Patients with recent or long-standing hypertension should undergo renal angiography at the time of catheterization to assess renal artery stenosis, which if significant, can be treated preoperatively in hope of improving postoperative renal function. To optimize preoperative renal function, contrast loads should be minimized and patients should be well hydrated and receive renoprotective agents (eg, *N*-acetylcysteine).

Effects of Cardiopulmonary Bypass on Renal Function

Operative considerations include limiting the duration of CPB and maintenance of mean arterial pressures greater than 60 mm Hg. Additional effects of CPB include trauma to the blood constituents, especially erythrocytes, with increased free hemoglobin levels and microparticle embolic insults to the kidneys. Hypothermia (during rewarming, vasodilation, and hyperemia of tissue beds result in third spacing of fluid), hemodilution (reduces viscosity of blood and plasma oncotic pressure), and ischemia reperfusion injury can influence renal function. Additionally, CPB leads to an increased release of catecholomines, hormones (rennin, aldosterone, angiotensin II, vasopressin, atrial natriuretic peptide, urodilan)[53] and inflammatory cytokines (kallikrein, bradykinin), which also affect renal function adversely. These adverse stimuli cause low renal blood flow, decreased glomerular filtration rate (GFR), and an increase in renal vascular resistance. Hypotension and pressor agents accentuate this response. Ultrafiltration is used in long pump runs to decrease volume overload in patients with renal dysfunction.

Independent of preoperative renal function, the primary postoperative goal is the maintenance of adequate renal perfusion pressure and a urine output greater than the 0.5 cc/kg/h. Brisk diuresis (greater than 200 to 300 cc/h) is common after CPB. Volume replacement and maintenance of adequate blood pressure and cardiac output are required for adequate renal perfusion. The best measure of kidney perfusion is adequate urine output independent of diuretics. Beyond optimizing hemodynamics and avoiding nephrotoxic medications, there is no convincing evidence that treatment with diuretics, mannitol, dopamine, fenoldapam, nesiritide, or any other agent is renoprotective. This is not to say, however, that these agents are not beneficial in promoting diuresis and avoiding renal replacement therapies in the event of renal dysfunction.

Electrolyte Disturbances

Calcium

Levels of ionized calcium (normal, 1.1 to 1.3 mmol/L) are critical for myocardial performance and are involved in reperfusion injury. Hypocalcemia causes a prolonged QT interval. Postoperatively hypocalcemia is common after CPB or an episode of hemodilution, sepsis, or citrated blood transfusions. The concentration of calcium ion is greatest in the intracellular space, with small amounts in the extracellular fluid (ECF). Calcium levels bound to albumin change with the levels of serum albumin, whereas ionized levels remain unchanged.

Potassium

Potassium fluxes during cardiac surgery can be significant and affect cardiac automaticity and conduction. Cardioplegia, decreased urine output, decreased insulin levels, and RBC hemolysis all contribute to hyperkalemia.[54] Brisk diuresis, insulin, and alkalosis can cause hypokalemia.[55] Aggressive treatment of hypokalemia decreases the incidence of perioperative arrhythmias. Serum potassium levels and replacement protocols are integral parts of the early postoperative management. Serum potassium rises logarithmically with replacement; larger quantities are required to treat significant hypokalemia.

Magnesium

Magnesium (normal, 1.5 to 2 mEq/L) is the second most common intracellular cation after potassium. It is involved in endothelial cell homeostasis,[56] cardiac excitability, and muscle contraction through its role as an ATP cofactor and calcium antagonist, it is also closely involved in the regulation of intracellular potassium.[57] After hemodilution and CPB, hypomagnesaemia is common (greater than 70% of patients), and is associated with an increased risk of atrial fibrillation and torsades de pointes.[58]

Endocrine Dysfunction

Diabetes Mellitus

Up to 30% of patients have diabetes (type I or II) in the cardiac surgery population. After CPB the hormonal stress response (increased growth hormone, catecholomines, and cortisol) causes hyperglycemia (even in nondiabetics) with a decrease in insulin production; this may persist for up to 24 hours postoperatively and is exacerbated by exogenous catecholamine administration. Tight control of blood glucose levels with continuous insulin infusions has been shown to reduce the incidence of sternal wound infection by an order of magnitude. Recently, a more aggressive approach aimed at maintaining blood glucose levels at or below 110 mg/dL in critically ill

patients resulted in a reduction in mortality rate from 8.0 to 4.6% at 12 months.[59]

NICE-Sugar Study. The NICE-Sugar Study was performed to determine the optimal target range for blood glucose in critically ill patients.[60] Therefore, the study investigators investigated in 6104 patients intensive glucose control within 24 hours after admission to an intensive care unit (ICU). Adults who were expected to require treatment in the ICU on three or more consecutive days were randomly assigned to undergo either intensive glucose control, with a target blood glucose range of 81 to 108 mg/dL (4.5 to 6.0 mmol/L), or conventional glucose control, with a target of less than or equal to 180 mg/dL (less than or equal to 10.0 mmol/L). Both groups had similar characteristics at baseline. A total of 829 patients (27.5%) in the intensive-control group and 751 (24.9%) in the conventional-control group died (odds ratio for intensive control, 1.14; 95% confidence interval, 1.02 to 1.28; $p = .02$). The treatment effect did not differ significantly between operative (surgical) patients and nonoperative (medical) patients (odds ratio for death in the intensive-control group, 1.31 and 1.07, respectively; $p = .10$). Severe hypoglycemia (blood glucose level, p, 1.31 and 1.07, respectimmol per liter]) was reported in 206 of 3016 patients (6.8%) in the intensive-control group and 15 of 3014 (0.5%) in the conventional-control group ($p < .001$). There was no significant difference between the two treatment groups in the median number of days in the ICU ($p = .84$) or hospital ($p = .86$) or the median number of days of mechanical ventilation ($p = .56$) or renal-replacement therapy ($p = .39$).

In conclusion, the study investigators of the NICE-Sugar Study summarize that intensive glucose control leads to an increase of mortality among adults in the ICU; a blood glucose target of less than or equal to 180 mg/dL resulted in lower mortality than did a target of 81 to 108 mg/dL.

Adrenal Dysfunction

The strain of cardiac surgery activates the hypothalamic-pituitary-adrenal (HPA) axis and increases plasma ACTH and cortisol levels. Subclinical adrenal insufficiency is present in up to 20% of the elderly population and can be unmasked by the stress of surgery. Any patient taking exogenous steroids within 6 months of surgery should receive stress-dose steroids perioperatively. Any patient exhibiting prolonged, unexplained vasodilatory shock should be suspected of having adrenal insufficiency. A cosyntropin stimulation test should be performed for diagnosis. In the interim, dexamethasone may be administered IV without interfering with the test.

RELEVANT POSTOPERATIVE COMPLICATIONS

Neurologic

Central Nervous System

The incidence of stroke after cardiac surgery is procedure specific and varies between 1 to 4%. Ricotta and colleagues associated carotid stenosis (greater than 50%), redo heart surgery, valve surgery, and prior stroke with increased postoperative neurologic risk.[61] John and colleagues reviewed 19,224 patients in New York state.[62] The stroke rate was 1.4% after CABG, with a 24.8% mortality rate in that group. Multivariable logistic regression identified the after predictor variables: calcified aorta, prior stroke, age, carotid artery disease, duration of CPB, renal failure, peripheral vascular disease, smoking, and diabetes. Intraoperative factors that may cause postoperative neurologic deficits include particulate macroembolization of air, debris, or thrombus, microembolization of white blood cells, platelets, or fibrin,[63] duration of CPB,[64] cerebral hypoperfusion during nonpulsatile CPB, and hypothermic circulatory arrest.[65]

Neuropsychiatric deficits (neurocognitive dysfunction, delirium, seizures) are very common, occurring in up to 50 to 70% of patients after cardiac surgery. The cause of these neuropsychiatric disorders is uncertain and remains controversial. Although the dysfunction remains unclear, patients remain at risk for long-term cognitive decline. Van Dijk and colleagues[66] reviewed 12 cohort studies; a pooled analysis of six comparable studies showed 22.5% of patients to have a cognitive deficit at 2 months after operation. However, this may be related to progression of underlying cerebrovascular disease rather than CABG or cardiopulmonary bypass.[67]

Up to 50% of cardiac surgery patients experience delirium, particularly those with preexisting organic mental disorders, significant prior alcohol consumption, advanced age, or intracranial cerebral artery disease.[68] Perioperative opiate, anesthetic, and sedative administrations are a significant contributing factor. Right-sided parietal lobe lesions may present as delirium. Other causes of postoperative delirium in the cardiac intensive care patient include renal failure, hepatic failure, and thyroid abnormalities. EEGs on these patients are usually abnormal, whereas in primary psychiatric diseases they are normal. Treatment involves correcting metabolic abnormalities, establishing a normal sleep-wake cycle, and minimizing medications likely to cause delirium.

Brachial Plexus Injury/Peripheral Nerve Injury

Excessive sternal retraction during a median sternotomy may cause a brachial plexus injury, as the first rib may impinge the lower trunk and branches.[69] IMA harvesting may also cause damage to the brachial plexus with serious consequences.[70] Malpositioning of the upper limbs during surgery may result in a neuropraxia because of compression of the ulnar nerve.[71] Palsy or plegia of dorsiflexion and eversion of the foot can be caused by common peroneal nerve stretch or compression at the level of the head of the fibula.[72] Saphenous neuropathy (sensory changes on the medial side of the calf to the great toe) after open vein graft harvesting (less so with endoscopic harvest) is also a potential complication secondary to the avulsion of pretibial or infrapatellar branches of the nerve.[73]

Gastrointestinal

Mesenteric ischemia after cardiac surgery is infrequent but usually catastrophic.[74] Risk factors include duration of bypass (hypoperfusion), use of pressor support (sympathetic vasoconstriction), use of the IABP or other sources of atherosclerotic embolism, atrial fibrillation, peripheral vascular disease, and

heparin-induced thrombocytopenia. Early surgical intervention (less than 6 hours) is associated with a 48% mortality rate, and this rises to 99% with delays (greater than 6 hours) in surgical intervention. Gastrointestinal bleeding is common and can cause significant morbidity. The incidence of gastrointestinal bleeding can be reduced with the use of H_2-inhibitors, proton pump inhibitors and sucralfate.[75] Other pertinent complications affecting the gastrointestinal system include pancreatitis (hyperamylasemia, 35 to 65% leads to 0.4 to 3% with overt pancreatitis)[76] occasionally seen after CPB (etiology unknown), acute acalculous cholecystitis (2 to 15% of all acute cholecystitis cases, likely owing to hypoperfusion, narcotics or parenteral nutrition that promote biliary stasis),[77] swallowing dysfunction, oropharyngeal dysphasia secondary to tracheal intubation or perioperative use of TEE,[78] or small or large bowel ileus. (Olgilvie's syndrome is associated with long-term ventilation.)[79] Preoperative liver dysfunction (noncardiac cirrhosis) is associated with a high incidence of postoperative morbidity and mortality (Child class A cirrhosis: 20% morbidity, 0% mortality; Child class B cirrhosis: 80% morbidity, 100% mortality). Although 20% of patients develop a transient hyperbilirubinemia, fewer than 1% have significant hepatocellular damage that progresses to chronic hepatitis or liver failure.[80]

Infections

Nosocomial Infections

Ten to twenty percent of cardiac surgery patients develop a nosocomial infection. Infections may be related to the surgical wound, lung, urinary tract, invasive lines or devices, or the gastrointestinal tract. Prolonged mechanical ventilation is associated with nosocomial pneumonia. These are second only to urinary tract infection in frequency and carry the highest mortality rate.[44] Smokers and COPD patients are most likely to be colonized preoperatively and have a higher incidence of pneumonia (15.3 versus 3.6% in controls).[81]

Catheter-related infections (ie, bladder and vascular related) are common in the ICU. The most common pathogens are *Staphylococcus aureus* (12%), coagulase-negative staphylococci (11%), *Candida albicans* (11%), *Pseudomonas aeruginosa* (10%), and *Enterococcus* sp.[82]

Fever

Fevers are common in the intensive care setting, but are a poor indicator of postoperative bacteremia (3.2% incidence in 835 febrile CABG patients).[83] The yield of true positive bacteremia ranges from 4 to 5%, with a contamination rate ranging from 32 to 47%.[84] Noninfectious causes of fever relative to cardiac surgery include myocardial infarction, postpericardiotomy syndrome, and drug fever. Infectious causes include wound infection, UTI, pneumonia, catheter sepsis, and loculated areas of contaminated blood accumulation (eg, pericardial, pleural, retroperitoneal, and leg wound spaces).

Sepsis/Septic Shock

Septic shock after cardiac surgery can have devastating consequences. Pathophysiologic features of sepsis include systemic inflammation, coagulation changes, impaired fibrinolysis, and subsequent target organ failure, with overall multiorgan failure, irreversible shock, and death (20 to 50%).[85] Mixed venous oxygen saturation can be abnormally high secondary to shunting and a failure to extract oxygen at the cellular level. In vasodilatory shock the maintenance of end-organ tissue perfusion is critical; this includes aggressive fluid management and vasopressin.[86] Methylene blue (which inhibits NO synthesis) has been used successfully in refractory hypotension. Bernard and colleagues[87] for the PROWESS study group showed a distinct survival advantage in the treatment of severe sepsis utilizing drotrecogin alfa (activated) or recombinant human activated protein C (Zigris). The mechanism of action is a modulation of the systemic inflammatory, procoagulant, and fibrinolytic reaction to infection. In a randomized study of 1690 patients the mortality rate was 30.8% in the placebo group versus 24.7% in the treatment group.

Wounds

Delayed Sternal Closure/Sternal Infection. Complicated operations with persistent bleeding and hemodynamic instability (owing to tissue edema) may preclude primary sternal closure. Delayed sternal closure allows hemodynamic stabilization, and diuresis.[88] Anderson and colleagues[89] outlined the recent Brigham and Women's Hospital experience; 1.7% (87 of 5177) open chests were managed with a hospital survival rate of 76%. Complications included deep sternal infection ($n = 4$), stroke ($n = 8$), and dialysis ($n = 13$). Multivariate analysis revealed mechanical ventricular assistance and reoperation for bleeding as independent predictors of in-hospital mortality.

Superficial and Deep Sternal Wounds. Superficial and deep sternal wound infections are significant complications of cardiac surgery. Deep sternal infection with associated mediastinitis occurs in 1 to 2% of cardiac operations, with a resultant mortality rate approaching 10%.[90] Common organisms are *Staphylococcus epidermidis, Staphylococcus* (including methicillin-resistant *Staphylococcus aureus* [MRSA]), *Corynebacterium*, and enteric gram-negative bacilli.[91] Patients predisposed to sternal infections include those with significant comorbidities (eg, obesity, diabetes, COPD, renal dysfunction, low serum albumin), prolonged CPB, reoperations, diabetics with bilateral IMA harvests,[92] and patients with hyperglycemia.[93] Simple preoperative measures such as clipping of chest hair, using Hibiclens washes, administration of adequate prophylactic antibiotics before skin incision, ensuring good intraoperative hemostasis without the use of bone wax, and closure with subcuticular sutures and Dermabond (topical adhesive) rather than skin staples; additionally, tight glucose control during surgery and in the days after surgery have a significantly lower sternal wound infection rate.

Minor infections frequently respond to intravenous antibiotics, opening of the wound, and local wound care. Deeper infections require intravenous antibiotics (6 weeks); initial empiric therapy should consist of broad coverage against gram-positive cocci and gram-negative bacilli with the regimen adjusted when cultures (blood, mediastinal, or deep sternal wound drainage) have been speciated. The mainstay of treatment is

surgical exploration and extensive debridement, which may require removal of the sternum with primary or secondary closure with muscle or an omental flap.[94] Postoperative vacuum-assisted closure (VAC)[95] of mediastinal wounds improves wound healing and reduces hospital length of stay.

Nutrition

Preoperative debilitated or cachectic patients (ie, more than 10% weight loss over 6 months) with albumin levels of less than 3.5 g/dL[96] are exceptionally prone to complications such as infections after surgery. There is no evidence to support a role for preoperative hyperalimentation. BMI (a good nutritional index) of less than 15 kg/m^2 is associated with increased in morbidity. Postoperative patients have accelerated catabolic protein loss, usually requiring 25 to 40 Kcal/kg/day. Advances in immunonutritional pharmacology (arginine, glutamine, and n-3 fatty acids) in complex postoperative cardiac surgery patients may have a defined role in the future.[97]

CHAPTER 17

Cardiopulmonary Resuscitation

Mark P. Anstadt
James E. Lowe

INTRODUCTION

Cardiovascular disease remains the leading cause of death in the United States.[1,2] Acute myocardial infarctions associated with ischemic heart disease accounts for the majority of sudden deaths.[3]

Sudden cardiac death is the unexpected, nontraumatic, abrupt cessation of effective cardiac function associated with absent or acute symptoms of less than 1 hour.[4,5] Prodromes such as chest pain, palpitations, or fatigue may occur within the preceding 24 hours.[4] The majority of deaths occur within 2 hours of the onset of symptoms.[1,2,6–8] Most victims die before reaching a hospital.[1,2]

Cardiopulmonary resuscitation (CPR) describes the emergency measures used to restore cardiovascular and respiratory function. Notably, cardiocerebral resuscitation represents preferable terminology as it conveys more appropriate emphasis on neurologic recovery. Clinical interventions have been formulated as Advanced Cardiac Life Support (ACLS) guidelines[9] based on scientific data established by the American Heart Association (AHA) and International Liaison Committee on Resuscitation.[10]

CPR and/or ACLS are performed in 1 to 2% of patients admitted to teaching hospitals (including approximately 30% of patients who die).[11,12] The goals are to restore spontaneous circulation (ROSC), and ultimately, survive. Early defibrillation is the single most effective means for ROSC. Otherwise, ROSC depends on improving myocardial perfusion and treating underlying disorders. Mechanical circulatory support devices and therapeutic hypothermia represent treatment interventions that may improve these life-saving endeavors. Overall survival rates remain low (Table 17-1), and successful resuscitation frequently results in neurologic impairment.[13–15,129] The clinical integration of rapid response, early defibrillation, circulatory support devices, hypothermia, and neuroprotective agents should improve future outcomes.

PHARMACOLOGIC THERAPY DURING CPR

Peripheral venous access is preferred for speed, and avoiding CPR interruption. Drugs take 1 to 2 minutes to reach the central circulation during CPR. Administration should be by bolus followed by flushes and extremity elevation. Peak drug concentrations are lower with peripheral versus central injection. Central access should be considered when responses to peripheral administration are absent. Internal jugular and supraclavicular sites are preferred to the femoral because return to the inferior vena cava is impaired during CPR. Long femoral lines may overcome this problem. Routine fluid administration is not indicated without evidence of hypovolemia as this may adversely affect coronary pressure by raising right atrial pressure.

When venous access is not possible, drugs may be administered via an endotracheal tube. Medications are given via a catheter passed beyond the tube's tip using twice the IV dose diluted in saline or water. Water provides better absorption but results in more adverse effects on Pa_{O_2}. Rapid insufflations are given after each bolus for drug dispersion. Intracardiac injection is not recommended during routine CPR. It may be used for epinephrine during open chest cardiac massage (OCM), or if no other access is obtainable. Intracardiac injection can result in complications including: cardiac injury, tamponade, and pneumothorax.

The principal agents recommended for ACLS are adrenergic agonists and antiarrhythmics. Alpha-adrenergic agonists have been the only drugs that definitively improved outcome in

CPR. Their primary benefit is vasoconstriction. Increased peripheral resistance results in elevated aortic pressure, improving coronary perfusion. The minimum coronary perfusion pressure and blood flow needed for successful defibrillation are 15 mm Hg and 15 to 20 mL/min/100 g, respectively. CPR rarely achieves these minimums without pressors. Epinephrine has this beneficial effect. Its beta-adrenergic effect may improve the treatment of cardiac arrest. One milligram is recommended every 3 to 5 minutes during resuscitation attempts.[10] Epinephrine improves ROSC and survival in animal models of cardiac arrest. Clinical trials using higher epinephrine doses demonstrated higher rates of ROSC, but no survival advantage.[16,17] One trial found high-dose epinephrine had more adverse effects, which may be partly explained by increased oxygen demands.

Other nonadrenergic vasoconstrictive agents have been studied as alternatives to epinephrine. Vasopressin acts on unique receptors and may be beneficial for treating cardiac arrest refractory to epinephrine. Laboratory and clinical data indicate vasopressin may be preferable to epinephrine.[18,19] A recent meta-analyses of five randomized clinical trials comparing vasopressin to epinephrine during cardiac arrest[20] found no evidence to support the use of one drug over the other. Epinephrine is less expensive. However, vasopressin continues to be an acceptable alternative for treating cardiac arrest.

Vasopressin also mediates adrenocorticotropin release during CPR.[21] The hypothalamic-pituitary-adrenal axis is suppressed in cardiac arrest victims,[21–23] and low serum cortisol levels have been identified as a poor prognostic factor for ROSC.[22,23] Adrenal function in patients who have ROSC may also be insufficient for survival.[24] Further clinical trials are needed to determine if administration of corticosteroids during CPR and/or following ROSC may benefit outcome.

The effectiveness of antiarrhythmics in sudden death has not been well substantiated. Randomized clinical trials have demonstrated amiodarone effectiveness in treating cardiac arrest.[25–29] Amiodarone significantly improved survival to hospital admission compared with placebo for VF/VT.[28] The most recent randomized clinical trial found amiodarone significantly increased survival to hospital admission compared to lidocaine when used to treat sudden death.[25] Survival to discharge was observed, but did not reach statistical significance. Amiodarone is recommended for the treatment of persistent VT and/or VF. Lidocaine is an acceptable alternative.

Magnesium sulfate should be administered for suspected hypomagnesemia or torsades de pointes. It is recommended for refractory VF/VT. Hypomagnesemia is associated with ventricular arrhythmias and sudden cardiac death and may hinder potassium replenishment in hypokalemic patients. Hypermagnesemia can cause flaccid paralysis and cardiorespiratory arrest.

Atropine enhances atrioventricular node conduction and sinus node automaticity. It is indicated for symptomatic bradycardia and asystolic arrest. Asystole from prolonged ischemia is usually fatal. Atropine is unlikely to benefit, but is not harmful in such circumstances. Adverse effects include tachycardia and anticholinergic effects.

Judicious use of $NaHCO_3$ may be appropriate for correcting severe acidosis during cardiac arrest. Notably, $NaHCO_3$ increases CO_2, which may accumulate rapidly, leading to a hypercarbic venous acidemia. Diffusion of CO_2 across cell membranes may result in paradoxic intracellular acidosis and decrease the likelihood of successful resuscitation. Hypocarbic arterial alkalemia or the so-called venoarterial paradox may develop. Therefore, $NaHCO_3$ may increase CO_2 levels, worsen the venoarterial paradox, and exacerbate intracellular acidosis. Other potential adverse effects include alkalemia with leftward shifts in the oxyhemoglobin desaturation curve, hyperosmolality, hypernatremia, and hypotension. Finally, $NaHCO_3$ has not been shown to improve results in cardiac arrest and is only recommended for severe acidosis, hyperkalemia, tricyclic antidepressant overdose, or prolonged CPR.[9]

TECHNIQUES IN CARDIOPULMONARY RESUSCITATION

Basic life support (BLS) defines the methods used to sustain ventilation and blood flow until ACLS can restore spontaneous circulation. Airway, breathing, circulation, defibrillation (ABCD) algorithms describe these standardized approaches (Fig. 17-1).[3]

Airway Management

Initial management of unresponsive patients is ensuring a patent airway.[9] The airway is open using the head-tilt–chin-lift

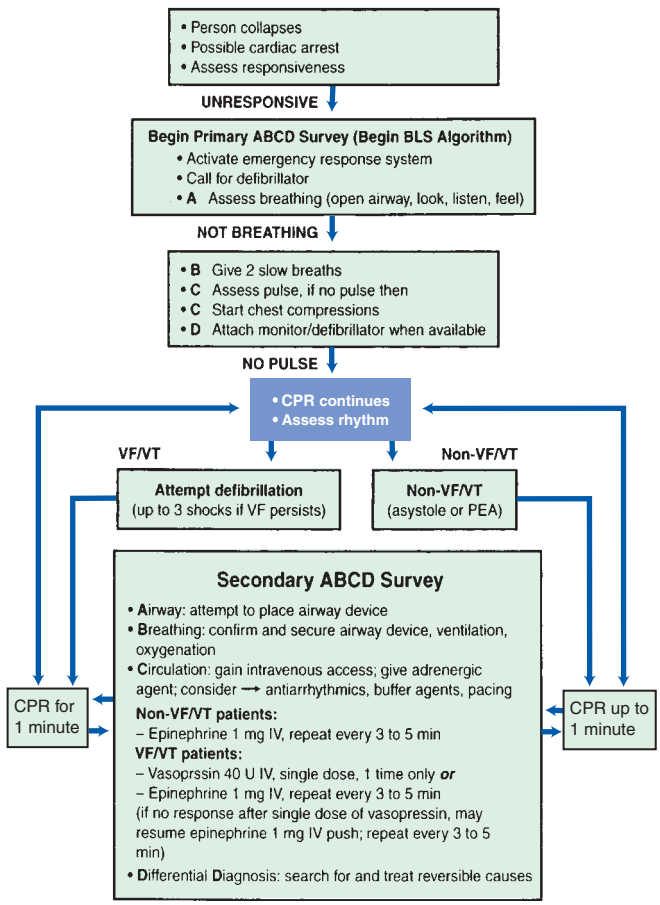

FIGURE 17-1 Universal treatment algorithm for adult emergency cardiac care.

maneuver. The jaw-thrust technique is an alternative for suspected neck trauma; however, it is more difficult to perform. Both relieve posterior displacement of the tongue, which is a common cause of airway obstruction. Difficult ventilation should be addressed by repositioning and considering foreign body obstruction. The Heimlich maneuver, or *subdiaphragmatic abdominal thrust,* is recommended for relieving obstruction from foreign bodies. Rapid thrusts to the subxiphoid region can dislodge a foreign body by increasing expiratory pressure. Chest thrusts are more appropriate for obese patients and women in late stages of pregnancy. Magill forceps can be used to retrieve foreign bodies when necessary.

Masks, and oral and nasal airways may be used with mouth-to-mask ventilation or bag-valve devices. Bag-valve devices reduce exposure to potential infection, but require two rescuers.[10] Nasopharyngeal airways are considered for nonintubated patients. Oropharyngeal airways can be used in unconscious patients but add risk for laryngospasm and regurgitation.[10]

Endotracheal intubation (ETT) is the preferred method of airway management. ETT maintains an open airway, decreases risk of gastric distention and aspiration, and is an alternative drug administration route. Orotracheal intubation is ideal unless a neck injury is suspected, in which case nasotracheal intubation is recommended. ETT can be complicated by esophageal intubation, oral trauma, pharyngeal laceration, vocal cord injury, pharyngeal-esophageal perforation, mainstem bronchus intubation, and aspiration. Esophageal intubation is likely with a low end-tidal CO_2 ($ETCO_2$).

Transtracheal catheter ventilation (TTC) can be instituted when routine methods fail using a catheter passed across the cricothyroid membrane. TTC may cause suboptimal ventilation, including pneumothorax, hemorrhage, and esophageal perforation. Cricothyroidotomy may also be considered for difficult airways. Otherwise, tracheostomy is indicated when ventilation cannot be achieved.

Mouth-to-mouth ventilation/nasal is used in the absence of airway devices and generally results in adequate ventilation. Respiratory rates of 10 to 12 per minute are recommended.[10] Cricoid pressure (Sellick maneuver), maintaining a patent airway, and slow breaths decrease risk for gastric distention, regurgitation, and aspiration. Concern of transmissible diseases during resuscitation has reduced enthusiasm for CPR. Barrier devices (face shields and masks) have been developed to protect from exposure. Chest compressions alone are better than no resuscitation attempt. Interestingly, there is increasing evidence that chest compressions alone may result in survival rates and neurologic outcomes comparable to CPR with ventilation.[29,30,128]

Closed Chest Cardiac Massage

Closed chest cardiac massage (CCM) is the principal means of restoring blood flow during CPR. CCM is best when the victim is supine on a firm surface (Fig. 17-2). Compressions are given to the lower sternum at 100/min, with a rate of 30 compressions: 2 breaths. Compressions of 4 to 6 cm should occupy 50% of the cycle. At best, CCM creates minimal perfusion to vital organs and is unable to sustain life.[31–34] Survival becomes exceedingly low with more than 30 minutes of CCM. ROSC is dependent on proper CCM techniques,[33] but studies have demonstrated these techniques are frequently suboptimal.[31,32]

Discontinuation of CPR

Discontinuation of CPR remains controversial, with no clearly defined criteria. Determining the adequacy of CCM is subjective

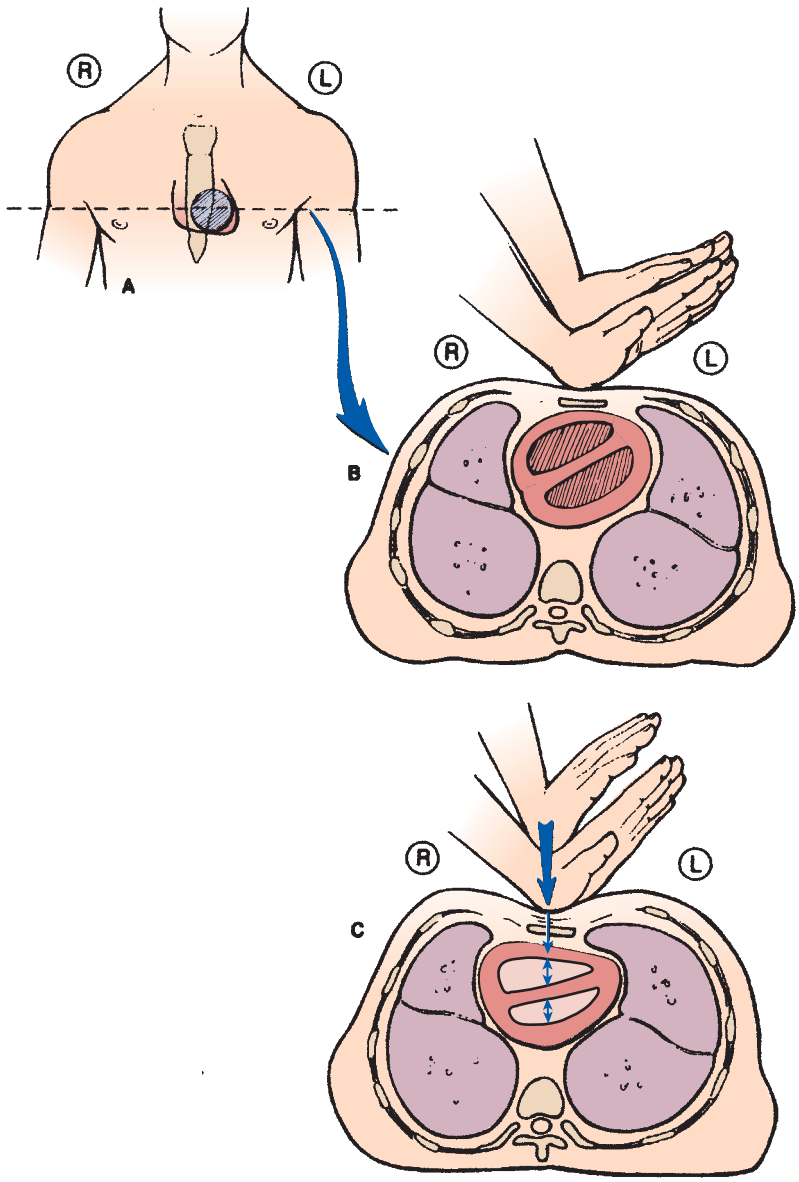

FIGURE 17-2 Cross-sectional view of closed chest cardiac massage. Compressions are delivered with high velocity and moderate force, resulting in cardiac compression.

because palpable pulses do not signify forward flow. Reactive pupils and/or spontaneous respirations indicate some cerebral perfusion, but correlate poorly with outcome. Aortic diastolic pressure may be the best measure of CPR effectiveness[35] but is usually not available.

Alternatively, $ETCO_2$ can provide useful information and predict ROSC.[36,37] Low $ETCO_2$ suggests poor perfusion, esophageal intubation, airway obstruction, massive pulmonary embolus, or hypothermia.

Successful ROSC and survival are influenced by many factors. Ventricular fibrillation (VF), early defibrillation, rapid onset of CPR or ACLS, witnessed arrest, and early age all have favorable implications.[38,39–41,42] These factors, should all be considered before abandoning resuscitation.

Complications of CPR

Common complications associated with CCM are rib and sternal fractures.[43] Others include aspiration, gastric dilatation, anterior mediastinal hemorrhage, epicardial hematoma, hemopericardium, myocardial contusion, pneumothorax, air embolus, hemothorax, lung contusion, and oral/dental injuries.[43–45] The liver and spleen are the most commonly injured intra-abdominal organs, reported in 1 to 2% of cases.[43] Significant injuries can involve the trachea, esophagus, stomach, cervical spine, vena cava, retroperitoneum, and myocardium.[43]

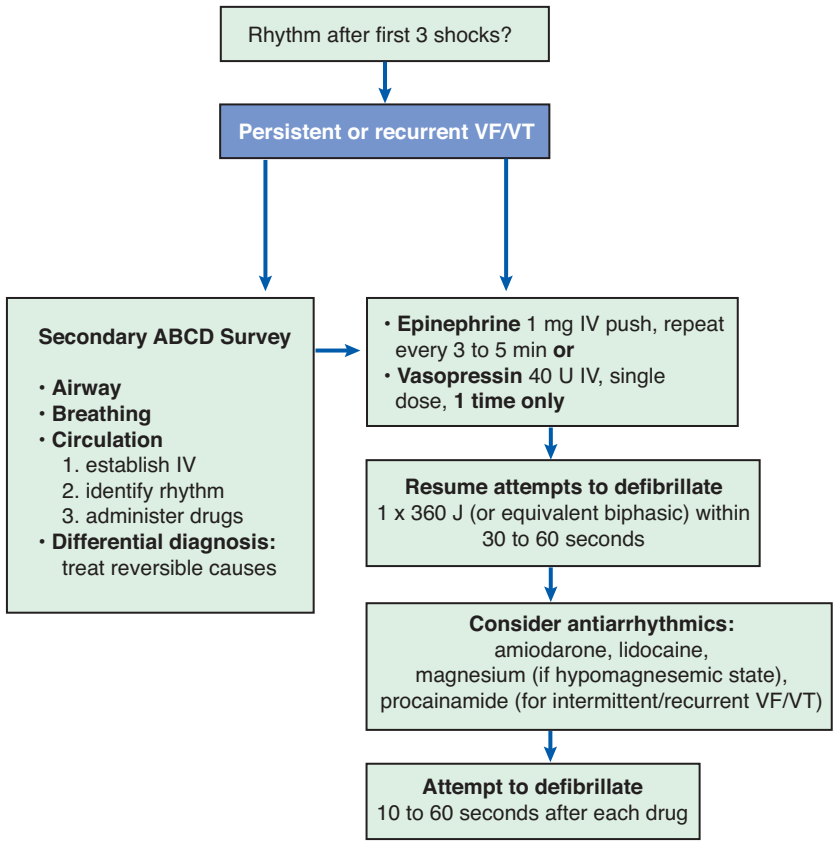

FIGURE 17-3 Treatment algorithm for persistent ventricular fibrillation and pulseless ventricular tachycardia (VF/VT).

SUDDEN DEATH TREATMENT CONSIDERATIONS

Sudden death generally presents as ventricular fibrillation/tachycardia (VF/VT), asystole, or electromechanical dissociation (EMD), also called pulseless electrical activity (PEA). VF may continue after defibrillation attempts (*shock-resistant*) or persist despite other therapeutic interventions (*persistent* or *refractory*). Also, successfully treated VF may recur (*recurrent*). These patterns are felt to have different etiologies, priorities of treatment, and prognoses. Early identification of the underlying rhythm is important for selecting the recommended treatment algorithm (see Fig. 17-1).

Ventricular Tachycardia

Ventricular tachycardia (VT) is an arrhythmia characterized by premature ventricular depolarizations (>100/min). Cardiac arrest occurs with rapid, sustained VT. VF is uncoordinated, continuous contraction of the ventricles. More than 80% of monitored cardiac arrests originate with VF/VT.[46] Most survivors have VF/VT as the initial rhythm.[38,41,47] Rapid defibrillation is the key determinant for survival[38,48,49] and should precede all other therapy if immediately available.[9,10] Delay negatively impacts successful defibrillation.[50] Mortality increases 4 to 10% for every minute preceding defibrillation attempts.[48] Survival rates approach zero when countershocks are attempted more than 10 to 12 minutes after arrest.[51] Current guidelines therefore emphasize early defibrillation and use of automated external defibrillation systems.[10]

Optimal treatment VF or pulseless VT begins with immediate defibrillation, when possible. Energy for initial defibrillation is 200 J. If VF continues, a second shock (200 to 300 J) is given immediately. A third countershock (360 J) is given if the second fails. It is vital that three consecutive shocks are given without delay for other interventions. CPR is performed whenever defibrillation attempts fail. Figure 17-3 outlines treatment algorithms for persistent VF/VT. Epinephrine or vasopressin is given IV or via the endotracheal tube. Vasopressin should only be given once, and subsequent defibrillation attempted (360 J). Epinephrine is given every 3 to 5 minutes. Refractory VF is treated with antiarrhythmics. Amiodarone may be the most efficacious in this setting.[25–27,52] Lidocaine is also acceptable for recurrent VF or pulseless VT; however, it is not recommended over amiodarone.[38] Defibrillation should be attempted 30 to 60 seconds after each drug.[10]

Prognosis for VF or pulseless VT is better than for asystole or PEA. Up to 30% of patients with witnessed VF/VT arrest are successfully resuscitated.[41,47,53,54] Failure of initial defibrillation attempts is a poor prognostic sign.

Asystole

Asystole is absence of electrical and mechanical cardiac activity and frequently indicates a terminal event. ACLS is indicated while other treatable causes are considered. Priorities include effective CPR and rhythm confirmation. Low-amplitude VF may occasionally masquerade as asystole. Incorrect lead placement or equipment malfunction should be considered. Countershocks do not benefit *true* asystole, and may induce parasympathetic discharge diminishing the chance of ROSC.

Once verified, asystole is managed by ABCD guidelines. Epinephrine raises perfusion pressures[10] and is repeated every 3 to 5 minutes. Atropine treats the high parasympathetic tone underlying severe brady-asystolic arrests. Transcutaneous or transvenous pacing may be effective if applied early. Timely pacing can result in successful capture and effective cardiac contraction.[55] The prognosis of asystole is grim, but may be better when preceded by VF versus prolonged CPR.

Pulseless Electrical Activity

Pulseless electrical activity generally carries a very poor prognosis. Characterized by organized electrical activity without effective cardiac contractions, PEA is synonymous with EMD and includes pulseless idioventricular, bradycardia, and ventricular escape rhythms.[10] These dysrhythmias are common proximate causes of death in delayed or difficult resuscitations. As with asystole, PEA mandates assessment for reversible causes. Rapid, narrow-complex activity may indicate a treatable condition. Associated trauma may be an indication for emergency thoracotomy[56] to address cardiac tamponade of cardiovascular injury. Thoracotomy allows cardiac massage and aortic occlusion, which may be lifesaving. PEA following open heart surgery is a clinical scenario in which chest reopening is generally recommended.[57]

Cardioversion

Cardioversion is the *only* effective treatment for VF. Defibrillation depolarizes and results in temporary asystole.[58] Pacemaker cells then restore myocardial activation. Myocardial contraction resumes if high-energy phosphates depleted by CPR are sufficient. The probability of successful defibrillation is best immediately after witnessed arrests. Success rates decline rapidly during CPR, which only slows the deteriorating state. Once available, a defibrillator should be positioned with quick-look paddles for rhythm evaluation. VF or pulseless VT is treated immediately. Blind defibrillation is rarely indicated. Asynchronous shocks are given for VF or pulseless VT. Synchronous shocks are given for stable rhythms (eg, atrial fib/flutter, monomorphic VT)[10] to avoid impinging on the relative refractory period.

Energy levels for cardioversion impact success. Low currents may be ineffective and excessive energy levels cause myocardial injury.[59,60] The lowest energy for defibrillation is desired. A prospective study demonstrated that 175 and 320 J were equally effective for initial defibrillation attempts;[61] therefore, 200 J is recommended for initial defibrillation attempts.[10] The range for second countershocks is 200 to 360 J.

Body size impacts defibrillation energy requirements.[10] The optimal current for defibrillation is 30 to 40 A.[62] Adult transthoracic impedance is 70 to 80 gV, requiring a 200-J countershock for a 30-A current.[63] However, impedance varies significantly depending on energy delivery, chest size, electrode size, interelectrode distance, paddle-skin coupling, respiration, and antecedent countershocks.[62] Keep one electrode positioned on the right parasternal border below the clavicle, and the other in the left midaxillary line, level with the nipple.[10] Electrodes must not touch so the currents pass through the heart. During open chest resuscitation, one paddle is placed over the right ventricle, and the other behind the apex. Larger paddles are preferred for their lower resistance. Small paddles should only be used if required to fit in the chest.[64] It is also noteworthy that compression of the heart reduces the defibrillation threshold.[65]

Defibrillation threshold (DFT) describes the amount of current required to defibrillate the heart. DFT increases during CPR and is primarily affected by coronary perfusion pressure. Catecholamines decrease the DFT.[66] It was thought epinephrine decreased the DFT through beta-adrenergic effects; instead, this is owing to alpha-adrenergic increases in systemic pressure. Time-dependent increases in DFT observed during CPR are not completely understood. Adenosine may act through A_1 receptors to increase DFT over time.[67] Aminophylline, an adenosine receptor antagonist, decreases DFTs.

The presence of pacemakers and automatic internal cardio defibrillators (AICDs) impact defibrillation management. Paddles should not be placed directly over pacemaker generators,[68] and these devices should be interrogated to reassess pacing thresholds after defibrillation. AICDs are not a contraindication to external defibrillation for VF/VT,[130] and are shielded to withstand countershocks. AICD patches may increase transthoracic resistance.[69] Therefore, paddle orientation should be changed if initial countershocks fail. After defibrillation, the AICD unit should be tested.

Automated external defibrillators (AED) are increasingly common. AEDs analyze ECG pattern, sounds an alarm and discharges when VF is detected. They require less training and are more rapid at administering countershocks.[51] AEDs have equivalent survival compared with manual defibrillators.[70] Clinical trials have confirmed AEDs can be used safely and effectively by the lay person.[71]

Current-controlled defibrillators may improve the success of defibrillation.[72] These devices enhance delivery of energy and reduce risk of excessive energy delivery. The delivery of biphasic (bidirectional) or multipulse, multipathway shocks are methods used for internal defibrillators,[63] but efficacy for external defibrillation has not been established.[73]

A precordial thump may achieve defibrillation and be used when a defibrillator is not immediately available. It may be successful in 11 to 25% during VT. Unfortunately, precordial thumps may result in VF, asystole, or EMD, and are less unlikely to convert VF.[74]

Chest compressions must be temporarily discontinued to avoid electrical shock of those performing CPR. This hands-off interval is also used for rhythm analysis before defibrillation. Prolonging the hands-off period can significantly reduce the probability of successful cardioversion, and be kept as short as possible.[74]

PHYSIOLOGY OF CARDIOPULMONARY RESUSCITATION

Mechanisms generating forward blood flow during CPR have been a subject of significant controversy. Investigations have demonstrated chest compressions translate directly to the heart.[75] However, other mechanisms have been elucidated.

At least two other mechanisms appear responsible for blood flow during CPR. The thoracic pump was discovered by observing that coughing during cardiac arrest generated forward flow. Chest compressions also cause a rise in thoracic pressures capable of forcing blood into the systemic circulation.[34] The heart in this circumstance merely functions as a conduit. Many studies have validated the thoracic pump mechanism during CPR.[31,76]

Another mechanism for blood flow generated during CPR is the abdominal pump. This emphasizes effects of abdominal compressions, which are now advocated for CPR.[77] The abdominal pump operates through arterial and venous components. The arterial component reflects compression of the abdominal aorta, forcing blood into the peripheral circulation. The aortic valve remains closed during abdominal compression and resists retrograde arterial flow. Simultaneously, the venous component fills the heart from venous pressure. Both contribute hemodynamic benefits during abdominal compressions in CPR.

Clearly, the cardiac, thoracic, and abdominal pump mechanisms are important concepts of CPR physiology. The technique(s) employed during CPR dictates which mechanism predominates. Other factors that can influence effectiveness of these pump mechanisms include: cycle rates, compression durations, body habitus, cardiac size, chest wall stiffness, and the presence of pulmonary disease, as well as the duration of the resuscitation effort. Understanding these mechanisms has led to improved CPR techniques and adjunctive devices, which are directed towards improved vital organ perfusion.

CPR TECHNIQUE AND MECHANICAL ADJUNCTS

The high mortality rates associated with cardiac arrest are in part attributed to inadequate perfusion generated by CCM. Therefore a number of adjunctive devices have been developed to enhance the effectiveness of CCM.

Active Compression-Decompression

Active compression-decompression (ACD) is one means for improving the effectiveness of CCM. Originating from successful resuscitation with a plunger, a device consisting of a handheld suction cup with a central piston was developed (Fig. 17-4). ACD-CPR can increase aortic pressures resulting in improved cerebral, coronary, and renal blood flow.[78] Ventricular filling and venous return are augmented by negative intrathoracic pressure during the active decompression phase. Two studies

CPR: Assessment, Adjuncts, and Alternatives. 2003; p 190*).

reported increased ROSC and 24-hour survival with the ACD device. Survival to discharge was higher with ACD in both studies but did not reach statistical significance.[79,80] Data from 2866 patients using the ACD device were subsequently combined.[81] ACD improved 1-hour survival, but long-term outcome was not significantly different from standard CPR. A randomized clinical trial demonstrated significantly improved 1-year survival following ACD compared with standard CPR.[82] Notably, a prospective trial found that combining ACD with controlled ventilation using an inspiratory impedance threshold device improved short-term survival when compared with standard CPR.[83]

Synchronizing chest and abdominal pumping techniques within the same compression cycle is another means for improving the effectiveness of CCM. Termed, "phased thoracic abdominal compression-decompression CPR" (PTACD-CPR), this technique employs abdominal compression during the relaxation phase of chest compression. Simplified applications involve compressing the chest and abdomen at equal durations. Initial clinical studies using PTACD-CPR yielded improvements in outcome measures.[84] Return of spontaneous circulation and survival to discharge were both significantly improved using PTACD-CPR for inpatient cardiac arrests.[84–86] A hand-held device has been developed that allows single rescuer PTACD-CPR combined with compression-decompression mechanics (Fig. 17-5). The method was deemed safe and effective by investigators.[54] Further studies are warranted to determine its potential impact on survival rates.

Noninvasive Mechanical Devices

Noninvasive mechanical devices have been developed to enhance the ergonomics of CPR. These devices assist in improving CPRs performance effectiveness, which can minimize the fatigue associated with performing CPR.

Fatigue becomes a particularly significant problem when attempting to perform ACD-CPR for extended periods of time. This led to developing an automatic chest compression device. Clinical applications have found its use feasible for out-of-hospital CPR.[87] Preliminary trials indicated the device improves the 30-day survival of patients suffering witnessed cardiac arrest.[88]

The pneumatic vest is another noninvasive mechanical device that alternates pressures around the thoracic cage (Vest-CPR). Vest-CPR utilizes a pneumatic bladder tailored to fit the chest wall. Air is forced into and out of the vest by a pneumatic drive. Clinical trials demonstrated improved outcomes with an increased rate of ROSC.[89] Another device has been described that employs a constricting band.[90] This portable device is currently available that provides mechanical vest-CPR (Fig. 17-6). Further trials are needed to determine the impact of vest-CPR devices on clinical outcomes.

Open Chest Cardiac Massage

Open chest cardiac massage is a valuable resuscitative method that is effective at returning blood flow during cardiac arrest. OCM was popularized by surgeons for resuscitation before 1960. The technique is currently advocated for specific circumstances such as cardiac arrest from penetrating chest trauma. Precluding effective CPR, OCM should also be considered for cardiac arrest resulting from hypothermia, massive pulmonary embolism, pericardial tamponade, intrathoracic hemorrhage, postcardiotomy arrest, and chest deformity. OCM is usually performed via a left lateral thoracotomy except after recent cardiac surgery for which the prior sternotomy is reentered. A

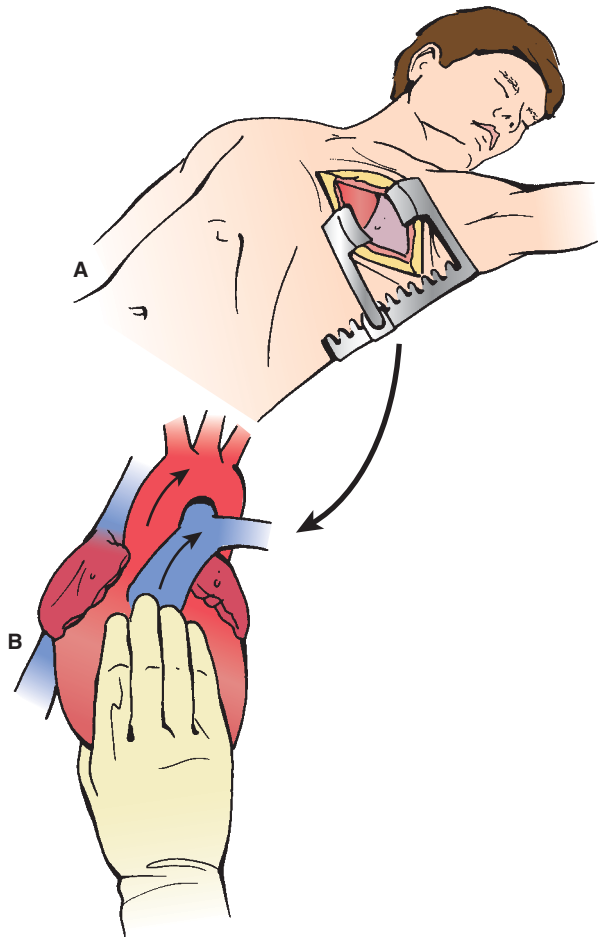

FIGURE 17-7 Technique of open chest cardiac massage. The heart is exposed via an anterolateral thoracotomy through the fifth intercostal space. The pericardium is opened if there is evidence of pericardial tamponade; otherwise, it is left intact. The heart is massaged at a rate of 60 to 80 beats per minute.

left thoracotomy is performed at approximately the fifth intercostal space. The pericardium is entered anterior to the phrenic nerve and the heart compressed between both hands. Alternatively, one-hand massage may be performed while using the other to control bleeding or occlude the descending thoracic aorta (Fig. 17-7).

Numerous studies have demonstrated superior hemodynamics during OCM compared with CCM.[91,92] Notable are increased diastolic pressures and reduced central venous pressures,[57] which favorably impacts coronary perfusion compared with CCM. Cardiac output and cerebral blood flow are higher during OCM,[92] explaining how OCM can successfully ROSC after failed efforts with CCM. However, outcomes cannot be expected to improve when OCM follows prolonged CPR.[93] Laboratory studies suggest that OCM can improve outcomes if applied after relatively short durations of ineffective CCM. A prospective, nonrandomized clinical trial illustrated the importance of instituting OCM earlier to improve outcome.[94] Patients who received OCM had improved outcomes, which declined as the duration of CCM before OCM increased.

Timely application of OCM can improve survival in a variety of clinical scenarios. One setting in which OCM has been used routinely is in the postcardiotomy ICU. One review strongly confirmed the benefit of open chest massage in patients suffering cardiac arrest following open heart surgery.[57] The study found that reopening the chest in this setting has the greatest potential benefit in patients arresting within 24 hours of surgery and performed within 10 minutes of cardiac arrest.

Potential complications of OCM include right ventricular perforation, hemorrhage, lung laceration, phrenic nerve injury, esophageal and aortic injury, cardiac lacerations, and empyema. Infection is surprisingly low (5%) given the nature of the procedure, and related limitations on sterile technique.

The intra-aortic balloon pump improves hemodynamics during CPR. However, its value in this setting appears limited.

Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB) has seen increased use for treating refractory cardiac arrest.[95] Hemodynamics, survival, and neurologic function are improved in experimental models of cardiac arrest treated with CPB versus standard CCM. Although clinical reports are uncontrolled, and frequently anecdotal, the growing body of evidence demonstrates CPB is efficacious for the treatment of not only cardiogenic shock,[131] but also cardiac arrest. It is noteworthy that several studies have demonstrated improved survival with good neurologic outcomes using CPB after prolonged periods of CPR. CPR efforts and patient selection are important considerations when interpreting these clinical results. Patients have been successfully bridged to transplantation utilizing CPB after cardiac arrest.[96–98]

Outcomes represented as percent of patients in which cannulation was attempted.

Most impressive are the improved outcomes when CPB was used to treat refractory cardiac arrest.[95,132,148] Because of the heterogeneity among these studies, it is difficult to arrive at objective selection criteria. There is also a paucity of reported complications. Therefore, future studies need to better define patient selection criteria and related risk/benefit considerations to guide CPB use (Table 17-2). Prognostic factors that are felt to be important include age, treatable conditions, adequacy of CPR, and timely intervention. Generally, CPB should be instituted within 30 to 45 minutes of witnessed arrests after more extended periods of CCM has been documented.[97,99] Clearly, CPB can result in successful resuscitation following prolonged periods of CPR in pediatric cases[100,101] and hypothermic cardiac arrests.

Hypothermic cardiac arrest is a unique category in which survival can follow prolonged cardiac arrest. CPB has a unique capability for rewarming during resuscitative circulatory support.[102,103] The largest experience in adults treated for hypothermia was reported from Finland.[104] Findings indicated that age and arterial pH at presentation had significant prognostic implications. The duration of CPR did not affect the likelihood of survival in these cases.

Direct Mechanical Ventricular Actuation

Direct mechanical ventricular actuation (DMVA) is a unique non–blood contacting device that provides systolic *and* diastolic actuation of the ventricular myocardium (Fig. 17-8). DMVA is pneumatically regulated with an atraumatic vacuum attachment. Rapid application is performed within minutes through a thoracotomy or sternotomy, which results in physiologic, pulsatile blood flow.[105,133] Pulsatile reperfusion probably best explains the improved neurologic outcome following resuscitative circulatory support using DMVA versus CPB in animals.[106–108] Lack of blood contact also circumvents the need for anticoagulants and reduces thromboembolic complications. DMVA has been used successfully in humans for bridge to transplantation, postcardiotomy support, and recovery from severe myocarditis.[105,134] Recent studies have demonstrated DMVA's favorable effect on maladaptive cell signaling when supporting the severely failing heart.[109,110] Myocardial strain analysis has demonstrated myocardial function improves within 10 minutes of DMVA resuscitative circulatory support.[111] Particularly notable are the findings of improved neurologic function following resuscitative support with DMVA versus CPB. DMVA's unique ability to provide

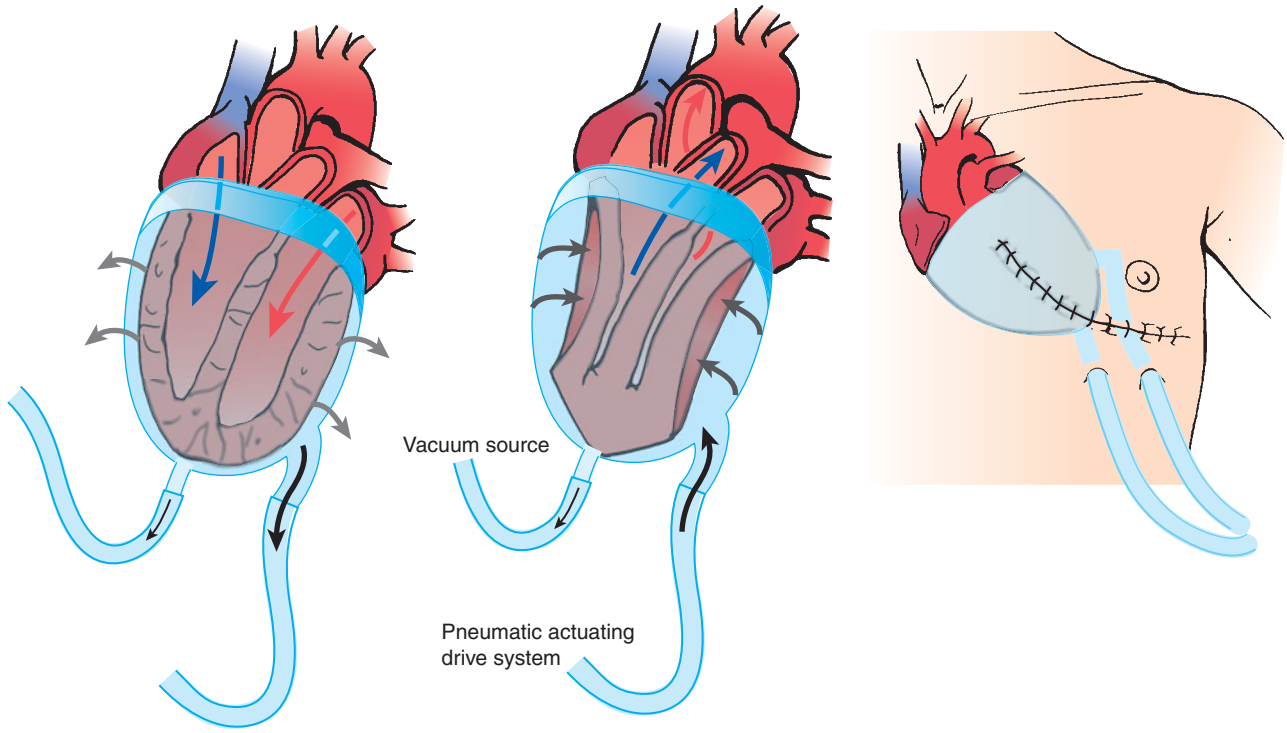

FIGURE 17-8 Direct mechanical ventricular actuation (DMVA). The ventricles are encompassed by a pneumatically driven device that is vacuum attached to the arrested heart.

immediate pulsatile reperfusion may best explain its beneficial impact on cerebral resuscitation.

CEREBRAL PROTECTION/RESUSCITATION

The goal of CPR is to provide sufficient blood flow to vital organs until definitive intervention. The brain is the organ most vulnerable to ischemia during cardiac arrest. Consciousness is lost in seconds, high-energy phosphates and glycogen stores are depleted in minutes with lactic acid accumulation causing secondary cytotoxic effects. Limited cerebral blood flow actually may exacerbate the sequelae by allowing anaerobic metabolism. These circumstances help explain why CPR out-of-hospital cardiac arrest results in so few neurologically intact survivors.[112]

Given the importance of cerebral resuscitation, it has been suggested that current CPR protocols put too much emphasis on ventilation. Cardiocerebral resuscitation appears to convey more appropriate emphasis on the brain and fosters the development of new treatment paradigms.[113] Recent examples include recommended techniques when performing basic CPR. The reluctance to perform mouth-to-mouth ventilation has led to guidelines for cardiac only resuscitation (chest compressions only). Data from multicenter trials have found cardiac only resuscitation may lead to improved survival and neurologic outcome.[30] The findings are best explained by improvements in cerebral blood flow. Specifically, chest compressions are used to initiate CPR and are not interrupted for ventilation.

CCM generates limited blood flow. During CPR, only venous valves can prevent transmission of high, intrathoracic pressures to the jugular venous system. Cerebral blood flow is kept at 50 mL/min/100 g by autoregulation when cerebral perfusion pressures are in the normal physiologic range.[114] CPR results in low cerebral perfusion pressures, seldom exceeding 40 mm Hg.[115] Cerebral flow is only 10 to 15% of normal, which may be more harmful than no flow at all.

Mechanical circulatory support is an obvious means for improving cerebral blood flow during CPR. This is supported by the growing body of clinical evidence indicating the implementation of CPB after failed CPR attempts improves outcomes. Laboratory investigations have demonstrated pulsatile flow is superior to nonpulsatile flow with regard to cerebral resuscitation. Pulsatile reperfusion results in favorable flow to the gray matter,[106] which correlates with increased postresuscitation cerebral high energy phosphate content.[107] Cerebral function and histopathology are significantly improved following pulsatile versus nonpulsatile reperfusion.[108,135]

There are other critical aspects related to cerebral resuscitation, which deserve further consideration. Neurons function for up to 60 minutes during ischemia. However, reperfusion can cause neuronal damage that is multifactorial in origin. Calcium overload, free-radical injury, and no-reflow phenomenon may all contribute to reperfusion injury.[114] No-reflow describes states of hypoperfusion that follow cerebral ischemia. Platelet aggregation, altered calcium flux, vasoconstriction, and pericapillary edema are all presumed causative factors. Intracranial pressure may not be as important because it commonly returns to normal after cardiac arrest except after cerebral trauma. Cerebral blood flow remains depressed for 18 to 24 hours after a severe ischemic insult. Subsequent hypoperfusion is believed secondary to calcium-induced precapillary vasoconstriction.

Cerebral blood flow after ischemic injury is critically dependent on perfusion pressure. Moderate hypotension can further cerebral ischemia and injury. Blood pressure should be normal or mildly elevated in the post-resuscitation period. Moderate hyperoxia (PO_2 = 100 mm Hg) and mild hyperventilation ($PaCO_2$ = 30 to 35 mm Hg) are desirable. Arterial pH is kept in the normal range. Anticonvulsants are given as needed, because seizures are not uncommon after ischemic brain injury.

One of the most significant advances in cerebral resuscitation has been the implementation of therapeutic hypothermia. Mild hypothermia decreases mortality and improves neurologic recovery after cardiac arrest. Two randomized, controlled, clinical trials[116,117] confirmed this association. This led to new AHA recommendations for therapeutic hypothermia.[118] The subsequent meta-analysis qualified these recommendations.[119] More recently, observational studies from growing clinical databases have found the safety and efficacy of hypothermia can be extended to routine clinical practice.[120,121] A new clinical device is now available to selectively chill the brain using intra-nasal cooling (Fig. 17-9). Further trials will be needed to demonstrate its effectiveness.

Other considerations after ROSC include continuous hemodynamic monitoring, and use of supplemental oxygen. Antiarrhythmics are continued as arrhythmias commonly occur from increased circulating catecholamines. Beta-adrenergic blockade should be instituted, unless bradycardia is a problem. Bradycardia requires airway and ventilation be carefully assessed. Atropine, epinephrine, and/or pacing are indicated if hypotension accompanies bradyarrhythias.

Antiarrhythmics, pacemakers, and automatic internal cardiodefibrillators are also important considerations for patients surviving sudden death. Clinical studies have shown survival can be significantly improved with these interventions.[72,122,123] Amiodarone has also been shown to be effective in this regard.

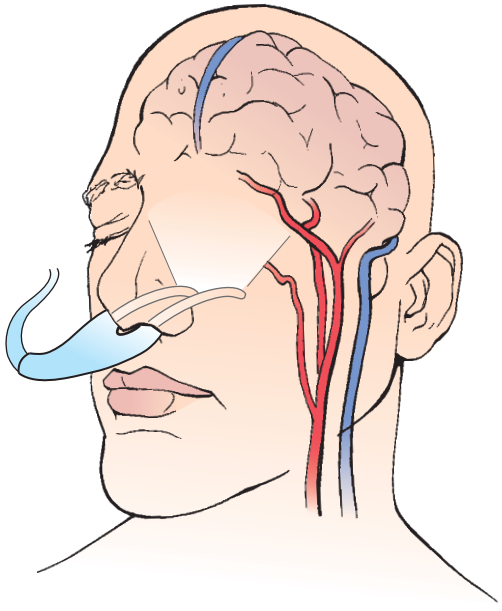

FIGURE 17-9 The RhinoChill delivers an intra-nasal agent to selectively cool the brain. (*Reproduced with permission from BeneChill, Inc., San Diego, CA.*)

Predicting which patients will survive resuscitation efforts remains elusive. Patients presenting in VF/VT have a better prognosis compared with asystole or PEA.[11,41,47] Advanced age may not be a prognostic indicator when considering other comorbidities.[11,12,42,47] Location of the arrest (ICU versus non-ICU) also impacts outcome.[11,12] Comorbid conditions are associated with more than 95% of mortalities after cardiac arrest including renal failure, metastatic cancer, pneumonia, sepsis, hypotension, stroke, and homebound lifestyle.[11] Survival is more likely for witnessed arrests, early defibrillation CPR initiated within 5 minutes, CPR durations less than 15 minutes, and postresuscitation hypothermia is implemented. Mortality increases from 44% for CPR less than 15 minutes to 95% for CPR that is longer in duration.[11,42]

In contrast to inpatients, where comorbidities play a major role, delayed therapy outweighs all other prognostic factors for out-of-hospital arrests. Other key determinants for survival include the initial rhythm, witnessed arrest, downtime before CPR, and any delay in treatment. Early definitive care is associated with improved outcome. As with in-hospital arrest, VF/VT has the best prognosis, and bystander CPR is strongly associated with improved survival rates.[118] Decreased mortality from bystander CPR is primarily from reduced postresuscitation anoxic encephalopathy. Return of consciousness within 24 to 48 hours of arrest is a favorable prognostic sign.[11] Therapeutic hypothermia has significantly enhanced the likelihood of neurologic recovery and survival.

Long-term survival in patients discharged after an out-of-hospital arrest is very reasonable. Reported 1-year survival rate ranges from 75 to 85%, and approximately 50% are still alive at four years (see Table 17-1). The majority of these patients ultimately die of cardiac causes.[14,124] Positive predictors for long-term survival are: cardiac arrest associated with acute myocardial infarction (MI), no prior history of MI, and also short-time intervals between arrest, CPR, and definitive care.[125] Primary antiarrhythmic events, congestive heart failure, impaired left ventricular function, extensive coronary artery disease, and complex premature ventricular depolarizations are less likely to result in long-term survival after discharge.

Unfortunately, not all patients who survive sudden death have a subsequent good quality of life.[126] Depression is a common problem following discharge, but usually resolves within a few months.[11] The incidence and characteristics of mental impairment in those who survive is variable. Significant neurologic impairment usually results in death before hospital discharge. While neurologic deficits can be very disabling,[127,134] many survivors of sudden death retain normal neurologic function.

ETHICAL CONSIDERATIONS

Resuscitation efforts should be discontinued when ACLS efforts do not result in ROSC. Discontinuation is based on clinical judgment. Although several studies have shown that CPR for longer than 30 minutes is unlikely to result in long-term

survival. There are many growing reports of neurologically intact survivors after prolonged resuscitation.[11] This is particularly evident when examining the use of mechanical circulatory support. Considerations for discontinuing ACLS should also include underlying medical conditions.

CONCLUSION

Early defibrillation, effective BLS, and timely ACLS measures represent the major theme in the treatment of cardiac arrest. Unfortunately, survival rates have remained disappointingly low. A more appropriate focus on cerebral resuscitation should substantially improve future clinical outcomes. The use of circulatory support in patients that fail initial ACLS efforts has clearly demonstrated promise when initial resuscitation efforts fail. Defining qualified selection criteria and treatment protocols will require further study. Additionally, it will be important to implement those therapies that improve neurologic recovery. Therapeutic hypothermia has clearly had one of the greatest recent impacts in this regard. Integrating hypothermia, resuscitative circulatory support devices, and cerebroprotective agents has compelling potential. They can justify and help guide future clinical trials. New paradigms and treatment protocols for CPR may evolve from these critically needed investigations.

CHAPTER 18

Temporary Mechanical Circulatory Support

Edwin C. McGee, Jr.
Nader Moazami

INTRODUCTION

A number of ventricular assist devices (VADs) are available for acute circulatory support. As opposed to long-term VADs, which are designed for bridge to transplantation or long-term support in the nontransplant patient, temporary VADs are designed to reestablish adequate organ perfusion rapidly. Patients in cardiogenic shock require early aggressive therapy. Despite relief of ischemia, inotropic drugs, and control of cardiac rhythm, some patients remain hemodynamically unstable and require some type of mechanical circulatory support in order to restore a normal cardiac output. Cardiogenic shock occurs in 2.4 to 12% of patients with acute myocardial infarction (AMI).[1] The Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial demonstrated mortality of greater than 50% despite revascularization.[2] If instituted promptly, temporary mechanical support potentially leads to improved survival in this group of patients.[3] The need for circulatory support in the postcardiotomy period is relatively low and has been estimated to be in the range of 0.2 to 0.6%,[4] but when it occurs, it needs to be managed effectively if the patient is to be salvaged. Additional indications for acute VADs are in chronic heart failure patients who suffer cardiovascular collapse, and severe cases of myocarditis and postpartum cardiomyopathy.

All practicing cardiac surgeons should have an understanding of current devices, and have at least one of these support systems available. Studies show that even smaller facilities that do not have advanced heart failure programs can have improved patient survival if a device can be implemented rapidly and the patient is transferred to a tertiary care facility with expanded capabilities.[5]

This chapter describes the devices currently available, indications for support, patient management, and the overall morbidity and mortality associated with temporary mechanical support. In addition, it describes some of the more promising devices that have just received approval or are currently undergoing trial. The goal of all temporary assist devices is to alleviate shock and establish an environment in which the native heart and end organs can recover. If recovery is unlikely, then a bridge to a long-term device, typically for bridging to a transplant (see Chapters 64 and 66), may be the best strategy. Rarely should individuals be supported directly to heart transplantation from an acute support device, because the newer generations of long-term devices typically provide more reliable support and allow for better rehabilitation in an out-of-hospital setting (see Chapter 66). In select patients, it may be possible to bridge a patient who is not a transplant candidate to a long-term device.

COUNTERPULSATION

Historical Notes

Intra-aortic balloon pumps (IABPs) are often the first line of mechanical assistance utilized for patients in cardiogenic shock. The concept of increasing coronary blood flow by counterpulsation was demonstrated by Kantrowitz and Kantrowitz in 1953 in a canine preparation and again by Kantrowitz and McKinnon in 1958 using an electrically stimulated muscle wrap around the descending thoracic aorta to increase diastolic aortic pressure.[6] In 1961, Clauss and colleagues used an external counterpulsation system synchronized to the heartbeat to withdraw blood from the femoral artery during systole and reinfuse it during diastole.[7,8] One year later, Moulopoulos and colleagues produced an inflatable latex balloon that was inserted into the descending thoracic aorta through the femoral artery and inflated with carbon dioxide.[8] Inflation and deflation

were synchronized to the electrocardiogram to produce counterpulsation that reduced end-systolic arterial pressure and increased diastolic pressure. In 1968, Kantrowitz reported survival of one of three patients with postinfarction cardiogenic shock refractory to medical therapy using an intra-aortic balloon pump.[9] These pioneering studies introduced the concept of supporting the failing circulation by mechanical means. Currently, intra-aortic balloon counterpulsation is used in an estimated 70,000 patients annually.[6]

Physiology

The major physiologic effects of the IABP are a concomitant reduction in left ventricular afterload along with an increase in coronary perfusion pressure secondary to an increase in aortic diastolic pressure.[10] Important related effects include reduction in left ventricular systolic wall tension and oxygen consumption, reduction in left ventricular end-systolic and end-diastolic volumes, reduced preload, and an increase in coronary artery and collateral vessel blood flow.[11] Cardiac output increases because of improved myocardial contractility owing to increased coronary blood flow and the reduced afterload and preload, but the IABP does not directly move or significantly redistribute blood flow.[12] Intra-aortic balloon pump counterpulsation reduces peak systolic wall stress (afterload) by 14 to 19% and left ventricular systolic pressure by approximately 15%.[12] Because peak systolic wall stress is related directly to myocardial oxygen consumption, myocardial oxygen requirements are reduced proportionately. As measured by echocardiography and color-flow Doppler mapping, peak diastolic flow velocity increases by 117% and the coronary flow velocity integral increases by 87% with counterpulsation.[13] Experimentally, collateral blood flow to ischemic areas increases up to 21% at mean arterial pressures greater than 90 mm Hg.[14]

Several variables affect the physiologic performance of the IABP. The position of the balloon should be just downstream of the left subclavian artery (Fig. 18-1). Diastolic augmentation of coronary blood flow increases with proximity to the aortic valve.[15] The balloon should fit the aorta so that inflation nearly occludes the vessel. Experimental work indicates that for adults, balloon volumes of 30 or 40 mL significantly improve both left ventricular unloading and diastolic coronary perfusion pressure when compared with smaller volumes. Inflation should be timed to coincide with closure of the aortic valve, which for clinical purposes occurs at the dicrotic notch of the aortic blood pressure trace (Fig. 18-2). Early inflation reduces stroke volume, increases ventricular end-systolic and -diastolic volumes, and increases both afterload and preload. Diastolic counterpulsation is visualized easily as a pressure curve in the arterial waveform and indicates increased diastolic perfusion of the coronary vessels (and/or bypass grafts).[16] Deflation should occur as late as possible to maintain the duration of the augmented diastolic blood pressure but before the aortic valve opens and the ventricle ejects. For practical purposes, deflation is timed to occur with the onset of the electrocardiographic R wave. Active deflation of the balloon creates a suction effect

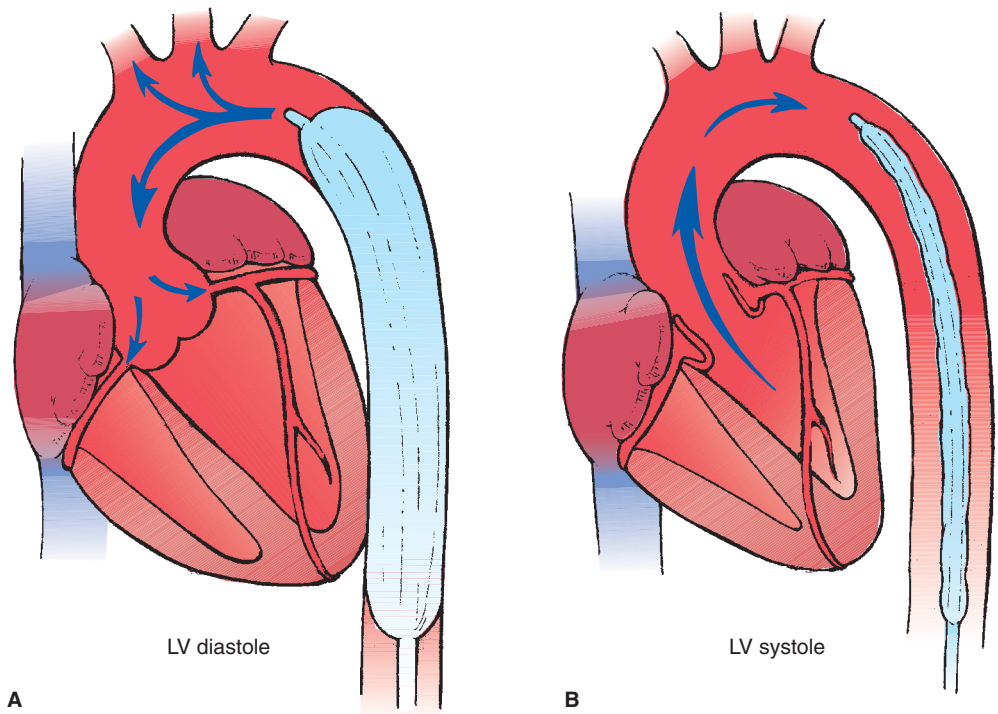

FIGURE 18-1 (A) Balloon inflation during left ventricular (LV) diastole occludes the descending thoracic aorta, closes the aortic valve, and increases proximal coronary and cerebral perfusion. (B) Balloon deflation during LV systole decreases LV afterload and myocardial oxygen demand.

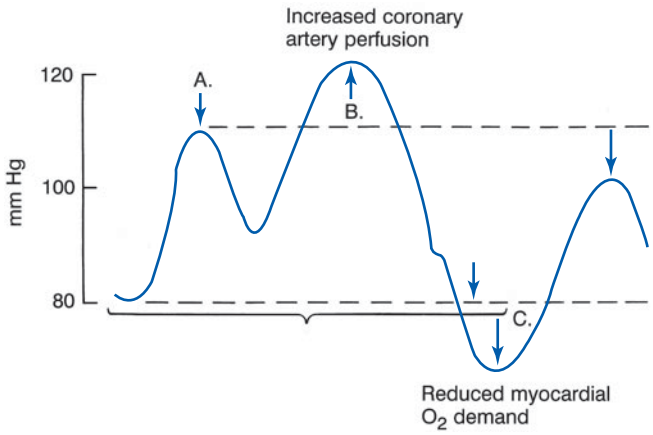

FIGURE 18-2 Illustration showing the effect of the intra-aortic balloon on aortic pressure. After ejection produces the pulse (A), inflation of the balloon increases aortic diastolic pressure (B). At end diastole, sudden deflation reduces aortic end-diastolic pressure (C) below that of an unassisted beat and reduces afterload and myocardial oxygen demand.

that acts to decrease left ventricular afterload (and therefore myocardial oxygen consumption).

Biologic factors that influence the in situ hemodynamic performance of the IABP include heart rate and rhythm, mean arterial diastolic pressure, competence of the aortic valve, and compliance of the aortic wall. Severe aortic regurgitation is a contraindication to use of the IABP as a very low mean aortic diastolic pressures reduce aortic root pressure augmentation and coronary blood flow. A calcified, noncompliant aorta increases diastolic pressure augmentation but risks injury to the aortic wall. On the other hand, young patients with a highly elastic, compliant aorta may manifest decreased diastolic pressure augmentation.

By far the most important biologic variables are heart rate and rhythm. Optimal performance requires a regular heart rate with an easily identified R wave or a good arterial pulse tracing with a discrete aortic dicrotic notch. Current balloon pumps trigger off the electrocardiographic R wave or the arterial pressure tracing. Both inflation and deflation are adjustable, and operators attempt to time inflation to coincide with closure of the aortic valve and descent of the R wave. During tachycardia, the IABP usually is timed to inflate every other beat; during chaotic rhythms, the device is timed to inflate in an asynchronous fixed mode that may or may not produce a mean decrease in afterload and an increase in preload. In unstable patients, every effort is made to establish a regular rhythm, including a paced rhythm, so that the IABP can be timed properly. The newer-generation IABP consoles come with algorithms that select the most appropriate trigger mode and time inflation and deflation automatically.

Indications

The traditional indications for insertion of the IABP are cardiogenic shock, uncontrolled myocardial ischemic pain, and postcardiotomy low cardiac output.[17] In recent years, indications for IABP have broadened to include patients with high-grade left main coronary artery stenosis, high-risk or failed percutaneous transluminal coronary angioplasty, atherectomy, or stents; patients with poorly controlled ventricular arrhythmias before or after operation; and patients with postinfarction ventricular septal defect (VSD) or acute mitral insufficiency after myocardial infarction (MI).[18] In addition, the IABP occasionally is used prophylactically in high-risk patients with poor left ventricular function (LVF) with either mitral regurgitation or preoperative low cardiac output owing to hibernating or stunned myocardium. These patients may benefit from temporary afterload reduction during weaning from cardiopulmonary bypass, particularly if myocardial contractility is not improved immediately by revascularization. In some institutions, a femoral artery catheter is inserted in anticipation of IABP use in patients undergoing complex procedures who have myocardial dysfunction. Some groups routinely insert an IABP before insertion of more long-term left ventricular assist systems to optimize perfusion and right ventricular function.

Techniques of Insertion

The IABP usually is inserted into the common femoral artery either by the percutaneous technique or surgical cut down. A cut down is used most often during cardiopulmonary bypass when the pulse is absent. The superficial femoral artery is avoided because of its smaller size and increased possibility of leg ischemia. For patients with small vessels, a 7-French catheter without a sheath is recommended to lessen the possibility of leg ischemia. The iliac and axillary arteries and, very rarely, the abdominal aorta are infrequently used alternate sites.[19,20] Direct insertion into the ascending aorta is used intraoperatively in patients with severe aortoiliac or femoral occlusive disease that prevents passage of the balloon catheter.[21,22]

An IABP is inserted using Seldinger's technique. Although percutaneous insertion was associated with a higher incidence of leg ischemia in the past, this is no longer true. In the catheterization laboratory, both the guidewire and balloon are monitored by fluoroscopy, but this is not essential if not readily available. In the operating room, the guidewire and balloon are typically placed and positioned under echocardiographic guidance.[23] The catheter can be inserted without the sheath in some instances.[24] The balloon catheter usually fits snugly in the arterial wound, so a pursestring suture is not needed. If bleeding is present around the entrance site, sutures are used for control.

The timing of inflation and deflation of the balloon must be monitored closely during counterpulsation. This usually is done easily by observing the continuously displayed arterial pressure tracing; a second systolic pulse should appear with every heartbeat and begin just after the smaller first pulse begins to decay. Timing the balloon for irregular rhythms is difficult, and the circulatory support provided by the balloon is compromised. In these patients, attempts are made to convert the patient to a sinus or paced rhythm or to slow (80 to 90 beats per minute) atrial fibrillation using appropriate drugs or cardioversion. For tachycardias greater than 110 to 120 beats per minute, the balloon is timed to provide inflation on alternate

beats if the machine is not able to follow each beat reliably. Generally, patients are not given heparin for the IABP, but the practice varies from center to center. The exit site of the catheter must be kept clean with antiseptics and covered in an effort to prevent local infection or septicemia.

A percutaneous IABP can be removed without exposing the femoral puncture site. The exit site is prepped and securing sutures are cut. The balloon catheter is disconnected from the pump and completely deflated using a 50-mL syringe. The balloon is removed, and retrograde bleeding is allowed from the femoral artery, which theoretically flushes any distal clot into the wound. The femoral artery then is compressed, and antegrade flushing then is allowed. Finally, steady nonocclusive pressure is held over the femoral puncture site. Pressure is maintained over the puncture site for 30 minutes to ensure that thrombus closes the hole. If the balloon is inserted via a cut down, the balloon preferably is removed in the operating room. The puncture site is closed with sutures. If blood flow to the lower limb is impaired after removal, a local thromboembolectomy using Fogarty catheters and potentially an angioplasty procedure with a vein patch are done to restore full flow to the limb.

If the percutaneous needle punctures the iliac artery above the inguinal ligament intentionally or inadvertently in obese individuals, removal should be done through a surgical incision in the operating room because the backward slope of the pelvis makes pressure difficult to maintain after withdrawal, and substantial occult retroperitoneal bleeding may occur.

If the common femoral or iliac arteries cannot be used because of occlusive disease or inability to advance the guidewire, the axillary artery usually is exposed below the middle third of the clavicle for insertion.[19,20] This vessel is smaller than the femoral artery but generally more compliant. Fluoroscopy or transesophageal echocardiography is recommended to ensure that the guidewire does not advance into the ascending aorta.

Transaortic insertion of an IABP can be done for postcardiotomy patients who have severe peripheral vascular or aortoiliac disease that precludes femoral insertion. A more effective strategy in such patients would be direct placement of a direct support VAD.

Complications

Reported complication rates of the IABP vary between 12.9 and 29% and average approximately 20%.[25] Life-threatening complications are rare. Leg ischemia is by far the most common complication (incidence 9 to 25%); other complications include balloon rupture, thrombosis within the balloon, septicemia, infection at the insertion site, bleeding, false aneurysm formation, lymph fistula, lymphocele, and femoral neuropathy.[26] There is no significant difference in limb ischemia in the different types of IABPs clinically available.[25,27]

Balloon rupture occurs in approximately 1.7% of patients and usually is manifested by the appearance of blood within the balloon catheter and only occasionally by the pump alarm. Rupture may be slightly more common with transaortic insertion. Although helium usually is used to inflate the balloon, gas embolism has not been a problem. If rupture occurs, the balloon should be deflated forcibly to minimize thrombus formation within the balloon and should be promptly removed. If the patient is IABP-dependent, a guidewire is introduced through the ruptured balloon, the original balloon is removed, and a second balloon catheter is inserted over the wire. If the ruptured balloon is not removed easily, a second balloon is inserted via the opposite femoral or iliac artery or through the axillary artery to maintain circulatory support.

Removal of a kinked or thrombosed ruptured balloon that cannot be withdrawn easily requires operation because it can severely lacerate the iliac or femoral artery upon removal and lead to uncontrollable hemorrhage. The catheter should be withdrawn as far as possible until resistance is met. The location of the tip should be determined by x-ray or ultrasound, and an incision should be planned to expose that segment of the vascular system. The trapped balloon is removed through an arteriotomy after control of the vascular segment is obtained.

Although the incidence of clinically significant lower leg ischemia varies in from 9 to 25% of patients, up to 47% have evidence of ischemia during the time the IABP is used.[26] Thus, the preinsertion status of the pedal pulses should be determined and recorded before the IABP is inserted in every patient. After insertion, the circulation of the foot is followed hourly by palpating pulses or Doppler ultrasound. Foot color, mottling, temperature, and capillary refill are observed. The appearance of pain, decreased sensation, and compromised circulation indicates severe ischemia that requires restoration of the circulation to the extremity as soon as possible. There are three alternatives. If the patient is not balloon-dependent, the balloon is removed immediately. In the majority of patients, this relieves the distal ischemia; a few patients require surgical exploration of the puncture site, removal of thrombus and/or emboli, and reconstruction of the femoral artery. If the patient is balloon-dependent, a second balloon catheter can be introduced into the opposite femoral or iliac artery and the first removed. Several risk factors for development of leg ischemia have emerged. Female gender, peripheral vascular disease, diabetes, cigarette smoking, advanced age, obesity, and cardiogenic shock are reported to increase the risk of ischemic complications after IABP. Because the IABP is inserted for compelling indications, identification of risk factors does not influence management, except to encourage removal of the device as soon as the cardiac status of the patient allows. In some series, longer duration of IABP counterpulsation is associated with an increased risk of complications.[26] Although most ischemic complications are the result of impairment of arterial inflow, severe atherosclerotic diseases of the descending thoracic aorta may produce embolization of atherosclerotic material. Approximately 1% of patients develop false aneurysms at the femoral puncture site either in the hospital or shortly after discharge, and rare patients develop an arteriovenous fistula. Both conditions are confirmed readily by duplex scanning.

Results

Very few complications of IABP cause death. Rare instances of bleeding (retroperitoneal or aortic), septicemia, central nervous system injury, or aortic dissection may cause or contribute to a patient's death. Mortality is higher in patients with ischemic leg complications than in those without this complication.

Without revascularization, IABP produces a marginal increase in survival, but with revascularization, both short- and long-term survival as well as quality of life have been shown to be improved.[28] However, mortality is high in patients who receive an IABP because of the cardiac problems that led to the need for the device. Overall hospital mortality ranges from 26 to 50%.[29,30] Risk factors for hospital mortality include advanced age, female gender, high New York Heart Association (NYHA) class, preoperative nitroglycerin, operative or postoperative insertion, and transaortic insertion in one study and age and diabetes mellitus in another. A third study correlates hospital death with AMI, ejection fraction of less than 30%, NYHA class IV, and prolonged aortic cross-clamp and bypass times.[30] Time of insertion affects hospital mortality. Preoperative insertion is associated with a mortality of 18.8 to 19.6%.[17] Mortality for intraoperative insertion is 27.6 to 32.3%.[17] Postoperative insertion produces a mortality of 39 to 40.5%. Mortality is highest at 68% for patients with pump failure, lowest at 34% for patients with coronary ischemia, and 48% for patients who had a cardiac operation. Long-term survival varies with the type of operation and is highest in patients who had cardiac transplantation or myocardial revascularization.[17] Patients who received an IABP and required valve surgery with or without revascularization have a poorer prognosis. Creswell and colleagues found 58.8% of all patients alive at 1 year and 47.2% alive at 5 years. Naunheim and associates found that nearly all survivors were in NYHA class I or II.[31] Approximately 18% of hospital survivors have some symptoms of lower extremity ischemia.

Given the overall ease of IABP insertion, excellent physiologic augmentation of coronary blood flow and left ventricular unloading, this form of therapy should be considered as the first line of mechanical support in patients who do not have significant peripheral vascular disease. There is some suggestion that preoperative prophylactic IABP insertion in high-risk patients (eg, left ventricular ejection fraction [LVEF] of less than 40%, unstable angina, left main stenosis of greater than 70%, or redo coronary artery bypass grafting [CABG]) can improve cardiac index, length of intensive care unit (ICU) stay, and reduce mortality.[32] However, with meticulous myocardial protection and the judicious use of inotropes, such as epinephrine and milrinone, most groups experienced in dealing with such high-risk patients do not find routine IABP insertion helpful. When an IABP is used, it is important to understand that it is not the final therapy in terms of mechanical support for the failing heart. If the shock state persists, as evidence by a depressed cardiac index, then some form of direct mechanical support must be implemented so as to restore adequate end-organ perfusion. Failure to adequately treat a patient in cardiogenic shock will most assuredly result in the patient's demise.

DIRECT CIRCULATORY SUPPORT

Background

The need for acute cardiac support beyond cardiopulmonary bypass was clear from the early days of cardiac surgery. Spencer and colleagues reported the first successful clinical use of a temporary device in 1965 after four patients were placed on femoral-femoral cardiopulmonary bypass. Only one patient survived to discharge. Subsequently, in 1966, the first successful use of a left ventricular assist device was reported after a double-valve operation.[33] DeBakey used an assist device that was implanted in an extracorporeal location between the left atrium and the axillary artery, marking the first use of an extracorporeal temporary device support system. The patient survived for 10 days on the pump, eventually was discharged home, and became a long-term survivor.

The excitement surrounding these events prompted the formation of the Artificial Heart Program in 1964 and propelled the National Heart Institute to support and encourage the development of mechanical circulatory support systems. One of the objectives of this program was to promote the development of a support system that would be used in cases of acute hemodynamic collapse.

Ideal Device

Despite recent advances in biotechnology, recognition of many of the problems and complications associated with extracorporeal circulation has delineated the limitations of these devices. The components of an ideal device must overcome some of the existing problems.

An ideal device should be capable of supporting adequate flow, maximizing hemodynamics, and unloading the ventricle for patients of all sizes. Current devices have addressed the problem associated with variations in patient size by being designed as extracorporeal systems. Therefore, by virtue of having small-diameter cannulae transversing the chest, the pumps can support patients with varying body surface area. The disadvantage of such a system is the potential for driveline and mediastinal infections. In addition, the length of the cannula between the heart and the device, particularly the inflow cannula, predisposes to areas of stasis and potential thrombus generation. All current pumps require anticoagulation, which increases the ever-present threat of early postoperative bleeding. In addition, requirements for transfusion of large amounts of coagulation factors and platelets enhance the inflammatory response that is induced by surgery and is further perpetuated by the circuit. Activation of the contact and complement systems and the release of cytokines by leukocytes, endothelial cells, and macrophages further increase the potential negative and detrimental effects of use of temporary assist devices.[34,35] The ensuing inflammatory cascade and volume overload can have detrimental effects on the pulmonary vascular resistance and lead to right ventricular overload, often necessitating the addition of a right ventricular assist device.

Current temporary assist devices all have the capability of biventricular support as needed, provided that the lungs can support oxygenation and ventilation. In cases of acute lung injury superimposed on circulatory failure, extracorporeal life support (ECLS) can be configured with conventional or the more recent centrifugal pumps.

The multitude of clinical scenarios that often lead to the need for mechanical support all require that support be instituted in an expeditious manner. Therefore, all current devices

TABLE 18-1 Characteristics of an Ideal Temporary Support Device

Accommodates patients of all sizes, regardless of body surface area
Easy to insert
Maximizes hemodynamics while unloading the heart to allow for myocardial recovery
Is adaptable for patients who require biventricular support
Supports the use of an oxygenator as needed, particularly in the group of patients with acute lung injury
Requires minimal anticoagulation
Has a biocompatible surface that does not promote thrombus generation
Causes minimal destruction of blood or plasma components
Allows for ambulation and physical rehabilitation
Converts easily to a long-term implantable device

must be easily implantable. In the postcardiotomy setting with access to the great vessels, the cannulae should allow the versatility of choosing any inflow or outflow site that is clinically indicated (see the following). In an active resuscitative setting, such as cardiac arrest in the catheterization laboratory, in which time is critical and transport to the operating room often impractical, percutaneous cannulation must be an option.

Table 18-1 summarizes some of the components of an ideal temporary support device. At present, no single device is inclusive of all the components. Until the rapid innovations in this field lead to the development of an ideal device, the currently available technology must be tailored to the specific requirements of each patient, taking into consideration the duration of support needed.

Indications for Support and Patient Selection

A wide range of indications exist for acute mechanical support, the primary goal of all being rapid restoration of the circulation and stabilization of hemodynamics. The routine use of transesophageal echocardiography (TEE) has helped greatly in assessing the etiology of cardiogenic shock by allowing evaluation of ventricular function, regional wall motion abnormalities, and valvular mechanics. In a patient with mechanical complications secondary to MI such as acute rupture with tamponade, acute papillary muscle rupture, or postinfarction VSD, emergent surgical correction may obviate the need for device support. Similarly, in the postcardiotomy setting with failure to separate from cardiopulmonary bypass, TEE may direct the surgeon to the need for additional revascularization and reparative valve surgery and successful weaning from bypass.

If echocardiography fails to reveal a surgically correctable cause for cardiogenic shock, most surgeons use hemodynamic data to consider the need for mechanical assistance. These criteria include a cardiac index of less than 2.2 L/min/m^2, systolic blood pressure of less than 90 mm Hg, mean pulmonary capillary wedge pressure or central venous pressure of greater than 20 mm Hg, and concomitant use of high doses of at least two inotropic agents.[36] These situations may be associated clinically with arrhythmias, pulmonary edema, and oliguria. In such circumstances, use of an IABP may be considered as the first step. In the postcardiotomy setting, the preceding hemodynamic criteria, in absence of mechanical support, are associated with a greater than 50% chance of mortality.[29] In this setting, some believe that earlier implantation of an assist device capable of supporting higher flows and allowing the heart to rest may improve results and allow for recovery of stunned myocardium.[37] Furthermore, new pharmacologic agents such as the phosphodiesterase inhibitor milrinone, nitric oxide, and vasopressin have helped to optimize hemodynamics during this critical initial period, reducing the need for concomitant right ventricular support.[38,39]

Once mechanical assistance has been instituted, the stabilized patient can undergo periodic evaluation to assess native heart recovery, end-organ function, and neurologic status. If appropriate, evaluation for cardiac transplantation ensues. Patients without malignancy, severe untreated infection, or neurologic deficit and who are not at an advanced age are selected for cardiac transplantation if all other criteria are met, and there is no sign of cardiac recovery. In this subgroup, we generally transition to a chronic ventricular assist device until an organ becomes available. In patients with gradual improvement in myocardial pump function, the devices may be weaned and removed.

DEVICES

Devices currently approved by the Food and Drug Administration (FDA) for temporary support include centrifugal pumps, roller pumps, venoarterial extracorporeal membrane oxygenation (ECLS, ECMO), the ABIOMED blood pumps and Impella devices, the Thoratec paracorporeal pump (PVAD), CentriMag (Levitronix, LLC), and the TandemHeart system (CardiacAssist, Inc). A number of other devices are undergoing investigation for short-term support.

Continuous-Flow Pumps

Two types of pumps are available commercially for extracorporeal circulation: roller pumps and centrifugal pumps. In adults, roller pumps are used rarely, if ever, for temporary circulatory support beyond routine cardiopulmonary bypass applications because of important disadvantages. Although inexpensive, roller pumps are insensitive to line pressure and require unobstructed inflow. Additionally, roller pumps may cause spallation of tubing particles and are subject to tubing failure at unpredictable times. These systems require constant vigilance and are difficult to operate for extended periods. Use of roller pumps beyond 4 to 5 hours is associated with hemolysis and, for this reason, is inappropriate for mechanical assistance that may involve several days to weeks of support.[40] Axial flow pumps, in which the pump rotor is parallel to the blood path, have entered the field of temporary support with the introduction of

the Impella devices,[41] but most of the experience with temporary support devices has been with centrifugal pumps.

Centrifugal Pumps

Centrifugal pumps are familiar assist systems because of their routine use in cardiopulmonary bypass. In these devices, the blood path is perpendicular to rotor. Although many different pump-head designs are available, they all work on the principle of generating a rotary motion by virtue of moving blades, impellers, or concentric cones. These pumps generally can provide high flow rates with relatively modest increases in pressure. They require priming and deairing prior to use in the circuit, and the amount of flow generated is sensitive to outflow resistance and filling pressures. The differences in design of the various commercially available pump heads are in the numbers of impellers, the shape and angle of the blades, and the priming volume. The only exception is the Medtronic Bio-Pump (Medtronic Bio-Medicus, Inc., Eden Prairie, MN), which is based on two concentric cones generating the rotary motion. The pump heads are disposable, relatively cheap to manufacture, and mounted on a magnetic motorized unit that generates the power. Despite design differences, in vitro and in vivo testing has shown no clear superiority of one pump over the other.[40,42] Although earlier designs caused mechanical trauma to the blood elements leading to excessive hemolysis, the newly engineered pumps are less traumatic and can be used for longer periods.

Complications. Complications with temporary mechanical assistance are high and are very similar for patients on centrifugal pump support or ECLS. The major complications reported by a voluntary registry for temporary circulatory assistance using primarily left ventricular, right ventricular, and biventricular assist devices (LVADs, RVADs, and BVADs) are bleeding, persistent shock, renal failure, infection, neurologic deficits, thrombosis and emboli, hemolysis, and technical problems. The incidence of these complications in 1279 reported patients differed significantly between continuous perfusion systems and pneumatically driven systems (see the following) with respect to bleeding, renal failure, infection, and hemolysis. Neurologic deficits occurred in approximately 12% of patients, and in Golding's experience, noncerebral emboli occurred equally often.[43] Golding also found that 13% of patients also developed hepatic failure. An autopsy study found anatomical evidence of embolization in 63% of patients, even though none had emboli detected clinically.[44]

Results. Although a meaningful comparison of results of centrifugal support from different institutions is not possible, in general, overall survival has been in the range of 21 to 41%. The voluntary registry reported the experience with 604 LVADs, 168 RVADs, and 507 BVADs; approximately 70% were with continuous-flow pumps and the remainder with pulsatile pumps.[45] There were no significant differences in the percentage of patients weaned from circulatory assistance or the percentage discharged from the hospital according to the type of perfusion circuitry. Overall, 45.7% of patients were weaned, and 25.3% were discharged from the hospital.[45] The registry also reports that long-term survival of patients weaned from circulatory support is 46% at 5 years.[45] Most of the mortality occurs in the hospital before discharge or within 5 months of discharge.

Golding reported an identical hospital survival rate for 91 patients in 1992 using only centrifugal pumps, and Noon reported that 21% of 129 patients were discharged.[43,46] Patients who received pulsatile circulatory assistance were supported significantly longer than those supported by centrifugal pumps, but there were no differences in the percentage of patients weaned or discharged. Survivors were supported an average of 3.1 days using continuous-flow pumps. Patients supported for AMI did poorly; only 11.5% survived to be discharged. Joyce reports that 42% of patients supported by Sarns impeller pumps eventually were discharged.[47]

Extracorporeal Life Support (ECLS/ECMO)

By the 1960s, it was clear that cardiopulmonary bypass was not suitable for patients requiring circulatory support for several days to weeks. The development of ECLS as a temporary assist device (also referred to as *extracorporeal membrane oxygenation* [ECMO]) is a direct extension of the principles of cardiopulmonary bypass and follows the pioneering efforts of Bartlett and colleagues in demonstrating the efficacy of this technology in neonatal respiratory distress syndrome.[48]

There are a number of key differences between cardiopulmonary bypass and ECLS. The most obvious difference is the duration of required support. Whereas cardiopulmonary bypass typically is employed for several hours during cardiac surgery, ECLS is designed for longer duration of support. With ECLS, lower doses of heparin are used, and reversal of heparin is not an issue. Because a continuous circuit is used, areas of stasis, such as the cardiotomy suction and venous reservoir, are not present. These differences are thought to reduce the inflammatory response and the more pronounced coagulopathy that can be seen with cardiopulmonary bypass,[49] although there is generally a rapid rise of inflammatory cytokines with initiation of ECLS support.[50]

A typical ECLS circuit is demonstrated in Fig. 18-3. The system consists of the following:

1. *Hollow-fiber membrane oxygenator with an integrated heat-exchange system.* The microporous membrane provides the necessary gas-transfer capability via the micropores where there is direct blood-gas interface with minimal resistance to diffusion. By virtue of the membranes being close to each other, the diffusion distance has been reduced without a significant pressure drop across the system.[51] Control of oxygenation and ventilation is relatively easy. Increasing the total gas flow rate increases CO_2 removal (increasing the "sweep") by reducing the gas-phase CO_2 partial pressure and promoting diffusion. Blood oxygenation is controlled simply by changing the fraction of O_2 in the gas supplied to the oxygenator.
2. *Centrifugal pump.* These pumps are totally nonocclusive and afterload-dependent. An increase in downstream resistance, such as significant hypertension, will decrease forward flow to the body. Therefore, flow is not determined

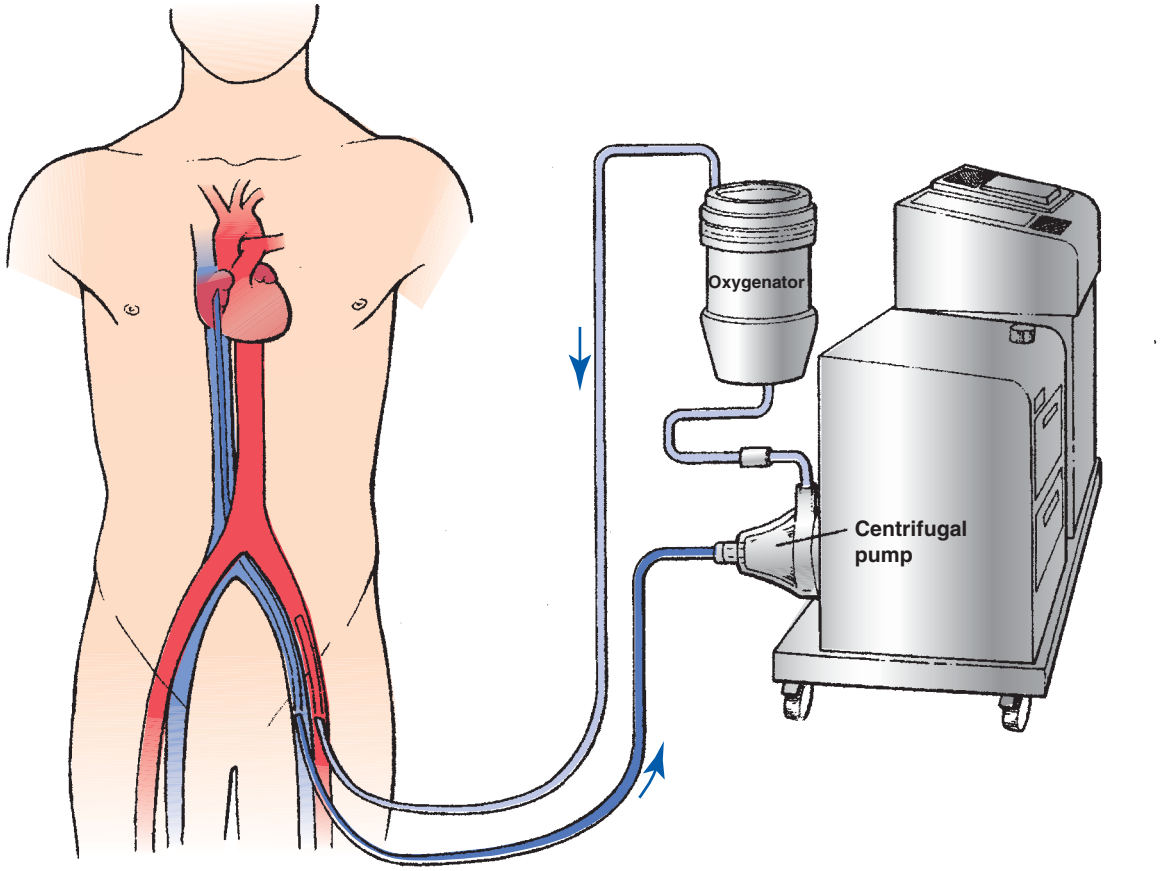

FIGURE 18-3 Percutaneous ECMO support is attained via femoral vessel access. Right atrial blood is drained via a catheter inserted into the femoral vein and advanced into the right atrium. Oxygenated blood is perfused retrograde via the femoral artery. Distal femoral artery perfusion is not illustrated.

by rotational flow alone, and a flowmeter needs to be incorporated in the arterial outflow to quantitate the actual pump output. If the pump outflow should become occluded, the pump will not generate excessive pressure and will not rupture the arterial line. Similarly, the pump will not generate significant negative pressure if the inflow becomes occluded. This protects against cavitation and microembolus formation. The newer generation magnetically levitated centrifugal pumps have been also used recently in the ECLS circuit and may have less traumatic effect on the blood elements.[52]

3. *Heat exchanger.* This allows for control of blood temperature as it passes through the extracorporeal circuit. Generally, the transfer of energy occurs by circulating nonsterile water in a countercurrent fashion against the circulating blood. Use of water as the heat-exchange medium provides an even temperature across the surface of the heat exchanger without localized hot spots. The use of a heat exchanger allows for maintenance of normothermia given the potential heal loss that can occur through the long circuit.
4. *Circuitry interfaced between the patient and the system.* The need for systemic anticoagulation on ECLS and the complications associated with massive coagulopathy and persistent bleeding during the postcardiotomy period led to the development of biocompatible heparin-bonded bypass circuits. In 1991, the Carmeda Corporation in Stockholm, Sweden, released a heparin-coating process that could be used to produce an antithrombotic surface.[51] This process was applied to extracorporeal tubing and the hollow-fiber microporous oxygenator surface.[53] Initial experience suggested that the need for systemic anticoagulation had been eliminated. In addition, heparin coating has been associated with a decrease in the inflammatory response with reduced granulocyte[54] and complement activation.[55] Bindslev and colleagues[56] and Mottaghy and colleagues[57] reported excellent hemodynamic support with minimal postoperative blood loss in experimental animals for up to 5 days. Magovern and Aranki reported similar excellent results with clinical application.[58,59]

Although these heparin-bonded circuits were initially thought to completely eliminate the need for heparinization, thrombus formation without anticoagulation remains a persistent problem. In a study of 30 adult patients with cardiogenic shock who underwent ECLS using the heparin-bonded circuits and no systemic anticoagulation, 20% of patients developed left ventricular thrombus by transesophageal echocardiography, and an additional 6% had a visible clot in the pump head.[60]

Protamine administration after starting ECLS can precipitate intracardiac clot. If the left ventricle does not eject and blood remains static within the ventricle, clot formation is more likely. Intracavitary clot is more likely in patients with MI owing to expression of tissue factor by the injured cells. Protamine may bind to the heparinized coating of the new circuit and negate an anticoagulant effect.[61]

Cannulation. The main difference between the centrifugal pump and ECLS is the presence of an in-line oxygenator. As a result, ECLS can be used for biventricular support by using central or peripheral cannulation. Intraoperatively, the most common application of ECLS has been for patients who cannot be weaned from cardiopulmonary bypass after heart surgery. In these cases, the existing right atrial and aortic cannulas can be used. An alternative strategy is to convert the system to peripheral cannulas, which potentially permits later decannulation without opening the chest.[62]

Cannulation is accomplished by surgical cut down or percutaneous insertion. The entire vessel does not need to be mobilized, and exposure of the anterior surface of the vessels typically suffices. A pursestring suture is placed over the anterior surface of the vessel. The largest cannula that the vessel can accommodate is selected. Typically, arterial cannulae of 16 to 20 French and venous cannulae of 18 to 28 French are used. The cannulation is performed under direct vision using Seldinger's technique. A stab incision is made in the skin with a no. 11 blade knife, a needle is inserted through the stab incision into the vessel, and a guidewire is advanced gently. Dilators then are passed sequentially to gently dilate the tract and the insertion point in the vessel. The cannulae then are inserted, the guidewire is removed, and a clamp is applied. For venous drainage, a long venous cannula is directed into the femoral vein to the level of the right atrium under transesophageal echocardiographic guidance.

To minimize limb complications from ischemia, one strategy is to place an 8- to 10-French perfusion cannula in the superficial femoral artery distal to the primary arterial inflow cannula to perfuse the leg (Fig. 18-4). This cannula is connected to a tubing circuit that is spliced into the arterial circuit with a Y-connector. The distal cannula directs continuous flow into the leg and significantly reduces the incidence of leg ischemia. It should be noted, however, that limb ischemia associated with long-term peripheral cannulation relates not just to arterial perfusion, but also to the relative venous obstruction that can occur with large venous lines. In such circumstances distal venous drainage can be established by splicing another small venous cannula into the circuit.

An alternative strategy is to completely mobilize the common femoral artery and sew a 8- or 10-mm short Dacron graft to its anterior surface as a "chimney." The graft serves as the conduit for the arterial cannula, and no obstruction to distal flow exists. This strategy also allows for a more secure connection and avoids problems with inadvertent dislodgement of the cannulae because of loosening of the pursestrings. In general, complete percutaneous placement of arterial cannulae is avoided to prevent iatrogenic injury during insertion and ensure proper positioning of the cannula. However, when venovenous bypass

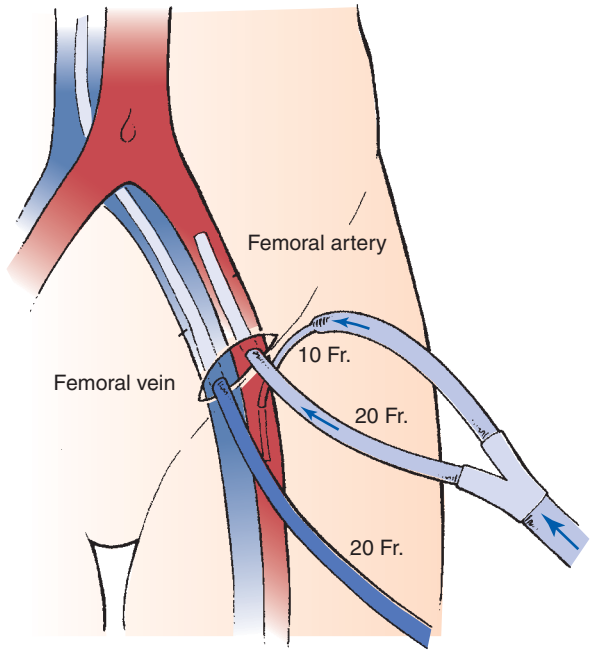

FIGURE 18-4 Surgical exposure of the femoral vessels facilitates cannulation for ECMO. A small 10-French cannula is used to perfuse the distal femoral artery.

is the only mode of support needed, percutaneous cannulation is performed. Surgical exposure is not necessary, and bleeding is less with this technique. Although traditionally the perfusion circuit involves atrial drainage and femoral reinfusion (aortofemoral flow), a recent prospective study has shown the reverse circuit (femoroatrial flow) to provide higher maximal extracorporeal flow and higher pulmonary arterial mixed venous oxygenation.[63]

Central cannulation sometimes is indicated because of either severe peripheral vascular disease or the desire to deliver the highly oxygenated blood directly to the coronary arteries and cerebral circulation. In patients with an open chest, aortic and right atrial cannulae are used. Reinforcing pursestring sutures are placed and tied over rubber chokers and buttons for later tying at decannulation. The catheters are brought through the chest wall through separate stab wounds, and after bleeding is secured, the chest is covered, but not closed, over mediastinal drainage tubes.[64]

An alternative central cannulation site is the axillary artery. Direct cannulation of this artery has been associated with progressive edema of the arm.[65] Therefore, the best strategy to maintain arm perfusion is to expose the axillary artery and sew a 8- or 10-mm graft to the vessel as a "chimney." The cannula then is placed in the graft and tied securely with several circumferential umbilical tapes.

Once instituted, the system is simple enough to be monitored by trained ICU nurses and maintained by a perfusionist on a daily basis. Evidence of clots in the pump head requires a change. Leakage of plasma across the membrane from the blood phase to the gas phase may be a problem, gradually decreasing the efficiency of the oxygenator and increasing resistance to

flow and necessitating oxygenator exchanges. Using this system, ECLS flows of 4 to 6 L/min are possible at pump speeds of 3000 to 3200 rpm. Higher pump speeds are avoided to minimize mechanical trauma to blood cells. Other means of improving flow include transfusion of blood, crystalloid, or other colloid solutions to increase the overall circulating volume.

Physiologically, ECLS will unload the right ventricle but will not unload the compromised left ventricle, even though left ventricular preload is reduced.[59] In normal hearts, the marked reduction in preload and small increase in afterload produced by the arterial inflow from the ECLS system reduces wall stress and produces smaller end-diastolic left ventricular volumes because the heart is able to eject the blood it receives. However, if the heart is dilated and poorly contracting, the marked increase in afterload provided by the ECLS system offsets any change in end-diastolic left ventricular volume produced by bypassing the heart. The heart remains dilated because the left ventricle cannot eject sufficient volume against the increased afterload to reduce either end-diastolic or -systolic volume. ECLS, therefore, theoretically may increase left ventricular wall stress and myocardial oxygen consumption unless an IABP or other means is used to unload the left ventricle mechanically and reduce left ventricular wall stress.[59]

As mentioned, the versatility of ECLS is that it allows rapid restoration of circulation by peripheral cannulation during active resuscitation in the setting of acute cardiac arrest, acute pulmonary embolism, or patients in cardiogenic shock who cannot be moved safely to the operating room.

An isolated RVAD is rarely indicated in the postcardiotomy setting because, in general, these patients have global biventricular dysfunction. ECLS as an RVAD (with outflow to the pulmonary artery) may be used only in patients with good function of the left ventricle who manifest right ventricular failure and hypoxia.

Complications. The experience in adults with ECLS for postoperative cardiogenic shock is associated with high rates of bleeding. Surgical bleeding from the chest is exacerbated by anticoagulation and the consumptive coagulopathy caused by the ECLS circuit.[66] Pennington reported massive bleeding in six of six adults supported by ECLS after cardiac surgery. Even without the chest wound, bleeding was the major complication in a large study of long-term ECLS for acute respiratory insufficiency.[67] Muehrcke reported experience with ECLS using heparin-coated circuitry with no or minimal heparin.[68] The incidence of reexploration was 52% in the Cleveland Clinic experience; transfusions averaged 43 units of packed cells, 59 units of platelets, 51 units of cryoprecipitate, and 10 units of fresh-frozen plasma. Magovern reported somewhat less use of blood products, but treated persistent bleeding by replacement therapy and did not observe evidence of intravascular clots; two patients developed stroke after perfusion stopped. Other important complications associated with ECLS using heparin-coated circuits included renal failure requiring dialysis (47%), bacteremia or mediastinitis (23%), stroke (10%), leg ischemia (70%), oxygenator failure requiring change (43%), and pump change (13%).[69] Nine of 21 patients with leg ischemia required thrombectomy and one amputation. Half the patients developed marked left ventricular dilatation, and six patients developed intracardiac clot detected by TEE. Intracardiac thrombus may form within a poorly contracting, nonejecting left ventricle or atrium because little blood reaches the left atrium with good right atrial drainage. We have observed intracardiac thrombus in heparinized patients and those perfused with pulsatile devices and a left atrial drainage cannula. Therefore, the problem is not unique to ECLS or the location of the left-sided drainage catheter, but is related to left ventricular dysfunction and stagnant flow. In patients on temporary VADs in whom LV clot forms, the clot is removed at the time of permanent VAD implantation.

Results. Magovern reported improved results in 14 patients supported by a heparin-coated ECLS circuit after operations for myocardial revascularization.[59] Eleven of 14 patients (79%) with revascularization survived, but none of three patients with mitral valve surgery and none of four patients who underwent elective circulatory arrest survived. Overall, 52% of the whole group survived, but two patients developed postperfusion strokes that probably were the result of thrombi produced during perfusion. Although the Cleveland Clinic experience with heparin-coated ECLS circuits produced a survival rate of 30%, the patient population was more diversified and represented only 0.38% of cardiac operations done during the same time period.[60]

The Cleveland Clinic reported their results looking at 202 adults with cardiac failure.[34] With an extended follow-up up of 7.5 years (mean 3.8 years), survival was reported to be 76% at 3 days, 38% at 30 days, and 24% at 5 years. Patients surviving 30 days had a 63% chance of being alive at 5 years, demonstrating that the high early mortality remains the Achilles heal of this technology. Interestingly, patients who were weaned or bridged to transplantation had a higher overall survival (40 and 45%, respectively). Failure to wean or bridge was secondary to end-organ dysfunction and included renal and hepatic failure and occurrence of a neurologic event while on support.[34] Another report from the Cleveland Clinic looking at 19,985 patients undergoing cardiac operations found that 107 (0.5%) required ECLS for postcardiotomy failure.[4] Younger age, number of reoperations, emergency operations, higher creatinine concentration, greater left ventricular dysfunction (LVD), and history of MI were significant predictors of the need for mechanical support. Although overall survival was 35%, in the subgroup bridged to a chronic implantable device, survival was 72%.

Newer Devices

TandemHeart. The TandemHeart PTVA (percutaneous ventricular assist) System (CardiacAssist, Inc., Pittsburgh, PA) has 510k FDA approval for short-term (<6 hours) mechanical support. It was envisioned for the short-term support of high-risk percutaneous interventions in the catheterization lab.[70] The device is powered by a small hydrodynamic centrifugal pump that resides in a paracorporeal location. The rotor of the pump is suspended and lubricated by a fluid interface of heparinized saline. Cannulas are introduced from the femoral vessels by either percutaneous or direct insertion techniques. Pump inflow

is achieved by a novel, proprietary 21-French cannula delivered across the atrial septum. Outflow typically is directed into the common femoral artery (Fig. 18-5). Position is facilitated and confirmed by fluoroscopy and intracardiac ultrasound (ICE).[71]

As opposed to an ECLS circuit, excellent left atrial decompression is achieved as long as the inflow cannula is appropriately positioned. The device can be introduced either in the catheterization laboratory using fluoroscopy or directly in the operating room using TEE guidance. Most of the experience with the device has been in the catheterization laboratory, where it has been used extensively to facilitate high-risk percutaneous interventions.[72] Flows of up to 4 L are typical. With surgically implanted larger cannulae flows up to 8 L are possible.

The TandemHeart can be configured in many ways to achieve effective mechanical support. The inlet and outlet connectors to the pump are 3/8 – 3/8 connectors, and as such can be connected to any of a number of commercially available percutaneous or surgically implanted cannulae.

Patients with this device are typically kept in bed, given that the device is inserted through the femoral vessels. An ACT of 200s is targeted while the patients are on support. The TandemHeart is a very versatile system that can be deployed and discontinued rapidly. One beneficial aspect for postcardiotomy support is that the entire device can be removed in the ICU without reopening the patient's chest. RVAD configurations with right atrial inflow and outflow to the main pulmonary artery are possible in both open[73] and percutaneous configurations.[74] With a percutaneous approach the 21-French transeptal cannula is directed into the main pulmonary artery under flouroscopy.[74]

Complete percutaneous biventricular support is also possible, but is somewhat cumbersome given the vascular access requirements. When faced with a patient that needs biventricular support, most groups are splicing an oxygenator into the circuit and using right atrial or biatrial drainage. In essence such a configuration converts the assist system to ECLS circuit.[75] With transeptal drainage the issues of left-sided congestion, which sometimes plague ECLS patients, are nonexistent. Gregoric and the group from Texas Heart Institute reported on the outcomes of nine patients with refractory shock, supported by the TandemHeart. Eight patients had an IABP and three were undergoing active chest compressions. Once neurologic and end-organ recovery ensued, the patients were transitioned to permanent continuous-flow VADs. Three patients were ultimately transplanted and 1-year survival for the entire group was 100%.[76] The Texas Heart Group has also had extensive

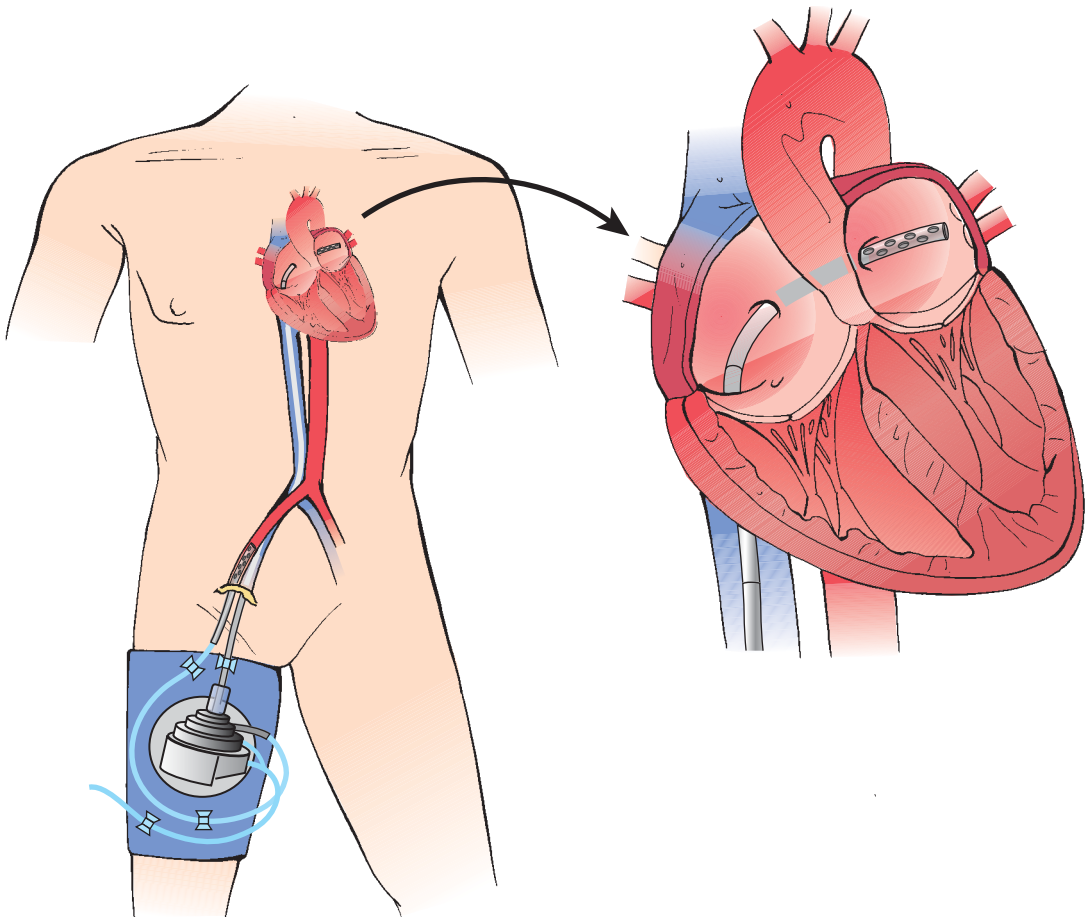

FIGURE 18-5 Transeptal inflow cannula of the TandemHeart device. (*Reproduced with permission from CardiacAssist, Inc., Pittsburgh, PA.*)

experience with using to the TandemHeart to support conventional surgery and recently reported the outcomes of eight patients in shock secondary to critical aortic stenosis supported with preoperative TandemHeart. Five were receiving chest compressions at the time of TandemHeart Insertion. All underwent conventional aortic valve replacement after a mean duration of support of 6 days. One patient died of postoperative sepsis. The other seven patients were discharged from the hospital and were all alive at the time of the report.[76]

Brinkman and the group at Medical City Dallas reported on the outcomes of 22 patients supported with the TandemHeart device. Mean duration of support was 6.8 days with no pump failures or pump related neurologic events. Three patients developed bleeding and two patients had lower extremity ischemic complications. In 11 patients who were neurologically intact at the time of TandemHeart Insertion, five went on to receive transplants while on TandemHeart support, three went on to permanent LVAD placement, and two recovered. Of 11 patients with indeterminate neurologic status or multiorgan failure, seven died, two went on to receive permanent LVADs, one was transplanted, and one recovered.[77] It should be noted that use of a TandemHeart beyond 6 hours and use with an oxygenator are off-label uses of the device. It is important to remember that when placing a long-term VAD in a patient on Tandem Support, it is necessary to repair the atrial septum. Failure to do so can lead to hypoxia caused by entrainment of unoxygenated blood across the atrial septal defect created by the TandemHeart inlet cannula.

Levitronix CentriMag. The Levitronix CentriMag pump is a centrifugal pump with a fully magnetically levitated impeller (Fig. 18-6).[78] Very little friction is generated and it requires only a very small priming volume. It can be configured for both right- and left-sided heart support, typically with central cannulation via median sternotomy. With good cannula placement, more than 9 L of support can be achieved. It has FDA 510K approval for 6 hours of use as an LVAD and has FDA approval for use as an RVAD for 30 days.

FIGURE 18-6 Levitronix CentriMag. (*Reproduced with permission from Levitronix, Waltham, MA.*)

The group at the University of Minnesota reported the outcomes of 12 patients supported with CentriMag BiVADs.[3] Of 12 patients who presented in cardiogenic shock, eight went on to receive long-term implantable VADs, two recovered, and two died. Thirty-day survival was 75% and 1-year survival was 63%.[3]

The group at the University of Pittsburgh recently reported the results of using CentriMag as a temporary RVAD. The indication for RV support was postcardiotomy RV failure in seven (24%), RV failure postcardiac transplant in 10 (35%), and RV failure post-LVAD placement in 12 (41%) patients. The RVAD was able to be weaned in 43% of postcardiotomy patients, 70% of transplant patients, and 58% of LVAD patients after a mean duration of support of 8 days. The authors concluded that the CentriMag was easy to implant, provided effective support, and was easy to wean,[79] with low overall morbidity.

As with similar pumps, the CentriMag can be configured with an oxygenator to create an ECLS circuit.[80]

Axial Flow Pumps

Impella. The Impella pump has been acquired by ABIOMED, Inc. and is being marketed as the Impella Recover system. The device is a microaxial pump, with both peripheral and central cannulation configurations available. In either case, the pump is directed across the aortic valve into the left ventricle (Fig. 18-7). The cannula portion of the device, which sits across the aortic valve, is contiguous with the integrated motor that comprises the largest-diameter section of the catheter (see Fig. 18-7). The

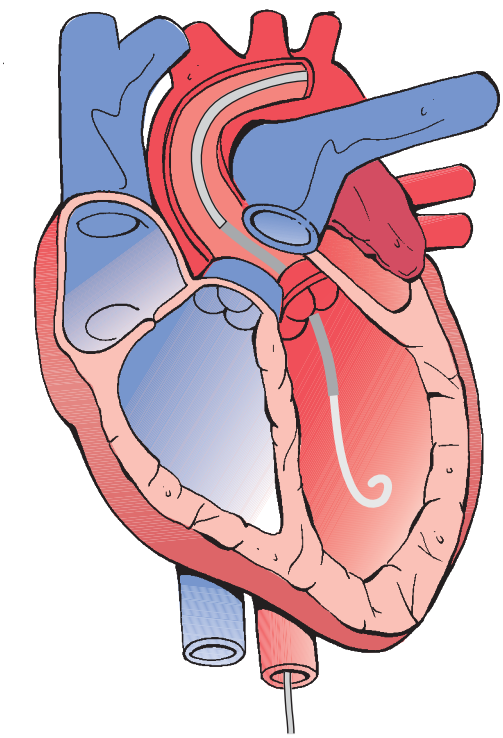

FIGURE 18-7 Impella device. (*Reproduced with permission from ABIOMED, Danvers, MA.*)

small diameter of the cannula is designed to allow easy coaptation of the aortic valve leaflets around it, resulting in minimal aortic valve insufficiency. Its hemodynamic support results from the design feature that provides active forward flow that increases net cardiac output, and its ability to address the needs for myocardial protection stems from simultaneously unloading work from the ventricle (decreasing myocardial oxygen demand) and augmenting coronary flow (increasing oxygen supply).[81–83]

The device comes in two sizes depending on indication for use and desired flow. The smaller Impella 2.5 is capable of generating flows up to 2.5 L/min. Experience with Impella 2.5 is largely with high-risk percutaneous interventions in which the device maintains hemodynamic stability during balloon inflation and stent deployment. In addition, in cases of myocardial infarction it may help in reducing infarct size. In a recent prospective randomized trial 20 patients underwent high-risk percutaneous coronary intervention while being supported with the Impella 2.5. All patients had poor left ventricular function and had interventions on the left main or the last remaining patent conduit. Patients with recent ST-segment elevation myocardial infarction or cardiogenic shock were excluded. The primary safety end point was the incidence of major adverse cardiac events at 30 days. The primary efficacy end point was freedom from hemodynamic compromise during intervention. The Impella 2.5 device was implanted successfully in all patients. The mean duration of circulatory support was 1.7 ± 0.6 hours (range, 0.4 to 2.5 hours). Mean pump flow during PCI was 2.2 ± 0.3 L/min. At 30 days, the incidence of major adverse cardiac events was 20%. (Two patients had a periprocedural myocardial infarction, and two patients died at days 12 and 14.) There was no evidence of aortic valve injury, cardiac perforation, or limb ischemia. Two patients (10%) developed mild, transient hemolysis without clinical sequelae. None of the patients developed hemodynamic compromise during PCI.[84]

The larger-size Impella 5.0 is designed to generate flows of up to 5 L/min and is more appropriate for hemodynamic support for cardiogenic shock. The device can be inserted percutaneously or directly through the aorta in the operating room. As with all left ventricular assist devices, the actual flow depends on adequacy of blood return to the left side on the heart, which in return depends on right ventricular function, pulmonary vascular resistance, and adequate blood volume. Although the device provides superior hemodynamic support compared with IABP, a recent meta-analysis suggested that early survival is not necessarily improved.[85]

The results of this limited study likely have to do more with the acuteness and duration of hemodynamic collapse in the patients than the efficacy of restoring circulatory flow. Several isolated reports suggest the novel ways that patients can be supported using this technology, including one as a bridge to a more long-term device, and another for support of primary graft failure status post-heart transplant.[86]

A right ventricular support device also has been developed and reported.[87] The development and implementation of this kind of device can be particularly useful in patients in need of chronic LVAD therapy. Theoretically, a percutaneously implanted device can support the right heart during the critical days after LVAD implantation to allow for recovery of the right ventricle and the gradual reduction in pulmonary vascular resistance. This kind of device will significantly facilitate patient management and reduce the need for high doses of inotropic support.[88]

Pulsatile Pumps

ABIOMED BVS 5000/AB5000

The ABIOMED BVS 5000 blood pump is an extracorporeal device designed to provide pulsatile univentricular or biventricular support. In 1992, it became the first such device to receive FDA approval. It has been used in thousands of patients in Europe and the United States for the purpose of postcardiotomy pump failure. The system is widely utilized for postcardiotomy support and is available in over 450 centers in the United States. The pump is configured as a dual-chamber device containing both an atrial chamber and a ventricular chamber that pumps the blood pneumatically to the outflow cannula (Fig. 18-8). The two chambers and the outflow tract are divided by trileaflet polyurethane valves that allow for unidirectional blood flow.

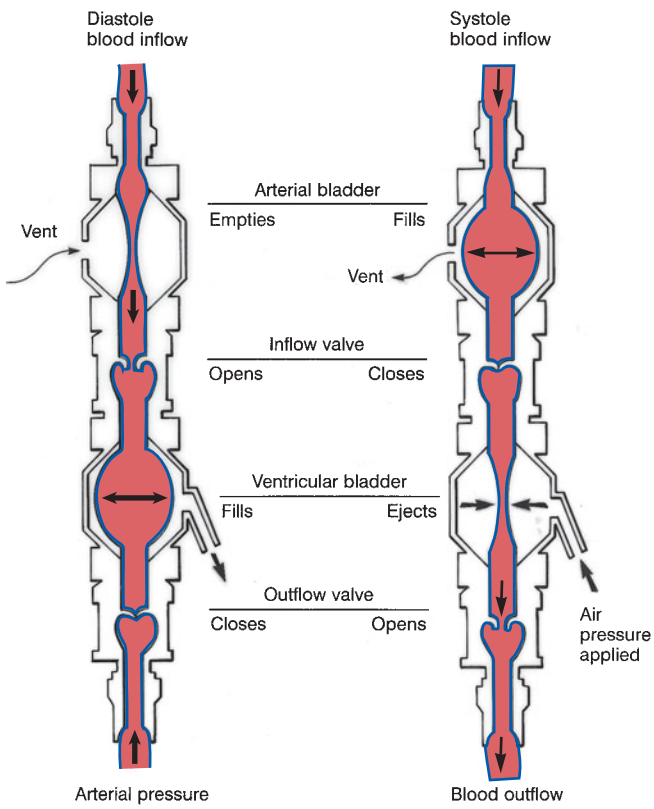

FIGURE 18-8 The ABIOMED BVS 5000. (*Left*) The atrial chamber empties through a one-way valve into the ventricular chamber (diastole). (*Right*) The pneumatically driven pump compresses the ventricular chamber, and blood flows through a one-way valve into the patient (systole). During pump systole, the atrial chamber fills by gravity.

The pump chamber itself consists of a collapsible polyurethane bladder with a capacity of 100 mL. With the BVS 5000 and BVS 5000i consoles, filling of the atrial chamber depends on gravity (the height of the chamber relative to the patient's atrium), the central venous pressure (preload), and the central venous capacitance. The atrial bladder operates in a fill-to-empty mode and therefore can be affected by changes in the height of the pump relative to the patient or the volume status of the patient. The pump usually is set approximately 25 cm below the bed. The adequacy of filling can be assessed visually because the pump is transparent. The passive filling (absence of negative-pressure generation) is designed to prevent atrial collapse with each pump cycle as well as to prevent entrainment of air into the circuitry.

The ventricular chamber requires active pulsatile pumping by a pneumatic driveline. Compressed air is delivered to the chamber, causing bladder collapse and forcing blood out of the pump to the patient. During diastole, air is vented to the atmosphere, allowing refilling of the chamber during the next cycle. The rate of pumping and the duration of pump systole and diastole are adjusted by the pump microprocessor that operates asynchronous to the native heart rate. The pump makes adjustments automatically to account for preload and afterload changes and delivers a constant stroke volume of approximately 80 mL. The maximum output is approximately 5 to 6 L/min with the BVS 5000i console. This design requires minimal input by personnel except during periods of weaning. Medical management should include optimizing the patient's hydration status and outflow resistance because the pump's performance depends on these parameters.

The device has not demonstrated any significant hemolysis, and provides excellent ventricular decompression if a proper cannulation strategy is employed. As opposed to the centrifugal pump and ECLS, patients can be extubated and have limited mobility, such as transfer from bed to chair or dangling of the legs from the bed. The BVS 5000 blood pump can be driven by both the BVS 5000 console and the newer AB5000 console.

The AB5000 circulatory support system, introduced in 2004, consists of the pneumatically driven AB5000 ventricle and the updated AB5000 console, which utilizes vacuum-assisted drainage. The ventricle is designed for short to intermediate (<3-month) support and incorporates many of the features of the ABIOCOR total artificial heart. It is driven pneumatically with valves that are constructed of Angioflex, Abiombed's proprietary polyether-based polyurethane plastic. The AB5000 system uses the same cannulae as the BVS 5000 system. Inflow cannulae can be configured for atrial or ventricular placement. Perhaps the most attractive aspect of the upgraded system is that bedside conversion from the BVS 5000 pump to the ventricle is made possible by quick-connect attachments. As such, patients implanted with a BVS 5000 system at an outlying hospital can be converted to the more long-term ventricle at the receiving institution without reopening the patient's chest or going on bypass. However, the combination of the high vacuum setting and smaller cannula size can lead to hemolysis.[89] Optimal cannula placement without chamber collapse or a high-velocity jet at the inflow cannula tip must be confirmed by transesophageal echocardiography before leaving the operating room. Anticoagulation to an activated clotting time (ACT) of 200 seconds is recommended.

Cannulation. ABIOMED cannulae are constructed from polyvinyl chloride and have a velour body sleeve that is tunneled subcutaneously. Three sizes of wire-reinforced inflow cannulas are available commercially. These include malleable 32-, 36-, and 42-French cannulas. Arterial cannulas have a precoated Dacron graft attached and are available in two sizes: a 10-mm graft for anastomosis to the smaller and lower-resistance pulmonary artery and a 12-mm graft for anastomosis to the ascending aorta.

Careful cannula insertion is important for optimal performance. Venous inflow must be unimpeded, and outflow grafts must not be kinked. In addition, careful consideration must be given to cannula position when bypass grafts cross the epicardial surface of the heart. Depending on the location of these grafts, these cannulae must be placed such that graft compression cannot occur. The three-dimensional layout of this geometry must be visualized and thought out in advance, particularly if chest closure is planned. Any graft compression will make recovery unlikely.

It is technically much easier to use cardiopulmonary bypass for placement of these cannulas, although off-pump insertion is possible and may be preferable in certain clinical situations, particularly for isolated right-sided support. A side-biting clamp typically is used on the aorta to perform the outflow anastomosis. If the patient is on cardiopulmonary bypass, the pulmonary artery anastomosis can be done without the need of a partial cross-clamp. The length of the graft is measured from the anticipated skin exit site to the site of anastomosis, and the preclotted Dacron graft is cut to an appropriate length such that there is no excessive tension or any kinking. The cutaneous exit site is planned so that approximately 2 cm of the velour cuff extends from the skin and the remainder is in the subcutaneous tunnel. The cannula is not tunneled subcutaneously until after completion of the anastomosis. For the aortic anastomosis, incorporation of a Teflon or pericardial strip helps to control suture-line bleeding. If an off pump insertion is planned, cannulae must be tunneled before anastomosis.

For atrial cannulation, a double-pledgeted pursestring suture using 3-0 polypropylene is placed concentrically. Tourniquets must be secured firmly to prevent inadvertent loosening of the pursestring suture and bleeding from the insertion sites. In addition, the heart generally is volume loaded to prevent air embolism during insertion.

For pump inflow, the 36-French malleable cannula is typically used because it provides versatility to accommodate variations in anatomy and clinical conditions. Left atrial cannulation can be achieved via the interatrial groove, the dome of the left atrium, or the left atrial appendage. The right atrial appendage provides the most hemostatic way to cannulate the right atrium because securing ligatures can be placed about the appendage and cannula to afford hemostasis. Alternatively, the body of the right ventricle or left ventricular apex may be cannulated. In the absence of left ventricular clot, the cannula can be introduced through a cruciate-shaped ventriculotomy. Ventricular cannulation offers the advantages of excellent ventricular decompression,

which may enhance ventricular recovery. Bleeding in the setting of a recent MI is a consideration, but usually is not a problem if careful reinforced sutures are placed. A purse string of 00 polypropylene suture passed through a collar of bovine pericardium is a helpful hemostatic adjunct in particularly friable ventricles. Additionally, a hand-made or preordered chimney made from a preclotted graft sewn to a felt collar facilitates ventricular cannulation. A "top-hat" type conduit is constructed and with the "brim" sewn to the left ventricle using mattress sutures. A ventriculotomy is made and a cannula is introduced through the conduit. If recovery occurs, the graft can be stapled to achieve hemostasis. It is simply removed and the site closed or converted to a more formal inlet cannulation if a long-term device must be used.

The consoles for the ABIOMED device are relatively simple to operate. The control system automatically adjusts the duration of pump diastole and systole primarily in response to changes in preload. Pump rate and flow are visible on the display monitor. With the AB5000, console vacuum is adjusted to the lowest possible setting that provides adequate flow.

Complications. As with all patients who require postcardiotomy mechanical support, complications are frequent. Guyton reported 75% bleeding complications, 54% respiratory failure, 52% renal failure, and 26% permanent neurologic deficit.[90] Infection occurred in 13 patients (28%) while on the device, but only three cases were considered device-related. Other complications included embolism in 13% and hemolysis in 17% and mechanical problems related to the atrial cannula site in 13% of patients. No major changes in platelet count or blood chemistries occur during the period of circulatory support.

Jett reported on 55 patients supported on the ABIOMED for a variety of indications, including postcardiotomy failure (28), failed transplant allograft (8), AMI (2), and myocarditis (1).[37] They reported a 40% incidence of bleeding, 50% respiratory complications, and 25% neurologic complications. Marelli and colleagues also reported a similar incidence of complications in 19 status I patients, with three developing renal failure, nine reexplored for bleeding, and three dying of sepsis and multisystem organ failure.[91] As with all acute mechanical support systems, these relatively high complication rates are a reflection of the significant preexisting hemodynamic insult necessitating implementation of mechanical support. Early device insertion should be considered and may improve overall outcome.[36]

Results. The ABIOMED system is available in more than 500 U.S centers, with more than 6000 patients supported to date. Results from several reports have been summarized in Table 18-2 In a multicenter study, Guyton and colleagues reported that 55% of postcardiotomy patients were weaned from support and 29% were discharged from the hospital.[90] However, 47% of patients who had not experienced cardiac arrest before being placed on circulatory support were discharged. Of 14 patients who had experienced cardiac arrest, only one (7%) was discharged. In another report of 500 patients treated with the BVS 5000 system that included 265 (53%) who could not be weaned from cardiopulmonary bypass, 27% of patients were discharged from the hospital.[92] Recent data using this device in a wide range of clinical situations, including postcardiotomy failure, have indicated successful wean in 83% and discharge to home in 45% of patients. These excellent results are also reported by Marelli and colleagues in 14 of 19 patients who were weaned or transplanted with a 1-year survival of 79%.[91] Korfer also reported 50% hospital discharge in 50 postcardiotomy patients supported with the ABIOMED and 7 of 14 patients transplanted with a 1-year survival of 86%.[93] The ABIOMED worldwide registry experience suggests that better results can be expected from experienced centers with heart transplant programs.[37]

A more recent report by Anderson and colleagues looked at the outcomes of patients transferred on the BVS 5000 at "spoke" centers and converted to the AB 5000 at "hubs."[94] Fifty patients were studied over a 2-year period with a survival to either recovery, transplant, or destination VAD of 42%.[94]

TABLE 18-2 Clinical Experience with ABIOMED Support for Postcardiotomy Cardiogenic Shock

Reference	Patients (no.)	Biventricular Support (%)	Mean Duration of Support (Days)	Weaned, no. (%)	Discharged, no. (%)
Guyton	31	52	4.7	17 (55)	9 (29)

Thoratec Ventricular Assist Device

The Thoratec paracorporeal (PVAD) (Thoratec Laboratories Corp., Pleasanton, CA) was introduced clinically in 1976 under an investigational device exemption (IDE) and was approved for bridge to heart transplantation in 1995 and postcardiotomy support in 1998, respectively.

The device is a pneumatically driven pulsatile pump that contains two seamless polyurethane bladders within a rigid housing.[95] The inlet and outlet ports contain mono-strut tilting-disk valves to provide unidirectional flow. The effective stroke volume of each prosthetic ventricle is 65 mL. The pneumatic drive console applies alternating negative and positive pressures to fill and empty each prosthetic bladder. Multiple settings can be adjusted to potentially optimize pump filling to provide univentricular (LVAD or RVAD) or biventricular support (BiVAD).

Thoratec pumps reside on the upper abdominal wall and are connected to the heart with large wire reinforced cannula. The Dual Drive Console (DDC) is a large, wheeled pneumatic controller that is used early in the patient's course to optimize VAD parameters. The TLC-II driver is smaller and is approved for out-of-hospital use.

Cannulation. Device implantation typically is performed on cardiopulmonary bypass. It is important to select the cannula position and cutaneous exit sites carefully. The pump should be planned to rest on the anterior abdominal wall. Lateral placement may lead to excessive tension at the skin exit sites and prevent formation of a seal. Approximately 1.5 to 2 cm of the felt covering of the cannulas must extend beyond the skin exit site, with the remainder in the subcutaneous tunnel to promote ingrowth of tissue and create a seal. The distance between the inlet and outlet portion of the pump is 4 cm, and the distance between the inlet and outlet cannulas of the pump should be planned accordingly. The cannulae must be long enough to allow for pump connection but should be trimmed to prevent the pump from kinking when the patient sits.

The arterial cannulas are available with a 14-mm graft (for the pulmonary artery) or an 18-mm graft (for the aorta) and must be cut to length after the appropriate exit site has been selected. They come in two lengths, 15 and 18 cm, which again are selected based on the patient's anatomy and the planned exit site. The graft is generally sewn on the aorta or pulmonary artery after applying a partial-occluding clamp and sewn with 4-0 polypropylene suture with or without a strip of pericardium or Teflon felt for reinforcement. Inflow can be accomplished by cannulation of the atria or the ventricles.[96] All cannulations generally are reinforced with a double layer of pledgeted concentric pursestring sutures. For atrial cannulation, a 51-French right-angled cannula is available in two lengths, 25 and 30 cm. For the left atrium, the cannula is inserted through the atrial appendage, the interatrial groove, or the superior dome of the left atrium. For right atrial cannulation, the cannula is inserted ideally into the right atrial appendage and directed toward the inferior vena cava.

Inflow cannulation of the left ventricle is preferred over left atrial cannulation,[96] because it provides better drainage, higher flows, and perhaps improves the chance of myocardial recovery. Left ventricular cannulation also decreases the amount of stasis in the LV in the poorly contractile heart, which decreases thrombus formation. Atrially cannulated patients who develop thrombus are at high risk for thromboembolic complication because the ventricle usually continues to eject. Left ventricular cannulation is achieved by placing a concentric layer of pledgeted horizontal mattress sutures at the apex of the left ventricle or the acute margin of the right ventricle (superior to the posterior descending artery). The previously placed sutures are passed sequentially through the cuff, the apex of the heart is elevated, the left ventricle cored, and the cannula seated. The cannula then is inserted and secured by tying the sutures. The free end can then be directed out through the previously planned cutaneous exit site, and a tubing clamp placed to maintain hemostasis until the pump is connected. Connecting the cannulae to the pump is difficult and must be done with care. The connections to the pump have a sharp, beveled edge that should be directed carefully under gentle pressure to fit the cannulas without damaging the inner surface of the tube. In addition, if this tip bends, it may provide a nidus for thrombus formation. Gentle hand pumping can be performed to ensure complete air evacuation using an aortic vent. Deairing of PVADs is best achieved by keeping the heart full and keeping the pumps full at all time.

Complications. The complications reported for patients bridged to transplantation are similar to those reported for postcardiotomy patients. In a multicenter trial, the most common complications were bleeding in 42%, renal failure in 36%, infection in 36%, neurologic events in 22%, and multisystem organ failure in 16% of patients.[95] Similar complications have been reported from other centers.[97,98]

Results. Most contemporary usage of the Thoratec PVADs has been for smaller individuals needing mechanical support or for those needing biventricular support as a bridge to transplant. Especially in cases of postpartum cardiomyopathy or myocarditis, recovering of adequate native heart function has been reported.[99] PVADs can also be used for postcardiotomy and post–MI shock patients, as well as for graft failure posttransplant. After cardiotomy, results are similar to those obtained with ECLS and the ABIOMED BVS 5000. In a review of 145 patients with nonbridge use of the Thoratec device, 37% were weaned and 21% were discharged. More experienced centers have achieved hospital survival rates of greater than 40%.[97,98]

The Thoratec premarket approval experience for the treatment of 53 patients with postcardiotomy heart failure had an in-hospital survival of 28%. The majority of these patients were supported with a BiVAD. The Bad Oeynhausen group, however, has reported a 60% survival for postcardiotomy patients supported with the Thoratec device.[97] Clearly the greatest advantage that the Thoratec device offers is that it can be applied for longer duration of support than any other temporary device mentioned previously. This feature may be uniquely advantageous, particularly because the duration of support necessary is usually unclear in advance. All other devices mentioned have an increasing complication rate with longer duration of support. Furthermore, the Thoratec device allows for physical rehabilitation, ambulation, and home discharge. The durability advantage

of the PVAD must be weighed against the ease with which the newer generation of acute support devices can be inserted and then easily be transitioned to newer-generation chronic devices with improved complication profiles.

BRIDGE-TO-BRIDGE STRATEGY

The *bridge-to-bridge strategy* refers to the use of one of the temporary support systems in an attempt to stabilize a moribund patient to allow for the institution of a more long-term support device if short-term stabilization occurs and more meaningful recovery is anticipated.

The clinical scenarios in which the bridge-to-bridge strategy is entertained include patients who remain in cardiogenic shock despite inotropic support and IABP counterpulsation, chronic heart failure patients with acute decompensation, and patients with cardiac arrest. Improved results with implantable ventricular assist devices have prompted implementation of strategies using acute support devices as a means to rapidly establish circulatory support to maintain hemodynamics as transplant evaluation is initiated and neurologic status is determined. This strategy is aimed at maximizing patient survival and limiting the duration of support with temporary assist devices by early transition to a chronic ventricular assist device that allow patient rehabilitation and eventual transplantation. Furthermore, operative and perioperative costs of implanting the more permanent LVADs are avoided in patients who already may have suffered irreversible sequelae of multisystem organ failure.[100]

Historically ECLS has been the device of choice as full cardiopulmonary support can be established rapidly by peripheral cannulation. Pagani and colleagues reported the results of 33 patients with primary cardiac failure who were placed on ECLS.[101] The etiology was ischemic in 58%, nonischemic in 30%, and postcardiotomy in 12%. Overall, 73% of these patients were in cardiac arrest or had experienced a cardiac arrest within 15 to 30 minutes of initiation of ECLS. Ten patients who were transplant candidates and could not be weaned from ECLS were bridged to an LVAD. Six patients were transplanted and discharged, two were alive on the LVAD awaiting transplantation, and two died. Overall, ECLS was discontinued in 27% of patients because of absolute contraindications to transplantation, primarily because of neurologic injury. However, 80% of patients transitioned to an LVAD survived. This aggressive strategy and remarkable survival are secondary to the selection of patients who are most likely to survive at the expense of more initial deaths on ECLS. If the entire group of patients in this study is considered, only 36% survived to discharge. Interestingly, the need for RVAD support in the group of patients with ECLS as a bridge strategy was 40%, significantly higher than the 10% reported for patients who receive an LVAD as the initial device. This may be secondary to the inflammatory response to ECLS and associated increase in pulmonary vascular resistance.[102,103] On the other hand, an increased frequency of multisystem organ failure may lead to a greater need for perioperative BiVAD support.[104–106]

More recently a number of centers are using the TandemHeart [77,107] and CentriMag[3] for bridging to long-term devices, as has been described in earlier sections of this chapter. As the field of temporary circulatory support advances, devices such as the TandemHeart and Impella, which can be placed percutaneously, offer a distinct advantage because they can be placed in the catheterization lab without major operative intervention. It is worthwhile to note that in a recent series from the Texas Heart Institute, five of eight patients were undergoing chest compressions when the TandemHeart was implanted.[76]

Device Selection

To date, insufficient data exist to recommend one device over another for patients who require temporary mechanical support. Use of a particular device often is based on availability rather than science.

For centers with multiple devices, patient presentation and cardiopulmonary status determine the device selected. Patients undergoing cardiopulmonary resuscitation are best served by urgent femoral cannulation. This avoids the time delay of transportation and sternotomy. Patients with severe hypoxia and lung injury either from aspiration or pulmonary edema benefit from the oxygenation and lung rest provided with ECLS. In all ECLS patients it is important to adequately lower the left atrial pressure, because hypoxia secondary to continued pulmonary venous congestion precludes weaning of the ECLS circuit.

For postcardiotomy support, typically patients are supported for 48 to 72 hours while transplant evaluation is completed. Then they are transitioned to a more long-term device if myocardial recovery has failed. This approach avoids high-risk emergency heart transplantation and provides the time necessary for improved organ function.

Biventricular support is often required for fulminant myocarditis. Recovery may be possible, but often requires long-term support with a chronic device.

The TandemHeart with percutaneous transseptal left atrial drainage is a very attractive option for patients sustaining arrest in the catheterization laboratory. The Impella 5.0 also has a role to play in this patient population.

Patient Management

The ultimate goal is to maintain optimal perfusion of all end organs, to allow time for recovery from an acute hemodynamic insult and prevent further deterioration of organ function. Ideally, pump flow would achieve a mixed venous saturation of greater than 70%. Low-flow states can often be corrected by intravascular volume expansion. With centrifugal pumps, speed can be adjusted to control flow and allow some degree of cardiac ejection to decrease the likelihood of stasis and intracardiac thrombus formation. Increasing flow rates by using excessive pump speeds can also cause significant hemolysis. Fluid administration to expand intravascular volume is the best way to increase flow. However, right-sided heart failure also may manifest as a low-flow state in the presence of low pulmonary artery pressures. This condition usually requires the institution of right-sided circulatory support and is associated with a lower overall survival.

Ventilatory Support

Peak inspiratory pressures are maintained below 35-cm H_2O. Inspired oxygen is set initially at 100% with a positive end-expiratory pressure of 5-cm H_2O. Fractional inspired oxygen then is decreased gradually to less than 50%, with partial pressure of oxygen maintained at between 85 and 100 mm Hg. These measures are instituted to diminish the deleterious effect of barotrauma and oxygen toxicity in the setting of lung injury.

Bleeding/Anticoagulation

Anticoagulation should be done judiciously to weigh the balance of excessive risk of bleeding against clot formation in the pump. Platelet counts decrease within the first 24 hours of support; therefore, counts are monitored every 8 hours, and platelets are transfused to maintain counts above 50,000/mm^3 during routine support and above 100,000/mm^3 if bleeding is present. Fresh-frozen plasma and cryoprecipitate are given to control coagulopathy and maintain the fibrinogen concentration at greater than 250 mg/dL and also replace other coagulation factors consumed by the circuit. Anticoagulation is achieved by systemic heparinization with a continuous infusion starting at 8 to 10 μg/kg per hour and titrated to maintain the partial thromboplastin time (PTT) at between 45 and 55 seconds once hemostasis is achieved. In most cases, heparin infusion is started within 24 hours if used in the postcardiotomy setting, but sooner in patients without a sternotomy. One must be constantly vigilant for the signs of tamponade, which is heralded by falling pump flows, falling mixed venous saturation, rising filling pressures, and falling hemoglobin. Every effort must be made to alleviate tamponade and achieve hemostasis before transferring a patient. An ambulance is far less suited to the management of tamponade or ongoing hemorrhage than is the operating room. In reality bleeding is far more of a lethal problem in the first days of support than is thromboembolism, and anticoagulation should be used judiciously.

Fluid Management

Patients are diuresed aggressively while on support to minimize third-space fluid accumulations. If response to diuretic therapy is suboptimal, we use continuous ultrafiltration or continuous venovenous hemodialysis (CVVHD). This system permits control over fluid balance that can be adjusted for volume removal and also allows for dialysis as needed.

Neurologic Monitoring

Patients are sedated with fentanyl or propofol infusion to maintain comfort. Muscle paralysis is used as needed to decrease the energy expenditure and chest wall stiffness to allow for optimal adjustment of the ventilation parameters. All patients are assessed periodically off sedation to establish neurologic function. Response to simple commands, ability to move all extremities, and spontaneous eye movements are used as gross indications of intact sensorium. A low threshold of obtaining computed tomographic (CT) scans of the head is exercised if any change is noted or index of suspicion is high.

Weaning

A weaning trial is usually attempted after 48 to 72 hours of support. It is critical not to rush weaning and to allow time for myocardial as well as end-organ recovery. The principle of weaning is common to all devices, and all have various controls available that allow reduction in flow, thereby enabling more work to be performed by the heart. Flow is reduced gradually at increments of 0.5 to 1 L/min. Adequate anticoagulation is critical during this low-flow phase to prevent pump thrombosis, and, in general, it is not recommended to reduce flow to less than 2.0 L/min for a prolonged period. We add additional heparin during this period to maintain an ACT of more than 300 seconds. With optimal pharmacologic support and continuous TEE evaluation of ventricular function, flows are reduced while monitoring systemic blood pressure, cardiac index, pulmonary pressures, and ventricular size. Maintenance of cardiac index and low pulmonary pressures with preserved LVF by echocardiography suggests that weaning is likely. A weaning failure manifests as a falling systemic blood pressure along with a drop in cardiac output and rising pulmonary artery pressures. A failed attempt at weaning should result in resumption of full flow. Absence of ventricular recovery after several weaning attempts is a poor prognostic sign. Patients who are transplant candidates undergo a full evaluation and subsequently are staged to a long-term ventricular assist device as a bridge to cardiac transplantation. We and others have found that early conversion to chronic ventricular support is beneficial and improves the low survival that is associated with cardiogenic shock, particularly in the postcardiotomy setting.[4,66,108]

CONCLUSION

Currently a number of options exist for temporary circulatory support, and with advances in technology, the number of devices will expand. Each device has advantages and disadvantages, and to date, none satisfies all the requirements of an ideal device. We have clearly learned many lessons that should direct the development of systems and strategies that maximize survival and reduce complications. In this arena, better understanding of the host inflammatory response, appreciation of the induced derangement in the coagulation cascade, and development of systems that do not require anticoagulation should improve overall outcomes. In addition, development of therapies that alter reperfusion injury and preserve organ function is important.

Risk analysis also has taught us that patients requiring postcardiotomy support generally fit into a particular profile. Specifically, these are patients who require emergency operations, have poor ventricular reserve, are older, and have extensive atherosclerotic coronary disease and preexisting renal dysfunction. Preoperative awareness should prompt maximization of medical pharmacologic support and a readiness to implement mechanical devices early in the face of cardiac pump failure.

Use of the standard centrifugal pump gradually has fallen out of favor. Use of the Thoratec PVAD has also waned with the emergence of less morbid and more patient-friendly long-term pumps. Traditional ECLS support has fallen out of favor

in centers that are experienced with newer acute support devices such as the TandemHeart and CentriMag. It will be interesting to see if devices such as the Impella, which can be placed percutaneously without advanced techniques such as transeptal puncture, will provide adequate support in patients with profound shock. Traditionally transplantation has been the only therapy available for patients supported with acute support devices who have not manifested recovery. Recently improved results have been reported with the use of a continuous-flow pump in stage D heart failure patients who are not transplant candidates.[109] Historically salvage rates for patients in cardiogenic shock, transitioned to destination VADs have been dismal.[110] Hopefully earlier use of more effective and less morbid acute support devices can improve results in this population.

KEY POINTS

1. Be familiar with and have available at least on of the available temporary support systems.
2. Be able to recognize cardiogenic shock in the preoperative and postoperative patient.
3. Initiate pharmacologic and first-line mechanical support (IABP) in the shock patient.
4. Attempt to treat the causative issue.
5. If conservative methods fail, act quickly to implement direct cardiac support to decompress the heart and restore adequate end-organ perfusion.
6. Initiate discussions with a center at which advanced heart failure therapies (transplant/long-term VAD) are possible.
7. Stabilize the patient and initiate transfer to a tertiary center for definitive therapy/weaning.

CHAPTER 19

Indications for Revascularization

Morgan L. Brown
Thoralf M. Sundt III

INTRODUCTION

Coronary artery disease remains the most common pathology with which cardiologists and cardiac surgeons are faced. Accordingly, the practicing cardiac surgeon is confronted with no clinical question more often than, "Is coronary bypass indicated in this patient?" It is the aim of this chapter to provide a practical overview of the current indications for myocardial revascularization with sufficient reference to the relevant studies on which they are based to afford the reader an appreciation for the strengths and limitations of their conclusions.

CLINICAL AND LABORATORY ASSESSMENT OF CORONARY ARTERY DISEASE

A surgeon's first introduction to a patient with coronary artery disease is frequently an angiogram. In addition to the coronary anatomy, however, the clinical presentation and results of noninvasive studies of myocardial perfusion and function are necessary to characterize the pathophysiologic implications of the angiographic disease and its impact on prognosis and, therefore, to make a clinically appropriate recommendation. In the technological era in which we practice, the importance of the clinical history bears emphasis—particularly in an aging population. Because one of the objectives of surgery is to improve symptoms and quality of life, a thorough appreciation of the patient's functional status is a prerequisite in selecting the optimal therapeutic strategy.

The system proposed by the Canadian Cardiovascular Society for grading the clinical severity of angina pectoris is widely accepted (Table 19-1). Unfortunately, angina is a highly subjective phenomenon for both patient and physician, and prospective evaluation of the assessment of functional classification by the CCS criteria has demonstrated a reproducibility of only 73%.[1] Furthermore, there may be a strikingly poor correlation between the severity of symptoms and the magnitude of ischemia, as is notoriously the case among diabetic patients with asymptomatic "silent ischemia."

Electrocardiography (ECG), if abnormal, is helpful in assessing ischemic burden. Unfortunately, it demonstrates no pathognomonic signs in half of patients with chronic stable angina. Still the monitoring of an ECG under stress conditions is simple and inexpensive, and is therefore useful as a screening examination. Among patients with anatomically defined disease, stress ECG provides additional information about the severity of ischemia and the prognosis of the disease. The sensitivity of the test increases with age, with the severity of the patient's disease, and with the magnitude of observed ST-segment shift.[2] If ST-segment depression is greater than 1 mm, stress ECG has a predictive value of 90%, whereas a 2-mm shift with accompanying angina is virtually diagnostic.[3] Early onset of ST-segment depression and prolonged depression after the discontinuation of exercise are strongly associated with significant multivessel disease. Unfortunately, many patients cannot achieve their target heart rates owing to beta blockade or a limitation to their exercise tolerance caused by coexisting disease, decreasing the usefulness of this test in these often high-risk patients. Resting abnormalities in the ECG may also limit the predictive accuracy of the test.

Perfusion imaging with thallium-201 or a technetium-99m–based tracer may be particularly useful in patients with abnormalities on their baseline ECG. Reversible defects demonstrated by comparison of images obtained after injection of the tracer at peak stress with rest images is indicative of ischemia, and hence viability. An irreversible defect indicates a nonviable scar. The results obtained with both tracers are similar, with the

TABLE 19-1 Canadian Cardiovascular Society Angina Classification

Canadian Cardiovascular Society
Angina Classification
0 = No angina
1 = Angina only with strenuous or prolonged exertion
2 = Angina with walking at a rapid pace on the level, on a grade, or upstairs (slight limitation of normal activities)
3 = Angina with walking at a normal pace less than 2 blocks or one flight of stairs (marked limitation)
4 = Angina with even mild activity

average sensitivity around 90% and specificity of approximately 75%.[4] For patients unable to exercise, pharmacologic vasodilators such as adenosine or dipyridamole may be used with similar sensitivity.[5]

Echocardiographic imaging during exercise or pharmacologic stress has gained increasing popularity among cardiologists. Comparative studies have demonstrated accuracy similar to that of nuclear studies with sensitivity and specificity both around 85%.[4] Patients unable to exercise may be stressed with high-dose dipyridamole, or more commonly dobutamine at doses from 5 to 40 μg/kg/min. An initial augmentation of contractility followed by loss or "drop out" is diagnostic of ischemia (and accordingly viability), whereas failure to augment contractility at low dose suggest scar. Additionally, information regarding concomitant valvular disease may be obtained during the examination.[6]

GUIDELINES FOR REVASCUARLIZATION

The guidelines for surgical revascularization established by the American College of Cardiology and American Heart Association are shown in Table 19-2.[7] The basis for these guidelines resides in the large body of literature comparing medical therapy with surgical revascularization and, more recently, percutaneous coronary interventions (PCI).

Before reviewing the results of the seminal trials of CABG versus medical therapy performed in the 1970s and those of newer prospectively randomized trials comparing the results of surgery with PCI and medical therapy, some limitations of these trials must be recognized. First, in retrospective or registry studies, it is difficult to ensure comparable patient populations by virtue of the extraordinary anatomical and physiologic complexity of coronary artery disease as well as the heterogeneity of the patient substrate. Differences in ventricular function and comorbidities such as age, diabetes, peripheral vascular disease, and pulmonary disease may have a profound impact on outcomes such as survival or quality of life. For example, caution must be exercised in interpreting the results of nonrandomized and registry reports of PCI versus surgery, because the patients subjected to the former more often have single- or double-vessel disease,[8,9] whereas the latter commonly have triple-vessel or left main disease.[8,9] Attempts to correct for selection bias with statistical techniques such as propensity matching are only as valid as the parameters entered into the model. Data less tangible than gender or chronologic age, such as socioeconomic status or "physiologic age," are not easily accounted for in such analyses and yet may be a critical determinant of outcomes. Despite this limitation, retrospective and registry data provide a better glimpse of the real world of coronary artery disease. Most prospective randomized trials include only a fraction of the total population undergoing revascularization by virtue of strict entry criteria. For example, the Bypass Angioplasty Revascularization Investigators (BARI) trial entered only 5% of total patients screened.[10] Therefore, although the prospectively randomized studies do provide objective data directly applicable to the specific patient subset represented in the study, extrapolation of the results to the more heterogeneous populations seen clinically can only be made if the implicit caveats are clearly understood. We must be mindful of the inescapable tradeoff between selection bias in registry studies and entry bias in randomized studies.

Second, as a consequence of the overrepresentation of patients at lowest risk of death in randomized trials, most are statistically underpowered with respect to survival analysis. For example, given current survival statistics, we would need approximately 2000 patients in each arm of a study to detect a 30% difference in mortality. The problem is compounded by the exclusion of the very patients for whom one would anticipate a survival advantage with adequate revascularization, such as those with depressed ventricular function. Randomized studies frequently employ softer end points such as angina or quality of life, or create composites of qualitatively different end points, such as death, stroke, and myocardial infarction (MI). Meaningful analysis is further complicated by relatively short-term follow-up in most studies. Events such as the need for subsequent revascularization and recurrence of angina characteristically occur at different time intervals after these therapies (restenosis after PCI versus graft occlusion after CABG), and an 8- to 10-year follow-up period is needed to adequately compare long-term results. Patients themselves are also generally interested in outcomes measured in years, not months.

Significant improvements in each of the treatment strategies for coronary artery disease are occurring constantly. Examples include the use of antiplatelet agents, angiotensin-converting enzyme inhibitors, lipid-lowering therapy, internal thoracic aortic (ITA) grafts, intravascular stents, and the development of drug eluting stents. These advances, along with aggressive secondary prevention after revascularization, have steadily reduced the morbidity and mortality of coronary artery disease in all patients, making differences in the hard end point of survival difficult to demonstrate for any therapy.[11] This trend will likely increase as the beneficial effect of secondary prevention becomes more widely appreciated.

TABLE 19-2 AHA/ACC Guidelines for CABG*

Asymptomatic/Mild Angina

Class I
1. Left main stenosis
2. Left main equivalent (proximal LAD and proximal circumflex)
3. Three-vessel disease

Class IIa
1. Proximal LAD stenosis and one- or two-vessel disease

Class IIb
1. One- or two-vessel disease not involving proximal LAD
   If a large territory at risk on noninvasive studies or LVEF <50%, IIa and IIb become class I indications

Stable Angina

Class I
1. Left main stenosis
2. Left main equivalent (proximal LAD and proximal circumflex)
3. Three-vessel disease
4. Two-vessel disease with proximal LAD stenosis and EF <50% or demonstrable ischemia
5. One- or two-vessel disease without proximal LAD stenosis but with a large territory at risk and high-risk criteria on noninvasive testing
6. Disabling angina refractory to medical therapy

Class IIa
1. Proximal LAD stenosis with one-vessel disease
2. One- or two-vessel disease without proximal LAD stenosis, but with a moderate territory at risk and demonstrable ischemia

Unstable Angina/Non–ST-Segment Elevation MI (NSTEMI)

Class I
1. Left main
2. Left main equivalent
3. Ongoing ischemia not responsive to maximal nonsurgical therapy

Class IIa
1. Proximal LAD stenosis with one- or two-vessel disease

Class IIb
1. One- or two-vessel disease without proximal LAD stenosis when PCI not possible (becomes class I if high-risk criteria on noninvasive testing)

ST-Segment Elevation (Q wave) MI

Class I
1. Failed PCI with persistent pain or shock and anatomically feasible
2. Persistent or recurrent ischemia refractory to medical treatment with acceptable anatomy who have a significant territory at risk and not a candidate for PCI
3. Requires surgical repair of post-infarct ventricular septal rupture or mitral valve insufficiency
4. Cardiogenic shock in patients <75 years of age who have ST elevation, LBBB, or a posterior MI within 18 hours of onset
5. Life-threatening ventricular arrhythmias in the presence of ≥50% left main stenosis or three-vessel disease

Class IIa
1. Primary reperfusion in patients who have failed fibrinolytics or PCI and are in the early stages (6–12 h) of an evolving STEMI
2. Mortality with CABG is elevated the first 3–7 days after STEMI/NSTEMI. After 7 days, criteria for revascularization in previous sections apply.

(*Continued*)

TABLE 19-2 AHA/ACC Guidelines for CABG* (*Continued*)

Poor LV Function
Class I 1. Left main stenosis 2. Left main equivalent 3. Proximal LAD stenosis and two- to three-vessel disease
Class IIa 1. Significant viable territory and noncontractile myocardium
Life-Threatening Ventricular Arrhythmias
Class I 1. Left main disease 2. Three-vessel disease
Class IIa 1. Bypassable one- or two-vessel disease 2. Proximal LAD disease and one- or two-vessel disease These become class I indications if arrhythmia is resuscitated cardiac death or sustained ventricular tachycardia.
Failed PCI
Class I 1. Ongoing ischemia with significant territory at risk 2. Shock
Class IIa 1. Foreign body in critical position 2. Shock with coagulopathy and no previous sternotomy
Class IIb 1. Shock with coagulopathy and previous sternotomy
Previous CABG
Class I 1. Disabling angina refractory to medical therapy 2. Nonpatent previous bypass grafts, but with class I indications for native CAD
Class IIa 1. Large territory at risk 2. Vein grafts supplying LAD or large territory are >50% stenosed

Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of a procedure.
Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.
Class IIb: Usefulness/efficacy is less well established by evidence/opinion.
Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.
ACC = American College of Cardiology; AHA = American Heart Association; CABG = coronary artery bypass grafting; EF = ejection fraction; LAD = left anterior descending; LITA = left internal thoracic artery; LVEF = left ventricular ejection fraction; PCI = percutaneous transluminal coronary angioplasty.

COMPARATIVE TRIALS OF REVASCULARIZATION VERSUS MEDICAL THERAPY IN STABLE ANGINA

Medical Therapy

In the decades since coronary artery bypass (CABG) surgery was popularized and coronary angioplasty introduced, an enormous volume of data on the results of invasive revascularization has been collected. Remarkably, almost from the outset many of these studies have been prospectively randomized. Yet in the current era there is a dearth of data concerning pharmacologic therapies for chronic coronary artery disease despite remarkable recent drug development. For example, although nitrates are unquestionably effective in relieving symptoms, the impact of long-acting nitrates on clinical outcomes has never been rigorously tested. Furthermore, there has been only one trial of beta-blocker therapy in the treatment of angina, the Atenolol Silent Ischemia Study (ASIST), which demonstrated benefit for patients with mild effort induced angina or silent ischemia.[12] A handful of studies of combination therapy with beta blockers and calcium channel blockers have also demonstrated antianginal benefit.[13–15]

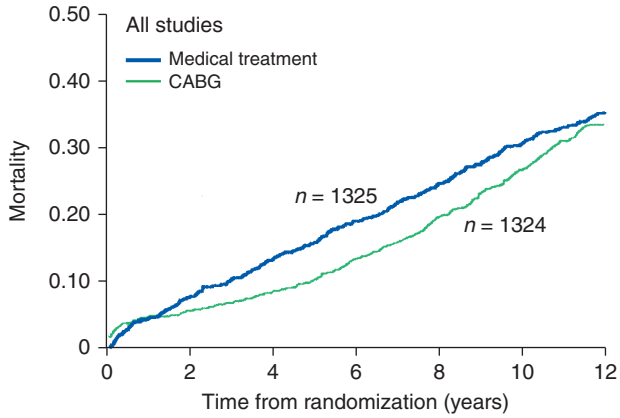

FIGURE 19-1 Survival (mortality) curves for all medically and surgically treated patients with chronic stable angina enrolled in seven prospective randomized controlled trials. (*Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: overview of 10-year results from randomized trials by the Coronary Artery Bypass Graft Surgery Trial: 1st collaboration. Lancet 1994; 344:563.*)

Surgical versus Medical Therapy

Three major randomized studies, the Coronary Artery Surgery Study (CASS),[16] the Veterans Administration Cooperative Study Group (VA),[17,18] and the European Coronary Surgery Study (ECSS),[19,20] as well as several other smaller randomized trials,[21–23] conducted between 1972 and 1984, provide the foundation for comparing the outcomes of medical and surgical therapy. Despite the limitations noted in the preceding, these studies are remarkably consistent in their major findings, and the qualitative conclusions drawn from them continue to be generalizable to current practice.

The central message from all of these studies is that the relative benefits of bypass surgery over medical therapy on survival are greatest in those patients at highest risk as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular dysfunction.[24] For example, thus far, no study has shown survival benefit for CABG over medical therapy for patients with single-vessel disease. It should be emphasized, however, that these trials involved primarily patients with moderate chronic stable angina. These conclusions may, therefore, not necessarily apply to patients with unstable angina or to those with more severe degrees of chronic stable angina.

A meta-analysis of the seven randomized trials cited in the preceding demonstrated a statistically enhanced survival at 5, 7, and 10 years, for surgically treated patients at highest risk (4.8% annual mortality) and moderate risk (2.5% annual mortality), but no evidence of a survival benefit for those patients at lowest risk.[24] The overall survival benefit at 12 years for the three large and four smaller randomized studies is shown in Fig. 19-1. Nonrandomized studies have also demonstrated a beneficial effect of surgery on survival of patients with multivessel disease and severe ischemia regardless of left ventricular function.[25–28]

There have been three recent randomized controlled trials of invasive revascularization by PCI or CABG versus medical therapy. Their results make an even stronger case for revascularization. In the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial, patients with anatomy amenable to CABG were randomized to angina-directed anti-ischemic therapy, drug therapy guided by noninvasive measures of ischemia, or revascularization by CABG or PCI.[29] At 2 years, there was a statistically significant difference in mortality of 6.6% in the angina-guided group, 4.4% in the ischemia-guided group, and 1.1% in the revascularization group. The rates of death or MI were also statistically different at 12.1%, 8.8%, and 4.7%, respectively. The Medicine, Angioplasty, or Surgery Study (MASS-II) trial randomized patients with multivessel disease among medical therapy, PCI, and CABG. Although survival at 1 year was equivalent, freedom from additional intervention was 99.5% for surgical patients and 93.7% for medically treated patients. Reintervention was, incidentally, even higher in the PCI group than the medical group, with 86.7% free of additional intervention. Angina was superior in the CABG group (88%) than in the PCI group (79%) or medical therapy group (46%).[30]

In the Trial of Invasive versus Medical Therapy in Elderly Patients with Chronic Symptomatic Coronary-Artery Disease (TIME) study, elderly patients were studied with chronic angina. This failed to demonstrate a difference between optimized medical therapy and an invasive revascularization strategy (PCI or CABG) in terms of symptoms, quality of life, and death or nonfatal myocardial infarction (20% versus 17%, $p = .71$). However, medically treated patients were at higher risk because of major clinical events (64% versus 26% for invasive, $p < .001$), which were mainly attributable to rehospitalization and revascularization.[31] In this trial of severely symptomatic elderly patients, it was encouraging that the price of an initially conservative strategy, followed by crossover to revascularization in approximately

50% of patients, was not paid for in terms of death or myocardial infarction.[31]

Early concern over a prohibitive operative mortality among patients with impaired ventricular function has been superseded by the recognition that the survival of these patients on medical therapy was much worse than their survival with revascularization. This, coupled with ever-improving surgical techniques, such as advances in myocardial preservation and perioperative support, has made this specific subgroup the one in which the relative survival benefit of surgical therapy is the greatest. Accordingly, left ventricular dysfunction in patients with documented ischemia is now considered an important indication—rather than contraindication—for surgical revascularization.[16,24,25,32] Recent evidence that ischemic, viable, hypokinetic myocardium (hibernating or stunned) regains stronger contractile function after effective revascularization, has prompted expansion of the indications for surgical revascularization among patients with severe left ventricular dysfunction to include patients who would otherwise be considered candidates for cardiac transplantation. This subject is discussed in more detail in the following.

In summary, in regard to chronic stable angina, a survival advantage is demonstrable for surgical revascularization over medical therapy in patients with: left main disease;[33] triple-vessel disease and left ventricular dysfunction;[34,35] two-vessel disease and proximal LAD disease;[36] and severe ischemia and multivessel disease (Fig. 19-2).[37,38] Those survival advantages have not been demonstrable among patients with single-vessel disease.[39–41]

Apart from affording a survival benefit, CABG is indicated for the relief of angina pectoris and improvement in the quality of life. Between 80 and 90% of patients who are symptomatic on medical therapy become symptom-free after CABG. This benefit extends to low-risk patients for whom survival benefit from surgery is not likely.[24] Relief of symptoms appears to relate to both the completeness of revascularization and maintenance of graft patency, with the benefit of CABG diminishing with time. Recurrence of angina following CABG surgery occurs at rates of 3 to 20% per year. Although enhanced survival is reported when an ITA graft is used to the LAD, there is no significant difference in postoperative freedom from angina.[41] This may be because of vein graft occlusion or progression of native disease in grafted or ungrafted vessels.[17]

Unfortunately, few patients experience an advantage in work rehabilitation with surgery as compared with medical management. Generally, employment declines in both groups and is determined nearly as much by socioeconomic factors as age, preoperative unemployment, and type of job as by type of therapy or clinical factors such as postoperative angina. Notably, surgical revascularization has not been shown to reduce the incidence of nonfatal events such as myocardial infarction (MI), although this may be because of perioperative infarctions that offset the lower incidence of infarction in each study follow-up.[26,42]

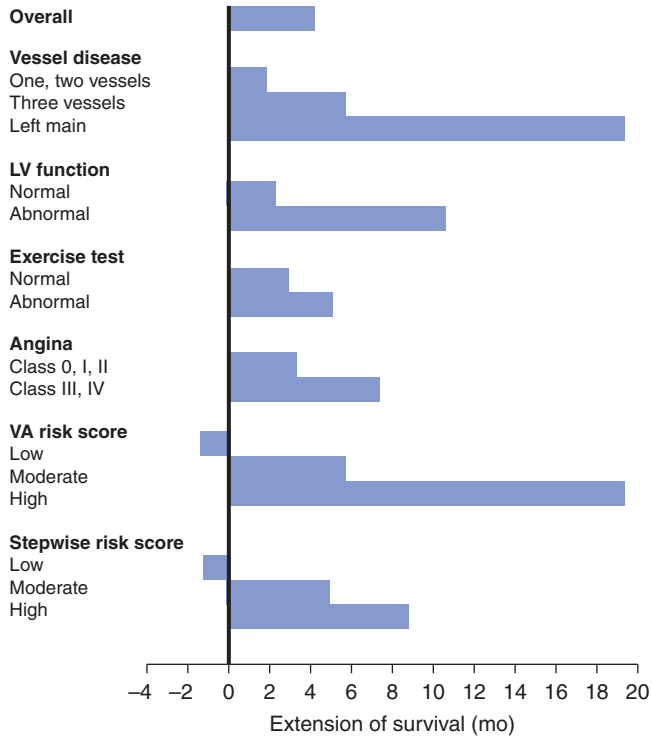

FIGURE 19-2 Extension of survival in months for various subgroups of patients with chronic stable angina treated by surgery as compared with those treated by medicine in seven prospective randomized controlled trials. (*Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: overview of 10-year results from randomized trials by the Coronary Artery Bypass Graft Surgery Trial: 1st collaboration. Lancet 1994; 344:563.*)

PCI versus Medical Therapy

Despite the increasing application of catheter-based technology to multivessel disease, the majority of interventions have historically been in single-vessel disease. Accordingly, most of the data comparing angioplasty with medical therapy are derived from studies comprised principally or exclusively of patients with a limited extent of obstructive disease, although most people with angiographically detectable stenosis in one vessel have more extensive atherosclerotic changes throughout most of their coronary vessels. Many of these trials also antedate the use of IIb/IIIa inhibitors, clopidogrel, and stents. Although angiographic success rates of 85 to 90% are commonplace, no study to date has ever shown a benefit in survival or subsequent MI for PCI over medical therapy in patients with stable angina pectoris. However, the results of several recent studies have demonstrated improvement in symptoms and exercise tolerance.

In the ACME (A Comparison of angioplasty with MEdical therapy)–I study, 212 patients with documented ischemia and a single coronary artery stenosis greater than 70% were randomly assigned to medical therapy or angioplasty.[43] After 6 months, there was no mortality difference in either treatment group; however, PCI provided more complete angina relief with fewer medications and better quality of life scores, as well as longer exercise duration on stress testing than medical therapy.[43] This benefit came at some cost, however; among the 100 angioplasty patients, 19 underwent repeat PCI and seven underwent CABG during the first 6 months, compared with 11 angioplasty procedures and no CABG surgery in the patients

randomized to medical therapy.[43] Moreover, nearly half of all patients assigned to initial medical therapy were asymptomatic at 6 months. Because this modest symptomatic benefit was achieved at such a large procedural and financial cost, patients who are either asymptomatic or have mild symptoms should have objective evidence of ischemia before PCI.[44] In a follow-up study by the same investigators, 101 patients with stable angina and two-vessel disease were randomized to PCI or medical therapy.[45] At 6 months, both groups had similar improvement in exercise duration, freedom from angina, and overall quality of life. These studies together suggest that, in many patients, an initial trial of medical therapy is appropriate.

Several other studies have included patients with multivessel disease. In the Randomized Intervention Treatment of Angina (RITA)–2, of 1018 patients with stable angina randomized to medicine or PCI, one-third had two-vessel disease and 7% had three-vessel disease.[46] Perhaps surprisingly, at a median follow-up of 2.7 years, the primary end points of death or MI had occurred twice as often in the PCI group (6.3 versus 3.3%, $p < .02$). Surgical revascularization was required during the follow-up interval in 7.9% of the PCI group and repeat angioplasty was required in 11%. In the medical group, 23% of patients required revascularization. Angina relief and exercise tolerance were improved to a greater degree in the angioplasty group early, but this difference disappeared by 3 years. These results are echoed in the MASS-II trial, in which angina relief was superior with PCI, but rates of intervention/reintervention were actually higher in the PCI group.[30] Again, this supports an initial strategy of medical therapy.

A comparison of PCI versus medicine as initial strategy among patients with hyperlipidemia was examined in the Atorvastatin versus REvascularization Trial (AVERT).[47] Among 341 patients with one- or two-vessel disease, ischemic events were actually less common in the medical than PCI groups (13% versus 21%, $p < .05$). Although criticized for employing outdated angioplasty technology and other issues, the results of this study are consonant with the demonstration that lipid-lowering agents may have a powerful impact on ischemic events.[48] In some respects, the lower use of aggressive lipid-lowering agents in the PCI arm biased the results in favor of medical therapy.

The most recently published trial, COURAGE, randomized 2287 patients with stable angina and objective evidence of ischemia to best medical therapy or PCI and medical management. All patients received long-acting metoprolol, amlodipine, and/or isosorbide mononitrate, as well as lisinopril or losartan. Patients had aggressive antilipid therapy and appropriate antiplatelet therapy. The primary finding of this trial was a lack of benefit of PCI over best medical therapy for death, myocardial infarction, or other major cardiovascular events.[49] Although this result has caused much controversy in the cardiology community, it is consistent with older studies.

A meta-analysis of percutaneous interventions versus medical management was published in 2005.[50] In patients with stable coronary artery disease, no benefit was found for invasive therapy in terms of death, MI, or need for subsequent revascularization. These studies provide compelling evidence that, thanks to substantial improvements in medical management, all patients should have a trial of optimized medical therapy before invasive intervention.

PCI versus CABG

Randomized Studies

A number of studies comparing an initial strategy of angioplasty versus early surgery have been carried out, all with similar results. It is important to recognize that these studies are comparisons of treatment strategies and not head-to-head comparisons of revascularization techniques. Accordingly, crossover is permitted and end points are selected to determine adverse consequences of the algorithm on an "intention to treat" basis.

A single-center Swiss study of 134 patients with isolated LAD disease was reported in 1994.[51] At 2.5 years of follow-up there was no significant difference in combined outcomes of MI and cardiac death between treatment groups. There was, however, a greater need for surgical revascularization in the initial PCI treatment group, with 25% requiring a second revascularization procedure compared with only 4.4% in the initial CABG group. Although the PCI patients were taking significantly more antianginal medication, clinical impairment level, stress test performance, and quality-of-life indices did not differ at 2 years. These findings held up at 5 years[52] with no difference between groups with respect to mortality or functional outcome despite repeat procedures in the PCI group.

The Medicine, Angioplasty or Surgery Study (MASS) from Brazil compared medical therapy, PCI, and CABG using an ITA bypass at a single center in 214 patients with stable angina, normal left ventricular function, and proximal stenosis of the left anterior descending coronary artery.[53] In this relatively small but nonetheless important randomized trial, the combined end point of cardiac death, MI, or refractory angina requiring revascularization was statistically significantly less in surgically treated patients. Moreover, there was no significant difference between patients treated medically or with PCI. In comparison with medical therapy, however, both PCI and CABG surgery were shown to provide improved relief of severe symptoms of angina pectoris and a lower frequency of inducible ischemia on treadmill exercise testing. There was no difference among the three strategies with respect to mortality or late MI at 1 year. Similar findings were obtained at 5-year follow-up.[54]

The results of the second MASS trial, which enrolled 611 patients with multivessel disease, reported 1-year outcomes as noted in the preceding.[39] Although technology is a moving target, this trial has the advantage that approximately 70% of PCI patients had stents placed. Despite this, the results were remarkably similar to MASS, with a lower incidence of adverse events in the medical group than PCI group. Surgical therapy provided the best angina relief and lowest incidence of adverse events. All therapies had similar survival rates.

A number of larger prospectively randomized studies comparing PCI with CABG have been reported in recent years. All share the limitation that, in general, only a very small minority of patients undergoing revascularization at any center were entered into these trials.[55,56] Accordingly, the populations

included in the trials may not be generally reflective of clinical practice. For instance, few patients in these studies had significant LV dysfunction and most randomized patients had only one- or two-vessel disease. In the RITA trial, approximately one-third of patients had single-vessel disease.[57] Among clinically eligible patients in the Bypass Angioplasty Reperfusion Investigation (BARI)[39] and Emory Angioplasty versus Surgery Trial (EAST)[40] trials, approximately two-thirds of patients were excluded on angiographic grounds that included chronic total occlusion, left main coronary artery stenosis, diffuse disease, or other anatomical factors making PCI potentially dangerous. Consequently these randomized trials contain only a portion of the spectrum of patients with coronary artery disease encountered clinically. Entry bias has a significant impact on the likelihood of observing an outcome difference among therapies. Because a high proportion of the randomized patients are in the low-risk group, it is possible that any potential survival benefit of CABG surgery over PCI in high- and moderate-risk groups may be masked.[56]

A second consideration in evaluating these studies is that the success of revascularization procedures depends not only on the criteria employed to define success, but also on the interpretation of those criteria by both patient and physician. In the 1985 to 1986 National Heart, Lung, and Blood Institute PCI Registry, 99% of patients were discharged alive from hospital, and 92% did not sustain a MI or require CABG surgery.[58] In the BARI trial, 99% of patients survived hospitalization and 88.6% of PCI-treated patients did not have MI or require repeat revascularization by angioplasty or surgery during the initial hospitalization.[39] Employing event-free criteria (death, MI, CABG) for the initial hospitalization, PCI can be judged successful. However, if a repeat revascularization procedure within 5 years is regarded as a negative outcome, then far fewer patients are treated successfully. Regardless, the lack of differences in mortality or MI rates permits individuals to select one or the other procedure as initial therapy without the likelihood that they will pay a price with their health.

In the BARI, EAST, RITA, CABRI, and GABI multivessel PCI versus CABG surgery trials,[39,40,57,59,60] mortality was similar between 1 and 5 years of follow-up in both the PCI and CABG treatment groups. Mortality ranged from 3% in the CABRI trial at 1 year follow-up[59] and 3.4% in the RITA trial at 2.5 years[57] to 13% in the BARI trial at 5 years.[61] A slightly higher incidence of MI was noted in some of these trials.

The incidence of repeat revascularization is higher among patients treated with angioplasty than surgery in all trials carried out to date, ranging from 36.5% in the CABRI trial at 1 year follow-up to 62% in the EAST trial at 3 years. Repeat revascularization in the EAST trial for angioplasty-treated patients was much higher than that in the BARI, CABRI, and RITA trials. In contrast with PCI, repeat revascularization is less common after CABG in these same studies. The incidence of repeat revascularization procedures in multivessel patients randomized to CABG surgery ranged from 3.5% in the CABRI trial to 13.5% in the EAST trial.[40,59] Generally, repeat revascularization procedures were required five to eight times more often in patients with multivessel disease initially treated with angioplasty as compared with those randomized to initial CABG surgery. The incidence of angina at follow-up also was generally greater in the PCI-treated patients.

In the BARI trial at 5 years, 54.5% of patients initially assigned to PCI had undergone a repeat revascularization procedure, including repeat PCI in 23.2%, CABG in 20.5%, and both in 10.8%.[61] Among angina-free patients at 5 years, only 48% of the angioplasty-treated patients compared with 94% of the CABG surgery patients had not had an additional revascularization procedure after their initial procedure. An important subgroup analysis of the BARI trial demonstrated a marked survival benefit with surgery for patients with insulin-dependent diabetes receiving an ITA.

Several more recent studies of PCI versus surgery have confirmed these findings. The Argentine Randomized Trial of Coronary Angioplasty versus Bypass Surgery in Multi-vessel Disease (ERACI) trial conducted between 1998 and 1990 demonstrated no difference in death or MI, but superior event-free survival in the CABG group at 1 and 3 years.[62,63] In the French Monocentric Study, 152 patients with multivessel disease underwent PCI or CABG.[64] Again, superior event-free survival was seen in the surgical group, driven predominantly by a lesser need for subsequent revascularization.

The impact of advanced stent technology on the comparative results of PCI and CABG has been recently investigated as well. In the Arterial Revascularization Therapy Study (ARTS), 1205 patients with multivessel disease underwent CABG or PCI with bare-metal stents.[65] No significant differences in the primary end point of freedom from death, stroke, or MI at 1 year were observed, although the need for revascularization remained higher in the angioplasty than surgery groups. Similarly the second Argentine Randomized Trial of Coronary Angioplasty versus Bypass Surgery in multivessel disease (ERACI II) study group[66] demonstrated that, even with the use of stents, repeat revascularization was more common in the PCI group, particularly among diabetics in whom repeat revascularization was required in 22.3% versus 3.1% in the CABG group. Of note, in this study, the 30-day mortality was higher in the CABG than PCI group, as was the incidence of Q wave MI. Despite a high operative mortality rate (5.7%) in the surgery group that raised many questions, at 5 years, there was no difference in survival and again, CABG patients had a lower incidence of revascularization. The Surgery Or Stent (SOS study), which compared outcomes in almost 1000 patients with multivessel disease, demonstrated similar all-cause mortality among surgical compared to angioplasty patients and confirmed higher rates of repeat revascularization after angioplasty and lower freedom from angina pectoris in both patients with and without a recent acute coronary syndrome.[67] Of interest in this study, the reintervention rate, while still higher than after surgery, was far below that previously reported for angioplasty at only 17%. Mercado et al. performed a meta-analysis of the ARTS, ERATSII, MASSII, and SOS trials that demonstrated similar rates of death, MI, or stroke at 1 year and higher repeat revascularization rates with PCI.[68] A meta-analysis of 5-year data was also recently published, confirming the 1-year results with repeat revascularization more frequent after PCI than CABG (29% versus 7.9%, $p < .001$) (Fig. 30-3).[69]

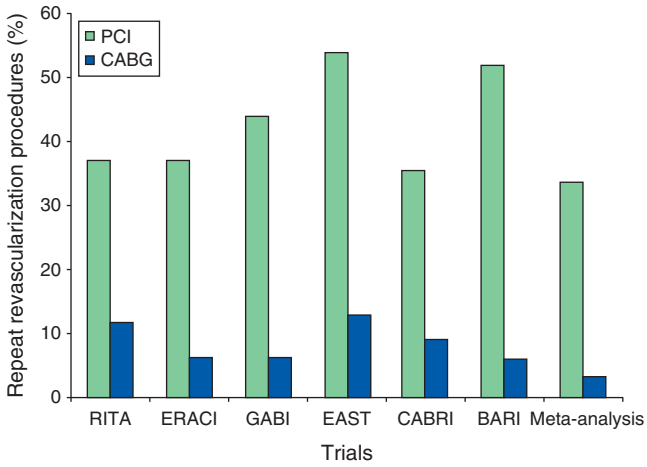

FIGURE 19-3 Risk of repeat revascularization in six randomized trials of PCI versus CABG surgery and a meta-analysis.[74] See references 58, 59, 76–78, and 80 for an explanation of acronyms.

The most recent trial, the Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial, assessed the optimal revascularization strategy for patients with three-vessel or left main coronary artery disease by randomizing 1800 patients to either CABG or drug-eluting stents.[70] At 12 months, the rates of myocardial infarction and death were similar between groups, but stroke was significantly more common in the CABG patients (2.2% versus 0.6% at 1 year). It should be noted that the CABG group had much less aggressive medical management postoperatively, including fewer patients on antiplatelet medications, which may account for some of the increase in stroke risk. Despite the use of DES, the rates of reintervention were still significantly higher (13.5% versus 5.9%) in the PCI group than the CABG group. Because of the lack of difference in early mortality and myocardial infarction, some cardiologists have begun to suggest that left main should no longer be an indication for CABG.[71] However, others maintain that the evidence for PCI is still inadequate and that the greater freedom from reintervention with CABG suggests that CABG remains the treatment of choice for patients with left main disease.[72]

In conclusion, the randomized trials of PCI versus CABG are useful, but only if results are interpreted in a context of patients entering or eligible to enter these trials.[55,56] PCI is a reasonable alternative to CABG surgery, and for many patients it is the preferred initial approach, provided the patient understands that there may be a higher incidence of recurrent angina and need for repeat revascularization procedures, as well as a year-long commitment to use of clopidogrel because of concern regarding catastrophic late stent thrombosis. For most patients similar to those included in these published trials, it is reassuring that a nonsurgical revascularization procedure does not place them at increased risk of MI or death in comparison with the outcomes of surgical therapy. To extrapolate these results to patients who would not have met entry criteria, however, it is intellectually flawed and potentially misleading.

Nonrandomized Database Comparisons

The information provided by randomized studies is complemented by information gleaned from large, prospectively managed, nonrandomized database studies. Such registries provide insight into the management of the sizeable population of patients who would not have been eligible for randomization. The Duke Cardiovascular Disease Databank followed 9263 patients undergoing clinically indicated coronary angiography between 1984 and 1990 for a mean of 5 years after nonrandomized treatment by CABG, PCI, or medical therapy.[9] Patients with valvular disease, prior revascularization, significant (>75%) left main disease, and congenital and nonischemic cardiomyopathy were excluded. Overall, 39% of the patients had one-vessel disease, 31% two-vessel disease, and 30% three-vessel disease. Initial therapy was medical in 3053 patients, PCI in 2788 patients, and CABG in 3422 patients. To correct for baseline differences among treatment groups, a standard covariate adjustment was performed that included all identified prognostic factors in a multivariate survival model. Complete follow-up was obtained in 97% of patients. The 5-year survival was 91%, remarkably similar to that reported from Emory, which showed an overall adjusted 5-year survival rate of 93% in both groups.[32] The mortality hazard ratios derived from the Cox regression model to evaluate relative survival differences in this database study are shown for medicine versus CABG surgery in Fig. 19-4, PCI versus medicine in Fig. 19-5, and PCI versus CABG in Fig. 19-6.[9]

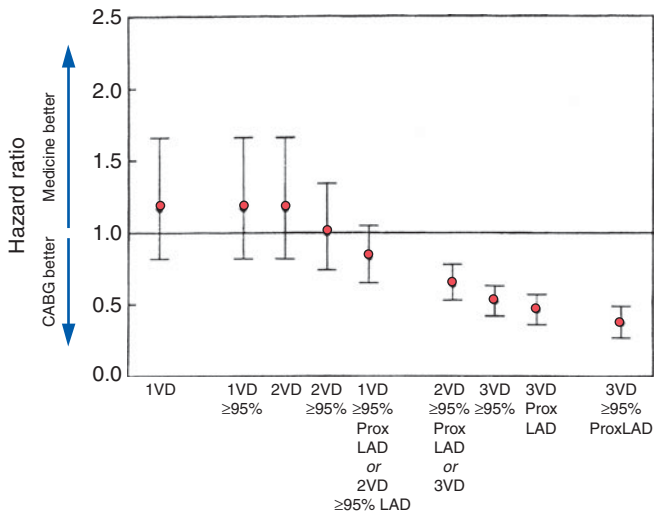

FIGURE 19-4 Hazard (mortality) ratios for CABG surgery versus medicine calculated from the Cox regression model to evaluate relative survival differences. Points indicate hazard ratios for each level of a weighted (0 to 100), hierarchical, prognostic coronary artery disease index. Bars indicate 99% confidence intervals. Horizontal line at 1.0 indicates point of prognostic equivalence between treatments. Hazard ratios below this line favor CABG; those above the line favor medicine. Prox LAD = Proximal left anterior descending coronary artery; VD = vessel disease. Circulation 1994; 89:2015.*)

From a practical standpoint, in this database study and in the randomized trials, the effect of revascularization on survival depended largely on the extent of the coronary artery disease and is an example of the concept of benefit in relationship to a "gradient of risk." For the least severe (one-vessel) disease, there were no survival advantages of revascularization over medical therapy in up to 5 years of follow-up.[9] For intermediate levels of coronary artery disease severity (ie, two-vessel disease), there

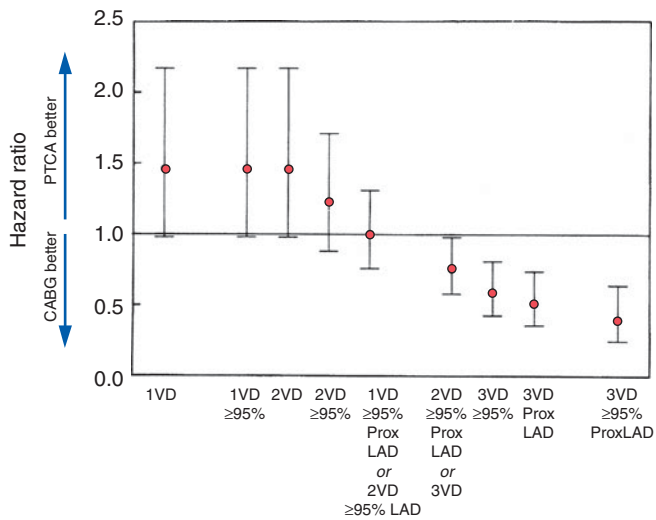

FIGURE 19-6 Hazard ratios for CABG surgery versus PCI. See Fig. 19-4 for explanation. Points below the horizontal line favor CABG. Circulation 1994; 89:2015.*)

was a higher 5-year survival rate for patients undergoing revascularization than for those treated medically. For patients with the most-severe coronary artery disease (ie, three-vessel disease), CABG surgery provided a significant and consistent survival advantage over medical therapy. PCI appeared prognostically equivalent to medical therapy in these patients, but only a small number of patients in this subgroup underwent angioplasty. In comparing PCI with CABG surgery, PCI demonstrated a small survival advantage over CABG surgery for patients with less-severe two-vessel disease, whereas CABG surgery was superior for more severe two-vessel disease (ie, proximal left anterior descending artery involvement).[9]

These important findings have been confirmed in the current era of PCI with stent implantation using the New York State Database published in 1999 using cases from 1993 to 1995.[73] In this study, a survival benefit was observed with angioplasty at 3 years for those patients with single-vessel disease not involving the LAD, whereas those with LAD or three-vessel disease had superior outcomes with surgery. In the more recent study of patients with multivessel disease who received PCI, survival was higher among the 37,212 patients who underwent CABG than among the 22,102 patients who underwent stent placement after adjustment for known risk factors. The adjusted hazard ratio for the long-term risk of death after CABG relative to stents was 0.64 (0.56 to 0.74) for three-vessel disease and proximal LAD disease. This hazard ratio increased to 0.76 (0.60 to 0.96) for patients with two-vessel disease and LAD involvement[74] (Fig. 19-7). This study has limitations of being a nonrandomized study and subject to bias; however, the surprising finding of a survival advantage apparent as early as 3 years postprocedure suggests that improvements in cardiac surgical anesthetic care, myocardial protection, and intensive care management have at least matched if not surpassed advances in percutaneous technology. It is important to note that PCI targets the culprit lesion. In contrast, CABG surgery targets both the culprit lesion and potential future culprit lesions by bypassing the diseased vessel. This in part may explain the apparent mortality benefit derived with CABG (Fig. 19-8).[75]

SPECIAL CIRCUMSTANCES

Acute Coronary Syndromes

The acute coronary syndromes (ACS) cover a wide spectrum from ST-segment elevation MI with underlying coronary obstruction to Prinzmetal's or variant angina in patients with coronary vasospasm in the absence of significant underlying obstruction. The term non–ST-segment elevation ACS encompasses the entities of unstable angina, non–Q wave MI, and postinfarction angina. They denote acute, symptomatic imbalances of the myocardial oxygen supply-demand ratio over a short time span. Prinzmetal angina, or coronary vasospasm, is diagnosed definitively by electrocardiograms obtained during the episode of pain and is treated medically. Unstable angina is not a uniform clinical entity, but comprises the spectrum of myocardial ischemia between chronic stable angina and MI, and is defined as a recent change in the severity, character, or trigger threshold of chronic stable angina or new-onset angina.

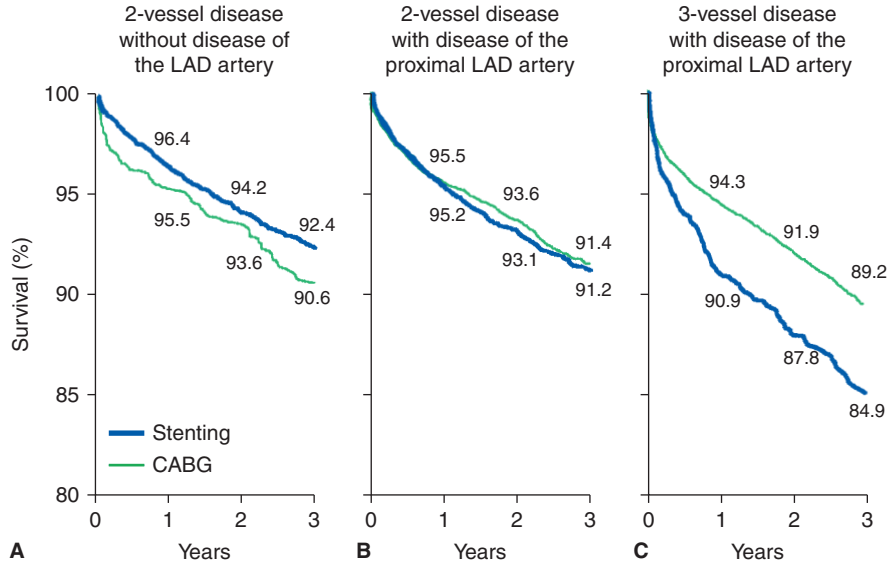

FIGURE 19-7 Unadjusted Kaplein-Meier survival curves in patients with two-vessel disease without involvement of the LAD artery (A), patients with two-vessel disease with involvement of the proximal LAD artery (B), and patients with three-vessel disease with involvement of the proximal LAD artery (C). (*Reproduced with permission from Hannan E, Racz M, Walford G, et al: Long-term outcomes of coronary-artery bypass grafting versus stent implantation. NEJM 2005; 352:2174.*)

Approximately 5.6 million Americans have chronic angina, and about 350,000 develop new-onset angina each year. Unstable angina develops in approximately 750,000 Americans each year and is associated with subsequent MI in approximately 10%. Postinfarction angina is defined as the presence of angina or other evidence of myocardial ischemia in a patient with a recent (1- to 2-week) Q wave or non–Q wave MI.

The initial approach to the patient with non–ST-segment elevation ACS (NSTEMI) is pharmacologic stabilization followed by risk stratification. The latter is based on multiple clinical, demographic, and ECG variables in addition to the use of serum biomarkers. In institutions with facilities for early angiography, patients at intermediate or high risk (the majority) undergo early angiography with a view to revascularization. In many parts of the world, however, angiographic facilities are limited and an alternative approach based upon pharmacologic stabilization followed by mobilization and risk stratification using stress testing is employed.

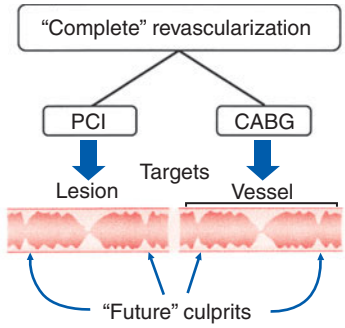

FIGURE 19-8 PCI is directed against specific culprit lesions. By bypassing diseased vessels, CABG surgery treats both culprit lesions and future culprit lesions. (*Reproduced with permission from Opie LH, Commerford PJ, Gersh BJ: Controversies in stable coronary artery disease. Lancet 2006; 367;69.*)

The most recent randomized controlled trials of aggressive versus conservative approaches to non–ST-segment elevation ACS are the FRISC II, TACTICS, and VINO trials.[76–78] Despite differences between these trials, the results favor an aggressive strategy with a view toward revascularization in the majority of the patients shown to be at high risk (eg, older patients, diabetics, those with ST-segment depression on ECG, and those with elevated CPK-MB or serum troponins).

CABG versus Medical Therapy in ACS

The technical advances in PCI in the setting of ACS have relegated CABG largely to a secondary position in most cases. The special circumstances of postinfarction mechanical complications of papillary muscle rupture, ventricular septal defect, and shock are addressed specifically in other chapters of this text. It should be noted here, however, that two multicenter trials and one single-center randomized trial involving a total of 823 patients have evaluated the relative merits of CABG surgery and medical therapy in unstable angina, excluding left main disease, poor left ventricular function (ejection fraction <30%), and age greater than 70 years during the 1970s.[79–81] The VA cooperative study demonstrated improved survival and a lower rate of recurrent angina with surgery, and at both 5 and 8 years there were fewer subsequent hospitalizations for cardiac reasons in the surgical group.[79] Interestingly, there was no difference in progression to Q wave MI between medical and surgical groups. Like the VA study, the National Cooperative Study Group Trial[80] showed no difference in progression to Q wave MI, but less severe subsequent angina with operation. Unlike the VA trial, however, there was no survival difference at 2 years

(90% in both groups). Of note, 32% of the medical group crossed over to surgery by 24 months. As current medical therapy was not available to these patients, there is significant difficulty in extrapolating the results of these trials to current clinical practice. Finally, Bertolasi and colleagues reported a single-center study of 113 patients, which demonstrated less subsequent angina, fewer infarctions, and a survival benefit for surgery in short-term follow-up.[81]

In the TIMI-IIIB trial of medical management followed by early PCI or CABG, 6-week mortality and nonfatal MI rates were 2.1 and 6.1% among 1473 patients with unstable angina or non–Q wave MI (NQWMI).[82] This study compared the results of a strategy of initial stabilization followed by aggressive treatment involving routine angiography followed by revascularization in the presence of suitable anatomy with a conservative arm reserving angiography for those with recurrent angina or a positive stress test. At 42 days and 1 year follow-up there was no difference in death or MI between the two groups. Subsequent subset analyses have demonstrated a trend in favor of an aggressive approach to revascularization over medical therapy in patients at higher risk as characterized by an elevated CPK-MB fraction (NQWMI).[82] In the end, revascularization rates were similar, with only the timing of that revascularization event being different.

The Veterans Affairs non–Q wave infarcts and strategies in hospitals (VANQUISH) trial[83] was a similar design to TIMI-IIIB. A higher early mortality rate was observed in the invasive group than in the medical group, possibly because of the extraordinarily high perioperative mortality rate of 7.7% in the CABG group. The opposite result was found in the second Fragmin and Fast Revascularization during Instability in Coronary Artery Disease trial (FRISC II).[76] These investigators found a benefit with early revascularization, particularly among patients with elevated troponins. The reason for such different results among these studies is likely owing to differences in patient populations studied. It is likely that higher-risk patients benefit from an aggressive approach, whereas lower-risk patients have less to gain and so are more likely to suffer adverse consequences.

The Angina With Extremely Serious Operative Mortality Evaluation (AWESOME) trial was reported in 2004,[84] comparing results from PCI and CABG among patients with more than one of the following risk factors: prior CABG; ACS within 7 days; LVEF less than 35%; age greater than 70 years; or intra-aortic balloon pump. The results suggested that PCI and CABG have similar outcomes for acute coronary syndromes in these patients even in the presence of low ejection fractions.

PCI for Acute MI

Because of the rapidity with which vessel patency can be restored using percutaneous techniques, PCI has all but replaced CABG in the setting of acute ST elevation MI (STEMI). Both thrombolytic therapy and direct or primary angioplasty can restore coronary artery patency and flow during acute STEMI. In the absence of hemorrhagic concerns, however, thrombolytic therapy is more widely available and is standard early therapy for acute transmural MI when immediate angioplasty is unavailable.

In the few instances in which surgical revascularization must be undertaken following thrombolysis or acute angioplasty, perioperative bleeding is increased. Bleeding has been shown not to be excessive if glycoprotein IIb/IIa inhibitors are discontinued at least 2 hours preoperatively[85] or if a platelet transfusion is provided in the presence of abciximab.[86] Clopidogrel should be held for 5 days before surgery if possible.[87]

Several early myocardial reperfusion trials have assessed the role of routine adjunctive angioplasty given that not all arteries can be reopened by thrombolysis, reocclusion occurs in some arteries initially opened, and reocclusion is associated with increased morbidity and mortality.[88,89] In these studies, the addition of routine angioplasty to thrombolytic therapy did not enhance patency, improve left ventricular function, or reduce early mortality in comparison with a more conservative approach of ischemia-driven angiography, but did increase expense and vascular bleeding problems.[90,91] A meta-analysis of adjunctive PCI and thrombolysis versus thrombolysis only showed no early benefit of PCI except in patients who have clinical indications for early revascularization (eg, postinfarction angina).[92] These studies were performed in an early phase of PCI, however, and the addition of stents as well as IIb/IIIa inhibitors and new lytics have more recently renewed interest in a combined strategy.

Asymptomatic Coronary Artery Disease

The role of revascularization either by PCI or CABG versus medical therapy in the setting of asymptomatic coronary artery disease has been studied in the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial.[93] Of 558 patients with coronary artery disease and medically controlled angina, treatment was randomized to either revascularization or medical therapy directed toward eliminating angina or eliminating ischemia during ambulatory ECG. Revascularization was more effective than medical therapy in relieving ischemia, and CABG was superior to PCI (70% freedom from ischemia versus 46%, $p < .002$). Mortality at 1 and 2 years was superior for revascularization as compared with angina-directed medical therapy, but not superior to ischemia directed medical therapy.[29,93] The greatest benefit was among those patients with the most severe disease. Importantly, many of these patients with "silent ischemia" on ambulatory ECG monitoring did have symptomatic angina at other times and thus were not truly asymptomatic.

The documentation of ischemia, however, is critical. Several studies emphasize the flaws in the assumption that one can identify future culprit lesions in the absence of symptoms or documentation of ischemia. Among patients undergoing serial coronary arteriography who subsequently developed acute MI or unstable angina, the severity of stenosis at the time of initial angiogram is poorly predictive of the culprit lesion causing the acute ischemic syndrome.[94,95] In most cases the severity of the lesion responsible for subsequent ischemia was less than 50%, and in many patients it was not present at all on the initial angiogram, raising concern regarding the number of asymptomatic or minimally symptomatic patients undergoing angioplasty without stress testing.[96] Bech and associates have demonstrated that fractional flow reserve exceeded 0.75 in 91 of 325 patients planned for PCI without noninvasive evaluation

of ischemia, and that among those patients, angioplasty had no impact on event-free survival or angina.[97]

Drug-Eluting Stents

Recent progress in stent technology, particularly the introduction of drug-eluting stents (DESs), promises to further reduce the incidence of restenosis. The use of stents has reduced adverse remodeling, and stents eluting medications such as sirolimus or paclitaxel, are having a profound effect on the patterns of interventions for CAD. When compared with bare-metal stents, DESs have not been shown to convey any advantage in terms of MI or mortality, but do demonstrate decreased rates of angiographic restenosis in a meta-analysis of 11 randomized trials.[98] In an observational study of 1680 patients who had CABG or PCI with a DES, CABG provided a benefit in terms of major cardiac events for patients with two- or three-vessel disease, as well as diabetic patients.[99] In another cohort of patients with multivessel disease, CABG was associated with lower rates of death, myocardial infarction, and target-vessel revascularization than drug-eluting stents. Thus, although DES may have some advantage over bare-metal stents, the indications for PCI and CABG have not changed.[100]

Left Main Disease

Significant left main disease has been considered an indication for CABG rather than PCI for many years, but recently studies have begun to question this. In a matched cohort of more than 1100 patients with unprotected left main disease, there was no difference in the rates of death or the composite outcome of death, Q wave myocardial infarction, or stroke between patients undergoing CABG or PCI despite a greater rate of target-vessel revascularization in the PCI group, including the patients who received DES.[101] Another single-center observational study focused on octogenarians reported no significant differences in cardiac death, myocardial infarction, or major adverse cardiac events between CABG and PCI at a mean follow-up of 2 years.[102] Recently, a randomized study enrolled 105 patients with unprotected left main coronary artery disease. The study had the unusual primary end point of the change in left ventricular ejection fraction after 1 year. The authors found that there was a significant increase in ejection fraction only in the PCI group (3.3%) compared with the CABG group (0.5%). There was no difference in survival at 1 year or in major cardiac adverse events. However, it should be noted that of the patients who received CABG, only 72% received a LIMA graft, which would generally not be reflective of current surgical practice.

Severe Left Ventricular Dysfunction

Left ventricular dysfunction is a predictor of increased operative risk for most cardiac surgical procedures, and in the early days of coronary revascularization these patients were not offered CABG. Like age, however, it is also a strong predictor of poor outcome with medical therapy. Accordingly, more recently significant LV dysfunction has been considered an indication rather than contraindication to surgical revascularization. In some patients, LV function has been shown to improve—sometimes dramatically so—after revascularization, leading to the concept of "hibernating" or "stunned" myocardium.[103–105] The identification of viable myocardium, which is potentially recoverable, depends on the identification of preserved metabolic activity by positron emission tomography (PET), cell membrane integrity by thallium-201 or technetium-99m SPECT, or dobutamine stress echocardiography.[106]

The only randomized trial in patients with severe LV dysfunction, the Surgical Treatment for Ischemic Heart Failure (STICH) trial, compared medical versus surgical therapy. The results from this hypothesis have not yet been published. However, a number of retrospective analyses of the impact of revascularization on outcome in patients with LV dysfunction with or without demonstrable viability have been reported (Fig. 19-9).[107] Allman and colleagues reported the results of a meta-analysis of these studies[108] demonstrating a 79.6% reduction in annual mortality (16% versus 3.2%, $p < .0001$) among patients with severe three-vessel disease, severely depressed LV function, and evidence of viability undergoing surgery versus medical therapy. Among those patients without demonstrable viability, the mortality rates were similar (7.7% versus 6.2%, $p = \text{NS}$). This study is subject to all of the limitations of a retrospective surgical series, however, including perhaps most importantly the unaccountable effect of clinical judgment employed in selecting patients for one therapy versus another.

The relative roles of CABG and PCI in this population are not clearly defined despite the number of randomized trials of angioplasty versus surgery, largely because these patients were excluded from trial entry. In a multicenter study of patients with left ventricular dysfunction (ejection fraction <40%), slightly more than one-fourth of the patients were dead in the 2 years following multivessel angioplasty.[109] Similar results have been reported from other studies of PCI in patients with multivessel disease and left ventricular dysfunction. Overall, the outcome with PCI appears less favorable than that obtained after CABG surgery,[32] possibly as a function of more complete revascularization in surgical patients.[110]

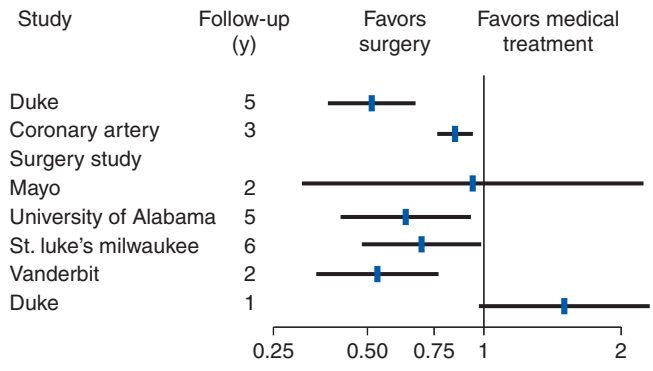

FIGURE 19-9 Relative risk of mortality for coronary artery bypass grafting compared with medical therapy in moderate-to-severe left ventricular systolic dysfunction, ranked in order of study quality. (*Reproduced with permission from Chareonthaitawee P, Gersch BJ, Araoz PA, et al: Revascularization in severe left ventricular dysfunction: the role of viability testing. J Am Coll Cardiol 2005; 46;567.*)

Completeness of revascularization may be particularly important in patients with left ventricular dysfunction. An analysis of data from the CASS registry demonstrated that, among patients with triple-vessel disease, 4-year survival was dependent on the number of vessels bypassed, particularly among those with more severe angina and those with worse ventricular function.[110] For PCI, complete of revascularization of target arteries ranged from 57 to 61% in the prospective randomized trials in which complete revascularization was not a protocol requirement (BARI, EAST, CABRI). In the GABI and RITA trials complete revascularization by PCI was targeted and was achieved in 86% in GABI and in 81 and 63% of patients with two- or three-vessel disease in RITA.[59,60]

Total Occlusion

In most patients with chronic, totally occluded coronary arteries, revascularization is not possible, although the advent of stent technology has offered some improvement in this area. In the randomized trials of multivessel PCI versus CABG, 35 to 37% of the patients excluded were disqualified because of the presence of a chronic total occlusion of a coronary artery serving viable myocardium. Thus the high proportion of trial patients with less than three-vessel disease, well-preserved ventricular function, and absence of chronically occluded arteries produces a study population that favors a higher incidence of complete revascularization by PCI and attenuated consequences of incomplete revascularization than expected in community practices. Among patients with severe angina, triple-vessel disease, and ventricular dysfunction, survival is greater in those with three or more coronary arteries bypassed than in those with only two vessels bypassed.[24,109] CABG surgery improves survival in patients with three- and two-vessel disease with left ventricular dysfunction compared with medical therapy. Although angioplasty may have a similar survival benefit, its influence on this high-risk subgroup has not been fully tested or reported.

The Elderly

Age is a predictor of operative risk in most models, but is also a predictor of poor outcome with medical therapy in the presence of coronary artery disease. The Swiss Multicenter Trial of invasive versus medical therapy in the elderly (TIME) trial briefly noted in the preceding, examined 301 patients greater the age of 75 with chronic angina were randomized to medical therapy with or without invasive evaluation.[31] Of those undergoing angiography, two-thirds had revascularization. At the 1-year follow-up interval, there was no statistical difference in death or nonfatal myocardial infarction rates. Symptoms and quality of life were also similar. However, there was a substantial increased risk of rehospitalization with revascularization in those who had medical treatment. These data suggest that invasive evaluation should be offered to elderly people who are symptomatic only after adequate medical therapy.

The choice of mode of revascularization will be particularly impacted in this group of patients by the presence of comorbidities that may increase the risk of surgical intervention, such as cerebrovascular disease, renal dysfunction, and pulmonary disease. The impact of a reduction in operative morbidity through "off-pump" coronary bypass (OPCAB) on this choice is as yet unclear. There are an increasing number of studies to suggest that it is in just this group of patients with comorbid conditions that "off-pump" surgery offers its greatest advantage over conventional surgery. The majority of these studies are not randomized, however, making their results less conclusive than one would hope. There are two retrospective and nonrandomized trials reviewing elderly patients who underwent OPCAB. There were more grafts in the standard CABG for both studies, but there were fewer strokes, incidences of prolonged respiratory failure, bleeding, transfusions in the OPCAB group, and both ICU and hospital length of stay were reduced. Reoperation for bleeding, MI, renal failure, wound infections, and operative mortality were not significantly different.[111,112] Among the randomized trials, there has been no consistent advantage to OPCAB with respect to neurocognitive outcomes, a particularly important end point in elderly people.[113] A meta-analysis of both randomized and observational studies of OPCAB and standard "on-pump" CABG in diverse populations[113,114] has failed to demonstrate any difference except for a reduction in atrial fibrillation in the OPCAB group (OR 0.59 [0.46–0.77]). The impact, therefore, of newer technologies on modifying the indications for CABG in elderly people is as yet unclear.

Diabetes Mellitus

It has been recognized for many years that patients with diabetes mellitus are at higher risk following percutaneous[115,116] or surgical[117] revascularization. The BARI trial was the first trial large enough to identify significant differences in outcome between diabetic and nondiabetic patients. In this study, which included 353 diabetic patients, a survival benefit was observed among insulin-dependent patients undergoing CABG with an ITA, as compared with those undergoing PCI. The explanation for this is not entirely clear, although an intriguing observation is that while the incidence of subsequent MI is similar between groups, survival after MI is superior among those who have undergone surgical revascularization.[118] In fact, diabetics suffering spontaneous Q wave MI were more than 10 times as likely to die with their infarction if they had been treated with PCI as compared with CABG. No such protective effect was seen among nondiabetic patients either with or without Q wave MI. This survival difference was even more pronounced at 7 years with 76.4% of diabetics in the surgical arm alive as compared with 55.7% in the angioplasty arm.[119]

The physiologic basis for this difference remains a matter of speculation, although the completeness of revascularization may be a factor. Because of the significant incidence of restenosis after PCI in diabetics, Van Belle and colleagues[120] analyzed ejection fraction at 6 months and long-term cardiac mortality and morbidity among 513 diabetic patients stratified according to the presence of occlusive restenosis ($n = 94$), nonocclusive restenosis ($n = 257$), and no restenosis ($n = 162$). The mortality rose with restenosis (24% without restenosis, 35% with nonocclusive restenosis, and 59% with occlusion), and ejection fraction fell with occlusion (decrease of 4.8% ± 12.6%).

Coronary occlusion was strongly predicted by coronary occlusion by multivariate analysis.

The results of the BARI trial prompted retrospective post hoc analyses of several earlier trials. The results have been variable. An analysis of diabetic patients from the CABRI trial at 8 years demonstrated a mortality rate of 3.5% for CABG patients versus 15.6% for PCI.[121] There was also a nonsignificant trend for better survival among diabetic patients treated surgically in the EAST trial.[122] A meta-analysis of pooled data pertaining to diabetic patients from CABRI, EAST, and RITA, however, found similar 5-year mortality rates following CABG or PCI.[123]

The follow-up study to BARI, BARI-2D, has recently been reported.[124] A total of 2368 patients with diabetes mellitus and stable coronary artery disease were randomized to receive either intensive medical therapy or intensive medical therapy and prompt revascularization (CABG or PCI left to clinical judgment). At 5 years there was no different in survival or freedom from major cardiovascular events (myocardial infarction or stroke) between medical therapy and revascularization groups. This trial was not designed to compare CABG and PCI in diabetes, but rather to examine a strategy of intensive medical therapy compared with revascularization. However, in the stratum of patients who received CABG, there were fewer major cardiovascular events when compared with medical therapy (22.4 versus 30.5%, $p = .002$). In the stratum of patients who received PCI, there was no difference in major cardiovascular events when compared with medical therapy.

Several other data bank studies have also been conducted. The Northern New England Cardiovascular Disease Study Group evaluated survival 5 years after treatment among 7159 diabetic patients with multivessel disease who were treated with CABG or PCI between 1992 and 1996.[125] Of this group, 38.6% of patients were clinically and angiographically similar to those randomized in BARI. Patients were treated according to physician preference. Those undergoing CABG were more likely to have three-vessel disease and tended to be older with greater degrees of ventricular impairment and obstructive lung disease. There were more women and more urgent interventions in the PCI group. After adjusting for these variables, PCI was associated with a significantly greater mortality rate at 5 years (risk ratio 1.49, 95% confidence interval 1.02 to 2.17, $p = .037$) and particularly among diabetics with three-vessel disease (hazard ratio 2.01, confidence interval 1.04 to 3.91, $p = .038$).

Diabetes is a condition characterized biologically by an inflammatory, proliferative, and prothrombotic state. This may account in part for the increased risk of restenosis and occlusion. Because diabetics tend to have more diffuse disease, the importance of complete revascularization, which is more often achieved surgically that percutaneously, may be enhanced. Another explanation may have more to do with patient selection than vascular biology. It has long been recognized from the previously cited studies that the survival advantage of CABG over medical therapy is greater the more extensive the coronary disease; and more recent studies of PCI versus CABG have demonstrated similar trends. Diabetic patients tend to have more extensive disease, and in BARI diabetics had a higher frequency of three-vessel disease, diffuse disease, proximal LAD disease, and left ventricular dysfunction.

In this respect, it is interesting to note that in community studies[126] and the BARI Registry, although diabetics have a poorer outcome with both PCI and CABG in comparison with nondiabetics, there were no significant differences in outcomes between these therapies in the diabetic subgroup. It must be emphasized that in these nonrandomized trials in which the selection of therapy was at the discretion of the physician and the patient, a very clear trend was noted. The "sicker" patients with left ventricular dysfunction and triple-vessel disease were far more likely to undergo CABG in contrast with patients with double-vessel disease and preserved left ventricular function. Therefore, these registry studies suggest that although the differences between bypass surgery and PCI in diabetics may be caused by altered vascular biology, these differences are magnified by the process of randomization in which patients who probably would have been treated with CABG in clinical practice were randomized to PCI.

From a clinical standpoint in regard to patient selection for coronary revascularization and the method of revascularization, the assessment of diabetics should be made on standard principles, namely, the severity and extent of coronary disease, the potential for complete revascularization, the presence or absence of left ventricular dysfunction, and the technical suitability of the lesions for PCI. The results of the aforementioned studies suggest that a preference for surgical over percutaneous revascularization is, at this time, appropriate among diabetics—at least those with extensive disease and/or ventricular dysfunction. This recommendation may change if new technologies such as drug-eluting stents and antiplatelet agents are successful in reducing the risk of restenosis and occlusion. DES are being used with greater frequency due to subset analysis of the TAXUS IV and SIRIUS trials showing a significant decrease in restenosis. However, these studies were not powered to determine restenosis rates in diabetics and there is significant risk of a type I error.[127–129] Furthermore, the potential impact of risk factor reduction may alter the risk:benefit balance in future in this important and increasing subset of patients presenting with coronary artery disease. Current data suggest that the decreased incidence of repeat revascularization, cardiac rehospitilization, and recurrent angina can be reduced to the level of nondiabetics if diabetics maintain optimal glycemic control (HbA1c ≤ 7%).[130] Irrespective of the mode of therapy, an aggressive approach to risk factor modification is required.

End-Stage Renal Disease

End-stage renal disease (ESRD) is a growing problem. Cardiovascular disease is the most common cause of death among those with ESRD; therefore, there will likely be high rates of revascularization required in these patients in the future. Comorbidities complicating surgical or percutaneous revascularization, such as diabetes, hypertension, and calcified vessels, are more common in patients with ESRD, increasing the risk of intervention. A study conducted by the Northern New England Consortium found dialysis-dependent patients with renal failure to be 3.1 times more likely to die after CABG after adjusting for known risk factors (OR 3.1, [2.1 to 3.7], $p < .001$).[131] They also found significantly increased rates of mediastinitis (3.6% versus 1.2%)

as well as postoperative stroke (4.3% versus 1.7%).[157] The long-term survival was also decreased with renal failure, which was found to be a highly significant predictor of mortality after adjustment.[132] Despite these risks, the prognosis without surgical correction of coronary artery disease is poor. Revascularization in patients with ESRD is associated with improved survival compared with medical management.[133]

CHAPTER 20

Myocardial Revascularization with Percutaneous Devices

James M. Wilson
James T. Willerson

INTRODUCTION

At its height, the popularity of surgical coronary revascularization spurred improvement in catheter-based technology—first for imaging quality and later for attempted therapy. In 1974, Andreas Gruentzig completed development of the double-lumen balloon catheter that was miniaturized for use in coronary arteries. Soon afterward, techniques for percutaneous transluminal coronary angioplasty (PTCA) expanded as technical breakthroughs were applied to subselective catheters, devices, guidewires, balloon materials, and lastly, coronary stents. Presently trial evidence attests that percutaneous therapy is useful as a treatment in patients with unacceptably controlled angina whose anatomy does not imply a survival benefit from revascularization or for patients with uncontrollable, unstable symptoms. However, surgical and percutaneous revascularization cannot be considered equivalent.[1]

BALLOON ANGIOPLASTY

Principles

In the early balloon angioplasty era, several technical limitations restricted percutaneous techniques to low-risk patients with proximal, discrete coronary artery stenoses, and procedural outcomes lacked predictability. As advances in tools and techniques were developed, higher-risk patients became candidates for percutaneous therapy. Over time, several principles for safety and success were recognized (Table 20-1).

Tools

Guiding Catheters

Guiding catheters differ from diagnostic catheters in that a wire-braid supports a thin catheter wall, allowing for a larger central lumen and providing enough rigidity to support the advance of subselective catheters to the distal regions of the coronary bed. The anatomy of the ascending aorta and the origin of the treated coronary artery determine the shape of the guiding catheter that will provide the most secure positioning (Fig. 20-1). The choice of guiding catheter often is the deciding factor for success when approaching challenging anatomy or when complications increase procedural difficulty. Guiding catheter manipulation is a common cause of procedural complications that necessitate urgent transition to coronary artery bypass surgery.

Guidewires

When the guiding catheter position remains secure, the guidewire allows control of the distal vessel. Different wires vary in stiffness, coatings, diameter, and design of the distal steering tip. For most procedures, the chosen wire is a 190- to 300-cm monofilament that is 0.0254 to 0.0356 cm in diameter, with either a graded tapering segment welded to the tip or a gradual taper of the monofilament. The central wire core at the tip is "plastic," or malleable, and may be shaped by the operator. In many wire designs, a wire coil wrapped around the central filament projects a blunter, less traumatic tip to the vessel that it

TABLE 20-1 Principles of Percutaneous Coronary Intervention

1. The patient's outcome is a function of age and comorbidity.
2. The procedure's outcome is a function of anatomy and proper planning (ie, sequence and equipment choices, such as guidewires and device).
3. Proximal and distal control of the treated vessel must be maintained.
   a. Choose proper guide catheter support.
   b. Maintain distal wire position.
   c. Keep the guide, device, and distal wire tip visible during any movement of any device.
4. Needs and limits to treatment options such as devices, adjuvant medical therapy, contrast use, and circulatory support are determined by
   a. Vascular access
   b. Clinical setting (eg, stable angina or acute myocardial infarction)
   c. Ventricular function
   d. Comorbidities: diabetes mellitus, renal insufficiency
5. The following factors can lead to failure:
   a. Incomplete understanding of the three-dimensional anatomy of the course to be taken and lesion to be treated
   b. Unrealistic interpretation of
      i. The capacity of available techniques to achieve success
      ii. The allowance of specific anatomy to accept percutaneous manipulation
      iii. Ignorance or inattention to technique in subselective device movement
   c. Inattention to anticoagulation
   d. Inattention to catheter hygiene (minimizing blood and contrast stagnation within the guiding catheter or other devices)

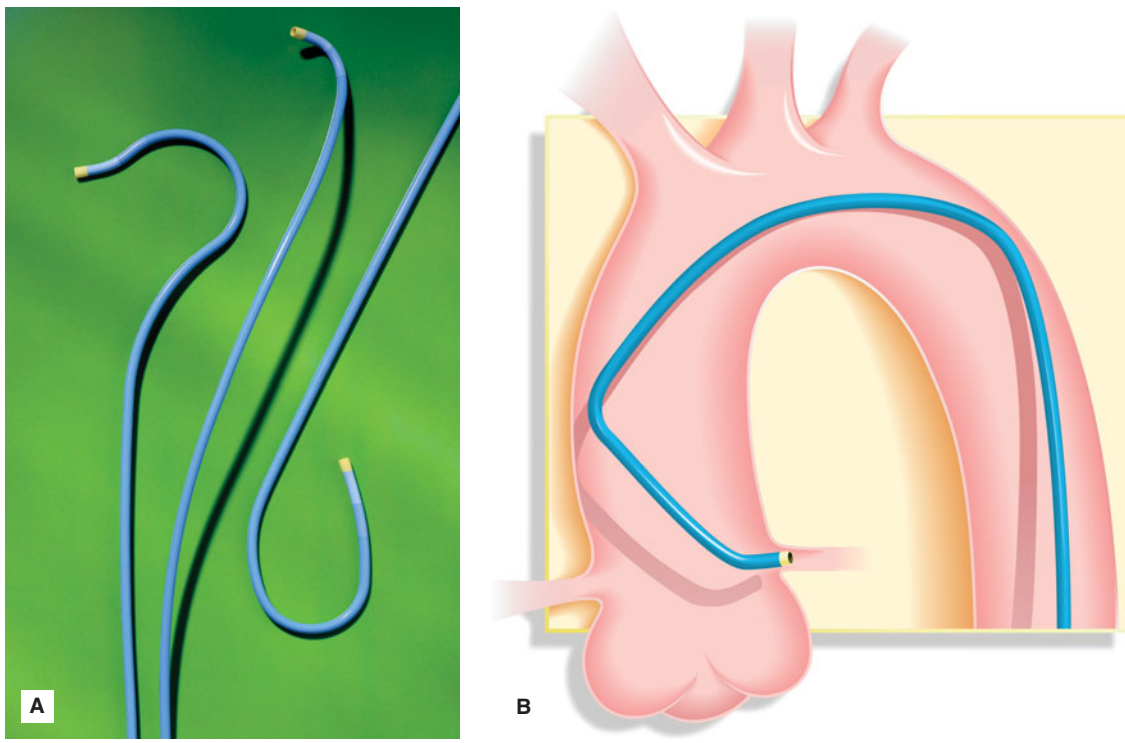

FIGURE 20-1 Commonly used guiding catheters are shown in the relaxed state (**A**) and as engaged with the coronary ostia in preparation for PCI: left Judkins (**B**), left Amplatz (**C**), XB (extra backup) (**D**), right Judkins (**E**), right Amplatz (**F**), and left coronary bypass (**G**). FIGURE 20-1 (*Continued*)

must traverse. Generally, the softest tip is the safest tip. However, in certain situations, such as treatment of a chronic total occlusion, a stiffer wire tip with a bonded, hydrophilic coating, rather than the wire coil, is frequently most effective. Although increasing the likelihood of crossing the lesion successfully, these stiffer, "slicker" wires also increase the risk of complications, such as creation of a subintimal wire course, dissection or perforation of the vessel (Fig. 20-2).

Tools for Lumen Expansion

The vast bulk of subselective devices for coronary artery manipulation are balloon inflation catheters or some variation of this theme. Balloon catheter designs vary in the placement of the proximal opening of the central lumen. The "on the wire" design has a central lumen extending the length of the catheter. This design affords the best trackability and capability for maneuvering through difficult anatomy but requires an assistant to manipulate the wire during device advance. The "monorail" design has a central lumen extending only through the distal balloon shaft of the catheter. The remaining catheter shaft communicates only with the balloon lumen. This design, although less trackable, allows the procedure to be performed without the need for an assistant.

Properties of the angioplasty balloon include compliance, maximally tolerated pressure, profile, and friction coefficient. Compliance, or growth under pressure, and maximally tolerated pressure are a function of balloon wall thickness and material. Compliance is divided into three categories: noncompliant, semicompliant, and compliant, depending upon the growth of the balloon under pressure. The thin-walled, compliant balloon has the lowest deflated profile, allowing the device to pass through the most severely occluded vessels. However, the balloon may not expand uniformly or lengthen when exposed to high pressures, such as pressures in excess of 20 atm (15,200 mm Hg), which are required to dilate hard and heavily calcified stenoses or stents. A variety of balloon coatings may be used to reduce the friction coefficient or protect from abrasion (as in passing a stent).

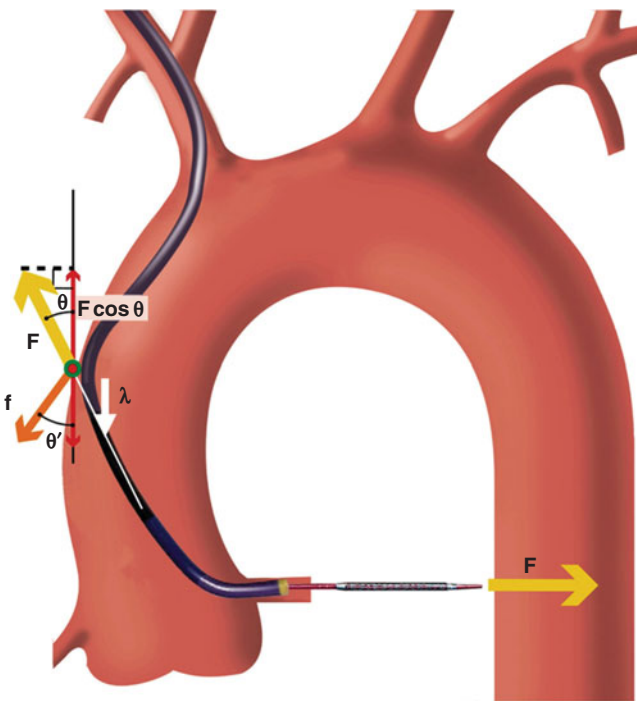

FIGURE 20-2 Support for subselective device introduction into the coronary vessels is determined primarily by the shape of the guiding catheter in relation to the anatomy of the ascending aorta and origin of the left main coronary artery. Shown graphically, advance of the device forces the catheter backward. This movement is opposed by the alignment of the catheter with the coronary artery and by friction developing through contact between the primary curve of the catheter and the opposing wall of the aorta. (*Reprinted with permission from Ikari Y, Nagaoka M, Kim JY, et al: The physics of guiding catheters for the left coronary artery in transfemoral and transradial interventions. J Invas Cardiol 2005; 17:636.*)

Antithrombotic Therapy

During an angioplasty procedure, blood may stagnate in the guiding catheter or near the treated lesion when a wire or device is placed within the lumen of the target lesion. In addition, metallic components of the guidewire or other devices attract fibrinogen, thus stimulating thrombosis. Therefore, a thrombus may form easily unless prevented with intense anticoagulation therapy (Table 20-2). Most angioplasty procedures are performed with unfractionated heparin (UFH) titrated to an activated clotting time (ACT) value of more than 300 seconds.[2] Alternative anticoagulants, such as low-molecular-weight heparins and direct antithrombin antagonists, may be used.[3–7] The DTI may be associated with reduced risk for major bleeding complications but are not reversible in the event of need for emergency surgical referral.[8] Antiplatelet therapy also reduces the risk of thrombosis at the treated lesion. In addition to aspirin and thienopyridines, glycoprotein IIb/IIIa (GP IIb/IIIa) complex inhibitors may be employed in specific circumstances. The GP IIb/IIIa complex inhibitors are unique in their ability to impair platelet–platelet aggregation, regardless of the type or intensity of stimulus. Anticoagulation is titrated to a lower intensity (an ACT of 200 to 250 seconds) when GP IIb/IIIa inhibitors are used.

Mechanisms

Balloon angioplasty transmits increased intraluminal pressures circumferentially to the rigid intimal surface of the diseased vessel. Because atherosclerotic lesions typically are heterogeneous in their circumferential distribution and physical characteristics, the nondiseased or less diseased wall may be overstretched during balloon inflation. In most instances, the lesion segment with the greatest structural integrity is a focal point for applied stress. Adjacent regions of the vascular wall can shift, and the diseased, inelastic intima can fracture. Although this mechanism allows balloon expansion and an increase in luminal diameter, extension of the fracture into the intima–media border creates a dissection plane, the growth of which will be determined by the mechanical characteristics of the lesion and the amount of force applied. If growth of the dissection plane results in

TABLE 20-2 Adjunctive Pharmacologic Therapy for PCI

	Use	Setting	Dose	Duration of Effect	Duration of Therapy	Complication
Aspirin	Antiplatelet	All PCI	81 mg	5–7 d	Permanent	GI bleeding
Clopidogrel	Antiplatelet	All PCI	600 mg 6 h before PCI; 75 mg/d	5–7 d	1 y	Bleeding TTP (rare)
Abciximab	Antiplatelet	ACS	0.25 μg/kg + 0.125 g/kg/min	72 h	12 h	Bleeding Thrombocytopenia
Prasugrel	Antiplatelet	All PCI	60 mg bolus; 10 mg/d	5–7 d	1 y	Bleeding
Eptifibatide	Antiplatelet	ACS	180 μg/kg bolus; repeat after 10 min + infusion 2 μg/kg/min	4 h	12–72 h	Bleeding
Tirofiban	Antiplatelet	ACS	0.4 μg/kg/min for 30 min 0.1 μg/kg/min	4 h	12–72 h	Bleeding
Heparin	Anticoagulation	All PCI	100 IU/kg 60 IU/kg*	6 h	During procedure	Bleeding Thrombocytopenia Thrombosis
Bivalirudin	Anticoagulation	UFH alternative	1 mg/kg bolus + 2.5 mg/kg/h for 4 h	2 h	During procedure + 4–6 h if no clopidogrel bolus	Bleeding
Argatroban	Anticoagulation	UFH alternative	350 μg/kg bolus + 25 μg/kg/min	2 h	During procedure + 4–6 h if no clopidogrel bolus	Bleeding
Enoxaparin	Anticoagulation	UFH alternative	1 mg/kg 0.7 mg/kg*	6 h	During procedure	Bleeding
Dalteparin	Anticoagulation	UFH alternative	100 IU/kg 70 IU/kg*	6 h	During procedure	Bleeding
Acetylcysteine	Contrast nephropathy prophylaxis	GFR <60 ML/min	600 mg every 12 h	Unknown	Begin 12 h before and continue for 12 h afterward	None
Verapamil/diltiazem/ nicardipine	Vasodilator	No/slow-reflow	0.1–0.5 mg IC	20–30 min	As needed	Hypotension Bradycardia
Nitroprusside	Vasodilator	No/slow-reflow	30 μcg IC	30–60 s	As needed	Hypotension
Adenosine	Vasodilator	No/slow-reflow	50 μcg IC	30 s	As needed	Bradycardia

*Recommended dose in conjunction with glycoprotein IIb/IIIa inhibitor therapy.
ACS = Acute coronary syndrome; GFR = glomerular filtration rate; GI = gastrointestinal; IC = intracoronary; PCI = percutaneous coronary intervention; TTP = thrombotic thrombocytopenic purpura; UFH = unfractionated heparin.

significant displacement of the diseased intima, the vessel will close. This event, termed *abrupt* or *acute occlusion,* complicates about 10% of balloon angioplasty procedures. Overstretching the minimally diseased or nondiseased wall without creating plaque fracture typically results in early recoil of the treated lesion to its original state.

After balloon deflation, a small amount of thrombus accumulates, providing the stimulus and framework for colonization by inflammatory cells and myofibroblasts and the eventual, local synthesis of temporary (intimal hyperplasia) and permanent (collagen-rich) connective tissue. In addition, mechanical injury to the media and adventitia results in scar formation. The scar's contracture may reduce vessel cross-sectional area—a phenomenon termed *negative remodeling.*[9,10] During vascular healing, the encroaching intimal hyperplasia that peaks in volume at about 3 months, combined with negative remodeling, results in restenosis after 40% to 50% of balloon angioplasty procedures.[11–13]

Outcomes

In approximately 2 to 10% of balloon angioplasty procedures, intimal dissection, thrombosis, and perhaps medial smooth muscle spasm combine to produce abrupt closure.[14,15] Abrupt closure may be treated successfully with repeat balloon inflation but is treated more commonly with stent implantation.[16] The specter of abrupt closure and myocardial infarction (MI) or emergency bypass surgery and its complications historically has limited the application of balloon angioplasty.

In patients with stable angina, mortality from a balloon angioplasty procedure is 1% at 1 month.[17] About half the deaths are the result of a procedural complication, and most are related to low cardiac output (Table 20-3).[18] Although the incidence of restenosis (>50% diameter stenosis during follow-up) is 40 to 50% within 6 to 9 months of a PTCA procedure,[11,13,19] only 25% of patients report recurrent angina that warrants further investigation.[20] Patients with restenosis have an increased risk of MI and coronary artery bypass surgery.[21]

TABLE 20-3 Causes of Death after PTCA[18]

Low-output failure	66.1%
Ventricular arrhythmias	10.7%
Stroke	4.1%
Preexisting renal failure	4.1%
Bleeding	2.5%
Ventricular rupture	2.5%
Respiratory failure	2.5%
Pulmonary embolism	1.7%
Infection	1.7%

PTCA = Percutaneous transluminal coronary angioplasty.

DEVICE-ASSISTED ANGIOPLASTY

Stents

The two failure modes of balloon angioplasty, abrupt closure and restenosis, have stimulated development of myriad devices, all with the goal of reducing the risk of the procedure, the risk of restenosis, or both. Only coronary stents have been shown to be advantageous over balloon angioplasty, except in cases of severely calcified lesions (Table 20-4). There are numerous coronary stent designs, but the majority of those in current use consist of a stainless steel (or alloy, such as cobalt chromium) cylinder that has been "carved," creating a so-called slotted-tube design. Stent expansion creates a series of interlocking cells, resembling a cylindrical meshwork (Fig. 20-3). Stents are thus deformable, but when expanded, they maintain sufficient rigidity to act as scaffolding after deflation of the angioplasty balloon. Intimal disruption is contained and far less likely to propagate and occlude the treated vessel. In addition, the rigid framework left behind becomes part of the vessel wall, addressing the issue of remodeling, which is one of the mechanisms of restenosis.

Stents allow safe expansion of the vessel beyond that typically achieved with PTCA at the time of balloon expansion; however, stent use increases thrombotic and inflammatory responses of the vessel wall. The increased injury and a foreign-body response to stent struts result in a more intense and prolonged local inflammatory response.[22] As a result, stent placement paradoxically exacerbates intimal hyperplasia.[23,24] Using the late (6- or 9-month) loss in lumen diameter after stent implantation as a measure of intimal hyperplasia, even the most modern stent designs fall within a range of about 0.8 mm, more than twice the loss incurred after PTCA (0.32 mm). As a result, when examining restenosis after angioplasty, the impact of stent for percutaneous coronary revascularization (PCR) is rather small in comparison with that of PTCA.[23,24] The bulk of intimal hyperplasia and risk of restenosis are functions of the size of the treated lumen on completion of the procedure, length of the treated lesion, and presence of unstable angina, hypertension, and diabetes mellitus (Table 20-5).[25–27] Long-term follow-up studies suggest that a stent that does not reocclude during the first 6 to 9 months after implantation is not subject to late, rapid disease progression.[28–32]

By reducing the likelihood of both abrupt closure requiring emergency coronary artery bypass surgery and restenosis, stent-assisted angioplasty is more effective than routine balloon angioplasty for virtually any type of coronary artery lesion. Registry data describe a risk for emergency surgery of only 0.3 to 1.1%, and a procedural mortality of less than 1%.[33–36] The likelihood of procedural complications may be estimated on the basis of lesion characteristics (Table 20-6).[37] Depending on lesion characteristics and the number of lesions treated, after 1 year, 5 to 10% of patients require coronary artery bypass surgery, and 15 to 20% undergo a second PTCR procedure.[38–41] After 5 years, 10 to 15% of patients require another revascularization procedure because of the development of severe stenosis at an

Aspiration (manual)	+	+++	+	++	Thrombus

ISR = In-stent restenosis; POBA = plain old balloon angioplasty.

untreated site.[32] Diabetes increases the risk for adverse outcomes by increasing the risk of restenosis and disease progression at untreated sites.

As noted in the description of the guidewire, iron components of stent struts attract fibrinogen and offer a site for platelet attachment and thrombosis. The increased risk of thrombosis at the treated site persists until endothelialization is complete. As a result, more intense antithrombotic therapy is required during the procedure and for up to 1 year afterward.[42,43]

Stents may be used as a drug-delivery system. However, rather than simply applying a drug to the stent surface, from which it will dissipate quickly, drug delivery is controlled by using a surface polymer or by altering the design or the material used to construct the stent.[44] This method of drug delivery, called a *drug-eluting stent* (DES), allows the drug to be applied at high concentrations at the site of interest and reduces the probability of systemic toxicity.

Drug-eluting stents reduce the primary determinant of restenosis by 50 to 100%, as determined by quantitation of late lumen loss after angioplasty (Fig. 20-4). Studies examining the efficacy of the DES introduced new nomenclature to the follow-up end points. The most useful follow-up end point is

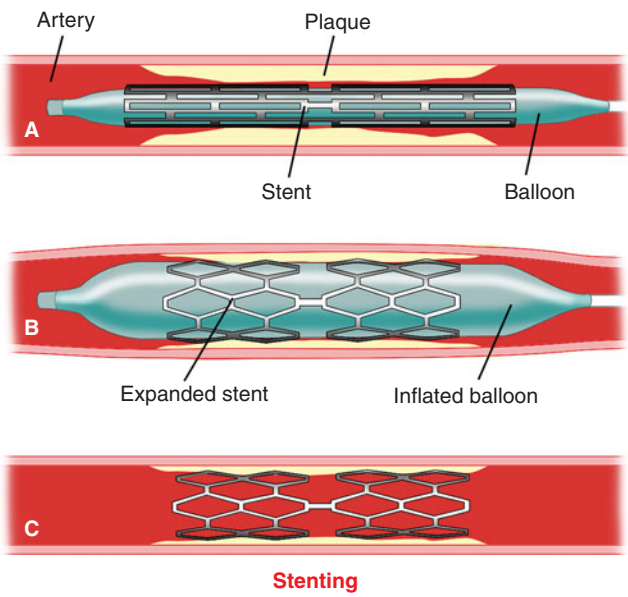

FIGURE 20-3 The coronary stent is a metallic "meshwork" that increases its rigidity when cold-worked by balloon expansion. Buttressing of the vascular wall, propagation of dissection, and early vascular recoil are reduced significantly. (*Reprinted by permission from Texas Heart Institute, www.texasheart.org.*)

TABLE 20-5 Approximate Risk of Restenosis Based on Final Lumen Diameter and Stent Length

	Final Lumen Diameter (mm)				
	2.0	2.5	3.0	3.5	4.0
Stent Length (mm)	**Percent Risk**				
15	32%	22%	14%	8%	4%
30	42%	30%	20%	11%	7%
45	52%	39%	28%	15%	10%
60	60%	47%	35%	20%	13%

Summarized and modified from de Feyter PJ, Kay P, Disco C, Serruys PW: Reference chart derived from post-stent-implantation intravascular ultrasound predictors of 6-month expected restenosis on quantitative coronary angiography. Circulation 1999;100(17):1777-1783.

Group	**Definition**	**Death/MI Emergency CABG**
Highest risk	Either of the strongest correlates	12.7%
High risk	≥3 moderate correlates	8.2%
Moderate risk	1-2 moderate correlates	3.4%
Low risk	No risk factors	2.1%

CABG = Coronary artery bypass graft surgery; MI = myocardial infarction; SVG = saphenous vein graft.

termed *target vessel failure* (TVF), signified by cardiac death, MI, or repeat revascularization of the treated vessel. One year after the procedure, TVF is reduced from 19.4 to 21% with a bare-metal stent (BMS) to 8.8 to 10% with a paclitaxel or sirolimus DES.[38,41]

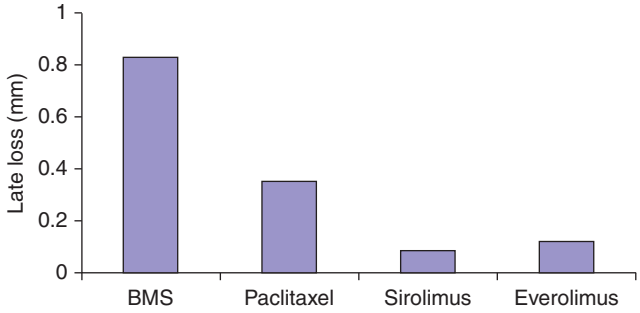

FIGURE 20-4 The effect of various stents on intimal hyperplasia in randomized trials is shown. A bare-metal stent's intimal hyperplasia thickness, or late loss, shown on the left, is compared with the late loss of drug-eluting stents shown at the right. BMS = Bare-metal stent.

Reduced rates of repeat intervention after DES placement have been reported for every type of lesion studied, except bifurcation lesions, in which the risk of restenosis remains significant, and the risk of potentially fatal early thrombosis is as high as 3.5% (Table 20-7).[38,45–52] However, the impact of DESs on failure of long-term treatment and repeat procedures does not translate to a reduced risk of procedure-related complications.[53] In addition, incomplete healing, a response to the eluting polymer, or both, confer an increased risk of stent thrombosis that extends beyond 1 year. As a result, dual antiplatelet therapy should be continued for at least 1 year after the procedure in all patients and indefinitely in patients with complex lesions.

Other Devices

Perfusion Balloons

Before the routine use of coronary stents, abrupt closure owing to dissection could be treated with repeat balloon inflation and, if unsuccessful, coronary artery bypass surgery. Prolonged balloon inflation generally was necessary for successful restoration of patency, but in the event of failure, transport for emergency

TABLE 20-7 The Clinical Impact of Drug-Eluting Stents

Population	End Point	BMS (%)	DES (%)
Total[38,41]	TVF	20-24.1	9.9-10.8
Diabetes mellitus[117]	MACE 9 mo	27.2-36.3	11.3-15
Insulin-treated[118]	MACE 9 mo	31.5	19.6
Myocardial infarction[119]	TVR 8 mo	32	18
"Complex" lesions[120]	TLR 12 mo	29.8	2.4
Long lesion small vessel[121-123]	MACE 9 mo	18.3-22.6	4-8
Small vessel[45]	MACE 8 mo	31.3	9.3

Saphenous vein graft lesion[47]	MACE 6 mos.	28.1	11.5

BMS = Bare-metal stent; DES = drug-eluting stent; MACE = major adverse cardiac event; TLR = target lesion revascularization; TVF = target vessel failure; TVR = target vessel revascularization.

surgery often was accompanied by severe ischemia of the treated territory. As a result, balloon catheters with a short third-lumen opening just proximal and distal to the balloon were developed. These catheters, or "perfusion balloons," allowed for prolonged balloon inflation with far less ischemia and could be used to ameliorate the severity of ischemia during transport for surgery after an unsuccessful procedure. Since the introduction of the coronary stent, perfusion balloons rarely are used.

Atherectomy

When introduced, the concept of reducing the bulk of the obstructing atheroma was quite attractive. The idea was to reduce vessel wall thickness or "debulk," allowing for balloon expansion at a lower pressure. With less force applied for lumen expansion, theoretically the likelihood of abrupt closure would be reduced, as would the degree of arterial injury at the time of treatment. Several devices used for debulking have been developed and studied, including directional coronary atherectomy, percutaneous transluminal rotational ablation, and laser ablation. Unfortunately, when subjected to rigorous examination, debulking devices provide no incremental gain over plain balloon angioplasty in achieving procedural success or avoiding restenosis.[54–57] Although each device has developed a specific niche (see Table 20-4), their routine use generally is associated with an increased risk of procedural complications, including perforation and MI.[57–59]

Rotational atherectomy requires additional discussion because, unlike the other types of atherectomy, it is still commonly used. The Rotablator (Boston Scientific Corporation, Natick, MA) is an olive-shaped device that is coated with diamond chips. It is attached to an electrical motor, which causes the device to rotate at high speeds. The device is designed to abrade a rigid atherosclerotic intima, creating microemboli that are small enough to pass through the coronary microcirculation without incident. It is also useful as an initial treatment method for very rigid, heavily calcified lesions. However, the concept is not without failings. Microembolization is likely to exacerbate ischemia and therefore is contraindicated when there are thrombotic lesions, if there is impaired microcirculatory flow associated with a recent MI, or if the treated vessel is the last remaining patent vessel. Use of this device is also associated with an increased risk of perforation in highly angulated lesions.

Aspiration Devices

A number of coronary aspiration devices are available to reduce the risk of distal embolization and diminish the local concentration of prothrombotic and vasoactive substances. These devices range from a simple end-hole catheter attached to a syringe to a complex suction catheter with or without an associated mechanical disrupter. These devices forcibly extract components of the thrombus or atheroma.[60] Their use may improve flow after treatment of thrombus-laden lesions or saphenous vein grafts (Fig. 20-5).[61]

Embolic Protection Devices

During balloon angioplasty, mechanical dissolution of thrombus, if present, may result in macroembolization and distal vessel occlusion. The high-pressure manipulation of an atheromatous lesion also may free cholesterol crystals and other components of the lesion, resulting in distal microembolization, thrombosis, and slow- or no-reflow phenomenon. Several devices have been developed to reduce the frequency or impact of distal

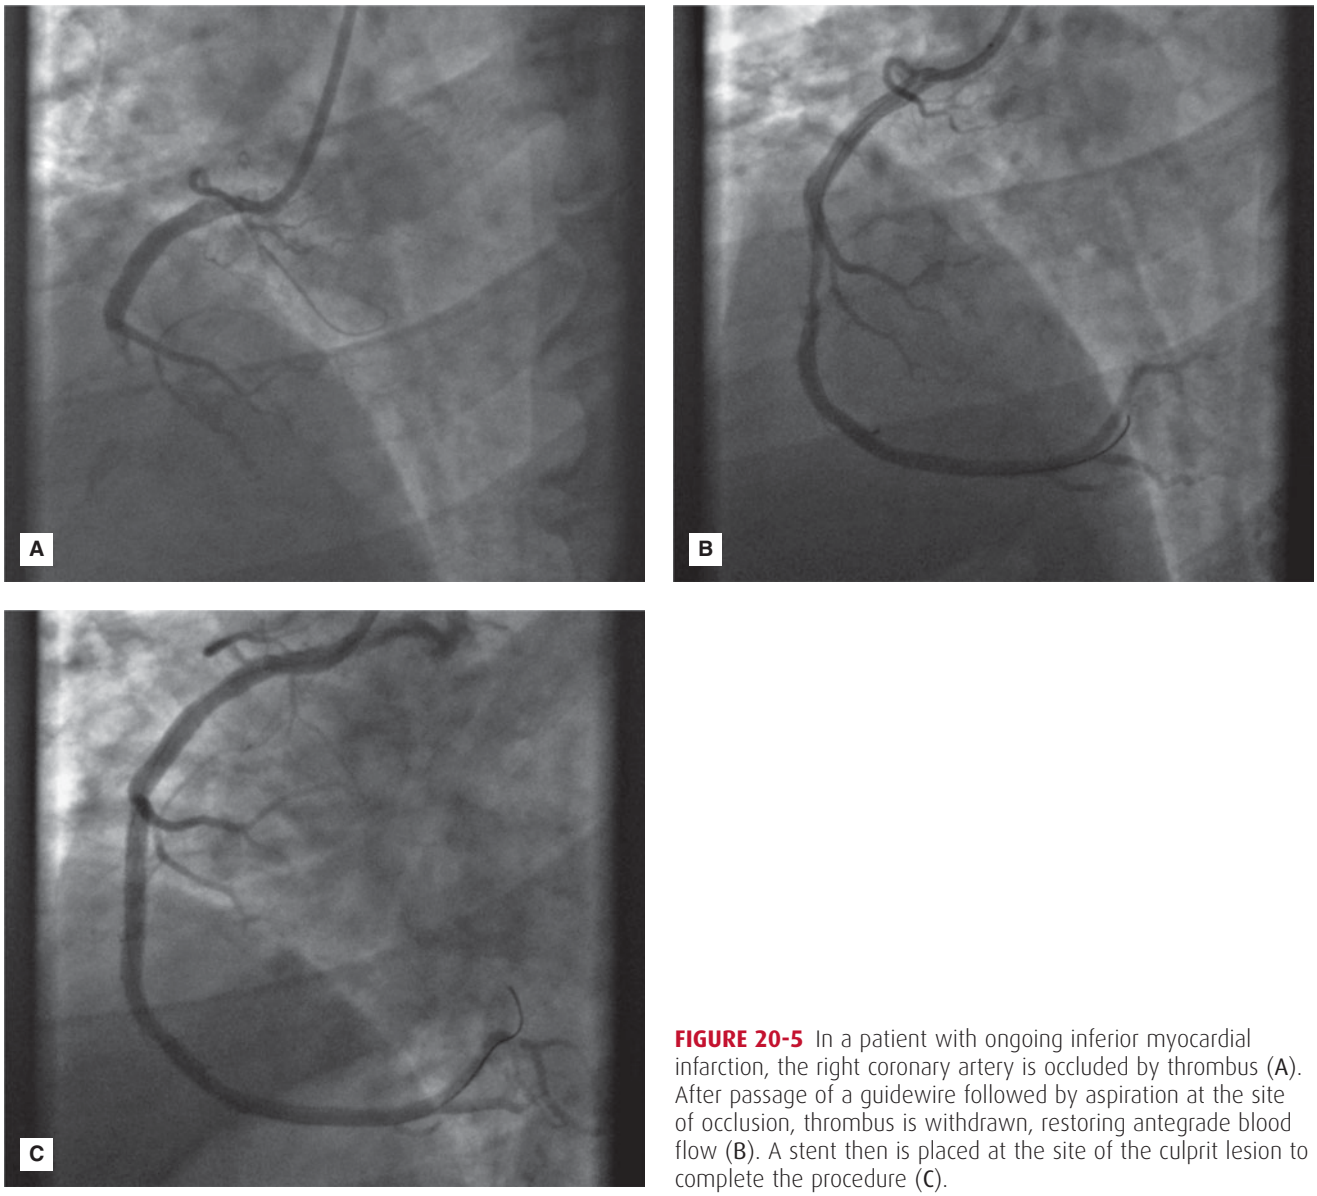

FIGURE 20-5 In a patient with ongoing inferior myocardial infarction, the right coronary artery is occluded by thrombus (**A**). After passage of a guidewire followed by aspiration at the site of occlusion, thrombus is withdrawn, restoring antegrade blood flow (**B**). A stent then is placed at the site of the culprit lesion to complete the procedure (**C**).

embolization. These devices may be placed distal or proximal to the treated lesion. Distal devices are mounted on the guidewire and use either a suspended micropore filter to trap particulate matter of 100 to 150 μm or larger or balloon occlusion of the treated vessel with posttreatment aspiration to capture embolized material. Proximally placed devices temporarily interrupt flow and aspirate the treated vessel. The PercuSurge GuardWire Plus (Medtronic, Minneapolis, MN) is a balloon occlusion and aspiration device that underwent testing in vein grafts in the Saphenous Vein Graft Angioplasty Free of Emboli Randomized (SAFER) trial.[62] The trial demonstrated a 42% reduction in creatine kinase (CK) elevations and more than a 50% reduction in the no-reflow phenomenon.[62] Unfortunately, these results did not apply to patients with MI.[63]

Imaging Devices

Angiographic imaging allows imaging of the coronary lumen but may be unreliable in the setting of severe calcification, difficult branching patterns, or previously placed coronary stents. Furthermore, a thrombus that may increase the risk of PCR may go undetected by standard angiographic imaging. Therefore, a number of alternative imaging methods have been developed to improve diagnosis, plan revascularization efforts, and evaluate the success of such efforts. Angioscopy or fiberoptic imaging requires occlusion of the imaged vessel and perfusion with saline. Although a useful tool to investigate the presence or components of thrombus within coronary vessels, angioscopy has not been a useful adjunct to PCR. In contrast, intracoronary ultrasound imaging has proved especially useful. Ultrasound imaging allows accurate determination of vessel size, luminal reduction, lesion components, and progress associated with revascularization attempts. Ultrasound guidance for stent implantation is associated with a greater than 30% reduction in the need for repeat procedures.[64] Of equal importance, intracoronary ultrasound is an invaluable research tool used to investigate the accuracy of contrast angiography and the impact

of mural lesion components on complications and outcomes after angioplasty.

Devices That Measure Lesion Severity

The hemodynamic significance of coronary lesions, the appropriateness of a treatment, and the success of treatment may be determined by the following two means: a guidewire that measures the velocity of blood flow within coronary arteries or a calculation that measures pressure distal to a coronary lesion.

A miniaturized Doppler-equipped guidewire with a 12-MHz transducer uses a pulsed interrogation that samples 5.2 mm beyond the guidewire tip at an angle of 14 degrees on either side. Assuming that the cross-sectional area of the interrogated vessel remains constant during all measurements, the ratio of velocities measured reflects the ratio of blood flow between any two measurements. The most important and reliable parameter that a flow probe measures is the ratio of resting flow to vasodilated coronary flow, a value known as *coronary flow reserve.* When measured using the Doppler probe, the value is termed *coronary velocity reserve* (CVR). As a coronary lesion becomes flow limiting, attempts to normalize tissue perfusion by autoregulation result in arteriolar dilatation at rest. Therefore, the administration of an arteriolar vasodilator such as adenosine will have little additional effect on flow velocity. The absence of an appropriate increase in velocity during adenosine- or dipyridamole-induced arteriolar vasodilation produces abnormal flow reserve. A CVR less than 2.0 indicates hemodynamically significant lesions.

CVR measurement reflects changes in flow relative to an assumed normal baseline state but is subject to error when baseline flow is abnormal. Examples of abnormal states include left ventricular (LV) hypertrophy, fibrosis, and perhaps anemia. In addition, abnormally large or small driving pressure gradients may fall outside the range of normal coronary autoregulation, altering the basal-to-hyperemic ratio. Failure to achieve arteriolar dilatation in response to adenosine or dipyridamole will produce an abnormal calculated flow reserve. Examples that affect arteriolar dilatation include diabetes mellitus, amyloidosis, and recent caffeine or theophylline ingestion.

An alternative to flow measurement is pressure measurement, proximally and distally to the lesion in question. Under normal conditions, epicardial vessels present little detectable resistance to flow. Therefore, driving pressure (P_{Ao}) and arteriolar resistance pressure (P_{RA}) determine maximal coronary blood flow. The presence of a flow-limiting coronary lesion will cause some of the driving pressure to be lost, so maximal flow will depend on the distal coronary pressure (P_d)-to-P_{RA} gradient and arteriolar resistance. Therefore, the fraction of maximal basal flow that remains possible in the presence of the lesion is

$$\dot{O}_{lesion}/\dot{O}_{no\ lesion} = (P_d - P_{RA}/R_{basal})/-(P_{Ao} - P_{RA}/R_{basal})$$

Canceling resistance and assuming that right atrial pressure remains constant results in a very simple relationship:

$$\dot{O}_{lesion}/\dot{O}_{no\ lesion} = P_d/P_{Ao}$$

This ratio, called the myocardial *fractional flow reserve* (FFR), is obtained after the administration of adenosine. An FFR of 0.75 or less identifies a hemodynamically significant lesion. Routine use of FFR to ensure the necessity of PCI reduces the risk of adverse events both immediately and at 1 year.[65]

BRACHYTHERAPY

Before the advent of DESs, restenosis after angioplasty or stent implantation could be treated by medical therapy, repeat angioplasty, or coronary artery bypass surgery. The frequency of restenosis led to a large population of patients with multiple treatment failures, intractable symptoms, and prohibitive risks for surgical treatment. Because a proportion of the cell population colonizing a treated lesion and contributing to restenosis arose from the media of the treated lesion, radiation therapy to prevent cell replication was proposed. The well-recognized dangers of high-dose, external-beam radiation limited dosing to local application, but this therapy still was seen as a substantial risk. Although a source of increased adverse events when used as a treatment for de novo coronary lesions, radiation brachytherapy for the treatment of refractory in-stent restenosis has met with limited success.[66,67]

CIRCULATORY SUPPORT

Performance of a percutaneous revascularization procedure includes an obligatory period of ischemia in the treated region. The duration of ischemia may be prolonged in the event of abrupt closure or distal embolization, and recovery may be incomplete or delayed for a period of days, as in the treatment of acute MI. For patients with depressed LV systolic function or those in whom the treated territory is large, there is a risk for developing cardiogenic shock during and after the procedure. This risk substantially increases the possibility of acute renal failure, stroke, and death. The likelihood of shock complicating an angioplasty procedure may be predicted by using a scoring method that incorporates the extent and severity of systolic dysfunction present before the procedure and the extent that can be expected as a result of the procedure (Table 20-8).[37]

TABLE 20-8 A Score Predicting the Need for Circulatory Support[128]

Six Arterial Segments	LAD, D_1,, S_1, OM, PLV, PDA
Score 1	Target lesion or any additional lesion >70% diameter stenosis
Score 0.5	Subtended region is hypokinetic but has no stenosis
For a score >3	Consider IABP

D_1 = First diagonal branch; IABP = intra-aortic balloon pump; LAD = left anterior descending artery; OM = obtuse marginal branch; PDA = posterior descending artery; PLV = posterior left ventricular artery; S_1 = first septal branch.

Elective placement of an intra-aortic balloon pump (IABP) is associated with a reduced risk of hypotension and major complications.[68]

The percutaneous left ventricular assist device (PLVAD) is a miniaturized axial-flow pump that is being used increasingly for support of patients in shock or during high-risk angioplasty procedures.[69] The PLVAD is capable of providing up to 4 L of additional blood flow per minute. Although it can provide superior circulatory support, the PLVAD has not shown any survival advantage when compared with the IABP, and vascular access-site complications are more frequent with the PLVAD.[70]

COMPLICATIONS OF PCR

In addition to abrupt closure and restenosis, there are several other potential complications of PCR that may influence the risk:benefit ratio for an individual patient. These complications include bleeding, vascular access–site complications, stroke, radiocontrast nephropathy, and MI owing to distal embolization.

Hemorrhage

Bleeding that requires transfusion or results in hemodynamic instability occurs in 0.5 to 4% of PCR procedures, depending on patient variables (eg, age, gender, and presence of peripheral vascular disease), procedural variables (eg, location of femoral arteriotomy and duration), and pharmacologic variables (eg, intensity of antithrombotic therapy).[2] A number of devices have been designed to improve femoral hemostasis after sheath removal, but none has proved superior to standard compression hemostasis.[71] With the availability of lower-profile equipment, the radial artery is being used with greater frequency, which results in a reduction in bleeding and access-site complications.[72]

Ischemia

Stroke complicates approximately 0.18% of PCR procedures.[73] Its occurrence is associated with increased age, depressed left ventricular ejection fraction (LVEF), diabetes mellitus, saphenous vein graft intervention, and complicated or prolonged procedures requiring the placement of an intra-aortic balloon pump.[74]

Myocardial infarction complicates 5 to 30% of PCR procedures, depending on the definition of infarction.[75] Using a definition of new Q wave, the incidence is 1%.[76] When any elevation of the MB fraction of CK (CK-MB) is used as the definition, as many as 38% of patients have a periprocedural MI.[75] Use of more stringent definitions of infarction, such as greater than three or 10 times the upper limit of normal, reduces the reported values to 11% to 18% or 5%, respectively.[76–78] Actually, any elevation carries prognostic significance, but elevation above three times the upper limit of normal is accepted as a definition of periprocedural MI.

Elevated markers of myocardial injury may be seen after apparently uncomplicated procedures.[75] One mechanism for such events is microscopic distal embolization. When severe, microscopic distal embolization of a coronary artery creates the angiographic appearance of slow vessel filling, it is termed *no-* or *slow-reflow*. No-reflow is seen most often in the setting of saphenous vein graft angioplasty, but also may complicate rotational atherectomy and primary PCR for acute MI. Methods of quantifying abnormal flow after PCR include a subjective estimation of flow velocity, the Thrombolysis in Myocardial Infarction (TIMI) flow rate (III, normal; II, slow; I, minimal contrast material flow beyond the treated site; and 0, no flow), and the more objective method of corrected TIMI frame count. Individual frames of the angiographic image are counted from the time of contrast material entry into the treated vessel until a predetermined distal landmark is reached. No-reflow may be a brief and self-limiting phenomenon, but when prolonged, it is associated with increased mortality.[79] Pharmacologic manipulations, including intracoronary verapamil, adenosine, and nitroprusside, may be used in an attempt to prevent or treat no-reflow phenomenon (see Table 20-2).

Perforation of the coronary artery complicates 0.5% of angioplasty procedures,[80] and its frequency increases almost 10-fold when ablation devices are used (1.3% for ablation versus 0.1% for PTCA; $p < .001$). Coronary artery perforation occurs more frequently in elderly and female patients (Table 20-9).[80,81]

TABLE 20-9 Coronary Artery Perforations Classified by Severity

Type	Incidence (%)	Treatment	Mortality
I: A visible extraluminal crater without extravasation*	26	Nonsurgical 95% of the time	Rarely fatal
II: Pericardial or myocardial blushing (Fig. 20-6)*	50	Require surgery 10% of the time	13%
III: 1-mm diameter perforation with contrast material streaming	26	Require surgery or covered stent	63%

*Typically a result of improper guidewire manipulation or placement.
Summarized and modified from Ellis SG, Ajluni S, Arnold AZ, et al: Increased coronary perforation in the new device era. Incidence, classification, management, and outcome. Circulation 1994; 90(6):2725-2730.

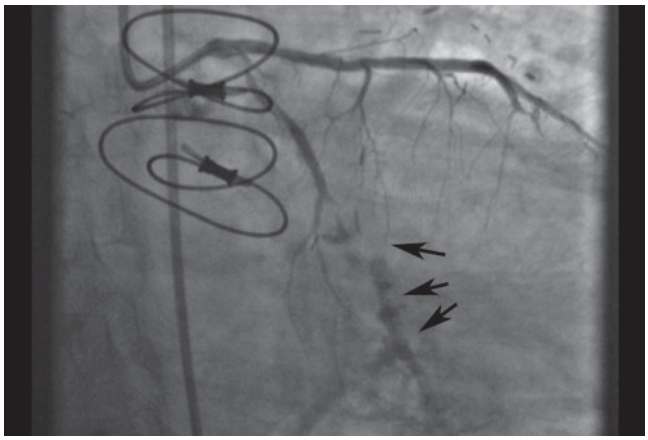

FIGURE 20-6 In the setting of early saphenous vein graft closure with myocardial infarction and postinfarction angina, attempts to access the culprit native vessel with a stiff guidewire have led to coronary perforation. Shown in this injection of the left coronary artery are occlusions of the left anterior descending and left circumflex coronary arteries. Staining is seen (*arrows*) in the region of the attempted recanalization of the left circumflex coronary artery identifying perforation (type II). The patient was treated successfully with reversal of anticoagulation and temporary occlusion of the circumflex using the PTCA balloon. PTCA = Percutaneous transluminal coronary angioplasty.

Pericardial tamponade is frequently but not invariably associated with coronary artery perforation. The overall incidence of tamponade after PCI is 0.12% and doubles when ablation devices are used. PCI-associated tamponade is recognized 55%[82] of the time during or after the procedure while the patient is still in the catheterization laboratory and 45% of the time after the patient leaves the laboratory. A minority of episodes of late tamponade (13%) are associated with recognized coronary artery perforation. Tamponade requires surgical treatment in 39% of patients, is closely associated with MI complicating PCR, and carries a mortality rate of 42%.[82]

The covered stent that was developed for, but failed to reduce the risk of, saphenous vein graft restenosis[83] presently is used as a rescue device after coronary artery perforation or for the treatment of coronary or saphenous vein graft aneurysms (Fig. 20-7).[84] When a covered stent is used for the treatment of coronary artery perforation, the need for emergency surgery is reduced, and the outcome of coronary artery perforation is improved. A small number of patients, however, still will require surgery.[85]

Toxicity

Acute renal failure after exposure to radiocontrast material, or *radiocontrast nephropathy* (RCN), is poorly understood. Its occurrence is a function of age, congestive heart failure, hemodynamic instability, diabetes mellitus, preexisting renal insufficiency, anemia, peripheral vascular disease, and the amount of contrast material administered.[86–88] The incidence of RCN after coronary angiography is 5 to 6%, with the nadir of renal function occurring 3 to 5 days after the procedure.[89] Even a transient decline in renal function leads to an increased risk of ischemic cardiovascular events during follow-up, and renal failure requiring hemodialysis is seen in about 10% of patients with RCN, increasing both short- and long-term mortality.[86,87,90]

The only methods for reducing the risk of RCN are the use of iso-osmolar contrast, volume expansion, and, perhaps, acetylcysteine administration. Iodixanol, an iso-osmolar nonionic contrast agent, reduced the incidence of RCN after noncardiac angiography.[91] Giving four oral doses (600 mg each of *N*-acetylcysteine; two doses on the day before and two on the day of the procedure) has met with varied outcomes in several studies but appears to be beneficial.[92,93] Administering crystalloid solution in volumes sufficient to maintain brisk urine flow, perhaps aided by alkalinization of urine pH, is the most effective intervention to ensure an adequate volume state.[94]

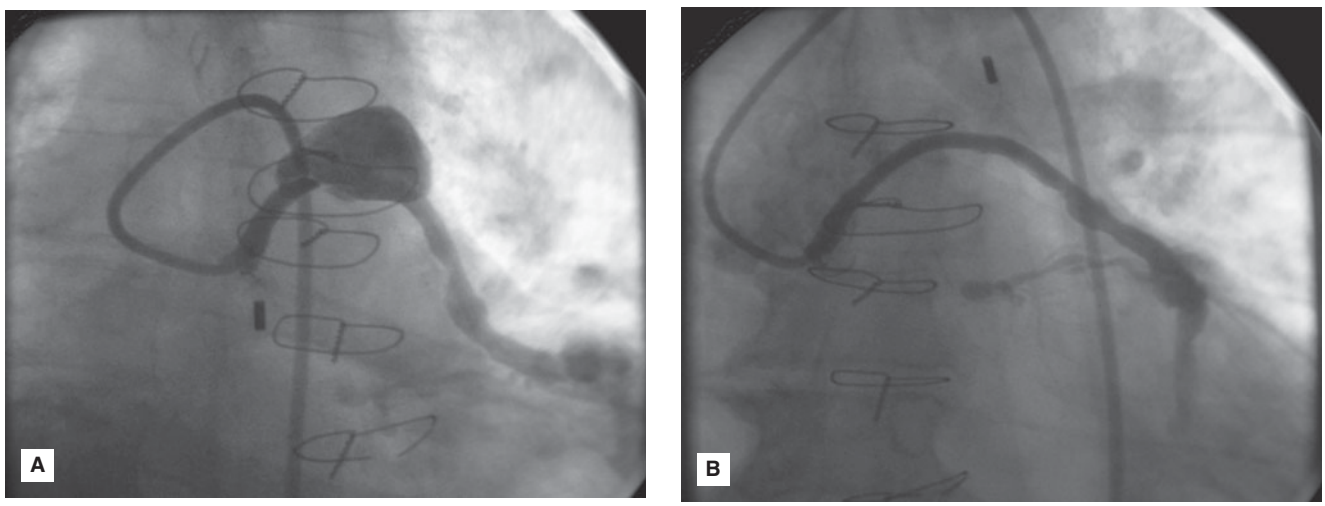

FIGURE 20-7 A large saphenous vein graft aneurysm (A) is treated with a covered stent (B).

SPECIAL CIRCUMSTANCES

Acute Coronary Syndromes (ACS)

Successful PTCA and stent implantation (in most instances) within the first 6 hours of ST-segment elevation MI is at least as effective as, and perhaps more effective than, thrombolytic agents in limiting myocardial damage and improving in-hospital survival.[95–97] The routine use of coronary stents for acute MI is associated with a restenosis rate of 17% and a 6-month event-free survival of 83 to 95%[98–101] The use of DESs reduces the risk of any adverse event from 17 to 9.4% at 300 days.[49] After failed attempts at thrombolysis or for patients with cardiogenic shock who received thrombolysis, stent revascularization increases myocardial salvage and reduces the risk of death, heart failure, or reinfarction.[102–105]

Previous Coronary Artery Bypass

Stent implantation with the assistance of embolic protection devices is the preferred method for percutaneous treatment of saphenous vein grafts.[62,103] The use of distal embolic protection reduces the risk of periprocedural MI from 14.7 to 8.6%.[62] Unfortunately, diseased grafts have a high probability of developing new lesions, reducing long-term event-free survival. After stent implantation, overall survival is 79% at 4 years, but survival free of MI or another revascularization procedure is only 29%.[106–110] Drug-eluting stents reduce the risk of restenosis after saphenous vein graft PCR but will not affect the likelihood of progression elsewhere in the diseased graft.[47]

THE FUTURE

The future of interventional cardiology lies in reducing procedural risk and extending treatment durability. For many patients, the goal of providing durable treatment success has been very nearly achieved with the introduction of DESs, an approach that has yet to be fully explored. However, a DES does not reduce procedural risk, and problems remain for patients with diffuse atherosclerosis, diabetes mellitus, bifurcation lesions, and acute coronary syndromes. The suggestion that poor outcomes may be expected after PCI and that surgical revascularization may be more appropriate have been recognized and can be measured objectively using the SYNTAX score.[111] Its adoption, utilization, and regular refinement will be difficult but necessary in order to match the right patient to the right treatment.[112]

Ironically, the goal of reducing procedural risk has been pursued most effectively for saphenous vein graft revascularization with the development of distal embolic protection devices. However, for native-vessel interventions, particularly during acute coronary syndromes, further advances likely will be pharmacologic rather than technical. Drawing on observations made in ischemic preconditioning, modification of myocardial energy metabolism with drugs, such as ranolazine, perhexiline maleate, and others, represents a means of improving the heart's ability to withstand ischemia, thus temporizing the impact of temporary vascular occlusion and macroembolization or microembolization.[113–115] In addition, inhibitors of the protein kinase family of enzymes, central to intracellular signaling, also may improve the heart's ability to withstand ischemia and reduce the severity of reperfusion injury.

Local drug delivery has met with great success in reducing the problem of restenosis. However, there are numerous methods of modifying the physiology driving intimal hyperplasia after stent implantation. New DES platforms offer the alternative of eluting multiple drugs at different rates, reducing the need for systemic medical therapy, such as prolonged dual antiplatelet therapy. In addition, complex molecules that can be absorbed by the body are being developed as stent platforms. The use of such a stent, one that delivers antithrombotic and antiproliferative drug therapy, could conceivably allow PCR protection from acute closure, recoil, thrombosis, and restenosis, without contributing to vessel rigidity that increases the difficulty of subsequent procedures.

A growing number of patients who are surviving longer with severe multivessel coronary artery disease remain hampered by severe angina pectoris. In many instances, years of slow, steady disease progression have left extensive collateral vessels that prevent infarction and the near or complete loss of major branch vessels. These patients currently have no option for percutaneous or surgical revascularization. For this population, the use of stem cells, perhaps the most efficient producers of cytokines and growth factors in their proper sequence, has met with early success. Direct injection of stem cells into regions of ischemic myocardium improves walking time and reduces the frequency of angina attacks.[116]

KEY POINTS

1. Percutaneous revascularization is best used as a treatment for unacceptable symptom control in patients who do not have anatomic indications for revascularization for prolonging survival.
2. Stent implantation substantially improves the safety of PCI, and the use of drug-eluting stents reduces the likelihood of long-term treatment failure. However, the use of drug-eluting stents requires that patients be candidates for long-term, dual antiplatelet drug therapy.
3. Measurement of the fractional flow reserve (FFR) is crucial for determining the necessity of PCI. Its routine use for the evaluation of moderate lesions results in a reduced risk of major complications of intervention compared with angiographic analysis alone.
4. When possible, all saphenous vein graft interventions should be performed with distal protection devices in place.
5. In patients who, for clinical reasons, can be treated by percutaneous or surgical means, the SYNTAX score should be used to ensure objective measurement of the most appropriate therapy.

CHAPTER 21

Myocardial Revascularization with Cardiopulmonary Bypass

Kevin L. Greason
Thoralf M. Sundt III

INTRODUCTION

Coronary artery disease (CAD) remains the single largest killer of Americans, accounting for almost half a million deaths per year. It imposes a particular burden on the elderly, with more than 80% of all CAD deaths occurring in those over age 65.[1] The magnitude of this impact takes on great significance because it is expected that the number of Americans older than 65 years of age will double over the next two decades.[2] If you add to this aging population the anticipated increase in the prevalence of important risk factors for CAD such as diabetes mellitus and obesity, the population at risk for CAD can only be expected to increase.

Myocardial revascularization represents an effective treatment strategy shown to prolong survival. Techniques of revascularization include percutaneous coronary intervention (PCI) and coronary artery bypass graft surgery (CABG), which can be performed with or without cardiopulmonary bypass. Current techniques for CABG can be carried out with low perioperative morbidity and mortality, with excellent long-term outcomes despite an increasing risk profile.[3] Coronary artery bypass graft surgery with cardiopulmonary bypass remains the standard by which the other techniques (ie, PCI, off-pump CABG) are measured.[4,5] It is expected that it will continue to be a cornerstone in the management of CAD in the foreseeable future.

HISTORY OF CORONARY ARTERY BYPASS GRAFTING

The modern era of myocardial revascularization with cardiopulmonary bypass began in 1954 when Dr. John Gibbon reported the development of the cardiopulmonary bypass machine.[6] An additional seminal advance occurred with the development of coronary angiography by Mason Sones at the Cleveland Clinic in 1957, which opened the door to the elective treatment of coronary atherosclerosis by means of direct revascularization.[7] Initial reports by Rene Favaloro and Donald B. Effler on their techniques to treat clinical events associated with stenotic lesions of the coronary arteries culminated in the first large series of aorto-to-coronary artery venous grafts reported in 1969.[8] Simultaneously Dudley Johnson of Milwaukee published a series of 301 patients in 1969.[9] The success of these techniques was soon demonstrated in larger series initiating the modern era of coronary artery surgery.

INDICATIONS FOR SURGICAL CORONARY REVASCULARIZATION

The indications for CABG are reviewed in detail in Chapter 19. In brief, the indications established by the American Heart Association and American College of Cardiology (AHA/ACC) consensus panel are based predominantly on the results of trials comparing surgical revascularization with medical therapy for patients with chronic stable angina.[10] Three major trials, the Coronary Artery Surgery Study (CASS), the Veterans Administration Coronary Artery Bypass Cooperative Study Group, and the European Coronary Surgery Study (ECSS), demonstrated the greatest survival benefit of revascularization to be among those patients at highest risk of death from the disease itself as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular dysfunction.[11–13]

PREDICTION OF OPERATIVE RISK

Prediction of risk-adjusted outcomes permits both the surgeon and the patient to weigh the potential benefits of operation against risks of perioperative morbidity and/or mortality. The patient's comprehension of benefit versus risk is paramount to informed consent before coronary artery bypass surgery. Accurate risk-adjusted prediction of postoperative morbidity and mortality also provides an important quality improvement tool to understand and examine the variability in institutional and individual surgeon performance.

A number of cardiac surgery databases have been used to develop risk models for predicting operative morbidity and mortality in patients undergoing CABG.[10] One of the more user-friendly risk assessment tools is that provided by the STS Risk Calculator (http://www.sts.org/quality-research-patient-safety/quality/risk-calculator-and-models/risk-calculator), which provides an assessment of individual patient operative risk derived using the Society of Thoracic Surgeons (STS) database (Table 21-1). The STS risk algorithm is proprietary and is based on data voluntarily submitted by participating centers on 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999; the application is available for public use.

Overall, the average risks of 30-day operative death and major complication for patients reported to the STS database undergoing CABG from 1997 to 1999 were 3.05 and 13.4%, respectively. Specific complications included stroke (1.6%), renal failure (3.5%), reoperation (5.2%), prolonged ventilation (5.9%), and sternal infection (0.63%). Risk models were developed using multivariate analysis to stratify the strength of the association from among 30 potential preoperative risk factors for mortality and major complications as shown in Tables 21-2 and 21-3. Except for deep sternal wound infection, the development of any of these complications correlated with an increased risk-adjusted operative mortality.[14]

A preliminary sense of operative mortality can be derived simply from an understanding of the core variables most predictive of risk in the aforementioned data sets. The strongest predictors of operative mortality include nonelective surgery, low ejection fraction, and prior heart surgery. Chronic comorbidities are also associated with an increased operative mortality after coronary bypass, including treated diabetes, peripheral vascular occlusive disease, chronic renal insufficiency, and chronic obstructive pulmonary disease (COPD).[10]

PREOPERATIVE ASSESSMENT

Patient Evaluation

Regardless of the risk model applied, there is no substitute for clinical evaluation of the patient. Unfortunately, all too often the assessment focuses disproportionately on coronary anatomy and insufficiently on the nature, duration, and severity of ischemic symptoms, as well as signs and symptoms of congestive heart failure (CHF). In addition, history of or coexisting cerebrovascular and/or peripheral vascular disease, malignancy, sternal radiation, COPD, diabetes mellitus, or renal and/or hepatic insufficiency can have major impact on the operative morbidity and even mortality, not all of which are captured in risk models.

Current medications and dosages with special attention to antiplatelet agents such as clopidogrel must be reviewed. Operation in the setting of recent clopidogrel use is associated

TABLE 21-1 Independent Variables Associated with Mortality after Isolated Coronary Artery Bypass Graft Surgery

Variable	Odds Ratio	95% Confidence Interval
Multiple reoperations	4.19	3.61–4.86
First reoperation	2.76	2.62–2.91
Shock	2.04	1.90–2.19
Surgery status	1.96	1.88–2.05
Renal failure/dialysis	1.88	1.80–1.96
Immunosuppressants	1.75	1.57–1.95
Insulin-dependent diabetes mellitus	1.5	1.42–1.58
Intra-aortic balloon pump use	1.46	1.37–1.55
Chronic lung disease	1.41	1.35–1.48
Percutaneous transluminal coronary angioplasty, 6 hours	1.32	1.18–1.48

Data were collected from 503,478 patients undergoing isolated CABG in the U.S. from 1997 to 1999 from Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.

with excessive bleeding and need for reoperation.[15] Most surgeons recommend 5 days from the last administered dose of clopidogrel before undertaking CABG with cardiopulmonary bypass.

Physical examination of the lungs and heart should focus on the stigma of ischemic and valvular heart disease. Cardiac murmurs warrant further evaluation. Additionally, the adequacy of presternal soft tissues to permit wound closure should be considered and evidence of venous varicosities or prior vein stripping may impact plans for conduit harvest. Peripheral pulses should be documented as their presence or absence may impact from which leg to harvest the vein or place an intra-aortic balloon pump. A detailed neurologic examination of the ulnar, radial, and median nerves should be document in the case of planned radial artery harvest.

Diagnostic evaluation should be directed by the clinical assessment, but at a minimum should include a renal panel (creatinine), complete blood count, and chest x-ray. The ECG should be reviewed for evidence of previous myocardial infarction and conduction abnormalities. Radiologic evaluation should rule out concomitant neoplasm, active pulmonary infection, and/or ascending aorta calcification; the latter should be further assessed with a noncontrast CT scan because it will impact the location for arterial cannulation and aortic cross-clamp placement.

Hemodynamically significant coronary artery lesions on angiography are conventionally defined as those lesions with a 50% loss of arterial diameter, which is sufficient to impair coronary blood flow reserve and distal coronary pressure.[10] An assessment should be made of left ventricular function and regional wall motion abnormalities as well as the presence and degree of valvular abnormalities, including aortic stenosis and mitral regurgitation either with left heart catheterization or echocardiography (our preferred method).

It is in the surgeon's best interest to develop a good relationship with the patient and his or her significant others. Specifics including the risks, benefits, and alternatives to surgery need to be discussed to permit an informed decision. Ideally, this discussion is held in the presence of the patient's significant others, because patients often have difficulty absorbing the details of the discussion at the time related to the stress of the situation. Should the patient experience a major complication or mortality, it is often the patient's significant others with whom the surgeon will most often interact. Additionally, anticipated need for postoperative rehabilitation, as well as the tempo and time course of recovery is also of interest to all parties. A clear understanding of the expectations for the perioperative period will reduce everyone's anxiety about surgery and may promote early patient recovery. Good rapport with patients and their significant others is also the physician's best protection from litigation should untoward events occur.

BYPASS CONDUITS

Internal Thoracic Artery

The left internal thoracic artery (ITA) as a bypass graft to the left anterior descending coronary artery has been proven to provide superior early and late survival and better event-free survival after CABG.[24] The unparalleled long-term patency and better clinical outcomes associated with the use of the ITA make it the conduit of first choice for anastomosis to the left anterior descending coronary artery in almost all patients regardless of age, and establish an argument to use the right ITA as conduit to other targets as well.

Characteristics

The ITA demonstrates remarkable resistance to development of atherosclerosis, which may be in part attributable to a greater resistance of its endothelium to harvest injury as compared with the saphenous vein. Under electron microscopy examination thrombogenic intimal defects are essentially nonexistent in the ITA but are commonly detected in venous grafts.[16] Perhaps more significantly, however, is the nonfenestrated internal elastic lamina of the ITA that may inhibit cellular migration, thereby preventing initiation of intimal hyperplasia. In addition, the medial layer of the ITA is thin, with fewer smooth muscle cells and a lesser proliferative response to known mitogens such as platelet-derived growth factor and pulsatile mechanical stretch.[17,18]

The endothelium of the ITA is itself unique as well. With a significantly higher basal production of the vasodilators nitric oxide and prostacyclin, the ITA demonstrates a favorable response to pharmacologic agents commonly used in the postoperative period. For instance, the ITA shows vasodilation in response to milrinone and yet does not vasoconstrict in response to norepinephrine.[19] Furthermore, nitroglycerin causes vasodilation in the ITA, but not in the saphenous vein.[20] The endogenous secretion of such vasodilators may also have a "downstream" effect on the coronary vasculature, explaining the common observation that the native coronary vessel itself often appears relatively protected from progressive atherosclerotic disease distal to the anastomosis. Finally, the ITA exhibits remarkable remodeling over time, adapting to the demand for increased flow by often increasing in diameter over time as observed on late postoperative angiograms, a phenomenon mediated by the endothelium.[21]

Surgical Anatomy of the Internal Thoracic Artery

The ITA arises from the undersurface of the first portion of the subclavian artery opposite the thyrocervical trunk. The left ITA originates as a single artery in 70% of patients and as a common trunk with other arteries in 30%. In contrast, the right ITA originates as a single artery in 95% of cases.[22] At the level of the clavicle and the first rib, the ITA passes at first downward and medially behind the subclavian vein and lateral to the innominate vein. In this area, the phrenic nerve crosses the ITA from its lateral to its medial side, before contacting the pericardium. The phrenic nerve crosses anterior to the ITA 66% of the time on the left and 74% of the time on the right.[22] It is important to keep these relations in mind to avoid phrenic nerve injury during proximal ITA harvest.

Below the first costal cartilage the ITA descends almost vertically and slightly laterally at a short distance from the margin of the sternum. The ITA lies posterior to the cartilages of the upper six ribs and the intervening internal intercostal muscles.

In the upper chest there is a bare area of variable length where the ITA is covered only by the endothoracic fascia and parietal pleura. Below this level the transversus thoracis muscle covers the posterior surface of the ITA. The mean distance of the left ITA from the sternal margin at the level of the first intercostal space is 10.5 ± 3.2 mm, whereas at the level of the sixth intercostal space the distance increases to 20.0 ± 6.7 mm. The right ITA is slightly closer to the sternal margin than the left ITA. At the level of the sixth rib the ITA bifurcates into its terminal branches: the musculophrenic and superior epigastric arteries. The length of the ITA in situ ranges from 15 to 26 cm, with a mean of 20.4 ± 2.1 cm; the left ITA is slightly longer than the right.[22] A pair of internal mammary veins accompanies the ITA; at the most superior portion these veins form a single vessel, which runs medial to the artery and drains into the innominate vein.

Pedicled Harvest Technique

After the sternum is divided, the left ITA is harvested using an internal mammary retractor to expose of the internal mammary bed (Fig. 21-1). Excessive distraction of the sternal leaves can cause costal fractures or dislocation of the costosternal joints, resulting in severe postoperative pain as well as brachial plexus injury. The parietal pleura and loose connective tissue with accompanying fat is dissected away from the chest wall. It is our preference to enter the left pleural space to allow easier exposure of the ITA, especially in its most proximal aspect, and to permit the ITA to fall into a more lateral and posterior path upon wound closure. Slightly rotating the operating table to the patient's left and decreasing the patient's tidal volume can aid in the visualization.

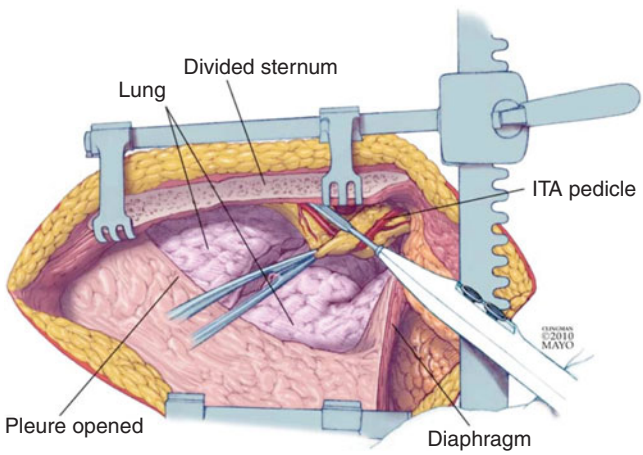

FIGURE 21-1 Internal thoracic artery (ITA) harvest. A self-retaining mammary retractor is used for exposure of the ITA bed. The left pleura is dissected away from the mammary pedicle and opened along the course of the ITA. The endothoracic fascia is incised medial and lateral to the ITA pedicle. The pedicle is carefully separated with blunt dissection from the underside of the rib. Gentle traction on the pedicle exposes arterial and venous branches at the level of the intercostal spaces; vessels are clipped on the ITA side and cauterized or clipped on the chest wall side. The proximal dissection is carried to the inferior border of the subclavian vein; the distal dissection is then carried to the level of the ITA bifurcation. The transversus thoracis muscle must be divided to expose the ITA bifurcation. The ITA is divided after full heparinization, either at the end of harvest or just before grafting of the left anterior descending (LAD) artery. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

The ITA is identified lateral to the border of the sternum by inspection of the bare area or by palpation in the area of artery covered by muscle. It can be harvested using either a pedicled, semiskeletonized, or a skeletonized technique. When taken as a pedicle, the dissection plane can be started in the bare area of the ITA at the level of the third or fourth rib or at the level of the lower sternum. The intercostal space is avoided as the initial point of exposure because it contains the branch vessels. The endothoracic fascia is incised medially for a distance of about 4 cm using the Bovey electrocautery at low setting (ie, 20). The pedicle is carefully separated from the chest wall using gentle blunt dissection with the Bovey electrocautery tip. Exposure can be enhanced by pushing the pedicle away with closed forceps or by gently grasping the fascia. The ITA is a fragile vessel and the conduit should never be grasped with the forceps. Gentle posterior traction on the pedicle allows exposure of arterial and venous branches, which should be clipped and divided.

After the pedicle has been freed for about 4 cm, the endothoracic fascia is incised laterally, allowing the pedicle to fall away from the chest wall. Dissection is continued proximally and distally to the level of the subclavian vein and ITA bifurcation. Attention should be given to avoid injury to the phrenic nerve during the proximal exposure. Once the dissection is completed, the patient is heparinized and the pedicle sprayed with a papaverine solution (1 cc [30 mg] of papaverine added to 9 cc of saline). Three minutes after heparinization, the distal ITA is doubly clipped just proximal to the bifurcation and the artery divided. An atraumatic bulldog clamp is applied to the distal end of the artery. Alternatively, the pedicle may be left in situ and transected just before using the conduit.

Skeletonization of the Internal Thoracic Artery

Sternal blood flow decreases significantly after pedicled ITA harvest. Skeletonized harvest, however, reduces the degree of sternal ischemia. Two prospective randomized studies assessing sternal blood supply using bone scan with single photon emission computed tomography after skeletonized and pedicled harvest have demonstrated significant reduction in sternal vascularity after pedicled harvest, whereas skeletonized harvest resulted in minimal change in sternal blood supply. Multivariate analysis found harvesting technique to be the only factor responsible for postoperative sternal ischemia.[23,24]

Low rates of sternal wound infection have been reported using skeletonized bilateral ITA harvest. Matsa and associates observed a deep sternal wound infection rate of 1.7% among 765 patients undergoing bilateral skeletonized ITA harvest. Of note, sternal complications occurred in only 2.6% of 231 diabetic patients in this study, which was not significantly different from that of the nondiabetic patients.[25] In Calafiore and coworkers' review of 842 patients undergoing bilateral skeletonized ITA

harvest compared with a historical nonskeletonized bilateral ITA control group, skeletonized harvest was associated with a reduced incidence of sternal wound complications (4.5%) versus pedicle harvest (1.7%). Diabetic patients in the study derived the greatest benefit from skeletonized harvest with respect to sternal wound complications: 10% in the pedicle harvest versus 2.2% in the skeletonized harvest groups.[26]

Using the skeletonized harvest technique, only the artery is mobilized, leaving the internal thoracic venous plexus intact. Although skeletonization is a technically more demanding and time-consuming procedure, it increases luminal diameter and free flow compared with a pedicled graft, and also provides a longer conduit.[26] Some surgeons have expressed concerns regarding functional integrity, vasoreactive profile, and early and long-term patency; however several investigators have shown no difference in endothelial integrity, endothelial-dependent or neurogenic-dependent vasoreactivity between the techniques of pedicle or skeletonized harvest.[27–29] Furthermore, there does not appear to be any difference with respect to early and midterm patency.[30,31]

Patency

The superior late patency of an ITA graft to the left anterior descending coronary artery compared to a saphenous vein graft (SVG) was initially demonstrated by Barner and colleagues in the 1985.[32] Superior patency translates into improved 10-year survival (LITA-to-LAD artery 82.6% versus SVG-to-LAD artery 71%) with less incidence of myocardial infarction (MI), hospitalization for cardiac events, and cardiac reoperations.[33] The superior performance of ITA grafts appears to persist in the current era despite the use of agents to improve vein graft performance. In the BARI trial the patency rates at 1 and 4 years for ITA grafts were 98 and 91% compared with vein grafts, which were 87 and 83%, respectively.[34,35] The superior patency of the ITA becomes even more prominent with longer follow-up. In an angiographic study of 1408 symptomatic post-CABG patients, patency rates for the LITA at 10 and 15 years were 95 and 88%, respectively, whereas SVG patencies were 61 and 32% at the same time intervals.[36]

Radial Artery

The use of the radial artery (RA) as a conduit for coronary bypass was originally described by Carpentier and associates in 1973. Spasm of the artery was common during surgery and was managed by mechanical dilation. The initial results were disappointing with 32% of grafts occluded at 2 years.[37] Accordingly, the RA was abandoned as a conduit for CABG. Acar and colleagues revived the use of the RA after several grafts, angiographically demonstrated to be "occluded" early postoperatively, were patent during restudy 15 years later. Acar postulated that harvest injury was responsible for the spasm/graft occlusion.[38] Proponents of the RA as a conduit have demonstrated encouraging mid- and long-term results with a pedicled harvesting technique and pharmacologic manipulation to prevent radial artery vasospasm[39] As a result, this conduit has enjoyed a remarkable resurgence of interest as a supplementary arterial conduit for coronary revascularization.

Characteristics

Histologically, the RA has a fenestrated internal elastic lamina and a thicker wall than the ITA with a higher density of myocytes in its media.[40] The RA is also more likely to have atherosclerotic changes at the time of harvest than the ITA, with 28% of RAs having some degree of demonstrable atherosclerosis, as compared with only 6% of ITAs. Whether these differences indicate that the RA will prove more susceptible to graft atherosclerosis with reduced patency is unknown.[41]

Physiologically, the RA is equally sensitive to norepinephrine as the ITA; however, given its greater muscle mass, it generates a higher force of contraction, accounting for its well-recognized propensity for spasm.[42] Fortunately, the RA also readily responds to a variety of vasodilators, including calcium channel blockers, papaverine, nitrates, and milrinone. In vitro, nitroglycerine appears to be the most effective agent for inhibiting and reversing RA spasm.[43] Additionally, nitroglycerin has been shown to be better tolerated clinically, equally effective, and less expensive than diltiazem in prophylaxis of RA spasm after CABG in a prospective randomized trial.[44]

Surgical Anatomy of the Radial Artery

The RA originates from the brachial artery just proximal to the biceps tendon. In the proximal forearm the RA courses underneath the brachioradialis muscle. As it courses distally, it emerges from the lower surface of the muscle, becoming more superficial, and runs beneath the antebrachial fascia between the tendon of the brachioradialis muscle and the flexor carpi radialis muscle and anterior to the radius and pronator quadratus muscle. The recurrent radial artery originates from the lateral aspect of the RA soon after its origin from the brachial artery. Multiple small muscular branches emerge from the deep and lateral surfaces of the artery. At the wrist the RA gives rise to the palmar carpal branch, the dorsal carpal branch, the superficial palmar branch, and the deep palm.[45] Throughout its course the RA is accompanied by a rich plexus of venae comitantes. The average length of the RA ranges between 18 and 22 cm with an internal diameter of 2 to 3 mm.[46]

Harvest Technique

It is most common to consider the patient's nondominant arm for harvest, partially out of concern for the impact of even subtle neurologic changes, and partially given the convenience of harvesting the left radial artery simultaneously with the left ITA. The extremity of interest must have adequate ulnar collateral circulation to ensure viability of the hand. Assessment of collateral circulation is best performed via noninvasive duplex ultrasonography.[47] The RA of the dominant hand can also be harvested if needed. Tatoulis and associates reported 261 patients undergoing bilateral RA harvesting with safe functional outcomes of both extremities.[48]

The arm is prepped circumferentially and the hand wrapped in a sterile fashion. The upper extremity is place on an arm board perpendicular to the long axis of the operating table. As shown in Fig. 21-2, a medially curved incision is made on the skin overlying the RA from a point 2 cm proximal to the styloid process of the radius to a point 2 cm distal to the elbow

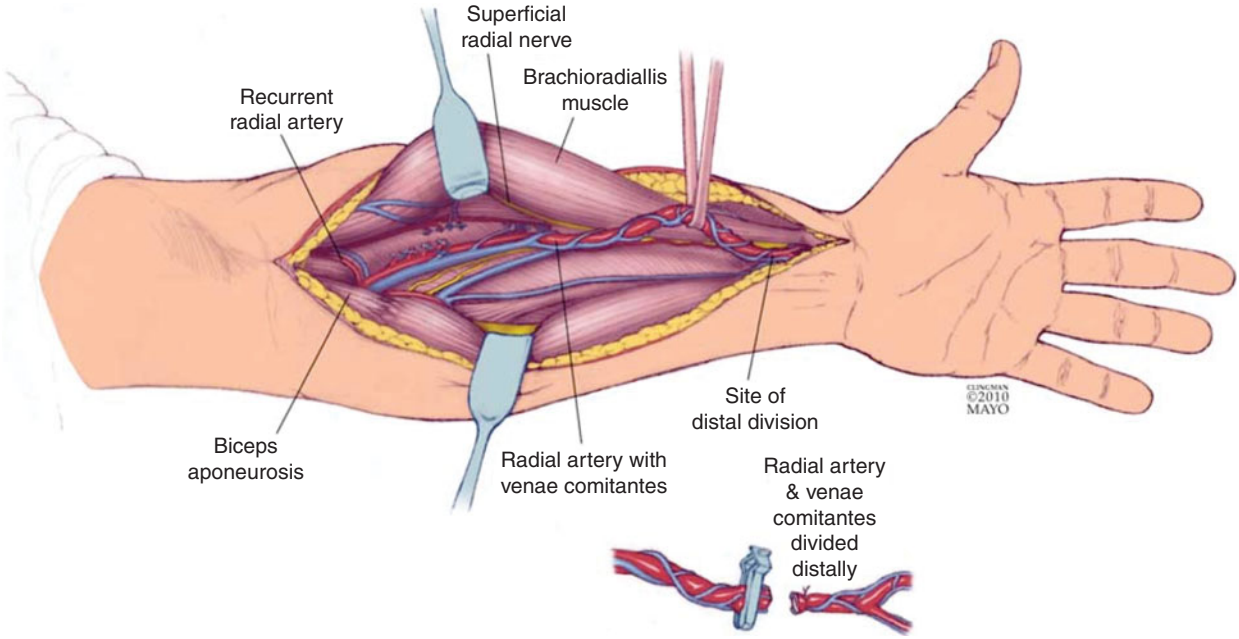

FIGURE 21-2 Radial artery harvest. A medially curved incision is made on the forearm over the artery. The deep fascia of the forearm is incised directly over the artery. The brachioradialis muscle is retracted laterally. Dissection is begun at the distal end and the satellite veins are divided. The RA is harvested as a pedicle with minimal manipulation. The proximal end of the dissection is marked by the radial recurrent branch, which is left intact. After the pedicle is free and heparin has been given, the artery is divided proximally and distally and stored in a room temperature solution of lactate, nitroglycerin, and papaverine. Hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain is placed. crease and 1 cm medial to the biceps tendon. The subcutaneous tissue is divided with the cautery. The dissection can be initiated at either end depending on the surgeons' preference. The deep fascia of the forearm is incised directly over the RA.

The RA is harvested as a pedicle with minimal manipulation using sharp dissection, diathermy, or the harmonic scalpel (our preferred method). There are data to suggest that early graft flow is superior when the harmonic scalpel is used.[49] On the proximal half of the forearm, gentle lateral retraction of the brachioradialis muscle aids exposure. At the distal end of the dissection the satellite veins are identified and divided. The proximal end of the dissection is marked by the radial recurrent artery branch and a large venous plexus in the medial aspect of the RA. It is our routine to leave the recurrent radial branch intact. The artery is divided proximally and distally and stored in a room temperature solution of lactate, nitroglycerin, and papaverine.

After the RA is removed from the forearm, hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain is placed, which we feel helps reduce postoperative seroma formation. A circumferential elastic wrap is applied. The arm is then abducted and secured to the table. Reports of endoscopic RA harvest are beginning to emerge with good functional and cosmetic results; nonetheless the impact of the technique on graft patency is unknown.[50] We have not adopted the technique.

Two cutaneous nerves are of importance to note during RA dissection. The lateral antebrachial cutaneous nerve lies superficial to the belly of the brachioradialis muscle and runs close to its medial border. Placing the skin incision medial to the edge of the brachioradialis prevents potential injury. Damage to this nerve will produce paresthesias and numbness of the radial aspect of the volar forearm. The superficial branch of the radial nerve lies under the brachioradialis muscle and in the proximal two-thirds of the forearm runs parallel to the RA. Injury to this nerve will result in paresthesias and numbness of the thumb and the dorsum of the hand. The nerve can best be protected by avoiding excessive lateral retraction on the brachioradialis muscle.[45,51] Transient paresthesias, numbness, and thumb weakness are common and are reported by almost a third of patients after RA harvest; fortunately, the symptoms gradually resolve with time so that after 1 year only 10% of patients have residual complaints with only 1% reporting their symptoms as severe.[52–54]

Patency

Acar and associates in 1992 reported on 122 radial grafts with a 100% patency rate at 2 weeks and 93% patency at 9 months.[55] The results appear durable with reported patencies at 48 months of 89%. Several factors may affect RA graft patency, however, including both target artery runoff and competitive flow. In the prospective, randomized Radial Artery Patency Study, more severe target coronary artery stenosis was associated with lower rate of occlusion (>90% stenosis = 5.9% versus 70 to 89% stenosis = 11.8%).[56] The graft failure rate is highest if the target vessel is the right coronary artery system, but this may be related more to the coronary artery than the bypass conduit; one study showed equal patency of radial artery and saphenous vein bypass grafts to the right coronary artery.[57–59]

The proximal radial artery can be sutured to the ITA as a T- or Y-graft (composite), sutured directly to the ascending aorta, or sutured to the proximal portion or hood of a separate vein graft. In addition, a segment of vein can be interposed between the aorta and proximal radial artery in an end-to-end fashion. Comparisons have been made between the T- or Y-graft and direct aortic anastomosis methods. Maniar et al. found at approximately 30 months follow-up, a significantly greater incidence of postoperative angiography for recurrent angina among patients with direct aortic anastomosis as compared with patients with composite anastomosis (19% versus 11%).[59] There is controversy here, however, as Jung et al. found that 1-, 2-, and 5-year patency rates were significantly better with direct aortic anastomosis as compared with composite anastomosis.[60] Importantly, it appears that the overall patency of radial artery grafts to ideal targets may be superior to that of saphenous vein bypass grafts at 5 years, 98% versus 86%.[61]

Other Arterial Conduits

A variety of arterial conduits have been used in patients in whom no other conduits are available. The gastroepiploic artery (GEA) for the most part is utilized as an alternative conduit or as part of an all-arterial revascularization strategy. Despite the enthusiastic support of a small cohort of surgeons, the widespread use of the GEA as a coronary conduit has not been adopted, perhaps because of the increased operative time and relative difficulty required to harvest the conduit, the potential for perioperative and long-term abdominal complications, and the lack of consensus on the long-term benefit for total arterial revascularization. Anecdotal use of the ulnar, left gastric, splenic, thoracodorsal, lateral femoral circumflex and inferior epigastric arteries as coronary graft conduits has been reported in the literature. The popularity of the RA, however, has in large measure superseded these options.

Greater Saphenous Vein

The saphenous vein continues to be one of the most commonly used conduits in coronary bypass grafting. Characteristics that have solidified the greater saphenous vein as a coronary artery bypass conduit include its ease of harvest, ready availability, versatility, resistance to spasm, and thoroughly studied long-term results. Unfortunately there is a loss of clinical benefit after CABG because of time-related attrition. Accordingly, there is interest in pharmacologic strategies to maximize early and late venous graft patency.

Prospective randomized trials have shown that early aspirin administration reduces mortality after CABG. Aspirin within 48 hours after CABG also reduces early postoperative complications, including mortality, myocardial infarction, stroke, renal failure, and bowel infarction.[62] More recently, it has been recognized that lipid-lowering agents reduce the progression of graft atherosclerosis.[63,64] Aggressive use of statins to achieve a low-density lipoprotein cholesterol <100 mg/dL decrease by one-third the number of grafts affected with atherosclerosis at angiographic follow-up and also decreased the need for repeat revascularization.[63] With clear documentation of improved outcomes with these two pharmacologic strategies, systematic approaches to ensure their universal application are needed.[10]

Finally, in the future, gene therapy may allow modification of the venous vascular endothelium to avert development of intimal hyperplasia. Unfortunately, the PREVENT IV trial, testing whether short-term angiographic vein graft failure could be diminished with treatment of the saphenous vein before grafting with edifoligide (an oligonucleotide decoy that binds to and inhibits E2F transcription factors), demonstrated no impact of the treatment.[65] The concept remains a valid one, however, and gene therapy will continue to be an exciting area of investigation in the future.

Harvest Technique

Saphenous vein harvest can be performed with an open or endoscopic technique. Open-vein harvest can be performed with a completely opened technique or bridged technique. In the completely open technique an extensile skin incision provides the best exposure of the vein and may allow for harvest with the least amount of surgical trauma, but that advantage comes at the risk of higher rates of wound complications and postoperative pain. Bridged skin incisions may decrease pain and wound complications but may also increase surgical manipulation of the vein conduit.

Open-vein dissection can be started either in the upper thigh, above the knee, or at the ankle (Fig. 21-3). Some surgeons prefer to harvest vein from the lower leg because of a more appropriate vein caliber and wall thickness, as well as greater distance from the perineum (a potential source of infection). Others prefer to harvest vein from the thigh, arguing improved wound healing, particularly among patients with distal peripheral arterial occlusive disease. We are not aware of any data supporting one location over another. Because of the greater amount of adipose tissue present in the thigh area, wound breakdown in that location may prove more of a nuisance to treat. The fundamentals of vein harvest are to procure the conduit with a minimal amount of trauma to the vein. Specifically, the vein should not be grasped with forceps, stretched, or overdistended, because patency rates may be related to endothelial damage induced during harvest and preparation of the conduit. Identification of the vein is easiest at the ankle, just lateral to the medial malleolus.

In the completely open technique, a skin incision directly over the trajectory of the vein is made, taking care not to create skin flaps. Purposeful, directed, sharp dissection is used to free the vein from the surrounding tissue. Side branches on the vein can initially be left long. Once dissection is completed, the vein is ligated and divided proximally and distally. A blunt-tipped vein cannula is inserted into the distal end of the vein and the vein gently flushed and dilated with a room temperature solution of plasmalyte. The side branches can be clipped flush with the vein at this time, taking care to avoid narrowing of the conduit lumen.

When using a bridged technique, several step incisions are performed over the course of the vein. Dissection of the vein is otherwise carried out in a similar fashion as describe above. Exposure of the vein with the bridge technique may be less than optimal. Caution is necessary here to avoid excessive tension or manipulation of the conduit as an adjunct to deal with less than adequate exposure of those segments of the vein covered by a skin

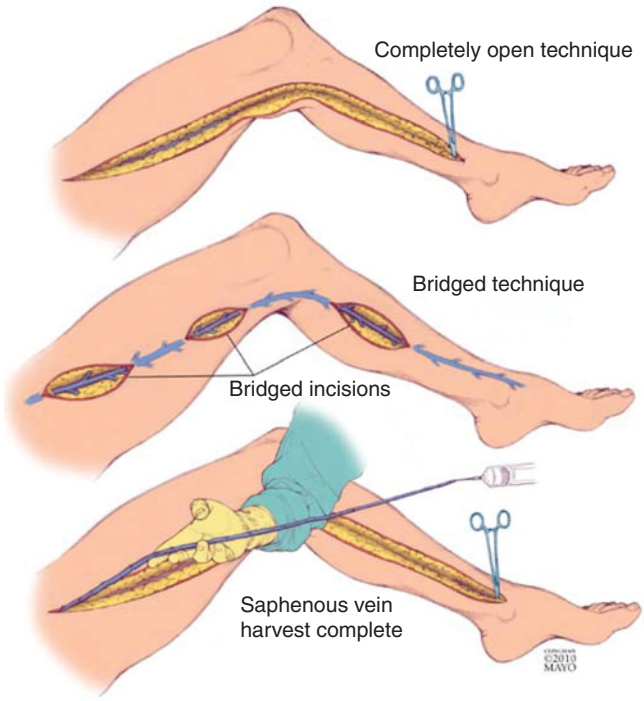

FIGURE 21-3 Saphenous vein harvest: open and bridged technique. Open technique (*top*): Dissection can be started in the upper thigh, above the knee, or at the ankle. Identification of the vein is easiest at the ankle, just above the medial malleolus. An incision is made overlying the vein and extended directly over its trajectory. The vein is dissected and all venous tributaries are ligated and divided in situ. Bridged technique (*middle*): Two- or three-step incisions are performed over the course of the vein. Dissection of the vein is carried in a similar fashion as the opened technique except that branches are divided in situ and ligated once the vein is explanted. Completed dissection (*bottom*): Once dissection is completed, the vein is ligated and divided proximally and distally. Stumps of side branches on the vein are left long and then are ligated flush with the vein, avoiding narrowing of the conduit. The vein is then gently flushed and stored in a solution of room temperature plasmalyte. The skin incisions are closed and the leg is wrapped with an elastic bandage. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

bridge. For all techniques of vein harvest located in the lower thigh and more distal, care should be taken to avoid trauma to the saphenous nerve, which is in close proximity to the vein. Injury to the nerve can result in debilitating postoperative neuralgia.

Endoscopic vein harvest starts with a 1.5- to 2.0-cm skin incision in the medial aspect of the extremity above the knee (Fig. 21-4). Carbon dioxide insufflation for visualization and dissection is established. Dissection is directed toward the groin region as far proximally as possible and then distally as far as needed to obtain the required length of conduit. Side branches are divided by using bipolar cauterizing scissors. Once dissection is completed, small skin punctures are made at the limits of the dissection and the vein exteriorized, ligated, and divided. The vein is removed and otherwise prepared in the standard fashion. Following skin closure, the leg is wrapped with a circumferential elastic bandage.

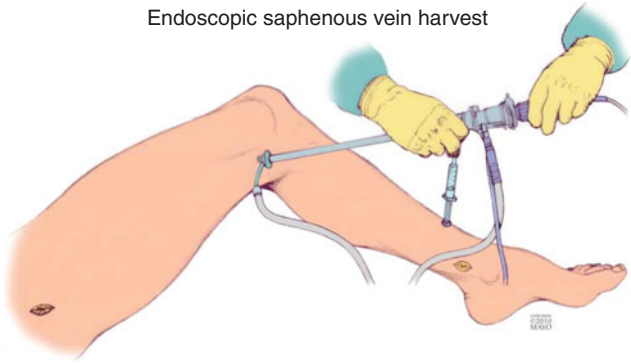

FIGURE 21-4 Endoscopic saphenous vein harvest. A 2.0-cm skin incision is made in the medial aspect of the knee. CO_2 insufflation is established. Harvesting is directed toward the groin region as far proximally as possible. Side branches are divided by using bipolar cauterizing scissors. Once dissection is completed, a small puncture is made in the groin directly over the vein and the vein is exteriorized under endoscopic guidance. After removing the vein from the leg, side branches are clipped. If any branches have been avulsed, the vein is repaired with interrupted 7-0 polypropylene sutures. Patency

Minimally invasive harvest of the saphenous vein using an endoscopic technique is gaining popularity because it greatly reduces the wound morbidity associated with the open harvest techniques. Endoscopic harvest decreases wound complication rates and produces an improved cosmetic result, although the operative time devoted to harvest is increased as are the number of defects to the harvested conduit requiring suture repair. Initial reports showed no detrimental effects of harvest technique on vein morphology, endothelial structure or function, or graft patency.[66,67] However, in recent report of 3000 patients treated with CABG, endovascular vein harvest was associated with higher rates of vein-graft failure, death, myocardial infarction, and repeat revascularization.[68]

The polar opposite to endoscopic vein harvest is the "no-touch" technique in which the vein is removed with a pedicle of surrounding tissue. The harvested vein is not distended and it is stored in heparinized blood. In a randomized study of 104 patients using this technique, the angiographic patency at 18 months was 89% for conventional versus 95% for no-touch grafts. At 8.5 years, patency rates were 76% for the conventional group versus 90% for the no-touch group. Multivariate analysis showed that the most important surgical factors for graft patency were the technique of harvesting the conduit and the vein quality. By comparison, the patency of internal thoracic artery grafts was 90% in the study.[69]

Other Venous Conduits

Alternative venous conduits such as the lesser saphenous and/or upper extremity cephalic veins are usually secondary choices for conduit. If it is planned to use either of these veins, preoperative vein mapping can help guide conduit harvest. The lesser

saphenous vein can be harvested in a supine position through a lateral approach by flexing the hip and medially rotating the knee or by an inferior approach with straight elevation of the extremity. A skin incision is usually started midway between the Achilles tendon and the lateral malleolus. Dissection is carried proximally up the leg to the popliteal fossa. Attention should be paid to avoid injuring the sural nerve.

The patency rate for arm veins is significantly lower than that of saphenous veins and for that reason they are considered conduits of last resort.[70] For cephalic vein harvest, the arm is prepared and positioned as during radial artery harvest. Incisions are placed along the medial and superior aspect of the arm. The cephalic vein is relatively thin-walled in comparison with the greater saphenous vein and is predisposed to aneurysmal dilatation.

CONDUCT OF OPERATION

Procedures are done under general anesthesia with central venous access, radial arterial lines, and pulmonary artery catheters. Transesophageal echocardiography may be helpful for identifying unsuspected intracardiac lesions or aortic atherosclerosis, and for evaluating ventricular function at the end of the procedure. If ventricular function is poor, a femoral arterial line will facilitate later placement of an intra-aortic balloon pump (IABP). We routinely use a temperature-monitoring urinary catheter. The patient is positioned in the supine position with arms tucked at the side. Care should be taken to avoid peripheral nerve complications caused by pressure injury. The lower extremities are positioned with a slight external rotation and flexion of the knees. The patient is prepared and draped to include the lower neck, the chest, and abdomen between the anterior axillary lines, and the lower extremities circumferentially.

Incisions

By far the most common approach for CABG is via median sternotomy. Cannulation for cardiopulmonary bypass, managing aortic valve insufficiency, monitoring the left ventricle for distention, and evacuating air all are easier with the midline approach. The skin incision extends from a point midway between the angle of Louis and the sternal notch to just below the tip of the xiphoid process. The scalpel is used to extend the incision through the subcutaneous tissues down to the sternum. Extensive Bovey cautery to the subcutaneous tissues should be avoided because tissue destruction here may result in increased risk of wound complication. Charcoal does not bleed, but neither does it heal.

Special attention should be devoted to identifying the middle of the sternum. The middle of the sternal periosteum is noted and marked with cautery, although we avoid scoring the periosteum continuously from notch to xiphoid as this devascularizes the periosteum unless the saw passes exactly down the line. The interclavicular ligament is divided in the sternal notch, allowing palpation of the posterior aspect of the sternal manubrium. The xiphoid process is identified and divided in the midline with heavy scissors and the midline diaphragmatic muscle attachments divided. A finger should be inserted under the sternum to document a free space anterior to the pericardium. If there are no significant adhesions present, the sternum is divided with the oscillating saw. If the prepericardial space is adhered, the sternum should be divided using the microsagittal saw. The saphenous vein or the RA can be harvested simultaneous with the sternotomy. Once the sternum has been divided, the ITA is harvested as previously described.

Cannulation and Establishment of Cardiopulmonary Bypass

The pericardium is divided vertically down to the diaphragm and the inferior attachment of the pericardium to the diaphragm is divided transversely. The remnant of thymic tissue and pericardial fat is divided in the midline to the inferior aspect of the left innominate vein. Pericardial retraction sutures create a pericardial cradle or well to improve exposure of the ascending aorta and right atrium. The left pericardium is divided at the level of the great vessels toward the phrenic nerve to allow the completed ITA bypass graft to fall laterally into the pleural space away from the sternum. The distal ascending aorta is inspected and palpated for soft nonatherosclerotic areas suitable for arterial cannulation, root ventilation, proximal graft anastomoses, and aortic cross-clamp placement (Fig. 21-5). In

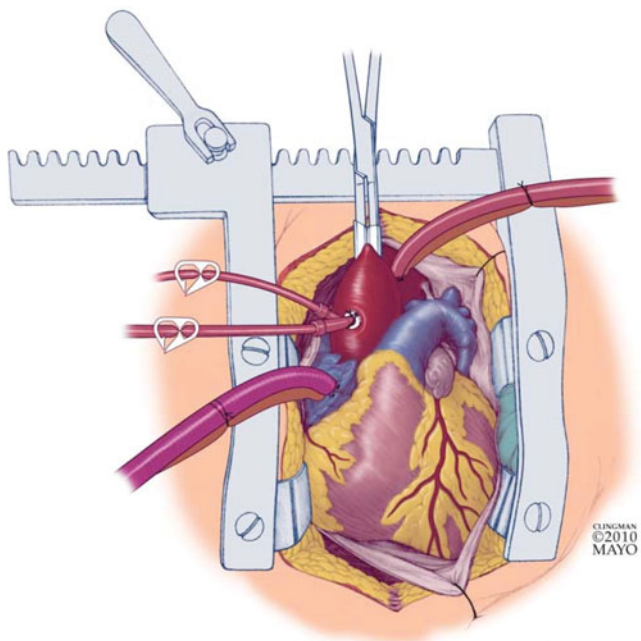

FIGURE 21-5 Cannulation. After full systemic heparinization, cannulation of the distal ascending aorta is performed with an appropriately sized curved or straight tip aortic cannula. A two-stage venous cannula is used for access to the right atrium, usually through the right atrial appendage. An aortic root cardioplegia/vent is placed. A retrograde cardioplegia cannula may be placed at the discretion of the surgeon. Patients with significant aortic regurgitation will benefit from placement of a left ventricle vent (placed via the right superior pulmonary) to avoid distention of the left ventricle during infusion of cardioplegia into the aortic root. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

some institutions epicardial ultrasound of the ascending aorta is performed. Now is the time to redirect the conduct of the operation should the aorta harbor areas of significant calcification, a topic of later discussion.

Systemic anticoagulation is achieved with the intravenous administration of 300 U/kg of unfractionated heparin and the adequacy of anticoagulation documented by an activated clotting time (ACT) over 450 seconds. In anticipation of aortic cannulation the systolic blood pressure should be reduced to about 100 mm Hg to minimize the risk of aortic dissection. Two partial-thickness concentric diamond-shaped purse-string sutures using 2-0 Ethibond suture are placed in the distal ascending aorta or proximal aortic arch, leaving enough room on the ascending aorta for all necessary proximal aortic work. The size of the purse strings should be large enough to accept the aortic cannula tip, usually 20-22 French. The ends of the sutures are passed through tourniquets that will be used for tightening the purse strings. The aortic adventitia within the purse strings is divided in preparation for aortotomy. The adventitia just superior to the planned aortotomy is grasped with a forceps and an aortotomy equal in size to the cannula tip is created with a no. 11 scalpel blade. Bleeding is easily controlled with slight inferior traction of the forceps on the adventitia. The aortic cannula is inserted and properly positioned, and the purse strings are tightened. The tourniquets are secured to the aortic cannula with a heavy silk tie and then the cannula is secured to the skin.

Placement of the aortic cannula can result in acute aortic dissection. Intraluminal positioning of the cannula is confirmed by watching for the cannula to fill with arterial blood. The aortic cannula is de-aired and connected to the arterial end of the pump tubing. An additional method to asses for the presence of aortic dissection is to have the perfusionist check the wave form and pressure of the arterial cannula pulse and to deliver a test infusion of 50 to 100 mL of fluid through the cannula. If an aortic dissection is present, often the test infusion will result in an increase in arterial cannula pressure.

Venous cannulation is accomplished with a two-stage venous cannula inserted in the right atrial appendage. A 2-0 Ethibond purse-string suture is placed around the tip of the right atrial appendage. The purse string should be wide enough for easy access of the selected venous cannula. An atriotomy is made with scissors at the tip of the appendage. Small bridging fibers of muscle are divided with scissors to permit easy entry of the cannula. The venous cannula is cautiously inserted, the tip of which should lie in the inferior vena cava. The purse-string suture is tightened and the tourniquet secured to the venous cannula with a heavy silk tie. The venous line is connected to the pump tubing.

An aortic root cannula is placed in the ascending aorta and retrograde cardioplegia cannula placed in the coronary sinus via the right atrium. The patient is placed on cardiopulmonary bypass at 2.4 L/min/m^2 and may be perfused at normothermia or may be cooled to 34°C. Once the patient is on full bypass, flow ventilation is stopped. A left ventricle vent may be placed via the right superior pulmonary vein at this time if there is significant aortic regurgitation. Target vessels are easier to identify before cardioplegic arrest while they are fully distended in their native state. The locations of planned distal anastomoses are marked with a scalpel. The pump flow is turned down temporarily and the aortic cross-clamp applied just proximal to the arterial cannula and bypass flow returned to normal.

Cold blood cardioplegia (10 mL/kg) is administered and may be delivered antegrade, retrograde, or both, with special attention given during this time to look for evidence of aortic regurgitation such as a flaccid aorta and/or left ventricle distention. Two available options to treat significant aortic regurgitation include completion of the procedure using only retrograde cardioplegia or placement of a left ventricle vent via the right superior pulmonary vein (our preferred method). Rarely is aortic valve replacement required. Additional doses of cardioplegia (5 mL/kg) are given via the antegrade and retrograde catheters approximately every 20 minutes throughout the remainder of the cross-clamp period.

DISTAL ANASTOMOSES

Location of Targets and Sequence of Anastomoses

Arteriotomy sites should be chosen proximal enough to offer the largest-sized coronary target but distal enough to avoid areas of obstruction or significant atherosclerotic disease. Arteriotomies at bifurcations should be avoided. Diseased vessels with an intramyocardial course can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is required to identify the desired target site. Often a very diseased vessel will be less diseased in the intramyocardial segment.

The LAD coronary artery can be particularly difficult to identify when it has an intramyocardial course. It can be relatively easy to inadvertently enter the right ventricular cavity while dissecting in the interventricular fat plane. If such a ventriculotomy is small, it can be closed with fine 6-0 polypropylene sutures, keeping in mind that the right ventricle is a low-pressure chamber and deep bites of myocardium are not necessary. However, if the right ventricle has been opened for a distance, it is best repaired using interrupted, pledgetted 2-0 Prolene suture (MH needle) in a horizontal mattress fashion, passing the needle under the ITA-LAD anastomosis. If difficulty is encountered in identifying an LAD artery, a fine probe may be passed retrograde via a small transverse arteriotomy into the LAD artery at the apex of the heart. The tip of the probe can be palpated in the proximal portion of the artery and cut down on appropriately. The distal arteriotomy is repaired with interrupted fine suture (7-0 or 8-0 Prolene). The repair can be done with or without a small vein patch.

The distribution of cardioplegia is usually relatively uniform; however, the sequence of anastomoses may be planned based on ischemic regions if myocardial protection is a particular concern. Grafting the most ischemic area first, using a distal-proximal routine, will permit early antegrade delivery of cardioplegia through the graft to the area of myocardial ischemia. Alternatively, the sequence of anastomoses may be dictated by the quality of the conduit itself, matching the best conduit to the most important

territories. It is customary to perform the left internal thoracic artery-to-LAD artery anastomosis last to avoid tension and potential disruption of the anastomosis.

Arteriotomy

The choice of the site of arteriotomy is critical. Opening into a plaque may force endarterectomy, whereas injury to the posterior wall with the knife transforms a straightforward anastomosis into a complex repair. Silastic tapes placed proximally and distally around the coronary artery may help to stabilize the vessel, a technique often employed when grafting the distal right coronary artery or when there is significant back bleeding from the opened vessel. The arteriotomy is performed with a fine scalpel blade and extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the luminal diameter of the distal coronary artery (Fig. 21-6).

Anastomotic Technique

The goal of the anastomosis is to join the conduit and the target vessel with precise endothelial approximation affording minimal resistance to flow. The wall of the vessel should be handled with care, avoiding endothelial injury to prevent thrombotic complications. Coronary anastomoses are typically constructed with continuous 7-0 polypropylene suture. Sutures should be evenly spaced to prevent leaks at the conclusion of the anastomosis. In order to increase anastomotic area, we prefer to bevel the conduits at approximately 30 degrees and notch them at the heel. Anastomoses are performed with continuous suture. We prefer a continuous, parachuting technique initiated at the heel for virtually all anastomoses regardless of their configuration (ie, end-to-side versus side-to-side sequential anastomosis).

Venous conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with continuous sutures (Fig. 21-7). Starting at the 3 o'clock position on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding location of the target coronary vessel. Two more sutures are taken before the heel (2 and 1 o-clock positions), one directly in the heel (12 o'clock), and then two more on the left side (11 and 10 o'clock positions) of the anastomosis before parachuting the conduit down to the target vessel.

The anastomosis is continued by placing additional sutures moving in a counterclockwise fashion around the anastomosis until the other thread is encountered. The technique encourages one to move out of the heel and toe areas of the anastomosis, minimizing the risk of narrowing the outflow. Care must be taken to prevent suturing the back wall of the coronary, and the proper amount of tension on the follow-through must be provided to avoid both leakage and a purse-string effect. Just before completion of the anastomosis, a 1-mm probe is passed proximally

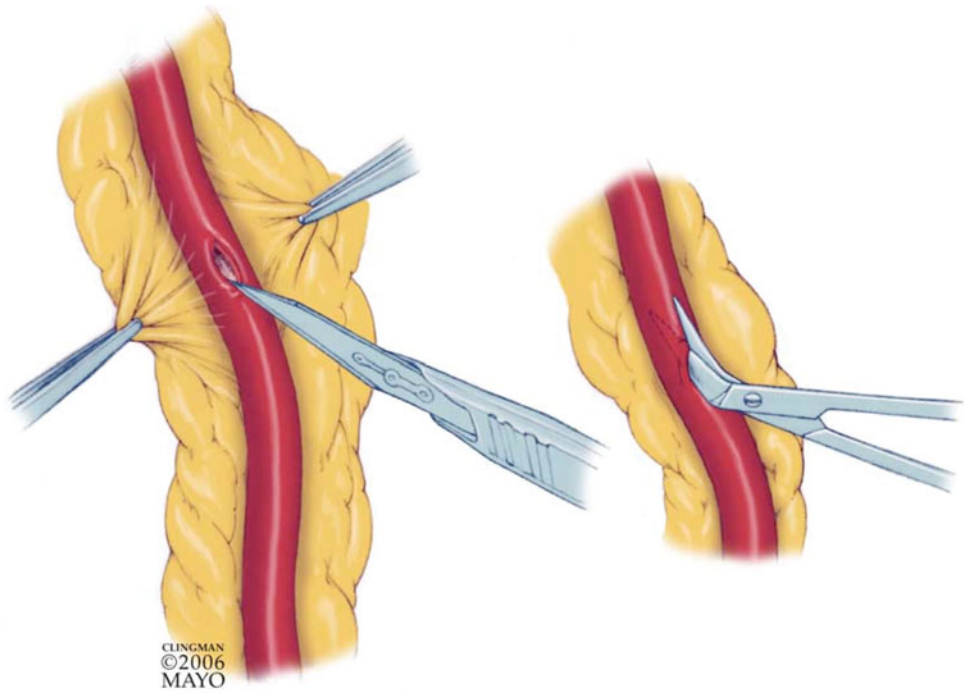

FIGURE 21-6 Distal anastomosis: Arteriotomy. Arteriotomy sites should be proximal enough to offer the largest-sized coronary target, and just distal enough to avoid the area of obstruction. Intramyocardial vessels can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is then required to identify the desired target site. The arteriotomy is then performed with a no. 11 blade. The arteriotomy is extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the diameter of the distal coronary. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

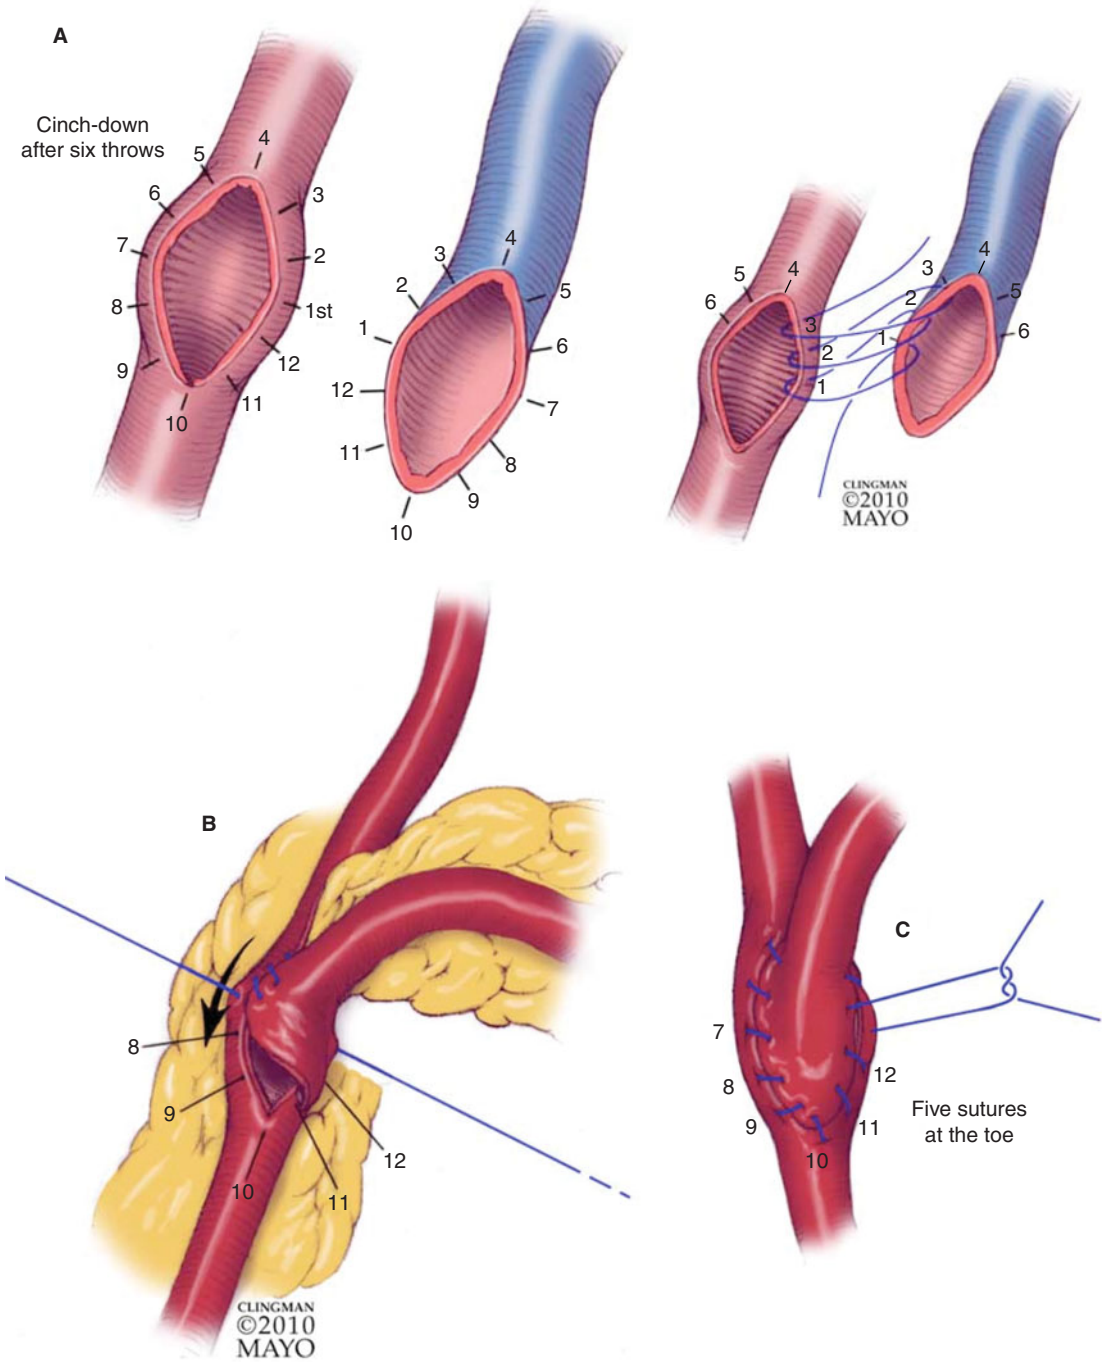

FIGURE 21-7 Distal anastomosis suture technique. (A) The conduit is beveled at 30 degrees and notched at the heel. We use a continuous, parachuting technique with 7-0 or 8-0 polypropylene suture. The conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with 12 sutures. Starting at 3 o'clock on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding location of the target vessel. (B) Two more stitches are taken before the heel, one directly in the heel, and then two more on the left side of the anastomosis before parachuting the conduit down to the target vessel. (C) The anastomosis is then completed by placing another six stitches evenly spaced in the same manner for the toe. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

and distally to ensure patency. To prevent anastomotic tension and torsion, pedicled conduits (ie, left ITA) can be suture-fixated to the adjacent epicardium.

Sequential grafting permits efficient use of conduit and has the potential for increased flow in the conduit. When planning sequential anastomoses, the most distal anastomosis should be to the largest target vessel with the greatest outflow potential. If the reverse situation is created, the most distal anastomosis is at increased risk for failure, given the likelihood of preferential flow to the larger more proximal anastomosis.[71,72] A clear

disadvantage of sequential grafting is the reliance of two or more distal targets on a single conduit and proximal anastomosis, placing a potentially larger region of myocardium at jeopardy.[72]

Some surgeons avoid using the ITA for sequential grafting or as a donor for composite T- or Y-grafting of other conduits because of concerns of compromising critical ITA-to-LAD flow. However, several series have demonstrated successful use of the ITA for sequential grafting of stenotic diagonal coronary arteries with excellent results.[73,74] The left ITA has also been used for multiple sequential anastomoses to the circumflex territory with grafting of the right ITA to the LAD artery.[75] Sequential grafting has also been performed with the right GEA as well as the RA.[76,77]

When constructing a sequential anastomosis, it is our preference to complete the distal anastomosis first and move proximally (Fig. 21-8). We feel that this facilitates determination of

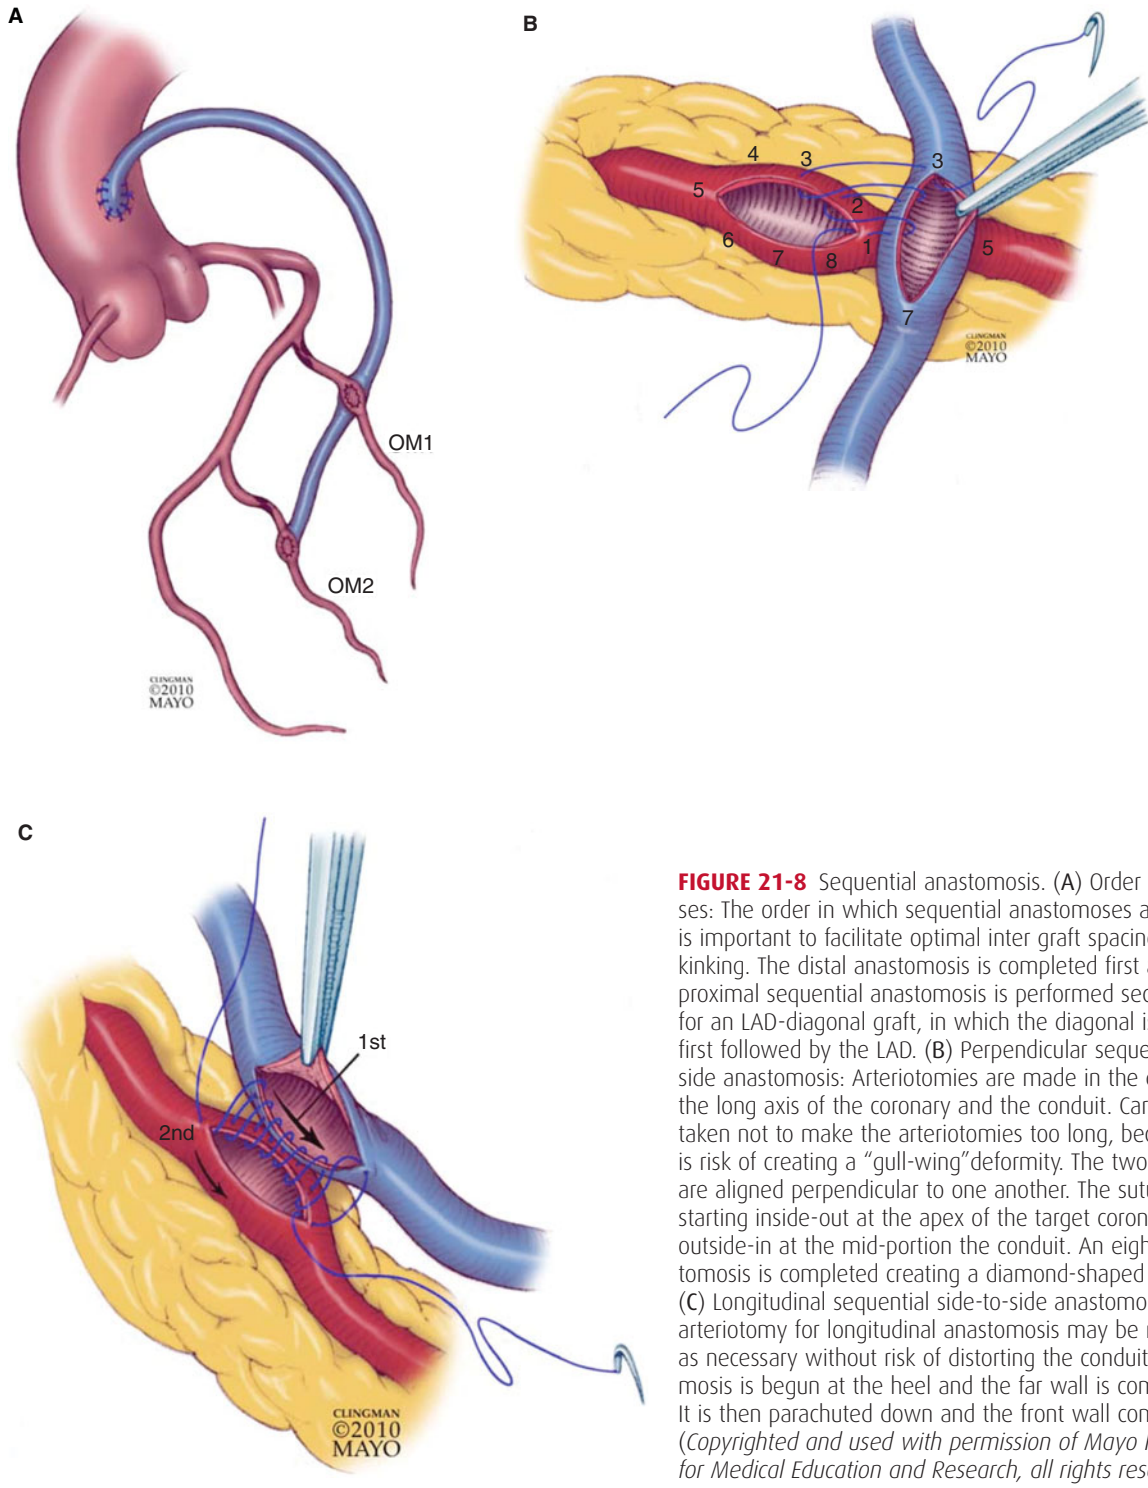

FIGURE 21-8 Sequential anastomosis. (A) Order of anastomoses: The order in which sequential anastomoses are performed is important to facilitate optimal inter graft spacing and avoid kinking. The distal anastomosis is completed first and the more proximal sequential anastomosis is performed second, except for an LAD-diagonal graft, in which the diagonal is performed first followed by the LAD. (B) Perpendicular sequential side-to-side anastomosis: Arteriotomies are made in the direction of the long axis of the coronary and the conduit. Care must be taken not to make the arteriotomies too long, because there is risk of creating a "gull-wing"deformity. The two incisions are aligned perpendicular to one another. The suture is passed starting inside-out at the apex of the target coronary and then outside-in at the mid-portion the conduit. An eight-stitch anastomosis is completed creating a diamond-shaped anastomosis. (C) Longitudinal sequential side-to-side anastomosis: The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. The anastomosis is begun at the heel and the far wall is completed open. It is then parachuted down and the front wall completed. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

optimal inter graft spacing. In the case of the LAD-diagonal graft, however, it is easier to move from proximal to distal, performing the diagonal anastomosis first. Sequential side-to-side anastomoses may be perpendicular or longitudinal. When constructing perpendicular anastomoses care must be taken not to make the arteriotomies too long, as there is risk of creating a "gull-wing" deformity and placing the graft at jeopardy. Arteriotomies in both the conduit and target are made in the direction of the long axis of the vessel. The two incisions are then aligned perpendicular to one another and the anastomosis completed, creating a diamond-shaped anastomosis. The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. Typically, the longitudinal anastomosis is begun at the heel as previously described.

CORONARY ENDARTERECTOMY

Coronary endarterectomy predated CABG as a direct surgical approach to relieving coronary occlusive disease. Coronary endarterectomy has been relegated to a position of secondary importance, however, thanks to the reliable and reproducible results obtained with CABG. Recently there has been increased interest in endarterectomy techniques, because the patient population coming to CABG has a greater atherosclerotic burden owing to diabetes, hyperlipidemia, and advanced age.[78] Most commonly, the need for endarterectomy arises intraoperatively when no soft site can be identified for arteriotomy or a vessel has been inadvertently opened in an extensively diseased area not amenable to grafting. Occasionally, endarterectomy is undertaken electively in patients with diffuse and extensive coronary disease with no other choices except transplantation.

The perioperative risk of CABG with endarterectomy is higher than that for CABG alone in most studies. In a retrospective study of 1478 patients, the reported mortality rate with endarterectomy was 3.2%, which was higher than for CABG alone (2.2%). Perioperative MI rate was also higher in the endarterectomy group, 4.2% versus 3.4%. The risk of mortality appears to increase when multiple vessels require endarterectomy: single-vessel endarterectomy mortality = 1.8% versus multiple-vessel endarterectomy mortality = 5.5%.[79,80] There has been controversy regarding the risk of endarterectomy of the LAD, with some studies showing increased risk whereas others demonstrate no increased risk.[79–81]

The late results of endarterectomy are inferior to those of routine CABG, with reported 3-year patency for ITA grafts to endarterectomized LAD targets ranging from 74 to 80%.[82,83] Despite this, angina relief is remarkably good initially. Unfortunately, the rate of recurrent angina is somewhat higher than after uncomplicated CABG; reported recurrence of angina is 25% at 5 years after endarterectomy.[79,84] The reported 5-year survival following coronary endarterectomy ranges from 76 to 83%.[79,84] Among patients in whom bypass to more distal nondiseased segments is not possible, coronary endarterectomy with subsequent bypass offers a viable alternative to leaving a territory ungrafted.

Technique

The technique of endarterectomy requires that the central core be extracted adequately in order to relieve obstruction of the branch vessels. Patency of a graft to the endarterectomized vessel depends upon the adequacy of runoff and therefore the distal endpoints of the endarterectomy core must be smoothly tapered. If the core fractures leaving behind disease in side branches, distal counter-incisions may be needed to obtain a satisfactory result.

The RCA is the vessel most often endarterectomized, usually at the level of its bifurcation. A manual eversion endarterectomy is performed after entering at the vessel approximately 1 cm proximal to the crux. A circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. The core is transected proximally and gently grasped with DeBakey forceps while the spatula is used to tease the adventitia away from the core. The core is regrasped hand over hand as distally as possible to avoid fracture. When the crux is reached, the posterior descending artery and the left ventricular branch are endarterectomized separately. If endarterectomy of the proximal segment of the RCA is needed, we prefer to use an open technique because it is difficult to obtain nice tapering of the core at the takeoff of the acute marginal branches with a retrograde eversion endarterectomy. The vessel wall is then reconstructed with a long hood created with the bypass conduit of choice.

We prefer open extended technique when the LAD is endarterectomized (Fig. 21-9). The vessel is opened as far proximal as possible if endarterectomy is anticipated. If the vessel has been opened in its mid-portion before it is apparent that endarterectomy is necessary, we extend the incision in the adventitia proximally before developing the endarterectomy plane. Retrograde eversion endarterectomy is dangerous because branch vessels will not be opened. Once the core is separated from the adventitia, it is transected proximally at the heel and the vessel is opened beyond the takeoff of the major diagonals to permit individual eversion endarterectomy of each of the branches. The segment is reconstructed with a long hood of the conduit of choice or a vein patch into which the ITA is anastomosed. The circumflex artery is the most infrequently endarterectomized vessel. Its rapid branching pattern makes satisfactory endarterectomy difficult. We tend to begin with an eversion technique, focusing our efforts on opening the largest distal branches as much as possible.

PROXIMAL ANASTOMOSES

Proximal anastomoses of saphenous vein or RA to the aorta are performed after the distal anastomoses under the same cross-clamp clamp. Our preferred technique is to complete each respective bypass graft in a distal anastomosis-proximal anastomosis fashion. Completion of the each respective bypass graft allows antegrade cardioplegia down the completed graft, aiding in myocardial protection. The single cross-clamp technique results in longer cross-clamp times than with the partial occlusion clamp method. However, the partial occlusion clamp technique requires additional aortic manipulation and has been

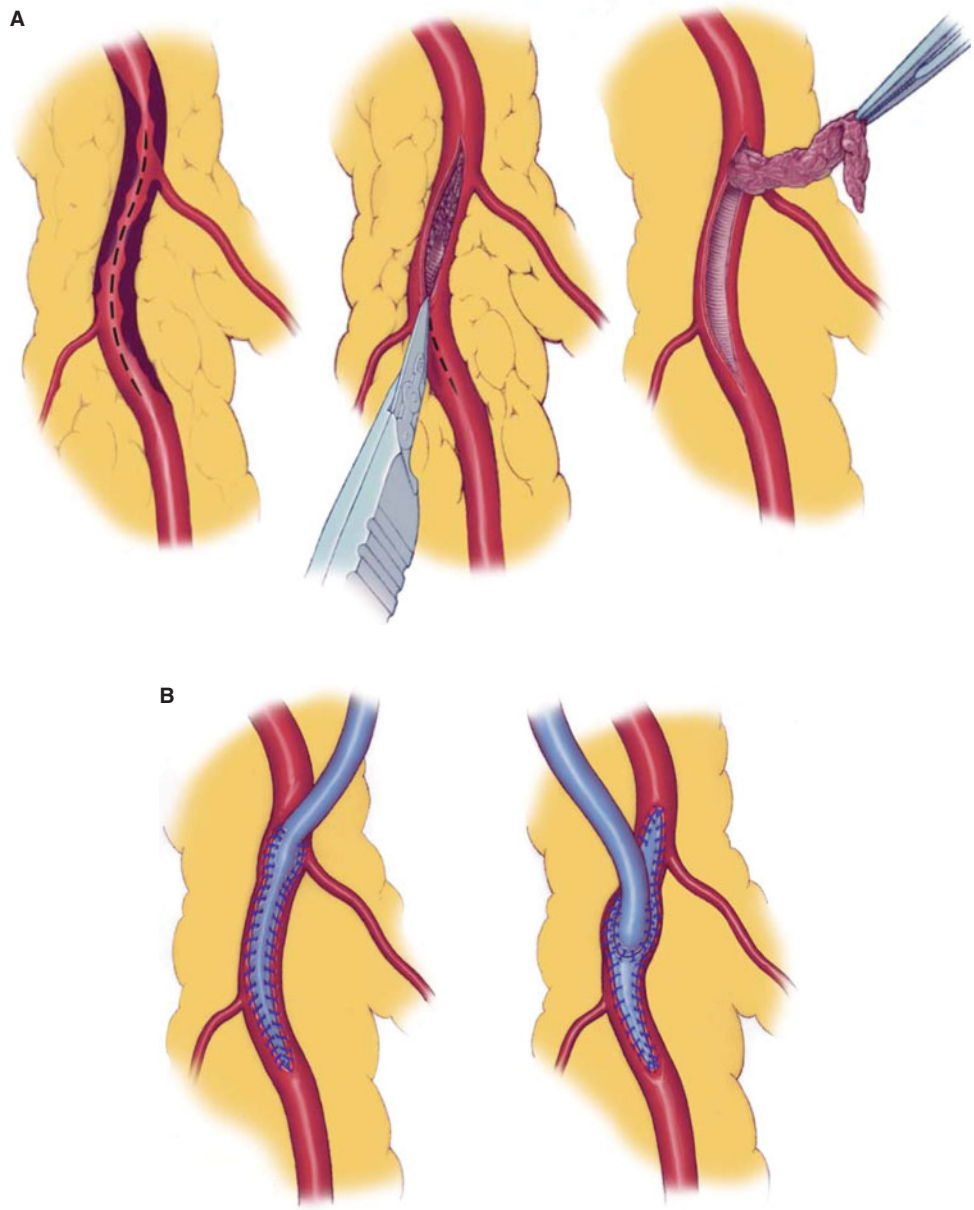

FIGURE 21-9 Coronary endarterectomy: Open extended technique. (A) The extent of disease is evaluated to plan the length of the arteriotomy and endarterectomy. The arteriotomy is performed and extended as proximal as needed before the circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. Once the core is separated from the adventitia, it is transected proximally at the heel and the vessel is opened beyond the takeoff of the major branches to permit individual eversion endarterectomy of each of the branches. (B) The segment is reconstructed with a long hood of the conduit of choice. The segment may be reconstructed with a vein patch into which the conduit is anastomosed. associated with a higher risk of neuropsychological deficits as compared with the single-clamp technique.[85]

Anastomotic Technique

Once an appropriate site for aortotomy is identified, the fatty tissue overlying the aorta is removed (Fig. 21-10). An arteriotomy is created with a no. 11 blade, and a 4.0-mm punch used to create a circular aortotomy. The size of the punch may vary depending on the size of the conduit graft. The graft is measured to length with the aorta, right heart, and pulmonary artery full of blood. The graft is cut and the proximal aspect of the conduit beveled and notched at the heel. A running 5-0 polypropylene suture is used for a venous graft and a 6-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. The anastomosis can be completed with continuous stitches. Symmetry in the spacing of sutures is paramount to obtain a

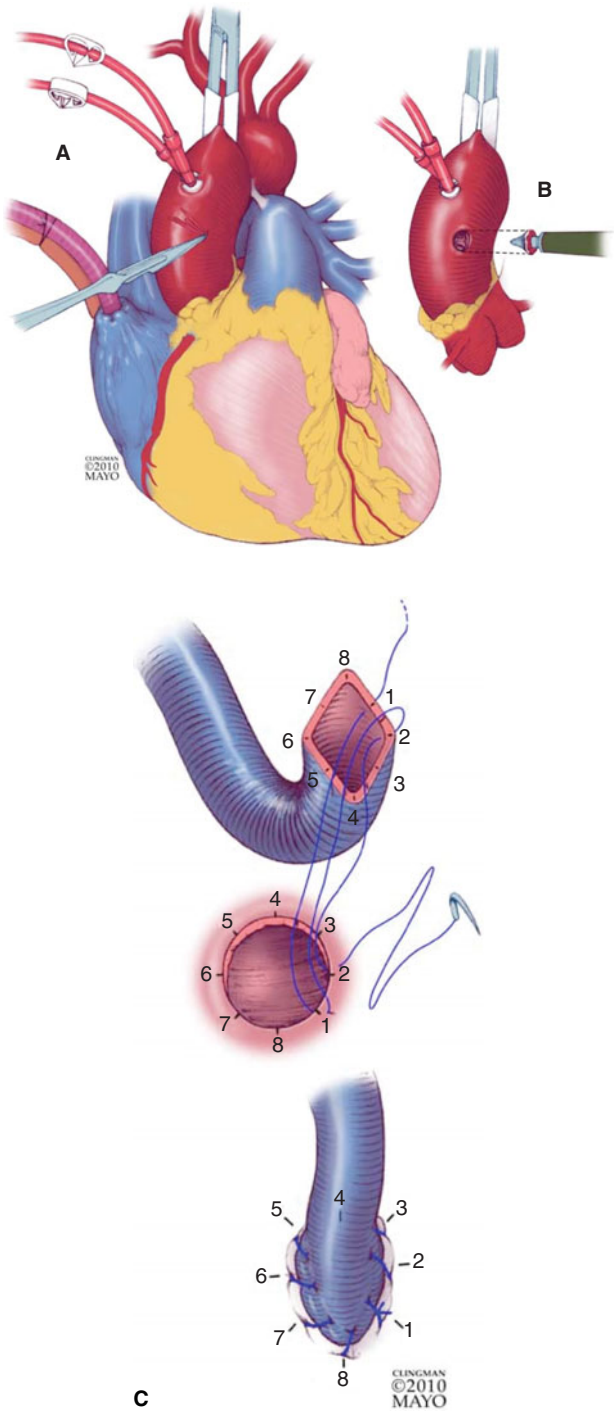

FIGURE 21-10 Proximal anastomosis. (A) The proximal anastomosis is performed using a single-clamp technique. The fatty tissue overlying the planned aortotomy site is removed. An arteriotomy is created with a no. 11 blade. (B) A 4- to 5-mm aortic punch is used to create a circular aortotomy. The size of the punch will vary depending on the size of the conduit graft. (C) The proximal aspect of the conduit is beveled and then notched at the heel. A running 5-0 or 6-0 polypropylene suture is used for a venous graft and a 6-0 or 7-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. The anastomosis can be completed with eight stitches in most cases; symmetry in the spacing between stitches is of paramount importance to ensure hemostasis. hemostatic anastomosis. Free arterial grafts may also be sutured to the hood of a vein graft with continuous 7-0 Prolene suture.

Composite Grafts

As an alternative to proximal anastomosis to the aorta, a free graft can be anastomosed proximally to the pedicled ITA (Fig. 21-11). This technique has the theoretical advantage of providing a more physiologic arterial pressure waveform by attaching the conduit to a third-order vessel rather than to the aorta. Composite grafting is also a useful tool for the hostile, calcified ascending aorta or when there is a limited length of conduit available. It is also advantageous when there is a marked mismatch between aortic wall thickness and arterial conduit size.

A combination of composite and sequential grafting allows the opportunity to perform complete arterial revascularization with only ITA or with ITA and other arterial conduits (Fig. 21-12). Multiple configurations of Y- and T-grafts can be devised to best suit the anatomic characteristics of each patient. The LITA has been shown to have more than sufficient flow reserve to supply flow to the entire coronary circulation.[86] The free right ITA, the RA, or other arterial conduit can be based in this manner.

All-arterial Y-grafts are usually planned in advance and constructed before the initiation of cardiopulmonary bypass. Special care must be taken during construction of composite grafts to avoid tension, rotational torsion, or narrowing of the inflow anastomosis. Disadvantages include technical difficulty and reliance upon a single inflow source for two or more distal targets.

MANAGEMENT OF THE ATHEROSCLEROTIC ASCENDING AORTA

Ascending aortic atherosclerosis has been consistently identified as a very important risk factor for stroke in multiple series. Epiaortic ultrasound can be performed to define the extent of atherosclerosis of the ascending aorta and its likelihood of embolization. Patients with severe atherosclerosis of the ascending aorta may require alternative strategies to prevent embolization of aortic atheroma. If the ascending aorta is hostile, we favor cannulation of the right axillary artery. The axillary artery is a good option to achieve arterial inflow by using a chimney side graft. If needed, aortic clamping may be performed in areas free of atheroma, usually in the more proximal ascending aorta.

Coronary revascularization can be achieved with a variety of methods. Using a "no-touch"technique, revascularization can be done using only pedicled arterial conduits, and if proximal anastomoses are required they can be based off pedicled conduits or brachiocephalic vessels. Distal anastomoses can be performed under cold fibrillatory arrest without aortic cross-clamping, and they also can be accomplished using off-pump techniques. Proximal anastomoses can be performed under deep hypothermic circulatory arrest or after graft replacement of the ascending aorta if there are large mobile atheromas.[87]

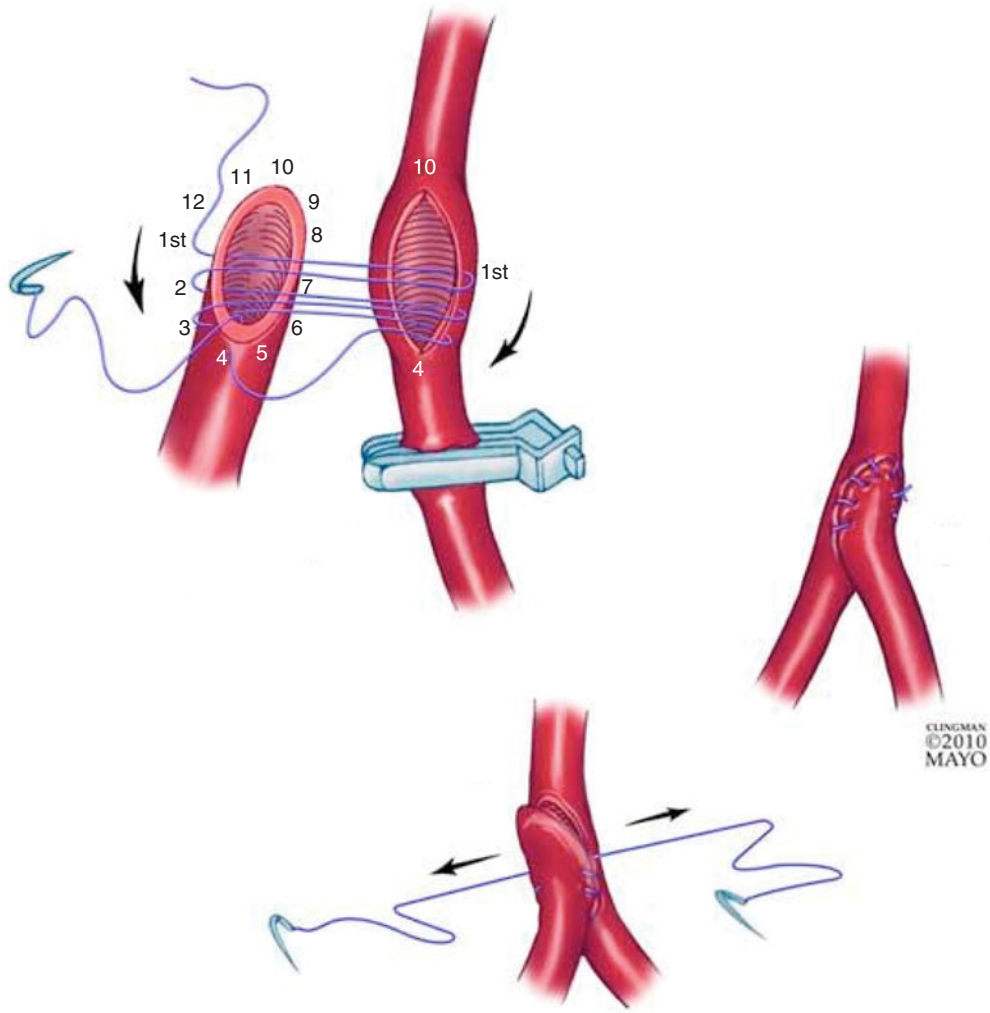

FIGURE 21-11 Composite Y-graft. Y-graft anastomotic technique: A coronary artery bypass graft (CABG) is used as a donor site for the proximal anastomosis of another conduit. An incision is created in the donor conduit. The proximal end of the recipient conduit is then anastomosed to the donor site in an end-to-side fashion as previously described for a distal anastomosis. The recipient conduit is then gently parachuted down onto the donor conduit. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

Weaning from Cardiopulmonary Bypass

On completion of all anastomoses, the aortic cross-clamp is removed and a stable heart rhythm established. Some advocate allowing the heart to recover on full bypass for 10 minutes for each 60 minutes of aortic cross-clamp time. During this time of recovery the patient is prepared for transition from supported circulation to native circulation. The aortic root vent and retrograde catheters are removed and the sites repaired with suture. The bypass grafts are checked for kinks, twists, or tension and for presence of hemostasis. The patient must be rewarmed to normothermia if cooled and the acid-base status and electrolyte abnormalities corrected. We place temporary atrial and ventricular pacing wires on all patients.

Weaning from cardiopulmonary bypass is otherwise the same as for other cardiac surgical cases. Issues particular to CABG include attention to avoid overdistention of the heart, which may place grafts on tension and disrupt anastomoses. If air has entered the heart, bubbles may pass into the aorta and down the bypass grafts causing arrhythmias and regional wall motion abnormalities. Treatment involves continued recovery on bypass and increasing the perfusion pressure as a means to drive the bubbles through the coronary circulation. Persistency of regional wall motion abnormalities may require bypass graft revision or placement of additional bypass grafts.

OUTCOMES

Operative Mortality

The risk profile of patients requiring isolated CABG in the United States has changed significantly in the past decade. Patients are older, with a greater number of comorbidities, decreased LVEF, and a higher burden of atherosclerotic disease; however, early outcomes after CABG continue to improve. The

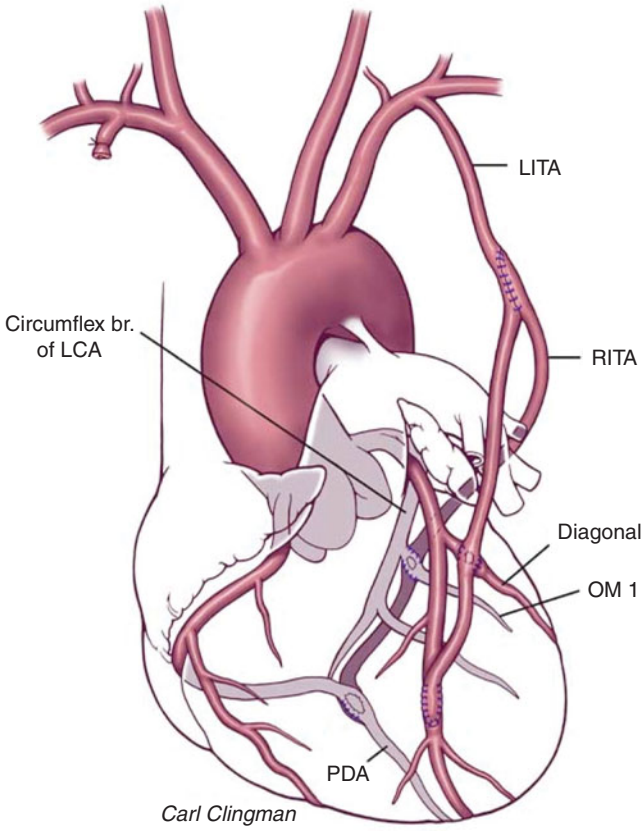

FIGURE 21-12 Total arterial revascularization: As shown, arterial revascularization can be performed using the right internal thoracic artery (RITA) off the left internal thoracic artery (LITA) as a Y-graft and liberal use of sequential grafting. (*Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.*)

STS database demonstrates that despite an increase in expected mortality from 2.6 to 3.4% (relative increase 30%) in the decade of the 1990s, the observed mortality has actually decreased from 3.9 to 3.0% (relative decrease 23%).[3]

Similar observations have been made using the Veterans Affairs mandatory national database, where the unadjusted mortality rate for isolated CABG fell from 4.3% in 1989 to 2.7% in the year 2000.[88] In the private sector similar trends have been observed. In an analysis of outcomes of patients undergoing isolated CABG in the HCA system, a nationwide for-profit health care system involving 200 hospitals in 23 states, Mack and associates reported an ongoing decrease in unadjusted operative mortality among 51,353 patients, 80% of whom received CABG with cardiopulmonary bypass. In this study the operative mortality decreased from 2.9% in 1999 to 2.2% in 2002.[89]

Causes of Death

In a multicenter prospective study performed by the Northern New England Cardiovascular Disease Study Group, 384 deaths among 8641 consecutive patients undergoing isolated CABG between 1990 and 1995 were analyzed with respect to the mode of death. The mode of death was defined as the seminal event that precipitated clinical deterioration and ultimately resulted in the patient's demise. Heart failure was judged to be the primary mode of death for 65% of the patients, followed in frequency by neurologic causes (7.3%), hemorrhage (7%), respiratory failure (5.5%), and dysrhythmia (5.5%). The greatest variability in mortality rates observed across surgeons in the study was attributable to differences in rates of heart failure.[90] Cardiac causes were also identified by Sergeant and colleagues as the most common causes of death in a series 5880 patients undergoing CABG between 1983 and 1988.[91]

Operative Morbidity

Myocardial Dysfunction

Postoperative myocardial dysfunction and cardiac failure after CABG may be related to preoperative ischemic injury, inadequate myocardial protection, incomplete revascularization, or postoperative graft failure. The spectrum of myocardial injury varies from subtle degrees of global myocardial ischemia to transmural infarction. The incidence of myocardial injury identified varies with the sensitivity of the method used for detection as well as the threshold set. Some studies have reported perioperative myocardial infarction rates as high as 10% of patients with associated worse clinical outcomes (death, MI, or revascularization).[92]

Some elevations of cardiac-specific enzymes are ubiquitous after CABG; however, most would agree that elevations in creatinine kinase-myocardial bound (CK-MB) greater than five times the upper limit of normal (ULN) value are considered significant. In a prospective study of 2918 patients undergoing CABG, 38% of patients had a CK-MB >5 ULN and 17% had a CK-MB >10 ULN with an incidence of new Q-wave MI of 4.7%.[93] Troponin may be a more sensitive marker than CK-MB, but its role in large populations of CABG patients is still to be defined.[94] Prominent elevations of CK-MB and troponin have been associated with global ischemia, MI, low cardiac output, and increased operative mortality, as well as increased midterm and long-term mortality.[93,94]

Transient myocardial dysfunction necessitating low-dose inotropic support for a short period of time is also common after CABG. Significant postoperative myocardial dysfunction manifest clinically as low cardiac output syndrome may be defined by the need for postoperative inotropic support or intra-aortic balloon pump support to maintain a systolic blood pressure >90 mm Hg or a cardiac index >2.2 L/min. The reported incidence of low output syndrome varies depending on the defining criteria and has a reported incidence of 4–9%.[95,96] Low output syndrome has been shown to be a marker for increased operative mortality by 10- to 15-fold.[97] Independent predictors of low output syndrome in order of importance include: LVEF <20%, reoperation, emergency operation, female gender, diabetes, age older than 70, left main disease, recent MI, and triple-vessel disease.[96]

Adverse Neurologic Outcome

Neurologic deficits after coronary surgery are divided into two types: type 1 deficits include major neurologic deficits, stupor,

and coma; type 2 deficits are characterized by deterioration of intellectual function and memory. The incidence of type 1 deficits was reported to be 1.6% in a large review by the Northern New England Cardiovascular Disease Study Group with 1-, 5-, and 10-year survival rates significantly reduced in affected patients.[98] Perioperative mortality is similarly increased among those with type 1 injury at over 24%.[99] Type 2 deficits are more difficult to characterize and may be more related to the underlying atherosclerosis than to the bypass operation per se. In one nonrandomized study, there was no evidence that the cognitive test performance of coronary artery bypass grafting (CABG) patients differed from that of heart healthy control groups with coronary artery disease over a 1-year period.[100]

Predictors of neurologic deficits included advanced age (≥70 years of age), and history or presence of severe hypertension. Independent predictors of type 1 deficits included proximal aortic atherosclerosis, history of prior neurologic disease, need for IABP, diabetes, unstable angina, and perioperative hypotension. Predictors of type 2 deficits included history of alcohol consumption, dysrhythmias, prior CABG, peripheral vascular disease, congestive heart failure (CHF), and perioperative hypotension. Similar predictors of adverse neurologic outcomes have been observed in other studies.[101]

Deep Sternal Wound Infection

Deep sternal wound infection occurs in 1 to 4% of CABG patients and carries a mortality rate of 25%.[102] Proven methods to reduce postoperative wound complications include the use of preoperative showers with chlorhexidine gluconate on the evening and morning before the procedure, prophylactic intranasal application of mupirocin given on the evening and the morning before the procedure and twice daily for 5 days postoperatively, hair clipping the morning of surgery, and administration of intravenous prophylactic antibiotics before skin incision.[103–105] Application of a cyanoacrylate-based microbial skin sealant may further reduce surgical site infection.[106]

Obesity and diabetes are strong independent predictors of mediastinitis. Insulin-dependent diabetics are especially susceptible to deep sternal wound infection.[107–109] Recent data suggest that tight glycemic control in the postoperative period decreases the risk of mediastinitis in the diabetic population.[110,111] Other preoperative variables independently associated with an increased incidence of deep sternal wound infection include reoperation, longer operative times, reexploration for bleeding, and blood transfusions.[108,109,112]

The use of bilateral ITAs had been implicated as a risk factor for sternal would complications, especially in diabetics.[113] However, this risk appears to be mitigated in part by using a skeletonized ITA harvesting technique.[114] Bilateral ITA harvest should likely be avoided in obese diabetic women, in cases of repeat sternotomy, and in patients with severe COPD, because they exhibit a higher risk of deep sternal wound infection even with skeletonization of the ITA.[25,115]

Acute Renal Failure

Acute renal failure ensuing after CABG with cardiopulmonary bypass is an ominous event. In a prospective observational study conducted at 24 university centers in the United States, including data on 2222 CABG patients,[116] renal dysfunction not requiring dialysis occurred in 6.3%, and renal dysfunction requiring hemodialysis developed in 1.4%. Mortality was directly related to postoperative renal function. Patients with no renal dysfunction had 0.9% mortality.[116] Postoperative renal dysfunction increased mortality to 19% if no dialysis was needed and increased mortality to 63% if hemodialysis was required. Patients with large creatinine increases (≥ 50%) after CABG surgery also have higher 90-day mortality.[117]

Independent predictors of postoperative renal dysfunction included increasing age, CHF, reoperation, diabetes mellitus, chronic renal insufficiency, prolonged cardiopulmonary bypass time, and low cardiac output.[116] These findings were confirmed in another series of 42,733 patients with similar incidence and mortality associated with postoperative renal dysfunction.[118] One in four patients with preoperative chronic renal insufficiency (creatinine >1.6 mg/dL) will require renal replacement therapy post-CABG, and patients at highest risk are older than 70 years and have a baseline creatinine >2.5 mg/dL.[119]

Continuous infusion of low-dose recombinant human B-type natriuretic peptide (nesiritide) from the start of cardiopulmonary bypass has been evaluated as a method to effectively maintain postoperative renal function. In the prospective, randomized, NAPA Trial, 272 patients with ejection fraction ≤ 40% undergoing CABG who receive nesiritide experienced a significantly attenuated peak increase in serum creatinine and a greater urine output during the initial 24 hours after surgery. In addition, they had a shorter hospital stay and lower 180-day mortality.[120] Similar renal protective results were noted in a randomized trial using human atrial natriuretic peptide in 251 patients. The treated group had fewer postoperative complications, lower serum creatinine, and higher urinary creatinine and creatinine clearance. The maximum postoperative creatinine level and percent increase of creatinine were also significantly lower in the treatment group. No patient in the natriuretic group required hemodialysis.[121] We are awaiting further study before adopting natriuretic peptides in our routine CABG practice.

Long-Term Outcomes

Long-term outcomes of surgical myocardial revascularization depend on the complex interaction of patient-related and procedure-related factors. Important patient-related factors include anatomic distribution of the CAD, the extent and severity of coronary atherosclerosis, the physiologic impact of ischemia on ventricular function at the time of the original operation, age, gender, overall health status, severity of atherosclerotic burden throughout the body, the presence and severity of associated comorbidities, development of operative complications such as stroke, and need for permanent hemodialysis. The progression rate of native coronary atherosclerosis after surgery and the development of coronary bypass graft failure are of extreme importance in the development of post-CABG angina recurrence, MI, need for reintervention, and cardiac-related mortality. Procedure-related factors that influence long-term outcomes include completeness of revascularization, myocardial protection, and selection of bypass conduits.

Sergeant and colleagues at the Gasthuiberg University Hospital of the Katholieke Universiteit (KU) Leuven, Belgium have provided several reports detailing clinical outcomes after myocardial revascularization.[122–125] From 1971 to 1993, 9600 consecutive CABG patients were prospectively followed with special attention to clinical outcomes after surgical myocardial revascularization; the investigators achieved a 99.9% complete follow-up in this cohort. Clinical outcomes prospectively followed included mortality, return of angina, MI, and coronary reintervention.[122]

Defining the return of angina as the first occurrence of angina of any intensity or duration unless it was associated on the same day with MI or death, and recording the severity of this event, was also recorded. The overall non–risk-adjusted freedom from return of angina was 95% at 1 year, 82% at 5 years, 61% at 10 years, 38% at 15 years, and 21% at 20 years. The data suggest that if followed long enough after CABG, the return of angina is almost inevitable; by 12 years one-half of operated patients had return of angina. The initial episode of recurrent angina was rated as mild in 59% of patients.[123] In the Bypass Angioplasty Revascularization Investigation (BARI) trial of 914 patients with symptomatic multivessel disease randomly assigned to receive CABG, freedom from angina was 84% at 5 and 10 years.[126]

The overall non–risk-adjusted freedom from MI after CABG at the KU Leuven was 97% at 30 days, 94% at 5 years, 86% at 10 years, 73% at 15 years, and 56% at 20 years.[124] The overall non–risk-adjusted freedom from a coronary reintervention, either PCI or reoperative CABG, was 99.7% at 30 days, 97% at 5 years, 89% at 10 years, 72% at 15 years, and 48% at 20 years (125). In the BARI trial, freedom from subsequent coronary reintervention intervention at 10 years was 80%.[126]

Overall risk-unadjusted survival after CABG in the KU Leuven experience was 98% at 30 days, 92% at 5 years, 81% at 10 years, 66% at 15 years, and 51% at 20 years. Mortality after CABG was characterized by an initial period of high risk in the first month after surgery, then risk declined to its lowest at 1 year after the operation, and thereafter the mortality risk rose slowly and steadily for as long as the patient was followed. This slow and steady rise in the risk of death over time paralleled that of the general population when matched for sex, age, and ethnicity.[125] In the BARI trial, survival was 89% at 5 years and 74% at 10 years.[126]

The occurrence of ischemic clinical events after CABG negatively influences survival. In the KU Leuven study, overall survival was lessened by return of angina, with an observed survival of 83% at 5 years and 54% at 15 years; the more intense the severity of angina at its return, the greater its influence on survival.[123] The occurrence of MI after CABG has a greater negative effect on survival. Observed long-term survival after post-CABG infarction at the KU Leuven was 80% at 30 days, 65% at 5 years, 52% at 10 years, and 41% at 15 years.[124]

Progression of Disease in Native Coronary Arteries

Progression of atherosclerosis in the native coronary arteries continues after CABG. Bourassa and associates studied the progression of atherosclerosis in the native circulation 10 years after surgery and found that progression of CAD occurs in approximately 50% of nongrafted arteries.[127] The rate of progression of disease in nongrafted arteries was no different from that of grafted arteries with patent grafts; however, progression was more frequent in grafted arteries with occluded grafts. Progression of preexisting stenoses in native coronaries was more frequent than appearance of new stenoses, and it was related to the severity of the preexisting stenosis only in nongrafted arteries.

Progression of native CAD was associated with deterioration in left ventricular function. Native coronary atherosclerosis progressed at a similar rate to that of equally diseased arteries in nonoperated patients.[127] Low levels of high-density lipoprotein cholesterol and elevated levels of plasma low-density lipoprotein cholesterol correlated with native disease progression and development of new atherosclerotic lesions.[128,129] Diabetes has been related to accelerated atherosclerosis. The VICTORY trial will be the first cardiometabolic study to evaluate the antiatherosclerotic and metabolic effects of rosiglitazone is post-CABG patients with type 2 diabetes in patients 1 to 10 years after CABG.[130]

Vein Graft Failure

Although the use of the saphenous vein helped popularize coronary bypass grafting, the propensity of the saphenous vein graft to fail over time has been the limiting factor of the procedure. It has been reported that approximately 15% of vein grafts occlude in the first year after CABG, and by 6 and 10 years after surgery patency rates fall to approximately 75% and approximately 60%, respectively.18 Three entities are responsible for saphenous vein graft failure: thrombosis, intimal hyperplasia, and graft atherosclerosis

Thrombosis accounts for graft failure within the first month after CABG, and graft occlusion is found on angiography in 3 to 12% of all venous grafts. Even when performed under optimal conditions, the harvesting of venous conduits is associated with focal endothelial disruption. In particular, the high pressure distension used to overcome venospasm during harvesting causes prominent endothelial cell loss, medial damage, activation of local factors (ie, fibrinogen) influencing hemostasis. Additionally, the inherent antithrombotic properties of veins are comparatively weak. The propensity for early graft occlusion resulting from these prothrombotic effects may, on occasion, be amplified by technical factors that reduce graft flow, including intact venous valves, anastomotic stricture, or graft implantation proximal to an atheromatous segment.[18]

Intimal hyperplasia, defined as the accumulation of smooth muscle cells and extracellular matrix in the intimal compartment, is the major disease process in venous grafts between 1 month and 1 year after implantation. Nearly all veins implanted into the arterial circulation develop intimal thickening within 4 to 6 weeks, which may reduce the lumen by up to 25%. Intimal hyperplasia rarely produces significant stenosis per se; more importantly, however, is that it may provide the foundation for later development of graft atheroma.[131]

Progression of atherosclerosis in aortocoronary saphenous vein grafts is frequent and represents the predominant cause of

late graft failure after CABG. Vein graft atherosclerosis may begin as early as the first year, but is fully developed only after about 5 years. Ten years after surgery, 50 to 60% of SVGs will be occluded and one-half of still patent grafts will show angiographic evidence of atherosclerosis; two-thirds of these lesions will have a luminal diameter reduction of 50% or greater. Vein graft atherosclerosis is the leading cause for reintervention following CABG, more so than progression of disease in native coronary arteries.[18]

Although the risk factors predisposing to vein graft atherosclerosis are broadly similar to those recognized for native coronary disease, the pathogenic effects of these risk factors are amplified by inherent deficiencies of the vein as a conduit when transposed into the coronary arterial circulation. A multifaceted strategy aimed at prevention of vein graft disease is emerging, elements of which include: continued improvements in surgical technique; more effective antiplatelet drugs; increasingly intensive risk factor modification, in particular early and aggressive lipid-lowering drug therapy; and a number of evolving therapies, such as gene transfer and nitric oxide donor administration, which target vein graft disease at an early and fundamental level. At present, a key measure is to circumvent the problem of vein graft disease by preferential selection of arterial conduits, in particular the internal mammary arteries, for coronary bypass surgery whenever possible.[18]

Extended Use of Arterial Grafting

Bilateral Internal Thoracic Artery Graft. In contrast to the easily demonstrated survival benefit conferred by an ITA graft to the LAD artery, it was more difficult to demonstrate a survival benefit to a second arterial graft. Buxton and colleagues studied 1243 patients undergoing primary CABG with bilateral ITA grafts compared with 1583 patients with single ITA grafts. This group demonstrated a 15% absolute improvement in actuarial survival rates 10 years after CABG with the use of bilateral ITA grafts, as compared with the use of a single ITA graft (10-year survival for bilateral ITA was 86 ± 3% versus 71 ± 5% for a single ITA).[131] Lytle and colleagues similarly demonstrated an improvement in survival at 12 years (79 versus 71%) as well as superior reoperation-free survival (77 versus 62%) among 2001 bilateral and 8123 single ITA graft patients.[132] The impact of selection bias in these studies is difficult to control, however, and although some surgeons have embraced bilateral ITA grafting, it still represents a small minority of cases reported to the STS database.

Complete Arterial Revascularization. The better long-term results achieved with the use of bilateral ITAs and the well-known time-related attrition in patency of venous conduits encouraged the exclusive use of arterial conduits for myocardial revascularization. Complete arterial revascularization can be achieved by a variety of strategies, including composite grafting using exclusively ITAs or secondary arterial conduits such as the RA and the GEA. The use of sequential anastomotic techniques maximizes the utilization of arterial conduits. Although technically demanding, sequential grafting can be performed safely and with excellent long-term results with reported 96% patency rates of 7.5 years of follow-up on 1150 sequential ITA anastomoses.[133]

Tector has championed complete arterial revascularization using bilateral ITAs in a T configuration with end-to-side anastomosis of one ITA as a free graft to the side of the second ITA, which is left as a pedicled graft, combined with liberal use of sequential anastomoses. In his series of 897 patients overall survival was 75%, and freedom from reintervention was 92% 8 years after revascularization.[134] Barner has reported similar encouraging results with composite grafting using one ITA and one RA.[135] Data from randomized studies are beginning to emerge supporting improvement in early outcomes with complete arterial revascularization compared with conventional CABG. Muneretto and associates randomized 200 patients to complete arterial revascularization (left ITA to the LAD artery and composite grafts with the right ITA, RA, or both) versus conventional CABG (left ITA to the LAD artery and SVGs). In midterm follow-up (20 months) superior event-free survival (freedom from non-fatal MI, angina recurrence, graft occlusion, need for percutaneous transluminal coronary angioplasty, and late death) was demonstrable in the complete arterial revascularization patients compared to conventional CABG.[136]

The same group conducted a second randomized trial comparing complete arterial revascularization to conventional CABG (ITA to LAD artery and SVG) in 160 patients older than 70 years of age undergoing first time nonemergent CABG. Early mortality was similar, but at 16 ± 3 months, there were significantly fewer graft occlusions and recurrences of angina among the complete arterial revascularization group. Independent predictors of graft occlusion and angina recurrence were use of SVGs, diabetes, and dyslipidemia.[137] The result of longer follow-up of these trials is still awaited.

CONCLUSION

Coronary artery bypass graft surgery with myocardial perfusion remains an excellent treatment strategy for myocardial ischemia. As the population grows older and acquires more relevant comorbidities, the risk of treatment will increase. New techniques and conduit choices, however, are proving effective as the associated morbidity and mortality of operation continue to decline. Alternative techniques such as off-pump CABG and PCI continue to be assessed against the current, best treatment option, CABG with cardiopulmonary bypass.

KEY POINTS

1. Coronary artery disease is the number one killer of Americans.
2. Coronary artery bypass is advantageous over medical therapy in patients with left main coronary artery stenosis, three-vessel disease with left ventricular dysfunction, two-vessel disease with proximal left anterior descending disease, and in patient with severe ischemia and multivessel disease.
3. The STS risk model for postoperative morbidity and mortality can be found on the STS web site (www.sts.org) and includes 30-day stroke and death rates of 1.6% and 3%, respectively.

4. The left internal mammary to left anterior descending coronary artery bypass graft confers a survival advantage to coronary artery bypass patients. In the BARI trial, patency rates at 1 and 4 years were 98% and 91%, respectively.
5. Skeletonization of the internal mammary artery is associated with reduced incidence of sternal wound complications.
6. Radial artery grafts have better 5 year patency (98% versus 86%) than saphenous vein grafts.
7. Cognitive test performance of patients after coronary artery bypass grafting is no different from that of heart healthy control groups over a 1-year period.
8. Freedom from angina after coronary artery bypass grafting in the BARI trial was 84% at 5 and 10 years.
9. Bilateral compared to single internal mammary artery bypass grafting is associated with improved survival, but the benefit is not noted until about 10 years after operation.

CHAPTER 22

Myocardial Revascularization without Cardiopulmonary Bypass

Michael E. Halkos
John D. Puskas

INTRODUCTION

Coronary artery bypass grafting (CABG) continues to be a valuable method of myocardial revascularization. Despite the increased prevalence of percutaneous coronary intervention to treat coronary disease, as well as improvements in medical therapy, surgical revascularization will continue to have a major role in patients with coronary disease. Currently, the majority of surgical revascularization is performed with the use of cardiopulmonary bypass, with most surgeons preferring to perform distal anastomoses on an arrested heart. Advocates of this approach cite low morbidity and mortality with outcomes that have continued to improve despite a surgical patient population with increasing comorbid conditions and more advanced and severe coronary disease. However, complications, albeit infrequent, continue to plague a small percentage of patients undergoing coronary artery bypass surgery. These include stroke, renal failure, and respiratory failure. These complications may occur not only because of the systemic inflammatory activation that occurs with extracorporeal circulation, but also because of the manipulation of the aorta required for cannulation, cardiopulmonary bypass, and aortic clamping. Off-pump coronary artery bypass grafting (OPCAB) has been increasingly used over the past decade for surgical coronary revascularization. The interest in off-pump techniques has largely been driven by the increased awareness of the deleterious effects of cardiopulmonary bypass and aortic manipulation. Although many centers have adopted this technique, OPCAB use appears to have reached a plateau in recent years and currently accounts for approximately 22% of coronary artery bypass cases (Data Analyses of the Society of Thoracic Surgeons National Adult Cardiac Database, 2008). For most surgeons, the lack of compelling evidence in randomized controlled trials supporting OPCAB over conventional on-pump coronary artery bypass (CCAB) has been an impediment to implementing this strategy in routine practice. Furthermore, many surgeons consider an off-pump approach more technically challenging, with new risks not familiar to on-pump surgery. It is important to note that the aforementioned randomized trials have enrolled predominantly low-risk patients and have sample sizes that are inadequate to demonstrate differences between groups for infrequently occurring events, such as death, stroke, and myocardial infarction. Nonetheless, randomized controlled trials have almost uniformly demonstrated reduced transfusion requirements, lower postoperative serum myocardial enzyme levels, and shorter length of stay. Moreover, there are many retrospective trials showing a survival benefit as well as reduced morbidity with OPCAB. These retrospective database studies have much larger sample size and include mixed-risk patients. However, inherent selection bias may limit the interpretation of these results, despite advanced statistical methodology. For many surgeons to consider implementing an off-pump approach, the following must be demonstrated: (1) equivalent short- and long-term patency rates; (2) complete revascularization; (3) reduced morbidity and even reduced mortality, especially in high-risk patients; and (4) cost efficiency both in the operating room and during the entire hospitalization. For certain high-risk subgroups, it would appear intuitive that avoiding the systemic effects of cardiopulmonary bypass as well as aortic manipulation would reduce the incidence of specific complications such as stroke and renal failure. However, until definitive studies yield superiority of one technique over the other, the preferred approach will ultimately be left to surgeon's discretion.

PREOPERATIVE CONSIDERATIONS

Surgeon Experience

The adoption of OPCAB into clinical practice requires a commitment to learning a unique skill set that has been associated with improved outcomes in certain patient subgroups. We consider that this is best achieved by routine adoption of OPCAB techniques such that the surgeon can employ this approach in patients likely to derive the most benefit. OPCAB surgery poses unique challenges to a surgeon who is accustomed to operating in a motionless and bloodless field. Furthermore, OPCAB requires an adept first and second assistant to provide exposure on a beating heart as well as excellent anesthesia management to maintain hemodynamics and alert the surgical team of potential hemodynamic problems. Thus, the commitment to OPCAB is usually tied to a belief that the technical challenges inherent in the procedure are worth overcoming so that the patient may benefit from the avoidance of cardiopulmonary bypass. Although the benefit may be small in low-risk patients, it is becoming apparent that certain high-risk subgroups may benefit from minimizing aortic manipulation as well as avoiding the systemic effects of cardiopulmonary bypass.

The inexperienced OPCAB surgeon embarking on the learning curve is best advised to choose his or her initial patients carefully and pay close attention to coronary anatomy as well as important patient variables. The surgeon must come to the operating room with an operative plan that is flexible enough to change as operative findings mandate. Unlike CCAB, in which graft sequence and hemodynamic management are relatively straightforward, OPCAB requires careful consideration of coronary anatomy, confounding patient variables, and attention to hemodynamic fluctuations. Early in a surgeon's experience, it is probably prudent to exclude patients with difficult lateral wall targets, especially multiple lateral wall targets, severe left ventricular dysfunction, left main disease, or other complex cases (Table 22-1). Ideal early candidates for OPCAB include those undergoing elective primary coronary revascularization with good target anatomy, preserved ventricular function, and one to three grafts with easily accessible or no lateral wall targets. When teaching OPCAB to residents, the left anterior descending coronary anastomosis is usually the easiest, given its anterior location. This is usually followed by easily accessible diagonal branches, then inferior wall vessels, and finally, lateral wall targets, which are the most difficult to expose and perform off-pump. As experience is gained in OPCAB, this technique can be safely and effectively applied to the vast majority of patients requiring coronary artery bypass surgery. Just as important, however, is the experience to know when it is better to use cardiopulmonary bypass in patients in which an off-pump approach will be exceedingly difficult, impractical, or poorly tolerated.

TABLE 22-1 Relative Exclusion Criteria during the Early Adoption of OPCAB

Recent myocardial infarction
More than three grafts required, especially multiple lateral wall targets
Left ventricular dysfunction
Intramyocardial coronary arteries
Small or diffusely diseased coronary arteries
Mild to moderate aortic or mitral regurgitation
Redosternotomy
Hemodynamically unstable
Pulmonary hypertension
Urgent/emergent cases
Difficult lateral wall targets
Left main coronary artery disease

Patient Variables

The preoperative evaluation of patients for OPCAB demands careful planning and consideration for certain risk factors. We routinely perform screening carotid duplex ultrasonography on all patients over the age of 65, smokers, those with a carotid bruit, history of transient ischemic attack or stroke, left main coronary disease, peripheral vascular disease, or history of prior carotid intervention. The remainder of the preoperative evaluation is similar to CCAB. In patients with a murmur, dyspnea, aortic or mitral regurgitation, or ventricular dysfunction on cardiac catheterization, preoperative echocardiography is also warranted. It is important to be aware of right ventricular dysfunction, valvular regurgitation, or pulmonary hypertension because positioning during OPCAB can result in dramatic changes in these parameters. Overall, the clinical condition of the patient, the urgency of the operation, and ventricular function need to be carefully assessed to determine whether an off-pump approach will be practical. Although patients operated on more acutely may benefit from an off-pump approach, it is important to have a backup plan explicitly prepared should an OPCAB approach be poorly tolerated. Patients with left ventricular dysfunction from a recent infarct pose a more difficult challenge than those with chronic ventricular dysfunction, with the former being much more sensitive to cardiac manipulation and displacement and more likely to develop intraoperative arrhythmias.

Anesthesia

As in other cardiac operations, all patients require invasive monitoring with a pulmonary artery catheter, arterial line, Foley catheter, and central venous line. We liberally use transesophageal echocardiography to provide valuable information about valvular regurgitation, regional myocardial function, and pulmonary hypertension. In our experience, a well-experienced anesthesia team is essential to maintaining stable hemodynamics and ensuring a smooth and uneventful operation. Unlike CCAB, which requires active coordination among surgeon, anesthesiologist, and perfusionist, the anesthesiologist and surgeon must work especially closely to maintain hemodynamic stability during OPCAB. Instead of relying on cardiopulmonary bypass to ensure adequate perfusion, other maneuvers are

required to avoid dramatic fluctuations in hemodynamic status that can have detrimental consequences. Subtle changes in hemodynamic status, gradual elevation in pulmonary artery pressures, frequent boluses, or increased requirement of inotropes and vasopressors to maintain hemodynamic stability, and rhythm changes can herald cardiovascular collapse. Such an event can reliably be avoided if these changes are verbalized and discussed between anesthesiologist and surgeon preemptively. When manipulating the heart, it is important for the surgeon to communicate these abrupt maneuvers to the anesthesia team so that appropriate action can be taken and inappropriate reactions (bolusing vasopressors) avoided. Changes in table position (Trendelenburg) can provide dramatic volume changes that affect cardiac output and blood pressure. Indeed, autotransfusion of intravascular volume from the lower extremities by Trendelenburg positioning should be the first maneuver to maintain hemodynamic stability. Placing the patient in steep Trendelenburg can provide a rapid increase in preload and subsequent cardiac output and blood pressure, whereas reverse Trendelenburg can be helpful in lowering blood pressure if partial aortic clamping is required for proximal anastomoses. We prefer to avoid giving massive volumes of intravenous fluids which requires later postoperative diuresis. Instead, aggressive use of Trendelenburg positioning and judicious use of alpha-adrenergic agents provides stable hemodynamics in the large majority of patients undergoing OPCAB. This includes patients with pulmonary hypertension, mild or moderate ischemic mitral regurgitation, or left ventricular dysfunction in which cardiac manipulation and displacement as well as regional myocardial ischemia may be poorly tolerated without inotropic support. If preload conditions have been optimized, then vasopressor agents such as norepinephrine or Neo-Synephrine may be used to assist with maintaining adequate blood pressure during distal anastomoses. In our experience, effective communication with a well-experienced anesthesiologist is of paramount importance to ensure an uneventful off-pump operation.

Maintaining normothermia is critically important and requires more effort during OPCAB procedures, because the luxury of the cardiopulmonary bypass circuit for rewarming does not exist. This usually can be accomplished by infusing intravenous fluids through warmers, warming inhalational anesthetic agents, maintaining warm room temperatures before and during the procedure, and using convective forced-air warming systems. These can be placed around the patient before draping the patient to maintain normothermia, but sterile systems can also be placed on the lower body and extremities after graft harvesting (Bair Hugger; Arizant Healthcare, Eden Prairie, MN).

At our institution, anticoagulation regimens vary according to surgeon preference. For surgeons in their early experience, a full "pump" dose of heparin is reasonable in the event that conversion to cardiopulmonary bypass becomes necessary. Some of our surgeons continue to implement a full dose with 400 IU/kg to maintain an activated clotting time (ACT) of greater than 400 seconds; others use a half dose or 180 IU/kg, whereas others start with 10,000 U and administer additional doses (3000 IU every half-hour) to maintain an ACT of 275 to 300 seconds. Reversal of anticoagulation with varying doses of protamine is usually administered to facilitate hemostasis.

SURGICAL TECHNIQUE

Preparation

After the induction of anesthesia, patients are positioned, prepped, and draped in an identical fashion to an on-pump procedure. At our institution, patients receive an aspirin rectal suppository (1000 mg) after induction. Aspirin 81 mg and clopidogrel (150 mg postoperatively, then 75 mg/day) are routinely administered early in the postoperative period after mediastinal drainage decreases below 100 cc/h for 4 hours. This has not been associated with an increased risk of mediastinal reexploration.[1] Because of the absence of cardiopulmonary bypass–related coagulopathy, patients may have a relative hypercoagulable perioperative state, which theoretically may jeopardize early graft patency. Bednar and colleagues demonstrated a significantly higher expression of P-selectin, a marker of platelet activity, in the OPCAB patients compared with CCAB patients, suggesting a procoagulant state.[2] For this reason, we administer aspirin preoperatively, aspirin and clopidogrel early postoperatively, and then continue dual antiplatelet therapy in the postoperative period.

Although OPCAB allows for minimally invasive approaches, including small thoracotomy, endoscopic, and robotic-assisted coronary artery bypass, the most common approach is via median sternotomy. Endoscopic radial artery and saphenous vein conduits are harvested simultaneously during internal mammary artery harvest. It is our practice to administer 5000 U of heparin before endoscopic vein harvest to minimize thrombus formation within the conduit during the harvest. Concern over graft quality with endoscopic vein harvest has prompted increased vigilance in atraumatic harvest technique to ensure adequate conduits for bypass.[3] After single or bilateral internal mammary artery harvest, the full heparin dose is administered (see the preceding) and the arterial conduits divided distally. The pericardium is incised in an inverted T configuration, and then incised laterally along the diaphragm to facilitate with cardiac displacement. It is essential to free the left lateral pericardium from the diaphragm to allow the pericardium to be retracted to displace the heart and effectively expose the lateral wall of the left ventricle. Nonetheless, the phrenic nerves must be identified and preserved during pericardial mobilization. With left internal mammary artery harvest, we routinely dissect the vessel distally to the bifurcation to provide a long pedicle. Unlike CCAB, the heart is not decompressed and the extra length is often necessary to avoid tension on the anastomosis during rightward displacement for lateral or inferolateral wall grafting. Dividing or removing the endothoracic fascia, skeletonizing the internal mammary artery during harvest, and dividing the left pericardium vertically toward the left phrenic nerve at the level of the pulmonary artery all provide for extra length and less tension on the anastomosis.

Several pericardial traction sutures are placed to assist with exposure and lateral displacement of the heart. To avoid compression on the right heart during lateral displacement, the

right pericardium can be dissected along the diaphragm or the right pleural space opened widely to allow the heart to fall into the right chest during lateral displacement. Additionally, one to two rolled towels placed along the inferior aspect of the right side of the retractor helps to elevate the right side of the sternum to allow the heart to be displaced toward or into the right chest. An important traction suture is the "deep stitch," which is placed approximately two-thirds of the way between the inferior vena cava and left pulmonary vein at the point where the pericardium reflects over the posterior left atrium (Fig. 22-1). Care should be taken with placement of this suture to avoid the underlying descending thoracic aorta, esophagus, left lung, and adjacent inferior pulmonary vein. This suture should be covered with a soft rubber catheter to prevent laceration of the epicardium during retraction. Furthermore, the manual elevation and compression of the heart required to take this stitch may be poorly tolerated in patients with marginal hemodynamics or significant left main coronary artery disease. In that case, grafting and reperfusion of the left anterior descending coronary artery should be accomplished before placing the deep pericardial traction suture.

Epiaortic Ultrasound

Epiaortic ultrasonography is used in all of our patients undergoing cardiac surgery. It adds only 2 to 3 minutes to the procedure and provides both the surgeon and the anesthesiologist a simple noninvasive and inexpensive tool for assessing the extent of atheromatous disease in the ascending aorta in preparation for aortic clamping[4] or selection of an alternative clampless technique. Through the operative incision, the ascending aorta from the aortic root to the origin of the innominate artery is scanned directly by the surgeon using an ultrasound probe connected to an echocardiography ultrasound scanner. The 8.5-MHz linear array probe is placed inside a sterile sleeve filled with sterile saline to act as a medium between the probe and the surface of the aorta (Fig. 22-2). The information obtained often dictates changes in operative strategy depending on the grade of atherosclerosis. Similarly, it allows the surgeon to individualize placement of aortic clamps and proximal anastomotic devices to minimize the risk of atheroembolism. Few studies using epiaortic ultrasound for aortic screening have suggested improvements in outcome as a result of intraoperative modifications of the surgical plan.[5–7] Most of these studies have been inadequately powered, limiting the interpretation of their results. However, a study by Rosenberger and coworkers, which evaluated greater than 6000 patients with epiaortic ultrasound, suggested that the operative course was changed in 4% of patients because of the finding of aortic pathology, resulting in improved neurologic outcomes.[8] Smaller studies have shown that epiaortic ultrasonography changed the operative strategy in a larger percentage (10 to 12%) of patients.[5,9,10] Importantly, intraoperative epiaortic ultrasound has been shown to be superior to transesophageal echocardiography or palpation alone in identifying aortic atheromatous lesions, especially in the mid- to distal ascending aorta,[11–13] thus making it the modality of choice in identifying ascending aortic atheroma. Davila-Roman and coworkers also reported that there was greater than 1.5-fold increase in the incidence of both neurologic events and mortality as the severity of atherosclerosis increased from normal-mild to moderate, and a greater than threefold increase in the incidence of death and neurologic events as the severity of atherosclerosis increased from normal-mild to severe[14] (Table 22-2). Schachner et al. also found a higher rate of mortality in patients undergoing CABG that had ascending atheromatous disease.[15] Nonetheless, intraoperative epiaortic ultrasound scanning of the ascending aorta is performed in only a small minority of centers nationwide. More convincing data linking epiaortic ultrasonography to successful intraoperative decision making to reduce postoperative stoke are needed to drive

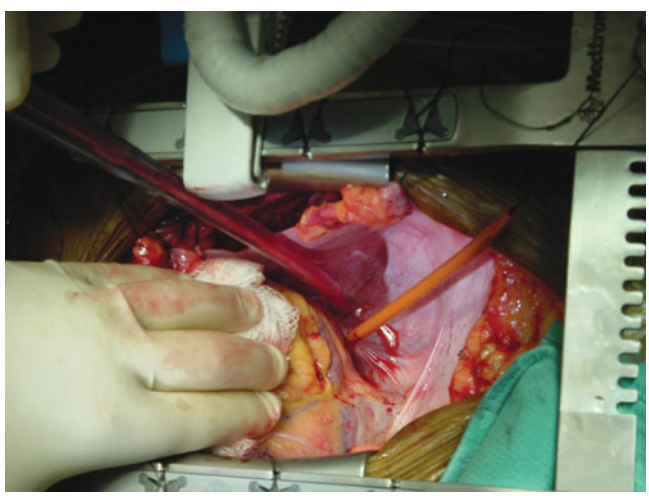

FIGURE 22-1 View from surgeon's side of the table. The heart is elevated toward the surgeon and superiorly for placement of the "deep stitch," which is placed two-thirds of the way between the inferior vena cava and inferior left pulmonary vein. With rightward retraction of the heart, the right-sided pericardial traction sutures should be relaxed to prevent compression of caval inflow.

FIGURE 22-2 Epiaortic ultrasonography is performed in all patients prior to aortic manipulation. The 8.5-MHz linear array probe is placed inside a sterile sleeve filled with sterile saline to act as a medium between the probe and the surface of the aorta.

TABLE 22-2 Epiaortic Ultrasound Grading System Used at Emory University

Epiaortic Ultrasound Grade of Ascending Aorta	Intimal Thickness/Severity of Disease
1	Normal (<2 mm)
2	Mild (2–3 mm)
3	Moderate (3–5 mm)
4	Severe (>5 mm)
5	Mobile plaque, irrespective of thickness

broader adoption and reimbursement of this promising diagnostic modality.

Exposure

Cardiac positioners and stabilizers have greatly increased the ability to manipulate the heart with minimal hemodynamic compromise. Two different systems are routinely used in our institution, the Medtronic Octopus Tissue Stabilizer and Starfish or Urchin Heart Positioner (Medtronic, Inc., Minneapolis, MN) and the Maquet ACROBAT stabilizer and XPOSE positioner (Maquet, GMBH & Co., Radstat, Germany). Cardiac positioning devices are frequently placed off of the apex, especially to the left of the apex, to expose the lateral wall and branches of the left circumflex coronary artery (Figs. 22-3 and 22-4). They are generally placed on the apex to expose the anterior wall (LAD territory) and inferior wall (posterior descending territory) of the heart and may be placed on the acute margin to expose the right coronary artery (Fig. 22-5). Because these suction-based

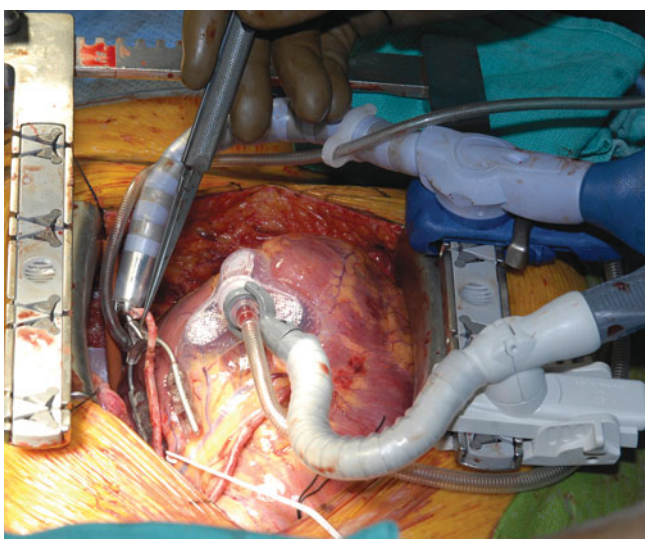

FIGURE 22-3 View from head of table. With the cardiac positioning device placed slightly off of the apex, the lateral wall can be exposed. The coronary stabilizers can then be placed to provide exposure of obtuse marginal vessels.

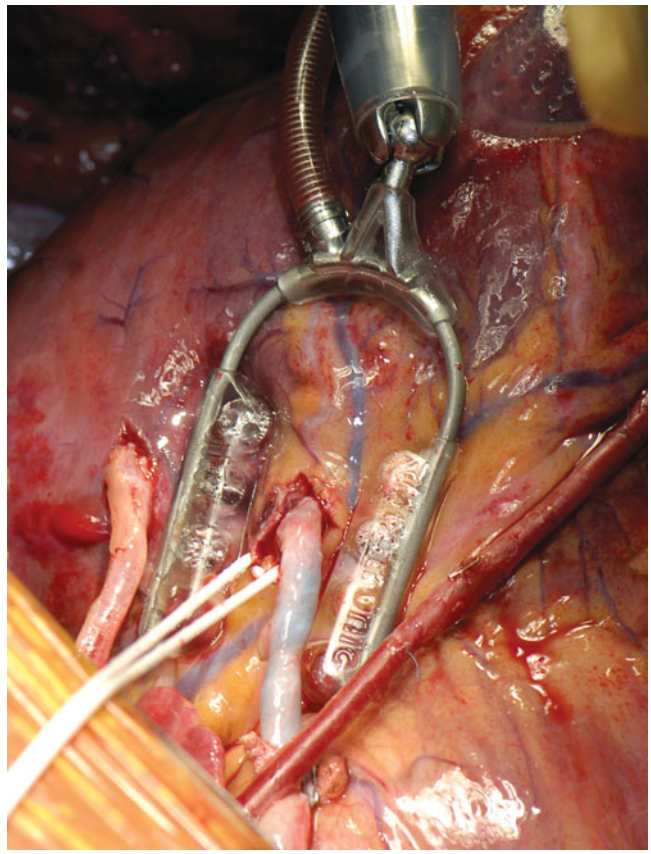

FIGURE 22-4 View from the head of table. An obtuse marginal artery is prepared for grafting. After positioning the coronary stabilizer, a Retract-o-tape is doubly looped around the proximal coronary artery to allow transient occlusion during the anastomosis.

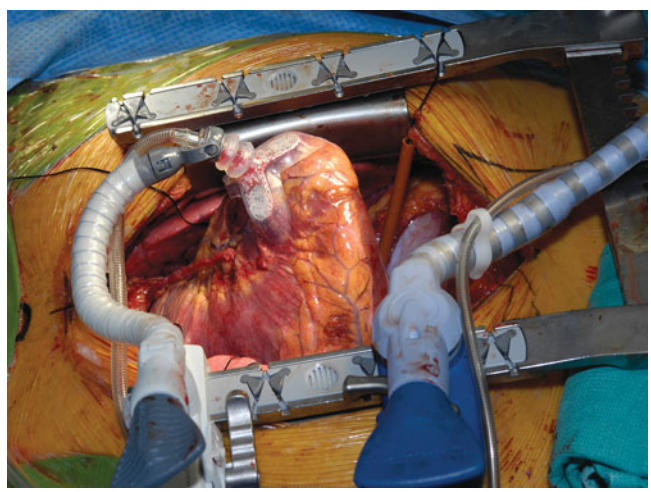

FIGURE 22-5 View from the surgeon's side of table. With cardiac positioner placed on the apex, the heart can be easily displaced to expose the inferior wall vessels. Because there is no compression used for displacement, this maneuver is usually accomplished with no hemodynamic sequelae. Note the positioning of the cardiac positioner and stabilizer on the surgeon's side of the retractor. Alternatively, the stabilizer can be placed on the assistant's side of the retractor. The right pericardial traction sutures are relaxed, and the "deep stitch" is retracted inferolaterally.

cardiac positioning devices pull the heart in the appropriate direction rather than pushing it, the heart is not compressed, functional geometry is maintained, and cardiac positioning is usually well tolerated. The coronary stabilizer devices can then be placed with minimal tension on the epicardium to allow for an area of mechanical stabilization. The anterior wall vessels often require only the coronary stabilizer for adequate exposure. The stabilizer is positioned along the caudal aspect of the retractor toward the left, with the retractor arm placed out of the way to prevent interference during the anastomosis. The location of these devices on the sternal retractor also requires consideration. For the lateral and inferior wall vessels, the cardiac positioner is usually placed on the surgeon's side at the most cephalad location of the retractor. The coronary stabilizers can then be placed on either side. A general rule is to put the stabilizer in the assistant's way instead of the surgeon's to prevent these devices from obstructing the surgeon's view or interfering with hand positioning during suture placement.

In addition to positioners and stabilizers, manipulating the traction sutures can greatly enhance exposure. The purpose of the "deep stitch" is to elevate the heart up and out of the pericardial well. When this suture is retracted toward the patient's feet, it elevates the heart toward the ceiling and points the apex vertically with remarkably little change in hemodynamics. When retracted toward the patient's left side, the heart rotates from left to right, exposing the lateral wall vessels. Variable tension on this stitch will enhance exposure to both the anterior and lateral wall. During positioning, the left-sided pericardial sutures should be pulled taut and the right-sided sutures completely relaxed to avoid compression on the right heart during cardiac displacement. Pericardial sutures on both the right and left sides are never under tension simultaneously when displacing the heart to expose coronary targets. Manipulation of the operating table can also facilitate exposure. Placing the patient in steep Trendelenburg exposes the inferior wall. Turning the table sharply toward the right will aid with exposure of the lateral wall targets. Usually, little manipulation is required for grafting the anterior wall vessels. The deep stitch can be pulled toward the patient's left side and clamped to the drapes or the retractor, and a coronary stabilizer can then be positioned to expose the target coronary artery (Fig. 22-6). Occasionally, a warm moist laparotomy pad can be placed between the heart and the "deep stitch" to assist with elevating the heart out of the pericardium.

In preparation for distal anastomosis, a soft silastic retractor tape mounted on a blunt needle (Retract-o-tape, Quest Medical, Inc., Allen, TX) is placed widely around the proximal vessel for transient occlusion. For inferior wall vessels, this suture can be displaced posteriorly and caudally by tying a more posterior pericardial suture loosely around the retractor tape (Fig. 22-7). The pericardial retraction suture serves as a "pulley" that not only enhances coronary exposure and the surgeon's view, but also keeps this retraction stitch from interfering with the sutures during the anastomosis. Similarly, this maneuver can be done for lateral wall targets. The field is kept free of blood with a humidified CO_2 blower (DLP, Medtronic, Inc.), which is managed by the scrub nurse or second assistant (Fig. 22-8). Occasionally an epicardial fat retractor can be used to expose the coronary target in patients with a large amount of epicardial fat.

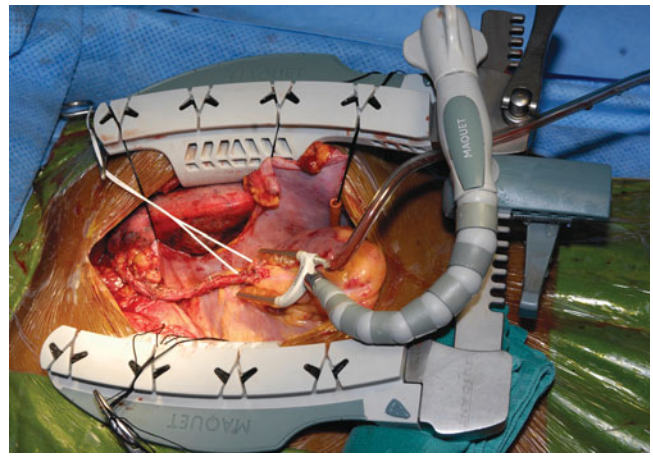

FIGURE 22-6 View from surgeon's side of table. With LAD grafting, excellent exposure can be obtained with lateral traction of the "deep stitch" and the coronary stabilizer. Note the right pericardial traction sutures are released from the retractor.

Although a well-trained first assistant is necessary for providing an effortless anastomosis, the second assistant, often the scrub nurse, also plays a major role in exposure. This assistant usually stands to the right of the surgeon, and controls the CO_2 blower and the Cell Saver (Haemonetics Corp, Braintree, MA). The blower is used to keep the field free of blood, but is also used to open the target vessel and graft during suture placement and can play a vital role in visualization during the anastomosis. During the inferior wall or lateral wall targets, the second assistant may occasionally provide better exposure by standing at the head of the bed, to the surgeon's left. In chronically occluded vessels that have collateral and/or retrograde flow, bleeding into the field can be controlled with another retractor tape distally,

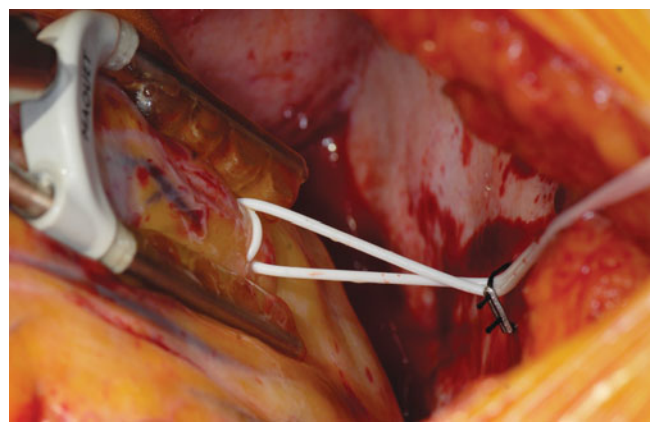

FIGURE 22-7 Close-up view from the surgeon's side of the table. For inferior vessel exposure (posterior descending or left ventricular branch) the Retract-o-tape is positioned as a "pulley" by placing a superficial pericardial traction suture posteriorly (below) to the placement around the coronary artery. A medium clip secures the suture and Retract-o-tape in place which can then be retracted to transiently occlude the artery.

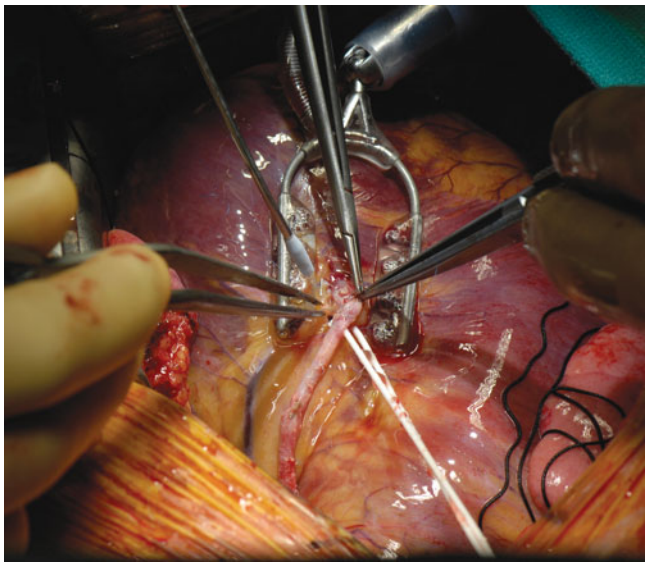

FIGURE 22-8 View from the head of the table. During the anastomosis, a humidified CO_2 blower managed by the second assistant or scrub nurse is used to expose the coronary artery (LAD in this figure).

a MyOcclude device (United States Surgical Corp., Norwalk, CT), or an intracoronary shunt.[16,17] A final preparatory measure is to place temporary atrial or ventricular pacing cables before positioning the heart. As the heart is rotated toward the right, visualization of the right atrium is more difficult, so it is often prudent to place and test these cables before positioning.

Coronary Grafting

The current generation of coronary stabilizers relies on epicardial suction rather than compression to maintain epicardial tissue capture and a motionless field in the region of grafting. A common mistake is to press down too hard on the epicardium, which will paradoxically cause increased movement in the target region. The malleable pods of the stabilizers can be bent or manipulated in any direction to stabilize the target vessel. Generally, gentle compression is applied to allow for epicardial capture. After positioning, the retractor tape can be placed and the coronary artery dissected. If there are concerns about hemodynamic stability during regional ischemia, the proximal vessel can be test occluded for 2 to 5 minutes. During this time the graft can be prepared. This gives the surgeon some assurance before committing to the anastomosis by creating an arteriotomy. After a brief period of reperfusion of 2 to 3 minutes, the vessel can be reoccluded and the artery prepared for anastomosis. The anastomosis is otherwise performed in a manner identical to on-pump grafting. It is essential to continue communication with the anesthesia team so that adequate steps can be promptly taken if hemodynamic conditions deteriorate. For example, if pulmonary artery pressures begin to rise and mean arterial pressures begin to fall during a lateral wall anastomosis, several steps can be taken to avoid cardiovascular collapse. Gently relaxing on the cardiac positioner or coronary stabilizer can often improve hemodynamics. Optimizing table positioning, fluid boluses, inotropes, vasopressors, or pacing may also help. However, if it appears that hemodynamic conditions are deteriorating, then the safe next step is to place an intracoronary shunt,[17] relax, and release both the stabilizer and positioner and allow the heart to recover. At this point a decision must be made to convert "electively" to an on-pump procedure or complete the procedure off-pump. With better preparation (eg, fluids, inotropes, vasopressors, pacing, shunt), the anastomosis can usually be completed off-pump. Another option that is frequently used in patients at high risk for complications of cardiopulmonary bypass is the use of intra-aortic balloon counterpulsation (IABP). An IABP can provide valuable mechanical support during cardiac displacement and positioning to enable safe and controlled completion of a distal anastomosis that would otherwise require cardiopulmonary bypass.

Sequence of Grafting

Careful assessment of the cardiac catheterization is imperative. During on-pump cases, the location and number of vessels requiring bypass usually suffice during evaluation of the catheterization films. However, when planning for OPCAB, particular attention needs to be paid to the collateralizing vessel, intramyocardial vessels, the size of the distal targets, the degree of stenosis, the complexity of coronary disease, and the number of lateral wall vessels requiring grafting. Careful attention must be paid to the sequence of grafting because regional myocardial perfusion is temporarily interrupted in the beating heart (Table 22-3). As

TABLE 22-3 Preferred Sequence of Grafting

Perform anastomosis to completely occluded or collateralized vessel first.
If LAD is not collateralizing vessel, perform LAD-LIMA anastomosis first to allow for anterior wall perfusion during lateral and inferior wall positioning.
Proximal anastomoses can be performed first to allow for perfusion of target vessels after each distal anastomosis. This can be helpful when cardiac positioning is not well tolerated.
Beware of large RCA with moderated proximal stenosis. Acute occlusion can cause bradycardia and hypotension. Be prepared for intracoronary shunt and epicardial pacing.
Patients with moderate MR may not tolerate prolonged cardiac displacement, which can exacerbate MR, and lead to elevated PA pressures and subsequent hemodynamic deterioration. Grafting the culprit causing papillary muscle dysfunction should be vessel performed early in the procedure.

a general rule, the collateralized vessel(s) is grafted first and the collateralizing vessel grafted last. For example, in patients with an occluded right coronary artery with a posterior descending artery supplied by collaterals from the left anterior descending artery, grafting the left anterior descending first would not only leave the anterior wall ischemic, but also disrupt flow to the septum, inferior wall, and right ventricle. Thus, a more reasonable approach would involve grafting the posterior descending artery first, then performing a proximal anastomosis to ensure adequate flow while the proximal left anterior descending is occluded during construction of the LAD anastomosis. Another scenario that may pose problems is a large moderately stenotic right coronary artery. Not uncommonly, temporary occlusion of this artery will result in profound bradycardia and hypotension. In these circumstances, the surgeon must be prepared to use an intracoronary shunt or provide temporary epicardial pacing. Additional options include a "proximals first" approach to allow adequate regional perfusion after completion of each distal anastomosis. Although concern for myocardial protection during OPCAB stems from the brief periods of coronary occlusion necessary to visualize distal target vessels, adequate perfusion can be achieved by maintaining adequate systemic perfusion pressure, selective use of coronary artery shunts, careful use of traction sutures and stabilizers, and proper sequencing of graft anastomoses. Careful placement of intracoronary shunts is important because at least one study demonstrated significant endothelial injury with the use of intracoronary shunts.[18]

Proximal Anastomosis

Traditionally, proximal anastomoses during OPCAB have been performed with the use of an aortic partial-occluding clamp. In preparation for an aortic clamp, the systolic blood pressure is lowered to less than 95 mm Hg. Once the clamp is applied, aortotomies can be made with a 4.0-mm aortic punch device. Proximal anastomoses are then performed using 5-0 or 6-0 polypropylene suture. Before tying down the most anterior proximal, the clamp is released and the aorta de-aired through the proximal anastomosis. After the suture is tied down, the vein grafts can be de-aired with a 25-gauge needle. Arterial grafts are not punctured but are allowed to bleed backward before clamp removal.

Unlike on-pump coronary artery bypass, OPCAB provides the opportunity to minimize or completely avoid manipulation of the aorta. Avoiding partial clamping during proximal anastomoses can be achieved by performing proximal anastomoses to in situ arterial grafts, or using proximal automated anastomotic connectors or facilitating devices.[19–22] This may be particularly relevant in patients with advanced aortic atheromatous disease detected by epiaortic ultrasound. Commercially available devices for clampless proximal anastomoses include the Heartstring III (Maquet Cardiovascular LLC, San Jose, CA) or PAS-Port Proximal Anastomosis System (Cardica Inc., Redwood City, CA). The Heartstring device creates a hemostatic seal with the inner surface of the ascending aorta that allows the creation of a hand-sewn anastomosis with a relatively bloodless field (Fig. 22-9). After completion of the anastomosis, the device is removed by unwinding the sealing cup from the aorta before tying down the suture. However, this device still requires a hand-sewn anastomosis to be performed between the graft and the aorta and can be associated with some blood loss. The PAS-Port Proximal Anastomosis System was specifically designed to create a consistent anastomosis between a saphenous vein graft and the aorta during either on- or off-pump coronary bypass surgery. It is a fully integrated, automated system that cuts the aortotomy and attaches the vein graft to the aorta in seconds, producing

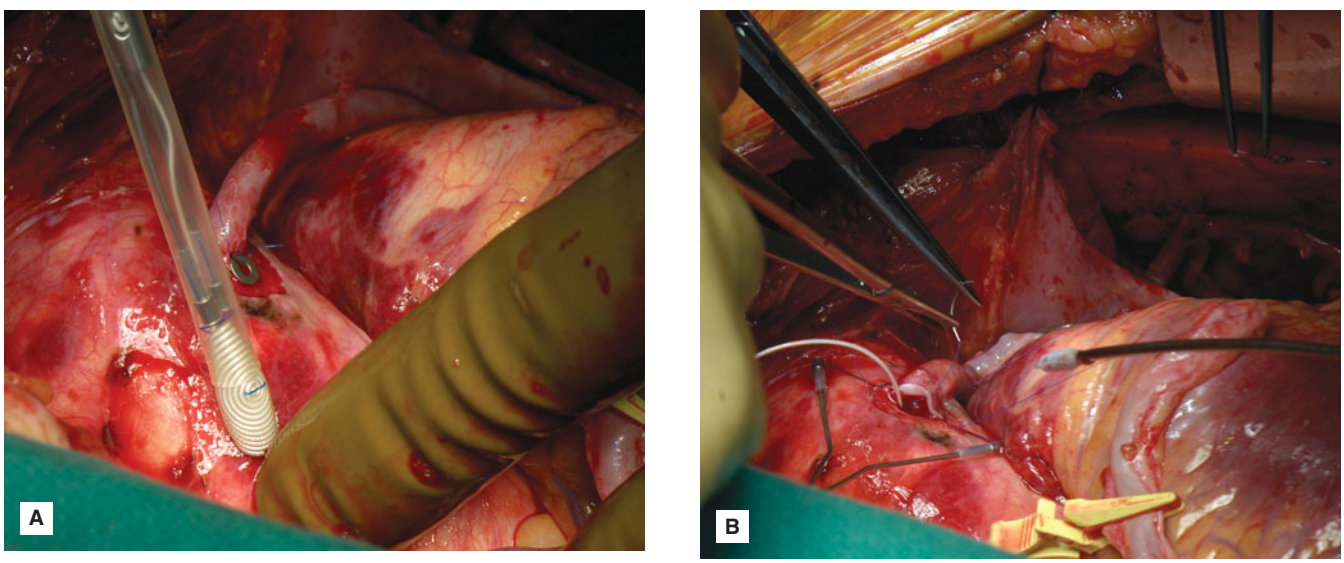

FIGURE 22-9 Proximal anastomoses can be performed without the use of an aortic clamp with either a Heartstring (in these figures) or PAS-Port device. The Heartstring device requires a hand-sewn anastomosis, whereas the PAS-Port device is an automated anastomosis.

consistent, reproducible anastomoses independent of surgical technique and skill.[22–24] Compared with earlier devices, the PAS-Port system allows the endothelium of the vein graft to be untouched during the loading and deployment process. Furthermore, there is no foreign material left within the graft lumen.[23,25–28]

On-Pump Beating Heart Coronary Artery Bypass

Performing coronary artery bypass with cardiopulmonary bypass support is especially useful in certain clinical scenarios such as acute coronary syndromes with cardiogenic shock or in patients with severe left ventricular dysfunction.[29,30] In many occasions, these patients already have tenuous hemodynamics and will not tolerate cardiac positioning and displacement during routine OPCAB maneuvers. One approach is to cannulate the ascending aorta and right atrium and complete the anastomoses on cardiopulmonary bypass with the heart beating but decompressed. This provides for hemodynamic support and also eliminates the global ischemic insult associated with cardioplegic arrest. Grafting can then be performed in a similar sequence as OPCAB. This approach has been supported in several recent studies,[31,32] specifically in the setting of acute coronary syndrome in an attempt to attenuate the ischemic insult associated with regional ischemia from acute coronary occlusion as well as global ischemia associated with cardioplegic arrest. Rastan and colleagues showed improved hospital outcomes in patients with acute coronary syndrome and cardiogenic shock who underwent revascularization with this strategy.[31] Miyahara and coworkers reported lower postoperative morbidity and mortality in patients undergoing emergency myocardial revascularization via an on-pump beating heart approach instead of conventional coronary artery bypass with cardioplegic arrest.[33]

OUTCOMES

Clinical outcomes between OPCAB and CCAB have been compared and reported for over a decade. Even with an abundance of literature, there is still no consensus for the optimal strategy, especially in low-risk patients. In higher-risk patients, it appears in recent studies that OPCAB may reduce both morbidity and mortality. These studies can generally be divided into smaller prospective randomized trials and larger observational or retrospective analyses. Prospective randomized trials provide the most accurate comparison between groups and avoid selection bias and confounding inherent to retrospective and observational analyses. However, these smaller studies are statistically underpowered to detect incremental improvements in morbidity or mortality rates that are already low with CCAB. This is especially true when predominantly low-risk patients are enrolled, which is the case for most of the randomized controlled trials. Furthermore, the cost associated with randomized trials usually prevents patients from being followed for extended periods of time after surgery. Retrospective and observational analyses provide much larger sample sizes with longer duration of follow-up but are limited by their retrospective nature and inherent selection bias despite the use of propensity matching or other advanced statistical methodologies designed to control for confounding variables. Because of their larger size, small differences in outcomes can often be detected. Taken together, both types of studies can provide valuable information to guide clinical practice. Because of the large number of patients required to adequately power important clinical outcomes such as death, stroke, and myocardial infarction, none of the randomized trials, even when analyzed by meta-analysis, are adequately powered to detect clinically or statistically significant differences. For these end points to be powered adequately to demonstrate a benefit in a randomized trial in the current clinical population would require approximately 85,000 patients to demonstrate a difference in death, 6000 patients to analyze any difference in stroke, and 12,000 patients to analyze any difference in myocardial infarction.[34] Most of the earlier trials focused on lower-risk patients. Recent trials, however, have focused on higher-risk cohorts such as elderly patients, those with renal dysfunction, or emergent patients in which a higher incidence of morbidity and mortality is expected.

Operative Mortality

Over the past decade, several randomized trials have documented the safety and efficacy of OPCAB.[28,35–47] However, none of these trials showed an in-hospital mortality advantage for OPCAB compared with CCAB. In a meta-analysis of 37 randomized trials (3369 predominantly low-risk patients), no significant differences were found for 30-day mortality (odds ratio [OR], 1.02; 95% confidence interval [CI] 0.58–1.80).[34] Only one randomized prospective study[48] has demonstrated a reduction in hospital mortality with OPCAB compared with CCAB, and this was in patients who underwent urgent/emergent surgery for ST-segment elevation myocardial infarction.

Several registry studies have been published that are adequately powered to detect differences in mortality outcomes. These retrospective studies, powered by their large sample size, are able to detect significant differences in adverse outcomes among a broad population of patients. In a study by Hannan et al.,[49] 49,830 patients from the New York State registry underwent risk-adjusted analysis (Cox proportional hazard models and propensity analysis) comparing outcomes after OPCAB versus CCAB. In this study, OPCAB patients had significantly lower 30-day mortality (adjusted OR 0.81, 95% CI 0.68 to 0.97, $p = .0022$). In a large registry study of California coronary artery bypass grafting outcomes, Li and colleagues also demonstrated a significant reduction in propensity-adjusted operative mortality with OPCAB compared with ONCAB (2.59% 95% CI 2.52 to 2.67% versus 3.22%, 95% CI 3.17 to 3.27%).[50] An intention-to-treat retrospective analysis of 42,477 patients from the Society of Thoracic Surgeons National Database showed a reduction in risk-adjusted operative mortality (adjusted OR 0.83, $p = .03$) as well as numerous morbidity outcomes favoring

Ann Thorac Surg 2007; 84(5):1447-1454; discussion 1454-1446.*)

patients undergoing OPCAB[51] (Fig. 22-10). These studies and others[52–56] have demonstrated that operative mortality may be reduced in patients undergoing OPCAB compared with CCAB (Fig. 22-11). Some other studies exist that challenge the aforementioned large registry and STS database conclusions. In a paper by Chu and associates that used an administrative database (Nationwide Inpatient Sample database) of 63,000 patients, there was no difference in hospital mortality between OPCAB and CCAB (3.0% versus 3.2%, $p = .14$).[57] Similarly, Williams and colleagues and Palmer and colleagues failed to show a difference in hospital mortality, although these studies had fewer than 6000 patients.[58,59]

Hospital Mortality in Patients Converted to On-Pump

A major complication of OPCAB is the occasional requirement of emergent conversion to cardiopulmonary support. In these circumstances, there is usually profound and acute hemodynamic compromise, either because of poorly tolerated regional ischemia, increased valvular regurgitation from positioning, bradycardia during right-sided or inferior wall grafting, hypotension during cardiac positioning and stabilization, or intractable ventricular tachycardia/fibrillation. It has become well recognized that an emergent conversion ("crash on pump") to CCAB is associated with significantly higher perioperative morbidity and mortality. There are five studies that quote mortality specifically for converted patients ranging from 6 to 15%.[60–64] Early skeptics of OPCAB appropriately criticized observational comparisons of outcomes after OPCAB versus CCAB because these observational studies were not analyzed on an intent-to-treat basis. Most publications now include patients who were converted urgently or emergently to on-pump in the OPCAB group. In more recent studies, Patel and colleagues reported an increased in-hospital mortality rate of 12% in those converted urgently to CCAB compared with 1.5% in those who did not require urgent conversion ($p = .001$).[65] Similarly, Jin and associates reported results from a large registry of greater than 70,000 patients. In this cohort, 5.8% of patients begun off-pump were converted to on-pump cases. In this group, hospital mortality was also significantly higher in converted patients compared with OPCAB patients or patients initially performed on-pump (9.9% versus 1.6% versus 3.0%, respectively).[66] Importantly, there does not appear to be an increased risk of complications in patients who are *electively* converted to CCAB. This usually occurs when the surgeon or anesthesiologist becomes aware of hemodynamic instability during a test period of regional ischemia or during initial cardiac positioning, displacement, or stabilization. In these circumstances, if these maneuvers are reversed, the hemodynamic status usually improves, and the decision can then be made to proceed with an on-pump approach under more controlled conditions.

Mid- and Long-Term Mortality

Because the previous edition of this textbook, mid- and long-term follow-up data has become available in patients undergoing OPCAB.[41,45,49,52,58,59,67] In all of these studies, which include data from two randomized prospective trials, mid- and long-term survival has been comparable among OPCAB and CCAB patients. In the observational study by Hannan et al., 3-year survival was equivalent in OPCAB versus CCAB patients (adjusted hazard ratio 1.01, 95% CI 0.92 to 1.10, $p = .89$; unadjusted 3-year survival 89.4% versus 90.1%, log-rank test, $p = .20$). Within our own institutional database, 10-year survival of over 12,000 patients was equivalent between OPCAB and CCAB groups.[52] In a long-term follow-up (6 to 8 years) study of two randomized trials, Angelini compared survival outcomes of OPCAB versus CCAB. In this study, there was no difference in long-term survival between the two groups (hazard ratio, 1.24; 95% CI 0.72 to 2.15, $p = .44$).[41] Based on these studies, it is reasonable to conclude that long-term survival after coronary artery bypass surgery is not affected by an on- or off-pump approach.

However, a recent randomized controlled trial (ROOBY) was published which reported a higher 1-year composite outcome of death, repeat revascularization, or nonfatal myocardial infarction for patients undergoing OPCAB compared with CCAB (9.9% versus 7.4%, $p = .04$),[47] although these individual end points were not statistically different. With sensitivity analysis, 1-year death from cardiac causes was slightly higher in the off-pump group compared with the on-pump group (2.7% versus 1.3%, $p = .03$). In this study, a minimum number of 20 cases performed off-pump for each study surgeon was required for study participation (median = 50 cases). The learning curve for OPCAB may extend well beyond this minimum number of cases, which may partly explain the difference in outcomes seen in this study.

Perioperative Morbidity

In a meta-analysis of 37 randomized trials comparing OPCAB with CCAB, OPCAB was associated with a reduced incidence of atrial fibrillation (OR 0.58; 95% CI 0.44 to 0.77), transfusion requirements (OR, 0.43; 95% CI 0.29 to 0.65), inotrope requirements (OR, 0.48; 95% CI, 0.29 to 0.65), respiratory infections (OR, 0.41; 95% CI 0.23 to 0.74), ventilation time (weighted mean difference, –3.4 hours; 95% CI –5.1 to –1.7 hours), intensive care unit stay (OR weighted mean difference, –0.3 days; 95% CI –0.6 to –0.1 days), and hospital stay (weighted mean difference, –1.0 days; 95% CI –1.5 to –0.5 days).[34] However, at least one study has challenged these findings reporting equivalent morbidity outcomes between OPCAB and CCAB,[68] although this trial was relatively small with only 150 patients in each group.

Neurologic Outcomes

Stroke remains a significant cause of morbidity and mortality after coronary artery bypass grafting, occurring in approximately 1 to 14% of patients.[69,70] In addition, long-term survival of post-CABG stroke patients is negatively impacted with reductions in 1- and 5-year survival to 66 and 44% compared with 94 and 81% without stroke.[70] The incremental cost of a postoperative stroke has been reported to be an additional $19,000 to the health system when there are no other associated complications and greater than $58,000 when combined with two or more other complications.[71] As our understanding of the risk factors for stroke has increased, more attention is being focused on the observation that most strokes are embolic in nature. Most cerebral embolic events have been shown to

occur at the time of clamp removal.[9] Other sources of emboli can occur from carotid artery disease, particulate matter aspirated from cardiotomy suction devices, delayed thromboembolism from clamp injuries to the ascending aortic intima or proximal anastomotic sites, or left atrial thrombi secondary to postoperative atrial fibrillation. Additional iatrogenic causes of emboli (gaseous) may include aggressive use of carbon dioxide blower devices to facilitate visualization during construction of clampless proximal anastomoses.

Studies utilizing transcranial Doppler ultrasonography have confirmed the production of aortic emboli associated with cannulation and application of aortic clamps.[72–74] Bowles et al. used transcranial Doppler ultrasonography to demonstrate production of large quantities of aortic emboli during cardiopulmonary bypass, even without manipulation of the aorta.[75] Furthermore, Kapetanakis and colleagues[76] and Calafiore and associates[77] concluded that aortic manipulation is independently associated with an increased risk of postoperative stroke. Hammon and colleagues reported reduced neuropsychological deficits in patients undergoing CCAB via single cross-clamp compared with patients undergoing CCAB with multiple cross-clamping or patients undergoing OPCAB and partial clamping.[78] Approaches used to decrease this embolic load include avoidance of aortic cannulation using off-pump techniques, avoidance of multiple aortic clamping, and use of clampless anastomotic devices.[19,79–81] Kim and associates reported a lower incidence of postoperative stroke in patients undergoing OPCAB without any manipulation of the aorta compared with patients undergoing OPCAB with partial clamping and patients undergoing CCAB.[82] Scarborough and colleagues showed that the use of OPCAB in combination with a clampless proximal anastomotic device decreased the number of intraoperative embolic events observed with transcranial Doppler monitoring in comparison with on-pump CABG with hand-sewn proximals.[80] Newer methods advocated to reduce the incidence of stroke include the use of proximal anastomotic devices that avoid the use of an aortic clamp and minimize aortic manipulation (eg, Heartstring or PAS-Port).

There are no prospective randomized trials or meta-analyses of randomized trials that have shown a reduction in stroke with OPCAB compared with CCAB. Large retrospective analyses[49,52,54,56,83,84] have shown that OPCAB may be associated with a reduced incidence of stroke compared with ONCAB. Hannan et al. reported a risk-adjusted decrease in postoperative stroke with OPCAB compared with CCAB (adjusted OR 0.70, 95% CI 0.57 to 0.86, $p = .0006$). Nishiyama and colleagues categorized postoperative strokes according to early (deficit upon awakening from anesthesia) or delayed (patient had a deficit after first awakening from anesthesia without a deficit).[85] In this study, OPCAB was associated with a significant reduction in early stroke compared with CCAB (0.1% versus 1.1%, $p = .0009$). Mishra and colleagues performed a propensity matched comparison of OPCAB versus ONCAB in 6991 patients with atheromatous aortic disease and found a significant decrease in hospital mortality and stroke incidence, with OPCAB being the only independent predictor of a decreased stroke rate.[86] On the contrary, postoperative stroke was not significantly reduced in two recent meta-analyses of off- versus on-pump CABG among relatively low-risk patients.[87,88] Furthermore, Chu and colleagues and Williams and colleagues did not find any differences in stroke between OPCAB and CCAB.[57,59] However, the mechanisms responsible for the observed reduction in postoperative stroke have not been well-defined in these studies. OPCAB eliminates the need for aortic cannulation, cardiopulmonary bypass, and application of a cross-clamp but does not eliminate the need for construction of proximal anastomoses. Furthermore, partial aortic clamping (partial-occluding clamp) for construction of proximal anastomoses is still routinely performed in our center and by others for patients undergoing OPCAB. Thus, the benefits of OPCAB with regard to postoperative stroke may be attenuated because of the aortic manipulation and atheroembolic risk associated with partial aortic clamping commonly performed during OPCAB. Aortic manipulation can be reduced by using clampless anastomotic or facilitating devices that are now available. However, the impact of these devices on reducing postoperative stroke has not been investigated in a large-scale, prospective randomized trial.

Neurocognitive Outcomes

Short- and long-term neurocognitive decline after coronary bypass surgery has usually been attributed to the use of cardiopulmonary bypass. Recent studies from Hammon and colleagues suggest that aortic manipulation associated with clamping may more likely be the culprit instead of extracorporeal circulation.[78,79] In their studies, neurocognitive decline occurred more frequently in on-pump patients with multiple clamping and OPCAB patients with partial clamping compared with on-pump patients with a single cross-clamp strategy. In three recent prospective randomized trials and one prospective nonrandomized study, there was no difference in short- or mid-term neurocognitive deficits between OPCAB and CCAB.[89–91] However, none of these trials differentiated the OPCAB cohort into those in which a partial occluding was used for proximals compared with the use of facilitating or anastomotic clampless devices or in patients in which no aorto-coronary proximal anastomoses were performed.

Renal Failure

Preoperative renal insufficiency is a significant predictor of postoperative renal failure and mortality in patients undergoing CABG.[92] In multiple studies, OPCAB has been shown to reduce morbidity and mortality in patients with normal renal function,[93,94] those with renal dysfunction not yet on hemodialysis[95] as well as those with end-stage renal failure on dialysis.[96] In a prospective randomized trial of 116 diabetic patients with preoperative non–dialysis-dependent renal insufficiency, Sajja et al.[95] demonstrated that the use of cardiopulmonary bypass was significantly associated with an adverse renal outcome. Two retrospective analyses, however, reported equivalent renal outcomes with either OPCAB or CCAB.[97,98] Therefore, the advantages of OPCAB to minimize or avoid renal dysfunction remain controversial.

High-Risk Patients

Several studies have documented improved outcomes in higher-risk patients undergoing OPCAB. Specifically, well-known

higher-risk groups such as women, patients with left ventricular dysfunction, prior stroke, renal insufficiency, and previous sternotomy have been investigated retrospectively. Dewey et al. showed improved operative mortality in favor of OPCAB among patients with dialysis-dependent renal failure.[96] In patients with left ventricular dysfunction[99,100] previous sternotomy,[101] advanced age,[101–104] previous stroke,[84] and in female patients,[54] more favorable outcomes have been reported with OPCAB compared with CCAB. In a recent publication, Puskas and colleagues reported that patients in the highest-risk quartile had a significant reduction in hospital mortality with OPCAB compared with CCAB (3.2% versus 6.7%, $p < 0.0001$, OR 0.45 95% CI 0.33 to 0.63, $p < .0001$)[105] (Fig. 22-12).

The safety and feasibility of OPCAB in select emergency situations has been confirmed in several series.[106–109] In a randomized trial, Fattouch and colleagues reported that patients undergoing emergency off-pump revascularization for acute ST-elevation myocardial infarction had a significantly lower in-hospital mortality and lower incidence of low cardiac output syndrome.[106] Locker and colleagues[110] also reported a survival advantage for emergent patients undergoing revascularization without cardiopulmonary bypass. In their study there was a similar incidence of perioperative cardiogenic shock in both groups. In hemodynamically stable patients taken to the operating room during an evolving myocardial infarction, off-pump revascularization appears to be feasible and safe in our experience as well. However, this must be approached with caution for several reasons. Data on patients undergoing truly emergent revascularization off-pump are relatively sparse. In addition, unloading the ventricle with cardiopulmonary bypass lowers the workload and decreases oxygen demand of an ischemic heart and may be beneficial by that mechanism. Finally, those few published studies are limited by selection bias; the most unstable patients are likely to be revascularized using cardiopulmonary bypass, whereas hemodynamically stable patients may be done off-pump. As always, good surgical judgment based on individual patient risk factors and surgeon experience must guide decision making. "Beating heart" coronary bypass implies that the heart will continue to beat throughout the surgical procedure. Although we have performed many urgent and emergent coronary bypass operations off-pump, in our experience patients suffering ischemic arrhythmias are best revascularized on cardiopulmonary bypass. The onset of ischemic arrhythmias during either elective or urgent/emergent OPCAB mandates either immediate revascularization of the likely culprit lesion or prompt conversion to cardiopulmonary bypass in a controlled fashion.

Graft Patency, Completeness of Revascularization, and Need for Repeat Revascularization

Completeness of revascularization has been critical for the success and durable benefit of coronary artery bypass surger.[111,112] The detrimental effect of incomplete revascularization on long-term mortality was reported in a study by Synnergren and associates.[112] In this study, leaving two vascular segments without a bypass graft in three-vessel disease was associated with an increased hazard ratio for death (hazard ratio, 1.82; 95% CI, 1.15 to 2.85, $p = .01$). Although incomplete revascularization was more common in the off-pump group, there was no significant influence of the use of on/off-pump techniques after adjusting for incomplete revascularization.

Currently, the ability to provide complete revascularization with OPCAB techniques with equivalent graft patency has been challenged, although the majority of evidence from randomized trials suggests equivalent revascularization.[42,43,68,113,114] In a multicenter study from Veterans Affairs medical centers, Shroyer and colleagues found that fewer grafts completed than originally planned were higher in the OPCAB group (17.8% versus 11.1%). A study by Khan and colleagues found a higher rate of graft failure and incomplete revascularization in patients undergoing OPCAB compared with CCAB by surgeons with relatively little experience in off-pump techniques.[42] A meta-analysis of randomized trials has consistently shown a lower number of grafts per patient in off-pump versus on-pump CABG (2.6 versus 2.8, $p < .0001$).[55] Even analysis of later trials in which surgeon experience was greater still showed fewer grafts performed off-pump versus on-pump (2.7 versus 2.9 grafts).[54] Lattouf and colleagues revealed that patients requiring more than three grafts were more likely to have coronary bypass performed on-pump.[53] In this study, completeness of revascularization rather than number of grafts was associated with an improved long-term survival and that there was no difference in completeness of revascularization among groups. Therefore, completeness of revascularization and number of grafts should not be used synonymously. A common formula has been to divide the number of grafts performed by the number of grafts needed (number of graftable vessels with angiographically significant

stenoses) by preoperative assessment of the cardiac catheterization. This value gives an index of complete revascularization. In a study of the Society of Thoracic Surgeons National Cardiac Database by Puskas and colleagues, OPCAB patients had a slightly lower index of complete revascularization than CCAB patients, although operative morbidity and mortality were significantly reduced in patients undergoing OPCAB.[51] In a recent study by Magee and coworkers, the number of grafts was fewer in the OPCAB group (2.75 ± 1.12) compared with the CCAB group (3.36 ± 1.01).[115] However, because the OPCAB group needed fewer grafts, the index of complete revascularization was comparable between OPCAB and CCAB (1.03 and 1.07, respectively). Thus, it appears that selection bias may be partly responsible for this observation, because surgeons may choose to use on-pump techniques on patients requiring more than three grafts. The issue of completeness of revascularization with OPCAB and its impact on long-term survival remains unsettled. Comparisons with older trials may not account for significant improvements in secondary medical prevention strategies or for advances in percutaneous coronary intervention. It is our policy that completeness of revascularization should not be compromised when deciding whether to use or avoid cardiopulmonary bypass unless the use of cardiopulmonary bypass poses obvious and significant risk for postoperative complications or mortality, which may be the case in patients with severe atherosclerotic disease of the ascending aorta. Because we perform the large majority of our coronary operations without cardiopulmonary bypass, complete revascularization, even in the more difficult lateral wall territory, is routinely accomplished.

Graft patency has been evaluated in five randomized trials from in-hospital to 1 year postoperatively. Puskas demonstrated no difference in graft patency at discharge and at 1 year,[114] whereas Khan showed a decreased graft patency in the off-pump group at 3 months.[42] Similarly, Widimsky and associates demonstrated equivalent arterial but reduced vein graft patency in OPCAB patients compared with CCAB patients.[28] Shroyer et al. found that the overall rate of graft patency (driven by vein graft patency) was lower in the OPCAB group compared with the CCAB group (82.6% versus 87.8%, $p < .001$).[47] Three other studies showed no difference in graft patency at 1 year.[26,43,116] Two meta-analyses reported no significant differences between off-pump and on-pump revascularization.[55,117] The largest study to challenge either completeness of revascularization or graft patency is the New York registry data from Hannan et al.[49] Although OPCAB was associated with lower in-hospital mortality and morbidity and equivalent long-term outcomes than CCAB, the need for repeat revascularization was greater in the OPCAB group (93.6% versus 89.9%). Because this was a retrospective analysis, this study was unable to differentiate whether this difference was a result of incomplete revascularization during OPCAB, reduced graft patency, or unrecognized confounding variables.

Minimally Invasive and Hybrid Approaches

Widespread familiarity with off-pump techniques has facilitated the development and application of minimally invasive revascularization procedures. Endoscopic atraumatic coronary artery bypass (EndoACAB) has been well described and involves a thoracoscopic or robotic-assisted left internal mammary artery dissection and harvest, followed by a direct off-pump anastomosis to the left anterior descending coronary artery via a left anterior minithoracotomy[118] (Fig. 22-13). So-called hybrid revascularization, which combines percutaneous intervention to non–left anterior descending targets with EndoACAB, has also been described[119] and is gaining in popularity, and early studies report acceptable outcomes.[120] Totally endoscopic coronary artery bypass, which is facilitated by off-pump and robotic techniques as well as anastomotic facilitating devices, has also been well described, and continued improvement in technology may make this approach more applicable.[121] The feasibility of these alternative minimally invasive approaches has been demonstrated and the use of minimally invasive techniques has generated much enthusiasm in the surgical and interventional communities. Nonetheless, these procedures remain technically challenging and have not become widespread to date.

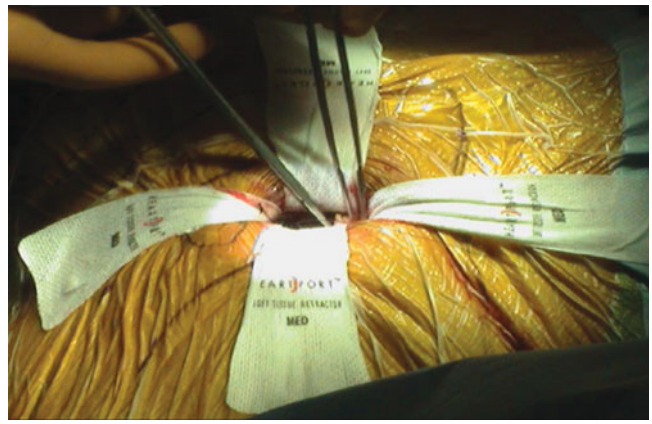

FIGURE 22-13 After endoscopic or robotic-assisted left internal mammary artery harvest, a direct hand-sewn anastomosis can be performed off-pump via a left anterolateral non-rib spreading minithoracotomy.

CONCLUSIONS

Despite the considerable amount of literature comparing OPCAB to CCAB, there is not widespread consensus about the relative advantages of these two techniques. Randomized controlled trials have reported equivalent short- and long-term mortality and major cardiovascular morbidity between groups. However, these trials are frequently underpowered to detect significant outcomes in relatively infrequent adverse events. Furthermore, most of these trials enrolled low-risk patients, thus further reducing their power. Randomized controlled trials have generally shown reduced incidence of myocardial enzyme release, fewer transfusions, shorter length of hospital stay, and reduced cost with OPCAB.[36]

Most retrospective and observational analyses have shown a benefit with regard to in-hospital mortality and both cardiovascular and noncardiac morbidity in favor of OPCAB. Such

observational studies are usually larger, have more statistical power to identify significant differences, and include more high-risk patients. Although most evidence points to equivalent completeness of revascularization and short-term graft patency between OPCAB and CCAB, OPCAB patients tend to receive a lower number of grafts, which likely represents a selection bias. Some general conclusions can be made from the available data:

- Low-risk patients undergoing surgical revascularization can be safely revascularized with either off- or on-pump coronary artery bypass.
- With the appropriate use of modern stabilizers and heart positioning devices as well as adequate surgeon experience and careful patient selection, equivalent completeness of revascularization and graft patency can be achieved with OPCAB.
- Certain high-risk groups appear to have better in-hospital morbidity and mortality outcomes when revascularized without the use of cardiopulmonary bypass. This includes patients with advanced ascending aortic atherosclerosis, renal insufficiency, chronic obstructive pulmonary disease, females, and elderly patients. These benefits are likely caused not only by the avoidance of cardiopulmonary bypass, but also by minimizing aortic manipulation.
- Long-term survival outcomes are equivalent in patients undergoing on- or off-pump coronary artery bypass surgery
- There is an improvement in resource utilization with OPCAB, including reduced transfusion requirements, shorter length of stay, less intensive care and ventilator time, and reduced cost.
- The choice of OPCAB versus CCAB requires careful attention to preoperative and intraoperative patient variables that may influence operative circumstances as well as short- and long-term morbidity and mortality. There are certain circumstances in which advantages and disadvantages exist with either approach. Patients with ischemic arrhythmias or cardiogenic shock should be supported on cardiopulmonary bypass for surgical revascularization.
- Urgent or emergent conversion from OPCAB to CCAB is associated with higher in-hospital morbidity and mortality.
- The quality of the anastomosis and the completeness of revascularization should not be compromised when performing off-pump anastomoses. If complete revascularization cannot be performed or precise anastomoses are not possible with off-pump approaches, then an on-pump strategy is preferred, unless cardiopulmonary bypass poses excessive risk to the patient.

CHAPTER 23

Myocardial Revascularization with Carotid Artery Disease

Cary W. Akins
Richard P. Cambria

INTRODUCTION

Next to operative mortality, permanent stroke is the most dreaded complication of myocardial revascularization, not only because of the potential devastating consequences to the patient but also because of the increased cost of hospitalization and posthospital care. Perioperative stroke following coronary artery bypass grafting (CABG) is of increasing concern because as the average age of coronary bypass patients rises, so does the risk of stroke. This chapter investigates the relationship of carotid artery disease to neurologic complications following myocardial revascularization and evaluates treatment options for dealing with severe concomitant carotid and coronary artery disease (CAD).

PERIOPERATIVE STROKE

Incidence of Perioperative Stroke

The risk of stroke coincident with CABG is well defined. In 1986, Gardner and colleagues[1] found the risk of stroke to be a direct function of patient age. Patients younger than 45 years of age had a stroke rate of 0.2%, which rose to 3.0% for patients in their 60s and to 8.0% for patients older than age 75. Other risk factors associated with stroke were preexisting cerebrovascular disease, ascending aortic atherosclerosis, long cardiopulmonary bypass time, and perioperative hypotension.

Tuman and colleagues[2] in 1992 investigated the effect of age on cardiac performance and neurologic injury in coronary bypass patients. Whereas the rates of low cardiac output and myocardial infarction (MI) were constant as patient age increased, the incidence of neurologic damage rose exponentially after age 65. The stroke rate rose from 0.9% for patients younger than 65 years to 8.9% for patients older than age 75.

To place the problem of the increasing patient age into a more contemporary context, at our institution the mean age of coronary artery bypass (CABG) patients rose from 56 years in 1980 to older than 67 years in 2007. In 1980 only 6% of patients were age 70 or older, whereas by 2007 more than 41% were age 70 or older, and 10% were age 80 or older.

In 2000, John and colleagues[3] reported a stroke rate of 1.4% for 19,224 coronary bypass patients from the New York State Cardiac Surgical Database. Multivariable predictors of stroke included aortic calcification, renal failure, prior stroke, smoking, carotid artery disease, age, peripheral vascular disease, and diabetes. In their review of 10,860 patients having primary myocardial revascularization, Puskas and colleagues noted that stroke occurred in 2.2%.[4] Multivariable predictors of stroke were age, previous transient ischemic attack, and carotid bruits.

Cost of Perioperative Stroke

Puskas and colleagues also found that perioperative stroke was associated with significantly more in-hospital morbidity, longer length of stay, and almost twice the hospital cost.[4] Patients who suffered a perioperative stroke had a 23% hospital mortality rate. Roach and colleagues[5] noted a 21% mortality rate for patients suffering a perioperative stroke following coronary artery bypass grafting (CABG), with a mean hospital stay of 25 days among survivors.

Causes of Perioperative Stroke

Possible causes of perioperative neurologic injury are listed in Table 23-1. The most common cause of perioperative stroke is atherosclerotic or thrombotic emboli from the heart or major vessels. Intracardiac emboli can arise from mural thrombus secondary to MI, left atrial thrombus associated with valvular disease or atrial fibrillation, or suture lines in the aorta or left side of the heart. Catheters in the left side of the heart also can be a source of perioperative emboli. Less commonly, entrapped air may cause neurologic events, although rarely focal deficits.

The aorta is also a possible source of emboli. Cannulation of the ascending aorta for bypass, aortic occlusion clamps, and intra-aortic cardioplegia delivery devices may dislodge existing atherosclerotic material from the aorta. Wareing and colleagues[6] found aortic atherosclerosis to be a risk factor for perioperative stroke. Intraoperative echocardiography of the ascending aorta to identify atherosclerosis and the subsequent alteration of operative techniques to address identified problems improved the stroke risk in their patients. Studies that examine the anatomic distribution of perioperative strokes emphasize the importance of cardiac and aortic sources because diffuse anterior and posterior cerebral circulation beds are often affected.[7,8]

Embolism from atherosclerotic carotid bifurcation disease is a well-defined cause of perioperative neurologic injury. Carotid plaque morphology has an important impact on the stroke risk of patients with carotid stenosis. A companion study to the North American Symptomatic Carotid Endarterectomy Trial found that plaque ulceration was a significant incremental risk factor for stroke across all degrees of carotid stenosis.[9]

Many studies list flow-limiting carotid stenosis as a risk factor for perioperative stroke, but whether the carotid lesion is an etiologic factor or only a nonspecific marker of overall risk is unclear.[1,10–12] The Buffalo Cardiac Cerebral Study Group found that although carotid stenosis predicted increased risk of perioperative stroke and death, most strokes occurred more than 24 hours after the myocardial revascularization, and the anatomic distribution of the strokes did not correlate well with the site of the carotid lesion.[12,13]

Neurologic injury can result from inadequate blood flow on cardiopulmonary bypass. Schwartz and colleagues, found that cerebral blood flow depends on arterial perfusion pressures, not on cardiopulmonary bypass flow rates.[14] Low cerebral blood flow occurred with perfusion pressures of less than 60 mm Hg and was not influenced by the pump flow rate. Adequate perfusion pressure is very important in the presence of carotid stenosis, particularly with internal carotid occlusion.[10] Some investigators have shown a linear relationship between the degree of carotid stenosis and the risk of perioperative stroke; in such analyses patients with total ICA occlusion are typically the subgroup at highest risk for stroke.[7] Yet carotid revascularization is not possible in the circumstance of total ICA occlusion. When there is occlusion of carotid or intracerebral arteries, brain blood flow depends on collateral circulation, which, in turn, depends on perfusion pressure. Whether carotid or intracerebral vascular spasm can contribute to neurologic injury is unknown.

Finally, intracranial hemorrhage can lead to neurologic injury following cardiopulmonary bypass, but this is truly rare, despite the fact that patients are fully anticoagulated for cardiopulmonary bypass. We routinely use computed tomographic (CT) scanning to evaluate suspected perioperative stroke to guide anticoagulation, and the finding of primary intracerebral bleeding is extraordinarily uncommon. Indeed in a study of nearly 400 strokes after CABG, investigators of the Northern New England Cardiovascular Study Group identified hemorrhage as the cause of 1% of post-CABG strokes, and hypoperfusion as being responsible in about 10%.[8]

Of the potential causes of perioperative neurologic injury listed in Table 23-1, carotid stenosis is the one situation for which the surgeon can take action to remove the pathology. Because carotid stenosis is a significant risk factor for perioperative stroke, the need to define carotid disease before coronary artery grafting becomes obvious. The logical extension that surgical correction of carotid stenosis can decrease the risk of stroke has been the basis of our approach for many years. Although Level I evidence to support this approach does not exist, the safety of the combined operative approach, which is key to its continued application, has been verified, as will be discussed.

TABLE 23–1 Potential Causes of Perioperative Neurologic Injury Associated with Coronary Artery Bypass Grafting

Vascular occlusion, usually embolic
Heart
Aorta
Innominate, carotid, or vertebral arteries
Low-flow phenomenon
Insufficient perfusion pressure on cardiopulmonary bypass
Bypass
Poor collateral circulation
Vascular spasm
Intracranial hemorrhage

Relationship of Carotid Stenosis to Perioperative Stroke

Early studies relating the presence of carotid stenosis to perioperative stroke used auscultatory evidence of carotid disease as a surrogate for carotid stenosis. In 1988, Reed and colleagues from our institution documented a 3.9-fold increase in the risk for stroke after coronary artery bypass grafting in the presence of a preoperative carotid bruit.[15]

Yet carotid bruits are not reliable indicators of either the presence or degree of carotid stenosis. Sauve and colleagues[16] found poor correlation between carotid bruits and the degree of stenosis. Indeed, as carotid lesions progress to high degrees of stenosis, bruits may become inaudible. Despite these limitations, auscultation for

carotid bruits is a common mode of detecting carotid stenosis, particularly in asymptomatic patients.

Currently, Doppler ultrasound–based noninvasive studies are the initially applied and often definitive (and sufficient) diagnostic testing modality for carotid stenosis. Although quality control is essential with noninvasive testing, verification of its accuracy has been demonstrated many times.[17,18]

Brener and colleagues[10] studied 4047 cardiac surgical patients and found a 9.2% rate of stroke or transient ischemic attack in patients with asymptomatic carotid stenosis, significantly greater than the 1.3% rate in patients with no carotid stenosis.

Faggioli and colleagues[19] in 1990 reported that routine carotid noninvasive testing in CABG patients with no ischemic neurologic symptoms yielded an odds ratio for stroke of 9.9 with greater than 75% carotid stenosis. In patients older than age 60 with greater than 75% carotid stenosis, the stroke rate was 15 versus 0.6% for patients of the same age with no carotid disease. Perioperative strokes occurred in 4 (14.3%) of 28 patients who had greater than 75% carotid stenosis who did not have concomitant carotid endarterectomy compared with no strokes in the 19 patients with greater than 75% carotid stenosis who had a prophylactic carotid endarterectomy with their CABG.

In 1992, Berens and colleagues,[20] using routine carotid duplex scanning for cardiac surgical patients 65 years of age or older, found that the risk of stroke was 2.5% for carotid stenoses greater than 50%, 7.6% for carotid stenoses greater than 50%, 10.9% for carotid stenoses greater than 80%, and 10.9% for unilateral carotid artery occlusion.

Thus, adequate evidence exists that significant carotid artery stenosis is an important incremental risk factor for the development of perioperative neurologic injury following CABG. In addition, the study by Faggioli and colleagues[19] suggested that carotid endarterectomy performed with CABG yielded a lower stroke rate.

Mechanism of Perioperative Stroke with Carotid Stenosis

How carotid stenoses cause perioperative strokes is not well understood, especially because patients are fully anticoagulated on cardiopulmonary bypass. Perioperative strokes may result from emboli from the carotid plaque, possibly caused by dynamic plaque events. Loss of pulsatile perfusion or inadequate perfusion pressure on bypass may lead to diminished flow distal to a significant stenosis, resulting in a watershed stroke. Indeed the belief that hypoperfusion is a mechanism whereby carotid lesions cause stroke is indirectly supported by several observations, including the high stroke risk in patients with total ICA occlusion. Hypoperfusion was identified as causing about 10% of strokes in one review of post-CABG stroke pathology.[8] However, Reed and colleagues[15] and Ricotta [12] found that more than one-half of strokes present after the immediate postoperative period. Such delayed strokes in patients with uncorrected carotid stenoses may be related to the prothrombotic milieu that occurs in the early days after cardiopulmonary bypass, potentially causing destabilization of a previously asymptomatic carotid lesion.

Relationship of Uncorrected Carotid Stenosis to Late Stroke

In 1985, Barnes [21] assessed the late risk of untreated asymptomatic carotid stenosis in 65 patients who had cardiovascular operations, of whom 40 had CABG. At mean follow-up of only 22 months, 10% of coronary bypass patients had died, and 17.5% had suffered a stroke. Noninvasive testing revealed progression of the carotid disease in one-half of the patients within 4 years. Ascher reported a 10% risk of stroke after CABG at a mean follow-up interval of 48 months when significant carotid disease was uncorrected, 10-fold higher than patients undergoing combined CABG and carotid endarterectomy.[22] Contemporary randomized trials of surgery versus medical therapy for significant carotid stenosis have defined the late risk of carotid-related stroke in medically treated patients. In the Asymptomatic Carotid Surgery Trial, actuarial risk of stroke at 5 years was 12% in medically treated patients with asymptomatic high-grade carotid stenosis.[23]

CAROTID STENOSIS IN CORONARY ARTERY BYPASS PATIENTS

Incidence of Carotid Stenosis in Coronary Artery Bypass Patients

In 1977, Mehigan and colleagues,[24] used noninvasive testing in 874 patients before coronary grafting and found a 6% incidence of significant extracranial cerebrovascular disease. Ivey and colleagues[25] reported that routine ultrasonic duplex scanning for a history of neurologic events or cervical bruits in 1035 patients having isolated CABG revealed significant carotid artery stenosis in 86 patients (8.3%). Faggioli evaluated 539 neurologically asymptomatic CABG patients and found 8.7% had a carotid stenosis greater than 75%.[19] The rate rose from 3.8% for patients less than age 60 to 11.3% for patients older than age 60. Berens and colleagues, using routine carotid artery scanning in 1087 cardiac surgery candidates 65 years of age or older (91% with coronary disease), found 186 (17.0%) had a greater than 50% carotid stenosis and 65 (5.9%) had a greater than 80% carotid stenosis.[20] Predictors of carotid artery disease were female gender, peripheral vascular disease, history of transient ischemic attacks (TIAs) or stroke, smoking history, and left main CAD. D'Agostino, using noninvasive testing in 1279 CABG candidates, found 262 (20.5%) had greater than 50% stenosis in at least one carotid artery and 23 (1.8%) had bilateral stenoses greater than 80%.[26] Significant multivariable predictors of carotid disease were age, diabetes, female sex, left main CAD, prior stroke, peripheral vascular disease, and smoking.

Virtually all studies have emphasized that patient age is the single highest risk variable. One report demonstrated a dramatic, statistically significant increase in patients older than 60 years of age. Diabetes, smoking, and hypertension were important associated risk factors, such that, with all three risk factors in patients older than age 60, the incidence of significant carotid stenosis nearly doubled from about 8% to 14%.[22]

Diagnosis of Carotid Artery Disease

Essentials of Noninvasive Testing

Ultrasound-based Doppler interrogation for carotid stenosis exploits the Doppler effect; namely, the reflected or altered frequency of an ultrasound wave is shifted in proportion to the velocities of the sampled, flowing blood, which are increased in regions of significant arterial stenosis.

Doppler interrogation produces two data sets—Doppler-shifted flow velocities in regions of interest, and spectral analysis of turbulent flow, which lends a qualitative determination of stenosis severity. Doppler samples must be obtained in the tightest portion of the stenosis for accuracy.

Derived Doppler velocities include peak systolic velocity (PSV), end-diastolic velocity (EDV), and the ratio between the PSV in the internal carotid artery and in the proximal common carotid artery (ICA/CCA ratio). The derived ratio corrects for baseline variations in hemodynamics, such as cardiac output and increased overall flows that might be noted in contralateral internal carotid occlusion. PSV is the single most important criterion, followed by the ICA/CCA ratio. EDV is helpful in discriminating severe versus "very severe" lesions. An ICA/CCA ratio of more than 4.0 equates to a greater than 70% diameter stenosis, the general threshold for a flow-reducing lesion at basal conditions according to the physics of critical arterial stenosis.

Some general comments about the efficacy of ultrasound-based carotid noninvasive tests are in order because many vascular surgeons proceed to carotid endarterectomy based solely on these preoperative studies.[15] Surgeons must be familiar with the specifics of noninvasive diagnostic criteria, and laboratories must have quality-control documentation of accuracy. Thorough knowledge of the translation of ultrasound-derived data to corresponding degrees of internal carotid artery stenosis is necessary.

Indications for Noninvasive Testing

Current indications for screening patients for carotid artery disease before surgical myocardial revascularization include:

1. An audible bruit in the neck
2. History of a prior stroke
3. History of transient ischemic attacks
4. Patients with severe peripheral vascular disease
5. Patients with a prior carotid endarterectomy
6. Elderly patients

All of these indications are self-explanatory except the last. Because the incidence of carotid stenosis rises dramatically in patients older than age 65, there must be an age above which it is cost-effective to screen all patients for carotid disease. However, that age has not yet been determined. One would have to demonstrate the cost advantage of routine carotid endarterectomy versus that of strokes related to uncorrected carotid stenoses.

Role of Carotid Imaging Modalities

Catheter-Based Carotid Angiography. Although catheter-based carotid angiography yields excellent detailed images of the carotid and intracranial vessels, angiography is expensive, requires potentially nephrotoxic contrast material, and is not without risks, including arterial dissection and stroke. Cholesterol embolization owing to catheter manipulation in a diseased aorta can cause emboli to other vascular distributions, especially renal and/or other visceral arteries. (Indeed, in the Asymptomatic Carotid Atherosclerosis Study, one-half of the 2.3% stroke risk with carotid endarterectomy was referable to mandated angiography.[27]) For these reasons, conventional carotid angiography had all but vanished from the practice of many vascular surgeons by the year 2000.[28] Ironically, current enthusiasm for carotid stenting has resurrected carotid angiography as a diagnostic and therapeutic tool.

Magnetic Resonance Angiography. Great enthusiasm in the 1990s arose for magnetic resonance angiography (MRA) to better define carotid lesions. Compared with catheter-based angiography, it was noninvasive, lacked nephrotoxicity, and when used with diffusion-weighted brain imaging, yielded an accurate map of the intracranial circulation. However, its limitations soon became obvious. Magnetic resonance vascular imaging relies on reflected magnetic pulses of flowing blood cells that vary as a function of flow turbulence. Because turbulent flow is characteristic of high-grade carotid stenoses, signal "dropout" in magnetic resonance imaging (MRI) is common. MRA suffers from low specificity with respect to detection of critical stenosis.[29] Indeed, MRA alone can overestimate carotid stenosis severity. Thus, in a reversal of prior algorithms, we insist that stenosis severity information from MRA be verified by a duplex study.

Computed Tomographic Angiography. Computed tomographic angiography (CTA) is the noninvasive test of choice when supplemental information is required after duplex scanning. Although CTA requires iodinated contrast material, it can provide excellent arterial mapping from the aortic arch to the intracranial vasculature, which can be important to both vascular and cardiac surgeons. Accurate assessment of residual lumen diameter within a carotid artery lesion is obtained from both axial and three-dimensional (3D) reconstructed images. Current processing capabilities and the generation of 3D models have improved CTA accuracy in highly calcified lesions.

EFFICACY OF CAROTID ENDARTERECTOMY AS A TREATMENT FOR CAROTID STENOSIS

C. Miller Fisher's original description of the relationship of ipsilateral hemispheric stroke to internal carotid artery occlusion in 1951[30] was followed by Eastcott's description of surgical therapy for symptomatic carotid artery atherosclerosis in 1953.[31] Thereafter, carotid endarterectomy became popular for stroke prevention until publication of the negative results in the multinational EC/IC bypass trial[32] in the mid-1980s. A vocal segment of the neurology community decried the apparent lack of evidence verifying the efficacy of carotid endarterectomy in stroke prevention, which led to a series of large-scale, prospective, randomized trials comparing carotid endarterectomy with medical therapy. In summary, there is now Level I evidence

verifying the efficacy of carotid endarterectomy for stroke prevention in both symptomatic and asymptomatic patients.

Carotid Endarterectomy for Symptomatic Carotid Stenosis

In 1991, the results of the randomized North American Symptomatic Carotid Endarterectomy Trial (NASCET) of medical treatment or carotid endarterectomy were reported.[33] All patients had either hemispheric retinal TIAs or nondisabling strokes within 120 days of entry into the trial and 70 to 99% stenosis in the symptomatic carotid artery. The actuarial risk of any ipsilateral stroke at 2 years was significantly lower at 9% in the 328 surgical patients versus 26% in the 331 medical patients. The data-safety monitoring committee halted further randomization given the widely disparate 18-month follow-up data. For major or fatal ipsilateral strokes, the risk was 2.5% for surgical patients versus 13.1% for medical patients ($p < .001$). When all strokes and deaths were included, carotid endarterectomy still was better than medical treatment. Subsequent follow-up studies from this trial indicated that the benefit of carotid endarterectomy in symptomatic patients extended to those with even moderate (50 to 69%) carotid artery lesions.[34]

The Veterans Affairs Cooperative Study of symptomatic carotid stenosis reported in 1991 results of randomizing 189 men with stenoses greater than 50% to medical or surgical treatment.[35] After 1 year, there was a significant reduction in stroke or TIAs in the patients having carotid endarterectomy (7.7%) compared with medically treated patients (19.4%), with even more divergent results with carotid stenosis greater than 70%.

The European Carotid Surgery Trial randomized 2518 patients with nondisabling stroke, TIA, or retinal infarction in conjunction with ipsilateral carotid stenosis to medical or surgical treatment.[36] For the 778 patients with stenoses of 70 to 99%, the cumulative risk of stroke at carotid endarterectomy of 7.5%, plus an additional late stroke rate at 3 years of 2.8%, was less than the 16.8% rate for medically treated patients. At 3 years the cumulative risk of operative death, operative stroke, ipsilateral ischemic stroke, and any other stroke was 12.3% for the surgical cohort versus 21.9% for the medical group ($p < .01$). Finally, the risk of fatal or disabling ipsilateral stroke at 3 years was 6.0% for the carotid endarterectomy patients versus 11.0% for the medical control patients ($p < .05$).

Although the benefit of endarterectomy in these studies was due in part to the high risk of stroke in medically treated patients, the results were significant even in an era when the 30-day combined stroke and death risk of endarterectomy was about 7.5%. Although the combined stroke and death risk of carotid endarterectomy is higher in symptomatic versus asymptomatic patients,[37] the current combined risk is about 2 to 4%.[23,28,38–44]

Carotid Endarterectomy for Asymptomatic Carotid Stenosis

Early studies suggested a significant stroke risk reduction for carotid endarterectomy versus best medical therapy in asymptomatic patients.[40,41] Contemporary randomized studies subsequently verified this position.

The Veterans Affairs Cooperative Study of asymptomatic carotid stenosis, defined as greater than 50% diameter reduction by angiography, randomized 444 men to medical or surgical treatment.[42] At a mean follow-up of 4 years, the combined incidence of ipsilateral neurologic events was 8.0% for the surgical patients versus 20.6% for the medical patients ($p < .001$). The difference in stroke alone between the two groups (8 versus 20%) did not achieve statistical significance because of the study's sample size, nor was there a significant difference when all strokes and deaths were analyzed. Excessive late mortality (about 40% at 4 years in both groups) was caused largely by associated CAD. These mitigating factors limited definitive conclusions about the efficacy of carotid endarterectomy in asymptomatic patients in this trial.

In 1995, results of the Asymptomatic Carotid Atherosclerosis Study of 1662 patients randomized to surgical or medical treatment were published.[27] At mean follow-up of 2.7 years, aggregate risk for ipsilateral stroke and any perioperative stroke or death for the surgical group was 5.1%, significantly lower than the rate of ipsilateral stroke of 11.0% for the medical group, a benefit limited to male patients. Critics suggested that the low combined stroke and death rate (2.3%) in the surgical patients was not representative of results across a broader spectrum of hospitals. However, low morbidity for carotid endarterectomy in asymptomatic patients has been verified in multiple large studies.[43,44]

In 2004, the Asymptomatic Carotid Surgery Trial (ACST),[23] touted as the world's largest surgical trial from 126 hospitals in more than 30 countries, randomized over 3000 patients to carotid endarterectomy or medical therapy. Greater than 40% of patients had more than 3 years of follow-up. Risk of any stroke, any ipsilateral stroke, or any disabling stroke was halved in surgical patients, who had a combined stroke and death rate of about 3%. The time threshold to achieve statistical benefit, ie, cancel perioperative morbidity, by actuarial analysis was 2 years, suggesting that patients selected for endarterectomy should have a life expectancy of greater than 2 years. The only subgroup in which endarterectomy did not achieve statistical significance was in patients older than 75 years of age.

In summary, Level I evidence supports the advantage of carotid endarterectomy over medical management for patients with severe asymptomatic carotid artery stenoses. Of note, large contemporary studies verify the low perioperative morbidity with carotid endarterectomy, even across a spectrum of hospitals and surgeons. In a recent NSQIP study, whose methodology involved independent nurse reviewer adjudication of 30-day endpoints, some 4000 carotid endarterectomy procedures in both symptomatic and asymptomatic patients was accompanied by a 2.2% combined stroke and death risk.[43]

CAROTID STENTING

Following the success of percutaneous transluminal coronary angioplasty, particularly with adjunctive stenting, percutaneous interventionalists increasingly sought to treat carotid stenosis with angioplasty and stenting.[45–47] Technical aspects of the procedure to guard against procedure-related stroke are the dominant

concern with this procedure. Emerging reports (mostly from industry-sponsored trials) indicate that carotid stenting can produce equivalent outcomes to carotid endarterectomy.[48–51] In one large series, the 30-day combined stroke and death rate was 7.4%, and most strokes were minor.[52] Results improved with experience, and late stroke-free survival was comparable with that for carotid endarterectomy.

In 2004, a randomized trial of carotid endarterectomy versus stenting with routine embolic protection, designed as a "noninferiority" trial, ie, insufficiently powered to detect superiority of one treatment, concluded that carotid stenting was not inferior to carotid endarterectomy in high-risk patients.[51] Study endpoints (composite death/stroke/MI at 30 days and 1 year), high 30-day combined stroke and death rate (5.7%) in asymptomatic patients, and small sample size limit the value of the data. Most large series and meta-analyses indicate a higher periprocedural complication rate for stenting versus endarterectomy.[53–57] In the French carotid endarterectomy versus stenting study in patients with symptomatic, severe carotid stenosis, stenting was associated with a 2.2-fold increased risk of stroke or death at 30 days compared with endarterectomy. The data-safety monitoring committee halted the trial after randomizing 527 patients.[58] The recently published International Carotid Stenting Study concluded that carotid endarterectomy, and not stenting, was the preferred treatment for symptomatic patients because of an unacceptable early stroke risk accompanying stenting.[59] A Society of Vascular Surgery registry study with risk adjustment methodology reported a nearly three-fold increased risk of 30-day stroke, death, and myocardial infarction with stenting as opposed to carotid endarterectomy.[54] Furthermore, published evidence documents an increased periprocedural risk of stroke after carotid stenting in elderly and symptomatic patients.[55,57,60,61]

Scant data are available about carotid stenting versus endarterectomy in patients requiring CABG. Investigators from the Cleveland Clinic compared patients treated with either carotid stenting before or carotid endarterectomy with open-heart surgery. After propensity scoring, the authors found no significant differences in combined stroke/death/MI in the two approaches.[62]

Given conflicting evidence to support combined carotid endarterectomy and CABG, not surprisingly many investigators have considered the strategy of antecedent carotid stenting, followed by interval CABG for combined disease. A logistic consideration in this strategy is the standard use of Clopidogrel with carotid stenting. One report from the Netherlands advocated such a strategy, but only if the CABG could be delayed for at least three weeks; overall death/stroke/myocardial infarction was still 8.7%.[63] Two collective reviews reflect the difficulty of improving upon reported results with combined carotid endarterectomy and CABG, and/or the conservative posture with respect to asymptomatic carotid stenosis in patients requiring CABG. Naylor collected 11 studies with 760 carotid stent procedures performed at variable intervals before CABG. The cumulative 30-day stroke/death risk was 9.1%, stated to be quite similar to the authors' prior review of concomitant carotid endarterectomy and CABG.[64,65] As in prior reports, that group supported a noninterventional approach in asymptomatic patients. Similarly, Guzman et al. reported a combined stroke/death rate of 12.3% for nearly 300 patients with carotid stenting followed by interval CABG performed at a mean of 32 days after the stenting. They concluded that the strategy of carotid stenting before CABG did not positively influence the stroke risk.[66]

MYOCARDIAL ISCHEMIC EVENTS IN PATIENTS AFTER CAROTID ENDARTERECTOMY

Although this chapter is focused primarily on managing CABG patients who have concomitant carotid artery disease, some comment on the impact of CAD on short- and long-term risks of carotid endarterectomy patients is appropriate.

Incidence of Coronary Artery Disease in Carotid Endarterectomy Patients

Mackey and colleagues[67] found that 53% of carotid endarterectomy patients had evidence of CAD by clinical history or electrocardiographic studies. Using thallium exercise testing in 106 carotid endarterectomy patients, Urbinati and colleagues[68] found that 27 (25%) had significant defects on myocardial scanning. In 1985, the Cleveland Clinic reported the results of routine preoperative coronary angiography in 506 carotid endarterectomy patients.[69] Only 7% of patients had normal coronary arteries, and 28% had mild to moderate CAD. However, 30% had advanced but compensated disease, 28% had severe, correctable disease, and 7% had severe, inoperable CAD.

Risk of Myocardial Ischemic Events

Short-Term Risks

The impact of CAD on short-term risks of carotid endarterectomy is well documented. In 1981, Hertzer and colleagues[70] reported hospital mortality in 335 carotid endarterectomy patients of 1.8%; 60% of deaths were caused by CAD. In the Mackey study cited earlier, carotid endarterectomy patients with clinical CAD had an operative mortality of 1.5% and an MI rate of 4.3% compared with no mortality and an MI rate of 0.5% for patients without CAD.[67] Although the frequent coexistence of CAD with carotid disease is often invoked as a principal cause of short- and long-term morbidity in carotid endarterectomy patients, the risk of perioperative MI vary with the risk profile of the cohort studied. For example, in the protected carotid artery stenting versus endarterectomy trial, 30-day non-Q wave MI occurred in 6.6%.[51] In our cohort of more than 2000 carotid endarterectomy patients, the perioperative MI rate was 1.2%.[28] A National Surgical Quality Improvement Program (NSQIP) database report of more than 13,000 endarterectomy procedures had a perioperative MI rate of 1.4%,[71] similar to results from the ACST trial.[23] In the Society for Vascular Surgery registry study myocardial infarction occurred in less than 1% of carotid endarterectomies.[54] Clearly, improved care, mostly in the form of adjunctive medical therapy with beta blockers, statins and aspirin, has substantially lowered the risk of coronary ischemic events complicating carotid endarterectomy.

Long-Term Risks

Mackey's study of carotid endarterectomy reported the 5- and 10-year survival rates of patients with CAD to be 68.6 and 44.9%, respectively, versus 86.4 and 72.3% for patients with no CAD.[67] Urbinati and colleagues reported the 7-year freedom from all cardiac events after carotid endarterectomy was 51% for patients with silent myocardial ischemia versus 98% for patients with normal thallium exercise testing.[68]

In the Hertzer study of 209 patients with clinically suspected CAD, 5-year mortality rate for hospital survivors was 27%, and 37% of late deaths were caused by MI.[70] Actuarial survival at 11 years was significantly better for the patients with CAD who had bypass grafting. A later study from the same group of 329 carotid endarterectomy patients followed to 10 years confirmed that MI caused more late deaths (37%) than did stroke (15%).[72] Again, 10-year survival was significantly better for patients having CABG.

In our Massachusetts General Hospital cohort of more than 2000 carotid endarterectomy patients treated between 1990 and 1999, 10-year actuarial survival was 45%. Among variables associated with increased late mortality, concomitant CAD [odds ratio (OR) 1.4; $p = .0002$] figured prominently.[28]

TIMING OF CAROTID AND CORONARY ARTERY SURGERY

If one accepts that (1) uncorrected carotid stenosis increases the risk of stroke for patients with severe carotid and CAD who have only isolated CABG, (2) carotid endarterectomy is the indicated treatment for severe symptomatic and asymptomatic carotid stenosis, (3) CAD increases the early and late risk of death for carotid endarterectomy patients, and (4) CABG is an indicated treatment for CAD, then the important question becomes not the indication for but the timing of the two operative procedures.

Staged Carotid and Coronary Artery Operations

One approach is to perform the carotid endarterectomy and CABG operations as staged procedures. By convention, doing the carotid endarterectomy before coronary bypass grafting is referred to as a *staged procedure,* whereas doing the CABG before the carotid artery operation is called a *reverse staged procedure.*

Most advocates of a sequential operative approach to patients with severe combined disease usually do the carotid endarterectomy first if the patient is hemodynamically stable and not ischemic. Improvements in patient management, especially use of regional anesthesia, may allow safe initial isolated carotid endarterectomy. Data from several studies powered to detect an impact of regional anesthesia have verified that composite outcomes of stroke/death/ MI after carotid endarterectomy are reduced significantly with use of regional anesthesia.[37,71] Alternatively, a large randomized study concluded that regional anesthesia for carotid endarterectomy had no significant impact on perioperative myocardial infarction when compared with general anesthesia.[73] Depending on the timing of the two procedures, practical considerations, such as imminent need for the large doses of heparin required for cardiopulmonary bypass, airway and/or neck swelling, and the risk of perioperative coronary ischemic events, remain real issues.

For unstable cardiac patients, particularly those with asymptomatic carotid stenosis, some cardiac surgeons opt to perform initial myocardial revascularization followed by an interval carotid endarterectomy. The principal risk with this approach is the potential for neurologic complications either during or shortly after the myocardial revascularization.

Currently, we advocate concomitant carotid and coronary artery operations for virtually all patients with severe combined disease. However, in patients with severe bilateral carotid stenosis, a staged approach may be appropriate, especially if the patient is cardiovascularly stable. We occasionally treat the more severe of the two carotid artery lesions with initial isolated endarterectomy, followed by combined CABG and endarterectomy of the other carotid artery within a few days. Use of a reversed staged approach, namely, doing one carotid endarterectomy with myocardial revascularization followed several days later by the other carotid endarterectomy, is rare because of an increased stroke risk with reversed staged procedures (to be discussed below).

Concomitant Carotid and Coronary Artery Operations

In 1972, Bernhard and colleagues[74] published the first report of successful combined carotid endarterectomy and CABG in 15 patients. The strategy of performing both operative procedures during one anesthetic is based on the premise that such an approach to severe combined disease ought to minimize cardiac events that frequently complicate isolated carotid endarterectomy and neurologic events that complicate isolated CABG.

Daily and colleagues[75] reported that doing both operative procedures together is more cost effective than a staged or reversed staged approach, which require two anesthetics and can incur the additional costs of two hospitalizations.

OPERATIVE TECHNIQUES FOR CONCOMITANT CAROTID AND CORONARY ARTERY OPERATIONS

Standard Approach

The usual operative technique for concomitant carotid endarterectomy and CABG has been to perform the carotid endarterectomy during harvesting of CAD conduits before cardiopulmonary bypass, the approach we use at our institution, where the carotid operation is performed by vascular surgeons as the cardiac surgical team harvests whatever saphenous vein or other conduits may be needed.

Technical aspects of carotid endarterectomy have evolved. Preoperative aspirin has been validated in large database studies.[76] We use routine electroencephalographic monitoring, selective shunting, and either eversion endarterectomy (presuming no need for a shunt) or patch closure. Simple primary closure is associated with a higher rate of restenosis.[77,78] After the carotid endarterectomy is completed, the neck incision is

loosely approximated over a sponge. Final closure, usually over a plastic drain, is done after cardiopulmonary bypass is completed and heparinization is reversed.

Alternative Approaches

Minami and colleagues reported using some perceived advantages of cardiopulmonary bypass, namely, heparinization, hypothermia, and hemodynamic control, to perform carotid endarterectomy in 116 patients while on bypass for CABG.[79] Operative mortality was 1.7%, and total stroke risk was 4.3%. Weiss and colleagues perform the carotid endarterectomy on bypass with systemic hypothermia to 20° C with the heart protected with cardioplegia.[80] They had no neurologic events and one postoperative death in 23 patients. Theoretically, hypothermia on cardiopulmonary bypass provides an extra margin of ischemic protection for the brain during the carotid endarterectomy and avoids the need for intravascular shunting.

Whether performing the carotid and coronary artery operations on cardiopulmonary bypass saves total operative time is not proven, but it prolongs aortic occlusion and cardiopulmonary bypass times, something most cardiac surgeons would prefer to avoid. A deeper level of hypothermia is not favored by most cardiac surgeons, particularly as the trend toward using lesser degrees of hypothermia has become more popular.

HIGHLIGHTS OF POSTOPERATIVE MANAGEMENT

Our postoperative management of patients following concomitant carotid endarterectomy and CABG does not differ importantly from that of patients having isolated myocardial revascularization. We believe that maintenance of a good coronary perfusion pressure and, by extension, good cerebral perfusion pressure in the early postoperative hours is beneficial. Early clearing of perioperative edema with diuresis is efficacious.

The routine anticoagulation protocol for our myocardial revascularization patients, aspirin begun within 6 hours of completion of the operation, is also adequate for patients with concomitant carotid endarterectomy. Permanent aspirin therapy is indicated for both parts of the concomitant procedure.

If a surgeon decides not to treat a severe carotid stenosis either with a staged approach or concomitant operation, the increased incidence of stroke in the early days after isolated myocardial revascularization seen with the reversed staged approach suggests that heparinization is appropriate once the acute bleeding risk of the CAB operation is past.

RESULTS OF STAGED AND CONCOMITANT CAROTID AND CORONARY ARTERY OPERATIONS

Early Results

Staged Carotid and Coronary Artery Operations

Several studies report the results of staged operations for concomitant carotid and CAD, but only one study randomized patients to concomitant or reversed staged operation. Hertzer et al. randomized subgroup of patients with unstable coronary syndromes and incidental asymptomatic carotid stenosis.[81] Over 5 years they treated 275 patients with severe combined disease. Their criteria for carotid endarterectomy was symptomatic and/or severe (>70%) carotid artery disease. Only 24 (9%) of the patients had CAD that was stable enough to allow carotid endarterectomy before CABG. Of those 24 patients, 1 (4.2%) suffered a perioperative stroke after the carotid endarterectomy and died of an MI awaiting CABG. Symptomatic or severe bilateral carotid artery disease in 122 patients was treated with combined carotid and coronary artery operation with an operative mortality rate of 6.1% and a perioperative stroke rate of 7.1%.

The remaining 129 patients with unstable coronary symptoms and severe, unilateral, asymptomatic carotid stenoses were randomized to either a combined or a reversed staged operation. Patients having concomitant carotid and coronary operations had a mortality rate of 4.2% versus a combined rate of 5.3% for the two operations in the staged patients. Stroke rate in the concomitant operations was 2.8%, significantly lower than the 14% risk of the reversed staged operations (6.9% during the isolated CABG and 7.5% during the delayed isolated carotid endarterectomy). This randomized study emphasizes the advantage of concomitant operations over reversed staged procedures.

Several conclusions of this study were validated by a cumulative review from nearly 100 studies encompassing some 9000 patients. The authors noted that carotid endarterectomy very shortly after CABG was accompanied by an unacceptable stroke risk. They reported the stroke risk of the combined operation in their review was 4.6% and that of death/any stroke was 8.7%.[65] These data are similar to other large administrative database studies (stroke/death of 9.6% for combined operation), although such studies are inherently flawed because details for the procedures being staged or combined are often imprecise.[82]

In 1999, Borger and colleagues performed a meta-analysis of nonrandomized observational studies from centers reporting results with both staged and concomitant operations.[83] They identified a trend toward increased risk of stroke and death with combined operations. The results of this study need to be viewed with caution for several reasons. First, using meta-analysis to compare observational and nonrandomized studies limits its statistical power. Second, in most series, unstable patients had combined operations and stable patients had staged procedures. Third, the criterion for entry into these studies was operations completed, not intention to treat. Possibly some patients for whom a staged approach was planned were not studied because the second operation was never performed because of a poor result from the first procedure.

Concomitant Carotid and Coronary Artery Operations

Since the late 1970s, some surgeons in our group have taken an aggressive approach to patients with combined carotid and CAD, using concomitant operation as the standard approach. Staged operations were reserved for the patients with very stable CAD. Our first report in 1989 suggested that combined operation was safe (2% stroke or death risk). That study was among

the first to document the disparate cardiac risk among patients having combined operations versus patients having isolated CABG.[84]

In 1995 we published our results of combined operations between 1979 and 1993 in the first 200 consecutive patients.[85] Hospital mortality was 3.5%, MI 2.5%, and perioperative stroke 4.0%.

More recently, we published results of concomitant operation between 1979 and 2001 in 500 patients.[86] Mean patient age was 69 years, about 6 years older than that for all CABG patients. Three-quarters of the patients had unstable angina pectoris, and 53% had prior MI. Although the distribution of single-, double-, and triple-vessel disease was as expected at 4%, 21%, and 75%, respectively, 42% of patients had significant left main CAD. Of the 500 patients, 329 (66%) were neurologically asymptomatic, 21% had transient ischemic attacks, and 13% had a prior stroke. Unilateral severe carotid stenosis was found in 336 patients (67%); 32% had disease in the contralateral carotid artery.

Urgent or emergency operations were required in 54% of patients; 3% were on the intra-aortic balloon preoperatively. The average number of grafts per patient was 3.7. Although only 50% of the first 200 patients received at least one mammary artery graft, 90% of the last 300 patients received a mammary artery graft.

Hospital mortality was 3.6%, MI was 2.0%, and stroke occurred in 4.6%. Of the 23 strokes, 12 were ipsilateral to the carotid endarterectomy and 11 contralateral or bilateral, suggesting that, in our experience, concomitant carotid endarterectomy and CABG have neutralized the impact of carotid stenosis as a risk factor for stroke during surgical myocardial revascularization.

Significant multivariate predictors of hospital death were preoperative TIAs, preoperative MI, and nonelective operation. Peripheral vascular disease predicted postoperative stroke. Significant predictors of prolonged postoperative hospital stay were failure to use a mammary artery graft, perioperative stroke, and advanced age.

Vermeulen and colleagues found that the only significant multivariate predictor of hospital death in 230 combined operations was left main CAD.[87] Postoperative neurologic events were predicted by severe left ventricular dysfunction and preoperative neurologic events, either stroke or TIAs.

Series of concomitant carotid endarterectomy and CABG published since 1985 are in Table 23-2. These results contrast to reports using administrative data. Brown reported a 17.7% stroke risk for combined operations in Medicare patients in Midwestern states.[88] In a Canadian study the combined risk of stroke and death for CABG alone was 4.9% versus 13% for combined carotid and coronary artery operations.[89] However, data from the New York State Registry indicate that such results can be explained largely by the disparate cardiac risk profiles of the two patient groups. Ricotta and colleagues used propensity scoring to match risk-factor profiling and found no difference

TABLE 23–2 Series of Combined Carotid and Coronary Operations with More than 100 Patients

Reference	Year	Patients (No.)	Mean Age (Y)	Deaths (%)	MI (%)	Stroke (%)
Dunn[92]	1986	130	60	6 (4.6)	—	13 (10.0)

TOTAL		2763	65	123 (4.4)	37 (2.0)	131 (4.7)
Akins et al.[86]	2005	500	69	18 (3.6)	10 (2.0)	23 (4.6)

in combined stroke and death risk for the two operations after case-control matching.[11] Finally, Cywinski et al., using similar methodology for patient matching, reported in a Cleveland Clinic series of combined operations versus isolated CABG that overall morbidity was higher for the concomitant carotid and coronary operations. Of interest, their study endpoints, in which significant differences were noted between the two groups including overall morbidity and mortality, did not find a significant difference in the risk of stroke.[90]

Late Results

Follow-up in our series of combined operations revealed the following 10-year actuarial freedoms from late events: death, 43%; MI, 87%; percutaneous transluminal coronary angioplasty, 92%; reoperative myocardial revascularization, 96%; total stroke, 85%; and ipsilateral stroke, 90%.[86]

Vermeulen and colleagues found their 10-year actuarial freedom from cardiac events to be 50%, from neurologic events to be 81%, and from all events to be 41%.[87] The only significant multivariate predictors of late cardiac mortality were advanced age and severe left ventricular dysfunction.

In a study of 127 combined carotid and coronary operations, Rizzo et al. reported a 5-year survival rate of 70%, freedom from MI of 84%, and freedom from stroke of 88%.[91] Survival was worse for patients with low ejection fractions. Late strokes were fewer in patients who were neurologically asymptomatic preoperatively, more common in patients who were transiently symptomatic, and most frequent in patients with prior stroke.

CONCLUSION

The risk of perioperative stroke following myocardial revascularization rises with the increasing age of CABG patients, and increasing age is accompanied by an increased incidence of carotid artery disease. Several studies have defined severe, uncorrected carotid stenosis as a major risk factor for perioperative stroke. Patients with carotid bruits or a history of ischemic neurologic events, plus patients who are 65 years old or older ought to have noninvasive carotid artery evaluation before CABG. Randomized trials have established the safety and efficacy of carotid endarterectomy as the most appropriate treatment for both symptomatic and asymptomatic severe carotid stenosis. Another randomized study has demonstrated the advantage of concomitant carotid endarterectomy and CABG over reversed staged operations. Thus, we advocate combined carotid and coronary artery operations for virtually all patients with severe concomitant coronary and carotid artery disease, which on their own merits would require treatment.

CHAPTER 24

Myocardial Revascularization after Acute Myocardial Infarction

Isaac George
Mathew Williams

INTRODUCTION

The ability of surgical interventions to minimize myocardial loss after myocardial infarction has advanced dramatically over the past two decades. Acute myocardial infarction still afflicts approximately 1.5 million individuals each year in the United States,[1] and 30% of these patients die before reaching the hospital, whereas 5% die during hospital admission.[1] Prompt medical attention, including transport to the hospital, diagnosis, and treatment of the myocardial infarction, is critical to patient survival. Since 1989, the death rate from acute myocardial infarctions has declined 24%, while the actual number of deaths declined only 7%.[2] Over the last 40 years, especially during the 1980s, new pharmacologic agents, interventional cardiology procedures, and coronary artery bypass surgical techniques have advanced and have led to a decrease in the overall morbidity and mortality associated with acute myocardial infarction. Despite this overall improvement, mechanical and electrical complications such as cardiogenic shock, rupture of the ventricular septum or free wall, acute mitral regurgitation, pericarditis, tamponade, and arrhythmias challenge the medical community caring for patients presenting with acute myocardial infarction on a daily basis.[3] Of these complications, cardiogenic shock complicating acute myocardial infarctions has the most significant impact on in-hospital mortality and long-term survival. The loss of more than 40% of functioning left ventricular mass and its accompanying systemic inflammatory response are major causes of cardiogenic shock and are determined by the degree of preinfarction ventricular dysfunction, the size of the infarcted vessel, and pathologic level of inflammatory mediators.[4,5] Restoration of blood flow to the threatened myocardium offers the best chance of survival following acute coronary occlusion, but the means and timing of revascularization continue to be a highly debated and studied topic. Thrombolytics, percutaneous transluminal coronary angioplasty (PTCA), intracoronary stenting, and coronary artery bypass (CABG) surgery have decreased the mortality associated with acute myocardial infarctions. Advances in myocardial preservation and mechanical support lead the surgical armamentarium in the treatment of acute myocardial infarctions.

PATHOGENESIS OF ACUTE OCCLUSION

Myocardial ischemia resulting from coronary occlusion for as little as 60 seconds causes ischemic zone changes from a state of active systolic shortening to one of passive systolic lengthening.[6] Occlusions for less than 20 minutes usually cause reversible cellular damage and depressed function with subsequent myocardial stunning. Furthermore, reperfusion of the infarct leads to variable amounts of salvageable myocardium. After 40 minutes of ischemia followed by reperfusion, 60 to 70% of the ultimate infarct is salvageable, but this decreases dramatically to 10% after 3 hours of ischemia.[7,8] Animal model evidence has also demonstrated that 6 hours of regional ischemia produces extensive transmural necrosis.[9] The exact timing in humans is even more difficult to analyze because of collateral flow, which is a major determinant of myocardial necrosis in the area at risk in humans.[8] The collateral blood supply is extremely variable, especially in patients with long-standing coronary disease. However, collateral flow is jeopardized with arrhythmias, hypotension, or the rise of left ventricular end-diastolic pressure above tissue capillary pressure.[7] Thus loss of collateral flow to the infarct area may lead to the cellular death of

CARDIOGENIC SHOCK

Definition

Cardiogenic shock is defined clinically as a systolic blood pressure below 80 mm Hg in the absence of hypovolemia, peripheral vasoconstriction with cold extremities, changes in mental status, and urine output of less than 20 mL/h. Hemodynamic parameters for cardiogenic shock include cardiac index less than 1.8 L/min/m^2, stroke volume index less than 20 mL/m^2, mean pulmonary capillary wedge pressure greater than 18 mm Hg, tachycardia, and a systemic vascular resistance of over 2400 dyn·sec/cm^5. These patients are defined as type IV by the Killip classification, a widely used system to classify myocardial infarctions.[10]

Prevalence

Shock is the most common cause of in-hospital mortality after myocardial infarction.[11] The in-hospital mortality associated with cardiogenic shock has remained unchanged at approximately 80% despite the development of new treatment modalities.[12] Cardiogenic shock occurs in 2.4 to 12.0% of patients with acute myocardial infarction.[13] Since 1975, the incidence of cardiogenic shock complicating acute myocardial infarctions has remained constant at 7.5%, ranging between 5 and 15% (Fig. 24-1).[11] The progressive reduction in time delay from symptom onset to treatment may account for these constant figures. Previously, patients with excessive time delays would have died before reaching the hospital or soon thereafter, as it is known that treatment delays increase 1-year mortality exponentially (Fig. 24-2).[14]

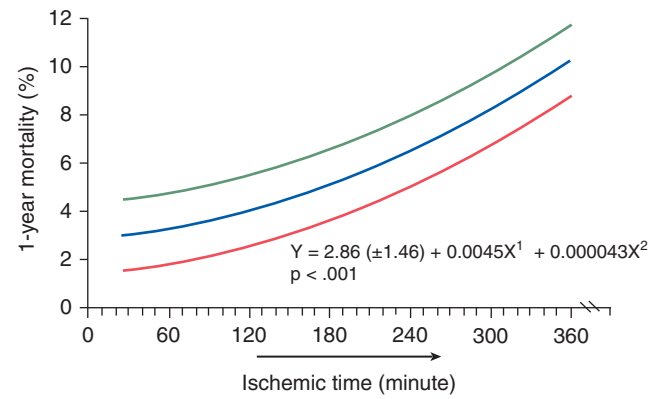

FIGURE 24-2 Relationship between time to treatment and 1-year mortality, as a continuous function, was assessed with a quadratic regression model. Dotted lines represent 95% confidence intervals of predicted mortality. (*Reproduced with permission from De Luca G, Suryapranata H, Ottervanger JP, et al: Time delay to treatment and mortality in primary angioplasty for acute myocardial infarction. Circulation 2004; 109:1223.*)

Pathophysiology and Infarct Size

Shock is directly related to the extent of the myocardium involved, and infarctions resulting in loss of at least 40% of the left ventricle have been found on autopsy in patients with cardiogenic shock.[4,15] Autopsy findings also revealed marginal extension of the recent infarct and focal areas of necrosis in patients with cardiogenic shock.[4] Extensive three-vessel disease is usually found in individuals with cardiogenic shock, and extension of the infarct is an important determinant in those individuals.[4,15] Limiting the size of the infarct and its extension is one of the key therapeutic interventions in patients with myocardial infarction.

MEDICAL MANAGEMENT OF MYOCARDIAL INFARCTION

The management of patients with acute myocardial infarctions demands expeditious treatment and decision making. With the ultimate goal of reperfusing the ischemic myocardium, treatment strategies should be directed toward reducing myocardial oxygen demand, maintaining circulatory support, and protecting the threatened myocardium before irreversible damage and expansion of the infarct occur.

Clinical assessment and risk stratification begins at triage during presentation, where electrocardiographic changes and cardiac biomarkers are used to identify patients suitable for revascularization versus medical management. At our center, clinical algorithms have been instituted to rapidly aid decision making.[16] Patients presenting with ongoing chest pain for more than 20 minutes and ST-segment elevation in two contiguous leads or new (or not known to be old) left bundle branch block *or* anterolateral ST depression are classified as having ST-segment Elevation Myocardial Infarction (STEMI). These patients are referred for primary percutaneous intervention in the cardiac catheterization suite 24 hours a day, 7 days a week, if no contraindications exist. The other group of patients, those with non–ST segment Elevation Myocardial Infarction (NSTEMI), present with chest pain at rest for 10 minutes or more and ST-segment depression greater than 0.5 mm or ST-segment elevation 0.6 to 1 mm or T-Wave inversions greater than 1 mm or positive troponin levels or a history of unstable angina in a patient with coronary artery disease risk factors. These patients are treated medically with a combination of antiplatelet therapy, intravenous heparin, and other traditional medications discussed in the following.

Both clinical and basic science research have demonstrated that reperfusion is the main treatment option for acute myocardial infarction. Unfortunately, the majority of patients with myocardial infarction receive only conservative medical management; only 40% of patients having an acute myocardial infarction receive thrombolytic therapy, the most common means of reperfusion.[17]

STATES OF IMPAIRED MYOCARDIUM

Coronary insufficiency can result in three states of impaired myocardium: infarcted, hibernating, and stunned. Each state requires separate clinical interventions and carries different prognostic implications. Infarcted myocardium is irreversible myocardial cell death owing to prolonged ischemia. Hibernating myocardium is a state of impaired myocardial and left ventricular function at rest resulting from reduced coronary blood flow and impaired coronary vasodilator reserve that can be restored to normal if a normal myocardial oxygen supply–demand relationship is reestablished.[18] Hibernating myocardium is defined as contractility-depressed myocardial function secondary to severe chronic ischemia that improves clinically immediately after myocardial revascularization. Stunned myocardium is left ventricular dysfunction without cell death that occurs after restoration of blood flow after an ischemic episode. If a patient survives the insult resulting from a temporary period of ischemia followed by reperfusion, the previously ischemic areas of cardiac muscle eventually demonstrate improved contractility (Table 24-2).

Hibernating Myocardium

Hibernation may be acute or chronic. Carlson and associates[31] showed that hibernating myocardium was present in up to 75% of patients with unstable angina and 28% with stable angina. The entity also occurs after myocardial infarction. Angina after myocardial infarction commonly occurs at a distance from the area of infarction.[19] In fact, mortality is significantly higher in patients with ischemia at a distance (72%) compared with ischemia adjacent to the infarct zone (33%).[19] It is the hibernating myocardium that may be in jeopardy and salvageable, although its presence is usually incidental to the occurrence of the acute infarction. By distinguishing between hibernating myocardium and irreversibly injured myocardium, a more aggressive approach to restoring or improving blood flow to the area at risk is reasonable. Function often improves immediately after revascularization of appropriately selected regions.

TABLE 24-2 States of Myocardial Cells after Periods of Ischemia

Condition	Viability of Cells	Cause of Injury	Return of Function
Infarcted	Nonviable	Prolonged ischemia	No recovery
Stunned viable	Limited ischemia	Delayed with reperfusion	Recovery
Hibernating	Viable	Ongoing ischemia	Prompt, sometimes unpredictable recovery

Stunned Myocardium

In the 1970s it was observed that after brief episodes of severe ischemia, prolonged dysfunction upon reperfusion with gradual return of contractile activity occurred. In 1982 Braunwald and Kloner[20] coined the phrase *stunned myocardium*. Stunning is a fully reversible process despite the severity and duration of the insult if the cells remain viable. However, myocardial dysfunction, biochemical alterations, and ultrastructural abnormalities continue to persist after return of blood flow. Within 60 seconds of coronary occlusion, the ischemic zone changes from a state of active shortening to one of passive shortening. Coronary occlusion lasting less than 20 minutes is the classic model reproducing the stunning phenomenon.[21] The most likely mechanisms of myocardial stunning are listed in Table 24-3.[21,22]

Stunned myocardium can occur adjacent to necrotic tissue after prolonged coronary occlusion and can be associated with demand-induced ischemia, coronary spasm, and cardioplegia-induced cardiac arrest during cardiopulmonary bypass. Clinically these regions are edematous, and even hemorrhagic, and can lead to both systolic and diastolic dysfunction.[23] They also have a propensity for arrhythmias, which can lead to more extensive ventricular stunning and hypotension with subsequent infarction of these regions.

Diagnosis of Viable Myocardium

Mechanisms to identify patients with myocardial stunning and hibernation include ECG findings, radionuclide imaging, positron emission tomography (PET), dobutamine echocardiography, and more recently magnetic resonance imaging (MRI). Thallium identifies perfusion-related defects of the myocardium and can distinguish between viable and scarred myocardium as well. However, early redistribution of thallium does not distinguish between hibernating and scarred myocardium because many segments with irreversible defects by thallium improve after reperfusion. Redistribution imaging and reinjection imaging improve the predictive value of thallium imaging in distinguishing hibernating myocardium.

PET measures the metabolic activity of myocardial cells. It has high positive and negative predictive values. It is now regarded as the best method to determine myocardial viability, particularly in patients with severe left ventricular dysfunction in whom other modalities are less accurate.[24]

Dobutamine echocardiography identifies hibernating and stunned myocardium by monitoring changes in segmental wall motion while the heart is stressed inotropically and chronotropically by dobutamine infusion. It has high specificity, sensitivity, and, more importantly, positive predictive value.[25]

MRI has also been established as an effective method to assess hibernating myocardium.[26] It has been proved to accurately diagnose the degree of both acute and chronic myocardial infarction and predict functional recovery.[27,28] A number of advantages exist with cardiac MRI, such as superior image resolution allowing accurate indentification of transmural infarction (Fig. 24-3). By providing morphologic, functional, and metabolic information, it may ultimately supplant other modalities for the diagnosis of cardiac injury and recovery.

Finally, multislice computed tomography has been used to measure hibernating myocardium, and early data suggest it may be a reliable and sensitive method compared with MRI, although its use in clinical practice is limited.[29]

RATIONALE FOR AGGRESSIVE MANAGEMENT OF MYOCARDIAL INFARCTION

Randomized trials have shown beneficial effects of early reperfusion within 12 hours and possibly up to 24 hours after acute myocardial infarction.[10,12,30,31] Early reperfusion clearly reduces infarct size in the major areas at risk. Controlled reperfusion may even be superior. The arguments are more difficult to make for patients outside the 24-hour window; however, patients with ongoing ischemia often have ischemic border regions that are prone to arrhythmias and necrosis. In addition, these patients are at risk for prolonged periods of hypotension with resulting end-organ injury and further left ventricular dysfunction. Even if revascularization does not appear critical, ventricular unloading with IABP or LVAD may provide the bridge to recovery needed in patients dying after myocardial infarction. The major limiting factors to aggressive surgical management are major comorbidities, which make continuation of life undesirable or unlikely, and an unclear neurologic status, especially after a period of cardiopulmonary arrest.

REPERFUSION

Although restoration of blood flow to ischemic regions is essential, the accompanying reperfusion injury initially can worsen rather than improve myocardial dysfunction. The area at risk is affected not only by reperfusion but also by the conditions of reperfusion and the composition of the reperfusate.[32] Thus controlling reperfusion itself may aid in reducing myocardial infarct size and ventricular injury.

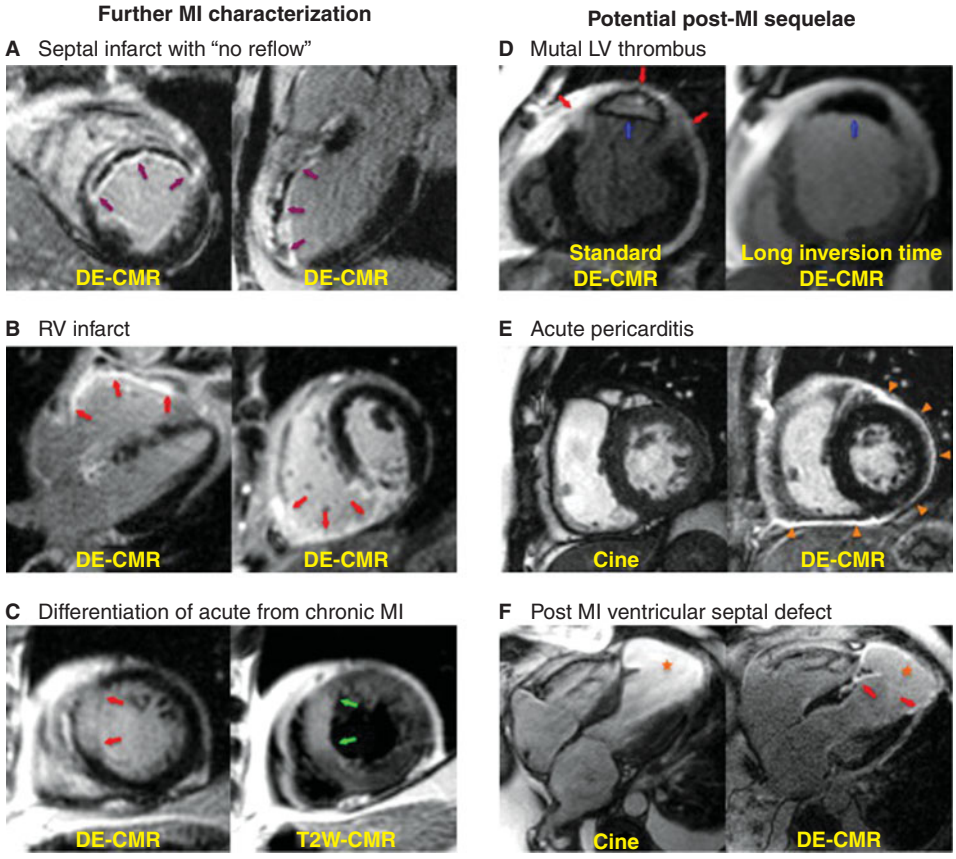

FIGURE 24-3 Cardiovascular MRI (CMR) characterization of myocardial infarction (MI) and post-myocardial infarction sequelae. Examples are shown of patients with myocardial infarction complicated by the presence of (A) microvascular damage (no reflow, *purple arrows*), and (B) right ventricular involvement (*red arrows*). (C) Acute infarcts (*red arrows*) can be differentiated from chronic infarcts by the use of T2-weighted imaging, which can show increased signal in areas of acute necrosis (*green arrows*). (D) Post-MI sequelae such as mural thrombus (*blue arrows*) can be identified by delayed-enhancement-CMR. Long-inversion-time imaging may improve detection because the image intensity of viable myocardium is gray rather than black. Thrombus is often immediately adjacent to infarcted myocardium (*red arrows*). (E) Acute pericarditis can be diagnosed by the presence of hyperenhanced pericardium (*orange arrowheads*). (F) CMR image may be used to define ventricular septal defect location (*orange stars*), extent of associated infarction (*red arrows*), and severity of shunting. (*Reproduced with permission from Kim HW, Farzaneh-Far A, Kim RJ: Cardiovascular magnetic resonance in patients with myocardial infarction. J Am Coll Cardiol 2010; 55:1-16.*)

At the cellular level, myocardial ischemia results in a change in energy production from aerobic to anaerobic metabolism. The consequences of ischemia vary from decreased adenosine triphosphate production and increased intracellular calcium to decreased amino acid precursors such as aspartate and glutamate. These changes can be reversed only by reperfusion.

However, as oxygen is reintroduced into a region, oxygen free radical generation ensues with resulting cellular damage. Cellular swelling and/or contracture leads to a "no-reflow phenomenon" that limits the recovery of some myocytes and possibly adds to irreversible injury of others. The production of oxygen free radicals during ischemia and at the time of reperfusion is the leading mechanism proposed to explain cellular injury. Four basic types of reperfusion injury have been described: lethal cell death, microvascular injury, stunned myocardium, and reperfusion arrhythmias (Table 24-4).

Buckberg and coworkers[33–38] conducted studies of controlled reperfusion after ischemia and produced a clinical application for controlled reperfusion. The surgical strategy of controlled

TABLE 24-4 Potential Types of Reperfusion Injury

Lethal	Cell death secondary to reperfusion
Vascular	Progressive damage causes an expanding zone of "no reflow" and deterioration of coronary flow reserve during the phase of reperfusion
Reperfusion arrhythmias	Arrhythmias, mainly ventricular, that occur shortly after reperfusion
Stunned myocardium	Postischemic ventricular dysfunction

Source: Modified with permission from Kloner RA: Does reperfusion injury exist in humans? J Am Coll Cardiol 1993; 21:537.

reperfusion, especially as espoused by Buckberg and associates, includes several elements. First, extracorporeal circulation is established as expeditiously as possible with venting of the left ventricle as required. Initially, antegrade cardioplegia is delivered using either a warm Buckberg solution to rebuild adenosine triphosphate stores or cold high-potassium cardioplegia to achieve rapid diastolic arrest. We routinely add retrograde cardioplegia to ensure global cooling, even in areas of active ischemia. The temperatures of the anterior and inferior walls of the ventricle are measured to ensure adequate cooling. After each distal anastomosis, cold cardioplegia is infused into each graft and the aorta at 200 mL/min over 1 minute. This is followed by retrograde infusion through the coronary sinus for 1 minute. After completion of the final distal anastomosis, warm substrate-enriched blood cardioplegia is given at 150 mL/min for 2 minutes into each anastomosis and the aorta. After removal of the aortic cross-clamp, regional blood cardioplegia is given at 50 mL/min into the graft supplying the region at risk for 18 minutes. This controlled rate of reperfusion minimizes cellular edema and myocyte damage. The proximal vein grafts are then completed, followed by reestablishment of normal blood flow. To decrease oxygen demand, the heart is allowed to beat in the empty state for 30 minutes. After this time, the patient is weaned off bypass.

Application of the Buckberg solution and technique has been shown to be effective in improving mortality rates and myocardial function after acute coronary occlusion. With ischemic times averaging 6 hours, a prevalence of multivessel disease, and cardiogenic shock, the overall mortality in patients with acute coronary arterial occlusions who underwent surgical revascularization applying this method of reperfusion was 3.9%. Postoperative ejection fractions averaged 50%.[39] Surgical revascularization in this series using controlled reperfusion compared favorably with PTCA in several large series. The superior results of this method for the treatment of cardiogenic shock, a 9% mortality, have brought this method to the forefront in the treatment of cardiogenic shock.

Methods of Reperfusion

Role of Thrombolytic Therapy

Because myocardial salvage depends on reperfusion of occluded coronary arteries, rapid dissolution of an occluding thrombus with thrombolytic therapy is an appealing intervention. Intracoronary streptokinase in patients with acute myocardial infarction demonstrates that thrombolytic therapy is a safe and efficient way to achieve the desired early reperfusion.[40] Following this study, a number of multi-institutional megatrials showed the effectiveness of thrombolytic therapy in treating acute myocardial infarctions.

The trial of the Italian Group for the Study of Streptokinase in Myocardial Infarction (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardio, [GISSI])[41] and the Second International Study of Infarct Survival [ISIS-2])[42] found a reduced hospital mortality in patients treated with streptokinase. The effectiveness of tissue-type t-PA also has been evaluated in randomized studies. The Thrombolysis in Myocardial Infarction (TIMI) study[43] and the European Cooperative Study Group (ECSG)[44] demonstrated the effectiveness of t-PA for the treatment of acute myocardial infarction.

When streptokinase and t-PA were compared, two studies failed to demonstrate any difference in mortality.[45,46] A third study, however, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, supported the use of t-PA by demonstrating a more rapid and complete restoration of coronary flow that resulted in improved ventricular performance and reduced mortality.[47,48]

Although thrombolysis improves survival and ventricular function, the patency of infarct-related arteries is reported to be between 50 and 85%.[41–48] Normal flow should be achieved in 60% of patients by today's standards. Thrombolytic therapy works well but is not without complications, including bleeding and intracranial hemorrhage.[49] Bleeding is usually minor and occurs mostly at the sites of vascular puncture. Intracranial hemorrhage and stroke rates are around 1% and are an "acceptable" risk. The relative benefits of thrombolytic therapy appear to decrease as patient age increases, and a higher risk of intracranial hemorrhage in the elderly may partially account for these findings.[47,50,51] Careful selection of patients suitable for fibrinolytic therapy is warranted, especially in an increasingly older population.

Cardiogenic Shock

Thrombolytic therapy for patients presenting in cardiogenic shock or heart failure does not appear to improve survival in this population but may decrease the incidence of patients developing heart failure after myocardial infarction.[52]

Summary

Thrombolytic agents for the treatment of myocardial infarction have demonstrated several important points. Survival is improved by decreasing time to reperfusion. The GUSTO trial showed that patients treated within the first hour had the greatest improvement in survival, with a 1% reduction in mortality for each hour of time saved.[47,48] Thrombolytic therapy is easy to administer in the community by trained personnel, although a significant risk of bleeding exists in certain patients. Because the time to reperfusion is a critical element in preserving myocardium, thrombolytic therapy is ideal for most communities without percutaneous interventional capabilities. In this setting, thrombolytics may be used for treatment of patients with acute myocardial infarction.

Role of Percutaneous Transluminal Coronary Angioplasty

Since the first reported use of PTCA by Gruntzig and associates[74] in 1979, the efficacy of this procedure in the treatment of coronary artery disease has been well recognized. A number of studies have evaluated the efficacy of primary PTCA in the treatment of acute myocardial infarction. Overall, PTCA hospital mortality rates range from 6 to 9%.[53–56]

Several different strategies employing PTCA for acute myocardial infarction have been developed and examined through

clinical trials. Primary, rescue, immediate, delayed, and elective PTCA are options for the treatment of acute myocardial infarction. Primary PTCA uses angioplasty as the method of reperfusion in patients presenting with acute myocardial infarction. Rescue, immediate, delayed, and elective PTCA all are done in conjunction with or following thrombolytic therapy. Rescue PTCA is done after recurrent angina or hemodynamic instability after thrombolytic therapy. Immediate PTCA is performed in conjunction with thrombolytic therapy, and delayed PTCA occurs during the intervening hospitalization. Finally, elective PTCA is done following thrombolytic therapy and medical management when a positive stress test is obtained during the same hospitalization or soon thereafter.

Primary PTCA functions in several roles for the treatment of acute myocardial infarctions. Because there are some absolute and relative contraindications to thrombolytics, PTCA is the one of best methods of reperfusion in patients with acute myocardial infarction, according to studies that evaluated PTCA as first-line therapy. Several studies evaluated the role of PTCA compared with thrombolytic therapy. The first study, the Primary Angioplasty in Myocardial Infarction Study Group trial in 1993, concluded that immediate PTCA without thrombolytics reduced occurrence of reinfarction and death and was associated with a lower rate of intracranial hemorrhage.[53] Since then, more than 20 studies have compared PTCA to thrombolysis. The results from these studies have consistently and conclusively demonstrated the superiority of PTCA to thrombolysis, regardless of the thrombolytic agent used. The findings include a lower short-term mortality rate, lower rates of reinfarction, reduced stroke and intracranial hemorrhage rates, and a decreased composite end point of death, reinfarction, and stroke.[57] These findings have been reconfirmed on long-term follow-up. A higher overall rate of bleeding was observed, likely because of vascular access complications. Myocardial salvage is similar for PTCA and thrombolytic therapy. However, primary PTCA may be slightly less costly than thrombolytic therapy.[54]

There are limits to the use of primary PTCA. Logistic and economic constraints apply to invasive modes of therapy. Catheterization laboratories and personnel must be ready at all times. This is not practical in most communities, and transportation to tertiary care centers raises costs considerably.

Intracoronary Stents

The use of intracoronary stents after myocardial infarction has expanded as PTCA has become more prevalent. Benefits of stenting include lowered rates of restenosis and abrupt closure, and a reduced need for target revascularization after PTCA. Although the STENT-PAMI trial in 1999 using first-generation stents showed lower restenosis rates compared with thrombolysis, a trend toward higher mortality was seen, and its effectiveness as first-line therapy was questioned.[58] Composite end points of death, reinfarction, and urgent target vessel revascularization at 30 days have now been shown to be lower in subsequent studies, such as the CADILLAC, ISAR-2, and ADMIRAL trials, which employed newer-generation stents.[59–61] In these trials, abciximab, a glycoprotein IIb/IIIa inhibitor, was added to primary stenting. A striking reduction in restenosis rates with stenting plus abciximab versus PTCA alone was evident at 12-month follow-up in the CADILLAC study (41 versus 22%).[59] Current data suggest that stenting combined with antiplatelet therapy provides superior benefit to PTCA alone. Drug-eluting stents offer the potential to lower restenosis even further through the use of anti-inflammatory medication delivered via the stent. Most recently, patients in the STRATEGY trial treated with drug-eluting stents after acute ST-elevation myocardial infarction (STEMI) had a significantly lower composite end point of death, reinfarction, stroke, and angiographic evidence of restenosis at 8-month follow-up compared with bare-metal stenting plus abciximab (50 versus 19%).[62] Using propensity score matching, retrospective analysis of patients post acute myocardial infarction in Massachusetts has shown a slight 2-year mortality benefit for drug-eluting stents when compared with bare-metal stents (10.7 versus 12.8%), as well as a lower need for repeat revascularization.[63] Further prospective studies are under way to determine if long-term data confirm these findings.

Antithrombotic agents continued for 12 to 18 hours after PTCA and stenting are an important adjunctive therapy to prevent further ischemic complications. Traditional agents, such as heparin, have been replaced by glycoprotein IIb/IIIa inhibitors, which may have survival benefit when used after PTCA.[64] Newer agents, such as direct thrombin inhibitors, have been introduced with the hope of reducing bleeding and/or heparin-associated complications. The Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI)[65,66] trial investigated bivalirudin, a direct thrombin inhibitor, versus heparin plus a glycoprotein IIb/IIIa inihibitor for use after primary PTCA with or without stenting. Both 30-day and 1-year outcomes revealed decreased hemorrhagic events, and 1-year cardiac mortality was lower in patients treated with bivalirudin, despite a higher 24-hour risk of stent thrombosis in the bivalirudin cohort. Concerns regarding increased thrombogenicity with drug-eluting stents persist; further research is warranted to ensure that late in-stent thrombosis does not preclude use in this setting. Intracoronary stenting with adjunctive antiplatlelet medications has been embraced by the medical community for off-label use after acute myocardial infarction since its recent introduction.

Cardiogenic Shock

Primary PTCA may play a greater role in patients presenting in cardiogenic shock, and percutaneous interventions have become more common over the past 10 years (Fig. 24-4). The GISSI-1 and GISSI-2 trials demonstrated no benefit from intravenous thrombolysis, with mortality rates of 70%.[41,45] In patients presenting in or developing cardiogenic shock after acute myocardial infarction, PTCA improved survival to 40 and 60%.[67] This improvement was even greater when angioplasty was successful; in-hospital survival rates increased to 70%. In most of these series an IABP was used in conjunction with PTCA. The SHOCK trial showed that revascularization by PTCA or CABG within 12 hours of the onset of cardiogenic shock results in improved 1- and 6-year survival rates versus medical stabilization followed by delayed revascularization (32.8 for PTCA/CABG versus 19.6% for initial medical stablization, 6-year follow-up)

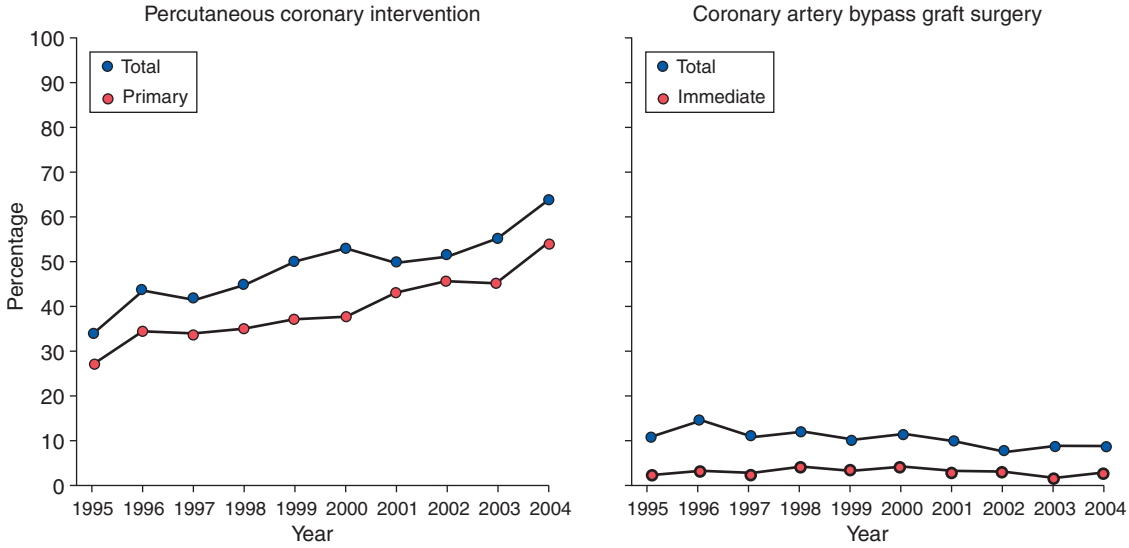

FIGURE 24-4 Survival estimates for early revascularization (n = 152) and initial medical stabilization (n = 150) groups in the SHOCK trial. Log-rank test, p = .03. in this high-risk group, particularly for those under the age of 75 years (Fig. 24-5).[12,30,31] Subgroup analysis in patients undergoing successful PTCA or with TIMI Grade 3 coronary flow after PTCA in the SHOCK trial revealed that 1-year survival was even higher, at 61%.[68] Independent predictors of mortality include age, hypotension, lower TIMI flow, and multivessel PTCA.

Summary

Primary PTCA or intracoronary stenting should be performed as first-line therapy in patients with acute myocardial infarction and those with contraindications to thrombolytic therapy. Patients with established or developing cardiogenic shock should be revascularized early by PTCA or stenting rather than initial medical stabilization by thrombolytic therapy. Specialized centers that have 24-hour catheterization facilities can provide primary PTCA or stenting as a first-line therapy. Rescue PTCA after failed thrombolytic therapy for patients with ongoing ischemia or clinical compromise is also recommended. Finally, elective PTCA should be performed on patients who have recurrent or provokable angina before hospital discharge.

Role of Coronary Artery Bypass Grafting

The role of surgical revascularization in the treatment of acute myocardial infarction has changed considerably over the past 30 years. Improvements in intraoperative management and myocardial preservation techniques have strengthened the surgeon's armamentarium. However, the development and use of thrombolytic therapy and PTCA offer effective alternatives to surgery.

During the 1980s, reports appeared recommending surgical revascularization in preference to medical therapy for acute myocardial infarction.[69,70] Mortality rates under 5% were reported. Critics argued that these studies lacked randomization or consecutive entry of patients, preoperative stratification was absent, and enzyme levels were not included. Inherent bias that favored surgery in low-risk patients was believed to be the reason for the excellent outcomes.[71]

At the time these reports surfaced, thrombolytic therapy and interventional cardiology were emerging as alternative options for acute infarction. With the availability of thrombolytics and PTCA, large multicenter trials began looking at the efficacy and usefulness of these two techniques. Randomized trials using CABG were not done, and thus this option was never established as an alternative for acute myocardial infarction.

However, several centers continued to use surgical revascularization to treat acute myocardial infarction. Excellent results

were achieved by coordinated community and hospital systems. However, practical, logistic, and economic constraints relegate surgical revascularization to a third option behind thrombolytics and PTCA for the primary treatment of acute myocardial infarction.

There continue to be several scenarios that require emergent or urgent surgical revascularization. Failure of thrombolytics, PTCA, or intracoronary stenting with acute occlusion may require surgical intervention. Additionally, CABG for postinfarction angina has become a critical step in the pathway of treating acute myocardial infarction. Finally, surgical revascularization may be indicated in patients with multivessel disease or left main coronary artery disease developing cardiogenic shock after myocardial infarction.

Timing after Infarction

If surgical revascularization within 6 hours after the onset of symptoms is feasible, the mortality rate is improved over that of medically treated, nonrevascularized patients.[69,70] Although these early studies were not controlled and were criticized for selection bias, they did demonstrate that surgical revascularization may be performed with an acceptable mortality in the presence of acute myocardial infarction with improved myocardial protection, anesthesia, and surgical techniques. However, with the advent of thrombolytic therapy, PTCA, and an aging population, the surgical patient we encounter today bears little resemblance to the patient population represented in these early data.

Recent analyses of the New York State Cardiac Surgery Registry, which included every patient undergoing a cardiac operation in the last decade in the state of New York, resulted in valuable information regarding the optimal timing of CABG in acute myocardial infarction. In this large and contemporary patient population, there is a significant correlation between hospital mortality and time interval from acute myocardial infarction to time of operation, particularly if CABG was performed within 1 week of acute myocardial infarction. In addition, patients with transmural and nontransmural acute myocardial infarction have different trends in mortality when the time course is taken into consideration. Mortality for the nontransmural group peaked if the operation was performed within 6 hours of acute myocardial infarction, and then decreased precipitously (Table 24-5).[72] On the other hand, mortality for the transmural group remained high during the first 3 days before returning to baseline.[73] Multivariate analyses confirmed that CABG within 6 hours for the nontransmural group and 3 days for the transmural group were independently associated with in-hospital mortality.[72,73] Optimal timing of CABG in patients with acute myocardial infarction is a controversial subject. Early surgical intervention has the advantage of limiting the infarct expansion and ventricular remodeling that may result in possible ventricular aneurysm and rupture.[74] However, there is the theoretical risk of reperfusion injury, which may lead to hemorrhagic infarction resulting in extension of infarct size, poor infarct healing, and scar development.[75] The data from these studies caution against early revascularization, particularly among patients with transmural acute myocardial infarction within 3 days of onset.

TABLE 24-5 Comparison of Hospital Mortality with Respect to Time of Surgery—Transmural Versus Nontransmural Myocardial Infarction

	Mortality	
Time between CABG and MI	Transmural MI (%)	Nontransmural MI (%)
<6 h	14	13
6-23 h	14*	6*
1-7 d	5	4
>7 d	3	3

*p <.01 nontransmural versus transmural.

Some have advocated the use of mechanical support to stabilize and allow elective rather than emergent surgery.[76,77] Using mechanical support "prophylactically" instead of CABG to improve outcome, however, would require placement of such support in many unnecessary cases. If revascularization cannot be delayed, aggressive mechanical support (such as an LVAD) must be available because mortality is most likely a result of pump failure. Furthermore, mechanical circulatory support has been shown to be efficacious as a bridge to ventricular recovery or transplantation for this patient cohort.[77] Although emergent cases such as structural complications and ongoing ischemia clearly cannot be delayed, nonemergent cases, particularly patients with transmural acute myocardial infarction, may benefit from delay of surgery. Early surgery after transmural acute myocardial infarction has a significantly higher risk and surgeons should be prepared to provide aggressive cardiac support including LVADs in this ailing population. Waiting in some cases may be warranted.

Risk Factors

In addition to timing of surgery as discussed in the preceding, risk factors include urgency of the operation, increasing patient age, renal insufficiency, number of previous myocardial infarctions, hypertension,[78] reoperation, cardiogenic shock, depressed left ventricular function, and the need for cardiopulmonary resuscitation, left main disease, female gender, left ventricular wall motion score, IABP, and transmural infarction.[79] Characteristics associated with better outcome early after myocardial infarction include preservation of left ventricular ejection fraction, male gender, younger patients, and subendocardial versus transmural myocardial infarction.

Cardiogenic Shock

Surgical revascularization in acute myocardial infarction complicated by cardiogenic shock has been shown to improve

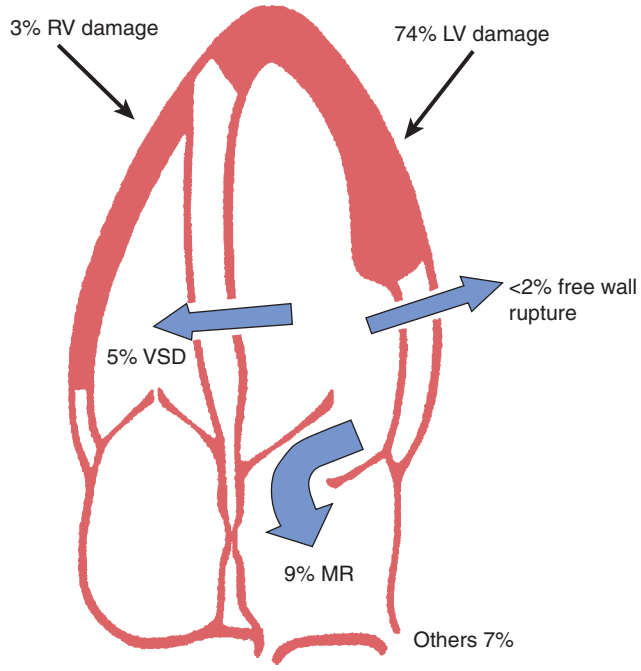

FIGURE 24-6 Mechanisms of cardiogenic shock. Apical four chamber echo view with relative incidence of the mechanisms responsible for cardiogenic shock in the SHOCK and MILIS 4 registries. Circulation 2005; 112:1992.*)

survival. Cardiogenic shock, as discussed earlier, is accompanied by 80 to 90% mortality rates; various mechanisms of cardiogenic shock are shown in Fig. 24-6. DeWood and colleagues[80] were the first to demonstrate improved results with revascularization in patients with cardiogenic shock complicating acute myocardial infarction. Patients who were stabilized with an IABP and underwent emergent surgical revascularization had survival rates of 75%. Early surgical revascularization is associated with survival rates of 40 to 88% in patients in cardiogenic shock resulting from nonmechanical causes. Guyton and coworkers[81] reported an 88% in-hospital survival and a 3-year survival of 88%, with no late deaths reported. Furthermore, the SHOCK trial demonstrated survival benefit in early revascularization by CABG or PTCA within 12 hours of the diagnosis of cardiogenic shock for patients of all ages.[30,31] Patients comprising the CABG cohort in the SHOCK trial had more severe disease, with higher rates of three-vessel disease, left main coronary artery disease, diabetes, and elevated mean coronary jeopardy scores than the PTCA cohort.[82] Despite this, 87.2% of these patients achieved successful *and* complete revascularization with CABG, compared with successful revascularizaton in 77.2% with PTCA and only 23.1% with complete revascularization with PTCA. Overall, mortality was no different between groups at 1 year (Fig. 24-7). On subgroup analysis, patients older than age 75, with left main coronary disease or three-vessel disease, or with diabetes had trends toward better survival at 30 days and 1 year after CABG compared to PTCA. Thus, for patients in cardiogenic shock, surgical revascularization has become an established and viable option for select patient groups.

Advantages of Coronary Artery Bypass Grafting

Reported survival rates are similar for CABG and PTCA in the treatment of acute myocardial infarction. To date there have been no large randomized clinical trials comparing CABG with PTCA and thrombolytics after myocardial infarction. For patients with stable angina and elective revascularization for ischemic heart disease, a number of trials have been conducted comparing CABG with stenting.[83–86] In these studies, trends

favoring CABG for multivessel disease were seen after 2 years in composite cardiac event end points, rate of reinfarction, and mortality; revascularization rates were five times higher in the stenting groups.[87] Most notably, survival after CABG for two or more diseased vessels was significantly higher than stenting with 2-year follow-up in a retrospective study of the New York State Cardiac Surgery Reporting System and Percutaneous Coronary Intervention Reporting System.[88] These results must be interpreted with caution, however, as patients with acute infarctions less than 24 hours pretreatment were excluded. Because of the lack of prospective, randomized trials, recommendations must be based on retrospective and observational studies. CABG offers several potential advantages. First, surgical revascularization is the most definitive form of treatment of the occlusion. CABG offers the longest patency of revascularized stenotic and occluded arteries in elective cases; 90% of internal mammary artery grafts are patent at 10 years. Second, CABG also offers more complete revascularization, because all vessel lesions are treated. This concept becomes especially important in patients with multivesssel disease or those in cardiogenic shock, in whom remote myocardium may continue to be comprised with only "culprit vessel" revascularization and inadequate restoration of collateral flow.[89] A complete revascularization returns global myocardial perfusion to normal levels and offers the best chance for myocardial salvage. Third, difficult distal obstructions can be reached. Fourth, there is controlled reperfusion to reverse ischemic injury and reduce reperfusion injury. Fifth, as with other forms of reperfusion, CABG interrupts the progression of ischemia and necrosis and limits infarct size.

Disadvantages of Coronary Artery Bypass Grafting

Disadvantages of immediate surgical revascularization include the high mortality associated with early CABG. Off-pump procedures may reduce perioperative complications in high-risk patients, but are not yet widely practiced and have limitations.[90] Rapid availability of catheterization and operating room personnel for emergency procedures imposes logistic and economic constraints. Thus, CABG is not readily applicable to the vast majority of patients in the community, and to provide this would strain health care resources. Second, it is difficult to analyze published results of CABG for acute myocardial infarction because randomized trials have not been done. Comparisons thus far have used medically treated patients as controls. Patients in the surgical group may be at lower risk; this might explain their progression to operation rather than continuing medical treatment. Crossover of patients from medical to surgical treatment also may have skewed the data.

Summary

Surgical revascularization following acute myocardial infarction can be performed with excellent results when the timing and patient cohort are appropriate. Most patients do not need such measures and would not benefit from this aggressive form of therapy. However, patients with mechanical complications, those in cardiogenic shock, and those with postinfarction angina are likely to benefit from early CABG.

USE OF THE INTRA-AORTIC BALLOON PUMP

The early use of aortic counterpulsation with an intra-aortic balloon pump (IABP) demonstrated the safety but not efficacy of this device for patients in cardiogenic shock following acute myocardial infarction.[91] Although survival was not improved, aortic counterpulsation did improve the myocardial oxygen requirements and myocardial energetics were reduced in patients in shock. The use of IABP is also effective for temporary hemodynamic stabilization in complications of acute myocardial infarction, such as ventricular septal rupture acute mitral valve insufficiency,[92] postinfarct angina,[93] ventricular arrythmias,[94] and acute heart failure following infarction.[95] As revascularization techniques for the repair of occluded coronary arteries of patients in cardiogenic shock have improved, use of aortic counterpulsation has found a role as an adjuvant to treatment protocols.

IABP counterpulsation in combination with early reperfusion is effective in the treatment of acute myocardial infarction complicated by cardiogenic shock.[80,96] Although the major improvement in survival is caused by early reperfusion, patients who had combined reperfusion and IABP additionally have improved long-term survival. IABP improves circulatory physiology and decreases end-organ damage in the early shock period before the myocardium is reperfused and recovers function.

Aortic counterpulsation decreases the reocclusion rate, recurrent ischemia, and need for emergency PTCA in patients who have coronary artery patency established by emergency cardiac catheterization after acute myocardial infarction.[97] Prophylactic counterpulsation for 48 hours sustains patency in coronary arteries after patency is reestablished after myocardial infarction. No increase in vascular or hemorrhagic complications is observed as compared with controls.[97]

Weaning from the IABP should take place only after there is clear evidence of myocardial and end-organ recovery. In general, inotropic requirements should be reduced first to minimize myocardial stress. The one exception is the development of limb ischemia resulting from the IABP catheter.

ROLE OF CIRCULATORY ASSIST

Circulatory support devices are reserved for patients who are hemodynamically unstable; however, intervention should not be delayed until after irreversible end-organ injury occurs. This group of shock patients has a mortality rate of 80%, and survival data with the use of assist devices reflect the critical condition of patients treated. Mortality rates have changed very little in the last 20 years despite improvements in medical and surgical therapy.

Patients in cardiogenic shock who are candidates for circulatory assist devices may be divided into two groups: individuals who have stunned myocardium and need a bridge to recovery, and those who have irreversible myocardial damage and need a bridge to cardiac transplantation. For example, if a patient with a previously normal ventricle develops a large myocardial infarction, we prefer short-term support, because enough recovery may occur to allow a fruitful existence with the native heart.

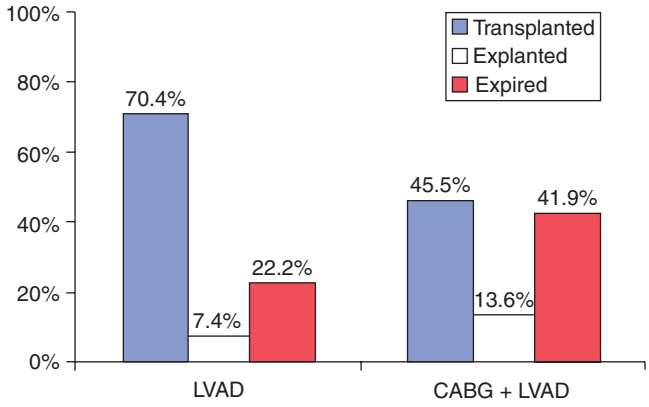

FIGURE 24-8 Outcomes of direct left ventricular assist device (LVAD) implantation versus coronary artery bypass graft (CABG) followed by LVAD implantation for cardiogenic shock. (*Reproduced with permission from Dang NC, Topkara VK, Leacche M, et al: Left ventricular assist device implantation after acute anterior wall myocardial infarction and cardiogenic shock: a two-center study. J Thorac Cardiovasc Surg 2005; 130:693.*)

However, if a patient with preexisting heart failure has another infarction, the need to definitively bridge the patient to transplant with a long-term implantable device is apparent. This approach is supported by results from a multicenter study, in which overall survival at 6 and 12 months was higher in patients who underwent direct LVAD implantation rather than revascularization followed by LVAD, in patients suffering cardiogenic shock (Fig. 24-8).[98] Difficulty arises in assessing the results of mechanical assistance for patients after acute myocardial infarction and cardiogenic shock because of these different objectives.

Mechanical assist devices augment systemic perfusion and prevent end-organ damage while resting the stunned ventricle with complete or partial pressure-volume unloading.[99] Early studies of implantable LVADs have shown that end-organ function is an early predictor of mortality. Treatment of patients before end-organ deterioration is essential to improving the odds for long-term survival. In addition to affecting end-organ function, assist devices promote "reverse remodeling" by improving myocardial contractility and calcium handling, altering the extracellular matrix, and decreasing myocardial fibrosis.[100,101] Recent studies have shown that circulatory support early after myocardial infarction improved survival and offered a feasible bridge to recovery or transplantation.[77,102]

Decisions regarding specific device use depend on the degree of circulatory support needed and many other factors. Selection criteria for device placement include:

1. Potential reversibility of cardiac dysfunction
2. Cause of the cardiac dysfunction
3. Degree of right and left ventricular dysfunction
4. Amount of circulatory support needed
5. Importance of the device for myocardial functional recovery
6. Patient size
7. Anatomical location of collapse or deterioration
8. Whether the patient is a candidate for cardiac transplantation
9. Whether the patient can be anticoagulated
10. Expected duration of support
11. The patient's age and severity of comorbid conditions

At the New York Presbyterian Hospital (Columbia Center), several circulatory assist devices are available to aid treatment of each group. Short-term devices that can be placed percutaneously include the IABP, extracorporeal membrane oxygenation, and percutaneous assist devices. Devices that require sternotomy and are beneficial for short-term use include both pulsatile and newer axial flow devices. These devices primarily treat stunned myocardium, but they are capable of bridging to transplant. These devices are easy to insert, do not require excision of ventricular muscle, and do not compromise ventricular function after device removal. These devices can be removed without the need to reinstitute cardiopulmonary bypass. These devices are effective in patients who require emergency support secondary to cardiogenic shock.

Percutaneous assist devices are an excellent option for patients in cardiogenic shock after catheter-based or surgical revascularization as a short-term bridge for recovery or transplant. Current devices include the Impella Recovery system (Impella Cardiosystems AG, Aachen, Germany) and the TandemHeart system (Cardiac Assist Inc., Pittsburgh, PA). These devices require vascular access, which can be obtained percutaneously, and angiography to guide placement. The TandemHeart provides up to 4 L/min of support producing a higher mean blood pressure and cardiac output, and lowering pulmonary capillary wedge pressure.[103] Clinical results of this device in a randomized trial in 42 patients suffering cardiogenic shock after acute myocardial infarction have shown an improvement in cardiac output, decreased pulmonary capillary wedge pressure, but no difference in 30-day overall mortality.[104] Likewise, the Impella device can provide either 2.5 L/min or 5 L/min depending on the model, and in small series, may offer superior hemodynamic support when compared with an IABP.[105]

Many of the implantable assist devices are suitable for bridging to transplantation. Initial reports of increased mortality in this high-risk patient population have been refuted by studies reporting higher than usual survival in acute myocardial infarction patients who received ventricular assist device support. At our facility, more than 80% of this patient cohort have survived until transplantation, a result threefold better than that seen in databases of extracorporeal systems.

Second-generation assist devices employ axial flow rotors that can generate up to 6 L of flow (partial unloading of the left ventricle). These devices are driven by an electromagnetically actuated impeller drive shaft, contain fewer moving parts, and are smaller than pulsatile devices, thus making them less prone to mechanical failure and driveline infections, at least in theory.[106] The major disadvantages to axial flow pumps are the need for systemic anticoagulation, the lack of pulsatile flow, and incomplete pressure-volume unloading of the left ventricle; these concerns have limited its use in the post-myocardial infarction setting and further research is needed to clarify its therapeutic potential for these patients.

A full discussion of short-term and long-term mechanical circulatory support is reported in Chapters 18 and 66.

SURGICAL MANAGEMENT

New York Presbyterian (Columbia Center) Approach

Patients who are potential transplant candidates and those who are dying of cardiogenic shock after myocardial infarction are all candidates for placement of a long-term implantable left ventricular assist device (LVAD) (Fig. 24-9). If at all possible, a coronary angiogram is obtained to allow revascularization with or without LVAD insertion. Surgery is delayed if the culprit vessel can be opened with angioplasty and the patient stabilized in the catheterization laboratory. If hemodynamics continue to deteriorate, the patient is taken directly to the operating suite, even if infarction occurred earlier than 6 hours before the planned procedure. Hemodynamic observations that favor early CABG are pulmonary artery pressures of less than 60/30 mm Hg and cardiac output of more than 3 L/min. If the hemodynamics are worse, early implantation of a long-term implantable LVAD may be needed, especially if the mixed venous oxygen saturation is less than or equal to 50%. The decision to place a long-term LVAD is influenced by the patient score on a screening scale designed for this purpose (Table 24-6). These scores were selected to identify end-organ dysfunction (lung, liver, or kidney) and operative constraints (right-sided heart failure and bleeding). We have nearly a 90% survival if the summed scores are less than 5 points, versus 30% survival with summed scores greater than 5 points.[107] For this reason, if the total score is greater than 5 points, an attempt is made to stabilize the patient before beginning long-term LVAD insertion. Patients with lower scores are offered temporary LVAD.

If a patient is not a potential transplant candidate, our approach is more conservative, because we do not have a safety net if coronary revascularization fails and a temporary support device is inserted. An angiogram must be obtained; if hemodynamics are not favorable and no acute ischemia is present, we delay surgery until pulmonary arterial pressures fall. If the patient is ischemic, we proceed with CABG as described in the following. If the patient cannot be separated from bypass without high-dose inotropic support, including alpha agonists, if the cardiac index is less than 2 L/min/m^2, and if left-sided filling pressures remain high with mixed venous oxygen saturations of less than 50%, short-term LVAD support is instituted. IABP alone in this patient population often does not prevent death and almost always results in significant renal, hepatic, and pulmonary dysfunction that significantly complicates patient recovery even if adequate cardiac function returns. Most important, stressing the heart with high-dose inotropic agents and high filling pressures when it is weakest during the early reperfusion period after acute infarction may compromise border zone regions. This concern is especially true of patients with older infarctions (more than 6 hours). We err on the side of implanting this short-term device early, because the survival rate is only 7% if the device is inserted after a cardiac arrest in the recovery room.

TABLE 24-6 Preoperative Risk Scale for Left Ventricular Assist Device Placement*

Criteria	Points
Urine output <30 cc/h	3
Intubated	2

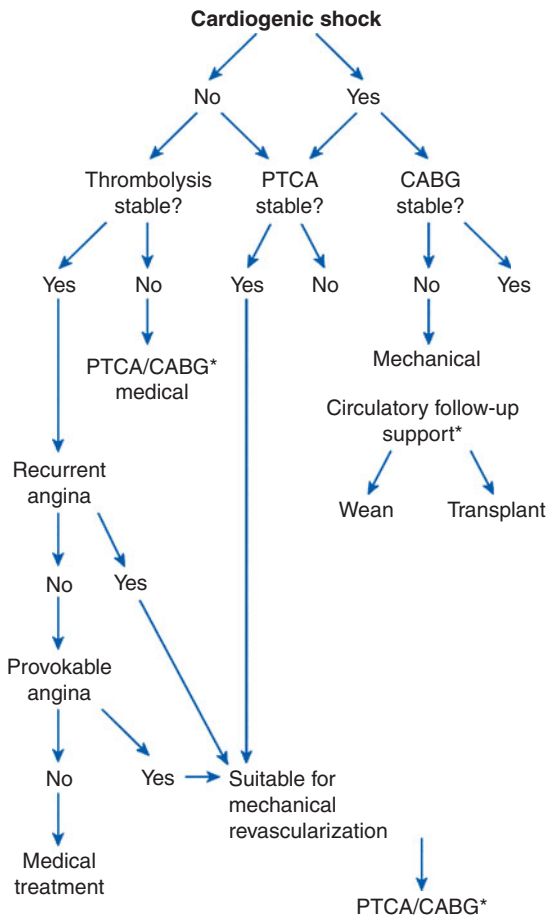
Reoperation	1

*A combined score of >5 is associated with a 70% mortality risk.



*PTCA = percutaneous transluminal coronary angioplasty; CABG = coronary artery bypass grafting. Choice of therapy is made based on the lesion(s) and comorbid factors.
†Choice of mechanical support is based on many factors (see text, along with other chapters).

FIGURE 24-9 Acute myocardial infarction algorithm.

Operative Techniques for Acute Myocardial Infarction

Anesthesia

Anesthesia is provided by a rapid narcotics-based regimen with perfusion and surgical teams prepared to respond to catastrophic

hypotension or cardiac arrest. Transesophageal probes are always placed in these patients if possible. As the patient is prepped, a test dose followed by a loading dose of aprotinin is given.

Bleeding

Bleeding is a significant complication of emergency CABG and often results in further myocardial depression and pulmonary hypertension. Cytokine release induced by infusion of blood products and thromboxane A2 released by cardiopulmonary bypass stimulate pulmonary hypertension, which can be catastrophic in the setting of right ventricular ischemia. Use of aminocaproic acid for reoperative, emergency, or high-risk CABG is common in many institutions.

The use of clopidogrel deserves special mention, and its expanding administration can pose unique problems for the cardiac surgeon. Clopidogrel, an oral irreversible antagonist of the 5′-adenosine diphosphate that inhibits platelet activation and aggregation, is used extensively in patients with acute coronary syndromes and has been shown to lower cardiovascular risk by up to 20%, and reduce reinfarction and stroke rates;[108,109] in addition, it is commonly given before percutaneous interventions and after intracoronary stenting to prevent thrombosis. Higher loading doses have been used with increasing efficacy against ischemic complications, which will likely expand its use in the future.[110] However, patients frequently require surgical revascularization after medical therapy or cardiac catheterization while taking clopidogrel. The risk of bleeding after clopidogrel and cardiac surgery can be substantial. In multiple reports, the risk of reoperation for hemorrhage in patients receiving clopidogrel within 7 days of cardiac surgery is six times higher, and patients required more blood, platelet, and fresh-frozen plasma transfusions.[111,112] Because of these complication rates and the inability to reverse clopidogrel's effect on platelets, surgery is often delayed until platelet function is restored, which may take 7 to 10 days, or the life of the platelets. Emergent surgery while taking clopidogrel necessitates frequent blood product transfusions and confers significant morbidity, and possibly mortality. Further study is underway to determine if current dosing regimens after acute myocardial infarction can be reduced to lessen bleeding complications.

Choice of Conduits

For emergency cases, the choice of conduit should not differ from elective cases in most circumstances. The internal mammary artery is not associated with a higher number of complications compared with saphenous vein grafting in emergent situations and can be used in most circumstances.[113,114]

Intraoperative Considerations

Decompression of the ventricle during revascularization after acute coronary occlusion decreases muscle damage and improves functional outcome by decreasing wall tension and reducing oxygen consumption (Figs. 24-10 and 24-11).[38] Indeed, ventricular decompression reduces metabolic energy consumption by 60%. Diastolic basal arrest, by avoiding the energy of

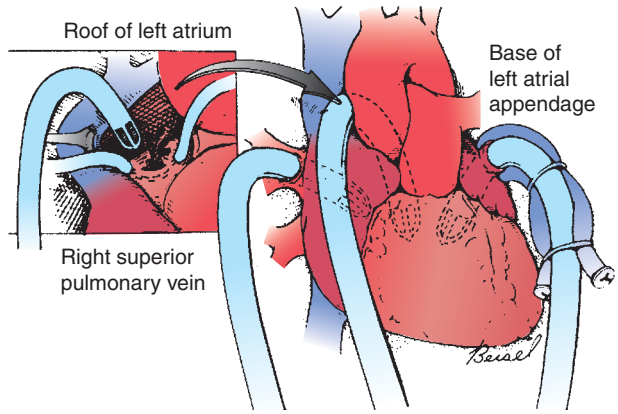


FIGURE 24-10 The inflow cannula for short-term left ventricular assist device support can be placed through the right superior pulmonary vein, the dome of the left atrium, or the left atrial appendage. Lighthouse tip cannulas allow improved venous return.

contraction, is the second most important means of minimizing oxygen consumption and further reduces metabolic energy consumption by 30%. Cooling of the patient and heart has an impact only on the final 10% of basal energy requirements.

Reduction of myocardial energy consumption is best achieved by early institution of cardiopulmonary bypass to maintain a high perfusion pressure. If a coronary salvage catheter has been placed across a tight coronary lesion, the catheter is left in place until just before cross-clamping. Antegrade and retrograde catheters are placed before cross-clamping to allow quick instillation of retrograde cardioplegia and protection of the territory supplied by the occluded or compromised vessel. The standard Buckberg protocol is followed, including warm induction to allow regeneration of depleted adenosine triphosphate stores.

If the territory at risk is grafted by saphenous vein, this anastamosis is performed first to allow direct instillation of cardioplegia into the territory at risk. The proximal anastomoses should be performed before removal of the cross-clamp to allow complete perfusion of the entire heart upon removal of the cross-clamp. The role of off-pump CABG in this setting is appealing, but remains unproved.

Although large ventricular aneurysms are treated by resection and patch, debate surrounds smaller aneurysms. Our group does not resect small aneurysms, but some groups are more aggressive. If an aneurysm is resected, the defect is repaired with a patch of bovine pericardium sewn to the fibrotic rim of the endoaneurysm surface. The native left ventricular wall is closed over the patch.

Utilization of the Dor procedure (endoventricular circular patch plasty repair) in the post myocardial infarction setting is a controversial subject. Recent data have shown that surgical remodeling improves systolic function, ejection fraction, and intraventricular dyssynchrony, whereas other data suggest no added benefit when added to CABG.[115–118] Further investigation is needed to definitively answer this question.

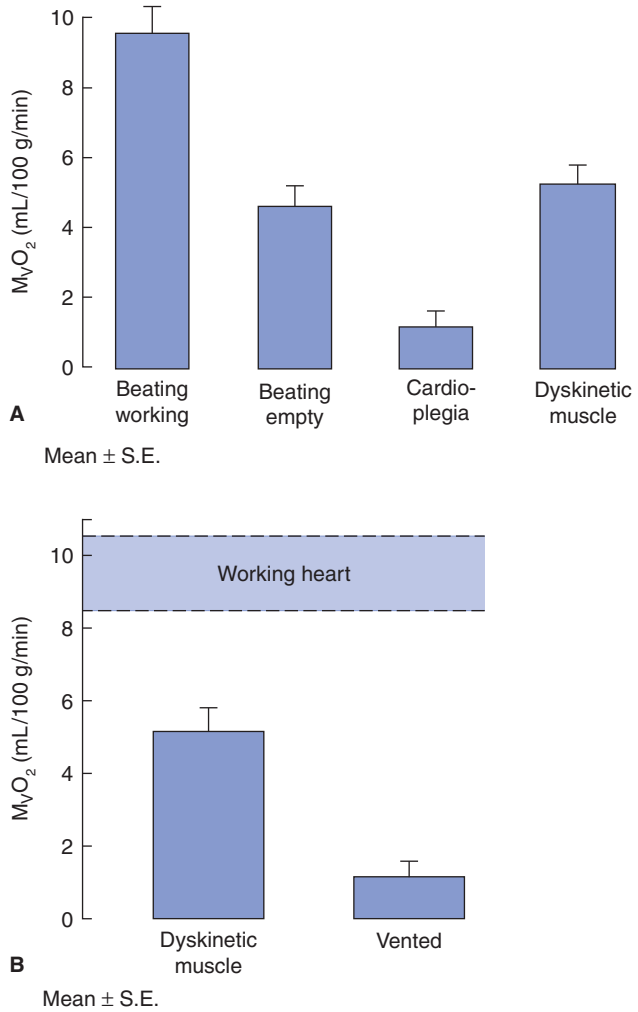

FIGURE 24-11 (A) Myocardial oxygen uptake (MvO_2), measured in milliliters per 100 grams per minute, in beating and working, beating and empty, and arrested hearts. Values after cardioplegia were determined both during cardiopulmonary bypass (cardioplegia) and during regional cardioplegic reperfusion in the working heart (dyskinetic muscle). Note (1) marked fall in MvO_2 with cardioplegia in the decompressed heart and (2) oxygen requirements of dyskinetic muscle increase fivefold over cardioplegia alone, and equal almost 55% of beating, working needs. (B) Regional oxygen uptake during selective cardioplegic reperfusion in dyskinetic and vented cardiac muscle. Stippled areas show requirements in working heart (8.5 to 10.5 mL/100 g/min). Note (1) high oxygen demands of dykinetic muscle and (2) marked reduction in demands when noncontracting muscle is decompressed by venting. (*Reproduced with permission from Allen BS, Rosenkranz ER, Buckberg GD, et al: Studies of controlled reperfusion after ischemia, VII: High oxygen requirements of dyskinetic cardiac muscle. J Thorac Cardiovasc Surg 1986; 92:543.*)

Postoperative Care

A higher incidence of complications in shock patients compared with nonshock emergencies has been reported. Guyton and associates[81] report a 47% complication rate associated with cardiogenic shock compared with 13% for patients with nonshock emergencies. This increase in complications probably reflects the preoperative condition of the patients rather than the treatment itself. Long-term follow-up in patients after emergency surgical revascularization shows that survival rates are closely correlated with postoperative ejection fraction and left ventricular size.[119,120]

FUTURE THERAPIES AND TRENDS

Improving outcomes in patients suffering acute myocardial infarction can occur through pharmacologic advances, optimization of existing practices, and application of new technology. Various medications have been described that reduce ischemic-reperfusion injury and limit infarct size in animal models, such as oxygen-derived free radical scavengers, folic acid, nitric oxide inhibitors, and others;[121] clinical study of these promising drugs will determine their efficacy. Sudden death after myocardial infarction may be reduced with administration of omega-3 fatty acids.[122] Reducing transport time to the hospital after the onset of symptoms and implementation of clinical guidelines have been initiatives of many hospitals and emergency services. The increased number of local hospitals able to perform primary percutaneous interventions has meant quicker revascularization, and thus improved outcomes.[14] This trend should continue in the future. Mechanical circulatory support has advanced greatly over the past 10 years, and pumps have become smaller, safer, less invasive, easier to use, and easier to implant. The indications for LVAD use are expanding in this population, and they may allow myocardial recovery to occur in select patients requiring hemodynamic support after acute infarction. The option of living long term with these devices has also become a reality. Finally, the rapidly emerging field of cellular therapy holds great promise for repair of damaged myocardium. A number of cell types, such as endothelial progenitor cells, mesenchymal stem cells, skeletal myoblasts, resident cardiac stem cells, and embryonic stem cells, are being investigated;[123] the optimal cell type, mode of delivery (intracoronary artery infusion, intravenous infusion, transendocardial injection, and transepicardial injection), and timing of administration have yet to be determined. Nevertheless, early clinical trials suggest that cellular therapy may offer benefits. One-year follow-up of 59 patients suffering acute myocardial infarction in the TOPCARE-AMI trial who received either circulating progenitor cells or bone marrow–derived progenitor cells demonstrated increased cardiac function and reduced ventricular dimensions, without adverse events.[124] Precultured mesenchymal cells also offer great promise by allowing cells from an unrelated donor to be administered without the complications of individual tissue harvest. The safety of these cells given intravenously after percutaneous revascularization in acute myocardial infarction was recently published, and efficacy studies are ongoing.[125] Numerous other clinical trials are underway to address questions regarding mechanisms of benefit, cell viability, and dosing. Future randomized clinical trials will be required to establish outcome benefit.

CONCLUSION

The treatment of acute myocardial infarction should be divided into two approaches. Uncomplicated acute myocardial infarction can be treated in most community hospitals. In most areas

of the country, these patients are treated effectively with thrombolytic therapy and medical management. For communities and facilities that have catheterization laboratories, primary angioplasty may be more cost effective and produces improved results. At this time, emergency coronary artery bypass surgery is not the most cost-effective approach; randomized, controlled studies to demonstrate advantages of emergency CABG have not yet been performed.

The approach to acute myocardial infarctions complicated by cardiogenic shock presents a more difficult problem. Mortality rates are high with medical management. Reperfusion therapy is the only real hope for improved survival in this group of patients. Thrombolytic therapy is associated with poor outcomes. Early PTCA and CABG are the primary options in all patients, including those greater than age 75. Mechanical circulatory assistance has an important role for supporting patients until the myocardium recovers. Use of pharmacologic agents and means to control reperfusion are important areas of current research and development. Assist devices and artificial heart programs offer indispensable options and must be considered in this patient population, especially because all therapies offer suboptimal results.

KEY POINTS

1. Early reperfusion within 24 hours of acute myocardial infarction using thrombolysis, PTCA, intracoronary stenting, and CABG provides the best chance for myocardial salvage and long-term survival.
2. Primary PTCA and intracoronary stenting are first-line therapies for patients suffering acute myocardial infarction, whereas thrombolysis is an acceptable alternative in select patient populations.
3. CABG after acute myocardial infarction may be appropriate for patients with ongoing angina or failure of percutaneous intervention, certain patients in cardiogenic shock, and those with structural complications of myocardial ischemia.
4. Circulatory assistance in the form of IABP and ventricular assist device insertion can provide temporary support until recovery or bridge to transplantation can occur in high-risk patients in cardiogenic shock.
5. Early institution of bypass, ventricular decompression, controlled reperfusion, and use of the Buckberg solution are important intraoperative techniques during CABG.

CHAPTER 25

Minimally Invasive Myocardial Revascularization

David M. Holzhey

Friedrich W. Mohr

INTRODUCTION

The term *minimally invasive coronary artery bypass grafting* is not well defined. According to one definition, avoidance of cardiopulmonary bypass (CPB) is considered essential in decreasing the morbidity associated with conventional coronary artery bypass grafting (CABG).[1] Other authors consider the median sternotomy as a potential source for morbidity, referring to the risk of mediastinitis and the associated delayed return to daily life activities.[2] Accordingly, a number of surgical strategies have evolved to avoid the need for extracorporeal circulation and to minimize surgical access. Furthermore, operative strategies as avoidance of aortic manipulation or complete arterial revascularization focus on improved short- and long-term results. At the same time, it was widely recognized that open harvesting techniques for bypass grafts often are associated with wound-healing problems, especially in diabetic patients. As a consequence, endoscopic harvesting techniques for both venous and radial artery grafts have been developed.

OFF-PUMP CORONARY ARTERY BYPASS GRAFTING (OPCAB)

For decades, CABG was routinely performed with cardioplegic arrest and using CPB. An empty, nonbeating heart, a bloodless surgical field, and an easy exposure were regarded as essential for success of the procedure. Results were excellent, mortality declined constantly, and standard CABG became the "bread and butter" of our profession.[3] Anecdotal reports on the deleterious effects of CPB and systematic reports examining the pathophysiology of extracorporeal circulation started to question the dogma of "the pump is your friend." CPB is associated with (1) a systemic inflammatory response, (2) release of cytokines, (3) activation of the clotting cascade, (4) metabolic changes, (5) microembolization and numerous other adverse effects. Although tolerated in most cases, these effects alone or in combination may cause substantial morbidity and thus affect the results of the procedure. With an ever-aging population and increasing comorbidity, surgeons all over the world sought to further minimize the risk of CABG, and it seemed logical to question the role of CPB in CABG.

The evolution of *off-pump coronary artery bypass grafting* (OPCAB) is closely linked to the development of stabilizers that became available in the early 1990s. Initially, pure pressure stabilizers were engineered, but it soon became obvious that exposure of the back wall of the heart would require additional means of support. With the introduction of vacuum-assisted stabilizers by the Utrecht group, local myocardial immobilization was greatly facilitated and independent of the area of revascularization and OPCAB gained popularity. Despite better stabilizers, it was recognized that OPCAB requires a team approach and awareness of the sudden hemodynamic changes that may occur during the procedure.

Anesthesia Requirements

In most centers, general anesthesia is applied, and the patient is intubated. Incidental reports indicate that the operation is also possible on the awake, spontaneously breathing patient under

high epidural anesthesia.[4] Standard monitoring is applied. In addition, some centers prefer online cardiac output measurement using the PICCO or similar methods.[5] A Swan-Ganz catheter is usually not helpful and can potentially cause arrhythmia when the heart is manipulated during the procedure. It is of utmost importance that the patient is kept warm at all times during the procedure. Temperature management includes placing the patient on a warming blanket, using warm infusions, and keeping the room temperature high. Volume management is essential because it is the preferred means for counterbalancing hemodynamic changes. Exposure of the back wall of the heart usually causes some degree of right ventricular outflow obstruction that can be treated adequately by increasing venous return by tilting the operating room table to the right with the head low. Because no CPB is used and filtering is not possible, intravenous volume overload must be avoided, especially in end-stage renal failure (ESRF) patients. The use of inotropes should be reserved for those with severe hemodynamic alterations only because they invariably increase the heart rate and thus complicate the procedure. In a review of human factors associated with manual control and tracking, it was pointed out that the human operator can at his or her best track a three-dimensional (3D) motion (such as the beating heart) only up to a frequency of 1 Hz, which happens to equal a heart rate of 60 beats per minute.[6] Higher frequencies cannot be tracked, thus the preferred heart rate should be kept in the range of 50 to 70 beats per minute to simplify suturing. In case of atrial fibrillation, pharmacologic slowing of the heart rate and temporary ventricular pacing using an epicardial pacing wire may facilitate the procedure. The use of a Cell Saver is recommended to minimize the risk for blood transfusion, which is rarely necessary. If less than 500 mL is collected, the blood usually is discarded.

Surgical Technique

After standard median sternotomy, single or bilateral internal thoracic artery (ITA) harvesting is performed. The patient is heparinized (150 to 200 units/kg, ie, about half of CPB dosage), keeping the activated clotting time (ACT) at a level above 300 seconds. In order to facilitate exposure of the heart, it is recommended to divide the pericardial and mediastinal attachments. Opening of the right pleura may become necessary in severely dilated hearts and some surgeons do it routinely to give the heart space during tilting, allowing easier access of the posterolateral wall. After the pericardium is opened, pericardial stay sutures are placed to aid in exposure of the heart. Numerous methods have been proposed for placing these sutures. Ideally, two or more sutures are placed beginning at the level of the right upper pulmonary vein all the way down distally to the lowest point of the epicardial sac (Fig. 25-1). To avoid damage to the myocardium, the sutures should be covered by plastic tubing; sponges may be used alternatively. Placement of the stay sutures should be done slowly because abrupt changes in positioning of the heart may cause undesired hemodynamic alterations or arrhythmia. The sequence for the grafts depends largely on the individual needs of the patient. In general, the left anterior descending (LAD) artery is the most important target vessel and the easiest to bypass. Therefore, revascularization should

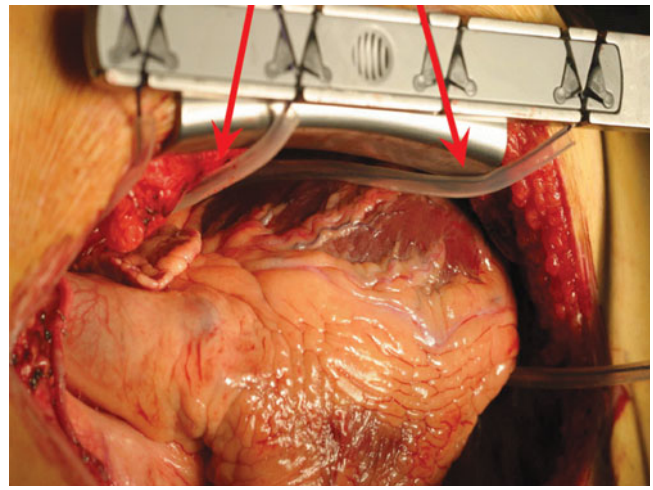

FIGURE 25-1 Setup for off-pump coronary artery bypass grafting. Placement of pericardial stay sutures.

start with an ITA graft to the LAD. By lifting the stay sutures, the LAD comes easily into view. The stabilizer is placed at the site of the anastomosis, and dissection of the surrounding tissue is begun. If the vessel is covered by excessive fat or muscle, low-energy cautery and clipping of epicardial veins may help to ensure minimal bleeding from the surrounding tissue. Once the site for the anastomosis is identified, the stabilizer is placed in a way to ensure enough space for suturing and equal distance to the stabilizer feet. Mechanical compromize of large diagonal branches should be avoided. Vacuum stabilizers should be locked only after vacuum is applied and the stabilizer sucks to the surface. Only a small amount of pressure will then be required to immobilize the heart. Excess pressure from the stabilizer will cause increasing wall motion as the heart works with more force against its compression. Temporary occlusion of the target vessel can be achieved in many ways. Surrounding 4-0 felt-pledgeted sutures or silastic tapes are used widely. The occlusion tapes ought to be placed at a distance of at least 5 to 10 mm from the anastomosis to avoid compression and distortion of the target vessel at the level of the anastomosis and thus allow for easy suturing. The suture needs to be placed deep enough in the tissue to avoid damage of the target vessel. The corresponding coronary vein should be respected to avoid disturbing side bleedings. Distal coronary artery occlusion should be avoided in general and is rarely necessary even in occluded vessels with strong backflow. Care must be taken to stay outside stented areas because the occlusion tapes may bend or kink an implanted stent. The incision usually is made before the occlusion suture is tightened to ensure complete filling of the vessel, which will minimize the risk of back wall injury. The suture then is tightened gently until bleeding stops. If there is only minimal coronary blood flow, eg, in chronic total vessel occusion, tightening may not at all be necessary. A CO_2 blower-mister is used to control residual bleeding from septal branches of the distal coronary at a rate not exceeding 5 L/min. Excessive blowing can cause dissection or injury to the intima of both the graft and the coronary artery or cause air embolism. The use of coronary artery shunts is controversial because they also may

cause endothelial damage. If shunts are used, care must be taken to ensure atraumatic placement. A very new development is a transparent reverse thermosensitive gel (LeGoo, Pleuromed Inc., Woburn, MA) which can be injected after incision of the coronary vessel for temporary blockage of the blood flow allowing an almost bloodfree anastomotic site. The anstomosis can then be sutured without the need for a blower-mister, shunts, or occlusion snares. The gel completely dissolves with time (after approximately 15 minutes) or with the application of local cold.[7,8]

The circumflex artery and its branches are grafted next in a sequence that is dictated mainly by the individual coronary pathology and the preference of grafts. The distal circumflex artery is regarded as the most challenging vessel to graft during OPCAB because exposure may be difficult. In large hearts and more importantly in patients with right ventricular dysfunction, it may be necessary to open the right pleura and divide the right-sided pericardium low to the level of the phrenic nerve. This will allow displacement of the heart underneath the sternum into the right pleural cavity. This maneuver minimizes right outflow tract obstruction and exposes all posterior vessels. After the circumflex artery, the right coronary artery (RCA) and its branches are grafted. If the RCA is the dominant vessel and the stenosis is less than 80%, it may be necessary to use a shunt because ischemia of the atrioventricular (AV) nodal artery during occlusion of the RCA can cause acute total AV block. It is therefore advisable to place and connect a temporary pacing wire before occluding the vessel.

To maximize both the short- and long-term benefit of an OPCAB procedure, arterial grafting is preferred. This will obviate the need for aortic clamping, another source for emboli and independent predictor of stroke.[9] In fact, some authors see avoidance of aortic manipulation as the key factor to bring the stroke risk of CABG below the stroke risk of PCI (Table 25-1).

TABLE 25-1 Comparison of Stroke Rates Using Different Coronary Artery Bypass Techniques

If vein grafts are used, the proximal or distal anastomosis can be performed first. It is of utmost importance to partially clamp the aorta under low pressure to minimize the risk of aortic embolie and to avoid aortic dissection. This can be achieved medically or by a brief period of inflow occlusion by manually compressing the inferior vena cava. This maneuver also should be repeated for declamping. Intraoperative graft patency control using transient-time Doppler or other means is recommended. If the operative field is dry, heparin usually is not completely antagonized. Postoperatively, aspirin is begun on the day of operation.

Special Situations

In patients with unstable angina, acute cardiogenic shock, or with ejection fraction (EF) below 20%, the preoperative implantation of an intra-aortic counterpulsation pump (IACP) may be useful. Alternatively these patients can be operated on-pump beating heart to combine the advantages of preserved native coronary blood flow, deloading the heart and adequate organ perfusion.[14,15] Patients with atrial fibrillation (AF) show an irregular contraction pattern that may distract during suturing (regular-motion patterns allow the development of coping strategies such as the "wait and see" strategy that are less effective when motion is unpredictable[5]). It therefore may be helpful to slow the heart rate pharmacologically and temporarily pace the patient in a VVI mode. If AF is paroxysmal, epicardial ablation for pulmonary vein isolation on the beating heart may be applied before bypass grafting.

Results

The number of OPCABs performed has reached 30% of all coronary revascularizations worldwide, in some countries especially with limited medical and financial resources exceeding today 80%. In some units, OPCAB is used almost exclusively with no patient selection.

When discussing outcomes, it is important to keep in mind that despite the fact that propensity scoring was applied for most analyses, some selection bias cannot be excluded. As pointed out by Sergeant and colleagues and also Puskas and coworkers, clinically relevant reductions of mortality, stroke, and renal failure with the OPCAB approach mandate large cohorts of patients to reach statistical significance in the presence of above-standard on-pump performance.[16,17]

When the first reports on OPCAB were published, concerns were raised regarding (1) incomplete revascularization[18–21] and (2) impaired graft patency owing to a more challenging technique.[22] These fears are fueled by some larger prospective studies. Khan and colleagues found a reduced graft patency in OPCAB patients after 3 months with no difference in all other outcome parameters.[22] In the ROOBY trial including more than a thousand patients in each group, the one-year outcome regarding cardiac death was inferior in the OPCAB group as well as the graft patency rate exept for the LIMA-LAD graft.[23] Other studies like the SMART and Prague IV study that provide angiographic data on graft patency reveal equal patency rates for on- and off-pump bypass surgery.[24–26]

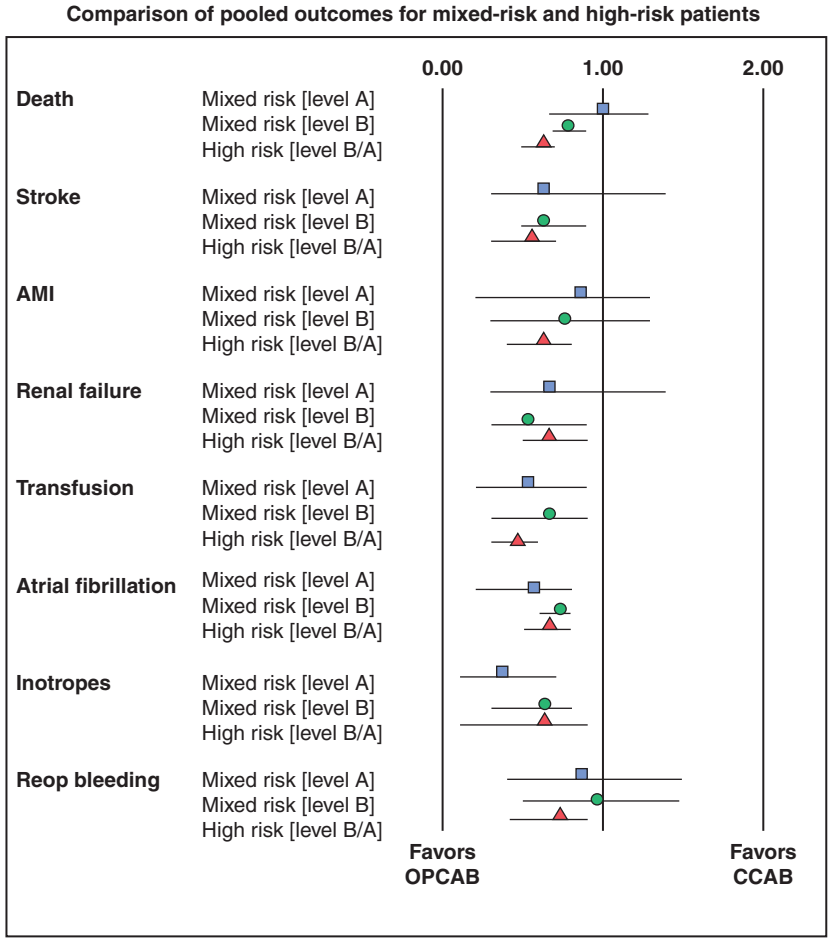
Regarding operative and short-term mortality, most studies are in favor of OPCAB. In a retrospective analysis of the Society

of Thoracic Surgeons database for the years 1999 and 2000, including 17,969 OPCAB patients (8.8% of total), a significant survival advantage with OPCAB compared with on-pump CABG was demonstrated by risk-adjusted multivariate logistic regression analysis (OR 0.76, 95% CI 0.68 to 0.84) and conditional logistic regression of propensity-matched groups (OR 0.83, 95% CI 0.73 to 0.96).[27] Similar results have been reported from another multicenter analysis consisting of some 7283 patients by Mack and colleagues. Following propensity score matching and multivariate regression analysis, the use of CPB was identified as an independent predictor of mortality (OR 2.08, 95% CI 1.52 to 2.83, $p < .001$).[28] Especially in high-risk populations (eg, the elderly, those with EFs below 30%, and obese patients), OPCAB seems to offer a survival benefit.[17,29–31] There are only sparse data on the midterm outcome. After 2 and 4 years, similar survival has been reported.[18,32]

There is growing evidence that neurocognitive outcome is better and stroke rate is reduced after OPCAB.[33–35] According to a number of studies, CPB is an independent predictor of adverse neurologic outcome.[36] The embolic burden measured by transit-time Doppler of the medial cerebral artery is reduced significantly during OPCAB.[37–39] The risk of acute renal failure is decreased in off-pump surgery,[40–42] especially in high-risk groups with preoperative renal insufficiency.[43,44]

The incidence of postoperative atrial fibrillation is reduced after OPCAB,[44,45] and biochemical markers for myocardial injury (eg, creatinine kinase and troponin) are reduced after OPCAB.[46–48] Blood loss is less, and transfusion rate is reduced.[17] Overall, OPCAB reduces hospital costs by 15 to 35%[31,49] possibly owing to decrease in length of stay and resource utilization.[31]

In a thorough meta-analysis, the International Society for Minimally Invasive Cardiac Surgery Consensus Group published the evidence for OPCAB.[17] Accordingly, OPCAB reduces mortality and length of stay and the incidence of postoperative myocardial infarction (MI), renal failure, AF, and transfusion rate in mixed-risk and high-risk patients (Fig. 25-2).



Mixed-risk patients [level A] = Cheng 2004 (37 randomized trials; 3369 patients)
Mixed-risk patients [level B] = Beattie 2004 (13 nonrandomized trials; 198,204 patients) or reston 2003 (53 trials; 46,621 patients)
High-risk patients [level B/A] = ISMICS consensus meta-analysis 2004 (42 nonrandomized trials and 3 randomized trials; 26,349 patients)

In conclusion, OPCAB is a highly demanding procedure with a prolonged learning curve compared with conventional byass graft surgery. Some surgeons perform OPCAB almost exclusively, whereas others never use it at all. Comparisons are therefore difficult and maybe OPCAB is not the best option for every patient or for all cardiac surgeons. It is, however, an important option and must be mastered with the same technical precision as conventional CABG.[50]

MINIMALLY INVASIVE DIRECT CORONARY ARTERY BYPASS (MIDCAB)

One goal of minimally invasive cardiac surgery has been to avoid sternotomy to reduce the amount of surgical trauma and avoid wound complications. Therefore, coronary artery bypass techniques on the beating heart without sternotomy were developed. The operation was termed *minimally invasive direct coronary artery bypass* (MIDCAB), and since its introduction in the mid-1990s,[51–55] it has found a widespread application. In some centers, MIDCAB is the preferred method of surgical revascularization for isolated coronary artery disease (CAD) of the LAD. In addition, MIDCAB is a valuable alternative to standard CABG or OPCAB in selected high-risk patients with multivessel disease and extensive comorbidity, who are at a prohibitively high risk for sternotomy.

Anesthesia

Standard monitoring is applied, and temperature management as for OPCAB is applied. Because single-lung ventilation is applied by using a double-lumen tube or bronchus blocker to provide selective right lung ventilation, short-acting anesthetics are used to allow for fast extubation.

Surgical Technique

Standard MIDCAB usually is performed through a left anterolateral minithoracotomy in a 10 to 20 degrees right lateral position. After making a 5- to 6-cm skin incision in the fifth intercostal space or the inframammary fold, the pectoralis muscle is displaced bluntly with minimal division following the muscle fiber orientation (muscle-sparing approach). This will decrease the likelihood of lung herniation that has been reported infrequently with this approach. The chest then usually is entered one intercostal space higher than the actual incision. Excessive rib spreading must be avoided at all times to prevent dislocation or fracture. Removal of a rib is almost never necessary. Take-down of the LITA usually is performed under direct vision, but endoscopic ITA takedown using a harmonic scalpel or telemanipulation systems has also been reported.[55–57]

The intrathoracic fascia is divided to facilitate take-down of the LITA, which usually is done in a pedicled manner. Takedown is performed from the fifth intercostal space to the origin of the subclavian artery. Using a sceletonized technique offers the advantage of gaining more graft length, but is, of course, more time consuming. Additional length can also be gained by dividing the mammary vein at its junction with the subclavian vein. Side branches are clipped or cauterized based on the preference of the surgeon. Heparin is administered prior to distal transsection of the graft. As in sternotomy OPCAB the ACT is kept at a level above 300 seconds. The pericardium should be opened above the course of the LAD and extended to the groove between the aorta and the pulmonary artery. This will facilitate location of the target vessel if excess epicardial fat or an intramuscular course is present. After that the target vessel is identified. To enhance exposure, one or two pericardial stay sutures may be used to position the heart. It is of utmost importance to have the region of anastomosis in direct and comfortable view. Standard reusable pressure stabilizers are then used to immobilize the target region (Fig. 25-3). Vacuum stabilizers in general are too bulky and not required for a single anastomosis to the LAD. Proximal LAD occlusion is performed using a 4-0 felt-pledgeted suture or vessel loops. Ischemic preconditioning is not helpful, but some surgeons use it to feel more comfortable when knowing that ischemia is well tolterated. The use of shunts is rarely necessary, but they may be applied based on the preference of the surgeon and indicated when strong coronary backflow is evident. Distal occlusion should be avoided whenever possible (99% of patients). A blower-mister is used in all cases to achieve a bloodless field. The anastomosis then is performed in a standard fashion using a 7-0 or 8-0 polypropylene running suture. Finally the LITA can be fixed on the pericardial tissue. Graft patency assessment is performed routinely using transit-time Doppler. A single chest tube is inserted into the left pleural space, and intercostal nerve blockade is applied using local anesthetics. Before closing the chest with one or two strong rib sutures the single lung ventilation is stopped and the left lung is inflated under direct view to control tension free course of the LITA. This is facilitated by keeping the LITA aside to the mediastinum using the suction tip or long forceps. Extubation usually is performed on the table for a few hours postoperatively. Patients are routinely started on antiplatelet therapy on the day of operation.

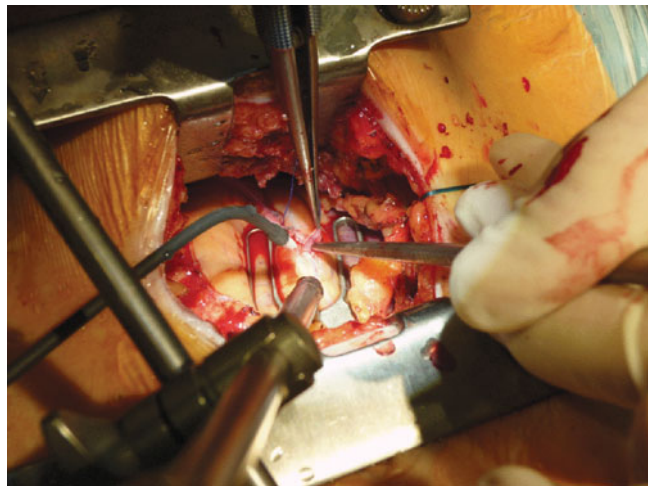

FIGURE 25-3 Minimally invasive direct coronary artery bypass. Through a muscle-sparing incision, the left anterior descending artery is easily exposed; standard pressure stabilizers are used.

Results

A number of papers have reported excellent results with this approach. Immediate angiographic patency rates are in the range of 94 to 98% and thus similar to those reported for conventional CABG.[54,58] At 6 months, patency rates of 94% have been reported.[59] Reported in-hospital mortality for MIDCAB is less than 1% and compares favorably with the off-pump single-bypass mortality of 1.4% and with the mortality of single bypass with CPB of 3.6% that was been reported in the registry of the German Society for Thoracic and Cardiovascular Surgery.[60] and is also lower than the 2.4% mortality that is reported from the STS database.[61] The rates of perioperative major complications such as myocardial infarction and the need for target-vessel reintervention are low and comparable with standard CABG. However, because of an aortic surgery perioperative stroke is rare and the rate considerably lower compared with conventional techniques.

In our own series of 1918 patients who underwent MIDCAB from 1996 to 2009, in-hospital mortality was 0.8% (predicted mortality by Euroscore 3.8%), and stroke rate was 0.3%. Conversion to sternotomy was necessary in 1.6%. A total of 745 patients received routine postoperative angiogram demonstrating a 96.3% early patency rate. At 6-month follow-up, graft patency was 95.2% ($n = 423$). Five-year survival is 91.5% (95% CI 89.51 to 93.5%). (Fig. 25-4A) The freedom from MACCE and angina after 5 and 7 years was 88.6% (95% CI 86.4 to 90.9%) (see Fig. 25-4B). These results are in accordance with the findings of other groups.[59,62,63]

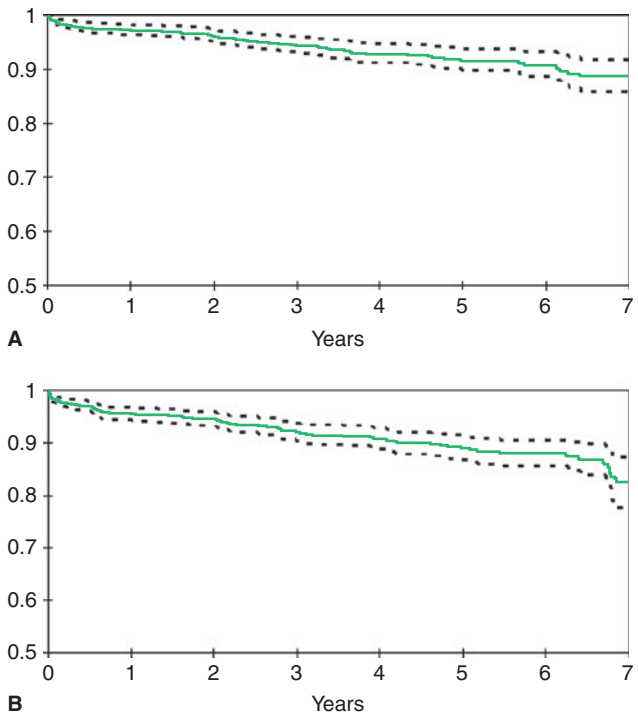

FIGURE 25-4 Kaplan-Meier (including 95% confidence interval) five-year survival curve (A) and event-free survival curve (freedom from death, myocardial infarction, stroke, freedom from angina, freedom from reintervention) (B) after minimally invasive direct coronary artery bypass. Data from 1483 patients undergoing MIDCAB at the Heartcenter Leipzig.

A few randomized trials comparing MIDCAB versus bare metal stenting in isolated proximal LAD lesions have demonstrated better early patency and superior freedom from target-vessel reintervention and angina for the MIDCAB group up to 5 years of follow-up.[64–69]

Some studies have pointed out that the lateral approach is associated with higher pain levels than sternotomy, mainly owing to the excessive rib spreading required for visualizing the LITA during takedown.[55] Rib dislocation or fracture has been reported infrequently with this approach. Direct harvesting of the LITA is regarded as technically challenging and has been one of the arguments for many surgeons to disregard MIDCAB as the primary operation for patients who require surgical revascularization of the LAD. Limited working space and incomplete vision are blamed for insufficient graft length, incomplete mobilization, and the occasional reports of LITA injury or injury of the subclavian vein.

MIDCAB is a highly demanding technical procedure that should be started by surgeons who have sufficient experience in conventional and off-pump surgery. It has been shown that the complication rate of MIDCAB (namely conversion to sternotomy, reexploration for bleeding, and reintervention on the target vessel) is significantly lowered after an experience of 100 to 150 MIDCAB procedures.[70] Therefore, it can be recommended to concentrate this operation on dedicated and experienced surgeons.

Even with improved outcomes of interventional procedures and less in-stent restenosis with the use of drug-eluting stents,[71] MIDCAB, based on its very good long-term results,[72] will remain an alternative revascularization strategy to PCI for patients with single-vessel disease, especially for complex ostial lesions, chronic occlusions, and in-stent restenosis.

TOTAL ENDOSCOPIC CORONARY ARTERY BYPASS GRAFTING (TECAB)

The possibly least invasive approach for surgical revascularization is *total endoscopic coronary artery bypass grafting* (TECAB) on the beating heart. Working through ports has long been known for limiting the available space to perform motions, for substantially decreasing the dexterity of the operator, and for altering the hand-eye coordination.[73] Active assistance, an indispensable component of open surgery, is difficult in thoracoscopic procedures. The transition from limited-access cardiac surgery to endoscopic cardiac surgery therefore complicates the procedure substantially and has rendered previous attempts at endoscopic CABG using conventional endoscopic instruments impossible. To overcome some of the instrument-related limitations, computer-enhanced instrumentation systems have been developed.

Principles of Telemanipulator-Assisted Cardiac Surgery

With the usage of telemanipulation devices the operator involved in the interaction is physically removed but not necessarily remote from the operation table. He instead operates at an *input manipulator* (surgical console, master console) from which he steers the *executing manipulator* (slave console) which

is situated at the patient site. The slave console consists of all nessesary electromechanical equipment to operate two or three exchangable endoscopic instruments plus a high definition 3D endoscopic camera. Both haptic and visual information is fed back to the master console. This way a virtual 3D operative field is created wherein the surgeon can manipulate steering handles with a perfect hand-eye alignment. The introduction of telemanipulation technology to endoscopic surgery was able to address the key performance limitations of conventional endoscopic surgery, namely, reduced articulation, monocular vision, and loss of hand-eye coordination.

Surgical Technique

Standard monitoring for cardiac surgery is applied. Defibrillator pads are placed on the back and to the right side of the chest. Single-lung ventilation of the right lung is applied using a double-lumen endotracheal tube or a bronchus blocker. Temperature management follows the principles of OPCAB surgery. After draping the instrument arms and camera arm, camera and scope calibration are performed and the endostabilizer is prepared. A holding arm for the endostabilizer is mounted to the operating table rail on the patient's right side, and the operating table is rotated 10 to 15 degrees to raise the patient's left side.

After single right-lung ventilation is initiated, the camera port is placed in the fifth intercostal space 2 cm medial to the anterior axillary line. CO_2 insufflation is begun for adequate visualization and to create working space as tolerated hemodynamically (usually 10 to 12 mm Hg of insufflation pressure). A 30-degree scope angled up is used for takedown of the LITA. The right instrument port is placed in the third intercostal space medial to the anterior axillary line, and the left instrument port is placed in the seventh intercostal space medial to the anterior axillary line. The instrument arms are centered for optimal range of motion by adjusting the respective setup joints, and the instruments are inserted. LITA takedown starts by dividing the intrathoracic fascia covering the LITA with low-power monopolar cautery. The LITA is dissected bluntly off the chest wall moving from the lateral to the medial aspect as a pedicle, keeping the lateral veins. Side branches are cauterized or clipped. Dissection is performed from the first intercostal space to the level of the bifurcation. The pedicle is not detached from the chest wall until the anastomosis is finally performed to avoid torsion of the graft. The distal end of the graft is skeletonized to facilitate suturing of the anastomosis. Epicardial fat is removed, and the mediastinal and diaphragmatic attachments to the pericardium are dissected bluntly to widen the available space. The pericardiotomy is performed with a longitudinal incision in the pericardium over the suspected course of the LAD. The ideal site for the anastomosis is determined by the absence of visible atheromatous plaques and avoiding proximity to bifurcations. At this point, changing the angle of the endoscope from looking upward to looking downward may enhance visualization. After heparinization (an ACT of 300 seconds is recommended), a vascular clamp is placed approximately 2 cm proximal to the transsection site. The LITA is clipped distally, cut, and spatulated in preparation for the anastomosis in situ. Graft patency is confirmed by briefly releasing the vascular clamp.

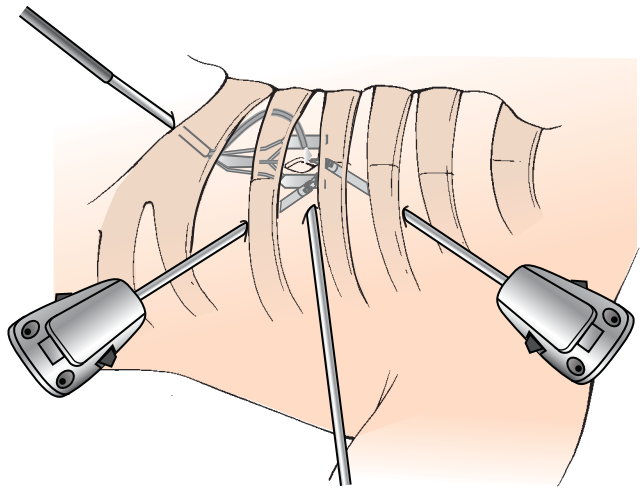

FIGURE 25-5 Setup for total endoscopic coronary artery bypass grafting. Two instrument ports, one central camera port, and a subxyphoidal port for the endostabilizer are required.

The LITA pedicle is still left attached to the chest wall in order to keep orientation of the graft until the anastomosis is performed. A 12-mm subxyphoid cannula is inserted under endoscopic vision. Before introduction of the endostabilizer, temporary silastic occlusion tapes and a 7-cm 7-0 double-armed Prolene suture are introduced through this port and stored in the mediastinum. Some surgeons prefer Gore-Tex sutures to avoid the memory effect. Alternatively, nitinol clips (U-clips) may be used. The endostabilizer then is introduced under endoscopic vision by the patient-side surgeon (Fig. 25-5). Vacuum lines and irrigating saline line are connected, and the multilink irrigator is advanced into the field of view. The console surgeon then positions the stabilizer feet parallel to the LAD target site. After suction is applied, the feet are locked into position. After blunt dissection of the anastomotic target site, the silastic tapes are placed proximal and distal to the anastomotic site, and temporary occlusion is applied. After a 5- to 6-mm arteriotomy is performed, transsection of the LITA is completed, and the graft is brought in close proximity of the target site. The anastomosis is best performed by beginning at the middle of the medial wall (12 o'clock position), suturing inside-out on the LITA and outside-in on the LAD toward and around the heel. Care has to be taken to tension the suture continuously. After the needles are broken off, an instrument knot is tied. The occlusion tapes and vascular clamp are released and evacuated through an instrument port. The pedicle may be fixed to the epicardium by stay sutures. For graft patency, control transient time Doppler flow measurements can be performed endoscopically if a probe without a handle is available. This probe can be advanced through the stabilizer port. Alternatively, intraoperative angiography has been performed using a mobile angiography unit or modern C-arm systems when TECAB operation is performed in a hybrid suite. After the pleural space is drained under vision, the stabilizer and instruments are withdrawn, and the left lung is ventilated. A chest tube is inserted through one of the port holes. In case a four-arm system is used, the fourth arm is introduced after

harvesting of the LITA in the third intercostal space in the anterior axillary line. It may be used to provide countertraction during epicardial fat removal and pericardiotomy and to present the pedicle during the anastomosis. The new version of the da Vinci system also will allow the use of a remotely controlled stabilizer that is placed on the fourth arm and thus can be adjusted from the console.

Results

Initially, TECAB was performed on the arrested heart using the Port-Access platform with femorofemoral cardiopulmonary bypass, endoaortic balloon clamping, and cardioplegic arrest. CPB time and cross-clamp times were in the range of 80 to 120 and 40 to 60 minutes, respectively. The reported patency rate for the TECAB procedure on the arrested heart ranged from 95 to 100% prior to discharge and 96% at 3-month follow-up angiography.[74–77] A large single center study including 100 patients reported, besides good overall results and patency rates, anastomotic times of 10 to 30 minutes after a longer learning curve. Even more pronounced than in MIDCAB procedures (see previous) they also acknowledged that the learning curve continues beyond 100 operations.[78]

Endoscopic CABG on the beating heart is even more challenging.[74,79,80] Based on an intention to treat basis, the conversion rate (elective conversion to a MIDCAB procedure) in a five-center registry was 33% (37 of 117). Conversions were mostly because of calcified target vessels or the inability to locate or dissect the LAD and rarely because of other conditions such as arrhythmia or hemodynamic instability. The patency rates for completed beating-heart TECAB procedures are in the range of 92 to 94%.[61]

TECAB can be performed safely but is currently restricted to few indications (eg, single-vessel bypass grafting of the LAD and occasionally double-vessel grafting), but it has the potential for endoscopic multivessel procedures.[81,82] A more commonly applied technique is an endoscopic harvesting of both internal mammary arteries and direct coronary anastomosis via a minithoracotomy. This yields excellent results and very short recovery times for the patients.[82,83]

Despite the use of advanced telemanipulator technology, the TECAB procedure remains technically demanding and is performed infrequently worldwide. Long operation times, extensive use of material and operation room capacity combined with a stretched learning curve and well established minimally invasive alternatives have confined TECAB to few centers and single dedicated surgeons.

MULTIPLE BYPASS GRAFTING USING MINMALLY INVASIVE TECHNIQUES

Talking about minimally invasive surgical revascularization almost always means revascularization of the anterior wall with the left internal mammary artery. The classical MIDCAB operation is only rarely extended to bypass a diagonal or even intermediate branch as well, typically with a Y-graft using a vein or radial artery.

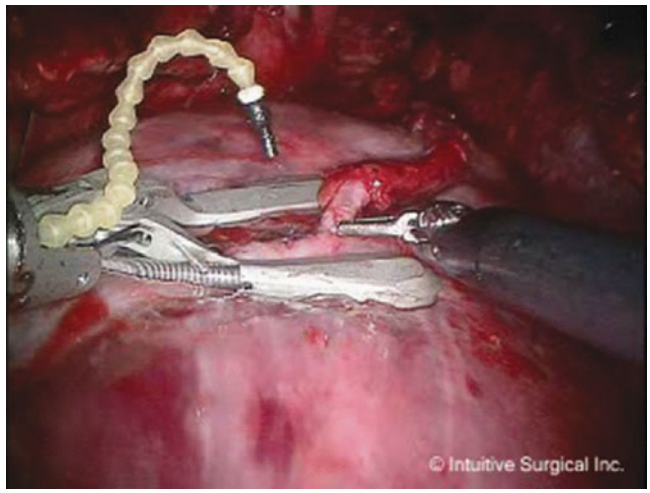

FIGURE 25-6 Endoscopic coronary artery bypass grafting. New endoscopic vacuum stabilizer including irrigating channel. The stabilizer is mounted to the fourth arm of the new da Vinci system and can be operated remotely by the surgeon at the console. (*Reproduced, with permission, from Intuitive Surgical, Inc, Sunnyvale, California.*)

Recent reports have proved the feasibility of complete revascularization for mutivessel disease. Through minimal incisions under direct vision or endoscopically with the help of a telemanipulator, harvesting of both mammary arteries is possible.[84] For proximal anastomoses the aorta can be mobilized and partially clamped or the mammary arteries serve as feeding grafts for a radial artery or saphenous vein.

Accessibility of all areas of the heart is made possible by special stabilizers and suction retractors that allow distal anastomoses even on the beating heart (Fig. 25-6). As an alterative, the Heartport system for endoaortic clamping and cardioplegia can be used.

These techniques have not yet found entry into the clinical routine. However, the published series of patients show excellent results often times superior to conventional CABG or OPCAB.[84] It can be assumed that all these operations were performed by dedicated, experienced surgeons on selected patients. Only a more widespread application of these procedures and the treatment of a broader variety of patients together with randomized studies would bring light to their significance in the future.

HYBRID REVASCULARISATION

The hybrid approach for patients with multivessel coronary artery disease seeks to combine the advantages of percutaneous coronary intervention (PCI) and minimally invasive CABG. The principle was first described by Angelini in 1996.[85] The goal is to minimize the surgical trauma but still gain complete revascularization. The rationale is that the excellent long-term results of LIMA to LAD grafting[72,86] cannot be transferred to other areas of revascularization. This is particularly true for the still widespread venous bypass grafting. Here PCI can potentially achieve similar long-term results, yet with a somewhat higher rate of reintervention. Although recent studies underline

the superiority of complete surgical revascularization,[87] the avoidance of sternotomy seems to be very appealing to both patients and treating cardiologists.

However, combining the benefits of two different procedures also means adding the different risk inherent to each type of procedure. The risk of a surgical procedure, including the risk of general anesthesia and artificial ventilation, is combined with an increased risk of inferior PCI long-term outcome that includes the necessity of reinterventions and the possibility of eventual surgical multiple bypass grafting. Therefore the indication for hybrid revascularization should be discussed and agreed on by the treating cardiologist, cardiac surgeon, and, most important, the patient himself.

Indication for the Hybrid Approach

Current recommendations for coronary artery revascularization do not include hybrid procedures. This is because of limited availability of outcome data and a lack of randomized trials. Thus, choosing a hybrid approach is usually based on an individual decision. In all cases the patients with multivessel disease including the proximal LAD need to be informed that the best evidence-based treatment is a sternotomy CABG procedure. However, the different reasons for choosing a hybrid approach can be summarized as follows:

- *Multimorbid or high risk patients:* This is probably the best accepted indication and includes patients with a high risk for sternotomy associated problems such as mediastinitis or with reduced life expectancy. Patients with malignancies, redo patients with a history of deep sternal wound infections, patients dependent on crutches or a wheel chair or patients with additional risk factors such as diabetes, severe obesety, COPD, end stage peripheral occlusive disease, porcelain aorta, and history of stroke with paraplegia might also benefit from the hybrid aproach.
- *Rescue PCI of CX/RCA:* Patients with acute coronary syndromes presenting a culprit lesion in the circumflex or right coronary artery and additional stenosis of the LAD may undergo primary emergency PCI of the culprit lesion by the referring cardiologist. A MIDCAB procedure is usually scheduled 4 to 6 weeks later. A control angiogram confirming the patency of the stent should be done prior to surgery. In the presence of in-stent restenosis the patient can be scheduled for a standard bypass procedure.
- *Patient preference:* Some well informed patients want to avoid sternotomy and opt for a hybrid approach. Patients need to be informed that they might require future reinterventions including repeat target vessel revascularization or bypass surgery. Because the choice of the hybrid revascularization in these patients is not for medical reasons it deserves informed collaboration of patient, interventional cardiologist, and cardiac surgeon.

Timing of the Procedures

The optimal timing and order of revascularization is still discussed controversly.[88] All three possible scenarios have inherent benefits and drawbacks:

- *PCI before CABG:* Performing the percutaneous intervention first is usually associated with an increased bleeding risk for the subsequent surgery because of double antiplatelet therapy. This can be avoided in stable patients who received a bare metal stent by postponing the CABG procedure for more than 4 weeks. When the interval between the two procedures is even longer, a preoperative control angiogram is reasonable to exclude early in-stent restenosis.

  The PCI-first strategy is most commonly applied when a culprit lesion other than the LAD requires urgent therapy.[89]
- *CABG before PCI:* This is the most frequently applied order. The percutaneous intervention is done after the patient has recovered from surgery. After protection of the anterior wall, the percutaneous aproach to the other coronary vessels is safer, even for the left main.[90] A welcome side effect is the angiographic contoll of the minimally invasive bypass procedure.
- *Simultaneous revascularization*: The growing number of novel operating suites that provide true integration of surgical and fluoroscopic capabilities allows for complete hybrid revascularization in one session without moving the patient. After performing a standard MIDCAB/TECAB procedure the bypass quality is verified and the percutanous intervention is undertaken with the patient still under general anesthesia. In the rare case of a failed PCI easy conversion to conventional bypass surgery is possible. Patient acceptance for this approach is high yet it requires good collaboration and syncronizing of the schedules of the cardiologist and the cardiac surgeon.

Results

Although the concept of hybrid revascularization has been applied for almost 15 years the series of published results is not long and the reports oftentimes only involve some 20 to 50 patients. Additionally, the patients represent a very heterogeneous group with a wide range of risk profiles. The various means of revascularization both surgically (MIDCAB or TECAB) and interventionally (different types of bare metal stents and drug eluting stents) and their possible combinations further impair the comparibility. Randomized studies are not available.

There is a general consent that hybrid integrated revascularization is feasible and safe.[91–95] Friedrich and colleagues reviewed the published results of eighteen studies including 367 patients. At six months, the LIMA stenosis rate was 2% and in-stent restenosis was 12%.[91] A larger single center series was recently published by our group.[89] During the follow-up period (208 patient years) 8 patients died. Kaplan-Meier survival was 92.5% (95% CI 86.5% to 98.4%) at one year and 84.8% (95% CI 73.5% to 94.9%) at 5 years. Twenty-three patients had an angiogram for recurrent symptoms of angina. One patient showed an occluded LIMA bypass. Five patients showed significant in-stent restenosis with the need for reintervention. At one year freedom from MACCE and angina was 85.5% (95% CI 76.9% to 94.1%) and 75.5% (95% CI 62.7% to 87.3%), respectively. (Fig. 25-7)

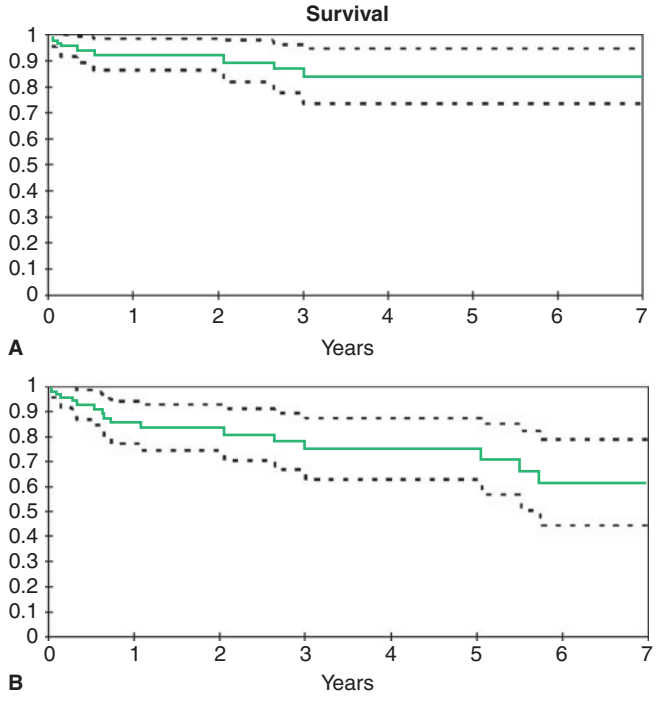

FIGURE 25-7 Kaplan-Meier (including 95% confidence interval) 5-year survival curve (A) and event-free survival curve (freedom from death, myocardial infarction, stroke, freedom from angina, freedom from reintervention) (B) after minimally invasive hybrid revascularization in 117 patients.

ENDOSCOPIC CONDUIT HARVEST

To minimize the overall trauma and wound healing problems of a bypass procedure, conduit harvest should be performed through limited incisions or endoscopically. There is a body of evidence indicating that although the quality of the conduit is not impaired by an endoscopic harvest, wound infections and other complications of the harvesting procedure are decreased substantially. The cosmetic advantage is obvious.

Endoscopic Saphenous Vein Harvesting

Despite the fact that arterial grafting yields better long-term results than venous grafting, and despite increased use of the IMA and other arterial grafts, the greater saphenous vein is still used frequently for CABG. The standard longitudinal open harvesting technique of the greater saphenous vein is associated with a 2 to 25% rate of wound complications (eg, dehiscence, delayed healing, infection, cellulitis, sepsis, and occasionally, limb amputation), complicating ambulation of the patient, prolonging hospitalization, and causing an economic burden.[96–99] In addition, open saphenous vein harvest is associated with postoperative pain, swelling, neuropathy, long-term pain, and scarring impairing patient satisfaction.

Various techniques for endoscopic vein harvest exist that require one or two 2-cm incisions. For a single-incision technique, the greater saphenous vein is identified through a 2-cm longitudinal incision at the crease of the knee posterior to the medial femoral condyle. A space anterior and posterior at the surface of the vein is dissected, and a subcutaneous retractor or dissection cannula is introduced. An endoscope is inserted into the subcutaneous tissue. Exposure can be enhanced by insufflating CO_2. The vein is mobilized circumferentially, and side branches are either clipped, coagulated using bipolar endoscopic cautery scissors, or vaporized using a harmonic scalpel. Whenever bipolar cautery is applied, a distance of at least 2 mm between the scissors and the vein should be kept in order to avoid thermal graft damage. Proximal and distal control of the greater saphenous vein is accomplished with endoscopic application of a Prolene suture, clips, or ligation loops. With this technique, the entire length of the vein can be harvested from the saphenous-femoral junction to the medial malleolus through a single incision. The wound is closed in a standard fashion, and the leg is wrapped circumferentially with bandages. In experienced hands, the procedure takes between 15 and 30 minutes.[100] As with all endoscopic techniques, a learning curve is associated with endoscopic vein harvesting, with training involving approximately 30 patients and a conversion rate ranging from 0 to 22%.

Results

The ISMICS Consensus Group reviewed the results of 1319 randomized and 8023 nonrandomized patients. In this meta-analysis, the risk of wound complications was reduced significantly by 69% with endoscopic vein harvesting compared with the open technique (OR 0.31, 95% CI 0.23 to 0.43; $p < .0001$).[101] The need for surgical intervention for wound infection also was reduced significantly (OR 0.29, 95% CI 0.12 to 0.70; $p = .007$). With regard to the incidence of moderate to severe postoperative pain, a reduction of 74% was found with endoscopic vein harvesting compared with the open technique (OR 0.26, 95% CI 0.12 to 0.55; $p < .0001$), and this reduction was 90% at 4 to 6-weeks follow-up (OR 0.10, 95% CI 0.03 to 0.37; $p < .0001$). The incidence of mobility disturbance at discharge was reduced by 69% (OR 0.31, 95% CI 0.15 to 0.65; $p = .002$).

One recent study reported worse angiographic and clinical outcome in patients after endoscopic vein harvest.[102] Most studies, however, found no difference for myocardial infarction, angina recurrence or reintervention, and death over the short and midterm.[101,103] However, the number of trials looking at cardiac outcomes and providing angiographic data on patency rates are too limited to allow any meaningful conclusion. The few trials that looked at vascular integrity and vessel wall trauma did not find a difference for the endoscopic versus open technique.[104,105]

Endoscopic Radial Artery Harvest

Use of the radial artery for CABG has regained popularity over the last decade. In conventional radial artery harvest, the incision runs from below the antecubital fossa to the wrist, along the medial border of the brachioradialis muscle. Although wound complications are reported infrequently, delayed healing of the forearm can cause severe discomfort.[106] Objective sensory loss in 10% of patients and forearm scar discomfort in 33% undergoing open radial artery harvest have been reported.[107,108] Endoscopic techniques for graft harvest have been developed subsequently.[109]

Surgical Technique

Collateral circulation from the ulnar artery to the palmar arch has to be verified pre- or intraoperatively using either the standard Allen test or modification of the test by applying Doppler or measuring oxygen saturation in patients in whom the signs of visual reperfusion are in doubt. In order to prevent brachial plexus injury, the arm should not be overextended above 90 degrees. One centimeter superior to the radial styloid prominence, a 2- to 3-cm incision is made, and the radial artery is identified and dissected. A subcutaneous retractor and a 5-mm, 30-degree endoscope are placed into the incision. By bluntly advancing the retractor through the subcutaneous tissue, the radial artery is visualized. Side branches and surrounding tissue are divided using an ultrasonic harmonic or thermowelding scalpel that is placed underneath the retractor. The fascia between the brachioradialis and flexor carpi radialis muscles is divided anterior to the radial artery with the scalpel to increase the space for insertion of the subcutaneous retractor.[110] After division of all side branches, a vessel retractor is advanced from the distal incision to verify complete isolation of the conduit. The proximal radial artery is occluded using an Endoloop or clipped distal to the origin of the ulnar artery branch and transsected with endoscopic scissors. The graft is recovered through the distal incision, and the distal end is ligated. The incision is closed in a standard fashion.

Results

The reported incidences of neurologic complications after standard open harvesting technique of the radial artery vary in the literature from 2.4 to 30% and can be related to injury of the superficial radial nerve or the lateral antebrachial cutaneous nerve. With endoscopic technique, the latter usually is not encountered, because the dissection is performed underneath the brachioradialis muscle. Superficial radial nerve injury, however, still may occur during distal dissection.[110] With regard to wound infections, endoscopic radial artery harvest is associated with a lower rate of infection (0 to 2.7%) compared with the open technique.[100,111]

Graft patency, clinical outcome, histological integrity, and in-vitro vasoreactivity are equal to open graft harvest.[112–114] Thus, endoscopic radial artery harvesting can be recommended for better patient satisfaction and fewer wound healing complications.[115]

CONCLUSION

In summary, minimally invasive bypass surgery continues to play an increasing role in surgical revascularization. There is growing evidence in favor of OPCAB, which is already the preferred method of bypass grafting in many centers. MIDCAB is still limited to patients with single-vessel disease, and excellent long-term data confirm the efficacy of this approach. Endoscopic bypass grafting using robotic assistance is still an evolving procedure that is applied only to selected patients, and its continued application will strongly depend on technological improvements. As for endoscopic vein graft harvesting, there is a body of evidence suggesting superior results compared with an open harvesting technique, which also may be true for the technique of endoscopic radial artery harvest in the future.

CHAPTER 26

Coronary Artery Reoperations

G. V. Gonzalez-Stawinski
Bruce W. Lytle

Coronary artery reoperations are more complicated than primary operations. Patients undergoing reoperations have distinct, more dangerous pathologies; reoperations are technically more difficult to perform; and the risks are greater.[1–12] Vein graft atherosclerosis, present in most reoperative candidates, is a unique and dangerous lesion. Reoperative candidates commonly have severe and diffuse native-vessel distal coronary artery disease (CAD), a problem that has had the time to develop only because these patients did not die from their original proximal coronary artery lesions. Aortic and noncardiac atherosclerosis are also often far advanced in many reoperative candidates. Some technical hazards, including the presence of patent arterial grafts and sternal reentry, are unique to reoperations, and others, such as lack of bypass conduits and difficult coronary artery exposure, are common.

INCIDENCE OF REOPERATION

After a primary bypass operation, the likelihood of a patient undergoing a reoperation depends on patient-related variables, primary operation-related variables, adherence to strict medical control of risk factors for disease progression after bypass surgery, the possibility of alternative treatments, physician opinion about the feasibility of reoperation, and time. Studies from our institution noted a cumulative incidence of reoperation of 3% by 5 years, 10% by 10 years, and 25% by 20 postoperative years[13] (Fig. 26-1). Factors associated statistically with an increased likelihood of reoperation have been variables predicting a favorable long-term survival (eg, young age, normal left ventricular function [LVF], and single- or double-vessel disease), variables designating an imperfect primary operation (eg, no internal thoracic artery [ITA] graft and incomplete revascularization), and symptom status (eg, class III or IV symptoms at primary operation). Young age at primary operation and incomplete revascularization are also markers of a severe atherogenic diathesis.

More recently, however, the proportion of isolated coronary artery operations that are reoperations has decreased. This decrease is related in part to the more aggressive use of coronary artery interventions for patients with previous bypass surgery and probably to more effective risk factor control. In 1990 about 37% of coronary artery revascularization operations were reoperative interventions, whereas in 2002 this figure decreased to 30%[14] (Fig. 26-2). Also, surgery has changed in directions that will decrease the rate of reoperation. Use of the left internal thoracic artery (LITA) to graft the left anterior descending (LAD) coronary artery decreases the risk of reoperation compared with the strategy of using only vein grafts, and the LITA-LAD graft has become a standard part of operations for coronary artery revascularization.[15] Furthermore, it now appears that use of bilateral ITA grafts decreases the likelihood of death and reoperation when compared with the single LITA-LAD strategy[16] (Fig. 26-3). The use of other arterial conduits such as the radial artery and the gastroepiploic artery in the context of total arterial revascularization may decrease the risk of reoperation further, but as yet the long-term data are insufficient to answer this question.

The patient population of reoperative candidates has evolved. Cleveland Clinic Foundation studies have shown that in the early years of bypass surgery (1967 to 1978), only 28% of patients underwent reoperation solely because of graft failure, and that graft failure often occurred early after the primary operation (mean postoperative interval of 28 months after primary operation). Reoperation because of the progression of atherosclerosis in nongrafted coronary arteries was common in

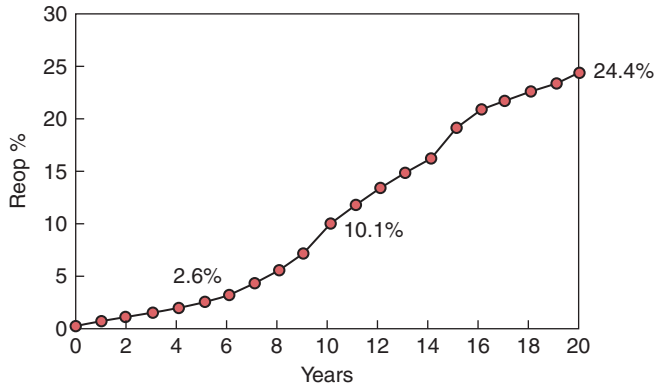

FIGURE 26-1 Study of 4000 patients who underwent bypass surgery from 1971 to 1974 showed that 25% of patients had undergone a reoperation within a period of 20 years after primary operation. (*Data from Cosgrove DM, Loop FD, Lytle BW, et al: Predictors of reoperation after myocardial revascularization. J Thorac Cardiovasc Surg 1986; 92:811.*)

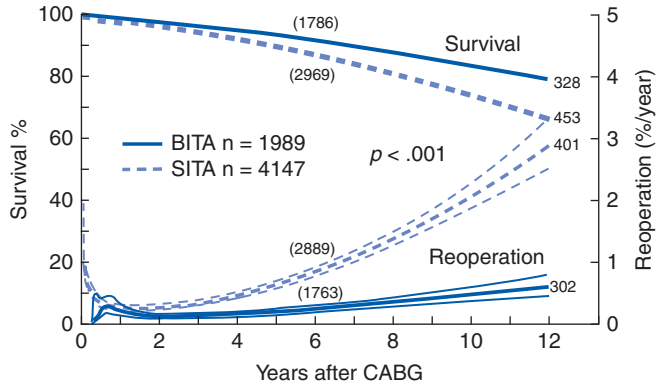

FIGURE 26-3 Comparison of survival and reoperation hazard function curves in the propensity-matched patients undergoing bilateral (BITA, *n* = 1989) or single ITA (SITA, *n* = 4147) CABG. (*Reproduced with permission from Lytle BW, Blackstone EH, Loop FD, et al: Two internal thoracic artery grafts are better than one. J Thorac Cardiovasc Surg 1999; 117:855.*)

the 1967 to 1978 time period (55% of patients).[1,2] Between 1988 and 1991, almost all patients had graft failure as at least part of the indication for reoperation (92%), but that graft failure occurred late after the primary operation at a mean interval of 116 months.[3] Today, patients undergoing reoperation usually had a successful primary operation at least 10 years previously for the treatment of multivessel CAD, and the angiographic indications for reoperation are progression of native-vessel distal CAD in combination with late graft failure caused by vein graft atherosclerosis.

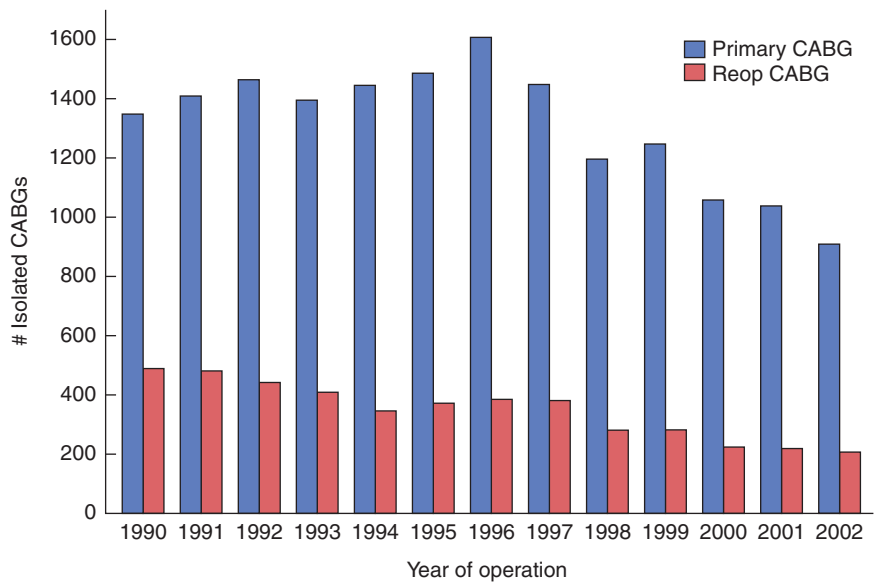

FIGURE 26-2 Study of 21,568 patients who underwent bypass surgery from 1990 to 2003 showed a steady decrease in the number of patients undergoing redo coronary artery operations. (*Data from Sabik JF, Blackstone EH, Houghtaling PL, et al: Is reoperation still a risk factor in coronary artery bypass surgery? Ann Thorac Surg 2005; 80:1719.*)

GRAFT FAILURE

An understanding of the pathology and causes of saphenous vein graft failure is important not only for an understanding of the causes of the need for reoperation, but also for understanding the dangers inherent in either the interventional or the conservative treatment of patients with previous bypass surgery. Saphenous vein to coronary artery grafts exhibit different pathologies at different intervals after operation.[17–20] Within a few months, they often have diffuse endothelial disruptions with associated mural thrombus. The mural thrombus usually is not obstructing, and when grafts do become occluded early after operation owing to thrombosis, it may not be a result of these intimal changes, but rather may be related to hemodynamic factors. Most saphenous vein grafts examined more than 2 to 3 months after operation have developed a proliferative intimal fibroplasia. This is a concentric cellular process, and it is diffuse, extending the entire length of the graft (Fig. 26-4). It evolves with time to a more fibrous lesion. It is not friable, and although intimal fibroplasia involves most vein grafts, it causes stenoses or occlusions of only a few.

Vein graft atherosclerosis is a distinct pathologic process that often is recognized as early as 3 to 4 years after operation and is characterized by lipid infiltration of areas of intimal fibroplasia (Fig. 26-5). The distribution of vein graft atherosclerosis mimics that of intimal fibroplasia in that it is concentric and diffuse, although as vein graft atherosclerosis progresses, stenotic lesions may become eccentric. In addition, vein graft atherosclerosis is a

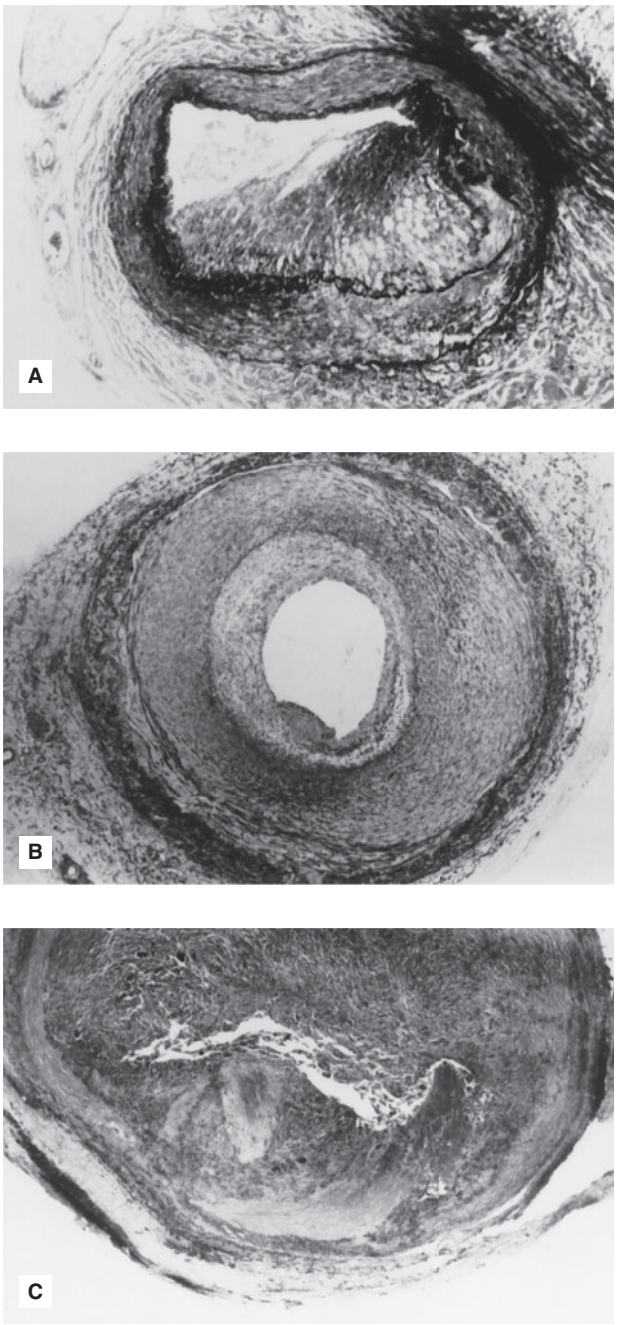

FIGURE 26-4 Pathology of (A) native coronary artery atherosclerosis, (B) vein graft intimal fibrosis, and (C) severe vein graft atherosclerosis. (*Reproduced with permission from Lytle BW, Cosgrove DM: Coronary artery bypass surgery, in Wells SA (ed): Current Problems in Surgery. Philadelphia, Saunders, 1992; p 733.*)

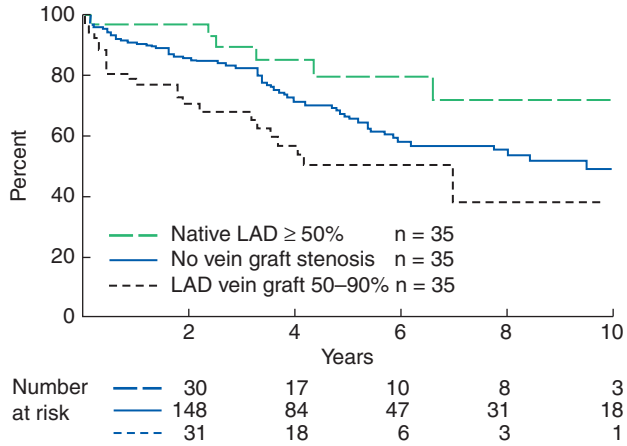

FIGURE 26-5 Patients with late stenoses in vein grafts to the LAD coronary artery had worse survival when compared with either patients with native coronary LAD stenoses or patients with no stenotic vein grafts. (*Reproduced with permission from Lytle BW, Loop FD, Taylor PC, et al: Vein graft disease: the clinical impact of stenoses in saphenous vein bypass grafts to coronary arteries. J Thorac Cardiovasc Surg 1992; 103:831.*)

superficial lesion, it is very friable, and it is often associated with overlying mural thrombus. These characteristics make it different from native-vessel coronary atherosclerosis, a process that is segmental and proximal, eccentric, encapsulated, usually not friable, and usually not associated with overlying mural thrombus. Vein graft atherosclerosis is seen in a majority of grafts explanted more than 10 years after surgery whether or not those grafts are stenotic, and atherosclerotic lesions appear to account for almost all late saphenous vein graft (SVG) stenoses. The extreme friability of vein graft atherosclerosis creates a substantial risk of distal coronary artery embolization during percutaneous interventions to treat stenotic lesions and during reoperations for patients with atherosclerotic vein grafts. It is also probable that spontaneous coronary artery embolization may occur from atherosclerotic grafts. In addition, atherosclerotic stenoses in vein grafts appear to predispose to graft thrombosis. Vein graft atherosclerosis appears to be an "active" event-producing lesion.

The exact incidence of late SVG stenoses and occlusions is difficult to determine even with prospective studies because death and reoperation are nonrandom events that remove patients from prospective populations available for late coronary artery angiography. However, it appears that by 10 years after operation, approximately 30% of vein grafts are totally occluded, and 30% of patent grafts exhibit some degree of stenosis or intimal irregularities characteristic of vein graft atherosclerosis.[21,22] Although vein graft atherosclerosis is not the only factor related to late SVG occlusion, it is an important one. Native-vessel stenoses distal to the insertion site of vein grafts may decrease SVG graft outflow and contribute to graft failure, but late graft occlusion usually occurs in the presence of vein graft atherosclerosis. Furthermore, when stenotic vein grafts are replaced at reoperation, the late patency rate of the new vein grafts is good.[2]

Progress has been made toward decreasing the rate of vein graft failure. The early patency rates of SVGs have been improved by the use of perioperative and long-term platelet inhibitors,[23–25] but the best data involving patients receiving platelet inhibitors indicate that the 10-year vein graft failure rate is approximately 35%. Some studies now indicate that lipid-lowering regimens decrease late vein graft disease and the risk of late cardiac events.[26,27] However, the overall level of improvement has been small.[26,27] So far, the only way known to avoid vein graft atherosclerosis is to avoid using vein grafts.

ITA grafts rarely develop late atherosclerosis, and the late attrition rate of patent ITA grafts is extremely low. Left ITA to LAD grafts have a very high late (20 years) patency rate, and for most patients, the LAD is a profoundly important coronary artery.[21,28] These factors account for the impact of the LITA-LAD graft not only in decreasing the rate of late death after primary bypass surgery, but also in decreasing the rate of reoperation.[15] Multiple ITA grafts provide incremental benefit in decreasing the risk of reoperation.[16] It is also important that ITA grafts do not develop graft atherosclerosis, and therefore do not create the risk of coronary artery embolization during reoperation. The presence of patent arterial grafts may create other technical problems during repeat surgery, but embolization is not among them.

INDICATIONS FOR REOPERATION

The randomized trials of bypass surgery versus medical management that were initiated in the 1970s provided a framework of information concerning the indications for bypass surgery, and subsequent observational studies have added substance to that framework. However, no randomized trials of medical versus surgical management pertain to patients with prior surgery. The coronary pathology of patients with previous bypass surgery is different from that of patients with only native-vessel stenoses, and we cannot assume that the natural history of, for example, triple-vessel disease based on atherosclerotic vein grafts, is equivalent to that of triple-native-vessel disease.

Two nonrandomized, retrospective studies of patients who had angiograms after bypass surgery addressed the issue of late survival.[29,30] One study showed that patients with early (fewer than 5 years after operation) stenoses in vein grafts and patients with no stenotic vein grafts had approximately the same outcomes and that these outcomes were relatively good.[29] *However, the presence of late (5 years or more after operation) stenoses in vein grafts predicted poor long-term outcomes, particularly if a stenotic vein graft supplied the LAD coronary artery. When late stenoses in LAD vein grafts were combined with other high-risk characteristics, the late survival rate was particularly dismal.* For example, patients with a 50 to 99% stenosis in an LAD vein graft combined with abnormal LVF and triple-vessel or left main stenoses had only a 46% 2-year survival without reoperation. Patients with late stenoses in an LAD vein graft had significantly worse long-term outcomes than did patients with the LAD jeopardized by a native lesion (see Fig. 26-5). This study showed that the difference in the pathology of early (intimal fibroplasia) and late (vein graft atherosclerosis) vein graft stenoses is associated with a difference in clinical outcome and that late stenoses in vein grafts are dangerous lesions.

A second study compared the outcomes of patients with stenotic vein grafts treated with reoperation (REOP group) versus those treated with medical treatment (MED group).[30] Again, this was a nonrandomized, retrospective study, and the patients in the REOP group were older and more symptomatic, had worse LVF, and had fewer patent grafts than the patients in the MED group.

The survival of patients with early (fewer than 5 years) SVG stenoses was not different in the two groups. The operative risk for the REOP group was low (no deaths among the 59 patients) and the long-term survival was good, but late survival was just as good for the patients treated medically (Fig. 26-6). It is important to note that the patients in the REOP group were more symptomatic to start with, and at late follow-up, they were less symptomatic than the patients in the MED group. Thus, reoperation for patients with early vein graft stenosis was an effective way of relieving symptoms of angina, but it appears that patients without symptoms can be treated medically with safety, at least over the short term.

However, the overall outcomes were worse for patients with late stenoses in vein grafts, and many subgroups had improved survival rates with reoperation. By multivariate testing (Table 26-1), a stenotic (20 to 99%) LAD vein graft predicted late death, and performing a reoperation increased late survival for these patients. Multivariate testing of smaller subgroups showed that the survival advantage for the REOP group was true even for patients with only class I or class II symptoms, and that reoperation still improved survival for the remaining patients when patients with stenoses in LAD vein grafts were excluded from the analysis.

Univariate comparisons for the REOP and MED subgroups of patients with stenotic LAD grafts are shown in Fig. 26-7, demonstrating the improved survival for the REOP group. When patients with stenotic LAD vein grafts were subgrouped on the basis of severity of the stenotic lesions (Fig. 26-8), the patients with severely stenotic (50 to 99%) vein grafts obviously benefited from surgery, exhibiting a decreased risk of death even early in the follow-up period. For patients with moderate stenoses (20 to 49%) in LAD vein grafts, the survivals of the MED and REOP groups were equivalent for about 2 years, but after that point survival of the patients in the MED group

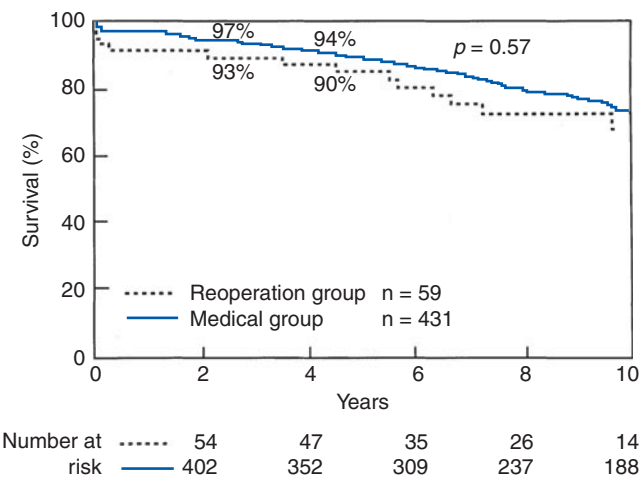

FIGURE 26-6 The survival of patients with early (<5 years after operation) stenoses in vein grafts was favorable with and without reoperation (p = NS). FIGURE 26-8 Patients with late stenoses in LAD vein grafts (*top*) had immediate improvement in their survival rate. Patients with moderate (20 to 49%) stenoses in LAD vein grafts had equivalent survival with or without reoperation for approximately 2 years, but after that point, the patients who did not have reoperation did poorly. (*Reproduced with permission from Lytle BW, Loop FD, Taylor PC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts. J Thorac Cardiovasc Surg 1993; 105:605.*)

became rapidly worse, so that by 3 to 4 years of follow-up, the survival benefit of reoperation became apparent. Although the patients in these studies did not have consistent functional testing, there is evidence that myocardial perfusion and functional studies can help to identify patients likely to benefit from reoperation.

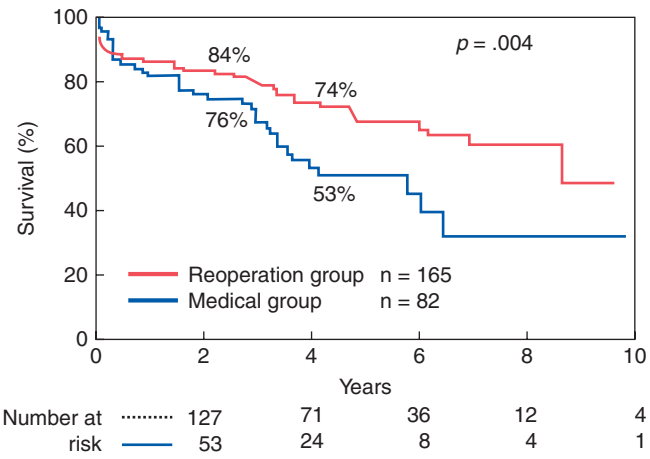

FIGURE 26-7 If patients had late (≥5 years after operation) stenoses in LAD vein grafts, they had a better survival rate (p = .004) with immediate reoperation than if they received initial nonoperative treatment. (*Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts. J Thorac Cardiovasc Surg 1993; 105:605.*)

Lauer and colleagues studied 873 symptom-free postoperative patients with symptom-limited exercise thallium-201 studies and found that patients with reversible perfusion defects were more likely to die or experience major cardiac events during a 3-year follow-up.[31] Impaired exercise capacity also was strongly predictive of unfavorable outcomes.

Anatomical indications for reoperation to improve survival prognosis include: (1) atherosclerotic (late) stenoses in vein grafts that supply the LAD artery; (2) multiple stenotic vein grafts that supply large areas of myocardium; and (3) multivessel disease with a proximal LAD lesion and/or abnormal LVF based on either native-vessel lesions or stenotic vein grafts or a combination of the two pathologies. Reoperation is also effective in other anatomical situations in which severe symptoms are the indication for invasive treatment, including patients with a patent ITA to LAD graft combined with other ischemia-producing pathology and multiple early vein graft stenoses. The combination of the anatomical characteristics just noted and reversible ischemia and/or worsening LVF during stress constitutes a particularly strong indication for reoperation.

PERCUTANEOUS TREATMENT OF POSTOPERATIVE PATIENTS

Percutaneous treatments (PCTs) represent alternative anatomical treatments for postoperative patients and often are useful. The effectiveness of PCTs is related to the vascular pathology to be treated and the clinical implications of treatment failure. Today, native coronary artery stenoses often can be treated with a low restenosis rate as long as those vessels are large enough to allow intracoronary stenting. Unfortunately, many postoperative patients have very diffuse native coronary atherosclerosis that makes PCT difficult or ineffective. Also, PCT has not been as effective in the treatment of diabetic native CAD.

The rate of technologic change in interventional cardiology has been rapid, and multiple percutaneous technologies have been used to treat stenotic vein grafts. Balloon angioplasty, first-generation PCT, was relatively dangerous to perform and produced ineffective long-term revascularization, particularly when used to treat older (atherosclerotic) vein grafts.[32] Direct coronary atherectomy (DCA) increased the risk of coronary embolization at the time of the procedure without improving the restenosis rate.[33] It has been hoped that the use of intracoronary stents, particularly covered stents and drug-eluting stents (DESs), in stenotic vein grafts might provide better outcomes, and stenting does represent an improvement over balloon angioplasty.[32] The Randomized Evaluation of Polytetrafluoroethylene Covered Stent in Saphenous Vein Grafts (RECOVERS) trial, a randomized study designed to compare rates of SVG restenosis between CABG patients treated with covered stents and with bare stents, showed identical restenosis rates at 6 months of follow-up (24.2% versus 24.8%; $p = .24$).[34] In a nonrandomized retrospective study comparing the effects of DESs with those of bare metal stents in treating SVG stenosis, Ge and colleagues reported significant differences in in-stent stenosis between groups at 6 months of follow-up (10 versus 26%; $p = .03$).[35] However, other reports comparing DES with bare metal stents showed that the use of DES lowered the rate of restenosis but increased the risk of death.[36]

The kinetics of treatment failure after PCT for vein grafts are different from those for native coronary vessels. Restenosis and new stenotic lesions in vein grafts continue to appear with time, and the shoulder on the adverse outcome curve that appears at 6 months to 1 year after PCT for native vessels does not appear for vein grafts. Thus, there is still some uncertainty about the clinical impact of PCTs of stenotic vein grafts. Patients with previous bypass surgery are an extremely heterogeneous group; some subgroups are at low risk without any anatomical treatment at all, and some subgroups are at high risk without effective therapy. To date, the reported studies of PCT of SVG lesions have not included clinical risk stratifications that would allow comparison of patient survival rates.

Despite persistently high restenosis rates after percutaneous interventions, there are still many indications for their use in the treatment of patients with previous bypass surgery. Realistically, the ideal uses of PCTs are in situations in which failure of the anatomical treatment is not likely to be catastrophic as the impact of stenting on survival is unclear. These situations include symptomatic patients with: (1) early vein graft stenoses; (2) native coronary stenoses; or (3) focal late SVG stenoses in vein grafts not supplying the LAD artery. There are many patients with previous surgery who will fall into a middle ground where it is not clear whether percutaneous transluminal coronary angioplasty (PTCA) or reoperation is likely to yield the best outcome, and judgments must be made on the specific advantages and disadvantages of the treatments for those particular patients. Factors making PTCA more attractive than reoperation are listed in Table 26-2.

TABLE 26-2 Reoperation versus PTCA for Patients with Stenotic Vein Grafts

Factors Favoring Reoperation	Factors Favoring PTCA
Late (≥5 years) stenoses	Early (<5 years) stenoses
Multiple stenotic vein grafts	Single stenotic vein graft
Diffusely atherosclerotic vein grafts	Other patent vein grafts
Stenotic LAD vein graft	Focal graft lesions
No patent ITA graft	Patent ITA-LAD graft
Abnormal left ventricular function	Normal left ventricular function

There are patients with postsurgical repeat ischemic syndromes and very unfavorable coronary anatomy for whom good options for anatomical treatment do not exist. For reoperative coronary surgery to be of benefit there must be bypass conduits available to construct new grafts to graftable coronary arteries that subtend substantial areas of ischemic but viable myocardium. If these conditions do not exist, surgery may not be in the interest of even a symptomatic patient. Studies of diabetic patients undergoing postsurgical repeat revascularization with PCT or surgery have shown unfavorable 10-year survival rates.[37] Unless good coronary targets to receive bypass grafts are available, PCT may be the best choice for marginal candidates because of lower initial costs and, in some settings, lower initial mortality.

TECHNICAL ASPECTS OF CORONARY REOPERATIONS

Reoperations are more complicated than primary operations. The specific technical challenges that surgeons must recognize and solve that are unique to or more common during coronary reoperation are

1. Sternal reentry
2. Stenotic or patent vein or arterial bypass grafts
3. Aortic atherosclerosis
4. Diffuse native-vessel coronary artery disease
5. Coronary arteries located amid old grafts and epicardial scarring
6. Lack of bypass conduits

The overall problem of myocardial protection is more difficult during reoperations, with perioperative myocardial infarction still being the most common cause of in-hospital death.[3,6] The metabolic concepts of myocardial protection in use today are valid, but the reasons that myocardial protection sometimes fails during reoperation are related to anatomical causes of myocardial infarction. These anatomical causes of perioperative myocardial infarction include injury to bypass grafts, atherosclerotic embolization from vein grafts or the aorta to distal coronary arteries, myocardial devascularization secondary to graft removal, hypoperfusion through new grafts, failure to deliver cardioplegic solution, early vein graft thrombosis, incomplete revascularization, diffuse air embolization, and technical error.[3,38–42] To be consistently successful, coronary reoperations must be designed to avoid these causes of myocardial infarction.

Preoperative Assessment

A complete understanding of the patient's native coronary and bypass graft anatomy is essential. Achieving this goal is sometimes not as easy as it sounds, particularly if the patient has had multiple previous coronary operations. If bypass grafts, venous or arterial, are not demonstrated by a preoperative coronary angiogram, it usually means that they are occluded, but it is also possible that the angiogram simply has failed to demonstrate their location. Examination of old angiograms performed before previous operations and review of previous operative records often help to illustrate the patient's coronary anatomy.

It is also important to know that graftable stenotic coronary arteries supply viable myocardium. Myocardial scar and viability can be differentiated by thallium scanning, positron-emission tomography, and stress (exercise or dobutamine) echocardiography. The intricacies of establishing myocardial viability are beyond this discussion, but it is an important issue. Before embarking on a reoperation, it makes sense to be reasonably sure that there is a matchup between the patient's graftable arteries and some viable myocardium such that grafting those arteries will provide some long-term benefits.

It is also wise to have a preoperative plan for bypass conduit selection and to document that potential bypass conduits are available. ITA angiography often is helpful. Venous Doppler studies can be used to assess the presence of greater and lesser saphenous vein segments, and arterial Doppler studies can assess the radial and inferior epigastric arteries and establish the adequacy of flow to the digits during radial artery occlusion.

Median Sternotomy Incision, Conduit Preparation, and Cannulation

Most coronary reoperations are performed through a median sternotomy. Situations associated with increased risk during a repeat median sternotomy include right ventricular or aortic enlargement, a patent vein graft to the right coronary artery, an in situ right ITA graft patent to a left coronary artery branch, an in situ left ITA graft that curls under the sternum, multiple previous operations, and difficulty reopening the sternum during a previous reoperation. In such situations, vessels for arterial (via the femoral or axillary artery) and venous access for cardiopulmonary bypass are dissected out before sternal reentry. All bypass grafts except for the internal thoracic arteries may be prepared before sternal reentry. Preparation of radial artery and greater and lesser saphenous vein segments can be carried out simultaneously. The most common structure injured during reentry is a bypass graft.[4]

When reopening a median sternotomy, the incision is made to the level of the sternal wires; the wires are cut anteriorly and bent back but are not removed (Fig. 26-9). An oscillating saw is used to divide the anterior table of the sternum. When the anterior table has been divided, ventilation is stopped, and the assistants elevate each side of the sternum with rake retractors while the posterior table of the sternum is divided in a caudal-cranial direction. The sternal wires that have been left in place posterior to the sternum help to protect underlying structures. Once the posterior table of the sternum has been divided with the saw, the wires are removed, and sharp dissection with scissors is used to separate each side of the sternum from underlying structures. Once the sternum has been divided, it is important that the assistants retract in an upward direction, not laterally. The right ventricle is injured more often by lateral retraction while it is still adherent to the underside of the sternum than it is by a direct saw injury.

In high-risk situations, it can be helpful to perform a small anterolateral right thoracotomy (Fig. 26-10) before the repeat median sternotomy. Underlying structures, such as the aorta, patent bypass grafts, and the right atrium and ventricle, can be dissected away from the sternum via this approach, and thus, with the surgeon's hand placed behind the sternum, reentry is safe. This small additional incision contributes little morbidity.

Another technique for sternal reentry in high-risk patients is to heparinize, cannulate, and initiate cardiopulmonary bypass

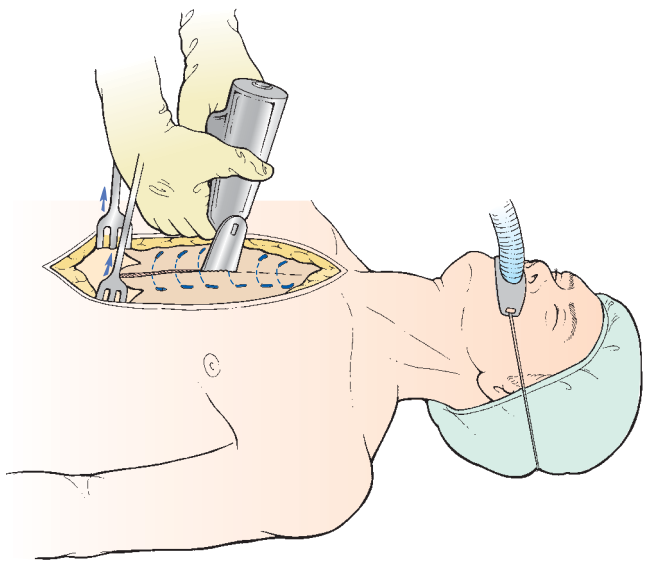

FIGURE 26-9 Leaving the sternal wires in place posteriorly helps to protect underlying structures while the posterior table of the sternum is divided with an oscillating saw. The direction of retraction with rake retractors should be anterior, not lateral.

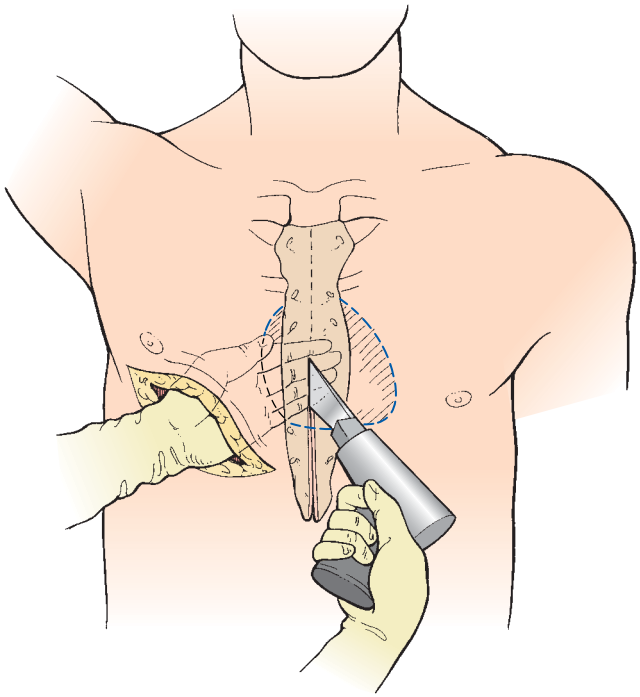

FIGURE 26-10 A small anterolateral right thoracotomy allows dissection of substernal structures such as patent grafts and the right ventricle or aorta away from the sternum under direct vision. While the sternum is being divided, the surgeon may place a hand behind the sternum for further safety.

before median sternotomy. The advantages of this strategy are that the heart can be emptied and allowed to fall away from the sternum, and cardiopulmonary bypass already has been initiated for protection if an injury does occur. The disadvantages of this approach are that extensive mediastinal dissection must be carried out in a heparinized patient, including dissection of the right internal thoracic artery if that is to be used. We rarely employ this approach except in situations in which adherence of an aortic aneurysm to the sternum or a patent right ITA-to-LAD graft creates a specific danger.

Once the sternum has been divided, the pleural cavities are entered. A general principle of dissection during reoperation is that starting at the level of the diaphragm and proceeding in a cranial direction is usually the safest approach. At the level of the diaphragm, few critical structures are injured if the wrong plane is entered. Therefore, at this point in the operation we usually dissect along the level of the diaphragm to the patient's right side until we enter the pleural cavity and then detach the pleural reflection from the chest wall in a cranial direction to the level of the innominate vein. The innominate vein is dissected away from both sides of the sternum with scissors, a maneuver that prevents a "stretch" injury to that vein.

Once the right side of the sternum is separated from the cardiac structures, it is usually possible to prepare a right ITA graft. Because of parietal pleural thickening, it is often more difficult to obtain length on ITA grafts during reoperation than it is during primary procedures, and the right ITA frequently is used as a "free" graft. Once the right ITA dissection is completed to the superior border of the first rib, an incision is made in the parietal pleura to separate the proximal ITA from the area of the phrenic nerve. Thus, if the right ITA needs to be converted to a "free" graft during aortic cross-clamping, it makes division at that point easier because the proximal ITA is clearly identifiable. Although intrapericardial dissection of the left side of the heart is left until later, freeing the left side of the anterior chest wall from the underlying structures (which may include a patent ITA graft) is undertaken now. This is difficult only if there is a patent ITA graft that is densely adherent to the chest wall. Again, it is best to enter the left pleural cavity at the level of the diaphragm and proceed in a cranial direction.

The most difficult point of dissection is usually at the level of the sternal angle, where a patent ITA graft may approach the midline and be adherent to the sternum or the aorta. There are no tricks for dissecting out a patent ITA graft except for being careful. The danger to a patent left ITA graft during sternal reentry and mediastinal dissection is entirely related to the location of the graft at the time of the primary operation. Ideally, the pericardium should be divided at a primary operation, and the left ITA graft should be allowed to run posterior to the lung through the incision in the pericardium and to the LAD or circumflex artery (Fig. 26-11). When this is done, the lung will lay anterior to the left ITA, and that graft will not become adherent to the aorta or to the chest wall.

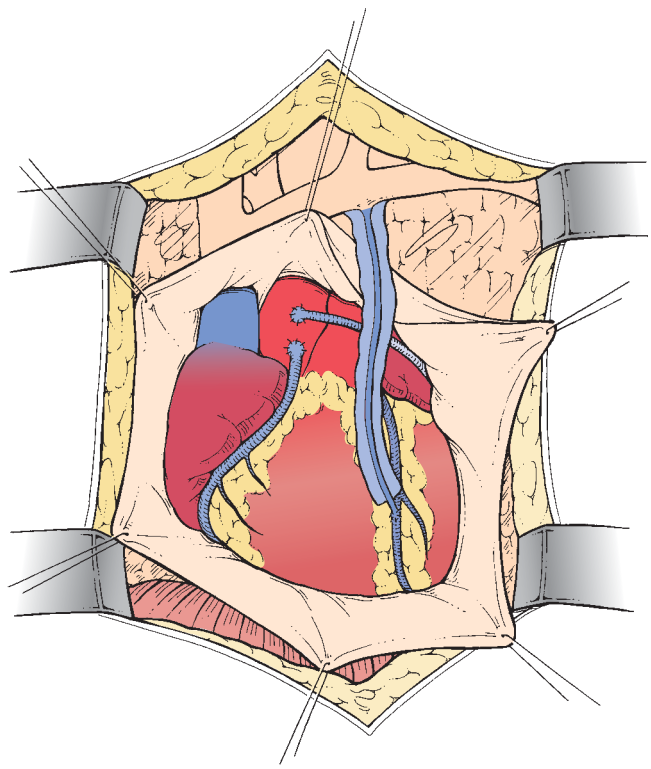

FIGURE 26-11 A patent left ITA-to-LAD graft should not pose a threat during reoperation. At a primary operation, the pericardium should be divided in a posterior direction, and the ITA graft should be placed in that incision. The ITA graft then will lie posterior to the lung and will not be pushed toward the midline by the lung or become adherent to the sternum.

Once the left side of the chest wall is free, the left IMA is prepared (if it has not been used at a previous operation), the sternal spreader is inserted, and the intrapericardial dissection of the aorta and right atrium is accomplished. Again, in most cases it is safest to find the correct dissection plane at the level of the diaphragm and then to continue around the right atrium to the aorta. The one situation in which this strategy may be dangerous is if an atherosclerotic vein graft to the right coronary artery lies over the right atrium. Manipulation of atherosclerotic vein grafts can cause embolization of atherosclerotic debris into coronary arteries, and it is best to employ a "no touch" technique with such grafts. If a vein graft to the right coronary artery lies in an awkward position over the right atrium, it is best to leave the right atrium alone and use the femoral vein and superior vena cava cannulation to establish venous drainage (Fig. 26-12). Once cardiopulmonary bypass has been established, the aorta has been cross-clamped, and cardioplegia has been given, the atherosclerotic vein graft then can be disconnected.

The goal of dissection of the ascending aorta is to obtain enough length for cannulation and cross-clamping and to avoid the most common error, aortic subadventitial dissection. The correct level of dissection on the aorta usually is found either by following the right atrium to the aorta in a caudal-to-cranial direction or by identifying the innominate vein and leaving all the tissue beneath the innominate vein on the aorta. At the level of the innominate vein, the pericardial reflection on each side of the aorta will be identifiable. Division of the pericardial reflection on the left side in a posterior direction will lead to the plane between the aorta and the pulmonary artery. Once the left side of the aorta is identified, the surgeon then may dissect posteriorly on the medial aspect of the left lung toward the hilum. The segment of tissue between these two dissection planes usually will include a patent left ITA graft, if present, and clamping that tissue will produce occlusion of the ITA graft.

When the aorta has been dissected out, heparin is given, and cannulation is undertaken. Cannulation of an atherosclerotic ascending aorta may cause atherosclerotic embolization leading to stroke, myocardial infarction, or multiorgan failure, so the ascending aorta should be studied with palpation and echocardiography to detect atherosclerosis before cannulation. Although the most widely used alternative arterial cannulation site is the femoral artery, arteriopathic patients often have severe femoral artery atherosclerosis. The axillary artery is an alternative arterial cannulation site that we have used with increasing frequency because atherosclerotic disease is usually not present in that vessel, and its cannulation allows antegrade perfusion[44] (Fig. 26-13). If atherosclerotic disease or calcification of the aorta makes any aortic occlusion hazardous, the options are off-pump bypass surgery (see Other Options) or replacement of the aorta with axillary artery cannulation, hypothermia, and circulatory arrest. Venous cannulation usually is accomplished with a single two-stage right atrial cannula. A transatrial coronary sinus cardioplegia cannula is inserted via a right atrial purse

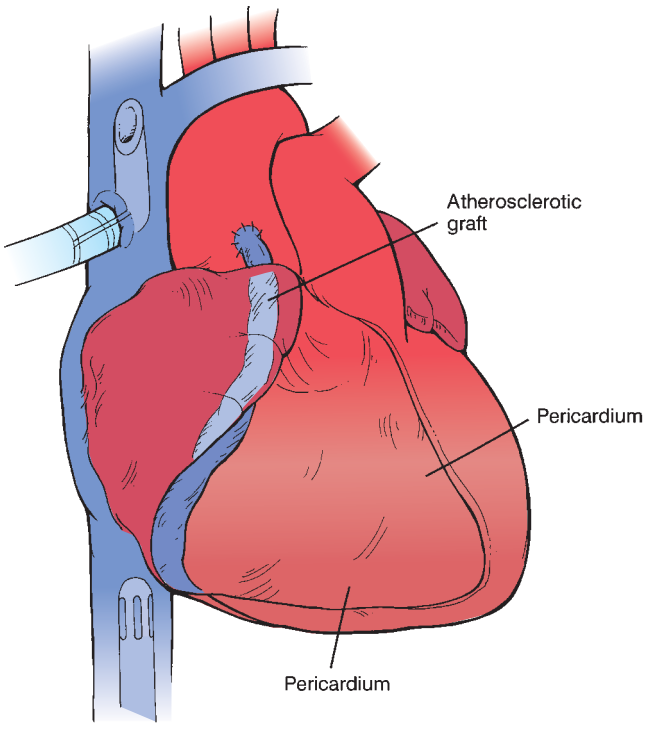

FIGURE 26-12 Manipulation of patent but atherosclerotic vein grafts should be avoided. If an atherosclerotic right coronary vein graft blocks access to the right atrium, femoral vein, and direct superior vena cava, cannulation is safer than mobilizing the vein graft so as to achieve right atrial cannulation.

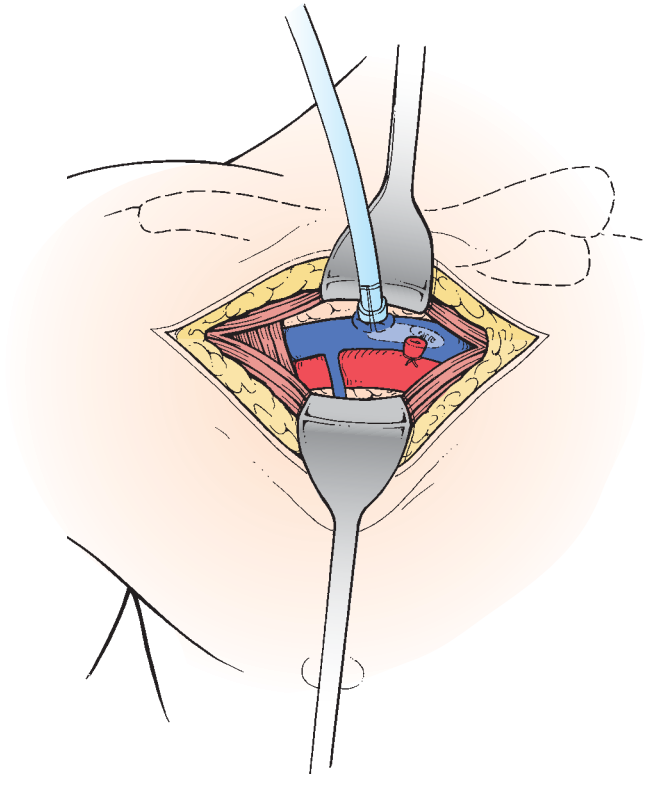

FIGURE 26-13 The axillary artery is an important alternative arterial cannulation site for patients with aortic and femoral artery atherosclerosis. A 21-gauge cannula will fit the axillary artery in most patients.

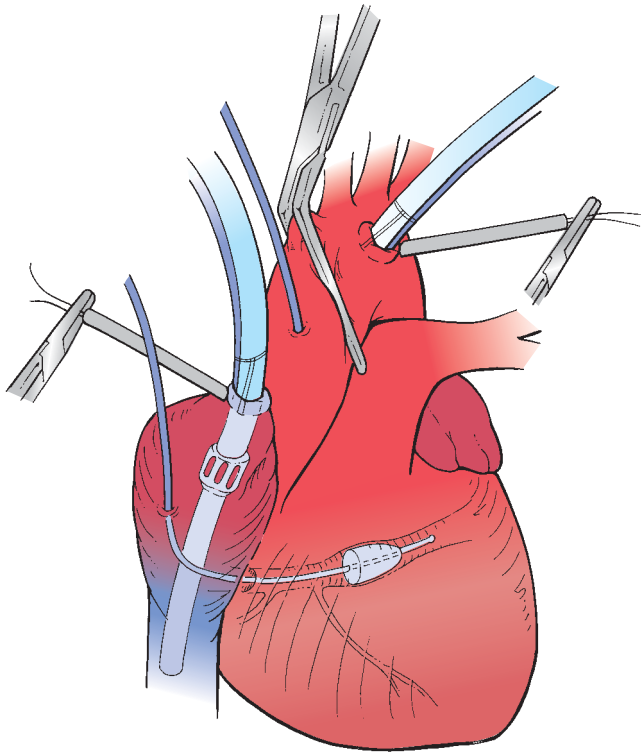

FIGURE 26-14 Standard cannulation for coronary artery reoperation includes aortic arterial cannulation, an aortic needle for antegrade delivery of cardioplegia and aortic root venting, a single two-stage venous cannula, and a transatrial coronary sinus catheter with a self-inflating balloon for delivery of retrograde cardioplegia. Cannulation is accomplished before dissection of the left ventricle.

string with the aid of a stylet, and a needle is placed in the ascending aorta for delivery of antegrade cardioplegia and for use as a vent (Fig. 26-14).

Myocardial Protection

The myocardial protection strategy used by us during most coronary artery reoperations is a combination of antegrade and retrograde delivery of intermittent cold blood cardioplegia combined with a dose of warm reperfusion cardioplegia ("hot shot") given before aortic unclamping, principles developed by Buckberg and colleagues.[45] Multiple types of cardioplegic solutions have been described, and most appear to provide a metabolic environment that effectively protects the myocardium. Because of the potential anatomical challenges to cardioplegic myocardial protection during reoperations, the details of how the cardioplegic solution is delivered are very important. In most primary bypass operations, antegrade cardioplegia works well by itself. During reoperations, however, antegrade cardioplegia may not be effective for areas of myocardium that are supplied by patent in situ arterial grafts and may be dangerous because of the risk of embolization of atherosclerotic debris into the coronary arteries from old vein grafts. The delivery of cardioplegia through the coronary sinus and through the cardiac venous system to the myocardium (retrograde cardioplegia) has been a step forward in myocardial protection during reoperations.[46,47] Retrograde cardioplegia delivery avoids atheroembolism from vein grafts, can be helpful in removing atherosclerotic debris and air from the coronary artery system, and can deliver cardioplegia to areas supplied by in situ arterial grafts. The biggest disadvantage of retrograde cardioplegia is that it is not always possible to place a catheter in the coronary sinuses that will deliver cardioplegia consistently. It is important to monitor the adequacy of cardioplegia delivery by measuring the pressure in the coronary sinus, noting the distention of cardiac veins with arterial blood, the cooling of the myocardium, and the return of desaturated blood from open coronary arteries.

Cardiopulmonary bypass is begun, the perfusionist empties the heart and produces mild systemic hypothermia (34°C), and the aorta is cross-clamped. We usually initiate cardioplegia induction with aortic root cardioplegia. To induce and maintain cardioplegic protection, it is helpful to be able to occlude patent arterial grafts. If it has not yet been possible to dissect out a patent arterial graft so that it can be clamped, the systemic perfusion temperature is decreased to 25°C until control of the graft is achieved. After antegrade cardioplegia has been given for 2 to 3 minutes, we shift to retrograde induction for another 2 to 3 minutes. Giving any antegrade cardioplegia does risk embolization from atherosclerotic vein grafts, but if these grafts have not yet been manipulated, that danger is relatively small. Once the adequacy of retrograde cardioplegia delivery has been established, it is often possible to use that route predominantly for maintenance doses.

Intrapericardial Dissection

When the heart has been arrested completely, intrapericardial dissection of the left ventricle is undertaken, starting at the diaphragm and extending out to the left of the apex of the heart. After the apex is identified, the surgeon divides the pericardium in a cranial direction on the left side of the LAD artery (Fig. 26-15). A patent LITA-to-LAD graft will be contained within the strip of pericardium that lies over the LAD artery. Dissection of this pedicle from the anterior aspect of the pulmonary artery will allow an atraumatic clamp to be placed across the patent ITA graft and also will allow the passage of new bypass grafts from the aorta underneath the patent ITA graft to left-sided coronary arteries. The advantages of waiting until after aortic clamping and arrest to dissect out the left ventricle are that dissection is more accurate, there is less damage to the epicardium and less bleeding, manipulation of atherosclerotic vein grafts is less likely to cause coronary embolization, and the dissection of patent ITA grafts is safer.

After the heart is dissected out completely, the coronary arteries to be grafted can be identified, the lengths that bypass conduits need to reach those vessels may be assessed, and the final operative plan can be established. The old grafts and epicardial scarring that are present during reoperations make the preoperative prediction of the lengths of conduits needed for bypass grafts quite difficult, particularly the lengths of arterial grafts, and it is wise to have some flexibility in the operative plan. Before the construction of the anastomoses, those patent

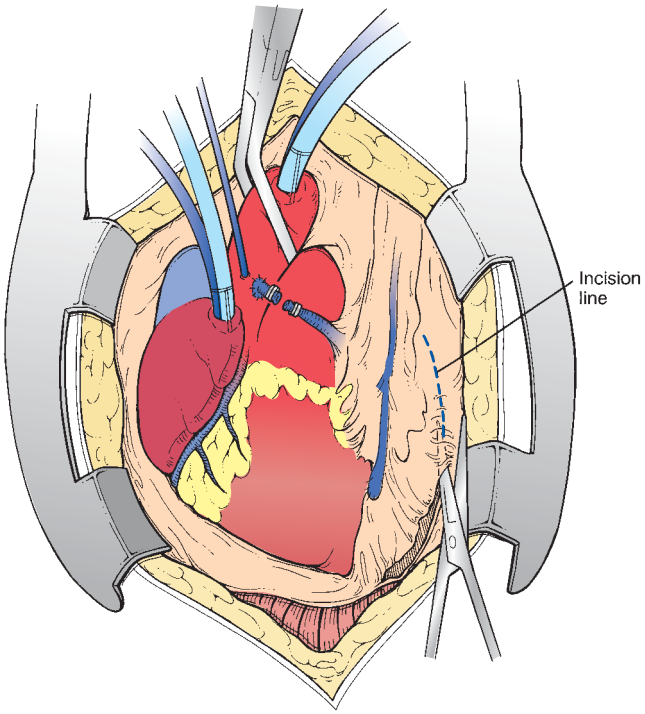

FIGURE 26-15 Division of the pericardium along the diaphragm allows the surgeon to reach a point to the left of the cardiac apex. From that point, the pericardium can be divided in a cranial direction to the left of the LAD artery, leaving a patent ITA graft in the strip of tissue overlying the LAD artery. Atherosclerotic vein grafts that are going to be replaced may be divided once a dose of antegrade cardioplegia is given.

but atherosclerotic vein grafts that are going to be disconnected are identified and are disconnected with a scalpel. The order of anastomosis construction that is used by the authors is: (1) distal vein graft anastomoses; (2) distal free arterial graft anastomoses; (3) distal in situ arterial graft anastomoses; and (4) proximal (aortic) anastomoses.

Stenotic Vein Grafts

When should patent or stenotic vein grafts be replaced, and with what should they be replaced? Atherosclerosis in vein grafts is common if those grafts are more than 5 years old, and leaving them in place risks embolization of atherosclerotic debris at the time of reoperation and subsequent development of premature graft stenoses or occlusions after reoperation. On the other hand, replacement of all vein grafts extends the operation and may use up available bypass conduits.

In the past, our general rule has been to replace all vein grafts that are more than 5 years old at the time of reoperation, even if those grafts are not diseased angiographically. However, this strategy assumes that conduits are available that can replace these old grafts. Today, many patients have very limited conduits at reoperation because of the large numbers of vein grafts used at primary surgery or because of multiple previous operations. Thus, graft replacement must be individualized. Inspection of vein grafts at reoperation occasionally will identify a graft that looks normal angiographically and does not appear to have any thickening or atherosclerosis on visual inspection. Often such vein grafts will be left alone.

Replacing old vein grafts with new vein grafts may often be accomplished by creating the new vein-to-coronary-artery anastomosis at the site of the previous distal anastomosis, leaving only 1 mm or so of the old vein in place (Fig. 26-16). If significant native-vessel stenoses have developed distal to the old vein graft, it is often best to place a new graft to the distal vessel in addition to replacing the vein graft. Many reoperative candidates have proximal occlusions of the native coronary artery system and multiple stenoses throughout the vessel, and if only new distal grafts are constructed, the proximal segments of coronary arteries and their branches that are supplied by atherosclerotic vein grafts may be jeopardized. More than one graft to a major coronary artery may be desirable during reoperation (Fig. 26-17).

Sequential vein grafts often are very helpful during reoperation because they allow more distal anastomoses and fewer proximal anastomoses. Sites for proximal anastomoses are often at a premium in the scarred reoperative aorta.

Artery-to-coronary-artery bypass grafts have many advantages during reoperations. First, they are often available. Second, the tendency of arteries to remain patent even when used as grafts to diffusely diseased coronary arteries makes them particularly applicable to reoperative candidates. Third, in situ arterial grafts do not require a proximal anastomosis. If the left ITA has not been used as a graft at a previous operation, a strong attempt should be made to use it as an in situ graft to the LAD artery. During primary operations, the right ITA usually can be crossed over as an in situ graft to left-sided vessels,

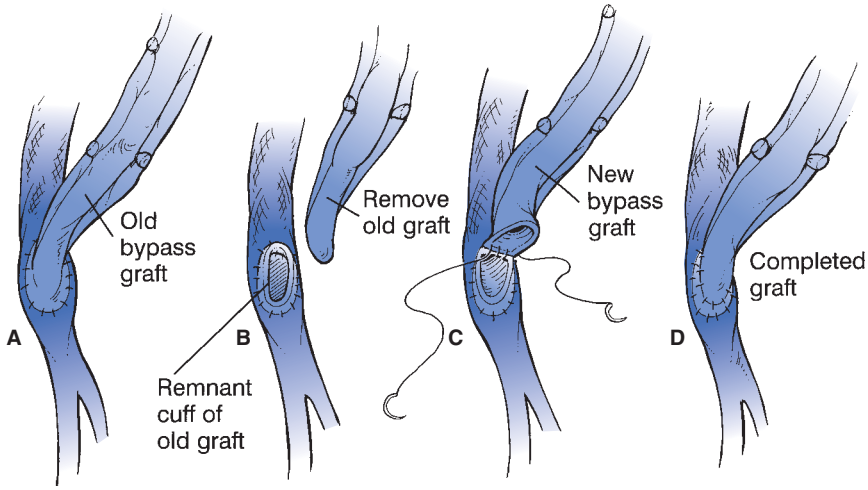

FIGURE 26-16 For patients with extensive native coronary atherosclerosis, the distal anastomotic site of an old vein graft is often the best spot for the distal anastomosis of a new graft. Only a small rim of the old graft should be left in place.

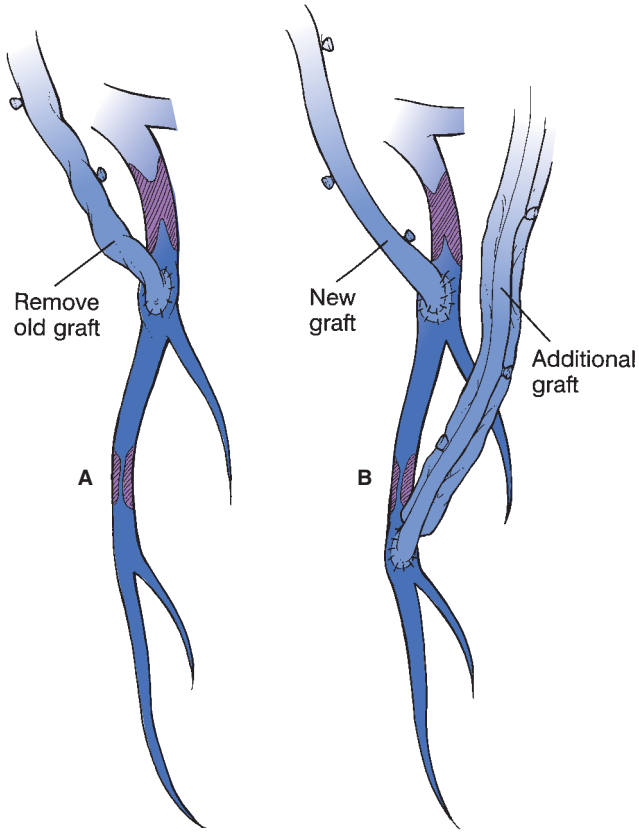

FIGURE 26-17 Extension of native-vessel coronary artery disease may indicate the placement of new distal grafts as well as replacement of diseased vein grafts supplying proximal coronary artery segments.

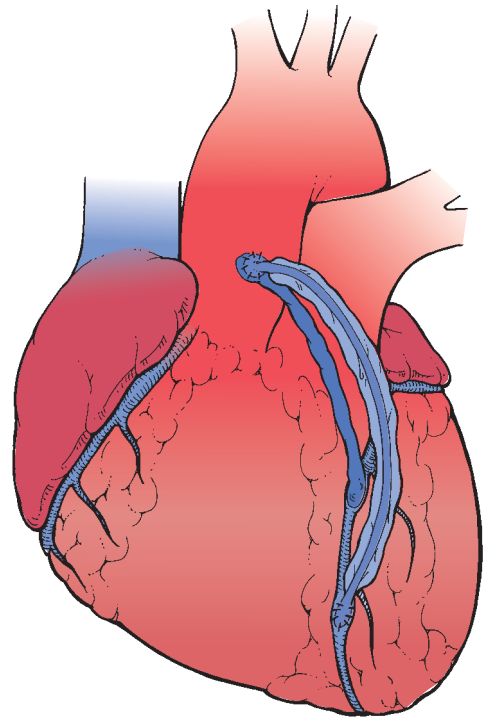

FIGURE 26-18 The hood of new or old vein grafts is often the best spot for the aortic anastomosis of free arterial grafts. Atherosclerosis rarely occurs in that "bubble" of vein.

but such a plan is more difficult during repeat surgery, so the right ITA is often used as a free graft.

Arterial graft proximal anastomoses are a problem at reoperation because the scarring and thickening of the reoperative aorta often make direct anastomoses of arterial grafts to the aorta unsatisfactory. However, when old vein grafts become occluded, there is usually a "bubble" of the hood of the old vein graft that is not atherosclerotic and that often is a good spot for construction of a free (aorta-to-coronary-artery) arterial graft anastomosis (Fig. 26-18). In addition, if new vein grafts are performed, the hood of that new vein graft represents a favorable location for an arterial graft anastomosis. Late angiographic data regarding this strategy are not available, but the relative freedom of the hood of vein grafts from the development of atherosclerosis means these grafts are likely to be successful.

Another effective strategy is to use either an old arterial graft or a newly constructed arterial graft for the proximal anastomosis of a free arterial graft (Fig. 26-19). Composite arterial grafts, usually using a new in situ left ITA graft at the proximal anastomotic site for a free right ITA graft, have been employed with increasing frequency, and early outcomes have been favorable.[48,49] This method is particularly useful during reoperations because it may avoid an aortic anastomosis, and less right ITA graft length is needed to reach distal circumflex arteries. Other advantages of using a previously performed patent ITA graft for

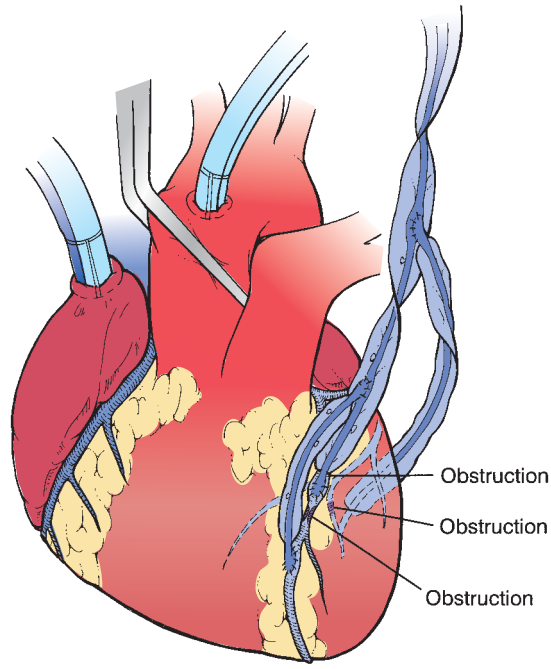

FIGURE 26-19 Composite arterial grafts can be constructed using a new or old left ITA graft as the inflow source. With its proximal anastomosis to the left ITA, a right ITA graft will easily reach the circumflex branches. Furthermore, a shorter segment of inferior epigastric artery or radial artery can be used to reach the distal LAD artery if intervening native LAD stenoses have limited the effectiveness of an old ITA graft.

the proximal anastomosis of a new arterial graft are that the old left ITA graft often has increased in size, and the preoperative angiogram has demonstrated its integrity. In situations in which the effectiveness of an LITA-to-LAD graft has been jeopardized by a distal LAD lesion, a short segment of a new arterial graft can be used to bridge that stenosis from the old arterial graft to the distal LAD artery (see Fig. 26-18).

Can an ITA graft be used to replace a vein graft during reoperation? When faced with replacing a stenotic or patent vein graft during reoperation, the surgeon has a number of options, all of which have some potential disadvantages:

1. The surgeon may leave the old vein graft in place and add an arterial graft to the same coronary vessel. The dangers of this approach are that atherosclerotic embolization from the old vein may occur during the reoperation, and competitive flow between the vein graft and the arterial graft may jeopardize the ITA graft after reoperation.
2. The surgeon may remove the old vein graft and replace it with an ITA graft. This decreases the likelihood of atherosclerotic embolization and competitive flow but risks hypoperfusion during reoperation if the arterial graft cannot supply all the flow that had been generated previously by the vein graft.
3. The surgeon may replace the old vein graft with a new vein graft. The disadvantage of this approach is a long-term one: The coronary vessel is left dependent on a vein graft.

When we examined these choices in a retrospective study of operations for patients with atherosclerotic vein grafts supplying the LAD artery, we found that the worst outcomes resulted from removing a patent (although stenotic) vein graft and replacing it with only an ITA graft.[39] This strategy was associated with a significant incidence of hypoperfusion and severe hemodynamic difficulties during reoperation that were treated effectively only by adding a vein graft to the same coronary artery. The incidence of myocardial infarction associated with leaving a stenotic vein graft in place was low. Thus, atherosclerotic embolization from an atherosclerotic vein graft is a danger, but it appears that with the use of retrograde cardioplegia, it is not commonly a major catastrophe.

Another potential disadvantage of the strategy of adding an ITA graft to a stenotic vein graft is that competition in flow from the stenotic vein graft may lead to failure of the new ITA graft. However, this is unlikely to occur as long as the stenosis in the SVG is severe.[50] Our usual approach, therefore, is to remove atherosclerotic vein grafts when replacing them with a new vein graft but leave stenotic vein grafts in place when grafting the same vessel with an arterial graft (Fig. 26-20).

Alternative arterial grafts often are very useful during reoperation. The radial artery has particular advantages during repeat surgery because it is larger and longer than other free arterial grafts. These qualities increase the range of coronary arteries that can be grafted. Early studies of radial artery grafts have shown favorable patency rates, but few long-term data currently exist. If the high patency rates that have been documented by early studies are confirmed by the tests of time, the radial artery will be used extensively during reoperations. The inferior epigastric artery often is too short to function as a separate aorta-to-coronary-artery graft during reoperation but can be extremely useful as a short composite arterial graft, as illustrated in Fig. 26-19.

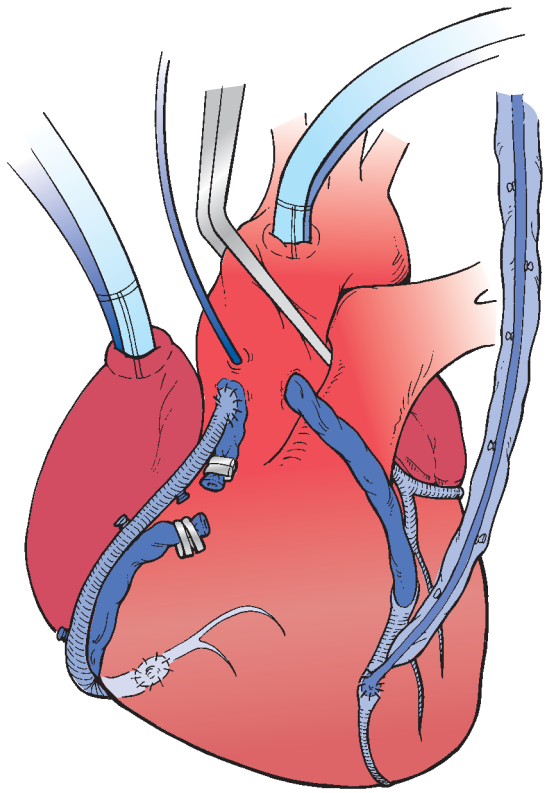

FIGURE 26-20 In this example, an atherosclerotic right coronary artery vein graft is disconnected and is replaced with a new vein graft. However, the stenotic vein graft to the LAD artery is left in place to avoid hypoperfusion, and a new ITA graft is added to the LAD artery.

The right gastroepiploic artery (RGEA) has established a good midterm graft patency rate record and often is useful during reoperation because it is an in situ graft.[51] Furthermore, it can be prepared before the median sternotomy. It is effective most often as an in situ graft to the posterior descending branch of the right coronary artery or the distal LAD artery (Fig. 26-21).

The aortic anastomoses of the vein and arterial grafts are performed last during the single period of aortic cross-clamping. Sites for aortic anastomoses are often at a premium owing to previous scarring, atherosclerotic disease, or the use of Teflon felt during the primary operation, and often the locations of the previous vein graft proximal anastomoses are the best locations for the new ones. The advantages of constructing aortic anastomoses during a single period of aortic cross-clamping are that it minimizes aortic trauma and allows excellent visualization of the proximal anastomoses. In addition, if patent or stenotic vein grafts have been removed and replaced, reperfusion is not accomplished by aortic declamping until the aortic anastomoses have been completed.

The disadvantage of this approach is that it prolongs the period of aortic cross-clamping. However, our strategies for reoperation are not based on trying to minimize myocardial

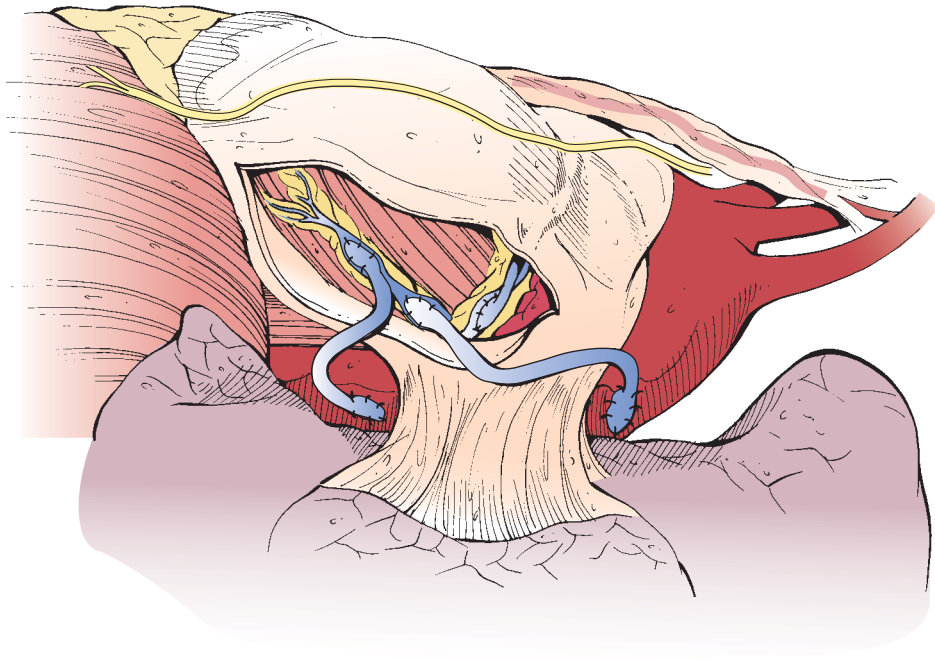

FIGURE 26-21 Circumflex vessels may be grafted through a left thoracotomy incision without cardiopulmonary bypass.

ischemic time. If cardioplegia can be delivered effectively, its metabolic concepts are valid, and myocardial protection is secure. Failure of myocardial protection usually is caused by anatomical events, not by metabolic failure. Once the proximal anastomosis has been constructed, a "hot shot" of substrate-enhanced blood cardioplegia is given, and the aortic cross-clamp is removed.

Other Options

Although most reoperations are performed through a median sternotomy with the use of cardiopulmonary bypass, the strategies of small-incision surgery and off-pump surgery that have been gaining increasing use for primary coronary artery operations also can be helpful during reoperations. Reoperations in situations in which a limited area of myocardium needs revascularization often can be accomplished through a limited incision and without the use of cardiopulmonary bypass (known as the *minimally invasive direct coronary artery bypass* [MIDCAB] *operation*). The distal LAD artery may be exposed with a small anterior thoracotomy, and the LAD or diagonal artery may be grafted with a left ITA graft. A stabilizing device usually is employed for anastomotic construction, although the intrapericardial adhesions provide some stability during reoperations. If the left ITA is not available, a segment of saphenous vein can be anastomosed to the subclavian artery and routed in a transthoracic path to the LAD artery. If the right ITA is to be used as an in situ graft to the LAD artery, a median sternotomy is indicated, but if this is the only graft, off-pump surgery usually is possible.

The lateral wall of the heart can be exposed through a left lateral thoracotomy (Fig. 26-22), and the circumflex and distal right coronary artery branches can be grafted with this approach. Often the LITA already has been used for a graft, but the descending thoracic aorta may be used as a site for the proximal anastomosis of a vein graft or a radial artery graft using a partial occluding clamp. The disadvantages of this

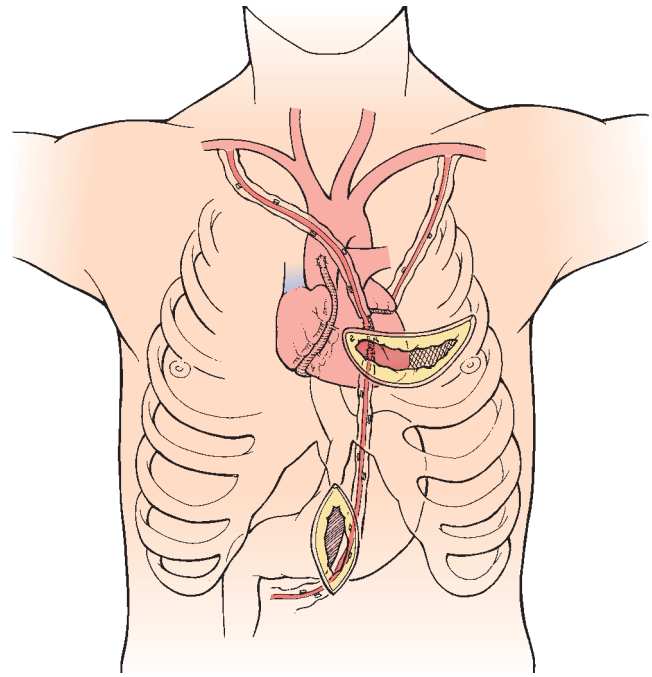

FIGURE 26-22 An in situ gastroepiploic artery (GEA) graft may be used for an on- or off-pump anastomosis to the distal LAD artery.

approach are that the right ITA is difficult to use as an in situ graft, and if the circumflex vessels are deeply intramyocardial, they may be difficult to expose and isolate with the off-pump strategy.

In addition to avoiding potential complications of cardiopulmonary bypass, the "limited-area, off-pump" approach also avoids extensive dissection of the heart and possible manipulation of atherosclerotic vein grafts. The disadvantage of this approach is that most patients who are candidates for reoperation need grafts to multiple vessels in multiple myocardial areas.

Use of a median sternotomy and the off-pump strategy to graft multiple myocardial areas is now a standard approach to primary coronary revascularization and also can be used during reoperation. However, because of the need to access all areas, extensive dissection sometimes is necessary for lysis of adhesions to be able to mobilize the heart. If patients have atherosclerotic vein grafts, dissection and manipulation create the dangers of embolization of atherosclerotic debris and myocardial infarction. This problem was encountered during the early years of bypass surgery when the risks of atherosclerotic embolization were less recognized. Another disadvantage of off-pump reoperative strategies is that reoperative candidates often have very distal and diffuse CAD, which leaves intramyocardial segments as the best areas for grafting. These characteristics stress off-pump isolation and immobilization techniques. In addition, the aortic anastomoses of vein or free arterial grafts may be difficult because of aortic atherosclerosis, adhesions, or previous aortic anastomoses that may limit the application of a partial occluding clamp. On the other hand, the use of off-pump techniques may minimize aortic trauma, particularly if in situ arterial grafts can be employed to provide inflow to new grafts.

In an individual case, the disadvantages of off-pump surgery may be important or irrelevant. Surgeons who perform reoperative coronary artery surgery in a wide spectrum of situations will find both on- and off-pump strategies helpful.

RESULTS OF CORONARY ARTERY REOPERATIONS

Coronary artery reoperations are riskier than primary operations. A study from the Society of Thoracic Surgeons (STS) database reported an in-hospital mortality rate of 6.95% associated with reoperations for the years 1991 to 1993, and in a multivariate analysis of all isolated coronary artery bypass surgery, "previous operation" was identified as a factor that increased the mortality rate.[12] At the Cleveland Clinic Foundation, the in-hospital mortality rate of a first reoperation ranged between 3 and 4% from 1967 through 1991, and the rate was 3.7% for 1663 patients having repeat surgery from 1988 through 1991.[1–3] Progress during the last decade has continued to lower this risk. In a recent report by Sabik and colleagues, the hospital mortality rate for patients undergoing reoperative CABG was reduced to 2.5% in 2002, and risk adjustment identified the comorbidity burden carried by reoperative patients as a factor that increased risk, not reoperative status itself.[14]

Recent mortality rates from other large series range from 4.2 to 11.4%, most being around 7%.[4–9,52] All these figures are two to five times higher than the rates we would expect for the risk of primary CABG.

Coronary artery reoperations have been associated with a higher in-hospital mortality mostly because of an increased risk of perioperative myocardial infarction. In the Cleveland Clinic Foundation series, the cause of perioperative death was cardiovascular in 85% of cases in the most recent cohort of patients undergoing reoperation, a figure that contrasts with recent studies of primary operations, in which noncardiac causes of death have been increasingly important.[3,15] Furthermore, in the reoperative series, in-hospital mortality was associated with new perioperative myocardial infarction in 67% of cases. Multiple causes of myocardial infarction have been identified, including incomplete revascularization owing to distal CAD, vein graft thrombosis, ITA graft failure, atherosclerotic embolization from vein grafts, injury to bypass grafts, hypoperfusion from arterial grafts, preoperative myocardial infarction, and complications of PTCA.

Sternal reentry still creates risk. In a study of 1847 patients undergoing reoperation, 7% were associated with an adverse event and only previous radiation and the number of previous operations could be identified as predictors of injury. Of the 127 patients sustaining an injury, 24 (19%) experienced a major adverse outcome (stroke, myocardial infarction, or death) compared with a risk of 6.2% for those without an injury.[43]

Multiple studies of patients undergoing reoperation have identified increased age, female gender, and emergency operation as clinical variables that have a high association with in-hospital mortality. Emergency operation is a particularly strong factor. Although there is not a standard definition of *emergency,* mortality rates after emergency reoperations that have been reported range from 13 to 40%.[3,5–8] Data from the STS for the year 1997 documented a risk of 5.2% for elective reoperations, 7.4% for urgent reoperations, 13.5% for emergency reoperations, and 40.7% for "salvage" reoperations. There is clearly a major increment in risk associated with emergency reoperations, a larger increment than has existed for patients undergoing primary surgery.

Advanced age, by itself, does not increase the risk of reoperation substantially but does so when combined with other variables. In a review of 739 patients aged 70 years or older undergoing reoperation, we noted an overall in-hospital mortality rate of 7.6% and identified emergency operation, female gender, left ventricular (LV) dysfunction, creatinine concentration greater than 1.6 μg/dL, and left main coronary artery stenosis as specific factors increasing risk. For patients with none of these characteristics, the in-hospital mortality rate was only 1.5%.[53]

Specific anatomical situations, in particular, the presence of patent ITA grafts and atherosclerotic vein grafts, can increase the risk of reoperation, but with experience, these technical factors largely have been neutralized. We have never documented an increased mortality rate for patients with patent ITA grafts but have noted that the risk of ITA damage has dropped from 8% in our early experience to 3.7% more recently, an improvement almost entirely related to increased surgical experience. With proper positioning of an ITA graft at primary operation, a patent LITA-to-LAD-artery or LITA-to-circumflex-artery

graft should not represent an impediment to reoperation. Situations in which a patent in situ right ITA graft crosses the midline to supply the LAD or circumflex system are more difficult and require extreme care in reoperating using a median sternotomy incision. Although these situations are uncommon and provide difficult technical challenges, the risks for these patients have not been increased.

Studies from the past noted that the presence of atherosclerotic vein grafts did increase perioperative risk. Perrault and colleagues documented mortality rates of 7, 17, and 29% for patients with one, two, or three stenotic vein grafts, respectively, and in a previous study of patients with atherosclerotic vein grafts, we noted that the presence of an atherosclerotic vein graft to the LAD artery increased in-hospital risk.[30,36] However, in our more recent study we found that atherosclerotic vein grafts did not increase mortality, although there was a nonsignificant trend toward increased risk for patients with multiple stenotic grafts.[3] The favorable results for these patients have been based on a combination of improved technology, the use of retrograde cardioplegia delivery, and increased surgeon experience.

Although arterial grafts may offer advantages at reoperation, their use may prolong an already complex operation, and the influence of arterial grafting on perioperative risk has been a concern. However, we have specifically studied this issue and found that the use of single or double ITA grafts at reoperation does not increase perioperative risk, and in fact, not having an ITA graft at either the first or second operation appeared to be a factor associated with increased in-hospital mortality.[3] Graft selection in that study was not randomized, and it is certainly possible that the increased risk for patients receiving only vein grafts was related to patient-related variables rather than surgical strategy. It does appear, however, that the use of arterial grafts does not increase risk. Except for an increased incidence of perioperative myocardial infarction, in-hospital morbidity does not seem to be increased for patients undergoing reoperation. One important observation relates to wound complications. Multiple groups, including ours, have noted an increased risk of wound complications when diabetic patients have received bilateral (simultaneous) ITA grafts. However, there does not appear to be an increased risk of wound complications for diabetic patients who receive staged ITA grafts, one at the first and another at a second operation.

It is important to note that only the variables that can be identified and quantified are included in studies consistent enough to be identified as risk factors. For example, experience and logic dictate that severe atherosclerosis of the ascending aorta is a major risk factor, but this is rarely identified in large studies because patients do not routinely undergo echocardiography to identify the presence of aortic atherosclerosis.

Late Results

Patients who are undergoing reoperation are at a later stage in the progression of their native coronary atherosclerosis compared with the point when they underwent primary surgery, and the anatomical corrections achieved at reoperation are less perfect. Although the definition of *complete revascularization* varies widely, few reoperative candidates undergo an operation in which all diseased segments of all arteries receive bypass grafts. It is not surprising that the long-term results of reoperation have not been as favorable as the long-term results of primary operations.

The likelihood of recurrent angina after any bypass operation is related to time, but angina symptoms are more common after repeat surgery than they are after primary operation. Follow-up of our reoperative patients at a mean interval of 72 months after reoperation showed that 64% of patients were in New York Heart Association (NYHA) functional class I, although only 10% of patients had class III or class IV symptoms.[2] Weintraub and colleagues also noted at a 4-year follow-up that 41% of reoperative patients had experienced some angina.[6]

Late survival rates after reoperation are also inferior to those after primary surgery. Weintraub and colleagues noted 76% 5-year and 55% 10-year survival rates, and our most recent follow-up study found a 10-year survival rate of 69% for in-hospital survivors[2,6] (Fig. 26-23). The predictors of late survival have varied among studies, but LV dysfunction, advanced age, and diabetes consistently have been associated with a decreased late survival rate. The variables identified by multivariate testing as decreasing the late survival for 2429 hospital survivors of a first reoperation are listed in Table 26-3. The influence of ITA grafts on late survival has been difficult to determine for reoperations. We found a positive influence of a single ITA graft on late survival, as have others,[54] but the effect was not as dramatic as has been noted after primary operations. Weintraub and colleagues did not document an improved survival associated with ITA grafting.[6]

Multiple Coronary Artery Reoperations

Patients who have had more than one previous coronary artery operation are like patients undergoing first reoperations, only more so. Many patients undergoing multiple reoperations had their first procedure more than 15 years ago,

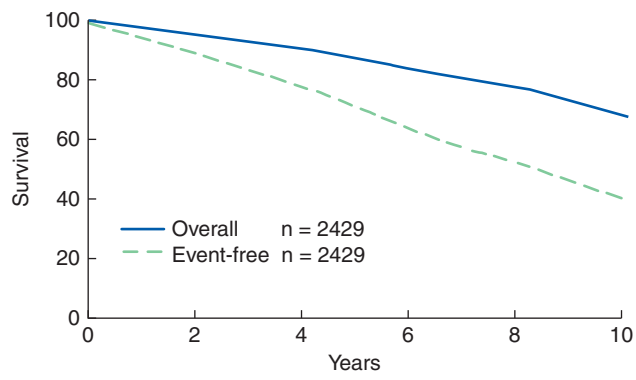

FIGURE 26-23 For 2429 hospital survivors who underwent reoperation between 1967 and 1987, the 10-year survival was 69%, and event-free survival was 41%. and severe native-vessel disease and lack of bypass conduits are a common combination of problems. Selection criteria vary widely among institutions, but in-hospital mortality rates are increased relative to first reoperations.[10,11] Through 1993, we reoperated on 392 patients who had more than one previous bypass operation, with an in-hospital mortality rate of 8%. Over the next 10 years, this mortality rate has decreased to 5.8%.[14] Follow-up of the in-hospital survivors in the former group found late survival rates of 84% at 5 and 66% at 10 postoperative years. Thus, although the in-hospital risks were increased for these patients, the long-term outcome has been relatively favorable. Age was a major determinant of outcome. Recently, in-hospital mortality for patients younger than 70 years of age has decreased to 1 to 2%, but for patients greater than age 70, it has remained higher than 10%. Furthermore, patients greater than age 70 who did survive operation in our series had only a 50% 5-year late survival.

CONCLUSION

Coronary artery reoperations continue to present adult cardiac surgeons with their most difficult challenges, in part because of the many technical pitfalls that exist, but also because significant comorbidity is common in reoperation candidates. The overall number of reoperations appears to be declining for multiple reasons, one important one being the increased use of arterial grafts at primary operations. However, when recurrent ischemia syndromes do occur reoperation will often be the best choice of therapy.

PEARLS

1. Make certain the end justifies the means before performing a coronary reoperation.
2. Avoid cardiac injury.
3. Do not replace a patent or stenotic vein graft with an ITA graft.
4. Dissect out the left side of the heart with the heart arrested.
5. Use the axillary artery as an alternative cannulation site.

CHAPTER 27

Transmyocardial Laser Revascularization and Extravascular Angiogenetic Techniques to Increase Myocardial Blood Flow

Keith A. Horvath
Yifu Zhou

TRANSMYOCARDIAL LASER REVASCULARIZATION (TMR) HISTORY

Despite the success of medical therapy, percutaneous coronary interventions (PCIs), and coronary artery bypass grafting (CABG) in the treatment of coronary artery disease (CAD), there are a significant number of patients with refractory angina owing to diffuse CAD that is not amenable to PCI or CABG. This severe CAD can lead to incomplete revascularization and is noted to occur in up to 25% of CABG surgery.[1] This incomplete revascularization is a powerful independent predictor of operative mortality and perioperative adverse events.[1,2] Additionally, the presence of diseased but nongrafted arteries carries a poor prognosis and poses a significant negative influence leading to an increased incidence of death, recurrent angina, myocardial infarction (MI), and the need for repeat CABG.[3,4]

Strategies to treat patients with end-stage coronary disease have sought to create or enhance myocardial angiogenesis. Such techniques include TMR as well as protein-, gene-, and cell-based therapies. TMR was founded, in part, on previous methods of providing direct perfusion to the myocardium. Prior attempts at direct perfusion were based on Wearn's description of sinusoids that allowed blood to flow directly from the ventricle into the myocardium.[5] These arterioluminal connections provide perfusion in more primitive vertebrate hearts and occur clinically in children with pulmonary atresia, an intact ventricular septum, and proximal obstruction of the coronary arteries. Sen and colleagues[6] used myocardial acupuncture to establish direct perfusion and theoretically to recreate a coronary microcirculation similar to that of the reptilian heart. Additional methods of attempting to improve myocardial blood flow include Beck's creation of a form of superficial angiogenesis as a response to epicardial and pericardial inflammation.[7] Combining the acupuncture, implantation, and inflammation techniques, Boffi[8] and Borst[9] used hollow tubes implanted in the myocardium to establish direct perfusion. Results from all these procedures yielded limited success. The angina relief obtained was not long lasting, was difficult to replicate, and most important, eventually was overshadowed by the ability to perform CABG. The mechanical trauma that resulted in poor long-term patency of myocardial acupuncture was overcome in theory by using a laser to create the channels. Although Mirhoseini and colleagues[10] and Okada and colleagues[11] pioneered the use of a laser to perform this type of revascularization in conjunction with CABG in the early 1980s, the use of a laser as sole therapy to establish its efficacy required advancements in the technology. The carbon dioxide (CO_2) laser used by Mirhoseini had a peak output of 80 W and, therefore, required a significant amount of time to complete a transmural channel. As a result, to perform TMR optimally, the heart had to be chilled and still. Increasing the output of the laser to 800 W allowed TMR to be performed on a beating heart. This breakthrough led to the widespread clinical application of TMR. Since then, more than 25,000 patients have been treated with TMR around the world, and results from individual institutions, multicenter studies, and prospective, randomized, controlled trials have been reported.[12–20]

CLINICAL TRIALS

The early nonrandomized trials demonstrated that sole-therapy TMR could be performed safely on patients with severe CAD who previously had no options. The significant angina relief seen in such patients led to prospective, randomized, controlled studies to further demonstrate the efficacy of TMR. In these pivotal trials, more than 1100 patients were enrolled and randomized to receive either TMR or medical management as treatment for their severe angina.[16–20] The trials employed a 1:1 randomization in which half the patients were treated with laser and those in the control group continued on maximal medical therapy. All patients were followed for 12 months.

TMR AS SOLE THERAPY

Patients

The entry criteria for these studies and for sole-therapy TMR in general are as follows. Patients had refractory angina that was not amenable to standard methods of revascularization, as verified by a recent angiogram; they had evidence of reversible ischemia based on myocardial perfusion scanning; and their left ventricular ejection fractions were greater than 25%.

The typical patient profiles of TMR patients in the randomized, controlled trials are listed in Table 27-1. Because the patients were equally randomized to the medical management group, there were no significant demographic differences between the TMR and control groups for any of these trials. Two different wavelengths of laser light were used. Two studies[16,17] employed a holmium:yttrium-aluminum-Garnett (Ho:YAG) laser, and three[18–20] used a CO_2 laser. The average patient age was 62 years, and most were male (86%). Although there were significant differences in the baseline distribution of patients according to Canadian Cardiovascular Society (CCS) angina class, the majority of the patients were in angina class IV (61%). The ejection fractions for all the patients were mildly diminished at 48 ± 10%. Many of the patients had suffered at least one previous MI, and most had some prior revascularization, CABG, and/or PCI. Two of the trials[16,18] permitted a crossover from the medical management group to laser treatment for the presence of unstable angina that necessitated intravenous antianginal therapy for which they were unweanable over a period of at least 48 hours. By definition, these crossover patients were less stable than and significantly different from those who had been randomized initially to TMR or medical management alone.

Operative Technique

For sole-therapy TMR, the patient is placed in a supine position with his or her left side slightly elevated. General anesthesia is established using a double-lumen endotracheal tube or a bronchial blocker to isolate the left lung. Although not mandatory,

TABLE 27-1 Patient Characteristics in RCTS of Sole-Therapy TMR

Characteristic	Allen	Frazier	Burkhoff	Schofield	Aaberge
Patients (*N*)	275	192	182	188	100
Age (years)	60	61	63	60	61
Male gender (%)	74	81	89	88	92
EF (%)	47	50	50	48	49
CCS class III/IV (%)	0/100	31/69	37/63	73/27	66/34

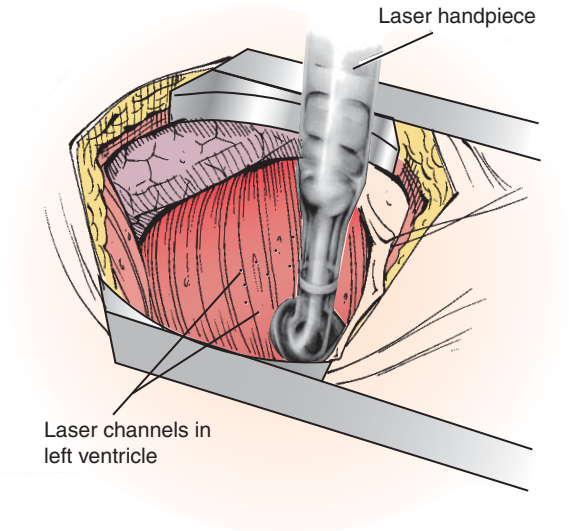

FIGURE 27-1 For TMR, channels of 1 mm diameter are created in a distribution of 1/cm^2 starting inferiorly and then working superiorly to the anterior surface of the heart. The number of channels created depends on the size of the heart and on the size of the ischemic area.

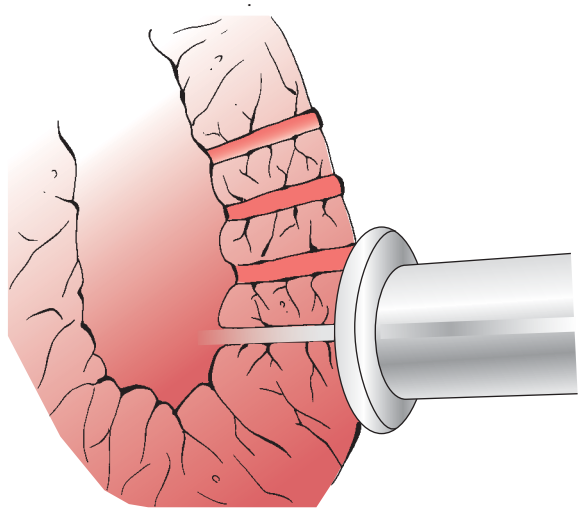

FIGURE 27-2 The CO_2 laser creates a transmural channel in a single 20-J pulse. Conceptually, direct perfusion may occur via the channel. Evidence indicates the laser stimulates angiogenesis in and around the channel that leads to improved perfusion.

this facilitates the operation, particularly because most of the patients have pleural and mediastinal adhesions from previous bypass surgery. Additionally, a thoracic epidural catheter can be employed to provide postoperative pain control.

A left anterior thoracotomy in the fifth intercostal space is the usual incision site. Once the ribs are spread by a retractor, the pericardium is opened to expose the epicardial surface of the heart (Fig. 27-1). Care must be taken to avoid previous bypass grafts. The left anterior descending (LAD) artery is identified and used as a landmark for the location of the septum. The inferior and posterolateral portions of the heart can be reached through this incision with a combination of manual traction, placement of packing behind the heart, and as illustrated, with the use of a right-angled laser handpiece. Channels are created starting near the base of the heart and then serially in a line approximately 1-cm apart toward the apex, starting inferiorly and working superiorly to the anterior surface of the heart. Because there is some bleeding from the channels, commencement of the TMR inferiorly keeps the anterior area clear and expedites the procedure. The number of channels created depends on the size of the heart and the size of the ischemic area. Myocardium that is thinned by scar, particularly when the scar is transmural, should be avoided because TMR will be of no benefit in these regions, and bleeding from channels in these areas may be problematic. The thoracotomy then is closed after placement of a chest tube, and in the majority of the cases the patient is extubated in the operating room.

The handpiece in Fig. 27-2 is from a CO_2 laser and illustrates one of the differences between the two lasers employed for TMR. The CO_2 laser energy is delivered via hollow tubes and is reflected by mirrors to reach the epicardial surface. One-millimeter channels are made with a 15- to 20-J pulse. Firing of the laser is synchronized to occur on the R wave of the electrocardiogram (ECG) to avoid arrhythmias. The transmural channel is created by a signal pulse in 40 milliseconds and can be confirmed by transesophageal echocardiography (TEE). The vaporization of blood by the laser energy as the laser beam enters the ventricle creates an obvious and characteristic acoustic effect on TEE. The Ho:YAG laser achieves a 1-mm channel by manually advancing a fiber bundle through the myocardium while the laser fires. Typical pulse energies are 2 J for this laser at a rate of five pulses per second; 10 to 20 pulses are required to traverse the myocardium. Detection of transmural penetration is done primarily by tactile and auditory feedback.

End Points

The principal subjective end point for all the trials was a change in angina symptoms. This was assessed by the investigator and/or a blinded independent observer. In addition to assigning an angina class, standardized questionnaires such as the Seattle Angina Questionnaire, the Short Form Questionnaire 36 (SF-36), and the Duke Activity Status Index were employed. These tests were used to detect changes in symptoms and quality of life. Objective measurements consisted of repeat exercise tolerance testing as well as repeat myocardial perfusion scans. Patients were reassessed at 3, 6, and 12 months after randomization.

RESULTS

Mortality

Before the randomized studies, mortality rates in the 10 to 20% range[12–15] were reported for TMR patients. In the randomized trials, lower perioperative mortality rates were reported ranging

from 1 to 5%[16–20] One of the important lessons learned from these controlled trials that differs from the earlier studies was a decrease in the mortality when patients taken to the operating room were stable, specifically not on intravenous (IV) heparin or nitroglycerin. When patients were allowed to recover from their most recent episode of unstable angina and were able to be weaned from intravenous medications such that their operation could be performed 2 weeks later, the mortality dropped to 1%.[18] The 1-year survival for TMR patients was 84 to 95% and for medical management patients was 79 to 96%. Meta-analysis of the 1-year survival demonstrated no statistically significant difference between the patients treated with a laser and those who continued with their medical therapy. Long-term survival of the randomized patients from two of these studies has been reported. Four-year follow-up from Aaberge and colleagues, in which both the TMR and medical management groups were kept intact, demonstrated a 78% survival for TMR versus 76% for medical management (p = ns).[21] In a 5-year follow-up using an intent-to-treat analysis, Allen reported a survival for TMR patients at 65% versus 52% for medical management patients ($p = .05$).[22]

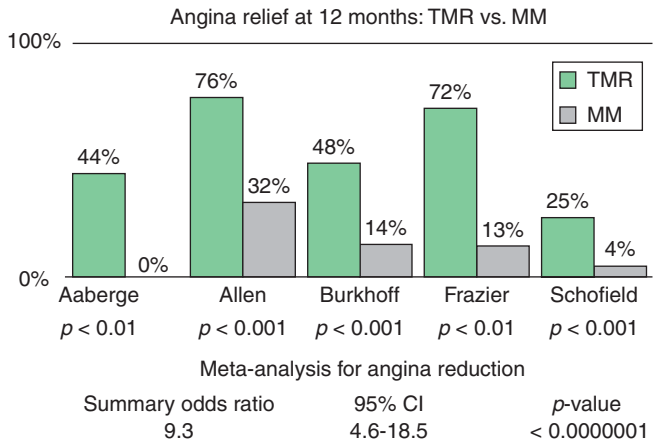

FIGURE 27-3 Summary of the angina relief results from five prospective, randomized, controlled trials comparing transmyocardial laser revascularization (TMR) and medical management (MM). Graph illustrates success rate for TMR or MM as measured by the percentage of patients that had a decrease of two or more angina classes. Meta-analysis of these results documents the significant advantage seen with TMR over MM.

Morbidity

Unlike mortality, the exact definition of various complications varied from one study protocol to the next, and therefore, morbidity data are difficult to pool. Nevertheless, the typical TMR patient's postoperative course had a lower incidence of MI, heart failure, and arrhythmias than what has been documented in a similar cohort of patients, those who have reoperative CABG.[16–20]

Angina Class

The principal reason for performing TMR is to reduce the patient's anginal symptoms. This can be quantified by assessing the angina class before and after the procedure. Angina class assessment was performed by a blinded independent observer in all studies. This was done as the only angina assessment or as comparison with the investigators' assessment. Significant symptomatic improvement was seen in all studies for patients treated with the laser. Using a definition of success as a decrease of two or more angina classes, all the studies demonstrated a significant success rate after TMR, with success rates ranging from 25 to 76% (Fig. 27-3). A meta-analysis of this angina reduction yielded a summary odds ratio of 9.3 (95% CI 4.6–18.5; $p < .000001$). Significantly fewer patients in the medical management group experienced symptomatic improvement, and the success rate for these patients ranged from 0 to 32%. The seemingly broad range of success is caused by differences among the baseline characteristics of the studies. It is more difficult to achieve a two-angina–class improvement if the baseline angina class is III. Studies that started with most of their patients in angina class III, not surprisingly, showed the lowest success rate. In contrast, the largest success rate for TMR was seen in the trial in which all the patients were in CCS class IV at enrollment. Of note, the medical management group in this study also showed the largest success rate.[16] This underscores some of the baseline differences among the studies.

Quality of Life and Myocardial Function

Quality-of-life indices as assessed by the Seattle Angina Questionnaire, the SF-36, and the Duke Activity Status Index demonstrated significant improvement for TMR-treated patients versus medical management in every study. Global assessment of myocardial function by ejection fraction using echocardiography or radionuclide multigated acquisition scans showed no significant change in overall ejection fraction for any of the patients regardless of group assignment or study.

Hospital Admission

Another indicator of the efficacy of TMR was demonstrated in a reduction in hospital admissions for unstable angina or cardiac-related events postprocedure. A meta-analysis of the data provided indicates that the 1-year hospitalization rate of patients in the laser-treated group was statistically significantly less than for those treated medically. Medical management patients were admitted four times more frequently than TMR patients over the year of follow-up.

Exercise Tolerance

Additional functional test assessment using exercise tolerance also was performed in three of the trials.[17,19,20] Although the method of treadmill testing differed among the trials, the results demonstrate an improvement in exercise tolerance for TMR-treated patients. Two studies showed an average of 65- to 70-second improvement in the TMR group at 12 months compared with their baseline, whereas the medical management

group had either an average of 5-second improvement or a 46-second decrease in exercise time over the same interval.[19,20] One additional trial demonstrated that the time to chest pain during exercise increased significantly, and fewer patients were limited by chest pain in the TMR group, whereas the medical management group showed no improvement.[20]

Medical Treatment

All the studies employed protocols that continued all the patients on maximal medical therapy. For each study, the frequencies and dosages of antianginal and cardiovascular drugs were similar between the two groups at baseline. TMR patients, as a result of their symptomatic improvement, had a reduction in their medication use over the year of follow-up. Because many of these patients used a combination of short- and long-acting nitrates preoperatively, the trials demonstrated a significant decrease in the use of nitrates in TMR-treated patients, whereas the medical management patients showed a slight increase in their nitrate usage. At 1 year, the overall medication use decreased or remained unchanged in 83% of the TMR patients, and conversely, the use of medications increased or remained unchanged in 86% of the medical management patients.[18] The significant angina relief seen following TMR was not owing to medication changes or increases for the TMR-treated patients.

Myocardial Perfusion

As stated, myocardial perfusion scans were obtained preoperatively to verify the extent and severity of reversible ischemia. The four largest randomized trials included follow-up scans as part of the study.[16–19] These results reflect more than 800 of the patients randomized. The methodology of recording and analyzing these results differed in each study, so it is difficult to pool the data. Nevertheless, review of the results demonstrated an improvement in perfusion for CO_2 TMR-treated patients. Fixed (scar) and reversible (ischemic) defects were tallied for both the TMR-treated patients and the medical management groups. One study demonstrated a significant decrease in the number of reversible defects for both the TMR and the medical management patients.[19] This improvement in the reversible defects in the TMR group was seen without a significant increase in the fixed defects at the end of the study. However, the number of fixed defects in the medical management group had nearly doubled over the same 12-month interval. Similarly, there was a 20% improvement in the perfusion of previously ischemic areas in the CO_2 TMR group of another trial, and in that same trial there was a 27% worsening of the perfusion of the ischemic areas in the medical management group at 12 months.[18] There was no difference in the number of fixed defects among the groups at 12 months, nor was there a significant change in the number of fixed defects for each patient compared with his or her baseline scan. The remaining two Ho:YAG studies that obtained follow-up scans showed no significant difference between the TMR and medical management groups at 12 months and no significant improvement in perfusion in the TMR-treated patients over the same interval.[16,17]

Nonrandomized data previously had demonstrated an improvement in perfusion using dual isotope scanning at 1 and 2 years after CO_2 TMR.[12] Additionally, using N-13 ammonia position-emission tomographic (PET) assessment, subendocardial perfusion improved significantly compared with subepicardial perfusion after CO_2 TMR treatment.[23]

Long-Term Results

Two reports of long-term follow-up of prospectively randomized patients are available. Similar to the 1-year results, intention-to-treat analyses determined that significantly more TMR than medical management patients continued to experience at least two-class angina improvement from baseline (88% versus 44%; $p < .001$) or were free from angina symptoms altogether (33% versus 11%; $p = .02$) at a mean of 5 years.[22] In long-term follow-up of the randomized trial that kept both the TMR and medical management groups intact (ie, no crossover), it was shown that angina symptoms still were improved significantly (24% versus 3%, TMR versus medical management; $p = .001$), and unstable angina hospitalizations were reduced significantly ($p < .05$) at a mean follow-up of 43 months.[21] Follow-up of a series of nonrandomized patients who received TMR and survived long term support these findings.[24] At a mean of 5 years and up to 7 years postprocedure, 81% of these patients improved to class II or better, 68% were found to have improved at least two angina classes from baseline, 17% were angina-free, and quality of life remained significantly improved. These last two reports reflect the sustained angina relief seen with CO_2 TMR because these patients had no additional procedures to account for their symptom improvement over the long term.

Based on an assessment of the cumulative results from these multiple randomized trials, the recently updated American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines[25] and the Society of Thoracic Surgeons (STS) practice guidelines[26] have determined that the weight of the evidence favors the use of TMR in the treatment of stable, medically refractory angina patients.

TMR AS AN ADJUNCT TO CABG

Clinical Trials

Owing to its success as sole therapy, TMR has been evaluated in conjunction with CABG in patients with diffuse CAD who would be incompletely revascularized by CABG alone. The safety and effectiveness of adjunctive TMR have been somewhat difficult to assess owing to the influence of coronary bypass grafts and the lack of randomized control arms in some studies.[27–29]

Two prospective, randomized, controlled multicentered trials have been performed using TMR adjunctively with CABG in patients. In these studies, patients with one or more viable myocardial target areas served by coronary vessels that were not amenable to bypass grafting received either CABG plus TMR or CABG alone.[30,31] Baseline and operative characteristics were similar between groups, including the location and number of bypass grafts placed (3.1 ± 1.2, CABG + TMR; 3.4 ± 1.2, CABG alone; $p = .07$). Patients were blinded to their treatment group through 1-year follow-up.

RESULTS

Mortality

Improved outcomes following TMR + CABG versus CABG alone in terms of a reduced operative mortality rate (1.5% versus 7.6%; $p = .02$), reduced postoperative inotropic support requirements (30% versus 55%; $p = .001$), increased 30-day freedom from major adverse cardiac events (97% versus 91%; $p = .04$), and improved 1-year Kaplan-Meier survival (95% versus 89%; $p = .05$) have been reported.[30] Multivariable predictors of operative mortality were CABG alone (OR 5.3; $p = 0.04$) and increased age (OR 1.1; $p = .03$).[30] A similar trend in operative mortality following TMR + CABG versus CABG alone (9% versus 33%; $p = .09$) was reported in a study of high-risk patients.[31]

Efficacy

The use of TMR adjunctively with CABG has been shown to decrease intensive care unit (ICU) times and length of hospitalization stay.[29] In a long-term follow-up of the randomized, controlled trial, the effectiveness of TMR + CABG versus CABG alone has been reported.[32] At a mean of 5 years, both groups experienced significant angina improvement from baseline; however, the TMR + CABG group had a lower mean number of angina-free patients (78% versus 63%; $p = .08$) compared with the CABG-alone group. Long-term survival was similar between randomized groups.

Observational data on the practice of TMR + CABG have been collected in the STS National Cardiac Database.[33] From 1998 to 2003, 5618 patients underwent TMR + CABG. These were compared with 932,715 patients who underwent CABG-only operations. The TMR + CABG patients therefore account for 0.6% of the surgical revascularization practice in the database. Table 27-2 outlines the significant baseline differences between the CABG-only patients and the TMR + CABG patients. The TMR + CABG patients have an increased incidence of every surrogate marker of diffuse arterial disease, and therefore, it is not surprising that their observed mortality was higher at 3.8% (versus 2.7% for CABG-only patients; $p < .001$). When unstable angina patients were removed, the observed mortality for TMR + CABG was decreased to 2.7%, and the observed:expected (O/E) ratio was 0.87. Comparison of use and outcomes from sites that have a TMR laser versus those that showed no evidence of overuse of TMR or difference in outcomes.[33]

TABLE 27-2 Comparison of CABG Only versus TMR + CABG Patients, STS Adult Cardiac Database 1998–2003

Characteristic	CABG Only	TMR + CABG	*p*-Value
N	932,715	5,618	
Body surface area, m^2 (SD)	1.96 (0.24)	1.99 (0.23)	<.001
Diabetes (all types)	34%	50%	<.001
Insulin-dependent diabetes	10%	19%	<.001
Renal failure	5%	7%	<.001
Dialysis	1%	2%	<.001
CVA	7%	9%	<.001
Chronic lung disease	14%	17%	<.001
Peripheral vascular disease	16%	20%	<.001
Cerebral vascular disease	12%	17%	<.001
MI	46%	49%	<.001
Reoperation	9%	26%	<.001
Three-vessel CAD	71%	80%	<.001

MECHANISMS

Laser–Tissue Interactions

Understanding the mechanism of TMR starts with understanding the laser-tissue interaction. While numerous devices,[34] including ultrasound,[35] cryogenic ablation,[36] radiofrequency revascularization,[37,38] heated needles,[39,40] and the aforementioned hollow and solid needles have been used; none has engendered the same response that is seen with a laser. Additionally, numerous wavelengths of laser light also have been employed. These include xenon chloride (XCl),[41] neodymium:YAG (Nd:YAG),[42] erbium:YAG (Er:YAG),[43] and thulium-holmium-chromium:YAG lasers (THC:YAG).[44] All these devices have been explored experimentally but have not been pursued on a significant scale clinically. Only CO_2 and Ho:YAG lasers are used for TMR. The result of any laser–tissue interaction depends on both laser and tissue variables.[43–45] A CO_2 laser has a wavelength of 10,600 nanometers, whereas a Ho:YAG laser has a wavelength of 2120 nanometers. These infrared wavelengths are absorbed primarily in water and therefore rely on thermal energy to ablate tissue. One significant difference, however, is that the Ho:YAG laser is pulsed, and the arrival of two successive pulses must be separated by time to allow for thermal dissipation. Otherwise, the accumulated heat will cause the tissue to explode under pressure. Such explosions create acoustic waves that travel along the planes of lower resistance between muscle fibers and cause structural trauma as well as thermocoagulation.[45] The standard operating parameters for the Ho:YAG laser are pulse energies of 1 to 2 J and 6 to 8 W/pulse. The energy is delivered at a rate of five pulses per second through a flexible 1 mm optical fiber bundle. Despite the low energy level and short pulse duration, very high levels of peak power are delivered to the tissue so that with each pulse there is an explosion (Fig. 27-4). Additionally, the fiber is advanced manually through the myocardium, and it is therefore impossible to know whether the channel is being created by the kinetic energy delivered via the mechanical effects of the fiber or there has been enough time for thermal dissipation before the next pulse.

In contrast, the CO_2 laser was used at an energy level of 15 to 20 J/pulse with a pulse duration of 25 to 40 milliseconds. At this level, the laser photons do not cause explosive ablation, and the extent of structural damage is limited. Additionally, a transmural channel can be created with a single pulse (see Fig. 27-4). Confirmation of this transmurality is obtained by observing the vaporization of blood within the ventricle using TEE.

Finally, the CO_2 laser is synchronized to fire on the R wave, and with its short pulse duration, arrhythmic complications are minimized. The Ho:YAG device is unsynchronized and, owing to the motion of the fiber through the myocardium over several cardiac cycles, is more prone to produce ventricular arrhythmias.

Patent Channels

As noted, the original concept of TMR was to create perfusion via channels connecting the ventricle with the myocardium. Clinical work has demonstrated some evidence of long-term patency.[46] Additional experimental work showed some evidence of patency as well.[47–49] There are also significant reports from autopsy series and laboratories that indicate that the channels do not remain patent.[50–52] The consensus is that while channels occasionally may remain patent, this is not the principal mechanism of TMR.

Denervation

In contrast to the open-channel mechanism, damage to the sympathetic nerve fibers may explain the angina relief noted in clinical trials. The nervous system of the heart can function independent of inputs from extracardiac neurons to regulate regional cardiac function by reflex action. This intrinsic system contains afferent neurons, sympathetic efferent postganglionic neurons, and parasympathetic efferent postganglionic neurons. Because of this complex system, it is difficult to demonstrate true denervation. However, several experimental studies have demonstrated that denervation indeed may play a role in Ho:YAG TMR.[53,54] Experimental evidence to the contrary was performed in a nonischemic animal model.[55] Although the studies were carried out carefully, it is difficult to isolate the sympathetic afferent nerve fibers, and the experiments were in the acute setting and only address short-term effects. Regardless of the methodology employed in the laboratory, there is significant evidence of sympathetic denervation following PET scanning of Ho:YAG TMR–treated patients.[56]

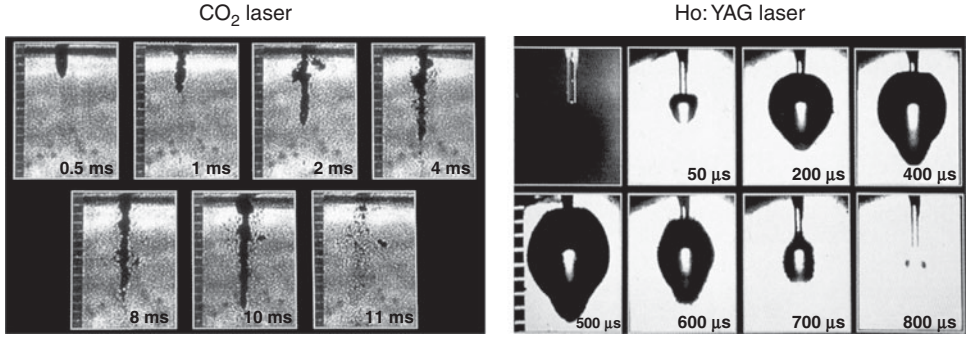

FIGURE 27-4 Sequential photography of the firing of a single pulse from a CO_2 laser and a Ho: YAG laser into water. The pulse duration and energy levels are the same as those employed clinically.

Angiogenesis

The likely underlying mechanism for the clinical efficacy of TMR is the stimulation of angiogenesis. This mechanism fits the clinical picture of significant improvement in symptoms over time, as well as a concomitant improvement in perfusion, as seen with the CO_2 laser. Numerous reports have demonstrated a histologic increase in neovascularization as a result of TMR channels.[51,57–61] More molecular evidence of this angiogenic phenomenon was derived from work that demonstrated an upregulation of vascular endothelial growth factor (VEGF) messenger RNA, expression of fibroblast growth factor 2 (FGF2), and matrix metalloproteinases following TMR.[62–64] Histologically, similar degrees of neovascularization have been noted after mechanical injury of various types. Needle injury has been demonstrated by immunohistochemistry to also stimulate growth factor expression and angiogenesis. The conclusion is that TMR-induced angiogenesis is a nonspecific response to injury.[65,66] Investigation of this using hot and cold needles, radiofrequency energy, and laser energy to perform TMR clearly demonstrates a spectrum of tissue response to the injury.[39] The results in a model of chronic myocardial ischemia to mimic the clinical scenario indicate that indeed neovascularization can occur after mechanical TMR, but if these new blood vessels grow in the midst of a scar, there will be little functional contribution from blood flow through these new vessels. The recovery of function with laser TMR was to the result of a minimization of scar formation and maximization of angiogenesis.

This then becomes a critical question: If TMR induces angiogenesis, is there an ensuing improvement in function? Clinically, this has been demonstrated subjectively with quality-of-life assessments, but more important, it has been demonstrated objectively with multiple techniques, including dobutamine stress echocardiography,[67] PET scanning,[23] and cardiac magnetic resonance imaging (MRI).[68,69] As further evidence of the angiogenic response, experimental data have mirrored the clinical perfusion results noted, with improvements in perfusion in porcine models of chronic ischemia where the ischemic zone was treated with CO_2 TMR.[70–73] This improved perfusion did lead to an improvement in myocardial function as well.

PERCUTANEOUS MYOCARDIAL LASER REVASCULARIZATION

Myocardial laser revascularization has been performed percutaneously,[74] thoracoscopically,[75] via thoracotomy,[16–20] and via sternotomy.[27–30] Aside from the PMR approach, any of the other surgical approaches have yielded similar symptomatic improvement. Several percutaneous trials have attempted to demonstrate a symptomatic improvement with the creation of 2- to 3-mm deep subendocardial divots achieved with a laser fiber fed via a peripheral artery into the left ventricle.[74] Even with the use of electromechanical mapping to verify the position of the fiber and creation of the channel, the results from PMR have been less favorable than those seen with TMR. A double-blinded, randomized, controlled trial showed no benefit to the laser-treated patients compared with the untreated control group.[74] Because the patients were blinded to their treatment, the possibility of a significant placebo effect for PMR has been raised. Of note, the morbidity and mortality of PMR reportedly are similar to those seen with TMR. As a result, the U.S. Food and Drug Administration (FDA) rendered PMR unapprovable.

The failure of PMR to achieve the same clinical results that have been seen with TMR may result from several significant limitations, the first of which is the partial-thickness treatment of the left ventricle. Even at the maximal estimated depth of 6 mm that has been reported with PMR, this is significantly less than the full-thickness treatment of the myocardium that is achieved with an open TMR approach. Furthermore, typically fewer of these partial-thickness channels are created with PMR. The exact location of the channel and the establishment of a wide distribution of the channels from inside a moving ventricle are also problematic. Finally, the limitations of Ho:YAG TMR are also applicable to PMR because that is the wavelength of light that has been employed.

FUTURE USES OF TMR

Other potential applications include the use of TMR in the treatment of cardiac transplant graft atherosclerosis. Although the procedure has been performed on a small number of patients, the results have indicated a benefit.[76] Finally, the combination of TMR plus other methods of angiogenesis may provide an even more robust response. Experimental work investigating these combinations has verified a synergistic effect with regard to histologic evidence of significant angiogenesis and, perhaps more important, an improvement in myocardial function with a combination of TMR and gene therapy versus either therapy alone.[77–79]

Cardiothoracic surgeons increasingly are faced with a more complex patient who has developed a pattern of diffuse CAD and has exhausted nonsurgical options. Results replicated in multiple randomized, controlled trials augmented by recently available long-term results have validated the safety, effectiveness, and substantially improved health outcomes achieved through application of TMR for the treatment of selected patients with severe angina owing to diffuse disease when used alone and as adjunctive therapy to achieve a more complete revascularization.

EXTRAVASCULAR ANGIOGENETIC TECHNIQUES

Before TMR, investigators have been trying different mechanical strategies to increase blood flow in ischemic hearts since the 1930s by obliterating the pericardial sac with mechanical abrasion and the addition of asbestos powder, tacking omentum to ischemic hearts, removing the epicardium, or combining several of these with the addition of implanting the internal mammary artery into the myocardium. Subsequently, pharmacologic strategies were employed in both experimental and clinical studies to ischemic hearts by using heparin and growth factors such as VEGF and fibroblast growth factors (FGF1 and FGF2). The angiogenic growth factors were first applied via direct delivery of specific proteins, and then gene delivery techniques, in both experimental and clinical studies. In the late 1990s, cell-based therapy was introduced in therapeutic angiogenesis

for ischemic heart diseases and has been the most rapidly progressing and hot research field over the past 12 years. This section discusses the topic of protein-, gene-, and cell-based therapeutic angiogenesis for the treatment of ischemic cardiovascular diseases.

Proteins

Experimental Studies

In early in vitro studies, VEGF, FGF1, and FGF2 proteins showed angiogenic potential.[80,81] These studies were followed by in vivo work showing that these factors actually do stimulate the growth of new vessels.[82] The more recent genetic studies of vasculogenesis in mouse embryogenesis documented the critical importance of synergetic effects of multiple molecules, such as VEGF and angiopoietin-1, to the development of mature, branching blood vessels.[83]

Basic FGF and VEGF proteins stimulate the development of collaterals to tissues supplied by an obstructed artery and augment tissue blood flow were first demonstrated in the early 1990s. In experiments on myocardial ischemia, a portion of the left ventricle of dogs was made ischemic by gradual occlusion of the circumflex coronary artery. The intracoronary or left atrial administration of bFGF or intracoronary administration of VEGF proteins daily for 28 days significantly increased collateral flow.[84] Likewise, studies in the rabbit ischemic hind limb model demonstrated that intramuscular administration of bFGF protein daily for 2 weeks improved limb perfusion significantly.[85]

However, when the effect of VEGF protein studied in the canine myocardial ischemia model using two different methods, controversial results were observed: While 28 days of administering boluses of VEGF into the left atrium improved collateral flow, 7 days of administration did not,[86] and although 7 and as few as 2 days of intracoronary administration of bFGF improved collateral flow, a single bolus injection did not.[87] These results demonstrated, at least in this model of myocardial ischemia, that the duration of exposure of the vessels supplying the ischemic tissue to angiogenesis factors is critical for a therapeutically relevant effect.

Additional studies employing ^{125}I-labeled bFGF demonstrated that route of administration is another critical factor in determining local tissue uptake and, potentially, therapeutic response.[88] The results showed that whereas 3 to 5% of an intracoronary dose of bFGF was recovered in the myocardium, only 0.5% of an intravenous dose was. The most plausible explanation of these findings derives from the fact that myocardial uptake depends on peak serum concentration; because bFGF has a heparin-binding domain, considerable first-pass uptake in the lungs will occur after intravenous administration (the lungs contain large amounts of heparin sulfates), resulting in a blunted peak serum concentration presented to the myocardium when compared with the very high concentrations presented to the myocardium with bolus injection directly into the coronary artery.

The biologic consequences of these differences were demonstrated in angiogenesis studies of the same canine ischemia model. Collateral flow improved with intracoronary administration of bFGF but did not increase when the drug was given intravenously, despite its being given for 1 week.[87] Although similar uptake studies have not been performed with VEGF, its 165 isoform ($VEGF_{165}$) also has a heparin-binding domain (whereas $VEGF_{121}$ does not), suggesting that similar results would be seen.

Animal studies that appear to be at variance with these results also have been reported. Thus, Lopez and colleagues[89] delivered $VEGF_{165}$ to a porcine model of myocardial ischemia (ameroid occlusion of the circumflex coronary artery) by three different local intracoronary delivery systems (via an InfusaSleeve catheter, intracoronary bolus infusion, and epicardial implantation of an osmotic delivery system). VEGF was administered 3 weeks after ameroid placement, and indices of collateral function were assessed at that time (baseline) and 3 weeks later. Whereas there was no significant improvement in circumflex territory perfusion in control pigs, improved circumflex perfusion was demonstrable within each VEGF-treated group using paired *t*-tests to compare pretreatment and posttreatment perfusion values. Although these data are suggestive of a VEGF treatment effect, they are not convincing. First, ongoing collateral development has been observed in pigs throughout the 6-week period after circumflex ameroid placement.[90] In the Lopez study, however, the control group did not exhibit the expected increase in circumflex territory perfusion during that interval. Second, direct comparisons between individual VEGF treatment groups and the control group were not statistically significant. Only when all three VEGF treatment groups were combined in a post hoc analysis was a statistically significant difference demonstrable between VEGF groups and the control group. Third, there were three deaths in VEGF-treated animals during the investigation. Elimination of three animals in a small study such as this could have an important effect on the results through selection bias. Thus, while suggestive, the data from this experiment do not demonstrate unequivocally that a *single* bolus intracoronary injection of VEGF is capable of increasing collateral flow to a greater extent than that which occurs in the absence of therapy.

Hariawala and colleagues[91] also reported improved flow in a similar model. However, this study is flawed by the fact that intracoronary bolus administration of VEGF (2 mg) caused severe hypotension that led to the acute death of four of eight animals in the treated group; hence the surviving animals, which were found to have greater collateral flow than the untreated controls, may have survived only *because* they had greater intrinsic collateral flow. These investigators also demonstrated in the rabbit hind limb model of ischemia that a single dose of intrafemoral bFGF or $VEGF_{165}$ improves collateral flow and, surprisingly, that a single intravenous dose of $VEGF_{165}$ also improves flow.[92] The conflicting results are reported in the literature relating to whether a *single* intra-arterial bolus injection of VEGF or bFGF protein improves collateral flow and whether improvement occurs following intravenous administration, at least for heparin-binding agents.

Clinical Trials

The clinical trials of protein-based angiogenesis have been reported by using growth factors like FGF and VEGF families.

The effect of FGF-1 on the ischemic myocardium was first performed by Schumacher and colleagues[93] in a series of 20 patients. In the study, 0.01 mg/kg of FGF-1 protein was injected directly into the ischemic myocardium along LAD while patients were undergoing bypass surgery. Three months later, neoangiogenesis, together with the development of a normal vascular appearance, was demonstrated angiographically. The first randomized, double-blind, placebo-controlled clinical trial for basic FGF was reported by the Simons' group.[94] Twenty-four patients undergoing CABG were randomized to three groups, receiving either 10 μg or 100 μg of bFGF, or placebo through delivery of microcapsules capable of sustained-release which were implanted in ischemic myocardium. During 16 months of follow-up, all patients in the 100 μg bFGF remained angina-free and a stress nuclear perfusion imaging test at baseline and 3 months showed significant improvement. The efficacy of single intracoronary infusion of FGF-2 (0, 0.3, 3, or 30 μg/kg; $n = 337$ patients) was tested by a multicenter FIRST trial.[95] At 90 days, in all FGF-2 treated groups angina symptoms were significantly reduced compared with placebo, but not in 180 days because of the continued improvement in the placebo. The effect of intracoronary injection of recombinant human VEGF on myocardial perfusion was first performed on 14 severe CAD patients,[96] and followed by a multicenter VIVA trial on a total of 178 patients.[97] In the small patients group study, seven patients who received high-dose VEGF (0.05–0.167 μg/kg) showed improvement in resting myocardial perfusion and collateral count density at 60 days follow-up.[96] In the VIVA trial, patients were randomized to receive a 20-minute intracoronary infusion of placebo, low-dose (17 ng/kg/min) or high-dose (50 ng/kg/min) rhVEGF and followed by 4-hour intravenous infusion on days 3, 6, and 9. However, the study showed no significant differences in primary end point of the trial and ETT time compared with placebo at 60 days follow-up. At day 120, high-dose patients showed improvement in angina class and favorable trends in exercise treadmill test time and quality of life.[97]

Genes

Experimental Studies

Gene therapy presents one of the solutions to the possible dosing conundrum because gene therapy can be considered a sophisticated form of a sustained delivery system. Once transfected, the target cell expresses gene product for days, weeks, or longer depending on the specific tissue transfected and the specific vector used.

Proof of concept that gene therapy can improve collateral function was demonstrated by Giordano and colleagues.[98] They found in a porcine model of myocardial ischemia (ameroid occlusion of the circumflex coronary artery) that a single-dose intracoronary administration of an adenoviral vector carrying the FGF5 transgene into the nonoccluded right coronary artery increased myocardial flow and function. Surprisingly, they found that about 95% first-pass myocardial uptake was achieved with intracoronary administration. Hammond and colleagues have since demonstrated that FGF4 produces similar effects in restoring myocardial flow and function.[99] Improvement of myocardial contractility in a porcine model of chronic ischemia has been reported recently by using a combined TMR and FGF-2 gene therapy approach.[100] In this study, adenoviral vector encoded FGF-2 was formulated in a collagen-based matrix and directly injected into ischemic myocardium. Other investigators also have performed studies employing the rabbit hind limb model of ischemia and have reported that injection into the femoral artery of the $VEGF_{165}$ transgene carried in a plasmid vector improves collateral flow.[101]

Direct Intramyocardial Injection

No matter how efficient first-pass uptake is, a considerable proportion of an angiogenesis factor *injected into an artery* supplying the target tissue will enter the systemic circulation and thereby expose nontarget tissues to its biologic effects.[102] Although there is no definitive evidence yet that such systemic spillover will produce serious side effects, there is always that possibility (see the following). Therefore, it appears that if *direct intramuscular injection* of the angiogenesis factor, either by the transepicardial or transendocardial route, does result in enhanced collateral flow, such an approach might be preferable.

A protein injected once intramuscularly would be unlikely to persist in the tissue long enough to exert an important biologic effect.[102] Although multiple injections of protein might well improve collateral flow,[85] such a strategy has practical limitations. Therefore, once it was demonstrated that an adenoviral vector carrying a reporter transgene efficiently expresses its gene product after intramyocardial injection,[103] this approach to gene delivery was explored as an approach for gene therapy.

Proof of concept that intramyocardial injection could enhance collateral flow and improve impaired myocardial function was demonstrated in a porcine model of myocardial ischemia. This was achieved by the transepicardial injection of an adenoviral vector carrying the $VEGF_{121}$ transgene performed after thoracotomy.[104] The feasibility of catheter-based transendocardial delivery of angiogenesis genes has been shown recently,[105] demonstrating that the direct injection of angiogenesis factors into the myocardium can be accomplished without the need for thoracotomy.

However, because VEGF induces marked increases in vascular permeability and tissue edema, excessive VEGF administration could develop deleterious effects. Recent reports showed that in a chronic ischemic rabbit ear model, both adenoviral encoded VEGF and Angiopoietin-1 (Ang-1) increased flow at one week after injection. However, Ang-1-induced flow was localized to larger vessels, with no visible inflammatory response, but VEGF produced a diffuse increase in flow that was associated with pronounced swelling, vessel leakage, and inflammatory cell infiltration. At 4 weeks, the flow in the VEGF treated group decreased from pretreatment values. In contrast, the Ang-1–induced improvement was maintained.[106] Similar deleterious effects of VEGF were also reported by Masaki et al in their mouse hind limb ischemia model.[107]

Clinical Trials

The first clinical trial on gene-based therapy using adenoviral vector was reported by Rosengart and colleagues.[108] In this phase I trial, 15 patients received adenoVEGF121 by direct

intramyocardial injection as an adjunct to conventional CABG and six patients received gene-therapy only. Thirty days after the treatment, all patients showed improvement of wall motion in the area of vector administration by coronary angiography and stress ^{99m}Tc-sestamibi perfusion scan, as well as improvement in angina class after therapy. There was no evidence of systemic or cardiac-related adverse events related to vector administration. The effect of plasmid encoded VEGF2 on chronic myocardial ischemia was studied in 19 patients using catheter-based delivery.[109] In this small phase 1/2 study, Losordo and colleagues used an injecting catheter device guided by NOGA mapping technique and administered 200 to 800 μg of phVEGF2 plasmid directly into the endomyocardium. The end point analysis at 3 months disclosed improvement in angina class and strong trends favoring efficacy of phVEGF2 versus placebo in exercise duration, functional improvement, and Seattle Angina Questionnaire data. The adenoviral encoded FGF4 was studied by AGENT trial by Grines et al. in a group of 79 patients with chronic stable angina pectoris.[110] In this trial, patients received one time intracoronary injection of five different doses of adenoviral encoded FGF4 (from 3.3×10^8 to 10^{11} viral particles in half-log increments). In this first report of a randomized, double-blind and placebo-controlled trial, ad5-FGF4 showed a trend to have greater improvements in exercise time versus placebo at 4 weeks' follow-up. The same group also reported an AGENT-2 study of 52 patients with chronic stable angina using a single dose of 10^{10} viral particle of ad5FGF4 intracoronary infusion. At 8 weeks after treatment, ischemic defect size was significantly decreased in ad5-FGF4–injected patients compared with placebo-treated patients and the viral vector was well tolerated and did not result in any permanent adverse sequelae.[111] Hedman et al. conducted a phase II Kuopio Angiogenesis Trial (KAT) to study the effects of VEGF on restenosis and chronic myocardial ischemia by intracoronary injection of either adenoviral or plasmid encoded VEGF165 on 103 patients who underwent PTCA and stenting.[112] At 6 months' follow-up, no difference was found in restenosis rate or minimal lumen diameter between all study groups. However, myocardial perfusion showed a significant improvement in the adenoVEGF treated group. Recently, the Euroinject One Trial was reported by Kastrup and colleagues[113] on direct intramyocardial plasmid VEGF-A_{165} gene therapy in patients with stable severe angina pectoris. In this study, 80 "no option" patients with severe stable ischemic heart disease were randomly assigned to receive either 0.5 mg of phVEGFA_{165} or placebo plasmid in the myocardial region showing stress-induced perfusion defects under the guidance of the NOGA-MyoStar system. At 3 months' follow-up, the VEGF gene transfer did not significantly improve stress-induced myocardial perfusion defect compared with placebo. However, improved regional wall motion indicated a favorable anti-ischemic effect.

In summary, single protein or gene-based therapy so far has not achieved significant convincing beneficial results in improving myocardial perfusion both experimentally and clinically. More clinical studies are needed to determine how to achieve optimal myocardial angiogenesis. Many aspects of gene transfer, including the appropriate vector dose, formulation, and administration route, are still to be tested.

Cell-Based Therapy

Two classical concepts have been challenged in recent years by cell-based therapy using either embryonic or adult stem cells. First, vasculogenesis, which previously referred to a process that occurred only in the embryo, in which the vascular system develops from mesodermal precursor cells called *angioblasts* that invade the different embryonic organs and assemble in situ to form the primary capillary plexus. However, many investigators now believe that in adults, bone marrow–derived stem cells or endothelial progenitor cells can be recruited to and incorporated into tissues undergoing neovascularization. Second, cardiac myocytes originally were considered to be terminally differentiated cells that cannot be regenerated in adulthood. However, recent studies have shown that a limited number of cardiomyocytes may be regenerated by locally sited or recruited circulating stem cells. Therefore, stem cells, which include hematopoietic stem cells (HSCs), endothelial progenitor cells (EPCs), mesenchymal stem cells/stromal stem cells (MSCs), myoblasts, and undifferentiated side population cells, have been used as an alternative therapeutic strategy for ischemic cardiovascular diseases that cannot be treated by routine interventional approaches. Theoretically, embryonic stem cells have more potential to differentiate into cardiomyocytes; however, clinical trials are now only limited to adult stem cells owing to the fact that they are relatively easier to handle, and autologous transplantation can be performed in clinical patients. Several centers around the world, including the United States, had reported an improved functional status in experimental animals and clinical patients after such therapy; however, it is still unclear how bone marrow–derived stem/progenitor cells are mobilized and recruited into ischemic tissues, if the injected cells in clinical trial patients differentiated into functional cardiomyocytes, and what particular cell type is better to use compared with others. This section focuses on the progress status of clinical trials, mechanisms of involving functional improvements by stem cell therapy, limitations for applications, and potential risks.

Clinical Trials

Intracoronary Infusion of Autologous Bone Marrow–Derived Cells.

TOPCARE-AMI. Assmus and colleagues first reported cell-based therapy for 20 acute myocardial infarction (AMI) patients in 2002.[114] In this study, the authors performed intracoronary infusion of autologous bone marrow–derived mononuclear cells (n = 9) or circulating blood-derived progenitor cells (n = 11) 4 to 5 days after AMI. The circulating blood-derived progenitor cells were expanded ex vivo for 3 days before injection. The bone marrow–derived cells were extracted on the same day as injection without expansion. At 4 months after cell injection, patients' cardiac function was improved compared with 11 matched controls. The authors also reported postinfarction remodeling outcome using serial contrast-enhanced MRI.[115] A total of 28 patients with reperfused AMI who received bone marrow–derived cells or circulating blood progenitor cells were analyzed. They found that intracoronary infusion of adult progenitor cells in patients with AMI beneficially affects postinfarction remodeling processes. The migratory capacity of the

infused cells is a major determinant of infarct remodeling, suggesting a causal effect of progenitor cell therapy on regeneration enhancement.[115] In 2004, the same group reported final 1-year results of 59 patients that showed similar functional improvements.[116]

TOPCARE-CHD. Assmus and colleagues also performed a clinical study of using functional competent BMCs in chronic postinfarction heart failure patients. In this study, 121 patients treated with BMCs showed statistically significant improvement in the serum level of natriuretic peptide and favorable clinical outcomes.[117]

Strauer and colleagues conducted a study to test the effect of autologous bone marrow–derived mononuclear cells (BMCs) on myocardial repair or regeneration. The authors first reported the data with 10 AMI patients who received BMCs by intracoronary injection and compared with 10 compatible patients treated with standard therapy alone. At 3 months after cell therapy, they found that the infarct region had decreased significantly and wall motion also significantly improved.[118] More recently, the same group reported another study using same cell therapy technique on 18 patients with chronic MI (5 months to 8.5 years old) for their effects on myocardial regeneration.[119] At 3 months, the patients with cell therapy showed that the infarct size was reduced by 30% and global left ventricular ejection fraction and infarction wall movement velocity increased significantly, whereas in the control group no significant changes were observed. The authors also found that following BMC transplantation there were improvements in maximum oxygen uptake and regional ^{18}F-fluor-desoxyglucose uptake into infarct tissue suggesting a regeneration of myocardium after infarction.

BOOST Trial. The initial BOne marrOw transfer to enhance ST-elevation infarct regeneration (BOOST) trial was reported by Meyer GP and colleagues,[120] which showed significant improvements in global and regional left ventricular systolic function. However, the 5-year follow-up from this trial proved that a single intracoronary infusion of BMCs did not promote a sustained improvement of LVEF in ST-elevation myocardial infarction patients.[121]

Catheter-Based Transendocardial Cell Injection. Perin and colleagues[122] reported their results using a NOGA catheter technique to transendocardialy inject autologous bone marrow stem cells for severe chronic ischemic heart failure patients. Fourteen patients who received cell injection showed significant functional improvement compared with seven controls. Similar methods also were reported by Fuchs and colleagues in Washington Hospital Center in 10 no-option patients with advanced CAD. The authors first initiated a porcine ischemic model to test the effect of freshly extracted autologous bone marrow on myocardial blood perfusion. Improved collateral flow and contractility in a treated group of animals was found.[123] Subsequently, in a pilot clinical study, the 10 no-option patients with advanced CAD autologous bone marrow direct myocardial injection induced a significant improved Canadian Cardiovascular Society angina score and stress-induced ischemia occurring within the injected territories.[124]

Intracoronary Injection of Extra Vivo Expanded BMCs. Chen and colleagues[125] were the first group to use autologous ex vivo expanded bone marrow–derived mesenchymal stem cells in patients with AMI. In their study, a total of 69 patients who received PCI 12 hours after AMI were chosen randomly for either cell injection (n = 34) or control (n = 35). The bone marrow–derived mononuclear cells were cultured in vitro for 10 days, and then patients underwent intracoronary injection of the fibroblast-like mesenchymal stem cells. Patients who received mononuclear stem cell injection showed significant improvement in left ventricular (LV) function at 3 to 6 months of follow-up.

Mobilized Peripheral Blood Mononuclear Cell Studies. Kang and colleagues[126] reported a mobilized peripheral blood mononuclear cell study for AMI patients after coronary stenting. A total of 27 patients with AMI who underwent PCI 48 hours later were studied. Ten patients received intracoronary injection of mobilized (granulocyte colony-stimulation factor [G-CSF] 10 μg/kg for 4 days) PBMC, and 10 patients received injection of G-CSF alone, seven as control. At 6 months, the cell infusion group showed improvement in LV function compared with the other two groups.

However, from later randomized placebo-controlled trials (REVIVAL-2) reported by Zohlnhofer and colleagues[127] showed that stem cells mobilized by G-CSF therapy did not improve the infarct size, left ventricular function, or coronary restenosis in patients with acute myocardial infarction who had successful mechanical reperfusion.

Autologous Myoclast Studies. Taylor and colleagues[128] first reported to use autologously transplanted skeletal myoblasts to improve ventricular function in animal models of heart failure. This has been a hot topic in the field of cell-based therapy for the last 10 years. However, recently reported first randomized placebo-controlled clinical study of autologous myoblast transplantation showed no evidence of functional improvement of the left ventricle, but did show an increased number of early postoperative arrhythmic events.[129]

Direct Epimyocardial Cell Transplantation. Patel and colleagues[130] recently reported direct myocardial injection of autologous bone marrow–derived stem cells in 10 patients who underwent bypass surgery. Six months later, the cell injection patients showed improvement in LV function compared with 10 patients who received bypass surgery alone. No side effects were found with this direct stem cell injection.

Allogenic Human Mesenchymal Stem Cell Therapy

Most recently, Osiris Therapeutics Inc. completed its first allogenic hMSCs clinical trial reported by Hare and colleagues.[131] In this study, hMSCs, developed by Osiris Therapeutics Inc. more than 10 years ago, were administered intravenously to patients with acute myocardial infarction at a dose range of 0.5, 1.6, and 5 million cells/kg. They found that the allogenic stem cell therapy was safe, and the arrhythmia events were significantly reduced, global symptom score and LV ejection fraction

in a subset of anterior MI patients was significantly better in hMSCs treated compared with placebo patients. The study suggested the potential usage of allogenic cell therapy in the future.

Safety and Efficacy

Potential for Deleterious Effects

For most potent therapeutic interventions, therapeutic efficacy is rarely free of the potential for harmful effects to occur. The biologic activities of most of the angiogenesis agents currently being tested clinically are very potent, and it is likely that the same activities that lead to a therapeutic effect also could cause unwanted side effects. It is therefore probable that some side effects consequent to the cellular effects of these agents inevitably will occur. If this concept is true, then the critical question we will have to address in large clinical trials is whether the incidence of these risks is sufficiently low that they will be outweighed by the therapeutic benefits.

Among the side effects that might occur as a result of the biologic effects of these agents is the development of new blood vessels in nontargeted tissues, a complication that would be particularly devastating if it were to occur, for example, in the retina. It is possible that this particular complication may not develop unless a tissue is "primed" to respond with an angiogenesis response. That is, quiescent cells have low constitutive expression of receptors for the VEGF and FGF family of agents—thus, unless the tissue is exposed to very high doses of the ligands for prolonged periods, it is possible that normal tissue is resistant to the neovascularization effects of angiogenesis factors, a result suggested by the study by Banai and colleagues.[132]

Other VEGF-specific complications could develop as a result of the potent activity of VEGF as an inducer of vascular permeability.[133] Although angiogenesis and vascular permeability might be considered two separate biologic activities, it is also possible that the vascular permeability properties of VEGF are essential for angiogenesis to occur.

Whatever the interrelation between these two actions, if vascular permeability increases in tissues other than the tissue targeted for angiogenesis, serious consequences could accrue. That this could occur was demonstrated in a recent study in which the effects of overexpression of VEGF (achieved by injecting an adenovirus carrying the VEGF transgene) in adult mice was investigated.[133] The mice, as expected, developed elevated circulating levels of VEGF following injection of the adenoviral vector. However, a high percentage died within days, developing increased vascular permeability and severe multiple-organ edema.

Other potential complications based on biologic activities are the expansion and induction of instability of atherogenic plaque and the growth of tumors. For example, Flugelman and colleagues demonstrated an association between unstable angina and the intraplaque presence of aFGF and bFGF.[134] They suggested that these agents might play a role in plaque instability. In addition, the broad range of cells on which the FGF family of agents exerts mitogenic effects could result in the growth of cells resident within plaques or of malignant cells.

Although the direct mitogenic effects of VEGF are limited largely to endothelial cells, it is of note that VEGF and its receptors, VEGFR1 and VEGFR2 (flt-1 and Flk-1), are overexpressed in atherosclerotic lesions.[135] Moreover, a number of nonendothelial tumor cells have been found to possess low levels of functional VEGFR1 and VEGFR2.[136] Also of possible relevance is the fact that the uterus possesses functional VEGF receptor tyrosine kinases[137] and VEGF is mitogenic for uterine smooth muscle. These observations raise the possibility that the atherosclerotic lesion, certain tumors, and the common leiomyoma (fibroid) could at least theoretically respond to direct exogenous stimulation by VEGF.

There is also increasing evidence suggesting that growth of microvessels into plaque or tumors, through angiogenesis processes, is critical to growth of both tumor and plaque.[138,139] Thus, microvascular angiogenesis per se, an activity inherent in most angiogenesis factors, could predispose to plaque or tumor growth. In addition, the potent vascular permeability effect of VEGF could result in exposing a plaque or tumor to many cytokines and growth factors that normally are confined to the plasma and through this indirect mechanism stimulate their growth.

It must be emphasized that there have been *no* conclusive reports in clinical studies demonstrating that angiogenesis agents actually induce new tumor development, increase growth of in situ tumors, or increase plaque size. However, several experimental studies have demonstrated that prolonged exposure of skeletal muscle or myocardium to high local levels of VEGF or FGF family peptides can cause hemangioma-like tumors and vascular malformations[140] and can increase neointimal development.[141]

A phase I randomized, dose-escalation trial also demonstrated that high doses of bFGF can lead to the development of thrombocytopenia and renal toxicity.[142] In addition, the immune surveillance system is not normally exposed to large amounts of these proteins. Therefore, it is possible that antibodies can develop to these cytokines and these could either impair the efficacy of repeated administration of the agents or even possibly lead to immunopathogenic processes. It also should be noted that one of the clinical trials in progress employs FGF2 of porcine origin[94,95]; although the high homology between the FGFs in different species makes it unlikely that recognition of nonself protein will occur, this certainly is not beyond the realm of possibility.

FGF and VEGF proteins, administered acutely, can produce hypotension through, at least in part, a nitric oxide–mediated pathway[143] and, in the case of FGF2, a potassium channel–mediated mechanism.[144] The hypotensive effect has resulted in the death of pigs that had chronic myocardial ischemia and were treated with the intracoronary injection of $VEGF_{165}$ protein[91] and in a prolonged hypotensive episode of a patient entered into a phase I study testing the safety of intracoronary administration of bFGF.[142] This complication appears to occur only when high systemic levels of bFGF and VEGF develop rapidly. Thus, it would appear to be of little or no concern if bFGF and VEGF proteins are not administered rapidly and of no concern when the factors are given as genes—which express the proteins they encode slowly.

We also need to consider, in the case of gene therapy employing viral vectors, the potential for the vectors themselves

to cause deleterious effects. The administration of large amounts of virus can lead to massive immune responses that could cause serious, even fatal immunopathology. Such responses are unlikely given the amount of adenovirus administered in current clinical cardiovascular protocols. However, the foreign proteins presented by the virus, even when administered in relatively small amounts, probably will induce immune responses that conceivably could decrease subsequent sensitivity to the beneficial effects of the transgene delivered by the virus if administered repeatedly or could possibly lead to immune-mediated tissue damage.

In cell-based therapy, most of the clinical trials so far are using non ex vivo expanded or short term expanded (4 to 5 days) cells. In animal studies, stem cells potentially can transform via in vitro expansion. These transformed cells can create tumors in nude mice.[145] Similar incidents have occurred occasionally in adult human bone marrow–derived mesenchymal stem cells as well. It is still not clear which cell type is best for myocardial ischemia patients; however, if it is decided to use ex vivo expanded cells, one has to be sure that they are not tumorigenic. It is absolutely necessary to test these cells for tumorigenic potential in nude mice and to perform a karyotyping test before injecting the cells into patients.

CHAPTER 28

Surgical Treatment of Complications of Acute Myocardial Infarction: Postinfarction Ventricular Septal Defect and Free Wall Rupture

Arvind K. Agnihotri
Joren C. Madsen
Willard M. Daggett, Jr.

INTRODUCTION

Rupture of the ventricular chamber (septum or free wall) after myocardial infarction is a relatively infrequent condition with high mortality. An *acute* postinfarction VSD is a perforation of the muscular ventricular septum occurring in an area of acutely infarcted myocardium. A ventricular septal rupture may be termed *chronic* when it has been present for more than 4 to 6 weeks. A *postinfarction ventricular rupture* is a perforation of the ventricular free wall occurring in an area of acutely infarcted myocardium. These conditions, resulting from transmural infarction, may cause rapid hemodynamic compromise and early death precluding surgical repair. Free wall rupture can result in tamponade and sudden cardiovascular collapse. In ventricular septal rupture, there is a variable amount of left-to-right shunting, but such defects typically lead to symptoms of heart failure. The clinical presentation ranges from an asymptomatic murmur to cardiogenic shock and sudden death.

The early evolution of successful surgical repair of an acute postinfarction ventricular septal rupture involved differentiating the surgical treatment of these acquired lesions from surgical approaches used to repair congenital ventricular septal defects (VSDs), which are for the most part not applicable. Initial success was achieved with methods involving infarctectomy and patching. Specific methods were developed for differing anatomical locations of postinfarction VSDs, including location of the cardiotomy and patch methodology. With experience, there was gradual appreciation of different clinical courses pursued by patients after postinfarction ventricular septal rupture, both in terms of location of the defect and the degree of right ventricular functional impairment, led to an increased urgency relative to the timing of surgical repair. An important paradigm shift had resulted from improved results utsing a technique of endocardial patching with infarct exclusion. Surgical management requires an understanding of the various approaches. The incorporation of specific anatomic concepts of surgical repair and a better understanding of the physiologic basis of the disease has led to an integrated approach to the patient that has improved salvage of patients suffering this catastrophic complication of acute myocardial infarction (AMI).

History

In 1845 Latham[1] described a postinfarction ventricular septal rupture at autopsy, but it was not until 1923 that Brunn[2] first made the diagnosis antemortem. Sager[3] in 1934 added the 18th case to the world literature and established specific clinical criteria for diagnosis, stressing the association of postinfarction septal rupture with coronary artery disease (CAD).

The treatment of this entity was medical and strictly palliative until 1956, when Cooley and associates[4] performed the first successful surgical repair in a patient 9 weeks after the diagnosis of septal rupture. These first patients who underwent similar repairs in the early 1960s usually presented with congestive heart failure (CHF), having survived for more than a month after acute septal perforation.[5,6] The success of operation in these patients and the precipitous, acute course of other patients with this complication gave rise to the belief that operative repair should be limited to patients surviving for 1 month or

longer.[6,7] This purportedly allowed for scarring at the edges of the defect, which was thought to be crucial to the secure and long-lasting closure of the septal rupture.[8,9]

In the late 1960s, more rapid recognition of septal rupture after infarction led to the recommendation that operation be attempted earlier in patients who were hemodynamically deteriorating. Notable among these was a superb early study by Heimbecker and associates of infarctectomy and its clinical application to patients with postinfarction VSDs. The surgical management of these patients was further refined by the inclusion of infarctectomy and aneurysmectomy and the development of techniques to repair perforations in different areas of the septum.[10–12] Improved surgical techniques, newer prosthetic materials, enhanced myocardial protection, and improved perioperative mechanical and pharmacologic support have led to more favorable results in the surgical management of patients with postinfarction septal rupture.

Incidence

Postinfarction ventricular septal defects complicate approximately 1 to 2% of cases of AMIs and account for about 5% of early deaths after MI.[13,14] The average time from infarction to rupture has been reported to be between 2 and 4 days, but it may be as short as a few hours or as long as 2 weeks.[15,16] These observations correlate well with the pathologic findings, which demonstrate that necrotic tissue is most abundant and ingrowth of blood vessels and connective tissue is only beginning 4 to 21 days after an MI.[17] Postinfarction ventricular septal defects occur in men more often than women (3:2), but more women experience rupture than what would be expected from the incidence of CAD in women. The average age of patients with this complication is 62.5 years, although there is some evidence that more elderly patients are being seen in the recent era. The vast majority of patients who experience ventricular septal rupture do so after their initial infarction.[18] The overall incidence of postinfarction ventricular septal rupture may have decreased slightly during the past decade as a result of aggressive pharmacologic treatment of ischemia and thrombolytic and interventional therapy in patients with evolving MI, as well as the prompt control of hypertension in these patients. The effect of widespread use of percutaneous angioplasty and stenting on the appearance of this complication of MI is not well documented, but several large centers, including ours, have had a decreased number of post-MI VSD patients in the past 10 years.

Angiographic evaluation of patients with postinfarction ventricular rupture indicates that septal rupture is usually associated with complete occlusion rather than severe stenosis of a coronary artery.[19] On average, these patients have slightly less extensive CAD, as well as less developed septal collaterals than do other patients with CAD.[20] The lack of collateral flow noted acutely may be secondary to anatomical configuration, edema, or associated arterial disease. Hill and associates,[21] in reviewing 19 cases of postinfarction ventricular septal rupture, found single-vessel disease in 64%, double-vessel disease in 7%, and triple-vessel disease in 29%. However, the frequency of single-, double-, and triple-vessel CAD is more evenly distributed in other series.[16,22]

Postinfarction ventricular septal defects are most commonly located in the anteroapical septum as the result of a full-thickness anterior infarction (in approximately 60% of cases). These anterior septal ruptures are caused by anteroseptal MI after occlusion of the left anterior descending (LAD) artery. In about 40% of patients, the rupture occurs in the posterior septum after an inferoseptal infarction, which is usually owing to occlusion of a dominant right coronary artery, or less frequently, a dominant circumflex artery. Thus, ventricular septal perforations occur most frequently in 65-year-old men with single-vessel coronary disease and poor collateral flow who present 2 to 4 days after their first anterior MI.

Pathogenesis

The infarct associated with septal rupture is transmural and generally quite extensive, involving, on average, 26% of the left ventricular wall in hearts with septal rupture, compared with only 15% in other acute infarctions.[14] In an autopsy study, Cummings and colleagues[23] found that in patients with acute anterior or inferior infarctions, the amount of right ventricular infarction was much greater in the hearts with septal ruptures as compared with those without septal defects. Likewise, hearts with posterior septal rupture had more extensive left ventricular necrosis than did hearts with inferior infarctions and no septal defects.

Why certain hearts rupture and others do not is not fully understood. Slippage of myocytes during infarct expansion may allow blood to dissect through the necrotic myocardium and enter either the right ventricle or pericardial space. Hyaline degeneration of cardiomyocytes with subsequent fragmentation and enzymatic digestion may allow fissures to form, predisposing to rupture.[24–26]

There are two types of rupture: simple, consisting of a direct through-and-through defect usually located anteriorly; and complex, consisting of a serpiginous dissection tract remote from the primary septal defect, which is usually located inferiorly. Multiple defects, which may develop within several days of each other, occur in 5 to 11% of cases and are probably caused by infarct extension. Because a successful surgical outcome is related to adequacy of closure of septal defects, multiple defects must be sought preoperatively if possible, and certainly at the time of operative repair.

Of the small number of patients who survive the early period of ventricular septal rupture, 35 to 68% go on to develop ventricular aneurysms through the process of ventricular remodeling.[27] This compares with an approximately 12% incidence of aneurysm formation in patients suffering an infarction but no septal rupture,[28] and probably relates to the size and transmural nature of the infarction associated with septal rupture. Postinfarction septal rupture, especially in the posterior septum, may be accompanied by mitral valve regurgitation resulting from papillary muscle infarction or dysfunction. In approximately one-third of cases of septal rupture, there is a degree of mitral insufficiency, usually functional in nature, secondary to left ventricular (LV) dysfunction with mitral annular dilation, which usually resolves with repair of the defect.[20]

Pathophysiology

The most important determinant of early outcome after postinfarction ventricular septal rupture is the development of heart

failure (left, right, or both). The associated cardiogenic shock leads to end-organ malperfusion, which may be irreversible.

The degree to which heart failure develops depends on the size of the ventricular infarction and the magnitude of the left-to-right shunt. Left ventricular dysfunction resulting from extensive necrosis of the left ventricle is the primary determinant of CHF and cardiogenic shock in patients with anterior septal rupture, whereas right ventricular dysfunction secondary to extensive infarction of the right ventricle is the principal determinant of heart failure and cardiogenic shock in patients with posterior septal rupture. However, the development of CHF and cardiogenic shock in a patient with postinfarction VSDs is not explained solely by the degree of damage sustained by the ventricle.

The magnitude of the left-to-right shunt is the other key variable in the development of hemodynamic compromise. With the opening of a VSD, the heart is challenged by an increase in pulmonary blood flow, and a decrease in systemic blood flow, as a portion of each stroke volume is diverted to the pulmonary circuit. As a consequence of the sudden increase in hemodynamic load imposed on a heart already compromised by acute infarction, and possibly by a ventricular aneurysm, mitral valve dysfunction, or a combination of these problems, a severe low cardiac output state results. The normally compliant right ventricle is especially susceptible to failure in this circumstance.[29,30] Patients with posterior ventricular septal rupture and right ventricular dysfunction may display shunt reversal during diastole because the end-diastolic pressure in the right ventricle can be higher than in the left. Ultimately, persistence of a low cardiac output state results in peripheral organ failure.

Diagnosis

The typical presentation of a ventricular septal rupture is that of a patient who has suffered an AMI, and who after convalescing for a few days develops a new systolic murmur, recurrent chest pain, and an abrupt deterioration in hemodynamics. The development of a loud systolic murmur, usually within the first week after an AMI, is the most consistent physical finding of postinfarction ventricular septal rupture (present in greater than 90% of patients). The murmur is usually harsh, pansystolic, and best heard at the left lower sternal border. The murmur is often associated with a palpable thrill. Depending on the location of the septal defect, the murmur may radiate to the left axilla, thereby mimicking mitral regurgitation. Up to one-half of these patients experience postinfarction chest pain in association with the appearance of the murmur.[14] Coincident with the onset of the murmur, there is usually an abrupt decline in the patient's clinical course, with the onset of congestive failure and often cardiogenic shock. The findings of cardiac failure that occur acutely in these patients are primarily the result of right-sided heart failure, with pulmonary edema being less prominent than that occurring in patients with acute mitral regurgitation caused by a ruptured papillary muscle.[32]

The electrocardiographic (ECG) findings in patients with acute septal rupture relate to the changes associated with antecedent anterior, inferior, posterior, or septal infarction. The localization of infarction by ECG correlates highly with the location of the associated septal perforation. In our review[18] of 55 patients with postinfarction septal rupture, the location of the defect corresponded to the territory of transmural infarction as determined by ECG in all but three patients. Up to one-third of patients develop some degree of atrioventricular conduction block (usually transient) that may precede rupture,[33] but there is no pathognomonic prognostic indicator of impending perforation. The chest radiograph usually shows increased pulmonary vascularity consistent with pulmonary venous hypertension.

It is important to realize that the sudden appearance of a systolic murmur and hemodynamic deterioration after infarction may also result from acute mitral regurgitation caused by a ruptured papillary muscle. Distinguishing these two lesions clinically is difficult, and an urgent echocardiogram should be obtained. A number of points may help with the initial evaluation. First, the systolic murmur associated with a septal rupture is more prominent at the left sternal border, whereas the murmur resulting from a ruptured papillary muscle is best heard at the apex. Second, the murmur associated with septal perforation is loud and associated with a thrill (in greater than 50% of patients), whereas the murmur of acute mitral regurgitation is softer and has no associated thrill. Third, septal rupture is often associated with anterior infarctions and conduction abnormalities, whereas papillary muscle rupture is commonly associated with an inferior infarction and no conduction defects. Finally, it should be noted that septal rupture and papillary muscle rupture may coexist after infarction.[34,35]

Historically, the mainstay of differentiating septal rupture from mitral valve dysfunction has been right heart catheterization using the Swan-Ganz catheter.[36] With septal rupture, there is an oxygen saturation step-up between the right atrium and pulmonary artery. Step-up in oxygen saturation greater than 9% between the right atrium and pulmonary artery confirms the presence of a shunt. The pulmonary-to-systemic flow ratios (Qp:Qs) obtained from oxygen saturation samples range from 1.4:1 to greater than 8:1 and roughly correlate with the size of the defect. In contrast, with acute mitral regurgitation secondary to papillary muscle rupture, there are classic giant V waves in the pulmonary artery wedge pressure trace. It should be noted, however, that up to one-third of patients with septal rupture also have mild mitral regurgitation secondary to LV dysfunction.[37]

Advances in transthoracic and transesophageal echocardiography, especially color flow Doppler mapping, have revolutionized the diagnosis of both the presence and site of septal rupture. Echocardiography can detect the defect, localize its site and size, determine right and left ventricular function, assess pulmonary artery and right ventricular pressures, and exclude coexisting mitral regurgitation or free wall rupture. Twenty years ago, Smyllie and associates[38] reported 100% specificity and 100% sensitivity when color flow Doppler mapping was used to differentiate ventricular septal rupture from acute severe mitral regurgitation following AMI. It also correctly demonstrated the site of septal rupture in 41 of 42 patients. Widespread use of this technology has made this imaging the primary method of diagnosis. Indeed, the trend in the past two decades toward early surgical referral and prompt operative repair is at

least partially explained by the routine use of color Doppler echocardiography for diagnosis in peripheral centers.

The necessity of preoperative left heart catheterization with coronary angiography has been a matter of debate. On one hand, left heart catheterization provides important information concerning associated CAD, left ventricular wall motion, and specifics of valvular dysfunction, which are all important in planning operative correction of postinfarction septal rupture. In most series, greater than 60% of patients with septal rupture have significant involvement of at least one vessel other than the one supplying the infarcted area. Arguably, bypassing associated CAD may increase long-term survival when compared with patients with unbypassed CAD.[39] However, left heart catheterization has disadvantages—it is time consuming, requires use of nephrotoxic dye, and may contribute to both the mortality and morbidity of these already compromised patients. Thus, some centers do not carry out preoperative left heart catheterization. Others use it selectively, avoiding invasive studies in patients with septal rupture caused by anterior wall infarction, which is associated with a much lower incidence of multiple-vessel disease than septal defects resulting from posterior infarctions. The issue of concomitant coronary bypassing is discussed in greater detail below.

Natural History

Reviews by Oyamada and Queen,[40] and Kirklin and coworkers[41] reveal that nearly 25% of patients with postinfarction septal rupture and no surgical intervention died within the first 24 hours, 50% died within 1 week, 65% within 2 weeks, and 80% within 4 weeks; only 7% lived longer than 1 year. Lemery and associates[42] reported that of 25 patients with postinfarction VSDs treated medically, 19 died within 1 month. Thus, the risk of death after postinfarction VSD is highest immediately after infarction and septal rupture, and then gradually declines. Interestingly, there are reports of spontaneous closure of small defects, although this is so rare that it would be unreasonable to manage a patient with the expectation of closure.

Despite the many advances in the nonoperative treatment of CHF and cardiogenic shock, including the intra-aortic balloon pump and a multitude of new inotropic agents and vasodilators, these do not supplant the need for operative intervention in these critically ill patients.

Management

It has become clear that the early practice of waiting for several weeks after ventricular septal rupture before proceeding with intervention only selects out the small minority of patients in whom the hemodynamic insult is less severe and is better tolerated.[22,24] Likewise, it has also become clear that to manage most patients supportively, in hopes of deferring intervention, is to deprive the great majority of those with postinfarction ventricular septal rupture of the benefits of definitive surgery before irreversible damage resulting from peripheral organ ischemia has occurred.[43]

In addition to definitive surgical closure, early intervention can include mechanical support and device closure. The routine use of the intra-aortic balloon pump (IABP), whenever technically feasible, frequently results in *transient* reversal of the hemodynamic deterioration. This period of stability often makes it possible to complete left heart catheterization before proceeding to operation, but should not significantly delay definitive surgical treatment. In general, an IABP should be placed once the diagnosis is made, unless more aggressive mechanical support is immediately planned. In patients who are deemed to be at unacceptable risk for definitive surgery, there may be a role for left or biventricular support to bridge the patient to surgery (see the following). The high-risk patient may also represent a category in whom catheter-based device placement may greatly improve hemodynamic function and lead to stabilization, with a planned operation after recovery from the acute illness (see the following).

Although we as well as others have advocated early intervention since the middle of the 1970s, some continue to prefer to defer operation in patients who are easily supported and exhibit no further hemodynamic deterioration. Persistence of CHF or marginal stabilization with rising blood urea nitrogen and borderline urine output necessitate aggressive therapy and prompt operation. Patients with septal rupture rarely die of cardiac failure per se, but rather of end-organ failure as a consequence of shock.

Our experience and the experience of others suggest that patients in cardiogenic shock represent a true surgical emergency requiring immediate intervention, which may include surgery, mechanical support, or catheter options. Because deaths in these patients result from multisystem failure secondary to organ hypoperfusion, delay in operative repair (or mechanical support) for patients in cardiogenic shock represents a failed therapeutic strategy. Those few patients who are completely stable, with no clinical deterioration, and who require no hemodynamic support, can undergo operative repair when convenient during that hospitalization. The large group of patients who are in an intermediate position between those with shock and those in stable condition should have intervention early (usually within 12 to 24 hours) after appropriate preoperative evaluation. Because the group of patients in stable condition constitutes 5% or less of the total population of patients with postinfarction ventricular septal rupture, the overwhelming majority of patients require prompt treatment.

Rarely, because of a delayed referral, a patient will be seen for surgical therapy who is already in a state of multisystem failure or has developed septic complications. Such a patient is unlikely to survive an emergency operation and thus may benefit from prolonged support with an IABP before an attempted operative repair. We have found it necessary to treat a small number of patients (3 of 92) in this fashion. Baillot and colleagues[44] have reported individual successes with such an approach, which we consider the exception rather than the rule.

Preoperative Management

Preoperative management is directed toward stabilization of the hemodynamic condition so that peripheral organ perfusion can be best maintained while any further diagnostic studies are obtained and while deciding on the optimal time for surgical

intervention. Although the early clinical course of patients with postinfarction ventricular septal rupture can be quite variable, 50 to 60% present with severe CHF and a low cardiac output state requiring intensive therapy.[45,74]

The goals of preoperative management are to: (1) reduce the systemic vascular resistance, and thus the left-to-right shunt; (2) maintain cardiac output and arterial pressure to ensure peripheral organ perfusion; and (3) maintain or improve coronary artery blood flow. This is best accomplished by the IABP. Counterpulsation reduces left ventricular afterload, thereby increasing cardiac output and decreasing the left-to-right shunt, as reported by Gold and associates in 1973.[46] In addition, IABP support is associated with decreased myocardial oxygen consumption, as well as improved myocardial and peripheral organ perfusion. Although counterpulsation produces an overall improvement in the patient's condition, a complete correction of the hemodynamic picture cannot be obtained.[47] Peak improvement occurs within 24 hours and no further benefit has been observed with prolonged balloon pumping.[48]

Pharmacologic therapy with inotropic agents and diuretics should be instituted promptly. The addition of vasodilators (ie, sodium nitroprusside or intravenous nitroglycerine) makes good theoretical sense, because it can decrease the left-to-right shunting associated with the mechanical defect, and thus increase cardiac output. However, these effects are often associated with a marked fall in mean arterial blood pressure and reduced coronary perfusion, both poorly tolerated in these critically ill patients. It must be stressed that pharmacologic therapy is intended primarily to support the patient in preparation for operation and should not in any way delay urgent operation in the critically ill patient. We now admit patients with postinfarction septal rupture directly to the surgical intensive care unit rather than to the coronary care or medical intensive care unit.

Other techniques that have been tried in an effort to improve the hemodynamics of patients with interventricular septal rupture include left ventricular mechanical support, venoarterial extracorporeal membrane oxygenation, and inflation of a balloon in the right ventricular outflow tract to decrease the left-to-right shunt. At the present, we believe these techniques should be reserved for patients with severe end-organ malperfusion deemed unlikely to survive surgery. To avoid shunting across the lesion (right to left at the ventricular level), atrial cannulation is necessary. Use of a catheter-mounted axial flow pump (Hemopump, Impella) in stabilizing these patients is controversial because of the risk of acute pump failure resulting from catheter blockage from pieces of necrotic tissue.[49]

Operative Techniques

Historical Development

The first repair by Cooley and colleagues of an acquired VSD was accomplished using an approach through the right ventricle with incision of the right ventricular outflow tract.[4] This approach, which was adapted from surgical techniques for closure of congenital VSDs, proved to be disadvantageous for many reasons. Exposure of the defect was frequently less than optimal, particularly for defects located in the apical septum. It involved unnecessary injury to normal right ventricular muscle and interruption of collaterals from the right coronary artery. Finally, it failed to eliminate the paradoxic bulging segment of infarcted left ventricular wall. Subsequently, Heimbecker and associates[9] introduced a left-sided approach (left ventriculotomy) with incision through the area of infarction. Such an approach frequently incorporates infarctectomy and aneurysmectomy, together with repair of septal rupture.[50]

Overview

For the purpose of planning an operative repair, there are three locations of defects: apical, anterior, and posterior/inferior. The apical defect can be considered as a subset of the anterior location, and provides the surgeon the possibility of a straightforward repair, similar to an aneurysmectomy. There are two very different surgical paradigms for repair, one using infarctectomy, and the other infarct exclusion. Posterior lesions are the most challenging with the infarctectomy technique, and there is now a general trend to approach those lesions with exclusion methods. As described in the following, the surgical approach to lesion in various locations requires specific considerations, but certain general principles apply (Tables 28-1A and 28-1B).

Anesthesia and Perfusion

Patients are anesthetized using a fentanyl-based regimen. Pancuronium is selected as the muscle relaxant so as to prevent bradycardia. Pulmonary bed vasodilators such as dobutamine are avoided to minimize the left-to-right shunt fraction. Preoperative

TABLE 28-1A Principles of Infarctectomy Repair of Postinfarction VSD

Transinfarct approach to ventricular septal defect

1. Thorough trimming of the left ventricular margins of the infarct back to viable muscle to prevent delayed rupture of the closure
2. Conservative trimming of the right ventricular muscle as required for complete visualization of the margins of the defect
3. Inspection of the left ventricular papillary muscles and concomitant replacement of the mitral valve only if there is frank papillary muscular rupture
4. Closure of the septal defect without tension, which in most instances will require the use of prosthetic material
5. Closure of the infarctectomy without tension with generous use of prosthetic material as indicated, and epicardial placement of the patch to the free wall to avoid strain on the friable endocardial tissue
6. Buttressing of the suture lines with pledgets or strips of Teflon felt or similar material to prevent sutures from cutting through friable muscle

TABLE 28-1B Principles of Exclusion Repair of Postinfarction VSD

Transinfarct approach to ventricular septal defect

1. No infarctectomy unless necrotic muscle along ventriculotomy is sloughing during closure
2. Bovine pericardial patch in either an oval (anterior defect) or triangular (posterior defect) shape is sutured securely with continuous Prolene around the defect to exclude it from the LV cavity
3. Where necessary, full-thickness bites are taken to the epicardial surface and anchored by strips of pericardium or Teflon (see text for details)
4. An anterior patch is anchored to noninfarcted septum below the defect, then the noninfarcted endocardium of the anterolateral ventricular wall. If the infarct involves the base of the anterior muscle, full thickness anchoring bites are used.
5. A posterior patch is anchored to the mitral annulus, noninfarcted septum, and through the infarcted posterior wall along a line corresponding to the medial margin of the posteromedial papillary muscle (with full thickness anchoring).
6. Closure of the infarctectomy using strips of pericardium or Teflon
7. When possible, infarcted right ventricular free wall is left undisturbed during closure

Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; RV = right ventricle; stippled region = infarcted myocardium.

antibiotics include both cefazolin and vancomycin, given the fact that prosthetic material may be left in the patient.

Cardiopulmonary bypass is accomplished with bicaval venous drainage. Standard techniques of myocardial protection for injured hearts are employed. Systemic cooling is begun to 25 to 30°C. Although a number of myocardial protection strategies are currently available, including warm continuous blood, we continue to use cold oxygenated, dilute blood cardioplegia to protect the heart during surgical correction of a VSD.[51] A total of 1200 to 2000 mL of cardioplegia solution is delivered, depending on the size of the heart and the degree of hypertrophy. Although we have not employed warm cardioplegic induction, we do administer warm reperfusion cardioplegia just before removing the aortic cross-clamp.[52] Patients with multivessel coronary disease and critical coronary stenoses are revascularized before opening the heart to optimize myocardial protection. In most of these patients, the saphenous vein rather than the left internal mammary artery is used.

Repair of Apical Septal Rupture

The technique of apical amputation was described by Daggett and colleagues in 1970.[11] An incision is made through the infarcted apex of the left ventricle. Excision of the necrotic myocardium back to healthy muscle results in amputation of the apical portion of the left ventricle, right ventricle, and septum (Figs. 28-1 A and B). The remaining apical portions of the left and right ventricle free walls are then approximated to the apical septum. This is accomplished by means of a row of interrupted mattress sutures of 1-0 Tevdek that are passed sequentially through a buttressing strip of Teflon felt, the left ventricular wall, a second strip of felt, the interventricular septum, a third strip of felt, the right ventricular wall, and a fourth strip of felt (Figs. 28-2 A and B). After all sutures have been tied, the closure is reinforced with an additional over-and-over suture, as in ventricular aneurysm repair, to ensure hemostasis of the ventriculotomy closure.

Anterior Repair with Infarctectomy

The approach to these defects is by a left ventricular transinfarct incision with infarctectomy (Fig. 28-3). Small defects beneath anterior infarcts can be closed by the technique of plication as suggested by Shumacker.[53] This involves approximation of the free anterior edge of the septum to the right ventricular free wall using mattress sutures of 1-0 Tevdek over strips of felt (Fig. 28-4A). The transinfarct incision is then closed with a second row of mattress sutures buttressed with strips of Teflon

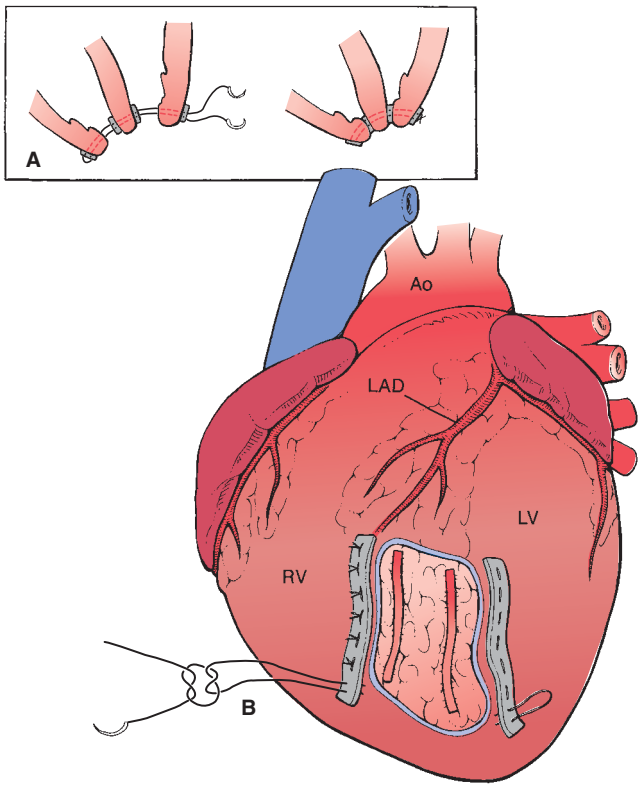

FIGURE 28-2 (A) The necrotic infarct and the apical septum have been débrided back to healthy muscle. Repair is made by approximating the left ventricle, apical septum, and right ventricle using interrupted mattress sutures of 1-0 Tevdek with but tressing strips of Teflon felt. Felt strips are used within the interior of the left and right ventricles as well as on the epicardial surface of each ventricle. (B) All sutures are placed before any are tied. A second running over-and-over suture (not shown) is used, as in left ventricular aneurysm repair, to ensure a secure hemostatic ventriculotomy closure. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; RV = right ventricle. (*Adapted with permission from Daggett et al. 16*)

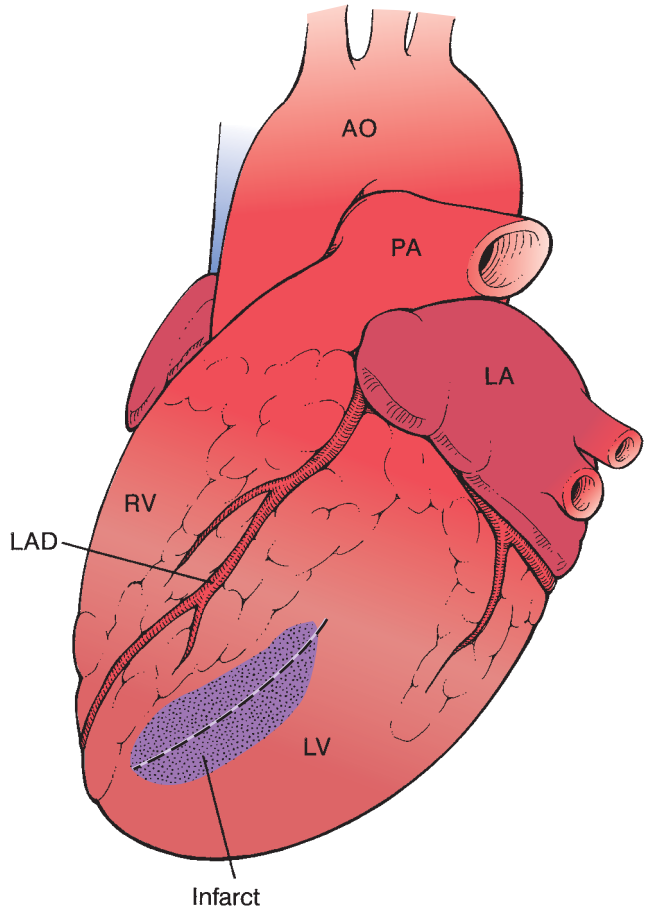

FIGURE 28-3 Transinfarct left ventricular incision to expose an anterior septal rupture. An incision (dashed line) is made parallel to the anterior descending branch of the left coronary artery (LAD) through the center of the infarct (stippled area) in the anterior left ventricle (LV). Ao = aorta; LA = left atrium; PA = pulmonary artery; RV = right ventricle.

felt (see Figs. 28-4 B–D). An over-and-over running suture completes the ventriculotomy closure.

Most anterior defects require closure with a prosthetic patch (DeBakey Elastic Dacron fabric, USCI Division of C.R. Bard, Inc., Billerica, MA) or pericardium to avoid tension that could lead to disruption of the repair (Fig. 28-5). After debridement of necrotic septum and left ventricular muscle, a series of pledgeted interrupted mattress sutures are placed around the perimeter of the defect (see Fig. 28-5A). Along the posterior aspect of the defect, sutures are passed through the septum from right to left. Along the anterior edge of the defect, sutures are passed from the epicardial surface of the right ventricle to the endocardial surface. All sutures are placed before the patch is inserted, and then passed through the edge of a synthetic patch, which is seated on the left side of the septum (see Fig. 28-5B). Each suture is then passed through an additional pledget and all are tied. We use additional pledgets on the left ventricular side overlying the patch (see Fig. 28-5C) to cushion each suture as it is tied down to prevent cutting through the friable muscle.

The edges of the ventriculotomy are then approximated by a two-layer closure consisting of interrupted mattress sutures passed through buttressing strips of Teflon felt (or glutaraldehyde-preserved bovine pericardium) and a final over-and-over running suture.

Posterior/Inferior Repair with Infarctectomy

Closure of inferoposterior septal defects, which result from transmural infarction in the distribution of the posterior descending artery, has posed the greatest technical challenge.[54,55] Because of the difficulty in surgical management of these defects by the method of infarctectomy, many surgeons now feel that these defects may be better suited to repair using exclusion techniques, which are described in detail in the next section.

Early attempts at primary closure of these posterior/inferior defects by simple plication techniques similar to those used in the repair of anterior defects were frequently unsuccessful because of the sutures tearing out of soft, friable myocardium that had been closed under tension. This resulted in either reopening of the defect or catastrophic disruption of the infarctectomy closure. It was, in large part, the analysis of such early

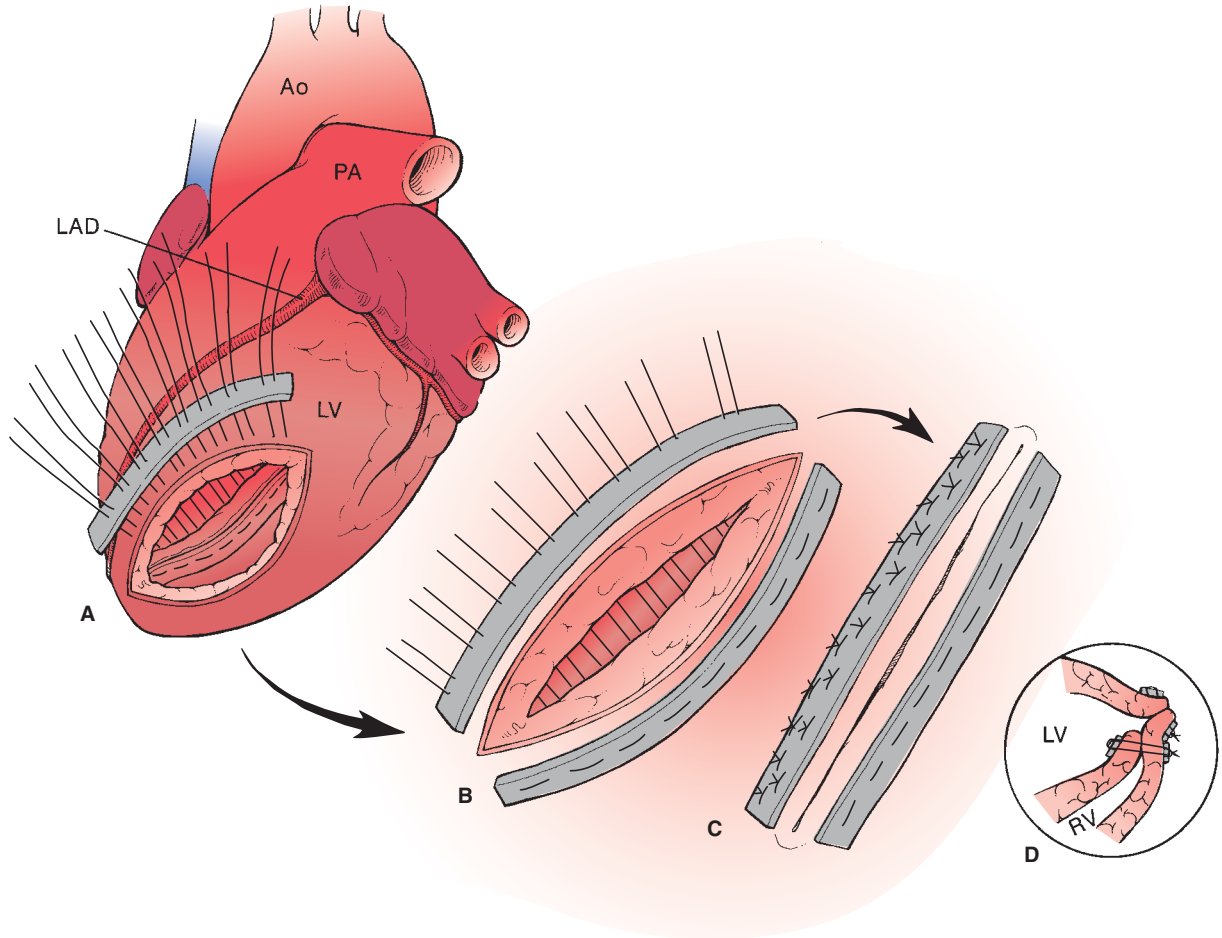

FIGURE 28-4 (A) Repair of an anterior septal rupture by plicating the free anterior edge of the septum to the right ventricular free wall with interrupted 1-0 Tevdek mattress sutures buttressed with strips of Teflon felt. (B, C, and D) The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture (not shown) is used to ensure a secure left ventriculotomy closure. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; PA = pulmonary artery; RV = right ventricle. (*Adapted with permission from Guyton SW, Daggett WM: Surgical repair of post-infarction ventricular septal rupture, in Cohn LH (ed): Modern Techniques in Surgery: Cardiac/Thoracic Surgery. Mt.Kisco, NY, Futura, 1983; installment 9, p 61-1.*)

results that led to the evolution of the operative principles enumerated in Table 28-1A.

Use of the following techniques has been associated with an improved operative survival. After the establishment of bypass with bicaval cannulation, the left side of the heart is vented via the right superior pulmonary vein. The heart is retracted out of the pericardial well as for bypass to the posterior descending coronary artery. The margins of the defect may involve the inferior aspects of both ventricles, or of the left ventricle only (Fig. 28-6A). A transinfarct incision is made in the left ventricle, and the left ventricular portion of the infarct is excised (see Fig. 28-6B), exposing the septal defect. The left ventricular papillary muscles are inspected. Only if there is frank papillary muscle rupture is mitral valve replacement performed. When it is indicated, we prefer to perform mitral valve replacement through a separate conventional left atrial incision, to avoid trauma to the friable ventricular muscle. After all infarcted left ventricular muscle has been excised, a less aggressive debridement of the right ventricle is accomplished, with the goal of resecting only as much muscle as is necessary to afford complete visualization of the defect(s). Using this technique, delayed rupture of the right ventricle has not been a problem. If the posterior septum has cracked or split from the adjacent ventricular free wall without loss of a great deal of septal tissue, then the septal rim of the posterior defect may be approximated to the edge of the diaphragmatic right ventricular free wall using mattress sutures buttressed with strips of Teflon felt or bovine pericardium (see Figs. 28-6 C and D).

Larger posterior defects require patch closure (Fig. 28-7). Pledgeted mattress sutures are placed from the right side of the septum and from the epicardial side of the right ventricular free wall (see Fig. 28-7B). All sutures are passed through the perimeter of the patch and then through additional pledgets, and are then tied (see Fig. 28-7C). Thus, as in closure of large anterior defects, the patch is secured on the left ventricular side of the septum. Direct closure of the remaining infarctectomy is rarely possible because of tension required to pull together the edges of the gaping defect. A prosthetic patch is generally required.

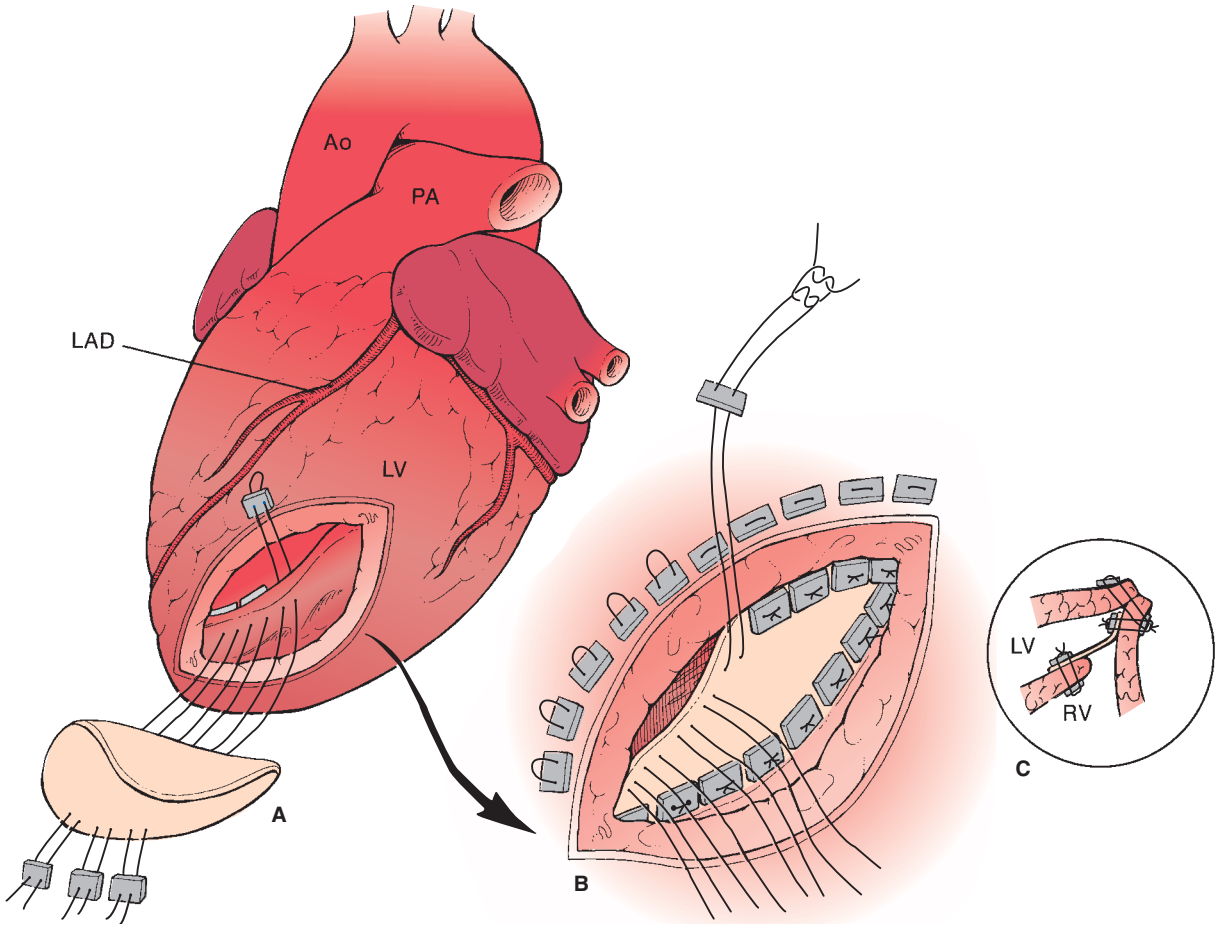

FIGURE 28-5 (A) Larger anterior septal defects require a patch (DeBakey Dacron fabric,USCI Division of C.R. Bard, Inc., Billerica, Mass), which is sewn to the left side of the ventricular septum with interrupted mattress sutures, each of which is buttressed with a pledget of Teflon felt on the right ventricular side of the septum and anteriorly on the epicardial surface of the right ventricular free wall. All sutures are placed before the patch is inserted. (B and C) We use additional pledgets on the left ventricular side overlying the patch to cushion each suture as it is tied down to prevent cutting through the friable muscle. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; PA = pulmonary artery; RV = right ventricle. (*Adapted with permission from Guyton SW, Daggett WM: Surgical repair of post-infarction ventricular septal rupture, in Cohn LH (ed): Modern Techniques in Surgery: Cardiac/Thoracic Surgery. Mt. Kisco, NY, Futura, 1983; installment 9, p 61-1.*)

Originally, we cut an oval patch from a Cooley low-porosity woven Dacron tube graft (Meadox Medicals, Inc., Oakland, NJ). Currently, we cut this patch from a Hemashield woven double velour Dacron collagen impregnated graft (Meadox Medicals). Pledgeted mattress sutures are passed out through the margin of the infarctectomy (endocardium to epicardium) and then through the patch (see Fig. 28-7D), which is seated on the epicardial surface of the heart. After each suture is passed through an additional pledget, all sutures are tied (see Fig. 28-7E). The cross-sectional view of the completed repair (Fig. 28-8) illustrates the restoration of relatively normal ventricular geometry, which is accomplished by the use of appropriately sized prosthetic patches.

Repair of Anterior and Posterior Defects by Infarct Exclusion

The concept that the preservation of left ventricular geometry plays a crucial role in the preservation of left ventricular function has laid the groundwork for evolution in the surgical approach to postinfarction VSDs—the technique of endocardial patch repair of postinfarction VSDs described by David,[50] Cooley,[56] and then by Ross[57] in the early 1990s. This operative technique, which is an application to ventricular septal rupture repair of Dor's technique of ventricular endoaneurysmorrhaphy,[58] involves intracavitary placement of an endocardial patch to exclude infarcted myocardium while maintaining ventricular geometry. Thus, instead of closing the septal defect, it is simply *excluded* from the high-pressure zone of the left ventricle. Some institutions have reported impressive results using infarct exclusion, but results in for other centers have been mixed. We currently consider this a particular helpful technique in selected patients with posterior/inferior defects, given the complexity of a infarctectomy repair in this location. The description that follows is based in large part on the work of David.[46]

In patients with anterior septal rupture, the interventricular septum is exposed via a left ventriculotomy, which is made through the infarcted anterolateral wall starting at the apex and

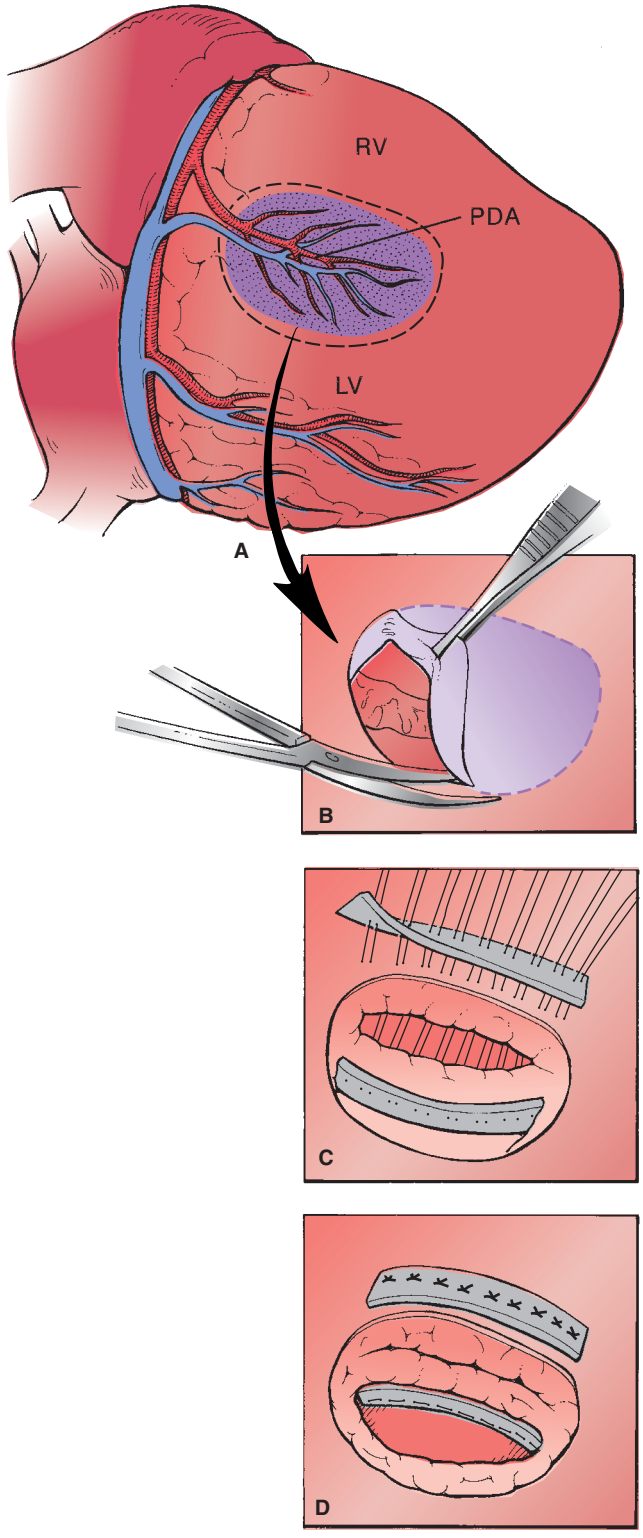

FIGURE 28-6 (A) View of an inferior infarct (stippled area) associated with posterior septal rupture. The apex of the heart is to the right. Exposure at operation is achieved by dislocating the heart up and out of the pericardial sac, and then retracting its cephalad, as in the performance of distal vein bypass and anastomosis to the posterior descending artery. (B) The inferoposterior infarct is excised to expose the posterior septal defect. Complete excision of the left ventricular portion of the infarct is important to prevent delayed rupture of the ventriculotomy repair. The free edge of the right ventricle is progressively shaved back to expose the margins of the defect clearly. (C and D) Repair of the posterior septal rupture is accomplished by approximating the edge of the posterior septum to the free wall of the diaphragmatic right ventricle with felt-buttressed mattress sutures. The repair is possible when the septum has cracked or split off from the posterior ventricular wall without necrosis of a great deal of septal muscle. The surgeon can perform repair of posterior septal rupture to best advantage by standing at the left side of the supine patient. The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture is used to ensure a secure left ventriculotomy closure (not shown). LV = posterior left ventricle; PDA = posterior descending artery; RV = diaphragmatic surface of the right ventricle. (*Adapted with permission from Daggett. 21*)

extending proximally parallel to, but 1 to 2 cm away from, the anterior descending artery (Fig. 28-9A). Stay sutures are passed through the margins of the ventriculotomy to aid in the exposure of the infarcted septum. The septal defect is located and the margins of the infarcted muscle identified. A glutaraldehyde-fixed bovine pericardial patch is tailored to the shape of the left ventricular infarction as seen from the endocardium but 1 to 2 cm larger. The patch is usually oval and measures approximately 4 × 6 cm in most patients. The pericardial patch is then sutured to healthy endocardium all around the infarct (see Fig. 28-9B). Suturing begins in the lowest and most proximal part of the noninfarcted endocardium of the septum with a continuous 3-0 polypropylene suture. Interrupted mattress sutures with felt pledgets may be used to reinforce the repair.[57] The

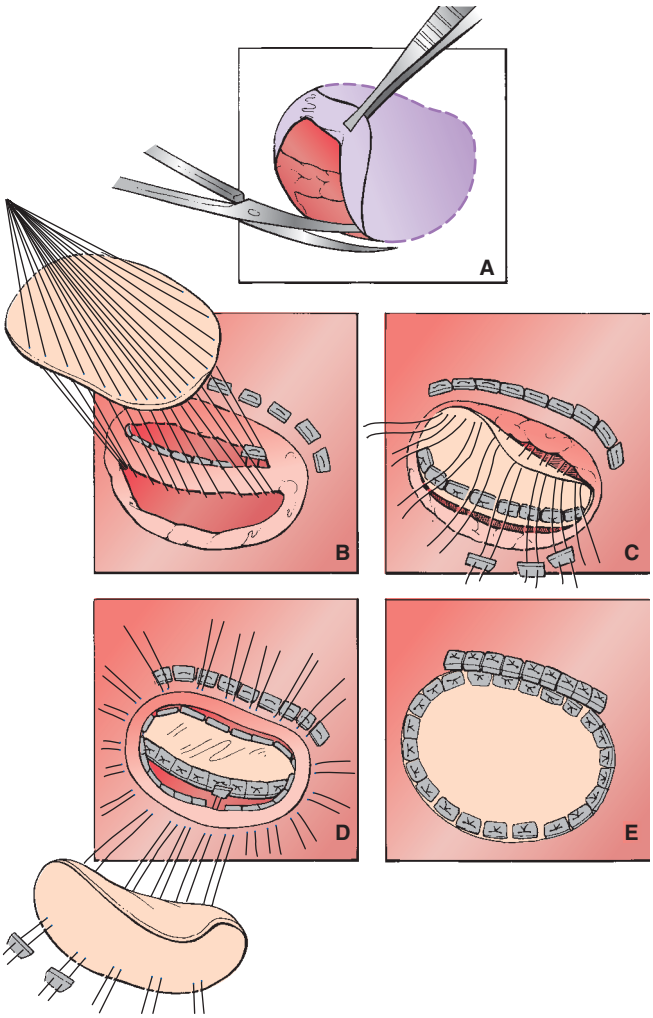

FIGURE 28-7 (A) Repair of posterior septal rupture when necrosis of a substantial portion of the posterior septum requires the use of patches. (B) Interrupted mattress sutures of 2-0 Tevdek are placed circumferentially around the defect. These sutures are buttressed with felt pledgets on the right ventricular side of the septum and on the epicardial surface of the diaphragmatic right ventricle. (C) All sutures are placed and then the patch (DeBakey elastic Dacron fabric) is slid into place on the left ventricular side of the septum. The patch sutures are tied down with an additional felt pledget placed on top of the patch (left ventricular side) as each suture is tied, to cushion the tie and prevent cutting through the friable muscle. These maneuvers are viewed by the authors as essential to the success of early repair of the posterior septal rupture. (D) Remaining to be repaired is the posterior left ventricular free wall defect created by infarctectomy. Mattress sutures of 2-0 Tevdek are placed circumferentially around the margins of the posterior left ventricular free wall defect. Each suture is buttressed with a Teflon felt pledget on the endocardial side of the left ventricle. With all sutures in place, a circular patch, fashioned from a Hemashield woven double velour Dacron collagen-impregnated graft (Meadox Medicals Inc., Oakland, NJ), is slid down onto the epicardial surface of the left ventricle. An additional pledget of Teflon felt is placed under each suture (on top of the patch) as it is tied to cushion the tie and prevent cutting through the friable underlying muscle. This onlay technique of patch placement prevents the cracking of friable left ventricular muscle that occurred with the eversion technique of patch insertion. (E) Completed repair. (*Adapted with permission from Daggett. 21*)

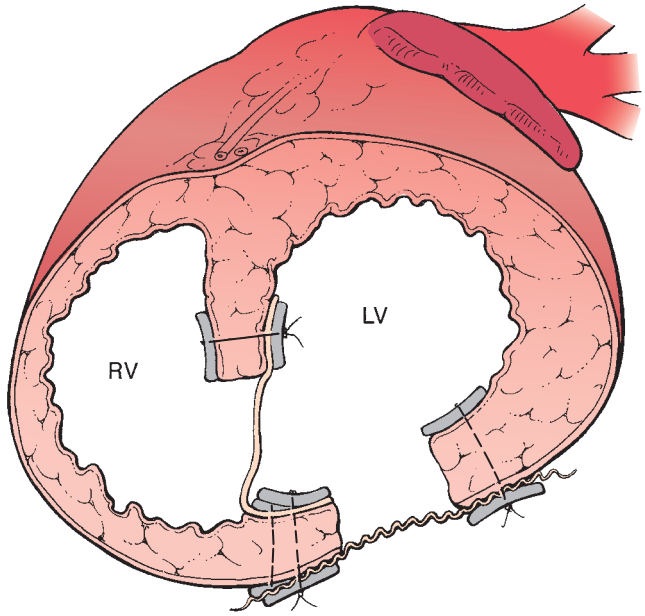

FIGURE 28-8 Cross-sectional view of the completed repair of posterior septal rupture with prosthetic patch placement of the posterior left ventricular free wall defect created by infarctectomy. LV = left ventricular cavity; RV = right vent ricular cavity. (*Adapted with permission from Daggett. 21*)

patch is also sutured to the noninfarcted endocardium of the anterolateral ventricular wall. The stitches should be inserted 5 to 7 mm deep in the muscle and 4 to 5 mm apart. The stitches in the patch should be at least 5 to 7 mm from its free margin so as to allow the patch to cover the area between the entrance and exit of the suture in the myocardium. This technique minimizes the risk of tearing muscle as the suture is pulled taut. If the infarct involves the base of the anterior papillary muscle, the suture is brought outside of the heart and buttressed on a strip of bovine pericardium or Teflon felt applied to the epicardial surface of the left ventricle. Once the patch is completely secured to the endocardium of the left ventricle, the left ventricular cavity becomes largely excluded from the infarcted myocardium. The ventriculotomy is closed in two layers over two strips of bovine pericardium or Teflon felt using 2-0 or 3-0 polypropylene sutures, as illustrated in Fig. 28-9C. No infarctectomy is performed unless the necrotic muscle along the ventriculotomy is sloughing at the time of its closure, and even then it is minimized, because infarcted muscle will not be exposed to left ventricular pressures when the heart begins to work (see Fig. 28-9D). Alternatively, sutures can be passed through the ventricular free wall and through a tailored external patch of Teflon or pericardium (Fig. 28-10).

In patients with posterior septal defects, an incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery (Fig. 28-11A). This incision is started at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. Stay sutures are passed through the fat pad of the apex of the ventricle and margins of the ventriculotomy to

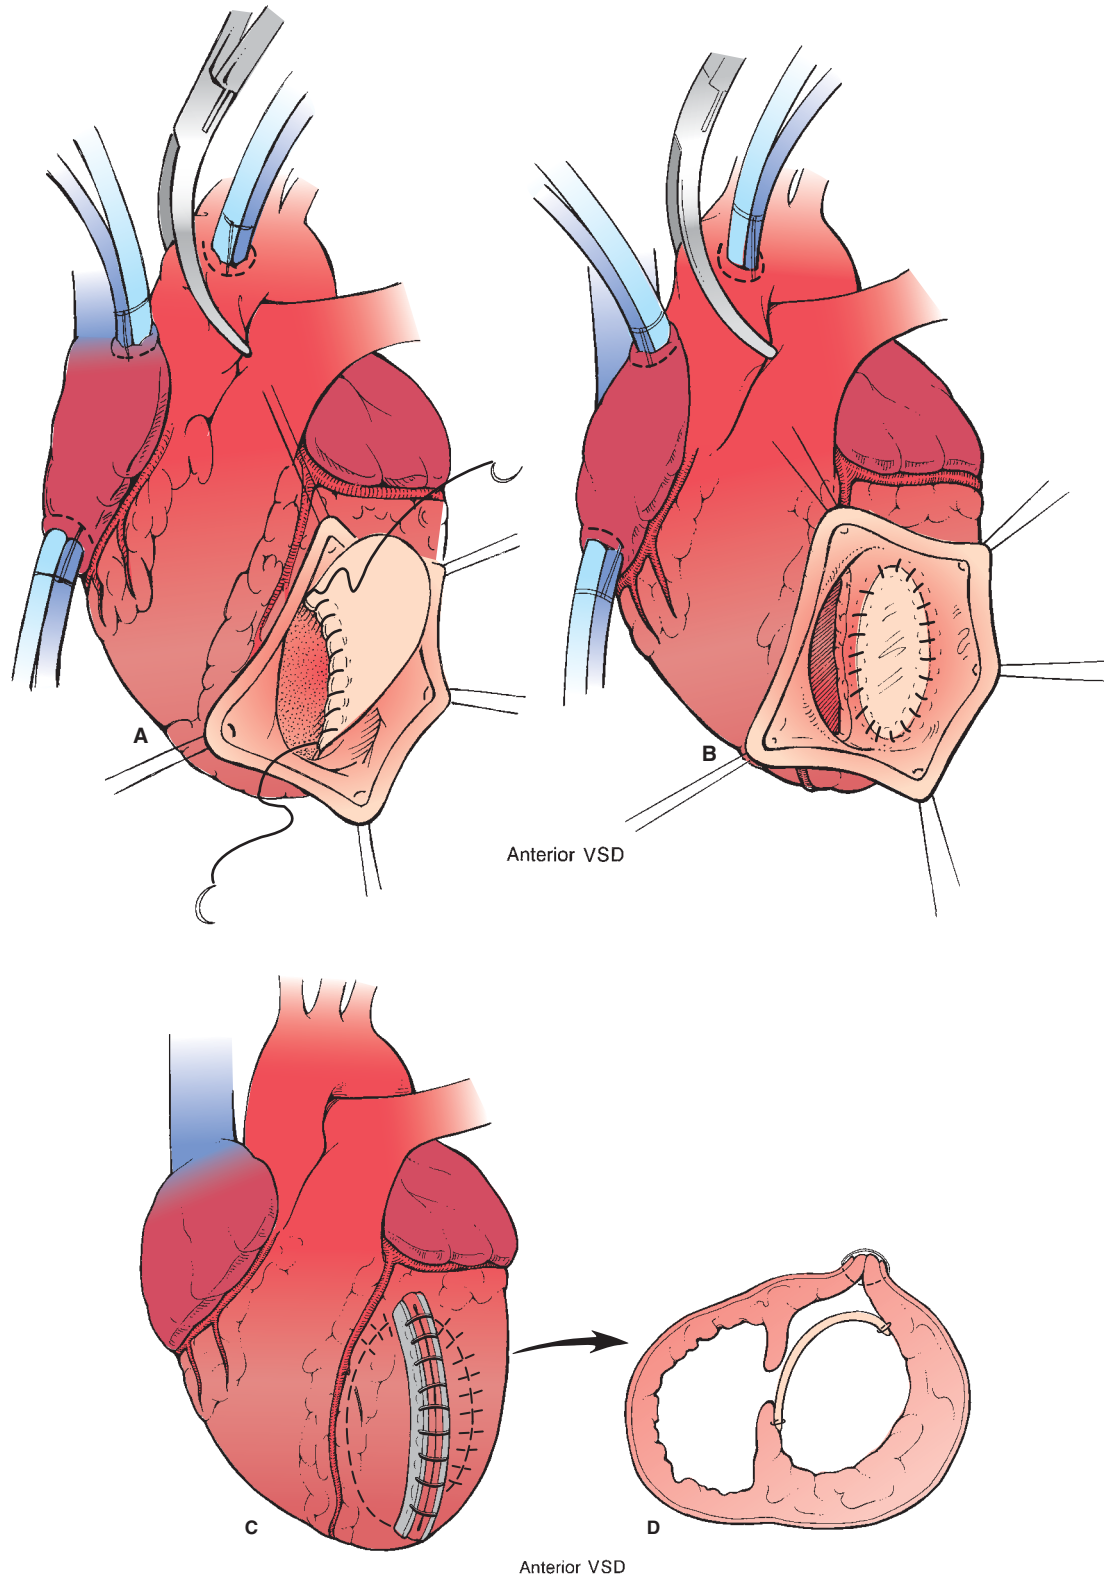

FIGURE 28-9 Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) The standard ventriculotomy is made in the infarcted area of left ventricular free wall. An interior patch of Dacron (Meadox Medicals Inc., Oakland, NJ), polytetrafluoroethylene, or glutaraldehyde-fixed pericardium is fashioned to replace and/or cover the diseased areas (ventricular septal defect [VSD], septal infarction, or free wall infarction). (B) The internal patch is secured to normal endocardium with a continuous monofilament suture, which may be reinforced with pledgeted mattress sutures. There is little, if any, resection of myocardium and no attempt is made to close the septal defect. Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (C) The ventriculotomy, which is outside the pressure zone of the left ventricle, may be repaired with a continuous suture. (D) On transverse section, one can see that the endocardial patch is secured at three levels: above and below the septal rupture and beyond the ventriculotomy. (*Adapted with permission from David et al. 46*)

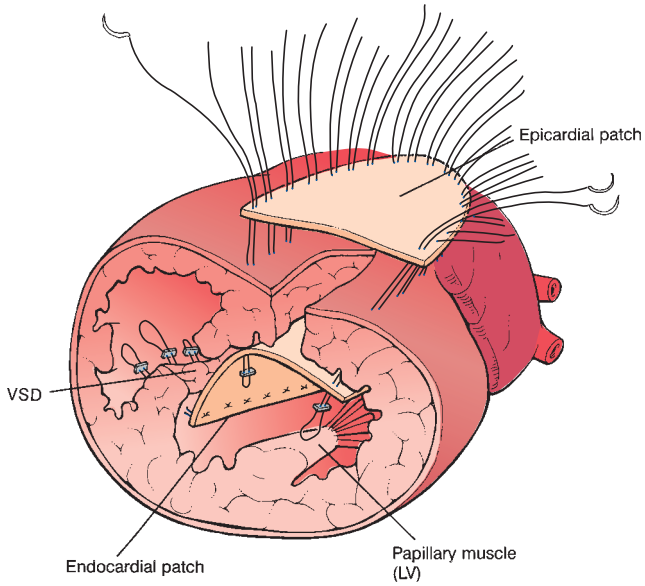

FIGURE 28-10 Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion with external patching of the ventricular free wall with tailored Teflon or pericardium. LV = left ventricle; VSD = ventricular septal defect. (*Adapted with permission from Cooley. 93*)

facilitate exposure of the ventricular cavity. In most cases, the rupture is found in the proximal half of the posterior septum and the posteromedial papillary muscle is involved by the infarction. A bovine pericardial patch is tailored in a triangular shape of approximately 4 × 7 cm in most patients. The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached (see Fig. 28-11B). At that level, the suture is interrupted and any excess patch material trimmed. The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture taking bites the same size as those described for anterior defects. In this area of the septum, reinforcing pledgeted sutures may be required. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. Because the posterior wall of the left ventricle is infarcted, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle right at the level of the posteromedial papillary muscle insertion, as shown in Fig. 28-11B. Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall (see Fig. 28-11C), the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt (see Fig. 28-11D). The infarcted right ventricular wall is left undisturbed. If the posteromedial papillary muscle is ruptured, mitral valve replacement is necessary.

There are several theoretical advantages in the technique of infarct exclusion: (1) It does not require resection of myocardium; excessive resection results in depression of ventricular function and insufficient resection predisposes to recurrence of septal rupture; (2) it maintains ventricular geometry, which enhances ventricular function; and (3) it avoids tension on friable muscle, which may diminish postoperative bleeding.

Other Techniques

Most other operative techniques that have resulted in successful management of postinfarction of ventricular septal rupture have adhered to the same general principles described in the preceding. For example, Tashiro and colleagues[59] described an extended endocardial repair in which a *saccular* patch of glutaraldehyde-fixed equine pericardium was used to exclude an anterior septal rupture. Usui and coworkers[60] reported the successful repair of a posterior septal rupture using two sheets of equine pericardium to sandwich the infarcted myocardium, including the septal defect and ventriculotomy. Others have modified the exclusion technique by using multiple patches or use of tissue sealants to aid in the septal closure.[61,62]

Percutaneous Closure

Successful transcatheter closure of postinfarction ventricular septal rupture has been reported using several types of catheter-deployed devices. Early experience was with the CardioSEAL device, a nitinol double-umbrella prosthesis. The device consists of two attached and opposing umbrellas formed by hinged steel arms covered in a Dacron meshwork that theoretically promotes endothelialization. The arms are manually everted to allow the device to be passed through a narrow percutaneous deployment system. When extruded from the guiding catheter, the arms spring backward, resembling a clamshell. The device approaches the septum via the systemic veins and through the atrial septum (or alternatively via the arterial system through the aortic valve). As reported by Landzberg and Lock,[63] the experience at Boston Children's Hospital and Brigham and Women's Hospital indicates that although the device can be routinely deployed in the setting of an acute infarction, the continued necrosis of septal tissue led to decompensation and death in four of seven patients. In contrast, they reported success in six of six patients treated for residual or recurrent septal defects discovered after primary operative repair. Other catheter devices have also been attempted, including the Amplatzer septal occluder and the Rashkind double umbrella.[64]

The recently developed Amplatzer VSD device allows closure of muscular and membranous VSDs, and it can be used for larger postinfarction defects, with the septal Amplatzer device favored for smaller lesions.[65] The device features a longer waist (10 mm) connecting the two umbrella ends, which corresponds more closely to the thickness expected for the adult ventricular septum

Results with device closure have been mixed. In a recent report involving use of these devices as a primary treatment strategy, "procedural success" was reported as 86%, but 41% of patients had important complications that included left ventricular rupture, device embolization, and major residual shunting.[66]

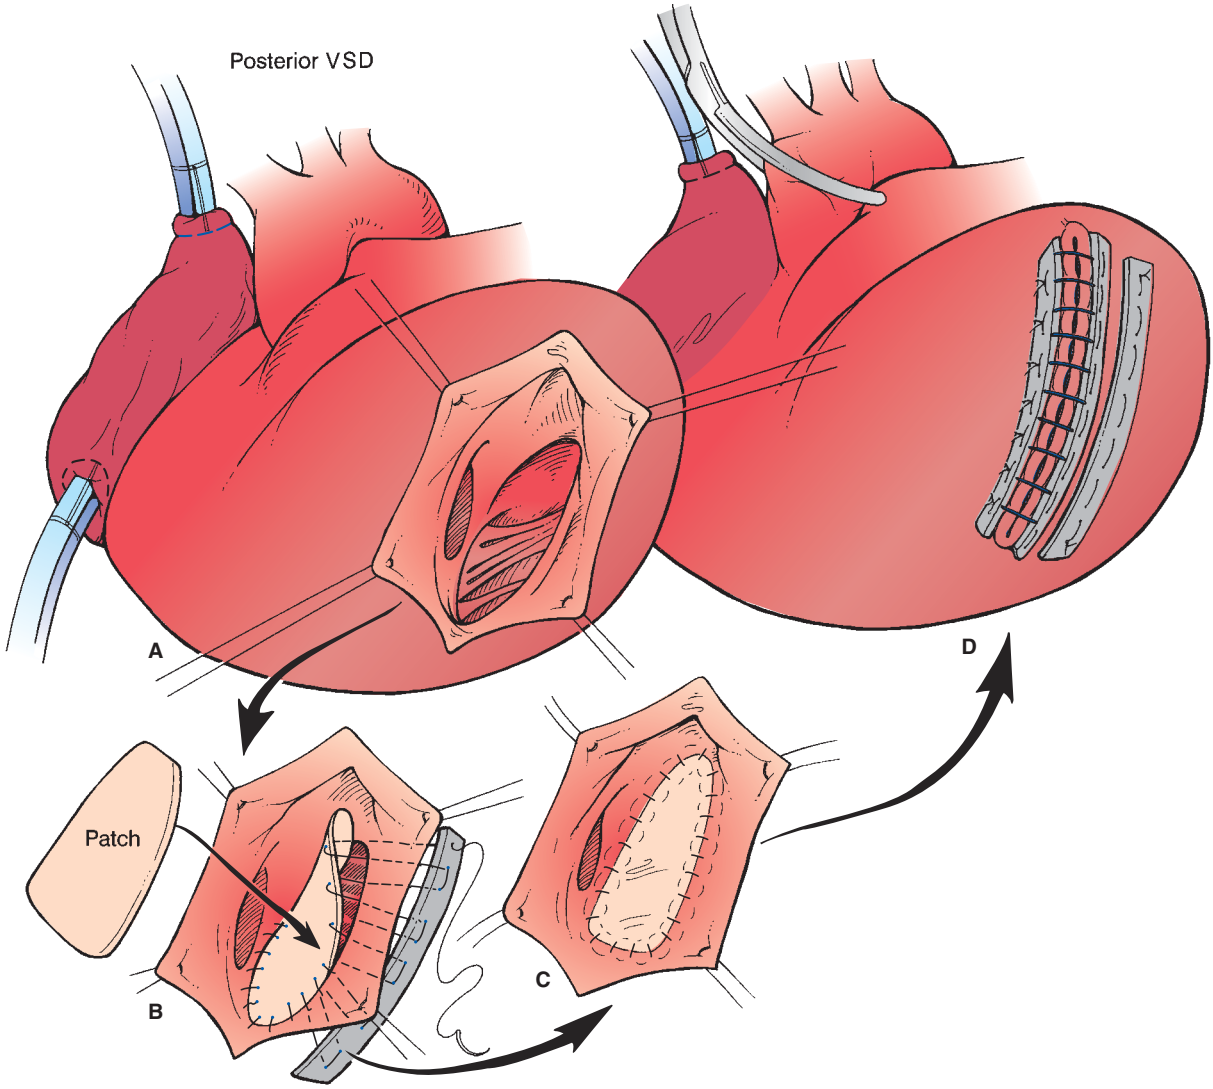

FIGURE 28-11 Endocardial repair of a posterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) An incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery starting at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. (B) A bovine pericardial patch is tailored in a triangular shape.The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached. (C) The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture.The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. At this point, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle. (D) Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall, the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt. The infarcted right ventricular wall is left undisturbed. (*Adapted with permission from David et al. 46*)

The 30-day survival rate was only 35%. Others have also reported that residual shunts are the norm, although often greatly improved by the procedure. Several series noted a poor outcome when this approach was attempted early after infarction, when the defect margins are fragile, but after about 2 weeks the results were considered acceptable.[67–69] Of course, surgical results after a delay are also considerably better, but many patients would die in the first 2 weeks without intervention.

The best use of such devices in an overall treatment strategy is unclear. As a primary treatment, data suggest that the devices have a high early failure rate, but their potential role in improving the risk of an unstable surgical patient is not yet well characterized. Currently, catheter approaches appear to be most effective in treatment of recurrent or residual defects,[70] and we preferentially employ them for these conditions. Device development is an ongoing process, and the future undoubtedly will see use of new devices, especially in the high-risk patient with multisystem failure. An additional area of use for catheter devices is to reduce shunt fraction in an attempt to stabilize a patient for a planned delayed operation. We are employing this technique

when we deem early surgery to be at extreme risk, with a planned operation either immediately if device closure is unsuccessful, or at approximately 6 to 8 weeks if stabilization is obtained.

Of interest, two centers have reported using a standard Swan-Ganz balloon catheter from the groin to abolish the shunt in unstable patients with postinfarction septal rupture.[71,72] Hemodynamic improvement was immediate in both patients, who underwent subsequent surgical repair of the defect.

Role of Ventricular Assist Devices

In patients who present for operation with evidence of potentially reversible multiorgan dysfunction, or in patients who have intractable failure after repair, there may be a role for temporary mechanical heart support. There have been multiple anecdotal cases of unstable patients being successfully managed by mechanical support followed by definitive operation.

The theoretical advantages that make mechanical support attractive as an initial therapy in very sick patients with postinfarction VSD include: (1) the potential to reverse end-organ dysfunction; (2) maturation of the infarct leading to firmer tissue, making the closure less prone to technical failure; and (3) recovery of the stunned and energy-depleted myocardium. However, there are potential hazards with mechanical support that are specific to the patient with postinfarction VSD. High right-to-left shunting across the ventricular septum has been reported to cause hypoxic brain injury in a postinfarction VSD patient placed on a Heart-Mate left ventricular support device.[107] This observation suggests that either partial left heart support or preferably biventricular support should be considered when using mechanical assistance in these patients. In a report using the Hemopump axial flow device, two of two patients supported experienced lethal pump failure. Examination of the device at autopsy disclosed necrotic material clogging the catheter system.[73a]

Simultaneous Myocardial Revascularization

There has been controversy in the literature concerning the advantages and disadvantages of concurrent coronary artery grafting in patients undergoing emergent repair of postinfarction ventricular septal rupture. The potential benefit of revascularization in a patient with significant lesions to living muscle is obvious: improved myocardial distribution, protection from postoperative ischemic, and reduced late ischemic events. However, in patients with postinfarction VSDs, there is already a completed myocardial injury and the involved territory is unlikely to benefit. For this reason, some have argued that revascularization provides no survival benefit and subjects patients to preoperative left heart catheterization, a time-consuming and potentially dangerous diagnostic procedure. Loisance and associates[73b] base their policy of not revascularizing patients with postinfarction septal ruptures on the fact that none of their 20 long-term survivors (five of whom were bypassed) had incapacitating angina or recurrent myocardial infarction.

Some groups use left heart catheterization and coronary bypassing selectively. Davies and colleagues[74] found that of 60 long-term survivors (median 70 months; range 1 to 174 months), only five patients developed exertional angina during follow-up and none required revascularization. Their current policy is to avoid left heart catheterization of patients in whom an acquired septal defect is suspected to be a consequence of their first anterior infarction, provided that the patient has no history of angina or electrocardiographic evidence of previous infarction in another territory.

Weaning from Cardiopulmonary Bypass

The two most common problems encountered in separating from bypass after repair of a postinfarction VSD are low cardiac output and bleeding. Although the treatment of low cardiac output after cardiac surgery is beyond the scope of this chapter, a few agents and principles are worth mentioning. First, most of these patients will have had an IABP inserted before surgery. If not, one should be inserted in the operating room, especially if the low-output state is secondary to LV dysfunction. Also, an IABP may benefit patients with right ventricular failure by improving right coronary artery blood flow resulting from diastolic augmentation. We have found intravenous milrinone, a phosphodiesterase inhibitor, to be very effective in reversing low-output states secondary to LV dysfunction. Milrinone possesses a balance of inotropic and vasodilatory properties that together produce an increase in cardiac output and reduction in right and left filling pressures and systemic vascular resistance. It is less arrhythmogenic than dobutamine, causes less hypotension than amrinone, and is not associated with thrombocytopenia.

Posterior defects are commonly associated with mitral regurgitation and right heart dysfunction secondary to extensive right ventricular infarction. Management of right heart failure is aimed at reducing right ventricular afterload while maintaining systemic pressure. Initial steps to manage right ventricular dysfunction include volume loading, inotropic support, and correction of acidosis, hypoxemia, and hypercarbia. If patients remain unresponsive to these measures, we have successfully treated right ventricular failure with a prostaglandin E_1 infusion (0.5 to 2.0 μg/min) into the right heart, counterbalanced with a norepinephrine infusion titrated into the left atrium.[75] Inhaled nitric oxide (20 to 80 ppm), which selectively dilates the pulmonary circuit, has also proved efficacious in the treatment of right heart failure.[76]

If a patient cannot be weaned from bypass using conventional therapy, we consider using a ventricular assist device. Indications for a left ventricular assist device are a cardiac index less than 1.8 L/min/m^2, a left atrial pressure above 18 to 25 mm Hg, a right atrial pressure below 15 mm Hg, and an aortic pressure below 90 mm Hg peak systolic. Indications for a right ventricular assist device are a cardiac index less than 1.8 L/min/m^2, an aortic pressure below 90 mm Hg peak systolic, and a left atrial pressure less than 15 mm Hg despite volume loading to a right atrial pressure of 25 mm Hg with a competent tricuspid valve. Important points to remember when instituting ventricular assistance are:

1. Right ventricular failure may not become evident until left ventricular assistance is instituted.
2. Once refractory ventricular failure has been identified, delay in initiating support is associated with increased morbidity and mortality.

3. Closure of a patent foramen ovale is mandatory before left ventricular support.
4. Postoperative hemorrhage should be treated aggressively and completely controlled.
5. Residual septal defects may result in right-to-left shunting and severe hypoxia when only left heart support is used.

Hemostatic Measures

To prevent postpump coagulopathy, we begin antifibrinolytic with ε-aminocaproic acid (Amicar) before commencing cardiopulmonary bypass. Amicar is administered by loading patients with 10 g before commencing bypass and then adding another 10 g to the pump prime. During the procedure Amicar is continuously infused at 1 g/h for the duration of surgery. Aprotinin was previously used routinely for this condition, but concerns regarding early and late complication led this drug to be withdrawn from the US market.

Postpump suture line bleeding may be reduced by application of a fibrin sealant to the ventricular septum around the septal defect *before* formal repair.[77] Biological glue may be effective in controlling bleeding suture lines after repair. As a last resort, Baldwin and Cooley[78] have suggested insertion of a left ventricular assist device solely as an adjunct to the repair of friable or damaged myocardium to reduce left ventricular distention and thus control bleeding. Finally, for intractable bleeding, there may be role for Factor VII concentrate, although results and risks of administration in cardiac surgery are limited.

Highlights of Postoperative Care

Early postoperative diuresis and positive end-expiratory pressure ventilation are used to decrease the alveolar-arterial gradient induced by the increased extravascular pulmonary water associated with cardiopulmonary bypass. Once the patient has warmed, we commonly use an intravenous infusion of furosemide combined with mannitol or, if needed, continuous venovenous hemofiltration is employed postoperatively.

Intractable postoperative ventricular arrhythmias secondary to reperfusion injury are sometimes difficult to control using standard therapy. We have been impressed with the efficacy of intravenous amiodarone in these situations (10 to 20 mg/kg over 24 hours).

Operative Mortality and Risk Factors for Death

Table 28-2 summarizes recently reported experience from several centers. Operative mortality, defined as death before discharge *or* within 30 days of operation, ranged from 30 to 50%. In the Massachusetts General Hospital experience of 114 patients, operative mortality was 37% (Fig. 28-12A). The risk for death

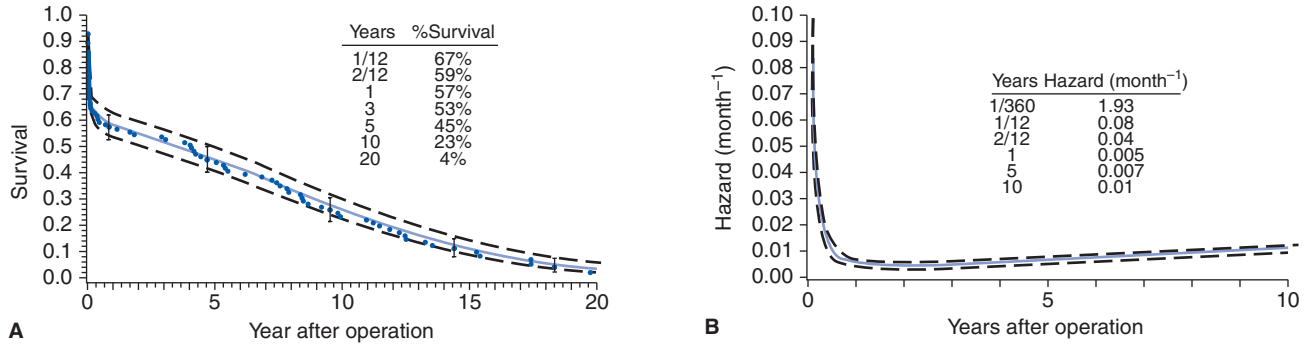

FIGURE 28-12 (A) Time-related survival after repair of postinfarction ventricular septal defect at the Massachusetts General Hospital (n = 114). Note that the horizontal axis extends to 20 years. Circles represent each death, positioned on the horizontal axis at the interval from operation to death, and actuarially (Kaplan-Meier method) along the vertical axis. The vertical bars represent 70% confidence limits (± 1 SD). The solid line represents the parametrically estimated freedom from death, and the dashed lines enclose the 70% confidence limits of that estimate. The table shows the nonparametric estimates at specified intervals. (B) Hazard function for death after repair of postinfarction ventricular septal defect (n = 114). The horizontal axis is expanded for better visualization of early risk. The hazard function has two phases, consisting of an early, rapidly declining phase, which gives way to a slowly rising phase at about 6 months.The estimate is shown with 70% confidence limits.

was found to be very high initially, but dropped rapidly (see Fig. 28-12B). We identified independent risk factors for early and late death using multivariate methods (Table 28-3). The most important predictor of operative mortality in our study, and in other reports, was preoperative hemodynamic instability. Patients in this group are usually in cardiogenic shock, are emergency cases, are on inotropic support, and usually have intraaortic balloon pumps. Several variables are highly correlated with hemodynamic instability, and different multivariate models may use one or more of these indicators of severe hemodynamic failure in their final model.

Additional risk factors for early and late death include the presence of left main CAD, previous MI, renal dysfunction, and right heart failure (Fig. 28-13). Other factors have been found to increase the risk of early death. Posterior location of the septal rupture has been associated with an increased operative mortality.[22,23,29,31] This has been attributed to a more technically difficult repair, the increased risk of associated mitral regurgitation, and associated right ventricular dysfunction that is an independent predictor of early mortality after posterior infarction. A short time interval between infarction and operation selects for sicker patients unable to be managed medically. Older patient age has also been associated with an increased early mortality, but in our analysis, we found that the impact of age was more pronounced in the high-risk patient. Thus, age alone should not be used as a reason for denying surgery in an otherwise low-risk candidate (Fig. 28-14).

Our review of the Massachusetts General Hospital experience underscored the large variability of risk to which

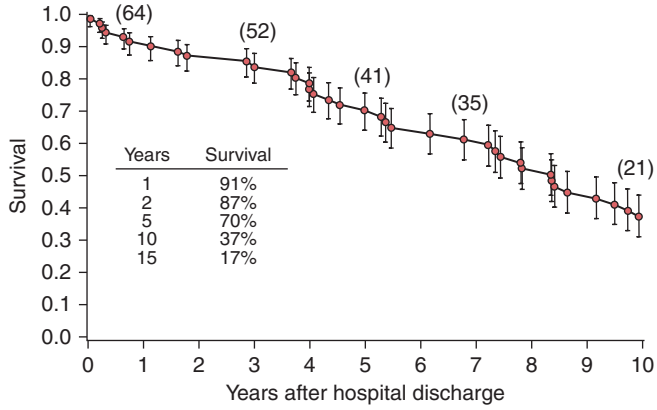

FIGURE 28-13 Survival in patients who were discharged after repair of postinfarction ventricular septal defect (Massachusetts General Hospital, n = 72). The horizontal axis is expanded and represents the time from hospital discharge to death. The depiction is otherwise similar to that seen in Fig. 28-12A.

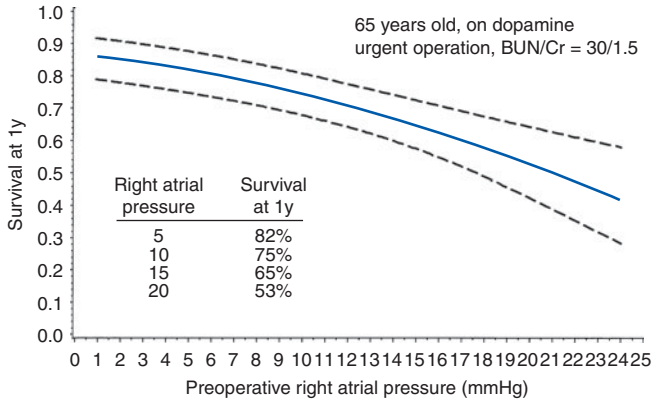

FIGURE 28-14 Survival at 1 year vs. preoperative right atrial pressure (Massachusetts General Hospital; n = 114). The depiction is a solution of the multivariate equation for a 65-year-old with a blood urea nitrogen of 30 mg/dL, a creatinine of 1.5 mg/dL, not on catecholamines, not an "emergency" case, and without a history of myocardial infarction or left main coronary artery disease.

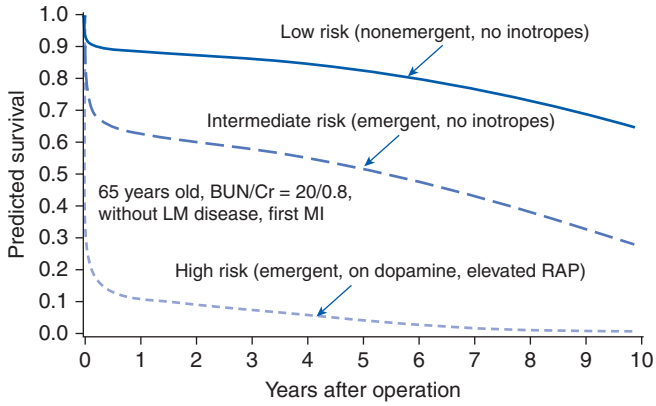

FIGURE 28-16 Nomograms (specific solutions of the multivariate equation) depicting the predicted survival in three hypothetical 65-year-old patients who present with ventricular septal defect. Each solution is for a patient who has no history of myocardial infarction and without left main coronary artery disease,blood urea nitrogen of 20 mg/dL, and creatinine of 0.8 mg/dL. The "low-risk" patient is nonemergent and not on inotropes with right atrial pressure (RAP) of 8 mm Hg. The "intermediaterisk" patient is emergent and not on inotropes with RAP of 12 mm Hg. The "high-risk"patient is emergent and on inotropes with RAP of 20 mm Hg. Confidence limits have been eliminated to improve clarity.

patients could be segregated using a few clinical variables (Figs. 28-15 and 28-16), most notably indicators of hemodynamic instability (emergency surgery and use of inotropes). The result was that a small group of high-risk patients dramatically affected the overall mortality rate. We believe that this phenomenon makes it very difficult to compare mortality among institutions. A slight difference in practice patterns, such as a tendency of a surgeon or referring cardiologist to deny operation, could substantially affect results. Additionally, any difference in transport dynamics to certain centers could lead to loss of unstable patients, which could create another type of selection bias. In our opinion, these issues are by far the most important source of mortality differences in modern series.

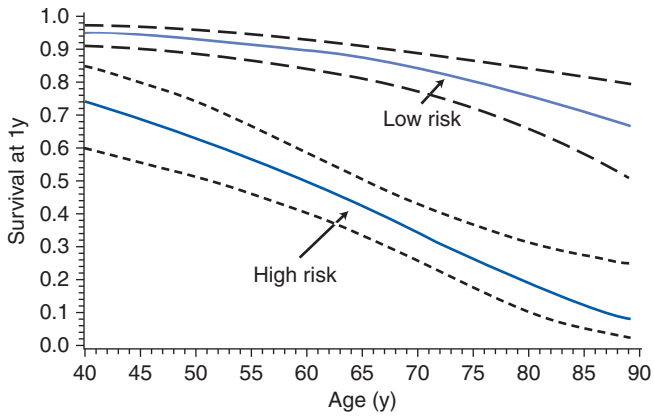

FIGURE 28-15 Nomograms (specific solutions to the multivariate equation) depicting the effect of age on risk in two different hypothetical patients. In both curves the patient was considered to have no left main disease, a blood urea nitrogen of 30 mg/dL, creatinine of 1.5 mg/dL, and no history of previous myocardial infarction. The curve for "low-risk" was solved for a patient who was not emergent and not on catecholamines.The curve for "high-risk"was for an emergent patient on inotropes. The vertical axis represents the calculated survival at 1 year.

Several centers have reported improved early results with an "exclusion" repair.[87,95] Our group has not been able to replicate these results, with a 60% mortality in 10 patients (higher than the rate achieved historically with traditional techniques). This is likely to the result of our tendency to use this technique on the most challenging type of defects in whom we anticipate a long and complex repair, and continued use of infarctectomy in the lower risk patients with anterior or apical defects.

Regardless of the technique, the most common cause of death after repair of acute postinfarction VSD was low cardiac output syndrome (52%). Technical failures, most commonly recurrent or residual VSD, but including bleeding, were the second most common (23%). Other causes of death include sepsis (17%), recurrent infarction (9%), cerebrovascular complications (4%), and intractable ventricular arrhythmias.

Long-Term Results

Long-term results have been favorable with regard to both mortality risk and functional rehabilitation. Actuarial survival at 5 years for most recent series generally ranges between 40 and 60% (see Table 28-2). Because of the overall high risk of the operation, it is rewarding to note that hospital survivors enjoy excellent longevity, with 1-, 5-, and 10-year survival of 91, 70, and 37%, respectively. They also are quite functional—among 15 of our patients contacted during follow-up of long-term survivors, 75% were in New York Heart Association functional class I, and 12.5% were class II.[18]

Recurrent Ventricular Septal Defects

Recurrent or residual septal defects have been diagnosed by Doppler color flow mapping early or late postoperatively in 10 to 25% of patients.[96] They may be caused by reopening of a closed defect, to the presence of an overlooked defect, or to the development of a new septal rupture during the early postoperative period. These recurrent defects should be closed when they cause symptoms or signs of heart failure or when the calculated shunt fraction (pulmonary-to-systemic flow ratio) is large (Qp:Qs >2.0). When they are small (Qp:Qs <2.0) and either asymptomatic or controlled with minimal diuretic therapy, a conservative approach is reasonable and late spontaneous closure can occur. Intervention in the catheterization laboratory may be useful in closing symptomatic residual or recurrent defects postoperatively.

Chronic Ventricular Septal Defects

In 1987 Rousou and associates reported successful closure of an acquired posterior VSD by means of a right transatrial approach.[97] Filgueira and colleagues have used the transatrial approach for *delayed* repair of chronic acquired posterior septal defects.[98] Approaching a postinfarction VSD through the tricuspid valve should not be used in acute cases because of the friability of the necrotic septum, poor exposure, and because this technique does not involve infarctectomy, and thus cannot achieve the hemodynamic advantages of elimination of a paradoxically bulging segment of ventricular wall. However, the right heart approach can be used in chronic postinfarction VSD when the septum is well scarred and the patch can be safely sutured to it from the right atrium. We emphasize that although the transatrial approach may be used selectively for the closure of chronic defects, it is unlikely to be an appropriate choice for the closure of acute defects, except perhaps in the rare circumstance when an infarct is localized to the septum with no evidence of necrosis of the free wall of the left ventricle.[25]

POSTINFARCTION VENTRICULAR FREE WALL RUPTURE

History

William Harvey first described rupture of the free wall of the heart after AMI in 1647.[99] In 1765, Morgagni reported 11 cases of myocardial rupture found postmortem.[100] Ironically, Morgagni later died of myocardial rupture.[101] Hatcher and colleagues from Emory University reported the first successful operation for free wall rupture of the right ventricle in 1970.[101] FitzGibbon and associates[102] in 1971 and Montegut[103] in 1972 reported the first successful repairs of left ventricular ruptures associated with ischemic heart disease.

Incidence

Autopsy studies reveal that ventricular free wall rupture occurs about 10 times more frequently than postinfarction ventricular septal rupture, occurring in about 11% of patients after AMI.[104] The incidence has been found to be as high as 31% in autopsy studies of anterior MI.[105] Ventricular rupture and cardiogenic shock are now the leading causes of death after AMI, and together account for greater than two-thirds of early deaths in patients suffering their first acute infarction. Postinfarction ventricular ruptures are more common in elderly women (mean age of 63 years) suffering their first infarction.[106] In the prethrombolytic era, 90% of ruptures occurred within 2 weeks after infarction with the peak incidence at 5 days.[107] In contrast, the time to cardiac rupture (not frequency of rupture) seems to be accelerated by thrombolysis and coronary reperfusion, sometimes occurring within hours from the onset of symptoms.[108]

Opinions differ as to the most common site of left ventricular rupture. The older literature suggests that the anterior wall is the most frequent site; however, more recent series have observed a preponderance of lateral and posterior wall ruptures.[104,105] Lateral wall infarction may be more likely to rupture than an anterior or inferior injury, but because anterior infarctions are much more frequent than lateral infarctions, overall the most common site of rupture is the anterior wall. Like postinfarction ventricular septal rupture, free wall ruptures may be simple or complex. A simple rupture results from a straight through-and-through tear that is perpendicular to the endothelial and epicardial surfaces, whereas a complex rupture results from a more serpiginous tear, often oblique to the endocardial and epicardial surfaces. Batts and coworkers[107] reported 100 consecutive cases of left ventricular free wall rupture and found that half were simple ruptures and the rest were complex.

Pathogenesis and Pathophysiology

Left ventricular free wall rupture can be divided into three clinicopathologic categories: acute, subacute, and chronic. An *acute* or "blow-out" rupture is characterized by sudden recurrent chest pain, electrical mechanical dissociation, profound shock, and death within a few minutes because of massive hemorrhage into the pericardial cavity. This type of rupture is probably not amenable to current management. A *subacute* rupture is characterized by a smaller tear, which may be temporarily sealed by clot or fibrinous pericardial adhesions. These usually present with the signs and symptoms of cardiac tamponade, and eventually cardiogenic shock. Subacute rupture may mimic other complications of AMI, such as infarct extension and right ventricular failure, and may be compatible with life for several hours or days or even longer.[109] A *chronic* rupture with *false aneurysm* formation occurs when the leakage of blood is slow and when surrounding pressure on the epicardium temporarily controls the hemorrhage. Adhesions form between the epicardium and pericardium, which reinforce and contain the rupture. The most common clinical presentation of patients with false aneurysms of the left ventricle is CHF.[110] A false aneurysm may also be an echocardiographic finding in an otherwise asymptomatic patient recovering from AMI. Angina, syncope, arrhythmias, and thromboembolic complications occur in a small percentage of patients. There are four major differences between a true and false aneurysm of the left ventricle:

1. The wall of a false aneurysm contains no myocardial cells.
2. False aneurysms are more likely to form posteriorly.
3. False aneurysms usually have a narrow neck.
4. False aneurysms have a great propensity for rupture.

Rupture of the free wall of the left ventricle may occur in isolation or with rupture of other ventricular structures such as the interventricular septum, papillary muscles, or right ventricle.[110,111]

The pathogenesis of cardiac rupture remains poorly understood. However, cardiac rupture occurs only with transmural MIs and infarction expansion appears to play an important role in its pathogenesis.[24,27,112] Infarct expansion is an acute regional thinning and dilatation of the infarct zone, seen as early as 24 hours after acute transmural MI and not related to additional myocardial necrosis.[113] This regional thinning and dilatation of the infarct zone is a consequence of slippage between muscle bundles, resulting in a reduction in the number of myocytes across the infarcted area. Infarct expansion increases the size of the ventricular cavity, with a consequent increase in wall tension (Laplace effect) that subjects the infarct zone to more tension and predisposes to endocardial tearing.[109] Systemic hypertension aggravates the problem of thinning and dilatation of the infarct wall and increases the probability of rupture.[114] Lack of collateral flow may also promote ventricular rupture.[115]

Because myocardial rupture occurs in regions of complete transmural myocardial necrosis, usually after extensive hemorrhagic transformation of the acute infarct, and because thrombolytic therapy is associated with the conversion of a bland infarct into a hemorrhagic infarct, there has been an ongoing concern that thrombolysis might increase the likelihood of ventricular rupture.[117] Honan and associates[116] performed a meta-analysis of four large clinical trials (1638 patients) in which streptokinase was used to treat AMIs and concluded that the risk of cardiac rupture was directly related to the timing of thrombolytic therapy. Early treatment (within 7 hours from the onset of symptoms) decreased the risk of cardiac rupture, whereas late treatment (after 17 hours) increased the risk of this complication even though, surprisingly, the overall mortality rate was diminished when streptokinase was given late after acute infarction. In a prospective ancillary study of 5711 patients, Late Assessment of Thrombolytic Efficacy, Becker and colleagues[108] were unable to show an increased risk of cardiac rupture in patients treated with recombinant tissue plasminogen activator 6 to 24 hours after the onset of symptoms. Thus, there is general agreement that early successful thrombolysis decreases the overall risk of cardiac rupture, probably by limiting the extent of necrosis, resulting in a nontransmural instead of transmural infarct, but the impact of late thrombolytic therapy on cardiac rupture remains unclear.

Diagnosis

The clinical picture of a subacute ventricular rupture is primarily that of pericardial tamponade, with pulsus paradoxus, distended neck veins, and cardiogenic shock. Although 5 to 37% of patients with AMI but no rupture may develop a pericardial effusion, echocardiographic signs that increase the sensitivity and specificity for cardiac rupture include effusion thickness greater than 10 mm, echodense masses in the effusion, ventricular wall defects, and signs of tamponade (eg, right atrial and right ventricular early diastolic collapse and increased respiratory variation in transvalvular blood flow velocities).[118,119] Pericardiocentesis and aspiration of uncoagulated blood have historically been considered the most reliable criteria of subacute ventricular rupture; however, false-positive and -negative diagnoses have been reported. The demonstration of a clear pericardial fluid on pericardiocentesis definitively excludes cardiac rupture.[118] Pericardiocentesis is of therapeutic value in some patients, often providing short-term circulatory improvement.

In an attempt to define symptomatic, electrocardiographic, and hemodynamic markers that may permit the prospective identification of patients prone to rupture of the heart after AMI, Oliva and colleagues[104] retrospectively studied 70 consecutive patients with rupture and 100 comparison patients with AMI but without rupture. They found a number of markers that were associated with a significant increase in the risk of rupture (Table 28-4). The presence of a lateral infarction,

TABLE 28-4 Sensitivity, Specificity and Predictive Value of Symptoms and Electrocardiographic Criteria for Cardiac Rupture

	Sensitivity (%)	Specificity (%)	Predictive value (%)
Pericarditis	86	72	68
Repetitive emesis	64	95	90
Restlessness, agitation	55	95	86
Two or more symptoms	84	97	95
ST segment deviations	61	72	58
T wave deviations	94	66	66
ST-T wave deviations	61	68	64

From Oliva PB, Hammill SC, Edwards WD: Cardiac rupture, a clinically predictable complication of acute myocardial infarction: report of 70 cases with clinicopathologic correlations. J Am Coll Cardiol 1993; 22:720.

especially with associated inferior or posterior infarction, identified a subset of patients at increased risk for rupture. Persistent, progressive, or recurrent ST-segment elevation, and especially persistent T-wave changes after 48 to 72 hours, or the gradual reversal of initially inverted T waves, are associated with an increased risk of rupture. Finally, the development of pericarditis, repetitive emesis, or restlessness and agitation, particularly two or three of these symptoms, conveyed predictive value.[105]

Natural History

Acute rupture of the free wall of the left ventricle is invariably fatal, with death usually occurring within minutes of the onset of recurrent chest pain.[107,109] In most of these cases, the sequence of events leading to death is so rapid that there is not enough time for surgical intervention. In contrast, patients with a subacute rupture usually survive hours or days, rarely weeks, following the myocardial tear. Pollack and colleagues[119] found that in 24 patients with postinfarction subacute rupture, survival time (ie, time from critical event to death) varied between 45 minutes and 6.5 weeks, with a median survival of 8 hours. Núñez and coworkers[120] found that in 29 patients with subacute rupture, 20 (69%) died within minutes of the onset of symptoms, and 9 (31%) lived several hours, allowing time for treatment. Subacute ventricular ruptures are generally considered to be less common than acute free wall ruptures. In recent studies, with high autopsy rates, 21 to 42% of all postinfarction free wall ruptures followed a subacute course.[119,121,122]

Because of its rarity, the natural history of false aneurysm of the left ventricle has not been well established. It is believed to have a poor prognosis because of its high probability of rupture;[122,123] however, there are patients in whom the diagnosis was made many years after MI.[124,125] The increasingly wide application of echocardiography after AMI gives promise of altering clinical outcome for many patients with the various forms of ventricular wall rupture.

Preoperative Management

Usually the sequence of events leading to death is so rapid in patients with acute rupture of the free wall of the left ventricle that there is not enough time for surgical intervention. These patients typically die within minutes of the onset of recurrent chest pain.[120] However, a high index of suspicion, emergent surgery, perhaps combined with a novel technique of percutaneous intrapericardial infusion of fibrin glue immediately after pericardiocentesis,[126] may afford at least a chance of survival in this surgically untreatable subgroup of patients.

In contrast, patients with subacute left ventricular rupture can be saved with surgery. Once the diagnosis of rupture of the free wall is established, the patient should be immediately transferred to the operating room. No time should be wasted attempting to perform coronary angiography.[108,110,125] Inotropic agents and fluids should be started while preparing for surgery. Pericardiocentesis often improves hemodynamics temporarily, and insertion of an intra-aortic balloon pump may be beneficial, even though the principal problem is cardiac tamponade.

The timing of surgery after the diagnosis of false aneurysm of the left ventricle is dependent upon the age of the MI. When a false aneurysm is discovered within the first 2 to 3 months after coronary infarction, surgery is urgently recommended after coronary angiography and ventriculography because of the unpredictability of rupture.[111,127] However, when the diagnosis is made several months or years after MI, the urgency of the operation is not determined so much by the risk of rupture, but rather by symptoms and the severity of the CAD.[109,124]

Operative Techniques

Subacute Rupture of the Free Wall

As soon as the diagnosis of rupture of the free wall of the left ventricle is confirmed by echocardiography, the patient should be transferred to the operating room. In patients with tamponade, severe hypotension may result during the induction of anesthesia. Therefore, we usually complete the sterile preparation and draping of the patient before inducing anesthesia, with preparations for rapid cannulation of the groin if needed. A median sternotomy is performed and upon decompressing the pericardium, the blood pressure commonly rises quickly. This should be anticipated and controlled because hypertension can cause ventricular bleeding to start again, or may even increase the size of the ventricular rent. In most cases, however, the ventricular tear is sealed off by clot, and there is no active bleeding.

Traditionally postinfarction rupture of the free wall of the left heart has been repaired on cardiopulmonary bypass; however, some surgeons have suggested that cardiopulmonary bypass is not necessary except perhaps in patients with posterior wall rupture, severe mitral regurgitation, ventricular septal rupture, or graftable CAD.[109,127] Although the ventricular tear can be repaired without aortic cross-clamping, cardiac standstill and left ventricular decompression make the procedure easier when the rupture is in the posterior wall of the left ventricle.[109]

The term *ventricular double rupture* has been applied when there is rupture of two of the following three structures: the ventricular septum, ventricular free wall, and papillary muscle.

Four surgical techniques have been used to control ventricular rupture. The first technique involves closing the rent with large horizontal mattress sutures buttressed with two strips of Teflon felt.[101] This method is not recommended because the sutures are placed into necrotic, friable myocardium that can easily tear. The second method combines infarct excision and closure of the defect with interrupted, pledgeted sutures[102,128] or a Dacron patch.[129] This method usually requires aortic cross-clamping and is probably best reserved for those patients who have an associated VSD. The third technique, described by Núñez and colleagues,[120] involves closing the defect with horizontal mattress sutures buttressed with two strips of Teflon felt, and then covering the closed ventricular tear and surrounding infarcted myocardium with a Teflon patch sutured to healthy epicardium with a continuous polypropylene suture (Fig. 28-17). Good control of active ventricular hemorrhage has been achieved with this method. The fourth method consists of simply gluing a patch of either Teflon[127] or autologous glutaraldehyde-preserved bovine pericardium to the ventricular tear and infarcted area

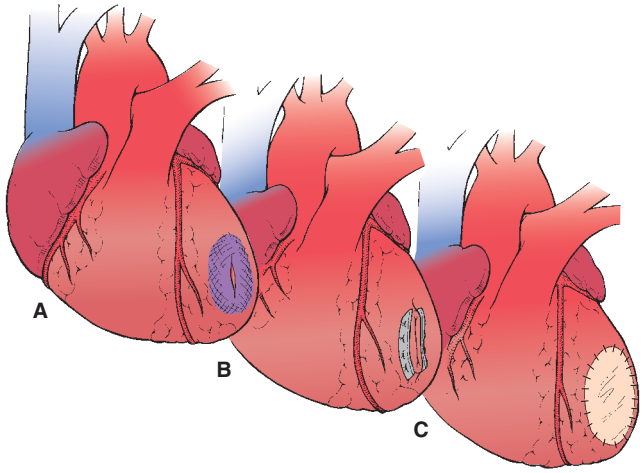

FIGURE 28-17 Technique to repair rupture of the free wall of the left ventricle. (A) Left ventricular free wall rupture. (B) A limited infarctectomy is closed with horizontal mattress sutures buttressed with two strips of Teflon felt. (C) Then the whole area is covered with a Teflon patch sutured to healthy epicardium with a continuous polypropylene suture. Alternatively, the Teflon patch can be glued to the ventricular tear and the infarcted area using a biocompatible glue. (*Adapted with permission from David.*[138])

using a biocompatible glue of either fibrin (Tissucol, Immuno AG, Vienna, Austria), butyl-2-cyanoacrylate monomer (Histoacryl Blue, B. Braun, Melsungen AG, Germany), or gelatin-resorcin-formaldehyde (Pharmacie Centrale, C.H.V. Henry Mondor, Créteil, France). This technique does not necessarily require institution of cardiopulmonary bypass and, because of its simplicity, may be the repair of choice when the ventricle is not actively bleeding.

False Aneurysm of the Left Ventricle

Acute false aneurysms are probably best repaired with an endocardial patch using the same methods as those used in repairing true ventricular aneurysms.[109] Chronic anterior false aneurysms can usually be closed primarily if the neck is fibrotic. However, primary closure of the neck of a posterior false aneurysm may exacerbate mitral regurgitation, and it therefore probably should be reconstructed with a patch of Dacron graft or glutaraldehyde-fixed bovine pericardium.[110,111]

Results

Subacute Rupture of the Free Wall

The surgical experience with this entity is largely anecdotal. The single largest experience with surgical repair of postinfarction left ventricular free wall rupture was reported by Padró and colleagues.[127] They treated 13 patients using a Teflon patch glued onto the ventricular tear and surrounding infarcted muscle, and used cardiopulmonary bypass in only one patient who presented with a posterior defect. All of their patients survived and were alive after a mean follow-up of 26 months. Eleven of them were asymptomatic and two had exertional angina. Núñez and associates[120] operated on seven patients, four of whom survived. Recently the use of unsupported felt secured with cyanoacrylate glue has been described by several authors with encouraging results.[130,131]

In ventricular double rupture involving the free wall and the septum, a recent series achieved an operative survival of 60% in five patients.[132] Four of the patients initially had only septal rupture but progressed to include free wall rupture, making this diagnosis a consideration in acute deterioration of medically managed patients with postinfarct VSD.

Although operative risk cannot be determined from these small numbers, it is likely that without surgery all these patients would have died, and patients who survive surgery tend to do well afterward.[109]

False Aneurysm of the Left Ventricle

Komeda and David[110] treated 12 patients with postinfarction left ventricular false aneurysms; four of them also had mitral valve replacements, one had repair of a fistula between the false aneurysm and the right ventricle, and nine had coronary artery bypass surgery. There were three operative deaths, all in patients who needed mitral valve replacements. Of the eight patients who underwent isolated repair of false aneurysms, all were alive after a mean follow-up of 62 months. Seven patients were asymptomatic and one had angina pectoris. Overall, the literature suggests that patients who have isolated repair of false aneurysms of the left ventricle have low operative mortality.

CHAPTER 29

Ischemic Mitral Regurgitation

Pavan Atluri
Robert C. Gorman
Joseph H. Gorman III
Michael A. Acker

INTRODUCTION

Ischemic mitral regurgitation (IMR), often termed *functional* mitral regurgitation, is mitral insufficiency as a result of myocardial ischemia or infarction. By definition, the mitral valve leaflets are structurally normal in IMR. The malcoaptation of the leaflets and resultant regurgitation of the mitral valve in IMR is a result of either acute papillary muscle dysfunction or rupture, or chronic changes with left ventricular remodeling and subsequent changes in geometry.

Ischemic mitral regurgitation (IMR) is associated with decreased quality of life and long-term survival. Although extensive mechanistic research has been conducted, the optimal management of IMR remains elusive. Clinical studies in the past often included MR of multiple etiologies, including degenerative or nonischemic origin and IMR grouped into the same category, leading to confusion and incorrect conclusions regarding the natural history and true long-term impact of IMR. It is important to distinguish IMR from mitral regurgitation resulting from nonischemic etiologies. Mitral regurgitation is often associated with coronary artery disease without a direct cause-and-effect relationship. Given the prevalence of coronary artery disease, the association of myocardial infarction and nonischemic mitral regurgitation is a common clinical association. IMR must be distinguished from mitral insufficiency caused by degenerative, rheumatic, congenital, and infectious etiologies, as well as that arising from idiopathic dilated cardiomyopathy. Our recognition of IMR as a distinct clinical entity has improved the understanding of the pathophysiology and natural history of this distinct disease process.

IMR can produce a variety of very variable clinical presentations depending on infarct characteristics and subsequent postinfarction ventricular remodeling. The size, location, and transmurality of the myocardial infarction (MI) sets in motion varying degrees of left ventricular remodeling that subsequently determine the severity, time course, and clinical manifestations of IMR. The presentation may be either acute and immediately life threatening, or develop insidiously over time in association with congestive heart failure (CHF).

PREVALENCE

The advancement in catheter-based intervention for coronary artery disease and medical therapy has resulted in dramatically improved survival from ischemic heart disease and acute myocardial infarctions (AMI). Although survival following an AMI has improved, there has been a subsequent increase in the incidence of congestive heart failure. The American Heart Association estimates that 5.7 million Americans were in various stages of congestive heart failure in 2006.[1] An increasing number of ischemic cardiomyopathy patients will develop left ventricular dysfunction and IMR as a result of annular dilatation and/or papillary muscle displacement.

Early after an acute myocardial infarction (AMI), between 11 and 55% of patients develop clinical (mitral systolic murmur), echocardiographic, or angiographic evidence of IMR. A recent echocardiographic study investigating the incidence of mechanical complications after acute myocardial infarction found a significantly reduced incidence of mitral regurgitation in the percutaneous coronary intervention (PCI) era, but still noted a very large incidence of post-MI acute ischemic MR, 28 versus 53%.[2] Many of the murmurs early after acute myocardial infarction are transient and disappear by the time of discharge

without further intervention, implying a correction of acute MR without intervention.

In one study, 19% of 11,748 patients who had elective cardiac catheterization for symptomatic coronary artery disease (CAD) had ventriculographic evidence of mitral regurgitation (MR).[3] In most of these patients the degree of mitral insufficiency was mild, but in 7.2% the degree of regurgitation was 2+ or greater, and in 3.4% MR was severe with evidence of heart failure.[3] In another study of consecutive cardiac catheterizations, 10.9% of 1739 patients with CAD had MR.[4]

Collectively, these data indicate that IMR is frequent early after AMI, but in many patients it is mild or disappears completely. The relatively high incidence of IMR in catheterized patients with symptomatic CAD suggests that chronic IMR persists in many patients after acute infarction and/or may subsequently develop in others. Approximately 16.8 million Americans have CAD, 7.9 million have had at least one myocardial infarction, 9.8 million suffer from angina, and millions more have asymptomatic coronary atherosclerosis that remains to be diagnosed.[1] Using these figures, the incidence of IMR in the United States is estimated to be 1.2 to 2.1 million patients, with approximately 425,000 patients having moderate or severe IMR with heart failure.[3,5]

CLASSIFICATION

IMR has traditionally been classified based on the time course of clinical presentation. Acute IMR occurs in the immediate postinfarction period, and the patients are often in hemodynamic distress. Fortunately, this population of patients represents a minority of the IMR cohort. Chronic IMR represents the clinical presentation for the majority of patients with IMR. The chronic presentation is one of progressive and insidious nature and is often associated with decremental decrease in left ventricular function.

In his landmark American Association for Thoracic Surgery–invited distiguinshed lecture and corresponding 1983 paper, *Cardiac Valve Surgery: The French Correction,* Dr. Carpentier provided an insightful way to mechanistically approach MR, including IMR. This classification scheme categorizes the improper leaflet coaptation of mitral regurgitation into three subsets based on leaflet and chordal pathology. In type I dysfuction, leaflet motion is normal and mitral regurgitation results from mitral annular dilatation. Type II is mitral regurgitation as a result of leaflet prolapse or excessive motion. In type III dysfunction, there is leaflet restriction or tethering, and is further subclassified into "a" (tethering during diastole) and "b" (tethering during systole and diastole).

IMR can result from type I, II, or IIIb dysfunction. Acute postinfarct mitral regurgitation can be a result of type II dysfunction, in which there is papillary muscle rupture. However, acute IMR is more often associated with much more subtle changes in the mitral valve apparatus. Chronic IMR classically presents as either type I or IIIb dysfunction. Pure annular dilatation with normal leaflets (type I) results from left ventricular remodeling and its geometric sequalae on the mitral valve apparatus. Type IIIb is the more common dysfunction associated with chronic IMR, and is the result of papillary muscle displacement and subsequent tethering of leaflets that results from ventricular dilatation and remodeling that occurs with ischemic cardiomyopathy. Often, a combination of type I and IIIb dysfunctions are seen in patients with chronic IMR and cardiomyopathy.

PATHOPHYSIOLOGY

Normal Valve Function

The mitral valve has six anatomical components: leaflets, chordae tendineae, annulus, papillary muscles, left ventricle (LV), and left atrium. The mitral annulus is saddle-shaped (hyperbolic paraboloid with two-directional curvature) with cephalad promontories near the mid portions of the anterior and posterior leaflets and caudad depressions at the commissures (Fig. 29-1).[6] This unique shape, which is present in all mammalian mitral valves, has been shown, using finite element analysis, to reduce leaflet, annular, and chordal stress.[7] Function of the normal mitral valve is complex and involves precisely timed interactions among the six components. These interactions are most easily described by relating the changes in each of the six components during a cardiac cycle. For this description the cardiac cycle is divided into four periods: systole, diastole, isovolumetric relaxation (IVR), and isovolumetric contraction (IVC), as defined in the following.

End systole (ES) is defined as the maximum negative left ventricular dP/dt and end diastole (ED) is defined as the peak of the QRS complex. End isovolumetric contraction (EIVC) is defined as the first time point at which the aortic root dP/dt is greater than zero. End isovolumetric relaxation (EIVR) is defined as the time at which the LVP is 10% of LVP_{max} and the left ventricular dP/dt less than 0.

During isovolumetric contraction (IVC), left atrial filling begins immediately after the mitral valve closes and before the

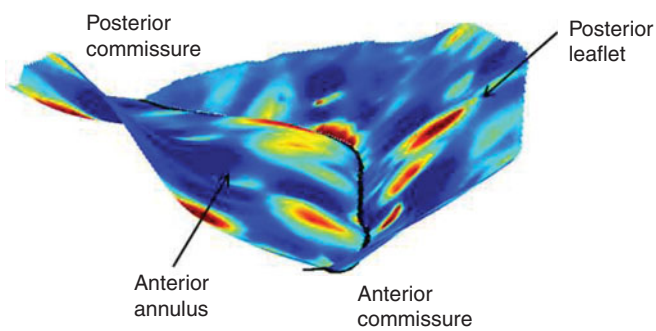

FIGURE 29-1 A rendering of a normal human mitral valve using an image analysis algorithm recently developed at the University of Pennsylvania. The technique uses real-time 3D echocardiography to assess mitral annular geometry and leaflet curvature. The pseudocolor map in the figure depicts regional Gaussian curvature in the anterior and posterior mitral leaflets. Deeper blue colors represent more negative Gaussian curvature, which is indicative of a hyperbolic (saddle-shaped) curvature and reduced leaflet stress.

aortic valve opens. Flow through the mitral valve briefly reverses as the leaflets coapt and bulge toward the atrium.

During systole the left atrium rapidly fills and reaches maximum volume near ES. The position of the annulus ascends (away from the apex) slightly during atrial contraction, which occurs during late diastole, does not change during IVC, and descends progressively 1 to 1.5 cm toward the apex throughout systole. The annulus asymmetrically contracts during atrial and ventricular systole and in humans reaches a minimal area (mean reduction of 27%) in mid systole.[8–10] Immediately after atrial contraction, the mitral leaflets approach each other and close within 20 to 60 milliseconds after pressure crossover when LV pressure exceeds LA pressure. Because the total area of leaflet tissue is approximately twice the total area of the annulus, the apposition point of the two leaflets at the time of pressure crossover is very near the plane of the annulus. At closure, approximately 30% of the anterior cusp and 50% of the longer posterior cusp are in apposition. Chordae tendineae attached to the free edges and body of the leaflets restrict the upward movement of the slightly compliant leaflets and produce a tight seal along the line of apposition. Chordal tension peaks in early systole and begins to fall slowly in late systole and rapidly during IVR. Papillary muscles begin to shorten during late IVC and throughout systole in synchrony with shortening of the adjacent ventricular wall. The actual distance the papillary muscles shorten is small and ranges between 2 and 4 mm.[11,12] During systole, the directions and timing of left ventricular contraction are not necessarily uniform throughout because of the complex anatomical arrangement of muscle bundles and the timing produced by the impulse conduction pattern.[13] LV shortening is greater in both equatorial axes than in the long axis.[13] LV wall thickness increases during IVC and decreases rapidly during IVR.[14] Peak wall thickness occurs near ES, but timing of the exact peak varies slightly between ventricular wall segments. During systole the ventricle progressively twists counterclockwise (as viewed from the apex) along its longitudinal axis to reach a maximum at ES.[15]

During IVR the left atrium begins to empty when left atrial pressure crosses over and exceeds LV pressure. The atrium empties rapidly in early diastole and further diminishes with atrial contraction in late diastole just before IVC. The LV may actually generate negative pressure in early diastole if left atrial pressures are low. During IVR, the mitral annulus to LV apex distance lengthens as the mitral annulus ascends in early diastole, descends slightly, and ascends again with atrial contraction. The area of the mitral orifice increases slightly during IVR and continues to increase during diastole until it reaches a maximum just before the left atrium contracts. In humans, the annular area index reaches a maximum of 3.9 ± 0.7 cm^2/m^2.[10] As the annular area increases, its shape changes asymmetrically; most of the area increase is caused by lengthening in the posterior and lateral parts of the annulus (away from the fibrous trigone).[8] During IVR the mitral leaflets separate approximately 30 milliseconds before left atrial pressure exceeds LV pressure.[16] Peak blood flow through the valve occurs early in diastole, but the mitral leaflets reach their maximal open position before peak flow occurs and begin closing while flow is still accelerating.

The papillary muscles may shorten very slightly during early IVR, but do not begin to lengthen until the beginning of diastole. Papillary muscles reach maximum length shortly after ED during IVC. Chordal tension decreases rapidly during IVR and remains near zero until late diastole, when a small increase occurs. The left ventricle relaxes and dilates after ES and reverses the complex deformations of LV shape produced by systole. During early diastole, and the period of rapid filling, the ventricle dilates primarily along both equatorial axes and much less along the longitudinal, base-to-apex axis. Only a little shape change occurs in mid diastole and after atrial contraction. Ventricular wall thickness decreases primarily during IVR. Last, the ventricle rapidly untwists (rotating clockwise) during early diastole and more gradually during mid and late diastole.

Mechanism of Ischemic Mitral Regurgitation

Acute Ischemic Mitral Regurgitation

Papillary muscle rupture is a rare, often fatal complication, occuring in 1 to 5% of patients who die after myocardial infarction, as determined by autopsy studies.[17] The rupture involves the posteromedial papillary muscle in approximately two-thirds of acute, severe IMR. The vascular supply to the posteromedial papillary muscle is dependent on a single coronary artery (the right coronary artery, or the circumflex coronary artery in a left-dominant system), whereas the anterolateral papillary muscle receives dual supply from the left anterior descending and circumflex coronary arteries. Papillary muscle rupture results in prolapse of the mitral leaflets, often causing severe acute IMR, hemodynamic instability, and acute pulmonary edema. Acute mitral regurgitation in this setting carries a poor prognosis with a high mortality rate.

More often, acute IMR occurs with subtle changes in the mitral valve apparatus in the absence of leaflet prolapse. Annular dilatation has traditionally been regarded as the mechanism of acute IMR. Laboratory work involving an ovine model from the Stanford group has demonstrated the importance of the septolateral (SL) dimension of the mitral annulus in the pathophysiology of IMR.[18–20] The SL dimension, the vertical distance of the mitral annulus from the middle of the anterior annulus to the middle of the posterior annulus, is clinically referred as the *anteroposterior* (AP) dimension. Timek and coworkers demonstrated that correcting SL distance alone may abolish acute IMR.[19]

However, other experimental studies have demonstrated subvalvular geometric changes as important contributors to the pathophysiology of acute IMR. With ischemia or infarction, the posterior papillary muscle elongates 2 to 4 mm in the sheep and dog[12,21]; the tip moves 1.5 to 3.0 mm closer to the annulus.[12,22] In the sheep model of acute IMR, the uninfarcted, preserved anterior papillary muscle contracts earlier and more vigorously than before infarction. This moves the tip 4 to 5 mm further away from the annular plane at mid systole than before infarction.[23] The Stanford group has meticulously characterized this discoordination of normal synchronous papillary muscle contraction and its complex effect on leaflet coaptation.[24,25] Tibayan and coworkers demonstrated that by using mitral suture

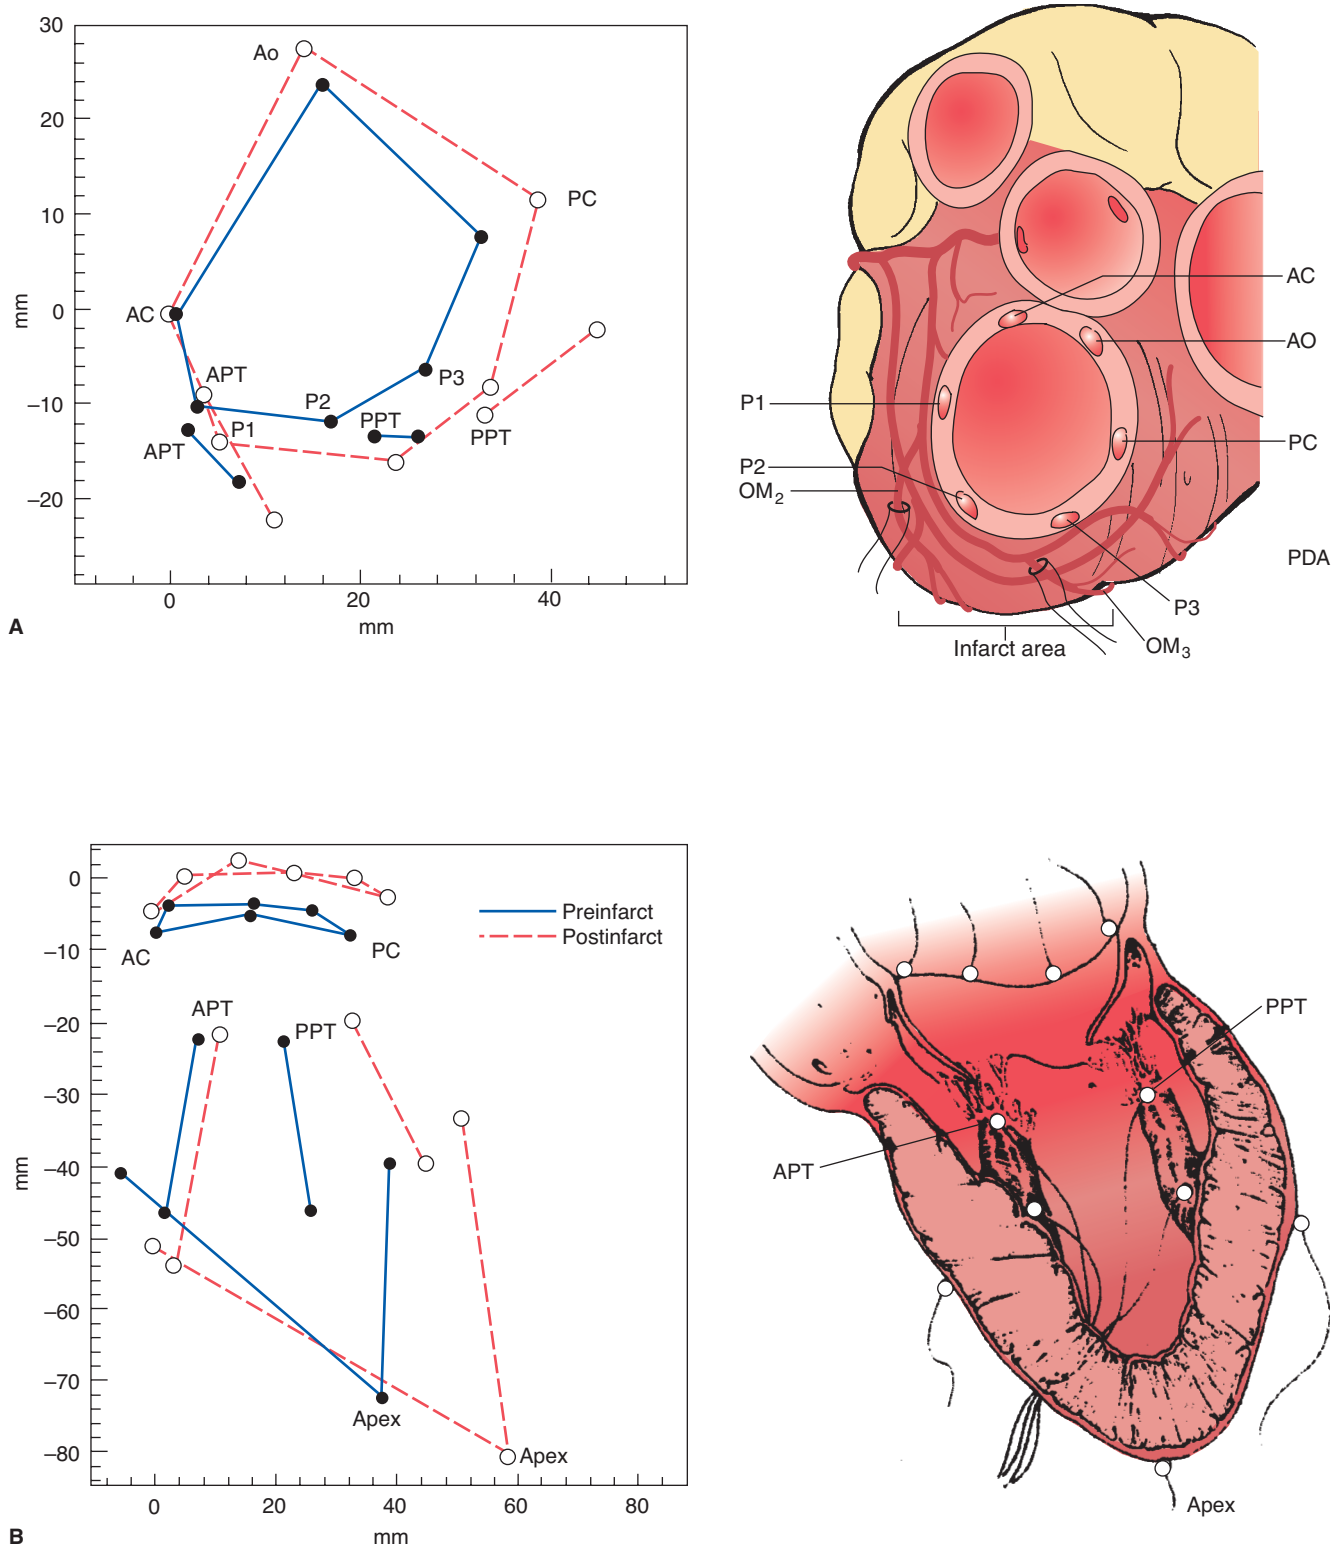

FIGURE 29-2 (A) *Left:* Two-dimensional axial view of the mitral valve annulus and papillary muscle transducers before (*solid line*) and 8 weeks after infarction (*dashed line*). *Right*: An artist's drawing of how the transducers are placed in relation to the mitral annulus and the location of the infarct. Note the stretching of both the posterior part of the aortic portion of the annulus (Ao to PC) and the anterior part of the mural portion of the annulus (Ao to P1 to P2). Also, note how the portion of the annulus between P2 and PC along with the posterior papillary muscle tip (PPT) pulls away from the relatively fixed anterior commissure. (B) *Left*: Two-dimensional sagital view of the sheep mitral annulus and its relationship to the LV and papillary muscles before and 8 weeks after infarction. *Right*: An artist's drawing is provided for orientation of the sonomicrometry transducers. Note how the PPT and the posterior annulus are retracted away form the anterior commissure. The heart shown in this figure is the same one shown in Figure 28-2. (*Reproduced with permission from Gorman JH III, Gorman RC, Jackson BM, et al: Annuloplasty ring selection for chronic ischemic mitral regurgitation: lessons from the ovine model. Ann Thorac Surg 2003; 76:1556-1563.*)

annuloplasty (Paneth-type), altered annular and subvalvular geometry can be corrected, and acute IMR is abolished.[26] Neilsen and coworkers in a pig model of acute IMR demonstrated that imbalanced chordal force distribution is directly related to the development of acute IMR.[27] The authors showed a decrease in tension of the primary chorda from the ischemic posterior left ventricular wall to the anterior leaflet, whereas the tension of the chorda from the nonischemic anterior left ventricluar wall to the anterior leaflet increased.

These data suggest that acute IMR is a result of complex interaction of small changes in the mitral valvular complex, and not merely simple annular dilatation, as previously believed.[23,28,29] These small changes are difficult to demonstrate by standard imaging techniques, making repair challenging in this acute setting. In addition, finite element analysis of the mitral annulus has suggested an association between the normal annular saddle shape of the mitral valve and its competency.[30]

Chronic Ischemic Mitral Regurgitation

In chronic IMR, mitral valve prolapse has been described in occasional patients, but the vast majority have incomplete mitral valve closure owing to left ventricular remodeling and papillary muscle displacement. Remodeling often manifests as annular dilatation with papillary muscle and chordal restriction of leaflet motion. Pathologic studies consistently show fibrosis and atrophy of infarcted papillary muscles, and none demonstrate papillary muscle or chordal elongation.[31–34] Nevertheless, surgeons describe elongated chordae in some patients with myocardial infarction and mitral regurgitation. Elongated chordae and mitral valve prolapse without mitral regurgitation probably antedate the infarction in these patients.[35] In a patient with preexisting mitral valve prolapse, ventricular infarction may cause the previously competent valve to leak. This hypothesis explains sporadic observations of mitral valve prolapse in patients with chronic IMR, but requires preinfarction echocardiograms for confirmation.

Ovine experiments using sonomicrometry array localization to study postinfarction MR that evolves during the first 8 weeks after infarction have added insight relevant to the pathogenesis of chronic IMR. As a result of ischemic left ventricular remodeling, a combination of asymmetric annular dilatation and leaflet tethering by *both* papillary muscles occurs to alter the normal saddle shape of the annulus and produce chronic IMR.[36] Previously thought to be fixed, the anterior portion of the annulus does dilate.[37] The intertrigonal distance has been shown to increase, in addition to the increase in the SL dimension.[38] The annular area dilates by at least 60% at all time points during systolic ejection, but the dilatation involves all of the muscular annulus. The posterior or mural portion of the annulus directly adjacent to the infarct moves away from the relatively fixed anterior commissure (at the anterior fibrous trigone) and stretches the anterior portion of the mural annulus and the posterior portion of the aortic-based annulus, which are remote from the infarct. This finding illustrates how a moderately sized (21% of the LV mass) localized infarct remodels and distorts remote, uninfarcted myocardium including the mitral valve annulus (Fig. 29-2A).[39]

Lateral displacement of the posterior papillary muscle appears to play a major role in the development of chronic IMR.[38] Interestingly, the posterior papillary muscle tip to posterior commissure relationship does not change significantly. Both these points are displaced together, away from the relatively fixed anterior commissure as a result of the remodeling process (Fig. 29-2B). This indicates that the posterior papillary muscle tethering is more pronounced at its most anterior connection with both leaflets near the center of the coaptation line and not at the commissure. The anterior papillary muscle tip is displaced significantly from both commissures but further from the posterior commissure. This indicates that the tethering effect of the anterior papillary muscle is greatest along both leaflets from the anterior commissure to the middle of the coaptation line. Together, these findings suggest that in this model, the postinfarction ventricular remodeling process tethers the anterior portion of both leaflets.

The concept of leaflet tethering as a contributing factor in the pathogenesis of chronic IMR is not new. Two echocardiographic reports, one studying the same sheep model presented here and one human study, demonstrated findings consistent with the experimental results cited in the preceding. Otsuji and coworkers applied a very effective three-dimensional echocardiographic technique to quantify leaflet tethering in the same ovine model.[40] These authors also reported mid-systolic distortions between both papillary muscle tips and the anterior commissure, but did not observe changes between papillary muscle tips and the posterior commissure or annular dilatation. Yiu and coworkers used quantitative two-dimensional echocardiography to corroborate these findings clinically by comparing normal controls with a cohort of patients with varying degrees of chronic IMR.[41] They found that ventricular distortions, which most closely correlated with the degree of mitral regurgitation, occurred between the posterior papillary muscle tip and anterior commissure and posterior displacement of the anterior papillary muscle tip.

To summarize, the geometric changes that lead to acute IMR are multiple but extremely subtle (<5 mm) and are not reliably imaged by currently available clinical modalities. Chronic IMR involves larger changes (1 to 2 cm) that cause moderate annular dilatation and complex leaflet tethering along the anterior and mid leaflet coaptation line. It is a process resulting from complex geometrical alteration of the mitral valve apparatus as a result of ischemic left ventricular remodeling (Fig. 29-3).

CLINICAL PRESENTATION AND MANAGEMENT

Acute Ischemic Mitral Regurgitation

Clinical Presentation

Clinically, acute IMR usually presents abruptly with chest pain and/or shortness of breath. The presentation is that of an acute myocardial infarction and occasionally may be silent. These patients are often hemodynamically unstable, in cardiogenic shock. They often present in extremis with symptoms of congestive heart failure, including pulmonary edema, systemic

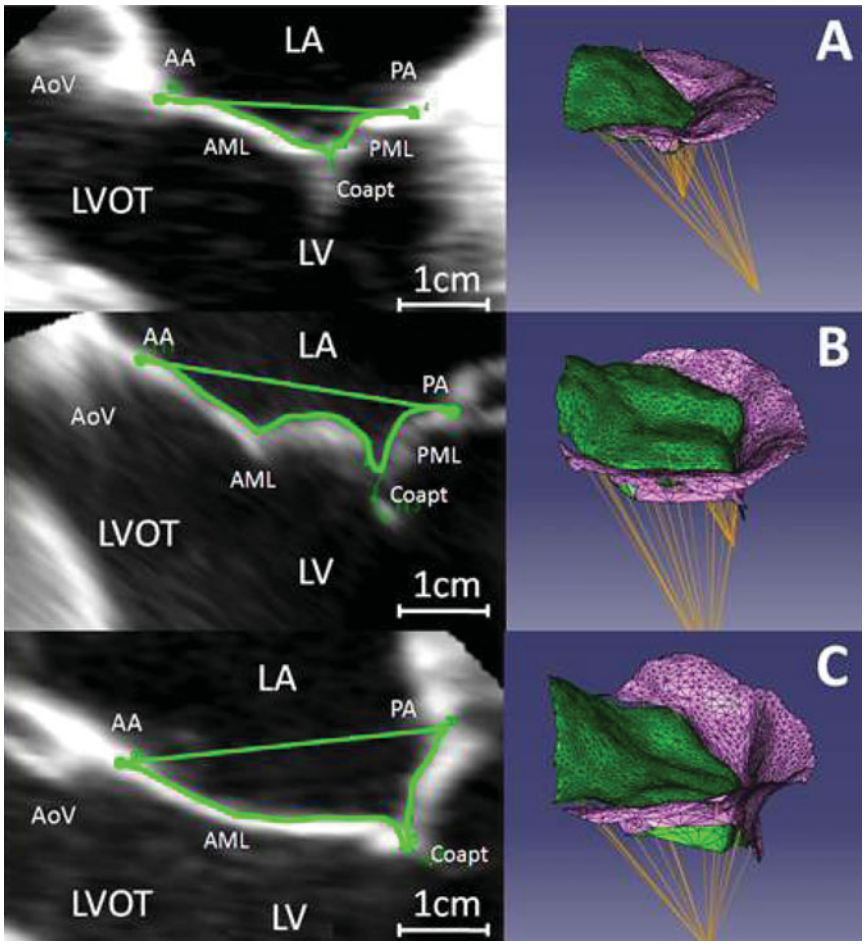

FIGURE 29-3 Three-dimensional rendering to compare normal mitral valve with ischemic mitral valve with either severe or minimal leaflet tethering. (A) A normal valve. (B) Ischemic mitral valve (3+ MR) with mild leaflet tethering. (C) An ischemic mitral valve (4+ MR) with severe bileaflet tethering. The left picture in each panel demonstrates the leaflet tracing technique used in serial 2D slices through the valve. The right picture in each panel demonstrates the completely traced valve rendered three-dimensionally from 1-mm slices through the valve. (Chordal structures have been added to help orient the viewer.)

hypotension, oliguria, acidosis, and poor periperhal perfusion. On physical examination, in the setting of profound MR, most patients have a loud apical, holosystolic murmur that radiates to the left axilla; but with lesser degrees of MR, a murmur is inconsistently detected.

Nearly all electrocardiograms are abnormal,[17,42,43] but only slightly more than half are diagnostic of AMI. Some of the nondiagnostic changes include right or left bundle branch block and nonspecific ST- and T-wave changes in the anteroseptal, lateral, or inferior leads.[17,42,44] Most patients are in sinus rhythm. In autopsy series, the incidence of subendocardial infarctions is approximately equal to the incidence of transmural infarctions.[17,43] Frequently patients with papillary muscle rupture have electrocardiographic evidence of an inferior MI. When the ECG is diagnostic, inferior wall infarctions are much more common than anterior and lateral wall infarctions. Conduction abnormalities are relatively uncommon and are more often found in patients with postinfarction ventricular septal defects. Chest x-rays nearly always show signs of pulmonary congestion, interstitial pulmonary edema, and pulmonary venous engorgement.[42] Cardiomegaly is usually not present, and there is usually no sign of left atrial enlargement in acute MR.[17]

The differential diagnosis for acute IMR includes postinfarction ventricular septal defect, massive AMI without significant MR, and ruptured chordae tendineae without AMI. Right heart catheterization usually shows elevated pulmonary arterial pressures with prominent V waves reaching 40 mm Hg or higher.[42,45] Mean pulmonary artery wedge pressures are greater than 20 mm Hg unless cardiac output is very low. Mixed venous oxygen saturations are often well below 50% and reflect low cardiac output with indices that range from 1.0 to 2.9 L/m^2/min.[45] In the presence of a loud systolic murmur, absence of an oxygen step-up in the pulmonary artery is strong evidence against the diagnosis of postinfarction ventricular septal defect. Electrocardiographic evidence of AMI distinguishes acute IMR from acute chordal rupture, but the lack of EKG changes does not differentiate the two diseases.[42]

Transthoracic echocardiography (TTE) assesses the degree of MR, confirms wall motion abnormalities, and may demonstrate flail mitral leaflets. However, transesophageal (TEE)

echocardiography is the diagnostic imaging tool of choice. This modality definitively documents the degree and characteristics of the MR jet of IMR, associated wall motion abnormalities, and the status of the posterior papillary muscle. In the modern era, the information provided by TEE is vital in making an accurate decision to repair versus replace the mitral valve. Typically the left atrium is not enlarged, but the left ventricle shows signs of volume overload and segmental wall motion abnormalities. Color flow Doppler velocity mapping documents the presence of MR after myocardial infarction and semiquantitates its severity. Ejection fractions vary widely, but do not reflect the extent of the LV infarction.

Despite hemodynamic instability, most patients have a diagnostic cardiac catheterization primarily for definition of coronary arterial anatomy. However, the wisdom of prescribing cardiac catheterization for patients in cardiogenic shock is highly questionable in that revascularization of obstructed, remote coronary vessels is not likely to improve a patient's chances for immediate survival. Approximately half of catheterized patients have single-vessel disease, most often of the right coronary artery.[42,45] Most of the remainder have three-vessel disease.[17,42–44] Ventriculography shows increased LV volume at both end diastole and end systole, severe MR, segmental wall motion abnormalities, and a wide range of ejection fractions, which are generally over 40% and frequently over 60%.[44,45] LV end-diastolic pressures are usually elevated, with prominent left atrial V waves and moderate pulmonary hypertension. Occasionally patients may have mild or moderate tricuspid regurgitation. Cardiac output is usually very low in this disease process.

Indication for Surgery

Immediate surgery is the best chance for survival for most patients with acute, severe postinfarction MR. The goal of medical therapy is to stabilize the patient and optimize hemodynamcs in preparation for surgical intervention. A few, highly selected patients without papillary muscle rupture early in their presentation have been treated by emergency PCI and/or thrombolytic therapy in an attempt to reduce the size of the infarct and thereby reduce mitral regurgitation.[46–49] PCI or thrombolysis carried out within 4 hours of the onset of AMI may on occasion produce spectacular reversal of both the infarction and mitral regurgitation.[47–49] However, less rapid PCI may not succeed in preempting the infarct and aborting mitral regurgitation.[49] PCI and thrombolysis in catheterized patients are potentially worth trying if patients reach medical attention soon after the onset of symptoms, are sufficiently stable, and can be followed by echocardiography. However, in many patients PCI and thrombolysis do not provide a favorable outcome.[46] In one study, 17% of patients with acute IMR and successful thrombolysis died in the hospital; in those with successful PCI, 50% died shortly afterward, and 77% were dead in 1 year.[46] Of the survivors, the majority continue to have 3+ or 4+ MR.[46]

For patients who have acute postinfarction angina with 1+ or 2+ MR, urgent myocardial revascularization is indicated to relieve angina and prevent extension of the infarction. It is important to prevent progression of MR and the development of congestive heart failure or cardiogenic shock. This is usually accomplished by thrombolysis or PCI. If these measures are unsuccessful, operation is rarely completed in time to reverse the infarction, but early operation may reduce the size of the ultimate infarct.[50–52] The presence of mild to moderate IMR does not increase operative mortality, but the presence of congestive heart failure is a risk factor.[53] In these patients, the mitral valve is generally not addressed unless intraoperative transesophageal echocardiography indicates 3+ or 4+ MR.

Indications for emergency surgery for acute, severe postinfarction MR vary among institutions and probably explain wide discrepancies in reports of hospital mortality.[54,55] In this group of patients, medical therapy does not produce survivors and patients denied operation are not reported.[42,44] Aged patients are less likely to survive operation, and there are only anecdotal reports of successful operation in octogenarians.[47,54,56] Other risk factors for hospital death are severe congestive heart failure, the number and severity of comorbid diseases such as renal or pulmonary problems, presence of an intra-aortic balloon pump, reduced ejection fraction, and greater number of diseased coronary arteries.[57]

Surgical intervention for acute, severe postinfarction MR consists of mitral valve repair or replacement with or without myocardial revascularization. Nearly all surgeons recommend revascularization of all significantly obstructed coronary vessels away from the site of the infarction.[55] Improved methods of cardioplegia support this recommendation even in patients with preoperative cardiogenic shock who have had cardiac catheterization. The wisdom of blind revascularization of remote coronary vessels in patients who have not had preoperative cardiac catheterization and revascularization of the infarct artery more than 4 to 6 hours after onset of pain is less clear.[58] On a statistical basis, only half of patients with acute IMR have multivessel coronary artery disease.[17,42,45] Revascularization of completed infarctions favorably influences subsequent ventricular remodeling.[51,52,59]

With echocardiographic findings amenable to repair, a simple, central regurgitant jet, minimally tethered leaflets, and no papillary muscle pathlogy such as rupture, a simple repair with an annuloplasty ring can be enterained. However, replacement of the diseased valve should be considered if the effectiveness and durability of the repair are at all in question. These patients are often critically ill, and will not tolerate the increased cardiopulmonary bypass time associated with mitral valve replacement after failed mitral repair. When performing mitral valve replacement, it is important to preserve the chordal attachments to the annulus to limit adverse ventricular remodeling (Fig. 29-4). Bioprosthestic valves are a reasonable choice since anticoagulation is not benign and durability is a relatively minor concern in these patients with poor long-term prognosis.[60,61]

Results

Published results of mitral valve replacement for acute IMR are poor. Hospital mortality ranges from 31 to 69% and probably reflects the selection process more than quality of care. Variables that increase early mortality include patient age, cardiogenic shock, comorbid conditions, the amount of infarcted myocardium, and delay in operation.[42,44,45,54] More recent experience

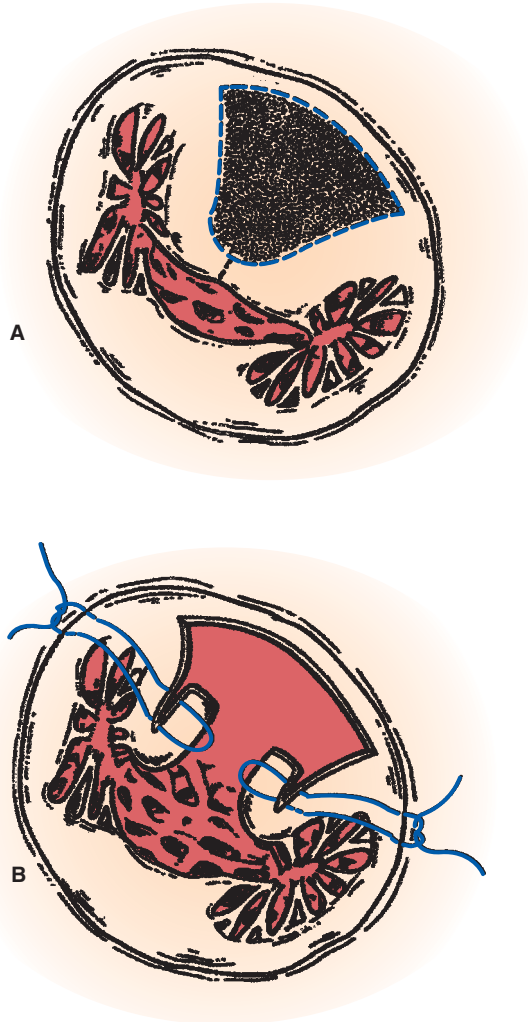

FIGURE 29-4 Okita's method for retaining chordal attachment to the mitral annulus during replacement of the mitral valve. (A) Diagram showing the mitral valve from the left atrium. The center of the anterior leaflet is excised (*shaded area*) and the leaflet is divided retaining the chordae from each papillary muscle attached to the residual anterior leaflet tissue. The posterior leaflet may be divided at its midpoint if necessary. (B) Remnants of the anterior leaflets are sutured to the annulus using a single stitch as shown. This tissue is later included in sutures used in sewing the valve to the annulus. (*Modified slightly with permission from Okita Y, Miki S, Kusuhara K, et al: Analysis of left ventricular motion after mitral valve replacement with a technique of preservation of all chordae tendineae. J Thorac Cardiovasc Surg 1992; 104:786.*)

may be better because of prompt diagnosis, early surgery, complete revascularization, and application of chordal preservation techniques that better preserve left ventricular function.[60–67] Several techniques are available for preserving chordae (see Fig. 29-4).[62,68,69]

Controversy exists over whether the mitral valve should be repaired or replaced in the setting of acute IMR. Repair of the valve in acute IMR potentially enhances the complexity of the operation as well as the cardiopulmonary bypass time as compared with mitral valve replacement. As demonstrated, the anatomical derangements in the acute IMR setting may be very subtle, resulting in annular dilatation and malcoaptation of the leaflets, in which case an undersized ring annuloplasty is a reasonable option. Long-term (5-year) survival in patients who survive the perioperative period is poor and even in modern reports hovers around 50%.[60,61] Even with poor prognosis, we believe mitral valve annuloplasty ring is a reasonable option for pathology amenable to repair.

Papillary muscle rupture is less common as the etiology for acute ischemic mitral regurgitation, and this subset of patients is usually much less ill. A recent retrospective analysis of post-MI papillary muscle rupture patients noted a marked improvement in postoperative survival when either valve repair (reimplantation of the papillary muscle and annuloplasty) or replacement was performed in combination with concomitant revascularization. It is encouraging that the authors noted normalization in 5-year survival (79%) and freedom from congestive heart failure to that of matched MI controls without papillary mucle rupture (28 ± 8% versus 36 ± 6%) was noted, predicting an optimistic outcome for this patient population in the modern surgical era.[70]

Chronic Ischemic Mitral Regurgitation

Clinical Presentation

Chronic IMR represents the majority of patients with IMR. Between 10.9 and 19.0% of patients with symptomatic coronary artery disease who have cardiac catheterization[3,4] and 3.5 to 7.0% of patients who have myocardial revascularization have IMR.[71–74] The majority of these patients have 1+ to 2+ mitral regurgitation, without evidence of heart failure.[3,4,71–73] In patients with chronic IMR, three major variables interrelate to produce the clinical spectrum of patients with varying combinations of symptomatic ischemia and heart failure. As with acute IMR, the three major variables are: (1) the presence and severity of ischemia, (2) the severity of mitral regurgitation, and (3) the magnitude of left ventricular dysfunction. First, patients with obstructive coronary artery disease may be asymptomatic or have stable, progressive, unstable, or postinfarction angina or its equivalent. Because of disabling symptoms, threat to left ventricular mass or statistically shortened survival, ischemia is a compelling problem that must be addressed therapeutically. The approach and methods do not differ from similar patients who do not have IMR.

The second variable is the severity of mitral regurgitation. At present, 1+ or 2+ mitral regurgitation in patients without symptoms of heart failure does not compel invasive therapy for mitral regurgitation. Severe mitral regurgitation and/or symptoms of heart failure require evaluation for possible operation irrespective of the therapy needed for ischemia. The third variable is the degree of left ventricular dysfunction. LV dysfunction is the most difficult to assess in the presence of mitral regurgitation. Symptoms of heart failure may be caused by left ventricular dysfunction secondary to ischemia, mitral regurgitation, or both.

The primary purpose of diagnostic studies is to determine the severity of coronary artery disease and its anatomy, the

severity and mechanism of mitral regurgitation, and the degree of left ventricular dysfunction. In chronic IMR, the ventricular geometry and function reflect remodeling owing to both the mitral regurgitation and infarction; therefore, these patients may require diagnostic studies and perhaps operative procedures that are different from patients with CAD associated with mitral regurgitation. It is also important to define comorbidity of other organ systems by appropriate diagnostic studies dictated by the patient's history, physical examination, and screening laboratory findings.

In patients with IMR, the ECG usually shows evidence of a prior myocardial infarction. The incidence of arrhythmias varies but atrial fibrillation as noted earlier is quite common. In patients without failure and mild mitral regurgitation, heart size by chest x-ray is normal or slightly enlarged; the left atrium is seldom enlarged. In those with moderate or severe mitral regurgitation and/or severe left ventricular dysfunction, the heart is enlarged and usually the left atrium is also enlarged.

Transthoracic echocardiography and TEE are useful in determining the etiology of mitral regurgitation. Two-dimensional echocardiography reliably detects ruptured chordae, annular calcification, and myxomatous degeneration, which are not features of chronic IMR, and differentiates rheumatic valve disease, endocarditis, and degenerative valve disease. Echocardiography also effectively assesses regional wall motion abnormalities and global left ventricular function. The degree of mitral regurgitation is also well quantified by color flow Doppler measurements. Characteristics of the mitral regurgitation demonstrated by TEE will also aid in the decision to repair or replace the mitral valve. Extremely dilated annulus with severe bileaflet tethering (Carpentier Type IIIB) and eccentric or complex regurgitation jet are echocardiographic findings that repair may not be effective or durable.

Cardiac catheterization provides information regarding the coronary arterial anatomy and pathology. Ventriculograms add little to the data provided by TTE or TEE and should be avoided, especially in patients with impaired renal function. Measurements of chamber pressures and estimates of cardiac output contribute to the overall evaluation of left ventricular function. Pulmonary hypertension, when present, is typically moderate and correlates with the degree of left ventricular dysfunction and/or severity of mitral regurgitation.

Indications for Surgery

The decision to intervene surgically in IMR can be a challenging process. Chronic IMR represents a set of patients with symptoms of insidious onset and often of chronic duration. Patients may primarily present with symptoms of ischemic coronary artery disease, and on preoperative workup are found to have significant concomitant mitral regurgitation. Although this group of patients may have preserved left ventricular function, compromised ventricular function is not uncommon. The surgical indication in this group of patients is coronary artery disease requiring CABG with coexistent significant mitral regurgitation. Important factors to consider in the decision to intervene on mitral regurgitation include the following: the impact of coronary artery bypass grafting (CABG) alone on the progression of IMR; the impact of CABG with or without MVR on survival; the additional risk of MVR at the time of CABG; and the choice of valve repair and replacement.

Other patients may primarily present with symptoms of congestive heart failure and signs of significant mitral regurgitation. Preoperative catheterization subsequently may reveal significant CAD. These patients tend to have more compromised left ventricular function compared with the first group. The indication for surgery is congestive heart failure. In reality, most patients present in a clinical spectrum somewhere along the two clinical scenerios. In this section, however, the indications for surgery of each scenerio are discussed separately.

Ischemic Mitral Regurgitation and Coronary Artery Disease

The optimal management of concomitant IMR at the time of CABG remains to be determined. Most surgeons agree that concomitant severe (4+) mitral regurgitation should be addressed at the time of CABG and that revascularization alone will not ameliorate severe mitral regurgitation. Similarly, most surgeons agree that trace to mild (1+) mitral regurgitation should be left alone because it will not adversly affect long-term symptomatology or prognosis. Yet, the optimal management of mild to moderate (2+) mitral regurgitation remains controversial.

Multiple factors must be addressed in deciding on the management of IMR at the time of CABG. First, IMR has been demonstrated to have a negative impact on long-term survival. Numerous studies have documented the negative impact of IMR on long-term survival after an acute MI.[75–78] Similarly, in patients undergoing PCI for acute coronary syndromes, IMR has been demonstrated to have a negative impact on survival. Three-year survival in this group ranges from 46 to 76%, based on the severity of mitral regurgitation.[79] Moreover, in the setting of CABG, myocardial revascularization alone in patients with chronic IMR has a higher hospital mortality than in patients without IMR.[74] Mild (1+) IMR increases operative mortality from 3.4 to 4.5%[72–74,80] and moderate (2+) IMR raises operative mortality from 6 to 11%.[72–74,81] Two-year survival for revascularization alone in patients with 1+ and 2+ mitral regurgitation is 78 and 88%, respectively.[82] Five-year survival rates for patients with mild mitral regurgitation range between 70 and 80%.[3,72,83,84] For moderate mitral regurgitation, 5-year survival ranges between 60 and 70%.[85,86] Many surgeons argue that these data suggest that concomitant IMR should be addressed during CABG to affect survival.

Those who advocate the conservative approach of revascularization alone, without treatment of the IMR, argue that revascularization will improve regional wall motion abnormalities, papillary muscle function, and potentially correct IMR.[71,87,88] Moreover, there are data that suggest that survival and long-term functional status are not improved with concomitant MVR,[89,90] thus bringing into question the benefit of the higher operative risk associated with simultaneous MVR. Surgeons who advocate mitral valve repair/replacement for moderate IMR during CABG cite studies that suggest revascularization does not correct IMR,[91] and that uncorrected IMR may result in late symptoms and decreased long-term survival.[76,82]

Furthermore, mitral valve repair with annuloplasty ring is nearly always technically feasible, obviating the need for valve replacement and the associated anticoagulation of mechanical valves or subsequent valve replacement required of bioprosthetic valves. Operative risk with combined CABG/MV repair today is much better than the older series, with operative mortality in the 3 to 4% range.[92–94] Kron and collegues have concluded that the addition of MVR does not increase the operative risk of CABG in ischemic cardiomyopathy.[95] Considering the increased complexity associated with redo sternotomy with patent grafts for MVR for recurrent or progressive IMR, some feel aggressive management of IMR is justified on initial sternotomy and revascularization, given simplicity of repair when compared with subsequent redo-operation.

The impact of isolated CABG without MVR on the progression of moderate IMR has been examined. Previous studies suggest that CABG alone improves IMR grade and functional status.[71,87,88] However, in contrast recent reports have suggested that CABG alone is not the optimal therapy for moderate IMR.[91,96,97] A study from the Cleveland Clinic Foundation reported that moderate (2+) IMR does not resolve with CABG alone, and furthermore, is associated with reduced survival.[98] Between 1980 to 2000, 467 patients with moderate IMR underwent CABG alone. Longitudinal analysis of 267 follow-up echocardiograms from 156 patients demonstrated that early postoperative improvements in IMR did not persist. IMR of moderate or greater severity was present in 60% of patients by postoperative week 6. Interestingly, postoperative IMR severity was not predicted by cardiac function or extent of CAD. Furthermore, early survival of patients with unrepaired moderate IMR was reduced compared with similar patients without IMR. Based on their results, the authors concluded that a mitral valve procedure is warranted for such patients at the time of CABG. A retrospective registry review of the progression of mitral regurgitation following isolated coronary artery bypass surgery, examined 438 patients with preoperative mitral regurgitation of less than or equal to 2+ requiring CABG.[99] New 3+ to 4+ mitral regurgitation developed in 10% of patients with no prior mitral regurgitation, 12% with pre-CABG 1+ mitral regurgitation, and 25% with pre-CABG 2+ mitral regurgitation, thereby implying significant progression of IMR without treatment. Preoperative left ventricular dysfunction and large left ventricular size were identified as predictors of mitral regurgitation progression post-CABG. Although no correlation was identified between the extent of CAD or the number of grafts performed, incomplete revascularization in the PDA territory was identified as a significant predictor of mitral regurgitation progression, suggesting a role for incomplete revascularization and left ventricular remodeling in the progression of IMR.

To directly address the impact of MVR for moderate IMR, studies have compared the results of CABG alone versus CABG with concomitant MVR in the setting of IMR.[100–105] The results do suggest that post-operative mitral regurgitation is improved with CABG with concomitant MVR. However, whether there exists an improvement in long-term survival remains unclear. Several studies suggest no improvement in survival following CABG with concomitant MVR.[102,104–107] In contrast, two studies[100,101] comparing CABG versus CABG/MVR in patients with CAD and IMR have found a significant improvement in survival. Both studies involved patients with 2+ to 3+ IMR with depressed LVEF. A recent study[103] examining 111 patients with moderate to severe IMR and multivessel CAD undergoing either medical therapy, isolated CABG, or CABG/MVR found a greater than 50% reduction in mortality in the CABG and CABG/MVR groups when compared with medical therapy. However, only CABG/MVR independently predicted survival. Moreover, a history of CHF was an independent predictor of cardiac death. Five-year survival has been found to be influenced by the severity of left ventricular dysfunction at the time of operation, age, and comorbid disease.[57] Collectively, these studies suggested that concomitant MVR with CABG may improve late survival, especially in the setting of LV dysfunction and CHF, but the definitive answer remains elusive. To clarify the appropriate management of moderate IMR during CABG, a multi-institutional randomized, prospective NIH NHLBI–sponsored clinical trial has begun. In this study, patients with moderate IMR at the time of CABG are randomized to either repair of the MR or isolated CABG alone.

The final factor to address when dealing with IMR is the decision to repair or replace the valve. Gillinov demonstrated the short-term efficacy of mitral valve repair in 97% of patients undergoing elective surgery for 3+ to 4+ chronic IMR.[60] Ring annuloplasty was employed in 98% of these repairs and was the sole surgical maneuver on the valve in greater than 80%. There was a distinct inclination in this study to undersize the annuloplasty ring; 79% of the rings were 30 mm or less. Iatrogenic mitral stenosis was not seen even in patients who received 26-mm annuloplasty devices. However, there was no benefit to repair versus replacement in high-risk patients, including older age, higher NYHA functional class, significant wall motion abnormalities, and renal dysfunction. In contrast, Calafiore and colleagues have found no difference in either short- or long-term mortality between MV repair and replacement for patients with 2+ to 4+ IMR.[92] Similarly, a recent study found no difference in either operative or 6-year mortality following MV repair as compared with replacement. A prospective, randomized multi-institutional NIH NHLBI–sponsored study is presently underway to definitively determine if there is a difference between MV repair and replacement in the setting of severe ischemic mitral regurgitation.

In summary, patients with CAD with concomitant moderate to severe (3+ to 4+) IMR should undergo CABG/MVR. In patients with moderate (2+) IMR, recent studies may suggest that CABG/MVR may be justified, given the lower rate of morbidity and mortality in the modern surgical era, but this remains to be determined. Left ventricular dysfunction and increased left ventricular dimension along with incomplete revascularization may predict a higher rate of progression of IMR, suggesting CABG/MVR should be performed in this particular group of patients. Patients with symptoms of CHF appear to benefit most from CABG/MVR. Mild (1+) IMR should be left alone, unless: (1) preoperative signs and symptoms are suggestive of periods of more severe mitral regurgitation; and (2) intraoperative TEE demonstrate anatomical findings requiring MVR (ie, significant annular dilatation, leaflet tenting). Most patients with IMR benefit from mitral valve repair. In the most complex,

high-risk settings, replacement may be preferable, with no demonstrable difference in survival between repair and replacement.

Ischemic Mitral Regurgitation and Congestive Heart Failure

The ischemic cardiomyopathy patient subset is a complex population to manage. In the current era of aggressive medical management and revascularization, there has been a dramatic decrease in the incidence of acute myocardial infarction and death. However, there is a significant increase in the number of patients suffering from ischemic cardiomyopathy. This disease is often coincident with ischemic mitral regurgitation. As described in previous sections, postinfarction LV remodeling is characterized by progressive LV dilatation with a change to a spherical shape with resultant functional MR secondary to annular dilatation, papillary muscle displacement, and chordal tethering. With functional MR there is increased ventricular volume overload (preload), myocardial wall tension, and LV workload; all of which further contribute to a deleterious cycle of progressive heart failure.

In the past, operative repair of mitral regurgitation was associated with a prohibitively high perioperative mortality, making surgeons cautious about MVR and MVR/CABG in the setting of left ventricular dysfunction. The traditional teaching incorporated the "popoff" valve hypothesis, which believed that the mitral valve functioned as a low-pressure runoff to decompress the failing ventricle. It was believed that surgical correction of mitral regurgitation in the failing ventricle would further contribute to ventricular overload and further contribute to myocardial failure.

However, this hypothesis has been challenged and disproved by Bolling who believes that there is an "annular solution for the ventricular problem."[108–111] It is believed that correction of mitral regurgitation alleviates excessive ventricular workload, improves ventricular geometry, and enhances ventricular function; a process referred to as reverse remodeling. The Stanford group has reported in an ovine model of ischemic mitral regurgitation, that reduction of the annulus by an undersized ring reduces the radius of curvature of the left ventricle at the base, equiatorial, and apical levels.[112] This decrease in the radius of curvature supports the concept that a small ring can restore a more elliptical shape. Reduction of left ventricular dimensions to a more elliptical shape, reverse remodeling, after annuloplasty have also been demonstrated by clinical studies.[113–115]

The previously published high operative mortality associated with mitral valve replacement was most likely the result of loss of the subvalvular apparatus, thus indicating the importance of maintaining the integrity of the annular and subvalvular continuity during mitral valve surgery. More recent series have indeed demonstrated much lower perioperative morbidity and mortality (1.6 to 5%), demonstrating safety in carefully selected patients.[60,61,116,117]

Data from most recently published series have demonstrated improvements in left ventricular ejection fraction, mitral regurgitation, clinical symptoms (NYHA classification), and left ventricular reverse remodeling with surgical intervention.[89,100,107–109,118–121] However, questions remain regarding improvements in long-term survival and its overall effect on the natural history of IMR. Some have recently raised questions, despite previous data, about the potential improvement in long-term survival in patients with IMR in the setting of depressed LVEF. In perhaps the largest experience of MVR in patients with severe left ventricular dysfunction, Wu and coworkers examined the impact of mitral valve annuloplasty on mortality risk in patients with mitral regurgitation and left ventricular dysfunction.[122] Reviewing their echocardiographic database ($n = 682$), the authors identified 419 patients who met the criteria for surgical intervention. One hundred twenty-six patients underwent MVR, whereas 263 continued conservative medical therapy. It should be noted that the etiology of mitral regurgitation included both ischemic and nonischemic subtypes. Their analysis demonstrated no improvements in long-term survival in the MVR group versus medical therapy. Talkwalkar and coworkers[89] reported a series of 338 patients who underwent MVR. Compared with the control group, patients with depressed left ventricular ejection fraction were more likely to be associated with IMR, concomitant CABG, and NYHA class IV symptoms. Five-year survival was 54%, and when associated with prior CABG, prior myocardial infarction, or concomitant CABG, it was 0, 37, and 63%, respectively.

In agreement with previous reports, these recent studies confirmed the poor prognosis associated with IMR in the presence of LV dysfunction. In Wu's series,[122] 5-year survival in the setting of IMR and left ventricular dysfunction is less than 50%, regardless of surgical versus medical therapy. A randomized study comparing surgical versus medical therapy for IMR is needed to clarify the benefit of mitral valve surgery in this population of patients.

Patients who present primarily with symptoms of congestive heart failure and IMR provide surgeons with a fairly straightforward indication for intervention. Although it remains unclear if there is a survival benefit with repair, it is clear that there are improvements in symptoms, exercise tolerance, and ventricular remodeling. Given the low operative mortality associated with modern surgical techniques it is reasonable to correct severe IMR in the setting of heart failure. The operative indications for this group of patients are similar to mitral regurgitation of nonischemic origin. Symptoms of CHF and depressed left ventricular function are indications for surgical mitral repair or replacement. The current ACC/AHA valve disease guidelines include a cautious recommendation for consideration of MV surgery in patients with advanced heart failure, but only if MV repair or replacement with chordal sparing are options. Most surgeons agree that concomitant CABG is indicated in the presence of significant CAD.

Results

An undersized annuloplasty ring is effective in the acute correction or reduction of IMR in the majority of patients. However, recurrent mitral regurgitation after annuloplasty has been reported to be present in 30 to 40% of patients. Although these studies are criticized for not addressing the appropriate annuloplasty ring selection and adequately downsizing the ring, both of which have been demonstrated to be vital in adequate long-term correction of IMR. These studies have often used flexible bands or partial rings, which fail to address the dilatation that occurs

along the anterior annulus and fail to adequately fix the septal-lateral dimension of the valve.

The Cleveland Clinic reported its series of 585 patients who underwent annuloplasty alone for IMR between 1985 and 2002 in which 678 postoperative echocardiograms were evaulated in 422 patients. The majority of recurrent IMR occurred within the first 6 months. Overall, 28% of patients 6 months after surgery demonstrated 3+ to 4+ mitral regurgitation.[123] These results stand in contrast to the findings by Spoor and Bolling, in which minimal recurrent MR was seen up to 4 years after mitral repair with rigid annuloplasty using a ring that was downsized by two sizes.[121] It has been found that there is an almost fourfold increase in recurrence rate of IMR with the use of a flexible ring as compared with a nonflexible ring in patients with a preoperative ejection fraction less than 30%.[124]

Evidence of left ventricular reverse remodeling after annuloplasty ring has been demonstrated in small clinical studies, with excellent results and freedom from recurrent IMR for up to 2 years.[113–115] Braun and coworkers reported a series of 87 patients with IMR and depressed left ventricular function (mean LVEF 32%) who underwent undersized mitral annuloplasty and coronary revascularization. Mitral regurgitation grade decreased significantly from a mean of 3.1 to 0.6 at 18 months. Both left ventricular end-systolic and end-diastolic dimensions decreased significantly when compared with preoperative echocardiograms. Interestingly, the left ventricular end-diastolic dimension was found to be the best predictor of reverse remodeling. Left ventricular end-diastolic dimension exceeding 65 mm was associated with a lower probability of reverse remodeling, suggesting a relationship between recurrent IMR and ventricular geometric dimension. Further studies would be useful to identify preoperative echocardiographic parameters predictive of durable mitral valve repair.

Operative results for mitral valve surgery with or without concomitant CABG have improved, with recent series reporting operative mortality of 3-4%.[60,61,116,117] However, 5-year survival remains very low, with reported values as low as 30 to 40%, depending on the series (Fig. 29-5).[3,72,73,83,125] More recently, Gillinov and coworkers reported 5-year survival in the propensity-matched best risk group of 58% for valve repair and 36% for replacement. This group had significantly fewer NYHA class IV patients and less severe mitral regurgitation preoperatively. In the propensity-matched poorer risk groups (more severe CHF, mitral regurgitation, and emergency surgery) and for the group as a whole, there was no difference between repair and replacement and 5-year survival was uniformly less than 50%.[60]

There has been no randomized study demonstrating a survival benefit with mitral valve repair/replacement in IMR. In a restrospective analysis of cardiomyopathy including both ischemic and nonischemic etiology, Wu and coworkers reported in their series 5-year survival of less than 50%, regardless of surgical versus medical therapy in patients with mitral regurgitation and left ventricular dysfunction.[122] Other series have also demonstrated no survival benefit with mitral valve surgery in patients with IMR.[104–106] The similarity of results between surgical and medical therapy points out a need for better understanding of the pathophysiology of IMR and left ventricular remodeling. A randomized study examining the clinical outcome and survival benefit of mitral valve surgery for IMR is warranted.

OPERATIVE TECHNIQUE

Given the unstable presentation of patients with acute, severe postinfarction mitral regurgitation, operative intervention is often emergent. A very large percentage of these patients require

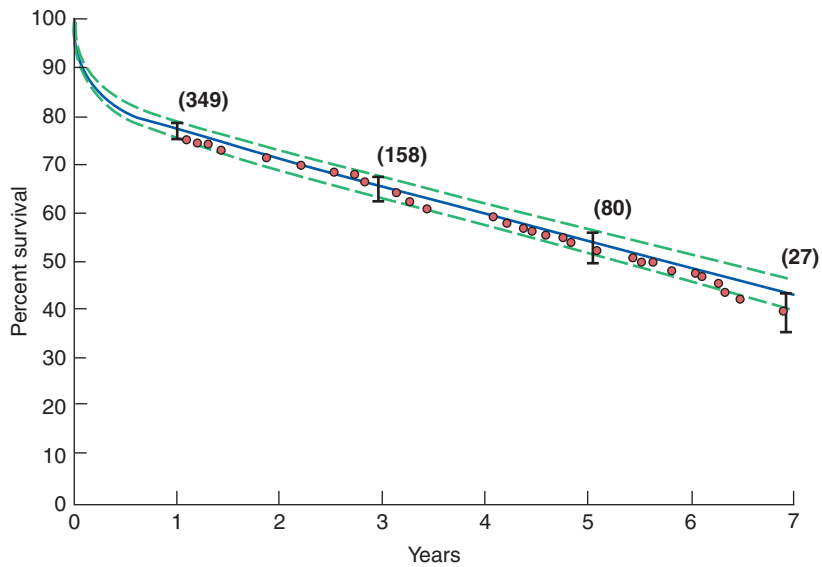

FIGURE 29-5 Survival after mitral valve surgery for all patients with ischemic mitral regurgitation. Each symbol represents a death according to Kaplan-Meier estimator. *Vertical bars* enclose asymmetric 68% confidence limits. *Solid lines* represent parametric survival estimates; these are enclosed between *dashed* 68% confidence limits. *Numbers in parentheses* are numbers of patients traced beyond that point. J Thorac Cardiovasc Surg 2001; 122[6]:1125-1141.*)

high-dose pharmacologic support or intra-aortic balloon pump counterpulsation for hemodynamic stablization in the immediate preoperative period.[45,58] Although intraoperative monitoring is very institution dependent, typical monitors include electrocardiogram, arterial blood pressure, pulmonary artery catheter with mixed venous oxygen electrode, nasopharyngeal and core body temperatures, and a urinary catheter for urine output. Additionally, a large proportion of centers use intraoperative TEE for optimal management of valvular repair and myocardial optimization.

Chronic IMR is most often performed in an elective manner, except in patients with uncontrolled symptoms of coronary ischemia who may require emergency or urgent operation to prevent myocardial infarction. Preoperative preparation and intraoperative monitors are similar to other cardiac operations. Transesophageal echocardiography and color flow Doppler velocity mapping are considered the standard of care in most centers that perform large volume valve repairs/replacements. After induction of anesthesia, TEE is used to assess: (1) anatomy of the valve; (2) degree of mitral regurgitation, include characteristics of the regurgitant jet; and (3) dimensions and segmental wall motion of the left ventricle. General anesthesia reduces systemic vascular resistance and afterload, thereby masking the degree of mitral regurgitation; therefore, assessment of the valve after administration of vasopressors to enhance afterload may unmask more severe mitral regurgitation. If the amount of mitral regurgitation remains in question or is only mild to moderate, then transfusion after aortic cannulation to increase preload to 1.5 to 2.0 times resting pulmonary capillary wedge pressure may further unmask more severe mitral regurgitation and prompt a decision to expose and repair the valve at the time of other cardiac interventions (ie, CABG). If there is a significant discrepancy between the intraoperative degree of mitral regurgitation and that diagnosed by preoperative TEE, it is probably best to treat according to the preoperative value because this is likely what the patient experiences under normal loading conditions. In patients with marginal left ventricular function, a pulmonary artery catheter with continuous cardiac output and mixed venous oxygen sensing capabilities along with a femoral arterial catheter for rapid intra-aortic balloon insertion, if needed to wean from cardiopulmonary bypass, are recommended.

The most common exposure to the mitral valve is via a median sternotomy, although over the past decade port-access and robotic platforms have afforded many surgeons expertise in exposure to the valve via the right pleural space. If revascularization is required, arterial and venous conduits are harvested before cannulation and initation of cardiopulmonary bypass. Bicaval cannulation is preferred for exposure of the mitral valve. Both antegrade and retrograde cardioplegia are recommended to minimize myocardial stunning and post-bypass ventricular dysfunction. After initiation of cardipulmonary bypass, the aorta is cross-clamped and cardioplegia is given in a standard fashion. If revascularization is needed, the distal coronary anastomoses are performed first to reduce manipulation of the heart and prevent potential atrioventricular disruption after mitral valve repair or replacement.

In patients with a history of CABG, right thoracotomy is an option to avoid injury to previous bypass grafts during a redo sternotomy. Patent grafts, especially the left internal mammary (LIMA) graft to the left anterior descending artery, may be immediately under the sternal table from previous surgery. Because of the inability to isolate and control the LIMA graft from a right thoracotomy, fibrillatory arrest is needed.

Once exposed, the left atrium is opened after developing the interatrial groove, Sondegaard's groove, extending the incision behind the inferior vena cava to the oblique sinus. In cases of redo sternotomy or acute IMR (in which case the left atrium may be small), exposure to the mitral valve can be diffcult and a transeptal approach via the right atrium may be required. Improved exposure may also be obtained by extending the atrial incision superiorly behind the superior caval–right atrial junction. Using a specialized mitral retractor (Cosgrove retractor), the left atrium is lifted and the mitral valve should be exposed for inspection. If further exposure is required the superior vena cava can be transected and the left atriotomy further extended. This is later reanastomosed much like is performed in a bicaval orthotopic heart transplant.

The first and most important step in mitral valve surgery is valve analysis. Inspection will reveal the degree of annular dilatation and leaflet and chordal pathology, and may indicate segments of the mural annulus that appear disproportionately elongated. Traction sutures in the annulus at each commissure elevate the valve and facilitate exposure of the leaflets, chordae, and papillary muscles. Careful inspection should include searching for ruptured, elongated, or sclerosed chordae; fibrotic, atrophied papillary muscle, and redundant or defective leaflet tissue. Most often the entire valve appears normal; sometimes the posterior papillary muscle seems slightly more yellowish brown than the rest of the ventricle and the posterior part of the mural annulus seems slightly elongated.

Echocardiographic evaluation of the valve is important in the decision to repair or replace the valve. A central regurgitant jet with a dilated annulus is suggestive of a successful simple repair with an annuloplasty ring. In contrast, eccentric, complex regurgitant jets with severe bileaflet tethering and papillary muscle pathology such as elongation or rupture suggest that mitral replacement may be the best durable option. In this scenario mitral valve repair may not be a long-term solution. Magne and coworkers have found that preoperative echocardiographic assessment of posterior-leaflet angle greater than 45 degrees to the annulus determines a higher rate of failure of mitral repair using an annuloplasty ring (**Fig. 29-6**).[126]

For mitral valves amenable to annuloplasty repair, 2-0 braided suture is routinely used. Often, exposure to posterior and medial portions of the mitral annulus is easiest to achieve. These sutures should be placed first and used to place tension on the mitral annulus to faciliate exposure of the lateral and anterior portions of the annulus. It is essential that the full curve of the needle be used to ensure optimal placement of the sutures in the mitral annulus. Significant tension can develop when the dilated annulus is downsized, so sutures should be placed close together and overlap may be warranted. It is vital that the sutures are placed in the annulus and not in the atrial tissue to avoid subsequent annuloplasty ring dehiscence.

Sizing of the annuloplasty ring can be performed before or after placement of the annuloplasty sutures, depending on the

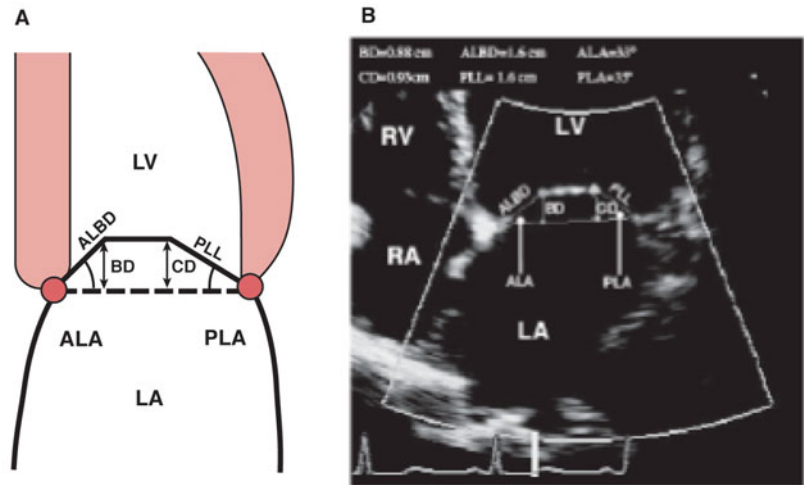

FIGURE 29-6 Method of mitral leaflet angle quantification. (A) Schema of transthoracic echocardiographic four-chamber view in mid-systole. (B) Echocardiographic image demonstrating technique of measurements of anterior leaflet angle (ALA) and posterior leaflet angle (PLA) using coaptation distance (CD), bending distance (BD), anterior leaflet bending distance (ALBD), and posterior leaflet length (PLL). RA = right atrial; RV = right ventricle. (*Reproduced with permission from Magne J, Pibarot P, Dagenais F, et al: Preoperative posterior leaflet angle accurately predicts outcome after restrictive mitral valve annuloplasty for ischemic mitral regurgitation. Circulation 2007; 115:782-791.*)

size of the left atrium and adequate exposure. Introduced by Bolling, the concept of reducing annular dilatation with aggressive annuloplasty downsizing aims to optimize leaflet coaptation. When choosing an annuloplasty ring, the intertrigonal distance and/or the surface area of the anterior leaflet are measured. Aggressive downsizing of the annulus (two sizes smaller than predicted by measuring the fibrous intertrigonal annulus) can be achieved with minimal risk of the development of systolic anterior motion, because the posterior leaflet in IMR is often tethered and restricted. Gorman and colleagues have demonstrated that use of a saddle-shaped annuloplasty ring restores normal annular geometry, decreases leaflet strain, and may increase repair durability.[127,128] Therefore, it may be prudent to choose a saddle-shaped annuloplasty ring as compared with a flat ring (Fig. 29-7). After the size of the ring is chosen, the annuloplasty sutures are placed in accordance with the geometry of the mitral annulus. Once all sutures are placed, the annuloplasty ring is slid down onto the mitral valve annulus and sutures tied to secure the ring. At this point, a saline test is usually employed to interrogate the competency of the mitral valve repair. If satisfied with the repair, the left atrium is then closed.

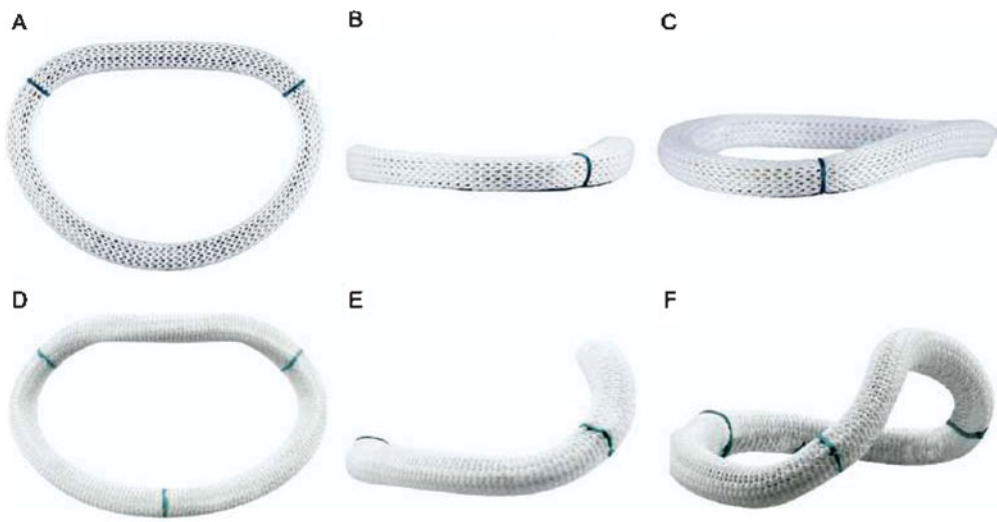

FIGURE 29-7 Images of the (A–C) Physio and (D–F) saddle ring as viewed from several orientations are provided. Subtle differences in the shape of the flow orifice (although the mitral annular areas are quite similar) can be appreciated in the short-axis views (A and D), whereas dramatic differences in annular height and nonplanarity are evident in the intercommissural (B and E) and oblique (C and F) views. (*Reproduced with permission from Ryan LP, Jackson BM, Hamamoto H, et al: The influence of annuloplasty ring geometry on mitral leaflet curvature. Ann Thorac Surg 2008; 86[3]:749-760.*)

If on inspection the valve is not amenable to annuloplasty repair, mitral valve replacement should be performed. Chordal sparing techniques[62–64,68,69,129] should be used if the valve is replaced. These methods have significantly reduced postoperative ventricular dysfunction observed after valve excision and have been found to produce no more left ventricular dysfunction than reparative operations.[69] Aged patients in sinus rhythm and patients with a life expectancy of less than 10 years who otherwise do not need anticoagulation are candidates for bioprosthetic valves; mechanical valves are recommended for others. The valve is inserted after excising a portion of anterior leaflet[63,69] and transposing[68] the remaining leaflet tissue to the commissures (see Fig. 29-4). Pledgeted everting sutures (atrial to ventricular, intra-annular placement) are used for intra-annular placement if downsizing and/or low profile valve (ie, mechanical valve) is desired. Noneverting, pledgeted sutures (ventricular to atrial, supra-annular placement) may be used for high-profile bioprosthetic valves or when a friable annulus is encountered. The mural leaflet is plicated into the valve insertion suture line and the struts of the prosthetic valve are placed along the commissural plane to prevent interference with the valve mechanism and left ventricular outflow tract obstruction.

The atriotomy is closed using running sutures, and any proximal coronary anastomoses are completed. Before removing the aortic clamp, all air is evacuated from the ventricle and the mitral valve is kept incompetent using a transvalvular catheter with ventricular and atrial holes. Absence of air and assessment of ventricular wall motion is made by transesophageal echocardiography. Anticipated pharmacologic support is started and satisfactory left ventricular contractility is established before loading the heart. After weaning, cardiopulmonary bypass is restarted. If the left ventricle begins to dilate and wall motion deteriorates, every effort is made to prevent any distention of the ventricle that might reduce myocardial contractile force. This may require placement of a pulmonary artery vent. Decisions for using intra-aortic balloon pump counterpulsation or even temporary left ventricular mechanical assistance are better made early than after multiple attempts to wean from cardiopulmonary bypass have failed.

FUTURE DIRECTIONS

There have been significant preliminary advances in novel approaches to treating mitral regurgitation, this has included subvalvar approaches, external fixation, and percutaneous repair strategies. Chordal cutting of two critical basal chordae of the anterior leaflet first described by Messas[130,131] has been shown to be effective in treating IMR. By relieving leaflet restriction and eliminating the angulation of the anterior leaflet, chordal cutting improves leaflet coaptation while the intact marginal chordae continue to prevent prolapse. Conflicting data from the Stanford group[132,133] demonstrate that cutting of second-order chords neither prevented nor decreased the severity of IMR in a sheep. Further investigation is required before this treatment modality is brought into mainstream management of IMR.

Kron and coworkers have reported a successful subvavular repair as an adjunct to standard annuloplasty.[134] Direct reposition of the displaced posterior papillary muscle toward the right fibrous trigone appear to ameliorate IMR. In a sheep model, Langer and coworkers confirmed Kron's findings.[135] Anchoring a suture at the right fibrous trigone and passing it through the posterior papillary muscle tip and left ventricular wall, the investigators demonstrated reduction of IMR by tightening the suture. Other groups have demonstrated that reapproximation of both papillary muscles may be beneficial in reducing leaflet tethering and IMR.[136–138]

Recent evidence argues that the development of IMR is a complex, multifactorial process resulting from left ventricular remodeling involving the entire mitral apparatus. Many investigators postulate that adjunctive surgical therapy directed at the remodeled ventricle may prove to be potential therapeutic strategies at treating IMR. Many have stated that IMR is not a valvular process, but a ventricular disease process. In a sheep model, Moaine and coworkers demonstrated that external restraint of the infarct zone attenuated remodeling and reduced chronic IMR.[139] Furthermore, external infarct restraint with mesh before infarction prevented left ventricular remodeling compared with the annuloplasty group. The data suggested that left ventricular remodeling associated with infarct expansion may serve as an important therapeutic target. The Acorn cardiac restrain device (CorCap) is a mesh device that is implanted around the heart to reduce wall stress and address left ventricular remodeling. Clinical trials with the Acorn device have shown that it is safe and effective in patients with advanced heart failure and remodeled ventricles, of mostly dilated etiology.[140–142] Further investigation is needed before definitive conclusions can be made.

Percutaneous therapies for MR have been attempted in multiple derivations. Rigid coronary sinus–based mitral annuloplasty devices deployed percutaneously have been demonstrated to reduce IMR in animal model.[143–145] Subseqent clinical trials have demonstrated clinical feasiblity.[146] A percutaneous approach to a modified Alfieri repair utilizing a clip to approximate the anterior and posterior mitral leaflets while creating a double outlet mitral valve has also been clinically tested. Initial results suggest feasibility and an acute reduction in MR.[147] Finally, the advent of percutaneous valve replacement technology has expanded to include transcatheter mitral valve prosthesis. Animal studies have been formulated and feasibility remains to be determined. The long-term results of these novel therapies remain to be elucidated. Further work is needed to explore the potential effectiveness and clinical applicability of these new technologies.

CHAPTER 30

Left Ventricular Aneurysm

Donald D. Glower
James E. Lowe

DEFINITION

Left ventricular aneurysm has been strictly defined as a distinct area of abnormal left ventricular diastolic contour with systolic dyskinesia or paradoxical bulging (Fig. 30-1).[1,2] Yet, a growing number of authors favor defining left ventricular aneurysm more loosely as any large area of left ventricular akinesia or dyskinesia that reduces left ventricular ejection fraction.[3–5] This broader definition has been justified by data suggesting that the pathophysiology and treatment may be the same for ventricular akinesia and for ventricular dyskinesia.[4,6] However, recent studies suggest that the optimal treatment and outcomes of patients with akinetic segments versus dyskinetic segments might be different.[7,8] Intraoperatively, a left ventricular aneurysm may also be identified as an area that collapses upon left ventricular decompression.[3,6,9] True left ventricular aneurysms involve bulging of the full thickness of the left ventricular wall, whereas a false aneurysm of the left ventricle is, in fact, a rupture of the left ventricular wall contained by surrounding pericardium.

HISTORY

Left ventricular aneurysms have long been described at autopsy, but left ventricular aneurysm was not recognized to be a consequence of coronary artery disease until 1881.[10] The angiographic diagnosis of left ventricular aneurysm was first made in 1951.[10] A congenital left ventricular aneurysm was first treated surgically by Weitland in 1912 using aneurysm ligation. In 1944, Beck[11] described fasciae latae plication to treat left ventricular aneurysms. Likoff and Bailey[12] successfully resected a left ventricular aneurysm through a thoracotomy in 1955 using a special clamp without cardiopulmonary bypass. The modern treatment era began in 1958 when Cooley et al.[13] successfully performed a linear repair of a left ventricular aneurysm using cardiopulmonary bypass. More geometric ventricular reconstruction or restoration techniques were subsequently devised by Stoney et al.,[14] Daggett et al.,[15] Dor et al.,[16] Jatene,[17] and Cooley et al.[18,19]

INCIDENCE

The incidence of left ventricular aneurysm in patients suffering from myocardial infarction has varied between 10 and 35% depending on the definition and the methods used. Of patients undergoing cardiac catheterization in the CASS study, 7.6% had angiographic evidence of left ventricular aneurysms.[20] The absolute incidence of left ventricular aneurysms may be declining because of the increased use of thrombolytics and revascularization after myocardial infarction.[21,22]

ETIOLOGY

More than 95% of true left ventricular aneurysms reported in the English literature result from coronary artery disease and myocardial infarction. True left ventricular aneurysms also may result from trauma,[23] Chagas' disease,[24] or sarcoidosis.[25] A very small number of congenital left ventricular aneurysms also have been reported and have been termed *diverticula* of the left ventricle.[26]

False aneurysms of the left ventricle result most commonly from contained rupture of the ventricle 5 to 10 days after myocardial infarction and often occur after circumflex coronary arterial occlusion. False aneurysm of the left ventricle also may result from submitral rupture of the ventricular wall, a dramatic event that generally occurs after mitral valve replacement with resection of the mitral valve apparatus.[27] Left ventricular pseudoaneurysm may also result from septic pericarditis[28] or any prior operation on the left ventricle, aortic annulus, or mitral annulus.

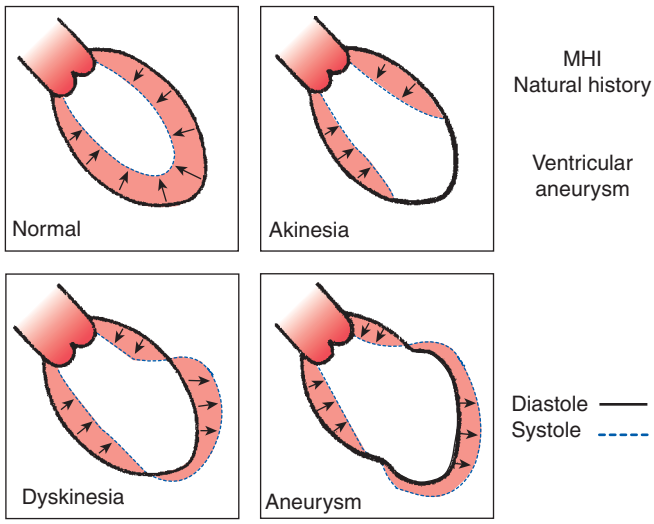

FIGURE 30-1 Diagrammatic distinction between aneurysm and other states of the left ventricle. (*Reproduced with permission from Grondin P, Kretz JG, Bical O, et al: Natural history of saccular aneurysm of the left ventricle. J Thorac Cardiovasc Surg 1979; 77:57.*)

PATHOPHYSIOLOGY

The development of a true left ventricular aneurysm involves two principal phases: early expansion and late remodeling.

Early Expansion Phase

The early expansion phase begins with the onset of myocardial infarction. Ventriculography can demonstrate left ventricular aneurysm formation within 48 hours of infarction in 50% of patients who develop ventricular aneurysms. The remaining patients have evidence of aneurysm formation by 2 weeks after infarction.[29]

True aneurysm of the left ventricle generally follows transmural myocardial infarction because of acute occlusion of the left anterior descending or dominant right coronary artery.

Lack of angiographic collaterals is strongly associated with aneurysm formation in patients with acute myocardial infarction and left anterior descending artery occlusion,[30] and absence of re-formed collateral circulation is probably a prerequisite for formation of a dyskinetic left ventricular aneurysm (Table 30-1).

TABLE 30-1 Factors Contributing to Left Ventricular Aneurysm Formation

Preserved contractility of surrounding myocardium
Transmural infarction
Lack of collateral circulation
Lack of reperfusion
Preserved contractility of surrounding myocardium
Elevated wall stress
Hypertension
Ventricular dilation
Wall thinning

At least 88% of dyskinetic ventricular aneurysms result from anterior infarction, and the remainder follow inferior infarction.[10] Posterior infarctions that produce a distinct dyskinetic left ventricular aneurysm are relatively unusual.

In experimental transmural infarction without collateral circulation, myocyte death begins 19 minutes after coronary occlusion. Infarctions that result in dyskinetic aneurysm formation are almost always transmural and may show gross thinning of the infarct zone within hours of infarction. Within a few days, the endocardial surface of the developing aneurysm becomes smooth with loss of trabeculae and deposition of fibrin and thrombus on the endocardial surface in at least 50% of patients. Because most myocytes within the infarct are necrotic, viable myocytes often remain within the infarct zone. In a minority of patients, extravascular hemorrhage occurs in the infarcted tissue and may further depress systolic and diastolic function of involved myocardium. Inflammatory cells migrate into the infarct zone by 2 to 3 days after infarction and contribute to lysis of necrotic myocytes by 5 to 10 days after infarction. Electron microscopy demonstrates disruption of the native collagen network several days after infarction. Collagen disruption and myocyte necrosis produce a nadir of myocardial tensile strength between 5 and 10 days after infarction, when rupture of the myocardial wall is most common. Left ventricular rupture is relatively rare after the ventricular aneurysmal wall becomes replaced with fibrous tissue.

Loss of systolic contraction in the large infarcted zone and preserved contraction of surrounding myocardium cause systolic bulging and thinning of the infarct. By Laplace's law ($T = Pr/2h$), at a constant ventricular pressure, P, increased radius of curvature, r, and decreased wall thickness, h, in the infarcted zone both contribute to increased muscle fiber tension, T, and further stretch the infarcted ventricular wall.

Relative to normal myocardium, ischemically injured or infarcted myocardium displays greater *plasticity* or *creep,* defined as deformation or stretch over time under a constant load.[31] Thus increased systolic and diastolic wall stress in the infarcted zone tends to produce progressive stretch of the infarcted myocardium (termed *infarct expansion*)[32] until healing reduces the plasticity of infarcted myocardium.

Transmural infarction without significant hibernating myocardium within the infarct region is necessary for subsequent development of a true left ventricular aneurysm. Angiographic ventricular aneurysms with evidence of hibernating myocardium (lack of Q waves or presence of uptake on technetium scan; Takotsubo cardiomyopathy, for example) may resolve over days to weeks and thus do not represent true left ventricular aneurysms by strict criteria.[33,34]

Because of increased diastolic stretch or preload and elevated catecholamines, remaining noninfarcted myocardium may demonstrate increased fiber shortening and, ultimately, myocardial hypertrophy in the presence of a left ventricular aneurysm.[35] This increased shortening and increased wall stress increase oxygen demand for noninfarcted myocardium and for the left ventricle as a whole.

In addition to increased regional wall stresses, left ventricular aneurysm can increase ventricular oxygen demand and decrease net forward cardiac output by producing a ventricular volume load because a portion of the stroke volume goes into

the aneurysm instead of out the aortic valve. Net mechanical efficiency of the left ventricle (external stroke work minus myocardial oxygen consumption) is decreased by reducing external stroke work (volume times pressure) and increasing myocardial oxygen consumption.

Left ventricular aneurysms can produce both systolic and diastolic ventricular dysfunction. Diastolic dysfunction results from increased stiffness of the distended and fibrotic aneurysmal wall, which impairs diastolic filling and increases left ventricular end-diastolic pressure.

Late Remodeling Phase

The remodeling phase of ventricular aneurysm formation begins 2 to 4 weeks after infarction when highly vascularized granulation tissue appears. This granulation tissue is subsequently replaced by fibrous tissue 6 to 8 weeks after infarction. As myocytes are lost, ventricular wall thickness decreases as the myocardium becomes largely replaced by fibrous tissue. In larger infarcts, the thin scar is often lined with mural thrombus.[36]

After acute myocardial infarction, animal studies show that ventricular load reduction with 8 weeks of nitrate therapy may reduce expected infarct thinning, decrease infarct stretch, and lessen hypertrophy of noninfarcted myocardium.[37] Interestingly, nitrate therapy for only 2 weeks after infarction does not prevent aneurysm formation. This observation emphasizes the importance of late remodeling from 2 to 8 weeks after infarction. Angiotensin converting-enzyme (ACE) inhibitors also reduce infarct expansion and subsequent development of ventricular aneurysm.[38] Because animal studies show that ACE inhibitors nonspecifically suppress ventricular hypertrophy, it is not clear whether suppression of the compensatory hypertrophy of surrounding myocardium is ultimately beneficial or harmful. Intravenous administration of atrial natriuretic factor for 4 weeks has improved ventricular function, dimensions, and fibrosis in rats.[39]

Lack of coronary reperfusion is probably prerequisite for development of left ventricular aneurysm. In humans, reperfusion of the infarct vessel either spontaneously,[33] by thrombolysis,[40] or by angioplasty[41] has been associated with a lower incidence of aneurysm formation. It is speculated that coronary reperfusion as late as 2 weeks after infarction prevents aneurysm formation by improving blood flow and fibroblast migration into the infarcted myocardium. The role of delayed infarct healing in aneurysm development is supported by observations that steroids after myocardial infarction may increase the likelihood of aneurysm formation.[42]

Arrhythmias such as ventricular tachycardia may occur at any time during the development of ventricular aneurysm, and all these patients have the substrate for reentrant conduction pathways within the heterogeneous ventricular myocardium. These pathways tend to involve border zones surrounding the ventricular aneurysm (see Chapter 57).

NATURAL HISTORY

The excellent prognosis of asymptomatic patients with dyskinetic ventricular aneurysms who were treated medically was demonstrated in a series of 40 patients followed for a mean of 5 years.[2] Of 18 initially asymptomatic patients, 6 developed class II symptoms and 12 remained asymptomatic. Ten-year survival was 90% for these patients but was only 46% at 10 years in patients who presented with symptoms (Fig. 30-2).

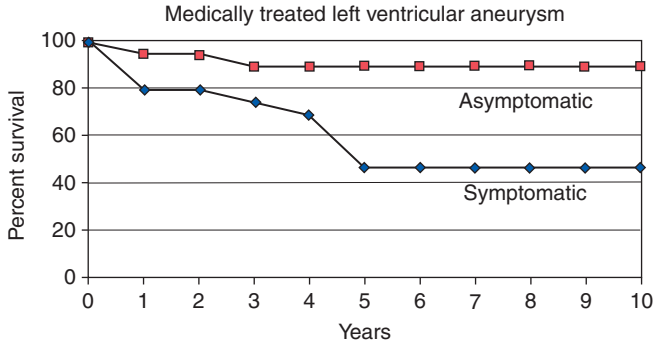

FIGURE 30-2 Survival in medically treated patients with left ventricular aneurysm based on presence (group B) or absence (group A) of symptoms. (*Based on Grondin P, Kretz JG, Bical O, et al: Natural history of saccular aneurysm of the left ventricle. J Thorac Cardiovasc Surg 1979; 77:57.*)

Although earlier autopsy series reported relatively poor survival in patients with medically managed left ventricular dyskinetic aneurysms (12% at 5 years), most recent studies report 5-year survival from 47 to 70%.[2,20,43–45] Causes of death include arrhythmia in 44%, heart failure in 33%, recurrent myocardial infarction in 11%, and noncardiac causes in 22%.[2] The natural history of patients with akinetic rather than dyskinetic left ventricular aneurysms is less well documented.[7]

Factors that influence survival with medically managed left ventricular dyskinetic aneurysm include age, heart failure score, extent of coronary disease, duration of angina, prior infarction, mitral regurgitation, ventricular arrhythmias, aneurysm size, function of residual ventricle, and left ventricular end-diastolic pressure.[2,45] Early development of aneurysm within 48 hours after infarction also diminishes survival.[29]

In general, the risk of thromboembolism is low for patients with aneurysms (0.35% per patient-year),[43] and long-term anticoagulation is not usually recommended. However, in the 50% of patients with mural thrombus visible by echocardiography after myocardial infarction, 19% develop thromboembolism over a mean follow-up of 24 months.[46] In these patients, anticoagulation and close echocardiographic follow-up may be indicated. Atrial fibrillation and large aneurysmal size are additional risk factors for thromboembolism.

The natural history of left ventricular pseudoaneurysm is not well documented. Frank rupture of chronic left ventricular pseudoaneurysms is less common than one might expect.[47] Rupture of left ventricular pseudoaneurysms may be most likely in the acute phase or in large sized pseudoaneurymsms.[48] Left ventricular pseudoaneurysms tend to behave similarly to true aneurysms in that they may present a volume load to the left ventricle or may be a source of embolization or endocarditis. Left ventricular pseudoaneurysms after prior cardiac surgery have also been reported to compress adjacent structures such as the pulmonary artery or esophagus.

CLINICAL PRESENTATION

Angina is the most frequent symptom in most series of operated patients with left ventricular aneurysm. Given that three-vessel coronary disease is present in 60% or more of these patients, the frequency of angina is not surprising.[49]

Dyspnea is the second most common symptom of ventricular aneurysm and often develops when 20% or more of the ventricular wall is infarcted. Dyspnea may occur from a combination of decreased systolic function and diastolic dysfunction.

Either atrial or ventricular arrhythmias may produce palpitations, syncope, or sudden death, or aggravate angina and dyspnea in up to one-third of patients.[49] Thromboembolism is unusual but may produce symptoms of stroke, myocardial infarction, or limb or visceral ischemia.

DIAGNOSIS

The electrocardiogram frequently demonstrates Q waves in the anterior leads along with persistent anterior ST-segment elevation (Fig. 30-3). The chest radiograph may show left ventricular enlargement and cardiomegaly (Fig. 30-4), but the chest radiograph is not usually specific for left ventricular aneurysm.

Left ventriculography is the gold standard for diagnosis of left ventricular aneurysm. The diagnosis is made by demonstrating a large, discrete area of dyskinesia (or akinesia), generally in the anteroseptal-apical walls. Occasionally, left ventriculography also may demonstrate mural thrombus. Quantitative definition of left ventricular aneurysms has been accomplished using a centerline analysis of left ventricular wall motion on left ventriculography in the 30 degree right anterior oblique view.[5] Hypocontractile segments contracting more than two standard deviations out of normal range have also been defined as aneurysmal (Fig. 30-5).[50] Outward motion is termed *dyskinetic*, and remaining aneurysmal segments are termed *akinetic*. The fraction of total left ventricular circumference that is aneurysmal can thus be computed as the value %A.[5]

Two-dimensional echocardiography is also a sensitive and specific means of diagnosing left ventricular aneurysm (Fig. 30-6). Echocardiography can detect mural thrombus or mitral valve regurgitation, and echocardiography can often distinguish false aneurysm from true aneurysm by demonstrating a defect in the true ventricular wall.

Magnetic resonance imaging (MRI) is the most reliable means of assessing left ventricular volume in the presence of left ventricular aneurysm.[51] Magnetic resonance imaging (MRI) can accurately define left ventricular aneurysms and can detect mural thrombus.[51] Yet, distinguishing true aneurysms from pseudoaneurysms remains difficult, even with magnetic resonance imaging.[52] Gated radionuclide angiography reliably detects left ventricular aneurysms, and thallium scanning or positron emission tomography (PET) can be helpful early after infarction to differentiate true aneurysm from hibernating myocardium with reversible dysfunction.

INDICATIONS FOR OPERATION

Because of the relatively good prognosis for asymptomatic left ventricular aneurysm,[2] no indications for repairing chronic, asymptomatic aneurysms are established. Yet, in low-risk patients during operation for associated coronary disease, investigators report repairing large, minimally symptomatic aneurysms.[10,53]

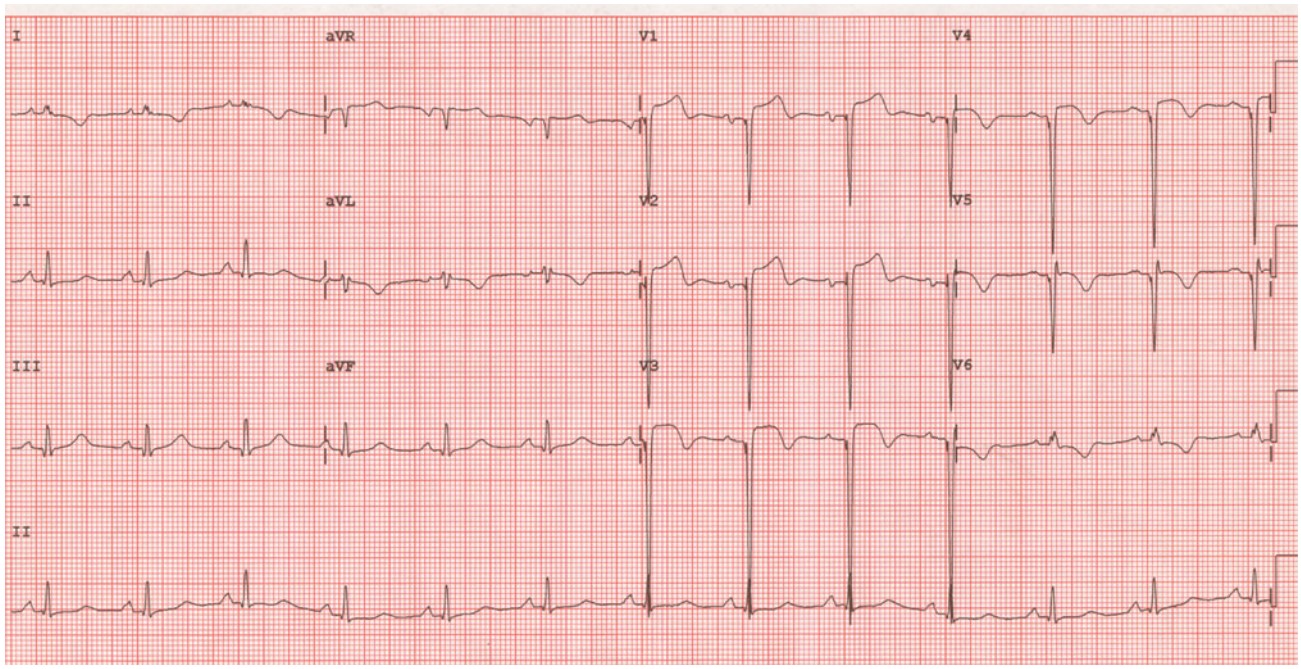

FIGURE 30-3 Electrocardiogram showing persistent ST-segment elevation with pathologic Q waves in a 72-year-old man with left ventricular aneurysm.

(*Reproduced with permission from Dor V, Sabatier M, DiDonato M: Efficacy of endoventricular patch plasty in large postinfarction akinetic scar and severe left ventricular dysfunction: comparison with a series of large dyskinetic scars. J Thorac Cardiovasc Surg 1998; 116:50.*)

On the other hand, operation is indicated for symptoms of angina, congestive heart failure, or selected ventricular arrhythmias (see Chapter 57) (Table 30-2). For these symptomatic patients, operation offers better outcome than medical therapy.

To be worthy of operation, a dyskinetic or akinetic left ventricular aneurysm should significantly enlarge left ventricular end-systolic volume index (>80 mL/m^2) and end-diastolic volume (>120 mL/m^2). These volume criteria are, however, poorly defined and limited by technical difficulty measuring left ventricular volume in aneurysmal left ventricles. Because of data suggesting that akinetic versus dyskinetic aneurysms have similar results, Dor and others feel that dyskinesia is not a prerequisite for aneurysm repair.[4,5] Nonetheless, the only randomized trial (the STICH trial) has suggested that little benefit is obtained in terms of survival or symptoms in patients who on average have smaller, akinetic aneurysmal segments (end-systolic volume index 82 mL/m^2 and 50 to 56% of anterior wall involved).[7]

Operation is indicated in viable patients with contained cardiac rupture, with or without development of a false aneurysm. Because left ventricular pseudoaneurysms may have a tendency to rupture when acute or of larger size (either with or without symptoms), operation is indicated.[47,48,54] Similarly, congenital aneurysms have a presumed risk of rupture and should undergo repair independently of symptoms. Rarely, embolism is an indication for operation in medically treated patients at high risk for repeated thromboembolism. The role of operation in asymptomatic patients with very large aneurysms or documented expansion of aneurysms is uncertain.

Relative contraindications to operation for left ventricular aneurysm include excessive anesthetic risk, impaired function of residual myocardium outside the aneurysm, resting cardiac index less than 2.0 L/min/m^2, significant mitral regurgitation, evidence of nontransmural infarction (hibernating myocardium), and lack of a discrete, thin-walled aneurysm with distinct margins. Global ejection fraction may be less useful than ejection fraction of the basal, contractile portion of the heart in determining operability.[55]

Angioplasty has an uncertain role in the treatment of left ventricular aneurysms but may be indicated in patients with

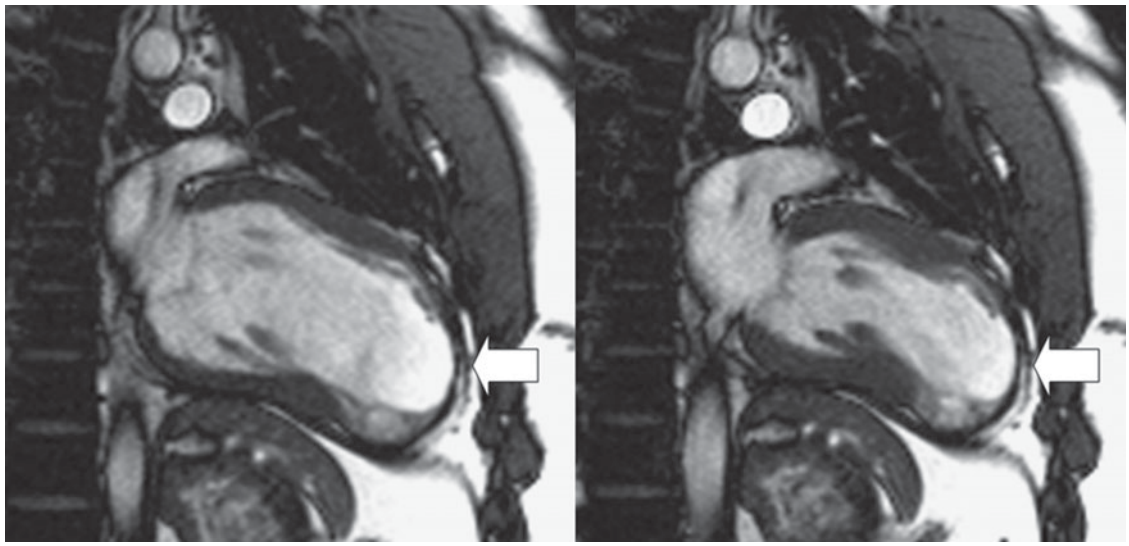

FIGURE 30-6 Magnetic resonance images of an apical left ventricular aneurysm during diastole (*left panel*) and systole (*right panel*).

suitable coronary anatomy, one- or two-vessel disease, a contraindication for operation, or asymptomatic status with inducible ischemia.

PREPARATION FOR OPERATION

All patients being considered for operation should undergo right- and left-sided heart catheterization with coronary arteriography and left ventriculography. Patients with at least 2+ mitral regurgitation at cardiac catheterization should have echocardiography to assess the mitral valve and to look for intrinsic mitral valve disease not amenable to annuloplasty. Magnetic resonance imaging can be helpful to assess left ventricular volumes and aid in planning the size and extent of left ventricular reconstruction.[51]

Preoperative electrophysiologic study is clearly indicated in any patient with preoperative ventricular tachycardia or ventricular fibrillation. The decision to perform an electrophysiologic study in patients without preoperative ventricular arrhythmias is controversial, because the incidence of postoperative ventricular arrhythmias is low and not changed by endocardial resection at the time of operation.[10] Electrophysiologic study is frequently not helpful in patients with polymorphic ventricular tachycardia occurring within 6 weeks of myocardial infarction.[10]

OPERATIVE TECHNIQUES

General Operation

Operation for left ventricular aneurysm (aneurysmectomy, aneurysmorrhaphy, ventricular restoration) requires cardiopulmonary bypass and a balanced anesthetic technique, as generally used for coronary bypass grafting. After induction of anesthesia and endotracheal intubation, an electrocardiogram monitor, a Foley catheter, a radial arterial line, and a Swan-Ganz catheter are placed. A median sternotomy is performed, and the patient is given heparin. Saphenous vein or arterial conduits are prepared.

Cardiopulmonary bypass is begun after cannulating the ascending aorta. A single, two-stage cannula is generally adequate to cannulate the right atrium, but dual venous cannulation should be considered if the right ventricle is to be opened. Epicardial mapping is performed if necessary. The left ventricle is inspected to identify an appropriate area of thinned ventricular wall. A linear vertical ventriculotomy, generally on the anterior wall 3 to 4 cm from the left anterior descending coronary artery, is made (Fig. 30-7). The left ventricle is opened (Fig. 30-8), all mural thrombus is carefully removed, and endocardial mapping is performed if necessary. A left ventricular vent is now placed through the right superior pulmonary vein–left atrial junction after mural thrombus is removed. Coronary arteries to be grafted are identified. Endocardial scar, if present, is resected, and afterwards, endocardial mapping is repeated. Body temperature is maintained at 37°C until intraoperative mapping is completed; thereafter, temperature is decreased to 28 to 32°C.

The ascending aorta is clamped, and the heart is arrested with cold anterograde and/or retrograde cardioplegic solution.

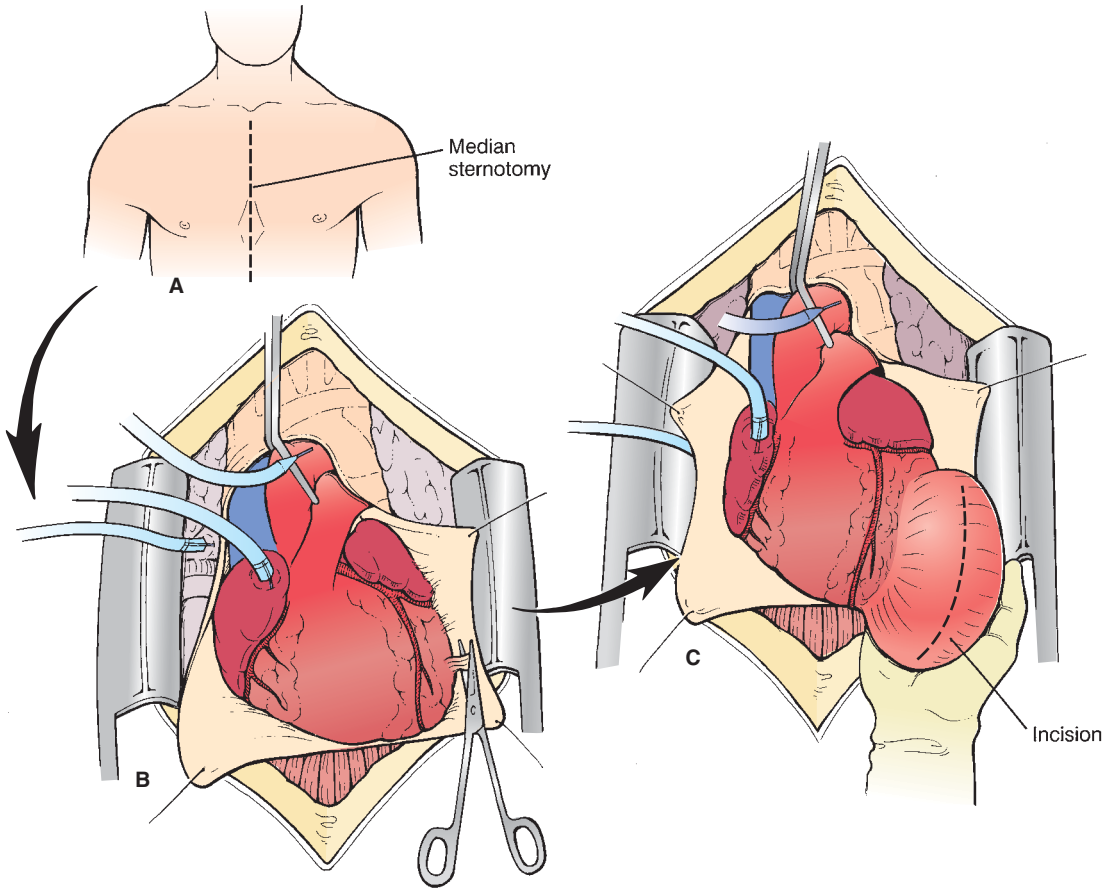

FIGURE 30-7 Technique of exposure for left ventricular aneurysm repair through a median sternotomy. The ascending aorta and right atrium are cannulated. A left ventricular vent is placed through the right superior pulmonary vein. Pericardial adhesions are divided, and the aneurysm is opened.

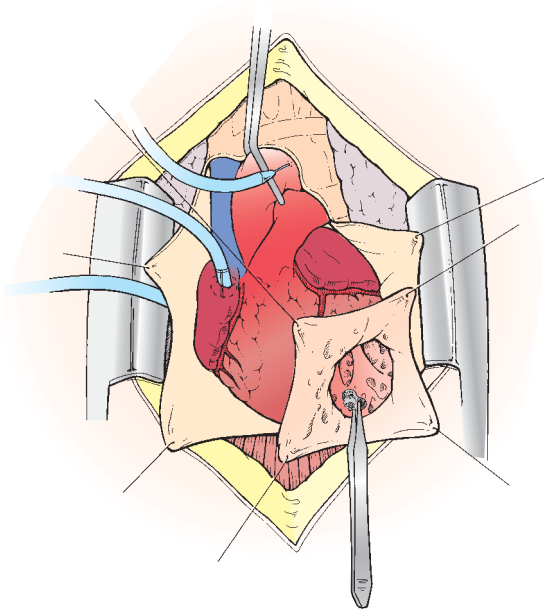

FIGURE 30-8 With the aneurysm wall opened, thrombus is removed, without injury to the papillary muscles.

Alternatively, the aorta is not clamped and the entire procedure is done during hypothermic fibrillation. The left ventricular aneurysm is repaired using one of the techniques described below. The distal coronary anastomoses are performed, followed by releasing the aortic clamp.[56] Air is removed by venting the ascending aorta and left ventricle while filling the heart and ventilating the lungs with the patient in the Trendelenberg position. The patient is rewarmed, and proximal coronary anastomoses are performed. Once normothermia is achieved, an electrophysiologic study may be repeated if indicated. Temporary pacing wires are placed on the right atrium and right ventricle, cardiopulmonary bypass is discontinued, and heparin is reversed. The heart is decannulated, and the median sternotomy is closed with mediastinal drains after hemostasis is achieved.

Weaning from cardiopulmonary bypass frequently requires some degree of inotropic support. Typically 5 μg/kg/min of dopamine, nitroglycerin to prevent coronary spasm, and nitroprusside for afterload reduction are used. An intraaortic balloon pump may be needed in patients with borderline ventricular function. Transesophageal echocardiography is useful for assessing left ventricular function and to detect residual intracardiac air.

Additional inotropic support may not increase cardiac output significantly because of abnormal ventricular compliance and may produce arrhythmias and poorly tolerated tachycardia. Hypokalemia and hypomagnesemia are corrected immediately to minimize arrhythmias. Intraoperative and postoperative ventricular ectopy is treated aggressively with intravenous lidocaine. Intravascular volume shifts are poorly tolerated in these patients because of poor ventricular compliance; therefore, rapid transfusions are avoided by meticulous hemostasis before closing. Because the left ventricle is poorly distensible, stroke volume is relatively fixed, and a resting heart rate between 90 and 115 beats per minute is not unusual to maintain a cardiac index of approximately 2.0 L/min/m^2.

Growing experience suggests that the ultimate size of the left ventricular cavity at the end of the procedure is critical to patient outcome.

Plication

Plication without opening the aneurysm is reserved for only the smallest aneurysms that do not contain mural thrombus. A two-layer suture line of 0 monofilament is placed across the aneurysm using a strip of Teflon felt on either side. The suture line is oriented to reconstruct a relatively normal left ventricular contour and does not exclude all aneurysmal tissue.

Linear Closure

After removing all mural thrombus, the aneurysmal wall is trimmed, leaving a 3-cm rim of scar to allow reconstruction of the normal left ventricular contour (Fig. 30-9). Care is taken not to resect too much aneurysmal wall and overly reduce ventricular cavity size. A monofilament 2-0 suture may be used to reduce the neck of the aneurysm to the proper size before closure of the ventricular wall.[17] Anterior aneurysm defects are closed vertically between two external 1.5-cm strips of Teflon felt, two layers of 0 monofilament horizontal mattress sutures, and finally, two layers of running 2-0 monofilament vertical sutures with large-diameter needles (Fig. 30-10). Similar techniques can be used in less frequent posterior aneurysm resections.[57]

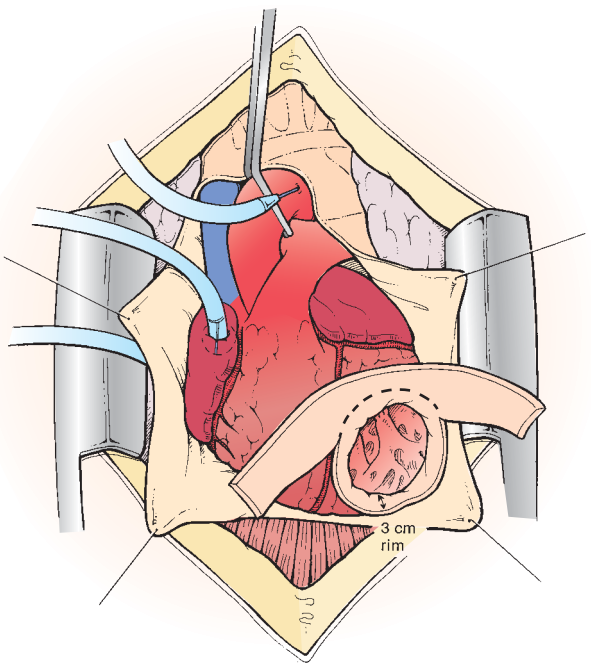

FIGURE 30-9 Linear repair. The fibrous aneurysm wall is excised, leaving a 3-cm rim of fibrous aneurysm wall attached to healthy muscle.

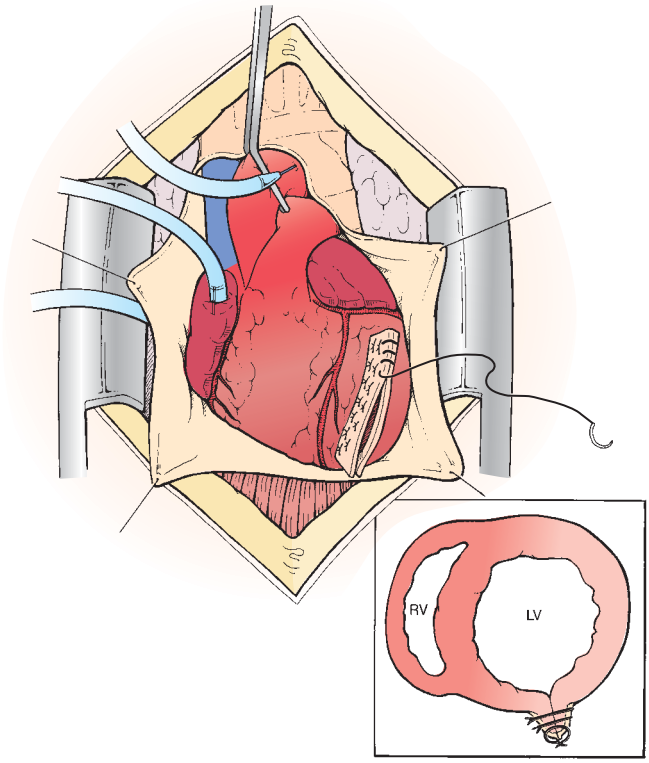

FIGURE 30-10 Linear repair. The aneurysm walls are closed in a vertical line between two layers of Teflon felt. Two layers of 0 monofilament interrupted horizontal mattress sutures are reinforced with two layers of running 2-0 monofilament sutures.

Circular Patch

Inferior or posterior aneurysms generally require circular patch closure, which also can be applied to anterior aneurysms. After opening the aneurysm (Fig. 30-11) and after debridement of thrombus and aneurysm wall (Fig. 30-12), a Dacron patch is cut to be 2 cm greater in diameter than the ventricular opening. Interrupted, pledgeted 0 monofilament horizontal mattress sutures are placed through the ventriculotomy rim and then through the patch, leaving the pledgets outside the ventricular cavity (Fig. 30-13). Sutures are tied, and additional interrupted sutures or a second layer of running 2-0 monofilament is placed for hemostasis.

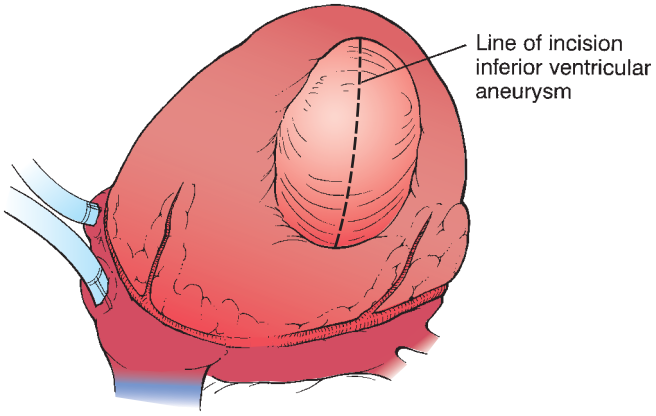

FIGURE 30-11 Circular patch repair. The aneurysm wall is incised. An inferior aneurysm is shown.

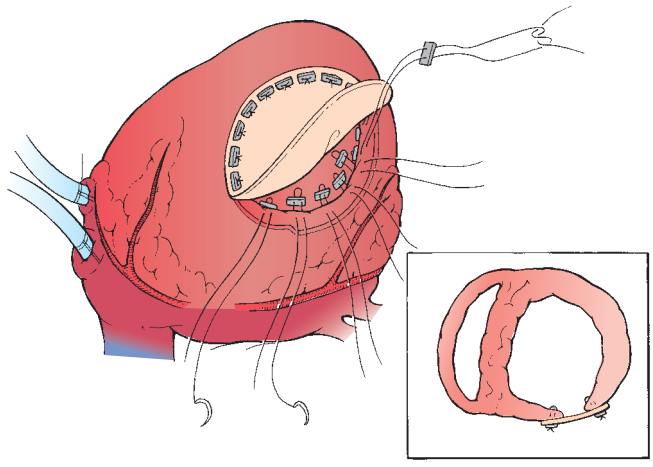

FIGURE 30-13 Circular patch repair. The aneurysmal defect is closed with a Dacron patch using interrupted 2-0 monofilament horizontal mattress sutures with reinforcing pledgets.

Endoventricular Patch

The endoventricular patch technique is suitable for anterior aneurysms but is less suited for inferior or posterior aneurysms, for which the standard (circular) patch technique is used. After debridement of thrombus, a running 2-0 polypropylene suture may be placed at the aneurysm rim to optimize left ventricular size.[4,17,50,55] Optimizing patch size and residual left ventricular cavity size can be facilitated with plastic or balloon forms (Chase Medical, Richardson, Texas) chosen to leave a left ventricular end-diastolic volume index of 50 to 60 mL/m^2.[58] If the remaining ventricular defect is small (<3 cm), then the ventricular wall may be closed linearly.[17] More commonly, a patch (bovine pericardium, Dacron cloth, or polytetrafluoroethylene) is cut to size sufficient to restore normal ventricular size and geometry when secured to the aneurysmal rim (Fig. 30-14). The patch is sutured to normal muscle at the aneurysmal circumference using a running 3-0 polypropylene suture that is secured with single sutures at three or four places around the patch circumference. The patch may extend onto the interventricular septum,[4,50,55] or aneurysmal septum may be plicated.[17] Interrupted 3-0 sutures are placed as needed to ensure good fit. Care is taken not to distort the papillary muscles. The aneurysmal rim is trimmed to allow primary closure of the native

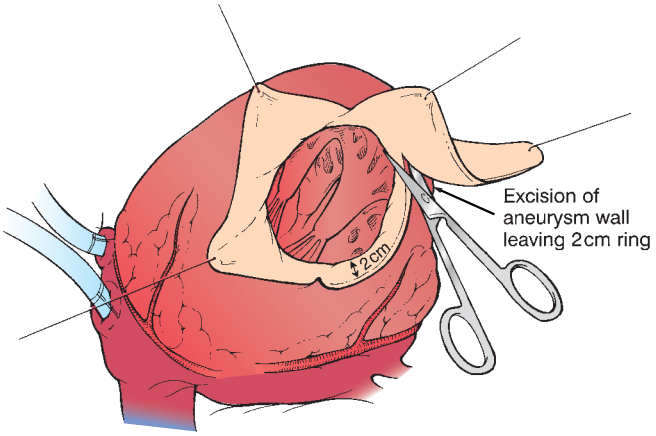

FIGURE 30-12 Circular patch repair. The aneurysmal wall is excised, leaving a 2-cm rim of fibrous aneurysmal wall attached to healthy muscle.

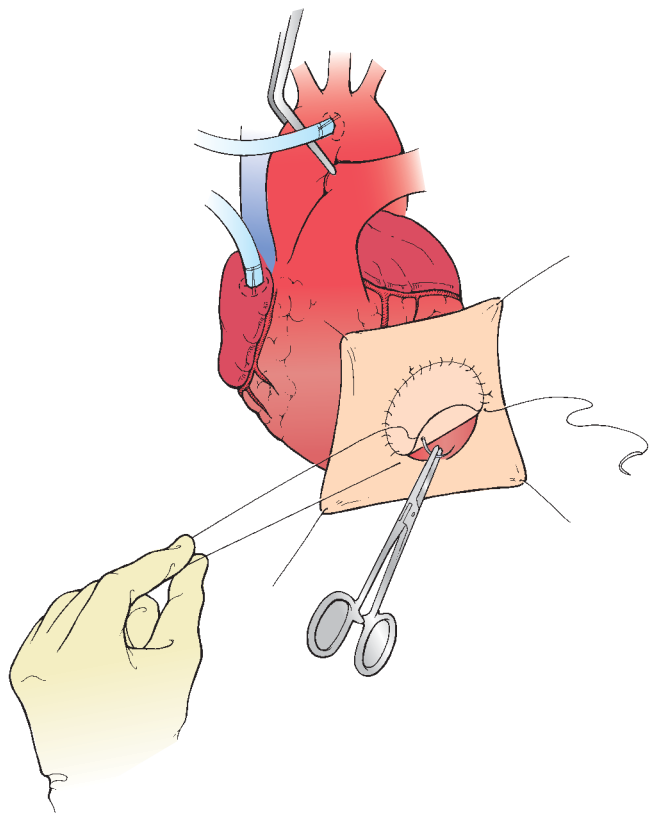

FIGURE 30-14 Endocardial patch. Without excising the aneurysm wall, the ventricular defect is closed with a Teflon felt patch using 3-0 polypropylene suture secured at three or four points along the suture line. Additional 3-0 pledgeted horizontal mattress sutures may be used to achieve hemostasis.

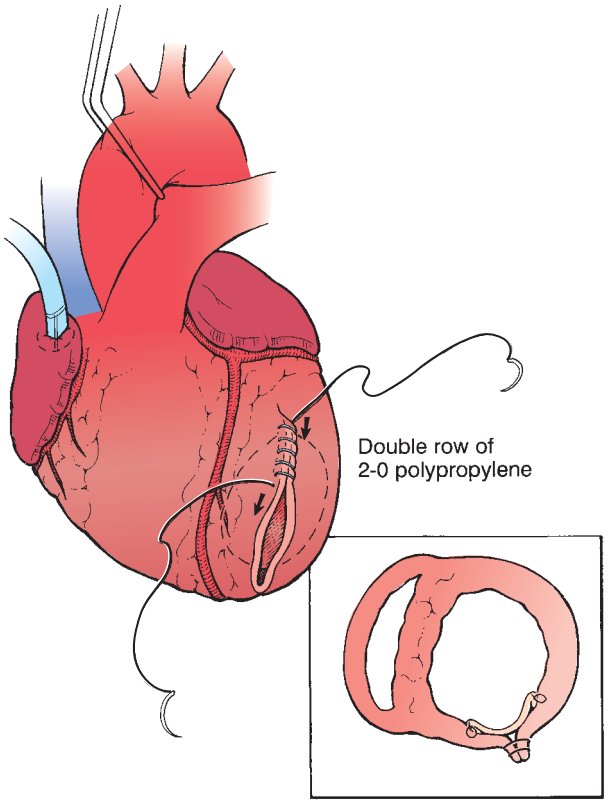

FIGURE 30-15 Endocardial patch. The aneurysm wall is closed over a Teflon patch after resecting excess aneurysm tissue. A double row of running vertical 2-0 polypropylene suture is used.

aneurysmal wall over the patch using two layers of running 2-0 monofilament suture without pledgets (Fig. 30-15).

Compared with linear and circular patch techniques, the endoventricular patch technique has technical advantages. An endoventricular patch preserves the left anterior descending artery for possible grafting and leaves no external prosthetic material to produce heavy pericardial adhesions. The technique facilitates patching the interventricular septum, and is suitable for acute infarctions when tissues are friable.[10,19,58,59]

Other Ventricular Remodeling Techniques

In addition to the techniques listed above where left ventricular infarct tissue is excised and/or replaced with patch material, an alternative would be to alter the biological properties of the infarct scar. Remaining infarct scar (whether aneurysmal or not) can then be seeded with myoblasts or stem cells which offer the potential to restore cardiac muscle mass and contraction. This technique has been termed *cellular cardiomyoplasty* and has been done only on a limited basis in humans.[60] In animals, cellular cardiomyoplasty has successfully improved global left ventricular performance and geometry using either myoblasts, stem cells that differentiate into myocytes, fibrocytes, or cells seeded onto a graft matrix.[61–63] Cellular cardiomyoplasty could be done by direct injection of cells at the time of coronary revascularization, or even by transcoronary or intramyocardial injection in the cardiac catheterization laboratory. Percutaneous insertion of a parachute-like device into the left ventricular apex has had some early success in humans in Europe (Cardiokinetix, Redwood City, CA).

Coronary Revascularization

Concurrent coronary revascularization is performed as in standard coronary bypass procedures. Because the endoventricular patch technique does not encroach on the left anterior descending coronary, the left internal mammary artery may be used to graft the left anterior descending coronary artery.

Mitral Regurgitation

The severity of mitral regurgitation should be evaluated before cardiopulmonary bypass by intraoperative transesophageal echocardiography. The need for concurrent mitral valve operation increases as the preoperative ejection fraction decreases (Fig 30-16).[64] The mitral valve is also inspected from below after opening the aneurysm and beginning repair of the aneurysm. Transventricular mitral valve repair may be done by placing pledgeted polypropylene sutures at both mitral commissures to reduce the circumference of the annulus.[57] This technique produces satisfactory short-term results, but long-term results are not known. Usually the mitral valve is repaired via left atriotomy after completion of the distal coronary anastomoses and before releasing the aortic cross-clamp. If mitral regurgitation results from annular dilatation and systolic restriction of leaflet motion (Carpentier type IIIB), an undersized, complete, rigid mitral annuloplasty is generally done.[65]

Cardiac Transplantation

In symptomatic patients with sufficient depression of global left ventricular function to preclude aneurysm repair, transplantation is a reasonable alternative and may have survival and

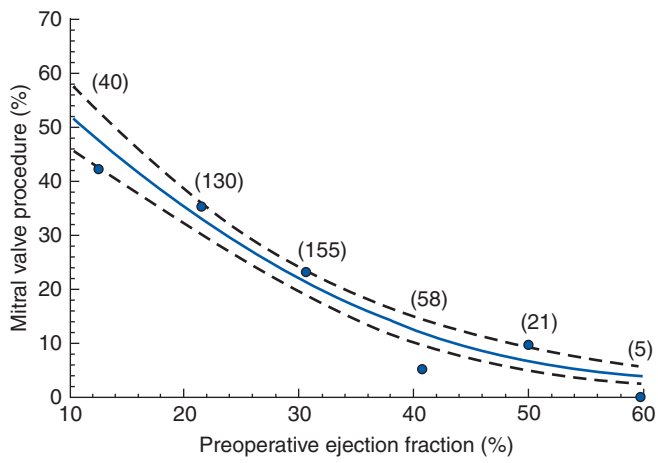

FIGURE 30-16 Prevalence of performing concomitant mitral valve procedures as a function of preoperative ejection fraction. (*Reproduced with permission from Athanasuleas CL, Stanley AWHJr, Buckberg GD, et al: Surgical anterior ventricular endocardial restoration [SAVER] in the dilated remodeled ventricle after anterior myocardial infarction. J Am Coll Cardiol 2001; 37:1199.*)

symptomatic benefit similar to ventricular aneurysm repair at a higher dollar cost.[66]

Ventricular False Aneurysm

Ventricular false aneurysms are repaired with the same techniques used for true ventricular aneurysms based according to the location and size of the aneurysm. The circular patch technique is particularly useful in that inferior false aneurysms are common and typically have narrow necks. Usually the wall of the false aneurysm is inadequate to close over the defect.

Ventricular Rupture

Any of the techniques described above may be used to manage a contained ventricular rupture. Because infarcted tissue is particularly friable 5 to 10 days after rupture, closure may be difficult. The endoventricular technique is particularly well suited for this uncommon operation because the patch can be sewn to the margins of healthy endocardium, which may be at some distance from the site of rupture. Patient survival also has been reported by gluing a biologic patch to the ventricular epicardium over the site of the rupture.

EARLY RESULTS

Hospital Mortality

In a compilation of 3439 operations for left ventricular aneurysm between 1972 and 1987[21] and in a series of 731 ventricular restoration patients from 2002 to 2004,[67] hospital mortality was 9.9 and 9.3% respectively and ranged from 2 to 19%. More recent reports suggest that hospital mortality can be as low as 3 to 7% using either patch[10,19,64,68,69] or linear closures.[22,53,69] The most common cause of hospital mortality is left ventricular failure, which occurs in 64% of deaths.[53]

Risk factors for hospital mortality include increased age,[21,53,64,67,69] incomplete revascularization,[53] increased heart failure class,[21,67,69–71] female gender,[21,67] emergent operation,[21] ejection fraction less than 20 to 30%,[64,69,70] concurrent mitral valve replacement,[10,21,64,67] preoperative cardiac index < 2.1 L/min/m^2,[5,67] mean pulmonary artery pressure >33 mmHg,[5] serum creatinine >1.8 mg/dl,[5] and failure to use the internal mammary artery.[71]

In-Hospital Complications

The most common in-hospital complications are shown in Table 30-3 and include low cardiac output, ventricular arrhythmias, and respiratory failure.[21,22,68,67,69,72] Low cardiac output may be more common in patients undergoing intraoperative mapping because of perioperative cardiac injury.[73]

Left Ventricular Function

The preponderance of data from the last two decades have shown that left ventricular function improves in most patients undergoing operation for left ventricular aneurysm. Operation improves ejection fraction whether linear repair[6,11,74–76] or patch repair[16,19,64,77–80] is used (Fig. 30-17). Both techniques decrease end-diastolic and end-systolic volumes[64,75,78,80] and improve exercise response[19,76] (Fig. 30-18). Aneurysmal repair in general may improve diastolic filling, left ventricular diastolic compliance, left ventricular contractility, effective arterial elastance (Ea), and left ventricular efficiency.[35,79–82] However, recent studies have suggested little improvement or even worsening of left ventricular diastolic compliance, particularly in patients with large resections or small ventricular size or without large dyskinetic aneurysms preoperatively.[83]

Controversy remains strong regarding whether patch techniques provide results superior to those achieved with linear closures. Stoney et al.[14,84] noted lower left ventricular end-diastolic pressure when more geometric reconstructions were performed. Hutchins and Brawley[85] first noted at autopsy that some patients had severe reduction and distortion of ventricular volume after linear repair. The authors proposed that a more geometric repair might avert these problems. Although no prospective studies compare results from the two procedures, several very experienced groups attribute improved symptoms, less low cardiac output, and greater improvement in ejection fraction to a switch to patch techniques.[10,19,86] In other retrospective

TABLE 30-3 In-Hospital Complications of Ventricular Aneurysm Repair

Low cardiac output 22–39%
Ventricular arrhythmias 9–19%
Respiratory failure 4–21%
Bleeding 4–7%
Dialysis-dependent renal failure 4%
Stroke 3–4%

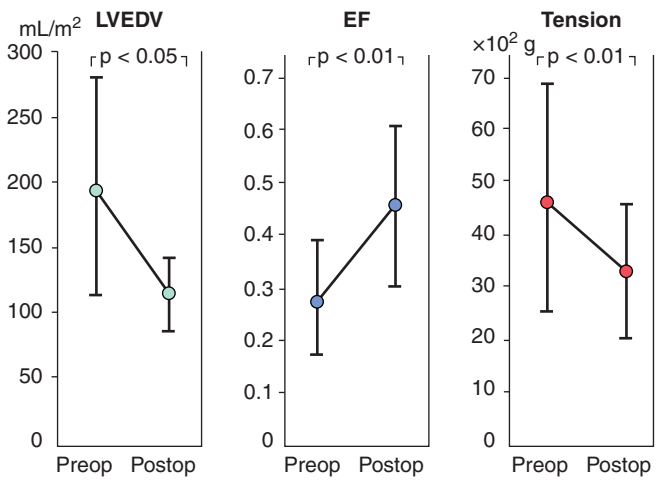

FIGURE 30-17 Effects of linear aneurysmectomy on left ventricular end-diastolic volume (LVEDV), ejection fraction (EF), and wall tension. (*Reproduced with permission from Kawachi K, Kitamura S, Kawata T, et al: Hemodynamic assessment during exercise after left ventricular aneurysmectomy. J Thorac Cardiovasc Surg 1994; 107:178.*)

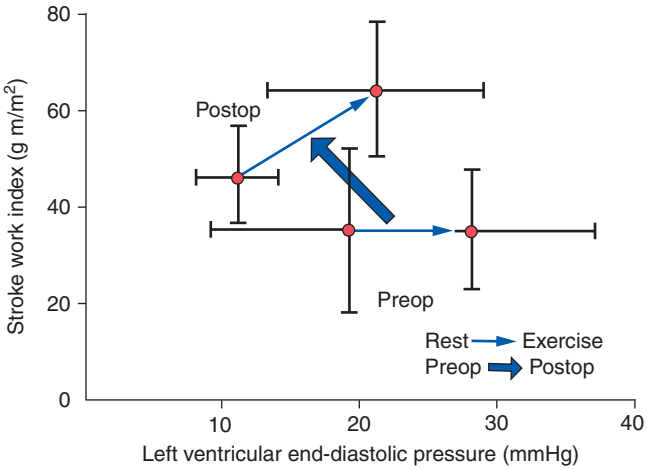

FIGURE 30-18 Relationship between stroke work index and left ventricular end-diastolic pressure. Data are shown at rest and during exercise before (preop) and after (postop) linear aneurysmectomy. Stroke work index increased only with exercise postoperatively. (*Reproduced with permission from Kawachi K, Kitamura S, Kawata T, et al: Hemodynamic assessment during exercise after left ventricular aneurysmectomy. J Thorac Cardiovasc Surg 1994; 107:178.*)

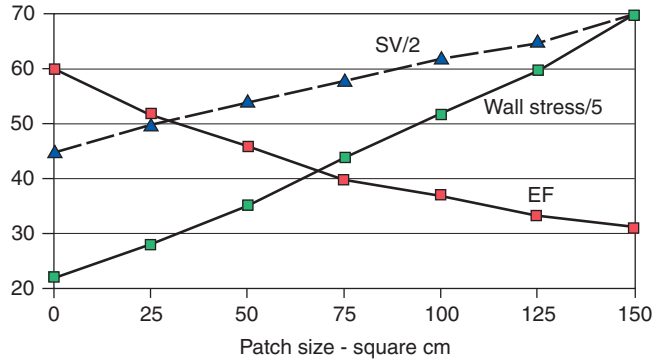

FIGURE 30-19 Computer prediction of the effects of patch size on stroke volume (SV), ejection fraction (EF), and wall stress (afterload) at a chamber pressure of 100 mm Hg. Predictions are based on data from an animal model of simulated aneurysm repair, neglecting the effects of afterload on stroke volume. Because increasing afterload in reality decreases muscle shortening, patch reconstruction can increase stroke volume only if contractile reserve is sufficient to overcome the afterload from increased ventricular size. (*Based on Nicolosi AC, Weng ZC, Detwiler PW, et al: Simulated left ventricular aneurysm and aneurysm repair in swine. J Thorac Cardiovasc Surg 1990; 100:745.*)

comparisons, no differences were seen in postoperative symptoms, ejection fraction, echocardiographic ventricular dimensions, or late survival between linear and patch repairs.[75,86–89] In an animal model of simulated aneurysm repair, Nicolosi et al.[83] found no difference in left ventricular systolic or diastolic function between linear and patch techniques. Two groups reported that switch to patch techniques was associated with increased operative mortality, perhaps because of excessive volume reduction, [90,91] whereas other groups found improved survival when switching from linear to patch techniques.[92] One meta-analysis has suggested that the better results with patch techniques are the result of more experience in more recent series.[86]

The durability of functional benefit from aneurysm repair remains poorly documented. In animals and humans, there is a tendency for the initial improvement in ejection fraction, ventricular volume, and filling pressures to diminish over the next 6 weeks to 12 months,[93,94] especially in patients with residual mitral regurgitation.

Although technical differences exist between patch and linear repairs, good functional results are possible with either technique. Suboptimal outcomes result from either technique when left ventricular cavitary volume is overly reduced with resultant decreased stroke volume and impaired diastolic filling.[85,94] Excessively small patches reduce stroke volume and impair diastolic filling, but excessively large patches reduce ejection fraction and increase wall stress (Fig. 30-19).

LATE RESULTS

Survival

Survival after operation for left ventricular aneurysm is variable, largely because of differences between patient populations. Five-year survival in recent series varies between 58 and 80%,[6,70] 10-year overall survival is 34%,[70] and 10-year cardiac survival is 57%[53] (Fig. 30-20). Cardiac causes are responsible for 57% of late deaths,[73] and most cardiac deaths result from new myocardial infarctions. In aneurysm patients randomized to medical or surgical therapy in the CASS study (most of the patients had minimal symptoms), survival was not different between medical or surgical therapy, except for patients with three-vessel disease.[45] These patients had better survival with surgery (Fig. 30-21).

Preoperative risk factors for late death include age, heart failure score, ejection fraction less than 35%, cardiomegaly on chest radiograph, left ventricular end-diastolic pressure greater than 20 mm Hg, and mitral regurgitation[45,53,73] (Fig. 30-22, Fig. 30-23).

The prospective, randomized STICH trial of 1000 patients with ejection fraction of 35% or less and anatomy amenable to ventricular restoration showed that, on average, left ventricular restoration techniques did not affect survival relative to coronary bypass grafting alone (see Fig 30-20).[7] The failure to see benefit in the STICH trial probably resulted from inclusion of relatively few patients with large, classical, dyskinetic aneurysms (mean reduction of end-systolic volume index of 16 mL/m^2 versus 48 mL/m^2 seen in classical aneurysms).[7,8] Although unproven, the net sum of evidence suggests that patients with large, classical, dyskinetic aneurysms probably obtain more benefit from aneurysm repair than do patients with diffuse ventricular dysfunction or small akinetic segments.[8]

SYMPTOMATIC IMPROVEMENT

Studies consistently demonstrate improvement in symptoms after operation relative to preoperative symptoms[6,74] (Fig. 30-24). In the study of Elefteriades et al.,[74] using a linear repair, mean angina class improved from 3.5 to 1.2 and mean CHF class

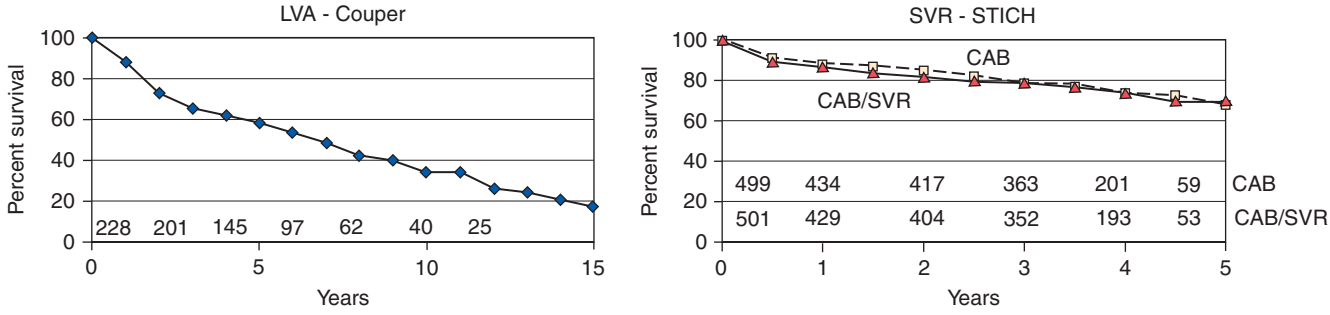

FIGURE 30-20 Survival in 303 patients undergoing left ventricular aneurysmectomy (LVA)(left panel). FIGURE 30-24 Preoperative (PRE) and latest follow-up (POST) symptoms of congestive heart failure (NYHA class) in patients undergoing coronary bypass alone (CABG) or CABG plus ventricular restoration (CABG/SVR) in the randomized STICH trial ($p = 0.7$ CABG versus CABG/SVR) (*Based on Jones RH, Velazquez EJ, Michler RE, et al: Coronary bypass surgery with or without surgical ventricular restoration. NEJM 2009; 360:1705.*)

improved from 3.0 to 1.7. In the randomized CASS study, the subset of patients with left ventricular aneurysm achieved a better heart failure class with surgical therapy than with medicine, and rehospitalization for heart failure was less common for the surgical therapy group than for the medicine group.[45] At 18 months, 85% of patients are free of rehospitalization for congestive heart failure, with rehospitalization peaking at 2 to 4 months.[64] Prucz found in a small, nonrandomized case-control study that ventricular restoration reduced hospitalization rate relative to coronary bypass alone.[95] However, the STICH trial found no benefit on average in symptoms or quality of life relative to coronary bypass alone.[7,96] (Fig 30-24) The STICH trial found that ventricular restoration significantly increased hospital cost by $14,500 or 26%.[96]

CHAPTER 31

Pathophysiology of Aortic Valve Disease

Craig M. Jarrett

Tomislav Mihaljevic

INTRODUCTION

The aortic valve (AV) is a semilunar valve positioned at the end of the left ventricular outflow tract (LVOT) between the left ventricle and aorta. Proper functioning of this valve is critical in maintaining efficient cardiac function. This chapter explores the anatomical and physiologic properties of the AV.

EMBRYOLOGIC DEVELOPMENT

Embryologic development of the AV is closely associated with development of the LVOT. In the primary heart tube, blood travels from the primitive ventricle into the bulbous cordis and out the aortic roots. The midportion of the bulbous cordis, the conus cordis, develops into the outflow tracts of the ventricles. The distal portion of the bulbous cordis, the truncus arteriosus (TA), develops into the proximal portion of the aorta and pulmonary arteries. During the fifth week of development, pairs of opposing swellings appear in the conus cordis and TA (Fig. 31-1). These conotruncal, or bulbar, ridges grow toward each other and fuse to form the aorticopulmonary (AP) septum. The AP septum divides the conus cordis into the left and right ventricular outflow tracts and the TA into the ascending aorta and pulmonary trunk.

When partitioning of the TA is nearly completed, the AV begins to develop from three swellings of subendocardial tissue (see Fig. 31-1). Two swellings arising from the fused truncal ridges develop into the right and left AV leaflets. A third dorsal swelling develops into the posterior leaflet. These swellings are reshaped and hollowed out to form the three thin-walled cusps of the fully developed AV. The pulmonary valve develops in a similar manner.

ANATOMY

The AV separates the terminal portion of the LVOT from the aorta. The normal AV consists of three semilunar leaflets or cusps projecting outward and upward into the lumen of the ascending aorta (Fig. 31-2). The space between the free edge of each leaflet and the points of attachment to the aorta comprise the sinuses of Valsalva. Because the coronary arteries arise from two of the three sinuses, the sinuses and the respective leaflets are named the right coronary, left coronary, and posterior (noncoronary) sinuses and leaflets. The ostia of coronary arteries arise from the upper part of the sinuses, with the ostium of the left coronary artery positioned slightly higher than the ostium of the right. The leaflets are separated from one another at the aorta by the right-left, right-posterior, and left-posterior commissures (Fig. 31-3). The area adjacent to the left-posterior commissure is the fibrous continuity, which interconnects the aorta and the mitral valve annulus. The area beneath this commissure is the aortomitral curtain, which is an important anatomical landmark for root enlargement procedures. The posterior leaflet attaches above the posterior diverticulum of the LVOT and opposes the right atrial wall. The right-posterior commissure is positioned directly above the penetrating atrioventricular bundle and membranous septum. The right-left commissure opposes the posterior commissure of the pulmonary valve and the two associated aortic cusps oppose the right ventricular infundibulum. The lateral part of the left coronary sinus is the only part of the AV that is not closely related to another cardiac chamber and is in direct relationship with the free pericardial space.

The AV leaflets meet centrally along a line of coaptation, at the center of which are the thickened nodules of Arantius.

Because of the semilunar shape of the leaflets, the AV does not have a true annulus in the traditional sense of a ringlike attachment. Instead, the leaflets have semilunar attachments along a hollow cylinder or cuff of tissue interconnecting the left ventricular (LV) chamber and the proximal aorta (Fig. 31-4).[1] The distal border of the cuff is the sinotubular junction, which is defined by imaginary lines connecting the commissures. The proximal border is the ventriculoarterial (VA) junction, which has both hemodynamic and anatomic parts. The hemodynamic VA junction is marked by the semilunar attachments of the leaflets, whereas, the anatomic VA junction is marked by the circular attachment of the proximal aorta and the muscular and membranous ventricular septums.

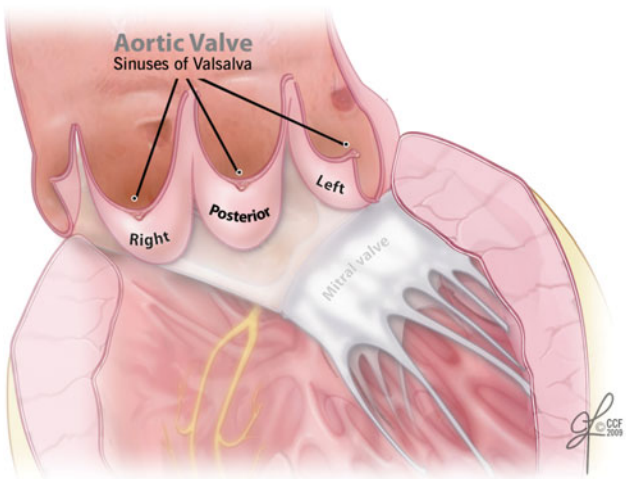

FIGURE 31-2 Anatomical relationship between the aortic valve leaflets and surrounding structures. (*Reproduced with permission of the Cleveland Clinic, Cleveland, OH.*)

The valve leaflets consist of three layers of endothelially invested connective tissue of distinctly different density and composition. There is no demarcation between the outer layers of the aortic and ventricular sides of the leaflets and outer layers of the corresponding aortic and ventricular walls; that is, leaflet endothelial cells form a continuum with aortic and ventricular endothelial cells (Fig. 31-5).[2,3] Endothelial cells of both the aortic and ventricular surfaces of the AV are arranged circumferentially. Beneath the endothelium, there are extensions of the aortic intima and ventricular endocardium, termed the *arterialis* and *ventricularis,* respectively. The next layer is the lamina fibrosa, which is composed of dense collagen mostly in a circumferential pattern. Because of the thickness and density of this layer, it is the strongest layer and important for bearing the stress of diastolic pressure. The middle layer, referred to as the *spongiosa,* forms the core of the leaflets at

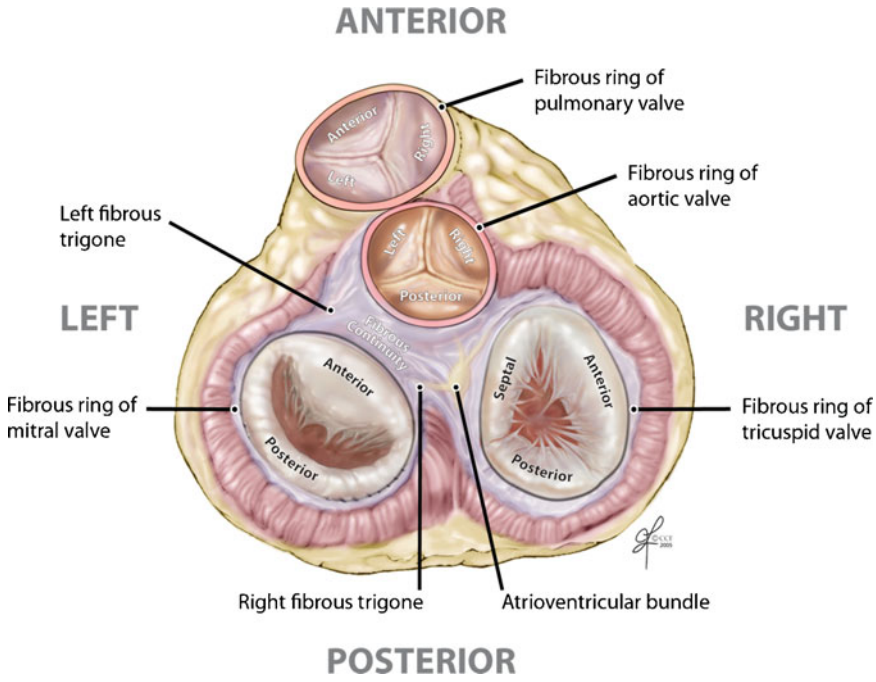

FIGURE 31-3 Anatomical relationship between the aortic valve and surrounding structures. (*Reproduced with permission of the Cleveland Clinic, Cleveland, OH.*)

their bases. It is made of loose connective tissue consisting of water and glycosaminoglycans with sparse fibers and cellularity. The semifluid nature of this layer gives the leaflet considerable plasticity.

MECHANICS OF MOVEMENT

The AV passively opens and closes in response to pressure differences between the left ventricle and aorta during the cardiac cycle. Pressure generated from ventricular contraction leads to valve opening, and the subsequent relatively higher pressure of the aorta leads to valve closure. The mechanical properties of the AV allow it to open with minimal transvalvular gradient and close completely with minimal flow reversal.

Opening

Pressure differences between the aorta and the ventricle coupled with compliance of the aortic root cause aortic root dilation and constriction during the cardiac cycle. This dynamic

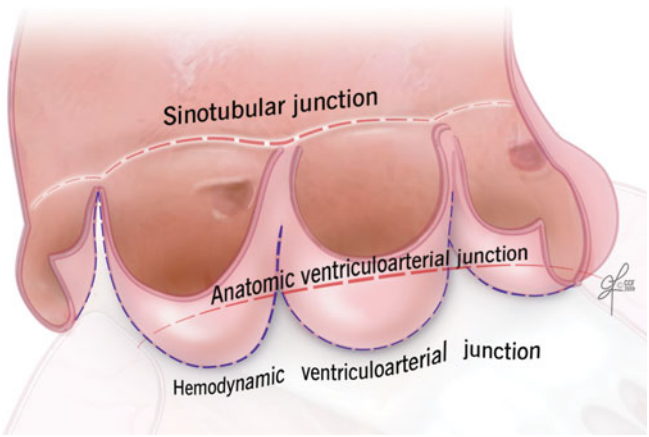

FIGURE 31-4 Schematic representation of the aortic valve cuff. The sinotubular junction marks the distal border. The ventriculoarterial junction, which has both hemodynamic and anatomic parts, marks the proximal border. (*Reproduced with permission of the Cleveland Clinic, Cleveland, OH.*)

motion of the root plays an important role in opening and closure of the AV. During late diastole, as blood fills the ventricle, a 12% expansion of the aortic root occurs 20 to 40 msec before AV opening.[4,5] The leaflets begin to open as a result of root dilation even before any generation of positive pressure from ventricular contraction. Root dilation alone opens the leaflets about 20%.[6] As pressure rises in the LVOT, tension across the leaflets produced from root dilation lessens. As pressure continues to rise, the pressure difference across the leaflets is minimal, and no tension is present within the leaflet.[4] This loss of tension allows the aortic root to further dilate and allows the valve to open rapidly at the beginning of ejection. Under normal circumstances, the AV presents little or no obstruction to flow because the specific gravity of the leaflets is equal to that of blood.[7] These mechanisms permit rapid opening of the valve and minimal resistance to ejection.[8]

Closure

Closure of the AV is an elegant mechanism, which has interested investigators since the time of Leonardo da Vinci.[9] A principal theory involved in closure is vortex theory, which recognizes the importance of the sinuses of Valsalva in valve closure.[10] As ejection occurs, blood creates small eddy currents or vortices along the aortic wall. At the end of ejection and before valve closure, these vortices fill the sinuses and balloon the leaflets away from the aortic wall toward the aortic axis. After the pressure difference across the open AV equalizes, a small flow reversal forces the leaflets completely closed. Apposition of the valve leaflets occurs briskly and the ensuing second heart sound occurs after complete closure of the AV. Upon closing, the elastic leaflets stretch and recoil to generate compression and expansion of blood. The subsequent pressure changes produce the second heart sound; the sound is not produced by physical apposition of the valve leaflets.[11]

AORTIC STENOSIS

Aortic stenosis (AS) is incomplete opening of the AV, which restricts blood flow out of the left ventricle during systole.

Prevalence and Etiology

In developed countries, AS is the most prevalent valvular heart disease in adults. Observational echocardiography studies demonstrate that 2% of people 65 years of age or older have isolated calcific AS, whereas 29% exhibit age-related AV sclerosis without stenosis.[12] AS is more common in men and prevalence increases with age. In patients aged 65 to 75 years, 75 to 85 years, and greater than 85 years, the prevalence of AS is 1.3, 2.4, and 4%, respectively.[13] The most common causes of AS are acquired degenerative disease, bicuspid AV, and rheumatic heart disease.

Acquired Aortic Stenosis

The most common cause of AS is degenerative calcification of the AV, which typically occurs in septuagenarians and octogenarians. Progressive calcification, initially along the flexion lines at the leaflet bases, leads to immobilization of the cusps. The characteristic pathologic findings are discrete, focal lesions on the aortic side of the leaflets that can extend deep into the aortic annulus. The deposits may involve the sinuses of Valsalva and the ascending aorta. Although long considered to be the result of years of mechanical stress on an otherwise normal valve, it is now understood that the mechanical stress leads to proliferative and inflammatory changes, with lipid accumulation, upregulation of angiotensin-converting enzyme (ACE) activity, and infiltration of macrophages and T lymphocytes in a process similar to atherosclerosis.[13–18] The risk factors for the development of calcific AS are also similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein (LDL) cholesterol, diabetes, smoking, and hypertension.[13] Therefore, coronary artery disease is commonly present in patients with AS. Age-related AV sclerosis is associated with an increased risk of cardiovascular death and myocardial infarction (MI).

Calcific AS is also observed in a number of other conditions, including Paget's disease of bone and end-stage renal disease.[19] Ochronosis with alkaptonuria is another rare cause of AS, which also can cause a rare greenish discoloration of the AV.[20]

Bicuspid Aortic Stenosis

A calcified bicuspid AV represents the most common form of congenital AS. Bicuspid AVs are present in approximately 2% of the general population. Gradual calcification of the bicuspid AV results in significant stenosis most often in the fifth and sixth decades of life, earlier in unicommissural than in bicuspid valves and earlier in men than women. The abnormal architecture of the unicommissural or bicuspid AV induces turbulent flow, which injures the leaflets and leads to fibrosis, increased rigidity, leaflet calcification, and narrowing of the AV orifice.[21] Bicuspid valves are often associated with dilatation of the ascending aorta related to accelerated degeneration of the aortic media that in some cases may progress to aneurysm formation. Recent work suggests that a DNA transcriptional error in the gene encoding endothelial nitric oxide synthetase may be implicated in the genetic abnormality that leads to bicuspid AV.[22] It appears that the microfibrils within the AV and the aortic root are defective in structure in patients with bicuspid AV disease. This leads to a decrease in mechanical support for the valve, thereby contributing to accelerated "wear and tear," and hence degenerative changes in the valve matrix.

Rheumatic Aortic Stenosis

In Western countries, rheumatic AS represents the least common form of AS in adults.[23] Rheumatic AS is rarely an isolated disease and usually occurs in conjunction with mitral valve stenosis.[24] Rheumatic AS is characterized by diffuse fibrous leaflet thickening with fusion, to a variable extent, of one or more commissures. The early stage of rheumatic AS is characterized by edema, lymphocytic infiltration, and revascularization of the leaflets, whereas the later stages are characterized by thickening, commissural fusion, and scarred leaflet edges.[25]

Pathophysiology

In adults with calcific disease, the AV slowly thickens over time. Early, it causes little hemodynamic disturbance as the valve area is reduced from the normal 3 to 4 cm^2 to 1.5 to 2 cm^2.[13] Past this point, hemodynamically significant obstruction of LV outflow develops with a concomitant increase in LV pressure and lengthening of the LV ejection time. The elevated LV pressure increases wall stress. Wall stress is normalized by increased wall thickness and LV hypertrophy (LVH). As it hypertrophies, the left ventricle becomes less compliant and LV end-diastolic pressure (LVEDP) increases without chamber dilatation. This reflects diastolic dysfunction and the ventricle becomes increasingly dependent on atrial systole for filling.[26] Hence, if a patient develops an atrial arrhythmia, he or she can rapidly decompensate.

Although adaptive, the concentric hypertrophy that develops has adverse consequences. LVH, increased systolic pressure, and prolonged ejection time all contribute to an increase in myocardial oxygen consumption. Increased diastolic pressure increases endocardial compression of the coronary arteries, reducing coronary flow reserve (or maximal coronary flow).[27] Prolonged ejection also results in decreased time in diastole and therefore reduced myocardial perfusion time. The increased demand of the hypertrophied ventricle and decreased delivery capacity can yield subendocardial ischemia with activity. This can result in angina and LV dysfunction. LVH also makes the heart more susceptible to ischemic injury. Severe LVH is only partly reversed by AV replacement (AVR) and is associated with decreased long-term survival even after initially successful surgery.[28]

In late stages of severe AS, the left ventricle decompensates with resulting dilated cardiomyopathy and heart failure. Cardiac output (CO) declines and the pulmonary artery pressure rises, leading to pulmonary hypertension.

Myocardial hypertrophy in patients with AS is characterized by increased gene expression for collagen I and II, and fibronectin that is associated with activation of the renin-angiotensin system.[22] Reduction in renin-angiotensin parallels regression of hypertrophy after AVR.[29] Experimental studies have indicated a role of apoptotic mechanisms in the progression to LVH and heart failure in patients with AS.[30] For 50% of patients who present with symptoms of congestive heart failure (CHF), mean survival is less than 1 year.[31]

Hemodynamics

The severity of AS can be assessed by measuring the AV orifice area (AVA), mean pressure gradient, and peak jet velocity. AVA is calculated by using CO, heart rate (HR), systolic ejection period (SEP), and mean pressure gradient in the Gorlin formula, which describes the fundamental relationships linking the area of an orifice to the flow and pressure drop across the orifice. The Gorlin formula is:

$$\text{AVA} = \frac{\text{CO}\left(\frac{\text{mL}}{\text{min}}\right)}{44.3 \times \text{HR}\left(\frac{\text{beats}}{\text{min}}\right) \times \text{SEP(sec)} \times \sqrt{\text{mean pressure gradient (mmHg)}}}$$

CO can be measured using the Fick or thermodilution technique. SEP is the time from AV opening to closure. The normal AVA is 2.6 to 3.5 cm^2 in adults. Valve areas of less than 1.0 cm^2 represent severe AS. In low-output states, the Gorlin formula may systematically predict smaller valve areas than are actually present. Several reports also indicate that the AVA from the Gorlin formula increases with increases in CO.[32]

In patients with AS, the transvalvular pressure gradient can be measured by simultaneous catheter pressure measurements in the left ventricle and proximal aorta. The peak-to-peak gradient, measured as the difference between peak LV pressure and peak aortic pressure, is used commonly to quantify the valve gradient.

Invasive measurements of AS severity have been largely replaced by echocardiographic measurements, which are currently the clinical standard. The Doppler acquired jet velocity is converted to a gradient using the Bernoulli equation, which is:

$$\text{Gradient} = 4 \times (\text{velocity})^2$$

Transesophageal echocardiography (TEE) is an alternative method for assessment of AVA that uses planimetry of the systolic short-axis view of the AV (Fig. 31-6).[33] Planimetry of the valve area is challenging because the valve orifice is a complex, three-dimensional shape, and area measurements assume the valve orifice lies entirely within the image plane.

Clinical Presentation

Symptoms

The cardinal symptoms of AS are angina pectoris, syncope, and symptoms of CHF (dyspnea, orthopnea, and paroxysmal nocturnal dyspnea).[34] Although the mechanisms of angina and heart failure are well understood, the mechanism of syncope is less clear. A common theory is that the augmented stroke volume that usually accompanies exercise is limited by the narrowed outflow orifice. With exercise-induced reduction in peripheral

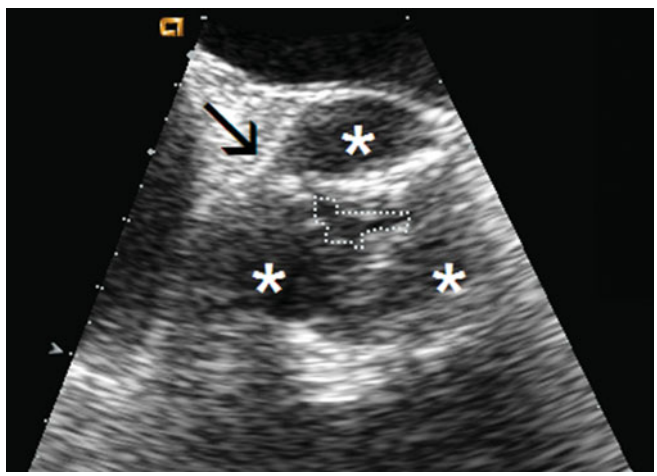

FIGURE 31-6 Transesophageal echocardiographic image of aortic stenosis resulting from severe degenerative calcification. arterial resistance, blood pressure drops, leading to cerebral hypoperfusion and syncope.[35] Syncope also may be the result of dysfunction of baroreceptor mechanisms and a vasodepressor response to the increased LV systolic pressure during exercise. Besides these cardinal symptoms, patients also commonly present with more subtle symptoms, such as fatigue, decreased exercise tolerance, and dyspnea on exertion.[36]

Another rare presentation of AS is gastrointestinal bleeding secondary to angiodysplasia occurring predominantly in the right colon as well as the small bowel or stomach. This complication arises from shear-stress–induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor and increases in proteolytic subunit fragments. These abnormalities correlate with the severity of AS and are correctable by AVR.[37] Other late manifestations of severe AS include atrial fibrillation and pulmonary hypertension. Infective endocarditis can occur in younger patients with AS; it is less common in elderly patients with a severely calcified valve.

Patients who develop severe AS have a long period of asymptomatic progression in which morbidity and mortality is relatively low (Fig. 31-7). Sudden death from AS before the onset of symptoms is estimated to be approximately 1% per year.[38] With the onset of symptoms, survival is dramatically reduced without surgical intervention. Of the 35% of patients who present with angina, 50% survive for 5 years. Of the 15% who present with syncope, 50% survive for 3 years, and mean survival for those who present with CHF is 2 years.[34]

Signs

AS is frequently first diagnosed before symptom onset by auscultation of a murmur on physical exam. Classically, AS causes a systolic crescendo-decrescendo murmur, heard loudest at the right upper sternal border. Another sign of AS is a delayed second heart sound (S_2) because of prolongation of the systolic ejection time. S_2 also may be single when the aortic component is absent, and if the aortic component is audible, this may give rise to a paradoxical splitting of S_2.

The classic pulsus parvus (small pulse) is a sign of severe AS or decompensated AS and occurs when stroke volume and systolic and pulse pressures fall. A wide pulse pressure is also characteristic of AS. Prolongation of the ejection phase with slow rise in the arterial pressure also gives rise to the pulsus tardus (late pulse). Pulsus parvus et tardus is diagnosed by palpation.

LVH is evident as a sustained apical thrust or heave. This sign is present only when failure occurs because until failure occurs, the hypertrophy is not accompanied by dilatation, and the apical impulse is not displaced. Conversely, absence of an apical thrust (except in muscular patients, or those with emphysema or adiposity) suggests mild or moderate AS. Other physical findings of significant AS include a prominent atrial kick and prominence of the jugular venous *a* wave secondary to decreased right ventricular compliance caused by right ventricular hypertrophy.[39]

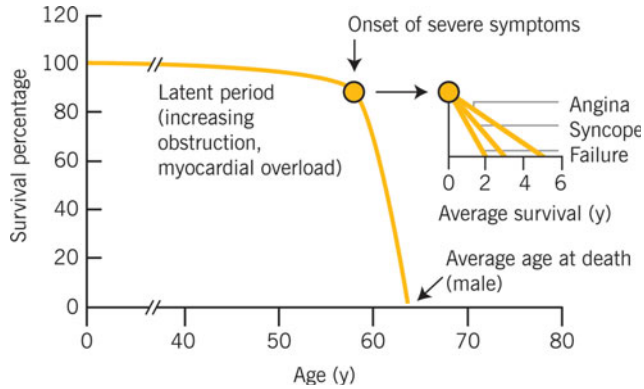

FIGURE 31-7 Natural history of aortic stenosis. (*From Ross J, Braunwald E. Aortic stenosis. Circulation 1968; 38(suppl 5): 61-67.*)

Electrocardiogram

Most patients with severe AS present with QRS complex or ST-T interval abnormalities reflecting LVH. Patients with a higher gradient are more likely to show a "strain" or "systolic overload" pattern. The conduction abnormalities may result from septal trauma secondary to high intramyocardial tension from hypoxic damage to the conducting fibers or from extension of valvular calcifications into the fibrous septum.

Roentgenogram

The roentgenographic characteristics of compensated AS include concentric hypertrophy of the left ventricle without cardiomegaly, poststenotic dilatation of the aorta, and calcification of the valve cusps. With decompensation, there is cardiomegaly in the posteroanterior projection and pulmonary venous congestion. It is important to recognize that a routine chest x-ray may be within normal limits in patients with hemodynamically compensated AS. The rounding of the lower-left heart border may be subtle, the poststenotic aortic dilatation may be equivocal, and the valvular calcification may be invisible on the posteroanterior view. Of equal importance, the presence of cardiomegaly in a normotensive patient with isolated AS indicates decompensated AS.

Echocardiography

Echocardiography is the diagnostic tool of choice for confirming the diagnosis of AS and quantification of disease severity. Echocardiography is used to define: (1) the severity and etiology of AS; (2) coexisting valvular abnormalities; and (3) cardiac chamber size and function.

The development of diastolic dysfunction in patients with AS can lead to symptom development, and may increase late mortality after AVR.[28,40] Hence, the quantification of diastolic dysfunction is important in the assessment of AS. LV filling pressures can be assessed by combining transmitral flow velocity and annular velocity obtained at the level of the mitral annulus with tissue Doppler (E/E').[41] In patients with normal LV function (LVF), stress echocardiography is used to determine if symptom development during exercise is due to diastolic dysfunction.[42] Diastolic dysfunction in patients with normal LVF may cause exercise intolerance for several reasons: (1) elevated LV diastolic and pulmonary venous pressures increase the work of breathing and cause dyspnea; (2) patients with LVH exhibit

a limited ability to use the Frank-Starling mechanism during exercise, resulting in a decrease in CO during exercise; and (3) elevated LV diastolic and pulmonary venous pressures result in abnormalities in the diastolic properties of the ventricle.

When AS is suspected, an initial Doppler echocardiogram can confirm the diagnosis and assess the severity. Periodic reexamination, every 5 years for mild AS, every 2 years for moderate AS, and annually for severe AS, is recommended to identify worsening stenosis, LV dysfunction, LVH, and mitral regurgitation.[43] Although AS is best understood as a disease continuum, severity can be graded by echocardiographic evaluation of hemodynamics. The current guidelines use definitions based on the AVA, mean pressure gradient, and peak jet velocity (Table 31-1).

Exercise Testing

Traditionally, severe AS has been regarded as a relative contraindication to exercise testing. Exercise testing should be avoided in symptomatic patients with AS as well. Recent studies have indicated that quantitative exercise Doppler echocardiography can be performed safely in asymptomatic patients and may be useful for identifying patients who at higher risk of becoming symptomatic and/or requiring AVR. Several studies have shown that asymptomatic patients with severe AS who become symptomatic on exercise stress testing, have a higher rate of cardiac death or progression to AVR.[44,45] Dobutamine stress echocardiography is occasionally used in severe AS, specifically to assess contractile reserve in patients with moderate to severe AS with a low AV gradient and depressed LVF.[46,47]

TABLE 31-1 Classification of Aortic Stenosis Severity

Indicator	Mild	Moderate	Severe
Aortic valve area (cm^2)	>1.5	1.0–1.5	<1.0
Aortic valve area index (cm^2 per m^2)			<0.6
Mean pressure gradient (mm Hg)	<25	25–40	>40
Peak jet velocity (m/sec)	<3.0	3.0–4.0	>4.0

Endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. J Am Coll Cardiol 2008; 52(13):e1-142.

Cardiac Catheterization

Although Doppler echocardiography is well validated, cardiac catheterization remains the gold standard for measuring the transvalvular gradient. Because coronary artery disease is common in patients with AS, coronary angiography is usually performed in patients with severe AS to assess coronary anatomy and evaluate the need for combined AVR and myocardial revascularization. Right-sided heart catheterization is also used to calculate the AVA based on the Gorlin equation, as described earlier. Cardiac catheterization can also provide an assessment of ejection fraction (EF) through ventriculography and also may provide information about the presence or absence of other valve lesions.

Computed Tomography

Computed tomography (CT) can be used to assess progression of AS. Electrocardiographically gated multidetector row CT has shown high accuracy and reproducibility in quantifying AV calcification and its progression[48] and estimating AVA by planimetry.[49] The quantification of calcification may develop into clinical applications with respect to the prognostic relevance of AV sclerosis, as well as the problem of calcification of bioprostheses after surgery.

Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (MRI) has emerged as an alternative noninvasive imaging modality for AS.[50] Similar to echocardiography, cardiac MRI records images throughout the cardiac cycle. Cardiac MRI uses a range of pulse sequences to assess structural heart disease. The steady-state free precession (SSFP) cine pulse sequence is commonly used in cardiac MRI and provides detailed images of AV leaflet number, leaflet thickening, valve calcification, and commissural fusion. This sequence is also useful for assessing the effects of AS, including LVH and LVF.[51] MRI is useful when acoustic windows in the echocardiogram are poor or there are discordant imaging and catheterization results.[52,53] MRI has also been used to demonstrate improvement in LVF, myocardial metabolism, and diastolic function, as well as reduced hypertrophy after AVR for AS.[54]

Management

Symptomatic Patients

There is no effective medical therapy for AS. Given the biologic similarity of the calcific lesions of AS to atherosclerosis, there has been substantial effort to investigate the role of lipid-lowering agents in slowing the progression of AS, but to date prospective randomized trials have not found any benefit.[55,56] Prophylactic antibiotics are recommended before any dental or surgical procedures as a prevention strategy for endocarditis.[43] Management of CHF from AS has traditionally consisted of diuretics and ionotropes. Beta-blockers are avoided as reduced inotropy may lead to decreased CO in an overloaded ventricle. Classically, vasodilators are avoided in AS because their administration can lead to hypotension, syncope, and reduced coronary perfusion.

Percutaneous balloon valvuloplasty (valvotomy) is effective in congenital AS, but in adults the valve tends to re-stenose, and the procedure has no effect on long-term mortality.[17] Currently, valvuloplasty is recommended only as a possible bridge to surgical intervention or a palliative measure.[43] AV repair for AS has yielded poor results compared with AVR.[57]

The definitive treatment for severe AS is AVR, and onset of symptoms is the primary indication for AVR. As the risk of asymptomatic severe AS is perceived to be low, symptom onset remains the primary indication. Survival after successful AVR is reduced in younger patients but mimics that of the normal population in older patients.[28,58,59]

Percutaneous AVR represents a novel, less invasive approach to the treatment of AS. This approach has been applied successfully in high-risk patients with severe symptomatic AS who were not deemed candidates for conventional surgery.[60]

Asymptomatic Patients

AVR in asymptomatic patients is currently controversial. Current guidelines recommend AVR for patients with symptomatic AS, for patients with asymptomatic moderate or severe AS who also require coronary revascularization or surgery of the aorta, and for patients with severe AS and reduced EF.[43] As AVR has become a safer procedure and technology for assessing disease severity has improved, it is likely that an identifiable high-risk subset of asymptomatic patients with severe AS could benefit from AVR. Studies show that asymptomatic patients with an aortic jet velocity greater than 4 m/sec,[36] patients with high rates of aortic jet velocity progression and valve calcification,[61] and those with small AVAs and LVH[38] progress to symptom development quickly and will soon require AVR. Exercise stress testing, as described earlier, is also useful to stratify high-risk patients.

A number of recent studies have explored the potential benefit of AVR in asymptomatic patients. In studies of propensity matched cohorts of asymptomatic patients with severe AS, those who had AVR had significantly improved survival.[62,63] It has also been shown that, among patients undergoing AVR for severe AS, LVH is only partly reversed and is associated with decreased long-term survival even after initially successful surgery. This suggests that intervening before development of LVH may improve outcomes.[28] In summary, there is increasing evidence that AVR can be beneficial in a subset of asymptomatic patients with severe AS.

AORTIC REGURGITATION

Aortic regurgitation (AR) is the diastolic reflux of blood from the aorta into the left ventricle due to failure of coaptation of the valve leaflets at the onset of diastole.

Prevalence and Etiology

AR has numerous causes, which can be grouped according to the structural components of the valve apparatus affected. AR may be caused by primary disease of the aortic leaflets and/or disease of the aortic root.

Aortic leaflet calcific degeneration, myxomatous degeneration, infective endocarditis, rheumatic disease, a bicuspid AV, and anorectic medications, such as fenfluramine and phentermine, all lead to distortion of the valve leaflets and prevent proper coaptation.[64–67] Aortic root dilatation caused by aortic dissection; trauma; chronic systemic hypertension; aortitis from syphilis, viral syndromes, or other systemic arteritides (eg, giant cell and Takayasu); and connective tissue disorders, such as Marfan's syndrome, Reiter's disease, Ehlers-Danlos syndrome, osteogenesis imperfecta, and rheumatoid arthritis, leads to improper leaflet coaptation and consequent AR.[68–73] AR is seen most commonly in combination with AS due to calcific or rheumatic disease in which some degree (usually mild) of AR is present in the vast majority of patients. However, AR secondary to aortic dilation is now more common than primary valve disease in patients undergoing AVR for pure AR.[74]

Pathophysiology

The pathophysiology of AR varies according to the onset and duration of the disease process.

Acute Aortic Regurgitation

AR that presents in the acute setting is typically caused by aortic dissection, endocarditis, or trauma. By definition, acute AR is a significant aortic incompetence of sudden onset across a previously competent AV. The blood returned to the left ventricle in diastole causes a sudden increase in LV end-diastolic volume (LVEDV) and reduces the effective or forward stroke volume. LVEDV only increases mildly (20 to 30%) because the ability of the left ventricle to dilate acutely is limited. This leads to a rapid increase in LVEDP. This increase is greatest in the less compliant, concentrically thickened, hypertrophic myocardium seen in those with AS or chronic systemic hypertension. Increased LVEDP results in increased mean LA and pulmonary venous pressures and produces varying degrees of pulmonary edema.[75] The rapid rise in LVEDP also blunts or abolishes the normally widened pulse pressure seen in chronic AR.[76] In the acute setting, two compensatory mechanisms attempt to maintain an effective CO: an increase in contractility attributable to the Frank-Starling mechanism and an increase in HR. The maintenance of an appropriate effective CO depends on the adequacy of these mechanisms, especially systolic pump function.

Chronic Aortic Regurgitation

In contrast, chronic AR is a slow, insidious process, which sets in motion numerous compensatory mechanisms. The diastolic regurgitant flow in AR increases LVEDV, LVEDP, and wall stress. Adaptive signals lead to an increase in myocyte length and addition of sarcomeres in series in a pattern of remodeling known as *eccentric hypertrophy*. Typically there is a modest increase in LV wall thickness such that the ratio of wall thickness to radius is close to normal. Chamber enlargement in the setting of normal systolic function increases total stroke volume and maintains forward stroke volume (total stroke volume minus regurgitant volume).[77] The increased total stroke volume coupled with a normal to slightly elevated LVEDP is responsible

for the wide pulse pressure seen in chronic AR. Forward stroke volume in AR is increased by any physiologic change that decreases afterload or increases HR. Increasing HR increases forward stroke volume by itself, but it also decreases diastolic filling time and hence regurgitant flow time and volume. The peripheral vasodilatation and increased HR that accompany exercise increase forward stroke volume in this manner.[78] This also illustrates the physiologic basis for vasodilator therapy in the treatment of AR, and explains why bradycardia and use of negative chronotropic agents should be avoided.

As AR progresses, the hypertrophic response becomes inadequate,[79] and/or the preload reserve is eventually exhausted.[80] Thereafter, any further increase in afterload creates afterload mismatch and results in a reduction in EF. Although the hypertrophied myocardium may provide adequate compensation for many years, eventually maladaptive signals, which lead to decreased myocyte survival and fibrosis, predominate. The myocardium becomes incapable of sustaining the increased work load imposed upon it and heart failure ensues.

Myocardial ischemia in AR, which can result from both decreased coronary artery perfusion and increased myocardial oxygen demand, may lead to further impairment of LVF. The decrease in diastolic coronary perfusion that occurs with a severe reduction in aortic diastolic pressure is only partially compensated by increased coronary arterial flow during systole. In severe AR, there may even be reversal of coronary arterial flow. Superimposed CAD only exacerbates the effect of decreased diastolic coronary perfusion pressure. On the other hand, increased LV muscle mass, wall tension, and systolic ventricular pressure all contribute to increased myocardial oxygen demand. The subsequent ischemia caused by decreased perfusion and increased oxygen demand can lead to cell death and fibrosis, and chronically, can contribute to systolic dysfunction.

Clinical Presentation

Symptoms

The presentation varies depending on the acuity of onset, severity of regurgitation, compliance of the ventricle and aorta, and hemodynamic conditions present at the time. Acute AR can be debilitating and life threatening if not treated emergently, whereas chronic AR is usually well tolerated for years. Severe acute AR commonly presents catastrophically with sudden cardiovascular collapse. Patients also often present with ischemic chest pain caused by decreased coronary blood flow coupled with rapidly increased myocardial oxygen consumption.

Patients with chronic, compensated AR remain asymptomatic for prolonged periods of time while the left ventricle gradually enlarges. Symptoms of heart failure, such as exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, usually develop gradually only after considerable ventricular hypertrophy and decompensation. Patients with severe AR may experience palpitations during emotional stress or exertion; an uncomfortable awareness of each heartbeat, especially at the ventricular apex; angina pectoris; nocturnal angina; or atypical chest pain syndromes, such as thoracic pain owing to pounding of the heart against the chest wall.[81]

Signs

Physical examination findings of AR vary with the chronicity of the disease process. Many of the classic findings of chronic AR are a result of the widened pulse pressure. They include a "water-hammer pulse" (Corrigan pulse), head bobbing with each heartbeat (De Musset sign), capillary pulsations in the lips and fingers (Quincke pulses), pulsus bisferiens, "pistol shot sounds" on auscultation of the femoral artery (Traube sign), pulsations of the uvula (Müller sign). Although interesting, these signs are not necessarily clinically useful. The classic auscultatory finding of AR is an immediate to early diastolic, blowing, decrescendo murmur. It is best heard with the diaphragm at the left sternal border while the patient is sitting, leaning forward, and holding respiration in deep exhalation. The murmur is often better heard along the right sternal border when AR is caused primarily by root disease.[82] When it is soft, isometric exercise, such as handgrip, can increase its intensity by increasing aortic diastolic pressure. In severe AR, the murmur may be holodiastolic. S_1 is usually soft because the mitral leaflets are close to each other at the onset of systole. S_2 is usually single because the AV does not close properly, or because LV ejection time is prolonged and P_2 is obscured by the early diastolic murmur. Other findings, if present, are associated with CHF, for example, rales, S3, etc.[81] As discussed, the pulse pressure in acute AR is not widened, hence many of the classic signs of chronic AR are not seen in the acute setting. Instead, signs of CHF predominate.

Electrocardiogram

The increased LV mass in chronic AR leads to left axis deviation and increased QRS complex amplitude. A strain pattern and reduction in the total QRS complex amplitude in patients with chronic severe AR is highly predictive of severe depression of EF resulting from inadequate hypertrophy.[83] Q waves in leads I, V1, and V3 through V6 are indicative of diastolic volume overload.[84] LV conduction defects occur late in the course and are usually associated with LV dysfunction. Overall, ECG is an inaccurate predictor of AR severity.

Roentgenogram

The chest radiograph typically shows a "normal"-sized heart with pulmonary edema, although there may be some enlargement of all cardiac chambers and the main pulmonary artery. The aorta may be dilated if aortic root disease is the cause of AR. There may be signs of pulmonary emboli in AR caused by endocarditis when there is concomitant tricuspid valve endocarditis.

Echocardiography

Echocardiography is the most useful diagnostic modality in both the initial diagnosis and continued monitoring of patients with AR. Transthoracic echocardiography (TTE) is the most commonly used imaging tool. TTE provides noninvasive assessment of the AV and aortic anatomy; the presence, severity, and etiology of regurgitation; and the size and function of the left ventricle. TEE is used when the patient's body habitus does not allow for adequate assessment with TTE and to evaluate the

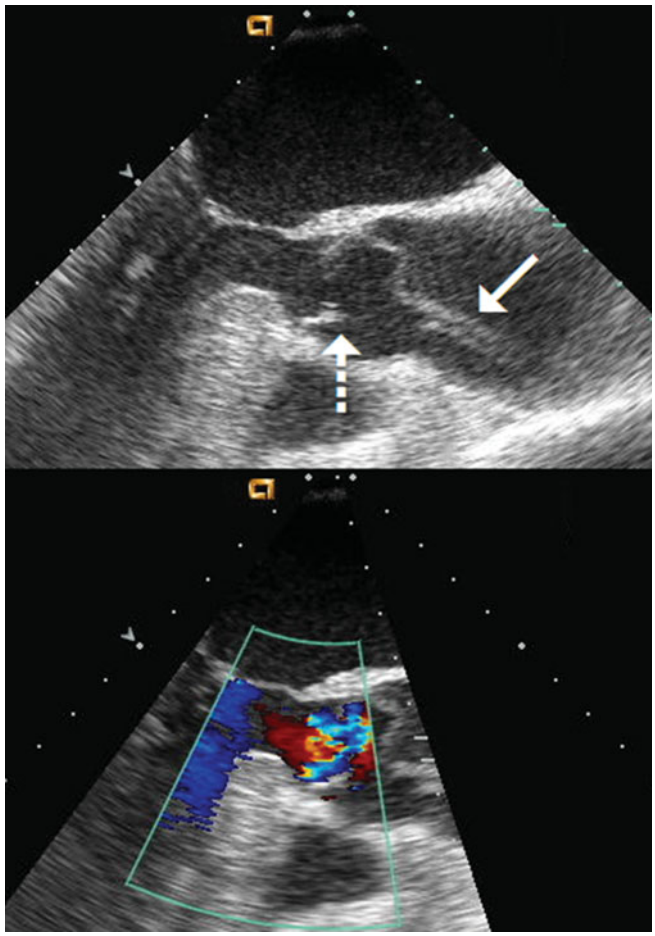

FIGURE 31-8 Transesophageal echocardiographic images of aortic regurgitation due to acute aortic dissection. (*Top*) Showing dilated annulus, prolapse of aortic valve leaflet (*dotted arrow*), and intimal flap (*solid arrow*). (*Bottom*) Color Doppler showing regurgitant flow.

AV and ascending aorta in patients with suspected aortic dissection (Fig. 31-8).

Two-dimensional (2D) echocardiography with Doppler color-flow mapping has been used routinely to assess the severity of AR.[85–87] The color-flow jets are typically composed of three components: (1) a proximal flow convergence zone (area of acceleration into the orifice); (2) the vena contracta (the narrowest and highest-velocity region of the jet); and (3) the distal jet itself in the LV cavity. Assessment of the severity of AR is determined qualitatively by jet width and vena contracta width, and quantitatively by regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 31-2). The regurgitant orifice area is calculated by dividing the regurgitant volume by the velocity time integral of the AR jet calculated by continuous wave Doppler.[88] Measurement of LV dimensions, such as end-systolic and end-diastolic volumes and wall thickness, are useful for determining LV changes and function. Additional echocardiographic findings in AR include premature closure of the mitral valve, diastolic fluttering of the anterior mitral leaflet from regurgitant flow, and less commonly, diastolic fluttering of the posterior mitral leaflet.[89]

TABLE 31-2 Classification of Aortic Regurgitation Severity

Indicator	Mild	Moderate	Severe
Angiographic grade	1+	2+	3-4+
Jet width	<25% LVOT	25–65% LVOT	>65% LVOT
Vena contracta width (cm)	<0.3	0.3–0.6	>0.6
Regurgitant volume (mL per beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Regurgitant orifice area (cm^2)	<0.10	0.10–0.29	≥0.30

Exercise Stress Testing

Exercise stress testing can provide valuable information in patients with AR, especially in those whose symptoms are equivocal or difficult to assess. In the management of AR, the presence of symptoms with exercise testing is equivalent to symptoms at rest because both circumstances warrant AVR.

Cardiac Catheterization

Cardiac catheterization is less frequently used to assess the severity of AR. It is most commonly used during preoperative assessment of coronary anatomy in patients requiring AV repair or replacement. The amount of regurgitant flow can be determined by calculating the angiographic stroke volume minus a measured fixed stroke volume. The difference between these two measured volumes divided by the angiographic stroke volume determines the regurgitant fraction. LVEDP is measured directly and EF is estimated roughly.

Computed Tomography

CT can be used to assess the severity of AR by measurement of the regurgitant orifice area, but currently the results are inferior to echocardiography.[90] Several studies have demonstrated the utility of CT to detect moderate and severe AR, but inaccuracies are seen with lesser degrees of AR.[91–93]

Magnetic Resonance Imaging

With the recent advancements in MRI technology, MRI cineangiography is able to provide some of the same information provided by TTE and TEE. MRI in some aspects provides superior resolution of the valves and better quantification of regurgitant flow and LVF. The regurgitant volume can be calculated by quantitative assessment, wherein aortic flow is subtracted from the ventricular stroke volume measured by the volumetric technique. It also can be assessed using flow mapping downstream from the AV by measuring the retrograde volume flow after valve closure. This method is more reproducible and is used more frequently for follow-up studies. However, MRI is costly,

and expertise is not available in most centers. Future improvements in technology may reduce costs and increase its availability, thereby making it a standard imaging modality along with or in substitution for echocardiography.[94–96]

Management

Acute AR is treated by early AV repair or replacement, depending on the etiology. With inadequate time for the left ventricle to compensate by eccentric hypertrophy, progressive CHF, tachycardia, and diminished CO occur rapidly. Vasodilators and inotropic agents, which augment forward flow and reduce LVEDP, may be helpful to manage the patient temporarily before surgery.

Compensated chronic AR is well tolerated by most patients.[97–99] Current recommendations for the management of chronic AR depend on the presence of symptoms, LVF, and LV dimensions. Patients with symptoms or EFs less than or equal to 50% should undergo AV repair or replacement.[100] Surgery is currently not recommended for patients who are asymptomatic, even with severe chronic AR. However, these patients must have normal LVF and LV dimensions. In asymptomatic patients with normal LVF, it is reasonable to perform surgery with an LV end-diastolic dimension (LVEDD) approaching 75 mm or an LV end-systolic dimension (LVESD) approaching 55 mm.[100]

After surgery, LVEDV and LVEDP decrease significantly and with the decrease in preload, EF also decreases.[101] LV size and function eventually return to normal if the operation is timed correctly.[102–113] The best postoperative predictor of recovery in systolic function is reduction in LVEDD because the magnitude of reduction correlates well with the magnitude of increase in EF.[102] Importantly, 80% of the total reduction in LVEDD after AVR occurs within 10 to 14 days after surgery.[102,107,114] Additional changes postoperatively include regression of myocardial hypertrophy, normalization of mass-to-volume ratio, increase in diastolic coronary perfusion, and decrease in peak systolic wall stress.[102,114,115]

Despite surgery, LV dilation and/or impaired LVF may continue in some patients. The best predictors of persistent LV dilation are greater preoperative LVESD and end-diastolic radius to wall thickness ratio.[116,117] In addition to these measures, greater preoperative LVEDD and duration of LV dysfunction, and reduced EF and fractional shortening predict persistent LV dysfunction.[102,106,118–121]

Medical management with chronic vasodilator therapy is indicated in patients with severe AR who have symptoms or LV dysfunction, and are poor candidates for surgery. Vasodilator therapy may be beneficial in asymptomatic patients with severe AR, normal LVF, and LV dilation. Other than these instances, chronic therapy with vasodilators is not indicated in patients with AR.

In asymptomatic patients with normal LVF, the overall rate of progression to symptoms or LV dysfunction averages 4.5% per year and the mortality rate is 0.2% per year.[100] Predictors for the development of future symptoms, LV dysfunction, or death include age, LVESV, LVEDV, and EF during exercise.[97,122–125] Currently, there is insufficient evidence to determine if EF during exercise is a reliable predictor because exercise EF is dependent on too many factors, such as myocardial contractility,[126] severity of volume overload,[97,126–128] and exercise-induced changes in preload and PVR.[128]

CHAPTER 32

Aortic Valve Replacement with a Mechanical Cardiac Valve Prosthesis

Robert W. Emery
Ann M. Emery
Jan Hommerding
Goya V. Raikar

INTRODUCTION

In 1931, Paul Dudley White stated, "There is no treatment for aortic stenosis." Even today the medical therapy of aortic stenosis has not significantly advanced (Fig. 32-1).[1] Conversely, patients may tolerate aortic insufficiency for many years, but as the ventricle starts to dilate, a progressive downhill course begins and early operation is warranted.[2] Definitive therapy for aortic valve disease was unavailable until the advent of cardiopulmonary bypass. Innovative cardiovascular surgeons then began to develop cardiac valve prostheses. Over the subsequent 50 years[3] the variety of prostheses that have become available for use have expanded greatly. Available aortic valve substitutes include mechanical valve prostheses, stented biologic valve prostheses, stentless biologic valve prostheses, human homograft tissue (both as isolated valve replacement and aortic root replacement), percutaneous or transapical biologic valves and a combination of a biologic valve using a pulmonary autograft, and pulmonary outflow tract replacement with heterograft prostheses (Ross procedure). This chapter focuses on the use of mechanical valve replacement in the aortic position.

HISTORY

In 1952, Hufnagel used an aortic valve ball and cage prosthesis heterotopically in the descending thoracic aorta to treat aortic insufficiency.[4] After the advent of cardiopulmonary bypass, initial attempts at aortic valve replacement (AVR) consisted of replacement of the individual aortic cusps with Ivalon gussets sewn to the annulus. When successful, these prostheses often calcified and results were short lived. Shortly thereafter, surgical pioneers Starr, Braunwald, and Harkin began replacement of the aortic valve in the orthotopic position. First-generation aortic valve prostheses, the ball and cage, became the standard for AVR for more than a decade (Fig. 32-2). Many of these prostheses have remained durable for up to 40 years.[5,6] Multiple modifications ensued, including changing the material of the ball from silastic to stellite, changes in the shape of the cage, depression of the ball occluder, the addition of cloth coating to the sewing ring and the cage, and changes in the sewing ring itself. These valves, however, required intense anticoagulation.[7] Hemodynamic performance was compromised because there were three areas of potential outflow obstruction: (1) the annular size of the sewing ring (the effective orifice area of the valve); (2) the distance between the cage and the walls of the ascending aorta (particularly in the small aortic root); and (3) obstruction to outflow by the ball itself distal to the tissue annulus. Flow patterns were also abnormal (Fig. 32-3). These problems led to the development of the next generation of aortic valve prostheses—the tilting disc valve. Innovators such as Björk, Hall, Kaster, and Lillehei developed three models of tilting disc prostheses that became the second generation of commonly implanted aortic valve replacement devices between 1968 and 1980. The low-profile configuration simplified surgical implantation (Fig. 32-4). Problems with the tilting disc valve included stasis and eddy current formation at the minor flow orifice (see Fig. 32-3), and sticking or embolization of the leaflet, the latter leading to discontinuation of the Björk prosthesis in spite of otherwise good

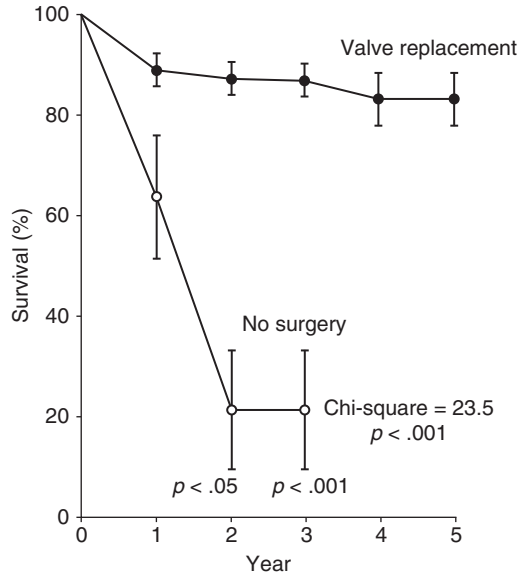

FIGURE 32-1 Survival of patients having aortic valve replacement compared to those not having valve replacement. (*Reproduced with permission from Carabello BA: Clinical practice. Aortic stenosis. NEJM 2002; 346:677.*)

long-term results.[8] The Lillehei-Kaster prosthesis has evolved into the Omniscience valve. The Medtronic Hall valve, the third tilting disc prosthesis, now discontinued (Fig. 32-5).

Kalke and Lillehei developed the first rigid bileaflet valve, but it had very limited clinical use. In 1977, the St. Jude Medical (SJM) prosthesis was developed and implanted by Nicoloff and associates (Fig. 32-6).[3,9] Over the following

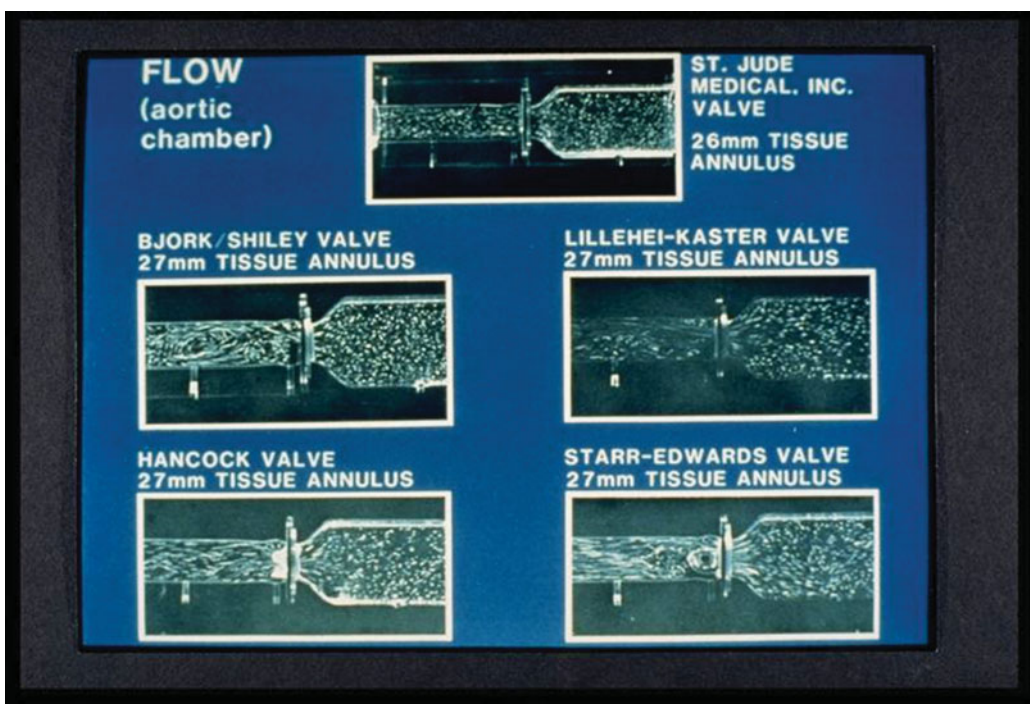

FIGURE 32-3 Prosthetic valve flow patterns using the Weiting CBA-77-03 pulse duplicator with high-speed photography and resin particles. Note the laminar flow with the bileaflet aortic valve as opposed to other clinically available prostheses and the flow similarity between the bileaflet valve and the tissue valve in the lower left corner. Tilting disk valves show directional flow, stasis at the minor flow orifice, and eddy current formation distally. The ball valve demonstrates stasis beyond the ball and eddy current formation around the ball itself. Note that the ball is obstructive to outflow, as is the proximity of the ball cage to the walls of the outflow chamber. (*Reproduced with permission from Emery RW, Nicoloff DM: The St. Jude Medical cardiac valve prosthesis: in vitro studies. J Thorac Cardiovasc Surg 1979; 78:269.*)

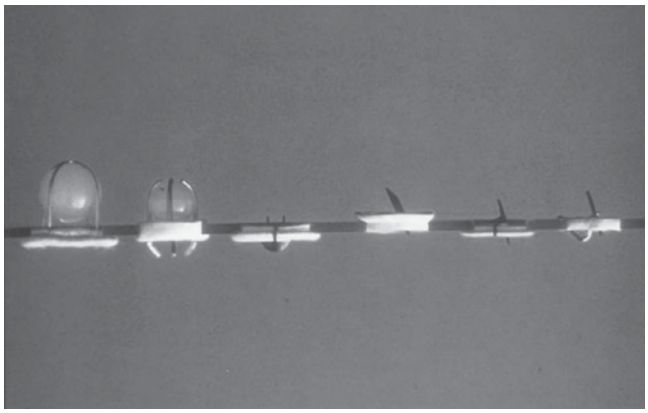

FIGURE 32-4 Low-profile prostheses simplify the surgical implant. The lowest profile is that of the bileaflet valve, and orientation of the leaflets is most commonly not necessary, as compared with tilting disc prostheses, for which the major flow orifice should be directed along the greater curvature of the aorta.

FIGURE 32-6 The original Kalke-Lillehei bileaflet valve as compared to the St. Jude Medical valve introduced nearly a decade later.

decades, the dramatic step of a bileaflet prosthesis nearly obviated the use of all other kinds of mechanical prosthetic valves in the United States and to a large extent elsewhere. The SJM valve demonstrated low aortic gradients, minimal aortic insufficiency, and low rates of thromboembolism (TE) (Fig. 32-7).[9–11] Anticoagulation continued to be necessary, but to a lesser extent than with previous design models.[12] Because of the low-profile design and lesser need for orientation, surgical implant was further simplified. After the introduction of the SJM valve, several other third-generation models of bileaflet prostheses were introduced, including the Sulzer Carbomedics valve (Sorin S.p.A., Milan, Italy) (Fig. 32-8), the ATS Medical prosthesis

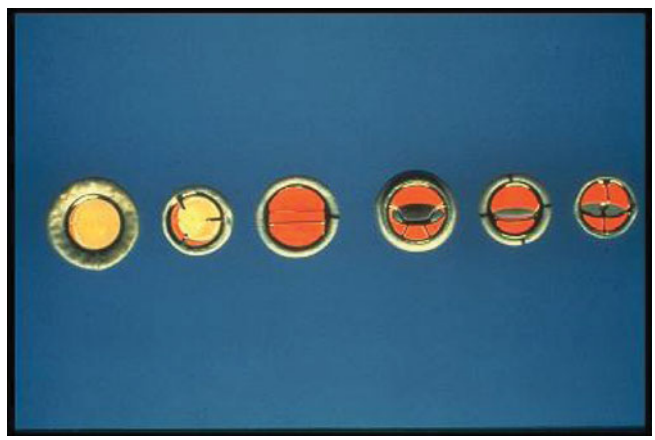

FIGURE 32-7 The increased flow orifice of the bileaflet valve is clearly shown as compared with ball valves and tilting disc valves available at the time of introduction of the bileaflet bioprosthesis.

FIGURE 32-5 The Medtronic Hall valve.

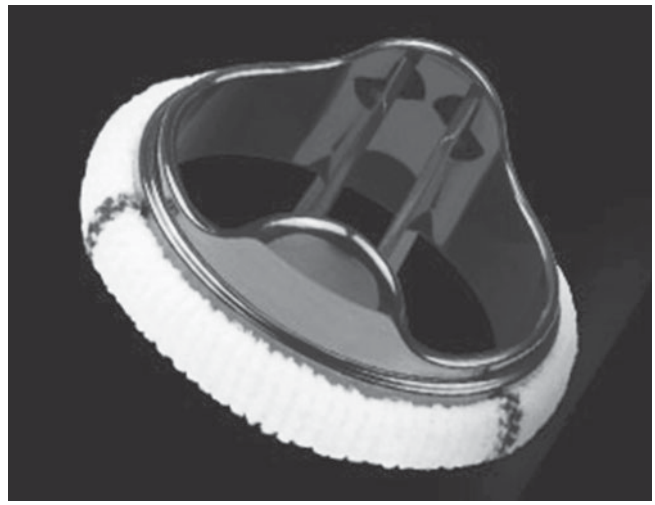

FIGURE 32-11 St. Jude Medical Regent valve.

(Medtronic, Minneapolis, MN) (Fig. 32-9), and the On-X prosthesis (On-X Life Technologies, Inc., Austen, TX) (Fig. 32-10). Since the introduction of the bileaflet valve, more than 2 million implants on a global basis have been accomplished and extensive literature has developed. Surgeons have become more confident in earlier aortic valve replacement, and guidelines for anticoagulation necessary for all mechanical valves have been developed for each generation of prosthesis at progressively decreasing target levels.[12]

Over the past 25 years, design and configurational changes have been made in bileaflet prostheses. The ATS Medical valve changed the "rabbit ears" pivot style of other bileaflet prostheses, incorporating a convex or open-pivot design allowing more complete washing of the moving parts of the valve and possibly a quieter valve closing.[13,14] The sewing ring of the SJM valve has changed (SJM HP) to allow a larger valve size implantation for any given tissue annulus, as has ATS Medical with its AP design. The sewing ring of the Sulzer Carbomedics valve has been modified such that this valve is implanted in a supravalvular position (top hat model). The On-X valve incorporates advanced pyrolytic carbon technology using a purer, more flexible coating to allow flanging of the inflow portion of the valve housing, mimicking the normal flow pattern.

The most recent development in bileaflet valve design was the introduction of the SJM Regent valve (Fig. 32-11). This valve model not only modified the sewing ring, but also redefined the external profile in a nonintrinsic structural portion of the valve, increasing the effective flow orifice area. Thus, a larger prosthesis could be implanted for any given tissue annulus diameter. This was the first mechanical prosthesis to demonstrate left ventricular mass regression across all valve sizes.[15,16] The Regent valve is seated supra-annular with only the pivot guards protruding into the aortic annulus.[17]

FIGURE 32-10 On-X valve. Note the flange of the inflow portion of the valve housing, which seats in the left ventricular outflow tract.

PATIENT SELECTION

As with any medical therapy, AVR with a mechanical prosthesis is not indicated for all patients. Several prospective randomized studies have shown no difference in survival in patients having biologic or mechanical valve prostheses or among mechanical prostheses per se.[18–22] However, follow-up was limited. Conversely, in other nonrandomized studies of patients followed over longer time frames, freedom from all valve-related events and from reoperation were improved in patients with mechanical valve prostheses as compared with patients with biologic prostheses.[8,23]

Most recently several publications have shown improved survival in patients having bileaflet mechanical valve prosthesis, most likely related to improved and longer patient follow-up.[24,25] Importantly quality of life was similar to that of a biologic prosthesis; even in elderly patients.[25]

Although the advantages of large effective flow orifice and durability with a mechanical valve are paramount, the confounding effects resulting from the necessity for anticoagulation continue. Patients who are transient, noncompliant, or incapable of managing medications are not good candidates for long-term chronic anticoagulation, nor are those with dangerous lifestyles or hobbies.[26] Patients with higher levels of education, and those from geographic areas with a sophisticated medical infrastructure and a static population have better compliance with necessary medication, anticoagulant monitoring, and fewer risk factors for TE are good candidate for AVR with a mechanical valve prothesis.[27]

A mechanical valve prosthesis is recommended to patients having second valve reoperations regardless of the nature of the first procedure, as re-reoperative risks are substantial.[28,29] Some studies report low mortality for reoperation of patients with failed biologic valves, but failures can occur abruptly, creating more risk.[30] Reoperative risk is also higher in those patients having combined procedures[28,31] or after prior coronary bypass.

Many surgeons have opted for an age of greater than 70 years as the indication for bioprosthetic AVR, based on data by Akins and associates.[28] In patients younger than 60 years of age, most would opt for a mechanical prosthesis based on prosthesis durability.[32] In the decade between 60 and 70 years of age, other factors have to be taken into account.[33,34]

SURGICAL TECHNIQUES

Implantation of mechanical valve prostheses has been previously described and is straightforward.[11] Historically, high-profile aortic valve prostheses could be difficult to implant, particularly in small aortic roots. In such cases, a hockey-stick aortotomy is used to "unroll" the aorta and expose the annulus. Although the implantation of low-profile bileaflet prostheses is simpler, problems can still arise in the small aortic root. If a tilting disc prosthesis is used, orienting the major flow orifice toward the greater curve of the aorta is necessary. Because bileaflet prostheses are the most commonly used, the surgical technique for implantation of these devices is described: A midline incision and sternotomy is made and a pericardial well created. Alternatively, a right anterior thoracotomy approach with femoral cannulation has been reported. A partial sternotomy is also an alternative in thin patients, creating a sternal T at the fourth inter-space.[35] These alternative techniques are particularly amenable to the implantation of low-profile aortic valve prostheses. The patient is cannulated via the aorta and a single atrial venous cannula. Most commonly, retrograde cardioplegic solution is used and a left ventricular vent is placed via the right superior pulmonary vein to maintain a dry operative field. After cross-clamping of the aorta, a transverse aortotomy is made approximately 1 cm above the takeoff of the right coronary artery, slightly above the level of the sinotubular ridge (Fig. 32-12). The incision is extended three-quarters of the way around the aorta, leaving the posterior one-quarter of the aorta intact, and allowing excellent visualization of the native aortic valve and annulus. The leaflets of the aortic valve are excised to the level of the annulus and the annulus is thoroughly debrided of any calcium. Extensive decalcification will minimize the risk of paravalvular leak, particularly in newer-generation prostheses with thinner sewing rings, and allows for better seating of the valve prosthesis. Braided 2-0 sutures with pledgets are used. Beginning at the noncoronary commissure, the annulus is encircled with interrupted mattress sutures (Fig. 32-13) extending from the aortic to the ventricular surface (everting). Alternatively, multiple single interrupted sutures may be placed. After placement, the suture bundles are divided into two equal portions and two individual sutures placed into the sewing ring at the level of the pivot guards, orienting the pivot guard toward the ostia of the

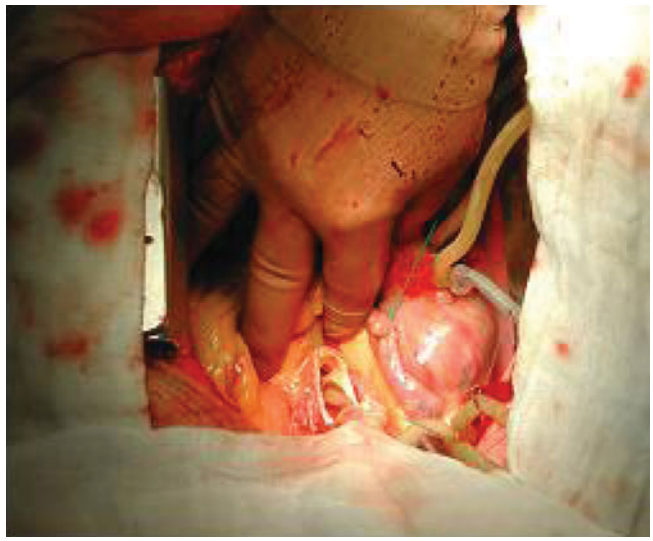

FIGURE 32-12 A transverse aortotomy has been made above the level of the sinotubular ridge. The diseased valve can be visualized readily and excised in toto.

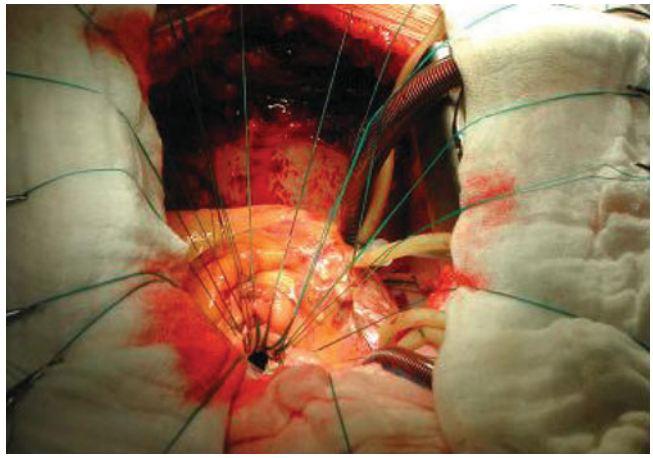

FIGURE 32-13 The annulus has been encircled with multiple interrupted pledgeted mattress sutures of 2-0 braided suture. The annulus can be readily visualized and all calcification has been extensively debrided.

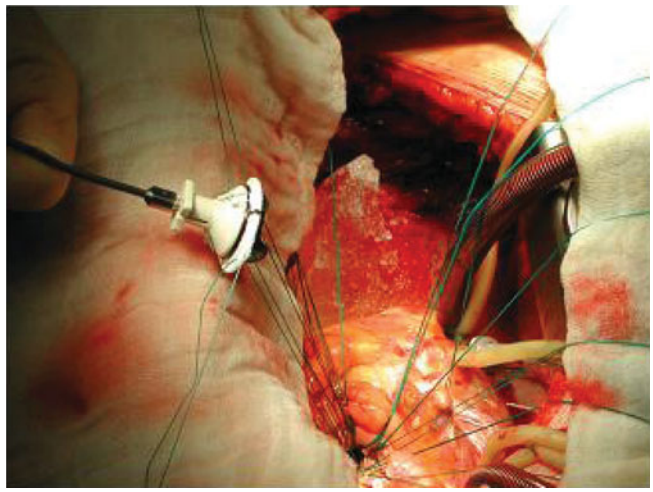

FIGURE 32-14 The pivot guard sutures have been placed aligning the pivot guards with the right and the left coronary arteries.

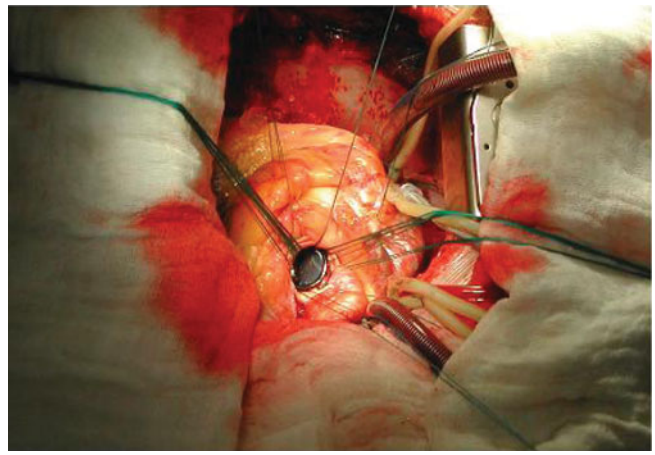

FIGURE 32-16 All sutures have been passed through the sewing ring and the valve is lowered to the aortic annulus and seated appropriately by placing gentle leverage on the valve sewing ring and traction on the suture bundles.

left and right coronary artery (Fig. 32-14). Next, each half of the suture bundles are implanted in the sewing ring and the prosthesis seated (Figs. 32-15 and 32-16).

The pivot guard sutures are tied first followed by the sutures beginning at the left coronary cusp extending to the midportion of the right coronary cusp. The sutures of the noncoronary cusp are secured last, seating the valve appropriately. In a small aortic root, if a valve is not able to be seated, a paravalvular leak can be prevented if the unseated area of the valve is in the noncoronary cusp. External aortic sutures can be placed from outside the aorta to the valve sewing ring, securing the prosthesis and preventing regurgitation. Because of the low-profile nature of the leaflets, opening and closing can still occur unimpeded. Leaflet motion should always be checked, and the surgeon must be assured that the coronary arteries are not obstructed. The aortotomy is closed with a double layer of polypropylene suture consisting of an underlying mattress suture and a more superficial over-and-over suture. The patient is placed in the Trendelenburg position and the heart filled with blood and cardioplegic solution, vented, and the cross-clamp removed. After resuscitation and de-airing of the heart, the procedure is completed and the patient transferred to the intensive care unit. On the first postoperative day the chest tubes are removed if output is less than 125 mL in the previous 8 hours. After the removal of the chest tube, the patient is begun on subcutaneous heparin (5000 U every 8 hours) or low molecular weight heparin (1 mg/kg twice a day), and warfarin therapy started. Valve implantation usually can be accomplished in less than 40 minutes of aortic cross-clamping and with cardiopulmonary bypass times of approximately 1 hour, allowing limited coagulopathic and homeopathic alterations.

When coronary bypass grafting is indicated, the order of the operation changes. The diseased valve is excised, distal vein or free arterial grafts constructed, the valve is replaced, and the aortotomy closed. Proximal anastomoses are then completed, with one left untied for de-airing. The distal anastomoses of pedicled grafts (internal mammary artery, IMA) are then completed. De-airing is accomplished through the untied proximal anastomosis.

FIGURE 32-15 The first half of the remaining suture bundles has been passed through the sewing ring of the valve. The valve has been moved to the opposite side of the patient and the remaining suture bundle is to be placed.

ANTICOAGULATION

The durability and function of mechanical valve prostheses, particularly those of the modern generation, is unquestioned.[23,32,36–39] It is the process of anticoagulation that is key and drives long-term success. The international normalized ratio (INR) is the standard to which anticoagulation levels should be targeted.[26,40] Anticoagulation is begun slowly after removal of the chest tubes, as the danger of overshooting target INR to dangerous levels is common.[41] Current data on anticoagulant regimens indicate that a one-size-fits-all recipe is inadequate to obtain excellent long-term results.[12,27] Horstkotte and associates noted that complications occur during fluctuations in the INR, and less often during steady-state levels, whether high or low.[42] When levels

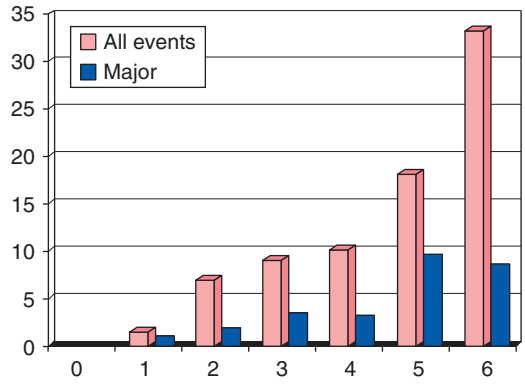

FIGURE 32-17 The correlation of number of risk factors to thromboembolic events. (*Reproduced with permission from Butchart EG, Ionescu A, Payne N, et al: A new scoring system to determine thromboembolic risk after heart valve replacement. Circulation 2003; 108[Suppl II]:II-68.*)

of INR increase, bleeding episodes become more common, and when levels of INR decrease, thromboembolic episodes become more common, both on the slope of the change. These events are opposite ends of the continuum of anticoagulation-related complications. The presence of a mechanical valve prosthesis is also not the only risk factor for TE.[27,43] Traditional risk factors for TE listed in Table 32-1 predispose patients to thromboembolic episodes, and as such higher therapeutic INRs are warranted. Similarly, as shown in Table 32-2, nontraditional risk factors for thromboembolism will also predispose patients to embolic events.[27,43] Butchart has noted that the more of these risk factors patients have, the greater the incidence of events and the greater the need for a higher target INR (Fig. 32-17).[27] Thus, it is imperative in the modern era that patient risk factors be taken into account and the INR individualized for a given patient.[12] Recommendations for INR target levels in our practice are shown in Table 32-3. These levels are more liberal than those offered by the American College of Cardiology/American Heart Association (ACC/AHA) and the American College of Chest Physicians (ACCP) guidelines, but more conservative than those recommended by the European self-anticoagulation trials.[44–46] These later reports are especially relevant, because they demonstrate that a lower INR is consistent with a lower incidence of TE if patients are maintained in the therapeutic target range.[44,47] Patients with home testing were maintained in the therapeutic range a substantially greater percentage of the time than those whose status was monitored at anticoagulation clinics.[44,47] Starting self-management early after mechanical valve replacement further reduced valve-related events.[41] In the United States, home testing has not become commonplace or popular. However, home testing could certainly be expected to lower the incidence of valve-related thromboembolic and bleeding events. It has recently been approved for reimbursement for weekly testing in patients with a mechanical valve prosthesis or atrial fibrillation, but only after a 3-month waiting period. Obtaining appropriate funding for access in the immediate postoperative period would be an important initiative that could acutely reduce the incidence of valve-related events.

A recent report of patients followed over 25 years noted that approximately 40% of the bleeding episodes occurred in the first year after surgery. It is thus important during this initial postoperative time frame when the patient's anticoagulant levels are more likely to fluctuate, that INR be measured more frequently.[32] In the early postoperative period, INR can occasionally jump to

supratherapeutic levels and result in significant bleeding events. This is an independent risk factor for mortality at 60 days.[48] Furthermore, the most important independent predictor of reduced survival is anticoagulant variability.[26] We and others therefore recommend in the early postoperative period that one proceed slowly to bring the INR to target levels while the patient is under the protection of subcutaneous enoxaparin (100 IU/kg twice a day) or heparin (5000 U every 8 hours) until the INR is therapeutic.[12,32,49,50]

The addition of aspirin to a warfarin regimen can be expected to result in a lower incidence of TE at any given therapeutic INR with a low probability for bleeding events and so is recommended.[51,52]

An educational program to teach patients how to manage their anticoagulation is an important part of the overall operative process. Patients should be instructed on the influence of alcohol and diet on anticoagulant levels, the need for regular dosing, and the potential impact of travel and gastrointestinal illnesses on fluctuations in anticoagulant levels. Warfarin is well known to be high-risk, as is insulin, yet both drugs can be managed with proper compliance and education so that the impact on lifestyle and quality of life is minimal.[7,25,53] Patient age does not appear to be a risk factor for anticoagulation[53–56] as long as there are no specific contraindications to anticoagulation. The presence of a mechanical valve is not a risk factor for long-term neurocognitive dysfunction.[57] The importance of regular testing cannot be overstated.

Newer antithrombin agents may obviate several of the issues discussed in the preceding. These agents are showing promise in the treatment of atrial fibrillation, with a lower incidence of embolism and bleeding complications. The drugs are expensive, require multiple administrations per day, and may cause hepatic dysfunction, yet they do not require blood testing or physician visits to maintain the therapeutic effect.[58] Their application to mechanical valve prostheses is as yet unknown.

Of importance platelet activation may be more important in the long-term therapy of an aortic prosthesis than mitral, where areas of stasis predominate.[10] This is likely the reason there is no difference in the freedom from embolic events in mechanical versus biologic prosthesis over the long term.[23] Thus aortic valve prostheses could in theory be managed with newer strong antiplatelet therapy. Garcia-Renaldi has tested this theory in 178 patients followed out to 7.8 years treated only with clopidogrel. Results were excellent, with few bleeding episodes and minimal thromboembolic events.[59] Importantly, this group found the majority of patients having thromboembolic events when tested were resistant to the drug or had been removed from the drug by themselves or a physician. The authors stressed the importance of measurement of platelet responsiveness if only antiplatelet therapy is used.[59] A prospective randomized trial is warranted to confirm those results.

RESULTS

Outcomes from aortic valve replacement with mechanical valve prostheses vary among reports depending on the patient population. Patients with higher-risk factors for TE and those with risk factors for anticoagulation will have a higher incidence of valve-related events, making meta-analyses less meaningful.[60] Older patients are at higher risk for valve-related events, particularly thromboembolic episodes, because of the greater number of risk factors that accumulate with aging.[27] The incidence of valve-related events is also determined by the intensity with which the investigators follow their patients. A higher incidence of early hemorrhagic events may also be diluted over the longer periods of follow-up.[61] Compliance is vital to good long-term outcomes. Traditional and nontraditional risk factors for embolism and risk factors for anticoagulation and valve-related events must be considered.[27,43] Several trials have indicated no significant differences in events among various mechanical prostheses, but follow-up was short.[19,21,62] There are, however, certain standards within which one should expect a mechanical valve to perform, and within which the medical decisions for anticoagulation must be made. The majority of valve-related morbidity is related to TE and anticoagulation-related hemorrhage.[26,29,39] The sections that follow deal with specific valve-related complications and acceptable current incidence.

Valve Type

Freedom from all valve-related events over the long term is shown in Fig. 32-18. In the early follow-up period, anticoagulation-related hemorrhage is the most common untoward event for mechanical valve prostheses. Thus, over the first 10 years of follow-up there is a higher incidence of valve-related events in patients with mechanical prostheses as opposed to those with biologic valves.[23] However, over the subsequent period of 10 to 20 years, the incidence of biologic valve failure changes this ratio such that the valve-related complications of biologic prostheses become more common than those with mechanical valve

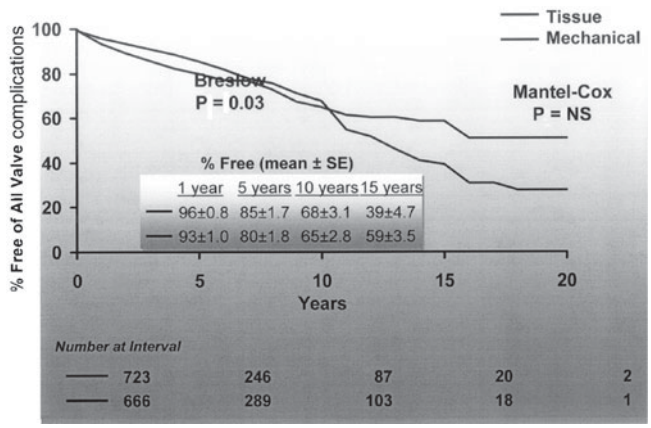

FIGURE 32-18 Freedom from all valve-related complications over 20 years. Note that in the first 10-year period of follow-up, complications related to mechanical valves exceeded those of tissue valves. The lines cross at approximately 10 years, and over the following period, complications from tissue valves were more frequent than those from mechanical valves. (*Reproduced with permission from Khan SS, Trento A, DeRobertis M, et al: Twenty-year comparison of tissue and mechanical valve replacement. J Thorac Cardiovasc Surg 2001; 122:257.*)

prostheses. In a series of aortic reoperations, Potter has noted that the time to biologic valve failure was only 7.6 years and Maganti 11 years.[30,63] This failure rate will increase over time.[23,64] Overall, freedom from valve-related events is more strongly influenced by preexisting comorbidities than the presence of a mechanical prosthesis per se.[23,27,32,36]

Anticoagulant-Related Hemorrhage

Anticoagulation-related hemorrhage (ARH) is the most common valve-related event. The more intense the anticoagulation regimen, the higher the incidence of valve-related hemorrhage. Most commonly ARH occurs during fluctuations in INR values commonly related to changes in warfarin dosing or medical or drug interactions.[42] The most common site for ARH is the gastrointestinal tract, and the second is the central nervous system.[32] ARH also accounts for the highest incidence of patient mortality for valve-related events. Acceptable ARH rates range from 1.0 to 2.5% per patient-year in long-term reports.[8,23,32,36–39] These long-term reports dilute the short-term impact, because ARH risks are higher early after valve replacement.[32,39,61] With individualized and home-monitored anticoagulant regimens, both related events, TE and ARH, are diminished.[44] Freedom from anticoagulation at 10 and 20 years are 75 to 80% and 65 to 70%, respectively. Importantly, one long-term study noted that nearly 40% of all ARH that occurred over a 25-year follow-up period occurred during the first year of anticoagulation (Fig. 32-19), indicating that a slow increase to therapeutic levels, coupled with close follow-up during this early period is warranted.[12,32,48,49] Results of the European self-anticoagulation study indicate that a lower INR target is appropriate if home testing is initiated, because greater time is spent in the therapeutic range.[44] Mortality more commonly occurs in relation to bleeding events than to thromboembolic events.[12,32]

Thromboembolism

Thromboembolic episodes are the second most common valve-related event and are the major reason that chronic anticoagulation is warranted. Khan and associates reported in a large series of patients that the incidence of thromboembolic events between bioprostheses and mechanical prostheses are the same (Fig. 32-20), but the mechanical valve patients are on warfarin.[23] Acceptable thromboembolic rates range between 0.8 and 2.3% per patient-year.[8,23,32,36–39,65] Approximately one-half of these events are neurologic, 40% are transient, and 10% peripheral.[32] Freedom from thromboembolic events at 10 and 20 years is approximately 80 to 85% and 65 to 70%, respectively.

Thromboembolism is a continuous risk factor that is present throughout the life of the mechanical valve prosthesis. As patients age, risk factors for TE increase, so one must be on guard to maintain therapeutic anticoagulant levels. Changes in the target INR may be necessary as individual risks increase.

Interestingly, not all neurologic events classified historically as embolic are indeed embolic. Piper and coworkers report a study of patients prospectively admitted to a single institution with a neurologic event postmechanical valve replacement and intensively worked up. More than 75% were found to have

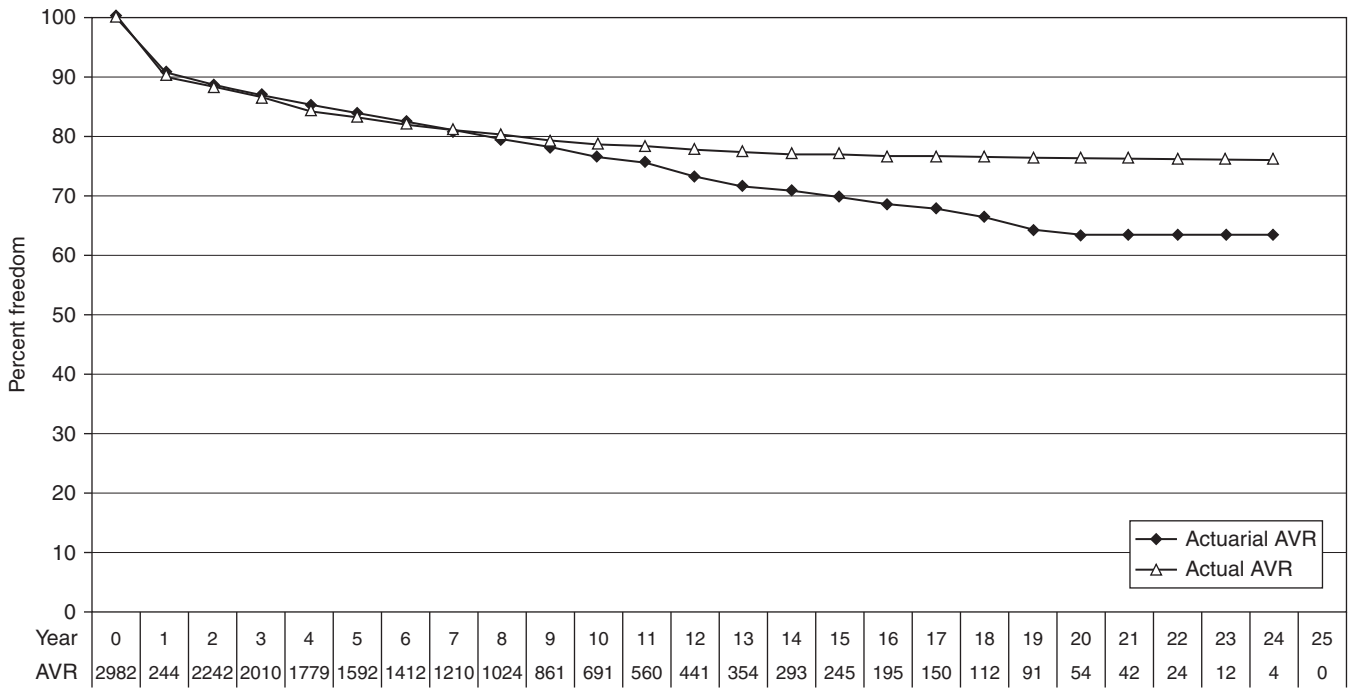

FIGURE 32-19 Kaplan-Meier curve of freedom from anticoagulation-related hemorrhage for patients having aortic valve replacement. FIGURE 32-20 Freedom from thromboembolism in patients followed for 20 years. Note that there is no difference in the incidence of thromboembolic events between mechanical and tissue valves. (*Reproduced with permission from Khan SS, Trento A, DeRobertis M, et al: Twenty-year comparison of tissue and mechanical valve replacement. J Thorac Cardiovasc Surg 2001; 122:257.*)

intracerebral hemorrhage as the etiology of the event as opposed to embolic. This would indicate that target anticoagulant levels may be artificially high, and that not all neurologic events that appear to be embolic in fact are so.[66]

Valve Thrombosis

Valve thrombosis in the aortic position is an unusual event that occurs late after valve replacement and is most commonly a result of inadequate anticoagulation or noncompliance.[67,68] In bileaflet valves, thrombus formation impinging valve function occurs at the pivot guards and in the crevices of the valve. Only one bileaflet design does not have convexities into which the leaflets fit.[69] In tilting disc valves, thrombus is most common at the minor flow orifice. The incidence of thrombosis is approximately less than 0.3% per patient-year, and freedom from valve thrombosis at 20 years is greater than 97%.[8,23,32,36–39]

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis is also a rare event in the modern era with prophylactic antibiotics. Approximately 60% of events occur early and are associated with staphylococci. The mortality for this event is high. The remainder appear late (>60 days). Prosthetic valve endocarditis is also a continuous variable, and patients must be cautioned to take prophylactic antibiotics for any invasive procedure. Freedom from endocarditis with mechanical valve prostheses is 97 to 98% at 20 to 25 years.[32,39]

Paravalvular Leak

Paravalvular leak is an operative complication and is most commonly related to operative technique but occasionally to endocarditis. With annular decalcification and closely placed sutures, these events can be minimized. The Silzone experience showed an increased incidence of paravalvular leak wherein the silver impregnated in the sewing ring not only impeded bacterial growth, but also healing of the annular ring, doubling the accepted rate of this complication.[70] The Silzone-coated sewing ring was removed from the market. There may be an anatomical predisposition to paravalvular leak in the area of the annulus extending from the right and noncoronary commissure, one-third the distance along the right coronary cusp, and two-thirds the distance to the noncoronary cusp, owing to intrinsic weakness in this area of the annulus.[71] The acceptable range of paravalvular leak is approximately less than .01% per patient-year, with early postoperative occurrence predominating.[29,32]

Structural Failure

Structural failure of bileaflet aortic prostheses resulting from wear has not been observed or reported in long-term studies totaling more than 50,000 patient-years of follow-up. This indicates the high structural integrity of these modern aortic devices.[23,32,39] In a single study totaling 21,742 patient-years with 94% complete follow-up, there was no structural failure.[49]

Freedom from Reoperation

The long-term durability of modern mechanical valve prostheses is excellent, and a valve replacement rate of less than 2% over 25 years (Fig. 32-21) can be expected, and re-reoperation after AVR replacement is even more rare.[29] Subvalvular pannus formation is also rare with aortic bileaflet valves.[32,39] The most common reasons for prosthetic valve reimplantation are preoperative and postoperative endocarditis, paravalvular leak, and valve thrombosis.

SPECIAL CIRCUMSTANCES

Technical Considerations

Although the technique of implanting a mechanical valve prosthesis is very straightforward, special circumstances arise. Because of the large size of the valve housing of the St. Jude Medical Regent valve compared to the tissue annulus, entry into the aorta can sometimes be difficult. Occasionally, patients have the smallest diameter of their aortic root at the sinotubular ridge. Although the sizer will pass readily through the aortic annulus, seating the Regent valve itself into the annulus can sometimes be difficult and frustrating. It is important to gently rock the valve back and forth through the sinotubular ridge, tilting the valve circumferentially through the narrowest part. Once the valve is below the level of the sinotubular ridge, it will seat readily in the annulus if sizing has been correct. When tying the valve into the annulus, sutures in the pivot guards and the left and right coronary cusps should be completed first. The last sutures ligated are those of the noncoronary cusp for two reasons. It may seem like the Regent valve will not seat because of the large-sized valve housing; however, with gentle persistence seating can be completed as long as sizing has been correct. The Regent valve sits supra-annular and only the pivot guards lie inside the annulus (Fig. 32-22). Therefore one should leave the last sutures to be tied in the mid-part of the noncoronary cusp with the valve oriented so the leaflets are parallel to the ventricular septum.[72] With proper annular decalcification and

Ann Thorac Surg 2005; 79:776.*)

flexibility of the annulus, we have not seen a Regent valve that has not been able to be seated properly.

Similarly, when using the On-X valve one has to be sure that the flare of the valve inflow is seated properly in the left ventricular outflow tract. Gentle manipulation and patience may be necessary. Walther and colleagues note that exact sizing requires some experience.[20]

If an oversized bileaflet valve has been implanted purposefully in a small aortic root, the valve can be tilted and will still function without coronary obstruction as long as the highest portion of the valve is in the noncoronary cusp. Pledgeted sutures placed from outside the aorta through the sewing ring of the valve can prevent paravalvular leak, and opening and closing can still occur because of the low-profile nature of the prosthetic valve. In our review of nearly 3000 bileaflet aortic valve replacements, no annular enlarging procedures were completed.[49]

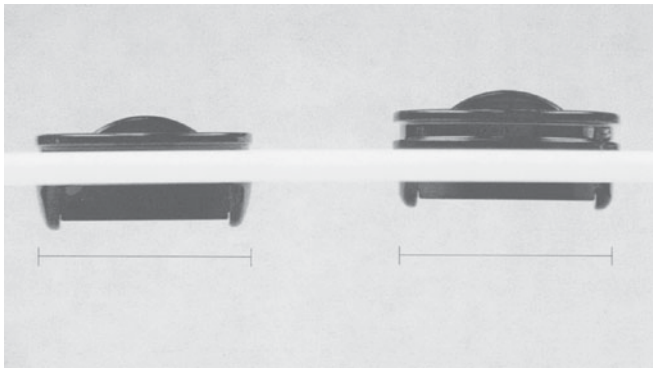

FIGURE 32-22 The St. Jude Medical Regent valve on the right, compared with the St. Jude Medical HP valve on the left. With the Regent valve only the pivot guards insert into the annulus, allowing a larger valve housing for any given tissue annulus diameter. Ann Thorac Surg 2005; 79:776.*)

Patient-Prosthesis Mismatch

Patient-prosthesis mismatch (PPM) is a concept first described by Rahimtoola and popularized by Pibarot and Dumesnil.[73,74] Unfortunately, views are varied on the importance of PPM.[75–78] This is because virtually all contributions to the literature study mixtures of mechanical and biologic prostheses and varying types of each. In a 25-year follow-up of patients with a single model mechanical valve prosthesis, no difference was found in overall valve-related mortality for patients who had severe PPM, moderate PPM, or insignificant PPM according to the criteria described by Blais and associates.[77] This similarity in long-term

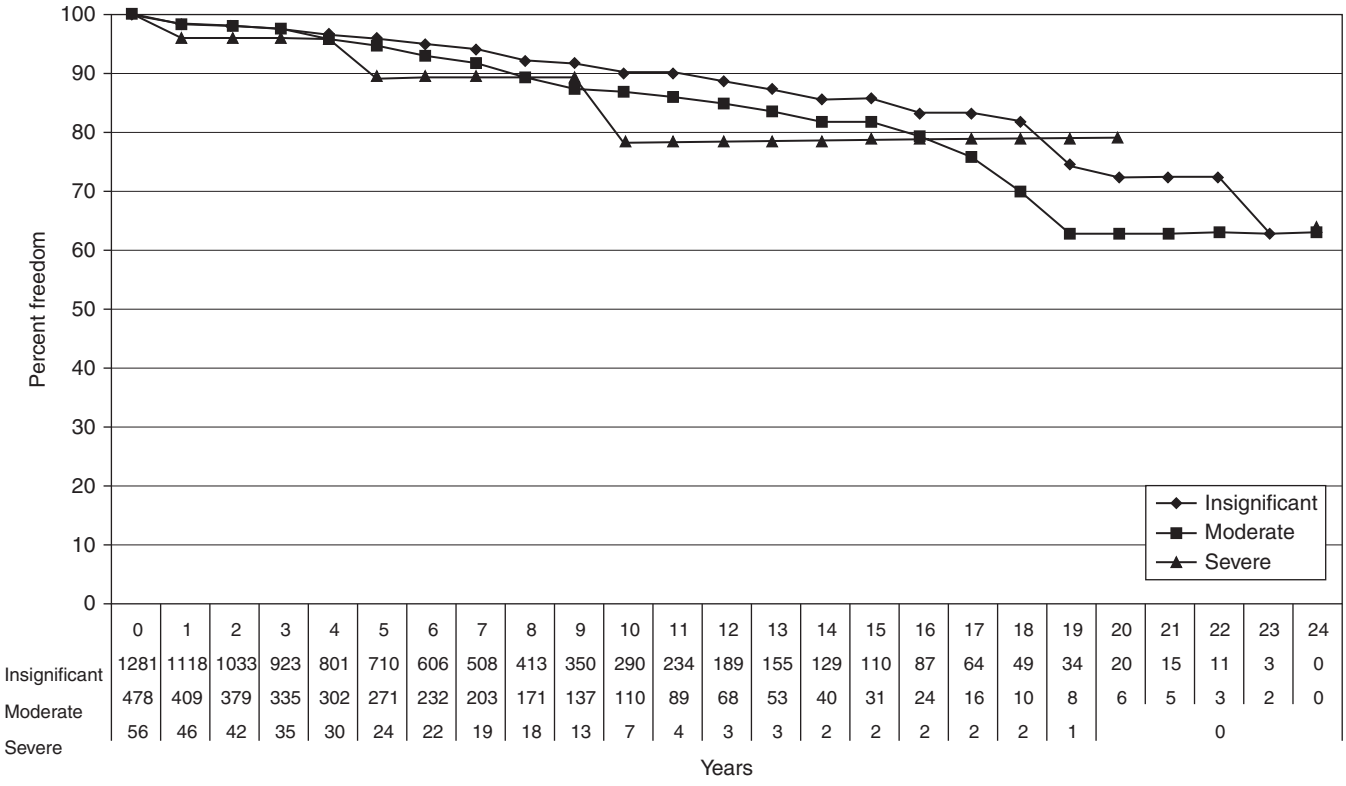

FIGURE 32-23 Kaplan-Meier determination of valve-related late mortality in patients having insignificant, moderate, or severe patient-prosthesis mismatch according to the criteria of Pibarot and colleagues. After implant of a bileaflet prosthesis, in vitro determination is calculated from the geometric flow orifice by the manufacturer. Note there is no difference in these three curves. Numbers at the bottom of the figure represent patients available for follow-up.

survival was sustained whether the effective area was measured by in vitro (internal geometric valve area) or in vivo criteria (echo-calculated valve area) as shown in Figs. 32-23 and 32-24. This study also found no difference in valve-related events, including operative mortality, long-term cumulative mortality, anticoagulant-related hemorrhage, TE, valve thrombosis, paravalvular leak, or diagnosis of congestive heart failure. Follow-up in this study was 94% complete and extended over 13,000 patient-years.[79] Therefore, with bileaflet mechanical valve prostheses, PPM does not appear to be an issue. This study was limited in that it did not address patient age (ie, younger versus older), patient activity, or ventricular function. Thus, it is likely that PPM is important in patients with small biologic prostheses, because as the valve leaflets stiffen, clinical aortic stenosis becomes prominent early in the postoperative follow-up period, affecting symptoms and survival in younger and more active patients and those with depressed ventricular function. However, if one is concerned about PPM, the indexed effective orifice area can be calculated for any given prosthetic valve and a determination made whether an annular enlarging procedure or a different model prosthesis with a larger effective orifice area is warranted.[80] PPM has been minimized by the new-generation Regent valve and is very rare with this prosthesis.[16,49]

Off Anticoagulation

Anticoagulation is recommended in all patients with mechanical valve prostheses. Limited trials have been undertaken with low-risk patients, but only after a several-month course of systemic anticoagulation. An increased incidence of valve thrombosis but with little increase in the incidence of TE has been reported in patients not taking chronic anticoagulation if antiplatelet agents are used.[67,81,82] One study found no significant differences in valve-related events in patients on warfarin as compared with antiplatelet therapy alone, but follow-up was limited.[83] One prospective study is currently ongoing, consisting of a randomized trial of antiplatelet therapy versus warfarin after 3 months of formal anticoagulation, but the results are not yet available.[84] Certainly one can expect that highly selected patients with mechanical valve prostheses will do well off warfarin on antiplatelet agents, but this is unproved.[17,85]

In a prospective nonrandomized trial of clopidogrel along after bileaflet aortic valve replacement, Garcia-Rinaldi and coworkers as noted, found thromboembolic events limited to those patients who had clopidogrel discontinued or were nonresponders. Although such an approach is rational based on deductive reasoning from available data, a prospective randomized trend is required before this approach can be recommended.

When anticoagulation requires reversal electively, as for scheduled surgery, the INR is allowed to slowly drift toward normal over 5 days and the patient is admitted for intravenous heparin therapy 24 hours before the procedure. Anticoagulation is restarted after the procedure with antiplatelet therapy, and subcutaneous heparin with warfarin restarted on postoperative day one. Abrupt reversal of INR in patients who have bleeding episodes may be warranted, but carries increased risk of TE. Fresh-frozen plasma will gently reverse INR when necessary,

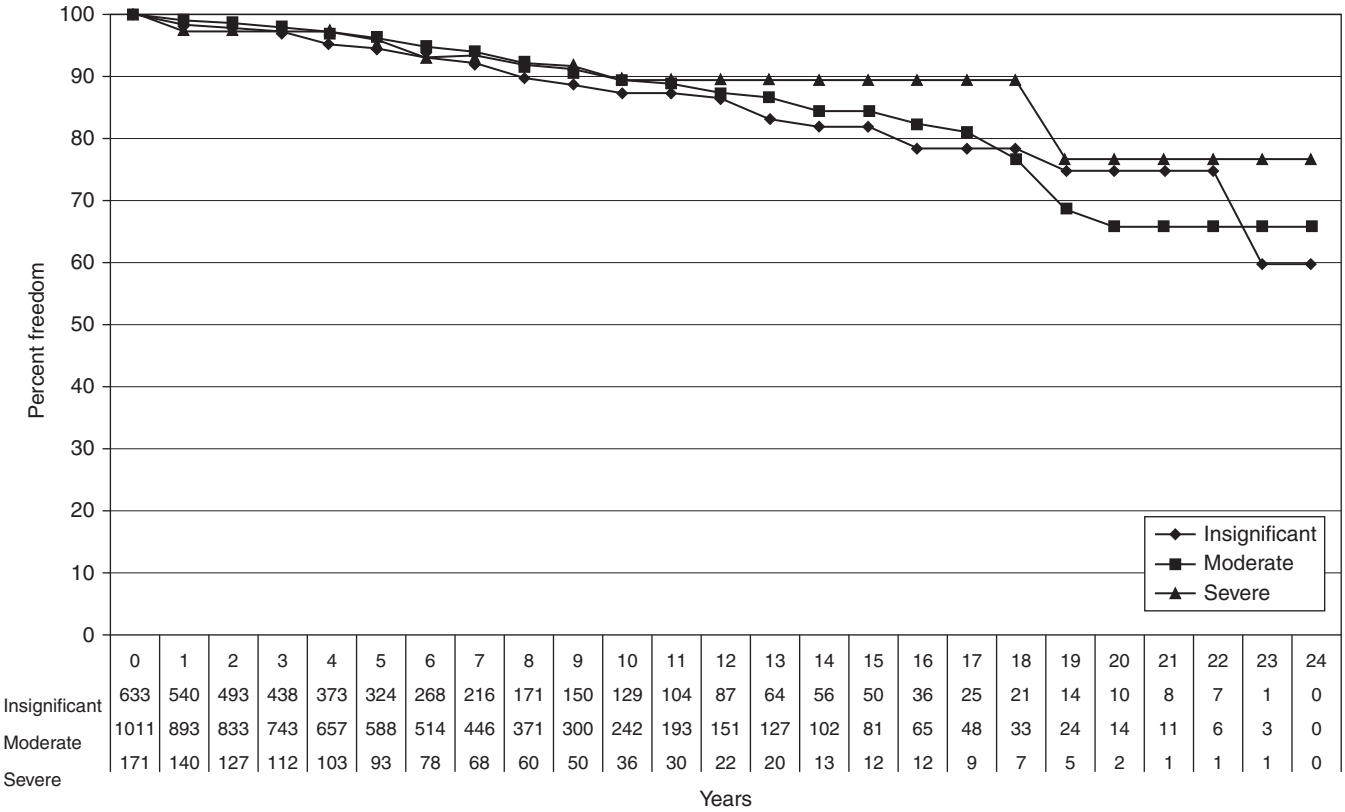

FIGURE 32-24 Kaplan-Meier determination of valve-related late mortality in patients having insignificant, moderate, or severe patient-prosthesis mismatch by the in vivo criteria according to Blais and associates determined echocardiographically. There is no difference in the survival curves after implant of a bileaflet prosthesis. The numbers at the bottom of the graph represent patients available for follow-up.

but it is best to avoid the use of vitamin K. Frequent INR checks are warranted.

After ARH episodes, when feasible, because of the high incidence of recurrent bleeding, anticoagulant therapy is withheld up to 2 weeks or until the source of the bleeding has been identified and definitively treated, using antiplatelet agents only.[82] For those patients in whom anticoagulant therapy cannot be restarted, antiplatelet therapy is warranted, but the patient should be informed of an increased incidence of thromboembolism to approximately 4% per patient-year and that of valve thrombosis to 2% per patient-year with bileaflet valves.[67,81,82,86]

Mechanical Valve Replacement in the Younger Patient

A major deterrent to mechanical valve replacement in the younger patient is the impact of long-term anticoagulation. Mechanical valves are, however, more ideal for younger patients because of their excellent durability characteristics. Most importantly, younger patients (i.e., patients less than age 50) are a low-risk subset for valve-related events. These individuals have very few risk factors for TE, and thus anticoagulation can be run at the lower end of the therapeutic target range, decreasing the incidence of anticoagulant-related hemorrhage without altering the incidence of TE. In fact, many infants and children have been managed with only aspirin with quite good long-term results.[87] Although this is not recommended in patients older than infants, it is a feasible alternative. A recent study in patients under 50 years of age followed 254 patients for up to 20 years and found an exceedingly low rate of valve-related events (Table 32-4), an exceptional long-term overall survival of nearly 88%, and event-free survival probability of 92% at 19 years.[88]

TABLE 32-4 Valve-Related Events with the St. Jude Medical Prosthetic Valve

Event	No. of Events	Percent Per Patient-Year	No. of Deaths

Age <60 years
Age 60–70 years with patient discussion
Reoperations
Good medical infrastructure

The longest surviving patient in a series of bileaflet valve replacement patients is currently more than 30 years from his procedure, which was completed in his early forties and has been without complication.[30] The low incidence of valve-related complications in younger patients should drive a discussion of the alternative prostheses available for such individuals, especially with new aggressive antiplatelet drugs. Operative mortality increases with each succeeding procedure; therefore, discussion of durability with patients becomes mandatory.[28–30]

Follow-up

With the use of any valve prosthesis, long-term follow-up is a vital factor. Ten years is certainly not long enough to ascertain the true durability of a prosthesis. Grunkemeier reviewed several types of biologic prostheses and found that the 10-year durability was excellent, but between 12 and 18 years durability fell off and prosthetic replacement was necessary.[64] These data were echoed by Khan and colleagues.[23] Valve-related failure of all biologic alternatives, including stented prosthetic replacements, stentless prostheses, and homograft and autograft replacements have all shown long-term durability to be less than that of modern mechanical valve prostheses.

Even with some mechanical valve prostheses, durability after 10 years has not been adequate. In recommending mechanical valve replacement, one should be assured to have clinically available data on the prostheses that extend beyond 15 years.

In conclusion, with proper selection of patients for mechanical valve replacement, one can expect excellent long-term results, long-term survival, and a low incidence of valve-related complications. Current indications for recommending aortic valve replacement with mechanical prostheses are shown in Table 32-5.

CHAPTER 33

Bioprosthetic Aortic Valve Replacement: Stented Pericardial and Porcine Valves

Bobby Yanagawa
George T. Christakis

INTRODUCTION

This chapter provides an overview of aortic valve replacement (AVR) with stented bioprostheses. The *indications for aortic valve surgery* are reviewed, with an emphasis on current evidence-based guidelines, and currently available stented aortic bioprostheses are described. Clinical and physiologic outcomes of aortic valve surgery are critically evaluated to create a rational basis for prosthesis selection.

NATURAL HISTORY AND INDICATIONS FOR OPERATION

Aortic Stenosis

Natural History

Aortic stenosis (AS) may be caused by: (1) degenerative calcification; (2) congenital malformations, most commonly bicuspid aortic valve; or (3) rheumatic fever. It is uncommonly associated with systemic diseases such as Paget's disease of bone and end-stage renal disease. Degenerative calcification is common in the elderly population and moderate to severe calcific AS is the most common pathology among patients undergoing AVR. The incidence of calcific AS is expected to rise with the increase in age of population in developed countries.

Valvular degenerative calcification is characterized as a progressive reduction of orifice cross-sectional area caused by calcification of the cusps. The pathogenesis of inflammation and lipid accumulation is reminiscent of atherosclerosis.[1] The normal human aortic valve area (AVA) is between 3.0 and 4.0 cm^2 with minimal to no gradient. Aortic stenosis is defined as mild, moderate, and severe AS, and the corresponding AVA, mean gradients, and peak jet velocities are shown in Table 33-1. In the presence of normal cardiac output, transvalvular gradient is usually greater than 50 mm Hg when the AVA is less than 1.0 cm^2.[2] A rapid increase in transvalvular gradient is seen when AVA is less than 0.8 to 1.0 cm^2.

Obstruction to flow created by the reduced orifice area of the aortic valve elevates intracavitary pressures, and resultant wall stress leads to compensatory concentric hypertrophy to maintain normal cardiac output.[3] With progressive hypertrophy, ventricular compliance progressively decreases and end-diastolic pressure rises.[4] In this situation, the contribution of atrial contraction to preload becomes more significant and loss of sinus rhythm may lead to rapid progression of symptoms.

Symptomatic Patients

As AS progresses to become hemodynamically significant, initial compensation occurs by left ventricular hypertrophy (LVH). The average AVA is 0.6 to 0.8 cm^2 at the onset of symptoms.[3] Gradual progression of outflow obstruction and ventricular hypertrophy lead to the cardinal symptoms of AS, which are: (1) angina, (2) syncope, and (3) dyspnea or congestive heart failure (CHF). Classic natural history studies have demonstrated that average life expectancy in patients with hemodynamically significant AS is 4 years with angina, 3 years with syncope, and 2 years with CHF.[5] Symptom development in the context of AS is an absolute indication for surgical intervention.[6] Excessive delay of AVR in symptomatic patients is associated with rate of sudden death of greater than 10% per year. Once a patient is symptomatic, average survival is less than 3 years typically from ventricular arrhythmia or CHF.[7]

TABLE 33-1 Classification of Aortic Stenosis (AS)

	Mild	Moderate	Severe
AVA (cm^2)	>1.5	1.5–1.0	<1.0
Mean gradient (mm Hg)	<25	25–40	>40
Peak jet velocity (m/s)	<3.0	3.0–4.0	>4.0

ASYMPTOMATIC PATIENTS

Managing asymptomatic patients with hemodynamically significant AS remains controversial. The average decrease in AVA is 0.12 cm^2 per year, whereas the average increase in transvalvular pressure is often 10 to 15 mm Hg per year.[8] However, considerable variation does exist in the rate of disease progression and many patients do not experience any change in gradient for several years. As such, there may exist a prolonged and stochastic latent periods before symptoms emerge. During this period, concentric LVH progresses as ventricle adapts to elevated chamber pressures.

Sudden death is rather uncommon in the asymptomatic patient unless the degree of AS is severe, in which case the rate is approximately 1% per year. However, the vast majority of patients who experience sudden death will become symptomatic in the months immediately before the fatal event.[9]

When considering AVR, the risk of sudden death should be weighed against the contemporary STS database surgical mortality of 3.5%. Although it is difficult to predict who will need surgical intervention, asymptomatic patients with increases in peak velocity jet greater than 0.45 m/s per year are substantially more likely to need an operation.[9] Overall, up to 7% of asymptomatic patients with AS experience death or aortic valve surgery 1 year after diagnosis.[10] After 5 years, the incidence of death or aortic valve surgery surges to 38%. Of note, early and late outcomes were similar among patients with severe AS who underwent surgery with or without symptoms.[11]

Low-Gradient Severe Aortic Stenosis

The significance of AS is often unclear in patients with very poor ventricular function (ejection fraction <20%) who have severely stenotic valves but small (<30 mm Hg) transvalvular gradients. Compromised left ventricular function (LVF) in these patients may be caused by afterload mismatch created by the stenotic valve or by intrinsic cardiomyopathy, particularly in the setting of chronic ischemia from diffuse coronary disease. In these patients, measurement of transvalvular gradient and valve area at rest and with positive inotropy (eg, dobutamine infusion) may distinguish cardiomyopathy versus true valvular stenosis as the most responsible diagnosis. Most patients with poor LVF and severe AS experience a significant survival benefit from valve replacement[12] (Fig. 33-1). However, a subset of patients with a preponderance of cardiomyopathy do not experience significant benefit.[13] A multivariate analysis to determine factors that predict poor LVF after AVR for AS identified poor preoperative LVF as the most significant predictor, indicating suboptimal outcome in the low-gradient group of patients.[14]

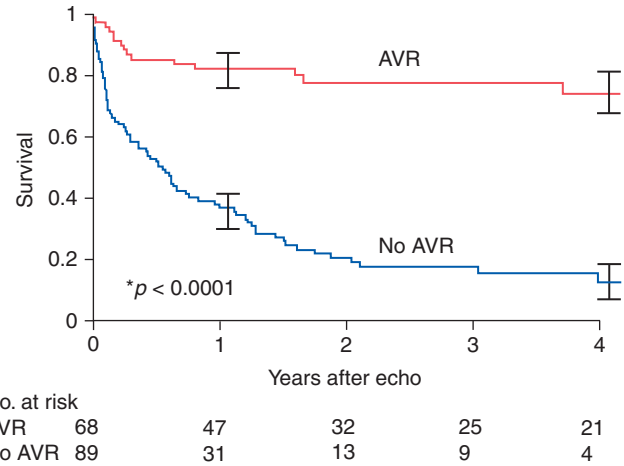

FIGURE 33-1 Impact of aortic valve replacement on survival in patients with low-gradient aortic stenosis. Survival by Kaplan-Meier analysis among all propensity-matched patients in the aortic valve replacement (AVR) and control (No AVR) groups ($p < .0001$). The number of patients at risk during follow-up is shown on the x-axis. (*Reproduced with permission from Pereira JJ, Lauer MS, Bashir M, et al: Survival after aortic valve replacement for severe aortic stenosis with low transvalvular gradients and severe left ventricular dysfunction. J Am Coll Cardiol 2002; 39:1356.*)

Medical Therapy

No known medical therapy has been shown to alter the natural history of AS. Although several small nonrandomized studies have shown a reduction in disease progression with antilipid therapy,[15] a recent prospective randomized clinical trial of aggressive antilipid therapy with atorvastatin did not demonstrate decreased rates of disease progression[16] (Fig. 33-2).

Indications for Operation

In 1998, a joint task force of the American College of Cardiology (ACC) and the American Heart Association (AHA) developed evidence-based consensus guidelines for management of valvular heart disease.[17] These were subsequently updated in 2006.[18] Their recommendations for AVR in the setting of AS are summarized in Table 33-2.

Aortic valve replacement is indicated in all symptomatic patients with severe AS or those with severe asymptomatic AS who require concomitant coronary bypass, aortic surgery, or other valve replacement. At Sunnybrook Health Sciences Center, it is our practice to perform AVR on patients with moderate AS requiring concomitant cardiac surgery. We do not routinely perform AVR on patients with mild AS undergoing concomitant cardiac surgery unless the aortic valve is heavily calcified and the stenosis likely to progress rapidly. Aortic valve replacement is commonly performed in otherwise asymptomatic patients with severe AS and severe left ventricular dysfunction (LVD), exercise-induced symptoms, significant hypertrophy, or ventricular arrhythmia. Asymptomatic patients with very high transvalvular gradients (>60 mm Hg) or highly stenotic valves (valve

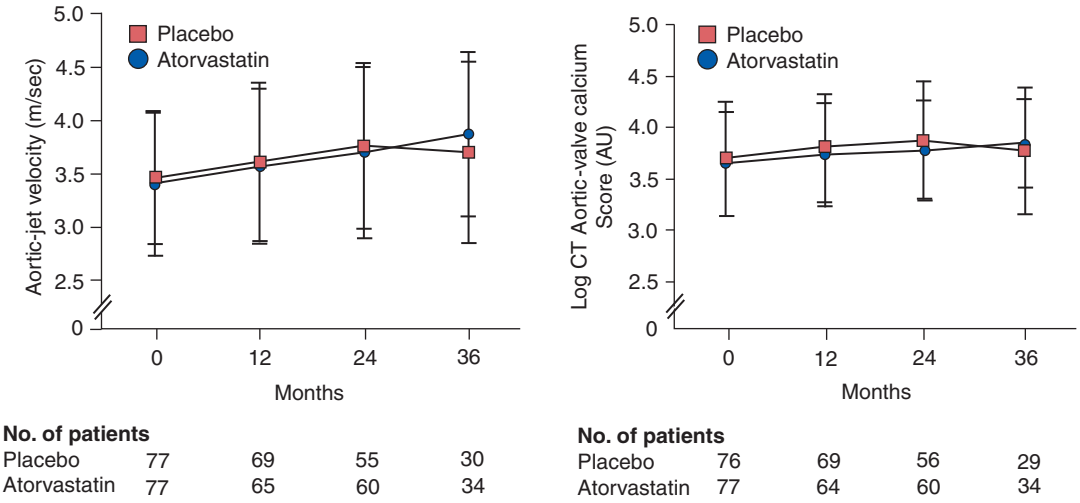

FIGURE 33-2 Progression of aortic valve jet velocity and calcification in patients treated with intensive atorvastatin therapy or matched placebo. (*Reproduced with permission from Cowell SJ, Newby DE, Prescott RJ, et al: A randomized trial of intensive lipid-lowering therapy in calcific aortic stenosis. NEJM 2005; 352:2389.*)

area <0.6 cm^2) are at higher risk for progression to symptoms and should have valve replacement before significant ventricular decompensation or sudden death.

Aortic Regurgitation

Acute Aortic Regurgitation

Acute aortic regurgitation (AR) is caused by: (1) acute dilatation of the aortic annulus preventing adequate cusp coaptation; or (2) disruption of the valve cusps themselves. The specific causes of AR include aortic dissection, infective endocarditis, trauma, aortic cusp prolapse secondary to VSD, aortitis (syphilitic or giant cell, and iatrogenic, such as postaortic balloon valvotomy).

The heart is rather intolerant of acute AR. Because the left ventricle is unable to compensate for the sudden increase in end-diastolic volume caused by a large regurgitant volume load, a dramatic reduction in forward stroke volume ensues.[19] In the context of a hypertrophic and poorly compliant LV, hemodynamic decompensation is significantly more dramatic.

TABLE 33-2 ACC/AHA Guidelines for Aortic Valve Replacement in Patients with Aortic Stenosis (AS)

Indication	Class
1. Symptomatic patients with severe AS	I
2. Patients with severe AS undergoing coronary bypass surgery	I
3. Patients with severe AS undergoing surgery on the aorta or other heart valves	I
4. Patients with severe AS and left ventricular systolic dysfunction (ejection fraction <50%)	I
5. Patients with moderate AS undergoing coronary artery bypass or other aortic or valvular surgery	IIA
6. Asymptomatic patients with severe AS and:	
a. Abnormal response to exercise (hypotension)	IIB
b. Likelihood of rapid progression (age, calcification, or coronary artery disease)	IIB
c. Ventricular tachycardia	IIB
d. Valve area <0.6 cm^2, mean gradient >60 mm Hg, jet velocity >5.0 m/s	IIB
7. Patients with mild AS and moderate to severe valve calcification undergoing coronary bypass surgery	IIB
8. Prevention of sudden death in an asymptomatic patient with none of the findings in 5–7	III

Source: Adapted with permission from Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Valvular Heart Disease). Available at: http://www.americanheart.org.

Tachycardia is the initial compensatory response to acute decline in forward stroke volume. Volume overload causes the left ventricular end-diastolic pressure to acutely rise above left atrial pressure, resulting in early closure of the mitral valve.[20] Although this protects the pulmonary venous circulation from excessively high end-diastolic pressures, rapid progression of pulmonary edema and cardiogenic shock are unavoidable. Death secondary to progressive cardiogenic shock and malignant ventricular arrhythmias is the common endpoint of acute AR regardless of etiology. Thus urgent surgical treatment is warranted for all causes of hemodynamically significant acute AR.

Chronic Aortic Regurgitation

Chronic AR is caused by either slow enlargement of the aortic root or dysfunction of the valve cusps. Common causes of chronic AR include congenital abnormalities (eg, bicuspid, unicuspid, quadricuspid aortic valve), calcific cusp degeneration, rheumatic fever, endocarditis, Marfan's syndrome, Ehlers-Danlos syndrome, myxomatous proliferation, osteogenesis imperfecta, and ankylosing spondylitis.

Chronic AR causes a persistent volume overload of the left ventricle. This volume burden leads to progressive chamber enlargement without increasing end-diastolic pressure during the asymptomatic phase of the disease. Chamber enlargement is accompanied by adaptive eccentric hypertrophy, associated at the cellular level with sarcomere replication and elongation of myocytes. The combination of chamber dilatation and hypertrophy leads to a massive increase in left ventricular mass. Initially, the ratio of wall thickness to chamber diameter, ejection fraction (EF), and fractional shortening are maintained.[21] However, a vicious cycle of chamber enlargement, continually increasing wall stress, and maladaptive ventricular hypertrophy ensues. Development of interstitial fibrosis is an important pathogenic mechanism that limits further ventricular dilitation, elevating end-diastolic pressure and leading to left ventricular systolic dysfunction, and CHF.[22] Vasodilator therapy may delay progression of ventricular dysfunction by decreasing afterload thus reducing regurgitant flow. Vasodilator therapy is currently indicated in asymptomatic patients with hypertension; asymptomatic patients with severe AR, ventricular dilatation, and preserved systolic function; and for short-term hemodynamic tailoring before operation. This therapy is not recommended in patients with severe AR and LVD, as it does not improve survival but may be used if such patients are considered inoperable.

The time course from diagnosis of AR to the development of symptoms is highly variable. Natural history studies of AR show that symptoms, LVD, or both develop in less than 6% of patients per year.[23] Progression to LVD without symptoms occurs in less than 4% of patients per year, and sudden death occurs in less than 0.2% per year.[24] Independent predictors of progression to symptoms, LVD, or death in asymptomatic patients include age, left ventricular end-systolic dimension, rate of change in end-systolic dimension, and resting EF LVD develops, the onset of symptoms occur at a rate exceeding 25% per year.[26] Because symptoms such as angina and dyspnea develop only after significant ventricular decompensation has occurred, surgery is advocated before the symptomatic phase of the disease. Symptomatic patients experience greater than 10% mortality per year; thus surgery is absolutely indicated.[27]

Indications for Operation

Surgical intervention for asymptomatic patients is based on the identification of subtle but measurable changes in myocardial function before they become irreversible and negatively affect the patient's long-term prognosis. Unfortunately, such deleterious changes are often missed by current imaging modalities. Patients with more severe LVD have decreased perioperative and late survival because of irreversible ventricular remodeling, including hypertrophy and interstitial fibrosis.[26,28] The decision to operate on this patient population is indeed challenging because the outcomes are poor with surgery or medical therapy.[4] A summary of the revised ACC/AHA Task Force guidelines for AVR for chronic AR is presented in Table 33-3.[18]

CORONARY ANGIOGRAPHY AND AORTIC VALVE REPLACEMENT

Many patients requiring AVR have coexistent coronary artery disease (CAD). In North America, more than one-third of AVR procedures are accompanied with coronary bypass graft surgery. This proportion will indeed increase as the surgical population continues to age. Risk assessment for ischemic heart disease is complicated in patients with aortic valve disease because angina may be related to true ischemia from hemodynamically significant coronary lesions, or other causes such as left ventricular wall stress with subendocardial ischemia or chamber enlargement in the setting of reduced coronary flow reserve. Because traditional coronary risk stratification is unreliable in aortic valve patients, at Sunnybrook Health Sciences Center, it is our practice to routinely perform diagnostic coronary angiography on all patients greater than age 35.

Technique of Operation

Myocardial Protection and Cardiopulmonary Bypass

Isolated AVR is performed using a single, two-stage right atrial venous cannula and an arterial cannula into the ascending aorta for systemic perfusion of oxygenated blood. A retrograde cardioplegia cannula may be placed into the coronary sinus via the right atrium. A left ventricular vent cannula is placed in the right superior pulmonary vein and advanced into the left ventricle to ensure a bloodless field and prevent ventricular distention with aortic insufficiency. Once cardiopulmonary bypass (CPB) is initiated, aorta and pulmonary artery are dissected to expose the anterior aortic root to the left coronary artery. Careful dissection of the pulmonary artery from the aorta ensures that the cross-clamp will be fully occlusive on the aorta and prevents inadvertent opening of the pulmonary artery with the aortotomy incision. Care is needed to present pulmonary artery injury, as this tissue is substantially more friable than the aorta.

After the cross-clamp is applied, myocardial protection is initially delivered as a single dose of high potassium blood through the ascending aorta. This will trigger prompt diastolic

TABLE 33-3 ACC/AHA Recommendations for Aortic Valve Replacement (AVR) in Chronic Severe Aortic Regurgitation (AR)

Indication	Class
1. AVR is indicated for symptomatic patients with severe AR irrespective of left ventricular systolic function	I
2. AVR is indicated for asymptomatic patients with chronic severe AR and left ventricular systolic dysfunction (ejection fraction ≤0.50) at rest	I
3. AVR is indicated for patients with chronic severe AR while undergoing coronary artery bypass graft or surgery on the aorta or other heart valves	I
4. AVR is reasonable for asymptomatic patients with severe AR with normal left ventricular systolic function (ejection fraction >0.50) but with severe left ventricular dilatation (end-diastolic dimension >75 mm or end-systolic dimension >55 mm)*	IIA
5. AVR may be considered in patients with moderate AR while undergoing surgery on the ascending aorta	IIB
6. AVR may be considered in patients with moderate AR while undergoing coronary artery bypass graft surgery	IIB
7. AVR may be considered for asymptomatic patients with severe AR and normal left ventricular systolic function at rest (ejection fraction >0.50) when the degree of left ventricular dilatation exceeds an end-diastolic dimension of 70 mm or end-systolic dimension of 50 mm, when there is evidence of progressive left ventricular dilatation, declining exercise tolerance, or abnormal hemodynamic responses to exercise*	IIB
8. AVR is not indicated for asymptomatic patients with mild, moderate, or severe AR and normal left ventricular systolic function at rest (ejection fraction >0.50) when the degree of dilatation is not moderate or severe (end-diastolic dimension <70 mm, and those with end-diastolic dimension >70 mm should have aortic valve replacement if there is evidence of serial deterioration of ventricular function or exercise intolerance)*	III

**Consider lower threshold values for patients of small stature of either gender.*
Source: Adapted with permission from Bonow RO, Carabello BA, Chatterjee K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Valvular Heart Disease). Available at: http://www.americanheart.org.

arrest unless there is moderate to severe AR. Myocardial protection is maintained by continuous infusion of cold or tepid oxygenated blood cardioplegia delivered via direct cannulation of both coronary ostia after the aorta has been opened. In the case of the short left main coronary artery, antegrade cannulation may preferentially perfuse either the LAD or circumflex system. In the presence of severe coronary artery disease, antegrade cardioplegia may not perfuse myocardial segments distal to significant coronary obstruction. Furthermore, direct cannulation of left main coronary artery risks endothelial injury and potential dissection or promotion of atherosclerosis development.

An alternative method of cardioprotection in aortic valve cases is retrograde cardioplegia, in either intermittent or continuous forms, and used in isolation or in combination with antegrade cardioplegia. This is helpful in patients with significant AR or severe concomitant coronary disease. However, there are some questions regarding the quality of RV perfusion using retrograde alone. If retrograde cannula cannot be guided into the coronary sinus, conversion to bicaval cannulation will allow opening the right atrium and direct placement of the cannula into the coronary sinus. Do not place the retrograde cannula beyond the origin of the right coronary vein ostium in the coronary sinus to ensure adequate right ventricular myocardial protection.

Aortotomy, Valve Excision, and Debridement

Once the cross-clamp has been applied and cardioplegic arrest has been achieved, the aorta is opened either with a transverse or oblique aortotomy. The low transverse aortotomy is a common approach to the aortic valve when using stented bioprostheses or mechanical valves. The aortotomy is started approximately 10 to 15 mm above the origin of the right coronary artery (RCA) and extended anteriorly and posteriorly. The initial transverse incision over the RCA may also be extended obliquely in the posterior direction into the noncoronary sinus or the commissure between the left and noncoronary cusps (Fig. 33-3). The oblique incision is often used in patients with small aortic roots, in whom root enlargement procedures may be required

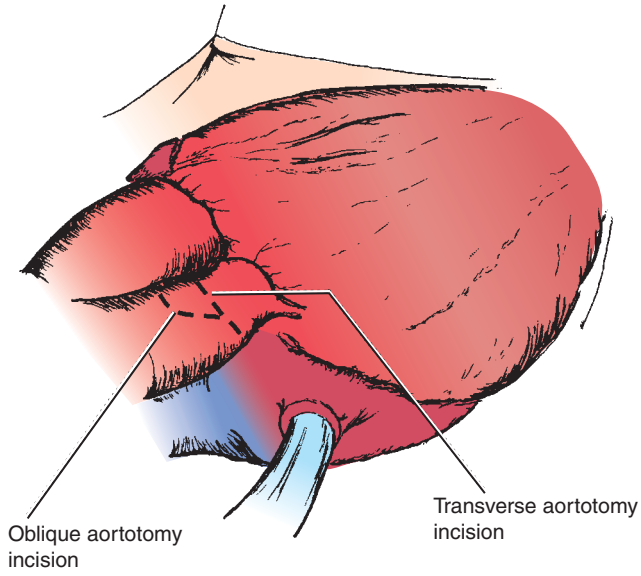

FIGURE 33-3 Exposure and aortotomy incision. A two-stage venous cannula is in place in the right atrial appendage. The aortotomy (*dashed line*) may be made in the transverse or oblique direction.

(see the following) and may also be used to tailor a larger ascending aorta.

Morphology of the valve is then inspected (Fig. 33-4). The valve cusps are incised with scissors at the right cusp between the right coronary ostium and the commissure between the right and noncoronary cusps (Fig. 33-5). Mayo scissors or special right-angled valve scissors are usually used at this stage and the calcific deposits are removed from the aortic wall. One to two millimeters of tissue are left behind to support a sewing surface. Right cusp excision is carried first toward the left coronary cusp and then toward the noncoronary cusp and the cusp is removed as a single piece if possible. Excision is then carried

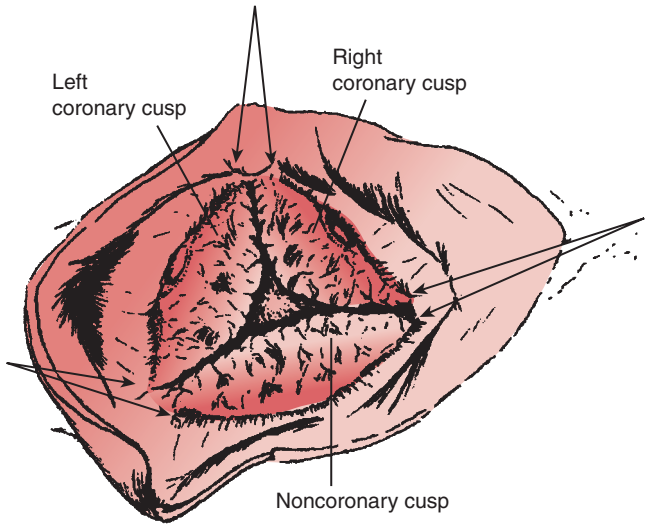

FIGURE 33-4 The exposed aortic valve.

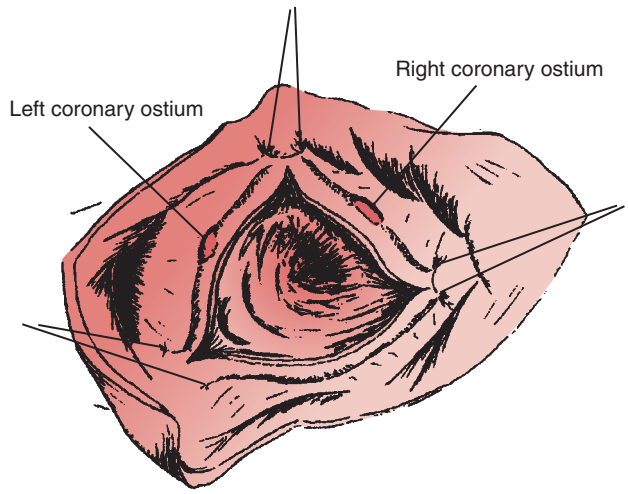

FIGURE 33-5 The aortic valve after leaflet excision.

toward the left and noncoronary commissure along the noncoronary cusp and then the left coronary cusp. A moistened radiopaque sponge is placed into the outflow area to catch calcific debris, which must be removed before placing the valve sutures. Thorough decalcification is then performed with a scalpel or rongeur. Debridement of all calcium deposits back to soft tissue improves seating of the prosthesis and decreases the incidence of paravalvular leak and dehiscence.

Care must be taken to prevent aortic perforation while calcific deposits are debrided from the aortic wall, particularly at the commissure between the left and noncoronary cusps, where perforation is most likely. Several anatomic relationships must be respected during valve excision (Fig. 33-6). The bundle of His (conduction system) is located below the junction of the right and noncoronary cusps in the membranous septum. Deep debridement in this area can result in permanent heart block. The anterior leaflet of the mitral valve is in direct continuity with the left aortic valve cusp. If it is damaged during decalcification, an autologous pericardial patch is used to repair the defect.

Once debridement is completed, the aortic root is copiously flushed with saline while the left ventricular vent is stopped. To prevent pushing debris into the left ventricle, saline in a bulb syringe is flushed through the left ventricular vent and out the aortic valve in an antegrade manner instead of retrograde through the valve. The irrigation solution is suctioned with the external wall suction and not into the cardiotomy suction.

Valve Implantation

After the native valve has been excised, the annulus is sized with a valve-sizer designed for the selected prosthetic device. The valve is secured to the annulus using 12 to 16 double-needled interrupted 2-0 synthetic braided pledgeted sutures that are alternating in color. The pledgets can be left on the inflow/ventricular side or the outflow/aortic side of the aortic annulus (Figs. 33-7 and 33-8). Placing the pledgets on the inside of the annulus allows supra-annular placement of the valve and generally

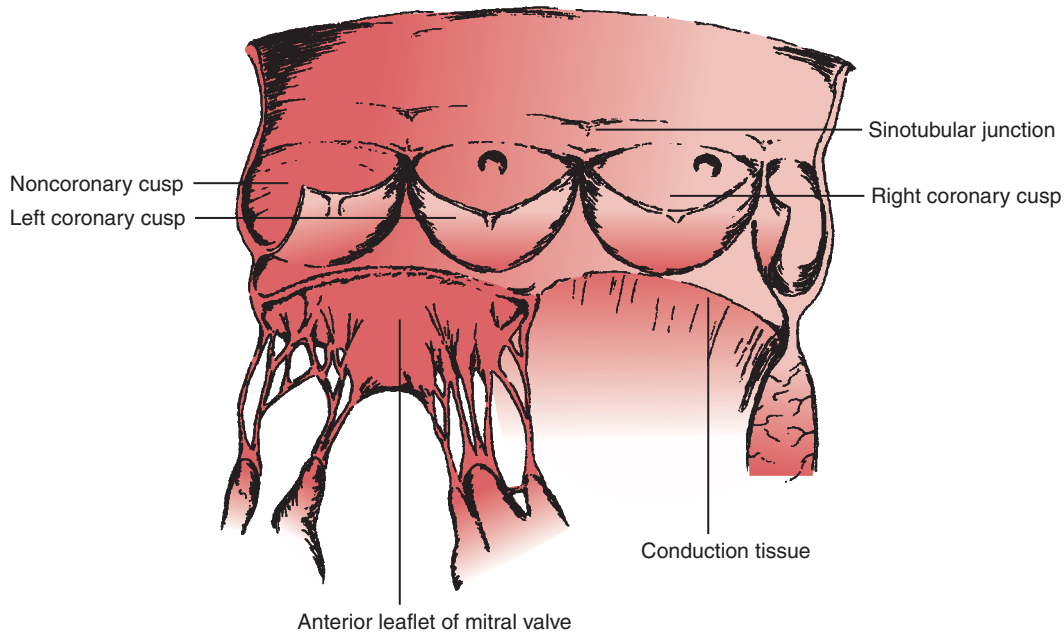

FIGURE 33-6 Anatomical relationships of the aortic valve.

will allow implantation of a slightly larger prosthesis. In cases in which the coronary ostia are close to the annulus, supra-annular placement may only be possible along the noncoronary cusp. Mattress sutures are first placed in the three commissures and retracted to assist visualization. Some surgeons will place the commissural suture between the right and noncoronary cusps from the outside of the aorta (ie, the pledget is left on the outside of the aorta) to prevent injury to the conduction system. Pledgeted mattress sutures are then placed in a clockwise fashion typically starting in the noncoronary cusp. Sutures may be placed into the sewing ring of the prosthetic valve with each annular suture or after all annular sutures are placed. The sutures for each of the three cusps are held separately with three hemostats and retracted while the prosthesis is slid into the annulus.

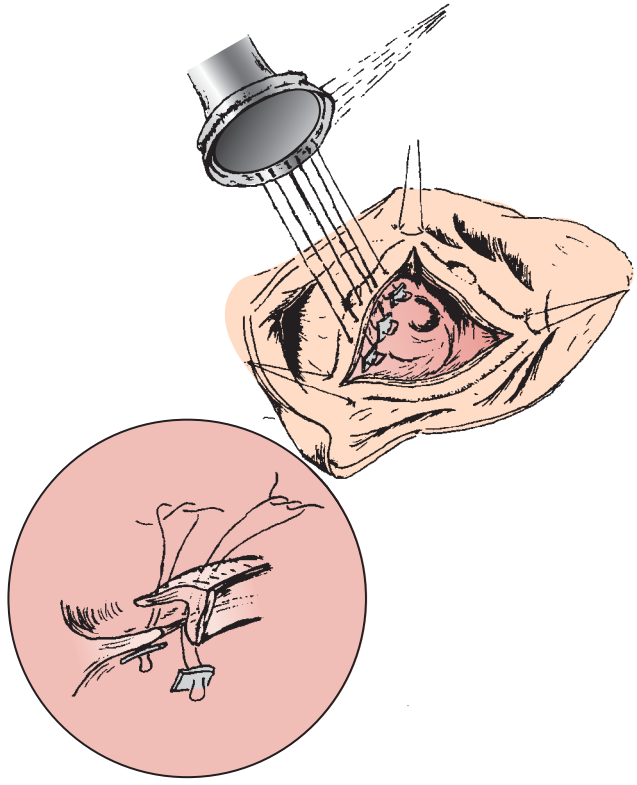

FIGURE 33-7 Placement of sutures with pledgets below the annulus.

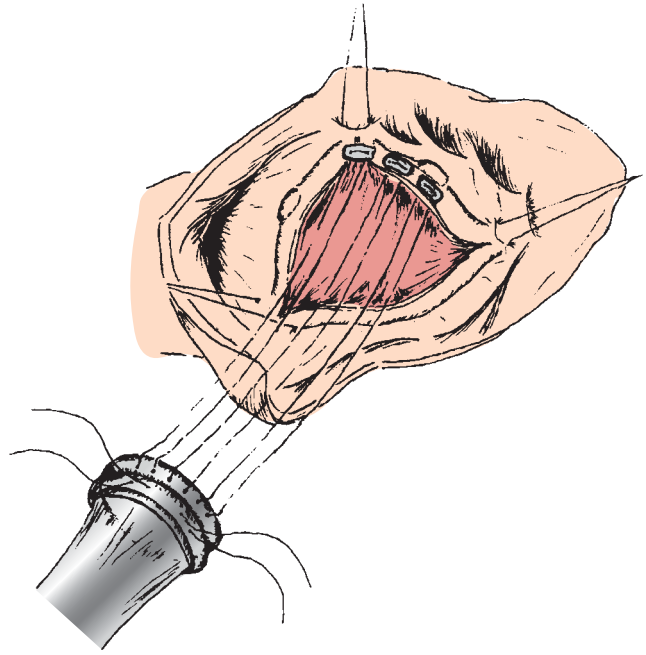

FIGURE 33-8 Placement of sutures with pledgets above the annulus.

Sutures are then tied down in a balanced fashion alternating among the three cusps.

Aortic Closure and De-airing

The aorta is closed with a double row of synthetic 4-0 polypropylene sutures. The first suture line is started on the right side at the posterior end of the aortotomy, and the double-needled suture is secured slightly beyond the incision to ensure there is no leak in this region. One end of the suture is run as a horizontal mattress anteriorly to the midpoint of the aortotomy, and then the second end of the suture is run anteriorly, slightly superficial to the horizontal mattress suture, in an over-and-over manner. On the left side, a similar technique is performed, the aorta is de-aired (described in the following), and the two sutures are tied to themselves and to each other at the aortotomy midpoint.

During AVR, air is entrained into the left atrium and ventricle, and aorta. This must be removed to prevent catastrophic air embolization. Immediately before tying the suture of the aortotomy, the heart is allowed to fill, the vent in the superior pulmonary vein is stopped, the lungs are inflated, and the cross-clamp is briefly partially opened. The influx of blood should expel most air from these cavities out of the partially open aortotomy. Closure of the aortotomy is then completed and the cross-clamp is fully removed. The cardioplegia cannula in the ascending aorta and the left ventricular vent are then placed on suction to remove any residual air as the heart begins electrical activity. A small needle (21-gauge) is used to aspirate the apex of the left ventricle and the dome of the left atrium. To prevent air entrainment, the left ventricular vent must be removed while the pericardium is filled with saline irrigation. De-airing maneuvers are verified with visualization using transesophageal echocardiography to verify that all air has been removed from the left side of the heart. Vigorous shaking and careful manual compression of the heart while suctioning through the aortic vent (ie, cardioplegia tack) is helpful to remove air trapped within trabeculations. Once de-airing is complete, the aortic vent is removed. The patient is then weaned from CPB and decannulated in the standard fashion. If patients are pacemaker-dependent when weaned from CPB in the operating room, it is recommended to insert atrial pacing wires to allow for synchronous atrioventricular pacing.

Concomitant Coronary Artery Bypass Grafting

Operative technique is modified when there is concomitant CAD to optimize myocardial protection. Distal anastomoses are performed before AVR so that antegrade cardioplegia may be administered through these grafts during the operation. The left internal mammary artery should be used for revascularization of the left anterior descending artery, because this may improve long-term survival in aortic valve patients.[29] This anastomosis is performed after the aortotomy is closed to ensure that the coronary circulation is not exposed to systemic circulation during cardioplegic arrest and to prevent trauma to the anastomosis during manipulation of the heart.

Concomitant Ascending Aortic Replacement

In general, the ascending aorta is replaced electively when maximal diameter exceeds 5.5 to 6.0 cm; however, with Marfan's syndrome or equivalent connective tissue disorder the cutoff is 4.5 to 5.0 cm. In the setting of concomitant AVR, aortic replacement is advised if the ascending aortic diameter is greater than 5.0 cm. Patients with bicuspid aortic valves have an underlying aortopathy that leads to significant risk of late ascending aortic complications, and these patients should have replacement of their ascending aorta if its diameter exceeds 4.5 cm at the time of AVR[30] (Fig. 33-9).

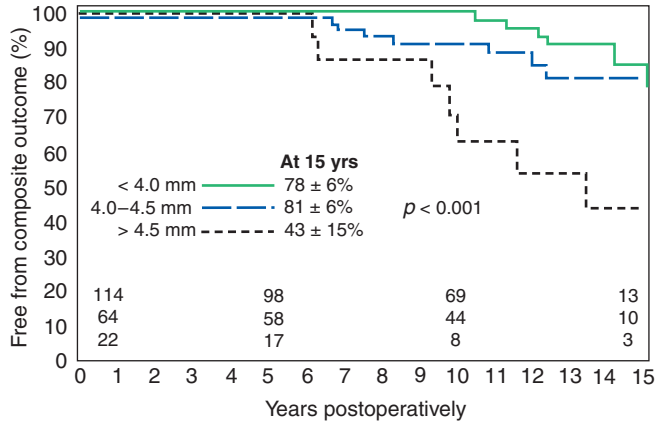

FIGURE 33-9 Freedom from ascending aortic complications for patients with a bicuspid aortic valve with an ascending aortic diameter of less than 4 cm, 4.0 to 4.5 cm, and 4.5 to 4.9 cm at the time of aortic valve replacement. (*Reproduced with permission from Borger MA, et al: Should the ascending aorta be replaced more frequently in patients with bicuspid aortic valve disease? J Thorac Cardiovasc Surg 2004; 128:677.*)

Aortic Root Enlargement Procedures

Detailed descriptions of aortic root enlargement procedures are presented in a later chapter. Briefly, either an anterior or posterior annular enlargement procedure may be performed in a patient with a small aortic root to allow for implantation of a larger valve. The posterior approach is the most commonly used aortic root enlargement procedure in adults and can increase the annular diameter by 2 to 4 mm. Nicks and colleagues in 1970 described a technique of root enlargement in which the aortotomy is extended downward through the noncoronary cusp, through the aortic annulus to the anterior mitral leaflet.[31] In 1979, Manouguian and Seybold-Epting described a procedure extending the aortotomy incision in a downward direction through the commissure between the left and noncoronary cusps into the interleaflet triangle and into the anterior leaflet of the mitral valve.[32] The anterior approach is generally used in the pediatric population. Described by Konno and colleagues in 1975, this technique, which is also known as aortoventriculoplasty, is used when more than 4 mm of annular enlargement is required.[33] Instead of a transverse incision, a longitudinal incision is made in the anterior aorta and extended to the right coronary sinus of Valsalva and then through the anterior wall of the right ventricle to open the right ventricular outflow tract. The ventricular septum is incised, allowing significant expansion of the aortic annulus and left ventricular outflow tract.

Reoperative Aortic Valve Surgery

Repeat sternotomy after AVR may be performed for valve-related complications, progressive ascending aortic disease, or CAD. Valve-related causes include structural valve deterioration, prosthetic endocarditis, prosthesis thrombosis, or paravalvular leak. Chest re-entry is the most hazardous portion of any repeat cardiac procedure. At Sunnybrook Health Sciences Center, our routine practice is to obtain an adequate lateral chest x-ray and computed tomography scan to determine the proximity of cardiac structures to the posterior sternum. Cardiopulmonary bypass is instituted through the femoral vessels for any concerns about chest re-entry. An oscillating saw is used to open the sternum and the dissection is kept as limited as possible. Extreme caution must be employed during dissection when there are patent bypass grafts.

Once cardioplegic arrest is established, the old prosthesis is excised with sharp dissection. Care must be taken to remove all sutures and pledgets from the annulus. Annular injuries caused while excising the prosthesis are repaired with pledgeted interrupted sutures. Removal of stentless prostheses may be particularly difficult in this regard. In the setting of endocarditis, aggressive debridement of infected tissue must be performed with appropriate annular reconstruction with pericardium when root abscesses are present.[34] All foreign graft material, including Dacron aortic grafts, must be excised in the presence of active endocarditis.

In the presence of a Dacron prosthesis in the ascending aorta, chest re-entry may be extremely hazardous because exsanguination will occur if the graft is inadvertently opened during dissection. To limit the systemic consequences of exsanguination at normothermia, the patient should be placed on femoro-femoral CPB and cooled to 20°C before chest reentry. If the Dacron graft is accidentally opened, local control of the bleeding is established and CPB is stopped. Under circulatory arrest, atrial venous cannulation is instituted and the graft is controlled distal to the tear. Cardiopulmonary bypass may then be restarted. In all repeat aortic procedures, rigorous myocardial protection must be applied because these procedures often have very long ischemic times. Antegrade cold blood cardioplegia is usually employed in a continuous fashion throughout the case by selective cannulation of the coronary ostia. Retrograde cardioplegia may have benefit in the setting of patent old saphenous vein grafts.[35]

POSTOPERATIVE MANAGEMENT

Special consideration must be given to the underlying pathologic changes to the ventricle during the immediate postoperative period. The severely hypertrophied, noncompliant LV resulting from AS is highly dependent on sufficient preload for adequate filling. Filling pressures should be carefully titrated between 15 and 18 mm Hg with intravenous volume infusion. In such cases, subvalvular left ventricular outflow obstruction with systolic anterior wall motion of the mitral valve may occur. Intravenous beta-adrenergic blockage may relieve this obstruction by decreasing inotropy. In extreme cases, reoperation and surgical myectomy may be required.

Maintenance of sinus rhythm is also essential because up to one-third of cardiac output is derived from atrial contraction in a noncompliant ventricle. Up to 10% of patients will experience low cardiac output syndrome in the immediate postoperative period. If pacing is required postoperatively, synchronous atrioventricular pacing is beneficial in preventing low cardiac output syndrome.

Complete heart block occurs in 3 to 5% of AVR patients. This complication may be caused by suture placement or injury from debridement near the conduction system. Transient complete heart block caused by perioperative edema usually resolves in 4 to 6 days. After this time, insertion of a permanent pacemaker is recommended if there is no resolution.

Profound peripheral vasodilation, often seen in patients with aortic insufficiency, is treated with vasoconstrictors, including alpha-adrenergic agonists or vasopressin. Adequate filling of the dilated left ventricle may also require volume infusion.

STENTED BIOPROSTHETIC AORTIC VALVE REPLACEMENT DEVICES

Stented biologic prostheses may be constructed of porcine aortic valves or bovine pericardium. Over the past 40 years, advances in tissue fixation methodology and chemical treatments have been developed to prevent extracellular matrix and calcium deposition. All heterograft valves are preserved with glutaraldehyde, which acts by cross-linking collagen fibers to reduce tissue antigenicity. Glutaraldehyde also ameliorates in vivo enzymatic degradation and causes the loss of cell viability, thereby preventing extracellular matrix turnover.[36] Glutaraldehyde fixation of porcine valves can be performed at high pressure (60 to 80 mm Hg), low pressure (0.1 to 2 mm Hg), or zero pressure (0 mm Hg). Pericardial prostheses are fixed in low- or zero-pressure conditions. Porcine prostheses fixed at zero pressure retain the collagen architecture of the relaxed aortic valve cusp.[37] When comparing various bioprostheses, it is important to be aware of lack of standardization in methodologies for labeling valve sizes by the different manufacturers. In general, label sizes refer to either the internal or external diameter of the stent, not the external diameter of the sewing cuff or the maximal opening diameter of the valve leaflets. Thus, the same aortic annulus will likely fit different-sized valves from different manufacturers, depending on the convention they use and the size of their sewing cuff. Figure 33-10 compares internal and external sizes for a variety of prostheses.

First-Generation Prostheses

First-generation bioprostheses were preserved with high-pressure fixation and were placed in the annular position. They include the Medtronic Hancock Standard and Modified Orifice (Medtronic, Minneapolis, MN), and Carpentier-Edwards Standard porcine prostheses (Edwards Life Sciences, Irvine, CA).

Second-Generation Prostheses

Second-generation prostheses are treated with low- or zero-pressure fixation. Several second-generation prostheses may also be placed

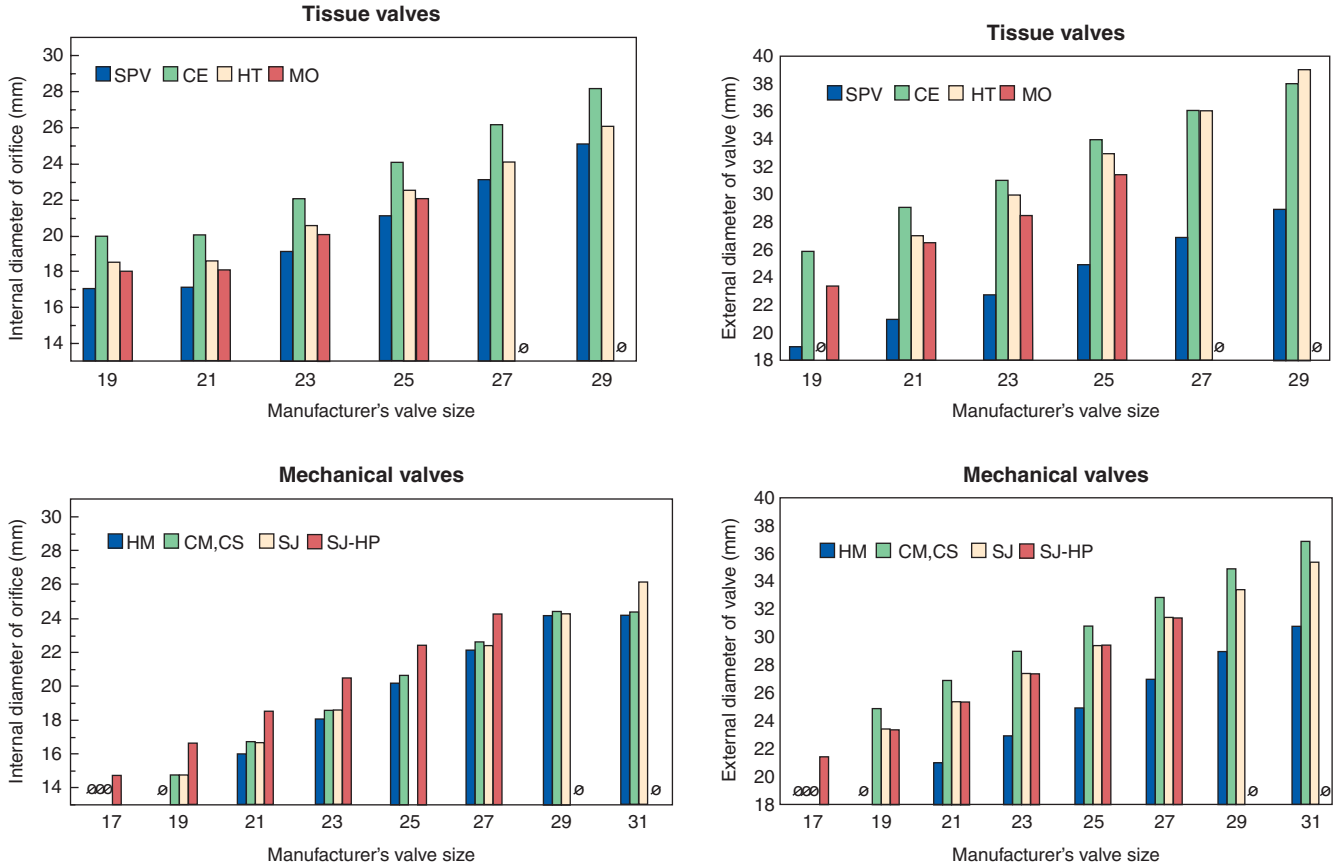

FIGURE 33-10 Comparison of the internal and external diameter of prosthetic aortic valves to the manufacturer's labeled size of each valve. No two manufacturers' valves have the same internal diameter for a given labeled size. CE = Carpentier-Edwards Pericardial valve; CM = Carbomedics Standard valve; CS = Carbomedics Supra-annular valve; HM = Medtronic Hall valve; HT = Hancock II Bioprosthesis; MO = Hancock Modified Orifice Bioprosthesis; SJ = St. Jude Standard valve; SJ-HP = St. Jude Hemodynamic Plus valve; SPV = stentless porcine valve. in the supra-annular position, which allows placement of a slightly larger prosthesis. Porcine second-generation prostheses include the Medtronic Hancock II valve (Medtronic), the Medtronic Intact porcine valve (Medtronic), and the Carpentier-Edwards Supraannular valve (SAV) (Edwards Life Sciences). Second-generation pericardial prostheses include the Carpentier-Edwards Perimount (Edwards Life Sciences), and the Pericarbon (Sorin Biomedica, Saluggia, Italy) prostheses.

Third-Generation Prostheses

Newer-generation prostheses incorporate zero- or low-pressure fixation with antimineralization processes that are designed to reduce material fatigue and calcification. Stents have become progressively thinner, have a lower profile, are more flexible, and sewing rings have become scalloped for supra-annular placement. The Medtronic Mosaic porcine valve (Medtronic) is fixed in a "physiologic" environment with equal pressure (40 mm Hg) applied to the ventricular and aortic sides of the leaflets, resulting in net zero pressure on the leaflets themselves (Figs. 33-11 and 33-12). The St. Jude Medical Epic valve (St. Jude Medical, Inc.) is a porcine valve with a very low stent post and base profile to minimize protrusion into the aortic wall and facilitate coronary clearance (Fig. 33-13). The Carpentier-Edwards Perimount Magna valve (Edwards Life Sciences) is the evolution of the Perimount pericardial valve, with a narrower sewing cuff and scalloped design for supra-annular placement (Fig. 33-14). The Mitroflow Pericardial aortic prosthesis (Carbomedics) is a pericardial valve that is unique in that the pericardium is placed around the exterior of the stent, presumably allowing for a larger opening diameter (Fig. 33-15).

OUTCOMES OF AORTIC VALVE REPLACEMENT

Operative Mortality

Operative mortality is defined as all-cause mortality within 30 days of operation or during the same hospital admission.[38] Contemporary series describe a very low operative mortality for isolated AVR between 1 and 8%, depending on the patient population, the presence of coronary disease, and the era of study.[39–43] In 1999, the Society of Thoracic Surgeons' (STS) database reviewed the results of 86,580 valve procedures to find an overall mortality of 4.3% for isolated AVR, and 8.0% for AVR

with CABG.[44] Aortic valve replacement with ascending aortic aneurysm repair was shown to have an increased operative mortality of 9.7%. The results of this study are summarized in Table 33-4. Then in 2009, they reviewed 67,292 cases of AVR and found 3.2% mortality rate (Table 33-5).[45] It is important to note that information in this database is voluntarily submitted and includes both low- and high-volume centers.

The preoperative risk factors of operative mortality for AVR derived from the STS database are presented in Table 33-6.[43,46–48] Most early deaths are attributable to renal failure, emergency status, and reoperations. In Table 33-7, mortality data for AVR-related procedures from an update of the STS database are presented describing the operative risk of isolated and combined valve procedures.[49]

Long-Term Survival

Longitudinal analysis demonstrates no difference in survival between patients receiving mechanical and bioprosthetic valves when they are implanted in similar age cohorts over 10 years of follow-up.[50] However, at 15 years' follow-up, structural valve deterioration in bioprosthetic valves leads to a survival benefit for patients with mechanical valves. In a prospective trial, 15-year mortality was 79 and 66% for bioprosthetic and mechanical

valves, respectively.[51] Substantially more bleeding events were found in patients with mechanical valves. It is important to note that increased bioprosthetic structural deterioration was likely influenced by the use of a first-generation prosthesis more prone to structural failure than newer devices.

In most published series, the expected survival after AVR is approximately 80 to 85% at 5 years, 65 to 75% at 10 years, and 45 to 55% at 15 years.[52–54] The outcomes of AVR are highly dependent on the functional status, comorbidities, and age of each individual patient.[55] The effect of age at the time of

surgery on late mortality for a variety of prostheses is depicted in Fig. 33-16. The comorbidities of age, concomitant CAD, LVD, and poor functional status on middle to late survival after bioprosthetic AVR are additive (Table 33-8).[56] Other risk factors for late mortality include concomitant renal disease, female gender, concomitant cardiac or vascular procedure, and atrial fibrillation.[57,58] Studies of mechanical valves often show superior long-term survival but patients are significantly younger at the time of operation. No prospective series of comparable patients has shown any survival benefit comparing pericardial with porcine valves in similar eras.

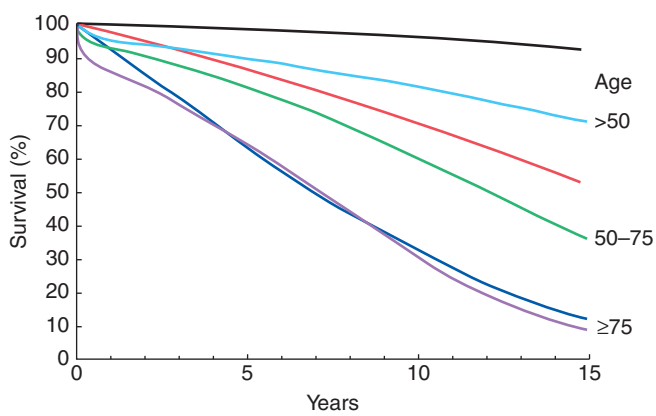

FIGURE 33-16 Projected long-term survival after aortic valve replacement stratified by age at time of surgery. For each age group the age-, race-, and ethnicity-matched population life table curve is shown as a dot-dashed line. Note that younger patients show more marked departure from normal life expectancy. (*Reproduced with permission from Blackstone EH, Kirklin JW: Death and other time-related events after valve replacement. Circulation 1985; 72:753.*)

Valve-Related Mortality

Long-term survival data distinguishes between valve-related mortality, non–valve-related cardiac mortality, and mortality from other causes. A revised consensus document from the STS and the American Association of Thoracic Surgeons (AATS) outlines a standardized method to report valve-related complications in prosthetic and repaired heart valves.[59] This panel defined valve-related mortality as all deaths caused by structural valve deterioration, nonstructural valve dysfunction, valve thrombosis, embolism, bleeding event, operated valvular endocarditis, or death related to reoperation of an operated valve. Sudden, unexplained, unexpected deaths of patients with an operated valve are included as valve-related mortality. Deaths caused by progressive heart failure in patients with satisfactorily functioning cardiac valves are not included. In the Hammermeister series, valve-related deaths accounted for 37% of all deaths in patients with mechanical valves and 41% of all deaths in patients with bioprostheses at 15 years.[51] Nonvalvular cardiac deaths accounted for 17 and 21% of deaths at 15 years in patients with mechanical and bioprostheses, respectively.[38] There are no well-designed prospective randomized series comparing the long-term outcomes of specific pericardial or porcine prostheses to each other.

Nonfatal Valve Events

The joint STS/AATS panel defined specific guidelines for reporting outcomes on structural and nonstructural valve deterioration, valve thrombosis, embolic events, bleeding events, and prosthetic endocarditis.[60] *Structural valve deterioration* refers to any change in function of an operated valve resulting from an intrinsic abnormality of the valve that causes stenosis or regurgitation (eg, leaflet tears, suture line disruption). *Nonstructural dysfunction* is any abnormality of an operated valve resulting in stenosis or regurgitation that is caused by factors not intrinsic to the valve itself (eg, pannus overgrowth, inappropriate sizing, or paravalvular leak). *Valve thrombosis* is any thrombus that interferes with valve function in the absence of infection. *Embolism* is any embolic event that occurs after the immediate postoperative period when perioperative anesthesia has been completely reversed. *Cerebral embolic events* are subclassified into: *transient ischemic attacks,* which are fully reversible neurologic events lasting less than 24 hours; *reversible ischemic neurologic deficits,* which are fully reversible neurologic events lasting between 24 hours and 3 weeks; and *strokes,* which are permanent neurologic deficits lasting longer than 3 weeks or causing death. A *bleeding event* is any episode of major internal or external bleeding that causes death, hospitalization, or permanent injury, or requires transfusion, regardless of the patient's anticoagulation status. This does not include embolic stroke followed by hemorrhagic transformation and intracranial bleed. Finally, *operated valvular endocarditis* is any infection involving an operated valve; or any structural or nonstructural valvular dysfunction, thrombosis, or embolic event associated with operated valvular endocarditis.

Structural Valve Deterioration

Stented Bioprostheses

Several large series describe long-term follow-up of first- and second-generation stented bioprostheses. These series are not directly comparable because they took place in different patient populations or different eras. Structural valve deterioration is the most common nonfatal valve-related complication in bioprosthetic aortic valve (Table 33-9). Long-term follow-up of currently available second-generation stented bioprostheses, including the Medtronic Hancock II porcine and Carpentier-Edwards pericardial valves, show freedom from structural valve deterioration less than 90% at 12-year follow-up.[52,61,62] However, beyond 15-year follow-up, freedom from SVD falls rapidly.[63] No good evidence exists to suggest that comparable, well-established second-generation pericardial or porcine prostheses differ in longevity; thus decisions regarding specific prosthesis should be made based on surgeon comfort and familiarity with the prosthesis and its sizing. Although newer third-generation prostheses with advanced tissue treatments eventually may be shown to have superior longevity, data about these prostheses are currently limited to 5- to 6-year outcomes, which appear comparable with those of the second-generation prostheses.[64]

Importantly, younger patients are predisposed to premature bioprosthetic SVD, particularly those less than the age of 40 years (Table 33-10).[65,66] Structural valve deterioration may be less common in elderly patients because of the decreased hemodynamic stress placed on the valve. The freedom from SVD may be underestimated in the literature because most series report SVD by the actuarial method instead of the actual or cumulative incidence method.[67] Actuarial statistical analysis overestimates SVD in older patients because it assumes that patients who have died of other causes will continue to be at risk for SVD.

Bioprostheses have a higher rate of reoperation then mechanical valves owing to structural valve dysfunction. In large series, freedom from reoperation is greater than 95% at 5 years, greater than 90% at 10 years, but less than 70% at 15 years.[52,68–73] The long-term freedom from reoperation for several commonly available valves is presented in Table 33-10.

Optimal Antithrombotic Therapy

Bioprosthetic Valves

Bioprosthetic valves thus do not require long-term anticoagulation with warfarin unless the patient is at high risk for

thromboembolism or has had a thromboembolic event with his or her prosthesis. Stented bioprostheses have a linearized risk for thromboembolism between 0.5 and 1% per year. This risk appears to be lower in patients with stentless heterograft, allograft, or autograft valves.[74–76] An increased hazard function exists for thromboembolism before the exposed surfaces of stented bioprostheses endothelialize.[77] The current ACC/AHA guidelines recommend anticoagulation with warfarin to an INR between 2.0 and 3.0 for the first 3 months for bioprosthetic valves as a class IIB recommendation.[18] This is discontinued at the end of the third month unless the patient is at high risk for thromboembolism. Low-dose aspirin is continued as monotherapy in low-risk patients. Aspirin significantly decreases the risk of thromboembolism in low-risk patients with bioprostheses versus no antiplatelet therapy.[78,79] High-risk patients require lifetime aspirin and warfarin treatment, which has a survival benefit over warfarin alone.[78] If a patient has identified high-risk factors for thrombosis preoperatively, a mechanical prosthesis should be implanted unless the risk factor is amenable to correction because formal anticoagulation with warfarin will still be necessary. With aspirin, bioprosthetic valves have approximately the same risk of thromboembolism as fully anticoagulated mechanical valves, with fewer bleeding complications.

Prosthesis Thrombosis

Prosthesis thrombosis is a rare but potentially devastating outcome after AVR. The incidence of prosthesis thrombosis is less than 0.2% per year and occurs more often in mechanical prostheses.[80] Thrombolytic therapy may be used in some patients but it is often ineffective. Thrombolysis is recommended in patients with left-sided thrombosis who are experiencing significant heart failure (NYHA class III or IV) and are considered too high risk for surgery.[81,82] Cerebral or peripheral thromboembolism occurs in 12% of patients after thrombolytic therapy.[81] Surgical treatment includes replacement of the valve or open thrombectomy, and mortality from either procedure is similar at approximately 10 to 15%.[81] Recurrent thrombosis after de-clotting occurs in up to 40% of patients and we recommend valve replacement in virtually all patients who are managed operatively.

Prosthetic Valve Endocarditis

Prosthetic valve endocarditis (PVE) is separated into two time frames: early (<60 days postimplantation) and late (>60 days postimplantation). Early PVE is usually a sequela of perioperative bacterial seeding of the valve, either during implantation or postoperatively from wound or intravascular catheter infections. *Staphylococcus aureus*, *S. epidermidis*, gram-negative bacteria, and fungal infections are common in this period.[52,72,83–86] Although most cases of late PVE are caused by septicemia from noncardiac sources, a small proportion of late cases in the first year are attributable to less virulent organisms introduced in the perioperative period, particularly *S. epidermidis*. Organisms responsible for late PVE include *Streptococcus* and *Staphylococcus* species and other organisms commonly found in native valve infectious endocarditis. All unexplained fevers should be meticulously investigated for PVE with serial blood cultures and TEE and/or TTE. Transesophageal echocardiography provides more detailed anatomical information such as the presence of vegetations, abscesses, and fistulas. Transthoracic views may provide better views of the anterior portion of the valve. The annual risk of PVE in the aortic position is 0.6 to 0.9% per patient year.[85–87] The 5-year freedom from PVE reported in many major series is greater than 97%.[52,85] Mechanical valves may have a slightly higher early hazard for PVE than stented bioprostheses.[86] However, no difference exists in risk between patients with mechanical and stented bioprosthetic prostheses after the early phase. Stentless porcine heterografts and allografts are less likely to develop PVE because they have less prosthetic material that may serve as a nidus of infection.[87] These valves may be particularly helpful in valve re-replacement for PVE.

Outcome for patients with PVE is very poor. Invasive paravalvular infection occurs in up to 40% of cases of PVE.[84] Early PVE is associated with 30 to 80% mortality, whereas late PVE is associated with 20 to 40% mortality.[52] Surgical indications for PVE include early PVE; concomitant heart failure and valvular dysfunction; paravalvular leak or partial dehiscence; presence of a new conduction defect, abscess, aneurysm, or fistula; persistent bacteremia despite a maximum of 5 days of appropriate antibiotic therapy and no other source of infection; vegetations (>10 mm); and multiple systemic emboli. Notably, all fungal and most virulent strains of *Staphylococcus aureus, Serratia marcescens,* and *Pseudomonas aeruginosa* require operation, as these organisms are highly invasive and antibiotic therapy is generally ineffective.

Paravalvular Leak and Hemolysis

Paravalvular leak is uncommon when pledgeted sutures are routinely used outside of the setting of infective endocarditis. Technical errors may result in inappropriately large gaps between sutures, leaving a small portion of the prosthesis unattached to the annulus. If paravalvular leak is sufficient to cause significant hemolysis, surgical correction may be performed with a few interrupted pledgeted sutures. Pannus overgrowth and prosthetic structural degeneration interfering with normal valve opening and closure may cause hemolysis severe enough to warrant reoperation. Milder cases of hemolysis may be managed conservatively by dietary supplementation with iron and folic acid, and routine measurement of hemoglobin, serum haptoglobin, and lactate dehydrogenase.

HEMODYNAMIC PERFORMANCE AND VENTRICULAR REMODELING

Left Ventricular Mass Regression

Pressure and volume overload caused by aortic valve disease leads to increased intracavitary left ventricular pressures and compensatory LVH. In severe AS, concentric ventricular hypertrophy occurs without increasing end-diastolic dimension until late in the disease process, thus maintaining the ventricular wall thickness:cavity radius ratio. On the other hand, severe AR causes volume overload with an increase in left ventricular end-diastolic

volume and eccentric hypertrophy, but may not change the ratio of ventricular wall thickness to cavity radius. Both pathologies result in an increase in LV mass (LVM), which has a strong negative prognostic effect.[88,89] The overall goal of AVR is to alleviate the pressure and volume overload on the left ventricle, allowing myocardial remodeling and regression of left ventricular mass.

The clinical impact of LVM regression is not as well understood, despite its widespread acceptance as a measure of outcome after aortic valve surgery. In hypertensive patients undergoing medical treatment, reduction of LVM was associated with fewer cardiac events than those whose left ventricular mass did not change or increased.[135] In patients after AVR for isolated AS, LVM generally regresses significantly over the first 18 months and returns to normal limits.[90,91] Ventricular mass regression may continue for up to 5 years after valve replacement.[92] However, some patients do not experience adequate ventricular mass regression. The prognostic implications of LVM regression after aortic valve surgery have not been rigorously studied but it is reasonable to suppose that lack of LVM regression is associated with poor clinical outcome. Several authors have identified a situation, referred to as patient-prosthesis mismatch (PPM), in which poor hemodynamic performance of a prosthesis results in poor regression of LVH and poor patient outcome.

Prosthesis-Patient Mismatch

Definitions

The term PPM has been applied to several different clinical situations. It has been used to describe absolute small valve size (ie, <21 mm), small valve size in a patient with a large body surface area, excessive transvalvular gradient postimplantation, increased transvalvular gradient with exercise, indexed effective orifice area, and various combinations of these variables. Rahimtoola defined PPM as a condition that occurs when the valve area of a prosthetic valve is less than the area of that patient's normal valve.[93] He further described a clinical condition in which the patient experienced either no relief or worsening of symptoms owing to the obstructive nature of the prosthesis, which creates a residual stenosis resulting in an elevated transvalvular gradient. To varying degrees, all valve prostheses are inherently stenotic.[94] The presence of rigid sewing rings, and in the case of stented bioprostheses, struts to hold the valve commissures, cause obstruction to outflow and will therefore cause a residual gradient despite normal prosthesis function. The EOA of commonly-available bioprosthetic valves are shown in Table 33-11. PPM is further exacerbated by annular fibrosis, annular calcification, and LVH, as seen in AS, that cause contraction of the native annulus, leading to the implantation of a smaller prosthesis. Two distinct terms are commonly used to describe the size of prosthetic valves: *effective orifice area* and *geometric orifice area.*

Effective Orifice Area

The most commonly cited definition of PPM is a low indexed effective orifice area (IEOA). The IEOA is calculated by dividing the echocardiographically determined effective orifice area (EOA) by the body surface area. Effective orifice area is calculated by a reconfiguration of the continuity equation:

$$EOA = (CSA_{LVOT} \times TVI_{LVOT})/TVI_{AO}$$

where EOA is effective orifice area (cm^2), CSA_{LVOT} is cross-sectional area of the LV outflow tract (LVOT; cm^2), TVI_{LVOT} is velocity time integral of forward blood flow (cm) as derived from pulse-wave Doppler in the LVOT, and TVI_{AO} is velocity

TABLE 33-11 The Effective Orifice Area (EOA) and Mean Systolic Gradient (MSG) of Commonly Available Bioprostheses

time integral of forward blood flow (cm) as derived from software integration of transvalvular continuous wave Doppler.

The EOA and mean systolic gradient of several commonly available bioprostheses are shown in Table 33-11.

Several authors suggest that PPM occurs at an IEOA of less than 0.85 cm^2/m^2.[95,96] Dumesnil and Pibarot have redefined PPM as a condition "when the EOA of the prosthesis is too small in relation to the patient's body size, resulting in abnormally high postoperative gradients."[96] This definition is based on the assumption that transvalvular gradients begin to rise substantially at IEOAs below this value, and that these elevated gradients result in increased left ventricular work preventing regression of LVH.[97]

The EOA is a functional estimate of the minimal cross-sectional area of the transvalvular flow jet downstream of a valve and dependent on the: (1) geometric area of the prosthesis, (2) shape and size of the LVOT and ascending aorta, (3) blood pressure, and (4) cardiac output (Fig. 33-17). Doppler-derived EOA correlates best with catheter-derived EOA (as determined by the Gorlin formula) when the ascending aortic diameter is 4 cm, but tends to underestimate EOA in patients with smaller aortic diameters.[98] The EOA cannot be known for a specific valve in a specific patient until the valve has actually been implanted. Studies examining the effect of low IEOA on clinical outcomes have typically used published tables of EOA derived from historical controls instead of actually measuring true in vivo postoperative EOA. Moreover, these tables have been derived from relatively small numbers of valves in each size for each manufacturer with wide variability between studies. EOA correlates with postoperative valve gradients, which is not surprising considering that they are mathematically related. Echocardiographic mean and peak gradients are calculated according to the Bernoulli equation:

$$\text{Peak gradient (mm Hg)} = 4 \times (V_{AVmax}^2 - V_{LVOTmax}^2)$$

$$\text{Mean gradient (mm Hg)} = 4 \times (V_{AVmean}^2 - V_{LVOTmean}^2)$$

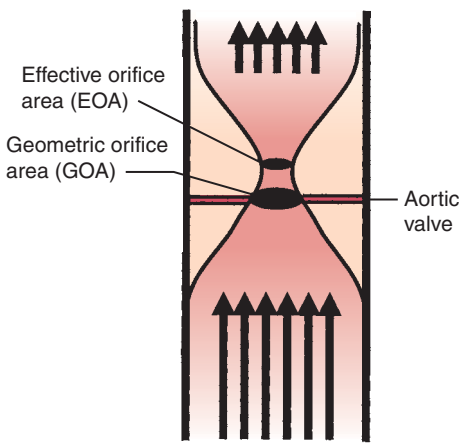

FIGURE 33-17 Diagrammatic representation of effective orifice area and geometric orifice area in relation to the left ventricular outflow tract and aortic root.

Geometric Orifice Area

Alternatively the geometric orifice area (GOA; also known as the internal geometric area) of the valve is the maximal cross-sectional area of the valve opening that does not vary significantly between same-sized valves from the same manufacturer. It is a static measure that is known preoperatively for any given prosthesis based on manufacturer specifications or by measurement with calipers. As seen in Fig. 33-17, the GOA is always larger than the EOA for any given prosthesis.

Clinical Significance

The significance of PPM is still controversial. Several studies have found that that lower IEOA is associated with diminished short- and long-term clinical results. Pibarot and Dumesnil[97] studied PPM in 1266 patients undergoing AVR and found moderate (IEOA <0.85 cm^2/m^2) or severe (IEOA <0.65 cm^2/m^2) PPM to be present in 38% of patients. Multivariate analysis showed that moderate and severe PPM are associated with a twofold and 11-fold increase of perioperative mortality, respectively. Retrospective analysis of PPM in 2154 patients undergoing AVR at two large centers showed similar overall mortality with and without PPM, but higher valve-related mortality with PPM at 10 years. A single-center analysis of 1563 mechanical and tissue aortic prostheses found that IEOA less than 0.8 cm^2/m^2 was associated with increased prevalence of heart failure symptoms at a mean follow-up time of 4.3 years but not with mortality.[99] Ruel and colleagues showed that overall survival and LVM regression was poorer in patients with PPM and LVD than those who had LVD without PPM.[100] In a series of 1400 patients, PPM affected long-term survival in patients less than 60 years old but not in older patients.[101]

On the other hand, several studies have also shown that PPM does not influence clinical outcomes. Medalion and colleagues studied 892 AVRs and demonstrated no differences in 15-year survival between patients with or without PPM, despite 25% of patients with an indexed internal orifice area less than two standard below predicted.[102] Hanayama and colleagues reported in 1129 patients with PPM post-AVR, no differences in LVM index or survival at midterm follow-up between patients with normal and abnormal gradients over a 10-year period.[103] They defined PPM as: (1) IEOA less than the 90th percentile in the study population (0.6 cm^2/m^2); and (2) valve gradient in the highest 90th percentile of the study population (peak gradient and mean gradient were 38 and 21 mm Hg), which would be considered severe by most groups. Fig. 33-18 shows no differences in LVM index or survival at midterm follow-up between patients with or without PPM. The average labeled size of valve in the low-IEOA and high-gradient groups were 22.4 and 23 mm, respectively. The only multivariate predictor of elevated postoperative gradient was valve size.

Blackstone and colleagues have compiled the largest and most statistically sound examination of the role of PPM in short- and long-term outcomes.[104] In a multi-institutional study of over 13,000 aortic prostheses, presence of an indexed GOA in the lowest 10th percentile was associated with a 1 to 2% increase in perioperative (30-day) mortality and had no effect

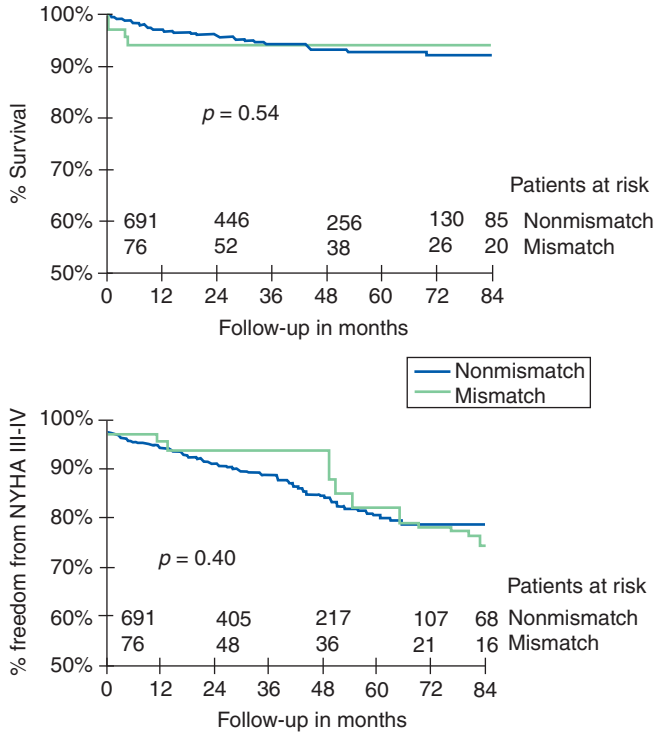

FIGURE 33-18 Actuarial survival and freedom from NYHA class III or IV in patients with and without prosthesis-patient mismatch. There were no significant differences in the two groups. (*Reproduced with permission from Hanayama N, Christakis GT, Mallidi HR, et al: Patient prosthesis mismatch is rare after aortic valve replacement: valve size may be irrelevant. Ann Thorac Surg 2002; 73:1822.*)

on medium- or long-term survival (Fig. 33-19). An important finding in this study was that virtually no stented bioprostheses were in the group of patients in the lowest 10th percentile of indexed GOA, who predominantly received mechanical prostheses. In a subsequent study from the same group, there was no relationship between indexed GOA and Duke Activity Status Index in 1108 patients undergoing AVR at a mean follow-up of 8.3 months. Predictors of postoperative functional status are presented in Table 33-12.

Small Aortic Root

Many surgeons express concern regarding postoperative outcomes in patients with small aortic roots in whom only very small (19 mm or smaller) valves can be implanted. However, several studies have shown no difference in LVM regression, NYHA functional class, CHF or survival with small diameter AVRs. [105–107] Khan and colleagues studied 19 mm to 23 mm Carpentier-Edwards pericardial valves and found that significant LVM regression occurred with each valve size, including 19 mm valves.[108] Studies by DePaulis and colleagues show no difference in LVM regression between patients receiving 19 and 21 mm mechanical valves versus those with 23 or 25 mm valves.[106] Kratz and associates also reported that small valve size was not predictive of CHF or late death.[107]

Data Synthesis

Although the literature regarding the clinical significance of PPM remains divided, proponents of the concept advocate use of mechanical prostheses. The presumption is less obstructive than stented bioprostheses, aortic root enlargement, and stentless valves when used in the subcoronary position and as full root replacement. However, whether mechanical prostheses alleviate PPM versus the current generation of tissue valves is an open question and indeed, they may even result in greater PPM.[109] Aortic root enlargement procedures require significant experience operating on the aortic root and may carry excessive mortality and wide variability in surgical outcomes even among highly experienced centers.

Alternatively, a stentless prosthesis in the subcoronary position may be a lower profile alternative but requires additional technical skill and cross-clamp time. Rao and colleagues compared hemodynamic data between stented Carpentier-Edwards pericardial valves and Toronto stentless porcine valves of equivalent diameter and found no hemodynamic differences in peak or mean gradient.[110]

Aortic root replacement in patients without ascending aortic pathology, solely to diminish the potential long-term effects of PPM, is a potentially high-risk strategy and is discouraged.

When faced with potential PPM in the operating room, the decision to perform a more complex, higher-risk procedure must be balanced carefully with the potential benefits of implanting a larger prosthesis. Some reports have shown that transvalvular gradients in patients with lower IEOA often rise substantially with exercise.[97,111] Although the majority of patients undergoing AVR are elderly and unlikely to experience functional limitations from this situation, in younger, highly active patients either root enlargement or stentless prostheses may provide better functional outcome with lower transvalvular gradients. In the rare circumstance of anticipated extreme mismatch (ie, IEOA <0.6 cm^2/m^2), root enlargement is an acceptable approach in the hands of an experienced surgeon. Except in these circumstances, given the paucity of long-term data to support more complex procedures and well-documented increased risk, routine AVR with modern standard prostheses is acceptable and preferable.

PROSTHESIS SELECTION

An ideal aortic prosthesis would be simple to implant, widely available, possess long-term durability, would have no intrinsic thrombogenicity, would not have a predilection for endocarditis, and would have no residual transvalvular pressure gradient. Such a valve does not currently exist. Currently available options include mechanical valves, stented biologic heterograft valves, stentless biologic heterograft valves, allograft valves, and pulmonary autograft valves. Among these options pulmonary autograft valves and allograft valves are the most physiologic prostheses. They are less prone to thrombosis or endocarditis and have excellent hemodynamic characteristics.[112,113] The longevity of such valves is dependent on patient factors, the preparation of the valve, and the technical skill of the operating surgeon. Despite their potential benefits, these prostheses are

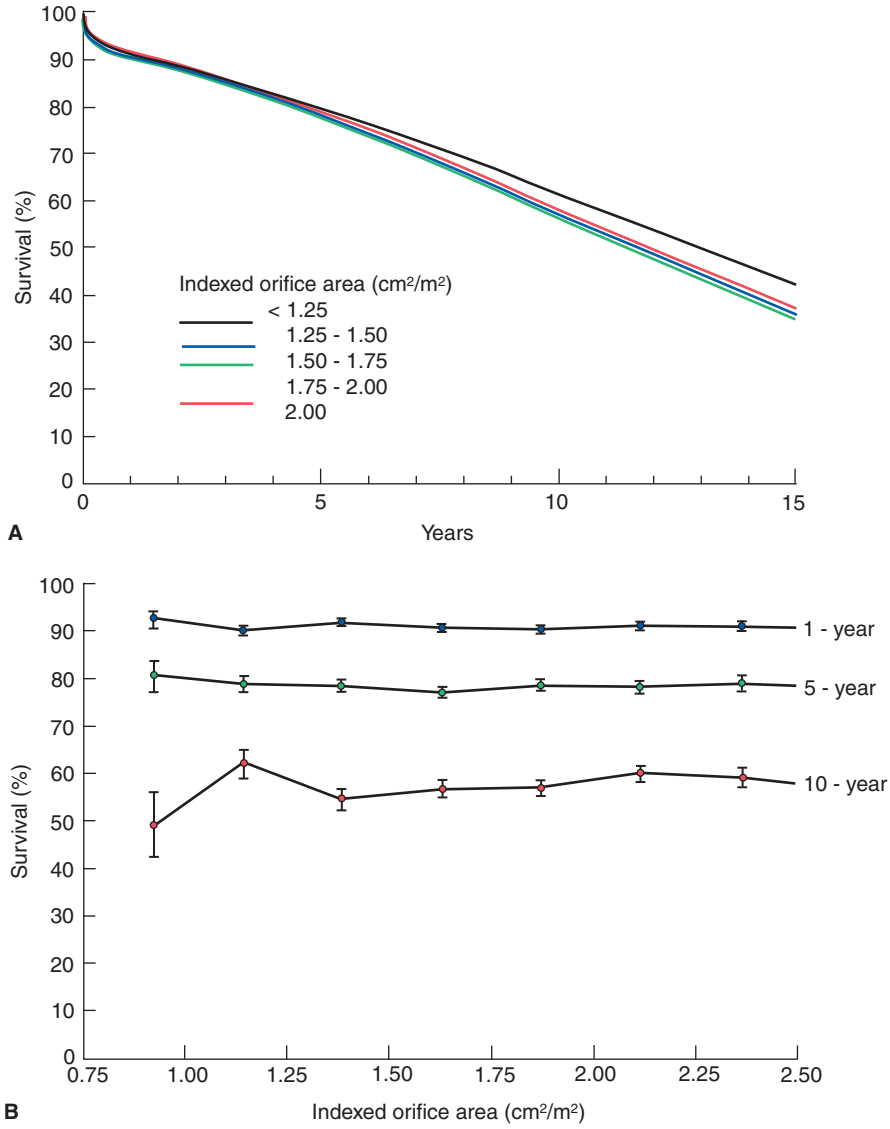

FIGURE 33-19 (A) Effect of indexed orifice area on non–risk-adjusted survival. (B) Time-related survival stratified by indexed orifice area. These are Kaplan-Meier estimates of 1-, 5-, and 10-year survivals in finely grouped strata of indexed orifice area. (*Reproduced with permission from Blackstone EH, Cosgrove DM, Jamieson WR, et al: Prosthesis size and long-term survival after aortic valve replacement. J Thorac Cardiovasc Surg 2003; 126:783.*)

not readily available and can be very technically demanding to implant compared with standard mechanical or stented bioprostheses. They are most beneficial in children and younger adults. Allograft valves may also improve the results of AVR in active endocarditis.[114] A further discussion of these valves is presented in subsequent chapters. As their use has remained confined to a few centers that perform such operations regularly, the remainder of this discussion focuses on issues regarding selection of mechanical or bioprosthetic valves.

Mechanical versus Biologic Valves

When selecting between mechanical and biologic heart valves, the surgeon and patient together must balance the risks and benefits of each choice. Mechanical valves are much less likely to undergo structural deterioration necessitating reoperation. Mechanical valves are more thrombogenic than bioprosthetic valves and require formal anticoagulation with oral warfarin, which carries a significantly increased risk of bleeding complications. Patients with mechanical valves and adequate anticoagulation do not have a greater risk of thromboembolic events than do those with bioprosthetic valves.[115] There is no difference in actuarial freedom from bacterial endocarditis between mechanical and bioprosthetic valves. Regarding overall survival, two randomized comparisons of mechanical and bioprosthetic aortic valves performed in the 1970s demonstrated equivalent survival between valve types at 12 years of follow-up.[116,117] Long-term survival beyond 15 years was superior in the mechanical valve groups as the risks of reoperation and structural failures of bioprostheses became more common.[118] However, the rate of structural valve deterioration was higher with first-generation prostheses than with newer-generation models.

TABLE 33-12 Multivariate Predictors of Functional Recovery after Aortic Valve Replacement

Follow-Up DASI	Factor	Estimate ± Standard Error	Estimated Odds Ratio (95% Upper and Lower Confidence Intervals)	*p*	Reliability (%)

Special Patient Groups

Patients with an absolute requirement for long-term anticoagulation such as atrial fibrillation, previous thromboembolic events, hypercoagulable state, severe LVD, another mechanical heart valve in place, or intracardiac thrombus, should receive a mechanical valve regardless of age.

Patients in whom anticoagulation with warfarin is contraindicated, such as women of child-bearing age wishing to become pregnant, patients with other bleeding disorders, or those who refuse anticoagulation should receive a bioprosthesis. Alternatively, implantation of mechanical prostheses in such women combined with anticoagulation using subcutaneous low-molecular weight heparin injections during the pregnancy is a possibility.

Patients with end-stage renal failure were previously believed to have significantly elevated risk for early bioprosthetic structural valve deterioration. However, increased anticoagulation-related complications are also more likely in this group, and the current ACC/AHA guidelines do not recommend routine use of mechanical prostheses in these patients.

Further considerations that may affect future patient decisions include testing for genetic variants of the *CYP2C9* and *VKORC1* genes, which influence warfarin response, use of devices to facilitate home INR monitoring, and use of novel nonwarfarin oral anticoagulants. A detailed and comprehensive discussion of these risks and benefits of prosthesis selection should occur with all patients and their families before entering the operating room.

Age Considerations

Currently available bioprostheses, such as the Medtronic Hancock II porcine and Carpentier-Edwards pericardial valve, have greater than 90% freedom from structural valve dysfunction and greater than 90% freedom from reoperation at 12-year follow-up.[52,60,61] The rate of structural deterioration is lower in patients over 65 to 70 years. Hence, patients greater than 65 years at the time of surgery should receive a biologic valve. Patients less than age 60 should have a mechanical prosthesis to minimize the risk of structural failure requiring repeat AVR as an octogenarian. Patients between 60 and 65 represent the group in whom there is still considerable debate regarding prosthesis selection. Those patients who have comorbidities such as severe CAD may be less likely to outlive their prosthesis and should receive a biologic valve. Prompted by improvements in durability of bioprostheses and lower reoperation risks, a recent retrospective study of patients 50 to 70 with AVR demonstrated worse 10-year unadjusted survival (50 versus 65%) and freedom from reoperation (91 versus 98%) with tissue compared with mechanical AVR.[11] On the other hand, Ruel et al.[119] found no difference in overall survival for patients less than 60 years old with tissue AVR versus those with mechanical AVR over a 20-year follow-up. Although age alone usually does not preclude one from surgery, advanced age and associated comorbidities may make someone a poor candidate for a classic valve replacement. In such patients, transcatheter aortic valve replacement (TAVR), discussed later, may be an alternative to medical management or balloon aortic valvuloplasty.

Stented versus Stentless Biologic Valves

Stentless porcine valves have gained popularity in cardiac surgery owing to the pioneering work done by Tirone David at the

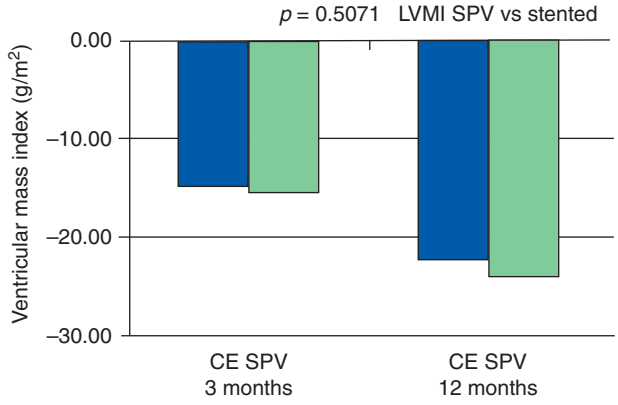

FIGURE 33-20 Indexed ventricular mass regression in stentless and stented valve patients over time. There were no significant differences in the two groups. CE = Carpentier-Edwards stented valve; LVMI = left ventricular mass index; SPV = Toronto stentless porcine valve. (*Reproduced with permission from Cohen G, Christakis GT, Joyner CD, et al: Are stentless valves hemodynamically superior to stented valves? A prospective randomized trial. Ann Thorac Surg 2002; 73:767.*)

Toronto General Hospital in 1988.[120] Stentless valves lack obstructive stents and strut posts, thus have residual gradients that are similar to those of freehand allografts. However, their use involves a more complex operation as they are more difficult to implant and require a longer cross-clamp time. Cohen and colleagues found no differences in aortic root size, IEOA, or LVM regression (Fig. 33-20) or functional outcome at 1 year between patients randomized to receive Carpentier-Edwards pericardial valves and Toronto stentless porcine valves (Fig. 33-21).[121] These findings challenge the notion that stentless porcine valves provide increased IEOA or hemodynamic or clinically

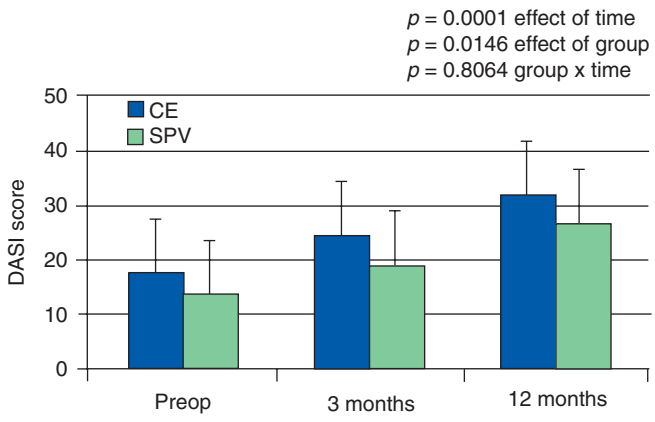

FIGURE 33-21 Change in Duke Activity Status Index (DASI) scores in stentless and stented valve patients over time. There were no significant differences in the two groups. CE = Carpentier-Edwards stented valve; SPV = Toronto stentless porcine valve; Preop = preoperative. (*Reproduced with permission from Cohen G, Christakis GT, Joyner CD, et al: Are stentless valves hemodynamically superior to stented valves? A prospective randomized trial. Ann Thorac Surg 2002; 73:767.*)

significant benefit. In a randomized trial comparing St. Jude Toronto stentless porcine valves with Carpentier-Edwards pericardial valves, Chambers and colleagues found no difference in IEOA, LVM regression, or mortality between groups. Arenaza and colleagues also performed a multicenter randomized trial comparing the Medtronic Freestyle valve with the Medtonic Mosaic valve and found increased IEOA in the stentless group, but no differences in LVM regression or clinical outcomes at 1 year.

However, Walther and colleagues performed a small randomized trial comparing the ability of stented porcine and stentless porcine valves which cause regression of LVH.[122] They showed that patients in the stentless valve group received larger valves for a given annular size and had a slightly higher degree of LVM regression. Borger and colleagues showed modestly lower mean gradients in stentless prostheses versus stented prostheses (9 versus 15 mm Hg) and LVMI (100 versus 107 g/m^2) but no difference in survival.[123]

Hence, conflicting evidence exists regarding benefit of stentless valves in LVM regression or clinical outcomes over stented bioprostheses. There is also little evidence that incremental improvements in LVM provide additional clinical benefit. Thus, the routine use of stentless bioprostheses cannot be recommended for most patients with small aortic roots based on currently available data. At this time, stentless porcine valves are most useful in a relatively younger patient with a small aortic root who is active and likely to be limited by the elevated residual gradient a small stented bioprosthesis may create.

PERCUTANEOUS VALVULAR INTERVENTIONS

Percutaneous Aortic Balloon Valvotomy

As an alternative to surgical management for AS, aortic balloon valvotomy has been performed percutaneously via a femoral artery puncture to treat AS.[124] Inflation of the balloon within the valve orifice can stretch the annular tissue and fracture calcified areas or open fused commissures. There is no role for valvotomy in the patient with significant AR, as this will become significantly worse after the procedure.[125,126] Balloon valvotomy is rarely successful if significant calcification is present and carries a prohibitive risk of stroke from calcific emboli.[127] The long-term outcomes of this procedure in adult patients are dismal, with restenosis usually occurring within 1 year.[126,127] Patients with severe symptomatic AS who are too hemodynamically unstable to tolerate operation or have comorbid illnesses, such as advanced malignancy, which contraindicate operation, may benefit from palliative balloon valvotomy.[128,129] More recently, techniques have developed to implant prosthetic valves using transfemoral and transapical catheter-based approaches.

Transcatheter Aortic Valve Replacement

Although surgical aortic valve replacement is the definitive treatment for aortic valve stenosis, up to one-third of patients are not candidates due to increasing age, heart failure, or other comorbidities.[130] The first clinical description of human transcatheter valve implantation took place in 2002.[131] Transcatheter

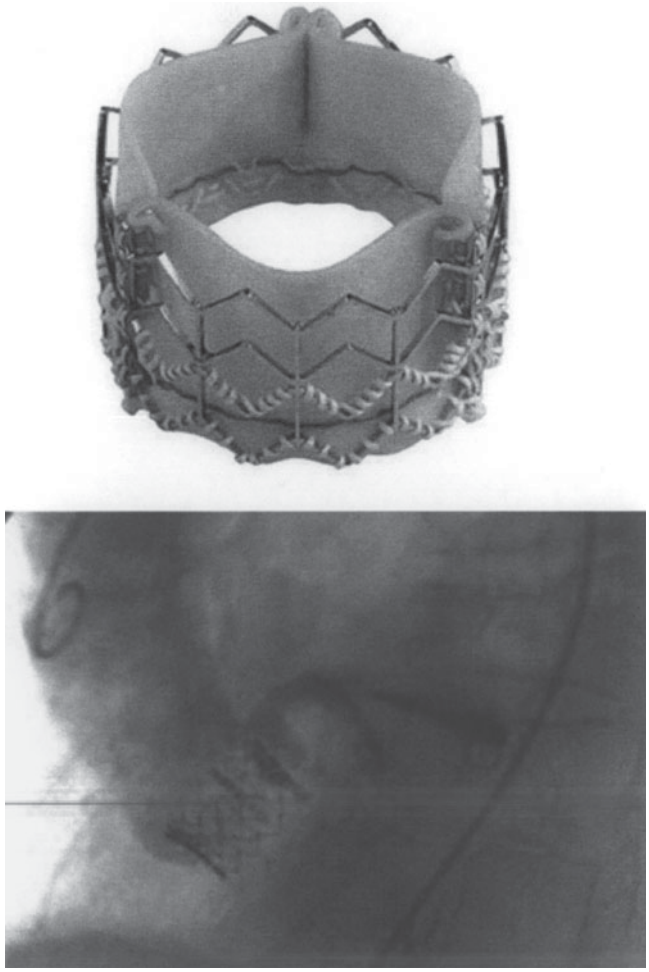

FIGURE 33-22 The Edwards Sapien aortic percutaneous heart valve (*upper panel*) and fluoroscopic view of this prosthesis deployed in the aortic root (*lower panel*). (*Figure courtesy of Edwards Life Sciences Inc., Irvine, CA.*)

heart valve technologies are now a clinical reality and have been shown to offer symptom relief and survival benefit to high-risk, elderly, and nonoperative patients.[132] Early experience from Webb and coworkers demonstrate overall mortality of 14.3% in the initial half to 8.3% in the second half of the study, and 74% 1-year survival with both percutaneous and transapical procedures.[133]

Currently, the two most extensively studied valve systems include the Edwards Sapien Valve and the CoreValve, although various other valves exist in different stages of development and evaluation (Fig. 33-22). Each valve system includes: (1) the valve prosthesis, (2) the stent or frame, (3) the loading system, and (4) the delivery system. The Edwards Lifesciences SAPIEN THV valve (Edwards Lifesciences Inc., Irvine, CA) is composed of a bovine pericardial valve on a balloon-expandable stent, whereas the CoreValve (Medtronic) is a porcine pericardial valve on a self-expanding nitonol frame.

The approach is accomplished via a retrograde transarterial or transapical manner. The percutaneous retrograde femoral approach involves femoral artery access, retrograde cannulation of the aortic valve, balloon dilatation, and device delivery. Alternatively, transapical transcatheter valve delivery involves creating a small thoracotomy, direct cannulation of the left ventricular apex, and passing of a wire and stent-mounted valve under fluoroscopic and echocardiographic guidance.[134] Both techniques require rapid ventricular pacing to ensure there is no cardiac output during device deployment.

At the time of writing this chapter, clinical trials are in progress in which issues regarding prosthesis durability, periprocedural stroke, coronary artery injury, and hemodynamic performance will be addressed. At present, these techniques are enabling very high-risk patients to experience some relief of their symptoms without undergoing a complex operation. Given the excellent current results of open operative AVR, the use of these procedures in lower-risk patients is not currently warranted.

CHAPTER 34

Stentless Aortic Valve Replacement: Autograft/Homograft

Paul Stelzer
Robin Varghese

INTRODUCTION

Unique among the many options now available for aortic valve surgery are the very old, but still useful "human" valve options, including the aortic homograft and the pulmonary autograft (Ross procedure) alternatives. Having reviewed the subject more than 20 years ago,[1] it is interesting to note how some things have changed but much has remained the same. Table 34-1 summarizes advantages and disadvantages of current replacement options.

HISTORICAL PERSPECTIVE

The first choice for aortic valve replacement was the homograft aortic valve. Gordon Murray created an animal model to implant an aortic homograft valve in the descending aorta[2] and was the first to apply the concept in the human demonstrating function for up to 4 years.[3]

Duran and Gunning at Oxford described a method for orthotopic (subcoronary) implantation of an aortic homograft valve in 1962,[4] and in 1962 both Donald Ross in London[5] and Sir Brian Barratt-Boyes in Auckland[6] did this successfully in humans.

Initially, homograft aortic valves were implanted shortly after collection.[7] This impractical method was rapidly supplanted by techniques to sterilize and preserve the valve for later use. Early methods employed beta-propiolactone[6,8] or 0.02% chlorhexidine,[9] followed by ethylene oxide[9] or radiation exposure.[10] Some were preserved by freeze-drying.[6,11] Recognizing that the incidence of valve rupture was high in chemically treated valves, Barratt-Boyes introduced antibiotic sterilization of homografts in 1968.[12] Cryopreservation of homografts was introduced in 1975 by O'Brien and continues to be the predominant method.[13,15] Experimental use of autologous valve transplantation began in 1961 when Lower and colleagues at Stanford transposed the autologous pulmonic valve to the mitral position in dogs[14] and shortly thereafter to the aortic position.[15] Donald Ross applied this to humans, reporting in 1967 clinical experience replacing either the aortic or mitral valve with a pulmonary autograft.[16] Nearly 20 years later the autograft was finally done in America by Elkins and Stelzer.[17] The operation came to be known as the Ross procedure. After an initial surge of interest in the 1990s (more than 240 surgeons worldwide reported their experience to the Ross Procedure International Registry[18]), its use diminished in the next decade.

HOMOGRAFTS

Procurement and Preservation

Homograft valves can be obtained from donors whose beating hearts are not suitable for transplantation but the larger source is tissue from nonbeating heart donors. This has been poorly understood and underappreciated by both medical professionals and the lay public.[19] Regional transplant organizations now participate in procurement of both solid organs and tissues. Specialized homograft processing centers receive hearts in sterile, refrigerated containers. Donor history is reviewed and serology tested for transmissible disease. The great vessels with their valves are separated from the heart under sterile conditions, carefully inspected for defects, measured, cultured, and immersed in antibiotic solution before being sealed in multiple-layer packaging containing dimethylsulfoxide, which prevents

TABLE 34-1 Comparison of Mechanical and Tissue Alternatives for Aortic Valve Replacement

	Mechanical	Stented Bioprosthetic	Stentless Bioprosthetic	Homograft	Autograft
Advantages	Long durability Easy implantation Good EOAI	Easy implantation No anticoagulation	Larger EOAI than stented valve Root replacement is available option	Excellent EOAI All biologic material good for use in endocarditis	Excellent EOAI Living valve Long durability possible
Disadvantages	Anticoagulation Emboli/bleeding Noise	Durability limited Poor EOAI in small valve sizes	Durability limited More complex operative technique Harder reoperation	Complex technique Availability limited Durability limited	Complex operation Double valve or root replacement with potential late failure of either or both

EOAI = effective orifice area index.

cellular rupture during the carefully controlled freezing process.[20] The homografts are then placed in vapor phase liquid nitrogen storage (about −195°C) until used.

Cellular and Immunologic Aspects of Homografts

The normal living valve contains multiple viable cell types, including endothelial cells, fibroblasts, and smooth muscle cells incorporated in a complex extracellular matrix. The cells and matrix elements are in a constant state of remodeling under the influence of regulatory systems that optimize the structure and function of the valve mechanism. It is understandable, therefore, that efforts to preserve homograft structure and function were translated into efforts to maintain homograft cellular viability. Radiation and chemical treatment led to very early failure and were quickly abandoned.[6,8,10,12,21] Antibiotic sterilization of homografts and storage at 4°C does not maintain cellular viability beyond a few days.[22,23] Cryopreservation became the gold standard when donor fibroblast viability was shown after implantation.[13] Although antigenicity of the fibroblast is low and other cell types do not survive the freezing process, panel reactive antibody (PRA) and donor-specific HLA I and II antibody testing is positive in 60 to 80% of homograft recipients.[24–26] The potential advantages of viability may be defeated by the detrimental effects of this on immune system reponse.[26] Animal studies have confirmed an immune mechanism by demonstrating that deterioration in homograft valve function is prevented by immunosuppression[27] and does not occur in T-cell–deficient rats.[28] Clinical use of immunosuppression, however, could not be justified for homograft patients.

Tissue engineering concepts led to decellularization, which lyses cells and "rinses" out antigenic proteins, leaving an inert matrix and intact structural framework. Preserved mechanical properties and structural integrity were demonstrated in a sheep model of such a scaffold. In addition, the empty matrix seemed to attract circulating recipient stem cells, which repopulated the framework and differentiated into appropriate cell lines capable of maintaining the matrix.[29] Initial use of the decellularized aortic homograft in humans demonstrated that structural integrity could be maintained with low, stable gradients and minimal regurgitation similar to standard cryopreserved homografts.[30] The same concept has been applied to the pulmonary homograft used in the Ross operation.[31,32] A decellularized xenograft valved conduit has also been used successfully for the right ventricular outflow (RVOT) reconstruction with the Ross.[33] Long-term studies are needed to determine if native cell ingrowth occurs reliably.

In summary, despite intensive investigation over decades, the relative contribution of the immune response, preservation techniques, and warm ischemia time to ultimate valve degeneration is not clear. More importantly, after consideration of the structural benefits and the immune-reaction risks, the net advantage of maintaining cellular (particularly fibroblast) viability in the homograft is not well defined.[34]

Indications for Aortic Homografts

Aortic valve replacement (AVR) with an aortic homograft has a number of advantages, including excellent hemodynamic profile with low transvalvular gradients and possibly enhanced regression of left ventricular mass,[35] low risk of thromboembolism without the need for systemic anticoagulation, and low risk of prosthetic valve infection. However, homografts are subject to structural deterioration which is inversely related to recipient age. Older donor age may also increase rates of degeneration. Furthermore, the availability of homografts is still limited, especially the larger sizes.

The strongest indication for a homograft is for treatment of active aortic valve endocarditis, particularly in patients with root abscess, fistula formation, or prosthetic valve infection.[36] The pliable handling characteristics, ease of coronary reimplantation, the potential for using the attached donor mitral anterior leaflet, and the ability to reconstruct the debrided root with

all biological material to minimize risk of persistent infection, all make the homograft exceptionally well suited to this challenging task. The homograft's very low early hazard rate for endocarditis sets it apart from other valve alternatives.[37]

Aortic homograft is also a reasonable option in the older patient (>60) with a small aortic root. The hemodynamic advantages of the homograft translate into better relief of outflow obstruction and improved exercise tolerance. Given its resistance to thromboembolic complications the aortic homograft can also be considered for younger patients requiring composite aortic valve or root replacement who cannot be anticoagulated. However, recent data from a prospective randomized trial would argue that most of the advantages of the homograft can be duplicated by the stentless porcine root replacement which has a significantly lower rate of calcification and valve dysfunction in this study.[38]

Preoperative Evaluation

Preoperative transthoracic echocardiography (TTE) is an invaluable diagnostic tool for evaluation of the AV and associated anatomic structures. Echo measurement of the left ventricular outflow tract (LVOT) can accurately predict aortic annulus diameter and thus the size of the homograft required.[39–41]

Computed tomographic angiography (CTA) or cardiac magnetic resonance (CMR) imaging can also be very useful in the evaluation of potential homograft patients, particularly those with aortic root abscess (Fig. 34-1). Coronary angiography should be employed with the standard indications but may be hazardous in patients with mobile vegetations on the aortic leaflets. Standard chest computed tomography with and without contrast should be considered in any reoperative setting to assess proximity of vital structures to the sternum and extent of ascending aortic or arch calcification or aneurysm. Heavy calcification around the coronary ostia may preclude safe reimplantation of coronary "buttons" or even a distal subcoronary suture line.

Transesophageal echocardiography (TEE) is often necessary to establish the presence of a root abscess, but its major role is for intraoperative confirmation of the anatomy and assessment of both valve and ventricular function.

The abscess projects from under the valve sewing ring near the left main coronary extending over the left atrial roof under the right pulmonary artery. (A) 3D reconstruction. (B) Standard CT showing prosthetic valve outline.

Operative Technique

General Preparation

Routine cardiac surgical monitoring including TEE is considered the standard of care. An antifibrinolytic agent such as epsilon-aminocaproic acid is helpful. A standard midline sternotomy incision provides full exposure of the heart, ease in cannulation, and access for optimal myocardial protection. Routine distal aortic cannulation and a dual-stage venous cannula usually can be employed.

Unless circulatory arrest is needed, minimal systemic cooling (32°C) is adequate if the heart is maintained at 10 to 15°C using a standard insulating pad and directly monitoring the myocardial septal temperature. A combination of antegrade and retrograde cold blood cardioplegia can be used with the bulk of the protection coming from the retrograde. The open aortic root reveals coronary return from both ostia to confirm effective retrograde.

A transverse aortotomy high above (1.5 to 2 cm) the commissures is usually best. The diseased aortic valve is excised and the annulus is measured with cylindrical sizers. The sinotubular

junction should also be evaluated for the subcoronary technique. The homograft is trimmed appropriately. In general, 2 to 3 mm of tissue, proximal to the nadir of each cusp, is advised for security in suture placement, leaving even more for full root replacements.

Techniques of Homograft Placement

Subcoronary Implant Technique

The subcoronary method involves two suture lines within the native root. The homograft is usually oriented anatomically to properly align the commissures and the coronaries. The proximal end of the homograft is sewn to the native annulus in a circular plane at the level of the nadir of each sinus curving upward slightly in the membranous septum to avoid injury to the conduction system. This anastomosis can be done with either interrupted or continuous sutures (Fig. 34-2).

The top of each commissure is tacked to the aortic wall. The right and left sinus walls are then scalloped out to a point 3 to 5 mm from the leaflets. The noncoronary sinus can also be removed but is usually left intact. A 4-0 or 5-0 polypropylene suture is started at the lowest point under each coronary ostium and a continuous suture line constructed from there up to the top of the commissure on either side. On the top of the noncoronary sinus, excess homograft tissue is trimmed down and tacked to the top of the aortotomy. The aortotomy is then closed with continuous 4-0 polypropylene suture incorporating the top of the homograft noncoronary sinus with the native aortic wall (Fig. 34-3). The ascending aorta is vented as the aortic clamp is removed. TEE can quickly assess any regurgitation at this point. Distention of the ventricle should be avoided by prompt defibrillation (if necessary) and pacing if required.

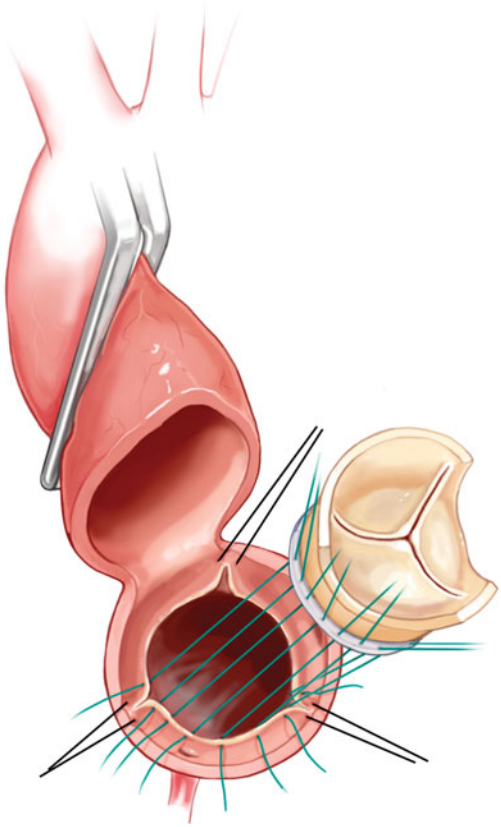

FIGURE 34-2 Subcoronary homograft implantation. The homograft is oriented anatomically and the proximal end attached in a circular plane at the level of the nadir of the recipient sinuses using either interrupted or continuous sutures.

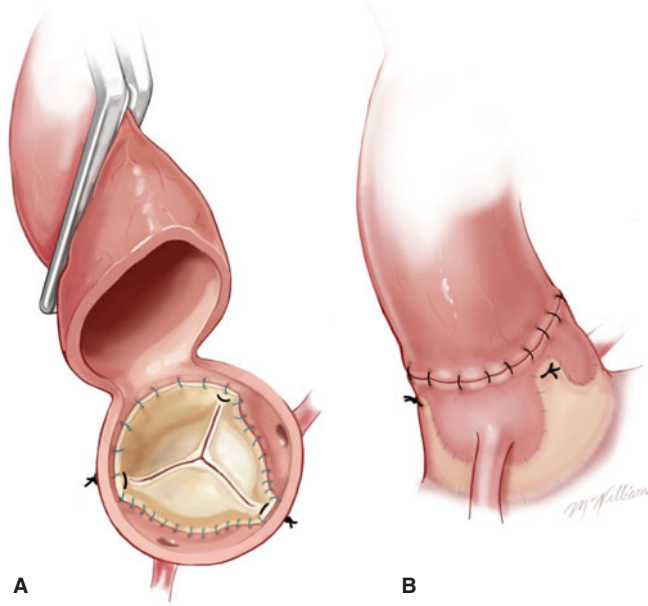

FIGURE 34-3 Distal homograft suture line. (A) The subcoronary implant is completed by tacking the aortic wall of the homograft to the recipient aortic wall with continuous fine polypropylene suture after trimming out the tissue in the coronary sinuses to allow blood flow to the native coronaries. The noncoronary sinus is usually left intact. (B) The aortotomy is closed in standard fashion incorporating the top of the homograft in the process.

Because even slight malalignment of the commissures can result in regurgitation, the subcoronary implant technique is considered more demanding than the other homograft techniques and may have poorer long-term results than the other methods.[42–46] It is a good technique for patients with small, symmetric aortic roots and sinotubular junctions, whereas it is a poor choice for those with dilated, asymmetric, or severely diseased roots.

Homograft Cylinder–Inclusion Root Technique

The cylinder modification of the subcoronary technique was developed in an attempt to preserve the native geometry of the homograft inside the recipient aortic root. The proximal suture line is identical to the subcoronary method but the sinuses are not scalloped out. Instead, a buttonhole is made in the right and left sinuses in such a way as to allow the homograft wall to be sewn to the native sinus wall around the coronary ostia. After the coronaries are secure, the distal end of the homograft is attached at the commissures and then incorporated circumferentially into the aortotomy closure. This method is the most difficult technically and is seldom used.

Homograft Root Replacement

The root replacement technique can be used in any root and is particularly useful in small roots or those destroyed by endocarditis. The root replacement allows size flexibility, which allows thawing an appropriate homograft without wasting clamp time. Very large roots may require commissural plication as described by Northrup.[47]

The aorta is opened transversely well above the commissures of the valve. The diseased valve is excised and annulus debrided. The aorta is transected and the coronary ostial buttons are mobilized in standard fashion. Antegrade cardioplegia should be avoided after this point to avoid injury to the mobilized ostia.

The homograft root is usually oriented anatomically, which makes matching the two roots easiest. The proximal suture line can be constructed with either continuous or interrupted technique. Interrupted is best in difficult reoperations, especially for prosthetic valve endocarditis because it allows for very accurate, deep placement of individual stitches. A strip of autologous (or bovine) pericardium is used to reinforce this crucial anastomosis. Polypropylene sutures of 3-0 or 4-0 are used and organization scrupulously maintained on suture guides. The homograft parachutes down as the sutures are carefully tightened (Fig. 34-4).

Routine cases can be expedited with a continuous suture technique with 4-0 polypropylene begun at the right-left commissure. The fibrous trigones and commissures of the native and homograft roots serve as anatomical landmarks and should match up as one proceeds around. The initially loose suture line is tightened carefully with nerve hooks and tied securely.

The coronary buttons are attached with continuous 5-0 or 6-0 polypropylene after excising the homograft coronary stumps. The distal end of the homograft and the native aorta are trimmed and sewn together with continuous 4-0 polypropylene incorporating another strip of pericardium for support. The native aorta is vented anteriorly and systemic flow rate lowered as the cross-clamp is removed.

Care is taken to avoid systemic hypertension or vigorous traction on the reconstructed root to avoid bleeding. Topical hemostatic agents and biological glues can be used, but they should not be routinely necessary. Blood and blood products are not routinely required unless the patient is coagulopathic.

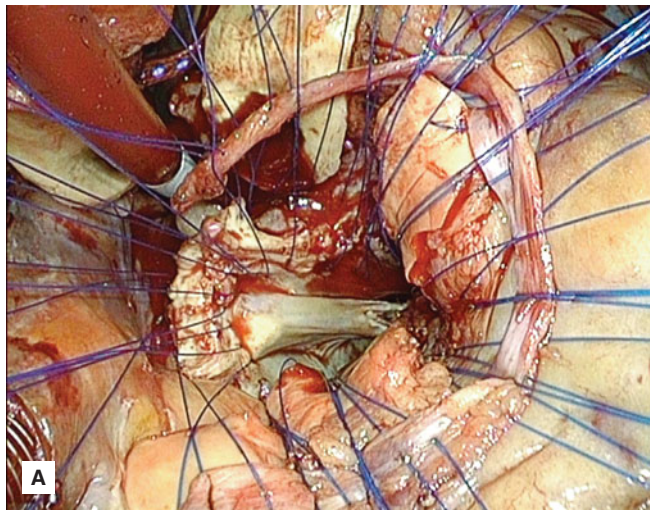
Postreplacement Assessment

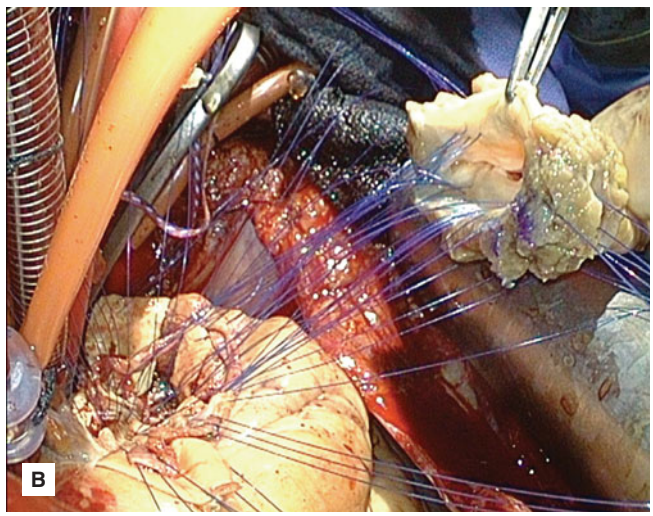
Ventricular function, regional wall motion abnormalities, and valve function may all be accurately determined with TEE. With appropriate loading conditions, moderate to severe AR warrants inspection and revision of the homograft. Mild AR is usually tolerated well and does not warrant reexploration.

Postoperative Management

Even mild hypertension should be avoided to prevent disruption of crucial aortic suture lines. Coagulopathic bleeding is best addressed with products targeted to specific abnormalities defined by laboratory studies.

Adequate volume replacement is required to keep the stiff ventricle of aortic stenosis filled and alpha adrenergic support is often required for the patient who is vasodilated. Atrial rhythm





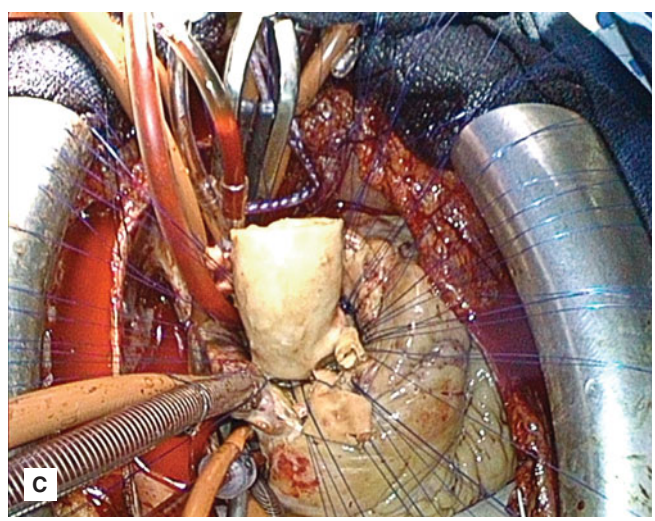


FIGURE 34-4 Homograft root replacement. (A) Interrupted 3-0 or 4-0 polypropylene sutures are placed deep in solid tissue, then passed through a pericardial strip and organization is scrupulously maintained on suture guides. (B) Sutures are then passed through the homograft from inside out. (C) The homograft parachutes down as the sutures are carefully tightened maintaining organization until each suture is tied precisely.

disturbances should be treated aggressively. Elderly patients, particularly females, with aortic stenosis and diastolic dysfunction are at increased risk of morbidity and even mortality from postoperative atrial fibrillation. The increased volume loading needed to overcome the loss of atrial transport often leads to pulmonary congestion requiring reintubation and prolonged support. Forward cardiac output is impaired and renal function deteriorates. Cardioversion should be considered early in these patients and loading with intravenous amiodarone is usually indicated. Preoperatively loading with amiodarone may minimize the incidence and consequences of this arrhythmia.[48]

Temporary pacing, preferably atrial as well as ventricular, should be enabled. Permanent pacing is indicated if epicardial wires become unreliable, heart block was present preoperatively, or the underlying rhythm fails to return within a week after surgery.

Stroke risk can be minimized by careful intraoperative epiaortic ultrasound to guide or avoid cannulation and clamping. TEE-guided evacuation of air is essential and flooding the field with carbon dioxide may be helpful.

Myocardial dysfunction is best prevented by careful temperature-monitored myocardial protection but long operations may still require temporary inotropic support. Caution must be used in the hyperdynamic ventricle with diastolic dysfunction. The combination of a hyperdynamic left ventricle and a dysfunctional right heart is very challenging. These patients may benefit from atrial pacing (if pacing is required), phosphodiesterase inhibitors, adequate volume replacement, and alpha agonists.

Renal insufficiency is a risk minimized by maintenance of adequate flows and pressure during bypass and generous volume administration in the early postoperative period. A thirsty patient with dry mucous membranes is a good clue that intravascular volume is still depleted. Later, diuretics are needed to encourage mobilization and excretion of this extra fluid. Hypotension should be avoided but vasopressors can have direct negative effects on renal blood flow.

Low-dose aspirin is often recommended for homograft patients, but is not necessary and formal anticoagulation with warfarin is not required at all unless dictated by other conditions. A routine predischarge echo should be done to confirm valve function, ventricular function, and freedom from pericardial effusion.

Results

Perioperative Complications

In patients without active endocarditis at the time of surgery, operative mortality in the current era is 1 to 5%.[44,49,50] The risk in experienced hands is comparable to using a stented bioprosthetic or mechanical valve. Ischemic time for a root replacement with either stentless porcine or aortic homograft is approximately 90 minutes.[51] A contemporary series of 100 consecutive aortic homografts (virtually all root replacements including 13 reoperations) demonstrated no hospital mortality with 100% survival at 1 year and 98% at 5 years.[52]

In contrast, patients with active endocarditis have a higher early mortality ranging from 8 to 16%.[44,53–56] Prosthetic valve endocarditis (17.9 to 18.8%) is worse than native (2.6 to 10%).[53,57]

Hemorrhage, heart block, stroke, myocardial infarction, and wound complications occur with similar frequency to those of other AVRs, but early risk of endocarditis is lower with homografts than any other replacement valve.[37]

Hemodynamics and Exercise Capacity

Hemodynamic characteristics of homografts are excellent at short- and medium-term follow-up, both at rest and during exercise.[58,59] A study of 31 patients demonstrated increases in peak and mean gradients of 6.6 and 3.0 mm Hg, respectively, without a significant change in effective orifice area (EOA).[58] Importantly, the EOA of even the 17- to 19-mm homografts was 1.7 cm^2 and larger valves approximated the normal aortic valve areas as high as 2.7 cm^2 for 24- to 27-mm homografts.

The typical subcoronary homograft implant demonstrates a 1- to 2-mm Hg drop in mean transvalvular gradient over the first 6 months but with full root replacement, the hemodynamic benefit is fully realized immediately. In the randomized trial of homograft versus stentless porcine root replacement the mean gradients were only 6 ± 1 mm Hg in the stentless and 5 ± 2 mm Hg in the homografts. Only one patient in each group had mild regurgitation after 5 years.[51] These authors concluded that stentless and homograft root replacements are hemodynamically equivalent in the mid-term.

Long-Term Outcomes

Long-term outcome has been shown to be technique dependent in a meta-analysis of more than 3000 patients (37% full root, 63% subcoronary) from 18 studies with a mean follow-up of 12.5 years. Reoperation was significantly lower in the root replacement group.[60] There may have been some bias against reoperation in failing roots, in which failing subcoronary implants were more readily subjected to reoperation.

The pioneering work of Mark O'Brien in Brisbane, Australia, produced a huge series of homograft patients over nearly three decades with 99.3% follow-up.[50] This series demonstrated that rates of reoperation were lower in the full root patients ($n = 3$, 0.85%) than the subcoronary ($n = 18$, 3.3%). Of note, operative mortality was only 1.13% in 352 root patients.

Long-term durability was compromised by young age of recipient to the point that those less than 20 years of age had a 47% rate of reoperation for structural valve degeneration at 10 years. Conversely, those more than 60 had a 94% freedom from reoperation at 15 years, and those between 21 and 60 had 81 to 85% freedom at 15 years. This series confirmed the very low incidence of thromboembolic phenomena (without anticoagulation) and a low but not insignificant rate of endocarditis.

Lund reported crude survival at 10 and 20 years to be 67 and 35%, respectively,[44] whereas Langley and O'Brien reported actuarial survival at 10, 20, and 25 years to be 81,[49] 58,[49] and 19%, respectively.[50]

Structural valve failure of homografts increases with time, and approximates 19 to 38% at 10 years and 69 to 82% at 20 years.[44,49] Freedom from repeat AVR, for any reason, parallels structural valve failure and is 86.5 and 38.8% at 10 and 20 years, respectively.[49] As heterograft tissue technology has progressed, the difference

between homograft and heterograft durability has narrowed to the point of near equivalency, with both showing a dramatic age-dependent relationship with youngest patients failing most rapidly.[61]

Freedom from endocarditis at 10 years is 93 to 98%,[49,50] and at 20 years 89 to 95%.[44,49,50] Freedom from thromboembolism at 15 and 20 years is 92 and 83%, respectively.[50] Thrombosis of a homograft has been reported, but in the setting of lupus anticardiolipin antibody syndrome.[62]

In patients with active endocarditis requiring AVR, results may be poorer, with survival ranging from 58% at 5 years[53] to 91% at 10 years,[56] and is significantly lower in patients with prosthetic valve endocarditis (PVE).[54] Of note, however, the risk of recurrent endocarditis is less than 4% up to 4 years postoperatively.[43,53,54,56] These results still compare favorably with alternatives; therefore, aortic homograft is considered by many to be the valve of choice for aortic valve or root replacement in patients with active endocarditis.

Homograft Reoperation

Because of extensive calcification after many years the risk at reoperation after homograft replacement can be as high as 20%.[63] The subcoronary implants may be easier in this regard because the native aortic root is preserved. The full root replacement is more of a problem. Up to about 10 years, calcification is limited and it is theoretically possible to place a new valve inside the homograft annulus after removing the leaflets.[64] Ultimately, however, the conduit becomes so rigid as to preclude such an alternative and complete re-replacement of the root is required (Fig. 34-5). The most hazardous part of this operation is related to the coronary ostial buttons, which must be protected and available for use again.

Reoperation can be made easier by anticipating the need for this at the original operation. Keeping the coronary buttons large at the initial operation is one way to avoid problems with dissecting them again. The homograft root should be kept as short as possible to minimize the extent of ultimately calcified wall and maximize the amount of normal aorta available for subsequent cannulation and clamping. Closing the pericardium or using a pericardial substitute can make sternal re-entry safer. Careful assessment of the aorta and mediastinum on CT preoperatively can alert one to the need for early peripheral cannulation and even sternotomy under circulatory arrest.

Clamping the aorta distal to the main pulmonary artery is very useful in these cases and avoids the hazards of entering a great vessel while dissecting between them before the clamp is on. Complete excision of the calcified wall is often the best policy, but leaving a little margin around each coronary ostium may make reconstruction easier. Another homograft is often an excellent solution because it is easier to reimplant the coronary ostia, but even a Ross operation can be done in this setting, as was done for the 40-year-old man shown in Fig. 34-5.

An increasingly attractive option in the future for older patients is transcatheter valve replacement, which should be well-suited to the calcified homograft root as reported from Milan[65] (Fig. 34-6).

Conclusions

Between the lack of availability of homografts and the improvements in readily available alternatives such as stentless porcine devices, homograft replacement of the aortic valve is less common than it was 20 years ago. However, it remains a versatile, highly effective tool with potential advantages in small aortic roots greater than age 60 and in settings of severe aortic root endocarditis. The homograft can be placed with a low operative

mortality risk and provide excellent hemodynamic function immediately without the need for any anticoagulation. Its major downside is the inexorable deterioration of its structure over time, which makes it a poor choice in very young patients. Those patients may well be best served by the autograft operation.

PULMONARY AUTOGRAFT: ROSS PROCEDURE

Theoretical Considerations

The pulmonary autograft shares the hemodynamic advantages and anti-thrombotic features of the homograft but is the only valve which has the benefit of being a fully viable autologous tissue. Pulmonary leaflets have been found to have equivalent breaking strain compared to aortic leaflets and even higher tensile strength.[66] The living pulmonary valve demonstrates the adaptability of human biology to change in response to changing physiologic conditions. The histologic features of this adaptation have been elegantly described and illustrated.[67] The initial response is to lay down a collagen-rich support on the ventricular aspect of the leaflets. This thins out later but remains slightly thicker than normal aortic leaflets. All three layers of the leaflets, fibrosa, spongiosa, and ventricularis contain viable cells which maintain a rich extracellular matrix to support the leaflet function. Endothelial cells are transformed to become capable of smooth muscle actin production becoming more like the aortic than the pulmonary phenotype. The autograft (pulmonary artery) walls are a different story. There is rapid loss of elastin with fragmentation and loss of cellularity and increasing collagen deposition. This may reflect the need to sacrifice elasticity for strength to withstand systemic pressure.

Patient Selection

The cardinal principle in selecting patients for the Ross procedure is that they must have a life expectancy of at least 20 to 25 years. Other simpler alternatives can be expected to give 10 to 15 years, even in young patients, although durability of tissue valves in patients less than 35 years of age can be very limited. Active lifestyle, potential for childbearing, and contraindications to anticoagulation favor the Ross procedure. Many young people seek out this option specifically to avoid the issues of anticoagulation and even to allow extreme athletic activity, such as mountain biking and triathlons. Practically speaking, the ideal patient is under 50 years of age but special circumstances can extend this to 65 or even slightly higher.

The generally accepted contraindications are significant pulmonary valve disease, congenitally abnormal pulmonary valves (eg, bicuspid or quadricuspid), Marfan's syndrome, other connective tissue disorders, complex coronary anomalies, and probably severe coexisting autoimmune disease, particularly if it is the cause of the aortic valve disease. Active rheumatic disease is a relative contraindication because the autograft can be attacked early by the acute rheumatic process and lead to early failure.[68] Bacterial endocarditis is not a contraindication for the Ross procedure, although it is best used when only leaflet destruction is present or root involvement can be reconstructed without distortion.[69]

Comorbid conditions should also be considered before offering this operation to any given patient. These conditions often limit life expectancy and also influence the ability of the patient to withstand this longer procedure. Poor left ventricular function, multivessel coronary disease, and need for complex mitral repair are examples. Ascending aortic dilatation or aneurysm have been considered contraindications by some, but these can be and should be easily addressed. Previous AVR or other open cardiac operations are not a contraindication to the Ross procedure, but all the standard considerations of reoperative surgery apply including appropriate imaging to allow safe sternal re-entry.

Bicuspid aortic valves (BAV) are the most common etiology of severe aortic stenosis or regurgitation in patients less than 65 years of age. Some have felt this group should not undergo the Ross procedure because of potential complications of intrinsic aortopathy, which is common in BAV patients.[70] Because this is the largest group of patients potentially to benefit from the operation, it has been the quest of Ross surgeons to find ways to make the operation safe and durable in this situation. Controversy still exists as to whether primary aortic regurgitation (AR) is less favorable than primary aortic stenosis.[71,72] The patient with aortic stenosis (AS) is more likely to have a smaller annulus, which is resistant to dilatation, as opposed to the AR patient, whose annulus is often dilated and continues to dilate if not supported. There is also more of a tendency to distal aortic dilatation in the setting of AR as opposed to AS. These issues are addressable by technical modifications, which is discussed later in detail.

Preoperative Evaluation

Because most candidates for the Ross procedure are less than 50 years of age, it is not usually necessary to subject them to cardiac catheterization. CTA is an excellent tool to evaluate the entire ascending aorta and arch as well as the proximal coronary arteries. Cardiac magnetic resonance (CMR) can be used as well but does not give as much resolution as CTA for the coronaries. Both give excellent imaging of the entire aorta (Fig. 34-7). Transthoracic echocardiography gives excellent assessment of the aortic valve, ventricular function, and aortic root. Approximately 1% of patients are found to have a bicuspid pulmonary valve at surgery. Unfortunately, echo, CTA, and CMR have all been limited in their ability to define the morphology of the pulmonary valve. With proper gating, timing of contrast, and attention to the pulmonary trunk, however, this can be determined fairly reliably (Fig. 34-8).

Technique

The original description by Donald Ross involved a fully scalloped subcoronary implant of the pulmonary autograft using essentially the same technique he had used for a subcoronary homograft implant. Modifications were adopted to decrease the immediate incidence of regurgitation by maintaining the cylindrical geometry of the autograft either within the aortic root or as a complete replacement thereof. The root replacement has become the most commonly employed technique.

Full median sternotomy is usually the best incision. Aortic cannulation should be kept high and bicaval cannulation is preferable because the open RVOT is a constant source of air. Initial antegrade and then generous retrograde cold blood cardioplegia is employed insulating the heart from surrounding structures and monitoring the effectiveness of myocardial

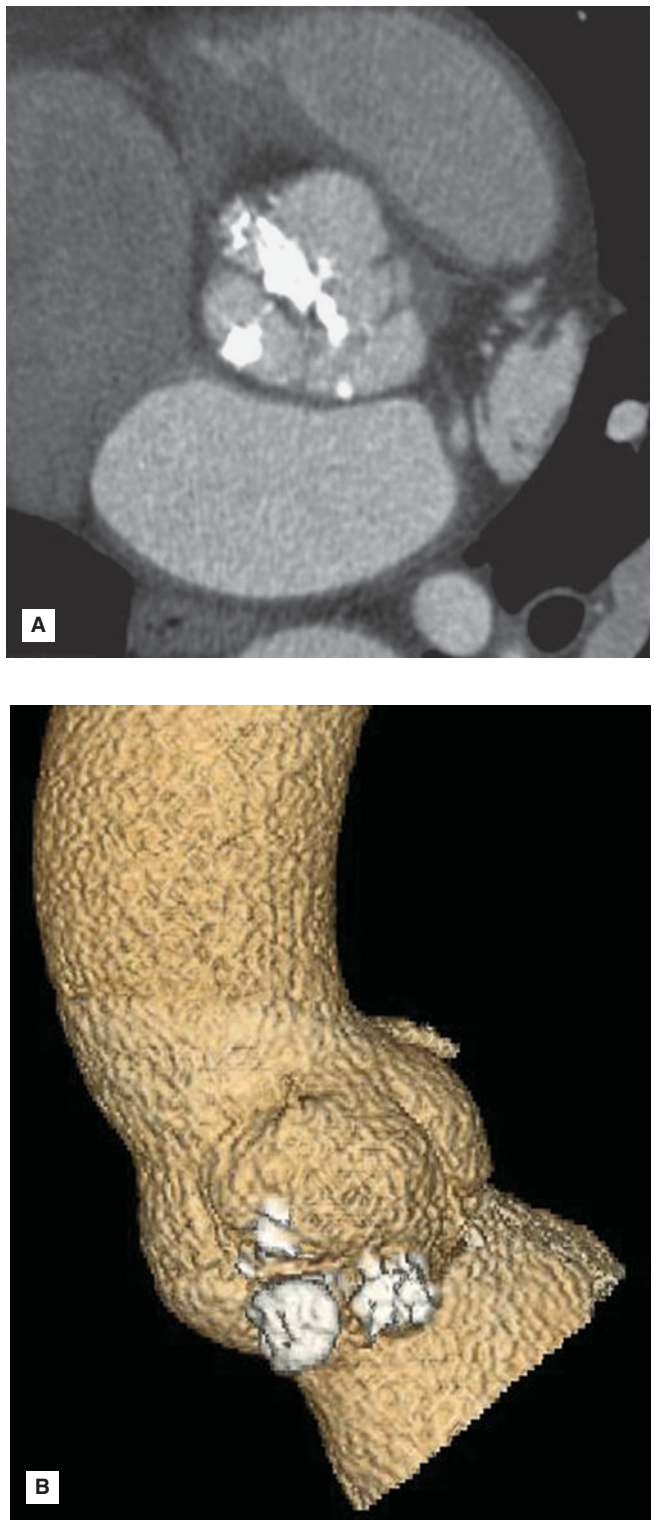

FIGURE 34-7 Preoperative imaging of the aorta. (A, B) Computed tomographic angiography. (C) Cardiac magnetic resonance.

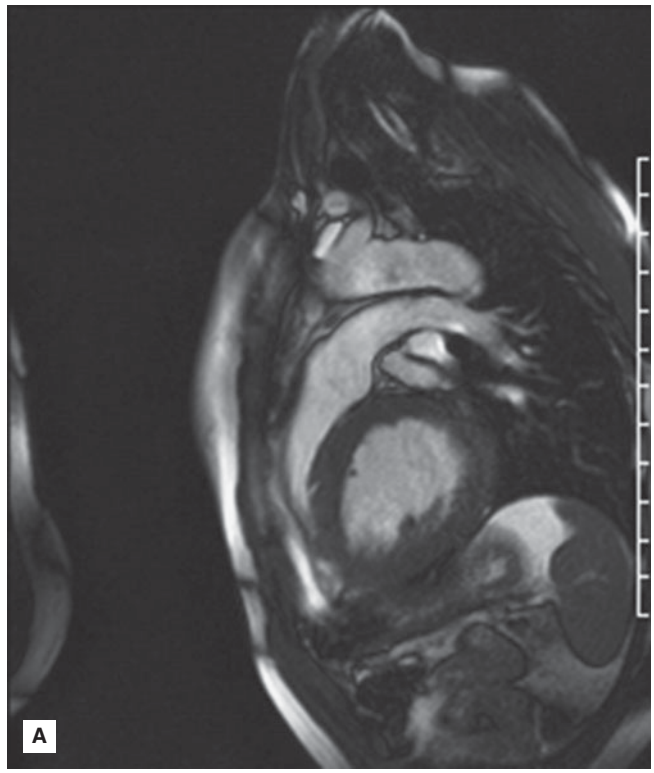
FIGURE 34-7 (*Continued*)

cooling with a septal temperature probe. Traditional venting via the right superior pulmonary vein is not necessary because the open pulmonary artery serves that purpose.

Extensive dissection between the great vessels allows retraction of the aorta with an umbilical tape and keeps the cross-clamp off the right pulmonary artery. After clamping the aorta, the space between the aortic and pulmonary roots is dissected until the roots are completely separated. Final separation is often safest after the aorta is opened and coronary locations can be readily identified.

A rather high transverse aortotomy incision keeps all technique options open, but if a subcoronary implant is planned, extending an oblique incision into the noncoronary sinus can be employed. The aortic valve pathology is inspected as well as coronary ostial positions. A stenotic valve can be excised at this point and the annulus debrided and measured.

Common to any of the techniques is the need to harvest the pulmonary autograft from the right ventricular outflow tract (RVOT). The close proximity of the left coronary system and general constraints of this maneuver are obvious from the elegant anatomical casts published by Muresian.[73] The main pulmonary artery is incised transversely just distal to the valve and the opening extended to either side taking care to avoid the left coronary. A flexible sucker can be placed in the distal PA as a vent. The pulmonic valve is inspected to make sure it is a healthy, three-leaflet valve with minimal fenestrations. The remainder of the PA is divided. The adipose tissue between the back of the PA and the left main is gently dissected down to the muscle in the back of the RVOT with the cautery.



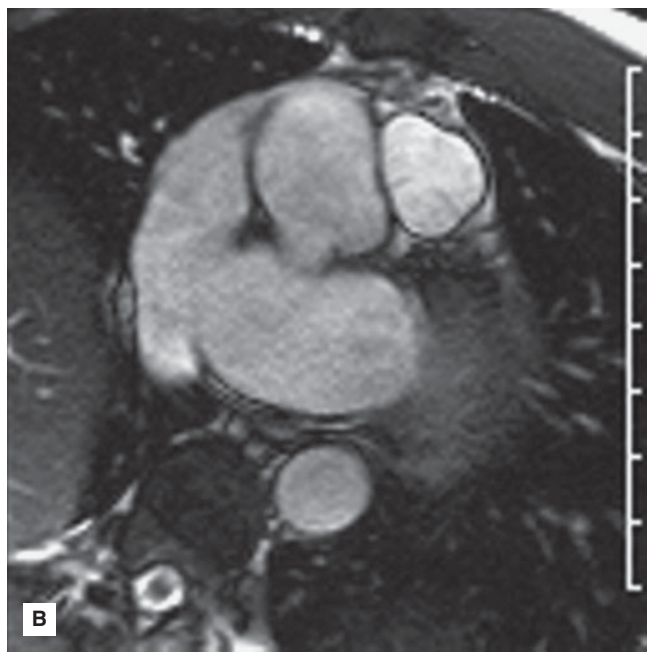


FIGURE 34-8 Evaluation of pulmonic valve by CMR. (A) Longitudinal view. (B) Cross-sectional view showing three distinct leaflets and sinuses.

The RVOT is opened with a no. 15 blade well below the anterior commissure as determined by palpation or by passing a suture or clamp through the muscle about 5- to 6-mm below the valve from inside out (Fig. 34-9). The initial incision is cautiously extended until the leaflet can be clearly seen. The dissection then continues around each side leaving 3 to 4 mm of

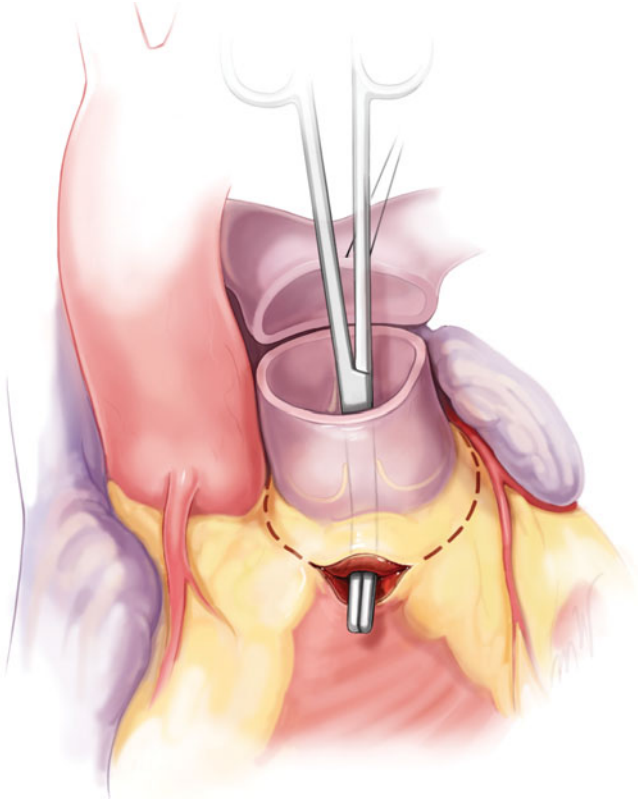

FIGURE 34-9 Pulmonary autograft harvest. A right-angle clamp can be passed through the right ventricular outflow tract muscle below the anterior commissure to assure safe beginning of the harvest incision.

muscle cuff. Posteriorly, a natural plane can be appreciated between the right and left ventricular septal components. The septal perforators are always in the left side and can be avoided by taking only the right ventricular part of the septum. Most often they are not seen. Small branches of the coronary sinus posteriorly can be the source of annoying venous bleeding at the end, so gentle administration of retrograde can identify these and allow control at this point.

The autograft is trimmed by following the curvilinear course of the leaflets on the inflow end leaving a smooth 3- to 4-mm cuff of muscle. The inflow end is measured by gently inserting cylindrical sizers. The RVOT opening can also be measured at this time. An appropriate pulmonary homograft can then be thawed.

Subcoronary Technique

If the subcoronary or inclusion cylinder technique is chosen, the operation proceeds similarly to subcoronary homograft replacement. Proximal and distal suture lines are constructed as described. Of note, the aortic root must match the autograft at both the annulus and the sinotubular junction. Accordingly, tailoring of the root with annuloplasty and/or downsizing the sinotubular junction may be required.[74] The potential advantage of this technique is to preserve the native root support around the autograft, which may prevent autograft dilatation and insufficiency. However, if the native aorta dilates, the autograft will do so as well.

Root Replacement Technique

In preparation for full root replacement the aortic transection is completed and the coronary ostial buttons are dissected out and mobilized appropriately. The native noncoronary sinus and the "pillar" of tissue between the right and the left buttons are preserved for later "re-inclusion" around the autograft root. The best orientation for the autograft is determined by placing it in the aortic root. Usually the bare area from the back of the PA is positioned in the left coronary sinus.

A strip of Teflon felt about 5- to 7-mm wide is cut to length around a size 2 mm larger than the inflow size of the autograft. The proximal autograft suture line is constructed incorporating the felt strip. This can be done with interrupted 3-0 or 4-0 simple sutures best organized on suture guides. Continuous 4-0 polypropylene can also be used beginning under the right-left commissure and working down the left sinus. The noncoronary and right sinuses follow. The sutures are left loose and slightly remote to facilitate visibility (Fig. 34-10). When completed, the suture line is carefully tightened with nerve hooks and tied securely.

The coronary buttons are then reimplanted with continuous 6-0 Prolene. The position of the right coronary is always higher than anticipated, usually just at the sinotubular junction of the autograft.

Excess pulmonary artery wall is trimmed from the autograft down to just above the commissures and very close to the tops

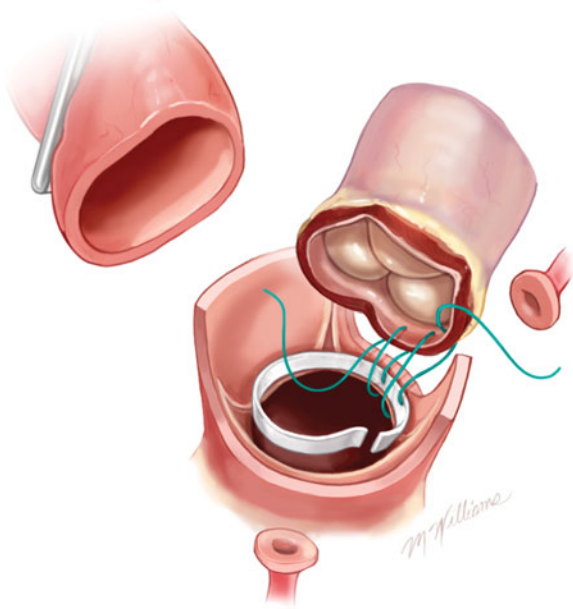

FIGURE 34-10 Proximal autograft suture line. The continuous suture technique is facilitated by leaving the sutures loose enough to easily see the leaflets to optimize depth and spacing and minimize tearing of this delicate muscle cuff. A measured strip of felt is incorporated in this suture line. Note that the noncoronary sinus tissue and the "pillar" of tissue between the coronary buttons has been preserved for later inclusion around the autograft root.

of the coronary buttons. The native aortic wall elements that were preserved earlier are now brought up beside the autograft and shortened if necessary. If the native root was dilated or frankly aneurismal, artificial support can be employed using felt patches or vascular graft material.

The distal autograft is attached to the ascending aorta with continuous 4-0 polypropylene incorporating the natural and/or fabric support elements along with another strip of felt placing the sutures right at the tops of the commissures to establish a new sinotubular junction (Fig. 34-11). With the aorta closed, antegrade cardioplegia can be administered to give a test of valve competence and integrity of the coronary and distal suture lines.

The pulmonary homograft is now attached to the RVOT with continuous 4-0 polypropylene. Care is taken to take long and superficial bites posteriorly over the area of the septal perforator. The distal suture line is completed with continuous 4-0 or 5-0 polypropylene.

The ascending aorta is vented and the cross-clamp removed. Generous reperfusion time is recommended. Bleeding is certainly a risk with so many needle holes in delicate tissue submitted to aortic pressure. For this reason care must be taken to avoid vigorous retraction, which can cause more harm than good. Amicar is recommended, as is autologous blood removal at the beginning of the operation for return at the end. Biological glues can be helpful but their use is not a substitute for accurate suture line construction.

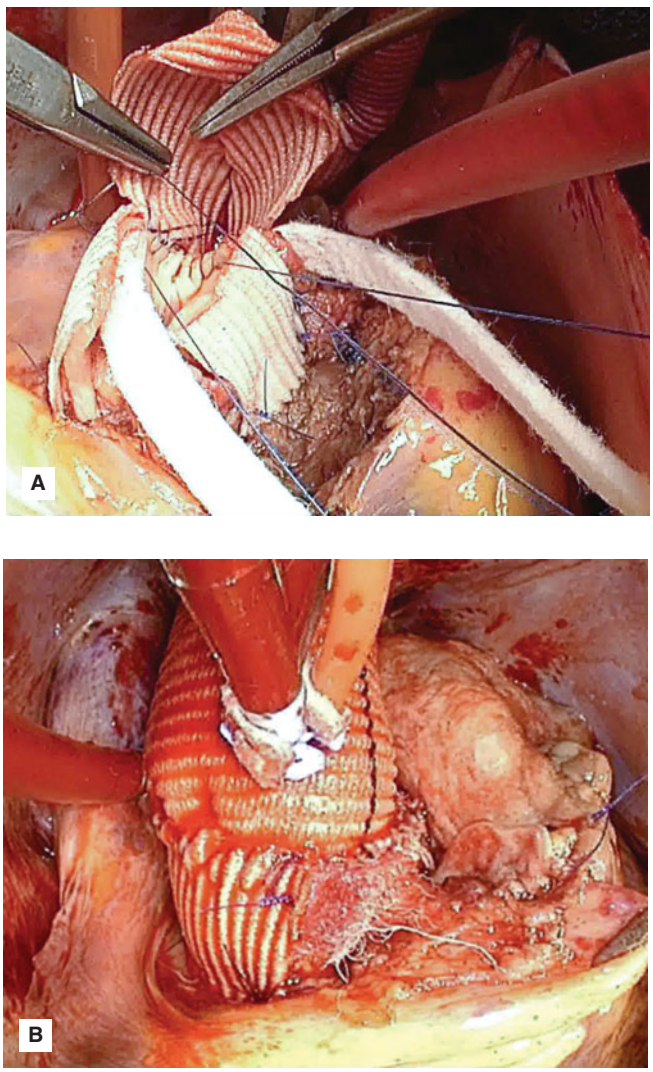

FIGURE 34-11 Fabric support of autograft wall. (A) The arterial wall of the autograft is supported by segments of vascular graft material especially when native aortic wall is intrinsically poor. The entire autograft is enclosed with a combination of native aortic wall and vascular graft material and attached to the ascending aortic graft incorporating another strip of felt. (B) Completed Ross with external fabric support and ascending aortic replacement as well.

Concomitant Aortic Surgery

Because of the recognition that patients with bicuspid aortic valves are at risk for late dilatation and aneurysm of the ascending aorta, one should resect any aorta greater than 5 cm in diameter. Below 3.5 cm it is hard to justify any treatment. Between 3.5 and 5 cm it is reasonable to employ plication or lateral aortorrhaphy concepts to bring the aorta down to 3.5 or less.[75,76] Because the vast majority of dissection in the BAV patient begins in the ascending aorta,[77] complete resection of aneurysms up to the arch (hemi-arch replacement) should be considered. This actually adds very little time to the operation if planned appropriately. The proximal end of the aortic graft is attached to the (usually reinforced) autograft root to restore aortic continuity.

Operative Risk

According to the International Ross Registry, overall perioperative mortality (i.e., <30 days) was 4.1% (129 deaths in 3922 patients).[18] Given the 1% risk of alternative operations, this may be unacceptably high. Like so many highly technical procedures, experience makes a big difference. The author's own experience demonstrated a "learning curve" with three deaths in the first 30, three more in the next 178 and no deaths in the next 260. Clearly the complexities of reoperative status, need for circulatory arrest, replacement of ascending aneurysm, and concomitant mitral repair should encourage referral to an experienced surgeon if a Ross procedure is to be considered. Individualized discussion with each patient should examine the options and consider the potential risks and benefits of each. Because a volume–outcome relationship may be apparent, the option of referral to regional "centers of excellence" should be included in this discussion.

Results

Pioneer Series Results

No discussion of the Ross operation could be complete without a careful look back at the pioneer series of patients treated by Donald Ross.[78] The 1997 paper from this seminal source analyzed 131 hospital survivors followed for 9 to 26 years with a mean of 20 years. The technical problems that led to early reoperation with the subcoronary technique were recognized in that series and the cylinder modification adopted. Even the full root replacement method was employed as an alternative by

Ross in 20 patients beginning as early as 1974.[79] Survival at 10 and 20 years was a remarkable 85 and 61%, respectively. Freedom from autograft replacement was 88 and 75%, where freedom from homograft replacement was 89 and 80% each at 10 and 20 years. Of 53 late deaths, 46 were cardiac. Importantly, of the 30 autografts that were explanted, only three had evidence of degenerative change, which was patchy and did not involve all leaflets. The remainder had completely viable structure as long as 24 years after implantation. Clearly, the transplanted pulmonary autograft is and remains a fully living valve. Homograft stenosis accounted for all but 1 of 20 late reoperations on the right side. Thromboembolic phenomena were documented in 20 patients, but only one did not have another systemic risk factor for a source.

Exercise Hemodynamics of the Ross Operation

Multiple studies demonstrate the excellent hemodynamic profile offered by the autograft in the Ross operation. A comparison with normal age- and gender-matched controls showed peak gradients going from only 2 to 4 mm Hg in both groups with exercise.[80] Effective orifice areas of 3.5 cm^2 (EOAI 1.9 cm^2/m^2) did not change with exercise in either group. Full root Ross patients had better hemodynamics than subcoronary Ross patients, but the difference (1.98 ± 0.57 versus 1.64 ± 0.43 cm^2/m^2) was more important statistically than it was clinically.[81] This study also documented the superiority of the Ross hemodynamics over stented and stentless valves and even over aortic homografts.

It is important to remember that the Ross operation includes RVOT reconstruction, and the hemodynamics of that structure can adversely affect exercise capacity. One study documented an average resting gradient of 14 ± 10 mm Hg rising to 25 ± 22 mm Hg for the pulmonary homografts of Ross patients compared with only 3 ± 1 mm Hg at rest and 5 ± 4 mm Hg with exercise in the normal native RVOT of aortic homograft recipients.[82] The higher gradients in the RVOT may contribute to slightly lower maximal oxygen consumption compared with normal controls, even though Ross patients easily exceeded 100% of predicted consumption.

Contemporary Results

With operative mortality now approaching that of alternative valve replacements, the long-term results are the vital point in considering the Ross operation for any given patient. The comparative incidence of reoperation for structural valve deterioration with present-generation tissue valves and the continuing risks of thromboembolism and anticoagulant-related hemorrhage with modern mechanical devices must be fairly presented to patients along with the data for the Ross.

A thorough review of available series confirms that survival is extremely good after the Ross operation and approximates that of the normal age-matched population.[83] Combined with its low incidence of thromboembolic complications and endocarditis as well as avoidance of anticoagulation with its risks of bleeding, the Ross is a very attractive option for young people. Some of these patients will undoubtedly require further surgery, but the outcomes of subsequent surgery have also been extremely good, which contributes to the long-term survival.

Elkins reported results in 487 patients operated on between 1986 and 2002.[84] Hospital mortality was 19 to 3.9%. Of 15 late deaths, none were owing to reoperation but only 7 were not cardiac related. Actuarial freedom from all cause mortality was $92 \pm 2\%$ at 10 years and $82\% \pm 6\%$ at 16 years. There was only one documented thromboembolic event. Actuarial freedom from endocarditis was $95 \pm 6\%$ at 16 years. Of 38 patients who needed further surgery, autograft reoperation was more common than homograft reoperation. Importantly, the vast majority of these patients had bicuspid or even unicuspid morphology, but their risk of reoperation was actually lower than the 9/78 three-leaflet valve patients. Patients with primary aortic regurgitation fared significantly worse until 1996 when the institution of routine annular reduction and fixation was initiated. Subsequent results in AR were then only slightly inferior to those in AS in whom the 15-year freedom from autograft valve failure was $82 \pm 6\%$. Technique seemed important as only 21/389 full roots required reoperation where 17/79 intra-aortic implants did.

Pulmonary Autograft Dysfunction

Pulmonary autograft stenosis has never been reported but the incidence of regurgitation increases with time and seems to be due to autograft or native aortic dilatation or both. The recognition of early AR due to technical problems with intra-aortic implants led to widespread acceptance of the root replacement method when we reported this in 1989.[85] Unfortunately, the totally unsupported autograft as a freestanding aortic root replacement proved to have potential for dilatation with root aneurysm and AR as a result. Annular dilatation was appreciated early and addressed with annuloplasty and external fixation with fixed pericardium or prosthetic material. Dilatation at the sinus and sinotubular junction levels was not appreciated and addressed until about a decade later. Incidence of this problem has been difficult to define and risk factors have been controversial. Autograft function can often remain excellent even with significant root dilatation (Fig. 34-12).

Brown found that preoperative ascending aortic dilatation, male gender, and postoperative systemic hypertension were significant in a Cox proportional hazard analysis for the development of moderate neo-aortic regurgitation.[86] Hypertension, particularly early postoperatively, can cause acute dilatation and damage to the delicate autograft leaflets before they have time to adapt to the systemic pressure environment. The unsupported root technique having failed in 22 of 142 patients in Rotterdam over a 17-year period, the adult Ross procedure was abandoned at Erasmus.[87] David expressed concern about the potential for dilatation at multiple levels particularly in bicuspid valve patients because of a higher incidence of aortic wall pathology.[88]

Multiple approaches have been developed to solve the dilatation problem. Sievers has demonstrated that a rigorously selected population of patients with frequent "tailoring" of the native aortic root can be treated with a subcoronary Ross implant with excellent results up to at least 10 years.[74] Others including this

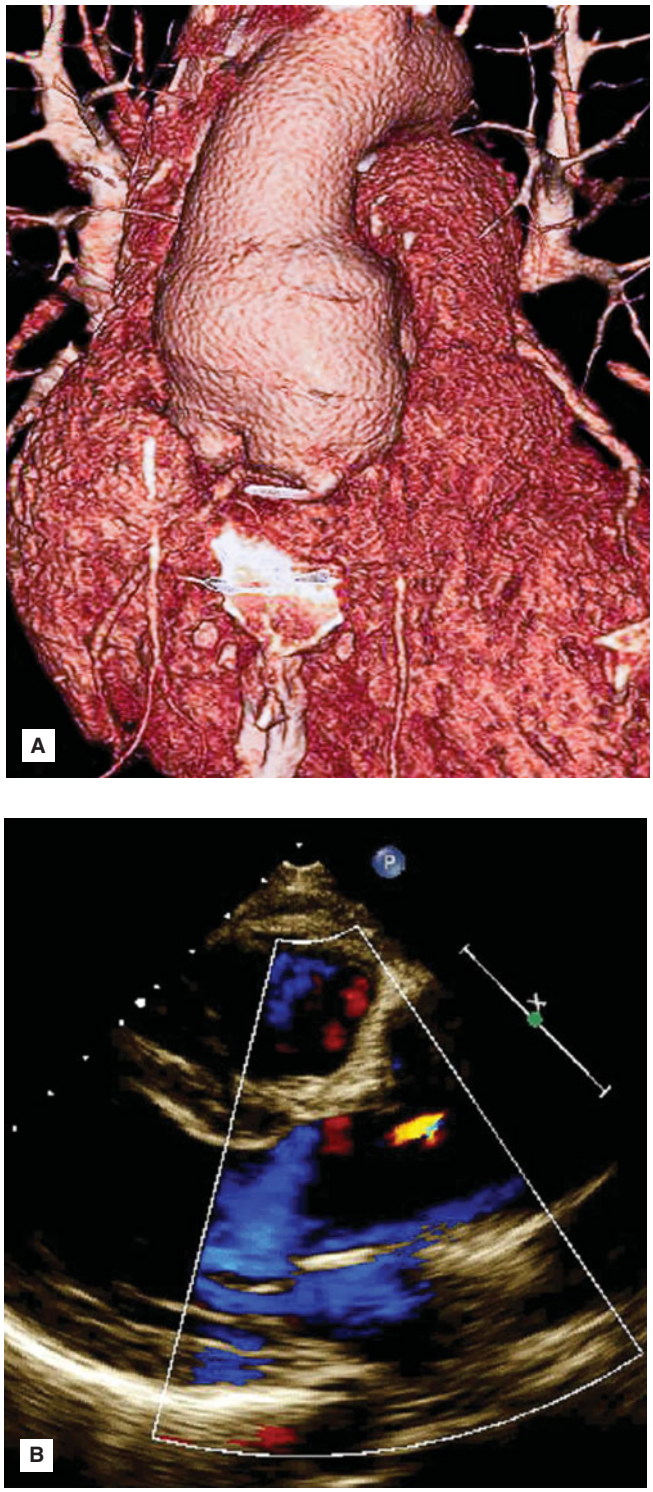

FIGURE 34-12 Dilated Ross procedure at 10 years. (A) CTA appearance. (B) Echocardiogram showing minimal central AR.

author[89] and Oswalt [90] stressed the need for multilevel fixation to support the autograft. Still others have suggested use of absorbable mesh,[91] pericardial,[92] or fabric[93] wrapping to completely enclose the autograft. The restrictive nature of this approach may produce other problems by compressing the pliable, dynamic autograft into a rigid cylinder with decrease in potential for vascular ingrowth. Clearly the patient with root and ascending aneurysm cannot be treated by a simple inclusion cylinder implant, but the patient with normal root anatomy and good size match can be served quite well by this alternative. Individualization is required to make sure that the autograft whether inside the intact or "tailored" aortic root or implanted as a full root has appropriate supporting autologous tissue and/or prosthetic material of appropriate dimensions to allow normal valve function and prevent late dilatation. With this approach it is not unreasonable to anticipate autograft failure rates of less than or equal to 10% at ten years and less than or equal to 20% at twenty years.

Pulmonary Homograft Dysfunction

As part of the Ross operation, the single aortic valve operation becomes a double valve operation also leaving the RVOT substitute at risk for future problems. The pioneer series clearly demonstrated the homograft to be superior to other alternatives of that day, but controversy remains particularly over the advantages and disadvantages of homograft viability on the right side. Although the initial hemodynamics of the cryopreserved pulmonary homografts are excellent, consistent increase in transvalvular gradients occurs within 6 to 12 months. This early increase in gradient usually stabilizes by 2 years, but can be progressive in 1 to 2% of patients. An immune system response has been implicated, but the mechanisms are poorly understood.[94]

The pulmonary homograft can develop extensive calcification of the inflow end indicative of an intense scar response to the homograft muscle cuff (Fig. 34-13). Schmidtke and associates tried to minimize this with a unique trimming of the muscle and replacing it with a cuff of pericardium.[95] This proved effective over the first two years but failed to make a long-term difference. An intense adventitial inflammatory reaction with diffuse thickening along the entire homograft was described with elegant MRI flow studies by Carr-White.[96] This caused extrinsic compression of the conduit portion of the homograft.

The incidence of homograft stenosis is probably 5 to 10% at 10 years. Risk factors proposed include younger donor age, shorter time of cryopreservation, and homograft size.[97] Because small size is the most consistent risk factor, oversizing helps reduce the effect of shrinkage.

Most patients tolerate peak gradients up to 50 mm Hg without symptoms so the clinical significance is less than the incidence of stenosis. In the Oklahoma series, homograft failure (reoperation or percutaneous intervention) occurred in 33 of 487 patients giving actuarial freedom from failure of 90 ± 2% at 10 years and 82 ± 4% at 16 years.[84] The advent of catheter-based valve replacement has made it possible to treat some of these patients percutaneously.[98]

Moderate or even severe homograft regurgitation may also be detected by echocardiography in as much as 10% of patients by 10 years but this lesion is well tolerated by the right ventricle in the absence of pulmonary hypertension. It is probable that most pulmonary homografts will ultimately suffer this mode of failure but the majority will last 20 to 25 years before they reach this point.

After four decades of use and research, the cryopreserved pulmonary homograft is the best RVOT substitute documented for use in the Ross procedure. Rarely, a stentless porcine

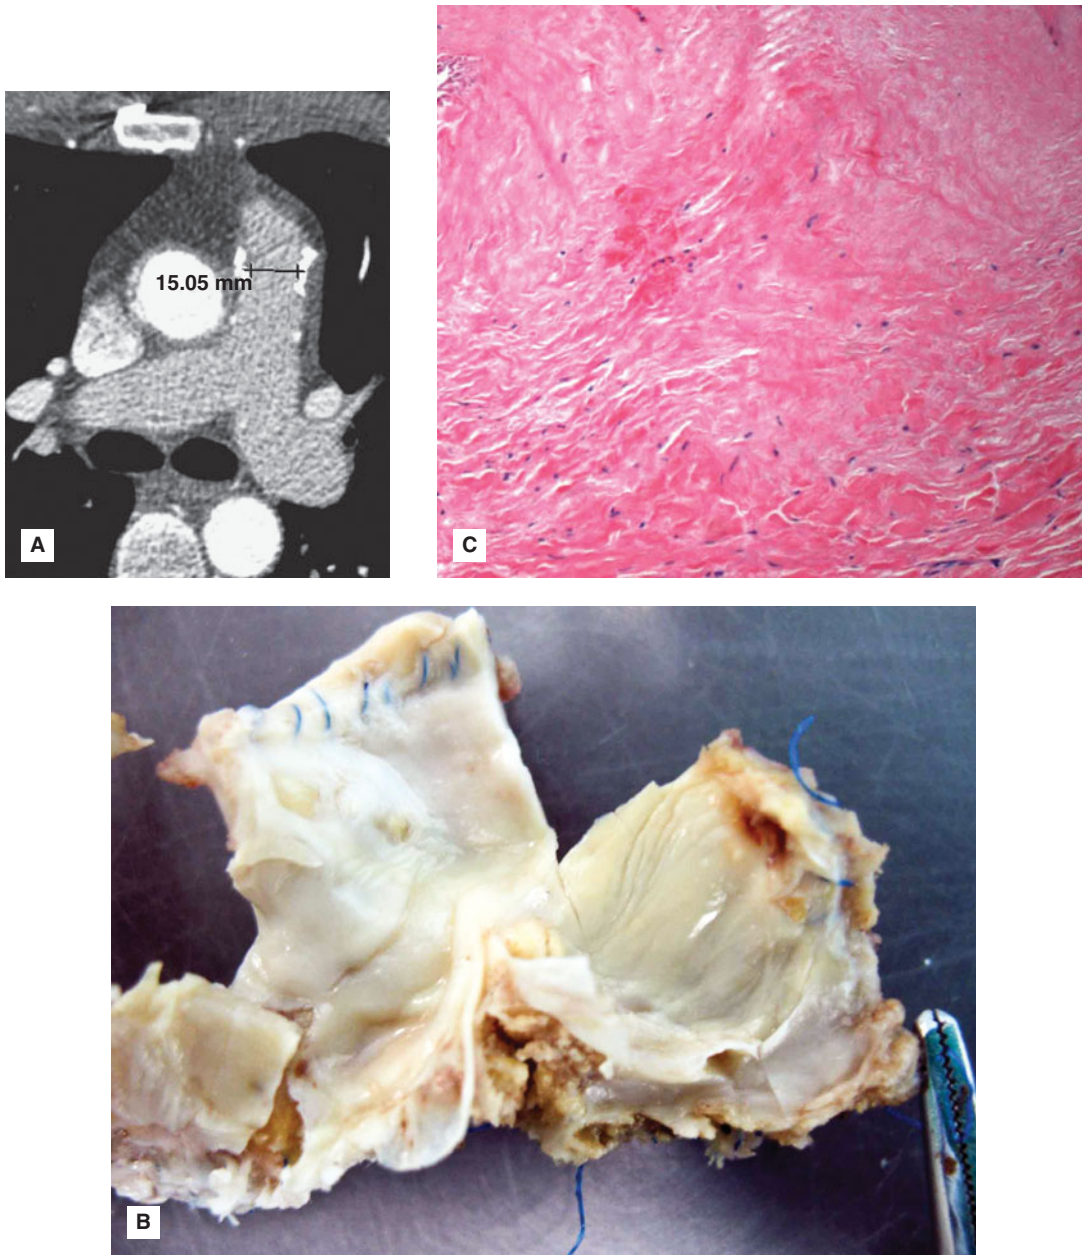

FIGURE 34-13 Calcified pulmonary homograft. The inflow anastomosis of this pulmonary homograft is markedly narrowed and calcified 16 years after a Ross procedure. Gradient was only 28 at rest but 75 mm Hg with exercise. (A) Appearance on CT scan. (B) Gross specimen at explant. (C) Microscopic showing acellular scar.

bioprosthesis has been used. Tissue engineering concepts seem ideally suited to this low pressure area where a decellularized homograft or even heterograft matrix can perform nicely while providing an environment suitable for maturation of new cellular elements derived from circulating stem cells, adjacent ingrowth, or preoperative seeding. Initial clinical studies with both show promise but await long term follow up.[33,99]

REOPERATION POST–ROSS PROCEDURE

The prospect of reoperation after a Ross procedure has been regarded as a complex and hazardous undertaking.[87] Concern about dissection and rupture is largely unsupported. Rupture of the autograft has never been reported. Localized dissection of the autograft does occur but does not extend across circumferential suture lines that protect the distal aorta and the coronary ostia. The wall of the autograft, although thinner than native aorta, is encased in scar tissue from the original surgery, making leakage into a free pericardial space extremely unlikely.

If moderate autograft regurgitation has developed with root dilatation, a policy of waiting for symptoms or ventricular dysfunction/dilatation typically indicative for surgical intervention should be considered appropriate, not just treating a sinus dimension. If distal native aorta dilates to 5.0 cm or greater, it may be reasonable to intervene before it gets to 5.5 cm in the setting of original bicuspid aortic valve disease. If other valve disease or

coronary disease dictates operative intervention, the dilated autograft should not be ignored. If the autograft has been supported at the inflow end with felt, the Yacoub valve–sparing approach may be appropriate because the annulus is already supported. If there is strictly a leaflet problem, such as prolapse or perforation, repair might be considered, but only if a durable repair can be anticipated. Complete redo root replacement should be considered if both the leaflets and the sinuses are problematic. The living, pliable autograft makes this much easier than a redo after a standard Bentall.

Safe reoperation begins with appropriate planning at the original operation where closure of the pericardium or coverage of the heart with pericardial substitute will allow safe sternal re-entry. Central cannulation is almost always possible, but peripheral cannulation should be considered in multiple reoperative settings or when preoperative imaging suggests perilous re-entry. Crucial to safe conduct of these operations is avoidance of the plane between the pulmonary homograft and the aorta. There is usually plenty of room distal to the pulmonary artery to clamp the aorta before this plane needs to be addressed. Coronary buttons are often very close to the distal autograft anastomosis, so aortotomy at reoperation should never be proximal to this suture line. The complete spectrum of replacement options is open at reoperation, including simple mechanical or stented tissue valves, subcoronary or full root stentless, aortic homograft, or Bentall operation with biologic or mechanical valved conduit. The RVOT homograft should be left alone unless grossly abnormal by preoperative evaluation. If reoperation is required for RVOT obstruction, this can be accomplished on the beating heart. The old conduit is opened longitudinally from normal right ventricular muscle to normal PA. The thick proximal scar is resected carefully and as much of the old conduit is removed as necessary to allow placement of a new homograft. The posterior wall and that facing the aorta can be left intact to avoid injury to the autograft and coronary tree.

SUMMARY

Of all the substitutes for the diseased aortic valve, only the pulmonary autograft has all the biologic advantages of a truly living structure. It is delicate and demands precise implantation technique for immediate and long-term success. Appropriate aortic tailoring or support is needed in the majority of patients to prevent late autograft dilatation and dysfunction. Approximately 20% of patients will probably require additional surgery for either the neo-aortic or the neo-pulmonary aspects of this operation by 20 years, but they will not require anticoagulation and will not be limited in activity or lifestyle during that time. In appropriate hands, this operation can be done very safely and is a durable and excellent choice for young active people with aortic valve disease. Compared with the virtually 100% reoperation rate at 20 years for animal tissue valves, unavoidable and ongoing risks of thromboembolic and hemorrhagic complications with mechanical valves, and proven advantage of the Ross procedure over aortic homograft in randomized prospective trial,[100] the Ross procedure is a very viable option. Long-term survival may actually be superior to any other aortic valve operation.

Appropriate imaging of patients after these patients is essential and should include a thorough echo evaluation at least every 2 years. CT or MRI evaluation of the aorta should probably be done at least every 10 years and more frequently if progressive aortic dilatation is observed. Reoperation when required can be done safely in experienced centers with preservation of the autograft possible in some cases. The Ross operation should be offered as an option for any patient under the age of 50 with aortic valve disease and a life expectancy in excess of 20 to 25 years. Under ideal circumstances, it can be considered in the 50- to 65-year-old population where the Ross procedure has the possibility of lasting to the end of a normal life span.

CHAPTER 35

Aortic Valve Replacement with a Stentless Bioprosthetic Valve: Porcine or Pericardial

Edward H. Kincaid
Neal D. Kon

INTRODUCTION

The history of stentless xenograft aortic valves follows in the footsteps of the aortic homograft, which was considered historically as the best biologic prosthesis for management of root pathology and for optimizing hemodynamics in the absence of root pathology. The original concept behind creating a stentless xenograft valve was to maintain the excellent hemodynamics of the homograft, while improving on the availability, durability, technical complexity, and costs associated with homografts.

Stentless, or "natural valve" substitutes closely mimic the native aortic root anatomy and are implanted without a stent, large sewing ring, or other supporting apparatus that can lead to persistent LV obstruction sometimes observed with stented bioprostheses or mechanical valves. In general, use of stentless valves also allows for implantation of larger prostheses with resultant larger effective orifice area for any given LV outflow tract diameter. Comparing homografts, autografts and xenografts, stentless porcine constructs have the most opportunity for wide-spread application because of their ready shelf availability and ease of implantation. Compared with traditional stented bioprostheses, touted advantages of stentless valves include better hemodynamics,[1-3] improved regression of left ventricular mass,[3-5] less risk of patient-prosthesis mismatch (ppm) in the small aortic root,[6] and possibly improved long-term survival.[7,8] Because of these advantages, over the past 15 years, aortic valve replacement (AVR) with stentless porcine bioprostheses has become an accepted technique for routine treatment of aortic valve and root diseases. Some of these advantages appear to be maximized with implantation using a total root replacement technique, which also is associated with less risk of late valve failure.[9] However, the potential benefits of stentless valves implanted as total roots may come at the cost of increased operative risks, including a potential for higher operative mortality compared with subcoronary stentless or stented AVR.[9] Although other large series have reported low operative mortality with stentless root replacement,[10-12] a learning curve of over 20 cases has been described.[13] Besides a learning curve for this more complex procedure, other factors that could potentially contribute to excess mortality include longer perfusion and myocardial ischemic times, and more suture lines exposed to the pericardial space. Thus, the use of stentless aortic bioprostheses has become a controversial topic within the cardiothoracic surgical community.

AVAILABLE PROSTHESES

Many stentless xenograft valves have come and gone in the marketplace over the past decade. Currently, the only two stentless prostheses available are the Medtronic Freestyle bioprosthesis and the ATS 3F valve, which has only recently been introduced to the North American market.

Medtronic Freestyle

The Medtronic Freestyle valve followed closely behind the development of the St Jude Toronto SPV, which is now out of production. From its beginning, the Freestyle valve had several options of implantation techniques, similar to the homograft, including full root, root inclusion, and subcoronary positions. The Freestyle valve began clinical application in the early 1990s, thus making some long-term outcome data available. The Freestyle is a complete porcine root with minimal polyester fabric covering all exposed porcine myocardium (Figs. 35-1, 35-2). This

FIGURE 35-1 The Medtronic Freestyle Aortic Root Bioprosthesis. The longitudinal view shows the fabric covering of the porcine septal muscle and the associated higher position of the right coronary stump. (*Reproduced with permission from Medtronic, Inc., Minneapolis, MN.*)

serves to strengthen the proximal (inflow) suture line and reduce antigenicity. There is a green demarcation line around the inner circumference of the polyester fabric covering indicating the suturing area. There are also markers for each commissure to aid in suture placement. The Freestyle tissue is crosslinked in a dilute glutaraldehyde solution using a tissue fixation method that allows valves to maintain natural leaflet structure and natural root geometry by simultaneously applying 40 mm Hg (diastolic pressure of the pig) to the inflow and outflow portions of the bioprosthesis, allowing the leaflets to relax at net zero pressure differential with a pressurized root.[14] This results in leaflets fixed under no load but in an anatomically distended root. Potential advantages of this process include maintenance of radial leaflet distensibility (corrugations), circumferential leaflet stability (crimp), maintenance of strength with elasticity, and mitigation of kinking. Using a combination of accelerated wear testing in a pulse duplicator and biaxial mechanical testing of the tissue, Christie and colleagues demonstrated better preservation of both circumferential and radial stretch in the Freestyle leaflets compared with leaflets fixed even at low pressure, which flattens the native collagen crimp.[15] The Freestyle bioprosthesis is treated with an alpha-amino oleic acid (AOA), a compound derived from oleic acid, designed to mitigate both leaflet and wall calcification. Various anticalcification treatments are now commonly used by all manufacturers with data based on animal and some short-term human efficacy studies. Minimal long-term human data exists on the effectiveness of any of these proprietary anticalcification treatments, although the group at Harefield recently reported lower calcium scores in Freestyle valves compared with homografts at 8 years.[16]

ATS 3F Valve

The ATS Aortic Bioprosthesis, Model 1000 is a stentless pericardial aortic heart valve replacement designed as a tubular structure and constructed from three equal sections of equine pericardium, with each section cut roughly in the shape of a square (Fig. 35-3). This unique construction design was based on the development of the embryonic tubular aortic valve subjected to computer modeling. The choice of equine pericardium is reportedly based on its strength in the areas of the leaflets where stress was found to be greatest. For the 3F valve,

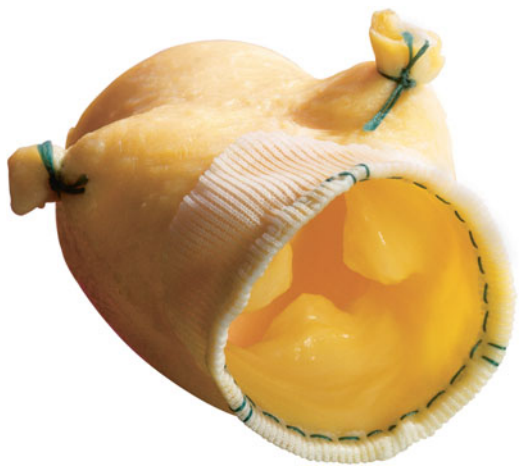

FIGURE 35-2 The Medtronic Freestyle Aortic Root Bioprosthesis. The porcine coronary arteries lie approximately 90 degrees apart. This is in contrast to the human orientation of 140 to 160 degrees apart.

FIGURE 35-3 The ATS 3F Aortic Bioprosthesis. The device is made of three pieces of equine pericardium with a thin cloth inflow covering and attachment patches for each commissure. (*Reproduced with permission from ATS Medical, Minneapolis, MN.*)

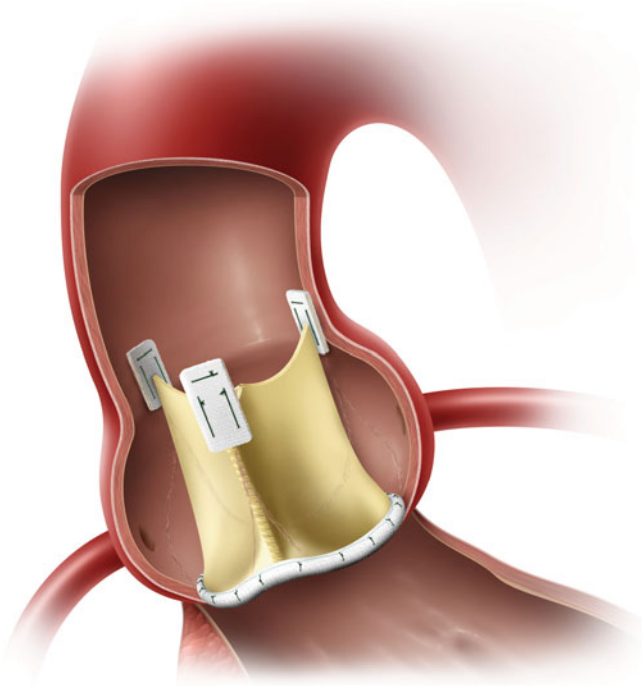

FIGURE 35-4 The ATS 3F Aortic Bioprosthesis. The tubular design allows the omission of the full subcoronary suture line. Instead, the three commissures are attached to the aorta at 120-degree spacing at appropriate height from the annulus. (*Reproduced with permission from ATS Medical, Minneapolis, MN.*)

this highest stress area is the midportion or "belly" of the leaflet. Equine pericardium is also reportedly thinner and more consistent in thickness compared with bovine pericardium. The equine pericardium is fixed with 0.25% buffered glutaraldehyde to preserve its collagen matrix and reduce its immunogenic and thrombogenic potentials while preserving its strength and flexibility. Anticalcification agents are not used. The proximal orifice of the valve has an attached thin polyester sewing ring used to attach the bioprosthesis to the aortic root orifice after resection of the diseased aortic valve. The distal portion of the valve has three commissural tabs, formed from contiguous sections of each of the leaflets and reinforcing polyester material that are used to attach the commissures to the native aortic wall. Similar to traditional subcoronary stentless valves, the 3F relies on normal root/annular ratios and geometry during implantation. The tubular design of the valve, however, allows the omission of the full subcoronary (outflow) suture line. Instead, the three commissures are attached to the aorta at 120-degree spacing at appropriate height from the annulus (Fig. 35-4).

Currently little data exist on the performance of the 3F valve, although at one year in a study of 35 implants, mean gradients ranged from 9 to13 mm Hg and there was minimal AI and no structural deterioration.[17]

INDICATIONS FOR STENTLESS AORTIC VALVES

Stentless aortic valves placed as a subcoronary or full root implant are indicated for the small aortic root, and root replacement provides better hemodynamic function than traditional root enlarging procedures. Stentless aortic valves placed as a total root are also useful in the following situations:

1. Aortic root disease when bioprosthesis is desired
2. Elderly patients with poor tissues. It is simpler to replace fragile disease tissues with synthetic material, thereby eliminating working with poor tissues and tension on critical suture lines.
3. Aortic dissection, when valve needs replacement. Extensive dissection in the sinuses of Valsalva is easily handled with a stentless root bioprosthesis.
4. Endocarditis. Similar to the homograft, the stentless root bioprosthesis allows maximal debridement prior to reconstruction, but has the advantage of immediate availability in all sizes.

IMPLANTATION METHODS

Subcoronary and Modified Subcoronary

Function of the subcoronary stentless valve relies on the intact native sinus geometry. For this reason, an oblique aortotomy should not be used to approach the aortic valve, and instead, a transverse aortotomy or complete aortic transsection should be used. At least 1 to 1.5 cm of clearance is needed to place the stentless device within the root and still close it above the tips of the commissures of the new valve. Complete transsection of the aorta is often helpful in gaining full exposure for implantation. For traditional subcoronary technique, all three sinuses of the prosthesis are scalloped out. For modified subcoronary implantation, the noncoronary sinus is left intact. The advantages are higher suture line, and two posts are fixed. The proximal suture line is usually done with simple interrupted technique using 2-0 to 4-0 braided sutures. Approximately 20 to 30 sutures are used depending on the size of the annulus (Fig. 35-5). Suture guides are very helpful in keeping these many sutures organized. The device is parachuted down into the root and the sutures tied and cut. The right and left sinuses are scalloped out either before or after this step (Fig. 35-6). A distal suture line of continuous small (4-0) caliber polypropylene suture is then constructed coursing below the coronary ostia, taking care not to buckle the stentless tissue or distort the positions of the commissural posts. Stay sutures can be placed at the top of each commissure to help maintain orientation. One suture is begun at the bottom of the left and another at the bottom of the right sinus and run up to the top of each commissure (Fig. 35-7). The porcine tissue and especially the cloth-covered portion of some devices must not encroach on the ostium of either coronary, because obstructive granulation tissue may form in this location. The top of the device is trimmed down to the level of the native aorta, taking care to stay above the top of each commissure. If the noncoronary sinus of the stentless valve is kept intact, the distal suture line can be completed by running along the top to join the two sutures. The aortotomy is closed with continuous suture incorporating the tops of the commissures and the retained noncoronary sinus edge. The completed concept of the complete and modified subcoronary implant technique is shown in Figs. 35-8 and 35-9.

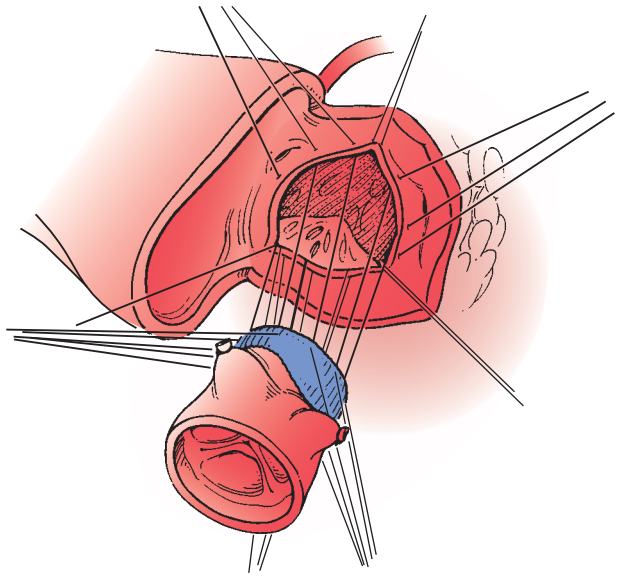

FIGURE 35-5 Modified subcoronary technique—proximal suture line. Interrupted sutures are placed in a circular plane coursing through the annulus itself at the lowest point of each sinus, but well below the commissures except anteriorly where the conduction system must be avoided. These are best organized on suture guides using alternating colors, then divided in thirds and passed through the inflow end of the stentless valve. (*Modified and reproduced, with permission, from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

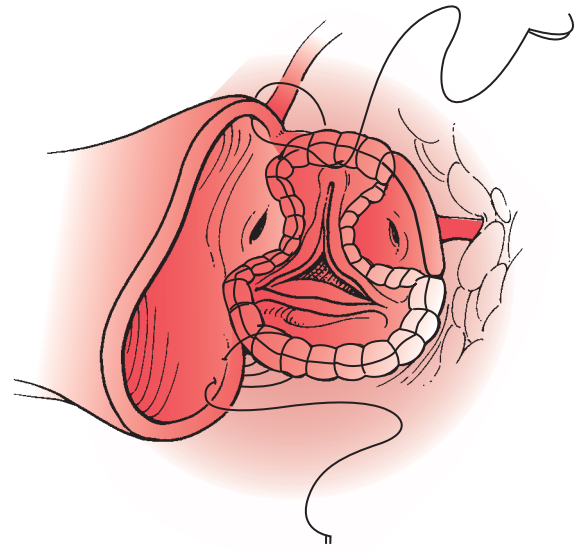

FIGURE 35-7 Modified subcoronary technique—distal suture line. A continuous 4-0 polypropylene suture is begun at the bottom of each sinus below the coronary ostium. This is brought around and up to the top of the adjacent commissures, where the top of the device is trimmed down to the level of the native aorta to allow completion of the suture line. This demonstrates the completed distal suture line and beginning of the aortic closure, which incorporates the tops of the commissures again as well as the top of the retained noncoronary sinus. (*Modified and reproduced, with permission, from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

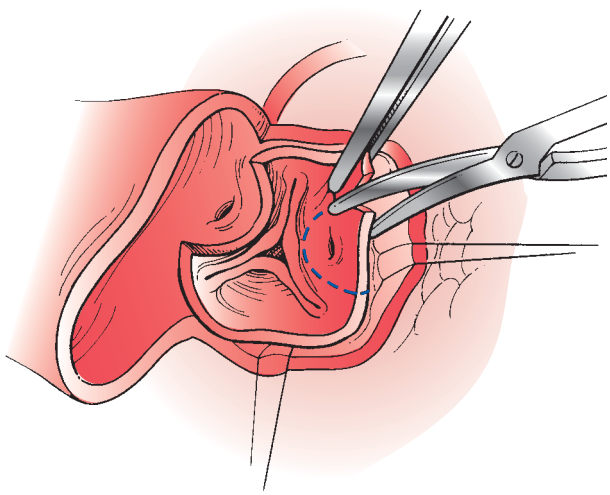

FIGURE 35-6 Modified subcoronary technique—preparing the sinuses. Either before or after the device is slid down and the proximal sutures tied, the sinuses facing the native left and right coronary ostia are scalloped out below the level of those recipient coronaries. Care is taken to avoid cutting into any cloth covering or getting too close to the leaflets of the new valve. (*Modified and reproduced, with permission, from Kon ND, Westaby S, Amarasena N, et al: Comparison of implantation techniques using Freestyle stentless porcine aortic valve. Ann Thorac Surg 1995; 59:857.*)

An expanding hematoma in the space between the native and the porcine noncoronary sinus walls is undesirable, but a small, fixed collection in this area usually resorbs over time. One technique to minimize this problem is to rotate the Freestyle root 120 degrees to put the porcine right coronary stump in the patient's noncoronary sinus. A small cut in the sinus allows the porcine stump to be extruded to the outside of the native

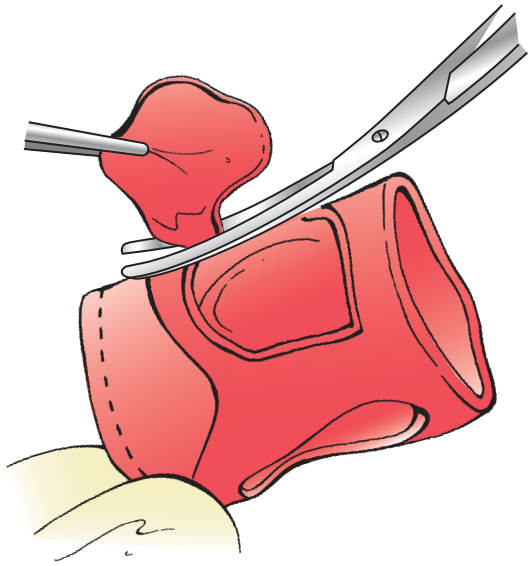

FIGURE 35-10 Root inclusion technique—trimming out sinuses. Very generous openings are made in the two appropriate sinuses facing the native coronaries without violating the sinotubular junction of the stentless valve. (*Modified and reproduced, with permission from Krause AH: Technique for complete subcoronary implantation of the Medtronic Freestyle porcine bioprosthesis. Ann Thorac Surg 1997; 64:1495.*)

sinus where it is secured with a pledgeted mattress suture of 4-0 polypropylene.

The subcoronary method has been preferred by most early adopters of the stentless valve because the first available, the Toronto SPV, was a completely scalloped device that required this method of implantation. In general, sizing and implantation of the subcoronary stentless valve is more prone to error compared with stented and full-root replacement operations. To assure valve competency, the recipient must have a normal ratio between annulus and ST junction diameter (<3 mm difference). Because relative dilatation of the ST junction can create valvular insufficiency, many surgeons choose a valve size based on this diameter, not the annular diameter. Sinus dilation can also cause insufficiency, but this would be unusual without concomitant ST junction effacement.

Oversizing of the stentless valve leads to higher transvalvular gradients. This is because of the compressible nature of the valve such that when placed in a fixed space such as the aortic root, excess tissue can lead to obstruction. Inflow buckling of the prosthesis may also lead to insufficiency and excessive turbulence. Undersizing leads to insufficiency by stretching of the prosthetic tissue with resultant loss of coaptation.

Root Inclusion

In an effort to completely preserve the three-dimensional geometry of the bioprosthetic root devices without completely replacing the native root, a minority of users have chosen to employ the root inclusion method. This involves a proximal suture line (continuous or interrupted) like the subcoronary technique in a circular plane coursing below the commissures. Generous openings are made by excising the sinuses facing the right and left main coronary ostia (Fig. 35-10). These are then tacked around the ostia much as a root inclusion Bentall procedure with continuous 4-0 polypropylene suture. The aortotomy is then closed in standard fashion after trimming the device top down as necessary to incorporate in the closure, making sure that the complete circle of the sinotubular junction is left intact. The only difference between the root inclusion method and the subcoronary technique is that the complete sinotubular ring of the stentless device is preserved, thus preventing any chance of dilatation at that level in the future. The top of the device is incorporated in the closure of the aortotomy (Fig.35-11). Practically, this method is the most difficult and should not be used unless the root is large enough to place a 23-mm or larger device. It may, however, be the most desirable in a younger patient with a larger aortic root. The bioprosthetic sinotubular junction will not dilate over time, and at a subsequent

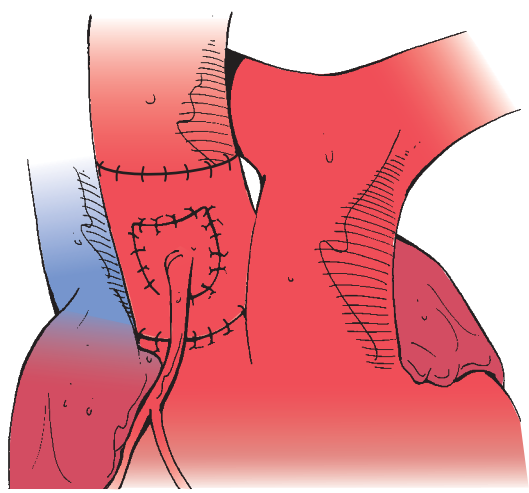

FIGURE 35-11 Root inclusion technique—final appearance. (*Reproduced with permission of Medtronic Inc., Minneapolis, MN.*)

operation, after gently removing this device, the entire native aortic root will be available for a complete range of replacement choices.

Full Root Replacement

Total replacement of the aortic root in most respects is the easiest and most reliable technique for stentless aortic valve replacement. Exposure of the annulus, calcified leaflets, and LV outflow tract is enhanced when the root is removed and the coronary ostia are mobilized out of the way. Decalcification of the annulus and aortomitral curtain becomes straightforward. Each suture is simple to place, making malalignment and poor bites of tissue less likely. Treatment of ascending aorta pathology with a Dacron tube graft extension becomes easy and logical. Perhaps most importantly, optimal hemodynamics are obtained.

The procedure begins with transection of the aorta just above the sinotubular junction (Fig. 35-12). Both coronary ostia are mobilized on generous buttons of aortic wall (Fig. 35-13). The remaining tissue of each sinus of Valsalva and the diseased aortic valve are excised. The valve is sized by identifying the largest sizer that will pass into the left ventricular cavity, then choosing one size larger valve so that the internal orifice of the prosthesis will match the left ventricular outflow tract diameter (Fig. 35-14). The proximal or inflow anastomosis is accomplished using 28 to 35 simple interrupted sutures of 3-0 braided Dacron tied around a 3-mm strip of Teflon felt (Fig. 35-15). The sutures are placed in a single plane in the left ventricular outflow tract to conform to the round inflow of the prosthesis. The coronary arteries on their buttons of aortic wall are sewn end-to-side to the corresponding sinus of Valsalva of the bioprosthesis with a continuous 5-0 polypropylene suture (Fig. 35-16). The distal end of the bioprosthesis is sewn end-to-end to the aorta with a continuous 5-0 polypropylene suture to complete the root replacement (Fig. 35-17).

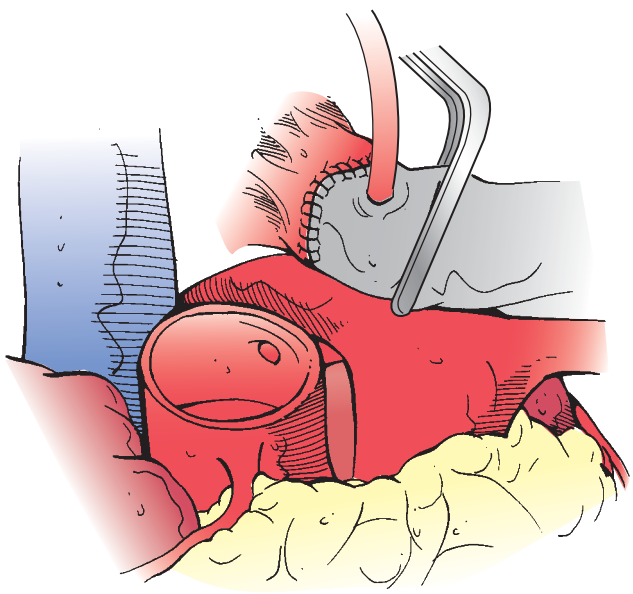

FIGURE 35-12 Placement of the stentless valve as a total root replacement begins with complete transaction of the aorta approximately 3-mm above the sinotubular junction. In this drawing, the ascending aorta has been replaced with a prosthetic graft.

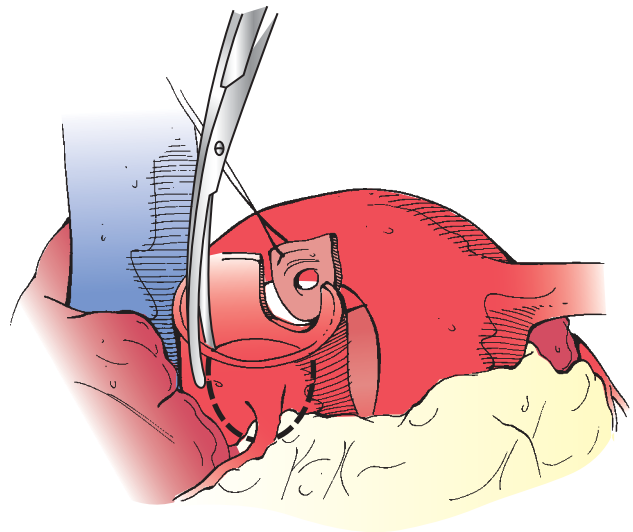

FIGURE 35-13 The coronary arteries are mobilized on generous buttons of aorta. A traction suture at the top of the button helps to maintain orientation.

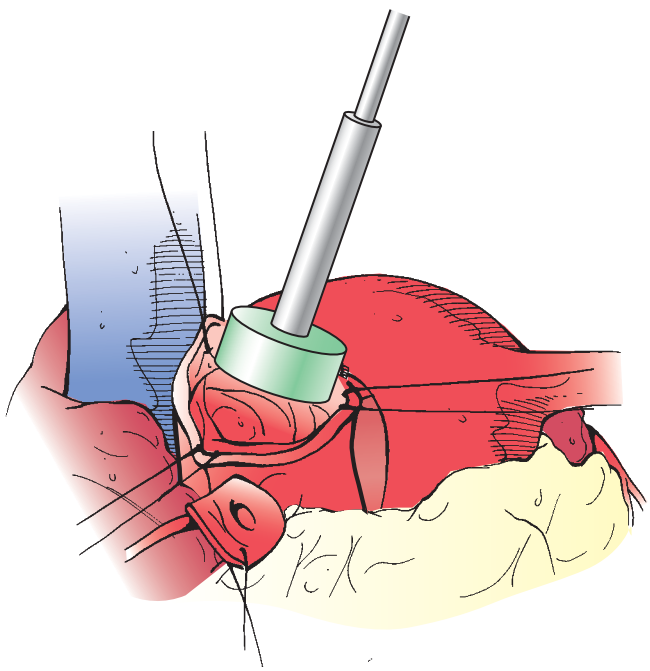

FIGURE 35-14 After excising the remaining tissue of each sinus of Valsalva and the diseased aortic valve, the valve is sized. After identifying the largest size that will pass into the left ventricular cavity, the valve chosen should be one size larger valve so that the internal orifice of the prosthesis will match the left ventricular outflow tract diameter. This will allow the entire orifice of the prosthesis to be exposed to the left ventricular outflow tract.

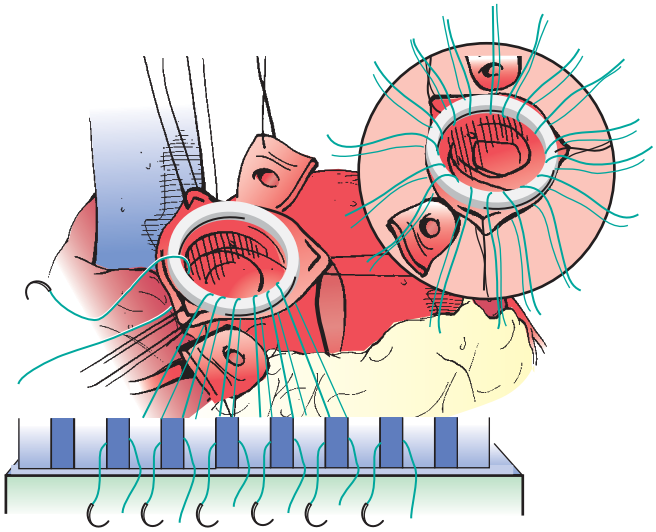

FIGURE 35-15 Valve sutures of 3-0 braided polyester are then placed in simple fashion through the LV outflow tract and around a narrow (approximately 3 mm) felt strip, which helps with hemostasis. The typical number of valve sutures used usually varies between 28 and 32. Use of suture guides simplifies placement and organization.

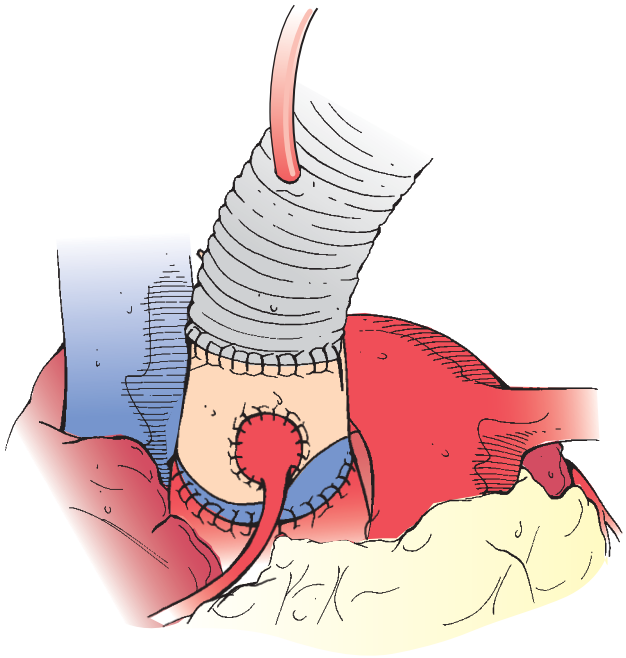

FIGURE 35-17 The native ascending aorta or vascular graft is then trimmed to appropriate level, and an end-to-end anastomosis is constructed using running monofilament suture.

TIPS AND PITFALLS FOR STENTLESS AORTIC ROOT REPLACEMENT

Coronary Alignment

To correctly align the coronary buttons on the porcine full root prosthesis, the similarities and differences between human and porcine aortic root anatomy must be appreciated. The anatomy between the two roots is similar in that the left main arises from the middle of the left sinus of Valsalva with similar heights from the annulus in both human and pig. Also similar to both roots, the right coronary artery is situated slightly higher (more distal) above the annulus. The right coronary artery arises closer to the left coronary in the pig compared with the human. Specifically, porcine coronary arteries are oriented approximately 90 to 110 degrees apart compared with human coronaries, which normally lie 140 to 160 degrees apart, but up to 180 degrees apart in patients with truly bicuspid valves. Practically, this means that the porcine root will need to be rotated 120 degrees during implantation in most situations, so that the porcine noncoronary sinus will be used for reimplantation of either the right or left coronary artery. Flexibility is crucial during coronary alignment, given the inherent anatomic differences seen between patients and prostheses. Native orientation and height must be maintained to prevent coronary insufficiency, an unusual event that most commonly involves the right coronary artery.[18] Signs of right coronary insufficiency include right ventricular dilatation, EKG changes, and otherwise unexplained arrhythmias. Frequently, these findings are only present upon ventricular filling, which may exacerbate a kinked or malaligned proximal right coronary artery. Saphenous vein grafting without repeat cross clamping should be liberally performed if there is any unexplained ventricular abnormality that prevents easy wean from cardiopulmonary bypass.

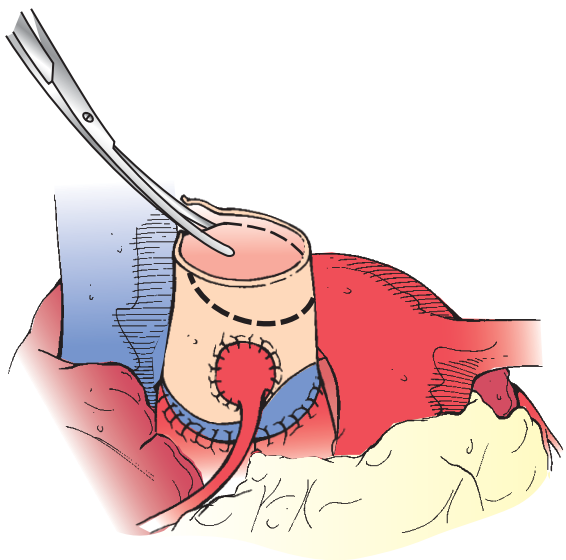

FIGURE 35-16 The coronary buttons are then sewn to the bioprosthesis using running 5-0 monofilament suture, taking care to maintain proper orientation. Excess tissue from the distal end of the bioprosthesis is removed, with more taken from the lesser curve of the ascending aorta to help reproduce its natural contour.

Calcified Coronary Buttons

Severe calcification of the sinuses of Valsalva is often cited as a contraindication to total root replacement. Typically, this calcification will not be isolated to the sinuses, and traditional

stented or mechanical valves are often difficult to place as well, with higher risks of paravalvular leak, bleeding from anastomoses, and coronary dissection. With appropriate recognition and button management, severe root calcification is often best managed with total root replacement, which allows for the most effective removal of calcified and poor quality tissue. Tailoring button size to avoid suturing of calcified sinus tissue is one option to facilitate reimplantation, as is ligation and bypass grafting. Usually, endarterectomy of the coronary ostium must be performed to achieve a hemostatic ligation.

Pathology of the Ascending Aorta

Replacement of the ascending aorta and arch is a natural extension of full root replacement and is performed in up to 55% of patients in large series.[10,19] This speaks to the frequency of atherosclerotic and aneurysmal changes of the ascending aorta in patients with aortic valve disease. Replacement of the ascending aorta with a prosthetic graft, even when performed with a brief period of hypothermic circulatory arrest, adds no additional morbidity or mortality.[20]

Bleeding

Increased risk of bleeding complications is often cited as a reason to avoid total root replacement. Bleeding can occur from any of the four suture lines, but is uncommon when adequate resection of calcified tissue is performed. We have found that placement of an interrupted proximal suture line as described along with careful inspection of the coronary button anastomoses has made bleeding complications less frequent than might be expected. Bleeding from the proximal suture line is usually not manifest until the left ventricle is ejecting, and usually requires reclamping of the aorta, especially early in a surgeon's experience. Coronary buttons may need to be removed to access proximal suture lines in these locations. Other potential areas of bleeding include the right ventricle underneath the right coronary button, and small venous or arterial branches on the adventitia of the mobilized left coronary artery or medial aspect of the main or right pulmonary artery.

Reoperation

Reoperation for a failed stentless bioprosthesis can be challenging. We believe that a full root replacement for the reoperation is preferable if the root or sinuses are extensively calcified. If the reoperation is performed early, ie, for a paravalvular leak with a subcoronary implant, a prosthesis can be inserted inside the previously placed valve after leaflet removal. However, most patients with degenerated calcified aortic root prostheses will be best served with redo total root replacement.

Technical Tips to Facilitate Redo Total Root Replacement

1. Preoperative cardiac CT scan. This tells you the location within the mediastinum of any previous coronary bypass grafts. Knowledge of how close vascular structures reside to the underside of the sternum simplifies the process of reopening the sternum. The presence or absence of coronary anomalies or atherosclerotic vascular disease also helps plan the operation.
2. After the heart and great vessels are freed up and the aorta is cross clamped to arrest the heart, the aorta is transected at the prior distal anastomosis. Next one begins to separate the aortic root from the pulmonary artery. If adherence of these structures is excessive, one can develop a safer plane within the adventitia of the degenerated porcine root.
3. The left main coronary button should be re-mobilized at this time. Preservation of the left main button facilitates the rest of the dissection. Then the right main button is mobilized.
4. Once the coronaries are freed up and out of the way, the rest of the root can be mobilized circumferentially down to the previous inflow suture line. Proper traction/countertraction simplifies this dissection.
5. At this point one can simply cut the rest of the old aortic root out at its junction with the left ventricular outflow tract out.

The surgical field is now ready for the new total root replacement.

RESULTS OF STENTLESS AORTIC VALVE REPLACEMENT

Evaluating the short and long term outcomes of stentless valves in the literature is difficult for several reasons: many manufactured valves are no longer in clinical use; long-term data is scarce; there exists little randomized prospective data comparing stentless versus stented valves; studies generally mix various AVR indications together (patients with root pathology differ from those with a small annulus undergoing stentless valves for avoidance of patient-prosthesis mismatch); and most importantly, the majority of studies on stentless valves include both subcoronary and full root implants together in the "stentless" arm. This results in a heterogeneous population undergoing surgery for differing indications, by surgeons with bias towards one technique over another, and using techniques that can result in vastly different hemodynamic and potentially long-term results.

Hemodynamics

It has been well proven that stentless valves offer superior hemodynamic profiles compared with their stented counterparts. Kunadian et al performed a meta-analysis of randomized, prospective trials of stentless versus stented AVR and included 10 studies and 919 patients from European centers.[21] They demonstrated an approximately 6-mm Hg lower peak gradient for the stentless group, but no survival advantage at 1 year. Importantly, the vast majority of the stentless valves were implanted by subcoronary technique. As a full root replacement, stentless valve hemodynamics compare favorably to homografts, with nonsignificant differences in mean gradients reported between the two prostheses.[22] Freedom from aortic insufficiency and degenerative changes also favors the Freestyle root over the

homograft.[23] Compared with subcoronary implantation, stentless full root replacement achieves lower gradients, larger effective orifice area, and greater freedom from at least moderate aortic insufficiency after 10 years of follow up.[9] Studies on the subcoronary implant technique have consistently shown a decrease in gradient and increase in EOA over time. Early and late gradients are both low for total root replacement and generally do not change over time. This discrepancy is most likely related to absorption of hematoma in the potential space between the porcine and native aortic walls, which occurs when performing a subcoronary implant.

Reverse Remodeling and Survival

Regardless of valve substitute, AVR in patients with severe, symptomatic AS consistently results in improvements in both structural and clinical outcome compared with medical treatment. However, long-term survival after AVR remains lower than age-matched populations, for known and unknown reasons.[24-26] Known factors related to higher death rates include bleeding with anticoagulation required for mechanical valves, thrombotic complications, endocarditis, and structural valve degeneration. Additionally, in patients with advanced myocardial damage and fibrosis, AVR would not be expected to allow for complete reverse remodeling, and lower long-term survival in this condition is intuitive. Indeed, low preoperative ejection fraction is perhaps the strongest predictor of long-term outcome.[27,28] In patients with less advanced structural disease, however, incomplete reverse remodeling of the pressure overload state is an unknown prognostic variable. Even seven years after AVR with stented or mechanical valves, increased muscle fiber diameter and percent interstitial fibrosis compared with normal is observed,[29] possibly because of persistent prosthetic LV obstruction and residual gradient.

To overcome the problem of residual gradient after AVR, stentless valves have been proposed as ideal for allowing reverse remodeling to occur. Using LV mass as the predominant surrogate marker, multiple small randomized and nonrandomized studies have attempted to assess for differences in reverse remodeling after AVR with different valve substitutes. Although demonstrating conflicting results, regression of LV mass does appear to be associated with achieving valvular competence and a low transvalvular gradient, regardless of prosthetic choice, and with treatment of postoperative hypertension.[30] The ASSERT trial[31] is one of the few randomized studies comparing the effects of stented versus stentless AVR on LV mass. In this study performed in Europe, 190 patients with aortic annulus size ≤25 mm were randomized to receive a Medtronic stented Mosaic porcine prosthesis or Medtronic stentless Freestyle prosthesis, implanted using a subcoronary technique. After one year, both groups demonstrated similar reductions in LV mass despite significant differences in effective orifice areas and flow velocities in favor of the stentless valves. Operative and postoperative clinical outcomes were also similar. A significant weaknesses of the study, however, was the use of the subcoronary technique for implantation of the stentless valve, which leads to higher gradients, more aortic insufficiency, and higher rates of late valve failure compared with the total root technique.[9,32] Additionally, one year follow-up may be an inadequate time to detect for differences in LV hypertrophy, because changes in LV geometry occur over many years after AVR.[33,34] This concept is supported by a small, randomized study of stented versus stentless valves that found no difference in LV mass regression at 6 months but a significant difference in favor of the stentless valve at 32 months.[35] The most recent large randomized study compared Edwards Lifesciences stented and nonstented subcoronary prostheses in 161 patients and again demonstrated similar reductions in LV mass at 1 year. However, in patients with LV ejection fraction less than 60%, subsequent improvement in ejection fraction was greater in the stentless group.[36] Because of these conflicting data, some have questioned the overall clinical importance of LV mass regression after AVR. Despite the known adverse prognostic implication of LV hypertrophy in the population as a whole, and importance of regression with treatment of hypertension, it has not been conclusively determined that regression after AVR correlates with survival.[37]

Gender issues are important to the topic of remodeling in aortic stenosis. For example, left ventricular adaptation to severe aortic stenosis is gender specific, with less compensatory increase in LV mass and wall tension in females compared with males.[38,39] Perhaps a better indicator of hypertrophy is the LV mass/volume ratio, a parameter that is increased in women with aortic stenosis compared with men.[39,40] Consequently, women with aortic stenosis tend to have worse diastolic function and exercise capacity compared with men.[41] Patient-prosthesis mismatch (PPM) is also more common in women and refers to implantation of a valve too small for a patient's size. Although PPM is generally defined as an in vivo effective orifice area indexed to body surface area (EOAI) of ≤ 0.75 to 0.85 cm^2/m^2,[42] EOAI may be preferentially evaluated on a continuum, similar to native aortic valve stenosis. Depending on definition, PPM is present in 20 to 60% of patients after AVR.[43-45] EOAI incorporates both size and functional considerations because postoperative gradients (ie, persistent LV pressure-overload state) are related to the area available for blood to leave the LV and to flow, or cardiac output in this instance, which correlates well with body size. Although controversial,[46-48] the preponderance of data, all retrospective, suggests that the presence of PPM is associated with reduced mid- and long-term survival.[45,49-54] Techniques to prevent PPM include annular enlargement procedures and implantation of stentless valves.

Durability

History teaches a good lesson in the story of the Toronto SPV stentless valve. Pioneered by David, this was the first prosthesis widely available for use. The Toronto SPV was designed to be implanted only by subcoronary technique. Numerous reports identified the hemodynamic advantages over stented valves, and remarkably, David reported improved survival over stented valves in midterm follow-up.[55] At 9 years, durability and hemodynamics were found to be excellent, with 90% freedom from structural failure.[56] At 12 years, however, freedom from structural valve degeneration was only 69%, and only 52% for patients under 65 years of age at time of implant.[57] Freedom from moderate or severe aortic insufficiency was only 48% for

the group as a whole. The mechanism for this finding was postulated to be dilatation of the sinotubular junction, and such a mechanism could theoretically affect late results of any subcoronary stentless valve. In a group of mostly subcoronary Freestyle implants, however, Bach et al reported 92% freedom from structural degeneration at 12 years with equivalent rates in patients less than 60 years of age at the time of implant.[58] One possible explanation, although not proven, for the discrepancy between SPV and Freestyle longevity is that most Freestyles have been implanted with the modified subcoronary technique compared with complete subcoronary for the Toronto SPV. The preservation of two commissural posts may create more sinotubular junction stability over time. In general, though, the lessons to be learned from the SPV data are that all valves are not created equal, even when implanted in similar manners, and that long-term and ongoing follow up is required to assess for durability because all bioprosthetic valves will eventually fail.

Operative Risk

Contemporary series of patients implanted with stentless valves do not support a higher operative risk, even with total root replacement. It is clear that the procedure requires slightly longer aortic cross-clamp and CPB times,[21] but this has not translated into higher mortality. Florath et al examined factors related to operative mortality in 1400 patients undergoing AVR, and neither stentless nor stented valve use was found to be predictive.[12]

CONCLUSIONS

As newer valve designs continue to be introduced to the market, ease and safety of implantation will continue to dominate as factors important for patients and surgeons. Closely followed in importance will be hemodynamic performance and durability. With the advent of transcatheter aortic valves, the bar will be set high for both implantation ease and hemodynamics. Already, effective orifice areas for first generation transcatheter valves exceeds those for 3rd generation stented bioprostheses,[59] albeit at the expense of trace-to-moderate aortic regurgitation. This issue will continue to drive the debate over the importance of patient-prosthesis mismatch. In the coming years, these issues may also highlight the hemodynamic advantages of stentless valves over stented and may also define the importance of different valves as platforms for performing transcatheter valve-in-valve implantation. Stentless total roots may have an advantage over other aortic valve prostheses in this setting given the larger orifices and root anatomy that is equivalent to the anatomy used during transcatheter valve development.

In summary, the stentless aortic valve, when implanted as a total root replacement, is an undeniably important tool for management of aortic root pathology. The debate continues, however, over the use of stentless valves in the absence of root pathology. Given that survival and functional outcomes often remain impaired after AVR for aortic stenosis, and that this suboptimal outcome appears to coincide with incomplete reverse remodeling of the left ventricle, surgeons should continue to seek the best option for long-term quantity and quality of life. Placement of larger valve substitutes intuitively will result in lower residual transvalvular gradients and may allow for better myocardial structural and functional outcomes. Use of stentless valves optimally achieves these surgical goals and may be appropriate for broader applications.

KEY POINTS

- The indication for subcoronary or modified subcoronary stentless AVR is for prevention of patient-prosthesis mismatch and can be considered an alternative to annular enlargement procedures.
- Stentless valves placed as full roots maximize the hemodynamic advantages of stentless technology and can be placed without excess mortality.
- Stentless valves placed as full roots are an excellent alternative to homografts when a bioprosthesis is desired for treatment of aortic root pathology.
- Long-term data on currently available stentless valves reveals acceptable rates of structural degeneration.
- Tips for successful stentless root replacement include paying close attention to coronary alignment, interrupted proximal suture line, complete resection of calcified or poor quality tissue, and close inspection of coronary button suture lines.
- All stentless valves are not the same. Various techniques are utilized for implantation resulting in heterogeneous populations for different indications with different valves by surgeons with bias towards one technique over another. The result is vastly different hemodynamic profiles and long term outcomes.

CHAPTER 36

Aortic Valve Repair and Aortic Valve-Sparing Operations

Tirone E. David

FUNCTIONAL ANATOMY OF THE AORTIC VALVE

The aortic valve is a complex structure that is best described as a functional and anatomic unit, the aortic root. The aortic root has four components: aorto-ventricular junction or aortic annulus, aortic cusps, aortic sinuses, and sinotubular junction. In addition, the triangles beneath the commissures of the aortic valve, although part of the left ventricular outflow tract, are also important for valve function.

The aortic annulus unites the aortic cusps and aortic sinuses to the left ventricle. It is attached to ventricular myocardium (interventricular septum) in approximately 45% of its circumference and to fibrous structures (anterior leaflet of the mitral valve and membranous septum) in the remaining 55% (Fig. 36-1). The aortic annulus has a scalloped shape. Histologic examination of the aortic annulus reveals that it is a fibrous structure with strands attaching itself to the muscular interventricular septum and has a fibrous continuity with the mitral valve and membranous septum. The fibrous structure that separates the aortic annulus from the anterior leaflet of the mitral valve is the intervalvular fibrous body. An important structure immediately below the membranous septum is the bundle of His. The atrioventricular node lies in the floor of the right atrium between the annulus of the septal leaflet of the tricuspid valve and the coronary sinus. This node gives origin to the bundle of His, which travels through the right fibrous trigone along the posterior edge of the membranous septum to the muscular interventricular septum. At this point, the bundle of His divides into left and right bundle branches that extend subendocardially along both sides of the muscular interventricular septum.

The aortic cusps are attached to the aortic annulus in a scalloped fashion (see Fig. 36-1). The aortic cusps have a semilunar shape whereby the length of the base is approximately 1.5 times longer than the length of the free margin, as illustrated in Fig. 36-2. There are three cusps and three aortic sinuses: left, right, and noncoronary. The aortic sinuses are also referred to as sinuses of Valsalva. The left coronary artery arises from the left aortic sinus and the right coronary artery arises from the right aortic sinus. The left coronary artery orifice is closer to the aortic annulus than is the right coronary artery orifice. The highest point where two cusps meet is called the commissure, and it is located immediately below the sinotubular junction. The scalloped shape of the aortic annulus creates three triangular spaces underneath the commissures. The two triangles beneath the commissures of the noncoronary cusp are fibrous structures, whereas the triangular space beneath the commissure between the left and right cusps is mostly muscular. These three triangles are seen in Fig. 36-1. The aortic annulus evolves along three horizontal planes within a cylindrical structure. Thus, the annulus of each cusp inserts itself in the aortic root along a single horizontal plane. The sinotubular junction represents the end of the aortic root. It is an important component of the aortic root because the commissures of the aortic valve are immediately below it and changes in the diameter of the sinotubular junction affect the function of the aortic cusps.

The geometry of the aortic root and its anatomic components varies among individuals, but the geometry of these components is somewhat interrelated. For instance, the larger the aortic cusps, the larger are the diameters of the aortic annulus and sinotubular junction. The aortic cusps are semilunar (crescent shape) and their bases are attached to the annulus; the free margins extend from commissure to commissure, and the cusps coapt centrally during diastole. The size of the aortic cusps varies among individuals and within the same person, but as a rule the noncoronary cusp is slightly larger than the right and left. The left is usually the smallest of the three. Because of the crescent

FIGURE 36-1 A photograph of a human left ventricular outflow tract and aortic root.

shape of the aortic cusps and the fact that their free margins extend from commissure to commissure, the diameter of the aortic valve orifice must be smaller than the length of the free margins. Indeed, anatomic studies of fresh human aortic roots demonstrated that the average length of the free margins of the aortic cusps was one-third longer than the diameter of the aortic orifice. The diameter of the aortic annulus is 15 to 20% larger than the diameter of the sinotubular junction in children, but this relationship changes with age and the diameter of the aortic annulus is often smaller than the diameter of aortic annulus in older persons (see Fig. 36-2).

The aortic annulus, the aortic cusps, and the sinotubular junction play an important role in maintaining valve competence. On the other hand, the aortic sinuses play no role in valve competence, but they are believed to be important in minimizing mechanical stress on the aortic cusps during the cardiac cycle by creating eddies currents between the cusps and the aortic sinuses.

All components of the aortic root are very elastic and compliant in children but compliance decreases with aging as elastic fibers are replaced by fibrous tissue. Expansion and contraction of the aortic annulus during the cardiac cycle are heterogeneous

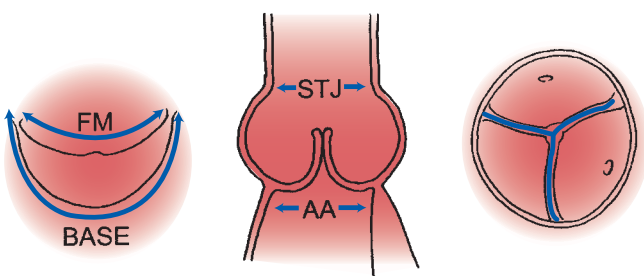

FIGURE 36-2 Geometric relationships of various components of the aortic root. The base of the aortic cusp is 1.5 times longer than its free margin. The diameter of the aortic annulus is 10 to 15% larger than the diameter of the sinotubular junction in children and young adults but it tends to become equal with aging. Three semilunar cusps seal the aortic orifice. The height of the cusps must be longer than the radius of the aortic annulus.

probably because of its attachments to contractile myocardium as well as to fibrous structures such as the membranous septum and intervalvular fibrous body. On the other hand, the expansion and contraction of the sinotubular junction are more uniform. The aortic root also displays some degree of torsion during isovolumic contraction and ejection of the left ventricle. The movements of the aortic annulus, cusps, sinuses, and sinotubular junction also change with aging as elastic fibers are replaced by fibrous tissue.

AORTIC VALVE PATHOLOGY

Anatomically normal aortic cusps may become calcified late in life and cause aortic stenosis. This type of lesion is called dystrophic calcification, senile calcification, or degenerative calcification. The range of histopathologic lesions includes calcification, chondroid and osseous metaplasia, neorevascularization, inflammation, and lipid deposition.

Bicuspid aortic valve is believed to occur in 1 to 2% of the population. Movahed and colleagues[1] recently reviewed the echocardiograms of 24,265 patients who had the study for various clinical reasons and 1742 teenage athletes in Southern California, and found a prevalence of bicuspid aortic valve of 0.6% in the large cohort and 0.5% in the smaller one. Males are affected more than females at a ratio of 4:1. There is a relatively high incidence of familial clustering, which suggests an autosomal dominant inheritance with reduced penetrance.[2] Extensive research in the genetics of bicuspid aortic valve is being presently conducted and this disorder is likely heritable. Most patients with bicuspid aortic valve have three aortic sinuses and two cusps of different sizes. The larger cusp often contains a raphe instead of a commissure. The raphe extends from the mid portion of the cusp to the aortic annulus, and its insertion in the aortic root is at a lower level than the other two commissures. Bicuspid aortic valves with two aortic sinuses and no raphe are least common and called "type 0"; the most common is with one raphe and is called "type 1"; and finally with two raphes is "type 2."[3] Types 1 and 2 can be subclassified according to the fused cusps: L-R is the most common form (a raphe in between the left and right cusps). Most patients with bicuspid aortic valves have a dominant circumflex artery and a small right coronary artery. Bicuspid aortic valve may function satisfactorily until late in life when it may become calcified and stenotic.[4] It may also become incompetent, particularly in younger patients and is often associated with dilated aortic annulus and cusp prolapsed.

Other congenital anomalies of the aortic valve are the unicusp and quadricuspid valves. Subaortic membranous ventricular septal defect can cause aortic insufficiency because of distortion of the aortic annulus and prolapse of the right cusp.

Numerous connective tissue disorders (ankylosing spondylitis, osteogenesis imperfecta, rheumatoid arthritis, Reiter's syndrome, lupus, etc.) can cause aortic insufficiency. The anorexigenic drugs phentermine and fenfluramine can also cause aortic insufficiency. Rheumatic aortic valve disease is still prevalent in developing countries and can cause aortic stenosis and/or insufficiency by causing fusion, fibrosis, and contraction of the cusps.

AORTIC ROOT AND ASCENDING AORTA PATHOLOGY

Degenerative diseases of the media with aneurysm formation are the most common disorders of the aortic root and ascending aorta. A broad spectrum of pathologic and clinical entities is grouped under degenerative disorders, and it ranges from severe degeneration of the media, which can become clinically important early in life in cases such as Loyes-Dietz syndrome, to cases of the not so important mild dilation of the ascending aorta in elderly patients. Bicuspid and unicusp aortic valve disease often display premature degeneration of the media with dilation of the aorta. Atherosclerosis, infectious and noninfectious aortitis are other pathologic entities.

Aneurysms of the ascending aorta are often caused by cystic medial degeneration (cystic medial necrosis). Histologically, necrosis and disappearance of muscle cells in the elastic lamina, and cystic spaces filled with mucoid material are often observed. Although these changes occur more often in the ascending aorta, they may affect any portion or the entire aorta. These changes weaken the arterial wall, which dilates and forms a fusiform aneurysm. The aortic root may be involved in this pathologic process, and in patients with Marfan syndrome, the aneurysm usually begins in the aortic sinuses. A large proportion of patients with aortic root aneurysms do not fulfill the criteria of diagnosis of Marfan syndrome, but the gross appearance of the aneurysm and the histology of the arterial wall may be indistinguishable from that of Marfan syndrome. These cases are referred to as *forma frusta* of Marfan syndrome.

Patients with aortic root aneurysms are usually in their second or third decade of life when the diagnosis is made. These patients develop aortic insufficiency because of dilation of the sinotubular junction and/or aortic annulus (Fig. 36-3). Annuloaortic ectasia is a term used to describe dilation of the aortic annulus.

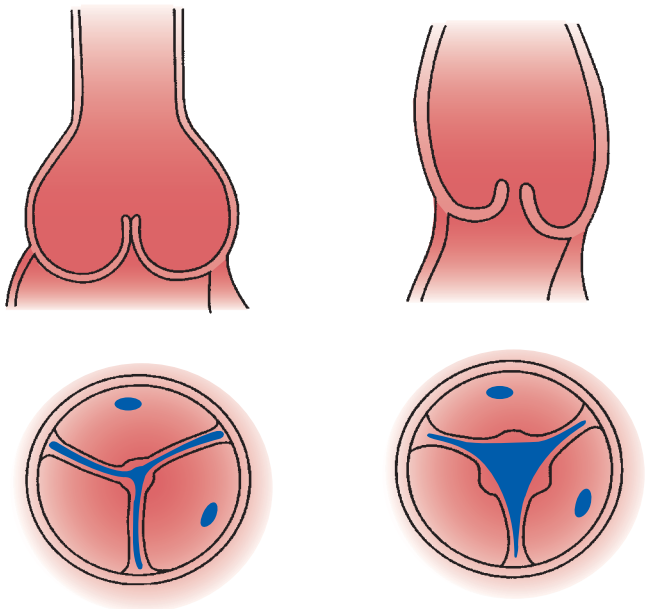

FIGURE 36-3 Dilation of the sinotubular junction causes aortic insufficiency because it displaces the commissures outward and prevents the cusps to coapt centrally.

Other patients have relatively normal aortic roots but develop ascending aortic aneurysms. These patients are usually in their fifth or sixth decade of life. Finally, certain patients have extensive degenerative disease of the entire aorta and develop the so-called mega-aorta syndrome with dilation of the entire thoracic and abdominal aorta. Ascending aortic aneurysm may cause dilation of the sinotubular junction with consequent aortic insufficiency (Fig. 36-3).

Marfan Syndrome

Marfan syndrome is an autosomal dominant variably penetrant inherited disorder of the connective tissue in which cardiovascular, skeletal, ocular, and other abnormalities may be present to a variable degree. The prevalence is estimated to be around 1 in 5000 individuals. It is caused by mutations in the gene that encodes fibrillin-1 (FBN1) on chromosome 15. This is a large gene (approximately 10,000 nucleotides in the mRNA), and identification of the mutation is a complex task. More than 1000 mutations in FBN1 have been identified. The phenotype presents a highly variable degree because of varying genotype expression.

The clinical features of Marfan syndrome were thought to be a result of weaker connective tissues caused by defects in fibrillin-1, a glycoprotein, and principal component of the extracellular matrix microfibril. This concept was inadequate to explain the overgrowth of long bones, osteopenia, reduced muscular mass, and adiposity and craniofacial abnormalities often seen in Marfan syndrome.[5] Dietz and colleagues[5,6] showed in an experimental mouse with Marfan syndrome that many findings are the result of abnormal levels of activation of tranforming growth factor beta (TGF-β), a potent stimulator of inflammation, fibrosis, and activation of certain matrix metalloproteinases, especially matrix metalloproteinases 2 and 9. Excess TGF-β activation in tissues correlates with failure of lung septation, development of a myxomatous mitral valve, and aortic root dilation in mice. This combination of structural microfibril matrix abnormality, dysregulation of matrix homestasis mediated by excess TGF-β, and abnormal cell-matrix interactions is responsible for the phenotype features of the Marfan syndrome. Ongoing destruction of the elastic and collagen lamelae and medial degeneration result in progressive dilation of the aortic root, as well as a predisposition to aortic dissection from the loss of appropriate medial layer support. Loss of elasticity in the media causes increased aortic stiffness and decreased distensibility.

The diagnosis of Marfan syndrome is made on clinical grounds, and it is not always simple because of the variability in clinical expression. A multidisciplinary approach is needed to diagnose and manage patients afflicted with this syndrome. Table 36-1 shows the criteria for the diagnosis of Marfan syndrome. The presence of major criteria in two separate systems and involvement of a third (minor or major) are needed to establish the diagnosis.[7]

The most common cardiovascular features are aortic root aneurysm and mitral valve prolapse. These anatomical abnormalities may cause aortic rupture, aortic dissection, aortic insufficiency, and mitral insufficiency.

TABLE 36-1 Diagnosis Criteria for Marfan Syndrome

Criteria	Major	Minor
Family history	Independent diagnosis in parent, child, sibling	None
Genetics	Mutation FBN1	None
Cardiovascular	Aortic root dilation Dissection of ascending aorta	Mitral valve prolapse Calcification of the mitral valve (<40 years) Dilation of the pulmonary artery Dilation or dissection of the descending aorta
Ocular	Ectopia lentis	(Two needed:) Flat cornea Myopia Elongated globe
Skeletal	(Four needed:) Pectus excavatum needing surgery Pectus carinatum Pes planus Wrist and thumb sign Scoliosis >20 degrees or spondylolisthesis Arm span–height ratio >1.05 Protrusio acetabulae (x-ray, MRI) Diminished extension elbows (<170 degrees)	(Two major or one major and two minor signs) Moderate pectus excavatum High narrowly arched palate Typical facies Joint hypermobility
Pulmonary		Spontaneous pneumothorax Apical bulla
Skin		Unexplained stretch marks (striae) Recurrent or incisional herniae
Central nervous system	Lumbosacral dural ectasia (CT or MRI)	

LOEYS-DIETZ SYNDROME

Mutations in the genes encoding TGF-ß receptors 1 and 2 have been found in association with a continuum of clinical features. On the mild end, the mutation have been found in association with presentation similar to that of the Marfan syndrome or with familial thoracic aneurysm and dissection, and on the severe end, they are associated with a complex phenotype in which aortic dissection or rupture commonly occurs in childhood.[8] This complex phenotype is characterized by the triad of hypertelorism, bifid uvula or cleft palate, and generalized arterial tortuosity with widespread vascular aneurysm and dissection. This phenotype has been classified as Loeys-Dietz syndrome. Affected patients have a high risk of aortic dissection or rupture at an early age and at relatively small diameters. CT angiograms should be obtained from head to pelvis.

Ehlers–Danlos Syndrome

Vascular Ehlers–Danlos syndrome is a rare autosomal dominant inherited disorder of the connective tissue resulting from mutation of the COL3A1 gene encoding type III collagen. Spontaneous rupture without dissection of large and medium-caliber arteries such as the abdominal aorta and its branches, the branches of the aortic arch, and the large arteries of the limbs accounts for most deaths. Aortic root dilation was present in 28% in a series of 71 patients with Ehlers–Danlos syndrome.[9] Aortic dissection is uncommon. Diagnosis is confirmed either by biochemical assays showing qualitative or quantitative abnormalities in type III collagen secretion or by molecular biology studies demonstrating mutation of the COL3A1 gene. Varied molecular mechanisms have been observed with different mutations in each family. No correlation has been established between genotype and phenotype. Diagnosis should be suspected in any young person presenting with arterial or visceral rupture or colonic perforation.

Other Pathologies

Atherosclerotic aneurysms of the ascending aorta are uncommon. They are more common in the abdominal aorta and to a

lesser degree in the descending thoracic aorta. Atherosclerosis often causes irregular and saccular aneurysms of the ascending aorta rather than a more fusiform shape as those caused by degenerative disease of the media.

Infectious aneurysms of the ascending aorta are rare. Syphilis was a common cause of aneurysm of the ascending aorta but it is seldom seen. The spirochetal infection destroys the muscular and elastic fibers of the media, which are replaced by fibrous and other inflammatory tissues. The ascending aorta is the most common site of involvement and the aneurysm is usually saccular. The wall of the ascending aorta is frequently calcified. Syphilitic aortitis also causes coronary ostial stenosis and aortic valve insufficiency. Other bacteria can also cause aneurysm of the ascending aorta.

Various types of aortitis may involve the ascending aorta. Giant cell arteritis is among the more common and it involves medium-sized arteries, but the aorta and its branches are involved in approximately 15% of the cases. The etiology is unknown. The characteristic lesion is a granulomatous inflammation of the media of large and medium-caliber arteries such as the temporal artery. Occasionally the inflammatory process weakens the aorta leading to aneurysm formation, aortoannular ectasia, and aortic insufficiency.

Ankylosinsg spondylitis, Reiter's syndrome, psoriatic arthritis, and polyarteritis nodosa can cause aortic insufficiency because of annuloaortic ectasia. Behçet's disease can cause aneurysm of the ascending aorta.

NATURAL HISTORY OF AORTIC VALVE DISEASE

Aortic Stenosis

Asymptomatic patients with aortic stenosis have a good prognosis.[10] Sudden death in asymptomatic patients is uncommon. However, when symptoms develop, the prognosis becomes poor and the average survival is 2 to 3 years for patients with symptoms of angina and syncope, and 1 to 2 years for those with congestive heart failure.[11]

Aortic Insufficiency

The prognosis of symptomatic patients with aortic insufficiency is poor with death occurring within 4 years after development of angina and within 2 years after the onset of congestive heart failure.[12]

Bicuspid Aortic Valve Disease

A prospective follow-up on 642 adult patients (mean age 35±9 years) with bicuspid aortic valve during a mean 9±5 years in our institution revealed a late survival similar to that of the general population in spite the fact that 161 patients had an adverse event (cardiac death, aortic valve/ascending aorta surgery, dissection or congestive heart failure).[13] Age greater than 30 years, and moderate or severe aortic stenosis or insufficiency were independent predictors of adverse event.[13] In a study from the Mayo Clinic on 212 patients (mean age 32±20 years) with normal or minimally dysfunctional bicuspid aortic valve who lived in Olmsted County and followed for a mean of 15±6 years revealed a 20-year survival similar to that of the general population but the incidence of surgery on the aortic valve and/or ascending aorta was 27±4% and the total adverse cardiovascular events was 42±5%.[4]

Aortic Root and Ascending Aortic Aneurysms

Aortic root/ascending aortic aneurysm can cause aortic insufficiency, aortic dissection or rupture. The transverse diameter of the aneurysm is the most important predictor of rupture or dissection. In a study by Coady and associates[14] on 370 patients with thoracic aneurysms (201 ascending aortic aneurysms), during a mean follow-up of 29.4 months the incidence of acute dissection or rupture was 8.8% for aneurysms less than 4 cm, 9.5% for aneurysms of 4 to 4.9 cm, 17.8% for 5 to 5.9 cm, and 27.9% for those greater than 6 cm. The median size of the ascending aortic aneurysm at the time of rupture or dissection was 5.9 cm. The growth rates of thoracic aneurysms are exponential.[14] In Coady's study, the growth rate ranged from 0.08 cm/year for small (<4 cm) aneurysms to 0.16 cm/year for large (8 cm) aneurysms.[14] The growth rates for chronic dissecting aneurysms were much higher than for chronic nondissecting aneurysms.

The growth rates for aortic root aneurysms may be higher than in ascending aortic aneurysms, particularly in patients with Marfan syndrome. Aortic dissection is rare in aortic root aneurysm of less than 50 mm, unless the patients have family history of aortic dissection. Without surgery most patients with Marfan syndrome die in the third decade of their lives from complications of aortic root aneurysm such as rupture, aortic dissection, or aortic insufficiency.[15] Pregnancy in women with Marfan syndrome has two potential problems: the risk of having a child who will inherit the disorder and the risk of acute aortic dissection during the third trimester, parturition, or the first month postpartum. The offspring has a 50% risk of inheriting the syndrome.

Patients affected with Loeys-Dietz syndrome have a high risk of aortic dissection or rupture at an early age and at relatively small aortic root diameters. Surgery is recommended in adults when the aortic root exceeds 4 cm.

Patients with bicuspid aortic valve had larger aortas than patients with tricuspid aortic valve and the rate of dilation of the ascending aorta was higher (0.19 cm versus 0.13 cm per year respectively) in a study by Davies et al.[16] Among patients with bicuspid aortic valve, those with aortic stensois had a higher risk of rupture, dissection, or death.

DIAGNOSIS OF AORTIC VALVE/ROOT DISEASE

Patients with aortic stenosis remain asymptomatic for many years. Symptoms usually appear late in the course of the disease. The symptoms are: angina pectoris, syncope, congestive

heart failure, and syncope. The clinical presentation of patients with aortic insufficiency is dependent on the rapidity with which aortic insufficiency develops. Patients with chronic aortic insufficiency remain asymptomatic for many years while the heart slowly enlarges. Palpitations and head pounding may occur during exertion. Angina pectoris may occur, but it is not as common as with aortic stenosis. Syncope is rare. Symptoms of congestive heart failure are usually an indication of left ventricular dysfunction. Acute aortic insufficiency is frequently associated with cardiovascular collapse, with extreme fatigue, dyspnea, and hypotension resulting from reduced stroke volume and elevated left atrial pressure. Echocardiography confirms the diagnosis of aortic valve dysfunction and provides information regarding its mechanism. Radionuclide imaging is useful in assessing the left ventricular function at rest and during exercise, valuable information in asymptomatic patients.

Most patients with aortic root aneurysm are asymptomatic and have no physical signs if the aortic valve is competent. Some patients may complain of vague chest pain. Severe chest pain is suggestive of rapid expansion or intimal tear with dissection. Echocardiography establishes the diagnosis and provides information regarding the aortic cusps. CT scan and MRI of the chest are also diagnostic and it is useful to provide information regarding the thoracic aorta.

INDICATIONS FOR SURGERY

Surgeons must be familiar with the guidelines for heart valve surgery established by a joint committee of the ACC and AHA.[17]

SELECTION OF PATIENTS FOR AORTIC VALVE REPAIR

Most candidates for aortic valve repair have aortic insufficiency or normally functioning aortic valve with aortic root aneurysm. Transesophageal echocardiography is the best diagnostic tool to study the aortic valve and the mechanism of aortic insufficiency. Each component of the aortic root must be carefully interrogated, and in particular the aortic cusps. The number of cusps, their thickness, the appearance of their free margins, and the excursion of each cusp during the cardiac cycle must be examined in multiple views. The lines of coaptation of the aortic cusps should be interrogated by color Doppler imaging. The direction and size of the regurgitant jets recorded in many views. Information regarding the morphologic features of the aortic annulus, aortic sinuses, sinotubular junction, and ascending aorta should be obtained.

Obviously, the aortic cusps are the most important determinant of aortic valve repair. If the cusps are thin, mobile, and smooth free margins, the feasibility of aortic valve repair is very high, including bicuspid aortic valve. Calcified or scarred and fibrotic aortic cusps preclude aortic valve repair unless autologous or xenograft glutaraldehyde fixed pericardium is used for cusp augmentation.

Patients with aortic root aneurysm often have normal or minimally stretched aortic cusps and reconstruction of the aortic root with preservation of the native aortic cusps is feasible. Grossly dilated aortic annulus and/or sinotubular junction are likely to have overstretched, thinned out aortic cusps with stress fenestrations along the commissural areas and may not be suitable for repair.

TECHNIQUES OF AORTIC VALVE REPAIR

Cusp Perforation

Occasionally a cups perforation is the sole reason for aortic insufficiency. The perforation may be iatrogenic, a sequelae of healed endocarditis, or the result of resection of a papillary fibroelastoma. A simple patch of fresh or glutaraldehyde fixed autologous pericardium is adequate to correct the problem. Fresh autologous pericardium can also be used to repair small holes (<5 mm) but the patch should be larger than the defect because it retracts during healing. We use a continuous 7-0 polypropylene to suture the patch around the defect on the aortic side of the cusp.

Cusp Extension

Cusp augmentation has been used to repair incompetent aortic valves due rheumatic and congenital disease. Glutaraldehyde-fixed bovine or autologous pericardium has been used for this purpose.

Cusp Prolapse

Cusp prolapse is caused by elongation of the free margin. This is corrected by plication along the nodule of Arantius as illustrated in Fig. 36-4. The degree of shortening is determined by examining the other cusps and their level of coaptation.

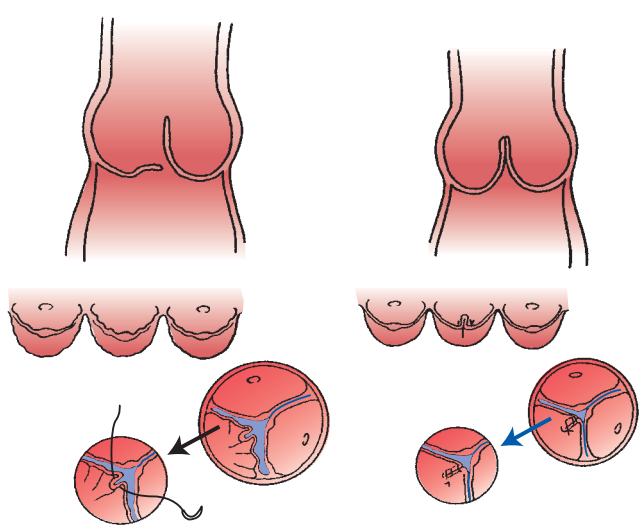

FIGURE 36-4 Repair of cusp prolapse. The free margin is shortened by plicating the area of the nodule of Arantii.

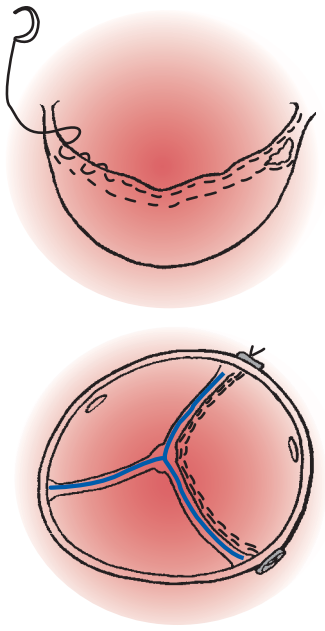

FIGURE 36-5 Reinforcement of the free margin with a double layer of 6-0 expanded polytetrafluoroethylene suture. This is often done in patients with stress fenestration.

Cusp with Stress Fenestration

Dilation of the sinotubular junction increases the mechanical stress along the free margin of the cusp near the commissures and may cause a stress fenestration with thinning and sometimes even detachment from the commissure. This type of lesion has been successfully corrected by weaving a double layer of 6-0 expanded polytetrafluoroethylene suture along the free margin of the cusp as illustrated in Fig. 36-5.

Bicuspid Aortic Valve

The most commonly performed aortic valve repair in adults is for bicuspid aortic valve with prolapse of one cusp. Although the anatomic arrangement of the bicuspid aortic valve varies, most patients have an anterior cusp attached to the interventricular septum and a posterior cusp attached to the fibrous components of the left ventricular outflow tract. The anterior cusp often contains a raphe at approximately where the commissure between the right and left cusps would be (Type 1, L-R). This cusp is usually the one that is elongated and prolapsed. As long as the posterior cusp is normal, repair is feasible and relatively simple. The raphe is excised and the free margin of the anterior cusp is shortened with plicating sutures as illustrated in Fig. 36-6. The lengths of the free margins of both cusps should be similar and should coapt at the same level. Suspending the arterial walls immediately above the commissures and observing the level of coaptation of each cusp gives an estimate of the level of coaptation of the cusps.

Because most patients with incompetent bicuspid aortic valves have dilated aortic annulus, aortic valve sparing operation may be more appropriate procedure than simple cusp repair. However, if the aortic sinuses are not aneurismal and the annulus is only mildly dilated, a reduction annuloplasty to increase the coaptation area of the cusps can be done. This is accomplished by plicating the subcommissural triangles using horizontal mattress sutures of 4-0 polypropylene with Teflon felt pledgets on the outside of the aortic root (Fig. 36-7). The suture is first passed from the outside to the inside of the aorta through the aortic annulus of both cusps 2 mm below their commissure. The same suture is passed again through the annulus and subcommissural triangle 4 or 5 mm below the first one and the ends are tied together over Teflon felt pledgets on the outside of the aorta.

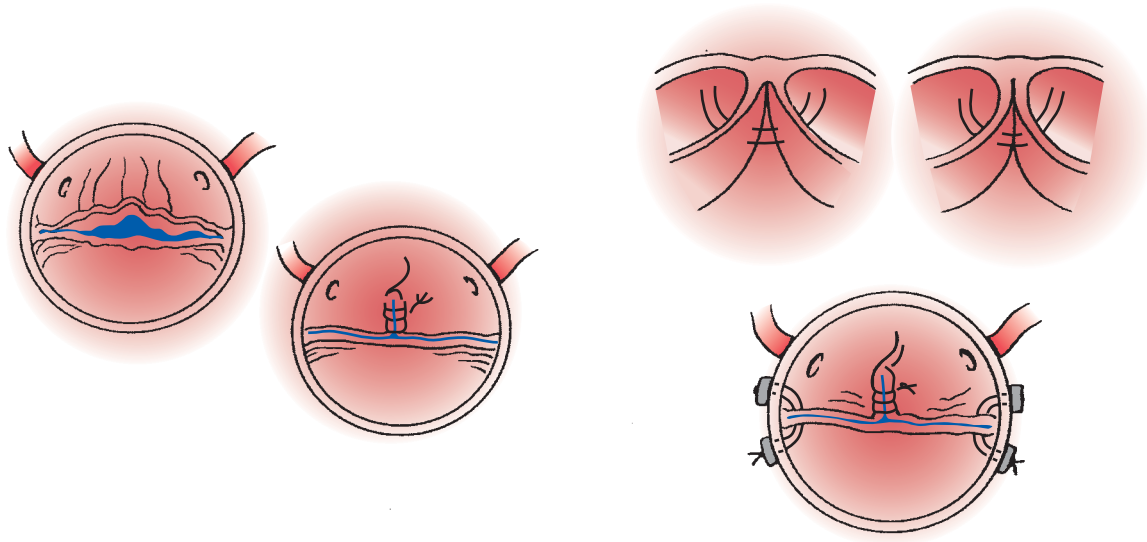

FIGURE 36-6 Repair of incompetent bicuspid aortic valve. The elongated cusp is shortened and the sub-commissural triangles narrowed with sutures.

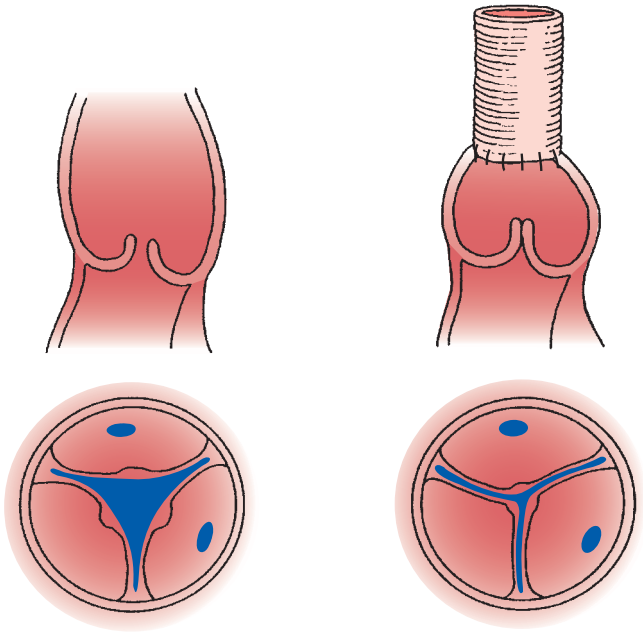

FIGURE 36-7 Dilation of the sinotubular junction causes aortic insufficiency. Correction of the dilation with a tubular Dacron graft of appropriate diameter corrects aortic insufficiency.

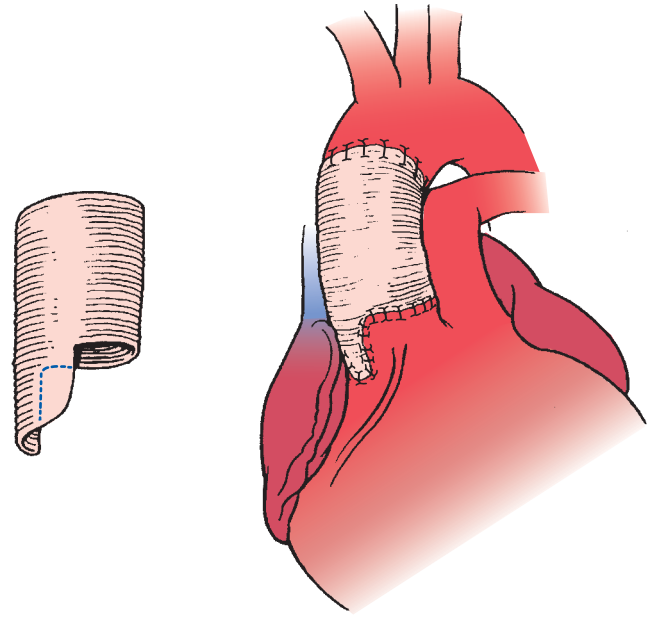

FIGURE 36-8 Correction of the sinotubular junction and replacement of the noncoronary aortic sinus.

AORTIC VALVE SPARING OPERATIONS

Aortic valve sparing operations include various procedures used to preserve the aortic cusps in patients with aortic root aneurysm or ascending aortic aneurysm with aortic insufficiency.[18,19]

Ascending Aortic Aneurysm with Aortic Insufficiency

Dilation of the sinotubular junction displaces the commissures of the aortic valve outward and prevents the cusps from coapting during diastole (see Fig. 36-3). These patients are often on the sixth, seventh, or eighth decade of their lives and have ascending aortic aneurysm. The dilation of the sinotubular junction is often asymmetrical, and the commissures of noncoronary aortic cusp are more affected than the other two. If the other components of the aortic root are normal, simple adjustment of the sinotubular junction restores valve competence. This is accomplished by transecting the ascending aorta 5 mm above the sinotubular junction and pulling the three commissures upward and close to each other until the cusps coapt. The three commissures form an imaginary triangle. The diameter of a circle that contains this imaginary triangle is the diameter of the graft that should be used to reconstruct the sinotubular junction. Because the aortic cusps and sinuses have different sizes, this triangle is not always equilateral and the commissures must be spaced according to the length of the free margin of each cusp. The diameter of the graft and the space between commissures are facilitated by sizing the diameter of the circle that contains all three commissures with a transparent valve sizer, such as the one used to size the aortic annulus for a stentless porcine aortic valve. Those valve sizers have three equidistant marks, and one can determine the space between the commissures by comparing to the distance between marks. The tubular Dacron graft is sutured right at the level of the sinotubular junction with a continuous 4-0 polypropylene suture (see Fig. 36-7). If after adjusting the sinotubular junction, the cusps do not coapt at the same level, one or more cusps may be elongated and the free margin has to be shortened as illustrated in Fig. 36-4. Aortic valve competence can be tested at this time by injecting cardioplegia into the graft under pressure and observing the left ventricle for distension.

If the noncoronary aortic sinus is dilated or altered by aortic dissection, a neosinus can be created by tailoring the graft with tongue of tissue that is sutured directly to the aortic annulus as illustrated in Fig. 36-8. The height of the neosinus of Dacron should be 3 or 4 mm more than the diameter of the graft, and the width should be 3 or 4 mm more than the estimated intercommissural distance to allow the graft to bulge and create a neoaortic sinus.

Small diameter grafts (<24 mm) should be avoided in adult patients because they may increase left ventricular afterload, particularly if long segments of aorta are replaced such as with concomitant transverse arch replacement using the elephant trunk technique. If the estimated diameter of the sinotubular junction is less than 24 mm, a larger graft should be used and the end that is anastomosed to the aortic root to recreate the sinotubular junction should be reduced by plicating the graft in the area of the anastomosis.

Aortic Root Aneurysm

A large proportion of patients with aortic root aneurysm have normal or minimally stretched aortic cusps and an aortic valve sparing operation is feasible. There are basically two types of

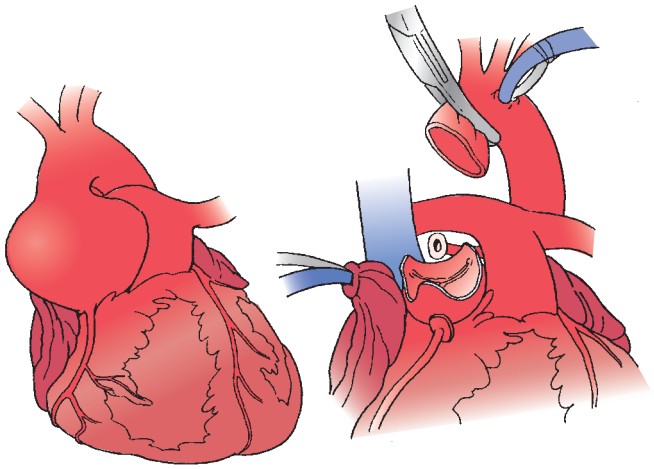

FIGURE 36-9 Remodeling of the aortic root. The aortic sinuses are excised leaving 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary arteries.

aortic valve-sparing operations for patients with aortic root aneurysm: remodeling of the aortic root and reimplantation of the aortic valve.[18,19]

Remodeling of the Aortic Root

The ascending aorta is transected and the aortic root is dissected circumferentially down to the level of the aortic annulus. All three aortic sinuses are excised, leaving approximately 4 to 6 mm of arterial wall attached to the aortic annulus and around the coronary artery orifices as illustrated in Fig. 36-9. The three commissures are gently pulled vertically and approximated until the cusps coapt. The three commissures form a triangle and the diameter of the circle that contains that triangle is the diameter of the graft to be used for remodeling. In our experience, most grafts are 24, 26, or 28 mm in diameter. Here again the stentless valve sizers are very useful to determine the diameter of the graft and also the distance between commissures because they may not be equidistant. The spaces in between the commissures are marked in one of the ends of the graft, and the graft is tailored to create three neo-aortic sinuses (Fig. 36-10). The heights of these neosinuses should be approximately equal to the diameter of the graft. The three commissures are suspended in the graft (Fig. 36-11), which is then sutured to the remnants of the aortic wall as close as possible to aortic annulus with continuous 4-0 polypropylene sutures. The coronary arteries are reimplanted into their respective neosinuses. The aortic cusps are inspected to make sure that all three coapt at the same level and well above the nadir of the aortic annulus. If one or more cusp is prolapsing, the free margin is shortened as described previously. If one or two cusps have stress fenestrations, the free margin should be reinforced with a fine expanded polytetrafluoroethylene suture. Aortic valve competence can be assessed by injecting cardioplegia under pressure into the reconstructed aortic root and observing the left ventricle for distension or by turning the echocardiography machine on. The graft is then anastomosed to the distal ascending aorta or transverse aortic arch graft depending on the extent of the aneurysm (Fig. 36-11).

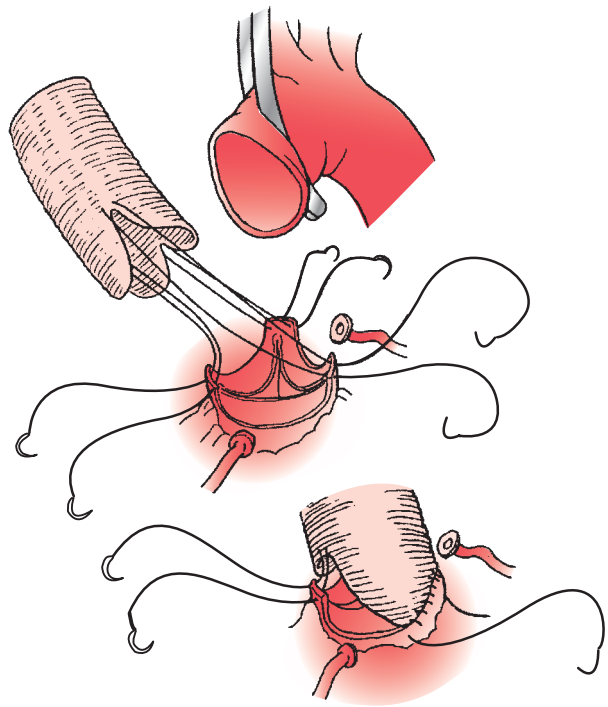

FIGURE 36-10 A graft of diameter equal to the diameter of the sinotubular junction is tailored to recreate three aortic sinuses. The three commissures are suspended into the tailored graft and the neoaortic sinuses are sutured to the aortic annulus and remnants of arterial wall.

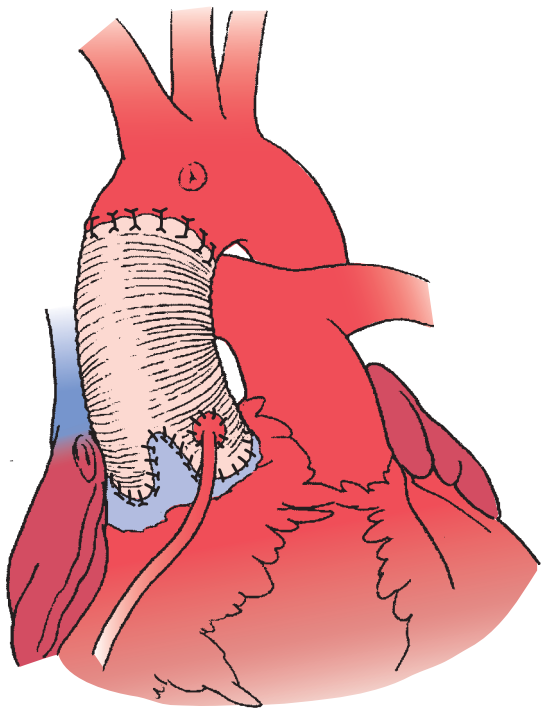

FIGURE 36-11 Remodeling of the aortic root. The coronary arteries are reimplanted into their respective neo-aortic sinuses and the graft anastomosed to the distal aorta.

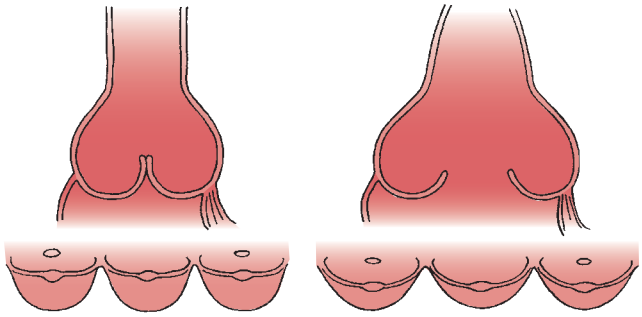

FIGURE 36-12 Annuloaortic ectasia. The subcommissural triangles of the noncoronary aortic cusps are flattened by dilation of the fibrous tissue.

Remodeling of the aortic root may be inappropriate for patients with Marfan syndrome or annuloaortic ectasia because the annulus may continue to dilate and cause aortic insufficiency. An aortic annuloplasty along the fibrous component of the left ventricular outflow tract[18] did not prevent late dilation of the aortic annulus in patients with Marfan syndrome in our experience. Thus, reimplantation of the aortic valve may be a better operative procedure for patients with annuloaortic ectasia (Fig. 36-12) because this operative procedure corrects and prevents annular dilation whereas remodeling of the aortic root may be more suitable for patients with normal aortic annulus.

Reimplantation of the Aortic Valve

This procedure can be performed in all patients with aortic root aneurysm, but it is particularly valuable in patients with annuloaortic ectasia and in those with acute type A aortic dissection. It is technically more demanding than remodeling of the aortic root because it requires greater knowledge of the functional anatomy of the aortic root. This is because the aortic annulus, the aortic sinuses, the sinotubular junction, and even the aortic cusps are reconstructed. In the original description of this procedure, the aortic valve was reimplanted into a tubular Dacron graft and no neoaortic sinuses were created. Some investigators have suggested that the presence of the aortic sinuses is important for normal cusp motion, and potentially, cusp durability. Several modifications to the reimplantation procedure were introduced to create neoaortic sinuses. There is now a commercially available graft with sinuses of Valsalva (Vascutek Ltd. Renfrewshire, Scotland); however, this graft distorts the aortic annulus because its sinuses are spherical whereas the normal aortic annulus develops along a crescent shape on a single horizontal plane. A cylindrical graft with neoaortic aortic sinuses that permits reimplantation of the aortic annulus along single horizontal planes has also been developed in Germany.[20]

Following is a description of this procedure as we have been performing it during the past decade, with excellent functional results. The three aortic sinuses are excised as described for the remodeling procedure (see Fig. 36-9). Multiple horizontal mattress sutures of 2-0 or 3-0 polyester are passed from the inside to the outside of the left ventricular outflow tract, immediately below the nadir of the aortic annulus, through a single horizontal plane along the fibrous portion of the outflow tract and along its scalloped shape in the interventricular septum as illustrated in Fig. 36-13. If the fibrous portion is thin, sutures with Teflon felt pledgets should be used. A tubular Dacron graft of diameter equal to double the average height of the cusps is selected and three equidistant marks placed in one of its ends. A small triangular segment is cut off along the mark that

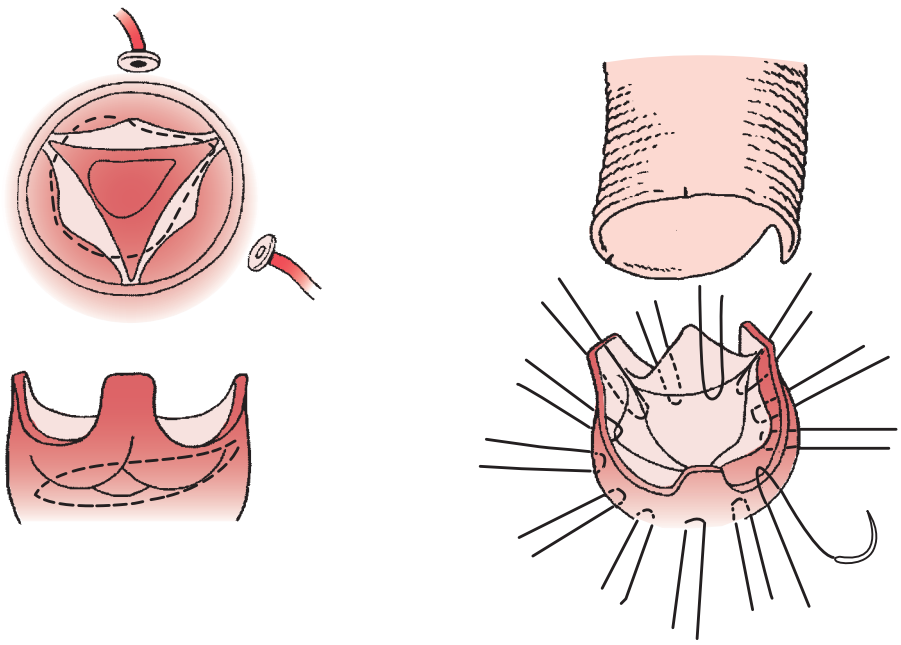

FIGURE 36-13 Reimplantation of the aortic valve. Sutures are passed below the aortic annulus in a single horizontal plane along the fibrous portion of the left ventricular outflow tract and following the scalloped shape of the aortic annulus along the muscular interventricular septum. These sutures are also passed from the inside to the outside of a tubular Dacron graft.

corresponds to the subcommissural triangle of the left and right cusps. If the diameter of the aortic annulus is smaller than the diameter of the graft by 10 mm or more, the diameter of the graft is reduced by plicating it in the areas corresponding to the nadir of the aortic annulus. The sutures previously placed in the left ventricular outflow tract are now passed through the graft. The sutures should be spaced symmetrically if the aortic annulus is not dilated. If there is obvious dilation of the aortic annulus, the sutures should be spaced symmetrically along the muscular interventricular septum and around the nadirs of the aortic annulus but closer together beneath the subcommissural triangles of the noncoronary cusp because that is where dilation occurs in patients with connective disorders. The sutures are then tied on the outside of the graft. Care must be exercised not to purse-string this suture line. The graft is then cut in a length of approximately 5 cm and pulled gently, and the three commissures are also pulled vertically and temporarily secured to the graft with transfixing 4-0 polypropylene sutures buttressed on small Teflon felt pledgets, but these sutures are not tied. Once all three commissures are suspended inside the graft, the commissures and the cusps are inspected to make sure they are all correctly aligned. The subcommissural triangles should also be inspected to make sure they are as narrow as the diameter of the graft allows, i.e., the triangles should have a narrower base than before surgery. Next, the sutures are tied on the outside of the graft and used to secure the aortic annulus into the graft. This is accomplished by passing the suture sequentially from the inside to the outside right at the level of the annulus and from the outside to the inside at the level of the remnants of the arterial wall. We start at the level of the commissure and stop at the nadir of the aortic annulus where the sutures are tied together. The coronary arteries are reimplanted into their respective sinuses (Fig. 36-14). The coaptation of the aortic cusps is inspected and prolapse is corrected if necessary. It is important that the coaptation level is well above the aortic annulus. Neoaortic sinuses are created by plicating the graft at the level of the commissure as illustrated in Fig. 36-15. Valve competence can be assessed by occluding the distal graft and injecting cardioplegia under pressure. If the ventricle does not distend, no more than trace aortic insufficiency is present. The aortic valve can also be examined by echocardiography during injection of cardioplegia. The distal anastomosis is performed either to the distal ascending aorta or transverse aortic arch depending on the pathology. The graft sizes in our patients ranged from 26 to 34 mm, mean of 31 mm.

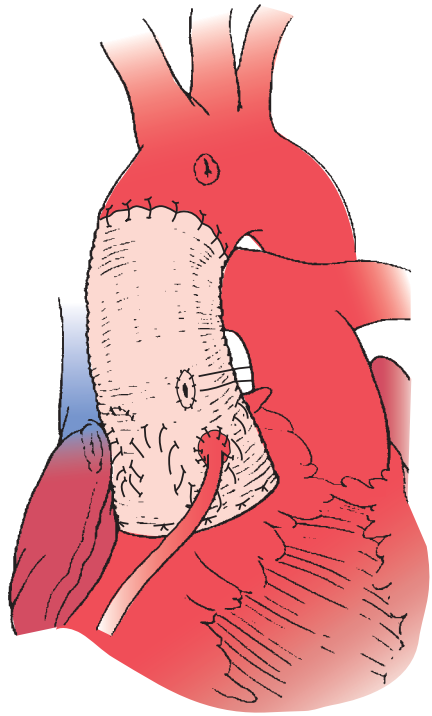

FIGURE 36-14 Reimplantation of the aortic valve. The commissures and the aortic annulus are sutured inside the graft and the coronary arteries reimplanted.

RESULTS OF AORTIC VALVE REPAIR

One of the earliest series of aortic valve repair for aortic insufficiency caused by prolapse of bicuspid aortic valve came from the Cleveland Clinic.[21] In a series of 94 patients with a mean age of 38 years, the freedom from reoperation was 84% at 7 years.[21] The only factor predictive of reoperation was residual aortic insufficiency at the time of repair.[21]

The appropriateness of aortic valve repair in patients with incompetent bicuspid aortic valve remains unclear. Competent bicuspid aortic valves appear to be durable because a large proportion of patients who require aortic valve replacement for aortic stenosis in their fifth, sixth, or seventh decades of life are found to have bicuspid aortic valve. Thus, aortic valve repair for incompetent bicuspid aortic valves is a reasonable surgical approach in young adults but the best type of repair remains to be determined. Incompetent bicuspid aortic valves are often

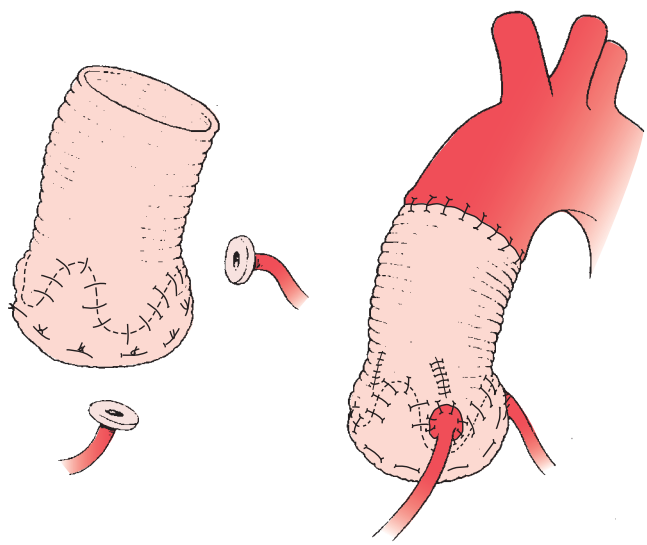

FIGURE 36-15 Reimplantation of the aortic valve. Neoaortic sinuses can be created by plicating the graft in the spaces in between the commissures at the level of the sinotubular junction.

associated with dilated aortic annulus and subcommissural plication may be inadequate to prevent future dilation and recurrent aortic insufficiency. A conservative aortic root procedure may be more appropriate for some of these patients.

Ascending Aortic Aneurysm with Aortic Insufficiency

We reported our experience with aortic valve repair in patients with ascending aortic aneurysm, normal or minimally dilated aortic sinuses, and moderate or severe aortic insufficiency.[22] There were 103 patients whose mean age was 65±12 years and 53% were men. The aneurysm extended into the transverse aortic arch in 60% of the patients and 20% had mega-aorta syndrome. The aortic valve repair consisted in adjusting the diameter of the sinotubular junction in all patients. In addition, repair of cusp prolapse was needed in 36 patients, and replacement of the noncoronary aortic sinus in 8. Associated procedures were: replacement of the transverse aortic arch in 62 patients, coronary artery bypass in 28, and mitral valve repair or replacement in 7. The follow-up was complete at 5.8±2.3 years. There were 2 operative and 30 late deaths. The survival at 10 years was 54±7%. Independent predictors of late death were transverse arch aneurysm, the use of elephant trunk technique to replace the arch and mega-aorta syndrome. Only 2 patients required aortic valve replacement: one for endocarditis and one for severe aortic insufficiency. The freedom from aortic valve replacement at 10 years was 98%. Only one patient developed severe and six developed moderate aortic insufficiency during the follow-up. The freedom from severe or moderate aortic insufficiency at 10 years was 80±7%. These findings suggest that aortic valve repair in these patients is an excellent alternative to valve replacement and the repair remains stable in most patients during the follow-up. Late survival was suboptimal because of the extensiveness of the vascular disease.

Aortic Root Aneurysm

We reported our current experience with aortic valve sparing operations for aortic root aneurysm in 220 patients.[23] Their mean age was 46±15 years, 78% were men and 40% had the Marfan syndrome. In addition, 17% had type A aortic dissection, 7% had bicuspid aortic valve, and 22% had transverse arch aneurysm. Previous replacement of the ascending aorta had been done in 10 patients and the Ross procedure in 2. Sixteen patients had severe mitral insufficiency. Approximately one-half of the patients had moderate or severe aortic insufficiency before surgery. The technique of remodeling of the aortic root was used in 53 patients and the reimplantation of the aortic valve in 167. The follow-up was complete at 5.2±3.7 years. All patients had echocardiographic studies during the follow-up. There were 3 operative and 13 late deaths. Patients' survival at 10 years was 88±3% and was similar to that of the general population of Ontario. Age greater than 65 years, advanced functional class, and ejection fraction less than 40% were independent predictors of death. Seven patients developed moderate and 5 developed severe aortic insufficiency. Overall freedom from moderate or severe aortic insufficiency at 10 years was 85±5%, but it was 94±4% after reimplantation of the aortic valve and 75 ±10% remodeling of the aortic root ($p = 0.04$). Five patients required aortic valve replacement; the freedom at 10 years was 95±3%. One patient developed endocarditis 11 years postoperatively, and 8 suffered thromboembolic events. At the latest follow-up 88% of the patients were in functional class I, and 10% were in class II. These findings suggested that reimplantation of the aortic valve provides more stable aortic valve function than remodeling of the aortic root.

Yacoub et al.[24] who used exclusively the remodeling of the aortic root to treat 158 patients with aortic root and ascending aortic aneurysms, reported a freedom from aortic valve replacement of 89% at 10 years, and moderate aortic insufficiency in one-third of the patients.

Aicher et al.[25] who also used the remodeling of the aortic root in 274 patients (mean age 59±15 years, 193 tricuspid and 81 bicuspid valves) reported a freedom from aortic insufficiency grade II or greater of 91% for bicuspid and 87% for tricuspid at 10 years, and a freedom from aortic valve replacement of 98% at 5 and at 10 years.

We recently reported the long-term results with aortic valve sparing operations in patients with Marfan syndrome.[26] A cohort of 103 consecutive patients with Marfan syndrome with a mean age of 37±12 years underwent either remodeling of the aortic root (26 patients) or reimplantation of the aortic valve (77 patients) and were prospectively followed for a mean of 7.3±4.2 years with annual echocardiography. The survival at 15 years was 87.2%, somewhat lower than the 95.6% for the general population largely because of complications of aortic dissection. The freedom from aortic insufficiency greater than mild was 79.2%. Only 3 patients required aortic valve replacement, two for aortic insufficiency and one for endocarditis.

There are several reports on early clinical and hemodynamic outcomes on these two types of aortic valve sparing procedures.[27-30] Most comparative studies suggest that the reimplantation of the aortic valve provides a more stable aortic valve function than the remodeling of the aortic root, particularly in patients with dilated aortic annulus, Marfan syndrome, and acute type A aortic dissection. Hemodynamic studies suggest that cusp motion and flow patterns across the reconstructed aortic root are more physiologic after remodeling of the aortic root than reimplantation of the aortic valve.[29] In patients who had the reimplantation procedure, flow patterns and cusp motion are better with neoaortic sinuses than without.[30] However, in our series of reimplantations of the aortic valve, there was no difference in aortic valve function after 10 years in patients with a straight tube or with neoaortic sinuses. Aortic sinuses seem to decrease the mechanical stress on the aortic cusps but it is not clinically apparent during the first decade of follow-up as far as durability of the procedure.

Aortic valve sparing operations may be inappropriate for young children because of future mismatch between the size of the graft and somatic growth.

Another important question regarding aortic valve sparing operations is whether they are better than the Bentall procedure with mechanical valves. There has been no randomized clinical trial comparing these two procedures for the treatment of aortic root aneurysms or ascending aortic aneurysm but retrospective

studies in patients with Marfan syndrome suggest that the outcomes may be similar.

We believe that aortic valve sparing operations offer an ideal method for treating patients with aortic root aneurysm and normal or minimally diseased aortic cusps. When correctly performed, they provide excellent results and are associated with very low rates of valve-related complications. However, because they are technically demanding operations, only surgeons with extensive experience in aortic surgery should perform them. The surgeon must have a sound knowledge of anatomy and pathology of the aortic valve and be able to apply the concepts of functional anatomy to create an anatomically and functionally satisfactory new aortic root.

CHAPTER 37

Surgical Treatment of Aortic Valve Endocarditis

Tirone E. David

INTRODUCTION

Infective endocarditis is a disease in which a microorganism colonizes a focus in the heart, producing fever, heart murmur, splenomegaly, embolic manifestations, and bacteremia or fungemia. Early diagnosis of this condition is extremely important because it almost invariably leads to devastating complications and death if not treated with antibiotics, combined or not with surgery. Infective endocarditis is defined as community-acquired or health care–associated infection. The latter can be nosocomial or non–nosocomial health care associated.

EPIDEMIOLOGY

Predisposing factors for infective endocarditis are cardiac abnormalities that disrupt the endocardium by means of a jet injury, as well as the presence of blood-borne microorganisms that colonize these abnormal surfaces. Among patients with aortic valve endocarditis, congenitally bicuspid aortic valve is the most common predisposing lesion.[1] Other congenital abnormalities of the aortic valve, degenerative calcific aortic stenosis, aortic insufficiency secondary to connective tissue disorders, and rheumatic aortic valve disease, are also predisposing lesions for infection. Depending on the virulence of the offending microorganism, normal aortic valves can also be affected. Patients with prosthetic heart valves have a constant risk of developing infective endocarditis.

It is difficult to determine the incidence and prevalence of native aortic valve endocarditis in the general population because this disease is continuously changing.[2] The annual incidence of infective endocarditis is estimated to range from 1.7 to 7.0 episodes per 100,000 person-years in North America.[3–5]

Patients with prosthetic aortic valves are reported to have an incidence of infective endocarditis of 0.2 to 1.4 episodes per 100 patient-years, which varies with the type of aortic valve.[6–12] Approximately 1.4% of patients undergoing aortic valve replacement develop prosthetic valve endocarditis during the first postoperative year.[13]

The incidence of nosocomial endocarditis is increasing because more patients undergo invasive procedures. Infective endocarditis in hemodialysis patients is relatively infrequent, but it is associated with high mortality.[14] Dental extractions have been demonstrated to produce bacteremia. Dental flossing can produce bacteremia in periodontally healthy and periodontally diseased individuals at a rate comparable with that caused by some dental treatments, for which antibiotic prophylaxis is usually given to prevent endocarditis.[15] Endoscopic procedures may also produce bacteremia. Intravenous drug users are particularly susceptible to infective endocarditis, which often occurs in structurally normal heart valves. (Please see prophylaxis of infective endocarditis elsewhere in this chapter.)

PATHOGENESIS AND PATHOLOGY

In 1928, Grant and colleagues[16] theorized that platelet-fibrin thrombi on the heart valve served as a nidus for bacteria adherence. In 1963, Angrist and Oka[17] introduced the term *nonbacterial thrombotic endocarditis* to describe sterile vegetations on a heart valve and provided experimental animal evidence supporting the role of these vegetations in the pathogenesis of endocarditis. Experimental inoculation in animals with preexisting nonbacterial thrombotic endocarditis produced by mechanical abrasion of the endothelial covering of heart valves causes a prompt leukocytic infiltration of the thrombi.[18] As the

microorganism multiplies, more leukocytes and thrombotic material accumulate in the area and a verrucous vegetation begins to form.

Depending on the virulence of the microorganism and the resistance of the host, the aortic valve can be destroyed and the infection may spread into the annulus and surrounding structures with abscess formation. The abscess may rupture into the pericardial or a cardiac cavity.

Infective endocarditis of the aortic valve not only causes destruction of the aortic cusps, paravalvular abscess, and cardiac fistulas but also can cause coronary and systemic embolization of vegetations.[19] Cerebral infarction, either ischemic because of arterial occlusion, or hemorrhagic, because of rupture of the mycotic aneurysm, is common in these patients.[20,21] Mycotic aneurysms, infarcts, and abscesses of other organs such as spleen, liver, kidneys, and limbs are also common.[18] Aortic valve endocarditis with a large vegetation that prolapses into the left ventricle and comes in contact with the anterior leaflet of the mitral valve can cause secondary involvement of this valve.[22,23]

Infection of a mechanical heart valve is usually located in its sewing ring.[24,25] Infection of a porcine or pericardial valve may involve the cusps, the sewing ring, or both.[26,27] Infection in aortic valve homografts and pulmonary autografts resembles that of the native aortic valve: It begins in the aortic cusps and destroys them, causing aortic insufficiency, but it may also extend into surrounding structures.[28] Endocarditis after aortic root replacement with mechanical valves frequently causes dehiscence of the valve from the aortic annulus with consequent false aneurysm.[29]

MICROBIOLOGY

The microbiology of infective endocarditis of the aortic valve depends on whether the valve is native or prosthetic, and whether the infection is hospital or community acquired. *Staphylococcus aureus* and *Streptococcus viridans* are the most common microorganisms responsible for native aortic valve endocarditis.[30,31] *Staphylococcus aureus* is extremely virulent and able to cause infection in patients with normal aortic valves. *Streptococcus viridans* is not as virulent and causes infection that often follows a protracted course. *Staphylococcus epidermidis* and various other streptococci can also cause endocarditis. Coagulase-negative staphylococci have emerged as an important cause of native valve endocarditis in both community and health care settings.[32]

Endocarditis caused by gram-negative bacteria is uncommon, but it is often resistant to antibiotic therapy and may cause serious complications. *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella* (the HACEK group) are gram-negative bacilli grouped together because of their characteristic fastidiousness requiring a prolonged incubation period before growth. Endocarditis resulting from the HACEK group is also uncommon. Fungal endocarditis is rare but extremely serious. *Candida albicans* and *Aspergillus fumigatus* are the usual agents.

The microbiology of prosthetic aortic valve endocarditis is somewhat different from that of the native valve.[25,33] Prosthetic valve endocarditis has been arbitrarily classified as *early* when it occurs within the first 2 months after surgery and *late* when it occurs after 2 months.[34] However, it is possible that many cases of prosthetic valve endocarditis that occur during the first year after surgery are acquired at the time of implantation of the artificial heart valve.[35,36] This may be particularly true when the infection is caused by coagulase-negative staphylococci and the HACEK group of bacteria. Early prosthetic valve endocarditis is caused by contamination of the valve at the time of implantation by perioperative bacteremia.[13] *Staphylococcus epidermidis, S. aureus,* and *Enterococcus faecalis* are among the more common microorganisms responsible for early prosthetic valve endocarditis.[13,33,36] The sources of late prosthetic valve endocarditis are more difficult to determine. Bacteremia is probably the principal cause of late endocarditis. Although streptococci and staphylococci are commonly encountered in these patients, a myriad of microorganisms can cause late prosthetic valve endocarditis.[33,36]

Nosocomial infections are often caused by *S. aureus* or other staphylococci.

In a small proportion of cases of aortic valve endocarditis, no microorganism can be cultured from either the blood or surgical specimens.[33,36] This is called "culture-negative endocarditis," but it is important to rule out fastidious microorganisms and every effort should be made to identify them.

CLINICAL PRESENTATION AND DIAGNOSIS

It is helpful to classify infective endocarditis as acute and subacute because there are major differences between these two clinical presentations. Subacute endocarditis is often caused by less virulent microorganisms such as *S. viridans.* When this organism affects a diseased aortic valve, the clinical course is protracted and antibiotics alone cure most cases. On the other hand, acute endocarditis is frequently caused by a virulent microorganism such as *S. aureus* and may affect a normal aortic valve. The clinical course is acute, and antibiotics alone often fail to cure the infection.

The onset of subacute endocarditis in most cases is subtle, with low-grade fever and malaise. Patients think they have the "flu" and are often treated with oral antibiotics for a week to 10 days with improvement of symptoms. However, in most cases the symptoms recur a few days after stopping antibiotics. In the majority of cases no predisposing factor is identified. An aortic valve murmur is present in nearly all patients because they have preexisting aortic valve disease. Splenomegaly is common. Clubbing of the fingers and toes may develop in long-standing cases. Skin and mucous membrane signs occur late in this form of endocarditis. Petechiae appear on any part of the body. Small areas of hemorrhage may be seen in the ocular fundi. Hemorrhages in the nail beds usually have a linear distribution near the distal end, hence the name splinter hemorrhages. Osler nodes are acute, tender, barely palpable nodular lesions in the pulp of the fingers and toes. Bacteria have been cultured from these lesions. Embolization of large vegetation fragments may cause dramatic clinical events such as acute myocardial infarction (AMI), stroke, or splenic or hepatic infarcts. Any other organ also may be involved. Destruction of the aortic cusps

causes aortic insufficiency and heart failure. The blood pathology is not distinctive in subacute endocarditis. Anemia without reticulocytosis develops in patients untreated for more than a few weeks. The leukocyte count is moderately elevated. Blood cultures frequently identify the offending microorganism.

The clinical course of acute endocarditis is often fulminating. A preexisting source of bacteremia may be identified. This form of endocarditis can present with all the symptoms and signs described under subacute endocarditis, but they are more acute and patients are often sicker with overwhelming signs of sepsis. Early metastatic infections are common. Two physical signs are seen only in acute endocarditis: the Janeway lesion (a painless red-blue hemorrhagic lesion a few millimeters in diameter found in the palms of the hands and the soles of the feet) and the Roth spot (an oval pale area surrounded by hemorrhage near the optic disc). Acute endocarditis is common in patients with no preexisting aortic valve disease. Early cardiac decompensation caused by aortic insufficiency is common. Paravalvular abscess is also common, and depending on the location of the abscess, the electrocardiogram may show an increased PR interval or heart block. The blood picture is one of acute sepsis. Blood culture often isolates the infecting agent.

Prosthetic valve endocarditis may present as acute or subacute endocarditis.

Doppler echocardiography is very useful in the diagnosis and management of infective endocarditis.[37–40] Transesophageal echocardiography is usually better than transthoracic echocardiography and multiplane is better than monoplane for the diagnosis of endocarditis. Echocardiography can detect vegetations as small as 1 or 2 mm in size, but it is more reliable in native than prosthetic valve endocarditis. It is more useful for tissue than for mechanical valves because of the acoustic shadowing of ball, disc, or leaflet motion of mechanical heart valves. Echocardiography is also highly sensitive for detecting paravalvular abscess and cardiac fistulas.[40,41]

Clinical investigators from Duke University proposed certain criteria for confirming or rejecting the diagnosis of infective endocarditis.[42] These criteria have been confirmed by other investigators and their limitations addressed by others.[43–45] A modified version of the Duke criteria has been proposed[45] and it is shown in Table 37-1.

Heart catheterization and coronary angiography increase the risk of embolization in patients with aortic valve vegetations and should be avoided. Newer computed tomography (CT) imaging techniques to diagnose coronary artery disease are useful in these patients.

The investigators of the International Collaboration on Endocarditis–Prospective Cohort Study (ICE-PCS), an international and multicenter database on patients with confirmed endocarditis maintained at the Duke Clinical Research Institute recently reported on the clinical presentation, etiology, and outcome of infective endocarditis with definite diagnosis according to Duke criteria (see Table 37-1).[31] The ICE-PCS report included a cohort of 2781 patients whose median age was 57.9 years. The endocarditis was native in 72%, prosthetic in 21% and pacemaker/ICD related in 7%. Approximately one-fourth of the patients had history of recent health care exposure. The mitral valve was infected in 41.1% of the patients and the aortic valve in 37.6%. *Staphylococcus aureus* was the offending microorganism in 31.2% of all cases. The diagnosis of stroke was made in 16.9% and other emboli were diagnosed in 22.6%. Congestive heart failure (CHF) developed 32.2%. Paravalvular abscess occurred in 14% of the patients. Surgical treatment was common for the entire cohort (48.2%), and overall in-hospital mortality was 17.7%.

TREATMENT

An appropriate antibiotic is the most important aspect of the management of patients with infective endocarditis.[30,31,36] Antibiotic therapy should be started soon after obtaining several blood cultures. The initial choice of antibiotics is based on clinical circumstances and the suspected source of infection. Patients who had recent dental work should receive antibiotics to counteract bacteria from the oral cavity; those who had recent urinary or colonic procedures should be treated with antibiotics that are effective against gram-negative bacteria.

Intravenous drug users are usually infected with *S. aureus* or coagulase-negative *staphylococci*, and antibiotics should be chosen accordingly. Once the microorganism is identified by blood cultures and its sensitivity to specific antibiotics is known, antibiotic therapy is adjusted accordingly. A combination of two or three antibiotics that potentiate each other is often needed in the treatment of endocarditis caused by virulent microorganisms. Intravenous antibiotic therapy is continued for 6 weeks.

It is difficult to eradicate infection caused by virulent microorganisms with antibiotics alone because these microorganisms often destroy the native aortic valve very rapidly and cause aortic insufficiency and CHF. These infections are usually caused by *S. aureus, Pseudomonas aeruginosa, Serratia marcescens*, or fungi.

Surveillance blood cultures are performed in 48 hours to monitor the efficacy of antibiotic therapy. The patient must be watched closely for signs of CHF, coronary and systemic embolization, and persistent infection. Daily electrocardiograms and frequent echocardiograms are performed during the first 2 weeks of treatment. With any evidence of increasing aortic insufficiency, enlarging vegetations, recurrent embolism, paravalvular abscess, or persistent infection, surgery should be immediately performed. It is important to operate on patients before they develop intractable heart failure, cardiogenic or septic shock, or extensive aortic root abscesses. Patients with vegetations larger than 10 mm present a clinical problem because they are more likely to develop serious complications and early surgery is justifiable.[37–39]

Anticoagulation is not effective in preventing embolization of vegetations in native and biologic valves and is associated with an increased risk of neurologic complications.[46,47]

Surgical treatment should be considered in patients with signs of CHF, acute valve dysfunction, paravalvular abscess or cardiac fistulas, recurrent systemic embolization when aortic valve vegetations are present, and persistent sepsis despite adequate antibiotic therapy for more than 4 to 5 days.

Patients with neurologic deficits should have CT or magnetic resonance imaging performed to determine if the cerebrovascular accident is ischemic or hemorrhagic. Ischemic damage

TABLE 37-1 Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Major Criteria

- Blood culture positive for infective endocarditis
  - Typical microorganisms consistent with infective endocarditis from two separate blood cultures: *Streptococcus viridans, S. bovis* HACEK group, *S. aureus,* or community-acquired enterococci, in the absence of a primary focus, or Microorganisms consistent with infective endocarditis from a persistently positive blood culture, defined as follows:
    - At least two positive cultures of blood drawn >12 hours apart, or
    - All of three or a majority of >four separate cultures of blood (with the first and last samples drawn at least 1 hour apart)
    - Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer to *C. burnetii*> 1:800
- Evidence of endocardial involvement:
- Echocardiogram positive for infective endocarditis: TEE recommended in patients with prosthetic valves, rated at least as "possible endocarditis" by clinical criteria, or complicated endocarditis, such as endocarditis with paravalvular abscess; TTE as the first test in other patients as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation;
  - Abscess:
  - New partial dehiscence of prosthetic valve
- New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

- Predisposition, predisposing heart condition, or injection drug use
- Fever
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above, or serologic evidence of active infection with an organism consistent with infective endocarditis
- Echocardiographic minor criteria eliminated

Definite endocarditis = two major criteria, or one major + three minor criteria, or five minor criteria
Possible endocarditis = one major + one minor, or three minor criteria
HACEK group = Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella; IE = infective endocarditis; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography

is far more common than hemorrhagic damage, but both are associated with increased mortality and morbidity.[46–49] Mycotic aneurysms should be treated before valve surgery. Aortic valve replacement should be postponed for 2 weeks after an ischemic stroke and 4 weeks after a hemorrhagic stroke if possible.[49]

SURGICAL TREATMENT

Patients who need surgery are often very sick and may be in CHF. For this reason and because they often require complex and long surgical procedures, myocardial protection is of utmost importance. Another important aspect of surgery for endocarditis is avoidance of contamination of the surgical field, instruments, drapes, and gloves with vegetations and pus. Instruments used to extirpate contaminated areas in the heart should be discarded before reconstruction of the ventricle and aortic root begins. In addition, local drapes, suction equipment, and surgical gloves should all be changed.

When the infection is limited to the cusps of the native aortic valve or a bioprosthetic valve, complete removal of the valve and implantation of a biologic or mechanical valve usually resolves the problem. There is no evidence that bioprostheses are better than mechanical valves in patients with active infective endocarditis.[50] Some investigators believe that aortic valve homograft is ideal for patients with active endocarditis,[51–53] but the fact is that it can become infected like other valves and there is no evidence that the risk of persistent or recurrent infection is different from other valves.[54,55] Some surgeons favor the pulmonary autograft, particularly in young patients.[56]

If the aortic annulus is involved in the infective process, resection of the necrotic or inflamed area is needed before a

prosthetic valve can be implanted. The defect created by the resection should be patched before a prosthetic valve is implanted. We prefer to use fresh autologous pericardium to patch small defects (1 or 2 cm wide) in the aortic root and left ventricular outflow tract (LVOT), and glutaraldehyde-fixed bovine pericardium for larger defects.[57,58] Some surgeons also use Dacron fabric to reconstruct the aortic root.[59,60] Here again, aortic valve homograft is believed to be ideal for reconstruction of the aortic root and LVOT.[52,61–63] The mitral valve of the aortic valve homograft can be used to patch defects in the LVOT by correctly orienting the homograft. However, an aortic valve homograft is by no means a substitute for radical resection of all infected tissues, because persistent infection can occur with this biologic valve.[64,65] The pulmonary autograft has also been used in cases of extensive destruction of the aortic root,[66] but again, this valve is no substitute for radical resection of all infected tissues.

Surgery for aortic root abscess and/or cardiac fistulas is challenging. The most important aspect in the surgical treatment of these patients is radical resection of all infected tissues.[25,55,57,58] We believe that the type of valve implanted is less important than complete extirpation of all infected and edematous tissues.[58] These patients frequently require replacement of the entire aortic root and reconstruction of the surrounding structures that are also involved by the abscess. These operations must be individualized because the pathology of aortic root abscess is variable. Extensive resection and reconstruction may be needed.[58,67–69] Thus, patching of the interventricular septum, dome of the left atrium, intervalvular fibrous body, right atrium, and pulmonary artery may be necessary, as well as repair of the left and/or right coronary arteries. The aortic root is often replaced with a valved conduit.

Aortic root abscess extending into the intervalvular fibrous body or into a prosthetic mitral valve is particularly difficult to treat.[67–69] In these cases, the resection and reconstruction can be performed through the aortic root and dome of the atrium.[67–69] When an aortic valve homograft is used for this type of reconstruction, the anterior leaflet of the mitral valve of the homograft can be used as patch material for the new fibrous body between the aortic and mitral valves. Actually, aortic and mitral valve homografts in a single bloc of tissue have been used to treat this condition.[70]

Postoperative complications are common after surgery for active infective endocarditis. Septic patients may have severe coagulopathy and may bleed excessively after cardiopulmonary bypass. Antifibrinolytic agents such as tranexaminic acid or aminocaproic acid should be used in addition to platelets, cryoprecipitate, and fresh-frozen plasma in patients with coagulopathy. The administration of recombinant Factor VII may also be necessary after correction of thrombocytopenia, fibrinogen level, and thromboplastin and prothrombin times. Radical resection of aortic root abscess may cause heart block, for which a permanent pacemaker will be needed postoperatively. Depending on the patient's clinical condition before surgery, multiorgan failure may develop postoperatively. Neurologic deterioration may occur in patients with preexisting cerebral emboli. Pulmonary, splenic, hepatic, and other metastatic abscesses seldom require surgical treatment. Large metastatic abscesses may have to be drained, and in the case of the spleen, splenectomy should be performed because of the risk of rupture.[71]

Clinical Results

The prognosis of aortic valve endocarditis depends largely on when the disease is diagnosed, on the offending microorganism, and how promptly it is treated.[30,31,72] Patients with prosthetic aortic valve endocarditis have a more serious prognosis than patients with native aortic valve endocarditis,[31,36] and nosocomial infections are associated with higher mortality than community-acquired infections.[73,74] The results of surgery for infective endocarditis have improved significantly since the introduction of antibiotics and surgery, but in-hospital mortality remains high at approximately 18%.[31] Prosthetic valve endocarditis, increasing age, pulmonary edema, *S. aureus* infection, coagulase-negative staphylococcal infection, mitral valve vegetation, and paravalvular abscess were associated with an increased risk of in-hospital mortality at the ICE-PCS report on 2781 patients.[31] Approximately one-half of those patients required surgery as part of their treatment.[31]

The operative mortality for patients with infection limited to the cusps of the aortic valve is largely dependent on the patients' clinical presentation at the time of surgery, age, and comorbidities. Most reports indicate that the operative mortality is under 10%.[36,55,75] The operative mortality is higher for prosthetic valve endocarditis and ranges from 20 to 30%.[25,26,31,76] Similarly, surgery for aortic root abscess is associated with higher operative mortality.[58–63]

We reviewed our 25-year experience with surgery for infective endocarditis in 383 consecutive patients.[36] There were 226 patients with native and 117 with prosthetic valve endocarditis. The overall operative mortality was 12%. Preoperative shock, prosthetic valve endocarditis, paravalvular abscess and *S. aureus* were independent predictors of operative mortality. The 15-year survival for patients with native valve endocarditis was 59% and for patients with prosthetic valve endocarditis was 25% ($p < .01$). The freedom from recurrent infective endocarditis at 15 years was 86%, and similar for patients with native and prosthetic valve endocarditis. In most of these patients, a different microorganism caused the second episode of endocarditis.

PROPHYLAXIS OF INFECTIVE ENDOCARDITIS

The American Heart Association guidelines for prophylaxis of infective endocarditis were updated in 2007.[77]

The major changes in the updated recommendations include the following: (1) The Committee concluded that only an extremely small number of cases of infective endocarditis might be prevented by antibiotic prophylaxis for dental procedures even if such prophylactic therapy were 100% effective. (2) Infective endocarditis prophylaxis for dental procedures is reasonable only for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis. (3) For patients with these underlying cardiac conditions, prophylaxis is reasonable for all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. (4) Prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis. (5) Administration of antibiotics solely to prevent endocarditis is not recommended for patients

who undergo a genitourinary or gastrointestinal tract procedure. These changes are intended to define more clearly when infective endocarditis prophylaxis is or is not recommended and provide more uniform and consistent global recommendations.

These new recommendations represent a dramatic shift with regard to which patients should receive antibiotic prophylaxis for prevention of infective endocarditis. However, they are "guidelines" and physicians caring for patients with organic heart valve disease should advise them according to the perceived risk of endocarditis and potential benefit of antibiotic prophylaxis.

CHAPTER 38

Minimally Invasive Aortic Valve Surgery

Prem S. Shekar
Lawrence H. Cohn

INTRODUCTION

Aortic valve surgery started with the implantation of the Hufnagel valve in the descending thoracic aorta in 1956. Its evolution over time has culminated with the advent of percutaneous catheter based aortic valve replacement techniques. There is a flurry of recent activity in the world literature about this new approach. As a new paradigm in aortic valve replacement is ushered, there will be new challenges for the cardiac surgeons to not only maintain the efficacy and outcomes of conventional valve replacement but to provide it in a less invasive approach. Modern techniques will be measured against conventional procedures, especially in the older patients with multiple comorbidities. Minimally invasive aortic valve surgery holds promise as an effective operation with reduced pain, improved respiratory function, early recovery and an overall reduction in trauma.

ESSENTIALS OF MINIMAL ACCESS AORTIC VALVE SURGERY

Reoperative minimal access aortic valve surgery is discussed in detail at the end of this chapter. We will first outline the known benefits and salient principles of and the essential ingredients for the conduct of primary minimal access aortic valve surgery.

There are many benefits of minimal access aortic valve surgery.

1. It provides a cosmetically superior incision.
2. There is reduced postoperative pain.
3. There is faster postoperative recovery.
4. There is improved postoperative respiratory function from preservation of a part of the sternum and the integrity of the costal margin.
5. It can be performed with the same degree of ease and speed as a conventional operation with no difference in mortality.
6. It provides access to the relevant parts of the heart and reduces dissection of other areas.
7. It greatly facilitates a reoperation at a later date as the lower part of the pericardium remains closed.

There are some salient inviolate principles of minimal access aortic valve surgery:

1. Ability to safely apply a stable aortic cross-clamp
2. Ability to visualize the aortic valve completely and perform a successful replacement with the standard techniques
3. Ability to achieve the same degree of myocardial protection as through a midline sternotomy approach
4. Ability to deal with issues of the aortic root, ascending and arch of the aorta with relative ease and without the need for conversion
5. Ability to quickly convert to a standard midline sternotomy if compromising situations arise

The safety and reproducibility of minimal access aortic valve surgery depend on:

1. Availability of experienced cardiac anesthesiologists
2. Availability of transesophageal echocardiography (TEE) in every case and an experienced echocardiographer to interpret findings
3. Ability to place pulmonary artery catheters with pacing capabilities and transjugular coronary sinus catheters, if and when necessary
4. Ability to place percutaneous arterial and venous cardiopulmonary bypass canulae
5. Ability to use vacuum-assisted venous drainage on cardiopulmonary bypass
6. Availability of minimal access retractors and other relevant instruments that facilitate this operation

7. Ability to remotely monitor myocardial protection and distention by TEE
8. Availability of surgeons experienced with conventional aortic valve surgery and minimal access surgery

Whatever the surgical approach, today aortic valve replacement is done with the use of cardiopulmonary bypass and diastolic arrest of the heart. There are at least four different minimal access surgical approaches to the aortic valve:

1. Upper hemisternotomy
2. Right parasternal approach
3. Right anterior thoracotomy
4. Transverse sternotomy

THE UPPER HEMISTERNOTOMY APPROACH

This is undoubtedly the most popular of all minimal access approaches to the aortic valve. This has been popularized by the surgeons of the Cleveland Clinic and Brigham and Women's Hospital.[1,2]

This is performed through a 6- to 8-cm vertical midline incision over the upper part of the sternum, starting at or just above the level of the manubrio-sternal angle. The sternotomy is performed with the standard saw starting at the level of the sternal notch up to the level of the third or fourth intercostal space (Fig. 38-1). The sternotomy is then T'd off into the right or left third or fourth intercostal space using a narrow blade oscillating saw, taking care not to dive too deeply with it for risk of injuring mediastinal or pericardial structures. The decision to T into the third or fourth space can be made preoperatively with the chest x-ray being a guide to the amount of exposure that will be needed. We favor the fourth interspace because this almost always produces the ideal exposure. It is very important to ensure that the sternotomy is absolutely midline and that the midline sternotomy is not carried beyond the level of the transverse T. Failure to adhere to these principles will result in either a lateral fracture with resultant three sternal fragments or a continued lower extension of midline fracture which with retraction could result in a slow ongoing intraoperative or postoperative blood loss and also difficulty in closure. There is no need to prophylactically divide the right or left internal mammary arteries with this incision. If care is taken not to damage them, they will usually gently retract away.

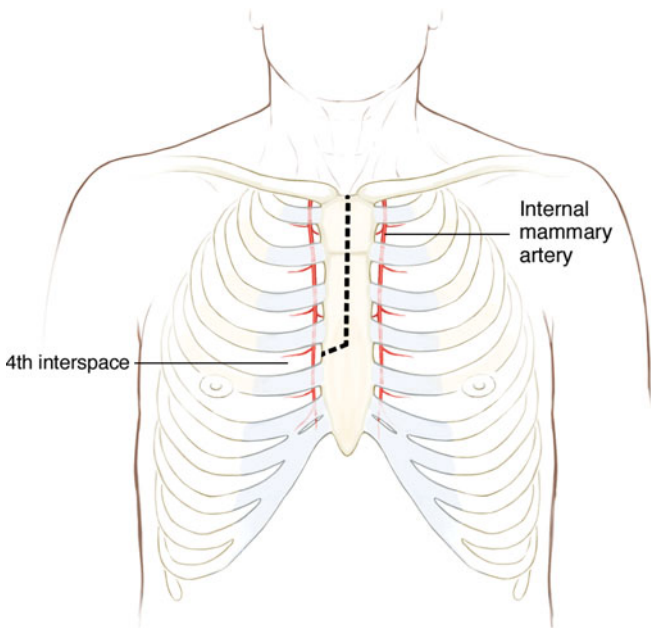

FIGURE 38-1 Upper hemisternotomy incision.

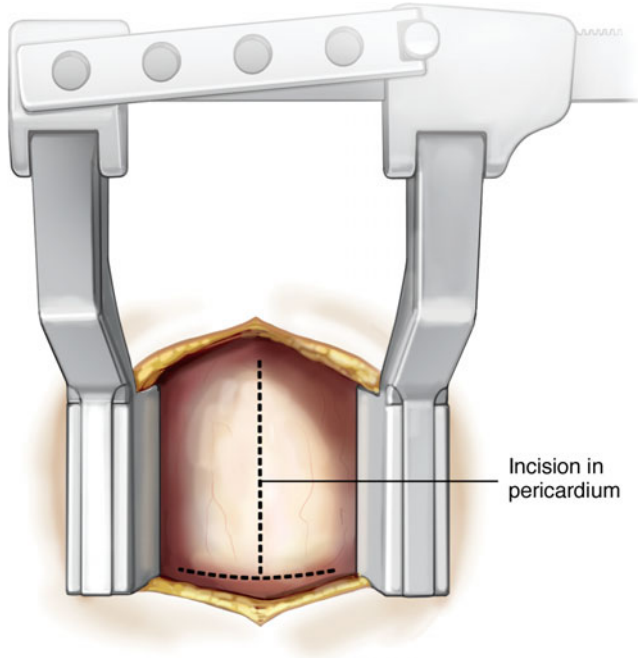

FIGURE 38-2 Midline incision in the pericardium.

We use a Kuros-Baxter® retractor to retract the sternal edges. The pericardium is opened in the midline (Fig. 38-2), T'd inferiorly, and at least three pericardial stay sutures are applied to either side and the needles are left on. The retractor is removed and the pericardium is tacked to the dermis of the skin and tied down. This facilitates exposure by elevating the pericardial contents forward into the operating field. The Kuros-Baxter® retractor is then replaced. Care must be taken during reopening the retractor because sudden retraction with elevated cardiac structures could impede venous return, causing a sudden drop in cardiac output, and leading to acute refractory decompensation in patients with severe aortic stenosis.

We perform an epiaortic ultrasound to exclude atheromatous disease in the ascending aorta before proceeding to systemic heparinization and ascending aortic cannulation in the standard fashion. Right atrial venous cannulation is accomplished directly through the appendage (when easily accessible) (Fig. 38-3) or with a percutaneous venous canula inserted via the right or left femoral vein. There are a variety of custom long venous canulae that are available for the same (usually 20- or 22-French), and they are inserted using the Seldinger technique. The canula is positioned within the right atrium with the tip in the superior venacava using transesophageal echocardiographic guidance. The patient is then placed on cardiopulmonary

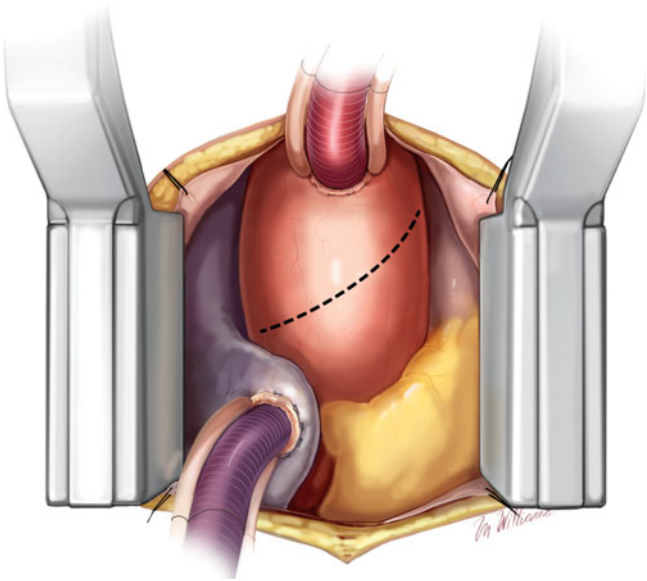

FIGURE 38-3 The pericardium has been tacked up and the patient has been canulated in the standard fashion. Oblique aortotomy has been marked.

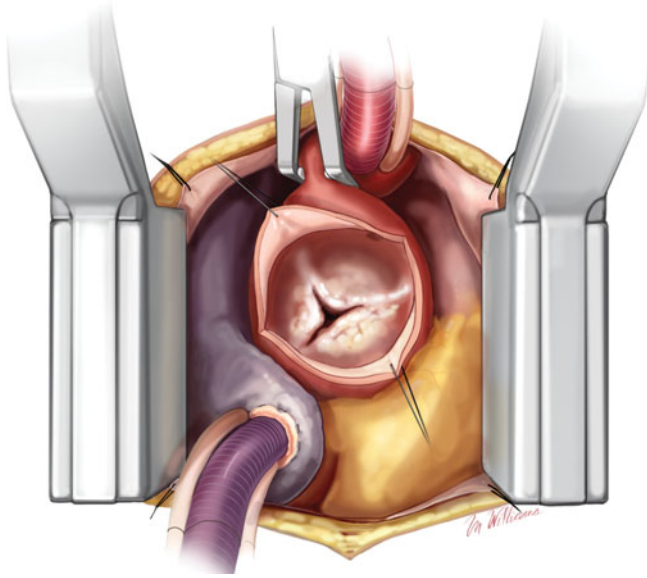

FIGURE 38-4 The aorta was opened after cross-clamping, exposing a calcified trileaflet aortic valve.

bypass. We use tepid bypass with core cooling to 34 to 35°C. The need for vacuum-assisted venous drainage to facilitate this operation cannot be overemphasized.

A retrograde cardioplegia catheter can be placed in the coronary sinus via the right atrial appendage. This may require a minor adjustment to reduce the angulation of the catheter and its insertion can be facilitated by the use of transesophageal echocardiography. Alternatively, this catheter can be placed by the anesthesiologists before surgical incision via the transjugular route. Although we routinely use a transaortic left ventricular vent, a right superior pulmonary vein or a left atrial dome vent can also be easily placed via this incision.

The operation then proceeds as usual. The aorta is cross-clamped and we use 1 L of 8:1 cold blood antegrade cardioplegia. TEE is used to monitor left ventricular distention in patients who may have aortic insufficiency. Retrograde cardioplegia and additional doses of cardioplegia are administered as necessary. Standard aortic valve replacement is then carried through an oblique aortotomy (Fig. 38-4). Upon completion of the procedure, the patient is rewarmed and the aortotomy is closed. A de-airing needle is placed in the ascending aorta before removal of the aortic cross-clamp.

Almost always the heart recovers spontaneous sinus rhythm. When the heart recovers into ventricular fibrillation, it will need to be defibrillated using the external defibrillator pads placed before commencement of the operation. Defibrillation can be facilitated by turning the cardiopulmonary bypass flows down to decompress the heart and other appropriate pharmacologic maneuvers. It is usually quite difficult to introduce internal defibrillator blades through this incision, although pediatric blades can be placed successfully on occasion. Appropriate preoperative placement of external defibrillator pads are of paramount importance. The heart is de-aired using TEE guidance. In the absence of the ability to reach in and agitate the heart, a combination of ventricular filling, table positioning, and external compression is used to successfully de-air the left heart. Although this can always be successfully completed, patience may be an important tool to facilitate this. It is important remember that successful and complete de-airing does not occur until the blood has begun to circulate through the pulmonary and systemic circuits and the heart has started to eject normally.

Before emergence from bypass, pacing wires and drainage tubes will have to be placed (Fig. 38-5). It is very important to perform these placements with the heart decompressed on bypass so as to prevent injury. Invariably, there is an adequate

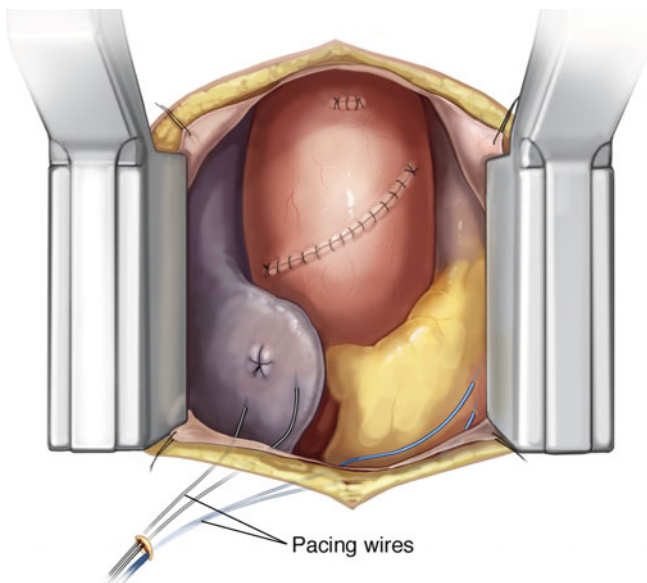

FIGURE 38-5 The aortotomy was closed after valve replacement, and epicardial pacing wires were placed.

amount of atrial and ventricular myocardium exposed to place pacing wires. We usually bring these wires out in the right inframammary area through the right-sided T. We place fluted silastic drains from a subxiphoid approach. Small incisions are made in the subxiphoid area and long grabbing forceps are used to make two retrosternal tunnels, one of which will puncture the pericardium to facilitate placement of a pericardial drain and the other will remain in the retrosternal plane. These are placed with a combination of tactile and visual control. In cases in which drains were not placed before separation from bypass and decannulation, we recommend opening the right or left pleural space and placement of transpleural drainage tubes. Placement of subxiphoid drains is not recommended after the heart is full. The wean from cardiopulmonary bypass is then performed in the standard fashion followed by decannulation and protamine administration.

The pericardium is left open. While policing the area for bleeding, some of the important sites are the coronary sinus from the placement of the retrograde catheter (which will need full sternotomy conversion for control), areas of pacing wire placement and drainage tube entry (which may or may not require conversion to full sternotomy and/or institution of bypass for visualization and control), sites of left ventricular vents, the lower edge of the sternotomy/pericardiotomy, and the internal mammary vessels on the side of the T. The sternum is closed using three or four horizontal sternal wires and an oblique wire placed between the lower intact segment of the sternum and the T'd off segment (Fig. 38-6).

Minimally invasive aortic valve replacement via the upper hemisternotomy approach was originally developed by Cosgrove and colleagues at the Cleveland Clinic[1] and soon after by Cohn and colleagues at the Brigham and Women's Hospital in Boston.[2] Gillinov and colleagues reported their excellent results in 365 cases by 2000,[3] and today upper hemisternotomy is the approach of choice for isolated aortic valve surgery at the Cleveland Clinic. Mihaljevic[4] and colleagues from the Brigham group reported their experience with 1000 minimally invasive valve operations between 1996 and 2003, of which 526 were aortic valve procedures. They reported low levels of morbidity and mortality equal to or better than conventional techniques.

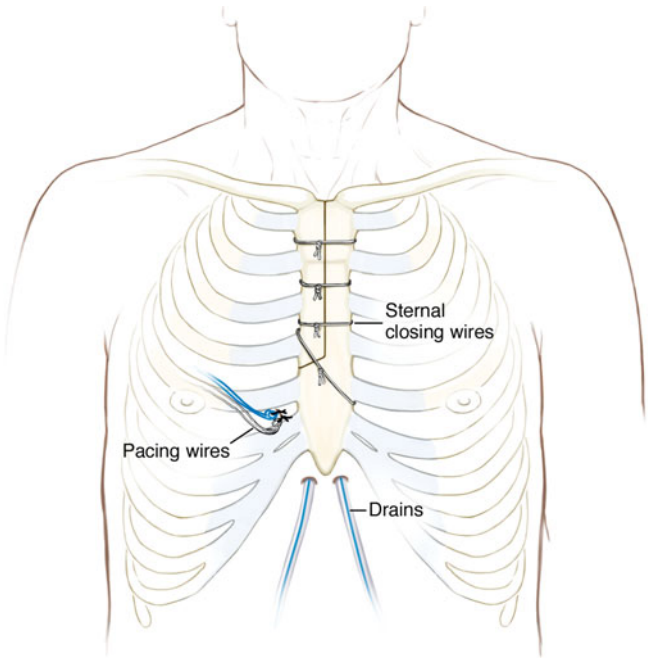

FIGURE 38-6 Final closure of the hemisternotomy incision.

Recently numerous authors have published their results with the upper hemisternotomy minimal access aortic valve replacement. Most, if not all, report excellent outcomes. Liu et al,[5] in their experience, reported easier surgical access, less pain, shorter respiratory support time, lower blood loss, decreased incidence of infection and sternal dehiscence, and shorter hospital stay. In a prospective randomized study, Bonacchi et al[6] and Bakir et al[7] reported similar findings in 2002 and 2006. Sharony et al[8] reported their experience with minimally invasive aortic valve surgery in elderly people and were able to demonstrate its safety in this fragile population with morbidity and mortality comparable to standard techniques.

Foghsgaard et al[9] demonstrated a lower incidence of left lower lobe atelectasis in the cardiac intensive care unit than patients who had AVR through a full sternotomy.

The surgeons from the Brigham and Women's Hospital continue to report excellent results from this approach. Tabata et al[10] demonstrated in 2007 that a minimal access AVR can be safely performed in patients with left ventricular dysfunction with mortality and morbidity outcomes similar to a full sternotomy approach. Tabata et al[11] reported excellent early and late results with this technique for their first 1000 patients.

THE RIGHT PARASTERNAL APPROACH

The first foray into the world of minimal access aortic valve surgery was with use of this approach. This approach seemed to be the most logical and elegant at a time when the focus was on the morbidity of the sternotomy and surgeons were compelled to come up with this alternative.

This was performed via a vertical upper right parasternal incision. The second, third, and fourth costal cartilages were removed and the right internal mammary vessels were usually ligated and divided. It provided a similar approach to the aortic valve as an upper hemisternotomy incision described before and techniques of cannulation, cardiopulmonary bypass, myocardial protection, and valve replacement were the same. It soon gave way to the more elegant and simple upper hemisternotomy approach. One particular problem associated with the right parasternal approach was the incidence of lung herniation, which was physiologically disturbing aside from being a cosmetic disaster and often required a second operation and mesh closure of the defect.

Cohn[12] and Minale et al[13] described their experiences with the right parasternal incision for aortic valve replacement in 1998. They reported fairly low mortality and morbidity rates and had, at that time, recommended the approach for minimal access aortic valve surgery, but soon moved to a hemisternotomy approach because of occasional right lung herniation.

THE RIGHT ANTERIOR THORACOTOMY APPROACH

This is another method to perform minimal access primary aortic valve replacement in adults.

This is usually performed via the second right intercostal space. Owing to the relatively high nature of the thoracotomy, it never reaches around to become a true anterolateral thoracotomy. One can visualize why this would be unappealing for a female patient because the incision would traverse horizontally across the upper part of the right breast, which could lead to scarring and disfigurement. This incision is carried to the right sternal edge and through this incision the right side of the aorta is easily visualized; and with appropriate strategically placed pericardial retraction sutures the area of interest could easily be moved into the operative field. Aortic and venous cannulation could be performed centrally or peripherally. The rest of the operation is fairly routine for any minimal access aortic valve surgery. Special cross-clamps may be required to facilitate this procedure.

This operation has some relevance and indication for patients requiring isolated aortic valve surgery in whom sternotomy needs to be avoided at all costs. A unique subset of such patients is those who are disabled and routinely ambulate with the use of shoulder crutches. These patients could be made to ambulate early with the use of their crutches without the risk of sternal dehiscence by the use of this approach. Another possible subset of patients includes those with heavily irradiated or damaged sternum.

The exposure via this incision could be optimized in cases with poor exposure by extending it across the sternum with a transverse sternotomy through the manubrio-sternal angle. Reoperative aortic valve replacement is particularly difficult via this incision and the authors sincerely discourage the approach for a reoperation.

Yakub et al[14] and Benetti et al[15] reported their results with the minimally invasive aortic valve replacement via the right anterior thoracotomy approach. Their small series report excellent operative exposure and low mortality and morbidity. Minale et al[16] reported a small series of submammary right thoracotomy approach to aortic valve replacement in women with excellent results, especially cosmesis.

More recently, in 2009, Plass et al[17] reported their series of 160 patients who underwent minimal access aortic valve replacement through a right minithoracotomy. They emphasize the need for careful evaluation of the preoperative multislice computed tomography for surgical planning. They had excellent results and reduced complication rates.

THE TRANSVERSE STERNOTOMY APPROACH

There are anecdotal reports of this incision for minimal access aortic valve surgery.

Typically an 8- to 10-cm transverse incision is made over the manubrio-sternal angle extending onto either side. Bilateral second costal cartilages have to be excised and both internal mammary pedicles have to be ligated and divided. A transverse sternotomy is performed across the sternal angle. The retractor is placed and the sternal edges are retracted in a craniocaudal plane. Adequate exposure is obtained through this incision to permit central aortic cannulation and a routine aortic valve replacement; however, venous cannulation, retrograde coronary sinus catheter placement and vent placement (except transaortic) may have to be performed percutaneously.

For reasons that the mammary arteries are sacrificed, this incision never gained much popularity.

Lee et al,[18] De Amicis et al,[19] and Aris et al[20] reported their small experiences with the transverse sternotomy approach and good results. However, Bridgewater et al[21] reported an unacceptably high incidence of morbidity (re-exploration for bleeding, paravalvular leaks, and longer hospital stay) and mortality with this approach.

Karimov et al,[22] from Italy, reported a series of 85 patients who underwent an upper V-type ministernotomy in the second intercostal space with excellent results.

REOPERATIVE MINIMAL ACCESS AORTIC VALVE SURGERY

The Brigham and Women's Hospital has pioneered minimal access reoperative aortic valve replacement in patients who previously have undergone coronary artery bypass grafting or other cardiac surgery. We popularized and published our data and have since had more experience with the technique.

According to the STS database, patients requiring a reoperative aortic valve replacement after previous coronary artery bypass grafting have a mortality risk of about 8 to 12% from the procedure. The risks are associated with the performance of a reoperation in an older patient with more comorbidities and patent/diseased bypass grafts.

The Need for This Operation

1. There is a definite subgroup of patients who have undergone coronary bypass surgery who had mild or no aortic stenosis at the time of their original operation who will eventually progress to have severe aortic stenosis over time. This has sparked off a whole discussion on the management of moderate aortic stenosis with coronary artery disease.[23]
2. These patients are older, sicker and have many comorbid conditions.
3. They need a simple, safe, and effective operation.
4. The areas of interest are the ascending aorta and aortic root.
5. Dissection of the rest of the heart and bypass grafts provide no additional benefit and are potentially harmful.
6. Clipping the left internal mammary artery is not mandatory with alternative protection strategies.

Operative Strategy

Preoperatively, a computed tomogram of the chest with angiography and three-dimensional reconstruction is performed to ascertain the exact location of the old bypass grafts and their relative location to the sternum (especially the left internal mammary artery).[24] Coronary angiography and percutaneous

coronary and graft intervention with drug-eluting stents are done as appropriate to optimize the revascularization as far as possible. Heart failure is controlled medically.

All patients need intraoperative transesophageal echocardiography and a pulmonary artery catheter with atrial and ventricular pacing wire placement capabilities, which should ideally be placed before incision. Accurate placement of external defibrillator pads is emphasized because internal paddles cannot be introduced in these patients.

All patients need peripheral cannulation for cardiopulmonary bypass. We prefer right axillary and percutaneous femoral venous cannulation. Appropriate arterial line placement is needed to facilitate need for circulatory arrest and antegrade cerebral perfusion if required.[25] A standard upper hemisternotomy incision is made with a T into the right fourth intercostal space (Figs. 38-7 and 38-8). The anterior table split is performed with the use of an oscillating saw, whereas the posterior table split is performed on cardiopulmonary bypass using straight Mayo scissors starting from the top down (preferably from the assistant's side of the table). When the left internal mammary artery graft is close to the left side or the middle of the sternum, a preplanned one-third to two-thirds sternotomy to the right is performed. The right pleural space is widely opened. Only 5 to 10 mm dissection is performed underneath the left sternal edge, enough to facilitate the placement of the Kuros-Baxter® retractor. The rest of the mediastinal and aortic dissection is performed on cardiopulmonary bypass. Care is taken not to injure previous saphenous vein or radial arterial bypasses. It is not necessary to visualize the left internal mammary artery graft.

We start core cooling to 25°C only after there is an ability to place an aortic cross-clamp. Moderate to deep hypothermia facilitates low flow states and reduces myocardial oxygen demand,

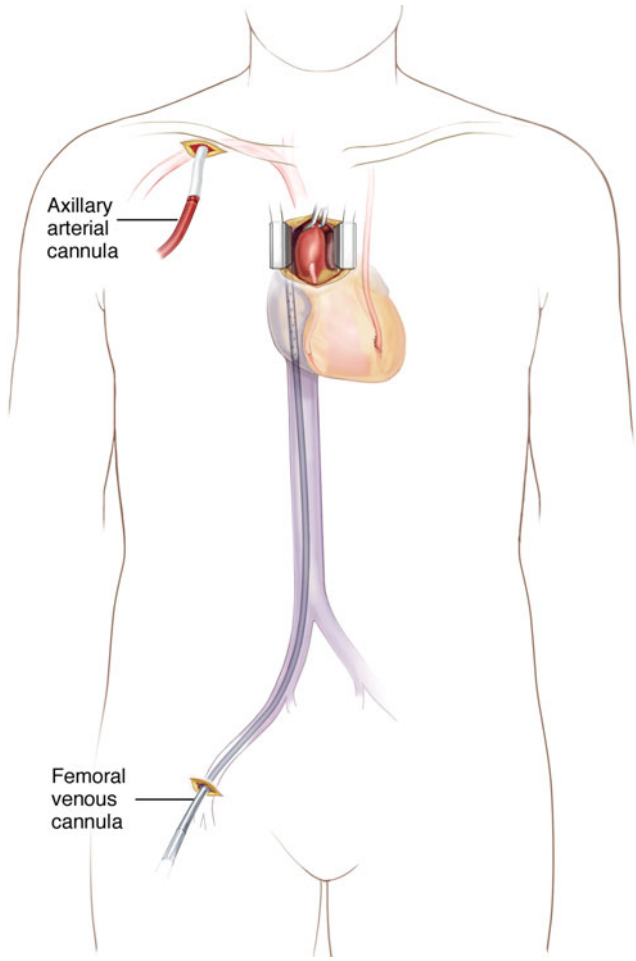

FIGURE 38-8 Peripheral cannulation for cardiopulmonary bypass.

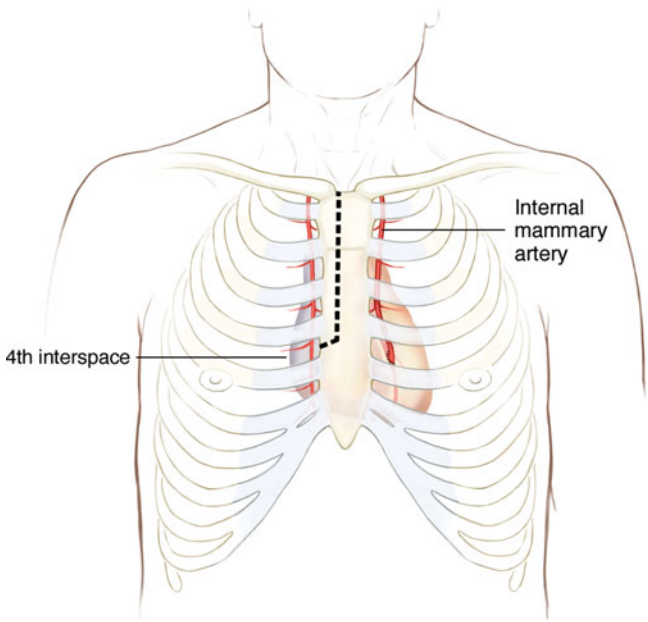

FIGURE 38-7 The upper hemisternotomy incision has been marked.

which is important because the left internal mammary artery will continue to perfuse the heart for the duration of the operation. A retrograde coronary sinus catheter is placed through the right atrial appendage using TEE guidance. Usually, enough right atrial appendage is seen to place this catheter. Alternatively, a transjugular catheter can be placed before incision. After cross-clamping the aorta, 1 L antegrade cold blood cardioplegia is delivered through the aortic root. Thereafter, 500 cc of cold retrograde blood cardioplegia is used. Simultaneously, systemic hyperkalemia is achieved by instilling 40 mEq of potassium into the cardiopulmonary bypass. Systemic hyperkalemia will achieve diastolic arrest in the left anterior descending artery territory that is perfused by the left internal mammary artery distal to the aortic cross-clamp. All through the operation, frequent doses of antegrade (through the coronaries and grafts using perfusion canulae) and retrograde cardioplegia are delivered. Systemic hyperkalemia is maintained at a level of 6 to 7 mEq/L. This keeps the myocardium fairly quiescent during the procedure. Needless to say, heavy doses of potassium may leave the patient with severe hyperkalemia that may not be cleared in the setting of renal dysfunction. In addition to being judicious in such cases, it is imperative that the perfusion technologists be able to provide ultrafiltration as well.

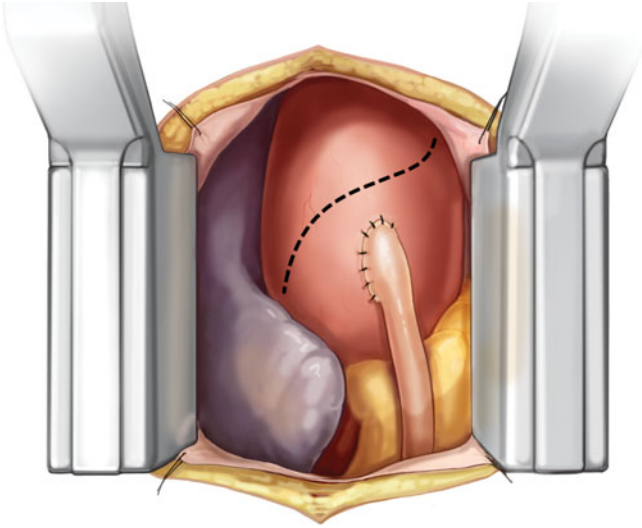

FIGURE 38-9 This is a lazy S oblique aortotomy keeping the grafts to the left.

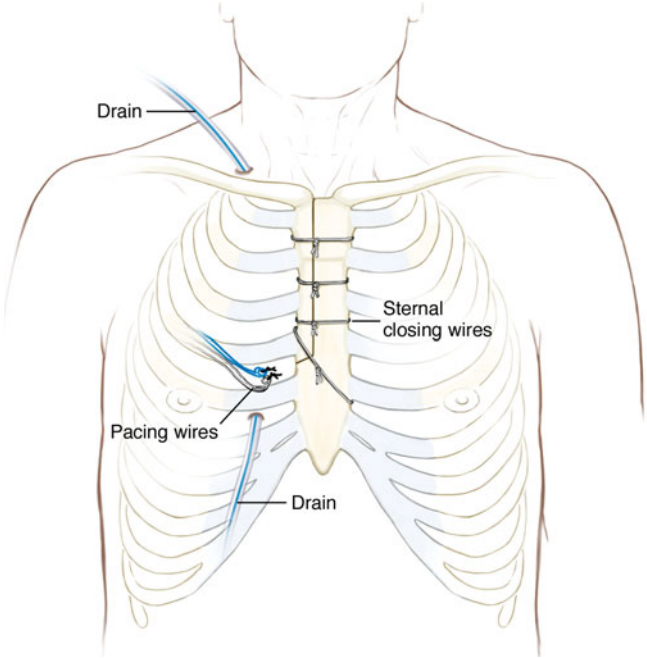

FIGURE 38-10 Final closure, also showing an occasional drainage tube in the supraclavicular space.

The aortotomy is dictated by the location of previous bypass grafts. Although in some cases a standard oblique aortotomy can be made, most cases require a modified aortotomy such as a lazy S or a lateral vertical aortotomy (Fig. 38-9). The exposure should be adequate and an expeditious valve replacement is the key to success. We aim to keep the cross-clamp time under 60 minutes. In most cases, there will be continuous back-bleeding through the left main orifice from the open left internal mammary artery graft. During debridement and suture placement in the left coronary area, the bypass flows can be reduced or briefly turned off to facilitate exposure. Rewarming is started after the valve is seated. The aortotomy is closed in the standard fashion and a de-airing needle is placed before removal of the aortic cross-clamp. The heart often recovers spontaneous sinus rhythm. Defibrillation is achieved via the external pads if required. The de-airing and wean from cardiopulmonary bypass is as described before.

Drainage tubes are always placed through the right pleural space. Subxiphoid placement is not possible and strongly discouraged. Rarely, when the right pleural space is completely fused, the silastic drain could be brought out in the supraclavicular area. It may be possible to place atrial pacing wires, but placement of ventricular wires is almost always quite difficult. We have routinely switched to the use of pulmonary artery catheter based pacing leads with good success. Closure is fairly standard, as described before, and care must be taken during the placement of wires on the left side of the sternum and the oblique lower wire (Fig. 38-10).

Our Experience with This Technique

Byrne et al[26–28] first published the Brigham experience with reoperative minimal access aortic valve replacement in patients who had previously undergone coronary artery bypass grafting or other cardiac surgery and compared it with conventional surgery through a full sternotomy approach. Patients having a conventional full sternotomy redo AVR had more blood loss, more transfusions, and longer operations.

Our positive experience has encouraged others to pursue this technique. Dell'Amore et al[29] report the suitability of this technique in their modest report of 10 patients, and Bakir et al[30] report similarly.

As of 2008, the Brigham experience has grown to 146 patients, reported by Tabata et al[31] The median times for cardiopulmonary bypass and aortic cross-clamp were 150 and 80 minutes, respectively, which are quite acceptable. The operative mortality was 4.1%.

This technique is clearly advantageous but has a fairly steep learning curve. When perfected, it can accomplish a successful operation, with lower mortality and morbidity in an older patient with multiple comorbidities who needs a redo AVR.

CHAPTER 39

Percutaneous Treatment of Aortic Valve Disease

Lars G. Svensson

INTRODUCTION

Over the last few years, data have accumulated that untreated aortic valve disease, particularly in elderly people, is a problem despite the success of surgery and newer methods of treatment.[1–32]

The history of percutaneous treatment of aortic valve disease with various types of device goes back to the work of Danish researcher, H.R. Andersen, who in the late 1980s experimented in an animal lab with a balloon-expandable stented valve.[15] The technology was later acquired by PVT Company and further developed and later sold to Edwards. The early work was done by Alain Cribier[21,22] and subsequently the expandable stented valve was adopted in the United States and further modified. The initial approach taken by Cribier was to insert the valve via the femoral vein and then using a transeptal technique to snake the catheter through the mitral valve and left ventricle to access the aortic annulus. This turned out to be a fairly cumbersome and difficult operation to do with a fairly high mortality rate and an 8.1% stroke rate. At the same time, animal experiments were carried out by Michael Mack, Todd Dewey, and Lars Svensson,[17,25] to use a transapical approach to insert the aortic valve. During this time period, John Webb and colleagues[18,19] were also developing a transapical aortic valve method, and subsequently they introduced the retrograde transfemoral artery approach. This latter technique became feasible once Edwards developed a catheter that could be flexed to get around the aortic arch to access the aortic valve.

The Revival Trial was started in the United States in 55 patients using the retrograde transarterial transfemoral approach (Transapical aortic valve insert, TFAVI; Figs. 39-1 to 39-3).[24] A separate Revival trial also included a transapical approach in 40 patients.[25] In the United States, the three centers involved in these studies were Cleveland Clinic in Ohio, Columbia in New York, and Medical City in Dallas. In the first transfemoral Revival series of patients, the mortality rate was 7% and the stroke rate 9.2%. The transapical (TA-AVI) (Figs. 39-4 to 39-6) had a higher mortality rate of 17% in the first 40 patients with no immediate strokes after successful insertion, although two patients did develop strokes, one after an open replacement for aortic valve disease in a very heavily calcified ascending aorta and the other in a patient who developed atrial fibrillation a few days after surgery. Based on the feasibility studies, the FDA then approved a prospective randomized trial to further evaluate the device technology.

At the same time as the Edwards balloon-expandable valve was being developed, Core-valve introduced a nitinol-based percutaneous valve system that was also inserted transfemorally but did not require balloon expansion, but rather expanded over time as the nitinol stretched the aortic valve and seated in the aortic valve annulus.

DESIGN

The Edwards balloon-expandable valve has evolved over time with two principal changes, which include the stent steel cage having a higher skirt sewn to the base of it and switching from equine to bovine biological leaflets. Furthermore, the bovine leaflets are manufactured to the same thickness as those found in regular pericardial valves. In the pulse duplicators the valve was tested to exceed the equivalent of some 10.4 years of implantation. To try and reduce the bulk of the stainless steel cage, newer modifications are going to become available that

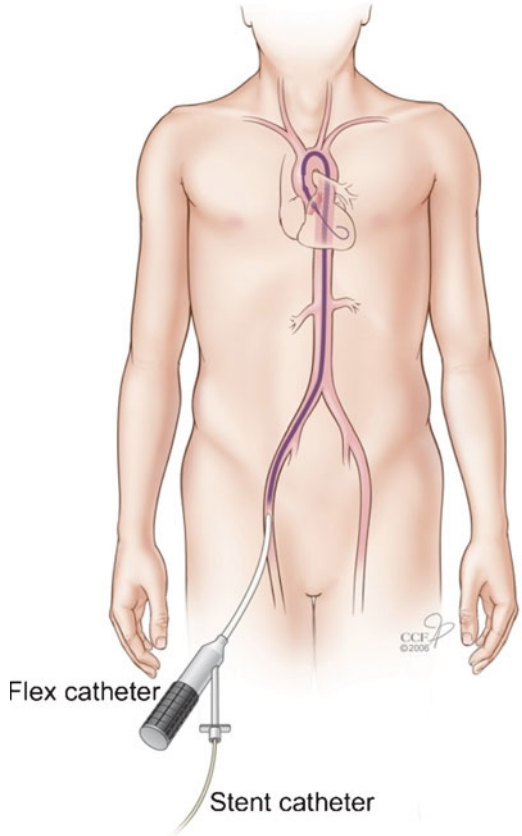

FIGURE 39-1 Transfemoral artery catheter insertion. (*Reproduced with permission of the Cleveland Clinic, Cleveland, OH.*)

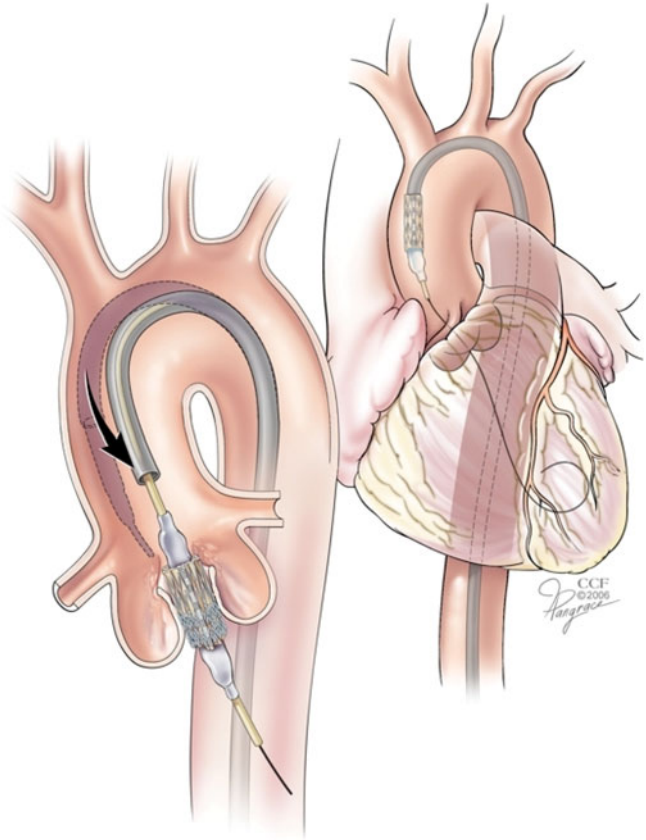

FIGURE 39-2 Catheter for delivery across the arch. (*Reproduced with permission of the Cleveland Clinic, Cleveland, OH.*)

involve the use of a different metal, altering the existing mounting system for the valve on the catheter for balloon expansion. Thus, the intent is that the valve will be able to be inserted in an "18-sheath system." The long-term durability of the bovine valve leaflets appears to be excellent with few reported failure of the devices at this time on long-term follow-up of the patients with the important caveat that the valve is both full and symmetrically expanded. Clearly, endocarditis is still a risk factor over time and has occurred occasionally, but leaflet calcification or tearing, at least in the first few years, has not been a problem. It is likely that further development of the valve skirt will reduce the incidence and the degree of perivalvular leak by changes in the cuff and height of the cuff of the balloon-expandable valve.

PROSPECTIVE RANDOMIZED TRIAL

The PARTNER Prospective Randomized Trial consisted of two arms. There was much debate as how to best conduct the study as far as methods, and whether or not randomization was needed and which groups to assign patients. After negotiations with the FDA, the final decision was to have a Group A and a Group B, with Group A patients being randomized either to regular open surgery, or transfemoral arterial or transapical valve insertion. Group B patients were randomized to either transfemoral insertion or best medical treatment, including the use of balloon valvuloplasty. The Group A patients in the treatment arm were to be compared with the open surgical patients on the basis of noninferiority, and in Group B the treated patients were to be compared with the best medical treatment control arm on the basis of superiority. A total of 1040 patients were placed in the study, with 450 in the Group B arm, which was completed in the first half of 2009. The Group A part of the study was completed on August 28, 2009, and thereafter patients will still be screened and will require approval by the panel for continued access in either Group B or Group A. Randomization will no longer be required.

Entry criteria for most patients in Group A was having an STS score above 10, a valve area of less than 0.8, and, thereafter, depending on arterial access of the groins, patients were assigned either to the transapical arm or the transfemoral arm. Patients in the open surgical arm were not allowed to undergo any coronary artery bypass surgery or any other valvular procedure but were allowed to have the ascending aorta replaced for calcification using deep hypothermia and circulatory arrest. Group B patients require a combined risk of serious morbidity or mortality exceeding at least 50% and two surgeons agreeing the patient was inoperable. Exclusions included bicuspid valve pathology, left ventricular outflow tract smaller than 1.8 cm or larger than 2.4 cm, creatinine above 2.5 or dialysis, infection within 6 months, and a PCI procedure within 30 days.

There are important caveats to bear in mind when considering the trial. In our experience at the Cleveland Clinic (Table 39-1) it is only patients greater than age 80 undergoing reoperation in whom the risk of aortic valve replacement and the risk of death exceeds 5%. Hence, most patients in the trial are elderly with severe comorbid disease and usually undergoing a reoperation. Indeed, a 90-year-old patient with no comorbid disease requiring a reoperation may not qualify for the study. Another important caveat is the influence of peripheral vascular disease on outcome. We showed in a study of our patients that peripheral vascular disease increased the risk of both death and stroke after surgery.[30] Hence, because TA-AVI patients have poor access by trial entry criteria, they are also at greater risk of death or complications.

The Group B patient data will clearly be available before the Group A randomized patients and in both categories, the follow-up required will be 30 days plus 1 year. The data will then be presented to the FDA and panel evaluation. In both groups, mortality at 1 year is the most important variable, although there are also the composite end points of outcomes for analysis. (See "PARTNER Results Update" at the end of this chapter.)

While the PARTNER Trial data is being evaluated, ongoing studies are being continued in Europe in which patients have not been randomized but are being followed. The method of insertion has varied somewhat from site to site, with some sites, for example the group in Leipzig, prefer a transapical approach, whereas those in other centers prefer a transfemoral approach. In the centers in which the transapical approach has been used almost exclusively in patients, the reported results have so far been equivalent to those for the transfemoral approach. We note that the perceived advantages for the transapical approach are a quicker time for insertion, less contrast, and less risk of stroke. On the other hand, patients with severe lung disease and oxygen dependency do not tolerate this procedure well because it requires a minithoracotomy. The obvious benefits for the transfemoral approach are quicker recovery and earlier mobilization of patients, but this may be burdened with a higher risk of stroke and, clearly, there is a risk of vascular injury, which was 17% in the initial series in the Revival trial. This, however, has been reduced considerably and with the 18-French device becoming available in 2010, it is likely that both the rate of injury will be reduced and also the number of patients who need a transapical approach. The other option is to use the subclavian artery or mini aortic approach for insertion of the device.

Core valve has been inserted in 79 patients in Europe via the left subclavian artery, with a 9% risk of death, but what has been more daunting has been the 38% risk of requirement for pacemaker insertion after the procedure. This may be related to the proximal stent sitting a little bit lower in the left ventricular

TABLE 39-1 Death Rates for Aortic Valve Procedures, Including Complex Aortic Procedures, at Cleveland Clinic: 2001 to December 2007

Group	N	Death Rate
Primary AVR <70 years	720	0.28%*
Primary AVR >70 years	426	1.6%*
Primary AVR >80 years	139	1.4%*
Primary AVR >90 years	3	0%*
Reoperative AVR <70 years	217	2.3%*
Reoperative AVR >70 years	238	2.9%*
Reoperative AVR >80 years	89	5.6%
Reoperative AVR >90 years	3	0
Valve-sparing technique	418	1.4%†
Repair of ascending aorta	2812	4.2%‡
Repair of ascending aorta and aortic arch	985	4.6%‡
Use of "elephant trunk" technique	275	7.3%‡

*Including those with endocarditis but excluding those with coronary artery disease.
†Including those with aortic dissection.
‡Including those with dissection and endocarditis involving the aorta.
AVR = aortic valve replacement.

on-flow tract, leading to continued expansion of pressure on the bundle of His, and thus resulting in the need for pacemaker insertion.

INSERTION OF THE VALVES: TRANSFEMORAL APPROACH

In our most recent patients at the Cleveland Clinic, the modified approach we have used for insertion of the transfemoral approach is to introduce the femoral, arterial, and venous lines percutaneously using a closure device at the end of the procedure. Thus, a venous pacing wire is inserted into the right ventricle and then two arterial wires are inserted into the groin, one for the pigtail catheter and the other for the insertion of the device. Typically, the patient is heparinized so the ACT is between 250 and 350 seconds. The sequence of insertion is the introduction of a straight wire via the straight catheter through the aortic valve and into the left ventricle. This is then exchanged with an extra stiff or Lunderquist wire, which is placed in the left ventricle after sliding the sheath across the aortic valve. A 3- or 5-cm balloon is then threaded over the guidewire and positioned across the aortic valve using fluoroscopy and then during rapid pacing, and breath holding, expanded to crack the calcium. If the balloon does not move, then the balloon is removed and the femoral 14-French sheath exchanged for progressive-sized Cook dilators and finally the largest-sized Edwards dilators are inserted into the femoral artery and into the distal abdominal aorta. The size is dependent on the valve selection, namely, a size 23 or 26 valve. The large sheath is then inserted. The size 23-mm valve is used for patients with left ventricular outflow tracts of 1.8 to approximately 2.1 to 2.2 cm, and the larger 26-mm valve is used for left ventricular outflow tract sizes from 2.2 to 2.4 cm. Generally, patients with left ventricular outflow tracts of 2.5 cm or larger are excluded from the study until the new 29-mm valve becomes available.

As a rule, patients who need the smaller-sized valve should have a femoral artery of at least 7 mm and for the size 26 valve a 7.5- to 8-mm external iliac artery, depending on the tortuosity of the vessel and degree of calcification. If there is more than 90-degree angulation of the iliac arteries, then generally it would be difficult to insert the large sheath unless the vessel straightens very easily with a Lunderquist wire. In measuring for the 22-mm-French sheath (internal diameter) the size varies from 7.45 to 7.72 mm for the internal diameter and external measurements vary from 8.21 to 8.50 mm. The 22-French sheath is used for the size 23-mm valve. In other words, the true internal size is 23-mm French and 25.5 French external diameter using a conversion factor of 0.333. For the 26-mm valve, a size 24-French sheath is used, which has an internal size measurement between 8.20 and 8.40 mm and an external size of 8.94 to 9.90 mm. By converting this to French sizes this would be equivalent to a 25.3 internal and 27.3 external French size. The 28 dilator sheath diameter is 9.24 mm, which is used before introducing the big 24-French sheath.

Once the sheath is inserted and the valve mounted on the balloon, it is checked to be correctly loaded, and is then threaded over the stiff wire and the loader pushed into the sheath to the black mark but not beyond it. Note that with the new sheath this requirement is not as critical. The valve is then pushed and threaded across the aortic arch with the steerable catheter being flexed to get around the aortic arch and then fed down to the aortic valve. With the flex-three system, the insertion and retraction of the dilators are much easier. Essentially, the valve with the leading little cone is fed across the valve to cross the valve and then the cone is pushed further into the ventricle so that the stent valve is free. Once the balloon is inflated, it can be expanded without limitation from the cone. We consider it very important to carefully check on the positioning of the valve across the hinged point of the native valve using both echocardiography and fluoroscopy and root injections with contrast via the pigtail catheter. With the flex-three system the valve is positioned at the valve hinged points, approximately 50/50 aortic/ventricular. Once everybody agrees that the position is correct, the patient's breath is held, the patient is paced at approximately 180 beats per minute, the balloon is inflated in position and then deflated, the pacer is switched off, and the patient is put back on the ventilator. There is virtually always some perivalvular regurgitation in the region of the noncoronary–left main leaflet commissure, probably because this is an area of less flexibility and a lot of calcium. Echocardiography is then used to inspect the function of the valve. Thereafter, cone is first withdrawn from the left ventricle followed by removal of the catheter and sheath, and lastly the previous closure device is tied down at the insertion sites.

TRANSAPICAL INSERTION

In the United States, the transapical approach is reserved for those patients who do not have access and, as such, they generally have more comorbidity than transfemoral patients based on comparative studies.

The way we prefer to do it at the Cleveland Clinic is to have the patient lie flat on his or her back on pillows rather than at a traditional left thoracotomy position, because this interferes with the positioning of the C-arms. All patients before surgery undergo an aortic root injection from which the ideal planes are calculated for positioning the valve with the nadir of each cusp being in the same plane. This is also obtained with the computer tomographic scans, which are done preoperatively to check for potential calcium obstruction of the native coronary arteries.

Once the patient is positioned, he or she is prepped in the usual manner with exposure of the groin and left chest. The femoral artery and vein are exposed on the right side and the left femoral venous pacing wires inserted. The femoral artery exposure is performed in case the patient has to be placed on a pump.

We continue to have all of our patients undergo general anesthesia but, more recently, we have not used a double-lumen tube for the transapical valves. Before opening the chest, an echo probe is placed on the chest to try to better define where the left ventricular apex is, and CAT scan images are also inspected to find the ideal place to open the left chest. Typically, the fifth intercostal space is entered and the apex of the left ventricle palpated. Once the apex of the left ventricle has been palpated,

a short piece of rib is removed to expose the apex. Originally we did not do this and rather spread the ribs, but we found that some patients had severe pain as with the mid-cab experience. We therefore opted to resect a short piece of rib to obtain both a better exposure and less pain after surgery, particularly because many of these patients have severe lung disease. The pericardium is then opened and stay sutures placed and then two pursestring sutures with Teflon felt pledgets are placed around the left ventricular apex. The site is selected by tapping on the left ventricular apex and then looking at the echo to make sure that the left ventricular apex is correctly identified. This is important because the heart can be anywhere from the fourth intercostal space to the seventh or eighth intercostal space. In addition, a horizontal mattress suture is also placed in the apex. A needle is then inserted followed by a guidewire into the left ventricle; then we insert a Berman catheter into the left ventricle, through the aortic valve, and across the aortic arch down to the renal arteries. An extra stiff wire is also fed down at the same time. The Berman catheter is then removed and the 14-gauge sheath exchanged for the large-bore introduction sheath. Balloon valvuloplasty is performed through this in the same sequence with rapid pacing as for the transfemoral approach. The valve is then loaded onto the sheath and pushed into position and the pusher retracted into the sheath. With the valve situated approximately 60% aortic and with rapid pacing the balloon is then inflated at this point. The balloon is then withdrawn into the left ventricle before stopping pacing. If all appears well, the sheath and wire are then removed and the pursestring sutures are tied down.

PARTNER RESULTS UPDATE

PARTNER B showed that TFAVI significantly improved 1 year survival despite a 30-day death rate of 6.4% and stroke/TIA rate of 5.5%. PARTNER A showed transcatheter aortic valve replacement (TAVR) was noninferior to open surgery for both 30-day and 1-year mortalities; however, the rate of stroke/TIA was higher for TAVR.

CONCLUSION

Percutaneous aortic valve procedures continue to improve and, despite our early skepticism with the approach based on early animal work that showed a high embolization rate in the animal valves, the procedure has established itself as a very effective way of treating high-risk patients with severe aortic valve stenosis. Undoubtedly with new iterations the procedure will become safer and even better, likely with retrievable devices and easier positioning of the devices.

THE NORMAL MITRAL VALVE

Anatomy

The mitral annulus is a pliable junctional zone of discontinuous fibrous and muscular tissue that joins the left atrium and left ventricle and anchors the hinge portions of the anterior and posterior mitral leaflets.[1–8] The annulus has two major collagenous structures: (1) the right fibrous trigone, which is part of the central fibrous body and is located at the intersection of the membranous septum, the tricuspid annulus, and the aortic annulus; and (2) the left fibrous trigone, which is located near the aortic annulus under the left aortic cusp (Fig. 40-1). The anterior mitral leaflet spans the distance between the commissures (including the trigones) and is in direct fibrous continuity with the aortic annulus under the left and noncoronary aortic valve cusps, including the fibrous triangle between the left and noncoronary aortic valve cusps. The posterior half to two-thirds of the annulus, which subtends the posterior leaflet, is primarily muscular with little or no fibrous tissue.[4]

The mitral valve has two major leaflets, the larger anterior (or aortic or septal) leaflet and the smaller posterior (or mural) leaflet; the latter usually contains three or more scallops separated by fetal clefts or *subcommissures,* which are developed to variable degrees in different individuals.[9] The three posterior leaflet scallops are anatomically termed anterolateral (P1), middle (P2), and posteromedial (P3) scallops (Fig. 40-2). The portions of the leaflets near the free margin on the atrial surface are called the *rough zone,* with the remainder of the leaflet surface closer to the annulus being termed the *smooth* (or *bare* or *membranous*) *zone.* The ratio of the height of the rough zone to the height of the clear zone is 0.6 for the anterior leaflet and 1.4 for the posterior leaflet because the clear zone on the posterior scallops occupies only about 2 mm.[9] The two leaflets are separated by the posteromedial and anterolateral commissures, which usually are distinctly developed but occasionally are incomplete.

The histologic structure of the leaflets includes three layers: (1) the fibrosa, the solid collagenous core that is continuous with the chordae tendineae; (2) the spongiosa, which is on the atrial surface and forms the leaflet leading edge (it consists of few collagen fibers but has abundant proteoglycans, elastin, and mixed connective tissue cells); and (3) a thin fibroelastic covering of most of the leaflets.[4] On the atrial aspect of both leaflets, this surface (the atrialis) is rich in elastin. The ventricular side of the fibroelastic cover (the ventricularis) is much thicker, confined mostly to the anterior leaflet, and densely packed with elastin. The fibroelastic layers become thickened with advancing age as a result of elaboration of more elastin and more collagen formation; accelerated similar changes also accompany the progression of myxomatous (degenerative or "floppy") mitral valvular disease in young patients with the Barlow syndrome. In addition to these complex connective tissue structures, the mitral leaflets contain myocardium, smooth muscle, contractile valvular interstitial cells, and blood vessels, as well as both adrenergic and cholinergic afferent and efferent nerves.[10–24] Leaflet contractile tissue is neurally controlled and plays a role in mitral valve function.[8,11–14,25–32] The atrial surface of the anterior leaflet exhibits a depolarizing electrocardiogram spike shortly before the onset of the QRS complex, and the resulting contraction of leaflet muscle (which can be abolished by beta-blockade), along with contraction of smooth muscle and valvular interstitial cells, possibly aids leaflet coaptation before the onset of systole, as well as stiffens the leaflet in response to rising left ventricular (LV) pressure.[11–14,29,31,33,34–38] Mitral leaflet stretch of 10% or

more also leads to an action potential that initiates leaflet muscle contraction.[34,39]

Annular Size, Shape, and Dynamics

The average mitral annular cross-sectional area ranges from 5.0 to 11.4 cm^2 in normal human hearts (average is 7.6 cm^2).[40] The annular perimeter of the posterior leaflet is longer than that subtending the anterior leaflet by a ratio of 2:1; ie, the posterior annulus circumscribes approximately two-thirds of the mitral annulus.[12] Annular area varies during the cardiac cycle and is influenced directly by both left atrial (LA) and LV contraction, size, and pressure.[41,42] The mitral annular area changes by 20 to 40% during the cardiac cycle.[6,41–47] Annular size increases beginning in late systole and continues through isovolumic relaxation and into diastole; maximal annular area occurs in late diastole around the time of the P wave on the electrocardiogram.[6,41,43,46,48] Importantly, half to two-thirds of the total decrease in annular area occurs during atrial contraction (or *presystolic*); this component of annular area change is smaller when the PR interval is short and is abolished completely when atrial fibrillation or ventricular pacing is present. Annular area decreases further (if LV end-diastolic volume is not abnormally elevated) to a minimum in early to midsystole.[5,6,41–43]

The normal human mitral annulus is roughly elliptical (or kidney-shaped), with greater eccentricity (ie, being less circular) in systole than in diastole.[3,6,40–42,45,47,49] In its most elliptical configuration, the ratio of minor to major diameters is approximately 0.75. In three-dimensional space, the annulus is saddle shaped (or more precisely, a hyperbolic paraboloid), with the highest point (farthest from the LV apex) located anteriorly in the middle of the anterior leaflet; this point is termed the *fibrosa* in the echocardiography literature and the *saddle horn* by surgeons, and is readily identified in echocardiographic images owing to the common junction with the aortic valve. The low points are located posteromedially and anterolaterally in the commissures, and another less prominent high point is located directly posterior.[41,50,51] During the cardiac cycle, annular regions adjacent to the posterior leaflet (where the leaflet attaches directly to the atrial and ventricular endocardium) move toward (during systole) and away (during diastole) from the relatively immobile anterior annulus.[41,47]

The mitral annulus moves upward into the left atrium in diastole and toward the LV apex during systole; the duration, average rate, and magnitude of annular displacement correlate with (and perhaps influence) the rate of LA filling and emptying.[6,41,43,46,52,53] The annulus moves slightly during late diastole (2 to 4 mm toward the left atrium during atrial systole). This movement does not occur in the presence of atrial fibrillation and may be an atriogenic contractile property. The annulus moves a greater distance (3 to 16 mm toward the

LV apex) during isovolumic contraction and ventricular ejection. This systolic motion, which aids subsequent LA filling, occurs in the presence or absence of atrial fibrillation and is related to the extent of ventricular emptying; thus, it is likely driven by LV contraction.[6,41,45,46,52–55] Subsequently, the annulus moves very little during isovolumic relaxation but then exhibits rapid recoil toward the left atrium in early diastole. This recoiling increases the net velocity of mitral inflow by as much as 20%.[46,56] Annular motion can be responsible for up to 20% of LV filling and ejection.[57]

Dynamic Leaflet Motion

The posterior mitral leaflet is attached to thinner chordae tendineae than the anterior leaflet, and its motion is restrained by chordae during both systole and diastole.[9,52] Regions of both leaflets are concave toward the left ventricle during systole,[58–60] but leaflet shape is complex, and anterior leaflet curvature near the annulus is convex to the left ventricle during systole, thus resulting in a sigmoid shape.[48,50,51,61] Leaflet opening does not start with the free margin but rather in the center of the leaflet; leaflet curvature flattens initially and then becomes reversed (making the leaflet convex toward the left ventricle) while the edges are still approximated.[48,59,60] The leading edge then moves into the left ventricle (like a traveling wave), and the leaflet straightens. The leaflet edges in the middle of the valve appear to separate before those portions closer to the commissures, and posterior leaflet opening occurs approximately 8 to 40 ms later.[60–63] Early leaflet opening (*e* wave) is very rapid; once reaching maximum opening, the edges exhibit a slow to-and-fro movement (like a flag flapping in a breeze) until another less forceful opening impulse occurs, associated with the *a* wave. During late diastole, the leaflets move gradually away from the LV wall.

Valve closure starts with the leaflet bulging toward the atrium at its attachment point to the annulus. The closure rate of the anterior leaflet is almost twice that of the posterior leaflet, thereby ensuring arrival of both cusps at their closed positions simultaneously (because the anterior leaflet is opened more widely than the posterior leaflet at the onset of ventricular systole).[63] The anterior leaflet actually arrives at the plane of the annulus in a bulged shape (concave to the ventricle), but as the closing movement proceeds and the leaflet ascends toward the atrium, this curvature appears to run through the whole leaflet, from the annulus toward the edge, in a rolling manner. The leaflet edge is the last part of the leaflet to approach the annular plane. Leaflet curvature is more pronounced with the onset of systolic ejection.[59,60]

Chordae Tendineae and Papillary Muscles

Epicardial fibers in the left ventricle descend from the base of the heart and proceed inward at the apex to form the two papillary muscles, which are characterized by vertically oriented myocardial fibers.[64,65] The anterolateral papillary muscle usually has one major head and is a more prominent structure; the posteromedial papillary muscle can have two or more subheads and is flatter.[9] A loop from the papillary muscles to the mitral annulus is completed by the chordae tendineae continuing into the mitral leaflets, which then are attached to the annulus. The posteromedial papillary muscle usually is supplied by the right coronary artery (or a dominant left circumflex artery in 10% of patients); the anterolateral papillary muscle is supplied by blood flow from both the left anterior descending and circumflex coronary arteries.[7,64,66,67]

The posteromedial and anterolateral papillary muscles give rise to chordae tendineae going to both leaflets[9] (**Fig. 40-3**). Classically, the chordae are divided functionally into three groups.[64,68] First-order chordae originate near the papillary muscle tips, divide progressively, and insert on the leading edge of the leaflets; these primary chordae prevent valve-edge prolapse during systole. The second-order chordae (including two or more larger and less branched "strut" chordae) originate from the same location and tend to be thicker and fewer in number;[9,68] they insert on the ventricular surface of the leaflets at the junction of the rough and clear zones, which is demarcated by a subtle ridge on the leaflet corresponding to the line of leaflet coaptation. The second-order chordae (including the strut chordae) serve to anchor the valve, are more prominent on the anterior leaflet, and are important for optimal ventricular systolic function. Second-order chordae also may arborize from large chordae that also give rise to first-order chordae. The third-order chordae, also called *tertiary* or *basal chordae,* originate directly from the trabeculae carneae of the ventricular wall, attach to the posterior leaflet near the annulus, and can be identified by their fan-shaped patterns.[68] Additionally, distinct commissural chordae and cleft chordae exist in the commissures. In total, about 25 major chordal trunks (range 15 to 32) arise from the papillary muscles in humans, equally divided between those going to the anterior and posterior leaflets; on the other end, greater than 100 smaller individual chordae attach to the leaflets.[68] Studies of porcine mitral valves demonstrate that the chordae have different microstructures based on chordal type.[69] The presence of blood vessels characterizes the chordae as complex living components that work in coordination with the other elements of the valvular and subvalvular apparatus.

During diastole, the papillary muscles form an inflow tract. During systole, they create an outflow tract that later becomes obliterated owing to systolic thickening of the papillary muscles, thereby augmenting LV ejection by volume displacement.[65] The contribution of the papillary muscles to LV chamber volume is 5 to 8% during diastole but 15 to 30% during systole.[65,70] The anterolateral and posteromedial papillary muscles contract simultaneously and are innervated by both sympathetic and parasympathetic (vagal) nerves.[71,72]

Studies of papillary muscle function during the cardiac cycle have yielded discordant results.[71,73–76] Although the papillary muscles shorten at some point during systole (by more than one-fourth their maximum length), this contraction may be isometric or substantially less than that of the LV free wall fibers.[73–75,77–80] In addition, there is no consensus as to the exact timing of papillary muscle contraction and elongation during the cardiac cycle.[71–73,75,76,78,79] Some studies suggest that the papillary muscles contract before the LV free wall so that the
