In a review of 72 centers performing ACHD surgery, Patel reported 2800 operations performed per year, ranging from 0 to 230 (median 28) per program. There were a median of two surgeons per program, with each surgeon averaging 20 cases per year.[43] Although individual surgeon and program results will vary, patients with ACHD appear to have better outcomes when repaired by surgeons who primarily perform pediatric congenital heart surgery (1.87% mortality), compared with surgeons who primarily operated on acquired adult heart disease (4.84% mortality, $p < .0001$).[44] Patients with congenital heart disease are living longer. Arrhythmia remains the primary contributing cause of death for those with cyanotic lesions. Myocardial infarction is now the leading contributing cause for adults with noncyanotic congenital heart disease consistent with late survival and an increasing impact of acquired heart disease.[16] With increasing experience and a team approach synthesizing surgery, intervention, and electrophysiology, adults with congenital heart disease should experience improved outcomes with less cumulative lifetime therapeutic trauma.

KEY POINTS

- Adult congenital heart procedures are best managed by multidisciplinary teams with dedicated cardiovascular surgeons, interventional cardiologists, electrophysiologists, and intensivists with high volume congenital experience.
- Web-based medical information systems may enhance the care of ACHD patients by providing the medical team, and the patients, with on-demand access to critical information over the patient's lifetime.
- Routine femoral cannulation may not be practical for reoperations in ACHD patients and alternate strategies should be considered.
- Surgical atrial septal defect repair in adults is best accomplished with patches, because primary repairs produce tension and may break down.
- Right ventricular outflow tract reconstructions should be performed with conduits that will allow future implantation of transcatheter stented valves.
- Anti-adhesion barriers and pericardial reconstructions may reduce the incidence of cardiac trauma during reoperations, which are common in the ACHD population.

CHAPTER 61

Pericardial Disease

John M. Craig
Jennifer D. Walker

INTRODUCTION

The pericardium envelops the heart and portions of the great vessels as a protective capsule. When incised longitudinally and transversely along the diaphragm it can be suspended from a chest retractor to present the heart for surgical procedures. The surgical importance of the pericardium stems from its involvement in alterations of cardiac filling. When the limited space between the noncompliant pericardium and heart acutely fills with blood or fluid, cardiac compression and tamponade may ensue. Constrictive disorders arise when inflammation and scarring cause the pericardium to shrink and densely adhere to the surface of the heart. This chapter discusses pericardial anatomy and function and describes the conditions that commonly give rise to the surgical problems of pericardial constriction and tamponade. The chapter also describes the diagnosis and therapy of these entities, the management of tamponade early and late after cardiac surgery, and the rationale for and against pericardial closure at the time of cardiac surgery.

ANATOMY AND FUNCTION

The pericardium serves two major functions. It maintains the position of the heart within the mediastinum and prevents cardiac distention by sudden volume overload. The pericardium attaches to the ascending aorta just inferior to the innominate vein and the superior vena cava (SVC) several centimeters above the sinoatrial node. The pericardial reflection encompasses the superior and inferior pulmonary veins and encircles the inferior vena cava, thereby making it possible for the surgeon to control the inferior vena cava from within the pericardium. The pericardial reflection attaches to the left atrium near the entrances of the pulmonary veins just below the atrioventricular groove (Fig. 61-1). The pericardiophrenic arteries that travel with the phrenic nerves as well as the branches of the internal mammary arteries and feeder branches directly from the aorta perfuse the pericardium. It is innervated by vagal fibers from the esophageal plexus, and the phrenic nerves course within it.

The pericardium is a conical fibroserous sac made up of two intimately connected layers. The inner layer (serous pericardium) is a transparent monolayer of mesothelial cells. The visceral portion of the serous pericardium, or epicardium, and the parietal portion, which lines the fibrous pericardial sac, are continuous. The oblique sinus lies within the venous confluence and the transverse sinus lies between the arterial (aorta and pulmonary artery) and venous reflections (dome of left atrium and SVC). Such potential spaces allow the pericardium to expand and accommodate a limited amount of fluid. Normal pericardial fluid volume is approximately 10 to 20 mL. The pericardial mesothelial cells contain dense microvilli that are 1 μm wide and 3 μm high, which facilitate fluid and ion exchange.[1] Visceral pericardial lymphatic drainage occurs via the tracheal and bronchial mediastinal nodes, whereas the anterior and posterior mediastinal lymph nodes drain the parietal pericardium.

The parietal layer or fibrous pericardium is composed mostly of dense parallel bundles of collagen, which render this layer relatively noncompliant. Because the pericardium is stiffer than cardiac muscle, it tends to equalize the compliance of both ventricles. By doing so, the pericardium contributes to the resting cavitary diastolic pressure of both ventricles, maximizing diastolic ventricular interaction.[2] An example of this phenomenon is the diminution of systemic arterial pressure during inspiration. Intrapericardial pressure tends to approximate pleural pressure, and varies with respiration. The negative intrathoracic pressure generated during inspiration augments right ventricular filling. The interventricular septum shifts toward the left to accommodate

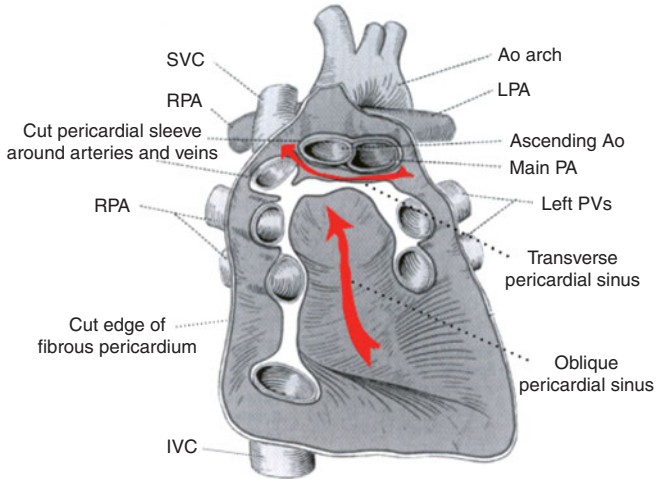

FIGURE 61-1 Pericardial attachments, reflections, and sinuses. Ao = aorta; IVC = inferior vena cava; LPA = left pulmonary artery; PA = pulmonary artery; PV = pulmonary vein; RPA = Right pulmonary artery; SVC = superior vena cava.

the increase in right ventricular volume. Because pericardial constraint does not allow equal filling of the left ventricle, the decrease in volume ejected by the systemic chamber results in a slight diminution of systemic arterial pressure during inspiration. This phenomenon is greatly magnified with an increase in intrapericardial pressure (eg, during acute filling of the pericardial space or circulatory volume overload), resulting in pulsus paradoxus.[3]

CONGENITAL ABNORMALITIES

Most congenital abnormalities of the pericardium are asymptomatic[4] and are often discovered incidentally at the time of surgery or investigation of unrelated problems.[5] They are rare and one-third are associated with cardiac, skeletal, and pulmonary abnormalaties.[6] Partial absence of the pericardium also occurs and is most commonly seen on the left (70%) due to premature atrophy of the left common cardinal vein. Right-sided and complete defects of the pericardium account for 17 and 13% of these defects, respectively. The right duct of Cuvier goes on to form the superior vena cava and ensures closure of the right pleuropericardial membrane.[7] Accordingly, right-sided defects tend to be lethal. MRI provides excellent pericardial imaging without contrast and is the imaging modality of choice. CT and echocardiography are useful for evaluation of pericardial thickening and extent and location of defects.[4] Although complete pericardial agenesis is rarely clinically significant, unilateral absence is potentially problematic because it may accentuate cardiac mobility and allow the heart to be displaced into the pleural space with resulting incarceration of the left atrial appendage or left ventricle. Treatment may involve pericardial resection or replacement with a prosthetic patch.[6] Both therapies appear to yield good outcomes.

Pericardial cysts are the most common congenital pericardial disorder and are surpassed only by lymphoma as the most prevalent of middle mediastinal masses.[8] They occur as asymptomatic incidental findings in 75% of patients; 70% occur in the right costophrenic angle and 22% on the left.[5] They do not communicate with the pericardial space and are typically unilocular, smooth, and less than 3 cm in diameter (Fig. 61-2). Symptoms may include chest pain, dyspnea, cough, and arrhythmias, probably owing to compression and inflammatory involvement of adjacent structures. They can also become secondarily infected.[9] Contrast CT scan is the modality of choice for diagnosis and follow-up.[10,11] Observation by CT in asymptomatic patients is suggested. Percutaneous aspiration is associated with a 30% recurrence rate at 3 years. Sclerosis has been reported to decrease recurrence after aspiration.[12] Indications for resection include large

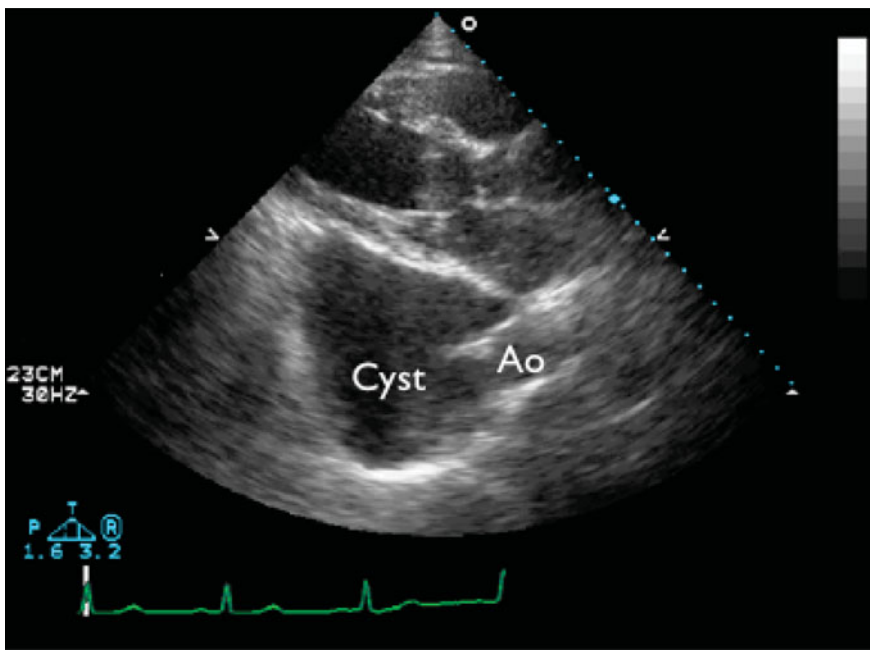

FIGURE 61-2 Transesophageal echocardiogram of large pericardial cyst.

size, symptoms, patient concern, and question of malignancy.[8] Video-assisted thoracoscopy is the surgical approach most commonly used for excision. Infrasternal mediastinoscopy can be used for anterior cysts. Thoracotomy is also an acceptable technique. Surgery is the only definitive cure.[12]

PATHOPHYSIOLOGY OF PERICARDIAL COMPRESSION

Pericardial compression results from disturbance of the normal anatomical and physiologic relationships among the pericardium, pericardial cavity, and the heart. Because the pericardium is relatively noncompliant and pericardial fluid noncompressible, the heart alone must compensate for acute changes in pericardial pressure. Acute volume overload within the confines of a fixed pericardial space results in a rapid, nonlinear increase in intrapericardial pressure (Fig. 61-3), producing cardiac compression.[13] The anatomical basis for pericardial compression involves either a space-occupying lesion (ie, cyst or excessive fluid) within the pericardial space or pericardial constriction.

Tamponade

Although blood in the pericardial space is the most common etiology, effusions, clot, pus, gas, or any combination may also produce tamponade. As fluid entering the pericardial space exceeds the ability of the pericardium to accommodate or absorb it, pericardial reserve volume (10 to 20 mL) is rapidly exceeded and intrapericardial pressure rises abruptly. At this point, pericardial fluid volume can only increase by reducing cardiac chamber volumes. Because of its lower filling pressures, the right heart is more susceptible to compression (Fig 61-4). The physiologic consequences are impaired diastolic filling with decreased cardiac output and increased central venous pressure.[14] Clinical manifestations include hypotension and jugular venous distention, and, along with decreased heart sounds, comprise Beck's triad.

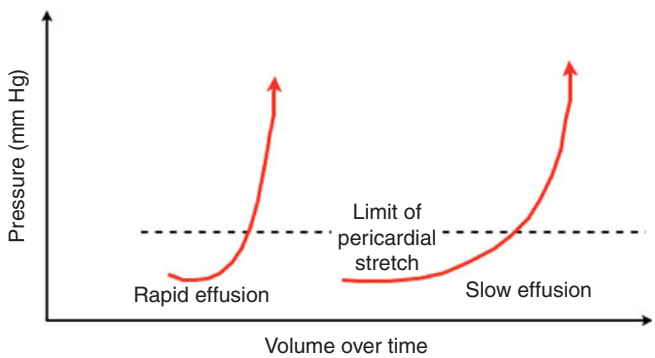

FIGURE 61-3 Relationship of pressure and volume in pericardial cavity. Normal pericardium will tolerate small amounts of fluid with a minimal increase in intrapericardial pressure. Above this small volume, small increases in volume result in large nonlinear increases in pressure. Gradual accumulation of fluid coincides with pericardial accommodation of much larger volumes of fluid up to a critical pressure.

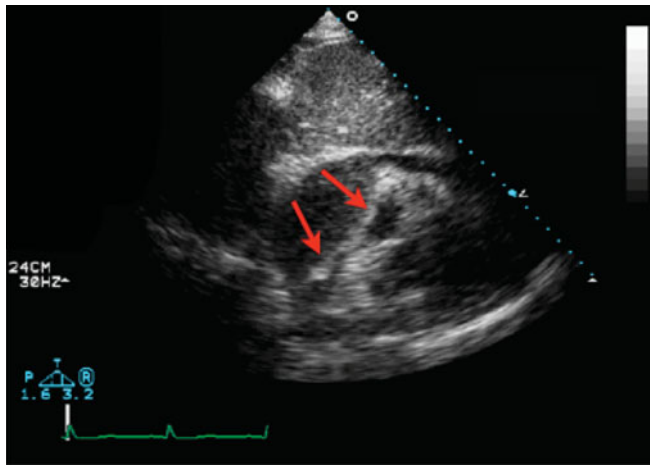

FIGURE 61-4 Transesophageal echocardiogram with right atrial inversion and cardiac tamponade.

To preserve cardiac output, higher pressures are required to fill the cardiac chambers, which may be partially achieved by parallel increases in systemic and pulmonary venous pressure by vasoconstriction.[15] Other compensatory mechanisms include tachycardia, chronic pericardial stretch, and blood volume expansion.[16] The latter two mechanisms have little impact in acute tamponade. As tamponade progresses, right heart filling becomes increasingly volume dependent and limited to inspiration. Increased filling of the right ventricle causes it to encroach on, and impair, filling of the left ventricle. However, during expiration the converse is true, and left ventricular filling and output increase. This exaggeration of physiologic ventricular interdependence is the basis of pulsus paradoxus.[13]

The clinical spectrum of tamponade varies widely, depending on the severity of hemodynamic impairment and degree of physiologic reserve. Rapid accumulation of as little as 100 mL of fluid in the pericardial space (eg, after a penetrating cardiac wound) may exceed the limited compliance of the parietal pericardium and produce critical tamponade. On the other hand, the pericardium may compensate for large pericardial effusions (>1 L) in chronic inflammatory conditions such as rheumatoid arthritis. The cardiac silhouette may appear normal in acute tamponade, but chronic pericardial distension is often obvious on plain chest radiography (Fig. 61-5), chest tomography (Fig. 61-6), and echocardiography (Fig. 61-7). Furthermore, low-pressure tamponade can also occur in which a pericardial effusion is not hemodynamically significant until the patient becomes hypovolemic, typically from dehydration, blood loss, or diuretic therapy. Venous filling pressures may be normal or mildly elevated in this setting, making this diagnosis difficult.[17]

Pericardial Constriction

A wide range of conditions promote pericardial scar formation, the pathologic process underlying constrictive pericarditis (CP). As with tamponade, the physiologic basis is compromised cardiac filling leading to systemic venous congestion and low cardiac output. In contrast with tamponade, however, onset is often

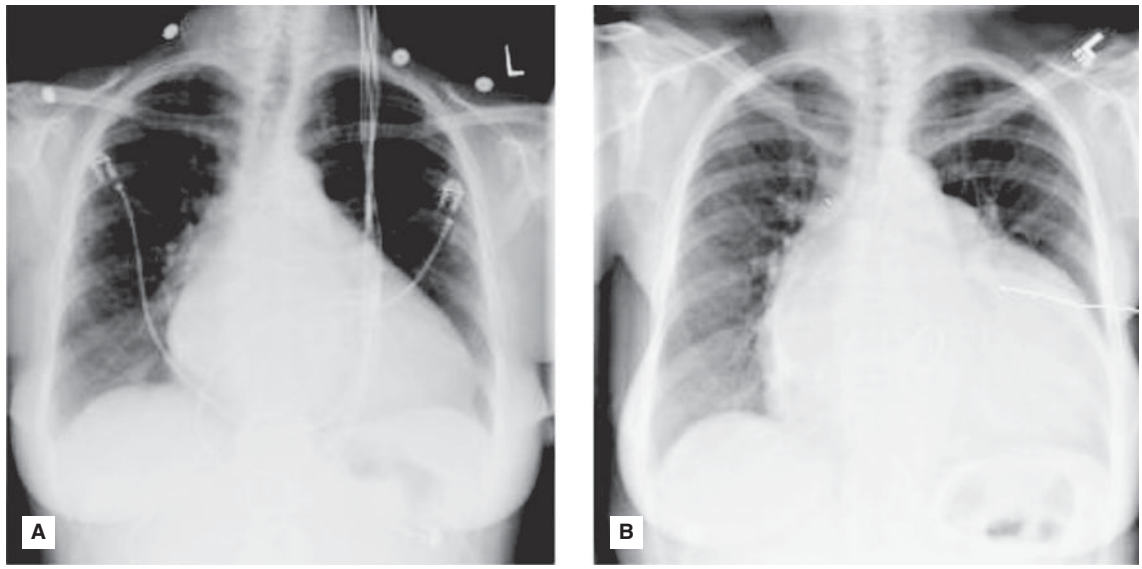

FIGURE 61-5 Slowly enlarging pericardial effusion detected on chest x-ray. (A) At discharge; (B) 3 weeks after discharge.

insidious and symptoms may be present for months or even years.[18] Common complaints include fatigue, decreased exercise tolerance with dyspnea/orthopnea, as well as peripheral edema and ascites from hepatic congestion in advanced disease. The principal etiologies behind pericardial scar formation have shifted over the past few decades, with declining incidence of infectious cases (particularly tuberculosis) and increasing incidence of iatrogenic cases (primarily from mediastinal radiation therapy and cardiac surgery).[19]

Pericardial constriction exerts its pathophysiologic effects by limiting cardiac filling. Unlike tamponade, in which cardiac filling is limited from the onset of diastole, constriction does not restrict filling in early diastole. During diastolic filling the ventricles are prevented from reaching full capacity as they encounter the contracted and noncompliant pericardium. As a result, 70 to 80% of diastolic filling occurs in the first 25 to 30% of diastole.[20] Although early diastolic filling pressures are normal (whereas ventricular expansion is not constrained by the surrounding stiff pericardium), later diastolic pressures abruptly increase. The ventricular free walls are then immobilized, leaving the interventricular septum as the last yielding structure; it is rapidly displaced in response to the sudden interventricular pressure differential. This produces the characteristic "septal bounce" seen echocardiographically. Other echocardiographic findings include pericardial thickening, caval plethora, and small chamber volumes. Inspiration exaggerates both leftward septal deviation as well as reciprocal Doppler flows between the right and left sides (the echocardiographic correlate of pulsus paradoxus).

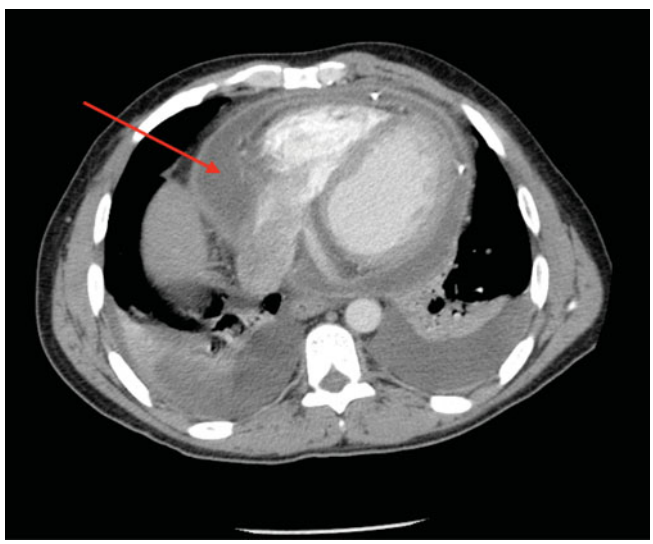

FIGURE 61-6 CT scan with large circumferential pericardial effusion and bilateral pleural effusions.

Modern axial imaging with spiral computed tomographic (CT) scanning (Fig. 61-8) or magnetic resonance (MR) imaging (Fig. 61-9) is often able to visualize thickened and/or calcified pericardium, with or without coexisting effusion. Dynamic CT and MR imaging also demonstrate many of the physiologic features seen sonographically.[21] Importantly, although pericardial thickening is usually present in constrictive pericarditis, it remains possible to have CP with normal pericardial thickness as well as thickening of the pericardium without CP.[22]

Prior to the modern era of echocardiography and axial imaging, the diagnosis of CP was dependent on hemodynamic tracings obtained during cardiac catheterization. The sudden increase in diastolic ventricular pressure is reflected in the dip and plateau or "square-root" sign (Fig 61-10). Similarly, right atrial pressure tracings reveal a steep *y* descent, which correlates with the nadir of the square-root sign. Under normal circumstances, inspiration results in a 3- to 7-mm Hg drop in right atrial pressure. The high pressure of pericardial constriction prevents the right atrium from accepting inspiratory acceleration of blood from the central veins. Instead, neck veins become prominently distended during inspiration in patients with CP, a phenomenon referred to as *Kussmaul's sign.*

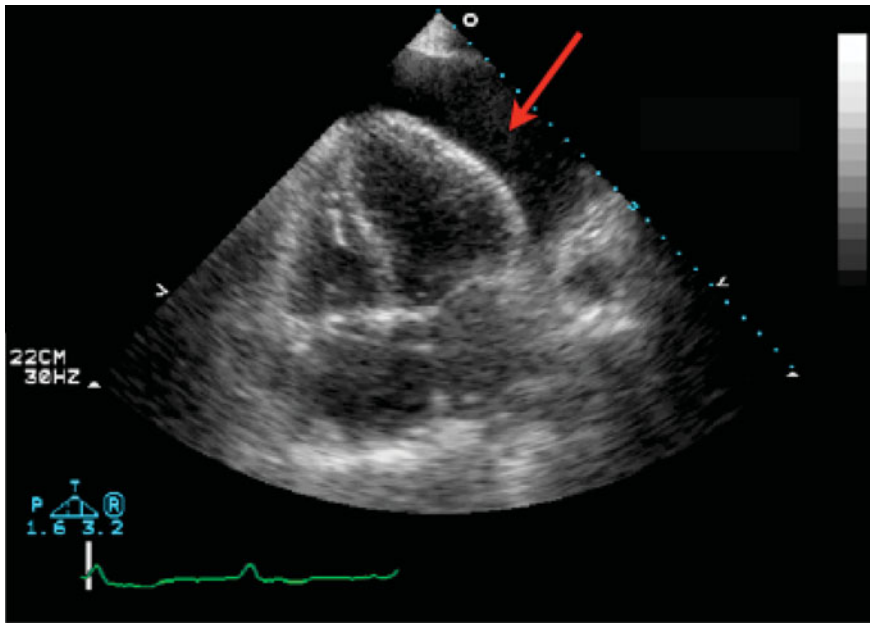

FIGURE 61-7 Transesophageal echocardiogram with very large pericardial effusion.

Catheterization remains a valuable illustration of the underlying physiology of CP. In some cases it may help differentiate between CP and restrictive cardiomyopathy (RCM), a nonsurgical condition with a poor prognosis.[23,24] RCM is characterized by noncompliant ventricular muscle and diastolic dysfunction, which impede cardiac filling. Restrictive cardiomyopathy is caused by a variety of infiltrative or fibrosing conditions (eg, amyloidosis, sarcoidosis, radiation, carcinoid, anthracycline toxicity). Although RCM may mimic many of the presenting features of CP, it is not a surgical disease and must be distinguished from CP for this reason (Table 61-1). Systolic ventricular function may be normal or near-normal in both conditions, but pulmonary and hepatic congestion are often present in RCM. Evidence of pericardial thickening (>2 mm) favors but does not confirm the diagnosis of CP over RCM. There are instances, particularly in radiation-induced CP, in which the conditions coexist. Distinctive myocardial speckling may be found on echo with amyloidosis or other infiltrative conditions. Endomyocardial biopsy is useful to establish the presence of one of the conditions known to be associated with RCM; unfortunately, a negative biopsy does not rule it out.

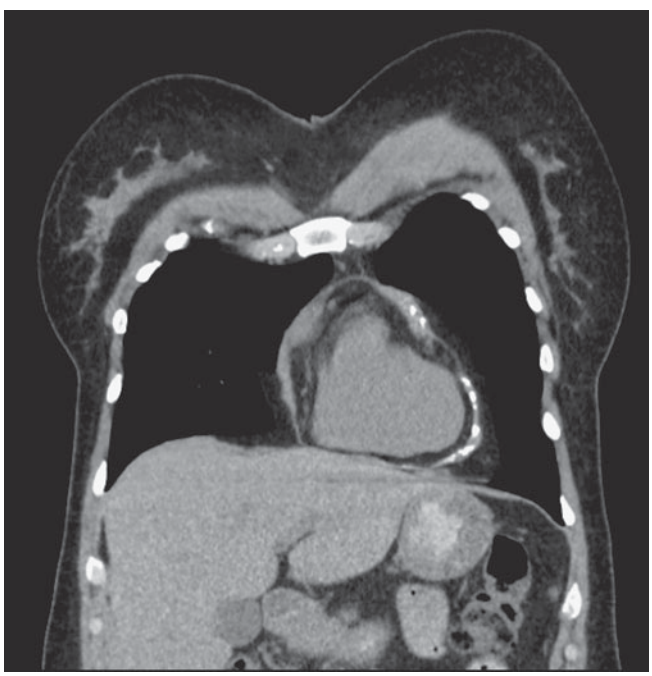

FIGURE 61-8 CT scan showing pericardial thickening and calcification.

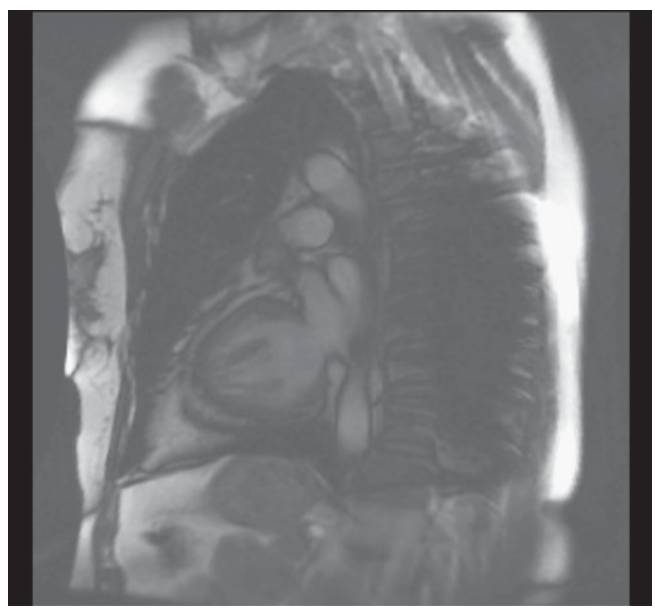

FIGURE 61-9 MRI showing pericardial thickening with pericarditis.

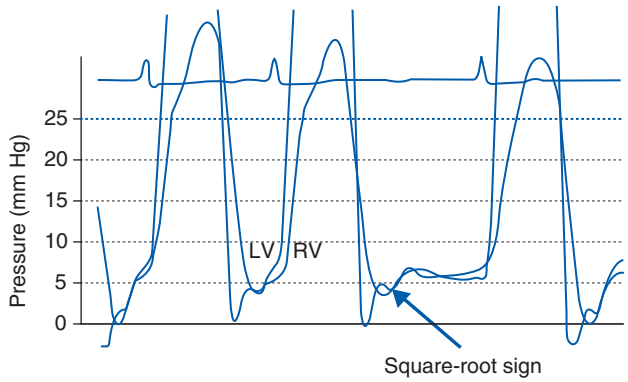

FIGURE 61-10 Square-root sign in right ventricular pressure tracing in constrictive pericarditis. (*Modified with permission from Spodick DH [ed]: The Pericardium: A Comprehensive Textbook. New York, Marcel Dekker, 1997; p 4.*)

In an attempt to provide additional criteria to differentiate patients with CP from RCM, Hurrell and colleagues[25] measured respiratory variation of the gradient between left ventricular pressure and pulmonary capillary wedge pressure during the rapid filling phase of diastole. This was done to assess the dissociation of intrathoracic and intracardiac pressures that accompanies constrictive pericarditis. A difference of 5 mm Hg in the gradient between inspiratory and expiratory cycles had 93% sensitivity and 81% specificity for constrictive pericarditis. Furthermore, increased ventricular interdependence was assessed by comparing left ventricular systolic pressure and right ventricular systolic pressure during respiration. Although concordant increases in left ventricular systolic pressure and right ventricular systolic pressure are expected during inspiration, discordant pressures are encountered during inspiration in patients with constrictive pericarditis. This finding has 100% sensitivity and 95% specificity for constrictive pericarditis.

ACQUIRED ABNORMALITIES

Pericarditis, the most common pericardial disorder, has many etiologies (Table 61-2), including infectious (viral, bacterial, fungal), metabolic (uremic, drug induced), autoimmune (arthritis, thyroid), postradiation, neoplastic, traumatic, postinfarction (Dressler's syndrome, 10 to 15%), post-pericardiotomy (5 to 30%), and idiopathic (Fig. 61-11). The clinical syndrome for all causes is similar. Chest pain (dull, aching, pressure) or chest tightness is usually present and may be associated with constitutional symptoms (eg, weakness and malaise), fever (occasionally with rigors), and other symptoms such as cough or odynophagia. The pain may be pleuritic, and thus exacerbated

TABLE 61-1 Differentiation between Constrictive Pericarditis and Restrictive Cardiomyopathy

Finding	Pericardial Constriction	Restrictive Cardiomyopathy
PHYSICAL EXAMINATION		
Pulsus paradoxus	Variable	Absent
Pericardial knock (high frequency)	Present	Absent
S3 (low frequency)	Absent	Present
HEMODYNAMICS		
Prominent *y* descent	Present	Variable
Equalization of right and left side filling pressures	Present	Left > right
RV end-diastolic pressure/systolic pressure	>1/3	<1/3
Pulmonary hypertension	Rare	Common
Square-root sign	Present	Variable
ECHOCARDIOGRAPHY		
Respiratory variation in left-right pressures/flows	Increased	Normal
Septal bounce	Present	Absent
Atrial enlargement	Variable	Biatrial
Ventricular hypertrophy	Absent	Usually present
Pericardial thickness	Increased	Normal

by inspiration, cough, or recumbency. These patients therefore often sit up and lean forward for relief. Acute disease may become chronic. The cardinal sign of pericarditis is the pericardial rub, which may be positional and muffled because of an effusion.[26]

Electrocardiography, chest x-ray, and echocardiography are useful in making the diagnosis. The electrocardiogram may range from normal, to nonspecific ST-segment deviations, to diffuse concave elevation of the ST segments without reciprocal depressions or Q waves. PR-segment depression may be present. Troponin may be elevated with a normal CPK. Ventricular arrhythmias and conduction abnormalities are not commonly seen in pericarditis and are suggestive of an underlying cardiac abnormality if present. Echocardiography may reveal fibrinous thickening of the pericardium with or without a small effusion.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay of treatment and may be supplemented with colchicine. Chronic pericardial effusion or constrictive pericarditis may follow acute pericarditis as well as tuberculosis, malignancy, radiation, rheumatoid arthritis, or surgery.[26]

Infectious Pericarditis

Viral Pericarditis

Infectious pericarditis is most often viral and results from immune complex deposits, direct viral attack, or both. The clinical syndrome involves pain, friction rub, and typical changes on the electrocardiogram. It is often difficult to diagnose and thus labeled as idiopathic disease. Treatment is expectant, and symptoms generally resolve within 2 weeks. Surgical intervention is rarely required.

Bacterial Pericarditis

This is currently an uncommon cause of pericarditis because of availability of effective antibiotic therapy. Microorganisms may invade the pericardial space from contiguous infections in the heart (endocarditis), lung (pneumonia, abscess), subdiaphragmatic space (liver or splenic abscess), or wounds (traumatic or surgical). Hematogenous seeding may also occur, most often in the setting of septicemia and immune compromise.

The most common bacteria implicated in bacterial pericarditis are *Haemophilus influenzae*, meningococci, pneumococci, staphylococci, or streptococci.[27] Gram-negative rods, *Salmonella* and opportunistic sources of infection must be excluded. Regardless of the source or organism, acute suppurative pericarditis is life threatening. A toxic presentation with a high fever is typical with an acute, fulminant clinical course. Purulent pericarditis with tamponade or septicemia may require acute surgical intervention via pericardial window or pericardiectomy and treatment of the inciting cause (eg, removal of foreign body or drainage of abscess) (Fig. 61-12). In adults, pneumopyopericardium is often caused by fistula formation between a hollow viscus and the pericardium. However, invasion from contiguous foci, implantation at the time of surgery or trauma, mediastinitis, endocarditis, and subdiaphragmatic abscess can all induce this condition. Scarring, which results in pericardial constriction, may require pericardiectomy. These patients have an excellent outcome when treated appropriately.[27]

Tuberculous Pericarditis

Although the incidence of tuberculosis (TB) has significantly declined in industrialized countries, it has increased dramatically in Africa, Asia, and Latin America, accounting for 95% of all cases of active TB. This resurgence in TB reflects the increasing incidence of human immunodeficiency virus (HIV) infection.[28] The immune response to the acid-fast bacilli penetrating the pericardium induces a delayed hypersensitivity reaction with lymphokine release and granuloma formation. Complement fixing antibodies initiate cytolysis mediated by antimyolemmal antibodies as the cause of the exudative TB pericarditis.[28] The definitive diagnosis is established by examining pericardium or pericardial fluid for mycobacteria.

FIGURE 61-13 CT scan of chronic pericardial thickening and calcification and larger pericardial effusion in a patient with TB.

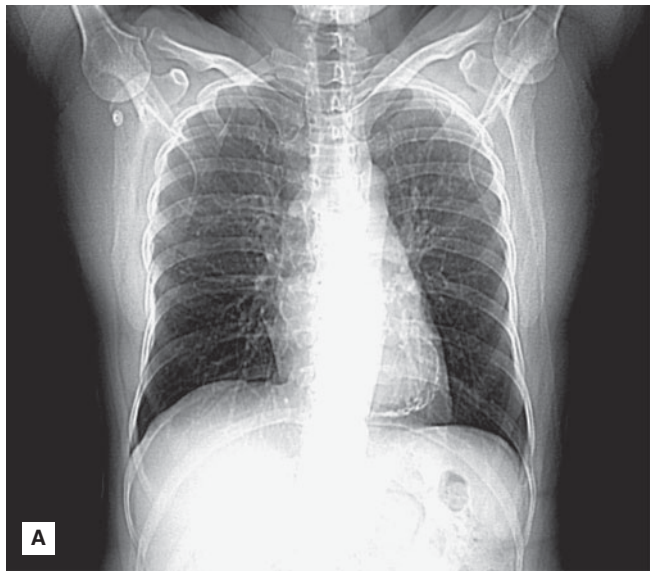
Four pathologic states are recognized:

1. Fibrinous exudation, with robust polymorphonuclear infiltration and abundant mycobacteria
2. Serous or serosanguineous effusions with a mainly lymphocytic exudation and foam cells (Fig. 61-13)
3. Absorption of effusion, with organization of caseating granulomas, and pericardial thickening caused by fibrin and collagen deposition and fibrosis
4. Constrictive scarring, often with extensive calcification occurring over a period of years (Fig. 61-14 A,B)

There is a variable clinical course. Effusion usually develops insidiously with fever, night sweats, fatigue, and weight loss to variable degrees. Children and immunocompromised patients may, however, present with a more fulminant course, often demonstrating both constrictive and tamponade physiology. Despite prompt anti-TB antibiotic treatment, constrictive pericarditis, one of the most severe sequelae, occurs in 30 to 60% of patients. Echocardiography is useful for diagnosing effusive and subacute constrictive TB pericarditis. Standard anti-TB therapy is instituted promptly. Steroids remain controversial, especially in HIV-infected patients. Based on physiology and response to therapy, immediate or interval pericardiectomy is performed to avoid chronic constrictive pericarditis. If calcific pericarditis is present, surgery is undertaken earlier.[29]

Fungal Pericarditis

Fungal infection is an uncommon cause of pericarditis. *Nocardia, Aspergillus, Candida,* and *Coccidioides* are implicated, with regional specification, in the setting of immunocompromise, debilitation, HIV, severe burns, infancy, or steroid therapy.



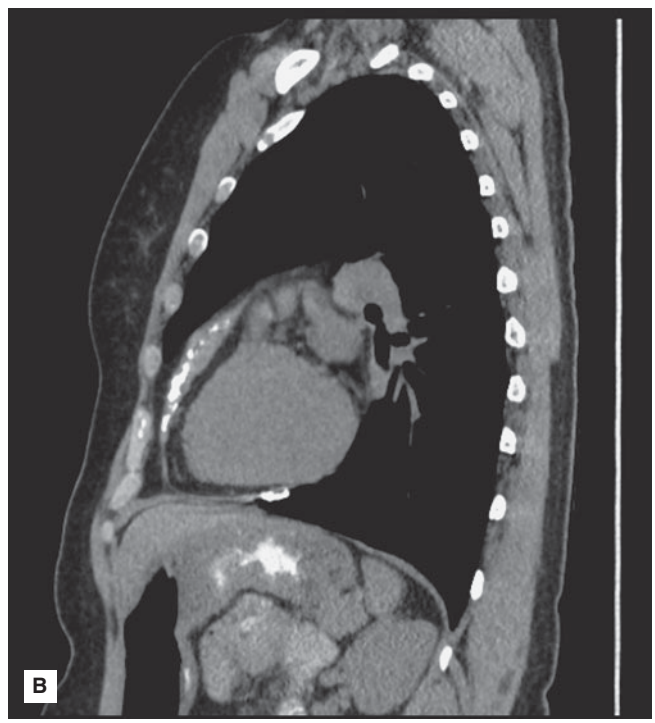


FIGURE 61-14 (A) PA CXR in patient with TB showing calcification of pericardium around LV apex. (B) CT scan of chronic pericardial thickening and calcification in patient with TB.

Candida and *Aspergillus* generate an insidious clinical picture, which may develop into tamponade or constriction. Fungi such as *Histoplasma* that tend to be endemic to certain geographic regions may cause pericarditis in young, healthy, immunocompetent patients. This is usually self-limited and resolves within 2 weeks. Similarly, *Coccidioides* can also infect young healthy individuals in the setting of pneumonia, osteomyelitis, meningitis, or adenopathy. These conditions often resolve either spontaneously or in response to appropriate antifungal regimens. Surgical intervention is not usually required in the acute setting.

Metabolic Causes of Pericarditis

Pericarditis is known to occur in the setting of renal failure, hypothyroidism, autoimmune diseases (such as rheumatoid arthritis), and pharmacotherapy with certain drugs (eg, procainamide and hydralazine).

Uremic Pericarditis

Uremic pericarditis was first recognized by Bright in 1836.[30] Although it is recognized that nitrogen retention (blood urea nitrogen levels are generally >60 mg/dL) is required for uremic pericarditis, the inciting agent is still unknown. The clinical profile typically involves a patient with chronic renal insufficiency who develops pain, fever, and a friction rub.[31] There is usually a pericardial fluid collection, which can be exudative or transudative, that is often hemorrhagic. Although the incidence of tamponade is decreasing because of more widespread use of renal replacement therapy,[32] it still occurs and remains a primary concern. Initial therapy includes NSAIDs and aggressive dialysis. Pericardial drainage is reserved for hemodynamically significant (tamponade) or refractory effusions (more than 2 weeks despite intensive dialysis), but the latter is the subject of debate.[33] Heparin should be administered cautiously, if at all, during dialysis because of the risk of hemorrhagic pericarditis and tamponade.[34] Pericardial effusions may also develop in this population because of a variety of conditions such as heart failure, volume overload, and hypoproteinemia. Nonuremic pericarditis is also known to occur in patients on longstanding dialysis.[35] Finally, pericardial effusion increases the risk of low-pressure tamponade during dialysis by mechanisms described in the preceding.[17]

Drug-Induced Pericarditis

Pericarditis may also occur in the setting of a drug-induced hypersensitivity reaction or lupus-like syndrome.[36] Procainamide, hydralazine, isoniazid, methysergide, cromolyn, penicillin, and emetine (among others) have been associated with pericardial inflammation. Minoxidil has been associated with pericardial effusion.[37] The clinical presentation and guidelines for management in these settings are similar to those for other types of pericarditis. The inciting agent should be discontinued.

Pericarditis Associated with Rheumatoid Arthritis

Pericarditis is common in patients with rheumatoid arthritis (RA). Approximately half of patients with RA have pericardial effusions, and almost half of all patients with RA have significant pericardial adhesions at autopsy.[38] The condition is encountered more often in patients with advanced RA, and is thought to be caused by the higher rheumatoid factor titers often seen with more severe underlying disease. Deposition of immune complexes in the pericardium appears to be the inciting event underlying the inflammatory response.[39] The diagnosis is often complicated by the many clinical variants and possible intercurrent diseases such as drug-induced and viral pericarditis. Pericardial drainage is often employed early for symptomatic effusions because response to medical therapy of the underlying RA is slow and unpredictable. Pericardiectomy should be considered in patients with longstanding RA who have developed constriction.[40]

Hypothyroidism

Severe hypothyroidism produces large, clear, high-protein, high-cholesterol, and high-specific-gravity effusions in 25 to 35% of patients.[41] The effusion may precede other signs of hypothyroidism. Clinical tamponade is rare because of the slow accumulation of fluid. However, acute exacerbations owing to acute pericarditis, hemorrhage, or cholesterol pericarditis can induce tamponade.[42]

Radiation Pericarditis

Radiation is now the most common etiology of constrictive pericarditis in the United States. This was first recognized in patients who received high-dose mantle radiation for Hodgkin's lymphoma in the 1960s and 1970s and developed cardiac and pericardial pathology, on average 10 to 15 years after therapy. Radiation induces acute pericarditis, pancarditis, and accelerated coronary artery disease in a dose-dependent relationship.[43] Patients may present with a combination of pericardial constriction, restrictive cardiomyopathy, valvular heart disease, and coronary artery disease with a predilection for ostial lesions.[44] When symptomatic effusions are drained, fluid should be analyzed to clarify the etiology (ie, malignancy versus radiation effect). Constrictive pericarditis can develop several years later and is best treated by pericardiectomy.[45]

Neoplastic Pericarditis

Secondary neoplasms of the pericardium (ie, tumors that involve the pericardium by metastasis or infiltration from adjoining structures) account for greater than 95% of pericardial neoplastic diseases. Primary pericardial tumors are rare, and paraneoplastic effusions can also occur in response to remote tumors.[46]

The most common secondary tumors involving the pericardium in males (including both metastasis and local extension) are carcinoma of the lung (31.7%) and esophagus (28.7%) and lymphoma (11.9%). In females, carcinoma of the lung (35.9%), lymphoma (17.0%), and carcinoma of the breast (7.5%) are most common. Primary pericardial tumors are very uncommon. Benign tumors are generally encountered in infancy or childhood. Malignant tumors such as mesotheliomas, sarcomas, and angiosarcomas most often present in the third or fourth decade of life.[47]

In both primary and secondary tumor involvement, the clinical presentation is usually silent, and may be associated with large pericardial effusions. Tamponade can result from hemorrhage into a malignant effusion. Occasionally tumors can induce constriction because of neoplastic tissue, adhesions, or both. The role of surgery is limited to diagnosis and palliation in most of these cases. Large refractory effusions associated with tamponade may need surgical drainage. In such cases, a fluid sample should be submitted to confirm the presence of malignant cells or evaluate for other causes of effusion in patients with cancer because this may influence management.[48]

In terms of therapeutic benefit, pericardiocentesis has a high failure rate, and subxiphoid drainage or percutaneous balloon pericardiotomy are only transiently effective.[49] Although extensive resection and debulking may be necessary in persistent or recurrent malignant pericardial constriction, it has only transient benefit without effective adjunctive chemotherapy and/or radiation therapy. Life expectancy of patients with malignant pericardial involvement averages less than 4 months.[50] The surgeon should individualize decisions regarding how aggressively to pursue diagnostic or therapeutic interventions.

Traumatic Pericardial Conditions

Penetrating Trauma

Knives, bullets, needles, and intracardiac instrumentation are the most common causes of penetrating trauma to the pericardium and heart. Tamponade is more common in stab wounds than gunshot wounds. The right ventricle is most often involved in anterior chest wounds. Because tamponade provides hemostasis and prevents exsanguination, patients with tamponade have better survival than those with uncontrolled hemorrhage from a penetrating cardiac injury. Diagnosis is often made on clinical grounds supplemented by ultrasonography.[51] Stable patients can be explored in the operating theater, but unstable patients should undergo thoracotomy in the emergency department.

Blunt Trauma

Blunt injuries to the heart and pericardium rarely occur in isolation. Trauma owing to compression (including cardiopulmonary resuscitation), blast, and deceleration can produce a spectrum of injuries ranging from cardiac contusion to cardiac rupture and pericardial laceration with herniation or luxation of the heart. Patients with pericardial rupture and cardiac herniation typically have suffered high-energy deceleration trauma and are invariably hypotensive from associated injuries. Hypovolemia may lead to rapid decompensation because cardiac filling becomes increasingly volume dependent in the setting of tamponade. Likewise, patients may initially respond to volume resuscitation. Chest imaging may demonstrate displacement of the heart or presence of free air or intra-abdominal organs within the pericardium. If the heart herniates into the pleura, positioning the patient with the contralateral side down may reduce the herniation. Thoracotomy is required for definitive treatment and repair of associated injuries.[52]

Acute Postinfarction Pericarditis and Dressler's Syndrome

Postinfarction pericarditis is thought to occur in almost half of patients suffering a transmural myocardial infarction (MI), although it is symptomatic in far fewer. The incidence is decreasing because of more aggressive revascularization in recent decades. Chest pain is almost universally present, and it is important to distinguish the pain of pericarditis from ischemic pain by its positional and pleuritic nature. The pain of early post-MI pericarditis occurs in the first 24 to 72 hours. Dressler's syndrome is a diffuse pleuropericardial inflammation thought to have an autoimmune etiology that occurs weeks to months after infarction. A pericardial rub and effusion may be present but tamponade is rare. In Dressler's syndrome, a pleural rub and effusion may also be present. The electrocardiographic signs of pericarditis may be obscured by those of infarction. Post-MI pericarditis is typically treated with aspirin and/or NSAIDs.[53,54] Steroids or colchicine may be used for persistent or recurrent symptoms; however, glucocorticoid use is associated with recurrence of pericarditis.[55]

Cardiac Surgery and the Pericardium

Postinfarction Pericarditis

Postinfarction pericarditis, as described in the preceding, is an important entity for the surgeon to consider in the evaluation of patients with acute coronary syndromes. To the unwary it may masquerade as postinfarction angina and prompt an unnecessarily early operation after myocardial infarction. Extensive fibrinous adhesions and murky gelatinous fluid may be present in the pericardial space and obscure epicardial vessels. When the pericardium is opened late in such a patient, the surgeon should expect dense pericardial adhesions.

Postpericardiotomy Syndrome

Pericardial friction rubs are almost universal after cardiac surgery; some patients develop Dressler's syndrome with pleural and pericardial effusions, pleuritic pain, and generalized malaise. Such patients almost always respond to NSAIDs or a short course of corticosteroids when the symptoms remain refractory.[56] Although this condition is benign, it is important (and sometimes difficult) to distinguish between postoperative pericarditis and myocardial ischemia. This distinction can often be made on clinical grounds based on symptoms, hemodynamics, and pattern of ECG changes.[57] Echocardiography or angiography may be used in borderline cases to clarify the etiology.

Postoperative Tamponade

Early postoperative tamponade rarely goes undetected for long because of the high level of vigilance and close hemodynamic monitoring that attend the patient during this time. A vital feature of postoperative tamponade is that a circumferential fluid collection is not required for compromised cardiac function. Hemodynamic deterioration can occur in the setting of localized clot within the pericardium, particularly if it is impinging on the right heart.[58] It is also important for surgeons to be aware of the potential for late cardiac tamponade that presents after hospital discharge and often to a clinician other than the cardiac surgeon. This entity is a potentially lethal complication and occurs in 0.5 to 6% of patients after heart surgery, almost exclusively in those on anticoagulation. Late cardiac tamponade (ie, tamponade occurring more than 7 days after cardiac surgery) is more common in younger patients who have undergone isolated valve (as opposed to coronary artery bypass graft) surgery. Patients present on average 3 weeks after surgery, frequently in the setting of an elevated prothrombin time. They are often severely symptomatic, with declining exercise tolerance, dyspnea, an inability to urinate, and sometimes hypotension. Any patient

on anticoagulation whose recovery begins an otherwise unexplained decline in this interval should be suspected of having late tamponade and undergo echocardiographic examination. Nearly all patients with late tamponade respond favorably to pericardiocentesis, and are able to safely resume anticoagulation.[59]

Pericardial Closure

Redo sternotomy may be more hazardous when the heart is adherent to the inner table of the sternum. Closing the pericardium at the time of surgery interposes a protective layer of tissue between the sternum and the heart and may reduce the risks of redo sternotomy. The value of any added protection against cardiac injury on sternal reentry is limited by the relative infrequency of reoperation and the already low incidence of cardiac injury at repeat sternotomy when the pericardium is left open. On the negative side, closing the pericardium can cause kinking of bypass grafts after coronary bypass surgery and may result in hemodynamic compromise caused by cardiac compression.

Several small studies have attempted to answer the question of whether pericardial closure should be performed after cardiac procedures. Rao and associates demonstrated that pericardial closure at the time of cardiac surgery adversely affects postoperative hemodynamics.[60] In this ingenious study, the pericardial edges were marked with radiopaque markers and the pericardium was closed with a running suture, the ends of which were exteriorized. After obtaining a postoperative chest film that demonstrated pericardial approximation, a set of baseline hemodynamics was measured. The suture was then removed, another x-ray taken to demonstrate distraction of the pericardial edges, and then the hemodynamic measurements were repeated. Pericardial closure reproducibly resulted in transient, moderate hemodynamic compromise in the first 8 hours after operation (Table 61-3). Although this and other studies have demonstrated adverse short-term hemodynamic consequences of pericardial closure, none have yet reported clinical evidence of worse outcomes.[61] Therefore, the risks of pericardial closure must be weighed against its potential benefits and clinical practice should be individualized to the patient.

OPERATIONS

Mediastinal Reexploration

Postoperative hemorrhage complicates approximately 3 to 5% of cardiac operations, a risk that nearly doubles in the setting of reoperations or valve surgery.[62] Common management for the postoperative cardiac surgical patient involves leaving the pericardium open and placing anterior and posterior mediastinal drains. Despite this, postoperative tamponade may still occur. The typical scenario involves declining chest tube output after a period of early postoperative bleeding, development of tachycardia, narrowing of the pulse pressure, increasing right-sided filling pressures, decreasing urine output, acidosis, escalating requirement for inotropes or vasopressors, and decreasing cardiac index. Echocardiography is not routinely helpful because the pericardial space and any associated thrombus may be difficult to visualize in the immediate postoperative period. Subtle echocardiographic findings that have been reported include an inspiratory increase in right ventricular end-diastolic diameter and a reciprocal decrease in left ventricular end-diastolic diameter,[63] as well as an increase in early peak tricuspid flow velocity and reduction in flow across the mitral valve.[64] Because postoperative hemorrhage and tamponade can precipitate rapid deterioration, expedient mediastinal drainage is imperative. The importance of simultaneous correction of coagulopathy, hypothermia, acidosis, and hypovolemia cannot be overstated.[65] Extreme circumstances may dictate that a temporizing decompression be performed in the intensive care unit (ICU) followed by definitive management in the operating room. Reported outcomes among patients explored in the ICU include perioperative survival of 85% and sternal wound infection rate as low as 2%.[66]

TABLE 61-3 Structural and Hemodynamic Changes after Pericardial Closure in Patients Undergoing Elective Isolated Coronary Artery Bypass Grafting

Parameters Measured	Open Pericardium	Closed Pericardium	*p*-value
Retrosternal space at 1 wk (cm)	13 ± 5	20 ± 7	.0003
Retrosternal space at 3 mo (cm)	7 ± 3	14 ± 7	.0001
CI L/min/m^2 1 h postoperation	3.1 ± 0.8	2.3 ± 0.6	.003
CI L/min/m^2 4 h postoperation	3.1 ± 0.9	2.7 ± 0.7	.156
CI L/min/m^2 8 h postoperation	3.0 ± 0.8	2.8 ± 0.5	.402
LVSWI g/m/m^2 1 h postoperation	72 ± 18	52 ± 13	.002
LVSWI g/m/m^2 4 h postoperation	68 ± 17	54 ± 8	.016
LVSWI g/m/m^2 8 h postoperation	62 ± 22	52 ± 10	.087

CI = cardiac index; LVSWI = left ventricular stroke work index.

During reexploration the first priority is to achieve prompt relief of tamponade by evacuating retained mediastinal blood and controlling sources of life-threatening hemorrhage. Dramatic hemodynamic improvement is frequently observed upon reopening the chest. Next, mediastinal reexploration is undertaken in a thorough and methodical manner with careful attention to all suture lines. Complete mediastinal evaluation should be performed even if the culprit source is thought to be identified. Inspection usually proceeds from top down while simultaneously obtaining hemostasis; this approach prevents "run-down" from obscuring small sources of bleeding. Copious warm saline irrigation and judicious use of gauze packing are helpful adjuncts.

Pericardiocentesis

Pericardiocentesis is usually performed in a procedure suite under fluoroscopic, sonographic, or computed tomographic guidance.[67] Arterial and right heart catheterizations are often performed for hemodynamic monitoring. After administration of 1% lidocaine to the skin and the deeper tissues of the left xiphocostal area, a 25-mL syringe is affixed to a three-way stopcock and then to an 18-gauge spinal needle. This pericardial needle is connected to an electrocardiograph V lead. Under electrocardiographic and imaging guidance, the needle is advanced from the left of the subxiphoid area aiming toward the left shoulder. ST-segment elevation may be seen on the V lead tracing when the needle touches the epicardium. Under these circumstances, the needle is retracted slightly until ST-segment elevation disappears. Once the pericardial space is entered, a guidewire is introduced into the pericardial space through the needle. The needle is removed and a catheter is inserted into the pericardial sac over the guidewire. At our institution, a pigtail-shaped drainage catheter with an end hole and multiple side holes is used. Intrapericardial pressure is measured by attaching a pressure transducer system to the intrapericardial catheter. Pericardial fluid may then be removed. Symptom relief may be immediate and dramatic. In the presence of pericardial tamponade, aspiration of fluid is continued until there is clear clinical and hemodynamic improvement. If blood is withdrawn, 5 mL should be placed on a sponge to see if it clots. Clotting blood suggests that the needle has either inadvertently entered a cardiac chamber or caused epicardial injury. Defibrinated blood that has been present in the pericardial space for even a short time usually does not clot. The pericardial space is drained every 8 hours and the catheter is flushed with heparinized solution and in general is removed within the next 24 to 72 hours. Pneumothorax is a potential complication, and chest radiography is mandatory after the procedure.

Pericardial Window

The purpose of partial pericardial resection (window) is to drain fluid into the pleural or peritoneal compartment to prevent reaccumulation. The procedure can be performed via thoracoscopy, anterior thoracotomy, or subxiphoid incision; although each approach has its unique merits, reported outcomes among the three are relatively similar.[68,69] General anesthesia may not be tolerated by some patients in tamponade, in which case the subxiphoid approach under local anesthesia in a semirecumbent position can be employed. When the pericardium is incised, fluid will invariably drain under pressure. The excised portion of pericardium should be as large as is feasible to prevent recurrence.[70] The surgeon should remain mindful of the rare possibility of cardiac prolapse. With the transthoracic or thoracoscopic approaches, all accessible pericardium ventral to the phrenic nerve should be excised. Similarly, via the subxiphoid approach, as much diaphragmatic pericardium should be excised as possible.

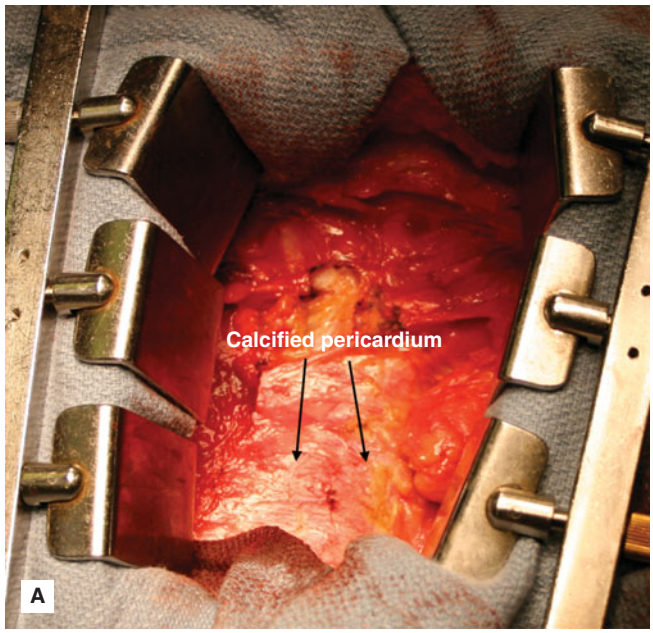
Pericardiectomy

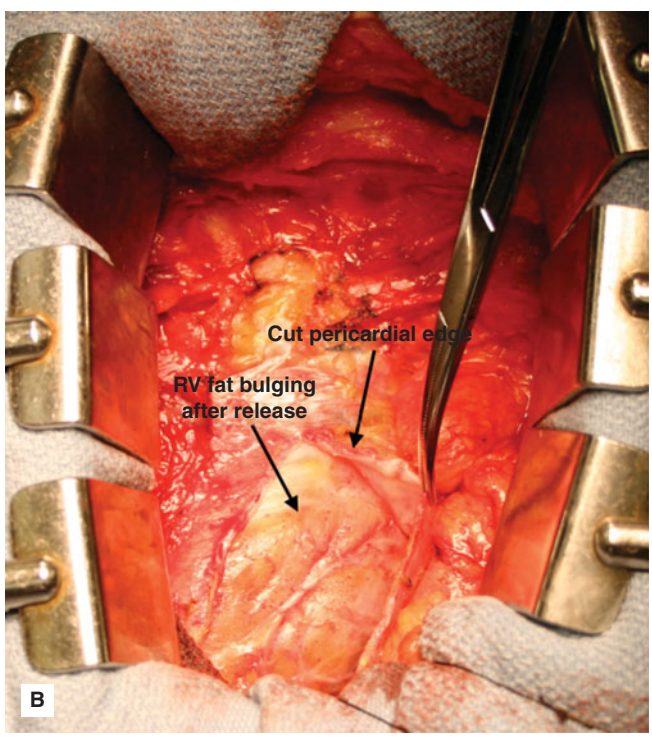
Chronic pericardial constriction is treated by pericardial excision (Fig. 61-15). Because dense adhesions and calcification can penetrate into the myocardium, pericardial resection can be technically challenging. At most centers, the procedure is done via median sternotomy with the capability to use cardiopulmonary bypass as needed.[29] Practice is variable, as some use cardiopulmonary bypass routinely, whereas others prefer to avoid the additional burden of coagulopathy unless absolutely necessary. Also, some surgeons prefer the countertraction provided by the filled heart, which facilitates pericardial stripping. Some surgeons use a left anterior thoracotomy, the approach taken by Edward Churchill, who reported the first pericardiectomy for CP done in the United States.[71] The objective of the procedure is to release the ventricles from the densely adherent pericardial shell. The lack of a surgical plane can make this a bloody operation, and attention must be paid to salvage and reinfusion of blood. Epicardial coronary vessels are at risk in this dissection, and particular care must be taken when dissecting in the regions of these vessels. The goal is to excise all anterior pericardium between the phrenic nerves as well as the posterior pericardium around its reflection on the venae cavae and pulmonary veins. Complete resection should restore pressure-volume loops to their normal position. Complete pericardial resection is not feasible in all cases, notably with radiation-induced disease, and leaving densely adherent scar, particularly over the venae cavae and atria, may be safer for the patient.

The results vary with the etiology and severity of the disease. Operative mortality has been reported as high as 10 to 20%,[72] but is typically 5 to 6% in most contemporary series,[73] and varies based on severity of heart failure, elevation of right atrial pressure, and comorbidities.[74] Although surgery alleviates or improves symptoms in the vast majority of patients, long-term survival is diminished in patients who have had prior heart surgery, and particularly in patients with radiation-induced constrictive pericarditis (Fig. 61-16).[75]

KEY POINTS

- Tamponade occurs when intrapericardial pressure impedes cardiac filling, causing increased venous pressure, decreased cardiac output and progression to shock, and death if left untreated.
- Pericardial reserve volume is limited; therefore, acute fluid collections can rapidly produce tamponade.





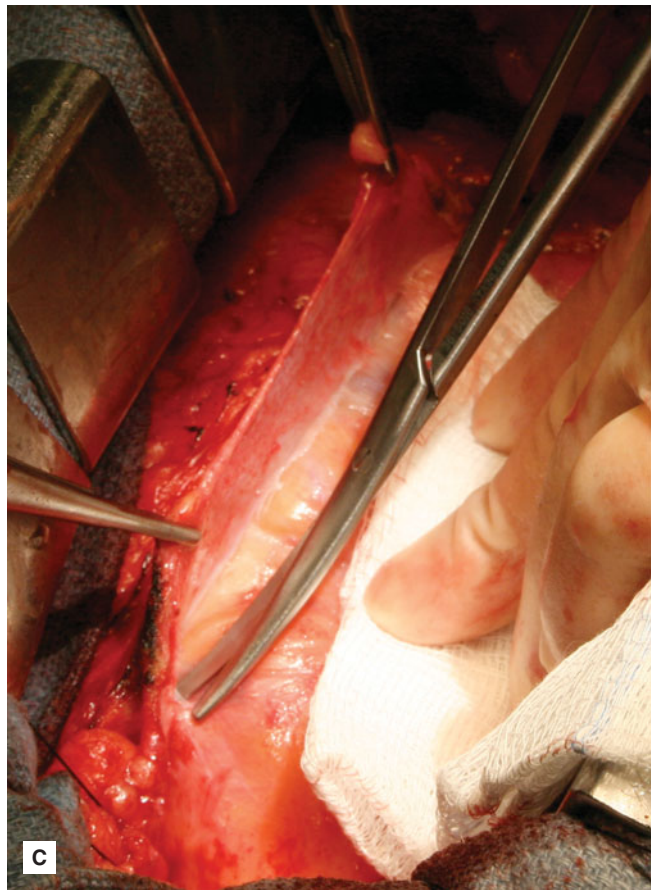


FIGURE 61-15 (A) Intraoperative photograph of TB pericardial thickening and calcification causing severe constriction. (B) Intraoperative photograph of pericardiectomy for constrictive TB pericarditis with RV free wall bulging through opening in pericardium, thick pericardial edge. (C) Adhesive pericarditis discovered incidentally in CABG patient. Technique for dividing adhesions over left ventricle and pulmonary artery.

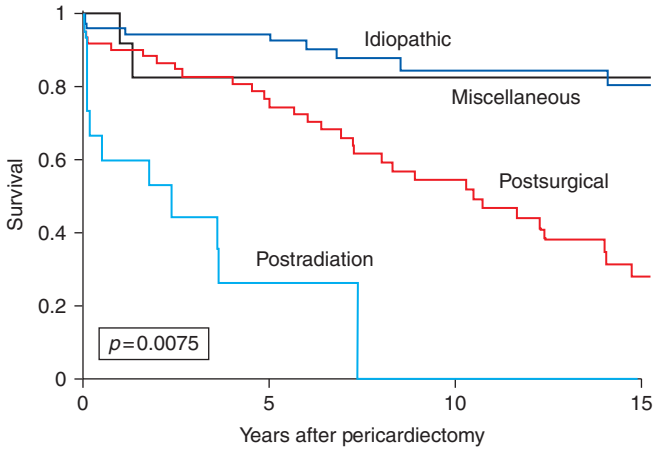
- Constrictive pericarditis, the end result of several inflammatory conditions, is characterized by a prominent *y* descent, square-root sign, septal bounce, and exaggerated respiratory variation in right- and left-sided flows; it is best treated with pericardiectomy.
- Restrictive cardiomyopathy, a myocardial disorder causing diastolic heart failure, is differentiated from pericardial constriction by the presence of pulmonary hypertension, biatrial enlargement and ventricular thickening; it is not treated surgically.
- Patients with pericardial disease should undergo echocardiography supplemented as needed with catheter-based hemodynamic measurements or drainage for diagnosis.
- Acute pericarditis is often self-limited and responds to NSAIDs.
- The underlying disorder in secondary pericarditis can often be modified to improve the course of the associated pericardial disease.
- Intervention for postoperative hemorrhage and tamponade is required in less than 5% of cardiac surgical cases.



Number at risk				
Idiopathic	75	48	30	21
Miscellaneous	12	10	10	5
Post-surgical	60	38	24	9

It should be undertaken promptly (in the ICU if necessary) with concurrent correction of coagulopathy, hypovolemia, hypothermia, and acidosis.

- Pericardiectomy is associated with decreased short- and long-term survival because of the severity of associated illnesses.

ACKNOWLEDGMENT

The authors would like to thank Mark S. Adams for the preparation of the figures, echocardiographic images, and photographs for the chapter.

CHAPTER 62

Cardiac Neoplasms

Shanda H. Blackmon
Michael J. Reardon

INTRODUCTION

Neoplasms of the heart can be divided into primary cardiac tumors arising in the heart and secondary cardiac tumors from metastasis. Primary cardiac tumors can be further stratified into benign and malignant tumors. Between 10 and 20% of patients dying of disseminated cancer have metastatic involvement of the heart or pericardium.[1,2] Surgical resection is seldom possible or advisable for these tumors, and intervention usually is limited to drainage of malignant pericardial effusions and/or diagnostic biopsies.

The incidence of primary cardiac neoplasm ranges between 0.17 and 0.19% in unselected autopsy series.[3-5] Seventy-five percent of primary cardiac tumors are benign, and 25% are malignant.[2,6] Fifty percent of the benign tumors are myxomas, and 75% of malignant tumors are sarcomas.[2,6] The clinical incidence of these tumors is 1 in 500 cardiac surgical patients. With the exception of myxomas, most surgeons will rarely encounter primary cardiac tumors. The purpose of this chapter is to summarize useful information for the evaluation and management of patients with cardiac tumors and to provide a reference for additional study.

HISTORICAL BACKGROUND

A primary cardiac neoplasm was first described by Realdo Colombo in 1559.[7] Alden Allen Burns of Edinburgh described a cardiac neoplasm and suggested valvular obstruction by an atrial tumor in 1809.[8] A series of six atrial tumors, with characteristics we now recognize as myxoma, was published in 1845 by King.[9] In 1931, Yates reported nine cases of primary cardiac tumor and established a classification system similar to what we use today.[10] The first antemortem diagnosis of a cardiac tumor was made in 1934 when Barnes diagnosed a cardiac sarcoma using electrocardiography and biopsy of a metastatic lymph node.[11] In 1936, Beck successfully resected a teratoma external to the right ventricle,[12] and Mauer removed a left ventricular lipoma in 1951.[13] Treatment of cardiac tumors was profoundly influenced by two events: the introduction of cardiopulmonary bypass in 1953 by John Gibbon, which allowed a safe and reproducible approach to the cardiac chambers, and the introduction of cardiac echocardiography, which allowed safe and noninvasive diagnosis of an intracardiac mass. The first echocardiographic diagnosis of an intracardiac tumor was made in 1959.[14] An intracardiac myxoma was diagnosed by angiography in 1952 by Goldberg, but attempts at surgical removal were unsuccessful.[9] A large right atrial myxoma was removed by Bhanson in 1952 using caval inflow occlusion, but the patient died 24 days later.[15] Crafoord in Sweden first successfully removed a left atrial myxoma in 1954 using cardiopulmonary bypass,[16] and Kay in Los Angeles first removed a left ventricular myxoma in 1959.[17] By 1964, 60 atrial myxomas had been removed successfully, with improved results owing to the increasing safety of cardiopulmonary bypass and use of echocardiography for detection. Operations are currently performed routinely on patients with atrial myxoma with minimal mortality.[6,18–21] Primary malignant tumors, however, continue to represent a challenge.

CLASSIFICATION

A pathologic classification is listed in Table 62-1. Mural thrombus is listed as a pseudotumor, although not really a cardiac tumor, its presentation may mimic myxoma clinically and pathologically. Most mural thrombi are associated with underlying valvular disease, myocardial infarction, dysfunction, or atrial fibrillation.[22] Mural thrombi also have been noted in

TABLE 62-1 Types of Cardiac Tumors by Pathology

Pseudotumors
Mural thrombi
Heterotopias and Tumors of Ectopic Tissue
Tumors of the atrioventricular nodal region
Teratoma
Ectopic thyroid
Tumors of Mesenchymal Tissue
Hamartoma of endocardial tissue
Papillary fibroelastoma
Hamartomas of Cardiac Muscle
Rhabdomyoma
Histiocytoid cardiomyopathy (Purkinje cell hamartoma)
Tumors and Neoplasms of Fat
Lipomatous hypertrophy, interarterial septum
Lipoma
Liposarcoma
Tumors and Neoplasms of Fibrous and Myofibroblastic Tissue
Fibroma
Inflammatory pseudotumor (inflammatory myofibroblastic tumor)
Sarcomas (malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma)
Vascular Tumors and Neoplasms
Hemangioma
Epithelioid hemangioendothelioma
Angiosarcoma
Neoplasm of Uncertain Histogenesis
Myxoma
Neoplasms of neural tissue
Granular cell tumor
Schwannoma/neurofibroma
Paraganglioma
Malignant schwannoma/neurofibrosarcoma (rare)
Malignant Lymphoma
Malignant Mesothelioma
Metastatic Tumors to the Heart

hypercoagulable syndromes, particularly antiphospholipid syndrome.[23] With increasing use of long-term central catheters, we have seen several right atrial masses that were difficult to define and upon removal were mural thrombi.

Heterotopias and tumors of ectopic tissue include cystic tumors of the atrioventricular node consisting of multiple benign cysts in the region of the atrioventricular node that can cause heart block or sudden death. Most are diagnosed at autopsy, but a biopsy diagnosis of atrioventricular nodal tumor has been reported.[24] Germ cell tumors of the heart usually are teratomas, occurring within the pericardial sac, but yolk sac tumors have been described in infants and children.[25] Ectopic thyroid tissue may occur within the myocardium and is referred to as *struma cordis*. Right ventricular outflow track obstruction may be present, but most patients are asymptomatic.

Most of the remaining tumors arise in the mesenchymal, fat, fibrous, neural, or vascular cells of the heart, with myxoma representing a tumor of undetermined histogenesis. Primary cardiac lymphoma, mesothelioma, and metastatic tumors to the heart represent the remaining pathologic categories that comprise the greater part of this chapter.

PRIMARY BENIGN TUMORS

Myxoma

Myxomata comprise 50% of all benign cardiac tumors in adults and 15% of such tumors in children. Occurrence during infancy is rare (Tables 62-2 and 62-3). A vast majority of myxomas occur sporadically and tend to be more common in women.[4,21] The peak incidence is between the third and sixth decades of life, and 94% of tumors are solitary.[26] Approximately 75% occur in the left atrium[28] and 10 to 20% occur in the right atrium. The remaining proportion are equally distributed between the ventricles.[2] The deoxyribonucleic acid (DNA) genotype of sporadic myxomas is normal in 80% of patients.[27] Myxomas are unlikely to be associated with other abnormal conditions and have a low recurrence rate.[4,28]

About 5% of myxoma patients show a familial pattern of tumor development based on autosomal dominant inheritance.[29,37,38] These patients and 20% of those with sporadic myxoma have an abnormal DNA genotype chromosomal pattern.[27] In contrast to the "typical" sporadic myxoma profile, familial patients are more likely to be younger, equally likely to be male or female, and more often (22%) have multicentric tumors originating from either the atrium or ventricle.[30-34] Although familial myxomas have the same histology, they have a higher recurrence rate after surgical resection (21 to 67%).[28,35] Approximately 20% of familial patients have associated conditions such as adrenocortical

TABLE 62-2 Benign Cardiac Neoplasms in Adults

Tumor	No.	Percentage
Myxoma	118	49
Lipoma	45	19
Papillary fibroelastoma	42	17
Hemangioma	11	5
AV node mesothelioma	9	4
Fibroma	5	2

nodule hyperplasia, Sertoli cell tumors of the testes, pituitary tumors, multiple myxoid breast fibroadenomas, cutaneous myomas, and facial or labial pigmented spots.[26,35] These conditions often are described as *complex myxomas* within the group of familial myxoma.[27] A familial syndrome with autosomal X-linked inheritance characterized by primary pigmented nodular adrenocortical disease with hypercortisolism, cutaneous pigmentous lentigines, and cardiac myxoma is referred to as *Carney's complex.*[26,35]

Pathology

Both biatrial and multicentric myxomas are more common in familial disease. Biatrial tumors probably arise from bidirectional growth of a tumor originating within the atrial septum.[36] Atrial myxomas generally arise from the interatrial septum at the border of the fossa ovalis but can originate anywhere within the atrium, including the appendage.[4] In addition, isolated reports confirm that myxomas can arise from the cardiac valves, pulmonary artery and vein, and vena cava.[37,38] Right atrial myxomas are more likely to have broad-based attachments than left atrial tumors; they also are more likely to be calcified,[32] and thus visible on chest radiographs. Ventricular myxomas occur more often in women and children and may be multicentric.[2,39] Right ventricular tumors typically arise from the free wall, and left ventricular tumors tend to originate in the proximity of the posterior papillary muscle.

Grossly, about two-thirds of myxomas are round or oval tumors with a smooth or lobulated surface (Fig. 62-1).[21] Most are polypoid, compact, pedunculated, mobile, and not likely to fragment spontaneously.[2,4] Mobility depends on stalk length, the extent of attachment to the heart, and the amount of tumor collagen.[4] Most are pedunculated with a short, broad base, and sessile forms are unusual.[2,40] Less common villous or papillary myxomas are gelatinous and fragile and prone to fragmentation and embolization, occurring about one-third of the time.[21,41] Myxomas are white, yellow, or brown in color, and are frequently covered with thrombus.[2] Focal areas of hemorrhage, cyst formation, or necrosis may be seen in cut section. The average size is about 5 cm in diameter, but growth to 15 cm in diameter and larger has been reported.[4] Myxomatous tumors appear to grow rapidly, but growth rates vary, and occasionally, tumor growth arrests spontaneously.[4] Weights range from 8 to 175 g, with a mean between 50 and 60 g.[5]

Histologically, myxomas are composed of polygonal-shaped cells and capillary channels within an acid mucopolysaccharide matrix.[4] The cells appear singularly or in small clusters throughout the matrix, and mitoses are rare.[42,51] The matrix also contains occasional smooth muscle cells, reticulocytes, collagen, elastin fibers, and a few blood cells. Cyst, areas of hemorrhage, and foci of extramedullary hematopoiesis are also found.[35,41] Ten percent of the tumors have microscopic deposits of calcium and metastatic bone deposits, as well as sometimes glandular-like structures.[35,41] The base of the tumor contains a large artery and veins that connect with the subendocardium but do not

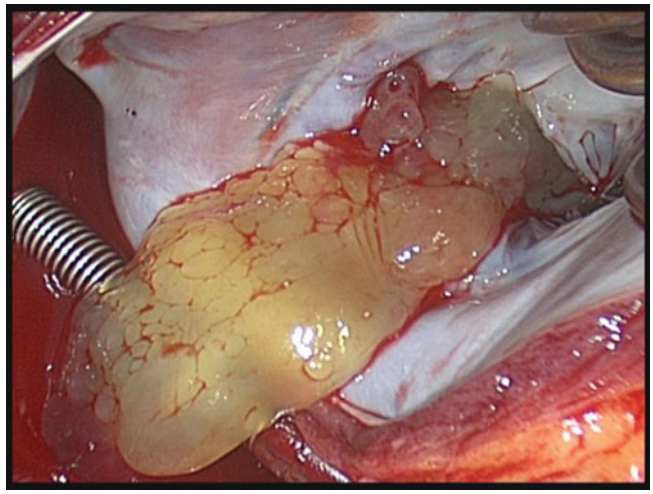

FIGURE 62-1 Large in situ left atrial myxoma as seen from the surgeon's perspective just before removal.

typically extend deep beyond the subendocardium.[35] A coronary angiography in our own institution revealed a large feeding vessel and was suspected originally of being an angiosarcoma but on histology proved to be a typical benign myxoma. Myxomas tend to grow into the overlying cardiac cavity rather than into the surrounding myocardium. Myxomas arise from the endocardium and are considered derivative of the subendocardial multipotential mesenchymal cell.[43,44,45] This accounts for the occasional presence of hematopoietic tissue and bone in these tumors. Interestingly, myxomas have developed after cardiac trauma, including repair of atrial septal defects and trans-septal puncture for percutaneous dilatation of the mitral valve.

Clinical Presentation

The classic clinical presentation of a myxoma is intracardiac obstruction with congestive heart failure (67%); signs of embolization (29%); systemic or constitutional symptoms of fever (19%); weight loss or fatigue (17%); and immunologic manifestations of myalgia, weakness, and arthralgia (5%).[21] Cardiac rhythm disturbances and infection occur less frequently.

Constitutional Symptoms. Nearly all myxoma patients admit to a variety of constitutional symptoms. These complaints may be accompanied by a leukocytosis, elevated erythrocyte levels and sedimentation rate, hemolytic anemia, thrombocytopenia, and elevated C-reactive protein. Immunoelectrophoresis may reveal abnormal immunoglobulin levels with increased circulating IgG.[46] The recent discovery of elevated levels of interleukin-6 in patients with myxoma has been linked to a variety of associated conditions, including lymphadenopathy, tumor metastasis, ventricular hypertrophy, and development of constitutional symptoms.[39,47,48] Other less frequent complaints include Raynaud's phenomenon, arthralgias, myalgias, erythematous rash, and clubbing of the digits.[4,49]

Possible etiologies of such varied complaints and symptoms include tumor embolization with secondary myalgias and arthralgias and elevated immunoglobulin response.[50] Circulating antibody–tumor antigen complexes with complement activation also may play a role.[51] Such symptom complexes tend to resolve following surgical resection of the tumor.[52]

Obstruction. Obstruction of blood flow in the heart is the most common cause of acute presenting symptoms. The nature of these symptoms is determined by which of the chambers is involved and the size of the tumor. Myxomas in the left atrium tend to mimic mitral disease. These produce positional dyspnea and other signs and symptoms of heart failure associated with elevated left atrial and pulmonary venous pressures. Clinically, mitral stenosis often is suspected and leads to echocardiography and diagnosis of myxoma. Syncopal episodes occur in some patients and are thought to result from temporary occlusion of the mitral orifice.[32,53] Right atrial myxomas can produce a clinical picture of right-sided heart failure with signs and symptoms of venous hypertension, including hepatomegaly, ascites, and dependent edema and can cause tricuspid valve stenosis by partially obstructing the orifice.[32,53] If a patent foramen ovale is present, right-to-left atrial shunting may occur with central cyanosis, and paradoxical embolization has been reported.[54] Large ventricular myxomas may mimic ventricular outflow obstruction. The left ventricular myxoma may produce the equivalent of subaortic or aortic valvular stenosis,[54,55] whereas right ventricular myxomas can simulate right ventricular outflow track or pulmonic valve obstruction.

Embolization. Systemic embolization is the second most common mode of myxomatous presentation, occurring in 30 to 40% of patients.[2,4,32] Because the majority of myxomas are left-sided, approximately 50% of embolic episodes affect the central nervous system owing to both intra- and extracranial vascular obstruction. The neurologic deficits following embolization can be transient but are often permanent.[56] Specific central nervous system consequences include intracranial aneurysms, seizures, hemiparesis, and brain necrosis.[57–59] Retinal artery embolization with visual loss has occurred in some patients.[60]

Embolic myxomatous material has been found blocking iliac and femoral arteries.[61–62] Other sites of tumor embolization include abdominal viscera and the renal and coronary arteries.[63] Histologic examination of surgically removed peripheral myxoma that has embolized provides the diagnosis of an otherwise unsuspected tumor.[32] Renal artery specimens from a nephrectomy have shown viable enlarging embolic myxoma after excision of the primary tumor. Right-sided myxomatous emboli mainly obstruct pulmonary arteries and cause pulmonary hypertension and even death from acute obstruction.[4,54]

Infection. Infection arising in a myxoma is a rare complication and produces a clinical picture of infectious endocarditis.[64,65] Infection increases the likelihood of systemic embolization,[4] and an infected myxoma warrants urgent surgical resection.

Diagnosis

Clinical Examination. Findings at the time of clinical assessment of a patient with cardiac myxoma vary according to the size, location, and mobility of the tumor. Left atrial myxomas may produce auscultatory or clinical findings similar to mitral disease. The well-described "tumor plop" can be confused with a third heart sound,[66] occurring just after the opening snap of the mitral valve created from contact between the tumor and endocardial wall.[66] Left atrial myxomas that cause partial obstruction of left ventricular filling may result in elevated pulmonary vascular pressures with augmentation of the pulmonary component of the second heart sound.[67]

Right atrial myxomas may produce similar auscultatory findings as left atrial myxomas with the exception that they are best heard along the lower right sternal border rather than at the cardiac apex. In addition, right atrial hypertension may produce a large *a* wave in the jugular venous pulse and, when severe, may mimic superior vena caval syndrome.

Chest Radiograph and Electrocardiogram. The findings on chest roentgenogram may include generalized cardiomegaly, individual cardiac chamber enlargement, and pulmonary venous congestion. More specific rare findings are density within the cardiac silhouette caused by calcification within the tumor (see Fig. 62-3) occurring more often with right-sided myxomas.[4]

Electrocardiographic Findings. Nonspecific abnormalities such as chamber enlargement, cardiomegaly, bundle-branch blocks, and axis deviation can be found.[68] Fewer than 20% of patients have atrial fibrillation.[39] Evaluation of nonspecific electrocardiographic abnormalities occasionally leads to an incidental diagnosis of myxoma most electrocardiograms are not helpful in establishing a diagnosis.

Echocardiography. Cross-sectional echocardiography is the most useful test employed for the diagnosis and evaluation of myxoma. The sensitivity of two-dimensional (2-D) echocardiography for myxoma is 100%, and this imaging technique largely has supplanted angiocardiography.[69] However, coronary angiography usually is performed in myxoma patients more than 40 years of age to rule out significant coronary disease. Transesophageal echocardiography (TEE) provides the best information concerning tumor size, location, mobility, and attachment.[70]

Transesophageal echocardiograms detect tumors as small as 1 to 3 mm in diameter.[71] Most surgeons obtain a transesophageal echocardiogram in the operating room before the operation (Fig. 62-2). We particularly evaluate the posterior left atrial wall, atrial septum, and right atrium, which often are not well displayed on transthoracic examination, to exclude the possibility of biatrial multiple tumors. Additionally, post operative TEE ensures a normal echocardiogram before leaving the operating room.

Computed Tomography and Magnetic Resonance Imaging. Although myxomas have been identified using computed tomography (CT),[69,72] this modality is most useful in malignant tumors of the heart because of its ability to demonstrate myocardial invasion and tumor involvement of adjacent structures.[68] Similarly, magnetic resonance imaging (MRI) has been employed in the diagnosis of myxomas and may yield a clear picture of tumor size, shape, and surface characteristics.[68–72]

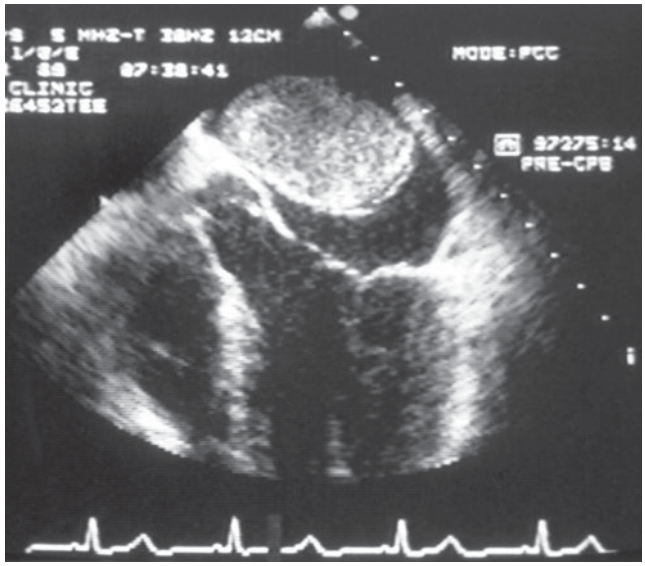

FIGURE 62-2 Transesophageal echocardiogram of a giant left atrial myxoma that does not appear attached to the mitral valve.

MRI is particularly useful in detecting intracardiac and pericardial extension, invasion of malignant secondary tumors, and the evaluation of ventricular masses that occasionally turn out to be myxoma. Both CT and MRI detect tumors as small as 0.5 to 1.0 cm and provide information regarding the composition of the tumor.[4] Neither CT nor MRI is needed for atrial myxomas if an adequate echocardiogram is available. The exception is the occasional right atrial myxoma that extends into one or both caval or tricuspid orifices. CT or MRI should be reserved for the situation in which the diagnosis or characterization of the tumor is unclear after complete echocardiographic evaluation.

Surgical Management

Surgical resection is the only effective therapeutic option for patients with cardiac myxoma and should not be delayed because death from obstruction to flow within the heart or embolization may occur in as many as 8% of patients awaiting operation.[73] A median sternotomy approach with ascending aortic and bicaval cannulation usually is employed. Manipulation of the heart before initiation of cardiopulmonary bypass is minimized in deference to the known friability and embolic tendency of myxomas. In the event of preoperative known cerebral embolization without hemorrhage, the tumor should be resected approximately seven days after the event to prevent further embolization and yet allow time for stabilization of the brain for cardiopulmonary bypass. For left atrial myxomas, the venae cavae are cannulated through the right atrial wall, with the inferior cannula placed close and laterally to the inferior vena cava–right atrial junction. Caval snares are always used to allow opening of the right atrium, if necessary. If extensive exposure of the left atrium is needed or a malignant left atrial tumor is suspected, we mobilize and directly cannulate the superior vena cava, which allows it to be transected if necessary for additional exposure. Body temperature is allowed to drift down, but there is no attempt to induce systemic hypothermia unless the need for reduced perfusion flow is anticipated. Modern cardioplegic techniques yield a quiet operative field and protect the myocardium from ischemic injury during aortic cross-clamping. Cardiopulmonary bypass is started, and the aorta is clamped before manipulation of the heart.

Exposure of left atrial myxomas is maximized by using several principles from mitral valve repair surgery. The surgeon desires the right side of the heart to rotate up and the left side of the heart to rotate down. Therefore, stay sutures are placed low on the pericardium on the right side, and no pericardial stay sutures are placed on the left before placing the chest retractor. This rotates the heart for optimal exposure of both the right and, particularly, the left atrium (Fig. 62-3). For left atrial tumors, the superior vena cava is mobilized extensively, as is the inferior vena cava–right atrial junction, allowing increased mobility and exposing the left atrial cavity. Left atrial myxomas can be approached by an incision through the anterior wall of the left atrium anterior to the right pulmonary veins (Fig. 62-4). This incision can be extended behind both cavae for greater exposure (Fig. 62-5). Exposure and removal of large tumors attached to the interatrial septum may be aided by a second incision parallel to the first in the right atrium. This biatrial

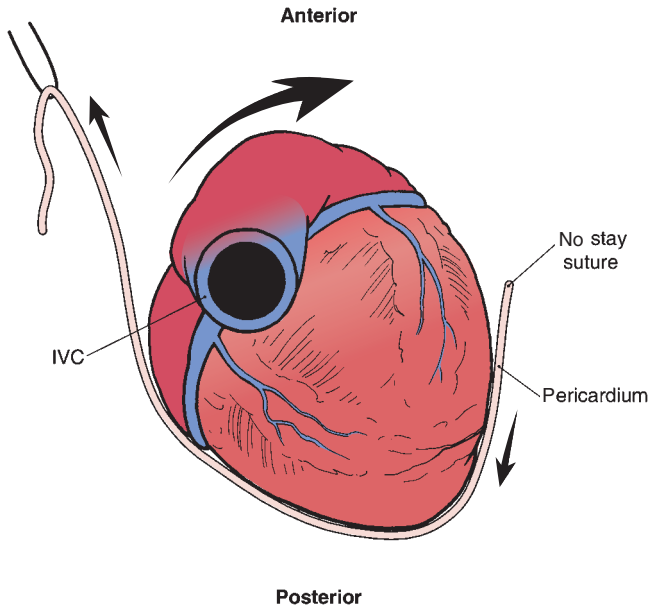

FIGURE 62-3 Rotation of the heart with pericardial stay sutures for left atrial exposure. IVC = inferior vena cava.

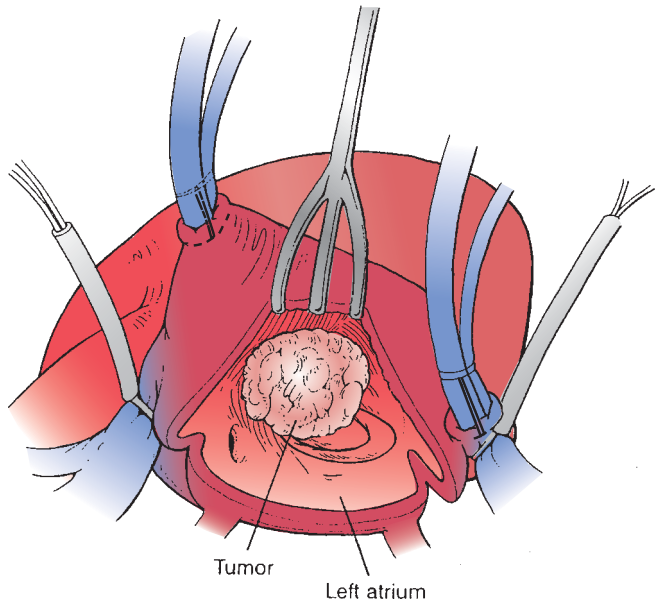

FIGURE 62-5 Left atrial atriotomy posterior to the inter-atrial groove to expose the left atrial tumor.

incision allows easy removal of tumor attached to the fossa ovalis with a full-thickness Ro (margin-negative) excision at the site of attachment and easy patch closure of the atrial septum if necessary (Fig. 62-6).

Right atrial myxomas pose special venous cannulation problems, and intraoperative echocardiography may be beneficial. Both venae cavae may be cannulated directly. When low- or high-lying tumor pedicles preclude safe transatrial cannulation, cannulation of the jugular or femoral vein can provide venous drainage of the upper or lower body. In general, we always can cannulate the superior vena cava distal enough from the right atrium to allow adequate tumor resection, but occasionally femoral venous cannula drainage has been necessary. If the tumor is large or attached near both caval orifices, peripheral cannulation of both jugular and femoral veins may be used to initiate cardiopulmonary bypass and deep hypothermia. After the aorta is cross-clamped and the heart is arrested with antegrade cardioplegia, the right atrium may be opened widely for resection of the tumor and reconstruction of the atrium during a period of circulatory arrest if this is needed for a dry field. Resection of large or critically placed right atrial myxomas often requires careful preoperative planning, intraoperative TEE, and special extracorporeal perfusion techniques to ensure complete removal of the tumor, protection of right atrial structures, and reconstruction of the atrium. Because myxomas rarely extend deep in the endocardium, it is not necessary to resect deeply around the conduction tissue. The tricuspid valve and the right

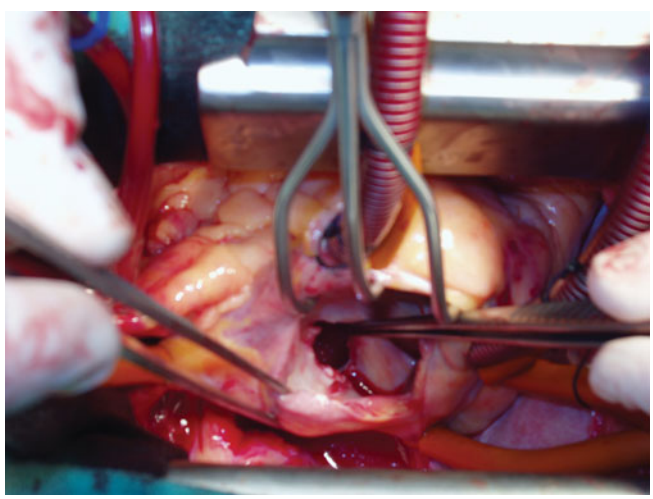

FIGURE 62-4 Left atriotomy and exposure of myxoma.

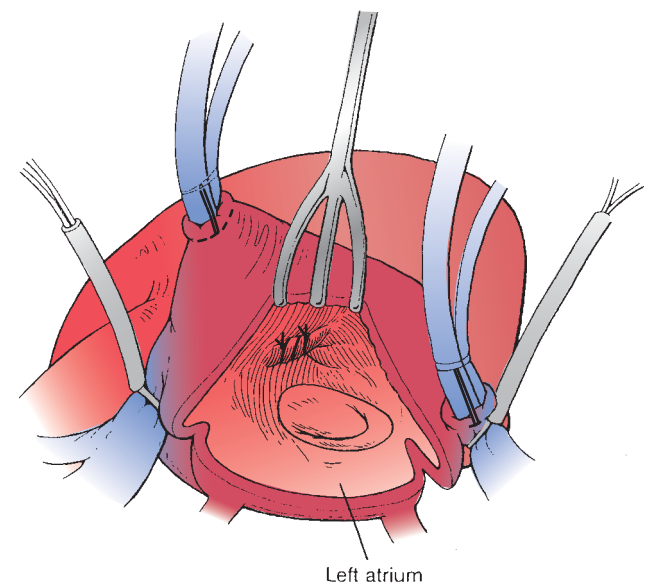

FIGURE 62-6 Repair of left atrial wall after removal of myxomas.

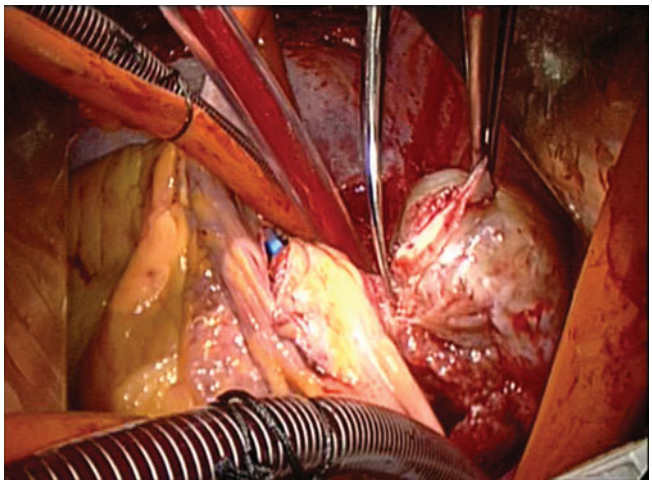

FIGURE 62-7 Giant left atrial myxoma just before removal.

atrium, as well as the left atrium and ventricle, should be inspected carefully for multicentric tumors in patients with right atrial myxoma. Regardless of the surgical approach, the ideal resection encompasses the tumor and a portion of the cardiac wall or interatrial septum to which it is attached (Fig. 62-7). Our policy is to perform a full thickness resection whenever possible. However, partial-thickness resection of the area of tumor attachment has been performed when anatomically necessary without a noted increase in recurrence rate.[74,75]

Ventricular myxomas usually are approached through the atrioventricular (AV) valve[76] or by detaching the anterior portion of the AV valve for exposure and resection and reattachment after resection. Occasional small tumors in either outflow tract can be removed through the outflow valve.[76] If necessary, the tumor is excised through a direct incision into the ventricle, but this is unusual and the least preferred approach. It is not necessary to remove the full thickness of the ventricular wall because no recurrences have been reported with partial-thickness excisions. As with right atrial myxoma, the presence of ventricular myxoma prompts inspection for other tumors because of the high incidence of multiple tumors.

Every care should be taken to remove the tumor without fragmentation. Following tumor removal from the field, the area should be liberally irrigated, suctioned, and inspected for loose fragments. There are rare instances of distant metastases from myxoma many years after tumor resection, and these reports raise the issue of potential intraoperative dissemination of tumor.[77] Cardiotomy suction can be used during the operation, but wall suction should strictly be used during the brief time that the tumor is exposed. The low malignant potential of the vast majority of myxomas and the rarity of metastasis support the author's current policy of retaining rather than discarding blood, and we believe that most cases of metastatic implantation of myxoma represent a preoperative embolic event.

Minimally Invasive Approaches to Surgical Removal. Minimally invasive approaches are being applied with increasing frequency in all areas of cardiac surgery, and cardiac tumors are no exception. Experience is confined to benign tumors and is quite limited. Approaches have included right parasternal or partial sternotomy exposure with standard cardioplegic techniques,[78] right submammary incision with femoral-femoral bypass and nonclamped ventricular fibrillation,[79] and the right submammary port access method with antegrade cardioplegia and ascending aortic balloon occlusion.[80] Thoracoscopic techniques have been used to aid in visualization and removal of ventricular fibroelastomas[81,82] (Fig. 62-8). Myxoma removal is possible via thoracoscopy.[83] Results in this limited number of selected patients have been good, but more experience and longer follow-up are needed before this can be recommended as a standard approach.

Results

Removal of atrial myxomas carries an operative mortality rate of 5% or less.[21] Operative mortality is related to advanced age or disability and comorbid conditions. Excision of ventricular myxomas can carry a higher risk (approximately 10%). Our experience over the last 15 years with 85 myxomas shows no operative or hospital mortality.

Recurrence of nonfamilial sporadic myxoma is approximately 1 to 4%.[4,74,75] Many large series report no recurrent tumors.[74,83–86] The 20% of patients with sporadic myxoma and abnormal DNA have a recurrence rate estimated at between 12 and 40%.[4] The recurrence rate is highest in patients with familial complex myxomas, all of whom exhibit DNA mutation, and this is estimated to be about 22%.[4] Overall, recurrences are more common in younger patients. The disease-free interval averages about 4 years and can be as brief as 6 months.[75] Most recurrent myxomas occur within the heart, in the same or different cardiac chambers, and may be multiple.[19,32,87] Extracardiac recurrence after resection of tumor, presumably from embolization and subsequent tumor growth and local invasion, has been observed.[19,87,88] The biology of the tumor, dictated by

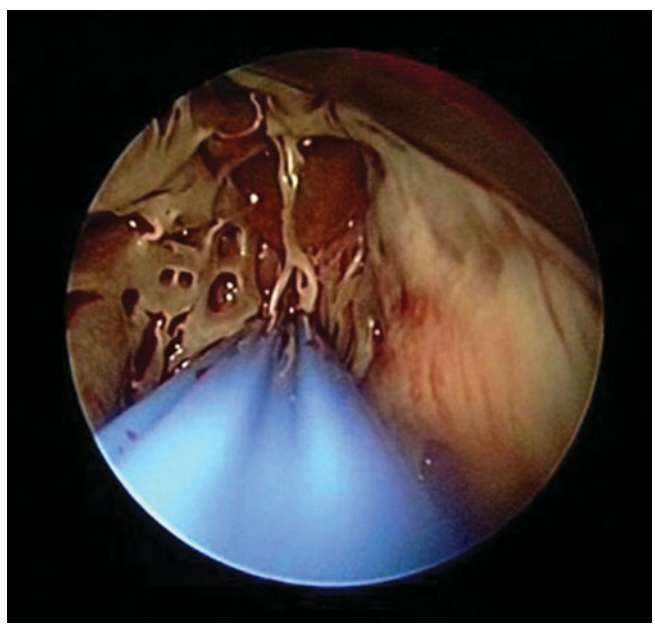

FIGURE 62-8 Thoracoscopic view of left atrial fibroelastoma.

gene expression rather than histology, may be the only reliable factor predicting recurrence. DNA testing of all patients with cardiac myxoma may prove to be the best predictor of the likelihood of recurrence.[89]

Myxomas generally classified as "malignant" are often found on subsequent review to be sarcomas with myxoid degeneration.[90] However, this issue also remains unsettled because of reports of metastatic growth of embolic myxoma fragments in the brain, arteries, soft tissue, and bones.[56,88,91–97] Symptomatic lesions of possible metastatic myxoma should be excised if feasible.[56,91]

The extent to which patients should be subjected to long-term echocardiographic surveillance after myxoma resection is not standardized. It would seem prudent to closely follow patients who are treated initially for multicentric tumors, those whose tumors are removed from unusual locations in the heart, all tumors believed to have been incompletely resected, and all tumors found to have an abnormal DNA genotype. Patients undergoing resection of tumors thought to be myxomas but with malignant characteristics at pathologic examination should have long-term, careful follow-up.

Other Benign Cardiac Tumors

As shown in Table 62-2, myxomas comprise approximately 41% of benign cardiac tumors, with three other tumors (ie, lipoma, papillary fibroelastoma, and rhabdomyoma) together contributing a similar proportion. A number of rarely encountered tumors account for the remainder.

Lipoma

Lipomas are well-encapsulated tumors consisting of mature fat cells that may occur anywhere in the pericardium, subendocardium, subepicardium, and intra-atrial septum.[2] They may occur at any age and have no sex predilection. Lipomas are slow growing and may attain considerable size before producing obstructive or arrhythmic symptoms. Many are asymptomatic and are discovered incidentally on routine chest roentgenogram, echocardiogram, or at surgery or autopsy.[98,99] Subepicardial and parietal lipomas tend to compress the heart and may be associated with pericardial effusion. Subendocardial tumors may produce chamber obstruction. The right atrium and left ventricle are the sites affected most often. Lipomas lying within the myocardium or septum can produce arrhythmias or conduction abnormalities. Large tumors that produce severe symptoms should be resected. Smaller, asymptomatic tumors encountered unexpectedly during cardiac operation should be removed if excision can be performed without adding risk to the primary procedure. These tumors are not known to recur.

Lipomatous Hypertrophy of the Interatrial Septum

Nonencapsulated hypertrophy of the fat within the atrial septum is known as *lipomatous hypertrophy.*[2] This abnormality is more common than cardiac lipoma and usually is encountered in elderly, obese, or female patients as an incidental finding during a variety of cardiac imaging procedures.[84] Various arrhythmias and conduction disturbances have been attributed to its presence.[85,100] The main difficulty is differentiating this from a cardiac neoplasm on echocardiography.[101] After the demonstration of a mass by echocardiography, the typical T1 and T2 signal intensity of fat on MRI usually can establish a diagnosis.[102,103] Arrhythmias and heart block are considered by some as indications for resection, but data are lacking as to the long-term benefits from resection.[104]

Papillary Fibroelastoma of the Heart Valves

Papillary fibroelastomas are tumors that arise characteristically from the cardiac valves or adjacent endocardium.[105] These tumors are described as resembling sea anemones with frondlike projections in gross description (Fig. 62-9). The AV and semilunar valves are affected with equal frequency. It is now known that these are capable of producing obstruction of flow, particularly coronary ostial flow, and may embolize to the brain and produce stroke.[106–115] They are usually asymptomatic until a critical event occurs. Papillary fibroelastomas of the cardiac valve should be resected whenever diagnosed, and valve repair rather than replacement should follow the resection of these benign tumors whenever technically feasible (Fig. 62-10). Cytomegalovirus has been recovered in these tumors, suggesting the possibility of viral induction of the tumor and chronic viral endocarditis.[111]

Rhabdomyoma

Rhabdomyoma is the most frequently occurring cardiac tumor in children. It usually presents during the first few days after birth. It is thought to be a myocardial hamartoma rather than a true neoplasm.[116] Although rhabdomyoma appears sporadically, it is associated strongly with tuberous sclerosis, a hereditary disorder characterized by hamartomas in various organs, epilepsy, mental deficiency, and sebaceous adenomas. Fifty percent of patients with tuberous sclerosis have rhabdomyoma, but

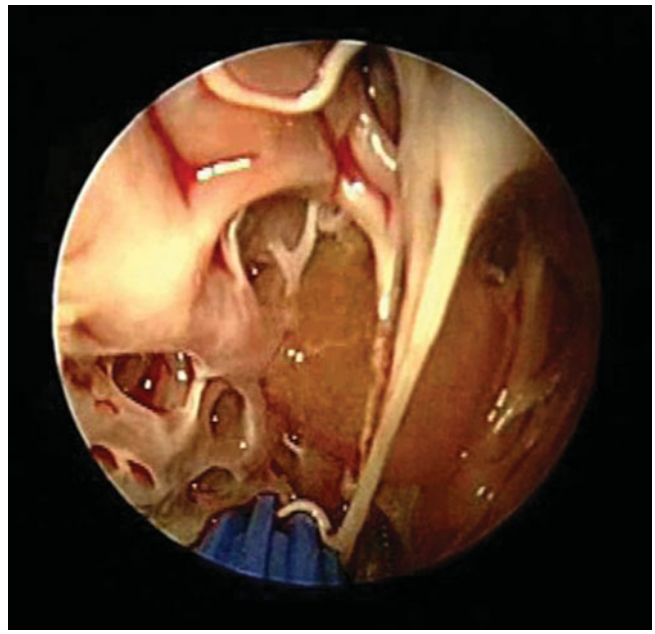

FIGURE 62-9 Additional enhanced view of an in-situ left atrial fibroelastoma.

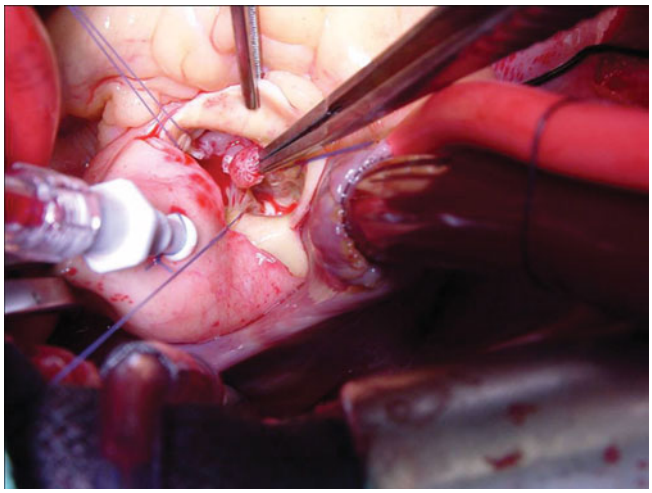

FIGURE 62-10 Surgical removal of a papillary fibroelastoma.

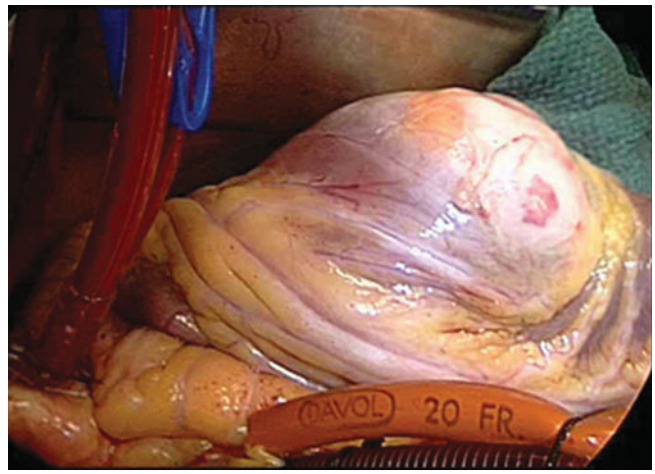

FIGURE 62-11 Left ventricular fibroma as seen from an external view of the heart.

more than 50% of patients with rhabdomyoma have or will develop tuberous sclerosis.[117] More than 90% of rhabdomyomas are multiple and occur with approximately equal frequency in both ventricles.[118] The atrium is involved in fewer than 30% of patients. Pathologically, these tumors are firm, gray, and nodular and tend to project into the ventricular cavity. Micrographs show myocytes of twice normal size filled with glycogen, containing hyperchromatic nuclei and eosinophilic-staining cytoplasmic granules.[2,119] Scattered bundles of myofibrils can be seen within cells by electron microscopy.[118]

Clinical findings may mimic valvular or subvalvular stenosis. Arrhythmias, particularly ventricular tachycardia and sudden death, may be a presenting symptom.[119] Atrial tumors may produce atrial arrhythmias.[119] The diagnosis is made by echocardiography. Rarely, no intramyocardial tumor is found in a patient with ventricular arrhythmias, and the site of rhabdomyoma is located by electrophysiologic study.[119]

Early operation is recommended in patients who do not have tuberous sclerosis before 1 year of age.[86] The tumor usually is removed easily in early infancy, and some can be enucleated.[86] Unfortunately, symptomatic tumors often are both multiple and extensive, particularly in patients with tuberous sclerosis, who, unfortunately, have a dismal long-term outlook. In such circumstances, surgery offers little benefit.

Fibroma

Fibromas are the second most common benign cardiac tumor, with more than 83% occurring in children. These tumors are solitary, occur exclusively within the ventricle and the ventricular septum, and affect the sexes equally. Fewer than 100 tumors have been reported, and most are diagnosed by age 2 years. These tumors are not associated with other disease, nor are they inherited. Fibromas are nonencapsulated, firm, nodular, gray-white tumors that can become bulky. They are composed of elongated fibroblasts in broad spiral bands and whirls mixed with collagen and elastin fibers. Calcium deposits or bone may occur within the tumor and occasionally are seen on roentgenography (Figs. 62-11 and 62-12).

Most fibromas produce symptoms through chamber obstruction, interference with contraction, or arrhythmias. Depending on size and location, such a tumor may interfere with valve function, obstruct flow paths, or cause sudden death from conduction disturbances in up to 25% of patients.[114] Intracardiac calcification on chest roentgenograms suggests the diagnosis, which is confirmed by echocardiogram.

Surgical excision is successful in some patients, particularly if the tumor is localized, does not involve vital structures, and can be enucleated.[86,120–122] However, it is not always possible to remove the tumor completely, and partial removal is only palliative, although some patients have survived many years.[86,121] Operative mortality may be high in infants. Most cases are in adolescents and adults.[186,120,121] Successful, complete excision is

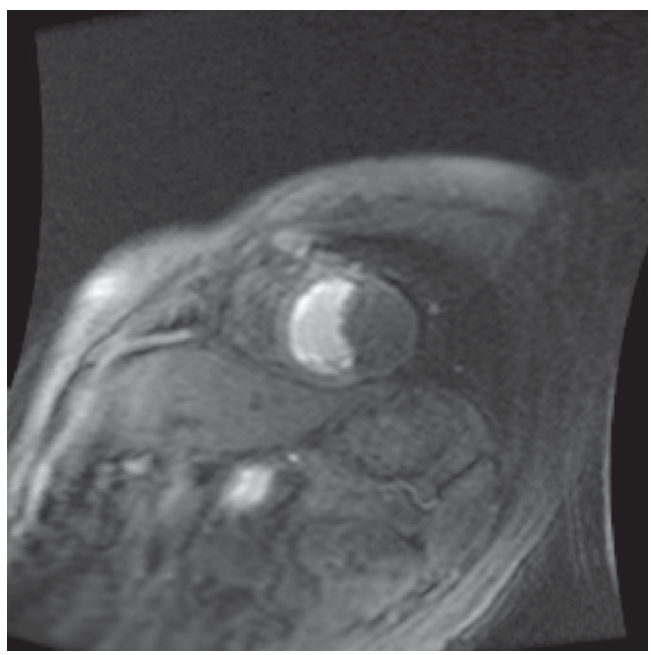

FIGURE 62-12 MRI of left ventricular fibroma.

curative.[120,121] Children with extensive fibromas have been treated with cardiac transplantation.[122,123]

Mesothelioma of the AV Node

Mesothelioma of the AV node, also termed *polycystic tumor, Purkinje tumor,* or *conduction tumor*. It is a relatively small, multicystic tumor that arises in proximity to the AV node and may extend upward into the interventricular septum and downward along the bundle of His.[2] Mesothelioma is associated with heart block, ventricular fibrillation,[124] and sudden death. Cardiac pacing alone does not prevent subsequent ventricular fibrillation. Surgical excision has been reported.[24]

Pheochromocytoma

Cardiac pheochromocytomas arise from chromaffin cells of the sympathetic nervous system and produce excess amounts of catecholamines, particularly norepinephrine. Approximately 90% of pheochromocytomas are in the adrenal glands. Fewer than 2% arise in the chest. Only 32 cardiac pheochromocytomas had been reported by 1991.[125] The tumor predominantly affects young and middle-aged adults with an equal distribution between the sexes. Approximately 60% occur in the roof of the left atrium. The remainders involve the interatrial septum or anterior surface of the heart. The tumor is reddish brown, soft, lobular, and consists of nests of chromatin cells.

The patients usually present with symptoms of uncontrolled hypertension or are found to have elevated urinary catecholamines. The tumor usually is located by scintigraphy using [I^{131}] metaiodobenzylguanidine[126] and CT or MRI.[126] Cardiac catheterization with differential blood chamber sampling sometimes is necessary in addition to coronary angiography.[125] After the tumor is located, it should be removed using cardiopulmonary bypass with cardioplegic arrest. Patients require preanesthetic alpha and beta blockade and careful intraoperative and immediate postoperative monitoring. Most tumors are extremely vascular, and uncontrollable operative hemorrhage has occurred.[126] Resection may require removal of the atrial and/or ventricular wall or a segment of a major coronary artery.[135] Explantation of the heart to allow resection of a large left atrial pheochromocytoma has been attempted.[127] Transplantation has been performed for unresectable tumor and complete excision produces cure.[121–123]

Paraganglioma

Paragangliomas are endocrine tumors that can secrete catecholamines. As a result, their presentation is often similar to that of pheochromocytomas. When found within the thoracic cavity, they are located most often in the posterior mediastinum. Paragangliomas typically present with atypical chest pain.[128,129] On echocardiography, they are often large and highly vascular tumors.[130] On cardiac catheterization, they may be intimately associated with the coronary arteries (Fig. 62-13). If they involve the left atrium, the technique of cardiac autotransplantation may be used to completely resect them[131] (Fig. 62-14).

Hemangioma

Hemangiomas of the heart are rare tumors (24 clinical cases reported), affect all ages, and may occur anywhere within the heart.[132,133] These are vascular tumors composed of capillaries or cavernous vascular channels. Patients usually develop dyspnea, occasional arrhythmias, or signs of right-sided heart failure.[134] Diagnosis is difficult, and echocardiography or cardiac catheterization can establish a diagnosis of cardiac tumor by showing an intracavity filling defect.[135] CT and MRI show axial T2-weighted MRI should show a high signal mass owing to vascularity (Fig. 62-15). Coronary angiography typically shows a tumor blush and maps the blood supply to the tumor. During resection, meticulous ligation of feeding vessels is required to prevent postoperative residual arteriovenous fistulas or intracavity communications. Partial resections have produced long-term benefits.[132] Tumors rarely resolve spontaneously.[136]

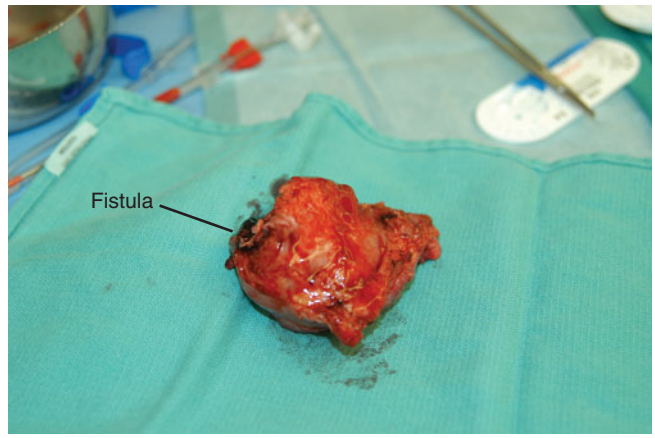

FIGURE 62-16 Castleman tumor showing fistula site indicated by insertion of a coronary probe.

Teratoma

Cardiac teratoma is a rare tumor that typically presents in infants and young children.[137] About 80% of the tumors are benign.[138] These tumors are discovered by echocardiography after a variety of symptoms lead to cardiac or mediastinal evaluation. There is little experience with surgical removal, which should be possible.

Castleman Tumor

Castleman disease is a poorly understood lymphoproliferative disorder. The disease was first described by Castleman and colleagues in 1956.[139] It typically presents as a solitary lesion in the mediastinum. The most common histologic type is hyaline vascular, which accounts for approximately 90% of cases and often behaves in a benign fashion. The more aggressive subgroups are the plasma and mixed-cell types, which have a more malignant behavior.[140] Patients may have a localized or multicentric disease with lymph node involvement, typically in the mediastinum. These tumors typically present as well-circumscribed masses. There have been reports of Castleman disease with myocardial and coronary artery invasion or development of a coronary pseudoaneurysm.[141] In these more aggressive cases, cardiac assist devices have been used as a bridge to recovery[141] (Figs. 62-16 and 62-17). CT imaging of the lesions reveals atypical or target-like enhancement that corresponds to various degrees of degeneration, necrosis, and fibrosis. Technetium-99m tetrofosmin and [I^{123}] beta-methyliodophenyl pentadecanoic acid (BMIPP) imaging may aid in the diagnosis. On BMIPP, these tumors show reduced uptake compared with the surrounding normal myocardium.[142] Complete surgical resection is considered curative.[143]

PRIMARY MALIGNANT TUMORS

Primary cardiac malignancy is very uncommon, with only 21 surgically treated cases noted in a 25-year surgical experience from 1964 to 1969, combining the experience of two large institutions, the Texas Heart Institute and the M. D. Anderson Cancer Center in Houston.[144] Additional current reports from the Texas Medical Center include a series from the Methodist Debakey Heart and Vascular Center and M D Anderson Cancer Center of 27 patients selected from 1990 to 2006.[144] Approximately 25% of primary cardiac tumors are malignant, and of these, about 75% are sarcomas. McAllister's survey of cardiac tumors found the most common to be angiosarcomas (31%), rhabdomyosarcomas (21%), malignant mesotheliomas (15%), and fibrosarcomas (11%),[2] see Table 62-4.

Rather than histologic classification of cardiac sarcoma, we propose a classification system based on anatomic location. Histology does not greatly affect treatment or prognosis as much as anatomic location.[144,145] The revised classification system divides primary cardiac sarcomas into right heart sarcomas, left heart sarcomas and pulmonary artery sarcomas, and these are the categories that will be used in the discussion to follow.

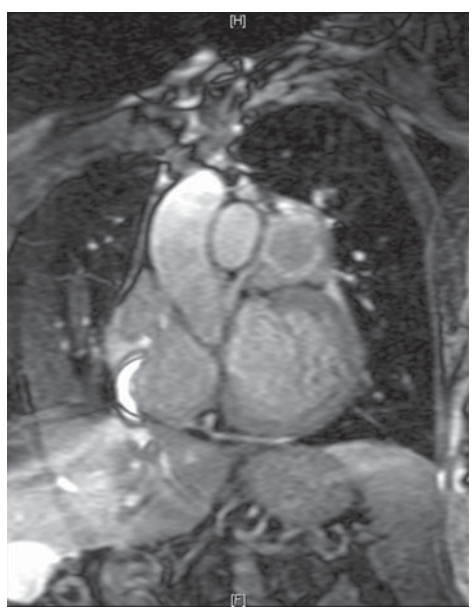

FIGURE 62-17 MRI of Castleman tumor.

Right heart sarcomas tend to metastasize early, present as bulky masses (Fig. 62-18), and are characteristically infiltrative.[145] Right heart sarcomas often occupy much of the right atrium growing largely in an outward pattern, and often avoid heart failure until the latest stage of presentation. This presentation often allows time for neoadjuvant chemotherapy in an attempt to shrink the tumor and sterilize the infiltrating edges to increase chances of obtaining a resection with microscopically negative margins.

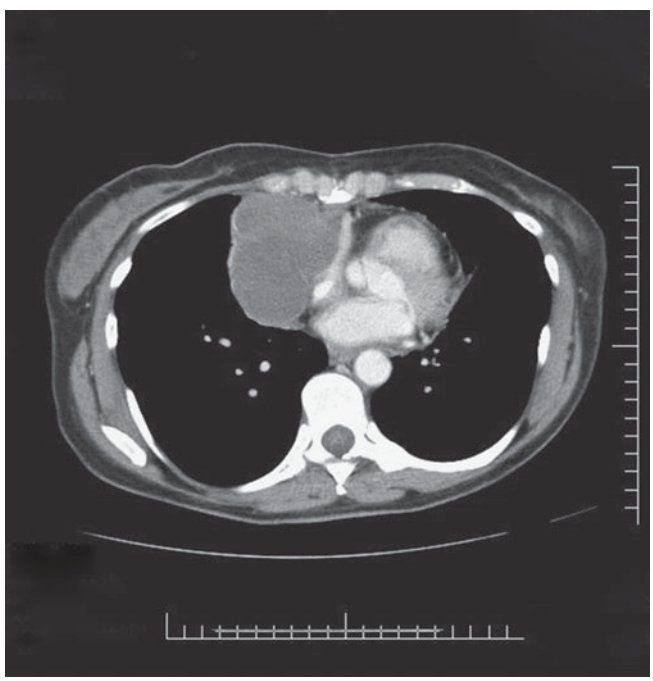

FIGURE 62-18 CT scan of a right heart tumor.

Left heart sarcomas tend to be more solid with less infiltration than right heart sarcomas and tend to metastasize later in the course of disease.[187] Left-sided sarcomas are most often located in the left atrium, and tend to grow into the wall. Diminution of blood flow quickly results in life-threatening heart failure. Neoadjuvant chemotherapy can rarely be used because of this presentation. Most left atrial sarcomas are initially clinically diagnosed as mxyomas, have a positive resection margin, rapidly recur, and require repeat resection.

Primary malignant cardiac tumors arise sporadically, showing no inherited linkage. Although they may span the entire age spectrum, they usually occur in adults more than 40 years of age. The patients usually present with symptoms of congestive heart failure, pleuritic chest pain, malaise, anorexia, and weight loss.[137,146] The most common symptom has been dyspnea[147] (Table 62-5). Some develop refractory arrhythmias, syncope, pericardial effusion, and tamponade.[147] The chest x-ray may be abnormal and even show a mass lesion, but the definite diagnosis usually is made with cardiac echocardiography.[146,148] Right atrial lesions are more frequently malignant (usually angiosarcoma) than left-sided lesions (usually myxoma but, when malignant, often malignant fibrous histiocytoma). If malignancy is suspected, chest CT or MRI may suggest histology and provide detailed anatomy and help in staging and assessing resectability. The current status of positron-emission tomographic (PET) scans in evaluating these patients remains controversial. We perform cardiac catheterization on all patients older than 40 years of age presenting with intracardiac masses and on all patients with large right atrial masses. Malignancy may be suggested and coronary involvement suspected by tumor blush. This is not pathognomic because we have seen a large feeding vessel and tumor blush in a histologically confirmed myxoma.

Unfortunately, primary cardiac malignancy may grow to a large size before detection and involve portions of the heart not amenable to resection. Some of these patients have been considered for transplantation and will be discussed later. Otherwise, palliative medical therapy can be attempted with radiation therapy, although success in both symptom relief and longevity has been somewhat limited. Whether the tumor is primary or secondary, the decision to resect is based on tumor size and location and an absence of

TABLE 62-5 Symptoms of Primary Malignant Cardiac Tumors

metastatic spread seen on complete evaluation. Unfortunately, most primary cardiac malignancies that have been referred to our center were considered to be benign initially and were resected incompletely at presentation. If malignancy is suspected or confirmed, and if the lesion appears anatomically resectable and there is no metastatic disease, then resection should be considered. If complete resection is possible, surgery provides better palliation and potentially can double survival.[149] After resection, we recommend adjuvant chemotherapy and believe that this can improve survival.[138,149] Complete resection will depend on the location of the tumor, the extent of involvement of the myocardium and/or fibrous skeleton of the heart, and histology.

Angiosarcoma

Angiosarcomas are two to three times more common in men than in women and have a predilection for the right side of the heart. Eighty percent arise in the right atrium.[147,150,151] These tumors tend to be bulky and aggressively invade adjacent structures, including the great veins, tricuspid valve, right ventricular free wall, interventricular septum, and right coronary artery[150] (Fig. 62-19). Obstruction and right-sided heart failure are not uncommon. Pathologic examination of resected specimens demonstrates anastomosing vascular channels lined with typical anaplastic epithelial cells. Unfortunately, most of these tumors have spread by the time of presentation, usually to the lung, liver, and brain.[147] Without resection, 90% of the patients are dead within 9 to 12 months of diagnosis despite radiation or chemotherapy.[22,147] We have seen carefully selected patients without evidence of spread on metastatic evaluation who have undergone complete surgical resection with subsequent chemotherapy (Fig. 62-20). In addition to surgical resection of the right atrium, right coronary bypass and even tricuspid valve repair or replacement may be undertaken (Fig. 62-21). We have had no hospital mortality in this small group, and most patients die from metastasis rather than recurrence at the local site.[152]

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft tissue sarcoma in adults. Its occurrence as a cardiac primary malignancy has been relatively recently accepted as a specific entity. It is characterized histologically by a mixture of spindle cells in a storiform pattern, polygonal cells resembling histiocytes, and malignant giant cells. The cell of origin is the fibroblast or histioblast.[148,153] It usually occurs in the left atrium and often mimics myxoma. In fact, every left atrial MFH referred to our institution has been previously incompletely resected when thought to represent a myxoma. The tendency to metastasize early is not as prominent as with angiosarcoma. Several reports document rapid symptomatic recurrence after incomplete resection despite chemotherapy. These patients often die of local cardiac disease before the development of metastases. We believe that if complete resection can be obtained (particularly if the malignant nature is recognized and complete resection can be done at the original operation) and adequate chemotherapy can be provided, we may improve survival in this otherwise dismal disease.

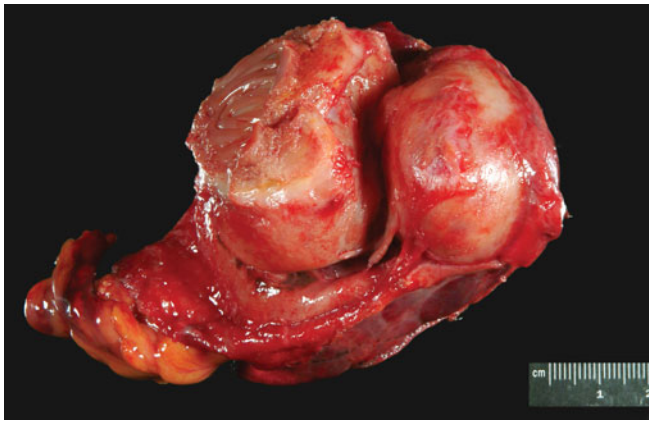

FIGURE 62-19 Pathology specimen photograph of a right atrial tumor.

Rhabdomyosarcoma

Rhabdomyosarcomas do not evolve from rhabdomyomas and occur equally in the sexes. The tumors are multicentric in 60% of patients and arise from either ventricle. These tumors frequently invade cardiac valves or interfere with valve function because of their intracavitary bulk. Microscopically, tumor cells demonstrate pleomorphic nuclei and spidery, wispy, streaming eosinophilic cytoplasm, usually in a muscle-like pattern.

The tumors are aggressive and may invade pericardium. Surgical excision of small tumors may be rational, but local and distant metastases and poor response to radiation or chemotherapy limit survival to less than 12 months in most of these patients.[120,137,138,149,154]

Other Sarcomas and Mesenchymal-Origin Tumors

McAllister and Fenoglio found that malignant mesotheliomas arising from the heart or pericardium and not from the surrounding pleura were the third most common malignant cardiac tumors and that fibrosarcomas were fourth.[2] However, in the two decades since their work, clinicians have rarely encountered these tumors. This apparent decrease in incidence may be related to changes in histologic criteria for classifying primary malignant neoplasms since their study.[5,132,138,147–149,154–155]

The histology of these tumors can be ambiguous and difficult. These neoplasms can resemble other sarcomas, and some might be deemed fibrous histiocytomas today. The behavior of these tumors is more important, and as with other cardiac sarcomas, resection of small tumors in the absence of known metastasis perhaps is justified, but data are scarce.[22,147,149,154] This being said, it is important to rule out more diffuse thoracic involvement with mesothelioma before considering resection of an isolated cardiac or pericardial mesothelioma. A PET scan may be considered, and any suspicious pleural thickening or effusion should be evaluated carefully both radiographically and histologically.

Myosarcoma, liposarcoma, osteosarcoma, chondromyxosarcoma, plasmacytoma, and carcinosarcoma arising from the

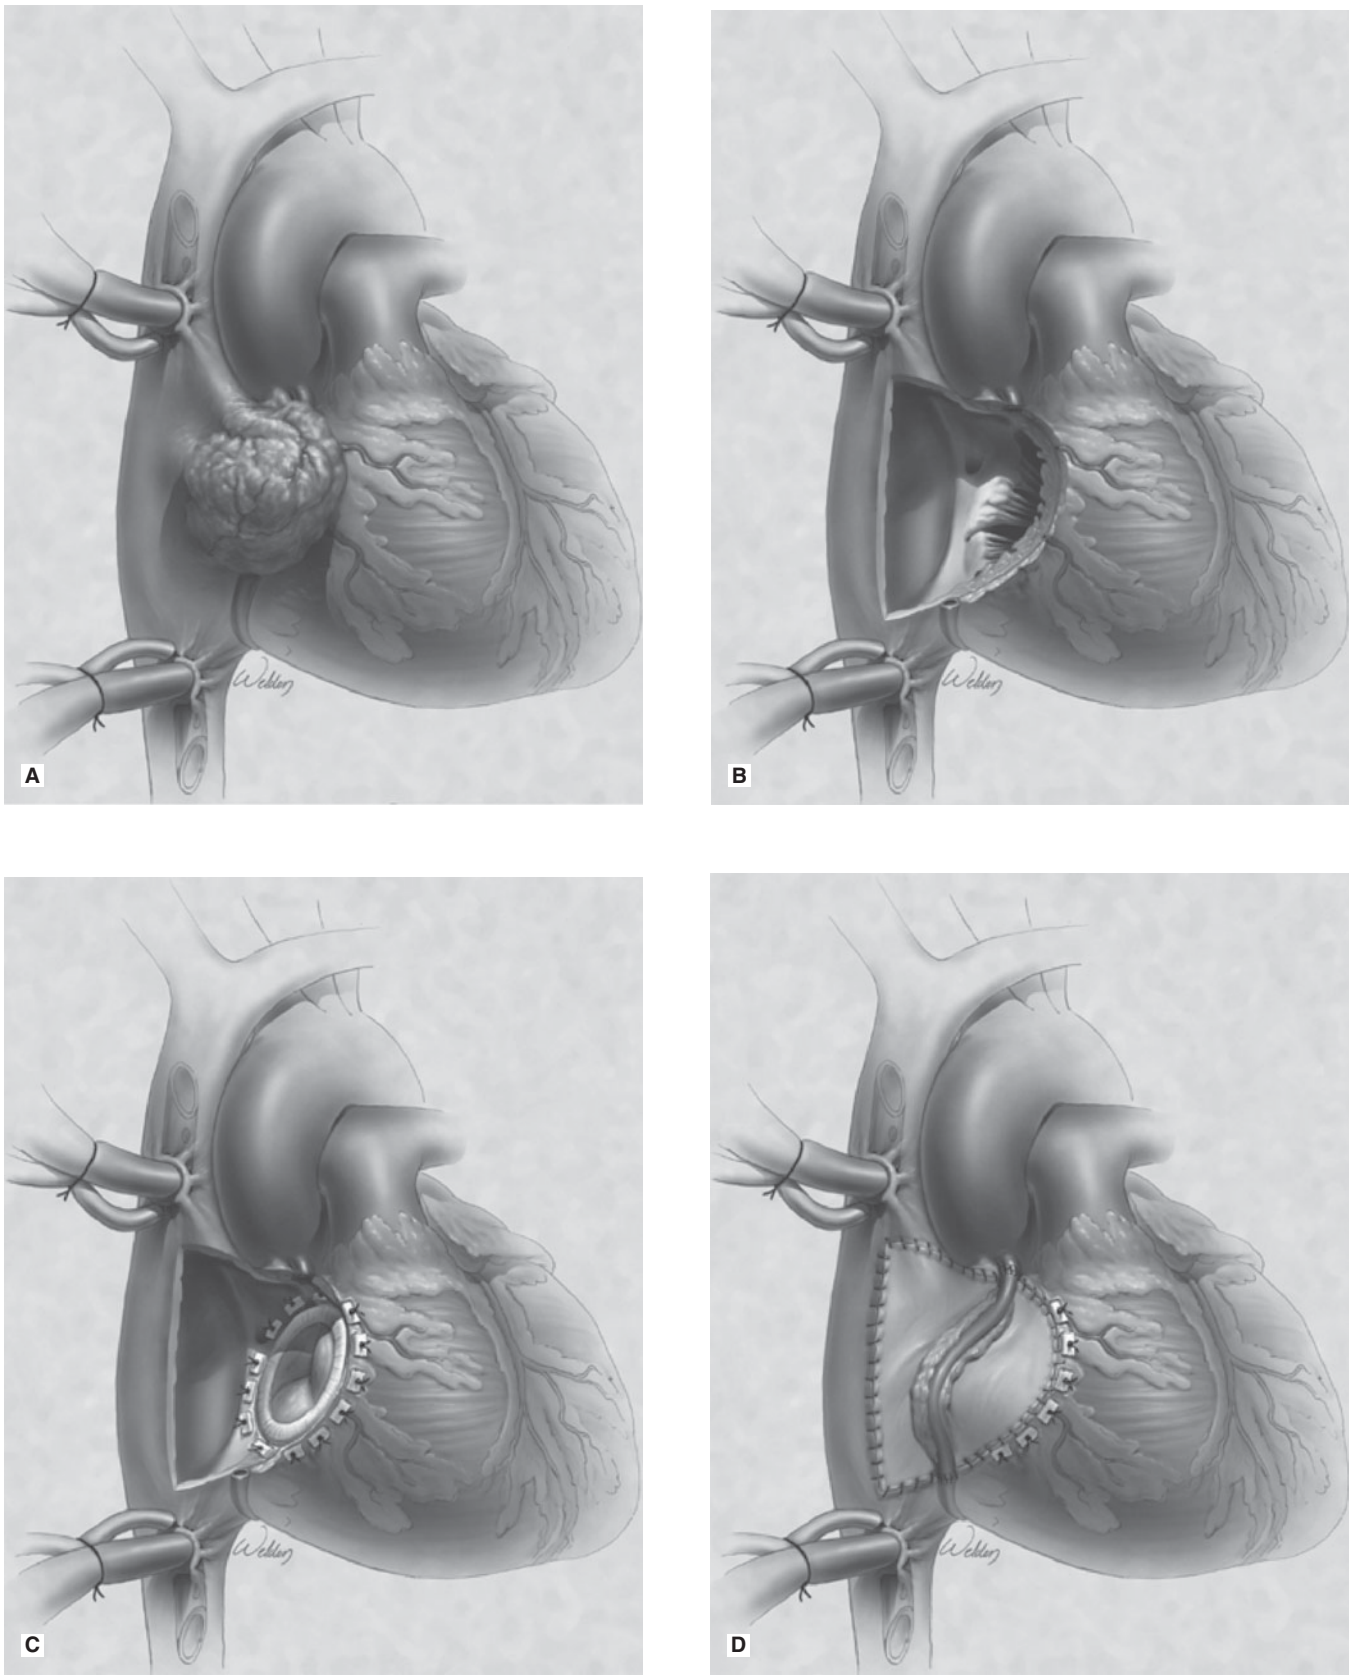

FIGURE 62-20 (A) Right atrial angiosarcoma involving right coronary artery and tricuspid valve, (B) excision of tumor with right coronary artery and tricuspid valve, (C) tricuspid valve replaced, (D) completed repair using bovine pericardium.

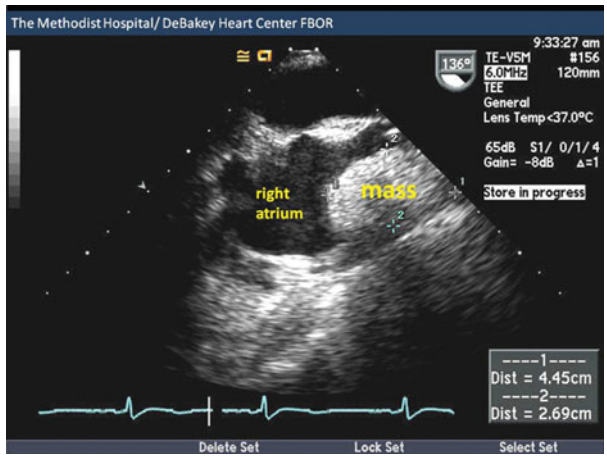

FIGURE 62-22 Transesophageal echocardiogram of a right atrial mass measuring 4.45 by 2.69 centimeters.

heart all have been reported,[155–158] but by the time diagnosis is made, only palliative therapy usually can be offered, and surgery is indicated only occasionally. Regardless of therapy, it is unusual for patients with these diagnoses to survive more than a year.

Right-Sided Cardiac Sarcomas

The prognosis without surgery for right heart sarcoma is dismal, and surgical resection is the only treatment modality shown to increase survival. Complete surgical resection is complicated both by the bulky infiltrative nature of right heart sarcoma and the high incidence of metastatic disease at presentation. The author's current approach to right heart sarcomas has been to begin with neoadjuvant chemotherapy once a definitive tissue diagnosis of sarcoma is made using a right heart catheterization biopsy. Occasionally, a diagnosis of lymphoma or other tumor is made. Multidisciplinary treatment planning based on the *correct* diagnosis is imperative. After 4 to 6 rounds of chemotherapy (with repeat imaging every other cycle to assess for tumor response), the patient is evaluated for surgical resection. This treatment regimen aims to improve on the current microscopic complete resection rate of 33%. The initial diagnostic test for right heart sarcomas is transthoracic echocardiography, which rarely misses these usually large tumors. Unlike large left atrial masses that are usually benign myxomas, the majority of large right atrial masses are typically malignant (Fig. 62-22). The majority of right heart sarcomas referred to our specialty center have yet to undergo attempted resection, unlike left-sided heart tumors which are typically resected under the presumption they are benign mymomas. The primary reason for local failure of a right heart sarcoma is incomplete resection, typically because of surgical hesitancy to achieve complete resection because of involvement of the right coronary artery.

Most right heart sarcomas are angiosarcomas.[2] (Fig. 62-23) These tumors may occur in the right atrium (Fig. 62-24) or the right ventricle but far more commonly arise from the right atrium. They replace the right atrial wall and frequently grow into the cardiac chamber and into adjacent tissues. Right heart

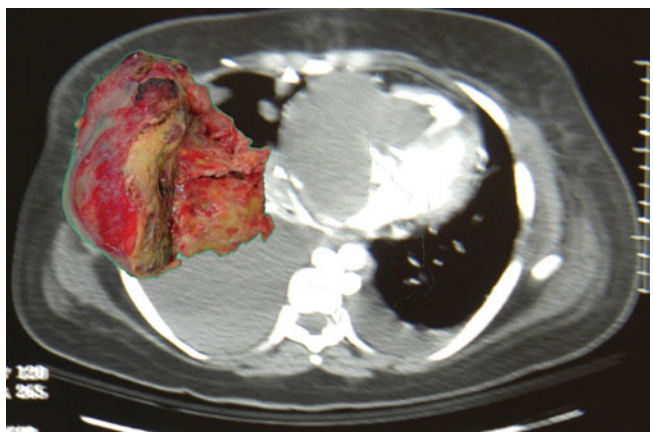

FIGURE 62-23 CT scan of a right atrial mass with the pathology specimen oriented in a similar fashion over the image.

FIGURE 62-24 Right atrial sarcoma.

tumors tend to be infiltrative and form microscopic "fingers" of tumor extending beyond the margins of gross disease. Diffuse pericardial involvement, right ventricular involvement, or encasement of great vessels or veins often precludes surgical resection. The tricuspid valve, right coronary artery, and up to about 30% of the right ventricular muscle mass may be resected and replaced or reconstructed with reasonable risk to achieve a complete resection. Thus, all patients are evaluated preoperatively with coronary arteriography. In patients treated without surgical resection, the survival is approximately 10% at 12 months.[159] A microscopically negative surgical resection margin has been shown to extend survival[149] and remains standard therapy. Although some patients having a radical resection still locally recur, the leading cause of death is distant metastatic disease. Complete resection followed by adjuvant chemotherapy has been shown to extend survival.[149,159]

Patients with even limited metastatic disease that did not respond well to chemotherapy or who developed new metastatic disease while on treatment are not considered candidates for surgery. Patients with widely metastatic disease are not considered candidates unless palliative surgery because of severe symptoms is recommended. Every patient should be referred to oncology for potential continuation of chemotherapy after recovery from surgery.

Based on the anatomic extent of tumor and the needed margins for resection, venous cannulation for cardiopulmonary bypass must be carefully planned and individualized to each patient. Directly cannulating the high superior vena cava (SVC) for upper body drainage and cannulating directly into the inferior vena cava (IVC) at the diaphragm usually allows adequate exposure for complete inferior resection, but occasionally femoral cannulation aids in exposing the more caudal structures of the right heart. Aortic cannulation is standard, as it is distant from the tumor. The right atrium can be completely resected and replaced with Bovine pericardium. If the resection involves the SVC or IVC, a vascular stapler can be used to staple lengthwise creating a tube from Bovine pericardium to recreate the vein segment (Fig. 62-25). One particular area of danger is at the right atrial junction with the root of the aorta, as overzealous resection in this area will result in damage to the fibrous skeleton of the heart, which is characteristically difficult to repair. Incomplete resection leaving gross disease rapidly leads to regrowth of the tumor and should be avoided if at all possible. When right coronary artery involvement is suspected, mobilization of the right internal mammary artery is performed at the beginning of the operation. Right ventricular wall can be simply partially replaced with Bovine pericardium or incorporated into a prosthetic tricuspid valve used for valve replacement. For an illustration of the steps involved in the resection and later reconstruction of a right heart sarcoma, please refer to Fig. 62-26.

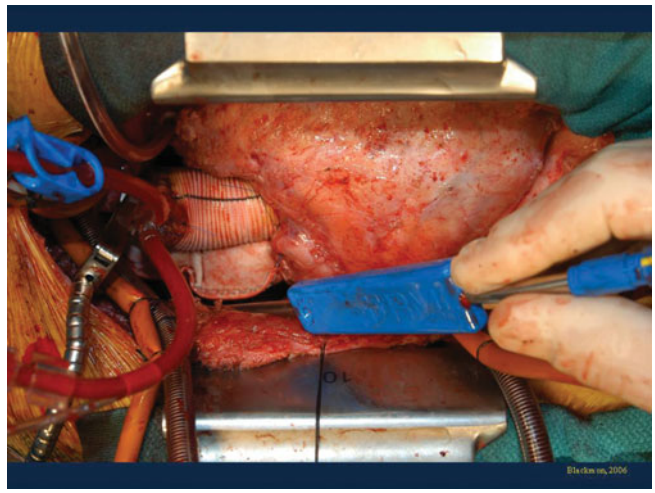

FIGURE 62-25 Bovine pericardium reconstruction of the superior vena cava (created by folding the pericardium in half and then firing an endo-GIA stapler longitudinally to form the conduit).

Left-Sided Cardiac Sarcomas

Surgical resection is the most effective therapeutic option for patients with malignant left-sided cardiac tumors. Delay can result in death from obstruction to flow within the heart or embolization, which may occur in as many as 8% of patients awaiting operation. The clinical presentation of patients with primary left heart sarcoma depends on the anatomic location and extent of the tumor and is not influenced by histology. Most primary left heart sarcomas are reported to occur in the left atrium, a concept supported by the author's experience; 22/24 (92%) occurred in the left atrium and 2/24 (8%) occurred in the left ventricle. Most left atrial masses seen by cardiac surgeons are mistaken to be benign myxomas. Every left atrial sarcoma patient referred to our center previously underwent resection for a presumed myxoma that was later found to be a cardiac sarcoma. Each of these cases had rapid reappearance of the left atrial tumor at the site of resection likely representing regrowth of persistent incompletely resected sarcoma. Intracavitary left ventricular tumors are very uncommon and are rarely mistaken for a simple cardiac myxoma. Heart failure caused by obstruction of intracardiac blood flow is the most common and concerning presenting symptom. Heart block from local invasion, arrhythmia, pericardial effusion, distal embolus, fever, weight loss, and malaise are also seen. The mean age of presentation is reported to be 40 years of age.[148] Transthoracic echocardiography is the most common initial diagnostic test. Transesophageal echocardiography is specifically recommended for in all left-sided cardiac tumors because of increased resolution of left-sided structures. Cardiac MRI and PET/CT scans are also obtained in patients known or suspected to have sarcoma.

Once diagnosed, primary cardiac sarcoma patients have an often dismal prognosis. When medically treated, the survival at 12 months is less than 10%.[159] Most reports in the literature are either autopsy series or individual case reports or small case series. Operative mortality usually exceeds 20 percent, and the mean survival is typically around 12 months.[160–162] Many published series focus on primary cardiac sarcoma in general without regard to anatomic location. The Mayo Clinic reported 34 patients over 32 years with a median survival of 12 months.[163] A combined series from the Texas Heart Institute and the MD Anderson

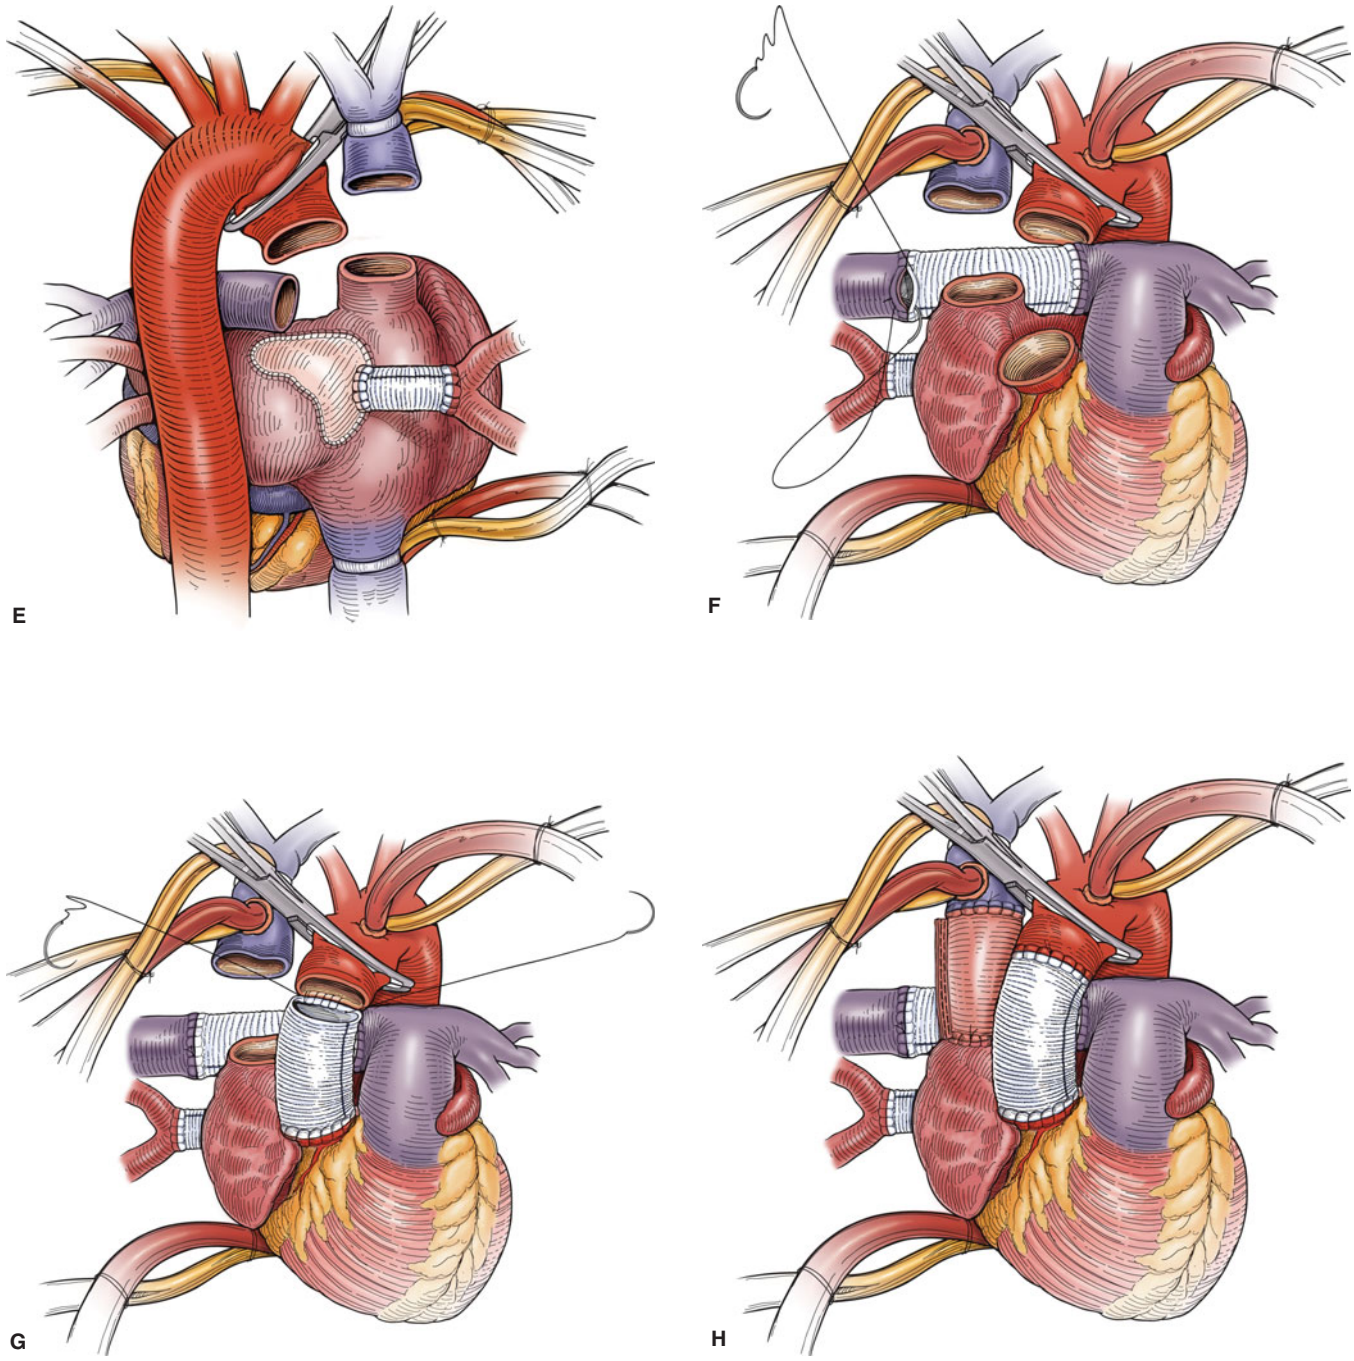

FIGURE 62-26 (*Continued*)

Cancer Center reported an actuarial survival of 14% at 2 years in 21 patients over a 26-year period.[156] The authors have previously reported a combined multimodality approach, and found a median survival of 23.5 months in 27 patients over 16 years with survival of 80.9% at one year and 61.9% at two years.[146] Subsequent analyses show histologic type does not influence survival or treatment approach.[164] The major determinant of clinical presentation and surgical approach is anatomic location. Currently, these tumors are grouped based on location, such as pulmonary artery sarcomas, right heart sarcomas, or left heart sarcomas.[165]

The high rate of local recurrence and secondary resections reported in the literature[166] indicate the left atrium and ventricle present unique anatomic exposure challenges. Complete resection and reconstruction is complicated because of the left heart proximity to vital structures. Often, a surgeon's inability to adequately visualize vital structures and reconstruct leads to an inadequate resection with rapid regrowth of tumor. Typically, left atrial tumors are approached through the interatrial groove. The interatrial groove is often an adequate approach for benign tumors, but is limited for malignant tumors that are often larger and require a more generous margin of resection. We

have considered complete cardiectomy and orthotopic cardiac transplantation for complete removal of these tumors. Although feasible, this approach requires the availability of a donor and postoperative immunosuppression; both of which present potential problems in cancer patients. Additionally series using orthotopic cardiac transplantation for this purpose have only shown a median survival of 12 months.[167] Left ventricular tumors can be approached through the aortic valve, the mitral valve or through a ventriculotomy. A transaortic valve approach works nicely for benign tumors[82] but is inadequate for malignant tumors because of their size and the amount of resection needed. A ventriculotomy through normal ventricular muscle is possible, but not ideal. The author's group adopted the approach of cardiac explantation, ex vivo tumor resection, cardiac reconstruction, and reimplantation of the heart (cardiac autotransplantation), which permits a radical tumor resection and accurate reconstruction.

Cardiac Autotransplantation. The technique of cardiac autotransplantation was introduced for cardiac tumors by Cooley in 1985 to deal with a large left atrial pheochromocytoma.[127] Although this case was not successful, it introduced the senior author (MJR) to the technique and its potential use for cardiac tumors. The author's group did the first successful cardiac auto transplant for cardiac sarcoma in 1998,[153] also reporting this for left atrial sarcoma and left ventricular sarcoma.[168] Working closely with the MD Anderson Cancer Center, the Methodist Hospital has now performed 28 cardiac auto transplants, with 23 of these for primary cardiac sarcoma.

Cardiac auto transplantation has several fundamental differences from standard orthotopic heart transplantation.[169] In orthotopic heart transplantation, unless a domino procedure is being done, the explanted heart is not to be used and any damage to its structures is inconsequential. For a complete video of an autotransplant including replacement of the mitral valve, please refer to the movie attached to this chapter. Therefore, the cardiectomy can be performed leaving a wide margin of remaining tissue to use in tailoring the heart to be implanted without regard to cutting critical structures such as the coronary sinus. Similarly, the donor heart can usually be harvested with extra tissue at its margins to be used to help tailor the implantation unlike traditional orthotopic heart transplant surgery. The heart must be excised in cardiac autotransplantation in a manner that does not damage any structures that cannot be repaired, replaced, or are vital to cardiac function. Additionally, if the heart is simply excised and reimplanted, loss of workable tissue makes reimplantation more challenging than orthotopic heart transplantation. Cannulation techniques must take into consideration planned explantation. The aorta can be cannulated distally in the transverse arch. Venous cannulation must be directly into the SVC and IVC just below the right atrial junction. This requires greater exposure and mobilization of the SVC and IVC. After commencing CPB, further mobilization of the SVC and IVC is performed until each is completely free and surround with umbilical tapes on a tourniquet. Wide mobilization of the interatrial groove and circumferential mobilization of the ascending aorta and pulmonary artery follows cannulation. This facilitates both accurate excision of the heart and reimplantation. The ascending aorta is cross-clamped and antegrade cold blood potassium cardioplegia is given (10 cc/kg) to achieve cardiac arrest. The left atrium is opened at the beginning of cardioplegia, and a sump drain placed to decompress the heart. After cardioplegia and cardiac quiescence, the left atrium is opened to confirm pathology and appropriateness of autotransplantation. The SVC first divided beyond the right atrial junction. This is followed by IVC division which should be transected near the right atrial and SVC junction. For each transection, it is important to note the rim of tissue being left behind retracts substantially towards the venous cannulae and an extraordinarily wide rim must be left or reimplantation at the IVC can be exceedingly difficult. The ascending aorta is divided about 1 cm distal to the sinotubular junction and the pulmonary artery is divided just proximal to its bifurcation. The left atrium transection is then completed, dividing the atrium just anterior to the pulmonary veins and on the left side equal distant between the pulmonary veins and the mitral valve and left atrial appendage. This allows complete removal of the heart which is placed into a basin of ice slush (Fig. 62-27). The posterior left atrium is then inspected, and any tumor is widely excised (Fig. 62-28). Bovine pericardium is used for reconstruction, and the pulmonary veins may be individually reimplanted into new orifices cut in the bovine pericardium or left as a cuff, if pathology permits. The anterior left atrium can be entirely removed, including the mitral valve, leaving only a mitral annulus.

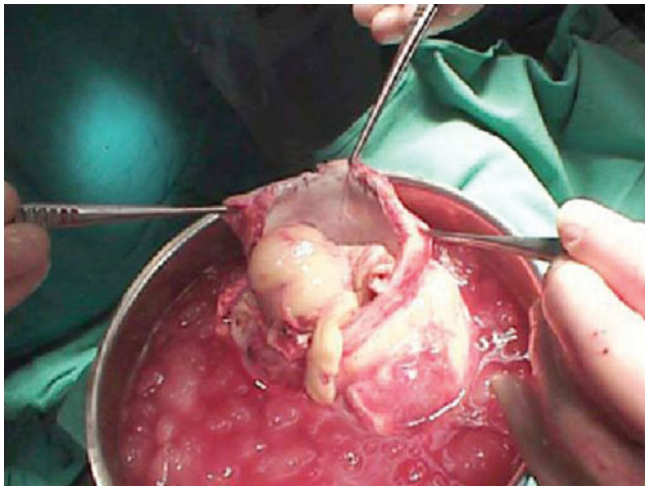

FIGURE 62-27 Ex vivo heart showing large sarcoma arising from the anterior left atrial wall.

Bovine pericardial reconstruction starts with cutting a hole to match the mitral annulus opening. Mitral valve replacement using pledgeted 2-0 ticron sutures begins with pledgets placed on the left ventricular side of the annulus, passing thru the annulus, through the bovine pericardium, and then through the prosthetic mitral valve. When the sutures are tied, the neo atrial wall is sealed to the valve and annulus. The anterior and posterior bovine pericardium can then be tailored by cutting darts and sewing them together before reanastomosis. Reimplantation is similar to standard cardiac transplantation, beginning with

the left atrium anastomosis. The right atrium is then attached to the IVC, and then the right atrium to the SVC. If either of these anastomoses appear to be under excess tension, an interposition graft of Gore-Tex, Dacron, or crafted pericardial tube graft can be used to bridge the defect successfully (Fig. 62-29). The pulmonary artery and aorta are reanastomosed in a standard fashion using Prolene suture, warm-blood potassium cardioplegia is given antegrade, and the aortic cross-clamp is removed. The procedure for left ventricular tumors is similar, and occasionally requires mitral valve excision or partial excision of the interventricular septum (Fig. 62-30). The interventricular septum can be reconstructed with bovine pericardium and valve replacement is typically done with a tissue valve. Although these patients are young, a tissue valve is often chosen to avoid anticoagulation. Issues with structural valve deterioration are of less concern because survival is counted now in years rather than decades.

Because of poor survival, lesions requiring a pneumonectomy in addition to cardiac autotransplant should be considered a contraindication to surgery. This can usually be determined preoperatively with cardiac MRI to evaluate restriction of blood flow through the pulmonary veins.

Lymphomas

Lymphomas may arise from the heart, although this is rare.[170] Most of these tumors respond to radiation and chemotherapy, and surgical resection is rarely indicated.[152] Even when complete resection is not possible, incomplete resection has been performed to relieve acute obstructive systems and, when followed with radiation and chemotherapy, has allowed for extended survival in selected patients.

Pulmonary Artery Sarcomas

Most pulmonary artery sarcomas are classified as. The most frequent presenting symptom is shortness of breath and peripheral edema from concomitant right-sided heart failure.[171] The diagnostic modalities of choice for both the initial evaluation and monitoring for recurrence after resection for pulmonary artery sarcomas are chest CT or MRI (Figs. 62-31, 62-32, and 62-33).

Pulmonary artery sarcomas are very rare tumors that are often confused with acute or chronic pulmonary embolus. This confusion has led to both delay in diagnosis and many being treated with a tumor thromboendarterectomy approach rather than radical resection. These tumors usually are discovered after they have grown to considerable size (Fig. 62-34). Pulmonary artery sarcoma can present with cough, dyspnea, hemoptysis and chest pain that may mimic pulmonary embolus (PE). Constitutional symptoms often present include fever, anemia and weight loss which are more consistent with malignancy than PE and these mass lesions will not decrease in size with anticoagulation. These tumors tend to arise from the dorsal surface of the main pulmonary artery just beyond the pulmonary valve.[172] They form from multipotential mesenchymal cells from the muscle remnant of the bulbus cordis[173] in the

intimal and subintimal surfaces.[164] The tumor then tends to grow distally along the artery, rarely penetrating the actual wall of the artery but rather distending it (Fig. 62-35). This characteristic is important to note when planning surgical resection. Distal extension can go to the lung parenchyma itself as emboli, infarction, or metastasis.[174] Although survival difference based on cell histology is found in limited cases, that has not been our experience in cardiac sarcoma in general.[171] Surgical resection remains the primary method of treatment in patients with PA sarcoma and the only method shown to increase survival. A staging system has been developed to further classify these patients and determine who should be offered surgical therapy (Table 62-6).

Resection often requires replacement of a portion of the pulmonary root and branch pulmonary arteries using a pulmonary homograft with or without artificial graft. Pneumonectomy may be required to resect the tumor completely. Because exposure of the right main pulmonary artery may require division of the aorta and possibly the SVC, we plan surgical cannulation for cardiopulmonary bypass by using dual venous cannulation with direct SVC cannulation and normal IVC cannulation via the right atrium. Arterial cannulation via the ascending aorta is routine. Both SVC and IVC are isolated with tourniquets to control blood flow into the right heart. Cardiopulmonary arrest is achieved with cold potassium blood cardioplegia. Fortunately,

TABLE 62-6 Staging System for Primary Pulmonary Artery Sarcomas

Stage I	tumor limited to the main pulmonary artery
Stage II	tumor involving one lung plus a main pulmonary artery
Stage III	bilateral lung involvement
Stage IV	extrathoracic spread

these tumors rarely penetrate the pulmonary artery wall, allowing reasonable mobilization. The main pulmonary artery has always been involved in our experience and the pulmonary valve is involved 30% of the time.[171] The main pulmonary arteries can be resected out to their first branch points on each side from a median approach. In cases where one pulmonary artery is relatively free and the other is involved deep into the lung, a pneumonectomy may be required. In this case, the pulmonary veins and main bronchus are dissected and divided before CPB is instituted to avoid bleeding while heparinized. The branch PAs and main pulmonary artery are mobilized, CPB is instituted, and the involved main PA is divided. In such cases, the involved lung with little blood flow once resected may result in improved hemodynamics; especially after removal of tumor obstructing the contralateral pulmonary artery. Once each pulmonary artery has been divided or in the case of pneumonectomy the lung and main PA removed, the main PA trunk can be assessed for pulmonary valve involvement. If the pulmonary valve is involved, the entire PA trunk must be removed and replaced by a pulmonary allograft. Removal of the entire PA trunk and replacement by an allograft is similar to mobilization and replacement techniques for a Ross procedure.[174] If the resection of the right and/or left main PA is limited, then the allograft branches may be adequate to span the defect. When tumor extension is too distal for this, a Gore-Tex (ePTFE) graft can be used to interpose between the distal right PA resection point to distal left PA resection point and then implantation of the pulmonary allograft into the side of the ePTFE graft is performed. Despite the extensive nature of the resection, separation from CPB has not been difficult. The surgery relieves the patient of severe PA obstruction that is present preoperatively.

The authors have successfully resected pulmonary artery sarcomas in 10 patients, three of whom required concomitant pneumonectomy. There were no in-hospital or 30-day deaths, and all patients were discharged home. Our longest survivor currently has lived more than 100 months and has no known disease. In most cases, adjuvant chemotherapy is used, even in the face of clear surgical margins. Radical PA resection is both safe and appears to prolong survival compared to minimal or palliative resection. Resection in conjunction with chemotherapy also appears to prolong survival. Currently, recommendations to record such rare tumors in a national registry may allow better analysis of long-term outcomes.

Heart Transplantation

Malignant primary cardiac tumors may grow to a large size before detection. Additionally, extensive myocardial involvement or location affecting the fibrous trigone of the heart may make complete resection impossible. Because complete resection yields better results than incomplete resection, orthotopic cardiac transplantation has been considered as a treatment option. Reports of transplantation for a number of cardiac tumors, including sarcoma,[174–177] pheochromocytoma,[170] lymphoma,[171] fibroma,[133] and myxoma have appeared. However, the long-term results are uncertain because some patients die from recurrent metastatic disease despite transplantation.[170,171,173] As of 2000, 28 patients had been reported involving orthotopic transplantation for primary cardiac tumors, and of these, 21 had malignant tumors.[173] The mean survival for patients with primary cardiac malignancy was 12 months. Although technically feasible in some cases, orthotopic transplantation is hindered by a scarcity of donor organs and coupled with an extensive recipient list of patients without cancer. In addition, the large size of the tumor when diagnosed often necessitates rapid intervention for progressive congestive heart failure. Finally, the effect of immunosuppression on any remaining malignancy is unknown. In most cases, orthotopic transplantation is reserved for unresectable benign tumors, such as cardiac fibroma.

SECONDARY METASTATIC TUMORS

Approximately 10% of metastatic tumors eventually reach the heart or pericardium, and almost every type of malignant tumor has been known to do so.[2,7] Secondary neoplasms are 20 to 40 times more common than primary.[4,174] Up to 50% of patients with leukemia develop cardiac lesions. Other cancers that commonly involve the heart include breast cancer, lung cancer, lymphoma, melanoma, and various sarcomas.[2,175,176] Metastases involving the pericardium, epicardium, myocardium, and endocardium roughly follow that order of frequency[2,7] as well (Table 62-7).

The most common means of spread, particularly for melanoma, sarcoma, and bronchogenic carcinoma, is hematogenous and ultimately via coronary arteries. In addition, metastasis can reach the heart through lymphatic channels; through direct extension from adjacent lung, breast, esophageal, and thymic tumors; and from the subdiaphragmatic vena cava.

TABLE 62-7 Metastatic Cardiac Disease

Tumor	Total (no.)	Cardiac (%)	Pericardial (%)

FIGURE 62-36 Hematogenous metastases within the myocardium of a patient with renal cell cancer. (*Reproduced with permission from Hurst JW et al: Atlas of the Heart. New York, McGraw-Hill, 1988.*)

The pericardium is involved most often by direct extension of thoracic cancer; the heart is the target of hematologous and/or retrograde lymphatic metastasis.[5] Cardiac metastases rarely are solitary and nearly always produce multiple microscopic nests and discrete nodules of tumor cells[2,7] (Fig. 62-36). Cardiac metastases produce clinical symptoms in only about 10% of afflicted patients.[177,178] The most common symptom is pericardial effusion or cardiac tamponade. Occasionally, patients develop refractory arrhythmias or congestive heart failure. Chest radiographs and electrocardiograms tend to show nonspecific changes, but echocardiography is particularly useful for diagnosis of pericardial effusion, irregular pericardial thickening, or intracavity masses interfering with blood flow.

Surgical therapy is limited to relief of recurrent pericardial effusions or, occasionally, cardiac tamponade. In most instances, these patients have widespread disease with limited life expectancies. Surgical therapy is directed at providing symptomatic palliation with minimal patient discomfort and hospital stay. This is most readily accomplished via subxiphoid pericardiotomy, which can be accomplished under local anesthesia if necessary with reliable relief of symptoms, a recurrence rate of about 3%, and little mortality.[176] Alternatively, a large pericardial window in the left pleural space can be created using thoracoscopy, but we would recommend this only under unusual circumstances.[179] This can be accomplished with minimal patient discomfort but does require general anesthesia with single-lung ventilation and may be poorly tolerated by patients with hemodynamic deterioration secondary to large effusions.

RIGHT ATRIAL EXTENSION OF SUBDIAPHRAGMATIC TUMORS

Abdominal and pelvic tumors on occasion may grow in a cephalad direction via the inferior vena cava to reach the right atrium. Subdiaphragmatic tumors are frequently renal carcinomas, although hepatic, adrenal, and uterine tumors occasionally have exhibited this behavior. Up to 10% of renal cell carcinomas invade the inferior vena cava, and nearly 40% of these reach the right atrium.[188] Radiation and chemotherapy are not effective in relieving the obstruction of blood flow. If the kidney can be fully removed, as well as the tail of the tumor thrombus, survival can approach 75% at 5 years.[96,182]

Renal cell tumors with atrial extension typically are resected with abdominal dissection to ensure resectability of the renal tumor. Initially, we performed a concomitant median sternotomy and often used cardiopulmonary bypass with hypothermic circulatory arrest when treating these patients. However, we have changed our approach and now work closely with our liver transplant surgeons who have extensive experience in the area of the retrohepatic vena cava. We have found that we can expose the vena cava up to the right atrium through an abdominal incision. With ligation of the arterial inflow, the tumor tail often shrinks below the diaphragm, and in almost all circumstances, this can be removed without the use of cardiopulmonary bypass. Occasionally venovenous bypass as used in hepatic transplantation is necessary to occlude inflow through the inferior vena cava, but this is unusual. If the tumor is too complex for this maneuver, then a median sternotomy is performed, and cardiopulmonary bypass with hypothermic circulatory arrest can be used to remove the tumor from the cardiac chambers down into the inferior vena cava. Perfusion can be restarted, followed by removal of the rest of the tumor. Although it leads to adequate exposure, significant problems with coagulopathy are often apparent after cardiopulmonary bypass and profound hypothermia.

A 5-year survival rate of 75% has been achieved following nephrectomy with resection of right atrial tumor extension.[181,182] Other subdiaphragmatic tumors with atrial extension that have been resected successfully include hepatic and adrenal carcinoma, as well gynecologic tumors.[183–186, 192]

MOLECULAR- AND BIOLOGIC-BASED DIAGNOSIS AND THERAPY FOR CARDIAC TUMORS

This is an exciting time for investigators involved in the search for novel therapies for tumors such as many of those discussed in this chapter. A "new biology" is being developed in laboratories around the world working in these areas, and this is supplanted by the knowledge that is being obtained from the concerted Human Genome Project and the subsequent development of proteomics.[187] It is incumbent on the thoracic surgeon involved in the care of patients with cardiac tumors to have some degree of familiarity with the terms and promise of these advances because significant additional improvement in survival of many of these patients is unlikely to result from further advances in surgical technique.

Interestingly, many sarcomas demonstrate reproducible translocations that allow for the production of novel chimeric genes that may code for a variety of fusion proteins. Many of these proteins have been found to engender cellular phenotypic malignant changes, resistance to apoptosis, and unfettered growth.[188] Although not associated with cardiac involvement,

the fusion proteins EWS-FL11 and EWS-ERG are noted in Ewing's sarcoma. When full-length antisense oligonucleotide constructs are used to target the mRNA of these proteins, protein expression is downregulated, and an eightfold increase in apoptosis sensitivity is noted.[180] These fusion proteins have been noted in some forms of rhabdomyosarcoma, and the most common is PAX3-FKHR. This oncoprotein combines components of two strong transcriptional activators and may increase the production of the downstream antiapoptotic protein BCL-XL. Antisense oligonucleotides directed at this oncoprotein mRNA have led to apoptosis in rhabdomyosarcoma cells.[189,190] A similar translocation and fusion protein have been noted in fibrosarcoma. This translocation [t(12;15)(p13q25)] brings together genes from chromosomes 12 and 15, which combines a transcription factor with a tyrosine kinase receptor. The resulting fusion protein is a tyrosine kinase that has oncogenic potential.[191] Reproducible translocations and fusion proteins with downstream effectors of malignant behavior have not been described for angiosarcoma, but they are actively being sought.[192] Antisense treatment has been maligned in the past owing to problems with both delivery and stability of therapeutic constructs. However, sophisticated biochemical alteration of these molecules has improved stability, and two recent solid tumor trials using antisense therapy for salvage have demonstrated positive results.[193] Additional methods of delivering antisense to tumor cells, including viral vector delivery, have been developed. Finally, in addition to antisense methods, small molecule inhibition of many of these fusion proteins should be possible.

Angiosarcoma is an obvious target for therapies based on antiangiogenesis. The weak antiangiogenic properties of interferon-alpha are presumed to be the mechanism that accounts for responses to this agent in this tumor.[194] Multiple new antiangiogenic agents are being evaluated currently in phase I and II trials, and a number of noncardiac angiosarcoma patients have been treated at our institution on this basis. We have noted several to develop stabilized disease, but no definitive data are yet published. Certainly, the use of these agents in these vascular-origin tumors is theoretically attractive.

Viral vector–mediated gene therapy has been evaluated for various sarcomas in the preclinical setting. A number of potential targets exist for these sorts of therapies. Although *p53* is not commonly mutated or absent, *mdm-2* is often overexpressed in many sarcomas, including angiosarcoma. This gene is a known oncogene that is able to directly induce cellular transformation. Importantly, when overexpressed, it binds to and inhibits *p53* activity, even though expression of *p53* may appear normal. Overexpression of *mdm-2* also has been associated with VEGF overproduction and angiogenesis.[194] Preclinical studies of adenoviral vector *p53* transduction of sarcoma in SCID mice have demonstrated growth delay, tumor regression, and decreases in VEGF expression.[195] Many other targets for this approach, including inhibition of NF-κB expression using an adenoviral-dominant negative Iκ-βα construct and prodrug-mediated gene therapy using a doxorubicin prodrug and adenoviral transfer of a metabolizing enzyme in sarcoma cells, have been shown to be effective.[183] Unfortunately, the application of viral-mediated gene therapy paradigms to this tumor suffers the same problems of targeting, transgene expression durability, and immune response that are problematic for the field in general.

In regard to molecular diagnosis, there are no reproducible familial patterns for development of most malignant tumors. However, familial cardiac myxoma, rhabdomyoma, and fibroma may exhibit reproducible genetic abnormalities that lend themselves to the development of genetic testing to identify individuals at risk. Familial myxoma syndrome, or Carney complex, has been associated with mutations in the 17q24 gene *PRKAR1α* that codes for the R1α regulatory subunit of cAMP-dependent protein kinase A (PKA).[195] Although not widely available, genetic diagnosis of this syndrome is now technically achievable.[196] Reproducible mutations in the *TSC-1* and *TSC-2* genes in patients with tuberous sclerosis and cardiac rhabdomyoma, as well as mutations in the *PTC* gene of patients with the Gorlin syndrome and cardiac fibroma, have been noted.[197–200] It is hoped that in the near future we will be able to predict who is at particular risk for these and other cardiac tumors. This could allow for more intense surveillance, earlier detection, and a higher rate of surgical or multimodality cure for these patients.

IMPORTANT POINTS

- Complete excision and radical resection is recommended to prevent local recurrence of cardiac tumors.
- All benign cardiac tumors are potentially curable with current surgical techniques.
- Multimodality therapy and multidisciplinary planning should be incorporated into the care of cardiac tumor patients.
- Cardiac sarcomas are best classified by anatomic location rather than histologic subtype, and the former dictates their presentation, treatment, and prognosis.
- Right heart sarcomas tend to be more bulky, infiltrative, metastasize earlier, and are usually amenable to neoadjuvant chemotherapy.
- Left heart sarcomas tend to be more solid, less infiltrative, and metastasize later.
- Pulmonary artery sarcomas usually present with obstruction, right heart failure, and tend to grow distally within the confinement of the pulmonary artery.
- Cardiac tumors located in the anterior left atrial wall may require autotransplantation for complete excision of the tumor, reconstruction, and reimplantation.
- Cardiac autotransplant and concomitant pneumonectomy carries an unacceptable 50% mortality rate.

CHAPTER 63

Immunobiology of Heart and Heart-Lung Transplantation

Bartley P. Griffith

INTRODUCTION

This chapter on the immunology of transplantation is a refreshed effort designed to promote a foundation for understanding the basic transplant immunologic fundamentals necessary for competency in caring for heart and lung transplant recipients. Although surgeons must acquire the technical expertise to perform these often demanding surgeries safely, the recipients' well-being additionally benefits from a surgical team well versed in basic transplant immunology. Comfort in treating patients who receive immunosuppressive therapies, both conventional and innovative, requires familiarity with the nonsurgical language of transplantation. The goal of this chapter is to squeeze the essentials[1] into an understandable short text. The knowledge gained should permit surgeons to read immunology-tilted manuscripts with better understanding and thus make better decisions in treating their own patients. The core features of this alloresponse and new science are presented with some specific references to hearts and lungs so that the surgeon participating in the care of thoracic organ recipients can more easily build an understanding of the complex and evolving science. The material is organized to reflect a unifying theory of the immune response that determines the fate of an allograft and most often the heart or lung recipient as well. This includes: (1) histocompatibility; (2) activation of alloresponse T lymphocytes and T-cell–mediated rejection (TMR); (3) antibody-mediated rejection (AMR); (4) the underappreciated immune pathways, natural killer (NK) cells, and memory lymphocytes; and (5) immune plus gene monitoring. The text will clarify acute, cell-mediated, hyperacute, and chronic rejection pathways (Fig. 63-1).

MAJOR HISTOCOMPATIBILITY COMPLEX

Major histocompatibility complex (MHC) molecules are a family of proteins that vary quite a lot between individuals (genetic polymorphism) and represent the molecular basis for how immune systems distinguish self from nonself with respect to infections and transplants. MHC molecules on donor cells or MHC fragments, shed from thoracic organ transplants, are determined to be foreign by the immune regulatory system of the host. Intact MHC molecules expressed on the surface of cells serve two key functions in the context of transplantation. Fragments of foreign proteins, including fragments of MHC molecules, are presented in the binding groove of MHC and are recognized by T-cell receptors of the recipient that happen to have high affinity for that protein fragment (indirect donor antigen presentation). In addition, recipient T cells directly recognize donor MHC as "foreign" (direct donor antigen presentation).

Human MHC molecules are known as human leukocyte antigens (HLA) because they are expressed at high levels on leukocytes and were first measured on peripheral blood lymphocytes. HLA are heterodimeric glycoproteins expressed on the surface of almost every cell in the human body. These proteins are immunologically active and can trigger a proliferative or cytotoxic T-cell response in vivo and in vitro. For these reasons, they are thought to play a critical role in graft rejection in solid-organ transplantation.

The genes coding for these antigens are located on the short arm of chromosome 6 (6p21.3). This region spans over 4 million base pairs in length and encodes for over 200 genes involved with host immune surveillance and immune regulation.

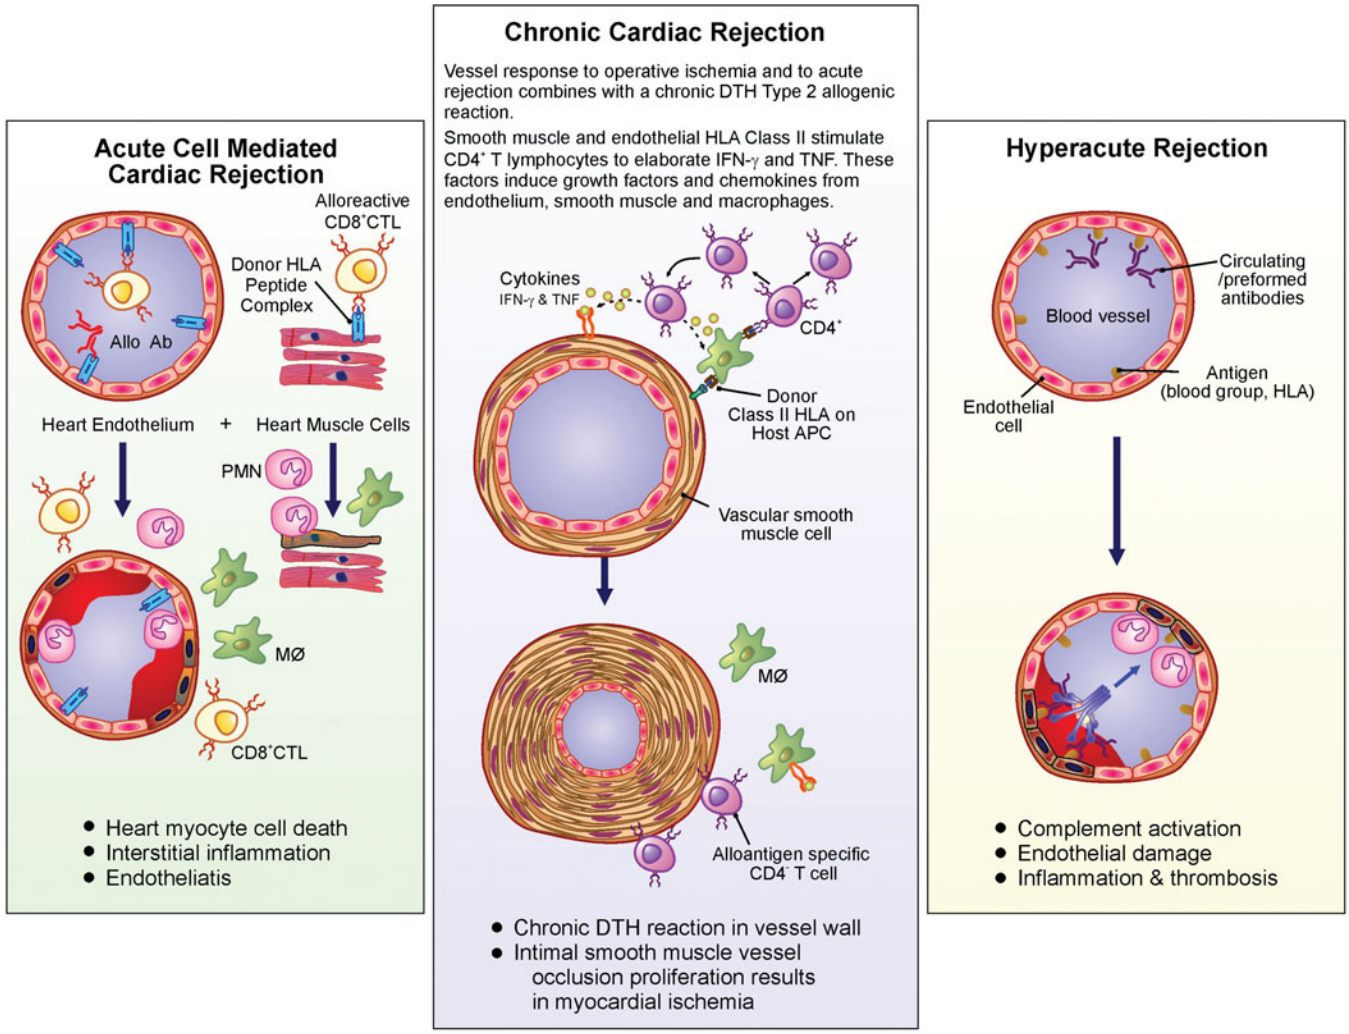

FIGURE 63-1 The alloresponse to a transplanted heart or lung may be grouped for simplicity into an early hyperacute rejection (HAR) based on preformed circulatory antibodies to blood group and in modern era HLA antigens (*right panel*) and acute cell-mediated rejection (AR) a more common and driving response that has been the focus of much of transplant immunology (*left panel*). AR is centered on the T lymphocytes becoming activated by specific HLA protein presented by antigen-processing cells. The $CD4^+$ cells recruit inflammatory cells to the allograft and amplify other immune cells. The $CD8^+$ T cells are directly involved with destruction of the allograft by cytotoxic intervention. Finally, chronic rejection (*center panel*) is the term given to describe progressive obliteration of the coronary arteries (chronic allograft vasculopathy, or CAV) in the heart or obstruction of small- and mid-sized airways (obliterative bronchiolitis, or OB) in the lung. These tubular structures are affected by injury and acute alloreactive hypersensitivity reaction.

The HLA is divided into three regions or Classes: Class I, II, and III (Fig. 63-2).

Classic Class I HLA proteins/antigens are HLA-A, HLA-B, and, more recently, HLA-C. These proteins consist of an α-heavy chain and a β-light chain (Fig. 63-3). The α-light chain is encoded in the MHC; however, the β-chain is β_2-microglobulin that is encoded on chromosome 15. When folded, the α-heavy chain only contains the peptide-binding region which presents peptide antigen to the T cell. Class I antigens are constitutively expressed on nearly all cells. B-cell lymphocytes may express Class I antigen at a higher density than the T-cell lymphocytes. Class I antigen expression is upregulated on the endothelium and parenchymal cells in many organs and tissues in association with inflammation, including after ischemia and reperfusion.

Classic Class II HLA proteins/antigens are HLA-DR, HLA-DRw, HLA-DQ, and more recently HLA-DP. These proteins consist of an α-heavy chain and a β-light chain, both of which are encoded in the MHC. When folded, the α-heavy chain and β-light chain come together with each contributing part of the peptide-binding region (Fig. 63-3). Class II antigens are expressed mainly on B-cell lymphocytes, activated T cells, and dendritic cells. Other cell types such as endothelial cells, may express Class II antigen expression after activation.

Each person has two different HLA genes at each HLA locus (HLA-A, B, D, etc). HLA antigens are codominantly expressed on the cell surface so that each cell has two different HLA proteins for each HLA locus. HLA haplotypes (the sequence of A, B, D genes on one chromosome, see Fig. 63-2) are usually inherited as a group from each parent in a Mendelian fashion.

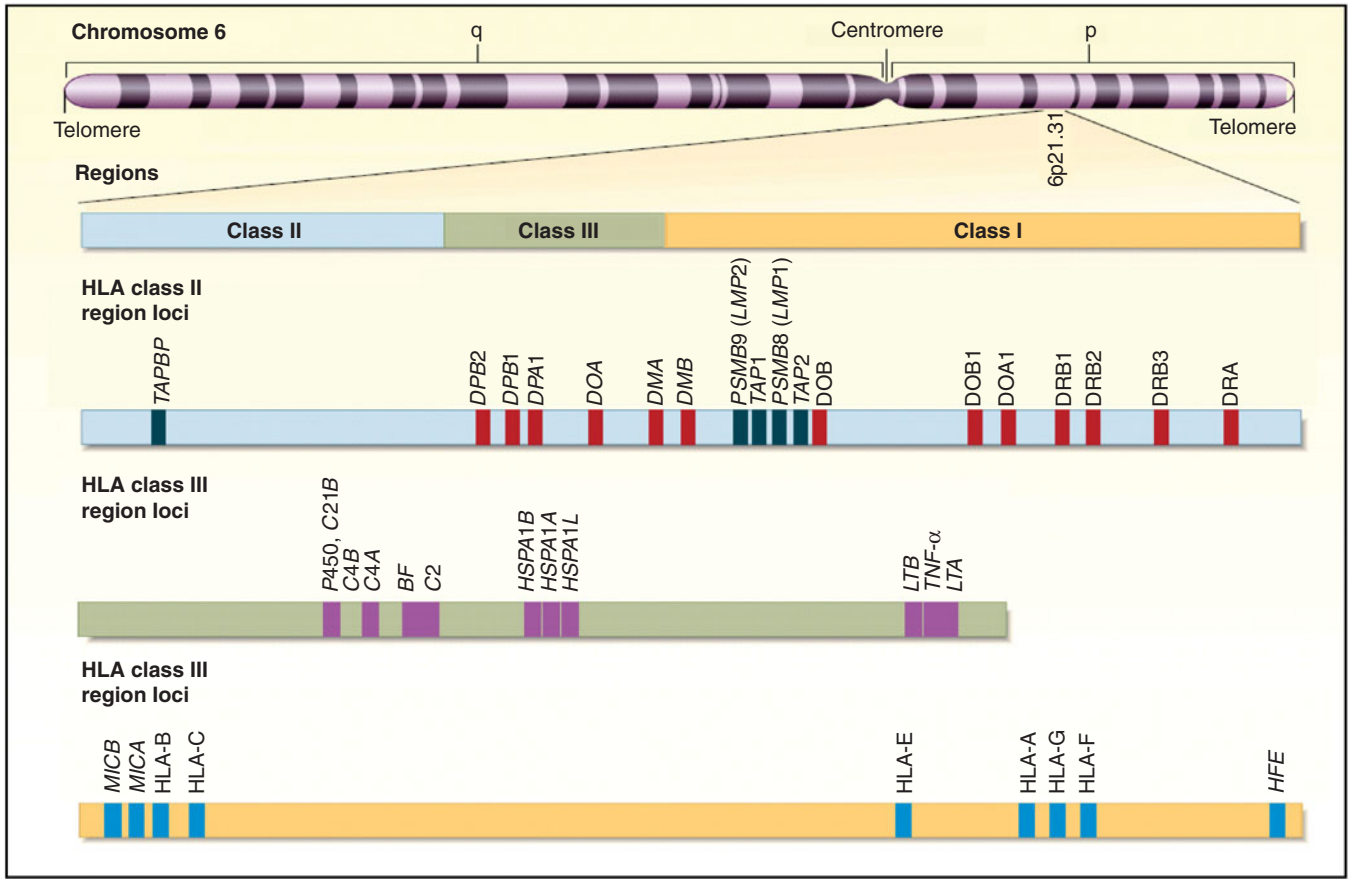

FIGURE 63-2 The major histocompatibility complex is divided into three regions or Classes: Class I, Class II, and Class III.

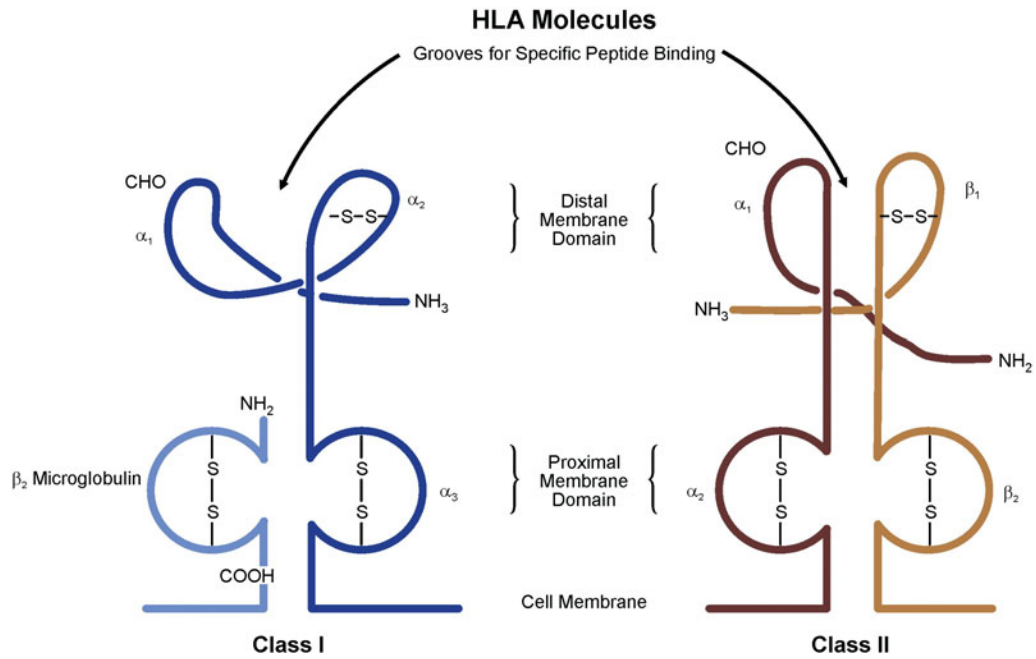

FIGURE 63-3 Classes I and II HLA molecules are made up of polypeptidic chains with intrachain disulfide bonds. The α_1 and α_2 distal domains of class I and the α_1 and β_1 domains of class II make up the peptide-binding site for alloantigen. (*Adapted with permission from Parham M, in Haber E [ed]: Immunobiology of Transplantation Molecular Cardiovascular Medicine, New York, Scientific American Press, 1995.*)

Thus, two offspring of the same parents have a 50% chance of inheriting one identical haplotype, 25% chance of inheriting two identical haplotypes, and 25% chance of having no haplotypes in common. In addition, because of the distance between these genes in the MHC, there are hot spots of gene recombination. Recombination in offspring occurs approximately 1 to 2% between HLA-A and C, or between HLA-B and HLA-DR, and approximately 30% between HLA-DP and HLA-DQ. This recombination accounts for most of the occasional exceptions to faithful transmission of intact parental haplotypes to their children. HLA haplotypes are found in varying frequencies across the major population groups (white, Hispanic, black, Asian, and American Indian).

HYPERACUTE REJECTION

In the early days of organ transplantation, hyperacute rejection occurred because of preexisting IgM alloantibodies. Best known examples of these are the ABO blood group IgM antibodies. Although still a barrier to xenotransplantation, blood group typing has virtually eliminated this particular cause of immediate organ destruction. Of interest is the success of blood group-mismatched organs in neonatal recipients who have not yet developed IgM antibodies to blood group antigens. Antibodies against blood group antigens arise between 6 and 18 months postnatal because of the presence of related carbohydrate antigens on intestinal bacteria. Today, when hyperacute rejection is seen, it is normally caused by preexisting IgG antibodies usually directed against donor HLA proteins (see Fig. 63-1). These antibodies are often the result of previous blood cell transfusions (most particularly multidonor platelets owing to the high HLA load) or previous pregnancies or transplants. After wide adoption of the first crossmatch technique by Patel and Terasaki in 1969, hyperacute rejection based on HLA antibodies became rare.[2] Further improvements in screening for HLA antibodies have nearly eliminated it. New flow cytometric crossmatch techniques occasionally reveal previously unsuspected anti-HLA antibodies (see Flow Cytometric Assays) at titers below the threshold detected by the crossmatch test; the importance of these low-titer antibodies is uncertain, but at least in some circumstances they are associated with an accelerated failure of the organ transplant.

T-CELL RESPONSE TO ALLOGRAFT

Success in heart and lung transplantation requires control over the adaptive immune response to donor MHC antigens expressed by the allograft. Rejection of allografts is initiated by T lymphocytes primed to donor antigens in the peripheral lymphoid tissues and recruited into the donor organ where those antigens are expressed. Much of the recent advance in clinical transplantation has been because of a better understanding of T-cell–mediated responses. Transplant immunologists are closing in on the critical steps that contribute to different effector mechanisms of tissue injury. The nature of allograft rejection is influenced by alloantigen specificity, frequencies (measured as absolute number or proportion), and cytokine profiles of naïve and "memory" donor-specific T cells.

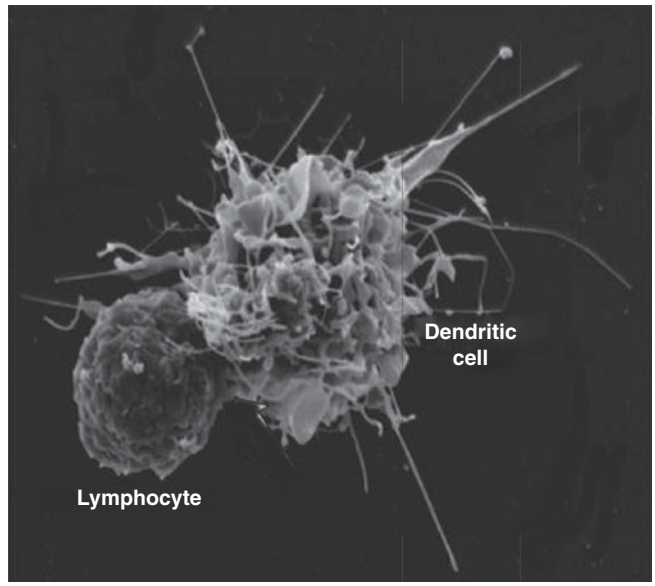

FIGURE 63-4 Dendritic cell with its typical membrane extensions engaged with T lymphocyte. (*www.dendriticcellresearch.com, Institute of Cellular Therapies, Noida, UP 201303, India.*)

Currently, it is held that alloreactive T lymphocytes are primed by alloantigens presented to them on donor (direct) and/or host (indirect) antigen-presenting cells (APCs). The T cells are the primary actors in the pathologic reaction to the transplanted organ. They participate in cytotoxicity and cytokine-mediated

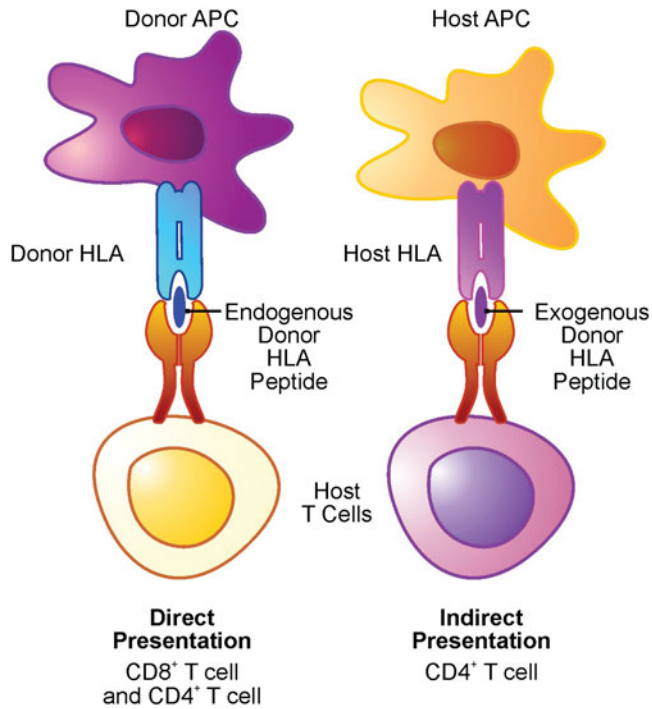

FIGURE 63-5 T cells are stimulated to proliferate when their TCR engages donor peptides processed and presented by an HLA molecule, expressed by donor or host APCs.

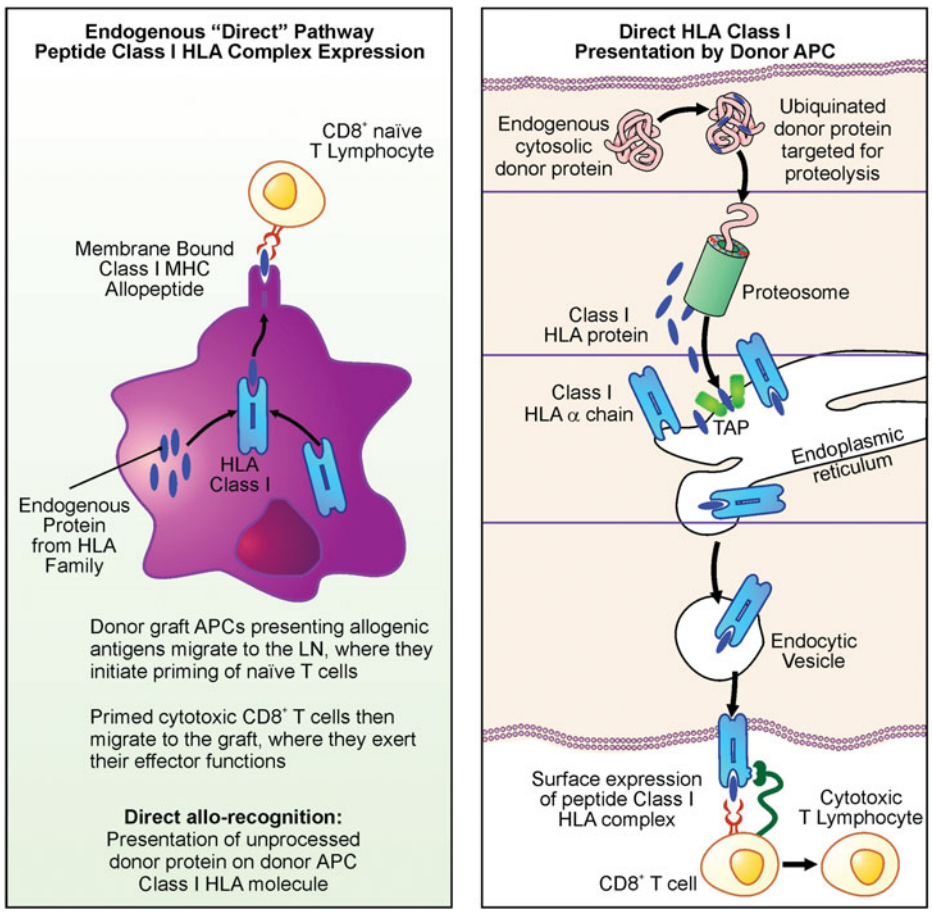
inflammation. B cells, antibodies, and macrophages contribute to destruction of the graft via a variety of effector pathways. Ischemia/reperfusion injury of the allograft triggers innate immunity that can amplify adaptive immunity. Molecular modulators of innate immunity have recently been an expanding area of interest. These include toll-like receptors (TLR), cytokines, chemokines and complement. Although APCs are emphasized, B cells and natural killer (NK) cells exert influence on a host's decision to reject an allograft.[3]

T-Lymphocyte Alloactivation

A T cell can only become triggered to proliferate and differentiate if it links to a specialized cell that presents fragments of donor peptides bound to HLA molecules on its surface (Fig. 63-4). These HLA-peptide displaying cells are called antigen-presenting cells (APCs). "Professional" APCs differ from other HLA-expressing cells in that they also express costimulatory molecules that efficiently stimulate reciprocal activation of both the APCs and the responding T cell. Professional APCs include dendritic cells, B lymphocytes, and macrophages. The peptide HLA antigen complex may be presented by resident *donor* passenger APCs found in the transplanted heart or lung (direct presentation) or *host* APCs that endocytose HLA protein shed from the allograft (indirect presentation) (Fig. 63-5). HLA-peptide antigens become the specific key that fits into the T-cell receptor. T cells react against alloantigens because of the cross-reactivity of the T-cell receptor (TCR) with self and foreign HLA molecules. Host and passenger donor dendritic cells are thought to be the most efficient type of APCs for activating naïve T cells.

Donor Antigen Presentation to T Cells by APCs

Donor passenger APCs transplanted with the heart or lung directly process endogenous HLA-derived peptides from within the graft or themselves and present them associated with a groove on Class I HLA complexes on their surfaces (Fig. 63-6A). $CD8^+$ T lymphocytes have Class I HLA T-cell receptor (TCR) molecules on their surfaces into which the Class I protein MHC complexes presented on the donor-derived APCs fit (lock and keys). This pathway is responsible for the majority of initial



A

FIGURE 63-6 (A) Direct presentation of Class I HLA donor antigen by donor APCs. Donor-derived APCs (dendritic cells within the transplant) ubiquitinate an endogenous cytosolic (donor) protein and transport it through the proteosome, where it is digested. Small proteins move with transporter associated with antigen processing (TAP) into the endoplasmic reticulum, where it becomes associated with Class I HLA α chain. The protein–HLA complex locates on the surface of the APC where $CD8^+$ T cells with TCR locks specific for the protein–HLA complex keys can associate. The association prompts $CD8^+$ T-cell activation.

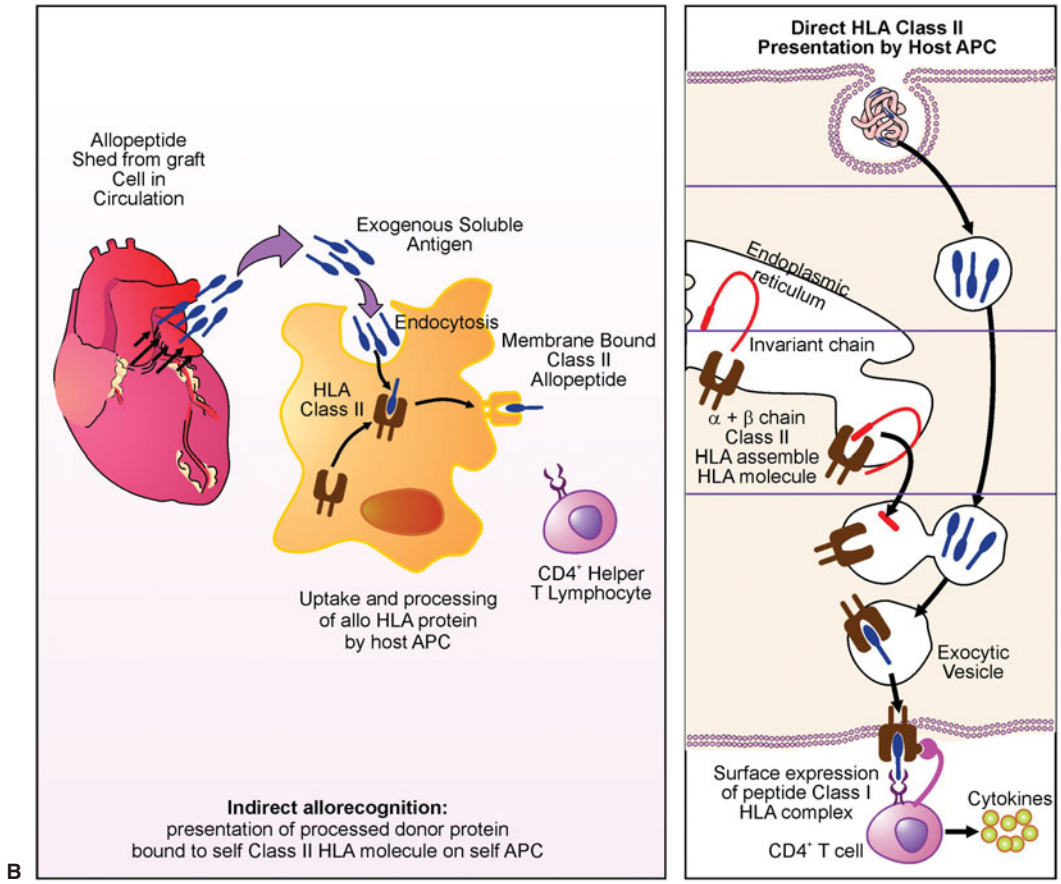


FIGURE 63-6 (B) Indirect Class II HLA donor-antigen presentation by host APC. Extracellular protein antigen shed from the heart or lung allograft is taken into a host APC by endocytosis. The protein is proteolyzed and transported into the Golgi. There it displaces the invariant chain held α and β chain Class II HLA molecule. The digested protein molecule finds its specific place within the HLA molecule and is moved to the APC surface where it can specifically adhere to a $CD4^+$ T cell. The attached $CD4^+$ T cell with donor-specific TCR is stimulated to proliferate and participate in the alloresponse.

T cells that react to alloantigens. It is known as the direct pathway of peptide presentation and is responsible for most early events of acute cell-mediated cytotoxicity.

Later alloresponses are directed more by $CD4^+$ T cells because they recognize Class II HLA donor-specific peptide-HLA surface molecules presented on recipient APCs. These recipient APCs gradually replace those donor APCs transplanted with the heart or lungs of the donor. Host APCs trafficking through the allograft phagocytose interstitial and nodal HLA protein antigen shed from the donor graft (Fig. 63-6B). This shedding is induced when the graft is stressed by ischemia (preservation), inflammation (bacterial and viral infection), and rejection. The donor protein undergoes endosmic proteolysis and is combined with a Class II HLA molecule. The donor peptide Class II HLA complex is transported to the surface of the host APC and presented indirectly as the key to the TCR complex on $CD4^+$ T cells. Because $CD4^+$ T cells provide help to donor-specific B cells, later alloresponses tend to be associated with appearance of alloantibody.

Activated dendritic cells also provide costimulators to the naïve T cells that are required for a full T-cell response. Macrophages present antigens to differentiated $CD4^+$ cells that activate the macrophage to promote cell-mediated immunity. B cells also serve an APC function by presenting antigens to helper T cells. These then activate the B cell to become part of the effector humoral immune response through production of antibodies (Fig. 63-7). Recently it has been learned that recipient APCs can acquire intact HLA molecules directly from contact with a donor APC bearing the HLA molecule. It can also receive the HLA molecules by fusing with exosomes from donor APCs containing the protein. These APCs can stimulate $CD4^+$ T cells by direct or indirect pathways.[4]

APC-Induced T-Cell Activation: Signal 1

T lymphocytes are able to respond to the peptide HLA complexes expressed on APCs because they express membrane receptors that: (1) keep the cells together via the APC-adherence ligands; (2) include the TCR that specifically recognize (cognate) the peptide–HLA complexes displayed in the APC; and (3) *costimulatory receptor* molecules accessory to the TCR that either facilitate (CD28) or inhibit (cytotoxic T lymphocyte-associated antigen 4 [CTLA-4]) the transduction of activation signals to the nucleus or provide second signals that strengthen the TCR activation. The TCR complex includes variable antigen-binding TCR heterodimer and invariant CD3, ζ, ε, and γ proteins, and ζ chains that enable activation signal transduction to the nucleus (Fig. 63-8).

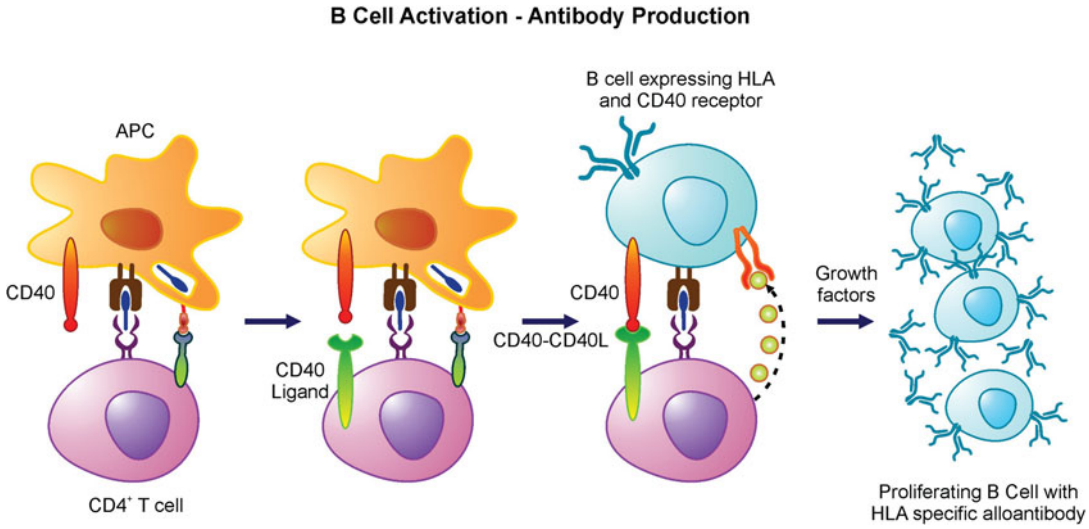

FIGURE 63-7 $CD4^+$ T lymphocytes are specifically activated by donor peptide proteins presented on APC–HLA complexes. These T cells in turn activate B lymphocytes expressing specific HLA Class II molecules and CD40. The B cells respond to growth factors by proliferative formation of germinal centers and production of specific alloantibody.

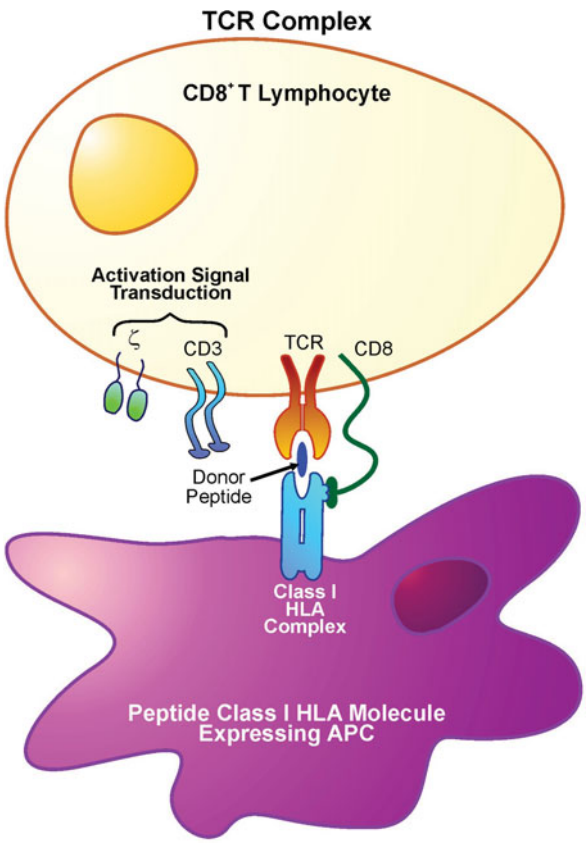

FIGURE 63-8 When an APC is specifically engaged with a T cell via the TCR lock and donor protein/MHC key, its intracellular pro-stimulator signaling response is generally dependent and strengthened by the docking of APC surface-bound costimulators such as B7-1, B7-2, and LFA-3 into T-cell coreceptors CD28 plus CD2, respectively. The stable adherence of the T cell and APC is the result of APC ICAM-1 and T cell LFA-1 union. These interactions are localized in a specific geographic zone on T cells and APC—the immunologic synapse.

CD8 and CD4 surface proteins act as coreceptors that bind to the Class I or II HLA molecule, respectively, displayed on the APC. As discussed, the CD8 and CD4 interact with Class I and II HLA, respectively, when a donor peptide–HLA complex is recognized. CD8 and CD4 strengthen the binding of the TCR to the HLA molecule and participate in the intracellular signaling process.

Costimulation Pathways: Signal 2

In addition to activation of the T cell by engagement of foreign peptides and its TCR, several other surface molecules participate in a T-cell activation. Those that enhance TCR signaling (CD4 in $CD4^+$ T cell and CD8 in $CD8^+$ T cell) are called *coreceptors* because they bind to part of the same HLA molecules that engage the TCR. Another group of T-cell activating surface molecules is called *costimulatory receptors* (Fig. 63-9). Blockade of costimulatory pathways provides important new possible therapy to prolong organ transplant survival and even reach a tolerant state. Costimulatory receptors or ligands on T cells recognize respective cognitive ligands or receptors presented on APCs or the graft tissue itself. The best defined costimulatory receptor and ligand pairs are the constitutively expressed CD28 T-cell costimulatory receptor and its APC ligands B7-1 (CD80) and B7-2 (CD86). This pathway is particularly important in activation of naïve T cells. When engaged, these pairs deliver antiapoptotic signals and trigger the expression of and growth factors, including IL-2 that encourage proliferation of the alloantigen-specific $CD4^+$ or $CD8^+$ cells. A second inducible costimulatory receptor for B7 molecules has been identified and termed CTLA-4 (CD152). Unlike the structurally homologous CD28, CTLA-4 appears on recently activated T cells and is a negative regulator that promotes pathways that limit proliferation. It is efficient that the same costimulator (B7) can prompt initial proliferative signals via constitutive CD28 engagement and later when CTLA-4 is induced subsequently limiting signals

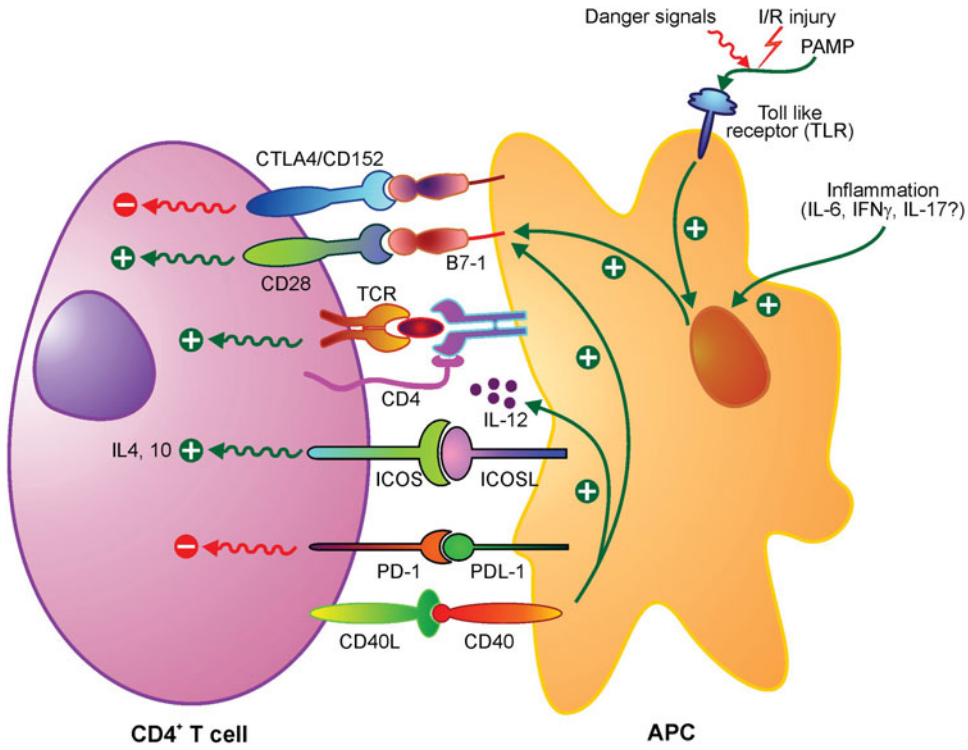

FIGURE 63-9 The process of regulating T cell ($CD4^+$ and $CD8^+$) activation involves engagement of the TCR/CD4 or CD8 with the foreign protein–HLA molecule and of several costimulators of the costimulatory pathway. The constitutively expressed CD28 coreceptor drives proliferation of naïve T cells when engaged by its ligand B7-1. Inducible CTLA-4 (CD154) coregulator acts to regulate this process negatively along with its APC-bound B7-2 ligand. Other CD28 family coreceptors include inducible ICOS that signals for proinflammatory IL-4 and IL-10 effector responses and PD-1 that has a negative regulatory effect on the T cell. The APC is made better by a reciprocal activation between T cells and APCs and the phenomena of "licensing" in which innate receptors (PAMP–Toll receptor) stimulates B7 expression. This has the effect on the T cell of inducing CD40 ligand (CD154). CD40 on the APC's membrane drives additional B7 and elaboration of IL-12.

to the T cell. Therapeutic targeting of this pathway with CD80 and CD86 blockade with CTLA-4 Ig–like molecules has been effective in primates and is currently in clinical trials in kidney transplantation.[5] Inducible costimulator (ICOS) and Programmed Death-1 (PD-1) are more recent discoveries in the T-cell CD28 family. When ICOS joins its ligand ICOS-L on an activated APC, it stimulates the T-cell effector response by promoting IL4 and IL10 production. PD-1 is the coreceptor for costimulator PD-ligand and, like CTLA-4, represses T-cell responses.

A second family of costimulatory molecules belong to the TNF superfamily. The prototypic pathway is represented by the costimulatory receptor CD40 on APC binding to CD40L on T cells. Transplantation immunobiology is influenced by the innate immunity directors against substances from microbes, including bacteria, viruses, and fungi. These substances, often nucleic acids, are called *pathogen-associated molecular patterns* (PAMPs) (see Fig. 63-9). PAMPs can bind to PAMP-receptors on APCs called toll-like receptors (TLR). This engagement has the effect of strengthening the APC response. This begins by increasing the expression of costimulatory molecules and proinflammatory cytokines. The CD40 signaling promotes additional B7 expression and elaboration of T-cell proliferation IC12. By reciprocal activation, CD40L on T cells makes the APC better and is thought to license additional APCs to participate in the T-cell activation process. A clinical trial of anti-CD154 was unexpectedly associated with thromboembolic complications. This led to consideration of blocking CD40, and a human trial is currently underway in transplant.

In severe rejection, B cells join the alloresponse when they receive help from $CD4^+$ T cells (see Fig. 63-7). $CD4^+$ T-cells are activated by APCs to express CD40L (CD154). Ligand B cells expressing CD40 and MHC Class II receptors engage helper $CD4^+$ T cells and proliferate. B cells participate in the rejection of allografts by efficiently providing APC function to helper $CD4^+$ T cells and by elaboration of antibodies that: (1) recognize and destroy the donor endothelial targets; (2) participate in antibody dependent cytotoxicity (ADCC); or (3) stimulate the proliferation and migration of activated endothelial cells.[6] In the former, the endothelial antigen–antibody complexes activate the classic complement pathway, causing C3 and C5 to cleave, inciting inflammation (C5a) and formation of the membrane attack complex (MAC), which is composed of C5b complexed with C6, 7, 8, and 9 (C5b-9). The MAC causes vascular cell death by inducing pores to form in the cell membrane. When endothelial cells are activated or killed by complement, this in turn results in microvascular thrombosis and inflammation. ADCC describes the process by which antidonor IgG antibodies coating donor cells bind to the Fcγ RIII receptor of natural killer lymphocytes (NK cell). Cells of the innate immune system such as natural killer cells are also present in

allografts during rejection. These recognize alloantigens because they constitutively express inhibiting receptors specific for self HLA Class I protein. The NK cell produces proinflammatory cytokines like IFN-γ and directly kills the antibody-engaged target cell by injecting its proteolytic enzymes into the donor cell.

Cell-Mediated Rejection

Despite use of immunosuppressive therapy, transplanted heart and lungs often acutely reject. Both $CD4^+$ and $CD8^+$ cells participate, but the response is primarily mediated by the CD4 T cells. The early cell-mediated response begins when specific clones of $CD8^+$ cells that bear TCR molecules which fit and engage donor-specific peptide HLA Class I on donor APCs are stimulated to proliferate. In the presence of help from $CD4^+$ T cells, they become cytolytic lymphocytes CTLs and directly attach to and kill graft endothelial and parenchymal cells bearing the identical Class I donor protein HLA presented to them by the APC activators. This is known as the direct pathway because the CD8 cell directly kills the allotarget. It is responsible for most acute cell-mediated rejection early (in the first few months) after transplant. In the presence of calcium, the protein perforin polymerizes onto the Class I bearing target cell and causes 16- to 20-nm pores to open in the cell membrane, resulting in osmotic collapse. CTL granular content, including granzyme B and other cytotoxic molecules, is directly injected into the target cell, causing necrosis. Alternatively, apoptosis (programmed cell death) can also be stimulated in the target cell by interaction of the lymphocyte Fas ligand with the APO-1/Fas receptor of the target cell. Second messengers are elicited that activate endonucleases and proteases to cause fragmentation of DNA and thus organize the dissolution of the Class I bearing donor target T cell (Fig. 63-10).

The $CD4^+$ T cells primarily follow an indirect alloresponsive pathway by secreting various cytokines that drive inflammation and graft loss (see Fig. 63-10). IL-2 increases the expression of its own receptors (IL-2R) on $CD4^+$ cells, driving the proliferation and further differentiation of $CD4^+$ cells. The activated CD4 cells secrete additional lymphokines, including interferon-γ (IFN-γ), which along with IL-2 stimulates $CD8^+$ CTLs to bind to the allograft cells presenting donor MHC protein molecules. $CD4^+$ T cells are very heterogeneous. The four major categories are now recognized: Th_1, Th_2, Th_{17}, and regulatory T cells (Tregs). Th_1 cells are the main mediators of cell-mediated rejection. They produce IFN-γ and favor IL-12 production by macrophages. Th_2 cells make IL-4, 5, and 13 and promote humoral responses. Th_{17} produce IL-17, a cytokine recently discovered and involved in inflammation. In conditions in which the immune response is partially inhibited, Tregs develop with the ability to inhibit immune responses.

Memory T Cells

With improvement in immunosuppression that limits activation of naïve T cells, donor-reactive memory cells have been recognized as a previously underappreciated risk to the allograft. This group of donor-specific cells has an effector-memory phenotype. This is defined by an immediate and strong recall that is no more or less sensitive to costimulation blockade. Memory cells are thought to arise from heterologous immunity. This occurs when there is a resemblance between microbial antigens and self-protein HLA complex antigens. Some $CD4^+$ and $CD8^+$ cells exposed to Epstein-Barr, herpes simplex, and cytomegalovirus (CMV) become primed to recognize allogenic HLA molecules. Memory T-cell numbers are proportionately increased following lymphoablative treatment with rabbit ATG or alemtuzumab (anti-CD52 ab). It is unclear whether these memory cells are more resistant to depletion or whether they represent a conversion from naïve T cells during repopulation. Memory $CD4^+$ cells provide help for the alloresponse. They provide growth and proinflammatory factors that affect $CD8^+$ T cells and B-cell antibody production. They can elicit the proinflammatory response from nodal-bearing tissue remote from the allograft. Memory $CD4^+$ cells recruit $CD8^+$ cells that infiltrate the allograft across the endothelium. The memory $CD8^+$ cells proliferate and recruit macrophages, neutrophils, and additional activated T effector cells into the donor organ.[7] To date, memory T cells continue to evade efforts of therapeutic targeting. LFA-1 is one target that is under study for this purpose. They are very heterogeneous and have multiple functions.

Immunologic Tolerance

Peripheral tolerance mechanisms are responsible for tolerance to transplant-specific HLA protein not present in the thymus. Immunomechanisms to achieve immunologic tolerance of an allograft include considerations of cell death by apoptosis (deletion) of alloreactive T cells or induction of functional unresponsiveness (anergy or ignorance) and active regulation of alloimmunity by either donor-antigen–specific or nondonor-antigen–specific mechanisms (regulation). Anergy has been induced by exposing $CD4^+$ T cells to MHC antigen in the absence of costimulation. In addition, much of the current interest has been in better understanding of a subset of $CD4^+$ T cells called regulatory T cells (Tregs) whose function is to suppress immune responses and maintain self-tolerance.[8] Tregs may occur naturally (nTreg) and are important in autoimmunity. Those that are inducible (iTregs) in response to an allograft are distinct. Most Tregs express the IL-2 receptor α chain (CD25). TGF-β, IL2, and B7, CTLA-4 costimulation are required for nTreg production and survival. It remains to be fully elucidated how these molecules direct naïve T cells to differentiate into effector, memory, or regulatory phenotypes under various clinically relevant circumstances. FoxP3 is a forkhead family transcription factor important for Treg-suppressive function, but is also found in activated T cells in humans, and thus is not specific to identify human Tregs.

There has been limited success in translation of laboratory rodent-based tolerance protocols in clinical practice. Freedom from immunosuppression rarely is accomplished universally in strictly controlled large animal models. Management of preexisting memory cells appears to be a major hurdle. Finally, redundant effector cell mechanisms, cytokines, and costimulatory pathways make single or even dual approaches seem underpowered to establish tolerance in the clinic. There has been a limited number of patients in whom tolerance was induced by a

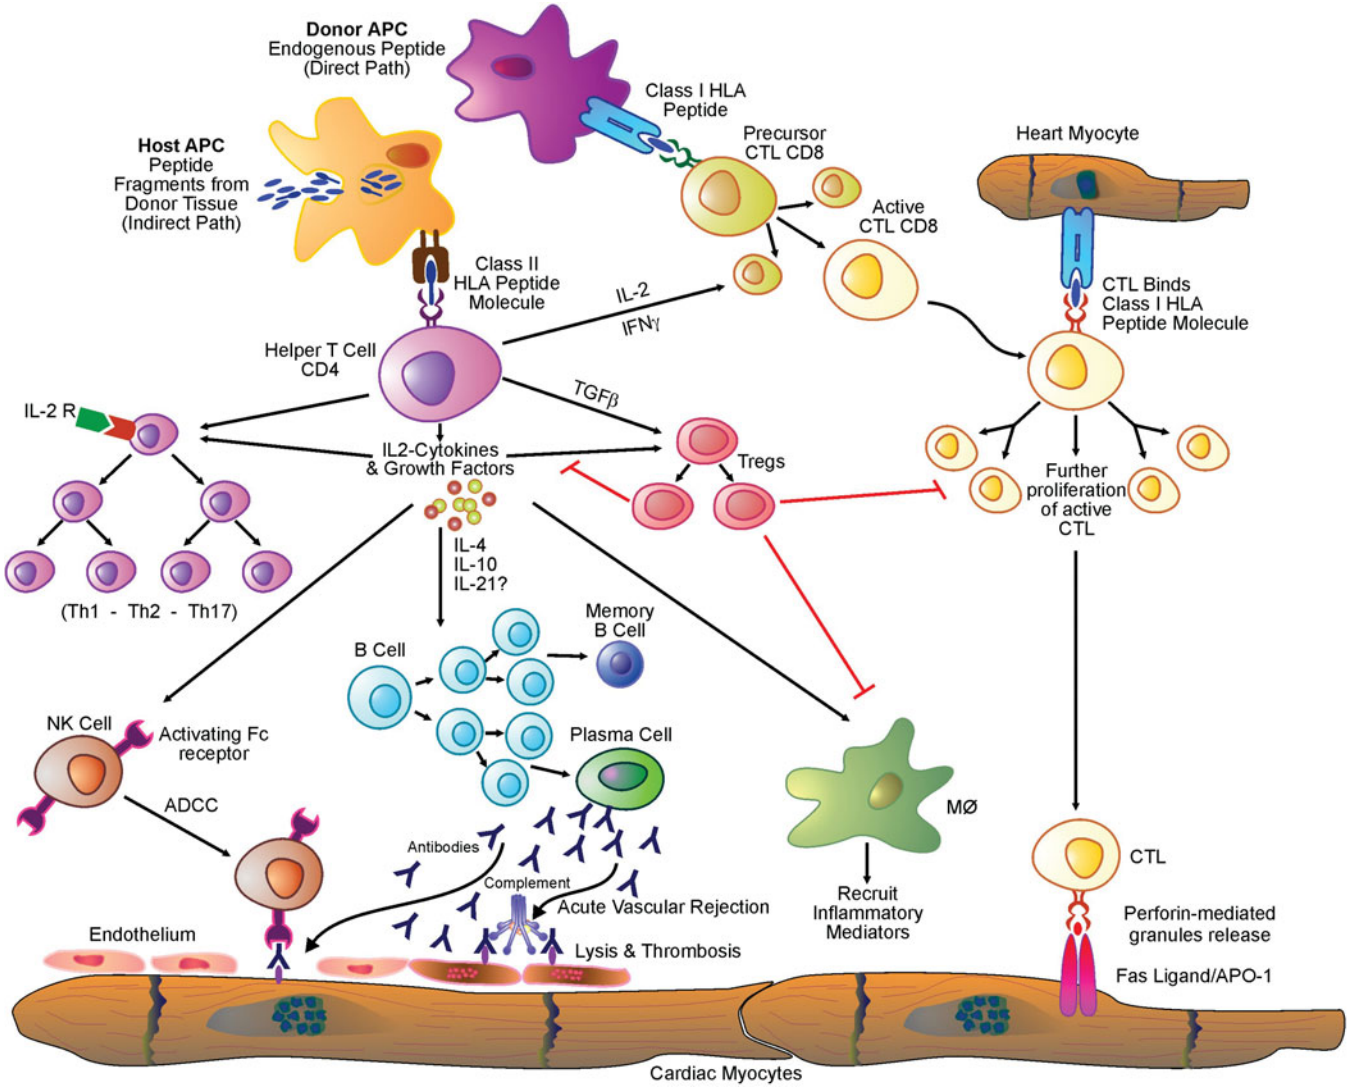

FIGURE 63-10 Complicated scheme of allograft rejection. $CD8^+$ lymphocytes become activated by donor-derived dendritic cells transplanted with the allograft. These cells enter a direct alloresponse pathway by proliferating into CTLs. The CTLs recognize and attach to Class I HLA donor peptide molecules on the surface of allograft cells. They directly kill the allotarget through cell-mediated cytotoxicity by injection of proteolytic granules, creating perforin-induced membrane pores and induction of apoptosis. $CD4^+$ T cells are activated by host APCs that engulf donor protein shed from the allograft. The host APCs process the donor protein into surface-bound Class II HLA peptide molecules. The CD4 cells follow an indirect pathway in the alloresponse by proliferating and secreting growth factors plus proinflammatory cytokines. This indirect paracrine function augments CTL proliferation, attracts cellular mediators of inflammation-like macrophages, and drives B-cell central humoral immunity.

regimen, inducing a mixed allogeneic chimerism (coexistence of recipient and donor cells) for kidney allografts. However, work in the nonhuman primate model showed that even this highly tolerogenic regimen did not induce tolerance to cardiac allografts.[9] Heart and lung allografts are less easily amendable to tolerance than kidney; in other words, they are more immunogenic.[10]

CHRONIC REJECTION: CORONARY GRAFT VASCULOPATHY AND OBLITERATIVE BRONCHIOLITIS

Chronic rejection of thoracic organs takes the form of induced obliterative fibrosis of small airways in the lung (obliterative bronchiolitis [OB]) or bronchiolitis obliterans syndrome (BOS) and diffuse obliterative transplant vasculopathy (TV) in heart (also termed cardiac allograft vasculopathy [CAV]). OB and CAV are likely caused by a response of the vessels and airways to a combination of peritransplant injury from preservation-related ischemia, acute rejection, and a chronic delayed-type hypersensitivity immune reaction (DTH) (see Fig. 63-1). DTH response is driven primarily by $CD4^+$ T cells reacting to Class II alloantigens on the endothelium and smooth muscle on the coronary arteries or the epithelium and bronchial smooth muscle of the donor airway. The responding $CD4^+$ T cells elaborate tumor necrosis factor (TNF) and interferon-γ (IFN-γ), which promotes release of growth factors and chemokines from the endothelial, epithelial, and smooth muscle cells and recruit regional macrophages. Smooth muscle cells in the vessel and

airway walls proliferate and move into the intima (subendothelial) or subepithelial compartment. The result is proliferation followed by fibrosis with resultant progressive luminal occlusion. As this process evolves, the transplanted organ parenchyma becomes progressively more fibrotic. CAV has been associated with systemic soluble markers of general inflammation. These include C-reactive protein, a marker of systemic inflammation, vascular cell adhesion molecule (VCAM-1), a marker of endothelial cell activation and neopterin, a marker of macrophage activation.[11] Further, these inflammatory mediators correlated with necrotic core and dense calcified components of the plaque. The necrotic core component is composed of lipid cells, necrotic and lymphocyte remnants together with tissue microcalcification.[12] At 5 years posttransplantation, CAV was responsible for death or retransplantation in 7%, and 50% patients with severe disease experienced these outcomes.[12] Its course more often is an indolent one, yet if present before 2 years, it acts like an inflammatory vasculitis and is associated with a poor survival.[13] The International Society for Heart and Lung Transplantation has recently published a consensus on the diagnosis and nomenclature for CAV.[14]

CIRCULATING ANTIBODIES IN HEART AND LUNG TRANSPLANTATION

Circulating HLA antibodies may form in a sensitization process through prior exposures to blood transfusions, pregnancy, organ transplantation, or use of a ventricular assist device. Transplant candidates with preexisting HLA antibodies not only are at risk of hyperacute and acute antibody-mediated rejection very early after transplantation, but also have lower rates of longer-term survival as well. Sensitive new bead methods now allow detection of circulatory antibodies and use of those antibody specificities to define "unacceptable" donor HLA antigens. The role of non-HLA antibodies in acute and chronic rejection and treatment strategies before transplant (desensitization), or when antibodies are detected after transplantation, is becoming better understood but remains in evolution.

HLA Antibody Analysis

Serologic Testing

The techniques used for identification of HLA antibodies have evolved significantly in recent years. The serological lymphocytotoxic assay for antibody screening is based on mixing patient serum (unknown) with a panel of cells whose HLA typing is known and adding complement (complement-dependent cytotoxicity or CDC assay). If antibodies are present in the patient serum that react with the cell's HLA molecules, cell death occurs because of complement activation. This method is limited to detection of antibodies represented by the panel of antigens tested and by issues with sensitivity and accuracy. The specificity of the antigen to which the antibody is reacting (HLA or non-HLA antibody) is sometimes not clear because of the presence of other proteins in the patient serum, or the antibody isotype (IgG or IgM, etc; some antibody isotypes do not fix complement), and the titer (low, high) is not determined. Several enhancements of this assay were developed to address these issues: (1) heat or chemical treatment of the patient serum to inactivate IgM antibodies and identify IgG antibodies, which were felt to be more important to outcomes; (2) additional washes of the target cells following incubation of the patients serum to "wash off" the nonspecific reactants; and (3) addition of antihuman globulin (AHG) to the reaction to increase the detection of low titer IgG antibody (CDC-AHG method). There are other subvariations of these serologic enhancements.

The antibody-screening assay consists of a panel of known HLA-typed cells, with each cell representing a unique set of antigen targets for the serum to react. The assay generates the panel reactive antibody titer (PRA), which is reported out as a percent of the prospective donor pool that would likely be killed by the patient's serum. The result of this analysis is termed percent calculated PRA or %cPRA. The %cPRA gives a better indication of the patient's likelihood of having a compatible offer of a UNOS deceased donor organ because it is based on actual UNOS-typed donors. The panel may consist of any number of cells; however, minimally, cells from at least 30 carefully selected individuals are needed to cover the most common HLA antigen targets. In addition to the %PRA, the specificity of the antigen targets could be identified based on the individual cell reactions. The more different HLA antigens to which the patient is sensitized, the higher the %PRA and the less likely the patient is to have a compatible donor identified. Using conventional matching criteria, %PRA greater than 10% and greater than 25% have been associated with incrementally lower survival large registry reports.

Despite the use of enhancing techniques, serological antibody screening and methods of identification are not able reliably to detect low levels of HLA antibody, and are relatively poor for characterizing Class II antibody.

Solid-Phase Assay

An ELISA plate method was the first solid-phase assay developed. In this assay, solubilized known HLA antigen protein targets are captured onto the surface of the wells of a microtiter plate. Patient serum is reacted with these proteins in each respective well. A secondary antihuman IgG antibody conjugated to a colorimetric reporter molecule is then added to the wells. This allows quantitative spectrophotometric determinations with a threshold absorbance used to distinguish a positive versus negative antigen–antibody reaction. Two additional hallmarks of the ELISA assay are the ability to: (1) objectively evaluate and quantify HLA antibody reactivity; and (2) eliminate the need for dependence on complement fixing for antibody detection, making ELISA a complement-independent assay. The colorimetric ELISA assay was able to evaluate better the presence of HLA Classes I and II antibody than the CDC-AHG method. Key faults of the ELISA assay are: (1) sensitivity of the colorimetric detection methods; and (2) purity and reliability of the solubilized HLA antigen captured in the well, because HLA can change its shape and thus antibody reactivity when bound to the plate.

Flow Cytometric Assays

The development of solid-phase microbead-based flow cytometry assays represents a monumental improvement from the initial solid-phase ELISA antibody screening and identification techniques. The use of fluorescent dyes is foremost as report molecules, allowing detection of the antigen–antibody reactions using a flow cytometer. Fluorescent dye light emissions are severalfold more sensitive than colorimetric dyes. As with the ELISA assay, the detection of the antibody–antigen reaction is made using beads coated with HLA molecules. Each HLA molecule-specific bead is identified by its unique mixture of two fluorescent dye colors incorporated into the bead. A secondary antihuman antibody is conjugated to a reporter molecule, in this case, a fluorescent dye of another color. The higher the titer of the antibody in the patient's serum, the more antibody is available to react to the antigen conjugated to the bead, and the more intense is binding of the secondary flouresceinated antibody. The more reporter dye becomes bound to the bead complex, the more fluorescent emission is produced from the bead when analyzed by the flow cytometer. The fluorescent emission signal of each bead type is then averaged and the normalized value is reported as the mean fluorescence intensity (MFI) of the bead. For most laboratories, the MFI value greater than or equal to 1000 is considered to be a positive reaction for the presence of the HLA antibody. This cutoff was derived in a similar fashion to that for the ELISA assay, namely, twice the MFI value for the negative control serum.

This resultant value is called the *shift median channel value* (sMCV). The sMCV cutoff for a positive versus negative flow crossmatch is statistically determined by each HLA laboratory initially and periodically by crossmatch of up to 100 individuals with serum that does not contain HLA antibody (negative). Shift values of less than or equal to two standard deviations from the mean of these histograms median channel value is considered to be negative, between two and three standard deviations to be equivocal, and three or more standard deviations to be positive.

The HLA antigen is conjugated directly to the microbead, not simply captured, and the source of which is recombinant cell lines. This allowed manufacturing of beads coated not only with the antigens of a single individual mimicking a cell (multiantigen beads), but also with a single HLA antigen (single antigen beads). These single antigens can be further described to the exact HLA allele of that antigen. Because individuals become sensitized to the amino acid epitopes encoded by the antigen allele, microbead-based antibody analysis opened a completely new level of insight into characterizing antibodies contained in patient serum. This process is called *epitope mapping*. In combination with allele level typing of patients and potential donors, epitope mapping of antibodies can better predict outcomes of transplants in highly sensitized patients. The flow cytometer instrument may be either a larger instrument, which can acquire data from cells or beads, or a mini-flow cytometer, which only acquires data from beads, such as a Luminexx instrument (Fig. 63-11).

Using solid-phase HLA assays (SPA) or flow cytometric assays, the laboratory can easily and reliably test for patient antibodies to HLA-A, -B, C, DRB1, DRB3, DRB4, DRB5, DQB1, DQA1, and DPB1.

The results of the serum antibody test and the donor crossmatch are interpreted together as a final assessment of recipient and donor compatibility. Composite MFI values of 4000 or greater are generally predictive of a positive flow crossmatch. This composite MFI value is derived from the sum of MFI values and the single antigen–antibody analysis for each donor target antigen present, either Class I or II. This is a rule of thumb, as cellular expression of these target antigens varies. Most centers post unacceptable antigens in UNOS for those single antigens with MFI values of 4000 or greater, because these single antigens alone may result in a positive flow crossmatch with donors. Based on these MFI values, a virtual or paper crossmatch can be reliable in predicting the actual cellular crossmatch, especially with high MFI values. In addition, unacceptable antigens can be identified by virtual crossmatch (discussed in the following), excluding a particular donor that expresses certain donor antigens from consideration for a recipient who is sensitized against one or more of those antigens.

HLA Crossmatch

Crossmatch of patient serum with potential donors is no different than performing antibody testing.

Virtual Crossmatch

Practical realities of matching sensitized candidates with nonlocal donors resulted in the acceptance of the virtual crossmatch (VXM). The VXM is a comparison of the donor HLA genotype determined by organ procurement organizations routinely as part of the donor (heart, lung) organ distribution process to the gene families represented by beads that bound antibody from the sensitized candidate recipient. If gene families are shared between donor and the bead, the VXM is positive. For example, a candidate with antibodies against A1, A11, and B7 by Luminexx single antigen beads would be incompatible with a donor typed as A11, A25, B55, and B57.[15] The anti-A1 antibody determined by SPA corresponds to the donor typed A1. Although currently there is no method to determine the functional characteristics of the antibodies, recently it was estimated that the positive predictive value of an incompatible VXM compared with cytotoxic crossmatch was nearly 80%. Most centers refuse nonlocal donors based on an incompatible VXM and insist on a prospective CDC-AHG crossmatch for sensitized patients when possible.

Non-HLA Antibodies

It has become increasingly clear that non-HLA antibodies that can cause injury in thoracic organ transplants.[16,17] About 16% of HLA antibody-negative heart recipients may lose their graft to the mixed diagnosis of primary failure within 30 days of transplant.[18] SPA does not detect non-HLA antibodies, *but flow cytometry methods can detect MICA/B.* Antibodies-to-donor endothelial antigens are the largest poorly discussed group of clinically important non-HLA antibodies. These include endothelial, autoantibodies and those to MHC Class I chain A (MICA) and B (MICB). Endothelial antigen targets may exist, constitutively or as induced autoantigens because of activation

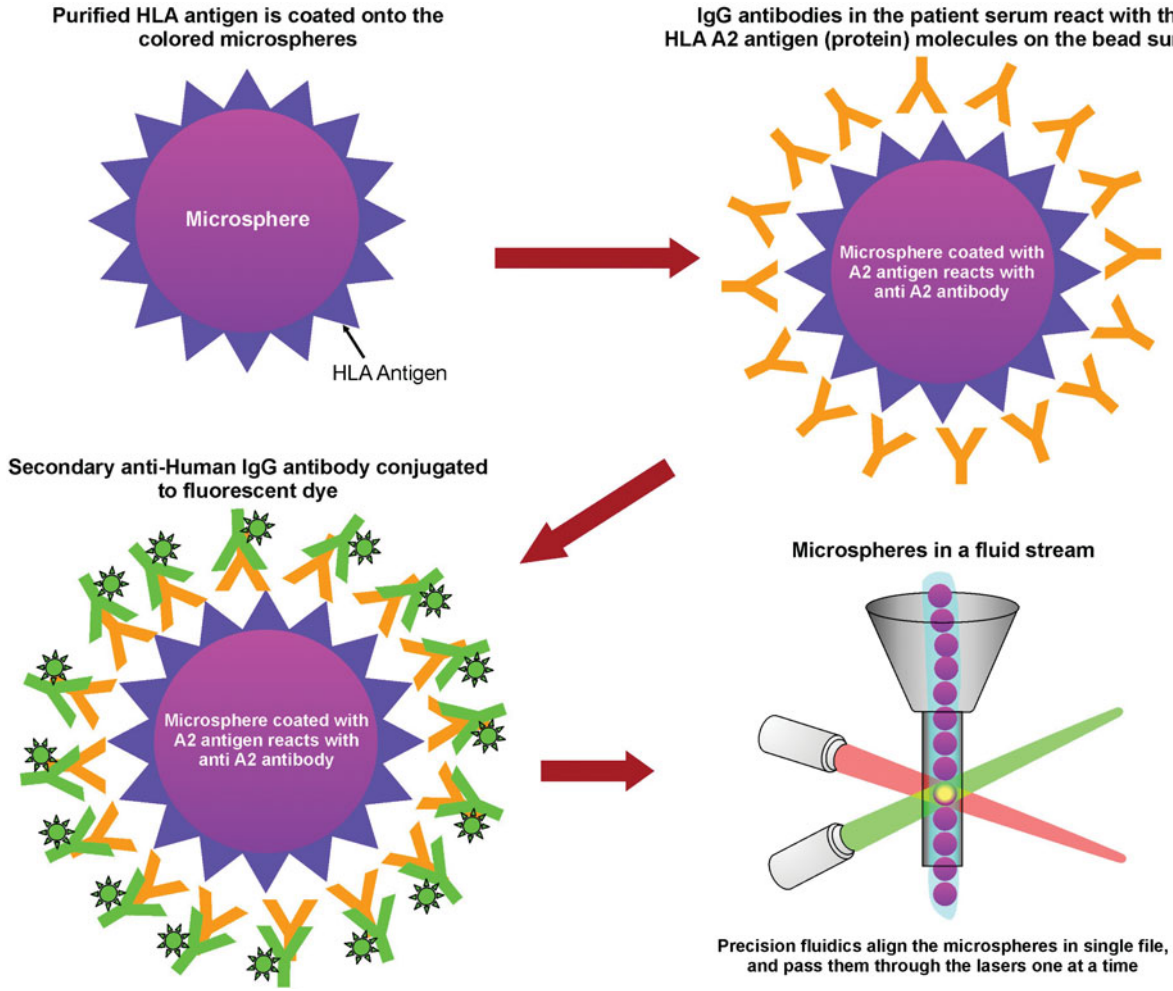

FIGURE 63-11 Solid-phase microbead-based assays for HLA antibodies have improved sensitivity and specificity of detection. Single HLA antigens from recombinant cell lines are conjugated to a colored microsphere. The bead is reacted against candidate or recipient serum, resulting in the specific adherence of circulating antibody to the selected HLA antigen. The microsphere HLA–serum antibody is reacted to an antihuman IgG antibody conjugated to a fluorescent dye. The microsphere complex is channeled through a flow cytometer and mean fluorescence intensity (MFI) for the combined emitting dye is measured. (*Adapted with permission from Luminexx Corporation, Austin, TX.*)

of the endothelium. MICA and MICB are polymorphic antigens expressed on epithelial and, to an unknown extent, on endothelium. MICA antibodies may occur in up to 20% of candidates and have been associated with poorer survival but not increased rejection.[18]

Autoantibodies against conserved (non-polymorphic) proteins are frequently found in the blood of thoracic transplant recipients in association with chronic rejection. Vimentin (an intracellular cytoskeletal protein found in vessel walls and activated lymphocytes), cardiac proteins (cardiac myosin), and collagen type 5 (expressed mainly in the lung) are among the antigens against which autoantibodies have been described. Antivimentin antibodies form earlier than anti-HLA after transplantation and are a response in up to 30% of heart recipients to exposure of antigens mounted on the surface of damaged and activated cells.[19] Antivimentin antibodies reflect tissue injury but might also activate platelets and neutrophils.[20] Antiheart antibodies exist preoperatively in some because of their primary cardiac disease. At present, it is difficult to know their true significance. Finally, IgM non-HLA antibodies are cytotoxic and can react to all leukocytes, even the patient's own. Antigen specificity is unknown, as is the clinical relevance.

Desensitization Therapy

Once unacceptable antigens are determined from SPA, they can be entered into the UNOS website (http://optn.transplant.hrsa.gov/resources/professionalResources.asp?index=10). This will provide the cPRA. If the percentage chance of any donor will not be acceptable is greater than 50%, then it is reasonable to initiate a desensitization protocol. An optimal protocol has not been established. High-dose IVIG (2 g/kg/over 2 days q 2-4 weeks), plasmapheresis (1.5 volume exchange ×5 days), monoclonal anti-CD20 B-cell therapy (rituximab 1 g IV weekly ×4), and in the past cyclophosphamide (1 mg/kg/day) have been used in various combinations.

At UCLA, plasmapheresis, IVIG, and rituximab reduced circulatory antibody levels from 70.5 to 30.2%. Heart transplantation of these candidates after negative CDC resulted in similar 5-year outcomes to control patients and untreated but high PRA patients (81.1%, 75.7%, 71.4%). Of interest, the freedom from CAV was 74.3, 72.7, and 76.2%, respectively.[21]

It has been agreed that patients waiting for transplantation with circulating HLA antibodies should be studied every 3 months, and those desensitized every 2 weeks after therapy. Patients on VADs or who receive blood transfusions or with infections should be closely monitored as well. After transplantation donor-specific antibody monitoring is recommended at regular intervals and when a humoral rejection event is suspected. Donor-specific titers should be measured daily for 1 to 2 weeks and frequently thereafter in desensitized patients and those considered high risk for antibody response. This higher-risk group of recipients is generally treated with thymoglobulin plus IVIG, plasmapheresis and/or rituximab. Maintenance immunosuppressive therapy that has best controlled cellular and antibody-mediated rejection includes tacrolimus, mycophenolate mofetil, and prednisone.[22]

Antibody-Mediated Rejection

Hyperacute antibody-mediated rejection (AMR) became extremely rare with improving crossmatch techniques, but clinical interest in AMR was renewed in 1990 by Halloran and associates who described features of pure AMR in a few renal transplant recipients.[23] Later, C4d became established as an important histologic associate.[24] The incidence of AMR after cardiac transplantation is uncertain because of a lack of universal screening in asymptomatic recipients. Symptomatic pure AMR without a component of acute cellular rejection occurs in 10 to 15% of cardiac transplant recipients, but AMR features have been reported in up to 40% of patients with acute cellular rejection (mixed rejection).[25] Clinical symptoms of cardiac AMR are those common in heart failure using echo. A greater than 25% decrease in ejection fraction and an increase in left ventricular mass distinguished antibody-mediated rejection from cell-mediated rejection.[26] Reduced R-wave voltage-conduction abnormalities, including bundle branch block, are electrocardiographic associates. As discussed, presensitization to HLA Class I or II antibodies predisposes to AMR.[27] Those recipients who develop presensitized antibodies, especially donor-specific, risk AMR.[28] Non-HLA antibodies, including those against cardiac myosin, vimentin, and endothelial cells have been less often associated with AMR.[29–31] Cardiac AMR occurs early (weeks to months) after transplant and, if avoided early, rarely occurs later.[32] Classically, histologic diagnosis of cardiac AMR has included evidence of endothelial swelling and activation macrophages in the graft plus confirming immunofluorescence or immunoperoxidase staining for immunoglobulin (IgG or IgM) (Figs. 63-12 and 63-13). Although absence of immunofluorescence seems reasonable to rule out AMR, capillary swelling (63%) and macrophage vascular adherence (30%) do not[33] and complement (C3d and C4d). Non-AMR causes of C4d staining include organ reperfusion injury, immunosuppression, treatment with monoclonal antibodies, and viral infections.[34] To date, the distribution

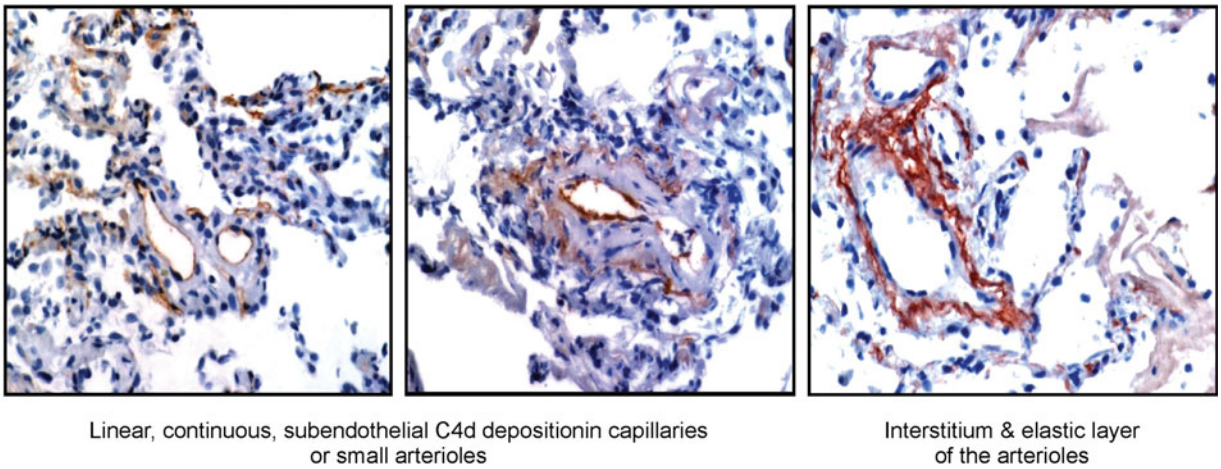

FIGURE 63-13 Specific C4d deposition on a lung transplant allograft in a recipient with circulating HLA antibody is continuous and subendothelial in capillaries and small arterioles (*left*). Specific C4d has been seen on 31% of transbronchial biopsies in recipients with HLA-Ab (*middle*). (diffuse versus localized) and intensity of the stains has not found a standardization for grading. The suggested algorithm for AMR includes: (1) Present clinical evidence of cardiac graft dysfunction and histologic evidence with or without interstitial edema and hemorrhage; and (2) positive immunofluorescence or immunoperoxidase for donor-specific antibodies. This creates further questions about the importance of asymptomatic (allograft function conserved) AMR-associated histopathology. It is likely that AMR is a pathologic continuum with clinical involvement in later or more aggressive forms. Asymptomatic AMR has been related to worse cardiovascular outcomes and the presence of cardiac allograft vasculopathy (CAV).[35,36]

Although a clinical phenotype for AMR after lung transplantation and its response to anti-antibody regimens has been discussed, unfortunately, no strong consensus exists regarding its diagnostic characteristics.[37] Recently, the Washington University program evaluated the effect on donor-specific HLA antibodies (DSA) and bronchiolitis obliterans syndrome (BOS) in 65/116 recipients developed DSA. Antibody-depleting therapy with IVIG, with or without rituximab, resulted in no differences in the incidence of acute rejection, lymphocytic bronchiolitis, and BOS between those with and those without antibody.[38]

Gene Expression Profiling

A DNA microarray-based real-time polymerase chain reaction–derived bio signature for cardiac rejection has been developed by XDx, the maker of allomap molecular expression testing (XDx, Brisbane, CA).[39] Peripheral blood mononuclear cells provided a panel of 11 informative genes that were associated with acute cellular rejection.[40] Several pathways were identified that participate in regulation of effector cell activation, trafficking and morphology, platelet activation, plus corticosteroid sensitivity. These included PDCD1 and ITGA4 for T-cell activation and migration, ILIR2 steroid-responsive gene, the decoy for IL-2, and WDR40A plus CMIR of the micro-RNA gene family. Peripheral blood samples are assigned a score with higher numbers associated with progressive risk of lack of immunologic quiescence. This approach was recently randomized against surveillance endomyocardial biopsy in a multicenter trial in low-risk rejection cardiac recipients, 6 months to 5 years after transplantation.[41] The evaluation excluded recipients with a significant history of rejection, CAV, or allograft dysfunction. Results indicated 14.5% of patients profiled versus 15.3% of those surveilled by endomyocardial biopsy reached a composite endpoint of rejection with hemodynamic compromise, graft dysfunction owing to other causes, death, or retransplantation. The low risk for rejection of the enrolled patients made interpretation to earlier and higher-risk recipients problematic.[42] Other reports found that the profiled genes regulatory T-cell homeostasis and corticosteroid sensitivity can distinguish mild from moderate and severe rejection and are evident before histologic, detectable rejection.[43,44]

Functional Activity of Immune System

A recipient's individual immune responses are affected by their susceptibility to immunosuppression, their clinical state, genetic background, age, gender, and diet. An assay of cell function would be useful to quantitate the dynamic positive and negative regulatory responses of the immune system. Clinicians have struggled, often in relative ignorance, to titrate doses of immunosuppressive drugs to achieve levels that deter the alloresponse while also minimizing the risk of infection. A long-imagined goal of selective treatment based on a quantitative assessment of the net state of immunosuppression has been approached clinically with some success. An assay has been developed (Cylex, ImmuKnow, Columbia, MD) to measure the intracellular concentration of adenosine triphosphate (ATP) of $CD4^+$ T cells. ImmuKnow measures T-cell responses by quantifying ATP activity[45] to phytohemagglutinin, a T-cell mitogen. In general, the collective studies suggest that ATP levels less than 100 ng/mL correlate with an increased risk of infection.[46] In a study in 296 heart recipients spanning 2 weeks to 10 years posttransplant, infection

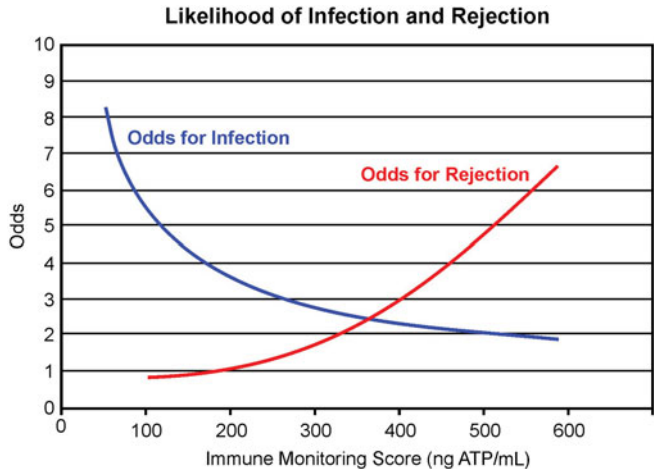

FIGURE 63-14 Immune monitoring scores are calculated from adenosine triphosphatase (ATP) released from activated lymphocytes (ImmuKnow; Cylex, Columbia, MD). The hazard curves above are plotted for risk of infection versus odds for rejection in 296 heart transplant recipients (864 assays). In theory, the crossing point defines a score that minimizes infection and rejection. (*Adapted with permission from Kobashigawa JA, Kiyosaki KK, Patel JK, et al: Benefit of immune monitoring in heart transplant patients using ATP production in activated lymphocytes. J Heart Lung Transplant 2010; 29:504-508.*)

in 39 recipients occurred with an average 187 + 126 ng/ATP/mL versus a steady state of 280 + 126 ng/ATP/mL (Fig. 63-14). Rejection scores in eight recipients averaged 328 ng/ATP/mL and did not differ from baseline. However, 3 of 8 with antibody-mediated rejection scored 49/I-12/ng/ATP.[46] This assay opens the field to personalized immunosuppression that might help balance risks of infection and rejection.

CHAPTER 64

Heart Transplantation

William A. Baumgartner

INTRODUCTION

The number of patients with heart failure is growing. End-stage heart failure is associated with significant morbidity, need for recurrent hospitalizations, decrease in quality of life, and increased mortality. Cardiac transplantation has evolved as an effective therapy for many of these patients. Tremendous advancements in the fields of immunosuppression, rejection, and infection have transformed what was once considered an experimental intervention into a routine treatment available worldwide.

HISTORY OF HEART TRANSPLANTATION

The innovative French surgeon Alexis Carrel performed the first heterotopic canine heart transplant with Charles Guthrie in 1905. Frank Mann at the Mayo Clinic further explored the idea of heterotopic heart transplantation in the 1930s. The neck became the preferred site of implantation in early experimental animal models because of the ease of monitoring the organ, the simplicity of access to major vessels, and because the recipient's native heart could serve as a built-in cardiac assist device for the transplanted organ. Mann also proposed the concept of cardiac allograft rejection, in which biologic incompatibility between donor and recipient was manifested as a leukocytic infiltration of the rejecting myocardium. In 1946, after unsuccessful attempts in the inguinal region, Vladimir Demikhov of the Soviet Union successfully implanted the first intrathoracic heterotopic heart allograft. He later demonstrated that heart-lung and isolated lung transplantation also were technically feasible.

The use of moderate hypothermia, cardiopulmonary bypass, and an atrial cuff anastomotic technique permitted Norman Shumway (Fig. 64-1) and Richard Lower at Stanford University to further explore orthotopic heart transplantation using a canine model in 1960. The first human cardiac transplant was a chimpanzee xenograft performed at the University of Mississippi by James Hardy in 1964. Although the procedure using Shumway's technique was technically satisfactory, the primate heart was unable to maintain the recipient's circulatory load and the patient succumbed several hours postoperatively. Despite great skepticism that cardiac transplantation ever would be performed successfully in humans, South African Christiaan Barnard surprised the world when he performed the first human-to-human heart transplant on December 3, 1967. Over the next several years, poor early clinical results led to a moratorium on heart transplantation, with only the most dedicated centers continuing experimental and clinical work in the field. The pioneering efforts of Shumway and colleagues at Stanford eventually paved the way for the reemergence of cardiac transplantation in the late 1970s. The introduction of transvenous endomyocardial biopsy by Philip Caves in 1973 finally provided a reliable means for monitoring allograft rejection. Ultimately, however, it was the advent of the immunosuppressive agent cyclosporine that dramatically increased patient survival and marked the beginning of the modern era of successful cardiac transplantation in 1981. Heart transplantation is now a widely accepted therapeutic option for end-stage cardiac failure; however, the annual number of transplants in the United States (approximately 2200 per year) has remained relatively constant over the last decade because of limited donor-organ availability (from United Network for Organ Sharing [UNOS] data, through September 2009).

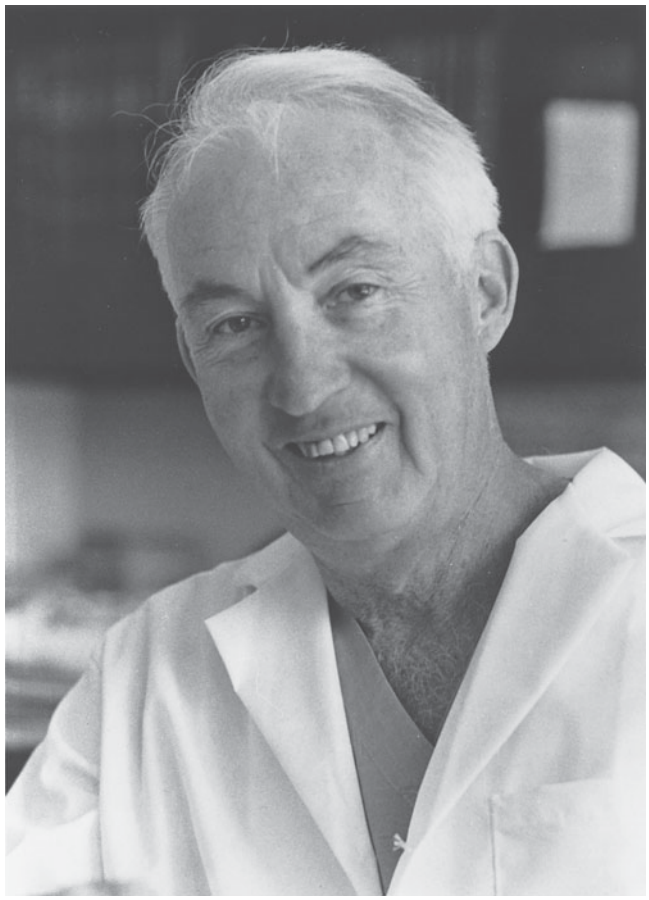

FIGURE 64-1 Norman Shumway.

THE CARDIAC TRANSPLANT RECIPIENT

Recipient Selection

The evaluation of potential candidates for cardiac transplantation is performed by a multidisciplinary committee to ensure the equitable, objective, and medically justified allocation of donor organs to those patients most likely to achieve long-term benefit. It is very important to establish a mutual long-term working relationship among patient, social support system, and the entire team at the beginning of this process.

Indications and potential contraindications for cardiac transplantation are outlined in Table 64-1.[1] These inclusion and exclusion criteria can vary somewhat among transplantation centers.[1–4] The basic objective is to identify those relatively healthy patients with end-stage cardiac disease, refractory to other appropriate medical and surgical therapies, who possess the potential to resume a normal active life and maintain compliance with a rigorous medical regimen after cardiac transplantation.

Etiology of End-Stage Cardiac Failure

Determination of the etiology and potential reversibility of end-stage heart failure is critical for the selection of transplant candidates. Overall, from 1982 to 2008, the indications for heart transplantation in adult recipients have been overwhelmingly ischemic heart failure and nonischemic cardiomyopathy (approximately 90%); with valvular (2 to 3%), adult congenital (2%), retransplantation (2%), and miscellaneous causes comprising the remainder.[5]

The perception of the irreversibility of advanced cardiac failure is changing with the growing efficacy of tailored medical therapy, high-risk revascularization procedures, and newer antiarrhythmic pharmacologic agents, as well as implantable defibrillators and biventricular pacing. Additionally, other surgical modalities, such as ventricular assist devices (VADs) and surgical ventricular restoration (SVR) have found increasing application.[6,7] Furthermore, it is important to consider that prognosis may differ in patients with cardiomyopathy who have neither ischemic nor valvular heart disease. Caution should be exercised when judging prognosis in these patient subgroups, and a period of observation, intense pharmacologic therapy, and/or mechanical support should be undertaken before heart transplantation is considered.[4]

Evaluation of the Potential Cardiac Transplant Recipient

The complexity of the recipient evaluation mandates a team approach. The initial evaluation involves a comprehensive history and physical examination because this will help to determine etiology and contraindications. Table 64-2[3] summarizes the cardiac transplant evaluation tests. Routine hematologic and biochemical analyses and pertinent tests as illustrated by organ system are performed.

For the assessment of the heart itself, in addition to routine 12-lead electrocardiogram, Holter monitor, and echocardiography, all patients should undergo cardiopulmonary exercise testing to evaluate functional capacity if disease severity allows. Peak exercise oxygen consumption measured during maximal exercise testing $\dot{V}O_{2,max}$ provides a measure of functional capacity and cardiovascular reserve, and an inverse relationship between $\dot{V}O_{2,max}$ and mortality in heart failure patients has been demonstrated.[8] Documentation of adequate effort during exercise, as evidenced by attaining a respiratory exchange ratio greater than 1.0 or achievement of an anaerobic threshold at 50 to 60% of $\dot{V}O_{2,max}$ is necessary to avoid underestimation of functional capacity.[2] Right-sided heart catheterization should be performed at the transplanting center to evaluate the severity of heart failure (and hence the status level for transplant listing) and evaluate for the presence of pulmonary hypertension. Right heart catheterization also can help guide therapy while awaiting transplantation. Coronary cineangiography should be reviewed to confirm the inoperability of coronary artery lesions in cases of ischemic cardiomyopathy. As well, either a positron emission tomographic (PET) scan, a thallium-201 redistribution study, or a cardiac magnetic resonance imaging (MRI) study should assess viability in selected patients who would be candidates for revascularization if sufficient viability is present.[2,3] Endomyocardial biopsy should be performed on all patients in whom the etiology of heart failure is in question, especially those with nonischemic cardiomyopathies symptomatic for fewer than 6 months.[3] This can assist in therapeutic decision making and exclude diagnoses such as amyloidosis, which are considered relative contraindications to transplantation.

TABLE 64-1 Recipient Selection for Heart Transplantation

INDICATIONS

I. Systolic heart failure (as defined by ejection fraction <35%)
   A. Inclusive etiology
      1. Ischemic
      2. Dilated
      3. Valvular
      4. Hypertensive
      5. Other
   B. Excluded etiology
      1. Amyloid (controversial)
      2. HIV infection
      3. Cardiac sarcoma

II. Ischemic heart disease with intractable angina
   A. Ineffective maximal tolerated medical therapy
   B. Not a candidate for direct myocardial revascularization, percutaneous revascularization, or transmyocardial revascularization procedure
   C. Unsuccessful myocardial revascularization

III. Intractable arrhythmia
   A. Uncontrolled with pacing cardioverter defibrillator
      1. Not amenable to electrophysiology-guided single or combination medical therapy
      2. Not a candidate for ablative therapy

IV. Hypertrophic cardiomyopathy
   A. Class IV symptoms persist despite interventional therapies
      1. Alcohol injection of septal artery
      2. Myotomy and myomectomy
      3. Mitral valve replacement
      4. Maximal medical therapy
      5. Pacemaker therapy

V. Congenital heart disease in which severe fixed pulmonary hypertension is not a complication

VI. Cardiac tumor
   A. Confined to the myocardium
   B. No evidence of distant disease revealed by extensive metastatic workup

ABSOLUTE CONTRAINDICATIONS

I. Age >70 years (may vary at different centers)

II. Fixed pulmonary hypertension (unresponsive to pharmacologic intervention)
   A. Pulmonary vascular resistance >5 Wood units
   B. Transpulmonary gradient >15 mm Hg

III. Systemic illness that will limit survival despite transplant
   A. Neoplasm other than skin cancer (<5 years disease-free survival)
   B. HIV/AIDS (CDC definition of CD4 count of <200 cells/mm^3)
   C. Systemic lupus erythematosus (SLE) or sarcoid that has multisystem involvement and is currently active
   D. Any systemic process with a high probability of recurrence in the transplanted heart
   E. Irreversible renal or hepatic dysfunction

(*Continued*)

TABLE 64-1 Recipient Selection for Heart Transplantation (*Continued*)

POTENTIAL RELATIVE CONTRAINDICATIONS
I. Recent malignancy
II. Chronic obstructive pulmonary disease
III. Recent and unresolved pulmonary infarction and pulmonary embolism
IV. Diabetes mellitus with end-organ damage (neuropathy, nephropathy, and retinopathy)
V. Peripheral vascular or cerebrovascular disease
VI. Active peptic ulcer disease
VI. Current or recent diverticulitis
VIII. Other systemic illness likely to limit survival or rehabilitation
IX. Severe obesity or cachexia
X. Severe osteoporosis
XI. Active alcohol or drug abuse
XII. History of noncompliance or psychiatric illness likely to interfere with long-term compliance
XIII. Absence of psychosocial support

The neuropsychiatric assessment should be performed by persons experienced in evaluating cardiac patients to determine if organic brain dysfunction or psychiatric illness is present. An experienced social worker should assess for the presence of adequate social and financial support. At the time of listing, the transplant coordinator should ensure that the patient and family understand the peculiarities of the waiting time, preoperative period, long-term maintenance medications, and the rules of living with the new heart. It is also of paramount importance that providers discuss the patient's preferences with regard to life support (duration and type), in case of a deterioration in his or her condition while awaiting transplant.

Indications for Cardiac Transplantation

Cardiac transplantation is reserved for a select group of patients with end-stage heart disease not amenable to optimal medical or surgical therapies. Prognosis for 1-year survival without transplantation should be less than 50%. Prediction of patient survival involves considerable subjective clinical judgment by the transplant committee because no reliable objective prognostic criteria are available currently. Low ejection fraction (<20%), reduced $\dot{V}O_{2,max}$ (<14 mL/kg/min), arrhythmias, high pulmonary capillary wedge pressure (>25 mm Hg), elevated plasma norepinephrine concentration (>600 pg/mL), reduced serum sodium concentration (<130 mEq/dL), and more recently N-terminal probrain natriuretic peptide (>5000 pg/mL) all have been proposed as predictors of poor prognosis and potential indications for transplantation in patients receiving optimal medical therapy.[8–11] Reduced left ventricular ejection fraction and low $\dot{V}O_{2,max}$ are widely identified as the strongest independent predictors of survival.

The indications for cardiac transplantation listing are continuously reviewed as new breakthroughs in the medical and surgical treatment of heart disease emerge.

Contraindications for Cardiac Transplantation

Table 64-1 lists the traditional absolute and relative contraindications. It should be acknowledged that strict guidelines can be problematic; therefore, each transplant program varies regarding absolute criteria based on clinical circumstances and experience. Furthermore, traditional contraindications for transplant listing are being questioned. Age is one of the most controversial exclusionary criteria for transplantation. The upper age limit for recipients is center-specific, but emphasis should be placed on the patient's physiologic rather than chronologic age. The Official Adult Heart Transplant Report 2009 from the registry of the International Society for Heart and Lung Transplantation (ISHLT) noted that over the last 25 years, the percentage of recipients older than 60 years of age has increased steadily, approaching 25% of all heart transplants between 2002 and 2008 compared with just above 5% between 1982 and 1988.[5] Although the elderly have a greater potential for occult systemic disease that may complicate their postoperative course, some recent reports have suggested that morbidity and mortality in carefully selected older patients are comparable with those of younger recipients, and they have fewer rejection episodes than younger patients.[12,13]

Fixed pulmonary hypertension (PH), usually manifested as elevated pulmonary vascular resistance (PVR), is one of the few

TABLE 64-2 Cardiac Transplant Evaluation Tests

Laboratory	Complete blood count with differential and platelet count, creatinine, blood urea nitrogen, electrolytes, liver panel, lipid panel, calcium, phosphorus, total protein, albumin, uric acid, thyroid panel, antinuclear antibodies, erythrocyte sedimentation rate (ESR), rapid plasma reagin (RPR), iron-binding tests, partial thromboplastin time, prothrombin time Blood type, IgG and IgM antibodies against cytomegalovirus, herpes simplex virus, HIV, varicella-zoster virus, hepatitis B surface antigen, hepatitis C antigen, toxoplasmosis, other titers when indicated Tuberculin skin test Prostate-specific antigen (male >50 years) Mammogram and Pap smear (female >40 years) Screening against a panel of donor antigens (panel reactive antibodies) and human leukocyte antigen phenotype 24-Hour urine for creatinine clearance and total protein, urinalysis, urine culture Baseline bacterial and fungal cultures, stool for ova and parasites if indicated
Cardiac	12-lead ECG, 24-hour Holter monitor Echocardiogram Thallium-201 imaging, positron-emission tomographic (PET) scan, or cardiac magnetic resonance imaging (MRI) to assess viability if indicated Exercise stress test and respiratory gas analysis with oxygen uptake measurements: peak exercise oxygen consumption ($\dot{V}O_{2,max}$) Right- and left-sided heart catheterization at the transplant center Myocardial biopsy on selected patients in whom etiology of heart failure is in question
Vascular	Peripheral vascular studies Carotid Doppler and duplex ultrasound 55 years
Renal	Renal ultrasound and or intravenous pyelogram if indicated
Pulmonary	Chest x-ray Pulmonary function tests Chest CT scan to evaluate abnormal chest x-ray or thoracic aorta in older patients (usually >65 years)
Gastrointestinal	Upper endoscopy/colonoscopy if indicated Upper gastrointestinal series and/or barium enema if indicated Percutaneous liver biopsy if indicated
Metabolic	Bone densitometry
Neurologic	Screening evaluation
Psychiatric	Screening evaluation
Dental	Complete dental evaluation
Physical therapy	Evaluation
Social work	Patient attitude and family support, medical insurance, and general financial resources
Transplant coordinator	Education

absolute contraindications to orthotopic cardiac transplantation. Fixed PH increases the risk of acute right ventricular failure when the right ventricle of the allograft is unable to adapt to significant PH in the immediate postoperative period.[14] Use of the transpulmonary gradient (TPG), which represents the pressure gradient across the pulmonary vascular bed independent of blood flow, may avoid erroneous estimations of PVR, such as those that may occur in patients with low cardiac output.[4]

Some have advocated the use of PVR index (PVRI) unit, which corrects for body size.

$$\text{PVR (Wood units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)}}$$

$$\text{PVRI (units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)} \times \text{BSA}} = \frac{\text{PVR}}{\text{BSA}}$$

$$\text{TPG (mm Hg)} = \text{PAP (mm Hg)} - \text{PCWP (mm Hg)}$$

where MPAP is mean pulmonary arterial pressure, PCWP is pulmonary capillary wedge pressure, CO is cardiac output, CI is cardiac index, and BSA is body surface area.

A fixed PVR greater than 5 to 6 Wood units and a TPG greater than 15 mm Hg generally are accepted as absolute criteria for rejection of a candidate.[1–4,11] Over the years, several studies have found PH to have a significant effect on posttransplant mortality using various parameters, threshold values, and follow-up periods.[15,16] However, a lack of mortality difference after heart transplantation between patients with and without preoperative PH has also been reported.[17] Perhaps more significantly, measurable parameters of pulmonary hypertension have been shown to improve following heart transplantation. A study of 172 patients followed for up to 15.1 years, published in 2005 from the Johns Hopkins Hospital, showed that mild to moderate pretransplantation PH (PVR = 2.5 to 5.0 Wood units) was not associated with higher mortality rate, although there was increased risk of posttransplantation PH within the first 6 months.[18] However, when the continuous variable PVR was examined, each 1 Wood unit increase in preoperative PVR demonstrated a 15% or more increase in mortality, especially within the first year, but these associations did not reach statistical significance. Severe preoperative PH (PVR ≥ 5 Wood units) was associated with death within the first year after adjusting for potential cofounders but not with overall mortality or mortality beyond the first year.

In the preoperative evaluation of the transplant recipient, if PH is discovered, an assessment of its reversibility should be performed in the cardiac catheterization laboratory.[16] Sodium nitroprusside traditionally has been used at a starting dose of 0.5 μg/kg per minute and titrated by 0.5 μg/kg per minute until there is an acceptable decline in PVR, ideally 2.5 Wood units or at least by 50%, with maintenance of adequate systemic systolic blood pressure. If sodium nitroprusside fails to produce an adequate response, other vasodilators such as adenosine, prostaglandin E_1, milrinone, or inhaled nitric oxide or prostacyclin (eg, aerosolized Iloprost) may be used.[2,19] Some patients who do not respond acutely may respond to continuous intravenous inotropic therapy, and repeat catheterization can be performed after 48 to 72 hours. Intravenous B-type natriuretic peptide, eg, nesiritide (Natrecor), has shown some efficacy in refractory pulmonary hypertension.[20] Recently, ventricular assist devices (VADs) are playing an important role in heart transplantation candidates with PH.[21] A period of left ventricular assist device (LVAD) support may allow for a decrease of pulmonary artery pressure secondary to unloading of the left ventricle. Patients with irreversible PH may be candidates for heterotopic heart transplantation, heart-lung transplantation, or LVAD destination therapy.[22] Use of modestly larger donor hearts for recipients with severe pretransplantation PH can provide additional right ventricular reserve.

Systemic diseases with poor prognosis and potential to recur in the transplanted heart or the potential to undergo exacerbation with immunosuppressive therapy are considered absolute contraindications for heart transplantation. Heart transplantation for amyloid remains controversial because amyloid deposits recur in the transplanted heart. Although case reports of long-term survival can be found in the literature,[23] survival beyond 1 year tends to be reduced.[24] Human immunodeficiency virus (HIV)–infected patients generally are excluded. Previously, any occurrence of neoplasm was a reason to exclude patients from transplantation. Currently available data do not appear to justify excluding some of these patients.[25] Most programs will consider patients who are free of disease for at least 5 years.

Irreversible renal dysfunction is a contraindication to heart transplantation. A creatinine clearance of less than 50 mL/min and a serum creatinine concentration of greater than 2 mg/dL are associated with increased risk of postoperative dialysis and decreased survival following heart transplantion.[4,26] However, patients may be considered for combined heart and kidney transplantation. Irreversible hepatic dysfunction has implications similar to renal dysfunction.[4] If transaminase levels are more than twice their normal value and associated with coagulation abnormalities, percutaneous liver biopsy should be performed to exclude primary liver disease. This should not be confused with chronic cardiac hepatopathy, which is characterized by elevated cholestatic parameters along with little or no changes in transaminases and is potentially reversible after heart transplantation.[27]

Severe chronic bronchitis or obstructive pulmonary disease may predispose patients to pulmonary infections and may result in prolonged ventilatory support after heart transplantation. Patients who have a ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC) of less than 40 to 50% of predicted or an FEV_1 of less than 50% of predicted despite optimal medical therapy are considered poor candidates for transplantation.[2,4] Transplantation in patients with diabetes mellitus is only contraindicated in the presence of significant end-organ damage (eg, diabetic nephropathy, retinopathy, or neuropathy).[2,4] Some centers have expanded their criteria successfully to include patients with mild to moderate end-organ damage.[28] Active infection was a sound reason to delay transplantation before assist devices became more commonplace. Up to 48% of patients with implanted LVADs reportedly have evidence of infection. Interestingly, treatment for LVAD infection in these patients is to proceed with urgent transplantation.[29]

Other relative contraindications include severe noncardiac atherosclerotic disease, severe osteoporosis, and active peptic ulcer disease or diverticulitis, all of which may lead to increased morbidity.[2,4] Cachexia, defined as a body mass index (BMI) of less than 20 or less than 80% ideal body weight (IBW), and obesity, defined as BMI greater than 35 or greater than 140% of IBW, are associated with increased mortality after transplantation.[30] Poor nutritional status also may limit early postoperative rehabilitation.

The ultimate success of transplantation depends on the psychosocial stability and compliance of the recipient.[31] The rigorous postoperative regimen of multidrug therapy, frequent clinic visits, and routine endomyocardial biopsies demand commitment on the part of the patient. A history of psychiatric illness, substance abuse, or previous noncompliance (particularly with medical therapy for end-stage heart failure) may be sufficient cause to reject the candidacy of a patient. Lack of a supportive social system is an additional relative contraindication.

Management of the Potential Cardiac Recipient

Preformed Anti-HLA Antibodies

Patients with elevated levels of preformed panel reactive antibodies (PRAs) to human leukocyte antigens (HLAs) have higher rates of organ rejection and decreased survival than do patients without such antibodies.[32] Consequently, before proceeding with transplantation, many medical centers do prospective cross-matching, ie, either by flow cytometry or ELISA, to determine whether a donor-specific antibodies that threaten the allograft are present. The problem has been compounded by the increased frequency of preformed reactive antibodies in patients with VADs who are awaiting cardiac transplantation.[33] Furthermore, not all antibodies are complement fixing or dangerous. Performing a prospective cross-match can be time consuming and often is impossible because of the unstable condition of the organ donor or travel logistics, leading to increased costs for transplantation and longer waiting times for recipients. Recently, virtual cross-matching has been used to eliminate the need for prospective tissue cross-matching. Modern laboratory techniques allow for identification and titer of antibodies. Because all donor antigens are known at the time of allocation, an assessment can be made without an actual tissue/sera assay. However, a particular patient's antibody population is dynamic and may change from the time of the antibody screen. As a result, care must be taken in patients with particularly diverse and high antibody titers. Plasmapheresis, intravenous immunoglobulins, cyclophosphamide, mycophenolate mofetil, and rituximab all have been used to lower the PRA levels with variable results.[2]

Pharmacologic Bridge to Transplantation

Critically compromised patients require admission to the intensive care unit for intravenous inotropic therapy. Dobutamine, a synthetic catecholamine, remains the prototype of this drug group. However, the phosphodiesterase III inhibitor milrinone is similarly effective.[34] The catecholamine dopamine is used often as a parenteral positive inotrope, but at moderate to high dose it evokes considerable systemic vasoconstriction. In candidates in whom an inotropic infusion has progressed to higher doses, combinations of dobutamine with milrinone are used. For transplant candidates dependent on inotropic infusions, eosinophilic myocarditis may develop as an allergic response to the dobutamine and may result in accelerated decline. VADs are being considered earlier, particularly as indices of nutrition decline.

Mechanical Bridge to Transplantation

Placement of an intra-aortic balloon pump (IABP) may be necessary in patients with heart failure who are refractory to initial pharmacologic measures. Ambulatory IABP through the axillary artery has been reported in few patients as a bridge to cardiac transplantation but is not commonly used today.[35]

The landmark Randomized Evaluation of Mechanical Assistance in Treatment of Chronic Heart Failure (REMATCH) trial provided evidence that LVAD support provided a statistically significant reduction in the risk of death from any cause when compared with optimal medical management. The survival rates for patients receiving LVADs (n = 68) versus patients receiving optimal medical management (n = 61) were 52% versus 28% at 1 year and 29% versus 13% at 2 years ($p = .008$, log-rank test).[6,36] The extended follow-up confirmed the initial observation that LVAD therapy renders significant survival and quality-of-life benefits compared with optimal medical management for patients with end-stage heart failure. A recent systematic review of the published literature supported these findings. In the studies reviewed, implantation of an LVAD provided support for up to 390 days, with as many as 70% of patients surviving to transplantation.[37]

The total artificial heart (TAH) positioned orthotopically replaces both native cardiac ventricles and all cardiac valves. Potential advantages of this device include eliminating problems commonly seen in the bridge to transplantation with left ventricular and biventricular assist devices, such as right-sided heart failure, valvular regurgitation, cardiac arrhythmias, ventricular clots, intraventricular communications, and low blood flows. Copeland and colleagues reported that the TAH allowed for bridge to transplantation in 79% of their patients with 1- and 5-year survival rates after transplantation of 86 and 64%, respectively.[38]

Because these devices cannot be weaned, it is imperative that the patient's candidacy for transplantation be scrutinized before placement of the device. Trends toward better device durability and reduced complication rates likely will continue to improve through the development of newer, more innovative VADs, allowing destination therapy to be considered more frequently.

Life-Threatening Ventricular Arrhythmias

Symptomatic ventricular tachycardia and a history of sudden cardiac death are indications for placement of an automatic implantable cardioverter-defibrillator (AICD), long-term antiarrhythmic therapy with amiodarone, or occasionally, radiofrequency catheter ablation, which have been shown to improve survival.[39]

Recipient Prioritization for Transplantation

The prioritization of appropriate recipients for transplantation is based on survival and quality of life expected to be gained in comparison with maximal medical and surgical alternatives.[3] The United Network for Organ Sharing (UNOS) is a national organization that maintains organ transplantation waiting lists and allocates identified donor organs on the basis of recipients' priority status. This priority status is based on a recipient's

TABLE 64-3 Current Recipient Status Criteria of the United Network for Organ Sharing (UNOS)*

STATUS IA
A. Patients who require mechanical circulatory assistance with one or more of the following devices: 1. Total artificial heart 2. Left and/or right ventricular assist device implanted for 30 days or less 3. Intra-aortic balloon pump 4. Extracorporeal membrane oxygenator (ECMO)
B. Mechanical circulatory support for more than 30 days with significant device-related complications
C. Mechanical ventilation
D. Continuous infusion of high-dose inotrope(s) in addition to continuous hemodynamic monitoring of left ventricular filling pressures
E. Life expectancy without transplant <7 days
STATUS IB
A. A patient who has at least one of the following devices or therapies in place: 1. Left and/or right ventricular assist device implanted for >30 days 2. Continuous infusion of intravenous inotropes
STATUS II
All other waiting patients who do not meet status Ia or Ib criteria

*UNOS Executive Order, August 1999.

status level (eg, IA, IB, or II), blood type, body size, and duration of time at a particular status level.[2] Geographic distance between donor and potential recipient is also taken into consideration. Highest priority is given to local status IA patients possessing the earliest listing dates. The recipient status criteria established by UNOS in 1999 are outlined in Table 64-3. In 1994, the percentage of patients awaiting transplantation for more than 2 years was 23%; this increased to 49% by 2003. From 1998 (with the institution of a new status system) to 2007, the distribution of patient status at transplant changed dramatically. In 1999, the distribution was 34% (1A), 36% (1B), and 26% (2). This shifted in 2007 to 50% (1A), 36% (1B), and 14% (2).[40]

Patients considered for transplantation should be examined at least every 3 months for reevaluation of recipient status. Yearly right-sided heart catheterization is indicated for all candidates on the waiting list and in selected cases for patients rejected because of pulmonary hypertension. Presently, there is no established method to delist patients who have stabilized on medical therapy without loss of their previously accrued waiting time.

THE CARDIAC DONOR

Donor Availability

The availability of donor organs remains the major limiting factor to heart transplantation. In the early years of heart transplantation, the number of heart transplants performed in the United States increased steadily to a peak in 1995 of 2363 and then reached a plateau in 1998. After 1998, there was a gradual decline in heart transplants per year to a nadir of 2015 in 2004, after which the number has steadily increased to 2207 in 2007.[40] Interestingly, likely owing to improved preoperative care, the death rate for patients on the waiting list for a cardiac allograft has decreased steadily.[40]

The Uniform Anatomic Gift Act of 1968 states that all competent individuals over the age of 18 may donate all or part of their bodies and established the current voluntary basis of organ donation practiced in the United States. To accommodate the increasing demand for organs, the original stringent criteria for donor eligibility have been relaxed, and educational campaigns have increased awareness of the need for a larger donor pool. In 1986, the Required Request Law, which required hospitals to request permission from next of kin to recover organs, was passed to encourage physician compliance in the donor request process. Future reforms will be molded by the evolving public attitude to transplantation and likely will focus on continued public and physician education.

Allocation of Donor Organs

In an effort to increase organ donation and to coordinate an equitable allocation of allografts, Congress passed the National Organ Transplant Act in 1984. This act resulted in the drafting of the aforementioned Required Request Law, as well as the awarding of a federal contract to the UNOS for the development of a national organ procurement and allocation network. To facilitate transplantation, the United States is divided into 11 geographic regions.

Organs are offered to sick patients within the region in which they were donated before being offered to other parts of the country. This helps to reduce organ preservation time, improve organ quality and survival outcomes, reduce the costs incurred by the transplant patient, and increase access to transplantation.

Donor Selection

Once a brain-dead individual has been identified as a potential cardiac donor, the patient undergoes a rigorous three-phase screening regimen. The primary screening is undertaken by the organ procurement agency. Information regarding the patient's age, height and weight, gender, ABO blood type, hospital course, cause of death, and routine laboratory data including cytomegalovirus (CMV), HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) serologies are collected. Cardiac surgeons and/or cardiologists perform the secondary screening, which involves further investigation in search of potential contraindications (Table 64-4), determination of the hemodynamic support necessary to sustain the donor, and review of the electrocardiogram, chest roentgenogram, arterial blood gas determination, and echocardiogram. Even when adverse donor criteria are reported, a team often is dispatched to the hospital to evaluate the donor on-site.

Although echocardiography is effective in screening for anatomical abnormalities of the heart, the use of a single echocardiogram to determine the physiologic suitability of a donor is not supported by evidence.[41] The Papworth Hospital transplant program in Great Britain increased its donor yield substantially by using a pulmonary artery catheter to guide the physiologic assessment and management of ventricular dysfunction.[42] Coronary angiography is indicated in the presence of advanced donor age (traditionally for male donors >45 years of age and female donors >50 years of age). Angiography also should be performed if there is a history of cocaine use or the donor has three risk factors for coronary artery disease (CAD), such as hypertension, diabetes, smoking history, dyslipidemia, or family history of premature CAD.[41]

The final and often most important screening of the donor occurs intraoperatively at the time of organ procurement by the cardiac surgical team. Direct visualization of the heart is performed for evidence of right ventricular or valvular dysfunction, previous infarction, or myocardial contusion secondary to closed-chest compressions or blunt chest trauma. The coronary arterial tree is palpated for gross calcifications indicative of atheromatous disease. If direct examination of the heart is unremarkable, the recipient hospital is notified, and the procurement surgeons proceed with donor cardiectomy, usually in conjunction with multiorgan procurement.

TABLE 64-4 Donor Selection for Heart Transplantation

I. Suggested criteria for cardiac donor
- A. Age <55
- B. Absence of the following:
  1. Prolonged cardiac arrest
  2. Prolonged severe hypotension
  3. Preexisting cardiac disease
  4. Intracardiac drug injection
  5. Severe chest trauma with evidence of cardiac injury
  6. Septicemia
  7. Extracerebral malignancy
  8. Positive serologies for human immunodeficiency virus, hepatitis B (active), or hepatitis C
  9. Hemodynamic stability without high-dose inotropic support (<20 μg/kg/min of dopamine)

II. Suggested cardiac donor evaluation
- A. Past medical history and physical examination
- B. Electrocardiogram
- C. Chest roentgenogram
- D. Arterial blood gases
- E. Laboratory tests (ABO, HIV, HBV, HCV)
- F. Echocardiogram, pulmonary artery catheter evaluation, and in selected cases, coronary angiogram

Expanded Donor Criteria and Alternate Listing

As the donor shortage has worsened and the number of patients waiting for transplants has increased, one of the areas of increasing interest is the use of marginal donors for marginal recipients. For this purpose, an alternate recipient list is being used by some centers to match certain recipients who might be excluded from a standard list with marginal donor hearts that otherwise would go unused. Expanded donor criteria include the use of donors substantially smaller than the recipients, donors with coronary artery disease that may require coronary artery bypass grafting (CABG), left ventricular dysfunction, or donors from older age groups.[41] Acceptable operative mortality has been reported, and the University of California, Los Angeles (UCLA) heart transplant group has shown that alternate listing did not independently predict early or late mortality.[43]

It also appears more beneficial in terms of patient survival to receive an allograft from a donor older than 40 years of age compared to remaining on the waiting list.[44] Other high-risk donors, such as HCV-positive or HBV (core IgM-negative)–positive donors, may be appropriate in selected higher-risk recipients.[41]

Also of special interest is the effect of donor alcohol and cocaine abuse on heart transplantation. A small single-center study showed unfavorable early outcome of patients receiving hearts from alcoholic donors (>2 oz of pure alcohol daily for 3 or more months), suggesting the presence of a subclinical preoperative alcoholic cardiomyopathy and poor tolerance of rejection episodes after transplantation.[45] Because of widespread cocaine abuse, donor guidelines have declared intravenous drug abuse a "relative" contraindication for donor selection. However, the dilemma of selecting donor hearts from nonintravenous drug abusers remains an open issue. A favorable outcome for patients who received transplanted hearts obtained from nonintravenous cocaine users has been reported.[46] However, judicious use of organs from donors with a history of cocaine use is strongly advised. Specific recommendations were made in a consensus report to improve the yield of donor hearts.[41]

Management of the Cardiac Donor

Medical management of cardiac donors, an integral part of organ preservation, is complicated by the complex physiologic phenomenon of brain death and the need to coordinate procurement with other organ donor teams. Brain death is associated with an "autonomic and cytokine storm." The release of noradrenaline (norepinephrine) leads to subendocardial ischemia. Subsequent cytokine release results in further myocardial depression. This is accompanied by pronounced vasodilatation and loss of temperature control.[3] Rapid afterload reduction may be achieved with sodium nitroprusside, whereas volatile anesthetics reduce the intensity of sympathetic bursts. The initial period of intense autonomic activity is followed by loss of sympathetic tone and a massive reduction in systemic vascular resistance. Overall, brain stem death results in severe hemodynamic instability, the degree of which appears to be directly related to the severity of the brain injury and may result from vasomotor autonomic dysfunction, hypovolemia, hypothermia, and dysrhythmias.[47]

Aggressive volume resuscitation sometimes is necessary, and the use of a Swan-Ganz catheter may be crucial to guide therapy.[48] Fluid overload should be avoided to prevent postoperative allograft dysfunction caused by chamber distention and myocardial edema. Inotropic support (eg, dopamine or dobutamine, epinephrine, or norepinephrine) to maintain a mean arterial blood pressure (MAP) of 60 mm Hg or more in the presence of a central venous pressure (CVP) of 6 to 10 mm Hg is recommended.[41] ATP is depleted rapidly by exogenous catecholamine administration, and this has an adverse effect on posttransplantation cardiac function.[47] Low-dose vasopressin is being used increasingly as first-line support because, in addition to treating diabetes insipidus, it independently improves arterial blood pressure and reduces exogenous inotrope requirements in brain stem dead donors.[49] Maintenance of normal temperature, electrolyte levels, osmolarity, acid-base balance, and oxygenation is critical for optimal donor management. Central diabetes insipidus develops in more than 50% of donors because of pituitary dysfunction, and massive diuresis complicates fluid and electrolyte management.[50] The initial treatment of diabetes insipidus is aimed at correcting hypovolemia and returning the plasma sodium concentration to normal levels by fluid replacement with 5% dextrose or nasogastric water. In severe cases, intermittent treatment with the synthetic analogue 1-D-amino-8-D-arginine vasopressin (DDAVP) also may be required in addition to vasopressin infusion.[47]

Several studies have demonstrated beneficial effects of thyroid hormones and steroids on cardiac performance in brain stem dead-organ donors.[42,49,51] Recent guidelines advocate the addition of a standardized hormonal resuscitation package consisting of methylprednisolone (15 mg/kg bolus), triiodothyronine (4-µg bolus followed by infusion of 3 µg/h), and arginine vasopressin (1-unit bolus followed by 0.5 to 4 units/h) to the standard donor management protocol.[41] Donors also receive insulin, titrated to keep blood glucose at 120 to 180 mg/dL. Other pertinent strategies include standard ventilator management with diligent endotracheal suctioning and a thermoregulation goal of 34 to 36°C using warming blankets and lights, warm intravenous fluids, and warm inspired air. Broad-spectrum antibiotic therapy with a cephalosporin is initiated following collection of blood, urine, and tracheal aspirate for culture. The approach for management of the cardiac donor recommended at the conference entitled, Maximizing Use of Organs Recovered from the Cadaver Donor: Cardiac Recommendations, is shown in Table 64-5 and summarized in Fig. 64-2.[41]

Donor Heart Procurement

A median sternotomy is performed, and the pericardium is incised longitudinally. The heart is inspected and palpated for evidence of cardiac disease or injury. The superior and inferior venae cavae and the azygous vein are mobilized circumferentially and encircled with ties. The aorta is dissected from the pulmonary artery and isolated with umbilical tape. To facilitate access to the epigastrium by the liver procurement team, the cardiac team often then temporarily retires from the operating room table or assists with retraction. Once preparation for liver, pancreas, lung, and kidney explantation is completed, the patient is administered 30,000 units of heparin intravenously. The azygous vein and superior vena cava are doubly ligated (or stapled) and divided distal to the azygous vein, leaving a long segment of superior vena cava (Fig. 64-3). The inferior vena cava is incised and the left atrium vented either at the left atrial appendage or via a transected pulmonary vein. The aortic cross-clamp is applied at the takeoff of the innominate artery, and the heart is arrested with a single flush (1000 mL or 10 to 20 mL/kg) of cardioplegia solution infused proximal to the cross-clamp. Rapid cooling of the heart is achieved with copious amounts of cold saline and cold saline slush poured into the pericardial well. After the delivery of cardioplegia, cardiectomy proceeds as the apex of the heart is elevated cephalad and any remaining intact pulmonary veins are divided. This maneuver is modified appropriately to retain adequate left atrial cuffs for both lungs and the heart if the lungs also are being procured. While applying caudal traction to the heart with the nondominant hand, the ascending aorta is transected proximal to the innominate artery, and the pulmonary arteries are divided distal to the bifurcation (again, modification is necessary if the lungs are being procured). More generous segments of the great vessels and superior vena cava may be required for recipients with congenital heart disease. Alternatively, the SVC and IVC are transected, followed by the aorta and pulmonary artery. The left atrium is then divided as the last step. This allows for optimal division of the left atrium, particularly when lungs are recovered. It is critically important to avoid left ventricular distention and ensure thorough cooling with ice saline.

Once the explantation is complete, the allograft is examined for evidence of a patent foramen ovale, which should be closed at that time. Any valvular anomalies are identified. The allograft then is placed in a sterile container for transport to the recipient hospital.

Organ Preservation

Current clinical graft preservation techniques generally permit a safe ischemic period of 4 to 6 hours.[52] Factors contributing to

TABLE 64-5 Management of the Cardiac Donor

I. Conventional management, before the initial echocardiogram
   A. Adjust volume status (target central venous pressure 6–10 mm Hg).
   B. Correct metabolic perturbations, including
      1. Acidosis (target pH 7.40–7.45)
      2. Hypoxemia (target Po_2 >80 mm Hg, O_2 saturation >95%)
      3. Hypercarbia (target Pco_2 30–35 mm Hg)
   C. Correct anemia (target hematocrit 30%, hemoglobin 10 g/dL).
   D. Adjust inotropes to maintain mean arterial pressure at 60 mm Hg. Norepinephrine and epinephrine should be tapered off rapidly in favor of dopamine or dobutamine.
   E. Target = dopamine <10 μg/kg/min or dobutamine <10 μg/kg/min.

II. Obtain an initial echocardiogram
   A. Rule out structural abnormalities (substantial left ventricular hypertrophy, valvular dysfunction, congenital lesions).
   B. If left ventricular ejection fraction is 45%, proceed with recovery (consider aggressive management as shown below to optimize cardiac function before recovery) with final evaluation in the operating room.
   C. If left ventricular ejection fraction is <45%, aggressive management with placement of a pulmonary arterial catheter and hormonal resuscitation is strongly recommended.

III. Hormonal resuscitation
   A. Triiodothyronine (T3): 4-μg bolus, then continuous infusion at 3 μg/h.
   B. Arginine vasopressin: 1-unit bolus, then continuous infusion at 0.5–4 units/h, titrated to a systemic vascular resistance of 800–1200 dyne/s/cm^5.
   C. Methylprednisolone: 15 mg/kg bolus.
   D. Insulin: 1 unit/h minimum; titrate to maintain blood sugar at 120–180 mg/dL.

IV. Aggressive hemodynamic management
   A. Initiated simultaneously with hormonal resuscitation.
   B. Placement of pulmonary artery catheter.
   C. Duration of therapy 2 hours.
   D. Adjustment of fluids, inotropes, and pressors every 15 minutes based on serial hemodynamic measurements to minimize use of beta-agonists and meet the following target (Papworth) criteria:
      1. Mean arterial pressure >60 mm Hg
      2. Central venous pressure 4–12 mm Hg
      3. Pulmonary capillary wedge pressure 8–12 mm Hg
      4. Systemic vascular resistance 800–1200 dyne/s/cm^5
      5. Cardiac index >2.4 L/min/m^2
      6. Dopamine <10 μg/kg/min or dobutamine 10 μg/kg/min

the severity of postoperative myocardial dysfunction include insults associated with suboptimal donor management, hypothermia, ischemia-reperfusion injury, and depletion of energy stores. A single flush of a cardioplegic or preservative solution followed by static hypothermic storage at 4 to 10°C is the preferred preservation method by most transplant centers. Crystalloid solutions of widely different compositions are available, and the debate over them speaks for the fact that no ideal solution currently exists. Depending on their ionic composition, solutions are classified as intracellular or extracellular.[52] Intracellular solutions, characterized by moderate to high concentrations of potassium and low concentrations of sodium, purportedly reduce hypothermia-induced cellular edema by mimicking the intracellular milieu. Commonly used examples of these solutions include University of Wisconsin, Euro-Collins, and in Europe, Bretschneider (HTK) and intracellular Stanford solutions. Extracellular solutions, characterized by low to moderate potassium and high sodium concentrations, avoid the theoretical potential for cellular damage and increased vascular resistance associated with hyperkalemic solutions. Hopkins, Celsior, Krebs, and St. Thomas Hospital solutions are representative extracellular cardioplegic solutions. Several comparisons

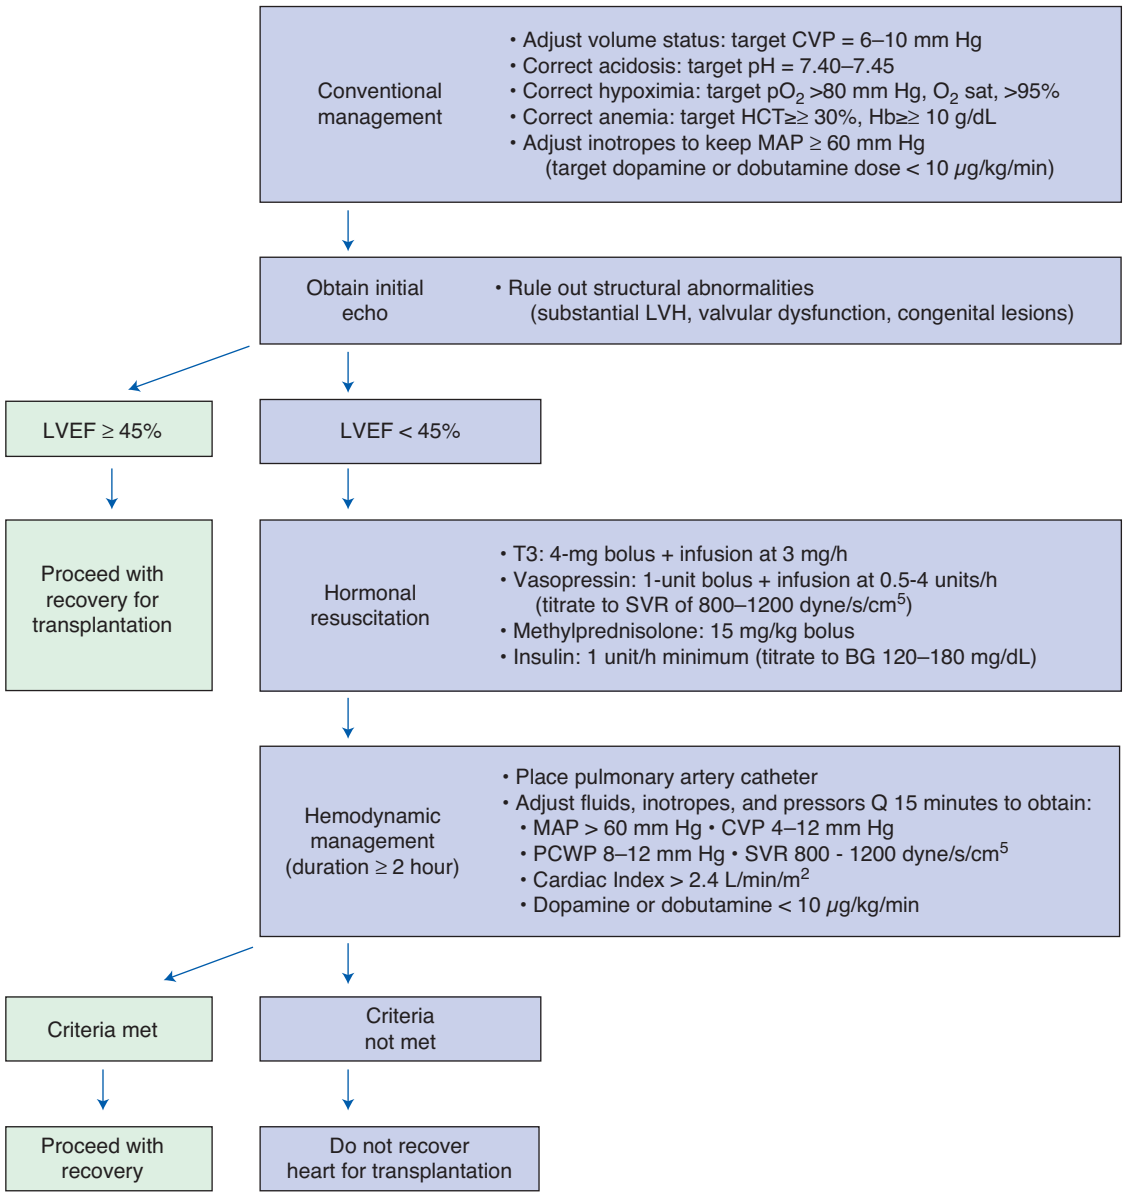

FIGURE 64-2 Recommended heart donor management algorithm. (*Reprinted with permission from Zaroff JG, Rosengard BR, Armstrong WF, et al: Consensus conference report: maximizing use of organs recovered from the cadaver donor: cardiac recommendations, March 28–29, 2001, Crystal City, VA. Circulation 2002; 106:836.*)

of the different types of intracellular and extracellular solutions have shown variable results.[53,54] Although a plethora of pharmacologic additives has been included in cardioplegic-storage solutions, the greatest potential for future routine use may lie with impermeants, substrates, and antioxidants.[55] A number of pharmacologic and mechanical strategies for leukocyte inhibition and depletion also have been explored.[56] Potential benefits of continuous hypothermic perfusion (CHP) preservation such as uniform myocardial cooling, continuous substrate supplementation, and metabolic by-product washout are currently overshadowed by exacerbation of extracellular cardiac edema and logistical problems inherent to a complex perfusion apparatus. Newer portable perfusion circuits are being developed, and recent studies showed reduction in oxidative stress and attenuation of DNA damage in canine heart transplant models preserved by 24-hour CHP compared with 4 hours of static preservation.[57]

Donor-Recipient Matching

Criteria for matching potential recipients with the appropriate donor are based primarily on ABO blood group compatibility and patient size. ABO barriers should not be crossed in adult heart transplantation because incompatibility may result in fatal hyperacute rejection. Donor weight should be within 30% of recipient weight except in pediatric patients, in whom closer size matching is required. In cases of elevated pulmonary vascular resistance in the recipient (5 to 6 Wood units), a larger donor is preferred to reduce the risk of right ventricular failure in the early postoperative period. Although practices vary by transplant

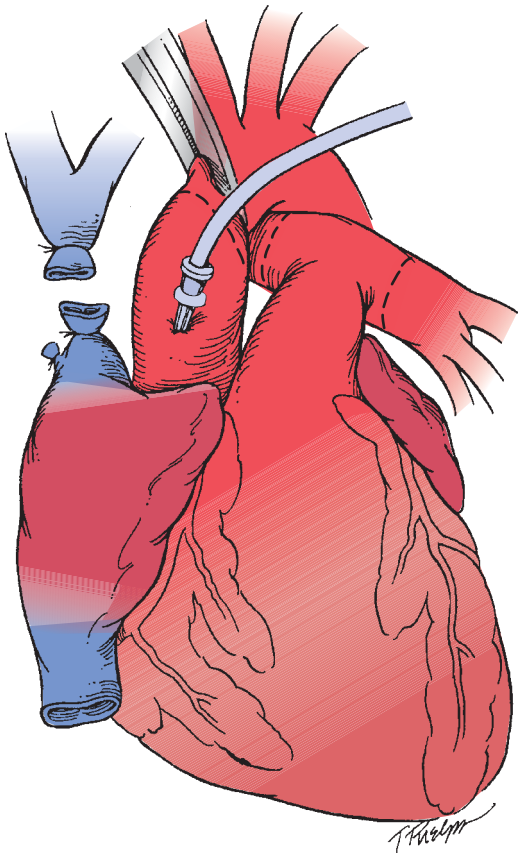

FIGURE 64-3 Donor cardiectomy.

program, generally if the percent of panel reactive antibody (PRA) is greater than 10%, indicating recipient presensitization to alloantigen, a prospective negative T-cell cross-match between the recipient and donor sera is mandatory before transplantation.[32,58] A cross-match is always performed retrospectively, even if the PRA is absent or low. Retrospective studies also have demonstrated that better matching at the HLA-DR locus results in fewer episodes of rejection and infection with an overall improved survival.[59] Because of current allocation criteria and limits on ischemic time of the cardiac allograft, routine prospective HLA matching is not logistically possible.

Hyperacute Rejection

Hyperacute rejection results from preformed donor-specific antibodies in the recipient. ABO blood group and panel reactive antibody screening have made this condition a rare complication. The onset of hyperacute rejection occurs within minutes to several hours after transplantation, and the results are catastrophic. Gross inspection reveals a mottled or dark red, flaccid allograft, and histologic examination confirms the characteristic global interstitial hemorrhage and edema without lymphocytic infiltrate. Immunofluorescence techniques reveal deposits of immunoglobulins and complement on the vascular endothelium. Immediate plasmapheresis, intravenous immunoglobulin (IVIG), and mechanical support are immediately instituted, and retransplantation may be the only successful strategy.

OPERATIVE TECHNIQUES IN HEART TRANSPLANTATION

Orthotopic Heart Transplantation

Operative Preparation of the Recipient

The original technique of orthotopic cardiac transplantation described by Shumway and Lower is still used commonly today. Following median sternotomy and vertical pericardiotomy, the patient is heparinized and prepared for cardiopulmonary bypass. Bicaval venous cannulation and distal ascending aortic cannulation just proximal to the origin of the innominate artery are optimal. Umbilical tape snares are passed around the superior and inferior venae cavae. Bypass is initiated, the patient is cooled to 28°C, caval snares are tightened, and the ascending aorta is cross-clamped. The great vessels are transected above the semilunar commissures, whereas the atria are incised along the atrioventricular grooves, leaving cuffs for allograft implantation. Removal of the atrial appendages reduces the risk of postoperative thrombus formation. Following cardiectomy, the proximal 1 to 2 cm of aorta and pulmonary artery are separated from one another with electrocautery, taking care to avoid injuring the right pulmonary artery. Continuous aspiration of pulmonary venous return from bronchial collaterals is achieved by insertion of a vent into the left atrial remnant either directly or via the right superior pulmonary vein.

Timing of donor and recipient cardiectomies is critical to minimize allograft ischemic time and recipient bypass time. Frequent communication between the procurement and transplant teams permits optimal coordination of the procedures. Ideally, the recipient cardiectomy is completed just before arrival of the cardiac allograft.

Implantation

The donor heart is removed from the transport cooler and placed in a basin of cold saline. If not previously performed, preparation of the donor heart is accomplished. Electrocautery and sharp dissection are used to separate the aorta and pulmonary artery. The left atrium is incised by connecting the pulmonary vein orifices, and excess atrial tissue is trimmed, forming a circular cuff tailored to the size of the recipient left atrial remnant (Fig. 64-4). Implantation begins with placement of a double-armed 3-0 Prolene suture through the recipient left atrial cuff at the level of the left superior pulmonary vein and then through the donor left atrial cuff near the base of the atrial appendage (Fig. 64-5). The allograft is lowered into the recipient mediastinum atop a cold sponge to insulate it from direct thermal transfer from adjacent thoracic structures. The suture is continued in a running fashion caudally and then medially to the inferior aspect of the interatrial septum (Fig. 64-6). The second arm of the suture is run along the roof of the left atrium and down the interatrial septum. It is important to continually assess size discrepancy between donor and recipient atria so that appropriate plication of excess tissue may be performed. The left atrium is filled with saline, and the two arms of suture are tied together on the outside of the heart. Most centers use constant

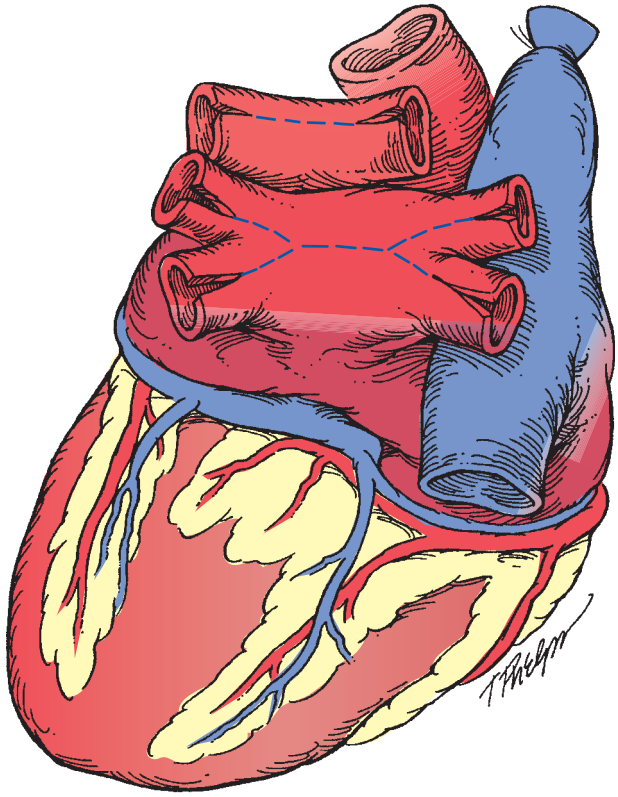

FIGURE 64-4 Donor allograft preparation for orthotopic heart transplantation. Pulmonary vein orifices joined to form left atrial cuff.

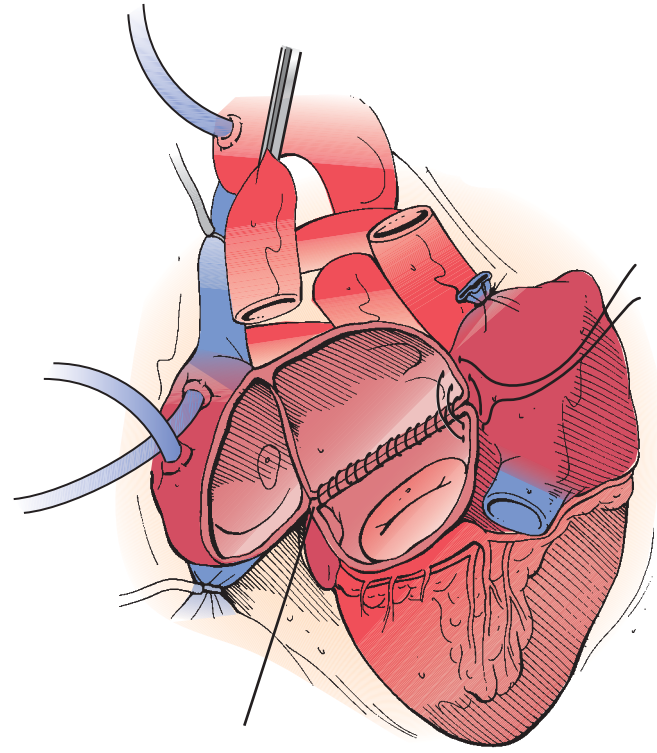

FIGURE 64-6 Implantation of allograft (continued). Left atrial anastomosis. (*Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, Theodore J [eds]: Heart and Lung Transplantation, 2nd ed. New York, Saunders, 2002; pp. 180-199.*)

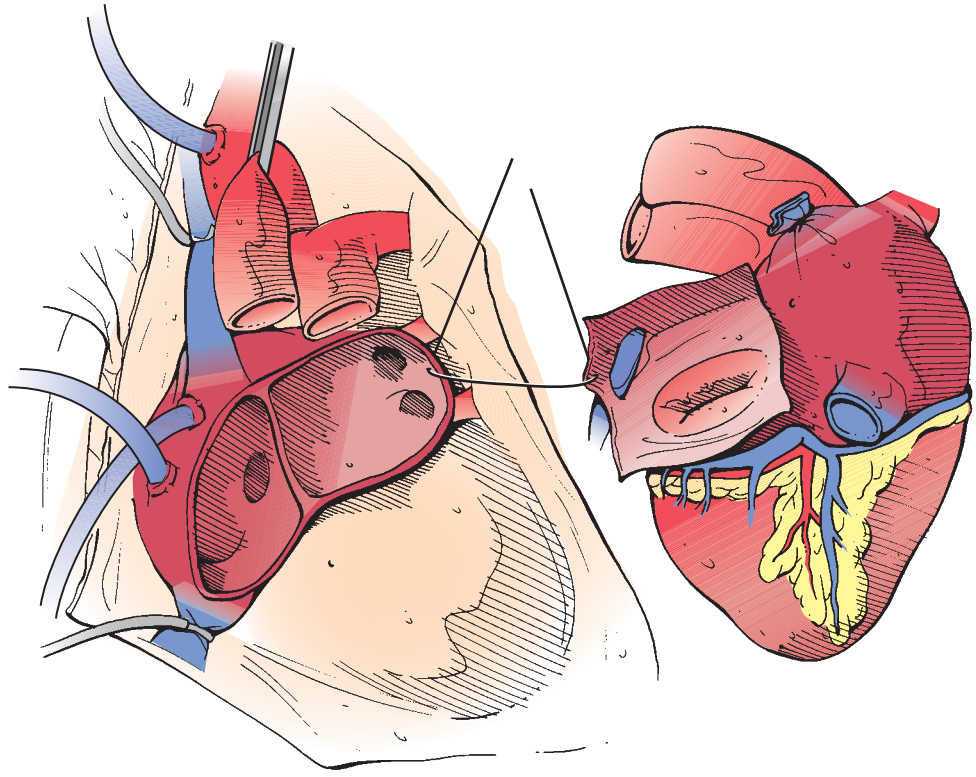

FIGURE 64-5 Implantation of allograft. First suture is placed at the level of the left superior pulmonary vein. (*Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, Theodore J [eds]: Heart and Lung Transplantation, 2nd ed. New York, Saunders, 2002; pp. 180-199.*)

insufflation of carbon dioxide into the mediastinum to reduce the amount of intracardiac air.

Once the left atrial anastomosis is complete, a curvilinear incision is made from the inferior vena caval orifice toward the right atrial appendage of the allograft. This modification in the right atriotomy initially introduced by Barnard reduces the risk of injury to the sinoatrial node and accounts for the preservation of sinus rhythm observed in most recipients. The tricuspid apparatus and interatrial septum are inspected. Recipients are predisposed to increased right-sided heart pressures in the early postoperative period owing to preexisting pulmonary hypertension and volume overload. Both conditions are poorly tolerated by the recovering right ventricle. To avoid refractory arterial desaturation associated with shunting, patent foramen ovale are closed. The right atrial anastomosis is performed in a running fashion similar to the left, with the initial anchor suture placed either at the most superior or inferior aspect of the interatrial septum so that the ends of the suture meet in the middle of the anterolateral wall (Fig. 64-7A,B).

The end-to-end pulmonary artery anastomosis is next performed using a 4-0 Prolene suture beginning with the posterior wall from inside of the vessel and then completing the anterior wall from the outside (Fig. 64-8). It is crucial that the pulmonary artery ends be trimmed to eliminate any redundancy in the vessel that might cause kinking.[60] Finally, the aortic anastomosis is performed using a technique similar to that for the pulmonary artery, except that some redundancy is desirable in the aorta because it facilitates visualization of the posterior suture line (Fig. 64-9). Rewarming usually is begun before the aortic anastomosis, which is performed in a standard end-to-end fashion. Routine deairing techniques are then employed. Lidocaine (100 to 200 mg intravenously) and methylprednisone (500 to 1000 mg) is administered, and the aortic cross-clamp is removed. Half of patients require electrical defibrillation. A needle vent is inserted in the ascending aorta for final deairing, with the patient in steep Trendelenburg position. Suture lines are inspected carefully for hemostasis. Inotrope infusion is initiated, and temporary pacing may be required. The patient is weaned from cardiopulmonary bypass, and the cannulae are removed. Temporary epicardial pacing wires are placed in the donor right atrium and ventricle. Following insertion of mediastinal and pleural tubes, the median sternotomy is closed in the standard fashion.

Cold-blood cardioplegia is used in many centers. An initial dose often is given following removal from the cold storage solution before implantation. A second dose, or the initial dose as given by some centers, is administered after the right atrial anastomosis or inferior vena cava (IVC) anastomosis, when a bicaval technique is used.

Alternative Techniques for Orthotopic Heart Transplantation

The most commonly employed technique today is a bicaval anastomotic method. With this technique, the recipient right atrium is excised completely, leaving a left atrial cuff and a

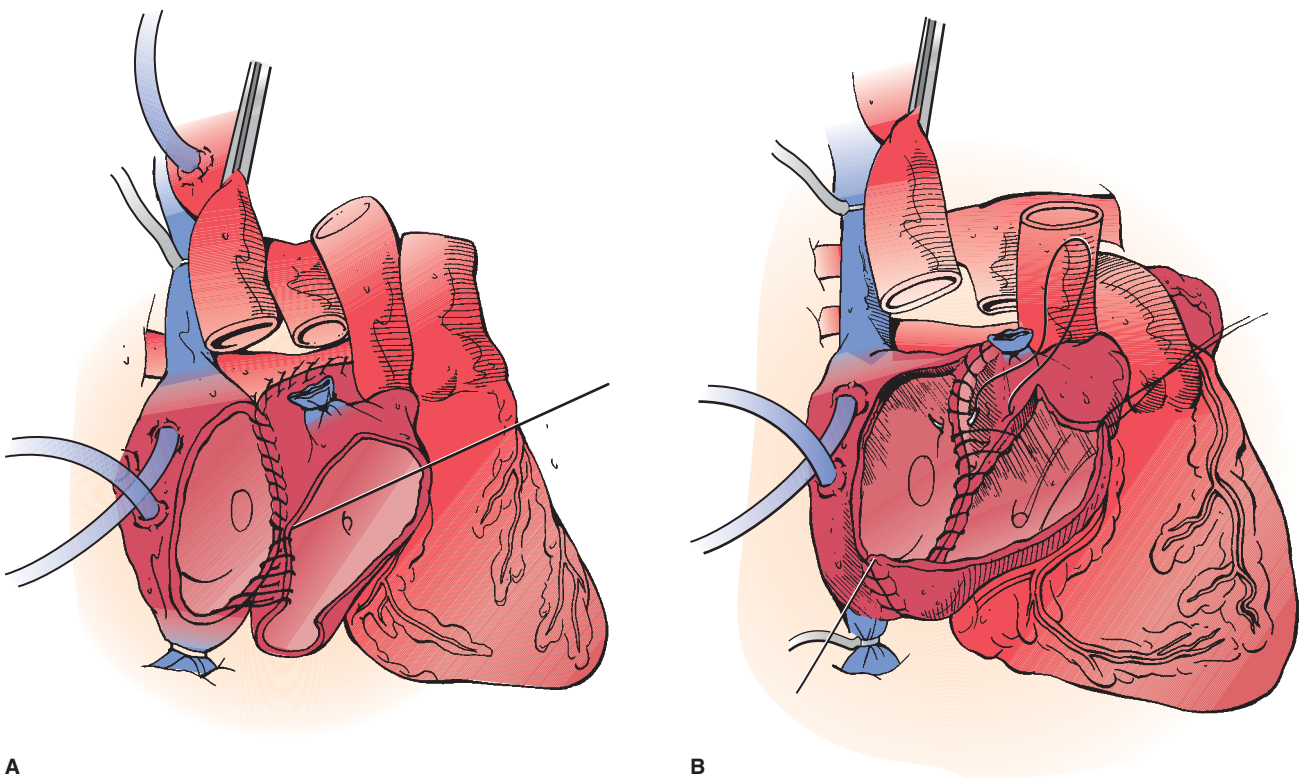

FIGURE 64-7 Implantation of allograft (continued). (A) Initiation of right atrial anastomosis. (B) Completion of right atrial anastomosis. FIGURE 64-8 Implantation of allograft (continued). Pulmonary arterial anastomosis. (*Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, Theodore J [eds]: Heart and Lung Transplantation, 2nd ed. New York, Saunders, 2002; pp. 180-199.*)

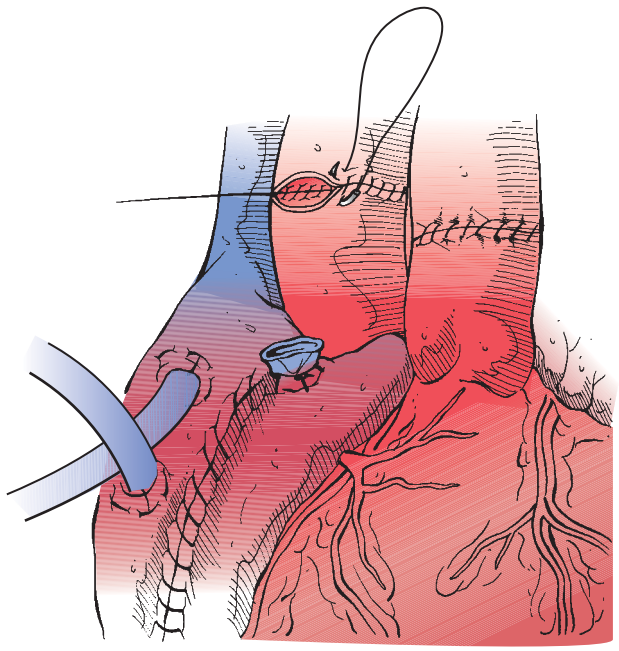

FIGURE 64-9 Implantation of allograft (continued). Aortic anastomosis. (*Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, Theodore J [eds]: Heart and Lung Transplantation, 2nd ed. New York, Saunders, 2002; pp. 180-199.*)

generous cuff of the IVC and superior vena cava (SVC), respectively. The left atrial cuff of the donor is anastomosed to the left atrial cuff of the recipient using the standard Shumway technique. Individual end-to-end anastomoses of the IVC and SVC are performed. The IVC anastomosis usually is performed following the left atrial anastomosis and the SVC anastomosis after the cross-clamp is removed. Total heart transplantation involves complete excision of the recipient heart with bicaval end-to-end anastomoses and bilateral pulmonary venous cuff anastomoses. The Wythenshawe bicaval technique is performed in a similar fashion except that the recipient left atrium is prepared as a single cuff with all four pulmonary vein orifices (Fig. 64-10). Although these procedures are more technically difficult than standard orthotopic transplantation, published series using these techniques have reported shorter hospital stays, reduced postoperative dependence on diuretics, and lower incidences of atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and right ventricular failure.[61] A single-center study comparing biatrial versus bicaval transplant showed an improved 12-month survival in the bicaval group.[62] However, a recent analysis of the UNOS database, including more than 11,000 patients, did not demonstrate a survival difference between patients in whom biatrial versus bicaval anastomotic techniques were used; although the bicaval technique was associated with decreased duration of hospital stay and postoperative pacemaker placement.[63] Long-term outcomes

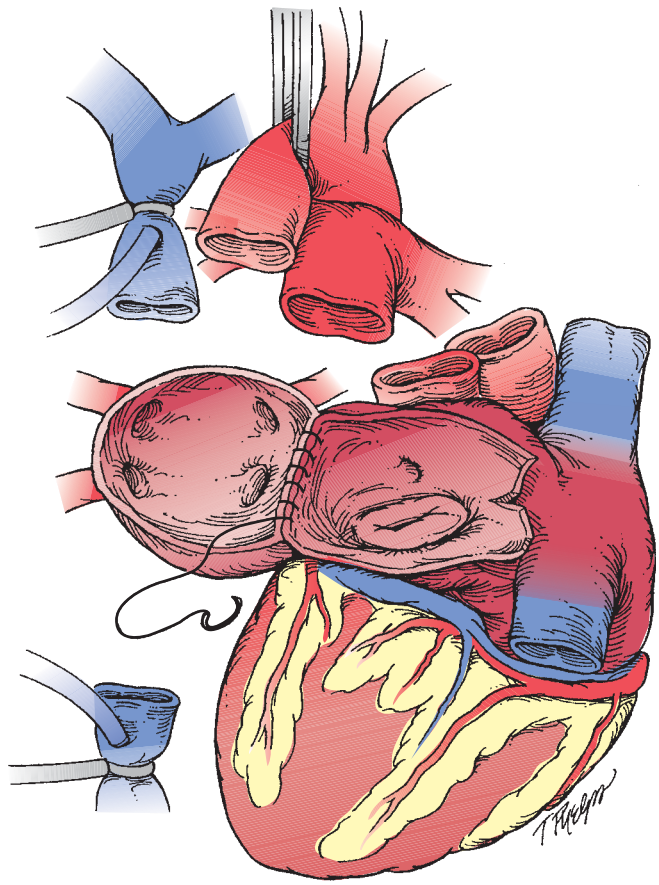

FIGURE 64-10 Bicaval heart transplantation.

and prospective, randomized studies evaluating these alternative techniques are still needed.

Heterotopic Heart Transplantation

Pulmonary hypertension and right-sided heart failure have remained the leading causes of early mortality in cardiac transplantation. This has led to an interest in heterotopic heart transplantation. Currently, heterotopic heart transplants are performed rarely but may be indicated in patients with irreversible pulmonary hypertension or significant donor–recipient size mismatch.[22]

Heart Transplantation after VAD

Cardiac transplantation after VAD poses unique challenges. All patients should have a recent contrasted chest CT to identify location and course of outflow grafts. The femoral artery and vein should be exposed for cannulation before redo sternotomy. Sternal reentry should carefully dissect the heart from pleura to pleura to safely place a retractor. The initial focus is on dissection of the IVC, SVC, and aorta. Further dissection is ideal, but may require cardiopulmonary bypass. The apex and left atrium should not be manipulated before bypass as there is a risk of entraining air, particularly with axial-flow devices. Finally, before initiating bypass, the outflow graft should be clamped to prevent regurgitation through the device. The sternotomy and adhesiolysis can be difficult and time consuming. Patience is critical.

POSTOPERATIVE MANAGEMENT

Hemodynamic Management

Heart Allograft Physiology

The intact heart is innervated by antagonistic sympathetic and parasympathetic fibers of the autonomic nervous system. Transplantation necessitates transection of these fibers, yielding a denervated heart with altered physiology. Devoid of autonomic input, the sinoatrial (SA) node of the transplanted allograft fires at its increased intrinsic resting rate of 90 to 110 beats per minute.[64] The allograft relies on distant noncardiac sites as its source for catecholamines; thus its response to stress (eg, hypovolemia, hypoxia, and anemia) is somewhat delayed until circulating catecholamines can exert their positive chronotropic effect on the heart. The absence of a normal reflex tachycardia in response to venous pooling accounts for the frequency of orthostatic hypotension in transplant patients.

Denervation alters the heart's response to therapeutic interventions that act directly through the cardiac autonomic nervous system.[64] Carotid sinus massage, Valsalva maneuver, and atropine have no effect on SA node firing or atrioventricular conduction. Because of depletion of myocardial catecholamine stores associated with prolonged inotropic support of the donor, the allograft often requires high doses of catecholamines.

Routine Hemodynamic Management

Donor myocardial performance is transiently depressed in the immediate postoperative period. Allograft injury associated with donor hemodynamic instability and the hypothermic, ischemic insult of preservation contribute to reduced ventricular compliance and contractility characteristics of the newly transplanted heart.[65] Abnormal atrial dynamics owing to the midatrial anastomosis exacerbate the reduction in ventricular diastolic loading. An infusion of epinephrine or dobutamine is initiated routinely in the operating room to provide temporary inotropic support. Cardiac denervation brings in several consequences, which may include a chronotropic and inotropic supersensitivity to exogenous catecholamines.[66] Restoration of normal myocardial function usually permits the cautious weaning of inotropic support within 2 to 4 days.

Early Allograft Failure

Early cardiac failure still accounts for up to 20% of perioperative deaths of heart transplant recipients.[67] The cause may be multifactorial, but the most important etiologies are myocardial dysfunction owing to donor instability, pulmonary hypertension, ischemic injury during preservation, and occasionally acute rejection. Mechanical support with an intra-aortic balloon pump, ventricular assist device, or ECMO can be used in patients refractory to pharmacologic interventions, although this measure, as well as retransplantation, has historically been associated with increased mortality.[68,69]

Chronic left ventricular failure frequently is associated with elevated pulmonary vascular resistance, and the unprepared donor right ventricle may be unable to overcome this increased afterload. Although recipients are screened to ensure that those with irreversible pulmonary hypertension are not considered for transplantation, right-sided heart failure remains a leading cause of early mortality. Initial management involves employing pulmonary vasodilators such as inhaled nitric oxide, nitroglycerin, or sodium nitroprusside. Pulmonary hypertension that is refractory to these vasodilators sometimes responds to prostaglandin E_1 (PGE_1) or prostacyclin.[14,70] Intra-aortic balloon counterpulsation and right ventricular assist devices also can be used in patients unresponsive to medical therapy.[71]

Arrhythmias

Denervation of the transplanted heart leads to loss of autonomic nervous system modulation of the heart's electrophysiologic properties. Parasympathetic denervation causes loss of basal suppression of SA node automaticity, leading to a persistent increase in resting heart rate and a loss of normal, rapid heart rate modulation. This parasympathetic loss also causes elimination of the chronotropic effects of digoxin and atropine after heart transplantation. At the same time, sympathetic denervation causes a decrease and delay in exercise- or stress-induced augmentation of SA node automaticity, resulting in a decreased maximum heart rate with exercise.[72]

Sinus or junctional bradycardia occurs in up to half of transplant recipients. Risk factors for sinus node dysfunction include prolonged organ ischemia, angiographic nodal artery abnormalities, biatrial versus bicaval anastomosis, preoperative amiodarone use, and rejection.[73] Adequate heart rate is achieved with inotropic drug infusions and/or temporary epicardial pacing. Most bradyarrhythmias resolve over 1 to 2 weeks. Theophylline

has been effective in patients with bradyarrhythmias and has decreased the need for permanent pacemakers in this patient population.[74]

Atrial fibrillation, atrial flutter, and other supraventricular arrhythmias have been reported in 5 to 30% of patients after heart transplantation.[72] Individual assessment of the risk:benefit ratio for anticoagulation therapy is necessary. Supraventricular tachycardia (SVT) in transplant patients should be treated in the same manner as in nontransplant patients but with lower doses. Recurrent arrhythmias from reentry circuits or defined ectopic foci often can be cured by radiofrequency ablation.

Premature ventricular complexes (PVCs) are generally not considered ominous. Because of their rapidly terminal nature, sustained ventricular tachycardia (VT) and ventricular fibrillation presumably are responsible for a significant portion of the 10% of sudden and unexplained deaths in heart transplant patients.[75]

Unique aspects of common antiarrhythmic drugs reflecting the differences in their therapeutic effects in heart transplant recipients compared with nontransplant patients are shown in Table 64-6.[72] Persistence of any form of arrhythmia should warrant further investigative efforts and an aggressive search for the presence of indicators of cardiac ischemia, rejection, pulmonary pathology, or infection. If arrhythmic episodes are frequent or underlying cardiac pathology is severe, retransplantation may be considered.

Systemic Hypertension

Systemic hypertension should be treated to prevent unnecessary afterload stress on the allograft. In the early postoperative period, intravenous sodium nitroprusside or nitroglycerin usually is administered. Nitroglycerin is associated with less pulmonary shunting because of a relative preservation of the pulmonary hypoxic vasoconstrictor reflex. Nicardipine infusion has been reported to control postoperative hypertension more rapidly and was superior to sodium nitroprusside in maintaining left ventricular performance immediately after drug infusion.[76] If hypertension persists, an oral antihypertensive can be added, if possible, to permit weaning of the parenteral agents.

Respiratory Management

The respiratory management of the cardiac transplant recipient uses the same protocols employed following routine cardiac surgery.

Renal Function

Preoperative renal insufficiency owing to chronic heart failure and the nephrotoxic effects of calcineurin inhibitors such as FK506 and cyclosporine place the recipient at increased risk of renal insufficiency. Acute calcineurin inhibitor–induced renal insufficiency usually will resolve with a reduction in dose. Continuous intravenous infusion to eliminate the wide fluctuations in levels associated with oral dosing can be attempted. Furthermore, concurrent administration of mannitol with calcineurin inhibitors may reduce their nephrotoxicity. Most centers administer a cytolytic agent in the immediate postoperative period and delay the initiation of calcineurin inhibitor therapy.

Outpatient Follow-up

Before discharge, patients should receive comprehensive education about their medications, diet, exercise, and infection recognition. Close follow-up by an experienced transplant team is the cornerstone for successful long-term survival after cardiac transplantation. This comprehensive team facilitates the early detection of rejection, opportunistic infections, patient noncompliance, and adverse sequelae of immunosuppression. Clinic visits routinely are scheduled concurrently with endomyocardial biopsies and include physical examination, a variety of laboratory studies, chest roentgenogram, and electrocardiogram.

ACUTE REJECTION

Cardiac allograft rejection is the normal host response to cells recognized as nonself. The vast majority of cases are mediated by the cellular limb of the immune response through an elegant cascade of events involving macrophages, cytokines, and T lymphocytes. Humoral-mediated rejection (also called *vascular rejection*) is less common. The highest risk factors are allografts from younger and female donors (irrespective of recipient sex). Although about 85% of episodes can be reversed with corticosteroid therapy alone,[77] rejection is still a major cause of morbidity in cardiac transplant recipients.[5,78]

Diagnosis of Acute Rejection

In the precyclosporine era, the classic clinical manifestations of acute rejection included low-grade fever, malaise, leukocytosis, pericardial friction rub, supraventricular arrhythmias, decreased voltage on ECG, low cardiac output, reduced exercise tolerance, and signs of congestive heart failure. In the cyclosporine era, however, most episodes of rejection characteristically are insidious, and patients can remain asymptomatic even with late stages of rejection. Thus routine surveillance studies for early detection are crucial to minimize cumulative injury to the allograft. Right ventricular endomyocardial biopsy remains the gold standard for the diagnosis of acute rejection. The most frequently used technique for orthotopic allografts is a percutaneous approach through the right internal jugular vein. Interventricular septal specimens are fixed in formalin for permanent section, although frozen sections are performed occasionally if urgent diagnosis is necessary. Hemodynamic parameters may also be obtained with a pulmonary artery catheter. Complications are infrequent (1 to 2%) but include venous hematoma, carotid puncture, pneumothorax, arrhythmias, heart block, and right ventricular perforation and injury to the tricuspid valve. The exact schedule for endomyocardial biopsies varies among institutions but usually reflects the associated risk of increased rejection during the first 6 months after transplantation. Biopsies are performed initially every 7 to 10 days in the early postoperative period and eventually tapered to 3- to 6-month intervals after the first year. Suspicion of rejection warrants additional biopsies.

TABLE 64-6 Differences in Therapeutic Agent Effects in Heart Transplant Recipients Compared with Nontransplant Patients

Arrhythmia Therapy	Differences in Posttransplantation
DRUGS	
AV nodal agents	
Digoxin	No effect on heart rate
β-Adrenergic antagonists	Exacerbation of exercise intolerance
Calcium channel antagonists	Accentuated slowing of SA and AV nodes; may alter cyclosporine levels
Adenosine	Accentuated slowing of SA and AV nodes
Adrenergic agonists	
Norepinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Epinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Dopamine	Unchanged peripheral effect, less inotropic effect
Dobutamine	Unchanged
Ephedrine	Unchanged peripheral effect, less inotropic effect
Neo-synephrine	Unchanged peripheral effect, no reflex bradycardia
Isoproterenol	Unchanged
Antiarrhythmic agents	
Class Ia (quinidine, disopyramide, procainamide)	No cardiac vagolytic effect
Class Ib (lidocaine, mexiletine)	None reported
Class Ic (flecainide, encainide, moricizine, propafenone)	None reported
Class III (amiodarone, sotalol, ibutilide, dofetilide)	Possible exaggerated or atypical response
Anticoagulants	
Heparin	None reported
Warfarin	None reported
Miscellaneous	
Atropine	No effect on heart rate
Methylxanthines (theophylline, aminophylline)	Possibly more chronotropic effect
Cardioversion	None reported
Radiofrequency catheter ablation	Possible differences in pathway or chamber anatomy
Electrical devices	
Pacemaker	None reported
Intracardiac defibrillator	None reported

AV = atrioventricular; SA = sinoatrial.

Evaluation of sample adequacy for the ISHLT grading scheme requires a minimum of four good endomyocardial tissue fragments, with less than 50% of each fragment being fibrous tissue, thrombus, or other noninterpretable tissues (eg, crush artifact or poorly processed fragments).[79] The pattern and density of lymphocyte infiltration, in addition to the presence or absence of myocyte necrosis in the endomyocardial biopsy, determine the severity grade of cellular rejection.[80] Further elaboration of the pathologic features and identification of antibody-mediated rejection were addressed more recently.[81] In 2004, the ISHLT Pathology Council proposed simplification of the 1990 diagnostic categories for cellular rejection to mild,

TABLE 64-7 ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection, 2004*

Grade 0 R†	No rejection
Grade 1 R (Mild)	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage
Grade 2 R	(Moderate) Two or more foci of infiltrate with associated myocyte damage
Grade 3 R	(Severe) Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage ± vasculitis

*The presence or absence of acute antibody-mediated rejection (AMR) may be recorded as AMR 0 or AMR 1, as required (see Table 64-8).
†Where R denotes revised grade to avoid confusion with 1990 scheme.

moderate, and severe and identification of the histologic characteristics of antibody-mediated rejection.[82] The new grading scale was developed to better address the challenges and inconsistencies in use of the old grading system. Tables 64-7 and 64-8 show the new 2004 ISHLT grading scale.[82]

Noninvasive studies for the diagnosis of acute rejection have been unreliable. Electrocardiographic voltage summation and E-rosette assay techniques were useful adjuncts in the early cardiac transplant experience[83]; however, they currently are of no value in patients receiving cyclosporine.[84] Attempts with signal-averaged electrocardiography,[85] echocardiography,[86] or in combination,[87] magnetic resonance imaging,[88] technetium ventriculography,[89] and a variety of immunologic markers[90] have not provided sufficient sensitivity and specificity to warrant widespread use.[91] Peripheral blood gene expression profiling is an exciting new field that may provide the answer to noninvasive discrimination of rejection in cardiac allograft recipients.[92]

TABLE 64-8 ISHLT Recommendations for Acute Antibody-Mediated Rejection (AMR), 2004

AMR 0	Negative for acute antibody-mediated rejection No histologic or immunopathologic features of AMR
AMR 1	Positive for AMR Histologic features of AMR Positive immunofluorescence or immunoperoxidase staining for AMR (positive CD68, C4D)

Treatment of Acute Rejection

Corticosteroids are the cornerstone for antirejection therapy. The treatment of choice for any rejection episode occurring during the first 1 to 3 postoperative months or for an episode considered to be severe is a short course (3 days) of intravenous methylprednisolone (1000 mg/d). Virtually all other episodes are treated initially with increased doses of oral prednisone (100 mg/d) followed by a taper to baseline over several weeks.[93] Although not yet universally accepted, many centers have reduced the doses of these corticosteroids successfully with reversal rates of rejection similar to traditional dosing.

Repeat endomyocardial biopsy should be performed 7 to 10 days after the cessation of antirejection therapy to assess adequacy of treatment. If the biopsy does not show significant improvement, a second trial of pulse-steroid therapy is recommended; if rejection has progressed (or if the patient becomes hemodynamically unstable), rescue therapy is indicated.

Substitution of tacrolimus for cyclosporine may obviate the need for admission in patients with steroid-refractory persistent rejection.[94] Alternatively, sirolimus may be substituted for mycophenolate or azathioprine.[95] The use of OKT3, antithymocyte globulin, and thymoglobulin generally is reserved for severe rejection with hemodynamic compromise.[96] Methotrexate has been particularly successful in eradicating chronic low-grade rejection. Total lymphoid irradiation and photopheresis also have demonstrated success in some cases of refractory rejection.[97] Cardiac retransplantation is the ultimate therapeutic option for patients who do not respond to the aforementioned interventions. However, the results of retransplantation for rejection are dismal, and in most centers, it is no longer performed for this indication.

Asymptomatic mild rejection (grade 1) usually is not treated but is monitored with repeat endomyocardial biopsies because only 20 to 40% of mild cases progress to moderate rejection.[98] On the other hand, the presence of myocyte necrosis (grades 3b and 4) represents a definite threat to allograft viability and is a universally accepted indication for therapy. Management of moderate rejection (grade 3a) is controversial and requires consideration of multiple variables.[99] Notably, Stoica and colleagues recently demonstrated that acute moderate to severe cellular rejection has a cumulative impact on cardiac allograft vasculopathy (CAV) onset.[100] Regardless of the biopsy results, allograft dysfunction is an indication for hospitalization, antirejection therapy, and if severe, invasive hemodynamic monitoring and inotropic support.

Acute Vascular Rejection

Vascular rejection is mediated by the humoral limb of the immune response. Unlike cellular rejection, hemodynamic instability requiring inotropic support is common in patients with vascular rejection.[101] Diagnosis requires evidence of endothelial cell swelling on light microscopy and immunoglobulin-complement deposition by immunofluorescence techniques.[102] Aggressive treatment of patients with allograft dysfunction consists of plasmapheresis, high-dose corticosteroids, heparin, IgG, and cyclophosphamide.[103] Despite these interventions, symptomatic acute vascular rejection is associated with a high mortality.[101,103] Repeated episodes of acute vascular rejection or chronic low-grade vascular rejection are believed to play a dominant role in the development of allograft coronary artery disease.[104]

INFECTIOUS COMPLICATIONS IN HEART TRANSPLANTATION

Organisms and Timing of Infections

Infection is a leading cause of morbidity and mortality in the cardiac transplant population.[5,105] The introduction of new chemoprophylactic regimens with the resultant prevention of serious disease caused by CMV has resulted in significant reductions in the number of infectious episodes and a delay in presentation after heart transplantation.[105] Patients are at greatest risk of life-threatening infections in the first 3 months after transplantation and following increases in immunosuppression for acute rejection episodes or retransplantation.[105] Table 64-9 illustrates the most common organisms causing infections in the cardiac recipient.

Preventive Measures and Prophylaxis Against Infection

Transmission of infections such as CMV, *Toxoplasma gondii,* HBV, HCV, and HIV after organ transplantation is well documented.[106] Prevention of postoperative infection begins with pretransplant screening of the donor and recipient.[107] Current suggested guidelines are outlined in Table 64-10. Perioperative and postoperative antimicrobial prophylaxes, as well as immunizations, are also outlined.

Specific Organisms Causing Infection Following Heart Transplantation

Bacteria

Gram-negative bacilli are the most common cause of bacterial infectious complications following heart transplantation. Furthermore, *Escherichia coli* and *Pseudomonas aeruginosa* are the most prevalent organisms and usually cause urinary tract infections and pneumonias, respectively.[105] *Staphylococcus* species have been shown to cause the majority of gram-positive–related infections.

Viruses

CMV remains the single most important cause of infectious disease morbidity and mortality in the heart transplant

TABLE 64-9 Infections in Cardiac Transplant Recipients

EARLY INFECTIONS (FIRST MONTH)

I. Pneumonia: Gram-negative bacilli (GNB)

II. Mediastinitis and sternal wound infections:
- *Staphylococcus epidermidis*
- *Staphylococcus aureus*
- GNB

III. Catheter-associated bacteremia:
- *S. epidermidis*
- *S. aureus*
- GNB
- *Candida albicans*

IV. Urinary tract infections:
- GNB
- *Enterococcus*
- *C. albicans*

V. Mucocutaneous infections:
- Herpes simplex virus (HSV)
- *Candida* spp.

LATE INFECTIONS (AFTER FIRST MONTH)

I. Pneumonia:
- A. Diffuse interstitial pneumonia:
  - *Pneumocystis carinii*
  - Cytomegalovirus (CMV)*
  - HSV
- B. Lobar or nodular (cavitary) pneumonia:
  - *Cryptococcus*
  - *Aspergillus*
  - Bacteria (community-acquired, nosocomial)
  - *Nocardia asteroides*
  - *Mycobacterium* spp.

II. Central nervous system infections:
- A. Abscess or meningoencephalitis
  - *Aspergillus*
  - *Toxoplasma gondii**
  - Meningitis
  - *Cryptococcus*
  - *Listeria*

III. Gastrointestinal (GI) infections:
- A. Esophagitis
  - *C. albicans*
  - HSV
- B. Diarrhea or lower GI hemorrhage
  - *Aspergillus*
  - *Candida* spp.

IV. Cutaneous infections:
- A. Vesicular lesions
  - HSV
  - Varicella-zoster
- B. Nodular or ulcerating lesions
  - *Nocardia*
  - *Candida* (disseminated)
  - Atypical *Mycobacterium* spp.
  - *Cryptococcus*

*Known donor-transmitted pathogens.

TABLE 64-10 Guidelines for Routine Screening and Prophylaxis of Infections in Heart Transplantation

I. Preoperative screening
- A. Donor
  1. Clinical assessment
  2. Serologic studies (HIV, HBV, HCV, CMV, *Toxoplasma gondii*)
- B. Recipient
  1. History and physical examination
  2. Serologic studies (HIV, HBV, HCV, CMV, *T. gondii*, herpes simplex virus, varicella-zoster virus, Epstein-Barr virus, endemic fungi)
  3. PPD (tuberculin) skin test
  4. Urine culture
  5. Stool for ova and parasites (*Strongyloides stercoralis*; center-specific)

II. Antimicrobial prophylaxis
- A. Perioperative
  1. First-generation cephalosporin (or vancomycin)
- B. Postoperative
  1. Trimethoprim-sulfamethoxazole or pentamidine (for *Pneumocystis carinii*)
  2. Nystatin or clotrimazole (for *Candida* spp.)
  3. Ganciclovir followed by acyclovir once discharged (for all patients except CMV-negative recipient and donor)
  4. Acyclovir (for herpes simplex and zoster; routine use is controversial)
  5. Standard endocarditis prophylaxis
- C. Postoperative immunizations
  1. Pneumococcal (booster every 5–7 years)
  2. Influenza A (yearly; center-specific)
  3. Exposure to measles, varicella, tetanus, or hepatitis B by a nonimmunized recipient often warrants specific immunoglobulin therapy (eg, varicella-zoster immune globulin, VZIG)

patient.[108] CMV not only results in infectious disease syndromes but also is indirectly associated with acute rejection episodes, acceleration of CAV, and posttransplant lymphoproliferative disease.[108] Furthermore, the reduction in leukocytes associated with CMV infection predisposes the patient to superinfection with other pathogens (eg, *Pneumocystis carinii* pneumonia). Infections develop secondary to donor transmission, reactivation of latent recipient infection, or reinfection of a CMV-seropositive patient with a different viral strain.[108] Variable regimens for CMV prophylaxis with ganciclovir are being used by different centers.[109] The standard of care for symptomatic CMV disease is 2 to 3 weeks of intravenous ganciclovir (at a dose of 5 mg/kg twice daily, with dosage adjustment for renal dysfunction). For tissue-invasive disease, particularly pneumonia, many centers add anti-CMV hyperimmune globulin to this regimen.[110] Preemptive treatment strategies employ periodic surveillance using techniques such as plasma polymerase chain reaction (PCR) and CMV antigenemia, a rapid diagnostic test that detects viral protein in peripheral blood leukocytes at a significant interval before clinical disease.[111] Valganciclovir (Valcyte) is an oral prodrug of ganciclovir with a 10-fold greater bioavailability than oral ganciclovir. It has been shown to be effective for prophylaxis and preemptive treatment of CMV and allows for more convenient use.[112,113]

Although not a cure for herpes simplex or zoster viruses, acyclovir can reduce recurrences and the discomfort associated with the vesicular lesions. Epstein-Barr virus infection may be associated with posttransplant lymphoproliferative disorders in immunocompromised hosts.[114]

Fungi

Mucocutaneous candidiasis is common and usually can be treated with topical antifungal agents (nystatin or clotrimazole). Fluconazole is indicated for candidiasis refractory to this therapy or involving the esophagus. It is also useful for therapy of candidemia. One important caveat in the treatment of *Candida* infection with fluconazole is that certain species such as *C. krusei* and *C. glabrata* have a low susceptibility in vitro.[105]

Among patients undergoing heart transplantation, *Aspergillus* is the opportunistic pathogen with the highest attributable mortality.[115] It causes a serious pneumonia in 5 to 10% of recipients during the first 3 months after transplantation. Dissemination of *Aspergillus* to the central nervous system is almost uniformly fatal.[116] Because aspergillosis is highly lethal in the immunocompromised host, even in the face of therapy, workup must be prompt and aggressive, and therapy may need to be initiated on suspicion of the diagnosis without definitive proof. Amphotericin B, itraconazole, and recently voriconazole are acceptable therapy.

Protozoa

In heart transplant recipients, the reported incidence of *P. carinii* pneumonia ranges from less than 1 to 10%.[117] Because the

organism resides in the alveoli, bronchoalveolar lavage usually is necessary for diagnosis.[118] In the case of lung biopsy specimens, histopathologic examination is also helpful. *P. carinii* pneumonia is treated with high-dose trimethoprim-sulfamethoxazole or intravenous pentamidine.[105]

Toxoplasmosis following heart transplantation usually is the result of reactivation of latent disease in the seropositive donor heart because of the predilection of the parasite to invade muscle tissue.[119] *T. gondii* infection may be acquired from undercooked meat and cat feces. The diagnosis is made with certainty only by histologic demonstration of trophozoites with surrounding inflammation in biopsy tissue; PCR also has been used.[120] *T. gondii* usually causes central nervous system infections and is treated with pyrimethamine with sulfadiazine or clindamycin.[105]

CHRONIC COMPLICATIONS FOLLOWING HEART TRANSPLANTATION

Cardiac Allograft Vasculopathy

CAV is a unique, rapidly progressive form of atherosclerosis in transplant recipients that is characterized in its early stages by intimal proliferation and in its later stages by luminal stenosis of epicardial branches, occlusion of smaller arteries, and myocardial infarction. Long-term survival of cardiac transplant recipients is limited primarily by the development of CAV, the leading cause of death after the first posttransplant year.[5] Angiographically detectable CAV is reported in approximately 40 to 50% of patients by 5 years after transplantation.[121] Although CAV resembles atherosclerosis, there are some important differences that are illustrated in Fig. 64-11.[122] In particular, intimal proliferation is concentric rather than eccentric, and the lesions are diffuse, involving both distal and proximal portions of the coronary tree. Calcification is uncommon, and the elastic lamina remains intact.

The detailed pathogenesis of CAV is unknown, but there are strong indications that immunologic mechanisms that are regulated by nonimmunologic risk factors are the major causes of this phenomenon.[123] The immunologic mechanisms include acute rejection and anti-HLA antibodies, and some of the implicated risk factors relating to the transplant itself or the recipient are donor age, hypertension, hyperlipidemia, and preexisting diabetes. The side effects often associated with immunosuppression with calcineurin inhibitors or corticosteroids, eg, CMV infection, nephrotoxicity, and new-onset diabetes, after transplantation also play significant roles.[124–126]

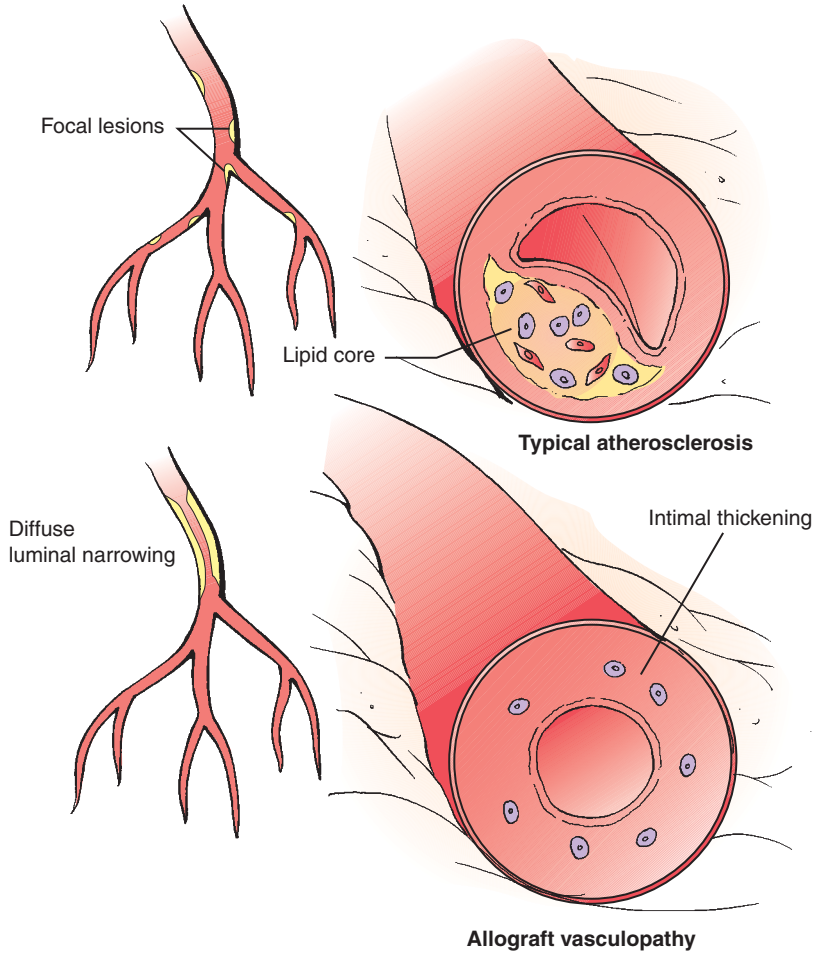

FIGURE 64-11 Schematic illustration of typical atherosclerosis and cardiac allograft vasculopathy. (*Source: Reprinted with permission from Avery RK: Cardiac-allograft vasculopathy. NEJM 2003; 349:829.*)

It is generally believed that the initiating event of CAV is subclinical endothelial cell injury in the coronary artery of the allograft, which leads to a cascade of immunologic processes involving cytokines, inflammatory mediators, complement activation, and leukocyte adhesion molecules. These changes produce inflammation and, ultimately, thrombosis, smooth muscle cell proliferation, and vessel constriction. The initial endothelial injury may be the result of ischemia-reperfusion damage or the host-versus-graft immune response.[125,126]

CAV may begin within several weeks posttransplantation and progress insidiously at an accelerated rate to complete obliteration of the coronary lumen with allograft failure secondary to ischemia. The clinical diagnosis of CAV is difficult and complicated by allograft denervation, resulting in silent myocardial ischemia. Ventricular arrhythmias, congestive heart failure, and sudden death are commonly the initial presentation of significant CAV.[127] An annual coronary angiogram usually is performed for CAV surveillance. Intravascular ultrasound (IVUS) is better equipped to provide important quantitative information regarding vessel wall morphology and the degree of intimal thickening.[128]

Because angiography and IVUS are invasive tests, they pose increased risks for patients. Noninvasive tests (eg, thallium scintigraphy and dobutamine stress echocardiography), however, have not been sensitive or specific enough to be a reliable screen for CAV.[129] Other possible modalities include pulse-wave tissue Doppler imaging, electron beam computed tomography (CT), fast CT scanning, and MRI. These modalities may replace invasive procedures in the future.

Currently, the only definitive treatment for advanced CAV is retransplantation, which has risks for the patient and poses problems associated with scarcity of donor organs.[127] Owing to the diffuse and distal nature of the disease, procedures such as stenting and angioplasty are inherently less effective than in nontransplant patients and result in a higher need for repeated procedures.[130] Therefore, prophylactic management is of paramount importance. Before transplantation, the focus should be on preventing endothelial injury at brain death, reducing cold ischemia time and improving myocardial preservation during storage and transportation.[127] Postransplantation care focuses on empiric risk factor modification (eg, dietary and pharmacologic reduction in serum cholesterol, cessation of smoking, hypertension control, etc). Several studies have demonstrated a decrease in CAV in patients treated with a calcium channel blocker and angiotensin-converting enzyme (ACE) and HMG-CoA reductase inhibitors.[131,132]

Newer immunosuppressive drugs, specifically the proliferation signal inhibitors (eg, everolimus and sirolimus), may be useful in reducing the incidence and severity of CAV and slowing disease progression.[133–137]

Renal Dysfunction

The 2009 ISHLT registry reported a significant improvement in long-term renal dysfunction in the most recent cohort of heart transplant recipients (2001 to 2007) as compared to the previous cohort (1994 to 2000). Whereas only 60% of heart transplant recipients from 1994 to 2000 were free of severe renal dysfunction (defined as a creatinine concentration of more than 2.5 mg/dL and the need for dialysis or renal transplantation) by Kaplan-Meier estimates at 10 years, recipients transplanted from 2001 to 2007 had an 11% absolute decrease in severe renal dysfunction at 5 years compared with the previous cohort.[5] Notably, the risk of death after heart transplantation is markedly increased by the development of end-stage renal failure.[138]

Cyclosporine nephrotoxicity after heart transplantation is well recognized and well documented. The improved bioavailability of cyclosporine microemulsion (Neoral) compared with the conventional formulation has led to investigations into monitoring of cyclosporine levels 2 hours after dosing (C2).[139] Neoral C2 monitoring may be a better indicator of immunosuppression efficacy than trough levels and a better measure to avoid nephrotoxicity and other cyclosporine-associated side effects.[140] Lowering cyclosporine dose may be helpful in slowing the progression of renal disease, especially with concomitant use of newer immunosuppressive regimens such as mycophenolate mofetil and sirolimus (rapamycin).[141,142] Calcineurin-free immunosuppression is also being implemented by some centers.[143]

Hypertension

Moderate to severe systemic hypertension afflicts 50 to 90% of cardiac transplant recipients.[5] Peripheral vasoconstriction in combination with fluid retention seems to play the greatest role. Although the exact mechanisms are unclear, it likely involves a combination of cyclosporine-induced tubular nephrotoxicity and vasoconstriction of renal and systemic arterioles mediated by sympathetic neural activation.[144] Tacrolimus is associated with a lower incidence of hypertension than is cyclosporine.[145] No single class of antihypertensive agents has proven uniformly effective, and treatment of this refractory hypertension remains empirical and difficult. In a prospective, randomized trial, titrated monotherapy with either diltiazem or lisinopril controlled the condition in fewer than 50% of patients.[146] Diuretics should be used cautiously because the balance between edema/hypertension and volume depletion/hypotension can be tenuous in a subset of these patients. Overzealous diuresis can potentiate the apparent nephrotoxicity of cyclosporine by further reducing renal blood flow and altering cyclosporine pharmacokinetics.[147] Beta-blockers also should be used with caution because they may further blunt the heart rate response to exercise.

Malignancy

Chronic immunosuppression is associated with an increased incidence of malignancy ranging from about 4 to 18%, which is 100-fold greater than in the general population.[148] Improved graft and patient survival, owing to pharmacologic advances in the area of immunosuppressive therapy, has led to an increase in the incidence of neoplasms.[148] Malignant neoplasias have become, along with graft vasculopathy, a significant limiting factor for the long-term survival of heart transplant recipients.[5] Lymphoproliferative disorders and carcinoma of the skin are the most common malignancies found in heart transplant recipients.[148] Loss of T-lymphocyte control over Epstein-Barr virus (EBV)–stimulated B-lymphocyte proliferation appears to be the primary mechanism for the development of lymphoproliferative

disorders.[149] The risk of these malignancies is increased further following monoclonal and polyclonal antibody therapy.[150,151] Treatment options in transplantation include a reduction in immunosuppression and initiation of high-dose acyclovir (to attenuate EBV replication), in addition to conventional therapies for carcinoma (eg, chemotherapy, radiation therapy, and surgical resection), which are associated with very high risk and limited success.

Other Chronic Complications

Hyperlipidemia eventually develops in the majority of recipients and is managed with dietary restrictions, exercise, and lipid-lowering agents.[152] Other complications that commonly contribute to posttransplant morbidity include osteoporosis, obesity, cachexia, and gastrointestinal complications, notably cholelithiasis.[153,154]

CARDIAC RETRANSPLANTATION

Retransplantation accounts for fewer than 3% of the cardiac transplants currently performed.[5] Primary indications for retransplantation are early graft failure, allograft coronary artery disease, and refractory acute rejection.[155,156] The operative technique and immunosuppressive regimen are similar to those employed for the initial transplantation. Despite reduced mortality in the cyclosporine era, actuarial survival remains markedly reduced. Analysis of the ISHLT registry for retransplantations performed between 1987 and 1998 reveals survival to be 65, 59, and 55% for 1, 2, and 3 years, respectively. Intertransplant interval of 6 months or less was associated with a dismal 1-year survival of 50% in this analysis. Conversely, when the interval between primary and retransplantation was more than 2 years, 1-year survival after retransplantation approached that of primary transplantation.[156] The 2009 ISHLT registry report indicates that the 5-year survival of retransplanted patients has increased by 15 to 17% with each successive decade (1982 to 1991, 1992 to 2001, 2002 to 2007). As well, in the most recent cohort (2002 to 2008), patients undergoing retransplantation at greater than 5 years from initial transplant had the same 1-year survival rate as primary transplants from the same era (86%).[5] Advanced donor age also was a predictor of increased mortality among these recipients.[156] These data suggest that although cardiac retransplantation is associated with significant morbidity and mortality, careful selection of patients, especially those who are younger and with longer intertransplant intervals, may be associated with more favorable outcome. Nonetheless, the disparity between the demand and supply for donor hearts continues to make cardiac retransplantation an ethical dilemma.[157]

RESULTS OF HEART TRANSPLANTATION

Although no direct comparative trials have been or are likely to be performed, survival following heart transplantation remains favorable if compared with both the medical and device arms of the REMATCH trial.[2,6] The superiority of heart transplantation is more clearly evident in medium- and high-risk patients with end-stage heart failure.[158] The overall results actually are improving despite increasing risk profiles.[5,67] The reported operative (ie, 30-day) mortality for cardiac transplantation ranges from 5 to 10%.[159] Overall 1-year survival is up to 86%.[5,67] After the steep fall in survival during the first 6 months, survival decreases at a linear rate (approximately 3.5% per year), even well beyond 15 years posttransplantation.[5] Graft failure (primary and nonspecific), multisystem organ failure, and infection account for most deaths within the first 30 days. Infection, graft failure, and acute rejection are the leading causes of death during the first year; thereafter, cardiac allograft vasculopathy and malignancy are the major causes of death.[5,67] Studies examining the health-related quality of life (HRQOL) in patients after cardiac transplantation demonstrate marked improvement, particularly in the absence of complications, and approaches the general population by 10 years after transplantation.[160]

Insights from the United Network for Organ Sharing Database

The recent literature on heart transplantation has seen a notable increase in clinical studies analyzing the multi-institutional UNOS open transplant cohort. This database is publically accessible and includes all heart transplants performed in the United States from October 1987 onward. The database also includes patients on the waitlist, donor information, and outcomes. As with all large administrative datasets, it is limited by potential errors in coding as well as incompletely populated variables. However, questions that had previously only been addressed using single or limited multi-institutional data can now be investigated using this cohort of over 20,000 patients.

Among those issues addressed have been the impact of various recipient factors, on short- and long-term survival after heart transplantation. Russo and coworkers reported that uncomplicated diabetes mellitus should not preclude listing for heart transplantation due to equivalent survival with nondiabetics.[161] However, severe diabetics did have poorer survival and should be considered for destination LVAD therapy or high-risk listing. Zaidi and coworkers reported better short and intermediate survival after heart transplantation in patients with sarcoidosis compared to recipients with other diagnoses, and concluded that a diagnosis of sarcoidosis should not preclude heart transplantation.[162] Kpodonu and coworkers demonstrated that 1-year survival after heart transplant for amyloid cardiomyopathy was significantly decreased in female recipients, whereas it was comparable with other diagnoses for male recipients.[163] Nwakanma and coworkers confirmed increasing risk of rejection in the year after transplantation and decreased survival with increasing panel reactive antibody levels.[164] Weiss and coworkers reported that advanced age (>60 years) was associated with acceptable long-term outcomes (>70% 5-year survival).[165] Although elderly recipients did have slightly higher rates of infection and acute renal failure, as well as a 2-day longer hospital length of stay, the survival benefit of transplantation in elderly CHF patients was compelling. Another study by Weiss and coworkers identified a potential provider bias in the listing of obese patients as potential heart transplant recipients.[166] Specifically, that obese individuals wait longer and have a lower likelihood

of receiving a donor heart after listing, despite similar short-term survival.

Insights into the impact of operative technique and the use of LVADs on posttransplant survival have also been gained from the UNOS database. As noted, Weiss and coworkers reported equivalent survival after heart transplantation using biatrial versus bicaval anastomotic techniques.[63] However, they did identify that the bicaval technique was associated with a shorted hospital length of stay and decreased rates of permanent pacemaker placement. Pal and coworkers investigated status 1 patients bridged to transplant using LVADs and IV inotropes, and found that patients bridged to transplant using LVADs were, by in large, those who failed bridging with IV inotropes.[167] In contrast with International Society of Heart and Lung Transplantation data, no increase in posttransplant morbidity or mortality was found in LVAD-bridged patients compared with nonbridged status 1 patients. Shuhaiber and coworkers compared patients bridged with transplant with Novacor versus HeartMate LVADs and found no difference in 1-year survival, rates of rejection, or rates of infection.[168] However, patients bridged with Novacor LVADs demonstrated lower 5-year survival posttransplant.

Weiss and coworkers also investigated the effect of transplant center volume on long-term outcomes after heart transplantation, and reported that annual center volume is an independent predictor of short-term mortality in OHT.[169] Although the current Centers for Medicare and Medicaid Services mandate is that heart transplant centers perform 10 per year to qualify for funding, this study found that a higher cutoff resulted in better outcomes; centers performing greater than 40 per year have a 30-day mortality less than 5%.

THE FUTURE

As a result of a series of unprecedented advances over the past decade, the clinical outcome of heart transplantation has improved dramatically. Although cardiac replacement remains the best therapeutic option for patients with end-stage heart failure, a number of challenges await future investigators to further improve survival and reduce transplant-related morbidity. A major factor limiting long-term survival of recipients is allograft rejection and the untoward effects of immunosuppression. Development of reliable, noninvasive diagnostic studies will permit more frequent evaluations for the early detection of rejection and for monitoring the effectiveness of therapy. Ultimately, this will allow more precise control of immunosuppression and, in turn, a reduction in cumulative allograft injury and infectious complications. Molecular tests and gene expression profiling could be available soon and may provide the best noninvasive option.[91]

Immunosuppressive strategists will continue their efforts to establish specific unresponsiveness to antigens of transplanted organs in hopes of preserving much of the recipient's immune responses. Proliferative signal inhibitors such as sirolimus and everolimus are showing promising results. Alternatively, donor organs may be made less susceptible to immunologic attack through genetic engineering techniques by altering the expression of cell membrane–bound molecules. This approach is being used currently in the pursuit of clinically applicable xenotransplant sources. Xenografts eventually may be an additional source of donor organs, although extended xenograft survival remains an elusive goal. Complicating this alternative are unresolved ethical issues concerning transgenic experimentation and the potential for transmission of veterinary pathogens to an immunosuppressed recipient.

Future improvements in organ preservation permitting extension of the storage interval will have several benefits. In addition to a modest increase in the donor pool, extension of storage times would permit better allocation of organs with respect to donor-recipient immunologic matching. Assist devices are being used currently both as a bridge to transplantation and as a destination therapy. It appears that as the technology of assist devices continues to improve, it is only a matter of time before they become a long-term solution for patients with severe congestive heart failure.

The concept of regenerating the failing heart using cardiomyocytes of different sources, autologous smooth muscle cells, and dermal fibroblasts is in the experimental stage. Lineage-negative bone marrow cells or bone marrow–derived endothelial precursor cells are also being studied to induce new blood vessel formation after experimental myocardial infarction.[170] Cardiac transplantation remains a remarkable achievement of the twentieth century and has revolutionized therapy for end-stage heart failure. Further investigations are needed to overcome the current obstacles to long-term graft function and patient survival.

CHAPTER 65

Lung Transplantation and Heart-Lung Transplantation

Ahmad Y. Sheikh
David L. Joyce
Hari R. Mallidi
Robert C. Robbins

INTRODUCTION

Human lung transplantation, performed as a single lung, double lung, or heart-lung bloc, has emerged as a life-saving procedure for patients with end-stage pulmonary disease. With improvement of operative techniques, organ preservation, and immunosuppressive regimens, combined heart-lung and isolated lung transplantation have become common treatments for patients with a variety of end-stage disease entities. To date, 3466 combined heart-lung transplants and 29,732 lung transplants have been reported worldwide.[1] Although the number of heart-lung transplants performed annually has declined in recent years, the number of single lung transplantation procedures remains stable, accompanied by a steady increase in bilateral lung transplant procedures (Fig. 65-1). Clinical progress in thoracic organ transplantation has been considerable, yet significant barriers that limit the scope of these procedures still remain. These include donor organ shortage, limited preservation techniques, graft rejection, and infectious complications. This chapter summarizes the state of the art in combined heart-lung and isolated lung transplantation.

LUNG TRANSPLANTATION

History of Lung Transplantation

In 1949, Henry Metras described many of the important technical concepts for lung transplantation, including preservation of the left atrial cuff for the pulmonary venous anastomoses and reimplantation of an aortic patch containing the origin of the bronchial arteries to prevent bronchial dehiscence.[2] Airway dehiscence was a major obstacle in experimental lung transplantation, and he proposed that preservation of the bronchial arterial supply was critical to airway healing. Unfortunately, this technique was technically cumbersome and never gained widespread popularity. In the 1960s, Blumenstock and Khan advocated transection of the transplant bronchus close to the lung parenchyma to prevent ischemic bronchial necrosis.[3] Additional surgical modifications were developed to prevent bronchial anastomotic complications, including telescoping of the bronchial anastomosis, described by Veith in 1970,[4] and coverage of the anastomosis with an omental pedicle flap, described by the Toronto group in 1982.[5] Corticosteroids were found to be another contributor to poor bronchial healing,[6] a problem ameliorated by the introduction of cyclosporine immunosuppression. Thus, by the 1970s, the stage was set for successful lung transplantation in the human.

The first human lung transplant was described in 1963 by Hardy and colleagues at the University of Mississippi.[7] The patient, a 58-year-old man with lung cancer, survived 18 days postoperatively. Over the next two decades, nearly 40 lung transplants were performed without long-term success. In 1986, the Toronto Lung Transplant Group reported the first successful series of single lung transplants with long-term survival.[8] Improved immunosuppression, along with careful recipient and donor selection, were pivotal to their success. For patients with bilateral lung disease, en-bloc double lung replacement was introduced by Patterson in 1988 as an alternative to heart-lung

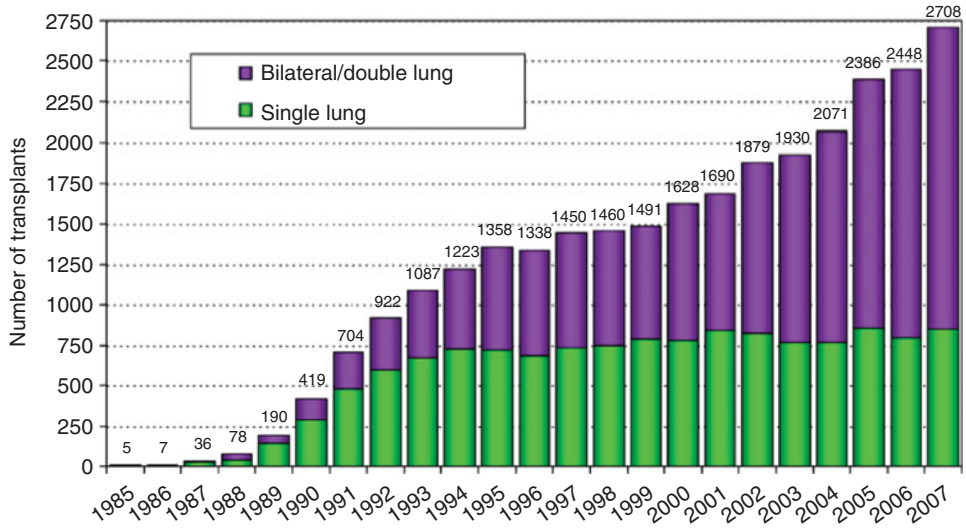

FIGURE 65-1 UNOS data representing the number of lung transplant procedures reported by year and procedure type, collected from data reported to the International Society of Heart and Lung Transplantation Registry. This figure may underestimate the total number of procedures worldwide. (*From Christie JD, et al: The Registry of the International Society for Heart and Lung Transplantation: Twenty-Sixth Official Adult Lung and Heart-Lung Transplantation Report—2009. J Heart Lung Transplant 2009; 28[10]:1031-1049.*)

transplantation with a domino procedure in which the explanted heart was offered to a second recipient with end-stage heart disease.[9] This technique was later replaced by sequential bilateral lung transplantation, described by Pasque and colleagues in 1990.[10] More recent operative innovations include living lobar transplantation, performed for the first time by Vaughn Starnes at Stanford in 1992.[11]

Lung transplantation has seen a steady growth over the past decade, with 2708 procedures reported to the International Society for Heart and Lung Transplantation (ISHLT) registry in 2007. Currently there are 153 centers reporting lung transplant data, with more than half of these performing more than 10 transplants per year. Although the number of single lung transplants performed has been relatively stable since the mid-1990s, bilateral lung transplant procedures have shown a consistent growth in volume.[1]

Indications for Lung Transplantation

General Guidelines

Organ allocation for lung transplantation underwent a major change in 2005 that has significantly affected the process of recipient selection. Historically, lung allocation was determined strictly by the amount of time a patient spent on the waiting list (matching for size and blood group). Consequently, the limited supply of donor organs resulted in an increasing number of patients on the waiting list with progressively longer wait times (Fig. 65-2).[12] To address these shortcomings, the organ allocation system was revised in 2005 to prioritize medical urgency and expected outcome after transplantation. Under this system, prioritization is based on a lung allocation score (LAS) that is calculated based on the following clinical criteria: age, height, weight, lung diagnosis code, functional status, diabetes, assisted ventilation, supplemental O_2 requirement, percent predicted FVC, pulmonary artery systemic pressure, mean pulmonary artery pressure, pulmonary capillary wedge pressure, current PCO_2, highest PCO_2, lowest PCO_2, change in PCO_2, 6-minute walk distance, and serum creatinine. These values can be entered into an online calculator to derive the LAS (http://optn.transplant.hrsa.gov/resources/professionalResources.asp?index=9). Based on these criteria, the waitlist urgency measure (defined as the expected number of days during the next year on the waiting list without a transplant) is subtracted from the posttransplant survival measure (defined as the expected number of days lived during the first year after transplantation) to determine the transplant benefit. This raw allocation score is then normalized to a scale of 0 to 100 to calculate the LAS. In this scoring system, posttransplant survival is limited to 1 year because the predictive variables are only relevant in the early postoperative period.[13]

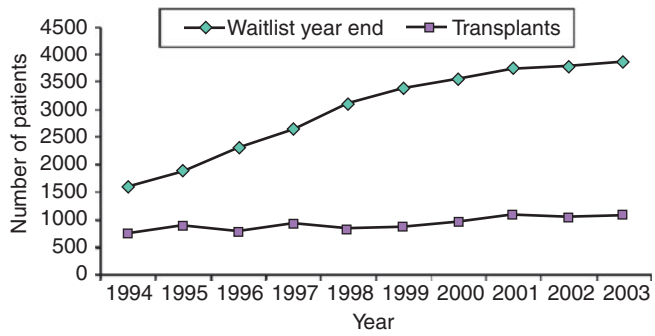

FIGURE 65-2 Between 1994 and 2003, the availability of donor organs held relatively constant, with an increasing number of patients placed on the waiting list. (*From Barr ML, et al: Thoracic organ transplantation in the United States, 1994-2003. Am J Transplant 2005; 5[4 Pt 2]:934-949.*)

The rationale for approaching recipient selection from the perspective of transplant benefit is based on the premise that patient selection for lung transplantation must balance the anticipated survival after transplantation (currently at a median of 5 years) with projected life expectancy on the waiting list. Although waiting times have historically averaged 432 days, the institution of the LAS has reduced this period to an average of 262 days.[14] Nevertheless, mortality while on the waiting list remains at nearly 20%, so it is imperative to identify recipients as early as possible within the "transplant window."[15] Ideally, recipient evaluation should select individuals with progressively disabling pulmonary disease who still possess the capacity for full rehabilitation after transplantation. Much of the current success in lung transplantation stems from improvement in recipient selection, because early attempts were thwarted by selection of patients with prohibitive operative risk factors. Candidates should have a less than 50% 2- to 3-year predicted survival despite appropriate medical or alternative surgical strategies. Disabling symptoms prompting consideration for transplantation typically include dyspnea, cyanosis, syncope, and hemoptysis. Potential recipients are identified by their local primary physicians and referred to transplantation centers for further evaluation.

Tests required for transplant listing are reviewed in Table 65-1. Diagnostic studies that are particularly useful in evaluating potential recipients include full pulmonary function tests, an exercise performance test, electrocardiogram, echocardiogram, 24-hour creatinine clearance, and liver function tests. Former smokers must undergo screening to exclude smoking-related illnesses, such as peripheral vascular disease and malignancy. A negative sputum cytology, thoracic computed tomographic (CT) scan, bronchoscopy, otolaryngologic evaluation, and carotid duplex scan are required. In addition, left heart catheterization and coronary angiography should be performed in recipient candidates who have a history of smoking.

Patients deemed suitable for transplantation during the initial evaluation are subjected to a final phase of testing (see Table 65-1). If accepted by the transplant review committee, they are listed on the national transplant registry based on LAS. Listed candidates should be seen every 3 to 6 months at the transplant center and regularly by their primary physicians, to maintain optimal medical condition. If appropriate, a period of exercise rehabilitation and nutritional modification may be initiated. Most transplant centers require patients to reside within several hours of the center by automobile or air charter.

ABO compatibilities are strictly adhered to, because isolated cases of hyperacute rejection have been reported in transplants performed across ABO barriers.[17] Donor-to-recipient lung volume matching is based on the vertical (apex to diaphragm along the midclavicular line) and transverse (level of diaphragmatic dome) radiologic dimensions on chest x-ray, as well as body weight, height, and chest circumference. Matching donor and recipient height seems the most reproducible method for selection of appropriate donor lung size, and donor lung dimensions should not be greater than 4 cm over those of the recipient. If need be, donor lungs may be downsized by lobectomy or wedge resection.

In contrast to renal transplantation, HLA matching is not a criterion for thoracic organ allocation. Because only short ischemic times are tolerated by lung and heart-lung blocs, it is not possible to perform this tissue typing preoperatively.[18] However, several retrospective studies have been performed evaluating the influence of HLA matching on long-term graft survival and development of obliterative bronchiolitis. Wisser and colleagues examined the relationship between HLA matching and long-term survival in 78 lung transplant recipients, finding improved graft survival with matching at the HLA-B locus.[19] In a retrospective

TABLE 65-1 Typical Laboratory Tests and Studies Obtained During Recipient Evaluation for Heart-Lung and Lung Transplantation

SUITABILITY FOR TRANSPLANTATION (PHASE I)

Required Laboratory Tests and Studies

- CBC with differential, platelet, and reticulocyte count
- Blood type and antibody screen (ABO, Rh)
- Prothrombin and activated partial thromboplastin time (PT, aPTT)
- Bleeding time
- Immunology panel (FANA, RF)
- Electrolytes, including Mg^{2+}
- CK with isoenzymes
- Serum protein electrophoresis
- Urinalysis
- Viral serologies
  - Compromised host panel (cytomegalovirus, adenovirus, Varicella-Zoster, herpes simplex, Epstein-Barr virus)
  - Hepatitis A, B, and C antibodies, Hepatitis B surface antigen (HBsAg)
  - Cytomegalovirus (quantitative antibodies and IgM)
  - Human immunodeficiency virus
- Electrocardiogram
- Chest x-ray

Studies Obtained as Indicated

- Echocardiogram with bubble study
- MUGA for right and left ventricular ejection fraction
- Cardiac catheterization with coronary angiogram
- Thoracic CT scan
- Quantitative ventilation-perfusion scans
- Carotid duplex
- Mammogram
- Colonoscopy
- Sputum for Gram stain, AFB smear, KOH, and routine bacterial, mycobacterial, and fungal cultures

REQUIRED FOR LISTING (PHASE II)

- HLA and DR typing
- Transplant antibody
- Quantitative immunoglobulins
- *Histoplasma, Coccidioides,* and *Toxoplasma* titers
- PPD
- Pulmonary function tests with arterial blood gases
- 12-Hour urine collection for creatinine clearance and total protein
- Urine viral culture

study of 74 lung transplant patients, Iwaki and coworkers also correlated matching at the HLA-B and HLA-DR loci with improved graft survival.[20] These studies suggest a relationship between HLA matching and long-term graft function.

Once an appropriate donor-recipient pairing is made, the recipient is screened for preformed antibodies against a panel of random donors. A percent reactive antibody (PRA) level greater than 25 prompts a prospective specific crossmatch between the donor and recipient. A positive crossmatch indicates the presence of antidonor circulating antibodies in the recipient, which would likely lead to hyperacute rejection. In the event of a positive crossmatch, the donor organ cannot be accepted for that recipient.

Disease-Specific Guidelines

Common indications for lung transplantation are listed in Table 65-2, with listing criteria given in Table 65-3. Chronic obstructive pulmonary disease (COPD) represents the most common indication for lung transplantation, accounting for 36% of lung transplants performed each year.[1] Decision making with respect to referral for transplantation and listing is based on worsening clinical deterioration as quantified by the BODE index. This predictive tool takes into account body mass index (B), degree of airflow obstruction (O), dyspnea (D, measured by the modified Medical Research Council MMRC dyspnea scale), and exercise capacity (E, measured by a 6-minute walk test).[21] The BODE index score ranges from 0 to 10, and patients are considered for transplant with a score of 7 to 10, because median survival in this cohort is only 3 years.[21] In patients with COPD who have apically predominant emphysema, lung volume reduction surgery (LVRS) may represent an alternative strategy to postpone or eliminate the need for transplantation. Patients who have undergone pleurodesis or who have advanced disease (FEV_1 and DLCO <20% or significant pulmonary hypertension) are not eligible for LVRS.[22] Based on the National Emphysema Treatment Trial, which studied the benefit of LVRS, a cohort of transplant-eligible high-risk patients (median survival of 3 years with medical therapy) was identified in which FEV1 was less than 20% and either DLCO less than 20% or homogeneously distributed emphysema was present.[22] The decision to perform single versus double lung transplantation in a patient with COPD must take into account the patient's ability to tolerate single lung ventilation, cardiopulmonary bypass, and the risk of ventilation-perfusion mismatch in single lung transplant when compressive atelectasis and restriction occurs in the donor lung. Interestingly, a statistical model derived from UNOS data between 1987 and 2004 estimated that 45% of COPD patients would gain a survival benefit of 1 year after double lung transplant, compared with only 22% of patients who underwent single lung transplant.[23]

Idiopathic pulmonary fibrosis (IPF) represents the second most common indication for lung transplantation worldwide, accounting for just over 20% of all lung transplants.[1] Median survival from the time of diagnosis is only 2.5 to 3.5 years, suggesting that transplant referral should be made as soon as

TABLE 65-2 Indications for Lung Transplantation from January 1995 Through June 2008

Diagnosis	SLT (*n* = 10,190) No. (%)	BLT (*n* = 13,338) No. (%)	Total (*N* = 23,528) No. (%)
COPD/emphysema	4,994 (49.0)	3,423 (25.7)	8,417 (35.8)
IPF	2,967 (29.1)	1,930 (14.5)	4,897 (20.8)
Cystic fibrosis	191 (1.9)	3,552 (26.6)	3,743 (15.9)
AAT	662 (6.5)	1,017 (7.6)	1,679 (7.1)
IPAH	74 (0.7)	714 (5.4)	788 (3.3)
Sarcoidosis	212 (2.1)	391 (2.9)	603 (2.6)
Bronchiectasis	40 (0.4)	596 (4.5)	636 (2.7)

Cancer	6 (0.1)	17 (0.1)	23 (0.1)
Other	527 (5.2)	874 (6.6)	1,401 (6.0)

UNOS data from January 1995 through June 2008.
From Christie JD, et al: The Registry of the International Society for Heart and Lung Transplantation: Twenty-Sixth Official Adult Lung and Heart-Lung Transplantation Report—2009. J Heart Lung Transplant 2009; 28[10]:1031-1049.

TABLE 65-3 Listing Criteria Specific to the Disease Entities Commonly Evaluated for Lung Transplantation

Chronic Obstructive Pulmonary Disease
- BODE index of 7 to 10 or at least one of the following:
  - History of hospitalization for exacerbation associated with acute hypercapnia (P_{CO_2} exceeding 50 mm Hg)
  - Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
  - FEV_1 <20% and either DLCO <20% or homogenous distribution of emphysema

Idiopathic Pulmonary Fibrosis
- Histologic or radiographic evidence of UIP and any of the following:
  - A DLCO <39% predicted
  - A 10% or greater decrement in FVC during 6 mo of follow-up
  - A decrease in pulse oximetry <88% during a 6-minute walk test
  - Honeycombing on HRCT (fibrosis score >2)

Cystic Fibrosis
- FEV_1 <30% of predicted, or rapidly declining lung function if FEV_1 >30% (females and patients <18 years of age have a poorer prognosis; consider earlier listing) and/or any of the following:
  - Increasing oxygen requirements
  - Hypercapnia
  - Pulmonary hypertension

Idiopathic Pulmonary Arterial Hypertension
- Persistent NYHA Class III or IV on maximal medical therapy
- Low (350 m) or declining 6-minute walk test
- Failing therapy with intravenous epoprostenol, or equivalent.
- Cardiac index of <2 L/min/m^2
- Right atrial pressure >15 mm Hg

Sarcoidosis
- NYHA functional Class III or IV and any of the following:
  - Hypoxemia at rest
  - Pulmonary hypertension
  - Elevated right atrial pressure >15 mm Hg

BODE = Body mass index, airflow Obstruction, Dyspnea, and Exercise capacity; HRCT = high-resolution computed tomography; NYHA = New York Heart Association; UIP = usual interstitial pneumonitis.
Modified from *Kreider M, Kotloff RM: Selection of candidates for lung transplantation. Proc Am Thorac Soc 2009; 6(1):20-27.*

histologic or radiographic evidence of the disease is present. Listing a patient with IPF must take into account the fact that many patients have an indolent form of the disease, and numerous studies have identified the following risk factors for rapid decline in patients with histologic or radiographic evidence of IPF[24]:

- DLCO less than 39% of predicted
- 10% or greater decrement in FVC during a 6-month period
- Oxygen saturation less than 88% during a 6-minute walk test
- Honeycombing on CT scan

Traditionally, IPF patients have been considered for either single or double lung transplantation. However, recent data suggest that there may be a survival advantage for double lung over single lung transplant—particularly among high-risk patients (defined as LAS >52).[25]

Cystic fibrosis (CF) is the third most common indication for lung transplant, accounting for 16% of the total number of transplants performed.[1] In these patients, bilateral sepsis mandates removal of both native lungs. In a landmark study from the Hospital for Sick Children in Toronto, Kerem and colleagues established that CF patients with an FEV_1 of less than 30% of predicted experienced a 2-year mortality rate of 50%.[26] However, subsequent risk stratification models have challenged these findings and presented conflicting data on the question of life expectancy in CF. Therefore, the current ISHLT guidelines state that an FEV_1 less than 30% should prompt a referral to a transplant center with the decision to proceed with listing dependent on other indicators of disease severity such as oxygen-dependent respiratory failure, hypercapnia, and pulmonary hypertension.[27] Cystic fibrosis recipients should have an otolaryngologic evaluation before being placed on an active waiting list. Most of these patients require endoscopic maxillary antrostomies for sinus access and monthly antibiotic irrigation to decrease the bacterial load of the upper respiratory tract. This measure has decreased the incidence of serious posttransplant bacterial infections.[28]

Idiopathic pulmonary arterial hypertension represents 3.3% of the total lung transplantation volume worldwide.[1] Survival with this condition has improved dramatically with the institution of vasodilator therapy, with 5-year survival of 55% on epoprostenol compared with 28% among historical controls.[29] Listing for transplantation is indicated when a patient remains in NYHA Class III or IV after 3 months of therapy (often seen in the setting of declining 6-minute walk test, cardiac index of <2 L/min/m^2, or right atrial pressure >15 mm Hg).[24]

Sarcoidosis accounts for 2.6% of all lung transplants.[1] The natural course of this disease can be highly variable, but in general patients should be referred for transplant if they develop NYHA class III or IV symptoms. Impairment of exercise tolerance and hypoxemia at rest, pulmonary hypertension, or right atrial pressure greater than 15 mm Hg serve as general guidelines for listing.[27]

Less than 2% of all single and bilateral lung transplants are retransplantations.[1] Overall, survival is poor compared with first-time transplantation, although certain subsets of patients perform better than others. In fact, the Pulmonary Retransplant Registry has collected data from 230 patients at over 40 centers and found that 1-year survival of ambulatory, nonventilated patients undergoing retransplantation after 1991 is comparable with first-time transplants.[30]

Contraindications to Lung Transplantation

There are well-established contraindications to lung transplantation (Table 65-4). In general, transplantation is an option that is restricted to patients less than 65 years old, although 9% of recipients in the first half of 2008 exceeded this cutoff.[1] Significant multisystem disease is a contraindication, although multiorgan transplants have occasionally been performed. Absolute contraindications include renal dysfunction, malignancy (bronchoalveolar carcinoma is a contraindication but not non-melanoma skin cancer), infection with HIV, hepatitis B antigen positivity or hepatitis C infection with biopsy-proven liver disease, infection with pan-resistant respiratory flora, active or recent cigarette smoking, drug abuse, alcohol abuse, severe psychiatric illness, noncompliance with medical care, extreme obesity, progressive unintentional weight loss, malnutrition, and absence of a consistent and reliable social support network.[24] Relative contraindications include active extrapulmonary infection, symptomatic osteoporosis, and recent history of active peptic ulcer disease. Cigarette smokers must quit smoking and remain abstinent for several months before transplantation. Patients with histories of previous thoracic surgery are evaluated on a case-by-case basis. For patients who require systemic corticosteroids, tapering to the lowest tolerable level, preferably below 10 mg/day, is critical to prevent airway healing complications. Finally, mechanical ventilation is generally considered a contraindication to transplantation; repeated studies have shown that these patients have significantly worse immediate and long-term survival after transplantation.[31] It is important that recipient candidates be educated about lifestyle modifications necessary for the success of a transplant, and willingness to comply with immunosuppression regimens and extensive posttransplant medical and surgical follow-up is mandatory.

TABLE 65-4 Recipient Contraindications to Lung Transplantation

Age ≥65
Significant systemic or multisystem disease (eg, peripheral or cerebrovascular disease, portal hypertension, poorly controlled diabetes mellitus)
Significant irreversible hepatic or renal dysfunction (eg, bilirubin >3.0 mg/dL, creatinine clearance <50 mg/mL/min
Active malignancy
Corticosteroid therapy (>10 mg/day)
Pan-resistant respiratory flora
Cachexia or obesity (<70% or >130% ideal body weight)
Current cigarette smoking
Psychiatric illness or history of medical noncompliance
Drug or alcohol abuse
Previous cardiothoracic surgery (considered on a case-by-case basis)
Severe osteoporosis
Prolonged mechanical ventilation
HIV
HBsAg positivity or Hepatitis C infection with biopsy proven liver disease

Recipient Management After Listing

It is essential that a candidate's medical condition be optimized before transplantation. Supplemental oxygen is recommended for any patient exhibiting arterial hypoxemia, defined as either an arterial oxygen saturation less than 90 percent or an arterial P_{O_2} less than 60 mm Hg at rest, during exertion, or while asleep. Fluid balance is optimized with restriction of dietary water and salt in conjunction with diuretic therapy. Care must be taken with the use of loop diuretics, as these can incite a metabolic alkalosis that can impair the effectiveness of plasma carbon dioxide as a stimulus for breathing.

Primary pulmonary hypertension often requires the use of supplemental oxygen to prevent hypoxia-induced pulmonary vasoconstriction and secondary erythropoiesis. Pulmonary vasodilator therapy with the use of calcium channel blockers and continuous prostacyclin infusions presents another therapeutic option in the management of these patients.[32] Although these drugs exhibit potent systemic effects and must be used with caution, the response rate for calcium channel blockers is approximately 20%. Although a favorable response to short-acting vasodilators during cardiac catheterization is predictive of a successful response to calcium channel therapy, this trend is not seen in long-term prostacyclin infusion.

Interstitial lung disease in patients awaiting transplantation results from a wide variety of diffuse inflammatory processes such as sarcoidosis, asbestosis, and collagen-vascular diseases. Increases in pulmonary vascular resistance leading to right-sided heart failure are thought to arise from interstitial inflammatory infiltrates that entrap and eventually destroy septal arterioles, thus reducing the distensibility of the remaining pulmonary vessels.[33] This process, coupled with closure of peripheral bronchioles, results in arterial hypoxemia, further aggravating pulmonary hypertension. Corticosteroids are the mainstay of treatment in this class of diseases. The adverse effects of steroids on airway healing are well established,[6,34] and mandate significant dose reductions in anticipation of transplantation.

The multisystem manifestations of cystic fibrosis, particularly chronic bronchopulmonary infection, malabsorption, malnutrition, and diabetes mellitus, pose difficult management problems in potential transplant recipients. These patients require aggressive chest physiotherapy, antibiotics, enteral or parenteral nutritional supplementation, and tight serum glucose control.[35]

Organ Procurement and Preservation

Donor Selection

Standard criteria have been established for donor selection (Table 65-5).[36,37] Donors must have sustained irreversible brain death, but owing to the susceptibility of the lungs to edema and infection in the setting of brain death and trauma, suitable organs are often difficult to obtain (available in <20% of all organ donors).

TABLE 65-5 Donor Selection Criteria

Age <40 (heart-lung), <50 (lung)
Smoking history less than 20 pack-years
Arterial P_{O_2} of 140 mm Hg on an F_{IO_2} of 40% or 300 mm Hg on an F_{IO_2} of 100%
Normal chest x-ray
Sputum free of bacteria, fungus, or significant numbers of white blood cells on Gram and fungal staining
Bronchoscopy showing absence of purulent secretions or signs of aspiration
Absence of thoracic trauma
HIV-negative

Initial donor evaluation consists of a directed history and physical examination, chest x-ray, 12-lead ECG, arterial blood gases, and serologic screening including human immunodeficiency virus (HIV), hepatitis B surface antigen, hepatitis C antibodies, herpes simplex virus (HSV), cytomegalovirus (CMV), *Toxoplasma*, and RPR. A donor age of less than 50 is preferred. The chest x-ray should be clear and the arterial P_{O_2} should exceed 140 mm Hg on an F_{IO_2} of 40% and 300 mm Hg on an F_{IO_2} of 100%. Lung compliance can be estimated by measuring peak inspiratory pressures, which should be less than 30 cm H_2O. Bronchoscopy should ensure the absence of purulent secretions or signs of aspiration. Finally, direct inspection and palpation of the lungs at explantation to verify full expansion of any atelectatic segments is an essential part of the donor organ evaluation.

Absolute contraindications to donation include prolonged cardiac arrest (30 minutes), arterial hypoxemia, active malignancy (excluding basal cell and squamous cell carcinoma of the skin), and positive HIV status. Relative contraindications include thoracic trauma, sepsis, significant smoking history, prolonged severe hypotension (ie, <60 mm Hg for >6 hours), HBsAg or hepatitis C antibodies, multiple resuscitation attempts, and a prolonged high inotropic requirement (eg, dopamine in excess of 15 μg/kg/min for 24 hours). It is important to rule out correctable metabolic or physiologic causes of cardiac rhythm disturbances and electrocardiographic anomalies (eg, brain herniation, hypothermia, hypokalemia).

Over the last decade, there has been a trend toward liberalization of standard donor selection criteria. This strategy, initiated in response to the shortage of donor organs, is employed at a large number of transplant centers.[38–42] Donors ranging in age from 50 to 64 have been used in thoracic transplantation with good long-term graft survival.[41] However, reports from the ISHLT document worse outcomes in recipients of lung allografts from donors older than 55 who had ischemic times greater than 6 to 8 hours.[43] In this group of recipients, long-term survival is impaired and the risk of developing bronchiolitis obliterans is increased. Smoking history is another criterion that has been liberalized, with conventional guidelines limiting donor selection to patients with less than 20 pack-years. Modified criteria allow for a more extensive smoking history, assuming there is no evidence of COPD or other lung disease on screening tests. Traditionally, donor lungs have been ruled out for transplantation based on evidence of infection. In that regard, prolonged ventilation before brain death and procurement has been viewed as a contraindication for organ selection. However, a positive sputum Gram stain (excluding fungus), which was once considered a basis for ruling out an organ has failed to predict the development of early pneumonia, impairment of oxygenation, or duration of mechanical ventilation in the postoperative setting.[44,45] Some groups have accepted donors with small pulmonary infiltrates on chest x-ray, although clinical correlation is necessary. Others have selectively used donor lungs in patients with P_{aO_2} less than 300 mm Hg on F_{IO_2} of 100%. Gabbay and coworkers in Australia have adopted an aggressive approach to donor management and "organ resuscitation."[39] By manipulating donors with antibiotic therapy, chest physiotherapy, careful fluid management, ventilator adjustments, and bronchial toilet, 34% of donors with an initial P_{aO_2} less than 300 mm Hg on F_{IO_2} of 100% had increases in their P_{aO_2}, becoming acceptable donors.

Areas of investigation in the field of donor organ procurement include the use of non–heart-beating donors. In 2001, Steen and coworkers reported transplantation of lungs from a non–heart-beating donor into a 54-year-old woman with COPD,[46] with good functional results during the first 5 months of follow-up. However, ethical, logistic, and scientific questions remain on the use of non–heart-beating donors, and this strategy is far from being widely applicable.

Donor Management

The overriding goal in managing the thoracic organ donor is to maintain hemodynamic stability and pulmonary function. Patients suffering from acute brain injury are often hemodynamically unstable because of neurogenic shock, excessive fluid losses, and bradycardia. Donor lungs are prone to neurogenic pulmonary edema, aspiration, nosocomial infection, and contusion. Continuous arterial and central venous pressure monitoring, judicious fluid resuscitation, vasopressors, and inotropes are usually required.

Intravascular volume replacement should be limited to maintain the central venous pressure between 5 and 8 mm Hg. In general, crystalloid fluid boluses are to be avoided. Diabetes insipidus is common in donors and requires the use of intravenous vasopressin (0.8 to 1.0 unit/h) to prevent excessive urine loss. Dopamine is the standard inotropic agent used to maintain adequate perfusion pressures, although alpha agonists (eg, phenylephrine) are often appropriate. Blood transfusions should be used sparingly to maintain a hemoglobin concentration of approximately10 g/dL, ensuring adequate myocardial oxygen delivery. CMV-negative and leukocyte-filtered blood should be used whenever possible. Hypothermia should be avoided as it predisposes to ventricular arrhythmias and metabolic acidosis.

With regard to mechanical ventilation, F_{IO_2} values in excess of 40%, especially 100% oxygen "challenges," should be avoided, because these oxygen levels may be toxic to the denervated lung. Ventilator settings should include positive end-expiratory pressures (PEEP) between 3 and 5 cm H_2O to prevent atelectasis.

Donor Operation

The donor operation is performed via a median sternotomy (Fig. 65-3A). After the sternum is divided, a standard chest retractor is placed, and both pleural spaces are opened followed by immediate inspection of the lungs and pleural spaces, particularly in cases involving trauma. The lungs are briefly deflated, and the pulmonary ligaments are divided inferiorly using electrocautery. After completely excising the thymic remnant, the pericardium is opened vertically and laterally on the diaphragm and cradled during dissection of the great vessels and trachea. The ascending aorta, pulmonary artery, and venae cavae are dissected. Umbilical tapes are placed around the ascending

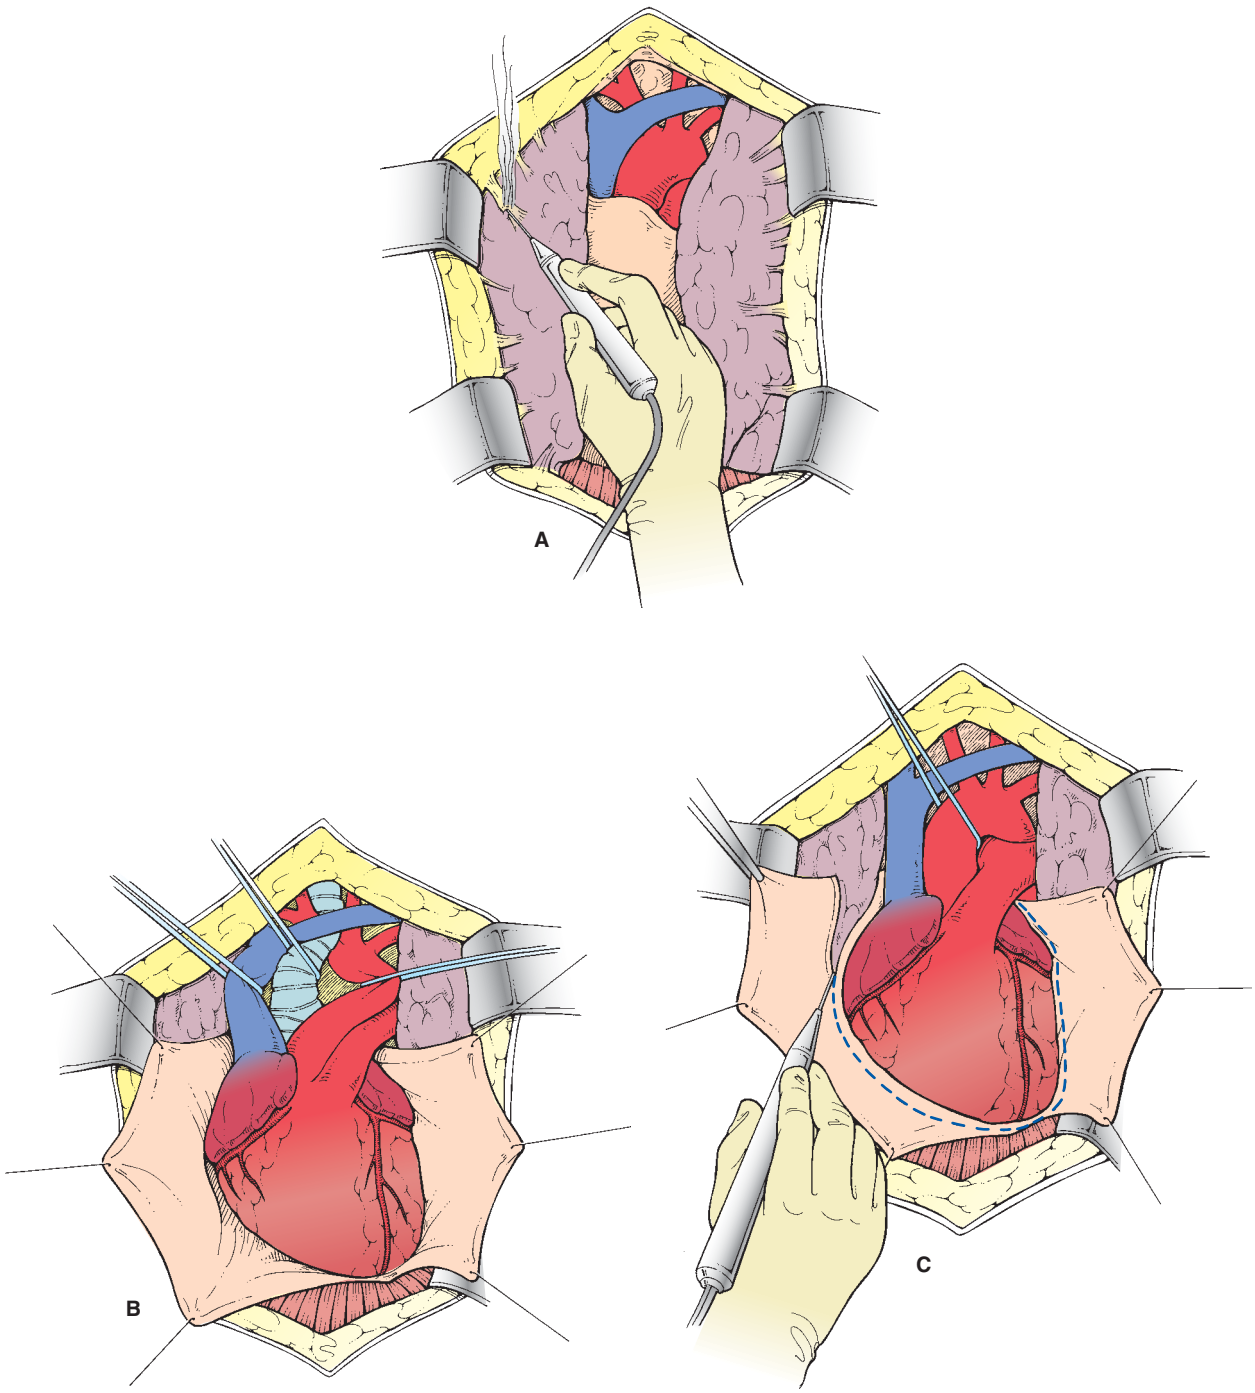

FIGURE 65-3 Donor operation for heart-lung transplantation. (A) Through a median sternotomy, adhesions are lysed and the pulmonary ligaments are divided inferiorly. (B) The pericardium is opened and cradled followed by dissection of the ascending aorta, venae cavae, pulmonary artery, and trachea. (C) The entire anterior pericardium is excised back to each hilum. (D) Cardioplegia and pulmonoplegia are infused simultaneously into the aorta and main pulmonary artery after aortic cross-clamping. Application of topical cold Physiosol follows immediately. (E) The venae cavae and aorta are divided, and the heart-lung bloc is dissected free from the esophagus and posterior hilar attachments. After the trachea is stapled and divided at the highest point possible, the entire heart-lung bloc is removed from the chest.

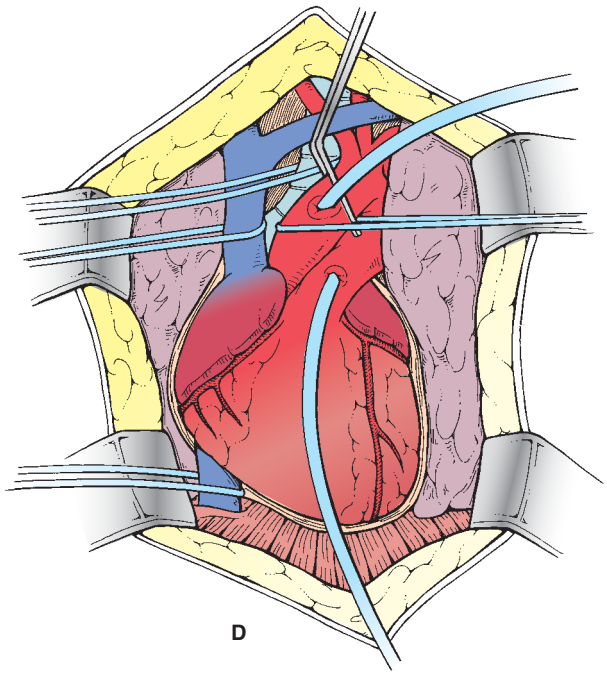

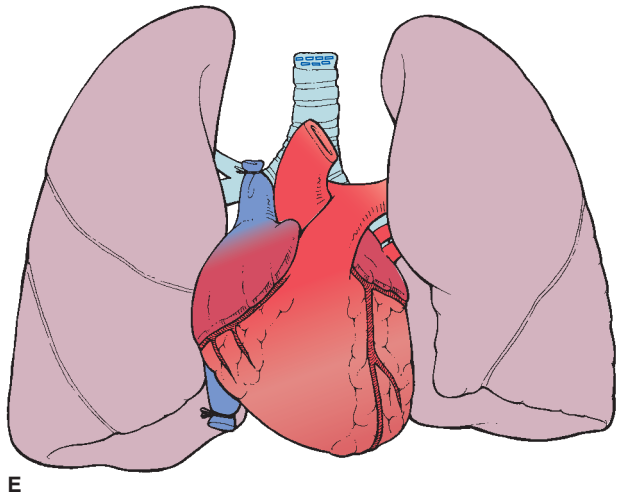

FIGURE 65-3 (*Continued*)

aorta and venae cavae (Fig. 65-3B). The pericardium overlying the trachea is incised vertically, and the trachea is encircled with an umbilical tape between the aorta and superior vena cava at the highest point possible and at least four rings above the carina (see Fig. 65-3B). The entire anterior pericardium is excised back to each hilum (Fig. 65-3C).

Approximately 15 minutes before applying the aortic cross-clamp, prostaglandin E_1 (PGE_1) is infused intravenously, initially at a rate of 20 ng/kg/min, followed by incremental increases of 10 ng/kg/min to a target rate of 100 ng/kg/min (Fig. 65-3D). During PGE_1 infusion, the mean arterial blood pressure should be maintained at or above 55 mm Hg. Ventilation is continued with a FIO_2 of 40% and a PEEP of 3 to 5 cm H_2O. The donor is heparinized with 30,000 units. Cannulation of the aorta and main pulmonary artery is performed, with care taken to ensure adequate flow to both branches of the pulmonary artery during pulmonary plegia.[47] The superior vena cava is ligated and a transverse incision is made across the inferior vena cava. After the heart is allowed to empty, the aortic cross-clamp is applied, and 10 mL/kg of cold crystalloid cardioplegia, commonly the Stanford formulation, is rapidly infused into the aortic root with the bag under pressure at 150 mm Hg. The inferior vena cava is incised, and the left atrial appendage is amputated to avoid cardiac distention. Although the antegrade cardioplegia is being delivered, Perfadex (Vitrolife Inc., Englewood, CO) is rapidly flushed into the main pulmonary artery at a rate of 15 mL/kg/min for 4 minutes. Ice-cold saline or Physiosol solution (Abbott Laboratories, North Chicago, IL) is immediately poured over the heart and lungs. During the cardioplegic and Perfadex infusions, ventilation is maintained with half-normal tidal volumes of room air.

After delivery of plegic solutions, the lungs are deflated and the great vessels are divided. The heart is reflected anteriorly and a left atriotomy is performed, leaving a 2-cm cuff of atrium around the pulmonary vein orifices. Once this division is complete, the heart is removed from the chest. The lung bloc is then dissected free along the pre-esophageal plane above the level of the carina. The lungs are inflated and the trachea is stapled at the highest possible point. If needed, the bilateral lung bloc can be further separated into left and right lung blocs. The left atrial cuff containing the orifices of the pulmonary veins is divided in half vertically. The left and right pulmonary arteries are divided at their junction. Finally, the left mainstem bronchus is stapled near its junction with the trachea.

Once removed from the donor, grafts are wrapped in sterile gauze pads and immersed in ice-cold saline at 2 to 4°C in several sterile plastic bags placed within a sterile plastic container. This, in turn, is placed in an ice-filled chest and transported to the transplant center.

Organ Preservation and Transport

The principal goal of preservation is to minimize injury to the allograft from ischemia and reperfusion.[48] Ischemia-reperfusion injury is mediated by reactive oxygen species, which disrupt the homeostatic mechanisms in myocytes and endothelial cells. As receptors for leukocyte adhesion molecules are upregulated and leukocyte chemotactic factors released, an inflammatory response ensues, leading to cellular injury. Several approaches for minimizing ischemia-reperfusion injury have developed, including donor pretreatment, use of specialized preservation solutions, and recipient treatments.

Hypothermia is considered by many to be the most important method of organ preservation. It works by reducing tissue metabolic demand by up to 99%. During explantation, organs are flushed with cold plegic solutions (0 to 10°C, depending on

the institution and solution employed). Organs are stored at 0 to 10°C, and during implantation they are covered with gauze soaked in saline slush or recipients are cooled through CPB.

A variety of crystalloid pulmonary artery flush solutions are used worldwide, and they can be divided into two categories based on their electrolyte compositions: intracellular and extracellular. Intracellular solutions contain moderate to high concentrations of potassium and little calcium and sodium. Euro-Collins, University of Wisconsin (UW), and Cardiazol are examples. Extracellular solutions contain high concentrations of sodium and low to moderate concentrations of potassium. Low-potassium dextran is an example of this type of solution (eg, Perfadex). Although Euro-Collins is the most frequently used preservation solution, there is a growing body of evidence in support of low potassium, dextran-containing extracellular solutions.[49–51]

Prostaglandins are commonly used for donor pretreatment and as an additive in pulmonary flush solutions. The administration of PGE_1 (a potent vasodilator) counteracts reflex pulmonary vasoconstriction induced by the cold flush and permits uniform distribution of perfusate throughout the lung. Studies in large animals also suggest that PGE_1 treatment may minimize reperfusion injury through its anti-inflammatory properties.[52] Another commonly used pretreatment strategy is steroid treatment. Administration of intravenous methylprednisone to the donor inactivates lymphocytes, which are thought to mediate ischemic lung graft injury.

Studies suggest that lung graft function is improved when the explanted organ is inflated, 100% oxygen is used for the inflation, and transport is carried out at 10°C.[53] Research in the field of lung preservation has recently focused on the role of various flush and storage solution additives, such as antioxidants, which may act as free radical scavengers. Other additives shown to decrease reperfusion injury in research models include nitric oxide donors and phosphodiesterase inhibitors. Areas of ongoing research include the development of leukocyte depletion strategies, examining the role of gene therapy to modify donor organ susceptibility to ischemia-reperfusion injury, and the development of colloid-based perfusates.

These preservation techniques, coupled with streamlined donor and recipient protocols, have permitted procurements as far as 1000 miles from the transplant center. Extensive communication and coordination must be maintained between the organ procurement agency, donor-recipient operative teams, medical centers, and abdominal procurement teams. Worldwide, the major procurement agencies include the United Network for Organ Sharing (UNOS) in the United States, Multiple Organ Retrieval (MORE) in Canada, and the EURO Transplant Organization in Europe.

Recipient Operation

The recipient operation proceeds in two phases. The first is excision of the native organ(s) and the second is implantation of the allograft. Cardiopulmonary bypass is occasionally required for lung transplantation. Regardless, CPB should be available as standby at all times. At Stanford, we have favored the use of CPB during bilateral lung transplantation for a variety of reasons. There is improved exposure of the hilar structures, which is particularly helpful in patients with dense adhesions and bronchial collaterals. CPB allows for early pneumonectomies without hemodynamic or respiratory instability, and ischemic time of the second lung is substantially reduced compared with off-CPB bilateral lung transplants. Its use also prevents overperfusion of the first lung graft with the entire cardiac output. In patients with suppurative lung disease, the use of CPB facilitates careful washout of the distal trachea and proximal bronchi to prevent contamination of the first implanted lung. Others prefer to avoid CPB, as it may be associated with increased blood loss, transfusion needs, and reperfusion injury. More detailed experimental and clinical studies are needed to resolve these questions. At present, the need for CBP should be determined on a case-by-case basis.

Anesthetic monitoring includes arterial pressure monitoring, pulse oximetry, continuous electrocardiography, pulmonary artery catheter monitoring, temperature monitoring, and urine output monitoring. The use of double-lumen endotracheal tubes is particularly helpful, allowing for single lung ventilation during certain portions of the dissection. Large-bore intravenous lines are placed for volume infusion. Transesophageal echocardiography is often performed during the procedure.

Single Lung Transplantation

If possible, the poorer functioning lung (as determined by preoperative ventilation-perfusion scan) is selected for replacement. The patient is placed in a standard thoracotomy position with access to the groin, should CPB be needed. A posterolateral thoracotomy is made at the level of the fourth or fifth intercostal space. Adhesions are lysed and the hilar dissection performed. The pulmonary artery, the superior and inferior pulmonary veins, and the mainstem bronchus are isolated. A trial occlusion of the pulmonary artery is used to determine whether the procedure can be conducted without CPB. If the occlusion is tolerated, the pulmonary artery is ligated and divided distal to the upper lobe branch. The pulmonary veins are also ligated and divided. The mainstem bronchus is stapled and divided, and the native lung is explanted.

The donor lung is removed from its transport container and prepared for implantation. The donor bronchus is opened and secretions are aspirated and cultured. The bronchus is trimmed, leaving two cartilaginous rings proximal to the orifice of the upper lobe. Any remaining pericardial and lymphatic tissue is removed, and the left atrial cuff is trimmed as needed. The donor lung is then placed in the recipient's chest and covered with saline slush and iced laparotomy pads.

The sequence of anastomoses is a matter of preference, although most perform the deepest anastomosis (the bronchial anastomosis) first and then proceed to the more superficial ones. The bronchial anastomosis is fashioned with 4-0 polypropylene suture. We favor a continuous suture technique for the entire anastomosis, although the membranous portion can be sewn with interrupted suture. Variations on the end-to-end bronchial anastomosis include the use of a telescoping technique, in which the donor bronchus is intussuscepted into the recipient bronchus, and an omental pedicle flap is placed

around the anastomosis. These techniques were developed to prevent bronchial anastomotic dehiscence but are now rarely performed.

Once the bronchial anastomosis is complete, attention is turned to the anastomoses of the pulmonary veins. A side-biting clamp is applied to the left atrium to include the pulmonary veins. The recipient pulmonary vein stumps are opened and the intervening atrial tissue is cut. This creates a cuff that is anastomosed to the donor atrial remnant using continuous 4-0 polypropylene suture. (This suture is not tied down until reperfusion.) Donor and recipient pulmonary arteries are anastomosed with 5-0 polypropylene suture. Arteries must be trimmed to an appropriate length before fashioning the anastomosis, because kinking can occur upon graft inflation if the vessels are left too long. The pulmonary artery anastomosis is then de-aired. The lung is inflated, and the pulmonary artery clamp is temporarily released to allow flushing of air through the atrial suture line. The left atrial clamp is removed to allow retrograde de-airing of the atrial anastomosis. The pulmonary venous anastomosis is then secured.

After hemostasis is ensured, apical and basal chest tubes are inserted. The ribs are reapproximated and the chest is closed in standard fashion. The double lumen endotracheal tube is exchanged for a single lumen tube and bronchoscopy is performed to evaluate the bronchial anastomosis.

Bilateral Lung Transplantation

Bilateral lung transplantation is performed as sequential single lung transplants. Although the traditional approach to this technique has been to access the chest via bilateral anterior thoracosternotomy (clamshell) incisions, we have recently transitioned our practice to a median sternotomy approach. The lung with the least amount of function (as determined by a preoperative ventilation-perfusion scan) is removed first and replaced with an allograft as described for single lung transplantation above. Once ventilation and perfusion are established in the first allograft, the remaining lung is explanted and the second allograft is implanted. Bilateral chest tubes are placed and the chest is closed. Bronchoscopy is performed to evaluate the bronchial anastomoses.

Although single lung transplants are usually performed off CBP, the majority of double lung transplants are still performed on-pump. The use of CPB allows for improved exposure, shorter graft ischemic times, controlled reperfusion, and the use of leukocyte-depleting filters. As the risk of bleeding may be increased with CPB, strategies have been developed to minimize the chance of hemorrhage. These include the use of heparin-coated CPB circuits as well as the argon beam coagulator. Despite these maneuvers, there remains considerable risk associated with CPB, and many centers prefer to perform all lung transplants off-pump if possible.

Postoperative Management

Graft Physiology

Denervation of the lungs results in a diminished cough reflex and impairment of mucociliary clearance mechanisms. This predisposes recipients to pulmonary infections and necessitates aggressive postoperative pulmonary toilet.[54] Moreover, in the transplanted lung, ischemia-reperfusion injury, along with disrupted pulmonary lymphatics may result in increased vascular permeability with varying degrees of interstitial edema.

Clinical Management in the Early Postoperative Period

Early postoperative management centers around careful fluid balance and ventilatory management. The primary objective in the immediate postoperative period is to maintain adequate perfusion and gas exchange while minimizing intravenous fluid administration, cardiac work, and barotrauma. Barotrauma and high airway pressures can compromise bronchial mucosal flow. Therefore, lower tidal volumes and flow rates may be necessary to limit peak airway pressures to less than 40 cm H_2O. After arrival in the ICU, ventilator settings are adjusted every 30 minutes to achieve an arterial P_{O_2} greater than 75 mm Hg on an F_{IO_2} of 40%, an arterial carbon dioxide pressure (Pa_{CO_2}) between 30 and 40 mm Hg, and a pH between 7.35 and 7.45. Pulmonary toilet with endotracheal suctioning is an effective means of reducing mucus plugging and atelectasis. Ventilatory weaning is initiated after the patient is stable, awake, and alert, with extubation typically achieved within 24 hours. Subsequent pulmonary care consists of vigorous diuresis, supplemental oxygen for several days, continued aggressive pulmonary toilet, incentive spirometry, and serial chest x-rays.

A diffuse interstitial infiltrate is often found on early postoperative chest x-rays. Previously referred to as a *reimplantation response*, this finding is better defined as graft edema owing to inadequate preservation, reperfusion injury, or early rejection.[55] It appears that the degree of pulmonary edema is inversely related to the quality of preservation. Judicious administration of fluid and loop diuretics is required to maintain fluid balance and minimize this pulmonary edema.

Early lung graft dysfunction occurs in less than 15% of transplants, and is manifest as persistent marginal gas exchange without evidence of infection or rejection.[56] This primary graft failure often results from ischemia-reperfusion injury and histologically evident as diffuse alveolar damage. Of course, technical causes of graft failure such as pulmonary venous anastomotic stenosis or thrombosis must always be considered. In cases of persistent, severe pulmonary graft dysfunction refractory to mechanical ventilatory maneuvers, extracorporeal membrane oxygenation (ECMO)[57] and inhaled nitric oxide[58] have been used successfully to stabilize gas exchange. Urgent retransplantation can also be considered if other interventions fail.

Immunosuppressive Management: Early and Late Postoperative Regimens

Immunosuppression protocols vary from center to center. At the Stanford University Hospital, we typically administer induction therapy of either rabbit antithymocyte globulin (RATG) at a dose of 1.5 mg/kg on POD 1, 2, 3, 5, and 7 or daclizumab at 1mg/kg (first dose given in OR then every other week for four additional doses). For highly sensitized patients, plasmapheresis with a 1:1.5 volume exchange with fresh-frozen plasma (FFP)

is performed intraoperatively, along with intravenous immunoglobulin (IVIG), which is started at 2 g/kg before releasing the cross-clamp. Methylprednisolone is given at 500 mg IV after protamine administration, and a stat retrospective crossmatch is performed.

On POD 1, T and B cell subset counts are performed and if the cytotoxic crossmatch is positive, RATG is given in 2 doses at 0.75 mg/kg. If the crossmatch is negative or pulmonary edema is present or expected from RATG, daclizumab is administered at 1 mg/kg and repeated every 14 days for a total of five doses. Methylprednisolone is given at 125 mg IV every 8 hours for 3 doses, CellCept is given at 500 mg PO BID, and Prograf is given at 0.5 mg BID and titrated to a level of 12 to 15 ng/mL. On POD 2, prednisone is started at 0.5 mg/kg PO BID. Hereafter, the patient is maintained on prednisone, Prograf, and CellCept. For sensitized patients, plasmapheresis is repeated in a 1:1.5 volume exchange with 1/2 5% albumin and 1/2 FFP. If the patient was given RATG, a second dose of 0.75 mg/kg is administered. Otherwise, IVIG 100 mg/kg is given. Plasmapheresis is repeated on POD 3 and 4, along with IVIG at 100 mg/kg. Plasmapheresis is completed on POD 5, with administration of IVIG at 1 g/kg on POD 5 and 6. A donor specific antibody (DSA) is sent before IVIG on POD 5 and after IVIG on POD 6. Finally, on POD 7 T and B cell subset counts are measured (and repeated weekly thereafter) along with administration of Rituximab for two doses with one dose of 375 mg/m^2 given at POD 7 and a second dose given a week later.

Infection Prophylaxis

Antiviral and antifungal prophylaxis remain important components of the postoperative management strategy in heart-lung and lung transplant recipients. Many centers employ cytomegalovirus prophylaxis (CMV) with ganciclovir for any CMV-positive recipient and in any CMV-negative recipient receiving an allograft from a CMV-positive donor. Ganciclovir is typically given for a several week course, and can be associated with leukopenia. Some patients may require G-CSF if their white blood cell count falls below 4000. Fungal prophylaxis against mucosal candida infection includes use of itraconazole and nystatin swish and swallow. *Pneumocystis carinii* prophylaxis consists of trimethoprim-sulfamethoxazole or aerosolized pentamidine. In the immediate postoperative period, *Aspergillus* colonization is inhibited by the use of aerosolized amphotericin B. For *Toxoplasma*-negative recipients of grafts from *Toxoplasma*-positive patients, pyrimethamine prophylaxis is maintained for the first 6 months after transplantation.

Graft Surveillance: Patient Follow-up Schedule

Routine clinical follow-up is required to monitor graft function and modify immunosuppressive regimens. Regular surveillance protocols developed to monitor graft function typically consist of serial pulmonary function tests, arterial blood gases, and bronchoscopic evaluation. Surveillance is usually conducted at 2, 4 to 6, and 12 weeks, followed by 6 months after transplantation and yearly thereafter. Transbronchial biopsies are obtained from each transplanted lung, and lavage specimens are submitted for staining (ie, Gram, fungal, acid-fast bacillus, silver), culture, and cytology. In addition to routine surveillance, follow-up is often needed to address changes in clinical status. Complications related to transplantation are many, and these must be addressed carefully and expediently to prevent long-term graft failure.

Postoperative Complications

Early morbidity and mortality after lung transplantation (within 30 days of operation or before initial discharge from hospital) are most commonly a result of primary graft failure or infection. Late mortality is most commonly caused by obliterative bronchiolitis or infection.[59] Causes of death at various time points after transplantation have been compiled by the ISHLT and are presented in Fig. 65-4.

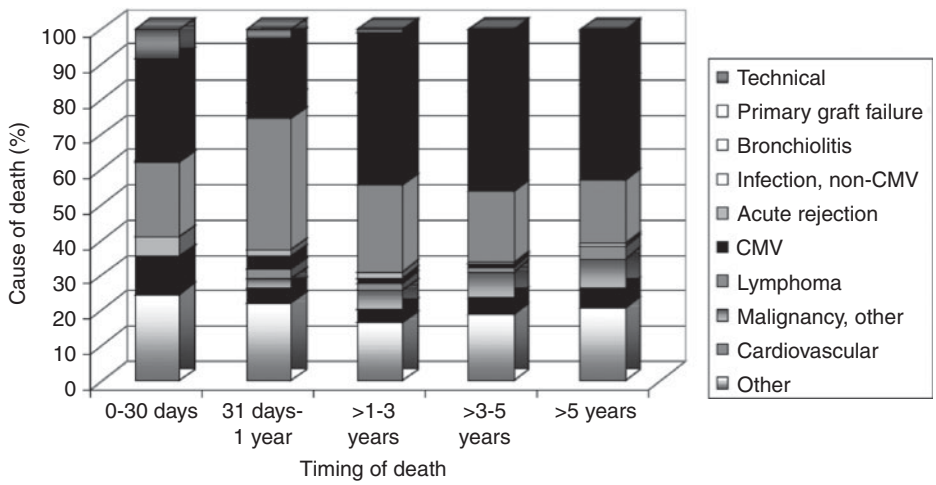

FIGURE 65-4 Causes of death at various periods after isolated lung transplantation. (*Adapted from Trulock EP, Edwards LB, Taylor DO, et al: Registry of the International Society for Heart and Lung Transplantation: Twenty-Second Official Adult Lung and Heart-Lung-Transplant Report—2005. J Heart Lung Transplant 2005; 24[8]:956-967 with permission from Elsevier Science.*)

Hemorrhage

Perioperative hemorrhage is an infrequent but significant cause of early death in heart-lung and lung transplantation. The majority of perioperative hemorrhagic complications stem from operating in the midst of dense adhesions caused by previous operations or inflammation from chronic lung infection. As mentioned previously, meticulous attention to hemostasis is mandatory, and all available means should be used to achieve a dry field on completion of the operation.

Hyperacute Rejection

ABO matching of donor and recipient has decreased the rate of hyperacute rejection. This complication, which is almost universally fatal, is mediated by preformed antibodies in the recipient that recognize antigens on the donor vascular endothelium. This humoral immune response results in activation of inflammatory and coagulation cascades, resulting in extensive thrombosis of graft vessels and subsequent graft failure.[68] To reduce the incidence of hyperacute rejection, a prospective crossmatch should be performed in recipients with a PRA greater than 25%.

Early Graft Dysfunction and Primary Graft Failure

Graft dysfunction in the first few days after transplantation is common. It is often referred to as the "reimplantation response," manifest by abnormal lung function, pulmonary edema, and pulmonary infiltrates on chest x-ray. This phenomenon is thought to be linked to ischemia and reperfusion. Other contributing factors may also include allograft contusion, inadequate preservation, or use of cardiopulmonary bypass during transplantation. Although most cases are mild and resolve with supportive care, some progress to primary graft failure. Reported rates of primary graft failure following lung transplantation range between 10 and 15%. Treatment may include the use of ECMO and inhaled nitric oxide (NO). Unfortunately, primary graft failure is associated with a mortality of more than 60%.[56]

Acute Rejection

As in cardiac transplantation, the majority of acute rejection episodes occur within the first year after transplant at a rate of 36%.[1] Despite its prevalence, death is very rarely a direct consequence of acute rejection. It is recognized, however, that the number and severity of acute rejection episodes is a risk factor for ultimately developing obliterative bronchiolitis.

Diagnosis of acute rejection in the early posttransplant period is often based on clinical parameters. Symptoms and signs of rejection include fever, dyspnea, impaired gas exchange (manifest as a decrease in arterial P_{O_2}), a diminished forced expiratory volume during 1 second (FEV_1, a measure of airway flow), a fall in vital capacity (VC), and the development of characteristic bilateral interstitial infiltrates on chest x-ray (Fig. 65-5). After the first postoperative month, the chest x-ray is frequently normal during episodes of acute rejection, placing greater emphasis on other clinical parameters characteristic of rejection.

It is often difficult to distinguish between the diagnosis of acute lung rejection and pulmonary infection based on clinical findings alone. It is of paramount importance to distinguish between acute rejection and infection before initiating therapy.

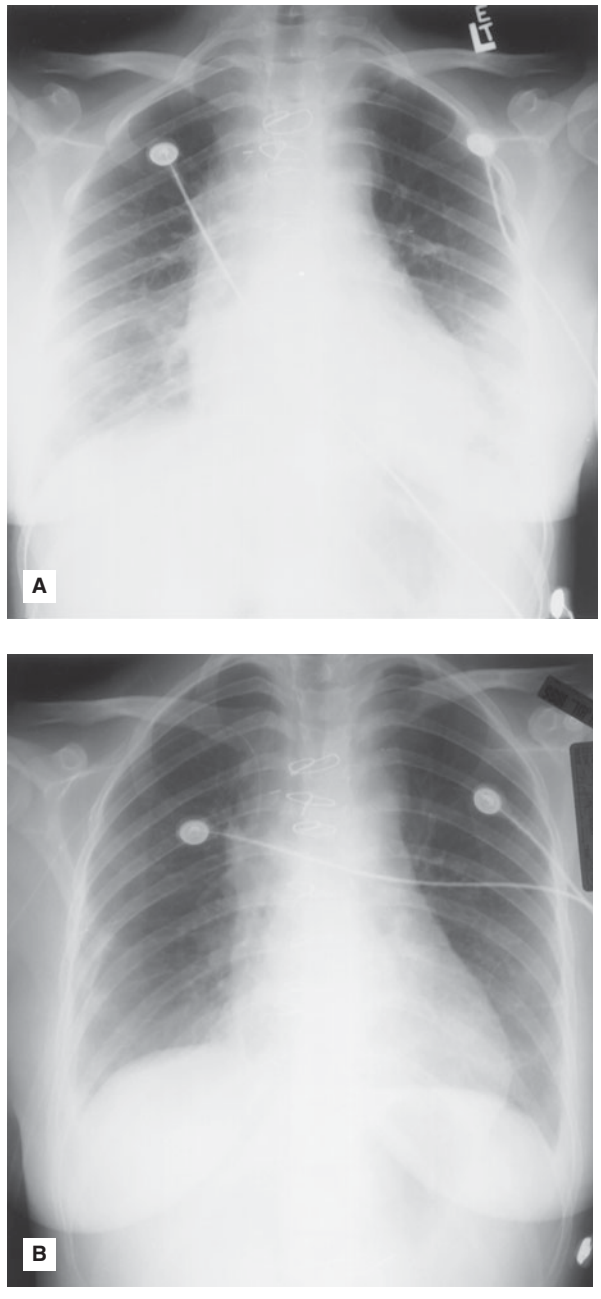

FIGURE 65-5 Acute and resolving lung rejection. (A) Chest radiograph illustrates bilateral infiltrates characteristic of acute pulmonary rejection. (B) Follow-up radiograph after pulsed methylprednisolone treatment of acute rejection demonstrating resolution of infiltrates.

Fiberoptic bronchoscopy (with transbronchial parenchymal lung biopsy and bronchoalveolar lavage) is the gold standard for the diagnosis of acute lung rejection and pulmonary infection. At least five biopsy specimens are taken from the lung allografts along with bronchoalveolar lavage, which is evaluated for cytology, undergoes microbial staining, and is cultured.[60] In addition to performing bronchoscopy with transbronchial biopsy in response to changes in clinical status and graft performance, most centers maintain a schedule of surveillance biopsies for lung recipients. Interestingly, surveillance bronchoscopy

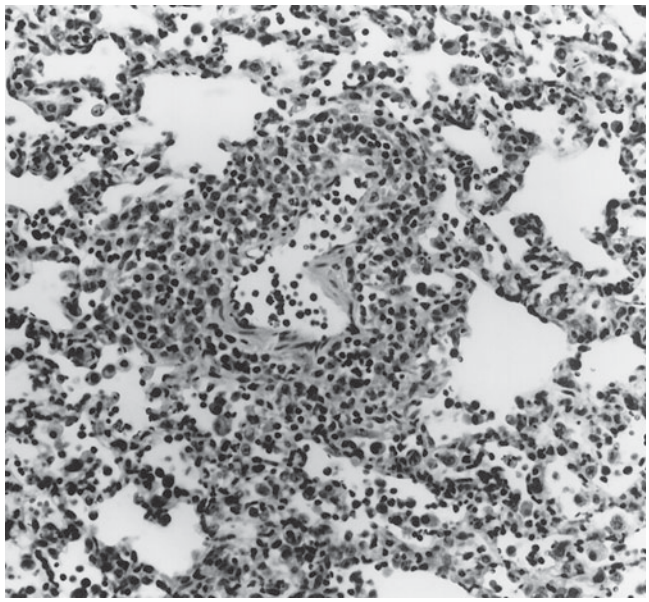

FIGURE 65-6 Moderate acute lung rejection. Moderate rejection is characterized by perivascular mononuclear cell infiltrates with extension into the adjacent alveolar septa (H&E stain; ×200).

reveals occult rejection or infection in 17 to 25% of transbronchial biopsy specimens from asymptomatic recipients. For patients undergoing bronchoscopy because of a change in clinical condition, 50 to 72% of biopsy specimens have shown evidence of rejection or infection. In most cases, positive biopsies directly guide successful treatment of rejection or infection.[61,62] Acute lung rejection is histologically characterized by lymphocytic perivascular infiltrates (Fig. 65-6). A grading scheme for acute lung rejection was developed by Clelland and Colin[63] and is presented in Table 65-6; a similar scheme was also developed by the Lung Rejection Study Group.[60]

As in cardiac transplantation, efforts are being made to develop noninvasive ways of diagnosing early acute lung rejection. Loubeyre and coworkers at the Hôpital Cardiovasculaire et Pneumologique report an association between "ground-glass" density areas seen on high-resolution computed tomography (HRCT) and histologically confirmed acute lung rejection in heart-lung transplant recipients.[64] They found that ground-glass opacities on HRCT had a sensitivity of 65% for detecting lung rejection and a specificity of 85% for detecting an acute lung complication.

TABLE 65-6 Grading System for Acute Lung Rejection

Grade	Histologic Appearance (Transbronchial Biopsy)
0	No significant inflammation; normal specimen
1	Small, infrequent perivascular infiltrates with or without bronchiolar lymphocytic infiltrates
2	Larger, more frequent perivascular lymphocytic infiltrates with or without moderate bronchiolar lymphocytic inflammation; occasional neutrophils and eosinophils
3	Extension of infiltrates into alveolar septa and alveolar spaces with or without bronchiolar mucosal ulceration

Treatment strategies for rejection involve augmentation of immunosuppression. At most institutions, the timing and severity of rejection episodes dictate therapy. A typical algorithm is shown in Fig. 65-7. Rejection episodes that are graded moderate or severe are treated with a "steroid pulse" (intravenous methylprednisolone 500 to 1000 mg/d for 3 consecutive days), followed by augmentation of the oral prednisone maintenance dose to 0.6 mg/kg/d. This maintenance dose is then tapered to 0.2 mg/kg/d over 3 to 4 weeks. Clinical and radiographic improvement (see Fig. 65-5B) after steroid therapy is often dramatic, rapid, and considered confirmatory of rejection. Mild episodes are initially treated by increasing oral prednisone dose, followed by a gradual taper over 3 to 4 weeks. Transbronchial biopsies are repeated 10 to 14 days following antirejection therapy to assess efficacy. Recurrent rejection episodes may be treated by a second steroid pulse and taper. Acute rejection refractory to steroid therapy may be treated with antilymphocyte preparations. Alternatively, primary immunosuppression may be switched between cyclosporine- and tacrolimus-based therapy. Finally, in especially difficult cases of persistent rejection, total lymphoid irradiation (TLI) may be useful.[65]

Chronic Rejection

Chronic lung allograft rejection poses the greatest limitation to the long-term benefits of lung transplantation. Chronic lung rejection most commonly presents as obliterative bronchiolitis (OB). The onset of OB typically occurs after the first 6 months to 1 year after transplantation, with a steadily increasing incidence thereafter. Recent data demonstrate that 70% of lung recipients are diagnosed with OB by the fifth postoperative year.[66]

Transbronchial biopsies remain the "gold standard" for diagnosing OB. The sensitivity of transbronchial biopsy for detecting OB has been reported between 17 and 87%.[62,67] Diagnostic yield of the biopsy procedure is related to the number of specimens taken, and current recommendations advise taking at least five specimens from each transplanted lung. Clearly, OB is a patchy process and therefore a large number of samples will be falsely negative owing to sampling error.

OB is a histologic diagnosis and is characterized by dense eosinophilic, submucosal scar tissue that partially or totally obliterates the lumen of small (2-mm) airways, particularly the terminal and respiratory bronchioles (Fig. 65-8). The physiologic consequences are decreased arterial P_{O_2}, FEV_1, $FEF_{25–75}$ forced expiratory flow at 25 to 75% (midrange) of lung volumes, and FEF_{50}/FVC (ratio of FEF_{50} to forced vital capacity). A characteristic "bowing" of the expiratory limb of the flow-volume loop has also been associated with OB. Clinical symptoms may be nonspecific, and include cough and dyspnea with or without exertion. The term *bronchiolitis obliterans syndrome* (BOS) was developed to refer to patients who have clinical manifestations of obliterative bronchiolitis with or without proven histologic characteristics (Table 65-7). A standardized working formulation

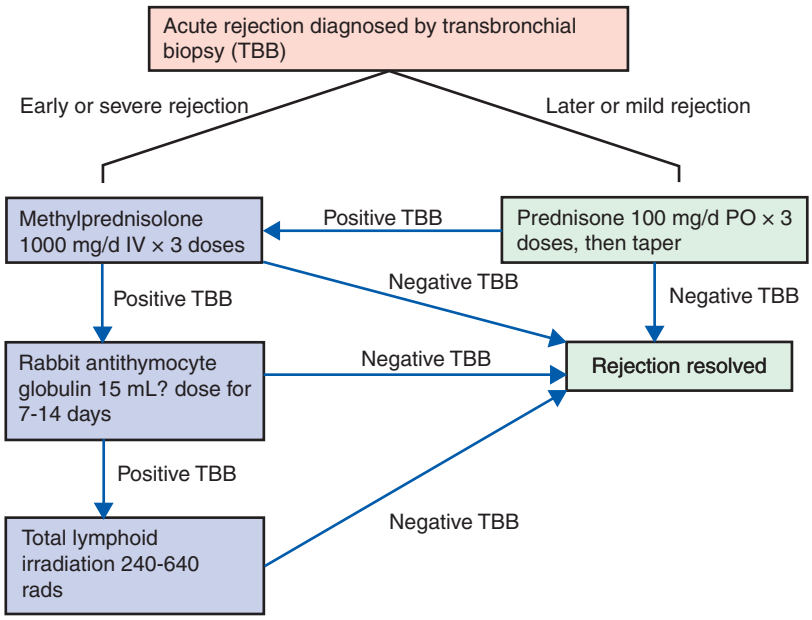

FIGURE 65-7 Typical algorithm for treating acute rejection in heart-lung and lung transplant recipients.

for the clinical staging of BOS was established by the ISHLT and is based on the ratio of the current FEV_1 to the best post-transplant FEV_1. Patients with a decline of 20% or greater in their FEV_1 (in the absence of infection or other process) are diagnosed with BOS, irrespective of pathologic evidence of obliterative bronchiolitis.[68]

Valentine and the Stanford group reported that measurements of small airway function (ie, FEF_{25-75}, FEF_{50}/FVC) are more sensitive indicators of BOS than the FEV_1 in bilateral lung transplant recipients.[66] An FEF_{50}/FVC persistently below 0.7 for 6 consecutive weeks was the most sensitive predictor of OB. Approximately 50% of bilateral lung recipients with biopsy-proven OB developed a fall in their FEF_{50}/FVC nearly 4 months before fulfilling the ISHLT working group criteria for BOS.

Experimental and clinical evidence suggests that the etiology of OB stems from the injury of the bronchial epithelium by one or more mechanisms. These include gastroesophageal reflux disease (GERD), infection (particularly CMV), chronic inflammation owing to impaired mucociliary clearance, and immunologic mechanisms.[55] These insults result in airway epithelial damage and, subsequently, an exaggerated healing response. Along with this injury, there is increased expression of major histocompatibility class II antigens in the bronchial epithelium. In a recent meta-analysis, Sharples and coworkers found that acute rejection is a risk factor for later development of OB.[69] In keeping with this finding is the association between BOS and decreased levels of immunosuppression (as may occur with noncompliance). Lymphocytic bronchitis and bronchiolitis were also closely associated with development of OB. CMV pneumonitis, other pulmonary infections, and HLA mismatching are also linked to the development of OB in small retrospective studies. Novick and coworkers recently reported on the relationship between OB, donor age, and graft ischemic times.[43] Using data from the ISHLT registry, they found a higher rate of OB at 3 years in recipients of grafts from donors greater than age 55 who were also subjected to 6 to 8 hours of ischemia. GERD has been recently proposed as a mechanism for the development of OB.[70] Up to 75% of patients have demonstrable postoperative reflux based on pH studies, which may result from intraoperative vagal damage, impaired cough and airway mucociliary clearance, immunosuppression, or preexisting GERD.[71] These patients have been shown to demonstrate a survival benefit as well as delayed onset of BOS after antireflux surgery in the postoperative setting.[72,73]

The current management of OB hinges on prevention, close surveillance, and immediate therapeutic intervention when patients become symptomatic or asymptomatic physiologic changes occur. Patients are encouraged to perform incentive spirometry

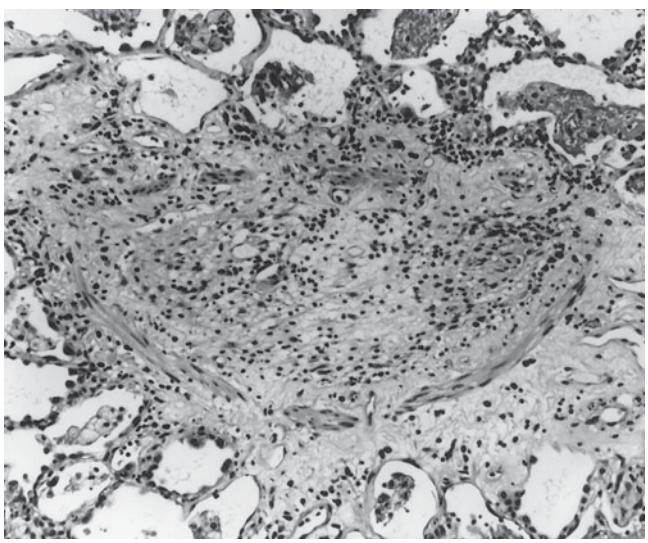

FIGURE 65-8 Bronchiolitis obliterans. Chronic airway rejection is characterized by luminal narrowing or replacement by dense eosinophilic collagenous scar tissue. Inflammatory cells may be seen in this case (H&E stain; ×150).

TABLE 65-7 Working formulation for bronchiolitis obliterans syndrome

$0_{a \text{ or } b}$	No significant abnormality: FEV_1 80% of baseline
$1_{a \text{ or } b}$	Mild bronchiolitis obliterans syndrome: FEV_1 66–80% of baseline
$2_{a \text{ or } b}$	Moderate bronchiolitis obliterans syndrome: FEV_1 51–65% of baseline
$3_{a \text{ or } b}$	Severe bronchiolitis obliterans syndrome: FEV_1 50% of baseline

a = Without pathologic evidence of obliterative bronchiolitis; b = with pathologic evidence of obliterative bronchiolitis.

to prevent microatelectasis of lungs that are deprived of native innervation, lack bronchial circulation, and have impaired mucociliary clearance mechanisms. Moreover, all recipients are instructed to contact their transplant center or primary care physician on development of respiratory tract symptoms so that pulmonary function tests can be performed. Any alterations in $FEF_{25–75}$, FEF_{50}/FVC, or specific changes in the flow-volume loop are indications for bronchoscopy with bronchoalveolar lavage and transbronchial biopsy, especially in the absence of infectious bronchitis or pulmonary edema.

Augmentation of immunosuppression is the mainstay of therapy for BOS. The prednisone dose is increased to 0.6 to 1.0 mg/kg/d and slowly tapered to 0.2 mg/kg/d while concomitantly optimizing cyclosporine and azathioprine dosing. Ganciclovir is reinstituted during treatment for those patients at risk of reactivation CMV infection, and antimicrobial therapy is directed against any organisms isolated from bronchoalveolar lavage. Follow-up pulmonary function tests are performed. Pulmonary function can be stabilized in most patients, but significant improvement is uncommon. Unfortunately, relapse rates are greater than 50% and progressive pulmonary failure or infection because of increased immunosuppression are the most common causes of death in lung transplant patients after the second year.

Retransplantation is the only option for terminal respiratory failure secondary to OB. Although survival for patients undergoing retransplantation for OB is better than for those undergoing retransplantation for other reasons, it is still worse than survival of first-time transplant recipients. Novick and coworkers recently reported results from the Pulmonary Retransplant Registry.[30] They reviewed survival rates in 237 patients who underwent pulmonary retransplantation between 1985 and 1996. At 1, 2, and 3 years after retransplantation, survival was 47, 40, and 33%, respectively. Survival was higher in nonventilated, ambulatory patients and their freedom for OB was comparable to first-time transplant recipients. The authors conclude that pulmonary retransplantation should only be performed in carefully selected recipients who have a reasonable likelihood of long-term survival.

Airway Complications

Improvements in surgical technique and posttransplant management have resulted in a relatively low incidence of airway complications after lung transplantation. Nevertheless, up to 27% of cases are complicated by stenosis, necrosis, or dehiscence.[75] The avoidance of perioperative steroids has long been considered important in preventing airway complications. However, recent experimental and clinical evidence suggests that the detrimental effect of steroids may be overestimated.[76] The most common airway complications are partial anastomotic dehiscence and stricture. Such complications are usually diagnosed by bronchoscopy. Airway dehiscence is treated by reoperation or close observation and supportive care. Strictures are treated by balloon or bougie dilatation, often with stent placement.

Infection

Bacterial, viral, and fungal infections are leading causes of morbidity and mortality in lung transplantation. The rate of infection is higher in this transplant group compared with other solid organ transplant recipients. This may be related to the lung allograft's direct exposure to airway colonization and aspiration, as well as its impaired cough reflex and mucociliary clearance. The risk of infection and infection-related death peaks in the first few months after transplantation, declining to a low persistent rate thereafter. Posttransplant infections can be classified broadly into those that occur early or late after transplantation. Early infections, occurring within the first month after transplantation, are commonly bacterial (especially gram-negative bacilli) and manifest as pneumonia, mediastinitis, urinary tract infections, catheter sepsis, and skin infections. In the late posttransplant period, opportunistic viral, fungal, and protozoan pathogens become more prevalent. The lungs, central nervous system, gastrointestinal tract, and skin are the usual sites of invasion.

Bacterial infections, particularly caused by gram-negative bacteria, predominate during the early postoperative period. Between 75 and 97% of bronchial washings obtained from donor lungs before organ retrieval culture at least one organism.[77] Posttransplant invasive infections are frequently caused by organisms cultured from the donor. Conversely, bacterial infections developing in patients with septic lung disease, particularly cystic fibrosis, most commonly originate from the recipient's airways and sinuses. Treatment of bacterial infections generally involves characterization of the infective agent (eg, cultures, antibiotic sensitivities), source control (eg, catheter removal, debridement), and appropriate antibiotic regimens.

CMV infection occurs most often at 1 to 3 months after transplantation and presents either as a primary infection or reactivation of a latent infection. By definition, primary infection results when a previously seronegative recipient is infected through contact with tissue or blood from a seropositive individual. The donor organ itself is thought to be the most common vector of primary CMV infections. Reactivation infection occurs when a recipient who is seropositive prior to transplant develops clinical CMV infection during immunosuppressive therapy. Seropositive recipients are also subject to infection by new strains of CMV. Primary infection in previously seronegative recipients is generally more serious than reactivation or reinfection in seropositive patients.

Clinically, CMV infection has protean manifestations, including leukopenia with fever, pneumonia, gastroenteritis, hepatitis, and retinitis. CMV pneumonitis is the most lethal of these, with 13% mortality, and retinitis remains the most refractory to treatment. Diagnosis of CMV infection is made by direct culture of the virus from blood, urine, or tissue specimens, a fourfold increase in antibody titers from baseline, or characteristic histologic changes (ie, markedly enlarged cells and nuclei containing basophilic inclusion bodies). Most cases respond to ganciclovir and hyperimmune globulin.

CMV has been implicated as a trigger for OB69 as well as an inhibitor of cell-mediated immunity. CMV negative donors comprise less than 20% of the donor organ pool, and owing to organ scarcity, most transplant centers perform transplants across CMV serologic barriers using ganciclovir and/or hyperimmune globulin prophylactic protocols in CMV-positive donors and/or recipients. A study by Valantine and coworkers found that

the combined use of ganciclovir and hyperimmune globulin was superior to ganciclovir alone as prophylaxis against CMV. Moreover, the ganciclovir/hyperimmune globulin cohort had longer survival at 3 years and greater freedom from obliterative bronchiolitis.[78]

Invasive fungal infections peak in frequency between 10 days and 2 months after transplantation. Treatment consists of fluconazole, itraconazole, or amphotericin B. Reichenspurner and coworkers have reported that the actuarial incidence and linearized rate of fungal infections were significantly reduced in recipients who received inhaled amphotericin prophylaxis.[79]

The institution of prophylaxis with oral trimethoprim-sulfamethoxazole (or inhalational pentamidine for sulfa-allergic patients) has effectively prevented *Pneumocystis carinii* pneumonia. The risk of *Pneumocystis* infection is highest during the first year after transplant. However, as infections can also occur late after transplant, most centers recommend prophylactic therapy be continued for life.

Infection prophylaxis is comprised of vaccinations, perioperative broad-spectrum antibiotics, and long-term prophylactic antibiotics. Pretransplant inoculations with pneumococcal and hepatitis B vaccines, as well as DPT boosters, are recommended. All transplant recipients should receive annual influenza vaccinations. Although perioperative antibiotic regimens vary widely between transplant centers, first-generation cephalosporins (eg, cefazolin) or vancomycin are commonly used. Long-term prophylaxis typically includes nystatin mouthwash, trimethoprim-sulfamethoxazole, aerosolized amphotericin B, and antivirals such as acyclovir or ganciclovir.

Neoplasm

Transplant recipients have a higher incidence of neoplasia than that of the general population.[80] This is undoubtedly due to chronic immunosuppression. Recipients are predisposed to a variety of tumors, including skin cancer, B-cell lymphoproliferative disorders, carcinoma in situ of the cervix, carcinoma of the vulva and anus, and Kaposi's sarcoma. On average, tumors appear approximately 5 years after transplantation.[59]

The incidence of B-cell lymphoproliferative disorders in transplant patients is a staggering 350 times greater than that of the normal age-matched population. Posttransplant lymphoproliferative disorder (PTLD) has been reported in 6% of lung transplant recipients.[81] PTLD most commonly occurs within the first year after transplantation, and is associated with Epstein-Barr virus infection. Treatment consists of reducing immunosuppression and administration of an antiviral agent such as acyclovir or ganciclovir. A response rate of 30 to 40% can be expected, and recurrence is uncommon. Chemotherapy and radiotherapy have been used successfully in some cases. During therapy, close monitoring of the graft, along with clinical assessment of tumor status is essential.

Long-Term Results in Lung Transplantation

Pulmonary function measured by spirometry and arterial blood gases is markedly improved within several months after transplantation, with a normalization of ventilation and gas exchange after 1 to 2 years.[82] The long-term survival for lung transplant recipients reported to the Registry of the International Society for Heart and Lung Transplantation is shown in Fig. 65-9. Survival rates among transplants performed between January 1994 and June 2007 were 89% at 3 months, 79% at 1 year, 64% at 3 years, 52% at 5 years, and 29% at 10 years.[1] Survival for double lung transplant exceeds that of single lung transplantation, but given the variety of factors that influence this outcome (recipient factors, donor factors, and implantation techniques) it is difficult to draw any conclusions from this trend. Survival is clearly influenced by recipient age, with 1-year survival at 72% among patients older than 65 compared with 80% survival among patients less than 50.[1] Patients with COPD and IPF (who often are older with more comorbidities) tend to fare poorer than those with CF, IPAH, sarcoidosis, and AAT deficiency emphysema (as shown in Fig. 65-10). In an analysis of 10-year survivors, double lung recipients and patients with fewer hospitalizations for rejection were found to have improved long-term survival after lung transplantation.[83] Operative mortality is clearly affected by center volume, with high volume centers (≥20 implants per year) having a 30-day mortality rate of just 4.1%.[84] With increasing experience with lung transplantation worldwide, both short- and long-term survival have improved over time.

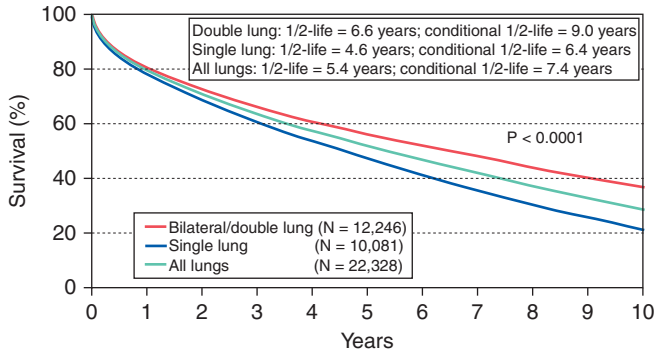

FIGURE 65-9 Kaplan-Meier survival by procedure type for adult lung transplants reported to the ISHLT registry from January 1994 through June 2007. (*From Christie JD, et al: The Registry of the International Society For Heart and Lung Transplantation: Twenty-Sixth Official Adult Lung and Heart-Lung Transplantation Report—2009. J Heart Lung Transplant 2009; 28[10]:1031-1049.*)

HEART-LUNG TRANSPLANTATION

History of Heart-Lung Transplantation

Long before the first successful human heart-lung transplants were reported, thoracic organ transplantation flourished in the laboratory. In the 1940s, Demikhov developed the first successful method of en bloc heart-lung transplantation in dogs. In his series of 67 dogs, the longest survivor lived for 6 days postoperatively.[85] These remarkable studies demonstrated the technical feasibility of heart and lung replacement, yet remained largely unknown in the West until the 1960s. In 1953, Marcus and colleagues at the Chicago Medical School described a technique for heterotopic heart-lung grafting to the abdominal aorta and inferior vena cava in dogs.[86] Later studies in the

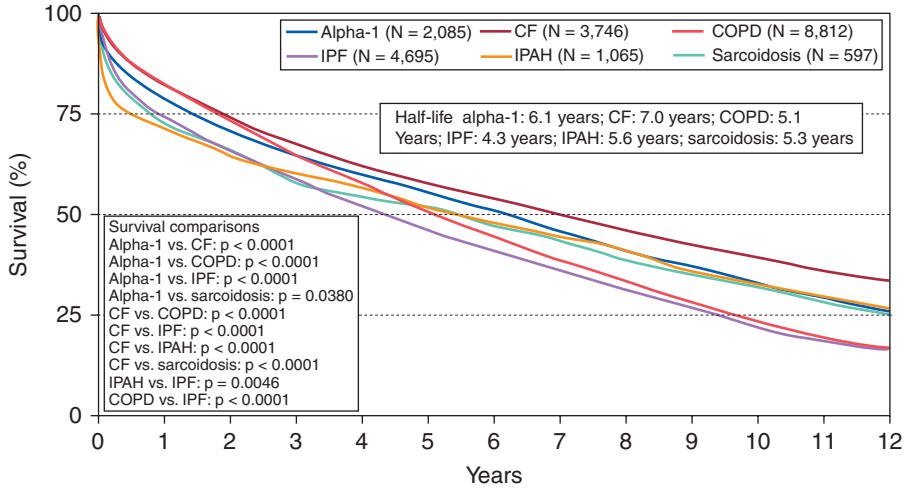

FIGURE 65-10 Kaplan-Meier survival by diagnosis for adult lung transplants reported to the ISHLT registry from January 1990 through June 2007. Alpha 1 = Alpha 1-antitrypsin deficiency emphysema; CF = cystic fibrosis; COPD = chronic obstructive pulmonary disease; IPAH = idiopathic pulmonary arterial hypertension; IPF = idiopathic pulmonary fibrosis. (*From Christie JD, et al: The Registry of the International Society for Heart And Lung Transplantation: Twenty-Sixth Official Adult Lung and Heart-Lung Transplantation Report—2009. J Heart Lung Transplant 2009; 28[10]:1031-1049.*)

1960s and early 1970s examined the physiologic effect of total denervation on heart and lung function. Studies by Webb and colleagues in 1961 proved discouraging as they showed failure to resume normal spontaneous respiration following heart-lung replacement in dogs.[87] This physiologic phenomenon was confirmed by several other groups using canine models, including Lower and colleagues in 1961.[88] Fortunately, later studies in primates by Haglin,[89] Nakae,[90] Castaneda,[91,92] and their colleagues showed that unlike dogs, primates resume a normal respiratory pattern after complete denervation with cardiopulmonary replacement. The 1970s saw the development of improved immunosuppressive medications, particularly cyclosporine, which prevented rejection of primate heart-lung allografts after transplantation. Studies from Stanford University showed survival for well over 5 years after heart-lung allografting in primates.[93] In the 1980s, Reitz and colleagues reported a modification to the standard technique of heart-lung replacement, using a retained portion of the right atrium for a single inflow anastomosis instead of separate caval anastomoses.[94] This technique preserved the donor sinoatrial node and eliminated the potential for caval anastomotic stenosis. These studies laid the groundwork for a clinical trial of heart-lung transplantation at Stanford University. On March 9, 1982, Reitz and colleagues performed the first successful human heart-lung transplant in a 45-year-old woman with end-stage primary pulmonary hypertension.[95]

Indications for Heart-Lung Transplantation

Upon its introduction in 1982, heart-lung transplantation provided a life-saving therapeutic option for patients with end-stage pulmonary and cardiopulmonary disease. However, the number of heart-lung transplants performed peaked in 1990 as the techniques of single and double lung transplantation began to achieve improved outcomes in patients with isolated end-stage lung disease. This, combined with the donor shortage of heart-lung blocs, has restricted the procedure to patients with severe cardiopulmonary diseases (most commonly congenital heart disease with Eisenmenger's syndrome, idiopathic pulmonary arterial hypertension, and cystic fibrosis). Since 2003, between 75 and 86 heart-lung transplant procedures have been performed worldwide each year.[1]

The diagnostic profile of heart-lung transplant recipients reported to the Registry of the International Society for Heart and Lung Transplantation (ISHLT) is shown in Table 65-8. Congenital heart disease (atrial and ventricular septal defects, patent ductus arteriosus) with secondary pulmonary hypertension (Eisenmenger's syndrome) is the most frequent indication, found in over one-third of the patients. Complex congenital heart defects that have been treated successfully with heart-lung transplantation include univentricular heart with pulmonary atresia, truncus arteriosus, and hypoplastic left heart syndrome. Data regarding the long-term survival benefit of heart-lung transplantation in patients with Eisenmenger's syndrome are mixed.[96] Some data suggest that pulmonary hypertension in these patients has a more favorable prognostic course than other types of pulmonary hypertension. There is clear evidence, however, that quality of life is improved by transplantation.[97] In patients with simpler cardiac defects, repair of the cardiac defect combined with single or bilateral lung transplantation is an alternative option.

Primary pulmonary hypertension with right-sided heart failure is the second most common diagnosis in heart-lung transplant recipients. Nearly one-fourths of patients in the ISHLT registry carry this diagnosis. Recently, there has been a shift toward single and bilateral lung transplantation in this population.[98] This new paradigm is based on the finding that normalization of pulmonary pressures following lung transplantation often allows for recovery of right heart function. However, in patients with severe right-sided heart failure and primary pulmonary hypertension, heart-lung transplantation is clearly the operation of choice.

TABLE 65-8 Distribution of Diagnoses Among Adult Heart-Lung Transplant Recipients

Diagnosis	No. (%)
Congenital heart disease	921 (34.9)
Idiopathic pulmonary arterial hypertension	719 (27.2)
Cystic fibrosis	373 (14.1)
COPD disease/emphysema	101 (3.8)
Acquired heart disease	77 (2.9)
Idiopathic pulmonary fibrosis	76 (2.9)
AAT deficiency emphysema	53 (2.0)
Sarcoidosis	37 (1.4)
Retransplant:	
Not obliterative bronchiolitis	31 (1.2)
Obliterative bronchiolitis	24 (0.9)

The remainder of heart-lung transplants are performed for a variety of cardiac and pulmonary diseases. These include cystic fibrosis and other septic lung diseases, severe coronary artery disease with concomitant end-stage lung disease, and primary parenchymal lung disease with severe right-sided heart failure (eg, idiopathic pulmonary fibrosis, lymphangioleiomyomatosis, sarcoidosis, and desquamative interstitial pneumonitis).

Patient Selection for Heart-Lung

As in lung transplantation, patients are stratified according to LAS with similar listing criteria and contraindications for both groups of patients. Age restrictions tend to be somewhat more selective in most centers, with an upper recipient age limit of 50 years. Most recipients for heart-lung transplantation also fall within New York Heart Association functional classes III or IV.[16] Careful attention to size matching must be carried out in the donor selection process. In a series of 82 heart-lung transplants at Papworth Hospital, Tamm and coworkers recorded recipient lung volumes posttransplantation, followed by a comparison to preoperative and predicted volumes to evaluate the influence of donor lung size and recipient underlying disease.[100] The investigators demonstrated that, by 1 year after surgery, total lung capacity (TLC) and dynamic lung volume returned to values predicted by the patient's sex, age, and height. They proposed that the simplest method of matching donor lung size to that of the recipient is to use their respective predicted TLC values. Moreover, they concluded that recipients should attain their predicted lung volumes by 1 year posttransplantation, and failure to do so suggests possible complications within the transplanted lungs.

As in lung transplantation, preoperative HLA matching is not feasible given the necessity of short ischemic times. However, histocompatibility does seem to impact on patient outcomes. Harjula and coworkers at Stanford evaluated the relationship between HLA matching and outcomes in heart-lung transplantation.[99] Among 40 heart-lung transplant recipients evaluated, they found a significant increase in graded obliterative bronchiolitis with total mismatch at the HLA-A locus.

Operative Technique

Procurement

Exposure and cannulation for heart-lung blocs follows the same procedure as for lung procurement. After cross-clamp, the bloc is dissected free from the esophagus commencing at the level of the diaphragm and continuing cephalad to the level of the carina. Dissection is kept close to the esophagus, and care is taken to avoid injury to the trachea, lung, or great vessels. The posterior hilar attachments are divided. The lungs are inflated to a full normal tidal volume, and the trachea is stapled at the highest point possible with a TA-55 stapler (US Surgical, Norwalk, CT), at least four rings above the carina (Fig. 65-3E). The trachea is then divided above the staple line, and the entire heart-lung bloc is removed from the chest.

Recipient Implant

The recipient is positioned supine and the chest is entered through a median sternotomy. A sternal retractor is placed, and both pleural spaces are opened anteriorly from the level of the diaphragm to the level of the great vessels (Fig. 65-11A). Electrocautery is used to divide any pleural adhesions. The anterior pericardium is excised, and the lateral segments are preserved to support the heart and protect the phrenic nerves. A 3-cm border of the pericardium should be left both anterior and posterior to each phrenic nerve extending from the level of the diaphragm to the level of the great vessels (Fig. 65-11B). An alternative approach is to create posterior pericardial apertures where the pulmonary veins enter into the pericardium. A border of pericardium is left posterior to the phrenic nerves, whereas the entire remaining pericardium anterior to the phrenic nerves is left intact. After fully heparinizing the recipient, the ascending aorta is cannulated near the base of the innominate artery, and the venae cavae are individually cannulated laterally and snared. Cardiopulmonary bypass with systemic cooling to 28 to 30°C is instituted, and the heart is excised at the midatrial level. The aorta is divided just above the aortic valve, and the pulmonary artery is divided at its bifurcation (Fig. 65-11C). The left atrial remnant is then divided vertically at a point halfway between the right and left pulmonary veins.

The posterior edge of the left atrial and pulmonary venous remnant is developed in a manner allowing the left inferior and superior pulmonary veins to be displaced over into the left

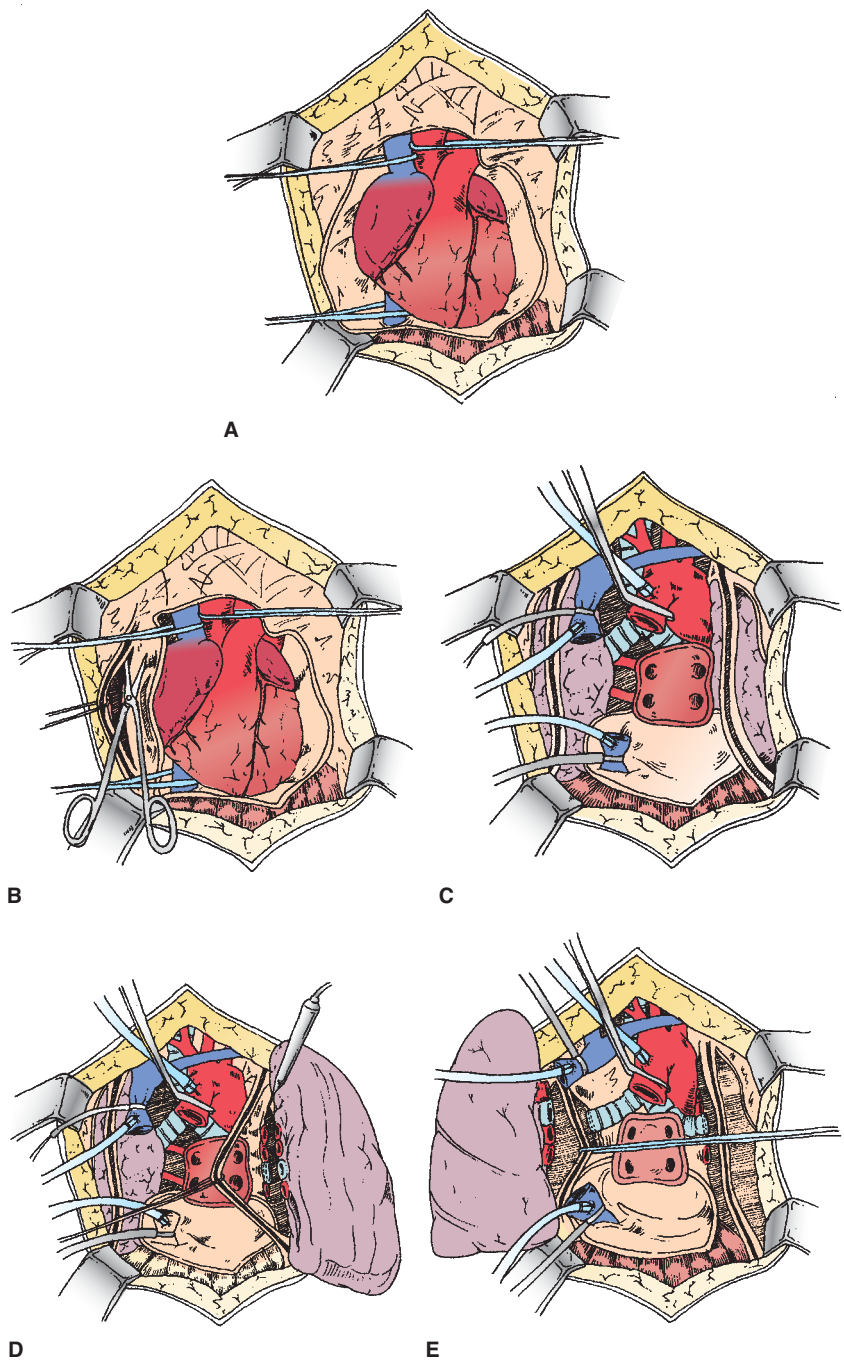

FIGURE 65-11 Recipient operation for heart-lung transplantation. (A) Through a median sternotomy, the anterior pericardium is partially removed and the ascending aorta and both venae cavae are dissected and encircled with tapes. (B) The right phrenic nerve is carefully separated from the right hilum, providing a space for inserting the right lung of the graft. (C) Cannulation for cardiopulmonary bypass consists of a cannula in the high ascending aorta and separate vena caval cannulas. Once on bypass, the native heart is excised in a manner similar to that for standard cardiac explantation. (D,E) Left and right pneumonectomies are performed by dividing the respective inferior pulmonary ligament, pulmonary artery and veins, and mainstem bronchus. (F) The heart-lung graft is moved into the chest beginning with passage of the right lung underneath the right phrenic nerve pedicle, followed by manipulation of the left lung beneath the left phrenic nerve pedicle. (G) The tracheal anastomosis is performed with a continuous 3-0 polypropylene suture. (H) The caval and aortic anastomoses are performed with a continuous 4-0 polypropylene suture.

chest. Following division of the pulmonary ligament, the left lung is moved into the field, allowing full dissection of the posterior aspect of the left hilum, with care taken to avoid the vagus nerve posteriorly. Once this is completed, the left main pulmonary artery is divided (Fig. 65-11D), and the left main bronchus is stapled with a TA-30 stapler and divided. The same technique of hilar dissection and division is repeated on the right side (Fig. 65-11E), and both lungs are removed from the chest.

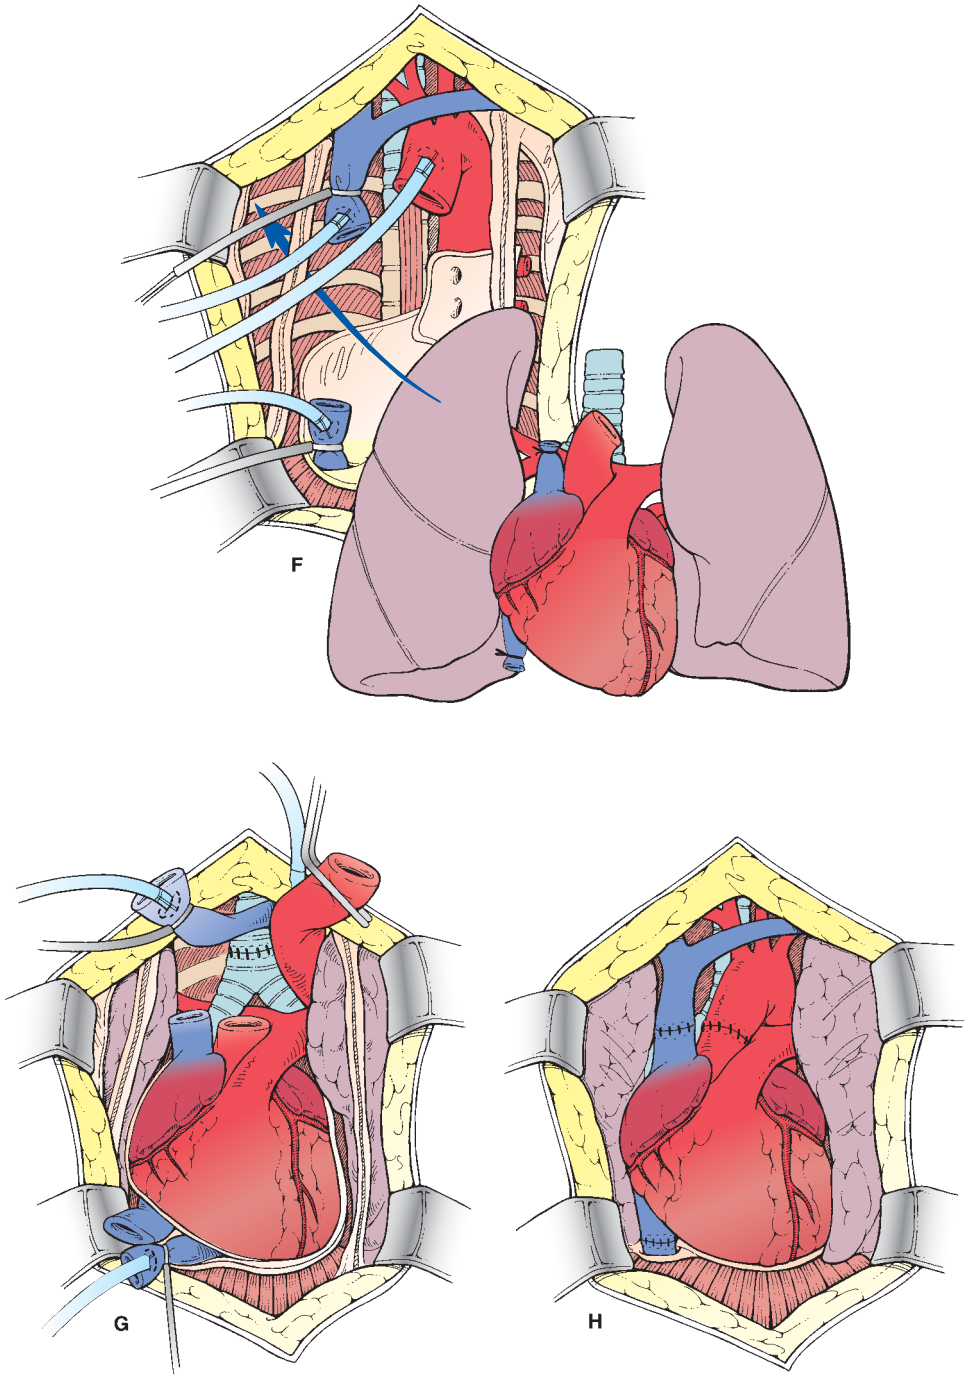

FIGURE 65-11 (*Continued*)

The native main pulmonary artery remnant is removed, leaving a portion of the pulmonary artery intact adjacent to the underside of the aorta (near the ligamentum arteriosus) to preserve the left recurrent laryngeal nerve. Attention is then turned to preparing the distal trachea for anastomosis. The stapled ends of the right and left bronchi are grasped and dissection is carried up to the level of the distal trachea. Bronchial vessels are individually identified and carefully ligated. Patients with congenital heart disease and pulmonary atresia or severe cyanosis secondary to Eisenmenger's syndrome may have large mediastinal bronchial collaterals that must be meticulously ligated. Perfect hemostasis is necessary in this area of the dissection, because it is obscured once graft implantation is complete. Once absolute hemostasis is achieved, the trachea is divided at the carina with a no. 15 blade. The chest is now prepared to receive the heart-lung graft.

The donor heart-lung bloc is removed from its transport container and prepared by irrigating, aspirating, and culturing the tracheobronchial tree followed by trimming of the trachea to leave one cartilaginous ring above the carina. The heart lung graft is then lowered into the chest, passing the right lung beneath the right phrenic nerve pedicle. The left lung is then

gently manipulated under the left phrenic nerve pedicle (Fig. 65-11F). The tracheal anastomosis is performed using continuous 3-0 polypropylene suture (Fig. 65-11G). The posterior membranous portion of the anastomosis is performed first, followed by completion of the anterior aspect. Ventilation is then carried out with room air at half-normal tidal volumes to inflate the lungs and reduce atelectasis. Topical cooling with a continuous infusion of cold Physiosol into both thoraces is begun. To augment endomyocardial cooling and to exclude air from the graft, a third cold, "bubble-free" line is placed directly into the left atrial appendage.

Next, the bicaval venous anastomosis is performed. The recipient inferior vena cava is anastomosed to the donor inferior vena cava-right atrial junction with a continuous 4-0 polypropylene suture. At this point the patient is warmed toward 37°C, and the superior vena caval and aortic anastomoses are performed end-to-end with continuous 4-0 polypropylene sutures (Fig. 65-11H). After the ascending aorta and pulmonary artery are cleared of air, the aortic cross-clamp and caval tapes are removed. The left atrial catheter is removed, and the atrium is allowed to drain. The amputated left atrial stump is oversewn, and the pulmonary artery pulmonoplegia infusion site closed. The heart is defibrillated, and the patient is gradually weaned from cardiopulmonary bypass in the standard fashion. Methylprednisolone (500 mg) is administered to the recipient after heparin reversal with protamine sulfate.

PEEP at 3 to 5 cm H_2O and an F_{IO_2} of 40% is maintained. As in cardiac transplantation, isoproterenol (0.005 to 0.01 μg/kg/min) is usually initiated on graft reperfusion to increase the heart rate (~100 to 110 bpm) and to lower pulmonary vascular resistance. Temporary right atrial and ventricular pacing wires are placed. Right and left pleural "right angle" chest tubes are placed along each diaphragm, as well as a single mediastinal tube. The chest is closed in the standard fashion. Finally, the double lumen endotracheal tube is exchanged for a single lumen tube and the tracheal anastomosis is visualized by bronchoscopy before transporting the patient to the intensive care unit.

Lick and coworkers describe an interesting alternative to the standard technique in which the pulmonary hila are placed anterior to the phrenic nerves and direct caval anastomoses are used whenever feasible.[101] This modification obviates extensive dissection of the phrenic nerves and posterior mediastinum, decreasing the likelihood of phrenic and vagus nerve injury. Furthermore, the posterior mediastinum can readily be inspected for bleeding after implantation by rotating the heart-lung bloc anterior-medially while still on bypass.

Graft Physiology

For heart-lung recipients, denervation of the cardiac allograft leads to additional physiologic characteristics beyond what is seen in isolated lung transplantation. The denervated heart loses its sympathetic and parasympathetic autonomic regulation, thereby impacting on heart rate, contractility, and coronary artery vasomotor tone. The resting heart rate is generally higher due to the absence of vagal input. Respiratory sinus arrhythmia and carotid reflex bradycardia are absent. Interestingly, the denervated heart develops an increased sensitivity to catecholamines because of increased beta-adrenergic receptor density and loss of norepinephrine uptake in postganglionic sympathetic neurons.[102,103] This augmented sensitivity plays an important role in maintaining an adequate cardiac response to exercise and stress. During exercise, the recipient experiences a steady but delayed increase in heart rate, primarily because of a rise in circulating catecholamines. This initial rise in heart rate is subsequently accompanied by an immediate increase in filling pressures resulting from increased venous return. These changes lead to increased stroke volume and cardiac output sufficient to sustain activity. Although the coronary circulation's ability to dilate to meet increased myocardial oxygen demand is not eliminated in an uncomplicated heart-lung transplant, this reserve is abnormal in the presence of rejection, hypertrophy, or regional wall abnormalities.

Postoperative Management

Approximately 10 to 20% of heart-lung graft recipients experience some degree of transient sinus node dysfunction in the immediate perioperative period. This often manifests as sinus bradycardia and usually resolves within a week. The use of bicaval venous anastomoses has been reported to lower the incidence of sinus node dysfunction and improve tricuspid valve function.[104] Because cardiac output is primarily rate dependent after heart-lung transplantation, the heart rate should be maintained between 90 and 110 beats per minute during the first few postoperative days using temporary pacing or isoproterenol (0.005 to 0.01 μg/kg/min) as needed. Although rarely seen, persistent sinus node dysfunction and bradycardia may require a permanent transvenous pacemaker. Systolic blood pressure should be maintained between 90 and 110 mm Hg using nitroglycerin or nitroprusside for afterload reduction, if necessary. "Renal-dose" dopamine (3 to 5 μg/kg/min) is used frequently to augment renal blood flow and urine output. The adequacy of cardiac output is indicated by warm extremities and a urine output greater than 0.5 mL/kg/h without diuretics. Cardiac function generally returns to normal within 3 to 4 days, at which time inotropes and vasodilators can be weaned.

Nevertheless, depressed global myocardial performance is occasionally seen during the acute postoperative setting. The myocardium may be subject to prolonged ischemia, inadequate preservation, or catecholamine depletion before implantation. Hypovolemia, cardiac tamponade, sepsis, and bradycardia are also potential contributors and should be treated expeditiously if they are present. A Swan-Ganz pulmonary artery catheter should be used in cases of persistently abnormal hemodynamics. Surveillance endomyocardial biopsies are performed at 3 months and then annually in heart-lung graft recipients.

Complications

The most common complications after heart-lung transplantation include hypertension (88.6%), renal dysfunction (28.1%), hyperlipidemia (66.4%), diabetes (20.9%), coronary artery vasculopathy (8.2%), and bronchiolitis obliterans (27.1%).[1] Common causes of death include graft failure and technical complications within the first 30 days, followed by non-CMV infections and BOS in the longer term.[1] Acute rejection remains

a challenge, occurring in more than 67% of heart-lung patients within the first year between 1981 and 1994 at Stanford University.[105] Experimental and clinical evidence suggests that pulmonary and cardiac rejections occur independently of one other. Nevertheless, Higenbottam and coworkers at Papworth Hospital reported a surprisingly low diagnostic yield from routine endomyocardial biopsies in heart-lung recipients compared with functional or histologic tests of pulmonary rejection. Based on these findings, the authors concluded that transbronchial biopsy eliminates the need for routine endomyocardial biopsies in heart-lung transplant recipients.[106] These findings were supported by Sibley and coworkers at Stanford University, who demonstrated discordance between findings on endomyocardial and transbronchial biopsies during episodes of acute rejection. Endomyocardial biopsies are most often normal despite findings of pulmonary rejection on transbronchial biopsy.[62] At Stanford, surveillance endomyocardial biopsies have been abandoned in patients in whom transbronchial biopsies can be reliably performed. Respiratory failure secondary OB represents a long-term complication of heart-lung transplant at a rate similar to double lung transplantation. Among heart-lung recipients with OB, Adams and coworkers at Harefield Hospital noted that retransplant survival rates were worse for those undergoing combined heart-lung replacement compared with patients who underwent isolated lung replacement.[74] The group also noted the following factors were associated with improved survival after retransplant: absence of preformed antibodies, retransplantation at least 18 months after the original transplantation, and negative preoperative sputum cultures.

Accelerated graft coronary artery disease (CAD) or graft atherosclerosis is another major obstacle to long-term survival in heart-lung transplant recipients. Significant graft CAD resulting in diminished coronary artery blood flow may lead to arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive heart failure. Classic angina caused by myocardial ischemia is usually not noted in transplant recipients because the cardiac graft is not innervated. Multiple etiologies for graft CAD have been proposed, all focusing on chronic, immune-mediated damage to the coronary vascular endothelium. In fact, elevated levels of antiendothelial antibodies have been correlated with graft CAD. Unlike coronary artery occlusive disease in the native heart, which tends to be a more focal process, transplant atherosclerosis is a more diffuse vascular narrowing extending symmetrically into distal branches. Histologically, transplant arteriopathy is characterized by concentric intimal proliferation with smooth muscle hyperplasia (Fig. 65-12).

Coronary angiograms are performed on a yearly basis to identify recipients with accelerated CAD. Angiography is limited, however, to assessment of luminal diameter. Intracoronary ultrasound, by contrast, can assess both vascular wall morphology and luminal diameter, making it a more sensitive tool to detect the diffuse coronary intimal thickening typical of graft atherosclerosis. Interestingly, graft CAD occurs at a reduced incidence in heart-lung recipients compared with the cardiac transplantation population.[107] A retrospective survey at Stanford revealed 89% of heart-lung recipients were free from graft CAD at 5 years, compared with 73% of heart transplant recipients.

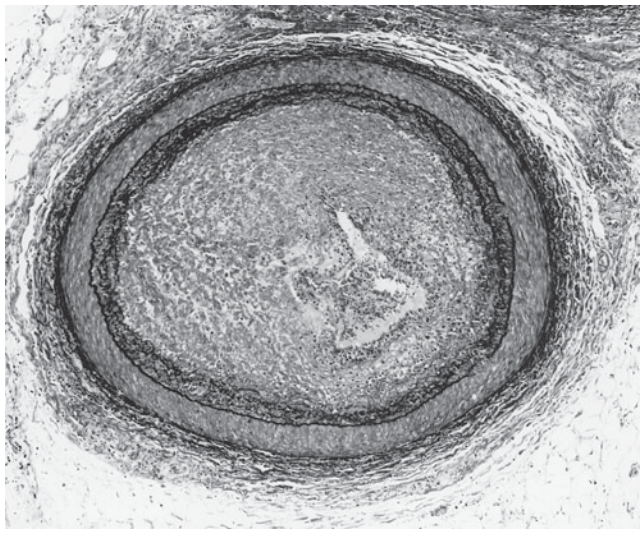

FIGURE 65-12 Cardiac graft atherosclerosis. Complete luminal obliteration by a concentric fibrointimal proliferation was observed at postmortem in this heart-lung transplant patient (Elastin von Gieson stain; ×60).

Clinically observed risk factors for developing this condition in heart transplant recipients include donor age greater than 35 years, incompatibility at the HLA-A1, A2, and DR loci, hypertriglyceridemia (serum concentration greater than 280 mg/dL), frequent acute rejection episodes, and documented recipient CMV infection. It is not clear whether these risk factors can be extended to the heart-lung transplant population, although CMV infection has been implicated.[108] Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used to treat discrete proximal lesions in some cases of graft CAD. However, the only definitive therapy for diffuse graft CAD is retransplantation. Effective prevention of graft CAD will rely on development of improved immunosuppression, recipient tolerance induction, improved CMV prophylaxis, and inhibition of vascular intimal proliferation.

Infection represents another significant postoperative challenge in heart-lung transplantation. Between 1981 and 1994 at Stanford, only 20% of heart-lung transplant recipients were free from infection 3 months after transplantation. In a retrospective analysis of 200 episodes of serious infections occurring in 73 heart-lung recipients at Stanford between 1981 and 1990, Kramer and coworkers[109] found that half of all infections were caused by bacteria, whereas fungal infections accounted for only 14% of total infections. The most common viral agent was CMV, occurring primarily in the second month after transplantation and comprising 15% of all viral infections. Other viral infections (ie, herpes simplex, adenovirus, respiratory syncytial virus) were less common. Five percent of infections were attributed to *Pneumocystis carinii*, typically occurring 4 to 6 months after transplantation, and 2% were caused by *Nocardia*, generally appearing after the first year. There was no significant difference in the incidence of infections between patients receiving triple-drug or double-drug (cyclosporine and prednisone) immunosuppression. Infectious mortality comprised 40% of all deaths.

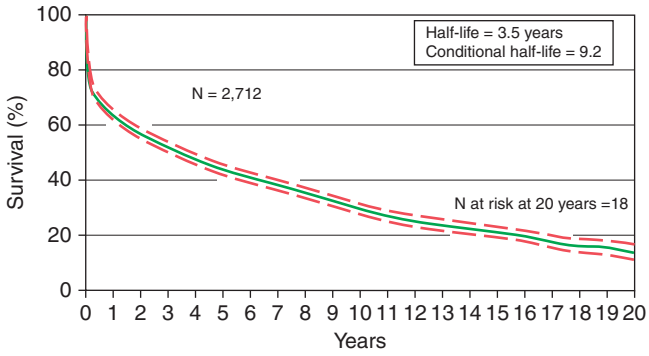

FIGURE 65-13 Kaplan-Meier survival for heart-lung transplantation, 1982 through 2007. (*From Christie JD, et al: The Registry of the International Society for Heart and Lung Transplantation: Twenty-Sixth Official Adult Lung and Heart-Lung Transplantation Report—2009. Long-Term Results in Heart-Lung Transplantation

Survival rates of 72% at 3 months and 64% at 1 year have been reported in the ISHLT registry.[1] Mortality rates taper off significantly at a year posttransplant, as illustrated in Fig. 65-13. As with lung transplantation, outcomes have improved over time and are affected by recipient diagnosis.[1] Graft failure, technical complications, and non-CMV infections are all common causes of 30-day mortality, with BO and non-CMV infections impairing long-term survival.

CONCLUSION

The evolution of heart-lung and lung transplantation from rudimentary laboratory experimentation to its current prominence as an accepted therapy for end-stage cardiopulmonary disease is a product of ingenuity, perseverance, skill, and courage. Many debilitated patients, both adult and pediatric, now have an opportunity to resume full and active lifestyles after heart-lung and lung transplantation. Nevertheless, significant hurdles have yet to be overcome, including issues of graft rejection, infection, and a limited donor pool. Important advances on the horizon include cross-species transplantation, improved immunosuppression, the induction of immunologic tolerance to foreign tissue, and improved organ preservation techniques.

CHAPTER 66

Long-Term Mechanical Circulatory Support

Hiroo Takayama
Berhane Worku
Yoshifumi Naka

INTRODUCTION

Heart failure (HF) remains one of the most common causes of death in the United States. Preventive measures and treatment options for HF have, however, improved significantly. The 2005 ACC/AHA guidelines introduced a comprehensive and systematic method of assessing and managing patients with risk factors and those with HF.[1] The suggested staging system is ambitiously inclusive, covering a wide range of patients with cardiovascular problems. It categorizes patients into Stages A (at high risk for HF but without structural heart disease or symptoms of HF) to D (refractory HF requiring specialized interventions). Surgical interventions play a significant role at each stage, and their role becomes more important as the stage advances. The surgical options described in the guidelines include, but are not limited to, coronary artery bypass grafting (CABG), valve replacement or repair, ventricular restoration surgery, heart transplantation, permanent mechanical support, and experimental surgery. A wide range of cardiac surgical procedures are covered, implying that HF is becoming one of the most important fields for cardiac surgeons.

Among the available surgical interventions for HF, mechanical circulatory support (MCS) is distinct from the others in that it, at least partially, replaces the pump function of the failing heart, similar to heart transplantation. Unlike heart transplantation, however, it does not rely on a human donor supply, which is a well-known limiting factor. As technologic advances have accrued, MCS has evolved into a reliable and well-described treatment option.

MCS may include intra-aortic balloon pump (IABP), ventricular assist device (VAD), total artificial heart (TAH), cardiopulmonary support (CPS) such as venoarterial (VA), extracorporeal membrane oxygenation (ECMO), and additional circulatory support systems. In this chapter we will focus on VAD, TAH, and CPS. Among these, VAD therapy as a method of ventricular support and TAH as a replacement of the heart are gaining particular attention. In this chapter, VAD therapy will be discussed in detail in relationship to other technologies.

HISTORY

Mechanical support of the cardiopulmonary system was first clinically introduced by John Gibbon in 1953, when he first successfully employed cardiopulmonary bypass for the repair of an atrial septal defect.[2] In 1963, DeBakey implanted the first VAD in a patient who suffered a cardiac arrest following aortic valve replacement. The patient subsequently died on postoperative day 4. In 1966, DeBakey reported the first successful bridge to recovery with implantation of a pneumatically driven VAD in a patient suffering from postcardiotomy shock. The patient was supported for 10 days, and ultimately survived to discharge.[3] Soon thereafter, Cooley reported the first successful bridge to transplantation (BTT) using a pneumatically driven implantable artificial heart.[4] During this time, the National Heart, Lung and Blood Institute (NHLBI) began funding initiatives to further the development of VADs and a TAH. DeVries and colleagues reported the successful implantation of the Jarvik-7-100 TAH in 1984.[5] Despite initial success, a high incidence of thromboembolic and infectious complications led to a moratorium on the use of the TAH in 1991. During this period, however, continued advances in the development of left ventricular assist devices (LVADs) were made. Early survival

data of patients undergoing LVAD insertion revealed greater than 30% hospital mortality. Advancements in perioperative care and technology have led to improvements in outcomes,[6] and this culminated in FDA approval of an LVAD as a BTT in 1994.

The feasibility of a mechanical-based approach to the treatment of end-stage HF was validated by the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial in 2001.[7] This landmark prospective randomized trial demonstrated a marked survival benefit in patients receiving an LVAD for the treatment of end-stage HF when compared with medical management alone. At the same time, the limitations of device technology using a volume displacement pump were highlighted by the high incidence of adverse events related to mechanical support, such as infection, device failure, and thromboembolic events.

Newer-generation VADs have been developed to overcome these limitations. These pumps are characterized by continuous flow driven by a rotary pump. A recently completed randomized trial demonstrated that a rotary pump (HeartMate II) compared with a volume displacement pump (HeartMate XVE) significantly improved the probability of survival free from stroke and device failure at 2 years.[8]

These continuous-flow second- and third-generation pumps generate low-grade pulsatility as opposed to the first-generation "pulsatile" pumps with volume displacement. With the growing number of patients receiving mechanical circulatory support device (MCSD) therapy, a national registry, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS), was initiated in 2005. This registry was devised as a joint effort of the NHLBI, the Centers for Medicare & Medicaid Services (CMS), the FDA, clinicians, scientists, and industry representatives in conjunction with the University of Alabama at Birmingham and the United Network for Organ Sharing (UNOS). This registry has and will continue to help improve the clinical outcomes of MCSD therapy, expedite new device clinical trials, and promote research.

TYPE OF MCSD

VA ECMO

Oxygenation of the blood using a membrane oxygenator can be achieved either with a venovenous (VV) or VA circuit. VV ECMO is used for respiratory failure relying on native heart function to move oxygenated blood through the systemic circulation. In order to support a failing heart, VA ECMO is necessary, and is established using a venous cannula(s) for inflow and an arterial cannula for outflow with a perfusion pump and an oxygenator bypassing the heart and lungs. These basic mechanisms are essentially the same as the cardiopulmonary bypass machine. The cannulation sites can be either central or peripheral depending on the situation. The ease of establishing VA ECMO makes this device suitable for emergent circumstances but only for short-term support (days). This device is also widely used in the pediatric population with success. Patients on VA ECMO need strict anticoagulation and in general have to be kept on a ventilator.

VAD

VADs are classified as short-term (or nonimplantable) and long-term (or implantable) devices from the duration of the support perspective, and univentricular (right or more commonly left ventricular) and biventricular assist devices from the configuration of the assist perspective. From the mechanism of driving pump system point of view, they are also divided into volume displacement (or pulsatile) devices and rotary (continuous-flow) devices. An appropriate device is chosen based on the individual patient's clinical status and the surgeon's comfort. The majority of these devices are placed surgically although recent advances have enabled percutaneous placement of certain devices, such as the Impella and TandemHeart.[9–11] The major limitations of percutaneous VADs as of 2009 are their somewhat limited flow capacity (up to approximately 5 L/min).

TAH

TAH is discussed elsewhere in this book, but in short, it replaces the patient's own heart in the orthotopic position and provides biventricular support. It has an advantage over the VAD in that conditions of the native heart, such as aortic insufficiency (AI), tricuspid regurgitation (TR), patent foramen ovale (PFO), mechanical valves, and cardiac tumors, have no influence on the function and maintenance of a TAH once it is implanted. The major drawbacks are the complexity of the implant procedure, and its size (body surface area [BSA] >1.7m^2 is required for the CardioWest TAH).

Currently used MCSDs are listed in Table 66-1, with some of their features described below.

First-Generation VADs

The HeartMate XVE (Fig. 66-1A) is the only FDA-approved device for destination therapy (DT) use. This device generates pulsatile flow through a pusher plate placed in a relatively large housing, which precludes implantation in small patients (BSA <1.5 kg/m^2). The unique textured inner surface allows patient management with no anticoagulation. It is used worldwide and has been tested extensively in large clinical trials, demonstrating superior outcome to medical management.[7] However, its long-term use is limited by high probability of device malfunction and infection. The Thoratec PVAD and Berlin Heart Excor enable implantation in small patients including the pediatric population. They can also provide BiVAD support. A major disadvantage is the exteriorized pump.

Second-Generation VADs

This group of VADs is currently gaining popularity. Miniaturization of mechanical support technology using a rotary pump of axial-flow design contributed to limiting the surface area exposed to blood allowed for the elimination of valves, air vents, and compliance chambers. The presence of fewer moving parts reduced device malfunction rates. Initial concerns over the potential influence of the continuous-flow

TABLE 66-1 Currently Used MCSDs (Not Inclusive)

- Short-term (or nonimplantable) devices
  - BVS and AB 5000 (ABIOMED, Danvers, MA)
  - CentriMag (Thoratec Corporation, Pleasanton, CA)
- Percutaneously/peripherally placed short-term devices
  - Impella 2.5, 5.0 (ABIOMED)
  - TandemHeart (CardiacAssist, Pittsburgh, PA)
- Long-term (or implantable) devices
  - First generation
    - HeartMate IP, VE, XVE (Thoratec)
    - Novacor (WorldHeart, Salt Lake City, UT)
    - Excore (Berlin Heart, Berlin, Germany)
    - Intracorporeal VAD (IVAD) (Thoratec)
    - Paracorporeal VAD (PVAD) (Thoratec)
  - Second generation
    - EVAHEART (Sun Medical Technology Research Corp., Nagano, Japan)
    - Jarvik 2000 (Jarvik Heart, Inc., New York, NY)
    - HeartMate II (Thoratec)
    - MicroMed-DeBakey VAD (MicroMed Cardiovascular, Inc., Houston, TX)
  - Third generation
    - Arrow CorAide (Cleveland Clinic, Cleveland, OH)
    - Duraheart (Terumo Heart, Inc., Ann Arbor, MI)
    - HeartMate 3 (Thoratec)
    - HeartWare (HeartWare, Sydney, Australia)
    - Incore (Berlin Heart, Berlin, Germany)
    - Levacore (WorldHeart)
    - Ventra-assist (VentraCor, Inc.)
- Total artificial heart
  - AbioCor total replacement heart (ABIOMED)
  - CardioWest TAH (SynCardia, Tucson, AZ)

feature on patient physiology appear to have been assuaged based on midterm outcomes. The HeartMate II (Fig. 66-1B) was shown in a randomized control trial to be superior to the HeartMate XVE.[8] Clinical experience has been accumulated with the MicroMed-DeBakey VAD and the Jarvik 2000 as well.[12,13] A unique power delivery system based on cochlear implant technology is adopted in the Jarvik 2000.[13] A titanium pedestal is screwed into the temporal bone behind the ear and conveys the electrical system through highly vascular scalp skin (Fig. 66-2). Device infection might be reduced with this technology because of immobility and the absence of subcutaneous fat.

Third-Generation VADs

The main feature of the third-generation VADs is that they eliminated bearings by using either hydrodynamic or electromagnetic suspension of an impeller to reduce mechanical wear and trauma to blood cells. The DuraHeart (Fig. 66-3) is a centrifugal pump with a magnetically levitated impeller that is composed of a magnetic bearing, an impeller, a housing, and a direct current brushless motor. The pump provides contact-free rotation of the impeller without any material wear, which predicts a high level of durability. The pump weighs 540 g and has a diameter of 72 mm and a height of 45 mm. The HeartWare (Fig. 66-4) is another example of a centrifugal pump that sits within the pericardial space. The left ventricular (LV) apical inflow cannula is an integral part of the pump itself. The device weighs only 145 g and yet provides up to 10 L/min of flow. These and other devices are currently undergoing clinical trials.

GOAL OF DEVICE SUPPORT

When considering MCSD placement, the cardiac surgeon and the team must be clear of their goal. This is particularly important in order for the surgeon and the team to be able to select the appropriate patient, the appropriate timing for placement, and the appropriate device to use. Five major goals are: "BTT," "DT," "bridge to recovery," "bridge to decision," and "bridge to bridge" (Fig. 66-5).

BTT

Patients who are evaluated by a multidisciplinary transplant team and are determined to be suitable candidates for heart transplantation may require MCSD placement while on the waiting list. With progressive lengthening of waiting times on transplantation lists, the use of a VAD as a BTT has become standard therapy in end-stage HF. This decision is made once it is felt that the patient is unlikely to survive to transplantation or if he/she is developing additional organ dysfunction which may compromise transplant eligibility. Currently, there are no widely accepted guidelines as to the indication and timing for VAD placement as a BTT, and therefore the decision has to be individualized by weighing the balance among three main factors: the estimated waiting time for a heart, the estimated chance of death on the waiting list, and the risk of the operation. For example, patients with blood type O have much longer waiting times on the transplant list compared with others in the United States, and therefore the threshold for device placement is lowered.

MCSD placement may also be considered for patients with borderline eligibility for heart transplantation, such as those with an elevated pulmonary vascular resistance (PVR) or moderate end-organ dysfunction. LVAD support was demonstrated to decrease the PVR of patients who were otherwise ineligible for transplantation with successful posttransplant outcomes.[14–19] This indication is known as "bridge to eligibility."

DT

Patients with end-stage HF who are not eligible for heart transplantation may benefit from MCSD placement because of prolongation and/or improvement in quality of life. They are

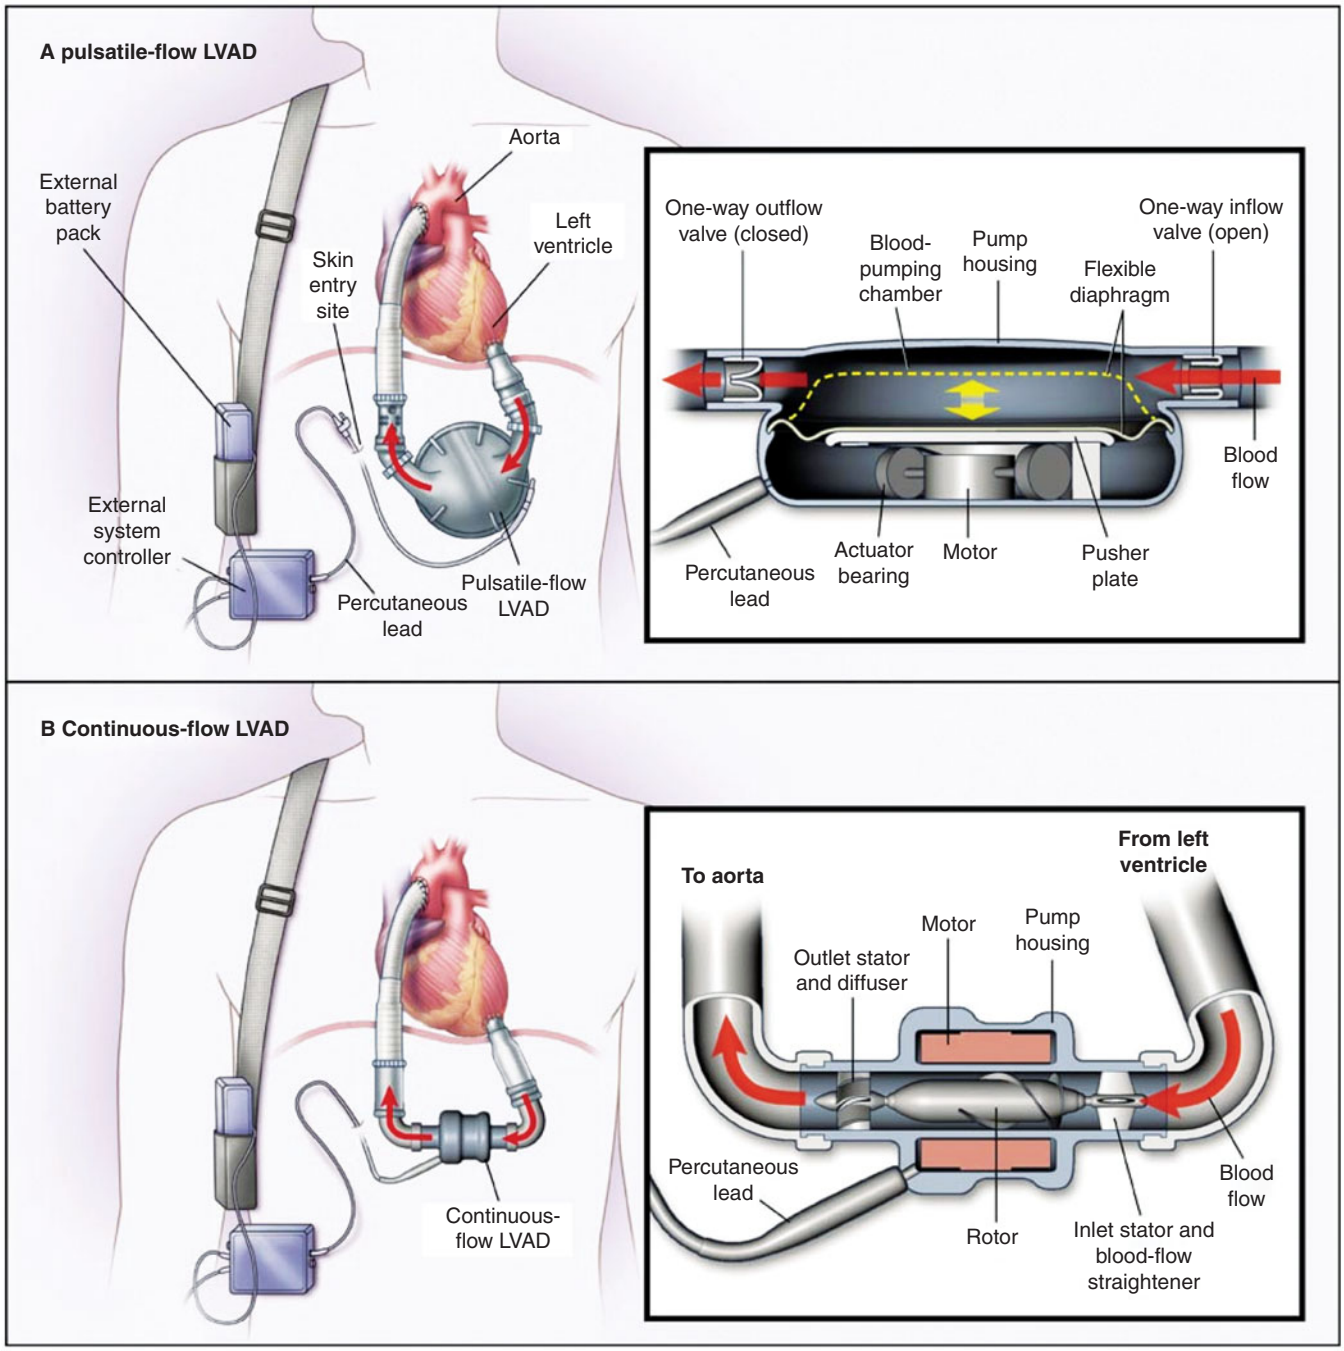

FIGURE 66-1 (A) HeartMate XVE. (B) HeartMate II. (*Reproduced, with permission, from Slaughter MS, Rogers JG, Milano CA, Russell SD, Conte JV, et al: Advanced heart failure treated with continuous-flow left ventricular assist device. NEJM 2009; 361[23]:2241-2251.*)

expected to receive circulatory support from the MCSD for life and this indication is called "DT." The REMATCH trial demonstrated that LVAD therapy is superior to medical management for this category of patients.[7] Based on this result the FDA approved the use of an LVAD (HeartMate VE) as DT. Currently accepted indications refer to the eligibility criteria for the REMATCH trial. As a reference, the current CMS criteria[20] are: patients who have chronic end-stage HF (New York Heart Association [NYHA] Class 4 end-stage LV failure for at least 90 days with a life expectancy of less than 2 years) are not candidates for heart transplantation and meet all of the following conditions:

1. The patient's Class 4 HF symptoms have failed to respond to optimal medical management, including dietary salt restriction, diuretics, digitalis, beta-blockers, and angiotensin-converting enzyme (ACE) inhibitors (if tolerated) for at least 60 of the last 90 days.

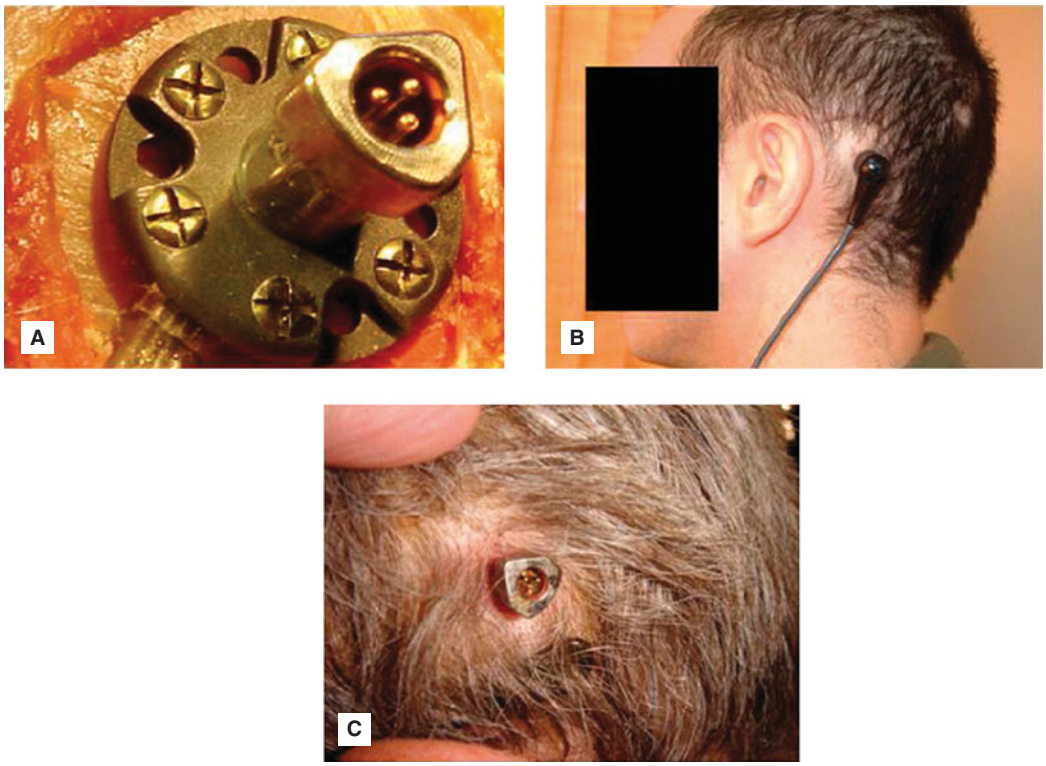

FIGURE 66-2 Skull pedestal power delivery. (A) The pedestal screwed to the skull of Jervik 2000. (B) Titanium pedestal with external power cable removed. (C) External cable plugged into the pedestal. (*Reproduced, with permission, from Westaby S, Siegenthaler M, Beyersdorf F, Massetti M, Pepper J, et al: Destination therapy with a rotary blood pump and novel power delivery. Eur J Cardiothorac Surg 2010; 37[2]:350-356.*)

2. The patient has an LV ejection fraction (EF) <25%.
3. The patient has demonstrated functional limitation with a peak oxygen consumption of <12 mL/kg/min, or the patient has a continued need for intravenous inotropic therapy owing to symptomatic hypotension, decreasing renal function, or worsening pulmonary congestion.
4. The patient has the appropriate body size (BSA ≥1.5m^2) to support the VAD implantation.

Of importance, one-third of BTT patients lost their transplant candidacy and were delisted with outcomes parallel to those of DT, and as many as 17% of DT patients eventually underwent heart transplantation.[21,22]

Bridge to Recovery

With an MCSD unloading the ventricle, some patients demonstrate recovery of myocardial function followed by successful

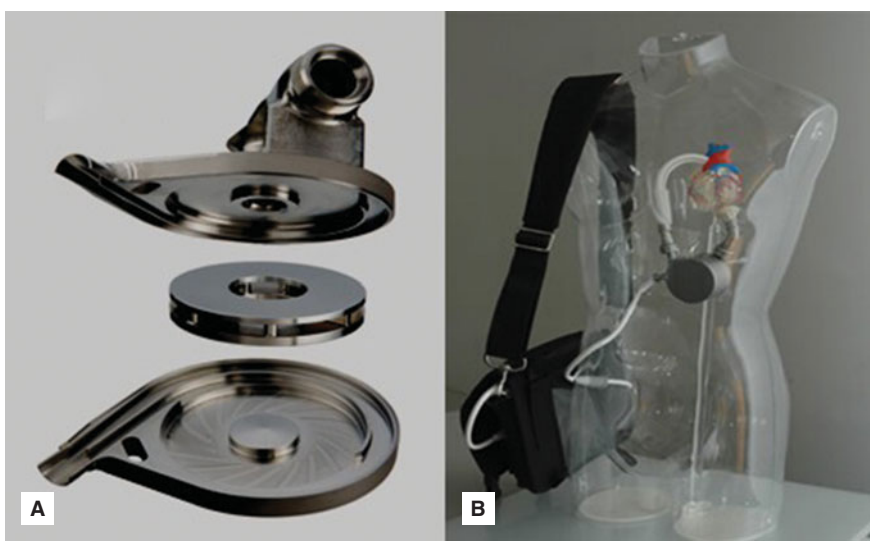

FIGURE 66-3 DuraHeart. (*Reproduced with permission from Terumo Heart Inc.*)

FIGURE 66-4 HeartWare. (*Reproduced, with permission, from Wood C, Maiorana A, Larbalestier R, Lovett M, Green G, et al: First successful bridge to myocardial recovery with a HeartWare HVAD. J Heart Lung Transplant 2008; 27[6]:695-697.*)[87]

MCSD explantation. MCSD placement for this purpose is called *bridge to recovery*. Only a few patients who received LVAD support demonstrated shifts in ventricular and myocardial properties back toward normal (myocardial "reverse remodeling") and successfully underwent explantation of the device with sustained cardiac function. The process of ventricular "remodeling," which is characterized by progressive ventricular dilatation and dysfunction, is mediated by many factors on molecular, biochemical, metabolic, cellular, extracellular matrix, and ventricular structural levels.[23] After the introduction of the LVAD, it was appreciated that many of these abnormalities could be reversed, at least to some degree.

At this point it is rather difficult to predict which patient will experience recovery of cardiac function with MCSD placement. MCSD placement may be undertaken for another indication with subsequent recovery of myocardial function. However, there have been promising reports on promoting myocardial recovery with pharmacologic or regenerative therapies in conjugation with MCSD placement, and this indication will likely continue to grow.

With wider interpretation of the definition, bridge to recovery has come to encompass placement of a temporary right ventricular assist device (RVAD) simultaneous with or shortly after an implantable LVAD placement, and this indication is not uncommon.

Bridge to Decision

MCS may be required for an acutely ill patient with cardiogenic shock. Acute hemodynamic decompensation may not permit the thorough evaluation required for BTT or DT. A short-term MCSD may be applied as a "bridge to decision."

Acute hemodynamic collapse can be caused by various processes, including, but not limited to acute myocardial infarction (AMI), cardiomyopathy, myocarditis, acute on chronic HF, severe rejection of a transplant heart, postcardiotomy shock, and unsuccessful percutaneous coronary intervention. Regardless of the etiology, the patient will need continuous assessment and may require progressively escalating support of care. If the patient deteriorates or does not improve despite inotrope/vasopressor administration, nitric oxide inhalation, and/or IABP placement, MCSD placement is considered. Another clinical scenario necessitating MCSD use as a bridge to decision is the patient who requires continuous cardiopulmonary resuscitation (CPR). In this setting, a clinical decision is made immediately, and

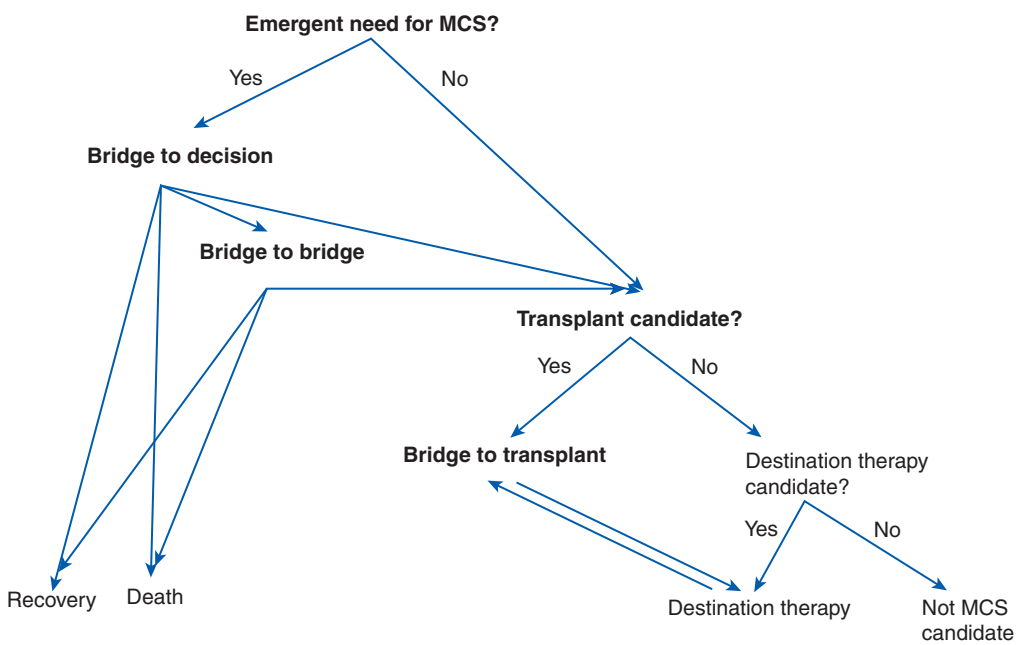

FIGURE 66-5 Goals of VAD support.

once it has been decided to proceed with MCSD placement, the cardiac surgeon/cardiologist should establish circulatory support using the quickest modality available at his or her facility.

Bridge to decision is a strategy used to defer the decision of whether to proceed with longer-term and more definitive therapy while the patient is supported with a short-term device. The patient, while on the device, may recover from or succumb to the decompensation in cardiac function, or may continue to rely on MCS. It has been proposed that the success of long-term implantable LVAD support relies on the optimization of the preoperative status of its candidates. In other words, LVAD implantation in moribund patients results in dismal outcomes. Bridge to decision use of short-term MCS allows selection of those patients who will benefit from a long-term device. Evaluation for candidacy for a longer-term strategy such as heart transplantation or DT is initiated as soon as the MCSD is placed.

Bridge to Bridge

In a small number of patients, a short-term MCSD becomes necessary to replace a previously placed short-term MCSD while the patient is awaiting a more definitive plan. This indication is called *bridge to bridge*. The most common clinical scenario involves replacing a short-term MCSD that is providing inadequate flow, or a VA ECMO, with a more reliable short-term MCSD in order to facilitate further improvement in the clinical status of the patient who is too ill to undergo a long-term implantable device placement. Bridge to bridge is usually applied for exchange of a short-term device to a long-term device.

A total of 420 patients from 75 institutions were entered into the INTERMACS database from June 2006 to December 2007.[24] The indication for MSCD placement was BTT in 336 patients (179 for BTT, 83 for "likely to be listed," 44 for "moderately likely to be listed," and 30 for "unlikely to be listed") and DT in 63 patients.

INDICATION FOR DEVICE SUPPORT: HEMODYNAMIC CONSIDERATION

The success of an MCSD is heavily dependent on appropriate patient selection.[21,25,26] Potential candidates are evaluated from a hemodynamic and nonhemodynamic standpoint. In 2006, the International Society for Heart and Lung Transplantation proposed Guidelines for the Care of Cardiac Transplant Candidates, in which recommendations for MCSD use are described.[18]

From a hemodynamic perspective, patients considered for MCSD placement can no longer sustain adequate systemic oxygen delivery to maintain normal end-organ function despite maximal medical therapy and/or IABP support. Such hemodynamic compromise can be the result of a variety of cardiac conditions. Traditional hemodynamic criteria for device placement include: blood pressure (BP) less than 80 mm Hg, mean arterial pressure less than 65 mm Hg, cardiac index less than 2.0 L/min/m^2, pulmonary capillary wedge pressure greater than 20 mm Hg, and a systemic vascular resistance (SVR) greater than 2100 dynes·sec/cm.[27] Malignant ventricular arrhythmias that cannot be adequately controlled with permanent pacemakers and/or implantable defibrillators are an additional hemodynamic indication for MCS.

Determining the hemodynamic indication for MCSD placement, however, is not always straightforward. Although the need for MCS is rather evident for a patient in acute cardiogenic shock, conflict may exist when a patient demonstrates an insidious course with congestive heart failure (CHF). Examples include: a hospitalized patient with CHF who worsens or fails to improve over a period of days; a patient managed on an outpatient basis for known CHF who slowly deteriorates, requiring incremental medical treatment; or a transplant candidate who is managed with an outpatient inotrope infusion. In order not to miss the appropriate window for MCSD placement, the clinician should be aware of the worrisome signals of CHF decompensation. These signals include worsening symptoms (recurrent admission, refractory to medical therapy, symptomatic at rest), medication issues (intolerance to or lower doses of ACE inhibitors/angiotensin receptor blockers [ARBs] and beta-blockers, increasing doses of diuretics), hyponatremia, and unresponsiveness to cardiac resynchronization therapy. Inotrope dependence is associated with a less than 50% 6-month survival.[28,29] In these situations, in addition to assessment with right heart catheterization and echocardiogram, end-organ function, in particular renal and hepatic function, is followed closely. It is becoming evident that outcomes after MCSD placement are better if the device is placed before the development of end-organ dysfunction. For patients with HF refractory to medical management, or for transplant candidates on inotropic support, a surgical consult should be obtained sooner than later, and the appropriate indication and timing of MCSD placement should be determined through a thorough discussion between the cardiac surgeon and cardiologist.

The INTERMACS registry proposed a series of seven clinical profiles with three modifiers for patient selection. These profiles help define the acuity and severity of illness and simplify the assessment of implant risk[30–32] (Table 66-2). The modifiers include arrhythmia, temporary circulatory support, and frequent flyer.[32] Approximately 60 to 80 % of indications for LVAD placement were INTERMACS level 1 ("crash and burn") or level 2 ("sliding on inotropes").[21,32]

Of note, because only LVAD support has been approved for DT, significant impairment of right ventricular (RV) function and high PVR may exclude patients from eligibility for DT.

INDICATION FOR DEVICE SUPPORT: NONHEMODYNAMIC CONSIDERATIONS

Patients in acute cardiogenic shock usually cannot wait for a thorough evaluation and thus the decision to proceed with MCSD may be made purely from a hemodynamics standpoint.

However, several additional factors discussed previously have to be taken into consideration to ensure the success of a long-term MCSD. Again, the treating team has to be clear of the goal of MCSD placement. The majority of long-term MCSDs are implanted either for BTT or DT purposes, each of which has different criteria for appropriate patient selection.

TABLE 66-2 INTERMACS Profiles

Profile	Description	Time Frame for Definitive Intervention
1	Patient with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion with increasing lactate levels and/or systemic acidosis. "*Crash and burn*"	Needed within hours
2	Patient with declining function despite intravenous inotropic support, may be manifest by worsening renal function, nutritional depletion, inability to restore volume balance. "*Sliding on inotropes*"	Needed within few days
3	Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support, but demonstrating repeated failure to wean owing to recurrent symptomatic hypotension or renal dysfunction. "*Dependent stability*"	Elective over a few weeks
4	Patient can be stabilized close to normal volume status but experiences frequent relapses into fluid retention, generally with high diuretic doses. Symptoms are recurrent rather than refractory. More intensive management strategies should be considered, which in some cases reveal poor compliance. "*Frequent flyer*"	Elective over weeks to months as long as treatment of episodes restores stable baseline, including nutrition
5	Patient is living predominantly within the house, performing activities of daily living and walking from room to room with some difficulty. Patient is comfortable at rest without congestive symptoms, but may have underlying refractory elevated volume status, often with renal dysfunction. "*Housebound*"	Variable, depends upon nutrition, organ function, and activity
6	Patient without evidence of fluid overload is comfortable at rest and with activities of daily living and minor activities outside the home, but fatigues after the first minutes of any meaningful activity. "*Walking wounded*"	Variable, depends upon nutrition, organ function, and activity
7	A placeholder for future specification, patients without recent unstable fluid balance, living comfortably with meaningful activity limited to mild exertion.	Transplantation or circulatory support not currently indicated

Specific requirements for DT were mentioned in the previous section. The following are general considerations applicable to patient selection for both treatment goals.

Assessment of Operative Risk

Operative mortality constitutes a large portion of mortality after MCSD placement. The common causes of early postoperative death are bleeding, RV failure, sepsis, multiple organ failure (MOF), and stroke. Although several screening scales, including one developed at our own program, have been developed to predict early mortality after long-term LVAD placement, they are not always helpful for the assessment of procedural difficulty.[22,33] The responsible surgeon has to address the surgical complexity of each case. Certain anatomical scenarios, such as the patient with multiple previous sternotomies for complex congenital heart disease, might possess a prohibitive operative risk regardless of the remainder of the patient's risk profile.

Assessment of Organ Function

Patients with end-stage HF commonly have significant comorbidities. Life-limiting comorbidities preclude eligibility for long-term MCSD placement. On the other hand, in the setting of impaired end-organ function, some degree of recovery may be seen after MCSD placement. Renal and hepatic functions were demonstrated to improve with both pulsatile and continuous-flow LVAD support.[34–40] Assessing and defining the severity and reversibility of vital organ function is critical in the patient selection process.

Renal dysfunction, which commonly coexists in HF patients, is strongly associated with poor outcomes after VAD

implantation.[41,42] Patients who are on chronic dialysis are generally excluded from implantable MCSD placement. Furthermore, patients on continuous venovenous hemofiltration (CVVH) or those with a serum creatinine of greater than 3.0 mg/dL are excluded from LVAD use for DT at our program.

Liver function is also carefully addressed. We have proposed a screening scale to predict survival after LVAD insertion.[33,43] Univariate and multivariate analyses of our patient cohort confirmed a prothrombin time of greater than 16 seconds to be one of the most significant variables included in the summation score. Reinhartz et al. demonstrated that patient survival after LVAD placement decreased (82% to 56% to 33%) as preoperative direct bilirubin levels increased (<1.2 to 1.2–3.6 to >3.6 mg/dL, respectively).[44] Liver function strongly correlates with patient outcomes after a VAD. For DT, we exclude patients whose intern ational normalized ratio is greater than 2.5 (even with efforts to reverse it), and/or patients whose ALT and AST are more than three times normal values.

Patients with advanced pulmonary disease who are on prolonged ventilatory support or whose FEV_1 is less than 1 L are not candidates for long-term MCSD. Other considerations include severe impairment of cognitive function, a history of neurologic events with significant residual deficits, active infection, active gastrointestinal bleeding, severe peripheral vascular disease (such as critical limb ischemia with rest pain or ulceration, or past limb amputation), and severe malnutrition. Malignancy is not necessarily a contraindication.

Other Considerations

MCSD operation and maintenance requires a large commitment on the part of the patient and his/her support structure. Our program requires that all patients referred for MCSD evaluation undergo a comprehensive multidisciplinary assessment. A psychiatrist assesses any psychiatric impairment that may contribute to the patient's inability to adhere to a postdevice regimen. In addition, neurocognitive function is evaluated by neuroscientists. The psychosocial evaluation performed by qualified healthcare personnel explore: social, personal, vocational, financial and environmental supports. A mental health history is also taken, assessing for substance abuse and alcohol use or abuse and its potential impact on the success or failure of device support. Nutritional status is screened with referral to a nutritionist as needed.

Lastly, age itself is not an absolute contraindication to MCSD placement.[18] Our program addresses the feasibility of device placement on an individual case basis with particular attention paid to end-organ functional reserve and psychosocial issues in older patients. It is a Class 1 recommendation from the ISHLT that patients older than 60 years of age undergo a thorough evaluation for the presence of other clinical risk factors.[18]

RISK SCREENING SCALES

Difficulties in predicting outcomes after long-term MCSD placement prompted several working groups to develop screening scales.

The revised Columbia screening scale published in 2003 offers a way of stratifying prospective device patients according to their risk of operative death from LVAD insertion based on several clinical factors: mechanical ventilation, postcardiotomy; prior LVAD insertion; central venous pressure greater than 16 mm Hg; and prothrombin time greater than 16 seconds.[43] Each factor is given a weight (4, 2, 2, 1, 1, respectively), with a cumulative score of >5 predicting an operative mortality of 46%, versus 12% for a score ≤5. This scoring system is a revision of a prior scale developed in conjunction with the Cleveland Clinic Foundation.[33] The revised scoring scale was the result of an analysis of 130 patients undergoing implantation of the HeartMate vented electrical device.

Lietz et al., focusing on DT, analyzed outcomes from 280 of 309 patients who underwent LVAD (HeartMate XVE) implantation as DT since the completion of the REMATCH trial. Nine variables, which were found to be significantly related to 90-day in-hospital mortality, were assigned a weighted risk score equal to the odds ratio rounded to the nearest integer (Table 66-3). The sum of the weighted risk scores is suggested as a risk score. Scores are categorized as low being risk score of 0 to 8, medium to high (9 to 18), and very high (>19). These risk factors are representative of severe deterioration of the general medical condition of the patient, as evidenced by poor nutritional status with a low serum albumin level, impaired renal function, markers of right heart failure such as low pulmonary artery pressures, or congestive elevation of liver enzymes. Probable infection, as evidenced by leukocytosis and coagulation abnormalities such as declining platelet count or prolonged international normalized ratio, anemia, and small body size further worsen the chance of operative survival. This screening scale was shown to correlate with 90-day and 1-year survival after LVAD implantation (Fig. 66-6). Other preexisting screening scales such as the APACHE II and Seattle Heart Failure Model were also shown to be predictive of midterm success of pulsatile LVAD therapy.[45,46]

Although the above scoring systems guide the preoperative risk assessment, they were developed based on the experience with the first-generation LVADs, and may not be directly applicable to newer devices. Using a cohort of 86 patients receiving a continuous-flow LVAD at the Johns Hopkins Hospital, Schaffer et al.[47] compared various risk screening scales including the Leitz-Miller, Columbia, APACHE II, INTERMACS, and Seattle Heart Failure Model risk scores to assess their ability to predict on 30-day, 90-day, and 1-year mortality, and found that the Seattle Heart Failure Model best differentiated low- and high-risk patients at all mortality end points.

UNIVENTRICULAR OR BIVENTRICULAR SUPPORT

Determining whether biventricular support will be necessary prior to MCSD placement is imperative in choosing an appropriate device or in determining candidacy for DT. It usually becomes evident which ventricle predominantly needs to be supported, and most often the it is the LV. Previously mentioned CMS criteria well summarize the indications for LVAD support: NYHA Class 4 HF refractory to optimal medical

TABLE 66-3 Multivariable Analysis of Risk Factors for 90-Day In-Hospital Mortality after LVAD as DT (n = 222).

Patient Characteristics	Odds Ratio (CI)	*p*	Weighted Risk Score
Platelet count ≤148 × $10^3/\mu L$	7.7 (3.0 to 19.4)	<.001	7
Serum albumin ≤3.3 g/dL	5.7 (1.7 to 13.1)	<.001	5
International normalization ratio >1.1	5.4 (1.4 to 21.8)	.01	4
Vasodilator therapy	5.2 (1.9 to 14.0)	.008	4
Mean pulmonary artery pressures ≤25 mm Hg	4.1 (1.5 to 11.2)	.009	3
Aspartate aminotransferase >45 U/mL	2.6 (1.0 to 6.9)	.002	2
Hematocrit 34%	3.0 (1.1 to 7.6)	.02	2
Blood urea nitrogen >51 U/dL	2.9 (1.1 to 8.0)	.03	2
No intravenous inotropes	2.9 (1.1 to 7.7)	.03	2

management, LVEF less than 25%, functional limitation with a peak oxygen consumption of less than 12 mL/kg/min or the patient has a continued need for intravenous inotropic therapy.[20] In addition, patients with malignant arrhythmias as well as anyone on the transplant waiting list could be considered for LVAD therapy.

The difficulty lies in determining whether another ventricle, usually the RV, needs to be supported or not. RV failure occurs in 20 to 40% of LVAD recipients and it correlates with worse outcomes.[48–50] In general, RV failure occurs in "sicker" patients reflecting more advanced HF with coexisting end-organ dysfunction owing to low organ perfusion pressures (low BP and high venous pressure). Despite technologic advances, Patel et al. demonstrated that the incidence of RV dysfunction remained constant with an incidence of 35% after HeartMate XVE implantation compared with 41% after HeartMate II implantation. However, fewer HeartMate II patients required RVAD placement and fewer required pure inotropic support

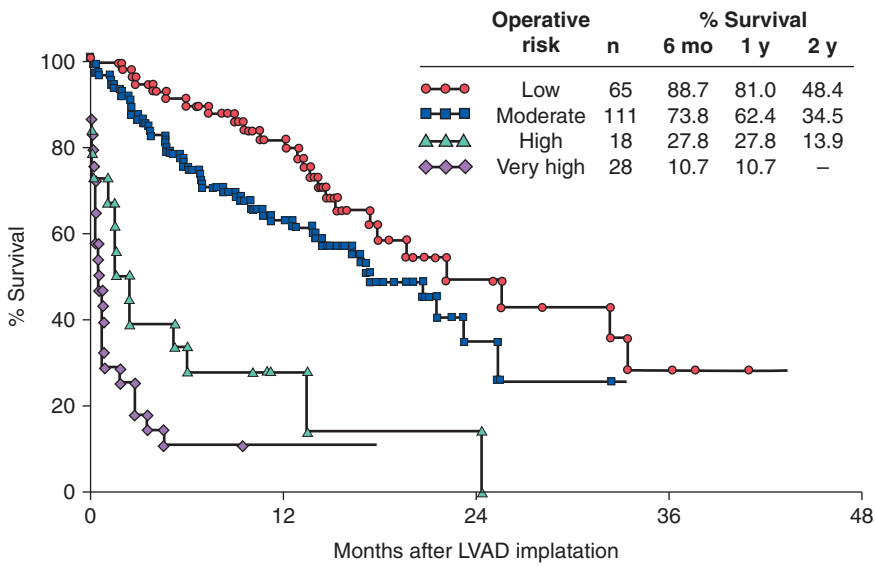

FIGURE 66-6 Survival after LVAD implantation as DT by the candidate's operative risk. (*Reproduced, with permission, from Lietz K, Long JW, Kfoury AG, Slaughter MS, Silver MA, et al: Outcomes of left ventricular assist device implantation as destination therapy in the post-REMATCH era: implications for patient selection. Circulation 2007; 116[5]:497-505.*)

for right heart failure.[49] Based on 68 patients who developed RV failure out of 197 LVAD recipients, the group from the University of Michigan proposed an RV failure risk score consisting of a vasopressor requirement, AST ≥80 IU/L, bilirubin ≥2.0 mg/dL, and creatinine ≥2.3 mg/dL.[51]

Several studies attempted to identify predictors of BiVAD need, identifying more than 20 variables. The results have been inconsistent. Ochiai et al. from the Cleveland Clinic reviewed 245 patients receiving pulsatile LVADs, among whom 23 patients required RVAD support, and reported that the need for pre-LVAD circulatory support, female gender, and nonischemic etiology were the most significant predictors of RVAD requirement after LVAD placement.[52] Fitzpatrick et al. reported a large series from the University of Pennsylvania. They retrospectively analyzed 266 LVAD recipients, of whom 99 (37%) required RVAD placement after LVAD placement. Cardiac index ≤2.2 L/min/m^2 (odds ratio 5.7), RV stroke work index ≤0.25 mm Hg/L/m^2 (odds ratio 5.1), severe preoperative RV dysfunction on echocardiographic assessment (odds ratio 5.0), preoperative creatinine ≥1.9 mg/dL (odds ratio 4.8), previous cardiac surgery (odds ratio 4.5), and systolic BP ≤96 mm Hg (odds ratio 2.9) were shown to be the best predictors of RVAD need. They proposed a risk score: 18 × (CI) + 18 × (RVSWI) + 17 × (creatinine) + 16 × (previous cardiac surgery) + 16 × (RV dysfunction) + 13 × (SBP), with a maximum possible score of 98. Applying the risk score to their cohort, a score of ≥50 predicted the need for BiVAD support with a sensitivity and specificity of 83% and 80%, respectively.[53] These scoring systems, however, remain to be validated.

Most malignant arrhythmias improve with LVAD support with or without automated implantable defibrillators/permanent pacemakers. BiVAD support, however, should be considered for recurrent sustained ventricular tachycardia or ventricular fibrillation in the presence of an untreatable arrhythmogenic pathologic substrate (eg, giant cell myocarditis).[18]

Isolated RVAD support is rarely indicated, especially as long-term support.[54] Potential indications include isolated RV infarct, isolated RV failure after heart transplantation or pulmonary embolism, or postcardiotomy RV failure.

INTERMACS data from 420 patients at 75 institutions entered into the INTERMACS database from June 2006 to December 2007demonstrated that 314 patients received LVADs, 5 RVADs, 77 BiVADs, and 24 TAHs.[24]

DEVICE SELECTION

Device selection starts with consideration of the goal of MCS placement from among the five goals described in the "Goal of Device Support" section. Also of importance is to determine which ventricle(s) will be supported.

For a bridge to decision purpose, a short-term MCSD is appropriate as they are quicker to place and less expensive. When a patient is too unstable to go to the operating room, VA ECMO via percutaneous cannulation may be the most realistic option. It is relatively easy and quick to establish, and is familiar to cardiac surgeons and paramedics compared with other types of devices. These features make it an excellent device of choice in emergent situations at a wide variety of institutions. This is also the only device available for biventricular support in extreme emergencies. The major shortcoming of VA ECMO is its mandatory use of an oxygenator, which requires strict anticoagulation and careful observation to prevent thromboembolic/hemorrhagic complications. Patients also have to remain on mechanical ventilation. Its use is limited to a relatively short period of support (hours to days). Percutaneous LVADs such as the Impella or TandemHeart for LV failure might be a reasonable option, especially when the deterioration occurs in the cardiac catheterization suite. These percutaneous devices may not be able to provide enough flow for a large patient or a very sick patient, in which case they may have to be replaced with some other device in the operating room. The options at this point include the CentriMag, Thoratec PVAD, and ABIOMED AB or BVS5000. These devices are easy to place, provide adequate flow, and can be used either as a BiVAD or a univentricular assist device. These devices are suitable in the rare bridge-to-bridge situation described earlier, in which an initial temporary device needs to be replaced (percutaneous VADs or ECMO). Another application is for temporary RVAD support at the time of or shortly after implantable LVAD placement. Our current preference for short-term MCS is to use the CentriMag, which enables establishment of high flow support through simple cannulation techniques almost equivalent to regular cannulation for routine cardiac surgery. In our experience, the CentriMag has been reliably used with support periods of greater than 1 month.

For BTT, unless the estimated waiting time to transplantation is short, in which case one of the above mentioned short-term devices may be used, a long-term implantable device is the device of choice. The Thoratec PVAD and IVAD are the only FDA-approved devices at this point for biventricular support with implantable features. FDA-approved and currently purchasable LVADs include the HeartMate XVE, HeartMate II, and Novacor LVAD. Many other devices are under clinical investigation and the options will continue to grow. Currently there is no comparison data among devices, except the HeartMate II was shown to be superior to the HeartMate XVE in a randomized controlled trial.[8] We currently use the HeartMate II or other investigational devices as part of clinical trials.

The only device currently approved by the FDA for DT is the HeartMate XVE. Again, several clinical investigations are undergoing, and likely more options will become available in the near future.

Anticoagulation

Continuous-flow devices generally require antiplatelet therapy and anticoagulation. Patients with contraindication to these regimens are considered for the HeartMate XVE.

Body Size

Patient body habitus is a very important factor in choosing a device. The size of an implantable VAD dictates the lower

limitation of body size, which is usually described in BSA. For example, a BSA of less than 1.5 m^2 is a contraindication for conventional pulsatile devices, such as the HeartMate XVE whereas the HeartMate II may be placed in patients with a BSA as low as 1.2 m^2. For smaller or pediatric patients, paracorporeal devices may have to be chosen.

OTHER ANATOMICAL CONSIDERATIONS

Significant semilunar valve regurgitation is repaired at any type of MCSD insertion. Important anatomical abnormalities that require surgical correction at LVAD implantation include PFO, AI, TR, and LV apical thrombus. Intraoperative transesophageal echocardiogram (TEE) plays an important role here.

An LVAD may create pressure gradient from the right to left atrium which exaggerates right to left shunt through a PFO, resulting in profound desaturation.[55] Any PFO is closed with bicaval cannulation. We also routinely ask the anesthesiologist to perform a bubble study with TEE after LVAD placement to rule out a small PFO that might have remained undetected.

The presence of AI creates a circuit from the ascending aorta, into the LV, and back to the ascending aorta through the LVAD. LVADs, especially ones with continuous flow, expose the aortic valve to a constant pressure gradient across the valve with the LV being suctioned through the inflow cannula, and a nonphysiologic reversal of blood flow coupled with stagnant blood flow at the base of the aortic root. These unique hemodynamic features may potentiate AI. Significant regurgitation is controlled surgically. The aortic valve can either be repaired or sewn shut. The aortic valve closure leaves patients with no LV outflow, which may become of consequence in the case of device malfunction. We therefore prefer to repair the aortic valve whenever it is feasible. Our procedure of choice involves approximating the center of the leaflets, the nodes of Arantis, with a 4-0 polypropylene suture reinforced with small bovine pericardial pledgets. Stagnant blood around the aortic root can be thrombogenic especially when patients have a preexisting mechanical aortic prosthesis, in which case we close off the aortic valve with a patch. The other option is to replace the mechanical valve with a bioprosthesis.

MCSD candidates are prone to develop TR because of dilatation of the tricuspid annulus, RV dysfunction, and the presence of pacing leads. We aggressively repair significant TR at the time of LVAD implantation to maximize forward flow from the RV. The repair is usually readily accomplished by placing a ring, but additional repair techniques may be necessary for leaflet pathology created by pacing leads.

LV mural thrombi occur in one-third of Q-wave AMI cases, 50% of LV aneurysms, and up to 18% of hearts with dilated cardiomyopathy.[56] Cardioplegic arrest may be required for removal of the LV thrombus to prevent systemic embolization.

SURGICAL TECHNIQUE

We describe our technique of long-term LVAD implantation. Most of the steps are shared by many implantable LVADs. Essential components of the operation include (1) mediastinal exposure and creation of the device pocket; (2) outflow graft construction to the ascending aorta; (3) placement of device inflow, usually at the LV apex; (4) de-airing of the device; and (5) device actuation. Preoperative antibiotic prophylaxis covering both gram-positive and gram-negative bacteria is administered and usually continued for 48 to 72 hours postoperatively. Our preference is the combination of rifampin, trimethoprim-sulfamethoxazole, and fluconazole. Autologous blood is drawn by the anesthesiologist before heparinization. Patients tolerate phlebotomy of up to 1 L very well as they are usually fluid overloaded. Administration of this blood helps with hemostasis at the completion of the procedure. We have abandoned serine protease inhibitor (eg, aprotinin) use.

A vertical midline incision is made with extension onto the abdominal wall. After standard median sternotomy, a preperitoneal pocket is created in the preperitoneal space in the left upper quadrant.[57] Sometimes the preperitoneal plane is very thin and attenuated, so the posterior rectus sheath is entered and a plane superficial to this is developed. The device is brought onto the field and positioned in the preperitoneal pocket. The driveline is tunneled percutaneously and brought out of the skin through the first counter-incision in the right upper quadrant and finally through the second punched-out incision placed in the left upper quadrant (Fig. 66-7). After systemic heparinization, the patient is cannulated for cardiopulmonary bypass. Venous cannulation can be achieved with a single dual-stage cannula placed in the right atrium, or with standard bicaval cannulation if concomitant procedures are being performed (ie, tricuspid valve repair or closure of a PFO). The ascending aorta is cannulated distally with consideration for future reoperation for cardiac transplantation. An effort is made to minimize cardiopulmonary bypass times in this ill group of patients. If the hemodynamic status permits, an attempt is made to perform the outflow graft anastomosis off-pump using a partial occluding clamp placed on the ascending aorta (Fig. 66-8). The outflow graft is measured and cut with enough length to allow for a gentle curvature toward the right chest without

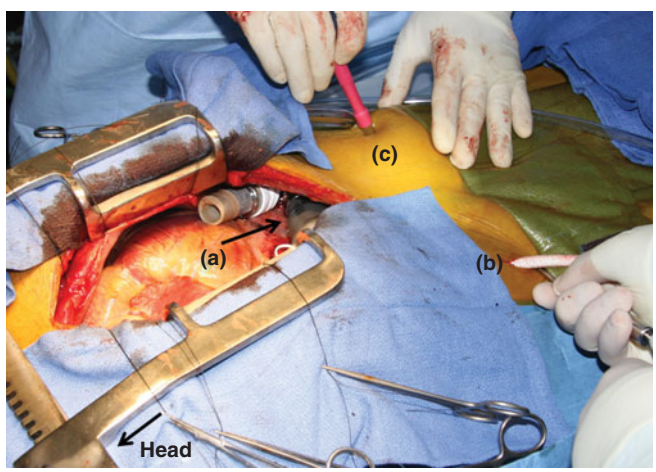

FIGURE 66-7 Placement of the device. (A) The LVAD pump placed in a pocket created in the preperitoneal space. (B) The percutaneous lead pulled through a temporarily incision at the right abdominal wall. (C) Final exit site for the lead.

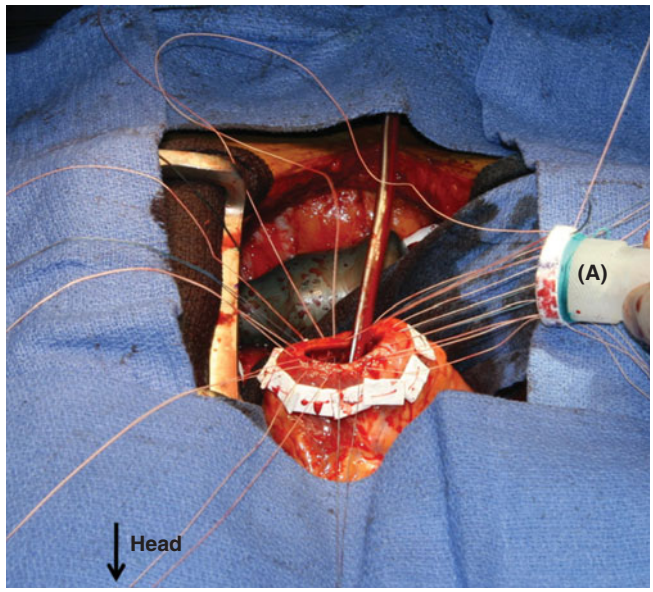

FIGURE 66-9 Placement of an inflow cuff (A) at the LV apex.

redundancy that may lead to outflow graft kinking. A longitudinal aortotomy is created and the anastomosis performed using continuous 4-0 polypropylene suture. The anastomosis is reinforced with BioGlue (CryoLife Inc., Kennesaw, GA). Cardiopulmonary bypass is initiated and attention is turned to the placement of the LV apical inflow cannula. This is usually done under conditions of normothermia with a beating heart. A specialized coring knife is used to create the apical core. Care must be taken to correctly identify the apex of the left ventricle and avoid deviation into the septum or the lateral wall. After coring of the apex, care is taken to ensure a clear inflow tract. Any excess trabeculations or myocardium that may impinge on the inflow cannula are excised. Ventricular thrombus is carefully removed. Sutures of 2-0 braided polyester reinforced with felt pledgets are then placed around the circumference of the core in a horizontal mattress fashion and passed through the sewing ring of the inflow cuff (Fig. 66-9). The cuff is secured and then attached to the inflow cannula of the device. The heart is allowed to fill with blood and the device is de-aired through a venting hole placed in the outflow graft. Evacuation of air is confirmed with TEE. The patient is then weaned from cardiopulmonary bypass, and the device is initiated. After ensuring adequate hemostasis, drains are placed in the mediastinum, pleural spaces, and device pocket. A synthetic pericardial membrane, such as Gore-Tex membrane (Gore Medical Products, Flagstaff, AZ), is placed over the anterior mediastinal structures and secured to the pericardial edges to minimize the risk of injury during reoperative median sternotomy. The sternum and soft tissues are then closed in the standard fashion. Particular attention is given to secure abdominal fascial closure to prevent wound dehiscence and subsequent device infection. In certain patients in whom excessive mediastinal bleeding is encountered secondary to coagulopathy, our preference is to pack the mediastinum and perform delayed sternal closure after approximately 24 hours, once bleeding has subsided and the patient has been adequately resuscitated.

POSTOPERATIVE MANAGEMENT

Postoperative care is crucial to successful outcomes in patients undergoing MCSD implantation, and management starts before surgery. Again appropriate patient selection is above all the most important key to success. Also important is identifying the appropriate timing of MCSD insertion; patients must first receive aggressive medical management as necessary with IABP to optimize end-organ function. Preexisting infection needs to be identified and treated. Appropriate MCSD configuration (LVAD, BiVAD, or TAH, etc) and device selection follow.

Meticulous surgical technique is the key to preventing unnecessary postoperative complications. Blood product transfusion with platelets, fresh frozen plasma, and cryoprecipitate is given as needed. Preheparinization harvest of autologous blood seems helpful in hemostasis. We are cautious about using recombinant factor 7 in this group of patients because of unknown interaction between the mechanical device and this product. Adequate hemostasis is achieved before leaving the operating room, because massive blood transfusion contributes to the development of RV failure after LVAD insertion. After device initiation, proper device function is ensured in the operating room to restore and maintain adequate end-organ perfusion. Inadequate device flows may be the result of mechanical problems such as inflow cannula obstruction or malposition, outflow graft kinking, or cardiac tamponade. Optimization of RV function (for isolated LVAD cases) is initiated before coming off CPB in

concert with the anesthesiologist. Continuous assessment of RV function throughout the operation is accomplished with direct visualization by the surgeon and TEE by the anesthesiologist. The following seven hemodynamic factors are to be taken into consideration and optimized: CVP (central ventricular pressure) (preload), PVR (afterload), RV contractility, interventricular interaction, heart rate (HR), rhythm, and SVR (for coronary perfusion to the RV). RV distension is avoided as it leads to increased stress on the thin RV wall, worsened TR, decreased end-organ perfusion, and right-to-left shunting via a PFO (if untreated). A CVP of over 15 mm Hg is an alarming sign. Inotropic agents such as phosphodiesterase inhibitors, dobutamine, and epinephrine as well as inhaled nitric oxide are used liberally to support the RV.[58] Dynamic interventricular interaction through the ventricular septum significantly changes after LVAD initiation and this may compromise RV function, especially with continuous-flow devices. With excessive unloading by the device, the ventricular septum is shifted toward the LV impairing the contraction of the RV. Flow through the device is adjusted to maintain an appropriate position of the septum based on TEE. The appropriate shape of the LV in TEE short-axis view is "round shape" whereas flattened septum (D-shaped LV) indicates excessive suction. HR and rhythm are controlled with pacing and/or administration of antiarrthymic agents. Maintaining SVR and adequate perfusion pressure (mean systemic BP approximately 80 mm Hg) to ensure RV coronary perfusion is achieved with vasopressors. Arginine vasopressin has been shown to be effective in treating vasodilatory hypotension in this group of patients.[59] Excessive afterload, however, may impair pump afterload and should be treated accordingly particularly with continuous-flow devices. If optimization of RV function can not be achieved, RVAD support is considered.

Postoperative care in the intensive care unit (ICU) is the continuation of intraoperative care, which is centered on optimization of RV function. The focus of the first several hours is on monitoring for blood loss and RV function. (Near)-normalization of coagulation status is achieved with proper warming and blood product transfusion. The surgeon should have a low threshold for mediastinal reexploration for excessive postoperative bleeding. RV function is assessed with hemodynamic parameters keeping the above-mentioned seven factors (CVP, PVR, RV contractility, interventricular interaction, HR, rhythm, and SVR) in mind. In a typical stable patient after LVAD insertion, a satisfactory mean BP of above 80 mm Hg and CVP below 10 are achievable with minimum to moderate doses of inotropes/vasopressors. Proactive and aggressive treatment of subtle signs of RV failure, such as increasing vasopressor requirement, elevated CVP with relatively low pulmonary artery pressures, low output from the LVAD (measured by the device) or the RV (measured by thermodilution method with a pulmonary artery [PA] catheter), low urine output, and low mixed venous oxygen saturation should be undertaken. This can help avoid deterioration of RV function and the subsequent cascades that ensues, including device low-output and eventual end-organ dysfunction. The treatment of RV dysfunction consists of liberal increase in dosage and/or addition of inotropes, vasopressors, and inhaled nitric oxide, aggressive diuresis, instituting CVVH, optimization of ventilator settings, and controlling the HR and rhythm with pacing and/or antiarrhythmic agents. Also, the interventricular effect of the LVAD needs to be addressed. This is a frequent cause of hemodynamic instability in the first 24 to 48 hours after LVAD insertion (especially with continuous-flow devices). Temporarily decreasing the pump speed usually restores hemodynamics. Some of the devices provide certain indices. For instance, the HeartMate II provides a pulse index (PI), which is a measure of the amount of pulsatility seen by the pump over interval of 15 seconds. PI relates to the amount of unloading of the LV and is a helpful guide for the adjustment of pump speed. Overdecompression of the LV might also manifest as ventricular arrhythmia caused by mechanical irritation of the ventricular wall with the inflow cannula. Reducing the speed will reshape the LV with resolution of the arrhythmia.

Once stabilized, the patient is weaned from sedatives and then from the ventilator support. Unexpected significant hypoxia could be related to an undiscovered PFO. Vasopressors/inotropes are weaned off as tolerated, maybe except for one of the inotropes (our preference is milrinone), which may be kept on for several more days to support the RV and help diuresis. Aggressive diuresis is initiated to maintain appropriate preload to the RV. A continuous IV infusion of furosemide is preferred in the ICU and it is converted to intermittent IV bolus. Bumetanide and nesiritide are added as needed. Temporary CVVH may be required. Inotropes and diuretics are used liberally until the patient excretes the excess fluid, which is assessed by daily measurement of weight and physical exam (pretibial edema, lung sounds). Transthoracic echocardiogram is obtained periodically to guide the amount of LV unloading (reflected by the LV end-diastolic dimension) and RV function. Should the patient not respond to escalating treatment for RV failure at any point, RVAD placement should proceed without delay. Once complete hemostasis is confirmed, usually by postoperative day 2 or 3, antiplatelet therapy and/or anticoagulation are started, based on the recommendation for the device used. We no longer routinely initiate anticoagulation with an IV heparin infusion because of high incidence of bleeding complications. Currently anticoagulation is started with oral warfarin approximately postoperative day 3 to 5 when the patient is ready to be transferred out of the ICU. Enteral feedings are resumed early in the postoperative course. Once the patient is extubated, attention is focused on physical therapy and rehabilitation.[60] Should the patient develop anemia with hyperbilirubinemia, hemolysis needs to be ruled out although it is very rare.[61]

Special Postoperative Care after Bivad Insertion

Obviously RV failure is not a concern with BiVAD support. Sometimes supernormal output from the BiVAD is required to meet the metabolic needs of various end organs because, generally speaking, patients who require BiVAD support are sicker than those who require isolated LVAD support. Flow, however, has to be balanced between the LVAD and the RVAD. The left side of the heart receives more return than the right because of bronchial circulation. RVAD flow is adjusted so as to not overflow the LVAD one unless flow through the aortic valve is maintained; otherwise pulmonary congestion will result.

OUTCOMES

Overall clinical outcomes have been improving owing to advances in technology and the accumulation of clinical experience.[8,39,62–64]

BTT

Success rates with pulsatile LVADs as a BTT increased from below 65% in the 1990s to 72% in early the 2000s at our program.[65] Further improvement was noticed with newer-generation LVADs. John et al. reported six month survival rate of 87% for 32 patients who received the HeartMate II as a BTT.[66] A prospective, multicenter study of 133 patients who received the HeartMate II as a BTT showed that at 6 months 75% reached the principal outcomes of heart transplantation (42%), cardiac recovery (1%), or ongoing device support (32%) with a mortality rate of 19%.[62] Overall actuarial survival for patients continuing to receive pump support was 68% at 12 months. Over the past decade, the number of heart transplant recipients supported by a VAD at the time of transplantation has more than doubled to over 400 per year.[67] Studies have concluded that long-term survival is not affected by pretransplant VAD support.[68,69] Using UNOS registry data, Russo et al. compared the long-term survival after heart transplantation between recipients who received a VAD as a BTT and those who did not. The VAD group was further divided into extracorporeal, intracorporeal, and paracorporeal VADs. Although the extracorporeal group had diminished graft survival in the first 90 days (likely related to the more morbid pre-VAD status of the recipients), there were not significant differences in risk-adjusted graft survival at up to 5 years between recipients who received any type of VAD as a BTT and those who did not.[67]

Success rates for BTT with BiVAD support, on the other hand, were reported to be only 25 to 60%.[48,51–53,70–72] Poorer success was reported specifically among those who required an RVAD following LVAD placement. Early planned institution of BiVAD support might improve outcomes.[73]

DT

Outcomes for LVADs placed for DT are well-summarized in two landmark randomized studies.[7,8] LVADs were shown to be superior to optimal medical management with regard to survival and quality of life. The REMATCH trial demonstrated a 48% reduction in the risk of death at 1 year with a pulsatile LVAD (HeartMate VE). Subsequently, a continuous-flow device (HeartMate II) was shown to improve survival at 2 years (58% vs 24% for a pulsatile LVAD, the HeartMate XVE). Interestingly, the 2-year survival with the pulsatile-flow device in these two randomized studies remained roughly the same, and this suggests that the main contributor to improvements in survival is technologic advancement.

Bridge to Recovery

Few LVAD recipients show recovery of ventricular function, and even if they do, they frequently suffer from recurrence of HF after LVAD explantation. We have shown that significant clinical recovery occurred in only 5 out of 111 patients, and in these patients, symptoms frequently returned and many died of consequences of HF.[74] In large case series, recovery with removal of LVAD support has been seen in 4 to 30% of patients with a 20 to 50% incidence of recurrent CHF.[75–78] The results of Birks et al. regarding intensive pharmacologic treatment are most promising.[79] Their patients underwent institution of LVAD support and were treated with lisinopril, carvedilol, spironolactone, and losartan to enhance reverse remodeling. Once regression of LV enlargement had been achieved, the beta$_2$-adrenergic receptor agonist clenbuterol was administered to prevent myocardial atrophy. Eleven of fifteen patients had sufficient myocardial recovery to undergo explantation of the LVAD. The cumulative rate of freedom from recurrent HF among the surviving patients was 100% and 88.9%, 1 and 4 years after explantation, respectively.

ADVERSE EVENTS

INTERMACS provides standardized definitions of adverse events. The defined events include major bleeding, cardiac arrhythmia, pericardial fluid collection, device malfunction, hemolysis, hepatic dysfunction, hypertension, major infection, myocardial infarction, neurologic dysfunction, psychiatric episode, renal dysfunction, respiratory failure, right heart failure, non–central nervous system (CNS) thromboembolic event, venous thromboembolism event, wound dehiscence, and other adverse events. Among these, CNS events, MOF, RV failure, and arrhythmias remain the most common cause of death.[24] The cumulative incidence rate of adverse events in the first 60 days after MCSD insertion can be as high as 89%.[61]

Operative Mortality

Recently reported 30-day survival rates after MCSD insertion are approximately 80 to 90%.[22] Higher INTERMACS profiles were shown to correlate with higher mortality,[80] and operative risk categories developed by Lietz et al. for DT patients estimate 90-day in-hospital mortality after LVAD placement at 2% in low-risk patients and 81% in very high-risk patients.[22] Estimated operative mortality rates from the revised Columbia screening scale, developed with a focus on the operative mortality, are approximately 5% for a score of 0–1, approximately 15% for a score of 2–4, and approximately 45% for a score of ≥5.[43] Better patient selection has contributed to decreasing operative mortality, and proceeding to MCSD insertion before a patient becomes too sick is the key. Postcardiotomy support remains one of the most challenging indications. The Thoratec registry data for PVAD placements by March 2005 showed a survival of 44.7% with LVAD support (n = 253) and 32.4% with BiVAD support (n = 241) for this indication.[81]

Major Bleeding

Bleeding is the most common complication after MCSD implantation and mediastinal reexploration is required in 20% up to 60% of MCSD recipients.[82] Resuscitation with massive blood

product transfusion is associated with increased morbidity and mortality. A recent study demonstrated that the number of bleeding events requiring packed red blood cell transfusion was 1.66 per patient-year for a continuous-flow device and 2.45 for a pulsatile-flow device.[8] Bleeding risk persists even after the acute postoperative period, and this seems to be above what is normally observed in patients receiving anticoagulation treatment. Late bleeding most commonly manifests as gastrointestinal bleeding, and continuous-flow devices appear to have a higher incidence of this complication compared with pulsatile-flow devices.[83] Development of arteriovenous malformations and impaired von Willebrand factor–dependent platelet aggregation are the proposed mechanisms.[83,84]

Right Heart Failure

RV failure occurs in 20 to 40% of LVAD recipients and approximately 5% of cases require RVAD support. A detailed discussion is found in Univentricular or Biventricular Support.

Device Malfunction

Device durability is an important limitation to the use of currently approved pulsatile-flow LVADs because valve or bearing failures occur frequently by 18 months.[7] The advent of continuous-flow devices dramatically reduced the incidence of this complication. In a recent randomized study, there were no primary-pump or bearing failures in patients with a continuous-flow LVAD.[8] It was suggested that redesign of the percutaneous lead and development of modular components may further reduce the infrequent need for replacement, which occurred in only 9% of patients. The University of Michigan group experienced an 11% incidence of device malfunction with BiVAD support compared with 9% with LVAD support.[61]

Major Infection (Device-Related)

Sepsis and device malfunction were the most common causes of death in patients who received a pulsatile-flow LVAD in the REMATCH trial. Within 3 months after implantation, the probability of device infection was 28%. Infections mostly involved the drive-line tract and pocket and were treated with local measures and antibiotics. The continuous-flow device reduced the rate of device-related infection to nearly half that seen with the pulsatile-flow device.[8]

Neurologic Dysfunction

MCSDs predispose recipients to the risk of thromboembolism, with ischemic stroke being the most devastating consequence. The combined risk of ischemic and hemorrhagic CVA was reported to be 8 to 20%. The type of device may correlate with the risk of stroke. Tsukui et al. reported an actuarial freedom from CVA at six months of 75%, 64%, and 33% with the

TABLE 66-4 The Adverse Events from the INTERMACS Registry between June 2006 and March 2008

Adverse Events	Episodes (Patients)	≤30 Days (Patients)	>30 Days (Patients)

HeartMate (X)VE and II device, Thoratec BiVAD, and Novacor device, respectively.[85]

Table 66-4 summarizes the current probability of adverse events from the INTERMACS registry between June 2006 and March 2008.[86]

FUTURE DIRECTION

Advances in technology have led to the creation of more durable and versatile devices, resulting in improved clinical outcomes for the MCSD recipients. Minimally invasive approaches for MCSD insertion will be developed. MCSDs may be used across a wider spectrum of patients and purposes, and patients with less advanced HF may receive partial circulatory support to improve quality of life. Approaches in which MCS combined with one or more addtitional treatment modalities, such as a drug therapy or cell therapy to prevent post-LVAD explant remodeling, may prove fruitful. In fact, clinical trials in these areas are ongoing.

Accumulation of clinical experience will allow consensus guidelines to be developed. However, at the current rapid pace of technologic progress, such guidelines may be outdated at the time of their publication, somewhat similar to the experience with coronary stents. Therefore, cardiac surgeons performing MCSD surgery should remain updated.

MCS is still a relatively new technology in the treatment of HF, and much research remains to be done to elucidate its role in clinical medicine and also to better understand HF itself. Both basic and clinical investigations are warranted with support from nonprofit organizations and industry.

KEY POINTS

- Patient selection is the most important component to achieve good outcomes with MCSD implantation.
- Elucidating the goal of MCSD placement (BTT, DT, bridge to recovery, bridge to dicision, bridge to bridge) is crucial for appropriate patient and device selection.
- Optimizing RV function is the key after LVAD implantation.

CHAPTER 67

Total Artificial Heart

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality in the United States and a significant public health problem in most industrialized nations. Since 1900, it has been the leading cause of death in the United States every year except 1918.[1] In 2005, CVD afflicted 80 million Americans and caused 864,500 deaths. Meanwhile, the number of people with CVD, and especially its advanced forms, has been increasing. There are two main reasons for this. First, although there is still no cure for CVD, palliative therapy has improved to the point that more people are surviving past their initial episodes of CVD to live on with some form of the disease. Second, the average age of the US population is rising as the "baby boom" generation ages.

An increasingly prevalent form of advanced CVD is heart failure (HF). Almost 5.7 million Americans (approximately 3.2 million men and 2.5 million women) are living with HF.[1] Its etiology can be ischemic, idiopathic, or viral. More than $37.2 billion is spent each year on the care of HF patients, and many therapeutic advances have been made. In 2005, HF directly caused 53,000 deaths and indirectly caused another 250,000. As large as the problem is now, its magnitude is expected to worsen as more cardiac patients are able to survive and live longer with their disease and thus increase their chances of developing end-stage HF.

At present, treatment of advanced HF takes three forms: medical therapy, surgical therapy, and cardiac support or replacement.[2,3] Medical therapy (eg, intravenous inotropes and vasodilators) relieves symptoms by reducing cardiac work and increasing myocardial contractility. However, although advances in medical therapy have helped improve quality of life for those with heart failure, mortality remains unaffected. Surgical therapy (eg, revascularization and valve replacement or repair) relieves symptoms of ischemia and valvular dysfunction, but in most cases does not stop the underlying disease process from progressing. When conventional medical and surgical therapies for HF are exhausted, cardiac support or replacement (ie, heart transplantation or implantation of an artificial heart or ventricular assist device) may in some cases become the only therapeutic alternative.

Heart transplantation has evolved into a suitable treatment for advanced HF. However, it has severe limitations related to patient selection, organ procurement and distribution, and cost-effectiveness. Slightly more than 2000 patients with end-stage heart failure receive heart transplants each year in the United States. However, about 3000 patients are on the active heart transplant waiting list at any given time, and as many as 40,000 more are potential candidates for heart transplantation.[4,5] Heart transplantation for the relatively young (<40 years old) is not very promising because the life expectancy of a donor heart recipient is about 10 years on average and 20 years at most. In 2004, 460 patients on the active waiting list died while awaiting a donor heart. Heart transplantation is also associated with continuous, lifelong, expensive medical therapy.

To help overcome these limitations, engineers and physicians have continued efforts begun over four decades ago to develop systems for providing either temporary or permanent mechanical circulatory support (MCS). Originally, such systems were intended to support patients indefinitely because

other forms of heart replacement did not appear to be feasible. Temporary MCS has been shown to be a suitable option for some HF patients who are awaiting heart transplants.[6,7] and for others who are not transplant candidates but need support for indefinite periods.[8] In recent clinical studies, myocardial function improved sufficiently in some cases to allow removal of the MCS device and avoid heart transplantation.[9,10] Nevertheless, in light of the shortcomings of medical therapy, surgical therapy, and heart transplantation, efforts have continued to develop a total artificial heart (TAH) that would not only save the lives of critically ill HF patients but also allow them to resume relatively normal lifestyles. Here, we review the historical development and current status of TAH technology.

EARLY DEVELOPMENT AND EXPERIENCE

In 1812, LeGallois first proposed the idea of supporting a failing heart with either a permanent or temporary device.[11] In the 1920s, Lindbergh and Carrel discussed and planned an artificial heart.[12] Throughout the 1940s researchers including Dennis and Gibbon were developing a machine that would bypass the circulation of the heart and lungs to allow open-heart surgery. The modern era of MCS began in 1951 when Dennis first used a heart-lung machine to sustain the circulation while the heart was opened to repair an atrial septal defect.[13] Two years later, Gibbon repeated this procedure.[14] However, high mortality in the first few cases led both Dennis and Gibbon to abandon the use of their heart-lung machines. In 1954, Lillehei began to use cross-circulation (human-to-human perfusion) as a means to support heart and lung function during congenital heart defect.[15] However, because of the controversy created by Lillehei's procedure, researchers continued efforts to develop a machine that would allow open-heart surgery.

By 1955, Kirklin and associates at the Mayo Clinic had refined the Mayo-Gibbon machine and the techniques that allowed open-heart surgery.[16] Likewise, Lillehei and associates had developed their machine that also allowed for safe open-heart operations.[17] By 1960, Kirklin and Lillehei in Minneapolis and DeBakey and Cooley in Houston had perfected their machines and techniques to the point where heart surgery was becoming routine in Minnesota and Texas. The early developmental work on the use of mechanical circulatory systems by Dennis, Lillehei, DeWall, Gibbon, and Kirklin allowed for many new cardiac operations, including coronary artery bypass, heart transplantation, valve repair, and implantation of a TAH. After refinements of the heart-lung machines, DeBakey and Cooley began to develop many of the surgical techniques that eventually made open-heart surgery routine around the world.

In 1957, Akutsu and Kolff became the first to implant a TAH in vivo.[18] Inserted into the chest of a dog, the pump adequately maintained the circulation for approximately 90 minutes. However, Akutsu and Kolff never applied their TAH technology clinically. In 1964, the National Heart Institute established the Artificial Heart Program to promote the development of the TAH and other cardiac assist devices. In the early 1960s, DeBakey and researchers at Baylor College of Medicine in Houston began developing a TAH. In 1963, DeBakey implanted the first clinical left ventricular assist device (LVAD) into a 42-year-old patient.[19] The pump functioned well, but the patient died of pulmonary complications after 4 days of support. In 1967, DeBakey implanted an LVAD into a 37-year-old who presented with symptoms of HF, including easy fatigability and severe dyspnea on slight exertion. This patient also had history of rheumatic heart disease since age 18 and closed mitral valvulotomy at age 25. The intention was to use the LVAD until sufficient myocardial recovery could be gained. The LVAD supported the patient's circulation for 10 days and was then electively removed. The patient was discharged from the hospital on postoperative day 29 and later resumed normal activity. On follow-up at 18 months after LVAD removal, the patient remained free of HF symptoms, and a chest x-ray showed a significant reduction in cardiac size.

FIRST TOTAL ARTIFICIAL HEART

The first implantation of a TAH into a human was done by Cooley on April 4, 1969, in a 47-year-old man who could not be weaned from cardiopulmonary bypass (CPB) following left ventricular aneurysmectomy.[20] The intent was to support the patient until a donor heart could be found. The TAH (Fig. 67-1), designed by Liotta, was a pneumatically powered, double-chambered pump with Dacron-lined right and left

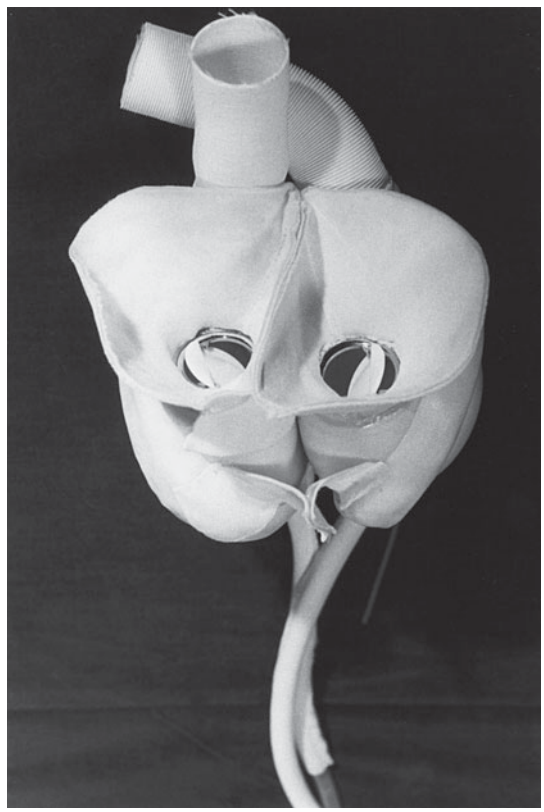

FIGURE 67-1 The Liotta total artificial heart, the first TAH implanted in a human.

inflow cuffs and outflow grafts. Wada-Cutter hingeless valves controlled the direction of blood flow through the pump. The TAH itself was connected to a large external power unit, which unfortunately severely restricted patient mobility. The TAH performed adequately for 64 hours until transplantation. The donor heart also functioned well, but the patient died of pseudomonal pneumonia 32 hours after transplantation. Though the Liotta device performed as designed, it was never used clinically again. Nevertheless, this case clearly demonstrated that a TAH could be used safely and effectively in a human as a bridge to transplantation.

AKUTSU-III TOTAL ARTIFICIAL HEART

The second implantation of a TAH in a human was also done by Cooley. On July 23, 1981, Cooley implanted the Akutsu-III TAH into a critically ill 26-year-old man who suffered heart failure after undergoing coronary artery bypass surgery for severe arteriosclerosis. Unable to be weaned from CPB after surgery, the patient was fitted with the TAH in a final effort to sustain his life. The Akutsu-III TAH (Fig. 67-2) consisted of two pneumatically powered, double-chambered pumps featuring reciprocating hemispherical diaphragms.[21] The TAH provided excellent hemodynamics and supported the patient in stable condition for a total of 55 hours until a suitable donor heart was found. The patient finally received a transplant but died of infectious, renal, and pulmonary complications 10 days later. Despite the fatal outcome, this case demonstrated that a TAH could adequately sustain a patient for several days, with no evidence of hemolysis or thromboembolism, until heart transplantation.

JARVIK-7/CARDIOWEST TOTAL ARTIFICIAL HEART

In the late 1970s, Kolff and his team at the University of Utah developed the Jarvik-7 TAH. In 1982, DeVries became the first to permanently implant a TAH when he implanted a Jarvik-7 into a dying patient.[22] The Jarvik-7 TAH (Fig. 67-3) was a pneumatically powered, biventricular pulsatile device that replaced the heart.[23,24] The pumps were connected to their respective native atria by synthetic cuffs and connectors. Each pump had chambers for air and blood separated by a smooth, flexible polyurethane diaphragm. The inflow and outflow conduits contained Medtronic-Hall tilting disk valves. The filling of the pumps was aided by vacuum. Pneumatic drivelines, brought out through the chest wall to connect with an external console, shuttled air to the pumps during systole, thereby causing collapse of the pump sac and blood ejection. Pump rate, drive pressure, and systolic duration were monitored and optimized from the external console. The Jarvik-7 had a stroke volume of 70 mL and a normal cardiac output of 6 to 8 L/min (maximum, 15 L/min).

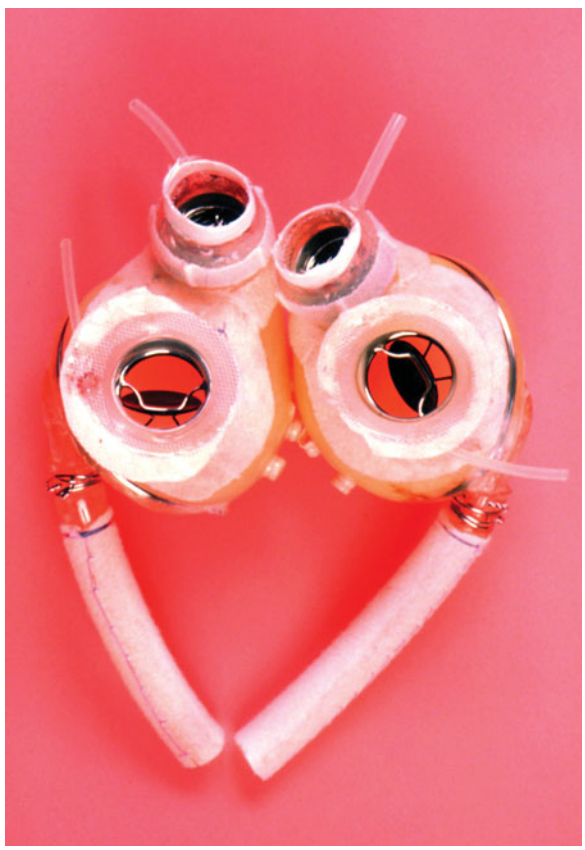

FIGURE 67-2 The Akutsu-III total artificial heart, the second TAH implanted in a human.

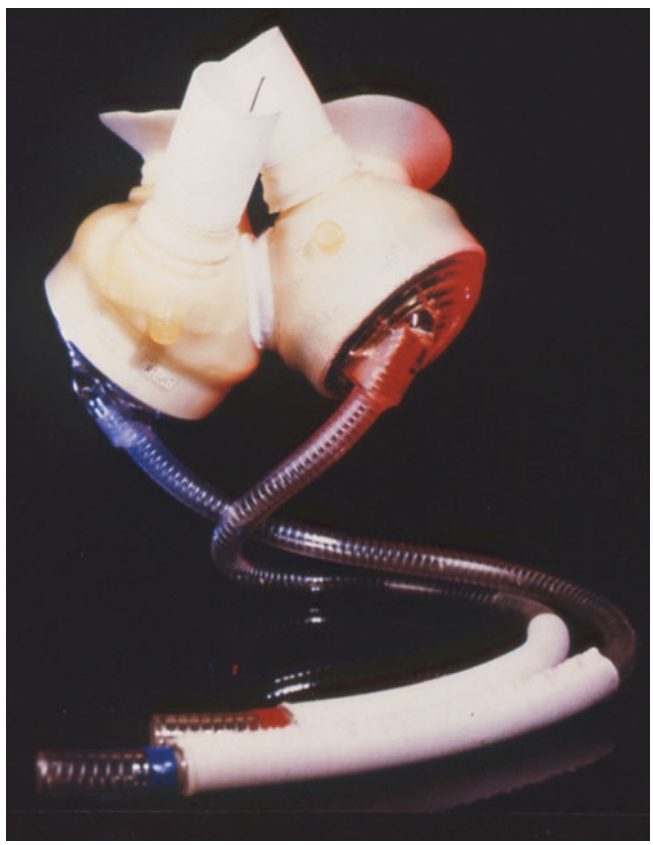

FIGURE 67-3 The CardioWest TAH-t (SynCardia, Inc., Tucson, AZ), formerly the Jarvik-7 and Symbion TAH.

In the initial clinical experience with the Jarvik-7 TAH, a total of five patients were permanently supported for periods ranging from 10 to 620 days. The TAH was able to adequately support circulation, but its large drive console and frequent medical complications limited patient activity. Four patients were able to make brief trips out of the hospital to see family and friends. Long-term outcomes, however, were poor. Patients supported by the Jarvik-7 for longer periods suffered several complications, including thromboembolism, stroke, infection, and multiorgan failure.

Despite these mixed results, in 1985 the Jarvik-7 (renamed the Symbion) TAH entered clinical trials as a bridge to transplantation. In 1986, Copeland reported the first successful use of this device for this indication.[25] Between 1985 and 1991, approximately 170 patients were supported with the Symbion TAH as a bridge to transplantation.[26] Sixty-six percent underwent successful heart transplantation, a rate similar to those in bridge-to-transplantation studies of left ventricular assist devices. Sepsis and multiple organ failure were the primary causes of death during TAH support.

Although the bridge-to-transplantation study demonstrated that the Jarvik-7 (Symbion) TAH was clinically safe and effective, the US Food and Drug Administration (FDA) withdrew the device's investigational device exemption (IDE) for clinical use in January 1991 because of inadequate compliance with FDA regulations.[27] In January 1993, the IDE was restored to the CardioWest TAH, which differed little from the original Jarvik-7. In 2001, Syncardia, Inc. was formed, and the CardioWest TAH-t (temporary) has since been used successfully in the United States, Canada, and France.[28] In the US clinical trials, survival to transplantation and overall 1-year survival rates were significantly higher for CardioWest TAH-t recipients (n = 81) than for controls (n = 35) (79% versus 46% and 70% versus 31%, respectively). These results led to market approval of the CardioWest TAH-t as a bridge-to-transplant device in 2004. By 2009, more than 800 implants have been performed at more than 40 centers worldwide.

ABIOCOR IMPLANTABLE REPLACEMENT HEART

On July 2, 2001, as part of an FDA-sponsored phase I clinical trial, surgeons at Jewish Hospital in Louisville, Kentucky, performed the first implantation of the AbioCor TAH in a 59-year-old man with end-stage HF.[29] The AbioCor Implantable Replacement Heart is a self-contained, electrohydraulic TAH (Fig. 67-4) that has been developed and tested by ABIOMED, Inc. (Danvers, MA) and the Texas Heart Institute, with the support of the National Heart, Lung, and Blood Institute (NHLBI).[30,31] It is designed to sustain the circulation and extend the lives of patients with end-stage HF who have suffered irreversible left and right ventricular failure, for whom surgery or medical therapy is inadequate, and who would otherwise soon die (Table 67-1). The AbioCor is the first TAH to be used clinically that is fully implantable and communicates to external hardware without penetrating the skin. The device utilizes a transcutaneous energy transfer system (TET) and a radiofrequency communication (RF Comm) system that allows it to be powered and controlled by signals transmitted across intact skin. A unique feature of the AbioCor is a right-left flow-balancing mechanism that eliminates the need for an external vent or internal compliance chamber.[32]

FIGURE 67-4 The AbioCor Implantable Replacement Heart. (*ABIOMED, Inc., Danvers, MA.*)

The internal components of the AbioCor system consist of a thoracic unit, internal TET coil, controller, and battery.[33] The thoracic unit (pump) weighs about 2 lb and consists of two artificial ventricles, four valves, and an innovative motor-driven hydraulic pumping system (Fig. 67-5). The pump's motor rotates at 6000 to 8000 rpm, which allows sufficient hydraulic fluid pressure to compress the diaphragm around the blood chamber and eject blood. A miniaturized electronics package implanted in the patient's abdomen monitors and controls the pump rate, right-left balance, and motor speed. An internal rechargeable battery, also implanted within the abdomen, provides emergency or backup power. The internal battery is continually recharged via the TET system and can provide up to 30 minutes of untethered operation.

The AbioCor's external components include a computer console, an external TET coil, and external battery packs. The

TABLE 67-1 Inclusion/Exclusion Criteria for FDA-Sponsored Phase I Clinical Trial of Abiocor Total Artificial Heart

Inclusion Criteria
End-stage heart failure
>70% probability of death within 30 days
Ineligibility for a heart transplant
No other surgical or medical treatment options
Biventricular failure
Exclusion Criteria
Significant potential for reversibility of heart failure
Chronic dialysis
Recent cerebrovascular accident (CVA)
Irreversible liver failure
Blood dyscrasia

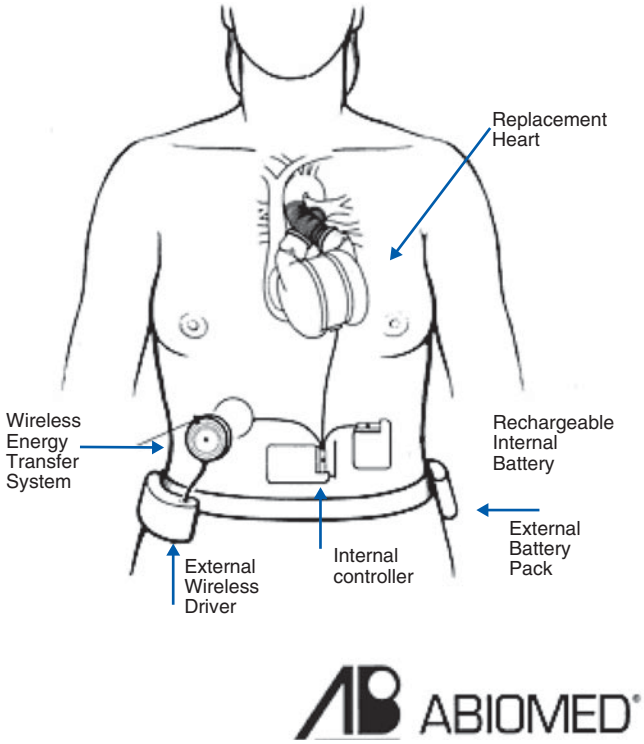

FIGURE 67-5 The AbioCor system is designed to increase or decrease its pump rate in response to the body's needs. The AbioCor also includes an active monitoring system that provides detailed performance feedback and alarms in the event of irregularities.

FIGURE 67-6 Third patient to receive the AbioCor Implantable Replacement Heart. This patient was supported by the AbioCor for 142 days and underwent physical rehabilitation but ultimately died of thromboembolic complications.

external computer communicates via the RF Comm system with the abdominally implanted controller, which controls the pump. The external TET coil provides the pump with power from the console or from the external battery packs. The external battery packs can power the AbioCor TAH for 2 to 4 hours (Fig. 67-6).

In the phase I feasibility trial, 14 patients received the AbioCor as destination therapy (Table 67-2). Thrombo-

TABLE 67-2 Summary of Initial Clinical Experience with AbioCor Total Artificial Heart*

embolism was a significant adverse event in this group of patients, and there were two pump failures. However, compared with the known rates of infection for implantable systems with percutaneous drivelines, device-related infections in this trial were relatively rare. The longest surviving patient was supported for 512 days, most of which were lived at home with a good quality of life. In 2006, the FDA approved the AbioCor for commercial use under a Humanitarian Device Exemption.

COMPLICATIONS

Use of a TAH is associated with serious complications. The most frequent complications are infection, severe postoperative bleeding, and thromboembolism.[34-37] Potentially serious but less frequent complications are renal, hepatic, pulmonary, and neurologic dysfunction and complications caused by technical problems.[34,38] Complicating factors include patient selection, device size, implantation timing and location, the need for extensive surgery at implantation, and the reliability of support equipment.

Life-threatening infections have been the most important complication for patients being supported permanently by a TAH.[39] In the Jarvik-7 experience, all patients supported for many months developed serious infections that eventually contributed to their deaths.[23,40] Patients supported by a TAH for shorter periods while awaiting heart transplantation had infection rates of 30 to 40%.[35-39] During the 1980s, driveline and mediastinal infections in TAH-supported patients were frequent and severe, regardless of the duration of support. However, in the more recent bridge-to-transplantation experience with the CardioWest TAH-t, serious infections contributing to death or delayed transplantation occurred in only 21% of patients.[41,42]

Patients supported with a TAH, regardless of the intended use, are very susceptible to infection. Predisposing factors include the tissue trauma associated with surgical implantation; contamination of the implanted device; depression of the body's immune defenses; the large amount of foreign material presented on the surface of the device; and use of the drivelines, tubes, catheters, and other devices that are necessary for the care of these patients. Infections can occur at any point during TAH support. Once an internal component of the TAH system is infectiously colonized, treatment is difficult and often ineffective. Infections are more likely to occur in the early postoperative period, especially in the most critically ill patients, as a result of (1) device contamination during the course of care and (2) postoperative bleeding caused by intensive care procedures and exposure during reoperation. Meticulous care and numerous infection prevention measures are vital in all TAH patients.

Postoperative bleeding is a frequent and serious complication of TAH implantation. It generally occurs in 40 to 50% of TAH or ventricular assist device recipients.[34] In the more recent CardioWest TAH-t experience, the rate was approximately 25%. Contributing factors include severe HF and associated hepatic dysfunction, the extensive surgery and lengthy CPB time required for implantation, and the necessity for postoperative anticoagulation therapy. Severe HF often leads to hepatic dysfunction and subsequent derangement of the coagulation system. Patients with severe HF are often receiving continuous preoperative anticoagulant or antiplatelet therapy, the effects of which are often difficult to reverse before TAH implantation. The extensive surgery and lengthy CPB time required for implantation can lead to severe depletion of clotting factors. The necessity for postoperative anticoagulation therapy requires that a proper balance be established between preventing thrombosis and allowing blood to clot, through the careful management of hemostasis and anticoagulant therapy.

Thrombosis within the TAH is of particular concern. Five of the first six Jarvik-7 recipients had thromboembolic events. However, the frequency of thromboembolism has decreased significantly since that initial experience and is now an estimated 10 to 15%.[34,35,43] Preventive measures are primarily targeted at precisely monitoring the thrombotic and fibrinolytic systems, maintaining sufficient flow through the device to avoid stasis, and providing adequate anticoagulation and antiplatelet therapy. Generally, heparin and warfarin are used as antithrombotic therapy to achieve a prothrombin time, activated thromboplastin time, or international normalized ratio two to three times greater than the baseline or normal value. Aspirin or dipyridamole or both are also used.

There is a complex though poorly understood interrelationship between infection, bleeding, and thromboembolism. Thrombus formation may lead to the development of infection, and bacterial colonization may lead to thrombus formation. Bacteria are often seen in thrombi found in cardiovascular devices.[44] Bacteria embedded in a thrombus are protected from circulating antibiotics and leukocytes. Bacteria, endotoxins, and inflammatory cells may contribute to thrombus formation by their effect on platelet aggregation.[44] Bacterial endotoxins can cause platelet aggregation, endothelial injury, and increased endothelial thromboplastin activity. Excessive bleeding most often results in reoperation, which increases the patient's exposure to contamination. Also, blood transfusions and intravascular monitoring for these critically ill patients are more extensive and result in frequent exposure to the external environment. Infection, bleeding, and thromboembolism can contribute individually and collectively to the development of multiple organ failure, one of the most frequent causes of death in TAH recipients.

Other important problems and issues related to TAH implantation are device malfunction, poor fit or size mismatch between TAH and patient, social and ethical issues, mobility, and nutrition. Device malfunction leading to catastrophic failure of the TAH or ventricular assist device is rare. Most technical issues have involved external components and have been readily resolved. Fit and size mismatch remains a problem. All TAH models used to date have been relatively large and only fit adequately into patients with a body surface area greater than 1.7 m^2. Because the cost of TAH technology is fairly high and most candidates for TAH implantation are in their sixth to seventh decade of life, many groups question whether society should bear the cost of developing this technology. Until recently, the external components of the TAH equipment have been large and cumbersome, thus limiting patient mobility,

exercise, and rehabilitation. More recent designs of the TAH allow for much more mobility.

TOTAL ARTIFICAL HEART RESEARCH AND DEVELOPMENT

It has been shown that HF can be treated with volume-displacement TAHs, such as the pneumatic CardioWest TAH-t or the AbioCor TAH. The CardioWest TAH-t has successfully supported patients awaiting transplantation.[40,45,46] However, its externalized pneumatic drivelines and pneumatic console limit durability and patient mobility, making this TAH poorly suited for permanent cardiac replacement. The electrohydraulic AbioCor Implantable Replacement Heart has been used in a small, select group of patients requiring biventricular replacement.[47] Although these TAHs have been used successfully in some patients, their large size, mechanical complexity, and poor durability have also limited their application.

Recently, new design applications using continuous-flow rotary blood pumps have emerged to create a smaller and more compact alternative to the larger volume-displacement TAHs. Unlike the pulsatile, volume-displacement TAHs, these rotary pumps have no flexible membranes, pusher-plates, or prosthetic valves that can wear out. They are actuated by rapidly spinning impellers, which reduce their mechanical complexity. Rotary pumps are more durable, making them less expensive to produce. In addition, these pumps are smaller, quieter, and more energy efficient than are volume-displacement pumps. Lastly, rotary pumps are inflow-pressure sensitive—they closely imitate the native heart by autonomously increasing pump flow in response to an increasing preload. Surprisingly, this technology has never been used clinically in a TAH configuration, despite the significant need for a cardiac replacement device (CRD) that is smaller, simpler, and less expensive. Therefore, constant-flow technology may be ideally suited for integration into the next generation of permanently implantable CRDs.

Recently, at the Texas Heart Institute, we have begun extensive testing of rotary blood pumps to assess the feasibility of using two continuous-flow pumps for totally implantable biventricular replacement.[48] Axial-flow and centrifugal-type blood pumps are being developed for use as CRDs.[48,49] Initially, the constant-flow pumps were designed and used clinically as left ventricular assist devices (LVADs). However, it was noted, particularly in pumps placed outside the ventricle, that the ventricle itself acted as a reservoir and that the aortic valve did not open. Therefore, technically, there was no pulse. Despite this, patients had normal physiologic function, even years after the device was implanted. This fact supports our belief that constant-flow pumps could be a feasible option for a CRD.

The use of two independent constant-flow pumps modifies and may even eliminate the need for a separate control mechanism for atrial balance. Each pump's flow will be regulated by the pressure differential between the inflow and the outflow, even at a constant rpm. Testing of that concept in our laboratory has also proved promising, with animal survival times of 7 weeks after total cardiac replacement with two rotary pumps. This was achieved by maintaining a constant rpm, even in treadmill studies. The normal physiologic response gives us some hope that an individualized flow might be assessed for each patient, without the need for a complex, integrated system. Continuous flow with an induced pulse (by modulating speed) and with pulseless flow is being investigated to study the physiologic effects in a chronic animal model.

Additional programs have also begun to investigate the use of rotary blood pumps as CRDs. The Cleveland Clinic is developing a valveless, sensorless, pulsatile, continuous-flow double-pump TAH.[50] The impellers of both pumps are attached to a single axial rotor. Atrial pressures are balanced by way of passive self-regulation (the rotor axial position and subsequent position of the impeller with regard to the right pump inflow). If the atrial pressure on either the left or right sides is increased, the rotor is pushed to the contralateral side, forcing the impeller either to block or open the right inflow opening, thus increasing or decreasing right pump flow. A group at Queensland University of Technology is also working on a single-unit rotary device CRD that uses a shared rotating hub with two impellers.[51] This device employs an interpump shunt (similar to a ventricular septal defect) for left-to-right atrial pressure balance, allowing blood to flow between the two pumps and beneath the pump impellers. At Tohoku University, two centrifugal pumps, each with independent control algorithms, are being tested as a CRD.[52]

COMMENT

Since the 1950s, when the heart-lung bypass machine was developed, many advances have been made in the surgical treatment of HF. Many surgical procedures considered impossible just 40 years ago are today considered routine. A classic example is heart transplantation. However, TAH technology has not evolved at the same pace. Although the first human heart transplantation and first human TAH implantation occurred within 2 years of each other, TAH implantation is still neither routine nor widely available. However, two TAHs are undergoing clinical trials at present in the United States. The CardioWest (formerly the Jarvik-7) TAH-t, which is the more widely used of the two, is now approved for use as a bridge to transplantation. The AbioCor TAH is still in the early stages of clinical testing and is likely years away from approval as an alternative to heart transplantation. However, should its unique TET system and flow-balancing mechanism prove to be reliable for extended periods of time, the AbioCor may become a widely used alternative to heart transplantation for those patients who have no other treatment options.

There are many obstacles to overcome before any TAH is widely accepted. Infection, bleeding, thromboembolism, and biocompatibility issues are serious problems that affect nearly all implantable cardiovascular devices including TAHs. Improved biomaterials, better prevention, and more effective antibiotic and anticoagulant medications may help overcome these problems. Acceptance by the public, by some critics in the health professions, and by third-party payors may be slow. Quality in manufacturing is needed to ensure reliability of TAH components.

Addressing these problems will help bring the TAH more quickly into routine clinical use.

KEY POINTS

- Careful patient selection is key to long-term, successful outcomes. An institution's medical review board should approve potential candidates to ensure that only appropriate patients are selected for CRD implantation. Biventricular function should be carefully assessed in patients to rule out if they are better candidates for LVAD implantation.
- Bleeding complications can be multifactorial. Patients with poor platelet and liver function, those who undergo prolonged cardiopulmonary bypass times during the implant procedure, or those who have preoperative coagulopathies will likely have bleeding complications. Attention to detail during the TAH implant procedure can minimize bleeding complications and ensure faster recovery times.
- Infection prevention measures must be used in TAH patients. Should large, blood-contacting foreign bodies in the chest become infected, they are difficult to treat. All indwelling catheters should be replaced often to minimize the risk of infection. Cardiac replacement devices with external drivelines must be meticulously cared for to reduce the risk of infection.
- Device size and portability are important factors. The AbioCor Implantable Replacement Heart can only be used in larger patients with the appropriate thoracic dimensions. Imaging studies must be performed to ensure that the thoracic anatomy will allow for optimal device fit. The CardioWest TAH-t employs a pneumatic external driver, which may limit patient mobility and normal activity.

CHAPTER 68

Nontransplant Surgical Options for Heart Failure

Lynn C. Huffman
Steven F. Bolling

INTRODUCTION

Congestive heart failure (CHF) has become a major worldwide public health problem. In our ever-aging population, medical advances that have extended our average life expectancy have also left more people living with chronic cardiac disease than ever before. More than 20 million people are affected worldwide. In the United States the estimated 2006 prevalence of heart failure in adults age 20 and older is 5.8 million yet less than 3000 are offered transplantation because of limitations of age, comorbid conditions, and donor availability. Despite the significant improvements with medical management hospital discharges for heart failure rose from 877,000 in 1996 to 1,106,000 in 2006 and mortality in the first year is one in five. CHF patients are repeatedly readmitted for inpatient care and the vast majority will die within 3 years of diagnosis.[1]

Orthotopic heart transplantation (OHT) offers successful and reproducible long-term results and is the treatment of choice for patients with medically refractory end-stage heart failure.[2] Unfortunately, the obvious limitations to OHT include the need for immunosuppression and the severe shortage of donor organs. This past decade has seen the annual number of transplants performed worldwide plateau at less than 4000, down to only 3353 in 2008.[3,4] This lack of donor availability has thus necessitated a rigorous selection criteria be applied to potential recipients in order to optimize the utility of these precious organs, indicated only for patients with end-stage cardiomyopathy in whom all other modes of therapy have been exhausted. Access to OHT has thus been restricted to those without comorbid medical conditions and relatively restricted to those younger than age 65. This leaves the vast majority of CHF patients seeking other options.

With significant technologic strides being made toward total implantability, the role for mechanical support is becoming more widely accepted as a bridge to recovery as well as a bridge to transplant. There have been a number of successful studies of ventricular assist devices (VADs) used as a bridge to recovery and the long-term efficacy for this purpose, and this use as a long-term therapy for chronic heart failure has become established by multicenter clinical trials.[5–10] As a result continuous-flow left ventricular assist devices (LVADs) have emerged as the standard of care for advanced heart failure patients requiring long-term mechanical circulatory support. The long-term survival of circulatory support is increasing but does not yet equal survival after OHT, the gold standard treatment. Because many more people can benefit from this therapy, and with their improved durability, these devices are now an option in the management of patients with heart failure.

This clinical dilemma has provided the impetus for surgeons to develop new alternatives for the treatment of heart failure. As OHT and VAD use is more stringently applied, techniques to restore myocardial perfusion, eliminate valvular regurgitation, and restore ventricular geometry have emerged as a possible first-line surgical approach to heart failure. In response to the growing need for the proficient application and critical appraisal of the expanding menu of surgical options, the new subspecialty of heart failure surgery has emerged. The following will briefly review established nontransplant surgical modalities for heart failure such as coronary revascularization, geometric mitral reconstruction, and ventricular reconstruction. Alternative options such as partial left ventriculectomy and cardiomyoplasty as well as some innovative devices currently being evaluated for clinical application will also be discussed.

CORONARY REVASCULARIZATION

We have known for nearly 25 years that revascularizing patients with left ventricular dysfunction can result in upward of a 25% improvement in long-term survival.[11,12] Early enthusiasm was tempered by reports of high operative mortality in patients with a low ejection fraction (EF). Since then, as success with the medical and surgical management of heart failure and transplantation grew, so did the interest in applying this experience to patients with ischemic cardiomyopathy. Successful revascularization can now be performed on patients with an EF less than 30% with hospital mortalities as low as 5%.[13,14]

The premise behind the improvements in EF, long-term survival, and quality of life of these patients following coronary artery bypass grafting (CABG) is believed to be owing to postoperative myocyte recruitment. Restoration of perfusion resuscitates dormant viable myocardium and serves to protect the previously functioning portions of the ventricle from further ischemic insults, arrhythmias, and infarction.

In order to minimize morbidity, a multidisciplinary approach to the preoperative management of heart failure is essential. Patients ideally suited for CABG are those who are medically optimized, with or without angina, who have good distal coronary targets, functional hibernating myocardium identified preoperatively, and no evidence of right ventricular dysfunction.[15] As experience in managing these patients increases, many surgeons have operated on patients with ejection fractions less than 10%, those requiring reoperation, and those with moderate elevations in pulmonary artery pressure. Nevertheless, patients with clear documentation of a poor right ventricular EF, clinical right-sided congestive symptoms, or fixed pulmonary hypertension above 60 mm Hg systolic should be approached cautiously, because these patients may in fact be better suited for transplantation.

The process of preoperative investigation should coincide with optimizing the patient's medical management. This should entail an aggressive regimen of diuretic and vasodilator therapy to minimize ventricular afterload and normalize the patient's circulating volume. For patients with severe heart failure, a brief period of inotropic therapy for ventricular resuscitation may be necessary to optimize their medical management.[16] Inability to be weaned from this support is often indicative of severe myocardial injury and poor overall prognosis with any surgical therapy other than mechanical ventricular assistance or transplantation.

Preoperative investigations should begin with transthoracic echocardiography to grossly evaluate ventricular function and identify any underlying valvular pathology. Baseline screening physiological studies of oxygen consumption, pulmonary function, and cardiopulmonary endurance are recommended. Identification of reversible ischemia by means of a nuclear study can be helpful; however, for patients with angina, many centers will proceed directly to coronary angiography. Though angina may be indicative of living ventricular muscle, perhaps the most important correlate of successful surgical recovery is the quantification of myocardial viability. Not only is a determination of myocardial contractile reserve essential to ensure that the patient can be safely separated from cardiopulmonary bypass (CPB), this information is predictive of ventricular recovery and long-term survival after operation. Though thallium-201 perfusion scans may distinguish myocytes with membrane integrity from scar, PET scanning and dobutamine stress echocardiography permit the preoperative identification of myocardial viability and the prediction of postoperative function.[16–18]

The fundamental premise behind a successful operation is to attain an expeditiously performed and yet complete revascularization. As the failing myocardium is particularly intolerant to further episodes of ischemia, careful consideration should be given to the quality of the distal vessels and the ease with which good anastomoses can be achieved. Operative time expended grafting small or extensively diseased vessels, or performing additional techniques such as endarterectomy, may be counterproductive. Because the price to pay for incomplete revascularization or transient ischemia may be severe, off-pump techniques may not be ideally suited for these patients unless performed flawlessly.

Multiple groups have been uniformly successful in demonstrating improvements in survival, ventricular function, and functional status with coronary revascularization in patients with ischemic cardiomyopathy with ejection fractions less than 25%.[19–21]

The 5-year survival with transplantation ranges from 62 to 82%, whereas with medical therapy alone, it is less than 20%. Most series report survival following CABG for ischemic cardiomyopathy ranging from 85 to 88% at 1 year, 75 to 82% at 2 years, 68 to 80% at 3 years, and 60 to 80% at 5 years. Operative mortality has been reported from 3 to 12%, with the main predictor of increased risk being urgency of operation. When compared to medical therapy, revascularized patients have significant improvements in quality of life. Most series consistently report considerable enhancements in patient mobility, peak oxygen consumption, and functional status. The average preoperative NYHA class of 3.5 reportedly drops to 1.5 after revascularization. Postoperatively, there are substantial reductions in readmissions for CHF and many patients return to work.

It is encouraging to note that the long-term survival of CHF patients following CABG is equivalent to transplantation in many series. The superior survival of CABG over transplant in the first 2 years postoperatively may be because of early attrition from rejection or infection in the latter group. Although there has been little reported on patients with ejection fractions under 10%, from the above data, one could infer that these patients would have a similarly better outcome than their nonrevascularized counterparts. As experience with heart failure surgery expands, refinements in preoperative and operative management of CABG patients will no doubt be reflected in the uniformity of future long-term results.

VENTRICULAR RECONSTRUCTION

Myocardial revascularization and mitral valve repair reliably improve ventricular function. However, there remains a high mortality for those patients with dilated hearts. Techniques that attempt to augment LV function through a reduction in

end-diastolic wall tension have been developed. From the principle of the law of LaPlace, ventricular wall tension is directly proportional to LV radius and pressure and inversely proportional to wall thickness. As heart failure progresses, the LV thins and dilates leading to increasing wall stress and regional LV dysfunction. Reducing wall stress through the surgical restoration of LV geometry is the guiding principle behind many innovative techniques, including those developed for the isolation of LV aneurysms and nonfunctioning ventricular segments.

After an acute myocardial infarction, the noncontractile myocardium undergoes thinning and fibrous replacement often following the segmental distribution of the arterial occlusion. This nonfunctional LV segment may remain akinetic or transform into a dyskinetic aneurysm depending on factors such as age and regional collateral circulation. Though such postinfarct pathologic remodeling may occur in any area of the heart, the most common clinically relevant region is the anteroapical segment of the LV. The resulting loss of contractile function in the affected segment results in global increases in LV wall tension and myocardial oxygen consumption in turn leading to compensatory LV dilatation. These geometric ventricular changes may also result in loss of the zone of coaptation and MR following infarction. Moreover, when a dyskinetic region expands and becomes aneurysmal, cardiac work is further increased because of the paradoxical systolic motion of the thinned segment. These pathological alterations often result in CHF. The principle of surgical restoration of LV geometry involves the isolation of these nonfunctional areas and a subsequent reduction in LV volumes. This concept has been clearly illustrated by Dor and others, who have revealed significant improvement in heart failure after endoventricular patch exclusion of dyskinetic or akinetic ventricular segments.[22–25]

Recently, many single-center reports revealed encouraging results with endoventricular repair of nondilated akinetic segments when combined with CABG. These findings spawned the multicenter Surgical Treatment of Ischemic Heart Failure (STICH) NIH trial to evaluate its long-term functional benefit. This study concluded that adding surgical ventricular reconstruction to CABG reduced the left ventricular volume, as compared to CABG alone.[26] However, this anatomical change was not associated with a greater improvement in symptoms or exercise tolerance or with a reduction in the rate of death or hospitalization for cardiac causes. Although questions have been raised regarding the analysis of the STICH report including inaccurate conclusions after volume reduction and end points that do not relate to the SVR procedure, many feel that this should be considered a "negative study."[27] Unfortunately therefore, left ventricular reconstruction by endoventricular exclusion of nonfunctional segments has not been accepted as a standard treatment of heart failure and should not be placed alongside high-risk CABG and CHF-MR repair as a potential first-line surgical option for heart failure.

PARTIAL LEFT VENTRICULECTOMY

Batista furthered the concept of surgical ventricular remodeling with the contention that all mammalian hearts should share the same mass-diameter ratio regardless of size. He proposed that all hearts not complying with this relationship should have a segment of the LV wall excised in order to diminish mural tension and improve myocardial oxygen consumption in accordance with the law of LaPlace.[28,29] Batista performed over 150 procedures predominantly on patients with Chagas disease and dilated cardiomyopathy. Though this experience stimulated much interest, no meaningful follow-up data or statistical analyses are available from this series.

To further evaluate the potential benefits of PLV, the Cleveland Clinic performed 62 such cases on patients with idiopathic dilated cardiomyopathy awaiting transplant. They reported a 3.5% operative mortality with seven late deaths and a 1-year actuarial survival of 82%. Of the total 62 patients, 24 (39%) were considered short-term treatment failures: 11 required LVAD support, 6 were listed for transplantation again, and 7 non-LVAD patients died.[29] Moreover, a further 30% attrition rate at 2 years following PLV has been reported.[30,31] These results may be superior to no surgical treatment but they fall short of those obtained by other surgical options for heart failure. As a result, PLV has fallen into disfavor in North America. In the Asian-Pacific region, where transplantation is not widely available, efforts by Suma et al to improve selection criteria and introduce echo-guided surgical decision making have resulted in PLV persisting as a possible option for heart failure in this part of the world.[32]

Though the concept of instantly remodeling the LV through PLV is mechanically appealing, discarding functioning myocardium is not. Patients with ischemic cardiomyopathy with a dyskinetic aneurysmal segment have undergone successful remodeling with an endoventricular patch repair. Patients with dilated cardiomyopathy and MR have undergone mitral reconstruction, thereby altering the angulation of the base of the heart and promoting favorable LV geometry and remodeling. Thus when similar, if not superior results, can be obtained by methods that preserve myocardial integrity, the application of PLV to patients with end-stage heart failure should be approached with an element of caution.

Currently, partial left ventriculectomy has not been widely accepted as a treatment option for dilated cardiomyopathy.

MITRAL RECONSTRUCTION

Functional mitral regurgitation (MR) is a significant complication of advanced systolic congestive heart failure (CHF) without organic mitral valve disease and it may affect almost all heart failure patients as a preterminal or terminal event. Its presence in these patients is associated with progressive ventricular dilatation, an escalation of CHF symptomatology, and significant reductions in long-term survival estimated between only 6 and 24 months. Patel et al., from the Mayo clinic, looked at the prognostic implications of functional MR in patients with advanced systolic CHF evaluated in a heart failure clinic. Of 558 NYHA III-IV patients, those with moderate MR had a 5-year survival of only 27%.[33] This is supported by several other studies that show that the severity of MR impacts survival as well.[34–37]

Historically, the surgical approach to MR was mitral valve replacement, yet little was understood of the interdependence of ventricular function and annulus-papillary muscle continuity. Consequently, patients with a low EF who underwent mitral valve replacement with removal of the subvalvular apparatus had prohibitively high mortality rates. In an attempt to explain these outcomes, the concept of a beneficial "pop-off" effect of mitral regurgitation was conceived. This idea erroneously proposed that mitral incompetence provided a low-pressure relief during systolic ejection from the failing ventricle, and that removal of this effect through mitral replacement was responsible for deterioration of ventricular function. Consequently, mitral valve replacement in patients with heart failure has been discouraged.

A firm understanding of the functional anatomy of the mitral valve is fundamental to the management of MR in heart failure. The mitral valve apparatus consists of the annulus, leaflets, chordae tendineae, and papillary muscles as well as the entire left ventricle (LV). These structures are aligned as if they form a cylinder with the papillary musculature directly aligned beneath the annulus. The maintenance of chordal, annular, and subvalvular continuity is essential for the preservation of mitral geometric relationships and overall ventricular function. MR in heart failure is not related to the valve but to ventricular pathology. The degree of LV distortion reflects the degree of MR.[38] As the ventricle fails, progressive dilatation of the LV results in lateral papillary muscle migration, loss of cylinder closure, and thus loss of the zone of coaptation (Fig. 68-1). This gives rise to MR, which begets more MR and further ventricular dilatation (Fig. 68-2). We know that even a small amount of MR to be harmful in these patients. Grigioni et al. showed that when

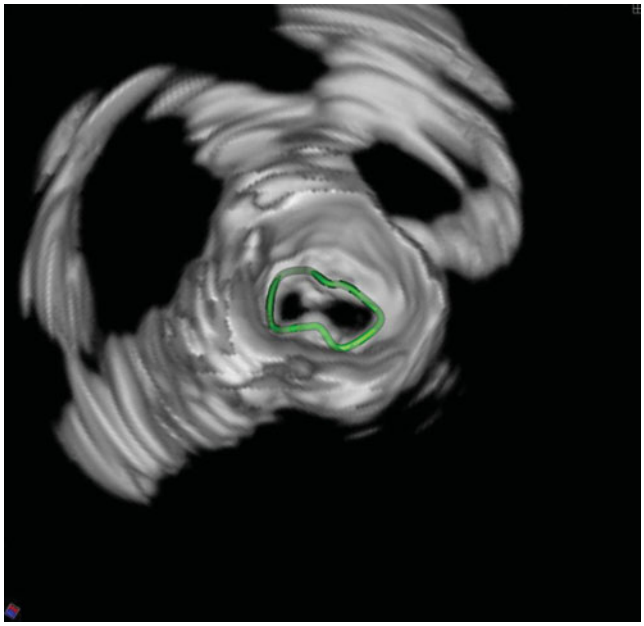

FIGURE 68-1 Postoperative three-dimensional echocardiography of a mitral repair performed using the Geoform mitral annuloplasty ring. Note the apposition of the central areas of the anterior and posterior mitral valve leaflets, which help to establish a zone of coaptation and abolish mitral regurgitation.

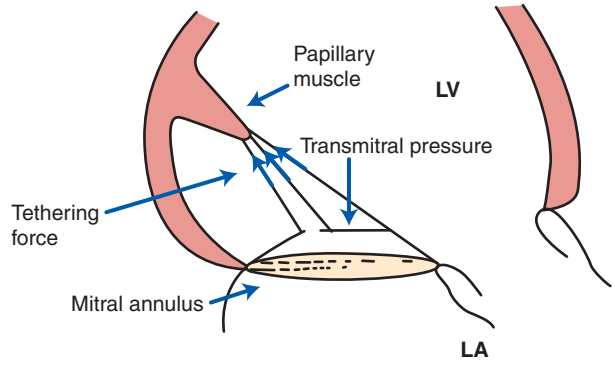

FIGURE 68-2 Various forces exerted on mitral valve leaflets are provided by the mitral valve apparatus, papillary muscles, and important three-dimensional relationships in the ventricle itself of all of the associated structures. Geometric mitral regurgitation results from a combination of annular dilatation, papillary muscle displacement, increased leaflet tethering forces, and weakened leaflet closing forces.

the regurgitant volume was greater than 30 mL, the 5-year survival was less than 35% compared with 44% for a regurgitant volume of 1 to 29 mL and 61% for no MR.[39] With postinfarction remodeling and lateral wall dysfunction, similar processes combine to result in ischemic mitral regurgitation (Fig. 68-3). Left uncorrected, the end result of progressive MR and global ventricular remodeling is similar regardless of the etiology of cardiomyopathy. Reconstruction of this geometric abnormality serves to not only restore valvular competency but also improve ventricular function.

Surgical mitral annuloplasty improves symptoms in these patients with advanced CHF but has not been shown to improve survival. This is likely because surgery for CHF has not been "too little–too late" but "too much–too late." We failed to correct mitral regurgitation early enough in the disease course because advanced heart failure patients were long felt to be nonoperative candidates. However, it has been shown that mitral repair is feasible with a low mortality, relief of MR, and better quality of life. Several authors have demonstrated 30-day mortality rates as low as 1 to 5 % for mitral repair for MR in CHF.[40–48]

The lack of a mortality benefit may also be explained by the absence of a durable repair. When McGee and associates showed no mortality benefit after mitral repair, they also noticed the rate of recurrent MR to be 30 to 40% in less than 1 year.[49] This has led to an attempt to identify surgical predictors of recurrent MR and for improved surgical techniques that result in a more permanent repair. In order to observe a survival benefit in these patients after mitral repair, MR must be fixed permanently, because residual and recurrent MR will obscure or obliterate a survival benefit in any CHF-MVR trial.

Ischemic MR is not caused by organic or intrinsic disease of the valve, but by LV remodeling, dilation, and dysfunction leading to geometric reconfiguration of the mitroventricular apparatus, including papillary muscle displacement and annular dilation. Mitral valve (MV) leaflets become tethered, with failure of anterior-posterior leaflet coaptation, resulting in symmetric or asymmetric regurgitation. Surgical treatment options in

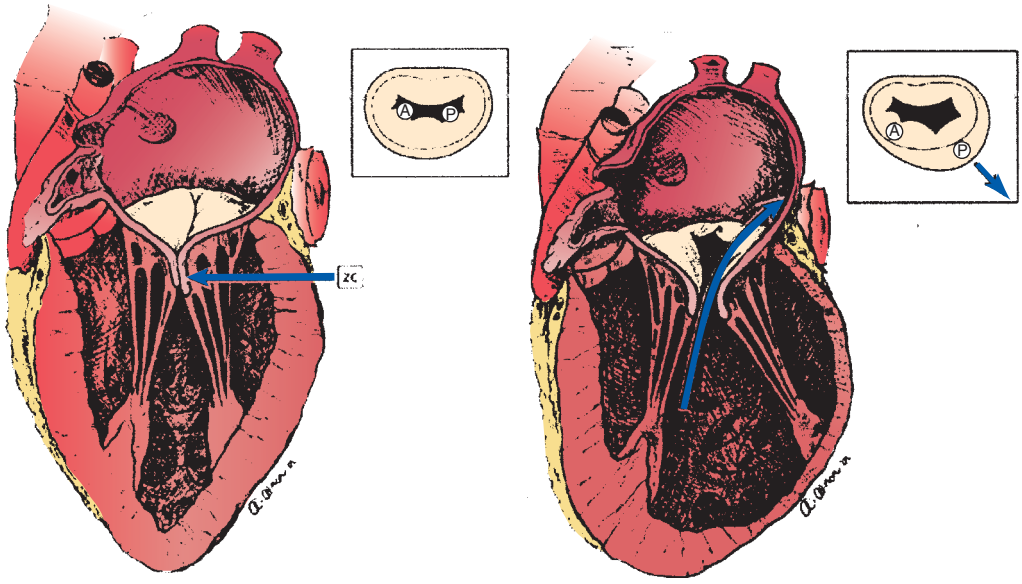

FIGURE 68-3 In ischemic cardiomyopathy, changes within the left ventricle may be asymmetrical and still lead to functional mitral regurgitation. With ischemic damage and thinning of the ventricular wall, there is lateral tethering, displacement of the papillary muscle, and loss of the zone of coaptation (ZC), resulting in an eccentric jet of mitral regurgitation. This illustrates the concept that ischemic mitral regurgitation results from lateral wall dysfunction that, if left untreated, will progress to global left ventricular dysfunction and severe heart failure.

ischemic MR include coronary artery bypass grafting (CABG) alone or with concomitant MV annuloplasty or replacement. Currently, the most common technique to restore valve competence is placing an undersized annuloplasty ring to reduce mitral annulus size. Mihaljevic et al. (Figs. 68-4 and 68-5).[55] Unfortunatety, ischemic mitral regurgitation (IMR) often persists after restrictive mitral valve annuloplasty, in which case it is associated with worse clinical outcomes. In an attempt to determine whether persistence of MR and/or clinical outcome could be predicted from preoperative analysis of mitral valve configuration, in patients undergoing restrictive annuloplasty for ischemic MR, preoperative analysis of mitral valve configuration was shown to accurately predict persistence of MR and 3-year event-free survival. Patients with a posterior leaflet angle >45 degrees (ie, with high posterolateral restriction) should thus be considered poor candidates for this procedure, and concomitant or alternative procedures should be contemplated.

Important LV predictors of recurrent MR are coaptation depth greater than 1 cm as shown by Calafiore et al., and left ventricular end diastolic dimension (LVEDD) less than 65 mm as shown by Braun.[43,50] At 4.3 years follow-up, intermediate-term cutoff values for left ventricular reverse remodeling proved to be predictors for late mortality. For patients with preoperative LVEDD of 65 mm or less, restrictive mitral annuloplasty with revascularization provides a mortality benefit for ischemic mitral regurgitation and heart failure; however, when LVEDD exceeded 65 mm, outcome is poor and a different approach to CHF should be considered.[50]

But perhaps, the strongest predictor of CHF MVR failure is anterior-posterior (AP) diameter greater than 3.7 cm.[51] When the AP diameter after annuloplasty is greater than 3.7 cm the repair should be considered as a potential predictor of a failed repair.[52] New and remodeling MV rings that significantly reduce the residual AP diameter have been shown to be a predictor of no recurrence of MR.[53,54]

FIGURE 68-4 Oblique view of the Geoform mitral annuloplasty ring. Note the posterior ring design element, which reverses the adverse changes in the posterior mitral annulus associated with geometric mitral regurgitation.

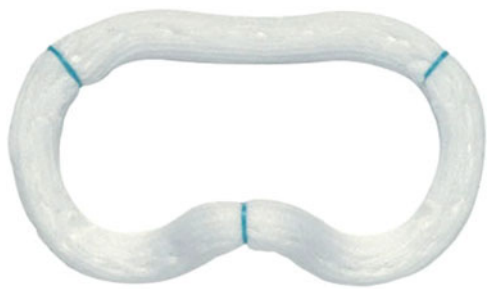

FIGURE 68-5 Superior view of the Geoform mitral annuloplasty ring. The three-dimensional cross-sectional area is not restrictive to atrial blood flow.

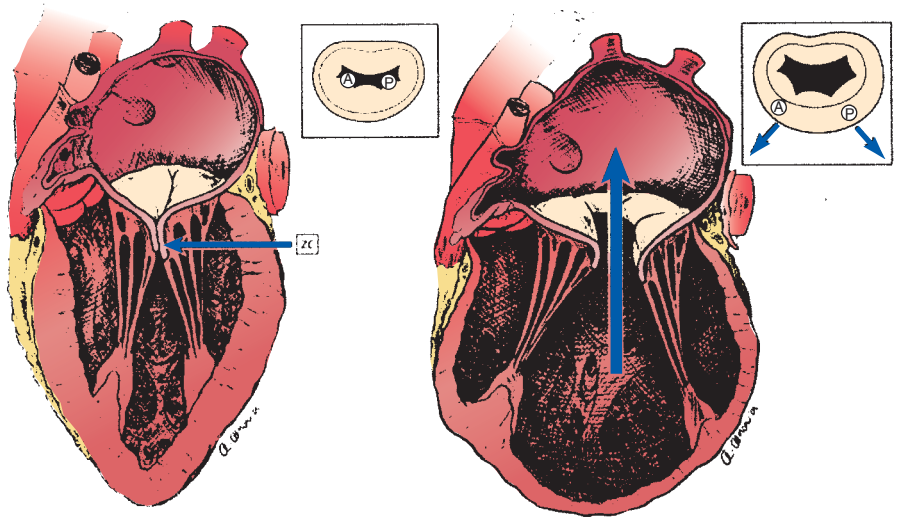

FIGURE 68-6 In nonischemic cardiomyopathy, note the geometric changes that occur from the normal to the failing left ventricle. With the ventricular and annular dilatation of heart failure, the mitral leaflets cannot adequately cover the enlarged mitral orifice, resulting in the loss of the zone of coaptation (ZC). Geometric mitral regurgitation results from a combination of annular dilatation, papillary muscle displacement, increased leaflet tethering forces, and weakened leaflet closing forces.

When considering surgical techniques used in treating heart failure patients, the most significant determinant of leaflet coaptation and MR is the diameter of the mitral valve annulus. Observations with medically managed patients with severe heart failure and MR reveal that decreasing filling pressure and systemic vascular resistance lead to reductions in the dynamic MR associated with their heart failure. This is attributed to a reduction in mitral orifice area relating to decreased LV volume and decreased annular distension. This complex relationship between mitral annular area and leaflet coaptation may thus explain why an undersized "valvular" repair may help a "ventricular" problem (Fig. 68-6).

Earlier use of flexible and incomplete annuloplasty rings was justified based on the belief that trigone distance was constant. However, Hueb et al., have demonstrated that trigone distance is not stable.[56] This has led to the use of complete and rigid annuloplasty rings. Spoor et al. experienced a recurrent MR rate five times higher when using flexible rings.[57] In addition, the Kaplan-Meier survival curve for the Acorn MV surgery stratum (rigid annuloplasty) showed a more enduring repair with less recurrence of MR with only 4.2% with 3+ or 4+ MR at 18 months. The overall survival for this group was 84%. In recent work, Bolling et al. have also shown a significant improvement in cumulative survival with undersizing the mitral valve annulus (Fig. 68-7).

The technique of undersizing in mitral reconstruction avoids SAM in these myopathic patients, likely because of widening of the aortomitral angle in these hearts with increased LV size. Furthermore, acute remodeling of the base of the heart with this reparative technique may also reestablish the somewhat normal geometry and ellipsoid shape the LV. As evidenced by the decreased sphericity index and LV volumes seen in these patients, the geometric restoration from mitral reconstruction not only effectively corrects MR but also achieves surgical unloading of the ventricle (Fig. 68-8).

Many centers have reported similar consistent findings following MR. With outcomes equating to transplant while avoiding immunosuppression, this straightforward reparative operation performed in conjunction with medical management may be offered to carefully selected patients with MR and cardiomyopathy as a potential first-line therapy.

DYNAMIC CARDIOMYOPLASTY

An alternative method to surgically optimize LaPlace's law is dynamic cardiomyoplasty (DCMP). The procedure uses the patient's own skeletal muscle to support the heart, helping to reduce wall stress and provide cardiac assistance. The latissimus dorsi muscle is wrapped around the failing heart and an implantable cardiomyostimulator is used to stimulate the muscle to contract in synchrony with cardiac systole. Long-term results show that this method was not considered to be satisfactory in

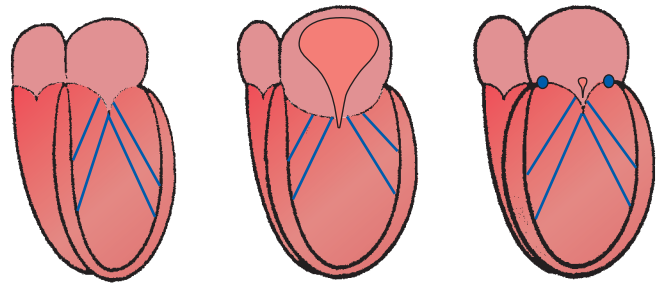

FIGURE 68-7 Geometric mitral reconstruction for heart failure. Successful augmentation of the zone of coaptation and prevention of recurrent MR can be achieved with placement of an undersized circumferential annuloplasty ring performed with multiple annular sutures. Note the changes in the relationship of the papillary muscles in the left ventricle in the new geometry following mitral repair.

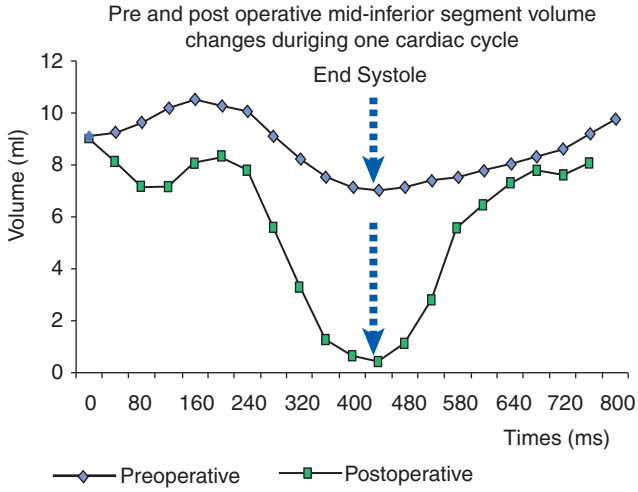

FIGURE 68-8 Left ventricular volume changes obtained on postoperative day 5 following geometric mitral valve repair. Increases in regional EF in the inferobasal wall are shown, which are the opposite of the decreased EF expected following MVR based on historical teaching. (*Courtesy of Nadia Nathan, MD.*)

terms of survival and antiarrhythmic effect because of fatigue of the skeletal muscle. DCMP is now only rarely performed in North America. Investigations into the mechanisms of DCMP have generated promising research in the fields of cellular cardiomyoplasty, myoblast transplantation, and remodeling surgery.[58,59]

EMERGING BIOMEDICAL DEVICES FOR HEART FAILURE

The CorCap Cardiac Support Device (Acorn Cardiovascular, St. Paul, MN) is a mesh device that is implanted around the heart to reduce wall stress and the first therapy specifically designed to address left ventricular remodeling. The ACORN trial, a prospective, randomized, controlled, multicenter evaluation of the CorCap cardiac support device in patients with New York Heart Association (NYHA) class III or IV heart failure of ischemic or nonischemic etiology enrolled a total of 300 patients. Results of the trial were reported in 2007, and although LV geometry was favorably improved, it was found that there was no difference in survival between the treatment and control groups (25 deaths among 148 patients in the treatment group versus 25 deaths among 152 patients in the control group) and no significant with respect to the mode of death. Survival rates, serious adverse events, and hospitalizations between those patients who received a cardiac support device and those who did not were not significantly different. As a result there has been a decline in the application of the CorCap device in the heart failure population.[60]

The Coapsys device (Myocar Inc., Maple Grove, MN) is a second device developed to reduce ventricular wall stress by directly altering cardiac geometry. Working on the premise of optimizing the law of LaPlace, it involves the placement of transventricular tension bands through the RV and LV walls that have the unique ability to be individually tightened in order to achieve a 20% reduction in wall stress.[61] However, the product manufacturer is developing a new device designed to achieve mitral valve repair along with ventricular volume reduction and the Myocor Myosplint has been set aside and further development is uncertain.

PERCUTANEOUS CORONARY SINUS DEVICES FOR CHF-MR

The Viacor percutaneous mitral annuloplasty system (PTMA) (Viacor, Wilmington, MA), Edwards Viking Endovascular coronary sinus ring (Edwards Lifesciences LLD, Irvine, CA), and Carillon mitral contour system (Cardiac Dimensions, Kirkwood, WA) all use an emerging technology approach to mitral annuloplasty using a catheter-based approach to the mitral valve. Using percutaneous catheters, a permanent nitinol strut is placed into the coronary sinus that wraps around the posterior annulus of the mitral valve and attempts to indirectly influence the action of the posterior mitral valve leaflet similar to a partial ring annuloplasty by reducing the anterior-posterior dimension of the mitral annulus. Initial results of mitral annular reduction to a more modest degree than after surgical correction have led to less improvement in MR.[62] As these devices are under investigation and not currently approved for routine use, their clinical impact at this time is unknown.

PERCUTANEOUS MITRAL VALVE REPAIR

The Milano endovascular edge-to-edge repair system (Edwards Lifesciences LLD, Irvine, CA) and MitraClip mitral repair system (Evalve, Menlo Park, CA) use a catheter-based approach to deliver a clip to both the anterior and posterior mitral valve leaflets using the principles of mitral repair pioneered by Dr Otavio Alfieri.[63] Percutaneous catheters are introduced via the femoral vein and cross the atrial septum to enter the left atrium similar to a percutaneous mitral balloon annuloplasty approach. A catheter-based clip is then used to create a permanent coaptation point between the leading-free edges of the anterior and posterior mitral leaflets. The EVEREST II trial compared the MitraClip to surgery.[64] A total of 279 patients enrolled completed 1-year follow-up. Early findings indicate that this technology is safe in the indicated patient population and not inferior in results compared with surgery. However, a clip was considered successful if MR was 2+ or less following application.[64] This makes percutaneous repair attractive for high-risk surgical candidates, but may not be entirely impactful. Further investigation is ongoing comparing surgery to the MitraClip device.[65]

CONCLUSIONS

As surgical therapies for heart failure rapidly evolve, the need for their critical appraisal is essential so that they may be offered to the growing population of CHF patients in a prompt yet effective manner. Transplantation continues to offer selected patients reliable long-term survival in a reproducible fashion,

and it thus remains as a gold standard surgical therapy for heart failure. Rapidly evolving mechanical assist devices are playing a more prevalent role in myocardial recovery and destination therapy. With the growing disparity between donor availability and heart failure patients, experience with assist devices has shown them to be an effective nontransplant surgical solution.

The results of the more conventional techniques of CABG and mitral reconstruction when combined with the optimal medical management of heart failure may now be on a par with transplantation. These modalities now form the new first-line surgical therapy for heart failure. Patients with primary ischemic cardiomyopathy and favorable anatomy may be effectively managed with revascularization alone or in combination with mitral repair. Myopathic patients with MR, regardless of etiology, may be effectively managed with mitral reconstruction. The use of other techniques such as SVR, PLV, and DCMP is no longer reserved as viable alternative surgical options for heart failure. The prudent and effective application of the growing menu of surgical strategies for heart failure enables the scarcely available donor hearts to be efficiently used for patients with no other surgical or medical alternatives. Along with the utility of emerging biomedical devices, each of these unique modalities has enhanced the clinically effective armamentarium of the modern surgeon treating patients with heart failure.

CHAPTER 69

Tissue Engineering for Cardiac Valve Surgery

Danielle Gottlieb
John E. Mayer, Jr.

INTRODUCTION

Tissue engineering is a developing science, comprising elements of engineering and biology, whose aim is to build replacement tissues de novo from individual cellular and structural components. The impetus for our work on tissue engineered cardiovascular structures arises from the need to replace cardiovascular tissues that failed to develop normally during embryogenesis or have become dysfunctional as a consequence of disease. In pediatric patients, the cardiovascular structures most often afflicted by congenital anomalies are the cardiac valves and great vessels.

Diseases of the heart valves and large "conduit" arteries account for approximately 60,000 cardiac surgical procedures each year in the United States, and all of the currently available replacement devices have significant limitations.[1,2] Ideally, any valve or artery substitute would function like a normal valve or artery, that is, to allow the passage of pulsatile blood flow without stenosis or regurgitation. The theoretical advantage of engineered tissue replacements is that they could also display other desirable characteristics, such as: (1) durability, (2) growth (for infants and children), (3) compatibility with blood components and the absence of thrombosis or destructive inflammation, and (4) resistance to infection. None of the currently available devices, constructed from either synthetic or biologic materials, meet these criteria. Mechanical heart valves are very durable, but they require anticoagulation to reduce the risk of thrombosis and thromboembolism.[1,2] Therapeutic anticoagulation carries associated morbidity, and even among patients who receive therapeutic anticoagulation, the incidence of thromboembolic complications of mechanical heart valve replacement is not zero.[1,2] Biologic valves, whether of allograft or heterograft origin, remain subject to structural deterioration after implantation.[2–4] Neither mechanical nor biologic valves have any growth potential, and this limitation represents a major source of morbidity for pediatric patients who must undergo multiple reoperations to replace valves and/or valved conduits during the period of maximum somatic growth.

Tissue engineering is an approach based on the hypothesis that when properly designed, living devices will simulate the biology of normal cardiovascular structures, thereby overcoming the shortcomings of currently available heart valve replacements. Of particular relevance to pediatric heart surgery is the long-term function of the engineered valve over time: its capacity to grow, self-repair, and remodel. This chapter summarizes some of the progress that has been made in tissue engineering research as it relates to cardiac valves and conduit arteries, and then outlines the areas where additional efforts must be focused in order to direct cardiovascular tissue engineering toward clinical utility.

NORMAL HEART VALVE BIOLOGY

Adult Valve Structure and Function

Heart valves open and close approximately 40 million times per year; this coordinated function occurs under the demands of hemodynamics. The normal valve presents minimal resistance to opening and no pressure gradient during systolic forward flow. In diastole, the same structure is responsible for rapid and complete closure in order to prevent valve regurgitation. Semilunar valves must additionally resist pressure differences between the diastolic arterial pressure and the diastolic ventricular pressure.

Like many other tissues, valve cusps are composed of cells residing within, and acting reciprocally on, the extracellular matrix (ECM). Semilunar valve cusps are thin, flexible

structures with impressive microscopic and molecular complexity. Much of the strength and flexibility of normal heart valve cusps is owing to the specialized proteins and polysaccharide-protein complexes of the extracellular matrix, produced by resident valve interstitial cells.[5,6] The microscopic and molecular structure of adult valves reflects the regional mechanical forces experienced by the valve cusps; valve cusp ECM is not homogeneous, and the arrangement of the extracellular matrix provides a high degree of flexibility during systole, and a high degree of strength to resist pressure loads during diastole.[5] On the surfaces, a specialized endothelium prevents thrombosis, and acts as a transducer of mechanical force.[7,8] Under the endothelium, valve interstitial cells receive signals sent by the endothelium, and respond by secreting suitable matrix.[9,10]

Valve ECM is stratified and related to valve mechanics.[11] Facing the sinus of Valsalva, where eddy currents occur with diastolic pressure loads, dense collagen is found in the fibrosa layer. A middle layer of connective tissue, the spongiosa, is particularly rich in glycosaminoglycans, large complex molecules that associate with water and act as "shock absorbers," bearing largely compressive mechanical loads. The ventricularis, an elastin-rich layer facing the great artery, is specialized to stretch as the cusps elongate during ejection in systole.

Valve structure and function are therefore closely related, and strategies to engineer valves are aimed to mimic normal valve structure and function, potentially at the subcellular, cellular, tissue, and whole heart valve levels.

Embryologic and Postnatal Development

Valves do not begin as stratified tissues; as circulatory patterns evolve in fetal and postnatal life, valve morphology also changes.[12] Embryologic valve development, therefore, has relevance to tissue engineering, as a model for normal in vivo valve remodeling as programmed by gene regulatory pathways and by applied biomechanical force.

By day 15 of human embryo development, specification of myocardial and endothelial cardiac cells occurs. At day 21, formation of a linear heart tube occurs. These events are followed by rightward looping of the heart, resulting in orientation of the cardiac chambers into their final adult positions, and opposition of two specialized segments of ECM, known as cardiac jelly.[13] The first evidence of valvulogenesis occurs in this cardiac jelly when a subset of endothelial cells delaminate, invade the ECM, and undergo endothelial-to-mesenchymal transformation (EMT).[14] In early fetal valve development, valve interstitial cells are highly proliferative, and reside in a glycosaminoglycan-rich, homogeneous microenvironment. Over the course of fetal development, cell proliferation slows, and production of extracellular matrix results in valve cusp elongation. During the late stages of fetal development (20 to 36 weeks of human gestation) and in early postnatal life, valve stratification into a trilaminar structure occurs, and organization and maturation of collagen fibers begins. At the time of birth, through a series of largely undefined molecular steps, changes in oxygenation and blood pressure distinguish the aortic from the pulmonary sides of the circulation.[12] Transitional neonatal circulation has been associated with a change in phenotype from activated to quiescent interstitial cells in pulmonary, but not aortic, valve cusps.[15] Valve maturation and remodeling continue during childhood; cellularity of valve interstitial cells continues to decrease into adulthood.[12] Once thought to be passive structures, increasing evidence shows cardiac valves to be dynamic organs. Mechanistically, the finding that cellular and extracellular components mature is thought to reflect the dramatic changes in flow and biomechanical loading conditions from fetal to adult life.[12,16] Further elucidation of the genetic regulatory events defining valve growth and maturation is critical to designing biomimetic replacement devices.

ENGINEERED VALVE INPUTS

Approaches to tissue engineered heart valves (TEHV) can be divided into two paradigms, based on the type of structural scaffold employed: bioresorbable scaffolds (nonwoven felts, electrospun scaffolds, knitted meshes, hydrogel-based, and combinations) and decellularized tissue-based scaffolds. The bioresorbable scaffold approach begins with seeding cells and culturing under appropriate biomechanical conditions (static flow, pulsatile flow) and nutrient medium. With regard to tissue mechanical properties, the goal of this approach is fabrication of an adequately strong tissue with approximately constant mechanical properties, requiring that the process of scaffold degradation occurs with a reciprocal increase in extracellular matrix production. Porosity is an important characteristic of bioresorbable scaffolds as it provides a permeable framework for cell migration, nutrient supply, and waste removal. Insufficient porosity leads to nutrient deprivation and cell death. Once a sufficiently stable tissue is formed, in vivo implantation would ideally follow, placing a newly synthesized tissue, devoid of foreign elements, in the required site.

This de novo approach is the one that has been predominantly employed in our laboratory at Children's Hospital, Boston.[17–26] This approach treats components of tissue as "building blocks," constructing valves from a variety of cell types and scaffold materials. Most in vivo studies have been carried out in the lower-pressure pulmonary circulation, which is a more tolerant system than the systemic circulation. This type of approach considers several basic questions as its foundation: (1) What cell type or combination of cell types is necessary to allow the production and maintenance of an appropriate extracellular matrix? (2) To what extent can cellular phenotype be altered, guided, or "engineered" to replicate cells found in the normal valve? (3) How can these cells be spatially organized during the development of this tissue engineered structures until the cells in the construct produce sufficient and appropriate extracellular matrix? (4) What biochemical signals are necessary during the development of these structures to ensure proper extracellular matrix production? (5) What mechanical signals are necessary for optimal tissue development and growth? (6) Should a tissue engineered valve construct be completely developed and appear as an adult valve before implantation, or can further maturation of an engineered construct occur in vivo after implantation?

Proponents of the decellularized tissue method base their approach on the premise that extracellular matrix geometry directs cell behavior, and that the closest structure to the normal valve scaffold is the normal valve scaffold itself. Human aortic valve homografts are currently implanted without tissue-type matching, become acellular after several months in vivo, yet retain their mechanical properties for decades. As the exact features endowing the aortic valve with such durability are unknown, it is hypothesized that these features are retained after ex vivo decellularization. Scaffolds are either seeded with cells before implantation, or implanted without seeded cells, in the expectation that appropriate circulating cell populations will populate the scaffolds in vivo. Without seeding of cells before implantation, however, some decellularized matrices are insufficiently endothelialized by circulating cells to resist surface thrombus formation in vivo.[27]

The literature of tissue engineered heart valves demonstrates the selection of a variety of cell types, scaffold conditions, and preconditioning regimens, and overall, methods are difficult to compare and results have been inconsistent. Systematic screening of engineered tissue elements and combinatorial approaches to building tissues have recently emerged.[28,29] A complete review of past investigations is beyond the scope of this chapter; however, a summary of the fundamental elements of synthetic, biomaterial-based TEHV will be considered in detail in the following sections. In vivo outcomes of these methods will also be considered.

Cell Origin and Phenotype

As in embryologic valvulogenesis, the ideal cell type for a tissue engineered heart valve would fulfill the function of both the valve interstitial and endothelial cells. Conceptually, these cells could be derived from fully differentiated cells capable of extracellular matrix synthesis, or from less committed, multipotent or pluripotent stem cells with the additional potential for differentiation into multiple cell types.

The first tissue engineered heart valve experiments were performed with differentiated cells from artery or vein, including vascular smooth muscle cells, fibroblasts, and endothelial cells derived from the vasculature of immature animals.[17–21] These cells were chosen because they were readily accessible, are derived from a cardiovascular source, and can synthesize extracellular matrix proteins. A comparison of myofibroblasts from the wall of the ascending aorta with those from segments of saphenous vein revealed that the latter cells exhibit superior collagen formation and mechanical strength when cultured on biodegradable polyurethane scaffolds.[30] In our laboratory at Children's Hospital, Boston, tissue engineered heart valves (TEHV) based on these differentiated cells from systemic blood vessels functioned for periods of up to 4 months in vivo.[17,19] However, enhanced collagen formation may be a double-edged sword. The rapid formation of new tissue in the early culture period could give rise to an overabundance of matrix elements, leading to tissue stiffness and potential tissue contraction. Early studies with dermal fibroblasts demonstrated that valve cusps constructed from these cells developed tissue contraction, which limited the ability of valve leaflets to coapt with each other, resulting in valve regurgitation.[31] In addition to production of excessive or unfavorable types of extracellular matrix, mature cells may present a problem of senescence in long-term cell cultures in vitro, which limits the ability to quickly produce sufficient numbers of cells to seed a TEHV construct. Finally, the prospect of harvesting segments of artery from an otherwise normal peripheral circulation in order to obtain cells for a TEHV represented an undesirable clinical situation, and therefore led to a search for alternative cell sources for engineered valves.

The emergence of the field of stem cell biology has changed the paradigm for candidate cell types for heart valve tissue engineering. As stem cells differentiate from their embryonic state, they lose pluripotency with each subsequent step. Multiple steps of differentiation form lineages of cells. In embryonic development, differentiation down a specific lineage occurs with biochemical signaling, occurring in a specific mechanical microenvironment.[32] How lineage specification occurs in the developing heart is currently an area of active research, with the goal of understanding the necessary cues to replicate differentiation down valve cell lineages. In normal development, differentiating cells are subject to a rapidly changing three-dimensional extracellular environment, and development is thought to occur by signals originating outside of the cell, from molecules originating in neighboring cells, and in the extracellular matrix. These reciprocal interactions between cells and their environment in developing valves, the regulatory mechanisms that induce cells to secrete and respond to components of appropriate extracellular matrix, are thought to be the underlying mechanisms stratifying valve cusps into their known compartments. These mechanisms are thought to be largely driven by hemodynamics in developing valves.

There is also recent evidence that stem cells with proliferative and regenerative capacities reside in many adult tissues. These stem cells are capable of not only acting locally on the tissues in which they reside, but they also may be recruited out of the circulation and enlisted in the regeneration of diverse tissues at distant sites. A recent review details emerging evidence that bone marrow–derived endothelial, hematopoietic stem and progenitor cells can also contribute to tissue vascularization during both embryonic and postnatal life.[33] Visconti and coworkers have made the intriguing observation that cardiac valve interstitial cells in mice appear to originate in the bone marrow as hematopoietic cells.[34] The idea that bone marrow contains cells capable of repairing damaged tissue has been applied to regeneration of cardiac muscle after myocardial infarction, whereby progenitor cells have been isolated from sites outside the heart, then injected back into the heart in an attempt to regain contractile function of ischemic or infarcted myocytes. Results of these trials have been equivocal, marginal, or negative, suggesting that the process of regeneration does not occur by the simple addition of multipotent cells.[35] The early experience with the SynerGraft decellularized heterograft valved conduits that were implanted in children as right ventricle-to-pulmonary artery conduits occurred with the expectation that circulating cells from the bloodstream, or ingrowth from adjacent normal tissue, would repopulate the grafts and grow. In this instance, repopulation of the graft by circulating cells occurred, but did not result in adequate function or tissue

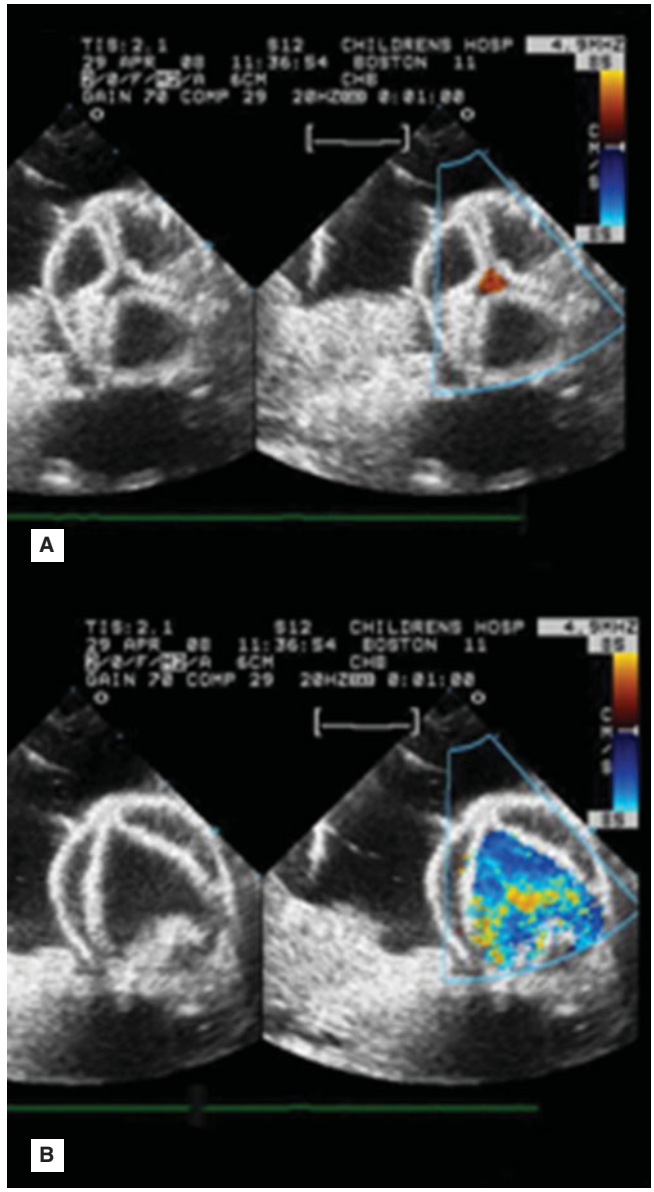

FIGURE 69-2. Representative echocardiogram images of functioning tissue engineered pulmonary valve following implantation.

growth.[36,37] Nonetheless, the progenitor cell populations represent an attractive source of cells for tissue engineering and regeneration, because they have the plasticity necessary to fulfill critical cell functions and are potentially programmable for lineage specification. In addition, these cells can be obtained less invasively than differentiated cells.[33] Our initial experience with progenitor cells in the Mayer laboratory was gained with autologous endothelial progenitor cells (EPCs) isolated from circulating blood in lambs and seeded onto decellularized arterial segments.[17] These seeded arterial grafts were then implanted as an interposition graft in the carotid artery of the donor lamb. These grafts remained patent and functional for up to 130 days. Subsequent animal studies by Sutherland and associates used bone marrow mesenchymal stem cells (MSC) to seed a bioresorbable scaffold formed into a three-leaflet valve within a conduit (Fig. 69-1). These valved conduits were implanted as valved conduits into the main pulmonary artery of neonatal sheep, and remained in place for up to 8 postoperative months.[24] This study was followed by that of Gottlieb et al., who implanted valves of similar elements into larger numbers of sheep and followed changes in function with growth of the animals using MRI and echocardiography. Although the valves had trace to mild regurgitation at the time of implantation (Fig. 69-2), a loss of valve leaflets surface area was observed, which correlated with increasing valve regurgitation over time.[26] Importantly, the valve leaflets underwent a remodeling process in vivo after implantation, seen also in earlier experiments using myofibroblasts and endothelial cells from systemic arteries, and in both sets of experiments a layered histologic appearance developed after implantation.[19,24,26]

Several types of progenitor cells have been used for tissue engineering applications in congenital heart disease. Cebotari and colleagues have recently reported an initial experience seeding EPCs onto homograft valves followed by implantation into two children.[38] Matsumura and associates have shown that when seeded onto a copolymer of lactic acid and ε-caprolactone, green fluorescent protein (GFP)–labeled cells contributed to the histogenesis of their explanted tissue engineered vascular graft. These grafts remained patent, and explanted constructs contained GFP-labeled cells expressing both endothelial and mesenchymal markers.[31] The group at Tokyo Women's Medical College has also carried out implants of tissue engineered vascular grafts in children with congenital heart disease using whole mononuclear cell fractions, seeded onto bioresorbable scaffolds.[39] This work is now ongoing at Yale University, because of encouraging early results.

Increasing evidence supports the idea that for cells, "geography is destiny." Many cell types including bone marrow–derived MSC exhibit surprising plasticity, and cell phenotype seems to be related to the microenvironment in which cells reside.[40–42]

However, many of the factors controlling differentiation in these environments remain incompletely defined. There is evidence that endothelial progenitor cells are able to transdifferentiate in response to biochemical signals. Dvorin and colleagues showed that in the presence of transforming growth factor (TGF)-β_1, EPCs express α-smooth muscle actin (α-SMA), after seeding on a bioresorbable copolymer scaffold.[43] This behavior is not characteristic of endothelium; SMA expression suggests a mesenchymal phenotype, and this observation is a potentially related phenomenon to EMT seen in embryologic valvulogenesis.[43] Human aortic valve endothelial cells, but not vascular endothelial cells, respond to TGF-β_1 in a similar fashion, suggesting that endothelial progenitor cells may be suitable as a replacement for valve endothelium. Though stem cells of many types remain promising candidates for tissue engineering, their full potential will be harnessed with an understanding of their normal generative and regenerative roles in vivo.

Structural Scaffold

Although it has been possible to grow individual cell types in culture for decades, it is more difficult to induce cells to assemble or organize into complex three-dimensional structural arrangements that are found in normal tissues, and to induce cells to produce specific extracellular matrix components on demand. Implantation of engineered tissues requires structural integrity, and for this reason, most tissue engineers employ a structural scaffold, in addition to cellular material.

Given this fundamental requirement, two main strategies for development of a three-dimensional tissue have been used: (1) de novo scaffold synthesis and arrangement into a three-dimensional structure; and (2) decellularization of a whole (usually xenograft) tissue.

Any scaffold for tissue engineering applications must be biocompatible and allow cells to adhere and proliferate. For congenital cardiac applications, tissue growth is our target, and therefore the scaffold must either degrade or be remodeled in vivo. The advantage of the biopolymer approach is that the chemistry of these scaffolds allows for in vivo degradation, usually by hydrolysis.[44] The disadvantage is that heart valves are structurally complex and anisotropic; designing the structural features of the normal heart valve de novo has presented a substantial engineering challenge. The obvious advantage of the decellularization approach is that the three-dimensional complexity is largely preserved; however, there is a shortage of homograft material relative to the clinical demand, and immunogenicity remains a concern with xenografts. Perhaps most importantly, the extracellular matrix of decellularized xenografts is dense, and may prevent the penetration of seeded cells into the interstices of the matrix. In our laboratory, we have constructed trileaflet valved conduits from small intestinal submucosa and seeded them with EPCs.[23] After implantation in an ovine model, there was satisfactory short-term function, but there was no penetration of any cells into the depths of the small intestinal submucosa scaffold. Extracellular matrix proteins, when exposed to blood components, can induce inflammation, thrombosis, and calcification, so this material has not been pursued further in our laboratory.

Our primary laboratory efforts to develop heart valves and large arteries have utilized the approach of seeding cells onto alternate bioresorbable polymer scaffolds. Ideally, there exists an inverse relationship between scaffold degradation and extracellular matrix formation by seeded cells. Polymer degradation is related to polymer chemistry, fabrication method, and mechanism of degradation, and therefore polymers used in tissue engineering differ in their degradation times. The first generation of scaffolds used in heart valve tissue engineering were highly porous, nonwoven felts produced from fibers of polyglycolic acid (PGA). PGA and related polymers continue to be the most widely used for multiple tissue engineering applications.[45–49] The advantage of PGA and related aliphatic polyesters, including poly-L-lactic acid (PLLA), is their safety, biocompatibility, lack of toxicity, and commercial availability. PGA has been used as the commercially available Dexon suture material since the 1970s.[49] PGA can be extruded as a fiber, which allows fabrication of nonwoven sheets with large, open pores. Open pore structures facilitate cell delivery and proliferation by allowing a large surface area for cell attachment, free diffusion of nutrients and dissolved gases, and removal of waste products of metabolism. Material properties of these nonwoven felts are well established, with reproducible hydrolytic degradation times; PGA alone degrades in 2 to 4 weeks, whereas the majority of fibers of the more hydrophobic PLLA degrade within 4 to 6 weeks. These scaffolds lose strength before losing mass, which challenges tissue engineers to seed sufficient numbers of matrix-producing cells so as to replace the scaffold strength as it is lost. Our laboratory has experimented with PGA coated with the thermoplastic polymer poly-4-hydroxybutyrate (P4HB), assembled into a trileaflet structure by attaching leaflets to a flat scaffold sheet, then wrapping the scaffold around a mandrel and heat-welding a seam of attachment. Despite promising early results using the PGA/P4HB composite, subsequent studies showed loss of structural integrity with longer periods of in vitro culture, followed by difficulties with suture retention and hemostasis in vivo. For these reasons, Sutherland and colleagues in our laboratory developed a scaffold composed of equal parts of PGA and PLLA fibers. Because PGA is a stronger but more rapidly degrading polymer, and PLLA is a less strong polymer with a longer degradation time, we expected more uniform strength from the tissue when constructed from this material. The composite nonwoven felt was fabricated into a valved conduit with a trileaflet valve, and had substantially improved surgical handling characteristics.[24]

Although satisfactorily strong, polymer fiber-based scaffolds are significantly stiffer than normal valve leaflets, and with the addition of cell-secreted extracellular matrix, these constructs are notably stiff.[44] Scaffold stiffness has been shown to affect cell behavior, and tissue engineers have sought less more flexible materials.[42] Wang and colleagues at the Massachusetts Institute of Technology designed an elastic polymer with a rapid degradation time, based on sebacic acid, a derivative of castor oil. Polyglycerol sebaceate is a strong but elastomeric material, and is currently under investigation for use in heart valve tissue engineering applications.[50]

In addition to their stiffness, polymer-based scaffolds are thick, relative to normal valve leaflets. A thick scaffold leads to a nutrient gradient in culture, and many tissue engineering studies based on nonwoven materials have been limited by the lack of nutrient delivery to the deepest areas of engineered tissues. Two solutions are proposed to overcome this limitation: addition of a blood supply and design of thinner scaffolds.

Hydrogel-based scaffolds, including collagen, alginate, agarose, gelatin, fibrin, chitosan, polyethylene glycol, hyaluronic acid, and dehydrated sheets of extracellular matrix have formed the basis of many experiments in tissue engineering. When gels become solid, cells are trapped in the cell, providing a homogeneous distribution of cells embedded in a temporary matrix. In addition, hydrogels can be laid into thin layers. A bileaflet heart valve was produced in the Tranquillo laboratory using a collagen-based scaffold seeded with dermal fibroblasts.[51] Recent advances in drug delivery technologies and microfluidics have resulted in further control of scaffold characteristics, including orchestration of scaffold polymerization with changes in temperature, pH, or exposure to light; engineering of nano- and micro-scale cell environments in order to direct cell distribution throughout a scaffold, and microencapsulation of growth factors and adhesion peptides on scaffolds for improved cell attachment and proliferation.[52–56]

Finally, cells and scaffold have been incorporated and directed in nanoscale fabrication techniques such as electrospinning. Still, no perfect material has been identified for heart valve tissue engineering, and in this regard, the search continues.

The complex anisotropy and three-dimensional structure of heart valves has provided another challenge for a biomimetic device. Even if the optimal scaffold material is identified, its fabrication into a three-dimensionally accurate valve geometry is not trivial. Using normal heart valve anatomy derived from computed tomographic images, Sodian and associates employed stereolithography to print a three-dimensional model for use as a mold for the thermoplastic polymer P4HB.[57] The mold was used for curing the polymer into three-dimensional valve anatomy. As improvements in imaging technology yield higher spatial and temporal resolution, anatomic definition of thin, moving, anisotropic structures in the heart such as valve leaflets will be more feasible. In addition, evolving microfabrication methods will further our ability to fabricate microscale features of valve anatomy. With defined anatomic dimensions and an understanding of outflow tract, great artery, and leaflet motion and growth, tissue engineers will have clear targets for three-dimensional fabrication of heart valve scaffolds.

Biochemical Signals

The migration and transdifferentiation of endothelial cells in the early stages of valvulogenesis (EMT) has been experimentally modeled in an ex vivo chick cardiac cushion explant system.[14] Much progress has been made to understand the signals required for the proper sequencing and execution of these early events. Vascular endothelial growth factor is one such molecule, thought to regulate EMT in an environment of adequate tissue glucose and oxygen saturation. Although VEGF is secreted by endothelial cells, other important signals, such as bone morphogenetic protein 2 and 4, are expressed by myocardium. Hyaluronic acid, a component of the extracellular matrix, is thought to regulate downstream signaling through its large, hydrated structure, which regulates ligand availability for receptor binding. Therefore, valvulogenesis is dependent in vivo on signals from myocardium, local extracellular matrix, and endothelium.[11,32] Though very early growth of endocardial cushions and valve primordia are less understood, and late regulatory events in valve growth are poorly understood, regulators of endothelial and mesenchymal cell proliferation have been identified. These known pathways have been largely studied in isolation, and as gene regulation in organogenesis is a highly complex process, synthesis of critical gene pathway data is necessary for developing a big-picture view of required events. Current microarray technologies will yield large volumes of data, and will likely provide additional insight into the critical regulatory steps involved in valve growth. This type of information will be high yield in future generations of engineered valves.

Mechanical Signals

Identification of a suitable cell phenotype is necessary but not sufficient for engineering replacement tissues. Proper cell orientation and three-dimensional microstructure are also required for tissue function; tissues demonstrate organization of cells and matrix across multiple levels of scale. In this regard, engineered tissues, like native tissues, require coordination. Hemodynamics are fundamental to the development and ongoing function of cardiovascular structures, and biomechanical signals are epigenetic regulators of tissue growth and development. Increasing evidence supports a role for endothelial cells as mechanotransducers, sending signals through the underlying extracellular matrix to the more deeply embedded valve interstitial cells.[16] Endothelial cells respond to shear stress and cyclic strains.[58] In an environment in which concentrations of soluble growth factors are held constant, endothelial cell programs can be switched between growth, differentiation, and apoptosis by varying the extent to which the cell is spread or stretched.[59] As cells are embedded in, and coupled to, their extracellular matrix, ECM serves as a vehicle through which signals must pass. Biochemical signals can be sequestered or amplified by ECM, and as cells bind to surrounding ECM via integrin receptors, the binding itself can induce phenotypic changes.[32] When human MSCs are plated onto large tissue islands that promote cell spreading, they efficiently differentiate into bone cells; when plated onto small islands, the same cells in the same culture medium differentiate into adipocytes.[60]

Clinical observations made from patients undergoing the Ross procedure have provided further evidence for the responsiveness of vascular and valve tissues to hemodynamic forces. In the Ross procedure, a pulmonary valve from the lower-pressure pulmonary circulation is transplanted into the aortic position and subjected to systemic pressure, leading to significant changes in the phenotype of valve interstitial cells, including an increase in matrix metalloproteinase activity, indicating ECM remodeling.[15]

Biophysical signaling is therefore considered fundamental to engineered tissue organization and conditioning, or training,

for the in vivo environment. Mechanical forces can be applied to growing engineered tissues in a flow-loop containing tissue culture medium, known as a bioreactor. Preconditioning of tissues is thought to be important for the biology and monitoring of engineered cardiovascular tissues. Bioreactors are thought to serve two predominant purposes for engineered heart valves: first, mechanical forces influence cell phenotype and gene expression, and therefore tissue development, and potentially growth, are controlled by biomechanical signals. In experiments from our laboratory reported by Hoerstrup and colleagues, flow and pressure were demonstrated to increase the production of collagen in tissue engineered semilunar valves.[19] In separate experiments, Lee and associates demonstrated the variation of extracellular matrix gene transcripts with changes in tightly controlled mechanical strains. Vascular smooth muscle cells seeded onto biodegradable scaffolds, then subjected to cyclic flexure produced more collagen and were stiffer than controls.[61] Similar findings were reproduced using mesenchymal stem cells, and porcine heart valves.[62,63]

In addition, because valves must not be regurgitant at the time of implantation, observation of engineered valve mechanics in a bioreactor before implantation has allowed investigators to monitor and predict in vivo valve function.

ENGINEERED VALVE EXPERIMENTAL OUTCOMES

Progress toward a clinically translatable engineered heart valve is not possible without in vitro study of valve development and remodeling. Developmental biology and in vitro experiments are the fundamental elements of this emerging field. However, in vivo experiments are the necessary complement to in vitro investigation, and represent the true test of engineered device function over time. The in vivo environment is more complex than can be approximated in vitro, and remodeling is dependent on the contributions of circulating progenitor and immune cells only present in whole living organisms.

Four major implantation studies of tissue engineered heart valves have been undertaken using the de novo engineered approach.[19,24,26,64] Several groups have implanted decellularized and recellularized valves into the juvenile lamb circulation,[65,66] and two major studies evaluate the growth of vascular conduits in the pulmonary circulation.[67,68] Several representative studies will be reviewed in terms of valve function, evaluation of valve/conduit growth, and observation of engineered tissue maturation.

In Vivo Valve Function, Growth, and Maturation

Heart valve tissue engineering was conceptually established through proof-of-concept experiments in large animals. The first in vivo tissue engineered heart valve experiment involved implantation of a single leaflet into the pulmonary circulation.[17] Cells were isolated from ovine arteries and sorted into endothelial and fibroblast populations. Cells were labeled, then seeded onto PGA scaffold and subsequently implanted. Labeled cells were visualized in explanted specimens after 6 hours and after 1, 6, 7, 9, or 11 weeks. Cells produced extracellular matrix, and leaflets persisted in the circulation at all time points.

A second set of experiments involved implantation of a pulmonary valve composed of autologous ovine endothelial cells and myofibroblasts seeded on a PGA-P4HB composite scaffold.[19] After 14 days of exposure to gradually increasing flow and pressure conditions in a pulse duplicator, valves were implanted into sheep for 1 day, 4, 6, 8, 16, and 20 weeks. Valves demonstrated acceptable hemodynamics and had no evidence of thrombosis, stenosis or aneurysm formation for up to 20 weeks. Central valvar regurgitation was noted after 16 weeks. Tissue analysis showed a layered structure with central glycosaminoglycans, collagen on the outflow surface, and elastin on the inflow surface. Elastin was detectable in the leaflets by 6 weeks in vivo. Over the 20-week study period, scaffold degradation corresponded to decreased leaflet stiffness. Histologic, biochemical, and biomechanical parameters were similar to those of native pulmonary artery and leaflet tissue.

Using bone marrow–derived mesenchymal stem cells on a PGA/PLLA scaffold, investigators fabricated and implanted valved conduits in the pulmonary position of juvenile sheep.[24] Valves were evaluated by in vivo echocardiography; explanted tissues were analyzed by histology and immunostaining. At the time of implantation, echocardiograms demonstrated a maximum instantaneous gradient of 17.2 ± 1.33 mm Hg, with estimates of regurgitation ranging from trivial to mild. Four animals survived the immediate postoperative period. After 4 months in vivo, there were no statistically significant difference between maximum instantaneous gradient, mean gradient, or effective orifice area from the time of implantation. Histologic analysis at 8 postoperative months showed explanted tissue to have a layered organization, with elastin fibers identified on the inflow surface and collagen dominating the outflow surface. Glycosaminoglycans were distributed throughout the remainder of the valve. At the time of implantation, cells uniformly expressed the mesenchymal cell marker a-SMA, but at the time of valve explant, these cells were confined to the subendothelial layer, whereas surface cells expressed von Willebrand factor, suggesting in vivo endothelialization of the graft. This study demonstrated the feasibility of implantation of a pulmonary valve using stem cells.

Further work in our laboratory has reproduced some of these initial findings, and studied valve function over time in larger numbers of animals.[26] Using the same scaffold material (PGA-PLLA composite nonwoven felt) and cells (MSCs), 19 animals underwent implantation of valved conduits into the main pulmonary artery of neonatal sheep after resection of the native pulmonary leaflets. Valve function, cusp, and conduit dimensions were evaluated at implantation (echocardiography), at the experimental midpoint (MRI), and at explant at 1 day, 6, 12, or 20 weeks postoperatively. At implantation, valved conduit function was excellent; maximum transvalvar pressure gradient by Doppler echocardiography was 17 mm Hg; most valved conduits showed trivial pulmonary regurgitation. At ≥12 weeks, valved conduit cusps were increasingly attenuated and regurgitant. Valved conduit diameter remained unchanged over 20 weeks. Dimensional measurements by MRI correlated with direct measurement at explant. These studies demonstrated autologous engineered valved conduits that functioned well at implantation, with subsequent monitoring of dimensions and

function in real time by MRI. The valves underwent structural and functional remodeling without stenosis, but worsening pulmonary regurgitation was noted after 6 weeks.

When fibrin-based valves were implanted in sheep for 3 months, valved conduits exhibited the gross appearance of intact tissue; however, leaflets demonstrated pulmonary regurgitation because of tissue contraction.[64]

To date, no group has implanted valve leaflets that demonstrated in vivo growth. In many experiments, however, the microscopic structure of the valve leaflets evolved from a relatively homogeneous appearance to a layered structure. The mechanisms by which this in vivo evolution of structure and cellular activity occurs remain completely unexplored, but these observations suggest that a tissue engineered valve may not have to be in a mature, adult form at the time of implantation into the circulation.

Present and Future

After a decade of effort toward a tissue engineered heart valve replacement, the clinical need for a more durable valve replacement still exists. Modes of failure of currently available heart valve replacements are well described and provide insight into strengths and weaknesses of valve designs. Though the appropriate cell source and scaffold material for heart valve tissue engineering have been areas of substantial experimental effort, the optimal cell type, scaffold material, and in vitro culture conditions for a tissue engineered heart vale still remain unknown. Stem cells and adult progenitor cells offer promise toward this end, because they possess the capacity for self-renewal and multilineage differentiation, and therefore, growth potential. Evolving imaging technologies will allow a more complete understanding of postimplantation remodeling and growth. Though many details of in vitro preconditioning regimens are yet to be understood, bioreactor preconditioning has the potential to reduce in vitro culture times by stimulating tissue formation, and may offer a controllable environment for evaluation of valve function before implantation.

Complex biological events, such as heart valve development, occur through both biochemical and biophysical cues, occurring in parallel at the cellular, tissue, and organ levels. A detailed understanding of the molecular sequence of critical developmental events may allow engineering of appropriate microenvironments and three-dimensional structures leading to the ultimate goal: a clinically translatable heart valve replacement with the capacity to grow and remain durable for a lifetime of cardiac cycles.

CHAPTER 70

Stem Cell–Induced Regeneration of Myocardium

Philippe Menasché

INTRODUCTION

Statistics recently published by the American Heart Association clearly outline the magnitude of the medical and economic problems associated with heart failure.[1] It is estimated that 6 million people in the United States are affected by this disease, with a yearly incidence of new episodes (per 1000 people) of 15.2 between 65 and 74 years of age, a figure that is two times higher between 75 and 84 years of age. Still in the United States, the number of hospitalizations for heart failure has thus increased from 877,000 to 1,106,000 in a 10-year time frame (1996–2006), but the problem is now worldwide. The mortality remains high as 80% of men and 70% of women under the age of 65 years in whom heart failure has been diagnosed are expected to die within the next 8 years with a risk of sudden death which is six to nine times that of the general population. As expected, these figures translate into a heavy economic burden with costs estimated to 37 billion dollars in 2008.

Although heart transplantation remains the only radical treatment for end-stage heart failure, its use is limited by organ shortage and the complications associated with major immunosuppression. Surgical remodeling procedures require well-defined anatomical indications, and the failure of the STITCH[2] trial may lead to revisit them. Mechanical assist devices are still primarily used as bridges to transplant (or recovery) and, despite its ability to provide symptomatic relief, biventricular stimulation fails in 20 to 30% of patients.[3] Finally, none of the large trials implemented over the last decade to investigate new drugs has yielded a positive outcome allowing to improve the survival of heart failure patients. Put together, these observations have provided a rationale for exploring new therapeutic options, among which "regeneration" of the chronically failing heart by stem cells has raised a tremendous interest. From the onset, however, it is fair to state that regeneration *bona fide,* ie, generation of a new myocardial tissue with the same properties as the native one, is a concept, a target, and a hope, but not yet a reality. This chapter first summarizes the current status of stem cell trials, then describes the strategies that can be considered for effecting a true myocardial regeneration, and finally emphasizes the importance of addressing the low cell engraftment issue to make these strategies successful.

CURRENT STATE OF THE ART: IMPROVED LEFT VENTRICULAR FUNCTION VERSUS MYOCARDIAL REGENERATION

So far, two types of stem cells, both of adult origin, have been tested clinically: skeletal myoblasts and bone marrow–derived cells.

Skeletal Myoblasts

In June, 2000, we performed the first human transplantation of autologous myoblasts in a patient with severe ischemic heart failure[4] who underwent a concomitant coronary artery bypass grafting (CABG). This case initiated a 10-patient pilot trial that was soon followed by three other adjunct-to-CABG myoblast transplantation studies,[5–7] which only differed from ours in that they systematically entailed a concomitant revascularization of the myoblast-injected areas.

Altogether, these studies have demonstrated the feasibility of the procedure as well as its safety with the caveat of an increased risk of ventricular arrhythmias. This has been attributed to the failure of engrafted myoblasts to express gap junction proteins and their subsequent electrical isolation from the surrounding cardiomyocytes,[8] which could slow conduction velocity and predispose to reentry circuits.[9] This hypothesis is supported by the in vitro finding that myoblast transfection with connexin 43 decreases arrhythmogenicity,[9] but clinically other myoblast-unrelated factors are likely in play, particularly the

needle-induced inflammatory tissue damage[10] and the intrinsically arrhythmogenic nature of the underlying heart failure substrate.

Although these initial studies had suggested improved functional outcomes following myoblast transplantation, they were neither designed nor powered to provide efficacy data, which led us to implement a randomized, double-blind, placebo-controlled trial (MAGIC, an acronym for Myoblast Autologous Grafting in Ischemic Cardiomyopathy), which was conducted in 21 centers across Europe.[11] Ninety-seven patients with severe left ventricular (LV) dysfunction, a postinfarction nonviable scar and an indication for bypass surgery were assigned to receive multiple in-scar injections of autologous myoblasts (at two different doses: 400 and 800 million) grown from a muscular biopsy taken 3 weeks earlier or similar injections of a placebo solution. An internal cardioverter-defibrillator (ICD) was implanted in each of these patients to provide objective readouts of arrhythmic events. At the 6-month study point, the proportion of patients who had experienced arrhythmias was not statistically different between the myoblast-treated and the placebo-injected groups despite a trend for a higher incidence of arrhythmic events early after myoblast implantations and there was not a single death that could be attributed to arrhythmias. This rather reassuring safety finding contrasted with the disappointing observation that regardless of the dose, myoblast injections had failed to improve LV function beyond that seen in the placebo group, even though the high-dose group experienced a significant reduction in remodeling (which was a prespecified secondary end point). Although this signal suggested that cells can exert some beneficial effects, these effects were clearly too limited to translate into meaningful improvements in contractile function, thereby ruling out the occurrence of a procedure-induced myocardial regeneration.

In parallel to these surgical trials, phase I catheter-based studies have assessed myoblast delivery through an ultrasound-guided coronary sinus catheter[12] or through an endoventricular catheter under electromechanical guidance.[13] Like their phase I surgical counterparts, these trials have primarily demonstrated the technical feasibility of these approaches. Efficacy data are more limited and are still controversial. At the 2008 Society of Cardiovascular Angiography and Interventions meeting, Serruys reported on 31 patients who were allocated to myoblast injections while 16 received "optimal medical therapy." In keeping with the MAGIC data, there was no added benefit of cell therapy on LV function measured at 6 months after the procedure. In contrast, Dib and coworkers[14] have reported improved outcomes in patients receiving transendocardial injections of skeletal myoblasts compared with a placebo group but with the caveat of a 1-year only follow-up.

Bone Marrow–Derived Cells

Most studies of bone marrow–derived cell therapy have been in the context of acute myocardial infarction and refractory angina and, comparatively, few of them have tackled heart failure. In this setting, they can be categorized in relation with the specific cell population that has been tested.

Mononuclear Cells

Beyond the anecdotal cases, five surgical studies have tested intramyocardial injections of bone marrow–derived unfractionated mononuclear cells (MNC) in conjunction with bypass surgery and, overall, their results are mixed. In a 36-patient trial, Mocini and coworkers[15] reported a 3-month significant improvement in regional and global LV function compared with baseline, but these outcome measures did not differ from those obtained in control patients who, surprisingly, failed to improve functionally following bypass surgery. The 20-patient study of Hendrikx and coworkers[16] showed that after 4 months, there was a significantly greater wall thickening in cell-transplanted patients (as assessed by magnetic resonance imaging [MRI]), but no improvement in ejection fraction or perfusion defects beyond values recorded in control patients. The third trial in which cells were injected both in the myocardium and in the bypass grafts also failed to meet its primary end point.[17] Conversely, two studies,[18,19] of which one was randomized,[18] have reported improved function and perfusion up to 6 months[18] and 5 years[19] after MNC transplantation combined with CABG. Of note, whereas the average numbers of injected cells ranged from 60 to 292 million in the mentioned negative trials, those with a positive outcome entailed transplantation of up to 6.59×10^8 and 1.23×10^9 MNC,[18,19] which calls attention to the importance of careful dose-effect relationship studies before definitive conclusions can be drawn.

Catheter-based studies of bone marrow cells in patients with heart failure have been initiated by an open-label nonrandomized 11-patient trial who were reported to have experienced a 1-year improvement in exercise capacity following endoventricular injections of MNC.[20] A limited number of studies entailing intracoronary MNC infusions have then claimed positive functional outcomes in both ischemic[21,22] and nonischemic[23] cardiomyopathy settings. However, their results should be interpreted cautiously in view of the methodologic limitations inherent in the usual lack of randomization, the functional impairment of cells taken from patients with chronic ischemic heart disease[24] and the small engraftment rate of intracoronary injected cells (see the following), particularly at the chronic stage, when the endothelial alterations associated with acute ischemic events and that may promote transvascular trafficking waned. Of note, the recent randomized controlled trial conducted by van Ramshorst and coworkers[25] has reported a 3% improvement in ejection fraction without changes in LV volumes after endomyocardial MNC injections, but the target population was chronic ischemia not amenable to conventional revascularization and these outcomes thus likely illustrate the expected angiogenic effect of bone marrow cells rather than de novo myogenesis.

Hematopoietic Progenitors

The well-documented angiogenic properties of bone marrow–derived cells (see the following) have led other investigators to rather focus on hematopoietic progenitors featuring a high angiogenic capacity. In this setting, the most convincing results have been reported by Stamm and coworkers[26] who have injected $CD133^+$ cells epicardially during CABG. Although

this trial was not strictly randomised, it has been rigorously conducted and provides encouraging hints in favor of the capacity of the $CD133^+$ population to safely improve LV function and perfusion at 6 months postoperatively, particularly in patients with the poorest preoperative LV function. It is likely, however, that these effects, which await further confirmation by the upcoming randomized PERFECT trial, proceed from a cell-induced increase in angiogenesis and not from the conversion of the $CD133^+$ progenitors into new cardiomyocyte. As such, they do not match the strict definition of myocardial regeneration.

Mesenchymal Stem Cells

The third category of BM-derived cells, which is raising a growing interest, even though clinical experience with them is still limited in the field of heart regeneration, comprises mesenchymal stem cells (MSC). These cells represent a rare population (0.01 to 0.001%) of the bone marrow and are usually defined by their adherence to plastic surfaces, their negativity for hematopoietic markers (CD45, CD34), the expression, among others, of the CD29, CD44, CD73, CD90, and CD105 antigens, and the capacity to differentiate along the osteogenic, chondrogenic, and adipogenic lineages in response to the appropriate cues. Most (but not all)[27] experimental studies conducted in small[28,29] and large[30–32] animal models of chronic myocardial infarction,[28,29,31,33] or dilated cardiomyopathy[34] have now documented that transplantation of autologous[30] or allogeneic[28,29,31,33] transplantation of MSC may improve LV function and attenuate adverse remodeling in a dose-dependent fashion,[32] at least at midterm.[28] These patterns of improvement are usually associated with increased angiogenesis and reduced fibrosis. As all these studies have failed to document the differentiation of MSC into cardiomyocytes, it is likely that improved outcomes after MSC treatment proceed from their trophic effects[35] reported to be more potent than those of MNC.[34]

Put together, these data have paved the way for upcoming or already ongoing trials of MSC in patients with chronic LV dysfunction in whom cells are delivered transendocardially as a stand-alone procedure or transepicardially as an adjunct to CABG or to placement of an assist device (which should yield useful histologic data when the heart will be removed for transplantation). In one of these studies, MSC are pretreated with a combination of growth factors targeted at increasing their cardiomyogenic differentiation potential[36] as exposure of cells to the demethylation agent 5-azacytidine, which had been initially proposed to drive MSC toward a cardiomyogenic lineage, is unsuitable for clinical applications. Interpretation of outcomes, however, might be complicated by the fact that some companies involved in these trials have developed proprietary processes allowing isolation of specific subsets of MSC. Because there are no cell surface markers that specifically and uniquely identify MSC, it remains difficult to determine whether these different MSC subsets really reflect different cell fractions with distinct properties or simply represent the same MSC population assessed at different developmental stages and with the use of different surface markers.

Although MSC have initially been retrieved from bone marrow, alternate tissue sources have then been proposed like the placenta,[37] menstrual blood,[38] or the periodontal ligament.[39] However, the greatest focus is currently on adipose tissue as a source of MSC derived from its stroma vascular fraction. Although there are differences in the global gene expression pattern between adipose tissue–derived MSC and their BM counterparts,[40] the two types of cells share in common lineage-specific differentiation potentials, immunomodulatory properties,[41] and cardioprotective effects.[42,43] These effects have been attributed to cell-derived antiapoptotic and angiogenic factors,[44] and the latter might be even greater in the case of adipose-derived MSC,[43] which also express the CD34 marker at the time of isolation.[40,41] Conversely, there is no evidence for differentiation of these cells into cardiomyocytes.[45] An additional attractive feature of adipose tissue–derived MSC is that their procurement by liposuction is patient friendly and their expansion capacity seems greater than that of their BM counterparts.[46] To make their availability still more expeditious, a device has been developed to extemporaneous process lipoaspirates so as to yield a mixed cell population that can be immediately transplanted at the point of care and a clinical trial (PRECISE) testing the endoventricular delivery of this cell product has just been completed in patients with coronary artery disease not amenable to revascularization in the target area. How this device-generated heterogeneous cell population compares with that comprising the stroma vascular fraction specifically isolated from liposuction products remains to be established. It is also fair to temper the current enthusiasm about these cells by mentioning the negative study of van der Bogt and coworkers,[47] who have used bioluminescence imaging for the in vivo tracking of injected cells and have reported an equally high rate of MSC death regardless of the tissue source (bone marrow or adipose tissue) and a corresponding lack of cardioprotection. However, it cannot be excluded that this negative outcome was strongly biased by the prolonged period of pretransplantation MSC cultures.

Regardless of the tissue source, what has largely driven the clinical interest in MSC is their alleged "immune privilege" and the related hope that they could be used as an allogeneic off-the-shelf readily available product with the attendant logistical, regulatory, and economic benefits. This paradigm is based on the in vitro mixed lymphocyte reactions-based findings that MSC do not evoke a response of allogeneic lymphocytes and inhibit lymphocyte proliferation induced by allogeneic peripheral blood MNC.[41] These immunomodulatory effects, which require direct contact between MSC and the responder T cells and release of soluble mediators have been attributed to three major mechanisms: (1) MSC are hypoimmunogenic because of their lack of major histocompatibility complex (MHC) class II and costimulatory molecules. (2) They prevent T-cell responses both directly by directing CD4 T cells to a suppressive phenotype and disrupting CD8 T cell and natural killer cell function, and indirectly by interfering with dendritic cell maturation. (3) They secrete soluble mediators, which induce a suppressive local microenvironment[48,49] through downmodulation of inflammatory cytokines (particularly TNF-α and IFN-γ) produced by activated T lymphocytes and inhibition of B-cell proliferation.

The current enthusiasm about MSC, however, needs to be tempered in light of several considerations. First, the plasticity

of MSC renders them extremely sensitive to the physical nature of the underlying substrate; the stiffer the substrate, the greater the likelihood of a differentiation along the osteogenic lineage.[50] Given the heterogeneous composition of postinfarction scars, there is a potential for some of the in-scar injected MSC to give rise to intramyocardial calcification, a complication that, so far, has only been observed experimentally.[51] Second, the demonstration of the immunosuppressive effects of MSC have been largely based on in vitro experiments and despite the successful results of MSC treatment of severe graft-versus-host disease by LeBlanc and associates,[52] the immune privilege of these cells is still debated. Indeed, it has been reported that MSC could function as antigen-presenting cells and intramyocardial injection of human MSC in rat myocardium have shown that although MSC could engraft in immunocompromised hosts, they triggered a robust immune response in those with an intact immune system.[53] Likewise, Poncelet and coworkers[54] have reported that intracardiac transplantation of allogeneic porcine MSC elicited a complete cellular and humoral immune response whereas the same cells had failed to trigger an in vitro proliferative response. A clinical industry–sponsored study of intravenous allogeneic MSC treatment has already been completed in patients with acute myocardial infarction and has yielded a quite reassuring safety record. Efficacy data are less conclusive and the study does not allow us to know whether the injected cells have been rejected or not. Fourth, the optimal route for MSC delivery is not straightforward. Their intravenous infusion is obviously the simplest and the safest approach and has been advocated on the premise that MSC would sense signals emitted by the infarcted tissue and preferentially home to the injured area. However, homing has been primarily reported in rodent experiments[55] and studies in large animals[56] and humans[57] have failed to show MSC engraftment in the heart. On the other hand, a direct intramyocardial injection, surgically or through an endoventricular catheter, does not raise safety issues, but such is no longer the case if one considers an intracoronary infusion because the relatively large size of MSC (twice that of MNC, ie, approximately 20 μm) may result in capillary plugging.[58,59] Although some data suggest that this hurdle can be overcome by appropriate cell dosing, concomitant implementation of a robust antithrombotic therapy,[43] and careful control of the rate of cell delivery,[59] it is clear that the intracoronary delivery of MSC in heart failure patients should still be viewed with caution. Finally, multiple passages of MSC may induce spontaneous transformation[60] leading to uncontrolled growth kinetics and this potential safety issue thus requires that accurate cytogenetic studies be performed if expanded MSC products are to be used clinically.

Mechanisms of Action of Transplanted Cells: The Paracrine Paradigm

The previously mentioned discrepancy between the improved functional outcome yielded by MSC treatment and the lack of direct tissue replacement by the grafted cells is indeed a phenomenon that encompasses the other cell types tested so far, and this has led some to hypothesize that the benefits of cardiac cell therapy reported so far were not mediated by a new onset graft–derived myogenesis, but rather by an increase in cell-associated wall thickness leading to a reduction in chamber volume and consequently in wall stress and/or the release of trophic factors promoting survival and repair of injured tissue. Support to the latter hypothesis has come from the finding that skeletal myoblasts[61,62] and bone marrow–derived cells[63–66] stimulate endogenous pathways leading to increased angiogenesis, decreased apoptosis, and a favorable shift of extracellular matrix remodeling toward improved scar elasticity, even though the two cell types differ by the nature of the paracrine mediators involved, the downstream signal transduction pathways, and the ultimate specific effects.[67] In line with this hypothesis, it has been reported that the beneficial effects of intravenously injected MSC, despite their low intramyocardial engraftment rate, were caused by trapping of the cells within the lungs and a subsequent upregulation of the anti-inflammatory factor TSG-6.[68] Importantly, the cell-triggered upregulation of host-associated cytoprotective mediators seems to be prolonged, which explains the functional recovery of the heart at a time in which the trigger cells have faded away.[69] By analogy with the ability of transplanted neural stem cells from fetal origin into the brain ventricles of aged rats to stimulate endogenous neurogenesis,[70] the recruitment of dormant cardiac progenitor cells residing in the myocardium has been proposed as another target for cell-released factors.[71] However, this hypothesis is more tenuous in view of the persisting uncertainties surrounding the existence of this stem cell niche in the adult heart (see the following). Finally, MSC have also been shown to release mediators that increase sympathetic nerve sprouting,[72] which could contribute to increase cardiac performance, but also carries the risk of promoting arrhythmias related to heterogeneous cardiac innervation.

The recognition that cells primarily act as delivery vehicles not by physically substituting for dead host cardiomyocytes has led to speculation that a more straightforward means of inducing protection could be the sole injection of the conditioned medium derived from these cells. This hypothesis has been pioneered by the group of Dzau and coworkers[73] who documented, in *acutely* infarcted rat hearts, infarct size limitation, and functional recovery as early as 72 hours after intramyocardial injection of the conditioned medium from hypoxic MSC genetically modified to overexpress the prosurvival gene Akt1. Likewise, delivery of the conditioned medium derived from MSC in a pig model of *acute* myocardial infarction has been shown cardioprotective, with the caveat of a very short (4 hours) period of observation.[74] Although these studies provide compelling evidence for paracrine protection, their relevance to regeneration of the chronically failing myocardium remains more questionable because of the specificities of their protocol design (acute model of infarction and short follow-up). Indeed, in a study in which MSC were compared with injection of angiogenic growth factor genes, the former were found to better improve myocardial performance,[75] which suggests that the physical presence of the cells, even transient, may be critical because the expected fast clearance of injectants from the target tissue likely decreases their efficacy (unless they are supplied with slow-release delivery systems). In addition, it may be

difficult for conditioned media retrieved at a single time point to fully replicate the complex blend of trophic factors released by the engrafted cells over time.

Although one cannot dispute that the mechanical (reduction in wall stress) and paracrine effects of engrafted cells may effect some cardioprotection, it is still quite uncertain that these effects may be robust enough to translate into clinically meaningful improvements in patient outcomes, which stimulates the search for strategies that could achieve such an improvement through a true myocardial regeneration.

POSSIBLE APPROACHES TO MYOCARDIAL REGENERATION

Conceptually, there are three major approaches that can be considered for inducing myocardial regeneration.

Stimulation of Endogenous Cardiomyocyte Proliferation

Whereas it has long been considered that the heart was a terminally differentiated organ, recent data have challenged this paradigm and elegant studies using ^{14}C dating have provided evidence for some renewal of human cardiomyocytes spanning the lifetime but with a low turnover, as percentages of dividing cells decreased from 1% per year at the age of 25 to 0.45% at the age of 75 years.[76] This has led some investigators to hypothesize that differentiated quiescent cardiomyocytes, which did not proliferate under resting conditions, could be induced to re-enter the cell cycle in response to extracellular mitogens. It has thus been demonstrated in mouse models of myocardial infarction that factors such as periostin[77] or neuregulin[78] triggered cardiomyocyte cell-cycle activity and that the resulting regeneration was associated with improved function, reduced fibrosis and infarct size, and increased angiogenesis. However, whether and how these basic science data can be translated into a safe and efficacious clinical therapy remains to be elucidated.

Transplantation of Putative Extracardiac Cell Niches Endowed with a Cardiomyogenic Differentiation Potential

In 2006, Witnisky and coworkers[79] described in the mouse skeletal muscle a population of cells committed to a cardiomyogenic lineage. Unfortunately, using similar surface markers, we failed to show that such a cardiac-directed cell fraction existed in the human muscle.[80] These findings are consistent with the increasing recognition that stem cells harbored in adult tissues are unlikely to cross lineages, except possibly under clinically irrelevant experimental conditions. It remains to be established whether this hurdle can be overcome by small molecules such as those of the sulfonyl hydrazone family, which have recently been reported as able to activate cardiac differentiation of human mobilized peripheral blood mononuclear cells,[81] thereby effecting myocardial regeneration in a nude model of myocardial infarction.

Transplantation of Cardiac Stem/Progenitor Cells

Endogenous Sources: The Heart Itself

The ^{14}C experiments mentioned in the preceding have actually been preceded in the early 2000s by studies from the group of Anversa who first claimed that despite being traditionally considered as a postmitotic organ, the heart actually harbored dividing cardiomyocytes evidenced by a positive expression for the cell proliferation marker Ki67, and that the proliferation rate of these cells was dramatically increased in patients with heart failure.[82] The phenotypic characterization of these cells, found in multiple species, has yielded puzzling results in that different surface markers occasionally expressed in a mutually exclusive fashion have been identified (reviewed in Barile)[83] and it is still uncertain whether this variability in marker distribution actually reflects distinct cell populations with specific functional properties or the ability of a unique pool of stem cells to express different markers at different stages of its maturation. C-*kit*+ cells have been the most extensively investigated; because they lacked expression of hematopoietic markers, a bone marrow origin, such as that reported in sex-mismatched heart transplant recipients in whom 0.04% cardiomyocytes were found to be repopulated from extracardiac cells,[84] has been excluded. Rather these c-*kit*+ cells have been considered to represent a myocardial pool of progenitor cells committed to a cardiomyogenic lineage. Proof-of-concept was putatively provided by demonstration of donor-derived cardiomyocytes (along with smooth muscle cells and endothelial cells) when human cardiac progenitors were injected intramyocardially[85] in a rat model of myocardial infarction and resulted in an improvement in contractile function, an attenuation of remodeling and histologic patterns of regeneration. This paradigm found a clinical application in July 2009 when a first patient was injected in Louisville, KY with his own cardiac stem cells derived from a right atrial biopsy that had been taken 4 months earlier during a CABG and subsequently expanded in Anversa's lab in Boston. Other investigators have adopted a slightly different approach in that instead of trying to isolate these putative cardiac stem cells, they grew fragments of myocardial tissue as cell clusters termed *cardiospheres*. These aggregates are composed of c-*kit*+ progenitor cells primarily in their core and of a mix of cells expressing cardiac, endothelial, and mesenchymal markers at their periphery. Following preclinical studies showing that intramyocardial[86] and intracoronary[87] delivery of human and porcine cardiospheres could regenerate acutely and chronically infarcted myocardium, respectively, the group of Marban in Los Angeles moved to the clinics in June 2009 and performed a first intracoronary transfer of these cardiospheres 1 month after removal of a right ventricular specimen by an endomyocardial biopsy. A trial exploring the potential of this approach (CADUCEUS for CArdiosphere-Derived aUtologous Stem Cells to Reverse ventricular dysfunction) is currently under way.

Whereas the use of cardiac stem cells is appealing because of the cardiac lineage commitment of these cells and the avoidance of immunological issues owing to their autologous origin, several caveats must be mentioned. The major concern is that it is still uncertain whether these cardiac stem cells really exist

in the adult diseased heart. In our experience, we have identified a few c-*kit*+ cells in right atrial tissue taken during CABG or through endomyocardial biopsies,[88] but all of them expressed hematopoietic markers and none expressed specific cardiac markers. Likewise, a high proportion of the c-*kit*+ cells isolated from failing human hearts by Kubo and coworkers[89] were positive for markers of the hematopoietic lineage, and although their number was fourfold higher that in nonfailing hearts, their reparative capacity was clearly inadequate because all failing hearts required transplantation. In keeping with these data, cells expressing both stem and differentiated cardiac markers have been identified in the human neonatal myocardium, but with a progressive decline in cell density over the first postnatal month,[90] thereby raising serious doubts about the persistence of cardiac "stem" cells in adult patients with coronary artery disease, ie, those who would them need most. The fact that 4 months were required for growing these cells in the recently reported clinical experience also highlights the technical challenges associated with their isolation and scale-up and raises some doubts about a realistic widespread clinical use. Finally, a recent study has further challenged these findings by showing that spontaneously beating neonatal rat cardiospheres resulted from contamination by myocardial tissue fragments and that these cardiospheres actually represented aggregated fibroblasts rather than clonally expanded cardiac stem cells.[91] Another more recently described variety of stem cells of cardiac origin is represented by those derived from the epicardium, but these cells also seem to improve function of infarcted hearts paracrinally as they fail to acquire a cardiac phenotype.[92]

Embryonic Stem Cells

Human embryonic stem cells (hESC) are derived from the inner cell mass of blastocyst-stage leftover embryos, which have been generated in the setting of assisted fertilization. Their most appealing feature is an intrinsic pluripotentiality that allows them to be committed in vitro toward the cardiac lineage in response to appropriate differentiation cues recapitulating those in play during the embryonic life and among which bone morphogenetic proteins (members of the TGF-β superfamily), Wnts, and fibroblast growth factors play a predominant role.[93] It has thus been demonstrated that hESC could generate cells displaying the three major attributes of cardiomyocytes: (1) excitation-contraction coupling, demonstrated by the expression of ionic currents;[94] intracellular calcium transients triggered by electrical activation and the resulting synchronous contractions; (2) responsiveness to the chronotropic effects of cardioactive drugs,[95] and (3) the capacity to couple with neighboring cells through connexin 43-supported gap junctions.[96] Following transplantation in rodent models of myocardial infarction, these cells have been shown to improve LV function, an effect usually associated with a beneficial effect on remodeling.[97–99] Of note, mouse ESC have also been shown functionally effective in a nonischemic genetic cardiomyopathy model.[100] One could legitimately argue that these cardioprotective effects have been reported with most cell types. However, an observation more specific for ESC is that, in contrast to their adult counterparts, they really differentiate into cardiomyocytes in transplanted areas, an event likely driven by cues originating from the infarcted tissue.[101] However, injected ESC derivatives share with other cell types a limited amount of long-term engraftment,[102] and this finding, along with the fact that increasing graft size has been reported not to positively correlate with a gain of function, has led to hypothesize that ESC-induced stimulation of vascularization was actually a major contributor to the cardiac functional improvement.[103] Indeed, whereas ESC derivatives may well act paracrinally by activating endogenous cytoprotective pathways,[104] one cannot fully exclude that they also directly contribute to cardiac contractility by generating a force transmitted to the surrounding tissues.[105] Furthermore, it is important to recognize that the assessment of hESC transplantation is hampered by the lack of appropriate preclinical models as all of them are fraught with the confounding effect of xenotransplantation. For this reason, we have conducted experiments in nonhuman infarcted primates transplanted with primate ESC–derived cardiac progenitors, thereby mimicking an allogeneic situation closer to clinical practice. The data have confirmed the ability of these progenitors to achieve their differentiation into cardiomyocytes following in-scar engraftment. Furthermore, the finding made in a pig model of iatrogenic atrioventricular block, that intramyocardial transplantation of hESC-derived cardiac derivatives could restore electrical activity,[106] provides compelling evidence for the ability of these cells to achieve an effective electromechanical integration within the recipient heart.

Asides from ethical considerations, the clinical use of hESC still raises several translational issues[107] that fall into three main categories: (1) derivation and propagation of a line endowed with a cardiogenic differentiation potential, under good manufacturing practice (GMP) conditions; this first step of the process should allow to scale-up the number of cells without the use of xeno-components while maintaining their pluripotentiality and ensuring their genetic and epigenetic stability over time; (2) directed differentiation of the propagated pluripotent cells toward a cardiomyogenic lineage; (3) sorting of the cells, so as to yield a "pure" population of cardiac progenitors for clinical use. (Progenitors are likely preferable to a terminally differentiated cell type because of their ability to still proliferate in the host tissue to a certain extent, thereby effecting myocardial regeneration.) Several purification methods are available and rely on negative or positive selection, depending on whether they target the elimination of still undifferentiated cells or the enrichment of the lineage-committed progenitors from other unwanted cell types, respectively. Introduction of a reporter-suicide gene into stem cells that could serve as a safety net against cellular misbehavior is another option that warrants further investigation. In our experience, a positive selection approach based on identification of the surface marker SSEA-1 (or CD15) has turned out to be efficacious in that this antigen reliably labels cells that have entered a differentiation pathway,[108] thereby allowing immunomagnetic sorting using an anti-CD15 antibody to selectively yield the clinically required cardiac progenitor cell population. The elimination of the contaminating cells is actually critical not only for efficacy, but also for safety reasons as a major concern with ESC is the development of a teratoma. Teratomas are complex tumors consisting of cell lines

originating from the three initial germ layers. Although several factors (cell number, transplant site, degree of immunosuppression) may affect whether these tumors form after transplantation of ESC,[109] a key role is played by the state of differentiation of the transplanted cells. Indeed, teratomas occur when cells are used in a still undifferentiated or poorly differentiated state and have thus retained an intrinsic capacity of uncontrolled proliferation, which can overcome the cardioinstructive signaling of the host heart. Conversely, animal models have failed to show evidence for teratomas following transplantation of hESC-derived cells committed to a given cell lineage,[101,105] as demonstrated by their loss of pluripotent markers and the concomitant upregulation of the lineage-specific ones. These considerations highlight the importance of the purification step during preparation of a clinically usable ESC-derived cell therapy product.

Another major clinical issue raised by the use of this allogeneic cell source is immunogenicity. Despite initial hopes, it is now widely recognized that although undifferentiated ESC lack expression of MHC type II antigens and costimulatory molecules, they trigger a cellular and humoral immune response,[110] which does not spare their differentiated progeny.[111] Even though the lack of antigen-presenting cells within ESC-derived grafts may contribute to a reduced immunogenicity compared with adult tissues,[111] it is still necessary to implement some form of immunosuppressive strategy to avoid cell loss by this immune process. Different approaches have thus been considered. Banking of hESC lines with a range of MHC profiles allowing an appropriate donor-recipient matching is likely not unrealistic, because about 150 randomly obtained cell lines could provide a worthwhile human leukocyte antigen (HLA) match for most potential recipients.[112] This figure, however, was based on matching only selected MHC loci and thus does not dismiss that additional immune suppression would be required to overcome residual immunogenicity. Also, it may underestimate the ethnic diversity of most Western populations. Furthermore, such a banking approach raises complicated logistical and economic issues and, as such, first requires the convincing demonstration that the use of hESC-derived cells is therapeutically effective. Given the risks associated with a protracted use of immunosuppressive drugs, induction of tolerance in the recipient looks a particularly appealing approach should it be possible at the cost of minimal host conditioning.[113] In practice, it might be achieved by the administration of hematopoietic stem cells derived from a given "donor" ESC line[114] and the resulting induction of a microchimerism ensuring specific tolerance to cardiac (or other) progenitors derived from that same donor ESC line. The use of costimulation blockade for inducing peripheral tolerance mediated by regulatory T cells could be another strategy.[115] In contrast, the creation of a "universal" cell line, for example by knockout of the β-2 microglobulin gene, which is essential for MHC-I presentation, remains a more uncertain perspective because MHC molecules also represent a surveillance mechanism whose deletion could create a favorable environment for viral infections and development of malignancies. Thus, from a practical standpoint, early clinical trials of hESC will likely have to rely on more conventional therapies based on immunosuppressive drugs. The challenge is then going to find an acceptable trade-off between the efficacy of these drugs and their well-known side-effects so as to optimize the risk-to-benefit ratio of the procedure. The additional use of autologous or allogeneic mesenchymal stem cells for further mitigating the immunorejection process is supported by a study in kidney transplant recipients,[116] although we have experimentally failed to show such a benefit in a rat model of hESC transplantation.[99]

The recent presidential lift on the US federal funding ban on ESC research and the attendant increase in resources allocated to this area make likely that many of the remaining hurdles will be overcome in a not too distant future.

Induced Pluripotent Cells

In 2006, Yamanaka made a real breakthrough in the stem cell field when he reported that mouse embryonic and adult fibroblasts could acquire properties similar to those of ESC after retrovirus-mediated transfection of genes encoding the four transcription factors Oct3/4, Sox2, Klf4, and c-Myc.[117] Since then, several groups have embarked in this research on induced pluripotent stem (iPS) cells and have successfully reprogrammed human adult somatic cells into an embryonic-like state, including from patients with a variety of neurodegenerative and genetic diseases.[117] Reprogrammed cells can then be redirected toward a given cell lineage, including cardiomyocytes, and this cardiomyogenesis process actually involves a temporal sequence of gene expression (specific for cardiac mesoderm, cardiac transcription factors, and cardiac-specific structural proteins, successively), which parallels that observed during differentiation of hESC.[118]

The use of iPS could potentially allow to address two limitations of ESC, ie, immune rejection and ethical concerns raised by the use of human embryos, with still the caveat that one does not know whether the reprogramming-redifferentiation process could not cause expression of otherwise hidden-self and lead to autoimmunity events. However, their clinical application also faces important obstacles. Some of them are shared with ESC, such as teratoma formation following unwanted transplantation of still undifferentiated cells; other hurdles are rather unique to iPS cells and specifically include the risk of incomplete/aberrant reprogramming that may impair their ability to be redifferentiated toward the required cell type. It also remains to determine which is the best somatic cell source to use (eg, skin fibroblasts, keratinocytes, blood cells) and how to increase the still low efficiency of the reprogramming process while improving its safety. This is indeed a key question as a major risk of the initially used retroviruses and lentiviruses is transgene reactivation leading to tumorigenesis, hence the more recent interest in plasmids, proteins,[119] and even chemicals that represent a mandatory step on the pathway to production of iPS for clinical use. However, even these virus-free approaches may induce genetic alterations and therefore would call for a sequencing of the whole genome of iPS cell clones to detect these alterations before any clinical application.

These considerations suggest that although iPS cell technology may be soon ready for prime time toxicology screening and patient-specific disease modeling, its application to "regenerative" medicine still requires many challenges to be surmounted.

Nevertheless, encouraging data have already been reported. Thus, the potential therapeutic value of iPS cells has yet been successfully tested in three noncardiac disease models (sickle cell anemia, Parkinson's disease, and hemophilia A). These data have more recently been extended to the heart by Nelson and coworkers,[120] who have pioneered the transplantation of fibroblast-derived iPS cells in a murine model of myocardial infarction and shown that it resulted in an improvement in LV function compared with the parental fibroblasts, associated with a differentiation of the iPS cell progeny into cardiomyocytes. However, because this study did not include "true" ESC-derived cardiomyocytes as another control, additional experiments remain necessary to thoroughly assess the comparative efficacy of these two types of pluripotent stem cells. This is particularly relevant in view of recent data that indicate that regardless of their origin or the method by which they have been generated, iPS retain a gene expression pattern distinct from that of hESC and that extends to the expression of noncoding (mi)RNAs.[121] Therefore, it is critical to assess the functional significance, if any, of these differences. Finally, although iPS have the major theoretical advantage over hESC of being patient-specific, one should not underscore the limitations of autologous cell therapy products when large patient populations are targeted; these limitations include intrinsic interindividual variability in cell functionality, which complicates the production of consistent cell products, logistical constraints inherent in cell shipments, and the huge cost of customized batch controls.

THE PREREQUISITE FOR AN EFFECTIVE MYOCARDIAL REGENERATION: THE ENHANCEMENT OF CELL ENGRAFTMENT

Regardless of the cell type used, a consistent finding is that only a tiny number (usually <1%) of the cells that have been initially delivered can still be identified after a few days or, at best, weeks. This massive attrition rate proceeds from two sequential events: an initially low retention of the grafted cells into the target tissue and a subsequent low survival rate of the cells that have been initially retained. It is thus clear that the optimization of regenerative cardiac cell therapy requires to address these two issues.

Low Retention of Grafted Cells

This low retention is caused by the interplay of several factors: mechanical leakage of the cells along the needle tracks, washout through the venous and lymphatic drainage systems of the heart[122] with a subsequent large extracardiac cell redistribution (primarily in the lungs and the spleen), and limited myocardial homing in cases in which cells are delivered intravascularly.

Factors of Cell Retention

Three factors of cell retention must be considered: the route of cell delivery, the phenotype of the cells, and the nature of the target tissue.

Cells can be delivered by intravenous infusion, intracoronary or endomyocardial catheterization (the latter usually under electromechanical mapping), and open-chest transpericardial injections. Each of these routes has advantages and drawbacks.

The intravenous route is clearly the simplest and the safest. Unfortunately, it is associated with a minimal, if any, myocardial uptake of the injected cells,[123] suggesting that homing signals are unlikely to be powerful enough to overcome trapping (particularly in the lungs) of the circulating cells and drive them toward the injured areas. Intracoronary injections with the stop-flow technique result in minimal myocardial retention and dynamic tracking of 18^{F}-fluorodeoxyglucose–labeled progenitor cells has clearly documented a loss of approximately 80% of the myocardiac activity of the tracer after balloon deflation.[124] Furthermore, direct intracoronary infusion of cells may be harmful if their size is such that it can result in microvascular obstruction, as reported with MSC.[58] Indeed, direct intramyocardial injections seem to be the most efficient route for delivering cells,[125] and at least in the case of skeletal myoblasts, it does not seem that engraftment is then different whether these intramyocardial injections are made from the endocardium or transepicardially.[126] In the latter case, the role of the heart status remains uncertain with one study reporting no difference between beating-heart and arrested-heart injections,[127] whereas another, using more sophisticated assessment tools (MRI and quantitative polymerase chain reaction) documented the higher intramyocardial cell numbers when injections were made in the cardioplegic heart.[128] The major limitation of this epicardial approach is clearly its invasiveness (unless an associated surgical procedure is indicated); hence, the potential interest of a recently developed miniature robotic device that can be introduced through a subxiphoid approach, navigates over the epicardial surface and, owing to a fine-positioning control system, allows multiple injections in predefined target spots.[129] Finally, retrograde infusion through the coronary sinus with a dedicated ultrasound-guided catheter[130] has gained limited clinical acceptance and would likely be technically challenging in heart failure patients whose coronary sinus is now often already filled with leads connected to a synchronization device.

The phenotype of delivered cells is also likely to affect the magnitude of their retention as demonstrated by the finding that intracoronary delivery of $CD34^{+}$ cells results in greater numbers of these progenitors in the myocardium compared with unfractionated MNC.[131]

The nature of the target tissue also plays a role in cell retention. This is illustrated by the finding that intramyocardial retention of MNC is dramatically reduced in chronic heart failure compared with acute myocardial infarction,[132] likely because chemoattractive forces that may promote cell trafficking at the time of acute injury are no longer present (or less operative) in the setting of a remodeled old infarction.

Improvements in Cell Retention

Improvements in cell retention need to be considered differently depending on whether cells are delivered intramyocardially or intravascularly.

Intramyocardial Delivery

A first strategy consists of acting on cells and to increase the viscosity of the injectate to minimize leakage at the time of injections. This can be achieved by incorporation of cells into biomaterials or by encapsulating them in microparticles.

Incorporation into Biomaterials. Cells sense matrix nano topography and stiffness cues[133] as well as mechanical signals such as strain and stretch and these factors can thus modulate important cell functions such as proliferation, alignment, and differentiation. This implies that the choice of a scaffold has to be customized to a given stem cell type. Basically, polymers can be categorized as naturally derived (collagen, fibrin, decellularized matrices) or synthetic. The interest of embedding cells into one of these biomaterials is not only to improve their retention for purely physical reasons (increased viscosity) but also to facilitate some key functions such as survival, proliferation, and differentiation owing to cell patterning within a tridimensional microenvironment. These speculations are supported by the finding that incorporation of different types of cells into supports such as collagen,[134] fibrin glue,[135] or self-assembling nanopeptides[136] have been successful in increasing angiogenesis and preserving cardiac function. In addition, these polymers can serve as delivery vehicles for growth factors, thereby contributing to further enhance the efficacy of the cell transplantation procedure.[137]

In line with this reasoning, some investigators have successfully tested injection of cell-free dermal fillers[138] or alginate-derived hydrogels[139] for limiting postinfarction remodeling. These results are consistent with the finding that injecting passive materials alone into a postinfarct scar and consequently replacing a stiff tissue by a more compliant material may improve function and reduce wall stress in the ventricle, thereby contributing to normalize mechanotransduction signaling.[140] However, exclusive reliance on the passive function of acellular biomaterials is unlikely to affect myocardial regeneration, which requires incorporation of contractile cells able to line up with the appropriate geometry and to be excited in synchrony with the native cardiomyocytes.

Encapsulation. This approach entails incorporation of cells into porous microbeads the membrane of which is engineered in such a way that cell-secreted therapeutic factors can freely diffuse into the surrounding myocardial environment, whereas influx of oxygen and nutrients, but not of immune cells, is made possible by the size of the pores. In addition of increasing cell retention because of the size and viscosity of the particles, encapsulation may protect nonautologous cells from the host immune system without drug-based immunosuppression.[141] In fact, this technology has been successfully used for encapsulating xeno Langerhans' islets in animal models of diabetes.[142] Some clinical trials are currently under way in this indication. However, in the context of myocardial regeneration, this approach is questionable because it exclusively relies on the paracrine effects of cells and inherently prevent any form of functional integration of the graft within the host myocardium.

A second strategy consists of acting on the delivery systems. If the system is based on conventional injections, the design of the device could be conceivably improved to maximize cell retention, for example through changes in needle configuration allowing better spatial dispersion of cells and/or computerized driving to allow for a more accurate control over flow rate, duration, and injection pressure.

However, needle-based injections are fraught with several limitations: leakage along the needle tracks; random and poorly reproducible distribution of cells; creation of multiple intramyocardial clusters that can physically impede the propagation of electrical impulses and result in conduction blocks facilitating arrhythmias;[10] induction of volume-dependent tissue damage; and dissociation of the cells promoting a particular form of apoptotic cell death called *anoikis*,[143] which occurs when anchorage-dependent cells lose their attachment to the extracellular matrix and the related survival signals.

Consequently, one can take advantage of open-chest interventions to step away from injections and switch to the epicardial delivery of cell constructs overlying the infarct area and simply glued or sutured to its edges. The group of Eschenhagen has shown that if the selected cells featured a contractile phenotype as occurs with rat cardiomyocytes, it was possible, by mixing these cells with collagen, to generate force-generating beating heart constructs that, following implantation onto the scar tissue, were found to improve function, prevent dilation, and provide electrical coupling with native myocardium.[144] In the future, it is possible that cell-scaffold interactions might benefit from the bioprinting technology that enables transfer of cells onto the matrix (just like an inkjet is printed by a desktop printer) according to a precisely defined pattern.[145]

One step further, Okano and his group in Japan have developed an original technology based on the manufacture of cell sheets cultured on temperature-sensitive dishes.[146] Upon cooling, a layer of contiguous viable cells can be collected without disrupting the cellular microenvironment caused by enzymatic digestion otherwise required for cell detachment. The multilayered construct is then applied onto the surface of the heart where it adheres spontaneously. This technique has been used successfully to a variety of cells (eg, skeletal myoblasts, fibroblasts, epithelial cells, rat cardiomyocytes, mesenchymal stem cells) and has the advantage of avoiding the presence of any foreign material and allowing cells to be anchored through the extracellular matrix adhesive proteins that they have secreted themselves. In cardiac applications, the cell sheet technology has been shown more effective than injections in both ischemic[147] and nonischemic[148] animal models of heart diseases and a myoblast cell sheet has already been used clinically as an adjunct to a LV assist device. In a head-to-head comparison of conventional injections of myoblasts versus the epicardial delivery of either a myoblast-seeded collagen patch or a myoblast cell sheet,[149] we have been able to confirm the superiority of the two latter techniques with regard to improvement of postinfarction function, reduction of fibrosis, and increase in angiogenesis.

Conceptually, the use of epicardial cell constructs raises the major concern of the coupling of superficially delivered cells with the underlying host cardiomyocytes. However, migration of the patch-bound cells in the myocardium has been reported[150] as well as their coupling with host cardiomyocytes through gap junction proteins.[150,151]

Intravascular Delivery

If cells are to be injected into the coronary arteries, *a first strategy consists of acting on the delivery systems*. This approach is illustrated by the recent development of a perforated intracoronary catheter that allows cell delivery in the perivascular space.

A second strategy consists of acting on the homing signals responsible for cell trafficking. This can be achieved by interventions targeting cells directly or the recipient tissue.

Cell Targeting. Homing of cells to sites of injury is orchestrated by a tightly coordinated sequence of events involving "sensing" of the damaged tissue–emitted signals, selectin-mediated rolling, integrin-mediated firm adhesion to the vascular wall and transendothelial migration in the extracellular matrix.[152] Among the multiple factors that participate in the recruitment and trafficking of circulating cells, a crucial role is played by the chemokine CXC receptor (CXCR) 4, which is expressed on early hematopoietic stem cells and endothelial progenitors and its receptor, the stromal cell–derived factor (SDF)-1α.

Interventions designed at enhancing homing have thus logically relied on cell engineering to make them overexpressing one component of the receptor-ligand pair, ie, CXCR4[153] or SDF-1.[154] Transfection of MSC with insulin growth factor-1[155] has been another means of reactivating SDF-1 signaling. Aside from these gene-based approaches, drugs that activate endothelial nitric oxide synthase (NOS) such as statins or NOS enhancers have also been successful in enhancing cell homing.[152]

Tissue Targeting. In this setting, direct myocardial SDF-1 gene transfer[156] has been proposed for re-establishing tissue levels of SDF-1 known to decrease shortly after infarction. However, the anticipated regulatory hurdles, resulting from the combination of cell and gene therapy make appealing potentially safer and simpler techniques based on physical interventions. So far, three of them have been successfully tested: (1) Low-energy shock wave aims to induce expression of SDF-1,[157] and the CELLWAVE trial is already testing the effects of extracorporeal shock wave before bone marrow progenitor cell therapy in an effort to improve homing of these cells and subsequent angiogenesis in patients with chronic ischemic heart disease following anterior myocardial infarction. (2) Focused ultrasound-mediated destruction of microbubbles has been shown to create a series of biochemical responses (eg, release of proinflammatory cytokines, induction of metalloproteinase activity, reduction of laminin content), which result in enhanced transendothelial migration and interstitial invasion of MSC without causing endothelial damage.[158] (3) Finally, magnetic targeting could also be useful for driving cells toward the site of injury based on the seminal proof-of-principle finding that an externally applied magnetic device was effective in enhancing iron-loaded endothelial progenitor cell engraftment at a site of vascular injury.[159]

It is finally important to note that while enhancement of homing is particularly important in the context of acute myocardial infarction where the intravascular route is the only one available for stem cell delivery, this issue is somewhat less critical in the context of regeneration of the chronically failing heart, which allows a greater versatility in the stem cell transfer approaches and, in particular, a direct catheter-based or surgical intramyocardial delivery.

Low Survival of Retained Cells

Although cell death results from the complex interplay of multiple factors, ischemia inherent in the poor vascularization of the target areas, apoptosis subsequent to the loss of cell anchorage to their matrix and immune destruction of allogeneic cells have been identified as key players. Consequently, adjunctive interventions targeted at optimizing graft survival have focused on these events.

Induction of Angiogenesis

When the grafted area cannot be revascularized directly by CABG or angioplasty, two different types of strategies can be considered for increasing blood supply to the areas of engraftment and therefore promoting survival of the injected cells.

The first is based on the direct intramyocardial injection of *exogenous* angiogenic inducers which fall into four main categories: (1) genes-encoding angiogenic factors;[160] (2) growth factors themselves with the caveat that their fast clearance requires appropriate delivery systems; (3) genetically modified cells overexpressing an angiogenic factor;[161,162] and (4) cotransplanted cells featuring an angiogenic potential such as $CD133^+$ hematopoietic progenitors,[163] or the more recently described epicardium-derived cells.[164] Although there are no conclusive data about the most efficacious of these interventions, the importance of a cellular carrier is suggested by the finding that myoblast transfection with VEGF provides better cardiac protection than direct adenoviral VEGF delivery.[165]

The second strategy relies on the induction on an *endogenous* angiogenesis through an enhanced homing of circulating bone marrow cells in the areas of cell engraftment. As mentioned, this approach has largely relied on manipulation of the CXCR4-SDF1 axis to successfully increase the influx of angiogenic cells into the cell-transplanted regions.

Although one is missing a comprehensive head-to-head comparison of these various interventions, overall they all have met the objective of increasing angiogenesis, which has usually translated into a better LV function and an enhanced survival of the cellular graft. An advantage of targeting SDF-1 could be that in addition of its stem cell-recruiting effects through its interaction with CXCR4, it may exert direct cardioprotective effects by activating downstream signaling pathways involved in cardiomyocyte survival.[166] However, a potential clinical use of SDF-1 should be cautiously considered as the proteolytic cleavage of SDF-1α by matrix metalloproteinase-2 could yield a highly neurotoxic molecule, SDF.[5–67,167] Along the same line, malignant transformation has been reported in a mouse model of myocardial infarction following intramyocardial transplantation of MSC that had been engineered to overexpress stem cell factor.[168]

Limitation of Apoptosis

As pointed out, injection of dispersed cells promotes their apoptotic death because of the loss of survival signals originating from physiologic cell-cell and cell-matrix interactions.

A first means of addressing this issue is to deliver cells that have been transfected with antiapoptotic factors such as Akt[169] or Bcl2.[170] However, given the safety issues associated with gene therapy, a more attractive option could be to upregulate endogenous survival pathways though preconditioning of cells either physically by heat shock[171] or pharmacologically by potassium channel agonists.[172] Finally, where direct access to the heart is feasible, the use of three-dimensional cell-seeded patches or scaffold-free cell-sheets, particularly if they are multilayered,[173] is probably the best approach with regard to the risk-to-benefit ratio. The advantage of these constructs is not only that they do not cause disruption of myocardial tissue and preserve cell cohesiveness, but also that they allow incorporation of several different cell populations such as cardiomyocytes (regardless of their origin), endothelial cells, and fibroblasts.[174–176] Cross-talks between these cell populations may synergize trophic and particularly angiogenic effects which may enhance survival of the contractile cells "of interest."[150,176] Of note, studies of composite sheets made of cardiomyocytes and endothelial cells have shown that blood vessels originated from the construct and bridged to connect with host capillaries,[175,176] thereby providing additional evidence for the coupling between these epicardial cell constructs and the myocardium underneath.

Limitation of the Immune Response to Allogeneic Cells

This issue can be addressed by immunomodulatory strategies (such as those described about ESC) when the objective is a sustained cell engraftment or by encapsulation (also described in the preceding) if one admits that cells will not integrate within the recipient myocardium and exclusively relies on their paracrine effects.

To close this section, it is fair to acknowledge that the importance of keeping cells alive has recently been challenged by a study showing in a mouse model of myocardial infarction that extracts from unfractionated bone marrow cells, ie, their intracellular soluble contents, were actually as cardioprotective as factors released by living cells.[71] This conclusion, however, implies that protection exclusively relies on paracrine effects and is therefore not relevant to the generation of new myocardial tissue by donor-derived cells.

Tracking of Stem Cells

Clearly, the objective assessment of the above mentioned approaches for optimizing cell engraftment requires the use of safe, reliable, and noninvasive techniques for tracking cell fate over time, both in the target myocardium and remote organs.[177] Specific constraints on contrast agents include the lack of genetic modification of the labeled cells, of dilution with cell division and of transfer to non-stem cells. Experimentally, radionuclides, MRI, and reporter genes are the most extensively used molecular imaging techniques. Reporter genes are particularly attractive. Once transfected into the cell of interest, they yield a product that, following exposure to the corresponding radioactive or optical reporter probe, turns on a signal that can be imaged by positron emission tomography, single-photon emission computed tomography, or MRI. A first advantage of this approach is that it should only detect viable cells because expression of the imaging signal requires intracellular expression of the reporter gene product. This contrasts with MRI-based tracking of iron-loaded cells, which may generate false-positives when iron released by dead stem cells is engulfed by host macrophages and results in MRI signals mistakenly interpreted as originating from the transplanted cells.[178] Second, the reporter gene can be genetically integrated and transmitted to the transfected cell's progeny, thereby allowing to monitor cell proliferation. Finally, combination of several reporters can allow to set up a multimodal imaging platform such as that achieved with a triple-fusion reporter gene, which allowed a successful noninvasive monitoring of the kinetics of cell survival, proliferation, and migration by bioluminescence and PET imaging.[179] Validation of these data is supported by the critical finding that reporter genes do not seem to adversely affect cell integrity and function. Multimodality imaging is likely important because there is currently no single technique that can optimally combine resolution, sensitivity, safety, accuracy of cell quantification, and clinical applicability. Bioluminescence, for example, which uses light generated by the enzyme luciferase is limited to small animals because of the poor tissue penetration of external illumination sources and a similar limitation applies to near-infrared fluorophores. In the future, however, this issue might be addressed by nanometer-sized light-emitting quantum dots conjugated to bioluminescent agents. Improved imaging techniques are thus eagerly awaited for experimental stem cell tracking and subsequent clinical translation without adding significant cost or regulatory roadblocks.

Because there is no animal model that can fully reproduce the complex situation of patients with advanced heart failure in need for myocardial regeneration, it seems legitimate to continue clinical trials, provided that their experimental grounds are robust and consistent enough to suggest that the selected cell type has a reasonable potential of effecting some myocardial regeneration without causing adverse events. Beyond the stage of pilot small-sized feasibility studies, these trials should comply with the standard methodologic guidelines (randomization, control groups, blind assessment) and their protocol should carefully take into account some key variables such as cell dosing, delivery modalities, and realistic approvability by the regulatory authorities. Until large mortality trials can be launched, surrogate end points and imaging modalities should also be selected in light of the expected objective of regeneration and, as such, the commonly used measurements of global LV function may have to be shifted toward the assessment of cell-related morphologic changes such as infarct size, LV remodeling, or regional wall thickness areas. At the end, a continuous cross-talk between different disciplines including clinical cardiology, developmental biology, cell culture technology, tissue engineering, imaging and high-throughput production of scalable, and reproducible biologics appears mandatory for moving the field forward and successfully achieving the goal of myocardial regeneration under conditions of an optimal risk-to-benefit ratio.
