example in which the heart pumps blood for 4 seconds at a constant flow of 100 mL/s (6 L/min) into rigid arteries with a resistance of 16.67 peripheral resistance units (PRUs). This would then generate a constant pressure of 100 mm Hg, and cardiac work over the 4 seconds would be simply pressure (P) × total volume (V) or 100 mm Hg × 400 mL = 40,000 mm Hg mL. If the heart pumped intermittently and ejected blood at 100 mL/s into noncompliant arteries during the first half-second of the cycle only (i.e., 200 mL/s for 0.5 seconds), the same volume of 400 mL would be moved over the 4-second interval in this example. However, pressure would rise to 200 mm Hg during each ejection and drop to 0 mm Hg during relaxation. Although no work would be done during relaxation, work done during the contraction would be 80,000 mm Hg mL (200 mm Hg × 400 mL). In this situation, the oxygen demand on the heart would be substantially increased even though the output of the heart over 4 seconds was no better than that in the steady flow example. In contrast, if this same intermittent flow was ejected into arteries with infinite compliance (i.e., infinite ability to expand with an increase in volume), the pressure in the system would neither rise during systole nor fall during diastole and thus remain at an average of 100 mm Hg. The same 400 mL would be ejected over 4 seconds in this situation but, against a constant pressure of 100 mm Hg, the work done would again equal to 40,000 mm Hg mL.

Of course, arteries in the human body are neither totally rigid nor infinitely compliant. This example serves to demonstrate that decreased arterial compliance increases cardiac work and oxygen demand. By extension, myocardial oxygen demand will be increased by any factor that reduces arterial compliance, even if all other factors, such as arterial pressure, stroke volume, and heart rate, do not change. For this reason, because arterial compliance decreases as we age, the heart of an older person is confronted by increased oxygen demand compared to a younger person even if all other variables affecting cardiac oxygen demand are the same between the two individuals.

Increasing venous filling pressure increases cardiac output, but increasing cardiac output decreases venous pressure.

Central venous pressure is one of the key determinants of the filling of the right heart and, by extension of Starling's law of the heart, a key determinant of CO; increased pressure leads to increased diastolic filling and thus increased cardiac output. However, the heart is a pump set in a *circulatory* system. An increase in CO into the arterial segment of the circulation must come at the expense of volume and pressure in the venous side of the circulation. Yet, this would then reduce venous pressure and ventricular filling and CO according to Starling's law. This poses two questions: (1) how is CO maintained above or below the resting value and (2) what determines equilibrium between CO and central venous pressure when each variable can independently affect the other?

A demonstration of how CO alters central venous and arterial pressure is shown in Figure 14.5 A to D, where a theoretical circulation is depicted with a pump, a "venous" side of the circulation, and an "arterial" side of the circulation. For the sake of example, peripheral vascular resistance is set at 25 PRUs, and the veins are 24 times more compliant than the arteries. When the heart is stopped (CO equals zero), arterial and venous pressures are in equilibrium and dependent only on blood volume and the compliance of the vascular system. This value is called the **MCP** and is generally about 7 mm Hg. MCP is the value from which arterial pressure increases and venous pressure decreases once the heart starts to pump blood.

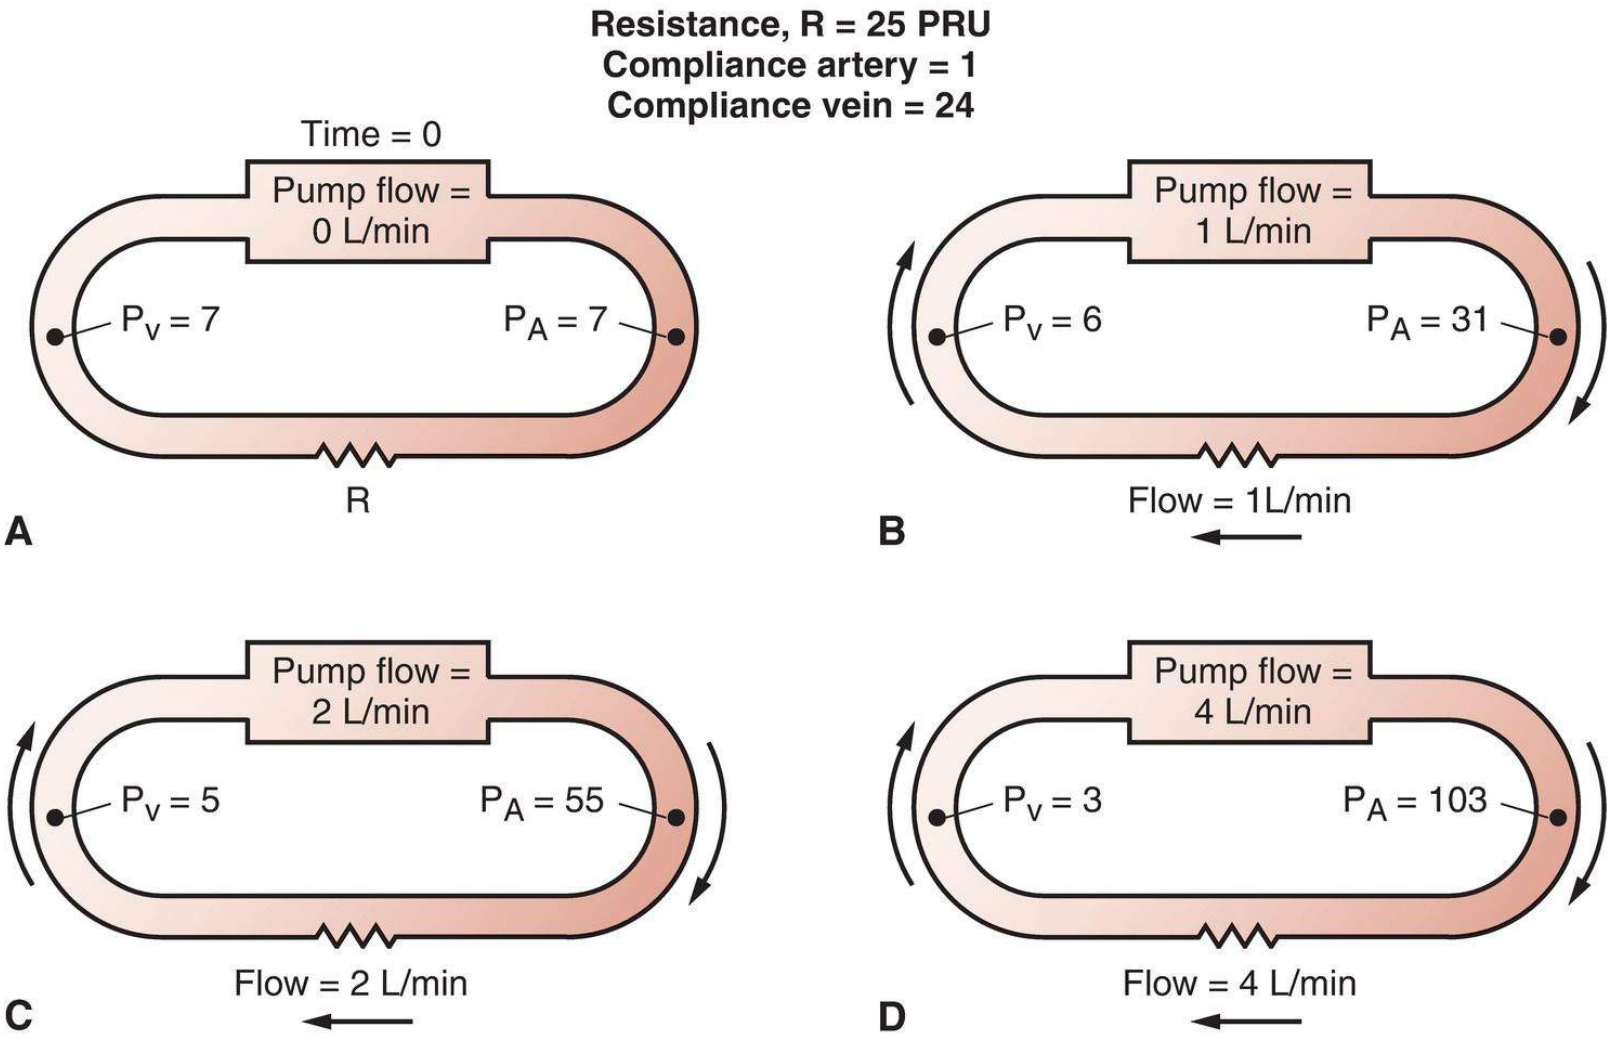

Figure 14.5 A model of the effect of cardiac output (CO) on arterial and central venous pressures. **(A)** At zero CO, all pressures equal the mean circulatory pressure. **(B)** Changes in pressures once CO is increased to 1 L/min. **(C)** Changes in pressures once CO is increased to 2 L/min. **(D)** Changes in pressures once CO is increased to 4 L/min. P_A, arterial pressure; P_V, central venous pressure; PRU, peripheral resistance unit; R, resistance.

Using the example in Figure 14.5 with an MCP of 7 mm Hg, let us start the heart at an output of 1 L/min. The initial effect of this pumping by the heart will be to translocate blood from the venous side into the arterial side of the circulation. This will increase pressure in the arterial component of the circulation while it reduces pressure on the venous side. These changes in pressure will continue until enough pressure difference between the arteries and veins has been created to move blood at a rate of 1 L/min across the resistance vessels in the circulation. At that point, the rate of blood moving across the resistance and into the "venous" side of the circulation will match the rate of blood exiting the "venous" side of the circulation through the pump and into the "arterial side." By Poiseuille's law, this will occur when the pressure difference is 25 mm Hg. What needs to be determined next is how much of this 25 mm Hg is added to the arterial side and how much is subtracted from the venous side of the circulation. In this example, the veins are 24 times more compliant than the arteries. Stated another way, this means the arteries are 24 times stiffer than the veins. Consequently, for every 25 mm Hg of pressure difference between the arterial and venous sides of the circulation, 24 mm Hg is added to the MCP on the arterial side (increasing its pressure to 31 mm Hg) and 1 mm Hg is subtracted from the MCP on the venous side (reducing it to 6 mm Hg). Thus, for every 1 L/min of increase in CO, 24 mm Hg will be added to arterial pressure and 1 mm Hg subtracted from the venous pressure once the system reaches its steady state. In our example, at a CO of 2 L/min, arterial pressure becomes 55 mm Hg and venous pressure becomes 5 mm Hg (Fig. 14.5C); a CO of 4 L/min would yield an arterial pressure of 103 mm Hg and a central venous pressure of 3 mm Hg (Fig. 14.5D).

Depictions of the interrelationships between venous pressure and cardiac output are used to predict how cardiac output and central venous pressure are altered by changes in vascular and cardiac variables.

Two graphical means can be used to depict the interrelationship between CO and central venous pressure. One relationship, called the **cardiac function curve**, plots CO as a function of central venous pressure (Fig. 14.6A). This is simply an extension of Starling's law of the heart and shows that CO will increase with an increase in central venous pressure. The cardiac function curve is characteristic of the heart itself in that only factors affecting the heart affect the position and shape of this curve. This curve can be produced even in a heart separated from the vasculature.

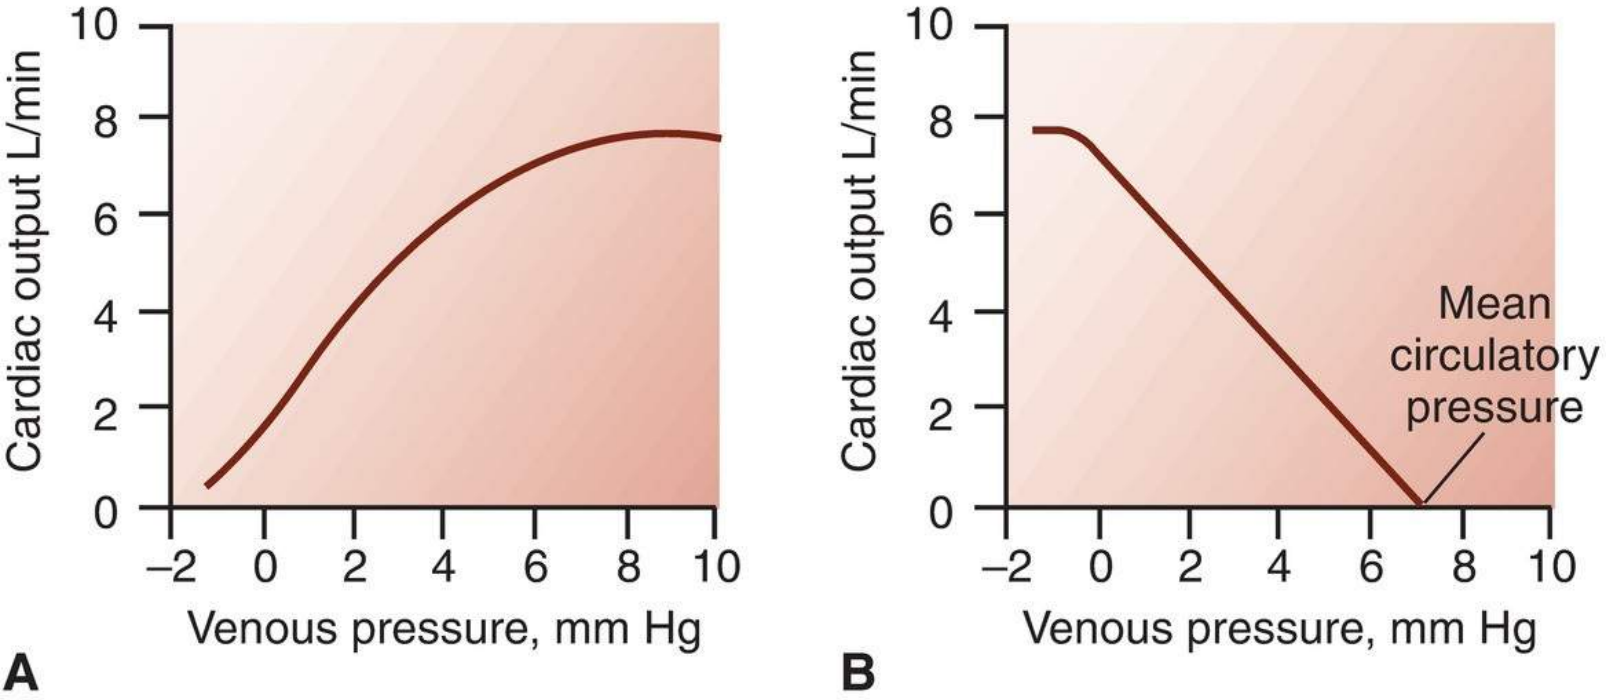

Figure 14.6 (A) The cardiac function curve. The curve is a representation of Starling's law of the heart. It is a function of characteristics of the heart only. **(B) The vascular function curve.** The relationship shows how venous pressure changes in response to a change in cardiac output (CO). It is a function of vascular variables only. The independent variable, CO, in this depiction is placed by convention on the *y* axis.

A second relationship, called the **vascular function curve**, shows how central venous pressure changes as a function of CO (Fig. 14.6B). First note that, contrary to mathematical convention, the independent variable of the vascular function curve (CO) is placed on the *y* axis and the dependent variable in this relationship, the venous pressure, is placed on the *x* axis. (For reasons to be seen below, this facilitates combining the cardiac function curve with the vascular function curve on the same plot.) The position and slope of the vascular function curve are affected only by factors associated with blood vessels, such as vascular resistance, vascular compliance, and blood volume. The vascular function curve is independent of characteristics of the heart and can be observed even if the heart in the circulation is

replaced by an artificial pump. This curve shows that when CO is zero, venous pressure equals MCP and that venous pressure *decreases* as CO increases, until it results in venous collapse (at approximately −2 mm Hg), which limits further increases in CO.

Figure 14.7 A to F depicts vascular and cardiac function curves plotted together and demonstrates how equilibrium between CO and venous pressure is obtained in a variety of altered states. The cardiac function and vascular function curves both depict true functional relationships between cardiac output and venous pressure. Both of these must operate simultaneously in the intact cardiovascular system. Consequently, in any condition of the intact cardiovascular system, the value of CO and venous pressure must satisfy both the functional expression for the cardiac function curve and the vascular function curve at the same time. Although this could be solved mathematically, this can be seen more easily by reading the CO and venous pressure at the intersection of the cardiac function and venous function curve. Equilibrium for this system exists at the point of intersection between the two curves because it is at the intersection where one pair of CO and central venous pressure satisfies both the cardiac and vascular function curves (see Fig. 14.7A). If venous pressure were to suddenly increase, an increased CO would initially result. However, this elevated output would tend to reduce venous pressure, which would then reduce CO, and so on. The end result, after an initial perturbation in either venous pressure or CO, will be to return these two variables to the intersection of the cardiac function and vascular function curves. This is, therefore, the equilibrium point for the system.

Figure 14.7 Various equilibriums in cardiac output (CO) and venous pressure resulting from changes in cardiac function or vascular variables. **(A)** The equilibrium point for concurrent cardiac and vascular function curves; only one set of values for cardiac output and venous pressure can satisfy both relationships at the same time. **(B)** Effect of changing either blood volume or venous tone on the vascular function curve. **(C)** Effect of changes in arteriolar resistance on the vascular function curve. **(D)** Effect of changes in inotropic state on the cardiac function curve. **(E)** Possible equilibrium points obtained by the conjunction of altered myocardial contractility and vascular function curves. **(F)** Effects of alteration in vascular resistance on cardiac and vascular function curves and the resulting equilibrium points for CO and venous pressure.

Several factors influence the vascular and cardiac function curves. For example, increases in blood or plasma volume (hypervolemia) "fill" the cardiovascular system more and thus raise MCP. This does not significantly alter venous compliance but does shift the entire vascular function curve in parallel fashion to the right of the normal relationship (Fig. 14.7B). This shift will also be seen with increased venous tone (venous smooth muscle contraction), which "squeezes" the blood contained in the veins, thus raising their internal pressure. Conversely, hypovolemia or decreased venous tone has the opposite effect.

A change in arteriolar tone has a different effect on the vascular function curves than does a change in venous tone (Fig. 14.7C). Because little blood volume is contained in the arterioles, changes in arteriolar tone do not significantly affect MCP. However, reduced arteriolar resistance makes it easier for the heart to eject a given stroke volume with any venous filling pressure, whereas increased resistance has the opposite effect. In other words, with reduced systemic resistance, a smaller than normal ΔP is required to maintain flow through the peripheral arterial and into the veins at the same rate it is being pumped out of the veins and into the arteries (i.e., the CO). This diminishes the rise in arterial pressure and the drop in venous pressure at any cardiac output. By extension, therefore, at any central venous pressure, reducing arteriolar resistance augments CO and increasing such resistance impedes CO.

Changes in the inotropic state of the heart alter the cardiac, but not the vascular, function curve. By definition, a positive inotropic influence will allow the heart to produce a larger output at any given venous pressure, whereas a negative inotropic influence will have the opposite effect (Fig. 14.7D).

The net effect of changes in cardiac and venous function curves on the equilibrium values for CO and venous pressure is shown in Figure 14.7E, where point "A" represents the normal equilibrium. Factors that increase blood volume such as an intravenous infusion of blood or fluid will shift the vascular function curve in parallel to the right, whereas loss of volume (i.e., hemorrhage, loss of body water, etc.) will shift that curve to the left. The new equilibrium points for these conditions, points "B" and "C," respectively, correctly show the interrelationship between CO and venous pressure that would be predicted by Starling's law of the heart; an increased CO is associated with an elevated venous (and hence filling) pressure, whereas a decreased CO is associated with a decreased venous pressure. Similarly, the equilibrium points associated with changes in the inotropic state of the heart, "D" and "E," also correspond with our understanding of the definition of contractility. A positive inotropic influence allows for an elevated CO at a lower-than-normal venous pressure, whereas a negative inotropic influence has the opposite effect. A positive inotrope, according to cardiac muscle mechanics, will allow the heart to empty more in spite of reduced preload. Stated another way, by Starling's law of the heart, a decreased filling pressure must decrease CO, and therefore, the only way the heart can produce a larger-than-normal output in spite of reduced filling is to enhance its intrinsic cellular contractile ability by inotropic mechanisms.

Figure 14.7E also serves to illustrate how the body can compensate for a failing heart. In acute heart failure, a patient's condition is likely best represented by point "D" on the graph, with reduced CO in spite of an elevated venous pressure because of the inability of the weakened heart to move blood from the veins to the arteries. However, with continued failure, the body's compensatory mechanisms stimulate the kidneys to retain salt and water, resulting in a hypervolemic shift in the vascular function curve to the right. This shift, through Starling mechanism, helps augment the CO of the failing myocardium, as shown by point "F" on the diagram. Again, stated another way, one way in which a heart in a negative inotropic state (as in heart failure) can increase its output is to exploit Starling's law and increase its preload.

Figure 14.7F demonstrates the effects of alterations in vascular resistance on the cardiac and vascular function curves. Elevated resistance impedes CO and also requires an increased drop in venous pressure to establish the elevated gradient across the elevated resistance that will be needed to produce peripheral flow that matches a given CO. Decreased resistance has the opposite effect. The precise location of the new equilibrium depends on the relative degree to which the vascular and cardiac function curves are affected by changes in resistance.

Atherosclerosis and Unexpected Consequences of Drug Therapies for Hyperlipoproteinemia

In Chapter 11, it was noted that hemodynamics influences the localization of the development of atherosclerosis in the arterial tree. However, it is not correct to conclude from that phenomenon that atherosclerotic development is a simple accumulation or "sludging" of cholesterol in favorable loci along the arterial system. In reality, atherosclerosis is a vessel wall injury/inflammation phenomenon involving infiltration of the arterial wall by immune system cells, transformation of arterial macrophages, and stimulation of cytokines and mitotic events leading to infiltrative growth into the vessel lumen and eventual cellular necrosis and calcification in the vascular wall. A fully developed atherosclerotic lesion in the arterial wall is called a **plaque**, and it is composed of a necrotic core of dead cells, fibrin, cholesterol crystals, and calcium covered with a fibrotic cap. Plaques are unstable lesions. They do not just encroach on the arterial lumen but can also rupture. When this occurs, the exposed plaque interior and related debris from the rupture activate a blood coagulation cascade resulting in a thrombus forming in the artery that can completely occlude the vessel lumen. Such occlusion in cerebral or coronary arteries and infarction downstream tissue in those organs, can occur, often resulting in death.

The initiating injury in the pathogenesis of atherosclerosis or factors that appear to initiate the process are currently the subject of significant research efforts, as are investigations into the mechanism of plaque rupture. High intra-arterial pressure, diabetes mellitus, and tobacco smoking are thought to cause vessel wall and/or endothelial injury that may induce or at least accelerate the atherosclerotic process, especially in the context of increased vessel wall oxygen radical production associated with those diseases. Genetic factors (i.e., family history) also seem to be involved in the development of the disease in some individuals. Regardless of the nature of initial endothelial injury, such injury causes monocytes to enter the vessel intima where they release cytokines that stimulate

smooth muscle movement into the subendothelium.

It has long been known that high plasma cholesterol and triglyceride levels (i.e., hyperlipidemia), and in particular high low-density lipoprotein cholesterol levels (LDL), are associated with significant atherosclerotic development. LDLs are responsible for cholesterol transport into cells and are now known to become oxidized in this process. These particles are thought to radicalize other organic molecules in the vessel wall and initiate a cascade of vessel wall injury if present in too high a concentration. Oxidized LDLs stimulate inflammatory cytokine production in the vessel wall and reduce wall NO production, which is a natural antiatherogenic molecule. The monocytes that were attracted into the intima transform into macrophages, which scavenge and ingest oxidized LDL. These cells undergo apoptosis as they collect lipids into the wall forming the necrotic core of a developing atherosclerotic lesion. Such cascading processes have been postulated to be key factors in the development of atherosclerosis.

Diets that are high in cholesterol are a known risk factor in the development of atherosclerosis, and efforts to limit fats and cholesterol in the diet have long been a mainstay in the clinical treatment and management of hyperlipidemia and hypercholesterolemia. However, dietary restriction presents difficult problems for the long-term management of hyperlipidemic conditions as patient compliance can be erratic or difficult to maintain over a long period of time. In such instances, pharmacotherapies are now available to help patients control lipids in their bloodstream. One of the more popular of these agents is the HMG-CoA reductase inhibitors, which are more generically known as **statins**. Statins inhibit the conversion of HMG-CoA to mevalonate, which is a very early step in cholesterol synthesis. This reduces intracellular cholesterol levels, primarily in the liver, which activates a protease that cleaves sterol regulatory element–binding proteins (SREBP). SREBP upregulates LDL receptor expression, which then increases endocytosis of LDL, thereby lowering serum LDL levels. This effect also stimulates the hepatic extraction of LDL precursors (very low–density lipoprotein remnants; VLDL remnants), which further decreases circulating LDL levels.

Statins have become key pharmacological agents for the treatment of hyperlipoproteinemias. However, they have also proven to be an example of the many instances in which drugs originally designed for one purpose produce side effects that could not be predicted based on known actions of the drug. Early use of statins was shown to unexpectedly produce various forms of myotoxicities in patients taking them, especially in skeletal muscle. These serious effects included various myopathies, muscle inflammation, myalgia and rhabdomyolysis, or breakdown of muscle fibers. This breakdown can cause severe pain. More importantly, myoglobin released from the muscle cell breakdown is converted to other products in the kidney, which results in renal damage as well.

The causes of myotoxicity associated with statin use are not fully understood at this time. However, HMG-CoA reductase is also needed to synthesize coenzyme Q10 (ubiquinone), which is found in the mitochondria of the heart, skeletal muscle, liver, and kidney. Coenzyme Q10 is a potent antioxidant, and it is speculated that statins may reduce the content of this factor in skeletal muscle thereby interfering with muscle energy processes in a manner that can cause myopathy. Although this may be a reasonable hypothesis, ubiquinone consumption as a dietary supplement has not proven to be effective in reducing statin myopathies and clinical trials to date have failed to show a connection between such induced myopathies and tissue coenzyme Q10 levels. ■

Chapter Summary

- Cardiac output and systemic vascular resistance determine mean arterial pressure.
- Stroke volume and arterial compliance are the main determinants of pulse pressure.
- Arterial compliance decreases as transmural arterial pressure increases.
- Changes in arterial pulse waveforms can be used to ascertain changes in hemodynamic variables that affect blood pressure.
- Shifts in blood volume between the periphery (extrathoracic blood volume) and the chest (central blood volume) influence preload and cardiac output.
- Central venous pressure and cardiac output are interrelated.
- The cardiac function curve depicts how cardiac output varies as a function of central venous pressure.
- The vascular function curve depicts how central venous pressure varies as a function of cardiac output.
- Cardiac and vascular function curves can predict new equilibriums for cardiac output and central venous pressure whenever cardiac or vascular properties are changed.

Chapter Review Questions

1. Mean arterial pressure changes if:

A. Heart rate increases, with no changes in cardiac output or systemic vascular resistance

B. Stroke volume changes, with no changes in heart rate or systemic vascular resistance

C. Arterial compliance changes, with no changes in cardiac output or systemic vascular resistance

D. Heart rate doubles, and systemic vascular resistance is halved, with no change in stroke volume

E. Cardiac output doubles, and systemic vascular resistance is halved, with no change in heart rate

The correct answer is B. Mean arterial pressure is given by $P = CO \times TPR$. An increase in stroke volume without a change in heart rate would increase cardiac output, and without an opposing change in vascular resistance, mean arterial pressure will then increase. Mean arterial pressure will not change if there is no change in both cardiac output and total vascular resistance. When there is no change in cardiac output and systemic vascular resistance, a change in arterial compliance will alter pulse pressure but not mean arterial pressure. Doubling heart rate without changing stroke volume will double cardiac output. If cardiac output is doubled while total vascular resistance is halved, the changes in the two components of mean arterial pressure will be in equal but opposite directions, and therefore, there will be no change in mean arterial pressure.

2. If the compliance of veins were equal to that of arteries, the change in central blood volume with standing would be:

A. Less than normal

B. Greater than normal

C. The same as normal

D. Less than normal but still more than the change in the arteries

E. Less than normal and less than the change in the arteries

The correct answer is A. Blood pools in peripheral veins at the expense of the central circulation upon standing because veins are about 20 times more compliant than arteries. Equal compliances in the arteries and veins would translocate blood into the lower extremities in the same proportion under the influence of gravity. If the compliance of veins were the same collectively as the arteries, there would be no such preferential pooling of blood into the peripheral venous system and, because the veins would have a lower-than-normal compliance, that pooling would be less than normal.

3. Dobutamine is a pure β1-adrenergic receptor agonist that is used to augment stroke volume in the heart following acute heart failure from myocardial infarction (heart attack). It does not affect smooth muscle tone in blood vessels. Which of the following effects best describes the effect of dobutamine on the cardiac and vascular function curves?

A. It will shift the cardiac function curve downward and to the right without changing the position of the vascular function curve.

B. It will shift the cardiac function curve upward and to the left while shifting the vascular function curve parallel and to the right.

C. It will shift the cardiac function curve upward and to the left without changing the position of the vascular function curve.

D. It will shift the cardiac function curve upward and to the left while decreasing mean

circulatory filling pressure.

E. It will shift the cardiac function curve upward and to the left while increasing mean circulatory filling pressure.

The correct answer is C. Dobutamine, by activating beta1-adrenergic receptors, is a positive inotrope. Inotropism is a characteristic of the heart. Dobutamine, as a positive inotrope, will shift the cardiac function curve upward and to the left. This drug does not alter smooth muscle tone in blood vessels and therefore would not have any direct effect on the position of the vascular function curve. Mean circulatory filling pressure is a function of the vascular system and blood volume when the heart is stopped, not when it is active under any inotropic condition.

4. Which of the following would be characteristic of an individual with compensated heart failure (i.e., one in which the body attempts to compensate for the consequences of reduced myocardial contractility of the failing heart by retaining fluid in the body and activating the sympathetic nervous system)?

A. An increased mean circulatory pressure and reduced cardiac output
B. A decreased central venous pressure and decreased cardiac output
C. An increased mean circulatory pressure and increased cardiac output
D. No change in central venous pressure and cardiac output
E. A decreased central venous pressure and increased cardiac output

The correct answer is A. Heart failure is defined as a cardiac output that is too low for normal patient function. Therefore, almost always, a patient in heart failure, especially that bad enough to activate compensatory mechanisms in the body, will have a lower-than-normal cardiac output in spite of activation of the sympathetic nervous system, which attempts to stimulate the heart to compensate for its failing muscle. Furthermore, activation of hormonal and neurological systems in the body (see Chapter 17 for details) causes the patient to retain salt and water. This retention elevates mean circulatory and, thus, central venous pressure as a means to augment the stroke output of the failing heart via Starling mechanism.

5. A supine patient's blood pressure is measured in a clinical setting using the sphygmomanometric method with the measurement made in a patient's arm that is dangling over the edge of the table on which the patient is supine. A patient's blood pressure measured in this manner will:

A. Underestimate the patient's true blood pressure
B. Yield an accurate estimate of the patient's blood pressure
C. Overestimate the patient's true blood pressure
D. Prevent measurement of the patient's blood pressure
E. Negate an ability to hear Korotkoff sounds in the brachial artery

The correct answer is C. Measuring blood pressure in an arm at a level below the level of the heart will not negate hearing Korotkoff sounds or obtaining a value for systolic and diastolic blood pressure. However, the effect of gravity will add pressure along any column of blood below the level of the heart in proportion to its distance below the level of the right atrium (i.e., along the arm). Therefore, the recording of the patient's arterial blood pressure will be higher than that obtained if the arm was in the correct position for measurement, that is, at the level of the right atrium.

Clinical Application Exercises 14.1

A 20-year-old male with no history of cardiopulmonary illness undergoes surgery to repair fractures

to his right femur and tibia resulting from an auto accident. He is placed in a large full-leg cast with screws and pins to set the bones in their proper position. The cast and pins effectively immobilize the patient's leg. Three days postoperatively while lying in bed, he experiences sudden onset of chest discomfort and shortness of breath. His blood pressure is 100/75 mm Hg, and his heart rate is 105 beats/min. However, the ECG shows no changes suggestive of cardiac ischemia. There is swelling and tenderness in the left leg, which began about 3 days earlier. The attending physician performs a Wells bedside score to rule out the presence of a pulmonary embolism (needed score should be <4); however, the patient's score is 6. He orders a D-dimer ELISA test, which tests for cross-linked fibrin degradation products indicative of fibrinolysis of venous thromboembolism. High levels of fibrin degradation products are indicated, but because such test results can occur in the postoperative state, the physician decides to order a multidetector rotating CT scan of the patient's chest. This scan confirms the presence of a large pulmonary embolism involving the right pulmonary artery.

QUESTIONS

Note: For this set of questions, you will only be concerned with the broad immediate hemodynamic aspects of this patient's condition.

1. How are the patient's chest discomfort, shortness of breath, and arterial hypotension explained?
2. Is right ventricular pressure likely to be increased or decreased? Why?
3. Would intravenous infusion of additional fluids (such as blood or plasma) help the patient's arterial blood pressure?

ANSWERS

1. The patient's symptoms are caused by pulmonary embolism. In reality, the full effects of pulmonary embolism are complex and lead to systemic hypoxia through a cascade of alterations in the lungs. For the purpose of just the hemodynamic consequences of this condition, one should note that with a pulmonary embolism, a piece of blood clot located in a peripheral vein (in this case, a leg vein) breaks off and is carried through the right heart to a pulmonary artery where it lodges. Such emboli often arise from deep vein thrombosis following fractures and surgery to the limbs and leg bones. With a pulmonary embolism, blood flow from the pulmonary artery to the left heart is obstructed (i.e., pulmonary vascular resistance increases), resulting in elevated pulmonary arterial pressure. The sudden rise in pressure causes distention of the artery, which may contribute to the sensation of chest discomfort. Increased pulmonary arterial pressure (pulmonary hypertension) leads to right heart failure. Because left atrial (and left ventricular) filling is reduced (as a result of lack of blood flow from the lungs), left-side cardiac output also falls. The fall in cardiac output causes a reflex increase in heart rate (see Chapter 17). The result is a combination of right- and left-side heart failure, producing the signs and symptoms seen in this patient.
2. The right ventricular pressure is likely to be increased because the blood clot in the pulmonary artery acts as a form of obstruction that raises the pulmonary artery resistance.
3. The problem here is increased afterload of the right ventricle caused by partial obstruction of the outflow tract. Because of this obstructed outflow, the diastolic volume of the right ventricle is already high. It is unlikely that infusing additional fluids into the veins will improve cardiac output because the extra filling of the right ventricle is unlikely to increase the force of contraction.

15 Microcirculation and Lymphatic System

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Predict how changes in the blood concentration, tissue concentration, and capillary permeability of a substance alter its transport by diffusion across the capillaries.
- Explain how changes in perfused capillary density affect transport of substances across capillaries.
- Predict whether a capillary will reabsorb or filter water based on changes in mean capillary hydrostatic pressure, plasma oncotic pressure, interstitial hydrostatic pressure, or interstitial oncotic pressure.
- Predict whether tissue edema will form based on changes in factors that affect capillary fluid filtration or lymph drainage of tissue.
- Explain how changes in precapillary and postcapillary resistances can increase or decrease fluid movement out of capillaries and how these changes may induce or attenuate edema formation.
- Identify and explain the changes in capillary filtration and lymph flow that are associated with, anaphylaxis, hypovolemic shock, diabetes mellitus, tissue inflammation, tissue traumas, and common disorders of plasma proteins.
- Explain myogenic and metabolic mechanisms responsible for autoregulation of blood flow.
- Explain the phenomena of active hyperemia, reactive hyperemia, and flow-mediated vasodilation.
- Explain the effects of the sympathetic nervous system on vascular resistance, venous pressure and capacitance, capillary transport, and capillary filtration in the microcirculation.
- Predict the effects of impairment of the endothelial NO system on arterial function.

STRUCTURE AND FUNCTION OF THE MICROCIRCULATION

The microvasculature (Fig. 15.1) is considered to begin where the smallest arteries enter organs and end where the smallest veins, the venules, exit organs. In between are microscopic arteries, the arterioles, precapillary sphincters, and the capillaries. The arterioles divide into progressively smaller vessels so that each section of the tissue has its own specific microvessels. Depending on an animal's size, the largest arterioles have an inner diameter of 100 to 400 μm, and the largest venules have a diameter of 200 to 800 μm.

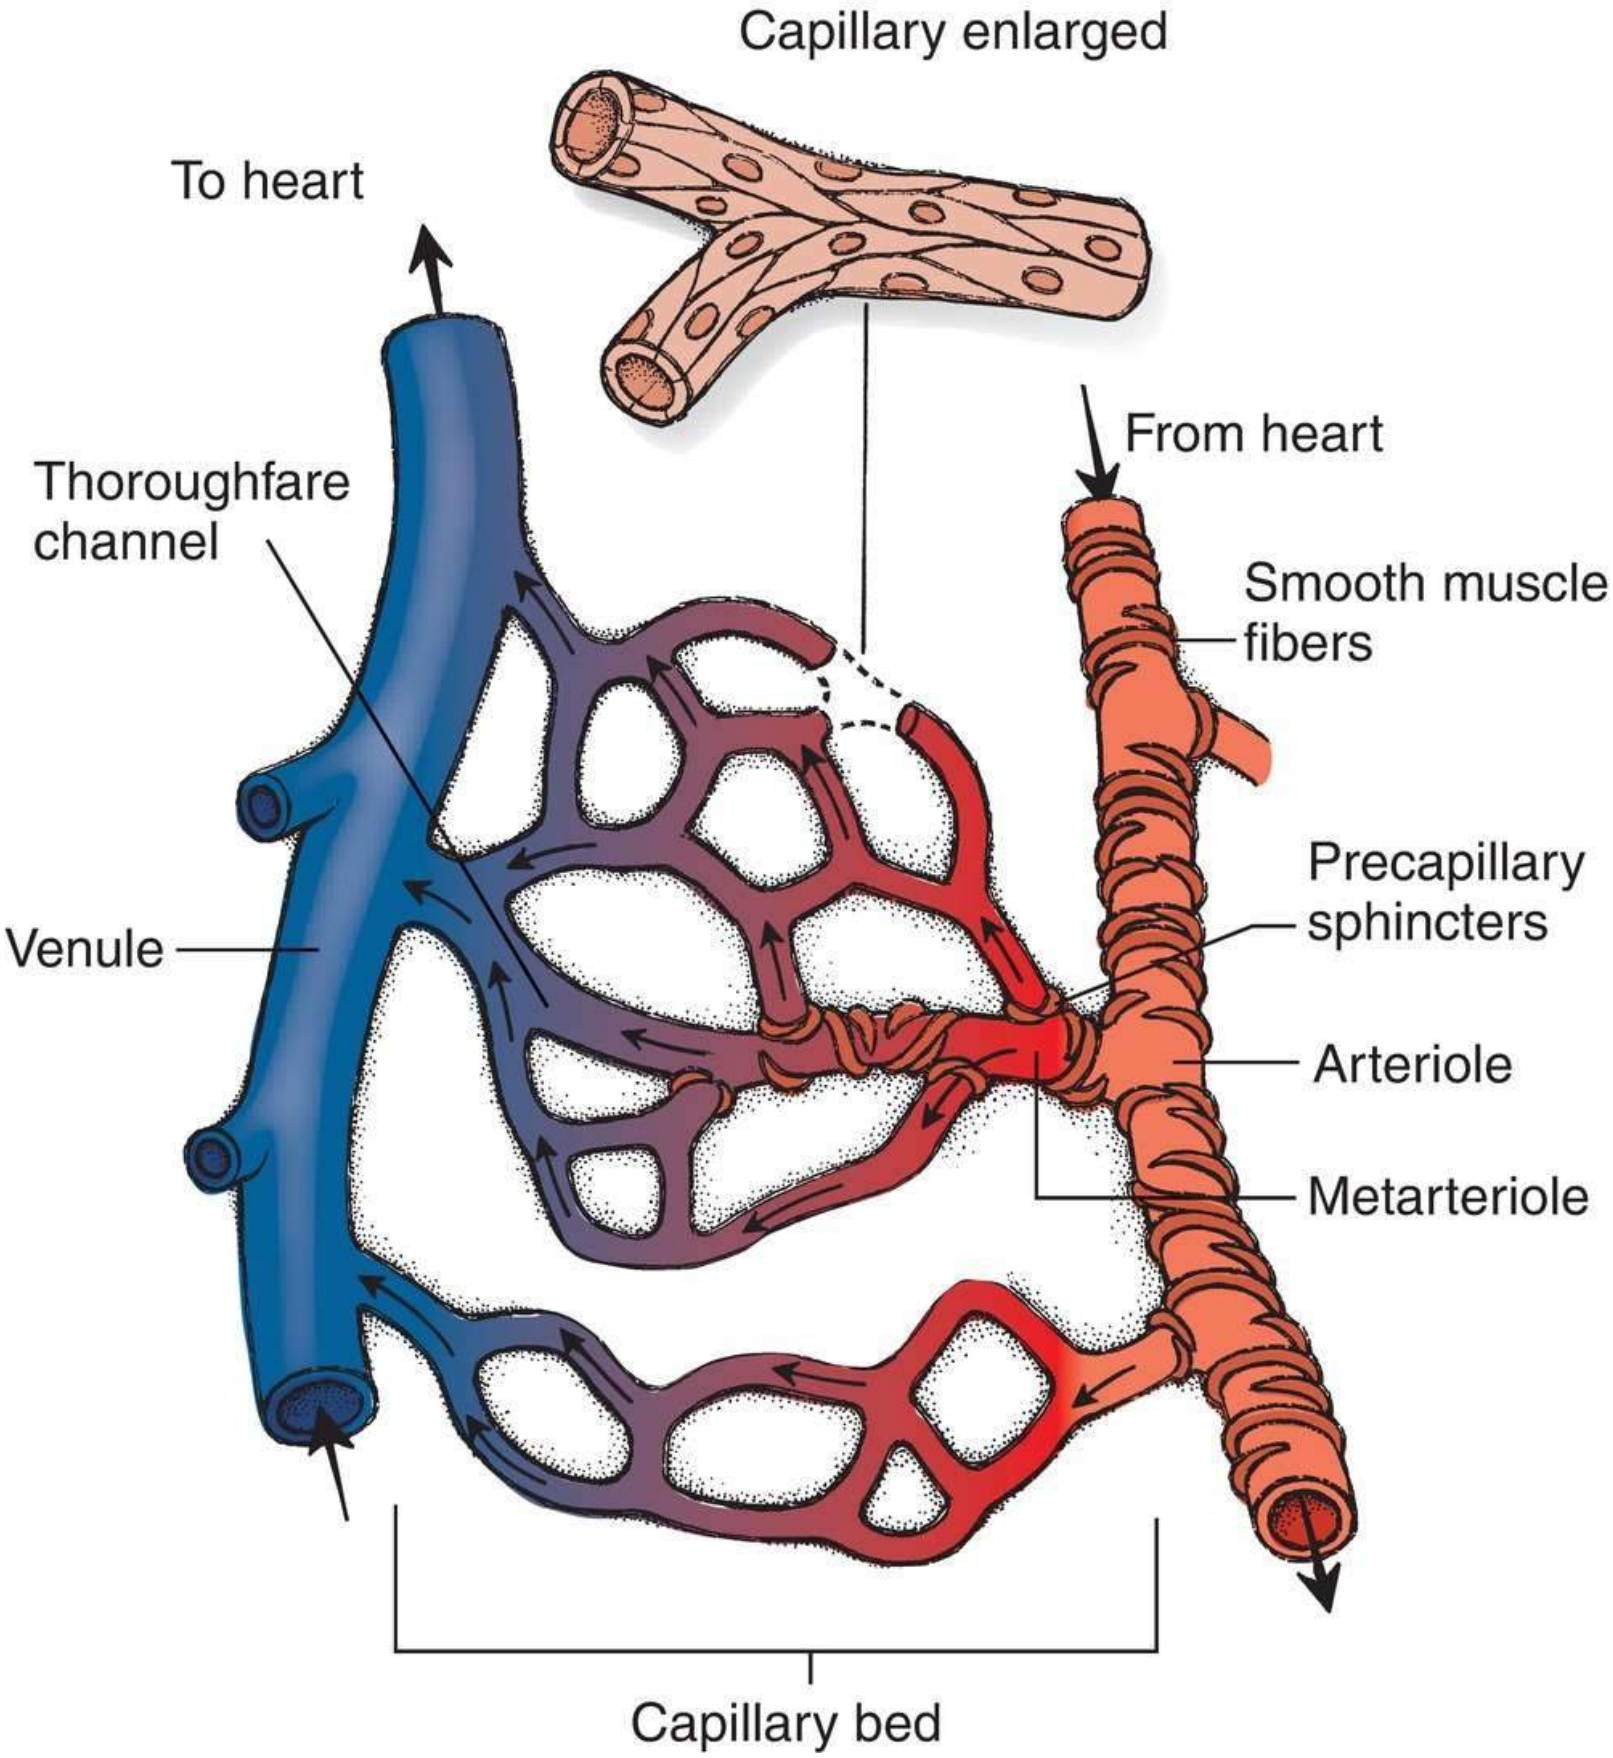

Figure 15.1 A diagrammatic representation of the components of the microvasculature. Arterioles control blood flow into a region of tissue and, along with precapillary sphincters, control the distribution of blood flow within the capillary network.

The microcirculation is the site of exchange of nutrients, water, gas, and small molecules between the plasma and the tissues. Under normal conditions, the capillaries do not allow exchange of peptides,

proteins, and other large molecules between tissues and plasma. Virtually every cell in the body is in close contact with a capillary. The microcirculation regulates blood flow to individual organs, the distribution of blood flow within organs, diffusion distances between an organ's blood supply and tissues, as well as the capillary surface area available for exchange of materials between the plasma and tissues. In conjunction with cardiac output, it helps maintain arterial blood pressure by altering total peripheral vascular resistance and diastolic filling of the heart (see Chapters 11, 13, and 14).

Control of total peripheral vascular resistance is predominantly at the level of the arterial microvasculature.

VSM cells wrap around the arterioles at an ~90° angle to the long axis of the vessel. This arrangement is efficient because the tension developed by the VSM cell can then be almost totally directed toward maintaining or changing vessel diameter against the pressure within the vessel. In most organs, arteriolar muscle cells operate at about half their maximal length. If the muscle cells fully relax, the diameter of the vessel can nearly double, which increases blood flow dramatically because flow increases as the fourth power of the vessel radius. When the muscle cells contract, the arterioles constrict; with intense stimulation, the arterioles can literally close for brief periods of time.

Normally, all microvessels, other than capillaries, are partially, tonically constricted. However, the magnitude of contraction can be variable from maximum relaxation (no contraction) to total closure of small arterioles and sphincters (maximum contraction). Tonic constriction of small arteries and arterioles maintains the relatively high vascular resistance in organs. Constriction results from the release of norepinephrine by the sympathetic nervous system, from a myogenic mechanism intrinsic to the smooth muscle (to be discussed later) and from other chemical and physical factors that are active at the level of the smooth muscle cell. The smallest arteries, combined with the arterioles of the microcirculation, constitute the resistance blood vessels; together, they regulate about 70% to 80% of the total vascular resistance with the remainder of the resistance about equally divided between the capillary beds and venules. For this reason, this portion of the microvasculature is the site of control of organ blood flow as well as arterial blood pressure in the whole organism.

Vessel radius of arterioles controls the major portion of vascular resistance and is determined by the transmural pressure gradient and wall tension, as expressed by the law of Laplace (see Chapter 11). Changes in wall tension developed by the level of contraction of arteriolar smooth muscle cells directly alter vessel radius and, thus, vascular resistance. Most arterioles can dilate 60% to 100% from their resting diameter and can maintain a 40% to 50% constriction for long periods because of the latch state properties of VSM. Therefore, large decreases and increases in organ vascular resistance and blood flow are well within the capability of the microscopic blood vessels. For example, a 20-fold increase in blood flow can occur in contracting skeletal muscle during exercise because of intense dilation of arterioles in the muscle circulation, whereas blood flow in the same vasculature can be reduced to 20% to 30% of normal during reflex activation of sympathetic nerve activity. There is a constant balance between the regulation of vascular resistance to help maintain arterial pressure (see Chapter 17) and the regulation required to allow each tissue to receive sufficient blood flow to sustain its metabolism. If needed, the body will reduce blood flow to most organs, such as the skeletal muscles and splanchnic organs, in order to sustain arterial pressure to preserve flow to the heart and brain.

Exchange of water and materials between blood and tissues occurs across capillaries.

Capillaries, with inner diameters of about 4 to 8 μm, are the smallest vessels of the vascular system. Networks of capillaries arranged in parallel provide for most of the exchange area between blood plasma and tissue cells. A capillary is an endothelial tube surrounded by a basement membrane composed of dense connective tissue (Fig. 15.2). Capillaries in mammals do not have VSM cells and are unable to actively change their inner diameter. Pericytes (Rouget cells), wrapped around the outside of the basement membrane, may be a primitive form of VSM cell and may add structural integrity to the capillary.

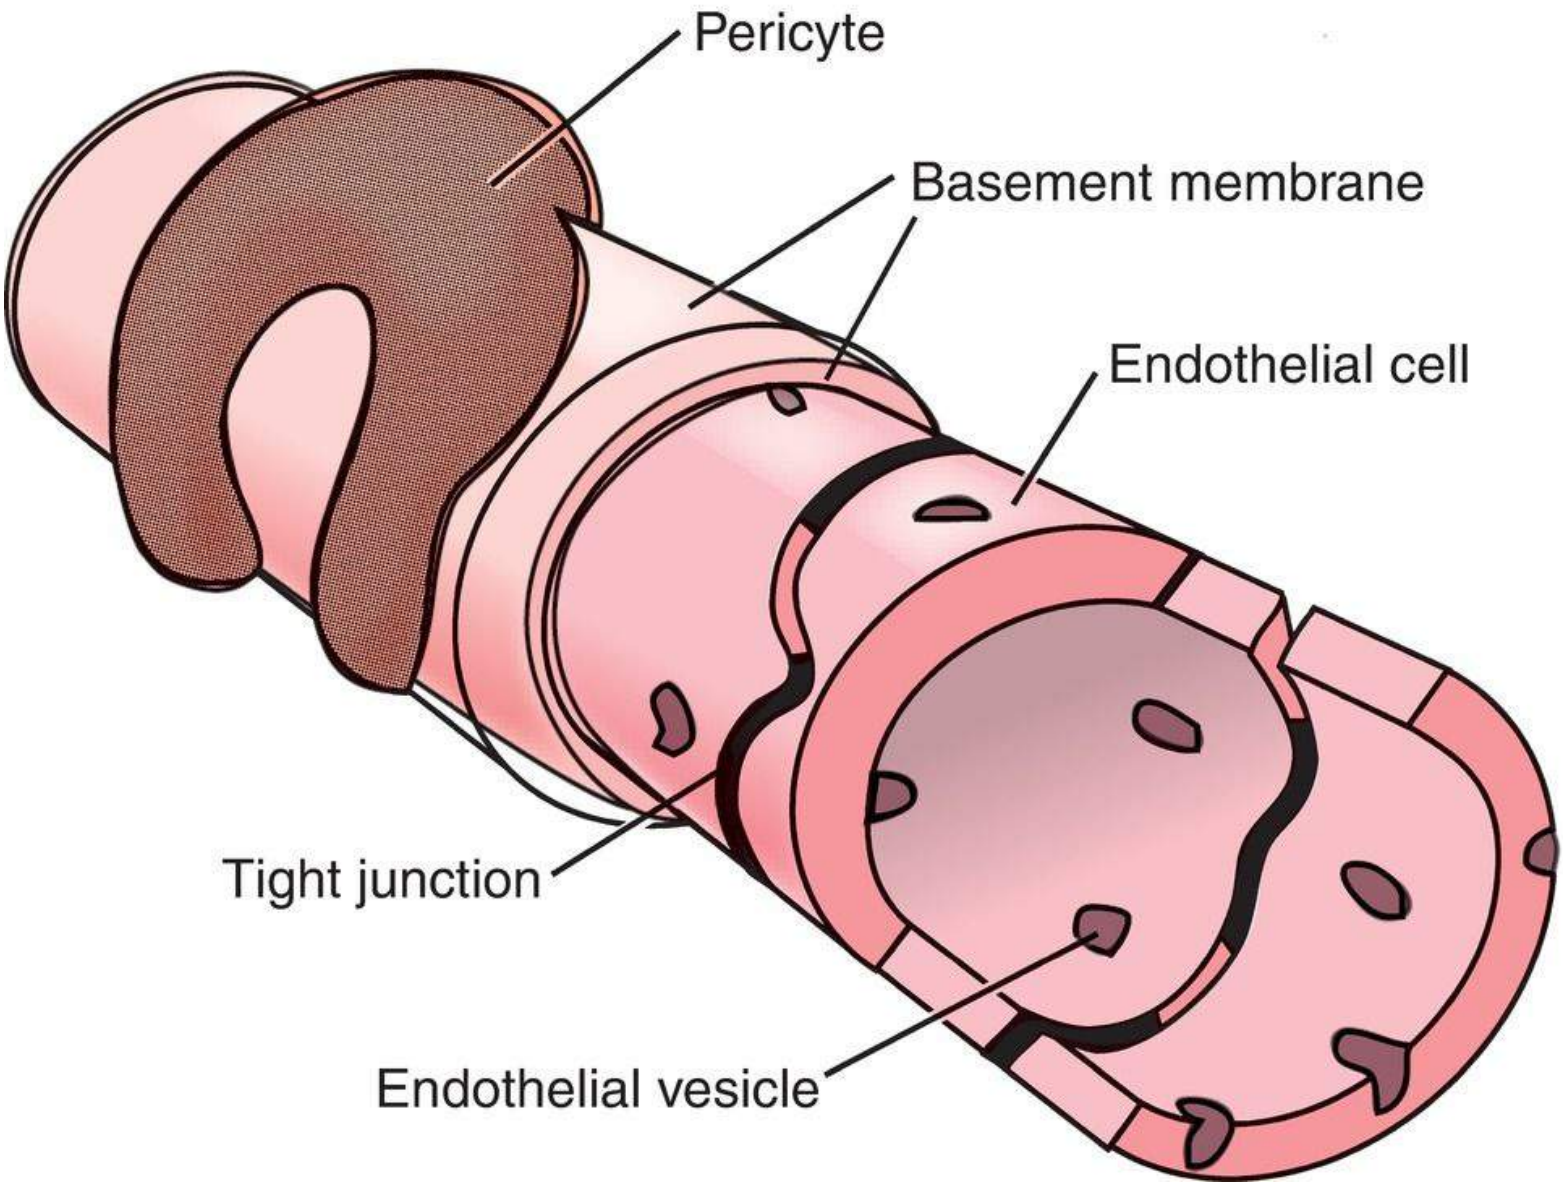

Figure 15.2 The various layers of a mammalian capillary. Adjacent endothelial cells are held together by tight junctions, which have occasional gaps. Water-soluble molecules pass through pores formed where tight junctions are imperfect. Vesicle formation and the diffusion of lipid-soluble molecules through endothelial cells provide other pathways for exchange.

Although they are small in diameter and individually have a high vascular resistance, the parallel arrangement of many thousands of capillaries per cubic millimeter of tissue minimizes their collective resistance. Nevertheless, the capillary lumen is so small that red blood cells must fold into a shape resembling a parachute as they pass through and virtually fill the entire lumen. The small diameter of the capillary and the thin endothelial wall minimize the diffusion path for molecules from the capillary core to the tissue just outside the vessel. In fact, the diffusion path is so short that most gases and inorganic ions can pass through the capillary wall in <2 ms.

Passage of molecules occurs between and through capillary endothelial cells.

The exchange function of the capillary is intimately linked to the structure of its endothelial cells and basement membrane. Lipid-soluble molecules and gases such as oxygen and carbon dioxide readily pass through the lipid components of endothelial cell membranes. Water-soluble molecules, however, must diffuse through water-filled pathways formed in the capillary wall between adjacent endothelial cells. These pathways, known as **pores**, are not cylindrical holes but complex passageways formed by irregular tight junctions (see Fig. 15.2). The pores are partially filled with a matrix of small fibers of submicron dimensions, which acts partially to sieve the molecules approaching the water-filled pore. Most pores permit only molecules with a radius <3 to 6 nm to pass through the vessel wall. Thus, only water, inorganic ions, glucose, amino acids, and similar small, water-soluble solutes pass through the pores, whereas large molecules, such as serum albumin, globular proteins and blood cell components, are excluded.

The fiber matrix and the small spaces in the basement membrane, as well as those between endothelial cells, explain why the vessel wall behaves as if only about 1% of the total surface area were available for the exchange of water-soluble molecules. A limited number of large pores, or possibly defects, allow virtually any large molecule in blood plasma to pass through the capillary wall. Even though few large pores exist, there is enough that nearly all the serum albumin molecules leak out of the cardiovascular system each day.

The porosity of capillaries is not the same in all organs. The capillaries of the brain and spinal cord have virtually continuous tight junctions between adjacent endothelial cells; consequently, only the smallest water-soluble molecules pass through their capillary walls. Capillaries in cardiac and skeletal muscle also have relatively low porosity to water and small water-soluble molecules. In contrast, capillaries in the intestines, the liver, and the glomerulus of the kidney have capacities for large water transport. Those in the spleen and bone marrow have capillary pores so large that they allow for the passage of cellular elements between the blood and those organs.

An alternative pathway for water-soluble molecules through the capillary wall is via **endothelial vesicles** (see Fig. 15.2). Membrane-bound vesicles form on either side of the capillary wall by pinocytosis. Exocytosis occurs when the vesicle reaches the opposite side of the endothelial cell. The vesicles appear to migrate randomly between the luminal and abluminal sides of the endothelial cell. Even the largest molecules may cross the capillary wall in this way.

Venules collect blood from capillaries and act as a blood reservoir.

After the blood passes through the capillaries, it enters the venules, which are endothelial tubes usually surrounded by a monolayer of VSM cells. The venule vascular muscle cells are smaller in diameter and longer than those of arterioles, which may reflect that they do not need powerful muscles to oppose their internal pressure, which is much lower than those in arterioles. The smallest venules are unique because they are more permeable than capillaries to large and small molecules. This property appears to be related to frequent and large pores at tight junctions between adjacent venular endothelial cells. It is probable that much of the exchange of large water-soluble molecules occurs as the blood passes through small venules. The permeability of this venular microvasculature can be affected by local agents. Histamine, for example, increases venular permeability. This is part of the mechanism responsible for local tissue fluid accumulation in cutaneous tissue and mucous membranes in response to allergic reactions.

Venules are an important component of the blood reservoir system. At rest, approximately two thirds of the total blood volume is within the venous system with perhaps more than half of this volume within venules. Although the blood moves within this venous reservoir, it moves slowly, much like water in a reservoir behind a river dam. If venule radius is decreased, the volume of blood in this tissue reservoir can decrease up to 20 mL/kg of tissue and be translocated into the large veins. In this manner, the volume of blood readily available for circulation can increase by more than 1 L in a 70-kg person. Such a large change in the available blood volume can substantially improve the venous return of blood to the heart in response to a loss of blood volume due to hemorrhage or severe dehydration. Another example of this reservoir translocation occurs during blood donation procedures. The volume of blood typically removed from blood donors is about 500 mL, or about 10% of the total blood volume. However, this usually causes no ill effects because the venules and veins decrease their reservoir volume to restore the circulating blood volume.

THE LYMPHATIC SYSTEM

Lymphatic vessels are microvessels that form an interconnected system of simple endothelial “drainage” tubes within tissues. They transport fluid, serum proteins, lipids, and even foreign substances from the interstitial spaces back to the circulation. Collecting lymphatic fluid from the organs is important because a volume of fluid equal to the plasma volume is filtered from the blood through the capillary pores and into the interstitium every day. The gastrointestinal tract, liver, skin, and lungs have the most extensive lymphatic systems; the latter helps prevent excess fluid accumulation in lung tissue, which would otherwise impair gas exchange. The central nervous system, in contrast, may not contain any lymph vessels.

The lymphatic system typically begins as blind-ended tubes, or **lymphatic bulbs**, which drain into the meshwork of interconnected lymphatic vessels. These vessels, like veins, contain one-way valves that open in the direction of larger vessels downstream (Fig. 15.3). The lymphatic vessels coalesce into increasingly more developed and larger collection vessels. These larger vessels in the tissue and the macroscopic lymphatic vessels outside the organs have contractile cells similar to VSM cells. These cells spontaneously contract, perhaps as a result of contractile endothelial cells, to generate pressure and thus flow toward the larger lymphatic vessels downstream. In addition, external compression of these lymphatic structures helps propel lymphatic fluid away from the tissues and toward the central circulation. Physical massage of body structures, such as the limbs, or organ movements, such as those that occur with intestinal motility during digestion or those associated with skeletal muscle contractions during movement, externally compress lymphatic vessels and move lymph away from the interstitium of the organ.

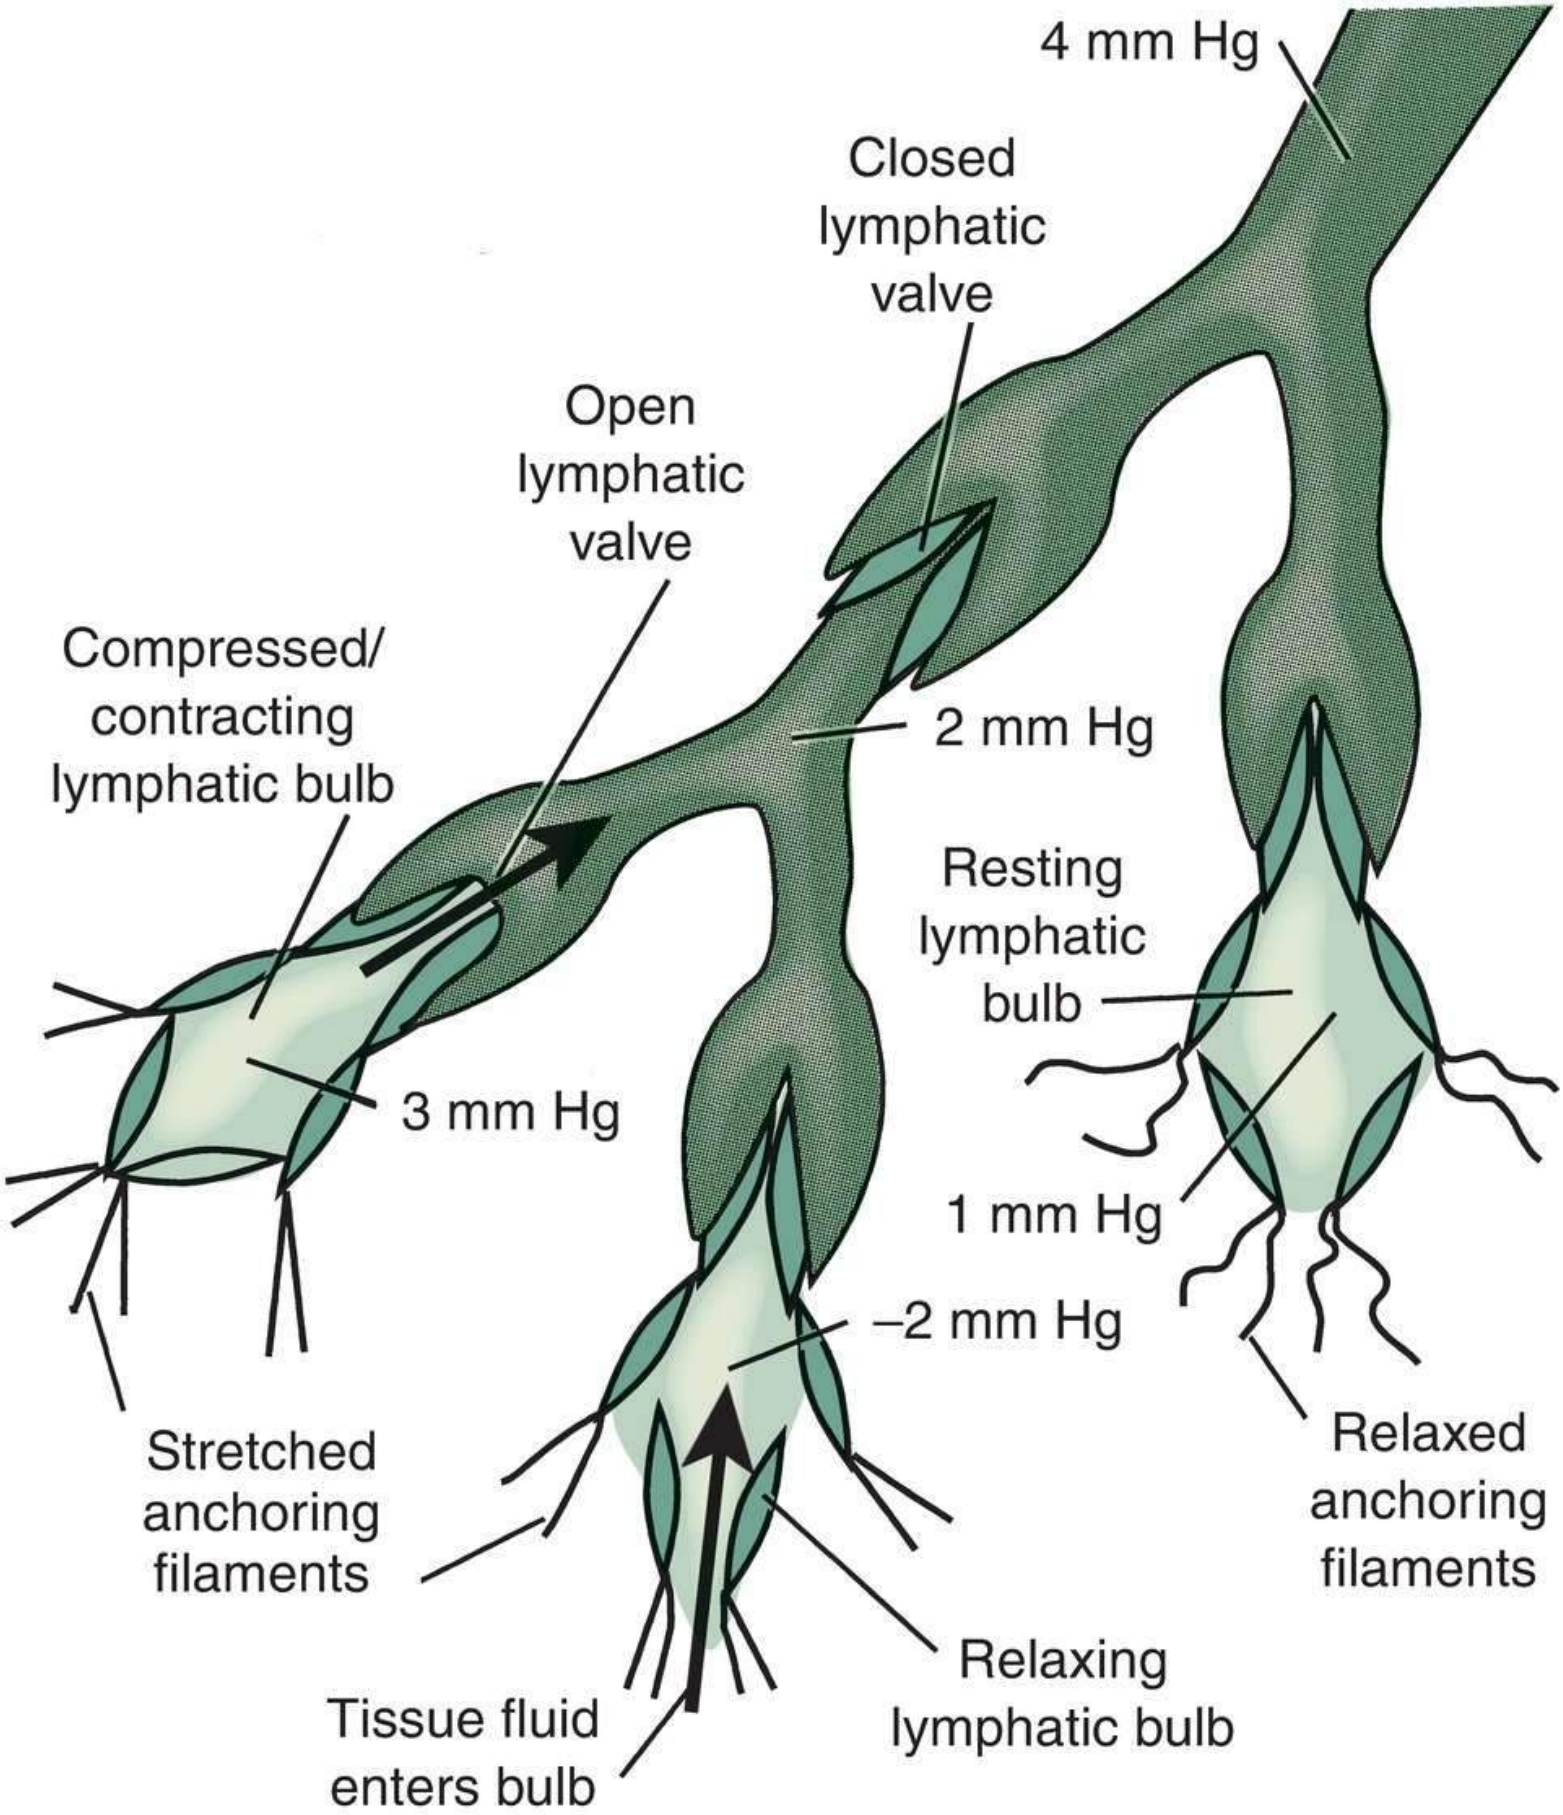

Figure 15.3 Lymphatic vessels: basic structure and functions. The contraction–relaxation cycle of lymphatic bulbs **(bottom)** is the fundamental process that removes excess water and plasma proteins from the interstitial spaces. Pressures along the lymphatics are generated by lymphatic vessel contractions and by organ movements, which cause alternately external compression and relaxation stimuli.

Lymphatic vessels mechanically collect fluid from tissue fluid between cells.

In all organ systems, more fluid is filtered than absorbed by the capillaries and plasma proteins diffuse into the interstitial spaces through the large pore system. By removing the fluid, the lymphatic vessels also collect the proteins and return them back into the bloodstream. This process is essential because the osmotic attraction of water by plasma proteins is the most important factor that retains water in the vascular system (see below).

The ability of lymphatic vessels to change diameter extrinsically or intrinsically is important for lymph formation and protein removal. The movement of fluid from tissue to the lymphatic vessel lumen is passive. The lymphatic vessels relax after a compression or contraction and allow fluid to enter. Once the interstitial fluid is in a lymphatic vessel, it is called **lymph**. In the smallest lymphatic vessels and, to some extent, in the larger lymphatic vessels, the endothelial cells are overlapped rather than fused together, as in blood capillaries. The overlapped portions of the cells are attached to anchoring filaments, which extend into the tissue (see Fig. 15.3). When stretched, anchoring filaments pull apart the free edges of the endothelial cells and create openings that allow tissue fluid and molecules carried in the fluid to enter. When lymphatic vessels are allowed to passively relax, the pressure in the lumen becomes slightly lower than in the interstitial space, and tissue fluid enters the lymphatic vessel. When the lymphatic bulb or vessel next actively contracts or is compressed, the overlapped cells are mechanically sealed to hold the lymph. The pressure developed inside the lymphatic vessel forces the lymph into the next downstream segment of the lymphatic system. Because the anchoring filaments are stretched during this process, the overlapped cells can again be parted during the relaxation of the lymphatic vessel the way in which a stretched rubber band snaps back after the release of its stretch. This compression–relaxation cycle facilitates the uptake and flow of fluid from the interstitium into and down the lymphatic channels. The compression–relaxation cycle increases in frequency and vigor when excess water is in the lymph vessels, whether lymphatic smooth muscle cells or the contractile lymphatic endothelial cells control it. Conversely, less fluid in the lymphatic vessels allows the vessels to become quiet and pump less fluid. This simple regulatory system ensures that the fluid status of the organ's interstitial environment is appropriate.

The active and passive compression of lymphatic bulbs and vessels also provides the force needed to propel the lymph back to the venous side of the blood circulation. To maintain directional lymph flow, microscopic lymphatic bulbs and vessels as well as large lymphatic vessels have one-way valves (see Fig. 15.3). These valves allow lymph to flow only from the tissue toward the progressively larger lymphatic vessels and, finally, into large veins in the chest cavity.

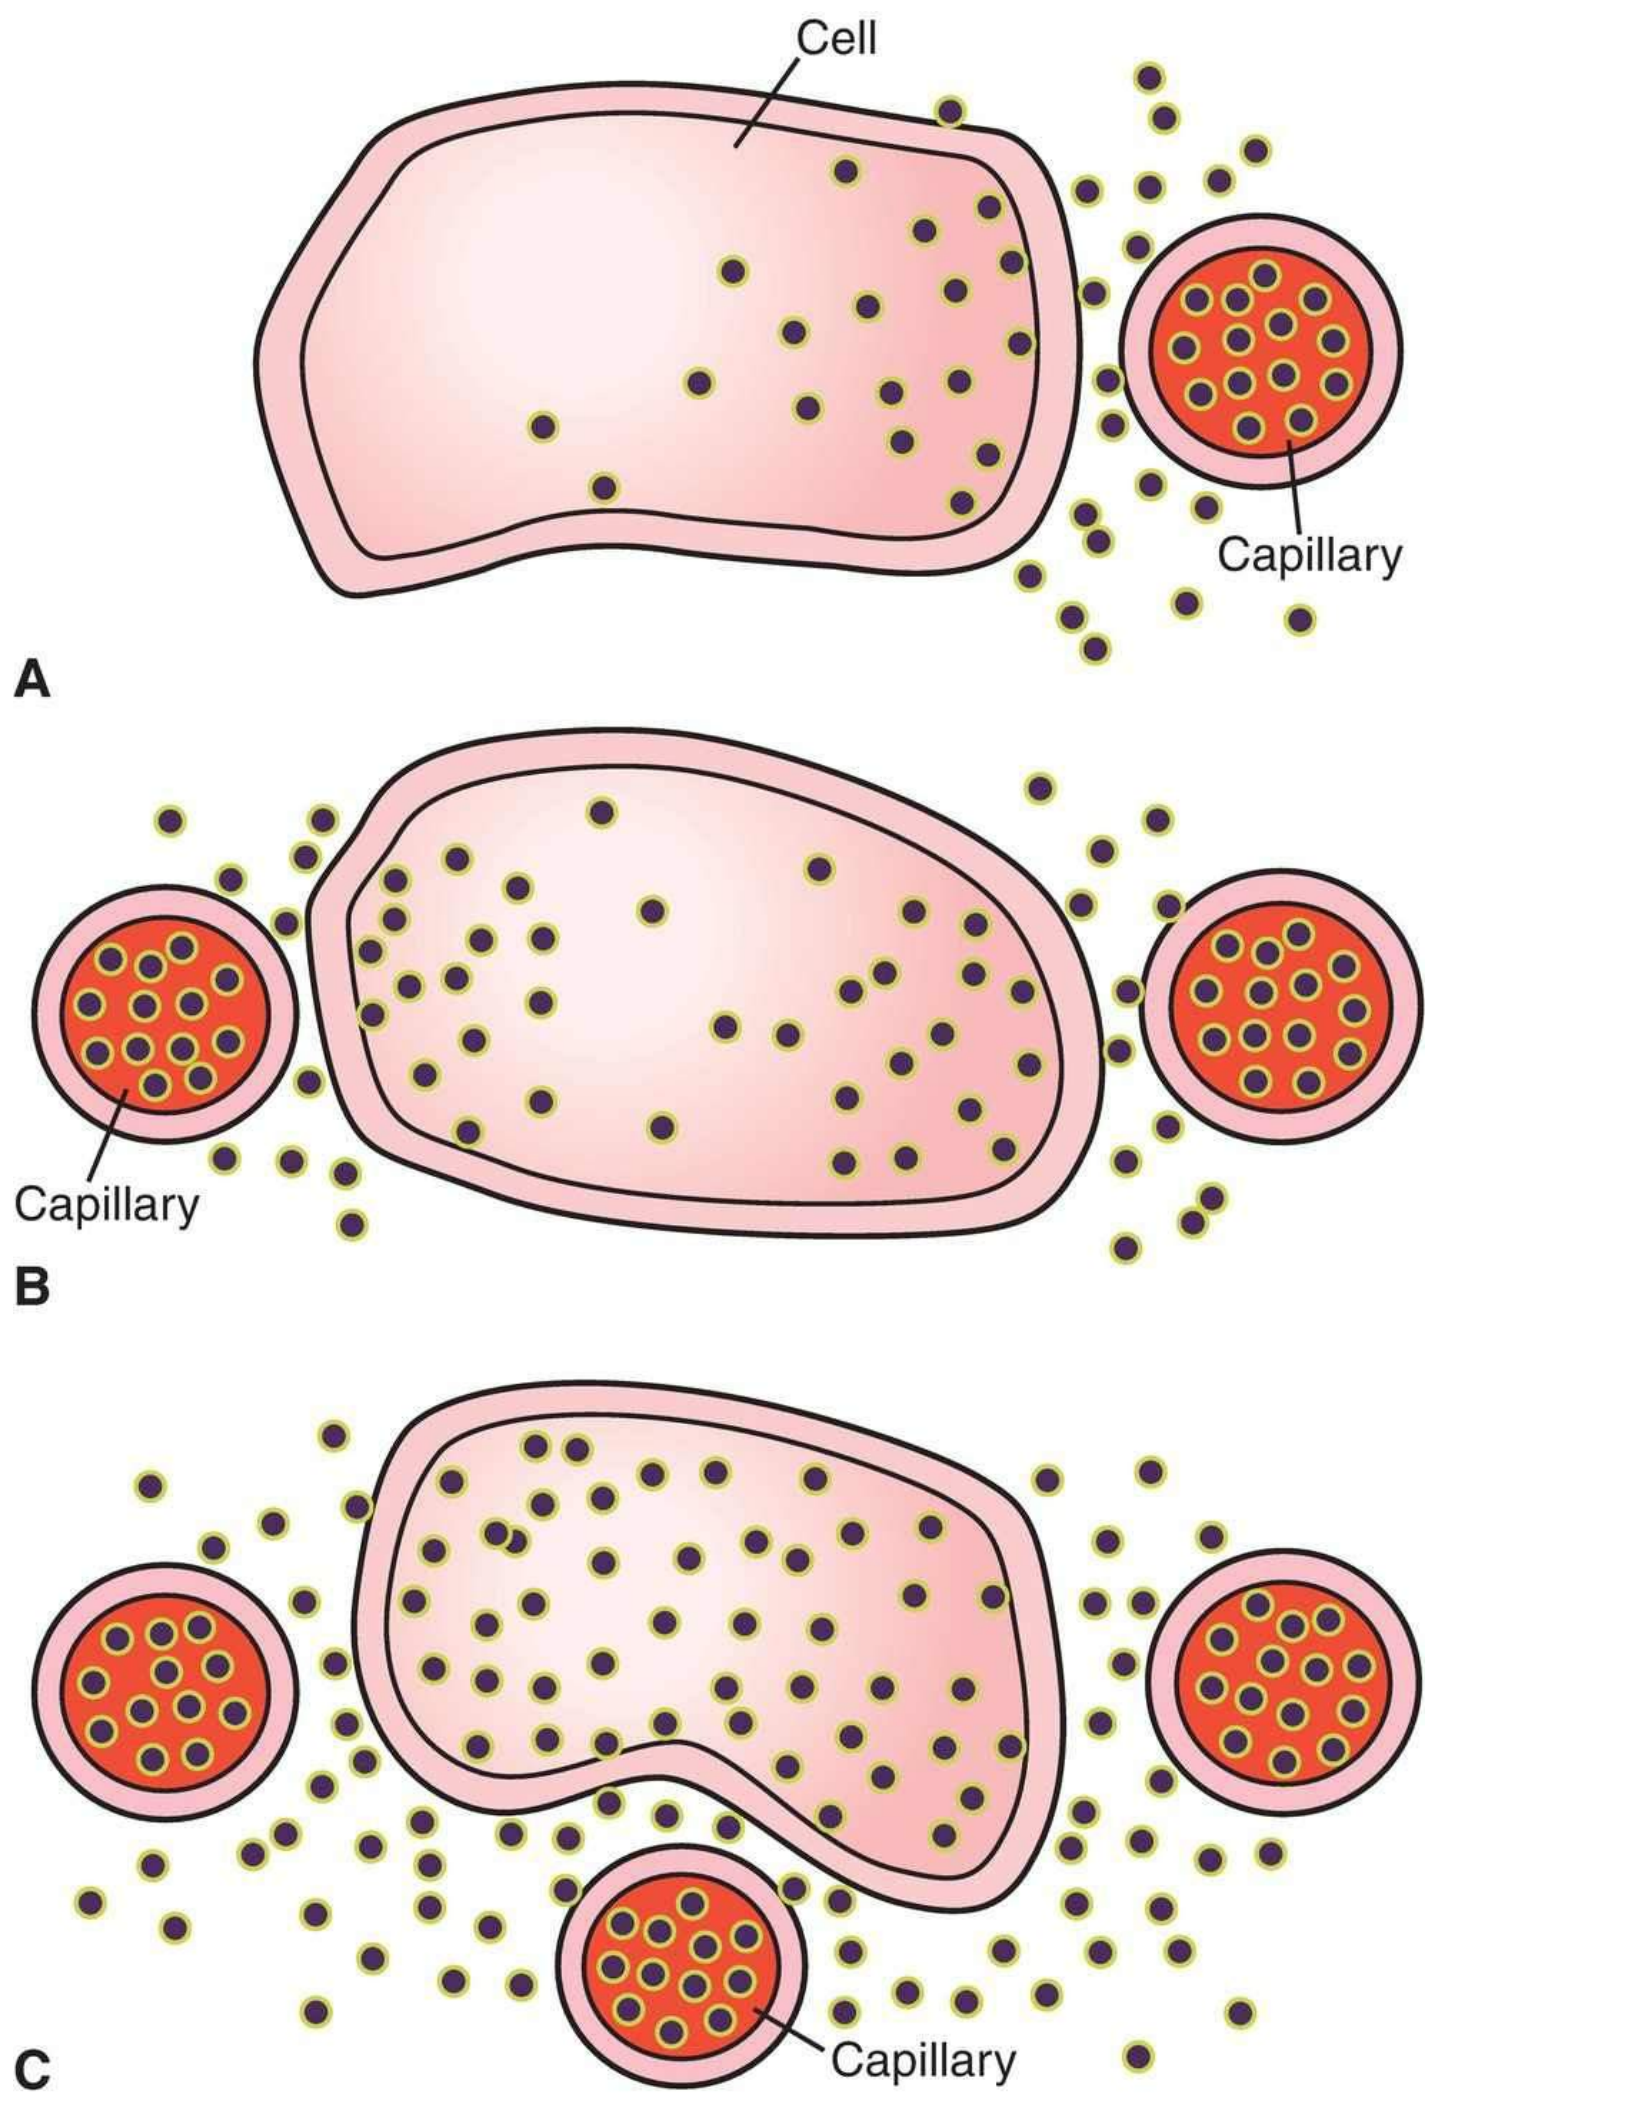
Lymphatic pressures are only a few mm Hg in the bulbs and smallest lymphatic vessels and as high as 10 to 20 mm Hg during contractions of larger lymphatic vessels. This progression from lower to higher lymphatic pressures is possible because, as each lymphatic segment contracts, it develops a slightly higher pressure than in the next lymphatic vessel, and the lymphatic valve momentarily opens to allow lymph flow. When the activated lymphatic vessel relaxes, its pressure is again lower than that in the next vessel, and the lymphatic valve closes.

SOLUTE EXCHANGE BETWEEN THE VASCULATURE AND TISSUES

The increasing numbers of vessels through successive branches of the arterial tree and on into the capillaries and venules dramatically increase the surface area of the microvasculature. The large surface area of the capillaries and smallest venules is important because most exchange of nutrients, wastes, and fluid occurs across these tiny vessels. Exchange between the interstitial fluid and capillaries occur via three processes: (1) diffusion, (2) filtration, and (3) vesicular transport.

Transport across capillaries is enhanced by increasing their collective surface area and reducing diffusion distances from capillaries to cells.

The spacing of microvessels in the tissues determines the distance molecules must diffuse from the blood to the interior of the tissue cells. In the example shown in Figure 15.4A, nutrients are supplied to a single cell by a single capillary. The density of dots at various locations represents the concentration of blood-borne molecules across the cell interior. Note that as molecules travel farther from the capillary, their concentration decreases substantially because the volume into which diffusion proceeds increases as the square of the distance. Furthermore, the time required for traversing a given distance by diffusion increases as an exponential function of distance (see Chapter 11). Consequently, if molecules are consumed by cells (e.g., oxygen), the concentration of substances surrounding them will decrease dramatically as the distance between the cell and its nearest capillary is increased.



Cell
Capillary
A
Capillary
B
Capillary
C

Figure 15.4 The effect of the number of perfused capillaries on cell concentration of blood-borne molecules. Molecules are represented by *dots* in the figure. **(A)** With one capillary, the left side of the cell has a low concentration. **(B)**The concentration can be substantially increased if a second capillary is perfused. **(C)**The perfusion of three capillaries around the cell increases concentrations of blood-borne molecules throughout the cell.

Increasing the number of microvessels reduces diffusion distances from a given point inside a cell to the nearest capillary. Doing so minimizes the dilution of molecules within the cells caused by large diffusion distances. At any given moment during resting conditions, only about 40% to 60% of the capillaries are perfused by red blood cells in most organs. The capillaries not in use do contain blood, but it is not moving. As shown in Figure 15.4B and C, increasing the number of perfused capillaries with moving blood decreases diffusion distances and elevates cell concentrations of molecules derived from the blood. However, it is equally true that decreasing the number of perfused capillaries increases diffusion distances, decreases exchange, and reduces cell concentration of molecules, thereby threatening cell function and survival. This can result from severely constricting arterioles or by destroying existing capillaries in disease states such as diabetes mellitus.

Transport of a solute across capillaries is enhanced by increasing the capillary permeability and concentration gradient for the solute across the capillaries.

Diffusion is by far the most important means for moving solutes across capillary walls. Fick's law of diffusion (see Chapter 2) states that the rate of diffusion, or flux, of a solute between blood and tissue is represented by

$$J_s = PS(C_b - C_t) \quad (1)$$

where J_s is the net movement of solute (often expressed in mol/min per 100 g of tissue), PS is the **permeability surface area coefficient**, and C_b and C_t are the blood and tissue concentrations of the solute, respectively. The PS coefficient is directly related to the diffusion coefficient of the solute in the capillary wall and the vascular surface area available for exchange, whereas it is inversely related to the diffusion distance. The surface area and diffusion distance are determined, in part, by the number of microvessels with active blood flow as explained in the previous section. The diffusion coefficient is relatively constant, unless the capillaries are damaged, because it depends on the anatomic properties of the vessel wall (e.g., the size and abundance of pores) and the chemical nature of the material that is diffusing.

Concentrations of solutes in tissue and blood, as well as the number of perfused capillaries and thus diffusional surface area and distances, are all affected by physiological and pathophysiological conditions whether they occur acutely or chronically. Consequently, microvascular exchange can be altered dynamically. For example, perfused capillary density increases significantly when metabolic activity in a tissue increases as compared with the tissue at rest. This is seen in exercising muscle or in the intestinal circulation during digestion.

It is important to remember that diffusion rate for a molecule between two points depends on the *difference* between the high and low concentrations, not the specific concentrations at each point. For example, if the cell consumes a particular solute, the concentration in the cell will decrease, and for a constant concentration in blood plasma, the diffusion gradient will enlarge and thus increase the rate of diffusion into the cell, providing the tissue is supplied with sufficient blood. If the cell ceases to use as much of a given solute, the concentration in the cell will increase and the rate of diffusion consequently will decrease.

Increases in vascular permeability, surface area, or blood flow enhance the diffusion of small molecules from the blood.

As a result of diffusional losses and gains of molecules as blood passes through the tissues, the concentrations of various molecules in venous blood can be very different from those in arterial blood. The **extraction** (E), or **extraction ratio**, of material from blood perfusing a tissue can be calculated from the arterial (C_a) and venous (C_v) blood concentration as

$$E = (C_a - C_v)/C_a \quad (2)$$

If the blood loses material to the tissue, the value of E is positive and has a maximum value of 1 (e.g., if all material is removed from the arterial blood in which case $C_v = 0$). An E value of 0 indicates that no loss or gain occurred. A negative E value indicates that the tissue added material to the blood.

The total mass of material lost or gained by the blood can be calculated as

$$\text{Amount lost or gained} = E \times \dot{Q} \times C_a \quad (3)$$

where E is extraction, $\dot{Q}$ is blood flow, and C_a is the arterial concentration. Although this equation is useful for calculating the total amount of material exchanged between tissue and blood, it does not allow a direct determination of how changes in vascular permeability and exchange surface area influence the extraction process. The extraction can be related to the permeability (P) and surface area (A) available for exchange as well as the blood flow, ($\dot{Q}$), by the equation:

$$E = 1 - e^{-(PA/\dot{Q})} \quad (4)$$

where e is the base of the natural system of logarithms. This equation predicts that physiologically induced changes in the number of perfused capillaries, which alter surface area, and changes in blood

flow are important determinants of exchange processes. A change that increases permeability, increases surface area, or decreases flow will increase extraction. Changes in the opposite direction decrease extraction. The inverse effect of blood flow on extraction occurs because, as flow increases, less time is available for exchange whereas a slowing of flow allows more time for exchange.

Ordinarily, the blood flow and total perfused surface area change in the same direction, although by different relative amounts. For example, surface area can generally, at most, double or be reduced by about half; however, blood flow can increase threefold to fivefold or more in some tissues, such as skeletal muscle during exercise, or decrease by about half in many organs without threatening viable tissue. The net effect is that extraction is rarely more than doubled or decreased by half relative to the resting value in most organs. This is still an important range because changes in extraction can compensate for reduced blood flow, or enhance exchange when blood flow is increased.

Diffusion-limited and flow-limited transport

Gases, small lipid-soluble molecules, water, simple sugars, and ions can diffuse so rapidly across capillaries that their transport from capillary to tissue or vice versa is not limited by their rate of diffusion. Their transport is limited only by their rate of delivery into the capillary network from blood perfusing the network. Therefore, such transport is called **flow-limited transport**. For a flow-limited transport substance, increasing blood flow increases the effective concentration of a substance in the capillary and thus accelerates its outward diffusion; that is, the faster materials are brought into the capillary by blood flow, relative to their diffusion out of the capillary, the higher will be their flux out of the capillaries and into the tissues.

In contrast to solutes characterized by flow-limited transport, larger lipophobic molecules, such as sucrose, polysaccharides, and proteins, have difficulty diffusing across the capillary membrane or through capillary pores. These substances may be delivered in large quantities into capillaries by blood flow but nevertheless exhibit low transcapillary flux. Their transport between the bloodstream and tissues is therefore limited by their rate of diffusion into or out of capillaries and not appreciably altered by their rate of delivery into the capillary network by blood flow. Such transport is called **diffusion-limited transport**.

In pathologic conditions, substances that otherwise exhibit flow-limited transport can become diffusion limited. This can occur when diffusion distances between capillaries and cells become too great to allow the rapid exchange of materials, as seen in the lungs when the transport of normally highly diffusible oxygen is impaired by infection or fluid accumulation in the pulmonary interstitium, which markedly increases diffusion distances. This phenomenon can also occur in any organ when the number of perfused capillaries is radically reduced (e.g., by low flow, blood clots, etc.), thereby reducing the capillary surface area available for diffusion while also increasing the distance between tissue cells and the nearest capillaries with blood flow.

WATER EXCHANGE BETWEEN THE VASCULATURE AND INTERSTITIUM

To supply blood into the microvessels of tissues, the heart generates pressure and pumps blood into the arterial system. However, because the intercapillary hydrostatic pressure is greater than that in the interstitium, pressurized filtration of water occurs through pores in capillaries. This loss of water out of the cardiovascular system, if unchecked, could lead to severe hypovolemia and collapse of the cardiovascular system. However, plasma contains a significant amount of proteins (mostly albumin) that cannot cross the capillary membrane or pores. They are considered, therefore, “effective osmols” across the capillary membrane. Coupled with the fact that there is little protein in interstitial fluid, a net osmotic force favoring fluid flow into the capillaries exists. The osmotic pressure due to protein is often called a colloid oncotic, or just oncotic, pressure to indicate that the osmotic force is generated by the colligative properties of proteins. Intercapillary oncotic pressure is the major factor maintaining fluid retention in the cardiovascular system and thus is the key factor counteracting capillary fluid losses through capillary pores.

The interplay between net hydrostatic and oncotic forces determines the net direction of fluid exchange across the capillaries.

In organs other than the kidney, capillary hydrostatic pressure declines from the arterial to the venule end of the capillary. Typically, capillary hydrostatic pressure is ~40 mm Hg at its arteriolar end and ~15 mm Hg at the venule end. The average capillary pressure is different in each organ, ranging from about 15 mm Hg in intestinal villus capillaries to 55 mm Hg in the kidney glomerulus. The interstitial hydrostatic pressure ranges from slightly negative to 8 to 10 mm Hg. The oncotic pressure of plasma proteins is typically 18 to 25 mm Hg in mammals and is highly dependent on the plasma albumin concentration, which can change in abnormal conditions.

In the body as a whole, the net inward oncotic force does not balance the net outward hydrostatic pressure forces. Thus, there exists a slightly positive overall force for the filtration of fluid out of the capillaries. Most organs continuously form lymph, which supports the concept that capillary and venular filtration pressures generally are larger than absorption pressures. The balance of pressures is likely +1 to +2 mm Hg outward in most organs. However, this is not true for each capillary in the body all the time. Some capillaries can be net reabsorbers of water; others filter along their entire length, whereas still others can filter at their arteriolar end and reabsorb at their venule end, depending on existing hydrostatic pressure in both capillary locations. Based on directly measured capillary hydrostatic and plasma oncotic pressures, the entire length of the capillaries in skeletal muscle filter slightly all of the time, whereas the lower capillary pressures in the intestinal mucosa, brain, and pulmonary capillaries primarily favor absorption along the entire capillary length. Standing also causes high capillary hydrostatic pressures from gravitational effects on the blood in the arterial and venous vessels and results in excessive filtration in the lower extremities.

Effects of capillary oncotic and hydrostatic pressure on fluid flux are modified by these pressures in the interstitium.

A small amount of plasma protein enters the interstitial space; these proteins and, perhaps, native proteins of the space generate the tissue colloid osmotic pressure. This pressure of 2 to 5 mm Hg offsets part of the colloid osmotic pressure in the plasma. This is, in a sense, a filtration, or outward “drawing,” pressure that opposes the blood colloid osmotic pressure. The hydrostatic pressure on the tissue side of the endothelial pores is the tissue hydrostatic pressure. The water volume in the interstitial space and tissue distensibility determine this pressure. The magnitude of tissue hydrostatic pressure in various tissues during resting conditions is a matter of debate. Tissue pressure is probably slightly below atmospheric pressure (negative) to slightly positive (about +3 mm Hg) during normal hydration of the interstitial space and becomes positive when that space contains excess water. Tissue hydrostatic pressure thus is a filtration force when negative and is an absorption force when positive. Tissue hydrostatic pressure can be increased by organ compression, such as in a skeletal muscle during contraction and decreased by severe dehydration.

If water is removed from the interstitial space, the hydrostatic pressure becomes negative (Fig. 15.5). As a general rule, about 500 to 1,000 mL of fluid can be withdrawn from the interstitial space of the entire body to help replace water losses resulting, for example, from excessive sweating, diarrhea, vomiting, or blood loss. In contrast, if a substantial amount of water is added to the interstitial space, the tissue hydrostatic pressure increases. However, a margin of safety exists over a wide range of tissue fluid volumes (see Fig. 15.5), which helps avoid excessive tissue hydration. The ability of tissues to allow substantial changes in interstitial volume with only small changes in pressure indicates that the interstitial space is distensible.

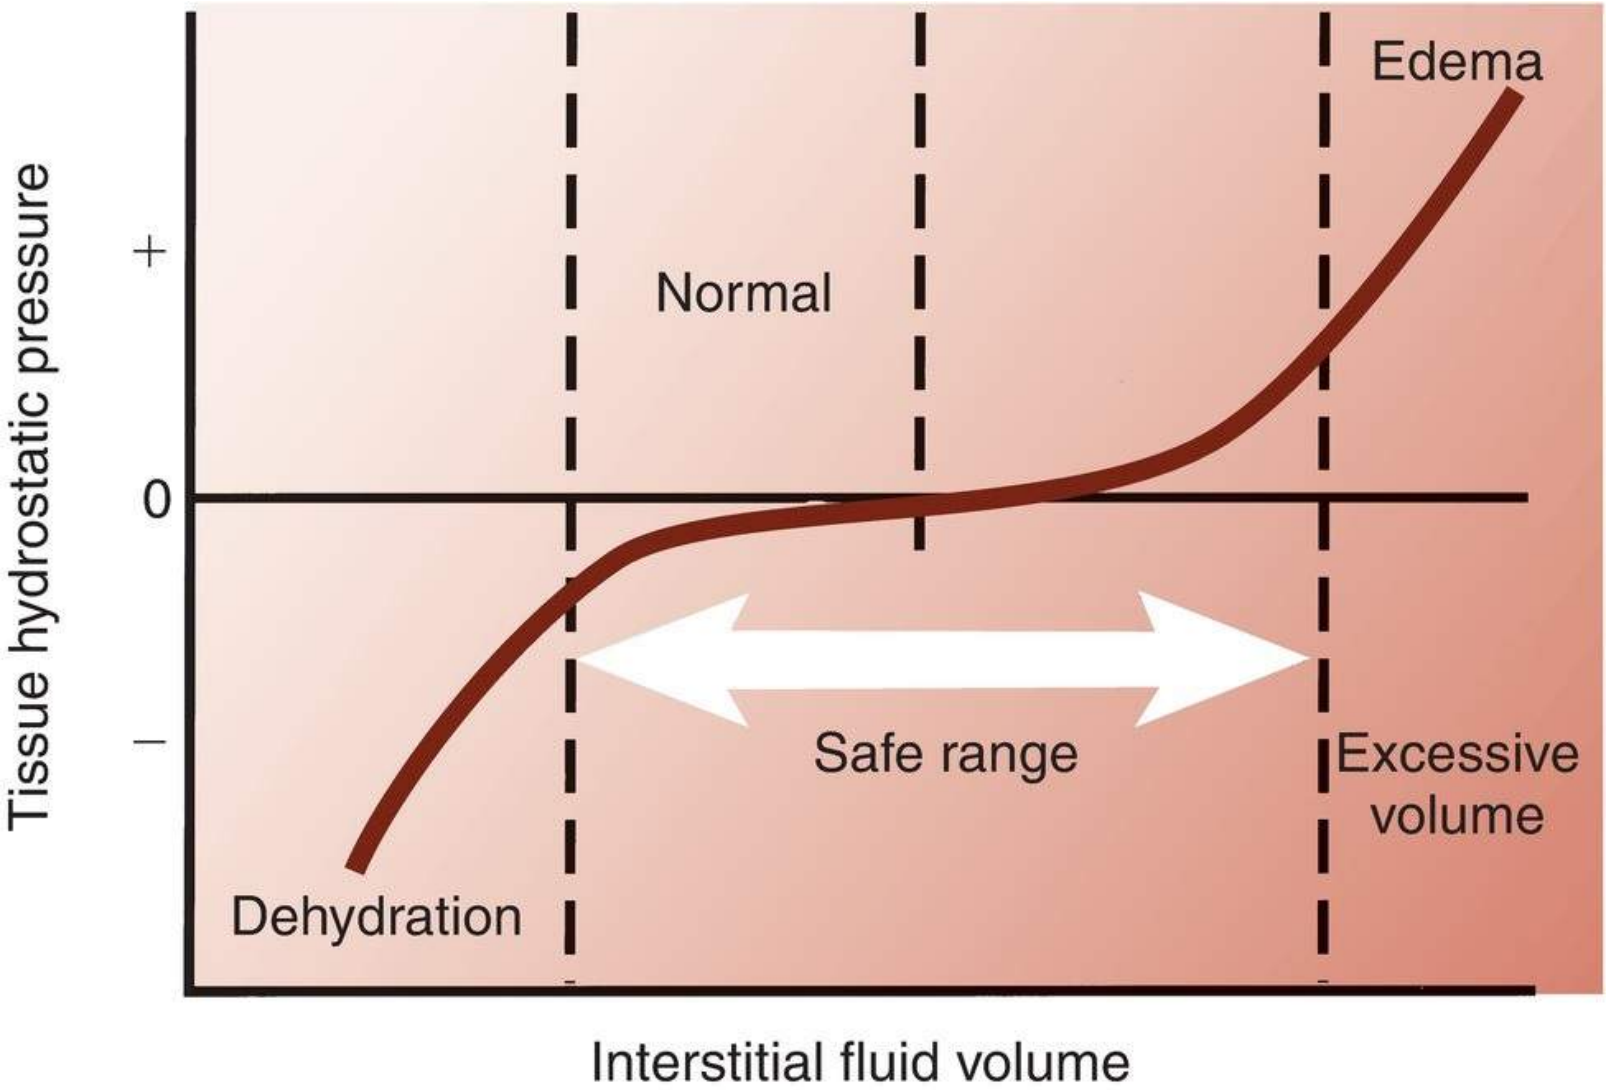


Figure 15.5 Variations in tissue hydrostatic pressure as interstitial fluid volume is altered. Under normal conditions, tissue pressure is slightly negative (subatmospheric), but an increase in volume can cause the pressure to become positive. If the interstitial fluid volume exceeds the "safe range," high tissue hydrostatic pressures and edema will be present. Tissue dehydration can cause negative tissue hydrostatic pressures.

The Starling-Landis equation quantifies fluid flow across the capillaries.

At the end of the 19th century, the English physiologist Ernest Starling first postulated the role of hydrostatic and colloid osmotic pressures in determining fluid movement across capillaries. In the 1920s, the American physiologist Eugene Landis obtained experimental proof for Starling's hypothesis. The relationship is defined for a single capillary by the **Starling-Landis equation**:

$$J_V = K_h A \left[(P_c - P_t) - \sigma (COP_p - COP_t) \right]$$

(5)

J_V is the net volume of fluid moving across the capillary wall per unit of time (μm^3/min). K_h is the **hydraulic conductivity for water**, which is the fluid permeability of the capillary wall. It can be thought of as the ease with which water crosses the capillary wall. K_h is expressed as μm^3/min/mm Hg (μm^2 of capillary surface area per minute per mm Hg pressure difference). The value of K_h increases up to fourfold from the arterial to the venous end of a typical capillary. A, in equation 5, is the vascular surface area, P_c is the capillary hydrostatic pressure, and P_t is the tissue hydrostatic pressure. COP_p and COP_t represent the plasma and tissue colloid osmotic pressures, respectively, and σ is the **reflection coefficient** for plasma proteins. The value of σ is 1 when molecules cannot cross the membrane (i.e., they are 100% "reflected") and 0 when molecules freely cross the membrane (i.e., they are not reflected at all). This coefficient is included because the microvascular wall is slightly permeable to plasma proteins, preventing the full expression of the two colloid osmotic pressures. Typical σ values for plasma proteins in the microvasculature exceed 0.9 in most organs other than the liver and spleen, which have capillaries that are permeable to plasma proteins. The reflection coefficient is normally relatively constant but can be decreased dramatically by hypoxia, inflammatory processes, and tissue injury. This leads to increased fluid filtration because the effective fluid-retaining power of the colloid osmotic pressure is reduced when the vessel wall becomes more permeable to plasma proteins.

The extrapolation of fluid filtration or absorption for a single capillary to fluid exchange in a whole tissue is difficult. Within organs, there are regional variations in microvascular pressures, possible filtration and absorption of fluid in vessels other than capillaries, and physiologically and pathologically induced variations in the available surface area for capillary exchange. Therefore, for whole organs, a measurement of total fluid movement relative to the mass of the tissue is used. To take into account the various hydraulic conductivities and total surface areas of all vessels involved, the volume (mL) of fluid moved per minute for a change of 1 mm Hg in net capillary filtration pressure for each 100 g of tissue is determined. This value is called the **capillary filtration coefficient (CFC**, or $\mathbf{K_f}$**)**, even though it is likely that fluid exchange also occurs in venules. CFC values in tissues such as skeletal muscle and the small intestine are typically in the range of 0.025 to 0.16 mL/min/mm Hg per 100 g of tissue. The CFC replaces the combined hydraulic conductivity (K_h) and capillary surface area (A) variables in the Starling-Landis equation that apply for filtration across a single capillary.

The CFC can change if fluid permeability, the surface area (determined by the number of perfused microvessels), or both are altered. For example, during the intestinal absorption of products of digestion,

especially lipids, both capillary fluid permeability and perfused surface area increase. Therefore, CFC increases dramatically. In contrast, during exercise, CFC increases in the skeletal muscle vasculature occur primarily through increased perfused capillary surface area with only small increases in fluid permeability.

The hydrostatic and colloid osmotic pressure differences across capillary walls, called the **Starling forces**, cause the movement of solutes along with the water into the interstitial spaces. However, most solutes transferred to the tissues move across capillary walls by simple diffusion, not by bulk flow of fluid.

Capillary hydrostatic pressure is altered by changes in precapillary and postcapillary resistance as well as arteriolar and venule blood pressure.

Normal physiologic processes in the body do not control plasma colloid osmotic pressure, tissue hydrostatic pressure, or tissue colloid osmotic pressure. Thus, manipulation of these parameters cannot be used to regulate filtration and reabsorption of fluid at the capillary. Such regulation is accomplished, therefore, by the adjustment of capillary hydrostatic pressure.

Capillary hydrostatic pressure (P_c) is influenced by four major variables: precapillary resistance (R_{pre}), postcapillary resistance (R_{post}), arterial blood pressure (P_a), and venous blood pressure (P_v). Precapillary and postcapillary resistances can be calculated from the pressure dissipated across the respective vascular regions divided by the total tissue blood flow $(\dot{Q})$, which is essentially equal for both regions:

$$R_{pre} = (P_a - P_c)/\dot{Q} \quad (6)$$

$$R_{post} = (P_c - P_v)/\dot{Q} \quad (7)$$

In most organ vasculatures, the precapillary resistance is three to six times higher than the postcapillary resistance. This has a substantial effect on capillary pressure. To demonstrate the effect of precapillary and postcapillary resistances on capillary pressure, we use the equations for the precapillary and postcapillary resistances to solve for blood flow:

$$\dot{Q} = (P_a - P_c)/R_{pre} = (P_c - P_v)/R_{post} \quad (8)$$

The two equations to the right of the flow term can be solved for capillary pressure:

$$P_c = \frac{(R_{post}/R_{pre})P_a + P_v}{1 + (R_{post}/R_{pre})}$$

(9)

Equation 9 indicates that the ratio of postcapillary to precapillary resistance, rather than the absolute magnitude of either resistance, determines the effect of arterial pressure (P_a) on capillary hydrostatic pressure. It also shows that venous pressure substantially influences capillary pressure and that the denominator influences both pressure effects. At a typical postcapillary to precapillary resistance ratio of 0.16:1, it is obvious that venous pressure has a larger effect on capillary hydrostatic pressure than does arteriolar pressure. Furthermore, with this ratio, the denominator of equation 9 will be 1.16, which means about 80% of a change in venous pressure will be reflected back to the capillaries.

As can be seen by equation 9, capillary hydrostatic pressure will increase with arteriolar vasodilation. This is a change that accompanies increased tissue metabolism. Furthermore, with increased tissue metabolism, the postcapillary to precapillary resistance ratio increases because precapillary resistance decreases more than postcapillary resistance. This change in the ratio will increase P_c. Because the balance of hydrostatic and colloid osmotic pressures is usually −2 to +2 mm Hg, a 10- to 15-mm Hg increase in capillary pressure during maximum vasodilation can cause a profound increase in filtration. The increased filtration associated with microvascular dilation is usually associated with a large increase in lymph production, which removes excess tissue fluid.

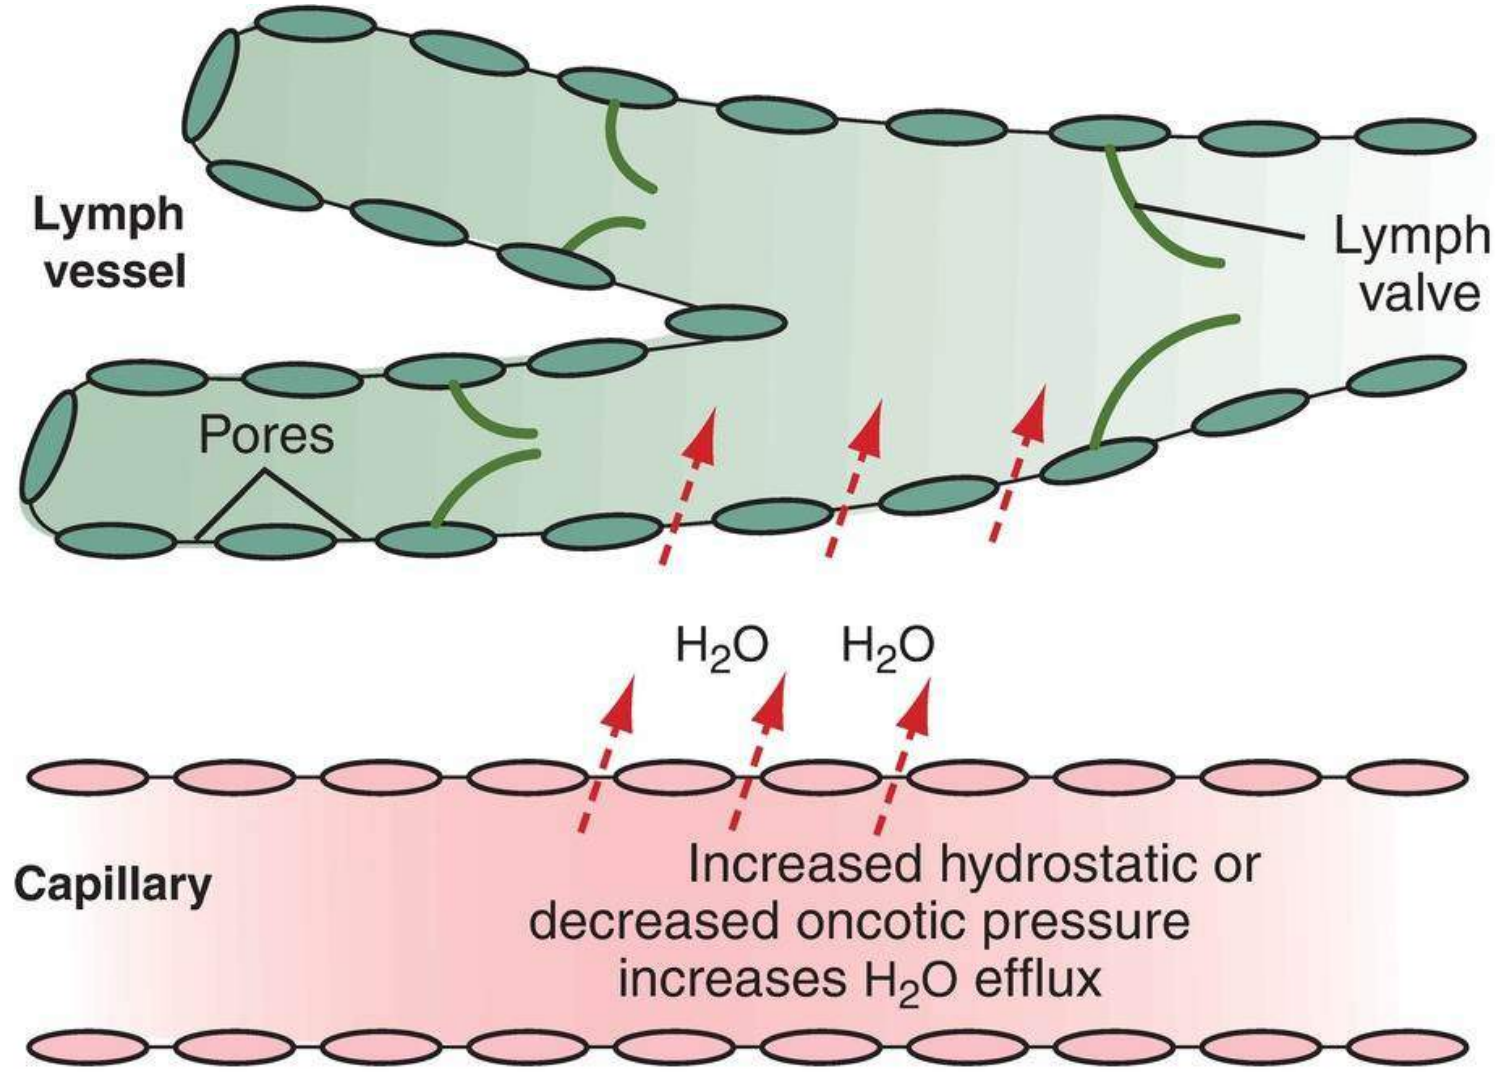
When sympathetic nervous system stimulation causes a substantial increase in precapillary resistance and a proportionately smaller increase in postcapillary resistance, the capillary pressure can decrease up to 15 mm Hg and, thereby, greatly increase the absorption of tissue fluid. This process is an important compensatory mechanism the body uses to combat the early stages of circulatory shock (see Chapter 17).

Edema impairs diffusional transport across the capillaries.

Changes in capillary hydrostatic pressure and plasma protein concentration can have a profound effect on filtration at the capillary. The hydrostatic pressure involved in transcapillary fluid exchange depends on how the microvasculature dissipates the prevailing arterial and venous pressures. As seen above, certain interplay of these variables can lead to substantial filtration across the capillaries. Although plasma protein concentration does not vary moment to moment, its circulating value in normal circumstances is determined largely by the rate of protein synthesis in the liver, where most of the plasma proteins are made. Disorders that either impair albumin synthesis or promote the loss of albumin result in reduced plasma protein concentration, a lowered plasma colloid osmotic pressure, and excessive fluid filtration at the capillaries.

Edema is a condition in which there is excessive accumulation of fluid in tissue spaces (i.e., the interstitium). Edema interferes with capillary transport by increasing diffusion distances between capillaries and tissue cells. Sometimes this accumulation can be substantial, and in addition to affecting capillary transport, this extreme can cause circulatory collapse if the edematous fluid was derived from a loss of plasma volume. For example, edema formation in the abdominal cavity (known as **ascites**) can allow large quantities of fluid to collect in the abdominal space.

Anything that causes excess fluid filtration at the capillaries or impairs fluid transport through the lymph channels can create edema (Fig. 15.6). One of the common causes of edema formation is a loss of albumin from the plasma. Edema will occur when albumin concentrations drop below 2.5 g/100 mL. This is common in diseases in which the liver is unable to manufacture albumin or in kidney diseases in which albumin and other proteins are lost into the urine. Burns, by destroying capillary integrity, cause edema through increased capillary permeability, loss of albumin through damaged vessels, and inflammatory vasodilation. Hives, which are a form of localized edema associated with allergic reactions, result from an increase in capillary permeability, venule permeability, and arterial dilation, all caused by histamine release during the allergic response. Obstruction of veins, usually from blood clot formation after surgery, is another common cause of edema, as is the obstruction of lymph channels at lymph nodes by infections.



↑ Lymph flow:

- ↑ capillary hydrostatic pressure
- ↑ capillary surface area
- ↑ capillary permeability
- ↑ tissue metabolism
- ↑ muscle activity (massage)

↑ Edema formation:

- ↓ plasma protein concentration
- arteriolar dilation
- venous obstruction
- lymphatic obstruction
- histamine (↑ capillary permeability)
- all factors that ↑ lymph flow except muscle massage

Figure 15.6 Determinants of water efflux from the capillary and into a lymph vessel. Factors that increase lymph flow or favor the formation of edema are listed in the figure.

REGULATION OF MICROVASCULAR RESISTANCE

The VSM cells around arterioles and venules respond to a wide variety of physical and chemical stimuli, which alter their diameter and resistance. The following sections consider the various physical and chemical conditions in tissues that affect the contractile state of VSM and, thus, affect resistance in the microvasculature.

Myogenic regulation causes arterioles to actively contract or relax in response to changes in intravascular pressure.

VSM can rapidly *actively* contract in response to being stretched and, conversely, can *actively* relax, when passively shortened. This process, called *myogenic regulation*, is activated in arterioles (and somewhat in venules) when microvascular pressure is increased or decreased. Myogenic mechanisms are extremely fast and appear to be able to adjust to the most rapid pressure changes. In fact, VSM may be able to contract or relax when the load on the muscle is increased or decreased, respectively, without any change in muscle length. These responses are known to persist for as long as the initial stimulus is present, unless vasoconstriction reduces blood flow to the extent that tissue becomes severely hypoxic and nonfunctional.

The cellular mechanisms responsible for myogenic regulation are not entirely understood, but several possibilities are likely involved. VSM contraction is sensitive to external calcium concentration. Adding calcium to the cytoplasm from the extracellular fluid through membrane channels would activate the smooth muscle cell and result in contraction. Conversely, limiting calcium entry through channels would allow calcium pumps to remove calcium ions from the cytoplasm and favor relaxation. VSM contains calcium ion-selective channels that open in response to increased membrane stretch or tension. These **stretch-activated calcium channels** are distinct from receptor-operated or voltage-gated calcium channels. These channels may contribute to myogenic adjustments of VSM contraction and thus vascular resistance whenever internal arterial pressure changes.

Another mechanism postulated for the myogenic response is that a nonspecific cation channel is opened in proportion to cell membrane stretch or tension. The entry of sodium ions through these open channels could depolarize the cell and lead to the opening of voltage-activated calcium channels, followed by calcium entry into the cell and contraction. During reduced stretch or tension, the nonspecific channels would close and allow hyperpolarization to occur. Most recently, evidence suggests that the modulation of the calcium sensitivity of the contractile apparatus in VSM is a key factor in the myogenic response. The sensitivity of the apparatus to calcium is modified by the relative activities of myosin light chain kinase and myosin light chain phosphatase in the smooth muscle and appears to suggest a role for latch state mechanisms in the myogenic response. Regardless of the precise mechanism involved, arteries contract and depolarize as their intravascular pressure is increased and relax and hyperpolarize as their intravascular pressure is decreased.

The myogenic response is particularly helpful in preventing tissue edema when venous pressure is elevated by more than 5 to 10 mm Hg above the typical resting values. The elevation of venous pressure results in an increase in capillary pressure, which would normally favor filtration and edema formation. However, some of this pressure is transmitted back into the arteriolar segment of the microcirculation. Myogenic arteriolar constriction in response to the stretch caused by this increase in pressure lowers the transmission of arterial pressure into the capillaries and thus minimizes the risk of edema (although this occurs at the expense of decreased blood flow). This mechanism is called the **venous–arteriolar response**.

Myogenic regulation may also be one factor that helps control organ blood flow in the face of changes in arterial pressure. This process, called **autoregulation**, or autoregulation of blood flow, is discussed in greater detail later in this chapter.

CLINICAL FOCUS 15.1

Methods of Assessing Endothelial Function in Cardiovascular Disease

Hypertension, atherosclerosis, and diabetes mellitus all damage arterial endothelium and impair beneficial nitric oxide (NO)–mediated functions in those vessels. This damage and loss of NO invariably causes the vasculature to become prospasmodic, prothrombotic, and proatherogenic, which worsens the cardiovascular outcomes with these diseases. Assessment of the patient's condition and future risks in these diseases often focuses on the key variable associated with the condition: blood pressure in hypertension, high serum LDL to HDL ratios in atherosclerosis, and blood glucose levels in diabetes. More recent use of biochemical markers of NO biology, vascular inflammation, endothelial damage, adhesion molecules, and vascular repair have also been used to assess endothelial damage in cardiovascular disease. However, biochemical markers of NO or vascular disease are generally poor indicators of endothelial function, owing to the large variability in individual production and response to these biomarkers. From the perspective of the vascular system, what is of greater importance for the individual is what variables actually reflect the *functional state of the vasculature and its endothelium.* A patient could have modest hypertension, borderline plasma lipoprotein levels, and minimal glucose intolerance but could be at extreme risk for cardiovascular complications if these conditions were causing serious damage to the arterial endothelium. A physician could intervene earlier and more aggressively than he or she might otherwise if there were indications that these modest risk factors were causing more than modest disease in the vasculature.

The determination of impaired function of arterial endothelium in cardiovascular disease is relatively easy when assessments are made invasively on isolated arteries or in experimental animals. Indeed, these types of invasive studies have been the primary means by which the impairment of the endothelium NO system has been shown to be associated so extensively with cardiovascular disease. This type of invasive analysis, however, cannot be employed as a clinical test for patients. To be able to detect impaired endothelial function in patients as a regular clinical test, any technique employed needs to be noninvasive.

Recently, a noninvasive indicator for the assessment of vascular damage in cardiovascular disease, called flow-mediated vasodilation (FMD), has become increasingly used in clinical practice as a means of assessing the functional integrity of the vascular endothelium in various cardiovascular diseases. FMD is caused by shear stress–induced release of endothelial NO when arteries are exposed to high laminar flow. It is known that the endothelial NO system is impaired in all forms of cardiovascular disease and that it may be an early sign of the damaging effects of a disease on the vascular system. FMD can be induced in patients by placing an inflatable blood pressure cuff around a patient's arm, pressurizing the cuff to stop blood flow for 5 minutes, and then releasing the cuff pressure rapidly to allow a reactive hyperemia to occur. The hyperemia increases blood flow and shear stress on the intima of the brachial artery. This shear induces an FMD that can be measured as a diameter change of the brachial artery using Doppler ultrasound. Poor dilation is taken to be a measure of impaired endothelial function in the patient. This method of FMD is superior in clinical applications to intra-arterial drug infusion dilation methods that were first used for assessment of endothelial

function because the former, but not the latter, is noninvasive. Clinical studies continue to demonstrate correlations between impaired FMD and poor cardiovascular outcomes or cardiovascular disease. This likely reflects findings of numerous studies that have shown a strong correlation between endothelial dysfunction and increased risk of cardiovascular events, such as myocardial ischemia, infarction, and cardiac death. Several studies have shown that impaired FMD in the brachial artery is actually a good indicator of the severity of coronary artery disease in the patient. The relative success of this technique has spurred the development and investigation of additional FDM applications and additional noninvasive measures designed to assess endothelial function in patients. Most recently, FDM has been investigated as a tool to assess the functional state of penile cavernous arteries in erectile dysfunction. Newer, non-FMD vasodilation assessment methods are now being employed for clinical assessment of endothelial function. Digital pulse volume amplitude tonometry, where reactive hyperemia is measured by monitoring changes in the arterial pulse wave during the hyperemia, is one such hyperemia-based noninvasive method used to assess endothelial function in the microcirculation. Oscillometric ezFMD is a recently developed, sophisticated, noninvasive method for measuring endothelial function. This technique measures oscillations in arterial volume due to changes in blood pressure at different external inflatable cuff pressures. ezFMD is lower in patients with cardiovascular disease and is easier to perform and more reliable than standard FMD for assessment of endothelial function in CV disease. However, the future usefulness of this technique awaits further clinical validation. ■

Organ blood flow is increased by increased tissue metabolism through local, nonneurogenic mechanisms.

In almost all organs, an increase in tissue metabolism is associated with increased blood flow and extraction of oxygen to meet the increased metabolic needs of the tissues. This phenomenon is called **active hyperemia**. In addition, a reduction in oxygen within the blood, hypoxia, and hypoxemia are associated with the dilation of the arterioles and increased blood flow (assuming neural reflexes to hypoxia are not activated). In both active hyperemia and local ischemia, the changes in arteriolar resistance are in the direction of increasing blood flow, thereby indirectly increasing oxygen delivery to the tissue. This helps tissues receive the oxygen necessary to meet their metabolic requirements.

The mechanisms behind the local regulation of the microvasculature in response to the metabolic needs of tissues involve many different types of cellular events. Decreased O_2, increased CO_2, increased H^+, and increased adenosine all accompany increased tissue metabolism and all are vasodilators, but none of these alone seems to be able to explain active hyperemia or the local vascular response to ischemia.

Oxygen is not stored in appreciable amounts in tissues, and the oxygen concentration will fall to nearly zero in about 1 minute if blood flow is stopped in any organ. Therefore, an increase in metabolic rate would decrease the tissue oxygen concentration and possibly directly signal the vascular muscle to relax by limiting the production of adenosine triphosphate (ATP) needed for the contraction of smooth muscle cells. Alternatively, the depletion of ATP could release the inhibitory effect of ATP on K^+ channels, which would result in hyperpolarization of the cell membrane, reduced activation of voltage-gated calcium channels, and vasodilation. Oxygen, or the lack thereof, has been shown to play a role at the molecular level in the operation of L-type calcium channels as well as the ATP-gated K^+ channels. However, no known effect of oxygen on these channels appears to adequately explain the effects of oxygen on smooth muscle contraction. Most recent evidence appears to point to H_2S metabolism in the mitochondria as the intercellular molecular link between hypoxia and vasodilation. H_2S metabolism in the mitochondria decreases during hypoxia, and thus, H_2S increases intracellularly. H_2S is a direct vasodilator at very low concentrations and it mimics the tissue effects of hypoxia in arteries as well as other oxygen-sensing tissues (i.e., peripheral neural chemoreceptors; see Chapter 17).

Although there are many possibilities to consider for cellular mediators of hypoxic vasodilation or active hyperemia in the vascular system, practical concerns exist as to cause and effect mechanisms. For example, many arterioles have a normal to slightly increased periarteriolar oxygen tension during skeletal muscle contractions because the increased delivery of oxygen through elevated blood flow offsets the increased use of oxygen by tissues immediately around the arteriole. Yet, the skeletal muscle arterioles remain dilated. Therefore, as long as blood flow is allowed to increase substantially, it is unlikely that oxygen availability at the arteriolar wall is a major factor in the sustained vasodilation that occurs during increased metabolism. In fact, it appears that the signal causing arteries to dilate when tissue metabolism increases may not exist in the arterial wall at all but, instead, may originate in the surrounding tissues. In addition, recent studies indicate that VSM cells are not particularly responsive to a broad range of oxygen tensions. Only unusually low or high oxygen tensions seem to be associated with direct changes in VSM force. However, either oxygen depletion from an organ's cells or an increased metabolic rate does cause the formation and release of free adenosine, Krebs cycle intermediates, and, in hypoxic conditions, lactic acid. It is possible then that these factors contribute to the phenomenon of active hyperemia. In addition to

hypoxia itself, high concentration of either CO_2 or H^+ causes relaxation of the VSM. However, the levels of CO_2 and H^+ produced at the tissue, even with high metabolism, cannot dilate arterioles to the level seen during the active hyperemia. Furthermore, usually only transient increases in venous blood and interstitial tissue acidity occur if blood flow through an organ with increased metabolism is allowed to increase appropriately.

Of all the metabolite concentrations that change during both tissue metabolism and hypoxic conditions, adenosine is the best situated to account for arteriolar dilation and increased blood flow. Adenosine increases during both hypoxia and increased tissue metabolism, readily diffuses out of tissue cells to the adjacent microcirculation, and is a potent vasodilator. It appears to be an important mediator of active hyperemia in the heart and brain but is not believed to be the sole mediator of the ability of tissues to match their blood flow to their moment-to-moment metabolic needs. A summary of the metabolic regulation of blood flow is shown in Figure 15.7.

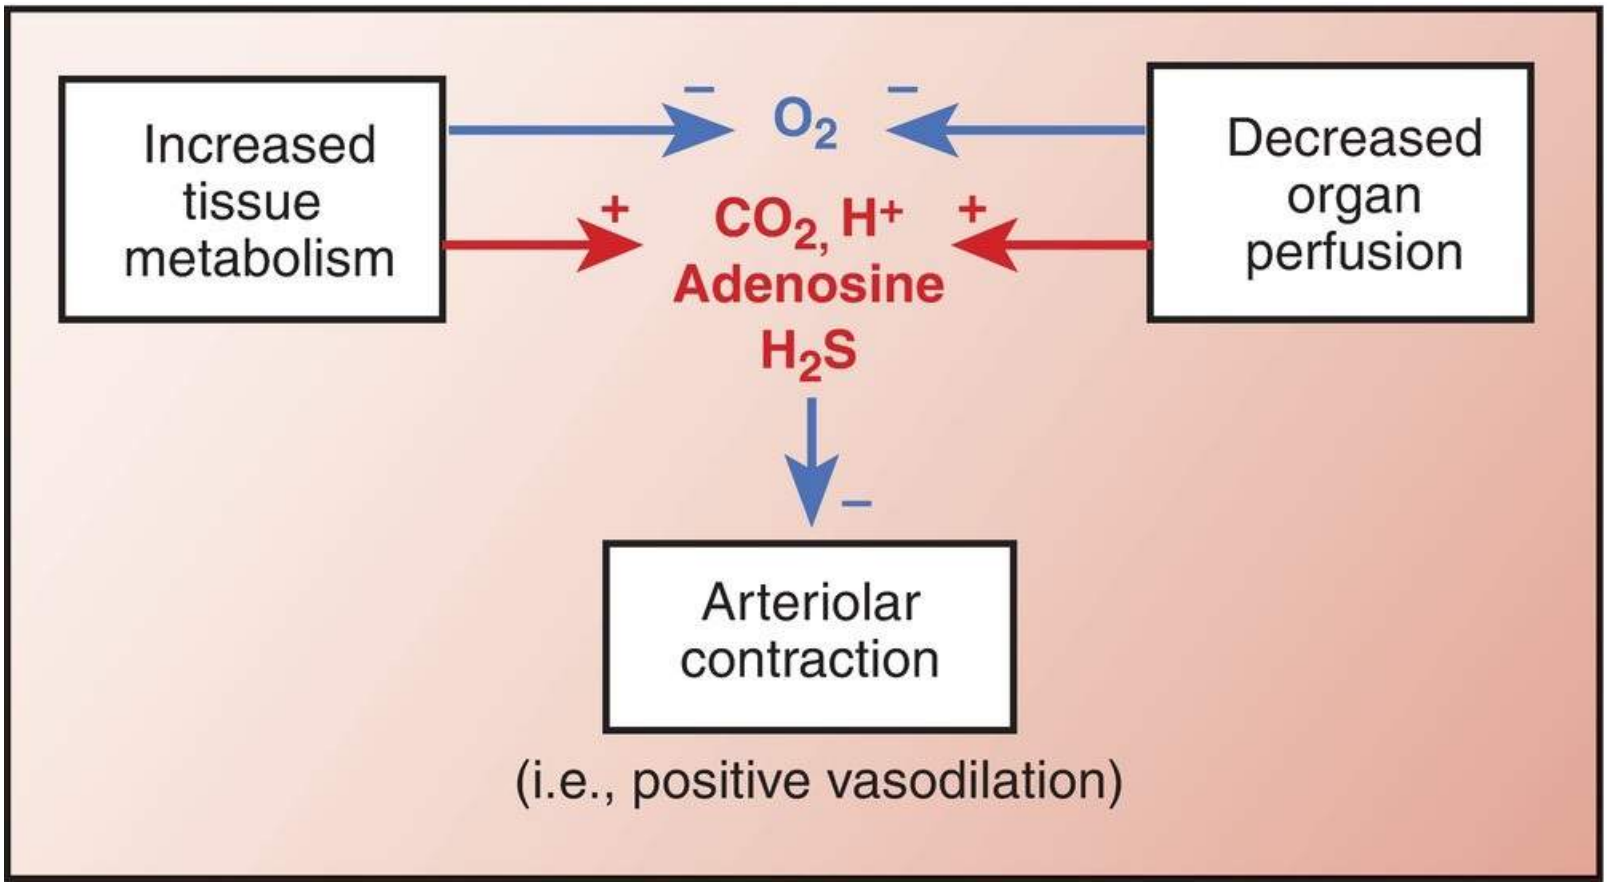


Figure 15.7 An overview of metabolic effects on arteriolar contraction. Decreased organ perfusion or increased tissue metabolism produce factors that dilate microcirculatory arteries and veins.

Arteriolar contractile state is affected by vasoactive chemicals released by endothelial cells.

Substances released by endothelial cells are important contributors to local vascular regulation. The most important of these is **nitric oxide (NO)** (formerly known as **endothelium-derived relaxing factor** or **EDRF**). NO is a potent vasodilator. It is formed by Ca^{2+}–calmodulin complex activation of endothelial **NO synthase** (**eNOS**) that acts on the amino acid l-arginine to produce l-citrulline and NO (Fig. 15.8). Endothelial NO synthase is constitutively expressed in endothelial cells and NO is released continuously at rest from all arterial, microvascular, venular, and lymphatic endothelial cells. It causes the relaxation of VSM by activating guanylate cyclase within the muscle cells to increase the production of cyclic guanosine monophosphate (cGMP). cGMP activates various cGMP-dependent protein kinases that, in turn, activate calcium-lowering mechanisms in the smooth muscle cell, thus inhibiting contraction. Numerous compounds, such as acetylcholine, histamine, and adenine nucleotides (ATP and ADP) as well as hypertonic conditions and hypoxia, cause the release of NO. Adenosine causes NO release from endothelial cells, although it also directly relaxes VSM cells through adenosine receptors.

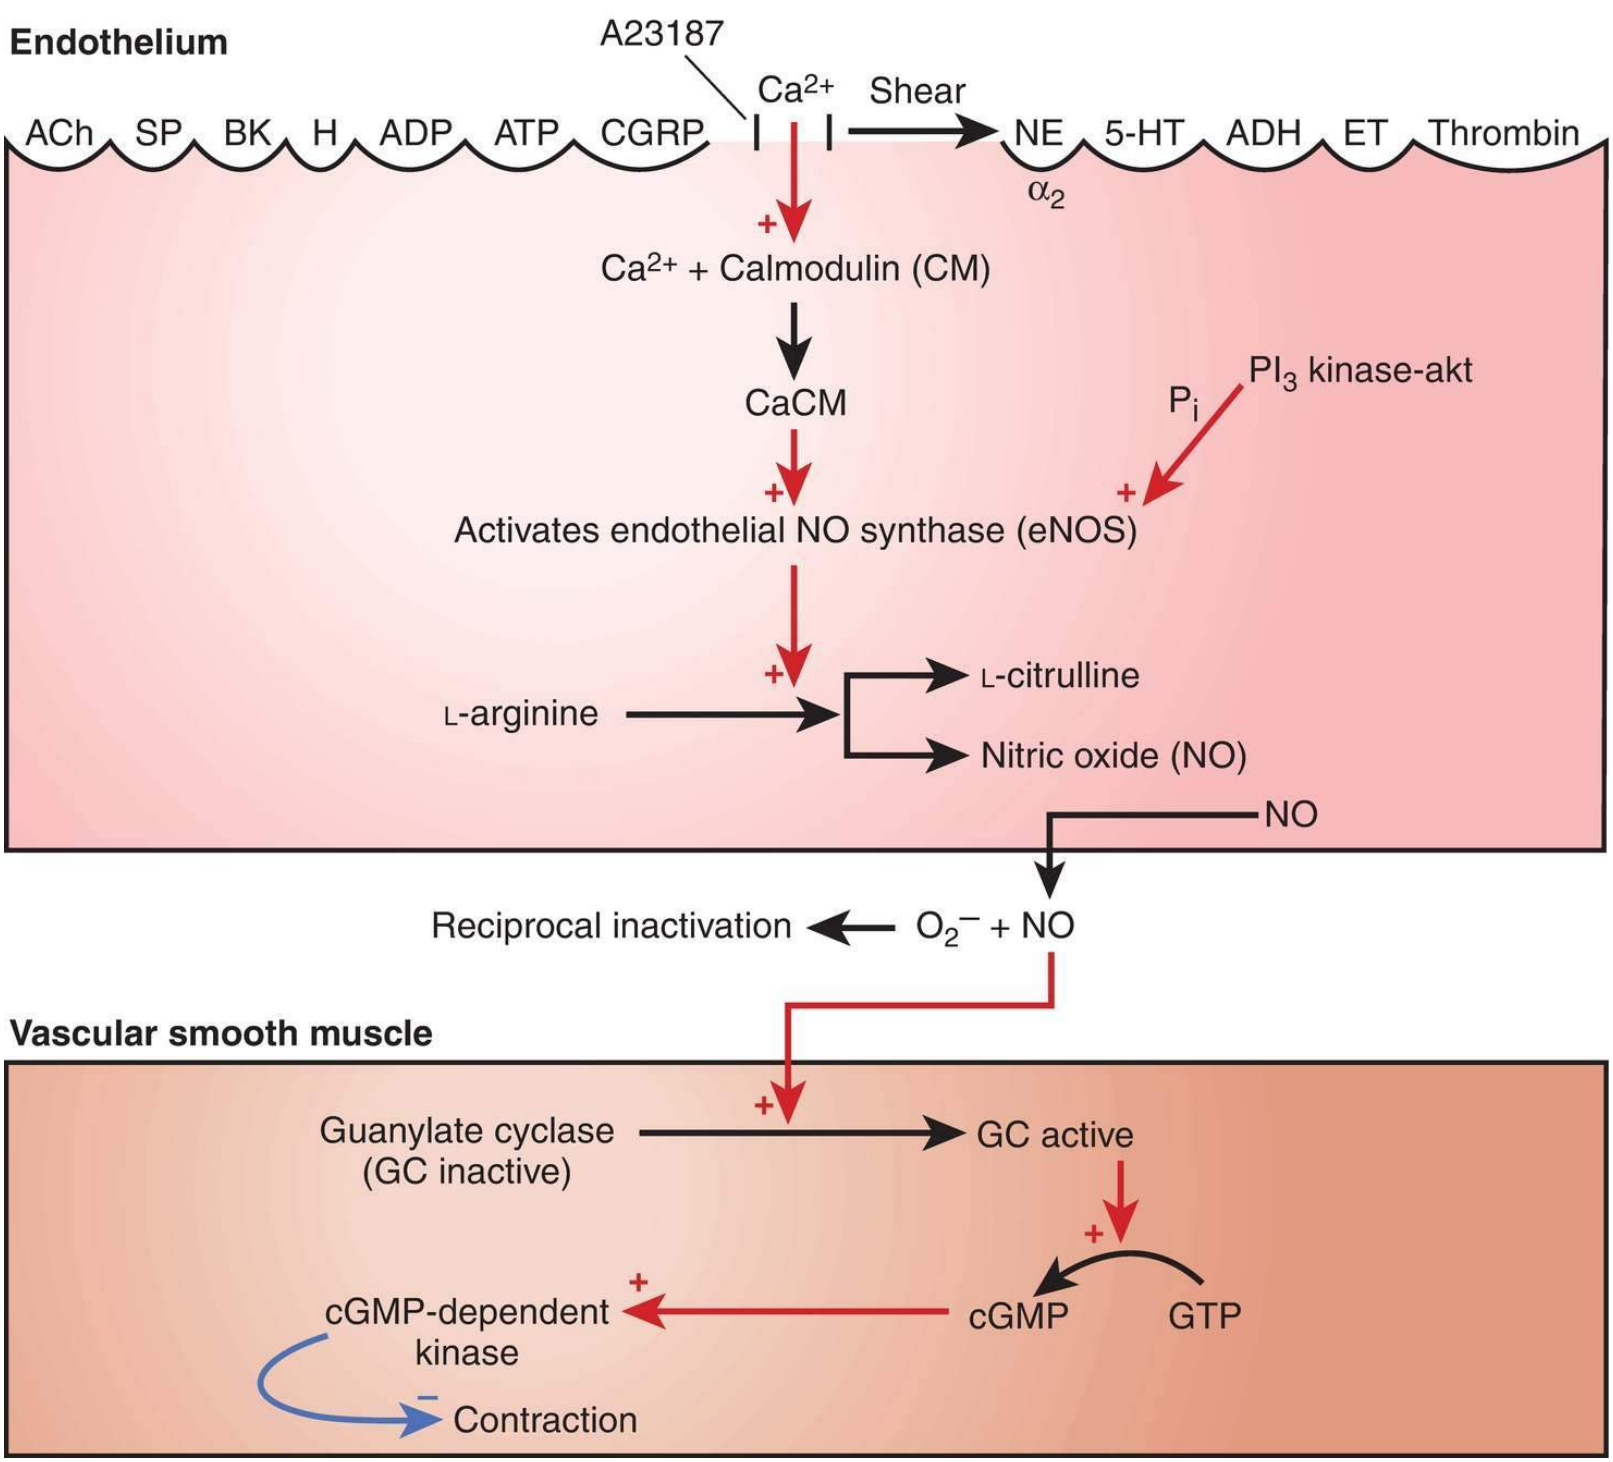

Figure 15.8 The mechanism of endothelium-dependent relaxation of vascular smooth muscle by nitric oxide (NO). Ach, acetylcholine; SP, substance P; BK, bradykinin; H, histamine; ADP, adenosine diphosphate; ATP, adenosine triphosphate; CGRP, calcitonin gene–related peptide; A23187, calcium ionophore; NE, norepinephrine; 5-HT, serotonin; ADH, antidiuretic hormone (vasopressin); ET, endothelin; +, stimulation; cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; eNOS, endothelial constitutive nitric oxide synthase. Phosphorylation of eNOS by an IP_3–akt pathway enhances eNOS sensitivity and NO generation.

Shear stress generated by blood moving past endothelial cells is an important mechanism for endothelial NO release and may represent the major, truly physiological, NO agonist in the cardiovascular system. Frictional forces between moving blood and the stationary endothelial cells distort the endothelial cells, opening special potassium channels and causing endothelial cell hyperpolarization. This increases calcium ion entry into the cell down the increased electrical gradient.

The elevated cytosolic calcium ion concentration in the endothelium activates endothelial NOS to form more NO, and the blood vessels dilate in response.

This mechanism is used to coordinate vasodilation among various-sized arterioles and small arteries in the same vascular network. For example, an increase in metabolism in a small area of tissue will result in an initial local dilation of small arterioles and precapillary sphincters in that area. This dilation reduces arteriolar resistance, opens/fills additional capillary vessels, and thus increases blood flow into the tissue. However, because blood flow has increased, initial flow velocity and thus endothelial shear stress must increase in the larger arterioles upstream from the initial dilated network as well. This increased shear stress in upstream arteries causes their endothelial cells to release NO and relax their smooth muscle thereby allowing more flow to enter the downstream, open and dilated network. This process is called **flow-mediated vasodilation** and has been observed in cerebral, skeletal muscle, and small intestinal vasculatures. This process repeats further upstream in a phenomenon that has been called *ascending dilation*. As larger arterioles and small arteries control much more of the total vascular resistance than do small arterioles, the dilation of the larger resistance vessels enhances blood flow to meet the needs of the tissue downstream, which at this time has more open capillaries to receive and distribute flow.

Flow-mediated dilation is also seen in conduit arteries. However, the dilation of these vessels has no significant effect on vascular resistance and likely represents a negative feedback mechanism to control shear stress on the arterial endothelium; small dilation of larger arteries has no effect on blood flow per se but does reduce flow velocity and wall shear stress. This effect may be important because many transport processes across the endothelium as well as the interaction of blood cell elements with this vascular barrier are altered by changes in endothelial shear stress. Endothelial cells of arterioles also release vasodilatory prostaglandins and an uncharacterized hyperpolarizing factor when blood flow and shear stress are increased. However, NO appears to be the dominant vasodilator molecule for flow-dependent regulation.

In healthy individuals, basal release of NO exerts important bioregulatory effects in the cardiovascular system. Its basal vasodilatory contribution provides a major antihypertensive effect. Blood pressure increases rapidly by 75% or more if a person is given an agent that blocks endothelial NO production. NO also inhibits platelet aggregation and therefore serves as an anticoagulant. It inhibits neutrophil–endothelial interactions, is antimitogenic to VSM, and promotes the recovery of the endothelium from injury. As these processes are all involved in the pathogenesis of atherosclerosis, NO is considered an antiatherogenic agent.

NO is now known to be generated by NO synthase isoforms in other tissues and some of these have been implicated in cell communication and pathological conditions. Some neural cells contain a neuronal NOS (nNOS) and use NO as a signaling molecule. Smooth muscle and some immune cells contain an inducible form of NOS called iNOS. Inducible NOS is activated by endotoxins, LPS, and other infectious and inflammatory response molecules. Septic shock (see Chapter 17), especially that caused by abdominal infections (i.e., from a ruptured appendix, perforated ulcer, or, in females, from a reproductive organ infection) causes so much activation of iNOS in the VSM of arteries in splanchnic organs that blood pressure plummets rendering the body as a whole ischemic. Such septic shock, if not corrected rapidly, results in death.

Endothelial cells release a 21- amino acid peptide called **endothelin**, which is the most potent vasoconstrictor of blood vessels in the body. Although extremely small amounts are released under natural conditions, endothelin is thought to play a role in several vascular diseases such as hypertension and atherosclerosis. The vasoconstriction occurs because of a cascade of events beginning with

phospholipase C activation and leading to activation of protein kinase C (PKC) (see Chapter 2). Two major types of endothelin receptors have been identified and others may exist. The constrictor function of endothelin is mediated by type B endothelin receptors. Type A endothelin receptors cause hyperplasia and hypertrophy of vascular muscle cells and the release of NO from endothelial cells. The precise function of endothelin in the normal vasculature is not clear; however, it is active during embryologic development. In knockout mice, the absence of the endothelin A receptor results in serious cardiac defects so that newborns are not viable. An absence of the type B receptor is associated with an enlarged colon, eventually leading to death.

In damaged heart tissue, such as in an infarct, cardiac endothelial cells increase endothelin production. The endothelin stimulates both VSM and cardiac muscle to contract more vigorously and induces the growth of surviving cardiac cells. However, excessive stimulation and hypertrophy of cells appear to contribute to heart failure, failure of contractility, and excessive enlargement of the heart. Part of the stimulation of endothelin production in the injured heart may be the cause of the damage per se. Also, increased formation of angiotensin II and norepinephrine during chronic heart disease stimulates endothelin production, probably at the gene expression level. The activation of PKC increases the expression of the c-*jun* protooncogene, which, in turn, activates the preproendothelin-1 gene.

Endothelin has also been implicated as a contributor to renal vascular failure, the pulmonary and systemic hypertension associated with insulin resistance, and the spasmodic contraction of cerebral blood vessels exposed to blood after a brain injury or a hemorrhagic stroke.

Sympathetic nervous system regulates blood pressure and flow by constricting the microvessels.

Although the microvasculature uses local control mechanisms to adjust vascular resistance based on the physical and chemical environment of the tissue, the active tone of all arteries and veins is significantly affected by the sympathetic nervous system, which is tonically active to all such vessels. Sympathetic nerves release norepinephrine, which is a vasoconstrictor, onto the surface of smooth muscle cells in arteries and veins. Because sympathetic nerves form an extensive meshwork of axons over the exterior of the microvessels, all VSM cells are likely to receive norepinephrine tonically. Furthermore, the diffusion path from nerve terminals to vascular smooth muscle is only a few microns. Thus, norepinephrine released from sympathetic nerves rapidly reaches the vascular muscle, where it activates membrane α_1-adrenergic receptors, resulting in vasoconstriction within 2 to 5 seconds.

Although changes in sympathetic nerve activity to blood vessels can markedly change organ blood flow, sympathetic neural effects on the vasculature are not used to control local tissue flow. Instead, they are used as part of the mechanisms used to modify total peripheral vascular resistance in order to control arterial blood pressure. As explained in more detail in Chapter 17, the arterial pressure is monitored moment to moment by neural reflex mechanisms that adjust the cardiac output and systemic vascular resistance via autonomic efferent nerves leading to the heart, arteries, and veins. This system is used to buffer moment-to-moment deviations in blood pressure from normal. This neural-based system allows for rapid adjustment of vascular resistance, which must occur quickly because rapid changes in body position or sudden exertion require immediate responses to maintain or increase arterial pressure. In the defense against hypotension, the sympathetic nervous system routinely overrides local regulatory mechanisms in most organs, with the exception of the brain and the heart. In addition, although activation of sympathetic nerves to the skeletal muscle vasculature is intense during exercise, this vasoconstrictive action is overcome by massive local dilatory signals within skeletal muscle during such activity (see Chapter 26 for details).

CLINICAL FOCUS 15.2

Ischemia–Reperfusion Injury

Ischemia causes a condition of reduced oxygen availability in which the oxygen demand of the tissue is greater than its oxygen supply. This can arise from impaired tissue blood flow or stimulation of excessive demand relative to the blood flow a tissue is capable of receiving. In the heart, ischemia most often occurs acutely by the development of an obstruction in one of the major coronary arteries, usually from a blood clot forming in the area of an advanced or ruptured atherosclerotic plaque. Ischemia cannot be tolerated for long in myocardial tissue. Immediately upon the start of ischemia, the myocardial tissue affected becomes noncontractile. Within 1 hour, the oxygen-dependent cellular ionic and water balance mechanisms fail creating cellular and mitochondrial swelling with loss of membrane integrity. Calcium extrusion mechanisms fail, and the resultant increase in intracellular calcium activates enzymes that destroy myocardial tissue. If acute ischemia involves enough myocardial tissue,

the initial loss of contractile ability may be enough to cause acute failure of the heart and circulatory collapse (cardiogenic shock; see Chapter 17). However, even with small ischemic episodes, the resulting tissue damage within hours after the initial insult may be enough to cause death from cardiac failure.

The best course of action to reduce ischemic damage in the heart would seem to be to restore myocardial blood flow as quickly as possible and/or change hemodynamic variables in such a way as to reduce myocardial oxygen demand. If the ischemia results from a blood clot in a major coronary artery, the physician can inject "clot-busting" drugs, such as streptokinase or tissue-type plasminogen activator (t-PA), through a catheter into the major coronary artery affected by the clot. These drugs dissolve the clot and restore flow. However, in reality, restoration of blood flow is often associated with the induction of additional damage to the myocardium rather than preservation of tissue. This phenomenon is called *ischemia–reperfusion injury*. During the ischemic period, the arterioles downstream from the coronary arterial obstruction dilate through myogenic and metabolic mechanisms, lowering vascular resistance. On removal of the obstruction, this lowered resistance allows for a substantial reactive hyperemia, which floods the previously ischemic area with blood elements and oxygen. This hyperemia is associated with cell death from necrosis and apoptosis. The area also becomes infiltrated with neutrophils.

Tissue damage from ischemia–reperfusion injury results from the increased generation of oxygen radicals in the myocardium and endothelium as well as from infiltrating neutrophils and macrophages. Myocardial sources may result from the ischemic conversion of xanthine dehydrogenase to xanthine oxidase, which produces superoxide from xanthine. Damaged mitochondria likely also act as a source of oxygen radicals. The radicals also impair mitochondrial recovery and adenosine triphosphate generation, which leads to cell death. The neutrophil infiltration also sets up a local inflammatory response, which produces damaging cytokines and additional reactive oxygen species in the tissues as well as complement activation. Recent studies suggest that nitric oxide attenuates ischemia–reperfusion injury, perhaps by quenching superoxide produced in the condition. ■

Most organs control their blood flow via local autoregulation.

If the arterial blood pressure to an organ is decreased to the extent that blood flow is compromised, the arterioles of that organ respond by vasodilating. This resistance change counteracts the effects of reduced arterial pressure on organ blood flow and thereby returns it toward its original value in spite of the drop in perfusion pressure. If arterial pressure is elevated, flow is initially increased. However, with a minute or so, vascular resistance increases to the extent that blood flow is returned to, or close to, its original level. These responses of an organ system's vasculature to changes in perfusion pressure stand in stark contrast to what would be observed in a rigid, nonliving tube where flow is directly proportional to perfusion pressure. The ability of an organ to maintain normal or near normal blood flow in the face of changes in the pressure driving flow is called *autoregulation of blood flow*, or simply **autoregulation** (Fig. 15.9). Autoregulation is a local control phenomenon involving responses of the arterial smooth muscle to local stimuli; it occurs independently of any nerve activity on the organ and can be observed in circulations with impaired functions of arterial endothelium. Autoregulation appears to be primarily related to metabolic and myogenic control mechanisms as well as to an increased release of NO if tissue oxygen availability decreases.

Mean arterial pressure (mm Hg)

Figure 15.9 Autoregulation of blood flow and vascular resistance as mean arterial pressure is altered. The safe range for blood flow is about 80% to 125% of normal and usually occurs at arterial pressures of 60 to 160 mm Hg as a result of active adjustments of vascular resistance. At pressures above about 160 mm Hg, vascular resistance decreases because the pressure forces dilation to occur; at pressures below 60 mm Hg, the vessels are fully dilated, and resistance cannot be appreciably decreased further.

The efficacy of autoregulation is not 100% in all organs, and there are upper and lower pressure limits to its effectiveness as well. When arterial pressure in vessels to an organ decreases, the vasodilation that ensues from autoregulation may bring organ blood flow back toward, but not fully to, its original value. Even if the blood flow might not be brought all the way back to its original level before the pressure dropped, autoregulation is still considered to have occurred; it is just that the efficacy of this autoregulation is <100%. The cerebral, cardiac, and renal circulations have the highest autoregulation efficacy. Skeletal muscle and intestinal vasculatures exhibit less well-developed autoregulation, whereas autoregulation is essentially absent in the circulation of the skin. Furthermore, in all organs, there are limits to the vasodilation of arteries that occurs during autoregulation; once vessels are maximally dilated, there is no capacity left to serve as an autoregulatory correction for further drops in pressure. Autoregulation capacity ceases at arterial pressures below 50 mm Hg in most organs because at that point, the small vessels that predominantly control resistance and blood flow are maximally dilated. In an analogous manner, the ability of arterioles to constrict against progressively higher pressures has a maximum. Eventually, the pressure pushing the vessel open is too much for the contractile force generated by the arterial smooth muscle. Pressures beyond this point tend then to increase organ blood flow and capillary hydrostatic pressure. Thus, there is an upper pressure limit as well to the autoregulation of blood flow in organs.

An example of autoregulation, based on data from the cerebral vasculature, is shown in Figure 15.9. Note that the arterioles continue to dilate at arterial pressures below 60 mm Hg, when blood flow begins to decrease significantly as arterial pressure is further lowered though they clearly cannot dilate sufficiently to maintain normal blood flow at those low arterial pressures. At greater-than-normal arterial pressures, the arterioles constrict via autoregulatory mechanisms. However, if the mean arterial pressure is elevated appreciably above 150 to 160 mm Hg, the vessel walls cannot maintain sufficient tension to oppose passive distention by the high arterial pressure. The result is excessive blood flow and high microvascular pressures, eventually leading to the rupture of small vessels, excess fluid filtration into the tissue, and edema. In fact, the reason that autoregulation regulates to counteract too much of an increase in blood flow to an organ likely represents a means to control against excessively high intracapillary pressure whenever blood pressure is increased.

A phenomenon related to autoregulation is **reactive hyperemia**. When blood flow to any organ is stopped or reduced by vascular compression for more than a few seconds, vascular resistance dramatically decreases. The absence of blood flow allows vasodilatory chemicals to accumulate while hypoxia occurs; the vessels also dilate as a result of decreased myogenic stimulation (low intravascular pressure). As soon as the vascular compression is removed, blood flow is dramatically increased for a few minutes because the vessels became dilated during the stoppage of flow. This phenomenon represents reactive hyperemia because it is a reaction to the previous period of ischemia.

Diabetes Mellitus and Microvascular Disease: Prognosis and Current Treatments

Diabetes mellitus is a condition in which the body cannot regulate uptake and storage of glucose and lipids in tissues. Most commonly, this is due to either a lack of insulin production (type 1 or juvenile diabetes) or a primary inability of tissues to respond to insulin (type 2 or what is sometimes called adult-onset diabetes; see Chapter 34 for more details). This disease is reaching worldwide epidemic proportions and is the source of serious cardiovascular and other end organ morbidities. Both types of diabetes are associated with significant genetic, inheritance components. In addition, obesity is believed to play a causal role in type 2 diabetes in that it increases the requirement for insulin to the extent that even the high insulin concentrations provided by the pancreatic beta cells are insufficient. This overall condition is called insulin resistance.

More than 95% of persons with diabetes go through acute complications associated with periodic swings of hyperglycemia and hypoglycemia. Acute hyperglycemia leads to ketoacidosis and dehydration caused by excessive loss of water in the urine, which results from a high filtration of glucose at the glomerular capillaries such that the glucose entering the renal tubule exceeds its transport capacity. Consequently, this excess tubular fluid glucose generates osmotic retention of water in the tubules, which is subsequently lost out of the body by urination. Acute ketoacidosis and dehydration can lead to diabetic coma and death. The latter can occur with hypoglycemia as well, which can also acutely impair cognitive function and consciousness (see Chapter 34 for details).

Repeated exposure to hyperglycemic conditions brings about pathologies in the cardiovascular system involving both micro and macro blood vessels. Macrovascular complications center around inflammation-induced acceleration of atherosclerosis caused by tissue hyperglycemia. This accelerates peripheral, coronary, and cerebral vascular disease leading to increased incidence of ischemic disease, infarction in the heart, brain, and peripheral organs (i.e., heart attacks and strokes). Microvascular disease involves primarily the retina, kidneys, and nervous system. The microvasculature of the retina experiences microaneurysms, excessive angiogenesis, and edema in the retinal tissue caused by a leaky microvasculature after repeated exposures to hyperglycemic conditions. These conditions are associated with blindness, which is a common outcome of chronic diabetes. The glomerulus of the kidney becomes damaged in diabetes due to intrarenal hypertension and leakage of protein into the renal tubule. Intrarenal hypertension is linked to elevated levels of angiotensin II, and the exposure of the tubule to protein chronically leads to a glomerular inflammatory response. This along with intrarenal hypertension causes renal microvascular damage and glomerular fibrosis and scarring. These in turn can lead to end-stage renal disease in diabetics.

Periods of hyperglycemia over time cause reduced nitric oxide (NO) production by endothelial cells, increased reactivity of vascular smooth muscle to norepinephrine, and a reduced ability of microvessels to participate in tissue repair. The mechanism of many of the vascular abnormalities associated with diabetes appears to stem from the fact that hyperglycemia activates protein kinase C (PKC) in endothelial cells. PKC inhibits NO synthase, so NO formation is gradually suppressed. This leads to the loss of an important vasodilatory stimulus (NO) and results in vasoconstriction. PKC-beta

has been shown to be activated by glucose and is thought to mediate microvascular leakage and angiogenesis. Hyperglycemia also increases activity in the polyol pathway resulting in increased sorbitol in tissues. This causes increases in extracellular osmolality, fluid accumulation, and pressure, which further damages tissues, including nerve axons. This latter effect may contribute to neuropathies, which are common in chronic diabetes.

Currently, treatment of type 1 diabetes is centered around aggressive control of plasma glucose levels with the goal of reducing exposure of the body to hyperglycemic conditions. Clinical trials have shown that when doing so, such control greatly reduces the microvascular consequences of hyperglycemia and thereby delays impaired vision and renal function. Other than insulin administration and strict adherence to diet regimens, there is little that pharmacotherapy can do in type 1 diabetes because of the loss of pancreatic beta cells. Type II diabetes though has many pharmacological options that can be used to help patients although such individuals also eventually lose beta cells over time and become increasingly dependent on insulin. However, other pharmacological agents are available to help with various pathological consequences of type 2 diabetes. Antihyperglycemic agents such as biguanides can help control hyperglycemic episodes by increasing tissue uptake of glucose and increasing islet cell responsiveness. In addition, insulin release can be enhanced by sulfonylureas and meglitinides. Both these agents bind (at different sites) to ATP-dependent K^+ channels on beta cell membranes, causing depolarization-mediated calcium entry into the cells, which stimulate insulin release. Glucose-stimulated insulin secretion can be effected by GLP-1 receptor analogues, which mimic natural incretins in the body. These agents also suppress appetite by increasing the feeling of satiety. Finally, alpha-glucosidase inhibitors help moderate the spikes in plasma glucose levels that occur after a meal by suppressing digestion of carbohydrates in the intestine and thus diminishing the amount of glucose absorbed during a meal. ■

Chapter Summary

- The microcirculation controls the transport of water and substances between the tissues and blood.
- Transport of gases and lipid-soluble molecules occurs by diffusion across endothelial cells.
- Transport of water-soluble molecules occurs by diffusion through pores in adjacent endothelial cells.
- Transport of substances across a capillary by diffusion depends on the concentration gradient of the substance and the permeability of the capillary to the substance.
- Flow-limited transport of a substance is limited by the amount of blood flow that can be delivered to the tissues.
- Diffusion-limited transport of a substance is limited by the diffusion of the substance across the capillary membrane rather than by the amount of flow delivered to the tissues.
- Bulk filtration or absorption of water occurs across capillaries through pores in adjacent endothelial cells.
- Plasma hydrostatic and colloid osmotic pressures are the primary forces affecting fluid filtration and absorption across capillary walls.
- The ratio of postcapillary to precapillary resistance is a major determinant of capillary hydrostatic pressure.
- Lymphatic vessels collect excess water and protein molecules from the interstitial space between cells.
- Myogenic arteriolar regulation is a response to increased tension or stretch of the vessel wall muscle cells.
- By-products of metabolism cause the dilation of arterioles.
- Nitric oxide from the endothelium is a major local vasodilator of arterioles and controller of multiple vascular functions and properties.
- The axons of the sympathetic nervous system release norepinephrine, which constricts the arterioles and venules.
- Autoregulation of blood flow allows some organs to maintain nearly constant blood flow when arterial blood pressure is changed.

Chapter Review Questions

1. During digestion, intestinal smooth muscle motility as well as the energy requiring processes used for cellular transport of substrates across the intestinal mucosa are greatly increased. Oxygen transport in the intestine during digestion would therefore likely be characterized by:

A. increased delivery into the microcirculation and increased transport across the capillary network into the intestinal tissues.

B. decreased delivery into the microcirculation and decreased transport across the capillary network into the intestinal tissues.

C. conversion of flow-limited transport of oxygen into diffusion-limited transport of oxygen due to low capillary blood oxygen concentration.

D. decreased capillary surface area available for transport of oxygen.

E. increased diffusion distances between the capillaries for the transport of oxygen.

The correct answer is A. Increased oxygen requiring activities by the intestine during digestion would induce an active hyperemia through dilation of arterioles. This would increase blood flow to the intestine and increase the number of open perfused capillaries. Therefore, oxygen delivery to the intestine would be increased, the capillary surface area available for diffusion would increase, and the distance between an intestinal cell and its nearest capillary would decrease. Thus, transport into and across the intestinal capillaries would increase and help meet the increased oxygen demand of that tissue during digestion. Diffusion parameters would be improved, not reduced, so that diffusion-limited transport would not occur.

2. Which of the following would limit local edema formation following traumatic injury to a lower limb?

A. Capillary injury

B. Formation of blood clots in the veins of the limb

C. Sympathetic nerve–mediated arteriolar vasoconstriction

D. Traumatic arterial dilation in the limb

E. Rupture of lymphatic channels in the limb

The correct answer is C. Arteriolar vasoconstriction will decrease the postcapillary:precapillary ratio of resistance and therefore reduce hydrostatic pressure in the capillary. This reduces filtration of fluid at the capillary and can even cause the capillary to absorb water from the interstitium. Either of these would attenuate edema formation. Arteriolar dilation would have opposite effect. Capillary injury would disrupt capillary integrity and increase their hydraulic conductance, which would exacerbate edema formation. Blood clots in the large veins will increase back pressure into the capillaries that favor water filtration and edema formation. Rupture of lymph channels would remove the vascular component used to drain excess fluid from the interstitial spaces and thereby favor edema formation.

3. Chronic high arterial pressure severely damages the arterial endothelium. Compared to a normal arteriole, an arteriole in an individual with chronic arterial hypertension would:

A. not constrict when intravascular pressure is increased.

B. dilate when exogenous NO is applied to the vessel wall.

C. constrict in response to norepinephrine.

D. dilate less in response to increased blood flow (flow-mediated dilation.

E. dilate when blood flow is reduced.

The correct answer is D. The endothelium is the key source of the potent vasodilator NO. NO production by the endothelium is increased by fluid shear stress resulting in arterial dilation (flow-mediated dilation). Arteries with impaired endothelium would display impaired flow-mediated dilation. Endothelial damage in hypertension would not affect myogenic constriction in response to an increase in intravascular pressure or metabolic dilation in response to low blood flow because these factors work at the level of the smooth muscle cell. Similarly, the receptors for norepinephrine that link the sympathetic nervous system to vasoconstriction are on the smooth muscle cells and not the endothelium.

4. Histamine is released in tissues in response to allergens and mediates characteristic changes in the microcirculation associated with an allergic reaction. Histamine is an arterial vasodilator that also affects the cytoskeleton of capillary endothelium such that the clefts between cells are opened. Which of the following would characterize the microcirculation in response to histamine?

A. Capillary hydrostatic pressure and the capillary filtration coefficient are reduced.
B. Capillary hydrostatic pressure is reduced, but the capillary filtration coefficient is increased.
C. Capillary hydrostatic pressure is increased, but the capillary filtration coefficient is decreased.
D. Capillary hydrostatic pressure and the capillary filtration coefficient are increased.
E. Capillary hydrostatic pressure and the capillary filtration coefficient are unchanged.

The correct answer is D. Arteriolar dilation favors an increase in capillary hydrostatic pressure and an increase in blood flow into the capillary network. Venules also are dilated by histamine, which further augments blood flow, although it mitigates somewhat the increase in pressure caused by precapillary vasodilation. The capillary filtration coefficient is a measure of the hydraulic conductance across the capillary and is increased by anything that increases capillary permeability. The increase in filtration across capillary networks in response to an allergic reaction is often great enough to cause local edema in the tissue.

5. All of the following will favor tissue edema formation in splanchnic organs except:

A. metabolic dilation of arterioles.
B. activation of sympathetic nerves to the organs.
C. chronic congestive heart failure.
D. hypoalbuminemia.
E. portal hypertension.

The correct answer is B. Arterial vasoconstriction to splenic organs will reduce intracapillary hydrostatic pressure and thus reduce the probability of edema formation. Dilation of arterioles in such organs will have the opposite effect, especially because organs of the digestive tract have such high capillary filtration coefficients. Hypoalbuminemia reduces plasma oncotic pressure everywhere in the body and favors capillary fluid filtration and edema formation. Portal hypertension increases capillary hydrostatic pressure in the small intestines and, in spite of a notable venous–arteriolar response in that organ, is almost always associated with intestinal edema formation and ascites.

Clinical Application Exercises 15.1

ANAPHYLACTIC SHOCK

A 5-year-old female child with no apparent medical problems is stung by a bee while playing in a park near her home. Her reaction to the sting is a greater-than-normal redness and itching at the site of

the sting but is otherwise uneventful. During her regularly scheduled physical exam, her physician warns her mother that this child might be allergic to bee venom and should try to avoid being stung again. Unfortunately, 1 month later while playing in her backyard near a bed of flowers, she gets stung on her hand by a bee. Her mother cleans the sting with some rubbing alcohol and applies a bandage. However, the area of the sting begins to turn red and swells, developing a wheal of about a 3-cm radius around the sting within 2 minutes. The girl then rapidly develops severe difficulty breathing and is rushed to the emergency room. Examination in the ER reveals a swollen stiff abdomen, inflamed bronchi and evidence of significant airway restriction suggestive of angioedema, blood pressure of 80/50, and a heart rate of 120 with urticaria and angioedema over her arms, abdomen, and thighs.

QUESTIONS

1. What is the cause of the redness and swelling at the site of the bee sting on this girl's hand?
2. What is the likely predominant mediator of the redness and swelling at the sight of the bee sting?
3. What is the cause of the patient's low systolic, diastolic, and pulse pressures?
4. Treatment for a patient in anaphylactic shock includes an IM injection of epinephrine. This agent activates β-adrenergic receptors in the bronchi, which dilates airways. This helps counteract bronchial constriction caused by histamine and other anaphylactic agents during an anaphylaxis. How does this injection of epinephrine also help counteract the shock associated with anaphylaxis?

ANSWERS

1. The redness is caused by local cutaneous vasodilation. This contributes to the swelling, but the presence of a wheal in the area of the sting is indicative of local edema formation.
2. The girl is likely experiencing an IgE-mediated hypersensitivity reaction in response to bee venom, which serves as an antigen in the reaction. This reaction is characterized by extensive and severe degranulation of basophils with release of histamine. Histamine dilates arteries while increasing capillary and venule permeability. The vasodilation reddens the skin, whereas that effect in conjunction with increased capillary permeability causes enhanced local capillary filtration, protein exudation, and edema responsible for the wheal.
3. Low systolic and pulse pressure results from decreased stroke volume, increased arterial compliance, or both. Although histamine dilates arteries, compliance is a function of large arteries, and histamine acts predominantly at the microcirculatory level. The girl in this case exhibits sign of anaphylactic shock from her second bee sting. In this situation, excessive high levels of histamine are generated systemically and cause massive arterial dilation, resulting in a decrease in mean arterial and diastolic blood pressure. Furthermore, as in the case of local edema formation, systemic release of histamine causes massive capillary filtration and edema formation, especially in the abdomen where organ capillary filtration coefficients and surface area are naturally high. This effect is consistent with the presentation of a swollen stiff abdomen. The massive plasma efflux from the splanchnic area as well as other areas of the body (responsible for the angioedema) causes a large translocation of fluid out of the circulation, a drop in central venous filling pressure, and a decrease in stroke volume, which contributes to the low pulse pressure. The decreased stroke volume depresses cardiac output, which, with the decrease in vascular resistance, leads to shock.
4. Stimulation of β-adrenergic receptors in the heart increase contractility and thereby enhances

stroke volume and cardiac output. Epinephrine activates both β- and α-adrenergic receptors on arteries. Because the latter predominate in all vascular beds except the brain and heart, this vascular effect increases vascular resistance and helps raise blood pressure.

16 Special Circulations

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain why coronary blood flow is greater during diastole than during systole.
- Explain why myocardial ischemia and infarction are more likely and potentially more severe in the endocardium than in the epicardium.
- Explain why the heart must depend solely on autoregulation of blood flow to maintain myocardial oxygen delivery in the face of decreased perfusion pressure.
- Predict how variables related to myocardial oxygen demand will affect blood flow to the heart including activation of the sympathetic nervous system.
- Explain why general sympathetic nervous system activation has no appreciable effect on blood flow to the brain.
- Explain how autoregulation of blood flow protects the blood–brain barrier.
- Explain the importance of cerebral hyperemia following exposure to CO_2 or H^+.
- Explain the mechanism responsible for adjusting the efficacy of autoregulation in the intestine and skeletal muscle on the basis of tissue metabolic demand.
- Explain the mechanisms responsible for active hyperemia in the intestine and skeletal muscle.
- Explain the benefit of the hepatic arterial buffer response.
- Explain the role of the sympathetic nervous system in the control of the cutaneous circulation.
- Explain gas exchange limitations and the fetus's susceptibility to ischemia in the context of the arrangement of the fetal circulation.
- Explain the advantages and disadvantages to the close connection between the fetal circulation and maternal blood chemistry.
- Explain the mechanisms responsible for the transition from the fetal cardiovascular system to that of a newborn.

The vascular system of every organ has special characteristics that are designed to meet the specific functions and specialized needs of that organ. In this chapter, the characteristics unique to the circulations of the heart, brain, small intestine, liver, skeletal muscle, and skin are described. Table 16.1 presents data on blood flow and oxygen use by these different organs and tissues. In addition, the anatomy and physiology of the fetal/placental circulation are presented along with the circulatory changes that occur at birth. The pulmonary and renal circulations are discussed in Chapters 19 and 22, respectively.

TABLE 16.1 Blood Flow and Oxygen Consumption of the Major Systemic Organs Estimated for a 70-kg Adult Man

Organ	Mass (kg)	Flow (mL/100 g/min)	Total Flow (mL/min)	Oxygen Use (mL/100 g/min)	Total Oxygen Use (mL/min)
Heart	0.5				
Rest		60–80	250	7.0–9.0	25–40
Exercise		200–300	1,000–1,200	25.0–40.0	65–85
Brain	1.4	50–60	750	4.0–5.0	50–60
Small intestine	3				
Rest		30–40	1,500	1.5–2.0	50–60
Absorption		45–70	2,200–2,600	2.5–3.5	80–110
Liver	1.8–2.0				
Total		100–300	1,400–1,500	13.0–14.0	180–200
Portal		70–90	1,100	5.0–7.0	
Hepatic artery		30–40	350	5.0–7.0	
Muscle	28				
Rest		2–6	750–1,000	0.2–0.4	60
Exercise		40–100	15,000–20,000	8.0–15.0	2,400
Skin	2.0–2.5				
Rest		1–3	200–500	0.1–0.2	2–4
Exercise		5–15	1,000–2,500		

CORONARY CIRCULATION

The coronary circulation provides blood flow to the heart, which consumes as much or more oxygen at rest as does the same mass of skeletal muscle during vigorous exercise (see Table 16.1). Furthermore, the heart can increase its flow four- to fivefold in order to provide for increased oxygen needs during exercise. This increase in available blood flow above that at rest constitutes what is called **coronary reserve**. The ability to increase blood flow to provide additional oxygen is imperative for the heart because even during resting conditions it extracts a near-maximum amount of oxygen from blood. Essentially, all capillaries are open and perfused in the heart during resting conditions, and its oxygen extraction at rest is greater than any other organ in the body. Coupled with the fact that the heart's ability to use anaerobic glycolysis is limited, the only way remaining to increase its tissue oxygen delivery is for it to increase its blood flow.

Cardiac blood flow occurs primarily during diastole because of inhibition of flow from cardiac contraction during systole.

An examination of the data in Table 16.1 reveals that, as a ratio of its blood flow at rest to its oxygen demand (O_2 consumption), the heart is the most *under*perfused organ in the body! This may seem surprising considering the importance of the heart to the well-being of the body as a whole. However, it reflects the fact that the contraction of the heart gets in the way of its own blood supply. Blood flow through the left ventricle decreases to a minimum during systole because the small intramuscular blood vessels are compressed and actually physically "sheared" closed by contraction and compressed by pressure generated in the muscle. Blood flow in the left coronary artery during cardiac systole is only 10% to 30% of that during diastole, and much of that represents flow to the epicardium where arteries are either outside cardiac muscle or shallowly imbedded there. The heart is perfused from the epicardial (outside) surface to the endocardial (inside) surface. The mechanical compression of systole has a more negative effect on the blood flow through the endocardial layers, where compressive forces are higher and microvascular pressures are lower, than it does in the epicardium. In heart diseases of all types, therefore, the subendocardial layers of the heart suffer more severe impairment and ischemia than do the epicardial layers.

In diastole, the heart musculature is relaxed and blood flow to the heart is not impeded by cardiac muscle effects (Fig. 16.1). Compared to its effect in the left ventricle, the compression effect of systole on blood flow is minimal in the right ventricle as a result of the lower pressures developed by that chamber. The heart's dependence on receiving most of its blood flow during diastole has no obvious deleterious effects on total coronary blood flow even during maximal exercise. However, in people with partially occluded coronary arteries (i.e., as in coronary artery disease), a simple increase in heart rate may decrease the time spent in diastole to the extent that any coronary blood flow increase needed to match increased myocardial demands is impaired.

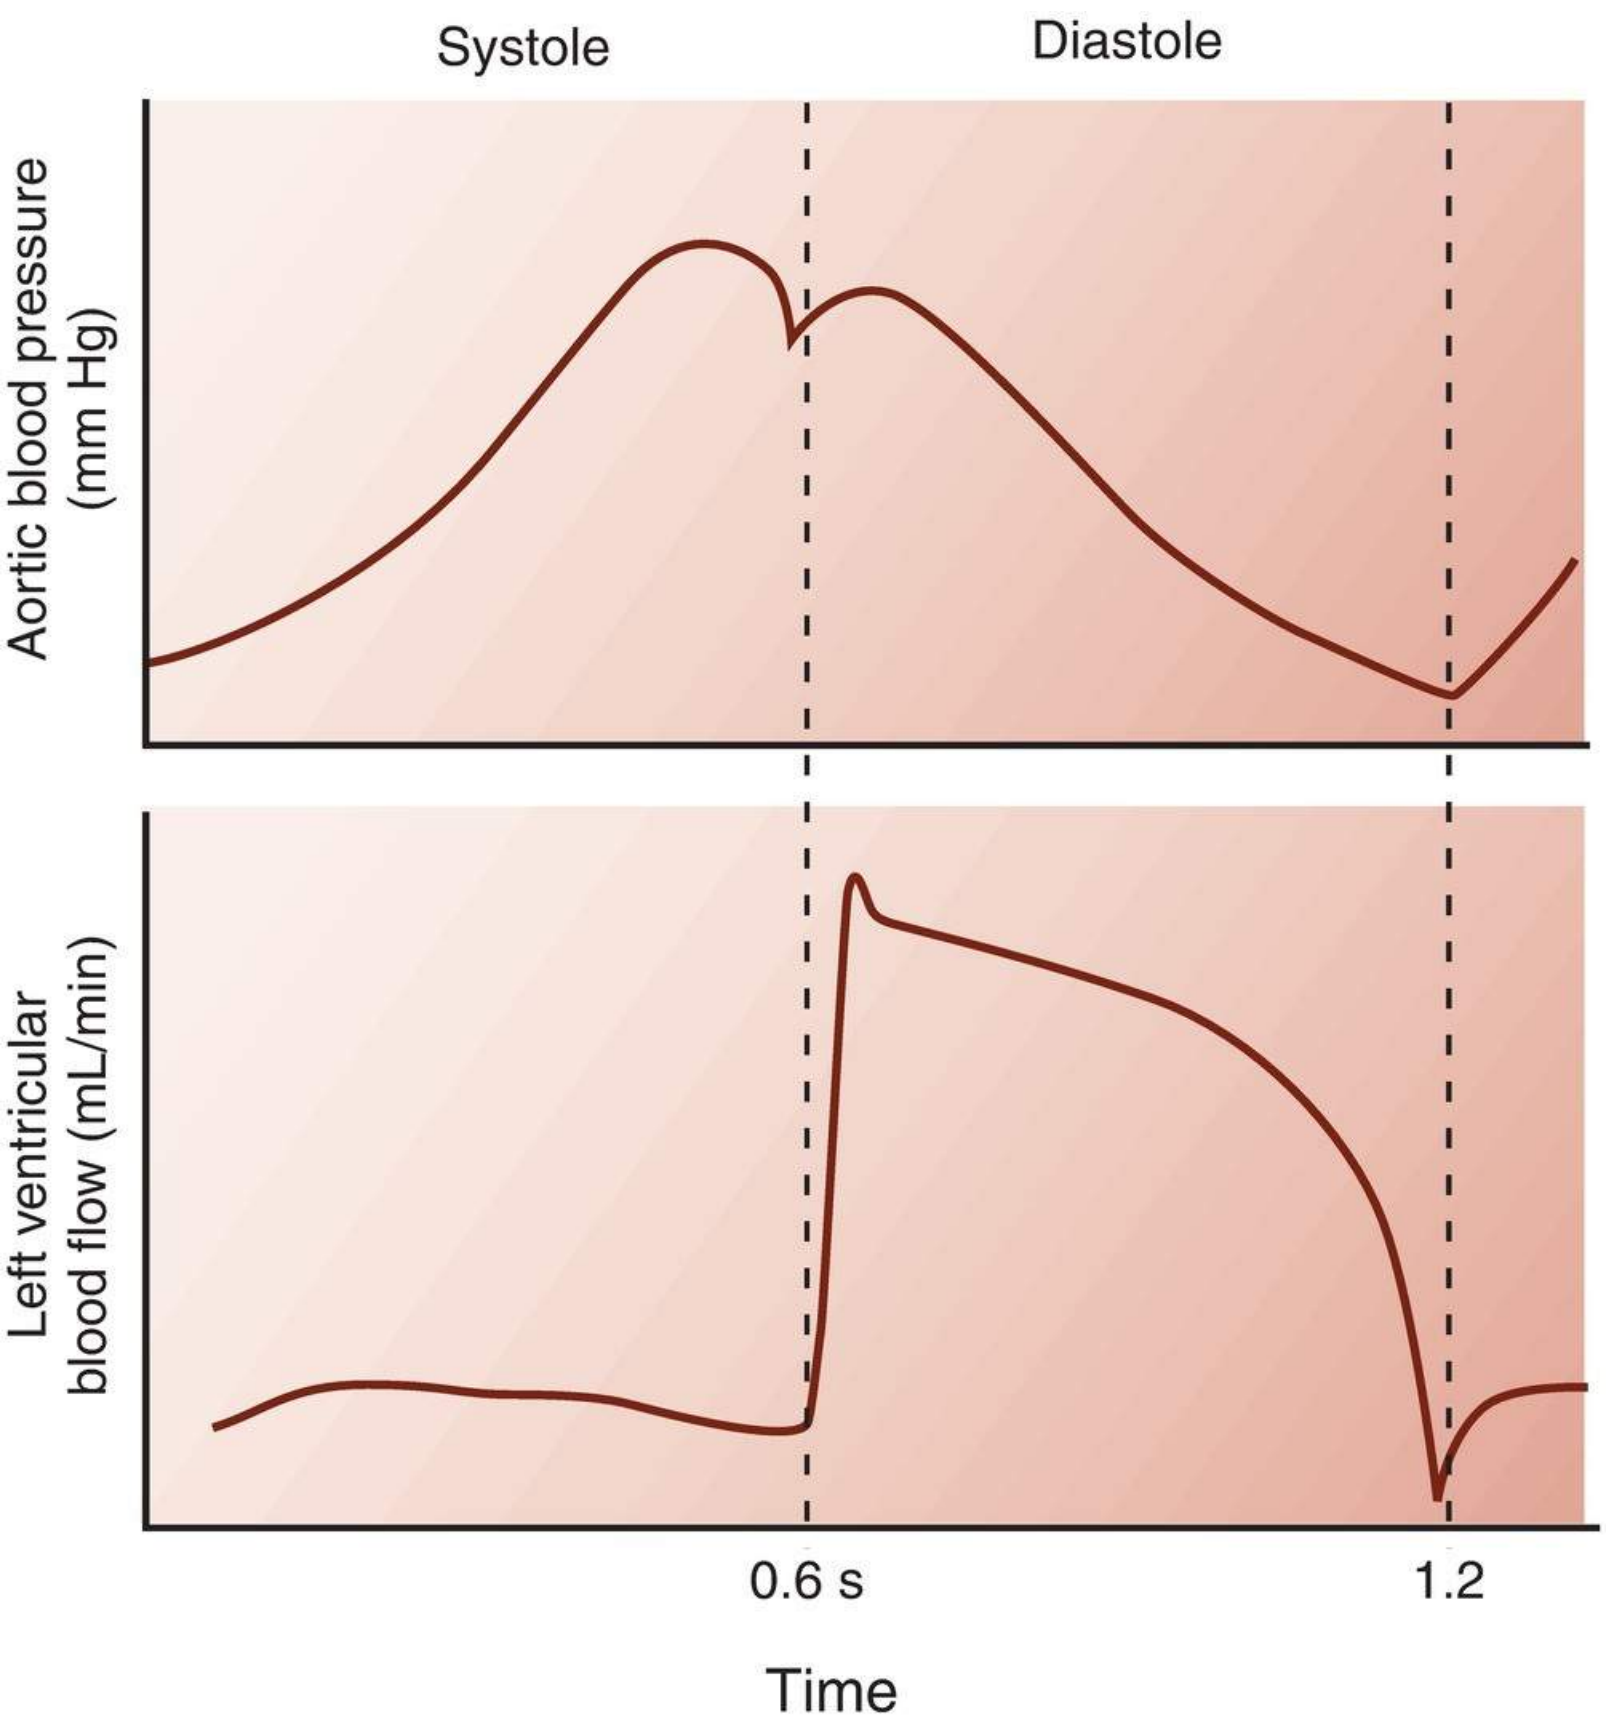

Figure 16.1 Aortic blood pressure and left coronary blood flow during the cardiac cycle. Note that left coronary artery blood flow decreases dramatically during the isovolumetric phase of systole, prior to opening of the aortic valve. Left coronary artery blood flow remains lower during systole than during diastole because of compression of the coronary blood vessels in the contracting myocardium. The left ventricle receives most of its arterial blood inflow during diastole.

Coronary blood flow is closely linked to cardiac oxygen demand.

Mean coronary blood flow increases significantly whenever myocardial oxygen demand is increased, as occurs with positive inotropic stimuli, increased systolic pressure and wall stress, or an increase in heart rate. Most of the small arteries and arterioles of the heart are surrounded by cardiac muscle cells and are exposed to molecules released by cardiac cells into the interstitial space. Many of these molecules cause dilation of the coronary arterioles and therefore could be responsible for coronary active hyperemia. However, no single mechanism adequately explains the dilation of coronary arterioles and small arteries when the metabolic rate of the heart is increased or when pathologic or experimental means are used to restrict blood flow. For example, the concentration of the potent vasodilator adenosine, which is derived from the breakdown of adenosine triphosphate in cardiac cells, increases whenever cardiac metabolism is increased or blood flow to the heart is decreased. Blockade of the vasodilator actions of adenosine with theophylline, however, does not prevent coronary vasodilation when cardiac work is increased, blood flow is suppressed, or the arterial blood is depleted of oxygen. This implies that other vasodilatory stimuli may be involved in metabolic regulation of coronary blood flow. Vasodilatory prostaglandins, H^+, CO_2, nitric oxide (NO), and decreased availability of oxygen, as well as myogenic mechanisms, are capable of contributing to coronary vascular regulation. However, the exact nature of the link between coronary blood flow and cardiac metabolism is not fully understood at this time.

Direct and indirect actions of sympathetic nerves dilate coronary arteries.

Coronary arteries and arterioles are innervated by the sympathetic nervous system and contain predominantly β_2-adrenergic receptors (in fact coronary arterioles may contain only β_2-adrenergic receptors). The large-surface epicardial arteries also contain some α_1-adrenergic receptors. Activation of the sympathetic nervous system to the heart, such as during exercise, results in coronary vasodilation and a marked increase in coronary blood flow. This increase is primarily an active hyperemia in response to increased cardiac metabolism brought about by sympathetic nerve stimulation of heart rate and myocardial contractility. However, direct β-adrenergic–mediated coronary vasodilation also contributes to the hyperemia following sympathetic nerve activation.

It appears that the α_1-adrenergic receptors of the epicardial arteries may play a role in supporting endocardial perfusion during exercise. Intramural pressure in the heart during contraction is greater in the endocardium than in the epicardium. This creates a tendency for blood to be pushed backward away from the endocardium and toward the epicardium during systole. Adding some α-adrenergic constrictor influence to the epicardial vessels during heavy exercise helps minimize backflow and loss of blood from endocardial muscle.

Autoregulation of coronary blood flow has different limits in the endocardium versus the epicardium.

All of the heart's capillaries receive blood flow, even at normal heart rates and cardiac outputs. Thus, at rest, extraction of oxygen from the coronary circulation by the heart is essentially maximized. The only way the heart can maintain oxygen delivery in the face of a reduction in perfusion pressure is by local autoregulation of blood flow. The heart is a strong autoregulator of blood flow and can maintain near-normal flows over a wide range of perfusion pressures. However, higher pressure and compressive forces in the endocardium versus the epicardium make blood flow more constrained during systole in the endocardium than in the outer layers of the heart. Consequently, the endocardial arterioles must dilate more during diastole to compensate for a more severe reduction of flow during systole. This means that the endocardium has less coronary reserve than does the epicardium. For this reason, the low-pressure limit for autoregulation in the endocardial layer is greater (i.e., at a higher intravascular pressure) than that in the epicardial layer. Endocardial arterial dilation reaches a maximum when arterial pressure drops to ~70 mm Hg, whereas maximum dilation in the epicardial arteries is not reached until pressure is ~40 mm Hg. For this reason, whenever blood flow to the heart is severely restricted, the endocardium is first to suffer damage, and the resulting area of myocardial injury and infarction is larger in the endocardium than in the epicardium.

CEREBRAL CIRCULATION

The ultimate organ of life is the brain. Even the determination of death often depends on whether the brain is viable. The most common cause of brain injury results from some form of impaired brain blood flow. This may occur as the result of occlusion of vessels secondary to atherosclerotic processes and thrombosis, accidents to arteries in the neck or brain resulting in intercranial hemorrhage, or **aneurysms** that occur as a result of vessel wall tearing.

Brain blood flow remains essentially constant over a large range of arterial blood pressures.

The cerebral circulation shares many of the overarching physiologic characteristics of the coronary circulation. Like the heart, the brain has a high metabolic rate (see Table 16.1), extracts a large amount of oxygen from blood, and has a limited ability to use anaerobic glycolysis for metabolism. However, the blood vessels of the brain either are not, or at best sparsely, innervated by sympathetic nerves (e.g., in pial arteries) or are largely unresponsive to catecholamines. The brain, like the coronary vasculature, has an excellent ability to autoregulate blood flow with a range encompassing about 50 to 160 mm Hg. The vasculature of the brainstem exhibits the most precise autoregulation, with good but less precise regulation of blood flow in the cerebral cortex. This regional variation in autoregulatory ability has clinical implications because the region of the brain most likely to suffer at low arterial pressure is the cortex. Thus, hypotension will lead to unconsciousness before the automatic cardiovascular and ventilatory regulatory functions of the brainstem are compromised.

Both the cerebral arteries and cerebral arterioles appear to be involved in cerebral vascular autoregulation and other types of vascular responses. In fact, the arteries can change their resistance almost proportionately to the arterioles during autoregulation. This may occur in part because cerebral arteries exhibit myogenic vascular responses and because they are partially to fully embedded in the brain tissues. As such, they are likely influenced by the same vasoactive chemicals in the interstitial space as the arterioles. Although the brain vasculature exhibits myogenic vascular responses and may use this mechanism as a major contributor to autoregulation, a variety of mechanisms appear to be responsible for cerebral vascular autoregulation with no one variable as a clear, sole mediator. For example, when blood flow is maintained at normal levels, regardless of the arterial blood pressure, little extra adenosine, K^+, H^+, or other vasodilator metabolites are released, and brain tissue PO_2 remains relatively constant. However, increasing concentrations of any of these chemicals can cause significant vasodilation and increased blood flow.

Brain microvessels are uniquely sensitive to vasodilation by CO_2 and H^+.

Neural function is significantly impaired by acidosis. The cerebral circulation dilates markedly in response to elevations of CO_2 and H^+, and it is the most sensitive circulation in the body to these metabolites. Cerebral blood flow increases markedly when CO_2 levels increase in brain tissue or the cerebral spinal fluid. Cerebral hyperemia in response to hypercapnia, or acidosis, which is created by hypercapnia, is likely a means to wash these neurologically damaging agents out of the brain tissue. Both CO_2 and H^+ are formed when cerebral metabolism is increased by nerve action potentials, such as during normal brain activation. In addition, interstitial K^+ is elevated when many action potentials are fired. The cause of dilation in response to both K^+ and CO_2 involves the formation of NO. However, the mechanism is not necessarily the typical endothelial formation of NO. The source of NO appears to be NO synthase in neurons as well as endothelial cells. Recent evidence indicates that the upper and lower limits of autoregulation in the brain are influenced by CO_2. Hypercapnia, which increases cerebral blood flow, shifts the upper limit of autoregulation at this higher flow to the left and the lower limit to the right. This narrows the range of pressure over which autoregulation is effective in hypercapnic states.

Reactions of cerebral blood flow to chemicals released by increased brain activity, such as CO_2, H^+, adenosine, and K^+, are part of the overall process of matching the brain's metabolic needs to the blood supply containing nutrients and oxygen. The 10% to 30% increase in blood flow in brain areas excited by peripheral nerve stimulation, mental activity, or visual activity may be related to these three substances released from active nerve cells. The cerebral vasculature also dilates when the oxygen content of arterial blood is reduced, but this effect is not as pronounced as that seen with an elevation of CO_2 in the vicinity of cerebral vessels.

CLINICAL FOCUS 16.1

Exertional Angina

Coronary artery disease can produce many focal atherosclerotic lesions in the main coronary arteries. In spite of what may be extensive vascular disease, patients with this disease often do not present with any symptoms when they are at rest. However, once they increase their activity (e.g., walking upstairs, doing physical work, etc.), they suddenly exhibit shortness of breath and severe chest pain (angina pectoris). Angina is a sign that the myocardium is ischemic and injured. The angina induced by physical activity is often called "exertional angina," and it is the most common form of angina in patients with coronary artery disease.

The reason that patients with this condition are asymptomatic at rest, but show signs of myocardial ischemia upon exertion, is rooted in the flow autoregulation capacity of the myocardium and the strong link between coronary blood flow and tissue metabolism. When focal lesions within the large coronary arteries encroach on the lumen, they raise resistance to flow at that point. This increased resistance

dissipates pressure downstream and would decrease flow in the artery as a whole if the downstream arterioles could not alter their resistance. However, the arterioles downstream are the site of autoregulation in the coronary circulation. When their internal pressure decreases, they respond by dilating in an effort to reduce resistance so that flow can be restored to its original value. Thus, any upstream increase in vascular resistance, such as that caused by a partial obstruction, is compensated by a decrease in resistance in the vessels downstream from the obstruction. In this manner, the total resistance of the arterial circuit is returned to normal and, therefore, so is blood flow. The patient would obviously be unaware of this situation and exhibit no untoward symptoms. It has been estimated that a single focal obstruction in a major coronary must reduce lumen diameter by more than 90% before arteriolar diameter is maximized through autoregulatory mechanisms at rest. Thus, no resting ischemia and symptoms would occur until further reduction of the lumen beyond that point.

With coronary obstructions that are not severe enough to cause ischemia at rest, problems occur once the metabolic demands of the heart increase. The same arterioles that are dilated to compensate for upstream obstructions in the main coronary arteries are also the vessels that need to dilate to increase blood flow to the myocardium whenever activity of the heart is increased. If a portion of their dilating capacity is used to simply maintain resting flow, there may not be enough dilating capacity left (or **coronary reserve**) to augment blood flow to meet an increased oxygen demand by the heart. In that situation, the oxygen demand of the heart exceeds its oxygen supply, and ischemia, with the appearance of angina, occurs. This is why people with coronary artery disease can suffer from ischemia and angina upon exertion yet experience no ill effects at rest. ■

Cerebral vessels are insensitive to hormones and sympathetic nerve activity.

Catecholamines, as well as other circulating vasoconstrictor and vasodilator hormones, do not play much of a role in moment-to-moment regulation of cerebral blood flow. The blood–brain barrier effectively prevents constrictor and dilator agents in blood plasma from reaching the cerebral vascular smooth muscle, and the vessel wall contains enzymes that inactivate catecholamines, serotonin, and other neurological transmitters. Sympathetic nerves sparsely innervate the cerebral arteries and arterioles, if at all, and these vessels are essentially devoid of α-adrenergic or β-adrenergic receptors. Most of the adrenergic innervations appear to be located on the pial vessels rather than on the brain parenchyma. Stimulation of these nerves produces only mild vasoconstriction. If, however, sympathetic activity to the cerebral vasculature is permanently interrupted, the cerebral vasculature has a decreased ability to autoregulate blood flow at high arterial pressures, and the integrity of the blood–brain barrier is more easily disrupted. Therefore, some aspect of sympathetic nerve activity other than the routine regulation of vascular resistance is important for the maintenance of normal cerebral vascular function. This may relate to a neurogenic trophic factor that promotes the health of endothelial and smooth muscle cells in the cerebral microvessels.

The cerebral vasculature adapts to chronic high blood pressure.

In conditions of chronic hypertension, cerebral vascular resistance increases, thereby allowing cerebral blood flow and, presumably, capillary pressures to be normal. The adaptation of cerebral vessels to sustained hypertension lets them maintain vasoconstriction at arterial pressures that would overcome the contractile ability of a normal vasculature (Fig. 16.2).

Figure 16.2 Effects of chronic hypertension on cerebral autoregulation. This condition is associated with a rightward shift in the arterial pressure range over which autoregulation of cerebral blood flow occurs (*upper panel*) because, for any given arterial pressure, resistance vessels of the brain have smaller-than-normal diameters (*lower panel*). As a consequence, people with hypertension can tolerate high arterial pressures that would otherwise cause vascular damage in healthy people. However, they risk reduced blood flow and brain hypoxia at low arterial pressures that are easily tolerated by healthy people. Effect of hypertension = solid line.

The mechanisms that enable the cerebral vasculature to adjust the autoregulatory range upward appear to be hypertrophy of the vascular smooth muscle as well as a mechanical constraint to vasodilation as a result of more muscle tissue, more connective tissue, or both. The drawback to such adaptation is partial loss of the ability to dilate and regulate blood flow at low arterial pressures. This loss occurs because the changed passive structural properties of the resistance vessels restrict increases in vessel diameter at subnormal pressures and, in doing so, increase resistance. In fact, the lower pressure limit for autoregulation of blood flow can be almost as high as the normal mean arterial pressure (see Fig. 16.2). This can be problematic if the arterial blood pressure is rapidly lowered to normal in a person whose vasculature has adapted to hypertension. The person may faint from inadequate brain blood flow, even though the arterial pressure is in the normal range. Fortunately, a gradual reduction in arterial pressure, over weeks or months, returns autoregulation to a more normal pressure range.

Cerebral edema impairs blood flow to the brain.

The cranium encases the brain in a rigid bony structure. As such, should the brain begin to swell, intracranial pressure will increase dramatically. **Cerebral edema**, or an excessive accumulation of fluid in the brain tissue, can greatly increase intracranial pressure. Such edema can be caused by a variety of traumatic or pathological conditions including infection, tumors, or trauma to the head that causes massive arteriolar dilation. In addition, frank bleeding into the brain tissue after a hemorrhagic stroke or trauma can increase intracranial pressure as well. In each case, as the intracranial pressure increases, the venules and veins are partially collapsed because their intravascular pressure is low. As these outflow vessels collapse, their resistance increases and capillary pressure rises (see Chapter 15). This increased capillary pressure favors increased filtration of fluid into the brain, which further raises the intracranial pressure. The end result is a positive feedback system in which intracranial pressure will become so high as to begin to compress small arterioles and decrease blood flow.

Excessive intracranial pressure is life threatening and a major clinical problem. Various means are used to try to reduce high intracranial pressure. For example, hypertonic mannitol can be infused into the circulation as a means of osmotically extracting water from an edematous brain. Sometimes opening of the skull and drainage of cerebrospinal fluid or hemorrhaged blood, if any, may be necessary. Hemorrhaged blood is particularly a problem because clotted blood contains denatured hemoglobin that destroys NO. This, in turn, leads to inappropriate vasoconstriction of the arterioles in the area of the hemorrhage, which further compromises blood supply to the brain.

If blood flow to the pons and medulla of the brain is decreased, tissue hypoxia activates sympathetic nervous system control centers in the brain. This results in massive sympathetic outflow to the organs of the body, resulting in severe vasoconstriction. This response is called the **Cushing reflex**. During this reflex, flow to the kidney may be so compromised as to prevent the formation of urine. The skin pales from removal of blood from that circulation, and ischemia can be produced in the intestine. However, this massive systemic vasoconstriction creates a marked elevation of mean arterial pressure (up to ~270 mm Hg), which helps open brain arterioles in the face of high external compression. Nevertheless, although blood flow may improve, the increase in arterial pressure elevates microvascular pressures, which worsens cerebral edema.

CIRCULATION OF THE SMALL INTESTINE

The small intestine completes the digestion of food, which releases nutrients that are then absorbed into the circulation. At rest, the intestine receives about 20% of the cardiac output and uses about 20% of the body's oxygen consumption; both of these numbers nearly double after a large meal. Unless intestinal blood flow can increase during a large meal, food digestion and absorption simply do not occur.

The vasculature of the small intestine is elaborate. Small arteries and veins penetrate the muscular wall of the bowel and form a microvascular distribution system in the submucosa (Fig. 16.3). The muscle layers receive small arterioles from the submucosal vascular plexus; other small arterioles continue into individual vessels of the deep submucosa around glands and to the villi of the mucosa. Small arteries and larger arterioles preceding the separate muscle and submucosal–mucosal vasculatures control about 70% of the intestinal vascular resistance. The small arterioles of the muscle, submucosa, and mucosal layers can partially adjust blood flow locally to meet the needs of these small areas of tissue.

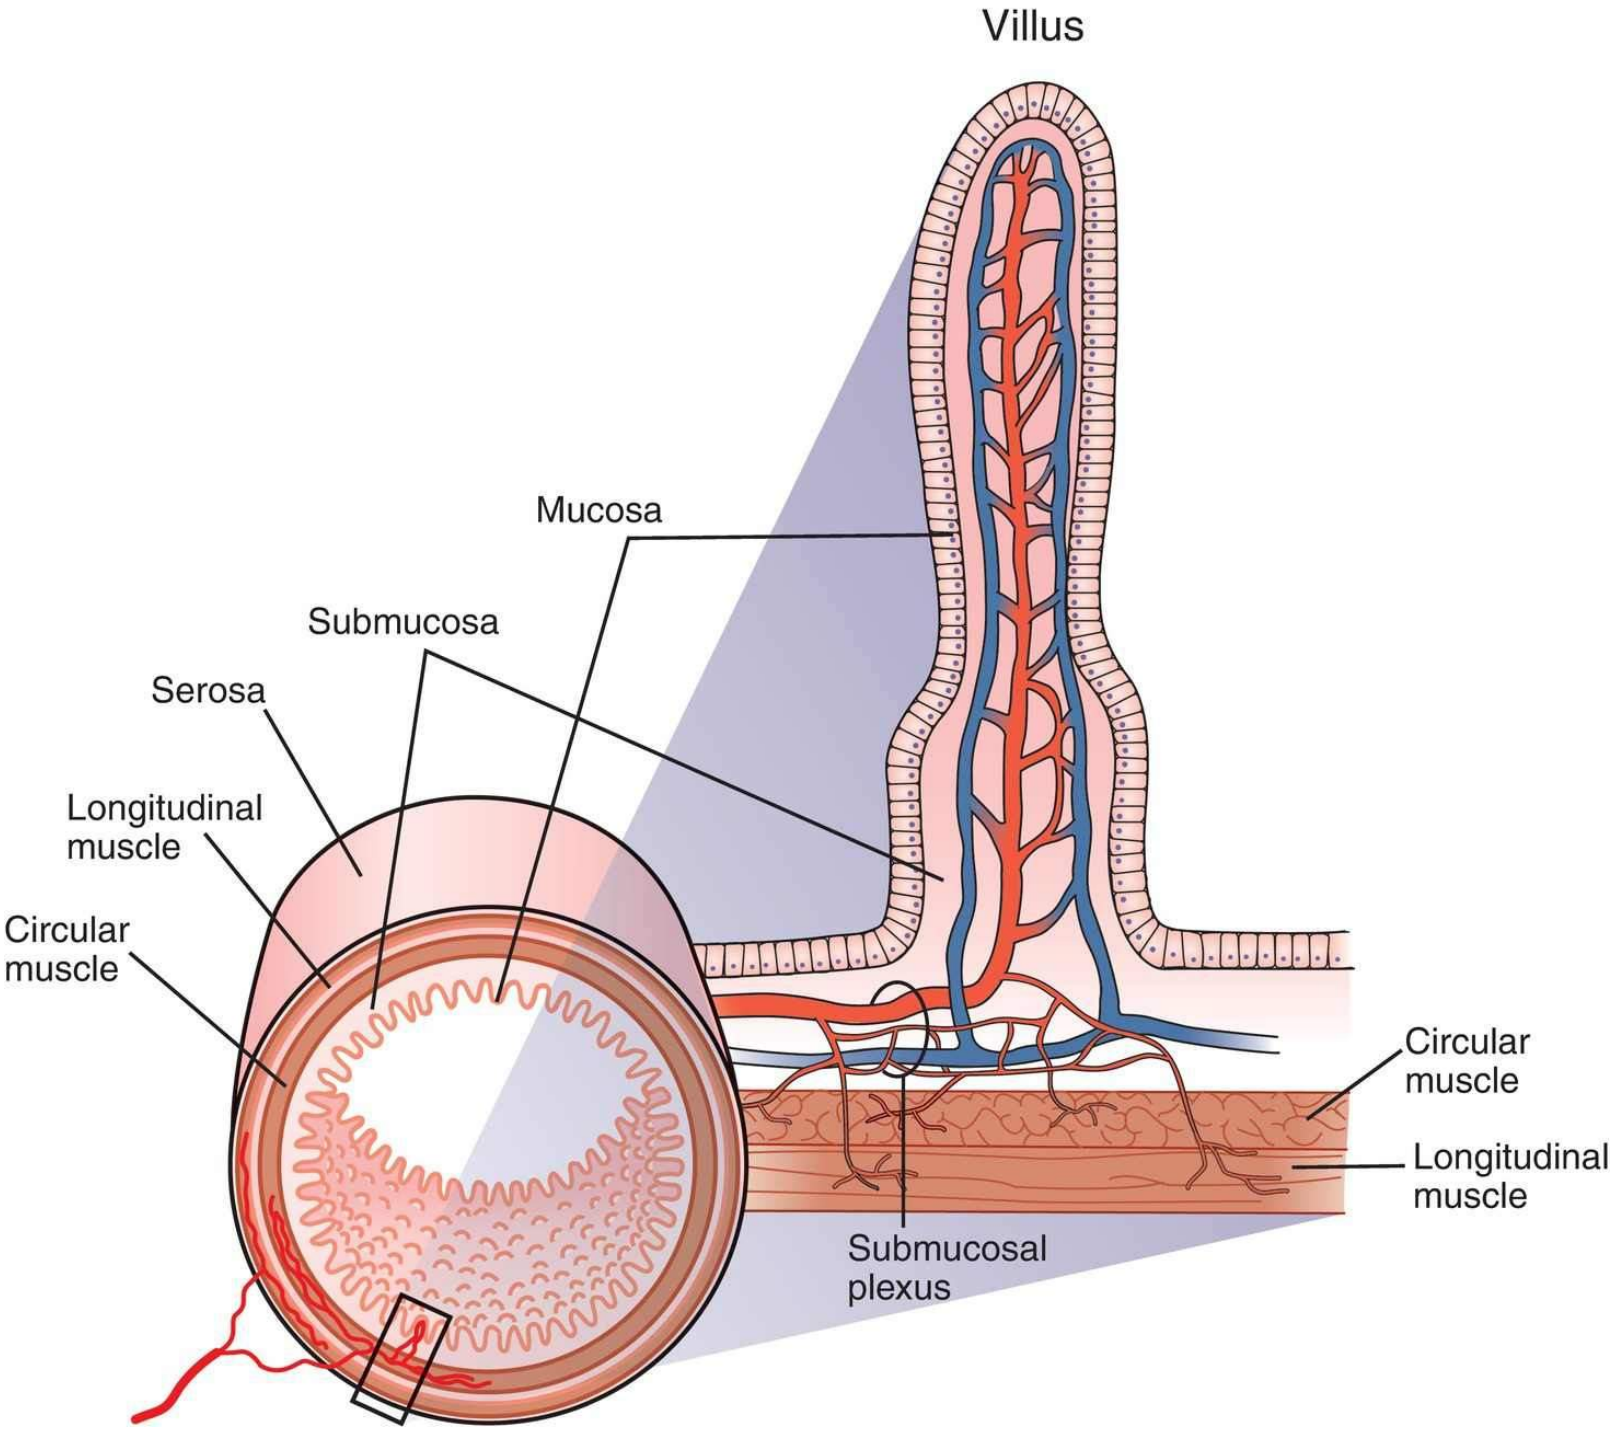

Figure 16.3 The circulation of the small intestine. The intestinal vasculature is unusual because branches from a common set of vessels located in the submucosa serve three different tissues, the muscle layers, submucosa, and mucosal layer. Small arteries and arterioles preceding the separate muscle, submucosal, and mucosal vasculatures regulate most of the intestinal vascular resistance.

Autoregulation efficiency in the small intestine is modulated by intestinal oxygen consumption.

Compared with other major organs, the circulation of the small intestine has a poorly developed autoregulatory response in most conditions. As a result, blood flow usually declines in response to locally decreased arterial pressure because resistance does not adequately decrease to help counteract the effect of low pressure on blood flow. However, this is not true for all metabolic states of the intestine. Results of experiments on autoregulation in the small intestine indicate that the intestine is a poor autoregulator of blood flow when it is not occupied with digestion, and thus, its oxygen consumption is low, whereas it is a much better autoregulator during digestion, when its oxygen consumption is high. An understanding of this phenomenon is clear if one realizes that what the intestine needs during high metabolic demand is the oxygen in the blood more so than the blood itself. This can be accomplished by opening more capillaries, thereby increasing extraction of oxygen from the blood flow the intestine is receiving, rather than increasing total blood flow in order to increase total bulk oxygen delivery to the intestine. Applying this concept to the response of intestinal blood flow to a drop in arterial pressure, it follows that if perfusion pressure to the intestine were to drop, causing an initial drop in flow, the intestine could obtain the *oxygen* it needed to compensate for the drop in blood flow by simply taking the flow it gets and extracting more oxygen from it, rather than initiating an autoregulatory vasodilation to restore total flow. Indeed, this is exactly what happens as the intestinal permeability surface area coefficient increases, following a drop in perfusion pressure and blood flow, before frank vasodilation of the arterioles are used to correct the decrease in flow. Thus, when intestinal metabolism is low, a local decrease in oxygen delivery, brought on by an initial drop in blood pressure and blood flow, is compensated for first by dilating precapillary sphincters to open more capillary surface area for diffusion of oxygen. Should demand increase or total flow be compromised further, more capillaries will open until perfused capillary surface area is maximized. At that point, any further compensation for the effects of a drop in perfusion pressure and blood flow would have to be met by autoregulation of blood flow. Experimental evidence has validated this scenario repeatedly. In short, when oxygen delivery to the intestine is compromised, the intestine extracts more oxygen from its blood supply first and adjusts its total blood supply second. During digestion, all capillaries are open or nearly so in the intestine. While in this state, with oxygen extraction essentially maximized, any reduction in oxygen supply to the intestine caused by a temporary local drop in perfusion pressure and blood flow is then compensated for by strong local autoregulation.

The fact that the intestine seems to extract oxygen from blood before altering vascular resistance has a certain appeal for whole-body homeostatic mechanisms. Even though effects of changes in vascular resistance in the intestine on the body as a whole are lessened by the parallel arrangement of organ circulations in the body, the intestine and splanchnic circulations are still enormous. Manipulating extraction of oxygen before adjusting vascular resistance and flow might be a means of meeting the metabolic needs of the intestine while minimizing the effects of those needs on the blood supply to other organs.

Effects of elevated venous pressure on fluid filtration by intestinal capillaries.

The intestine has one of the highest capillary filtration coefficients among organ systems in the body. This could be potentially troublesome because the small intestine has a very large anatomical capillary surface area and it is not a good autoregulator of blood flow for most of the time during the day (i.e., when it is

not occupied with digestion). These two factors make the intestine a prime source of fluid loss in the body whenever mean capillary hydrostatic pressure increases, such as what might occur whenever arterial or venous pressure increase.

Recall that, when arterial pressure is increased, strong autoregulation in an organ not only controls organ blood flow, but it also attenuates any increase in mean capillary hydrostatic pressure that would otherwise cause increased capillary fluid filtration. In a weak autoregulatory state, arteriolar constrictor responses to an increase in arterial pressure are weak and loss of fluid through the intestinal capillaries is likely. Furthermore, loss of fluid from the capillaries of the huge intestinal circulation could be significant in situations in which intestinal venous pressures rise. Such venous pressure rises can occur in liver disease or with portal vein obstructions because the intestinal veins are connected in series to the portal circulation of the liver. However, elevation of venous pressure in the intestinal circulation, which would increase capillary hydrostatic pressure, causes sustained myogenic arteriolar constriction that decreases capillary hydrostatic pressure. This is called the **venous–arteriolar response** and is a means by which major fluid loss from the capillaries is prevented in the intestine in the face of an elevation of intestinal venous pressure. Although the venous arteriolar response occurs in other organ systems, it appears to be strongest in the intestinal circulation.

High blood flow is required in the intestinal mucosal for absorption of nutrients.

The intestinal mucosa receives about 60% to 70% of the total intestinal blood flow. Blood flows of 70 to 100 mL/min/100 g in this specialized tissue are probable and much higher than the average blood flow for the total intestinal wall (see Table 16.1). This blood flow can exceed the resting blood flow in the heart and brain. The intestinal mucosa is composed of individual projections of tissue called *villi*. The interstitial space of the villi is mildly hyperosmotic (~400 mOsm/kg H_2O) at rest as a result of NaCl. During food absorption, the interstitial osmolality increases to 600 to 800 mOsm/kg H_2O near the villus tip, compared with 400 mOsm/kg H_2O near the villus base. The primary cause of high osmolalities in the villi appears to be greater absorption than removal of NaCl and nutrient molecules. There is also a possible countercurrent exchange process in which materials absorbed into the capillary blood diffuse from the venules into the incoming blood in the arterioles thus trapping them in the interstitium of the villus.

Lipid absorption causes a greater increase in intestinal blood flow and oxygen consumption, a condition known as **absorptive hyperemia**, than either carbohydrate or amino acid absorption. During absorption of all three classes of nutrients, the mucosa releases adenosine and CO_2 and oxygen is depleted, which may all stimulate mucosal hyperemia. The hyperosmotic lymph and venous blood that leave the villus to enter the submucosal tissues around the major resistance vessels are also major contributors to absorptive hyperemia. Hyperosmolality resulting from NaCl induces endothelial cells to release NO and dilate the major resistance arterioles in the submucosa. In contrast, hyperosmolality resulting from large organic molecules that do not enter endothelial cells does not cause appreciable increases in NO formation and produces much less of an increase in blood flow than equivalent hyperosmolality resulting from NaCl. These observations suggest that NaCl entering the endothelial cells is essential to induce NO formation though the mechanism of this effect is not clearly known at this time.

The active absorption of amino acids and carbohydrates and the metabolic processing of lipids into chylomicrons by mucosal epithelial cells place a major burden on the microvasculature of the small intestine. There is an extensive network of capillaries just below the villus epithelial cells. The villus capillaries are unusual in that portions of the cytoplasm are missing, so that the two opposing surfaces of the endothelial cell membranes appear to be fused. These areas of fusion, or closed fenestrae, are thought to facilitate the uptake of absorbed materials by capillaries. However, large molecules, such as plasma proteins, do not easily cross the fenestrated areas because the reflection coefficient for the intestinal vasculature is >0.9, about the same as in skeletal muscle and the heart.

Low capillary pressure in intestinal villi facilitates water absorption.

Although the mucosal layer of the small intestine has a high blood flow both at rest and during food absorption, the capillary blood pressure is usually 13 to 18 mm Hg and seldom higher than 20 mm Hg during food absorption. Therefore, plasma colloidal osmotic pressure is higher than capillary blood pressure, favoring the absorption of water brought into the villi. During lipid absorption, the plasma protein reflection coefficient for the overall intestinal vasculature is decreased from a normal value of more than 0.9 to about 0.7. It is assumed that most of the decrease in reflection coefficient occurs in the mucosal capillaries. This lowers the ability of plasma proteins to counteract capillary filtration, with the net result that fluid is added to the interstitial space. Eventually, this fluid must be removed. Not surprisingly, the highest rates of intestinal lymph formation normally occur during fat absorption.

Sympathetic nerve activity greatly decreases intestinal blood flow and volume.

The intestinal vasculature is richly innervated by sympathetic nerve fibers and contains predominantly α_1-adrenoceptors. Thus, major reductions in gastrointestinal blood flow and venous volume occur whenever sympathetic nerve activity is increased, such as during strenuous exercise or periods of pathologically low arterial blood pressure. In particular, venoconstriction in the intestine during hemorrhage helps to mobilize blood to the central circulation and helps compensates for the blood loss. Gastrointestinal blood flow is about 25% of the cardiac output at rest; a reduction in this blood flow, by heightened sympathetic activity, allows more vital functions to be supported with the available cardiac output. However, in combination with a low arterial blood pressure (**hypotension**), gastrointestinal blood flow can be so drastically decreased by sympathetically mediated vasoconstriction that mucosal tissue damage can result. Nevertheless, this intestinal vasoconstriction can be seen as using the large size of the intestinal vasculature to the advantage of the body as a whole by providing a significant contribution of increased total peripheral vascular resistance to help counteract hypotension. In severe hypotension, perfusion to the heart and brain takes priority over that to other organs.

HEPATIC CIRCULATION

The hepatic circulation perfuses the liver, which is one of the largest organs in the body. The liver is primarily an organ that maintains the organic chemical composition of the blood plasma. For example, all plasma proteins are produced by the liver, and the liver adds glucose from stored glycogen to the blood. The liver also removes damaged blood cells and bacteria and detoxifies many man-made or natural organic chemicals that have entered the body.

The hepatic circulation is perfused by gastrointestinal venous blood and hepatic arterial supply.

The human liver has a large blood flow, about 1.5 L/min or 25% of the resting cardiac output. It is perfused by both arterial blood through the hepatic artery and venous blood from the portal vein that has passed through the stomach, small intestine, pancreas, spleen, and portions of the large intestine. The venous blood arriving via the hepatic portal vein accounts for about 67% to 80% of the total liver blood flow (see Table 16.1). The remaining 20% to 33% of the total flow is through the hepatic artery. The majority of hepatic portal blood flow is determined by the flow through the stomach and small intestine.

The liver tissue efficiently extracts oxygen from the blood. About half of the oxygen used by the liver is derived from venous blood, even though the splanchnic organs have removed one third to one half of the available oxygen. The hepatic arterial circulation provides additional oxygen. The liver has a high metabolic rate and is a large organ; consequently, it has the largest oxygen consumption of all organs in a resting person (see Chapter 27). The liver vasculature is arranged into subunits that allow the arterial and portal blood to mix and provide nutrition for the liver cells (Fig. 16.4). Each subunit, called an *acinus*, is about 300 to 350 μm long and wide. In humans, usually three acini occur together. The core of each acinus is supplied by a single terminal portal venule; sinusoidal capillaries originate from this venule (see Fig. 16.4). The endothelial cells of the capillaries have fenestrated regions with discrete openings that facilitate exchange between the plasma and interstitial spaces. The capillaries do not have a basement membrane, which partially contributes to their high permeability. The terminal hepatic arteriole to each acinus is paired with the terminal portal venule at the acinus core, and blood from the arteriole and blood from the venule jointly perfuse the capillaries. The intermixing of the arterial and portal blood tends to be intermittent because the vascular smooth muscle of the small arteriole alternately constricts and relaxes. This prevents arteriolar pressure from causing a sustained reversed flow in the sinusoidal capillaries, where pressures are 7 to 10 mm Hg. The best evidence for this is that hepatic artery and portal venous blood first mix at the level of the capillaries in each acinus. The sinusoidal capillaries are drained by the terminal hepatic venules at the outer margins of each acinus; usually, at least two hepatic venules drain each acinus.

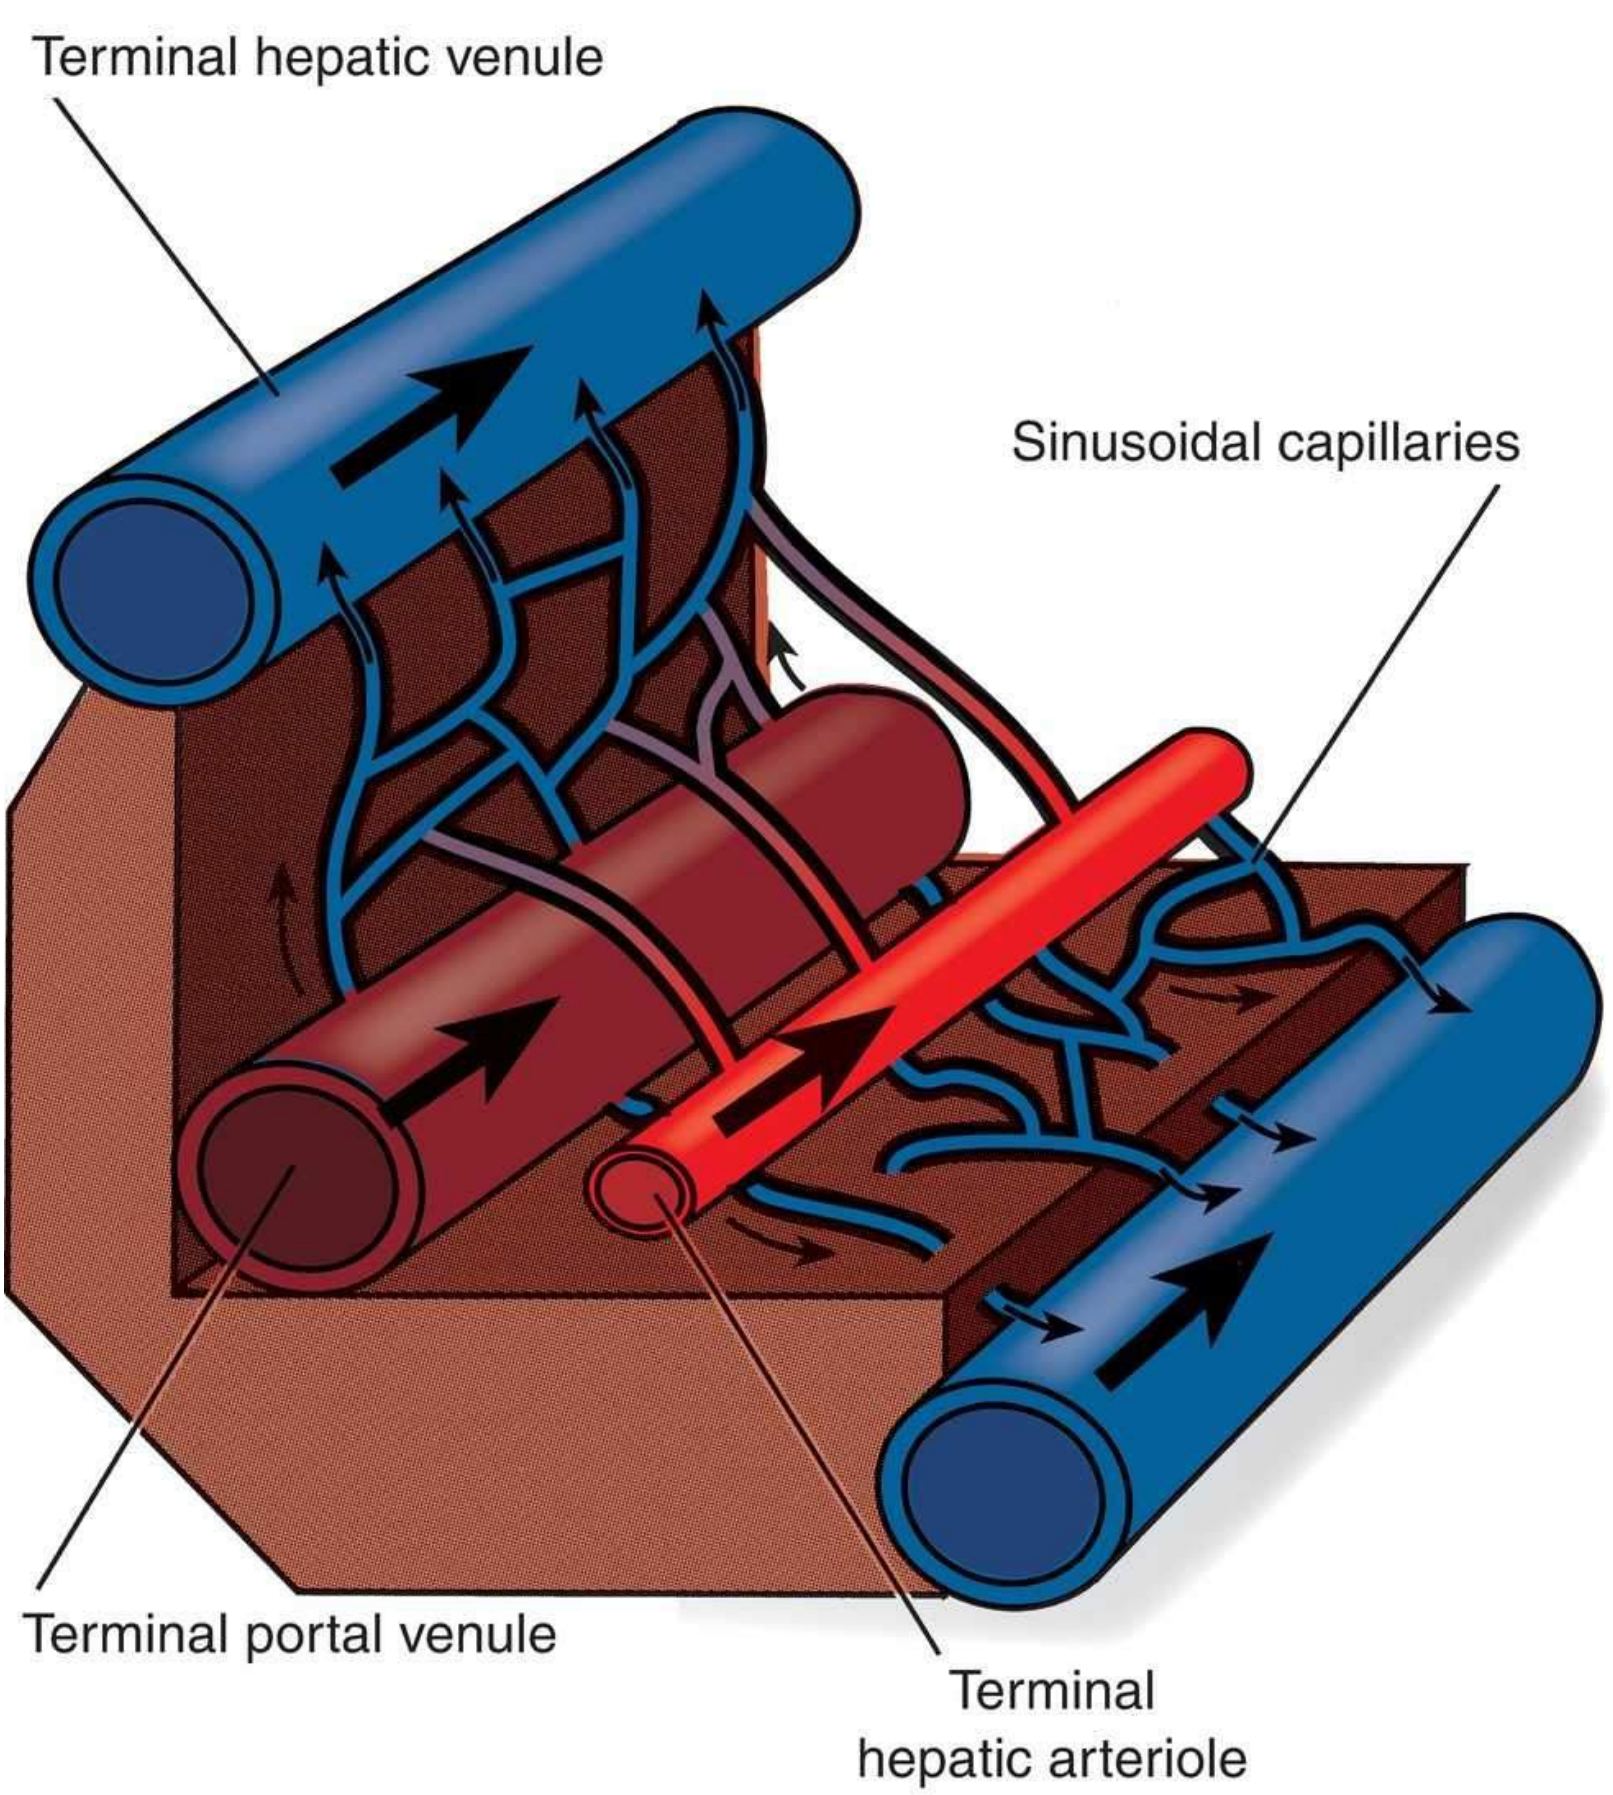

Figure 16.4 Liver acinus microvascular anatomy. A single liver acinus, the basic subunit of liver structure, is supplied by a terminal portal venule and a terminal hepatic arteriole. The mixture of portal venous and arterial blood occurs in the sinusoidal capillaries formed from the terminal portal venule. Usually, two terminal hepatic venules drain the sinusoidal capillaries at the external margins of each acinus.

Regulation of hepatic arterial and portal venous blood flow requires an interactive control system.

The regulation of portal venous and hepatic arterial blood flows is an interactive process: hepatic arterial flow increases and decreases reciprocally with the portal venous blood flow. This mechanism, known as the **hepatic arterial buffer response**, can compensate or buffer about 25% of the decrease or increase in portal blood flow. Exactly how this is accomplished is still under investigation, but vasodilatory metabolite accumulation, possibly adenosine, during decreased portal flow, as well as increased metabolite removal during elevated portal flow, is thought to influence the resistance of the hepatic arterioles.

One might suspect that during digestion, when gastrointestinal blood flow and, therefore, portal venous blood flow are increased, the gastrointestinal hormones in portal venous blood would influence hepatic vascular resistance. However, at concentrations in portal venous blood equivalent to those during digestion, none of the major hormones appears to influence hepatic blood flow. Therefore, the increased hepatic blood flow during digestion would appear to be determined primarily by vascular responses of the gastrointestinal vasculatures.

The vascular resistances of the hepatic arterial and portal venous vasculatures are increased during sympathetic nerve activation, which also suppresses the hepatic arterial buffer mechanism. When the sympathetic nervous system is activated, about half the blood volume of the liver can be expelled into the general circulation. Because up to 15% of the total blood volume is in the liver, constriction of the hepatic vasculature can significantly increase the circulating blood volume during times of cardiovascular stress.

SKELETAL MUSCLE CIRCULATION

The circulation of skeletal muscle makes up 30% to 40% of an adult's body weight and is the largest mass of tissue in the body. At rest, the skeletal muscle vasculature accounts for about 25% of systemic vascular resistance and individual muscles receive a low blood flow of about 2 to 6 mL/min/100 g. The dominant mechanism controlling skeletal muscle resistance at rest is the sympathetic nervous system; local regulatory mechanisms become more significant with high muscle metabolism (e.g., during exercise). Resting skeletal muscle has remarkably low oxygen consumption per 100 g of tissue, but its large mass makes its metabolic rate a major contributor to the total oxygen consumption in a resting person.

Skeletal muscle blood flow is varied by both sympathetic neural and local metabolic factors.

Skeletal muscle blood flow can increase 10- to 20-fold or more during the maximal vasodilation associated with high-performance aerobic exercise. During exercise, the effects of accumulation of local vasodilator agents in active skeletal muscle far exceed the effect of sympathetic neural vasoconstriction on vessels within the skeletal muscle. Under such circumstances, total muscle blood flow may increase to values three or more times higher than resting cardiac output. Cardiac output itself can increase fivefold during strenuous exercise, with most all of that increase due to an increase in skeletal muscle blood flow.

Skeletal muscle arteries contain both α- and β-adrenoceptors, but the former predominate. Thus, activation of the sympathetic nervous system causes vasoconstriction in skeletal muscle. Vascular resistance can easily double from resting values as a result of increased sympathetic nerve activity, with a resulting significant decrease in muscle blood flow. Such neurogenic vasoconstriction in skeletal muscle can override local metabolic demands of the tissue to such an extent that the muscle can become modestly ischemic even though metabolism in resting skeletal muscle is very low. Fortunately, skeletal muscle cells can survive long periods with minimal oxygen supply so this low blood flow does not result in marked cell damage or death. The effects of the sympathetic nervous system on the skeletal muscle circulation is a means to exploit this very large circulation for the benefit of the body as a whole rather than to control muscle blood flow. Activation of the sympathetic nervous system to the large mass that is skeletal muscle causes a large increase in total systemic vascular resistance that is used to help maintain or limit a drop in arterial blood pressure when cardiac output is compromised (i.e., as in hemorrhage or dehydration). Like in the small intestine, this ability enables the heart and brain to be perfused in preference to other organs less critical to the acute survival of the individual. In addition, contraction of the skeletal muscle venules and veins forces blood from these vessels into the central circulation. This action helps counteract deficits in cardiac output that accompany losses of blood volume. In sum, the skeletal muscle vasculature can either place major demands on the cardiopulmonary system through massive vasodilation during exercise or respond as if expendable with intense vasoconstriction during a hypovolemic and/or hypotensive crisis.

Muscle blood flow is markedly affected by numerous local vasoactive agents.

As discussed in Chapter 15, many potential local regulatory mechanisms adjust blood flow to the metabolic needs of tissues. In skeletal muscle, as in the small intestine, autoregulation efficacy is dependent on local metabolism with increased efficacy associated with high metabolism. In addition, to ensure the best possible supply of nutrients, particularly oxygen, even mild exercise causes sufficient vasodilation to perfuse virtually all of the capillaries, rather than just 25% to 50% of them as occur at rest. Like the small intestine, skeletal muscle first recruits more capillaries to enhance oxygen extraction in times of increased oxygen need and adjusts blood flow if needed after extraction is essentially maximized.

The most dynamic local vascular regulatory phenomenon in skeletal muscle is the coupling of muscle blood flow to its activity (i.e., active hyperemia). In fast-twitch muscles, which primarily depend on anaerobic metabolism, the accumulation of hydrogen ions from lactic acid is potentially a major contributor to active hyperemia in that muscle type. In slow-twitch skeletal muscles, oxidative metabolic requirements can increase up to 20 times during heavy exercise. This level of muscle activity is associated with a very large muscle hyperemia. It is not hard to imagine that whatever causes metabolically linked vasodilation is in ample supply at high metabolic rates and/or possesses strong vasodilator activity. Increased CO_2, H^+, K^+, and adenosine as well as hypoxia are all vasodilatory to skeletal muscle arterioles, and such changes in these metabolites occur in exercising muscle. However, none of the observed changes of these metabolites alone explains muscle active hyperemia. Recently, the skeletal muscle vasodilation and hyperemia associated with exercise have been shown to be dependent upon NO, although the mechanism by which muscle activity is linked to NO in active hyperemia is not known.

It is difficult to account for large active hyperemia in skeletal muscle on the vasodilatory effect of low tissue oxygen tensions alone. During rhythmic muscle contractions, the blood flow during the relaxation phase can be high, and thus it is unlikely that the muscle becomes significantly hypoxic during submaximal aerobic exercise (i.e., high flow enhances oxygen delivery in the relaxation phase). Although the tissue oxygen content likely decreases as exercise intensity increases, the reduction does not compromise the high aerobic metabolic rate except with the most demanding forms of exercise. Once the vasodilation and increased blood flow associated with exercise are established (in 1 to 2 minutes), the microvasculature is probably capable of maintaining ample oxygen for most workloads, perhaps up to 75% to 80% of maximum performance, because remarkably little additional lactic acid accumulates in the blood. Although H^+ is a vasodilator and lactic acid formation increases during hypoxia as well as with anaerobic metabolism, studies in humans and animals indicate that this acid is present only during the first several minutes of submaximal exercise.

The ability of skeletal muscle to meet its oxygen needs for sustained activity is not limitless. Near-maximum or maximum exercise exhausts the ability of the microvasculature to meet tissue oxygen needs, and hypoxic conditions rapidly develop, limiting the performance of the muscles. The burning sensation and muscle fatigue during maximum exercise, or at any time that muscle blood flow is inadequate to provide adequate oxygen, are partially a consequence of hypoxia. This type of burning sensation is particularly evident when a muscle must hold a weight in a steady position. In this situation, the contraction of the muscle compresses the microvessels, which severely reduces muscle blood flow. The combination of throttled flow with the energy demands of holding a weight against gravity creates marked

hypoxia in muscle tissues.

CUTANEOUS CIRCULATION

The structure of the skin vasculature differs according to location in the body. In all areas, an arcade of arterioles exists at the boundary of the dermis and the subcutaneous tissue over fatty tissues and skeletal muscles (Fig. 16.5). From this arteriolar arcade, arterioles ascend through the dermis into the superficial layers of the dermis, adjacent to the epidermal layers. These arterioles form a second network in the superficial dermal tissue and perfuse the extensive capillary loops that extend upward into the dermal papillae just beneath the epidermis. The dermal vasculature also provides the vessels that surround hair follicles, sebaceous glands, and sweat glands. The capillary loops are essentially perpendicular to the surface of the skin such that only the tips are in close proximity to the outermost layer of that tissue. All the capillaries from the superficial skin layers are drained by venules, which form a venous plexus in the superficial dermis and eventually drain into many large venules and small veins beneath the dermis. The vascular pattern just described is modified in the tissues of the hand, feet, ears, nose, and some areas of the face, in that direct vascular connections between arterioles and venules, known as **arteriovenous anastomoses**, occur primarily in the superficial dermal tissues (see Fig. 16.5). By contrast, relatively few arteriovenous anastomoses exist in the major portion of human skin over the limbs and torso. The anastomoses lead to a venous plexus that lies parallel to the skin surface and thus are positioned, when open, to direct blood into a large surface area of small blood vessels just underlying the surface of the skin.

Figure 16.5 Vascular organization in the skin. The microcirculation of the skin is composed of a network of large arterioles and venules in the deep dermis, which send branches to the superficial network of smaller arterioles and venules. Arteriovenous anastomoses allow direct flow from arterioles into venules, which increase blood flow into a venous plexus when dilated. The capillary loops into the dermal papillae beneath the epidermis are supplied and drained by microvessels of the superficial dermal vasculature. Only the tips of the loops are in close contact with the surface of the skin.

Control of the cutaneous circulation is dominated by the sympathetic nervous system. At rest in a cool room, cutaneous vessels are significantly constricted by norepinephrine from sympathetic nerves that innervate all areas of the circulation except the cutaneous capillaries. Innervation is especially dense on the arteriovenous anastomoses. Nerve blockade of the cutaneous circulation results in maximal vasodilation of its vessels because the vessels possess essentially no intrinsic active smooth muscle tone.

Adjustment of cutaneous blood flow is used for temperature regulation.

The skin is a large organ, representing 10% to 15% of total body mass, with a large external surface area that is positioned at the interface of the body with the external environment. The primary functions of the skin are protection of the body from the external environment and dissipation or conservation of heat as part of the mechanisms involved in body temperature regulation. If a great amount of heat must be conserved, the sympathetic nerves to the cutaneous circulation are activated, and all vessels there, especially the anastomoses, constrict and restrict blood from entering the skin near the external environment (see Chapter 28 for details). If a great amount of heat must be dissipated, dilation of the arteriovenous anastomoses allows substantially increased skin blood flow to the venous plexuses, thereby increasing heat loss to the environment. This allows vasculatures of the hands and feet and, to a lesser extent, the face, neck, and ears to lose heat efficiently in a warm environment.

The skin has one of the lowest metabolic rates in the body and requires relatively little blood flow for purely nutritive functions. Consequently, despite its large mass, its resting metabolism does not place a major flow demand on the cardiovascular system. However, in warm climates, body temperature regulation requires that warm blood from the body core be carried to the external surface, where heat transfer to the environment can occur. Therefore, at typical indoor temperatures and during warm weather, skin blood flow is usually far in excess of the need for tissue nutrition. The reddish color of the skin during exercise in a warm environment reflects the large blood flow and dilation of skin arterioles and venules brought into play for dissipation of excess body heat (see Table 16.1).

The increase in the skin's blood flow when the body is exposed to heat probably occurs through two main mechanisms. First, an increase in body core temperature causes a reflex increase in the activity of *sympathetic cholinergic nerves*, which release acetylcholine. Acetylcholine release near sweat glands leads to the breakdown of a plasma protein (kininogen) to form bradykinin, a potent dilator of skin blood vessels, which also increases the release of NO as a major component of the dilatory mechanism. Second, simply increasing skin temperature will cause the blood vessels to dilate. This can result from heat applied to the skin from the external environment, heat from underlying active skeletal muscle, or increased blood temperature as it enters the skin.

Total skin blood flows of 5 to 8 L/min have been estimated in humans during vigorous exercise in a hot environment. During mild-to-moderate exercise in a warm environment, skin blood flow can equal or exceed blood flow to the skeletal muscles. Exercise tolerance can, therefore, be lower in a warm environment because the vascular resistance of the skin, combined with very low vascular resistance in muscle, is too low to maintain an appropriate arterial blood pressure, even at maximum cardiac output. One of the adaptations to exercise is an ability to increase blood flow in skin and dissipate more heat. In addition, aerobically trained humans are capable of higher sweat production rates than normal, which accelerates heat loss from the surface of the skin (see Chapter 28).

Most humans live in cool-to-cold regions, where body heat conservation is imperative. The sensation of cool or cold skin or a lowered body core temperature elicits a reflex increase in sympathetic nerve activity, which causes vasoconstriction of blood vessels in the skin, especially the arteriovenous anastamoses. Heat loss is minimized because the skin becomes a poorly perfused insulator, rather than a heat dissipater. As long as the skin temperature is higher than about 10°C to 13°C (50°F to 55°F), the neurally induced vasoconstriction is sustained. However, at lower tissue temperatures, the vascular smooth muscle cells progressively lose their contractile ability, and the vessels passively dilate to

various extents. The reddish color of the hands, face, and ears on a cold day demonstrates increased blood flow and vasodilation as a result of low skin temperatures. To some extent, this cold-mediated vasodilation is useful because it lessens the chance of cold injury to exposed skin. However, if this process included most of the body surface, such as occurs when the body is submerged in cold water or inadequate clothing is worn hypothermia can result (see Chapters 28 and 29 for more detail).

FETAL AND PLACENTAL CIRCULATIONS

The development of a human fetus depends on nutrient, gas, water, and waste exchange in the maternal and fetal portions of the placenta. The human fetal placenta is supplied by two **umbilical arteries**, which branch from the internal iliac arteries of the fetus. The fetal placenta is drained by a single **umbilical vein** (Fig. 16.6). The umbilical vein of the fetus returns oxygen and nutrients from the mother's body to the fetal cardiovascular system, and the umbilical arteries bring in blood laden with carbon dioxide and waste products from the fetus to be transferred to the mother's blood. Although many liters of oxygen and carbon dioxide, together with hundreds of grams of nutrients and wastes, are exchanged between the mother and fetus each day, the exchange of red blood cells or white blood cells is a rare event. This large chemical exchange without cellular exchange is possible because the fetal and maternal bloods are kept almost completely separate.

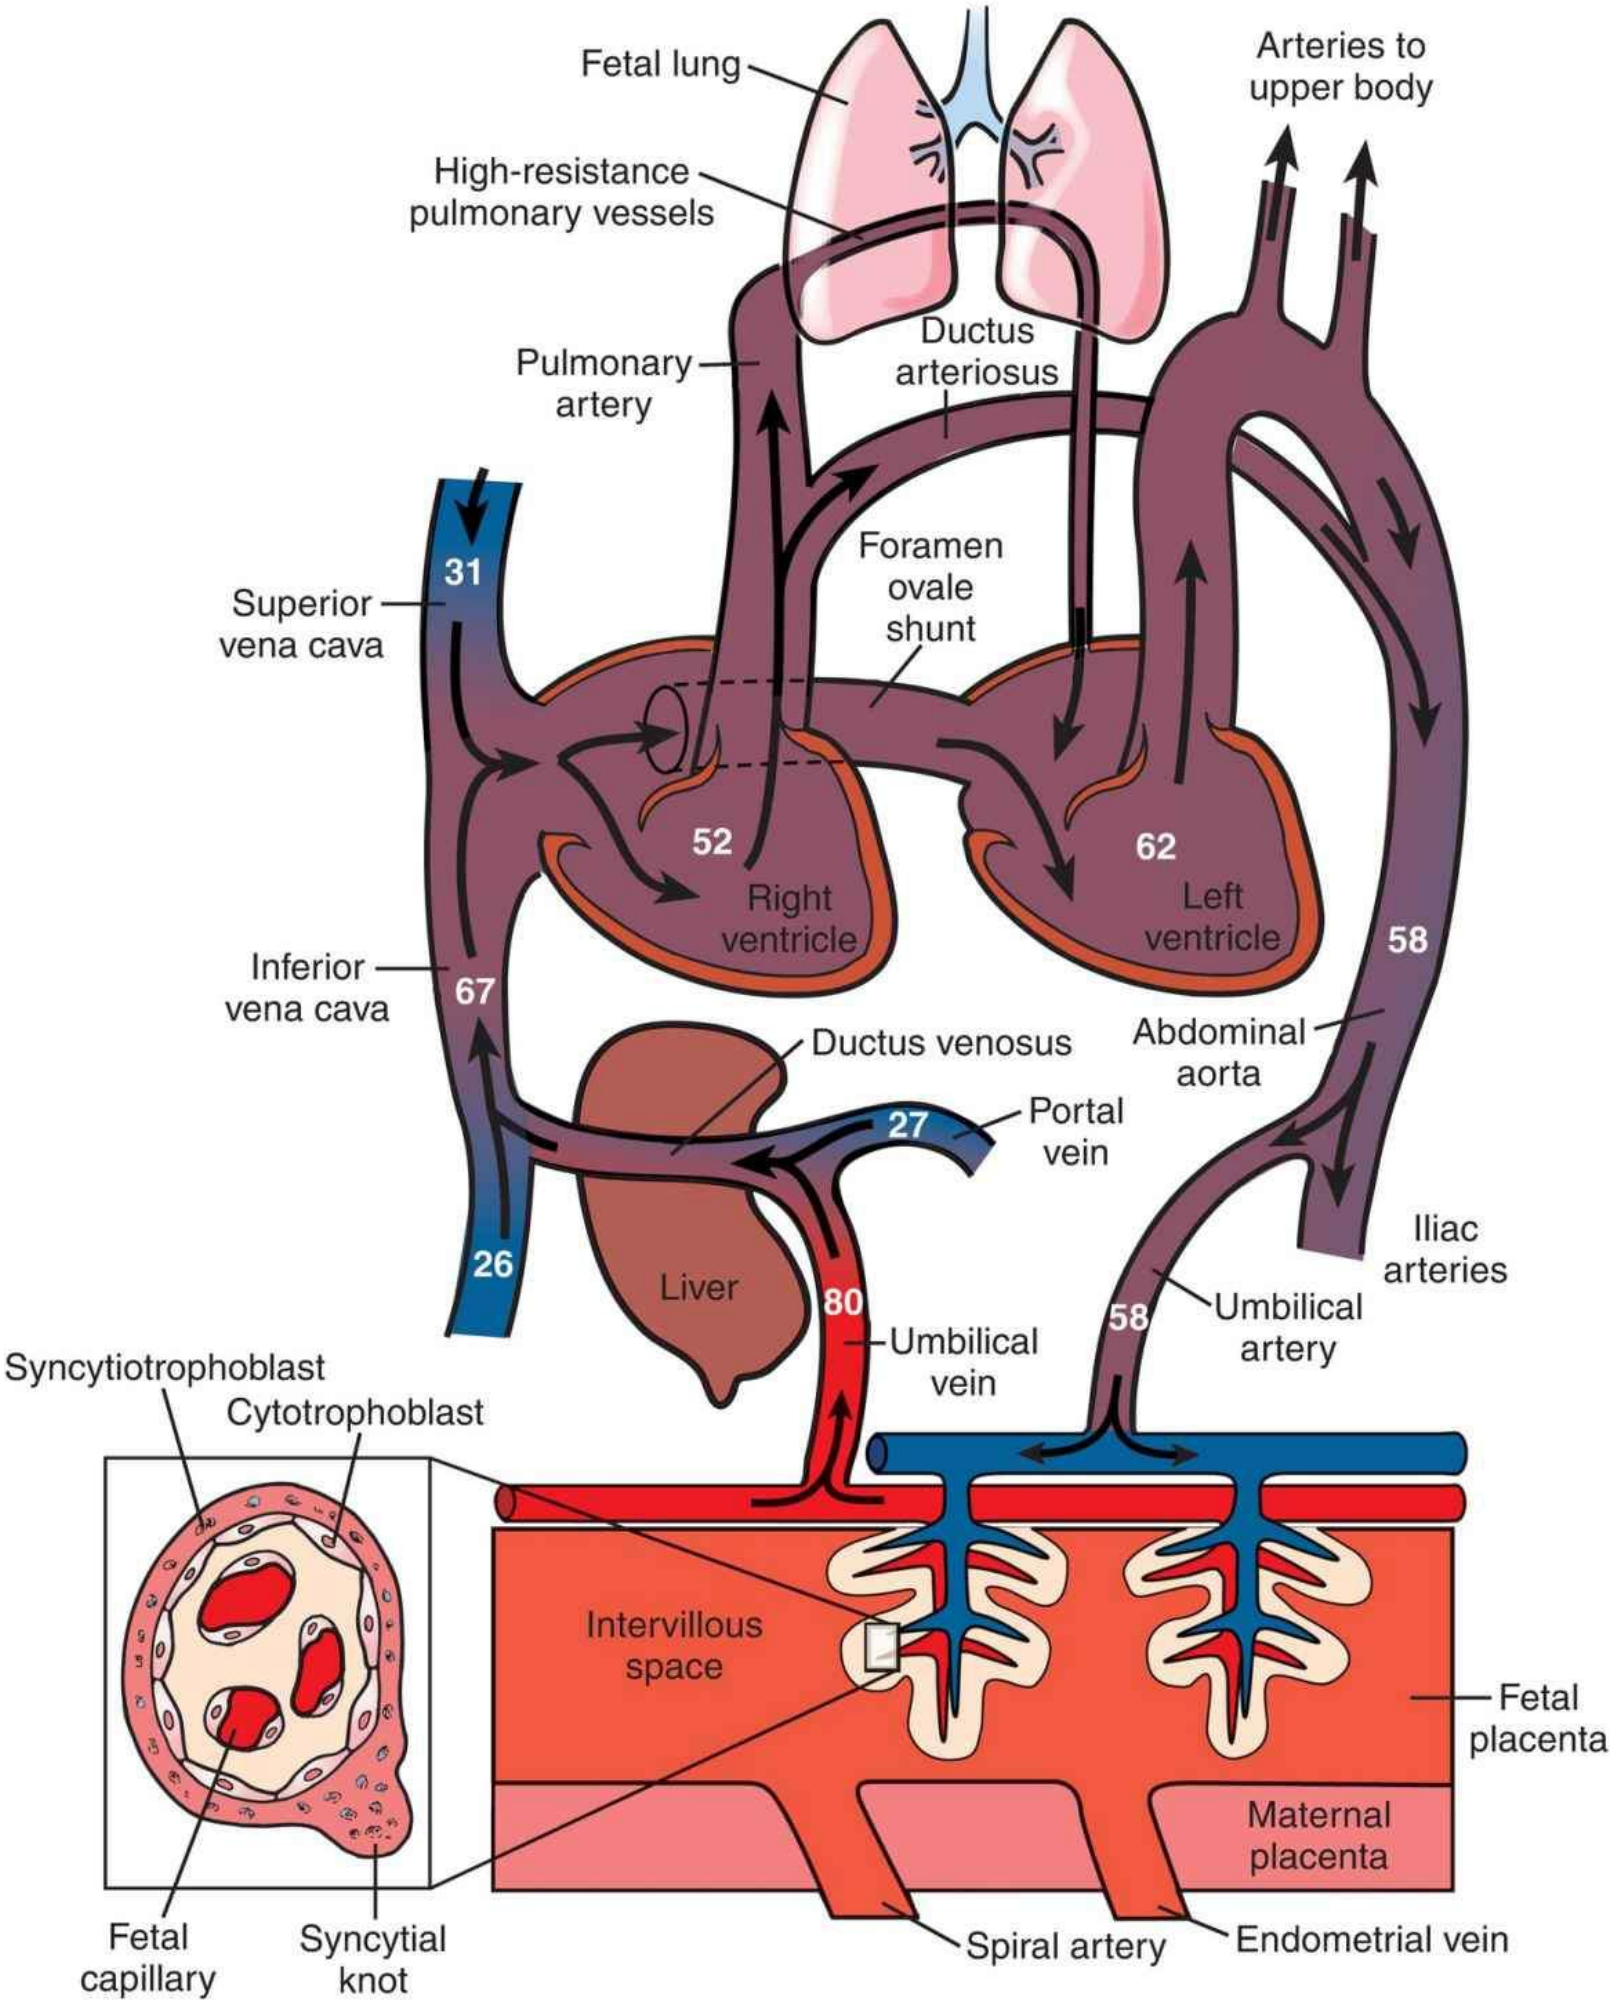

Figure 16.6 The fetal and placental circulations. The left and right sides of the fetal heart are separated

solely for the purpose of illustration to emphasize the right-to-left shunt of blood through the open foramen ovale in the atrial septum and the right-to-left shunt through the ductus arteriosus. *Arrows* indicate the direction of blood flow. The numbers represent the percent saturation of blood hemoglobin with oxygen in the fetal circulation. Closure of the ductus venosus, foramen ovale, ductus arteriosus, and placental vessels at birth and the dilation of the pulmonary vasculature establish the adult circulation pattern. The insert is a cross-sectional view of a fetal placental villus, one of the branches of the treelike fetal vascular system in the placenta. The fetal capillaries provide incoming blood, and the sinusoidal capillaries act as the venous drainage. The villus is completely surrounded by the maternal blood, and the exchange of nutrients and wastes occurs across the fetal syncytiotrophoblast.

The fundamental anatomic and physiologic structure for fetal/maternal exchange is the placental villus. As the umbilical arteries enter the fetal placenta, they divide into many branches that penetrate the placenta toward the maternal system. These small arteries divide in a pattern similar to a fir tree, the placental villi being the small branches. The fetal capillaries bring in the fetal blood from the umbilical arteries, and then, blood leaves through sinusoidal capillaries to the umbilical venous system. Exchange occurs in the fetal capillaries and probably to some extent in the sinusoidal capillaries. The mother's vascular system forms a reservoir around the treelike structure such that her blood envelops the placental villi.

As shown in Figure 16.6, the outermost layer of the placental villus is the syncytiotrophoblast, where exchange by passive diffusion, facilitated diffusion, and active transport between fetus and mother occurs through fully differentiated epithelial cells. The underlying cytotrophoblast is composed of less differentiated cells, which can form additional syncytiotrophoblast cells as required. As cells of the syncytiotrophoblast die, they form syncytial knots, and eventually, these break off into the mother's blood system surrounding the fetal placental villi.

The placental vasculatures of both the fetus and the mother adapt to the size of the fetus as well as to the oxygen available within the maternal blood. For example, a minimal placental vascular anatomy will provide for a small fetus, but as the fetus develops and grows, a complex tree of placental vessels is essential to provide the surface area needed for the fetal–maternal exchange of gases, nutrients, and wastes. If the mother moves to a higher altitude, where less oxygen is available, the complexity of the placental vascular tree increases, compensating with additional areas for exchange. If this type of adaptation does not take place, the fetus may be underdeveloped or may die from a lack of oxygen.

During fetal development, the fetal tissues invade and cause partial degeneration of the maternal endometrial lining of the uterus. The result, after about 10 to 16 weeks of gestation, is an intervillous space between fetal placental villi that is filled with maternal blood. Instead of microvessels, there is a cavernous blood-filled space. The intervillous space is supplied by 100 to 200 **spiral arteries** of the maternal endometrium and is drained by the **endometrial veins**. During gestation, the spiral arteries enlarge in diameter and simultaneously lose their vascular smooth muscle layer. It is the arteries preceding them that actually regulate blood flow through the placenta. At the end of gestation, the total maternal blood flow to the intervillous space is ~600 to 1,000 mL/min, which represents about 15% to 25% of the resting cardiac output. In comparison, the fetal placenta has a blood flow of about 600 mL/min, which represents about 50% of the fetal cardiac output.

The exchange of materials across the syncytiotrophoblast layer follows the typical pattern for all cells. Gases, primarily oxygen and carbon dioxide, and nutrient lipids move by simple diffusion from the site of highest concentration to the site of lowest concentration. Small ions are moved predominantly by active transport processes. The GLUT1 transport protein passively transfers glucose, and amino acids

require primarily facilitated diffusion through specific carrier proteins in the cell membranes, such as the system A transporter protein.

Large molecular weight peptides and proteins and many large, charged, water-soluble molecules used in pharmacologic treatments do not readily cross the placenta. Part of the transfer of large molecules probably occurs between the cells of the syncytiotrophoblast layer and by pinocytosis and exocytosis. Lipid-soluble molecules diffuse through the lipid bilayer of cell membranes. For example, lipid-soluble anesthetic agents in the mother’s blood do enter and depress the fetus. As a consequence, anesthesia during pregnancy is somewhat risky for the fetus.

Placental exchange of oxygen and carbon dioxide is limited.

In spite of intimate contact between fetal and maternal circulations in the placenta, the combined structures of this interface still create a significant diffusion barrier for oxygen. Special fetal adaptations are required for oxygen exchange, because of the limitations of passive exchange across the placenta. The PO_2 of maternal arterial blood is about 80 to 100 mm Hg, whereas that of the incoming blood in the umbilical artery is about 20 to 25 mm Hg. This difference in oxygen tension provides a large driving force for exchange, but results in an increase in the PO_2 of fetal blood in the umbilical vein to only 30 to 35 mm Hg. Fortunately, **fetal hemoglobin** carries more oxygen at a low PO_2 than adult hemoglobin carries at a PO_2 two to three times higher. In addition, the concentration of hemoglobin in fetal blood is about 20% higher than in adult blood. The net result is that the fetus has sufficient oxygen to support its metabolism and growth but does so at low oxygen tensions, using the unique properties of fetal hemoglobin. After birth, when much more efficient oxygen exchange occurs in the lung, the newborn gradually replaces the red cells containing fetal hemoglobin with red cells containing adult hemoglobin.

Absence of lung ventilation in the fetus necessitates a bypass arrangement around the fetal pulmonary circulation.

After the umbilical vein leaves the fetal placenta, it passes through the abdominal wall at the future site of the umbilicus (navel). The umbilical vein enters the liver's portal venous circulation, although the bulk of the oxygenated venous blood passes directly through the liver in the **ductus venosus** (see Fig. 16.6). However, the liver receives blood with relatively high oxygen content. This content supports red blood cell development in the liver, which is the site of such development in the fetus, unlike the bone marrow in an adult. The low-oxygen-content venous blood from the lower body and the high-oxygen-content placental venous blood mix in the inferior vena cava. The oxygen content of the blood returning from the lower body is about twice that of venous blood returning from the upper body in the superior vena cava. The two streams of blood from the superior and inferior vena cava do not completely mix as they enter the right atrium. In addition, in the fetus, the lungs are collapsed and have a high vascular resistance. The net result is that oxygen-rich blood from the inferior vena cava is shunted from the right atrium into the left atrium through an opening in the atrial septum called the **foramen ovale**. Thus, the more oxygen-rich blood largely bypasses the fetal lungs. The upper-body blood generally enters the right ventricle as in the adult and is used to support growth of the lungs, which remain collapsed in the fetus. Perfusion of the collapsed (or noninflated) lungs of the fetus is minimal because the pulmonary vascular resistance is high in collapsed lungs. High fetal pulmonary vascular resistance may also result because the pulmonary vasculature has the unusual characteristic of vasoconstriction at low oxygen tensions. The minimal amount of venous blood returning from the lungs to the left atrium and the preferential passage of oxygenated venous blood into the left atrium through the foramen ovale allows blood in the left ventricle to have oxygen content about 20% higher than that in the right ventricle. This relatively high-oxygen-content blood supplies the coronary vasculature, the head, and the brain.

The right ventricle actually pumps at least twice as much blood as the left ventricle during fetal life. In fact, the infant at birth has a relatively more muscular right ventricular wall than the adult. The right ventricle pumps blood into the systemic arterial circulation via a shunt called the **ductus arteriosus**, which connects the pulmonary artery and aorta (see Fig. 16.6). For ductus arteriosus blood to enter the initial part of the descending aorta, the right ventricle must develop a higher pressure than the left ventricle, which is the exact opposite of the pattern in the adult. The blood in the descending aorta has less oxygen content than that in the left ventricle and ascending aorta because of the mixture of less well-oxygenated blood from the right ventricle. This difference is crucial because about two thirds of this blood must be used to perfuse the placenta and pick up additional oxygen. In this situation, a lack of oxygen content is useful.

Transition from fetal to neonatal life requires complex changes in the structure of the fetal circulation after birth.

After the newborn is delivered, the initial ventilatory movements cause the lungs to expand with air thereby reducing pulmonary vascular resistance substantially (along with pulmonary arterial pressure). The right ventricle now perfuses the lungs, and the circulation pattern in the newborn switches to that of an adult. The highly perfused, ventilated lungs immediately after birth allow a large amount of oxygen-rich blood to enter the left atrium and left ventricle and out into the aorta during systole. The increased oxygen tension in the aortic blood may provide the signal for closure of the ductus arteriosus, although suppression of vasodilator prostaglandins cannot be discounted. In any event, the ductus arteriosus constricts to virtual closure and, over time, becomes anatomically fused. Simultaneously, the increased oxygen to the peripheral tissues causes constriction in most body organs, and the sympathetic nervous system also stimulates the peripheral arterioles to constrict. The net result is that the left ventricle now pumps against a higher resistance. The combination of greater resistance and higher blood flow raises systemic arterial pressure and, in doing so, increases the mechanical load on the left ventricle, which leads to ventricle hypertrophy over time. In time, the reduced workload on the right ventricle, which now pumps against a much lower pressure, causes its larger mass to subside, as that of the left ventricle increases. A larger left ventricular mass versus that of the right ventricle is eventually complete and set in about 6 months after birth.

During all the processes just described, the open foramen ovale must be sealed after birth to prevent backflow of blood from the left to the right atrium. After birth, left atrial pressure increases from the returning blood from the lungs and exceeds right atrial pressure. This pressure difference passively pushes a tissue flap on the left side of the foramen ovale against the open atrial septum. In time, the tissues of the atrial septum fuse; however, an anatomic passage that is probably only passively sealed can be documented in some adults. The ductus venosus in the liver is open for several days after birth but gradually closes and is obliterated within 2 to 3 months.

After the fetus begins breathing, the fetal placental and umbilical vessels undergo progressive vasoconstriction to force placental blood into the fetal body, minimizing the possibility of fetal hemorrhage through the placental vessels. Vasoconstriction is related to physical trauma, increased oxygen availability, sensitivity of these vessels to circulating catecholamines, and less of a signal for vasodilator chemicals and prostaglandins in the fetal tissue. The intense vasoconstriction of the umbilical vessels helps collapse the ductus venous and increase systemic vascular resistance in the newborn because the placenta, which lies in parallel with the fetal cardiovascular system, is removed from the vascular circuitry. This also helps systemic, or left-sided, pressure exceed that in the right thus facilitating reversal of flow through the ductus arteriosus, exposing it to the vasoconstrictive effects of high oxygen tensions.

The final event of gestation is separation of the fetal and maternal placenta as a unit from the lining of the uterus. The separation process begins almost immediately after the fetus is expelled, but external delivery of the placenta can require up to 30 minutes. The separation occurs along the decidua spongiosa, a maternal structure, and requires that blood flow in the mother’s spiral arteries be stopped. The cause of the placental separation may be mechanical, as the uterus surface area is greatly reduced by removal of the fetus and folds away from the uterine lining. Normally, about 500 to 600 mL of maternal blood is lost in the process of placental separation. However, as maternal blood volume increases 1,000 to 1,500 mL during gestation, this blood loss is not a significant concern.

CLINICAL FOCUS 16.2

Atrial Septal Defects

The four-chamber configuration of the adult heart is necessary for the proper oxygenation of blood and the delivery of carbon dioxide to the lungs. The separation of the ventricles into the mammalian right and left chambers occurs early during normal fetal development of the ventricular septum. The atria in the fetus communicate through the foramen ovale. This is a normal configuration in the fetus, which provides a beneficial mechanism for diverting oxygenated blood from the inferior vena cava away from the lungs (which are nonfunctional in utero) and into the systemic circulation. In some people, the foramen ovale does not close after birth. This is called an atrial septal defect.

ASD is twice as prevalent in women as in men. The consequences of retaining this defect through childhood and on into adulthood vary. People with atrial septal defects (ASDs) can live well into their seventh or eighth decade, although life expectancy is not normal; mortality increases about 6% per year after age 40. The primary hemodynamic abnormality associated with ASD is shunting of blood from the left to the right atrium, which can cause right ventricular overload and mild pulmonary hypertension. Mixing of blood between the right and left heart can be minimal, in which case the individual can be largely asymptomatic, or more severe, resulting in slowed growth and reduced exercise endurance. In this case, young patients often exhibit increased endurance after surgical correction of ASD. More serious effects from ASD can arise about the fourth decade of life, as the patient accumulates additional cardiovascular diseases, such as stiffened ventricles from chronic arterial hypertension and coronary artery disease. In those cases, the communication between the atria allows for more serious right-side overload, resulting in symptomatic pulmonary hypertension and distended atria. The latter can cause tricuspid regurgitation and atrial fibrillation. Surgical correction is required to remedy ASD. This often involves simply inserting a catheter tipped with a collapsed patch through the ASD, opening the patch, pulling it against the septal opening, and thereby sealing the ASD. Tissue then grows over the patch, making the repair permanent. ■

INTEGRATED MEDICAL SCIENCES

The Evolution of Drug-Eluting Stents (DES) for the Treatment of Coronary Artery Disease

Coronary artery bypass grafts (CABGs) were one of the first solutions for the prevention of angina and heart attack caused by blockage of coronary arteries from atherosclerotic plaques. However, CABG procedures involve significant invasive surgery and risk for the patient. Furthermore, such graphs have proven to be susceptible to restenosis over time. Balloon angioplasty, when first developed, was intended as a less invasive, more risk-adverse treatment for alleviating the

hemodynamic consequences of atherosclerotic plaques in the coronary arteries. This technique used a coronary arterial catheter fitted with an inflatable balloon on its tip that was inserted into the vascular system percutaneously and then guided into the coronary artery to the site of the plaque. Once opposite the plaque, the balloon was inflated and deflated repeatedly to "smash, flatten, and stretch" the plaque and artery, which was often sclerotic. This physical dilation effectively removed the narrowing at the site of the plaque. The problem with this procedure was that such repeated stretching and smashing of the lesion and arterial wall traumatized the artery, which would then trigger a local injury and inflammatory response. This inflammation would stimulate smooth muscle cell growth, resulting in intimal hyperplasia and significant restenosis of the artery.

An early solution to the restenosis problem was to outfit the balloon catheter with a cylindrical, flexible wire mesh that could be expanded to a wide diameter directly into the coronary arterial wall upon inflation of the balloon. This wire mesh tube, called a stent, provided support scaffolding in the arterial wall at the site of plaques and held the artery in an open position. Early arterial stents were made of bare metal and proved to be a nidus for thrombosis and focal inflammation. Laser polishing of the stent surface to an ultrasmooth finish was an early attempt at making the stent less procoagulant. However, implanting a bare metal mesh into the artery acted as an injury stimulus of its own, which in turn stimulated local tissue growth and restenosis.

For this reason, drug-eluting stents (DESs) impregnated with antiproliferative agents were developed to counteract the inflammatory tissue growth associated with earlier bare metal stents. DES is essentially a local drug-delivery system to help stop the process of restenosis and thrombosis in the stented arterial wall at the site of coronary plaques. The first DESs were coated with polymers containing either antimitogenic agents or antirejection agents. Some contained a reabsorbable polymer coating that reduced the risk of blood clot formation.

The first U.S. Food and Drug Administration–approved DESs contained sirolimus (an antirejection drug) or paclitaxel (an antimitotic) as the eluent. In healthy arteries, such as those of animals used to test the stents, antimitotic eluents proved beneficial by preventing intimal hyperplasia without affecting the endothelial growth and integrity surrounding the metal stent. However, in atherosclerotic arteries of humans, the function and health of the endothelium are severely impaired. In these vessels, antimitotic eluents impaired protective and antithrombotic endothelial growth over the metal stents leaving the stented region susceptible to blood clot formation. As DESs continued to increase in clinical use, it was discovered that although DESs were an improvement over bare metal stents, especially in terms of preventing neointimal proliferation and restenosis, evidence accumulated suggesting problematic "delayed reactions" to the stents resulting in thrombus formation in the artery long after the stent had be placed. This late stent thrombosis was often lethal. It is now understood that early polymers that contained the active antiproliferative drugs used to coat the DES stayed on the stent long after their drug is gone. The remaining polymer was shown to then act as a source of delayed reactions and inflammation leading to thrombosis. For this reason, the latest generation of DES designs has been developed to avoid this polymer-based reaction. This has led to the development of biodegradable polymer coatings on the stents, bioresorbable scaffolds, biocompatible polymers, and polymer-free DES. One of the latest developments are gene-eluting stents, which are intended to relieve restenosis and thrombosis by accelerating re-endothelialization around the stent scaffold, thereby reestablishing the natural antimitotic and antithrombotic properties of the endothelium of healthy arteries. ■

Chapter Summary

- The coronary and cerebral circulations are predominantly controlled by local metabolic factors.
- The coronary and cerebral circulations have high autoregulatory efficacy.
- Activation of the sympathetic nerves to the heart results in direct and indirect coronary arterial dilation.
- The blood vessels of the brain are largely unaffected by circulating hormones and vasoactive compounds because of the blood–brain barrier.
- Cerebral arteries are more sensitive to dilating effects of CO_2 and H^+ than are other systemic arteries.
- Blood flow to specific regions of the brain increase in response to increase neuronal activity and metabolism in those regions.
- Intestinal hyperemia during digestion is related to increased metabolism during digestion and nutrient absorption and is mediated in part by elevated sodium chloride concentration in the tissue and the release of nitric oxide.
- Autoregulation efficiency in the intestine and skeletal muscle is enhanced by increased tissue metabolism in those organs.
- The liver receives the portal venous blood from the gastrointestinal organs as its main blood supply, which is supplemented by hepatic arterial blood.
- Skeletal muscle tissue receives minimal blood flow at rest because of its limited oxygen requirements, but flow and oxygen use can increase markedly during intense muscle activity.
- The skin has a low oxygen requirement, but the high blood flow during warm temperatures or exercise allows for dissipation of a large amount of heat to the environment from the skin.
- Sympathetic neural vasoconstriction in the intestines, skeletal muscles, and skin help counteract hypotensive episodes.
- The fetus obtains nutrients and oxygen from the mother’s blood supply using the combined maternal and fetal placental circulations.
- The circulation in the fetus bypasses the fetal lungs and obtains oxygen from placental exchange. The fetal circulation is designed to deliver blood with the highest-oxygen content to the developing brain, liver (for red blood cell generation), and upper extremities.
- Closures of the foramen ovale, ductus venous, and ductus arteriosus in the fetus, as well as collapse of the umbilical arteries and vein, are essential for the transformation of the fetal circulatory system into that of an air-breathing newborn.

Chapter Review Questions

1. Which of the following would be an expected response by the coronary vasculature to changes in blood or systemic hemodynamics in the body? (To simplify your answer, ignore any reflex actions that may accompany the following situations.)
   A. Increased blood flow when the heart workload is increased
   B. Decreased vascular resistance when coronary arterial blood pressure is increased
   C. Increased vascular resistance when mean arterial pressure is reduced from 90 to 70 mm Hg by hemorrhage
   D. Decreased blood flow when blood oxygen content is reduced
   E. Increased vascular resistance during aerobic exercise

The correct answer is A. Increased workload on the heart increases myocardial oxygen consumption, which results in coronary vasodilation and increased coronary blood flow (an active hyperemia response). Intra-arterial pressure increases in the coronary artery would cause a myogenic (autoregulatory) increase in resistance. A drop in arterial pressure from 90 to 70 mm Hg, if transferred to the coronary arteries, would not increase but rather decrease coronary vascular resistance due to strong autoregulation in the coronary circulation. Decreased blood oxygen content increases coronary blood flow. Exercise increases heart rate and contraction that increase myocardial metabolism, which in turn causes vasodilation.

2. In a generalized whole-body activation of the sympathetic nervous system, which of the following special circulations would show the least change in blood flow?
   A. Coronary
   B. Cerebral
   C. Small intestine
   D. Skeletal muscle
   E. Skin

The correct answer is B. The cerebral circulation is essentially unresponsive to sympathetic nerve stimulation. Flow in the skin, intestine, and skeletal muscle decreases markedly in response to activation of their sympathetic nerve supply. Coronary blood flow will increase upon activation of sympathetic nerves to the heart through direct and indirect mechanisms.

3. Which of the following will decrease cutaneous blood flow?
   A. Fever
   B. Histamine
   C. Chemical components of sweat
   D. Local subcutaneous anesthetics (i.e., procaine, Xylocaine, etc.)
   E. Exposure of the body to atmospheric temperatures of 35°F

The correct answer is E. Exposure of the body to cold temperatures results in sympathetic nerve–mediated cutaneous vasoconstriction and reduced blood flow. Histamine is an endothelium-dependent dilator, which relaxes skin vessels. Sweat contains the vasodilator bradykinin and facilitates increased cutaneous blood flow when body temperature increases. Neurogenic tone in the cutaneous circulation is higher than in any other organ system, and its abolition by anesthetics results in marked cutaneous vasodilation.

4. If arterial pressure downstream from a thrombus in the superior mesenteric artery is reduced by 20

mm Hg and the intestine is in the fasting state (i.e., not in the midst of digestion), which of the following would then best represent the condition of the intestinal circulation as compared to its condition during a fasting state?

A. Decreased blood flow and decreased oxygen delivery to the intestine
B. Increased blood flow and increased oxygen delivery to the intestine
C. Decreased blood flow and normal oxygen delivery to the intestine
D. Decreased blood flow and increased oxygen delivery to the intestine
E. No change in blood flow or oxygen delivery to the intestine

The correct answer is C. The intestine is a poor autoregulator of blood flow in the fasted state, so flow decreases with a decrease in perfusion pressure. However, oxygen delivery to the intestine is maintained by increasing extraction of oxygen by the intestinal capillaries.

5. Myocardial ischemia and potential infarction following reduction of blood flow in the left anterior descending coronary artery generally occur in the endocardium before the epicardium and are generally more severe in deep layers of the heart than those near its surface. What is the primary reason for these phenomena?

A. There are no β-adrenergic receptors on arterioles in the endocardium.
B. The endocardium does not receive blood flow from the left anterior descending coronary artery.
C. Inotropic stimulation of the endocardium is greater than that in the epicardium.
D. The epicardium supplied by the left anterior descending coronary artery receives significant collateral blood flow from the right coronary artery.
E. The lower limit of blood flow autoregulatory capacity in the endocardium is at a higher mean arterial pressure than that for the epicardium.

The correct answer is E. All coronary arteries and arterioles contain beta receptors. The endocardium receives blood flow from the left anterior descending artery (LAD) via septal and other penetrating arteries. There is no known difference between the epi- and endocardium in terms of their response to inotropic stimuli. In humans, there are essentially no collateral arterial connections between the LAD, circumflex, or right coronary arteries to supply blood to any myocardial layer. On the other hand, intramyocardial pressure from muscle contraction and transmission of ventricular blood pressure is greatest in the endocardium of the heart and diminishes considerably toward the epicardium. As a consequence, blood supply to the endocardium is more severely restricted for a longer time in the endocardium during systole, which necessitates a greater dilation of the endocardial arterioles during diastole to supply the oxygen demand of the myocardial tissue. Thus, during diastole, endocardial arterioles are more dilated than those in the epicardium, and their dilatory reserve is used up to a greater extent. The endocardium, therefore, will reach maximum dilation and thence progress into ischemia at a higher mean arterial pressure before the epicardium (usually commencing at ~70 mm Hg compared to ~40 mm Hg for the epicardium).

Clinical Application Exercises 16.1

A 55-year-old male 5′10″ tall weighing 220 lb with a history of high plasma cholesterol and moderate hypertension has come to his family physician complaining of an increasing occurrence of chest pains and “tightness in the middle of my chest” while doing basic yard work. However, he does not experience these pains whenever he is sitting quietly while watching TV or upon arising in the morning after a good night’s rest. In the office, the patient’s physical exam reveals a blood pressure of

155/93 and heart rate of 85 with no evidence of any heart murmurs or pulmonary congestion. Upon orders from his physician, the patient undergoes a treadmill stress test in which his ECG is monitored continually. The patient's heart rate increases rapidly to over 110 beats/min during the early portion of the test, but upon the first increase in the slope of the treadmill, his ECG shows ST-segment depression, followed in rapid succession by ECG tracings showing ST-segment elevation. With this change in the ECG, the treadmill test is stopped.

The patient is then scheduled for a coronary angiography. Contrast dye imaging of the patient's coronary circulation during the angiography reveals a 5-mm long stenosis in the proximal portion of the LAD encroaching on 50% of that vessel's lumen. This stenosis is corrected by placement of a coronary stent in the stenotic region and expanding the stent until the artery assumes a normal internal diameter in that region. Six months after this procedure, the patient reports that he no longer has chest pains upon simple physical exertion.

QUESTIONS

1. What is the source of the patient's original chest pain?
2. What is the most likely effect of the patient's LAD stenosis on resting coronary blood flow? Could this effect be related to the lack of chest pain in the patient at rest?
3. What does ST-segment elevation signify in a patient?
4. Why did the patient experience chest pain during physical exertion but not during a resting state?
5. Nitroglycerin is a potent, fast-acting dilator of arteries and veins that is prescribed to patients to prevent exertional angina. However, the ability of nitroglycerin to relieve exertional angina in patients with coronary arterial stenosis is unrelated to its ability to directly dilate the coronary circulation and increase myocardial oxygen supply. What physiological mechanism is responsible for this lack of effect of nitroglycerin on the coronary circulation?

ANSWERS

1. The patient's chest pain results from myocardial ischemia, which can occur through any mechanism by which the myocardial oxygen supply cannot meet myocardial oxygen demand. This condition is called angina pectoris.
2. The stenosis will likely have no effect on the patient's resting coronary blood flow because the heart is an effective autoregulator of blood flow. Any increase in coronary vascular resistance (and potential decrease in coronary blood flow) caused by the stenosis will be counteracted by autoregulatory dilation of downstream arterioles in the vascular bed supplied by the LAD. Thus, total coronary vascular resistance and blood flow will be restored. This is likely in the patient in this case because the patient did not complain of any chest pain while at rest. Such chest pain would have occurred if the stenosis was severe enough to reduce resting blood flow to the LAD region below the metabolic needs of that segment of myocardium. If metabolic demands of the heart can be met by its blood supply, no ischemia or chest pain will occur.
3. The changes in the ST segment during exercise are a cardinal sign of myocardial ischemia and injury.
4. During physical exertion, heart rate and myocardial contractility must increase in order to increase cardiac output to meet the demand for blood flow from exercising skeletal muscles. In addition, in unfit individuals, the increase in heart rate upon physical exertion is greater than in a physically fit individual and such individuals also experience an increase in blood pressure because their skeletal muscle vasodilation with exercise is poor. The increases in heart rate,

blood pressure, and contractility all contribute to a great increase in oxygen demand in the heart. This demand can only be met by increasing myocardial blood flow because the heart cannot extract more oxygen from its arterial supply above that which occurs during resting conditions. The increase in myocardial blood flow following increased myocardial activity and oxygen demand (active hyperemia) occurs normally as the result of metabolic dilation of myocardial arterioles. However, in the patient in this case, a portion of that arteriolar dilating capacity (**coronary reserve**) has been used up in order to compensate for the resistance of the upstream stenosis. Ischemia will occur if the remaining coronary reserve is not sufficient to produce the myocardial blood flow necessary to match myocardial oxygen supply with its increased exercise-induced demand. When this occurs, demand exceeds supply and ischemia with angina occurs.

5. Any increase in oxygen demand by the heart from any source is met by arteriolar dilation of the coronary circulation; thus, oxygen supply is matched with oxygen demand. In moderate coronary artery disease, autoregulation of blood flow in the heart compensates for the increased resistance caused by stenoses in the coronary arteries, and there is no ischemia at rest. However, anything that increases myocardial oxygen demand requires further dilation of coronary arterioles. If the arterioles are driven by this demand to use up their coronary reserve, they reach maximum dilation, that is, they cannot dilate any further. Thus, any more myocardial oxygen demand will exceed oxygen supply by blood flow; ischemia with angina will ensue. Although a potent vasodilator, nitroglycerin cannot relieve angina in a patient by dilating coronary arteries to increase blood supply because if the patient is at the point of experiencing angina, the arteries in the ischemic area are already maximally dilated. Nitroglycerin relieves ischemia by reducing myocardial oxygen demand. By dilating peripheral arteries and veins, nitroglycerin "unloads" the heart by allowing blood to redistribute to the veins and arteries and out of the cardiac chambers. This reduces chamber diameter throughout the cardiac cycle, which reduces myocardial wall stress (via the law of Laplace) and thus myocardial oxygen demand.

17 Control Mechanisms in Cardiovascular Function

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Correctly identify changes in cardiovascular variables that can cause hypotension and explain the mechanism of their effect.
- Explain the mechanisms whereby hypotension leads to the activation of the baroreceptor reflex that corrects the hypotension.
- Explain the mechanisms that activate the chemoreceptor reflexes and the CNS ischemic response as they relate to support of blood pressure to support human survival.
- Explain why the baroreceptor reflex and not the chemoreceptor reflex or CNS ischemic reflex is responsible for buffering moment-to-moment changes in mean arterial pressure.
- Explain the neurohumoral mechanisms used in the body to counteract hypotension and how these synergize with neurogenic reflexes to control blood pressure.
- Explain why the baroreceptors do not set the mean arterial pressure in the body.
- Explain the mechanism of pressure diuresis and how this is involved with the kidney's role in setting the long-term level of mean arterial pressure.
- Explain how standing results in a decrease in cardiac output and blood pressure and what mechanisms are used by the body to restore normal blood pressure and cardiac output after standing.
- Explain the mechanisms responsible for progressive shock.
- Correctly identify the initiating causes and characteristic complications of shock caused by each of the following: hemorrhage, severe vomiting, sweating, diarrhea, decreased fluid and electrolyte intake, kidney damage, adrenal cortical destruction, severe burns, intestinal obstructions, general or spinal anesthesia, fever, emotional stress, anaphylaxis, and sepsis.

The mechanisms controlling the cardiovascular system involve individual and cooperative processes among neural, humoral, and local organ control mechanisms. Local vascular control mechanisms were discussed in Chapter 15. This chapter will focus on neural and humoral mechanisms that are primarily involved with the control of central blood volume and arterial pressure. Central blood volume plays a key role in determining cardiac output, whereas the ability of the body to maintain a relatively constant arterial blood pressure ensures proper regulation of organ blood flow.

Neural control of the cardiovascular system involves sympathetic and parasympathetic branches of the autonomic nervous system (ANS). Blood volume and arterial pressure are monitored by stretch receptors in the heart and arteries. Afferent nerve traffic from these receptors is integrated in the medulla oblongata with other afferent information to modulate activity in sympathetic and parasympathetic nerves that adjust heart rate, myocardial contraction, arterial resistance, and venous tone. In this way, cardiac output and systemic vascular resistance (SVR) are adjusted to maintain arterial pressure. This control is further refined by the action of hormones, such as **arginine vasopressin (AVP)** (also called **antidiuretic hormone** or **ADH**), **angiotensin II**, **aldosterone**, and **atrial natriuretic peptide (ANP),** that participate

in the regulation of blood volume through their effects on salt and water balance.

Neural control of cardiac output and SVR plays a larger role in the rapid moment-to-moment regulation of arterial pressure, whereas hormones contribute to longer-term regulatory mechanisms. In some situations, factors other than blood volume and arterial pressure regulation strongly influence cardiovascular control mechanisms. These situations include the fight-or-flight response, diving under water, thermoregulation, transferring from the supine to standing position, and exercise.

AUTONOMIC NEURAL CONTROL OF THE CARDIOVASCULAR SYSTEM

Neural regulation of the cardiovascular system involves the postganglionic parasympathetic and sympathetic neurons, which are triggered by preganglionic neurons in the brain (parasympathetic) and spinal cord (sympathetic and parasympathetic). Afferent inputs influencing these neurons operate as sensors for arterial pressure and blood volume within locations in the cardiovascular system. They also sense conditions within other organs and the external environment.

Neurogenic control of the heart involves reciprocal activation of parasympathetic and sympathetic nerves.

Autonomic control of the heart and blood vessels was described in the section on the ANS earlier in this text. The heart is innervated by parasympathetic (vagus) and sympathetic nerve fibers (Fig. 17.1). Both types of fibers are tonically active; that is, they exhibit a steady stream of action potential firing at rest. Acetylcholine (ACh) released from parasympathetic fibers binds to muscarinic receptors of the sinoatrial (SA) and atrioventricular nodes as well as the specialized conducting tissues. Stimulation of parasympathetic fibers causes a slowing of the heart rate and a reduction in conduction velocity through the AV node. The ventricular muscle is only sparsely innervated by parasympathetic nerve fibers. Stimulation of these fibers has a negative, but small, inotropic effect. Some cardiac parasympathetic fibers end on sympathetic nerves and inhibit the release of norepinephrine (NE) from sympathetic nerve fibers. Therefore, even in the presence of sympathetic nervous system activity, parasympathetic activation reduces cardiac contractility.

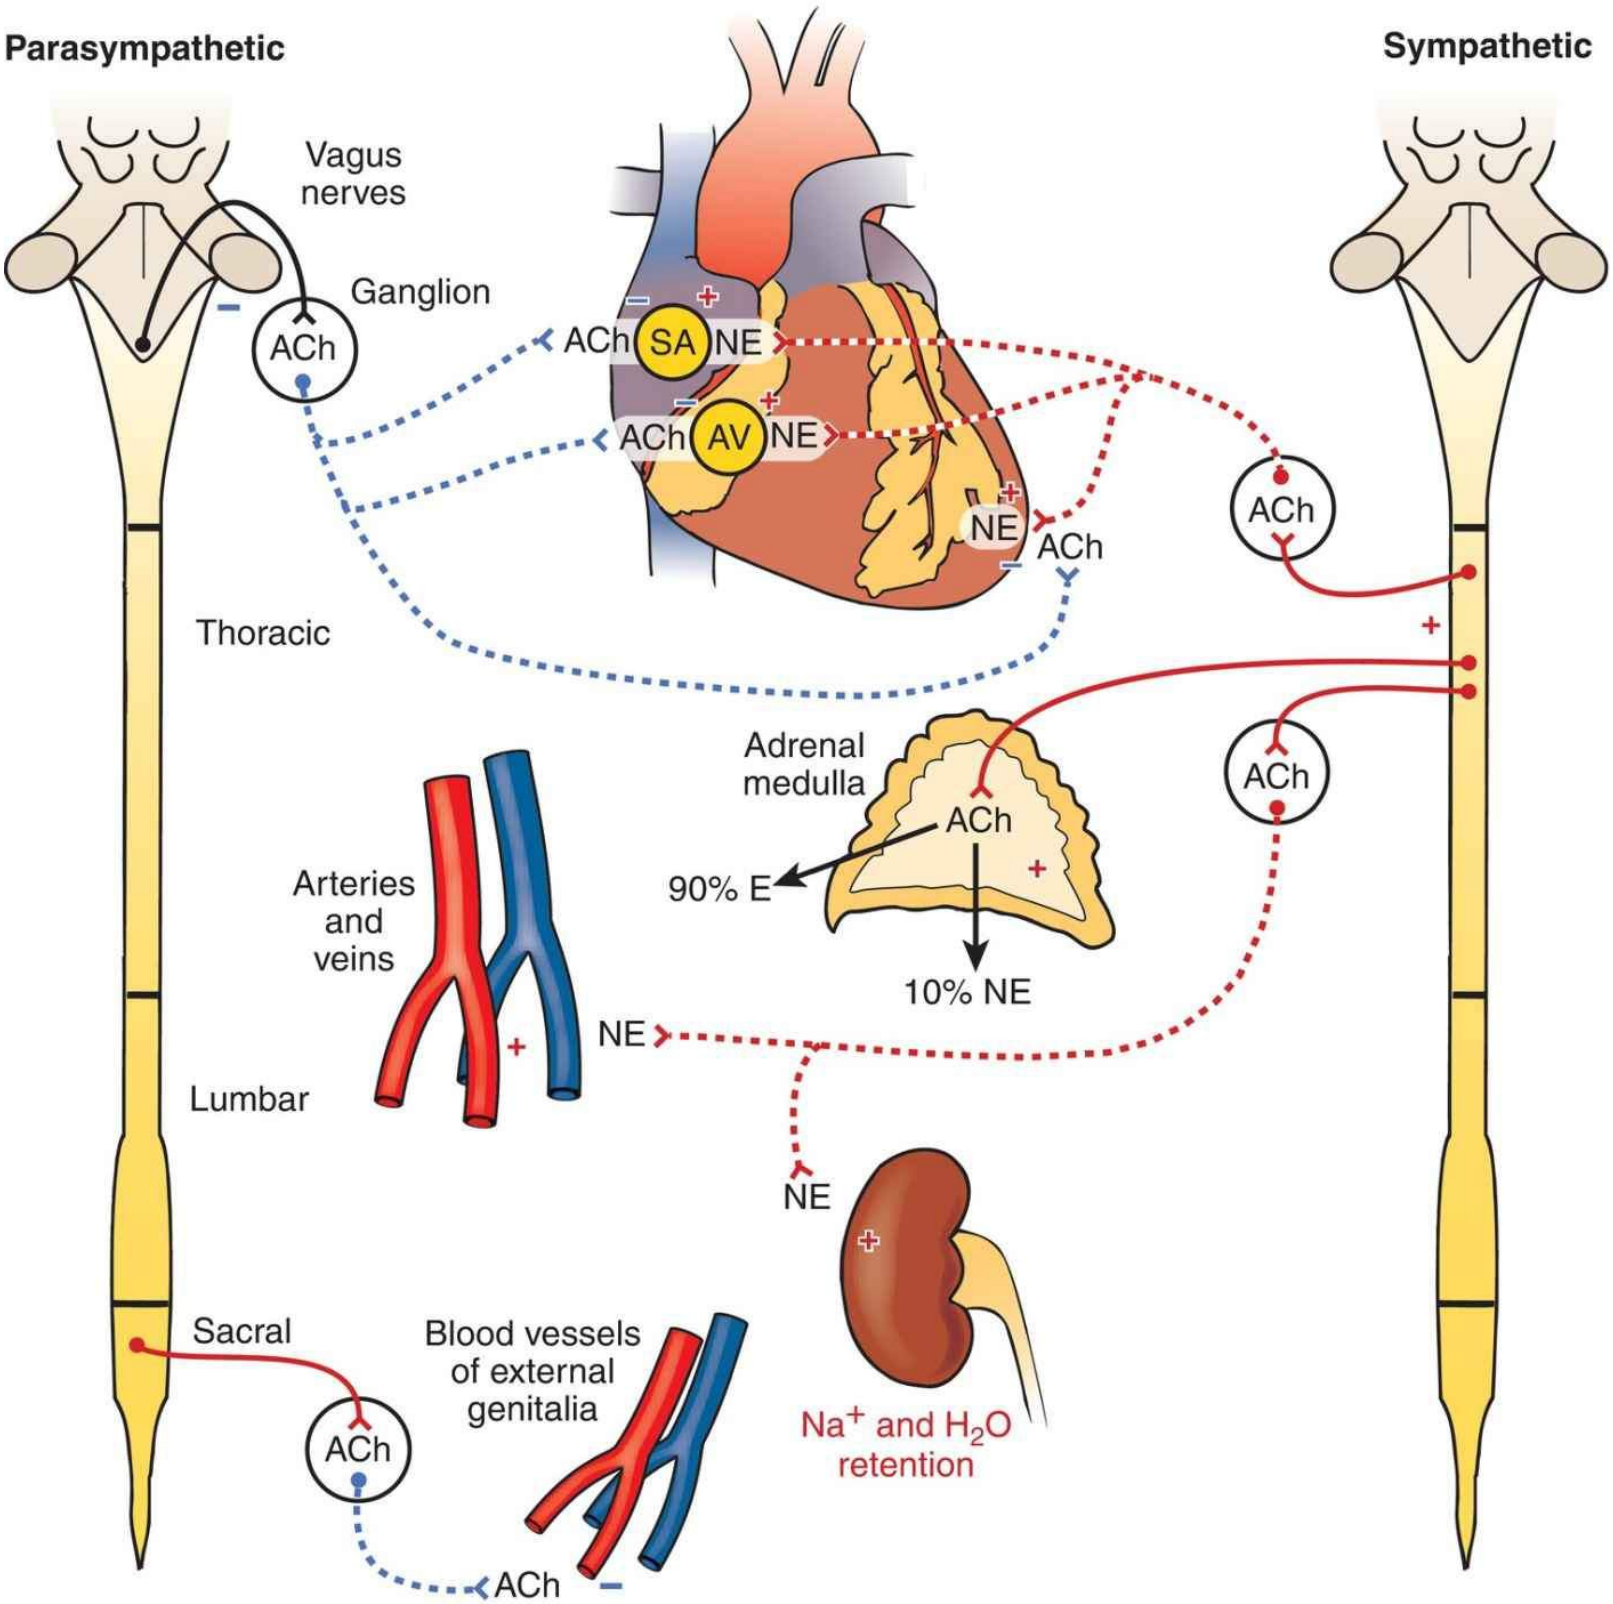

Figure 17.1 Autonomic innervation of the cardiovascular system. *Solid lines* represent preganglionic fibers; *dashed lines* represent postganglionic fibers. *Red lines* represent sympathetic nerve pathways. *Blue lines* represent parasympathetic pathways. ACh, acetylcholine; NE, norepinephrine; E, epinephrine; SA, sinoatrial node; AV, atrioventricular node.

Sympathetic fibers to the heart release NE, which binds to β_1-adrenergic receptors in the SA node, the atrioventricular node, specialized conducting tissues, and cardiac muscle. Stimulation of these fibers cause increased heart rate, increased conduction velocity through the AV node, and a positive inotropic effect (contractility). Activity along the two divisions of the ANS changes in a reciprocal manner to

create changes in heart rate. For example, an increase in heart rate is brought about by a simultaneous decrease in parasympathetic and an increase in sympathetic nerve activity to the heart. However, control of heart rate is dominated by parasympathetic effects. Activation of the parasympathetic system can slow the heart even when the sympathetic system is maximally activated. At submaximal sympathetic rates, activation of the vagus nerve can totally suppress the SA node and temporarily cause the heart to stop.

In contrast to the relationships controlling heart rate, control of cardiac contractility is dominated by sympathetic effects; the inotropic state is only minimally affected by vagal activity. Consequently, myocardial contractility is primarily modulated by the level of the activity in the sympathetic nerves to ventricular muscle.

Sympathetic fibers innervate arteries and veins of all the major systemic organs except the brain (see Fig. 17.1). These fibers tonically release NE, which binds to α_1-adrenergic and β_2-adrenergic receptors on blood vessels. However, because the arteries of all vascular beds except the heart and brain contain more α_1- than β_2-adrenergic receptors, activation of the sympathetic nerves to the systemic circulations causes vasoconstriction and an increase in vascular resistance. Circulating epinephrine, released from modified sympathetic nerve endings in the adrenal medulla, binds to α_1-adrenergic and β_2-adrenergic receptors of vascular smooth muscle cells, as well. However, the affinity of both β_1 and β_2 receptors for epinephrine is greater than that for NE. Therefore, at low circulating concentrations, epinephrine essentially activates only β receptors, with the effect of increasing cardiac output (chronotropic and inotropic effects) while *decreasing* SVR.

There is no known parasympathetic innervation of blood vessels in systemic organs with the exception of those of the external genitalia. Postganglionic parasympathetic fibers release ACh and nitric oxide (NO) to blood vessels in the external genitalia. ACh causes the further release of NO from endothelial cells, which results in vascular smooth muscle relaxation and vasodilation. These fibers mediate erection in males and engorgement of the female genitalia during sexual arousal.

Arterial effects of spinal cord injury

The steady train of sympathetic nerve activity, or tone, to blood vessels, the heart, and the adrenal medulla produces a background level of sympathetic vasoconstriction, cardiac stimulation, and adrenal catecholamine secretion in the body. All of these factors contribute to the maintenance of normal blood pressure. This tonic activity is generated by excitatory signals from the medulla oblongata. When the spinal cord is acutely transected and these excitatory signals can no longer reach sympathetic preganglionic fibers, their tonic firing is reduced and blood pressure falls. This effect is known as **spinal shock**. Humans have spinal reflexes of cardiovascular significance. For example, the stimulation of pain fibers entering the spinal cord below the level of a chronic spinal cord transection can cause reflex vasoconstriction and increased blood pressure.

Integrative functions of the medulla and functional cardiovascular centers

The medulla oblongata has three major cardiovascular functions: (1) generating tonic excitatory signals to spinal sympathetic preganglionic fibers, (2) integrating cardiovascular reflexes, and (3) integrating signals from supramedullary neural networks, circulating hormones, and drugs. Specific pools of neurons are responsible for elements of these functions. Neurons in the rostral ventrolateral nucleus (RVL) are normally active and provide tonic excitatory activity to the spinal cord. Specific pools of neurons within the RVL have actions on the heart and blood vessels. RVL neurons are critical in mediating reflex inhibition or activation of sympathetic nerves to the heart and blood vessels.

The cell bodies of cardiac preganglionic parasympathetic neurons are located in the nucleus ambiguus; the activity of these neurons is influenced by reflex input as well as input from respiratory neurons. Respiratory sinus arrhythmia (an oscillating momentary increase in heart rate with inspiration followed by a decreased rate with expiration) is primarily the result of the influence of medullary respiratory neurons that inhibit firing of preganglionic parasympathetic neurons during inspiration and excite these neurons during expiration.

Centers in the hypothalamus and medulla that mediate cardiovascular reflexes to control arterial blood pressure are not anatomically precise locales in those regions of the brain. For that reason, cardiovascular “centers” affecting the heart and blood vessels are often identified by their functional effects. Classically, three cardiovascular control centers have been so identified in the brain. These are (1) the vasomotor center, (2) the cardioaccelerating center, and (3) the cardioinhibitory center. The vasomotor is tonically active and subdivided into a *pressor area*, which causes vasoconstriction, and a *depressor area*, which causes vasodilation by inhibiting the pressor area. The cardioaccelerating center increases heart rate and myocardial contractility by activating sympathetic nerves to the heart. The cardioinhibitory center decreases heart rate and contractility by activating parasympathetic nerves to the heart.

The baroreceptor reflex buffers changes in mean arterial pressure by modulating cardiac output and total peripheral vascular resistance.

The most important reflex controls of the cardiovascular system originate in mechanoreceptors located in the aorta, carotid sinuses, atria, ventricles, and pulmonary vessels. These mechanoreceptors are sensitive to the stretch of the walls of these structures. The firing rate of nerves from these mechanoreceptors increases when the wall is stretched by increased transmural pressure. For this reason, mechanoreceptors in the aorta and carotid sinuses are called **baroreceptors**, or, sometimes, arterial baroreceptors or high-pressure receptors. Mechanoreceptors in the atria, ventricles, and pulmonary vessels primarily sense pressure changes brought about by changes in blood volume. Therefore, these receptors are referred to as volume receptors, low-pressure baroreceptors, or **cardiopulmonary baroreceptors**.

Increased pressure in the carotid sinus and aorta stretches **carotid sinus baroreceptors** and **aortic baroreceptors** and raises their firing rate. Nerve fibers from carotid sinus baroreceptors join the glossopharyngeal (cranial nerve IX) nerves and travel to the NTS. Nerve fibers from the aortic baroreceptors, located in the wall of the arch of the aorta, travel with the vagus (cranial nerve X) nerves to the NTS. The increased action potential traffic reaching the NTS leads to excitation of nucleus ambiguus neurons and inhibition of firing of RVL neurons. This results in increased parasympathetic and decreased sympathetic neural activity to the heart, resistance vessels (primarily arterioles), and veins (Fig. 17.2).

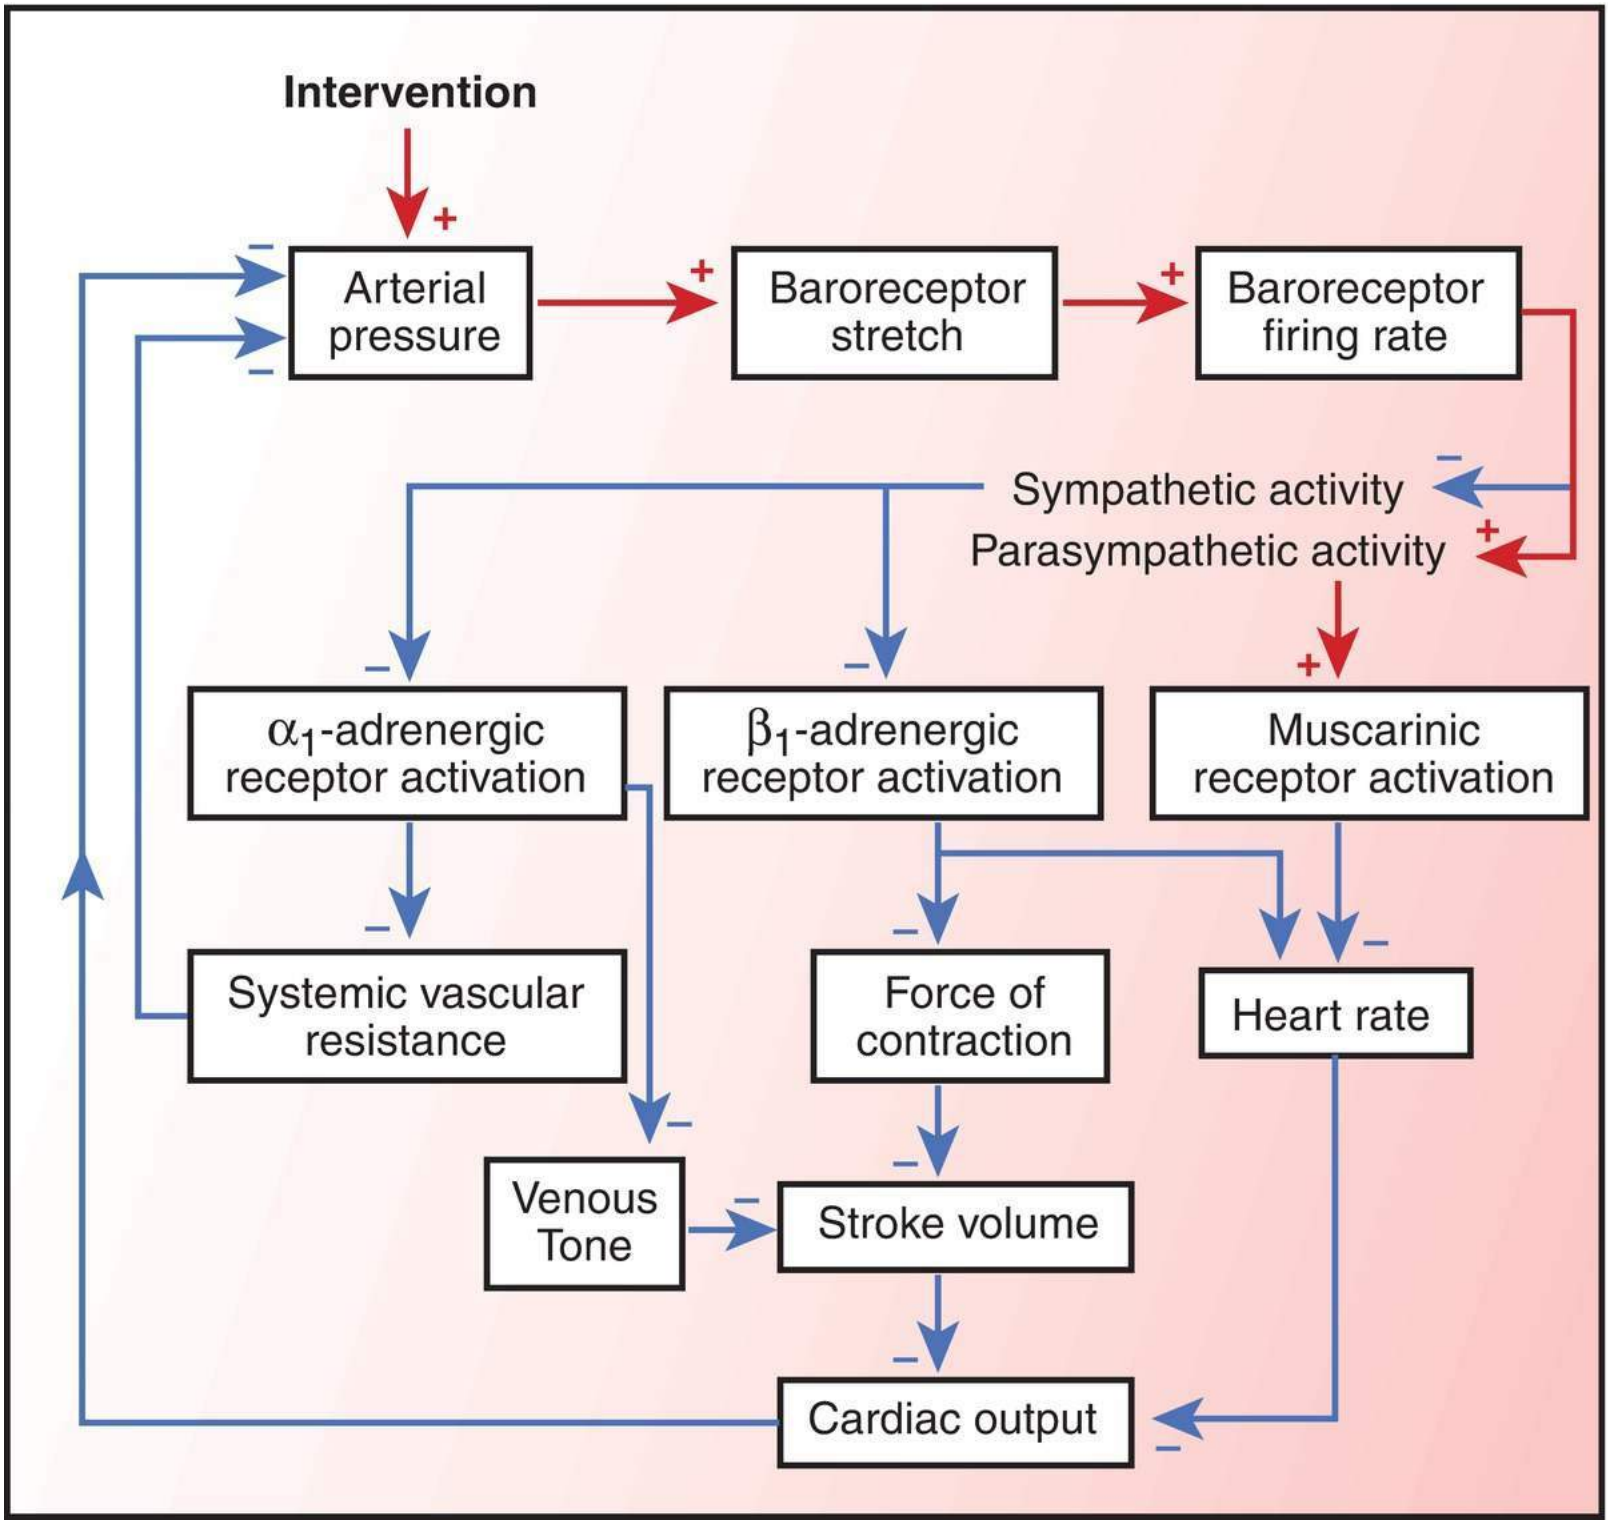

Figure 17.2 Baroreceptor neural reflex responses to increased arterial pressure. An intervention that elevates arterial pressure (either mean arterial pressure or pulse pressure), stretches the baroreceptors, and initiates the reflex. The resulting reduced systemic vascular resistance and cardiac output return arterial pressure toward the level existing before the intervention. Hormonal responses (not shown in the figure) involving adrenal epinephrine and the renin–angiotensin system are also involved in the reflex but more so as a response to hypotension rather than to hypertension. *Red* (+) *arrows* signify that an increase in the variable at the *arrow tail* leads to an increase in the variable at the *arrowhead* (and a decrease at the tail leads to a decrease at the head). *Blue* (−) *arrows* signify that a decrease in the variable at the *arrow tail* leads to a decrease in the variable at the *arrowhead*.

Stimulation of baroreceptor nerves stimulates the vasodepressor area and the cardioinhibitory area

while depressing the cardiostimulatory area. The net effect of an increase in BP in the carotid sinus and/or aortic arch, therefore, is to reflexively decrease peripheral vascular resistance, venous tone, heart rate, and ventricular contraction. The combined effects on the veins and heart reduce cardiac output, which, when combined with the decreased SVR, reduces blood pressure back toward normal levels. This completes a negative feedback loop by which an increase in mean arterial pressure can be attenuated and returned to normal. Conversely, decreases in arterial pressure (and decreased stretch of the baroreceptors) increase sympathetic neural activity and decrease parasympathetic neural activity, resulting in increased heart rate, stroke volume, and SVR; this increases blood pressure toward the normal level. If the fall in mean arterial pressure is large, increased sympathetic neural activity to veins is added to the above responses, causing contraction of the venous smooth muscle and reducing venous compliance. Decreased venous compliance shifts blood toward the central circulation thereby increasing right atrial pressure, which increases stroke volume.

The neural reflex activation of the cardiovascular system in response to changes in mean arterial pressure in order to maintain that pressure within narrow limits is called the **baroreceptor reflex**. This reflex is extremely sensitive; the firing rate from nerves exiting the baroreceptors can sense changes in arterial pressure as little as 0.001 mm Hg. These receptors also respond rapidly to the rate of rise in arterial pressure and changes in pulse pressure; firing rate is greater in systole compared to diastole and greater early rather than later in systole. Increased pulse pressure will activate baroreceptor firing even in the absence of a change in mean arterial pressure.

The baroreceptor reflex also activates hormonal systems affecting blood pressure.

In addition to its effects on autonomic neural outflow to the heart and blood vessels, the baroreceptor reflex modifies the level of hormones that affect arterial pressure. Its most important influence is on the **renin–angiotensin–aldosterone system** (**RAAS**). Decreased baroreceptor firing from decreased systemic arterial pressure results in increased sympathetic nerve activity to the kidneys, which, through activation of renal β_2 receptors, causes the kidneys to release renin. Renin converts a precursor peptide, formed in the liver, called angiotensinogen into the peptide angiotensin I. Angiotensin I is then enzymatically cleaved by **angiotensin-converting enzyme (ACE)** in the pulmonary endothelium to produce an active peptide called **angiotensin II**. In addition to neurogenic effects on renal release of renin, a reduction in arterial pressure in the renal artery, specifically in the afferent arteriole, also stimulates renin release. Finally, renin release is stimulated by a systemic decrease in plasma sodium concentration. Angiotensin II is a potent vasoconstrictor and stimulates the release of a steroid hormone called **aldosterone** from the adrenal gland, which causes the kidney to reabsorb salt and water. Activation of RAAS increases vascular resistance and blood volume, ultimately causing blood pressure to rise. The details of the renin–angiotensin–aldosterone system (RAAS) are discussed later in this chapter and in Chapter 23.

Information on the firing rate of the baroreceptors is also projected to the paraventricular nucleus of the hypothalamus, where the release of **arginine vasopressin** (**AVP**; also called **antidiuretic hormone** or **ADH**) by the posterior pituitary is controlled (see Chapter 23 for more detail). AVP release is increased by a decrease in circulating plasma volume, which decreases the firing rate or atrial low-pressure baroreceptors. AVP is a vasoconstrictor that also activates vasopressin receptors in the kidney to cause an increase in renal reabsorption of water, which in turn increases blood volume. An increase in arterial pressure causes decreased AVP release and increased excretion of water by the kidneys. Hormonal effects on salt and water balance and, ultimately, on cardiac output and blood pressure are powerful, but they occur more slowly (a timescale of many hours to days) than neurogenic effects, which work in seconds to minutes.

Baroreceptor activation is site-, pressure-, and time-dependent.

The effective range of the carotid sinus baroreceptor mechanism is ~40 mm Hg (when the receptor stops firing) to 180 mm Hg (when the firing rate reaches a maximum) (Fig. 17.3). Aortic baroreceptors initiate activation at about 70 mm Hg and reach maximum firing at a higher pressure.

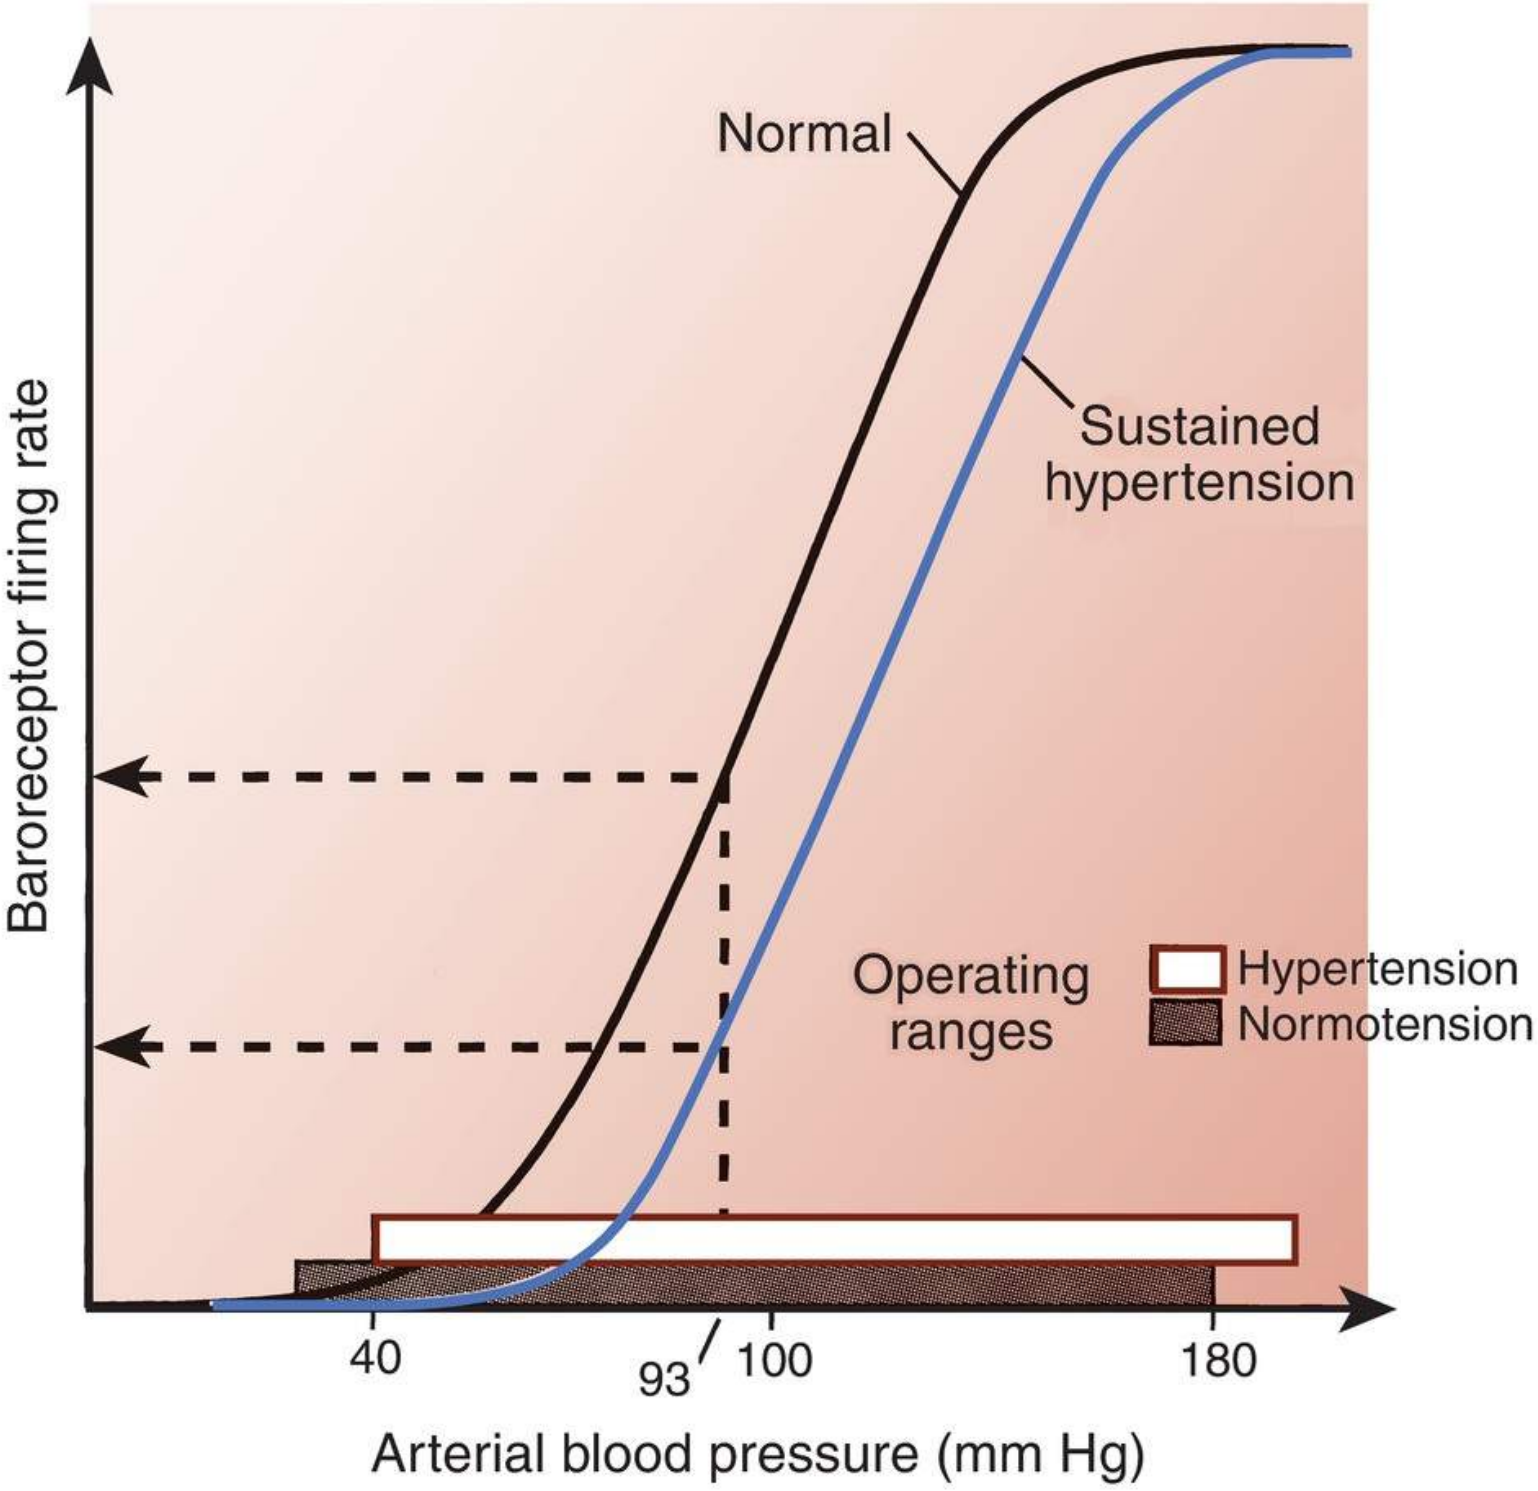

Figure 17.3 Carotid sinus baroreceptor nerve firing rate and mean arterial pressure. With normal conditions, a mean arterial pressure of 93 mm Hg is near the midrange of the firing rates for the nerves. Sustained hypertension causes the operating range to shift to the right, putting 93 mm Hg at the lower end of the firing range for the nerves. Aortic baroreceptors show similar relationships, except the point at

which pressure activates the receptor and reaches maximum response is higher than that seen in carotid receptors (not shown).

An important property of the baroreceptor reflex is that it adapts during a period of 1 to 2 days to the prevailing mean arterial pressure. When the mean arterial pressure is suddenly raised, baroreceptor firing increases. If arterial pressure is held at the higher level, baroreceptor firing declines during the next few seconds. Firing rate then continues to decline more slowly until it returns to the original firing rate over the next 1 to 2 days. Consequently, if the mean arterial pressure is maintained at an elevated level, the tendency for the baroreceptors to initiate a decrease in cardiac output and SVR quickly disappears. This occurs, in part, because of a reduction in the rate of baroreceptor firing for a given mean arterial pressure (see Fig. 17.3). This is an example of **receptor adaptation**. A "resetting" of the reflex in the central nervous system (CNS) occurs as well.

The baroreceptor mechanism can be viewed as a "first line of defense" in the maintenance of normal blood pressure; it makes possible the rapid control of blood pressure needed with changes in posture or acute blood or water loss. However, this control mechanism does not provide for the long-term control of blood pressure.

Baroreceptor reflex in the preservation of cerebral and coronary blood flow during hypotension

By contributing to the control of mean arterial pressure, the baroreceptor reflex indirectly functions to help secure blood flow to two vital organs: the heart and brain. The increase in SVR caused by activation of the baroreceptor reflex whenever arterial pressure drops does not include sympathetic arterial constriction in the heart and brain. The combination of a minimal or no vasoconstrictor effect of sympathetic nerves on cerebral blood vessels and a robust autoregulatory response keep brain blood flow nearly normal despite modest decreases in arterial pressure (see Chapter 15). Activation of sympathetic nerves to the heart causes β_2-adrenergic receptor–mediated dilation of coronary arterioles and β_1-adrenergic receptor–mediated increases in cardiac muscle metabolism (see Chapter 16). The net effect is a marked increase in coronary blood flow. In summary, when arterial pressure drops, the generalized vasoconstriction caused by the baroreceptor reflex restores blood pressure without vasoconstricting the brain and heart. This, coupled with strong local autoregulatory capacity, prevents, within limits, a reduction in blood flow in the heart and brain whenever blood pressure falls.

Cardiopulmonary baroreceptors sense central blood volume.

Cardiopulmonary baroreceptors are located in the cardiac atria, at the junction of the great veins and atria, in the ventricular myocardium, and in pulmonary vessels. Their nerve fibers run in the vagus nerve to the NTS, with projections to supramedullary areas as well. Unloading (i.e., decreasing the stretch) of the cardiopulmonary receptors by reducing central blood volume results in increased sympathetic nerve activity to the heart and blood vessels and decreased parasympathetic nerve activity to the heart. In addition, the cardiopulmonary reflex interacts with the baroreceptor reflex. Unloading of the cardiopulmonary receptors enhances the baroreceptor reflex, and loading the cardiopulmonary receptors, by increasing central blood volume, inhibits the baroreceptor reflex. Like the arterial baroreceptors, decreased stretch of the cardiopulmonary baroreceptors activates the RAAS and increases the release of AVP; this latter effect plays a role in regulating plasma volume whenever there are significant losses in plasma (~15%).

Chemoreceptors for PCO_2, pH, and PO_2 affect mean arterial pressure.

The **carotid** and **aortic bodies** are specialized structures located in the areas of the carotid sinus and aortic arch that sense changes in blood O_2, CO_2, and pH. These structures are sometimes referred to as **chemoreceptors**. The carotid and aortic chemoreceptors are primarily involved with control of ventilation (see Chapter 21), but they also affect the cardiovascular system through neurogenic reflexes. Peripheral chemoreceptors send impulses to the NTS and increase firing rate when the PO_2 or pH of the arterial blood is low, the PCO_2 of arterial blood is increased, or the flow through the bodies is low or stopped. There are also central medullary chemoreceptors that increase their firing rate primarily in response to elevated arterial PCO_2, which likely reflects a response to a decrease in pH in the brain.

The increased firing of both peripheral and central chemoreceptors leads to profound peripheral vasoconstriction that significantly elevates arterial pressure. If respiratory movements are voluntarily stopped, the vasoconstriction is more intense and a striking bradycardia and decreased cardiac output occur. This response pattern is typical of the diving response (discussed later). As in the case of the baroreceptor reflex, the coronary and cerebral circulations are not subject to sympathetic vasoconstrictor effects and instead exhibit vasodilation as a result of the combination of the direct effect of the abnormal blood gases and local metabolism.

In addition to its importance when arterial blood gases are abnormal, the chemoreceptor reflex is important in the cardiovascular response to severe hypotension. As blood pressure falls, blood flow through the carotid and aortic bodies decreases and chemoreceptor firing increases, probably because of changes in local PCO_2, pH, and PO_2. The chemoreceptor reflex, however, does not respond to a change in blood pressure itself until mean arterial pressure drops to about 80 mm Hg. Therefore, this reflex is not involved in maintenance of normal blood pressure on a moment-to-moment basis but rather serves as a secondary emergency reflex if blood pressure continues to fall in spite of activation of the baroreceptor reflex.

Pain and myocardial ischemia initiate cardiovascular reflexes.

Two reflex cardiovascular responses to pain occur. In the most common reflex, pain causes increased sympathetic activity to the heart and blood vessels, coupled with decreased parasympathetic activity to the heart. These events lead to increases in cardiac output, SVR, and mean arterial pressure. An example of this reaction is the **cold pressor response**, which is the elevated blood pressure that normally occurs from pain associated with placing an extremity in ice water. The increase in blood pressure produced by this challenge is exaggerated in several forms of hypertension.

A second type of response is produced by deep pain. The stimulation of deep pain fibers associated with crushing injuries, disruption of joints, testicular trauma, or distention of the abdominal organs results in diminished sympathetic activity and enhanced parasympathetic activity with decreased cardiac output, SVR, and blood pressure. This hypotensive response contributes to cardiovascular shock from severe trauma (see below).

Myocardial ischemia in the posterior and inferior myocardium causes reflex bradycardia and hypotension. The bradycardia results from increased parasympathetic tone. Dilation of systemic arterioles and veins in this situation is caused by withdrawal of sympathetic tone. This response mimics that following an injection of bradykinin, 5-hydroxytryptamine (serotonin), certain prostaglandins, or various other compounds into the coronary arteries supplying the posterior and inferior regions of the ventricles. This reflex is responsible for the bradycardia and hypotension that can occur in response to acute infarction of the posterior or inferior myocardium.

Higher-order ANS responses alter blood pressure and cardiac output.

The highest levels of organization in the ANS are the supramedullary networks of neurons with centers in the limbic cortex, amygdala, and hypothalamus. These supramedullary networks orchestrate cardiovascular responses to specific patterns of emotion and behavior by their projections to the ANS. Unlike the medulla, supramedullary networks do not contribute to the tonic maintenance of blood pressure, nor are they necessary for most cardiovascular reflexes. However, they do modulate reflex reactivity and can affect the behavior of the heart and systemic circulation.

Fear

On stimulation of certain areas in the hypothalamus, cats demonstrate a stereotypical rage response, with spitting, clawing, tail lashing, and back arching. This is accompanied by the autonomic fight-or-flight response described in Chapter 6. This reaction occurs naturally whenever the cat feels threatened and/or experiences fear. Cardiovascular responses include elevated heart rate and blood pressure. The initial behavioral pattern during the fight-or-flight response includes increased skeletal muscle tone and general alertness. There is increased sympathetic neural activity to blood vessels and the heart. The result of this cardiovascular response is an increase in cardiac output (by increasing both heart rate and stroke volume), SVR, and arterial pressure. There is some evidence that sympathetic cholinergic fibers to the muscle arteries elicit a neurogenic vasodilation in skeletal muscles in lower placental mammals like cats and dogs. However, whether these fibers exist in humans is questionable and it is believed that skeletal muscle vasodilation in the pre-exercise phase of fight-or-flight scenarios in humans is likely due to extraneuronal cholinergic mechanisms that stimulate NO release from the arterial endothelium. When the fight-or-flight response is consummated by actual fight or flight, arterioles in skeletal muscle dilate because of accumulation of local metabolites from the exercising muscles. This vasodilation may outweigh the sympathetic vasoconstriction in other organs, and SVR may actually fall. With a fall in SVR, mean arterial pressure returns toward normal despite the increase in cardiac output.

Emotional stress

Emotional situations often provoke the fight-or-flight response in humans, but it is usually not accompanied by muscle activity and vasodilation (e.g., medical students taking an examination). The massive vasodilation in skeletal muscle associated with exercise, which helps prevent an elevation of blood pressure upon activation of the sympathetic nervous system, is lost when the system is activated by emotional stress alone. For this reason, it has been postulated that repeated elevations in arterial pressure caused by dissociation of the cardiovascular component of the fight-or-flight response from the muscular exercise component are harmful.

Certain emotional experiences induce **vasovagal syncope** (fainting). Stimulation of specific areas of the cerebral cortex can lead to a sudden relaxation of skeletal muscles, depression of respiration, and loss of consciousness. The cardiovascular events accompanying these somatic changes include profound parasympathetic-induced bradycardia and withdrawal of resting sympathetic vasoconstrictor tone. There is a dramatic drop in heart rate, cardiac output, and SVR. The resultant decrease in mean arterial pressure results in unconsciousness (fainting) because of lowered cerebral blood flow. Vasovagal syncope appears in lower animals as the “playing dead” response typical of the opossum.

Exercise

Exercise causes activation of supramedullary neural networks that inhibit the activity of the baroreceptor reflex. The inhibition of medullary regions involved in the baroreceptor reflex is called *central command*. Central command results in withdrawal of parasympathetic tone to the heart, with a resulting increase in heart rate and cardiac output. The increased cardiac output supplies the added requirement for blood flow to exercising muscle. As exercise intensity increases, central command adds sympathetic tone that further increases heart rate and contractility. It also recruits sympathetic vasoconstriction that redistributes blood flow away from splanchnic organs and resting skeletal muscle to exercising muscle. In addition, afferent impulses from exercising skeletal muscle terminate in the RVL, where they further augment sympathetic tone. In spite of augmentation of sympathetic activity during exercise, the local metabolic vasodilator influences in exercising muscle overwhelm any enhanced sympathetic activity to its arteries, resulting in a net vasodilation and hyperemia in the exercising muscle. During exercise, blood flow of the skin is largely influenced by temperature regulation and dilates with an increase in body temperature as described in Chapters 16, 28, and 29.

Diving response

The **diving response** is best observed in seals and ducks, but it also occurs in humans. An experienced diver can exhibit intense slowing of the heart rate (parasympathetic) and peripheral vasoconstriction (sympathetic) of the extremities and splanchnic regions when his or her face is submerged in cold water. With breath holding during the dive, arterial PO_2 falls and pH falls as PCO_2 rises. This activates the chemoreceptor reflex, which reinforces the diving response. The arterioles of the brain and heart do not constrict, and therefore, they preferentially receive the cardiac output. This heart–brain circuit makes use of the oxygen stored in the blood that would normally be used by the other tissues, especially skeletal muscle. Once the diver surfaces, the heart rate and cardiac output increase substantially; vasodilation replaces peripheral vasoconstriction, restoring nutrient flow and washing out accumulated waste products.

Behavioral conditioning

Cardiovascular responses can be conditioned. Both classical and operant conditioning techniques have been used to raise and lower the blood pressure and heart rate of animals. Humans can also be taught to alter their heart rate and blood pressure using a variety of behavioral techniques, such as biofeedback. Behavioral conditioning of cardiovascular responses has significant clinical implications. Animal and human studies indicate that psychological stress can raise blood pressure, increase atherogenesis, and predispose the person to fatal cardiac arrhythmias. These effects are thought to result from activation of the fight-or-flight response in the absence of actual muscle activity. Other studies have shown beneficial effects of behavior patterns designed to introduce a sense of relaxation and well-being such as meditation. Some clinical regimens have employed these factors in the management of cardiovascular disease as an adjunct to pharmacotherapies.

Baroreceptor override

Supramedullary responses can override the baroreceptor reflex. For example, the fight-or-flight response causes the heart rate to rise above normal levels despite a simultaneous rise in arterial pressure. In such circumstances, the neurons connecting the hypothalamus to medullary areas inhibit the baroreceptor reflex and allow the corticohypothalamic response to predominate. Also, during exercise, input from supramedullary regions inhibits the baroreceptor reflex, promoting increased sympathetic tone and

decreased parasympathetic tone despite an increase in arterial pressure. Moreover, the various cardiovascular response patterns do not necessarily occur in isolation, as previously described. Many response patterns interact, reflecting the extensive neural interconnections between all levels of the CNS and interaction with various elements of the local control systems. For example, the baroreceptor reflex interacts with thermoregulatory responses. Cutaneous arterial tone is totally dependent on the activity of sympathetic nerves to the arteries and veins in the skin; local, nonneurogenic, regulatory control is minor or absent in the cutaneous circulation. This circulation participates in body temperature regulation but also serve the baroreceptor reflex. At moderate levels of heat stress, the baroreceptor reflex can cause cutaneous arteriolar and venule constriction, to support arterial blood pressure, despite elevated core temperature. However, with severe heat stress, the baroreceptor reflex cannot overcome the neurogenic cutaneous vasodilation; as a result, arterial pressure regulation may fail.

HORMONAL CONTROL OF THE CARDIOVASCULAR SYSTEM

As introduced earlier in this chapter, various hormones play a role in the control of the cardiovascular system. Important hormonal control mechanisms involved in cardiovascular homeostasis include epinephrine from the adrenal medulla, AVP (ADH) from the posterior pituitary gland, renin from the kidney, and ANP from the cardiac atrium.

Circulating epinephrine exerts different cardiovascular effects from those caused by sympathetic nerves.

When the sympathetic nervous system is activated, the adrenal medulla releases epinephrine (>90%) and NE (<10%) into the bloodstream. Changes in the circulating NE concentration from medullary release are small relative to changes in NE resulting from the direct release from nerve endings close to vascular smooth muscle and cardiac cells. Increased circulating epinephrine, however, is significant and contributes to skeletal muscle vasodilation during the fight-or-flight response and exercise. In these cases, epinephrine binds to β_2-adrenergic receptors of skeletal muscle arteriolar smooth muscle cells and causes vasorelaxation. In the heart, circulating epinephrine binds to cardiac cell β_1-adrenergic receptors and reinforces the effect of NE released from sympathetic nerve endings to increase myocardial contractility (and thus SV) and heart rate, which together increase cardiac output.

A comparison of the responses to infusions of low concentrations of epinephrine and NE illustrates not only the different effects of the two hormones but also the different reflex response each one elicits (Fig. 17.4). Epinephrine and NE have similar direct positive inotropic and chronotropic effects on the heart, but NE elicits a powerful baroreceptor reflex because it causes significant systemic vasoconstriction that increases SVR and thus mean arterial pressure. The increased arterial pressure reflexively increases parasympathetic tone to the heart, which significantly decreases heart rate and masks some of the direct cardiac effects of NE. The net effect of the cardiovascular systems response to NE is to create little change in cardiac output while increasing SVR along with systolic, diastolic, and mean arterial pressure (i.e., a pressor response). In contrast, low concentrations of epinephrine cause vasodilation in skeletal muscle and splanchnic beds because it preferentially activates the β_2 over the α_1-adrenoceptors on the arterial system of those vascular beds. SVR may actually fall, but the cardiac output increases and mean arterial pressure does not rise. Consequently, the baroreceptor reflex is not elicited, parasympathetic tone to the heart is not increased, and the direct effects of epinephrine to increase heart rate and myocardial contractility are evident. At high concentrations, epinephrine binds to α_1-adrenergic receptors and causes peripheral vasoconstriction; this level of epinephrine is probably never reached except when it is administered as a drug.

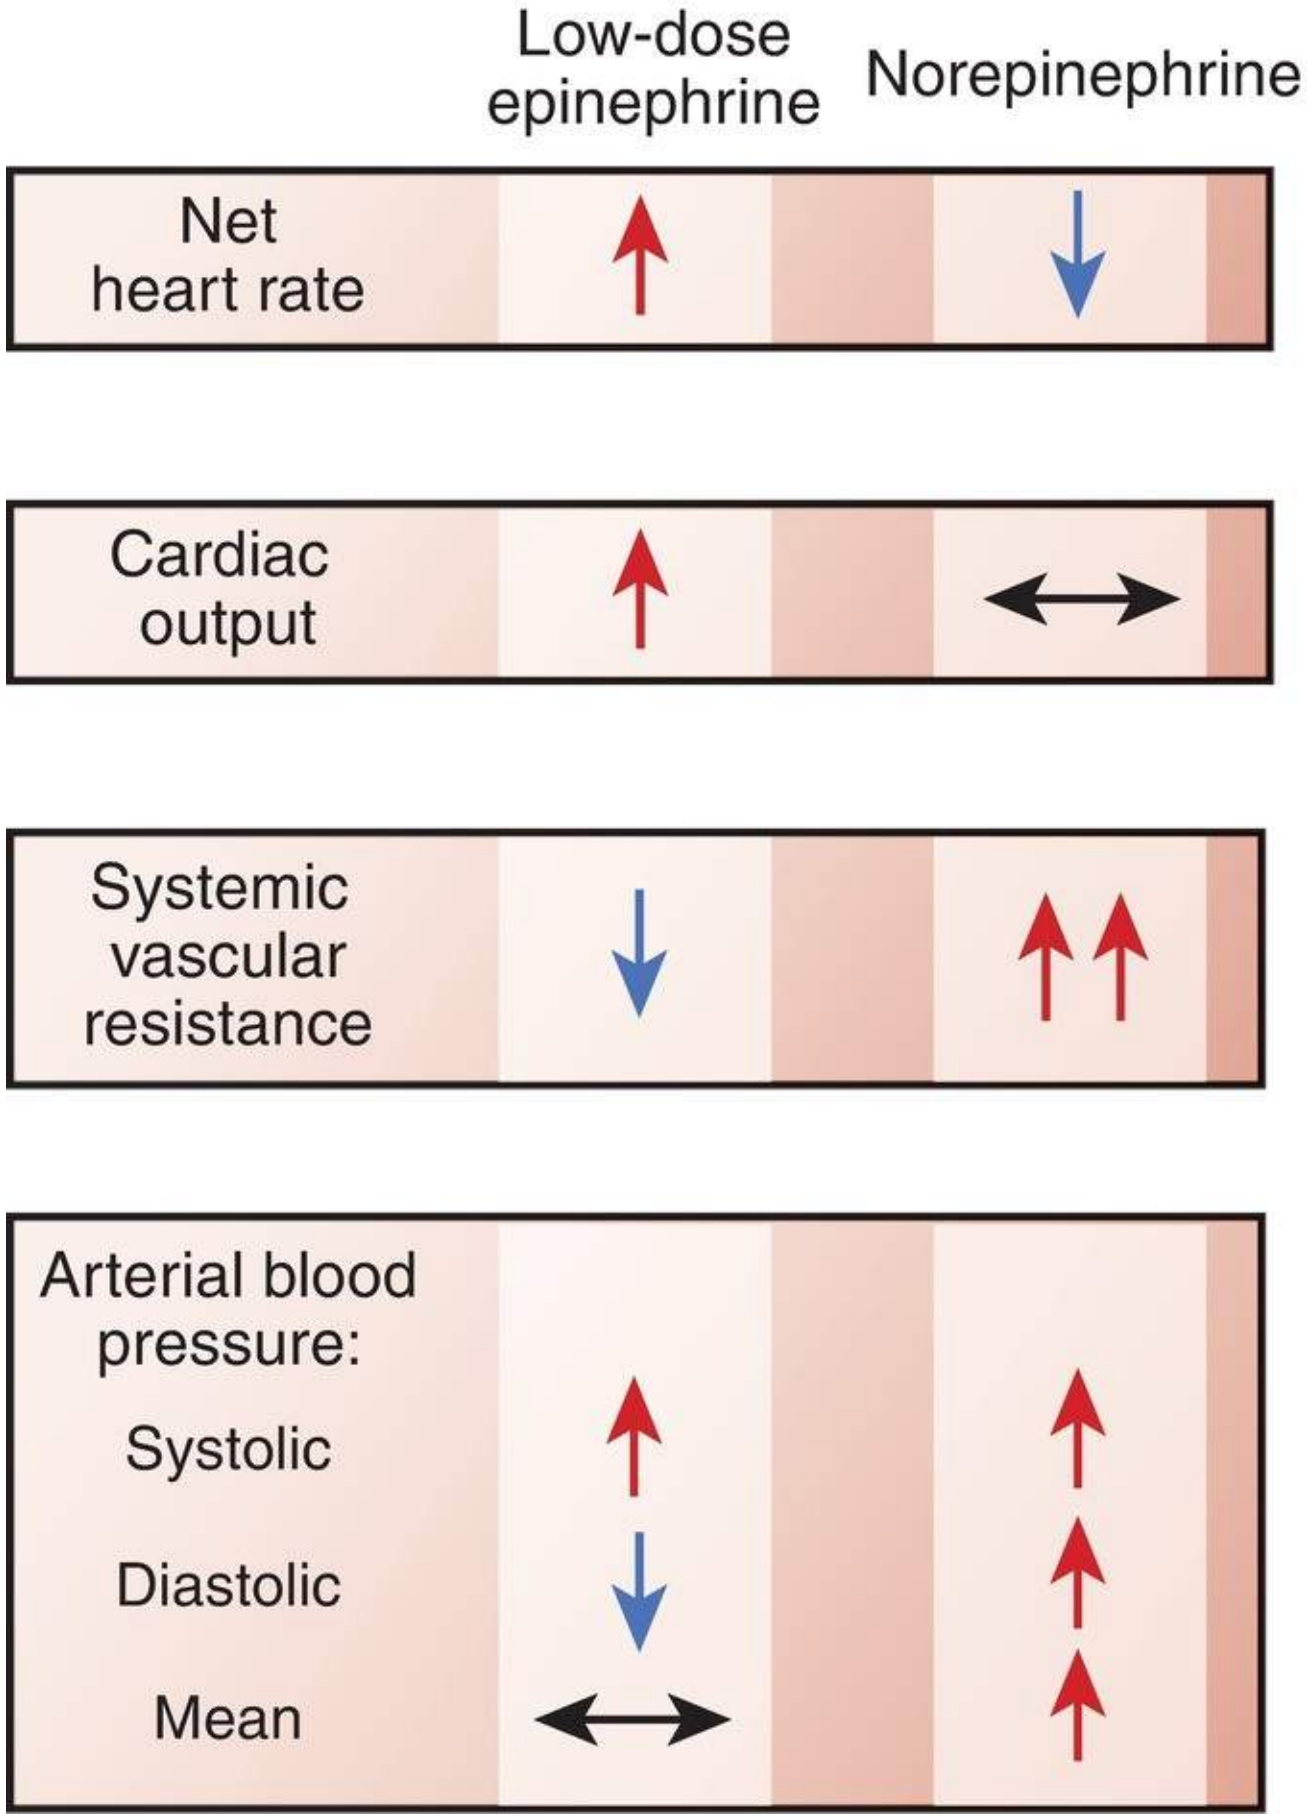

Figure 17.4 A comparison of the effects of intravenous infusions of low concentrations of epinephrine and norepinephrine. ↑, increase; ↓, decrease; ↔, no change; ↑↑, marked increase.

Denervated organs, such as transplanted hearts, are hyperresponsive to circulating levels of epinephrine and NE. This increased sensitivity to neurotransmitters is referred to as **denervation**

hypersensitivity. Several factors contribute to denervation hypersensitivity, including the absence of sympathetic nerve endings to take up circulating NE and epinephrine actively, leaving more transmitter available for binding to receptors. In addition, denervation results in upregulation of neurotransmitter receptors in target cells. This situation occurs in transplanted hearts, which are denervated because they have to be removed from a donor. During exercise, circulating levels of NE and epinephrine increase. A transplanted heart cannot get direct inotropic benefit from sympathetic nerves to the heart; they have none. However, because of denervation hypersensitivity, transplanted hearts exhibit enhanced responsiveness to circulating catecholamines, which allow them to perform almost as well as normal hearts.

CLINICAL FOCUS 17.1

Nitric Oxide in Cardiovascular Disease

The vascular endothelial nitric oxide (NO) system is responsible for some of the most important and beneficial functions involved with the maintenance and health of the cardiovascular system. Its intense vasodilatory effect antagonizes arterial spasm that might otherwise restrict organ blood flow while it also prevents significant resting hypertension. It has antithrombotic (antiplatelet aggregation) and antiatherogenic properties, attenuates ischemia–reperfusion injury, and suppresses smooth muscle growth after vascular injury while stimulating endothelial wound healing. In addition, it chemically quenches superoxide (O_2^-), which can cause extensive vascular damage.

It is reasonable to postulate that the endothelial NO system might be recruited by the cardiovascular system to counteract the effects of various cardiovascular diseases. Unfortunately, the endothelial NO system has been shown to be impaired in all forms of cardiovascular disease, including acute and chronic hypertension, hyperlipidemia and atherosclerosis, diabetes mellitus, ischemic injury, stroke, vascular transplantations, and heart failure.

As a result of an impaired NO system, people with cardiovascular disease are left with a cardiovascular system that is prone to vascular spasm and hypertension, thrombosis, atherosclerosis, and stenosis from abnormal vascular wall growth following arterial injury. In addition, NO from the endothelium cannot abate the presence of oxygen radicals, or reactive oxygen species, in the vasculature. Such radicals, which arise from extravascular and intravascular sources, are overproduced in all cardiovascular disease. The enzyme NADP oxidase appears to be a prime source of the radicals. Exposure of vessels to reactive oxygen species damages the arterial endothelium and converts NO synthase to a form that makes oxygen radicals from L-arginine instead of NO.

NO itself seems to be able to attenuate ischemia–reperfusion injury, but widespread use of nitrates as substitutes for endogenous NO has not proven effective in treating many cardiovascular diseases. Instead, additional therapies are being directed to combat the effects of reactive oxygen species on the vasculature. Attenuation of these effects may cause the vascular endothelium to sustain less damage, thereby enhancing their ability to produce NO while at the same time improving the bioavailability of NO to the arterial smooth muscle by removing chemical species that quench any NO produced. ■

Renin–angiotensin–aldosterone system supports blood pressure and volume.

The control of total blood volume is involved in regulating arterial pressure. Because changes in total blood volume lead to changes in central blood volume, changes in total blood volume alter ventricular end-diastolic volume and cardiac output, which in turn can alter arterial pressure. Hormonal control of blood volume depends on hormones that regulate salt and water balance as well as red blood cell formation.

Reduced arterial pressure and reduced blood volume cause the release of **renin** from the kidneys. Renin release is mediated by the sympathetic nervous system and by the direct effect of lowered arterial pressure within the afferent arterioles of the kidneys. Renin is a proteolytic enzyme that catalyzes the conversion of angiotensinogen, a plasma protein, to angiotensin I, which, in turn, is converted to angiotensin II in the lung by **angiotensin-converting enzyme (ACE)** (Fig. 17.5). Renin is released during blood loss, even before blood pressure falls, and the resulting rise in plasma angiotensin II from renin release increases the SVR.

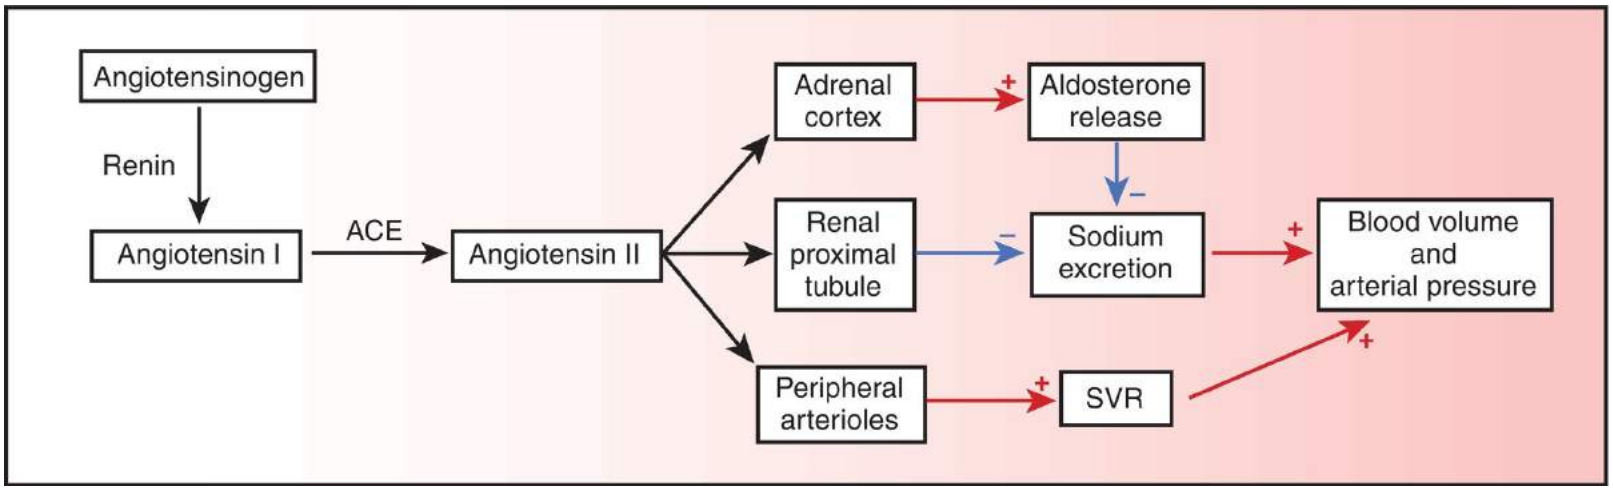

Figure 17.5 The renin–angiotensin–aldosterone system (RAAS). This system plays an important role in the regulation of arterial blood pressure and blood volume. Angiotensin II stimulates receptors in the adrenal cortex to produce aldosterone, the renal proximal tubule to promote sodium reabsorption, and arterial smooth muscle to cause vasoconstriction. *Red* (+) *arrows* signify that an increase in the variable at the *arrow tail* leads to an increase in the variable at the *arrowhead* (and a decrease at the tail leads to a decrease at the head). *Blue* (−) *arrows* signify that an increase in the variable at the *arrow tail* leads to a decrease in the variable at the *arrowhead* (and a decrease at the tail leads to an increase at the head). ACE, angiotensin-converting enzyme; SVR, systemic vascular resistance.

Angiotensin II elevates arterial pressure by the following actions: (1) it is a powerful direct arteriolar vasoconstrictor. In some circumstances, it is present in plasma in concentrations sufficient to increase SVR; (2) it potentiates the vasoconstrictive effects of the sympathetic nervous system on blood vessels by enhancing NE release from sympathetic nerve endings, reducing neuronal reuptake of NE, and sensitizing vascular smooth muscle to the actions of NE; (3) it causes the release of **aldosterone** from the adrenal cortex, which in turn promotes sodium reabsorption in the distal convoluted tubules of the kidney; (4) it reduces sodium excretion by increasing sodium reabsorption by proximal tubules of the kidney; (5) it

causes the release of AVP from the posterior pituitary gland, which both promotes water reabsorption from the collecting ducts of the kidney and directly causes systemic arterial vasoconstriction; and (6) it stimulates thirst to promote ingestion of water. Thus, the RAAS promotes elevation of arterial pressure by rapid effects to increase SVR and longer-term effects to promote increases in circulating blood volume through retention of sodium in the body (which indirectly leads to water retention), a reduction in water excretion, and a stimulation of water intake by stimulating thirst.

The RAAS is activated by pathophysiological states.

The RAAS is also involved as a common cause of secondary hypertension (i.e., an increased blood pressure that occurs secondary to a primary pathological condition). Renal artery stenosis, most commonly resulting from atherosclerotic plaques that encroach on the lumen of the main renal arteries, reduces afferent arteriolar pressure in the kidney. This activates the RAAS resulting in elevated renin and angiotensin II levels, which raise arterial pressure.

In patients with congestive heart failure, the reduced output of the failing heart activates the RAAS and increases plasma renin and angiotensin II concentrations. AII stimulates sodium and thus water retention in the body, which augments central venous pressure. This represents the body's attempt to compensate for a failing heart by augmenting ventricular preload to increase output via Starling's law of the heart. However, this action of the RAAS also creates pulmonary edema and congestion as well as an elevation of SVR. This latter effect impairs stroke output of the heart. More importantly, chronic activation of the RAAS stimulates malignant ventricular remodeling resulting in a dilated heart and increased ventricular wall stress. Over time, this leads to a vicious cycle of progressive heart failure. Recognition of the role of RAAS in progressive heart failure has led to the successful use of drugs that inhibit this system as a means of treating all levels of heart failure.

The RAAS also plays a critical role when salt and water intake is reduced. Angiotensin II plays an important role in increasing SVR, as well as blood volume, in people on a low-salt diet. Consequently, if an ACE inhibitor is given to such people, blood pressure falls.

Arginine vasopressin primarily regulates blood volume.

AVP (also called antidiuretic hormone or ADH) is released by the posterior pituitary gland controlled by the hypothalamus. AVP is released by increased plasma osmolality, decreased baroreceptor and cardiopulmonary receptor firing (i.e., from a decrease in plasma volume), and various types of stress, such as physical injury or surgery. In addition, circulating angiotensin II stimulates AVP release and excess AVP is secreted by lung cancer cells. Although AVP is a vasoconstrictor, it is not ordinarily present in plasma in high enough concentrations to exert an effect on blood vessels. However, in special circumstances (e.g., severe hemorrhage), it probably contributes to increased SVR in support of blood pressure. AVP exerts its major effect on the cardiovascular system by causing the retention of water by the kidneys, which is an important part of the neural/humoral mechanisms that regulate blood volume (see Chapter 23).

Stretch-activated release of atrial natriuretic peptide counteracts volume overload.

Atrial natriuretic peptide (ANP) is a 28-amino acid polypeptide that is synthesized and stored in the atrial muscle cells and released into the bloodstream when the atria are stretched. When central blood volume and atrial stretch are increased, ANP secretion rises, leading to higher sodium excretion and a reduction in blood volume (see Chapter 23). It also inhibits renin release as well as aldosterone and AVP secretion. The role of ANP in controlling blood volume appears to be important in submammalian sea-dwelling animals (e.g., fish), and its role in the day-to-day control of volume and pressure in the cardiovascular system is questionable. However, increased ANP (along with decreased aldosterone and AVP) may be partially responsible for the reduction in blood volume that occurs with prolonged bed rest. Furthermore, ANP is elevated in conditions associated with abnormal retention of fluid in the body such as that which occurs in congestive heart failure (CHF). ANP is known to exist in two subtypes, ANP-A and ANP-B. A blood test for the B type has been developed and is currently used to assess the severity of CHF with ANP-B levels positively correlated with the severity of CHF.

Renal hypoxia stimulates red blood cell production.

The final step in blood volume regulation is production of erythrocytes. **Erythropoietin** is a hormone released by the kidneys in response to either hypoxia or reduced hematocrit (which reduces the total oxygen content in the blood). This hormone causes bone marrow to increase production of red blood cells, raising the total mass of circulating red cells. This can occur when the individual breathes air with a low PO_2 (i.e., at high altitude) for long periods of time or following hemorrhage.

A reduced hematocrit can result not just from frank loss of red blood cells but also from dilution of the existing number of red blood cells in the circulation. For example, an increase in circulating AVP and aldosterone that enhances salt and water retention lowers (dilutes) the hematocrit. The decrease in hematocrit stimulates erythropoietin release, which stimulates red blood cell synthesis and, therefore, balances the increase in plasma volume with a larger red blood cell mass.

Short- and long-term blood pressure control involves different cardiovascular mechanisms.

Different mechanisms are responsible for the short-term and long-term control of blood pressure. Short-term control depends on activation of neurohumoral reflexes and systems as described earlier. A good example of short-term control of blood pressure occurs in the body's response to standing (Fig. 17.6). Upon standing, blood immediately pools in the peripheral veins. This pooling results in an initial decrease in cardiac output and blood pressure that activates neural mechanisms, primarily the baroreceptor reflex that rapidly restores cardiac output and mean arterial pressure. Standing also activates the low-pressure, volume-receptor control mechanisms involving AVP and ANP as well as the RAAS. These mechanisms are not critical in restoring pressure in the short term but can become important if the person is required to stand for long periods of time without moving. The activation of the RAAS on acute standing, however, can confound clinical measurements of plasma renin activity, leading to temporary increases in plasma renin levels that do not reflect the concentration of renin at rest. Therefore, such measurements are obtained with the patient in the supine position. In contrast to standing, contracting muscles in the lower limbs compresses veins and moves blood out of the periphery and into the central circulation thereby having a negative effect on peripheral venous pooling.

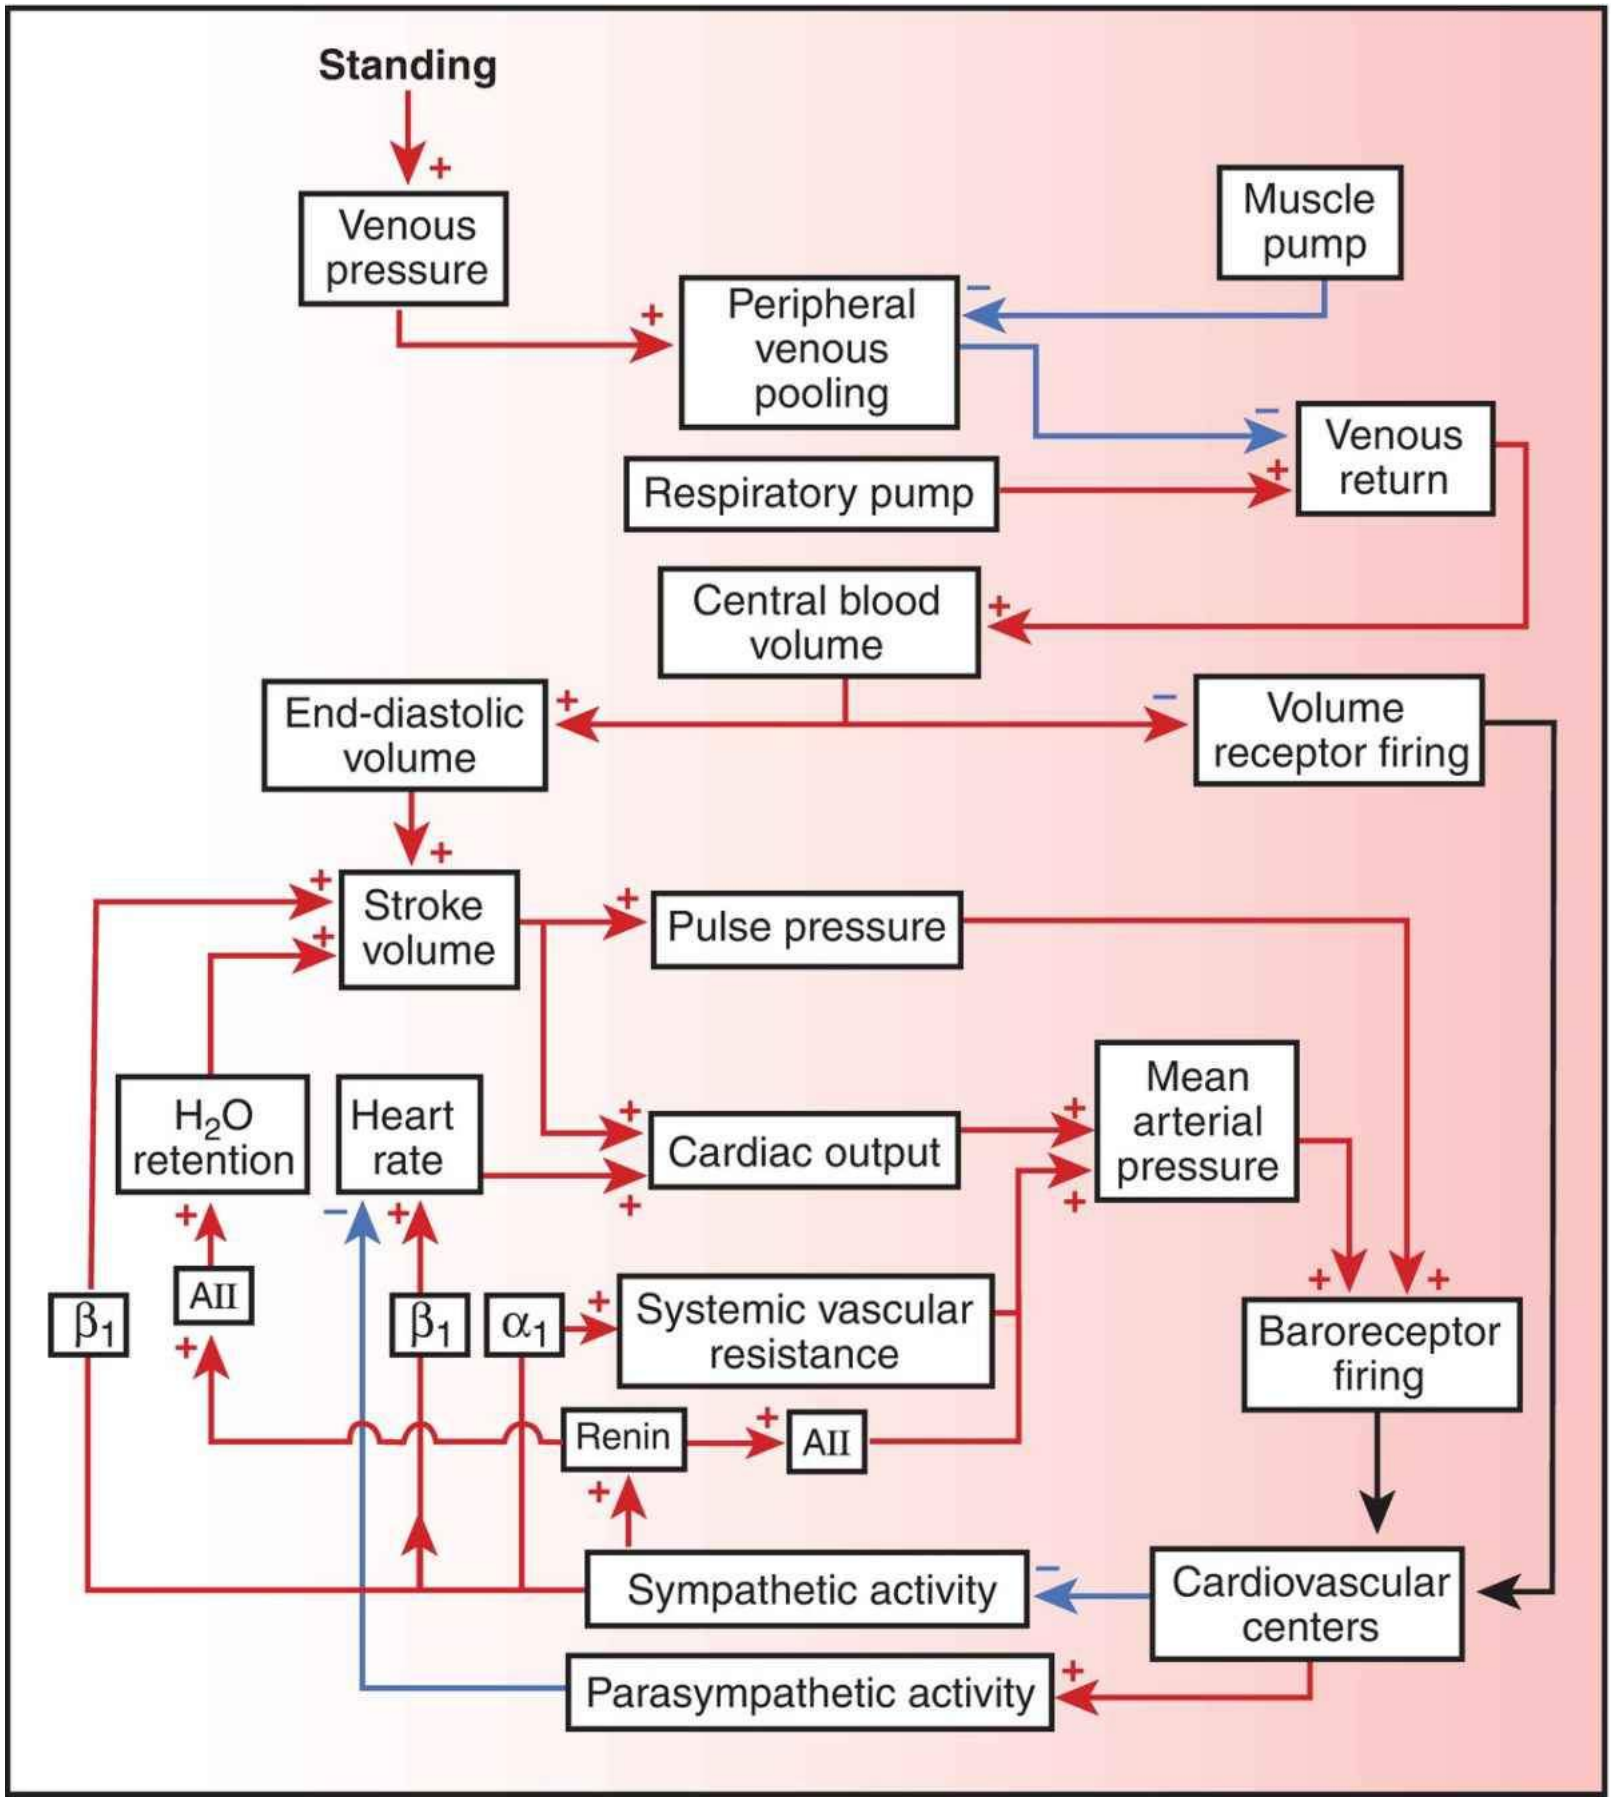

Figure 17.6 Cardiovascular events associated with standing. Enhanced venous pooling of blood, as with standing, reduces venous return and central blood volume, which leads to a series of events that reduce mean arterial pressure. Contraction of skeletal muscle (the muscle pump) and inhalation (the respiratory pump) enhance venous return and central blood volume, which enhance the flow output of the heart. *Red* (+) *arrows* signify that an increase in the variable at the *arrow tail* leads to an increase in the variable at the *arrowhead* (and a decrease at the tail leads to a decrease at the head). *Blue* (−) *arrows*

signify that an increase in the variable at the *arrow tail* leads to a decrease in the variable at the *arrowhead* (and a decrease at the tail leads to an increase at the head).

None of the neural and humoral mechanisms that are used by the body to control blood pressure in the short term seem to be involved in the long-term setting of mean arterial pressure. It appears that the kidney is responsible for setting the absolute level of mean arterial pressure, about which the neural/humoral mechanisms described above try to control on a moment-to-moment basis. The setting of mean arterial pressure and its long-term control depend on salt and water excretion by the kidneys. Although the excretion of salt and water by the kidneys is regulated by some of the neural and hormonal mechanisms mentioned earlier in this chapter, it is also regulated by arterial pressure. Increased arterial pressure results in increased excretion of salt and water. This phenomenon is known as **pressure diuresis**. As long as mean arterial pressure is elevated, salt and water excretion will exceed the normal rate because of pressure diuresis. Importantly, pressure diuresis persists until it lowers blood volume and cardiac output sufficiently to return mean arterial pressure to its original set level. A decrease in mean arterial pressure has the opposite effect on salt and water excretion; reduced pressure diuresis increases blood volume and cardiac output until mean arterial pressure is returned to its original set level.

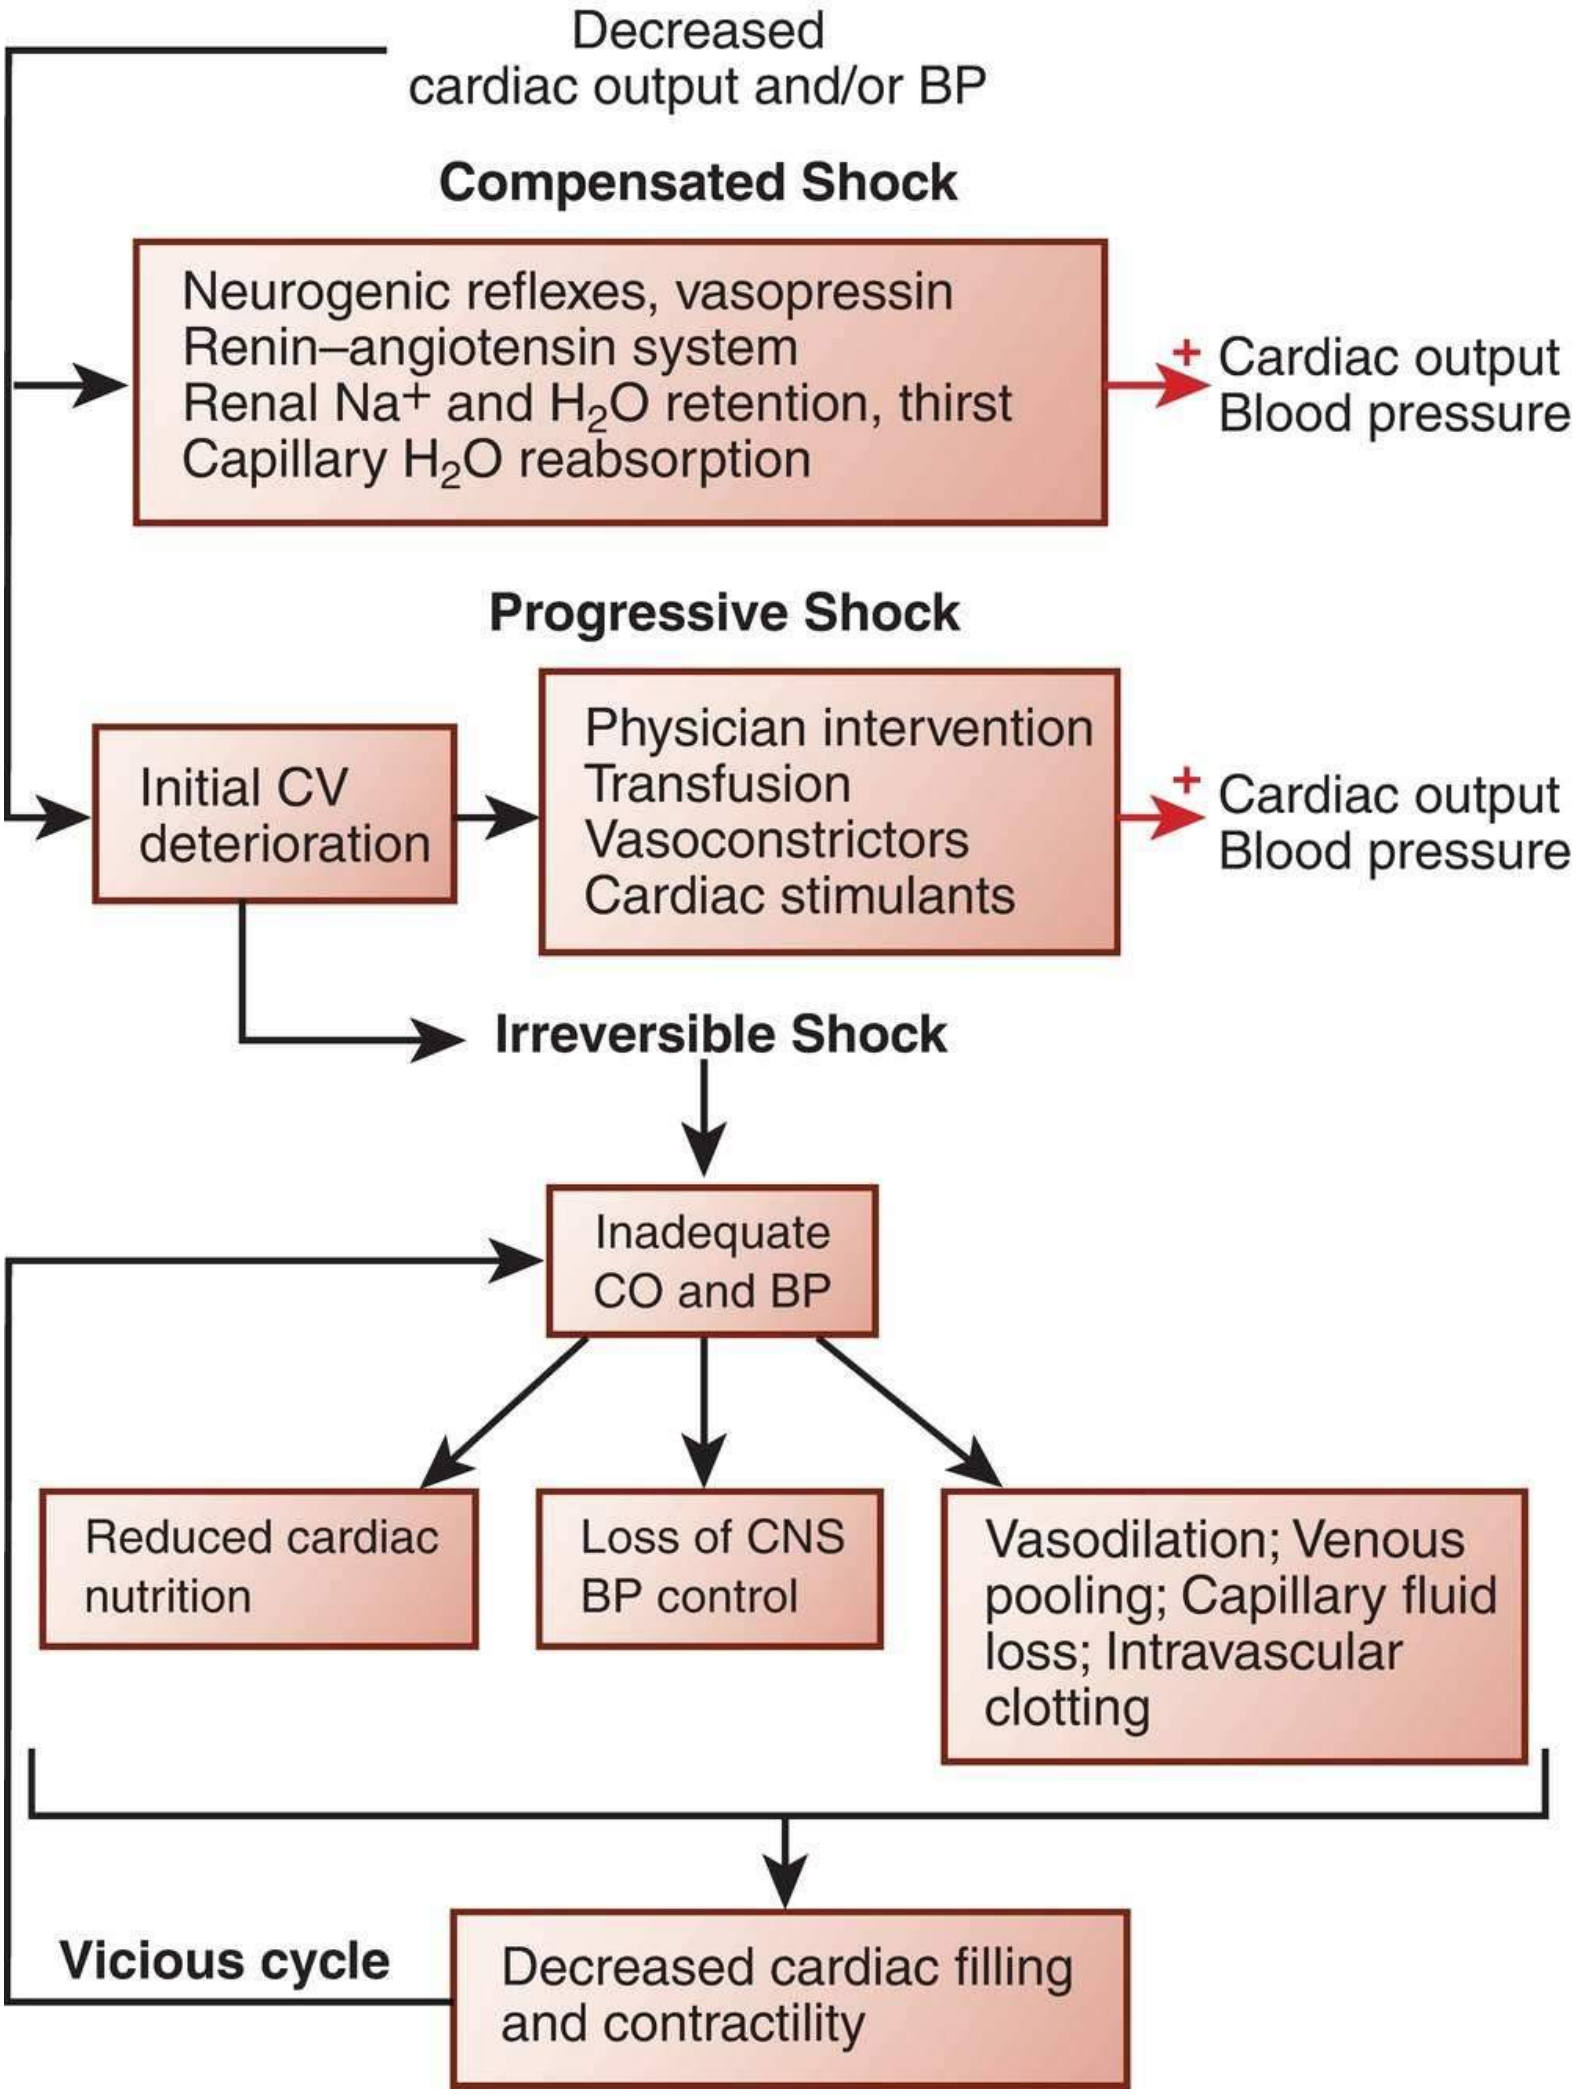
Pressure diuresis is a slow but persistent mechanism for regulating arterial pressure. It will eventually return pressure to its original set point. In hypertensive patients, salt and water excretion are normal, but at a higher arterial pressure. If this were not the case, pressure diuresis would inexorably bring arterial pressure back to normal.

CIRCULATORY SHOCK

Circulatory shock is a condition of generalized cardiovascular failure characterized by insufficient organ blood flow. It is also often accompanied by hypotension. This condition can result in deterioration of all tissues in the body and eventual death. In general, if shock is not corrected, it will result in impaired tissue oxygen delivery, generalized muscle weakness, renal failure, depressed mental function, or even unconsciousness. Decreased body temperature resulting from the effects of poor oxygen delivery on tissue metabolism is also a general characteristic of most forms of shock (except that resulting from sepsis; see below). The basic cause of shock is a loss of support of cardiac output. This may arise from direct cardiac dysfunction caused by myocardial ischemia, infarction, arrhythmias, etc., or from diminished venous filling pressure resulting from loss of whole blood, plasma volume, or venous tone.

Shock is divided into three stages of increasing severity.

Shock can be divided into three, progressively more serious stages, as diagrammed in Figure 17.7. The mildest form of shock is called *nonprogressive* or **compensated shock** because the normal cardiovascular regulatory mechanisms will compensate for the initial decrease in cardiac output and/or arterial pressure. These mechanisms will eventually lead to recovery of the person without the need for clinical intervention. The body's response after an individual donates a unit of blood is a common form of compensated shock.



Decreased
cardiac output and/or BP
Compensated Shock
Neurogenic reflexes, vasopressin
Renin–angiotensin system
Renal Na^+ and H_2O retention, thirst
Capillary H_2O reabsorption
+ Cardiac output
Blood pressure
Progressive Shock
Initial CV deterioration
Physician intervention
Transfusion
Vasoconstrictors
Cardiac stimulants
+ Cardiac output
Blood pressure
Irreversible Shock
Inadequate CO and BP
Reduced cardiac nutrition
Loss of CNS BP control
Vasodilation; Venous pooling; Capillary fluid loss; Intravascular clotting
Vicious cycle
Decreased cardiac filling and contractility

Figure 17.7 Mechanisms of circulatory shock. (See text for details.) BP, blood pressure; CNS, central nervous system; CO, cardiac output; CV, cardiovascular.

The compensatory mechanisms in nonprogressive shock are the same as those activated by an acute decrease in blood pressure. These include activation of baroreceptor and other neurogenic pressor reflexes, stimulation of the renin–angiotensin system, and release of AVP. These reflexes and hormones tend to increase blood pressure and cardiac output by increasing heart rate, myocardial contractility, and vascular resistance (especially in skin, splanchnic organs, skeletal muscle, and the kidney) while also promoting renal Na^+ and H_2O retention to increase central venous pressure and stroke volume. In addition, low arterial pressure and increased arterial resistance in the compensated stage of shock reduce capillary hydrostatic pressure. This augments fluid reabsorption from the interstitial fluid, especially in the intestine and kidney. Collectively, these compensatory mechanisms result in the initial clinical presentation of shock, which includes pale/cold skin, rapid pulse, sensation of thirst, hypotension, and reduced urine output.

CLINICAL FOCUS 17.2

Sex Steroids and Cardiovascular Disease in Women

With the exception of reproduction, the physiologic processes presented in most medical physiology textbooks often reflect the basic physiology of the healthy adult male. However, it is widely known that the incidence, morbidity, and mortality associated with cardiovascular disease are much lower in premenopausal women than in men of similar age. After menopause, however, whether surgically induced or from natural processes, women rapidly catch up to men such that by age 60 to 70, their incidence and mortality of cardiovascular disease are as great or greater than it is for men. Currently, cardiovascular disease is the number one source of mortality in women in the United States.

The difference in the prevalence of cardiovascular disease before and after menopause has led to the suggestion that estrogen is cardioprotective in women. Numerous studies and clinical trials have been conducted to investigate this possibility. However, evidence gathered on experimental animals versus that in women in clinical trials, especially in regard to hormone replacement therapy (HRT), has created conflicting insights into the role of estrogens and sex steroids in cardiovascular disease in women. In short, estrogen appears to stimulate the NO system in experimental animals and provide cardiovascular benefits, whereas such benefits appear to be absent in women given HRT. In fact, there is concern that HRT may exacerbate the incidence of morbid cardiovascular events in postmenopausal women. There is evidence that equine estrogens, other estrogens, or estrogen + progesterone combinations are prothrombotic and precipitate such events.

Estrogen has been shown to be a direct coronary vasodilatory. However, much early evidence to this effect showed that the direct dilatory actions of the steroid occur at dose of 1 μM or more and were thus highly nonphysiologic. Furthermore, other phenol-containing compounds such as plant polyphenolics as well as α-estradiol, the nonactive isomer of physiologically active β-estradiol, are also direct vasodilators at such concentrations. Nevertheless, work conducted over the last decade has

uncovered a membrane-bound G-protein–linked estrogen receptor on blood vessels and endothelial cells with some studies revealing that activation of these receptors can lead to vasodilation. More importantly, overnight exposure of coronary arteries to physiologic concentrations of estrogen (1 nM) has been shown to enhance NO-mediated vasodilation or bioavailability and enhance cell mechanisms that inactivate oxygen radicals. Such actions of estrogen would be favorable in reducing the incidence and severity of certain cardiovascular diseases in women.

Nevertheless, past clinical trials testing the effectiveness of hormone replacement therapy on cardiovascular outcomes in postmenopausal women were stopped early because of both a lack of demonstrated efficacy and a slight increase in thrombosis-associated myocardial infarctions associated with postmenopausal women given HRT. Current medical recommendations are that estrogens or HRT not be used in postmenopausal women for potential cardiovascular conditions and instead be reserved for treatment of postmenopausal symptoms or osteoporosis.

An explanation for the extreme difference in suggested benefits of estrogen based on laboratory animal findings and the reality of clinical trials could be rooted in the concept that curatives and preventatives are not the same thing. It is likely that estrogen in premenopausal women protects their cardiovascular system for all the reasons suggested by laboratory studies. However, after menopause, this preventative aspect is lost. Cardiovascular disease then proceeds unabated in a manner similar to that seen in men. Recent laboratory studies support this postulate at least as it relates to the age of an individual receiving estrogen. For example, protective effects of estrogen on inflammatory responses and mitochondrial oxygen radical production are diminished in older versus younger animals. Furthermore, women live decades past menopause, and during that time, many do not take any hormonal replacement therapy. Women in this state likely have accumulated cardiovascular disease that cannot be reversed by the simple addition of estrogen into the woman’s system, even though such estrogen prevented the progression of the disease earlier in her life. Indeed, estrogen is slightly prothrombotic, and addition of this steroid to a woman with existing cardiovascular disease, especially coronary artery disease, might be enough to tip the balance into a thrombotic state that causes myocardial infarction. It is interesting that the average age of women was about 65 years in some clinical trials that were stopped because of adverse cardiovascular events associated with estrogen and hormone replacement therapy and included women several years or decades past menopause. Thus, the lack of benefit from estrogen at this stage may have resulted from the buildup of cardiovascular insults prior to taking estrogen rather than from a direct lack of effect of estrogen on the cardiovascular system. Still, additional evidence involving a growing understanding of genomics and metabolomics suggests that not all women may have the genetic/metabolic infrastructure that supports beneficial effects of estradiol on the cardiovascular system. Such women may benefit from more targeted application of specific different types of estrogens, even while their systems are not able to respond favorably to others. In this regard, it has been suggested that estrogen analogs that could target the membrane-bound estrogen receptor, rather than its genomic nuclear receptor, might provide an avenue of providing postmenopausal women with a cardiovascular benefit to estrogen without the other complications of the agent, including potential increased risks of developing cancers. It has also been suggested that SERMs (selective estrogen receptor modulators), such as tamoxifen or raloxifene, which are partial nuclear estrogen receptor agonists, may also provide an avenue for triggering beneficial cardiovascular effects of estrogen while at the same time reducing cancer risks associated with sex steroids. ■

Progressive shock causes a vicious cycle of cardiac and brain deterioration.

If the initial causes of shock are severe or the body is unable to compensate fully for the malfunctioning cardiovascular system, shock enters into a vicious positive feedback cycle known as **progressive shock**. This occurs when organs maintaining the cardiovascular system, notably the heart and brain, deteriorate as a result of poor blood supply. This usually ensues when, in spite of the efforts of short-term neural/hormonal control mechanisms, blood pressure decreases to a level below the limit of autoregulation in the heart and brain. At this point, because the body's own compensatory mechanisms require proper function of the heart and brain, the body cannot correct the progression of shock. A person in this stage cannot recover without clinical intervention to support the cardiovascular system.

The most important factor involved in the progression of shock is deterioration of the heart itself. During progressive shock, the coronary circulation is compromised and myocardial contractility progressively decreases, which further causes a drop in arterial pressure and further reduction of coronary blood supply. In addition, progressive shock is exacerbated by deterioration of vasomotor centers in the brain, because of impaired cerebral blood flow. These centers are needed to support the heart and increase vascular resistance during hypotension. In addition, during progressive shock, the pre- to postcapillary resistance ratio shifts from that favoring water reabsorption, as in compensated shock, to that favoring water loss through the capillaries. This exacerbates collapse of the circulatory system. Finally, acidotic conditions in peripheral organs, brought on by poor oxygen delivery as well as release of toxins from deteriorating tissues, promote arterial blood clotting, thus exacerbating the already reduced tissue oxygen delivery. Acidosis and toxins also increase capillary permeability, which further enhances fluid loss from the vascular compartment. Without proper intervention, progressive shock will enter into an irreversible phase. In **irreversible shock**, cardiac and cerebral function are so compromised that no intervention is able to restore normal cardiovascular function. Death is inevitable.

Malfunctions involving the heart, brain, vascular system, or blood volume can cause shock.

Several different conditions can lead to circulatory shock. In addition to blood volume losses resulting from hemorrhage, any loss of plasma volume, or hypovolemia, can reduce cardiac output and induce shock. This can occur from dehydration as a result of severe vomiting, sweating, or diarrhea, as well as from decreased fluid and electrolyte intake, kidney damage, or adrenal cortical destruction (i.e., loss of aldosterone or its effects). Severe burns result in capillary destruction with loss of albumin from the vascular space. This causes transcapillary loss of plasma and a reduction in circulating blood volume. A similar capillary fluid loss is associated with intestinal obstructions that greatly increase intestinal venous pressure. Capillary damage from severe physical injury or trauma also causes transcapillary loss of plasma. An important complication of shock resulting from plasma loss is an increase in blood viscosity, which further impairs the heart's ability to move blood through the peripheral circulation.

Neurogenic shock is a form of circulatory collapse brought about by loss of neurogenic tone to veins and arteries secondary to inhibition or dysfunction of the CNS. This can result from general or spinal anesthesia (i.e., spinal blocks used in childbirth), traumatic brain injury, or depressed vasomotor center function resulting from fever, stress, insomnia, or even severe emotional distress (the last resulting in emotional fainting).

Many people are severely allergic to certain antigens (bee venom, certain foods, etc.). In a serious antigen to antibody reaction, called **anaphylaxis**, tremendous amounts of histamine and other toxins are released into the tissue spaces. This results in destruction of surrounding tissue that increases interstitial osmolality, thus promoting fluid efflux from the capillaries. Histamine also causes arteriolar dilation while increasing the permeability of capillaries and venules to water and proteins. These factors further exacerbate fluid loss from the vascular compartment and result in a decrease in circulating blood volume. A characteristic of anaphylactic shock is that it is not caused by a loss of total body fluid volume but rather from translocation of the volume out of the vascular space into the interstitium.

Septic shock is a form of shock caused by disseminated infection throughout the body. Next to cardiogenic shock, this is the leading cause of death from shock in the United States. It is often brought on by peritonitis secondary to female reproductive organ infection, rupture of the gut during appendicitis, or the introduction of skin bacteria into the bloodstream. Unlike other forms of shock, septic shock is characterized by high body temperature as a result of infection and high cardiac output as a result of intense vasodilation in the infected area. This latter effect is the result of activation of iNOS in vascular smooth muscle in response to endotoxin, LPS, TNF-α, and possibly other cytokines. The excess cardiac output in septic shock represents useless blood flow to infected regions at the expense of perfusion of other organ systems including, potentially, the brain and heart. In addition, tissue destruction in this form of shock produces widespread microvascular blood clots, called *disseminated intervascular coagulation*. This condition greatly impairs O_2 delivery to tissues, thus exacerbating the primary shock condition.

Pharmacological Monotherapy for the Treatment and Management of Chronic Arterial Hypertension

Systemic primary arterial hypertension (essential hypertension) afflicts up to a third of the adult population in Western acculturated societies. Although lifestyle modifications such as cessation of smoking, becoming physically active, or losing weight can reduce blood pressure, these changes alone are often not sufficient to reduce blood pressure to a desired level. Therefore, antihypertensive drug therapy is often needed for blood pressure reduction and management in patients with hypertension. The aim of initial pharmacotherapy for hypertension is to "get the pressure down any way you can" because, left untreated, hypertension progresses and results in increased incidence of myocardial ischemia/infarction, stroke, and renal damage. In contrast, it has long been established that treatment of hypertension is of unquestioned benefit.

Currently, there are five types of "first-line" agents recommended as initial monotherapy for the treatment of essential hypertension each of which has a different mechanism of action: thiazide diuretics, β-blockers, ACE inhibitors, angiotensin receptor blockers, and calcium channel antagonists. Thiazide diuretics, such as *chlorothiazide*, produce a mild diuresis and natriuresis. An acute reduction in water volume results along with a decrease in arterial pressure. However, a sustained loss of sodium and water is not compatible with life, and eventually, water and sodium come into balance through activation of the sympathetic nervous system, the RAAS and AVP. This restoration of balance in the presence of chronic diuretic exposure is called diuretic braking. However, even after water and sodium are brought back into balance in the body, blood pressure remains lowered by the diuretic, but at this time, that antihypertensive effect occurs through a reduction in SVR. The mechanism behind this chronic effect of thiazide diuretics is not known though it has been speculated that a reduction in total body sodium content by the diuretic may reduce arterial stiffness.

There are three major classes of β-blockers called first-generation, second-generation, and third-generation beta-blockers. All are effective long-term pharmacotherapeutics for hypertension. First-generation blockers are nonselective for β_1 or β_2 receptors and some, such as *propranolol*, have a cell membrane stabilizing effect in cardiac tissue. Second-generation agents, such as *metoprolol*, are selective for β_1 receptors, whereas third-generation beta-blockers possess additional properties such as stimulation of NO (*celiprolol*), α_1-blockade (*carvedilol*), and antagonism of calcium channels (*carvedilol*). Beta-blockers were first developed as antianginal agents and their antihypertensive action was an unexpected finding revealed in initial clinical trials. The antihypertensive action of these agents is not known completely although inhibition of the RAAS and some central action of the drugs has been implicated. Beta-blockers possess antiremodeling effects on the heart in CHF and are therefore especially beneficial to patients with the comorbidities of heart failure and hypertension.

Inhibition of the RAAS has an established history as effective pharmacotherapy for chronic hypertension. ACE inhibitors (i.e., *captopril*, *enalapril*, *fosinopril*) have widespread use in patients with hypertension and are effective in patients with either normal or high plasma renin levels. ACE inhibitors are also renal protective and therefore favored in patients with combined diabetes and

hypertension. Like beta-blockers, ACE inhibitors prevent ventricular remodeling. This effect, which is added to the ability of ACE inhibitors to reduce elevated plasma volumes, makes ACE inhibitors a mainstay in treating patients with combined hypertension and CHF. Angiotensin receptor blockers ([ARBs], i.e., *losartan*, *candesartan*, etc.) are newer pharmacological agents that inhibit the effects of the RAAS. They are effective in hypertension, especially in patients with concurrent diabetes. Unlike ACE inhibitors, they do not block inactivation of bradykinin in the lungs and therefore are not associated with the complications of cough and angioedema that can occur with ACE inhibitors. ARBs are potent inhibitors of the RAAS and no amount of stimulation of that system can restore normal tissue responses to angiotensin II.

There are three classes of calcium antagonists currently in use for a variety of cardiovascular diseases including hypertension. The three classes are all effective in treating hypertension but differ in their relative efficacy in inducing vasodilation (an antihypertensive effect) and their cardiac action to reduce myocardial contractility and conduction through the AV node (a property useful in treating myocardial ischemia and supraventricular tachycardia). *Verapamil* and *diltiazem*, respectively, strongly or moderately reduce contractility and conduction, though both are effective antihypertensives. However, members of the 1,4-dihydropyridine class of calcium antagonists (e.g., *nifedipine*, *amlodipine*, *nicardipine*, etc.) are the strongest vasodilators and antihypertensive agents among the calcium antagonists. 1,4-dihydropyridines are therefore the generally favored calcium antagonist for treatment of uncomplicated moderate to severe arterial hypertension. ■

Chapter Summary

- The sympathetic and parasympathetic branches of the autonomic nervous system innervate the heart and act through β-adrenergic and muscarinic cholinergic receptors, respectively.
- Control of heart rate is predominantly by the parasympathetic nervous system, whereas control of contractility of the heart and vascular tone is dominated by the sympathetic nervous system.
- The sympathetic nervous system acts on blood vessels primarily through activation of α-adrenergic receptors.
- Reflex control of the blood pressure involves neurogenic mechanisms that control heart rate, stroke volume, and systemic vascular resistance.
- Behaviors involved in emotion and stress affect cardiovascular responses.
- Baroreceptors and cardiopulmonary receptors are important in the moment-to-moment neural reflex regulation of arterial pressure.
- The renin–angiotensin–aldosterone system, arginine vasopressin, and atrial natriuretic peptide are important in slow hormonal regulation of blood volume and arterial pressure.
- Pressure diuresis in the kidney is the mechanism that ultimately sets the level of mean arterial pressure.
- Circulatory shock occurs in the stages of compensation, progression, and irreversibility.
- Compromised function of the heart and brain as well as abnormalities in the function of blood vessels and blood volume control mechanisms can cause shock.

Chapter Review Questions

1. Which of the following is true with respect to peripheral chemoreceptors?

A. Activation is important in establishing the set point for mean arterial pressure control.
B. Activity is increased by increased pH.
C. They are responsible for moment-to-moment control of mean arterial pressure.
D. Activation is important in the cardiovascular response to hemorrhagic shock that reduces blood pressure below 80 mm Hg.
E. They are activated by elevation of the PO_2, of arterial blood.

The correct answer is D. Carotid chemoreceptors are important in control of blood pressure in emergency situations. They are not involved in setting mean arterial pressure or controlling pressure about that set point during normal activities, such as standing. The chemoreceptors respond to decreased PO_2 and pH in the blood.

2. A patient suffers a severe hemorrhagic shock resulting in a lowered mean arterial pressure. Which of the following would be elevated *above normal* levels in the compensatory stage of this shock?

A. Splanchnic blood flow
B. Cardiopulmonary receptor activity
C. Right ventricular end-diastolic volume
D. Heart rate
E. Carotid baroreceptor activity

The correct answer is D. Heart rate would be increased in response to removal of baroreceptor stimulation by the hypotension. The volume loss would reduce ventricular volumes and cardiopulmonary stretch receptor activity in the atria and vena cava. The splanchnic circulation is one of the key components of increased vascular resistance and recruitment of blood in the veins as part of the neural reflex defense against hypotension.

3. Sodium nitroprusside is a powerful arterial vasodilator used in cardiovascular emergencies such as acute heart failure. Which of the following phenomena would be expected to be seen in a patient shortly after being given an IV bolus of sodium nitroprusside?

A. Tachycardia
B. Decreased cardiac output
C. Activation of the vasodepressor area in the medulla
D. Depressed myocardial contractility with decreased heart rate
E. Decreased stroke volume with decreased myocardial oxygen demand

The correct answer is A. A powerful arterial dilator will cause a sudden drop in arterial pressure, which, in turn, will activate the baroreceptor reflex. This reflex will result in activation of sympathetic nerves to the heart and blood vessels and a suppression of vagal activation to the heart. The result, following the initial effect of the nitroprusside, is to increase heart rate, myocardial contractility, and stroke volume. Together, these effects attenuate the initial drop in blood pressure caused by the drug. Depending on the balance between myocardial stimulatory effects on rate and contractility versus the final level of blood pressure, myocardial oxygen consumption may actually increase 1 to 2 minutes after administration of nitroprusside.

4. An older form of treatment for severe chronic hypertension was to use combined pharmacological alpha- and beta-receptor blockade. In this condition, blood pressure regulation in the patient

becomes extremely dependent on:

A. Chemoreceptor reflexes
B. The central nervous system ischemic response
C. Factors that alter salt and water balance in the body
D. Adrenal catecholamines
E. Vascular resistance

The correct answer is C. Blockade of all adrenergic receptors in the body by combined drug therapy results in a "chemical" sympathectomy. Blood pressure in patients on this therapy becomes exquisitely dependent upon blood volume. Therefore, factors that affect salt and water balance in the body have profound influence over blood pressure (e.g., salt intake, volume depletion, actions of drugs that affect salt and water excretion, and the renin–angiotensin system). The neural arms of the chemoreceptor and central nervous system ischemic reflexes would not function well, if at all, in an individual with chemical sympathectomy. Adrenal or any other catecholamines would have limited effect on the cardiovascular system in which adrenergic receptors were blocked (although the diminution of response would depend on the level of the blockade and the magnitude of catecholamine concentration). The effect of vascular resistance on blood pressure would be markedly blunted by alpha blockade.

Clinical Application Exercises 17.1

MEDICATION-INDUCED POSTURAL HYPOTENSION

A 70-year-old female with a history of angina and mild heart failure is placed on vasodilator therapy with nitroglycerin. She is given this drug as a skin patch, which is to be worn during the day and which releases small amounts of this vasodilator into her circulation continuously through the skin. She is also given nitroglycerin tablets to be taken in case of an anginal attack or as a prophylaxis against angina in anticipation of physical exertion beyond normal daily activities. During one morning, a couple of hours after applying her nitroglycerin skin patch, she takes a nitroglycerin tablet in anticipation of doing some gardening but decides to lie down for a few moments before starting work. Within 10 minutes of lying down, the patient bolts from her supine position to answer her telephone. However, within seconds of rising from the supine to the standing position, she becomes light-headed and dizzy. Her heart rate starts to increase rapidly and she can feel her heart pounding in her chest. Within a couple of steps, her vision narrows and blackens and she collapses onto the floor unconscious. Shortly after this episode, the patient regains consciousness and is able to stand only after slowly arising.

QUESTIONS

1. What cardiovascular phenomenon is most likely responsible for the loss of consciousness in this patient?
2. What changes in blood volume distribution normally occur immediately when one moves from a supine to a standing position? What immediate effects do these have on cardiac output and arterial blood pressure? What reflex mechanisms are brought into play in response to these changes in blood pressure?
3. Nitroglycerin is a rapidly absorbed, quick-acting direct vasodilator that relaxes smooth muscle in veins more than arteries. How does this selective effect of nitroglycerin relate to the responses

of the patient suddenly standing?

ANSWERS

1. Loss of consciousness can result from numerous factors, but the most likely related to the cardiovascular system is a sudden severe drop in blood pressure below the autoregulatory limit of the cerebral circulation. This would cause a drop in blood flow and oxygen supply to the brain that would likely induce neurological effects such as darkening vision, dizziness, and fainting.
2. Upon changing from the supine to the standing position, blood tends to fall toward the lower extremities due to the influence of gravity. Blood vessels are compliant with veins being much more compliant and distensible than arteries. Consequently, upon standing, blood tends to pool in the veins of the lower extremities, effectively translocating blood volume away from the central circulation. This causes a sudden drop in ventricular filling and cardiac output along with a drop in arterial pressure. Normally, cardiovascular reflexes activate sympathetic nerves to veins and arteries resulting in venous and arteriolar constriction in response to this initial drop in arterial pressure. Venous constriction helps move blood from the lower extremities into the central circulation and thus supports cardiac output. This output is further augmented by reflex tachycardia upon standing. Stimulation of cardiac output helps prevent any drop in arterial blood pressure when rising to a standing position. Blood pressure is further supported by increased vascular resistance from reflex sympathetic–mediated constriction of systemic arteries in all vascular beds except the heart and brain. This support of blood pressure, along with strong autoregulation of blood flow in the brain, prevents any significant drop in cerebral blood flow that would otherwise occur should the body not be able to compensate for the drop in blood pressure that occurs upon standing against gravity.
3. By directly relaxing smooth muscle in veins and arteries, nitroglycerin antagonizes any constrictor effect on those blood vessels. Because this agent relaxes veins more than arteries, there is a greater reduction in venous than arterial compliance and blood tends to pool more easily in the veins than normal. In addition, the actions of nitroglycerin blunt any reflex sympathetic vasoconstriction of veins in response to standing, preventing those reflexes from counteracting pooling of blood away from the central circulation and into the lower extremities. The action of nitroglycerin on arteries also antagonizes reflex arterial vasoconstriction during standing. As a result, a patient on nitroglycerin can experience a significant, precipitous drop in arterial pressure when moving suddenly from a supine to a standing position such that blood supply to the brain may become inadequate. If this happens, the patient will likely experience CNS disturbances such as dizziness, loss of vision, and loss of consciousness. Nitroglycerin does not have any direct effect on cardiac or skeletal muscle contraction. Therefore, the drop in arterial pressure seen upon standing while on nitroglycerin will activate neurogenic reflexes that will increase heart rate and myocardial contractility. Therefore, the patient in this study also experienced tachycardia and palpitations upon standing.

PART V RESPIRATORY PHYSIOLOGY

18 Ventilation and the Mechanics of Breathing

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Explain how a pleural pressure is generated.
- Describe how transairway pressure maintains airway patency.
- Explain how changes in alveolar pressure move air in and out of the lungs.
- Explain how spirometry measures lung volumes and airflow in patients.
- Explain why alveolar ventilation measures the amount of fresh air that enters the lung.
- Describe how expired carbon dioxide can be used to measure alveolar ventilation.
- Distinguish between hyperventilation and hyperpnea.
- Explain how lung elastic recoil affects lung compliance.
- Explain how regional lung compliance affects airflow in the lung.
- Explain how surfactant stabilizes alveoli at low lung volumes.
- Explain what keeps the airways from becoming compressed during forced explanation.
- Predict how restrictive and obstructive lung disorders affect the work of breathing.

Breathing is essential to life. The inrush of air at birth sets off a series of events that allows the newborn to progress from a dependent, placental life support system to an independent air breathing system. A breath in and a breath out 12 to 15 times every minute may seem like a simple process to build the entire human respiratory system, which brings in, on an average, 7 L (~1.85 gal) of air per minute into the lungs. At rest, breathing 7 L of air per minute supplies enough oxygen to sustain the metabolism of trillions of cells in the body. However, this simplicity is deceptive because breathing is amazingly responsive to small changes in blood chemistry, mood, level of alertness, and physical activity.

In the previous chapters, you learned that a major function of the cardiovascular system was to distribute blood throughout the body in order to deliver nutrients, oxygen, and other chemicals to the tissues and remove carbon dioxide and other metabolic waste products. In the respiratory chapters, you will learn that the respiratory and cardiovascular systems are closely linked, and the lungs are solely responsible for transferring oxygen from the atmosphere to the blood and removing carbon dioxide from the blood to the atmosphere. You will also learn that the human lungs are so efficiently designed that gas exchange can increase over 20-fold to remove carbon dioxide and to supply oxygen to tissues in order to meet the body's energy demands. The gas exchange process rarely limits body's activity. For example, a marathon runner who staggers across the 26-mile finish line in <3 hours or someone who swims the English Channel in record time is rarely limited by the amount of oxygen taken up or carbon dioxide removed by the lungs. These examples of human activity not only underscore the functional capacity of the lungs but also illustrate the important role respiration plays in body's extraordinary adaptability to the external environment. Finally, you will learn that respiratory physiology plays a critical role in medicine, because of the impact that many of the respiratory diseases (e.g., **cystic fibrosis**, **asthma**, **chronic obstructive pulmonary disease**, **pulmonary hypertension**, **pulmonary fibrosis**, **pulmonary edema**, **sleep apnea**, and **pneumonia**) have on human health. As a result, respiratory physiology impacts many of the subspecialties including pediatrics, internal medicine, radiology, surgery, ENT, and geriatrics.

Respiration takes place in two stages. The first stage is known as **gas exchange** and the second as

cellular respiration. Gas exchange involves the transfer of oxygen and carbon dioxide between the atmosphere and the lungs. The second stage, cellular respiration, occurs in two steps. The first involves the exchange of oxygen and carbon dioxide from the cells of the body. The second step is intracellular and involves a series of complex metabolic reactions that burns fuel, releasing carbon dioxide and energy. Recall that oxygen is required in the final step of cellular respiration to serve as an electron acceptor in the process by which cells obtain energy.

The respiratory system can be divided into the following components: ventilation and the mechanics of breathing, gas transfer and transport, pulmonary circulation, and the control of breathing. This chapter discusses ventilation, the mechanics of breathing, and the work of breathing. Chapter 19 discusses gas uptake and transport. Chapter 20 discusses the pulmonary circulation and the matching of airflow with blood flow in the lungs. Chapter 21 deals with basic breathing rhythms, breathing reflexes, integrated control of breathing, and the control of breathing in unusual environments.

LUNG STRUCTURAL AND FUNCTIONAL RELATIONSHIPS

Although the two lungs are clearly an essential component to the process of breathing, they do not provide the entire picture. The lungs alone cannot bring air in and out of the lungs or exchange oxygen and carbon dioxide from the blood. For example, without respiratory muscles and an airtight chest wall to create a negative pressure within the chest, the lungs would become nonfunctional in gas exchange. Moreover, without blood flow going to the lungs and the matching of airflow with blood flow, there would be essentially no gas exchange.

Airway tree divides repeatedly to increase lung surface area for gas exchange.

The human gas exchange organ consists of two lungs, each divided into several lobes. The lungs comprise two tree-like structures, the vascular tree and the airway tree, which are embedded in highly elastic connective tissue. The vascular tree consists of arteries and veins connected by capillaries (see Chapter 20). The airway tree consists of a series of hollow branching tubes that decrease in diameter at each branching (Fig. 18.1). The main airway, the **trachea**, branches into two **bronchi**. Each bronchus enters a lung and branches many times into progressively smaller bronchi, which, in turn, form **bronchioles**.

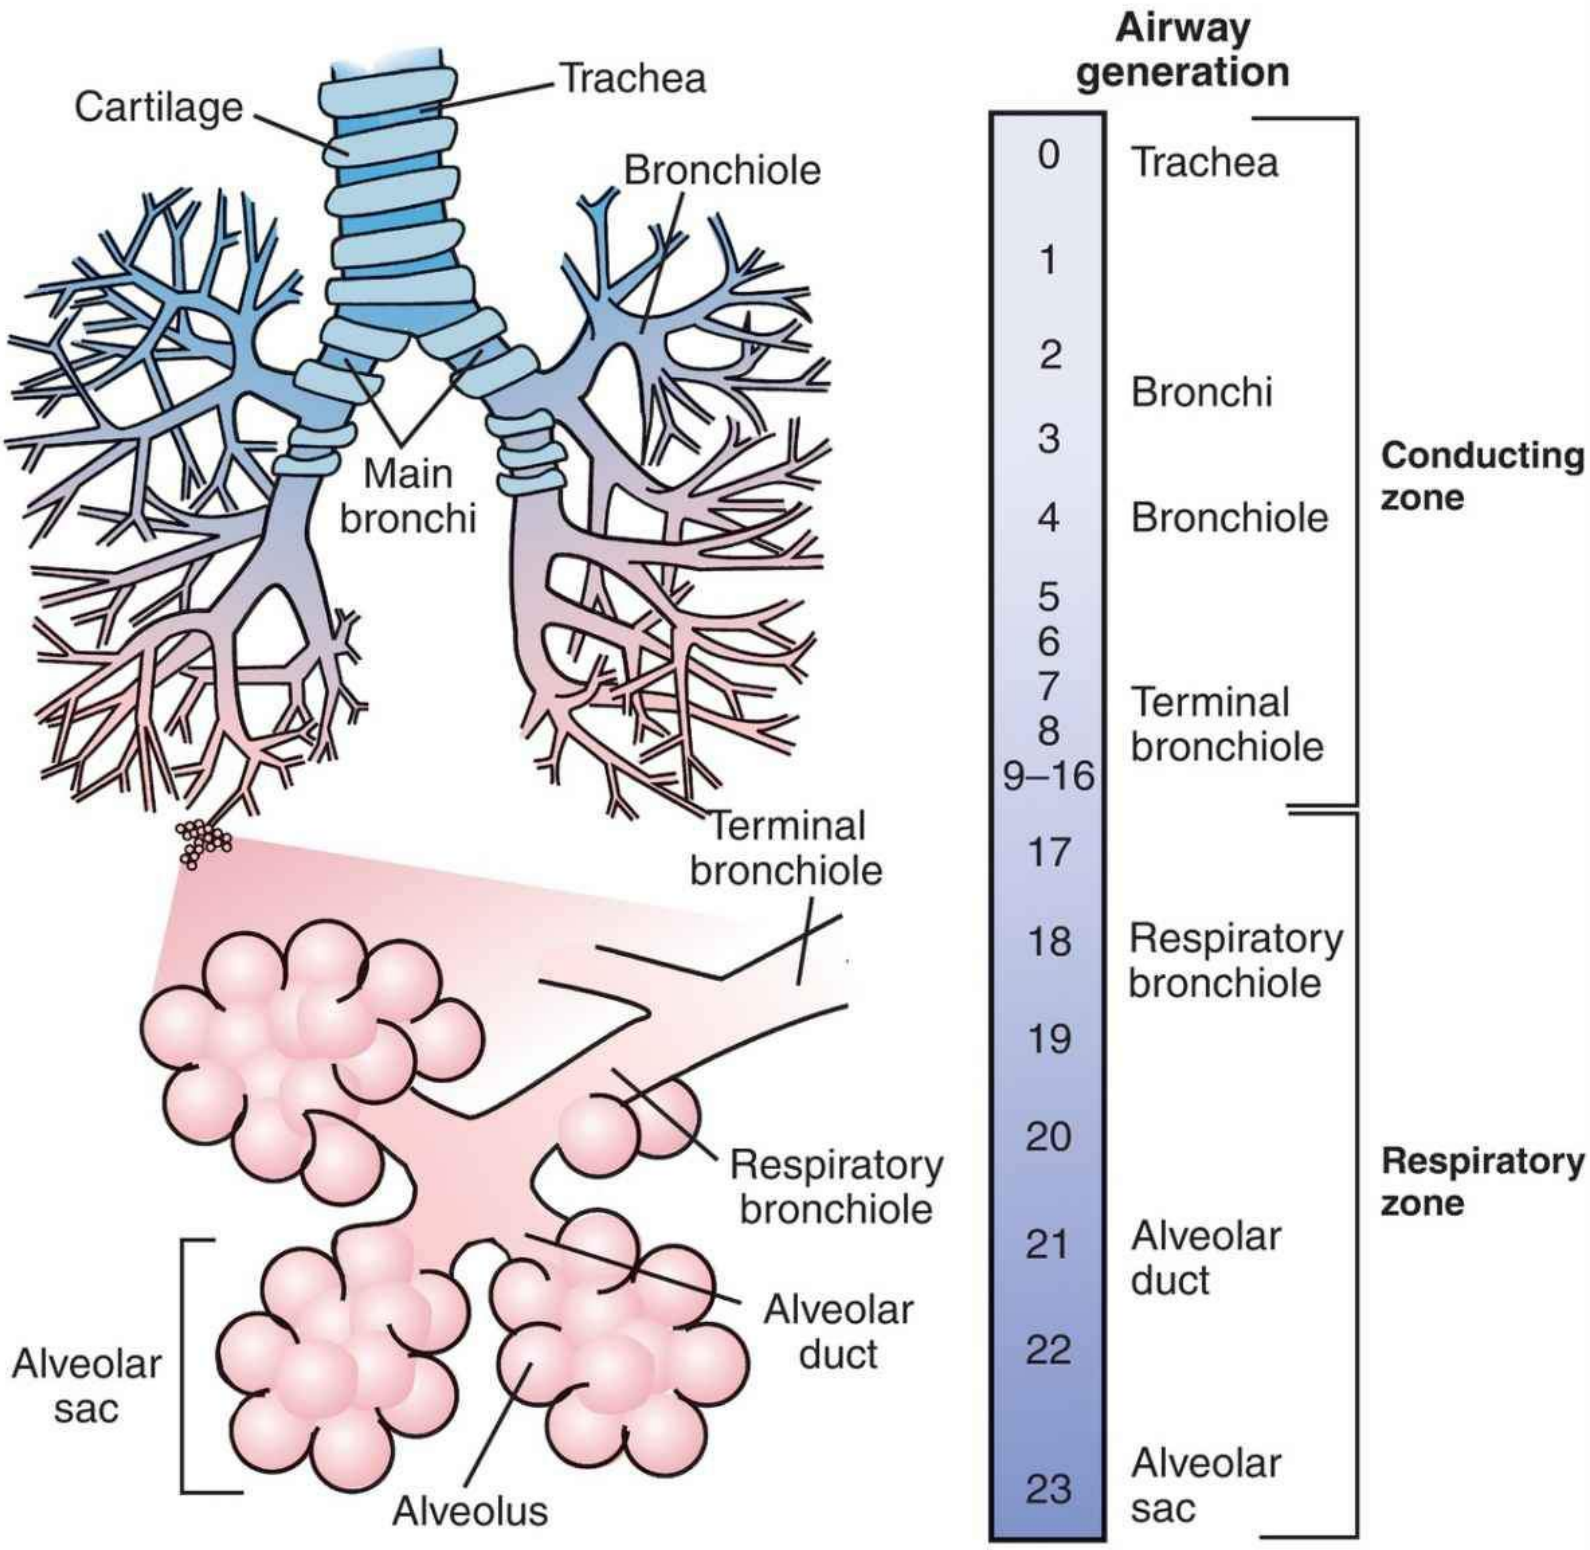

Figure 18.1 Airway tree divides repeatedly. The airway tree consists of a series of highly branched hollow tubes that become narrower, shorter, and more numerous as they penetrate the deeper parts of the lung. The airways are divided into two functional zones with the first 16 generations of branches comprising the conducting zone and functioning to conduct air to the deeper parts of the lungs. The last seven generations participate in gas exchange and comprise the respiratory zone.

A functional model of the airway tree is presented in Figure 18.1. The trachea and the first 16 generations of airway branches make up the **conducting zone**. The trachea, bronchi, and bronchioles of the conducting zone have three important functions to (1) warm and humidify inspired air, (2) distribute

air evenly to all regions of the lungs, and (3) serve as part of the body's defense system (removal of dust, bacteria, and noxious gases from the lungs). The first four generations of the conducting zone are subjected to changes in negative and positive pressures and contain a considerable amount of cartilage to prevent airway collapse. In the trachea and main bronchi, the cartilage consists of U-shaped rings. Further down, in the lobar and segmental bronchi, the cartilaginous rings give way to small plates of cartilage. In the bronchioles, the cartilage disappears altogether. The smallest airways in the conducting zone are the terminal bronchioles. Bronchioles are suspended by elastic tissue in the lung parenchyma, and the elasticity of the lung tissue helps keep these airways open. The conducting zone has its own separate circulation, the **bronchial circulation**, which originates from the descending aorta and drains into the pulmonary veins. No gas exchange occurs in the conducting zone.

The last seven generations of airways make up the respiratory zone and is the site of gas exchange. The exchange of gases is accomplished in the mosaic of millions of specialized cells that form thin-walled air sacs called **alveoli**. Like the conducting zone, the respiratory zone has its own separate and distinct circulation, the pulmonary circulation. The lungs have the most extensive capillary network of any organ in the body. Pulmonary capillaries occupy 70% to 80% of the alveolar surface area. The pulmonary circulation receives all of the cardiac output, and therefore, blood flow is high. One pulmonary arterial branch accompanies each airway and branches with it. Red blood cells can pass through the pulmonary capillaries in <1 second.

The formation of outpockets from the small airways to form alveoli accomplishes an increase in internal surface area (see Fig. 18.1). As mentioned above, a network of capillaries surrounds each alveolus and brings blood into close proximity with air inside the alveolus. Oxygen and carbon dioxide move across the thin-walled alveolus by diffusion. Adult lungs contain 300 to 500 million alveoli, with a combined internal surface area of ~75 m^2, which is approximately the size of a tennis court. This represents one of the largest biologic membranes in the body. During growth, alveolar surface area increases in two ways: in alveolar number and in diameter, as seen in Table 18.1. However, after adolescence, alveoli only increase in size and, if damaged, have limited ability to repair themselves. Cigarette smoke, for example, can destroy alveoli and lead to concomitant decrease in alveolar surface area for gas exchange.

TABLE 18.1 Age-Related Changes in Alveolar Number and Surface Area in the Human Lung

Age	Number of Alveoli (10^6)	Alveolar Surface Area (m^2)	Skin Surface Area (m^2)
Birth	24	2.8	0.2
8 y	300	32.0	0.9
Adult	300	75.0	1.8

Vascular and airway trees merge to form a blood–gas interface for gas diffusion.

In the respiratory zone, a group of alveolar ducts and their alveoli merge with pulmonary capillaries to form a terminal respiratory unit; there are ~60,000 of these units in both lungs. The alveolar–capillary membrane of these units forms a blood–gas interface, sometimes referred to as blood–gas barrier that separates the blood in the pulmonary capillaries from the gas in the alveoli (Fig. 18.2). It consists of an alveolar membrane separated by a capillary membrane by interstitial fluid and is essentially a fluid barrier.

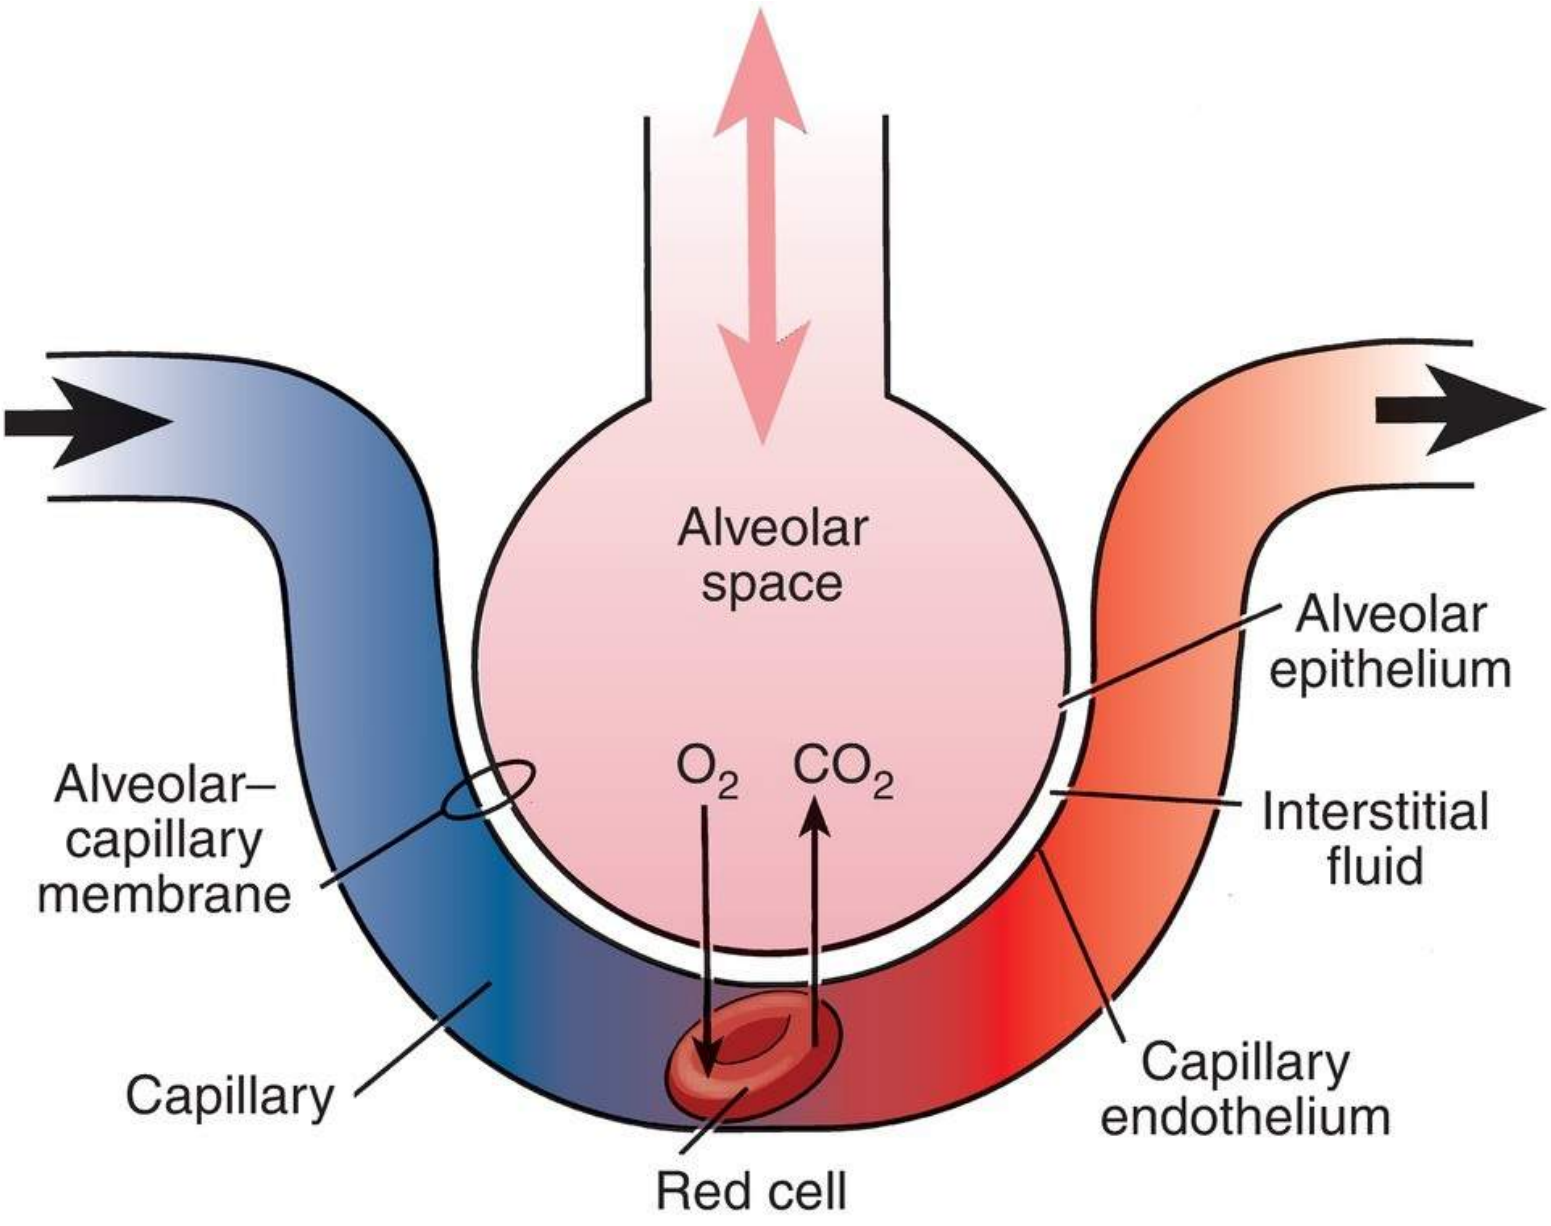

Figure 18.2 Blood–gas interface is the site of gas exchange. The pulmonary capillaries and alveoli form a blood–gas interface. *Thick arrows* indicate direction of blood flow and ventilation, and *thin arrows* indicate the diffusion paths for O_2 and CO_2. The alveolar–capillary membrane is thin (~0.5 mm), and therefore, the diffusion distance for gases is small.

The architectural design provides a large surface area for the diffusion of oxygen and carbon dioxide. The alveolar–capillary membrane is exceedingly thin (in some places <0.5 μm) and is composed of alveolar epithelium, interstitial fluid layer, and capillary endothelium. Air is brought to one side of the interface by ventilation—the movement of air to and from the alveoli. Blood is brought to the other side of the interface by the pulmonary circulation. As the blood perfuses the alveolar capillaries, oxygen is taken up and carbon dioxide crosses the blood–gas interface by diffusion.

PULMONARY PRESSURES AND AIRFLOW DURING BREATHING

The movement of air in and out of the lungs requires an airtight chest and a set of respiratory muscles. The respiratory muscles include the **diaphragm**, **intercostal muscles**, **scalene muscles** of the neck, and the **sternocleidomastoids**, which are inserted into the top of the sternum. The lungs are housed in an airtight thoracic cavity and are separated from the abdomen by the large dome-shaped skeletal muscle, the diaphragm (Fig. 18.3). The thoracic cavity is made up of 12 pairs of ribs, the sternum, and internal and external intercostal muscles, which lie between the ribs. The rib cage is hinged to the vertebral column, allowing it to be raised and lowered during breathing. The space between the lungs and chest wall is the **pleural space**, which contains a thin layer of fluid (~10 μm thick), that functions, in part, as a lubricant so the lungs can slide against the chest wall.

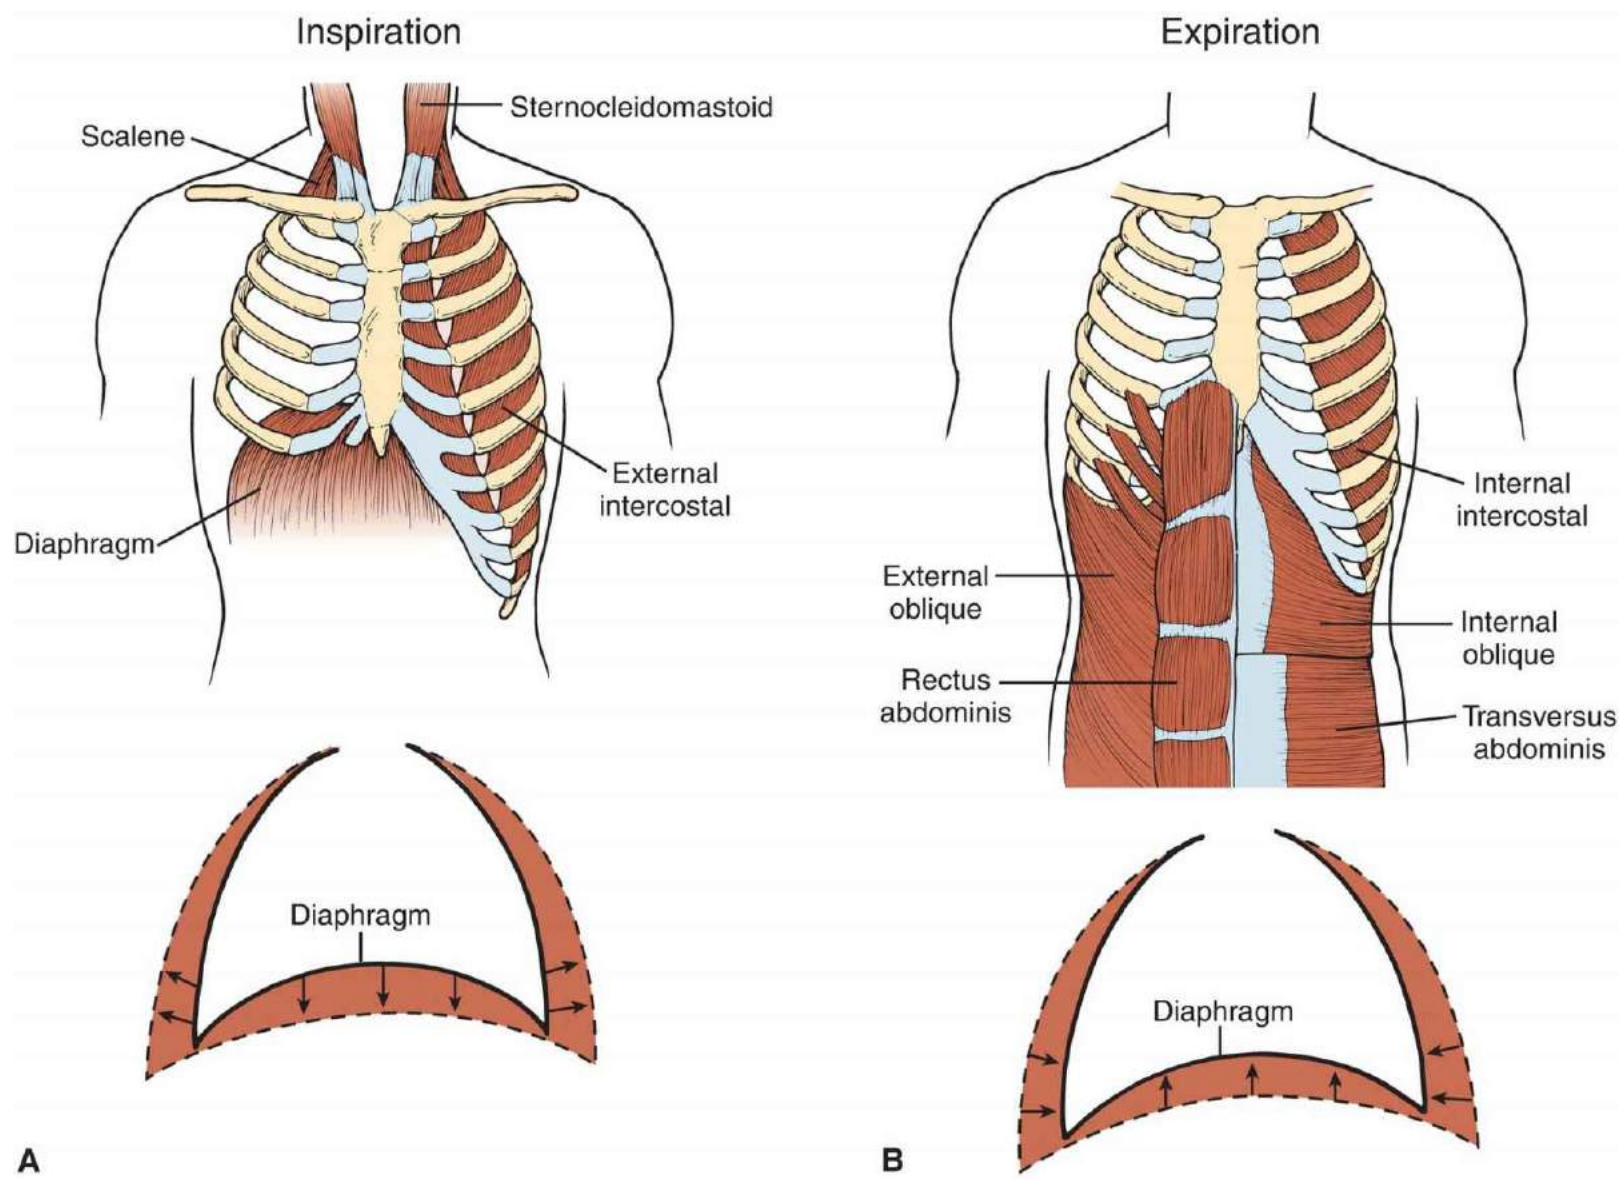

Figure 18.3 Changes in thoracic volume during the breathing cycle. Movements of the diaphragm and rib cage change thoracic volume, which allows the lungs to inflate during inspiration and deflate during expiration. **(A)** At rest, during inspiration, the diaphragm contracts and pushes the abdominal contents downward. The downward movement also pushes the rib cage outward. With deep and heavy breathing, the accessory muscles (the external intercostals and sternocleidomastoids) also contract and pull the rib cage upward and outward. **(B)** Expiration is passive during resting conditions. The diaphragm relaxes and returns to its dome shape, and the rib cage is lowered. During forced expiration, however, the internal intercostal muscles contract and pull the rib cage downward and inward. The abdominal muscles also contract and help pull the rib cage downward, compressing thoracic volume.

The diaphragm, the main muscle of breathing, expands the thoracic cavity.

Breathing is largely driven by the muscular diaphragm at the bottom of the thorax. Contraction of the diaphragm enlarges the airtight chest cavity with a concomitant, increase in chest volume. When the volume increases in the airtight chest, the pressure decreases causing air to flow into the lungs (and alveoli) (see Fig. 18.3). This enlargement of the airtight thoracic cavity is accomplished in two ways. First, contraction of the diaphragm (which is attached to the lower ribs and sternum) pushes the abdominal contents downward, enlarging the thoracic cavity in the vertical plane. Second, the external intercostal muscles raise the rib cage up and outward, further enlarging the thoracic cavity. The effectiveness of bringing air into the lungs is related to the strength of the contraction of the diaphragm and the intercostal muscles. The more the intercostals and diaphragm contract the more the lungs expand. Obesity, pregnancy, and tight clothing around the abdominal wall can impede the effectiveness of the diaphragm in enlarging the thoracic cavity. Damage to the phrenic nerves (the diaphragm is innervated by two phrenic nerves, one to each lateral half) can lead to paralysis of the diaphragm. When a phrenic nerve is damaged, that portion of the diaphragm moves up rather than down during inspiration.

During forced inspiration, in which a large volume of air is taken in, additional accessory muscles are also used. These include the scalene muscles and the sternocleidomastoids, and contraction of these muscles further elevates the upper rib cage and increases the thoracic volume.

The procedure of breathing air out of the lungs is much simpler. During expiration, the process is passive, and the respiratory muscles relax and the lung volume decreases causing pressure in the lungs (and alveoli) to increase. However, with exercise or forced expiration, the expiratory muscles do become active. These muscles include not only the diaphragm, but also those of the abdominal wall and the internal intercostal muscles (see Fig. 18.3B). Contraction of the abdominal wall pushes the diaphragm upward into the chest, and the internal intercostal muscles pull the rib cage down, reducing thoracic volume. These accessory respiratory muscles are also necessary for such functions as coughing, straining, vomiting, and defecating. The expiratory muscles are extremely important in endurance running and are one of the reasons competitive long-distance runners, as part of their training program, often do exercises to strengthen their abdominal and chest muscles.

Partial pressure drives the diffusion of oxygen and carbon dioxide.

At this point, ventilation has been examined at the systems level. We have reviewed the components, some properties of lung and the chest wall, and the interaction between these structures during inspiration and expiration. A more complete understanding of how the lungs are inflated/deflated and air is inhaled/exhaled, however, requires knowledge of the pressure changes at the biophysical level. A brief review of the gas laws is in order before explaining how changes in pressures within the thoracic cavity and lungs cause changes in lung volumes and air movement.

The atmosphere, the air we breathe and live in, exerts a pressure (P) known as **barometric pressure** (PB). At sea level, PB is equal to 760 mm Hg. The relationship between the total pressure exerted by a mixture of gases and the pressure of individual gases is governed by the **Dalton law**, which states that the total barometric pressure (PB) is equal to the sum of the **partial pressures** of the individual gases and can be written as follows:

$$P_B = P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} \quad (1)$$

where PN_2 equals partial pressure of nitrogen, PO_2 equals partial pressure of oxygen, PH_2O equals partial pressure of water vapor, and PCO_2 equals partial pressure of carbon dioxide. Partial pressure is the individual pressure exerted independently by a particular gas within an air mixture. The air we breathe is a mixture of gases: primarily nitrogen, oxygen, and carbon dioxide. For example, the air you blow into a balloon creates a pressure that causes the balloon to expand. This pressure that is generated is due to all of the molecules of nitrogen, oxygen, and carbon dioxide that collide with the walls of the balloon. However, the total pressure generated inside the balloon is the sum of the individual partial pressure of oxygen, nitrogen, and carbon dioxide. A gas' partial pressure, therefore, is the pressure that the gas exerts if each gas were present alone. Partial pressure is also used to measure how much of that gas is present. To calculate the gas's partial pressure requires rearranging the Dalton law. For example, the partial pressure of oxygen (PO_2), according to the Dalton law, is determined as $PO_2 = PB \times FO_2$, where FO_2 is the fractional concentration of oxygen. Because 21% of air is made up of oxygen, the partial pressure (PO_2) exerted by oxygen is 160 mm Hg (760 × 0.21) at sea level. If all of the other gases in the balloon were removed, the remaining oxygen would still exert a pressure of 160 mm Hg. Partial pressure of a gas is often referred to as **gas tension**, and partial pressure and gas tension are used synonymously.

Why is the partial pressure of oxygen inside the airways less than the PO_2 in the atmospheric air at sea level? When air is inspired, it is warmed and humidified. The inspired air becomes saturated with water vapor at 37°C. The water vapor exerts a partial pressure that is a function of body temperature, not barometric pressure. At 37°C, water vapor exerts a partial pressure (PH_2O) of 47 mm Hg. Water vapor pressure does not change the percentage of oxygen or nitrogen in a dry gas mixture; however, water vapor does lower the partial pressure of oxygen inside the lungs. The partial pressures of gases in the lungs are calculated on the basis of a dry gas pressure; therefore, water vapor pressure is subtracted when the partial pressure of a gas is determined. The dry gas pressure in the trachea is 760 − 47 = 713 mm Hg, and the individual partial pressures of O_2 and N_2 are:

$$P_{O_2} = 0.21 \times (760 - 47) = 150 \text{ mm Hg}$$

(2)

and

$$P_{N_2} = 0.79 \times (760 - 47) = 563 \text{ mm Hg}$$

(3)

Table 18.2 lists normal partial pressures of respiratory gases in different locations in the body. When calculating gas tensions in the lung, a good way to remember is as soon as the air hits the nose, always subtract water vapor pressure when converting gas fraction to partial pressure. In Figure 18.2, the schematic depicts mixed venous blood (i.e., blood from organs) coming into the alveolar capillary as blue and the blood leaving the alveolar capillary as red. The color change is due to the partial pressure adding oxygen to hemoglobin. As seen from Table 18.2, these pressures that occur during alveolar gas exchange can be summarized under resting conditions:

TABLE 18.2 Partial Pressures and Percentages of Respiratory Gases at Sea Level (PB = 760 mm Hg)

Gas	Ambient Dry Air		Moist Tracheal Air		Alveolar Air		Systemic Arterial Blood	Mixed Venous Blood
	mm Hg	%	mm Hg	%	mm Hg	%	mm Hg	mm Hg
O_2	160	21	150	20	102	14	95	40
CO_2	0	0	0	0	40	5	40	46
Water vapor	0	0	47	6	47	6	47	47
N_2	600	79	563	74	571	75*	571	571
Total	760	100	760	100	760	100	760	704†

*Alveolar PN_2 increased by 1% because R < 1.

† Total pressure in venous blood is reduced because PO_2 decreases more than PCO_2 increases.

Entering Alveolar Capillaries	Alveoli	Leaving Alveolar Capillaries
P_{O_2} = 40 mm Hg	P_{O_2} = 102 mm Hg	P_{O_2} = 95 mm Hg
P_{CO_2} = 46 mm Hg	P_{CO_2} = 40 mm Hg	P_{CO_2} = 40 mm Hg

In respiratory physiology, pressures are measured both in mm Hg and centimeters of water (cm H_2O).

Gas tensions are measured in mm Hg, but airflow and lung pressures are so small that they are measured in cm H_2O. A pressure of 1 cm H_2O is equal to 0.74 mm Hg (or 1 mm Hg = 1.36 cm H_2O). Changes in lung pressures during breathing are often expressed as *relative pressure*, a pressure relative to atmospheric pressure. For example, the pressure inside the alveoli can be −2 cm H_2O during inspiration. The minus sign indicates that the pressure is subatmospheric, that is, −2 cm below PB. Conversely, during expiration, the pressure inside the alveoli can be +3 cm H_2O. This means that the pressure is 3 cm H_2O above PB. A positive or negative pressure indicates that the pressure is relative to atmospheric pressure and is, respectively, above or below PB. When relative pressures are used, it is important to remember that PB is set at zero. For example, if airway pressure is zero, the pressure inside the airway equals atmospheric pressure. Unless otherwise specified, the pressures of breathing are relative pressures and the unit is cm H_2O. A list of symbols and abbreviations used in respiratory physiology is shown in Table 18.3.

TABLE 18.3 Symbols and Terminology Used in Respiratory Physiology

Symbol	Term
B	Barometric
D	Dead space
E	Expiratory
I	Inspiratory
L	Lung
c'	Pulmonary end capillary
pl	Pleural
pw	Pulmonary wedge
S	Shunt
T	Tidal
Tp	Transpulmonary
V	Venous
Examples of combinations	
C_L	Lung compliance
D_{LCO}	Lung-diffusing capacity for carbon monoxide
F_{IO_2}	Fractional concentration of inspired O_2
P_B	Barometric pressure
P_{CO_2}	Partial pressure of carbon dioxide
P_A	Alveolar pressure
P_{O_2}	Partial pressure of oxygen
Pa_{CO_2}	Partial pressure of carbon dioxide in arterial blood
P_{ACO_2}	Partial pressure of carbon dioxide in alveoli
P_{IO_2}	Partial pressure of inspired O_2
P_{ECO_2}	Partial pressure of CO_2 in expired gas
$P_{AO_2} - Pa_{O_2}$	Alveolar–arterial difference in partial pressure of O_2
P_{pl}	Pleural pressure
R_{aw}	Airway resistance
Sa_{O_2}	Saturation of hemoglobin with oxygen in O_2 in arterial blood
T_I	Inspiratory time
T_E	Expiratory time
$\dot{V}_A$	Alveolar ventilation
$\dot{V}_A\dot{Q}$	Alveolar ventilation–perfusion ratio
V_D	Dead space volume
$\dot{V}_D$	Dead space ventilation
$\dot{V}_E$	Expired minute ventilation
$\dot{V}_{O_2}$	Oxygen consumption per minute

Note: A dot above a primary symbol denotes flow per unit time.

Symbol	Term
Primary	
C	Compliance
D	Diffusion
F	Fractional concentration of a gas
f	Frequency
P	Pressure or partial pressure
$\dot{Q}$	Volume of blood per unit time (blood flow or perfusion)
R	Resistance
S	Saturation
T	Time
V	Gas volume
$\dot{V}$	Volume of gas per unit time (airflow)
Secondary	
A	Alveolar
a	Arterial
Aw	Airway

Note: A dot above a primary symbol denotes flow per unit time.

Pleural pressure is critical for lung inflation and deflation.

Because the thoracic cavity is airtight, an increase in thoracic volume causes the **pleural pressure** ($\mathbf{P_{pl}}$), the pressure in the pleural fluid between the lung and chest wall, to fall. A decrease in P_{pl} causes the lungs to expand and fill with air. This key pressure–volume relationship in breathing is based on two gas laws. The **Boyle law** states that, at a constant temperature, the pressure (P) of the gas varies inversely with the volume (V) of gas, or P = 1/V. If either pressure or volume changes and if temperature remains constant, the product of pressure and volume remains constant:

$$P_1 V_1 = P_2 V_2 \quad (4)$$

The **Charles law** states that if pressure is constant, the volume of a gas and its temperature vary proportionately (V ≈ T). If either temperature or volume changes and pressure remains constant, then:

$$V_1 / T_1 = V_2 / T_2 \quad (5)$$

These two gas laws can be combined into the **general gas law**:

$$P_1 V_1 / T_1 = P_2 V_2 / T_2 \quad (6)$$

From the general gas law, at constant temperature, an increase in thoracic volume leads to a decrease in pleural pressure.

Transpulmonary and transairway pressures prevent lung and airway collapse.

In addition to pleural pressure, several other pressures are associated with breathing and airflow (Fig. 18.4). **Alveolar pressure** (**PA**) is the pressure inside the alveoli. **Transmural pressure** (P_{tm}) is the pressure difference across a wall. In respiration, transmural pressure is the pressure across the airway or across the lung wall or the alveolar wall. Two major transmural pressures are involved in breathing. First, is the pressure difference across the lung wall termed **transpulmonary pressure** (**PL**). Transpulmonary pressure describes the difference between the alveolar pressure and the pleural pressure in the lungs and is measured by subtracting pleural pressure from alveolar pressure ($PL = PA - P_{pl}$). At rest, pleural pressure is −5 cm H_2O ($P_{pl} = -5$ cm H_2O) and alveolar pressure is zero (PA = 0 cm H_2O). This means, for example, that transpulmonary pressure at rest is 5 cm H_2O [$PL = 0 - (-5) = 5$ cm H_2O]. It is important to remember that transpulmonary pressure is the pressure that keeps the lungs inflated and prevents the lungs from collapsing. The more positive it becomes, the more the lungs are distended or inflated. In the example above, at rest, the PL is 5 cm H_2O. An increase in PL is responsible for inflating the lungs above the resting volume. The second transmural pressure is **transairway pressure** (P_{ta}), the pressure difference across the airways ($P_{ta} = P_{aw} - P_{pl}$), where P_{aw} is the pressure inside the airway. Transairway pressure is important in keeping the airways open during forced expiration. One way to remember in calculating transairway or transpulmonary pressure is “in minus out,” where P_{pl} is always the pressure outside the lung or airway.

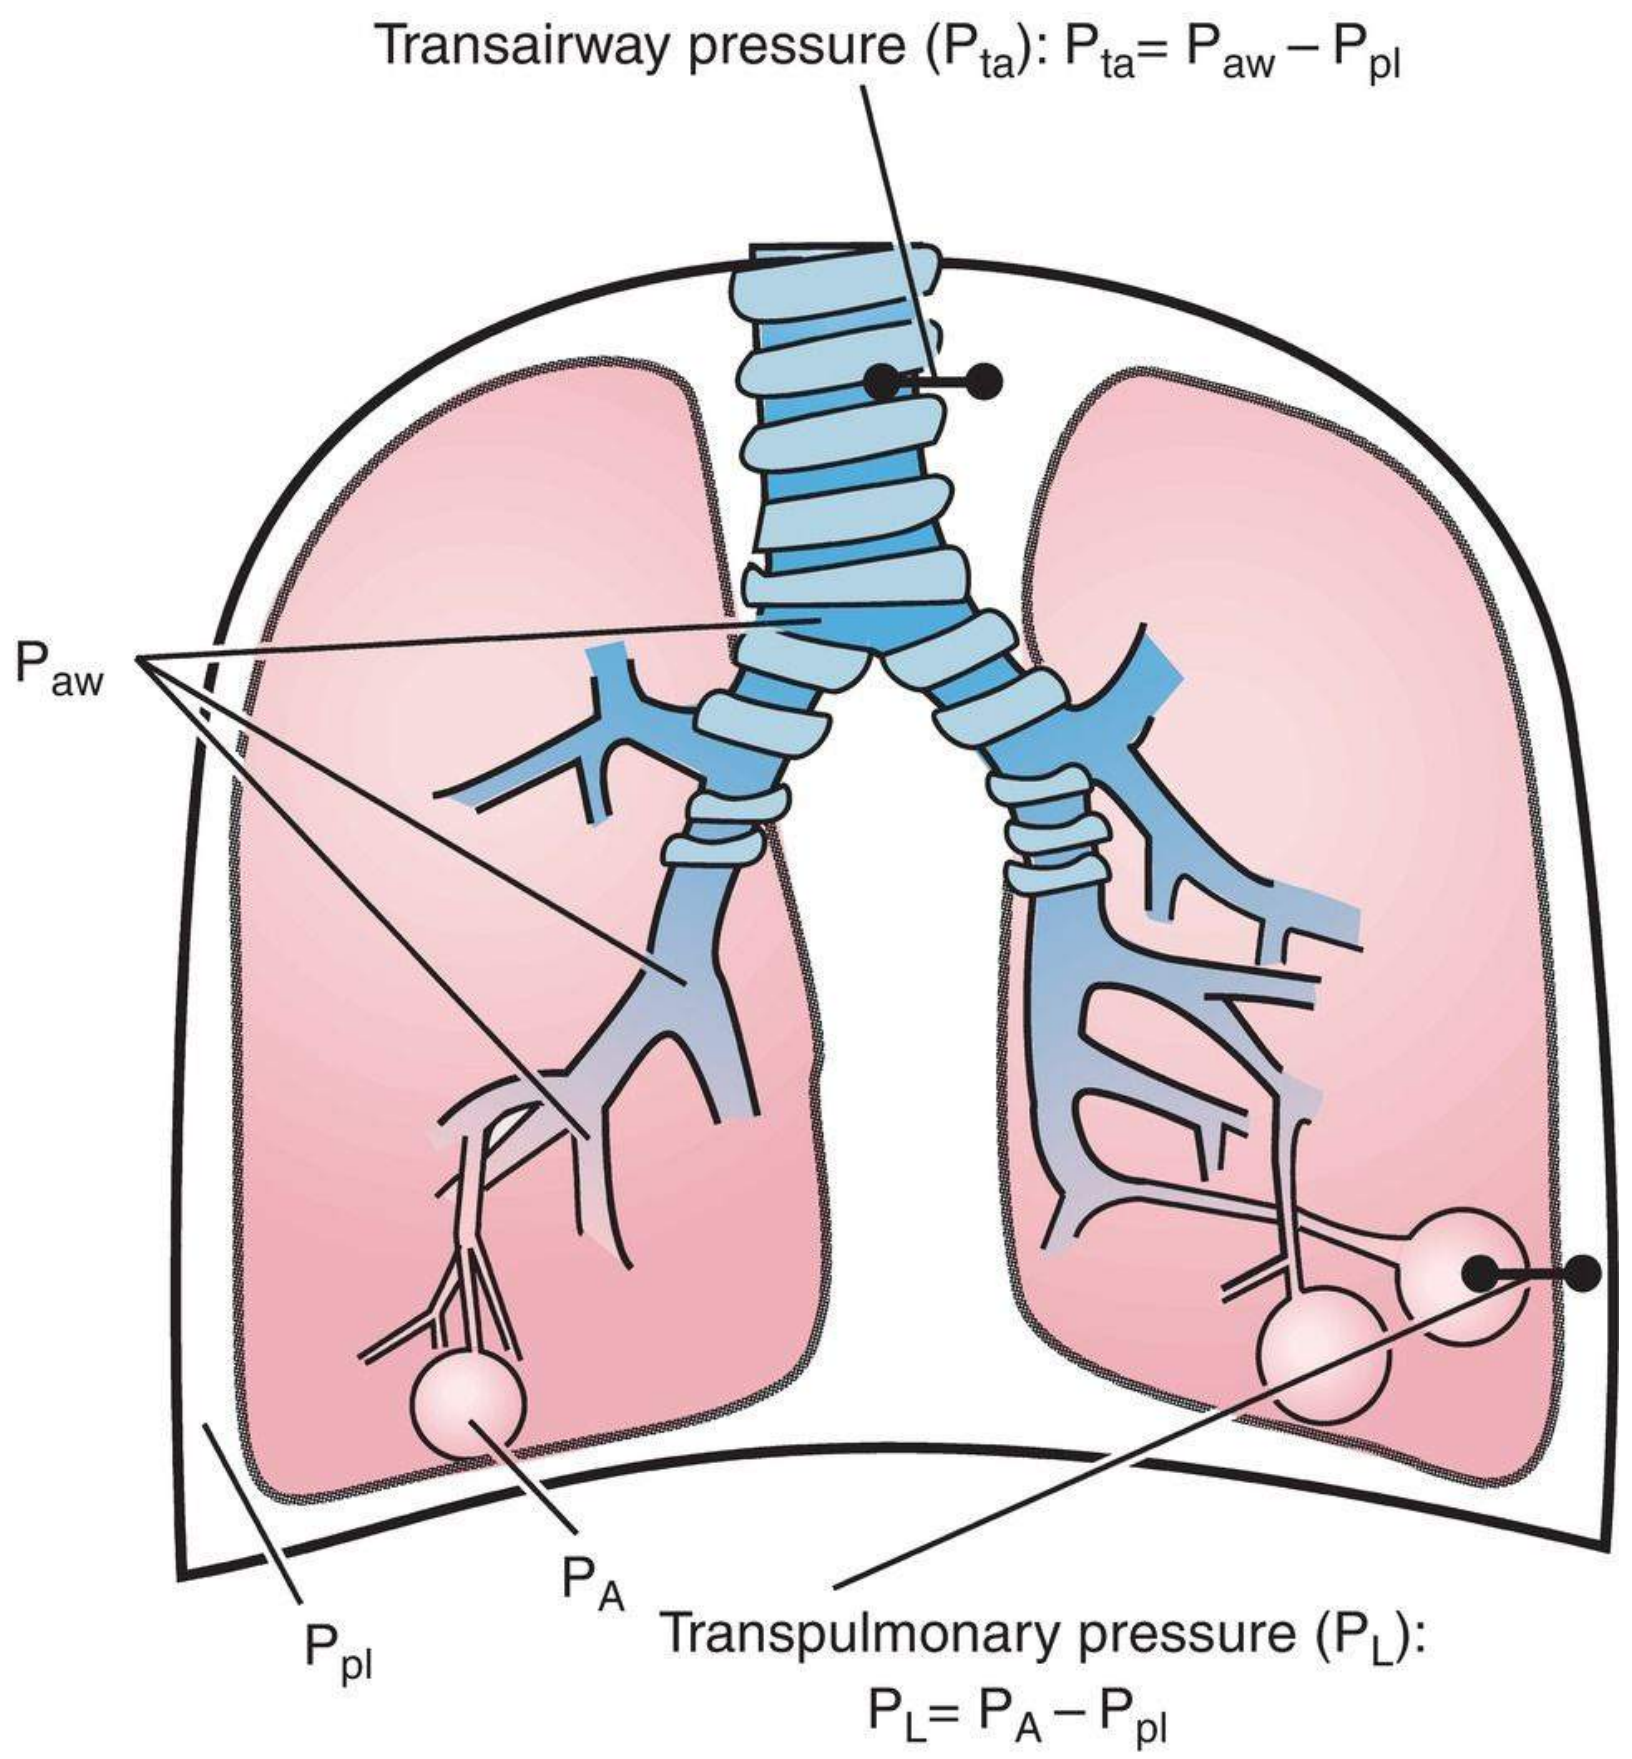

Figure 18.4 Pressures change during breathing. Several important pressures are involved in breathing: airway pressure (P_{aw}), alveolar pressure (PA), pleural pressure (P_{pl}), transpulmonary pressure (PL), and transairway pressure (P_{ta}). Both transpulmonary pressure and transairway pressure can be defined as the pressure inside minus the pressure outside. In both cases, the pressure outside is pleural pressure (P_{pl}).

Why is pleural pressure negative or subatmospheric? The reason is because of the elastic recoil of the

lungs and chest wall. Elastic recoil is analogous to a spring in which the lungs and chest wall when stretched recoils back to their unstretched configuration. At the end of a normal inspiration, the lungs and chest wall are stretched in equal but opposite directions (Fig. 18.5). The stretched lungs have the potential to recoil inwardly, and the stretched chest wall has the potential to recoil outwardly. These two equal but opposing forces cause the pleural pressure to decrease below atmospheric pressure. Pleural pressure is negative or subatmospheric during quiet breathing and becomes more negative with deep inspiration. Only during forced expiration does pleural pressure become positive or rise above atmospheric pressure.

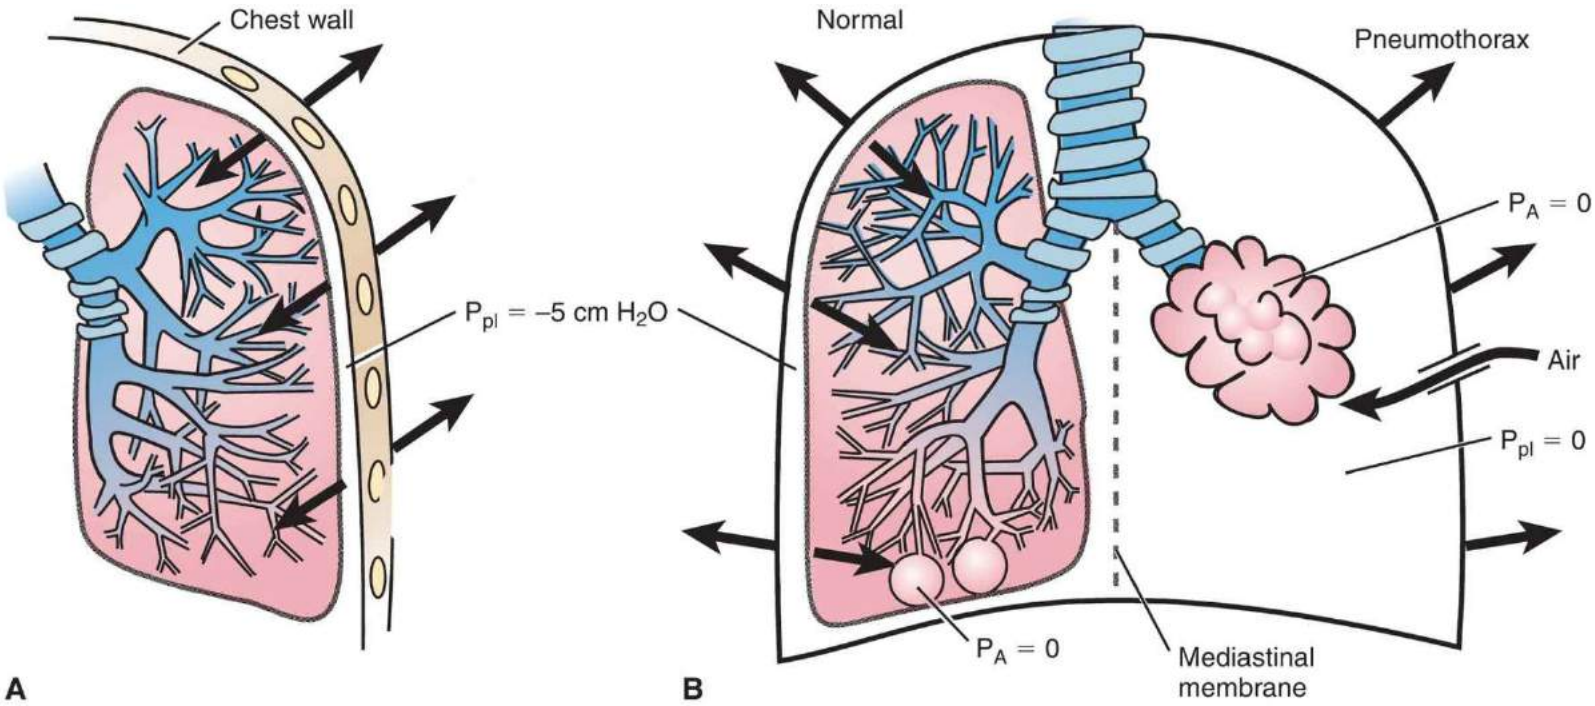

Figure 18.5 A negative pleural pressure results from the elastic recoil of the lungs and chest wall pulling in opposite directions. (A) The stretched lung (at the end of a normal inspiration) tends to recoil inwardly, and the chest wall tends to recoil outwardly, but in equal and opposite directions. Consequently, pleural pressure (P_{pl}) becomes negative (i.e., less than atmospheric pressure). **(B)** Rupture or puncture of the lung or chest wall results in a pneumothorax, during which the transpulmonary pressure becomes zero and elastic recoil causes the lung to collapse. The mediastinal membrane prevents the other lung from collapsing. PA, alveolar pressure.

The importance of pleural pressure is seen when the chest wall is punctured (see Fig. 18.5B) and air enters into the pleural space. The stretched lung collapses immediately (recoils inwardly), and the rib cage simultaneously expands outwardly (recoils outwardly). Because the normal pleural pressure is subatmospheric, air will rush into the pleural space any time the chest wall or lung is punctured, and the pleural pressure will become equal to atmospheric pressure because air moves from regions of high to low pressure. In this situation, transpulmonary pressure is zero (PL = 0) because the pressure difference across the lung is eliminated. This condition, in which air or gas accumulates in the pleural space and the lung collapses, is known as **pneumothorax** (see Fig. 18.5B, *right side*). A pneumothorax occurs with a knife or gunshot wound in which the chest wall is punctured or when the lung ruptures from an abscess or severe coughing. In the treatment of some lung disorders (e.g., tuberculosis), a pneumothorax is purposely created by inserting a sterile needle between the ribs and injecting nitrogen into the pleural fluid to rest the diseased lung. It is important to note that the mediastinal membrane keeps the other lung from

collapsing.

Changes in alveolar pressure move air in and out of the lungs.

Pressure changes during a normal breathing cycle are illustrated in Figure 18.6. At the end of expiration, the respiratory muscles are relaxed and there is no airflow. At this point, alveolar pressure is zero (equal to atmospheric pressure or PB). Pleural pressure is −5 cm H_2O, and transpulmonary pressure is, therefore, 5 cm H_2O [$P_{pl} = 0 - (-5 \text{ cm } H_2O) = 5 \text{ cm } H_2O$].

Time (sec)

Figure 18.6 Airflow resistance affects expiratory time. The inspiratory time (TI) is 2 seconds and is less than the expiratory time (TE) of 3 seconds. This difference is a result of, in part, a higher airflow resistance during expiration, as is reflected by a higher alveolar pressure (PA) change during expiration (1.2 cm H_2O) than during inspiration (0.8 cm H_2O). An increase in airway resistance will decrease the TI/TE ratio. Only a small pressure change between the mouth and alveoli is required for a normal tidal volume.

Inflation of the lungs is initiated by contraction of the diaphragm. If inspiration is started from the end of a maximal expiration, the chest wall can be felt to expand during inhalation. At no time, as our lungs fill, do we feel the need to close our epiglottis to keep the air in. This is because only a slight pressure difference holds air in our lungs. In the example shown in Figure 18.6, pleural pressure goes from −5 to −8 cm H_2O. One of the basic characteristics of gases, such as air, is that the pressures between two regions tend to equilibrate. Therefore, when pleural pressure decreases, transpulmonary pressure increases, and the lungs inflate. Inflation of the lungs causes the alveolar diameter to increase and alveolar pressure to decrease below atmospheric pressure (see Fig. 18.6). This produces a pressure difference between the mouth and alveoli, which causes air to rush into the alveoli. Airflow stops at the end of inspiration because alveolar pressure again equals atmospheric pressure (see Fig. 18.6). The sequence of events is summarized in Figure 18.7.

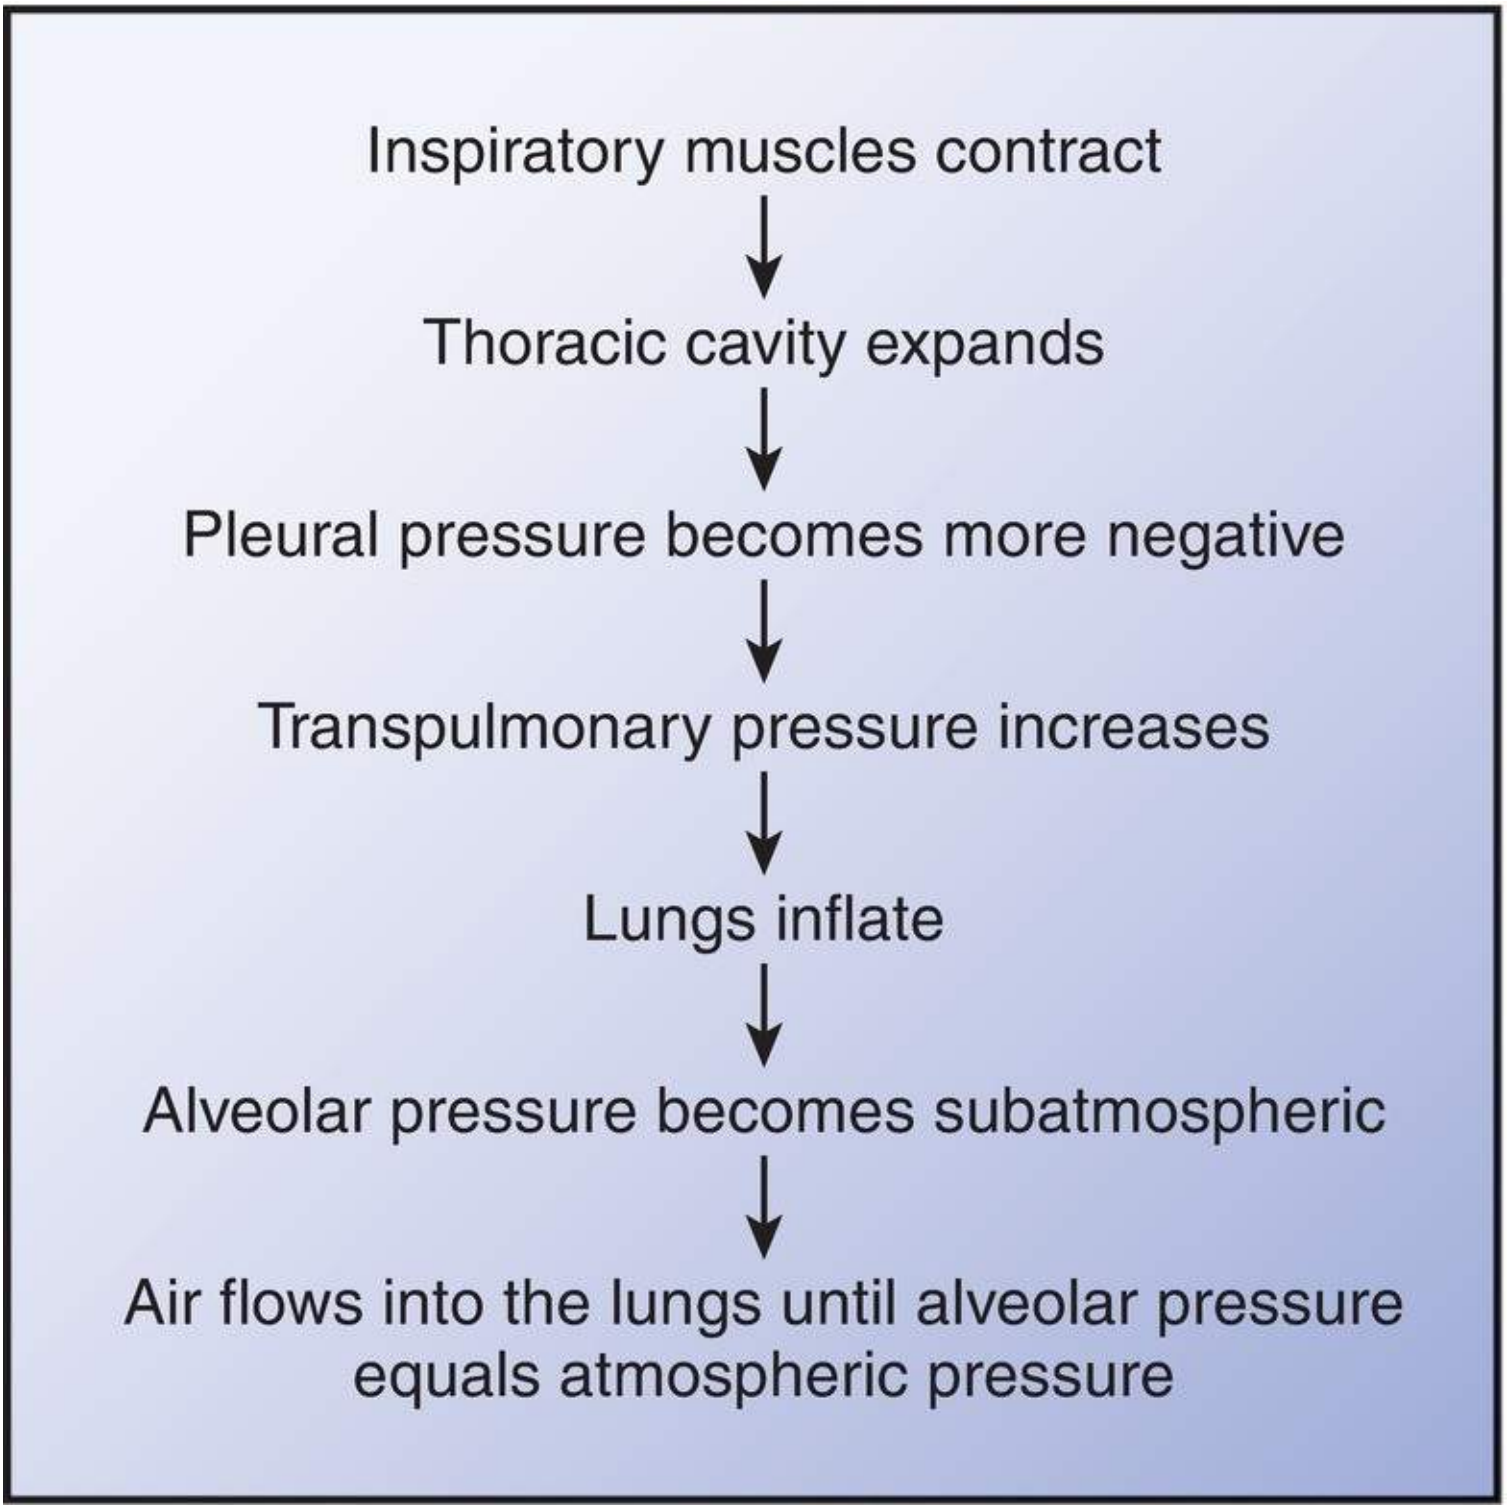

Figure 18.7 Airflow parallels alveolar pressure during breathing. The sequence during inspiration results in a fall in alveolar pressure causing air to flow into the lungs.

During expiration, the inspiratory muscles relax, the rib cage drops, pleural pressure becomes less negative, transpulmonary pressure decreases, and the stretched lungs deflate. When alveolar diameter decreases during deflation, alveolar pressure becomes greater than atmospheric pressure and pushes air out of the lungs. Airflow out of the lungs occurs until alveolar pressure equals atmospheric pressure.

SPIROMETRY AND LUNG VOLUMES

Spirometry is the most common of the pulmonary function tests and is used to assess lung function. Specifically, spirometry measures the lung volumes and airflow during inhalation and exhalation. A spirometer displays a *volume–time curve*, showing volume (liters) along the *Y*-axis and time (seconds) along the *X*-axis (Fig. 18.8). The recording from the spirometer is called a **spirogram**.

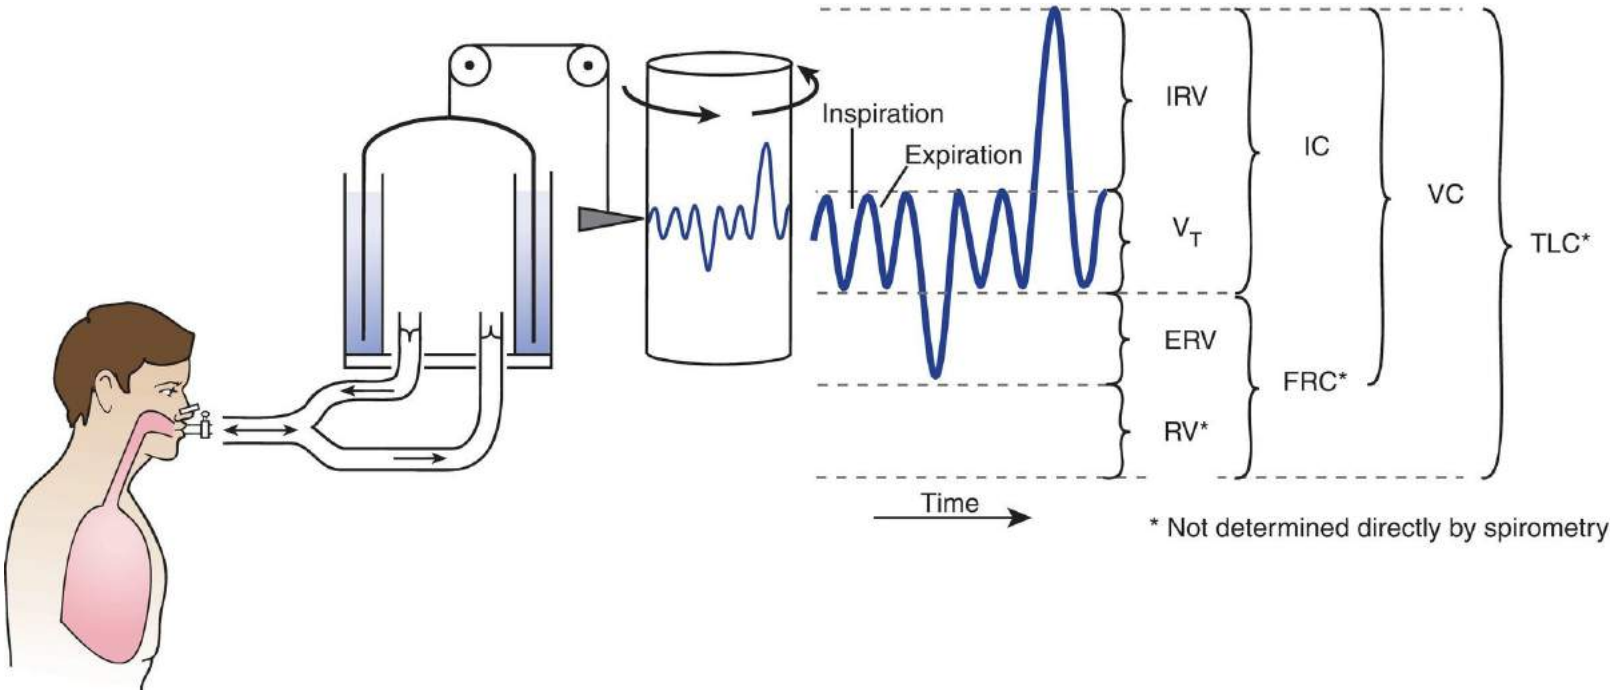

Figure 18.8 Spirometry measures lung volume. With expiration, the marker records a downward deflection. Note that residual volume (RV), functional residual capacity (FRC), and total lung capacity (TLC) cannot be measured directly by spirometry. IRV, inspiratory reserve volume; V_T, tidal volume; ERV, expiratory reserve volume; IC, inspiratory capacity; VC, vital capacity.

Spirometry measures specific lung volumes.

The volume of air leaving the lungs during a single breath is called **tidal volume** (**VT**). In the adult lung, under resting conditions, VT is ~500 mL and represents only a fraction of the air in the lungs. The maximum amount of air in the lungs at the end of a maximal inhalation is the **total lung capacity** (**TLC**) and is ~6 L in an adult man. Another important spirometry measurement is the **functional residual capacity** (**FRC**), the volume of air remaining in the lungs at the end of a normal tidal volume (end of expiration). Note the use of "volume" in the first term and "capacity" in the next two. *Volume* is used when only one volume is involved, and *capacity* is used when a volume can be broken down into two or more smaller volumes; for example, FRC equals **expiratory reserve volume** (**ERV**) plus **residual volume** (**RV**). The various lung volumes and capacities are summarized in Table 18.4.

TABLE 18.4 Abbreviations and Definitions Used in Pulmonary Function

Abbreviation	Term	Definition	Normal Value*
EPP	Equal pressure point	The point at which the pressure inside the airway equals the pressure outside of the airway (i.e., P_{pl})	
ERV	Expiratory reserve volume	The maximum volume of air exhaled at the end of the tidal volume	1.2 L
FEF_{25-75}	Forced expiratory flow	The maximum midexpiratory flow rate, measured by drawing a line between points representing 25% and 75% of the forced vital capacity	5 L/s
FEV_1	Forced expiratory volume	The maximum volume of air forcibly exhaled in 1 s	4.0 L
FEV_1/FVC%	Forced expired volume/ forced vital capacity ratio	The percentage of FVC forcibly exhaled in 1 s	80%
FRC	Functional residual capacity	The volume of air remaining in the lungs at the end of a normal tidal volume	2.4 L
FVC	Forced vital capacity	The maximum volume of air forcibly exhaled after a maximum inhalation	4.8 L
IC	Inspiratory capacity	The maximum volume of air inhaled after a normal expiration	3.6 L
IRV	Inspiratory reserve volume	The maximum volume of air inhaled at the end of a normal inspiration	3.1 L
PEF	Peak expiratory flow	The maximal expiratory flow during an FVC maneuver	7.5 L/s
RV	Residual volume	The volume of air remaining in the lungs after maximum expiration	1.2 L
RV/TLC	Residual volume/total lung capacity ratio	The percentage of total lung capacity made up of residual volume	20%
TLC	Total lung capacity	The volume of air in the lungs at the end of a maximum inspiration	6.0 L
VC	Vital capacity	The maximum volume of air that can be exhaled. (Note that the values for FVC and VC are the same.) VC is calculated from static lung volumes (VC = ERV + VT + IRV). FVC is determined from direct spirometry.	4.8 L
V_D/V_T	Dead space–tidal volume ratio	The fraction of tidal volume made up of dead space	30%
V_T	Tidal volume	The volume of air inhaled or exhaled with each breath	0.5%

*Values are for an average, healthy, young man.

*Values are for an average, healthy, young man.

Forced vital capacity is one the most important test in assessing lung function.

The maximum volume of air that can be exhaled after a maximum inspiration is **vital capacity** (**VC**). When expiration is performed as rapidly and as forcibly as possible into a spirometer, this volume is called **forced vital capacity** (**FVC**) and is about 5 L in an adult man (see Fig. 18.8). VC and FVC are the same volume. VC is determined by the sum of ERV, tidal volume, and inspiratory reserve volume. FVC is a direct volume measurement from spirometry and is one of the most useful measurements to assess ventilatory function of the lungs. To measure FVC, the person inspires maximally and then exhales into the spirometer as forcefully, rapidly, and completely as possible.

Two additional measurements can be obtained from the FVC spirogram (Fig. 18.9). One is **forced expiratory volume of air exhaled in 1 second** (**FEV_1**). This volume has the least variability of the measurements obtained from a forced expiratory maneuver and is considered one of the most reliable spirometry measurements. Another useful way of expressing FEV_1 is as a percentage of FVC (i.e., $FEV_1/FVC \times 100$), which corrects for differences in lung size. Normally, the FEV_1/FVC ratio is 0.8, which means that 80% of a person's FVC can be exhaled in the first second of FVC. This is rather remarkable because small pressure changes are involved to move this volume of air. As you will see later in this chapter FVC and FEV_1 are important measurements in the diagnosis of certain types of lung diseases.

Figure 18.9 Forced vital capacity (FVC) is a useful measurement in assessing ventilatory function. **(A)** A healthy subject inspires maximally to total lung capacity and then exhales as forcefully and completely as possible into the spirometer. Two other measurements can be obtained from this maneuver: the forced expiratory volume in 1 second (FEV_1) and the flow rate over the middle half of the forced vital capacity ($FEF_{25–75}$). Measurements of FVC, FEV_1, FEV_1/FVC ratio, and $FEF_{25–75}$ are used to detect obstructive and restrictive disorders. **(B)** In an obstructive disorder, expiratory flow rate is significantly decreased, and the FEV_1/FVC ratio is low. **(C)** In a restrictive disorder, lung inflation is decreased, resulting in reduced residual volume (RV) and total lung capacity (TLC). Although FVC is decreased, it is important to note that the FEV_1/FVC ratio is normal or increased in a restrictive disorder.

A second measurement obtained from the FVC spirogram is forced expiratory flow ($FEF_{25–75}$); it has the greatest sensitivity in terms of detecting early airflow obstruction (see Fig. 18.9). This measurement represents the expiratory flow rate over the middle half of the FVC (between 25% and 75%). $FEF_{25–75}$ is obtained by identifying the 25% and 75% volume points of the FVC and then measuring the volume and time between these two points. The calculated flow rate is expressed in liters per second.

Residual lung volume cannot be measured directly by spirometry.

Because the lungs cannot be emptied completely following forced expiration, neither RV nor FRC can be measured directly by simple spirometry. Instead, they are measured indirectly using a dilution technique involving helium, an inert and relatively insoluble gas that is not readily taken up by blood in the lungs. The subject is connected to a spirometer filled with 10% helium in oxygen (Fig. 18.10). The lungs initially contain no helium. After the subject rebreathes the helium–oxygen mixture and equilibrates with the spirometer, the helium concentration in the lungs will become the same as in the spirometer. From the conservation of mass principle, we can write:

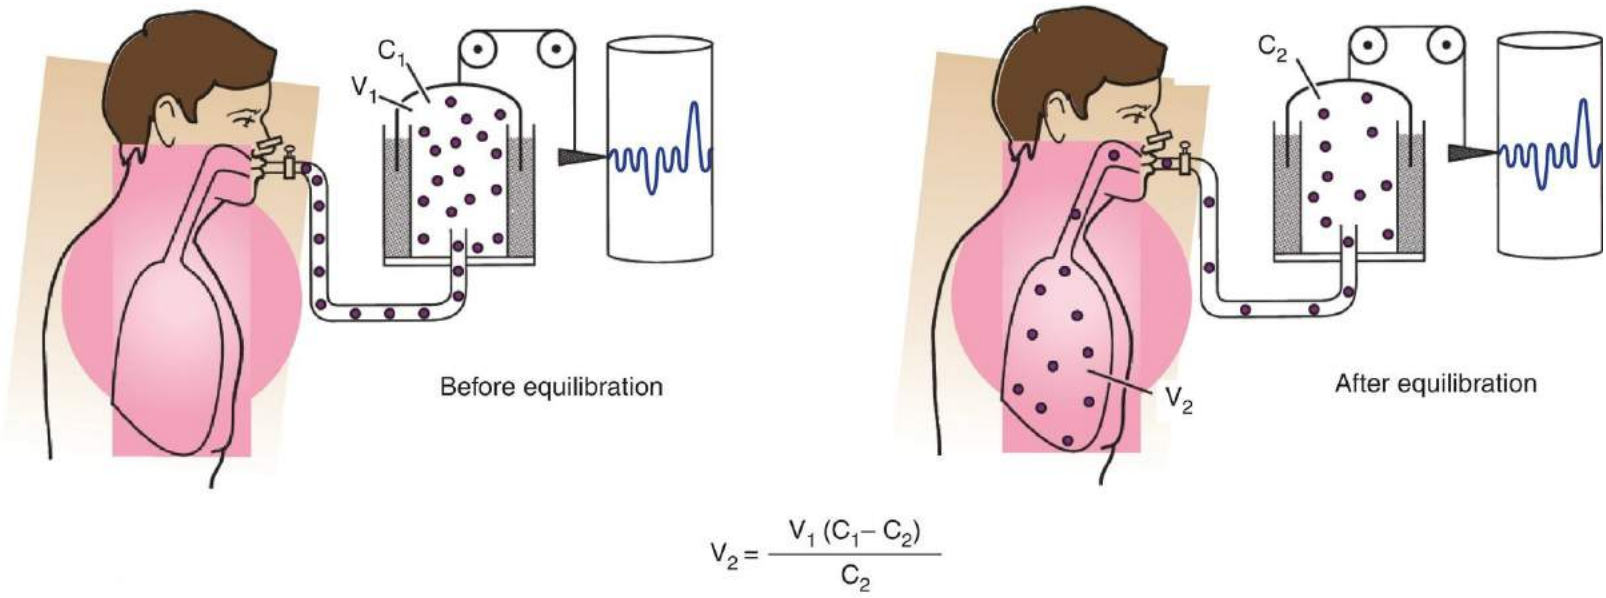

Figure 18.10 Helium dilution is used to measure residual volume (RV). *Dots* represent helium before and after equilibration. C, concentration; V, volume.

$$C_1 \times V_1 = C_2 (V_1 + V_2) \quad (7)$$

where C_1 equals the initial concentration of helium in the spirometer, V_1 equals the initial volume of helium–oxygen mixture in the spirometer, C_2 equals helium concentration after equilibration, and V_2 equals unknown volume in the lungs.

$$V_2 = \frac{V_1(C_1 - C_2)}{C_2}$$

(8)

Starting the test at precisely the right time is important. If the test begins at the end of a normal tidal volume (end of expiration), the volume of air remaining in the lungs represents FRC. If the test begins at the end of an FVC, then the test will measure RV. Similarly, if the test starts after a maximal inspiration, then V_2 would equal TLC. In practice, carbon dioxide is absorbed and oxygen is added to the spirometer to make up for the oxygen consumed by the person during the test. Although the helium dilution technique is an excellent test for the measurement of FRC and RV in healthy people, it has a major limitation in patients whose lungs are poorly ventilated because of plugged airways or high airway resistance. In these diseased lungs, helium gives a falsely low FRC value.

MINUTE VENTILATION

So far, ventilation has been described in terms of measurements of static lung volumes and forced lung volumes. Breathing is a dynamic process involving how much air is brought in and out of the lungs in a minute. If 500 mL of air is inspired with each breath (VT) and the breathing rate (f) is 14 times a minute, then the total **minute ventilation** $(\dot{V}_A)$ is the amount of air that enters the lungs each minute (500 × 14 = 7,000 mL/min or 7 L/min). Expired minute ventilation $(\dot{V}_E)$ is calculated from the amount of expired air per minute and can be represented by the equation:

$$\dot{V}_E = V_T \times f \quad (9)$$

Minute ventilation and expired minute ventilation are the same, based on the assumption that the volume of air inhaled equals the volume exhaled. This is not quite true because more oxygen is consumed than carbon dioxide is produced. This difference, for all practical purposes, is ignored.

Not all of the inspired air reaches the alveoli and becomes wasted air.

The tidal volume is distributed between the conducting airways and alveoli. Because gas exchange occurs only in the alveoli and not in the conducting airways, a fraction of the minute ventilation is wasted air. For each 500 mL of air inhaled, ~150 mL remains in the conducting airways and is not involved in gas exchange (Fig. 18.11). This volume of wasted air is known as **dead space volume** (**VD**). Because VD is a result of the anatomy of the airways, the volume is often referred to as *anatomic VD*.

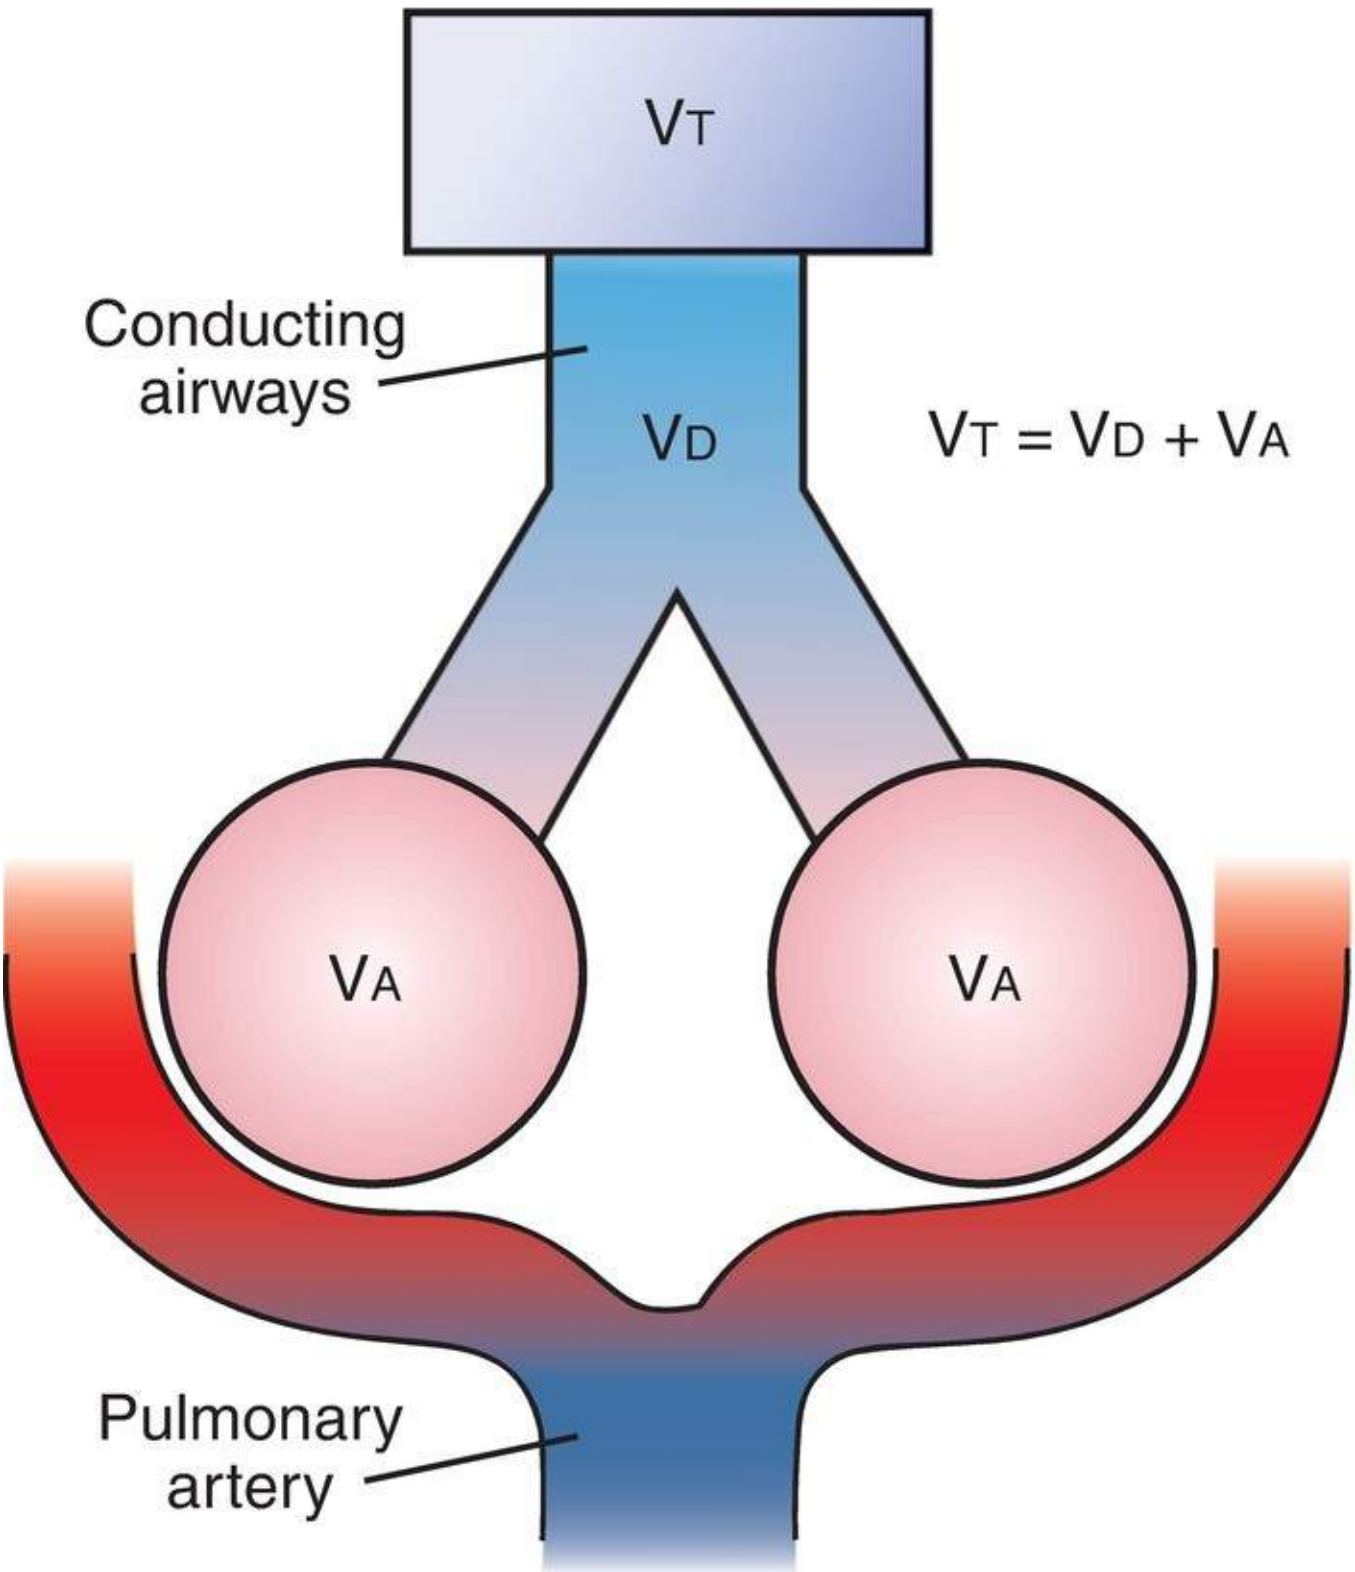

Figure 18.11 Some of the air in the tidal volume does not participate in gas exchange. Tidal volume

(VT) is represented by the *rectangle* and is the volume of air that will be drawn in during inspiration. VT will be distributed between the conducting airways and alveoli. The volume of air in the conducting airways does not participate in gas exchange and constitutes dead space volume (VD). VA is the volume of fresh air added to the alveoli.

Picture what occurs during a normal breathing cycle. A normal tidal volume of 500 mL is expired. During the next inspiration, another 500 mL is taken in, but the first 150 mL of air entering the alveoli is VD (old alveolar gas left behind). Thus, only 350 mL of fresh air reaches the alveoli and 150 mL is left in the conducting airways. The normal ratio of dead space volume to tidal volume (VD/VT) is in the range of 0.25 to 0.35. In this example, the ratio (150:500) is 0.30, which means that 30% of the tidal volume or 30% of the minute ventilation does not participate in gas exchange and constitutes dead or wasted air.

Dead space air is not confined to the conducting airways alone. Any time gases in the alveoli do not participate in gas exchange; these gases also become part of the wasted air. For example, if inspired air is distributed to alveoli that have no blood flow, this constitutes dead space and is referred to as **alveolar dead space volume** (Fig. 18.12A). Alveolar dead space volume is not confined to alveoli without blood flow. Alveoli that have reduced blood flow exchange less inspired air than normal (see Fig. 18.12B); any portion of alveolar air in excess of that needed to maintain normal gas exchange constitutes alveolar dead space volume. Therefore, dead space volume (VD) may be either anatomic or alveolar in nature. The sum of the two types of dead space is **physiologic dead space volume**. Therefore, physiologic VD = anatomic VD + alveolar VD. Physiologic dead space can be measured using the following equation:

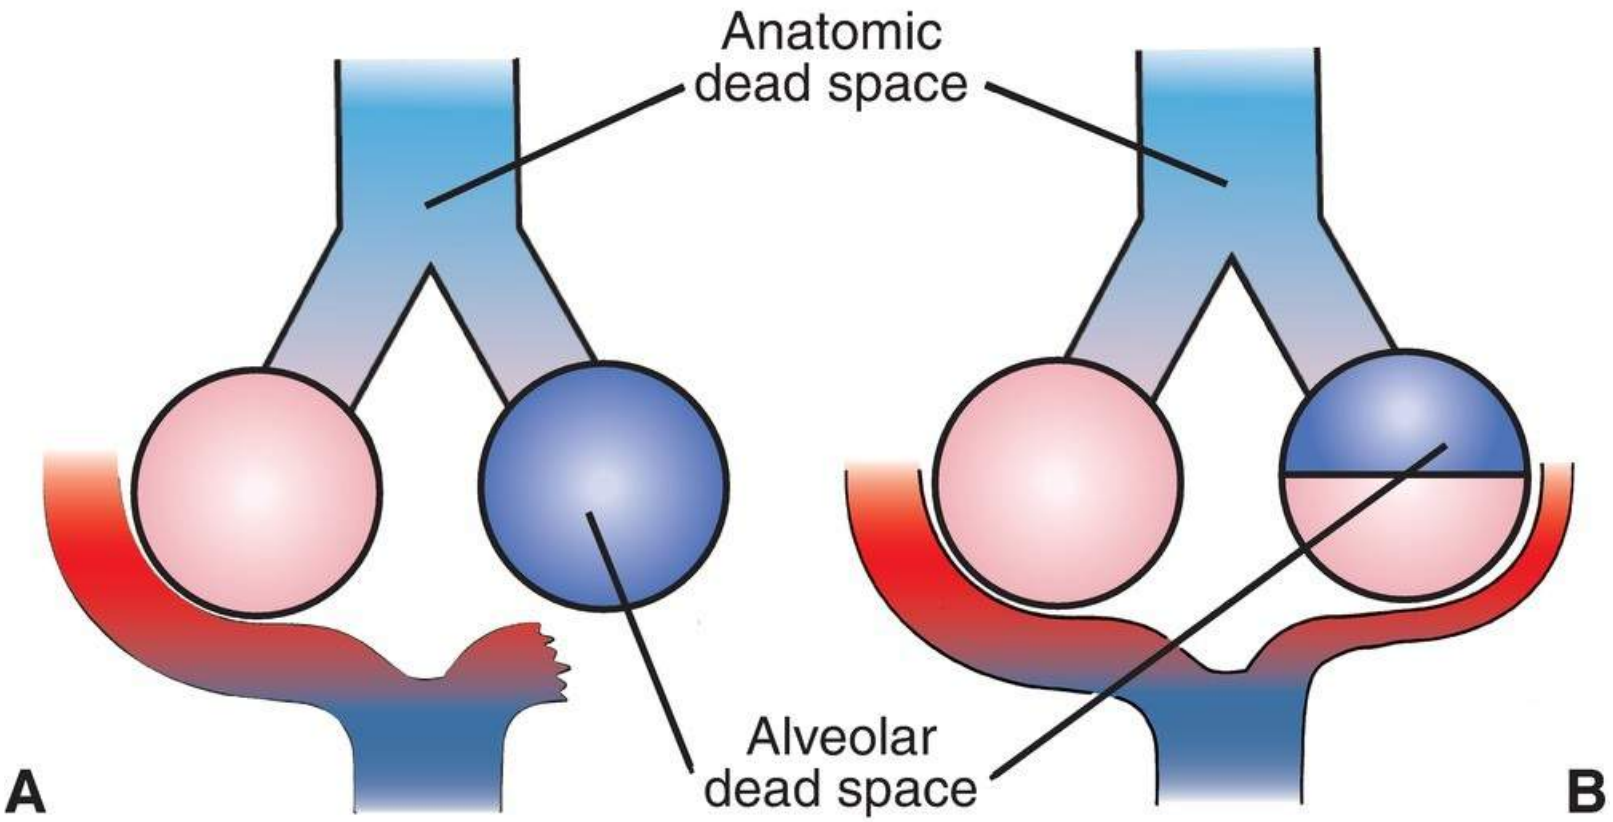

Figure 18.12 Total wasted air in the lungs is computed from the physiologic dead space volume. Dead space volume occurs in the conducting airways and in alveoli with poor capillary circulation. **(A)** There is no blood flow to an alveolar region. **(B)** There is reduced blood flow. In both cases, a portion of alveolar air does not participate in gas exchange and constitutes alveolar dead space volume. Note that physiologic dead space is the sum of alveolar dead space plus anatomic dead space.

$$\frac{V_D}{V_T} = \frac{F_{ACO_2} - F_{ECO_2}}{F_{ACO_2}}$$

(10)

Normal values for the VD/VT ratio are 0.2 to 0.35. Once the ratio is determined, physiologic dead space can be computed. For example, if a patient has a tidal volume of 500 mL and the VD/VT ratio is 0.35, then the physiologic dead space is 175 mL (physiologic VD = 500 × 0.35). Basically, anatomic VD, alveolar VD, and physiologic VD are terms that denote the volume of inspired gas that does not participate in gas exchange. In one case, there is a fraction of VT that does not reach the alveoli (anatomic dead space volume). In another, a fraction of the VT reaches the alveoli, but there is reduced or no blood flow, leading to alveolar dead space volume. Physiologic dead space volume represents the sum of anatomic and alveolar dead space volumes. In healthy people, physiologic VD is approximately the same as anatomic dead space.

Alveolar ventilation is the amount of fresh air that participates in alveolar gas exchange.

The volume of fresh air per minute actually reaching the alveoli is known as **alveolar ventilation** ($\dot{V}_A$). To determine how much fresh air reaches the alveoli per minute, dead space volume is subtracted from the tidal volume and the result is multiplied by breathing frequency, f, and can be represented by:

$$\dot{V}_A = (V_T - V_D) \times f \quad (11)$$

where VT equals tidal volume, VD equals dead space volume, and f equals breathing frequency. For example, if a person has a breathing rate of 14 breaths/min, a VT of 500 mL, and a VD of 150 mL, then the volume of air entering the alveoli is 4.9 L/min [(500 − 150 mL) × 14 = 4,900 mL/min]. Only alveolar ventilation represents the amount of fresh air reaching the alveoli, and it is the only air that participates in gas exchange. For instance, a swimmer using a snorkel breathes through a tube that increases dead space volume. Similarly, a patient connected to a mechanical ventilator also has increased dead space volume. Indeed, if minute ventilation is held constant, then alveolar ventilation is decreased with snorkel breathing or with mechanical ventilation.

The significance of dead space volume, minute ventilation, and alveolar ventilation is shown in Table 18.5. Subject C's breathing is slow and deep, B's breathing is normal, and A's breathing is rapid and shallow. Note that each subject has the same minute ventilation (i.e., the total amount of expired air per minute), but each has marked differences in alveolar ventilation. Subject A has no alveolar ventilation and would die in a matter of minutes, whereas subject C has alveolar ventilation greater than normal. The important lesson from the examples presented in Table 18.5 is that increasing the depth of breathing is far more effective in elevating alveolar ventilation than is increasing the frequency or rate of breathing. A good example is exercise because in most exercise situations, increased alveolar ventilation is accomplished by increases in the depth of breathing rather than in the rate. A well-trained athlete can often increase alveolar ventilation during moderate exercise with little or no increase in breathing frequency (Clinical Focus 18.1).

TABLE 18.5 Effect of Breathing Patterns on Alveolar Ventilation

Subject	Tidal Volume	×	Frequency	=	Minute Ventilation	–	Dead Space Ventilation*	=	Alveolar Ventilation
	(mL)		(breaths/min)		(mL/min)		(mL/min)		(mL/min)
A	150	×	40	=	6,000	–	150 × 40	=	0
B	500	×	12	=	6,000	–	150 × 12	=	4,200
C	1,000	×	6	=	6,000	–	150 × 6	=	5,100

*Dead space volume is 150 mL in all three subjects.

*Dead space volume is 150 mL in all three subjects.

CLINICAL FOCUS 18.1

Chronic Obstructive Pulmonary Disease

Chronic bronchitis, emphysema, and asthma are major pathophysiologic disorders of the lungs. Bronchitis is an inflammatory condition that affects one or more bronchi. Emphysema stems from loss of lung elastic recoil and over distention of alveoli. Asthma is marked by spasmodic contractions of smooth muscle in the bronchi. Although the pathophysiology and etiology of chronic bronchitis, emphysema, and asthma are different, they all are classified collectively as **chronic obstructive pulmonary disease** (**COPD**). The hallmark of COPD is decreased airflow during forced expiration, which leads to a decrease in **forced vital capacity** (**FVC**) and **forced expiratory volume in 1 second** (**FEV_1**).

COPD is characterized by chronic obstruction of the small airways. Airflow can become obstructed in three ways: excessive mucus production (as in bronchitis), airway narrowing caused by bronchial spasms (as in asthma), and airway collapse during expiration (as in emphysema). In the last case, airway collapse stems from abnormally high compliance and concomitant loss of lung elastic recoil. In severe COPD, air is trapped in the lungs during forced expiration, leading to abnormally high residual volume.

Chronic bronchitis and emphysema often coexist. Bronchitis leads to excessive mucus production, which plugs the small airways. A cough is produced to clear the excess mucus from the airways; on repeated exposure to a bronchial irritant, such as tobacco smoke, a persistent cough develops. As a result, the alveoli become over distended and can rupture from excessive pressure, especially in plugged airways.

Late in COPD, patients often experience hypoxemia (low blood oxygen) and hypercapnia (high blood carbon dioxide). These two conditions, especially hypoxemia, cause pulmonary arteries to constrict. Hypoxia-induced pulmonary vasoconstriction leads to further complication by causing pulmonary hypertension (high blood pressure in the pulmonary circulation). If pulmonary hypertension becomes sever, it will cause right heart failure. Based on changes in blood oxygen levels, patients with COPD can be categorized into two types. Those exhibiting predominantly emphysema are referred to as “pink puffers” because their oxygen levels are usually satisfactory and their skin remains pink. They develop a puffing style of breathing to help exhaust the air out of the lungs. Those manifesting

predominantly chronic bronchitis are called “blue bloaters” because low oxygen levels give their skin a blue cast and fluid retention from heart failure gives them a bloated appearance.

COPD is by far the most common chronic lung disease in the United States. More than 10 million Americans suffer from COPD, and it is the fifth leading cause of death nationwide. The single most common cause of chronic bronchitis and emphysema is tobacco smoke. ■

Alveolar ventilation is determined by measuring the patient's volume of expired carbon dioxide.

Alveolar ventilation is easy to calculate if dead space volume is known. However, dead space volume is not easily determined in a human subject or a patient. Often, dead space is approximated for a seated subject by assuming that dead space (in milliliters) is equal to the subject's weight in pounds (e.g., a subject who weighs 170 lb would have a dead space volume of 170 mL). This assumption is fairly reliable for healthy people but is not in patients with respiratory problems. Alveolar ventilation is calculated in the pulmonary function laboratory from the volume of expired carbon dioxide per minute and fractional concentration of carbon dioxide in the alveolar gas (Fig. 18.13).

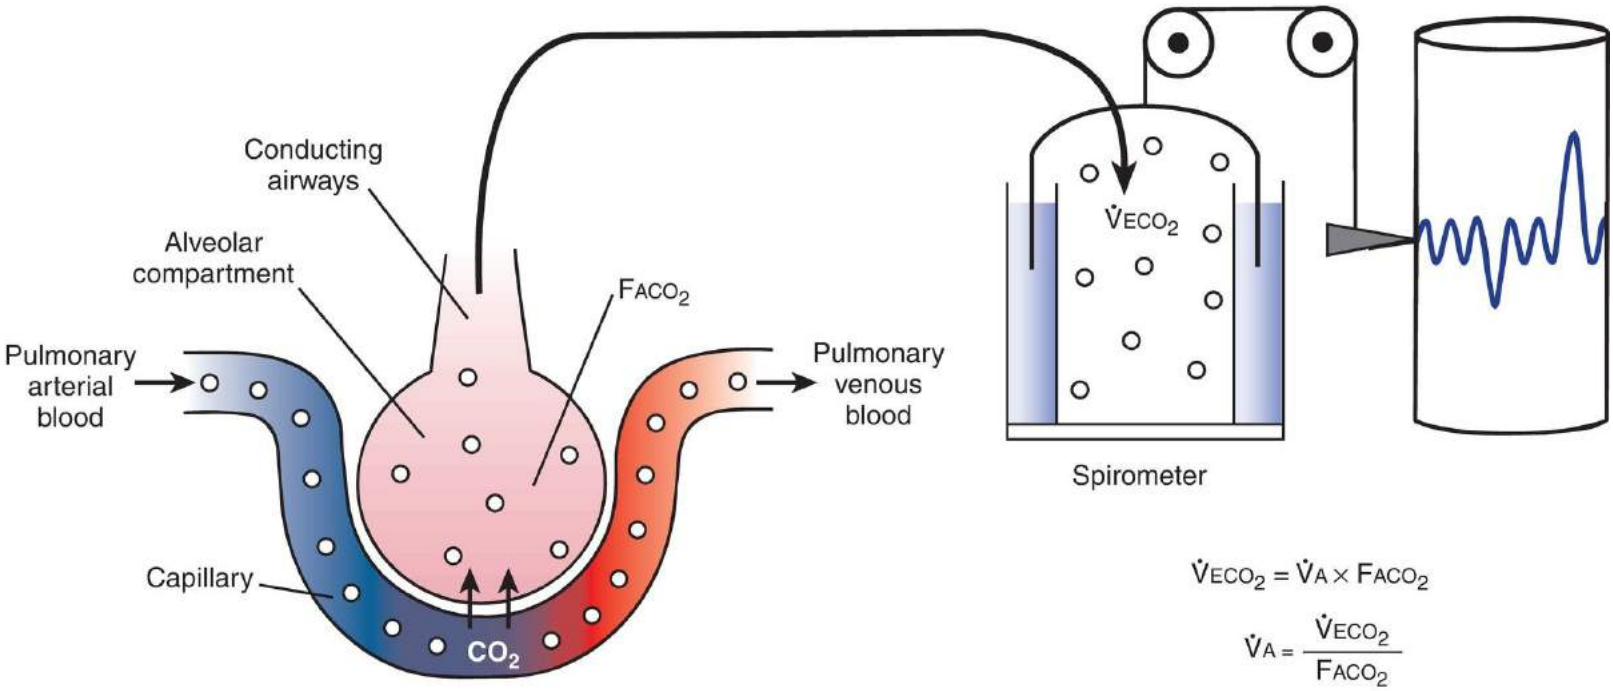

Figure 18.13 The expired carbon dioxide is used to calculate alveolar ventilation. Because all of the CO_2 (represented by *dots*) in the expired air originates from the alveoli, the fractional concentration of CO_2 in alveolar gas ($FACO_2$) can be obtained at the end of a tidal volume (often referred to as *end-tidal CO_2*). $\dot{V}_A$, alveolar ventilation; $\dot{V}_{ECO_2}$, volume of carbon dioxide expired per minute.

This pulmonary function test is based on the concept that (1) no gas exchange occurs in the conducting airways, (2) the inspired air contains essentially no carbon dioxide, and (3) all of the expired carbon dioxide originates from alveoli. Therefore:

$$\dot{V}_{ECO_2} = \dot{V}_A \times F_{ACO_2}$$

(12)

where $\dot{V}_{ECO_2}$ equals the volume of carbon dioxide expired per minute and $FACO_2$ equals the fractional concentration of carbon dioxide in alveolar gas. Rearranging yields the alveolar ventilation equation:

$$\dot{V}_A = \dot{V}_{ECO_2} / F_{ACO_2}$$

(13)

The carbon dioxide concentration in the alveoli can be obtained by sampling the last portion of the tidal volume during expiration (end-tidal volume), which contains alveolar gas. Alveolar ventilation can also be determined from the partial pressure of carbon dioxide in the alveoli ($PACO_2$) based on the fact that $PACO_2$ is equal to $FACO_2$ times total alveolar gas pressure. Equation 13 can be written as:

$$\dot{V}_A\,(\text{L/min}) = \frac{\dot{V}_{ECO_2}\,(\text{mL/min}) \times 0.863}{P_{ACO_2}\,(\text{mm Hg})}$$

(14)

where 0.863 is a constant. Carbon dioxide diffuses readily between the blood and alveoli, and as a result, $PACO_2$ is in equilibrium with the partial pressure of carbon dioxide in the arterial blood ($PaCO_2$). Recall that a capital “A” signifies alveolar gas and the lower case “a” denotes arterial gas. Because carbon dioxide is in equilibrium between the alveoli and the arterial blood, arterial carbon dioxide tension ($PACO_2$) can be used to calculate alveolar ventilation as follows:

$$\dot{V}_A = \frac{\dot{V}_{ECO_2} \times 0.863}{P_{ACO_2}}$$

(15)

From the above equation, it is important to recognize the inverse relationship between $\dot{V}_A$ and $PaCO_2$ (Fig. 18.14). If alveolar ventilation is halved, alveolar PCO_2 will double (assuming a steady-state and constant carbon dioxide production). This decrease in alveolar ventilation below normal is called **hypoventilation**. Conversely, increased ventilation, referred to as **hyperventilation**, leads to a fall in blood $PaCO_2$. Clinically, the adequacy of alveolar ventilation is usually evaluated in terms of arterial PCO_2. An increase in blood $PaCO_2$ reflects hypoventilation, and a decrease in blood $PaCO_2$ reflects hyperventilation. It is important to make the distinction between *hyperventilation* and *hyperpnea*. Remember, hyperventilation is increased alveolar ventilation with a concomitant decrease in arterial PCO_2. **Hyperpnea** is increased alveolar ventilation with *no change* in arterial PCO_2. The reason for this physiologic response is that alveolar ventilation increases proportionally to carbon dioxide production. An example of hyperpnea is seen with exercise. With exercise, the production of CO_2 increases and offsets the increased CO_2 blown off with increased alveolar ventilation.

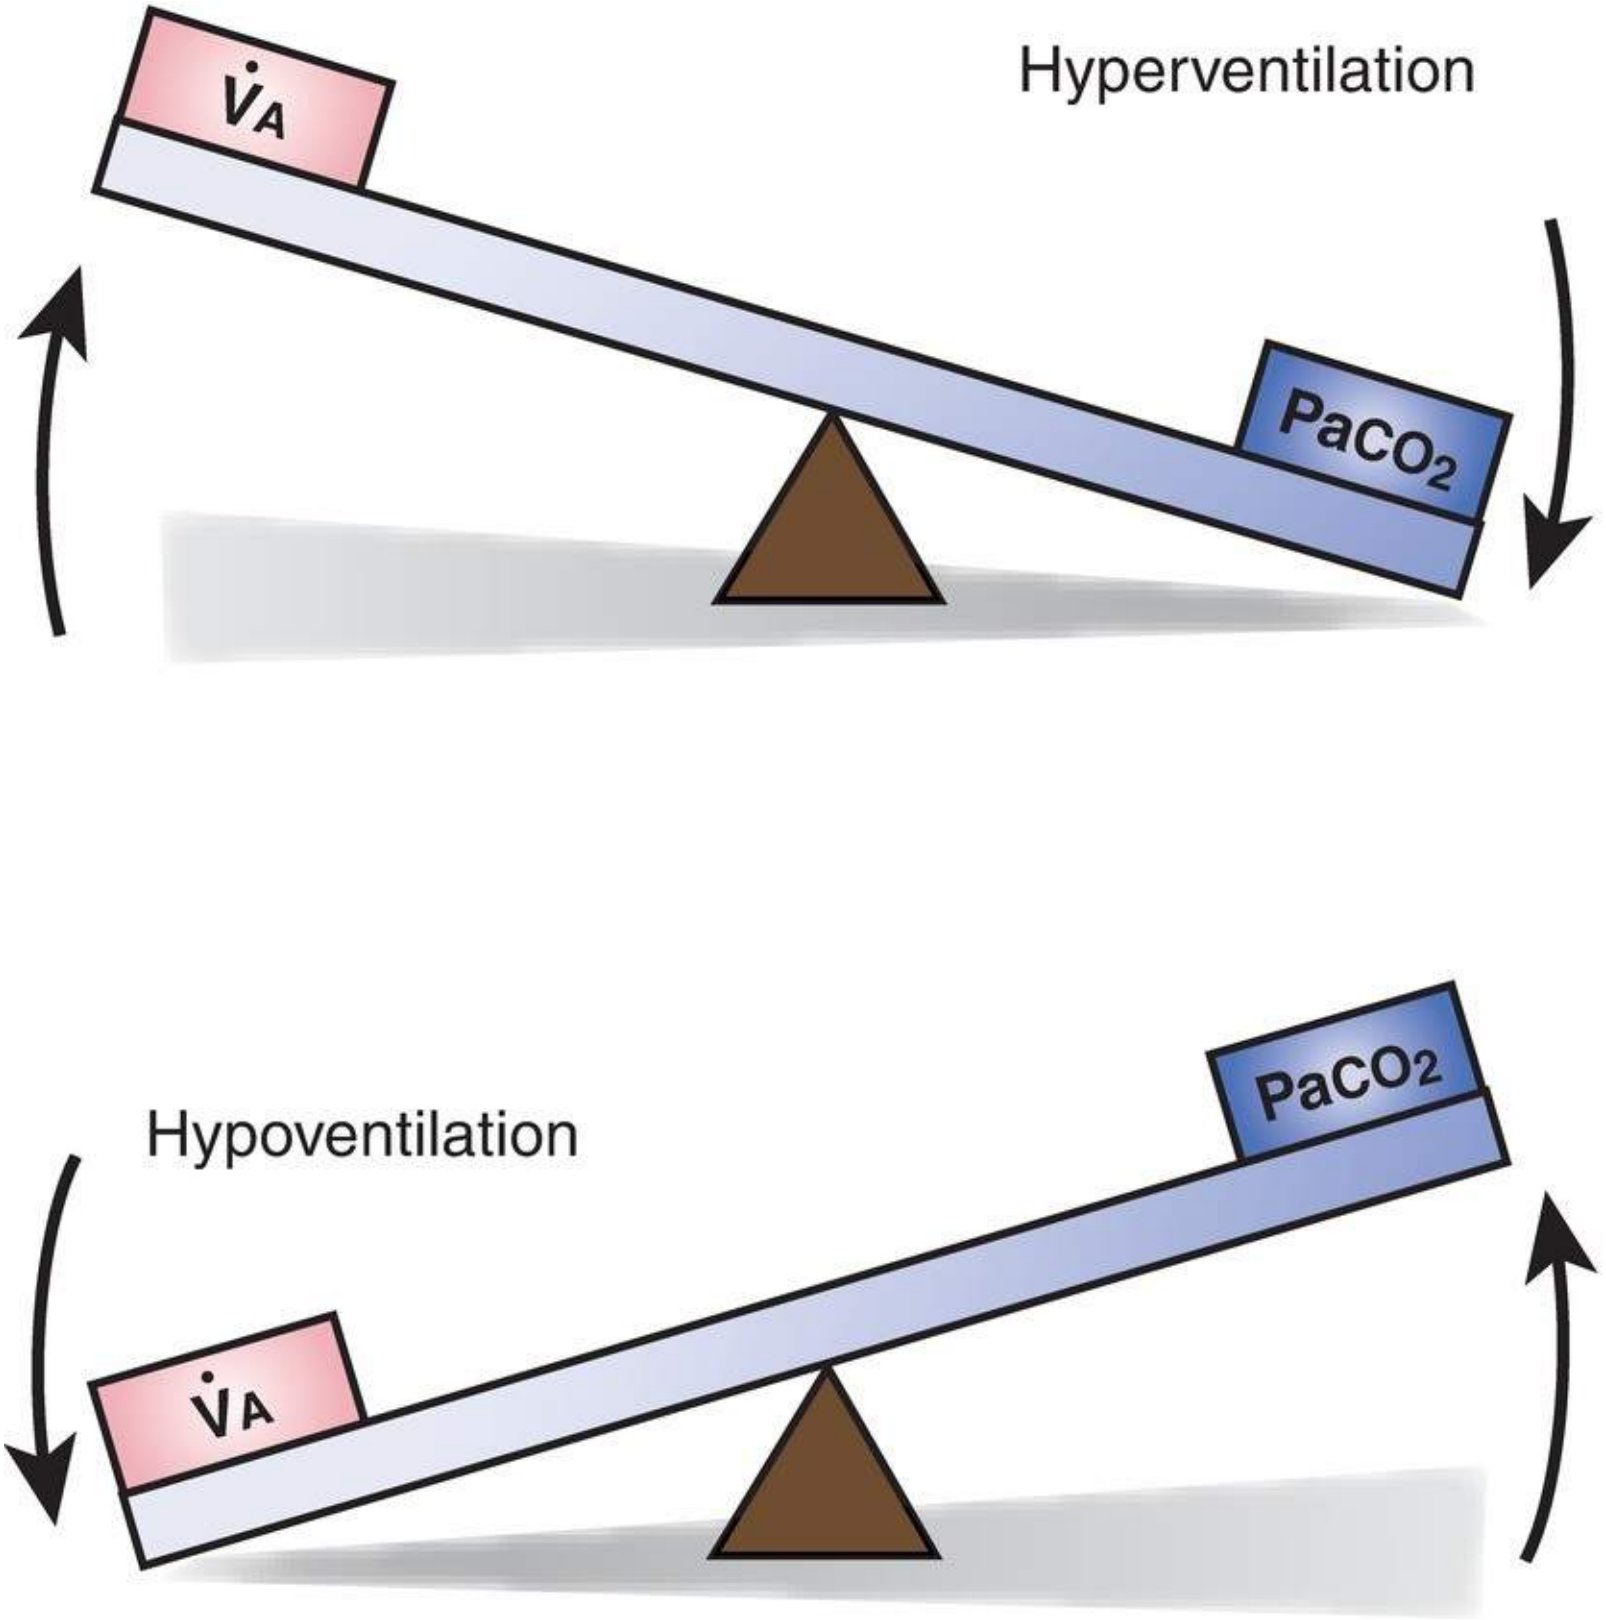

Figure 18.14 Alveolar ventilation and $PaCO_2$ are inversely related. Alveolar ventilation is a key determinant of $PaCO_2$. In the above figure, the inverse relationship is illustrated. For example, if alveolar ventilation is halved, $PaCO_2$ will double, and conversely, if alveolar ventilation is doubled, $PaCO_2$ will be halved.

What happens to PaO_2 when alveolar ventilation increases? When alveolar ventilation increases, PaO_2 will also increase. However, doubling alveolar ventilation will not lead to a doubling of PaO_2. The quantitative relationship between alveolar ventilation and PaO_2 is more complex than that for $PaCO_2$, for

two reasons. First, the inspired PO_2 is obviously not zero. Second, the respiratory exchange ratio (R), defined as the ratio of the volume of carbon dioxide exhaled to the volume of oxygen taken up, $(\dot{V}_{CO_2}/\dot{V}_{O_2})$ is usually <1, which means more oxygen is removed from the alveolar gas per unit time than carbon dioxide is added. The alveolar partial pressure of oxygen (PAO_2) can be calculated by using the alveolar gas equation:

$$P_{AO_2} = P_{IO_2} - P_{ACO_2}[F_{IO_2} + (1 - F_{IO_2})/R] \quad (16)$$

where PIO_2 equals the partial pressure of inspired oxygen (moist tracheal air), $PaCO_2$ equals the partial pressure of carbon dioxide in the alveoli, FIO_2 equals the fractional concentration of oxygen in the inspired air, and R equals the **respiratory exchange ratio**. When R is 1, the complex term in the brackets equals 1. Also, if a subject breathes 100% oxygen ($FIO_2 = 1.0$) for a brief period, the correction factor in the brackets reduces to 1.

In a normal resting person breathing air at sea level with an R of 0.82, a $PaCO_2$ of 40 mm Hg, and a PIO_2 of 150 mm Hg, PaO_2 is calculated as follows:

$$P_{AO_2} = 150\ \text{mm Hg} - 40\ \text{mm Hg}[0.21 + (1 - 0.21)/0.82]$$

$$P_{AO_2} = 150\ \text{mm Hg} - 40\ \text{mm Hg} \times [1.2] + 102\ \text{mm Hg} \quad (17)$$

Because PIO_2 and FIO_2 stay fairly constant and $PACO_2$ equals $PaCO_2$, the alveolar gas equation can be simplified to:

$$P_{AO_2} = 150 \times 1.2(P_{ACO_2}) \quad (18)$$

The alveolar gas equation for calculating PAO_2 is essential to understand any PaO_2 value as well as assessing if the lungs are properly transferring O_2 into the alveolar capillary blood.

ELASTIC PROPERTIES OF LUNG AND CHEST WALL

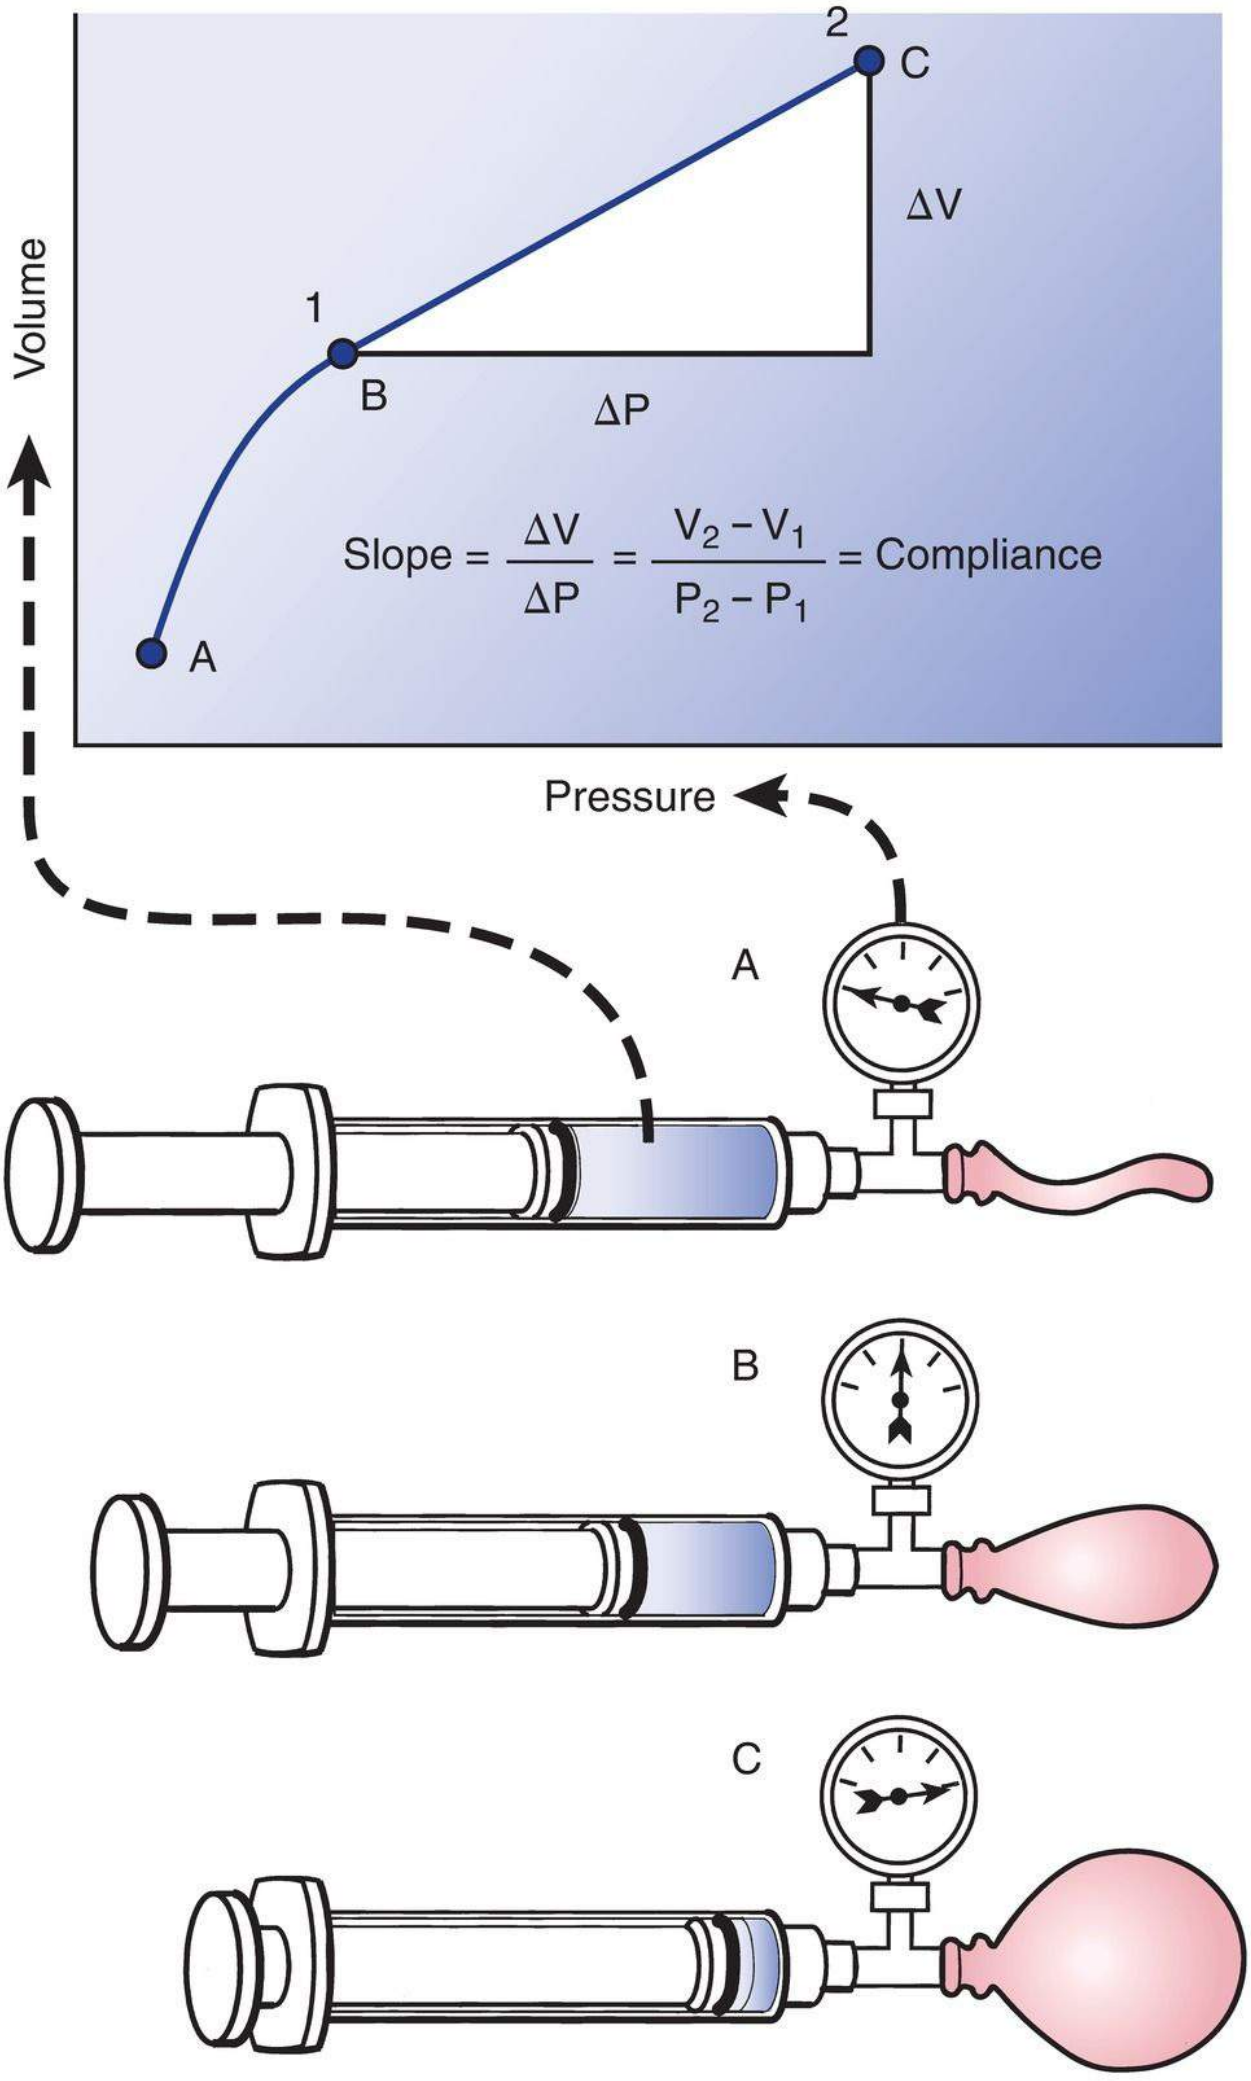
The lungs, airway tree, and vascular tree are embedded in elastic tissue. When the lungs are inflated, this elastic component is stretched. The degree of lung expansion at any given time in the breathing cycle is proportional to transpulmonary pressure. How well a lung inflates and deflates with a change in transpulmonary pressure depends on its elastic properties. An important feature of an elastic material is that, once stretched, it will recoil to its unstretched position. Therefore, the lung is like a spring; it recoils when stretched.

Elastic recoil of the lungs directly affects inflation and deflation.

When discussing the elastic properties of the lung, there are three basic components that are involved with respiration. These include elastic recoil, stiffness, and lung distensibility. **Distensibility** is the term applied to the ease with which the lungs can be stretched or inflated. Stiffness is defined as resistance to stretch or to inflation. **Elastic recoil** is defined as the ability of a stretched or inflated lung to return to its resting volume (FRC). Elastic recoil of the lung is directly related to lung stiffness, that is, the stiffer the lung, the greater the elastic recoil. An analogy of this relationship is a coiled spring—the more difficult it is to stretch the spring (greater stiffness), the greater the ability to snap back (greater elastic recoil); similarly, a lung that is stiff is more difficult to stretch (inflate), but the inflated lung has a greater ability to recoil back. Elastic recoil plays a key role during expiration in forcing air out of the lungs. Distensibility and elastic recoil, however, are inversely related to each other. A lung that is easily inflated has less elastic recoil. Overstretching causes the lungs to lose elastic recoil. Lung distensibility and elastic recoil arise from the elastin and collagen fibers enmeshed around the alveolar walls, adjacent bronchioles, and small blood vessels. Elastin fibers are highly distensible and can be stretched to almost double their resting length. Collagen fibers, however, resist stretch and limit lung expansion at high lung volumes. As the lungs expand during inflation, the fiber network around alveoli, small blood vessels, and small airways unfolds and rearranges—similar to stretching a nylon stocking. When the stocking is stretched, there is not much change in individual fiber length, but the unfolding and rearrangement of the nylon mesh allows the stocking to be easily stretched out to fit the contour of the legs. However, if the nylon stocking is overstretched, it loses its elastic recoil, no longer fits the contour of the legs, and sags or becomes “baggy.” In the same way, lungs that lose their elastic recoil also become “baggy.” In other words, “baggy lungs” are easy to inflate (stretched) but are difficult to deflate because of their inability to recoil inwardly and force air out of the lungs.

Lung compliance measures distensibility.

Lung distensibility and elastic recoil can be determined from a pressure–volume curve. A simple analogy is the inflation of a balloon with a syringe (Fig. 18.15). For each change in pressure, the balloon inflates to a new volume. The slope of the line of the pressure–volume curve is known as **lung compliance** (**CL**). Compliance is a measure of distensibility and is represented by:



2
C
ΔV
Volume
1
B
ΔP
Slope = ΔV/ΔP = V2 − V1/P2 − P1 = Compliance
A
Pressure
A
B
C

Figure 18.15 Pressure–volume measurements of a balloon illustrate its elastic properties. For each change in pressure (shown by movement of the *arrow* on the manometer dial), the balloon inflates to a new volume (plotted on the graph at points A, B, and C). The slope of the line determined by ΔV/ΔP between any two points on a pressure–volume curve is compliance. Compliance and elastic recoil are inversely related (CL = 1/elastic recoil). For example, the lower the compliance, the greater the elastic recoil. P, pressure; V, volume.

$$C_L = \Delta volume / \Delta pressure \quad (19)$$

where Δvolume equals change in volume and Δpressure equals change in pressure (see Chapter 11).

A similar pressure–volume curve can be generated for the human lungs by simultaneously measuring changes in lung volume with a spirometer and changes in pleural pressure with a pressure gauge (Fig. 18.16). Because the esophagus passes through the thorax, changes in pleural pressure can be obtained indirectly from the pressure changes in the esophageal pressure by using a balloon catheter. In practice, a pressure–volume curve is obtained by having the person first inspire maximally to TLC and then expire slowly. During the slow expiration, airflow is periodically interrupted (so that alveolar pressure is zero), and lung volume and pleural pressure are measured. Under these conditions, in which no airflow is occurring, the volume change per unit pressure change (ΔV/ΔP) is called *static compliance*. Lung compliance is affected by lung volume, lung size, and surface tension inside the alveoli. Because the pressure–volume curve of the lung is nonlinear, compliance is not the same at all lung volumes; it is high at low lung volumes and low at high lung volumes. In the midrange of the pressure–volume curve, lung compliance is about 0.2 L/cm H_2O in adult humans. Lung size affects lung compliance. A mouse lung, for example, has a different compliance than an elephant lung. To allow comparisons among lungs of different sizes, lung compliance is normalized by dividing it by FRC to give a specific compliance.

Figure 18.16 Lung compliance is measured from a pressure–volume curve. The subject first inspires maximally to total lung capacity (TLC) and then expires slowly, while airflow is periodically stopped to simultaneously measure pleural pressure and lung volume. Lung compliance (CL) is measured in L/cm H_2O. Note that pleural pressure is determined by measuring esophageal pressure. FRC, functional residual capacity; P, pressure; RV, residual volume; VT, tidal volume.

What is the significance of an abnormally low or abnormally high compliance? Remember lung compliance is inversely related to lung stiffness (CL = 1/stiffness). For example, abnormally low lung compliance indicates a stiff lung, which means more work is required to inflate the lungs to bring in a normal tidal volume. An example of abnormally low compliance is seen in a restrictive disorder, a disease state that is characterized by restriction of lung inflation (stiff lungs). The compliance of these lungs is decreased compared with that of a normal lung (Fig. 18.17). Restrictive disorders can be caused by infection or by toxic environmental insults in which the elastic properties are altered. As a result, these lungs become stiffer and lung compliance is decreased. An abnormally high compliance is just as detrimental as a low compliance. Consider the disease **emphysema**, a disease in which lungs have been overstretched from chronic coughing and congested airways. Lungs of patients with emphysema (which is strongly linked to smoking) have a high compliance (high distensibility) and are extremely easy to inflate. However, getting air out again is another matter. Lungs with abnormally high compliance have low elastic recoil, and additional effort is required to force air out of the lungs. Emphysema is part of a broader category termed **chronic obstructive pulmonary disease** (**COPD**), which is a diseased state defined as an obstruction of airflow out of the lungs. It is important to remember that lungs with increased compliance have high static lung volumes (increased TLC, FRC, and RV) and low airflow. Therefore, patients with COPD have high lung volumes and retain an abnormally high RV of air.

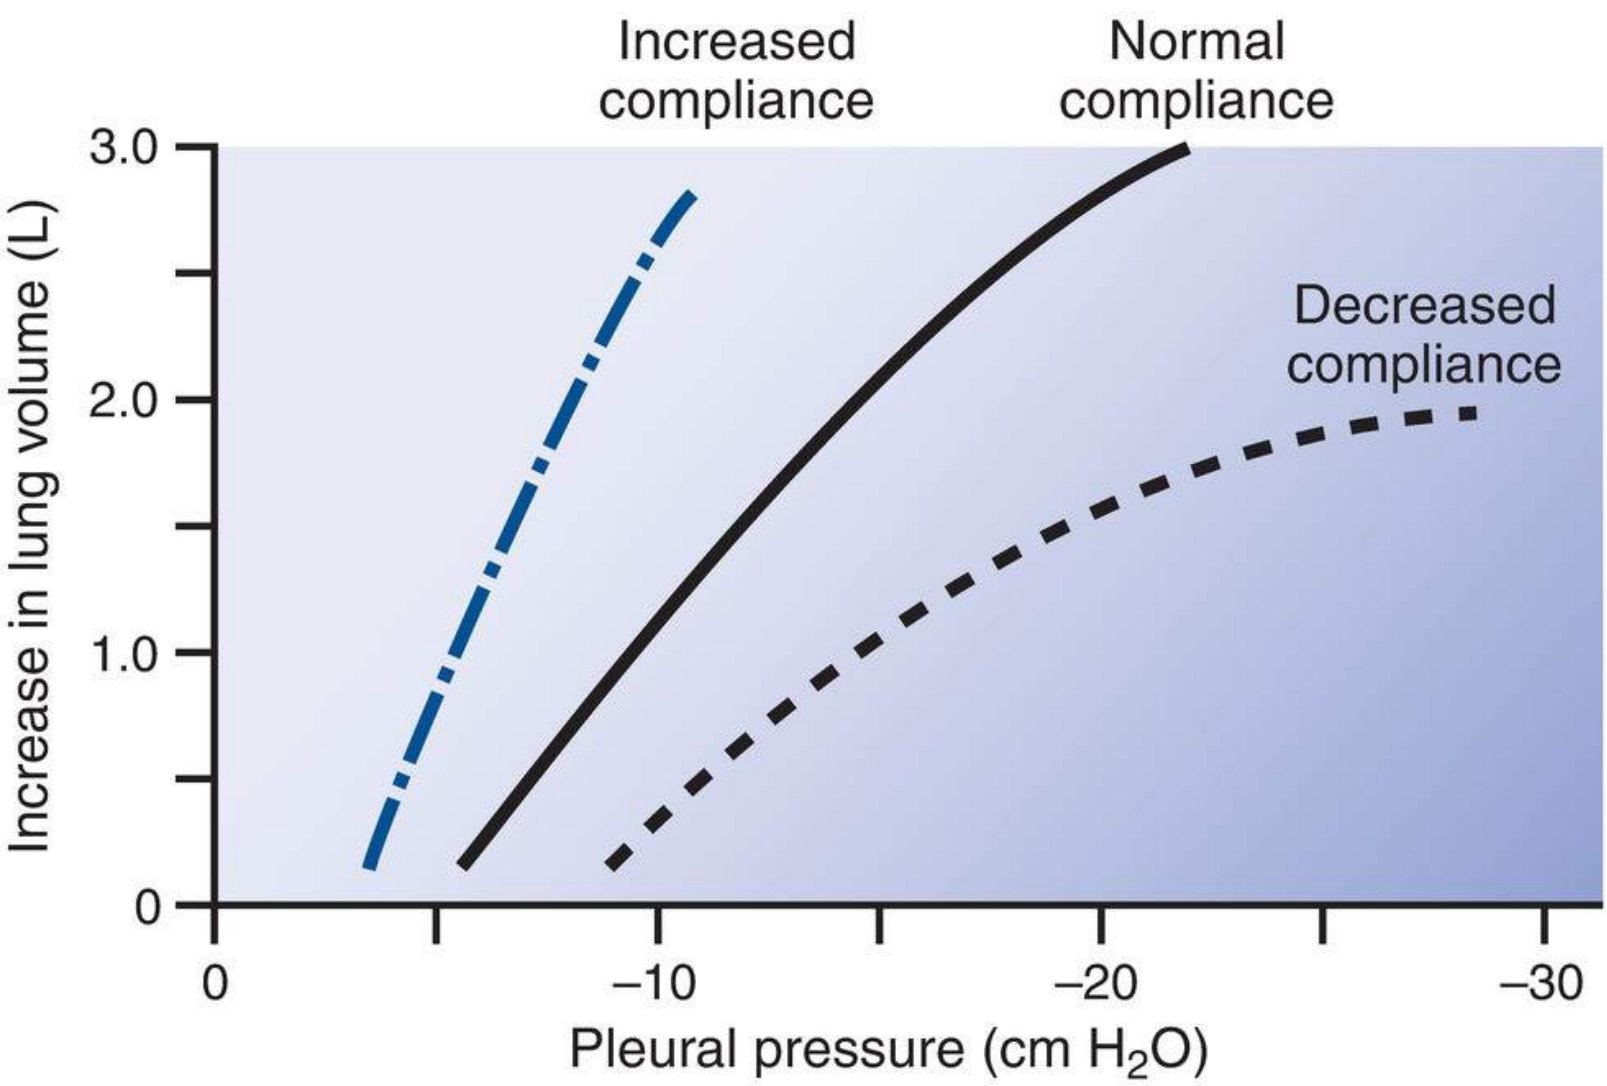

Figure 18.17 Obstructive and restrictive diseases alter lung compliance. Patients with a chronic obstructive lung disease, such as emphysema, have abnormally high lung compliance. Patients with restrictive diseases, such as respiratory distress syndrome, have abnormally low lung compliance (see Clinical Focus 18.2).

Elastic recoil of the chest wall affects lung volumes.

Just as the lungs have elastic properties, so does the chest wall. The outward elastic recoil of the chest wall aids lung expansion, whereas the inward elastic recoil of the lungs pulls in the chest wall. The elastic recoil of the chest wall is such that if the chest were unopposed by the recoil of the lung, it would expand to about 70% of TLC. This volume represents the resting position of the chest wall unopposed by the lung. If the chest wall is mechanically expanded beyond its resting position, it recoils inward. At volumes <70% of TLC, the recoil of the chest wall is directed outward and is opposite to the elastic recoil of the lung. Therefore, the outward elastic recoil of the chest wall is greatest at RV, whereas the inward elastic recoil of the lung is greatest at TLC.

The lung volume at which lung and chest are at equilibrium (i.e., equal elastic recoil but in opposite directions) is represented by FRC. Since the lungs and chest walls are recoiling equally but in opposite directions at FRC, FRC is often referred to as the resting volume of the lungs. A change in the elastic properties of either the lungs or chest wall has a significant effect on FRC. For example, if the elastic recoil of the lungs is increased (i.e., lower CL), a new equilibrium is established between the lungs and chest wall, resulting in a decreased FRC. Conversely, if the elastic recoil of the chest wall is increased, FRC is higher than normal. The elastic recoil of the chest wall at low lung volumes is a major determinant of RV in young people.

Differences in regional lung compliance cause uneven ventilation.

Lung compliance also causes inspired air to be unevenly distributed in the lungs. In a healthy upright person, compliance at the top part of the lungs is less than that at the base. This difference in compliance between the apex and base, known as **regional compliance**, is caused by gravity (Fig. 18.18). The gravitational effect occurs because lung tissue is ~80% water and gravity exerts a "downward pull," resulting in a lower pleural pressure (i.e., more negative) at the apex than at the base of the lungs. As a result, there is a greater transpulmonary pressure at the apex (see Fig. 18.18A). The higher transpulmonary pressure at the apex causes the alveoli to be more expanded and leads to regional differences in compliance. At any given volume from the FRC and above, the apex of the lung is less distensible (i.e., lower regional compliance) than at the base. This means the base of the lung has both a larger change in volume for the same pressure change and a smaller resting volume than at the apex. In other words, as one takes a breath in from FRC, a greater portion of the tidal volume will go to the base of the lungs, resulting in greater ventilation at the base.

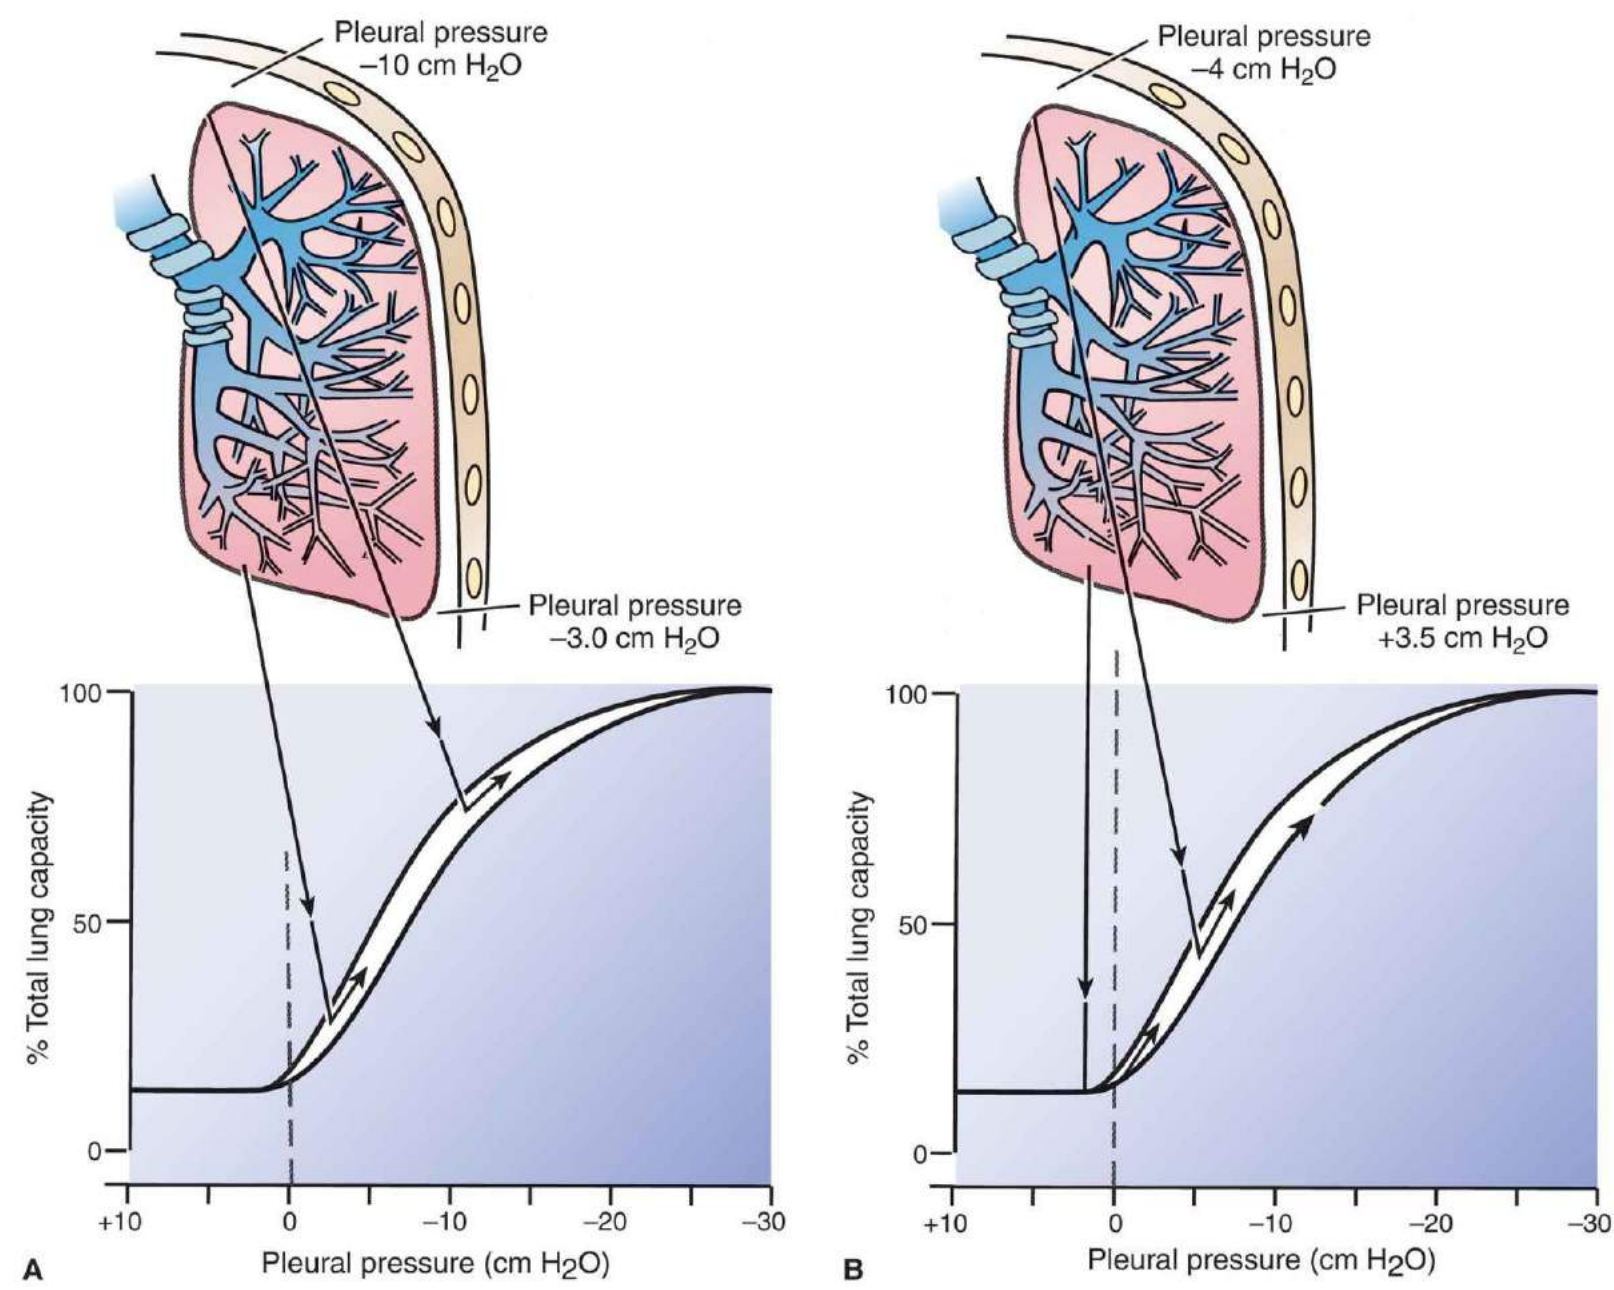

Figure 18.18 Regional differences in lung compliance affect airflow. (A) Because of gravity, pleural pressure in the upright person is more negative at the apex than at the base of the lungs. Consequently, the base of the lungs is more compliant at functional residual capacity. Because the base of the lung is more distensible, proportionally more of the tidal volume will go to the base with inspiration. **(B)** At low lung volumes (e.g., residual volume), pleural pressure at the base becomes positive. This results in more air going to the top part of the lung during a tidal volume because the apical region of the lung is more compliant.

At low lung volumes, alveoli at the apex of the lung are more compliant than that at the base (see Fig. 18.18B). At lung volumes approaching RV, the pleural pressure at the base of the lungs actually exceeds the pressure inside the airways, leading to airway closure. At RV, the base is compressed, and ventilation in the base is impossible until pleural pressure falls below atmospheric pressure. By contrast, the apex of the lung is in a more favorable portion of the compliance curve. Consequently, the first portion of the breath taken in from RV enters the alveoli in the apex, and the distribution of ventilation is inverted at low lung volumes (i.e., the apex is better ventilated than the base).

Alveolar surface tension affects lung compliance.

Another property that significantly affects lung compliance is surface tension, which occurs at the air–liquid interface of the alveoli. The surface of the alveolar membrane is moist, contains water molecules, and is in contact with air, producing a large air–liquid interface. Surface tension increases as water molecules come closer together, which is what happens when the lungs are deflated and the alveoli become smaller (like air leaving a balloon). Potentially, surface tension can cause alveoli to collapse, which would create two serious problems. First, no gas exchange would occur in collapsed alveoli. Second, collapsed alveoli would lead to labored breathing because it is difficult to re-expand the collapsed alveoli during inflation. Fortunately, alveoli don't collapse and inhalation is relatively easy because the lung produces a surface-reducing agent that coats the alveolar lining called **pulmonary surfactant**.

Surface tension of the lungs can be studied by examining a pressure–volume curve. Figure 18.19 shows results from lungs that have been removed from the chest (excised lungs) and inflated and deflated in a stepwise fashion, first with air and then with saline. With air-filled lungs, the gas–liquid interface creates surface tension. However, with saline-filled lungs, the air–liquid interface is eliminated and the surface tension is eliminated. In comparing these two pressure–volume curves, two important observations can be made. First, the slope of the deflation limb of the saline curve is much steeper than that of the air curve. This means that when surface tension is eliminated, the lung is far more compliant (more distensible). Second, the different areas to the left of the saline and air inflation curves show that surface tension significantly contributes to the work required to inflate the lungs. Because the area to the left of each curve is equal to work, which can be defined as force (change in pressure) times distance (change in volume), the elastic forces and surface tension can be separated. The area to the left of the saline inflation curve is the work required to overcome the elastic recoil of the lung tissue. The area to the left of the air inflation curve is the work required to overcome both elastic tissue recoil and surface tension. Subtracting the area to the left of the saline curve from the area to the left of the air curve shows that approximately two thirds of the work required to inflate the lungs is needed to overcome surface tension. Lung distensibility and the work of breathing are significantly affected by surface tension.

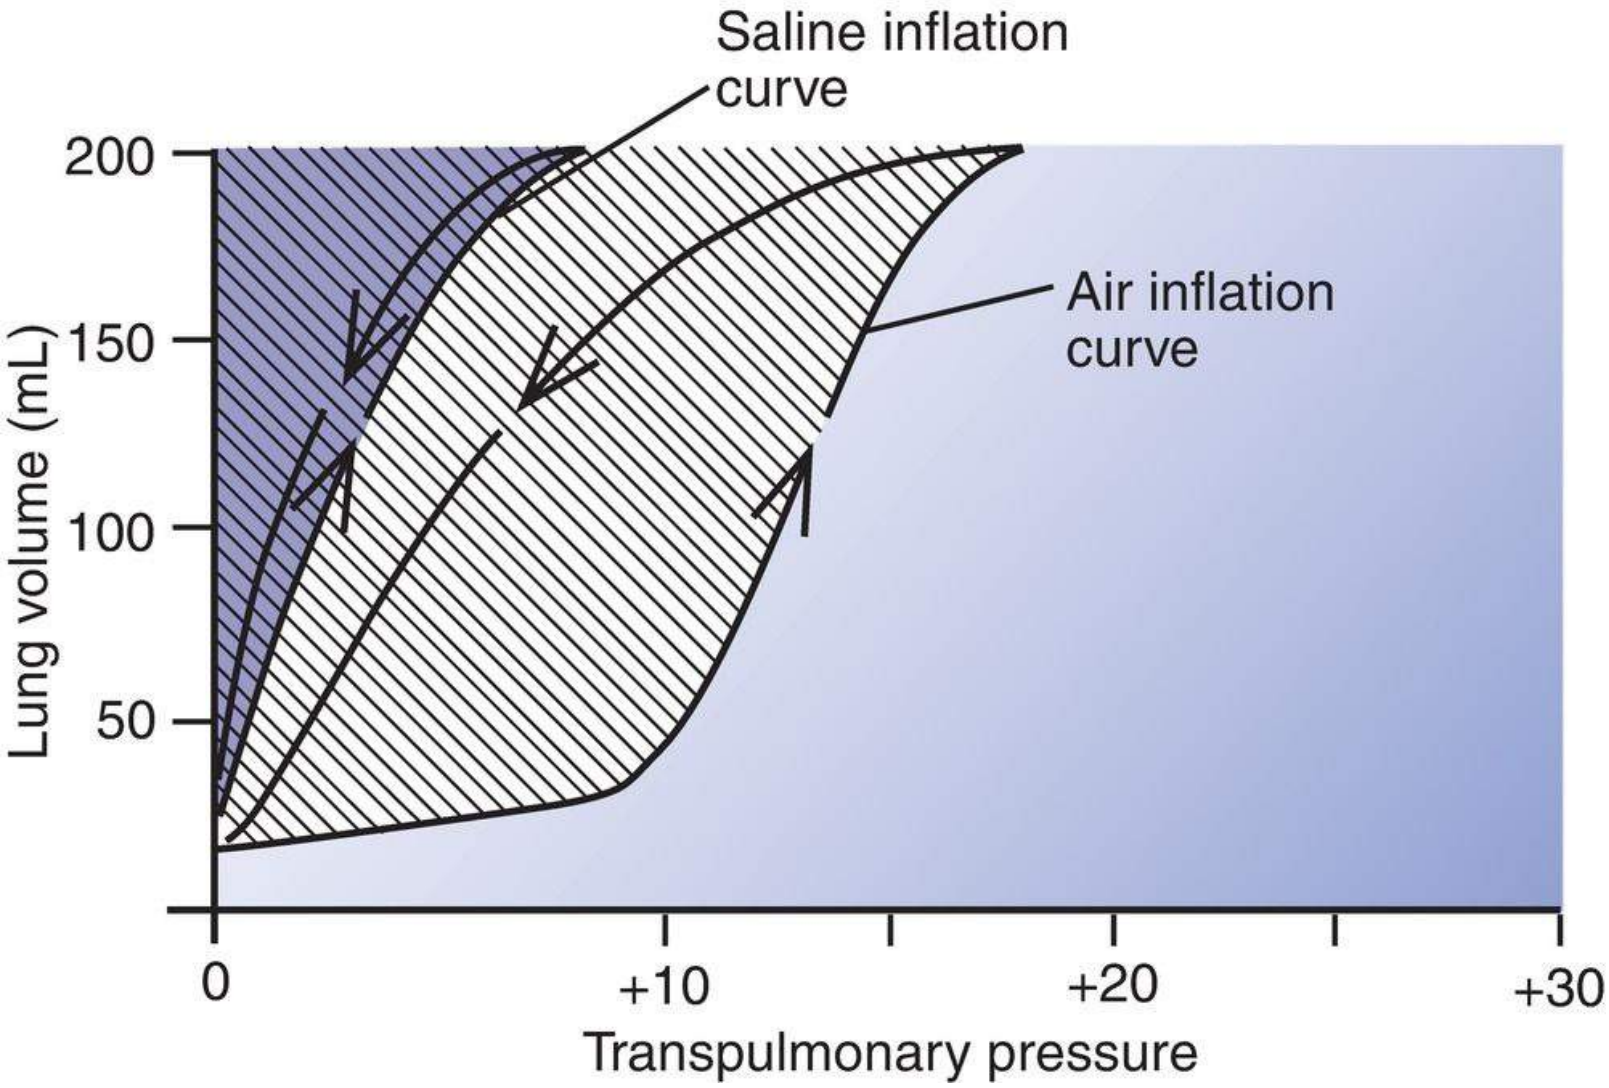

Figure 18.19 Alveolar surface tension affects lung compliance. Inflating lungs with saline instead of air eliminates surface tension. Two pressure–volume curves for lungs inflated to the same volume are shown, first with air and then with saline. The differences in the two curves occur because surface tension contributes significantly to lung compliance in the air-filled lungs. When lungs are inflated and deflated with saline, the lungs are more distensible, with a concomitant increase in lung compliance. The *shaded areas* are equal to the work done in inflating the lungs.

Surface tension has important ramifications for maintaining alveolar stability. In a sphere such as an alveolus, surface tension produces a force that pulls inwardly and creates an internal pressure. The relationship between surface tension and pressure inside a sphere is shown in Figure 18.20. The pressure developed in an alveolus is given by **the Law of Laplace** (see Chapter 11, “Overview of the Cardiovascular System and Hemodynamics”):

Figure 18.20 Surfactant promotes alveolar stability at low lung volumes. (A) If surface tension remains constant (50 dyne/cm), alveoli that are interconnected but differ in diameter become unstable and cannot coexist. Pressure in the smaller alveolus is greater than that in the larger alveolus, which causes air from the smaller alveolus to empty into the larger alveolus. At low lung volumes, the smaller alveoli tend to collapse, a phenomenon known as atelectasis. **(B)** Surfactant lowers surface tension proportionately more in the smaller alveolus. As a result, pressures in the two alveoli are equal, and alveoli of different diameters can coexist. P, pressure; r, radius; T, tension.

$$P = 2T/r \quad (20)$$

where T equals surface tension and r equals radius. Because alveoli are interconnected and vary in diameter, the Laplace equation assumes functional importance in the lung. In the example shown in Figure 18.20, a surface tension is constant at 50 dyne/cm, and an unstable condition results because pressure is greater in the smaller alveolus than in the larger one. Consequently, smaller alveoli tend to collapse, especially at low lung volumes, a phenomenon known as **atelectasis**. Larger alveoli become overdistended when atelectasis occurs. Therefore, two questions arise: How do alveoli of different sizes coexist in the intact lung when interconnected? How does the normal lung prevent atelectasis at low lung volumes? The answers lie, in part, in the fact that the alveolar surface tension is not constant at 50 dyne/cm, as in other biologic fluids (Clinical Focus 18.2).

CLINICAL FOCUS 18.2

Acute Respiratory Distress Syndrome

Scot was a healthy 20-year-old man who was starting his 2nd year of college. He was in good condition and worked out regularly by lifting weights and swimming 1 mile each day. However, one fall afternoon, he began to feel ill. He went to the student health center with complaints of a severe headache and pain in the neck and lower abdomen. He was told that he was coming down with the flu and was advised to go back to the dorm and rest. The next day his symptoms, which included fever, cold sweats, skin rash, and nausea, became worse. His roommate took him back to the health center, and Scot was placed in one of the student beds for closer observation. When his condition started deteriorating, he was rushed to the emergency department at the university medical center. On arrival, Scot was in shock with a high fever and a breathing rate of 36 (normal is 12 to 15/min). Because of the danger of respiratory failure, the attending physician immediately had Scot intubated and placed on assisted ventilation. The decision was made to transfer him to the intensive care unit (ICU). Upon arrival at the ICU, Scot's chest radiograph showed patchy infiltrate and pulmonary edema. He was diagnosed as having **acute respiratory distress syndrome** (**ARDS**), with a secondary widespread infection of unknown origin.

Scot's case is similar to those of the other 200,000 to 250,000 persons who develop ARDS each

year. Despite Scot's youth and previous history, his anticipated mortality for ARDS was ~80%. Scot was lucky and was able to return to his classes after 12 weeks in the hospital and a bill of >$200,000.

ARDS is the name given to diffuse lung injury of various causes. Few patients have a history of previous lung disorders. The causes include trauma from chest injury (e.g., car accidents), long bone injury, and pelvic injury. During the Vietnam era, the trauma that caused ARDS was coined "Da Nang lung." Two other major causes include sepsis (presence of pathogen or toxin in the blood) and aspiration of gastric contents. The latter occurs with gastric reflux and usually occurs at night during sleep. Other causes include cardiopulmonary bypass, smoke inhalation, high altitude, and exposure to irritant gases. Exposure to irritant gases was the cause of the widespread ARDS cases that occurred at the disaster in Bhopal, India.

Although the etiology for ARDS is varied in different cases, the pathophysiology is nearly identical. ARDS is characterized by decreased lung compliance, pulmonary edema, focal atelectasis, and hypoxemia (low partial pressure of O_2 in the arterial blood), with an inflammatory reaction that leads to an infiltration of neutrophils into the lung. The increase in lung stiffness (i.e., decreased compliance) is a result of loss of surfactant, which is unrelated to edema.

Neutrophil aggregation is a key underlying mechanism of ARDS. Aggregation of neutrophils causes capillary endothelial damage by releasing a number of toxic products. These include oxygen free radicals, proteolytic enzymes, arachidonic acid metabolites (leukotrienes, thromboxane, prostaglandin), and platelet-activating factor.

New approaches to therapy involve ways to reduce neutrophil chemoattraction and aggregation in the pulmonary capillaries and ways to reduce the amount of toxic substances released by neutrophils. ■

Surfactant lowers surface tension and stabilizes alveoli at low lung volumes.

The alveolar lining is coated with a special surface-active agent, pulmonary surfactant, which not only lowers surface tension at the gas–liquid interface but also changes surface tension with changes in alveolar diameter (see Fig. 18.20B). Pulmonary surfactant is a lipoprotein rich in phospholipid. The principal agent responsible for its surface tension–reducing properties is **dipalmitoylphosphatidylcholine** (**DPPC**).

The functional importance of surfactant can be demonstrated by using a surface tension balance (Fig. 18.21). Surface tension is measured by placing a platinum flag connected to a force transducer into a trough of liquid. Surface tension creates a meniscus on each side of the platinum flag, and the greater the contact angles of the meniscus, the greater the surface tension. The surface is repeatedly expanded and compressed by a movable barrier that skims the surface of the liquid (simulating lung inflation and deflation). Surface tension of pure water is 72 dyne/cm, a value that is independent of the surface area of water in the balance. Therefore, when the surface is expanded and compressed, surface tension does not change. When a detergent is added, surface tension is reduced but again is independent of surface area. However, when a **lung lavage** (a saline flush from the lungs) is added that contains pulmonary surfactant, surface tension not only is reduced but also changes in a nonlinear fashion with surface area. Therefore, pulmonary surfactant makes it possible for alveoli of different diameters that are connected in parallel to coexist and be stable at low lung volumes, by lowering surface tension proportionately more in the smaller alveoli (see Fig. 18.20B).

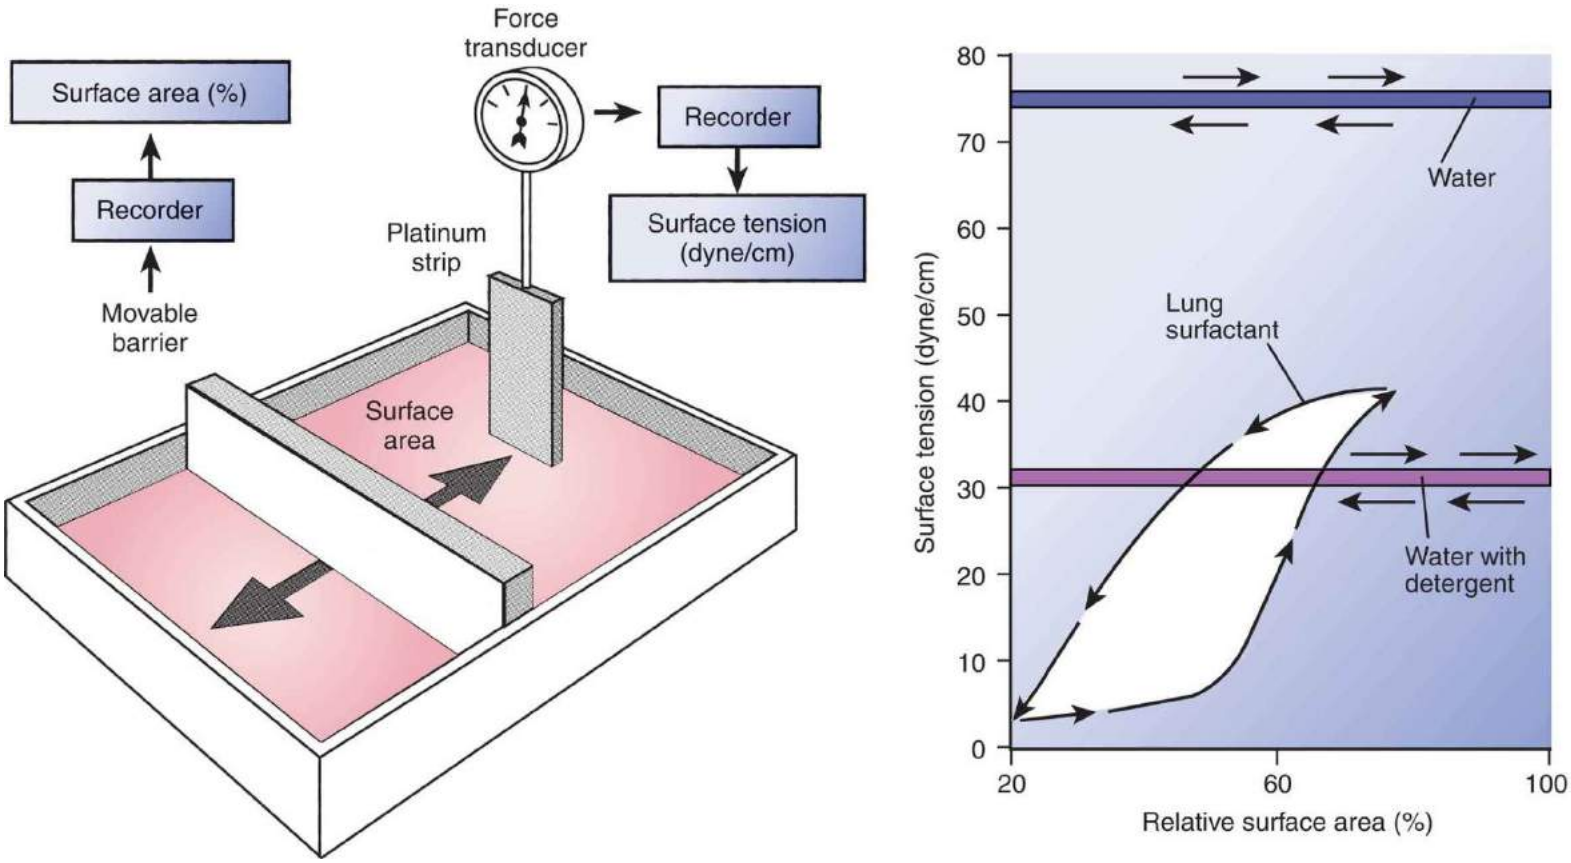

Figure 18.21 Lung surfactant lowers alveolar surface tension. A surface tension balance is used to measure surface tension at the air–liquid interface. When distilled water is placed in the balance, surface

tension is independent of surface area (a constant 72 dynes/cm). The addition of a detergent reduces surface tension, but it is still independent of surface area. When lung surfactant (obtained from a lung lavage—a volume of saline flushed into the airways to rinse the alveoli) is placed in the balance, surface tension not only is decreased but also changes with surface area.

A schematic showing how pulmonary surfactant works is depicted in Figure 18.22. At low lung volumes, when the molecules are tightly compressed, some surfactant is squeezed out of the surface and forms micelles. On expansion (reinflation), new surfactant is required to form a new film that is spread on the alveolar surface lining. When surface area remains fairly constant during quiet or shallow breathing, the spreading of surfactant is often impaired. A deep sigh or yawn causes the lungs to inflate to a larger volume and new surfactant molecules spread onto the gas–liquid interface. Patients recovering from anesthesia are often encouraged to breathe deeply to enhance the spreading of surfactant and prevent alveolar collapse, a phenomenon known as **atelectasis.** Patients who have undergone abdominal or thoracic surgery often find it too painful to breathe deeply; poor surfactant spreading results, causing part of their lungs to become atelectatic.

Stage 4
Stage 5

Figure 18.22 Biophysical mechanism of lung surfactant for lowering alveolar surface tension. Surfactant molecules are compressed during lung deflation. At stage 3, surfactant molecules form micelles and are removed from the surface. On lung inflation, new surfactant is spread onto the surface film (stage 4). Turnover of lung surfactant is high because of continual replacement of surfactant during lung expansion.

Where is pulmonary surfactant produced? The alveolar epithelium consists basically of two cell types: alveolar type I and type II cells (Fig. 18.23). Alveolar type II cells are often referred to as **type II pneumocytes**. The ratio of these cells in the epithelial lining is about 1:1, but type I cells occupy approximately two thirds of the surface area. Type II cells seem to aggregate around the alveolar septa. Surfactant is synthesized in the alveolar type II cell. Compared with type I cells, they are rich in mitochondria and are metabolically very active. Electron-dense **lamellar inclusion bodies** are one of the distinguishing features of the type II cell. These lamellar inclusion bodies, rich in surfactant, are thought to be the storage sites for surfactant.

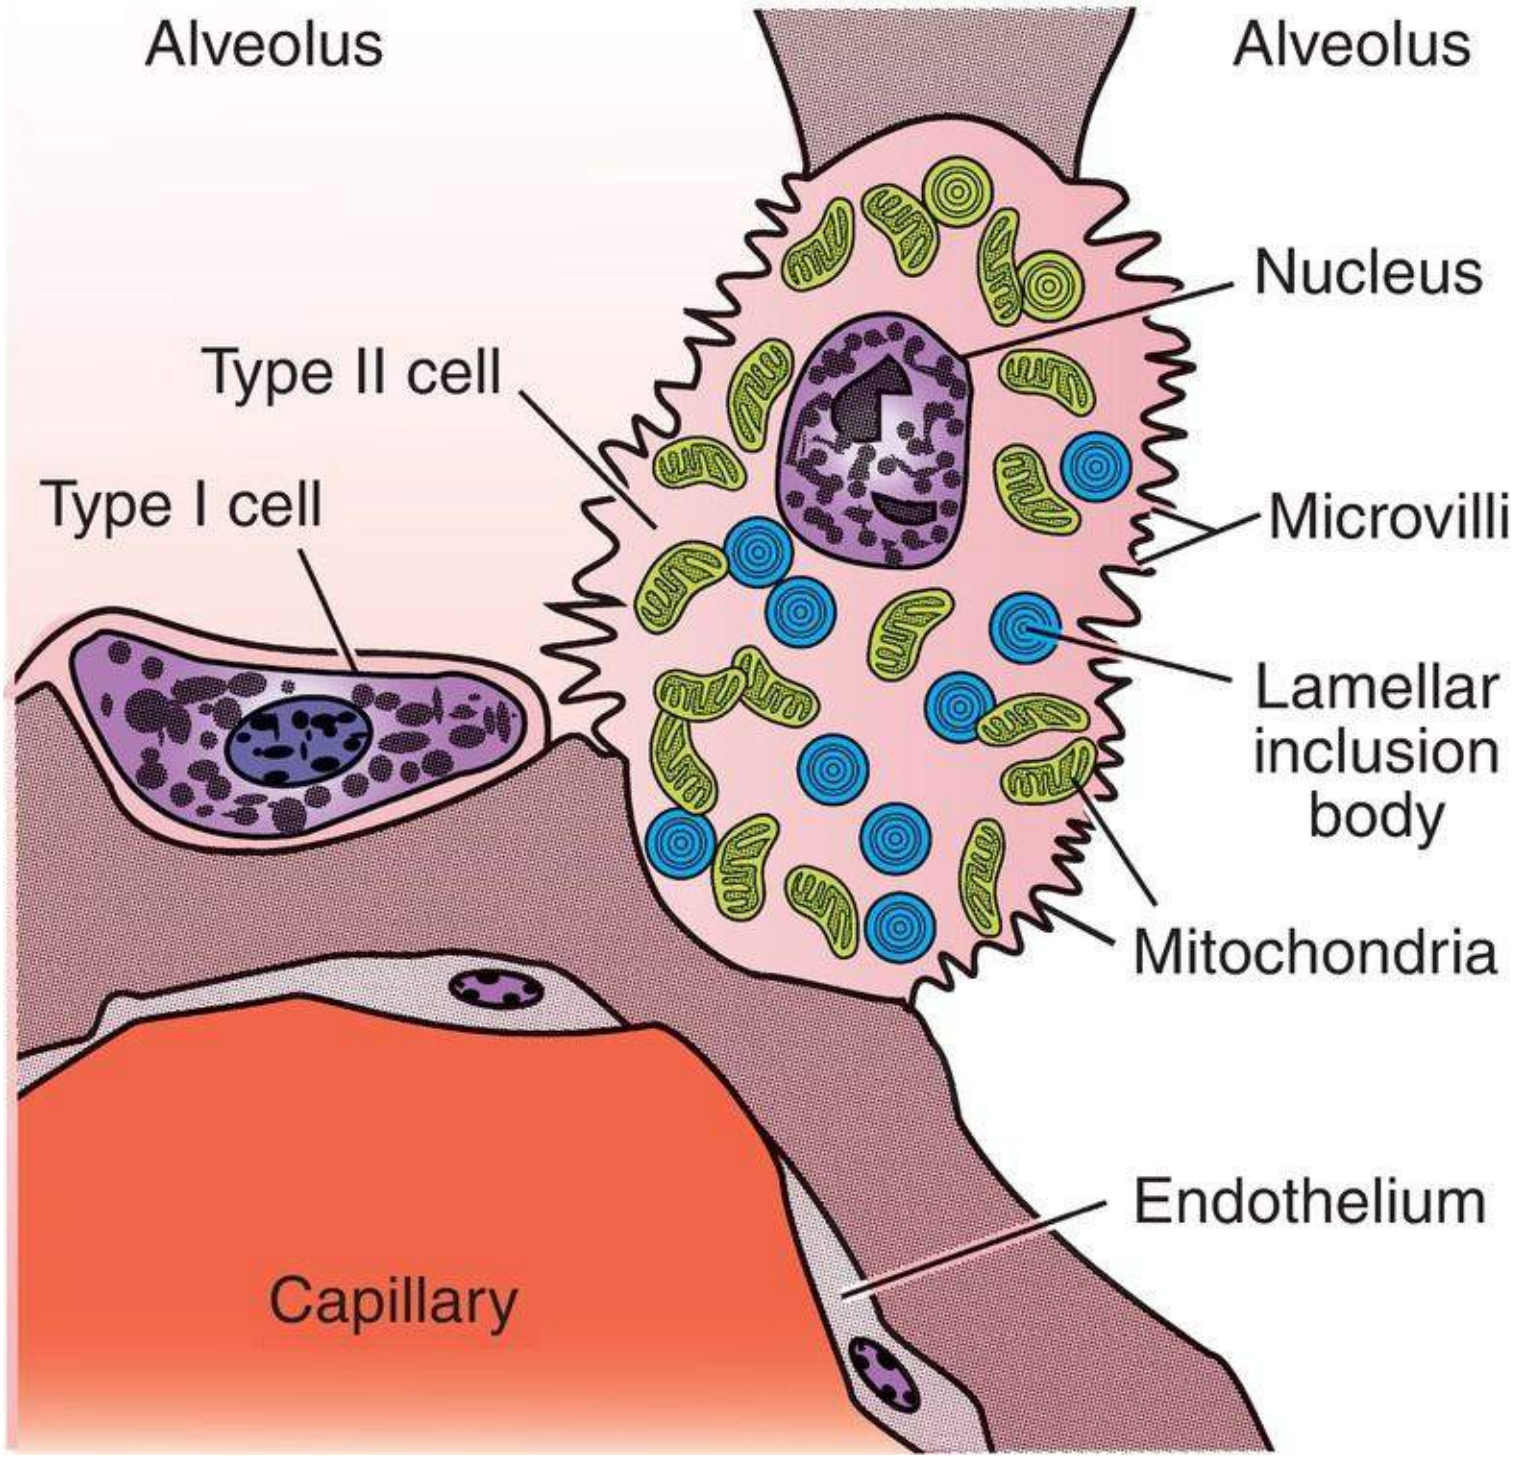

Figure 18.23 Alveolar type II cells synthesize lung surfactant. Alveolar type I cells occupy most of the alveolar surface, and alveolar type II cells are located in the corners between two adjacent alveoli. Alveolar type II cells produce lung surfactant. Also shown are endothelial cells that line the pulmonary capillaries.

The process of surfactant synthesis is shown in Figure 18.24. Basic substrates, such as glucose, palmitate, and choline, are taken up from the circulating blood and synthesized into DPPC by alveolar type II cells. Stored surfactant from the lamellar inclusion bodies is discharged onto the alveolar surface. The turnover of surfactant is high because of the continual renewal of surfactant at the alveolar surface during each expansion of the lung. The high rate of replacement of surfactant probably accounts for the active lipid synthesis that occurs in the lung. Because the lungs are among the last organs to develop, the synthesis of surfactant appears rather late in gestation. In humans, surfactant appears at about week 34 (a full-term pregnancy is 40 weeks). Regardless of the total duration of gestation in any mammalian species,

the process of lung maturation seems to be “triggered” about the time gestation is 85% to 90% complete. Clearly, the fetal lung is endowed with a special regulatory mechanism to control the timing and appearance of surfactant. Failure of proper lung maturation during the perinatal period is still a major cause of death in newborns. Anatomically, the lung may be structurally intact but functionally immature due to the inadequate amounts of surfactant available to reduce surface tension and stabilize surface forces during breathing.

Figure 18.24 Metabolic synthesis of lung surfactant. Substrates for lung surfactant synthesis are taken up by alveolar type II cells from the pulmonary capillary blood. Surfactant (dipalmitoylphosphatidylcholine or DPPC) is stored in lamellar inclusion bodies and subsequently discharged onto the alveolar surface. Surfactant is oriented perpendicularly to the gas–liquid interface at the alveolar surface; the polar end is immersed in the liquid phase, whereas the nonpolar portion is in the gas phase.

Premature birth and certain hormonal disturbances (such as those seen in diabetic pregnancies) interfere with the normal control and timing of lung maturation. These infants have immature lungs at birth, which often leads to **neonatal respiratory distress syndrome**. Breathing is extremely labored because surface tension is high, making it difficult to inflate the lungs. Because of the high surface tension, these infants often develop regional atelectasis and pulmonary edema. These infants are at high risk until the lungs become mature enough to secrete surfactant. In addition to lowering alveolar surface tension and promoting alveolar stability, surfactant helps to prevent edema in the lung. The inwardly contracting force that tends to collapse alveoli also tends to lower interstitial pressure, which “pulls” fluid from the capillaries. Pulmonary surfactant reduces this tendency by lowering surface forces. Some pulmonary physiologists think that keeping the lungs dry may be the major role of surfactant, especially in adults.

Alveolar interdependence promotes alveolar stability.

Another mechanism that plays a role in promoting alveolar stability and preventing atelectasis and edema is interdependence or mutual support among adjacent alveoli. Because alveoli (except those next to the pleural surface) are interconnected with surrounding alveoli, they support each other. Studies have shown that this type of structural arrangement, with many connecting links, prevents the collapse of adjacent alveoli. For example, if alveoli tend to collapse, surrounding alveoli would develop large expanding forces. Therefore, interdependence can play a role in preventing atelectasis as well as in opening up lungs that have collapsed. Alveolar interdependence seems to be more important in adults than in newborns because newborns have fewer interconnecting links.

AIRWAY RESISTANCE AND THE WORK OF BREATHING

In addition to the elastic recoil of the lungs and chest wall, resistance to airflow in the respiratory tree is a key factor in contributing to the movement of air in and out of the lungs. Total resistance to airflow in the lungs has two components: (1) tissue resistance of the lungs and chest wall and (2) airway resistance. Tissue resistance is encountered when the lungs and chest wall expand and contributes about 20% of the total resistance. Airway resistance, on the other hand, is the major factor opposing the flow of air in and out of the lungs and constitutes about 80% of the total resistance. In general, resistance is defined as the ratio of driving pressure (ΔP) to airflow $(\dot{V})$. For total airway resistance (R_{aw}), the driving pressure is the pressure difference between the mouth (P_{mouth}) and the alveoli (PA). The equation can be written as:

$$R_{aw} = \frac{P_{mouth} - P_A}{\dot{V}}$$

(21)

The unit for resistance is H_2O/L/sec. Note that resistance is only meaningful when airflow is occurring. Total airway resistance is small during normal breathing. For example, peak flow is about 2 cm H_2O/L/s

$$(R = P_{mouth} - P_A/\dot{V} = 1.0 \text{ cm } H_2O/0.5 \text{ L/sec})$$

during quiet inspiration. The low resistance is due to the uniqueness of the airway architecture.

Airway resistance decreases airflow in the lung.

The major site of airway resistance is the medium bronchi (lobar and segmental) and bronchi down to about the seventh generation (Fig. 18.25). One would expect the major site of resistance, based on **Poiseuille's law** (see Chapter 11), to be located in the narrow airways (the bronchioles), which have the smallest radius. However, measurements show that only 10% to 20% of total airway resistance can be attributed to the small airways (those <2 mm in diameter). This apparent paradox results because so many small airways are arranged in parallel, and their resistances are added as reciprocals. Resistance of each individual bronchiole is relatively high, but the great number of them results in a large total cross-sectional area, causing their total combined resistance to be low.

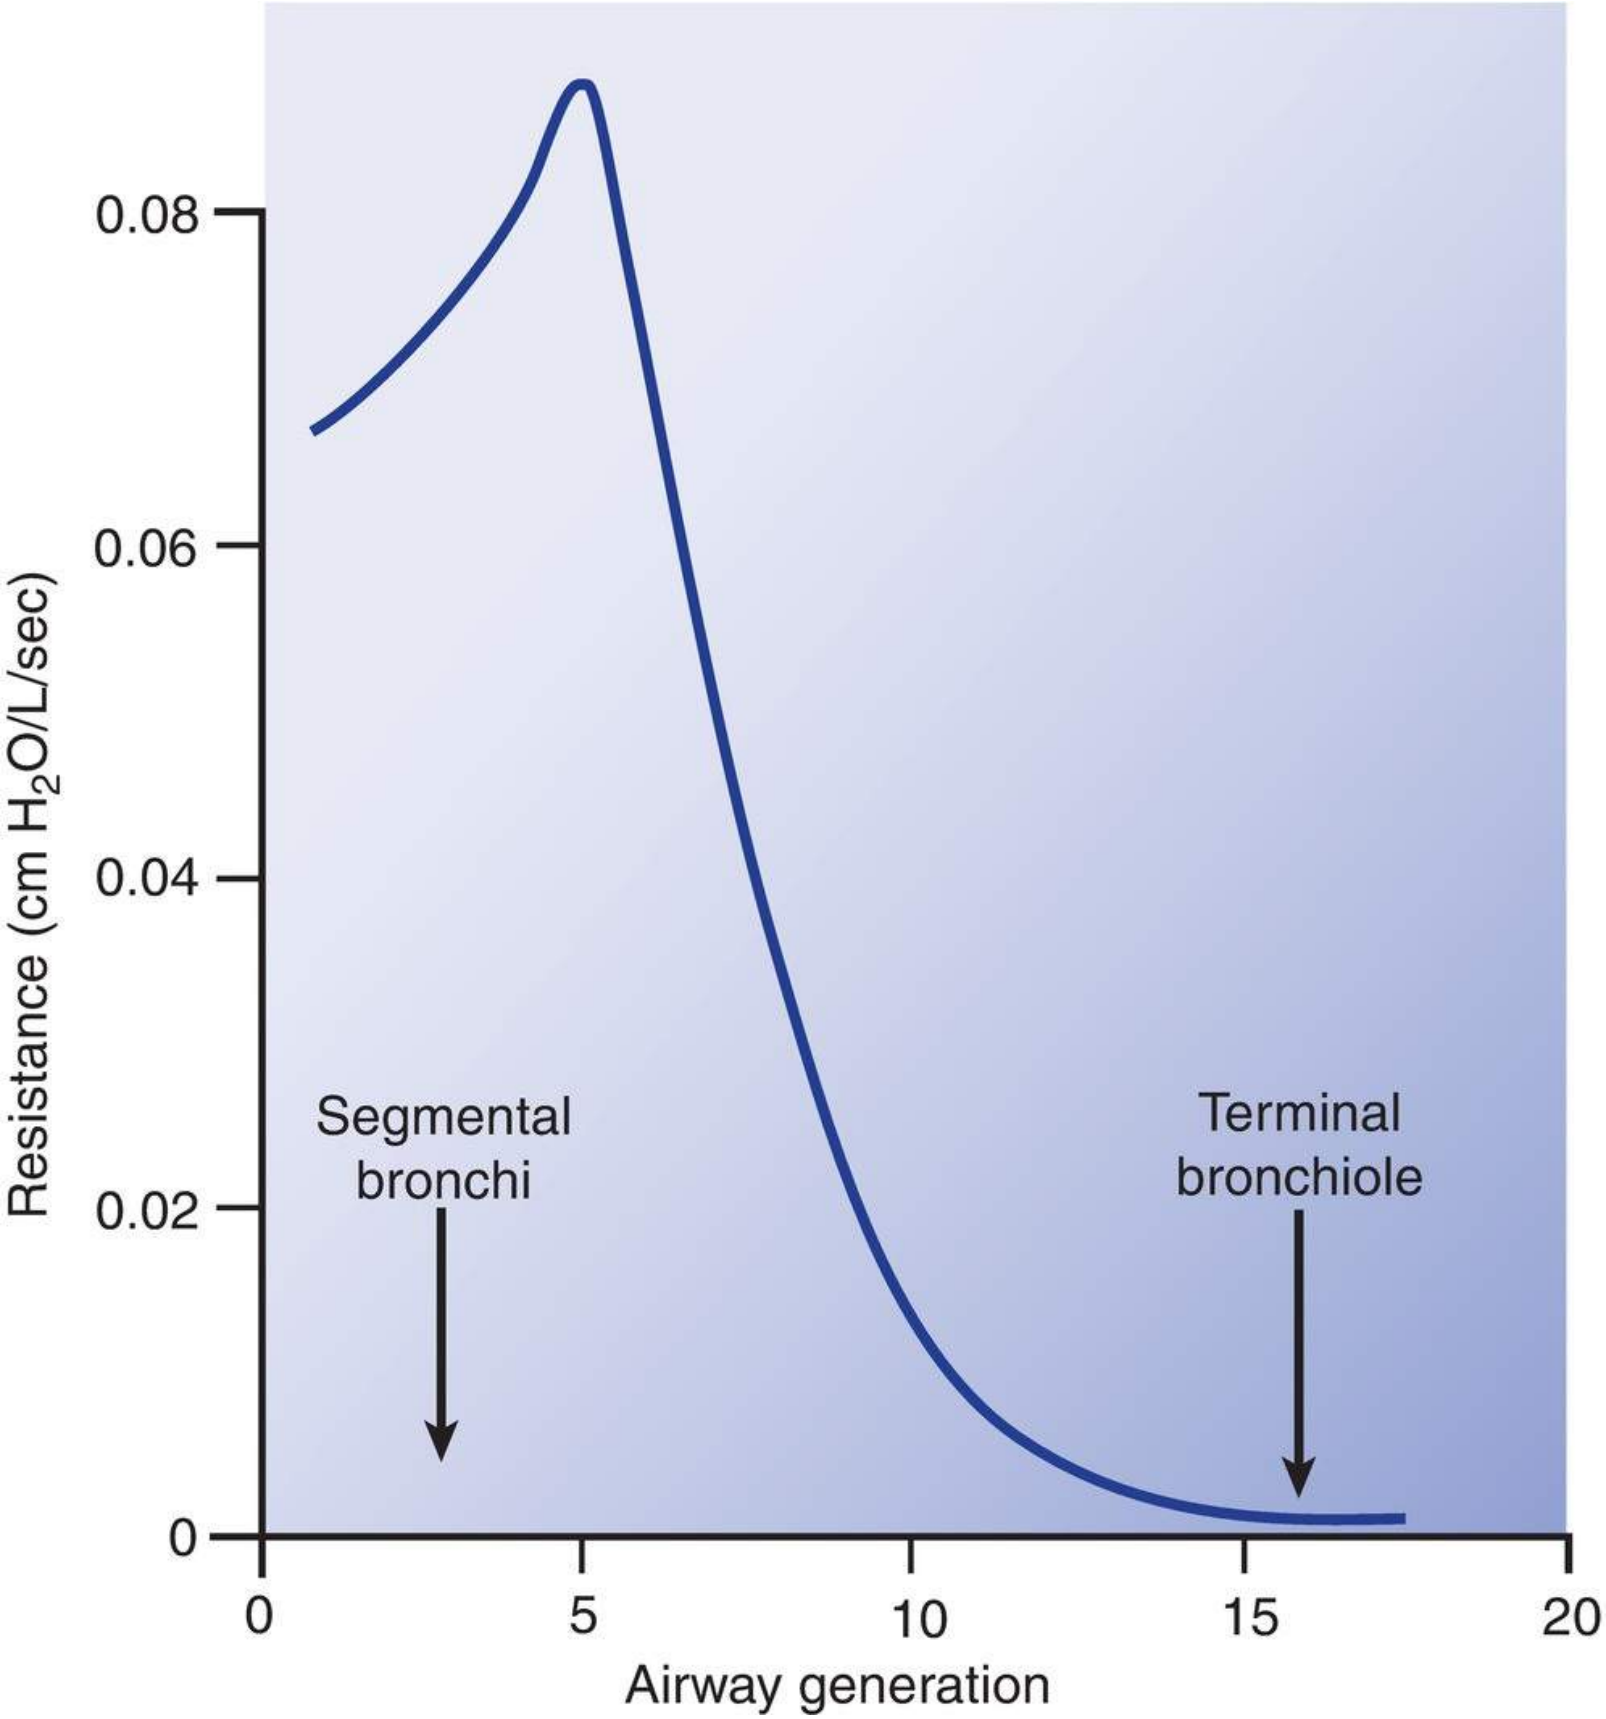

Figure 18.25 Airflow turbulence significantly increases airway resistance. The major sites of resistance are the lobar and segmental bronchi, where airway turbulence is the greatest, down to about the seventh generation of airway branches.

Many airway diseases often begin in the small airways. Diagnosing a disease in the small airways is difficult, however, because the small airways account for such a low percentage of the total R_{aw}. Early detection is difficult because changes in airway resistance are not noticeable until the disease becomes

severe.

Airways are compressed at low lung volumes, causing an increase in airway resistance.

One of the major factors affecting airway diameter, especially the bronchioles, is lung volume. The smaller airways are capable of being distended or compressed. Bronchi and smaller airways are embedded in lung parenchyma and are connected by “guy wires” to surrounding tissue. As the lung enlarges, airway diameter increases, which results in a concomitant decrease in airway resistance during inspiration (Fig. 18.26). Conversely, at low lung volumes, airways are compressed, and airway resistance rises. Note that the inverse relationship between lung volume and airway resistance is nonlinear. At low lung volumes, airway resistance rises sharply.

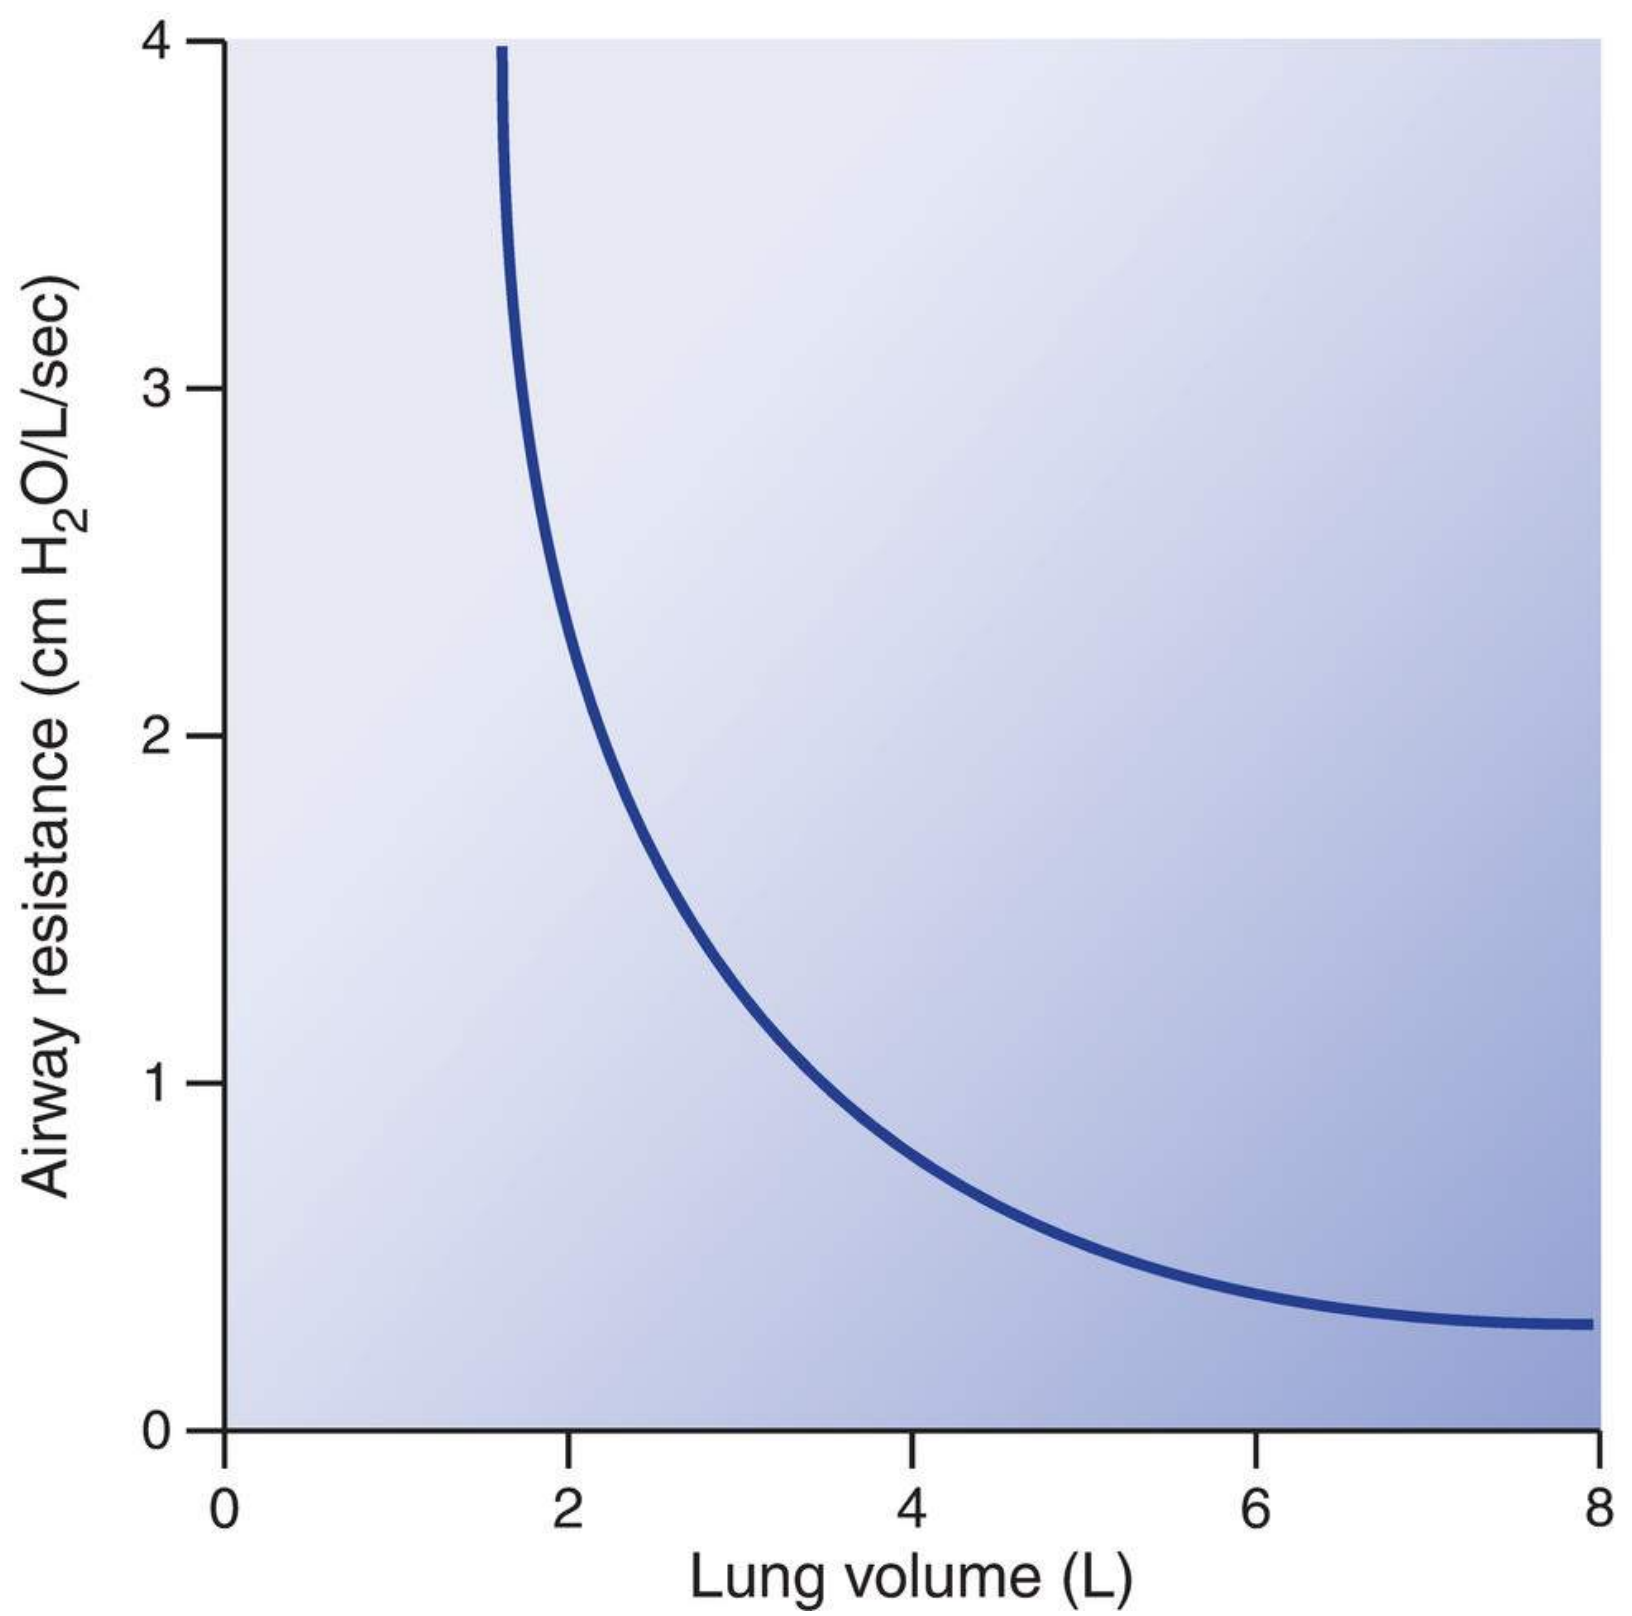

Figure 18.26 Low lung volumes increase airway resistance. Airways are connected to lung parenchyma. During inflation, airway diameter is increased. During deflation, airways are compressed resulting in a concomitant increase in airway resistance.

Airway patency is affected by changes in smooth muscle tone.

Bronchial smooth muscle tone also affects airway diameter with a concomitant change in airway resistance. A change in smooth muscle tone will change airway diameter. The smooth muscles in the airway, from the trachea down to the terminal bronchioles, are under autonomic control. Stimulation of parasympathetic cholinergic postganglionic fibers causes bronchial constriction as well as increased mucus secretion. Stimulation of sympathetic adrenergic fibers causes dilation of bronchial and bronchiolar airways and inhibition of glandular secretion. Drugs, such as isoproterenol and epinephrine, which stimulate β_2-adrenergic receptors in the airways, cause dilation. These drugs alleviate bronchial constriction and are often used to treat asthmatic attacks. Environmental insults, such as breathing chemical irritants, dust, or smoke particles, can cause reflex constriction of the airways. Increased PCO_2 in the conducting airways can cause a local dilation. More important, a decrease in PCO_2 causes airway smooth muscle to contract.

Unusual gaseous environments alter airway resistance.

In unusual environments in which gas density is changed, airway resistance is altered. The effect of gas density on airway resistance is seen most dramatically in deep-sea diving, in which the diver breathes air the density of which may be greatly increased because of increased barometric pressure. The barometric pressure increases 1 atm for each 10 m or 33 ft underwater (e.g., at 10 m below the surface, PB = 2 atm or 1,520 mm Hg). As a result of increased resistance, a large pressure gradient is required just to move a normal tidal volume. Instead of breathing air during diving, the diver uses a helium–oxygen mixture because helium is less dense than air and, consequently, makes breathing easier. The fact that density has a marked effect on airway resistance again indicates that the medium airways are the main site of resistance and that airflow here is primarily turbulent (see Chapter 11).

Forced expiration causes airway compression and increases airway resistance.

Airway resistance does not change much during normal quiet breathing. It is significantly increased, however, during forced expiration, such as in vigorous exercise. The marked change during forced expiration is a result of airway compression. This effect of airway compression on airway resistance can be demonstrated with a **flow–volume curve**. A flow–volume curve shows the relationship between airflow and lung volume during a forced inspiratory and expiratory effort (Fig. 18.27). The curve is generated by taking the spirometer tracings of forced inspiratory and expiratory flow and then closing them by connecting the end of maximum expiration back to the beginning of maximum inspiration. The small loop in Figure 18.28 is the flow–volume curve for a normal tidal volume. The large loop shows the maximal flow–volume curve. During forced inspiration, inspiratory flow is limited only by effort—that is, how hard the person tries. During forced expiration (FVC), flow rises rapidly to a maximum value, **peak expiratory flow** (**PEF**), and then decreases linearly over most of expiration as lung volume decreases.

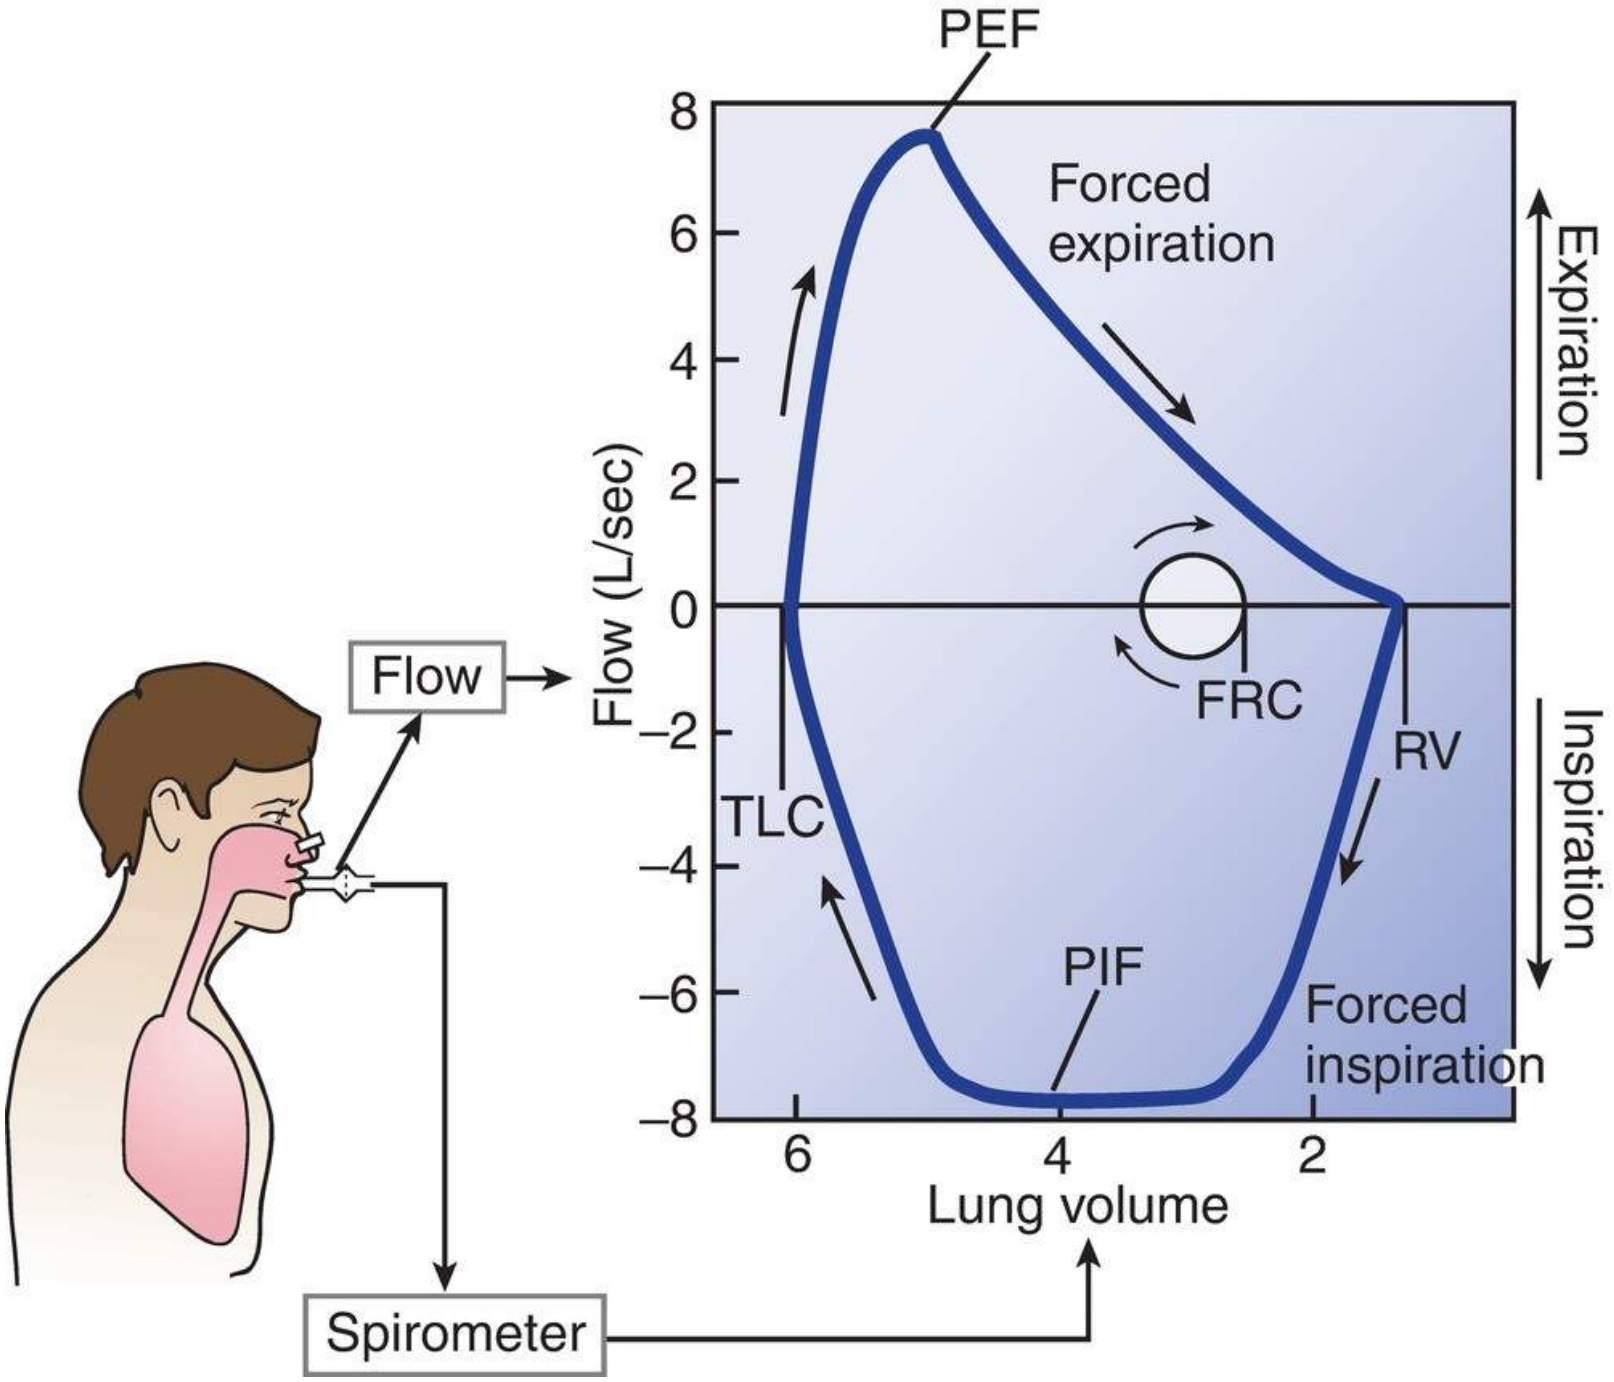

Figure 18.27 Flow–volume curve illustrates the functional importance of airflow. The relationship between lung volume and airflow can be seen from a flow–volume curve. During tidal breathing, airflow is small (small loop labeled FRC [functional residual capacity]). However, during forced expiration, airflow rises rapidly and reaches a maximum, termed *peak expiratory flow* (*PEF*). PEF occurs before there is much change in lung volume. However, during the last part of the expiratory portion of the flow–volume curve (or a forced vital capacity), airflow is effort independent because of dynamic airway compression. Once PEF is achieved, airflow rate decreases proportionately as lung volume decreases to residual volume (RV). Maximum airflow during inspiration, termed *peak inspiratory flow* (*PIF*), is maintained over a large change in lung volume because airways are distended and not compressed. TLC, total lung capacity.

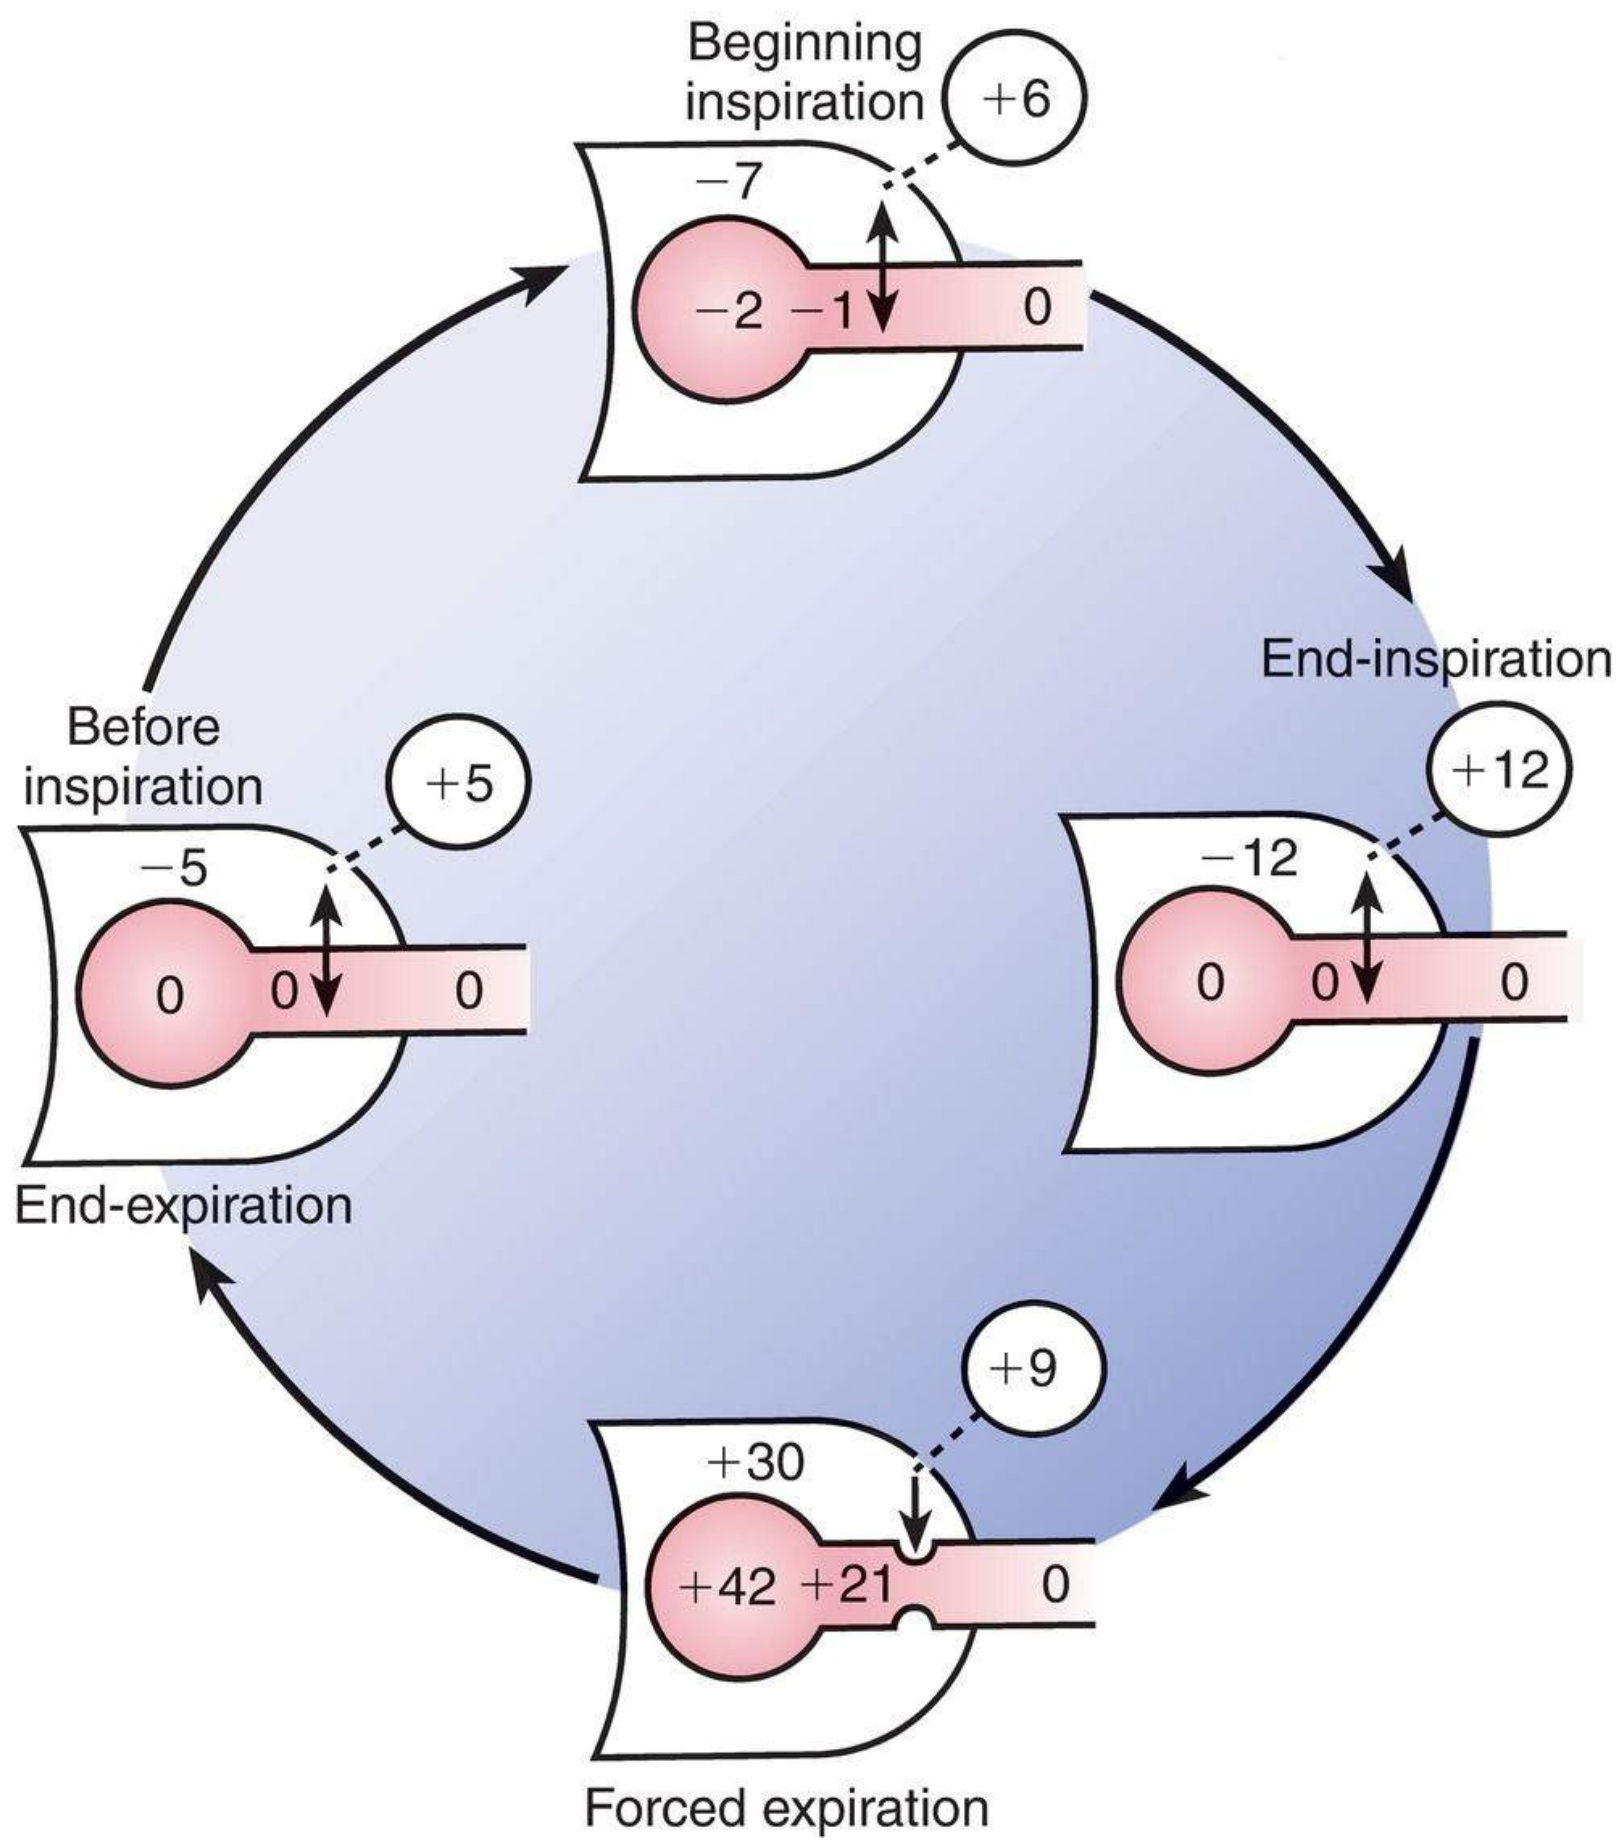

Figure 18.28 Airways are compressed during forced expiration. Transairway pressure is +5 cm H_2O before inspiration and reaches +12 cm H_2O at the end of inspiration. During forced expiration, transairway pressure becomes negative and the small airways are compressed.

The first part of the $FEF_{25–75}$–volume curve is dependent on effort. Once PEF is achieved, flow is independent of effort in the last part of the flow–volume curve. Actually, over most of the expiratory flow–volume curve, flow is virtually independent of effort. The $FEF_{25–75}$ limitation illustrates the importance of dynamic airway compression. Dynamic airway compression increases airway resistance, which effectively limits the $FEF_{25–75}$.

How does dynamic airway compression occur during forced expiration? The mechanism is related to changes in transairway pressure (i.e., pressure across the airway) and the compressibility of the airways. For example, in Figure 18.28, pleural pressure (P_{pl}) is ~5 cm H_2O and airway pressure (P_{aw}) is zero before inspiration (no airflow). Transairway pressure ($P_{aw} - P_{pl}$) is 5 cm H_2O [0 − (−5) = +5] and holds the airways open. At the start of maximum inspiration, pleural pressure decreases to ~7 cm H_2O and alveolar pressure falls to ~2 cm H_2O. The difference between alveolar pressure and pleural pressure is still 5 cm H_2O [−2 − (−7) = +5]. However, there is a pressure drop from the mouth to the alveoli because of resistance to airflow, and the transairway pressure will change along the airway. At the end of maximum inspiration, pleural pressure decreases further, to ~12 cm H_2O, and airway pressure is again zero because of no airflow. During maximum inspiration, airway resistance actually decreases because transairway pressure increases, which enlarges the diameter of the airways, especially the small airways.

On forced expiration, pleural pressure is no longer negative but rises above atmospheric pressure and can increase up to +30 cm H_2O. The added pressure in the alveoli is a result of the elastic recoil of the lungs, is termed *recoil pressure (P_{recoil})*, and can be written as:

$$P_{recoil} = P_A - P_{pl} \quad (22)$$

where PA equals alveolar pressure and P_{pl} equals pleural pressure.

The recoil pressure in Figure 18.28 is 12 cm H_2O, because, at the beginning of expiration, lung volume has not appreciably decreased. Note that at the beginning of FVC, a pressure drop occurs along the airway because of airway resistance. Airway pressure falls progressively from the alveolar region to the airway opening (the mouth). The transairway pressure gradient along the airways reverses and tends to compress the airways. For example, at a point inside the airway where the pressure is 21 cm H_2O, the transairway pressure would be 9 cm H_2O, which would tend to close the airway.

At some point along the airway, the airway pressure equals pleural pressure and transairway pressure is zero (Fig. 18.29). This is the **equal pressure point** (**EPP**). Theoretically, the EPP divides the airways into an upstream segment (from alveoli to EPP) and a downstream segment (EPP to the mouth). In the downstream segment, the airway pressure is below pleural pressure and the transairway pressure becomes negative. As a result, airways in the downstream segment are compressed or collapsed. The large airways (the trachea and bronchi) are protected from collapse because they are supported by cartilage. However, small airways without this structural support are easily compressed and can collapse.

Figure 18.29 An equal pressure point establishes the driving pressure in the airways. An equal pressure point (EPP) divides the airways into downstream and upstream segments. The EPP is established at peak expiratory flow (PEF) and occurs when the pressure inside the airway equals the pressure outside the airway (pleural pressure). The upstream segment is represented from the alveoli to the EPP, and the downstream segment is represented from the EPP to the mouth. The driving pressure for airflow is now alveolar pressure minus the pleural pressure. Airways are subjected to compression during forced expiration from the EPP to the trachea.

Lung compliance affects where the equal pressure point is established in airways.

The EPP is established after the PEF is achieved (see Fig. 18.27). As the forced expiratory effort continues, the EPP moves down the airways from larger to smaller airways because the recoil pressure decreases. A greater length of the downstream segment collapses. The driving pressure for airflow, once the EPP is established, is no longer the difference between alveolar pressure and mouth pressure but is alveolar pressure minus pleural pressure (see Fig. 18.29).

Two basic conclusions follow. First, regardless of the forcefulness of the expiratory effort, airflow cannot be increased because pleural pressure increases, causing more airway compression. This explains why the last part of the FVC is independent of effort.

Second, elastic recoil of the lung determines maximum flow rates because it is the elastic recoil pressure that generates the alveolar–pleural pressure difference. As lung volume decreases, so does elastic recoil. The decrease in elastic recoil is the main reason maximum flow falls so rapidly at low lung volumes.

The effect of elastic recoil on expiratory airflow can be demonstrated by comparing a normal lung with an emphysematous lung, in which the compliance is abnormally high. As seen in Figure 18.30, in both instances, pleural pressure rises to +30 cm H_2O with forced expiration. In the normal lung, the recoil pressure of 10 cm H_2O is added to produce an alveolar pressure of +40 cm H_2O. With forced expiration, there is a progressive fall in airway pressure. Because of the elastic recoil, the normal lung has “added” pressure to the small airways that keeps their pressures above pleural pressure, and less collapse occurs. With emphysema, however, the lungs have diminished elastic recoil, resulting in less elastic recoil pressure. In the example shown in Figure 18.31, elastic recoil adds only 2 cm H_2O to alveolar pressure, resulting in an alveolar pressure of +32 cm H_2O. With expiratory effort, flow proceeds along the pressure gradient. But in the emphysematous lungs, the pressure inside the small airways falls below pleural pressure well before the large airways, resulting in more airway compression and collapsed airways at low lung volumes. As a result, flow stops temporarily in these collapsed airways. Airway pressure upstream to the collapsed segment then rises to equal alveolar pressure, causing the airways to open again. This process repeats itself continually, leading to the “wheeze” that is often heard in emphysematous patients.

Figure 18.30 The equal pressure point is influenced by the lung elastic recoil. (A) In healthy lungs, elastic recoil adds 10 cm H_2O pressure, to produce an alveolar pressure of 40 cm H_2O at the beginning of a forced expiration. As a result, the equal pressure point (EPP) is established in the larger airways. Airway collapse is minimal in the large airways because cartilage supports the airways. **(B)** A loss of elastic recoil causes the EPP to shift downward and to be established in the small airways. In emphysematous lungs, the elastic recoil pressure is low, and little recoil pressure is added to the alveolus. As a result, the EPP is shifted downward and is established in the smaller airways. The small airways are more easily compressed because they are thin and lack cartilaginous support. PA, alveolar pressure; P_{atm}, atmospheric pressure; PL, transpulmonary pressure; P_{pl}, pleural pressure.

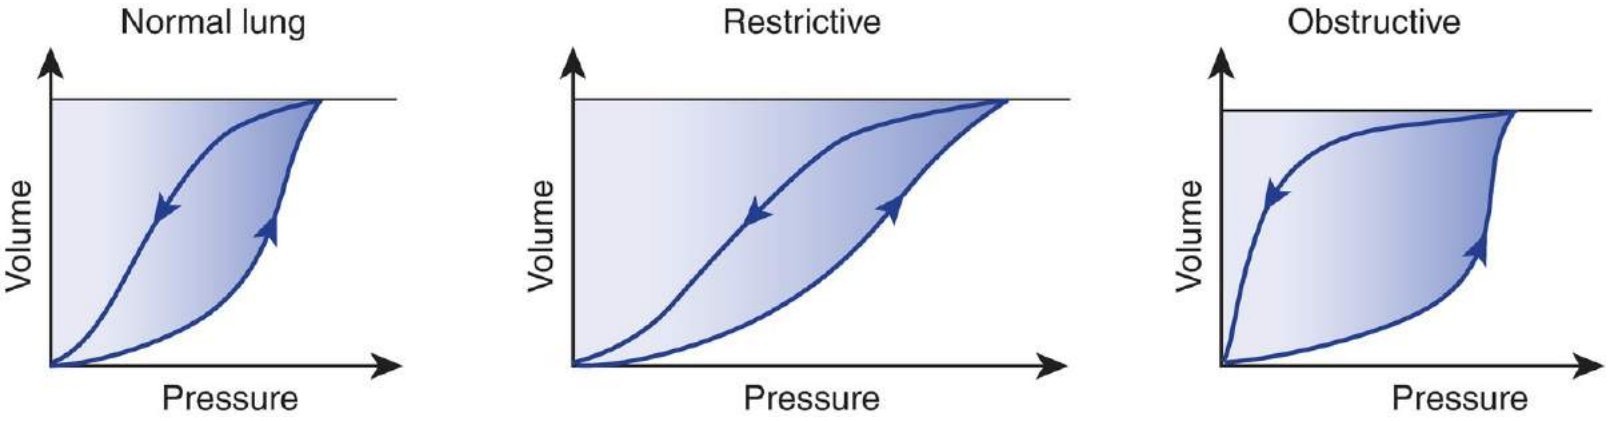

Figure 18.31 Work of breathing is measured from a pressure–volume curve. Pressure is plotted on the *x*-axis, and volume is plotted on the *y*-axis. Work equals force times distance and is represented by the *blue area* above the pressure–volume curve. This area represents the inspiratory work of breathing. Note that with a restrictive disorder, the inspiratory work of breathing is increased. Airway resistance is increased in an obstructive disorder, which requires more energy to force air out of the lungs during expiration.

In lungs with abnormally high compliance, the position of the EPP with forced expiration is established further down in the small airways, where there is no cartilage to keep them distended. Therefore, these patients are much more vulnerable to compression and airway collapse. The greatest problem for patients with emphysema is not getting air into the lungs but getting it out. Consequently, they tend to breathe at higher lung volumes, thereby increasing elastic recoil, which reduces airway resistance and facilitates expiration.

Inspiratory muscles inflate the lungs and overcome airway resistance.

During inspiration, muscular work is involved in expanding the thoracic cavity, inflating the lungs, and overcoming airway resistance. Because work can be measured as force x distance, the amount of work involved in breathing can be expressed as a change in lung volume (distance) multiplied by the change in transpulmonary pressure (force). Thus, work (W) is equal to the product of pressure (P) and volume (V). With a volume change, the work involved in taking a breath is defined by this equation:

$$W = P \times \Delta V \quad (23)$$

where P equals transpulmonary pressure and ΔV equals change in lung volume. During work, energy is expended with muscular contraction to create a force (transpulmonary pressure) to inflate the lungs. When a greater transpulmonary pressure is required to bring more air into the lungs, more muscular work and, hence, greater energy are required.

Figure 18.31 shows how a pressure–volume curve can be used to determine the work required for breathing. The *shaded area* in blue represents the inspiratory work of breathing. In healthy people at rest, the energy needed for breathing represents ~5% of the body's total energy expenditure. During heavy exercise, about 20% of the total energy expenditure is involved in breathing. Breathing is efficient and is most economical when elastic and resistive forces yield the lowest work. Note that the total inspiratory work of breathing in a restrictive lung disorder, compared with the normal lung, is increased and is a result of a greater inspiratory effort required. It is important to remember that lungs with a marked decrease in lung compliance (i.e., restrictive lung disorder) require more work to overcome increase in elastic recoil and surface forces. Patients with a restrictive disorder economize their ventilation by taking rapid and shallow breaths. In contrast, patients with severe airway obstruction tend to do the opposite; they take deeper breaths and breathe more slowly, to reduce their work resulting from the increased airway resistance. Despite this tendency, patients with obstructive disease still expend a considerable portion of their basal energy for breathing. The reason for this is that the expiratory muscles must do additional work to overcome the increased airway resistance. These different breathing patterns help minimize the amount of work required for breathing.

INTEGRATED MEDICAL SCIENCES

The Case of Labored Breathing: Asthma

Jack is a 10-year-old boy who was admitted to the emergency at the university's Children's Hospital with difficulty breathing. His mother reported that Jack had an upper respiratory tract infection for two days and had been using an inhaler more frequently. Today, he has received treatment every three hours, but still complains of shortness of breath and frequent episodes of coughing. His inhaler

medication is Flovent (a prescription inhaled corticosteroid medicine for the long-term treatment of asthma in people aged 4 years and older). A call to the pharmacy verifies the correct dosage, and the prescription has been refilled at appropriate interviews. Upon further assessment by the attending resident, Jack's heart rate was 150; respiratory rate 45; blood pressure 95/65; temperature 37°C; and breathing sounds faint expiratory wheezes throughout all lung fields. Physical exam revealed some confusion, sweating, and tightness in the chest.

This case is an example of what many patients with asthma experience. The follow discussion will cover the immunology, pathophysiology, pharmacology, etiology, and the treatment of asthma. Asthma is defined as a chronic inflammatory disease of the airways characterized by reversible bronchospasm. There are three main characteristics of asthma: (1) inflammation, (2) hyperresponsiveness, and (3) airway obstruction. In inflammation, the lining of the airways becomes swollen and produces mucus. In asthma patients, the inflammation is induced by an overreaction to triggers (allergens, pollutants, animal dander, etc.). When the airways (bronchi) become hyperresponsive, they have an exaggerated response that leads to bronchospasms. As a result of the inflammation and hyperresponsiveness, asthmatic patient have severely constricted airways. Airway constriction interferes with gas exchange (CO_2 builds up in the blood, and less O_2 is transferred to the blood). In response to low oxygen, heart and respiratory rate are increased as compensatory mechanism.

The cellular mechanism for induced bronchospasms is mast cells degranulation and the release a variety of mediators (histamine, prostaglandins, thromboxane, and bradykinin). All cause smooth muscle contraction, swelling, and inflammation. The treatment of asthma involves bronchodilators and long-term anti-inflammatory medications. Bronchodilators dilate the bronchi and bronchioles, decrease airway resistance, and increase airflow to the lungs. Bronchodilators are either short acting or long lasting. Short-term dilators provide quick relief from acute bronchoconstriction. Long-term dilators help to control and prevent the symptoms. The bronchodilators are available in inhaled, tablet, liquid, and injection forms, but the preferred method is by inhalation. There three types of bronchodilators: beta agonists (short acting and long acting), anticholinergics (short acting), and theophylline (long acting). Beta agonists and anticholinergic act to increase cellular cAMP. The elevated cAMP, in turn, triggers a cascade of events within the muscle that leads to smooth muscle relaxation.

Long-term anti-inflammatory medicines are prescribed to prevent asthma attacks and reduce inflammation, swelling, and mucus production. These anti-inflammatory asthma inhalers include (1) steroids (e.g., Aerospan and Flovent) and (2) mast cell stabilizers (e.g., Cromolyn). Like most medications, inhaled corticosteroids can have side effects. One common side effect from inhaled corticosteroids is *thrush* (a mouth infection). If taken for long periods, these medications can increase the risk of cataracts and osteoporosis. ■

Chapter Summary

- The primary function of the lungs is gas exchange, which involves five components (ventilation, gas uptake, blood flow, matching airflow and blood flow, and gas transport).
- The alveolar–capillary membrane forms a large blood–gas interface for diffusion of oxygen and carbon dioxide.
- Airflow parallels alveolar pressure.
- A negative alveolar pressure is created during inspiration to bring air into the lungs.
- A positive alveolar pressure is created during expiration to exhaust air out of the lungs.
- Forced vital capacity is one of the most useful spirometry tests to assess lung function.
- Helium dilution is an indirect method for determining residual lung volume.
- Minute ventilation is the volume of air expired per minute and is equal to expired minute ventilation .
- Alveolar ventilation is the amount of fresh air that reaches alveoli and regulates carbon dioxide levels in the blood.
- Physiologic dead space volume is the portion of tidal volume that is wasted air and does not participate in gas exchange. It is the sum of anatomic dead space volume minus the volume of air in the conducting zone alveolar dead space volume minus volume of air in alveoli that does not participate in gas uptake.
- Compliance is a measure of lung distensibility.
- Surfactant and alveolar interdependence maintain alveolar stability.
- Total airway resistance consists of two components: (1) tissue resistance of lungs and chest wall and (2) resistance to airflow in the airways.
- Lung compliance affects airway compression during forced expiration.
- The work of breathing is required to expand the lungs and overcome airway resistance.
- Major lung diseases are categorized into two groups: obstructive and restrictive. Chronic obstructive pulmonary disease obstructs airflow out of the lungs. Restrictive disease restricts lung inflation.

Chapter Review Questions

1. Asthma is a disease that affects primarily the peripheral airways. Which of the following would best characterize pulmonary function in a patient diagnosed with asthma compared to normal predicted values?

A. FEV_1/FVC ratio is increased.
B. Residual volume is increased.
C. Total lung capacity is decreased.
D. Resistance to airflow is decreased.
E. Both airway resistance and total lung capacity are decreased.

The correct answer is B. Asthma is one of the diseases that falls under chronic obstructive pulmonary disease (COPD). COPD is characterized by high static lung volumes and low airflow. This means total lung capacity and residual volumes are increased. Airflow is restricted due to the increase in airway resistance. FEV_1, FVC, and FEV_1/FVC ratio are also decreased because of the increase in airway resistance.

2. A 48-year-old patient undergoes a pulmonary function test. At which lung volume would her pleural pressure be most negative?

A. Residual volume
B. Functional residual capacity
C. End of tidal volume
D. Total lung capacity
E. Middle of forced vital capacity

The correct answer is D. During inspiration, pleural pressure becomes more negative. Pleural pressure would be the most negative at maximal inspiration (total lung capacity). Pleural pressure is the least negative at residual volume. During forced vital capacity, pleural pressure is positive. FRC and end-tidal volume are distracters.

3. If alveolar ventilation is doubled while breathing room air, and if CO_2 production remains unchanged, then the most likely effect (increase, decrease, or no change) on alveolar CO_2 tension ($PACO_2$), alveolar O_2 tension (PAO_2), arterial O_2 tension (PaO_2), and arterial CO_2 tension ($PaCO_2$) will be that:

	P_{ACO_2}	P_{AO_2}	Pa_{O_2}	Pa_{CO_2}
A.	↓	↑	↔	↓
B.	↓	↔	↔	↓
C.	↑	↑	↔	↓
D.	↑	↑	↑	↑
E.	↓	↑	↔	↔

The correct answer is A. If carbon production remains unchanged, one hyperventilates for 2 minutes, both alveolar and arterial carbon tensions decrease. Hyperventilation increases oxygen tension in the alveolar but has little effect on arterial oxygen tension.

4. The following measurements were made on a normal subject:

Arterial PCO_2 = 36 mm Hg

Arterial PO_2 = 100 mm Hg

Minute ventilation = 9 L/minute

Alveolar ventilation = 6 L/minute

Frequency = 15 breaths/minute

Which one of the following breathing patterns would result in the highest alveolar ventilation?

	Tidal volume, mL	frequency, breaths/minute
A.	400	36
B.	500	30
C.	800	7.5
D.	800	10
E.	900	10

The correct answer is B. The key to measuring alveolar ventilation is to determine the dead space volume. Dead space ventilation = minute ventilation – alveolar ventilation (9 L/minute – 6 L/minute = 3 L/minute). Dead space volume equals dead space ventilation/breathing frequency (3 L/minute/15 breaths/minute = 200 mL).

Alveolar ventilation = tidal volume – dead space volume × frequency.

5. In a healthy individual, which of the following combination of changes from normal values in chest wall and lung compliance would result in the greatest decrease in functional residual capacity?
   A. A 10% increase in lung compliance and a 10% decrease in chest wall compliance
   B. A 10% decrease in lung compliance and a 10% decrease in chest wall compliance
   C. A 10% decrease in lung compliance and a 10% increase in chest wall compliance
   D. A 10% increase in lung compliance and a 10% increase in chest wall compliance
   E. A 5% increase in lung compliance and a 5% increase in chest wall compliance

The correct answer is C. Since the lung elastic recoil and chest wall elastic recoil are in equal but opposite directions, an increase in lung elastic recoil (decreased lung compliance) and a decrease in chest wall elastic recoil will favor the greatest decrease in functional residual capacity (FRC). Options A and E would result in an increase in FRC. Options B and D would essentially result in no change in FRC.

Clinical Application Exercises 18.1

A DEADLY LUNG DISORDER: EMPHYSEMA

Recovering from a heart attack and fighting pneumonia, a 65-year-old Vietnam veteran was transferred from the VA hospital to the university hospital to be evaluated for surgery to repair his blocked arteries. Wheezing and coughing badly, he learned that he had another deadly ailment that would require treatment first. Upon further evaluation, he had a history of shortness of breath and difficulty breathing on exertion. He also complained of a cough productive of green sputum. He appeared pale and said he felt feverish at home, but denied any shaking chills, sore throat, nausea, vomiting, or diarrhea. He said he was a 2-pack-a-day cigarette smoker who had given up smoking 10 years ago. He had not been previously hospitalized. He is a retired cab driver and lives with his wife; they have no pets. Although he has had dyspnea upon exertion for the past 2 years, he continues to maintain an active lifestyle. Prior to his heart attack, he still mowed his lawn without much difficulty and continued to walk 1 to 2 miles on a flat surface at a moderate pace. The patient said he rarely drinks alcohol. He denied having had any other significant past medical problems, including childhood asthma or any allergies. He did state that his father, also a heavy smoker, died of emphysema at age 55.

An initial exam shows that the patient is thin but has a large chest. He is in moderate respiratory distress. His blood pressure is 130/80 mm Hg; respiratory rate, 28 to 32 breaths/minute; heart rate, 92/minute; and oral temperature, 37.9°C. His trachea is midline, and his chest expands symmetrically. He has decreased but audible breath sounds in both lung fields, with expiratory wheezing and a prolonged expiratory phase. Head, eyes, ears, nose, and throat findings are unremarkable. A pulse oximetry reading reveals his blood hemoglobin oxygen saturation is 91% when breathing room air.

Pulmonary function tests reveal severe limitation of airflow rates, particularly expiratory airflow. The patient is diagnosed with pulmonary emphysema.

QUESTIONS

1. What are the common spirometry findings associated with emphysema?
2. What are the mechanisms of airflow limitation in emphysema?
3. What is the most commonly held theory explaining the development of emphysema?

ANSWERS

1. The hallmark of emphysema is the limitation of airflow out of the lungs. In emphysema, expiratory flow rates (FVC, FEV_1, and FEV_1/FVC ratio) are significantly decreased. However, some lung volumes (TLC, FRC, and RV) are increased, and the increase is a result of the loss of lung elastic recoil (increased compliance).
2. The mechanisms that limit expiratory airflow in emphysema include hypersensitivity of airway smooth muscle, mucus hypersecretion, and bronchial wall inflammation and increased dynamic airway compression as a result of increased compliance.
3. The patient is one of the estimated 24 million Americans with emphysema, half of whom remain undiagnosed. Many of the pathophysiological changes in emphysema are a result of the loss of lung elastic recoil and destruction of the alveolar–capillary membrane. This is thought to be a result of an imbalance between the proteases and antiproteases (α_1 antitrypsin) in the lower respiratory tree. Normally, proteolytic enzyme activity is inactivated by antiproteases. In emphysema, excess proteolytic activity destroys elastin and collagen, the major extracellular matrix proteins responsible for maintaining the integrity of the alveolar–capillary membrane and the elasticity of the lung. Cigarette smoke increases proteolytic activity, which may arise through an increase in protease levels, a decrease in antiprotease activity, or a combination of the two.

19 Gas Transfer and Transport

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Describe how alveolar surface area and membrane thickness affect gas diffusion.
- Describe how pulmonary blood flow and blood hematocrit affect lung diffusion capacity.
- Describe how oxygen binds to hemoglobin.
- Describe the concept P_{50} and its effect on hemoglobin's affinity for oxygen.
- Predict how changes in blood pH, blood PCO_2, body temperature, and carbon monoxide will affect the oxyhemoglobin–equilibrium curve.
- Predict the effect of hematocrit on arterial PO_2 and O_2 content.
- Describe the mechanisms by which CO_2 is transported by the blood.
- Describe the physiologic causes of hypoxemia.
- Describe the relationship between venous admixture and the alveolar–arterial oxygen gradient.
- Describe how a low ventilation/perfusion ratio () differs from an anatomic shunt as a cause of hypoxemia.

GAS DIFFUSION AND UPTAKE

In the previous chapter, you learned the unique architecture of the lungs allows for a large alveolar–capillary membrane that forms an interface for the exchange of oxygen and carbon dioxide. You also learned how small pressure changes in the lung can bring large volumes of air into the lungs for gas exchange. You will learn in this chapter that gas exchange is closely linked to pulmonary circulation, and they can increase 20-fold in order to meet the body's energy demands.

Oxygen and carbon dioxide move across the alveolar–capillary membrane by diffusion.

Gas exchange can be defined as the delivery of oxygen from the lungs to the pulmonary capillaries and the removal of carbon dioxide from the capillaries to the lungs. The movement of gases in the alveoli and across the alveolar–capillary membrane is by diffusion; partly due to partial pressure gradients of individual gases. Recall from Chapter 18 that partial pressure or gas tension can be determined by measuring barometric pressure and the fractional concentration (F) of the gas (Dalton law). At sea level, PO_2 is 160 mm Hg (760 mm Hg × 0.21). FO_2 does not change with altitude, which means that the percentage of O_2 in the atmosphere is essentially the same at 30,000 ft (about 9,000 m) as it is at sea level. Therefore, the difficulty in breathing at high altitudes is due to a decrease in PO_2 rather than a decrease in FO_2 (Fig. 19.1).

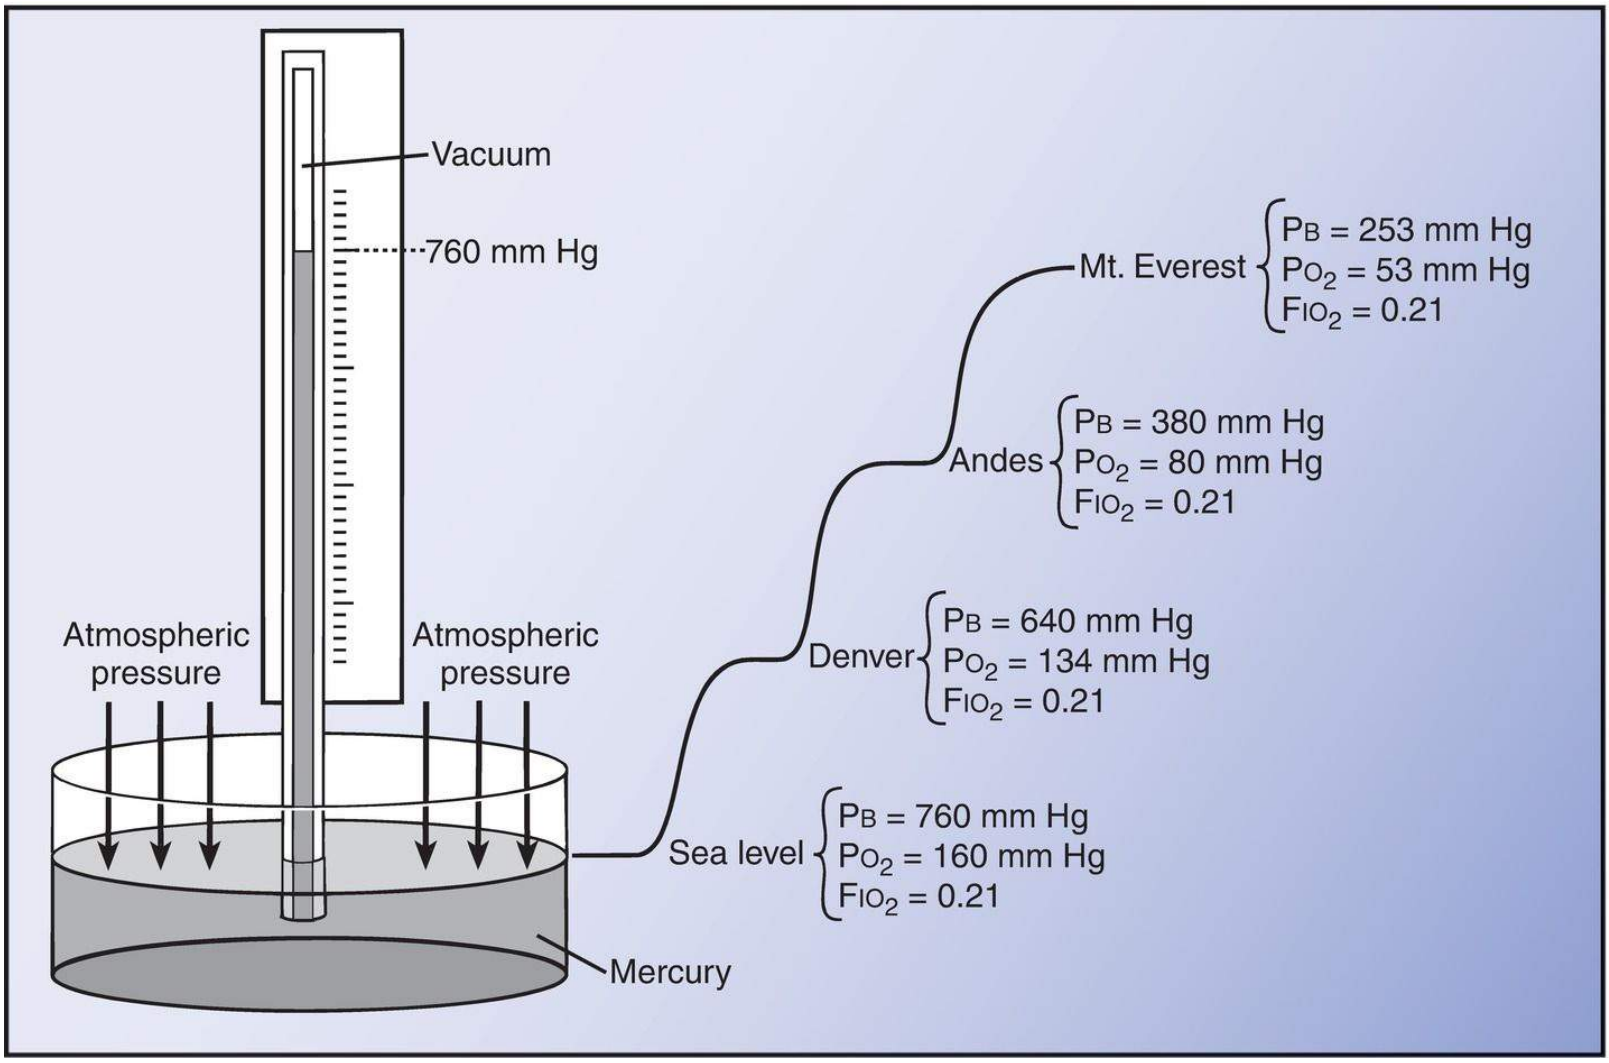

Figure 19.1 Oxygen tension changes with altitude. The height of the column of mercury that is supported by air pressure decreases with altitude, which is a result of a fall in barometric pressure (PB). Because the fractional concentration of inspired O_2 (FIO_2) does not change with altitude, the decrease in PO_2 with altitude is caused entirely by a decrease in PB.

Oxygen is taken up by blood in the lungs and is transported to the tissues. The transfer of oxygen from the alveolar spaces, across the alveolar–capillary membrane to the blood, is referred to as oxygen uptake. Oxygen uptake is determined by three factors: the diffusion properties of the alveolar–capillary membrane, the partial pressure gradient of oxygen, and pulmonary capillary blood flow.

The diffusion of gases is a function of the partial pressure difference of the individual gases. For example, oxygen diffuses across the alveolar–capillary membrane because of the difference in PO_2 between the alveoli and pulmonary capillaries (Fig. 19.2). The partial pressure difference for oxygen is referred to as the **oxygen diffusion gradient**. In the normal lung, the initial oxygen diffusion gradient, alveolar PO_2 (102 mm Hg) minus venous PO_2 (40 mm Hg), is 62 mm Hg. The initial diffusion gradient across the alveolar–capillary membrane for carbon dioxide (venous PCO_2 [$PVCO_2$] minus alveolar PCO_2 [$PACO_2$]) is about 6 mm Hg, which is much smaller than that of oxygen.

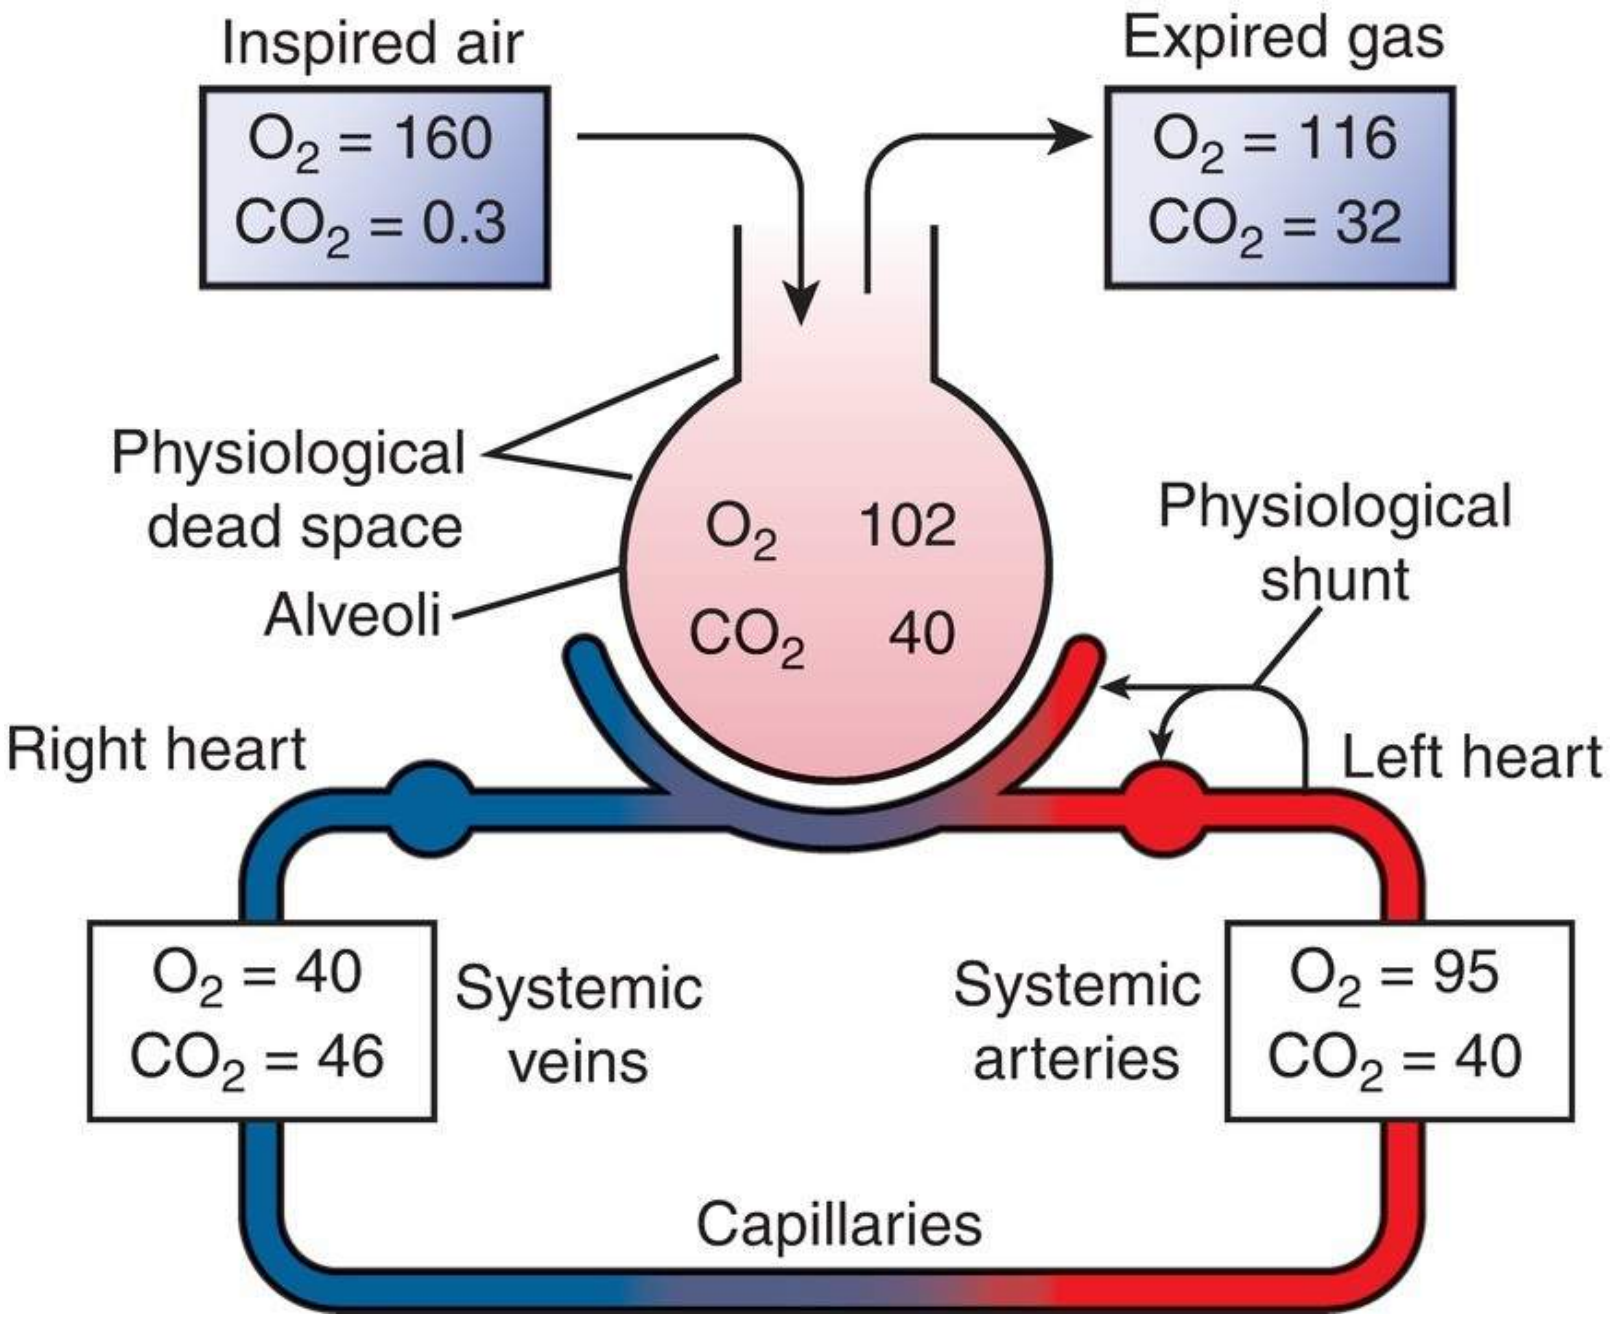

Figure 19.2 Carbon and oxygen tensions vary between the systemic and pulmonary circulation. Partial pressure of oxygen (PO_2) is highest when it leaves the lungs, and that of carbon dioxide (PCO_2) is highest when it enters the lungs.

When gases are exposed to a liquid such as plasma, gas molecules diffuse into the liquid and exist in a dissolved state. The dissolved gases also exert a partial pressure. A gas will continue to dissolve in the liquid until the partial pressure of the dissolved gas equals the partial pressure above the liquid. The **Henry law** states that at equilibrium, the amount of gas dissolved in a liquid at a given temperature is directly proportional to the partial pressure and the solubility of the gas. The Henry law accounts only for the gas that is physically dissolved and not for chemically combined gases (e.g., oxygen bound to hemoglobin).

Gas diffusion in the lungs can be described by **Fick's law**, which states that the volume of gas $(\dot{V}_{gas})$ diffusing per minute across a membrane is directly proportional to the membrane surface area (A_s), the diffusion coefficient of the gas (D), and the partial pressure difference (ΔP) of the gas and is inversely proportional to the membrane thickness (T) (Fig. 19.3):

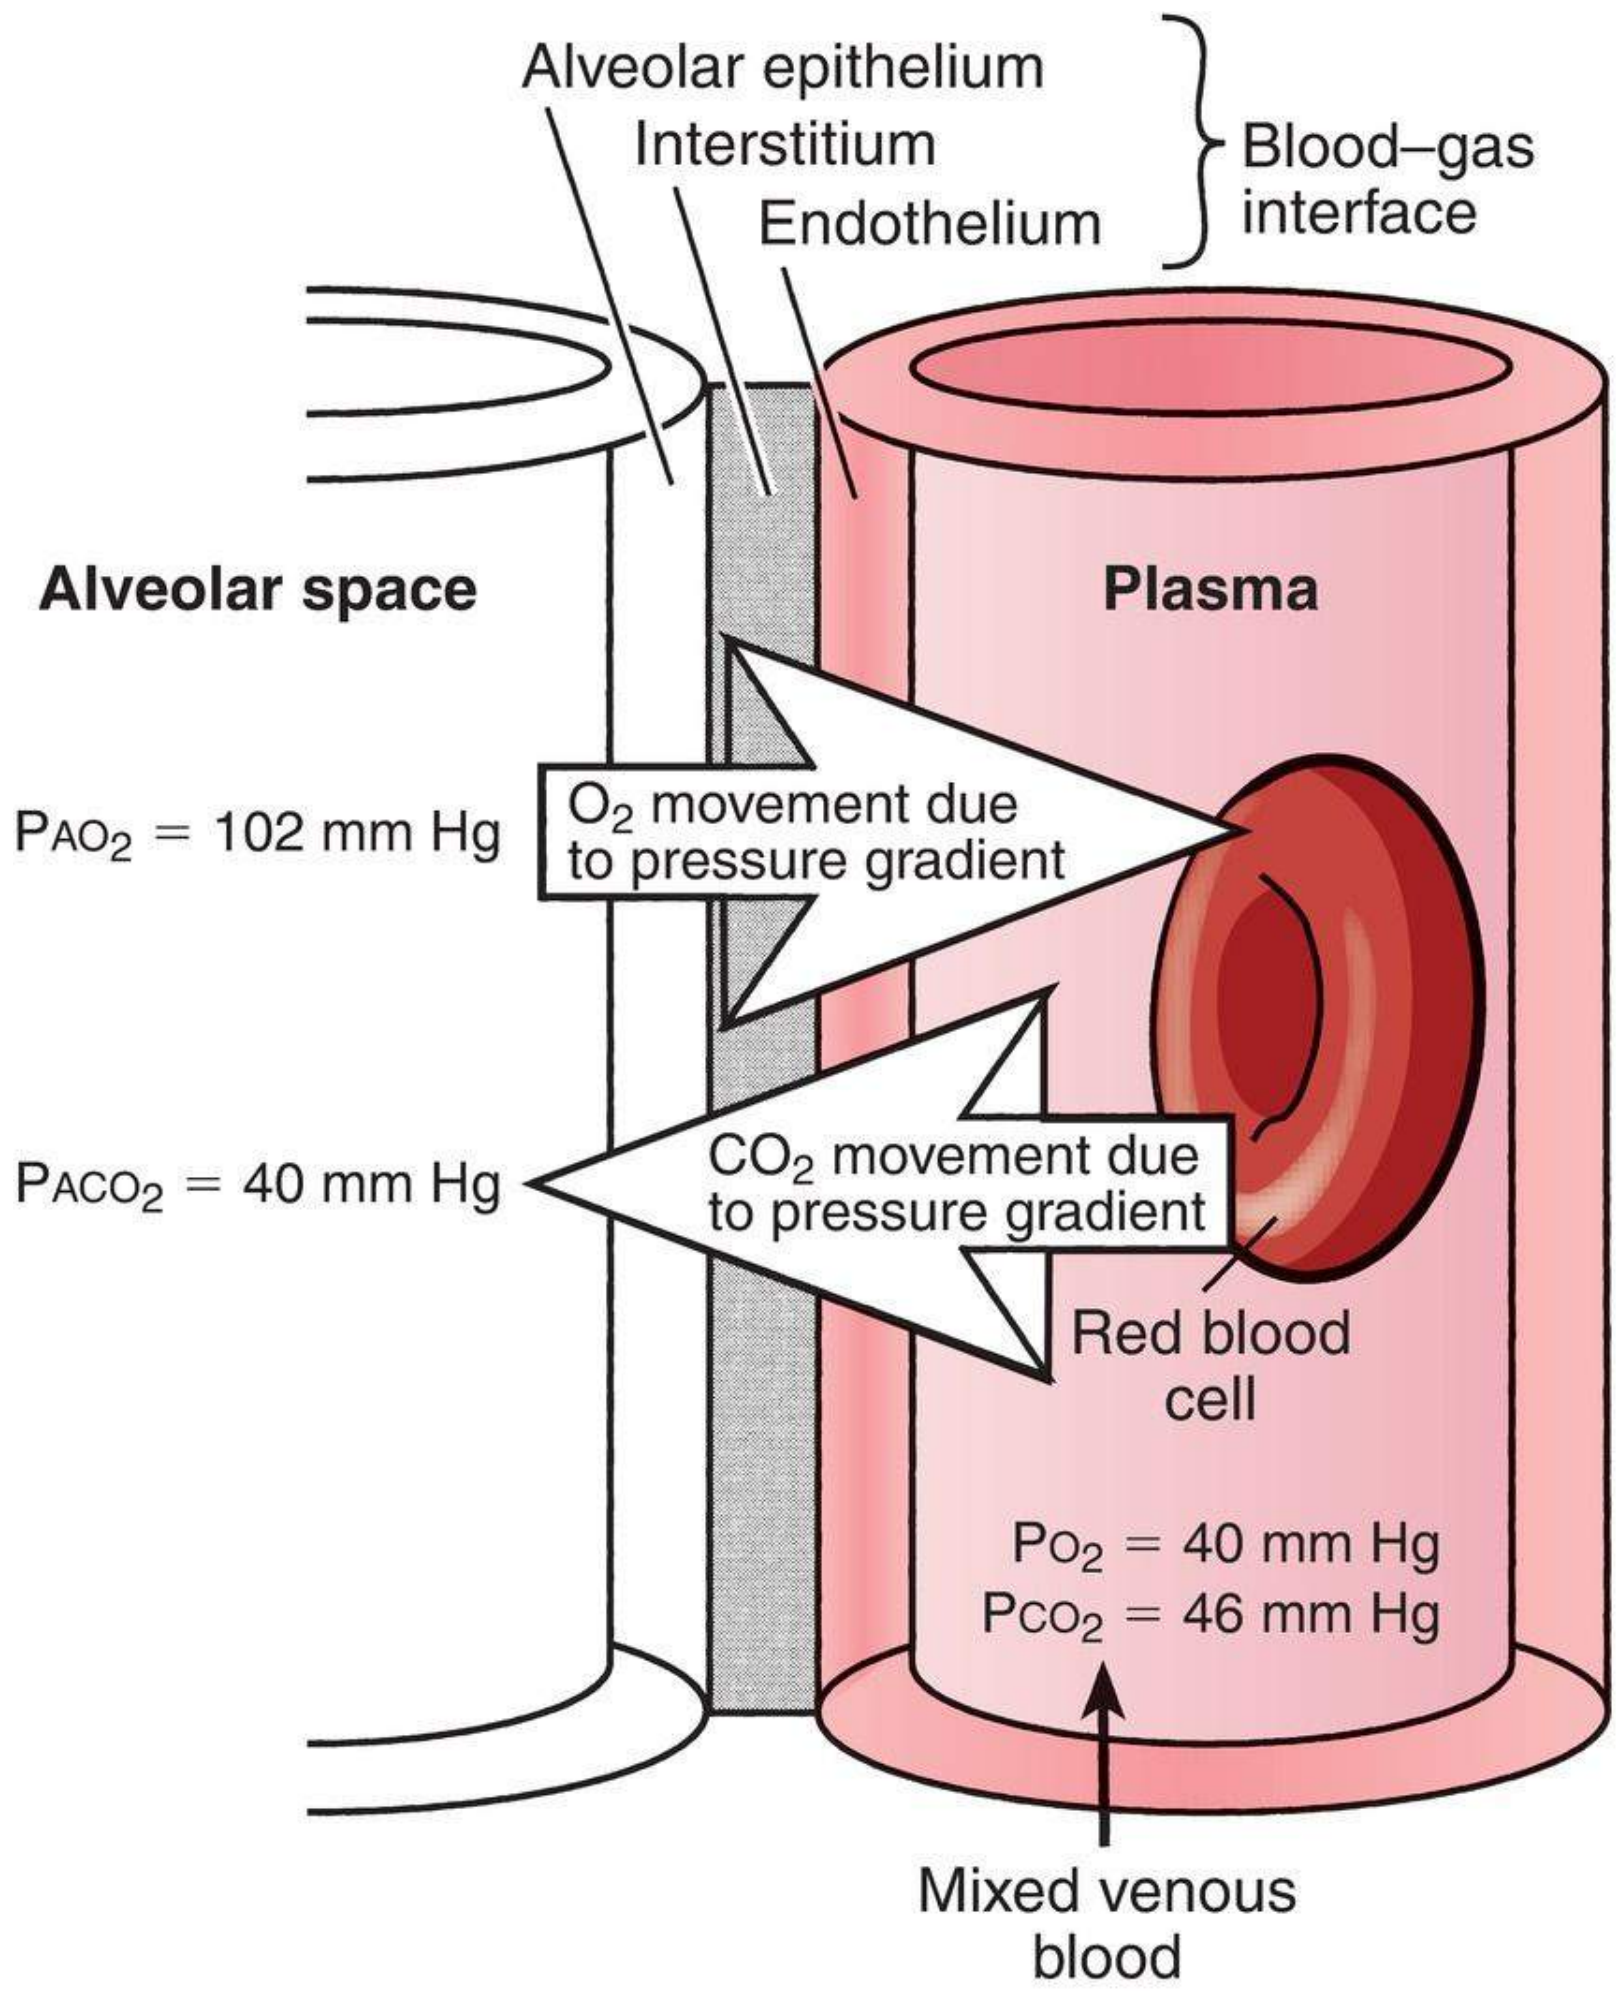

Figure 19.3 Movement of O_2 and CO_2 across the alveolar–capillary membrane is by diffusion. Gases

move across the blood–gas interface (alveolar–capillary membrane) by diffusion, following Fick's law. PAO_2, partial pressure of alveolar oxygen; $PACO_2$, partial pressure of alveolar carbon dioxide.

$$\dot{V}_{gas} = \frac{A_s \times D \times \Delta P}{T} \quad (1)$$

The diffusion coefficient of a gas is directly proportional to its solubility and inversely related to the square root of its molecular weight (MW):

$$D = \frac{\text{solubility}}{(MW)^{1/2}} \quad (2)$$

Therefore, a small molecule or one that is very soluble will diffuse at a fast rate; for example, the diffusion coefficient of carbon dioxide in aqueous solutions is about 20 times greater than that of oxygen because of its higher solubility, even though it is a larger molecule than O_2.

Therefore, Fick's law states that the rate of gas diffusion is inversely related to membrane thickness. This means that the diffusion of a gas will be halved if membrane thickness is doubled. Fick's law also states that the rate of diffusion is directly proportional to surface area (A_s). If two lungs have the same oxygen diffusion gradient and membrane thickness but one has twice the alveolar–capillary surface area, the rate of diffusion will differ by twofold.

Under steady-state conditions, ~250 mL of oxygen per minute are transferred to the pulmonary circulation $\dot{V}_{O_2}$, whereas 200 mL of carbon dioxide per minute are removed

$\dot{V}_{CO_2}$. The ratio $\dot{V}_{CO_2}/\dot{V}_{CO_2}$ is the **respiratory exchange ratio (R)**, and it is 0.8 in this case.

Pulmonary capillary blood flow is a major determinant in transferring oxygen from the alveoli to the blood.

Pulmonary capillary blood flow has a significant influence on oxygen uptake, and its effect is illustrated in Figure 19.4. The time required for the red cells to move through the capillary, referred to as **transit time**, is ~0.75 seconds. During transit time, the gas tension in the blood equilibrates with the alveolar gas tension. Transit time can change dramatically with cardiac output. For example, when cardiac output increases, blood flow through the pulmonary capillaries increases, but transit time decreases (i.e., the time blood is in capillaries is less). Figure 19.4 illustrates the effect of blood flow on the uptake of three test gases. In the first case, a trace amount of nitrous oxide (laughing gas), a common dental anesthetic, is breathed. Nitrous oxide (N_2O) is chosen because it diffuses across the alveolar–capillary membrane and dissolves in the blood but does not combine with hemoglobin. The partial pressure in the blood rises rapidly and virtually reaches equilibrium with the partial pressure of N_2O in the alveoli by the time the blood has spent one tenth of the time in the capillary. At this point, the diffusion gradient for N_2O is zero. Once the pressure gradient becomes zero, no additional N_2O is transferred. The only way the transfer of N_2O can be increased is by increasing blood flow. The amount of N_2O that can be taken up is entirely limited by blood flow, not by diffusion of the gas. Therefore, the net transfer or uptake of N_2O is **perfusion limited**.

Figure 19.4 Pulmonary blood flow increases oxygen uptake. Gas transfer across the alveolar–capillary membrane is affected by pulmonary capillary blood flow. The horizontal axis shows time in the capillary. The average transit time it takes blood to pass through the pulmonary capillaries is 0.75 seconds. The vertical axis indicates gas tension in the pulmonary capillary blood, and the top of the vertical axis indicates gas tension in the alveoli. Individual curves indicate the time it takes for the partial pressure of a specific gas in the pulmonary capillaries to equal the partial pressure in the alveoli. Nitrous oxide (N_2O) is used to illustrate how gas transfer is limited by blood flow; carbon monoxide (CO) illustrates how gas transfer is limited by diffusion. The profile for oxygen is more like that of N_2O, which means oxygen transfer is limited primarily by blood flow. Pulmonary capillary PO_2 equilibrates with the alveolar PO_2 in about 0.25 seconds (*arrow*).

When a trace amount of carbon monoxide (CO) is breathed, the transfer shows a different pattern (see Fig. 19.4). CO readily diffuses across the alveolar–capillary membrane, but, unlike N_2O, CO has a strong affinity for hemoglobin. As the red cell moves through the pulmonary capillary, CO rapidly diffuses across the alveolar–capillary membrane into the blood and binds to hemoglobin. When a trace amount of CO is breathed, most is chemically bound in the blood, resulting in low partial pressure (Pco) in the plasma. Consequently, equilibrium for CO across the alveolar–capillary membrane is never reached, and the transfer of CO to the blood is, therefore, **diffusion limited** and not limited by the blood flow.

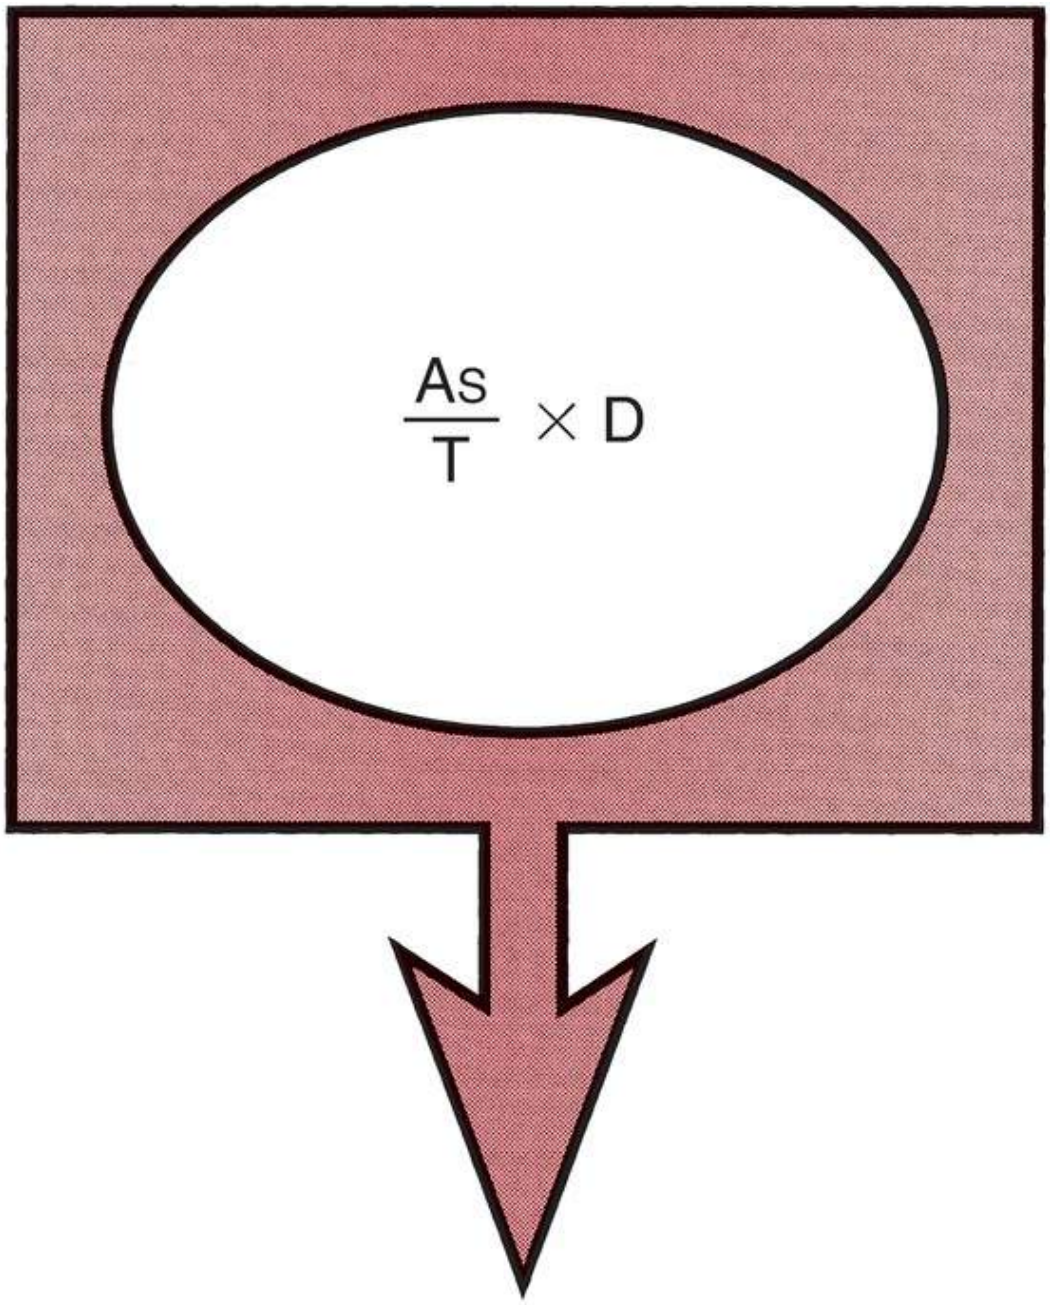
Figure 19.4 shows that the equilibration curve for oxygen lies between the curves for N_2O and CO. Oxygen combines with hemoglobin but not as readily as CO because it has a lower binding affinity. As blood moves along the pulmonary capillary, the rise in PO_2 is much greater than the rise in PCO because of differences in binding affinity. Under resting conditions, the capillary PO_2 equilibrates with alveolar PO_2 when the blood has spent about one third of its time in the capillary. Beyond this point, there is no additional transfer of oxygen. Under normal conditions, oxygen transfer is more like that of N_2O and is limited primarily by blood flow in the capillary (perfusion limited). Hence, an increase in cardiac output will increase oxygen uptake. Not only does cardiac output increase capillary blood flow, but also it increases capillary hydrostatic pressure. The latter increases the surface area for diffusion by opening up more capillary beds by recruitment, which will be discussed later in the chapter.

The transit time at rest is normally about 0.75 seconds, during which capillary oxygen tension equilibrates with alveolar oxygen tension. Ordinarily, this equilibration takes only about one third of the available time, leaving a wide safety margin to ensure that the end-capillary PO_2 is equilibrated with alveolar PO_2. With vigorous exercise, the transit time may be reduced to one third of a second (see Fig. 19.4). Therefore, with vigorous exercise, there is still time to fully oxygenate the blood. Pulmonary end-capillary PO_2 still equals alveolar PO_2 and rarely falls with vigorous exercise. In abnormal situations, in which there is a thickening of the alveolar–capillary membrane (e.g., edema) so that oxygen diffusion is impaired, end-capillary PO_2 may not reach equilibrium with alveolar PO_2. In this case, there is measurable difference between alveolar and end-capillary PO_2.

DIFFUSING CAPACITY

In practice, direct measurements of A_s, T, and D in intact lungs are impossible to make. To circumvent this problem, Fick's law can be rewritten as shown in Figure 19.5, in which the three terms are combined as lung **diffusing capacity** (**DL**) and is a measure of the lung's ability to transfer gases.

$$\dot{V}_{gas} = \frac{A_S}{T} \times D \; (P_1 - P_2)$$



$$\dot{V}_{gas} = D_L \times (P_1 - P_2)$$

$$D_L = \frac{\dot{V}_{gas}}{(P_1 - P_2)}$$

Figure 19.5 Lung diffusing capacity measures the volume of O_2 taken up per minute. Membrane surface area (As), the gas diffusion coefficient (D), and membrane thickness (T) affect gas diffusion in the lungs. These properties are combined into one term, *lung diffusion capacity* (DL). The patients DL is equal to the volume of gas transferred per minute ($\dot{V}_{gas}$) divided by the mean partial pressure gradient ($P_1 - P_2$).

Diffusing capacity measures the rate of oxygen transfer across the alveolar–capillary membrane.

The diffusing capacity provides a measure of the rate of gas transfer in the lungs per partial pressure gradient. For example, if 250 mL of O_2 per minute are taken up and the average alveolar–capillary PO_2 difference during a normal transit time is 14 mm Hg, then the DL for oxygen is 18 mL/min/mm Hg. Because the initial alveolar–capillary difference for oxygen cannot be measured and can only be estimated, CO is used to determine the lung diffusing capacity in patients. CO offers several advantages for measuring DL:

- Its uptake is limited by diffusion and not by blood flow.
- There is essentially no CO in the venous blood.
- The affinity of CO for hemoglobin is 210 times greater than that of oxygen, which causes the partial pressure of CO to remain essentially zero in the pulmonary capillaries.

To measure the diffusing capacity in a patient with CO, the equation is

$$DL = \frac{\dot{V}_{CO}}{P_{ACO}} \quad (3)$$

where $\dot{V}_{CO}$ equals CO uptake in milliliters per minute and PACO equals alveolar partial pressure of CO.

The most common technique for making this measurement is called the **single-breath test**. The patient inhales a single breath of a dilute mixture of CO and holds his or her breath for about 10 seconds. By determining the percentage of CO in the alveolar gas at the beginning and the end of 10 seconds and by measuring lung volume, one can calculate $\dot{V}_{CO}$. The normal resting value for DLCO depends on age, sex, and body size. DLCO ranges from 20 to 30 mL/min/mm Hg and decreases with pulmonary edema or a loss of alveolar membrane (e.g., emphysema).

Blood hematocrit and pulmonary capillary blood volume affect lung diffusing capacity for oxygen.

Diffusing capacity does not depend solely on the diffusion properties of the lungs; it is also affected by blood hematocrit and pulmonary capillary blood volume. Both the hematocrit and capillary blood volume affect DL in the same direction (i.e., a decrease in either the hematocrit or capillary blood volume will lower the diffusing capacity in otherwise normal lungs). For example, if two people have the same pulmonary diffusion properties but one is anemic (reduced hematocrit), the anemic person will have a decreased lung diffusing capacity. An abnormally low cardiac output lowers the pulmonary capillary blood volume, which decreases the alveolar capillary surface area and will, in turn, decrease the diffusing capacity in otherwise normal lungs.

GAS TRANSPORT BY THE BLOOD

The transport of O_2 and CO_2 by the blood, often referred to as *gas transport*, is an important step in the overall gas exchange process and is one of the functions of the systemic circulation.

Most of the oxygen in the blood is transported by hemoglobin.

Oxygen is transported to the tissues in two forms: combined with **hemoglobin** (**Hb**) in the red cell or physically dissolved in the blood. Approximately 98% of the oxygen is carried by hemoglobin, and the remaining 2% is carried in the physically dissolved form. The amount of physically dissolved oxygen in the blood can be calculated from the following equation:

$$\text{Dissolved } O_2 \text{ (mL/dL)} = 0.003(\text{mL/dL/mm Hg}) \times \text{Pao}_2 \text{ (mm Hg)} \quad (4)$$

If arterial oxygen tension (PaO_2) equals 100 mm Hg, then dissolved O_2 equals 0.3 mL/dL.

The hemoglobin molecule consists of four oxygen-binding heme sites and a globular protein chain. When hemoglobin binds with oxygen, it is called **oxyhemoglobin** (**HbO_2**). The hemoglobin that does not bind with O_2 is called **deoxyhemoglobin** (**Hb**). Each gram of hemoglobin can bind with 1.34 mL of oxygen. Oxygen binds rapidly and reversibly to hemoglobin: $O_2 + Hb \leftrightarrow Hbo_2$. The amount of oxyhemoglobin is a function of the partial pressure of oxygen in the blood. In the pulmonary capillaries, in which PO_2 is high, the reaction is shifted to the right to form oxyhemoglobin. In tissue capillaries, in which PO_2 is low, the reaction is shifted to the left; oxygen is unloaded from hemoglobin and becomes available to the cells. The maximum amount of oxygen that can be carried by hemoglobin is called the **oxygen-carrying capacity**—about 20 mL O_2/dL blood in a healthy young adult. This value is calculated assuming a normal hemoglobin concentration of 15 g Hb/dL of blood (1.34 mL O_2/g Hb × 15 g Hb/dL blood = 20.1 mL O_2/dL blood).

Oxygen content is the amount of oxygen actually bound to hemoglobin (whereas capacity is the amount that can potentially be bound). **Oxygen saturation** is the percentage saturation of hemoglobin with oxygen (SO_2) and is calculated from the ratio of oxyhemoglobin content over capacity:

$$\text{So}_2 = \frac{\text{Hbo}_2 \text{ content}}{\text{Hbo}_2 \text{ capacity}} \times 100 \quad (5)$$

Therefore, oxygen saturation is the ratio of the quantity of oxygen *actually bound* to the quantity that can be *potentially bound*. For example, if oxygen content is 16 mL O_2/dL blood and oxygen capacity is 20 mL O_2/dL blood, then the blood is 80% saturated. Arterial blood saturation of hemoglobin with oxygen (SaO_2) is normally about 98%.

Oxyhemoglobin–equilibrium curve illustrates the effect that plasma PO_2 has on the loading and unloading of oxygen from hemoglobin.

Blood PO_2, O_2 saturation, and oxygen content are three closely related indices of oxygen transport. The relationship between these three entities is illustrated by the **oxyhemoglobin–equilibrium curve** (Fig. 19.6). The S shape of the curve results because the hemoglobin affinity for oxygen increases progressively as blood PO_2 increases.

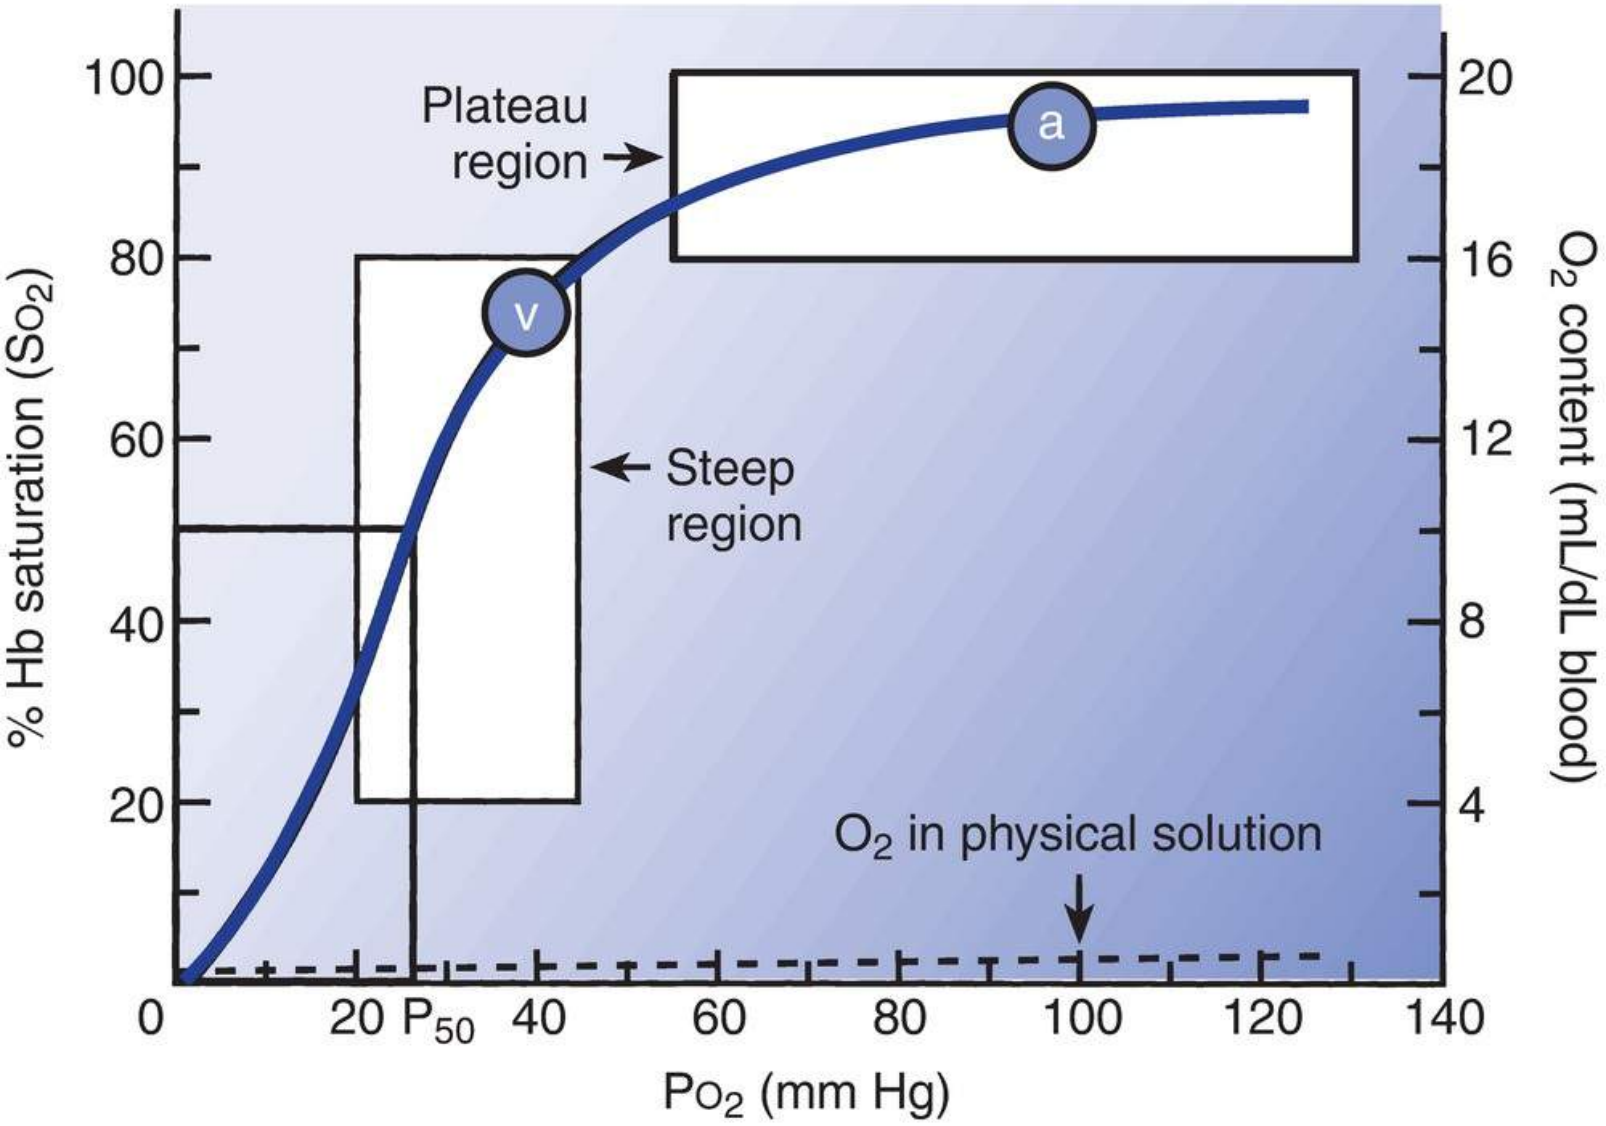


Figure 19.6 The oxyhemoglobin equilibrium curve is nonlinear. The oxygen saturation (left vertical axis) or oxygen content (right vertical axis) is plotted against the partial pressure of oxygen (horizontal axis) to generate an oxyhemoglobin equilibrium curve. The curve is S shaped and can be divided into a *plateau region* and a *steep region*. The *dashed line* indicates the amount of oxygen dissolved in the plasma. a, arterial; v, venous; Hb, hemoglobin; SO_2, oxygen saturation; P_{50}, partial pressure of O_2 required to saturate 50% of the hemoglobin with oxygen.

The shape of the oxyhemoglobin–equilibrium (O_2–Hb) curve also reflects several important physiologic advantages. The *plateau region* of the curve is the **loading phase**, in which oxygen is loaded onto

hemoglobin to form oxyhemoglobin in the pulmonary capillaries. In particular, the plateau region illustrates how oxygen saturation and content remain fairly constant despite wide fluctuations in alveolar PO_2. For example, if PaO_2 were to rise from 100 to 120 mm Hg, hemoglobin would become only slightly more saturated (from 97% to 98%). For this reason, oxygen content cannot be raised appreciably by hyperventilation. The *steep region* is the **unloading phase** of the curve and illustrates that large quantities of oxygen are released or unloaded from hemoglobin. The unloading phase occurs in the tissue capillaries where low capillary PO_2 prevails. Thus, the functional importance of the S-shaped oxyhemoglobin–equilibrium curve enables oxygen to saturate hemoglobin under high partial pressures in the lungs and to give up large amounts of oxygen with small changes in PO_2 at the tissue level.

A change in the binding affinity of hemoglobin for O_2 shifts the oxyhemoglobin–equilibrium curve to the right or left of normal (Fig. 19.7). A functional way to assess the binding affinity of Hb for O_2 is the P_{50}—the PO_2 at which 50% of the hemoglobin is saturated. As seen in Figure 19.6, the normal P_{50} for arterial blood is 26 to 28 mm Hg. A high P_{50} signifies a decrease in hemoglobin's affinity for oxygen and results in a rightward shift in the oxyhemoglobin–equilibrium curve, whereas a low P_{50} signifies the opposite and shifts the curve to the left. A shift in the P_{50} in either direction has the greatest effect on the steep phase and only a small effect on the loading of oxygen in the normal lung, because loading occurs at the plateau.

Figure 19.7 Oxygen has a strong binding affinity for hemoglobin (Hb). (A) P_{50} is a measure of Hb's affinity to bind with oxygen. **(B)** An increase in temperature, $[H^+]$, or arterial PCO_2 causes a rightward shift of the oxyhemoglobin equilibrium curve. An increase in P_{50} indicates a lower binding affinity for oxygen, which favors the unloading of O_2 from Hb at the tissue level. An increase in red cell levels of 2,3-diphosphoglycerate (DPG) will also shift the curve to the right. The increase in DPG occurs with hypoxemic conditions. P_{50}, partial pressure of O_2 required to saturate 50% of the hemoglobin with oxygen.

Blood pH, body temperature, and arterial PCO_2 significantly alter the P_{50}.

Several factors affect the binding affinity of hemoglobin for O_2, including blood temperature, arterial carbon dioxide tension, and arterial pH. A rise in PCO_2, a fall in pH, and a rise in temperature all shift the O_2–Hb curve to the right (see Fig. 19.7). The effect of carbon dioxide and hydrogen ions on hemoglobin's affinity for oxygen is known as the **Bohr effect**. A shift of the O_2–Hb curve to the right is physiologically advantageous at the tissue level because the affinity is lowered (increased P_{50}). A rightward shift enhances the unloading of oxygen for a given PO_2 in the tissue, and a leftward shift increases the affinity of hemoglobin for oxygen, thereby lowering the ability to release oxygen to the tissues. A simple way to remember the functional importance of these shifts is that an exercising muscle is hot and acidic and produces large amounts of carbon dioxide (high PCO_2), all of which favor the unloading of more oxygen to metabolically active muscles.

Red blood cells contain 2,3-diphosphoglycerate (2,3-DPG), an organic phosphate compound that can also affect the affinity of hemoglobin for oxygen. In red cells, 2,3-DPG levels are much higher than in other cells because erythrocytes lack mitochondria. An increase in 2,3-DPG facilitates unloading of oxygen from the red cell at the tissue level (shifts the curve to the right). An increase in red cell 2,3-DPG occurs with exercise and with hypoxia (e.g., high-altitude, chronic lung disease).

It is important to remember that oxygen content, rather than PO_2 or SaO_2, is what keeps us alive and serves as a better gauge for oxygenation. For example, a person can have a normal arterial PO_2 and SaO_2 but reduced oxygen content. This situation is seen in patients who have **anemia** (a decreased number of circulating red cells). A patient with anemia who has a hemoglobin concentration half of normal (7.5 g/dL instead of 15 g/dL) will have a normal arterial PO_2 and SaO_2, but oxygen content will be reduced to half of normal. A patient with anemia has a normal SaO_2 because that content and capacity are proportionally reduced. The usual oxyhemoglobin–equilibrium curve does not show changes in blood oxygen content, because the vertical axis is saturation. As a result, the vertical axis is often changed to oxygen content (mL O_2/dL blood) and then changes in content are seen (Fig. 19.8). The shape of the oxyhemoglobin–equilibrium curve does not change, but the curve moves down to reflect the reduction in oxygen content. A good analogy for comparing an anemic patient with a healthy patient is comparing a bicycle tire with a truck tire: Both can have the same air pressure, but the amount of air each tire holds is different.

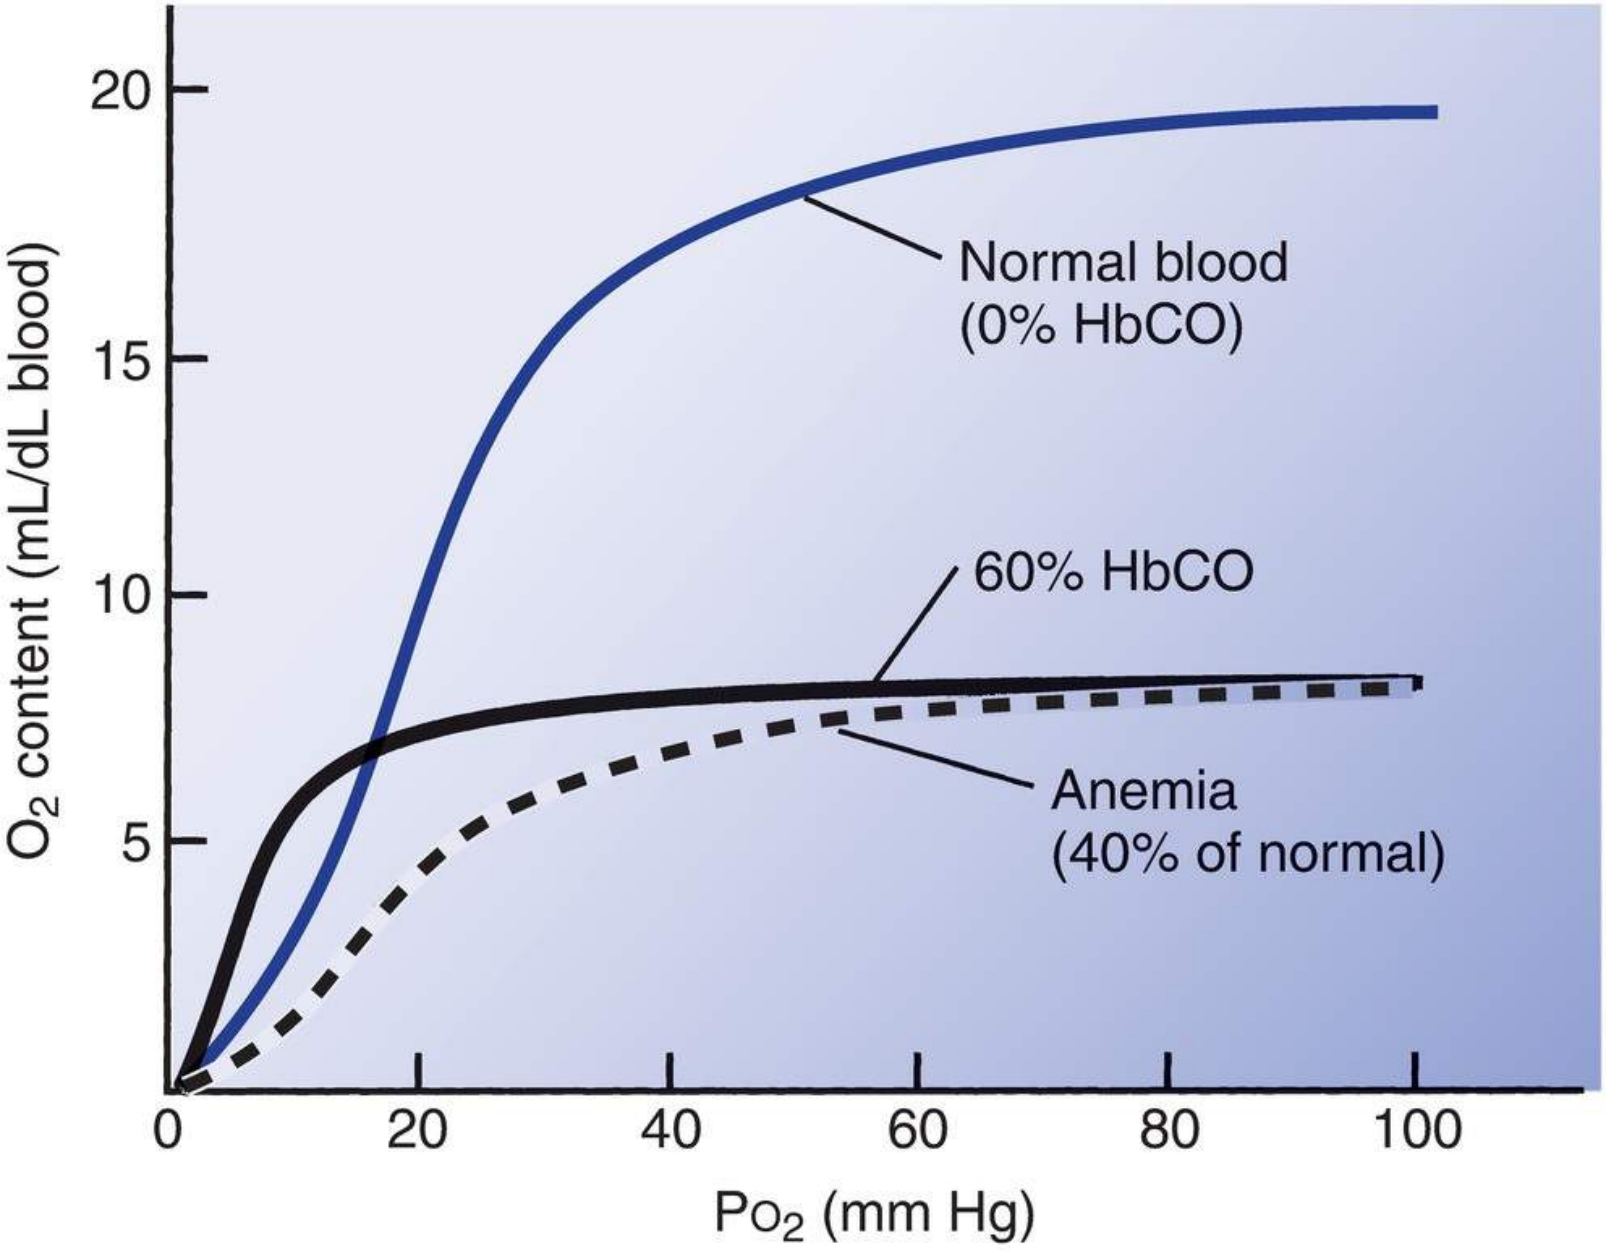

Figure 19.8 Hematocrit and CO poisoning affect the oxyhemoglobin equilibrium curve. Severe anemia can lower the O_2 content to 40% of normal. The blood O_2 content of a person exposed to CO is shown for comparison. When the blood is 60% saturated with carbon monoxide (HbCO), O_2 content is reduced to about 8 mL/dL of blood. Note the leftward shift of the oxyhemoglobin equilibrium curve when CO binds with hemoglobin.

Carbon monoxide has a greater binding affinity for hemoglobin than that of oxygen.

CO interferes with oxygen transport by competing for the same binding sites on hemoglobin as O_2. CO binds to hemoglobin to form **carboxyhemoglobin** (**HbCO**). The reaction (Hb + CO ↔ HbCO) is reversible and is a function of PCO. This means that breathing higher concentrations of CO will favor the reaction to the right and form more HbCO. Breathing fresh air will favor the reaction to the left, which will cause CO to be released from the hemoglobin. A striking feature of CO is a binding affinity about 210 times that of oxygen. Consequently, CO will bind with the same amount of hemoglobin as oxygen at a partial pressure 210 times lower than that of oxygen. For example, breathing normal air (21% O_2) contaminated with 0.1% CO would cause half of the hemoglobin to be saturated with CO and half with O_2. With the high affinity of hemoglobin for CO, breathing a small amount of CO can result in the formation of large amounts of HbCO. Arterial PO_2 in the plasma will still be normal because the oxygen diffusion gradient has not changed. However, oxygen content will be greatly reduced because oxygen cannot bind to hemoglobin. This is seen in Figure 19.8, which shows the effect of CO on the oxyhemoglobin–equilibrium curve. When the blood is 60% saturated with CO (carboxyhemoglobin), the oxygen content is reduced to <10 mL/dL. The presence of CO also shifts the curve to the left, making it more difficult to unload or release oxygen to the tissues. CO is dangerous for several reasons:

- It has a strong binding affinity for hemoglobin.
- As an odorless, colorless, and nonirritating gas, it is virtually undetectable.
- PaO_2 is normal, and there is no feedback mechanism to indicate that oxygen content is low.
- There are no physical signs of hypoxemia (i.e., lack of **cyanosis** or bluish color around the lips and fingers) because the blood is bright cherry red when CO binds with hemoglobin.

Therefore, a person can be exposed to CO and have oxygen content reduced to a level that becomes lethal, by causing tissue anoxia, without the person being aware of the danger. The brain is one of the first organs affected by lack of oxygen. CO can alter reaction time and cause blurred vision and, if severe enough, unconsciousness.

The best treatment for CO poisoning is breathing 100% oxygen. Because O_2 and CO compete for the same binding site on the hemoglobin molecule, breathing a high oxygen concentration will drive off the CO and favor the formation of oxyhemoglobin. The addition of 5% carbon dioxide to the inspired gas stimulates ventilation, which lowers the CO and enhances the release of CO from hemoglobin. The loading and unloading of CO from hemoglobin are functions of PCO. Oxygen is not always beneficial—oxygen metabolism can produce harmful products that injure tissues.

Most of the carbon dioxide in the blood is transported as bicarbonate.

Figure 19.9 illustrates the processes involved in carbon dioxide transport. Carbon dioxide is carried in the blood in three forms:

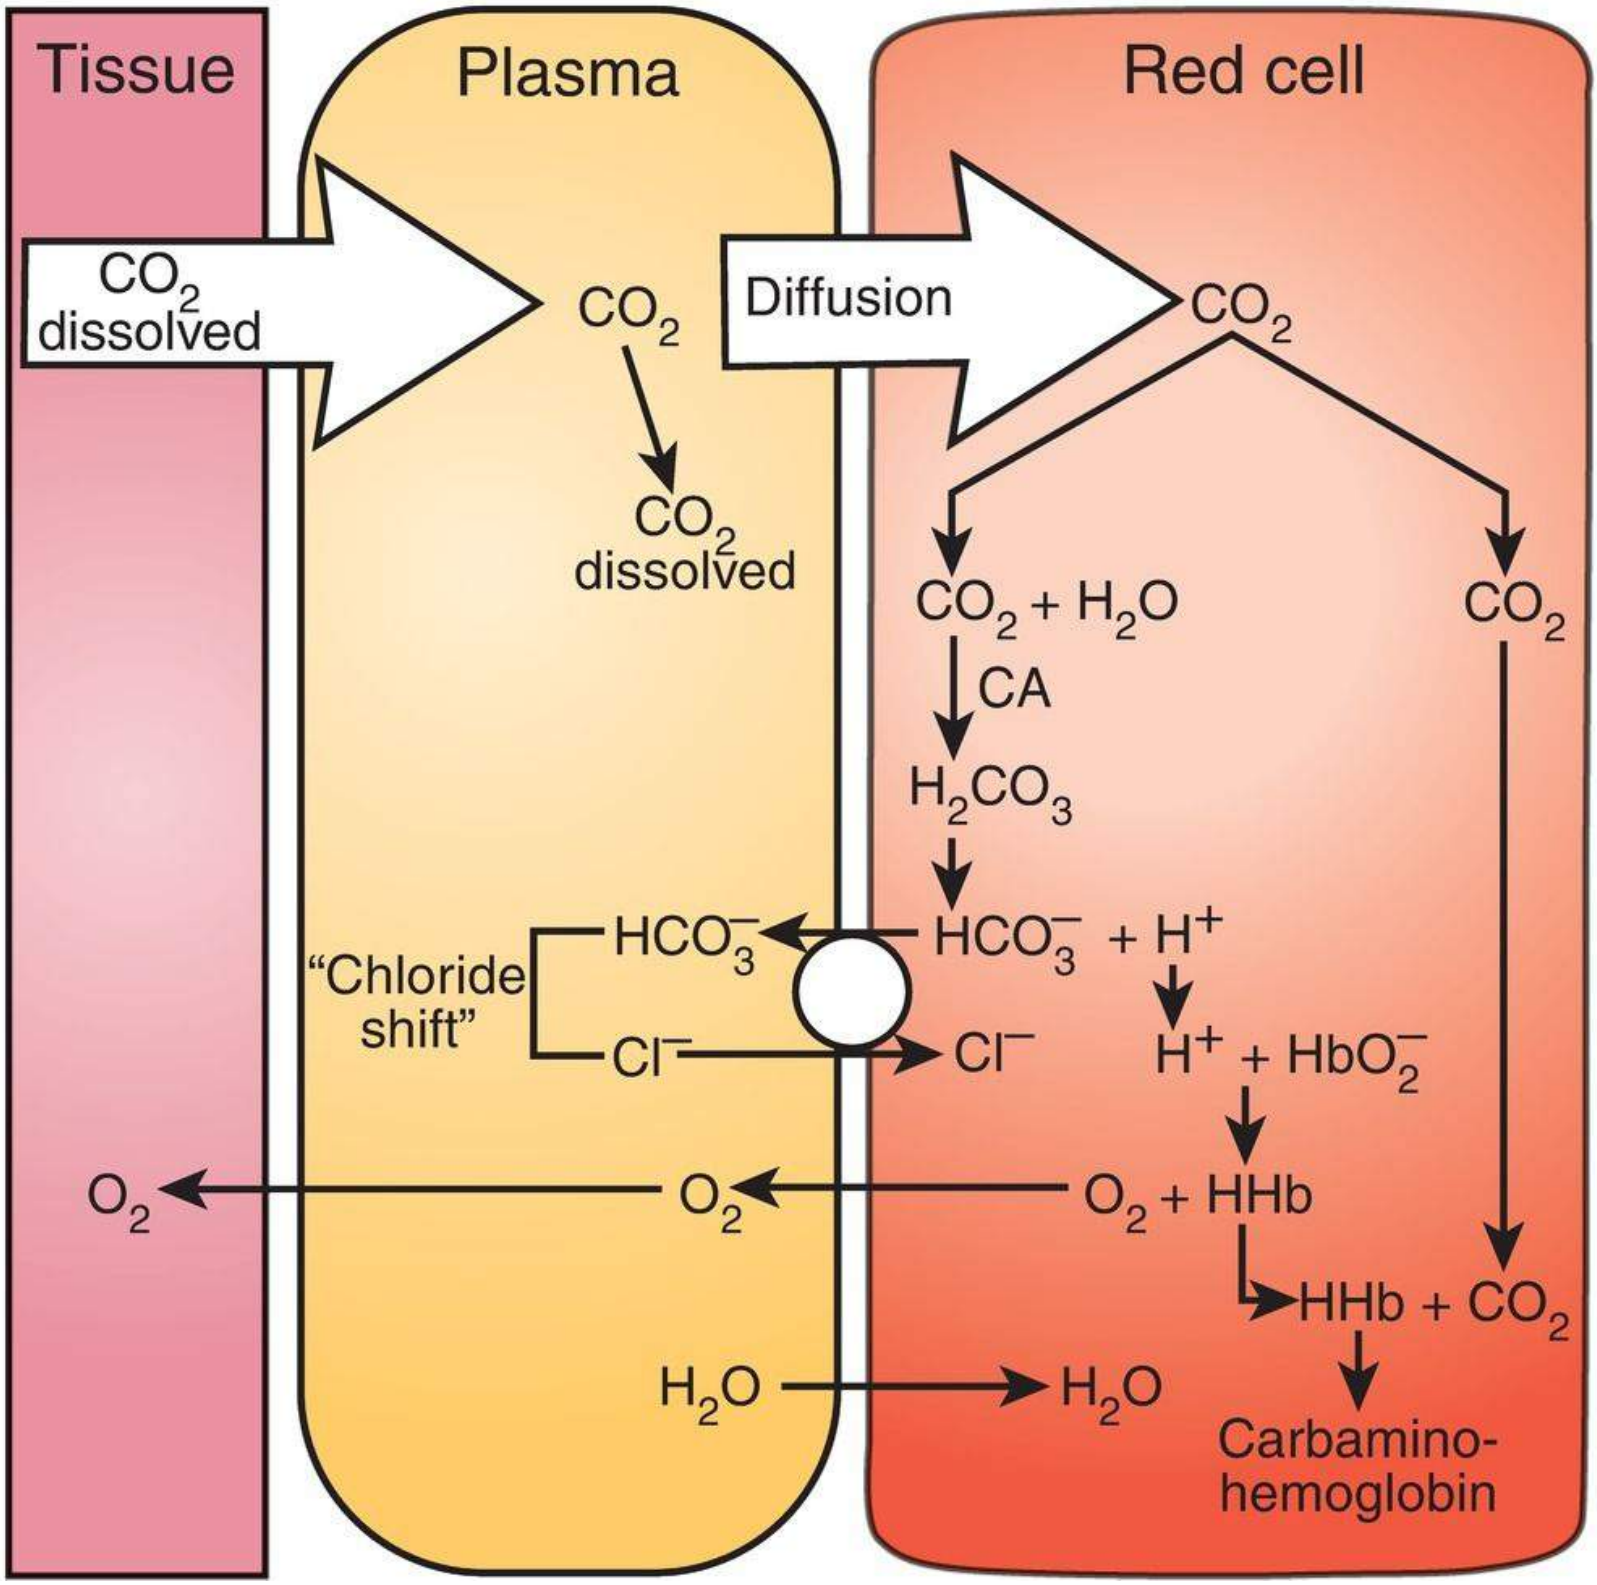

Figure 19.9 Bicarbonate is the main transporter of carbon dioxide. CO_2 is transported in the blood in three forms: physically dissolved, as HCO_3^-, and as carbaminohemoglobin in the red cell (see text for

details). The uptake of CO_2 favors the release of O_2. A major portion of the CO_2 is carried in the form of bicarbonate. CA, carbonic anhydrase; Hb, hemoglobin.

- Physically dissolved in the plasma (10%)
- As bicarbonate ions in the plasma and in the red cells (60%)
- As carbamino proteins (30%)

The high PCO_2 in the interstitial fluid drives carbon dioxide from the tissue into the blood, but only a small amount stays as dissolved CO_2 in the plasma. The bulk of the carbon dioxide diffuses into the red cell, in which it forms either carbonic acid (H_2CO_3) or **carbaminohemoglobin**. In the red cell, carbonic acid is formed in the following reaction:

$$CO_2 + H_2O \xleftrightarrow{CA} H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (6)$$

The hydration of CO_2 would take place slowly if it were not accelerated about 1,000 times in red cells by the enzyme **carbonic anhydrase (CA)**. This enzyme is also found in renal tubular cells, gastrointestinal mucosa, muscle, and other tissues, but its activity is highest in red blood cells.

Carbonic acid readily dissociates in red blood cells to form bicarbonate (HCO_3^-) and H^+. HCO_3^- leaves the red blood cells, and chloride diffuses in from the plasma to maintain electrical neutrality (see Fig. 19.9). The chloride movement is known as the *chloride shift* and is facilitated by a chloride–bicarbonate exchanger (anion exchanger) in the red blood cell membrane. The H^+ cannot readily move out because of the low permeability of the membrane to H^+. Most of the H^+ is buffered by hemoglobin: $H^+ + HbO_2^- \leftrightarrow HHb + O_2$. As H^+ binds to hemoglobin, it decreases oxygen binding and shifts the oxyhemoglobin–equilibrium curve to the right. This promotes the unloading of oxygen from hemoglobin in the tissues and favors the carrying of carbon dioxide. In the pulmonary capillaries, the oxygenation of hemoglobin favors the unloading of carbon dioxide.

Carbaminohemoglobin is formed in red cells from the reaction of carbon dioxide with free amine groups (NH_2) on the hemoglobin molecule:

$$CO_2 + HbNH_2 \leftrightarrow HbNHCOOH \quad (7)$$

Deoxygenated hemoglobin can bind much more CO_2 in this way than oxygenated hemoglobin. Although major reactions related to CO_2 transport occur in the red cells, the bulk of the CO_2 is actually carried in the plasma in the form of bicarbonate.

A **carbon dioxide equilibrium curve** can be constructed in a fashion similar to that for oxygen (Fig. 19.10). The carbon dioxide equilibrium curve is nearly a straight-line function of PCO_2 in the normal arterial CO_2 range. Note that a higher PO_2 will shift the curve downward and to the right. This is known as the **Haldane effect**, and its advantage is that it allows the blood to load more CO_2 in the tissues and unload more CO_2 in the lungs.

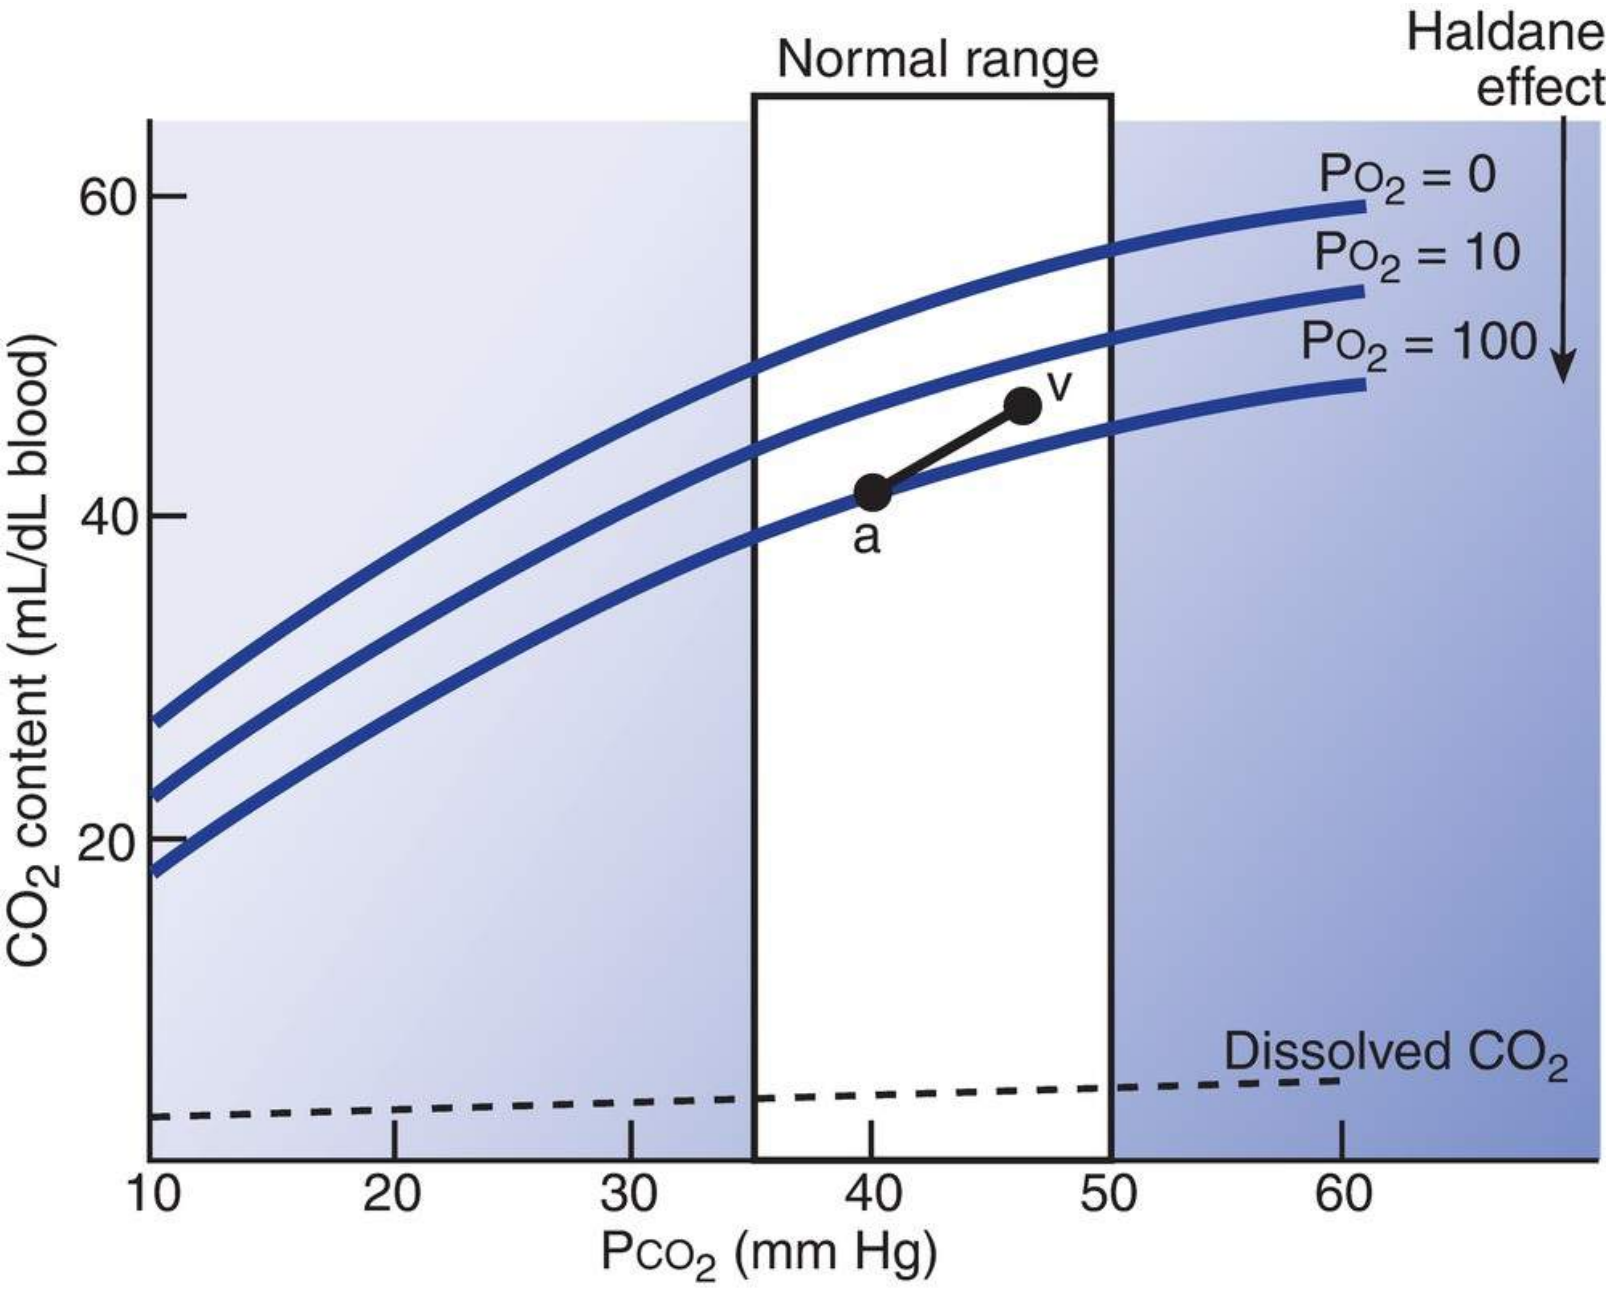

Figure 19.10 Increased O_2 tension shifts the carbon dioxide equilibrium curve. The carbon dioxide equilibrium curve is relatively linear. An increase in PO_2 tension causes a rightward and downward shift of the curve. The PO_2 effect on the CO_2 equilibrium curve is known as the *Haldane effect*. The *dashed line* indicates the amount dissolved in plasma. a, arterial CO_2 content; v, CO_2 content in mixed venous blood.

Important differences are observed between the carbon dioxide and oxygen equilibrium curves (see Figs. 19.7 and 19.10). First, 1 L of blood can hold much more carbon dioxide than oxygen. Second, the CO_2 equilibrium curve is steeper and more linear, and because of its shape, large amounts of CO_2 can be loaded and unloaded from the blood with a small change in PCO_2. This is important not only in gas exchange and transport but also in the regulation of acid–base balance.

RESPIRATORY CAUSES OF HYPOXEMIA

Under normal conditions, hemoglobin is 100% saturated with oxygen when the blood leaves the pulmonary capillaries, and the PO_2 at the end of the capillary (end-capillary PO_2) equals alveolar PO_2. However, the blood that leaves the lungs (via the pulmonary veins) and returns to the left side of the heart has a lower PO_2 than does the pulmonary end-capillary blood. As a result, the systemic arterial blood has an average oxygen tension (PaO_2) of about 95 mm Hg and is only 98% saturated.

Alveolar–arterial oxygen difference originates because bronchial circulation mixes with oxygenated blood.

The difference between alveolar oxygen tension (PAO_2) and arterial oxygen tension (PaO_2) is the **alveolar–arterial oxygen gradient** or A–aO_2 gradient (Fig. 19.11). Because alveolar PO_2 is normally 100 to 102 mm Hg and arterial PO_2 is 85 to 95 mm Hg, a normal A–aO_2 gradient is between 5 and 15 mm Hg. The A–aO_2 gradient is obtained from blood gas measurements and the alveolar gas equation to determine PAO_2. Recall from Chapter 18 that the simplified equation is $PAO_2 = FIO_2 \times (PB - 47) - 1.2 \times PaCO_2$.

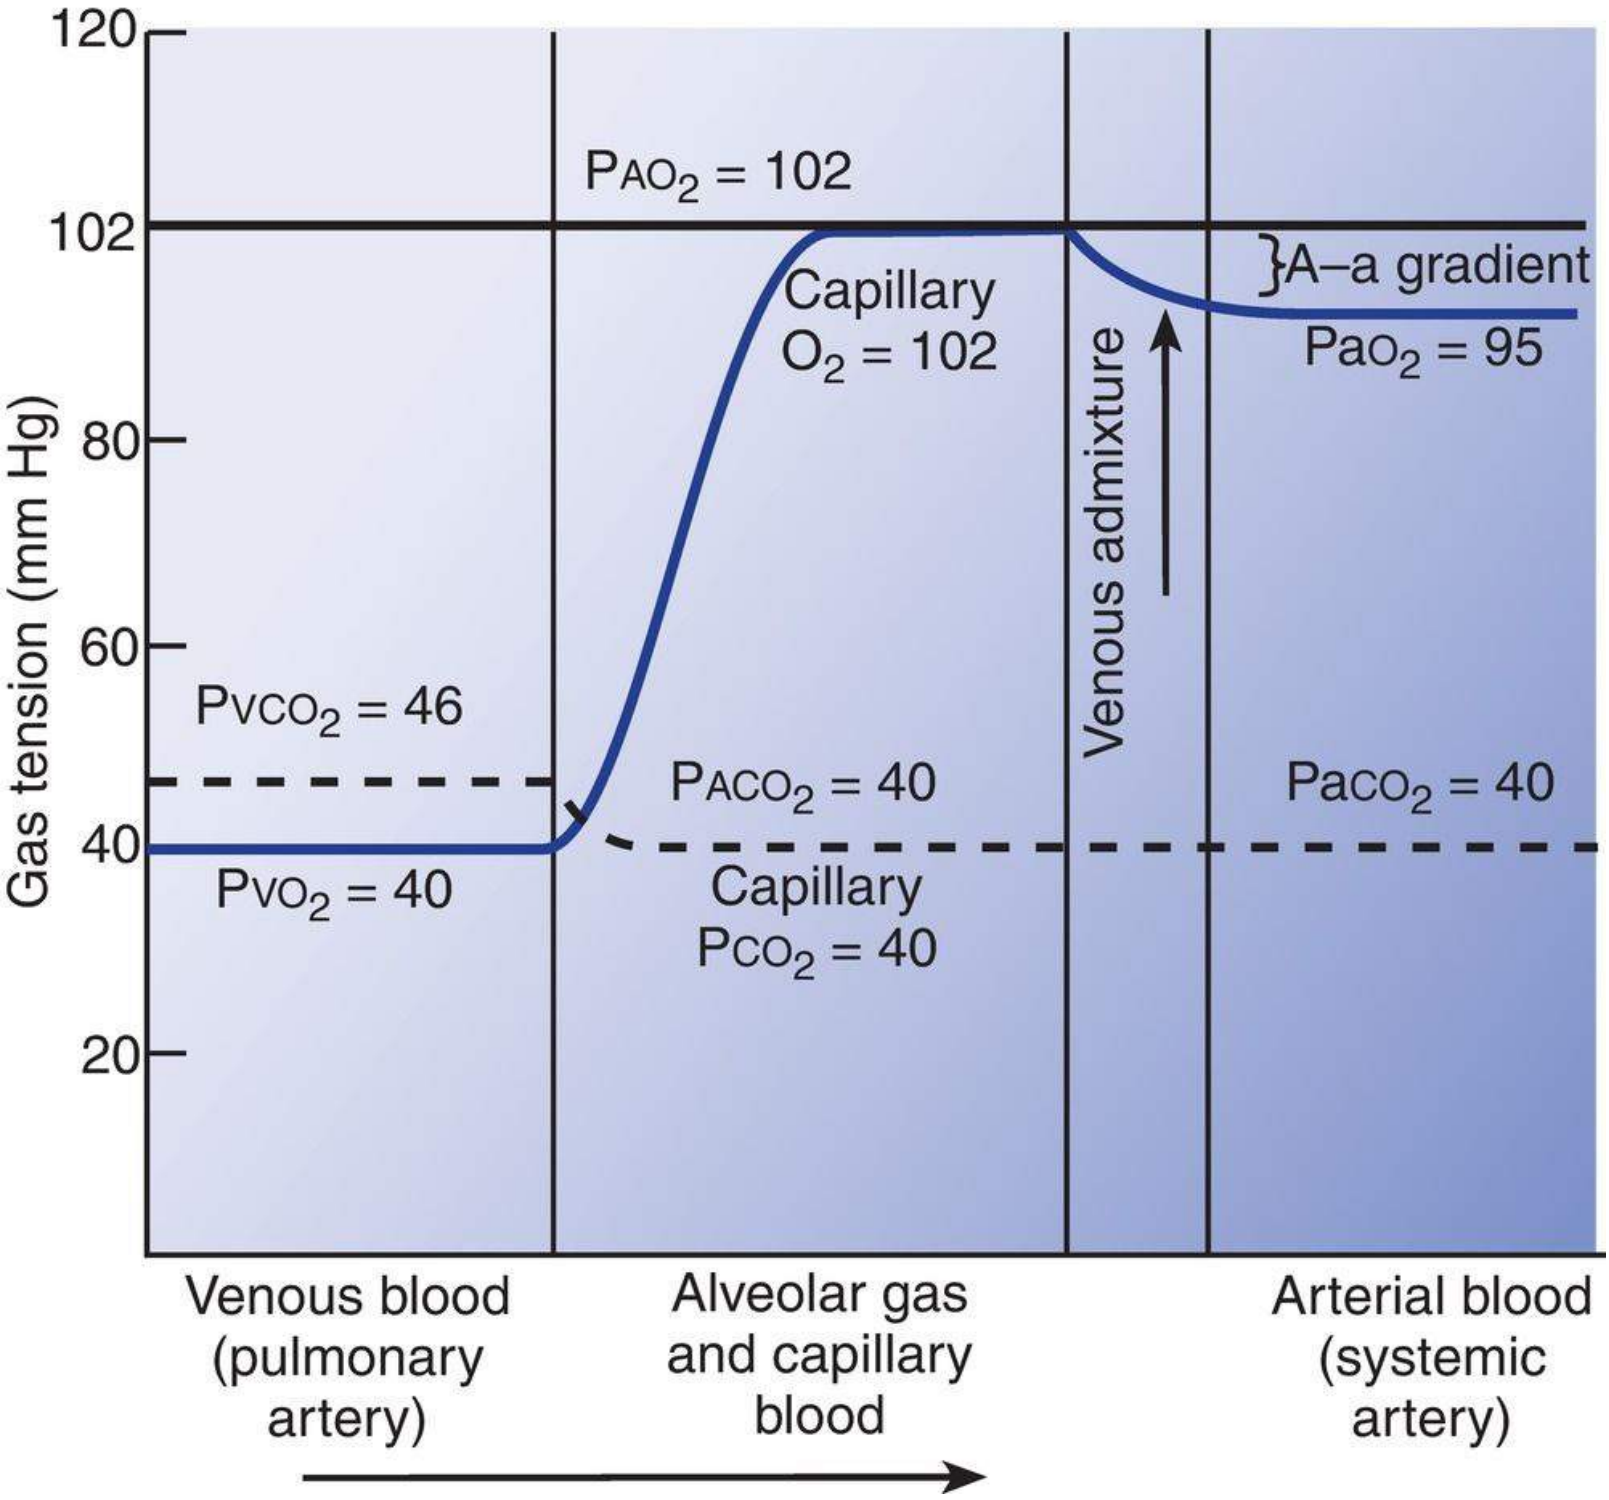

Figure 19.11 An oxygen gradient is established between the alveoli and arterial blood. The diagram shows O_2 and CO_2 tensions in blood in the pulmonary artery, pulmonary capillaries, and systemic arterial blood. The PO_2 leaving the pulmonary capillary has equilibrated with alveolar PO_2. However, systemic arterial PO_2 is below alveolar PO_2. Venous admixture results in the alveolar–arterial oxygen gradient (A–aO_2). $PACO_2$, partial pressure of alveolar carbon dioxide; $PaCO_2$, partial pressure of arterial carbon dioxide; PAO_2, partial pressure of alveolar oxygen; PaO_2, partial pressure of arterial oxygen; $PvCO_2$, partial pressure of venous carbon dioxide; PvO_2, partial pressure of oxygen.

The A–aO_2 gradient arises in the healthy person because a fraction of venous blood mixes with oxygenated blood. This mixing of unoxygenated and oxygenated blood is known as **venous admixture**. The venous admixture is the result of two unique feature of the pulmonary circulation. One is due to a

small anatomical shunt (e.g., bronchial circulation) that dumps venous blood back into the pulmonary oxygenated venous blood. The second cause is due to regional variations in the ventilation/perfusion $(\dot{V}_A/\dot{Q})$ ratio. The $(\dot{V}_A/\dot{Q})$ ratio is simply the ratio of minute alveolar ventilation to pulmonary blood flow in any unit of the lung. Proper oxygenation of blood in the pulmonary circulation leaving any region of the lung (regional alveoli and their blood supply) occurs when ventilation and perfusion are equally matched in that region. Oxygenation of blood leaving a region of the lung decreases any time there is too little ventilation per minute for the amount of blood perfusing that region per minute. A more extensive evaluation of changes in the $(\dot{V}_A/\dot{Q})$ ratio is provided in Chapter 20. Approximately half of the normal A–aO_2 gradient is caused by the bronchial circulation and half is caused by regional variations of the $(\dot{V}_A/\dot{Q})$ ratio. In some pathophysiologic disorders, the A–aO_2 gradient can be greatly increased. A value of >15 mm Hg is considered abnormal and leads to low oxygen in the blood or **hypoxemia**. The normal ranges of blood gases are shown in Table 19.1. Values for PaO_2 below 85 mm Hg indicate hypoxemia. A $PaCO_2$ < 35 mm Hg is called **hypocapnia**, and a $PaCO_2$ > 48 mm Hg is called **hypercapnia**. A pH value for arterial blood of <7.35 or >7.45 is called **acidemia** or **alkalemia**, respectively.

TABLE 19.1 Arterial Blood Gases

Parameter	Normal Range*
Pao_2	85–95 mm Hg
$Paco_2$	35–48 mm Hg
Sao_2	94%–98%
pH	7.35–7.45
HCO_3^-	23–28 mEq/L

*Normal range at sea level.
Pao_2, partial pressure of arterial oxygen; $Paco_2$, partial pressure of carbon dioxide; Sao_2, saturation of arterial oxygen.

*Normal range at sea level.
PaO_2, partial pressure of arterial oxygen; $PaCO_2$, partial pressure of carbon dioxide; SaO_2, saturation of arterial oxygen.

CLINICAL FOCUS 19.1

Free Radical–Induced Lung Injury

An "oxygen paradox" has long been recognized in biology, but only recently has it been well understood: Oxygen is essential for life, but too much oxygen can be harmful to both cells and the organism. The synthesis of **adenosine triphosphate** (**ATP**) involves reactions in which molecular oxygen is reduced to form water. This reduction is accomplished by the addition of four electrons by the mitochondrial electron transport system. About 98% of the oxygen consumed is reduced to water in the mitochondria. "Leaks" in the mitochondrial electron transport system, however, allow oxygen to accept fewer than four electrons, forming a **free radical**.

A free radical is any atom, molecule, or group of molecules with an unpaired electron in its outermost orbit. Free radicals include the **superoxide ion** (**$O_2\bullet^-$**) and the **hydroxyl radical** (**•OH**). The single unpaired electron in the free radical is denoted by a dot. The •OH radical is the most reactive and most damaging to cells. **Hydrogen peroxide** (**H_2O_2**), although not a free radical, is also reactive to tissues and has the potential to generate the hydroxyl radical (•OH). These three substances are collectively called **reactive oxygen species** (**ROS**). In addition to free radicals produced by leaks in

the mitochondrial transport system, ROS can also be formed by cytochrome P450, in the production of nicotinamide adenine dinucleotide phosphate and in arachidonic acid metabolism. A superoxide ion in the presence of nitric oxide will form peroxynitrite, another free radical that is also extremely toxic to cells. Under normal conditions, ROS are neutralized by the protective enzymes superoxide dismutase, catalase, and peroxidases, and no damage occurs. However, when ROS are greatly increased, they overwhelm the protective enzyme systems and damage cells by oxidizing membrane lipids, cellular proteins, and DNA.

The lungs are a major target organ for free radical injury, and the pulmonary vessels are most susceptible as the primary site of injury. Damage to the pulmonary capillaries by free radicals causes the capillaries to become leaky, leading to pulmonary edema. In addition to intracellular production, ROS are produced during inflammation and episodes of oxidant exposure (i.e., oxygen therapy or breathing ozone and nitrogen dioxide from polluted air). During the inflammatory response, neutrophils become sequestered and activated; they undergo a respiratory burst (which produces free radicals) and release catalytic enzymes. This release of free radicals and catalytic enzymes functions to kill bacteria, but endothelial cells can become damaged in the process.

Paraquat, an agricultural herbicide, is another source of free radical–induced injury to the lungs. Crop dusters and migrant workers are particularly at risk because of exposure to paraquat through the lungs and skin. Tobacco or marijuana that has been sprayed with paraquat and subsequently smoked can also produce lung injury from ROS.

Ischemia reperfusion is another cause of free radical–induced injury in organs. In the lungs, ischemia–reperfusion injury results from a blood clot that gets lodged in the pulmonary circulation. Tissues beyond the clot (or embolus) become ischemic, cellular ATP decreases, and hypoxanthine accumulates. When the clot dissolves, blood flow is reestablished. During the reperfusion phase, hypoxanthine, in the presence of oxygen, is converted to xanthine and then to urate. These reactions are catalyzed by the enzyme xanthine oxidase on the pulmonary endothelium, resulting in the production of superoxide ions. Neutrophils also become sequestered and activated in these vessels during the reperfusion phase. Therefore, the pulmonary vasculature and surrounding lung parenchyma become damaged from a double hit of free radicals—those produced from the oxidation of hypoxanthine and those from activated neutrophils. ■

Regional hypoventilation is the major cause of hypoxemia.

The causes of hypoxemia are classified as respiratory or nonrespiratory (Table 19.2). The respiratory causes of hypoxemia are by far the most common, and they are listed in order of frequency in Table 19.2. As seen from Table **19.2**, **regional hypoventilation** is the major cause of hypoxemia (about 90% of cases) and reflects a local $(\dot{V}_A/\dot{Q})$ ratio imbalance. The matching of airflow and blood flow is best examined by considering the **ventilation/perfusion ratio**, which compares alveolar ventilation with blood flow in lung regions. Because resting healthy people have an alveolar ventilation $(\dot{V}_A)$ of 4 L/min and a cardiac output $(\dot{Q})$ of 5 L/min, the ideal alveolar ventilation/perfusion ratio $(\dot{V}_A/\dot{Q})$ should be 0.8 (there are no units; this is a ratio). When a partially obstructed airway occurs, a fraction of the blood that passes through the capillary bed of the obstructed airway does not get fully oxygenated, resulting in an increase in venous admixture. Only a small amount of venous admixture is required to lower systemic arterial PO_2 as a result of the nature of the oxyhemoglobin–equilibrium curve. This can be seen from Figure 19.12, which depicts oxygen content from three groups of alveoli with low, normal, and high $(\dot{V}_A/\dot{Q})$ ratios. The oxygen content of the blood leaving these alveoli is 16.0, 19.5, and 20.0 mL/dL of blood, respectively. As Figure 19.12 shows, a low $(\dot{V}_A/\dot{Q})$ ratio is far more serious because it has the greatest effect on lowering both the Po_2 and the O_2 content because of the nonlinear shape of the oxyhemoglobin equilibrium curve. Patients who have an abnormally low $(\dot{V}_A/\dot{Q})$ ratio have a high A–aO_2 gradient, low PO_2, and low O_2 content, but usually a normal or slightly elevated $PaCO_2$. $PaCO_2$ does

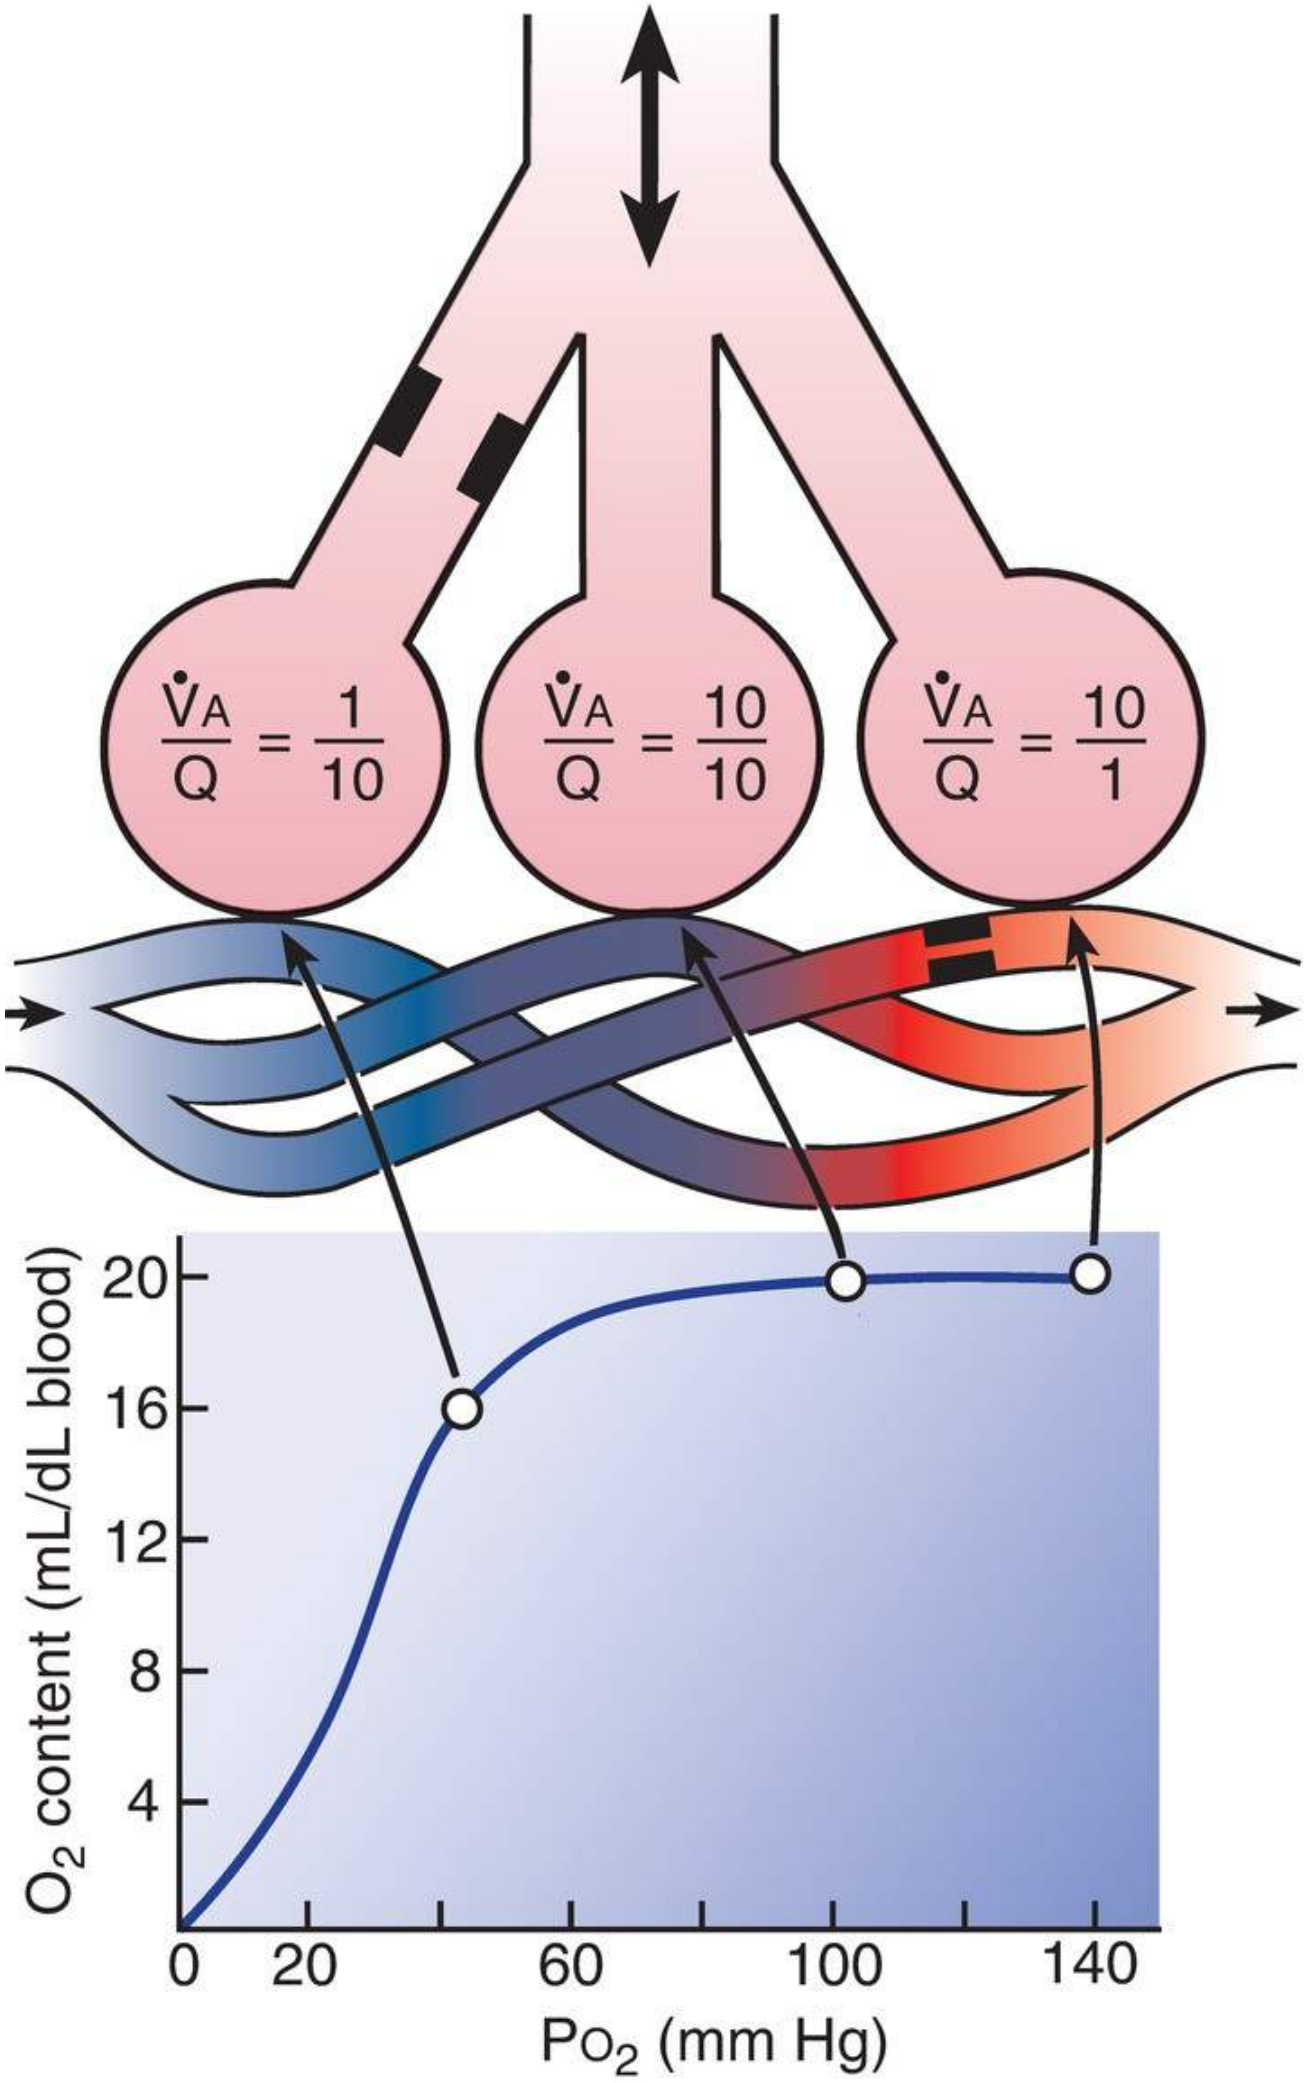
not change much because the CO_2 equilibrium curve is nearly linear, which allows excess CO_2 to be removed from the blood by the lungs.

TABLE 19.2 Pathophysiologic Causes of Hypoxemia

Causes	Effect on $A–aO_2$ Gradient
Respiratory	
Regional low $(\dot{V}_A/\dot{Q})$ ratio	Increased
Anatomic shunt	Increased
Generalized hypoventilation	Normal
Diffusion block	Increased
Nonrespiratory	
Intracardiac right-to-left shunt	Increased
Decreased P_{IO_2}, low P_B, low F_{IO_2}	Normal
Reduced oxygen content (anemia and CO poisoning)	Normal

$A–aO_2$, alveolar–arterial oxygen gradient; F_{IO_2}, fractional concentration of inspired oxygen; P_B, barometric pressure; P_{IO_2}, partial pressure of inspired oxygen; $(\dot{V}_A/\dot{Q})$ ratio, ventilation/perfusion ratio.

$A–aO_2$, alveolar–arterial oxygen gradient; FIO_2, fractional concentration of inspired oxygen; PB, barometric pressure; PIO_2, partial pressure of inspired oxygen; $(\dot{V}_A/\dot{Q})$ ratio, ventilation/perfusion ratio.



$\frac{\dot{V}_A}{Q} = \frac{1}{10}$
$\frac{\dot{V}_A}{Q} = \frac{10}{10}$
$\frac{\dot{V}_A}{Q} = \frac{10}{1}$

Figure 19.12 Venous admixture lowers arterial O_2 content. Because of the S-shaped oxyhemoglobin equilibrium curve, a high ventilation/perfusion ratio (ratio) has little effect on arterial O_2 content. However, mixing with blood from a region with a low $(\dot{V}_A/\dot{Q})$ ratio can dramatically lower PO_2 in blood leaving the lungs.

Another cause for a regionally low $(\dot{V}_A/\dot{Q})$ ratio is a large blood clot that occludes a major artery in the lungs. When a major pulmonary artery becomes occluded, a greater portion of the cardiac output is redirected to another part of the lungs, resulting in overperfusion with respect to alveolar ventilation. This causes a regionally low $(\dot{V}_A/\dot{Q})$ and leads to an increase in venous admixture.

The next most common cause of hypoxemia is a **shunt**, either an intracardiac right-to-left anatomic shunt or an intrapulmonary shunt. The latter occurs when an airway is totally obstructed by a foreign object (such as a peanut) or by a lung tumor. Patients with hypoxemia stemming from a shunt also have a high A–aO_2 gradient, low PO_2, low O_2 content, and a normal or slightly elevated $PaCO_2$. A test that is often used to distinguish between an abnormally low $(\dot{V}_A/\dot{Q})$ ratio and a shunt is to have the patient breathe 100% O_2 for 15 minutes. If the PaO_2 is >150 mm Hg, the cause is a low $(\dot{V}_A/\dot{Q})$ ratio. If the patient's PaO_2 is <150 mm Hg, the cause of hypoxemia is a shunt. The principle for using 100% O_2 is illustrated in Figure 19.13. The patient with regional hypoventilation who breathes 100% O_2 compensates for the low $(\dot{V}_A/\dot{Q})$ ratio, and because all of the blood leaving the pulmonary

capillaries is now fully saturated, the venous admixture is eliminated. However, the low arterial PO_2 does not get corrected by breathing 100% O_2 in a patient with a shunt because the enriched oxygen mixture never comes into contact with the shunted blood.

Figure 19.13 Breathing 100% oxygen can be used to diagnose a shunt. A shunt can be diagnosed by having the subject breathe 100% O_2 for 15 minutes. PO_2 in systemic arterial blood in a patient with a shunt does not increase above 150 mm Hg during the 15-minute period. The shunted blood is not exposed to 100% O_2, and the venous admixture reduces arterial PO_2.

CLINICAL FOCUS 19.2

Anemia

Anemia, an abnormally low hematocrit or hemoglobin concentration, is by far the most common disorder affecting erythrocytes. The different causes of anemia can be grouped into three categories: decreased erythropoiesis by bone marrow, blood loss, and increased rate of red cell destruction (hemolytic anemia).

Several mechanisms lead to decreased production of red cells by the bone marrow, including aplastic anemia, malignant neoplasms, chronic renal disease, defective DNA synthesis, defective hemoglobin synthesis, and chronic liver disease. **Aplastic anemia** is the result of stem cell destruction in the bone marrow, which leads to decreased production of white cells, platelets, and erythrocytes. Malignant neoplasms (e.g., leukemia) cause an overproduction of immature red cells. Patients with chronic renal disease have a decreased production of erythropoietin, with a concomitant decrease in red cell production.

Patients with defective DNA synthesis have **megaloblastic anemia**, a condition in which red cell maturation in the bone marrow is abnormal; this may result from vitamin B12 or folic acid deficiency. These cofactors are essential for DNA synthesis. Vitamin B12 is present in high concentration in liver and, to some degree, in most meat, but it is absent in plants. Vitamin B12 deficiency is rare except in strict vegetarians. Folic acid is widely distributed in leafy vegetables; folic acid deficiency commonly occurs when malnutrition is prevalent. **Pernicious anemia** is a form of megaloblastic anemia resulting from vitamin B12 deficiency. Most common in adults over 60, it results not from deficient dietary intake but from a decreased vitamin B12 absorption by the small intestine. Pernicious anemia is linked to an autoimmune disease in which there is immunologic destruction of the intestinal mucosa, particularly the gastric mucosa.

Iron deficiency anemia is the most common cause of anemia worldwide. Although it occurs in both developed and undeveloped countries, the causes are different. In developed countries, the cause is usually a result of pregnancy or chronic blood loss resulting from gastrointestinal ulcers or neoplasms. In undeveloped countries, hookworm infections account for most cases of iron deficiency anemia.

Acute or chronic blood loss is another cause of anemia. With hemorrhage, red cells are lost and the hypovolemia causes the kidneys to retain water and electrolytes as compensation. Retention of water and electrolytes restores the blood volume, but the concomitant dilution of the blood causes a further decrease in the red cell count, hemoglobin concentration, and hematocrit. Chronic bleeding is compensated by erythroid hyperplasia, which eventually depletes iron stores. Therefore, chronic blood

loss results in iron deficiency anemia.

The last category, increased rate of red cell destruction, includes the Rh factor and sickle cell anemia. The Rhesus (Rh) blood group antigens are involved in maintaining erythrocyte structure. Patients who lack Rh antigens (Rh null) have severe deformation of the red cells.

Sickle cell anemia, associated with the abnormal hemoglobin HbS gene, is common in Africa, India, and among African Americans but is rare in the Caucasian and Asian populations. In the sickle cell trait, which occurs in about 9% of African Americans, one abnormal gene is present. A single point mutation occurs in the hemoglobin molecule, causing the normal glutamic acid at position 6 of the beta chain to be replaced with valine, resulting in HbS. The amino acid substitution is on the surface, resulting in a tendency for the hemoglobin molecule to crystallize with anoxia. However, heterozygous people have no symptoms, and oxygen transport by fetal (HbF) and adult hemoglobin (HbA) is normal. The sickle cell trait (i.e., heterozygous people) offers protection against malaria, and this selective advantage is thought to have favored the persistence of the HbS gene, especially in regions in which malaria is common. Sickle cell disease represents the homozygous condition (S/S) and occurs in about 0.2% of African Americans. The onset of sickle cell anemia occurs in infancy as HbS replaces HbF; death often occurs early in adult life. Patients with sickle cell anemia have >80% HbS in their blood with a decrease or an absence of normal HbA.

Whatever the cause of anemia, the pathophysiologic effect is the same—hypoxemia. Symptoms include pallor of the lips and skin, weakness, fatigue, lethargy, dizziness, and fainting. If the anemia is severe, myocardial hypoxia can lead to angina pain. ■

Generalized hypoventilation, the third most common cause of hypoxemia, occurs when alveolar ventilation is abnormally decreased. This situation can arise from a chronic obstructive pulmonary disorder (such as emphysema) or depressed respiration (as a result of a head injury or a drug overdose, for example). Because alveolar ventilation is depressed, there is also a significant increase in arterial PCO_2, with a concomitant decrease in arterial pH. In generalized hypoventilation, total ventilation is insufficient to maintain normal systemic arterial PO_2 and PCO_2. A feature that distinguishes generalized hypoventilation from the other causes of hypoxemia is a normal $A–aO_2$ gradient, as a result of the alveolar and arterial PO_2 being lowered equally. If a patient has a low PaO_2 and a normal $A–aO_2$ gradient, the cause of hypoxemia is entirely a result of generalized hypoventilation. The best corrective measure for generalized hypoventilation is to place the patient on a mechanical ventilator, breathing room air. This treatment will return both arterial PO_2 and PCO_2 to normal. Administering supplemental oxygen to a patient with generalized hypoventilation will correct hypoxemia but not hypercapnia because ventilation is still depressed.

The least common cause of hypoxemia is a **diffusion block**. This condition occurs when the diffusion distance across the alveolar–capillary membrane is increased or the permeability of the alveolar–capillary membrane is decreased. It is characterized by a low PaO_2, a high $A–aO_2$ gradient, and a high $PaCO_2$. Pulmonary edema is one of the major causes of diffusion block.

In summary, there are four basic respiratory disturbances that cause hypoxemia. Examining the $A–aO_2$ gradient or $PaCO_2$ and/or breathing 100% oxygen distinguishes the four types. For example, if a patient has a low PaO_2, high $PaCO_2$, and normal $A–aO_2$ gradient, the cause of hypoxemia is generalized hypoventilation. If the PaO_2 is low and the $A–aO_2$ gradient is high, then the cause can be a shunt, a

regional low $\left(\dot{V}_A/\dot{Q}\right)$ ratio, or a diffusion block. Breathing 100% O_2 will distinguish between a low $\left(\dot{V}_A/\dot{Q}\right)$ ratio and a shunt. Diffusion impairment is the least likely cause and can be deduced if the other three causes have been eliminated.

INTEGRATED MEDICAL SCIENCES

Lethargy and Shortness of Breath

A 28-year-old Hispanic American woman had felt well and worked full time with a landscaping company until she became short of breath whenever she exerted herself. She went to the university hospital with progressive shortness of breath and generalized lethargy. She had a dry cough and some leg swelling. She had no reported fever or chest discomfort. She stated that she lost 15 lb over the last 3 months and had a total loss of energy, which was devastating because she was so active. Following her admission, hypoxia persisted despite the administration of oxygen. She was transferred to the intensive care unit for further observation and monitoring.

The patient was married, was a nonsmoker, and had no history of intravenous drug use. She had no prior history of pulmonary or cardiac conditions and was not taking any prescription or herbal medications. Her older sibling had no significant medical or surgical history. The clinical examination revealed oxygen saturation of 87% breathing ambient air, tachypnea, tachycardia, bilateral pulmonary rales in basal fields, and a low-intensity systolic murmur. The remainder of the examination was normal. The patient received packed red blood cell transfusions to correct for her low O_2 saturation and her low red cell count.

However, her symptoms did not improve and was readmitted to the university hospital. Further blood tests and a transthoracic echocardiogram were performed. The echocardiogram revealed an enlarged heart, tricuspid regurgitation, and moderate-to-severe pulmonary hypertension. A noncontrast computerized tomography (CT) of her thorax was performed and revealed no pulmonary emboli. Her O_2–Hb saturation showed a persistent low 85% breathing room air. Due to multisystem manifestations including moderately severe pulmonary hypertension and profound anemia, human immunodeficiency virus (HIV) testing was performed. She had generalized elevated white cell count and tested positive for HIV. Antiviral therapy was initiated in addition to presumptive antibiotics for possible *Pneumocystis* (*carinii*) *jiroveci* infection. *Pneumocystis jiroveci* is a fungal infection of the lungs. The disease used to be called *Pneumocystis carinii* and is often present in HIV patients. The HIV was traced back to the time patient had a blood transfusion 3 years ago following a work-related accident in which she received a serve cut on the leg with a significant loss of blood.

She did not demonstrate clinical improvement, however, and her cardiopulmonary decline was attributed to HIV-associated pulmonary hypertension. She required transfer to a specialized center for further management.

This case is a common presentation of pulmonary hypertension: a previously health young woman develops a life-threatening disease with no outward manifestation. Because these individuals look normal at rest, family, friends, and coworkers have a difficult time accepting they are sick or have a serious disease. Often, they are initially misdiagnosed when seen by a physician.

Pulmonary arterial hypertension (PAH) is defined as an increased mean pulmonary artery pressure > 25 mm Hg at rest or >30 mm Hg during exercise and a pulmonary capillary wedge pressure of <15 mm Hg. Whatever the initial cause, this devastating disease involves the narrowing of pulmonary blood vessels that increase pulmonary vascular resistance, which makes it harder for the heart to pump blood through the lungs. Over time, the affected blood vessels become stiffer and thicker known as *fibrosis*. This further increases the blood pressure within the lungs and impairs blood flow. As a result, PAH increases the workload of the heart, causing hypertrophy of the right ventricle, ultimately causing right heart failure. Symptoms of PAH are usually nonspecific and include dyspnea (shortness of breath), dizziness, leg swelling, and fatigue.

The molecular mechanism of PAH is not fully known, but it is believed to be linked to endothelial dysfunction, which results in a decreased synthesis of endothelium-derived vasodilators such as nitric oxide and prostacyclin. Moreover, there is increased stimulation of vasoconstrictors such as thromboxane and vascular endothelial growth factor (VEGF). They cause severe vasoconstriction and smooth muscle hypertrophy. Under normal conditions, in the presence of oxygen, the nitric oxide synthase produces nitric oxide from L-arginine. Adenylate cyclase and guanylate cyclase are activated in the presence of nitric oxide, and these enzymes produce cAMP and cGMP, respectively.

In the vascular endothelium, cGMP activates cGMP kinase, which activates the potassium smooth muscle channels subsequently inhibiting the calcium channels. Thus, activation of cGMP leads to a reduction of intracellular calcium and vasodilation. Phosphodiesterase type V (PDE-5) is abundant in the pulmonary tissue. Activation of PDE-5 inhibits cGMP concentration and vasodilation is stopped. The molecular pathway in patients with PAH becomes dysfunctional. They produce less NO, and other vasodilators, and produce more vasoconstrictors.

The etiology of the development of PAH varies. Multiple causes include hypoxia associated with pulmonary and nonpulmonary conditions, thromboembolism, left ventricular muscle or valve diseases, connective tissue disorders, congenital heart diseases, and human immunodeficiency virus (HIV) infection and idiopathic PAH. PAH is a well-established complication of HIV infection and HIV-infected individuals are at higher risk for development of PAH compared to the general population. This suggests that either the virus itself or the consequences of infection may directly be linked with development of PAH. Despite the strong association of PAH with HIV, the underlying pathogenesis of this association remains unclear. A number of HIV viral proteins have been proposed to promote the development of PAH during the course of HIV infection, the most likely of which is the “Nef” protein (negative factor). The Nef protein is an N-myristoylated protein, originally identified as a negative regulatory factor for HIV replication and later recognized as an important protein for the maintenance of high viral loads during the course of HIV infection. The Nef protein is abundantly expressed during early viral infection and appears to promote the initiation and persistence of HIV infection and enhancement of HIV infectivity. The Nef protein also plays an important role in the alteration in pulmonary vascular cells by decreasing endothelin-dependent vasorelaxation as well as NOS (nitrous oxide systems) expression and induces oxidative stress in an experimental model in porcine

pulmonary arteries.

Various treatment options are available for PAH. These include phoshoidesterase-5 inhibitors, such as sildenafil; prostanoids, such as epoprostenol; endothelin receptor antagonists, such as bosentan; calcium channel blocker, such as diltiazem; diuretics to reduce swelling in ankles and feet (e.g., hydrochlorothiazide); blood thinner to prevent clots forming (e.g., Coumadin); and digoxin, which helps cardiac contraction.

In conclusion, the advent of newer drugs has doubled the survival of PAH, and many patients are now living well beyond a decade with reasonable function and satisfaction. ■

Chapter Summary

- Oxygen uptake across the alveolar–capillary membrane is determined by the O_2 diffusion gradient, pulmonary capillary blood flow, capillary blood volume, and blood hematocrit.
- Under normal conditions, oxygen uptake in the pulmonary capillaries is limited primarily by blood flow.
- Lung diffusion capacity is a measure of the total amount of oxygen transferred. Under resting conditions, ~250 mL of oxygen per minute is transferred to the pulmonary circulation. Total amount of oxygen uptake is measured by lung diffusion capacity.
- Oxygen is transported by the blood in two forms: oxyhemoglobin and dissolved O_2 in the plasma.
- P_{50} is a measure of the binding affinity of hemoglobin (Hb) to oxygen. When Hb-binding affinity to O_2 increases, the P_{50} changes in the opposite direction.
- Changes in blood pH, $PaCO_2$, and temperature alter the oxyhemoglobin–equilibrium curve.
- Oxygen content is a better determinant for adequate tissue oxygenation than arterial Po_2 or percentage O_2 saturation. Hematocrit, $PaCO_2$, and CO poisoning can affect oxygen content.
- Carbon dioxide is transported in three forms: dissolved, bicarbonate, and hemoglobin.
- An alveolar–arterial oxygen gradient is caused by venous admixture.
- A normal alveolar–arterial oxygen gradient is present because alveolar ventilation and capillary blood flow are not evenly matched in regions of the lung and because bronchial circulation mixes with oxygenated blood.
- Regional hypoventilation (low ventilation/perfusion ratio) is the major cause of hypoxemia.

Chapter Review Questions

1. One of the main causes of a normal A–aO_2 gradient in a healthy individual is:

A. low diffusing capacity for oxygen compared with that for carbon dioxide.

B. a high  ratio in the apex of the lungs.

C. overventilation in the base of the lung.

D. a small shunt from bronchial circulation.

E. a right-to-left shunt in the heart.

The correct answer is D. The A–aO_2 gradient in a healthy person is due to both a low ratio at the base of the lungs and a small shunt from the bronchial circulation.

2. Which of the following will *not* cause a low lung diffusing capacity (DL)?

A. Decreased diffusion distance

B. Decreased capillary blood volume

C. Decreased surface area

D. Decreased cardiac output

E. Decreased hemoglobin concentration in the blood

The correct answer is A. A decrease in the diffusion distance will lead to an increase in DL. A decrease in capillary blood volume, surface area, cardiac output, and blood hemoglobin concentration will decrease DL.

3. Which of the following parameters would best reflect adequate oxygenation to the tissues?

A. Arterial oxygen tension

B. Arterial oxygen saturation

C. Arterial oxygen tension required to make the blood 50% saturated (P50)

D. Arterial–venous O_2 tension difference

E. Arterial O_2 content

The correct answer is E. Arterial oxygen content provides the best index to tissue oxygenation. Arterial oxygen tension and arterial oxygen saturation can be normal in situations like anemia. Arterial–venous oxygen tension difference can also be unchanged in anemic patients. The P50 reflects the ability of the hemoglobin-binding affinity for oxygen and provides little information about tissue oxygenation.

4. A 40-year-old patient had normal blood gas values with an arterial oxygen tension (PaO_2) = 95 mm Hg, O_2 content = 19 mL/dL, O_2 capacity = 20 mL/dL, and arterial oxygen saturation (SaO_2) = 95%. Three weeks later, she developed a severe case of anemia. Which of the following would best describe her blood gases following anemia compared to her normal values?

	Pao_2	O_2 Content	O_2 Capacity	Sao_2
A.	No change	Decreases	No change	Decreases
B.	Decreases	Decreases	Decreases	No change
C.	Decreases	No change	No change	No change
D.	No change	Decreases	Decreases	No change
E.	Decreases	No change	Decreases	Increases

The correct answer is D. Anemia lowers the hemoglobin concentration in the blood. Consequently, oxygen content and capacity are both decreased. However, the percent oxygen saturation is unchanged. Arterial oxygen tension is unchanged with anemia.

5. An ideal lung unit has a ventilation/perfusion ratio $(\dot{V}_A/\dot{Q})$ of 0.8, with an alveolar oxygen tension (PAO_2) = 100 mm Hg and an alveolar carbon dioxide tension ($PACO_2$) = 40 mm Hg. Which of the following gas tensions would most likely be predicted in a lung unit with a $(\dot{V}_A/\dot{Q})$ ratio of 2?

	P_{AO_2}, mm Hg	P_{ACO_2}, mm Hg
A.	130	30
B.	104	40
C.	95	40
D.	86	46
E.	112	46

The correct answer is A. A lung unit with a high results in that region being overventilated with respect to blood flow. This is essentially equivalent to more fresh air reaching these alveoli, which results in a higher oxygen tension and a lower carbon dioxide tension.

Clinical Application Exercises 19.1

CHEST PAIN

A 27-year-old accountant recently drove cross-country to start a new job in Denver, Colorado. A week after her move, she started to experience chest pains. She drove to the emergency department after experiencing 24 hours of right-sided chest pain, which was worse with inspiration. She also experienced shortness of breath and stated that she felt warm. She denied any sputum production, hemoptysis, coughing, or wheezing. She is active and walks daily and never has experienced any swelling in her legs. She has never been treated for any respiratory problems and has never undergone any surgical procedures. Her medical history is negative, and she has no known drug allergies. Oral contraceptives are her only medication. She smokes a pack of cigarettes a day and consumes wine occasionally. She does not use intravenous drugs and has no other risk factors for HIV disease. Her family history is negative for asthma and any cardiovascular diseases.

Physical examination reveals a mildly obese woman in moderate respiratory distress. Her respiratory rate is 24 breaths/min and her pulse is 115 beats/min. Her blood pressure is 140/80 mm Hg, and no jugular vein distention is observed. Heart rate and rhythm are regular, with normal heart sounds and no murmurs. Her chest is clear, and her temperature is 38°C. Her extremities show signs of cyanosis, but no clubbing or edema is detected. Blood gases, obtained while she was breathing room air, reveal a PO_2 of 60 mm Hg and a PCO_2 of 32 mm Hg; her arterial blood pH is 7.49. Her $A–aO_2$ gradient is 40 mm Hg. A Gram-stain sputum specimen exhibited a normal flora. A chest x-ray

study reveals a normal heart shadow and clear lung fields, except for a small peripheral infiltrate in the left lower lobe. A lung scan reveals an embolus in the left lower lobe.

QUESTIONS

1. What is the cause of a widened alveolar–arterial gradient in patients with pulmonary embolism?
2. What causes the decreased arterial PCO_2 and elevated arterial pH?
3. Why do oral contraceptives induce hypercoagulability?

ANSWERS

1. A normal $A–aO_2$ gradient is 5 to 15 mm Hg. A pulmonary embolus will cause blood flow to be shunted to another region of the lung. Because cardiac output is unchanged, the shunting of blood causes overperfusion, which causes an abnormally low ratio in another region of the lungs. Thus, blood leaving the lungs has a low PO_2, resulting in hypoxemia (a low arterial PO_2). The decrease in arterial PO_2 accounts in part for the increase in the $A–aO_2$ gradient. However, ventilation is also stimulated as a compensatory mechanism to hypoxemia, which leads to hyperventilation with a concomitant increase in alveolar PO_2. The $A–aO_2$ gradient is, therefore, further increased because of the increased alveolar PO_2 caused by hyperventilation.
2. The decreased PCO_2 and increased pH are the result of hyperventilation as a result of the hypoxic drive (low PO_2) that stimulates ventilation.
3. The mechanisms by which oral contraceptives increase the risk of thrombus formation are not completely understood. The risk appears to be correlated best with the estrogen content of the pills. Hypotheses include increased endothelial cell proliferation, decreased rates of venous blood flow, and increased coagulability secondary to changes in platelets, coagulation factors, and the fibrinolytic system. Furthermore, there are changes in serum lipoprotein levels with an increase in LDL and VLDL and a variable effect on HDL. Driving cross-country, with long sedentary periods, may have exacerbated the patient's condition.

20 Pulmonary Circulation and Ventilation/Perfusion

Active Learning Objectives

Upon mastering the material in this chapter, you should be able to:

- Predict how changes in cardiac output will affect pulmonary vascular resistance.
- Describe the relationship between capillary recruitment and vascular resistance.
- Describe how low oxygen affects pulmonary vascular resistance.
- Explain the difference between regional and generalized hypoxia and their effect on pulmonary arterial pressure.
- Explain how changes in surface tension will affect interstitial fluid pressure in the lungs.
- Describe how gravity alters blood flow in the base and apex of the lungs.
- Describe how regional ventilation and regional blood flow are matched in the lungs.
- Describe how an anatomic shunt affects the regional ventilation/perfusion ratio.

FUNCTIONAL ORGANIZATION

In the previous chapter, you learned that gas exchange was determined by the partial pressure gradient across the alveolar–capillary membrane. You also learned that uptake of O_2 and the unloading of CO_2 were affected primarily by blood flow. Also, the previous chapter showed that most of the oxygen transported in the systemic circulation was carried in the form of oxyhemoglobin (Hb-O_2), and the amount carried was influenced by changes in blood chemistry (pH, $PaCO_2$, and temperature). You also learned that blood flow in the lung was not ideal and some venous admixture occurred that resulted in alveolar–arterial gradient, causing blood leaving the lung to have a lower PO_2 and O_2 content.

In this chapter, you will learn that the pulmonary circulation is a high-flow, low-flow, low-resistance, and a low-pressure system. You also will learn that air flow and blood flow in the lungs are not matched and is the major cause of hypoxemia.

The heart drives two separate and distinct circulatory systems in the body: the pulmonary circulation and the systemic circulation. The pulmonary circulation carries venous blood from the heart to the lungs and arterialized blood in pulmonary veins from the lungs back to the heart. Pulmonary circulation is analogous to the entire systemic circulation because the pulmonary circulation receives all of the cardiac output. Therefore, the pulmonary circulation is not like regional circulation such as the renal, hepatic, or coronary circulations. A change in pulmonary vascular resistance has the same implications for the right ventricle as a change in systemic vascular resistance has for the left ventricle.

The pulmonary arteries branch in the same treelike manner as the airways. Each time an airway branches, the arterial tree branches so that the two parallel each other (Fig. 20.1). Blood in the pulmonary blood vessels comprises >40% of lung weight. The total blood volume of the pulmonary circulation (main pulmonary artery to left atrium) is ~500 mL or 10% of the total circulating blood volume (5,000 mL). The pulmonary veins contain more blood (~270 mL) than do the arteries (~150 mL). The blood volume in the pulmonary capillaries is approximately equal to the stroke volume of the right ventricle (~80 mL), under most physiologic conditions.

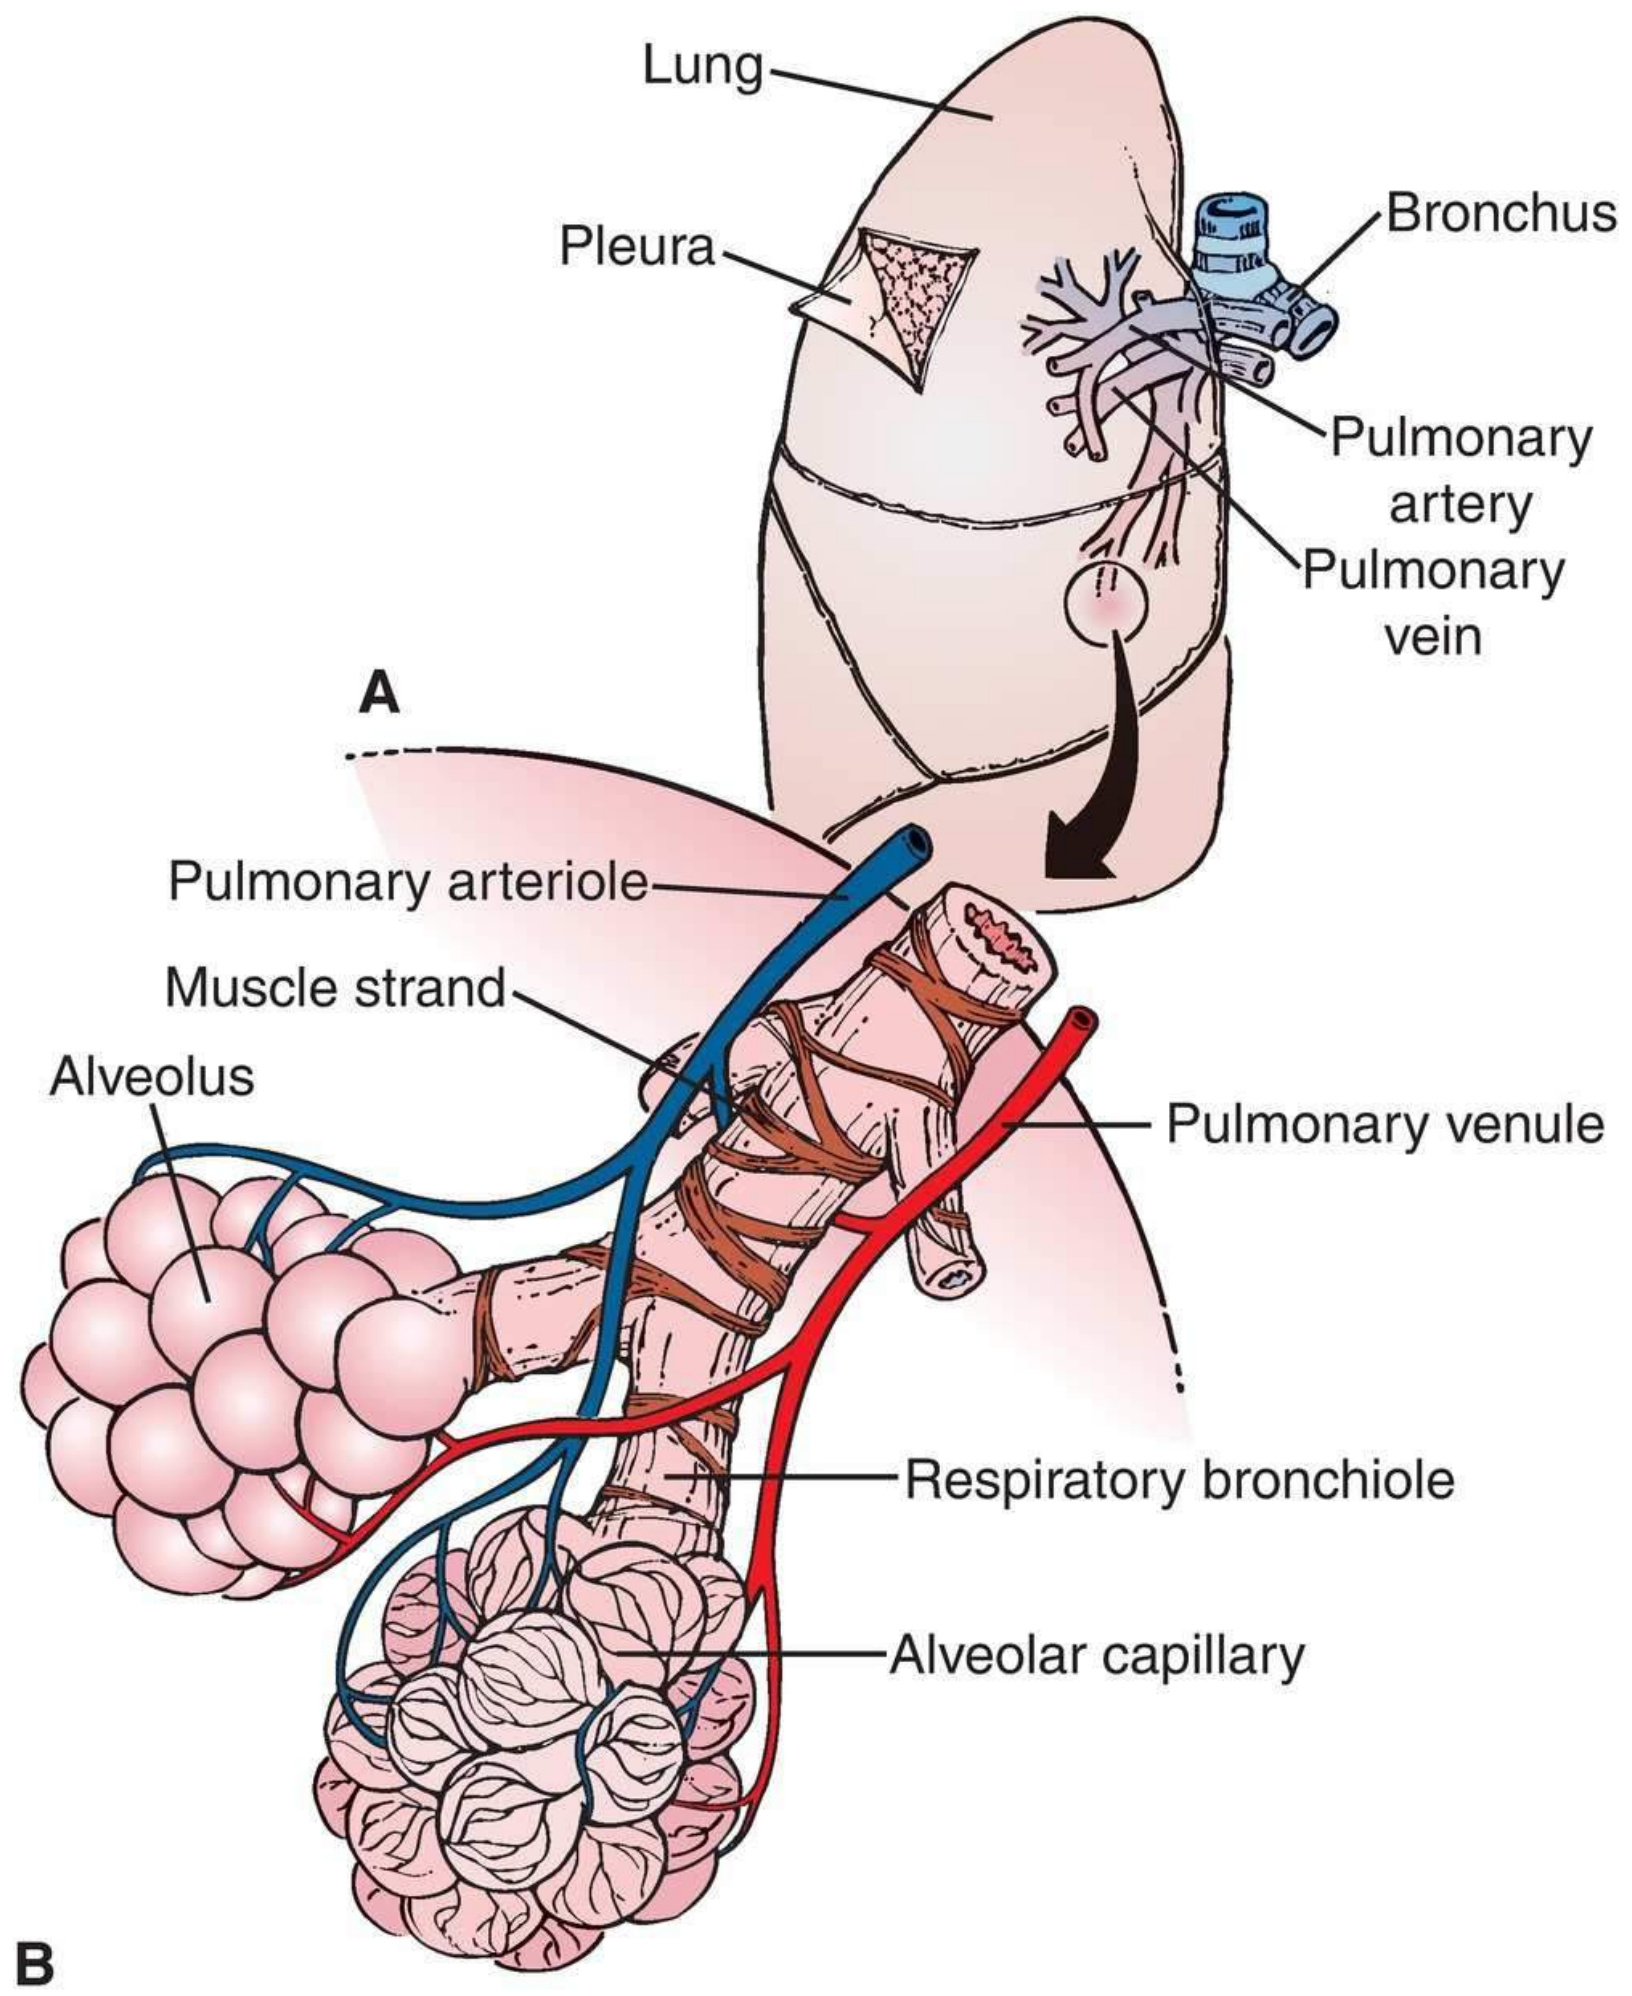

Figure 20.1 Pulmonary vessels branch in a treelike fashion similar to the airways. (A) Systemic

venous blood flows through the pulmonary arteries into the alveolar capillaries and back to the heart via the pulmonary veins, to be pumped into the systemic circulation. **(B)** A mesh of capillaries surrounds each alveolus. As the blood passes through the capillaries, it gives up carbon dioxide and takes up oxygen.

Pulmonary circulation has many secondary functions.

The primary function of the pulmonary circulation is to bring venous blood from the superior and inferior vena cava into contact with alveoli for gas exchange. In addition to gas exchange, the pulmonary circulation has three secondary functions: it serves as a filter, a metabolic organ, and a blood reservoir.

Pulmonary vessels protect the body against **thrombi** (blood clots) and **emboli** (fat globules or air bubbles), preventing them from entering important vessels in other organs. Thrombi and emboli often occur with a sedentary lifestyle, after surgery or injury, and enter the systemic venous blood. Small pulmonary arterial vessels and capillaries trap the thrombi and emboli and prevent them from obstructing the vital coronary, cerebral, and renal vessels. Endothelial cells lining the pulmonary vessels release fibrinolytic substances that help dissolve thrombi. Emboli, especially air emboli, are absorbed through the pulmonary capillary walls. If a large thrombus occludes a large pulmonary vessel, gas exchange can be severely impaired and can cause death. A similar situation occurs if emboli are extremely numerous and lodge all over the pulmonary arterial tree.

Vasoactive hormones are metabolized in the pulmonary circulation. One such hormone is angiotensin I (AI), which is activated and converted to angiotensin II (AII) in the lungs by **angiotensin-converting enzyme** (**ACE**) located on the surface of the pulmonary capillary endothelial cells. Activation is rapid; 80% of AI can be converted to AII during a single passage through the pulmonary circulation. In addition to being a potent vasoconstrictor, AII has other important actions in the body (see Chapter 23). Metabolism of vasoactive hormones by the pulmonary circulation appears to be selective. Pulmonary endothelial cells inactivate bradykinin, serotonin, and the prostaglandins E_1, E_2, and $F_{2\alpha}$. Other prostaglandins, such as PGA_1 and PGA_2, pass through the lungs unaltered. Norepinephrine is inactivated, but epinephrine, histamine, and arginine vasopressin pass through the pulmonary circulation unchanged. With acute lung injury (e.g., oxygen toxicity, fat emboli), the lungs can release histamine, prostaglandins, and leukotrienes, which can cause vasoconstriction of pulmonary arteries and pulmonary endothelial damage.

The lungs serve as a blood reservoir. Approximately 500 mL or 10% of the total circulating blood volume is in the pulmonary circulation. During hemorrhagic shock, some of this blood can be mobilized to improve the cardiac output.

The conducting airways have their own separate circulation.

The **bronchial circulation** is distinct and separate from the pulmonary circulation. The primary function of the bronchial circulation is to nourish the walls of the conducting airways and surrounding tissues by distributing blood to the supporting structures of the lungs. Under normal conditions, the bronchial circulation does not supply blood to the terminal respiratory units (respiratory bronchioles, alveolar ducts, and alveoli); they receive their blood from the pulmonary circulation. Venous return from the bronchial circulation is by two routes: bronchial veins and pulmonary veins. About half of the bronchial blood flow returns to the right atrium by way of the bronchial veins, which empty into the azygos vein. The remainder returns through small bronchopulmonary anastomoses into the pulmonary veins.

Bronchial arterial pressure is approximately the same as aortic pressure, and bronchial vascular resistance is much higher than resistance in the pulmonary circulation. Bronchial blood flow is ~1% to 2% of cardiac output, but in certain inflammatory disorders of the airways (e.g., chronic bronchitis), it can be as high as 10% of cardiac output.

The bronchial circulation is the only portion of the circulation in the adult lung that is capable of undergoing angiogenesis, the formation of new vessels. This is extremely important in providing collateral circulation to the lung parenchyma, especially when the pulmonary circulation is compromised. When a clot or embolus obstructs pulmonary blood flow, the adjacent parenchyma is kept alive by the development of new blood vessels.

HEMODYNAMIC FEATURES

In contrast to the systemic circulation, the pulmonary circulation is a high-flow, low-pressure, low-resistance system. The pulmonary artery and its branches have much thinner walls than the aorta and are more compliant. The pulmonary artery also contains less elastin and smooth muscle in its walls. The pulmonary arterioles are thin walled and contain little smooth muscle and, consequently, have less ability to constrict than the thick-walled, highly muscular systemic arterioles. The pulmonary veins are also highly compliant and contain little smooth muscle compared with their counterparts in the systemic circulation.

The pulmonary capillary bed is also different. Unlike the systemic capillaries, which are often arranged as a network of tubular vessels with some interconnections, the pulmonary capillaries mesh together in the alveolar wall so that blood flows as a thin sheet. It is, therefore, misleading to refer to pulmonary capillaries as a capillary network; they comprise a dense capillary bed. The walls of the capillary bed are exceedingly thin, and a whole capillary bed can collapse if local alveolar pressure exceeds capillary pressure.

The systemic and pulmonary circulations differ strikingly in their pressure profiles (Fig. 20.2). Mean pulmonary arterial pressure is 15 mm Hg, compared with 93 mm Hg in the aorta. The driving pressure (10 mm Hg) for pulmonary flow is the difference between the mean pressure in the pulmonary artery (15 mm Hg) and the pressure in the left atrium (5 mm Hg). Changes in pulmonary venous and left atrial pressures have a profound effect on gas exchange, and pulmonary wedge pressure provides an indirect measure of these important pressures.

Figure 20.2 Pulmonary circulation has unique hemodynamic features. Unlike the systemic circulation, the pulmonary circulation is a low-pressure and low-resistance system. Pulmonary circulation is characterized as normally dilated, whereas the systemic circulation is characterized as normally constricted. Pressures are given in mm Hg; a bar over the number indicates mean pressure. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

The right ventricle pumps mixed venous blood through the pulmonary arterial tree, the alveolar capillaries (where oxygen is taken up and carbon dioxide is removed), the pulmonary veins, and then onto the left atrium. All of the cardiac output is pumped through the pulmonary circulation at a much lower pressure than through the systemic circulation. As shown in Figure 20.2, the 10 mm Hg pressure gradient across the pulmonary circulation drives the same blood flow (5 L/min) as in the systemic circulation, where the pressure gradient is almost 100 mm Hg. Remember that vascular resistance (R) is equal to the pressure gradient (ΔP) divided by blood flow (see Chapter 12):

$$R = \Delta P / \dot{Q} \quad (1)$$

Pulmonary vascular resistance is extremely low, about 1/10 that of systemic vascular resistance. The difference in resistances is a result, in part, of the enormous number of small pulmonary resistance vessels that are dilated. By contrast, systemic arterioles and precapillary sphincters are partially constricted.

Pulmonary vascular resistance falls with increased cardiac output.

Another unique feature of the pulmonary circulation is its ability to decrease resistance when pulmonary arterial pressure rises. When cardiac output increases, pulmonary pressure rises, resulting in a marked decrease in pulmonary vascular resistance (Fig. 20.3). Similarly, increasing pulmonary venous pressure causes pulmonary vascular resistance to fall. These responses are different from those of the systemic circulation, where an increase in perfusion pressure increases vascular resistance. Two local mechanisms in the pulmonary circulation are responsible (Fig. 20.4). The first mechanism is known as **capillary recruitment**. Under normal conditions, some capillaries are partially or completely closed, particularly in the top part of the lungs, because of the low perfusion pressure. As blood flow increases, the pressure rises, and the closed vessels are opened, lowering the overall resistance. Capillary recruitment is the primary mechanism for the fall in pulmonary vascular resistance when cardiac output increases. The second mechanism is **capillary distention** or widening of capillary segments. This occurs because the pulmonary arterioles and capillaries are exceedingly thin and highly compliant.

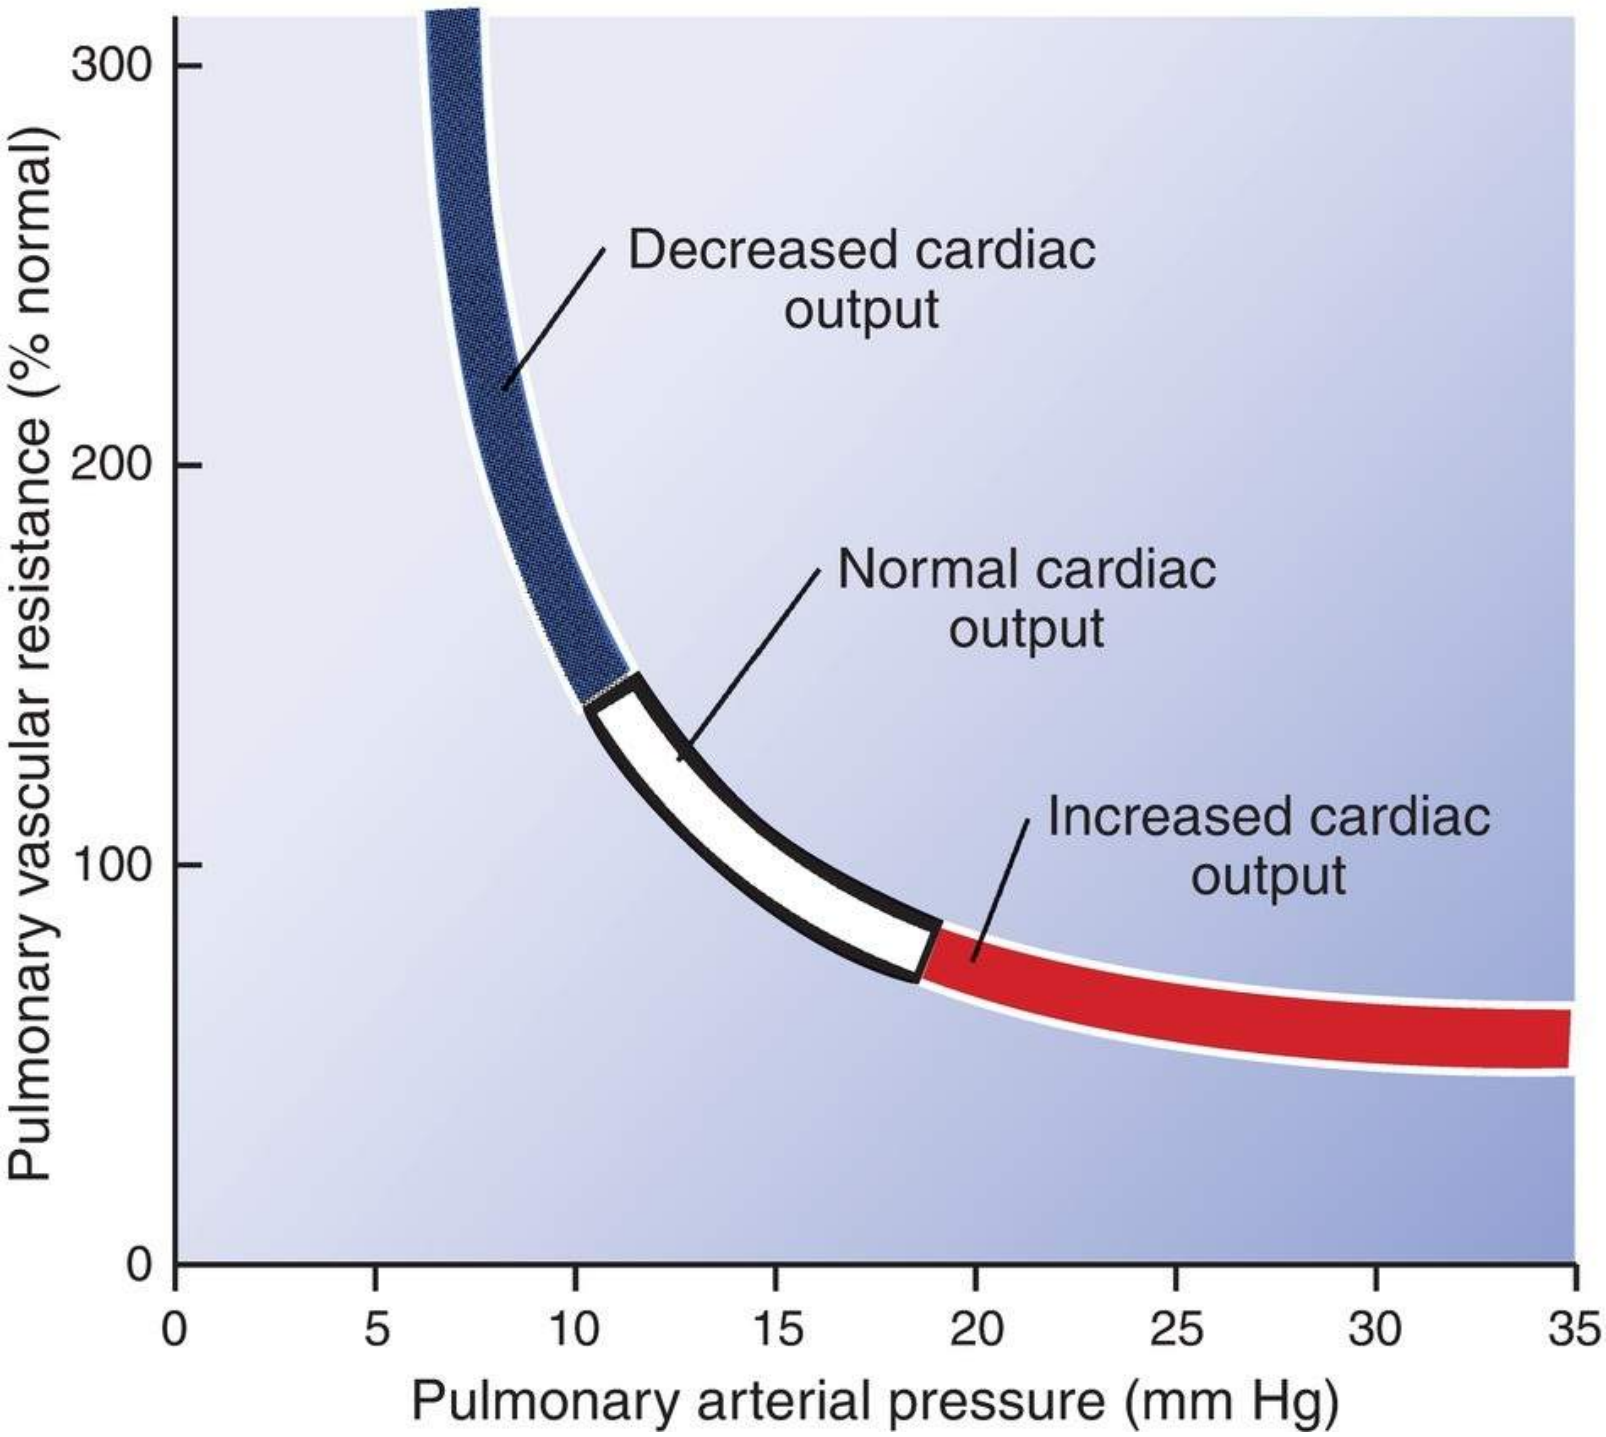

Figure 20.3 Pulmonary vascular resistance falls with a rise in cardiac output. Unlike in the systemic circulation, vascular resistance decreases when perfusion pressure rises (pulmonary arterial pressure). Note that if cardiac output increases, there is a rise in pulmonary arterial pressure and a concomitant fall in pulmonary vascular resistance.

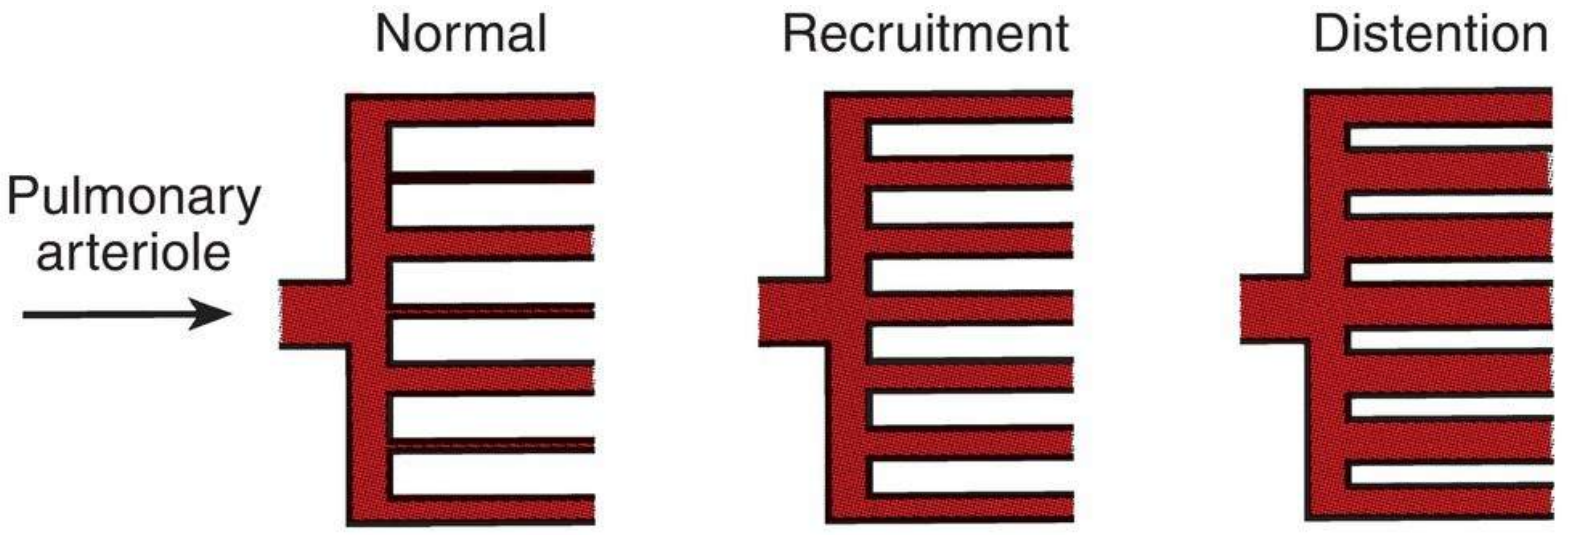

Figure 20.4 Capillary recruitment and capillary distention decrease pulmonary vascular resistance. In the normal condition, not all capillaries are perfused. Capillary recruitment (the opening up of previously closed vessels) results in the perfusion of an increased number of vessels with a concomitant decrease in resistance. Capillary distention (an increase in the caliber of vessels) resulting from high vessel compliance also results in a lower resistance and higher blood flow.

The fall in pulmonary vascular resistance with increased cardiac output has two beneficial effects. It opposes the tendency of blood velocity to speed up with increased flow rate, maintaining adequate time for pulmonary capillary blood to take up oxygen and dispose of carbon dioxide. It also results in an increase in capillary surface area, which enhances the diffusion of oxygen into and carbon dioxide out of the pulmonary capillary blood.

Capillary recruitment and distention also have a protective function. High capillary pressure can cause **pulmonary edema** and is a major threat to lung dysfunction. Pulmonary edema is abnormal accumulation of fluid, which can flood the alveoli and impair gas exchange. When cardiac output increases from a resting level of 5 to 25 L/min with vigorous exercise, the decrease in pulmonary vascular resistance not only minimizes the load on the right heart but also keeps the capillary pressure low and prevents excess fluid from leaking out of the pulmonary capillaries.

CLINICAL FOCUS 20.1

Pulmonary Embolism

Pulmonary embolism is clearly one of the more important disorders affecting the pulmonary circulation. The incidence of pulmonary embolism exceeds 500,000 per year, with a mortality rate of ~10%. Pulmonary embolism is often misdiagnosed and, if improperly diagnosed, the mortality rate can exceed 30%.

The term *pulmonary embolism* refers to the movement of a blood clot or other plug from the systemic veins through the right heart and into the pulmonary circulation, where it lodges in one or more branches of the pulmonary artery. Although most pulmonary emboli originate from thrombosis in

the leg veins, they can originate from the upper extremities as well. A thrombus is the major source of pulmonary emboli; however, air bubbles introduced during intravenous injections, hemodialysis, or the placement of central catheters can also cause emboli. Other sources of pulmonary emboli include fat emboli (a result of multiple long-bone fractures), tumor cells, amniotic fluid (secondary to strong uterine contractions), parasites, and various foreign materials in intravenous drug abusers.

The etiology of pulmonary emboli focuses on three factors that potentially contribute to the genesis of venous thrombosis: (1) hypercoagulability (e.g., a deficiency of antithrombin III, malignancies, the use of oral contraceptives, the presence of lupus anticoagulant), (2) endothelial damage (e.g., caused by atherosclerosis), and (3) stagnant blood flow (e.g., varicose veins). Risk factors for thrombi include immobilization (e.g., prolonged bed rest, prolonged sitting during travel, or immobilization of an extremity after a fracture), congestive heart failure, obesity, underlying carcinoma, and chronic venous insufficiency.

When a thrombus migrates into the pulmonary circulation and lodges in pulmonary vessels, several pathophysiologic consequences ensue. When a vessel is occluded, blood flow stops, perfusion to pulmonary capillaries ceases, and the ventilation/perfusion ratio in that lung unit becomes high because ventilation is wasted. As a result, there is a significant increase in physiologic dead space. Besides the direct mechanical effects of vessel occlusion, thrombi release vasoactive mediators that cause bronchoconstriction of small airways, which leads to hypoxemia. These vasoactive mediators also cause endothelial damage that leads to edema and atelectasis. If the pulmonary embolus is large and occludes a major pulmonary vessel, an additional complication occurs in the lung parenchyma distal to the site of the occlusion. The distal lung tissue becomes anoxic because it does not receive oxygen (either from airways or from the bronchial circulation). Oxygen deprivation leads to necrosis of lung parenchyma (pulmonary infarction). The parenchyma will subsequently contract and form a permanent scar.

Pulmonary emboli are difficult to diagnose because they do not manifest any specific symptoms. The most common clinical features include dyspnea and sometimes pleuritic chest pains. If the embolism is severe enough, a decreased arterial PO_2, decreased PCO_2, and increased pH result. The major screening test for pulmonary embolism is the perfusion scan, which involves the injection of aggregates of human serum albumin labeled with a radionuclide into a peripheral vein. These albumin aggregates (~10 to 50 μm wide) travel through the right side of the heart, enter the pulmonary vasculature, and lodge in small pulmonary vessels. Only lung areas receiving blood flow will manifest an uptake of the tracer; the nonperfused region will not show any uptake of the tagged albumin. The aggregates fragment and are removed from the lungs in about a day. ■

Pulmonary vascular resistance increases at high and low lung volumes.

Pulmonary vascular resistance is also significantly affected by lung volume. Because pulmonary arterioles, capillaries, and venules have little structural support, they can be easily distended or collapsed, depending on the pressure surrounding them. It is the change in transmural pressure (pressure across the capillaries) that influences vessel diameter. From a functional point of view, pulmonary vessels can be classified into two types: **extra-alveolar vessels** (pulmonary arteries and veins) and alveolar vessels (arterioles, capillaries, and venules). The *extra-alveolar vessels* are subjected to pleural pressure—any change in pleural pressure affects pulmonary vascular resistance in these vessels by changing the transmural pressure. *Alveolar vessels*, however, are subjected primarily to alveolar pressure.

At high lung volumes, the pleural pressure is more negative. The transmural pressure in the extra-alveolar vessels increases, and they become distended (Fig. 20.5A). However, alveolar diameter increases at high lung volumes, causing the transmural pressure in alveolar vessels to decrease. As the alveolar vessels become compressed, pulmonary vascular resistance increases. At low lung volumes, pulmonary vascular resistance also increases, as a result of more positive pleural pressure, which compresses the extra-alveolar vessels. Because alveolar and extra-alveolar vessels can be viewed as two groups of resistance vessels connected in series, their resistances are additive at any lung volume. Pulmonary vascular resistance is lowest at **functional residual capacity** (**FRC**) and increases at both higher and lower lung volumes (Fig. 20.5B).

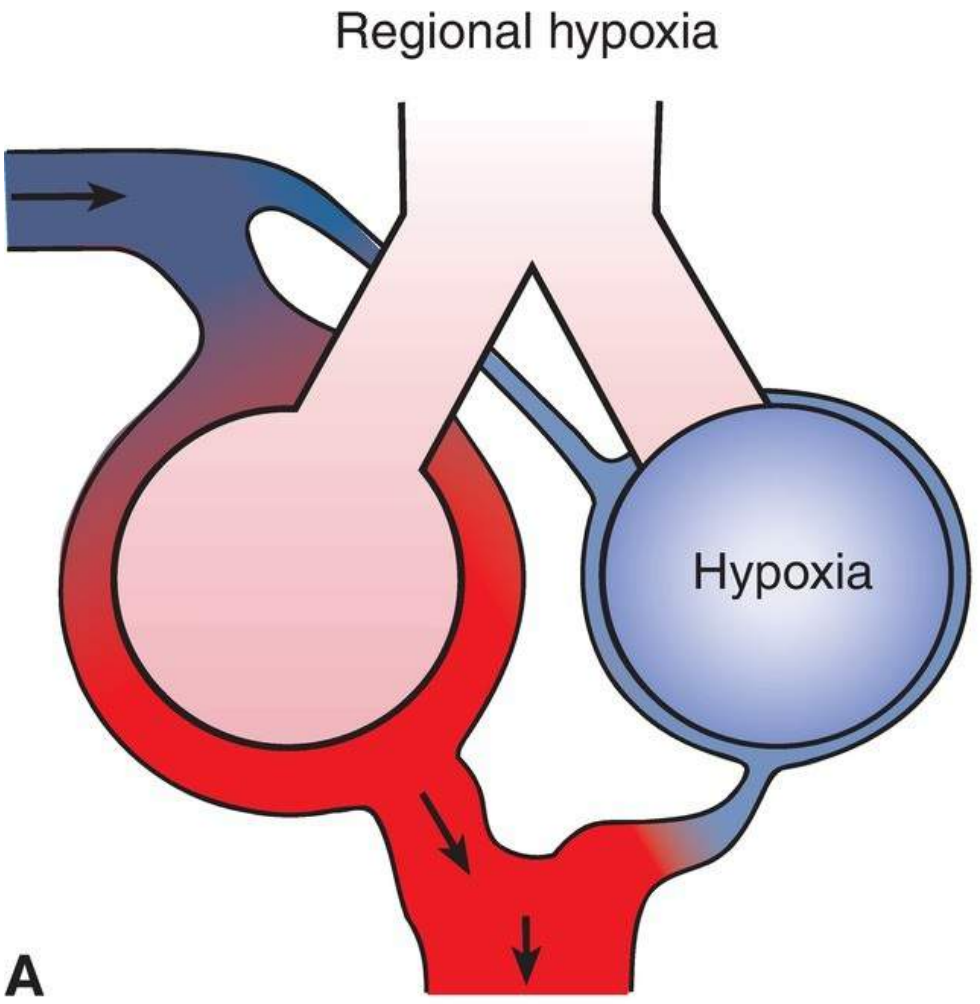
Figure 20.5 Changes in lung volumes affect pulmonary vascular resistance. (A) At high lung volumes, extra-alveolar vessels are actually distended because of the lower pleural pressure. However, alveolar vessels are compressed, causing a rise in pulmonary vascular resistance. At low lung volumes, alveolar vessels are distended, but the extra-alveolar vessels are compressed from the rise in pleural pressure, which results in a rise in pulmonary vascular resistance. **(B)** Total pulmonary vascular resistance as a function of lung volumes follows a U-shaped curve, with resistance lowest at functional residual capacity (FRC). RV, residual volume; TLC, total lung capacity.

Because smooth muscle plays a key role in determining the caliber of extra-alveolar vessels, drugs can also cause a change in resistance. Serotonin, norepinephrine, histamine, thromboxane A_2, and leukotrienes are potent vasoconstrictors, particularly at low lung volumes when the vessel walls are already compressed. Drugs that relax smooth muscle in the pulmonary circulation include adenosine, acetylcholine, prostacyclin (prostaglandin I_2), and isoproterenol. Although the pulmonary circulation is richly innervated with sympathetic nerves, surprisingly, pulmonary vascular resistance is virtually unaffected by autonomic nerves under normal conditions.

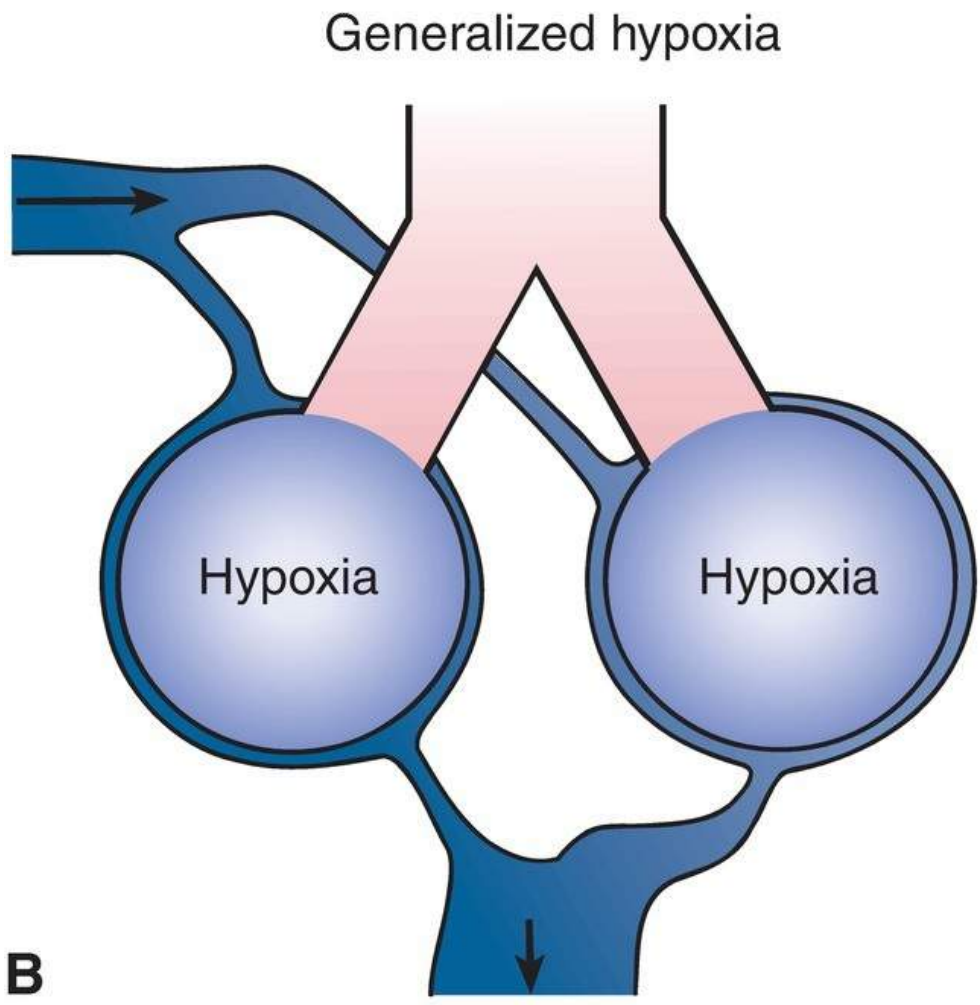
Low oxygen tension in the lung causes pulmonary vasoconstriction.

Although changes in pulmonary vascular resistance are accomplished mainly by passive mechanisms, resistance can be increased by low oxygen in the alveoli, alveolar **hypoxia**, and low oxygen in the blood, **hypoxemia**. Recall from Chapter 17 that hypoxemia causes vasodilation in systemic vessels, but in pulmonary vessels, hypoxemia or alveolar hypoxia causes vasoconstriction of small pulmonary arteries. This unique phenomenon is called **hypoxia-induced pulmonary vasoconstriction** and is accentuated by high carbon dioxide and low blood pH. The exact mechanism is not known, but hypoxia can directly stimulate pulmonary vascular smooth muscle cells, independent of any agonist or neurotransmitter released by hypoxia.

Two types of alveolar hypoxia (**regional hypoxia** and **generalized hypoxia**) are encountered in altered lung function, with different implications for pulmonary vascular resistance. In regional hypoxia, pulmonary vasoconstriction is localized to a specific region of the lungs and diverts blood away from a poorly ventilated region, which minimizes the effect on gas exchange (Fig. 20.6A). Regional hypoxia is often caused by bronchial obstruction. Regional hypoxia has little effect on pulmonary arterial pressure, or resistance, and when alveolar hypoxia no longer exists, the vessels dilate and blood flow is restored. Generalized hypoxia, on the other hand, causes vasoconstriction throughout both lungs, leading to a significant rise in resistance and pulmonary artery pressure (Fig. 20.6B). Generalized hypoxia occurs when the partial pressure of alveolar oxygen (PAO_2) is decreased with high altitude or with the chronic hypoxia seen in certain types of respiratory diseases (e.g., asthma, emphysema, and cystic fibrosis). Generalized hypoxia can lead to pulmonary hypertension (high pulmonary arterial pressure), which leads to pathophysiologic changes (hypertrophy and proliferation of smooth muscle cells, narrowing of arterial lumens, and a change in contractile function). Pulmonary hypertension causes a substantial increase in workload of the right heart, often leading to right heart hypertrophy.



Regional hypoxia
Hypoxia
A



Generalized hypoxia
Hypoxia
Hypoxia
B

Figure 20.6 Hypoxia-induced vasoconstriction is a unique feature to the pulmonary circulation. Low oxygen tension in the alveoli (alveolar hypoxia) is the major mechanism regulating blood flow within normal lungs. **(A)** With regional hypoxia, precapillary constriction diverts blood flow from poorly ventilated regions, with little change in pulmonary arterial pressure. **(B)** In generalized hypoxia, which can occur with high altitude or with certain lung diseases, precapillary constriction occurs throughout the lungs and there is a marked increase in pulmonary arterial pressure.

Generalized hypoxia plays an important nonpathophysiologic role before birth. In the fetus, pulmonary vascular resistance is extremely high as a result of generalized hypoxia: <15% of the cardiac output goes to the lungs, and the remainder is diverted to the left side of the heart via the foramen ovale and to the aorta via the ductus arteriosus. When alveoli are oxygenated on the newborn's first breath, pulmonary vascular smooth muscle relaxes, the vessels dilate, and vascular resistance falls dramatically. The foramen ovale and the ductus arteriosus close and pulmonary blood flow increases enormously.

FLUID EXCHANGE IN PULMONARY CAPILLARIES

The forces that govern the exchange of fluid across capillary walls in the systemic circulation also operate in the pulmonary capillaries (see **Starling forces** in Chapter 16). Net fluid transfer across the pulmonary capillaries depends on the difference between hydrostatic and colloid osmotic pressures inside and outside the capillaries. In the pulmonary circulation, two additional forces play a role in fluid transfer—surface tension and alveolar pressure. The force of alveolar surface tension (see Chapter 19) pulls inwardly, which tends to lower the interstitial pressure and draw fluid into the interstitial space. By contrast, the alveolar pressure tends to compress the interstitial space and the interstitial pressure is increased (Fig. 20.7).

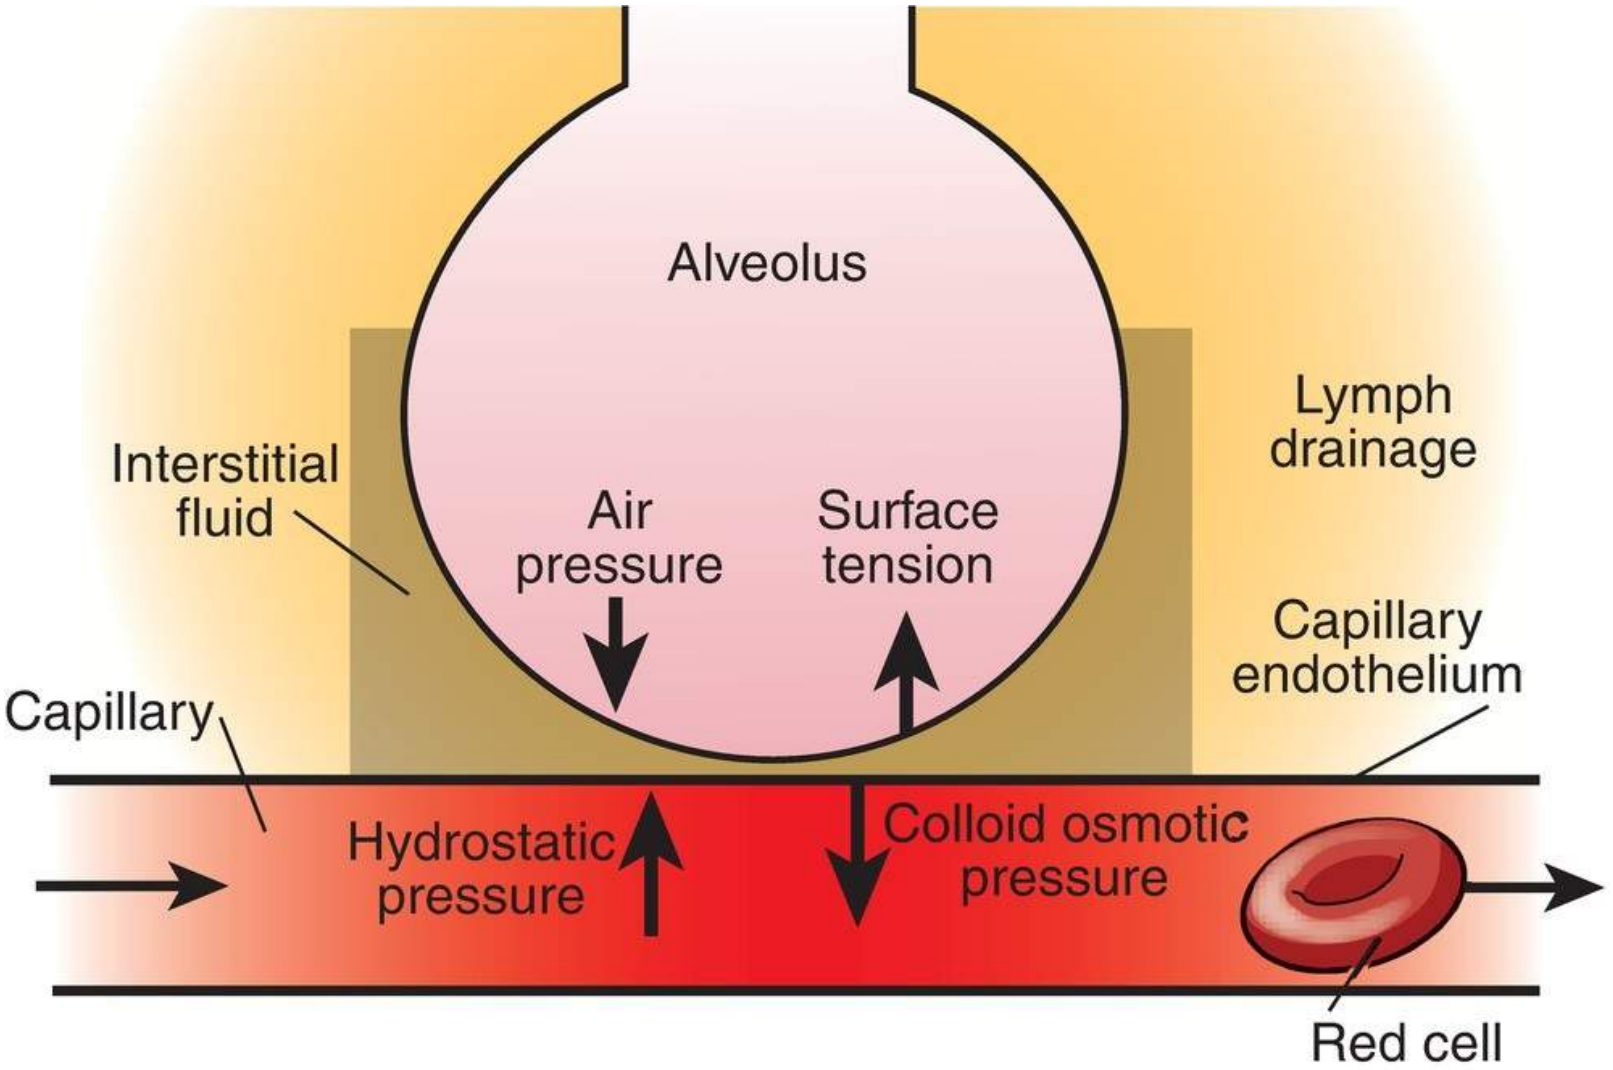


Figure 20.7 Alveolar surface tension and alveolar pressure affect fluid exchange in pulmonary capillaries. Fluid movement in and out of capillaries depends on the net difference between hydrostatic and colloidal osmotic pressures. In the lung, two additional factors (alveolar surface tension and pressure) are involved in fluid exchange. Alveolar surface tension enhances filtration, whereas alveolar pressure opposes filtration. The relatively low pulmonary capillary hydrostatic pressure helps keep the alveoli “dry” and prevents pulmonary edema.

Surface tension affects fluid exchange.

Mean pulmonary capillary hydrostatic pressure is normally 8 to 10 mm Hg, which is lower than the plasma colloid osmotic pressure (25 mm Hg). This is functionally important because the low hydrostatic pressure in the pulmonary capillaries favors the net absorption of fluid. Alveolar surface tension tends to offset this advantage and results in a net force that still favors a small continuous flux of fluid out of the capillaries and into the interstitial space. This excess fluid travels through the interstitium to the perivascular and peribronchial spaces in the lungs, where it then passes into the lymphatic channels (see Fig. 20.7). The lungs have a more extensive lymphatic system than most organs. The lymphatic vessels are not found in the alveolar–capillary area but are strategically located near the terminal bronchioles to drain off excess fluid. Lymphatic channels, like small pulmonary blood vessels, are held open by tethers from surrounding connective tissue. Total lung lymph flow is about 0.5 mL/min, and the lymph is propelled by smooth muscle in the lymphatic walls and by ventilatory movements of the lungs.

Pulmonary edema occurs when excess fluid accumulates in the lung interstitial spaces and alveoli and usually results when capillary filtration exceeds fluid removal. Pulmonary edema can be classified as *cardiogenic* pulmonary edema (due to heart dysfunction) or *noncardiogenic* pulmonary edema (due to lung injury). Cardiogenic pulmonary edema is caused by an increase in capillary hydrostatic pressure or by a decrease in plasma colloidal osmotic pressure. The latter occurs when plasma protein concentration is reduced (e.g., starvation).
