The rate of urinary tract infection (UTI) following ureteroscopy varies between 4% and 25% of cases even when prophylactic antibiotics are administered (Rao et al, 1991; Hendrikx et al, 1999; Puppo et al, 1999; Christiano et al, 2000; Grabe, 2001; Grabe, 2004). **European guidelines advocate a single dose of preoperative antibiotic prophylaxis** (Naber et al, 2001); **however, a randomized study by Knopf and colleagues revealed no difference in the rate of clinical UTI between patients randomly assigned to antibiotic prophylaxis and those without antibiotic prophylaxis** (Knopf et al, 2003). This study demonstrated a higher rate of postoperative bacteriuria in those who did not receive antibiotic prophylaxis (12.5%) than in those who did receive prophylaxis (1.8%); however, there were no clinically active UTIs in either group, suggesting that postoperative asymptomatic bacteriuria does not necessarily lead to a clinical UTI (Christiano et al, 2000; Knopf et al, 2003).

In a review of the literature reported by Grabe, it is recommended that intravenous antibiotic prophylaxis be given to patients undergoing ureteroscopy for the treatment of a proximal or impacted stone (Grabe, 2004). **Grabe further recommends that antibiotic prophylaxis is not necessary in the ureteroscopic treatment of more distal stones in uncomplicated cases but should be utilized in patients at risk (e.g., significant comorbidities, diabetes). Patients with a preoperative stent, catheter, or nephrostomy tube should be treated with prophylactic antibiotics** (Grabe, 2004). Christiano and associates (2000) determined that a single preoperative oral dose of ciprofloxacin provided protection equivalent to that of a single intravenous dose of cefazolin at reduced cost.

Patients with heart valves and murmurs at risk for bacterial endocarditis require antibiotic prophylaxis (Amin, 1992). The American Urological Association (AUA) and American Academy of Orthopaedic Surgeons (2003) published a joint advisory statement regarding antibiotic prophylaxis stating that **all patients who have undergone prosthetic joint replacement within the past 2 years are at increased risk for bacteremia and should be administered prophylactic antibiotics. Immunocompromised patients with inflammatory arthropathies, those with drug- or radiation-induced immunosuppression, and patients with comorbidities (malnourishment, hemophilia, human immunodeficiency virus, diabetes, or malignancy) should also undergo antibiotic prophylaxis.**

Video Monitoring and Camera

Video monitoring of ureteroscopy provides several advantages. The camera is ergonomically beneficial, particularly when using the semirigid ureteroscope and for teaching trainees and coordinating operating room personnel. Documentation devices such as digital capture devices can take still photographs as well as digital motion film through the endoscope. Digital capture allows endoscopic images to be filed into a patient's electronic chart or electronic radiology file for later reference.

Positioning of the Patient

Ureteroscopy has been described with patients in the supine, prone, and flank positions (Clayman et al, 1987; Bercowsky et al, 1999; Herrell and Buchanan, 2002). Flank positioning requires the exclusive use of flexible instruments and has the advantage of placing the renal pelvis in the most dependent position to facilitate stone clearance and access to fragments during intracorporeal lithotripsy (Herrell and Buchanan, 2002). **The authors' preference is to position the patient in the dorsal lithotomy position** with the ipsilateral leg somewhat straighter and lower than the contralateral leg to allow the surgeon more room to operate rigid instruments in line with the affected ureter. The lower, straighter ipsilateral leg is also believed to align the affected ureter in order to facilitate ureteroscopy. **When operating in the proximal ureter or kidney, slight Trendelenburg positioning may help the stone or any fragments to be displaced into an upper calyx, which is typically in line with the ureter and is easier to reach than the lower pole.**

Cystoscopy

Flexible or rigid cystoscopes can be used for initial guide wire placement into the ureter; the technique depends on the urologist's training and available equipment. At the authors' institution, flexible cystoscopy is the preferred modality. Although rigid cystoscopes are more durable, they may cause more urethral trauma and discomfort, particularly in males. Rigid ureteroscopes produce clearer images because of the glass rod-lens system. Various angles that are not attainable with a rigid instrument may, however, be achieved with a flexible cystoscope. For instance, in males with a prominent prostate and large median lobe, it may be difficult to visualize and cannulate the ureteral orifice with a rigid cystoscope, whereas the flexible counterpart has increased maneuverability to perform this task. **Cystoscopy** is carried out in order to insert a 0.035- or 0.038-inch PTFE-coated floppy-tip guide wire into the ureter up to the renal pelvis until it is coiled in the kidney. If difficulty occurs in visualizing the ureteral orifice, certain steps may be taken: (1) identify the contralateral orifice and look across the intertrigonal ridge, (2) empty the bladder if it is full, (3) fill the bladder if it is empty, and (4) switch from the flexible to rigid cystoscope or vice versa. A colored dye may also be given intravenously (e.g., indigo carmine), but this may be time consuming while waiting for renal filtration.

Safety Guide Wire

Fluoroscopy is used to confirm the position of the guide wire as it is advanced. For ureteral stones, the wire should be advanced past the stone before beginning intracorporeal lithotripsy. In this manner, **the wire acts as a safety wire, and should ureteral perforation or excessive bleeding occur such that vision is obscured and the procedure can no longer be safely performed, access to the kidney is preserved and a ureteral stent may be left indwelling. A general principle of ureteroscopy is always to have a safety guide wire present intraoperatively.** If the wire cannot traverse past an obstructing stone, the wire is left at the level of the obstruction, the cystoscope is removed, and the following steps may be attempted:

1. Insert a 5 Fr ureteral catheter over the guide wire to buttress the guide wire and provide backing to propel the guide wire past the stone. If this is unsuccessful . . .
2. Exchange the PTFE guide wire for an angled hydrophilic wire or combination wire with an angled hydrophilic tip and attempt to maneuver past the stone (Leveillee and Bird, 2000; Hofmann et al, 1995). If this is unsuccessful . . .
3. Exchange the 5 Fr ureteral catheter for an angled ureteral catheter or vascular catheter (see Fig. 45–4) in combination with the angled hydrophilic wire to manipulate past the obstructing stone (Schwalb and Eshghi, 1994).

If there is any question about where the guide wire has traversed, a 5 Fr ureteral catheter can be exchanged over the guide wire and a retrograde pyelogram obtained to outline the collecting system. Ureteral edema, inflammation, and thinning of the mucosa may occur with an obstructing stone, resulting in ureteral perforation during wire manipulation indicated by extravasation of contrast material on the retrograde pyelo-

gram. If the wire cannot be manipulated into the collecting system and confirmed with contrast, antegrade percutaneous nephrostomy tube drainage is indicated to relieve obstruction and prevent urinary extravasation.

Ureteroscope Insertion

When a safety guide wire is in place, the cystoscope is backed out and a straight urethral catheter is inserted and removed to drain the bladder. The next step depends on whether rigid or flexible ureteroscopy is planned. During **rigid ureteroscopy**, the endoscope is generally inserted alongside the guide wire under direct vision (Abdel-Razzak and Bagley, 1993). Care must be taken to observe the presence of the wire at all times to avoid creation of a false passage. The ureteroscope is advanced only when the instrument slides freely and there is a clear field of view. When performing **flexible ureteroscopy**, a second "working" wire must be inserted in order to backload the endoscope, allowing the wire to act as a guide for the instrument to be advanced into the ureter or kidney under fluoroscopic guidance (Afane et al, 2000). Placement of a second wire can be achieved by insertion of a dual-lumen catheter (6/10 Fr) or an 8/10 Fr coaxial dilator inserted over the initial guide wire. Adequate tension should be placed on the guide wire by the assistant as the ureteroscope is advanced. The ureteral orifice is a location where advancement of the endoscope may be hindered because the working channel is typically eccentrically located in ureteroscopes. Simply rotating the ureteroscope during advancement often overcomes this obstacle. Failing this, the ureter should be gently dilated using an 8/10 Fr coaxial or similar dilator and insertion attempted again (Table 45–4). This degree of dilation is typically sufficient to insert the current generation of small flexible ureteroscopes. A UAS can also dilate the ureter, improve irrigation and visibility, and facilitate repeated ureteroscope insertions as noted previously (Aslan et al, 1998).

Table 45–4. Algorithm for Troubleshooting Advancement of the Flexible Ureteroscope

1. **Rotate the ureteroscope at the ureteral orifice while attempting to advance.** Rotation of the eccentrically placed working channel where the guide wire exits often allows passage of the flexible ureteroscope into the ureter. If this fails, . . .
2. **Dilate ureteral orifice using an 8/10 Fr coaxial dilator over a guide wire.** Reattempt ureteroscope insertion. If this fails, . . .
3. **One-step dilation with a balloon dilator or serial dilation using coaxial dilators.** One-step dilators may be less traumatic. Deflation of the balloon is necessary before removing the balloon. If the balloon cannot be advanced, use an extra-stiff guide wire, which is less likely to buckle. If it cannot be advanced over the stiff wire, load an 8/10 Fr coaxial dilator and remove the 8 Fr dilator leaving the 10 Fr sheath. Pass the balloon dilator over the wire through the 10 Fr sheath, which gives it backing to advance through the tight part of the ureter. If this fails, . . .
4. Place a **ureteral access sheath** that has a dilating obturator that, once removed, provides a conduit for insertion of the ureteroscope. If this fails, . . .
5. The last resort is to **leave a self-retaining ureteral stent and defer the definitive procedure.** The stent passively dilates the ureter after 7 to 10 days and ureteroscopy can be attempted again at that time.

If the ureteroscope still cannot be advanced, the last step is to leave a ureteral stent, defer the definitive procedure, and return after 7 to 10 days when the stent has passively dilated the ureter.

Upon successful advancement of the endoscope, fluoroscopy is used to guide the flexible ureteroscope to the area of interest, which is then visualized directly. Instillation of contrast material through the ureteroscope and concurrent fluoroscopy are used to provide intrarenal orientation, and the endoscope is manipulated into each calyx and visually evaluated. All calyces should be systematically inspected to ensure a complete examination.

IS ROUTINE STENTING NECESSARY FOLLOWING URETEROSCOPY?

Placement of a ureteral catheter or internal ureteral stent has been the standard of care following ureteroscopy. The main advantage of a postoperative ureteral stent is to prevent renal colic from obstruction related to stone fragments or ureteral edema from balloon dilation. Furthermore, passive ureteral dilation by the stent is thought to facilitate passage of stone fragments when the stent is removed. Stenting the ureter is also thought to prevent ureteral stricture formation and to facilitate ureteral healing. Disadvantages of ureteral stents include morbidity associated with infection, dysuria, flank pain, hematuria, or stent migration (Stoller et al, 1992; Joshi et al, 2002; Joshi et al, 2003).

Randomized controlled clinical trials have demonstrated that not all patients require routine stenting after ureteroscopy. Of 93 patients who were not stented following ureteroscopy, 40 had no postoperative discomfort, and of the 53 patients with discomfort, 45 complained of only mild discomfort that was easily resolved by oral analgesics (Hosking et al, 1999). Although this was a case series and there were no controls, this was the first report to demonstrate that ureteroscopy patients did not routinely require a ureteral stent (Hosking et al, 1999). **Patients prospectively randomly assigned to ureteral stents following ureteroscopy have increased pain compared with nonstented patients, yet the incidence of emergency room visits, urosepsis, and hospitalization and stone-free rates did not differ between the two groups** (Borboroglu et al, 2001; Denstedt et al, 2001). Similarly, nonstented patients did not have more complications than patients in whom a stent was left indwelling. Several randomized controlled trials have shown similar results (Cheung et al, 2001a; Hollenbeck et al, 2001; Netto et al, 2001; Byrne et al, 2002; Cheung et al, 2003; Srivastava et al, 2003; Damiano et al, 2004). **At our institution, if the stone burden is small, the ureter has not been balloon dilated, and the holmium:YAG laser has been used without ureteral trauma, a ureteral stent is not routinely placed** (Denstedt et al, 2001). Other authors have demonstrated that a stent is not necessary even with balloon or coaxial ureteral dilation (Hosking et al, 1999; Borboroglu et al, 2001; Hollenbeck et al, 2001; Byrne et al, 2002). **Ureteral stenting after ureteroscopy is not routinely necessary and should be determined on a case-by-case basis** (Knudsen et al, 2004). Indications for insertion of a ureteral stent following ureteroscopy and lithotripsy are outlined in Table 45–5.

Table 45-5. Indications for Ureteral Stent Placement following Ureteroscopy

Ureteral perforation intraoperatively
Ureteral dilation greater than 10 Fr (either coaxial or balloon dilator)
Significant ureteral edema due to stone (e.g., impacted stone)
Failure to advance the ureteroscope due to a narrow ureter or ureteral orifice and in preparation for a subsequent ureteroscopy after 7 days
Infected urinary system with an obstructing system
Large stone burden with many fragments remaining to pass
Solitary kidney

URETERAL STENTS AND BIOMATERIALS

All stents may cause morbidity such as flank pain, dysuria, hematuria, infection, migration, and encrustation. **The ideal stent material should be biocompatible and radiopaque, relieve intraluminal and extraluminal obstruction, resist encrustation and infection, cause little discomfort to the patient, and be widely available at a reasonable cost. To date, no stent material meets all of these criteria.**

Polyethylene was the first synthetic polymer used to produce stents, but it has been abandoned because of its fragility and tendency to fracture (Mitty et al, 1987; Mardis and Kroeger, 1988; Roemer, 2000). Various materials have been utilized to manufacture stents including silicone and polyurethane. **Silicone** stents are the most biocompatible of materials used, but they lack rigidity because of their flexibility and elasticity and are difficult to manipulate within the urinary tract. The low tensile strength of silicone makes it easy to compress the stent extrinsically. The development of biomaterials has evolved to produce **polyurethane, the commonest polymer used in today's stents.** As a single polymer, polyurethane is very rigid and causes discomfort in patients and ureteral ulceration and erosion in animal ureters (Marx et al, 1988). Blended polymers of polyurethane have a reduced tendency to cause mucosal damage. Newer materials and combination polymers are softer, more comfortable, and easier to maneuver within the urinary tract (Beiko et al, 2004; Chew and Denstedt, 2004). Examples include various proprietary blends such as Percuflex (Boston Scientific Corporation, Natick, MA), Silitek (Surgitek, Medical Engineering Corporation, Racine, WI), C-Flex (Consolidated Polymer Technologies, Clearwater, FL), Tecoflex (Thermedics, Wilmington, MA), and ethylene vinyl acetate (from the polyolefin family, of which polyethylene is a member).

Infection and encrustation, in particular, limit long-term use of stents to the extent that patients who require long-term indwelling stents must undergo stent changes every 3 to 4 months. Infection and encrustation arise from the formation of biofilm on the surface of the stent, which occurs within hours after insertion (Tieszer et al, 1998; Wollin et al, 1998). After a conditioning film coats the surface of any foreign object in the urinary system, glycoproteins, exopolymer, and matrix form a biofilm in which bacteria may become embedded (Choong and Whitfield, 2000). Embedded bacteria in biofilms are difficult to eradicate as antibiotics poorly penetrate the biofilm, the bacteria upregulate genes to produce resistance, or the bacteria enter a low-energy hibernation state that is immune to antibiotics that rely on high cellular metabolism for their bactericidal activity. Improvements in biomaterials and surface coatings have attempted to reduce biofilm formation and, thus, subsequent infection and encrustation (Roemer, 2000; Beiko et al, 2004; Chew and Denstedt, 2004). Coatings such as hydrophilic polymers (Gorman et al, 1998), heparin (Riedl et al, 2002), pentosan polysulfate (Zupkas et al, 2000), or oxalate-degrading enzymes (Watterson et al, 2003) have been used in an attempt to reduce stent encrustation.

Stent design has varied in newer stents, including biodegradable, spiral, tail, and dual durometer stents. Biodegradable stents are composed of a polymer containing poly-L-lactic and glycolic acids that is designed to disintegrate after 48 hours in the urinary tract after it has provided kidney drainage following ureteroscopy (Lingeman et al, 2003b). Although it successfully provided drainage for 48 hours in 78% of patients (68 of 81), its widespread use was prevented by such complications as early disintegration (<48 hours) and retained fragments (>3 months) requiring SWL and ureteroscopic removal (Lingeman et al, 2003a). **Spiral stents** were designed with a helical ridge that spiral from proximal to distal and were believed to facilitate stone fragment expulsion after lithotripsy (Stoller et al, 2000). A clinical prospective study found no difference in stone clearance rates following extracorporeal SWL in patients with spiral stents compared with control stents (Gerber et al, 2004). **Tail stents** have a regular 7 Fr hollow lumen proximal pigtail within the kidney and a tapered 3 Fr lumenless tail that starts in the distal ureter and extends into the bladder but does not coil (Dunn et al, 2000). In one clinical trial, the tail stent was reported to produce less irritative stent symptoms than control stents (Liatsikos et al, 2002). **Dual durometer stents** are composed of materials with different stiffness in the bladder pigtail compared with the kidney pigtail. The proximal pigtail is more rigid to prevent stent migration, whereas the bladder portion is softer and hypothesized to produce less irritative symptoms. To date, there are no clinical trials evaluating symptoms associated with dual durometer stents.

Encrustation and bacterial colonization related to stents and catheters are problematic and potentially lead to morbidity such as infection, sepsis, or renal failure. Between 44% and 69% of indwelling stents have bacteria adherent to their surface (Reid et al, 1992; Wollin et al, 1998; Paick et al, 2003; Kehinde et al, 2004). Oral antibiotics administered at the time of stent insertion have been found to be adsorbed to the stent surface biofilm (Reid et al, 2001). This provides evidence for the short-term administration of oral antibiotics following ureteral stent insertion. The utility of long-term antibiotic use in patients with indwelling stents has not been proved, and such patients should be treated only if symptomatic (Kehinde et al, 2004).

Loading the antimicrobial triclosan, a common antimicrobial constituent of many commercial products such as soaps and toothpaste, directly into the ureteral stent to elute over time has resulted in clearance of bacteria in an animal model of UTI (Chew et al, 2004). This type of drug-eluting stent may reduce biofilm formation and, hence, infection and encrustation. The next generation of stents will see drugs delivered directly out of the stent to decrease stent-related irritation, infection, and encrustation.

Technique of Ureteral Stent Placement

A variety of techniques have been described for stent placement. The general principles include fluoroscopic observation and passage over a guide wire. The first step is to cystoscopically insert a guide wire up to the kidney. A retrograde pyelogram to outline the collecting system may be obtained by exchanging the wire for a 5 Fr ureteral catheter. The stent can be inserted directly over the wire through the cystoscope as it is visualized directly and a stent pusher is used to deploy the stent. Alternatively, the cystoscope can be removed and the stent can be inserted using fluoroscopy and a stent pusher with a radiopaque tip. Care must be taken not to advance the distal end of the stent too far proximally into the ureter. A stenting method using a UAS and fluoroscopy has been described (Wu et al, 2001).

POSTOPERATIVE CARE

Ureteroscopy is typically performed as an outpatient day surgery procedure. If a stent is left indwelling, it is typically removed 3 to 10 days after the procedure. Postoperative radiographs are obtained within 1 to 2 weeks to determine the success of the procedure. **Small stone fragments (<4 mm) normally pass after the stent has been removed because of the passive ureteral dilation that occurs from stenting** (Deliveliotis et al, 1996a, 1996b). Patients are asked to strain their urine and collect any fragments for stone analysis if samples were not obtained during surgery.

The requirement for routine imaging to rule out obstruction after ureteroscopy is controversial. Postoperative imaging has been recommended in a routine fashion to determine whether there are any residual calculi (Biester and Gillenwater, 1986; Harmon et al, 1997; Roberts et al, 1998). Silent obstruction may occur secondarily from ureteral edema, trauma, or stricture and result in renal failure if it remains undetected (Biester and Gillenwater, 1986; Harmon et al, 1997; Roberts et al, 1998). Weizer and colleagues (2002) reviewed a series of 241 patients of whom 30 had obstruction postoperatively and 7 of these 30 had silent obstruction. They recommended that all patients undergo postoperative imaging as 28% of obstructed patients had silent obstruction and did not have any identifiable risk factors for ureteral stricture at the time of surgery. Others believe that routine imaging is not necessary if there is no history of preexisting ureteral stricture, ureteral perforation, or significant stone impaction at the time of surgery (Karod et al, 1999; Bugg et al, 2002; Beiko et al, 2003). Asymptomatic patients had normal postoperative imaging, and urinary obstruction was present only in patients who experienced flank pain or had identifiable risk factors at surgery such as preexisting evidence of ureteral stricture or significant ureteral trauma intraoperatively.

Postoperative imaging of asymptomatic patients to rule out urinary obstruction and ureteral stricture remains a point of controversy.

RESULTS OF URETEROSCOPY FOR TREATMENT OF URETERAL STONES

The 1997 AUA panel guidelines recommended ureteroscopy or shockwave lithotripsy as acceptable treatment for stones in the distal ureter that are unlikely to pass spontaneously or cause significant symptoms requiring multiple hospital visits (Segura et al, 1997). Stone-free rates in the distal ureter exceed 95% after ureteroscopy (Peschel et al, 1999; Strohmaier et al, 1999; Sofer et al, 2002) and 75% to 97% after SWL (Eden et al, 1998; Park et al, 1998; Peschel et al, 1999; Turk and Jenkins, 1999; Pearle et al, 2001). Ureteroscopy may produce consistently higher stone-free rates but is more invasive than SWL. Furthermore, SWL is likely to require more than one session, ancillary treatments, and is not as widely available as ureteroscopy in some healthcare settings. For distal ureteral stones larger than 1 cm, ureteroscopy and intracorporeal lithotripsy decrease the need for ancillary treatment and typically render the patient stone free following one treatment compared with SWL. **Studies comparing SWL with ureteroscopy for distal stones demonstrate that patients treated with ureteroscopy not only had higher stone-free rates but also required less operating room time, less fluoroscopy time, and less time to achieve a stone-free status** (Hendrikx et al, 1999; Peschel et al, 1999; Chang et al, 2001; Hautmann et al, 2004). **Both ureteroscopy and SWL are viable options in the treatment of distal ureteral stones, and the decision on which treatment to employ should be based on patients' preferences and the availability of each modality** (Segura et al, 1997).

AUA panel guidelines recommend SWL as first-line therapy for proximal ureteral stones smaller than 1 cm. Ureteroscopy and percutaneous nephrolithotomy are acceptable choices for failed SWL. SWL produces stone-free rates ranging from 65% to 75% for proximal ureteral stones (Schmidt et al, 1995; Kim et al, 1996; Osti et al, 1997; Park et al, 1998). Ureteroscopy and holmium:YAG laser lithotripsy produce excellent stone-free rates (>92%) in the treatment of proximal ureteral stones smaller than 1 cm (Psihramis, 1992; Erhard et al, 1996; Lam et al, 2002; Wu et al, 2004).

For proximal ureteral stones larger than 1 cm, SWL, percutaneous nephrolithotomy, and ureteroscopy are all equally viable options according to AUA panel guidelines (Segura et al, 1997). Patients with stones larger than 1 cm in the proximal ureter treated by ureteroscopy have excellent stone-free rates ranging from 92% to 97% (Lam et al, 2002; Sofer et al, 2002; Wu et al, 2004) compared with 65% to 75% in those treated with SWL (Schmidt et al, 1995; Kim et al, 1996; Osti et al, 1997; Park et al, 1998). Table 45–6 outlines the stone- and patient-related considerations for when ureteroscopy is preferable to SWL in the treatment of ureteral stones.

Ureteroscopy for intrarenal stones is very effective and produces stone-free rates ranging from 84% to 92% (Andersen et al, 1993; Grasso and Chalik, 1998; Grasso et al, 1998; Tawfiek and Bagley, 1999; Sofer et al, 2002; Chow et al, 2003). Intrarenal stones smaller than 2 cm may be successfully treated ureteroscopically while larger stones (>2 cm) are better managed with a percutaneous approach. One study with a small number of patients with stones larger than 2 cm reported a success rate (fragments < 2 mm) of 76% using ureteroscopy in patients who were medically unfit to undergo a percutaneous procedure (Grasso et al, 1998). Stones located in the lower pole usually have lower rates of clearance compared to other intrarenal locations and the optimal management of stones in this location is controversial. Success rates

Table 45-6. Indications for Ureteroscopy Rather than Shockwave Lithotripsy in Stone Ureteral Disease

Salvage for failed shockwave lithotripsy (SWL)
Known hard stone (calcium oxalate monohydrate, cystine, brushite)
Morbidly obese (>300 lb or above the focusing limit of the lithotriptor)
Uncorrectable bleeding diathesis (or in a patient in whom it is unsafe to discontinue anticoagulation)
Multiple proximal ureteral stones
Stones >1 cm (decreased rate of success with SWL when stone is >1 cm)
Radiolucent stones
Patient's preference
Social reasons (i.e., for patients who must be completely stone free, such as pilots, bus drivers)

of 85% have been reported for lower pole stones treated ureteroscopically (Grasso and Chalik, 1998). A randomized, prospective trial of SWL versus ureteroscopy in the treatment of lower pole stones revealed no statistically significant difference between stone-free rates at 3 months (35% vs 50%, respectively) (Pearle et al, 2005). Using a flexible ureteroscope and nitinol basket or graspers to re-position lower pole stones smaller than 1 cm to an upper calyx before employing intracorporeal lithotripsy improved the stone-free rate from 77% to 89% (Schuster et al, 2002). Ureteroscopy for intrarenal stones smaller than 2 cm provides good success rates.

Salvage Ureteroscopy after Failed Extracorporeal Shockwave Lithotripsy

Ureteroscopy is typically recommended as a salvage ancillary procedure for ureteral stones after failed SWL (Boline and Belis, 1993; Singal et al, 1998). Pace and coworkers (2000) determined that after one SWL treatment, the stone-free rate is 68%, and with the addition of a second treatment, a small incremental improvement up to 76% is achieved. Subsequent SWL treatments increase the cumulative stone-free rate to 77% and 78% for the third and fourth treatments, respectively. Results of this study strongly suggest that after one failed SWL treatment, salvage ureteroscopy provides the best chance for a stone-free status (Singal et al, 1998; Pace et al, 2000).

URETEROSCOPY IN SPECIAL CASES

Urolithiasis in Pregnancy

Urolithiasis in pregnancy is relatively uncommon with an incidence rate of approximately 1 in 1000 pregnancies (Stothers and Lee, 1992). It must be differentiated from hydronephrosis of pregnancy, which can occur in 90% of pregnant women by the third trimester (Puskar et al, 2001). **More than 84% of pregnant women with renal colic pass their stone spontaneously, making conservative therapy the first-line treatment** (Rodriguez and Klein, 1988; Hendricks et al, 1991; Stothers and Lee, 1992). Initial management should include intravenous hydration, analgesics, antiemetics, and antibiotics where appropriate. Urinary sepsis, obstruction, or azotemia in conjunction with urolithiasis requires urgent urinary decompression. Conservative management itself is not entirely benign and can result in premature labor or pyelonephritis (Parulkar et al, 1998). Given the high rate of spontaneous stone passage, a trial of conservative management is advocated. The urologist can always proceed to more invasive therapies if symptoms or obstruction persists. If urinary drainage is required for sepsis or persistent obstruction, nephrostomy tube or ureteral stent drainage may be used to provide upper tract drainage until after the time of delivery with postpartum treatment of the stone (Denstedt and Razvi, 1992; Evans and Wollin, 2001; McAleer and Loughlin, 2004).

Pregnant women have been shown to have an increased incidence of hypercalciuria compared with their nongravid counterparts, yet stone formation rates and stone composition types are no different (Swanson et al, 1995). The increase in urinary calcium is caused by an increased filtered load and intestinal hyperabsorption from elevated serum vitamin D levels during gestation. An increase in urinary excretion of inhibitors such as citrate, magnesium, and glycoproteins occurs during pregnancy to offset the lithogenic tendency of hypercalciuria.

The diagnosis of urolithiasis typically requires diagnostic tests utilizing radiation. Exposure to potentially teratogenic ionizing radiation must be reduced or eliminated in pregnant patients. Ultrasonography is a safe initial radiologic study of choice for evaluating urolithiasis during pregnancy. A limited intravenous pyelogram may be obtained safely with proper shielding and produces only 200 millirads, well below the 1-rad threshold that has been linked to teratogenic effects (Gianopoulos, 1995). The fetus is thought to be most susceptible during organogenesis (4 to 10 weeks of gestation) to radiation-induced malformation (Houston, 1977). After this time frame, much higher radiation doses are required to induce anomalies. If fluoroscopy is required, pulsed fluoroscopy minimizes radiation to the fetus. With radiation, there is a small but tangible risk of future malignancy in the child. There is an epidemiologic link between diagnostic irradiation and solid malignancy and leukemia (Stewart and Kneale, 1973; Harvey et al, 1985).

In the management of pregnant patients with urolithiasis, anesthesia may be necessary for procedures to provide urinary drainage or to treat the stone definitively. Special consideration must be given as many anesthetic agents are highly lipid soluble and cross the placenta. During the first trimester, an estimated risk of 0.5% of morphogenic anomaly may be associated with volatile gas anesthetic agents (Pedersen and Finster, 1979); therefore, nonemergent surgery should be delayed until the second trimester, when organogenesis is complete. Furthermore, there is an increased risk of spontaneous abortion during the first and second trimesters in women who have undergone general anesthesia for various procedures (Duncan et al, 1986).

Not all of the potential modalities normally used to treat urolithiasis are available in the treatment of pregnant patients. Extracorporeal SWL is absolutely contraindicated in pregnant patients as animal studies have demonstrated deleterious effects of shockwaves on developing fetal tissue (Chaussy and Fuchs, 1989). With the myriad of other available treatment options, SWL should be deferred until the postpartum period. Ureteroscopic manipulation of stones during pregnancy is

possible, but not all methods of intracorporeal lithotripsy are compatible with pregnancy. The peak pressures generated by EHL are transmitted some distance from the probe, may harm the fetus, and should be avoided in pregnancy (Vorreuther, 1993). Ultrasonic lithotripsy is theorized to produce fetal hearing damage and should likewise be avoided during pregnancy (Ulvik et al, 1995). **The intracorporeal modality of choice in the pregnant patient is the holmium:YAG laser because of its excellent safety profile** (Carringer et al, 1996; Gross, 1996; Scarpa et al, 1996; Scarpa et al, 1997; Irving et al, 1998; Shokeir and Mutabagani, 1998; Evans and Wollin, 2001; Lifshitz and Lingeman, 2002; Watterson et al, 2002a). Other methods such as pulsed dye laser and pneumatic lithotripsy have been utilized, but the latter is available only in conjunction with semirigid ureteroscopy because of the rigid nature of the pneumatic probe. Reported stone-free rates with the holmium:YAG laser are greater than 90% with no episodes of preterm labor. Regional anesthesia can be used in the first and second trimesters with general anesthesia in the third trimester without increasing the risk of spontaneous abortion or developmental anomaly. **If conservative therapy fails, ureteroscopy may be performed safely and effectively in pregnant patients with urolithiasis** (Lifshitz and Lingeman, 2002; Watterson et al, 2002a).

Ureteroscopy in Children

Urolithiasis in children may be managed with the same modalities utilized in the adult, namely percutaneous nephrolithotomy, ureteroscopy, and SWL. SWL provides stone-free rates ranging from 60% to 100%, depending on the size and location of the stone (Demirkesen et al, 1999; Delakas et al, 2001; Gofrit et al, 2001; Tan et al, 2004).

Advances in technology including the miniaturization of ureteroscopes have made ureteroscopy with intracorporeal lithotripsy in children feasible in cases in which SWL would have been considered first-line treatment. Ureteroscopy has produced excellent stone-free rates in excess of 92%, similar to those achieved in adults (Schuster et al, 2002; Al-Busaidy et al, 2004). The smaller endoscopes allow access to the majority of ureters without ureteral dilation. **All three modalities of intracorporeal lithotripsy (holmium:YAG laser, pneumatic lithotripsy, EHL) and basket extraction have been used successfully and safely with both flexible and semirigid ureteroscopy** (Shroff and Watson, 1995; al Busaidy et al, 1997; Wollin et al, 1999; Bassiri et al, 2002; Schuster et al, 2002; Al-Busaidy et al, 2004; Satar et al, 2004; Tan et al, 2005). The holmium:YAG laser is the intracorporeal lithotriptor of choice because of its effectiveness against all stone compositions and high margin of safety. The rate of complications remains similar to those reported in adults; for example, ureteral perforation occurs in 1.4% of pediatric cases (Schuster et al, 2002).

Ureteroscopy for the treatment of renal and ureteral calculi has become more feasible, safe, and efficient in the pediatric population and rivals SWL as a first-line treatment in many clinical scenarios. At our institution, ureteroscopy is emerging as the preferred first-line therapy for many of our pediatric patients with urinary tract stones, especially those with stones in the distal ureter.

Ureteroscopy in the Morbidly Obese Patient

Obesity is a major health care issue in the developed world and is a factor contributing to the increasing incidence of stone disease (Meschi et al, 2004; Straub and Hautmann, 2005). Obese patients present a particular challenge and are often not amenable to extracorporeal SWL because of focal length limitations and positioning difficulty on SWL machines. Nguyen and Belis (1998) reported on ureteroscopy in 52 patients with an average weight of 288 pounds (205 to 385 pounds) with a stone-free rate of 78% after one procedure and 97% after a second procedure with no significant complications. Dash and colleagues (2002) demonstrated that the stone-free and complication rates are equal in morbidly obese patients and nonobese patients. Special attention should be given to anesthetic concerns, particularly regarding airway management, ventilation, and obesity-related diseases. Equipment such as the surgical bed and stirrups must be able to sustain the weight of morbidly obese patients. **The ureteroscopic techniques and principles used in nonobese patients are the same as those for obese patients, in whom they are only marginally more difficult. Ureteroscopy and intracorporeal lithotripsy offer the obese population a minimally invasive treatment with results that rival stone-free rates in nonobese patients.**

Patients with Bleeding Diatheses

Endourologic management of upper tract urinary calculi in patients with a bleeding diathesis can present a therapeutic challenge. Uncorrected coagulopathy remains an absolute contraindication to SWL and percutaneous nephrolithotomy. Traditionally, the management of bleeding diathesis includes preoperative normalization of hemostatic parameters to minimize the risk of bleeding. However, perioperative discontinuation and reinitiation of anticoagulation increase health care costs and hospitalization and can be associated with increased bleeding and thromboembolic complications. Furthermore, the administration of clotting factors and platelet concentrates can be complicated by transfusion reactions and the transmission of bloodborne disease. With the improved ureteroscopic instrumentation, complete access to the upper urinary tract can be achieved in a relatively atraumatic manner without the need for ureteral dilation. Furthermore, the holmium:YAG laser has been shown to be an extremely safe modality for intracorporeal lithotripsy. A series of 29 patients with urolithiasis and an average international normalized ratio of 2.3 were treated by ureteroscopy and holmium:YAG laser lithotripsy (Watterson et al, 2002b). The stone-free rate was 93%, and 27 of 30 surgeries were performed as same-day outpatient procedures. Only one patient who was treated using EHL suffered from retroperitoneal bleeding postoperatively and required a blood transfusion. None of the patients treated with the holmium:YAG laser had any bleeding complications because of its excellent margin of safety.

Points to consider during ureteroscopy of patients with bleeding diatheses include avoiding EHL (because of the high peak pressures that may be transmitted beyond the ureter, resulting in significant bleeding), using only the

holmium:YAG laser, avoiding high-pressure irrigation, minimizing ureteral dilation (8/10 Fr coaxial dilation is typically sufficient), and routinely stenting all patients (Kuo et al, 1998; Watterson et al, 2002b). With these points in mind, ureteroscopy may be safely performed in fully anticoagulated patients on an outpatient surgery basis, providing significant health cost savings.

Ureteroscopic Treatment of Calyceal Diverticula

Calyceal diverticula are thought to be ureteral buds that failed to degenerate and are incidentally found in up to 0.45% of intravenous pyelograms (Canales and Monga, 2003). Flank pain and associated stones are the presenting features in the majority of patients. Prior to the availability of endourologic procedures, standard treatment was open surgery. Percutaneous, retrograde ureteroscopic and laparoscopic approaches all present less invasive alternatives to open surgery for the treatment of calyceal diverticula. SWL is an unattractive option for management of stones within calyceal diverticula as fragments are unlikely to evacuate through the narrow infundibulum, leaving persistent stones and symptoms (Psihramis and Dretler, 1987).

The technique for retrograde treatment of calyceal diverticula begins with flexible ureteroscopy to inspect the entire renal pelvis for the narrow infundibulum connecting to the calyceal diverticulum. Using fluoroscopy and contrast material infused through the endoscope, a "road map" is established to identify the infundibulum of the diverticulum. Once it is located, a guide wire is traversed through the narrow opening and a balloon dilator or holmium:YAG laser is used to incise and enlarge the infundibulum, after which a stent is left indwelling. In up to 30% of patients, however, the opening cannot be found ureteroscopically and these patients require a percutaneous or laparoscopic approach (Batter and Dretler, 1997; Auge et al, 2002; Canales and Monga, 2003). **Percutaneous neoinfundibulotomy and nephrolithotomy remain the standard for treatment of calyceal diverticula. Ureteroscopy is less attractive for lower pole diverticula and is more likely to be successful in upper pole anterior calyces in patients with a small stone burden** (Canales and Monga, 2003).

Urolithiasis in Anomalous Kidneys

Anomalous kidneys include abnormalities in fusion, ascent, and form during development of the kidney. Horseshoe and pelvic kidneys are most common. The stone-free rate for treatment of intrarenal calculi in pelvic kidneys treated with SWL is 54% (Kupeli et al, 1999), compared with 75% to 87% in patients treated with ureteroscopy (Rigatti et al, 1991; Weizer et al, 2005). Holmium:YAG laser, nitinol baskets, and graspers are effectively utilized in the ureteroscopic treatment of urolithiasis in pelvic and horseshoe kidneys to provide an effective first-line therapy (Weizer et al, 2005). Larger stones and those failing ureteroscopy require treatment by percutaneous nephrolithotomy (Shokeir et al, 2004). UASs can facilitate ureteroscope insertion and repeated removal of small stone fragments with nitinol baskets in horseshoe kidneys (Andreoni et al, 2000). In summary, percutaneous nephrolithotomy is performed in anomalous kidneys with large stone burdens, and ureteroscopy may be successfully employed for smaller stone burdens in anomalous kidneys.

RETROGRADE URETEROSCOPIC TREATMENT OF URETERAL STRICTURES

Ureteral strictures result from ureteral injury during surgery. Strictures occur with a reported rate of 0.5% to 11% of all surgeries involving upper tract manipulation in urology, gynecology, and general surgery (Selzman and Spirnak, 1996). Other causes include urinary reconstruction, radiation, malignancy, spontaneous stone passage, and chronic inflammatory disorders (e.g., tuberculosis and schistosomiasis). Davis and colleagues (1948) were the first to describe reepithelialization of ureteral defects, a principle of the modern endourologic endoureterotomy procedure. The standard treatment of strictures has been open repair, but advances in endourologic techniques and instrumentation as well as in interventional radiology have led to minimally invasive approaches to ureteral stricture resulting in decreased morbidity, operative time, hospitalization, and cost.

Various endourologic techniques in the treatment of ureteral strictures have been described including holmium:YAG laser incision (Gerber et al, 1999; Giddens and Grasso, 2000; Kristo et al, 2003), cold-knife incision (Poulakis et al, 2003), electrocautery, and hot-wire balloon dilation (Wolf et al, 1997; Erdogru et al, 2005). Simple balloon dilatation is effective in patients with nonischemic strictures that are short in length but ineffective in longer strictures caused by ischemia (Netto Junior et al, 1990; Osther et al, 1998; Richter et al, 2000; Byun et al, 2003). Ischemic strictures, in general, respond poorly to endourologic procedures compared with open reconstruction (Byun et al, 2003). The length of stricture is one of the most important factors in predicting success of endourologic treatment. Success rates for strictures shorter than 1.5 to 2 cm are significantly better than for longer strictures treated by ureteroscopic endoureterotomy (Meretyk et al, 1992; Razdan et al, 2005). In addition to the postoperative ureteral stent that is left indwelling, urine flow through the area of incision appears to be necessary for successful endourologic treatment of strictures. Renal units contributing less than 25% of the total renal function were more likely to fail ureteroscopic endoureterotomy than highly functioning kidneys (Wolf et al, 1997).

The widespread use of bowel segments in urinary reconstruction has resulted in a subset of strictures that present a particular challenge to urologists. The reported incidence of ureterointestinal stricture is 4% to 8% in patients who undergo ureteral ileal conduit procedures (Sullivan et al, 1980; Weijerman et al, 1998) with a higher rate of stenosis in those with nonrefluxing continent urinary diversions (13%) (Studer et al, 1996) or ureterosigmoidostomy (22%) (Allen, 1993). The management of ureterointestinal strictures in patients who have undergone urinary diversion typically required open surgical reimplantation. Open surgery has been relegated from its role as primary therapy to salvage therapy for failed endourologic management of ureterointestinal strictures. Endoscopic ureteral incision utilizing the holmium:YAG

laser provides a precise incision with good hemostatic qualities and is the modality of choice (Singal et al, 1997; Watterson et al, 2002c; Razdan et al, 2005).

Currently, the endourologic techniques for managing ureteral stricture do not have the same success rates as open surgery. However, these approaches are preferred for initial treatment because of decreased associated morbidity, operative time, hospitalization, and cost. If required, subsequent open revision does not seem to be compromised by initial endourologic procedures.

Retrograde Ureteroscopic Treatment of Ureteropelvic Junction Obstruction

In addition to open or laparoscopic pyeloplasty, minimally invasive techniques such as antegrade and retrograde endopyelotomy are accepted forms of treatment for ureteropelvic junction (UPJ) obstruction (Nakada and Johnson, 2000). Retrograde endopyelotomy may be performed with balloon dilation (Osther et al, 1998; Albani et al, 2004), hot-wire balloon dilation (Sofras et al, 2004), laser incision (Biyani et al, 2000; Hibi et al, 2002; Matin et al, 2003; Bagley, 2004), or a combination of laser and balloon dilation (Van Cangh et al, 2001; Ng and Streem, 2004). A combined antegrade approach with percutaneous introduction of a guide wire followed by retrograde ureteroscopy and laser endoureterotomy has also been described (Lopatkin et al, 2000). Following endopyelotomy, a ureteral stent is left indwelling in an attempt to provide a larger lumen when the UPJ heals.

Reported success rates for retrograde endopyelotomy range from approximately 65% (Lopatkin et al, 2000; Matin et al, 2003; Albani et al, 2004) **to 87%** (Conlin and Bagley, 1998; Tawfiek et al, 1998; Biyani et al, 2000; Gerber and Kim, 2000; Giddens and Grasso, 2000; Hibi et al, 2002). In these series, various methods of retrograde ureteroscopic endopyelotomy as mentioned previously were utilized. Balloon dilation alone has a low success rate and should be used only in conjunction with another modality (Osther et al, 1998).

In summary, retrograde endopyelotomy provides a 65% to 87% chance of success in the treatment of UPJ obstruction, and patients need to be followed up with imaging for at least 3 years for recurrence of symptoms or obstruction (Albani et al, 2004).

URETEROSCOPIC MANAGEMENT OF UPPER TRACT TRANSITIONAL CELL CARCINOMA

Upper tract transitional cell carcinoma (TCC) constitutes approximately 5% of urothelial tumors, and the standard treatment has been radical extirpative surgery of the kidney, ureter, and cuff of bladder (Anderstrom et al, 1989; Munoz and Ellison, 2000). Radical nephroureterectomy is an extensive procedure with significant potential morbidity and mortality, particularly in the older age group in which TCC is more prevalent. In patients with significant comorbidities, conservative minimally invasive renal-sparing techniques have been applied with the thought that these patients would succumb to their comorbidities before the TCC could recur and progress. Surprisingly, many of these patients not only outlived their comorbidities but also were successfully treated for their upper tract TCC (Brown and Roumani, 1974; Elliott et al, 1996; Engelmyer and Belis, 1996; Martinez-Pineiro et al, 1996; Fuchs, 1997; Keeley et al, 1997a; Stoller et al, 1997).

Filling defects seen on intravenous or retrograde pyelography, positive cytology with normal cystoscopic findings, and lesions seen during ureteroscopy should lead to the suspicion of ureteral or renal pelvis TCC (Figs. 45–6 to 45–8) (Chen and Bagley, 2001). **Ureteroscopy is particularly indicated in the patient who has positive cytology in combination with a normal bladder on cystoscopy** (Chen et al, 2000; Dooley and Pietrow, 2004). Biopsy of any urothelial lesions can be performed through the ureteroscope using a basket for papillary tumors or cup biopsy forceps for sessile tumors (Keeley et al, 1997b; Shiraishi et al, 2003). The accuracy of visually grading TCC ureteral tumors by ureteroscopy was reported as 70%, suggesting that biopsies are necessary for the proper diagnosis and treatment of this disease (El-Hakim et al, 2004). Metastatic evaluation should be performed, and in combination with the pathology results of the biopsy, discussions with the patient should determine the appropriate treatment options.

Small or low-grade TCCs have been successfully treated retrogradely with ureteroscopy and a variety of energy sources

Figure 45–6. A retrograde pyelogram illustrating a "moth-eaten" filling defect in the left renal pelvis. The pathology demonstrated transitional cell carcinoma. (Photograph courtesy of Dr. Justin Amann.)

Figure 45–7. A proximal ureteral filling defect on retrograde pyelogram. Note that the radiolucencies in the ureter at the iliac level represent injected air bubbles. (Photograph courtesy of Dr. Stephen E. Pautler.)

Figure 45–8. A large filling defect seen on retrograde pyelogram. The final diagnosis was fibroepithelial polyp. (Photograph courtesy of Dr. Justin Amann.)

including the holmium:YAG laser (Johnson and Grasso, 2005), electrocautery (Grasso et al, 1999; Elliott et al, 2001), and the Nd:YAG laser (Kaufman and Carson, 1993; Bagley, 1998; Lee et al, 2002).

The best success rates in terms of cure are in patients with low-grade, small tumor burdens (Martinez-Pineiro et al, 1996; Elliott et al, 2001; Deligne et al, 2002; Lee et al, 2002). It is recommended that healthy patients with a normal contralateral kidney with high-grade TCC undergo radical nephroureterectomy by an open or laparoscopic approach; however, it has been shown that even healthy patients with a normal contralateral kidney and low-grade disease may undergo conservative therapy provided that they are compliant with regular ureteroscopic follow-up with a urologist who is vigilant and is ready to perform a nephroureterectomy in the event of recurrence or progression (Hendin et al, 1999; Chen and Bagley, 2000; Elliott et al, 2001; Liatsikos et al, 2001; Yamada et al, 2003). In carefully selected patients who are compliant with strict follow-up, the death rate from progression and recurrence has been very low, approaching 0%.

Table 45–7. Complications of Ureteroscopy

Intraoperative
Failure to access (ureter, kidney, or stone)
Failure to fragment the stone
Stone migration into the ureteral wall
Mucosal trauma
Ureteral perforation
Ureteral avulsion
Early Postoperative
Gross hematuria
Renal colic (small residual stone fragments, blood clot, or ureteral edema)
Large residual stone fragments (that require ancillary procedures)
Pyelonephritis
Urinoma
Ureteral stent symptoms
Late Postoperative
Ureteral stricture
"Forgotten" encrusted ureteral stent

In patients appropriately chosen for conservative management, the next decision is whether to perform percutaneous resection or retrograde ureteroscopy. In larger tumors of the renal pelvis and proximal ureter, the percutaneous approach is favored. Smaller tumors located in the kidney and ureter are accessible by the flexible ureteroscope and may be ablated with the holmium:YAG laser, Nd:YAG laser, or electrocautery. When performing retrograde ureteroscopy, ureteral tumors may be managed with the semirigid ureteroscope and a 365 or 400 μm laser fiber with initial settings of 0.8 J and a pulse rate of 15 Hz. A safety guide wire should be in place and coiled within the renal pelvis for ureteral stent insertion at completion of the case. The holmium:YAG laser should be "defocused" by not placing it directly on the tumor. When held 2 to 3 mm away from the tumor, it has a coagulative and ablative effect on tumor tissue. The tumor should be resected at the stalk if possible. When the tumor has been resected, a ureteral stent should be left in place to reduce the possibility of extravasation and ureteral stricture. If there is a suspicion of residual tumor, a second ureteroscopy in 1 to 2 weeks with further ablation should be carried out.

Postoperative bacillus Calmette-Guérin (BCG) immunotherapy is difficult to deliver to the upper tracts and has been instilled by percutaneous nephrostomy tubes or intravesically with a ureteral stent in place to allow the medication to reflux to the diseased area. Although the benefits of BCG have been demonstrated in TCC of the bladder, its

role has not been proved in upper tract TCC and remains controversial (Chen and Bagley, 2000; Elliott et al, 2001; Lam and Gupta, 2004).

Ureteroscopic management in select cases of upper tract TCC can provide good results. Patients treated with this modality must undergo routine diagnostic ureteroscopy (e.g., every 3 to 6 months) in addition to urine cytology and renal imaging studies to rule out recurrence (Martinez-Pineiro et al, 1996; Lam and Gupta, 2004).

COMPLICATIONS OF URETEROSCOPY

Ureteral Stricture

Complications during ureteroscopy (Table 45–7) have decreased over the past 20 years because of improvements in ureteroscopes, ancillary devices, intracorporeal lithotriptors, and surgical skills. In 1986, Carter and coauthors reported that 8% of patients suffered ureteral perforation or stricture and 3% of patients required a ureteral reimplantation. More recent experience has demonstrated that the perforation rate has decreased to between 0% and 4.7% (Harmon et al, 1997; Daneshmand et al, 2003; Boorjian et al, 2004). Risk factors for ureteral perforation included longer operating room times, stones located in the kidney, use of EHL, and surgeon inexperience.

Decreasing the rate of ureteral perforation has significantly decreased the rate of ureteral stricture formation. The reported ureteral stricture rate of approximately 3.5% increases to 5.9% if a ureteral perforation occurs (Stoller et al, 1992; Harmon et al, 1997; Netto Junior et al, 1997; Grasso and Ficazzola, 1999; Tawfiek and Bagley, 1999; Schuster et al, 2001; Chow et al, 2003). Both smaller endoscopes and use of the holmium:YAG laser have contributed to this improvement. Other general tips to prevent ureteral trauma include (1) advancing the semirigid ureteroscope under direct vision only when the lumen is in view and a safety guide wire is in place, (2) using the holmium:YAG laser as the primary modality for intracorporeal lithotripsy, and (3) performing less basket extraction of stones or performing the extraction through a UAS.

Ureteral Avulsion

Ureteral avulsion is an uncommon but serious complication of ureteroscopy. **Avulsion typically occurs during basket extraction of a stone fragment that is too large and becomes caught in ureteral mucosa, telescoping and avulsing the ureter as the stone is extracted.** Open surgery is necessary and ureteroureterostomy or ureteroneocystotomy is performed if only a short segment of the ureter is avulsed (Bernhard and Reddy, 1996; Alapont et al, 2003). If complete avulsion of the ureter occurs, the treatment options become ileal interposition, autotransplantation, and nephrectomy (Puppo et al, 1999; Gupta et al, 2005). To avoid ureteral avulsion, stones must be broken into fragments small enough to pass spontaneously or be extracted by a basket inserted through the ureteroscope. **To reduce catastrophic complications, a safety guide wire should be present, and when basket extraction is used, the basket and stone should be positioned slightly away from the tip of the ureteroscope so that the lumen can be visualized during extraction. Excluding basket extraction altogether reduces the chances of ureteral avulsion.**

Urosepsis

In patients who present with an infected collecting system and an obstructing stone, urinary decompression in combination with antibiotics is the initial treatment. Manipulation of the stone in the presence of infection is likely to result in bacteremia and possible urosepsis. Insertion of a percutaneous nephrostomy tube or ureteral stent has been demonstrated to drain the kidney equally well (Fabrizio et al, 2000; Shekarriz et al, 2001; Lutter et al, 2002). When the infection has been adequately treated, definitive management of the stone can proceed. Challenges arise when dealing with infection and stones in patients who cannot completely clear their infection until they are free of their stone but cannot be treated for their stone until their urine is clear. In these cases, a few days of preoperative oral antibiotics followed by intravenous antibiotic prophylaxis at the time of surgery decreases the rate of septicemia.

Postoperative bacteremia and sepsis should be treated with culture-sensitive intravenous antibiotics followed by oral antibiotics when the patient has defervesced. Imaging should be carried out, and if obstruction is present, upper tract drainage in addition to antibiotics is necessary.

Ureteroscope Damage

All components of the ureteroscope including the working channel, deflection tip, cables, and the entire length of the fiberoptic bundles are susceptible to damage by several mechanisms. Gentle care and handling should be used at all times, particularly at the end of the procedure, when equipment tends to accumulate on the operating room table, potentially crushing delicate endoscopes. The ureteroscope should be kept as "straight" as possible during manipulation and handling, as bending tends to break the delicate fiberoptic bundles. Ureteroscopes should be stored carefully in suitable containers. Reports have demonstrated that the current generation of ureteroscopes require maintenance or repairs ranging from every 6 to 15 uses (Pearle et al, 1998; Mokhmalji et al, 2001) to 10 to 34 uses (Afane et al, 2000).

The working channel can be damaged by sharp objects such as a beveled laser fiber, which should be inserted gently and with the endoscope, particularly the deflecting tip, as straight as possible. **Channel perforation by manipulation of laser fibers is a common cause of endoscope damage** (Pietrow et al, 2002; User et al, 2004). Laser fibers are prone to breakage, particularly during maximal deflection as when accessing the lower pole calyces (User et al, 2004). Laser fiber fracture while in the ureteroscope can have devastating effects on the instrument, including perforation of the entire sealed channel. Communication between surgeon and operating room staff needs to be clear, and placing the laser on standby when the laser fiber is within the endoscope prevents accidental triggering of the laser and ureteroscope damage (Nazif et al, 2004).

Use of a UAS has been shown to decrease the number of repairs to flexible ureteroscopes by relieving the endoscope of

the axial forces and the requirement for backloading of a guide wire normally used to "railroad" the endoscope into the kidney (McDougall et al, 2001). The type of cleaning method (Steris versus Cidex) does not affect the durability of ureteroscopes; however, human handling has been documented to be responsible for many instances of endoscope damage outside the operating room (Pietrow et al, 2002).

CONCLUSIONS

Almost any patent ureteral lumen, no matter how narrow, can be cannulated and reached if the correct wires and equipment are available. Ureteroscopy is a mainstay in the treatment of urologic stone disease, and despite the introduction of extracorporeal SWL in the 1980s, ureteroscopy has remained a prominent therapy for stones. It provides an effective method of lithotripsy with stone-free rates in excess of 90% and can also be used for the diagnosis and treatment of upper tract transitional cell cancer, ureteral stricture, and ureteropelvic junction obstruction.

KEY POINTS: URETEROSCOPY AND RETROGRADE URETERAL ACCESS

- Retrograde ureteral access is achievable in nearly every case provided the proper equipment, including endoscopes, guide wires, and catheters is available.
- Flexible ureteroscopes are used to gain access to the entire renal system, particularly above the iliac vessels. Semirigid ureteroscopes are typically used in the distal ureter below the iliac vessels but can be advanced up to the middle and proximal ureter, especially in female patients, with the advantages of a larger working channel and better optics.
- The holmium:YAG laser is a safe and effective method of intracorporeal lithotripsy as its energy travels only 0.5 mm in a liquid medium. This modality has been proved safe and effective in children, obese patients, pregnant patients, and patients with bleeding diatheses.
- Ureteral dilation is not routinely necessary for ureteroscopy.
- Placement of a ureteral stent is not routinely necessary following uncomplicated ureteroscopy.

FUTURE DIRECTIONS

Since 1955, when Willard Goodwin and colleagues first described the use of a needle to decompress a hydronephrotic kidney, the discipline of endourology has grown to encompass a vast array of percutaneous procedures involving the kidneys and upper urinary tracts. When percutaneous nephrostomy was first performed in the late 1970s, the primary indications were limited to diversion of urine and treatment of stone disease in poor surgical candidates. By the early 1980s percutaneous nephrolithotomy had gained widespread popularity for treatment of all renal stones. With the advent of extracorporeal shockwave lithotripsy (ESWL) in the mid 1980s, the indications for percutaneous stone extraction were narrowed. However, **as the limitations of ESWL were recognized, percutaneous surgery once again rose in popularity with a redefined role in stone management.** In addition, continued experience with percutaneous access has led to an extraordinary expansion in the indications for establishment of a nephrostomy tract.

INDICATIONS FOR PERCUTANEOUS NEPHROSTOMY

Percutaneous nephrostomy is the cornerstone of every percutaneous procedure of the upper urinary tract. As a minimally invasive conduit to the pelvicalyceal system, the percutaneous approach provides a convenient route for the diagnosis of upper tract pathology. The majority of diseases affecting the upper urinary tract fall into one of four categories—(1) stone disease, (2) obstruction, (3) malignant or benign tumors, and (4) infection—and percutaneous procedures have been used to manage each of these entities.

Whereas ESWL remains appropriate for patients with uncomplicated renal stones and normal renal anatomy, percutaneous stone extraction is the preferred treatment for patients with large, obstructing renal stones (e.g., staghorn calculi) or stones with composition resistant to fragmentation with extracorporeal lithotripsy. In addition, for patients with concomitant renal stones and distal narrowing (e.g., infundibular stenoses and coexisting calyceal stones, stones in calyceal diverticula, or renal stones with ureteropelvic junction [UPJ] narrowing), the percutaneous route allows a convenient approach to address both problems simultaneously. For patients with UPJ obstruction (even in the absence of stones), percutaneous endopyelotomy provides an effective alternative to laparoscopic or open pyeloplasty with acceptable success rates (Bernardo and Smith, 1999).

Although nephroureterectomy was previously considered the standard of care for all upper tract transitional cell carcinoma, in recent decades it has been shown that percutaneous resection of the tumor and instillation of chemotherapeutic agents into the upper tract can provide acceptable outcomes for select patients (Goel et al, 2003; Palou et al, 2004). For these patients, the nephrostomy tract serves as both a conduit for tumor resection as well as a channel for antegrade chemotherapy instillation if necessary (See, 2000).

In some cases, percutaneous nephrostomy may be preferable to retrograde ureteral stenting for patients presenting with ureteral obstruction and signs of impending sepsis (Ng et al, 2002). The percutaneous route can also be used to manage less common entities affecting the kidneys. Renal cysts, fungal bezoars, and fibroepithelial polyps have all been safely treated via a percutaneous nephrostomy.

Although patient preference is not considered an absolute indication, **patients generally favor the decreased morbidity of a percutaneous renal procedure to that of open surgery.** The less invasive nature of percutaneous surgery affords patients both a quicker recovery and a more desirable cosmetic result. It also translates into shorter lengths of stay and lower overall costs for the hospital. It was initially believed that percutaneous renal surgery would have limited efficacy in obese patients. However, it has since been shown that with slight modifications in technique and instrumentation, obese patients have similar outcomes to control subjects after percutaneous nephrolithotomy (Hofmann and Stoller, 1992; Giblin et al, 1995; Curtis et al, 1997; Pearle et al, 1998).

Despite the numerous indications for the establishment of a percutaneous nephrostomy tract, many urologists have only limited experience obtaining access to the pelvicalyceal system and are dependent on the assistance of an interventional radiologist. **In the age of minimally invasive surgery, urologists who are able to master the technique of percutaneous renal access have a distinct advantage in remaining at the forefront of the rapidly evolving field of endourology.** The current chapter can serve to help motivated urologists achieve competence with percutaneous access. After reviewing the relevant anatomy of the kidneys and surrounding structures and presenting the various imaging modalities available for percutaneous access, the technical aspects of establishing a percutaneous nephrostomy tract are reviewed. In the second half of the chapter, various procedures of the upper urinary tract that can be performed via a nephrostomy tract are reviewed. Percutaneous management of stone disease, UPJ obstruction, and upper tract transitional cell carcinoma are covered elsewhere in this textbook and are not discussed at length in this chapter.

PERTINENT RENAL ANATOMY

An intimate understanding of the anatomic relationships of the kidneys and surrounding structures is crucial for successful and safe percutaneous entry into the renal collecting system. The unique anatomic considerations of the right and left kidneys as well as variability in intrarenal anatomy can make the attainment of percutaneous access frustrating for the inexperienced surgeon.

Perirenal Anatomy

The kidneys are retroperitoneal structures located in the paravertebral gutters between the levels of the 12th thoracic vertebra and the 2nd or 3rd lumbar vertebrae (Fig. 46–1). The superior poles are located more medially than the inferior poles, and both kidneys are angled 30 degrees posterior to the frontal plane of the body. The longitudinal axis of each kidney parallels the oblique course of the adjacent psoas major muscle. The right kidney lies 2 to 3 cm lower than the left kidney owing to the large size of the right lobe of the liver.

The anteromedial aspect of the superior pole of each kidney is covered by the corresponding adrenal gland (Fig. 46–2A). The right kidney is related to the liver superiorly, the descending portion of the duodenum medially, and the right colic flexure anteriorly. The left kidney is bounded anteriorly by the stomach and spleen at the superior pole and the descending colon at the inferior pole. The tail of the pancreas lies immediately anterior to the left renal hilum. During attempted percutaneous puncture of the kidneys, any of these adjacent organs are at risk for inadvertent injury. The colon is particularly susceptible to injury because up to 16% of patients may demonstrate a retrorenal colon during percutaneous puncture

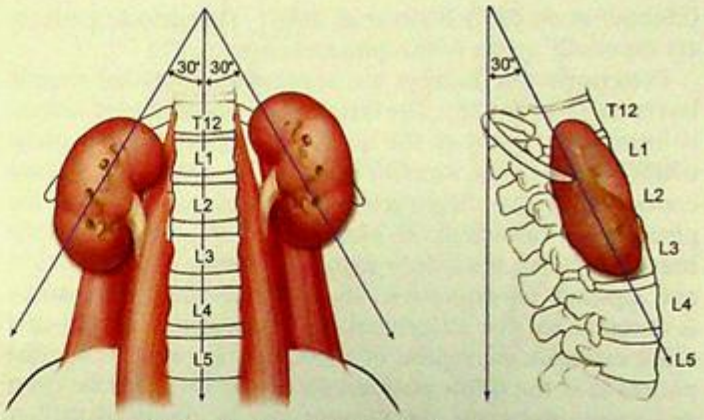

Figure 46–1. Location of kidneys in the retroperitoneum.

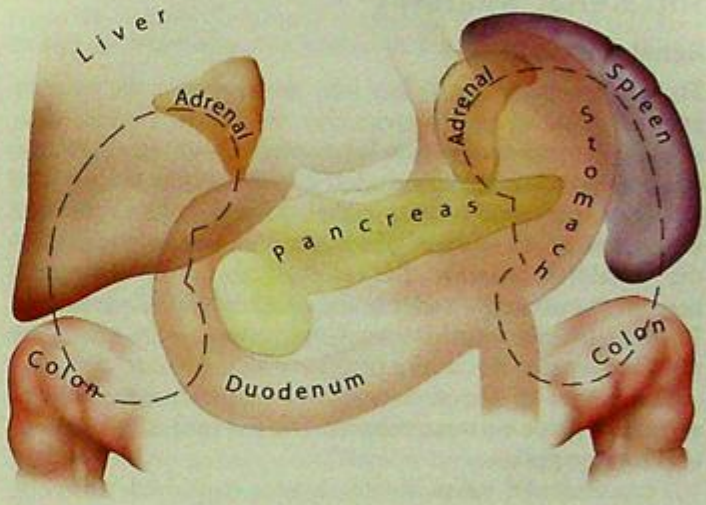
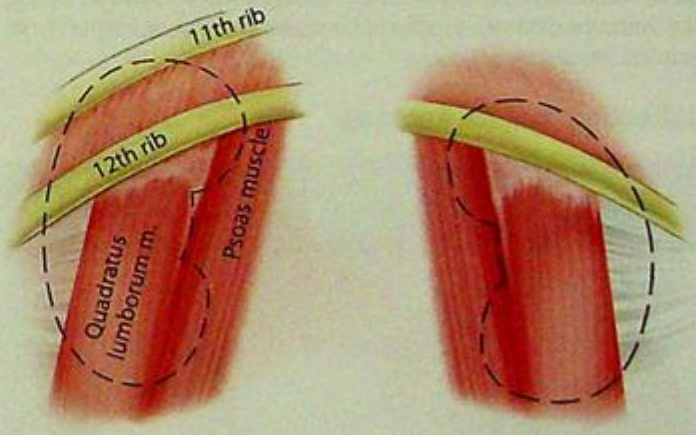


A



B

Figure 46–2. Anterior (**A**) and posterior (**B**) relations of kidneys to adjacent organs.

(Hopper et al, 1987; Boon et al, 2001). Thin female patients are especially prone to this phenomenon.

Posteriorly, the kidneys are supported by several muscle layers (see Fig. 46–2B). The inferior two thirds of each kidney is intimately related to the quadratus lumborum and psoas major muscles. The superior pole of each kidney is in direct contact with the diaphragm, which separates it from the pleural cavity and 12th rib. Movement of the diaphragm with breathing causes the kidney to move downward in inspiration and upward in expiration. In addition, when the patient is anesthetized the abdominal wall musculature relaxes and more extensive excursions of the kidney are seen. When the patient is in the prone position with bolsters under the chest and upper abdomen, the kidneys may be displaced further cephalad.

Intrarenal Anatomy

Renal Vasculature

The main renal artery divides into two branches: the anterior and the posterior renal arteries (Fig. 46–3). The anterior division further subdivides into four anterior segmental arteries, which supply the anterior and polar areas of the kidney. The posterior segmental artery supplies the remainder of the posterior area of the kidney. The segmental arteries divide into the interlobar arteries after crossing the renal sinus and become the arcuate arteries at the corticomedullary junction. The interlobular arteries branch from the arcuate arteries at right angles and run to the periphery giving rise to the afferent arterioles of the glomeruli. **Brödel's line delineates an avascular plane between the anterior and posterior segmental blood supplies.**

The intrarenal veins do not have a segmental structure. Unlike the arteries, there is free circulation throughout the renal venous system. Multiple anastomotic arcades between the veins prevent parenchymal congestion and ischemia from venous injury.

Collecting System Anatomy

The anatomic landmarks dividing the renal parenchyma from the collecting system are the renal papilla. Calyces in direct apposition to the renal papilla are defined as minor calyces and vary in number from 5 to 14 (mean: 8). A minor calyx may be single (draining only one papilla) or compound (draining two or three papillae). Minor calyces may drain directly into an infundibulum or join to form major calyces, which then drain into an infundibulum (Fig. 46–4). The infundibula are the principal divisions of the pelvicalyceal system, draining directly into the renal pelvis.

There are usually three renal calyceal groups: the superior, midzone, and inferior major calyces. Barcellos Sampaio and Mandarim-de-Lacerda (1988) analyzed 140 three-dimensional polyester resin corrosion endocasts of human kidneys and contributed significantly to our understanding of the intricate anatomy of the pelvicalyceal system. They observed that the superior and inferior major calyces usually consist of compound calyces that project toward the polar regions at various angles (Fig. 46–5). The midzone calyces, on the other hand, are generally arranged in paired sets of anterior and posterior calyces. These paired calyces have been observed to display one of two configurations (Fig. 46–6). In the Brödel type configuration, the anterior calyx is short and medially directed (forming a 70-degree angle to the frontal plane of the kidney), whereas the posterior calyx is longer and more laterally directed (positioned only 20 degrees from the frontal plane of the kidney). The second configuration is the Hodson type in which the posterior calyx is shorter and more medially directed and the anterior calyx is longer and closer to the lateral edge of the kidney. It has been shown that 69% of right kidneys exhibit the Brödel configuration and 79% of left kidneys exhibit the Hodson configuration (Kaye and Reinke, 1984).

In studying the pelvicalyceal endocasts, Barcellos Sampaio (1988) noted significant variability in the drainage patterns of the three calyceal groups. The midzone calyceal group was variably found to have drainage dependent on one of the polar calyceal groups (62%) or to drain directly into the renal pelvis independent of either polar group (38%). In 18% of the endocasts studied, the kidney midzone was drained simultaneously by crossed calyces, one draining into the superior calyceal group and the other draining into the inferior calyceal group. In addition, a perpendicular minor calyx draining directly into the renal pelvis was noted in 11% of the endocasts. **The only**

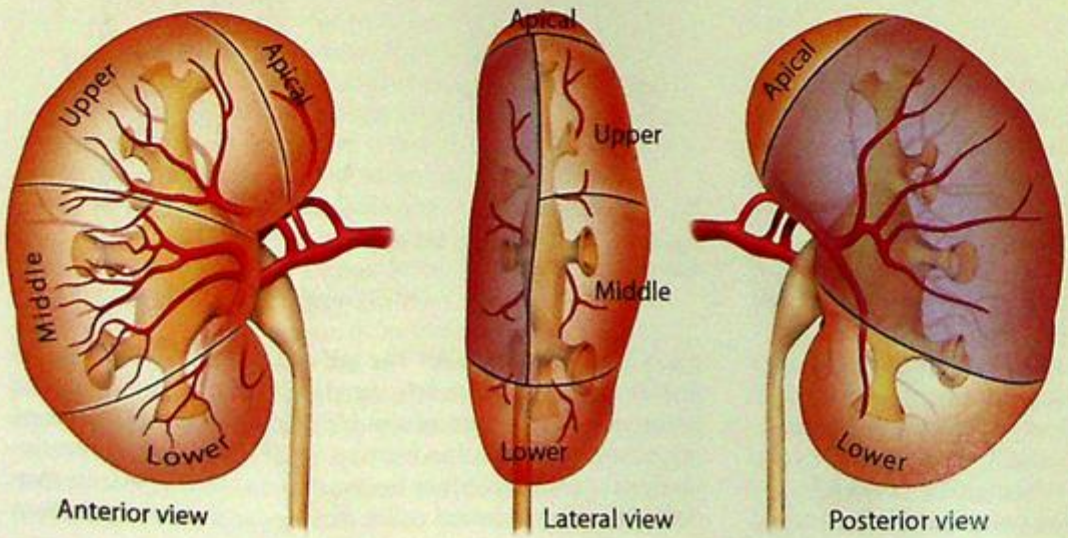


Figure 46–3. Arterial supply to the kidney. The kidney is supplied by the anterior and posterior segmental branches of the main renal artery. The anterior segmental artery supplies both the anterior half of the kidney and the polar regions. The posterior segmental artery supplies only the posterior aspect of the kidney *(represented by the shaded region)*. An avascular plane, known as Brödel's line, separates the anterior and posterior circulations.

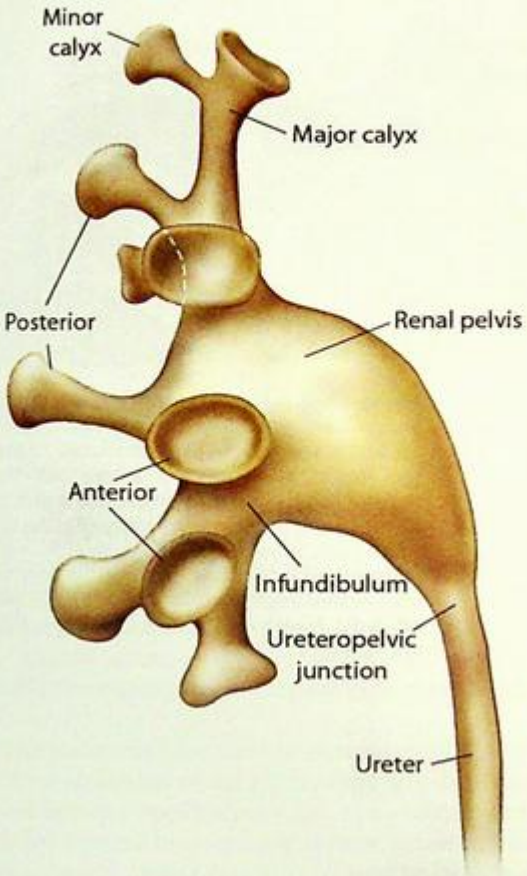

Figure 46–4. Basic pelvicalyceal anatomy.

consistently noted findings were that the superior calyceal group was drained by only one midline infundibulum in 99% of the endocasts and that the midzone was drained by paired calyces arranged in two rows (anterior and posterior) in 96% of cases.

Clinical Relevance of Intrarenal Anatomy

A thorough understanding of intrarenal anatomy can greatly facilitate percutaneous entry into the renal collecting system and minimize complications. Appreciation of the anterior and posterior segmental blood supply of the kidney can allow the urologist to utilize Brödel's line during percutaneous puncture. A needle traversing the renal parenchyma posterolaterally through this avascular plane avoids damage to any major blood vessels (see Fig. 46–1). In more than 50% of kidneys, the posterior segmental artery (retropelvic artery) is located in the middle or upper half of the posterior renal surface, and it may be damaged with an excessively medial needle puncture of an upper calyx. **The posterior segmental artery is the most commonly injured vessel in endourologic procedures.**

Knowledge of the Hodson and Brödel configurations of calyceal anatomy is crucial for precise preoperative localization of a stone or other lesion on intravenous pyelogram. Awareness of the great variability in calyceal drainage patterns can aid greatly during intraoperative decision-making for appropriate puncture sites. The results of the Sampaio endocast studies imply that it is easier to access a polar region drained by a single infundibulum than a polar region drained by paired calyces. Furthermore, the anatomic relationships of

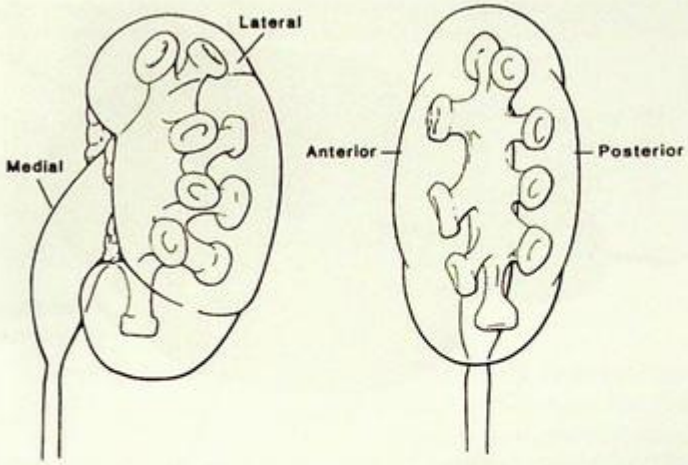

Figure 46–5. Calyceal orientations of the kidney. Polar regions have minor calyces that are oriented toward their respective poles, and the middle calyces have anterior and posterior orientations. (From Smith AD [ed]: Controversies in Endourology. Philadelphia, WB Saunders, 1995.)

the intrarenal vessels to the kidney collecting system predict a high rate of vascular injury for attempted puncture directly into any infundibulum. **This suggests that percutaneous entry directly into the fornix of a calyx is the safest route** (Sampaio, 1996).

Preview of any renal access involves examination of the desired calyx. The calyx is inspected for three factors: relation to the 12th rib, extent of hydronephrosis, and presence of malrotation. Whether the desired calyx resides above or below the 12th rib has critical significance for the technique chosen for renal access and the possibility of thoracic complications. The degree of hydronephrosis influences the difficulty of renal access. Although dilated calyces are technically less demanding to puncture, improper technique may still result in failure. Finally, the unusual case of the malrotated or ectopic kidney may necessitate minor adjustments in the access technique.

KEY POINTS: PERTINENT RENAL ANATOMY

- The anterior and posterior segmental blood supply of the kidney is divided by Brödel's line, an avascular plane that may be used to guide safe percutaneous puncture.
- Excessively medial needle punctures risk damage to the posterior segmental artery, the most frequently injured vessel during endourologic procedures.
- Despite the significant variability in pelvicalyceal drainage patterns, the superior pole is generally drained by a single midline infundibulum and the midzone is drained by paired calyces arranged in two rows (anterior and posterior).
- Needle puncture directly into the fornix of a calyx is the safest route of percutaneous entry into the renal collecting system.

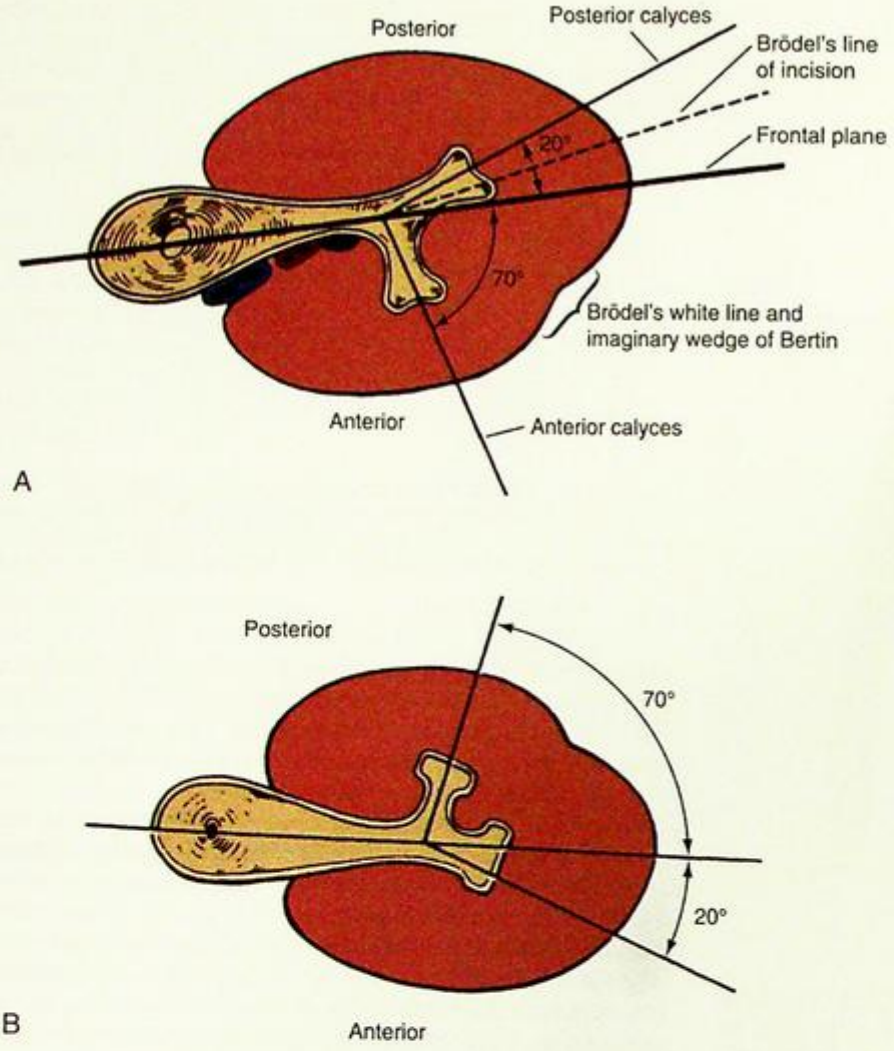

Figure 46–6. Calyceal orientations in the Brödel and Hodson configurations. In the Brödel-type kidney (**A**), the longer posterior calyx is positioned 20 degrees from the frontal plane of the kidney and the shorter anterior calyx forms a 70-degree angle with the frontal plane. In the Hodson-type kidney (**B**), the shorter posterior calyx is positioned 70 degrees from the frontal plane of the kidney and the larger anterior calyx forms a 20-degree angle with the frontal plane. (From Smith AD [ed]: Controversies in Endourology. Philadelphia, WB Saunders, 1995.)

IMAGING MODALITIES FOR PERCUTANEOUS ACCESS

Ultrasonography

Percutaneous ultrasound-guided nephrostomy is perhaps the simplest and most direct technique to access and drain a hydronephrotic collecting system. It is most often utilized to place a temporary urinary diversion in the instances of an obstructing stone or pyonephrosis and has also been used successfully to relieve obstruction secondary to malignant compression. Although the technique has been especially popular among interventional radiologists, it has gained popularity among endourologists who are comfortable with ultrasonography. Allergies to topical or injectable local anesthetic and coagulopathy are the only relative contraindications to ultrasound-guided renal access. The ultrasonographic approach has the advantages of minimizing radiation exposure and allowing imaging of intervening structures between skin and kidney.

When the kidney is evaluated with ultrasound, its various compartments have different sonographic appearances that can be seen quickly and accurately in three-dimensional orientation. The renal capsule is clearly visible. The renal cortex produces low-level homogeneous echoes, and the medulla presents as a relatively sonolucent structure. Most importantly, **hydronephrosis can easily be identified as a hypoechoic cavity surrounded by a central echo complex** (Kumari-Subaiya and Phillips, 1995).

The principles of a successful ultrasound-guided puncture do not differ from those of the fluoroscopic approach. However, sonographic identification of the needle may be technically demanding. There are a variety of transducers with lumens designed to accommodate the needle to help guide the puncture more easily (Fig. 46–7). Because the tip of the needle is difficult to visualize, successful puncture of the collecting system is ultimately confirmed by the return of urine through the needle. Porcine experiments on ultrasound-guided nephrostomy with the aid of a magnetic field–based navigation device have addressed this limitation, allowing for accurate puncture needle placement in plane or out of plane from any direction, independent of transducer position (Krombach et al, 2001).

Large retrospective studies have shown ultrasound-guided percutaneous nephrostomy insertion to be highly successful (88% to 99%) with a low complication rate (4% to 8%) (Farrell and Hicks, 1997; Wah et al, 2004). In instances of malignant ureteral obstruction with hydroureteronephrosis,

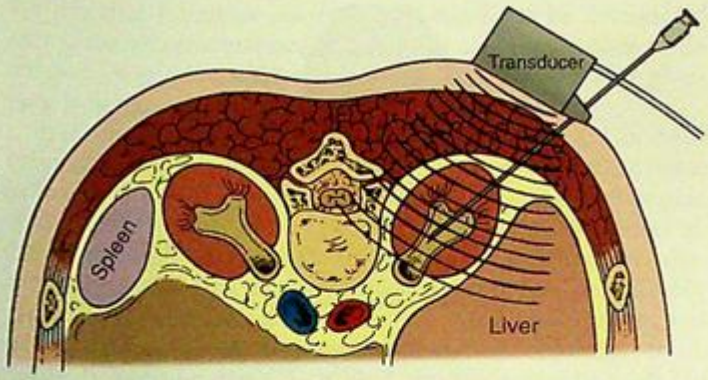

Figure 46–7. The needle is advanced using ultrasound guidance.

diversion by percutaneous puncture utilizing *both* ultrasonic and fluoroscopic imaging modalities has been shown to be successful 99% of the time (Pappas et al, 2000). Ultrasound-fluoroscopic guided access can be more precise than the fluoroscopic guided access alone, making the procedure less invasive and more precise for surgical planning (Montanari et al, 1999).

The main indication for the ultrasound-guided approach is percutaneous drainage of an obstructed and hydronephrotic kidney. However, application of the ultrasound-guided approach for antegrade collecting system access before percutaneous nephrolithotomy has also proved to be safe and efficacious in the pediatric population (Desai et al, 1999) and in the instances of both transplanted kidneys (Francesca et al, 2002) and pelvic renal ectopia (Desai and Jasani, 2000). Although bowel may be visualized ultrasonically, **one should remain wary of the risk of viscus injury during ultrasound-guided access to an ectopic pelvic kidney.** In light of this, preventive measures with Trendelenburg positioning and tilting the table away from the pelvic kidney of interest will reduce the risk of bowel injury. Digital subtraction angiography–assisted ultrasound has also been described as an alternative modality to help reduce the risk of enteric and vascular injury when accessing a pelvic kidney (Touloupidis et al, 2003).

The ultrasonic depiction of the dilated calyces is easily obtained. However, when the pelvicalyceal system is not dilated, localization and puncture of the specific calyx may require special expertise. Use of a diuretic to transiently dilate collapsed calyces has been reported to facilitate ultrasound-guided puncture without complications (Gupta et al, 1998). **Ultrasound-guided nephrostomy puncture is also preferred for patients in whom retrograde ureteral catheterization is unsuccessful and in pregnant women in whom there is a need for decompression of an obstructed kidney** (von der Recke et al, 1994; Gupta et al, 1997; Gupta et al, 1998; Khoo et al, 2004). **A distinct disadvantage of using ultrasound is the inability to clearly visualize and manipulate a guide wire once it is placed through the percutaneous access site.**

Fluoroscopy

The technical aspects of using fluoroscopy for percutaneous access are discussed later in this chapter. In this section, we focus on the issue of radiation safety. Presently, endourologic procedures most often rely on fluoroscopy. Although the risk is relatively small, the patient, surgeon, and participating staff will be exposed to some level of ionizing radiation. The endourologist, in particular, must undertake protective measures because he or she will likely be exposed to radiation on a regular and cumulative basis (Table 46–1). Likewise, certain patients such as children with nephrolithiasis secondary to cystinuria may be subjected to repeated fluoroscopy-based procedures. In this regard, radiation dose is an extremely important issue in the young child, who is significantly more radiosensitive and more likely to manifest radiation-induced changes over his or her lifetime (Seibert, 2004). In fact, radiation exposure has been linked to malignancies, including leukemia and thyroid cancer.

Table 46–1. Radiation Safety for Urologists

Put fluoroscopy beam under table.
Use lead apron and thyroid shields.
Use minimal fluoroscopic time: "Think before or after fluoroscopy, not during."
Collimate.
Wear radiation detection devices.
Wear lead-impregnated glasses.
Use lead gloves?

The main principle for protection from radiation energy is ALARA: as low as reasonably achievable. The maximum yearly whole-body exposure recommended by the National Council on Radiation Protection is 5000 mrem, or 5 rem (Giblin et al, 1996). Dosages exceeding the standard limits likely carry with them only a small short-term health risk. Nevertheless, particularly over the course of a professional lifetime, the hazards of radiation exposure may be substantial (Castaneda, 1996; Brateman, 1999). Experimental data suggest that a mixture of dietary antioxidants and glutathione-elevating agents may protect tissues from radiation's mutagenic effects (Prasad et al, 2004). The use of such antioxidant preparations may soon extend the concept of ALARA from dose to biologic damage.

Time, distance, and shielding are critical factors that determine radiation exposure. **Limiting fluoroscopy time during endourologic procedures is of paramount importance, because the radiation dose to the operating room personnel is a function of exposure time.** Modern fluoroscopic equipment features, including under-table fluoroscopic sources, timer alarms, collimation of the x-ray beam, and last-image-hold/memory capability help the urologist limit the fluoroscopy time. **Grid-controlled fluoroscopic technique may also reduce overall radiation dose by decreasing the selected film frame rate.** Use of this technique, as opposed to continuous fluoroscopy, has led to substantial dose reduction for the patient and fluoroscopy operator without sacrificing image quality or diagnostic confidence (Boland et al, 2000).

The major source of radiation to the endourologist is scatter from the patient's body. Radiation is emitted from a source in all directions, and its intensity decreases proportionally as the square of the distance from the source. **Because scattered radiation follows the inverse square law, operators near the radiation beam can make significant reductions in**

exposure by increasing their distance from the patient (Ramakumar and Jarrett, 2000). For example, if one stands 3 feet from the fluoroscopy table during imaging, there is one ninth the radiation exposure, or an approximate 89% dose reduction. At a distance of 12 feet, however, the dose will approximate natural background levels, not registering on radiation monitoring devices (dosimeters).

During fluoroscopy, the kilovoltage and milliamperage are adjusted automatically and the operator can control only the duration of the exposure. Exposure doses may be reduced significantly by minimizing the total "active" fluoroscopic time for a procedure through cautious use of the exposure switch to ensure that irradiation occurs only when there is a need for active viewing of the image. **The use of a last-image-hold feature is of great importance in reducing the overall irradiation time.** With this feature, anatomic details can be scrutinized without a competing concern about additional radiation dose. Thus, all fluoroscopes used for percutaneous surgery should have a last-image-hold feature so the urologist does not need to "think with a foot on the pedal."

The irradiated site of the patient affects the scatter rate to the endourologist. When the field is closer to the midline of the patient, less radiation is scattered to the operator because it is attenuated through a greater thickness of overlying tissue. When the field is more lateral, the radiation is less attenuated by the patient and thus there is more radiation scatter. Furthermore, obese patients require more primary radiation than do thinner patients to allow the formation of an adequate image, creating a potential for more scatter. Protective surgical drapes composed primarily of bismuth, specialized urologic radiation shields, and special radioprotective gloves can be used to substantially reduce scattered radiation dose (King et al, 2002; Yang et al, 2002).

Collimation narrows the beam and limits the imaging area to the exact position of interest, thus reducing the scattered radiation to and from the patient. Keeping the image receiver as close to the patient as possible minimizes the distance between the focal spot and the image receptor, keeps the fluoroscopic beam intensity as low as possible, decreases image blur, and serves as a scatter barrier between the patient and the operator. In addition, **the direction of the beam significantly influences the amount of scattered radiation reaching the operator.** When the tube is above the operating table, there is a combination of leakage and scattered radiation. However, when the image intensifier is placed superiorly, radiation leakage is minimized, as the emission tube is shielded by an additional layer of material. The scattered radiation to the operator is also reduced (Fig. 46–8).

Shielding involves the use of flexible protective clothing such as aprons, skirts, thyroid shields, eyeglasses, and gloves. The basic protection for every urologist during percutaneous surgery is a lead apron, thyroid shield, and eyeglasses. The use of protective glasses is prudent, even though there is debate about their absolute necessity. Nevertheless, approximately 1100 mrem/hr may be deviated toward the urologist's upper extremities as a result of radiation scatter, which certainly suggests that the use of eye protection may be beneficial (Bowsher et al, 1992; Brateman, 1999). The standard flexible material for protective clothing is lead-impregnated rubber. The goal is to provide a barrier between the radiation source and the operator so that radiation is attenuated by the shield. Lead aprons

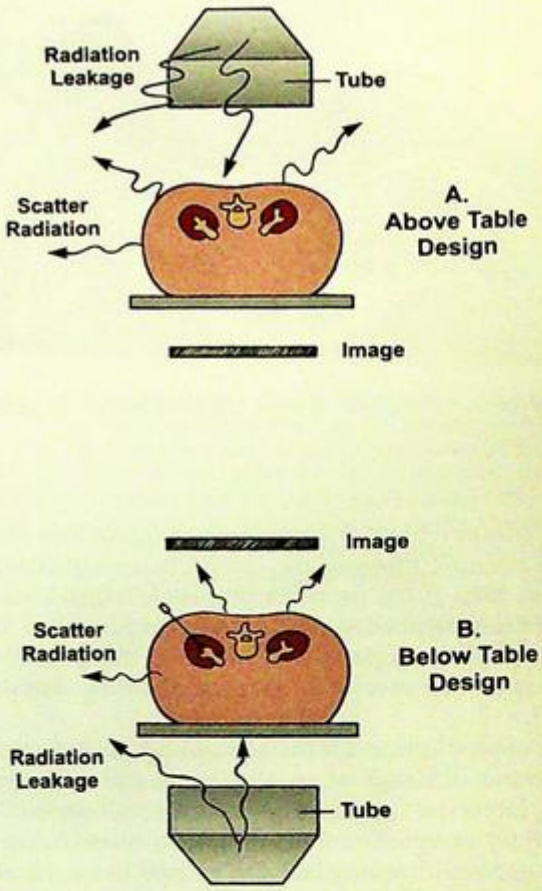

Figure 46–8. Emission tube placed over (**A**) and under (**B**) the operating table. In the first case, there is a combination of leakage and scattered radiation to the urologist. In the second case, the leakage is greatly reduced.

are heavy and can become uncomfortable when the operator is wearing them for a protracted period of time. The amount of lead required for efficacy has been established as 0.5 mm, and it has been estimated that the weight of aprons with this much lead ranges from 2.5 to 7 kg. Today, however, some aprons are made of composites of lead with elements of lower atomic numbers so that the weight can be reduced but the efficacy maintained (Castaneda, 1996; Giblin et al, 1996; Brateman, 1999).

Finally, **all personnel exposed to radiation should wear dosimeters** positioned where the operator receives the maximal radiation. It has been estimated that the radiation exposure to the underlying body is as little as 1% of the measured value. In modern radiation protection practices, active personal dosimeters are absolutely essential operational tools for satisfying the ALARA principle (Bolognese-Milsztajn et al, 2004).

Computed Tomography and Magnetic Resonance Imaging

Although some investigators have advocated the use of CT-guided percutaneous access (Barbaric et al, 1997), cross-sectional imaging is only needed to facilitate safe percutaneous access in special circumstances. A CT- or MRI-guided approach is a time-consuming and expensive method that is

not practical for most patients and needs to be considered only if the aforementioned techniques are not feasible or do not provide good results or if sophisticated preoperative planning is necessary.

Preoperative evaluation with the aid of either CT or MRI may aid in minimizing the risk of pulmonary, visceral, splenic, or hepatic injury if a percutaneous puncture of the upper pole of the kidney above the 11th rib is necessary (Robert et al, 1999). **Patients with a retrorenal colon or a severely distorted body habitus due to spinal dysraphism predictably require cross-sectional imaging to facilitate safe access before percutaneous nephrostolithotomy** (Matlaga et al, 2003). In addition, the CT-guided approach may be useful in obtaining renal access in patients with ileal conduits, renal uric acid stones, or nephrolithiasis in the presence of angiomyolipomas at risk for bleeding (Eiley et al, 1999). Three-dimensional CT has been described as a valuable tool for obtaining percutaneous access in the morbidly obese with malrotated kidneys and large staghorn calculi (Buchholz, 2000). Newer technology involving real-time CT fluoroscopy under laser guidance has also allowed for efficient and safe percutaneous nephrostomy placement when difficult access to the pelvicalyceal system has been encountered (LeMaitre et al, 2000). This newer imaging modality can maximize operator hand distances away from the gantry (>25 cm) and reduce the radiation dose to the operator's hand to 0.4 mrad/s (4 μGy/s) (de Mey et al, 2000). In the instance of nephrostomy dislodgement or malpositioning, CT may be used to successfully reposition drainage tubes into the collecting system (Jones and McGahan, 1999). There are no specific indications for MRI-guided percutaneous nephrostomy, although the technique has been shown to be feasible and accurate in nondilated collecting systems (Hagspiel et al, 1998; Nolte-Ernsting et al, 1999; Merkle et al, 1999).

Percutaneous Access without Imaging—"Blind Access"

Attempting percutaneous access without the aid of imaging is reserved for the rare instances when retrograde or intravenous opacification is precluded, the pelvicalyceal system cannot be opacified, or imaging machinery such as a fluoroscopic unit or sonography is inaccessible. Poor renal function in the presence of ureteral obstruction, for example, may represent such a situation, especially if emergent collecting system decompression is required (i.e., urosepsis from pyonephrosis). Percutaneous access without imaging relies on anatomic landmarks and the assumption that anatomy is not aberrant.

The lumbar notch, bounded superiorly by the latissimus dorsi muscle and the 12th rib, medially by the sacrospinalis and the quadratus lumborum muscles, and laterally by the transversus abdominis and the external oblique muscles, has been shown to be a useful anatomic window for successful blind percutaneous calyceal access (Chien and Bellman, 2002). An 18-gauge access needle can be inserted into the notch at a 30-degree angle directed cephalad under the 12th rib to a depth of 3 to 4 cm (Fig. 46–9). Alternatively, the renal pelvis may be accessed at a point 1.0 to 1.5 cm lateral to the L1 vertebral body. A 22-gauge "skinny" needle may be used to perform a blind perpendicular puncture lateral to the psoas and just below the level of the 12th rib. Often, initial blind access through the lumbar notch or perpendicular to the psoas may be suboptimal. Once urine can be aspirated from the

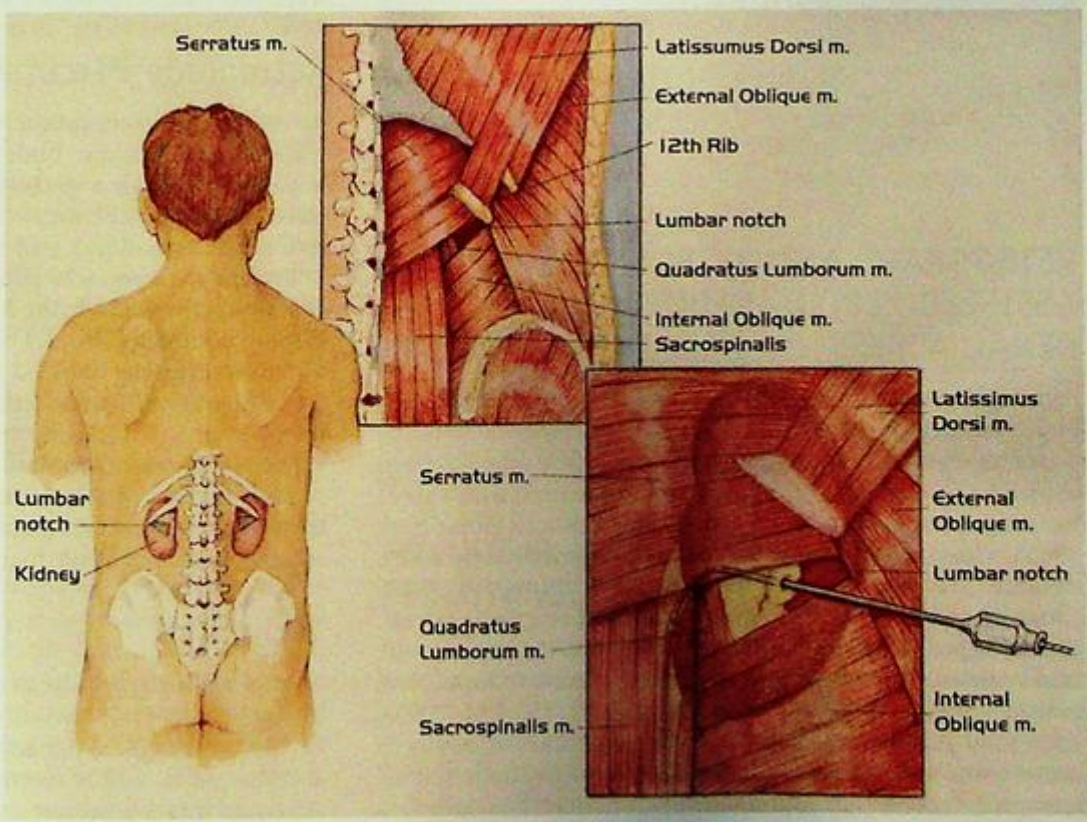

Figure 46–9. The lumbar notch is a useful anatomic landmark for blind percutaneous access to the renal collecting system. It is bounded superiorly by the latissimus dorsi muscle and the 12th rib, medially by the sacrospinalis and quadratus lumborum muscles, laterally by the transverses abdominis and external oblique muscles, and inferiorly by the internal oblique muscle.

initial access needle, contrast material can be instilled to outline the upper collecting system and direct an appropriate calyceal puncture. If a smaller access needle is used there is less of a chance of causing an arteriovenous fistula should any vessels be traversed. If doubt exists as to whether the collecting system has been entered with the puncture needle (e.g., no return of urine), attempts to opacify the system should not be undertaken because extravasated contrast media can distort anatomic landmarks.

KEY POINTS: IMAGING MODALITIES FOR PERCUTANEOUS ACCESS

- Percutaneous access to the upper urinary tract is most commonly performed with fluoroscopic guidance. Ultrasonography is preferred for patients in whom retrograde ureteral catheterization is unsuccessful and in pregnant women in whom there is a need for decompression of an obstructed kidney.
- The main principle for protection from radiation energy during fluoroscopy and CT fluoroscopy is ALARA: as low as reasonably achievable. The maximum yearly whole-body exposure as recommended by the National Council on Radiation Protection is 5000 mrem, or 5 rem. Urologists performing radiation-based procedures should wear dosimeters, which should be positioned where the operator receives the maximal radiation.
- Urologists are mostly exposed to scattered radiation, which follows the inverse square law; operators near the radiation beam can make significant reductions in exposure by increasing their distance from the patient and assuring that the radiation source is positioned under the patient.
- Blind access is reserved primarily for emergent situations and relies on known anatomic landmarks.

RETROGRADE AND RETROGRADE-ASSISTED PERCUTANEOUS RENAL ACCESS

Although uncommon, some urologists may chose to obtain upper tract access by a pure retrograde method or by retrograde-assisted techniques. Retrograde nephrostomy has been shown to be a safe procedure that can be mastered with a short learning curve and minimal radiation exposure (Wong et al, 1995). Conditions that make standard percutaneous access difficult may be overcome by utilizing a retrograde route. **Cases of morbid obesity, tightly branched staghorn calculi, and a hypermobile, malrotated, or ptotic kidney may be more amenable to retrograde-based access** (Gupta and Smith, 1996; Hosking, 1996; Kidd and Conlin, 2003). Presently, ureteroscopically assisted percutaneous access is more commonly utilized than older fluoroscopically guided retrograde access techniques.

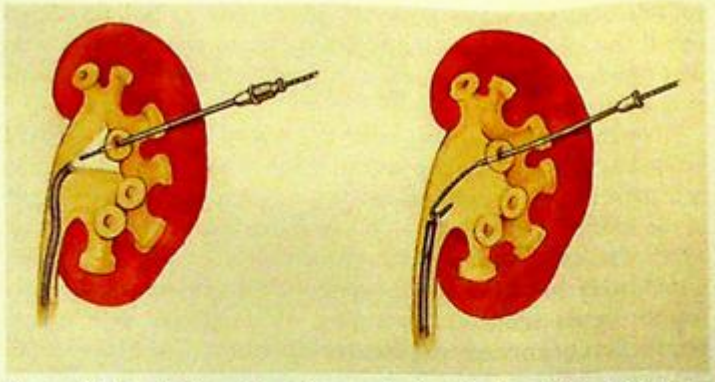

Figure 46–10. Retrograde ureteroscopic visualization of the desired calyx of entry can be used to facilitate percutaneous access.

Ureteroscopically Assisted Percutaneous Access

With the patient in a prone split-leg position, wire access to the collecting system is obtained by flexible cystoscopy. Under direct vision a flexible ureteroscope with either single or dual deflection is advanced to select the exact calyx of interest. A fluoroscopically guided percutaneous puncture is performed using the distal end of the ureteroscope as a landmark. The tip of the puncture needle is in correct position when confirmed endoscopically (Fig. 46–10). An antegrade guide wire can then be advanced through a ureteroscopically positioned snare or basket and withdrawn through the urethra. With this through-and-through guide wire access, standard percutaneous access, tract dilation, and percutaneous procedures of choice can be performed expeditiously (Grasso et al, 1995; Kidd and Conlin, 2003).

Retrograde Percutaneous Access

A retrograde transcutaneous nephrostomy is performed transurethrally under fluoroscopic guidance. **A sharp wire is passed through a ureteral catheter and directed out the selected calyx.** The selection of the appropriate calyx can be technically demanding and time consuming.

Presently, retrograde percutaneous access to the kidney can be obtained using the Lawson Retrograde Nephrostomy Wire Puncture Set (Cook Urological; Spencer, IN). This technique is primarily utilized in centers not familiar with the more direct and controlled approach of antegrade percutaneous access. Increasing expertise with antegrade access ureteroscopic assistance has decreased the indications for retrograde nephrostomy. Nevertheless, this technique has proved to be successful for the management of complex nephrolithiasis (Mokulis and Peretsman, 1997).

Technique

Retrograde urography is performed, and a floppy-tip, 0.038-inch guide wire is advanced into the collecting system. A 7.5-Fr Torcon deflectable catheter is passed over the guide wire, and the guide wire is removed (Fig. 46–11). The catheter is advanced into a posterior calyx under fluoroscopic control to

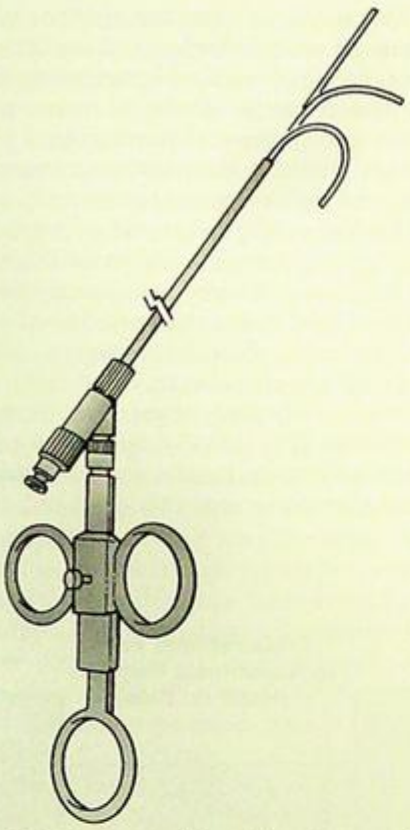

Figure 46–11. A 7.5-Fr Torcon deflectable catheter used for retrograde fluoroscopic access.

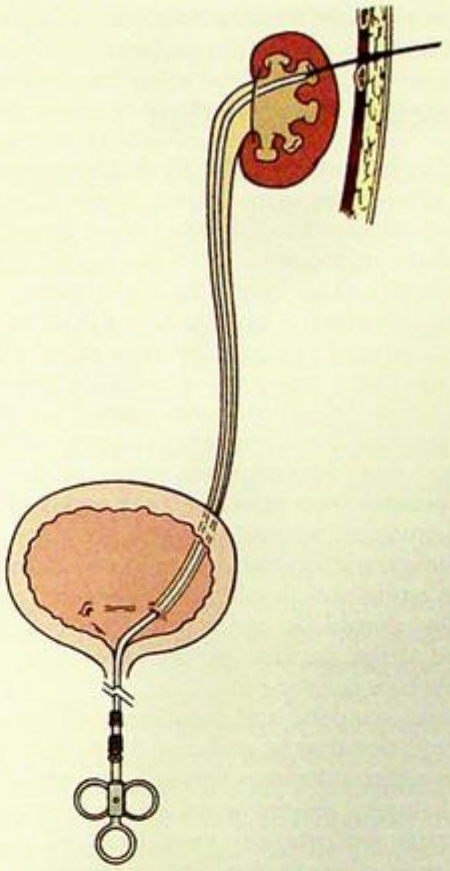

Figure 46–12. Retrograde fluoroscopic nephrostomy access. A puncture wire is advanced through the Torcon catheter into the calyx and through the abdominal wall to the skin.

ascertain accurate placement. **A posterior calyx is always chosen to avoid injuring adjacent structures (i.e., liver, spleen, bowel, and lung).** On fluoroscopy, the catheter should be aiming away from the spine. The Torcon catheter can be actively deflected from 0 to 140 degrees and locked into any desired position.

A sheathed puncture wire (3-Fr sheath, 0.017-inch wire) is advanced through the Torcon catheter and into the calyx and is secured with its Luer-Lok fitting. The wire is pushed through the kidney and subcutaneous tissues under fluoroscopic control (Fig. 46–12). If the needle finds any obstacles on its way to the skin (e.g., rib) it should be withdrawn and readvanced until it finds the correct path. A small skin incision may be needed to grasp the wire and advance it out, gaining through-and-through access.

If organ injury is suspected, CT can confirm the course of the needle. It is crucial not to dilate the tract unless the urologist is certain that the tract is posterior and inferior enough to avoid organ injury.

The tract is sequentially dilated to 10 Fr with the aid of fascial dilators passed over the puncture wire. The Torcon catheter is advanced out through the tract, and the wire is exchanged for a 0.038-inch Lunderquist-Ring torque wire. The torque wire is clamped near the urethra and has a dual function of a safety and a working wire, thus obviating the need for a second wire (Gupta and Smith, 1996; Hosking, 1996).

KEY POINTS: RETROGRADE AND RETROGRADE-ASSISTED PERCUTANEOUS RENAL ACCESS

- Retrograde nephrostomy is safe, has a short learning curve, and involves minimal radiation exposure to the urologist.
- Ureteroscopically assisted percutaneous access is more commonly employed than older fluoroscopically guided retrograde access techniques.
- During retrograde percutaneous access, it is crucial not to dilate the tract unless the urologist is certain that the tract is sufficiently posterior and inferior to avoid injury to adjacent organs.

TECHNICAL ASPECTS OF PERCUTANEOUS ENTRY

Percutaneous entry is the initial and most important part of percutaneous renal surgery. Improper site selection can lead to difficulty performing the procedure at best and devastating complications at worst. This is also the portion of the procedure most often feared and often relegated to interventional radiology colleagues. Anatomic considerations were discussed

earlier. In this section we describe technical aspects of entry and complications.

Preoperative Preparation

Urine sterility is mandatory for all elective procedures. This should be achieved by urine culture followed by sensitivity-specific antibiotics for 5 to 7 days before the procedure. Documented follow-up sterile urine is preferable but may not always be feasible (e.g., indwelling nephrostomy or urethral catheter, struvite stone). Consideration should be given for 1 to 2 days or more of preoperative intravenous antibiotics in select patients with a history of urosepsis, struvite calculi, or indwelling tubes. In patients with indwelling tubes, urine should be obtained directly from the catheter lumen, not from the drainage bag. **Percutaneous entry in the setting of untreated urinary tract infection risks sepsis and death.** In emergency situations where drainage is necessary but sterility is not immediately achievable or is unknown, broad-spectrum intravenous antibiotics should be administered and minimal manipulation should be performed. Even in patients with documented urine sterility, preoperative intravenous antibiotic prophylaxis is desirable.

Intravenous analgesia and sedation combined with local anesthetic injection may be sufficient for patients undergoing drainage procedures. Patients having more extensive percutaneous renal surgery require spinal blockade or general anesthesia. Because patients will most likely be in the prone position, airway access is poor and endotracheal intubation is necessary if general anesthesia is being administered. In patients receiving spinal blockade, a higher level than usually utilized for lower urinary tract procedures is desirable, but not to the detriment of pulmonary function.

Patient Positioning

Correct patient positioning is mandatory to facilitate the procedure and prevent respiratory problems, neurologic damage (e.g., brachial plexus injury), compression injury (including compartment syndrome and rhabdomyolysis), and adjacent organ injury. After induction of anesthesia the patient is repositioned in low dorsal lithotomy (if cystoscopy is to be performed), flank (for ultrasound-guided nephrostomy placement), or prone position with or without spreader bars. If retrograde access is being used to opacify the collecting system or distend it with saline, cystoscopy can be performed with the patient in lithotomy or prone position with spreader bars for placement of a urethral catheter. Bladder drainage should be provided by means of an indwelling urethral catheter.

Options for ureteral catheterization include a 5- or 6-Fr open-ended catheter, an occlusion balloon catheter, a dual-lumen catheter, or a ureteral access sheath. Each has its advantages and disadvantages. Simple open-ended catheters are generally nonobstructive, thereby preventing high intrarenal pressure. In addition, they generally are least likely to cause ureteral injury. They may not prevent stone fragments from migrating down the ureter during the procedure, however. A dual-lumen catheter has the advantage of allowing simultaneous retrograde injection of more than one medium (e.g., contrast medium and/or indigo carmine), allowing simultaneous guide wire access and contrast agent or saline injection, providing drainage via one lumen and injection through the other to prevent high pressure, and preventing stone fragment migration. It does dilate the ureter, however, and may result in ureteral edema or injury requiring stent placement. An occlusion balloon prevents fragment migration but can cause ureteral injury and high intrarenal pressure. A ureteral access sheath facilitates fragment passage and prevents high pressure while allowing for injection via the inner dilator but significantly dilates the ureter (thereby mandating stent placement), can cause ureteral injury, does not provide adequate remaining urethral lumen for bladder drainage, and requires a makeshift drainage apparatus at its distal end.

For more extensive percutaneous procedures prone positioning is preferable (Fig. 46–13). Specifically designed mirrored head rests with foam inserts are now available to allow the anesthesiologist to access the oral and nasal cavities,

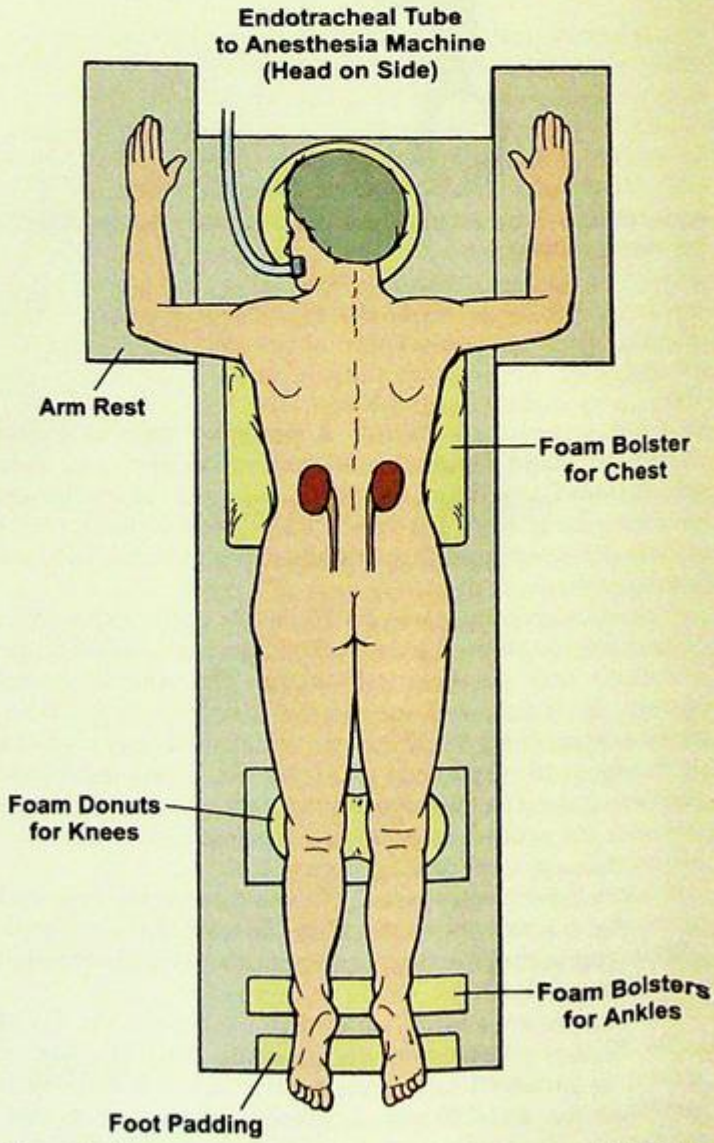

Figure 46–13. Prone positioning for percutaneous access. Two bolsters are placed on each side of the chest to facilitate ventilation; additional bolsters are placed under the knees and ankles. The head is carefully supported by an additional bolster.

prevent ocular compression, and visualize the airway during the procedure. Bolsters are placed under the patient from the shoulder to the iliac crest on each side to facilitate ventilation. Care should be taken in female patients to place the breasts medial to the longitudinal bolsters to prevent compression injury. The patient's arms are brought up at right angles to the body with the elbows bent to remove the arms from the path of the fluoroscopic beam and to allow the anesthesiologist to access the arms. The thighs, knees, legs, ankles, and feet are also padded, supported, and secured. Cleansing alcohol can be applied after a povidone-iodine skin preparation to enhance adhesion of the surgical drapes. A specially designed sterile endourology drape with a plastic side pouch for the collection of irrigation fluid is generally used.

For patients who cannot tolerate the prone position, the supine oblique position (with the kidney of interest elevated off the table) can be used. This position results in a more lateral renal puncture site and may theoretically increase the risk of injury to major renal vessels or adjacent organs. However, multiple investigators have reported success and complication rates with percutaneous nephrolithotomy in the supine position comparable to the prone approach (Urìa et al, 1998; Shoma et al, 2002, Ng et al, 2004). For ultrasound-guided access the supine position avoids rib-generated artifacts often seen with patients in the prone position. For CT-guided access, precise delineation of the relations of the kidney to surrounding structures allows for safe percutaneous entry even in the supine position.

Site Selection

It is very important to select the percutaneous nephrostomy tract that is most suited for a particular procedure. The preferred approach is by way of a posterior calyx because major vascular structures surrounding the renal pelvis are avoided and the transparenchymal route stabilizes the nephrostomy catheter in an appropriate position. However, puncture of anterior calyces may be required for some stones or a calyceal diverticulum but is used only if access from posterior calyces is not possible. In addition, access from an anterior calyx to the renal pelvis is technically demanding because it requires directing the wire backward. Direct puncture of the renal pelvis should be avoided because it carries a significant risk of injury to the posterior branch of the renal artery. In general, the risk of injuring larger branches of the renal artery increases with progressively more medial punctures. In addition, the tract created from such a medial puncture provides no stability for the nephrostomy tube because it lacks parenchymal support (Niles and Smith, 1996).

Injection of contrast material through the ureteral catheter may assist opacification of the collecting system. Alternatively, a small amount of air may be injected to provide an air pyelogram. The advantage of air is that it is lighter than urine or contrast material and therefore identifies the posterior calyces first, with the patient in the prone position. The typical appearance of air in a posterior calyx filled with contrast agent has been described as "Mickey Mouse ears." With a single stone in the renal pelvis or when the anatomy is unclear, the use of contrast material is recommended to precisely delineate the intrarenal anatomy. However, in the case of multiple radiopaque calyceal or complete staghorn calculi, an air pyelogram outlines the collecting system satisfactorily and will not interfere with the evaluation of residual stones or fragments due to retained or extravasated contrast material. **In general, anterior calyces are more laterally located and posterior calyces are more medially located (mnemonic LAMP: Lateral-Anterior, Medial-Posterior).**

Subcostal Approach. With the C-arm in the vertical position, the collecting system is inspected and the appropriate calyx is identified. The ideal site provides the shortest tract to the calyx from below the 12th rib (Fig. 46–14). Examination with the C-arm at 90 degrees defines the medial vertical plane for entry into the calyx. The C-arm is then rotated approximately 30 degrees toward the surgeon. This places the axis of the C-arm in the same central posterior plane of the kidney, providing a direct end-on view of the posterior calyces. After the calyx has been identified, the overlying skin site is marked with a curved hemostat (Kessaris and Smith, 1995; LeRoy, 1996; Niles and Smith, 1996).

An 18-gauge translumbar angiography needle is advanced in the plane of the fluoroscope beam with the C-arm in the 30-degree position. The diamond tip prevents deflection by sharply cutting through muscle and fascia while causing minimal shearing (Fig. 46–15). In general, the shorter the needle (11 to 15 cm) the easier it is to control. Longer needles are necessary for obese patients or when triangulation is utilized (see later), because this latter technique may require a longer tract or more flexibility to "bend around" a rib. **The appropriate direction for needle advancement is determined by obtaining a "bull's-eye sign" on the fluoroscopic screen.** This effect can be observed only when the needle hub is superimposed on the needle shaft and is evident when the plane of the needle is the same as that of the x-ray beam. If the axis of the needle advancement is not parallel to the axis of the C-arm beam, a segment of the needle shaft is visible (Fig. 46–16).

After determination of the appropriate plane, the needle is advanced in 1- to 2-cm increments using a hemostat to minimize radiation exposure to the surgeon. The needle should

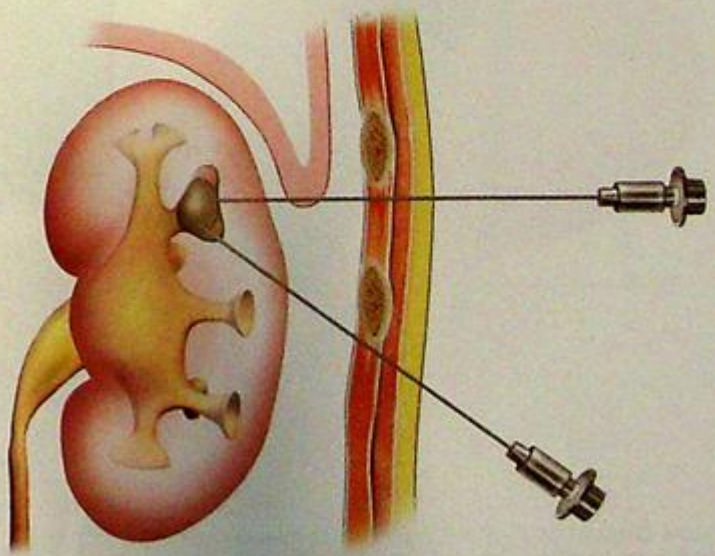

Figure 46–14. The ideal site for percutaneous puncture is one that provides the shortest tract to the calyx from below the 12th rib. In this particular case, although an intercostal approach would provide the shortest tract, it would also greatly increase the risk of injury to the pleura or lung.

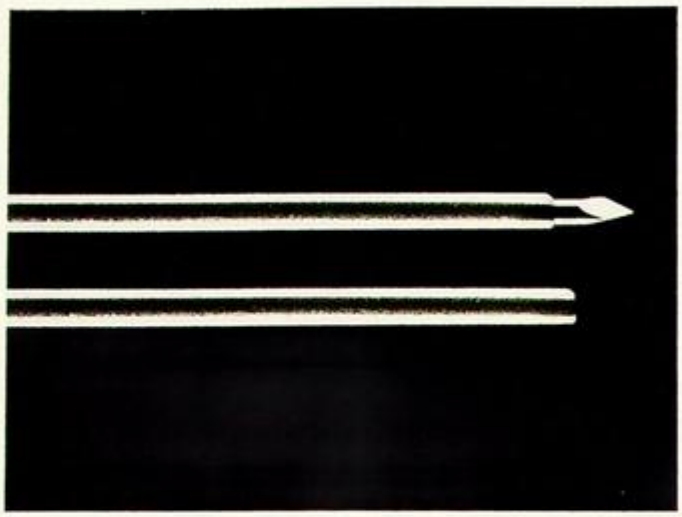

Figure 46–15. An 18-gauge translumbar angiography diamond-tipped needle. Notice that the tip protrudes approximately 1 mm from the distal end of the trocar.

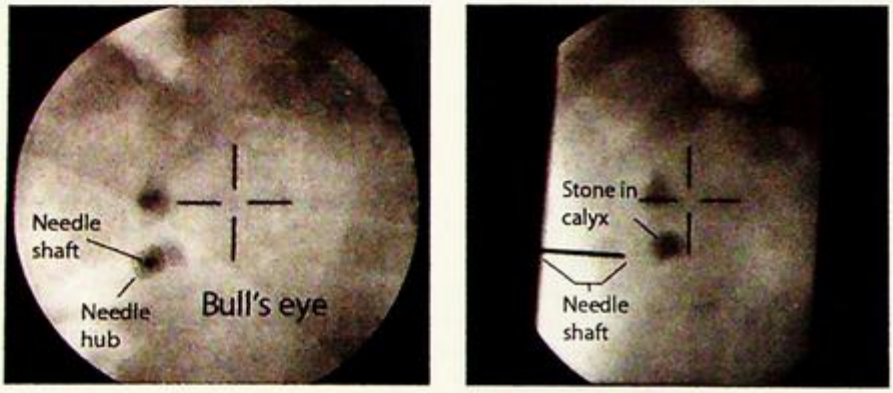
approximate the avascular line of Brödel, because this provides the safest access to the posterior calyceal system. A transparenchymal route avoids the hilar vessels and seals the nephrostomy tract from urine leakage. **The depth of needle penetration is monitored by rotating the C-arm back to the vertical position.** With the C-arm in the vertical position, the approximation of the tip of the needle to the predetermined calyx can be seen and guided fluoroscopically. For example, the needle is too deep if it appears to be past the calyx on the fluoroscopic screen. Periodically, it is important to evaluate the correct direction of needle advancement by rotating the C-arm 30 degrees toward the surgeon and observing for the bull's-eye effect. Both the appropriate axis and the needle depth are prerequisites for a successful percutaneous access. The needle has reached its intended target when its tip is in the desired calyx on both planes of fluoroscopy.

When the needle appears to be in a calyx, the stylet is removed and the correct needle position is verified by aspira-



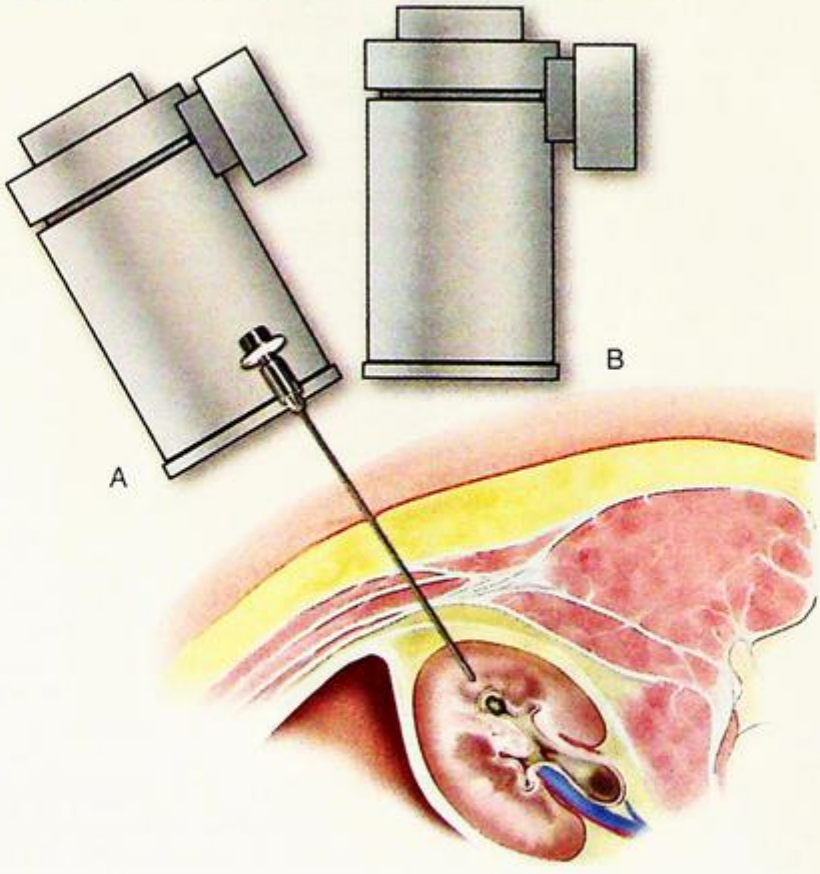


Figure 46–16. The use of two-plane fluoroscopy to achieve accurate needle entry. With the C-arm rotated 30 degrees from the vertical position (**A**), the "bull's eye" sign confirms passage of the needle at the proper angle. The depth of needle penetration can be checked by intermittently rotating the C-arm to the vertical position (**B**).

tion of urine or air, or both. A 0.038-inch floppy-tip J-shaped guide wire is inserted into the needle and either advanced across the UPJ or coiled within the renal pelvis. With the needle left in place, a 1-cm skin incision is made. The needle is then removed and the tract is dilated over the wire.

Intercostal Approach. The risk of hydrothorax and hemothorax is increased when percutaneous access to the calyces is performed above the 12th rib. Several endourologic techniques to access the superior calyces while minimizing complications have been described (Lang and Glorioso, 1986; Irby et al, 1999). The direct intercostal approach, triangulation, indirect access by way of lower calyces, and retrograde percutaneous nephrostomy have all been described.

Direct percutaneous access to an upper pole calyx can be difficult by a subcostal approach, and the endourologist needs to be familiar with the intercostal approach. Many urologists favor this approach for gaining access to the upper pole and suggest that it provides direct and optimal access to most staghorn calculi, even though it carries a slight and acceptable increase in morbidity (Fuchs and Forsyth, 1990; Golijanin et al, 1998). Contemporary series, in contrast to older literature, indicate that with caution intercostal puncture may be safe and effective. In particular, care should always be taken to ensure that the access sheath always remains in the collecting system.

Karlin and Smith (1989) described a technique for minimizing the potential morbidity of the intercostal approach by displacing the kidney caudally. This is achieved by placing an Amplatz sheath through a central or lower pole calyx and rotating the back of the dilator cranially, which causes caudal displacement of the kidney that can be viewed fluoroscopically. A second distinct puncture or a Y-tract is created into the upper pole. This method was successful in 21 of 25 cases without complications (Fig. 46–17). Also, an occlusion balloon catheter can be used to apply gentle caudal traction and displace the kidney downward and below the costal margin during the initial access approach. Alternatively, the needle can be advanced gradually only when the kidney is at its lowest excursion point, either incrementally during consecutive end-inspirations or while the patient is made to perform a Valsalva maneuver by the anesthesiologist.

Another frequently used technique for access to a superior calyx is triangulation. The C-arm is placed over the patient in the vertical position. A retrograde pyelogram is obtained, and the skin over the desired calyx is marked with a hemostat while the C-arm is maintained in the vertical position. This plane defines the medial extent of needle penetration for access to the desired calyx. The C-arm is then rotated 30 degrees toward the surgeon for an end-on view of the posterior group of calyces. With the C-arm at 30 degrees, the skin site over the calyx is marked lateral to the first site. The surgeon uses this point on the skin surface to move in a vertical line inferiorly until a site 1 to 2 cm below the 12th rib is reached. This third site is marked and serves as the site of needle entry. From this point, the needle is advanced to the junction of the vertical plane and the 30-degree plane. Access is achieved at the junction of all three axes, hence the term *triangulation* (Niles and Smith, 1996) (Fig. 46–18).

In the latter approach, the bull's-eye sign does not exist; and thus the axis for needle advancement is based on the surgeon's appreciation of the principles of two-plane fluoroscopic viewing, especially regarding the needle tip and calyceal position. It is also very important to be familiar with the perception of the angle of advancement of the needle as it relates to the depth of penetration along the medially defined plane described previously. This approach is technically more demanding and requires more experience with percutaneous

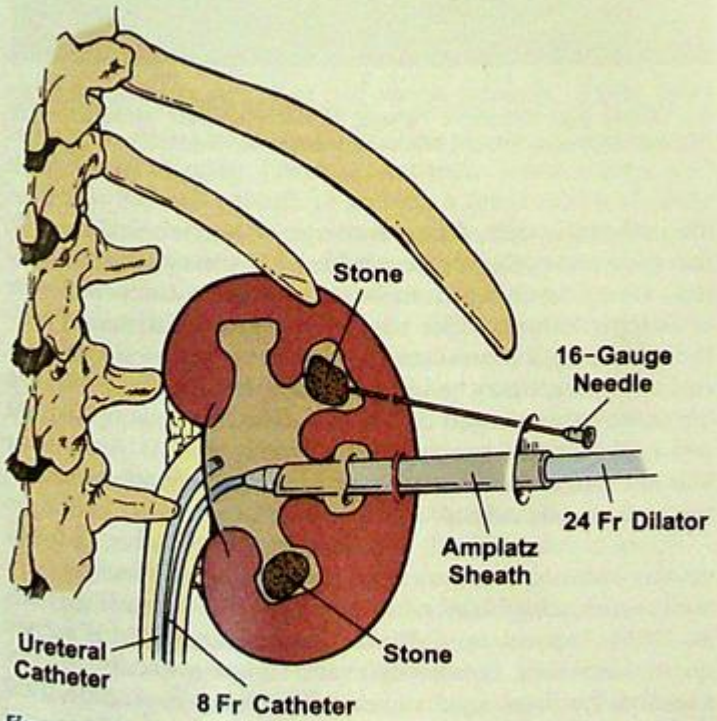

Figure 46–17. Caudal mobilization of the kidney using an Amplatz sheath in a middle calyx presents a lower position for superior calyceal puncture.

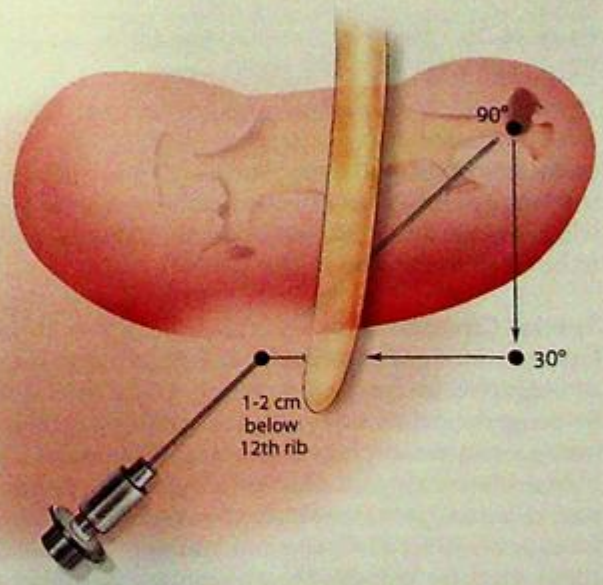

Figure 46–18. The triangulation technique can be used to avoid intercostal needle puncture. The vertical (90-degree) plane defines the medial extent of needle penetration, and the 30-degree plane provides an end-on view of the posterior calyces. In the triangulation technique, the needle is advanced from a point 1 to 2 cm below the 12th rib to the junction of the vertical and 30-degree planes.

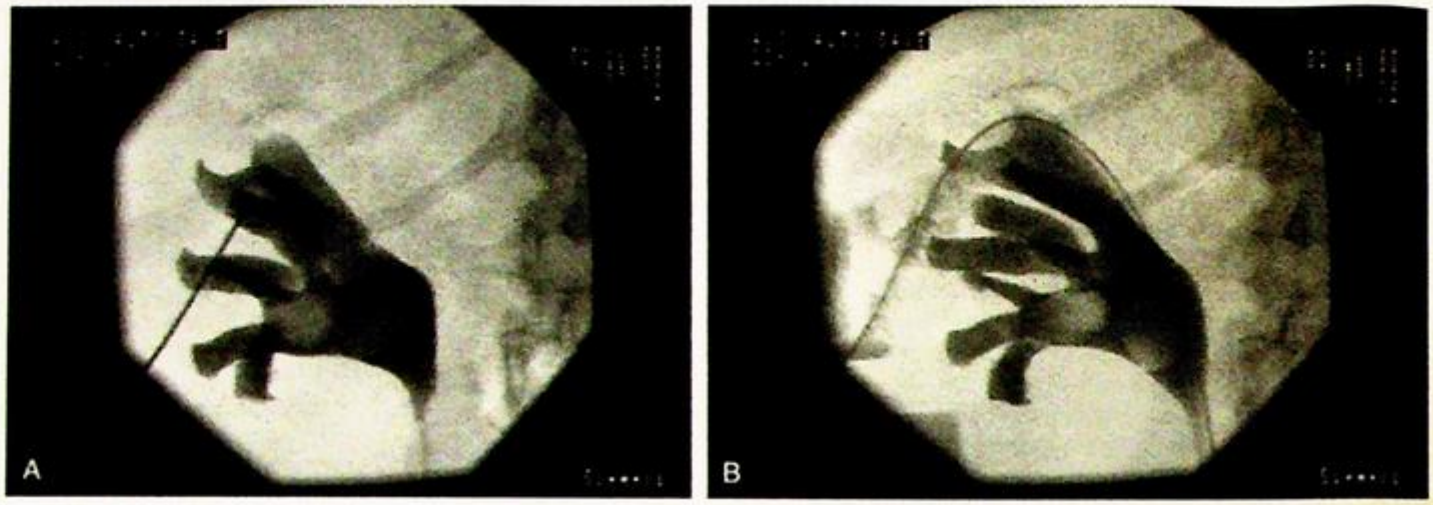

Figure 46–19. **A,** Subcostal point of entry with the tip of the needle puncturing the superior pole calyx. **B,** After aspiration of urine confirms the correct position, the guide wire is advanced into the ureter.

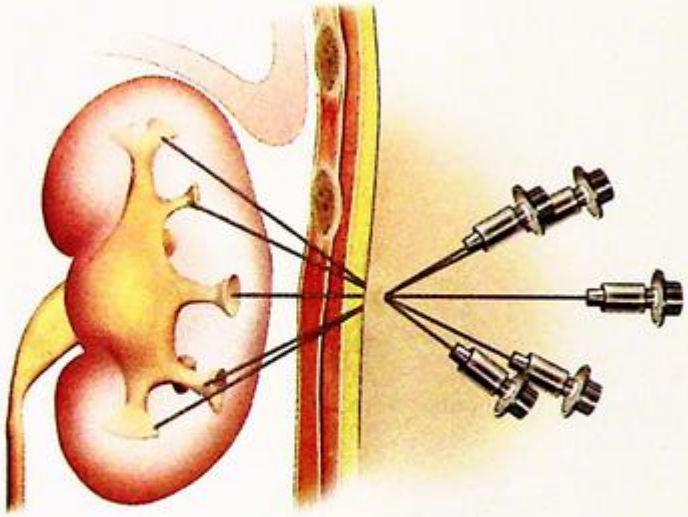

Figure 46–20. The Y-tract technique allows the use of a single skin incision to gain access to multiple calyces.

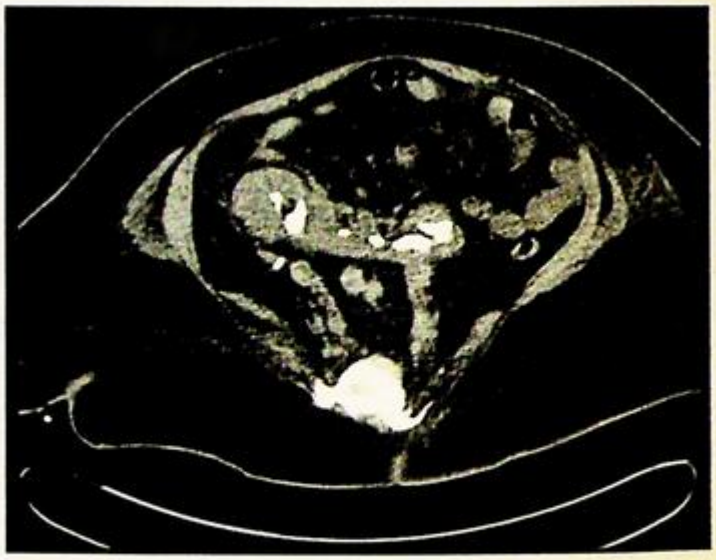

Figure 46–21. Horseshoe kidneys tend to be more anteriorly and inferiorly located than orthotopic kidneys. In morbidly obese patients such as this one, extra-long dilators and nephroscopes are required.

punctures (Figs. 46-19 and 46-20). This procedure can place some torque on the renal parenchyma and should only be used when the normal renal excursion allows the superior calyces to be close to the level of the 12th rib.

Special Circumstances. Percutaneous access to anomalous kidneys for endourologic procedures requires excellent radiographic imaging for guidance. CT or MRI is imperative to properly define anatomy and guide puncture. In some instances laparoscopic guidance may be needed.

Malrotated kidneys and horseshoe kidneys are relatively easy to access percutaneously (Janetschek and Kunzel, 1988; Jones et al, 1991; Al-Otaibi and Hosking, 1999; Shokeir et al, 2004). In these kidneys, the majority of the calyces are facing posteriorly while the renal pelvis is anterior. In general, the more medial the calyx, the more likely it is to be posterior. Because of the possible aberrant vasculature, however, preoperative CT is extremely helpful in deciding which calyx is best to access in terms of safety and efficacy (being able to reach the pathologic site). One advantage of horseshoe kidneys is that their embryologic ascent is limited by the inferior mesenteric artery, resulting in an inferior location compared with orthotopic kidneys. This results in a low incidence of pulmonary complications because the tract is almost always subcostal. The tract may be long, however, because these kidneys are more anterior; and in obese patients extra-long dilators and nephroscopes may be necessary (Fig. 46–21). Also, these kidneys tend to have supernumerary calyces, making maneuvering from one calyx to another difficult.

Access is more difficult with pelvic kidneys and cross-fused ectopic kidneys. The very anterior location of these kidneys with surrounding bowel often precludes safe access (Eshghi et al, 1985). Laparoscopic displacement of bowel with subsequent combined laparoscopic and fluoroscopically guided puncture has been used successfully (Troxel et al, 2002; Dos Santos et al, 2004; Aron et al, 2005). Cross-fused ectopic kidneys associated with UPJ obstruction may be able to be

accessed through the anterior abdominal wall providing there are no intervening bowel segments. This can be ensured with a combination of a preoperative CT scan and intraoperative ultrasound and/or cross-table lateral fluoroscopy to guide the puncture.

Guide Wires and Catheters

In general, the wire preferred by most surgeons for initial access is the J-wire. This wire has the benefit of being nonperforating, because its distal end is in the shape of a soft J. It has a tendency to coil in the calyx of access or in the renal pelvis and can be maneuvered in the collecting system with low risk of injury. J-wires come in various lengths, coatings, and stiffness, each having distinct advantages and disadvantages, which are beyond the scope of this chapter to discuss. Hydrophilic coated wires are also commonly used for initial access, because they are very slippery and are most likely to find their way through a tight infundibulum, past an impacted stone, or through the UPJ. The major advantages of these wires are their ability to find their way through obstructions, to coil generously in the collecting system or bladder, and to have innate resistance to kinking. Their four disadvantages are their extreme slipperiness when wet, which can result in inadvertent loss of access; their blunt tip, which can cause perforation of the collecting system; their high coefficient of friction when dry, which can cause difficulty passing catheters over them; and their lack of memory, which can result in recoil if not physically held in position. A third wire commonly used for access as well as for manipulating down the UPJ is the coaxial wire. This wire has an inner movable core, allowing the end of the wire to be flexible or stiff, depending on the desire of the surgeon and the particular situation. Once access is obtained to the collecting system with the distal end of the wire being flexible, the shaft of the wire leading into the collecting system can be stiffened, allowing for easier dilation and preventing kinking and loss of access.

Catheters are necessary once guide wire access has been obtained to the collecting system. The tract initially should be serially expanded to 10 to 12 Fr. This can be achieved using short fascial dilators. These are tapered, Teflon-coated, and malleable but stiff enough to go over a guide wire and dilate through fascia, muscle, and renal capsule. If a guide wire gets kinked during passage of a dilator, the kinked portion can be pulled into the dilator and the dilator is then advanced with back tension on the wire. Once the dilating catheter is in the collecting system, the wire can be exchanged for a stiffer wire or an attempt can be made to maneuver a new wire down the UPJ. Other catheters, such as a coudé-tipped catheter, Kumpe catheter, or a Cobra catheter, can be used to manipulate the guide wire into desired locations. These catheters have tapered ends that are curved to varying degrees, allowing access around corners or tortuosities.

In patients who have had previous renal surgery or have scarring from infections, the fascia may be too fibrotic to dilate with a Teflon-coated catheter or a balloon. In these situations a fascial incising needle may be helpful. This device is a butterfly-shaped needle that goes over a guide wire. The wings have cutting surfaces that can slice through the scar, allowing subsequent catheter placement.

KEY POINTS: TECHNICAL ASPECTS OF PERCUTANEOUS ENTRY

- Whenever possible, urine sterility should be confirmed before any percutaneous procedures of the renal collecting system.
- Attention to patient positioning is critical to minimize the risk of respiratory problems, neurologic damage, or compression injury to the patient.
- Retrograde opacification may be used to identify pelvicalyceal anatomy before percutaneous puncture. In general, anterior calyces may be identified by their more lateral location and posterior calyces may be identified by their more medial location (LAMP: Lateral-Anterior, Medial-Posterior).
- Two-plane fluoroscopy allows for accurate determination of appropriate direction and depth of needle advancement.
- Although the risk of pulmonary complications is higher than in the subcostal approach, an intercostal approach to the renal collecting system may be the most feasible option in select circumstances.

DILATION OF THE NEPHROSTOMY TRACT

Needle entry into the desired location of the pelvicalyceal system represents the first step of a successful percutaneous intervention. The tract also must be secured and dilated to allow for the passage of nephroscopic equipment or drainage catheters. In the early experience with percutaneous techniques, dilation of existing nephrostomy tracts was carried out gradually using sequentially larger telescopic dilators over a period of 8 days. Castañeda-Zúñiga (1982) first described acute dilation of the nephrostomy tract in a single session with no untoward effects. **Since then, multiple techniques have been developed that allow for safe, rapid nephrostomy tract dilation so that percutaneous access and intrarenal surgery now can be routinely performed during the same setting.**

Guide Wire Introduction

The main principle of acute tract dilation is that it must *always* be performed over a guide wire. After needle entry into the collecting system is confirmed by return of urine after removal of the stylet, the Seldinger technique is used to advance a guide wire through the needle into the collecting system. The wire should be stiff enough to support the subsequent dilation. Passage of the wire down the ureter into the bladder should be attempted to minimize the risk of wire dislodgement during fascial dilation. In situations in which this is not possible (e.g., impacted ureteral stone, narrow UPJ), the wire should be positioned in a calyx that is distant from the initial nephrostomy tract to prevent dislodgement during dilation. In patients with complete staghorn calculi, the guide wire may

coil within the punctured calyx because it cannot pass into the renal pelvis. In this case, dilation must be performed very gently because the guide wire can be easily displaced.

In addition to the initial working guide wire, a second safety guide wire may also be used. The safety wire is inserted immediately adjacent to the working wire and serves to protect access to the nephrostomy tract in case the working wire becomes kinked or displaced. Insertion of the safety guide wire requires the use of a double-lumen catheter or a coaxial system to accommodate two wires. This coaxial system consists of an inner dilator tapered to the size of the guide wire and an outer sheath. After the inner dilator is removed, the external sheath allows the safe insertion of the second guide wire, ensuring its correct positioning within the ureteral lumen. Various safety guide wire introducers are available (Press and Smith, 1995).

Figure 46–22. Amplatz dilator and sheath set.

Types of Dilators

A variety of techniques exist for acute dilation of the nephrostomy tract. **The most commonly used systems include progressive fascial dilators, malleable dilators, metal coaxial dilators, and high-pressure balloon dilators.** The decision of which type of dilation system is used varies among urologists on the basis of personal preference and experience. Multiple investigators have found no differences in renal parenchymal damage among the various dilation methods (Clayman et al, 1987; Stoller et al, 1994). It should be noted, however, that when comparing balloon dilators and malleable dilators several groups of investigators observed lower renal hemorrhage rates and lower transfusion rates in patients undergoing balloon dilation (Davidoff and Bellman, 1997; Safak et al, 2003).

Fascial Dilators. The fascial dilator system consists of progressively larger polytetrafluoroethylene (Teflon) tubes designed to slide over a 0.038-inch guide wire. They range in size from 8 to 36 Fr and are inserted in a rotating, screw-type fashion with the entire dilation procedure performed under fluoroscopic control. The main advantage of this system is that it is safe. Once the 8-Fr catheter is in place, subsequent dilation is unlikely to kink the guide wire. The stability conferred by the firm polytef composition also makes fascial dilators ideal for dilation of fibrous tracts such as may be seen in patients with a history of retroperitoneal surgery, percutaneous surgery, or inflammatory processes of the kidney (Press and Smith, 1995). The main drawback of this system is its dependence on the integrity of the guide wire (LeRoy, 1996). In addition, despite their purported safety, caution must be exercised when introducing fascial dilators because their tips can perforate the renal pelvis medially, causing excessive blood loss or extravasation of irrigating fluid into the retroperitoneum.

Malleable Dilators. Malleable dilators were developed in 1982 by Kurt Amplatz to improve upon some of the weaknesses of the older fascial dilators and are now widely referred to as Amplatz dilators (Rusnak et al, 1982). A tapered 8-Fr angiographic catheter is initially inserted down the ureter over the working guide wire, and progressively larger polyurethane catheters are serially passed over the catheter/guide wire combination. The additional stability conferred by the tapered 8-Fr catheter facilitates the entire dilation process by preventing the guide wire from kinking and by allowing the larger dilating catheters to slide more easily. These dilating catheters range in diameter from 12 to 30 Fr in increments of 2 Fr (Fig. 46–22).

The nephrostomy tract either can be dilated in a stepwise fashion with the full set of dilators or some sizes can be skipped. The dilators must be advanced over the working guide wire until they enter the calyceal lumen. However, further insertion may damage the integrity of the pelvicalyceal system and should be avoided. Thus, to avoid collecting system tears, the distal end of the dilators should not be advanced across the UPJ. When nephrostomy tract dilation is performed to treat large renal stones, the dilators should be advanced only to the peripheral edge of the stone. Calyceal or infundibular lacerations have been reported when large dilators were forced past stones that were impacted in the pelvicalyceal system (LeRoy, 1996).

Once the tract is adequately dilated, an outer sheath is passed in coaxial fashion over the polyurethane dilators. The external sheath secures access to the kidney and allows the repeated introduction and withdrawal of endourologic equipment. The sheaths range in size from 28 to 34 Fr, and the outer diameter exceeds the inner diameter by 4 Fr; thus, the 34-Fr sheath is designed to slide over the 30-Fr dilator. The sheaths are impregnated with polytef to reduce the coefficient of friction and to minimize buckling.

Complications that may occur with the malleable dilators include perforation of the pelvicalyceal system, hemorrhage, extravasation, and trauma to the renal capsule. Dilation of the nephrostomy tract must always be performed under fluoroscopic observation. If excessive force is used during the insertion of the dilators, the renal pelvis may be perforated despite the presence of the 8-Fr catheter. When the medial segment of the renal pelvis is perforated, there is the possibility of extravasation of irrigation fluid into the retroperitoneum. Trauma to the renal capsule with resultant perirenal hematoma can be caused by irregularities on the leading edge of the Amplatz dilator. The disposable dilator sets ensure a smooth leading edge on the sheath each time (Press and Smith, 1995).

Metal Coaxial Dilators. Metal coaxial dilators are made of stainless steel and are mounted together in a telescopic fashion, mimicking a collapsible radio antenna. Progressively larger dilators are added until the tract is dilated to the desired size (Alken, 1985). The metal telescopic dilators consist of an 8-Fr hollow guide rod that slides over a guide wire and a set of six metal tubes ranging in diameter from 9 to 24 Fr. Each dilator adapts exactly to the lumen of the next dilator. A bulge at the end of the rod represents the endpoint for the progression of the dilators, ensuring that they cannot be advanced farther. After all dilators have been advanced, their tips are in the same horizontal plane, close to the tip of the guide rod.

The metal coaxial dilation system is rigid and theoretically is excellent for patients with previous surgery and associated perirenal fibrous tissue. However, several notable drawbacks have limited its use. The main disadvantage is that it is difficult to control the pressure exerted during dilation. The central core of the apparatus must be held firmly while the outer dilator is advanced to avoid untoward events such as perforation of the renal pelvis and the resultant risks of extravasation and hemorrhage (Seeman and Alken, 1995).

Balloon Dilation Catheters. For the fascial, malleable, and metal coaxial dilation systems, the major risk of injury stems from the uncontrolled repetitive passage of progressively larger dilators. In an attempt to minimize the morbidity of nephrostomy tract dilation, balloon dilation catheters capable of achieving tract dilation in a single step were developed (Fig. 46–23). Before inserting the balloon catheter, a 30-Fr polytef working sheath is backloaded behind the uninflated balloon. The catheter is then inserted over the guide wire until the inflatable segment traverses the nephrostomy tract. The tip of the balloon, indicated by the radiographic marker, is advanced just inside the calyx. Passing the balloon tip beyond the calyx or stone may result in infundibular tears or urothelial injury from the impaction of the stone. Once appropriately positioned, the balloon is inflated to acutely dilate the tract. Pressures of 15 to 20 atm can easily be reached with the balloon catheter. In patients with no previous renal surgery, pressures of 4 to 5 atm are usually enough to dilate a nephrostomy tract. In those who have had surgery, higher pressures are required to achieve the final dilatation. As the balloon is inflated, a characteristic "waist" appears in areas of high resistance, such as the renal capsule or a previous operative scar (Fig. 46–24). With persistent inflation, the balloon expands fully and the waist disappears, allowing the backloaded sheath to be advanced into the collecting system in a rotating fashion. This sheath is advanced into the tract to the end of the balloon, not the end of the catheter. The balloon is then deflated and retrieved from the tract. The working sheath provides the access for further endourologic manipulations.

The purpose of balloon dilation is to achieve tract formation in a single step, avoiding the need for serial dilation. Among the major advantages of the balloon dilation system is its ease of use. Also, unlike serial dilators, which repetitively generate angular shearing forces, the balloons generate lateral compressive forces and are therefore less traumatic. Theoretically, balloon dilation should generate less hemorrhage, but this has yet to be definitively proved. Among the drawbacks of the balloon dilation system are the relative inability to dilate dense fascial tissue or scar tissue and the greater expense compared with other dilation systems.

Novel Dilation Methods. Several groups have reported on alternative techniques of nephrostomy tract dilation to avoid the morbidity associated with repetitive insertion and withdrawal of malleable dilators. In contrast to the traditional method, which employs sequential insertion of dilators of increasing size, a "one-shot" method consisting of a single dilation of the tract with a 25- or 30-Fr Amplatz dilator has been described (Travis et al, 1991; Frattini et al, 2001). Similar to the "one-shot" method, single-step dilation using an expanding malleable sheath preloaded on a laparoscopic trocar has also been described (Goharderakhshan et al, 2001). Preliminary results using these novel methods suggest that they may be feasible and perhaps less time consuming than some of the traditional methods of tract dilation (Frattini et al, 2001; Goharderakhshan et al, 2001).

The indication for percutaneous access and the size of the endoscopic instruments that will be used dictate the final extent of tract dilation. With the access tract dilated, either endourologic equipment or a nephrostomy tube is

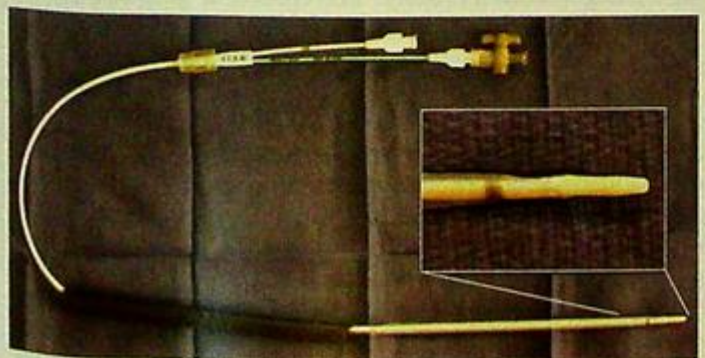

Figure 46–23. Balloon dilation catheter and preloaded sheath. As shown in the *inset*, the balloon cuff does not extend to the distal tip of the catheter. This must be kept in mind during advancement of the balloon dilation catheter into the collecting system.

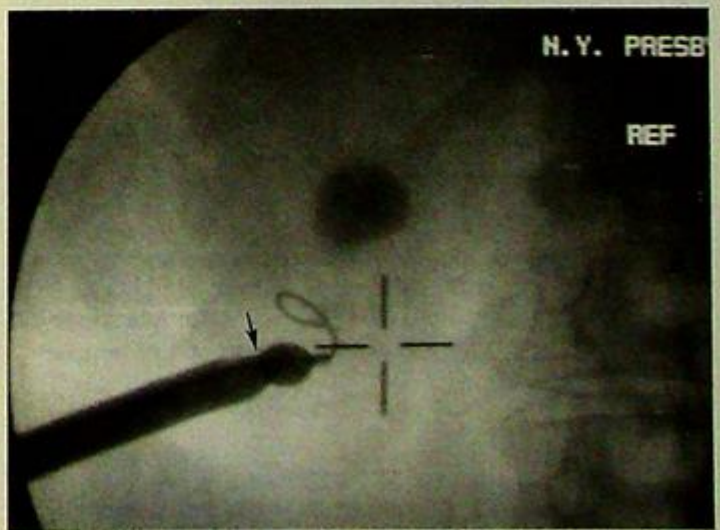

Figure 46–24. During balloon dilation of the nephrostomy tract, a waist can be seen at areas of high resistance such as the renal capsule and previous operative scar. In this instance, the waist *(arrow)* corresponds to dilation of the renal capsule.

introduced. When simple renal drainage is needed, a 10-Fr nephrostomy tube may be sufficient and there is no need for greater tract dilation. The final diameter of the tract should exceed the tube or instrument size by 2 to 4 Fr, to allow adequate flow of fluid around the instrument. When percutaneous access is needed for the management of stone disease, the tract is usually dilated to 30 Fr to accommodate a rigid nephroscope. Various authors have investigated the use of a "mini-perc" technique in which the tract is dilated between 13 and 20 Fr. The early literature suggests that a smaller volume of renal parenchyma is dilated, leading to a corresponding decrease in blood loss and postoperative pain (Jackman et al, 1998; Monga and Oglevie, 2000). **However, the only randomized study in the literature comparing the mini-perc and standard techniques showed no advantage with the mini-perc technique,** suggesting instead that poorer visualization and more difficult instrument handling may even place the mini-perc technique at a slight disadvantage (Feng et al, 2001).

KEY POINTS: DILATION OF THE NEPHROSTOMY TRACT

- Modern nephrostomy tract dilation techniques allow for establishment of a nephrostomy tract and performance of complex intrarenal surgery at the same setting.
- Progressive dilators such as fascial dilators, malleable dilators, and metal coaxial dilators achieve tract formation by the generation of repetitive angular shearing forces.
- Balloon dilators achieve tract formation using lateral compressive forces and are theoretically less traumatic.
- Both standard and "mini-perc" techniques have been used successfully for tract dilation, but no clear advantage has yet been demonstrated for either technique.

COMPLICATIONS OF PERCUTANEOUS RENAL SURGERY

Although percutaneous procedures of the kidney are associated with less morbidity than open surgery, the potential for significant complications still exists (Farrell and Hicks, 1997). Prompt recognition and management of complications are critical. Equally important are prevention and minimization of these complications.

Hemorrhage

Blood loss is a common occurrence during percutaneous procedures of the kidney. **In particular, excessively medial punctures, multiple punctures, and punctures into kidneys with abnormal anatomy are associated with an increased risk of bleeding** (Sampaio, 1996; Martin et al, 1999). In addition, patients on anticoagulant or antiplatelet medications are more likely to experience bleeding. In the majority of cases, the amount of blood lost during percutaneous procedures is not significant enough to require transfusion and conservative management is generally sufficient. Occasionally, blood transfusion may be warranted depending on baseline hematocrit, presence of comorbidities, and amount of blood lost. Rarely, angiographic embolization of the injured vessel is necessary. In a series of 2200 patients who underwent percutaneous renal surgery, only 17 patients (0.8%) had uncontrollable bleeding requiring angiography and embolization (Kessaris et al, 1995). The most common sources of refractory bleeding in this series were arteriovenous fistulas (41%) and pseudoaneurysms (35%). For patients with bleeding refractory to angiographic embolization, open surgical exploration is warranted.

Acute bleeding associated with percutaneous renal surgery may be secondary to injury to renal parenchymal vasculature or to branches of the renal vein or artery adjacent to the pelvicalyceal system. Parenchymal bleeding is usually seen at the site of nephrostomy tract dilation. Advancement of the distal segment of the working sheath into the collecting system provides effective parenchymal tamponade, allowing the procedure to continue. After completion of surgery, a large-bore nephrostomy tube (26 or 28 Fr) is usually sufficient to quell oozing from the tract. **When tract bleeding is refractory to this or is brisk, a nephrostomy tamponading balloon catheter (Kaye catheter) may be invaluable and should be readily available in the surgical suite.** This is essentially a large nephrostomy tube surrounded by a balloon that can be inflated with varying pressure, thereby providing effective tamponade from the pelvicalyceal system to the skin. This can be maintained for 2 to 4 days if necessary. Urine drainage is provided through the inner lumen of the catheter (Kaye and Clayman, 1986; Kerbl et al, 1994). This high-pressure Kaye tamponade balloon catheter should be removed under fluoroscopic control with guide wire access down the ureter. This allows immediate reinsertion if bleeding recurs. Several studies have demonstrated that dilation of the tract using balloon dilating catheters as opposed to metal Alken telescopic dilators or the Teflon-coated Amplatz dilators results in less blood loss. They may also cause less renal damage. The reason is that the balloon dilates radially and minimizes the shearing forces associated with other methods.

Renal venous lacerations are not uncommon and may also be managed conservatively. The insertion of a large (26 or 28 Fr) nephrostomy tube aids in controlling venous bleeding. The tube can be clamped, allowing the pelvicalyceal system to fill with clot and creating enough pressure to tamponade venous bleeding. This maneuver may not be sufficient if bleeding is brisk or from a large branch of the renal vein. Gupta and coworkers (1997) presented a technique utilizing a selectively positioned and inflated Councill balloon catheter that was successful in controlling hemorrhage without affecting renal function in five patients with renal vein injury during percutaneous renal surgery. The technique involves first a nephrostogram at the end of the procedure to delineate the exact site of egress of contrast medium into a vein (Fig. 46–25A). Usually a blush will be seen entering the branch vein and then subsequently the main renal vein and even the inferior vena cava. The most common sites of injury are an

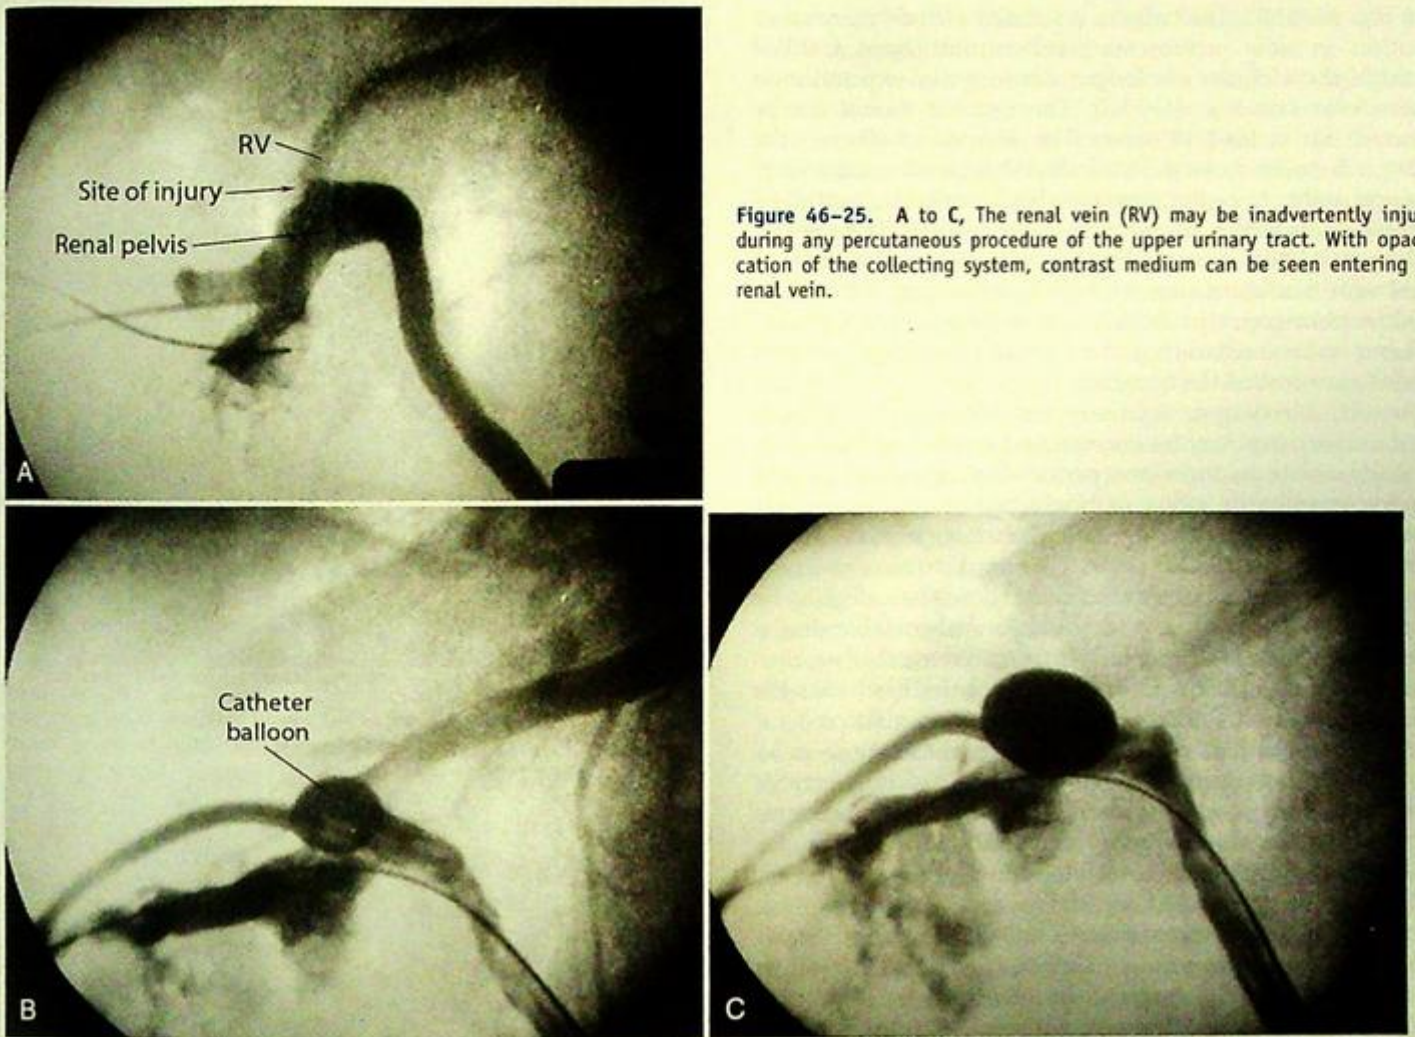

Figure 46–25. A to C, The renal vein (RV) may be inadvertently injured during any percutaneous procedure of the upper urinary tract. With opacification of the collecting system, contrast medium can be seen entering the renal vein.

infundibulum between the renal pelvis and a calyx or the wall of a calyx and the renal pelvis after endoscopic resection of malignant tumor. A guide wire is passed through the infundibulum if it is not already present, and a Councill catheter (18 to 26 Fr) is placed over the guide wire. Before the catheter is passed, an extra side hole should be created proximal to the balloon (Fig. 46–26). This can be achieved by placing a curved mosquito clamp through an existing side hole and passing it through the lumen of the catheter proximally until its tip is felt to be beyond the area of the balloon. The clamp should be curved away from the balloon lumen, which is on the same side of the catheter as the balloon inflation port. A sharp tenotomy scissors or scalpel can then be used to cut over the tip of the clamp as the tip is pressing into the wall of the catheter. A tiny window is thus created that can then be enlarged by grasping a cut edge and trimming further. This proximal side hole serves to allow drainage of the calyx or calyces that are about to be obstructed by the balloon of the Councill catheter. If this is not done, the patient may have tremendous flank pain due to the obstructed calyx or calyces and/or may have copious extravasation of urine into the retroperitoneum or through the skin adjacent to the catheter. Next the balloon is positioned such that it is straddling the infundibulum or the site of egress in the calyx or renal pelvis

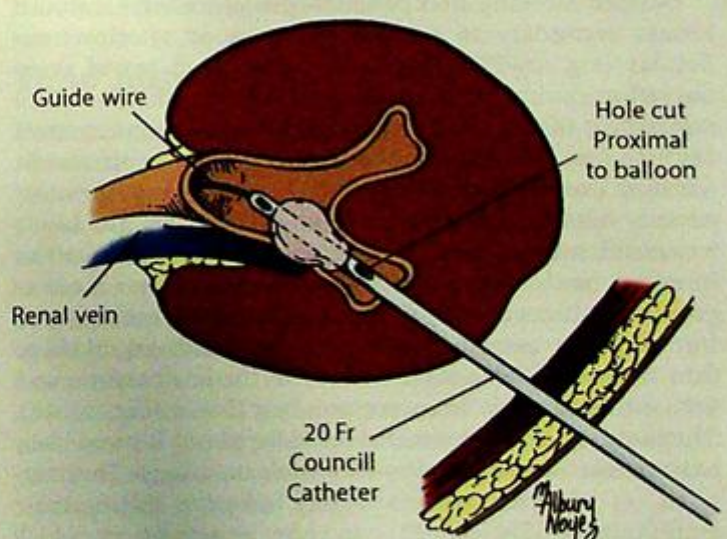

Figure 46–26. When using a Councill catheter to effect tamponade of an injured renal vein, an extra side hole should be created proximal to the catheter balloon. This allows for drainage of any calyces obstructed by the balloon.

(see Fig. 46–25B). The balloon is inflated with dilute contrast solution in slow increments until contrast agent instilled through the catheter no longer demonstrates extravasation into a vein (see Fig. 46–25C). The catheter should not be removed for at least 48 hours. The decision of whether the balloon is ready to be deflated should be made in the fluoroscopy suite. A nephrostogram should rule out continued venous egress as the balloon is partially deflated. Delakas and colleagues (1994) reported their experience with two cases of renal vein laceration large enough to allow entry of a 24-Fr rigid nephroscope. In both cases, inflation of a Councill catheter balloon adjacent to the injured venous segment successfully controlled the bleeding.

Arterial bleeding is relatively rare during percutaneous renal surgery but may be encountered intraoperatively or in the early or late postoperative period. Intraoperatively, it may present as pulsatile efflux of bright red blood through the puncture needle or working sheath and may not respond to conservative measures. If it occurs during dilation of the tract, the vessel is usually a tiny arteriole and tamponade may be successful. Endoscopic fulguration of parenchymal bleeding is rarely successful and is more likely to exacerbate than ameliorate the situation. If the injury is more central (i.e., near the collecting system), endoscopic fulguration may succeed for tiny vessels. Most of the time, however, bleeding is brisk enough to prevent continuation of surgery and angiographic evaluation is necessary and should not be delayed. As a temporizing method, the Kaye tamponade balloon catheter may be maximally inflated to limit blood loss in preparation for definitive management. Many patients require blood transfusion and subsequent superselective embolization under angiographic control (Beaujeux et al, 1995; Martin et al, 2000). **If the exact site of bleeding can be identified, angiographic embolization is virtually universally successful in controlling hemorrhage.** Open surgical exploration in these situations rarely succeeds and most often results in nephrectomy.

Delayed bleeding after percutaneous procedures is almost always secondary to pseudoaneurysms or arteriovenous fistulas (Fig. 46–27). The former occur from partial vessel laceration during initial access or dilation with subsequent weakening of the vessel wall and eventually intermittent rupture into the collecting system, resulting in spasmodic bleeding that is intermittently severely brisk and then spontaneously resolves only to recur hours or days later. The key to successful management is renal angiography during active bleeding (with the aid of an arterial vasodilator such as papaverine if necessary). Arteriovenous fistulas usually result from injury to proximate artery and veins, allowing blood to flow from the high pressure artery to the low pressure vein without tamponade from surrounding tissues (Fig. 46–28). The bleeding can be immediate or delayed but is more likely to be continuous compared with pseudoaneurysms. The treatment of choice again is highly selective angiographic embolization (Fig. 46–29). In rare situations in which embolization is relatively contraindicated due to preexisting moderate to severe renal insufficiency, the Gupta Councill catheter technique described earlier has proven successful.

The reported incidence of serious arterial injuries ranges from 0.9% to 3% after percutaneous procedures. Patterson and coworkers (1985) reported success in all seven of their angiographic embolizations. Martin and associates (2000) reported a 1% incidence of severe bleeding after percutaneous nephrolithotomy requiring superselective embolization. The need for a blood transfusion is dictated by a variety of factors, including operative technique, the patient's general condition, and the initial stone burden. The incidence of transfusion after percutaneous procedures differs among series. Segura and associates (1985) reported a need for transfusion in only 3% of their patients, whereas Stoller and colleagues (1994) had a 23% transfusion rate. In the literature, the reported transfusion rate among patients with large, complex stones is approximately 11%. An aggressive approach is associated with increased blood loss and a higher transfusion rate. **For technically demanding cases such as those involving multiple angular punctures for complex staghorn calculi, transfusion**

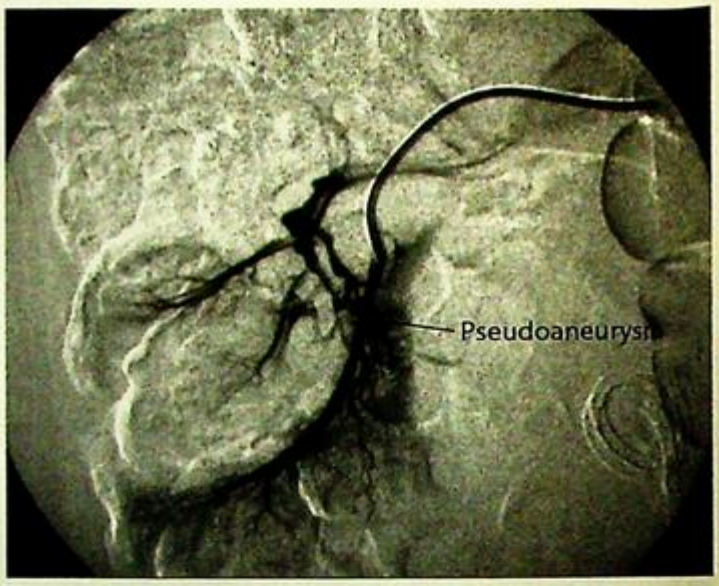

Figure 46–27. Angiography demonstrates a pseudoaneurysm in the lower pole of the right kidney. This patient presented with persistent severe hematuria after a percutaneous renal procedure. His pseudoaneurysm most likely developed after a percutaneous endopyelotomy performed 2 years earlier.

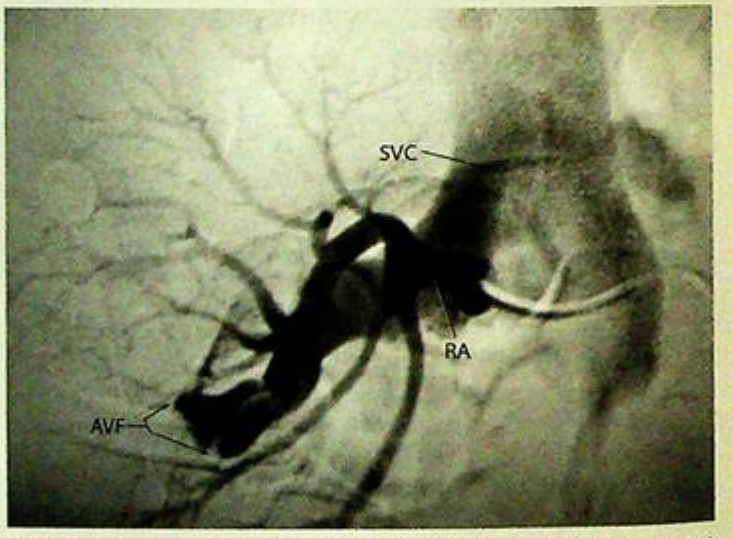

Figure 46–28. Injection of contrast medium into the renal artery (RA) promptly results in a blush in the superior vena cava (SVC), suggesting the presence of an arteriovenous fistula (AVF).

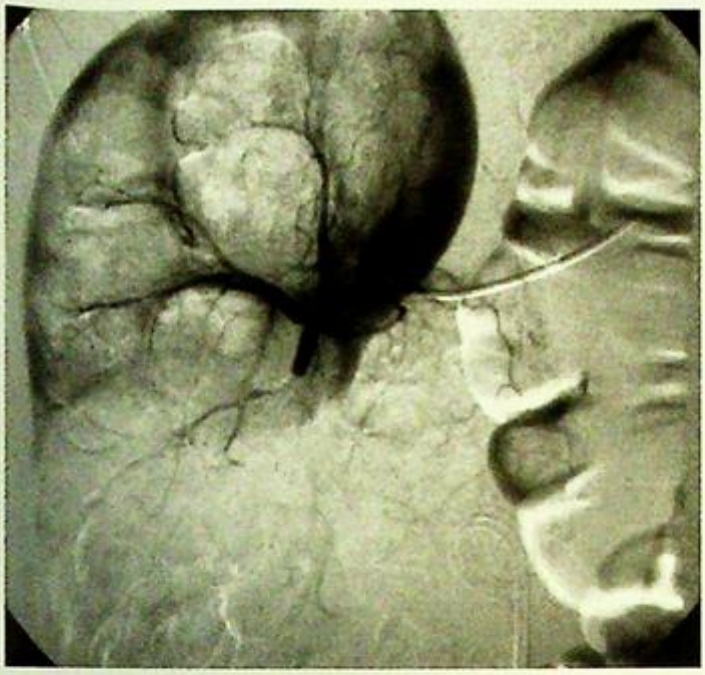

Figure 46–29. Embolization of the pseudoaneurysm pictured in Figure 46-27 resulted in complete absence of filling of the lower pole of the kidney as well as prompt resolution of hematuria.

rates may approach 50%. Martin and coworkers (1999) reported their results with the treatment of staghorn calculi and showed that transfusion rates increased from 20% when one or two punctures were required to 42% when more than two punctures were deemed necessary.

Injury to the Renal Pelvis

Perforation of the renal pelvis is usually diagnosed intraoperatively. The most frequent causes of perforation are aggressive passage of serial dilators and percutaneous lithotripsy-induced damage. Perforation during dilation of the nephrostomy tract can result from transgression of the medial pelvic wall during initial passage of a guide wire or needle. Dilation over the inappropriately positioned guide wire then results in a relatively large tear. Perforation by the guide wire can also occur during passage of serial dilators, especially if the initial tract is tortuous, access is too medial, the dilating catheter is too large and requires excessive force to pass, or a kink is created in the guide wire. Kinks usually occur when the dilator cannot pass smoothly over the guide wire because of angulation or unusual resistance from fibrosis. Angulation tends to occur at the renal capsule, because the kidney moves up and down but the body wall stays stationary, at the junction between a calyx and renal pelvis (infundibulum), and at the medial pelvic wall where the guide wire curves down toward the UPJ or a lower pole calyx or up toward an upper pole calyx (especially in lower pole punctures). The incidence of kinking and angulation is higher for lower pole punctures. In the case of a kink, the force of dilation is misdirected to the kinked portion, resulting in the entire kinked portion of the guide wire being forced outside the collecting system. Balloon dilation over a guide wire that has traversed through the collecting system or through a tight infundibulum can also result in renal pelvis perforation.

Lithotripsy using mechanical devices such as rigid ultrasound probes or pneumatic probes can also result in renal pelvis perforation. This is especially likely if the force of lithotripsy is being directed directly against the medial pelvic wall. Recent infection or inflammation can make the renal pelvis more friable and susceptible to perforation. Careful attention to technique may prevent perforation. First, undue pressure of the probe against the stone should not be used. In cases of very durable stones that do not fragment without mechanical pressure of the probe, gentle continuous pressure is preferable to intermittent "banging" of the probe against the stone. Moving the probe to multiple positions on the stone (so-called painting the stone) can aid in fragmentation. Also helpful is to relocate the stone to another location away from the medial wall (e.g., toward the upper pole, lower pole, or UPJ) before lithotripsy is employed. Rotating the stone such that a softer portion of the stone is tackled first may be effective. The use of stronger suction so that less mechanical pressure is required may also help.

If perforation is recognized, the rate of irrigation should be slowed, the fluid should be switched to normal saline, and judgment should be used as to whether the procedure can continue. In the case of a relatively short procedure (e.g., solitary relatively small stone at the UPJ that is clearly visible and does not require lithotripsy) the procedure can sometimes be expeditiously completed by placing the access sheath past the perforation to minimize extravasation. **In the vast majority of such situations, however, the procedure should be discontinued and ureteral stent placement and nephrostomy tube drainage should be accomplished and are usually sufficient** (Pardalidis and Smith, 1995; Dyer et al, 1997). An antegrade nephrostogram confirming resolution of extravasation of contrast material dictates when a secondary percutaneous procedure can occur or when removal of the nephrostomy tube or ureteral stent is possible.

Fluid Absorption

Patients with venous injury or collecting system perforation should be monitored for volume overload. Continued high-pressure irrigation in the presence of venous injury or perforation can lead to intravascular absorption of large volumes of fluid. Irrigation should always be performed with normal saline to minimize the risk of dilutional hyponatremia (Gallucci et al, 1998). In cases in which electrocautery is being used, glycine should be used in place of saline to prevent the hemolysis associated with use of nonisotonic solutions such as sterile water. A "TUR" syndrome can occur similar to that described for transurethral prostate resection. The treatment of this is identical to that described for prostate surgery and its discussion is beyond the scope of this chapter.

Injury to the Pleural Cavity

Pulmonary complications may be encountered during formation of a percutaneous nephrostomy tract. **The risk of injury to the lungs or pleura increases with more superior punctures: subcostal approaches have the lowest risk and intercostal approaches between the 10th and 11th ribs have the**

highest risk. In addition, needle advancements during end inspiration increase the risk of intrathoracic complications. Hopper and Yakes (1990) reported their experience with intercostal punctures and suggested that the incidence of lung injury during full expiration was 29% on the right side and 14% on the left side. Other investigators have reported pneumothorax rates from 0% to 4% and pleural effusion rates from 0% to 8% with intercostal punctures (Picus et al, 1986; Forsyth and Fuchs, 1987; Stening and Bourne, 1998). Pardalidis and Smith (1995) suggested that in the case of nephrostomy access between the 11th and 12th ribs, approximately 10% of patients present with fluid accumulation within the pleural space. Intraoperative fluoroscopy of the chest should be used in every case of intercostal access to evaluate for fluid. Of particular use is visualization of the normally sharp costophrenic angle. If a small effusion is recognized, it may be tapped with relative ease with the patient still under anesthesia. If the effusion is larger or contains bloody fluid, a thoracostomy tube can be easily placed with the patient still prone and under anesthesia. Even in cases when intraoperative fluoroscopy is negative, some patients do present later with pneumothorax or pleural effusion (Ogan et al, 2003). The vast majority of these cases will be detected by a postoperative chest radiograph in the recovery room. **Therefore, a postoperative chest radiograph is deemed necessary to rule out hydrothorax or pneumothorax in all patients undergoing intercostal punctures.** If the clinical findings suggest either of these complications, placement of a chest tube is mandatory. Immediate aspiration is performed, and the tube is removed within 24 hours. If the hemothorax is extensive, a large chest tube is advisable.

Bowel Perforation

Colonic perforation is a rare complication of the percutaneous procedures, being reported in less than 1% of cases (Neustein et al, 1986; Morse et al, 1988; Gerspach et al, 1997). After studying the anatomic relation of the colon to the kidneys, Hadar and Gadoth (1984) reported finding a retrorenal colon in 0.6% of the evaluated cases. A retrorenal colon is more common in thin female patients. Patients with horseshoe kidneys and other irregularities of renal anatomy (e.g., renal fusion, ectopia) and those with previous jejunoileal surgery present a higher incidence of colonic perforation during percutaneous procedures. In addition, patients in whom the nephrostomy puncture is performed too laterally have an increased risk of colon injury. CT should be considered if colon enlargement is suspected, the patient is very thin, or the patient has had prior renal surgery or retroperitoneal surgery. Because usually most patients have a preoperative CT, it should be available and used to guide the puncture. The diagnosis of colonic perforation should be considered in the presence of intraoperative hematochezia, peritonitis or sepsis, or drainage of gas or feces from the nephrostomy tube. Colonic perforation may have a silent onset and eventually present only during the postoperative nephrostography, when contrast medium is seen entering the colon.

If the perforation is extraperitoneal, it can be treated conservatively. A double-pigtail ureteral stent is positioned to ensure adequate urinary drainage, and the nephrostomy tube is withdrawn to lie within the lumen of the colon. **Separation of the gastrointestinal and urinary systems is achieved and healing is facilitated, thus avoiding fistula formation.** Broad-spectrum antibiotics are administered, and radiographic studies are performed through the colostomy tube 7 to 10 days after the initial manipulation. If there is no communication between the gastrointestinal and urinary tracts, the tube is removed. Surgical correction is considered only in cases of intraperitoneal perforation of the colon or in the presence of peritonitis or sepsis.

The duodenum is positioned anteromedial to the right kidney and can be injured during right-sided percutaneous procedures if a needle or an instrument is advanced too deeply. In addition, the duodenum can be perforated if the back, stiff part of a guide wire is erroneously used for dilatation of the nephrostomy tract. This complication is less common than colonic perforation (Culkin et al, 1985). Diagnosis is based on the formation of a nephroduodenal fistula, which is seen when the postoperative nephrostography is performed.

Duodenal perforation can usually be treated conservatively with the placement of a nephrostomy tube and of a nasogastric tube to divert gastric secretions. In addition, parenteral hyperalimentation is advised. Appropriate radiographic evaluation is performed 2 weeks after the initial procedure to determine resolution of the fistula.

Injury to the Spleen and Liver

Injury of the spleen is an uncommon finding, especially when the dimensions of the organ are within the normal range. Hopper and Yakes (1990) evaluated the anatomic relations of the kidney, spleen, and ribs and showed that when a supracostal approach was used, the incidence of splenic laceration was very low. In cases of splenomegaly, the incidence of injury is higher and CT-guided nephrostomy puncture is advised to avoid perforation of the spleen. If the spleen is perforated or lacerated, there is usually significant bleeding and a surgical exploration is necessary, often leading to splenectomy.

Injuries to the liver are less common than injuries to the spleen. In cases of hepatomegaly, an increased risk arises. CT-guided nephrostomy is advised in these cases to ensure a correct and uneventful percutaneous puncture. Treatment of liver injuries is usually conservative, and open surgical exploration is rarely needed.

Sepsis

It is advised that all patients undergoing percutaneous procedures have urine cultures preoperatively with the administration of an appropriate antibiotic to sterilize the urine. Despite this precaution, sepsis has been reported in 0.25% to 1.5% of patients undergoing percutaneous stone removal (Segura et al, 1985; Rao et al, 1991). In these cases, infected urine has been systemically absorbed. Segura and colleagues (1985) suggested that 600 mL of infected extravasated fluid is enough to overcome the patient's defense mechanisms and cause sepsis. When staghorn calculi are treated, the antibiotic administered should be effective against the patient's specific pathogen as well as the usual urease-producing organisms associated with stones.

KEY POINTS: COMPLICATIONS OF PERCUTANEOUS RENAL SURGERY

- The risk of blood loss during percutaneous renal surgery is increased by excessively medial punctures, multiple punctures, and punctures into kidneys with abnormal anatomy.
- A tamponading balloon catheter (Kaye catheter) should be readily available in the surgical suite in case brisk bleeding or bleeding refractory to a large-bore nephrostomy catheter is encountered.
- Delayed bleeding after percutaneous procedures usually indicates the presence of a pseudoaneurysm or an arteriovenous fistula.
- If the renal pelvis is perforated during percutaneous surgery, maximal decompression with a ureteral stent and a nephrostomy tube should be accomplished and the procedure should be discontinued.
- Because the risk of injury to the lungs or pleura increases with more superior punctures, a postoperative chest radiograph should be obtained for all patients in whom an intercostal puncture is performed.
- In the case of colonic perforation during percutaneous renal surgery, the gastrointestinal and urinary systems should be separated to avoid fistula formation. A double-pigtail stent should be placed in the ureter and a nephrostomy tube should be placed in the colon.

PERCUTANEOUS PROCEDURES OF THE UPPER URINARY TRACT

Successful entry into the collecting system and dilation of the nephrostomy tract represent the common initial pathway of all percutaneous procedures of the upper urinary tract. Once secure access into the collecting system has been achieved, numerous therapeutic options are available to the urologist. From this vantage point, the urologist may choose to address disease processes as varied as kidney stones, UPJ obstruction, malignant or benign tumors, infections of the collecting system, and symptomatic renal cysts among many others. We review here the treatment of various disease processes of the upper urinary tract. Percutaneous management of stone disease, UPJ obstruction, and upper tract transitional cell carcinoma is covered elsewhere in this textbook.

Drainage Procedures

The most common indication for percutaneous drainage of the collecting system is obstruction that cannot be decompressed by internal retrograde means. This may be in the form of either intrinsic or extrinsic obstruction affecting the ureter, UPJ, or an infundibulum. Obstruction may be intraluminal (e.g., stone or tumor), in the ureteral wall (e.g., scarring from prior instrumentation), or extrinsic. Extrinsic obstruction is often the result of malignant compression (e.g., metastatic colon cancer, cervical cancer) or an inflammatory and fibrotic process (e.g., retroperitoneal fibrosis, prior pelvic radiation). The indications for nephrostomy tube placement include preservation of renal function, relief of pain, and emergency drainage of infected urine in the setting of obstruction.

In the instance of obstructing ureterolithiasis, either a percutaneous nephrostomy or a ureteral stent may serve to decompress the upper tract. The efficacy of one modality over the other remains controversial. One randomized prospective trial has demonstrated the superiority of percutaneous nephrostomy to ureteral stenting in the decompression of hydronephrosis caused by obstructing stones, especially in patients who are febrile (Mokhmalji et al, 2001). Yet, in a different randomized prospective trial, including patients presenting with obstructing ureteral calculi and clinical signs of infection (temperature >38°C [100.4°F] and/or a white blood cell count >17,000/mm^3), there was no advantage to percutaneous nephrostomy over retrograde stenting in terms of recovery (Pearle et al, 1998). Some studies indicate that in the instance of an obstructing stone, ureteral stenting causes more irritative urinary symptoms and local discomfort than nephrostomy tube drainage (Joshi et al, 2001). The decision of which mode of drainage to use can therefore be largely based on the clinical scenario, patient's preference, and urologist's discretion.

Similarly, the optimal method of drainage in the situation of extrinsic ureteral obstruction is controversial. In one retrospective study involving 148 patients with malignant ureteral obstruction, the difference in overall stent-related or catheter-related complications between the internal ureteral stent and percutaneous nephrostomy groups was not statistically significant (Ku et al, 2004b). However, primary stenting has demonstrated early failure rates in 51% to 58% of this patient population, ultimately necessitating percutaneous drainage (Feng et al, 1999; Shekarriz et al, 1999). In light of this, percutaneous nephrostomy drainage has been recommended as the management option of choice in instances of extrinsic obstruction by cervical cancer, bladder cancer, and other advanced abdominal malignancies (Ekici et al, 2001; Park et al, 2002; Little et al, 2003). For patients in whom life-long nephrostomy drainage is necessary, a novel technique involving subcutaneous tunneling of a nephrostomy tube with insertion of the distal end of the tube into the bladder has been reported with encouraging early results (Paterson and Forrester, 1997; Jabbour et al, 2001). **Alternatively, in the instance of malignant compression, placing two ureteral stents into one collecting system (double ureteral stenting) may be beneficial** (Fromer et al, 2002).

Uninfected Obstruction

Technique. The goal in these patients is simply to place a small percutaneous drainage tube to decompress the system with minimal manipulation. A dilated system contributes to the high success rate of this procedure. Often, because of the obstruction, the collecting system cannot be visualized by the intravenous administration of contrast material. Ultrasound guidance may be of assistance or one may use anatomic landmarks as described in the section "Percutaneous Access

without Imaging." Passage of a 22-gauge Chiba needle opposite the second lumbar process usually results in puncture of the dilated renal pelvis. With the stylet in place, the needle is advanced in increments. Every 1 to 2 cm, the stylet is removed and a syringe is placed on the end of the Chiba needle. The syringe is used to aspirate while the needle is held in place. If no urine can be aspirated, the stylet is replaced and the needle is advanced farther. It is important to prevent advancement of the needle without the stylet in place because this can clog the needle and prevent aspiration of urine even after the collecting system is entered. With alternating advancement and aspiration of the needle the collecting system is gradually approached. The aspiration of urine into the syringe signals entry of the needle tip into the collecting system. The collecting system can then be opacified by injecting contrast medium to guide a larger needle from a more appropriate posterolateral location.

The safest, most expeditious entry is by way of a posterior lower pole calyx. A 10-Fr Cope loop-type catheter is positioned in the renal pelvis and secured to the flank. When placing a nephrostomy tube, consideration should be given to the site of the lesion and to the eventual treatment modality to be used. For example, if an antegrade endopyelotomy is planned, attempts should be made to place the nephrostomy tube in an upper or middle posterior calyx to provide straight-line access to the obstructed UPJ.

Results. Successful percutaneous access to the obstructed collecting system is routinely achieved in 99% of adult patients (Pappas et al, 2000; Sim et al, 2002). Failure is most often associated with a collecting system that has become decompressed because of a ruptured fornix. In these rare instances, retrograde access may be necessary and is recommended. Interestingly, in a pediatric cohort with unilateral UPJ obstruction in a poorly functioning kidney (split renal function < 10%), placement of a nephrostomy tube improved renal function in 12 (71%) of 17 children. In these 12 patients, mean split renal function increased to 29% on the affected side (Gupta et al, 2001).

Pyonephrosis and Emphysematous Pyelonephritis

Natural History and Presentation. Pyonephrosis or pyocalyx most often results secondary to an obstructing calculus in a patient with infected urine. Patients present with acute septicemia or a chronic condition with minimal symptoms. **In the acute case, emergency drainage of the obstructed collecting system is mandatory because any delay in establishing drainage can be fatal.** In the instance of acute pyonephrosis, percutaneous nephrostomy drainage is associated with minimal morbidity, facilitates definitive treatment, and provides therapeutic benefit (Ng et al, 2002). It is important that bacterial cultures are taken from the nephrostomy at the time of placement to define causative organisms and appropriate antibiotic sensitivities.

In the instance of chronic pyonephrosis the patient's symptoms may be so minimal that the diagnosis is not initially entertained. Indeed, the patient may be afebrile and complain of only a slight amount of flank discomfort. These patients may have only a mild leukocytosis. The urine culture is often sterile. In some patients, nonvisualization of the stone-bearing calyx (e.g., "missing" or "phantom" calyx) on the intravenous urogram is the first sign of a pyocalyx (Brennan and Pollack, 1979; Meretyk et al, 1992). For any patient undergoing ESWL, intravenous urograms must be carefully reviewed to identify the presence of a phantom calyx. If a pyocalyx is inadvertently missed, the result of ESWL can be immediate urosepsis and septicemia, necessitating emergency hospital admission with subsequent percutaneous drainage of the pyocalyx and delayed percutaneous stone removal (Albala et al, 1991; Meretyk et al, 1992).

Immediate nephrectomy has been considered the standard treatment for the rare instance of emphysematous pyelonephritis (Shokeir et al, 1997). Evidence exists, however, that a minimally invasive approach consisting of CT-guided percutaneous drainage and intravenous antibiotics may be an acceptable alternative for treatment of this life-threatening condition (Chen et al, 1997; Lim et al, 2000; Mallet et al, 2002; Narlawar et al, 2004). Percutaneous drainage as opposed to immediate nephrectomy may be considered a first-line therapy more readily in those patients with emphysematous pyelonephritis who are too unstable to tolerate an operation or cannot afford additional nephron loss (e.g., renal transplant allograft) (Cheng et al, 2001). Alternatively, percutaneous drainage may complement nephrectomy if the need exists; and, therefore, treatment may be staged (Mydlo et al, 2003).

Technique. Treatment of pyonephrosis, pyocalyx, or emphysematous pyelonephritis can be most rapidly done with percutaneous antegrade drainage of the affected calyx or renal pelvis. Initially, a 22-gauge Chiba needle is passed into the obstructed system under CT or ultrasound guidance. On return of purulent material, a slight amount of contrast material is introduced to opacify the affected area of obstruction; the amount of contrast material instilled should be less than the amount of purulent material removed to preclude any pyelovenous or pyelosinus backflow and resultant septicemia. Injection of contrast agent should be avoided in the instances of emphysematous pyelonephritis or existing sepsis. Aspirated material is sent for bacterial and fungal cultures. To avoid an incidental pleurotomy, the recommended approach for the nephrostomy catheter is by way of the subcostal puncture, especially if the affected calyx is in the upper pole. As such, when trying to drain an upper pole calyx, the needle may need to be steeply angled caudally to ensure entry into the calyx below the 12th rib.

Next, a 10- or 12-Fr locking loop-type catheter is placed using a trocar or guide wire technique as previously described. As mentioned previously, no attempt is made at this time to obtain an antegrade nephrostogram because injection of contrast material into a pressurized, infected system may result in iatrogenic septicemia.

Attempts at retrograde drainage of a pyonephrotic kidney by way of a ureteral catheter are not recommended. This approach requires significant anesthesia, is more invasive, and provides less effective drainage (e.g., smaller catheter) than a percutaneous antegrade approach. In addition, maneuvering the catheter beyond the obstructed lesion may be difficult and could result in potential ureteral perforation. Also, in the situation of a pyocalyx, the placement of a retrograde catheter

into the affected obstructed calyx may not be possible, especially if the calyx is in the lower pole.

Results. Among patients with pyonephrosis or pyocalyx, adherence to the aforementioned principles can give excellent results. The importance of a subcostal approach, however, cannot be overemphasized. Indeed, in one series in which two patients were managed with intercostal (e.g., 11th intercostal space) puncture, pulmonary complications resulted. In one patient, a massive pleural effusion developed, requiring prolonged chest tube drainage. A second patient developed empyema and needed open drainage.

Renal Cysts

Presentation and Natural History. With increasing use of abdominal ultrasonography and CT over the past 3 decades, it has become apparent that simple renal cysts are a common finding in the general population. They are more often seen in men and in the elderly. By 40 years of age 27% of adults have radiographically detectable cysts; by 80 years of age, this number increases to 61% (Carrim and Murchison, 2003). In the modern era, the majority of renal cysts are discovered incidentally during abdominal imaging for nonurologic indications.

Renal cysts may grow in both number and size over time, but the majority remain clinically insignificant and do not require treatment (Terada et al, 2002). Very few patients experience symptomatic progression. Studies exploring the association between simple renal cysts and symptoms such as flank pain, hematuria, erythrocytosis, and hypertension have shown mixed results (Caglioti et al, 1993; Terada et al, 2004). It should be noted, however, that among patients with autosomal dominant polycystic kidney disease, a greater constellation of cyst-related complications may be seen: back and abdominal pain (47%), urinary tract infection (41%), urolithiasis (34%), hypertension (69%), palpable mass (15%), macroscopic hematuria (31%), and renal failure (47%) (Delaney et al, 1985; Milutinovic et al, 1990).

Most patients presenting to a urologist for treatment of renal cysts do so for relief of symptoms caused by the large size of the cysts. In the majority of these patients, the cysts have grown large enough to cause obstruction of the renal collecting system and/or compression of adjacent organs.

Percutaneous options for treatment of renal cysts include aspiration and sclerotherapy or endoscopic resection. In the past, percutaneous aspiration of cyst fluid followed by injection of sclerosing agents was considered first-line therapy for all renal cysts. Early reports suggested acceptable outcomes with this technique (Wahlqvist and Grumstedt, 1966; Ozgur et al, 1988). However, long-term data supporting the durability of sclerotherapy are not available. In addition, with reports of an increasing number of significant complications, including UPJ obstruction, cyst abscess formation, fever, pain, and recurrences, the role of cyst puncture has been limited (Perugia and Hubner, 1991; Paananen et al, 2001). **For those patients who fail sclerotherapy, have cysts in communication with the collecting system, or have cysts deemed too large to be adequately treated with aspiration and sclerotherapy, percutaneous resection should be considered.**

Technique. For both aspiration/sclerotherapy and percutaneous resection, access must first be gained directly into the cyst to be treated. Before percutaneous puncture, retrograde opacification of the collecting system using a mixture of diluted contrast material and indigo carmine can aid in directing needle entry into the cyst. Aspiration of blue fluid suggests inadvertent entry into the collecting system instead of the cyst and requires the needle to be passed again. Once access is obtained, the contents of the cyst are drained and sent for laboratory evaluation (culture, cytology, protein, lactate dehydrogenase, creatinine). A thin, clear yellow fluid is suggestive of a benign cyst, whereas sanguineous fluid may be associated with a traumatic puncture or a neoplasm. Contrast material is injected into the cyst to be certain it does not communicate with the collecting system. In addition, a slight amount of air may be injected into the cyst, thereby providing additional contrast for determining if there is any nodularity along the cyst wall; a benign cyst should have a completely smooth wall.

To proceed with sclerotherapy, after the cyst is drained, 95% ethanol (equal to 25% of the cyst volume) is instilled into the cyst. It has been shown that the epithelial lining cells are fixed by the ethanol within 3 minutes of exposure (Ozgur et al, 1988). In practice, the ethanol is left indwelling for 10 to 20 minutes to ensure complete fixation. Alternative cyst-sclerosing agents that have been reported include bismuth phosphate, tetracycline, povidone-iodine, and polidocanol among many others (Holmberg and Hietala, 1989; Peyromaure et al, 2002; Brunken et al, 2002).

After direct access into the cyst has been gained, the nephrostomy tract is dilated over a guide wire and a 30-Fr sheath is placed into the cyst if percutaneous resection is to be carried out. After the cyst is internally inspected with a 26-Fr rigid nephroscope, a standard 26-Fr resectoscope is inserted. The entire cyst wall is fulgurated using a rollerball electrode. Glycine is used for irrigation throughout the procedure. After the fulguration, a portion of cyst wall can be excised with grasping forceps to marsupialize the cyst into the retroperitoneum. Alternatively, the cyst can be marsupialized directly into the collecting system, either to the renal pelvis or a calyx by viewing the indigo carmine in the collecting system through the nearly transparent cyst wall (Fig. 46–30) (Kang et al, 2001). Marsupialization of the cyst cavity into the collecting system does not necessarily reduce the risk of recurrence and some urologists do not consider it an imperative step of the procedure. In all patients, a percutaneous drain is left inside the cyst cavity overnight and the patient is discharged after its removal.

As an alternative to the direct method of percutaneous resection, the cyst may be approached indirectly from the collecting system. With the indirect method, a calyx adjacent to the cyst is accessed and the cyst is approached from within the collecting system. Similar to the direct method, the cyst is marsupialized into the collecting system and the portions of the cyst wall that do not border the collecting system are fulgurated to promote obliteration of the cystic cavity.

Results. Aspiration without sclerosis is known to be of little therapeutic value (Raskin et al, 1975). With aspiration alone, only 10% to 20% of the cysts disappear or have a 50% or more reduction in volume over the ensuing follow-up (Wahlquist

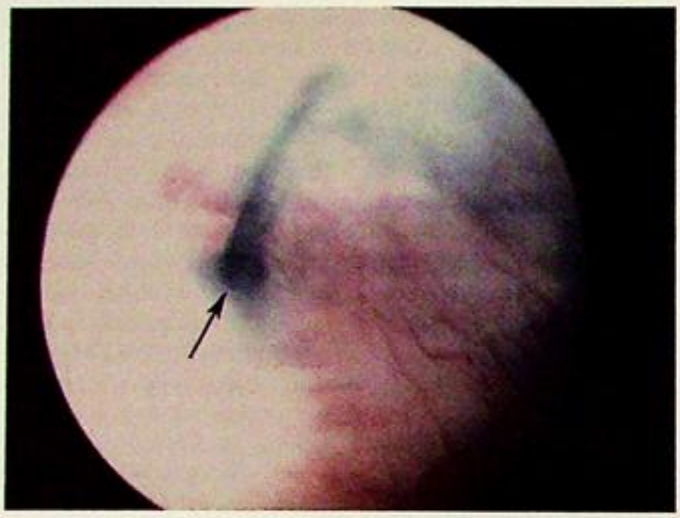

Figure 46–30. Indigo blue dye seen entering a renal cyst *(arrow)* through small communication channel.

and Grumstedt, 1966; Holmberg and Hietala, 1989). Sclerotherapy results in a satisfactory outcome in 75% to 100% of patients with small cysts (Bean, 1981; Zachrisson, 1982; Ozgur et al, 1988; Holmberg and Hiatala, 1989). Some investigators have found multiple sessions of percutaneous sclerotherapy for simple renal cysts to be more effective in reducing the recurrence of simple renal cysts than single-session percutaneous sclerotherapy (Hanna and Dahniya, 1996; Chung et al, 2000). Chung and colleagues (2000) noted 95% complete regression of simple cysts with two sclerotherapy sessions compared with only 19% complete regression with single-session percutaneous sclerotherapy. Long-term data supporting the durability of sclerotherapy to 5 years or beyond, however, are not available. Also, some physicians have not been able to duplicate the initial sanguine reports previously cited. Perugia and associates (1991) noted that with a 20% volume of the cyst replaced with 98% ethanol, none of five patients had a satisfactory result (defined as >50% decrease in the size of the renal cyst).

Reports of an endoscopic approach to simple renal cysts have appeared sporadically in the literature (Eikenberg, 1985; Hulbert et al, 1988b; Wong and Griffith, 1994). Hubner and colleagues (1990) reported one of the largest experiences and noted an early success rate of 93%; however, when follow-up was extended to 46 months in 10 patients, 50% of the treated cysts were again either detectable or close to their preoperative size (Plas and Hubner, 1993). In a modern series of 9 patients followed for a mean of 21 months after percutaneous cyst resection, Kang and colleagues (2001) reported complete resolution of pain in 8 patients (89%) and complete obliteration of the cyst in 7 patients (78%).

Alternative Treatment Options. Other methods that may be considered in the management of renal cysts include open and laparoscopic cyst decortication. These modalities are often reserved for patients who fail percutaneous resection or who are deemed poor candidates for the percutaneous approach. In particular, patients with multiple cysts or cysts difficult to approach percutaneously (e.g., anteriorly located cysts) may be treated most effectively with the laparoscopic approach (Hemal, 2001; Lam and Gupta, 2002).

Calyceal Diverticula

Presentation and Natural History. Calyceal diverticula are congenital cystic extensions of the renal collecting system into the normal renal parenchyma that communicate with the main collecting system via a narrow channel. They are lined with nonsecretory transitional cell epithelium and are thought to arise from minor calyceal fornices. Unlike a hydrocalyx, which may be acquired later in life, calyceal diverticula are believed to be congenital lesions. They are relatively rare entities, diagnosed in less than 0.5 % of all intravenous urograms. One third to one half of patients with calyceal diverticula present with pain, infection, hematuria, or calculi (Timmons et al, 1975).

Calyceal diverticula do not produce urine because their epithelial lining is nonsecretory. They do, however, fill with urine flowing retrograde from the collecting system. Hence, they may sometimes only be seen on delayed images of an intravenous urogram or by relatively high-pressure retrograde pyelography.

For patients with incidentally discovered calyceal diverticula no treatment is necessary. However, for patients presenting with pain, recurrent urinary tract infection, hematuria, symptomatic calculi, or progressive renal damage, treatment should be undertaken. The surgical approach to these lesions involves either excision or marsupialization of the diverticulum with occlusion of the neck of the diverticulum by suture or electrocautery. If the diverticulum is large, a partial nephrectomy may be necessary (Abeshouse and Abeshouse, 1963). Since the early 1990s, the treatment of calyceal diverticula has shifted increasingly toward minimally invasive methods (Clayman et al, 1984; Hulbert et al, 1988a). Minimally invasive treatment has included ESWL (of stones in a diverticulum), ureteroscopy (dilation or incision of the neck with or without fulguration of the lining), and percutaneous methods (fulguration of the lining, dilation or incision of the neck, or both).

Technique. After retrograde placement of an occlusion balloon ureteral catheter, the collecting system is opacified until the calyceal diverticulum is well outlined. Then, using an 18-gauge nephrostomy needle a fluoroscopically guided puncture is made directly into the calyceal diverticulum itself. A hydrophilic coated guide wire may be successful with perseverance in slipping through the neck of the diverticulum, but more often than not the neck is not blindly accessible and the wire must be coiled in the diverticular cavity. If the diverticulum is large enough to accommodate a second wire, a safety wire is also placed before the nephrostomy tract is dilated. For dilation, a 10-mm balloon catheter may be preferable. Dilating the tract with sheath dilators is more difficult and may result in an anterior false passage of the diverticulum. A 30-Fr Amplatz sheath is placed into the diverticulum, after which the rigid nephroscope is introduced. Any calculus present is treated by either intact removal or ultrasonic nephrolithotripsy (Clayman et al, 1984).

Next, saline with indigo carmine stain, or room air, is gently instilled through the retrograde ureteral occlusion balloon

catheter while the surgeon examines the interior of the calyceal diverticulum with the rigid or flexible nephroscope. Blue fluid or air bubbles should be seen traversing the neck of the diverticulum. If this is not the case, the Amplatz sheath may be too deep into the diverticulum. The sheath should be carefully withdrawn 1 to 2 cm under endoscopic control while the assistant continues to instill air (10-mL bolus) or fluid gently into the retrograde ureteral catheter. Once the neck of the diverticulum is visualized, a guide wire can be passed across the neck of the diverticulum and coiled in the renal pelvis. If a metal guide wire is used, after its passage across the diverticular neck, a 5-Fr angiographic catheter is passed over the guide wire to insulate it. In the case of an anterior calyceal diverticulum, the neck will likely never be seen, in which case cannulation will not be possible and the interior of the diverticulum should be thoroughly fulgurated.

At this point, the rollerball or barrel electrode mounted on a standard 24- or 26-Fr resectoscope is introduced into the diverticular cavity. The entire surface of the diverticulum is then electrocoagulated except for the immediate area surrounding the neck of the diverticulum (Fig. 46–31) (Hulbert et al, 1987).

Next, the neck of the diverticulum is treated. This can be done most simply by balloon dilation of the neck of the diverticulum with a 4-cm-long ureteral dilating balloon. Some urologists prefer to cut the neck of the diverticulum under direct vision with either a cold knife (e.g., direct vision urethrotome), electrosurgical probe (2- or 3-Fr Greenwald electrode) or holmium:yttrium-aluminum-garnet (YAG) laser. Again, if electrosurgery is to be used, any metal guide wire in the surgical field must be covered with a 5-Fr angiographic catheter so that no electric current is transmitted to the guide wire. Several shallow incisions (2 to 4 mm) are made in the

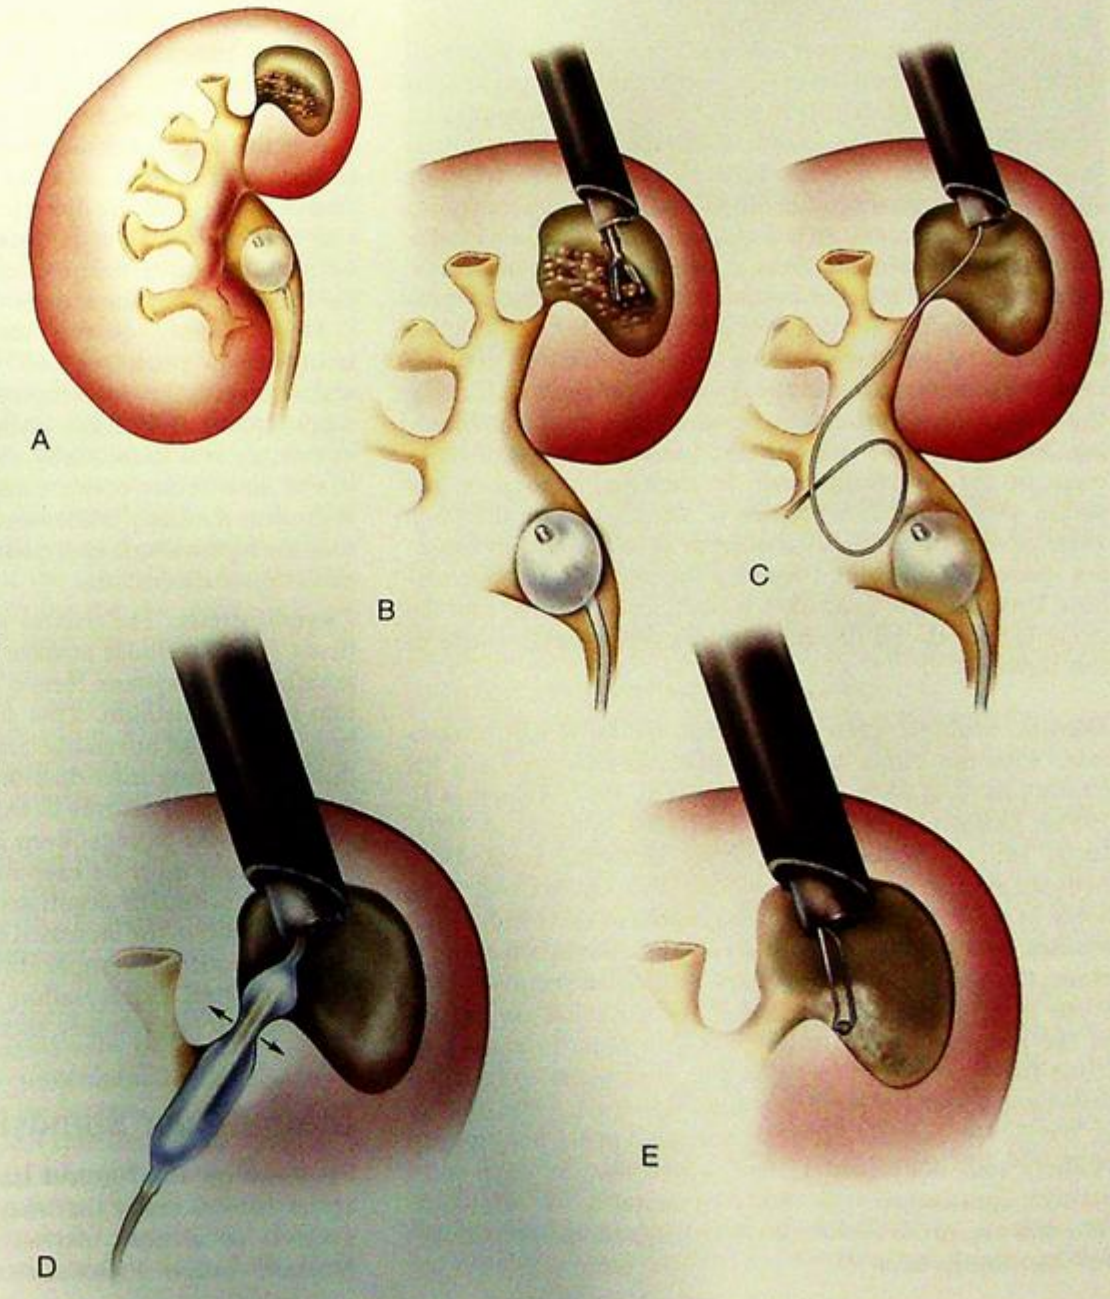

Figure 46–31. **A,** Superior pole calyceal diverticulum containing multiple small stones. **B,** A percutaneous tract is established directly into the diverticulum and the stones are extracted with grasping forceps. **C,** A guide wire is negotiated through the narrow neck of the diverticulum and into the main collecting system. **D,** A balloon dilation catheter is advanced over the wire until the balloon cuff sits in the neck of the diverticulum. Inflation of the balloon in this position allows for dilation of the diverticular neck. **E,** A rollerball or barrel electrode is used to fulgurate the diverticular cavity. Last, a large-bore nephrostomy tube traversing the diverticular neck is placed *(not shown)*.

neck of the diverticulum in a radial fashion (12, 3, 6, and 9 o'clock). A solitary deep cut into the diverticular neck should be avoided because this may result in significant hemorrhage (Clayman et al, 1984).

After the neck of the diverticulum is opened, a large-bore (22 Fr) nephrostomy tube is placed such that its shaft traverses the diverticulum and the tip of the catheter lies in the renal pelvis. The nephrostomy tube can be removed as early as 3 days after the procedure (Hulbert et al, 1986). Indeed, prolonged drainage of the kidney and stenting of the diverticular neck do not appear to improve results (Hulbert et al, 1988a; Jones et al, 1991).

A faster, and perhaps simpler, alternative is not to identify the diverticular neck. Instead, the entire surface of the diverticulum, including the area of the unidentified diverticular neck, is thoroughly cauterized using the roller electrode. A 22-Fr drainage catheter is placed only to tamponade the percutaneous tract; the tip of the catheter thus resides in the calyceal diverticulum. The "calycostomy" tube is removed on the following morning, provided that there is no drainage.

In addition to the direct antegrade percutaneous approach to calyceal diverticula, an *indirect* percutaneous approach has also been reported (Hulbert et al, 1986). For this approach, access to the collecting system is obtained at a site removed from the calyceal diverticulum and the diverticulum is approached from within the collecting system. This method is not preferred by many endourologists and is fraught with difficulty and poor results. First, a usually nonhydronephrotic collecting system must be punctured. Next, the surgeon must locate the diminutive communication between the calyceal diverticulum and the collecting system. After this step, the neck must be opened and the diverticulum entered. Incising the neck of the diverticulum, however, often results in bleeding, which obscures visibility and impairs subsequent treatment of the diverticular wall. In addition, removal of any stones within the diverticulum is complicated by the steep angle of entry into the diverticulum as well as by any bleeding caused by dilating or incising the neck of the diverticulum. Ureteroscopic and ESWL techniques for dealing with the stone-laden calyceal diverticulum are discussed elsewhere in this textbook.

Results. Multiple authors have reported fairly high success rates with the direct antegrade percutaneous approach for treating calyceal diverticula (Eshghi et al, 1987; Hulbert et al, 1988a; Janetschek, 1988; Ellis et al, 1991; Jones et al, 1991; Lang, 1991; Schneider et al, 1991; Hendrikx et al, 1992; Bellman et al, 1993; Van Cangh et al, 1994; Grasso et al, 1995; Soble et al, 1995). **Combining the results of these individual studies, of 134 patients with a calyceal diverticulum and a stone, the percutaneous approach resulted in removal of the stone in 86% and obliteration of the diverticulum in 80% of the patients.** Recent studies confirm these findings with stone-free rates of 78% to 95% and diverticular obliteration rates around 80% (Donnellan and Harewood, 1999; Auge et al, 2002). The indirect percutaneous method has poor results. Hulbert and colleagues (1986) noted that in their three patients approached with indirect punctures, the diverticula were still present in all three on follow-up radiographic studies 4 to 14 months later.

Alternative Treatments. Nonpercutaneous minimally invasive modalities for treatment of calyceal diverticula include ureteroscopy, ESWL, or a combination of ureteroscopy and ESWL. With ureteroscopy, Mikkelsen and coworkers (1989) successfully treated only two of six calyceal diverticula. In one of the successful cases, two ureteroscopic procedures were required because of postoperative bleeding from the diverticulum. In their series of 17 patients treated ureteroscopically for calyceal diverticula, Auge and colleagues (2002) reported a stone-free rate of only 19%.

Similarly, with ESWL as front-line therapy, Psihramis and Dretler (1987) noted that 70% of patients became asymptomatic after treatment. At the time of follow-up, however, 80% still had stone fragments within the diverticula. In all patients studied, the diverticula remained intact. Indeed, even under the most favorable circumstances, the stone-free rate after ESWL is only 40% (Streem and Yost, 1992; Van Cangh et al, 1994) and can be as poor as 6% (Jones et al, 1991). In none of the ESWL patients did the calyceal diverticulum disappear.

Fuchs and David (1989) have combined ESWL with ureteroscopy for dilation of the calyceal neck and stone extraction in 15 patients with stone-containing calyceal diverticula. Their overall stone-free rate of 73% is an improvement over ESWL monotherapy; however, although less morbid, it is not as effective as an antegrade percutaneous approach. Likewise, treatment of the diverticulum was limited to balloon dilatation of the neck of the diverticulum; in only 47% of the cases was obliteration or a decrease in size of the diverticulum noted. With this technique, only diverticula in the upper and middle portion of the kidney can be effectively accessed.

More recently, several investigators have reported on laparoscopic treatment of calyceal diverticula. Hoznek and coworkers (1998) employed an extraperitoneal laparoscopic approach in three women with symptomatic calyceal diverticula and successfully obtained watertight obliteration of the diverticular cavity using gelatin resorcinol formaldehyde glue. Similarly, Miller and associates (2002) successfully used the laparoscopic approach to treat five patients with anterior calyceal diverticula.

Complications. The narrow ostium of many calyceal diverticula often precludes passage of a guide wire into the main renal collecting system. Hence, the guide wire is advanced only into the diverticulum. This small amount of wire provides little mechanical advantage and can easily become kinked or dislodged during tract dilation. The repetitive insertion and removal of serial dilators in this situation can lead to the creation of a false passage. Even if a balloon dilation catheter is used, caution must be exercised during tract dilation if the guide wire cannot be negotiated through the diverticular neck.

In addition to the increased risks of nephrostomy tract dilation, the potential complications of significant hemorrhage, retroperitoneal extravasation, pneumothorax, hemothorax, and adjacent organ injury should be kept in mind.

Infundibular Stenosis

Presentation and Natural History. Infundibular stenosis is a rare clinical entity that may be caused by extrinsic compression or intrinsic narrowing of a renal infundibulum. Extrinsic causes include retroperitoneal malignancy and

retroperitoneal fibrosis. Intrinsic conditions affecting the wall of the infundibulum include neoplasm, tuberculosis, and chronic scarring induced by multiple renal calculi, long-standing calculi, prior renal surgery, and so on. Rarely, infundibular obstruction may be caused by an upper pole crossing a segmental artery, in which case the condition is known as Fraley's syndrome (Fraley, 1966; Eshghi et al, 1987). In some situations, infundibular stenosis may be complete, resulting in a condition described as an excluded calyx (Elashry et al, 1996).

Similar to patients with calyceal diverticula, patients with infundibular stenosis may present with flank pain, hematuria, recurrent urinary tract infection, or, less commonly, progressive renal damage. They also commonly present with a radiologic finding of a dilated calyx (hydrocalyx). Hydrocalyces and calyceal diverticula often can be difficult to distinguish only from clinical and radiologic information. In these instances, nephroscopy can be useful because the presence (hydrocalyx) or absence (calyceal diverticulum) of a renal papilla is diagnostic. Treatment of patients with infundibular stenosis is indicated to relieve obstruction and to restore adequate drainage of urine into the main collecting system. If one suspects the presence of an obstructing crossing segmental renal artery, an arteriogram should be obtained before any endourologic therapeutic maneuvers because this condition mandates an open surgical repair (Eshghi et al, 1987).

Figure 46–32. Intravenous pyelogram shows a radiolucent filling defect of the left ureter in a healthy young woman who presented with left flank pain. The patient underwent percutaneous resection of the mass, and pathologic examination revealed fibrovascular stroma covered by nonpapillary transitional cell epithelium consistent with the diagnosis of fibroepithelial polyp.

Technique. The percutaneous antegrade technique for infundibular stenosis is initially similar to the approach for treating a calyceal diverticulum (Fig. 46–32). Retrograde opacification of the collecting system with a ureteral occlusion balloon catheter is used to facilitate direct percutaneous puncture onto the hydrocalyx. If the calyx is not visualized, as in the case of an excluded calyx, ultrasound or CT guidance may be necessary for puncture. After insertion of a working wire (and safety wire if possible) the nephrostomy tract is dilated and an Amplatz sheath is advanced directly into the calyx. The stenotic infundibulum is visualized and cannulated with a wire if possible. If the mouth of the infundibulum cannot be located, air or dilute indigo carmine may be injected via the retrograde catheter to facilitate detection of the opening. In the situation of an excluded calyx, a wire may be advanced up the retrograde catheter (under fluoroscopic guidance) and directed up to the point of obstruction. Manipulation of the wire from below while the operator observes with the nephroscope may permit successful cutdown through the stenosed segment.

Once a wire has been negotiated into the main collecting system, the narrowed segment may be addressed in one of several ways. It may be dilated with a balloon dilation catheter, incised with a direct vision urethrotome, cauterized with a 2- or 3-Fr electrosurgical probe, or radially incised with a holmium:YAG laser. If electrocautery is to be used, the metal guide wire must either be insulated with a 5-Fr angiographic catheter or exchanged for a nonconductive plastic wire. According to anatomic studies by Sampaio (1996), the incision should be made along the less vascular superior and inferior aspects of the middle calyceal infundibulum or the medial and lateral aspects of the upper calyceal infundibulum. Usually, a 2-mm incision is made on the superior and the inferior aspect of the infundibulum. A single deep cut is to be avoided because this may result in marked bleeding. Before making an incision, the area to be incised should be carefully inspected for the presence of any arterial pulsations. After the incision is completed, the patency of the infundibulum can be further gauged by passing a 7-mm dilating balloon catheter across the incised infundibulum. The balloon should inflate to 21 Fr at low pressure (less than 1 atm).

For postoperative drainage a nephrostomy tube of any size can be left through the infundibulum to drain the renal pelvis with or without a separate double-pigtail stent and Foley catheter. Alternatively, a large caliber (e.g., 8 Fr) double-pigtail stent can be placed to drain the hydrocalyx across its infundibulum and a separate nephrostomy tube placed into the hydrocalyx. No studies have ever demonstrated that eventual patency of the infundibulum is dependent on the type, size, or duration of drainage used.

Another therapeutic approach to infundibular stenosis is an indirect percutaneous approach. Puncturing the collecting system through an unaffected calyx and trying to approach the stenotic infundibulum in a retrograde fashion with a nephroscope is tedious and may be less efficacious than a direct antegrade approach. As with calyceal diverticula, this approach should be avoided.

Results. Reported series of percutaneously treated infundibular stenoses are few. Commonly, reports on calyceal

diverticula are mixed with cases of hydrocalyx, such that the "true" success rates may appear overly sanguine (Eshghi et al, 1987; Janetschek, 1988). Lang (1991) reported a 60% success rate in six patients with an isolated hydrocalyx using simple balloon dilation of the infundibular stenosis and a 4-week period of stenting. With regard to actual incision of the infundibulum, Schneider and coworkers reported a 67% success rate in nine patients with infundibular stenosis with a mean follow-up of 15 months (Schneider et al, 1991). More recently, Hwang and Park (1994) recorded an 80% success rate in 10 patients with tuberculous infundibular strictures who had undergone a cold knife incision. **It appears that in contrast to calyceal diverticula, in which a successful outcome is obtainable in nearly 90%, infundibular stenosis is a more difficult entity to treat via the endourologic approach, with only a 60% to 80% success rate.**

Fungal Bezoars

Fungal bezoars are rare infectious concretions of the kidney that may be seen in patients with funguria. They have been reported in patients with fulminant fungal pyelonephritis as well as in patients with asymptomatic fungal colonization of the urine. The clinical presentation can vary greatly ranging from urinary obstruction to gross hematuria to sepsis. *Candida* species are most commonly associated with fungal bezoars, but *Aspergillus* infections have also been reported (Irby et al, 1990). Risk factors for the development of fungal bezoars include diabetes mellitus, neurogenic bladder, chronic antibiotic use, and the presence of indwelling urinary catheters (Schonebeck and Ansehn, 1972; Dembner and Pfister, 1977). Elderly, transplant, and human immunodeficiency virus–infected patients as well as premature infants may also be at risk depending on their level of immunocompromise (Wise, 2001; Ku et al, 2004a).

Fungal bezoars may be treated with medical and surgical therapies. In the preoperative or seriously ill patient, a course of amphotericin B or flucytosine is initiated. Once adequate serum levels are obtained, topical irrigation of the affected collecting system with amphotericin B (50 mg/L at 25 to 50 ml/hr) can be given through either two retrograde ureteral catheters (one for inflow; one for outflow) or an antegrade nephrostomy tube (Harbach et al, 1970; Wise, 1990). After antibiotic coverage has resulted in sterile urine cultures, the bezoar can be removed percutaneously or by open surgery (Karlin et al, 1987).

Technique. Percutaneous removal of a fungal bezoar requires meticulous attention to detail. Initially, the renal pelvis is irrigated with amphotericin B via a retrograde catheter to decrease the hypothetical possibility of retroperitoneal seeding of fungus. A subcostal lower pole approach is used to access the collecting system, and the nephrostomy tract is dilated with a 10-mm balloon dilation catheter. An intercostal approach should be avoided because inadvertent entry into the pleural cavity may result in fungal empyema.

Manipulation of the renal parenchyma and the potential for retroperitoneal extravasation are minimized by the use of a balloon dilation catheter and a 30-Fr Amplatz sheath.

On visual inspection bezoars have a gray-white or yellow-gray appearance. The consistency is similar to that of a blood clot. If smaller than 1 cm, the bezoar may be extracted intact from the collecting system; however, for larger concretions, the suction on the ultrasonic lithotriptor probe is useful for bezoar evacuation. The flexible nephroscope is helpful to access every calyx to ensure that all fungal concretions have been cleared from the collecting system. At the end of the procedure, a large catheter is secured as a nephrostomy tube and the retrograde ureteral catheter can be left in place. If antegrade nephrostogram on postoperative day 1 reveals no extravasation and no remaining concretions, irrigation with amphotericin B (50 mg/L at 50 mL/hr) can be performed by way of the ureteral catheter for 48 to 72 hours (Wise et al, 1982).

Results. In general, reports of fungal bezoars are rare. Schonebeck and Ansehn (1972) noted only 29 cases of upper tract fungal concretions in the literature. The presence of an upper tract fungal bezoar in association with an unrelieved ureteral obstruction has a mortality rate in the 80% range. Given the infrequent occurrence of this problem, it is not surprising that there is a paucity of experience with regard to the percutaneous management and removal of fungal concretions (Dembner and Pfister, 1977; Abramowitz et al, 1986; Karlin et al, 1987; Banner et al, 1988; Doemeny et al, 1988; Keane et al, 1993). Since the early 1990s, fewer than 50 cases of percutaneous therapy for renal fungal bezoars have been reported (Irby et al, 1990; Babut et al, 1995; Karpman et al, 2003; Campbell et al, 2004; Ku et al, 2004a). In this limited group of patients, successful endourologic treatment has occurred in approximately 80% with minimal attendant morbidity and mortality.

Fibroepithelial Polyps

Fibroepithelial polyps of the renal pelvis and ureter are rare benign mesodermal tumors. Grossly, most fibroepithelial polyps are long slender projections with a smooth surface presenting as a single or multiple fronds arising from a common base. Histologically, these polyps are composed of a cone of fibrovascular stroma emerging from the submucosa and covered by a layer of nonpapillary transitional cell epithelium (Bolton et al, 1994). These lesions are typically found in young patients, with the most common presenting complaints being hematuria and flank pain. In children, fibroepithelial polyps have been described as an uncommon cause of UPJ obstruction (Macksood et al, 1985). A fibroepithelial polyp should be suspected when an intravenous urogram or a retrograde pyelogram reveals a radiolucent filling defect of the upper urinary tract with persistently negative urine cytology (see Fig. 46–32). The treatment of these benign polyps is dictated by the degree of obstruction, involvement of the urinary tract, and intraoperative impression of carcinoma. In the past, open exploration and resection was the mainstay of therapy. Recently, percutaneous resection also has been shown to be an effective treatment option (Lam et al, 2003).

Technique. With the assistance of retrograde opacification, a percutaneous access tract into an upper or middle pole posterior calyx is created and secured. Nephroscopy is used to identify the stalk of the fibroepithelial polyp, and a resectoscope with a thin wire loop is used to excise the stalk completely from the renal pelvis. Biopsy forceps are then used to

extract the mass in piecemeal fashion until it is removed in its entirety.

For polyps located in the ureter, a 12/14-Fr ureteral access sheath is placed down the ureter after the percutaneous tract is established. A flexible 7-Fr ureteroscope is used to identify the stalk of the polyp, and a holmium:YAG laser is used to resect the base of the stalk from the ureteral wall. A large ureteroscopic basket is used to remove the specimen in its entirety.

At the end of the procedure, both a ureteral stent and a nephrostomy tube are placed. The nephrostomy tube is removed before discharge from the hospital. An intravenous urogram may be performed 3 months after fibroepithelial polyp resection to confirm disappearance of the filling defect.

Results. Fibroepithelial polyps are rarely encountered in clinical practice. Fewer than 200 cases have been documented in published reports. Experience with percutaneous resection of fibroepithelial polyps remains predictably limited. One patient with a large polyp (>20 cm) in the renal pelvis and two patients with smaller ureteral polyps were all successfully managed with percutaneous resection (Lam et al, 2003). With a mean follow-up period of 19.6 months, all three patients remained free of recurrence and none developed ureteral strictures.

Ureteroenteric Anastomotic Strictures

In patients who have undergone urinary diversion or bladder substitution with bowel segments, strictures at the ureteroenteric anastomotic site occur not uncommonly. Early strictures are typically due to ureteral ischemia, and late strictures may be due to fibrosis or progression of malignant disease. Retrograde endoscopic management often proves impossible, owing to acute angulation at the ureteral insertion sites. Although frequently employed, open surgical repair can be complicated by dense scarring and adhesions as well as by comorbid conditions in these generally elderly patients.

Percutaneous approaches to ureteroenteric anastomotic strictures have been described (Gupta and Smith, 1996). After establishment of a nephrostomy tract, strictures may be treated by balloon dilation or endoscopic incisional ureterotomy followed by stent placement across the anastomosis. Results of balloon dilation of ureteroenteric strictures vary widely in the literature (Martin et al, 1982; Banner and Pollack, 1984; Shapiro et al, 1988). One series of 14 patients who underwent endoscopic incisional ureterotomy for ureteroenteric strictures reported a 57% success rate with over 2 years of follow-up (Meretyk et al, 1991).

Other Therapeutic Uses

The urologic conditions discussed earlier represent only a minority of the disease processes of the upper urinary tract that may be managed percutaneously. Currently, the most common indications for establishment of a nephrostomy tract are management of large burden stone disease, treatment of UPJ obstruction, and decompression of an acutely obstructed urinary system. Treatment of upper tract transitional cell carcinoma via the percutaneous route is also becoming increasingly more common.

As experience with percutaneous access to the renal collecting system has increased, this approach has been broadened for the treatment of other intra-abdominal pathology. Interventional radiologists are frequently called on to drain retroperitoneal fluid collections such as perinephric abscesses, urinomas, and lymphoceles with percutaneously placed catheters.

The percutaneous approach to the kidney has also been used for diagnostic purposes. Radiologists and nephrologists routinely perform percutaneous renal biopsies for patients with medicorenal disease. For patients in whom UPJ obstruction is suspected and radionuclide renal imaging is equivocal, the Whitaker test represents another option for diagnosing UPJ obstruction (Whitaker, 1979). Although rarely performed, it remains an accurate method for quantifying hydrostatic pressure differences between the renal pelvis and the bladder.

KEY POINTS: PERCUTANEOUS PROCEDURES OF THE UPPER URINARY TRACT

- In the instance of urosepsis secondary to collecting system obstruction, drainage by a percutaneous nephrostomy tube or a ureteral stent is mandatory because any delay in establishing drainage can be fatal.

NEPHROSTOMY DRAINAGE

Nephrostomy Drainage and Addressing the Access Tract

External drainage of the pelvicalyceal system after percutaneous procedures of the upper urinary tract (i.e., percutaneous nephrolithotomy) has been routine practice among endourologists. Evidence that once suggested there was not a definitive role for external drainage after some percutaneous procedures (Wickham et al, 1984; Bellman et al, 1997; Delaney and Wake, 1998; Goh and Wolf, 1999) has translated into the modality of "tubeless percutaneous renal surgery" in select patients at some institutions (Limb and Bellman, 2002). In addition, use of hemostatic sealants at the renal parenchymal defect after tubeless percutaneous procedures (i.e., nephrolithotomy) has shown some benefit in limiting postoperative urine extravasation and aiding in hemostasis (Mikhail et al, 2003; Lee et al, 2004; Noller et al, 2004). Nevertheless, **postoperative drainage with a nephrostomy tube after percutaneous renal surgery remains a safe and standard practice.** The decision on which type of external drainage device, if any, to use postoperatively largely depends on the extent of postprocedure bleeding and whether a repeat intervention through the nephrostomy tract will be undertaken in a relative short period of time.

The main function of a postprocedure nephrostomy tube is to divert and drain urine from the structures acutely expanded and inflamed during dilatation and instrumenta-

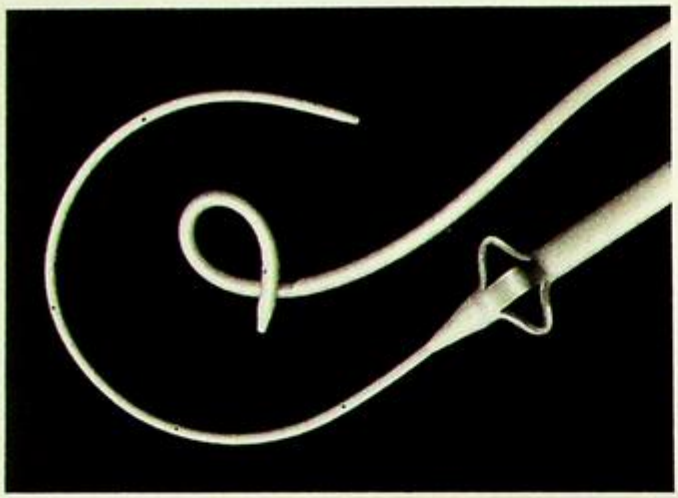

Figure 46–33. Pigtail nephrostomy catheter.

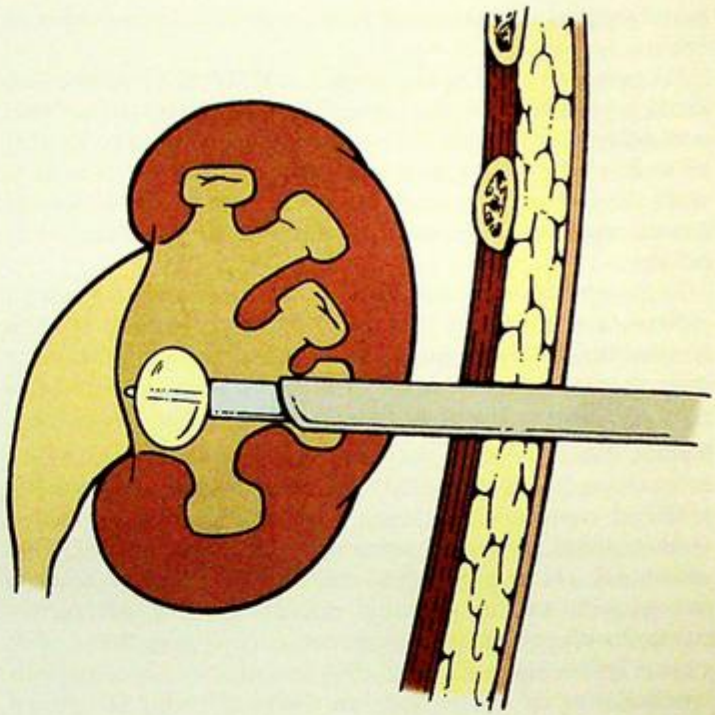

Figure 46–34. Councill catheter.

tion of the renal parenchyma and urothelium. Postprocedure edema will obstruct antegrade urinary flow. Furthermore, a sizeable nephrostomy tube will rapidly drain bloody urine before obstructing clot forms and serve to tamponade postoperative bleeding. The minimal diameter of the nephrostomy tube required for satisfactory percutaneous urinary drainage is considered to be 8 or 10 Fr. The untoward event of tube dislodgment has greatly been reduced by the use of self-locking pigtail nephrostomy catheters, which are available in sizes up to 14 Fr (Fig. 46–33). Many investigators favor the use of larger catheters for urinary drainage after acute tract dilatation to 24 to 30 Fr. Among the most widely used tubes are the Councill-type catheters with a retention balloon close to their tips. These tubes can be inserted by sliding them over a guide wire. If a working sheath is being used during the endoscopic procedure, a large nephrostomy drainage tube can be inserted through it before its removal. The sheath will then have to be excised with scissors (Fig. 46–34). One disadvantage of these catheters is that the balloon can occlude certain calyces and can subsequently cause pain.

Malecot Tubes

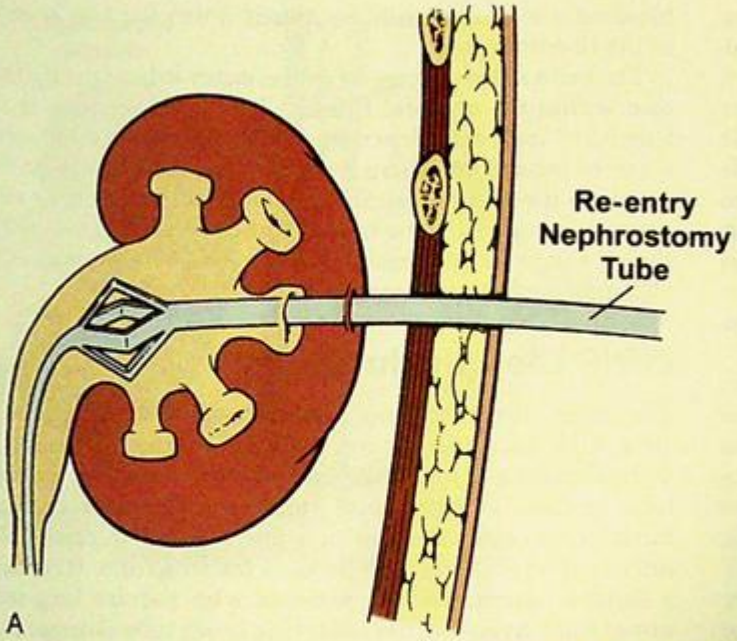
Other commonly used nephrostomy drainage tubes are those with Malecot tips. The mushroom-style tip design of these catheters allows for unimpeded nephrostomy drainage without the concern of obstructing a calyx. A very popular variation of these catheters is available with a distal 18-cm extension that is 5 to 8 Fr. This re-entry Malecot catheter is inserted over a guide wire and is provided with an internal stiffener. When the stiffener is introduced, the wings collapse and the tube is easily placed. When the tube is in position, it provides external urinary drainage with the Malecot tip in the renal pelvis while its 8-Fr tip lies within the distal end of the ureteral lumen. These catheters have the advantage of maintaining ureteral access if needed and also provide stenting at the UPJ if needed. A disadvantage of these catheters, however, is that their retention mechanism is not very secure (Fig. 46–35).

Pigtail Catheters

The standard pigtail external drainage catheter is an angiographic-type polyethylene tube, usually ranging in size from 5 to 14 Fr, with the distal end tapered (see Fig. 46–33). Pigtail catheters are typically used for simple percutaneous drainage. Urinary drainage is ensured by multiple side holes in the pigtail portion. Pigtail catheters are available in polyethylene, polyurethane, silicone, C-Flex, and Percuflex. **Percuflex offers the best ratio of internal to external diameter, excellent tensile strength and coil retention, a relatively low coefficient of friction, and good biocompatibility.** C-Flex is not as strong as Percuflex but has good coil retention strength, durability, and biocompatibility. Polyurethane has a high tensile strength and strong coil retentive properties but suboptimal biocompatibility. Silicone and hydrogel-coated catheters seem to be more biocompatible (Mardis et al, 1993; Cormio et al, 1995).

The pigtail design of the distal segment reduces the risk of accidental dislocation. The small diameter of these catheters facilitates their insertion and provides satisfactory drainage, obviating use of a larger tube. Even though they are equipped with the pigtail form, they do not have a self-retaining mechanism. Thus, one of the greatest drawbacks of these catheters is the ease with which they can move out of their original position, hindering drainage.

The Cope loop catheter was designed to overcome this problem of the standard pigtail catheters (Fig. 46–36). The Cope catheter has a nylon suture connecting the most distal side hole to the end of the catheter. When traction is exerted on this suture, a loop is formed by a locking mechanism triggered when the suture is tied to the external end of the catheter just below the hub and covered with a rubber sleeve. The catheter is secured to the skin either by a plastic retention disk



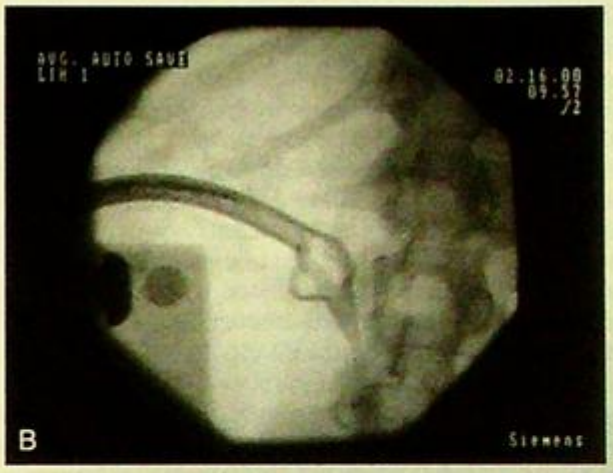


Figure 46–35. A and B, Malecot catheter.

Figure 46–36. Cope loop catheter.

or a nylon suture. A simple gravity drainage bag is connected to the system (Lee, 1995).

The self-locking capability, softness, and high coefficient of friction of C-Flex material are the main advantages of the Cope loop catheter (Banner and Pollack, 1985). Its insertion can be simplified with the use of a flexible cannula stiffener that slides over a 0.038-inch guide wire, following gentle curves along the tract.

Even the Cope loop catheter presents certain drawbacks. The main problem is that if a **tight loop forms and the end hole becomes encrusted, the catheter becomes very difficult to remove. In addition, if the catheter is mistakenly cut, string may be left within the collecting system acting as a nidus for infection and stone formation.** Furthermore, the passage of the guide wire for catheter exchange can be very demanding. This catheter is suitable mainly for patients with a large renal pelvis. The loop formation requires the insertion of approximately 3 cm of pigtail catheter into the renal pelvis. Thus, the insertion of the catheter into a nondilated system could become particularly difficult. The tension of the nylon string of the locking mechanism in a patient with a small pelvis can cause serious tears by an action mimicking that of a cheese cutter. For this same reason, it is absolutely necessary to fully release the string before removing this catheter to avoid a serious renal parenchymal laceration.

Even though smaller catheters may be appealing, they have limitations in function and drainage capabilities. **The retention mechanism of the Malecot and the pigtail catheters often proves to be inefficient. In obese and hypermobile patients, these tubes are often pulled out.** The tubes also may not serve their purpose in patients with significant intrarenal bleeding, fragmented calculi, or mucus production. Furthermore, if there is a need to use the nephrostomy tract for repeated percutaneous procedures, a larger tube may allow such intervention, under local anesthesia and without the need for further tract dilatation.

Balloon Retention Catheters: Councill and Foley

Because of the problems of tube dislodgement, many urologists favor the use of a larger, self-retaining nephrostomy drainage catheter. One of the design specifications of all nephrostomy catheters is an end hole for passing a guide wire through the catheter tip. The presence of this wire is essential for initial placement, subsequent replacement, and repeat access to the kidney.

Most Councill and Foley catheters are constructed of latex rubber with a variety of coatings. Silicone, polytef, and hydrophilic coatings are available for these latex catheters (Carson, 1995) (see Fig. 46–34). Self-retaining balloon catheters have balloon capacities of 5 mL and range from 12 Fr to 32 Fr. Drainage through the Foley catheters is through two side holes located in offset positions on the distal portion. **Balloons should always be inflated with water or saline. The use of contrast material should be avoided, because the contrast materials have a higher viscosity than water and can occlude the balloon inflation port, jeopardizing balloon deflation for catheter removal.**

Re-entry Tubes

The re-entry nephrostomy tube is made of C-Flex and is structured as a 24-Fr Malecot catheter in association with an 18-cm extension from the distal end of the Malecot tip. This extension has a diameter of 8 Fr, and its distal tip has drainage holes. The Malecot configuration secures the catheter within the renal pelvis. When a hollow introducer is inserted, the Malecot wings are flattened, enabling catheter insertion. **The advantages of the re-entry tube are the ability to access the renal pelvis and ureter, a wider lumen for drainage, softer material (and thus more comfort for the patient), and the safety of removing the tube.**

The percutaneous tract is dilated to a minimum of 26 Fr, and the guide wire is advanced down the ureter toward the bladder. The re-entry tube, with an introducer in place and the wings collapsed, is advanced over the guide wire under fluoroscopic control. We favor the use of a guide wire, thus avoiding kinking of the wire or buckling of the tube in the pelvicalyceal system. **The final position of the nephrostomy tube is ascertained fluoroscopically to be certain the Malecot wings are within the renal pelvis, the distal tip of the catheter is at the UPJ, and its tail is down the ureter** (see Fig. 46–35).

One of the great advantages of this tube is that, as its names indicates, **it enables easy access to the pelvicalyceal system and ureter when re-entry is needed.** The introducer is inserted under fluoroscopic control and locked into the Luer-Lok exterior end of the tube. This connection must be made cautiously because the distal end of the introducer may exit the Malecot wings. If this occurs, the tube should be slowly and partly withdrawn, causing the collapse of the Malecot wings against the renal parenchyma. With this technique, the introducer can be aligned with the tube, and then a guide wire can be advanced down the ureter. After wire placement, the tube can safely be removed (Badlani, 1995).

When debris is present, the guide wire often cannot be advanced through the tip of the re-entry tube. The tube should be retracted until the tip of the Malecot catheter is seen to protrude outside the nephrostomy tract. Access to the ureter is maintained by the 18-cm tail of the tube. A guide wire can then be forwarded directly through the tip.

In addition, when the nephrostomy tube is removed (48 to 72 hours after the initial percutaneous procedure), the re-entry tube enables the **safe monitoring of any potential bleeding from the tract.** This can be achieved by removing the Malecot wings from the nephrostomy tract. The tract should then be observed before removing the tail. In case of bleeding, a wire can easily be passed down the 8-Fr segment of the re-entry tube.

The main disadvantage of the re-entry tube is the tip location within the ureteral lumen. The distal segment is one length (18 cm), and, depending on the patient's dimensions, it can be located anywhere from the site of the common iliac vessels to the ureterovesical junction. Caution must be exercised when advancing the tip down the ureter, a maneuver that should always be performed over a guide wire to avoid complications such as perforation.

Circle Loop Nephrostomy

The circle tube or U-loop nephrostomy was introduced in 1954, and since then there has been a great evolution in ureteral stents and nephrostomy catheters. However, the circle tube remains an alternative because it is easily changed, rarely encourages infection or stone formation, causes little intrarenal trauma, and can be used for irrigation. **It remains a suitable alternative for patients who require long-term upper tract diversion, necessitating fewer tube changes than the single nephrostomy catheters** (Oshinsky and Smith, 1995).

Initially, percutaneous access is achieved through a lower pole calyx, the tract is dilated to 12 Fr, and a Malecot-type catheter is positioned. With the aid of fluoroscopy, a second site is selected for the next percutaneous access. The new site must not be in proximity to the previous one: otherwise, the circle tube may kink in the renal pelvis. After the correct position has been identified, an 18-gauge needle is inserted into the predetermined calyx and a guide wire is advanced through the needle into the renal pelvis.

A flexible nephroscope or a rigid ureteroscope is then inserted through the lower pole tract, sliding along the guide wire, and the guide wire in the upper tract is grasped. After through-and-through communication has been established between the two tracts, an 8-Fr coaxial dilator is advanced over the guide wire and the circle tube is advanced over this catheter. The circle tube must have radiopaque markings in the region of the drainage holes to assist with positioning under fluoroscopic guidance such that the drainage holes are within the pelvicalyceal system.

When the insertion is concluded, the circle tube is clamped and nephrostography is performed to confirm its accurate position. The ends of the tube are then assembled to a Y-connector and connected to a drainage bag (Fig. 46–37).

Large Bore versus Small Bore

Nephrostomy tubes are available in sizes ranging from 5 to 32 Fr. Larger tubes usually provide better drainage at the expense of greater patient discomfort and urinary leak. In one prospective study, for example, there was a statistically significant difference in the analgesic need and the duration of urinary leak, favoring use of a 9-Fr pigtail catheter over a 28-Fr nephrostomy tube after percutaneous nephrolithotomy (Maheshwari et al, 2000). In an additional percutaneous nephrolithotomy (PCNL) study, use of smaller drainage catheters after PCNL (10-Fr pigtail vs. 22-Fr Councill) was associated with lower pain scores during the immediate postoperative period. However, no statistical benefit, with regard

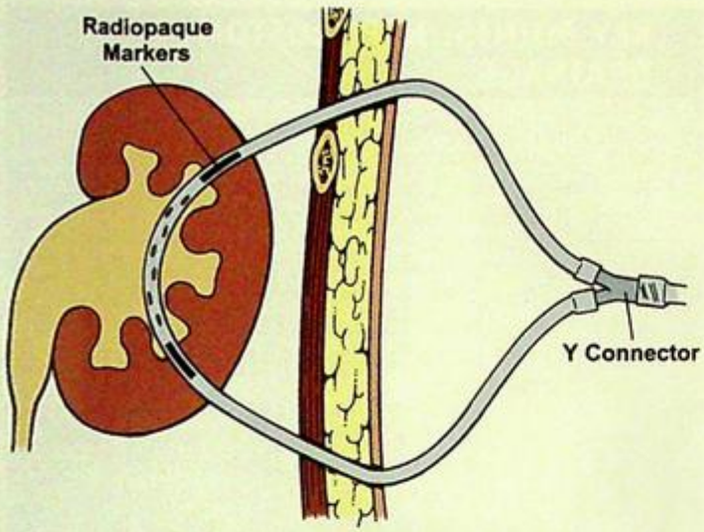

Figure 46–37. Circle loop nephrostomy.

to comfort, was demonstrated regardless of tube size after 6 hours (Pietrow et al, 2003). Similarly, 7-Fr tail stents have been better tolerated after PCNL compared with 24-Fr re-entry Malecot nephrostomy tubes (Liatsikos et al, 2002). Desai and colleagues (2004) compared postoperative outcomes among tubeless, conventional large-bore (20 Fr) and small-bore nephrostomy (9 Fr) drainage after PCNL in a randomized prospective fashion. Postoperative analgesic requirements, urinary extravasation, duration of hematuria, duration of urinary leak, decrease in hematocrit, and hospital stay were compared among the three groups. Tubeless PCNL was associated with the least postoperative pain, urinary leakage, and hospital stay. Important to note was that there was no difference in duration of hematuria or decrease in hematocrit whether a nephrostomy tube was used or not, regardless of size. In contrast, a prospective randomized study comparing use of either a 24-Fr re-entry tube, an 8-Fr pigtail catheter, or a ureteral stent (with removal of an 18-Fr Councill catheter on postoperative day 1) after PCNL, there was no overwhelming advantage of any one drainage system over the other (Marcovich et al, 2004).

With regard to prolonged urinary drainage from a nephrostomy tract after PCNL without evidence of obstruction, oral desmopressin has been shown to be an alternative modality to decrease urinary leak (Cimentepe et al, 2004).

Tubeless Nephrostomy and Use of Sealants and Hemostatic Agents

Just over 20 years ago, Wickham and associates (1984) introduced the concept of a one-stage tubeless nephrolithotomy with a reported high success rate. What was once conceptual and novel in practice has now become routine at some institutions in select cases. Tubeless percutaneous renal surgery has also been shown to be safe and effective in the morbidly obese requiring PCNL or endopyelotomy (Yang and Bellman, 2004) and in instances of bilateral percutaneous nephrolithotomy (Weld and Wake, 2000).

Approaching the realm of tubeless renal surgery, Lojanapiwat and colleagues (2001) demonstrated a reduction in patient discomfort in patients who underwent an uncomplicated tubeless PCNL with an externalized 6-Fr ureteral stent for 48 hours. However, Feng and associates (2001) performed a prospective randomized trial to assess the efficacy and morbidity of standard PCNL (34-Fr sheath), "mini-PCNL" (26-Fr sheath), and tubeless PCNL (double J ureteral stent used for drainage). Compared with those who underwent standard and "mini" PCNL, the tubeless PCNL population required less morphine and had a decreased length of hospitalization. In addition, the tubeless technique was associated with the least morbidity and greatest cost efficiency.

Limb and Bellman (2002) also assessed the outcomes and safety of tubeless percutaneous renal surgery in select patients who underwent PCNL (n = 86; mean stone burden = 3.30 cm^2) and antegrade endopyelotomy (n = 26). When internal ureteral stents were placed without external drainage tubes in this cohort, there was a reduction in hospital stay and analgesic requirements with an earlier return to normal activities. These findings have recently been reproduced in similar, albeit smaller, studies (Aghamir et al, 2004; Karami and Gholamrezaie, 2004; Patel and Abubacker, 2004). To overcome the possible bothersome bladder symptoms and need for cystoscopic removal of a standard ureteral stent, use of a 7-Fr/3-Fr tail stent with the string exiting the urethral meatus has been described as a modification to the standard tubeless nephrostomy technique (Yew and Bellman, 2003). In addition to the obvious clinical benefit of tubeless percutaneous renal surgery, it is important to note the economic advantage when utilizing the tubeless technique (Bellman et al, 1997; Candela et al, 1997; Feng et al, 2001).

Mikhail and coworkers (2003) retrospectively compared outcomes after the use of fibrin glue (Tissel Vapor Heated Fibrin Sealant, Baxter Healthcare) in the nephrostomy tract after tubeless PCNL. Differences in the hematocrit drop between the experimental and control groups were not statistically different. **Although the use of fibrin glue was demonstrated to be safe in this study, a definitive clinical benefit was not demonstrated.** In contrast, a noncomparative study by Noller and colleagues (2004) assessed the ability of fibrin sealant (2 mL of HEMASEEL APR—Hemacure Corp., Sarasota, FL) to facilitate tubeless PCNL in 10 renal units with an average stone burden of 3.37 cm^2. The goal was to prevent urinary extravasation and promote early hospital discharge without the inconvenience of urinary leak from the access site after antegrade placement of a ureteral stent. All patients in this study were discharged on postoperative day 1 without evidence of soaked dressings or extravasation on postoperative CT. Similarly, in a small pilot study (n = 2), injection of a gelatin matrix hemostatic sealant (FloSeal, Baxter Medical, Fremont, CA) into the nephrostomy tract after tubeless PCNL demonstrated value in providing immediate and effective hemostasis (Lee et al, 2004). **It is clear that injection of hemostatic agents into nephrostomy tracts after tubeless PCNL is safe and feasible. However, additional clinical studies are needed to prove a definitive clinical benefit after percutaneous renal surgery.**

Cauterization of the Access Tract

Placement of a large-bore nephrostomy tube at the conclusion of an extensive percutaneous procedure such as a PCNL has

been the traditional method to control and tamponade postoperative hemorrhage. In an effort to reduce bleeding after a percutaneous procedure, the efficacy and safety of access tract cauterization has been investigated. Jou and colleagues (2004a, 2004b), for example, described the use of an 8-Fr, 20-inch elongated electrode probe through the working channel of a nephroscope to cauterize obvious points of bleeding in a large cohort of patients after tubeless PCNL. In these studies, use of electrocautery proved to be safe and effective in decreasing the transfusion rate without increasing patient morbidity. In contrast, Aron and associates (2004) showed no statistical difference between change in hemoglobin after tubeless PCNL with or without the use of diathermy coagulation. Interestingly, however, the length of hospitalization and postoperative analgesic requirements were significantly less in the fulguration group. If one wishes to cauterize identifiable bleeding points after percutaneous renal surgery a holmium:YAG laser or a flexible Bugbee cautery may alternatively be used. **It is difficult to fulgurate bleeding of renal parenchymal origin; in doing so, bleeding may be aggravated rather than quelled.**

Conclusions

If used, the *ideal* nephrostomy tube should have excellent biocompatibility and strength, be well tolerated by the patient, resist obstruction or dislodging, and be simple to insert and replace (Paul et al, 2003). Regardless of these parameters, there is really no panacea for drainage after percutaneous surgeries (Marcovich et al, 2004). **The choice as to which drainage modality used is largely dependent on the clinical scenario (i.e., complicated vs. uncomplicated, degree of bleeding, likelihood of obstructing edema), the endourologist's preference, the likelihood of repeat interventions, and patient tolerability** (Table 46–2). Foregoing placement of nephrostomy drainage after a percutaneous procedure (tubeless nephrostomy) is safe and feasible in select patients (i.e., minimal bleeding and no need for repeat nephroscopy). Future studies on tubeless percutaneous procedures with the use of hemostatic agents and sealants, with or without the use of cautery, will determine the exact role of these compounds in percutaneous renal surgery.

Table 46-2. Choosing Appropriate Nephrostomy Tube Drainage

Clinical Indication	*Suggested Nephrostomy Tube and Tract Management*
Acute obstruction, simple temporary drainage	Pigtail, Cope loop catheter
Uncomplicated percutaneous renal surgery	Tubeless ± cautery or hemostatic sealants, Malecot catheter, Balloon catheter
Complicated percutaneous renal surgery	Councill tip Catheter, Kaye tamponade catheter
Minor mucosal damage or post-endopyelotomy care	Malecot re-entry tube, Smith endopyelotomy stent (14 Fr/7 Fr)
Long-term drainage, administration of topical chemotherapy, pyelopyelostomy	Circle loop nephrostomy tube

KEY POINTS: NEPHROSTOMY DRAINAGE

- Postoperative drainage with a nephrostomy tube after percutaneous renal surgery remains a safe and standard practice. Choice of tube placement is largely dependent on the clinical scenario.
- The advantages of using a Malecot re-entry tube are the ability to access the renal pelvis and ureter, a wider lumen for drainage, softer material (and thus more comfort for the patient), and the safety of removing the tube.
- Tubeless nephrostomy is an option in select patients when there is no significant postprocedure bleeding, perforation, or extravasation; the renal unit is not obstructed; and repeat nephroscopy will not be required.
- If an obvious site of bleeding is noted in the nephrostomy tract, cautery may be used to promote hemostasis; fibrin sealant may then be used to seal the tract or a large-bore nephrostomy tube can be placed.

FUTURE DIRECTIONS

The future for percutaneous renal surgery is bright. Continued technologic advancements in endourologic training (Hammond et al, 2004), imaging (Krombach et al, 2001), ureteroscopic design (Ankem et al, 2004; Bratslavsky et al, 2004; Monga and Beeman, 2004), bio-impedance–based access needles (Hernandez et al, 2001), and robotic systems (Eichel et al, 2004) will ultimately refine assisted percutaneous access techniques to pinpoint accuracy. Ongoing evolution and progression in endourologic science will translate into more efficacious percutaneous renal surgeries for the disease processes affecting the upper urinary tracts.

Innovations in Imaging

Although significant advances have been made in CT and MRI to perfect three-dimensional tissue imaging, the future role that these expensive and cumbersome imaging modalities will play in access for standard percutaneous renal surgery access is questionable. CT and MRI, however, will continue to facilitate safer percutaneous access in special circumstances (i.e., retrorenal colon, spinal dysraphism) in which other imaging modalities cannot ensure secure access. Newer technology involving **real-time CT fluoroscopy under laser guidance** has also allowed for efficient and safe percutaneous nephrostomy placement when difficult access to the pelvicalyceal system has been encountered while minimizing radiation exposure (LeMaitre et al, 2000). This advanced imaging modality can maximize operator hand distances away from the gantry (>25 cm) and reduce the radiation dose to the operator's hand to 0.4 mrad/s (4 μGy/s) (de Mey et al, 2000).

Successful puncture of the collecting system, however, is ultimately confirmed by the return of urine through the needle. Porcine experiments on **ultrasound-guided nephros-**

tomy with the aid of a magnetic field-based navigation device have addressed this limitation, allowing for accurate puncture needle placement in plane or out of plane from any direction, independently of the position of the transducer (Krombach et al, 2001). Perhaps in the future, this technology may play an increased role in effective real-time imaging for obtaining standard percutaneous access.

Innovations in Access: PAKY, Smart Needle, and Ureteroscopically Assisted Access (UAA)

Attempts have been made to apply robotics to nephrostomy puncture, with the intent to make access easier and more precise. The Urobotics Laboratory at Johns Hopkins University (Caddedu et al, 1997, 1998) has developed and assessed a fluoroscopic-based mechanical robot arm with an active remote center of motion translational device for percutaneous access to the kidney (PAKY-RCM). The device is mounted to the operating table and works in conjunction with a fluoroscopic unit to monitor the path and depth of needle insertion. Important to note is that the PAKY-RCM system does not require computer-based image processing for image correction and calibration (Kim and Schulman, 2004).

In pilot studies the PAKY-RCM arm has provided a steady needle holder and an effective method for obtaining percutaneous renal access. Early findings suggested that the PAKY might be the mechanical platform necessary for the development of a complete robotic system for ensuring percutaneous renal access. Since then robotic **PAKY has proved to be a safe and efficacious method of obtaining access before percutaneous nephrolithotomy** (Su et al, 2002); the number of attempts, blood loss, and time to access are comparable to those of standard manual percutaneous access techniques. Use of the PAKY-RCM system has also proved to be safe and effective in international telementoring, promoting collaborative efforts to teach percutaneous access techniques among urologists at remote locations (Micali et al, 2000; Bauer et al, 2001; Netto et al, 2003). Perhaps in the future, robotic technology will continue to be a driving force in the progress of percutaneous renal surgery.

Standard percutaneous access to the upper urinary tract without a robotic system relies on a sound foundation of renal anatomy coupled with the aid of imaging modalities. Even so, multiple attempts to enter a desired calyx may often have to be undertaken to ensure proper placement. Furthermore, until urine is aspirated or flows from the needle sheath, appropriate access cannot be confirmed. In light of this, **an impedance-based percutaneous Smart Needle system has been developed to provide an objective means to confirm proper collecting system access** (Hernandez et al, 2001). The impedance system is built into an 18-gauge percutaneous access needle system in which the inner stylet is electrically insulated from the outer sheath. In ex-vivo porcine kidneys, a characteristic drop in resistivity can be demonstrated when the needle transitions from the renal parenchyma into a saline-infused collecting system. An impedance-based percutaneous access system may prove to be useful to endourologists performing percutaneous renal surgery, easily differentiating between renal parenchyma, blood, and urine.

Advances in flexible dual active deflection ureteroscope design (e.g., ACMI DUR-8 Elite, Storz Flex-X) have facilitated retrograde access to any calyx of interest (Ankem et al, 2004). As discussed in the section on retrograde access techniques, ureteroscopic-assisted access is a technique that may be utilized in instances of morbid obesity, tightly branched staghorn calculi, and a hypermobile, malrotated, or ptotic kidney. The present status of ureteroscopic design allows for better retrograde assisted access technique. Further innovations in ureteroscope technology and durability will continue to perfect ureteroscopically assisted access as an option for retrograde access.

Innovations in Drainage

As discussed in the section on nephrostomy drainage, the concept of tubeless nephrostomy in select cases (i.e., uncomplicated without urothelial damage or significant bleeding) has proved to be a well-tolerated and economically beneficial modality at the conclusion of some percutaneous renal surgeries. Any future innovations in nephrostomy tube drainage will adhere to the principles of excellent biocompatibility and strength and resistance to obstruction or dislodgement, will be well tolerated, and be simple to insert and replace. It is clear that injection of hemostatic agents into nephrostomy tracts after tubeless PCNL is safe and feasible. However, additional clinical studies will clarify the role of such agents in the paradigm of percutaneous renal surgery.

HISTORICAL CONSIDERATIONS

The introduction of nephrectomy and other subsequent surgical interventions for renal diseases provided the clinical information and histopathologic insight that form the basis of current concepts of renal tumors. Harris (1882) reported on 100 surgical extirpations of the kidney, a sufficient number to permit analysis of clinical, surgical, and pathologic features of renal disorders that require surgery. The first documented nephrectomy was apparently accomplished in 1861 by Wolcott, who operated with the mistaken assumption that the tumor mass was a hepatoma. In 1867, Spiegelberg removed a kidney incidentally in the course of excising an echinococcus cyst. The first planned nephrectomy was performed by Simon in 1869 for persistent ureteral fistula, and this patient survived with cure of the fistula. One year later (1870), the first planned nephrectomy in the United States was successfully accomplished by Gilmore in Mobile, Alabama, for treatment of atrophic pyelonephritis and persistent urinary tract infection (Glenn, 1980).

With surgical intervention, tissue became available to pathologists for histologic interpretation. Unfortunately, such interpretation was not always accurate, and there were often serious professional differences of opinion. According to Carson (1928), the first accurate gross description of kidney tumors dates to 1826, with Konig's observations. In 1855, Robin examined solid tumors apparently arising in the kidney and concluded that renal carcinoma arose from renal tubular epithelium. This interpretation was confirmed by Waldeyer in 1867. Unfortunately, theoretical and practical considerations of renal tumors were confused by Grawitz (1883), who contended that such apparent renal tumors arose from adrenal rests within the kidney. He introduced the terminology *struma lipomatodes aberrata renis* as descriptive nomenclature for the tumors of clear cells that he believed were derived from the adrenal glands. He based his conclusions not only on the fatty content of the tumors, analogous to that seen in the adrenal glands, but also on the location of the tumors beneath the renal capsule, the approximation to the adrenal glands, the lack of similarity of the cells to uriniferous tubules, and the demonstration of amyloid similar to that seen with adrenal degeneration.

This histogenetic concept was adopted by subsequent investigators, and pathologists of the era readily embraced the idea that renal tumors truly arose from the adrenal glands. In 1894, Lubarch endorsed the idea of a suprarenal origin of renal tumors, and the term *hypernephroid tumors,* indicating origin above the kidneys, was advocated by Birch-Hirschfeld (Birch-Hirschfeld and Doederlein, 1894). This semantic and conceptual mistake led to the introduction of the term *hypernephroma,* which predominates in the literature describing parenchymal tumors of primary renal origin.

Weichselbaum and Greenish (1883) described renal adenomas containing both papillary and alveolar cell types. Some clarification of the histopathology of renal tumors is derived from the work of Albarran and Imbert (1903), and the four-volume contribution of Wolff (1883), written between 1883 and 1928, adds further historical significance to the understanding of renal tumors today (Glenn, 1980).

The modern era has brought an appreciation that renal cell carcinoma includes a number of distinct subtypes derived from the various parts of the nephron, each with a unique genetic basis and tumor biology (Linehan et al, 2003). **Other major advances in the past several decades have included the introduction of radical nephrectomy followed by a trend toward nephron-sparing surgery and, more recently, a variety of minimally invasive approaches** (Robson, 1963; Uzzo and Novick, 2001; Abreu and Gill, 2003; Herr, 2005). **One common theme that has persisted is that renal cell carcinoma remains primarily a surgical disease—it is still considered the paradigm of the chemorefractory tumor,** and although immune-based therapies have shown

promise, overall response rates remain low (Negrier et al, 2002; Milowsky and Nanus, 2003). Recent efforts have focused on multimodal strategies in addition to a variety of novel therapeutic approaches (Flanigan et al, 2004). Unfortunately, the incidence of renal cell carcinoma is gradually increasing, and despite a trend toward earlier detection, mortality rates remain high.

CLASSIFICATION

The most comprehensive classification of renal tumors is that offered by Deming and Harvard (1970) in a previous edition of this text. They established 11 categories of renal tumors, with multiple subdivisions embracing virtually every known new growth that may involve the kidney, including various renal cystic disorders as well as perirenal retroperitoneal tumors that may involve the kidney secondarily. This classification is reproduced here (Table 47–1) because it provides the most succinct presentation of renal tumors yet retains accuracy and inclusiveness.

An effort must be made, however, to provide a classification that is both complete and uncomplicated, embracing all the lesions that predispose an individual to a renal mass or new growth. Such a simplified classification was proposed by Glenn (1980) (Table 47–2). Benign tumors include those of the renal capsule (such as fibroma), renal parenchymatous adenomas, vascular tumors, various cystic lesions and dysplasias, heteroplastic and mesenchymal tumors, and even various hydronephroses. Tumors of the renal pelvis, not a primary consideration here, include benign papillomas as well as transitional, squamous, and adenocarcinomatous malignant neoplasms. Pararenal tumors are those that involve the kidney by extension and invasion, and they may be either benign or malignant. Embryonic tumors include predominantly nephroblastoma (Wilms' tumor) and the embryonic or mesotheliomatous carcinomas and sarcomas of childhood.

Table 47–1. Classification of Renal Tumors

Tumors of the Renal Capsule

Fibroma
Leiomyoma
Lipoma
Mixed

Tumors of the Mature Renal Parenchyma

Adenoma
Adenocarcinoma
  Hypernephroma
  Renal cell carcinoma
  Alveolar carcinoma

Tumors of the Immature Renal Parenchyma

Nephroblastoma (Wilms' tumor)
Embryonic carcinoma
Sarcoma

Epithelial Tumors of the Renal Pelvis

Transitional cell papilloma
Transitional cell carcinoma
Squamous cell carcinoma
Adenocarcinoma

Cysts

Solitary
Unilateral multiple
Calyceal
Pyogenic
Calcified
Tubular ectasia
Tuberous sclerosis
Cystadenoma
Papillary cystadenoma
Dermoid
Pararenal or perirenal cysts
  Hydrocele renalis
  Lymphatic
  Wolffian
Malignant

Vascular Tumors

Hemangioma
Hamartoma
Lymphangioma

Neurogenic Tumors

Neuroblastoma
Sympathicoblastoma
Schwannoma

Heteroplastic Tissue Tumors

Adipose
Smooth muscle
Adrenal rests
Endometriosis
Cartilage

Benign Tumors

Renal capsule
Renal parenchyma
Vascular tumors
Cystic lesions, dysplasia, hydronephrosis
Heteroplastic, mesenchymal tumors
True oncocytoma

Tumors of Renal Pelvis

Benign papilloma
Transitional and squamous cell carcinomas, adenocarcinomas

Pararenal Tumors

Benign
Malignant

Embryonic Tumors

Nephroblastoma (Wilms' tumor)
Embryonic, mesotheliomatous tumors
Sarcomas

Nephrocarcinoma

Renal cell carcinoma, adenocarcinoma, "hypernephroma"
Papillary cystadenocarcinoma

Other Malignant Tumors

Primary: mesenchymal, hemangiopericytoma, myeloma
Secondary: metastatic lesions

Table 47–3. Renal Masses Classified by Pathologic Features

Malignant	*Benign*	*Inflammatory*
Renal cell carcinoma	Simple cyst	Abscess
Conventional	Angiomyolipoma	Focal pyelonephritis
Chromophilic	Oncocytoma	Xanthogranulomatous pyelonephritis
Chromophobic	Renal adenoma	Infected renal cyst
Collecting duct	Metanephric adenoma	Tuberculosis
Urothelium based	Cystic nephroma	Rheumatic granuloma
Transitional cell carcinoma	Mixed epithelial-stromal tumor	
Squamous cell carcinoma	Reninoma (JG cell tumor)	
Adenocarcinoma	Leiomyoma	
Sarcoma	Fibroma	
Leiomyosarcoma	Hemangioma	
Liposarcoma	Vascular	
Angiosarcoma	Renal artery aneurysm	
Hemangiopericytoma	Arteriovenous malformation	
Malignant fibrous histiocytoma	Pseudotumor	
Synovial sarcoma		
Osteogenic sarcoma		
Clear cell sarcoma		
Rhabdomyosarcoma		
Wilms' tumor		
Primitive neuroectodermal tumor		
Carcinoid		
Lymphoma		
Leukemia		
Metastases		
Invasion by adjacent neoplasm		

Wilms' tumor, the common renal malignant neoplasm of childhood, is addressed elsewhere in this book, as are neuroblastoma, renal cystic disorders, and primary retroperitoneal tumors. Nephrocarcinoma is the generic category that includes adult renal parenchymatous malignant neoplasms, primarily the classic hypernephroma and papillary adenocarcinoma. The category of other malignant tumors comprises relatively rare mesenchymal malignant neoplasms, such as the various sarcomas, hemangiopericytomas, infiltrative malignant neoplasms such as myeloma, and secondary or metastatic malignant neoplasms manifesting within the renal substance. Oncocytoma has been added to Glenn's original classification in the category of benign tumors.

Another approach has been taken by Barbaric (1994) **in which renal masses are classified on the basis of pathologic features (malignant, benign, or inflammatory)** (Table 47–3) **or radiographic appearance (simple cysts, complex cysts, fatty tumors, and others)** (Table 47–4). We have updated this classification scheme on the basis of current knowledge about the distinct subtypes of renal cell carcinoma and recent advances in our understanding of the various benign and malignant tumors of the kidney. This classification is practical and should assist in the differential diagnosis of renal masses.

RADIOGRAPHIC EVALUATION OF RENAL MASSES

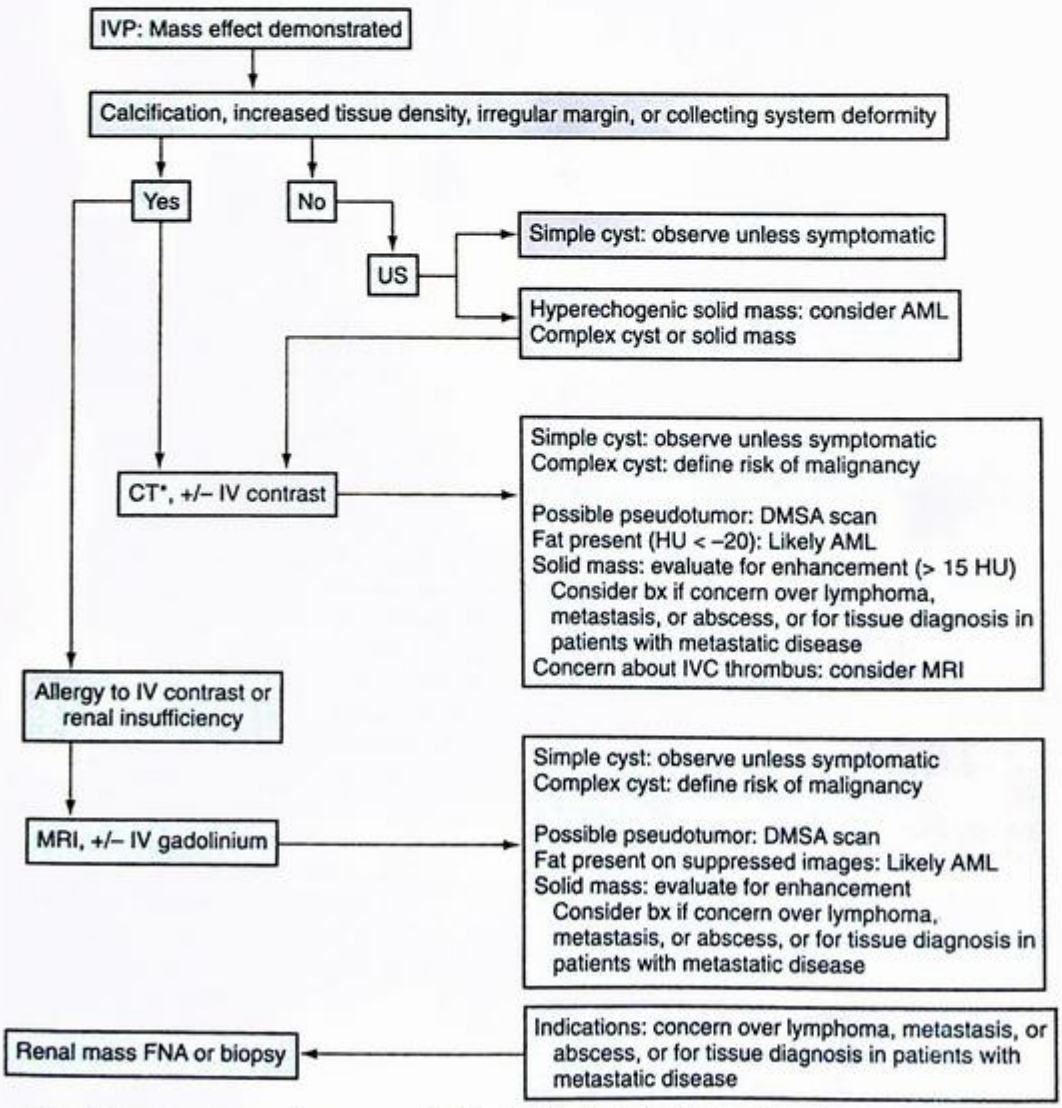
Several radiographic modalities are currently available for detection and evaluation of renal masses, each with relative strengths and weaknesses (Davidson et al, 1997; Zagoria, 2000; Israel and Bosniak, 2003a). A systematic method is necessary to ensure complete evaluation of suspected renal masses, given the large differential diagnosis and considerable overlap between benign and malignant renal lesions (Fig. 47–1; see Table 47–4).

Intravenous pyelography remains a commonly used test for the evaluation of hematuria; in the past, it was often the first test that indicated a renal mass in many patients. However, the lack of sensitivity and specificity of intravenous pyelography for the detection of parenchyma tumors is well documented. In particular, intravenous pyelography may miss small anterior or posterior lesions that do not distort the collecting system or the contour of the kidney. **When a renal mass is identified on intravenous pyelography, features suggestive of malignancy include calcification within the mass, increased tissue density, irregularity of the margin, and distortion of the collecting system** (Zagoria, 2000).

When a renal mass is identified by intravenous pyelography, unless the mass has features suggestive of malignancy, ultrasonography should be the next study performed because it is noninvasive, accurate, and relatively inexpensive (Davidson et al, 1997). Ultrasonography is reliable for differentiation of solid tissue from fluid and can establish the diagnosis of a simple renal cyst. **Strict sonographic criteria for simple cysts have been defined and include a smooth cyst wall, a round or oval shape without internal echoes, and through-transmission with strong acoustic shadows posteriorly.** If these criteria are met, observation is sufficient in an asymptomatic patient.

Table 47–4. Renal Masses Classified by Radiographic Appearance

Simple Cystic	*Complex Cystic*	*Fatty Tumors*	*All Others*
Cyst	Cystic nephroma	Angiomyolipoma	Renal cell carcinoma
Multiple cysts	Cystic renal cell carcinoma	Lipoma	Sarcomas
Peripelvic cysts	Hemorrhagic cyst	Liposarcoma	Lymphoma, leukemia
Calyceal diverticulum	Infected cyst		Metastases
Hydronephrosis	Renal abscess		Lobar nephronia
	Septated cyst		Abscess
	Hydrocalyx		Tuberculosis
	Cystic Wilms' tumor		Xanthogranulomatous pyelonephritis
	Mixed epithelial-stromal tumor		Urothelium-based tumors
	Vascular		Transitional cell carcinoma
	Renal artery aneurysm		Squamous cell carcinoma
	Arteriovenous malformation		Adenocarcinoma
	Tuberculosis		Wilms' tumor
			Oncocytoma
			Renal adenoma
			Metanephric adenoma
			Reninoma (JG cell tumor)
			Leiomyoma
			Fibroma
			Hemangioma
			Carcinoid
			Primitive neuroectodermal tumor



*In modern era, many renal masses are initially identified with CT obtained for other purposes and in this setting a dedicated CT of the kidneys should be considered.

Figure 47–1. Algorithm for radiographic evaluation of renal masses. IVP, intravenous pyelography; US, ultrasonography; AML, angiomyolipoma; CT, computed tomography; DMSA, dimercaptosuccinic acid; MRI, magnetic resonance imaging; FNA, fine-needle aspiration.

In evaluating complicated renal cysts, important sonographic features include thickness and contour of the cyst wall, number and thickness of any septa, presence of any calcifications, density of the renal cyst fluid, and presence of solid components. Sonography is helpful in suggesting the fat content of an angiomyolipoma (AML) by its characteristic increased echogenicity (Nelson and Sanda, 2002). **A renal mass that is not clearly a simple cyst by strict ultrasound criteria should be evaluated further with computed tomography (CT) scanning.** Percutaneous needle puncture of cysts with aspiration of cystic fluid for cytology and biochemical studies and further injection of the cyst cavity with contrast medium for radiographic evaluation were often performed in the past. However, these assessments are frequently nondiagnostic and have thus largely been abandoned.

A dedicated (thin-slice) renal CT scan remains the single most important radiographic test for delineating the nature of a renal mass. CT scanning, with and without the administration of contrast material, is necessary to take full advantage of the contrast enhancement characteristics of highly vascular renal parenchymal tumors (Davidson et al, 1997; Zagoria, 2000). **In general, any renal mass that enhances with intravenous administration of contrast material on CT scanning by more than 15 Hounsfield units (HU) should be considered a renal cell carcinoma (RCC) until proved otherwise** (Fig. 47–2) (Hartman et al, 2004). **Solid masses that also have substantial areas of negative CT attenuation numbers (below –20 HU) indicative of fat are diagnostic of AMLs** (Nelson and Sanda, 2002). In approximately 10% of solid renal masses, CT findings are indeterminate, and additional testing or surgical exploration is needed to establish a definitive diagnosis. On occasion, CT scanning demonstrates an enhancing renal segment that is isodense with the remainder of the kidney, suggestive of a renal pseudotumor. Renal pseudotumors may be due to a hypertrophied column of Bertin, renal dysmorphism, or an unusually shaped kidney. In this situation, the diagnosis of a pseudotumor can be confirmed by isotope renography with technetium-labeled dimercaptosuccinic acid or glucoheptonate (Fig. 47–3). These isotope studies demonstrate an area of increased density if the mass is a pseudotumor and an area of decreased density if the mass is a cyst or solid tumor (Israel and Bosniak, 2003b).

Magnetic resonance imaging (MRI) was initially employed only infrequently for evaluation of renal masses because routine sequences were not specific or sensitive enough to characterize these lesions. However, with the introduction of gadolinium-enhanced MRI, its use has increased significantly (Pretorius et al, 2000). **A basic consideration in the evaluation of a renal mass is that for such a mass to be considered malignant, it must enhance with the intravenous administration of contrast material. Such enhancement can now be determined equally well by magnetic resonance angiography with intravenous gadolinium-labeled diethylenetriaminepentaacetic acid.** On T1-weighted scans before and after administration of gadolinium, enhancement (vascularity) of the mass is detected (Fig. 47–4). This technique is most helpful in patients for whom iodinated contrast medium is contraindicated because of significant renal insufficiency or severe allergy.

Renal arteriography has a limited role in the diagnostic evaluation of renal masses. In equivocal cases, the presence or absence of neovascularity may help establish the diagnosis of RCC. However, approximately 20% to 25% of RCCs are angiographically indistinct, even though most of these tumors are not truly avascular and demonstrate contrast enhancement by 10 to 25 HU on CT scanning.

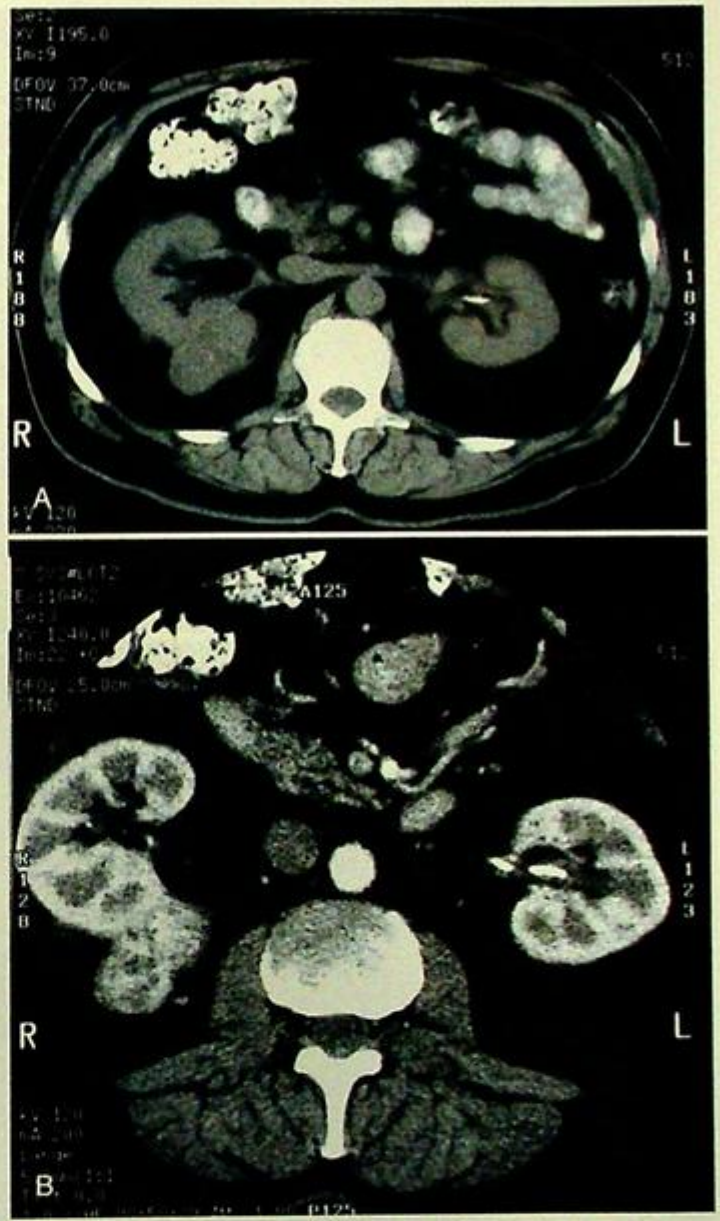


Figure 47–2. **A**, CT scan without administration of contrast material shows solid, right posterior renal mass. **B**, After administration of the contrast agent, CT scan shows that the mass enhances more than 20 Hounsfield units and is thus highly suggestive of renal cell carcinoma. This mass was excised and confirmed to be a clear cell renal cell carcinoma. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

Fine-needle aspiration or biopsy has traditionally been of limited value in the evaluation of renal masses. Although there have been relatively few reports of spread of tumor by needle puncture of an RCC, this is an invasive study that occasionally causes perirenal bleeding. The major problems with this technique are the high incidence of false-negative biopsy findings in patients with renal malignant neoplasms and the difficulty differentiating renal oncocytoma from the common eosinophilic variants of RCC with limited pathologic material

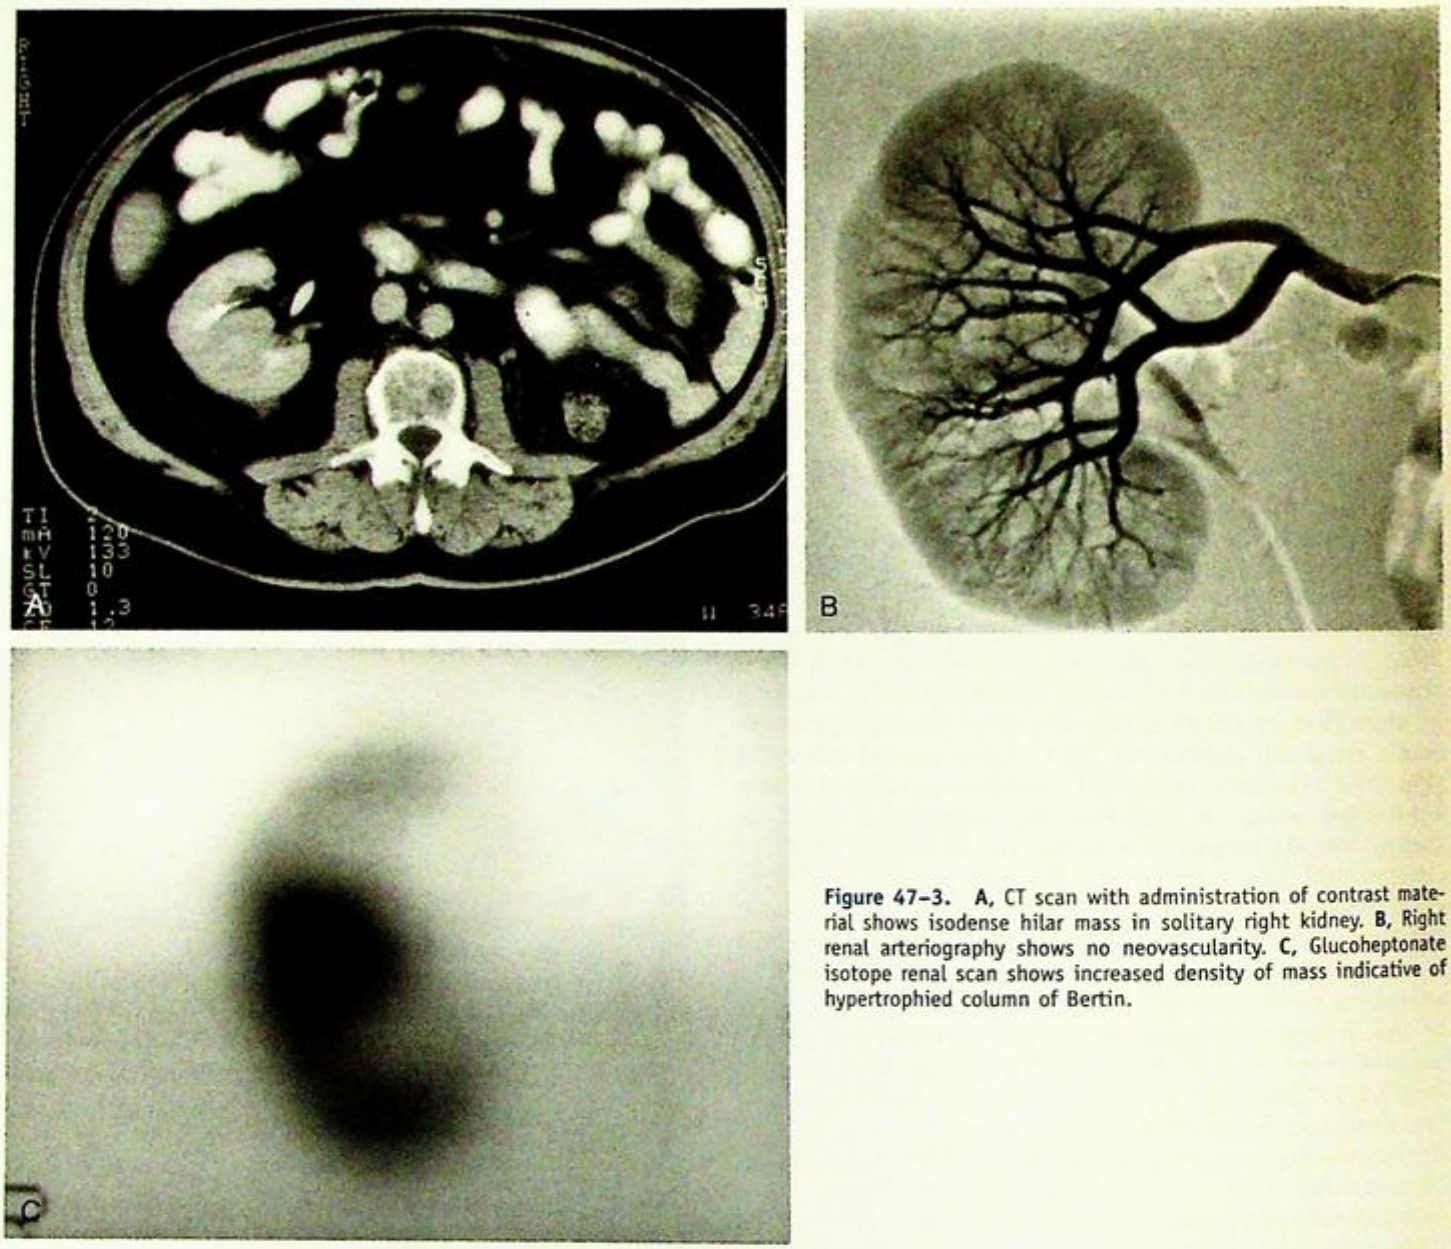

Figure 47–3. **A,** CT scan with administration of contrast material shows isodense hilar mass in solitary right kidney. **B,** Right renal arteriography shows no neovascularity. **C,** Glucoheptonate isotope renal scan shows increased density of mass indicative of hypertrophied column of Bertin.

(Herts and Baker, 1995; Schatz and Lieber, 2003). **The primary indications for needle aspiration or biopsy of a renal mass are when a renal abscess or infected cyst is suspected and when RCC must be differentiated from metastatic malignant disease or renal lymphoma** (Herts and Remer, 2000). More recently, fine-needle aspiration or biopsy has been reevaluated; several series suggested an improved sensitivity and specificity, particularly when it is combined with molecular analysis (Truong et al, 1999; Wood et al, 1999; Lechevallier et al, 2000; Richter et al, 2000; Hara et al, 2001; Liu and Fanning, 2001; Caoili et al, 2002; Rybicki et al, 2003). In one such study, fine-needle aspiration was combined with molecular analysis for *MN/CA9* gene expression that is characteristic of conventional RCC, yielding promising results (Li et al, 2004).

The differentiation between a benign renal cyst and a cystic RCC remains one of the more common and difficult problems in renal imaging (Balci et al, 1999; Harada et al, 2002; Kausik et al, 2002). When a complicated renal cyst is identified, determination of its benign or malignant nature is based on evaluation of the wall of the lesion; its thickness and contour; the number, contour, and thickness of any septa; the amount, character, and location of any calcifications; the density of fluid in the lesion; and the margination of the lesion and the presence of solid components. **Bosniak has developed a useful classification scheme that divides renal cystic lesions into four categories that are distinct from one another in terms of the likelihood of malignancy** (Bosniak, 1997). Category I lesions are uncomplicated, simple, benign cysts of the kidney that are straightforward to diagnose on ultrasonography, CT scan, or MRI scan. These are by far the most common renal cystic lesions, and in the absence of associated symptoms, no treatment is necessary.

Category II lesions are minimally complicated cysts that are benign but have some radiologic findings that cause concern (Fig. 47–5). These lesions include septated cysts, cysts

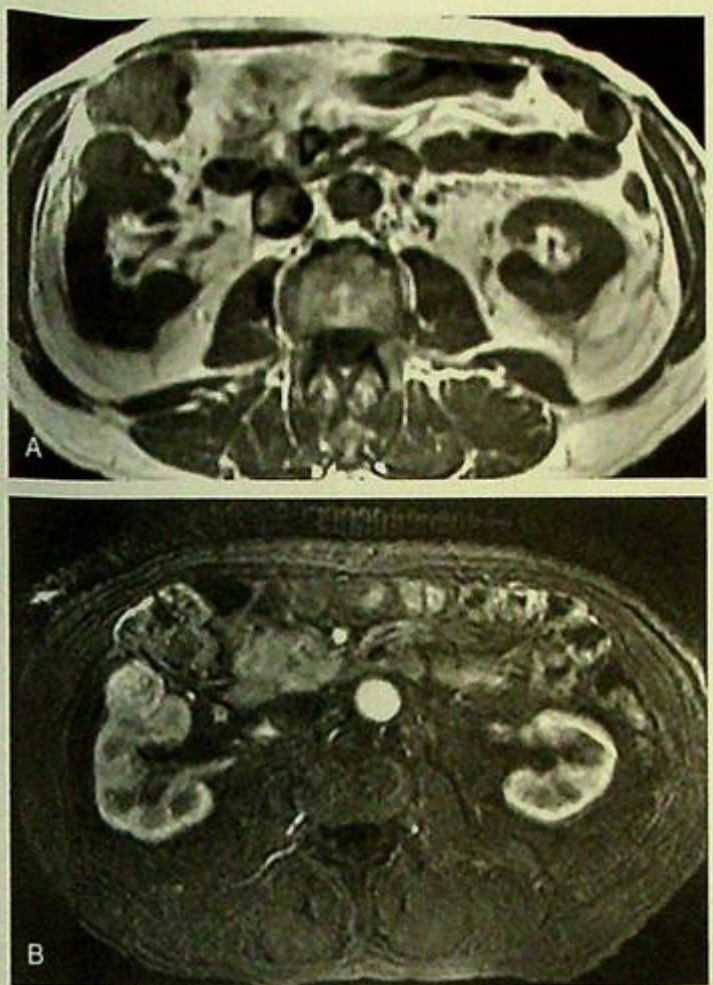

Figure 47–4. **A,** Magnetic resonance scan of kidneys without administration of gadolinium suggests anterior right renal mass. **B,** After intravenous administration of gadolinium-labeled diethylenetriaminepentaacetic acid, MRI shows enhancement of this mass indicative of malignancy. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

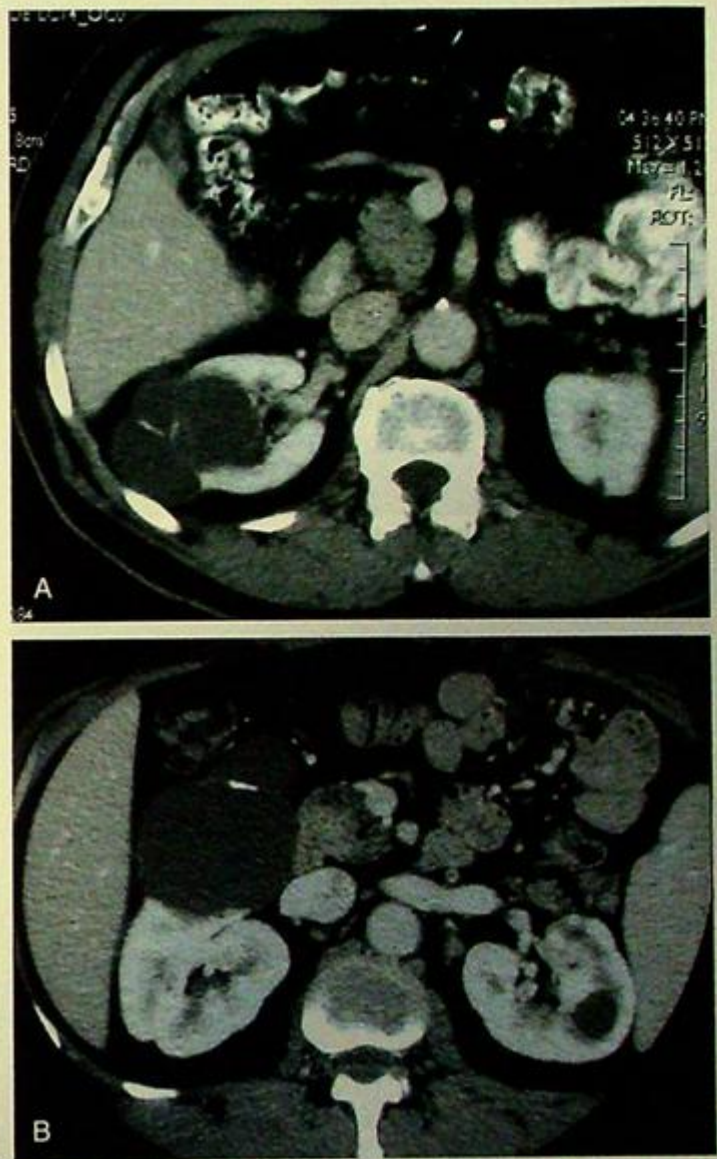

Figure 47–5. Bosniak's class II renal cysts. **A,** CT scan shows right renal cyst with thin internal septation. **B,** CT scan in another patient shows relatively thin, curvilinear calcification in the septa of the wall of right renal cyst. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

with minimal calcium in the wall or septum, infected cysts, and hyperdense (high-density) cysts (Bosniak, 1997). Hyperdense cysts are benign lesions that contain old, degenerated, or clotted blood; therefore, the CT attenuation of their contents is increased (>20 HU). Classic hyperdense renal cysts are small (<3 cm), round, and sharply marginated and do not enhance after the administration of contrast material (Fig. 47–6). **The risk of malignancy for category II renal cysts is 0% to 5%, and these lesions should be observed with periodic renal imaging** (Kausik, 2002; Israel and Bosniak, 2003b).

Category III lesions are more complicated renal cysts that are indeterminate and cannot be confidently distinguished from malignant neoplasms (Kausik, 2002). **The radiographic features include an irregular margin, thickened septa, and thick irregular calcification** (Fig. 47–7). In the absence of a mitigating factor such as renal trauma or infection, surgical exploration is usually indicated in young patients of good operative risk. About 50% of these lesions are malignant; the remainder prove to be benign multiloculated, hemorrhagic, or densely calcified cysts (see Table 47–4). Fine-needle aspiration of complex cysts is rarely performed because of concern about sampling error and tumor cell spillage. However, one report suggested that analysis of cyst fluid for expression of matrix metalloproteins might differentiate benign lesions from malignant, which express elevated levels of matrix metalloproteinases 2 and 9 (Harada et al, 2002).

Category IV lesions have large cystic components; irregular, shaggy margins; and, most important, some solid enhancing portions that provide a definitive diagnosis of malignancy (Fig. 47–8) (Bosniak, 1997; Israel and Bosniak, 2003c). Category IV lesions are invariably cystic RCCs that, if localized, require surgical treatment.

For radiographically detected solid renal masses, the differential diagnosis is extensive and includes conditions such as RCC, renal adenoma, oncocytoma, AML, transitional cell carcinoma, metastatic tumor, abscess, infarct, vascular malformation, and renal pseudotumor (see Table 47–4). The diagnosis of most of these lesions can be established on the basis of the clinical presentation and the characteristic

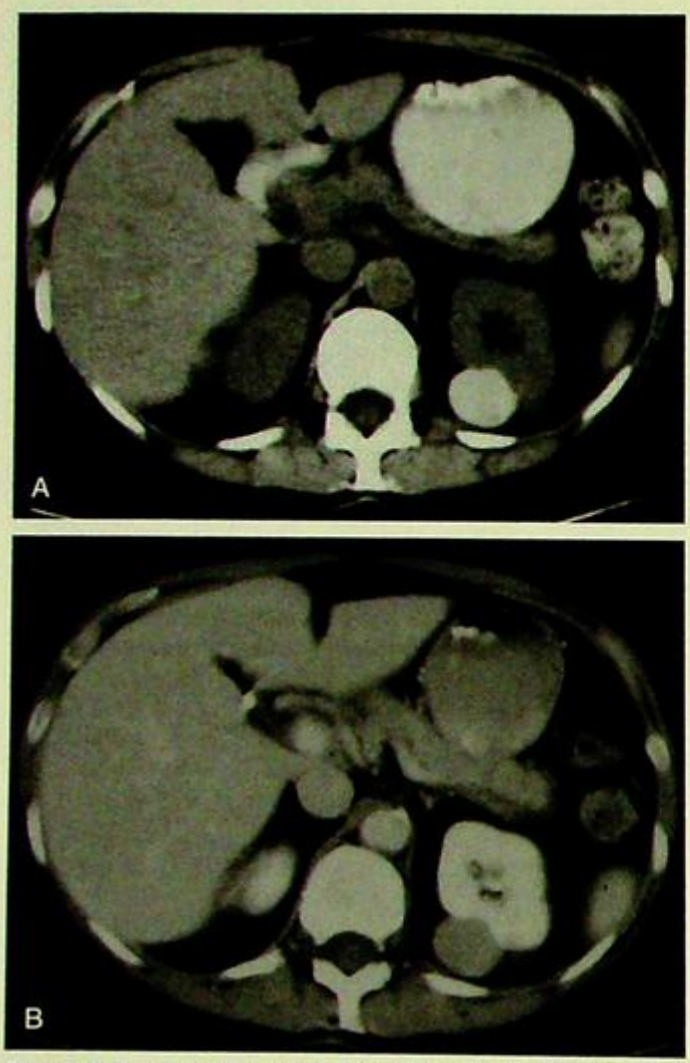

Figure 47–6. Bosniak's class II hyperdense cyst. **A,** CT scan without administration of contrast material shows small, smooth-walled, high-density left renal cyst. **B,** CT scan after administration of contrast material shows no enhancement of the cyst. This is an extreme example of a hyperdense cyst. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

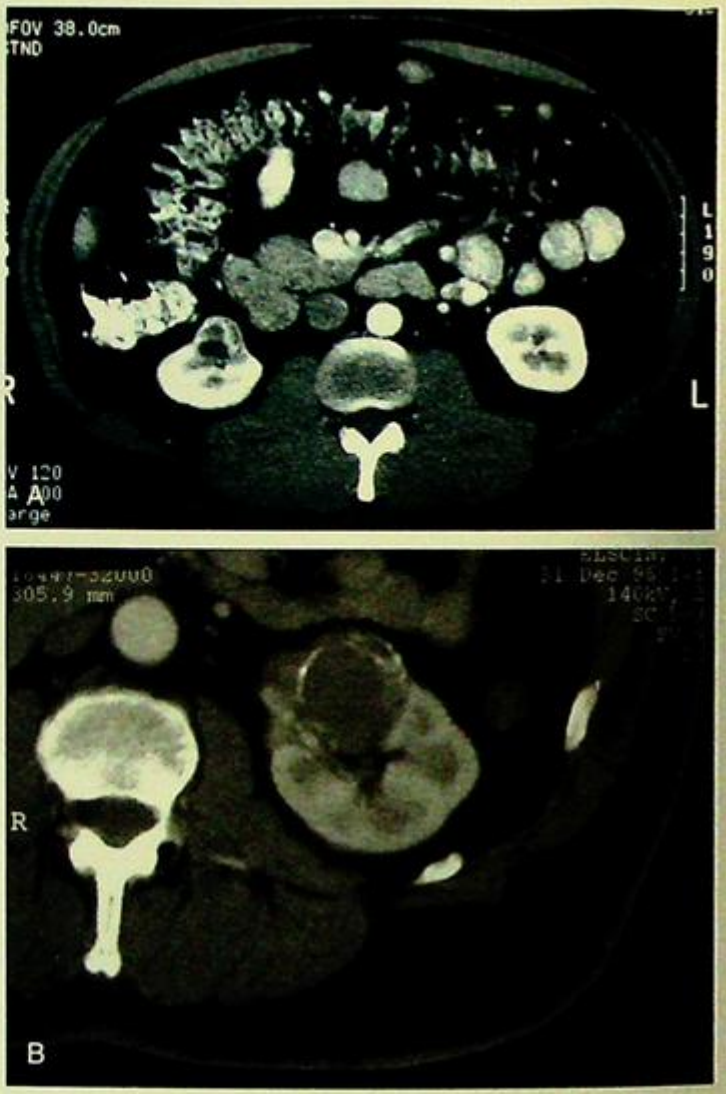

Figure 47–7. Bosniak's class III cysts. **A,** CT scan shows complex right renal cyst with thick and irregular septa and inhomogeneous character. **B,** CT scan shows somewhat thick-walled, complex left renal cyst also exhibiting irregular calcification and moderate heterogeneity. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

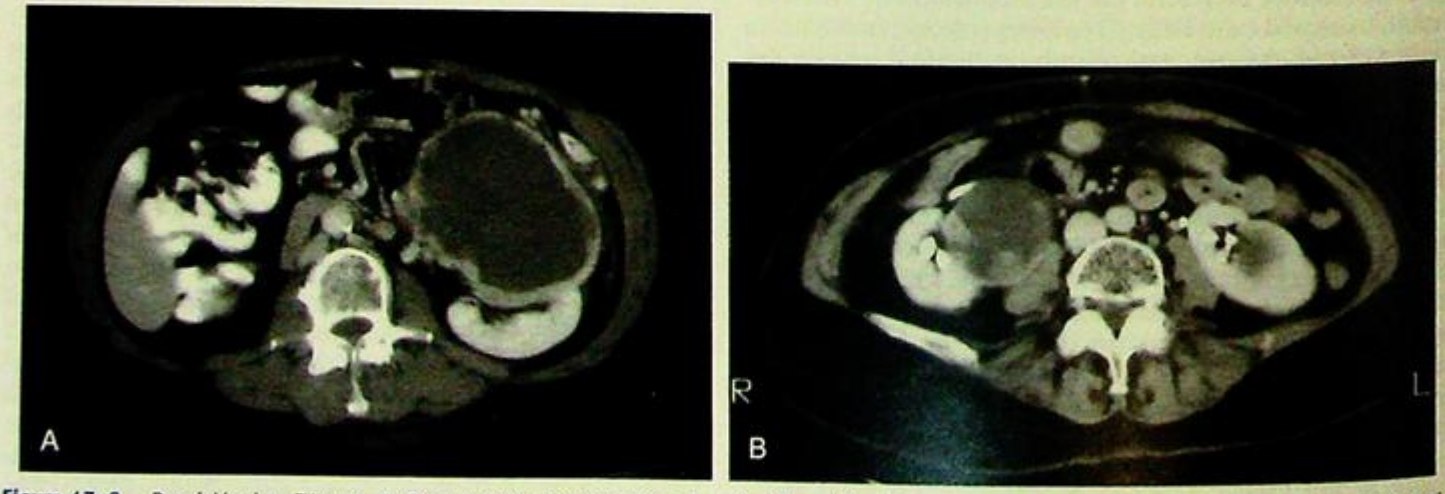

Figure 47–8. Bosniak's class IV cysts. **A,** CT scan shows complex left renal cystic lesion with thick, enhancing walls. **B,** CT scan shows complex right cystic lesion with enhancing nodular areas and inhomogeneity. Both lesions proved to be renal cell carcinoma. (Courtesy of Dr. Terrence Demos, Maywood, Illinois.)

radiographic features, occasionally combined with endourologic studies or needle biopsy of the mass. **However, it is not possible to reliably distinguish RCC, adenoma, and oncocytoma with current diagnostic techniques. Approximately 10% to 20% of small, solid, CT-enhancing renal masses with features suggestive of RCC prove to be benign after surgical excision** (Silver et al, 1997). Although oncocytoma is a benign tumor, associated RCC in the same or the opposite kidney has been found in as many as 30% of patients (Licht, 1995).

KEY POINTS: COMPLEX RENAL CYSTS

Bosniak Classification	Radiographic Features	Risk of Malignancy	Management
I	Water density	None	Only if symptomatic
	Homogeneous		Surveillance not necessary
	No septa		
	No calcification		
	No enhancement		
II	Thin septa	0%-5%	Periodic surveillance
	Thin, curvilinear calcification		
	No enhancement		
	Hyperdense lesion with no enhancement	0%-5%	Periodic surveillance
III	Thick or irregular septa	50%	Surgical excision
	Thick or irregular calcification		
	Mild to moderate heterogeneity		
	No enhancement		
IV	Thick walls or nodular areas	75%-90%	Surgical excision
	Marked heterogeneity		
	Enhancement		

BENIGN RENAL TUMORS

Benign renal tumors may arise from cortical tissue (e.g., adenoma, oncocytoma) or from the various mesenchymal derivatives within the parenchyma or capsule of the kidney. Differentiation from malignant renal masses by radiographic or clinical means can be challenging if not impossible in some instances, and some benign renal masses can also achieve clinical significance by growth to large size that leads to flank pain or, more acutely, by hemorrhage. **Women are more likely to have benign histologic types, and in one series, young women (<45 years) with renal masses suggestive of RCC were found to have benign pathologic processes in 36% of cases** (Eggener et al, 2004).

Benign Renal Cyst

Simple cysts, the most common benign renal lesions, represent more than 70% of all asymptomatic renal masses. Benign renal cysts are more common in men than in women (2:1 ratio) and can be solitary or multiple (Terada et al, 2002). **Prevalence increases with age, and renal cysts can be found in more than 50% of patients older than 50 years** (Kissane, 1976). Longitudinal study of more than 1700 individuals demonstrated a mean growth rate of 2.8 mm per year, and these lesions tended to grow more rapidly in younger individuals (Terada et al, 2002).

Renal cysts are readily identified and characterized radiographically, as previously described. They may, however, grow to large size and become symptomatic, and various minimally invasive techniques for drainage or sclerosis have been described. One common outpatient protocol uses percutaneous drainage and sclerosis with 95% alcohol, resulting in successful ablation of the cyst cavity in more than 90% of cases (Hanna and Dahniya, 1996). One relative contraindication to percutaneous management is peripelvic location adjacent to the renal vessels; in this circumstance, laparoscopic approaches may be safer (Hemal, 2001; Roberts et al, 2001). However, all patients should be advised that multiple treatment sessions may be required to achieve complete ablation and that chronic pain may persist.

Renal Cortical Adenoma

Small, evidently benign, solid renal cortical lesions have been found at autopsy with an incidence of 7% to 23% and have been designated renal adenomas (Licht, 1995; Renshaw, 2002; Minor et al, 2003). The majority of such lesions are solitary; 25% are multicentric (Corwin, 1940). Incidence increases with the patient's age, and renal adenomas have also been found to be more common in patients with von Hippel–Lindau disease and acquired renal cystic disease associated with end-stage renal failure (Grantham and Levine, 1985; Solomon and Schwartz, 1988). The male-to-female ratio is 3:1, slightly higher than that for RCC, and an association with tobacco use has also been reported (Bennington et al, 1968; Xipell, 1971). The overwhelming majority of renal adenomas remain asymptomatic, and most are undetectable radiographically because of size less than 1 cm. A large ultrasound screening effort designed to detect renal tumors in more than 40,000 asymptomatic adults yielded an incidence of adenoma of significantly less than 1% (Tosaka et al, 1990).

The histologic appearance of a typical renal adenoma is a small, well-circumscribed lesion characterized by uniform basophilic or eosinophilic cells with monotonous nuclear and cellular characteristics, often arranged in a tubulopapillary or purely papillary growth pattern (Fig. 47–9). Many lesions classified as renal adenoma exhibit trisomy of chromosomes 7 and 17 and thus share cytogenetic features with papillary RCC (Minor et al, 2003). Although most pathologists would be comfortable making this diagnosis in an autopsy setting, a pathologic diagnosis of renal adenoma is rendered much less often after surgical excision or biopsy because most pathologists believe that there are no reliable histopathologic, ultrastructural, or immunohistochemical criteria to distinguish benign from malignant renal epithelium–derived neoplasms (Cooper and Waisman, 1973; Bennington, 1987; Licht, 1995). Tumor size has historically been evoked in an effort to make this important but difficult differentiation. In his original autopsy series, Bell found 1 of

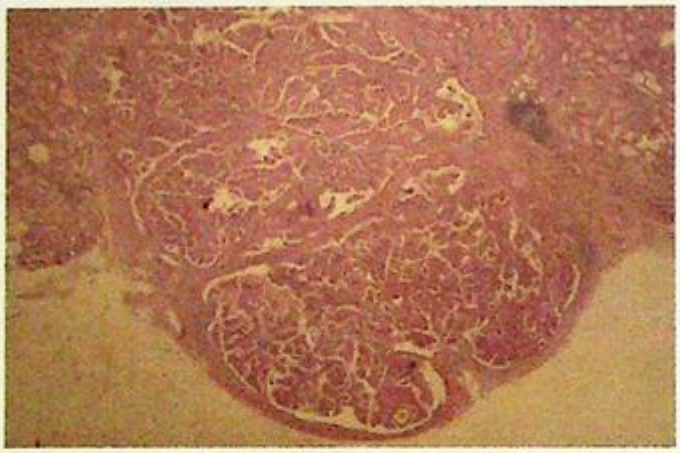

Figure 47–9. Small renal cortical adenoma demonstrating typical papillary architecture.

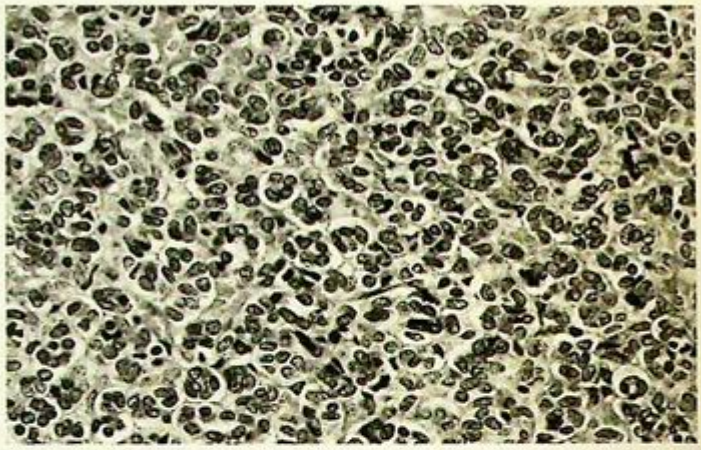

Figure 47–10. Classic metanephric adenoma with small, intensely basophilic cells arranged in an acinar pattern.

38 renal cortical tumors smaller than 3 cm in diameter to be associated with metastases, in contrast to 70 of 106 tumors larger than 3 cm (Bell, 1938). A subsequent update revealed that 3 of 62 tumors smaller than 3 cm had metastasized, reflecting the unpredictable behavior of RCC (Bell, 1950). **Nevertheless, the "3-cm rule" remained pervasive in the urologic literature for many years, despite the documented 5% incidence of metastasis and Bell's precaution that he could not make a definitive distinction between adenoma and carcinoma on the basis of histologic analysis.** Many pathologists continue to use tumor size for the classification of renal adenoma. Thoenes and colleagues (1986), in their provocative reassessment of the histologic classification of renal tumors, defined renal adenoma as tumors with nuclear grade 1 and diameter of more than 1 cm. Most authors agree that larger tumors or those with clear cell histology or any degree of cytologic atypia should not be classified as renal cortical adenoma.

The diagnosis of renal adenoma remains controversial; many believe that all solid renal epithelium–derived masses are potentially malignant and should be treated as such (Renshaw, 2002; Minor et al, 2003). **Renal exploration and wedge resection or other ablative therapies should be strongly considered for all such clinically evident lesions, with appropriate consideration of the patient's age, comorbidities, and other relevant factors.**

Metanephric Adenoma

In 1995, Davis and colleagues reported 50 cases of an unusual and novel renal mass lesion with distinctive histologic features and a benign clinical course despite occasional symptomatic presentation and large tumor size (Davis et al, 1995a). In this series, mean tumor size was 5.5 cm (range, 0.3 to 15 cm), and 22 patients presented with flank pain, gross hematuria, or a palpable mass. Six additional patients presented with polycythemia, and hypercalcemia has also been reported in association with this tumor type, which was designated *metanephric adenoma* (Davis et al, 1995a; Mahoney et al, 1997; Kuroda et al, 2003b). The male-to-female ratio in the series of Davis and colleagues was 2:1, but a female predominance has been reported in other series (Jones et al, 1995). Incidental presentation is most common, and peak incidence is in the fifth decade of life (Renshaw, 2002).

On microscopic examination, these tumors consist of very small, often highly basophilic epithelial cells that form small acini and occasionally tubular or papillary structures within a predominantly acellular stroma (Fig. 47–10). Davis and colleagues (1995a) argued that metanephric adenoma might be histologically related to epithelial Wilms' tumor because they believed that it exhibited histologic similarities to the metanephric, hamartomatous elements of nephroblastomatosis. Along these lines, it is interesting to note that many of these tumors exhibit evidence of regression in the form of scarring or calcification. In addition, Muir and colleagues (2001) have shown positive staining for the Wilms' tumor protein WT-1 and an immunohistochemical staining profile that suggests a histogenetic relationship to Wilms' tumor. An alternative theory for the origin of metanephric adenoma was proposed by Brown and associates (1997), who found gain of chromosomes 7 and 17 by fluorescent in situ hybridization in 8 of 11 of these tumors. These findings suggest a clonal neoplastic disorder potentially related to papillary RCC, but others have argued that this series may have been contaminated by inclusion of some cases of papillary RCC, which can be difficult to differentiate from metanephric adenoma (Brown et al, 1997; Renshaw, 2002; Brunelli et al, 2003a). Pesti and colleagues (2001) have described a putative tumor suppressor gene for metanephric adenoma at chromosome 2p13.

Only one case of metastasis has been described in association with classic metanephric adenoma, into a regional lymph node, and death related to this entity has not been reported (Renshaw, 2002). **However, Picken and colleagues** (2001) **have described malignant stromal elements associated with a metanephric neoplasm of the kidney in a 21-year-old woman who died of progressive cancer, and they have proposed that there may be a spectrum of metanephric tumors that includes rare, aggressive variants. Given these concerns about the true natural history of metanephric adenomas, its rarity, and the lack of clinical, radiographic, or cytologic means to establish a definite diagnosis, metanephric adenoma remains primarily a pathologic diagnosis. Most if not all patients require surgical excision because of concern about malignancy.**

Oncocytoma

The diagnosis of renal oncocytoma first gained acceptance as a distinct clinicopathologic entity after a report of 13 cases by Klein and Valensi in 1976. Since then, several reports have further characterized this essentially benign renal histiotype, which represents 3% to 7% of all solid renal masses (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Lieber, 1993; Amin et al, 1997b; Perez-Ordonez et al, 1997; Dechet et al, 1999; Chao et al, 2002a; Kuroda et al, 2003d). In gross appearance, these tumors are light brown or tan, homogeneous, and well circumscribed, but like most renal tumors, they are not truly encapsulated (Fig. 47–11). A central scar is commonly found, but prominent necrosis or hypervascularity is lacking. On microscopic examination, uniform round or polygonal eosinophilic cells predominate, most commonly arranged in a nested or organoid growth pattern (Farrow, 1997; Renshaw, 2002).

Ultrastructurally, oncocytomas are packed with numerous large mitochondria, which contributes to their distinctive staining characteristics (Farrow, 1997). Although most oncocytomas are cytologically low grade, prominent nucleoli are not uncommon, and conspicuous pleomorphism or cellular atypia has been reported in 12% to 30% of cases. Such findings are generally accepted within the diagnosis of renal oncocytoma if all other diagnostic criteria are met (Amin et al, 1997b; Perez-Ordonez et al, 1997). Other atypical features include hemorrhage, which is found in 20% to 30% of cases, and extension into the perinephric fat, which has been reported in 11% to 20% of cases (Amin et al, 1997b; Perez-Ordonez et al, 1997). In light of this information, it is interesting to note that Rainwater and colleagues (1986) found that 50% of their oncocytomas were nondiploid and that more than 20% were frankly aneuploid. The acceptance of tumors with such atypical features as oncocytomas has not been complete, and despite the almost uniformly benign course for these lesions, some pathologists prefer to reserve the diagnosis of oncocytoma for tumors exhibiting only low-grade characteristics.

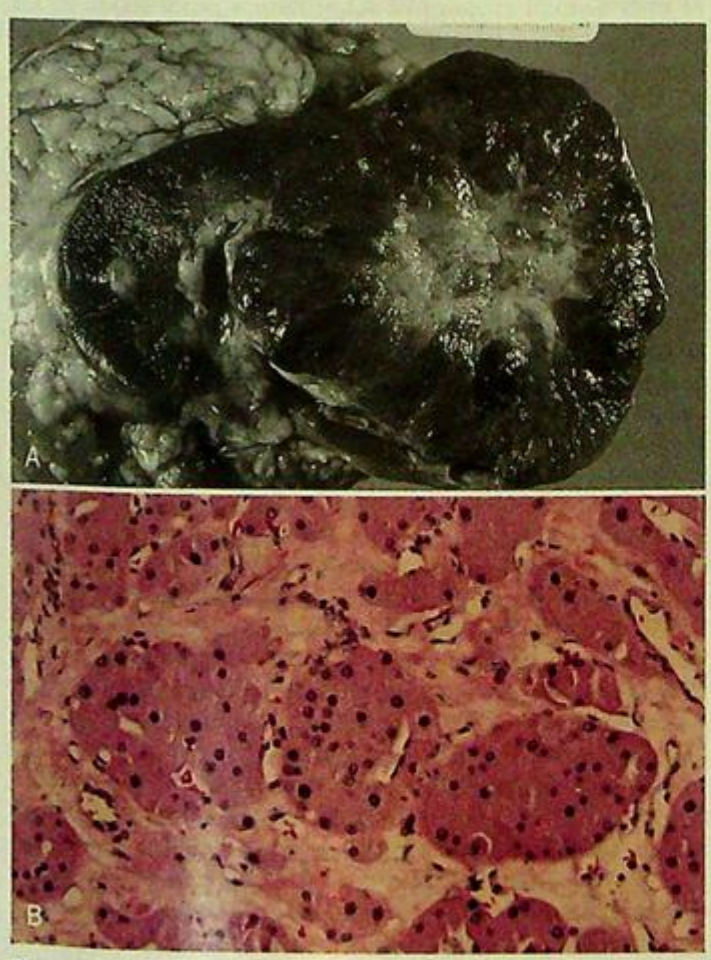

Figure 47–11. A, Bivalved renal oncocytoma demonstrating central scar. B, Oncocytoma with large eosinophilic cells arranged in distinct nests.

Common cytogenetic findings for oncocytomas include loss of the first and Y chromosomes, loss of heterozygosity on chromosome 14q, and rearrangements at 11q13 (Crotty et al, 1992; Schwerdtle et al, 1997; Chao et al, 2002a; Polascik et al, 2002; Lindgren et al, 2004). In contrast, abnormalities of chromosomes 3, 7, and 17 are rarely found in association with oncocytomas (Minor et al, 2003). The genetic alterations observed with renal oncocytomas are thus characteristic and distinct from those described for the various subtypes of RCC. Oncocytoma and chromophobe cell carcinoma are both derived from the distal tubules, and histologic similarities do exist, particularly for the eosinophilic variant of chromophobic carcinoma (Weiss et al, 1995; Renshaw, 2002). A transitional histiotype has been described in the Birt-Hogg-Dubé syndrome, in which renal oncocytomas, chromophobe RCC, and distinctive cutaneous lesions commonly develop (Minor et al, 2003). These transitional neoplasms exhibit features of both oncocytoma and chromophobe RCC, and some authors have hypothesized that there may be a spectrum of tumors spanning both of these histiotypes (Chao et al, 2002a; Linehan et al, 2003; Minor et al, 2003; Pavlovich et al, 2005). Nevertheless, the distinctive cytogenetics and immunohistochemical staining profiles suggest an individuality of these tumor types (Leroy et al, 2000; Chu and Weiss, 2001; Chao et al, 2002a).

Unfortunately, most renal oncocytomas cannot be differentiated from malignant RCC by clinical or radiographic means (Chao et al, 2002a). Mean age at presentation and male-to-female predominance are similar for oncocytoma and RCC, and although oncocytomas are more likely to be asymptomatic (58% to 83%), most RCCs are now also diagnosed incidentally (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Lieber, 1993; Amin et al, 1997b; Perez-Ordonez et al, 1997; Dechet et al, 1999). Mean tumor size for oncocytomas has ranged from 4 to 6 cm in most series—again, similar to RCC. The central stellate scar observed on CT scan and the spoke-wheel pattern of feeding arteries observed on angiography can suggest the diagnosis of oncocytoma, but extended experience has proved these findings to be unreliable and of poor predictive value (Levine and Huntrakoon, 1983; Davidson et al, 1993; Licht et al, 1993; Licht, 1995). The nuclear agent technetium sestamibi is evidently retained in mitochondria, and Gormley and colleagues (1996) reported increased uptake in oncocytomas compared with RCC, AML, and renal cysts. The biologic rationale for nuclear scanning is therefore strong, but these results have not been confirmed, and their clinical utility has not been defined. Characteristic

findings for oncocytoma on MRI include well-defined capsule, central stellate scar, and distinctive intensities on T1 and T2 images, all of which can suggest the diagnosis but cannot be considered definitive (Harmon et al, 1996). **Renal fine-needle aspiration or biopsy is compromised by difficulty distinguishing oncocytoma from the granular forms of conventional RCC or the eosinophilic variants of chromophobe or chromophilic RCC** (Weiss et al, 1995). Another factor limiting the utility of fine-needle aspiration or biopsy is the well-documented coexistence of RCC and oncocytoma in the same lesion or at other locations in the same kidney, which has been reported in 7% to 32% of cases (Davis et al, 1991; Licht et al, 1993; Licht, 1995).

Given these uncertainties about a preoperative diagnosis, most authors have emphasized the need to treat these tumors aggressively with thermal ablation, partial nephrectomy, or radical nephrectomy, depending on the clinical circumstances (Licht, 1995). A nephron-sparing approach is clearly desirable if oncocytoma is suspected and if tumor size and location are amenable, given the propensity of these tumors for multicentricity, bilaterality, and metachronous recurrence, all of which have been reported in 4% to 13% of cases (Lieber et al, 1987; Davis et al, 1991; Licht et al, 1993; Lieber, 1993; Amin et al, 1997b; Perez-Ordonez et al, 1997; Dechet et al, 1999; Tickoo et al, 1999; Minor et al, 2003). A thermal ablative approach unfortunately condemns the patient to long-term surveillance, given uncertainty about the diagnosis of oncocytoma, even if a biopsy was performed before ablation. Nephron-sparing approaches are also preferred in patients with familial renal oncocytomatosis, which was identified by Weirich and colleagues (1998) at the National Cancer Institute. They described five families with this syndrome, which exhibits an increased propensity for bilaterality, multicentricity, and early age at onset. The molecular genetics responsible for the development of this syndrome have not been defined.

Angiomyolipoma

AML is a benign clonal neoplasm consisting of varying amounts of mature adipose tissue, smooth muscle, and thick-walled vessels (Tamboli et al, 2000; Nelson and Sanda, 2002; Bissler and Kingswood, 2004). This tumor type, which is found in 0.3% of all autopsies and in 0.13% of the population screened by ultrasonography, was originally identified by Fischer in 1911 and was designated AML by Morgan in 1951 (Eble, 1998). AML is most likely derived from the perivascular epithelioid cells, and its growth may be hormone dependent, as suggested by its female predominance and rarity before puberty. **Approximately 20% to 30% of AMLs are found in patients with tuberous sclerosis syndrome (TS), an autosomal dominant disorder characterized by mental retardation, epilepsy, and adenoma sebaceum, a distinctive skin lesion** (Eble, 1998; Neumann et al, 1998; Tamboli et al, 2000; Minor et al, 2003; Lendvay and Marshall, 2003). Penetrance for each of these traits is far from complete, and approximately 50% of patients with TS develop AMLs. Among this group, mean age at presentation is 30 years, and a female-to-male predominance of 2:1 has been observed (Lendvay and Marshall, 2003). In contrast, of the 70% to 80% of patients with AML who do not have TS, a more pronounced female predominance is found, and most patients present later in life, during the fifth or sixth decade (Eble, 1998; Neumann et al, 1998). AML in TS is more likely to be bilateral and multicentric, and a tendency toward accelerated growth rates and symptomatic presentation has been reported (Neumann et al, 1998; Lendvay and Marshall, 2003).

Previously, most AMLs were diagnosed only after symptomatic presentation, and much of the data correlating tumor size and symptoms were derived from this era. **Massive retroperitoneal hemorrhage from AML, also known as Wunderlich's syndrome,** has been found in up to 10% of patients and represents the most significant and feared complication (Oesterling et al, 1986; Eble, 1998). Common signs or symptoms include flank pain, hematuria, palpable mass, and hypovolemic shock, which can be fatal if it is not identified and promptly treated (Oesterling et al, 1986; Steiner et al, 1993; Eble, 1998). Pregnancy appears to increase the risk of hemorrhage from AML, a factor that can influence clinical decision-making (Eble, 1998). More subtle presentations of AML include anemia and hypertension, and more than 50% of AMLs are now found incidentally because of the more prevalent use of abdominal imaging for the evaluation of a wide variety of nonspecific complaints (Lemaitre et al, 1997).

A number of distinctive radiographic findings associated with AML allow a definitive diagnosis in the majority of cases (Fig. 47–12). CT scan has been the most useful and reliable modality for this purpose (Lemaitre et al, 1997). **The presence of even a small amount of fat within a renal lesion on CT scan (confirmed by a value of –25 HU or lower) virtually excludes the diagnosis of RCC and is considered diagnostic of AML** (Jinkazi et al, 1997; Lemaitre et al, 1997; Bosniak et al, 1998). All five reported cases of RCC containing fat density have also been calcified, and even these extremely rare exceptions can thus be identified because calcification has never been reported within an AML (Henderson et al, 1997; Lemaitre et al, 1997; Roy et al, 1998). In 14% of AMLs, fat cannot be identified with CT, presumably related to a reduced proportion of mature adipose tissue, and a definite diagnosis cannot be made (Lemaitre et al, 1997; Kim et al, 2004; Milner et al, 2005). Patients with tumors with indeterminate features or calcifications should be managed proactively because the likely diagnosis in most such cases is RCC. The typical but not diagnostic finding of AML on ultrasonography is a well-circumscribed, highly echogenic lesion, often associated with shadowing (Siegel et al, 1996; Lemaitre et al, 1997). The finding of shadowing should suggest an AML rather than a small, echogenic RCC, which rarely shadows (Siegel et al, 1996). Aneurysmal dilation is found in 50% of AMLs when they are visualized by angiography and can also suggest the diagnosis (Lemaitre et al, 1997). Finally, fat-suppressed images on MRI may be helpful in difficult cases or when CT is contraindicated for other reasons.

Although a benign status is well accepted for AML, extrarenal occurrences have been reported in the hilar lymph nodes, retroperitoneum, and liver, and direct extension into the venous system has been reported in 21 cases (Eble, 1998; Turker Koksal et al, 2000; Gogus et al, 2001; Nelson and Sanda, 2002; Bissler and Kingswood, 2004). A uniformly benign clinical course in such cases has argued in favor of multicentric origin rather than metastasis. Many AMLs exhibit regions of

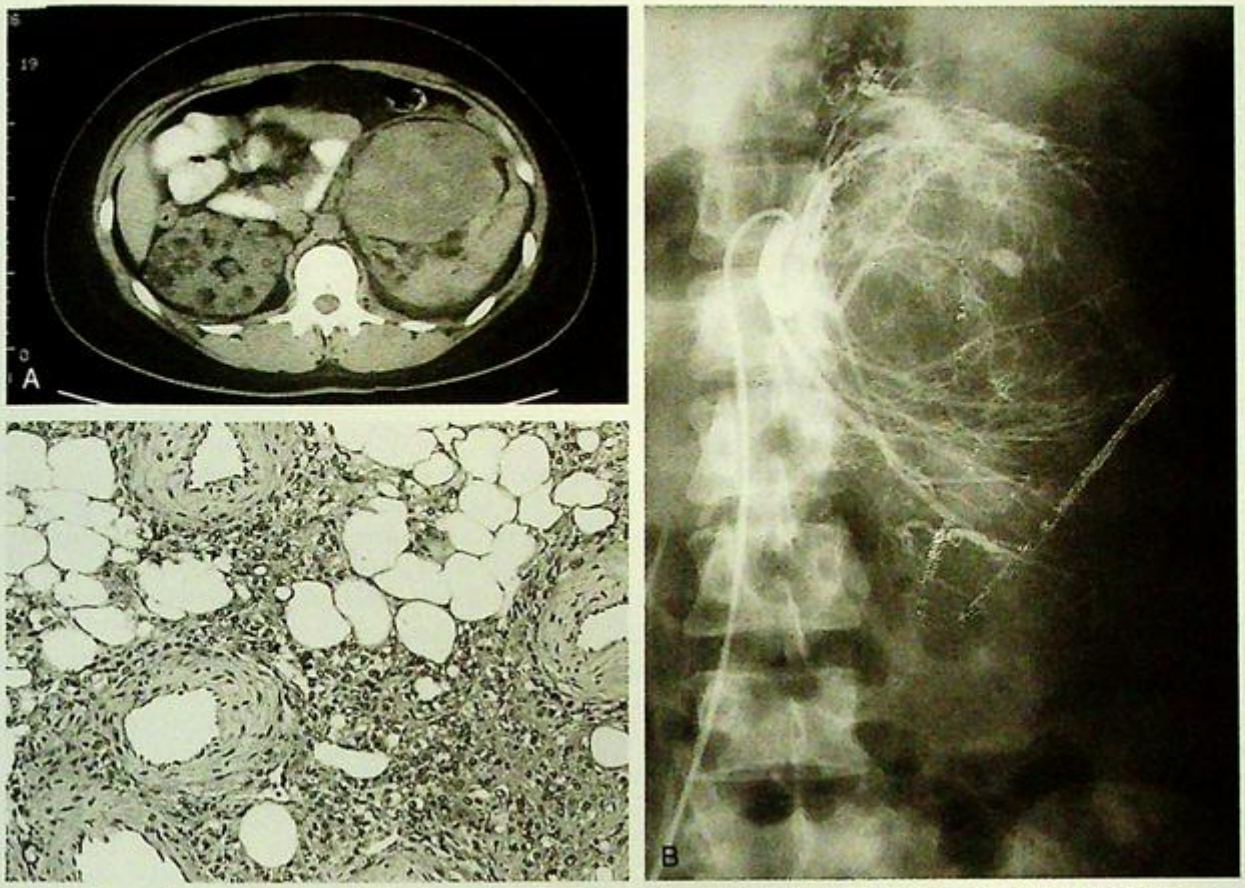

Figure 47–12. **A,** CT scan demonstrates large bilateral renal angiomyolipomas in a patient with tuberous sclerosis. **B,** Renal angiogram shows increased vascularity and aneurysmal dilation characteristic of angiomyolipoma. **C,** Typical microscopic appearance of angiomyolipoma with admixture of mature adipose tissue, smooth muscle, and thick-walled blood vessels.

cellular atypia, and the pathologic differential diagnosis can include a number of subtypes of sarcoma, including fibrosarcoma, leiomyosarcoma, and liposarcoma, depending on the relative amounts of adipose, vascular, or smooth muscle tissue present (Wang et al, 2002). **Positive immunoreactivity for HMB-45, a monoclonal antibody raised against a melanoma-associated antigen, is characteristic for AML and can be used to differentiate AML from sarcoma in such cases** (Eble, 1998). Nevertheless, one should be aware that there have been two reports of high-grade and eventually lethal leiomyosarcoma arising within an AML, and Christiano and colleagues (1999) have described a highly pleomorphic AML that was associated with the development of multiple pulmonary nodules, the majority of which stained positive for HMB-45 (Ferry et al, 1991). They believed that this case represented a malignant transformation of AML, which—if it does occur—must be exceedingly rare. More recently, a malignant epithelioid variant of AML has been described that can metastasize (Cibas et al, 2001; Nelson and Sanda, 2002; Saito et al, 2002; Yamamoto et al, 2002; Bissler and Kingswood, 2004). Such malignant variants of AML are extremely rare; the overwhelming majority pursue a benign course.

The management of AML must take into account the natural history and, in particular, the risk of hemorrhage. In general, most symptomatic AMLs have been relatively large, and most studies in the literature have focused on a 4-cm cut point (Nelson and Sanda, 2002). On the basis of an extensive literature review, Oesterling and coworkers (1986) reported that 82% of patients with AMLs larger than 4 cm in diameter were symptomatic, with 9% in hemorrhagic shock at the time of presentation; in contrast, patients with smaller tumors were symptomatic 23% of the time. Echoing these findings, Dickinson and colleagues (1998) reported that all 18 patients with AMLs smaller than 4 cm in their series were asymptomatic, whereas 7 of 13 with AMLs of 4 to 8 cm and 5 of 6 with tumors larger than 8 cm required intervention, primarily related to pain or bleeding. These observations have been confirmed and extended by a number of investigators (Blute et al, 1988; Steiner et al, 1993; Lemaitre et al, 1995; De Luca et al, 1999). Steiner and colleagues (1993) reported that patients with AMLs larger than 4 cm were symptomatic 52% of the time, with 30% requiring surgical intervention, whereas patients with smaller tumors never required surgery and were asymptomatic 76% of the time. Although it was primarily retrospective, limited follow-up with a mean of 4 years was available for 24 patients with 28 AMLs in this series. Interval growth was documented in 6 of 13 tumors with diameter of more than 4 cm and in 4 of 15 tumors smaller than 4 cm. A slower growth rate and a low risk of hemorrhage for smaller tumors was also supported by Kennelly and colleagues (1994), who observed 17 AMLs with tumor size of less than 4 cm for a mean of 3.8 years. They reported that only one such tumor

demonstrated interval growth, and even it remained asymptomatic for 18 years; no patients in this series required intervention. Similarly, De Luca and colleagues (1999) studied 32 incidentally discovered AMLs smaller than 5 cm in diameter and found that 92% remained asymptomatic and unchanged in size. **Multicentric AMLs and those in patients with TS represent a special group that has demonstrated increased growth rates of approximately 20% per year, in contrast with a mean growth rate of 5% per year for solitary AMLs** (Steiner et al, 1993; Nelson and Sanda, 2002; Harabayashi et al, 2004).

Although a large prospective study providing long-term outcomes of AMLs of various sizes has not yet been reported, the information reviewed here allows one to propose guidelines for management. **In general, asymptomatic, smaller AMLs, which by convention have been those with tumor diameter of less than 4 cm, can be observed expectantly, with repeated evaluation and imaging at 6- to 12-month intervals to define the growth rate and clinical significance. Intervention should be considered for larger tumors, particularly if the patient is symptomatic, taking into account the patient's age, comorbidities, and other related factors. Women of childbearing age and patients with limited access to surveillance or to emergency care should also consider a proactive approach** (Nelson and Sanda, 2002). **A nephron-sparing approach, by either selective embolization or partial nephrectomy, is clearly preferred in patients with small AMLs requiring intervention because of symptoms, in patients with TS or multicentric AML, and in patients for whom preservation of renal function is at issue.** The feasibility and efficacy of partial nephrectomy in patients with AML are established, with preservation of renal function achieved even in patients with large lesions and a solitary kidney (Fazeli-Matin and Novick, 1998). Selective embolization is now often chosen as the preferred modality, and data of 76 patients in six series have documented long-term success in most cases (Nelson and Sanda, 2002; Harabayashi et al, 2004). However, 17% of patients experienced recurrence of symptoms or hemorrhage, and most of these required repeated embolization (Hamlin et al, 1997; Han et al, 1997; Nelson and Sanda, 2002). The overall complication rate with embolization in these series was 10% and included abscess formation or sterile liquefaction of the tumor requiring percutaneous drainage or surgical intervention. These data highlight the need for extended follow-up after selective embolization (Nelson and Sanda, 2002).

Most patients with acute or potentially life-threatening hemorrhage require total nephrectomy if it is explored; and if a patient has TS, bilateral disease, preexisting renal insufficiency, or other medical or urologic disease that could affect renal function in the future, selective embolization should be considered. In such circumstances, selective embolization can temporize and in many cases prove definitive.

Cystic Nephroma

Cystic nephroma is a characteristic renal lesion with a bimodal age distribution and a benign clinical course (Tamboli et al, 2000; Minor et al, 2003; Truong et al, 2003). **A wide variety of synonyms have been used in the past, most notably multiloculated cystic nephroma, but the more simple terminology is now preferred.** In gross appearance, these lesions are well circumscribed and encapsulated and consist of multiple, noncommunicating, fluid-filled spaces partitioned by septa. On microscopic examination, the cysts are lined by cuboidal epithelial cells arranged in a hobnailed pattern, and the intervening stroma is characteristic for its pronounced cellularity (Fig. 47–13). The age distribution is bimodal, occurring primarily in the first 2 to 3 years of life and again primarily in the fourth and fifth decades (Madewell et al, 1983; Upadhyay and Neely, 1989; Castillo et al, 1991; Kajani et al, 1993; Murphy et al, 1994). **A male predominance is observed in children, and a female predominance is observed in adults. Children tend to present with an asymptomatic abdominal mass detected on routine physical examination, whereas symptomatic presentation with abdominal pain, hematuria, urinary tract infection, or hypertension is more common in adults** (Madewell et al, 1983; Castillo et al, 1991; Minor et al, 2003). Familial cases are rare, and most cystic nephromas are unilateral and unifocal.

Most cystic nephromas are centrally located, and distinctive radiographic findings have been described but are not universally present and cannot be considered diagnostic (Minor et al, 2003). **All cystic nephromas are, by definition, multilocular, and almost all qualify as a complex renal cyst suspicious for malignancy, specifically class III-IV in Bosniak's classification scheme** (Madewell et al, 1983). Curvilinear calcification and herniation into the renal pelvis occur in 10% to 20% of cases and can suggest the diagnosis of cystic nephroma, but this must be proved pathologically (Gettman and Segura, 1999). Most lesions are avascular or hypovascular on angiography, but hypervascular variants have been reported, and enhancement within the septa on CT or MRI is not uncommon (Madewell et al, 1983). **At present, there is no reliable clinical or radiographic means to differentiate cystic nephroma from cystic RCC in adults or from cystic Wilms' tumor in children.**

Most cystic nephromas in adults have traditionally been managed with radical nephrectomy because of the concern for malignancy. Now many such lesions are being managed with partial nephrectomy, and this is certainly a reasonable option when tumor size and location are amenable and when the diagnosis of cystic nephroma is suspected on the basis of clinical and radiologic characteristics. Most children continue to be managed by radical nephrectomy related to concern for cystic Wilms' tumor, which is much more common in this population (Vujanic et al, 2000). Although this condition is generally considered a benign neoplasm, sarcomatous stromal elements have been reported in some adult patients with cystic nephroma, and foci of nephroblastoma, including blastemal, epithelial, or mesenchymal elements alone or in combination, have been reported in children with this diagnosis (Tamboli et al, 2000). Careful microscopic inspection for such potentially malignant features is indicated because metastases from the sarcomatous stromal elements were reported in three adults in the Armed Forces Institute of Pathology series (Madewell et al, 1983). However, classification of such tumors as cystic nephromas is controversial; many pathologists prefer to exclude lesions with such ominous features.

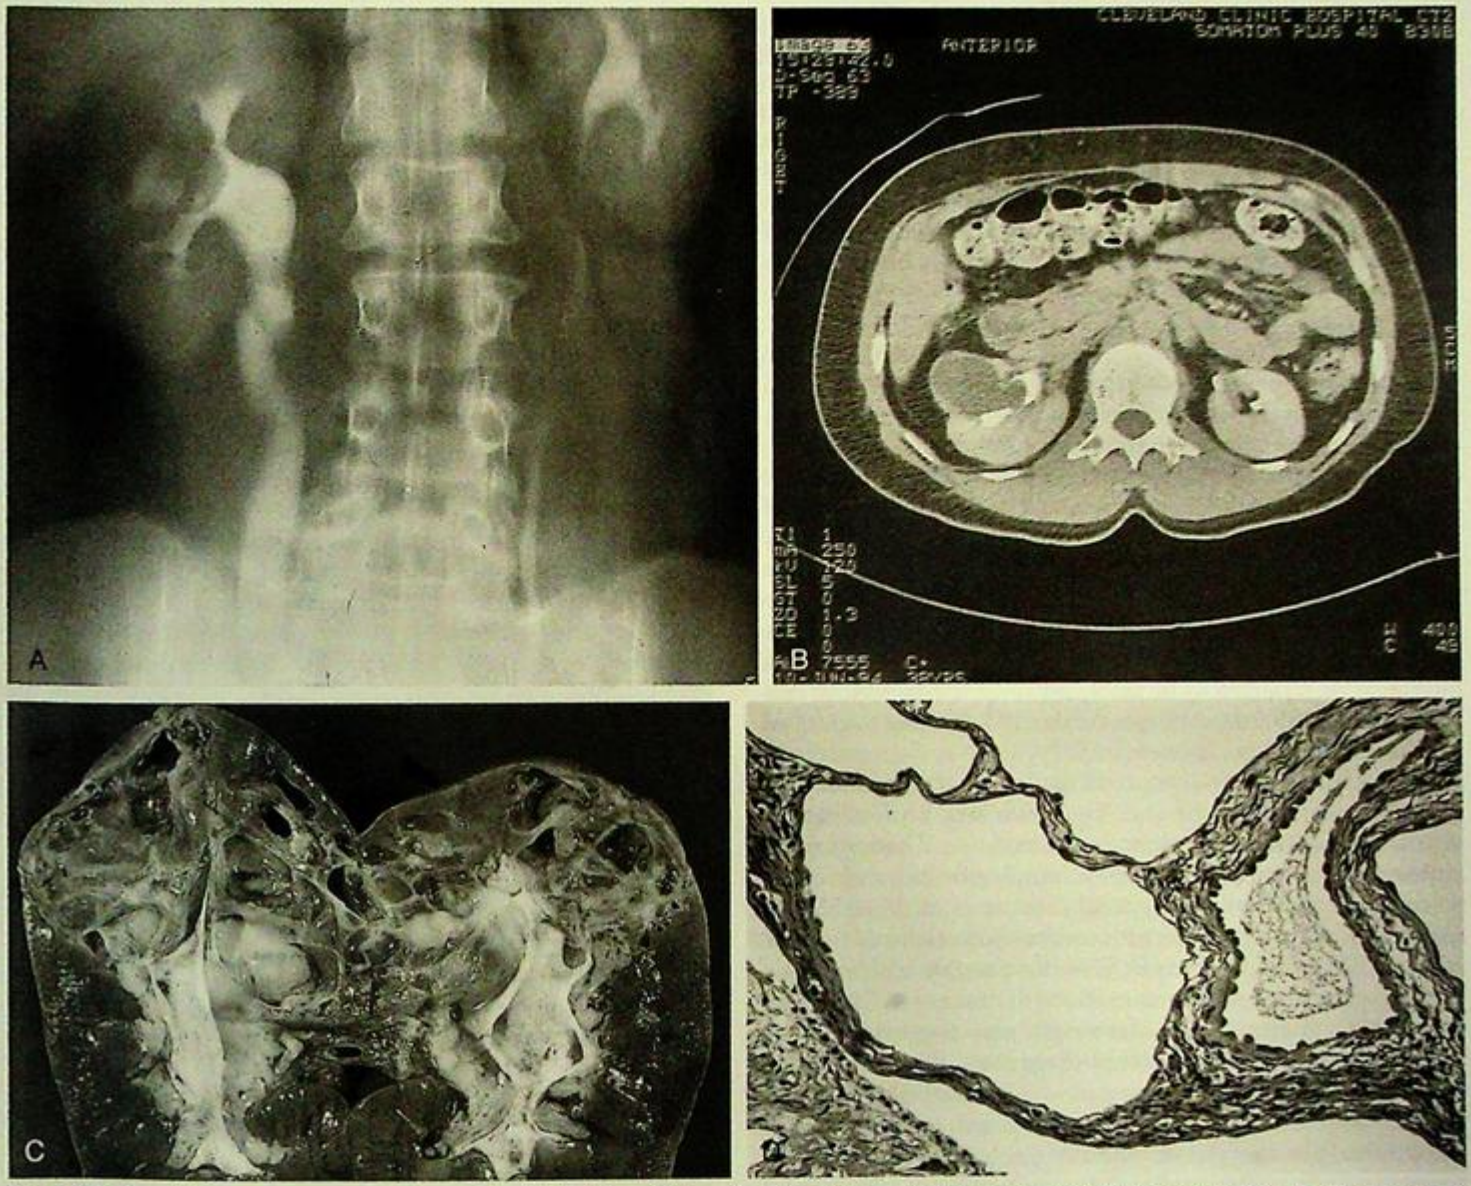

Figure 47–13. **A,** Intravenous urogram demonstrates indentation of the midportion of the right renal pelvis, suggesting a mass effect. **B,** CT scan reveals a multiloculated cystic mass herniating into the collecting system. **C,** Nephrectomy specimen harboring a multiloculated mass that protrudes into the collecting system. **D,** Cystic nephroma illustrating diagnostic findings: multiple cysts lined by hobnail-shaped epithelial cells and intervening stroma notable for increased cellularity.

Mixed Epithelial Stromal Tumor of the Kidney

Mixed epithelial stromal tumor of the kidney (MESTK) has only recently been described, and its essential characteristics are still being defined (Adsay et al, 2000; Beiko et al, 2001; Pierson et al, 2001; Minor et al, 2003). As the name implies, these tumors are composed of a mixture of epithelial and stromal elements that form solid and cystic growth patterns. The epithelial elements tend to be scattered among the stromal cells, occasionally organized into large cysts lined by eosinophilic cells, often with a hobnail appearance. The stromal component can range from scarlike fibrous tissue to interlacing fascicles suggestive of leiomyoma, and these cells tend to stain strongly for desmin and smooth muscle actin (Adsay et al, 2000). **A gross cystic appearance is common, and a complex cystic pattern is predominant radiographically, typically classifying as Bosniak III-IV lesion** (Adsay et al, 2000). It was originally thought that most tumors previously classified as adult mesoblastic nephroma were actually MESTK, but molecular analysis refutes this (Pierson et al, 2001). **The current theory is that MESTK may be related to cystic nephroma and that there may be a spectrum of lesions that lies between these two entities.**

MESTK occurs primarily in perimenopausal women, a large proportion of whom are receiving estrogen therapy; in Adsay's series, the only man with MESTK had a long history of androgen deprivation therapy for prostate cancer (Adsay et al, 2000). **In addition, most MESTKs stain positively for estrogen and progesterone receptors, further suggesting that the hormonal milieu may play an important role in the pathogenesis of this tumor type.** Mean age at presentation in Adsay's series was 56 years; six patients presented symptomatically and six were incidentally discovered (Adsay et al,

2000). A preoperative diagnosis of MESTK should be considered in perimenopausal women receiving hormone therapy, and a nephron-sparing approach is preferred if this diagnosis is suspected. In Adsay's series, all patients were managed with radical nephrectomy and have remained cancer free at mean follow-up of 49 months (Adsay et al, 2000). A benign clinical course is also supported by other reports in the literature, but further data are required to define the natural history and malignant potential of MESTK.

Leiomyoma

Renal leiomyoma, a slow-growing, benign neoplasm, can arise from the capsule or peripelvic tissues and, less often, from the renal vein (Uchida et al, 1980; Wells et al, 1981; Steiner et al, 1989; O'Brien et al, 1992; Mohammed et al, 1999; Tamboli et al, 2000). These lesions are found at autopsy with a frequency of 4.2% to 5.2%, but only a minority are discovered clinically (Minor et al, 2003). In the past, most of these tumors presented symptomatically with pain, hematuria, or gastrointestinal complaints, and many were large and palpable on routine abdominal examination. Of the 30 renal leiomyomas reported as of 1989 and reviewed by Steiner and colleagues (1989), the average size was 12.3 cm, and the largest tumor was 57 cm in diameter.

Now, renal leiomyomas are diagnosed with increased frequency; most are small and asymptomatic, representing a significant change in clinical presentation. Radiographic appearance can be highly variable, ranging from purely cystic to complex cystic or purely solid (Steiner et al, 1989). Some renal leiomyomas enhance with contrast material, and in most cases, differentiation from RCC is not possible by clinical or radiographic means (Steiner et al, 1989; Inoue et al, 2000; Rao et al, 2001). **A clearly capsular origin may suggest the diagnosis but cannot be considered diagnostic.** On microscopic examination, leiomyomas are spindle cell tumors with rare mitoses and no pleomorphism. Increased mitotic rate or significant pleomorphism should suggest a diagnosis of leiomyosarcoma, the malignant counterpart. Large lesions have traditionally been managed with radical nephrectomy, but nephron-sparing approaches should be considered for peripherally located lesions, particularly if they are small and apparently derived from the capsule.

Other Benign Tumors

Other benign renal tumors, all of which are rare, are derived primarily from the various mesenchymal derivatives present within the kidney and its environs. These include virtually all conceivable histiotypes, such as fibromas, lipomas, lymphangiomas, and hemangiomas (Tamboli et al, 2000; Minor et al, 2003). Small medullary fibromas (1 to 7 mm in diameter) are commonly found at autopsy, usually escaping radiologic detection. Ten clinically evident cases have been reported, most presenting with hematuria or filling defect on urography or retrograde pyelography (Ohkawa et al, 1993). Renal lipoma can grow to a large size, typically presents with pain or hematuria, and must be differentiated from liposarcoma (Robertson and Hand, 1941; Safak et al, 1989; Mydlo et al, 1991). Renal lipomas can easily be confused with AMLs on the basis of clinical and radiographic evaluation, but most are confined to the renal capsule, and microscopic features and staining for HMB-45 should allow differentiation of these entities. Average age at presentation of the 20 patients described with lymphangioma cavernosum of the kidney was 34 years, and as with most of these lesions, a female predominance was reported (Joost et al, 1977; Nakai et al, 1999; Honma et al, 2002). Solitary fibrous tumor has also been described in the kidney, with two case reports (Wang et al, 2001; Magro et al, 2002). All these lesions are best managed with wide surgical excision, given the possible presence of sarcomatous elements. In most cases, this has required radical nephrectomy, although partial nephrectomy is a reasonable option, depending on the clinical circumstances.

Another rare but fascinating benign renal tumor is the renin-secreting juxtaglomerular tumor, or reninoma (Martin et al, 2001; Rubenstein et al, 2002). First described by Robertson and colleagues (1967), this tumor is actually a specialized form of a hemangiopericytoma, specifically derived from the juxtaglomerular cell. Strong immunostaining for factor VIII and factor VIII–related antigens is characteristic and confirms derivation from endothelial cell lineage (Sanfillipo et al, 1982). Most are small (<3 cm), solitary, and hypovascular and are well visualized by ultrasonography or CT scan as a solid parenchymal mass (Dunnick et al, 1983; Tanabe et al, 2001). **Clinical presentation is dominated by hypersecretion of renin and includes hypertension and hypokalemia and associated symptoms such as polydipsia, polyuria, myalgia, and headaches** (Dunnick et al, 1983). Most patients are in the third or fourth decade of life; predominantly females are affected. Almost all patients may be cured with surgical excision, which typically leads to normalization of blood pressure and resolution of other related symptoms (Dunnick et al, 1983; Schoenfeld et al, 1991). The first case of a juxtaglomerular cell tumor demonstrating metastatic behavior was recently reported (Duan et al, 2004). The 70 previously reported cases of this tumor type all exhibited benign clinical course, suggesting that this is an uncommon occurrence. The diagnosis of juxtaglomerular tumor should be considered in any patient with pronounced hyperreninemia and hypertension in whom renal artery disease has been rigorously excluded.

RENAL CELL CARCINOMA

Incidence

RCC, which accounts for 2% to 3% of all adult malignant neoplasms, is the most lethal of the urologic cancers. Traditionally, more than 40% of patients with RCC have died of their cancer, in contrast with the 20% mortality rates associated with prostate and bladder carcinomas (Landis et al, 1999; Pantuck et al, 2001b). Approximately 31,000 new diagnoses of RCC are made each year in the United States, and 11,900 patients die of disease (Landis et al, 1999; Pantuck et al, 2001b). Overall, 8.9 new cases are diagnosed per 100,000 population per year, with a male-to-female predominance of 3:2 (Landis et al, 1999). This is primarily a disease of the elderly patient, with typical presentation in the sixth and seventh decades of life (Pantuck et al, 2001b). Incidence rates are 10% to 20% higher in African Americans for unknown reasons (Chow et al, 1999). The majority of cases of RCC are believed

KEY POINTS: BENIGN RENAL TUMORS

Tumor Type	Distinctive Features
Benign renal cyst	Typically asymptomatic Water density and homogeneous
Renal cortical adenoma	Commonly found at autopsy Difficult to differentiate from RCC—controversial More commonly found with papillary RCC and in end-stage renal failure Working definition: small (<1 cm), well circumscribed, low grade, and papillary
Metanephric adenoma	Incidental presentation, peak incidence is fifth decade May be related to Wilms' tumor or papillary RCC Cannot be differentiated from RCC by clinical or radiographic means
Oncocytoma	Typically tan and homogeneous in gross appearance Eosinophilic with nested or organoid appearance Multiple mitochondria on electron microscopy Common loss of chromosomes 1 and Y; alterations of 14q and 11q13 Seen along with chromophobe RCC in Birt-Hogg-Dubé syndrome Cannot be differentiated from RCC by clinical or radiographic means
Angiomyolipoma	Sporadic or associated with tuberous sclerosis syndrome Fat density found with CT; hyperechoic on ultrasonography Stains positive for HMB-45 Typically intervene if symptomatic or large (>4 cm) Options for management: selective embolization, partial nephrectomy
Cystic nephroma	Middle-aged women or young males Radiographically presents as Bosniak III-IV cyst Herniation into collecting system can be clinical clue Difficult to differentiate from cystic malignancy Partial nephrectomy if diagnosis suspected
MESTK	Perimenopausal women, typically with history of hormonal manipulation Often stains for estrogen or progesterone receptors
Leiomyoma	Often arises from the capsule
Reninoma	Derived from juxtaglomerular cells Secretes renin; associated with hypertension and hypokalemia

to be sporadic; the National Cancer Institute estimates that only 4% are familial.

The incidence of RCC has increased since the 1970s by an average of 3% per year for whites and 4% per year for African Americans, largely related to the more prevalent use of ultrasonography and CT scan for the evaluation of a variety of abdominal or gastrointestinal complaints (Chow et al, 1999). This trend has correlated with an increased proportion of incidentally discovered and localized tumors and with improved 5-year survival rates for patients with this stage of disease (Konnak and Grossman, 1985; Thompson and Peek, 1988; Kessler et al, 1994; Pantuck et al, 2001b; Parsons et al, 2001). However, other factors must also be at play because Chow and colleagues (1999) have documented a steadily increasing mortality rate from RCC per unit population since the 1980s, and this was observed in all ethnic and both sex groups. They reported that the incidence of advanced tumors per unit population has also increased and that although the proportion of advanced tumors has decreased, the mortality rate per unit population has been negatively affected (Chow et al, 1999; Hock et al, 2002). This suggests that a deleterious change in tumor biology may have occurred during the past several decades, perhaps related to environmental factors such as diet, tobacco use, and exposure to other carcinogens. The mortality rates from RCC would presumably be even higher if not for the trend toward incidental detection (Chow et al, 1999; Pantuck et al, 2001b; Hock et al, 2002; Parsons et al, 2002).

RCC in childhood is uncommon, representing only 2.3% to 6.6% of all renal tumors in children (Castellanos et al, 1974; Chan et al, 1983; Freedman et al, 1996; Asanuma et al, 1999; Broecker, 2000). Mean age at presentation in children is 8 to 9 years, and the incidence is similar in boys and in girls. Although Wilms' tumor is much more common in younger children, RCC is as common as Wilms' tumor during the second decade of life. RCC in children and young adults is more likely to exhibit papillary histology and a predilection for locally advanced, high-grade disease, and unfavorable histologic subtypes have also been reported (Freedman et al, 1996; Renshaw et al, 1999; Sanchez-Ortiz et al, 2004b). TFE3 protein overexpression, which correlates with the presence of *ASPL-TFE3* and *PRCC-TFE3* gene translocation events involving the X and first chromosomes, is relatively common in children and young adults with RCC and is unique to this population (Heimann et al, 2001). The clinical significance of TFE3 protein overexpression is not well defined, although preliminary data suggest that these tumors may show differential sensitivity to certain chemotherapeutic agents (Argani et al, 2002; Heimann et al, 2001; Perot et al, 2003; Bruder et al, 2004). Most studies suggest that stage for stage, children and young adults with RCC may respond better to surgical therapy, and a number of long-term survivors have been reported after radical nephrectomy and lymphadenectomy for lymph node–positive disease (Freedman et al, 1996; Asanuma et al, 1999; Abou El Fettouh et al, 2002; Geller et al, 2004; Sanchez-Ortiz et al, 2004b). An aggressive surgical approach with formal lymphadenectomy has thus been recommended at the time of radical nephrectomy when RCC is suspected in children or young adults (Freedman et al, 1996; Asanuma et al, 1999; Geller et al, 2004).

Etiology

RCCs were traditionally thought to arise primarily from the proximal convoluted tubules, and this is probably true for most clear cell and papillary variants. However, more recent data suggest that the other histologic subtypes of RCC, such as chromophobe and collecting duct RCC, are derived from the more distal components of the nephron (Störkel, 1996; Oyasu, 1998; Pantuck et al, 2001a).

The only generally accepted environmental risk factor for RCC is tobacco exposure, although the relative associated risks have been modest, ranging from 1.4 to 2.5 compared with controls. All forms of tobacco use have been implicated, and risk increases with cumulative dose or pack-years (Kantor, 1977; La Vecchia et al, 1990; McLaughlin et al, 1995;

McLaughlin and Lipworth, 2000; Moyad, 2001; Dhote et al, 2004; Lindblad, 2004). Relative risk is directly related to duration of smoking and begins to fall after cessation, further supporting a cause-and-effect relationship (La Vecchia et al, 1990; McLaughlin et al, 1995; Parker et al, 2003b). A particularly high risk for RCC has been reported in smokers who also chew tobacco (Goodman et al, 1986). The relative risk associated with tobacco use in women has approached normality in some of the more highly powered case-control studies, suggesting that smoking may not be as important a risk factor for RCC in women (McLaughlin et al, 1995).

Although a number of potential etiologic factors have been identified in animal models, including viruses, lead compounds, and more than 100 chemicals such as aromatic hydrocarbons, no specific agent has been definitively established as causative in human RCC (Bennington and Beckwith, 1947; Kantor, 1977). The potential role of trichloroethylene exposure has been actively investigated; some studies showed relative risks ranging from twofold to sixfold, but others have argued that inherent biases may account for these results (Vamvakas et al, 2000; Mandel, 2001; Moyad, 2001; Bruning et al, 2003). However, Brauch and colleagues (1999) have reported an increased incidence and unique pattern of von Hippel–Lindau gene (*VHL*) mutations in this population, which would argue in favor of a causative role for this compound. Slightly increased relative risks for RCC have been reported for workers in the metal, chemical, rubber, and printing industries and those exposed to asbestos or cadmium, but the data are not particularly convincing (Kolonel, 1976; Pesch et al, 2000; Hu et al, 2002; Dhote et al, 2004; Lindblad, 2004; Moyad, 2001). One report described a 13.1-fold increased risk of RCC for workers in factories that synthesize vitamins A and E, but this has not yet been validated (Richard et al, 2004).

Case-control studies have shown that RCC is more common among individuals with long-standing obesity, low socioeconomic status, and urban background, although the causative factors have not been defined (Kantor, 1977; Goodman et al, 1986; Muscat et al, 1995; Yuan et al, 1998). The typical modern Western diet (high in fat and protein and low in fruits and vegetables), increased intake of dairy products, and increased consumption of coffee or tea have been associated with RCC, but the relative risks have been modest, and conflicting data are available in most instances (Yu et al, 1986; Lindblad et al, 1997; Moyad, 2001; Handa and Kreiger, 2002; Dhote et al, 2004; Lindblad, 2004). A family history of RCC may also be a factor; one study showed a relative risk of 2.9 for individuals with a first- or second-degree relative with RCC (Gago-Dominguez et al, 2001).

Other potential iatrogenic causes include Thorotrast (which was used as a contrast agent in the past), radiation therapy, and antihypertensive medications; but again, the relative risks are low (Wenz, 1967; Romanenko et al, 2000). Vogelzang and colleagues (1998) reported four cases of RCC developing in a previously irradiated field, and a slightly increased incidence of RCC has been reported in men who received retroperitoneal irradiation for the treatment of testicular cancer. Survivors of childhood Wilms' tumor also appear to be at increased risk for RCC, possibly related to prior radiation therapy or chemotherapy (Cherullo et al, 2001). A 1.4- to 2-fold increased risk of RCC has been reported in patients with hypertension, and diuretics, particularly thiazides, and other antihypertensive medications have been implicated (Mellemgaard et al, 1992; Hiatt et al, 1994; McLaughlin et al, 1995; Yuan et al, 1998; Shapiro et al, 1999; Chow et al, 2000; Schmieder et al, 2000; Grossman et al, 2001; Mimi and Ross, 2001; Moyad, 2001; Gago-Dominguez et al, 2002; Dhote et al, 2004; Lindblad, 2004). However, in some studies, the relative risk associated with diuretic use has evaporated when multivariate analysis has been applied, suggesting that the real risk factor is hypertension (Shapiro et al, 1999). An increased incidence of RCC is also observed in patients with end-stage renal failure and certain familial syndromes such as TS, as discussed later (Ishikawa et al, 1990; Bjornsson et al, 1996; Neumann et al, 1998).

Familial Renal Cell Carcinoma and Molecular Genetics

Since the early 1990s, significant advances have been made in our understanding of the molecular genetics of RCC. Novel familial syndromes of RCC have been identified, and the tumor suppressor genes and oncogenes contributing to the development of both sporadic and familial forms of this malignant disease have been characterized (Table 47–5) (Linehan et al, 1995; Zbar et al, 1995; Schmidt et al, 1997; Weirich et al, 1998; Choyke et al, 2003; Linehan et al, 2003; Pavlovich et al, 2003; Zimmer and Iliopoulos, 2003; Pavlovich and Schmidt, 2004). The impact of this new information should not be underestimated because it has changed our perceptions about RCC. **We now, more than ever, recognize the distinct nature of the various histologic subtypes of RCC, and advances in molecular genetics have contributed to a major revision in the histologic classification of this malignant neoplasm** (Oyasu, 1998; Linehan et al, 2003). In certain cases, a direct and beneficial impact on management of patients has also been achieved, and potential therapeutic targets have been identified (Linehan, 2002).

Knudson and Strong recognized that familial forms of cancer might hold the key to the identification of important

Table 47–5. Familial Renal Cell Carcinoma Syndromes

Syndrome	*Genetic Element*	*Major Clinical Manifestations*
von Hippel–Lindau	*VHL* gene (chromosome 3p25-26)	Clear cell RCC Hemangioblastomas of the central nervous system Retinal angiomas Pheochromocytoma
Hereditary papillary RCC	*c-met* proto-oncogene (chromosome 7q34)	Type 1 papillary RCC
Familial leiomyomatosis and RCC	Fumarate hydratase (chromosome 1q42-43)	Type 2 papillary RCC Cutaneous leiomyomas Uterine leiomyomas
Birt-Hogg-Dubé	*BHD1* gene (chromosome 17p11.2)	Chromophobe RCC Oncocytoma Transitional tumors* Cutaneous fibrofolliculomas Lung cysts Pneumothorax

*Features of both chromophobe RCC and oncocytoma.

Linehan, 2002; Choyke et al, 2003; Linehan et al, 2003; Maranchie and Linehan, 2003; Pavlovich et al, 2003; Pavlovich and Schmidt, 2004.

regulatory elements known as tumor suppressor genes (Knudson, 1971; Knudson and Strong, 1972). Their observations about the childhood tumor retinoblastoma, in which familial cases tend to be multifocal and early onset (whereas sporadic tumors tend to be unifocal and late onset), led them to propose a two-hit theory of carcinogenesis. They hypothesized that a gene product that could suppress tumor development must be involved and that both alleles of this "tumor suppressor gene" must be mutated or inactivated for tumorigenesis to occur. Furthermore, Knudson postulated that patients with the familial form of the cancer would be born with one mutant allele and that all cells in that organ or tissue would be at risk, accounting for the early onset and multifocal nature of the disease. In contrast, sporadic tumors would develop only if a mutation occurred in both alleles within the same cell, and because each event would be expected to occur with low frequency, most tumors would develop late in life and in a unifocal manner (Knudson, 1971; Knudson and Strong, 1972). Knudson's hypothesis has proved true for retinoblastoma and a number of other tumor types, including RCC (Choyke et al, 2003; Linehan et al, 2003; Pavlovich et al, 2003; Zimmer and Iliopoulos, 2003; Pavlovich and Schmidt, 2004). Identification of familial cases of RCC is particularly important because it allows linkage analysis between affected family members.

von Hippel–Lindau Disease, *VHL* Gene, and Genetics of Clear Cell Renal Cell Carcinoma

The familial form of the common clear cell variant of RCC is von Hippel–Lindau disease. This is a relatively rare autosomal dominant disorder that occurs with a frequency of 1 per 36,000 population. **Major manifestations include the development of RCC, pheochromocytoma, retinal angiomas, and hemangioblastomas of the brain stem, cerebellum, or spinal cord** (Table 47–6) (Horton et al, 1976; Go et al, 1984; Green, 1986; Jennings et al, 1988; Lamiell et al, 1989; Maher et al, 1990; Neumann and Zbar, 1997). All these tumor types are highly vascular and can lead to substantial morbidity, much of which can be avoided with prompt recognition and careful, skilled management. In particular, central nervous system lesions can lead to paralysis or death and the retinal lesions to blindness if they are not identified and managed in an expedient manner. Other common or important manifestations of von Hippel–Lindau disease include renal and pancreatic cysts, inner ear tumors, and papillary cystadenomas of the epididymis (Neumann and Zbar, 1997). An increased incidence of neuroendocrine tumors of the pancreas has also been reported in von Hippel–Lindau disease (Zbar et al, 1999). Penetrance for all of these traits is far from complete, and some, such as pheochromocytomas, tend to be clustered in certain families but do not occur in others (Neumann and Zbar, 1997). **RCC develops in about 50% of patients with von Hippel–Lindau disease and is distinctive for its early age at onset, often in the third, fourth, or fifth decade of life, and for its bilateral and multifocal involvement** (Horton et al, 1976; Go et al, 1984; Green, 1986; Jennings et al, 1988; Lamiell et al, 1989; Maher et al, 1990; Neumann and Zbar, 1997). With improved management of the central nervous system manifestations of the disease, RCC has now become the most common cause of mortality in patients with von Hippel–Lindau disease (Maher et al, 1990; Neumann and Zbar, 1997). Screening for von Hippel–Lindau disease and important considerations for the management of RCC in von Hippel–Lindau disease are reviewed later in this chapter.

Table 47–6. Manifestations of the von Hippel–Lindau Syndrome

Organ System	Lesion	Incidence (%)
Eye	Benign retinal angiomas	49-59
Central nervous system	Benign hemangioblastomas	42-72
Kidney	Clear cell RCC	24-70
	Renal cysts	22-59
Adrenal gland	Pheochromocytoma	18
Pancreas	Islet cell tumors	12
	Malignant islet cell tumor	2
	Pancreatic cysts	21-72
Epididymis	Cystadenoma	10-26
Ear	Endolymphatic sac tumor	10

Horton et al, 1976; Green, 1986; Lamiell et al, 1989; Maher et al, 1990; Neumann and Zbar, 1997; Friedrich, 1999; Choyke et al, 2003; Linehan et al, 2003; Maranchie and Linehan, 2003; Pavlovich et al, 2003.

Early clues to the genetic elements involved in the development of RCC came from cytogenetics. These studies demonstrated a common loss of chromosome 3 in kidney cancer, particularly the clear cell variants, and led to intensive efforts to find a tumor suppressor gene in this region (Zbar et al, 1987; Seizinger et al, 1988; Hosoe et al, 1990; Lerman et al, 1991). Reports by Kovacs and colleagues (1989) and Cohen and associates (1979) of translocations involving chromosome 3 further implicated this chromosome as an important regulatory element. Southern blot testing and analysis for restriction fragment length polymorphisms with a wide variety of genetic markers subsequently demonstrated loss of heterozygosity in distinct regions on the short arm of chromosome 3 (reviewed by Jennings et al, 1995). **Sophisticated molecular genetic linkage studies in patients with von Hippel–Lindau disease eventually led to the identification of the *VHL* tumor suppressor gene** (Latif et al, 1993). **This gene, which is located at chromosome 3p25-26, has now been completely sequenced, and its role as a tumor suppressor gene for both the sporadic and the familial forms of clear cell RCC has been confirmed** (Gnarra et al, 1994; Linehan et al, 1995; Zbar, 1995). The *VHL* gene consists of three exons, and it encodes a protein of 213 amino acids. A large number of common mutations or "hot spots" in the gene have been identified, and a direct correlation between genotype and phenotype has been established in some cases (Gnarra et al, 1994; Linehan et al, 1995; Zbar, 1995; Brauch et al, 2000; Pavlovich and Schmidt, 2004). For instance, missense mutations (type 2 mutations) that result in a full-length but nonfunctional protein are commonly found in families with von Hippel–Lindau disease that develop pheochromocytomas, whereas deletions leading to a truncated protein (type 1 mutations) are typically found in families that do not develop pheochromocytomas (Crossey et al, 1994; Linehan et al, 1995; Maher and Kaelin, 1997; Neumann and Zbar, 1997; Walther et al, 1999b; Hes et al, 2000; Friedrich, 2001; Pavlovich and Schmidt, 2004). The identification of this tumor suppressor gene represented a major advance in the field and required close collaboration between clinical urologic-oncologists and molecular geneticists. The important historical steps in solving this challenging puzzle

were reviewed by Linehan and colleagues (1995) and Zbar (1995), who spearheaded this important effort.

As with most tumor suppressor genes, both alleles of the *VHL* gene must be mutated or inactivated for development of the disease; the observed inheritance patterns have conformed to Knudson's hypotheses. As expected, almost all patients with von Hippel–Lindau disease were found to have germline mutations of one allele of the *VHL* tumor suppressor gene, and autosomal dominant inheritance from the affected parent was confirmed (Gnarra et al, 1994; Linehan et al, 1995, 2003). The second allele is commonly lost by gene or chromosome deletion (Zbar, 1995). Also, as predicted, most sporadic clear cell RCCs were found to harbor mutations or other genetic mechanisms that inactivated both alleles of the *VHL* gene (Zbar, 1995; Linehan et al, 2003). However, they differ in that both mutations must be acquired after birth, accounting for the late onset and the unifocal nature of the sporadic form of the disease. Knudson's hypothesis about tumor suppressor genes and their role in familial and sporadic tumors thus holds true for RCC.

Subsequent work has focused on the function of the VHL protein and its potential mechanisms of action. The VHL protein is known to bind to elongins B and C and CUL-2 to form an E3 ubiquitin ligase complex and may thereby influence the degradation of important regulatory proteins (Gorospe et al, 1999; Lisztwan et al, 1999; Zbar et al, 1999; Wiesener et al, 2001; George and Kaelin, 2003; Linehan et al, 2003; Pavlovich and Schmidt, 2004). **A critically important function of the VHL protein complex is to target the hypoxia-inducible factor 1 (HIF-1) for ubiquitin-mediated degradation, keeping the levels of HIF-1 low under normal conditions. HIF-1 is an intracellular protein that plays an important role in regulating cellular responses to hypoxia, starvation, and other stresses. Inactivation or mutation of the *VHL* gene leads to dysregulated expression of HIF-1** (Maxwell et al, 1999; Yu et al, 2001), and this protein begins to accumulate in the cell. **This in turn leads to a several-fold upregulation of the expression of vascular endothelial growth factor (VEGF), the primary proangiogenic growth factor in RCC, contributing to the pronounced neovascularity associated with clear cell RCC** (Gnarra et al, 1996; Iliopoulos et al, 1996; Gunningham et al, 2001; Igarashi et al, 2002; Linehan et al, 2003). HIF-1 also upregulates the expression of tumor growth factor-α, platelet-derived growth factor (PDGF), glucose transporter (Glut 1), erythropoietin, and carbonic anhydrase 9 (CA-9), a tumor-associated antigen with specificity for clear cell RCC (Fig. 47–14) (Zbar et al, 1999; Wykoff et al, 2000; Turner et al, 2002; Wiesener et al, 2002; Linehan et al, 2003; Grabmaier et al, 2004). In addition, the VHL protein appears to influence the cell cycle, cellular differentiation, and intracellular processing of important matrix molecules such as fibronectin; all these functions may contribute to the pathogenesis and distinctive character of this disease (Lieubeau-Teillet et al, 1998; Kamada et al, 2001; Bindra et al, 2002; Hergovich et al, 2003; Linehan et al, 2003; Na et al, 2003; Pavlovich and Schmidt, 2004).

Other genetic elements potentially involved in the development of sporadic clear cell RCC include the *p53* tumor suppressor gene, the PTEN/Akt pathway, and additional loci on the short arm of chromosome 3. Sophisticated and thorough molecular analysis, including complete gene sequencing and assessment for inactivation by hypermethylation of the promoter, has failed to reveal *VHL* gene abnormalities in a small proportion of sporadic clear cell RCCs, and the search for additional regulatory elements has continued (Clifford et al, 1998b; Hamano et al, 2002). Loss of heterozygosity has also been observed at 3p12-p14 and 3p21.2-p21.3 and is particularly common in tumors with wild-type VHL status (Shridhar et al, 1997; van den Berg and Buys, 1997; Clifford et al, 1998a; Lott et al, 1998; Velickovic et al, 2001; Bodmer et al, 2002). The functional importance of these loci is suggested by experiments showing that the transfer of fragments of chromosome

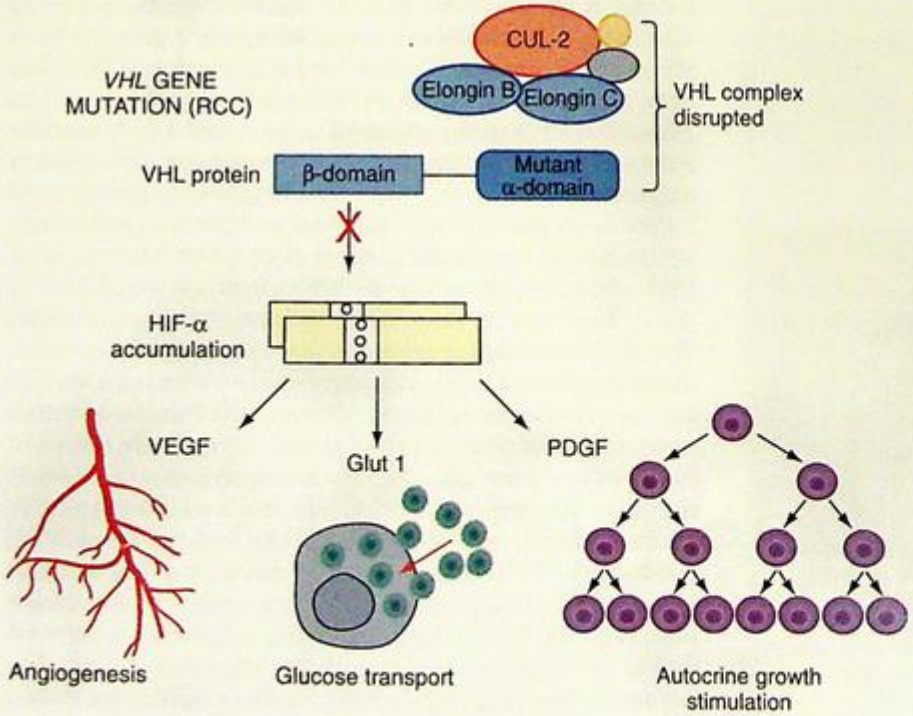

Figure 47–14. Biologic functions of the VHL protein. The wild-type VHL protein targets HIF-α for degradation. Mutation of the *VHL* gene allows HIF-α to accumulate, leading to increased expression of VEGF, Glut 1, and PDGF. This in turn has important implications with respect to tumor angiogenesis, metabolic activity, and autocrine stimulation. (From Linehan WM, Walther MM, Zbar B: The genetic basis of cancer of the kidney. J Urol 2003;170:2163-2172.)

3 containing only these genetic elements can suppress tumorigenesis in RCC cell lines (van den Berg and Buys, 1997; Lovell et al, 1999; Bodmer et al, 2002). A candidate tumor suppressor gene at 3p12 has been described and may contribute to a *VHL*-independent pathway to RCC (Lovell et al, 1999). Increased immunostaining for p53 has been reported in 6% to 40% of RCCs, with some studies suggesting a correlation with tumor grade and stage (Reiter et al, 1993; Uhlman et al, 1994; Haitel et al, 1999). Gurova and colleagues (2004) have shown inactivation of the p53 pathway in RCC cell lines in the absence of mutations in the gene itself, and a dominant mechanism was demonstrated suggesting suppression by an inhibitor of *p53* transactivation. However, the data regarding *p53* in RCC have been controversial, and no clear consensus is available at this time.

Oncogenes, such as c-*myc*, c-*erbB-1*, c-*Ha-ras*, c-*fos*, and *raf-1*, have also been studied in RCC, but the available data suggest limited involvement (Slamon et al, 1984). Finally, studies suggest that mutations in the PTEN/Akt pathway may play a role in the progression of clear cell RCC, with mutations commonly found in patients with advanced disease (Brenner et al, 2002; Velickovic et al, 2002; Horiguchi et al, 2003; Shin et al, 2003; Hara et al, 2004). Downregulation of DNA mismatch repair genes may contribute to genetic instability in RCC and allow accumulation of multiple genetic defects (Deguchi et al, 2003).

Familial Papillary Renal Cell Carcinoma and Genetics of Papillary Renal Cell Carcinoma

Several studies have documented distinct cytogenetic findings in non–clear cell histiotypes of RCC; chromosome 3 and *VHL* gene abnormalities are uncommon in these variants (Störkel et al, 1997; Oyasu, 1998). These observations suggested a distinct genetic basis for non–clear cell RCC. Papillary RCC, the second most common histologic subtype of RCC, is characterized by trisomy for chromosomes 7 and 17 as well as by abnormalities on chromosomes 1, 12, 16, 20, and Y (Störkel et al, 1997; Oyasu, 1998; Pavlovich et al, 2003). In 1995, Zbar and colleagues at the National Cancer Institute reported a **second familial form of RCC, the hereditary papillary RCC (HPRCC).** This followed a number of isolated case reports that suggested clustering of papillary RCCs within certain families (Zbar et al, 1994). In Zbar's series, there were 10 families with 41 affected members (29 men and 12 women). Median age at diagnosis was 45 years, and most patients developed multifocal and bilateral papillary RCC (Zbar et al, 1995). Type 1 papillary RCC is typically found in this syndrome rather than type 2, which is commonly seen in the familial leiomyomatosis and RCC syndrome. Unlike in von Hippel–Lindau disease, there have been only occasional reports of associated tumors in other organ systems (Czene and Hemminki, 2003). Mean survival in affected individuals was only 52 years in Zbar's series, although the number of patients dying of RCC was not defined, and it is not known whether a more aggressive course is characteristic (Zbar et al, 1995).

Studies of families with HPRCC demonstrate an autosomal dominant mode of transmission and provide insight into the molecular genetics of papillary RCC (Zbar et al, 1995; Linehan et al, 2003). Schmidt and colleagues (1997) reported the identification and characterization of a gene that appears to be responsible for the development of type 1 papillary RCC. Again, molecular linkage analysis in affected families played a key role in the discovery of this gene, which was localized to chromosome 7q31-34. However, in this case, activation of a proto-oncogene is the inciting event, rather than inactivation of a tumor suppressor gene. **Missense mutations of the *met* proto-oncogene at 7q31 were found to segregate with the disease, implicating it as the relevant genetic locus** (Schmidt et al, 1997; Pavlovich et al, 2003). The protein product of this gene is the receptor tyrosine kinase for the hepatocyte growth factor (also known as scatter factor), which plays an important role in the regulation of the proliferation and differentiation of epithelial and endothelial cells in a wide variety of organs, including the kidney. **Most of the mutations in HPRCC have been found in the tyrosine kinase domain of *met* and apparently lead to constitutive activation** (Schmidt et al, 1997; Pavlovich et al, 2003). The mutated met protein can transform NIH 3T3 murine fibroblasts and has proved to be tumorigenic in immunodeficient murine models. Trisomy for chromosome 7, which is commonly found in HPRCC and sporadic papillary RCC, develops primarily through duplication of the chromosome harboring the mutant allele of the *met* proto-oncogene and effectively increases the dosage of the activated receptor (Zhuang et al, 1998). It is thought that this nonrandom event also contributes to the development of the tumor diathesis (Zhuang et al, 1998). Early onset and multifocality in HPRCC are due to inheritance of the mutated *met* gene, which places all the cells in the kidney at risk from birth, but the incomplete penetrance and variable clinical courses associated with this syndrome have not been explained and suggest that additional genetic loci or epigenetic phenomena may modulate the phenotype (Choyke et al, 2003; Linehan et al, 2003; Pavlovich et al, 2003; Pavlovich and Schmidt, 2004). Schmidt and colleagues (2004) have described three more families with HPRCC and have shown age-dependent penetrance and a variable clinical course according to the site of mutation and family involved. Whereas tumors in HPRCC tend to be less aggressive, Schmidt and colleagues (2004) have emphasized that some can metastasize and lead to mortality.

Hereditary Leiomyomatosis and Renal Cell Carcinoma

In 2001, Launonen and colleagues described a new familial renal cancer syndrome in which patients commonly develop cutaneous and uterine leiomyomas and type 2 papillary RCC (Choyke et al, 2003; Pavlovich and Schmidt, 2004). **Renal tumors in this syndrome are unusual for familial RCC in that they are often solitary and unilateral, and they are more likely to be aggressive than are other forms of familial RCC** (Linehan et al, 2003; Maranchie and Linehan, 2003; Pavlovich and Schmidt, 2004). Collecting duct RCC, another highly malignant variant of RCC, has also been observed in this syndrome, which was named **hereditary leiomyomatosis and renal cell cancer (HLRCC) syndrome** (Linehan et al, 2003). The HLRCC locus was mapped to a region on 1q42-44, and this was later shown to be the site of the fumarate hydratase gene (Tomlinson et al, 2002; Linehan et al, 2003; Toro et al, 2003; Pavlovich and Schmidt, 2004). Fumarate hydratase is an essential enzyme in the Krebs cycle of oxidative metabolism. Again, autosomal dominant inheritance was observed, and this appears to be a tumor suppressor gene rather than an

oncogene (Linehan et al, 2003; Pavlovich and Schmidt, 2004). The mechanistic link between a metabolic enzyme located in the mitochondria and tumorigenesis is still an enigma and is now an active area of investigation (Pollard et al, 2003; Pavlovich and Schmidt, 2004). Penetrance for RCC is lower than for the cutaneous and uterine manifestations, with only a minority (20%) of patients developing RCC (Choyke et al, 2003). In contrast, almost all individuals with this syndrome will develop cutaneous leiomyomas and uterine fibroids (female patients), usually manifesting at the age of 20 to 35 years. A high proportion of women have had a hysterectomy for fibroids before formal diagnosis of this syndrome. Prompt surgical management of the renal tumors is recommended in this syndrome, given their tendency toward invasive and aggressive behavior (Linehan et al, 2003; Grubb et al, 2005b).

Birt-Hogg-Dubé Syndrome

Birt-Hogg-Dubé syndrome, in which patients develop cutaneous fibrofolliculomas, lung cysts, spontaneous pneumothoraces, and a variety of renal tumors primarily derived from the distal nephron, is named after three Canadian physicians who first described the cutaneous lesions in 1977 (Toro et al, 1999; Linehan et al, 2003; Pavlovich et al, 2003, 2005; Pavlovich and Schmidt, 2004). **The renal tumors typically include chromophobe RCC, oncocytomas, and hybrid or transitional tumors that exhibit features of both of these entities.** However, other forms of RCC, even a substantial proportion of clear cell RCC, have been observed in this syndrome (Pavlovich et al, 2002). Overall penetrance for renal tumors is about 20% to 30%, but when they occur, they are often bilateral and multifocal (Choyke et al, 2003; Pavlovich et al, 2002; Linehan et al, 2003; Pavlovich and Schmidt, 2004). The *BHD1* gene responsible for this syndrome has been mapped to chromosome 17p11.2 and is now fully sequenced (Khoo et al, 2001). Germline mutations in this gene have been found in 89% of kindreds. As with all of the familial RCC syndromes, an autosomal dominant pattern of inheritance is observed (Choyke et al, 2003; Maranchie and Linehan, 2003; Pavlovich et al, 2005).

Tumor Biology and Clinical Implications

Immunobiology and Immune Tolerance

Several lines of evidence demonstrate that RCC is immunogenic, and this knowledge has stimulated intensive efforts to harness the immune system to improve outcomes for patients with advanced disease. RCC has been shown to express a variety of tumor-associated antigens, including PRAME, RAGE-1, MUC-1, gp47, and CA-9, which contribute to its immunogenicity (Liao et al, 1997; McKiernan et al, 1997; Neumann E et al, 1998; Mulders et al, 2003; Uzzo et al, 2003). Tumor-infiltrating immune cells can be readily isolated from RCC, including natural killer cells, cytotoxic T cells with specificity for autologous tumor cells, and helper T cells and dendritic cells, which express interleukin (IL)-1 and IL-2 and function as antigen-presenting cells (Finke et al, 1992; Gaudin et al, 1995; Elsasser-Beile et al, 1999; Schwaab et al, 1999). **Of the tumor-associated antigens for RCC, CA-9 (also known as MN-9) has demonstrated the most specificity** (Liao et al, 1997; McKiernan et al, 1997). **This antigen, which is recognized by the G250 monoclonal antibody, is expressed in 70% to 90% of RCCs, primarily of clear cell histology.** In normal tissues, the expression of CA-9 is restricted to the gastric mucosa, large bile ducts, and pancreas, and its expression in normal renal epithelial cells is suppressed by wild-type VHL protein (McKiernan et al, 1997; Ivanov et al, 1998; Vissers et al, 1999). Peptides derived from CA-9 can activate cytotoxic T cells, suggesting functional relevance of CA-9 in the generation of the immune response (Vissers et al, 1999). Radioactively labeled G250 has shown promise for the detection of RCC metastases by radionuclide scanning (Brouwers et al, 2003), and conjugates between G250 and various toxins have proved effective in the renal carcinoma cell line (RenCa) animal model of RCC (Steffens et al, 1999). CA-9 is also being investigated for reverse transcriptase–polymerase chain reaction detection of circulating RCC cells in the peripheral blood (McKiernan et al, 1999), and a CA-9 based vaccine protocol has been developed (Hernandez et al, 2002). All these potential applications of MN-9 are, at present, promising but experimental.

Clinical observations such as spontaneous tumor regression, prolonged disease stabilization, and durable responses to immunotherapy also support the immunogenicity of RCC. Spontaneous regression is seen in all types of cancer, but more than 50% of reported cases have been associated with neuroblastoma, RCC, melanoma, lymphoma, or leukemia (Papac, 1998; Elhilali et al, 2000). As of 1986, there were more than 80 reported cases of spontaneous regression of RCC in the literature, and 22 were histologically proved (Kavoussi et al, 1986). The estimated incidence of spontaneous regression of RCC has ranged from 0.3% to as high as 7%, although most experienced clinicians believe that the lower figure is more accurate (Oliver et al, 1989; Vogelzang et al, 1992). Most responses have been noted in patients with pulmonary metastases and have occurred after cytoreductive nephrectomy, but regression of primary RCC has also been reported in the absence of any form of treatment (Vogelzang et al, 1992). Remission can be durable, and this phenomenon, although rare, is thought to be real (Young, 1998). It has been assumed to be due to immune surveillance, although other possibilities cannot be excluded (Papac, 1998). Response of RCC to immunomodulators, such as protocols employing IL-2, interferon alfa, and tumor-infiltrating lymphocytes, can be durable and also argues in favor of an important role for the immune system in the tumor biology of RCC (Rosenberg et al, 1998; Motzer and Russo, 2000).

Unfortunately, response rates of immunotherapy for RCC have been disappointing, typically ranging from 15% to 20% despite a variety of creative treatment strategies, suggesting immune tolerance (Motzer and Russo, 2000; Ng et al, 2002). A number of observations support impaired immune surveillance in RCC, and a variety of mechanisms affecting virtually all levels of regulation of the immune system have been proposed. These mechanisms include deficient recruitment and activation of dendritic cells (Troy et al, 1998); reduced expression of major histocompatibility complex (MHC) antigens by tumor cells (Seliger et al, 1996); deficient processing of MHC antigens by lymphocytes (Kallfelz et al, 1999); impaired proliferation, locomotion, and cytotoxicity of tumor-infiltrating lymphocytes (Alexander et al, 1993); enhanced expression of

various immunosuppressive cytokines, such as IL-10 (Lahn et al, 1999); reduced expression of caspases required for immune-mediated apoptosis of RCC cells (Kolenko et al, 1999); and increased expression of the Fas receptor (CD95) by tumor-infiltrating lymphocytes (Cardi et al, 1998; Wu et al, 2000). Interaction between the Fas ligand, which is expressed by most RCCs, and its receptor results in apoptosis and depletion of the tumor-infiltrating lymphocytes (Uzzo et al, 1999b).

Data suggest that defects in signal transduction in lymphocytes may also play an important role in the immunotolerance of RCC (Ng et al, 2002). Uzzo and colleagues have shown that nuclear factor κB (NF-κB), a transcription factor that regulates lymphocyte activity and viability, is integrally involved in these signaling pathways (Bukowski et al, 1998; Uzzo et al, 1999a, 1999b). They report impaired activation of NF-κB in tumor-infiltrating lymphocytes and dendritic cells of 60% of RCCs, which predisposes the lymphocytes to induction of apoptosis and contributes to immune dysfunction (Finke et al, 2001; Thornton et al, 2004). Defects in IL-2 receptor signaling and aberrant regulation of IκBα, which sequesters NF-κB in an inactive form in the cytoplasm, contribute to this process (Kolenko et al, 1997; Ling et al, 1998; Uzzo et al, 1999). VEGF, which is produced by the tumor cells at high levels, also promotes immunotolerance by blocking activation of NF-κB in hematopoietic progenitor cells and thereby inhibiting the maturation of dendritic cells (Gabrilovich et al, 1998; Oyama et al, 1998). This defect may be particularly important because dendritic cells are the most efficient antigen-presenting cells in the immune system. Improved understanding of the mechanisms contributing to immunotolerance in RCC should suggest novel and rational strategies for improving outcomes for patients with advanced disease.

Multidrug Resistance

Expression of multidrug resistance (MDR) proteins, such as MDR-1 (also known as P-glycoprotein), also contributes to the refractory nature of advanced RCC. P-glycoprotein is a 170-kD transmembrane protein expressed by 80% to 90% of RCCs that acts as an energy-dependent efflux pump for a wide variety of large hydrophobic compounds, including several cytotoxic drugs (Fojo et al, 1987; Kakehi et al, 1988; Mickisch, 1994). The vinca alkaloids paclitaxel, actinomycin D, and mitomycin C are processed by P-glycoprotein, thereby lowering their effective intracellular concentrations (Mickisch, 1994; Chapman and Goldstein, 1995). P-glycoprotein is expressed by proximal tubule cells in the normal kidney and tends to be downregulated in high-grade tumors and metastases, suggesting that other resistance mechanisms must also be operative (Tobe et al, 1995; Gamelin et al, 1999). Resistance of RCC to cisplatin-based therapy and to other agents that are not recognized or handled by P-glycoprotein also suggests redundancy in resistance mechanisms. The MDR-related protein, another transmembrane efflux protein, glutathione detoxification mechanisms, and altered topoisomerase activity have all been reported in RCC and may contribute to this redundancy (Mickisch, 1994; Chapman and Goldstein, 1995; Ramp et al, 2000).

A variety of drugs that can reverse the MDR-1 phenotype have been described and tested, both in vitro and in clinical trials. These agents include calcium channel blockers, calmodulin antagonists, steroids, cyclosporine, tamoxifen, toremifene, amiodarone, and quinidine (Mickisch, 1994; Chapman and Goldstein, 1995; Braybrooke et al, 2000). The primary mode of action is to bind P-glycoprotein competitively and prevent it from interacting with cytotoxic agents. A transgenic murine model with increased expression of P-glycoprotein is available and has facilitated studies in this field, allowing identification of synergistic or additive combinations of drugs (Mickisch et al, 1991). Thus far, however, clinical trials of such strategies have not significantly enhanced the response rates for cytotoxic therapies for RCC, and further research is required to define more efficacious approaches (Mickisch, 1994; Motzer and Russo, 2000).

Angiogenesis

RCC has long been recognized as one of the most vascular of cancers as reflected by the distinctive neovascular pattern exhibited on renal angiography (Fig. 47–15). Dependence on angiogenesis is also suggested by a number of studies assessing the effect of antiangiogenic agents in experimental models, such as the RenCa or xenograft models of RCC in mice. In these studies, the growth and metastasis of RCC have been blocked by endostatin, IL-12, ZD1839, PTK787/ZK 222584, and TNP-40 (fumagillin analog), all well-established antiangiogenic compounds (Fujioka et al, 1996; Tan et al, 1996; Dhanabal et al, 1999; Drevs et al, 2000). In contrast, microvessel density studies in RCC have often been inconclusive, perhaps reflecting the fact that the kidney is a highly vascular organ at baseline, making detection of increased microvessel density within tumors more difficult (Yoshino et al, 1995; Delahunt et al, 1997; Gelb et al, 1997; Nativ et al, 1998). **The primary angiogenesis inducer in clear cell RCC appears to be VEGF, which is suppressed by the wild-type VHL protein under normal conditions and is dramatically upregulated during tumor development**

Figure 47–15. Neovascularity associated with renal cell carcinoma. Right renal angiogram shows right renal mass exhibiting markedly increased neovascularity consistent with renal cell carcinoma.

(Gnarra et al, 1996; Iliopoulos et al, 1996; Tomisawa et al, 1999). Functional relevance of VEGF is demonstrated by studies showing increased levels of VEGF transcript in most hypervascular tumors, whereas the less common hypovascular counterparts exhibit reduced expression of VEGF (Takahashi et al, 1994). Increased levels of VEGF have also been found in the serum and urine of patients with RCC, and a correlation with stage and grade has been reported (Tsuchiya et al, 1998; Chang et al, 2001; Horstmann et al, 2005). Elevated serum levels of basic fibroblast growth factor have also been reported in RCC, and other putative angiogenesis inducers for this malignant neoplasm include placental growth factor, tumor growth factor-β1, angiogenin, angiopoietins, IL-8, and hepatocyte growth factor, all of which have been detected at increased levels in patients with RCC compared with normal controls (Campbell, 1997; Slaton et al, 2001; Currie et al, 2002; Yagasaki et al, 2003).

Given the angiogenesis dependence of RCC and the lack of generally effective forms of systemic therapies, it is not surprising that RCC has been targeted for antiangiogenic approaches. Thus far, TNP-470 and roquinimex (Linomide), an oral antibiotic with antiangiogenic activity, have demonstrated only limited activity in patients with advanced RCC (de Wit et al, 1997; Pawinski et al, 1997; Stadler et al, 1998). Thalidomide has been investigated extensively for patients with RCC because of its antiangiogenic effects but has likewise shown only rare responses. In addition, toxicity with thalidomide can be substantial, including thrombotic events and neurologic morbidity (Daliani et al, 2002; Escudier et al, 2002b; Nathan et al, 2002; Fanelli et al, 2003; Matthews and McCoy, 2003). The most promising results have been reported for bevacizumab, a humanized anti-VEGF antibody, which was associated with a significant delay in time to progression for patients with metastatic RCC compared with placebo (Yang et al, 2003a). Partial responses were uncommon and there were no complete responses, consistent with a tumoristatic rather than a tumoricidal mechanism of action. A number of other agents that target the VEGF pathway are now being tested in clinical trials, including SU5416, SU11248, and PTK787/ZK 222584, and various combinations of these drugs and interferon alfa are also under study (Lara et al, 2003; Pantuck et al, 2003b).

Antiangiogenic agents offer a number of potential advantages because they are not genotoxic and target stable endothelial cells rather than genetically unstable tumor cells. They are thus unlikely to induce secondary cancers or tumor resistance. In addition, many antiangiogenic agents have proved to be synergistic with one another and with cytotoxic therapies, and their side effects are limited and should not overlap those of conventional forms of therapy (Campbell, 1997). Antiangiogenic agents have been tested primarily as monotherapy in patients with refractory disease, and it is likely that more potent combinations of agents or multimodal approaches will be required to optimize results.

Growth Factors, Signal Transduction, and Regulation of the Cell Cycle

Proliferative index, as defined by PCNA or Ki-67 staining, has correlated with pathologic parameters and clinical outcomes in RCC, suggesting that regulation of the cell cycle plays an important role in the tumor biology of RCC (de Riese et al, 1993; Delahunt et al, 1995; Tannapfel et al, 1996). Increased expression of tumor growth factor-α and its receptor tyrosine kinase, the epidermal growth factor receptor (EGFR), have been reported in RCC and may contribute to tumorigenesis by promoting cell proliferation or transformation through an autocrine mechanism (Gomella et al, 1989; Mydlo et al, 1989; Sargent et al, 1989; Lager et al, 1994; Moch et al, 1997; Ramp et al, 1997). The functional relevance of EGFR in the development of RCC is also suggested by studies testing the efficacy of the C225 monoclonal antibody, which binds and neutralizes EGFR. In murine xenograft models of RCC, C225 can block tumor growth and metastasis (Prewett et al, 1998; Brouwers et al, 2004). Increased expression of the proto-oncogene *erbB-2*, which is homologous to EGFR, has also been reported in RCC, and a correlation between EGFR and erbB-2 staining and tumor grade and stage has been observed in some studies (Stumm et al, 1996). Agents that target the EGFR, such as erlotinib (Tarceva), gefitinib (Iressa, ZD1839), and C225, are now being tested in clinical trials for RCC (Tian and Dawson, 2001; Drucker et al, 2003; Mendelsohn and Baselga, 2003; Motzer et al, 2003; Dancey, 2004).

Aberrant activation of signal transduction pathways in RCC may also contribute to altered cell cycle kinetics and represent excellent targets for therapeutic intervention. Constitutive activity of the Ras, Raf-1, MEK, and other mitogen-activated protein (MAP) kinases, which mediate the effects of growth factor–EGFR interactions, have been reported in RCC, potentially increasing the proliferative index (Oka et al, 1995). **Small molecule inhibitors of these and other pathways are currently being studied in patients with advanced RCC, and this "targeted molecular approach" has generated much interest and excitement.** Many of these agents, such as BAY43-9006 (sorafenib), are multifunctional inhibitors of various tyrosine receptor kinases and may block several pathways important for tumor growth and metastasis. BAY43-9006 blocks receptors for VEGF and PDGF, and in a study of 63 evaluable patients with advanced RCC, oral treatment with this agent for a 12-week course yielded 25 responders (39.7%) and 18 patients with stable disease (Ratain et al, 2005; Sridhar et al, 2005). A subsequent phase III study with this agent reported improved progression-free survival for patients with advanced RCC. In this study, mean progression-free survival for controls was 12 weeks versus 24 weeks for actively treated patients (Escudier et al, 2005). Other signal transduction pathways involving the mTOR protein also appear to be important in the tumor biology of RCC and are being targeted for molecular therapeutics, in this case rapamycin and related compounds such as CCI-779 (Atkins et al, 2004).

Other important growth regulatory elements in RCC include the insulin-like growth factor axis (Takahashi et al, 2005), telomerase, and Bcl-2. Insulin-like growth factor receptor expression has been documented in RCC, and Parker and colleagues (2003a) have correlated this factor with survival. Increased telomerase activity, which has been found in 56% to 93% of RCCs, may also affect the cell cycle by maintaining telomere length (Mehle et al, 1996; Yoshida et al, 1998; Orlando et al, 2001). Progressive telomere loss occurs each time a normal cell divides and eventually leads to growth inhibition and cellular senescence. Increased expression of Bcl-2, which protects against programmed cell death, has also been reported in RCC and may contribute to tumor viability and treatment failure (Huang et al, 1999; Gobe et al, 2002).

The hepatocyte growth factor and its receptor, the *met* proto-oncogene, may also contribute to the pathogenesis of RCC (Sweeney et al, 2002a). The role of activating mutations of the *met* proto-oncogene in the etiology of both sporadic and familial forms of papillary RCC has already been discussed, but data suggest that upregulated expression of the ligand may occur in most of the histologic subtypes of RCC (Natali et al, 1996; Pisters et al, 1997; Schmidt et al, 1997; Clifford et al, 1998a; Horie et al, 1999). Hepatocyte growth factor (also known as scatter factor) is expressed by proximal tubular cells in the normal kidney, where it is involved in the branching tubulogenesis of the developing kidney and regeneration after renal injury. In vitro, hepatocyte growth factor has mitogenic, motogenic, and morphogenic effects on renal epithelial cells (Clifford et al, 1998a). Expression of hepatocyte growth factor and its receptor has been found in the majority of RCCs, including most histiotypes, and correlation with tumor volume was reported in one study (Horie et al, 1999). Increased serum levels of hepatocyte growth factor have also been reported in most patients with RCC, independent of histologic subtype (Petri et al, 1997). Taken together, these data suggest that hepatocyte growth factor and its receptor may play an important role in the tumor biology of RCC, although constitutive activation of the receptor, which may be the most potent mechanism, appears to be limited to papillary RCC.

Proteases, Adhesion, and the Extracellular Matrix

Interactions among cancer cells, adjacent cells, and the surrounding matrix can strongly influence their pathogenic potential. Altered intracellular processing and secretion of fibronectin and other matrix proteins is found in RCC, representing one consequence of *VHL* gene mutation (Lieubeau-Teillet et al, 1998; Ohh et al, 1998). This fundamental defect most likely has important effects on tumor biology, given the important role of the matrix in regulating cellular differentiation and tumor invasiveness and metastasis. Increased expression of proteases, such as plasmin and the matrix metalloproteinases, has correlated with reduced survival in RCC and may also contribute to the aggressive behavior of RCC (Walther et al, 1997a; Kugler et al, 1998). **Downregulation of E-cadherin and cadherin-6, which mediate adhesion between cancer cells, is well documented in RCC and has correlated with poor outcomes in most studies** (Morton et al, 1995; Paul et al, 2004). Aberrant regulation of α-catenins, the cytoplasmic proteins that bind cadherins and mediate their effects on the cytoskeleton, has also been observed in RCC, and a correlation with compromised survival has been reported (Shimazui et al, 1996; Paul et al, 1997).

Other studies have defined the adhesion molecules that facilitate interactions between tumor cells and endothelial cells in RCC. Steinbach and colleagues (1996) have shown that sialyl-Lewis^x/endothelial leukocyte adhesion molecule 1 and VLA-4/vascular cell adhesion molecule 1 interactions regulate this process, which presumably influences the ability of tumor cells to move into or out of the vascular system during the metastatic cascade.

Pathology

Most RCCs are round to ovoid and circumscribed by a pseudocapsule of compressed parenchyma and fibrous tissue rather than a true histologic capsule. Unlike upper tract transitional cell carcinomas, most RCCs are not grossly infiltrative, with the notable exception of collecting duct RCC and some sarcomatoid variants (Farrow, 1997). Tumor size has ranged from 5 to 8 cm in most series but can vary from a few millimeters to large enough to fill the entire abdomen. Tumors smaller than 3 cm were previously classified as benign adenomas, but some small tumors have been associated with metastases, and most pathologists agree that with the exception of oncocytoma, there are no reliable histologic or ultrastructural criteria to differentiate benign from malignant renal epithelial tumors (Farrow, 1997). When they are bivalved, RCCs consist of yellow, tan, or brown tumor interspersed with fibrotic, necrotic, or hemorrhagic areas; few are uniform in gross appearance. Cystic degeneration is found in 10% to 25% of RCCs and appears to be associated with a better prognosis compared with purely solid RCC (Corica et al, 1999; Koga et al, 2000; Onishi et al, 2001; Nassir et al, 2002; Imura et al, 2004). Calcification can be stippled or plaquelike and is found in 10% to 20% of RCCs.

Nuclear features can be highly variable, and a number of grading systems have been based on such features as nuclear size and shape and the presence or absence of prominent nucleoli. Fuhrman's system has been most generally adopted and is now recognized as an important independent prognostic factor for RCC (Table 47–7) (Fuhrman et al, 1982; Pantuck et al, 2001a).

Aggressive local behavior is not uncommon with RCC and can be expressed in a variety of ways. **Frank invasion and perforation of the collecting system or renal capsule are found in approximately 20% of cases, although displacement of these structures is a more common finding.** Further spread to involve adjacent organs or the abdominal wall is often precluded by Gerota's fascia, although some high-grade RCCs are able to overcome this natural barrier. One unique feature of RCC is its predilection for involvement of the venous system, which is found in 10% of RCCs, more often than in any other tumor type (Skinner et al, 1972; Schefft et al, 1978). This is most commonly manifested in the form of a contiguous tumor thrombus that can extend into the inferior vena cava as high as the right atrium. Many such tumor thrombi are highly vascularized by arterial blood flow (Novick et al, 1990).

Most sporadic RCCs are unilateral and unifocal. Bilateral involvement can be synchronous or asynchronous and is found in 2% to 4% of sporadic RCCs, although it is considerably more common in patients with von Hippel–Lindau disease or other familial forms of RCC (Farrow, 1997; Linehan et al, 2003). Multicentricity, which is found in 10% to 20% of cases, is more common in association with papil-

Table 47–7. Fuhrman's Classification System for Nuclear Grade in Renal Cell Carcinoma

Grade	Nuclear Size	Nuclear Outline	Nucleoli
1	10 mm	Round, uniform	Absent or inconspicuous
2	15 mm	Irregular	Small (visible at 400× magnification)
3	20 mm	Irregular	Prominent
4	≥20 mm	Bizarre, often multilobed	Prominent, heavy chromatin clumps present

lary histology and familial RCC (Mukamel et al, 1988; Cheng et al, 1991; Whang et al, 1995; Campbell et al, 1997; Richstone et al, 2004). Satellite lesions are often small and difficult to identify by preoperative imaging, intraoperative ultrasonography, or visual inspection; they appear to be the main factor contributing to local recurrence after partial nephrectomy (Campbell et al, 1996a; Richstone et al, 2004). Microsatellite analysis suggests a clonal origin for most multifocal RCC within the same kidney (Junker et al, 2002), but tumor in the contralateral kidney is likely to be an independent growth if it is synchronous or a metastasis if it is asynchronous (Kito et al, 2002).

All RCCs are, by definition, adenocarcinomas, derived from renal tubular epithelial cells (Zambrano et al, 1999; Pantuck et al, 2001a; Renshaw, 2002). **Most RCCs share ultrastructural features, such as surface microvilli and complex intracellular junctions, with normal proximal tubular cells, and they are believed to be derived from this region of the nephron** (reviewed in Farrow, 1997). Similarly, immunohistochemistry for lectins and other cell surface antigens has supported derivation from the proximal convoluted tubule (Kim and Kim, 2002). **However, more recent data suggest that this information applies primarily to the more common conventional and chromophilic variants of RCC** (Table 47–8), **whereas most other histologic subtypes of RCC appear to be derived from the more distal elements of the nephron** (Störkel et al, 1997; Zambrano et al, 1999; Pantuck et al, 2001a; Renshaw, 2002; Linehan et al, 2003; Pavlovich and Schmidt, 2004). Almost all RCCs express keratins 8 and 18, and 50% express vimentin, which is more commonly found in association with sarcomatoid differentiation (DeLong et al, 1993; Farrow, 1997).

Since the early 1990s, the histologic classification of RCC has undergone a major revision (Zambrano et al, 1999; Renshaw, 2002; Linehan et al, 2003). **Traditionally, RCC was divided into four histologic subtypes: clear cell, granular cell, tubulopapillary, and sarcomatoid. On the basis of advances in the molecular genetics of RCC and a more discerning interpretation of histologic and ultrastructural features, a new classification scheme was proposed by Kovacs** (1993). This new classification system was reviewed by Weiss and colleagues (1995) and was approved by an international consensus workshop of clinicians and researchers in the field (see Table 47–8) (Störkel et al, 1997; Zambrano et al, 1999; Pantuck et al, 2001a; Renshaw, 2002; Linehan et al, 2003; Pavlovich and Schmidt, 2004). Major changes included the addition of a new histologic subtype, the chromophobe cell carcinoma; the reclassification of granular cell tumors into other categories; and the recognition that sarcomatoid lesions represent poorly differentiated elements derived from other histologic subtypes rather than a distinct tumor type (Weiss et al, 1995; Störkel et al, 1997; Oyasu, 1998; Zambrano et al, 1999; Renshaw, 2002; Linehan et al, 2003; Pavlovich and Schmidt, 2004). With respect to the last point, current practice is to identify the primary histologic subtype and comment on the presence and extent of sarcomatoid differentiation rather than to separate these tumors into a distinct category, although the prognostic implications have not changed (Mian et al, 2002; Cheville et al, 2004). Depending on well-defined histologic and ultrastructural criteria, granular cell tumors are

Table 47–8. Histologic Classification of Renal Cell Carcinoma[1]

Histology	*Subtype*	*Genetic Factors*	*Characteristics*
Conventional (70%–80%)	Clear cell Granular Mixed	Deletions of chromosome 3p Mutations of *VHL* gene Loss of chromosomes 8p, 9p, and 14q Gain of chromosome 5q	Hypervascular Aggressive behavior more common May respond to immunotherapy Familial form is von Hippel–Lindau syndrome From proximal tubule
Chromophilic[2] (10%–15%)	Type 1 Type 2	Trisomy of chromosomes 7 and 17 Abnormalities of *met* proto-oncogene Loss of chromosomes 14 and Y Gain of chromosomes 12, 16, and 20	Typically hypovascular Multicentricity common Prognosis variable Type 2: worse prognosis Type 1 seen in HPRCC[3] Type 2 seen in HLRCC[4] Common in acquired renal cystic disease From proximal tubule
Chromophobic (3%–5%)	Type 1—classic Type 2—eosinophilic	Loss of chromosomes 1, 2, 6, 10, 13, 17, and 21	Prognosis better than conventional Aggressive variants exist Seen in Birt-Hogg-Dubé syndrome From intercalated cells of collecting duct
Collecting duct (1%)	Medullary cell is one variant	Loss of chromosomes 1, 6, 8, 11, 18, 21, and Y Gain of chromosomes 7, 12, 17, and 20	Centrally located Infiltrative Poor prognosis May respond to chemotherapy From collecting duct
Unclassified (1%)		Poorly defined	Poor prognosis Origin not defined

[1]Sarcomatoid variants of all of these subtypes have been described and are associated with compromised prognosis.
[2]Also known as papillary RCC.
[3]Hereditary papillary RCC.
[4]Hereditary leiomyomatosis and RCC.
Störkel et al, 1997; Zambrano et al, 1999; Pantuck et al, 2001; Renshaw, 2002; Linehan et al, 2003; Pavlovich and Schmidt, 2004.

now reclassified as papillary RCC, collecting duct RCC, or eosinophilic variants of chromophobic RCC, or they are combined with clear cell RCC into a broader category that has been designated common or conventional RCC (Weiss et al, 1995; Kovacs et al, 1997; Störkel et al, 1997; Oyasu, 1998; Zambrano et al, 1999; Renshaw, 2002). Another important development has been the identification of the medullary cell variant of RCC that is common in young African Americans with sickle cell trait (Davis et al, 1995b; Störkel et al, 1997).

All of these recent developments indicate that RCC is not a single malignant neoplasm but rather comprises several different tumor subtypes, each with a distinct genetic basis and unique clinical features (see Table 47–8). Sophisticated gene expression profiling and proteomic analyses support the individuality of each of these tumor subtypes and hold great promise for differentiating these subtypes in the future (Takahashi et al, 2003, 2004; Amy-Bazille et al, 2004; Furge et al, 2004; Sugimura et al, 2004; Yang et al, 2004). This is clearly a field in evolution, with changes stimulated by basic science advances and astute clinical observation.

Conventional RCC accounts for approximately 70% to 80% of all RCCs, representing the garden variety of RCC (Störkel et al, 1997). **These tumors are typically yellow when they are bivalved and are highly vascular,** containing a network of delicate vascular sinusoids interspersed between sheets or acini of tumor cells (Fig. 47–16). **On microscopic examination, common or conventional RCC can include clear cell, granular cell, or mixed types.** Clear cells are typically round or polygonal with abundant cytoplasm containing glycogen, cholesterol, cholesterol esters, and phospholipids, all of which are readily extracted by the solvents used in routine histologic preparations, contributing to the clear appearance of the tumor cells (Farrow, 1997). However, granular cells, which have eosinophilic cytoplasm and abundant mitochondria, can predominate. Two percent to 5% of conventional RCCs also demonstrate sarcomatoid features, and conventional RCC is more likely to exhibit venous tumor extension than is any other subtype of RCC (Rabbani et al, 2004). **In general, patients with conventional RCC have a worse prognosis compared with chromophilic or chromophobic RCC, even after stratification for stage and grade** (Cheville et al, 2003; Beck et al, 2004). **However, most responders in immunotherapy protocols have had conventional RCC, and these protocols are now being reserved primarily for this population** (Childs et al, 2000; Drachenberg and Childs, 2003). **Chromosome 3 alterations and *VHL* mutations are common in conventional RCC, and mutation or inactivation of this gene has been found in a majority of sporadic cases** (Clifford et al, 1998b; Zambrano et al, 1999; Renshaw, 2002; Linehan et al, 2003). The familial form of clear cell RCC, the von Hippel–Lindau syndrome, has already been reviewed.

Chromophilic RCC, which has also been designated papillary RCC in other classification schemes, is the second

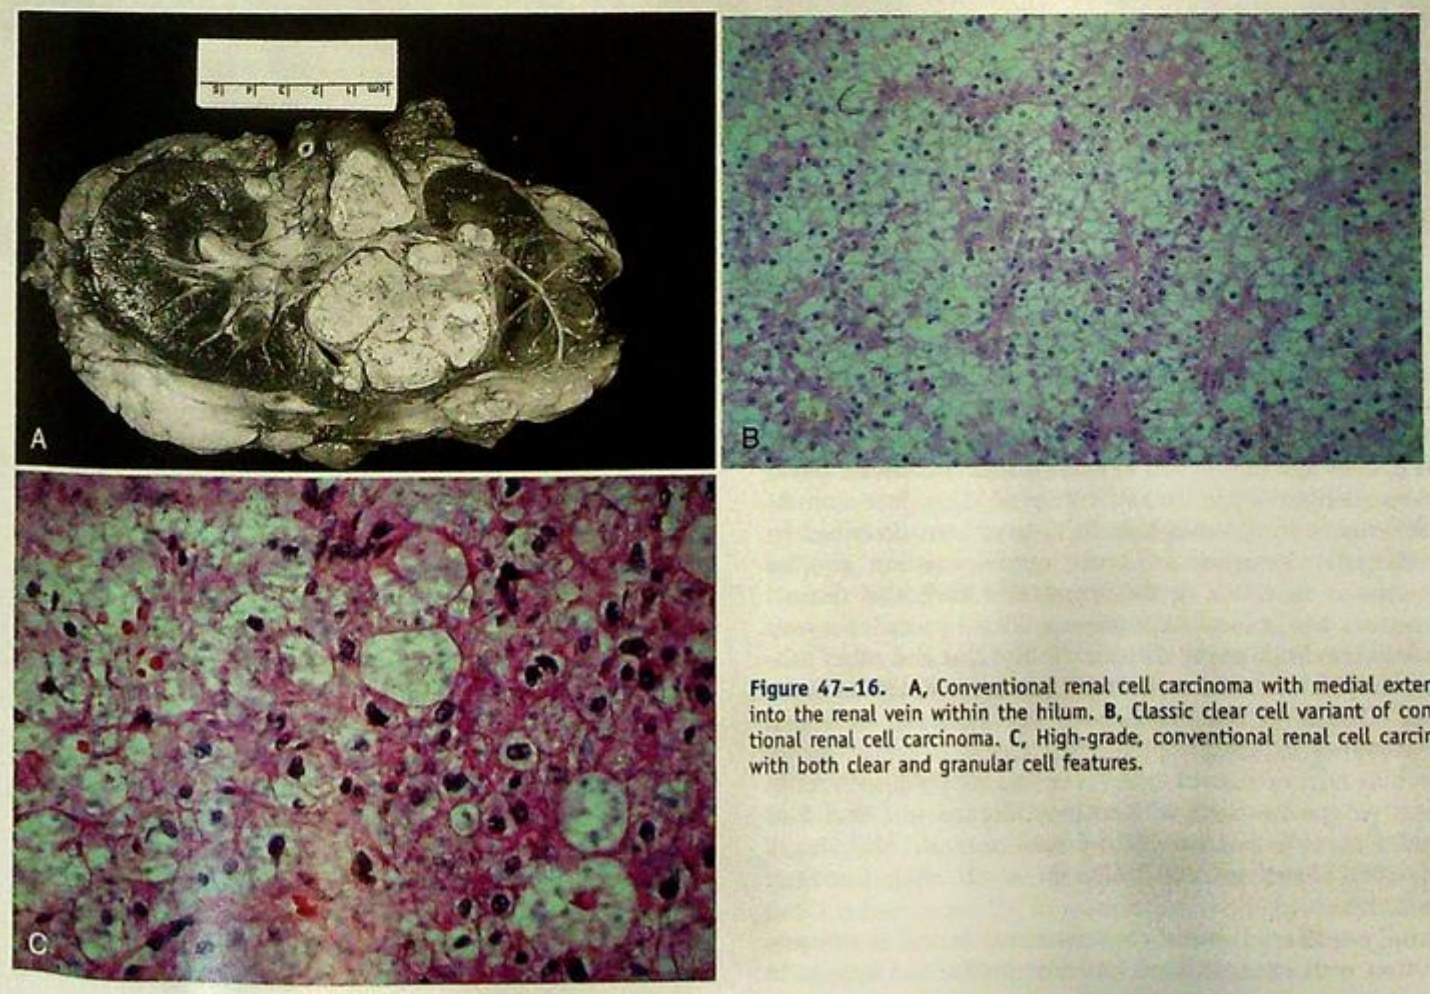

Figure 47–16. **A,** Conventional renal cell carcinoma with medial extension into the renal vein within the hilum. **B,** Classic clear cell variant of conventional renal cell carcinoma. **C,** High-grade, conventional renal cell carcinoma with both clear and granular cell features.

most common histologic subtype (Störkel et al, 1997). It represents 10% to 15% of all RCCs, although it is more commonly found in certain populations, such as patients with end-stage renal failure and acquired renal cystic disease (Ishikawa and Kovacs, 1993; Störkel et al, 1997). On microscopic examination, most tumors in this category consist of basophilic or eosinophilic cells arranged in papillary or tubular configuration; previously, more than 50% or more than 75% of the tumor had to exhibit such architectural features to qualify as a papillary RCC (Fig. 47–17). More recently, solid variants of chromophilic RCC have been described by characteristic cytogenetics and immunostaining profiles (Renshaw et al, 1997). In the future, it is likely that distinct cytogenetic and molecular features will take precedence over histologic findings in the classification of this and other subtypes of RCC (Renshaw et al, 1997; Störkel et al, 1997; Oyasu, 1998). Delahunt and colleagues (2001) have described two subtypes of chromophilic RCC: type 1, consisting of basophilic cells with scant cytoplasm; and the potentially more aggressive type 2 variant, with eosinophilic cells and abundant granular cytoplasm (Amsellem-Ouazana et al, 2002; Leroy et al, 2002; Renshaw, 2002; Choyke et al, 2003; Gunawan et al, 2003).

Small papillary tumors are commonly found at autopsy, are often well encapsulated and low grade, and appear to have low malignant potential (Farrow, 1997; Renshaw, 2002). These lesions, which possess many of the same genetic alterations found in larger papillary RCCs, have been classified as renal adenomas. Indeed, many pathologists believe that if renal adenoma does exist as a distinct entity, small, well-differentiated papillary tumors are the most likely candidates (Farrow, 1997; Renshaw, 2002).

The cytogenetic abnormalities associated with chromophilic RCC are characteristic and include trisomy of chromosomes 7 and 17 and loss of the Y chromosome. Other common findings include gain of chromosomes 12, 16, and 20 and loss of heterozygosity on chromosome 14 (Oyasu, 1998; Brunelli et al, 2003b; Kuroda et al, 2003a; Pavlovich and Schmidt, 2004). *VHL* mutations are rare in chromophilic RCC, confirming distinct genetic pathways to tumorigenesis (Kenck et al, 1996; Zambrano et al, 1999; Linehan et al, 2003). Chromophilic RCC is more likely to be hypovascular, perhaps owing to the lack of *VHL* mutations that regulate VEGF, the primary proangiogenic molecule in RCC (Blath et al, 1976; Herts et al, 2002; Kim JK et al, 2002). As discussed earlier, activating mutations of the *met* proto-oncogene located on chromosome 7, which encodes the receptor for hepatocyte growth factor, appear to be common and pathogenic in chromophilic RCC (Schmidt et al, 1997; Pavlovich and Schmidt, 2004). Indeed, this genetic defect is now being targeted for novel

treatment approaches with use of small molecule inhibitors (Schmidt et al, 1997; Linehan et al, 2003). **Another unique feature of chromophilic RCC is its tendency toward multicentricity, which approaches 40% in many series** (Renshaw and Corless, 1995; Amin et al, 1997a; Campbell et al, 1997; Baltaci et al, 2000; Chow et al, 2001).

The prognosis associated with chromophilic RCC remains controversial. Many older studies suggested a tendency toward low-grade disease, and one literature review found that 80% of papillary RCCs were confined to the kidney, which has obvious prognostic implications (Blath et al, 1976; Mancilla-Jimenez et al, 1976; Boczko et al, 1979; Mydlo and Bard, 1987; Farrow, 1997; Chow et al, 2001). On the other hand, more recent studies contain an increased proportion of high-grade and advanced tumors, often leading to the patient's demise (Lager et al, 1995; Amin et al, 1997a; Renshaw, 2002). Evolving definitions of this entity and corresponding differences in interpretation and classification may contribute to the lack of consensus about this issue. **At present, many authors believe that grade for grade and stage for stage, a significant difference in outcome for patients with chromophilic RCC versus conventional RCC may be difficult to demonstrate** (Renshaw et al, 1997; Renshaw, 2002).

Chromophobe cell carcinoma, first described by Thoenes and colleagues in 1985, is a distinctive histologic subtype of RCC that appears to be derived from the cortical portion of the collecting duct (Störkel et al, 1997). It represents 3% to 5% of all RCCs (Oyasu, 1998). The tumor cells typically exhibit a relatively transparent cytoplasm with a fine reticular pattern that has been described as a "plant cell" appearance. The chromophobic nature of this classic variant is responsible for the name of this histologic subtype (Fig. 47–18) (Nagashima, 2000; Kuroda et al, 2003a). However, eosinophilic variants of chromophobic RCC have also been described and constitute about 30% of cases (Thoenes et al, 1988; Störkel et al, 1997; Latham et al, 1999; Kuroda et al, 2003a). In either case, **a perinuclear halo is typically found, and electron microscopic findings consist of numerous 150- to 300-nm microvesicles, which are the single most distinctive and defining feature of chromophobe cell carcinoma** (Nagashima, 2000; Krishnan and Truong, 2002). **These microvesicles characteristically stain positive for Hale's colloidal iron, indicating the presence of a mucopolysaccharide unique to RCC** (Thoenes et al, 1988). Most chromophobic RCCs also stain positive for various cytokeratins, but most are negative for vimentin (Cochand-Priollet et al, 1997). Genetic analysis has revealed loss of heterozygosity at chromosomes 1, 2, 6, 10, 13, 17, and 21, and flow cytometric analysis has demonstrated hypodiploid DNA content in most cases (Schwerdtle et al, 1996; Bugert et al, 1997; Iqbal et al, 2000; Polascik et al, 2002). Some studies have reported an increased incidence of *p53* mutations in this histologic subtype, and upregulated expression of the c-*kit* oncogene has also been reported (Contractor et al, 1997; Yamazaki et al, 2003; Pan et al, 2004; Petit et al, 2004). The latter finding may have clinical relevance because it suggests that such tumors may respond to imatinib mesylate (Gleevec) (Voelzke et al, 2002). Again, chromosome 3 abnormalities and *VHL* mutations are uncommon (Schwerdtle et al, 1996). Chromophobic RCC is commonly seen in the Birt-Hogg-Dubé syndrome, but most cases are sporadic (Pavlovich et al, 2002).

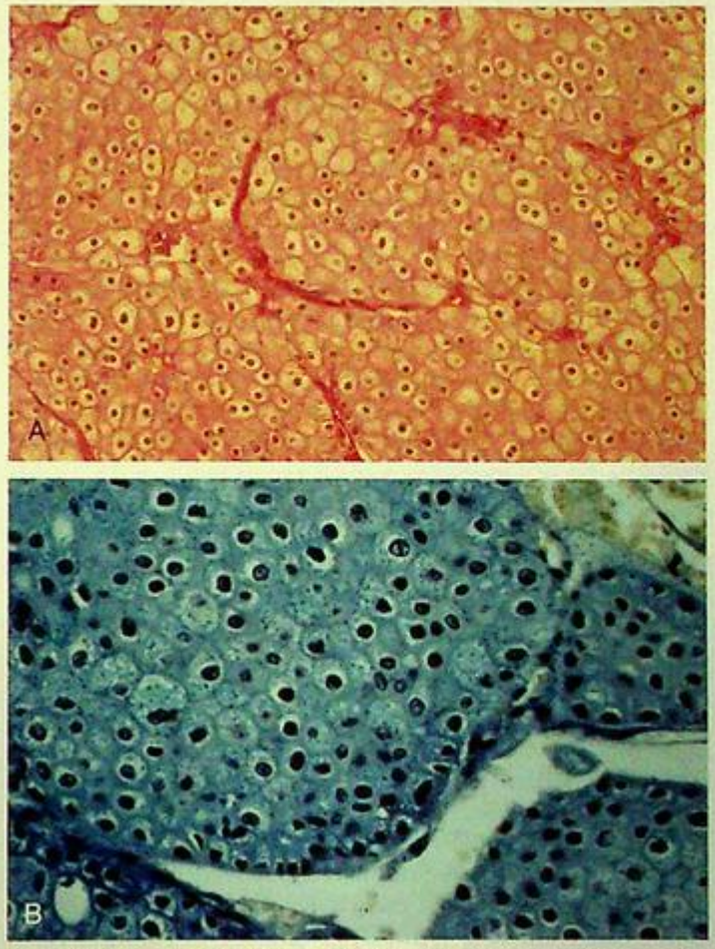

Figure 47–18. **A** and **B**, Chromophobic renal cell carcinoma with admixture of classic (chromophobic) and eosinophilic cells. Characteristic features include distinct cytoplasmic borders and perinuclear halos. The classic variant is notable for its "plant cell" appearance. Both variants stain positive for Hale's colloidal iron (**B**) and demonstrate multiple microvesicles on analysis by electron microscopy.

The clinical behavior of chromophobic RCC has not yet been adequately defined, although must studies suggest a better prognosis than for conventional RCC (Polascik et al, 2002; Peyromaure et al, 2003). Most early reports suggested a tendency to remain localized despite growth to large size as well as a predominance of low-grade disease (Thoenes et al, 1988). Crotty and colleagues (1995) reported that 86% of their 50 cases of chromophobic RCC were Robson stage I, and 94% remained cancer free with mean follow-up of 6 years. Similarly, in the series from Memorial Sloan-Kettering Cancer Center, 48 of 49 chromophobic RCCs were confined to Gerota's fascia, and 45 patients (92%) remained cancer free with mean follow-up of 52 months (Campbell et al, 1996b). Peyromaure and colleagues (2003) also reported good outcomes for patients with chromophobic RCC, with no recurrences in a series of 61 patients. In contrast, Renshaw and colleagues (1996) reported a more adverse prognosis associated with chromophobic RCC. In their series, high-grade disease was common, and 7 of 25 patients eventually developed metastatic disease. In addition, sarcomatoid differentiation has been reported in association with chromophobe cell carcinoma, and such tumors are almost invariably aggressive (Campbell et al, 1996b; Kuroda et al, 2003a).

Collecting duct, or Bellini's duct, carcinoma is a relatively rare subtype of RCC, accounting for less than 1% of all RCCs (Kennedy et al, 1990; Rumpelt et al, 1991; Carter et al, 1992; Störkel et al, 1997; Srigley and Eble, 1998; Swartz et al, 2002). Many reported cases have occurred in younger patients, often in the third, fourth, or fifth decade of life (Carter et al, 1992). Affinity for the *Ulex europaeus* lectin and expression of high-molecular-weight keratins (34βE12) support a collecting duct origin (Rumpelt et al, 1991; Oyasu, 1998; Polascik et al, 2002). Collecting duct carcinomas are derived from the medulla, but many are infiltrative, and extension into the cortex is common (Pickhardt et al, 2001). On microscopic examination, these tumors consist of an admixture of dilated tubules and papillary structures typically lined by a single layer of cuboidal cells, often creating a cobblestone appearance. Deletions on chromosome 1q and monosomy of chromosomes 6, 8, 11, 18, 21, and Y have been reported, but the number of tumors analyzed thus far has been limited (Fuzesi et al, 1992; Steiner et al, 1996; Polascik et al, 2002). Most reported cases have been high grade and advanced stage and have not responded to conventional therapies (Carter et al, 1992; Chao et al, 2002b; Polascik et al, 2002; Mejean et al, 2003; Tokuda et al, 2004). Most patients are symptomatic at presentation (Tokuda et al, 2004). Immunohistochemical and molecular analyses suggest that collecting duct RCC may resemble transitional cell carcinoma, and some patients with advanced collecting duct RCC have responded to cisplatin- or gemcitabine-based chemotherapy (Milowsky et al, 2002; Peyromaure et al, 2003).

Renal medullary carcinoma is a relatively new subtype of RCC that occurs almost exclusively in association with the sickle cell trait. It is typically diagnosed in young African Americans, often in the third decade of life (Davis et al, 1995b; Polascik et al, 2002; Swartz et al, 2002). Renal medullary carcinoma is thought to arise from the calyceal epithelium near the renal papillae but is often highly infiltrative (Davidson et al, 1995; Davis et al, 1995b). Many cases are both locally advanced and metastatic at the time of diagnosis. Most patients do not respond to therapy and succumb to their disease in a few to several months (Davis et al, 1995b; Herring et al, 1997; Figenshau et al, 1998; Polascik et al, 2002). Mean survival in Davis and coworkers' series (1995b), which consisted of 34 patients, was only 15 weeks. **This tumor shares many histologic features with collecting duct carcinoma, and some consider it a subtype of collecting duct carcinoma or at least a closely related tumor** (Störkel et al, 1997; Polascik et al, 2002; Swartz et al, 2002). The site of origin (renal papillae) and association with sickle cell trait suggest that a relatively hypoxic environment may contribute to tumorigenesis.

Sarcomatoid variants of almost all the histologic subtypes of RCC have been described, and this entity has now been reclassified because it is no longer considered a distinct histologic subtype of RCC (Weiss et al, 1995; Störkel et al, 1997; Oyasu, 1998; Delahunt, 1999; de Peralta-Venturina et al, 2001; Kuroda et al, 2003e; Cheville et al, 2004). Thorough search for epithelium-derived malignant components is almost always fruitful; it is rare to find a truly pure sarcomatoid renal mass (Delahunt, 1999). Most authors now believe that sarcomatoid lesions represent poorly differentiated regions of other histologic subtypes of RCC rather than independently derived tumors (DeLong et al, 1993; Oyasu, 1998; Delahunt, 1999). Sarcomatoid differentiation is found in 1% to 5% of RCCs, most commonly in association with conventional or chromophobic RCC (Oyasu, 1998; Cheville et al, 2004). It is characterized by spindle cell histology, positive staining for vimentin, infiltrative growth pattern, aggressive local and metastatic behavior, and poor prognosis (Fig. 47–19) (Ro et al, 1987; DeLong et al, 1993; Cangiano et al, 1999). Invasion of adjacent organs is common, and median survival has been less than 1 year in most series (Ro et al, 1987; Cangiano et al, 1999; Escudier et al, 2002a; Mian et al, 2002; Nanus et al, 2004). Multimodal approaches should be considered if performance status allows because Cangiano and colleagues (1999) reported improved response rates in patients receiving IL-2–based immunotherapy and surgery compared with patients receiving surgery alone. Other reports suggest occasional responses to chemotherapy (Bangalore et al, 2001). Some sarcomatoid tumors may express the c-*kit* proto-oncogene, suggesting that they may respond to imatinib mesylate, but clinical experience with this is limited (Voelzke et al, 2002; Castillo et al, 2004).

Unclassified RCC represents a small minority of cases (<3%) of presumed RCC with features that remain indeterminate even after careful analysis (Zisman et al, 2002a). Most

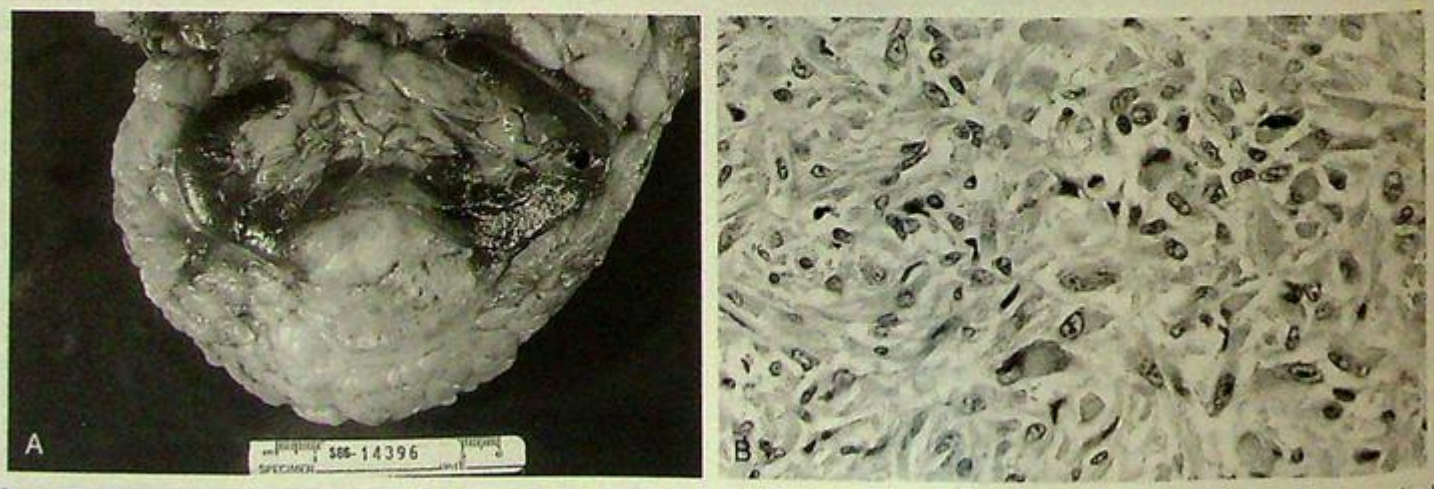

Figure 47–19. A, Conventional renal cell carcinoma with sarcomatoid differentiation demonstrating infiltrative growth pattern. B, High-grade renal cell carcinoma with sarcomatoid differentiation and rhabdoid cells.

are poorly differentiated and are associated with a highly aggressive biologic behavior and a particularly poor prognosis (Zisman et al, 2002a).

Clinical Presentation

Because of the sequestered location of the kidney within the retroperitoneum, many renal masses remain asymptomatic and nonpalpable until they are advanced. With the more pervasive use of noninvasive imaging for the evaluation of a variety of nonspecific symptom complexes, more than 50% of RCCs are now detected incidentally (Pantuck et al, 2000). Several studies have shown that such tumors are more likely to be confined to the kidney, and a positive impact on survival of patients has been reported, although the potential contributions of lead and length time biases have not been defined (Konnak and Grossman, 1985; Thompson and Peek, 1988; Kessler et al, 1994; Tsui et al, 2000b; Parsons et al, 2001; Lee et al, 2002; Leslie et al, 2003). **Symptoms associated with RCC can be due to local tumor growth, hemorrhage, paraneoplastic syndromes, or metastatic disease.** Flank pain is usually due to hemorrhage and clot obstruction, although it can also occur with locally advanced or invasive disease. **The classic triad of flank pain, gross hematuria, and palpable abdominal mass is now rarely found** (Jayson and Sanders, 1998). This is fortunate because this constellation of findings almost always denotes advanced disease, and some refer to it as the "too late triad." Before the advent of ultrasonography and CT scanning, most patients with RCC presented with one or more of these signs or symptoms, and many were incurable. Other indicators of advanced disease include constitutional symptoms, such as weight loss, fever, and night sweats; physical examination findings such as palpable cervical lymphadenopathy, nonreducing varicocele, and bilateral lower extremity edema suggest venous involvement. A minority of patients present with symptoms directly related to metastatic disease, such as bone pain or persistent cough. A less common but important presentation of RCC is that of spontaneous perirenal hemorrhage, although the underlying mass is often obscured by the blood. Zhang and colleagues (2002) have shown that more than 50% of patients with perirenal hematoma of unclear etiology have an occult renal tumor, most often AML or RCC. Repeated CT a few months later will often provide a definitive diagnosis.

Paraneoplastic syndromes are found in 20% of patients with RCC, and few tumors are associated with the diversity of such syndromes (Table 47–9). **In fact, RCC was previously referred to as the internist's tumor because of the predominance of systemic rather than local manifestations** (Sufrin et al, 1989; Gold et al, 1996; Moein and Dehghani, 2000; De Luca et al, 2002; Kamra et al, 2002). Now, a more appropriate name would be the radiologist's tumor, given the frequency of incidental detection (Parsons et al, 2001). Nevertheless, it is still important to evaluate for paraneoplastic phenomena because they can be a source of major morbidity and can affect clinical decision-making. Under normal circumstances, the kidney produces 1,25-dihydroxycholecalciferol, renin, erythropoietin, and various prostaglandins, all of which are tightly regulated to maintain homeostasis. RCC may produce these substances in pathologic amounts, and it may also elaborate a variety of other physiologically important factors, such as parathyroid hormone–like peptides, lupus-type anticoagulant, human chorionic gonadotropin, insulin, and various cytokines and inflammatory mediators (Sufrin et al, 1989; Gold et al, 1996; Ather et al, 2002). These substances are believed to be responsible for the development of constitutional symptoms such as weight loss, fever, and anemia.

Table 47–9. Incidence of Systemic Syndromes Associated with Renal Cell Carcinoma

Syndrome	Percentage
Elevated erythrocyte sedimentation rate	55.6
Hypertension	37.5
Anemia	36.3
Cachexia, weight loss	34.5
Pyrexia	17.2
Abnormal liver function	14.4
Hypercalcemia	4.9
Polycythemia	3.5
Neuromyopathy	3.2
Amyloidosis	2.0

Hypercalcemia has been reported in up to 13% of patients with RCC and can be due to either paraneoplastic phenomena or osteolytic metastatic involvement of the bone (Sufrin et al, 1989; Gold et al, 1996; Magera et al, 2004). The production of parathyroid hormone–like peptides is the most common paraneoplastic etiology, although tumor-derived 1,25-dihydroxycholecalciferol and prostaglandins may contribute in a minority of cases (Goldberg et al, 1964; Mangin et al, 1988; Sufrin et al, 1989; Gold et al, 1996; Walther et al, 1997b; Magera et al, 2004; Massfelder et al, 2004). Recent data suggest that the expression of parathyroid hormone–like peptides is suppressed by the wild-type VHL protein, and these peptides may act as potent growth factors for RCC (Massfelder et al, 2004). This may account in part for the observation that patients with RCC who present with hypercalcemia have a compromised prognosis, with a relative risk of death from cancer progression of 1.78 compared with patients with normal serum calcium levels (Magera et al, 2004). **The signs and symptoms of hypercalcemia are often nonspecific and include nausea, anorexia, fatigue, and decreased deep tendon reflexes. Medical management predominates and includes vigorous hydration followed by diuresis with furosemide and the selective use of bisphosphonates, corticosteroids, or calcitonin** (reviewed in Gold et al, 1996; Coleman, 2004). Bisphosphonate therapy is now established as standard of care for patients with hypercalcemia of malignancy, as long as renal function is adequate. Zoledronic acid, 4 mg intravenously every 4 weeks, appears to be particularly effective in patients with RCC but must be withheld in the presence of renal insufficiency (Lipton et al, 2003, 2004; Coleman et al, 2004). Indomethacin has also proved useful in a minority of cases (Gold et al, 1996; Walther et al, 1997b). More definite management would include nephrectomy or cytoreductive nephrectomy, depending on the clinical circumstances, and systemic immunotherapy to reduce the burden of disease (Goldberg et al, 1980). Hypercalcemia related to extensive osteolytic metastases is much more difficult to palliate because it is unresponsive to cytoreductive nephrectomy, but many such patients may respond to bisphosphonate therapy (Lipton et al, 2003, 2004; Coleman et al, 2004). Some patients with hypercalcemia related to osteolytic

metastases may benefit from focused radiation therapy if limited sites of involvement can be identified (Gold et al, 1996).

Hypertension and polycythemia are other important paraneoplastic syndromes commonly found in patients with RCC (Moein and Dehghani, 2000). Hypertension associated with RCC can be secondary to increased production of renin directly by the tumor; compression or encasement of the renal artery or its branches, effectively leading to renal artery stenosis; or arteriovenous fistula within the tumor (Robertson et al, 1967; Sufrin et al, 1989). Less common causes include polycythemia, hypercalcemia, ureteral obstruction, and increased intracranial pressure associated with cerebral metastases (Sufrin et al, 1989). Polycythemia associated with RCC can be due to increased production of erythropoietin, either directly by the tumor or by the adjacent parenchyma in response to hypoxia induced by tumor growth (Gross et al, 1994).

One of the more fascinating paraneoplastic syndromes associated with RCC is nonmetastatic hepatic dysfunction, or Stauffer's syndrome, which has been reported in 3% to 20% of cases (Stauffer, 1961; Rosenblum, 1987). Almost all patients with Stauffer's syndrome have elevated serum alkaline phosphatase, 67% have elevated prothrombin time or hypoalbuminemia, and 20% to 30% have elevated serum bilirubin or transaminases (Sufrin et al, 1989). Other common findings include thrombocytopenia and neutropenia, and typical symptoms include fever and weight loss, which is not surprising given that many patients are found to harbor discrete regions of hepatic necrosis (Sufrin et al, 1989; Gold et al, 1996). Hepatic metastases must be excluded. Biopsy, when it is indicated, often demonstrates nonspecific hepatitis associated with a prominent lymphocytic infiltrate (Hanash, 1982). Elevated serum levels of IL-6 have been found in patients with Stauffer's syndrome, and it is believed that this and other cytokines may play a pathogenic role (Blay et al, 1997). Hepatic function normalizes after nephrectomy in 60% to 70% of cases. Persistence or recurrence of hepatic dysfunction is almost always indicative of the presence of viable tumor and thus represents a poor prognostic finding (reviewed in Sufrin, 1989).

A variety of other less common paraneoplastic syndromes associated with RCC have been reviewed by Sufrin and colleagues (1989), including Cushing's syndrome, hyperglycemia, galactorrhea, neuromyopathy, and clotting disorders (Ather et al, 2002; Kamra et al, 2002).

In general, treatment of paraneoplastic syndromes associated with RCC has required nephrectomy or systemic immunotherapy, and except for hypercalcemia, medical therapies have not proved helpful.

Screening and Clinical Associations

A number of factors make screening for RCC appealing (Cohn and Campbell, 2000). **Most important, RCC remains primarily a surgical disease requiring early diagnosis to optimize the opportunity for cure.** Unfortunately, our ability to salvage patients with advanced disease remains limited. Consistent with these observations, several studies have demonstrated an apparent advantage to early or incidental diagnosis of RCC (Konnak and Grossman, 1985; Thompson and Peek, 1988; Kessler et al, 1994; Cohn and Campbell, 2000; Tsui et al, 2000b; Parsons et al, 2001; Lee et al, 2002; Leslie et al, 2003).

The primary factor that limits the widespread implementation of screening for RCC is the relatively low incidence of RCC in the general population (8.9 cases per 100,000 population/year) (Landis et al, 1999; Cohn and Campbell, 2000). A screening test needs to be almost 100% specific to avoid an unacceptably high false-positive rate, which would lead to unnecessary, expensive, and potentially harmful diagnostic or therapeutic procedures. In addition, even if the test were 100% sensitive and specific, the yield from screening would be so low that it would not be considered cost-effective (Cohn and Campbell, 2000). Even when one considers populations with established risk factors for RCC, such as male sex, increased age, and heavy tobacco use, generalized screening would be difficult to justify because the increase in relative risk associated with each of these factors is at best twofold to threefold (Paganini-Hill et al, 1988; Cohn and Campbell, 2000). Another confounding factor is the prevalence of clinically insignificant tumors such as renal adenomas, which are found at autopsy in 10% to 20% of individuals, and other benign or slow-growing tumors (Xipell, 1971; Bosniak et al, 1995; Cohn and Campbell, 2000; Pantuck et al, 2000; Parsons et al, 2001). There is clearly a risk that such clinically insignificant lesions could be detected, leading to unnecessary evaluation and treatment (Pantuck et al, 2000; Parsons et al, 2001). All these factors recommend against generalized screening efforts for the detection of RCC.

Review of the literature describing the use of dipstick analysis for hematuria and ultrasonography or CT scanning for screening for RCC supports these conclusions (Cohn and Campbell, 2000). Urinalysis is simple and inexpensive, but the yield of RCC in several screening studies has been exceedingly low (Mohr et al, 1986; Thompson, 1987; Mariani et al, 1989; Murakami et al, 1990). In part, this may be due to the fact that small RCCs are often not associated with hematuria (gross or microscopic) because this is a parenchymal rather than a urothelium-based malignant neoplasm (Tosaka et al, 1990). The incidence of RCC in ultrasound or CT screening studies has ranged from 23 to 300 per 100,000 population, and an apparent advantage of screening has been debated because an increased proportion of organ-confined tumors has been found in screened populations compared with historical controls (Sohma et al, 1989; Tosaka et al, 1990; Spouge et al, 1996; Tsuboi et al, 2000; Filipas et al, 2003; Fenton and Weiss, 2004). However, although the yield of RCC has been higher than expected, it is still relatively low, and it is unlikely that such efforts would be considered cost-effective (Cohn and Campbell, 2000). Overall, the yield of RCC in such studies is more than an order lower than the yield from prostate-specific antigen–based screening for prostate cancer, and many of the same controversies about lead and length time biases that have plagued the debate about screening for prostate cancer also apply to RCC (Cohn and Campbell, 2000; Pantuck et al, 2000; Parsons et al, 2001; Fenton and Weiss, 2004). Because of these considerations, it is difficult to justify generalized screening efforts for RCC given the currently available technology.

Several investigators are now reporting novel molecular assays to detect RCC-related biomarkers in the urine or serum that may substantially alter our perspective about screening for RCC. These assays can detect microsatellite alterations in the DNA, *VHL* gene mutations or hypermethylation of the

VHL gene, expression of RCC-specific proteins such as CA-9, or upregulation of angiogenic factors such as VEGF (Eisenberger et al, 1999; de la Taille et al, 2000; Chang et al, 2001; Ashida et al, 2003; Battagli et al, 2003; Chen and Getzenberg, 2004; Uzzo et al, 2004). Proteomic profiling of the urine to detect RCC-specific markers also holds much promise for the future (Rogers et al, 2003).

For now, however, the focus for screening for RCC must be on well-defined target populations, such as patients with end-stage renal failure and acquired renal cystic disease, TS, and familial RCC (Table 47–10). Eighty percent of patients with end-stage renal failure eventually develop acquired renal cystic disease, and 1% to 2% of this subgroup develops RCC (Ishikawa et al, 1980, 1990; Matson and Cohen, 1990; Levine et al, 1991; Cheuk et al, 2002; Brown, 2004). **Overall, the relative risk of RCC in patients with end-stage renal failure has been estimated to be 5- to 20-fold higher than that in the general population** (Ishikawa et al, 1990; Matson and Cohen, 1990; Ishikawa, 1991, 2004; Levine et al, 1991; Levine, 1992; Cowie, 2002; Denton et al, 2002; Brown, 2004). Fifteen percent of patients with RCC in the setting of end-stage renal failure have metastases at the time of presentation, and many such patients die of malignant progression (Levine et al, 1991; Brown, 2004; Ishikawa, 2004). Given these considerations, screening for RCC is recommended in this population, which is substantial, representing almost 300,000 patients in the United States alone. There are, however, a number of problems associated with screening this population of patients. These include concerns about short life expectancy, increased incidence of adenomas (20% to 40% versus 10% to 20% in the general population), complexity of imaging given the altered architecture associated with acquired renal cystic disease, and inevitable cost-related issues (Mindell, 1989; Levine et al, 1991, 1997; Sarasin et al, 1995; Cowie, 2002). **A reasonable compromise is to target end-stage renal failure patients without other major comorbidities, to delay screening until the third year on dialysis, and to take into account the sex and type of renal replacement therapy, although data about the last factors are admittedly controversial** (Brown, 2004). Ishizuka and colleagues (2000) have demonstrated elevated serum levels of VEGF in dialysis patients with RCC, suggesting a potential role for biomarkers for screening this population in the future. Interestingly, recent data suggest that renal transplant recipients remain at high risk for RCC in the native kidneys, and Neuzillet and colleagues (2004) have recommended continued periodic radiologic screening even after transplantation.

Table 47–10. Screening for Renal Cell Carcinoma: Target Populations

Patients with end-stage renal failure
Screen only patients with long life expectancy and no major comorbidities
Periodic ultrasound examination or CT scan beginning during third year on dialysis
Patients with known von Hippel–Lindau syndrome
Obtain biannual abdominal CT or ultrasound study beginning at the age of 15 to 20 years
Periodic clinical and radiographic screening for nonrenal manifestations
Relatives of patients with von Hippel–Lindau syndrome
Obtain genetic analysis
If positive, follow screening recommendations for patients with known von Hippel–Lindau syndrome
If negative, less stringent follow-up is required
Relatives of patients with other familial forms of RCC
Obtain periodic ultrasound or CT study and consider genetic analysis
Patients with tuberous sclerosis
Periodic screening with ultrasound examination or CT scan
Patients with autosomal-dominant polycystic kidney disease
Routine screening not justified

An increased incidence of RCC has also been debated in TS, an autosomal dominant disorder in which patients can develop adenoma sebaceum (a distinctive skin lesion), epilepsy, mental retardation, and renal cysts and AMLs (Shapiro et al, 1984; Bernstein et al, 1986; Washecka and Hanna, 1991; Aoyama et al, 1996; Bjornsson et al, 1996; Robertson et al, 1996; Sampson, 1996; Tello et al, 1998; Choyke et al, 2003; Lendvay and Marshall, 2003; Narayanan, 2003). Many cases of RCC in this syndrome have been characterized by early onset and multifocality, suggesting a genetic predisposition (Washecka and Hanna, 1991; Lendvay and Marshall, 2003). In addition, the Eker rat, which is mutant for the rodent homologue of the *TSC2* gene responsible for the development of TS in humans, develops RCC at high frequency, as do *Tsc2*-deficient knockout mice (Yeung et al, 1994; Kobayashi et al, 1997, 1999; Hino et al, 1999; Lendvay and Marshall, 2003; McDorman and Wolf, 2002). Furthermore, an increased incidence of *TSC2* mutations has been found in human RCC (Duffy et al, 2002; Lendvay and Marshall, 2003), and Liu and colleagues (2003) have shown that loss of this tumor suppressor gene leads to upregulated expression of VEGF through an mTOR and HIF-2α–mediated mechanism, analogous to the role of the VHL protein. **Such biologic and clinical observations argue in favor of an increased predisposition for RCC in this syndrome, which is consistent with most, although admittedly not all, relevant demographic data** (Shapiro et al, 1984; Bernstein et al, 1986; Washecka and Hanna, 1991; Aoyama et al, 1996; Bjornsson et al, 1996; Robertson et al, 1996; Sampson, 1996; Tello et al, 1998; Lendvay and Marshall, 2003; Martignoni et al, 2003). **A reasonable conclusion is that periodic renal imaging should be pursued in patients with TS; such a policy will also facilitate follow-up for the development and progression of AML.**

Screening for RCC in autosomal dominant polycystic kidney disease (ADPKD) was previously recommended, but several factors have prompted a reassessment of this policy. More recent studies suggest no significantly increased risk of RCC in ADPKD, and imaging is extremely difficult in this population related to the altered intrarenal architecture (Torres et al, 1985; Gregoire et al, 1987; Keith et al, 1994; Sessa et al, 1997; Soderdahl et al, 1997; Cohn and Campbell, 2000; Gupta et al, 2000; Mosetti et al, 2003). The increased incidence of adenomas in ADPKD would also militate against a potential benefit of screening (Torres et al, 1985; Gregoire et al, 1987). **Taken together, these considerations suggest that screening for RCC in patients with ADPKD should not be pursued.**

Special consideration should also be given to von Hippel–Lindau disease in any discussion of the value of

screening for RCC. This syndrome should be considered in any patient with early-onset or multifocal RCC or RCC in combination with any of the following: a history of visual or neurologic symptoms; a family history of blindness, central nervous system tumors, or renal cancer; or coexistent pancreatic cysts, epididymal lesions, or inner ear tumors (Neumann and Zbar, 1997; Choyke et al, 2003; Linehan et al, 2003; Pavlovich and Schmidt, 2004). Patients suspected of having von Hippel–Lindau disease, or the appropriate relatives of those with documented disease, should strongly consider genetic evaluation. The entire *VHL* gene has now been sequenced and detailed, and sophisticated molecular analysis is readily available and offers a number of important advantages (Zbar et al, 1999; Linehan et al, 2003). Patients with germline mutations can be identified and offered clinical and radiographic screening that can identify the major manifestations of von Hippel–Lindau disease at a presymptomatic phase, allowing potential amelioration of the considerable morbidity associated with this syndrome (Glenn et al, 1992; Maranchie and Linehan, 2003). Investigators at the National Institutes of Health have recommended that such patients be evaluated with (1) annual physical examination and ophthalmologic evaluation beginning in infancy; (2) estimation of urinary catecholamines at the age of 2 years and every 1 to 2 years thereafter; (3) MRI of the central nervous system biannually beginning at the age of 11 years; (4) ultrasound examination of the abdomen and pelvis annually beginning at the age of 11 years, followed by CT scanning every 6 months if cysts or tumors develop; and (5) periodic auditory examinations (Choyke et al, 1995; Friedrich, 1999; Maranchie and Linehan, 2003). Individuals who are found to be wild type for both alleles of *VHL* also benefit because they can be spared much of the expense and anxiety associated with such intensive surveillance protocols.

Molecular screening is also available for patients suspected of having hereditary papillary RCC and other familial forms of RCC and should be discussed with appropriate family members (Schmidt et al, 1997; Linehan et al, 2003). Again, individuals at risk, as defined by the presence of mutations of the *met* proto-oncogene or other relevant genetic alterations, and those with suggestive clinical or family histories should be evaluated with abdominal ultrasonography or CT scanning at periodic intervals. Further testing may be indicated according to the syndrome involved.

Staging and Diagnosis

Until the 1990s, the most commonly used staging system for RCC was Robson's modification of the system of Flocks and Kadesky, and this schema is still embedded in the mindset of most urologists (Fig. 47–20) (Robson, 1963; Robson et al, 1969). In retrospect, the limitations of this classification scheme are readily evident. The primary problem can be found in stage III, where tumors with lymphatic metastases, a very poor prognostic finding, were combined with those with venous involvement, many of which can be treated and potentially cured with an aggressive surgical approach (Gettman and Blute, 2002; Leibovich et al, 2003b). Further imprecision resulted from the fact that the extent of nodal and venous involvement was not delineated in this system. The net effect was that the prognostic significance of the various stages was

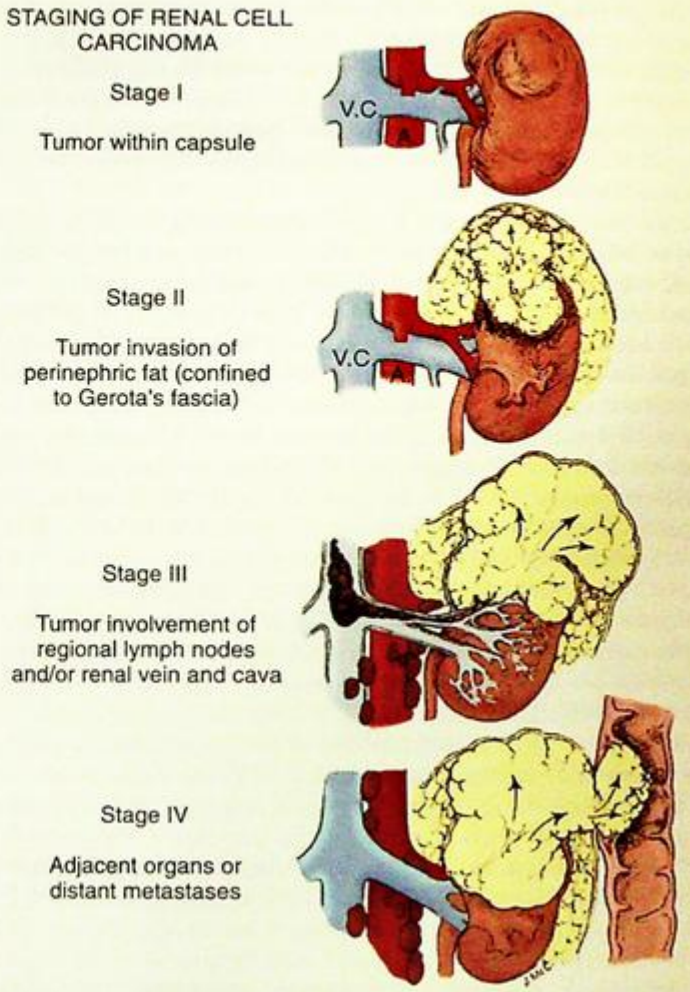

Figure 47–20. Staging of renal cell carcinoma as proposed by Holland, in accordance with classification systems developed by Robson, Murphy, and Flocks and Kadesky. (From Holland JM: Cancer of the kidney: Natural history and staging. Cancer 1973;32:1030. Copyright © 1973 American Cancer Society.)

blunted, with some studies reporting equivalent survival for patients with stage II and stage III tumors (Skinner et al, 1971).

The tumor, nodes, and metastasis (TNM) system proposed by the International Union Against Cancer represented a major improvement because it separated tumors with venous involvement from those with lymphatic invasion, quantified each, and defined the anatomic extent of disease more explicitly (Beahrs et al, 1988; Leibovich et al, 2003b). Another advantage of the TNM system is that it has facilitated comparison of clinical and pathologic data from various centers across the globe (Leung and Ghavamian, 2002; Leibovich et al, 2003b).

In 2002, the American Joint Committee on Cancer proposed a revision of the TNM system that is now the recommended staging system for RCC (Tables 47–11 and 47–12). This staging classification has undergone several modifications in the past two decades in an effort to more accurately reflect tumor biology and prognosis and to guide clinical management. It is important to be cognizant of these changes in comparing studies from different eras. In 1997, the previous division of stages T1 and T2 at tumor size of 2.5 cm was

Table 47–11. International TNM Staging System for Renal Cell Carcinoma

T: Primary tumor

TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
T1a: Tumor ≤ 4.0 cm and confined to the kidney
T1b: Tumor > 4.0 cm and ≤ 7.0 cm and confined to the kidney
T2: Tumor > 7.0 cm and confined to the kidney
T3a: Tumor invades adrenal gland or perinephric fat but not beyond Gerota's fascia
T3b: Tumor extents into the renal vein (or its segmental branches) or vena cava below diaphragm
T3c: Tumor extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4: Tumor invades beyond Gerota's fascia

N: Regional lymph nodes

NX: Regional lymph nodes cannot be assessed
N0: No regional lymph nodes metastasis
N1: Metastasis in a single regional lymph node
N2: Metastases in more than one regional lymph node

M: Distant metastases

MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis present

Stage grouping

Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	N0 or N1	M0
Stage IV	T4	any N	M0
	any T	N2	M0
	any T	any N	M1

Modified from the AJCC Cancer Staging Manual, 6th ed. New York, Springer-Verlag, 2002.

Table 47–12. Comparison of Robson and TNM Staging Systems for Renal Cell Carcinoma

Tumor Status	*Robson Stage*	*TNM Stage (2002)*
Tumor ≤ 4.0 cm, confined to kidney	I	T1a
Tumor > 4.0 cm and ≤ 7.0 cm and confined to kidney	I	T1b
Tumor > 7.0 cm and confined to kidney	I	T2
Extension to adrenal gland or perinephric fat	II	T3a
Renal vein or vena caval involvement below diaphragm	IIIa	T3b
Vena caval involvement above the diaphragm	IIIa	T3c
Single lymph node involved	IIIb	N1
More than one lymph node involved	IIIb	N2
Combination of venous and nodal involvement	IIIc	T3b or c, N1 or N2
Local extension beyond Gerota's fascia	IVa	T4
Distant metastasis	IVb	M1

abandoned because several studies showed no prognostic significance at this level. Analysis of the Surveillance, Epidemiology, and End Results (SEER) program database demonstrated survival differences associated with 5-, 7.5-, and 10-cm cut points, and the 7-cm cut point between stages T1 and T2 was adopted because it reflected the mean tumor size in the database (Guinan et al, 1995a; Gettman et al, 2001a). Other significant changes included a reclassification of venous tumor thrombi and a simplification of the classification of extent of nodal involvement (Guinan et al, 1997). These changes were substantiated by Gettmann and colleagues (2001a), who showed that this schema provided improved prognostication. Another important change clarified the status of tumors that invade the perinephric fat medially, near the renal sinus. These tumors were often classified as stage pT2 in the past. Consensus is that these tumors should now be classified as T3a because there is no biologic rationale for excluding them from this category, and studies suggest that such tumors actually may be at increased risk for metastasis related to enhanced access to the venous system (Bonsib et al, 2000; Uzzo et al, 2002). Regarding venous involvement, macroscopic invasion of the caval wall is now classified as stage T3c since this has been found to be a poor prognostic indicator (Hatcher et al, 1991).

In the 2002 version, stage T1 was subdivided; T1a represents tumor size of 4 cm or less and T1b represents tumor size between 4 and 7 cm, reflecting data in the literature demonstrating excellent outcomes for patients with small (4 cm or less), unilateral, confined tumors managed by either partial or radical nephrectomy (Butler et al, 1994; Lerner et al, 1996; Hafez et al, 1999; Igarashi et al, 2001). This change was validated in a large review of 1593 patients with nonmetastatic clear cell RCC treated with radical nephrectomy at the Mayo Clinic (Frank et al, 2004b). Subclassification of T2 tumors into T2a (7 to 10 cm) and T2b (>10.0 cm) has also been proposed by Frank and colleagues (2005b), who presented data showing a substantial prognostic difference between these two subgroups of patients. Nevertheless, the cut point for classification of organ-confined RCC remains controversial; some authors argue that a single cut point of 4.5 to 5.5 cm would provide optimal prognostication while having the advantage of simplicity (Zisman et al, 2001a; Sagalowsky, 2002; Elmore et al, 2003; Ficarra et al, 2004).

Other proposed changes in the staging system for RCC have focused on patients with stages T3a-c, specifically related to adrenal gland involvement, tumor thrombus, and invasion of the perinephric fat. Several reports now document a poor prognosis associated with adrenal metastasis from RCC, and one proposal is to reclassify tumors with direct extension into the adrenal gland as T4 and others as M1, reflecting a likely hematogenous route of spread (Sagalowsky et al, 1994; Sandock et al, 1997; Paul et al, 2001a; von Knobloch et al, 2004; Lam et al, 2005; Siemer et al, 2005; Thompson et al, 2005). Leibovich and colleagues (2005) have proposed reclassification of patients with T3 RCC into four categories: (1) tumor thrombus limited to renal vein but no invasion of the perinephric fat; (2) invasion of the perinephric fat but no tumor thrombus; (3) tumor thrombus limited to the renal vein and invasion of the perinephric fat *or* caval thrombus below the diaphragm; and (4) caval thrombus below the diaphragm and invasion of the perinephric fat *or* caval thrombus above the diaphragm. Their series of 675 patients with pT3 RCC demonstrated substantially improved prognostication with

this combined classification system, which also makes intuitive sense with respect to the tumor biology of the disease (deKernion, 2005). Five-year cancer-specific survival rates in these four groups were 64%, 55%, 42%, and 26%, respectively.

The clinical staging of renal malignant disease begins with a thorough history, physical examination, and judicious use of laboratory tests. Symptomatic presentation, significant weight loss (>10% of body weight), bone pain, and poor performance status all suggest advanced disease, as do physical examination findings of a palpable mass or lymphadenopathy. A nonreducing varicocele and lower extremity edema suggest venous involvement. Abnormal liver function test results, elevated serum alkaline phosphatase or sedimentation rate, and significant anemia point to the probability of advanced disease (Gelb, 1997; Srigley et al, 1997).

The radiographic staging of RCC can be accomplished with a high-quality abdominal CT scan and a routine chest radiograph in most cases, with selective use of MRI and other studies as indicated (reviewed in Bechtold and Zagoria, 1997; Choyke et al, 2001). MRI can be reserved primarily for patients with locally advanced malignant disease, possible venous involvement, renal insufficiency, or allergy to intravenous contrast material (Choyke, 1997; Pretorius et al, 2000; Choyke et al, 2001). CT findings suggestive of extension into the perinephric fat include perinephric stranding (Fig. 47–21), which is a nonspecific finding, and a distinct soft tissue density within the perinephric space, which is an uncommon finding (Bechtold and Zagoria, 1997). Overall, the accuracy of CT or MRI for detection of involvement of the perinephric fat is low, reflecting the fact that extracapsular spread often occurs microscopically (Pretorius et al, 2000; Choyke et al, 2001; Leung and Ghavamian, 2002; Kamel et al, 2004). Most of these cases are managed with radical nephrectomy, so the clinical relevance of this imprecision in staging is blunted. Ipsilateral adrenal involvement can be assessed with reasonable accuracy through a combination of preoperative CT and intraoperative inspection. **Patients with an enlarged adrenal gland on CT, upper pole tumor location, extensive malignant replacement of the kidney, or palpably abnormal adrenal gland are at risk for ipsilateral adrenal involvement and should be managed accordingly** (Sagalowsky et al, 1994; Sandock et al, 1997; Tsui et al, 2000a; Sawai et al, 2002; Kobayashi et al, 2003). **Enlarged hilar or retroperitoneal lymph nodes 2 cm or more in diameter on CT almost always harbor malignant change, but this should be confirmed by percutaneous aspiration or surgical exploration. Many smaller nodes prove to be inflammatory rather than neoplastic and should not preclude surgical therapy** (Studer et al, 1990; Choyke et al, 2001; Israel and Bosniak, 2003b). MRI can add specificity to the evaluation of retroperitoneal nodes by distinguishing vascular structures from lymphatic ones (Bechtold and Zagoria, 1997). MRI is the premier study for evaluation of invasion of tumor into adjacent structures and for surgical planning in these challenging cases (Bechtold and Zagoria, 1997; Choyke, 1997; Pretorius et al, 2000; Choyke et al, 2001). Obliteration of the fat plane between the tumor and the adjacent organs (such as the liver) can be a misleading finding on CT and should prompt further imaging with MRI.

Figure 47–21. CT scan after administration of contrast agent shows right renal tumor with perinephric stranding suggesting invasion of the perinephric fat.

The sensitivities of CT for detection of renal venous tumor thrombus and inferior vena caval involvement are 78% and 96%, respectively (Bechtold and Zagoria, 1997). CT findings suggestive of venous involvement include venous enlargement, abrupt change in the caliber of the vein, and intraluminal areas of decreased density or filling defects. The diagnosis is strengthened by the demonstration of collateral vessels. Most false negatives occur in patients with right-sided tumors in whom the short length of the vein and the mass effect from the tumor combine to make detection of the tumor thrombus difficult (Bechtold and Zagoria, 1997). Fortunately, such cases are readily identified and dealt with intraoperatively. **MRI is well established as the premier study for the evaluation and staging of inferior vena caval tumor thrombus, although recent data suggest that multiplanar CT may be equivalent** (Goldfarb et al, 1990; Kallman et al, 1992; Bechtold and Zagoria, 1997; Choyke, 1997; Oto et al, 1998; Sun et al, 1999; Pretorius et al, 2000; Choyke et al, 1987; Sohaib et al, 2002; Israel and Bosniak, 2003a; Ergen et al, 2004; Hallscheidt et al, 2004). MRI provides reliable information about both the cephalad and caudad extent of the thrombus and can often distinguish bland from tumor thrombus. In addition, MRI is noninvasive and does not place the patient at risk for contrast nephropathy (Pretorius et al, 2000; Choyke et al, 2001). **Venacavography is now best reserved for patients with equivocal MRI findings and for patients who cannot tolerate MRI or have other contraindications to MRI.** Transesophageal echocardiography also appears to be accurate for establishing the cephalad extent of the tumor thrombus, but it is invasive and provides no distinct advantages over MRI in the preoperative setting (Glazer and Novick, 1997). Doppler ultrasonography is operator dependent and does not provide the anatomic resolution available with MRI (Habboub et al, 1997).

Metastatic evaluation in all cases should include a routine chest radiograph, careful and systematic review of the abdominal and pelvic CT findings, and liver function tests (Choyke et al, 1987). Most investigators agree that a bone scan can be reserved for patients with elevated serum alkaline phosphatase or bone pain and that a chest CT scan can be reserved

for patients with pulmonary symptoms or an abnormal chest radiograph (Lim and Carter, 1993; Seaman et al, 1996; Choyke et al, 2001). However, patients with locally advanced disease, enlarged retroperitoneal lymph nodes, or significant comorbid disease may mandate more thorough imaging to rule out metastatic disease and to aid in treatment planning (Choyke et al, 2001). As always, evaluation and management must be individualized on the basis of the clinical circumstances. Shvarts and colleagues (2004) have shown that performance status is a powerful predictor of bone metastasis. In their analysis, patients with good performance status (Eastern Cooperative Oncology Group performance status score of 0), no evidence of extraosseous metastases, and no bone pain were extremely low risk and did not benefit from bone scanning. They recommended a bone scan for all other patients, and the incidence of bone metastasis in this group was above 15%.

Positron emission tomography has also been investigated for patients with high risk or metastatic RCC, with most studies showing good specificity but suboptimal sensitivity. At present, its best role is for patients with equivocal findings on conventional imaging. In this setting, an abnormal positron emission tomographic scan indicates metastatic disease and could strongly influence further evaluation and management (Hoh et al, 1998; Ramdave et al, 2001; Nimeh et al, 2002; Jadvar et al, 2003; Kang et al, 2004). Immunoscintigraphy with radiolabeled monoclonal antibodies to CA-9 is also being explored in this population, analogous to the ProstaScint scan for prostate cancer (Brouwers et al, 2002).

The indications for percutaneous renal biopsy or aspiration in the evaluation of renal masses have traditionally been limited, primarily related to concerns about sampling error, difficulty interpreting limited tissue given the inherent similarities between the eosinophilic variants of RCC and oncocytoma, and recognition of the improved diagnostic accuracy of cross-sectional imaging such as CT or MRI (Herts and Baker, 1995; Schatz and Lieber, 2003). Eighty-three percent to 90% of solid renal masses thought to be suspicious for RCC based on careful radiographic evaluation prove to be RCC on final pathologic analysis (Silver et al, 1997). Fine-needle aspiration biopsy (FNAB) cannot significantly improve on this degree of diagnostic certainty and is unlikely to influence clinical management in the majority of cases (Dechet et al, 2003). **The sensitivities and specificities of FNAB for the diagnosis of RCC are well documented and range from 80% to 95%** (Herts and Baker, 1995; Dechet et al, 2003; Neuzillet et al, 2004). Five percent to 15% of RCCs are thus misdiagnosed by FNAB, and given the high likelihood of malignancy, most investigators are appropriately unwilling to proceed with this invasive procedure. Notable exceptions include patients suspected of having metastatic disease, renal abscess, or lymphoma, all of which are primarily managed medically (Herts and Baker, 1995; Herts and Remer, 2000). Patients with flank pain, febrile urinary tract infection, and renal mass may be considered for percutaneous biopsy or aspiration to establish a diagnosis of renal abscess rather than malignant disease; a drainage tube can be placed concomitantly if it is clinically indicated. Lymphoma should be suspected in patients with massive retroperitoneal lymphadenopathy, especially in the setting of distant lymphadenopathy or splenomegaly, and a percutaneous biopsy is often diagnostic, precluding the need for major surgery. Metastasis to the kidney is usually multifocal and is particularly common in patients with lung, breast, and gastrointestinal cancers and malignant melanoma (Choyke et al, 1987; Pollack et al, 1987). However, FNAB should be strongly considered in any patient with a history of primary nonrenal malignant disease, unless clinical circumstances, such as a prolonged interval between diagnoses and unifocal renal involvement with a well-vascularized mass, point toward RCC rather than metastatic disease. Another indication for FNAB is a need to establish a pathologic diagnosis of RCC in patients presenting with disseminated metastases or unresectable primary tumors or in patients with extensive comorbid disease or other contraindications to surgery. In this setting, FNAB can confirm the diagnosis, guide management, and potentially obviate the need for surgery.

More recently, FNAB has been reassessed, and several groups have shown enthusiasm for this approach. Some studies suggest improved sensitivity and specificity, particularly when FNAB is combined with molecular analysis for CA-9 expression or other markers for RCC (Truong et al, 2001; Wood et al, 1999; Lechevallier et al, 2000; Richter et al, 2000; Hara et al, 2001; Liu and Fanning, 2001; Caoili et al, 2002; Rybicki et al, 2003; Li et al, 2004). Molecular analysis could also assess HMB-45 expression to evaluate for atypical AML, and genetic analysis for oncocytoma may also be available in the near future. In addition, FNAB could influence clinical management of small renal masses if markers of clinical aggressiveness could be established and reliably evaluated on limited pathologic material (Neuzillet et al, 2004).

The potential complications of FNAB include bleeding, infection, arteriovenous fistula, needle track seeding, and pneumothorax (reviewed in Herts and Baker, 1995). In general, the incidence of complications has been reduced significantly since the introduction of smaller gauge needles. Tumor location, operator expertise, and number of biopsy attempts can also influence complication rates. Perinephric bleeding can be detected by CT scan in 90% of cases, but clinically significant hemorrhage resulting in gross hematuria is much less common (5% to 7%) and is almost always self-limited (Hopper and Yakes, 1990; Vassiliades and Bernardino, 1991). Blood transfusion is only rarely required. Persistent bleeding may indicate an arteriovenous fistula or a laceration of a major branch artery or vein and may require angiography and embolization. All other complications of FNAB are uncommon, with clinically significant morbidity occurring in less than 5% of cases. Only five cases of needle track seeding have been reported with RCC. Overall, the estimated incidence of needle track seeding with urologic malignant neoplasms is less than 0.01%; most occur with poorly differentiated transitional cell carcinoma (Herts and Baker, 1995).

Prognostic Factors

Important prognostic factors for RCC include specific clinical signs or symptoms, tumor-related factors, and various laboratory findings (Kontak and Campbell, 2003). **Overall, tumor-related factors such as pathologic stage, tumor size, nuclear grade, and histologic subtype have the greatest utility on an independent basis. However, an integrative approach, combining a variety of factors that have proved to**

have independent value on multivariate analysis, appears to be most powerful (Kattan et al, 2001; Zisman et al, 2001b; Kontak and Campbell, 2003; Patard et al, 2004a).

Clinical findings suggestive of a compromised prognosis include symptomatic presentation, weight loss of more than 10% of body weight, and poor performance status (Gelb, 1997; Srigley et al, 1997; Zisman et al, 2001b; Kim et al, 2003; Kontak and Campbell, 2003; Schips et al, 2003). Anemia, thrombocytosis, hypercalcemia, albuminuria, elevated serum alkaline phosphatase or erythrocyte sedimentation rate, and other paraneoplastic signs or symptoms have also correlated with poor outcomes for patients with RCC (Gelb, 1997; Srigley et al, 1997; Symbas et al, 2000; O'Keefe et al, 2002; Kim et al, 2003; Kontak and Campbell, 2003; Vaglio et al, 2003). Several molecular markers are now showing prognostic significance and may provide important insight into the tumor biology (Bui et al, 2001; Han et al, 2003; Kontak and Campbell, 2003). The most promising of these factors appears to be CA-9, which is regulated by the *VHL* gene and is overexpressed in many conventional RCCs (Bui et al, 2003, 2004). High CA-9 expression has correlated with improved survival in this population, suggesting that tumors with *VHL*-independent pathogenesis may have increased aggressiveness, and Yao and colleagues (2002) have presented data to support this (Mukouyama et al, 2004). Decreased proliferative index as assessed by Ki-67 has also correlated with improved survival in clear cell RCC (Bui et al, 2004). Other factors that may prove to be useful include apoptotic indices; the status of various genetic elements, such as *p53* (Shvarts et al, 2005); and evaluation of the expression and function of various growth factors and their receptors, proteins that regulate apoptosis (Miyake et al, 2002), and important adhesion molecules and proteases (see section on tumor biology) (Bui et al, 2001; Zhou and Rubin, 2001; Uchida et al, 2002; Cho et al, 2003; Kontak and Campbell, 2003; Shimazui et al, 2004). Assays for the levels of proangiogenic factors such as VEGF or basic fibroblast growth factor in the serum or urine may also improve prognostication (Gelb, 1997; Srigley et al, 1997; Jacobsen et al, 2000; Zhou and Rubin, 2001; Mizutani et al, 2003). Gene array and proteomic technology are likely to identify additional prognostic factors in the near future (Kim et al, 2004b).

Pathologic stage has proved to be the single most important prognostic factor for RCC (Thrasher and Paulson, 1993; Delahunt, 1998; Kontak and Campbell, 2003). Various studies have shown a strong correlation between Robson's pathologic stage and 5-year survival rates for RCC, as shown in Table 47–13. Similar but more discerning results have been reported for tumors staged with the TNM classification system (Table 47–14), confirming that the extent of locoregional or systemic disease at diagnosis is the primary determinant of outcome for this disease (Bassil et al, 1985; Hermanek and Schrott, 1990; Kontak and Campbell, 2003). These studies demonstrate 5-year survival rates of 70% to 90% for organ-confined disease and document a 15% to 20% reduction in survival associated with invasion of the perinephric fat (Kontak and Campbell, 2003; Leibovich et al, 2005). Renal sinus involvement should definitely be classified as T3a, and studies suggest that these patients may be at higher risk for metastasis related to increased access to the venous system (Bonsib et al, 2000; Uzzo et al, 2002). Several reports have shown that most patients with ipsilateral adrenal involvement, which is found in 1% to 2% of cases, eventually succumb to systemic disease progression, suggesting a hematogenous route of dissemination or a highly invasive phenotype (Sagalowsky et al, 1994; Sandock et al, 1997; Paul et al, 2001a; von Knobloch et al, 2004; Siemer et al, 2005; Thompson et al, 2005). Some authors have proposed that such tumors be reclassified as T4 if there is direct inva

Table 47–14. TNM Stage and 5-Year Survival for Renal Cell Carcinoma

Butler et al, 1994; Sagalowsky et al, 1994; Targonski et al, 1994; Guinan et al, 1995; Lerner et al, 1996; Sandock et al, 1997; Hafez et al, 1999; Motzer et al, 1999; Igarashi et al, 2001; Paul et al, 2001; Vasselli et al, 2001; Pantuck et al, 2002; Kontak and Campbell, 2003; von Knobloch et al, 2004; Patard et al, 2004; Phillips and Taneja, 2004; Leibovich et al, 2005; Siemer et al, 2005; Thompson et al, 2005.

sion of the adrenal gland, or M1 otherwise, to reflect this poor prognosis (Guinan et al, 1997; Thompson et al, 2005).

Venous involvement was once thought to be a poor prognostic finding for RCC, but several reports demonstrate that many patients with tumor thrombi can be salvaged with an aggressive surgical approach. These studies document 45% to 69% 5-year survival rates for patients with venous tumor thrombi as long as the tumor is otherwise confined to the kidney (Table 47–15). At one extreme, Golimbu and associates (1986) reported 84% 5-year survival in the best of circumstances—tumor thrombus limited to the main renal vein and tumor otherwise confined to the kidney. Patients with venous tumor thrombi and concomitant lymph node or systemic metastases have markedly decreased survival, and those with tumor extending into the perinephric fat have intermediate survival (see Table 47–15) (Montie et al, 1991; Glazer and Novick, 1996; Gettman et al, 1999; Naitoh et al, 1999; Sweeney et al, 2002b; Bissada et al, 2003; Kim et al, 2004a; Moinzadeh and Libertino, 2004; Leibovich et al, 2005). The importance of tumor invasion into the perinephric fat and its negative impact on prognosis for patients with tumor thrombi are highlighted in the series by Leibovich and colleagues (2005).

The prognostic significance of the cephalad extent of tumor thrombus has been controversial, and it is difficult to compare various series because of differences in selection of patients and related covariables (Leibovich et al, 2005). In a series by Sosa and coworkers (1984), the incidence of advanced locoregional or systemic disease increased with the cephalad extent of the tumor thrombus, accounting for the reduced survival associated with tumor thrombus extending into or above the level of the hepatic veins. However, other data suggest that the cephalad extent of tumor thrombus is not of prognostic significance as long as the tumor is otherwise confined. Libertino and colleagues (1987) reported no difference in survival of patients with supradiaphragmatic versus infradiaphragmatic tumor thrombi, and Glazer and Novick (1996) reported an excellent 5-year survival of 56% in 18 patients with tumor thrombus extending into the right atrium, demonstrating that many patients with tumor thrombi even at this extreme can be salvaged. Again, the caveat is that the tumor is otherwise confined, and this is less likely with level 3-4 inferior vena cava thrombi (Sosa et al, 1984; Kim et al, 2004a; Moinzadeh and Libertino, 2004). Direct invasion of the wall of the vein appears to be a more important prognostic factor than cephalad extent of tumor thrombus and should be noted during tumor staging. Hatcher and colleagues (1991) reported 69% 5-year survival when the wall of the vein was clean, which was reduced to 25% when direct invasion of the caval wall was observed.

Table 47–15. Survival for Patients with Renal Cell Carcinoma and Inferior Vena Cava Tumor Thrombus: Effect of Associated Metastases*

Author	N	M0	N+	M1
Novick et al (1990)	43	64%		11%
Thrasher and Paulson (1993)	44	69%		0%
Swierzewski et al (1994)	100	64%		20%
Staehler and Brkovic (2000)	79	39%†		
Quek et al (2001)	99	59%	33%	0%
Zisman et al (2003)	100	72%		
Blute et al (2004)	191	59%	17%	15%

*Data represent 5-year survival except in the series by Novick et al, which reported 3-year survival percentages.
†Predominance of level III and level IV inferior vena cava thrombi (29 of 59 with M0 disease, 49%) probably accounts for lower survival in this series.

The major drop in prognosis comes in patients whose tumor extends beyond Gerota's fascia to involve contiguous organs, which is rarely associated with 5-year survival, and in patients with lymph node or systemic metastases (Thrasher and Paulson, 1993; Thompson et al, 2005). **Lymph node involvement has long been recognized as a dire prognostic sign because it is associated with 5- and 10-year survival rates of 5% to 30% and 0% to 5%, respectively** (Bassil et al, 1985; Phillips and Taneja, 2004). Some have argued that an extensive lymph node dissection can improve survival in this setting, particularly for patients with early or microscopic involvement of the nodes. At one extreme, Giuliani and associates (1990) reported 52% 5-year survival for 25 patients with node-positive disease managed with radical nephrectomy and extensive lymph node dissection, which is certainly better than historical controls. Other studies suggest improved survival in patients with pathologic stage N0 disease managed with extensive lymph node dissection, and proponents of this procedure have argued that a small but finite proportion of patients with microscopically occult positive nodes may benefit from a more proactive surgical approach (Golimbu et al, 1986; Herrlinger et al, 1991; Phillips and Taneja, 2004). However, randomized data to prove the therapeutic value of an extensive lymph node dissection for RCC are not available, and these results could also be explained by more accurate staging. Identification of tumors with early nodal involvement, which is facilitated by an extensive lymph node dissection, allows them to be classified as stage N+ rather than stage N0, which would improve outcomes for both groups. The stage N0 group is improved by the removal of a small proportion of patients who actually have positive nodes, and the N+ group is improved by the addition of a subgroup with early nodal involvement (Phillips and Taneja, 2004). Although it is likely that the controversy about the therapeutic value of lymphadenectomy for RCC will persist, most authors agree that a limited dissection should be considered in most patients primarily for staging and prognostic purposes.

Systemic metastases portend a particularly poor prognosis for RCC, with 1-year survival of less than 50%, 5-year survival of 5% to 30%, and 10-year survival of 0% to 5% (Motzer et al, 1999; Motzer and Russo, 2000; Negrier et al, 2002; Sella et al, 2003). The statistics for patients presenting with synchronous metastases are even worse, with most patients dying of disease progression within a year. For patients with asynchronous metastases, the metastasis-free interval has proved to be a useful prognosticator because it reflects the tempo of disease progression (Maldazys and deKernion, 1986; Negrier et al, 2002). Other important prognostic factors for patients with systemic metastases include performance status, number and sites of metastases, anemia, hypercalcemia, elevated alkaline phosphatase or lactate dehydrogenase levels, and sarcomatoid histology (Maldazys and deKernion, 1986; Motzer and Russo, 2000; Negrier et al, 2002; Leibovich et al, 2003b; Motzer et al, 2004). Visceral metastases have been associated with a particularly poor prognosis, in contrast to pulmonary-only disease, which accounts for most

of the complete remissions observed in immunotherapy trials (Negrier et al, 2002). Bulky retroperitoneal lymphadenopathy is now also established as a strong negative prognostic factor in patients with metastatic RCC (Vasselli et al, 2001; Pantuck et al, 2003a, 2003b). Prior nephrectomy has correlated with improved survival in this population of patients, although it has been difficult to determine whether this is due to selection bias rather than a direct effect achieved by surgical debulking (Motzer et al, 1999; Negrier et al, 2002). Recent randomized data suggest that cytoreductive nephrectomy may provide a modest survival benefit, although the mechanism for this is still under debate (Flanigan et al, 2001).

Another significant prognostic factor for RCC is tumor size, particularly at the ends of the spectrum (Kontak and Campbell, 2003). Giuliani and colleagues (1990) reported 5-year survival rates of 84% for patients with tumor diameter less than 5 cm, 50% for tumors between 5 and 10 cm, and 0% for tumors more than 10 cm in diameter. To a large extent, this is due to a strong correlation between tumor size and pathologic tumor stage, but Guinan and coworkers (1995b) have also shown that tumor size can function as an independent prognostic factor. In their review of the SEER database of 2473 patients with RCC, tumor size was found to provide prognostic information for patients with Robson stages II, III, and IV disease. Organ-confined tumors tended to do well regardless of tumor size, but Frank and colleagues (2003a) have shown that larger tumors are more likely to exhibit clear cell histology and high nuclear grade, and both of these factors correlate with a compromised prognosis. A review of 1771 patients with organ-confined RCC showed 10-year cancer-specific survival rates of 90% to 95%, 80% to 85%, and 75% for patients with pT1a, pT1b, and pT2 tumor, respectively (Patard et al, 2004a). Other studies have also shown a particularly favorable prognosis for the unilateral pT1a tumors that are now being discovered with increased frequency. In series from the Cleveland Clinic and the Mayo Clinic, such tumors were associated with greater than 95% 5-year survival rates, whether they were managed with nephron-sparing surgery or radical nephrectomy (Butler et al, 1994; Lerner et al, 1996; Cheville et al, 2001).

Other important prognostic factors for RCC include nuclear grade and histologic subtype. Several grading systems for RCC have been proposed on the basis of nuclear size and morphology and presence or absence of nucleoli. Unfortunately, interobserver variability is common in the assignment of nuclear grade because it is primarily a subjective exercise; there is no ideal classification system that can overcome this subjectivity. Nevertheless, almost all the proposed grading systems have provided prognostic information for RCC, and nuclear grade has proved in many cases to be an independent prognostic factor when it is subjected to multivariate analysis (Goldstein, 1997; Ficarra et al, 2001; Kattan et al, 2001; Zisman et al, 2001b; Lohse et al, 2002; True, 2002; Kontak and Campbell, 2003; Patard et al, 2004; Lang et al, 2005). In North America, Fuhrman's classification system has been most generally adopted. In Fuhrman's original report, the 5-year survival rates for grades 1 to 4 were 64%, 34%, 31%, and 10%, respectively, and nuclear grade proved to be the most significant prognostic factor for stage I tumors in this series (Fuhrman et al, 1982). Similarly, Bretheau and colleagues (1995) evaluated 190 patients with RCC and reported a correlation between Fuhrman's nuclear grade and tumor stage, synchronous metastases, lymph node involvement, venous tumor thrombi, tumor size, and invasion of the perinephric fat. In this series, the 5-year survival rates for grades 1 to 4 were 76%, 72%, 51%, and 35%, respectively, with significant differences observed between tumors of grades 1/2 and those of grades 3/4. In most series, prognostic significance has been found primarily at the ends of the spectrum (i.e., grades 1 and 4), and given the difficulties of distinguishing the intermediate grades, a consensus conference on tumor grading for RCC recommended changing to a three-tiered system (Medeiros et al, 1997; Lang et al, 2005).

Histologic subtype can also carry prognostic significance, although, again, primarily at the ends of the spectrum. The presence of sarcomatoid differentiation or collecting duct or medullary cell histologic subtype denotes a poor prognosis (Carter et al, 1992; Davis et al, 1995b; Chao et al, 2002b; Escudier et al, 2002a; Mian et al, 2002; Polascik et al, 2002; Mejean et al, 2003; Nanus et al, 2004; Tokuda et al, 2004). Several studies now suggest that conventional RCC may have a better prognosis on average compared with chromophilic or chromophobic RCC, although there are clearly poorly differentiated tumors in each of these subcategories that can be lethal (Moch et al, 2000; Amin et al, 2002; Lau et al, 2002; Cheville et al, 2003; Krejci et al, 2003; Beck et al, 2004).

Estimates of DNA ploidy and assessment of nuclear morphometry have also correlated with outcomes for patients with RCC, but the main utility of ploidy appears to be in patients with organ-confined disease, and the role of nuclear morphometry has not yet been defined (di Silverio et al, 2000; Abou-Rebyeh et al, 2001). Focusing on patients with Robson stage I tumors, Grignon and colleagues (1989) reported 10-year cancer-related mortality rates of 37% in patients with nondiploid tumors versus 8% in patients with diploid tumors. Similar studies have confirmed these findings, and Rainwater and associates (1987) reported that ploidy analysis can also separate patients with low-grade RCC into distinct prognostic groups. Carducci and colleagues (1999) showed that nuclear morphometry improved the prognostication of stage and grade in a multivariate model, confirming previous studies in the literature (Monge et al, 1999).

Several investigators have now combined various prognostic factors, and this has greatly improved our predictive capacity (Cindolo et al, 2005). For instance, Kattan and colleagues (2001) have combined manner of presentation (incidental, or local versus systemic symptoms), tumor histology, tumor size, and pathologic stage to develop a nomogram (Fig. 47–22) that predicts cancer-free survival after nephrectomy. Tumor grade was not included in this analysis because its role for nonconventional RCC has not been clearly defined. A subsequent analysis from this same group focused only on patients with conventional RCC and incorporated tumor grade, assessment of tumor necrosis, and vascular invasion to further improve prognostication (Sorbellini et al, 2005). A similar model for conventional RCC has also been proposed by Frank and colleagues (2002), in this case incorporating 1997 TNM stage, tumor size, nuclear grade, and presence of tumor necrosis to predict recurrence and survival after radical nephrectomy (Sengupta et al, 2005).

Pantuck and colleagues (2001a) have also performed an integrated analysis of prognostic factors for RCC, although

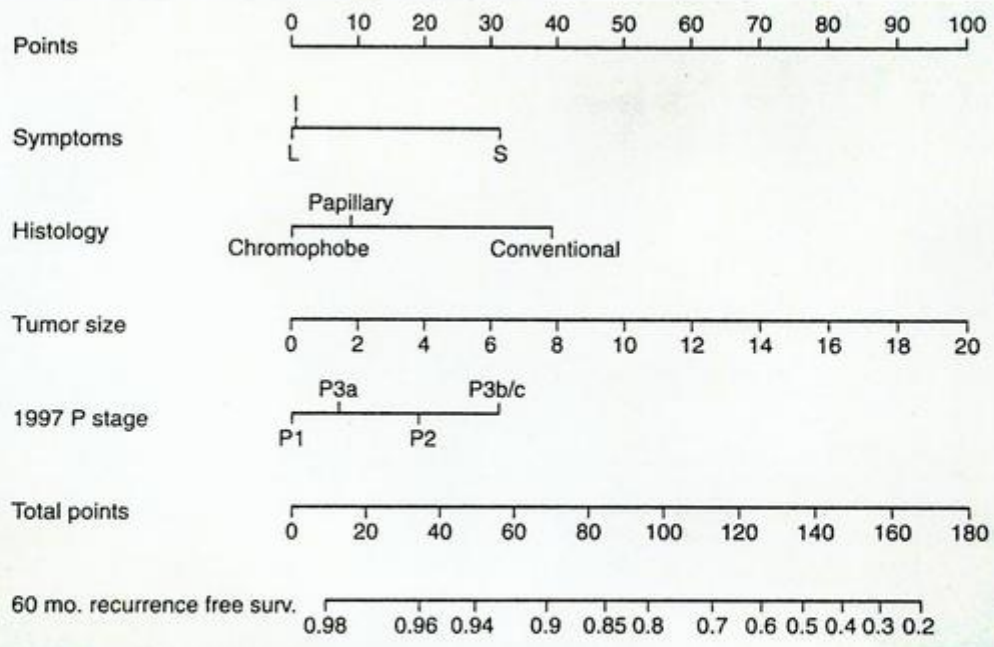

Figure 47–22. Nomogram for estimating the probability of 5-year recurrence-free survival after radical nephrectomy for renal cell carcinoma. (From Kattan MW, Reuter V, Motzer RJ, et al: A postoperative prognostic nomogram for renal cell carcinoma. J Urol 2001;166:63-67.)

Instructions for physician: Locate the patient's symptoms (I=incidental, L=local, S=systemic) on the Symptoms axis. Draw a line straight upwards to the Points axis to determine how many points towards recurrence the patient receives for his symptoms. Repeat this process for the other axes, each time drawing straight upward to the Points axis. Sum the points achieved for each predictor and locate this sum on the Total points axis. Draw a line straight down to find the patient's probability of remaining recurrence free for 5 years assuming he or she does not die of another cause first.

Instruction to patient: "Mr. X, if we had 100 men or women exactly like you, we would expect between <predicted percentage from nomogram – 10%> and <predicted percentage + 10%> to remain free of their disease at 5 years following surgery, though recurrence after 5 years is still possible."

their analysis included patients with all stages of the disease (Fig. 47–23). **A sophisticated multivariate analysis revealed three independent prognostic factors that were most robust for predicting outcomes, namely, TNM stage, performance status, and tumor grade** (Zisman et al, 2001b). Prediction of survival of patients has proved to be powerful, and this approach has now been validated in an independent analysis of 4202 patients from eight academic centers (Patard et al, 2004c). Subsequent reports segregated patients with N0 M0 tumors from those with N+ or M1 tumors and provided separate analyses for each subgroup, and this should be even more useful for the practicing clinician (Zisman et al, 2002c). Molecular factors such as staining for CA-9 and p53 and assessment of proliferation status with Ki-67 are now also being incorporated into algorithms to predict outcomes for patients with RCC (Kim et al, 2005).

For patients with clinically localized disease, Patard and colleagues (2004a) have shown that mode of presentation (incidental versus symptomatic) can be combined with tumor size to better stratify patients after primary surgical management. They have proposed a novel staging system for organ-confined RCC:

T1a: ≤4.0 cm and incidental
T1b: ≤4.0 cm and symptomatic or >4.0 cm and incidental
T2a: >4 to ≤7 cm and symptomatic
T2b: >7 cm and symptomatic

Cancer-specific mortality rates at 5 years of follow-up were 1.9%, 4.1%, 13.8%, and 23.7%, respectively, showing that this simple modification could potentially improve prognostication for this population of patients (Patard et al, 2004a). Improved prognostication such as this will help guide counseling and management of patients and is likely to stimulate a reassessment of the current staging protocols for RCC.

KEY POINTS: PROGNOSTIC FACTORS FOR RCC

Tumor Related	*Patient Related*	*Laboratory*
Stage	Performance status	Anemia
Grade	Symptomatic presentation	Thrombocytosis
Size		Hypercalcemia
Histologic subtype	Constitutional symptoms	Elevated erythrocyte sedimentation rate
Sarcomatoid histology	Paraneoplastic syndromes	Elevated alkaline phosphatase level
Tumor necrosis	Metastasis-free interval	CA-9 expression
Sites of metastasis		
Burden of metastasis

TREATMENT OF LOCALIZED RENAL CELL CARCINOMA

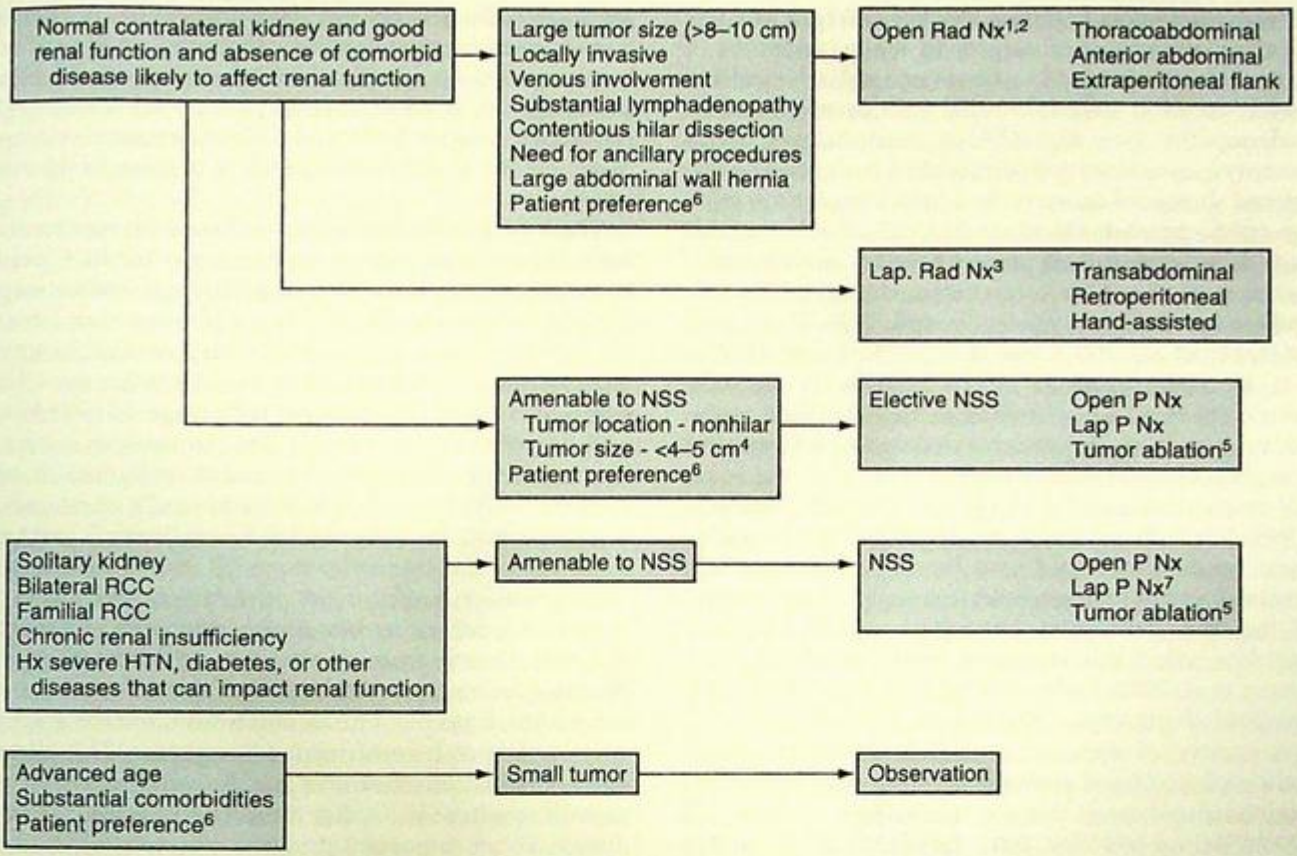
Radical Nephrectomy

Notwithstanding advances in our understanding of the genetics and biology of RCC, **surgery remains the mainstay for curative treatment of this disease. The objective of surgical therapy is to excise all tumor with an adequate surgical margin.** Simple nephrectomy was practiced for many decades but has been supplanted by radical nephrectomy, which is the treatment of choice for many patients with localized RCC.

Robson and colleagues (1969) established radical nephrectomy as the "gold standard" curative operation for localized RCC with their report of 66% and 64% overall survival for stages I and II tumors, respectively. These results demonstrated improved survival rates compared with those of patients treated by pericapsular nephrectomy. More recent reports indicate 5-year survival rates of 73% to 92% after radical nephrectomy for Robson stage I (pT1-pT2) RCC (see Table 47–13). Radical nephrectomy remains the established form of treatment for patients with localized unilateral RCC and a normal contralateral kidney (Fig. 47–24) (Lam et al, 2004b).

The prototypical concept of radical nephrectomy encompasses the basic principles of early ligation of the renal artery and vein, removal of the kidney outside Gerota's fascia, excision of the ipsilateral adrenal gland, and performance of a complete regional lymphadenectomy from the crus of the diaphragm to the aortic bifurcation. Controversy has arisen concerning the need for some of these practices in all patients (Lam et al, 2004b). Performance of a perifascial nephrectomy is of undoubted importance in preventing postoperative local tumor recurrence because approximately 25% of localized RCCs manifest perinephric fat involvement. Preliminary renal arterial ligation remains an accepted practice; however, in large tumors with abundant collateral vascular supply, it is not always possible to achieve complete preliminary control of the arterial circulation. It has been well demonstrated that removal of the ipsilateral adrenal gland is not routinely necessary in the absence of radiographic adrenal enlargement unless the malignant lesion extensively involves the kidney, is locally advanced, or is located in the upper portion of the kidney immediately adjacent to the adrenal gland (Sagalowsky et al, 1994; Leibovitch et al, 1995; Kletscher et al, 1996; Kozak et al, 1996; Sandock et al, 1997; Tsui et al, 2000a; Paul et al, 2001a; Lam et al, 2004a; Siemer et al, 2004).

The need for a complete regional lymphadenectomy in all patients undergoing radical nephrectomy remains controversial (Blom et al, 1999; Schafhauser et al, 1999; Terrone et al, 2003; Blute et al, 2004a; Phillips and Taneja, 2004). Regional lymph node extension is an important prognostic factor usually associated with poor survival (Pantuck et al, 2003b). However, several characteristics of RCC argue against a therapeutic role for lymphadenectomy. First, the tumor metastasizes through the bloodstream and the lymphatic system with equal frequency. Consequently, most patients with positive lymph nodes eventually develop bloodborne metastases despite undergoing lymphadenectomy, and many patients with RCC will develop disseminated metastases without ever having lymphatic involvement. In addition, the lymphatic drainage of the kidney is variable, and even an extensive retroperitoneal dissection cannot reasonably be expected to remove all possible sites of metastasis. These considerations militate against a therapeutic benefit for routine lymphadenectomy for most patients with localized RCC, and most believe that only a relatively small percentage of patients are likely to benefit (<2% to 3%), namely, the subset of patients with micrometastatic disease (Golimbu et al, 1986; Giuliani et al, 1990; Herrlinger et al, 1991). In all likelihood, the involved lymph nodes in these patients would be removed by a conventional radical nephrectomy, which incorporates the renal hilar and immediately adjacent paracaval or paraaortic lymph nodes. At the other end of the spectrum, patients with advanced disease undergoing cytoreductive nephrectomy should have all grossly enlarged lymph nodes removed if possible. Pantuck and colleagues (2003c) have shown that this subgroup of patients has a better outcome than do those in whom lymphadenectomy is not performed.



1. Rad Nx = radical nephrectomy, NSS = nephron sparing surgery, P Nx = partial nephrectomy, lap = laparoscopic
2. Surgical approach dependent on tumor size, location, body habitus, etc.
3. Surgical approach dependent on tumor size, location, and surgeon experience and expertise
4. Prognostic data about outcomes after partial nephrectomy support good results for pathologic tumor size of 4.0 cm or less, but corresponding radiographic sizes are 10–20% higher due to blood flow in vivo.
5. Long-term efficacy not established, but less invasive and a good option for elderly patients and/or those with substantial comorbid disease. Percutaneous approach can be considered when pancreas, bowel, or ureter not adjacent to mass.
6. Patient preference takes precedence assuming balanced counselling about various options and their potential advantages and disadvantages.
7. Assumes adequate expertise

Figure 47–24. Algorithm for management of localized renal cell carcinoma (RCC).

Although performance of a complete regional lymphadenectomy allows more accurate staging of the extent of RCC, the therapeutic value of this information is limited because there is no established form of systemic treatment for patients with advanced disease. **At present, the need for routine performance of a complete lymphadenectomy in all cases is not well defined, and there remains a divergence of clinical practice among urologists with respect to this aspect of radical nephrectomy** (Blom et al, 1999; Blute et al, 2004a; Daneshmand et al, 2004; Phillips and Taneja, 2004). Blute and colleagues (2004a) have reported risk factors for lymphatic involvement with RCC including high tumor grade, sarcomatoid component, histologic tumor necrosis, tumor size larger than 10 cm, and tumor stage pT3 or pT4. The incidence of lymph node involvement in their series was 10% if two or more of these factors were present and only 0.6% if fewer than two were present. Most of these factors can be assessed preoperatively or with intraoperative frozen-section analysis, and this analysis could be used to guide decision-making with respect to lymphadenectomy. With this approach, only the hilar and regional lymph nodes would be removed for low-risk patients.

Open surgical techniques for radical nephrectomy are described in detail in Chapter 50. **The surgical approach for radical nephrectomy is determined by the size and location of the tumor as well as by the body habitus of the patient.** The operation is usually performed through a transperitoneal incision to allow abdominal exploration for metastatic disease and early access to the renal vessels with minimal manipulation of the tumor. The authors prefer an extended subcostal or a bilateral subcostal incision for most patients undergoing radical nephrectomy. The thoracoabdominal approach is employed when radical nephrectomy is performed in patients with large tumors involving the upper portion of the kidney. On occasion, an extraperitoneal flank incision is appropriate in elderly patients or patients of poor surgical risk, but exposure can be limiting, particularly in patients with large tumors or those with contentious hilar anatomy.

Laparoscopic radical nephrectomy has emerged as a less morbid alternative to open surgery in the management of low- to moderate-volume (8 to 10 cm or smaller), localized RCCs with no local invasion, renal vein involvement, or lymphadenopathy (see Fig. 47–24). Laparoscopic radical nephrectomy is associated with diminished postoperative discomfort and shortened recovery, and costs compare favorably with the open approach (Meraney and Gill, 2002). Available outcome data suggest that cancer-specific survival after laparoscopic radical nephrectomy is comparable to that after open radical nephrectomy (Cadeddu et al, 1998; Dunn et al, 2000; Meraney et al, 2000; Chan et al, 2001; Gill et al, 2001; Portis et al, 2002; Saika et al, 2003; Wille et al, 2004; Permpongkosol et al, 2005; Yoshino et al, 2005). In a multiinstitutional report of 157 patients undergoing laparoscopic radical nephrectomy for clinical stage I (T1-2) RCC, the 5-year actuarial disease-free rate for all patients was 91% (Cadeddu et al, 1998). Only five patients developed retroperitoneal or metastatic tumor recurrence, and there were no port site recurrences. Current laparoscopic techniques allow replication of the important tenets of radical nephrectomy, and outcome data reflect this at several centers (Cadeddu et al, 1998; Dunn et al, 2000; Meraney et al, 2000; Chan et al, 2001; Gill et al, 2001; Portis et al, 2002; Saika et al, 2003; Wille et al, 2004). A variety of approaches including transperitoneal, retroperitoneal, and hand assisted have been popularized and are described elsewhere in this text (Cadeddu et al, 1998; Gill et al, 2000b; Nelson and Wolf, 2002; Desai et al, 2005). Studies suggest that elderly and morbidly obese patients, those with a history of previous abdominal surgery, and those with large tumor size may also be considered for laparoscopic renal surgery, although selection of patients must be careful, and surgical expertise and experience should also be taken into account (Fazeli-Matin et al, 1999; Parsons et al, 2002; Matin et al, 2003; Cobb et al, 2004; Fugita et al, 2004; Steinberg et al, 2004). The potential applications for laparoscopic approaches to the surgical management of RCC are evolving rapidly (Desai et al, 2003a, 2003b; Meraney et al, 2003; Steinberg et al, 2003; Abreu et al, 2004; Fenn and Gill, 2004; Finelli et al, 2004a, 2004b, 2005; Johnston et al, 2005).

Previously, there was no consensus regarding an appropriate follow-up regimen for patients who had undergone radical nephrectomy for localized RCC. **Several studies on outcomes after radical nephrectomy for localized RCC have now demonstrated that the risk for postoperative recurrent malignant disease is stage dependent** (Sandock et al, 1995; Levy et al, 1998; Eggener et al, 2001; Janzen et al, 2003; Stephenson et al, 2004a; Theodorescu et al, 2004). For instance, in a study from M. D. Anderson Cancer Center (Levy et al, 1998), 68 of 286 patients (23.8%) developed metastatic RCC after radical nephrectomy, and the incidence of this event, according to the initial pathologic tumor stage, was as follows: 7.1% for T1 N0 M0, 26.5% for T2 N0 M0, and 39.4% for T3 N0 M0. The risk for development of recurrent malignant disease was greatest during the first 3 postoperative years. Stephenson and colleagues (2004a) also reported substantially increased risk of recurrence in patients with stage pT3a and pT3b compared with pT1 and pT2, and recurrences were diagnosed earlier in the former, with a median of 12 versus 26 months.

These data indicate that surveillance for recurrent malignant disease after radical nephrectomy for RCC can be tailored according to the initial pathologic tumor stage. The recommended surveillance scheme is depicted in Table 47–16. All patients should be evaluated with a medical history, physical examination, and selected blood studies on a yearly or twice-yearly basis. For patients with stage T1 N0 M0 tumors, routine postoperative radiographic imaging is not necessary because of the low risk for recurrent malignant disease. For patients with stage T2 N0 M0 tumors, a chest radiograph every year and an abdominal CT scan every 2 years are recommended. Patients with stage T3 N0 M0 tumors have a higher risk for development of recurrent malignant disease, particularly during the first 3 years after radical nephrectomy, and may benefit from more frequent laboratory and radiographic follow-up as outlined in Table 47–16. Postoperative bone scans, bone plain films, and head CT scans are necessary only in the presence of related symptoms. This surveillance scheme is cost-effective and enables early detection of most cases of recurrent RCC after radical nephrectomy for localized disease. Other important prognostic factors for RCC, such as tumor size, grade, and histologic subtype, can also influence the risk and pattern of recurrence and are now integrated into predictive algorithms that will be useful for more individualized surveillance in the near future (Kattan et al, 2001; Pantuck et al, 2001a; Zisman et al, 2002c; Frank et al, 2003b, 2004b, 2005b; Sorbellini et al, 2005).

Nephron-Sparing Surgery

Nephron-sparing surgery for the treatment of a renal tumor was first described by Czerny in 1890 (reviewed in Herr, 2005). However, high morbidity limited its application. In 1950, Vermooten suggested that peripheral encapsulated renal neoplasms could be excised locally while leaving a margin of normal parenchyma around the tumor. **Interest in nephron-sparing surgery for RCC has been stimulated by advances in renal imaging, experience with renal vascular surgery for other conditions, improved methods of preventing ischemic renal damage, growing numbers of incidentally discovered low-stage RCCs, and good long-term survival in patients undergoing this form of treatment** (Uzzo and Novick, 2001). Nephron-sparing surgery entails complete local resection of a renal tumor while leaving the largest possible amount of normal functioning parenchyma in the involved kidney.

Table 47–16. Postoperative Surveillance after Radical Nephrectomy for Localized Renal Cell Carcinoma

Pathologic Tumor Stage	*History, Examination, and Blood Tests*	*Chest Radiograph*	*Abdominal CT Scan*
T1 N0 M0	Yearly	—	—
T2 N0 M0	Yearly	Yearly	Every 2 years
T3a-c N0 M0	Every 6 months for 3 years, then yearly	Every 6 months for 3 years, then yearly	At 1 year, then every 2 years

Accepted indications for nephron-sparing surgery include situations in which radical nephrectomy would render the patient anephric or at high risk for ultimate need of dialysis (see Fig. 47–24) (Licht et al, 1994; Ghavamian and Zincke, 2001; Uzzo and Novick, 2001). This encompasses patients with bilateral RCC or RCC involving a solitary functioning kidney. The solitary functioning kidney may be the result of unilateral renal agenesis, prior removal of the contralateral kidney, or irreversible impairment of contralateral renal function by a benign disorder. Another accepted indication for nephron-sparing surgery is represented by patients with unilateral carcinoma and a functioning opposite kidney affected by a condition that might threaten its future function, such as renal artery stenosis (Campbell et al, 1993; Hafez et al, 2000), hydronephrosis, chronic pyelonephritis, ureteral reflux, calculus disease, or systemic diseases such as diabetes and nephrosclerosis (Gilbert et al, 2003; Uzzo and Novick, 2001).

In patients with bilateral synchronous RCC, the authors' philosophy has been to attempt to preserve as much functioning renal tissue as possible. This entails performing bilateral nephron-sparing operations when feasible, usually as staged procedures if the tumors are relatively large. When a locally extensive tumor on one side precludes nephron-sparing surgery, a radical nephrectomy is performed on the more involved side along with a contralateral partial nephrectomy. Margin width appears to be immaterial as long as the final margins are negative, and this is particularly relevant when the tumor is located within the hilum and preservation of renal function is at a premium (Castilla et al, 2002; Sutherland et al, 2002). Patients with RCC involving a functionally or anatomically solitary kidney must be advised about the potential need of temporary or permanent dialysis postoperatively, which, according to our experience, occurs in 8% and 4% of cases, respectively (Campbell et al, 1994). Similarly, Ghavamian and colleagues (2002) reported a 12.7% incidence of acute renal failure when operating on a solitary kidney, with 15.9% developing proteinuria and 12.7% experiencing chronic renal insufficiency on a long-term basis. A functioning renal remnant of at least 20% of one normal kidney is necessary to avoid end-stage renal failure.

Evaluation of patients with RCC for nephron-sparing surgery should include preoperative testing to rule out locally extensive or metastatic disease and additional specific renal imaging to delineate the relationship of the tumor to the intrarenal vascular supply and collecting system. For centrally located tumors, this information has traditionally been obtained with a combination of studies including CT scanning, renal arteriography, and occasionally renal venography. Three-dimensional volume-rendered CT (or MRI) is now established as a noninvasive imaging modality that can accurately depict the renal parenchymal and vascular anatomy in a format familiar to urologic surgeons (Coll et al, 1999; Uzzo et al, 2000b; Berman et al, 2001; VanderBrink et al, 2004). This study integrates essential information from arteriography, venography, excretory urography, and conventional two-dimensional CT scanning into a single imaging modality and obviates the need for more invasive renal imaging (Derweesh et al, 2004).

The surgical techniques for performing nephron-sparing surgery in patients with RCC are reviewed in Chapter 50. **The technical success rate of nephron-sparing surgery for RCC is excellent, and many studies have reported extended cancer-specific survival rates of 78% to 100% in such patients** (Campbell et al, 1994; Uzzo and Novick, 2001) (Table 47–17). These survival rates are comparable to those obtained after radical nephrectomy, particularly for low-stage RCC. The major disadvantage of nephron-sparing surgery is the risk of postoperative local recurrence in the kidney that was operated on, which has occurred in up to 10% of patients. These local recurrences are most likely a manifestation of undetected

Table 47–17. Results of Nephron-Sparing Surgery for Renal Cell Carcinoma*

*Data for conventional RCC only.

microscopic multifocal RCC in the renal remnant—most are found distant from the previous tumor bed. The risk of local recurrence after radical nephrectomy has not been well studied, but it is presumably very low.

The largest reported study of partial nephrectomy is from the Cleveland Clinic and reviewed the results of nephron-sparing surgery for the treatment of localized, sporadic RCC in 485 patients (Hafez et al, 1999). The mean postoperative follow-up was 4 years, and overall and cancer-specific 5-year survival rates for patients in this series were 81% and 92%, respectively. Recurrent RCC developed postoperatively in 44 patients (9%), including 16 (3.2%) with local recurrence in the remnant kidney and 28 (5.8%) with metastatic disease. In another study from the Cleveland Clinic, longer term results of nephron-sparing surgery were reviewed in 107 patients with localized sporadic RCC treated before 1988, almost exclusively for imperative indications (Fergany et al, 2000). All patients were observed for a minimum of 10 years or until death. Cancer-specific survival was 88.2% at 5 years and 73% at 10 years. Long-term renal function was preserved in 100 patients (93%). Ten-year follow-up was also provided by Herr (1999), who reported that 97% of patients remained cancer free after partial nephrectomy in the setting of a normal contralateral kidney, a more select population of patients. These data confirm that **nephron-sparing surgery provides effective long-term therapy for patients with localized RCC and can preserve renal function when necessary** (Saad et al, 2005).

A more recent trend has been to perform partial nephrectomy by minimally invasive approaches, a considerable challenge given concerns about hemostasis and margin status without direct visualization and tactile input. Nevertheless, several series have now reported encouraging results, mostly with relatively small, polar or peripherally located tumors (Gill et al, 2002, 2003; Hsu et al, 2002; Guillonneau et al, 2003; Simon et al, 2003; Allaf et al, 2004; Finelli et al, 2004; Kane et al, 2004; Mabjeesh et al, 2004). Gill and colleagues (2002, 2003) have now essentially duplicated the open surgical technique, including occlusion of the renal vasculature, application of saline ice slush, and intracorporeal suturing to close the collecting system and repair the capsular defect (Desai et al, 2003a). Other methods to achieve renal hypothermia are also being explored, including antegrade perfusion of the renal artery or retrograde perfusion of the collecting system with cold solutions (Landman et al, 2002; Janetschek et al, 2004). Interestingly, recent data suggest that the kidney may tolerate longer periods of warm ischemia than previously appreciated, but this will require further study (Bhayani et al, 2004; Laven et al, 2004; Shekarriz et al, 2004). Hemostasis remains the primary concern, and a variety of approaches have been explored to accomplish this, including the use of hemostatic dissecting devices and tissue sealants (Gettman et al, 2001b; Yoshimura et al, 2001; Richter et al, 2003; Hasan et al, 2004a, 2004b; Herrell et al, 2004; Urena et al, 2004; Finley et al, 2005). Efficacy data including margin status and recurrence rates appear promising but must be considered preliminary, and further data will be required to substantiate these approaches (Kaouk et al, 2004; Porpiglia et al, 2005). Major complications are hemorrhagic, occasionally requiring delayed nephrectomy or embolization, but they have been reduced substantially with more extended experience and routine use of tissue sealants during reconstruction of the kidney (Ramani et al, 2005). Even centrally located tumors are now being managed laparoscopically (Gill et al, 2003; Frank et al, 2005c), and this field is rapidly progressing. Please refer to the chapter on laparoscopic renal surgery in this text for further details about these surgical developments.

Clinical guidelines for long-term surveillance after nephron-sparing surgery for sporadic localized RCC have been developed (Eggener et al, 2001; Janzen et al, 2003; Theodorescu et al, 2004), primarily based on a detailed analysis of tumor recurrence patterns in 327 patients treated at the Cleveland Clinic (Hafez et al, 1997). In this series, recurrent RCC developed after nephron-sparing surgery in 38 patients (11.6%), including 13 patients (4%) who developed local recurrence and 25 patients (7.6%) who developed metastatic disease (Hafez et al, 1997). The incidence of postoperative local recurrence and metastatic disease varied according to the initial pathologic tumor stage as follows: 0% and 4.4% for T1 N0 M0 tumors, 2% and 5.3% for T2 N0 M0 tumors, 8.2% and 11.5% for T3a N0 M0 tumors, and 10.6% and 14.9% for T3b N0 M0 tumors. The peak postoperative intervals for development of local recurrence were 6 to 24 months (in T3 tumors) and more than 48 months (in T2 tumors). T1 tumor stage in this series represented tumor size of less than 2.5 cm, based on the previous TNM classification system.

These data indicate that surveillance for recurrent malignant disease after nephron-sparing surgery for sporadic RCC can be tailored according to the initial pathologic tumor stage and tumor size. The recommended surveillance scheme is depicted in Table 47–18. All patients should be evaluated with a medical history, physical examination, and selected blood studies on a yearly or twice-yearly basis. The blood studies should include serum calcium, alkaline phosphatase, liver function, blood urea nitrogen, serum creatinine, and electrolyte studies.

The need for postoperative radiographic surveillance studies after nephron-sparing surgery varies according to the initial pathologic tumor stage. Patients who undergo nephron-sparing surgery for small (<2.5 cm) T1 N0 M0 tumors do not require radiographic imaging postoperatively in view of the low risk for recurrent malignant disease. A

Table 47–18. Postoperative Surveillance after Partial Nephrectomy for Localized Renal Cell Carcinoma

Pathologic Tumor Stage	*History, Examination, and Blood Tests*	*Chest Radiograph*	*Abdominal CT Scan*
T1 N0 M0*	Yearly	—	—
T2 N0 M0*	Yearly	Yearly	Every 2 years
T3 N0 M0	Every 6 months for 3 years, then yearly	Every 6 months for 3 years, then yearly	Every 6 months for 3 years, then every 2 years

*Based on 1997 AJCC classification system, with T1 ≤ 2.5 cm and T2 > 2.5 cm.

yearly chest radiograph is recommended after nephron-sparing surgery for other patients with confined RCC (stage T1 and larger than 2.5 cm or stage T2 N0 M0 tumors) because the lung is the most common site of postoperative metastasis. Abdominal or retroperitoneal tumor recurrence is uncommon in this group, particularly early after nephron-sparing surgery, and these patients require only occasional follow-up abdominal CT scanning; the authors recommend that this be done every 2 years. Patients with stage T3 N0 M0 tumors have a higher risk for development of local recurrence and metastatic disease, particularly during the first 2 years after partial nephrectomy, and may benefit from more frequent follow-up with chest radiography and abdominal CT scanning initially; the authors recommend that these be done every 6 months during the first 3 years, after which a chest radiograph is obtained yearly and an abdominal CT scan is done every 2 years.

Patients who undergo nephron-sparing surgery for RCC may be left with a relatively small amount of renal tissue and are at risk for development of long-term renal functional impairment from hyperfiltration renal injury (Modlin and Novick, 2001; Abdi et al, 2003). In a study of 14 patients observed for up to 17 years after partial nephrectomy in a solitary kidney, patients with more than 50% reduction in overall renal mass were found to be at increased risk for development of proteinuria, focal segmental glomerulosclerosis, and progressive renal failure (Novick et al, 1990). The development of proteinuria correlated directly with the length of follow-up and inversely with the amount of remaining renal tissue. Renal biopsy revealed focal segmental glomerulosclerosis in several patients with severe proteinuria (Fig. 47–25). These findings mirror those observed in experimental animal models of partial renal ablation (Brenner, 1983). Because proteinuria is the initial manifestation of this phenomenon, a 24-hour urinary protein measurement should be obtained yearly in patients with a solitary remnant kidney to screen for hyperfiltration nephropathy.

Efforts to prevent or to ameliorate the damaging effects of renal hyperfiltration have primarily focused on dietary and pharmacologic intervention (Modlin and Novick, 2001). Animal studies have suggested that dietary restriction of protein and angiotensin-converting enzyme inhibitor (ACEI) agents may mitigate this type of glomerulopathy (Meyer et al, 1985). Preliminary clinical data appear to support this concept. Novick and Schreiber (1995) studied five patients who had developed proteinuria with stable renal function after partial nephrectomy in a solitary kidney. Four of these patients had documented focal segmental glomerulosclerosis on renal biopsy. All five patients had normal renal morphologic features at the time of surgery. Treatment with ACEI therapy and a low-protein diet decreased the level of proteinuria in four patients. Data from other studies have also suggested that ACEI therapy can significantly diminish proteinuria in patients with established renal disease (Goldfarb, 1995). This information suggests that ACEI therapy and a low-protein diet may improve the long-term renal functional outcome for patients with a remnant kidney after partial nephrectomy. The optimal time for initiating the regimen is not clear, and it may be best to implement this therapy as early as possible to obviate the maladaptive

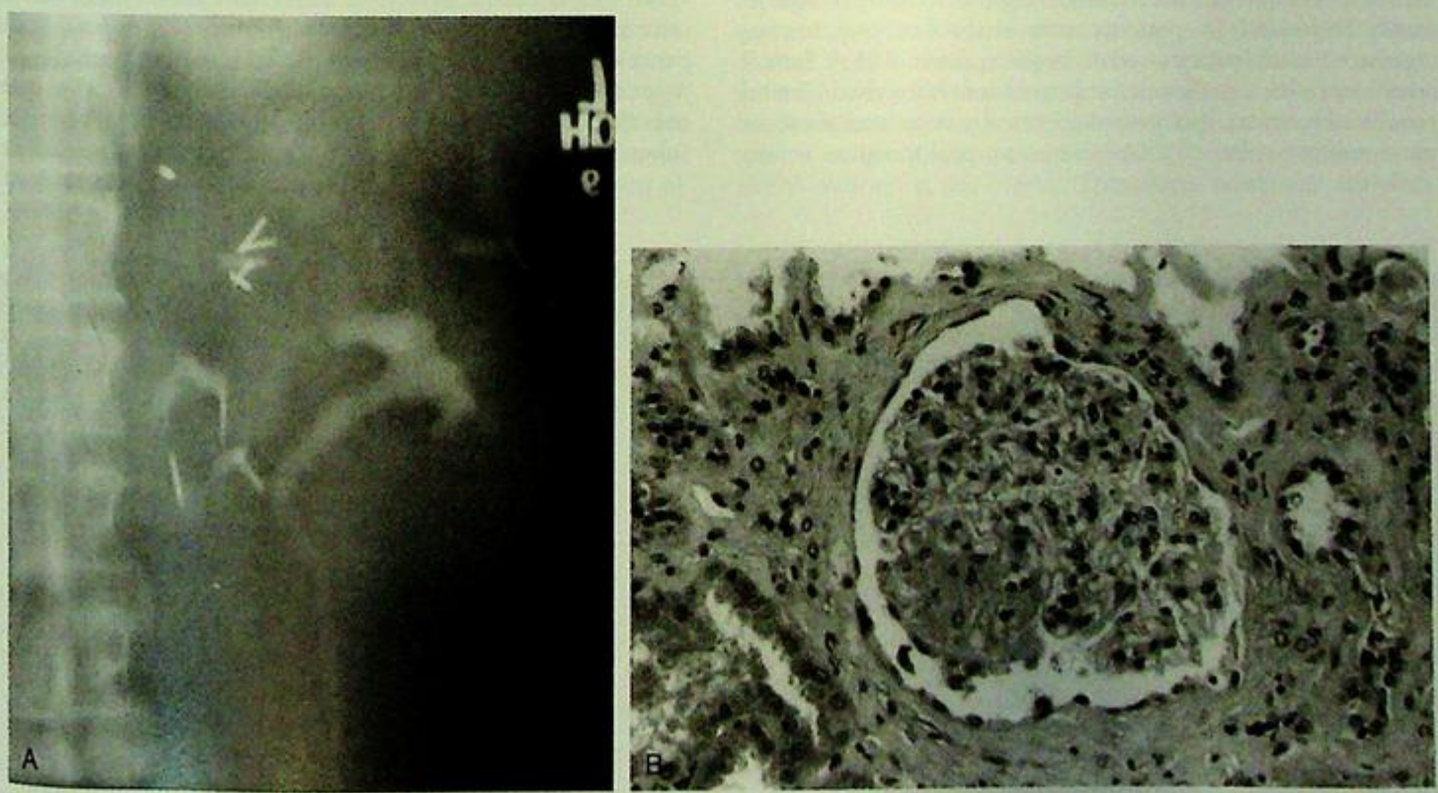

Figure 47–25. **A,** Ten years after partial nephrectomy for large tumor in solitary left kidney, intravenous pyelogram shows function of small remnant kidney. The patient had developed nephrotic syndrome at this time. **B,** Renal biopsy specimen shows focal segmental glomerulosclerosis indicative of hyperfiltration nephropathy.

responses that can lead to progressive sclerosis and renal failure in this setting.

There is experimental evidence that nonhemodynamic processes may also contribute to progression of sclerosis in the remnant kidney (Goldfarb, 1995). This raises other therapeutic possibilities, such as thromboxane inhibitors, anticoagulants, lipid-lowering agents, and other pharmacologic agents. Future clinical trials, it is hoped, will clarify the potential value of these treatment approaches.

Nephron-Sparing Surgery with a Normal Opposite Kidney

Although radical nephrectomy remains the standard treatment of localized renal carcinoma in patients with an anatomically and functionally normal opposite kidney, a growing number of authors have reported excellent results with nephron-sparing surgery in this "elective" setting (see Fig. 47–24) (Campbell and Novick, 1995). Table 47–19 details the outcome of nephron-sparing surgery in 909 patients with unilateral localized RCC and a normal opposite kidney. Extended cancer-specific survival ranges from 90% to 100%, and there have been only 20 cases of postoperative local tumor recurrence (2%). Significantly, the mean tumor size in most of these reports was less than 4 cm. Clearly, selection of patients on the basis of small tumor size was a significant factor accounting for the favorable outcome after nephron-sparing surgery in these studies.

Previous studies have defined optimal candidates for elective partial nephrectomy. In a study from the Cleveland Clinic, the outcome of nephron-sparing surgery was reviewed in 216 patients with sporadic RCC, mostly for imperative indications (Licht et al, 1994). The findings confirmed that extended cancer-free survival after partial nephrectomy was significantly improved in patients with small (<4 cm) tumors compared with patients with larger tumors. Other factors associated with significantly improved survival were unilateral renal involvement, low pathologic tumor stage, and presence of a solitary tumor. There were no postoperative tumor recurrences, and the cancer-specific 5-year survival rate was 100% in patients with small, unilateral, stage T1-2 RCCs.

These data suggest that **nephron-sparing surgery may be an acceptable therapeutic approach in patients who have a single, small (<4 cm) RCC and a normal contralateral kidney.** This hypothesis was tested in two subsequent studies (Butler et al, 1994; Lerner et al, 1996), in which the outcome after radical nephrectomy versus nephron-sparing surgery was compared in patients with a single, small, localized, unilateral, sporadic RCC. Butler noted cancer-specific 5-year survival rates for patients in the radical and nephron-sparing surgical groups of 97% and 100%, respectively. Similarly, Lerner reported cancer-specific survival rates for patients in the radical and nephron-sparing surgical groups of 96% and 92%, respectively. The data from these two studies affirm that radical nephrectomy and nephron-sparing surgery provide equally effective curative treatment of patients with a single, small, unilateral, localized RCC.

A related issue is whether the location of the tumor in the involved kidney is a significant factor affecting treatment outcome in patients with a single, small, unilateral, localized, sporadic RCC. This issue was addressed in another study wherein tumor characteristics and cancer-free survival were compared in patients with centrally versus peripherally located RCCs that fulfilled these criteria (Hafez et al, 1999). The study comprised 145 patients treated with either radical nephrectomy or nephron-sparing surgery, and the mean postoperative follow-up was 4.3 years. Pathologic tumor stage was T1-2 in 94% and 82% of central versus peripheral RCCs, respectively. Postoperatively, in comparing patients with central versus peripheral RCCs, there was no difference in 5-year cancer-specific survival (100% versus 97%), tumor recurrence (5.7% versus 4.5%), or renal function (mean serum creatinine concentration, 1.43 mg/dL in both groups). These parameters were also equivalent in patients treated with nephron-sparing surgery versus radical nephrectomy, both overall and within the central versus peripheral RCC subgroups. The results of this study indicate that **there are no**

significant biologic differences between centrally and peripherally located small, solitary, unilateral RCCs. Moreover, nephron-sparing surgery and radical nephrectomy appear to be equally effective treatments regardless of tumor location in these patients.

The primary advantages of elective partial nephrectomy are preservation of renal function and the very real possibility that the lesion of interest might be benign, particularly if it is small (<4.0 cm) (Johannes et al, 2005). Silver and colleagues (1997) found that 17% of all renal masses excised with radical nephrectomy at Memorial Sloan-Kettering Cancer Center were benign, and in the series from Young and colleagues (2002), 28% of renal masses smaller than 3.5 cm were benign compared with only 8% for larger tumors. A direct relationship between tumor size and risk of malignancy and high-risk features has also been reported by Frank and colleagues (2003a). In addition, matched comparisons demonstrate a small but statistically significant increased incidence of renal insufficiency after radical nephrectomy compared with nephron-sparing surgery, even when controlling for preoperative risk factors such as diabetes, hypertension, preoperative serum creatinine level, age, and other relevant comorbidities (Lau et al, 2000; Matin et al, 2002; McKiernan et al, 2002b). This decline in renal function is often not evident for several years but can lead to dialysis dependency in a small minority of patients (Weber et al, 2000). Factors that predict renal insufficiency after radical nephrectomy include elevated preoperative serum creatinine level, hypertension, and proteinuria (Ito et al, 2004), and a nomogram to predict renal insufficiency after radical nephrectomy has been reported (Sorbellini et al, 2005).

Analysis of costs and potential morbidity of partial nephrectomy versus radical nephrectomy, particularly by minimally invasive approaches, should also be taken into account in evaluating patients with a renal mass and a normal contralateral kidney (Campbell and Novick, 1995). Recent analyses suggest that the costs of these two procedures are similar when they are performed at a tertiary care center, and morbidity profiles are also comparable given careful selection of patients and honest and realistic assessment of the individual surgeon's experience and expertise (Uzzo et al, 1999c; McKiernan et al, 2002a; Shekarriz et al, 2002; Stephenson et al, 2004b). Interestingly, reports suggest that quality of life and psychological adaptation may be better after elective partial nephrectomy compared with radical nephrectomy (Clark et al, 2001; Poulakis et al, 2003). Minimally invasive approaches to elective partial nephrectomy and improved perioperative care could further tip the balance in favor of a nephron-sparing approach for some patients (Gill et al, 2002, 2003b; DiBlasio et al, 2004a, 2004b).

Given these considerations, some centers are now expanding their indications for elective partial nephrectomy to include select patients with larger tumors (4 to 7 cm). Leibovich and colleagues (2004) reported similar outcomes after elective partial nephrectomy and radical nephrectomy in this population of patients after adjusting for important pathologic features such as stage, grade, and histologic subtype, and other series support these findings (DiBlasio et al, 2004b; Lam et al, 2004a; Patard J, et al, 2004b). However, selection of patients is likely to play an important role in these series, and definitive data to support a strong consideration for elective partial nephrectomy in the general population of patients with clinical stage T1b tumor is clearly lacking at this time.

Nephron-Sparing Surgery in von Hippel–Lindau Disease

RCC in von Hippel–Lindau disease differs from its sporadic counterpart in that the diagnosis is made at a young age, and there are usually multiple bilateral renal tumors (Maher and Kaelin, 1997; Uzzo and Novick, 1999; Zbar et al, 1999). Although these are generally low-stage tumors, they are capable of progression with metastasis and represent a frequent cause of death in patients with von Hippel–Lindau disease. RCC in these patients is characterized histopathologically by both solid tumors and renal cysts that contain either frank carcinoma or a lining of hyperplastic clear cells representing incipient carcinoma (Fig. 47–26) (Christenson et al, 1982; Walther et al, 1995). **Therefore, adequate surgical**

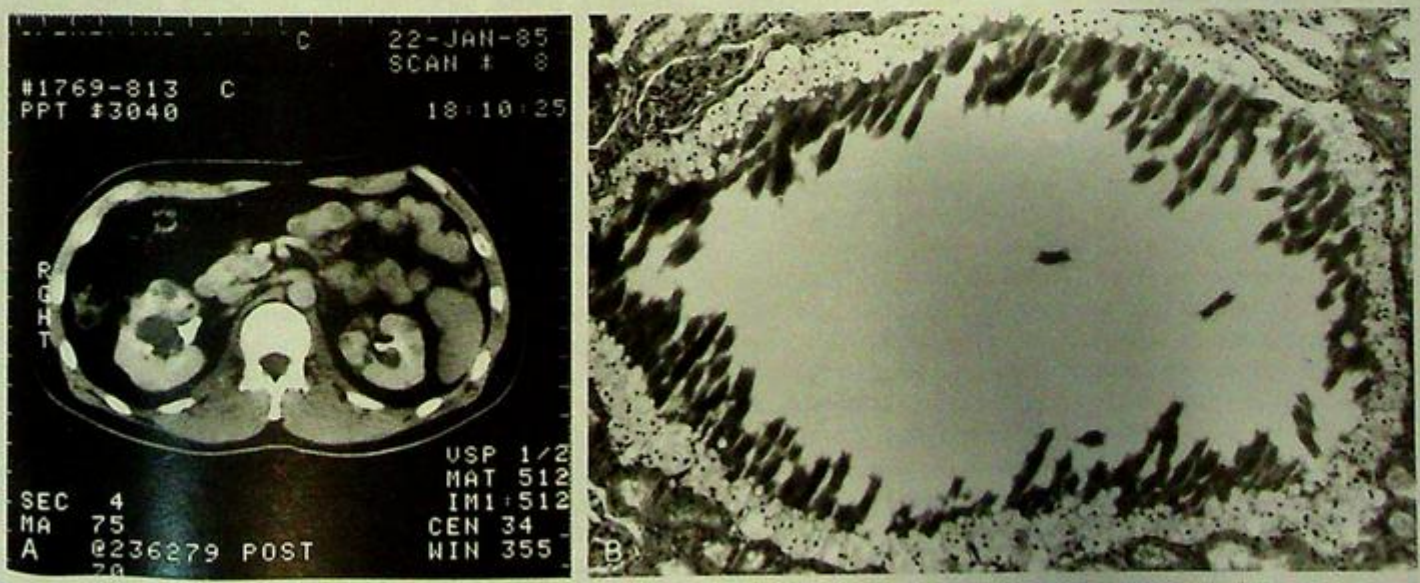

Figure 47–26. A, CT scan after administration of contrast agent shows bilateral solid and cystic renal masses in patient with von Hippel–Lindau disease. B, Histopathologic section of one of the renal cysts shows lining of clear cells representing incipient carcinoma.

treatment of localized RCC in von Hippel–Lindau disease requires excision of all solid and cystic renal lesions. Choyke and colleagues (2001) have shown that intraoperative ultrasonography may be a valuable adjunct for this population of patients. In their series, this study identified additional tumors in 25% of patients with hereditary renal cancer undergoing renal exploration.

The surgical options in patients with bilateral RCC and von Hippel–Lindau disease are bilateral nephrectomy and renal replacement therapy or partial nephrectomy to avoid end-stage renal failure (Herring et al, 2001; Roupret et al, 2003; Drachenberg et al, 2004). The general philosophy has been to pursue nephron-sparing surgery if possible, given the multifocal nature of the disease, even for centrally located tumors (Drachenberg et al, 2004). Although early results of partial nephrectomy were promising, subsequent studies suggested a high incidence of postoperative tumor recurrence in the remaining portion of the kidney (Novick and Streem, 1992). It is likely that most of these local recurrences were a manifestation of residual microscopic RCC that was not removed at the time of the original partial nephrectomy (Walther et al, 1995).

One multicenter study delineated the long-term outcomes after surgical treatment of localized RCC in 65 patients with von Hippel–Lindau disease managed at eight medical centers in the United States (Steinbach et al, 1995). RCC was present bilaterally and unilaterally in 54 and 11 patients, respectively. Radical nephrectomy and partial nephrectomy were performed in 16 and 49 patients, respectively. The mean postoperative follow-up interval was 68 months. The 5-year and 10-year cancer-specific survival rates for all patients were 95% and 77%, respectively. The corresponding rates for patients treated with partial nephrectomy were 100% and 81%, respectively. In the latter group, 25 patients (51%) developed postoperative local recurrence; however, only two of these patients had concomitant metastatic disease. Survival free of local recurrence was 71% at 5 years but only 15% at 10 years. **Similarly, Roupret and colleagues (2003) reported a 27.4% incidence of local recurrence at mean follow-up of 55.9 months after partial nephrectomy for patients with von Hippel–Lindau disease, confirming that these patients are at much higher risk for local recurrence than are patients with sporadic RCC.**

Duffey and colleagues (2004) at the National Cancer Institute have defined a 3-cm threshold for intervention in patients with von Hippel–Lindau disease. In their series, a total of 108 patients with von Hippel–Lindau disease and solid renal tumors smaller than 3 cm were observed a mean of 58 months, and none developed metastatic disease. In contrast, metastases developed in 20 of 73 patients (27.4%) with tumor larger than 3 cm, and the frequency of metastases increased with increasing tumor size. A 3-cm cut point has thus been proposed to reduce the number of surgical interventions, to optimize renal function, and to minimize the risk of metastatic disease. The authors have emphasized that this recommendation also applies to patients with the hereditary papillary RCC and Birt-Hogg-Dubé syndromes (Walther et al, 1999a; Herring et al, 2001; Duffey et al, 2004; Grubb et al, 2005a).

Taken together, these studies suggest that **partial nephrectomy can provide effective initial treatment of patients with RCC and von Hippel–Lindau disease but should be withheld until tumor size reaches or eclipses 3.0 cm. After nephron-sparing surgery, patients with von Hippel–Lindau disease must be observed closely because most will eventually develop locally recurrent RCC with the concomitant need for repeated renal surgery** (Campbell and Novick, 1995). In this setting, repeated partial nephrectomy can be challenging because of postoperative fibrosis, and some centers are moving toward thermal ablative modalities to reclaim local control (Shingleton and Sewell, 2002; Hwang et al, 2004; Mabjeesh et al, 2004). When removal of all renal tissue is necessary to achieve control of malignant disease, renal transplantation can provide satisfactory replacement therapy for end-stage renal disease and appears to be safe despite the tumor diathesis (Goldfarb et al, 1997).

Thermal Ablative Therapies

Thermal ablative therapies, including renal cryosurgery and radiofrequency ablation, have emerged as alternative nephron-sparing treatments of localized RCC (Marshall, 1999; Murphy and Gill, 2001; Lowry and Nakada, 2003; Hinshaw and Lee, 2004; Mabjeesh et al, 2004). **Both can be administered percutaneously or through laparoscopic exposure and thus offer the potential for reduced morbidity and more rapid recovery** (Johnson et al, 2004). **However, long-term efficacy is not established,** and preliminary data suggest that the local recurrence rate may be somewhat higher than that reported for traditional surgical approaches. Another concern has been the lack of accurate histologic and pathologic staging associated with these modalities, since the treated lesion is left in situ. **The ideal candidates for thermal ablative procedures may be patients with advanced age or significant comorbidities who prefer a proactive approach but are not considered good candidates for conventional surgery, patients with local recurrence after previous nephron-sparing surgery, and patients with hereditary renal cancer who present with multifocal lesions for which multiple partial nephrectomies might be cumbersome if not impossible.** In the last circumstance, a combination of conventional partial nephrectomy for select lesions complemented by thermal ablative approaches for the remainder may represent the optimal treatment plan. The patient's preference must also be considered, and some patients not fitting these criteria may also select thermal ablation, a decision that can be supported as long as balanced counseling about the current status of these modalities has been provided (see Fig. 47–24). Finally, tumor size can also be an important factor in selection of patients because the current technology does not allow reliable treatment of lesions larger than 3.5 cm in diameter.

Experience with renal cryosurgery predates that of radiofrequency ablation and has been much more extensive. The kidney may be an anatomically favored organ for cryosurgery, particularly compared with the prostate, another target organ for cryoablation. Unlike the prostate, which is in intimate, fixed contact with the rectum and the sphincteric mechanism, the kidney can be laparoscopically mobilized, thereby minimizing the risk of injury to adjacent vital structures. Furthermore, although the prostate often harbors multifocal carcinoma, the kidney usually presents with unifocal malignancy. Because the renal tumor can be readily visualized

with ultrasonography, the ice ball can be confirmed to completely and circumferentially obliterate the tumor margins, including a surrounding margin of healthy tissue, with increased precision and confidence. An extensive body of experimental work is now available to guide and support clinical cryoablation (Hinshaw and Lee, 2004).

Established prerequisites for successful cryosurgery include rapid freezing, gradual thawing, and a repetition of the freeze-thaw cycle. The mechanism underlying tissue cryodestruction is thought to involve immediate cellular damage and delayed microcirculatory failure (Gill and Novick, 1999). Ice formation occurs initially in the extracellular space, causing the extracellular fluid to become hyperosmotic. To equilibrate chemical osmolality, water permeates from the intracellular compartment into the extracellular compartment. Osmolality of the intracellular fluid is thus increased, leading to intracellular solute concentration and dehydration, which cause desiccation trauma—the first step of chemical cellular injury. Continued rapid supercooling leads to the second step of cellular damage—intracellular ice formation. Intracellular ice irreversibly disrupts cell organelles and the cell membrane, a lethal event. Delayed microcirculatory failure occurs during the slow thaw phase of the freeze-thaw cycle, leading to circulation arrest and cellular anoxia. Progressive failure of the microcirculation occurs along a cascade of events: vasoconstriction, endothelial cell destruction causing vessel walls to become porous, interstitial edema, platelet aggregation, microthrombi, and, ultimately, vascular congestion and obliteration. Cells that survive the initial cryogenic assault are destroyed by this secondary insult of ischemia. Repetition of the rapid freeze–slow thaw cycle potentiates the damage. The cryoablation area is thus rendered ischemic, leading ultimately to a circumcised necrosis (Hinshaw and Lee, 2004).

Further work has defined treatment parameters required to bring this treatment into the clinical sphere. Chosy and colleagues (1996) demonstrated that complete necrosis of in vivo porcine renal parenchyma could be consistently achieved only at temperatures of −19.4°C or lower; necrosis was incomplete and suboptimal at temperatures above this threshold. Campbell and coworkers (1998) confirmed that the target lethal temperature of −20°C was achieved at a distance of 3.1 mm inside the leading edge of the ice ball as visualized by real-time ultrasonography. Thus, to ensure complete cell kill, the ice ball must extend well beyond the visible margins of the targeted tumor. In practice, we routinely extend the ice ball approximately 1 cm beyond the edge of the tumor, as determined by both laparoscopic and real-time ultrasonographic imaging (Gill et al, 1998). The availability of sophisticated and reliable ultrasonography and the introduction of finer cryoprobes that allow more accurate and less traumatic probe placement have contributed to the current resurgence of interest in visceral cryosurgery (Onik et al, 1993; Pantuck et al, 2002b).

Clinical experience and follow-up of patients after renal cryoablative therapy remain somewhat limited, as summarized in Table 47–20. Diagnosis of local recurrence after thermal ablative treatments can be challenging because evolving fibrosis within the tumor bed can be difficult to differentiate from residual cancer. **In general, enhancement within the tumor bed on extended follow-up has been considered diagnostic of local recurrence, and the clinical experience thus far has supported this.** However, only one study has included routine post-therapy biopsies to provide histologic confirmation (Gill et al, 2000a). Reported rates of local recurrence in some of these series may be underestimates because 10% to 25% of small renal masses may be benign rather than RCC (Silver et al, 1997; Young et al, 2002). In addition, patients may have a recurrence at other sites in the kidney, and this should also be considered local recurrence although the mechanism is different (novel tumor occurrence due to multifocality rather than treatment failure). Hasan and colleagues (2004a) reported two such ipsilateral occurrences when their patients were observed for a minimum of 48 months, so the true incidence of local recurrence in the treated kidney in this series was 10%, not 5%, and somewhat higher than would be expected for conventional partial nephrectomy for an analogous population of patients with small renal tumors. Indeed, in this setting, recurrence in the tumor bed after conventional

partial nephrectomy is uncommon; most local recurrences are distant from the original tumor site. This limited experience suggests that local control after cryoablative therapy approaches but may not reach that attained by conventional surgical excision.

The experience with radiofrequency ablation, also summarized in Table 47–20, is even more limited—this technology is clearly at an earlier state of development than cryoablation (Corwin et al, 2001; Murphy and Gill, 2001; Rendon et al, 2001; Zelkovic and Resnick, 2003; Mabjeesh et al, 2004). Mechanistically, heat above 45°C leads to irreversible cellular damage, and temperatures higher than 55°C to 60°C result in immediate cell death. Application of high-frequency electrical current by radiofrequency ablation induces excitation of ions, frictional forces, and heat, which in turn causes denaturation of intracellular proteins and melting of cellular membranes, a lethal sequence of events. These effects are observed at tissue temperatures above 41°C but increase directly with increasing temperature and duration of treatment (Mabjeesh et al, 2004). Temperatures in excess of 100°C are typically obtained at the tips of the probes, and thermosensors near the tips are used to monitor progress during active treatment. Temperature dissipates at points more distant from the probe tip, and multiple probes are typically required to achieve adequate heating of the region of interest (Murphy and Gill, 2001). One disadvantage of radiofrequency ablation is that the treatment effect is more difficult to monitor in real time—there is no true "ice ball" equivalent (Zelkovic and Resnick, 2003). Rather, treatment is typically based on empirical results from previous probe alignments, and this allows a fairly predictable target zone of up to 4.0 cm to be treated in most cases. Successfully treated tumors demonstrate no enhancement during extended follow-up, similar to cryoablation (Matsumoto et al, 2004b; Svatek et al, 2005).

Early experience suggested that tumor kill might not be as reliable after radiofrequency ablation compared with cryoablation (Matlaga et al, 2002; Michaels et al, 2002; Rendon et al, 2002), but subsequent reports look more promising, probably reflecting improvements in the technology and increased operative experience (see Table 47–20). Most contemporary series report low rates of local recurrence, although some patients have required repeated treatments to achieve local control, an infrequent event with cryoablation and conventional treatments of localized RCC (Anderson et al, 2005; Coleman et al, 2005; Schenk et al, 2005). Complications are uncommon but have included acute renal failure, stricture of the ureteropelvic junction, necrotizing pancreatitis, and lumbar radiculopathy, so careful and judicious selection of patients is essential (Ogan et al, 2002; Coskun et al, 2003; Elias et al, 2004; Schenk et al, 2005; Weizer et al, 2005). Direct comparison with cryoablation is inevitable but perhaps unfair because radiofrequency ablation is earlier in its development, and recent advances suggest great promise (Anderson et al, 2005; Coleman et al, 2005; Schenk et al, 2005).

Other exciting new technologies, such as high-intensity focused ultrasound and frameless, image-guided radiosurgical treatments (CyberKnife), are also under development and may allow extracorporeal treatment of small renal tumors in the future (Kohrmann et al, 2002; Ponsky et al, 2003; Wu et al, 2003).

Observation

There was once relatively little information about the growth rate of RCC because when a renal tumor was detected, it was usually removed. The incidental discovery of many small RCCs in asymptomatic elderly patients or those of poor surgical risk has provided the opportunity to observe the growth rate of these tumors in patients who are unable or unwilling to undergo surgery (Table 47–21) (Derweesh and Novick, 2003). Bosniak and associates (1996) reported the largest such series that included 72 small (<3.5 cm) renal tumors in 68 patients who were observed with serial imaging studies for intervals ranging from 2 to 10 years (mean, 3.3 years). On CT scan, these were well-marginated, homogeneous, solid, enhancing tumors consistent with RCC. During the period of observation, these tumors grew at slow and variable rates of up to 1.1 cm per year, with a median growth rate of 0.36 cm per year. In 32 patients whose tumors grew larger than 3 cm, surgical excision was performed; all the excised tumors proved to be stage I RCCs, and the majority were grade 1 tumors. Significantly, none of the patients developed metastasis during the period of observation.

Subsequent series have confirmed that many small renal masses will grow relatively slowly (see Table 47–21), and there have been only two patients with metastasis in these series, suggesting that this may be a reasonable management strategy in carefully selected patients who are not candidates for conventional surgery or thermal ablative approaches (Chawla et al, 2005). However, a critical review of these data is required to recognize the limitations of this database. First, this is a

Table 47–21. Observation of Renal Masses

†Mean growth rate.

highly select population; most series included only relatively small, well-marginated, and homogeneous renal masses, a substantial proportion (approximately 20%) of which may have been benign (Frank et al, 2003b). Second, in some cases, the growth rate was calculated backward by obtaining old films for which the lesion of interest was either previously missed or dismissed, introducing a clear selection bias (Bosniak et al, 1996). Finally, in most of these series, there is a subpopulation of patients with rapidly growing tumors that appear to have more aggressive characteristics. For instance, in the series from Volpe and colleagues (2004), 25% of the masses doubled in volume in 12 months and 22% reached a diameter of 4 cm, triggering surgical intervention.

Nevertheless, these studies suggest that patients with small, solid, enhancing, well-marginated, homogeneous renal lesions, who are elderly or poor surgical risks, can safely be managed with observation and serial renal imaging at 6-month or 1-year intervals (Chawla et al, 2005; Viterbo et al, 2005). **This approach is not appropriate for patients with larger (>3 cm), poorly marginated, or nonhomogeneous solid renal lesions. Observation is also not advisable in younger, otherwise healthy patients with small, solid tumors that have radiographic characteristics consistent with RCC.** Even if these lesions are smaller than 3 cm, the current database (see Table 47–21) indicates that most will grow and eventually reach a size at which metastasis becomes more likely. Therefore, in this setting, it is more appropriate to undertake surgical excision of the tumor (or thermal ablation) when it is small, clearly localized, and potentially amenable to nephron-sparing approaches.

TREATMENT OF LOCALLY ADVANCED RENAL CELL CARCINOMA

Inferior Vena Caval Involvement

One of the unique features of RCC is its frequent pattern of growth intraluminally into the renal venous circulation, also known as venous tumor thrombus. In extreme cases, this growth may extend into the inferior vena cava (IVC) with cephalad migration as far as the right atrium. The absence of metastases in many patients with vena caval extension is an intriguing aspect of this cancer's behavior (Gettman and Blute, 2002). Approximately 45% to 70% of patients with RCC and IVC thrombus can be cured with an aggressive surgical approach including radical nephrectomy and IVC thrombectomy (see Table 47–15). In general, patients with tumor that is otherwise confined to the kidney and free-floating thrombi have the best prognosis; those with tumor extending into the perinephric fat, lymph node involvement, or direct invasion of the wall of the IVC are at much higher risk for recurrence (Hatcher et al, 1991; Montie et al, 1991; Glazer and Novick, 1996; Gettman et al, 1999; Naitoh et al, 1999; Sweeney et al, 2002b; Bissada et al, 2003; Kim et al, 2004a; Moinzadeh and Libertino, 2004; Leibovich et al, 2005).

Overall, involvement of the IVC with RCC occurs in 4% to 10% of patients. Venous tumor thrombus should be suspected in patients with a renal tumor who also have lower extremity edema, isolated right-sided varicocele or one that does not collapse with recumbency, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or nonfunction of the involved kidney. Staging of the level of IVC thrombus is as follows: I, adjacent to the ostium of renal vein; II, extending up to the lower aspect of the liver; III, involving the intrahepatic portion of the IVC but below the diaphragm; and IV, extending above the diaphragm. The prognostic significance of the cephalad extent of the IVC thrombus has been controversial. Most studies suggest that the incidence of locoregional or systemic progression is higher in patients with level III-IV IVC thrombus, and this probably accounts for the reduced survival reported in this subgroup in some series (Sosa et al, 1984; Quek et al, 2001; Zisman et al, 2003; Kim et al, 2004a; Leibovich et al, 2005). However, other reports confirm that many patients with level IV IVC thrombi can be cured of disease with surgical resection, as long as the tumor is otherwise confined (Libertino et al, 1987; Glazer and Novick, 1996; Sweeney et al, 2002b).

Accurate information about the presence and complete extent of IVC involvement is essential for surgical planning. Routine CT scanning and abdominal ultrasonography usually detect gross renal vein and inferior vena caval involvement but are less reliable in delineating the cephalad extent of a thrombus (Goldfarb et al, 1990). Transesophageal echocardiography and transabdominal color flow Doppler ultrasonography are occasionally employed in this setting (Glazer and Novick, 1997). Contrast inferior venacavography remains an accurate diagnostic study for assessment of IVC involvement (Fig. 47–27). However, this is an invasive technique that entails

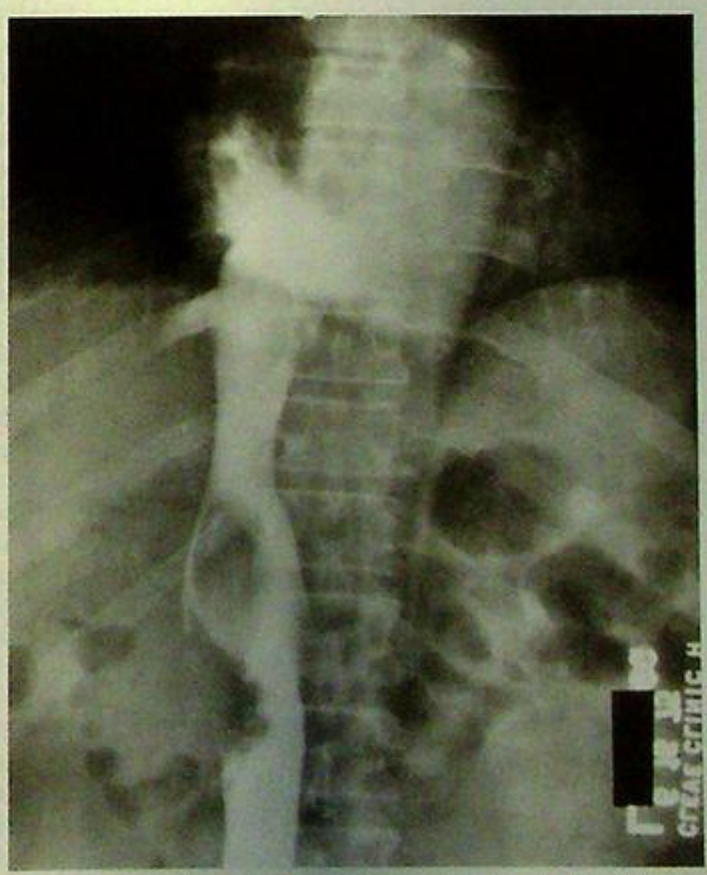

Figure 47–27. Contrast inferior venacavogram in patient with a right renal tumor shows involvement of the subdiaphragmatic vena cava.

administration of contrast material, and a single antegrade study may be insufficient in patients with complete caval occlusion (Fig. 47–28). In such cases, a second retrograde injection of the vena cava may be needed to define the distal limits of the thrombus.

MRI is a noninvasive and accurate modality for demonstrating both the presence and the cephalad extent of vena caval involvement and has become the preferred diagnostic study at most centers (Fig. 47–29) (Goldfarb et al, 1990; Kallman et al, 1992; Choyke, 1997). Venous thrombus detection, characterization, and extent are best evaluated by MRI on gradient-recalled echo sequences. Individual gradient-recalled echo sequences can be reconstructed by maximum-intensity projection algorithms to create magnetic resonance venograms. Gadolinium chelates can be given to patients with known thrombus to differentiate between tumor thrombus and bland thrombus. Most tumor thrombi will demonstrate enhancement after gadolinium administration, whereas this finding is absent in bland thrombi. A limitation of current vena caval imaging modalities is the inability to differentiate extrinsic vena caval compression from actual invasion of the vena caval wall, which is generally associated with a poor prognosis; unfortunately, the determination is most often established at the time of surgical exploration.

Renal arteriography remains a useful preoperative study in patients with RCC involving the inferior vena cava because in 35% to 40% of cases, distinct vascularization of a tumor thrombus is observed (Fig. 47–30). When this finding is present, preoperative embolization of the kidney often causes shrinkage of the thrombus, which can facilitate

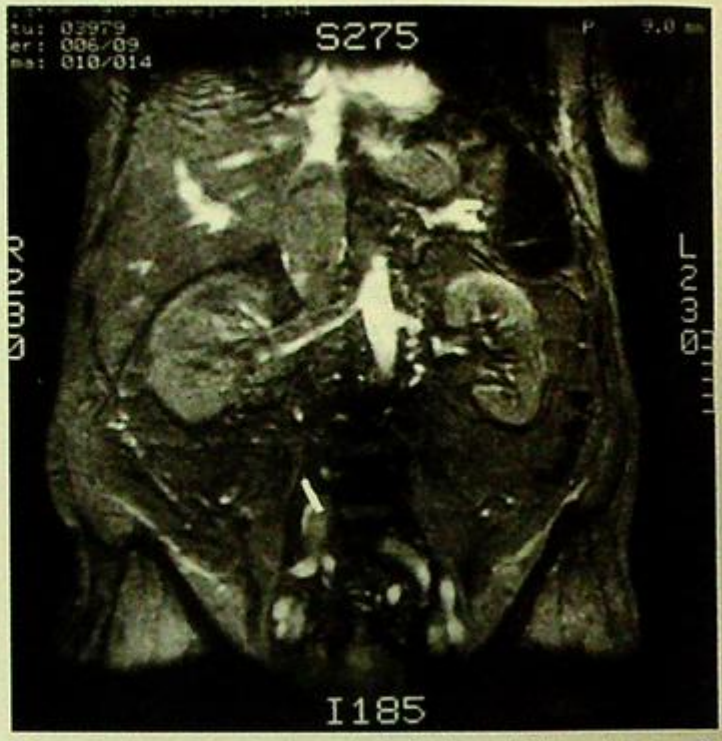

Figure 47–29. MRI scan (coronal view) shows right renal tumor with thrombus extending to intrahepatic vena cava.

Figure 47–28. Transfemoral venogram shows complete occlusion of the inferior vena cava in patient with renal tumor.

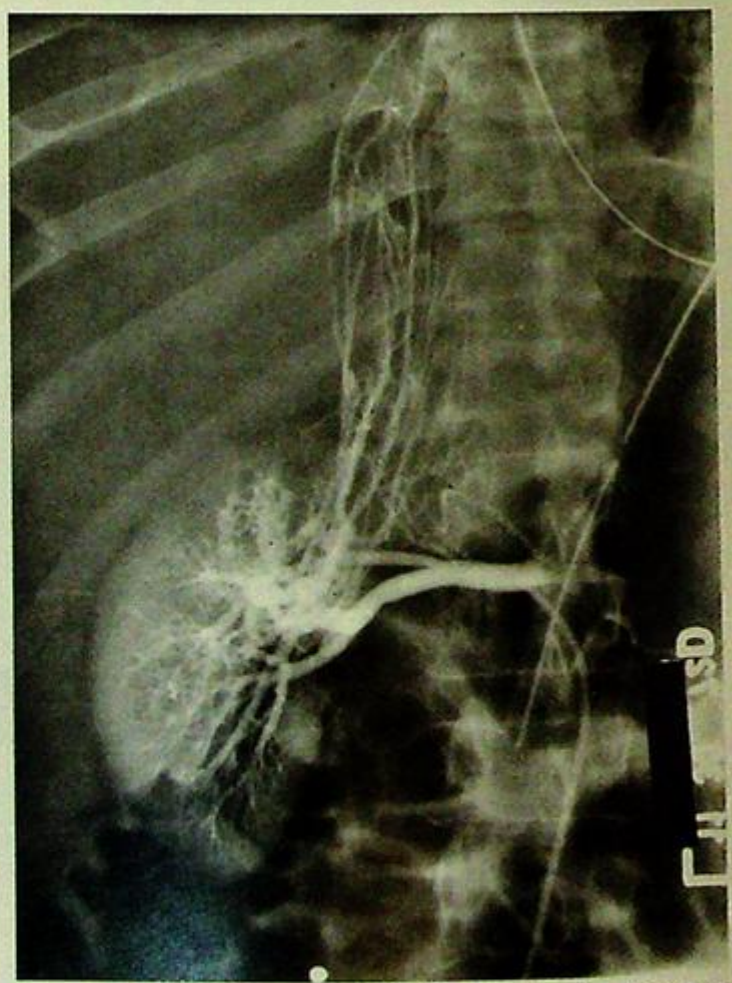

Figure 47–30. Right renal arteriogram shows arterialization of a supradiaphragmatic vena caval thrombus.

its intraoperative removal. In patients with extensive supradiaphragmatic vena caval thrombi, when adjunctive cardiopulmonary bypass with deep hypothermic circulatory arrest is considered, coronary angiography is also performed preoperatively (Novick et al, 1990). If significant obstructing coronary lesions are found, these can be repaired simultaneously during cardiopulmonary bypass.

Contrast inferior venacavography is reserved for patients in whom MRI findings are equivocal or for whom MRI is contraindicated, as in patients with claustrophobia, cardiac pacemakers, certain intracerebral vascular clips, cochlear implants, or intraocular foreign bodies. Another option in this group of patients is multiplanar CT, and recent data suggest that this study may approach the accuracy of MRI in the identification and characterization of IVC thrombi (Pretorius et al, 2000; Sohaib et al, 2002; Ergen et al, 2004; Hallscheidt et al, 2004).

Although involvement of the IVC with RCC renders the task of complete surgical excision more complicated, operative removal offers the only realistic hope for cure for most patients (Quek et al, 2001; Blute et al, 2004b). After mobilization of the kidney and ligation and transection of the arterial blood supply, vascular control of the involved portion of the IVC is then obtained. In general, level I thrombi are isolated by a Satinsky clamp and are thus readily removed. Level II thrombi require sequential clamping of the caudal IVC, contralateral renal vein, and cephalad IVC along with mobilization of the relevant segment of the IVC and occlusion of lumbar veins. The renal ostium is then opened and the thrombus is removed, all in a bloodless field. On occasion, a tumor thrombus may locally invade the wall of the vena cava. Aggressive resection of the vena caval wall and attainment of negative surgical margins in these patients appear to provide a survival benefit (Hatcher et al, 1991). IVC grafting or reconstitution is required in some instances, but patients with a completely occluded IVC do not require this because of collateral blood flow (Sarkar et al, 1998). Bland thrombus may be left in situ, although the cephalad IVC level should be occluded or clipped in this instance to prevent pulmonary embolism.

Vascular control for level III and level IV IVC thrombi requires more extensive dissection or cardiopulmonary bypass and hypothermic circulatory arrest. For level III thrombi, mobilization of the liver and exposure of the intrahepatic IVC will often allow the thrombus to be mobilized proximal to the hepatic veins, and dissection can then proceed as for a level II thrombus (Gallucci et al, 2004). If this is not possible, the IVC can be clamped above the liver and a Pringle maneuver can be performed, whereby the portal triad is temporarily occluded (Burt, 1991; Ciancio and Soloway, 2001, 2002; Vaidya et al, 2003; Jibiki et al, 2004). Venovenous bypass is commonly used in these cases but may not be required if adequate collateral flow is present (Ciancio et al, 2002). Level IV IVC thrombi have traditionally been managed with cardiopulmonary bypass and hypothermic circulatory arrest, and this is still the preferred approach in complex cases. However, many centers are now trying to avoid hypothermic circulatory arrest and the associated hypocoagulable state that ensues after coming off the pump and the increased risk of cerebrovascular accident and myocardial infarction that accompanies this procedure (Shinghal et al, 2003; Tasca et al, 2003). In this case, the thrombus is mobilized below the atrium, allowing sequential vascular control to be achieved without opening the heart. Further detail about these procedures can be found in Chapter 50.

Mortality rates associated with radical nephrectomy and IVC thrombectomy have ranged as high as 5% to 10% for upper level thrombi, depending on the patient's comorbidities and tumor characteristics, and the risk of morbidity can also be substantial in this setting (Staehler and Brkovic, 2000; Blute et al, 2004b). Hence, selection of patients is of paramount importance (Gettman et al, 2003), and this procedure has for the most part been reserved for patients with good performance status in whom preoperative studies show no substantial lymphadenopathy or systemic metastasis. However, there may be a palliative role for surgery in some patients with metastasis who experience severe disability from intractable edema, ascites, cardiac dysfunction, or associated local symptoms such as abdominal pain and hematuria (Slaton et al, 1997). In addition, cytoreductive nephrectomy and IVC thrombectomy can also be considered in some patients with metastatic disease, particularly those with level I-II or readily managed level III thrombi (Zisman et al, 2002b, 2003).

Locally Invasive Renal Cell Carcinoma

The sequestered location and propensity for aggressive behavior of RCC result in occasional patients presenting with large primary tumors that invade adjacent structures. **Such patients usually present with pain, generally from invasion of the posterior abdominal wall, nerve roots, or paraspinous muscles.** Liver extension is uncommon, and intrahepatic metastases occur more often than local extension. The capsules of large tumors may indent and compress adjacent liver parenchyma but seldom actually grow by direct extension into the liver. Duodenal and pancreatic invasion is uncommon and a poor prognostic sign. The propensity for RCC to parasitize vessels may account for extension into the colon and its mesentery. **In evaluation of patients with large, invasive upper quadrant abdominal masses, a broad differential diagnosis should be considered, including adrenocorticoid carcinoma, infiltrative transitional cell carcinoma, sarcoma, and lymphoma in addition to locally invasive RCC.**

Because surgical therapy is the only effective management for RCC, extended operations with en bloc resection of adjacent organs are sometimes indicated. Complete excision of the tumor, including resection of the involved bowel, spleen, or abdominal wall muscles, is the aim of therapy. En bloc partial hepatectomy is rarely curative but may occasionally be worthwhile. Important perioperative concerns for patients with locally advanced RCC include a full bowel preparation and consideration for preoperative embolization of the renal arterial blood supply, which can substantially facilitate the dissection.

Partial excision of the large primary tumor, or debulking, is rarely indicated. In one study, only 12% of patients who underwent incomplete excision of locally extensive tumor were alive at 1 year (deKernion et al, 1978). Most reports suggest that less than 5% of patients with extension into adjacent viscera (stage pT4) survive 5 years after surgery. The randomized studies evaluating the role of cytoreductive nephrectomy (Flanigan et al, 2004) did not include a substantial number of patients with this subcategory of disease,

and their conclusions should not be extrapolated to this population of patients. Resection of locally advanced disease can be a major undertaking, and its primary indication should be curative or palliative intent.

The role of radiation therapy in the treatment of locally extensive RCC is controversial. Several early studies suggested that preoperative radiotherapy could improve survival (Richie, 1966; Cox et al, 1970). A subsequent study by van der Werf–Messing (1973), however, compared results for preoperative therapy with those for no preoperative therapy and found no survival difference at 5 years. Routine postoperative radiotherapy has not been shown to influence overall survival and can be hazardous because of proximity of small bowel, which is highly radiosensitive. When tumor is known to have been left behind in the renal fossa or adjacent structures, postoperative radiotherapy may occasionally retard regrowth of tumor mass (Kao et al, 1994). This approach is rarely used today and has largely been replaced by the use of systemic immunotherapy.

Local Recurrence after Radical Nephrectomy or Nephron-Sparing Surgery

Local recurrence of RCC after radical nephrectomy is an uncommon event, occurring in approximately 2% to 4% of cases (Uson, 1982; Sandock et al, 1995; Levy et al, 1998; Ljungberg et al, 1999; Itano et al, 2000; Schrodter et al, 2002; Dimarco et al, 2004; Stephenson et al, 2004a). **Risk factors include increasing T stage and locally advanced or node-positive disease** (Esrig et al, 1992; Sandock et al, 1995; Levy et al, 1998). In contrast, local recurrence after radical nephrectomy is rare in patients with low-stage pT1-2 N0 M0 RCC. **Only about 40% of local recurrences are isolated; the majority of patients with local recurrence also have systemic disease, and a thorough metastatic evaluation should be pursued** (Uson, 1982; Phillips and Messing, 1993; Sandock et al, 1995; Itano et al, 2000; Schrodter et al, 2002). Isolated local recurrence of RCC after radical nephrectomy should be considered for surgical resection, which can provide long-term cancer-free status for about 30% to 40% of patients with this dilemma (Esrig et al, 1992; Tanguay et al, 1996a; Itano et al, 2000; Schrodter et al, 2002; Wiesner et al, 2002; Gogus et al, 2003). However, this is often a formidable task because the natural tissue barriers are no longer present and invasion of contiguous organs is not uncommon. En bloc resection of adjacent organs is often required, and the risk of morbidity can be substantial (Esrig et al, 1992; Tanguay et al, 1996a; Itano et al, 2000; Wiesner et al, 2002; Gogus et al, 2003). Radiation therapy may be of value for palliation of symptomatic local recurrence in patients who are not operative candidates.

Local recurrence in the remnant kidney after nephron-sparing surgery for RCC has been reported in 1.4% to 10% of patients, and the main risk factor is advanced T stage (see Table 47–17). Most of these local recurrences are distant from the tumor bed and are thus probably a result of unrecognized tumor multicentricity or de novo occurrence rather than true treatment failure (Campbell and Novick, 1994). Patients with isolated local recurrence after partial nephrectomy can be considered for repeated partial nephrectomy, complet nephrectomy, or thermal ablative therapies. The last optio now being used more frequently in this setting because concern about fibrosis within the renal fossa, but conventio partial nephrectomy can and should be performed wh preservation of renal function is important and the anato or tumor characteristics are not favorable for ablative mod ities (Gittes and Blute, 1982; Moll et al, 1993; Campbell a Novick, 1994; Frank et al, 2005a).

Local recurrence after thermal ablative modalities ofte represents treatment failure; many local recurrences develo within the previous tumor bed (see Table 47–20). The tru incidence of local recurrence in this population is not we defined because most series do not include longitudina follow-up. Diagnosis of local recurrence in this setting i established by the demonstration of persistent enhancemen within the tumor bed or at any other site within the ipsilateral kidney. Again, management is primarily surgical and most often will entail repeated thermal ablation or completion nephrectomy.

Adjuvant Therapy for Renal Cell Carcinoma

Although RCC can be cured surgically, recurrence develops in a significant proportion of patients. Rabinovitch and coworkers (1994) reviewed patterns of disease relapse in 172 patients after nephrectomy, and their experience is typical—**distant metastases developed in 26% and local recurrence in only 5%.** In view of these findings, a strong rationale for systemic postoperative adjuvant therapy exists in high-risk patients.

Studies have attempted to identify patients who are appropriate candidates for adjuvant therapy trials. Zisman and colleagues (2001b) investigated 661 patients who underwent nephrectomy, and **five patient groups were segregated on the basis of clinical and pathologic parameters with 5-year survival rates of 94%, 67%, 39%, 23%, and 0%, respectively.** This system was validated by an international cohort of 4202 patients (Patard et al, 2004c) with localized RCC. This group has reported a variety of molecular markers, such as CA-9, Ki-67, and EpCAM (Bui et al, 2004), that may also be useful biomarkers to predict outcomes. Approaches integrating clinical factors and molecular markers to define risk of recurrence will be employed to select patients for adjuvant trials in the future.

Clinical endpoints used in adjuvant trials include progression-free survival, time to progression, and overall survival. The determination of time to progression or progression-free survival requires either placebo-controlled and blinded designs or independent review of radiographic and clinical data. **The majority of adjuvant trials performed in patients with RCC have been underpowered to detect small differences in survival; endpoints of time to progression or progression-free survival have been difficult to assess in view of the study designs.**

Several different therapeutic modalities and systemic agents have been used in an adjuvant setting for patients with RCC, including hormonal manipulation, radiotherapy, vaccines, and cytokines. Most of these trials have been random-

ized and have incorporated a control arm of observation only. A series of clinical trials using postoperative medroxyprogesterone acetate (Pizzocaro et al, 1987) or perioperative radiotherapy (van der Werf–Messing, 1973; Kjaer et al, 1987) were all negative, **with no survival advantage demonstrated.**

A variety of autologous tumor vaccine–based approaches have been used to immunize RCC patients in the postoperative setting, most with negative results and one with controversial results (Table 47–22). Galligioni and associates (1996) conducted a prospective controlled trial in which patients were treated with three intradermal injections of 10^7 autologous irradiated tumor cells mixed with 10^7 bacille Calmette-Guérin (first two injections) or observed. A total of 120 patients were randomized, and at a median follow-up of 61 months, no difference in progression-free survival or overall survival was seen. Jocham and colleagues (2004) reported a prospective trial in which a group of 553 patients were apparently randomized to observation or intradermal treatment with an autologous vaccine. The final report included 202 patients on observation and 177 on active treatment, and this cohort of 379 patients was referred to as the intent-to-treat group by the investigators. At 5 years, the progression-free survival rates were significantly improved for the vaccine-treated group ($P = .0204$). However, this trial was not blinded, did not include a placebo control, and did not undergo external review of data; therefore, a confirmatory study is required. In addition, this study may not have included a true intent-to-treat analysis, and this has raised concern about potential bias.

Finally, Wood and colleagues (2004) have now conducted the largest adjuvant clinical trial testing an autologous tumor vaccine for RCC, in this case targeting patients with clear cell histology and incorporating autologous heat shock protein HSPPC-96 (Oncophage). HSPPC-96 binds peptide fragments and can act as a chaperone for antigen presentation. More than 2000 patients have been evaluated; 809 were eligible. This group was randomized to observation alone or therapy with intradermal HSPPC-96 (25 mg weekly × 4, then 1 every 4 weeks until vaccine supply was exhausted). A placebo arm was not incorporated, but independent review of the radiologic studies is planned. The review committee will independently determine time to progression. Accrual to this trial is complete, but results remain preliminary. **Despite this series of studies, it remains unclear whether adjuvant administration of a tumor vaccine influences the natural history of RCC.** Clearly, the nature of the vaccine, the population treated, and the trial design are major issues in these studies.

In view of their antitumor effects in patients with demonstrable metastatic disease, IL-2 and interferon alfa have also been studied in postoperative adjuvant trials. Four randomized studies have been performed, three with interferon alfa and one with IL-2 (Table 47–23). No improvement in disease-free or overall survival for treated patients has been found. The studies investigating interferon used various doses, preparations (L-interferon, interferon alfa-2a, interferon alfa-2b), and duration of therapy (6 to 12 months). The results demonstrate no protective effect of postoperative adjuvant interferon; however, only one trial (Messing et al, 2003) evaluated survival as the primary endpoint. In addition, these studies included patients with all histologic subtypes of RCC, which may not be optimal in view of the limited effects of systemic interferon alfa in non–clear cell histologic types (Motzer et al, 2002). Finally, lack of external review or a blinded design does not permit conclusions about time to progression. Given the modest survival benefit reported with interferon alfa in patients with metastatic RCC, further adjuvant trials with interferon alfa may be of interest.

IL-2 has also been evaluated in a postoperative adjuvant trial without success. Clark and colleagues (2003) randomized patients to observation alone or to high-dose IL-2 (600,000 units/kg every 8 hours on days 1 to 5 and 15 to 19). A total of 69 patients were registered, 25 with resected M1 disease and 38 with locally advanced but resectable disease. An interim analysis prompted closure of the trial with adjuvant IL-2 having demonstrated no clinically meaningful benefit for the population as a whole or in either subgroup.

In summary, the majority of postoperative adjuvant trials in patients with resected renal cancer have been negative, and the standard of care remains observation. In the future, trials using targeted oral agents such as sorafenib or SU11248 are planned for the population of patients with surgically resectable RCC who are at high risk for recurrence.

TREATMENT OF METASTATIC RENAL CELL CARCINOMA

Nephrectomy

Approximately one third of patients with RCC have metastatic disease at the time of initial diagnosis (synchronous metastatic disease), and 40% to 50% will develop distant metastases after initial diagnosis (Bukowski, 1997). **The value**

of nephrectomy has been examined retrospectively in patients with synchronous metastases. Prospective controlled trials have also examined the value of nephrectomy (Flanigan et al, 2001; Mickisch et al, 2001). Initially, the rationale for nephrectomy included palliation for severe bleeding, pain, and paraneoplastic symptoms. In addition, there have been occasional patients who demonstrate regression of metastases after nephrectomy; the frequency of this finding has been estimated as 1% to 2% (Walther et al, 1997c). These responses have been predominantly in pulmonary nodules, with a median duration of approximately 6 months. Several retrospective studies suggested that prior nephrectomy was a good prognostic factor for patients with metastatic RCC, but concerns about selection bias predominated. About 10% to 30% of patients undergoing cytoreductive nephrectomy were unable to receive systemic therapy because of postoperative medical complications or rapid cancer progression.

Two prospective trials have been reported in which untreated patients with synchronous metastatic disease were randomized to either nephrectomy followed by systemic interferon alfa or interferon alfa monotherapy alone (Table 47–24). **The results demonstrate that cytoreductive nephrectomy followed by systemic treatment should be considered in patients with synchronous metastatic disease. Careful selection of patients remains of paramount importance.** Eligibility for these trials included the histologic confirmation of RCC before study entry, a primary tumor considered surgically resectable, and an Eastern Cooperative Oncology Group performance status score of 0 to 1. Interferon alfa-2b (Intron A) was administered subcutaneously at a dose of 5×10^6 IU/m² three times weekly. In the study reported by Flanigan and colleagues (2001), the dose was gradually escalated from 1.25×10^6 IU/m² during 3 days, and interferon alfa was initiated in almost all patients within 4 weeks of nephrectomy. In a meta-analysis of both trials (Flanigan et al, 2004), the median survival in the nephrectomy-interferon group was found to be 13.6 months (95% CI, 9.7 to 17.4) versus 7.8 months (95% CI, 5.9 to 9.7) for patients receiving interferon alfa alone (HR, 0.69; 95% CI, 0.55 to 0.87; $P = .002$). The greatest survival advantages were observed in patients with good performance

status (17.4 versus 11.7 months median survival) and those with pulmonary-only metastasis (14.3 versus 10.3 months median survival), but this survival benefit of 30% to 50% persisted in other subgroups as well. Surgical morbidity and mortality were minimal, with a 1% operative and perioperative mortality noted in the Southwest Oncology Group trial. **These data therefore support the concept of cytoreductive nephrectomy before systemic therapy with a cytokine such as interferon.**

Two retrospective series (Walther et al, 1997c; Pantuck et al, 2002a) have examined institutional experience with cytoreductive nephrectomy followed by IL-2–based therapy. In the series from Walther and associates (1997c), 195 patients underwent cytoreductive nephrectomy but 31% did not subsequently receive systemic treatment because of postsurgical complications (9%) or rapidly progressive disease (22%). Pantuck and colleagues (2002a) reviewed 89 patients treated at the University of California, Los Angeles with nephrectomy followed by IL-2–based treatment. The median survival of this group was 16.7 months, somewhat better than that reported in the Southwest Oncology Group and European Organisation for Research and Treatment of Cancer trials with interferon-based systemic therapy. However, in view of potential selection bias in these trials, related in part to the high-dose IL-2 regimen used, comparisons to the data from the nephrectomy–interferon alfa trials is not possible. Nevertheless, the Walther and Pantuck reports do demonstrate that nephrectomy followed by high-dose IL-2 is possible.

Selection of patients for nephrectomy followed by cytokine therapy in the setting of advanced disease must be careful—this is not a pathway that should be used indiscriminately. **Individuals with advanced symptoms (performance status ≥ 2), metastases in critical areas (central nervous system, spinal cord compression), major organ dysfunction, and significant comorbid illnesses are not candidates for such approaches.** Figure 47–31 highlights the indications for cytoreductive nephrectomy and other treatment options for the management of patients with advanced RCC. **The role of this approach in patients with non–clear cell carcinoma is not well defined.**

Hormonal Therapy

The use of hormonal therapy for patients with metastatic RCC has minimal value. It was originally thought that progestational agents would be useful since they inhibit the growth of diethylstilbestrol-induced renal tumors in Syrian hamsters. Unfortunately, the collective experience with medroxyprogesterone acetate, androgens, and antiestrogens has shown that such preclinical models of renal cancer do not correlate with human RCC. Although the initial clinical trials using progestins for patients with advanced RCC looked promising, studies using modern objective response criteria have demonstrated only limited activity.

Two multicenter randomized trials (Medical Research Council Renal Cancer Collaborators, 1999; Negrier et al, 2005) tested oral medroxyprogesterone acetate as initial therapy for patients with metastatic RCC. In these reports, 174 and 123 patients received medroxyprogesterone acetate, 300 mg/day and 200 mg/day, respectively. Response rates to medroxyprogesterone acetate were uniformly low (2.0% and 2.5%, respectively), and overall median survival of the patients varied from 6.0 months (Medical Research Council Renal Cancer Collaborators, 1999) to more than 15.0 months (Negrier et al, 2005). The difference in survival probably reflects patient entry criteria used in the two studies rather

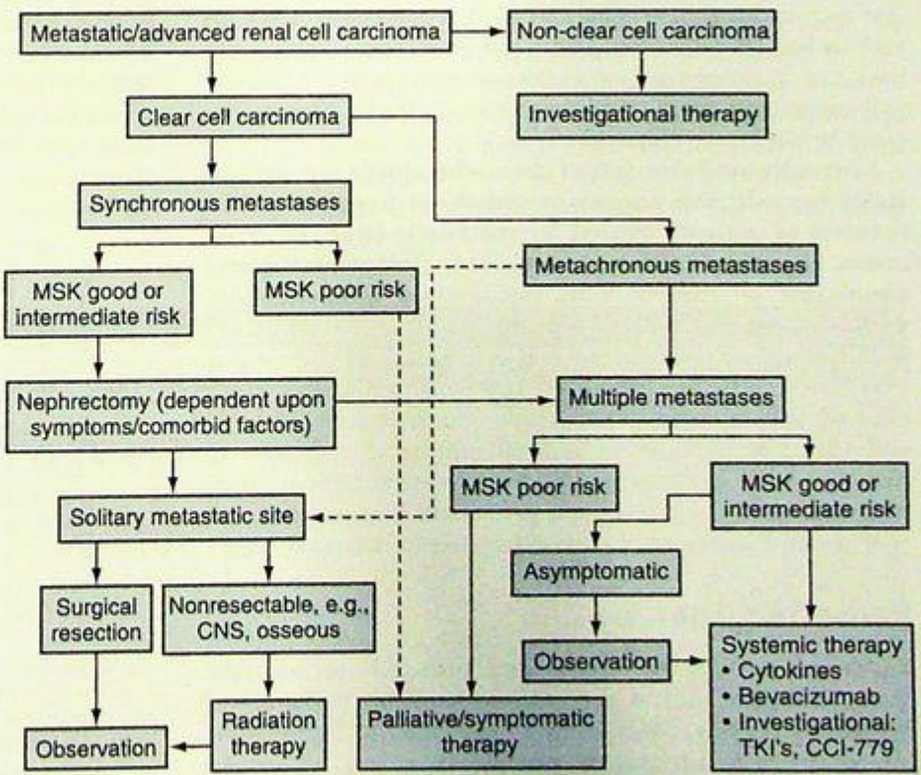

Figure 47–31. Algorithm for management of advanced RCC. MSK, Memorial Sloan Kettering.

than a true difference in biologic responsiveness. **Therefore, whereas progestational agents may be useful for symptom palliation, they do not appear to have any significant value in the treatment of patients with metastatic RCC.**

Chemotherapy

Multiple clinical trials performed during the 1980s established RCC as a prototype of a chemotherapy-resistant tumor. Yagoda and associates (1995) reviewed a total of 4542 patients treated with a variety of chemotherapeutic agents in a series of clinical trials (1983-1993) and found an overall response rate of 6.0% (95% CI, 5.3% to 6.8%). This series was updated by Ruiz and colleagues (2000), who reviewed an additional 2327 patients treated with chemotherapy between 1993 and 1998. The overall response rate in this review was 18.5%, but protocols incorporated immunotherapy in combination with chemotherapy, and this probably accounts for the marginal increase in activity. In the past, it has been suggested that the fluoropyrimidines or vinblastine might have antitumor activity in patients with metastatic RCC. However, when vinblastine was tested in a randomized prospective setting, the response rate was 2.5% in 81 patients receiving chemotherapy alone, and overall survival was inferior to the combination of vinblastine and interferon alfa (Pyrhonen et al, 1999). **Virtually every other cytotoxic agent has been tested for this disease, either alone or in combination with other chemotherapeutic approaches, almost uniformly with discouraging results.**

One factor contributing to this phenomenon is the expression of the MDR-associated glycoprotein on the surface of RCC cells (Fojo et al, 1987). *MDR1*, which encodes a 170-kD membrane glycoprotein (P-glycoprotein), can act as an efflux pump, reducing intracellular concentrations of agents such as vinblastine. In view of this, compounds inhibiting P-glycoprotein, such as toremifene, verapamil, nifedipine, and cyclosporine, have been investigated in combination with vinblastine (Braybrooke, 2000). To date, these approaches have not improved response rates to vinblastine. It is likely that additional mechanisms also contribute to chemoresistance in patients with advanced RCC.

Currently available data of chemotherapy do not demonstrate reproducible antitumor activity or improvement in survival of patients treated for metastatic clear cell carcinoma. In patients with metastatic non–clear cell malignant neoplasms or tumors with sarcomatoid differentiation, various agents including doxorubicin and gemcitabine may have clinical activity. Nanus and colleagues (2004) reported a response rate of 39% (two complete responses) in 18 patients with sarcomatoid or rapidly progressing RCC treated with this combination. Anecdotal reports of responses in patients with collecting duct cancers (Peyromaure et al, 2003) to agents such as cisplatin and gemcitabine suggest that this type of renal tumor may also be sensitive to chemotherapy.

Radiation Therapy

Radiation therapy has been used primarily as adjuvant treatment after radical nephrectomy and for palliation of metastatic lesions. Most studies have failed to demonstrate improvement in survival or a reduction in local recurrence rates after postoperative radiation therapy. **At present, the main role of radiation therapy for patients with metastatic RCC is for the palliation of symptomatic osseous metastases** (Halperin and Harisiadis, 1983; Cutuli et al, 1990). Radiation therapy has also been combined with surgery for the treatment of vertebral body metastases with spinal cord compression, allowing substantially reduced blood loss (Sundaresan et al, 1986). Standard radiation therapy may also be employed for palliation of brain metastases (Halperin and Harisiadis, 1983; Maor et al, 1988; Cutuli et al, 1990). Stereotactic radiosurgery has shown promise for the treatment of select patients with brain metastases, thereby avoiding the risks associated with craniotomy (Coffey et al, 1991).

Cytokines and Immunologic Therapy

The therapeutic potential of cytokines and immunotherapy has been investigated for the last 30 years in patients with metastatic RCC and has shown real but limited efficacy. The demonstration of T-cell infiltrates (Finke et al, 1988), **the development of T-cell lines ($CD8^+$) with specificity for autologous tumor** (Finke et al, 1994), **and the finding of tumor-associated antigens on renal tumors that are MHC restricted** (Tatsumi et al, 2002) **provide laboratory evidence for a specific antitumor immune response.** Coincident with these observations, a series of clinical trials demonstrated the antitumor activity of cytokines such as interferon alfa and IL-2 in patients with advanced disease.

Interferon alfa is one member of a pleiotropic group of proteins with antiviral, immunomodulatory, and antiproliferative activities (Vestal et al, 2001) related to modulation of gene expression in selected cell populations. IL-2 is a T-cell growth factor that was first described by Morgan and colleagues (1976) and is produced when T lymphocytes are activated (Alatrash et al, 2001). Its biologic effects are mediated by binding to the IL-2 receptor, with subsequent clonal expansion of cytotoxic T cells. **Since the 1980s, these two cytokines have been tested alone or in combination as therapy for metastatic RCC.** In a review of phase II and randomized phase III trials (Bukowski, 1997), the aggregate response rates for these cytokines were characterized (Fig. 47–32). With single-

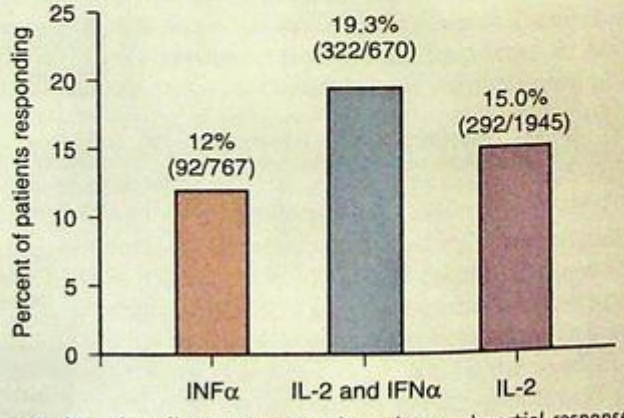

Figure 47–32. Overall response rates (complete and partial responses) in a review of therapy with various cytokines including interferon alfa (INF-α), interleukin-2 (IL-2), and the combination of interleukin-2 and interferon alfa. Patients included in prospective phase II and phase III trials receiving various doses and schedules of the cytokines are included.

agent interferon alfa or IL-2, the overall response rates were approximately 13% to 15%. With combination therapy, this increased to more than 20%.

The responses seen with interferon alfa monotherapy are generally partial, with a complete response rate of only 1.8%. Prospective phase III trials have examined the activity of interferon alfa in untreated patients compared with other agents with or without interferon alfa. Representative studies summarized in Table 47–25 demonstrate that interferon alfa monotherapy has a modest effect compared with medroxyprogesterone acetate or vinblastine. Increases in objective response rates, overall survival, and progression-free survival (Medical Research Council Renal Cancer Collaborators, 1999; Pyrhonen et al, 1999) were found. Addition of agents such as vinblastine and *cis*-retinoic acid to interferon alfa does not appear to improve results.

A series of meta-analyses have been performed to examine results of interferon alfa monotherapy in patients with metastatic RCC. Coppin and colleagues (2005) found four randomized controlled trials containing 644 patients that critically examined survival in patients receiving interferon alfa compared with a control population of patients treated with inactive or ineffective therapies. **The improvement in median survival (interferon alfa–treated patients) was 3.8 months (11.4 versus 7.6 months; hazard ratio, 0.74), with an overall response rate of 12.5% versus 1.5% in control patients.** In one such study, Motzer and colleagues (2001) examined their results with interferon alfa therapy in 463 patients receiving first-line therapy. The overall median survival was 13.0 months, and median progression-free survival was 4.7 months. The individuals most likely to benefit had good to intermediate risk status (Motzer et al, 2001), clear cell histology (Motzer et al, 2002), and lung or soft tissue predominant disease (Bukowski, 1997).

IL-2 has been the other primary immunotherapeutic agent used to treat patients with metastatic RCC (Bukowski, 1997). As shown in Figure 47–32, the overall response rate in 1714 patients treated with single-agent IL-2 is 15.0%. **IL-2 can be administered in a variety of ways, including bolus intravenous infusion, continuous intravenous infusion, and subcutaneous injection. These schedules use different dose levels and were developed in an effort to maintain efficacy while decreasing side effects, in particular the "vascular leak syndrome" that is associated with high-dose therapy. This syndrome can include hypotension, oliguria, and organ failure if it is not treated aggressively with fluid resuscitation and careful hemodynamic monitoring.**

In the United States, IL-2 is registered and approved for treatment of metastatic RCC on the basis of data from a high-dose bolus intravenous infusion protocol in which patients were given cytokine every 8 hours for 5 days (15 doses). This regimen may be more efficacious in terms of complete durable responses (≥5%), but it is associated with significant morbidity and requires hospitalization.

Several randomized trials and a retrospective analysis have investigated the optimal dose and schedule for IL-2 administration. Negrier and colleagues (2005) have reported preliminary results from a phase III trial comparing subcutaneous IL-2, interferon alfa, the combination of IL-2 and interferon alfa, and medroxyprogesterone in patients with an intermediate-prognosis RCC. A total of 492 patients were randomized, and no differences in overall survival between the treatment arms were detected (median overall survival, 15.0 months). Atzpodien and colleagues (2004) reported a randomized trial comparing various outpatient combinations of interferon alfa and IL-2 (Table 47–25). When the arms containing IL-2 and interferon alfa were compared with interferon alfa and vinblastine, median survival was significantly increased. Indirectly, this report suggests that adding IL-2 to interferon alfa and 5-fluorouracil may have an impact on survival.

Baaten and colleagues (2004) reviewed published results with IL-2 to assess the effects of the administration schedule (Fig. 47–33); 4946 patients receiving either intravenous bolus (1108 patients), subcutaneous (2394 patients), or continuous intravenous (1444 patients) IL-2–based therapy were described. Complete responses were seen less frequently in patients receiving continuous intravenous IL-2, and durable complete responses (≥36 months) were most frequent in patients receiving high-dose bolus IL-2. The heterogeneity of the patients treated, the variability in the regimens, and the absence of survival data make any conclusions tentative.

Table 47–26 summarizes a series of prospective phase III trials in which IL-2 monotherapy was included as a treatment arm. In one trial comparing IL-2 and interferon alfa (Negrier et al, 1998), essentially no differences were observed. In two reports (Yang et al, 2003b; McDermott et el, 2005) comparing

high-dose bolus IL-2 with lower doses of IL-2 or the combination of IL-2 and interferon alfa, the overall and complete response rates with high-dose IL-2 were increased, but no significant increase in survival or progression-free survival was seen.

High-dose IL-2 has been the schedule and dose recommended by a variety of investigators (Yang et al, 2003b; McDermott et al, 2005) on the basis of the frequency of complete durable responses. These are generally seen in 6% (Yang et al, 2003b) to 8% (McDermott et al, 2005) of selected patients. **However, in view of the significant toxicity associated with this approach, rigorous selection of patients is required, and these individuals may not represent the average patient with metastatic RCC, potentially biasing these results in a favorable manner. The absence of a demonstrable survival or progression-free survival improvement with this approach remains problematic.**

Figure 47–33. Complete and partial response rates in 4946 patients treated with interleukin-2 administered in a variety of ways and at various dose levels (Baaten et al, 2004). The data suggest that durable complete responses are more frequent in patients treated with intravenous bolus IL-2 at higher doses. CIV, continuous intravenous infusion; SC, subcutaneous; HD IV, high-dose intravenous.

In view of the single-agent data with IL-2 and interferon alfa and the preclinical data demonstrating potential synergy (Chikkala et al, 1990), these two cytokines have been combined. Data summarized in Figure 47–33 and Table 47–26 suggest that the combination has a higher response rate than monotherapy does, but no differences in overall survival have been reported (Negrier et al, 1998). The toxicity of regimens including IL-2 is increased; and in the absence of a survival benefit, careful selection of patients for a cytokine regimen such as IL-2 and interferon alfa is required.

Reports that address the issue of prognostic factors for response to cytokine therapy are useful for selection of patients (Motzer et al, 2001; Mekhail et al, 2005). More than 700 patients were included in these studies; the results are outlined in Table 47–27. **These studies demonstrate that prognosis in patients with metastatic RCC can be defined by a series of clinical criteria including performance status, metastasis-free interval, and several laboratory findings (hemoglobin, lactate dehydrogenase, and corrected calcium concentrations). Patients can then be divided into groups of favorable, intermediate, and poor risk differentiated by median survival as outlined in Table 47–27.** The initial analysis by Motzer and colleagues (2001) was then validated on an independent data set (Mekhail, 2005). This method provides a clinically defined set of criteria that can be used to select patients for various treatment approaches with cytokines. Patients in the poor-risk group (20% to 25%) have a short median survival, are unlikely to tolerate or to benefit from aggressive therapy, and may experience significant toxicity. The other two groups have median survivals of 14.0 and more than 26.0 months (intermediate and favorable risk, respectively) and are appropriate candidates for IL-2, interferon alfa, or investigational trials.

The overall approach to patients with metastatic RCC is outlined in Figure 47–31 and highlights the use of prognostic criteria for selecting initial treatment. In addition, information such as this can be used for clinical trial design to determine sample size and eligibility of patients. **Patients are also segregated on the basis of histology (clear cell versus non–clear cell) and the type of metastatic disease (synchronous versus metachronous). For patients receiving systemic**

*Favorable—no poor prognostic factors.
†Intermediate ≤ 2 poor prognostic factors.
‡Poor ≥ 3 poor prognostic factors.
Prognostic factors: Karnofsky performance status below 80%; time from diagnosis of metastatic disease less than 12 months; hemoglobin level below the lower limit of normal; lactate dehydrogenase level more than 1.5 times the upper limit of normal; corrected calcium concentration above 10.0 mg/dL.

therapy, the current standards include IL-2, interferon alfa, and investigational therapy.

Cytokine Combinations

IL-2 and interferon alfa have been combined, and currently available data suggest an increase in response rate but no improvement in overall survival. The randomized trial reported by Negrier and colleagues (1998) did find an increase in 1-year event-free survival (20%) associated with IL-2 and interferon alfa therapy (15%, IL-2; 12%, interferon alfa; $P = .01$), but the toxicity of the regimen was thought to preclude its general use.

IL-2 and interferon alfa have also been combined with other agents, including other cytokines (granulocyte-monocyte colony-stimulating factor, interferon gamma, IL-12), chemotherapeutic agents (5-fluorouracil, vinblastine, capecitabine, gemcitabine), and miscellaneous agents (*cis*-retinoic acid, thalidomide). Studies in which interferon alfa monotherapy or the combination of IL-2 and interferon has been compared with the same regimens plus vinblastine (Pyrhonen et al, 1999), 5-fluorouracil (Negrier et al, 2000), or *cis*-retinoic acid (Motzer et al, 2000; Fossa et al, 2004) have also been conducted but have not demonstrated improved outcomes compared with the standard cytokine protocols.

Adoptive Immunotherapy

In view of the T-cell response to RCC (Finke et al, 1994), a series of clinical studies investigating the role of adoptive transfer of autologous lymphocytes for treatment of metastatic RCC have been performed. These trials used various immune cell populations obtained from peripheral blood, including lymphokine-activated killer cells (Rosenberg et al, 1993), T lymphocytes (Graham et al, 1993), lymph node cells (Chang et al, 1997), and tumor-infiltrating T cells (Bukowski et al, 1991), which were then expanded ex vivo through exposure to IL-2. **Randomized trials comparing IL-2 monotherapy with IL-2 plus adoptive transfer cells have not demonstrated significant differences compared with cytokine therapy alone** (Figlin et al, 1999). **At present, use of adoptive immunotherapy remains investigational. It is unclear whether the addition of any ex vivo–expanded cell population enhances the clinical results with IL-2 monotherapy.**

Vaccines

Active specific immunotherapy refers to treatment of patients with biologic preparations designed to directly (antibodies) or indirectly (vaccines) enhance an immune response. In view of the active immune response in patients with RCC, a variety of vaccines have been employed as therapy for advanced disease. These can be administered with adjuvants, such as bacille Calmette-Guérin or incomplete Freund's adjuvant. **Vaccine preparations that have been employed in patients with RCC include autologous tumor cells** (Galligioni et al, 1996; Jocham et al, 2004), **autologous tumor cells fused with allogeneic dendritic cells** (Avigan, 2004), **autologous dendritic cells** (Gitlitz et al, 2003; Arroyo et al, 2004), **and heat shock protein** (Hoos and Levey, 2003). Of particular interest is the use of dendritic cells, which function as potent antigen-presenting cells for antigen in the context of MHC molecules, thereby stimulating T lymphocytes. These cells are found in a low frequency in peripheral blood (Banchereau and Palucka, 2005) and can be expanded ex vivo with growth factors such as IL-4, granulocyte-monocyte colony-stimulating factor, and tumor necrosis factor. The optimal preparation for clinical immunization remains unclear. Dendritic cells can be loaded with autologous tumor lysates, tumor antigens, or peptide sequences of defined tumor-associated antigens and administered intradermally, intravenously, or by lymphatic infusion. **Currently, use of tumor vaccines in patients with advanced renal cancer remains investigational.**

Targeted Agents

The *VHL* gene has been cloned, functions of the protein have been elucidated, and a high frequency of mutations or epigenetic silencing of this gene in sporadic clear cell carcinoma has been recognized. These findings led to a series of studies identifying the VEGF and PDGF pathways as molecular targets in this tumor (Kaelin, 2004). These growth factors bind to receptor tyrosine kinases that regulate cell proliferation and survival and can promote tumor-associated angiogenesis and growth. Inhibition of the VEGF and PDGF signaling pathways may therefore inhibit angiogenesis and tumor progression (Fig. 47–34). A series of agents inhibiting VEGF or tyrosine kinase receptors such as VEGFR types 1 to 3 and PDGFR are now under investigation and appear to have

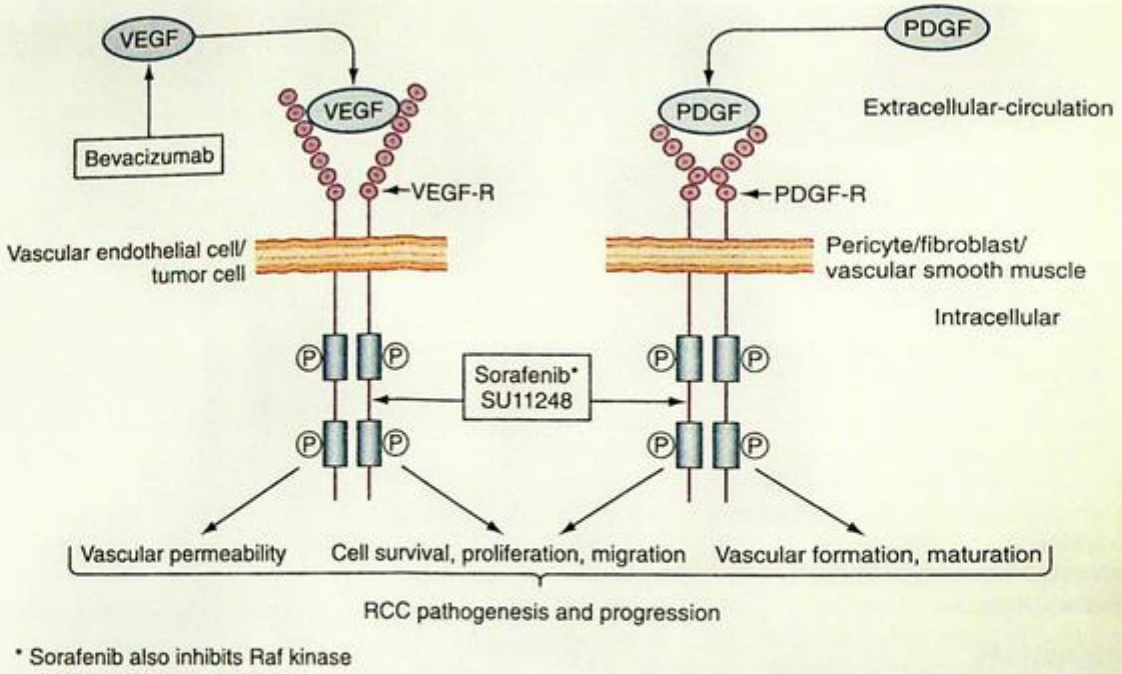

Figure 47–34. Illustration of the effects of various targeted agents (bevacizumab, sorafenib, SU011248) on endothelial and tumor cells. Bevacizumab binds and sequesters VEGF, and sorafenib and SU011248 inhibit the receptors for VEGF and PDGF.

antitumor effects in renal cancer patients. Table 47–28 outlines the preliminary results of several phase II and phase III trials in which these drugs have been investigated.

Bevacizumab is an IgG1 monoclonal antibody recognizing and binding all VEGF isoforms (Ferrara et al, 2003). **This agent inhibits signaling through the VEGF pathway by sequestering the circulating ligand.** Yang and colleagues (2003a) conducted a phase II randomized, placebo-controlled trial in patients with cytokine-refractory clear cell carcinoma. Two dose levels of bevacizumab (3.0 mg/kg and 10 mg/kg) were compared with a placebo; **116 patients were randomized, but the trial was stopped early when an interim analysis demonstrated that patients receiving 10.0 mg/kg had significant prolongation of time to progression (4.8 months) compared with the placebo group (2.5 months).** Partial responses (4 of 37, 10%) were seen in patients receiving 10.0 mg/kg bevacizumab every 2 weeks, in contrast to no partial responses in the other two arms. No overall survival advantage was seen, but the crossover design or the relatively small sample size studied may have precluded this. **A report** (Spigel et al, 2005) **tested the combination of erlotinib (150 mg/day) and bevacizumab (10 mg/kg intravenously every 2 weeks) in an effort to improve on these results.** Erlotinib is an orally administered tyrosine kinase inhibitor that blocks signaling through the EGFR. **Preclinical studies have suggested that dual inhibition of both the VEGF and EGF pathways can have additive antitumor effects for renal cancer** (Rini et al, 2005). Sixty-three patients with metastatic clear cell carcinoma of the kidney were treated. **An overall response rate of 26% and a progression-free survival of 11.0 months were found.** Therefore, at both the clinical and preclinical levels, co-administration of these two agents may enhance results. A phase II randomized trial with this combination is in progress. Finally, the activity of bevacizumab in untreated patients with metastatic clear cell carcinoma is under investigation in two prospectively randomized, phase III trials comparing the combination of interferon alfa and bevacizumab with interferon alfa monotherapy (Rini et al, 2005).

Table 47–28. Targeted Therapy for Cytokine-Refractory Renal Cell Carcinoma: Summary of Clinical Trials

Agent/Trial	*No. of Patients*	*ORR*	*TTP/PFS (months)*
SU11248 (Motzer et al, 2004, 2005)			
Trial 1	63	40%	8.7
Trial 2	106	39%	Too early
AG-013736 (Rini et al, 2005)	52	40%	Too early
Sorafenib (Escudier et al, 2005)			
Sorafenib	384	2%	6.0
Placebo	385	0	3.0
Bevacizumab (Yang et al, 2003)			
Bevacizumab (10 mg/kg)	39	10%	4.8
Bevacizumab (3.0 mg/kg)	37	0	3.0
Placebo	40	0	2.5
Bevacizumab + erlotinib (Spigel et al, 2005)	63	26%	11.0

ORR, overall response rate; TTP, time to progression; PFS, progression-free survival.

A series of oral agents that inhibit various tyrosine kinase receptors have also been studied in patients with cytokine-refractory clear cell carcinoma. **Three of these agents are outlined in Table 47–28, including SU11248** (Motzer et al, 2004, 2005), **AG-013736** (Rini et al, 2005), **and sorafenib** (Escudier et al, 2005). **These agents inhibit multiple tyrosine kinases, including VEGFR-2, PDGFR, c-Kit, and Flt3, and sorafenib also inhibits Raf kinase. SU11248** (Motzer et al, 2004, 2005) **and AG-013736** (Rini et al, 2005) **have been studied in a series of phase II trials, and the preliminary results demonstrate partial response rates of 38% to 40%, with**

Progression-free survival and median survival rates that are still preliminary. A phase III randomized trial comparing SU11248 with interferon alfa in untreated patients with metastatic clear cell carcinoma is currently in progress.

Sorafenib is an oral tyrosine kinase inhibitor that has an excellent toxicity profile and encouraging antitumor activity in patients with RCC (Escudier et al, 2005). A phase III trial was recently completed in which 905 cytokine-refractory patients with clear cell RCC were randomized to either sorafenib (400 mg twice daily) or a placebo. **An interim analysis in 763 individuals demonstrated a significant (P = .000001) prolongation of progression-free survival in patients receiving sorafenib compared with placebo (6.0 months versus 3.0 months).** The overall regression rate in patients receiving sorafenib was 2%; however, more than 70% of patients demonstrated a regression in tumor size, albeit not adequate to be scored as a partial or complete response. The study was terminated after this initial analysis in view of the large differences noted, and all patients were crossed over to active drug. Survival data in this trial remain preliminary, but again, these are encouraging results.

These results (see Table 47–28) clearly demonstrate that agents targeting the VEGF pathway can have significant antitumor effects in patients with advanced clear cell carcinoma. The studies that have been completed and those in progress will define the role of these and other targeted agents in patients with RCC. **The preliminary results suggest that targeted molecular therapeutics will have a role in the treatment paradigm for metastatic RCC in the near future.**

Multimodal Therapy

Combined modality approaches integrating surgery and systemic therapy have been applied successfully in genitourinary oncology, the best example being testicular cancer. In patients with either synchronous or metachronous metastatic RCC, multidisciplinary therapeutic approaches have been applied and are illustrated in Figure 47–35. **For patients presenting with synchronous metastatic disease, nephrectomy is often performed before initiation of systemic therapy, as reviewed before** (Flanigan et al, 2001; Mickisch et al, 2001). Two prospective randomized trials have demonstrated that median overall survival can be significantly improved in patients undergoing surgery followed by interferon alfa compared with treatment with interferon alfa alone. Immunosuppression induced by the primary tumor may contribute to this phenomenon. **In patients with advanced RCC, multiple T-cell abnormalities have been described. These include alterations in signal transduction pathways, abnormal activity of DNA-binding proteins, poor proliferative responses** (Bukowski et al, 1998; Uzzo et al, 1999a), **and increase in T-lymphocyte apoptosis** (Uzzo et al, 1999b). In vitro studies in which normal T lymphocytes are incubated with renal cancer supernatants can reproduce some of these deficiencies (Uzzo et al, 2000a). **When the primary tumor is resected, the factors responsible for this acquired immune dysfunction may be eliminated or removed, with subsequent normalization of T-cell function including cytokine production and tumor cell lysis.** An alternative hypothesis to explain the beneficial effects of cytoreductive surgery is that the primary tumor may express proangiogenic factors or other tumor-promoting growth factors, and removal of this source may allow a less aggressive course at other sites.

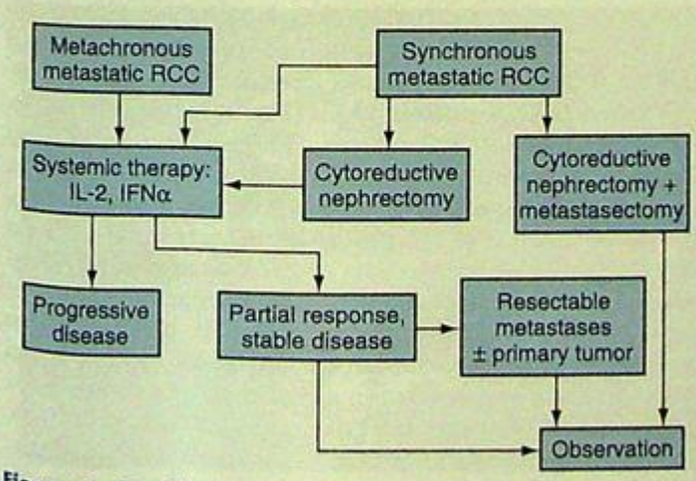

Figure 47–35. Algorithm for multimodality therapy in patients with metastatic renal cell carcinoma (RCC).

Other combined approaches in which surgery and immunotherapy have been used include initial immunotherapy followed by adjuvant nephrectomy in responding individuals, and immunotherapy with or without nephrectomy followed by resection of residual or recurrent metastatic lesions. The optimal timing of adjuvant nephrectomy in the setting of multimodality treatment remains unclear. Most investigators have advocated nephrectomy before cytokine or adoptive immune therapy, but a potential drawback of this approach is that many patients may undergo surgery without subsequently receiving immunotherapy. Postoperative mortality rates of 0% to 17% have been reported after nephrectomy in patients with metastatic renal cancer (reviewed in Flanigan, 2004). Some patients who undergo nephrectomy are unable to receive cytokine therapy because of rapid tumor progression or postoperative complications. In a series from the National Cancer Institute, 37 of 93 patients (40%) who underwent nephrectomy did not receive subsequent immunotherapy (Walther et al, 1993). In a study from the Cleveland Clinic, 8 of 37 RCC patients (22%) were unable to receive immunotherapy after nephrectomy for one of these reasons (Rackley et al, 1994).

For this problem to be avoided, the alternative of delayed nephrectomy has been proposed. This involves initial systemic treatment with delayed nephrectomy only in patients who demonstrate regression or stability of their metastatic lesions (Fleischmann and Kim, 1991). Rackley and associates (1994) found that patients treated with initial immunotherapy had slightly higher objective response rates and longer median survival times compared with patients undergoing primary nephrectomy and subsequent immunotherapy. Similarly, Tanguay and associates (1996b) compared initial and adjuvant surgery in patients with pulmonary metastases and observed higher survival rates in patients who received initial immunotherapy. A less common situation in which this approach has been applied involves the patient with metastatic renal cancer and a solitary, functioning kidney. In this setting, immunotherapy is administered first; and in patients whose metastatic lesions regress, a partial nephrectomy can be performed (Krishnamurthi et al, 1996).

The presence of a large primary tumor may decrease the effects of therapy, and response to systemic therapy is uncommon in this setting. Thus, the optimal timing of nephrectomy is still controversial in many patients. Delayed nephrectomy allows selection of patients who have biologically more responsive tumors, theoretically reserving the more aggressive pathway for this subgroup that may be more likely to benefit. A prospective, controlled comparison of appropriate systemic therapy combined with initial or delayed nephrectomy is needed to clarify the optimal timing of nephrectomy.

An aggressive surgical approach to RCC often offers the best chance for a long-term cure. In an effort to consolidate therapy, metastasectomy either before or after administration of systemic therapy should be considered in select patients with solitary or limited metastases. The prognostic factors associated with prolonged survival after resection of metastatic RCC lesions have been investigated and should be carefully evaluated during clinical decision-making—an individualized approach to each patient is of paramount importance.

Several reports provide useful information about selection of patients in this challenging population. Friedel and colleagues (1999) reviewed 77 patients who underwent resection of pulmonary metastases from RCC and reported a long disease-free interval (>48 months) with resected solitary metastases. In this study, solitary versus multiple metastases were also associated with prolonged survival. Piltz and associates (2002) reviewed 105 patients who underwent resection of pulmonary metastases. The median survival of the entire group was 43 months; 40% of these patients were alive at 5 years. In this study, a multivariate analysis identified complete surgical resection, metastases less than 4.0 cm in diameter, and tumor-free regional lymph nodes as independent prognostic factors. These studies involved patients with pulmonary metastases who had not received preoperative cytokine therapy. The literature suggests that pulmonary metastases may have a more favorable prognosis than metastases at other sites, both for response to systemic therapy and for surgical consolidation. This should also be taken into account during the decision-making process.

In addition to this approach, so-called salvage metastasectomy can be employed in patients with residual or recurrent metastatic RCC after an incomplete response to therapy. Kim and Louie (1992) described 11 patients with a partial response to IL-2–based therapy after a cytoreductive nephrectomy who then underwent surgical excision of residual metastases. At median follow-up of 21 months, all patients were alive and disease free, an encouraging finding for this disease. Similarly, Sella and colleagues (1993) described 17 patients who underwent excision of residual metastatic lesions after a partial response to interferon-based therapy. Eleven patients were alive and disease free at a median follow-up of 12 months. In a report from the Cleveland Clinic (Krishnamurthi et al, 1998), 14 patients underwent initial immunotherapy followed by surgical resection of the primary tumor and metastatic lesions. After immunotherapy, nine patients manifested an objective response; five patients had stable disease. All patients were then rendered disease free by surgery. Cancer-specific survival at 3 years was 81.5%.

Finally, Kavolius and associates (1998) reviewed a group of 278 patients who underwent "curative" metastasectomy. The 5-year overall survival was 44% compared with 14% for 67 patients who had noncurative surgery. A multivariate analysis indicated that a solitary metastatic site, curative surgical resection, prolonged disease-free interval (>12 months), and metachronous metastatic disease were associated with prolonged survival. These results are echoed by a study from the Cleveland Clinic (Murthy et al, 2005) that reviewed 417 patients with pulmonary metastases. Ninety-two individuals underwent metastasectomy, and 20 (22%) of these had received preoperative immunotherapy. Multivariate analysis identified incomplete resection as the strongest predictor of decreased survival (8% versus 45% 5-year survival for patients with complete resection). Of interest, preoperative cytokine therapy was not a factor associated with improved survival.

Taken together, these reports suggest that salvage surgery for removal of residual metastatic lesions may extend survival for some patients with metastatic RCC. Selection of patients clearly plays a role, and randomized clinical trials are required to validate this approach and to clarify the optimal timing of surgery relative to systemic therapy. In view of the low response rates associated with cytokine therapy, it seems unlikely this will occur. Finally, the multimodality approaches discussed have been applied primarily to patients with clear cell tumors; their application to patients with non–clear cell tumors is unknown.

OTHER MALIGNANT RENAL TUMORS

Sarcomas of the Kidney

Sarcomas represent 1% to 2% of all malignant renal tumors in adults, with a peak incidence in the fifth decade of life (Srinivas et al, 1984; Russo, 1991; Spellman et al, 1995; Frank et al, 2000). Renal sarcoma is less common but more lethal than sarcoma of any other genitourinary site, including the prostate, bladder, and paratesticular region (Russo, 1991; Russo et al, 1992). Differentiation of renal sarcoma from sarcomatoid RCC is often difficult on the basis of clinical presentation, radiographic findings, and, in some cases, pathologic analysis. Identification of any features of the various subtypes of RCC excludes the diagnosis of primary renal sarcoma. The common signs and symptoms associated with renal sarcoma in adults include palpable mass, abdominal or flank pain, and hematuria, similar to those seen with large, rapidly growing RCCs (Economou et al, 1987). Abdominal CT scan typically demonstrates a large soft tissue mass involving or derived from the kidney, a finding that is again similar to that associated with many sarcomatoid RCCs (Farrow et al, 1968; Shirkhoda and Lewis, 1987; Russo, 1991). Specific findings suggestive of sarcoma rather than of RCC include apparent origin from the capsule or perisinuous region, growth to large size in the absence of lymphadenopathy, presence of fat or bone suggestive of liposarcoma or osteosarcoma, and hypovascular pattern on angiography, although one notable exception is the hemangiopericytoma, which is highly vascular (Smullens et al, 1982; Shirkhoda and Lewis, 1987). Renal sarcoma should be suspected in any of these circumstances or in any patient with a very large or rapidly growing renal mass.

Sarcomas of the kidney, like sarcomas of any other site, share in common a distinct tumor biology that has important implications with respect to management (reviewed in

Russo, 1991). **These tumors are derived from mesenchymal components and are thus free of many of the natural barriers to dissemination that confine other tumor types. They are typically surrounded by a pseudocapsule that is readily identifiable but that cannot be relied on for surgical dissection because it is often infiltrated with cancer cells,** which can extend for some distance into the surrounding tissues. In many cases, this cannot be recognized macroscopically, although it is often manifested in the form of local recurrences, which are common after surgical extirpation, even when a wide excision has been performed. **High-grade sarcomas often metastasize, with the lungs being a primary site of spread, and prognosis is poor; many patients die of disease progression in a matter of months. Low-grade sarcomas tend to pursue a more indolent course,** although local recurrences often require repeated resection to prolong survival and minimize morbidity.

In general, the most important prognostic factors for sarcomas are margin status and tumor grade. The initial resection is the key event because, for many patients, this is their best chance for a long-term cure. For renal sarcomas, this often mandates radical nephrectomy along with en bloc excision of adjacent organs (Srinivas et al, 1984). MRI can be useful for preoperative planning by defining tissue planes and proximity to vital structures. This is primarily a surgical disease, and wide excision is the goal with intraoperative monitoring of margin status. Chemotherapeutic agents that have demonstrated activity against metastatic sarcomas include doxycycline and ifosfamide, but even in the best of circumstances, response rates are disappointing (Antman et al, 1993). A renal primary sarcoma is far from the best of circumstances, given the poor prognosis associated with this site of origin. The combination of radiation therapy and chemotherapy, which has proved effective in an adjuvant setting for the management of sarcomas of the extremity, has not provided much benefit for renal or retroperitoneal sarcomas (Russo, 1991). At present, the role of such adjuvant approaches for the management of renal sarcomas is not well defined, although a multimodal approach is often pursued if performance status allows, given the poor prognosis.

The largest single-institution series of renal sarcomas include only 15 to 26 cases and represent a composite experience extending for a period of several years (Farrow et al, 1968; Srinivas et al, 1984; Shirkhoda and Lewis, 1987). In all such series, leiomyosarcoma has been the most common histologic subtype, and in many series, liposarcoma has been the second most common. In contrast, for retroperitoneal sarcomas, the order is reversed, with liposarcoma being the most common histologic subtype (Karakousis et al, 1995). All such series report a poor prognosis; the experience of Srinivas and colleagues (1984) at Memorial Sloan-Kettering Cancer Center is representative. In this series of 16 patients with renal sarcomas, 15 underwent nephrectomy, often with en bloc excision of adjacent organs; 5 received adjuvant radiation therapy and chemotherapy without apparent benefit; and 13 died within 6 months after surgery. Vogelzang and associates (1993) reported a more encouraging experience with 21 patients with primary renal sarcomas; they had 6 long-term survivors after surgery alone. A predominance of low-grade disease may account for these favorable outcomes. However, even in this series, the majority of patients died of progressive disease within a few to several months after diagnosis. Saitoh and colleagues (1982) defined the common sites of metastases of renal sarcomas: lung first and foremost, but also lymph nodes and liver.

Leiomyosarcoma is the most common histologic subtype of renal sarcoma, accounting for 50% to 60% of such tumors (Fig. 47–36). The cell of origin is the smooth muscle cell of the capsule or other perinephric structures (Moudouni et al, 2001; Deyrup et al, 2004). Niceta and associates (1974) identified 66 cases of renal leiomyosarcoma in the literature and reported a female predominance; most patients presented in the fourth through sixth decades of life. Renal leiomyosarcoma, like many renal sarcomas, tends to displace rather than to invade the parenchyma, and it is characterized by rapid growth rate, frequent metastasis, and high local and systemic recurrence rates (Pollack et al, 1987; Deyrup et al, 2004). In the cases reviewed by Niceta, most patients were treated primarily with radical nephrectomy and died within 2 years. In the Mayo Clinic series, 14 of 15 patients with renal leiomyosarcoma died of disease progression within 4 months to 5.5 years after surgery (Farrow et al, 1968).

Other than leiomyosarcoma, a wide variety of histologic subtypes have been described because almost every con-

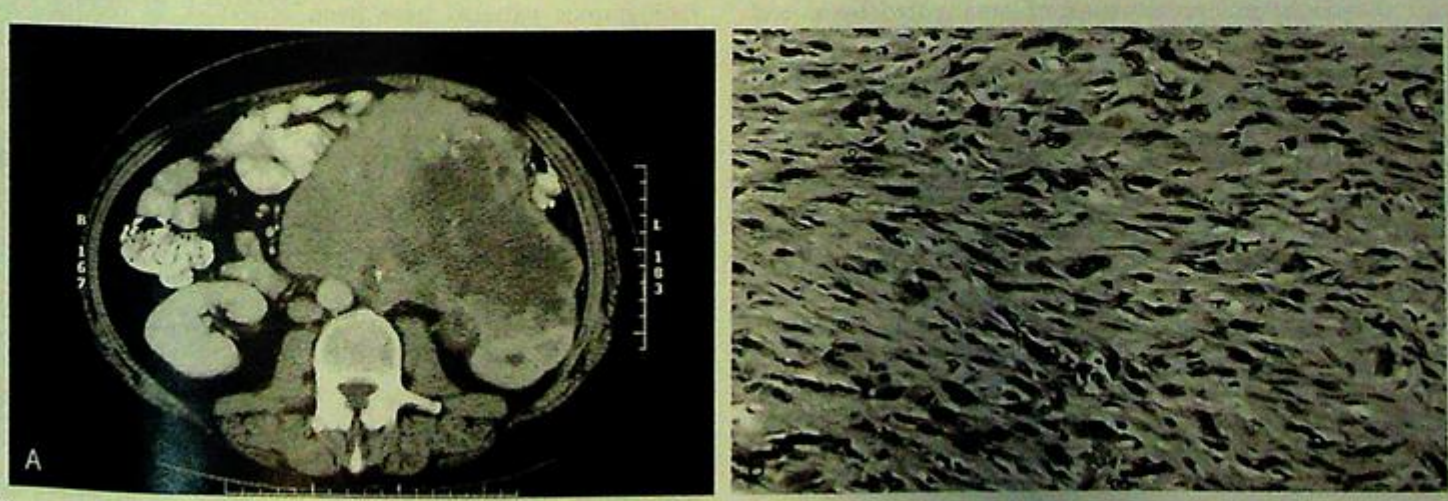

Figure 47–36. A, CT scan demonstrates a large leiomyosarcoma of the left kidney. B, Microscopic features of leiomyosarcoma include spindle cells, blunt-ended nuclei, and eosinophilic cytoplasm. (Courtesy of Dr. Michael McGuire, Evanston, Illinois.)

ceivable type of sarcoma has been found in the kidney. Liposarcoma is readily distinguished from RCC because of the presence of adipose tissue, but it is often confused with AMLs or with large, benign renal lipomas (Frank et al, 2000). Renal liposarcoma typically develops in the fifth and sixth decades of life and often grows to extremely large size (Economou et al, 1987). Response to radiation therapy and cisplatin-based chemotherapy in an adjuvant setting has been reported by Belldegrun and deKernion (1987) and should be considered in patients with high-grade disease or positive margins. Osteogenic sarcoma is a rare but distinctive form of renal sarcoma that contains calcium and is often rock hard (Micolonghi et al, 1984; Leventis et al, 1997). Extensive calcification in a large, hypovascular tumor should suggest the diagnosis. The appearance on plain films can mimic a staghorn calculus, but the readily evident mass effect should suggest xanthogranulomatous disease or, more rarely, osteogenic sarcoma. Again, prognosis is poor; most patients die of disease progression within a few years after diagnosis. Less common histologic subtypes include rhabdomyosarcoma, fibrosarcoma, carcinosarcoma, malignant fibrous histiocytoma, synovial sarcoma, angiosarcoma, and malignant hemangiopericytoma (Raghavaiah et al, 1979; Weiss et al, 1984; Mordkin et al, 1997; Tsuda et al, 1997; Cerilli et al, 1998; Merchant et al, 1998; Chhieng et al, 1999; Koyama et al, 2001; Bella et al, 2002; Chen et al, 2003). Malignant hemangiopericytomas are notable for their extensive vascularity. Preoperative catheter embolization has been described and can simplify surgical excision (Smullens et al, 1982).

Renal Lymphoma and Leukemia

Renal involvement with hematologic malignant neoplasms, which include the various lymphomas and leukemias, is common—found at autopsy in approximately 34% of patients dying of progressive lymphoma or leukemia. However, these processes are uncommonly seen in clinical practice because they are often silent and generally occur only as a late manifestation of systemic disease (Richmond et al, 1962; Pollack et al, 1987; McVary, 1991). The role of the urologist in the evaluation of renal lymphoma or leukemia is critically important and can include differentiation from other renal malignant neoplasms, timely provision of a pathologic diagnosis, and preservation of renal parenchyma and function (reviewed in McVary, 1991). Renal involvement is more common with non-Hodgkin's lymphoma than with Hodgkin's disease, and as with most other forms of extranodal non-Hodgkin's lymphoma, histologically diffuse forms predominate over nodular forms (Richmond et al, 1962; Pollack et al, 1987; Yasunaga et al, 1997; O'Riordan et al, 2001). Primary renal lymphoma is rare, with only a few well-documented case reports in the literature (Kandel et al, 1987; Pollack et al, 1987; Arranz-Arija et al, 1994; Dimopoulos et al, 1996; Yasunaga et al, 1997; Tuzel et al, 2003). This is not surprising given the relative paucity of lymphoid tissue in the normal renal parenchyma. Hematogenous dissemination of lymphoma to the kidney is most common and is thought to occur in 90% of cases; direct extension from retroperitoneal lymph nodes accounts for the remainder. Hartman and colleagues (1982) have correlated pathologic and radiographic patterns and have shown that the most common pattern of renal involvement consists of multiple small renal nodules that tend to develop between the individual nephrons. Eventually, these nodules become confluent, forming radiographically detectable masses. At the extreme, they can replace the entire parenchyma of the kidney, leading to renal failure.

The CT scan is the radiographic modality of choice for the diagnosis of renal lymphoma and for monitoring response to therapy (Jafri et al, 1982; Pollack et al, 1987; Sheeran and Sussman, 1998; Urban and Fishman, 2000). The common radiographic patterns associated with renal lymphoma have been defined by Heiken and associates (1991) and confirmed by a number of other investigators (Table 47–29). Renal lymphoma can present as multiple distinct renal masses; as a solitary renal mass, which can be difficult to differentiate from RCC; as diffuse renal infiltration; or as direct invasion of the kidney from enlarged retroperitoneal nodes (Cohan et al, 1990; Heiken et al, 1991; Eisenberg et al, 1994; Sheeran and Sussman, 1998). A hypovascular pattern on angiography is typical for renal lymphoma (Pollack et al, 1987). **Renal lymphoma should be suspected in patients with massive retroperitoneal lymphadenopathy, splenomegaly, or lymphadenopathy in other regions of the body or atypical regions within the retroperitoneum** (Jafri et al, 1982; Dimopoulos et al, 1996). Along these lines, the main landing zones for RCC should be kept in mind—the interaortocaval region for right RCC and para-aortic region for left RCC—and lymphadenopathy centered outside of these areas should raise suspicion for lymphoma. Any patient with a prior history of lymphoma and a renal mass should also be evaluated for renal recurrence rather than for RCC. In general, lymphomas are more common in patients with iatrogenic immune suppression, acquired immunodeficiency syndrome (AIDS), autoimmune diseases, or graft-versus-host disease and in patients with a history of radiation therapy (McVary, 1991). These clinical associations may also increase the index of suspicion about a diagnosis of systemic lymphoma.

Renal involvement related to leukemia is more common in children, paralleling the demographics of the disease, and is more commonly due to lymphocytic leukemia than the myelogenous forms (Araki, 1982; Pollack et al, 1987). Leukemia typically involves the kidney in a diffusely infiltrative pattern and most often represents a late manifestation of systemic disease. However, as for renal lymphoma, a variety of other radiographic patterns have been observed, as reviewed by Pollack and colleagues (1987).

Table 47–29. Radiographic Findings Associated with Lymphoma

Computed Tomography	*Incidence (%)*
Multiple renal masses	45
Solitary renal mass	15
Renal invasion from enlarged retroperitoneal lymph nodes	25
Diffuse renal involvement	10
Predominantly perinephric involvement	5

Data from Pollack HM, Banner MP, Amendola MA: Other malignant neoplasms of the renal parenchyma. Semin Roentgenol 1987;22:260-274; and Heiken JP, Gold RP, Schnur MJ: Computed tomography of renal lymphoma with ultrasound correlation. J Comput Assist Tomogr 1991;1:245-250.

If lymphoma or leukemic renal involvement is suspected, consideration should be given to percutaneous biopsy to obtain a pathologic diagnosis, and if exploratory surgery is necessary, intraoperative biopsy and frozen-section analysis should take priority. If lymphoma or leukemia is confirmed, the kidney should be spared, and complete staging of the neoplasm should be performed to preclude the need for a secondary procedure (McVary, 1991). Truong and colleagues (2001) have demonstrated the utility of fine-needle aspiration in the diagnosis of renal lymphoma, although additional tissue may be required in many cases to classify the lymphoma accurately and to guide further therapy. Extirpative surgery should be avoided if renal lymphoma and leukemia are suspected because the treatment of these processes is generally systemic chemotherapy with or without radiation therapy. The classic chemotherapy regimen for non-Hodgkin's lymphoma is the CHOP protocol, which includes cyclophosphamide, doxorubicin, vincristine, and prednisolone (Colevas et al, 2000). Nephrectomy is seldom indicated except in patients with severe symptoms, such as uncontrollable hemorrhage. The other notable exception is the extremely rare patient with primary renal lymphoma in whom a combination of nephrectomy and systemic chemotherapy may represent optimal therapy (Okuno et al, 1995).

Both renal lymphoma and leukemia are commonly silent but can be associated with hematuria, flank pain, or progressive renal failure. Fever, weight loss, and fatigue, the so-called B symptoms of lymphoma, are much more common (Yasunaga et al, 1997). Renal failure can be due to extensive replacement of the functioning parenchyma or bilateral ureteral obstruction associated with enlarged retroperitoneal lymph nodes (more common with lymphoma) (reviewed in McVary, 1991). In reality, renal failure in such patients is more often related to medical causes, such as hypercalcemia or urate nephropathy, that can develop during systemic treatment of advanced disease. The diagnosis of renal failure related to parenchymal replacement by lymphoma or leukemia requires exclusion of other related causes of renal failure and demonstration of improvement in renal function after administration of systemic chemotherapy or radiation therapy (Choi et al, 1997; O'Riordan et al, 2001).

Metastatic Tumors

Metastatic tumors are the most common malignant neoplasms in the kidney, outnumbering primary renal tumors by a wide margin. Autopsy studies have shown that 12% of patients dying of cancer have renal metastases, making the kidney one of the most common sites for metastatic dissemination (Pollack et al, 1987). **The high blood flow and profuse vascularity of the kidney make it a fertile soil for the deposition and growth of cancer cells.** Almost all renal metastases develop through a hematogenous route of spread; only a small minority are caused by direct invasion of tumors derived from adjacent organs such as the pancreas, colon, and adrenal gland. The most common sources of renal metastases include lung, breast, and gastrointestinal cancers; malignant melanoma; and the hematologic malignant neoplasms, which are reviewed in the preceding section (Klinger, 1951; Choyke et al, 1987; Pollack et al, 1987; Sanchez-Ortiz et al, 2004b). Of the solid malignant neoplasms, lung cancer is most commonly associated with renal metastases. Olsson and colleagues (1971) found that 20% of patients dying of lung cancer had renal metastases, 60% of which were bilateral. Klinger (1951) reviewed 5000 autopsies and found 17 cases of renal metastases from lung cancer, 11 from gastric cancer, 9 from breast cancer, 7 from pancreatic cancer, 4 from esophageal cancer, 6 from other gastrointestinal primary cancers, and 1 from malignant melanoma. In a series of 27 renal metastases reviewed by Choyke and associates (1987), 7 patients had primary lung cancer, 7 had gastrointestinal malignant neoplasms, 4 had malignant melanoma, 2 had breast cancer, and 2 had endometrial carcinoma. Most renal metastases are multifocal, and almost all are associated with widespread nonrenal metastases (Choyke et al, 1987; Pollack et al, 1987). Choyke and associates (1987) reported that renal metastases from lung, breast, and colon carcinomas are notable because they are occasionally large and solitary, making them difficult to differentiate from RCC.

The typical pattern of renal metastases consists of multiple small nodules that are often clinically silent, although they can lead to hematuria or flank pain in exceptional circumstances (Walther et al, 1979; Pollack et al, 1987). CT scan is the primary diagnostic modality for renal metastases and typically demonstrates isodense masses that enhance only moderately (5 to 30 HU) after administration of intravenous contrast material (Pollack et al, 1987; Ferrozzi et al, 1997). Arteriography usually shows a hypovascular pattern (Pollack et al, 1987).

Renal metastases should be suspected in any patient with multiple renal lesions and widespread systemic metastases or a history of nonrenal primary cancer. If there is any uncertainty about the diagnosis, a CT- or ultrasound-guided percutaneous renal biopsy usually provides pathologic confirmation (Sanchez-Ortiz, 2004a). Most patients with renal metastases are managed with systemic therapy or placed on a palliative care pathway, depending on the clinical circumstances. Nephrectomy is almost never required except in extenuating circumstances, such as uncontrollable renal hemorrhage. Patients with a solitary, strongly enhancing renal lesion and a history of organ-confined, nonrenal malignant disease are more likely to have RCC, particularly if the interval between the two diagnoses is substantial. However, even in this circumstance, a renal biopsy should be considered because it may preclude the need for surgical intervention.

Other Malignant Tumors of the Kidney

Other malignant tumors of the kidney include renal carcinoid, adult Wilms' tumor, primitive neuroectodermal tumor (PNET), and small cell carcinoma. All are relatively uncommon, but each has a distinct tumor biology.

Carcinoid tumors arise from neuroendocrine cells, which are not normally present in the kidney, and this is a rare renal malignant neoplasm with fewer than 40 cases reported in the English literature (Kawajiri et al, 2004). Primitive stem cells within the kidney or retained neural crest tissue may give rise to these tumors (Krishnan et al, 1997; Begin et al, 1998). A correlation with horseshoe kidneys has been reported, with previous studies showing an increased relative risk of 82-fold compared with normal kidneys (Begin et al, 1998). Carcinoid tumors stain positive for markers of neuroendocrine tissue

such as neuron-specific enolase and chromogranin (Kulke and Mayer, 1999). **Measurement of urinary or plasma serotonin or its metabolites can be diagnostic** (Kulke and Mayer, 1999). **Most patients are asymptomatic; a minority will present with the carcinoid syndrome—episodic flushing, wheezing, and diarrhea** (Jensen and Doherty, 2001). CT findings are nonspecific, and most renal carcinoids are small and nonaggressive. Surgical excision is the mainstay of treatment (Kawajiri et al, 2004). Nephron-sparing surgery is preferred if the diagnosis is suspected preoperatively. Prognosis is good, particularly when it is associated with a horseshoe kidney (Krishnan et al, 1997; Begin et al, 1998). Patients with renal carcinoid should be considered for evaluation with colonoscopy and esophagogastroscopy to assess for multifocal disease.

Wilms' tumor is the most common abdominal malignant neoplasm in children, but 3% of Wilms' tumors are seen in adults. Of these, 20% are found between the ages of 15 and 20 years, and the remaining 80% are distributed between the third and seventh decades of life (Winter et al, 1996). Adult and pediatric Wilms' tumors are histologically similar with a distinctive triphasic pattern consisting of varying amounts of blastema, epithelium, and stroma (Orditura et al, 1997). **Pathologic staging is the same as for pediatric Wilms' tumor, and most authors recommend treating adult patients with the same therapeutic protocols that have been tested and proven in children** (Firoozi and Kogan, 2003). Adult Wilms' tumor typically presents as a heterogeneous intrarenal mass on CT with a relatively hypovascular pattern, but differentiation from RCC can be difficult if not impossible in many cases (Winter et al, 1996; Orditura et al, 1997; Reinhard et al, 2004). Clinical presentation of adult Wilms' tumor is also similar to that of RCC, and this tends to be an unsuspected pathologic diagnosis in most cases. Multimodal therapy should be considered as in the treatment protocols for pediatric Wilms' tumor (Bozeman et al, 1995; Green, 1997; Neville and Ritchey, 2000; Terenziani et al, 2004). Prognosis is worse for adults with Wilms' tumor than for children with this malignant neoplasm because adults are more likely to present with advanced disease and a sudden drop in performance status (Winter et al, 1996; Akmansu et al, 1998).

PNET is related to the Ewing's sarcoma family of tumors that are more common in the pediatric population, typically manifesting in the bone or soft tissues of the extremities, trunk, and head and neck and only rarely in the viscera or kidneys (Jimenez et al, 2002; Maly et al, 2004). However, any age may be affected, and several cases of PNET have been reported in the kidneys of adults (Rodriquez-Galindo et al, 1997; Karnes et al, 2000; Doerfler et al, 2001; Parham et al, 2001; Thomas et al, 2002; Pomara et al, 2004). These tumors are derived from primitive neural crest cells, and positive staining for CD99 in addition to vimentin, cytokeratin, and neuron-specific enolase strongly supports the diagnosis (Gonlusen et al, 2001; Parham et al, 2001; Ginsberg et al, 2002; Maly et al, 2004). On microscopic examination, renal PNET typically shows small round cells that may form characteristic Homer Wright rosettes (Marley et al, 1997; Pomara et al, 2004). A characteristic t(11;22)(q24;q12) translocation is highly specific for PNET and can help differentiate it from neuroblastoma or adult Wilms' tumor (Marley et al, 1997; Quezado et al, 1997; Parham et al, 2001; Jimenez et al, 2002). Clinical symptoms are nonspecific, and CT often demonstrates a heterogeneous ill-defined mass with areas of necrosis (Doerfler et al, 2001). Again, minimal enhancement with contrast medium is typical, but differentiation from RCC is often difficult. Renal PNET appears to behave more aggressively than similar tumors at other sites and may represent a distinct clinical entity (Rodriquez-Galindo et al, 1997; Parham et al, 2001; Jimenez et al, 2002; Pomara et al, 2004). A strong propensity for local recurrence and early metastasis to lymph nodes, lung, liver, and bone has been described (Quezado et al, 1997; Rodriquez-Galindo, 1997; Gonlusen et al, 2001). **Multimodal treatment protocols combining tumor debulking, chemotherapy, and radiotherapy are often employed, but prognosis is poor with overall 5-year disease-free survival of 45% to 55%** (Casella et al, 2001).

Approximately 30 cases of small cell carcinoma of the kidney have been reported for which another primary site could not be identified (Mackey et al, 1998; Gonzalez-Lois et al, 2001; Akkaya et al, 2003; Majhail et al, 2003). **On pathologic examination, small cell carcinoma has features of neuroendocrine and epithelial neoplasms and must be differentiated from Wilms' tumor, PNET, lymphoma, and metastasis from pulmonary small cell carcinoma** (Gonzalez-Lois et al, 2001; Akkaya et al, 2003). **Positive staining for neuron-specific enolase, chromogranin, and synaptophysin is characteristic** (Akkaya et al, 2003). Preoperative differentiation from RCC is difficult, although a relatively hypovascular pattern may be an indication. Many small cell carcinomas of the kidney are locally advanced or metastatic at presentation, and flank pain or hematuria is common (Majhail et al, 2003). Multimodal therapy with nephrectomy or tumor debulking combined with platinum-based chemotherapy regimens is advocated for extrapulmonary small cell carcinoma in general and may also be useful for the renal manifestation of this malignant neoplasm (Majhail et al, 2003). Long-term survivors are described, but rare and new treatment regimens are needed.

BASIC AND CLINICAL BIOLOGY

Upper urinary tract tumors can be defined as any neoplastic growth that affects the lining of the urinary tract from the calyces to the distal ureter. These tumors display behaviors that are similar to those of tumors arising in bladder, but they also have many characteristics that separate them from those tumors. For example, unlike bladder urothelial cancers, upper tract cancers are relatively less common and are associated with several familial syndromes. They are more difficult to visualize directly and to reach with topical therapies, and given the anatomic difference between the upper and lower urinary tracts in terms of muscle thickness and other factors, they may have different prognoses.

EPIDEMIOLOGY

Incidence and Mortality Rates

Upper urinary tract urothelial tumors involving the renal pelvis or ureter are relatively uncommon, accounting for about 5% to 7% of all renal tumors and about 5% of all urothelial tumors (Fraley, 1978; Melamed and Reuter, 1993; Jemal et al, 2004). Because renal pelvic tumors are generally not reported separately, worldwide statistics vary substantially between nations and are not accurate. However, the highest incidence appears to occur in Balkan countries, where urothelial cancers represent 40% of all renal cancers.

The peak incidence of upper tract tumors is 10 per 100,000 per year, occurring in the age range of 75 to 79 years. Fortunately, synchronous bilateral urothelial upper urinary tract tumors are very rare (Holmang and Johansson, 2004). In one series from Sweden, the percentage of upper tract tumors that were bilateral was 1.6%, preceded in 80% of cases by a bladder cancer diagnosis. There may be a decreasing incidence of bilaterality secondary to the prohibition of phenacetin-containing analgesics in the 1960s. An evaluation of data from 1973 to 1996 with use of the Surveillance, Epidemiology, and End Results (SEER) database showed 9072 cases, 5379 of the renal pelvis and 3678 of the ureter.

In comparison of age-adjusted annual incidence rates, an increase in ureteral neoplasms from 0.69 to 0.73 per 100,000 person-years was found, but no change in the incidence of renal pelvic tumors was apparent. In addition, the rate of in situ neoplasm increased from 7.2% to 23.1%. Upper tract urothelial tumors are rarely diagnosed at autopsy but rather present clinically during the patient's lifetime (Ressequie et al, 1978). It also appears that the true incidence of upper tract tumors is increasing as the population ages. Patients with upper tract cancer are generally older than patients with bladder tumors (Melamed and Reuter, 1993). Upper tract tumors rarely present before the age of 40 years, and the mean age at presentation is 65 years (Anderstrom et al, 1989). **SEER data also demonstrate a 5-year overall survival rate that is significantly different as related to tumor stage (95.1% in situ, 88.9% localized, 62.6% regional, and 16.5% distant)** (Munoz and Ellison, 2000). **In conclusion, there appears to be a slight increase in the U.S. national incidence of ureteral cancers during the last two decades. Fortunately, this has been associated with a slight improvement in the overall and disease-specific survival of patients with upper tract malignant neoplasms.**

Variations by Sex and Race

Men are about twice as likely to develop upper tract tumors as are women (Greenlee et al, 2000). In addition, whites are about twice as likely as African Americans to develop upper tract tumors (Greenlee et al, 2000). On the other hand, SEER data suggest that disease-specific annual mortality is greater in black men than in white men (7.4% versus 4.9%) and greater in women than in men (6.1% versus 4.4%) (Munoz and Ellison, 2000). As is the case with bladder cancer, women

who develop upper tract cancer are 25% more likely than men to die of the cancer (Greenlee et al, 2000). Accurate data regarding racial differences in mortality are not available.

Upper Tract Tumors after Known Bladder Cancer

On the basis of SEER data from the period 1973 to 1996, upper tract cancers developed in 657 of 91,245 cases of bladder cancer with adequate follow-up (4.1 years median) (Rabbani et al, 2001). The relative risk for upper tract tumors for white men and women was 64.2% and 75.4% at or before 2 years, 44.3% and 40.5% at 2 to 5 years, 50.8% and 42.1% at 5 to 10 years, and 43.2 and 22.2% at more than 10 years. These authors concluded that the incidence of upper tract cancers is stable on long-term follow-up and that upper tract surveillance must remain rigorous for an extended period. **The incidence of upper tract recurrence has been shown to be higher in patients with carcinoma in situ than in patients with superficial transitional cell carcinoma and in patients treated with cystectomy for carcinoma in situ rather than for invasive cancer** (Solsona et al, 1997). On pathologic evaluation, recurrence is most likely to be superficial (Ta, T1, Tis) and to occur in the distal ureter only (47%). However, this finding has not been reported in all series. For example, in patients with Ta, T1, and Tis bladder cancers treated with bacille Calmette-Guérin (BCG), Herr and colleagues (1996) reported a 21% upper tract recurrence rate after a median interval of 7.3 years; the majority were invasive, and 38.8% of patients with recurrence died of their upper tract disease.

Etiology and Risk Factors

Balkan Nephropathy. Balkan nephropathy is characterized by a degenerative interstitial nephropathy occurring in Balkan countries. Afflicted families display a much higher incidence of upper tract transitional cell cancer, in some areas 100 to 200 times greater than in nonaffected individuals (Petkovic, 1975). Curiously, bladder cancer incidence is not affected. Tumors are generally low grade and are more frequently multiple and bilateral than are upper tract transitional cell carcinomas due to other causes (Radovanovic et al, 1985). Balkan nephropathy is familial but not obviously inherited, suggesting an environmental etiology that has yet to be identified. Interestingly, family members who leave home early in life may not be affected (Radovanovic et al, 1985).

Smoking. Cigarette smoking appears to be the most important of the modifiable risk factors for upper tract cancer, producing an incidence three times as that seen in nonsmokers. It appears that this risk is dose related, with a rate as high as 7.2 times normal for long-term (>45 years) smokers (McLaughlin et al, 1992). Former smokers also have a twofold increased risk compared with age-matched persons with no smoking history. This risk declines only partially after smoking ceases. In addition, the risk from smoking seems to more often lead to ureteral rather than to renal pelvic tumors.

Coffee Consumption. A relative risk of 1.8 times normal has been described in individuals who consumed more than seven cups of coffee per day (Ross et al, 1989). However, after controlling for cigarette smoking, this risk decreased to 1.3.

Analgesics. Analgesic abuse is a well-documented risk factor associated with the development of upper tract cancers (Morrison, 1984; McCredie et al, 1986). In one study, 22% of patients with renal pelvic tumors and 11% of patients with ureteral tumors reported a history of analgesic abuse with a latency period of approximately 2 years (Steffens and Nagel, 1988). Renal papillary necrosis and phenacetin consumption also appear to be independent but synergistic risk factors. Each alone resulted in relative risk factors of 6.9 and 3.6, respectively, but together increased risk 20 times (McCredie et al, 1986). Although phenacetin is the most well described causative agent in analgesic nephropathy, most patients have reported taking combination preparations that included caffeine, codeine, acetaminophen, and aspirin or other salicylates (De Broe and Elseviers, 1998). Histologic findings associated with analgesic abuse include thickening of the basement membrane (pathognomonic) and papillary scarring. Thickening of the basement membrane has been demonstrated in 15% of patients with upper tract tumors and should alert the physician to the presence of this etiologic agent and the subsequent risk of contralateral involvement (Palvio et al, 1987). The degree of papillary scarring also appears to be closely related to tumor grade although not with the development of squamous metaplasia or squamous cancer (Stewart et al, 1999).

Occupation. A significantly increased risk for upper tract tumors has been reported for persons employed in chemical, petroleum, and plastic industries (relative risk of 4); patients with exposure to coal or coke (relative risk of 4); and patients with exposure to asphalt or tar (relative risk of 5.5) (Jensen et al, 1988). Aniline dyes, β-naphthylamine, and benzidine have been implicated as causative agents, and tumors can occur at long intervals (up to 15 years or more) after exposure.

Chronic Inflammation, Infection, or Exposure to Chemotherapies. The development of squamous cell cancer (and less commonly adenocarcinoma) has been shown to be related to chronic bacterial infection associated with urinary stones and obstruction (Godec and Murrah, 1985; Spires et al, 1993). In addition, exposure to cyclophosphamide, an alkylating agent, also appears to confer an increased risk (Brenner and Schellhammer, 1987).

Heredity. Several familial syndromes have been associated with the development of upper tract transitional cell cancer (Frischer et al, 1985; Orphali et al, 1986; Lynch et al, 1990). Lynch syndrome II, for example, is characterized by the early development of colonic tumors (without polyposis) and extracolonic neoplasms, including upper tract urothelial tumors. Unlike with nonhereditary cancers, these patients are typically younger (mean, 55 years) and are more likely to be female (Lynch et al, 1990).

NATURAL HISTORY

Molecular Biology (Chromosome Abnormalities)

The molecular and genetic basis of upper tract transitional cell cancers appears to be similar to that of transitional cell cancers of the bladder. These events have been better described in bladder cancers and are reported in detail in Chapter 77.

Briefly, the genetic events leading to the development of upper tract tumors seem to be associated with the presence of tumor suppressor genes, including *p53* (on chromosome 17p), the retinoblastoma gene (*RB*) on chromosome 13q, and several gene foci on chromosome 9 (including the genes for p18 and p16 proteins located at 9p21 and 9p32-33). It is generally thought that chromosome 9 abnormalities occur early in the development of these cancers but are not typically associated with high grade and dysplastic changes, whereas *p53* is more often associated with increased grade and dysplasia. It would also seem, however, that by the time the tumor has been able to invade into the lamina propria, both genetic events are likely to have occurred (Spruck et al, 1994).

Location and Distribution of Tumors

Ureteral tumors occur more commonly in the lower than in the upper ureter. Overall, about 70% of ureteral tumors occur in the distal ureter, 25% in the midureter, and 5% in the proximal ureter (Anderstrom et al, 1989; Messing and Catalona, 1998). This phenomenon may be a reflection of downstream implantation. One area of consensus is that removal of the entire ureter is mandatory when upper urinary tract cancers are removed by nephroureterectomy. Bilateral involvement (either synchronous or metachronous) occurs in 1.6% to 6% of sporadic upper tract transitional cell cancers (Babaian et al, 1980; Murphy et al, 1981; Kang et al, 2003).

Patients with upper tract tumors are at risk for development of bladder cancer, with an estimated incidence that varies in multiple reports from 15% to 75% within 5 years of the development of the upper tract cancer (Kakizoe et al, 1980; Huben et al, 1988; Anderstrom et al, 1989; Hisataki et al, 2000; Miyake et al, 2000; Kang et al, 2003). **This high incidence of metachronous bladder involvement suggests that routine bladder surveillance should be performed.** Why are upper tract cancers followed by bladder cancers more often than bladder cancers are followed by upper tract cancers? Theories include downstream seeding, longer exposure time to carcinogens in the bladder, and greater number of urothelial cells in the bladder that are subject to random carcinogenic events. Studies have suggested that in high-grade cancers (with associated *p53* gene mutations), which also tend to be more rapidly recurrent, specific gene mutations noted in upper tract cancers are also demonstrated in subsequent bladder cancers (Harris and Neal, 1992; Lunec et al, 1992; Habuchi et al, 1993). In contrast, microsatellite studies in low-grade upper tract cancers, which tend to recur less rapidly in the bladder, have suggested genetic discordance between these upper tract tumors and subsequent bladder cancers in 46% of cases (Takahashi et al, 2000).

Upper tract cancers have traditionally been reported to develop in 2% to 4% of patients with bladder cancer, with a mean interval to recurrence of 17 to 170 months (Oldbring et al, 1989; Solsona et al, 1997; Rabbani et al, 2001). **Risk factors that have been reported to predict a higher likelihood of the development of upper tract cancers after bladder cancer treatment include stage, grade, multiplicity of tumors in the bladder, presence of ureteral reflux, presence of recurrent carcinoma in situ in the bladder after BCG treatment, multifocal carcinoma in situ in the bladder at the time of cystectomy, and presence of bladder cancers arising close to a ureteral orifice** (Hudson and Herr, 1995; Herr et al, 1992; Zincke et al, 1994). Two long-term follow-up series have reported that upper tract recurrence after bladder cancer diagnosis may be much higher than previously thought, occurring in approximately 25% of cases. This phenomenon may be the result of selection of patients, with more high-grade and dysplastic tumors reported in these series (Solsona et al, 1997; Herr et al, 1996).

Delayed recurrence is more common in the ureter than in the renal pelvis and appears to occur earlier (at 40 versus 67 months). In patients treated with BCG for carcinoma in situ of the bladder, upper tract cancer is even more common (about 30% of cases) and appears to occur distally (in the distal, juxtavesical, and intramural portions of the ureter), especially in those patients subjected to cystectomy who are BCG refractory. Therefore, in cases of high-risk bladder cancer (high-grade T1 disease or carcinoma in situ), upper tract imaging should probably be performed annually as part of routine follow-up (Herr et al, 1996).

Upper tract urothelial cancers are often associated with a poor prognosis. Up to 19% of patients with upper tract transitional cell carcinoma have been reported to present initially with metastatic disease (Akaza et al, 1970). **Several studies have suggested that renal pelvic tumors have a better overall prognosis and 5-year disease-specific and recurrence-free survival than do ureteral tumors** (Park et al, 2004). **However, overall prognosis of upper tract tumors seems to be principally related to tumor stage and to a lesser degree to tumor grade.** In one series, 5-year survival was 100% for Ta and Tis, 91.7% for T1, 72.6% for T2, and 40.5% for T3 tumors. Multivariate analysis in this series showed that tumor stage ($P = .0001$) and age of the patient ($P = .042$) were the only statistically significant predictors of survival (Hall et al, 1998).

Progression to Muscle Invasion and Metastases

The thin muscle layer of the renal pelvis and ureter probably allows earlier penetration of invasive upper tract tumors through the thinned muscle layer than is seen in bladder cancers (Cummings, 1980; Richie, 1988). In a recent report, 164 patients with upper tract tumors were compared with 2197 patients with bladder cancer. High-grade and deeply invasive transitional cell carcinoma occurred in 28.2% of bladder cancers compared with 39.5% of upper tract tumors (Stewart et al, 2005). The renal parenchyma itself may be a barrier to the spread of stage T3 cancers, whereas periureteral tumor extension is a risk factor for early tumor dissemination (Batata and Grabstald, 1976; Guinan et al, 1992). This anatomic phenomenon may be at least part of the explanation as to why renal pelvic tumors appear to have a better prognosis than ureteral tumors. In one large series of 611 patients treated at 97 hospitals, the 5-year survival rates of patients with stage T3 tumors of the renal pelvis and ureter were 54% and 24%, respectively (Guinan et al, 1992).

Patterns of Spread

Transitional cell carcinomas of the upper urinary tract may spread in several different ways, including direct invasion into

the renal parenchyma or surrounding structures, lymphatic or vascular invasion, and epithelial spread by seeding or direct extension. It is clear that high-grade tumors demonstrate a greater propensity to invade and that renal parenchymal invasion is the most significant predictor of the development of metastases (95%), followed by vascular invasion (83%) and lymphatic invasion (77%) (Davis et al, 1987).

Epithelial. To describe the clonal nature of urothelial tumors of the bladder and upper tract, two theories of the nature of this phenomenon have been proposed. The monoclonality theory describes the multiple tumors as the descendants of a single genetically transformed cell that populates the urothelium. In contrast, the field theory assumes a diffuse "cancerization" that is the result of exposure to a carcinogen and results in the independent development of nonrelated tumors at different sites. Although the majority of the evidence supports the monoclonality theory, most of this evidence has resulted from the study of advanced invasive cancers. It seems that a small but significant proportion of multifocal cancers are in fact derived from different clones (Hafner et al, 2002).

Epithelial spreading may occur in both antegrade (most common) and retrograde manners. Antegrade seeding is thought to be the most likely explanation for the high incidence of recurrence in patients in whom a ureteral stump is left in situ after nephrectomy and incomplete ureterectomy (Johnson and Babaian, 1979).

Lymphatic. Lymphatic spread from the upper urinary tract extends to the para-aortic, paracaval, and ipsilateral common iliac and pelvic lymph nodes (Batata and Grabstald, 1976). This extension, of course, depends on the location of the primary tumor and is directly related to the depth of invasion of the primary tumor. Whether lymphadenectomy should be performed routinely and the extent of lymphadenectomy remain controversial (Nakazono and Muraki, 1993; Komatsu et al, 1997). In a series of nephroureterectomy and lymph node dissection, Secin and associates (2005) reported positive lymph nodes in 20% of cases (mean number of lymph nodes sampled, 7.3; range, 1 to 17). Death from disease was 25% for patients with N0 tumors compared with 66.7% in the N1-2 group ($P < .001$). In this series, the presence of suspicious lymph nodes on preoperative imaging studies was the only preoperative predictor of lymph node metastasis on multivariate analysis ($P = .02$).

Hematogenous. The most common sites of hematogenous metastases from upper tract tumors are the liver, lung, and bone (Batata et al, 1975). Although it is very rare, direct extension into the renal veins and vena cava may occur in renal pelvic tumors (Jitsukawa et al, 1985; Geiger et al, 1986).

PATHOLOGY

The majority of upper tract tumors are urothelial cancers. Of these, the majority are transitional cell in origin; squamous cell cancers and adenocarcinomas represent a small minority (Bennington et al, 1975; Vincente et al, 1995; Flanigan and Kim, 2004).

Normal Upper Tract Urothelium

The urothelial lining of the upper urinary tract closely approximates that of the bladder except for the markedly reduced thickness of the muscle layer and the abutting of the urothelium to the renal parenchyma proximally. The epithelial layer is continuous from the level of the calyces to the distal ureter. It has been postulated that the urothelial layer may even "extend" into the collecting ducts, raising the possibility that collecting duct renal cancers may be closely related to urothelial cancers and perhaps better treated by agents used for urothelial cancers (Orsola et al, 2005). This observation needs further confirmation.

Renal Pelvis and Calyces (Fig. 48–1). The walls of the calyces and the pelvis contain fibrous connective tissue and two layers of smooth muscle and are lined on their inner surfaces by transitional epithelium (Dixon and Gosling, 1982) (Fig. 48–2). Thin muscle layers originate in the minor calyces and form a spiral, helical arrangement (Fig. 48–3).

Ureter. The ureter demonstrates two continuous thin muscle layers with a loosely spiraled internal layer and a more tightly spiraled external layer. In the lower third of the ureter, a third outer longitudinal layer is present. All three layers merge with the three layers (inner longitudinal, middle circular, and outer longitudinal) of the bladder wall, which run longitudinally, transversely, and obliquely. Beneath the outer muscle coat is the serosa, made up of loose connective tissue and containing

Figure 48–1. Low-magnification view of a section through the kidney. The renal medulla ends in the pointed renal papilla. Urine empties into the Y-shaped space made up of the renal calyces (the arms of the Y) and the pelvis (the base of the Y).

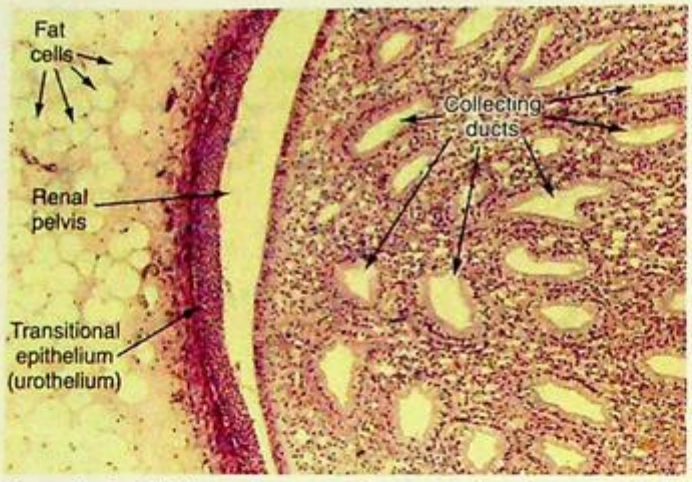

Figure 48–2. This image shows several large collecting ducts near the end of a medullary pyramid (i.e., close to their opening into the pelvis). The transitional epithelium of the renal pelvis is continuous with that of the ureters and bladder.

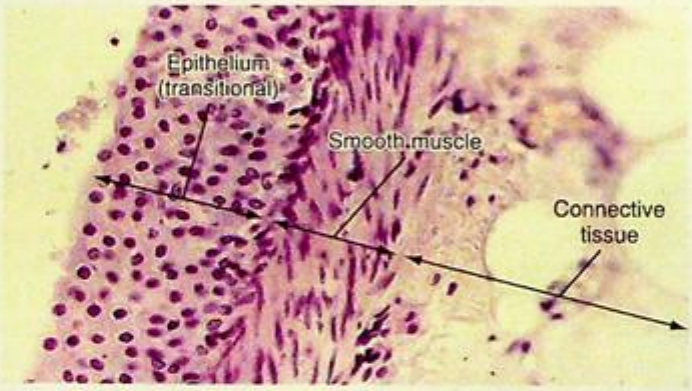

Figure 48–3. In this specimen from the renal pelvis, the connective tissue immediately beneath the epithelium is inconspicuous, obscured by a layer of smooth muscle (note elongated nuclei). Beneath the smooth muscle is loose connective tissue, including conspicuous adipocytes.

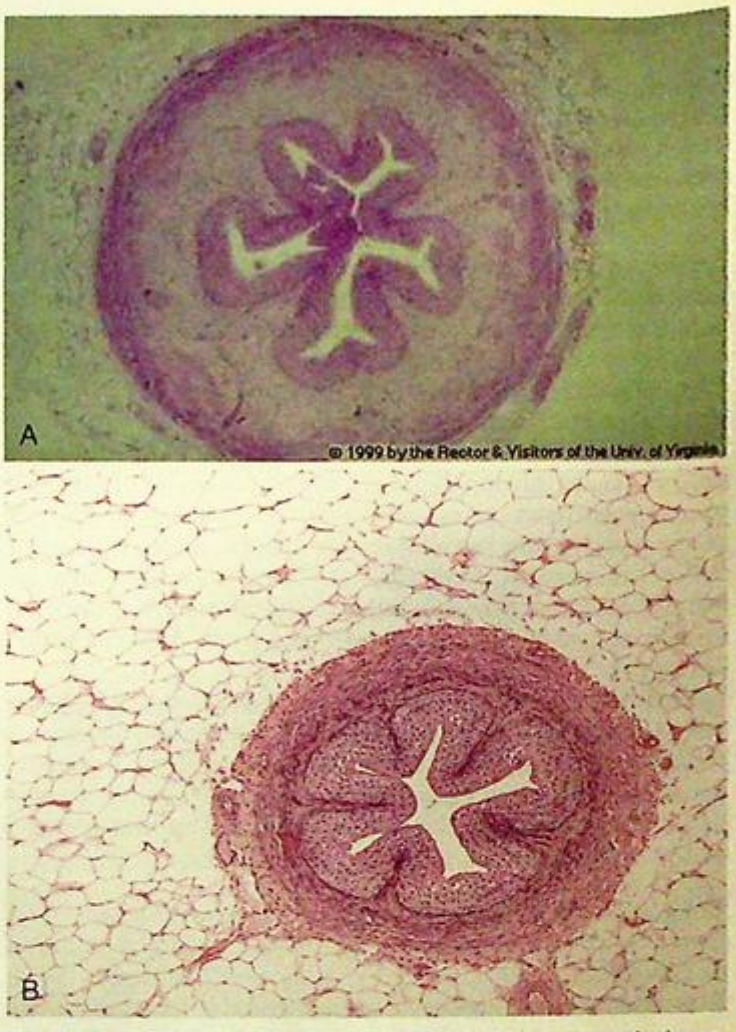

Figure 48–4. Cross section of ureter. The ureter has an irregular lumen, which is lined by transitional epithelium. Under the epithelium is a connective tissue layer and, beneath that, three layers of smooth muscle: inner longitudinal, middle circular, and outer longitudinal.

blood vessels and lymphatics (Hanna et al, 1976; Notley, 1978) (Figs. 48–4 and 48–5).

Abnormal Urothelium

Metaplasia and Dysplasia. Several studies have suggested that upper tract urothelial cancers progress through histologic changes from hyperplasia to dysplasia to frank carcinoma in situ in a significant proportion of patients (Heney et al, 1981; McCarron et al, 1982). Carcinoma in situ may be patchy and may extend proximally to the collecting ducts of the kidney (Mahadevia et al, 1983). More severe urothelial dysplastic changes are associated with a greater risk for tumor recurrence in the distal ureter and bladder and a reduced prognosis.

Benign Lesions: Inverted Papillomas and von Brunn's Nests. Inverted papillomas, although generally considered benign lesions, have been shown to often be associated with either synchronous or metachronous upper tract urothelial tumors (Renfer et al, 1988; Stower et al, 1990; Chan et al, 1996; Cheville et al, 2000). One series demonstrated an 18% incidence of malignancy associated with inverted papilloma of the

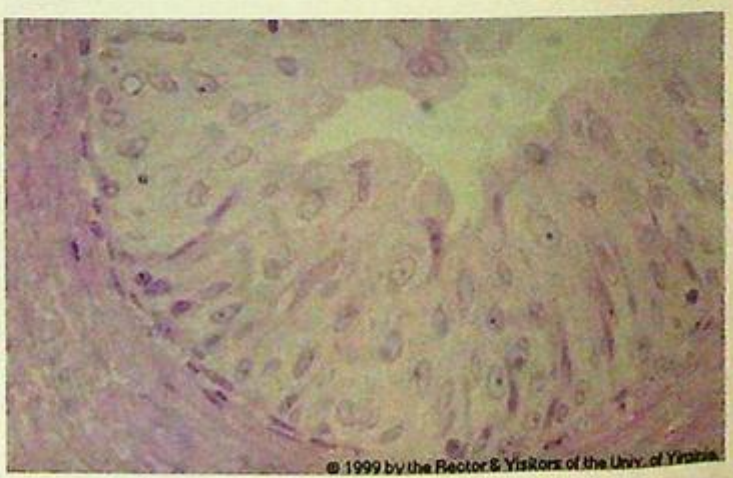

Figure 48–5. This image shows the transitional epithelium and loose connective tissue that compose the mucosa of the urinary tract. A transitional epithelium superficially resembles a nonkeratinized stratified squamous epithelium; but note that the epithelial cells nearest to the apical (outer) surface are not flattened but cuboidal. Transitional epithelium is a stratified epithelium characterized by the fact that the most apical cells are the roundest and largest in diameter. It is designed to be able to increase its surface area as the lumen is dilated by urine.

ureter (Grainger et al, 1990). Other studies have suggested that there are two types of urinary inverted papilloma. The lesions of type 1 behave in a benign fashion, whereas those of type 2 may have a malignant potential. Since there is currently no way to distinguish between these two types, it has been advised that follow-up for all cases of inverted papilloma be continued for at least 2 years after initial diagnosis (Asano et al, 2003). Similarly, these findings suggest close surveillance of the upper tracts for malignancy is warranted when inverted papilloma is diagnosed.

Transitional Cell Carcinoma. Transitional cell carcinoma makes up more than 90% of upper tract tumors, may present as papillary or sessile lesions, and may be unifocal or multifocal. On histologic examination, these lesions are similar to transitional cell cancers of the bladder, but the relative thinness of the muscle layer of the renal pelvis and ureter makes invasion through the muscle coat an earlier event. Carcinoma in situ, as in the bladder, can be particularly difficult to identify and can vary in appearance from a whitish plaque to epithelial hyperplasia or a velvety red patch due to increased submucosal vascularity (Melamed and Reuter, 1993). Progression to muscle invasion or invasion into the renal parenchyma or adventitial tissues may occur and is more likely, given the relative thinness of the muscle coat of the upper tracts.

Nontransitional Cell Tumors. Nontransitional cell tumors of the upper tracts represent a wide spectrum of lesions, from benign to highly malignant. The most common of these are squamous cell cancers and adenocarcinomas.

Squamous Cell Cancers. Squamous cell cancers make up 0.7% to 7% of upper tract cancers (Babaian and Johnson, 1980; Blacker et al, 1985). Squamous cancers are frequently associated with a condition of chronic inflammation or infection or with analgesic abuse (Stewart et al, 1999). These tumors occur six times more frequently in the renal pelvis than in the ureter and are generally moderately to poorly differentiated and more likely to be invasive at the time of presentation.

Adenocarcinoma. Adenocarcinomas account for less than 1% of all renal pelvic tumors and are typically associated with long-term obstruction, inflammation, or urinary calculi (Stein et al, 1988; Spires et al, 1993). These tumors typically present at advanced stage and display a poor prognosis.

Other Miscellaneous Tumors. Fibroepithelial polyps (benign) (Musselman and Kay, 1986; Blank et al, 1987) and neurofibromas (benign) (Varela-Duran, 1987) are uncommon lesions that are typically treated by simple excision.

Multiple types of sarcomas have also been reported to involve the upper urinary tracts, including leiomyosarcomas (Madgar et al, 1988), plasmacytomas (Igel et al, 1991), and angiosarcomas (Coup, 1988). Because of the rare nature of these tumors, they are typically treated by excision with adjuvant therapy that is based on the experience with tumors of similar histology occurring elsewhere in the body.

PROGNOSTIC FACTORS

Stage

Stage is currently the most important predictor of survival in patients with upper tract urothelial tumors. The most commonly used staging system is the TNM system (see later section on staging). Upper tract cancers can spread by direct invasion, mucosal seeding, and hematologic and lymphatic routes. Prognosis decreases as stage increases; the most significant decrease in survival is observed in T3 tumors that have penetrated into the perirenal or periureteral fat (Grabstald et al, 1971).

Grade

The traditional grading system used for bladder cancer is also applicable to upper tract tumors. Broder's original system, modified by Ash, grades tumors from grade 1 to grade 4; grade 1 tumors are primarily papillomas, and grade 4 tumors are highly anaplastic and poorly differentiated tumors (Melamed and Reuter, 1993). The World Health Organization's system, proposed by Mostofi, eliminates papillomas and grades tumors from grade 1 to grade 3. Recently, tumor grading has been divided into low grade and high grade (Epstein, 1998). Papillomas and papillary urothelial neoplasms of low malignant potential are also described. **Certainly, tumors of high grade are more likely to invade into the underlying connective tissue, muscle, and surrounding tissues. Tumors of high grade are also more likely to be associated with concomitant carcinoma in situ.**

Location

There remains disagreement as to whether the location of an upper tract tumor affects prognosis. Several studies have suggested that renal pelvic tumors have a better prognosis than ureteral cancers (Park et al, 2004). In contrast, others have argued that when renal pelvic and ureteral tumors are matched for stage, there is no significant difference in prognosis (Hall et al, 1998).

Associated Carcinoma In Situ

As in bladder cancer, carcinoma in situ of the upper tract is associated with a poor prognosis and a likelihood of future development of invasive urothelial cancers. Carcinoma in situ of the distal ureter is most common in patients with bladder carcinoma in situ treated with BCG (30% likelihood).

Molecular Markers

p53. The p53 nuclear protein staining of cytology specimens obtained ureteroscopically appears to correlate well with the presence of upper tract transitional cell carcinoma. In one study, of 36 p53-positive specimens, 28 had simultaneous evidence of upper tract transitional cell carcinoma; 80% of the remaining patients who were evaluated serially also had confirmed transitional cell carcinoma. All 14 p53-negative studies occurred in patients with no sign of concurrent malignant disease on ureteroscopy (Keeley et al, 1997c).

Lymphovascular Invasion. Lymphovascular invasion has been suggested to be an independent prognostic factor for disease-specific survival in upper tract transitional cell carcinoma. In a Japanese study, 173 consecutive patients undergoing surgical treatment of upper tract transitional cell carcinoma had lymphovascular invasion determined (Kikuchi

et al, 2005). Lymphovascular invasion was found in 30% of cases and was more frequent in advanced pathologic stage. Overall 5- and 10-year survival rates were 84.9% and 80.4%, respectively, in the absence of lymphovascular invasion compared with 40.2% and 21.1% with lymphovascular invasion. Further prospective, large-scale studies are needed to confirm this observation.

Loss of Heterozygosity. Loss of heterozygosity at 9p21 has been observed in bladder cancer and now in upper tract transitional cell carcinoma by microsatellite instability analysis. It has been shown that transitional cell carcinoma can occur in patients with hereditary nonpolyposis colorectal cancer syndrome. Patients with this syndrome show genomic lesions in DNA mismatch repair genes (Amira et al, 2003). Furthermore, an inverted growth pattern of cancer has also been associated with microsatellite instability, with a sensitivity and specificity of 0.82 in one study. This finding suggests that microsatellite instability may serve as a marker for inverted growth in upper tract cancers (Hartmann et al, 2003).

Ploidy–Flow Cytometry. Tumor ploidy has been shown to correlate with survival in upper tract tumors. In one study, tumor aneuploidy was associated with poor 5- and 10-year survival rates of 25% and 0%, respectively (Blute et al, 1988).

Other Markers. Telomerase activity has been shown to be present in most (>95%) upper tract urothelial cancers. It can be detected in exfoliated urinary specimens in a high percentage of patients and thus may prove to be a potentially useful marker (in addition to conventional cytology) to identify upper tract cancers (Wu et al, 2000).

Urinary levels of NMP22, a nuclear matrix protein–based marker, have been found to be elevated in patients with upper tract cancer (Carpinito et al, 1996). Although the sensitivity of this test for determining the presence of low-grade tumors is probably higher than that of cytology, the specificity is low.

Rapid urine tests for urothelial malignant neoplasms have been studied extensively for the purpose of identifying lower urinary tract tumors. Less is known about their value in upper tract cancers. In one series, an analysis of fibrinogen-fibrin degradation products (AuraTek FDP) was compared with the bladder tumor antigen (BTA) test and urine cytology. In this study, the accuracy of the FDP test was 83% compared with 62% for BTA and 59% for cytology (Siemens et al, 2003).

p27, a cyclin-dependent kinase inhibitor, has also been shown to predict the prognosis of upper tract tumors. In one study, low levels of p27 staining were indicative of a worse disease-specific survival (Kamai et al, 2000).

DIAGNOSIS

Symptoms and Signs

The most common presenting symptom of upper tract urothelial tumors is hematuria, either gross or microscopic. This occurs in 56% to 98% of patients (Murphy et al, 1981; Guinan et al, 1992; Raabe et al, 1992). Flank pain is the second most common symptom, occurring in 30% of tumors. This pain is typically dull and believed to be secondary to a gradual onset of obstruction and hydronephrotic distention. In some cases, pain can be acute and mimic renal colic, typically ascribed to the passage of clots that acutely obstruct the collecting system. About 15% of patients are asymptomatic at presentation and are diagnosed when an incidental lesion is found on radiologic evaluation. Patients may also present with symptoms of advanced disease, including flank or abdominal mass, weight loss, anorexia, and bone pain. Nearly all upper tract tumors are diagnosed during the patient's life, and therefore upper tract urothelial cancer represents a rare autopsy finding (Ressequie et al, 1978).

Radiologic Evaluation

Although intravenous pyelography has been the traditional means for diagnosis of upper tract lesions, computed tomographic (CT) urography is increasingly performed today. CT scanning is easier to perform and less labor intensive. It also has a higher degree of accuracy in determining the presence of renal parenchymal lesions. On the other hand, small urinary filling defects (<5 mm) may be missed between the "cuts" of the traditional CT scan. More recently, CT urography has been performed to obtain a three-dimensional image of the upper tracts. This technique appears to be equal to intravenous pyelography in imaging the ureters and renal pelvis (McTavish et al, 2002). With CT urography, the sensitivity for detecting upper tract malignant disease has been reported to approach 100% ,with a specificity of 60% and a negative predictive value of 100% (Caoili et al, 2002). CT urography does, however, expose the patient to higher doses of radiation.

Radiolucent filling defects, obstruction or incomplete filling of a part of the upper tract, and nonvisualization of the collecting system are the typical findings suggestive of an upper tract tumor. Filling defects, which account for 50% to 75% of cases, typically require the intravenous administration of contrast material to be identified (Fein and McClennan, 1986; Murphy et al, 1981). The differential diagnosis of these defects includes blood clot, stones, overlying bowel gas, external compression, sloughed papilla, and fungus ball. Stones can be ruled out most easily by confirmation of calcification by renal ultrasonography or CT scanning. Transitional cell cancers have an average density of 46 Hounsfield units (HU) and a range of 10 to 70 HU (Lantz and Hattery, 1984). This is in contrast to an average of 100 HU seen in radiolucent uric acid stones (range, 80 to 250 HU). Thus, CT scanning can be useful in distinguishing between these two common causes of radiolucent filling defect on excretory urography or retrograde ureterography.

Radiolucent, noncalcified lesions may require additional evaluation by retrograde urography or ureteroscopy, with or without biopsy and cytology. Overall, retrograde urography has an accuracy of 75% in diagnosis of an upper tract malignant neoplasm (Murphy et al, 1981). An incompletely filled or obstructed renal infundibulum or calyx, occurring in 10% to 30% of cases, again typically requires retrograde urography or ureteroscopy to confirm the diagnosis. Obstruction of the urinary tract is a poor prognostic sign for tumor invasion (Babaian and Johnson, 1980).

Evaluation of the contralateral kidney is important not only because of possible bilaterality of the disease but also because it allows a determination of the functionality of the contralateral kidney. This is an extremely important part of the management process. At times, a split-function renal scan may be helpful in determining the contribution of both the

"diseased" and the presumed "normal" kidney to the patient's overall renal function.

Some have suggested that ultrasonography has sensitivity equal to that of urography in evaluating patients with painless gross hematuria for upper tract malignant disease (Yip et al, 1999; Data et al, 2002). For staging purposes, CT or magnetic resonance scanning is most useful in determining the extent of invasion, an associated mass lesion outside the collecting system, and the presence of lymph node or distant metastases (Milestone et al, 1990). CT is also more sensitive than conventional radiography in determining minimally radiopaque substances, making it useful in identifying urine excreted by poorly functioning areas of kidney (as in obstructed areas) (Kenney and Stanley, 1987). The greatest downside of CT or magnetic resonance scanning is in the detection of small lesions that may be lost in volume averaging. In one series, CT scanning predicted TNM stage in 60% of patients; it understaged 16% and overstaged 24% (Scolieri et al, 2000).

Cystoscopy

Because upper tract tumors are often associated with bladder cancers, cystoscopy is mandatory in the evaluation to exclude coexistent bladder lesions.

Ureteroscopic Evaluation and Biopsy

The technical advances achieved in the realm of endoscopic equipment have made the flexible and rigid ureteroscope a key part of the evaluation (and treatment) of upper tract tumors. **Diagnostic accuracy can be improved from approximately 75% with excretory or retrograde urography alone to approximately 85% to 90% when it is combined with ureteroscopy** (Streem et al, 1986; Blute et al, 1989). Although pyelovenous and pyelolymphatic migration has been reported with ureteroscopy, this phenomenon appears to be uncommon and should not preclude its use (Lim et al, 1993).

As with bladder tumors, 55% to 75% of ureteral tumors are low grade and low stage (Cummings, 1980; Richie, 1988; Williams, 1991). **Also, like bladder cancers, approximately 85% of renal pelvic tumors are papillary and the remainder sessile.** Invasion of the lamina propria or muscle (stage T1 or T2) occurs in 50% of papillary and in more than 80% of sessile tumors. Overall, therefore, 50% to 60% of renal pelvic tumors are invasive into either the lamina propria or muscle. In ureteral tumors, invasion is also more common than in bladder tumors (Anderstrom et al, 1989; Williams, 1991).

In addition to visualization of the tumor, ureteroscopy allows more accurate biopsy of suspected areas, with either biopsy forceps or brushing (Fig. 48–6). Good histologic correlation (78% to 92%) between the ureteroscopic biopsy specimen and the final pathologic specimen has been established (Keeley et al, 1997b; Guarnizo et al, 2000). It appears that fresh samples obtained ureteroscopically provide the best chance of predicting eventual pathologic findings. In one study, a cell block from biopsies was prepared when a visible tumor was present, and grades of ureteroscopic biopsy specimens were compared with grades and stages of surgical specimens in 42 cases. Of 30 low- or moderate-grade specimens, 29 (90%) proved to be low- or moderate-grade transitional cell carcinoma; 11 of 12 high-grade specimens (92%) proved to be high-grade transitional cell carcinoma, and 8 (67%) were invasive (T2 or T3) (Keeley et al, 1997b). In contrast, the urologist's impression of the tumor grade based on ureteroscopic appearance is likely to be correct in only 70% of cases, suggesting that biopsy is also needed to further define this important aspect of staging (El-Hakim et al, 2004).

Because of the small size of ureteroscopic biopsy specimens, a precise correlation with eventual tumor *stage* is difficult. Therefore, in predicting the tumor stage, a combination of the radiographic studies, the visualized appearance of the tumor, and the tumor grade provides the surgeon with the best estimation of eventual tumor stage. Although, as stated before, grading of the tumors may be fairly accurate, staging is much more problematic. Of 40 urothelial tumors staged in one series (40% in the renal pelvis, 20% in the proximal ureter, and 40% in the distal ureter), ureteroscopic grade matched surgical grade in 78% of cases and was less than surgical grade in the remaining 22%. Lamina propria was present in 68% of biopsy specimens (62% of cup biopsies and 100% of loop biopsies), but tumors thought to be Ta were upstaged to T1 to T3 in 45% of cases at the time of complete resection of the lesion (Guarnizo et al, 2000). Therefore, accurate tumor grading on ureteroscopic biopsy is critical in estimating tumor stage. In one series, a biopsy specimen showing grade 3 tumor accurately predicted tumor stage in more than 90% of cases (Skolarikos et al, 2003).

Is ureteroscopy (with or without biopsy) necessary in all cases of suspected upper tract tumors? No. In fact, ureteroscopy should probably be reserved for situations in which the diagnosis remains in question after conventional radiographic studies and for those patients in whom the treatment plan may be modified on the basis of the ureteroscopic findings, for example, endoscopic resection. Although there is no evidence that ureteroscopy diminishes the prognosis of a patient destined to proceed to nephroureterectomy, and although the risks of tumor seeding, extravasations, and dissemination are low in experienced hands, these risks are real and should preclude ureteroscopy when it is unnecessary (Hendin et al, 1999).

Antegrade Endoscopy

In some cases of upper tract tumors, percutaneous access to the renal pelvis may be required for diagnosis or treatment. In such cases, antegrade urography and uroscopy may be useful for tumor resection, biopsy, or simple visualization. Larger caliber scopes that can be passed into the renal pelvis in this manner may be particularly helpful in resecting or debulking larger volumes of tumor in this area (Streem et al, 1986; Blute et al, 1989). One must remember, however, that tumor cell implantation in the retroperitoneum and along the nephrostomy tube track has been reported after these procedures (Tomera et al, 1982; Huang et al, 1995).

Role of Cytology and Other Tumor Markers

Urine cytology is a specific tool that is useful in the diagnosis of upper tract carcinomas. On the other hand, the sensitivity

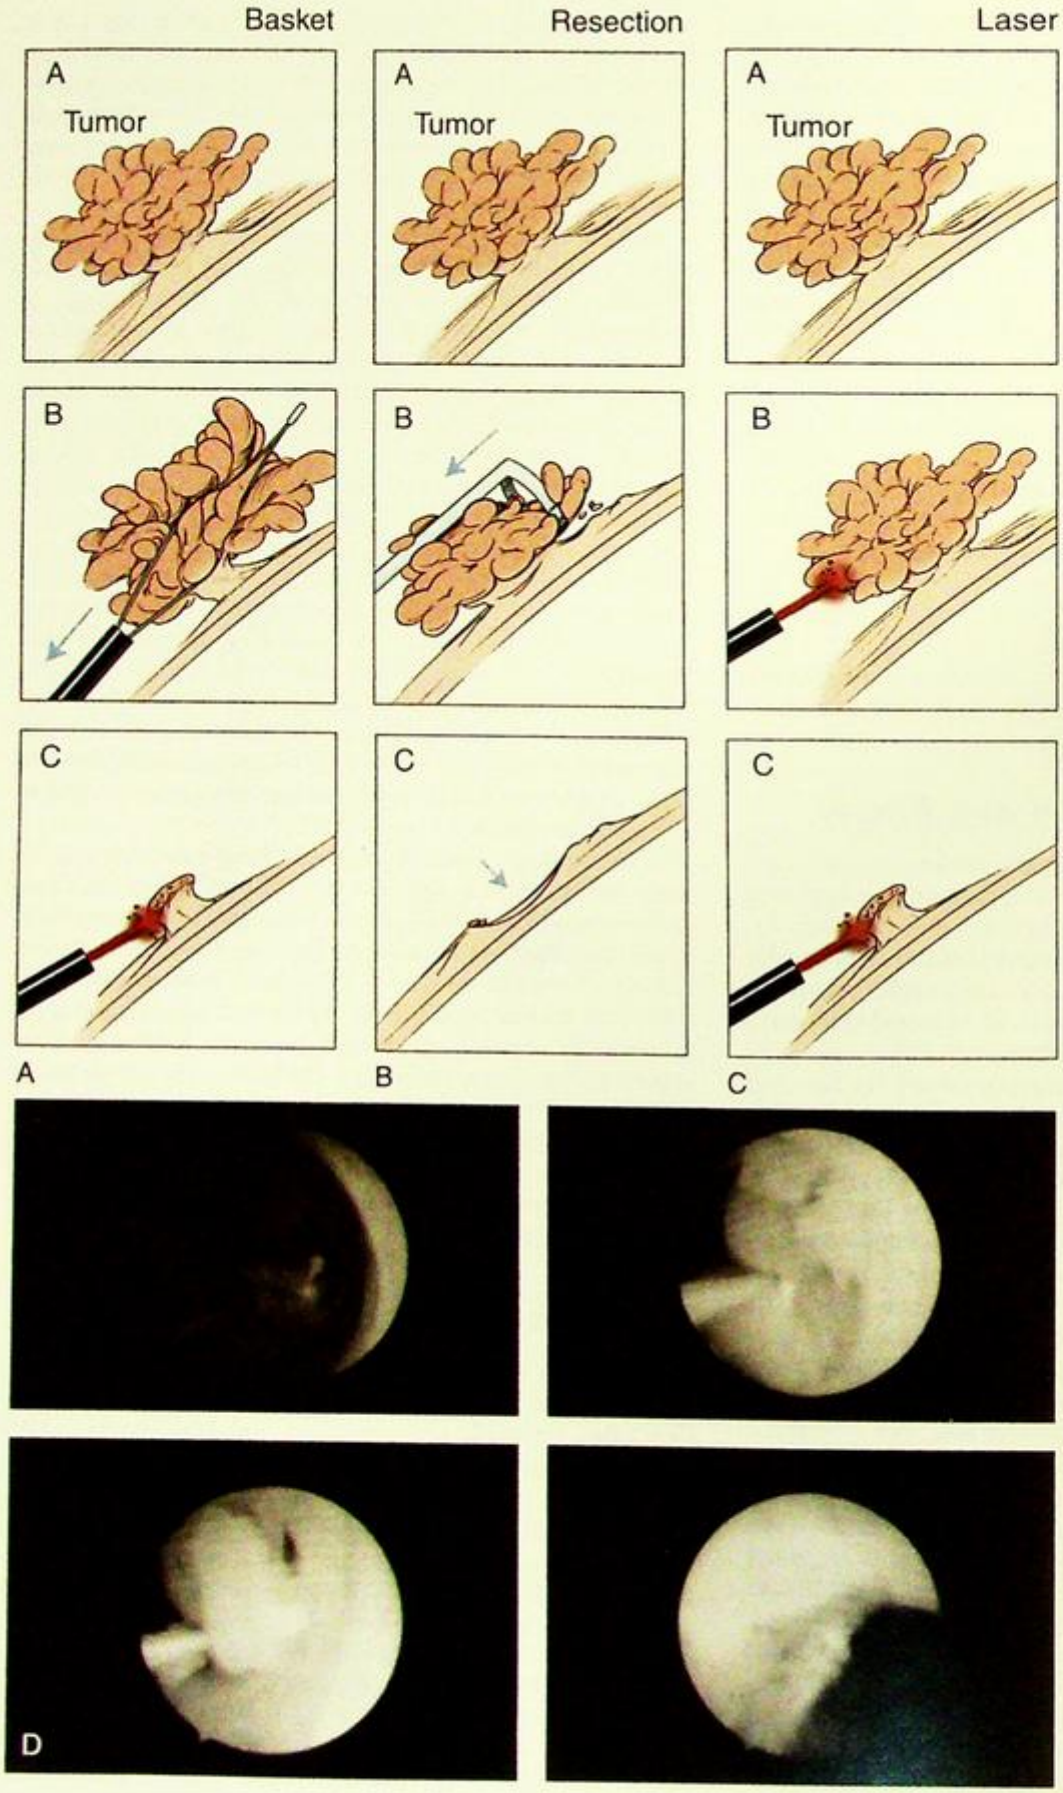

Figure 48–6. Techniques for ureteroscopic treatment of ureteral and renal tumors. **A,** The tumor is identified and removed piecemeal by grasping forceps to its base. **B,** Alternatively, a flat wire basket can be deployed alongside the tumor. The tumor is engaged and removed, with care taken not to avulse the adjacent ureter. With either of these techniques, the base is treated with electrocautery or a laser energy source. **C,** The tumor is identified and removed by a ureteroscopic resectoscope. The technique differs from the technique for bladder tumors in that only intraluminal tumor is resected. No attempt is made to resect deeply, as with a bladder tumor. The scope is not arching deep into the tissue. **D,** The tumor is sampled for diagnostic purposes. The bulk of the tumor is then ablated with electrosurgical or laser energy. Laser energy is generally preferred because it has more reliable delivery of energy and depth of penetration. The two most commonly used energy sources are holmium:yttrium-aluminum-garnet and neodymium:yttrium-aluminum-garnet.

of cytology remains an issue. In general, the sensitivity of voided urine (or bladder wash) cytology is directly related to tumor grade. Overall accuracy estimates of the sensitivity of cytology have ranged from about 20% for grade 1 tumors to 45% and 75% for grade 2 and grade 3 tumors, respectively (Murphy and Soloway, 1982; Konety and Getzenberg, 2001).

Even if a voided cytology specimen is abnormal in a patient with an upper tract filling defect, one must be cautious in determining the site of origin of the malignant cells. Ureteral catheterization for collection of urine or washings may provide more accurate cytologic results. However, even in this setting, a substantial false-negative or false-positive result (22% to 35%) can be expected (Zincke et al, 1976). It would appear that saline washing provides a better cell yield and improves cytologic results secondary to the release by hydroscopic forces of loosely adherent cells from the urothelium. Still better accuracy can be achieved by brush biopsy through a retrograde catheter or ureteroscope. Sensitivity in the 90% range with specificity approaching 90% may be possible with these techniques (Blute et al, 1989; Streem et al, 1986). Brush biopsies have, however, also been reported to result in severe complications, including massive hemorrhage and perforation of the urinary tract with extravasation (Blute et al, 1981).

It appears that the exposure of urothelial cells to ionic, high-osmolar contrast agents as in retrograde pyelography may worsen cytologic abnormalities. Thus, it is probably prudent to obtain cytologic specimens before the use of these agents (Terris, 2004).

STAGING

TNM Staging System

The TNM staging system is the most commonly used system.

Primary tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades the muscularis
T3	Tumor invades periureteral fat [for renal pelvis only] Tumor invades beyond muscularis into perinephric fat or the renal parenchyma
T4	Tumor invades adjacent organ, or through the kidney into the perinephric fat

Lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis to a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension

Distant metastasis (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

The American Joint Committee on Cancer (AJCC) staging system and the TNM system compare as follows:

AJCC	TNM
Stage 0	T0
Stage I	Ta, Tis, T1, N0, M0
Stage II	T2, N0, M0
Stage III	T3, N0, M0
Stage IV	T4 or any T, N+, M+

TREATMENT

Role and Limitations of Various Therapies

Endoscopic Resection or Fulguration (Retrograde and Antegrade)

Technical advances have made it possible to reach all parts of the urinary tract with instruments capable of visualizing lesions, obtaining specimens for histologic evaluation, and delivering treatment modalities. Tumors of the distal ureter can be typically managed well with use of a rigid ureteroscope. Tumors of the upper urinary tract can be reached by retrograde and antegrade approaches. In the retrograde approach, flexible ureteroscopy is most often used. In general, retrograde approaches are characterized as being less invasive than antegrade approaches but are limited to some degree by the size of instrument that can be introduced through the ureter. In contrast, antegrade approaches are characterized as being more invasive (requiring placement of a percutaneous nephrostomy tube) but also able to deliver larger instruments. The basic principles for the endoscopic treatment of urothelial cancers of the upper urinary tract are similar to those for treatment of bladder cancers. Endoscopic treatment of patients with upper tract transitional cell carcinoma is generally recommended in those patients with a solitary kidney, bilateral disease, renal dysfunction, or significant intercurrent illness that precludes a major abdominal procedure. **Endoscopic management may also be appropriate in selected patients with small, low-grade lesions in the presence of a normal contralateral kidney** (Gerber and Steinberg, 1999). **However, most series suggest that recurrence is likely even with frequent reinspection and that progression to invasive disease occurs in a significant number of patients, depending on the stage and grade of the initial tumor.**

The lesion is first sampled and then the underlying tissue is ablated by electrocautery or laser energy. Endoscopic resection is generally best suited for the treatment of low-grade, low-stage lesions, for which results with this approach are excellent. In high-grade lesions, even if they are noninvasive, the procedure is limited by the field effect or by the dysplasia or carcinoma in situ commonly associated with these lesions. In the case of invasive lesions (T1 or T2), the adequacy of determination of the depth of tumor invasion is problematic as deep biopsy of the renal pelvis or ureter can be associated with massive bleeding or penetration of the urinary tract. Retrospective reviews of patients who have undergone ureteroscopic biopsy followed by nephroureterectomy have demonstrated an accuracy of 89% to 94% in determining the diagnosis and 78% to 92% in determining grade. The depth of invasion is best estimated by the tumor grade; about 85% of grade 1 and grade 2 tumors are Ta or T1, whereas 67% of

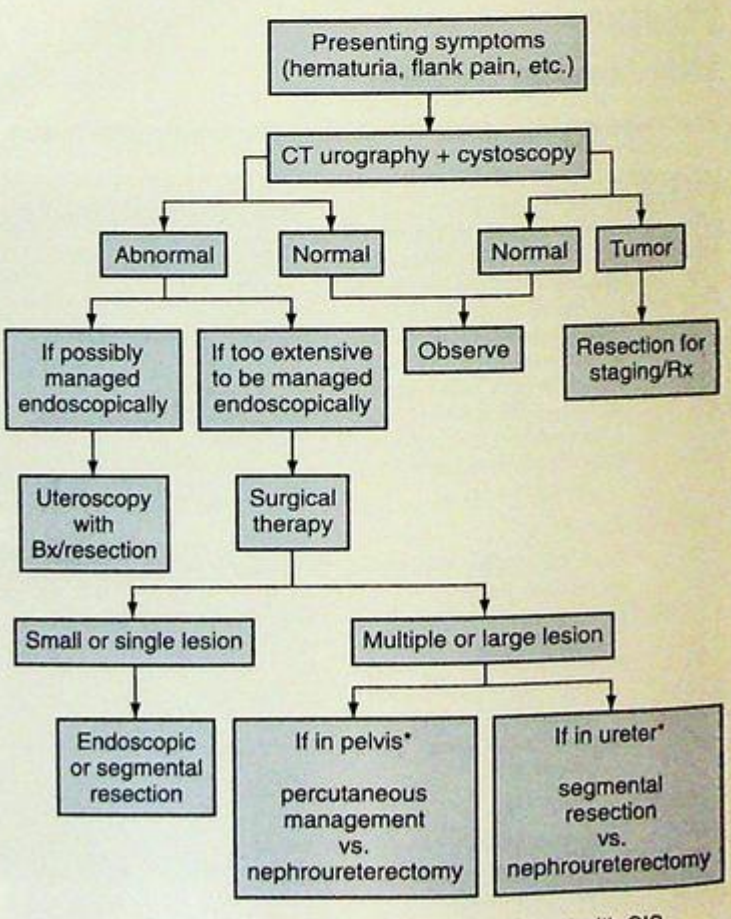
B, bladder; P, renal pelvis; RP, retroperitoneal; U, ureter; UT, upper tract.

grade 4 tumors demonstrate invasion (stage T2 or T3) (Chasko et al, 1981; Heney et al, 1981). Thus, patients with high-grade and high-stage lesions are probably best treated by formal resection, by either open or laparoscopic methods. On the other hand, patients who are at high risk for open or laparoscopic surgeries because of underlying comorbidities or patients with tumor in a solitary kidney or with impaired renal function, when resection of the kidney may result in renal insufficiency and dialysis, may be treated with some success with repeated endoscopic tumor ablation or topical immunotherapy or chemotherapy.

Results. Multiple studies have demonstrated the safety and efficacy of ureteroscopic treatment of upper urinary tract tumors (Elliott et al, 1996; Martinez-Pineiro et al, 1996; Keeley et al, 1997a; Chen and Bagley, 2000) (Table 48–1). **In one literature review of 205 patients, overall recurrence rates for ureteral and renal pelvic tumors were 33% and 31%, respectively** (Tawfiek and Bagley, 1997). **The risk of bladder recurrence in this review was 43%. The most important predictors of tumor recurrence are tumor grade and stage.** The recurrence rate for grade 1 tumors is about 25%, whereas it is about 45% for grade 2 tumors (Keeley et al, 1997b). It seems clear that frequent reinspections of the upper tract are necessary, probably every 3 months until "tumor free" and every 6 months thereafter (Chen et al, 2000). It also seems clear that this approach is best suited for low-grade, low-stage lesions, for which the risk of progression to invasion is lowest (Chen et al, 2000). Serious complications due to ureteroscopy are uncommon, including primarily ureteral perforation and ureteral stricture. These complications have become less common because of smaller endoscopes, improved sources of energy administration, and improved surgical techniques. Ureteral perforation can be effectively treated with ureteral stenting in most cases.

A percutaneous approach to upper tract lesions is typically indicated by tumor volume, location, or increased grade when complete resection of the lesions is the goal. The technical approach to the tumor depends on its location within the collecting system. High-grade and high-stage upper tract tumors are aggressive and associated with a high likelihood of progression and even death. In one series comparing percutaneous and open management of upper tract transitional cell carcinoma observed for 13 years, 26 of 110 patients (24%) died of metastases, and 60% of these were noted to have grade 3 disease initially (mean cancer survival period was 15.2 months after the initial procedure in this group). Although results with open management were better for patients with grade 3 tumors in this series with long-term follow-up, disease-specific survival rates for grade 2 tumors were similar for open (53.8 months) and percutaneous (53.3 months) approaches. Therefore, in high-grade cancers, nephroureterectomy is warranted if the patient is a surgical candidate (Lee et al, 1999) (Fig. 48–7).



*High grade lesions are often invasive and associated with CIS, making NU more appropriate

Figure 48–7. Algorithm for the management of upper tract tumors.

Segmental Resection (Nephron-Sparing Surgery) of Renal Pelvic Tumors

Although it is today largely supplanted by endoscopic approaches, open nephron-sparing surgery may be indicated in the rare patient with a large, localized tumor in a solitary kidney and synchronous bilateral tumors. Furthermore, in approaching a tumor located in the renal pelvis, a laparoscopic approach to partial nephrectomy *may* be less indicated than an open approach because of the significant likelihood for tumor spillage and subsequent implantation. In the open approach to a renal pelvic tumor, after standard flank incision and dissection of the kidney and renal pelvis are accomplished, pyelotomy and resection of the tumor are undertaken, and its base (if it is abutting the renal parenchyma) is cauterized with electrocautery, laser, or argon bean coagulator. Once resection is complete, the pyelotomy is closed. A temporary ureteral stent or percutaneous tube diversion is not always used but may be indicated in particularly aggressive resections of large-volume tumors. In larger tumors that invade the renal parenchyma, standard partial nephrectomy may be used, as is typical in cases of renal cell cancer, and it may be accomplished with open or laparoscopic techniques.

Results. The overall risk of tumor recurrence in the ipsilateral renal pelvis after segmental resection varies widely from 7% to 70% (Zincke and Neves, 1984; Ziegelbaum et al, 1987; Messing and Catalona, 1998). This risk is high correlated with the grade of tumor removed and ranges from 10% for grade 1 tumors to 30% for grade 2 and 60% for grade 3. This risk of recurrence is primarily determined by the inherent multifocal atypia and field change seen with increased tumor grade (Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983). Estimation of overall and cancer-specific survival for these highly selected patients with significant comorbidities is difficult. In one series, patients with grade 1 tumors displayed a 75% 5-year survival; those with grade 2 tumors displayed a 46% 2-year survival (Murphy et al, 1980). It therefore seems that high-grade, muscle-invasive, organ-confined tumors may be best treated by nephroureterectomy even if this means that dialysis will be necessary (Gittes, 1980; McCarron et al, 1983). On the other hand, dialysis is not without morbidity and mortality in the elderly, making thorough discussion of treatment options critical to the patient's decision process (Table 48–2).

Segmental (Partial) Ureterectomy

Segmental ureterectomy with ureteroureterotomy or bladder reimplantation is indicated for noninvasive, grade 1 or grade 2 tumors of the proximal or middle ureter that are too large for endoscopic management and for grade 3 or invasive tumors when nephron sparing must be done to preserve renal function.

Results. As with other approaches for removal of upper tract lesions, the outcome associated with segmental ureterectomy depends largely on tumor stage and grade. High-grade tumors are often associated with dysplasia or carcinoma in situ, and when possible, the proximal ureter should be inspected or even sampled to confirm or to disprove the presence of these conditions. When the upper ureter cannot be visualized preoperatively secondary to ureteral obstruction or the surgeon's preference not to pass the tumor with a scope, intraoperative flexible ureteroscopy may be easily performed to exclude proximal lesions. The outcomes for ureteral tumors are shown in Table 48–3. Reported 5-year survival is generally excellent for grade 1 and grade 2 Ta tumors. One series reported no tumor-related deaths and only one recurrence in 21 patients with low-grade, low-stage tumors treated with segmental ureterectomy who were observed for a median of 83 months (Anderstrom et al, 1989). In contrast, reported 5-year survival is approximately 65% for stage T1 tumors and approximately 50% for stage T2 tumors (McCarron et al, 1983). In the same series, 5-year survival for Ta tumors was similar for patients treated by open ureteral resection and endoscopic management. The risk of ipsilateral recurrence after segmental resection is 44% to 50% (Mazeman, 1976; Babaian et al, 1980; Williams, 1991). Lifelong periodic investigation is warranted because of this risk (Herr et al, 1996).

Nephroureterectomy

Radical nephroureterectomy with resection of a bladder cuff remains the "gold standard" for the treatment of upper tract tumors, especially those that are large, high grade, and invasive, and for large, multifocal or rapidly recurring, medium-grade, noninvasive tumors of the renal pelvis or proximal ureter (Batata and Grabstald, 1976; Babaian et al, 1980; Cummings, 1980; Murphy et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). This approach is based on the biologic behavior

Johnson and Babaian (1979)	6	16.6	44

of these tumors that is characterized by multifocality, a high incidence of ipsilateral recurrence after partial resection, and a low (<5%) incidence of contralateral disease. Nephroureterectomy can be done totally by open technique, totally laparoscopically, and by a combination of laparoscopic and open techniques (usually laparoscopic nephrectomy and ureterectomy except for the distal or intramural portion, which is done by an open approach).

Traditionally, ipsilateral adrenalectomy has been included in the procedure and is still probably useful in cases of advanced disease because the adrenal is a not-infrequent site of metastases in this disease. However, there appears to be little evidence for an advantage derived from removal of the adrenal gland unless the tumor is superior, appears to involve the gland by direct extension on preoperative radiographic evaluation, or is palpably abnormal intraoperatively.

The entire ureter, including the intramural portion and ureteral orifice, should be removed. The risk of tumor recurrence in a remaining ureteral stump is 33% to 75% (Bloom et al, 1970; Babaian et al, 1980; Kakizoe et al, 1980; McCarron et al, 1983). The entire specimen, including the kidney and ureter, may be removed en bloc or after division of the ureter at a site not involved with cancer. In this case, one must be aware of the possibility of tumor spillage and take appropriate steps to minimize its impact.

Regional lymphadenectomy is generally included in open nephroureterectomy. Although there are few data that confirm its value in terms of survival, extrapolation from bladder tumor data suggests that if lymph node metastases are confirmed, adjuvant chemotherapy is potentially useful. The limits of lymphadenectomy are also not as well defined as in bladder cancer; but for renal pelvic tumors, it probably should include the ipsilateral hilar lymph nodes and proceed medially to the adjacent para-aortic and paracaval lymph nodes. A series of 168 patients showed that 39 (23%) had lymph node metastases, including, on the right side, 30% in renal pelvic tumors, 14% in upper ureteral tumors, 20% in middle ureteral tumors, and 27% in lower ureteral tumors, and on the left side, 19%, 9%, 33%, and 18%, respectively (Kondo et al, 2005). This series also suggested that for right-sided tumors, interaortocaval nodes should be removed. What factors predict the presence of lymph node metastases? In another report of 120 patients with upper tract cancers, only suspicious lymph nodes on preoperative imaging studies significantly predicted lymph node metastases (44% of these patients had pathologically proven lymph node metastases) (Secin et al, 2005).

Laparoscopic nephroureterectomy can be performed by pure laparoscopic technique or a hand-assisted technique with an incision in the lower abdomen. With the hand-assisted approach, the lower incision is positioned to facilitate removal of the entire specimen en bloc and the bladder cuff. The indications for any of the laparoscopic approaches are identical to those for the open approach. In addition, either laparoscopic approach may be complemented by removal of the distal ureter and bladder cuff by an open, endoscopic, or pure laparoscopic approach. Long-term data are currently not available, but recent data suggest that this technique can be done safely. Local recurrence and port site seeding continue to be of some concern. At least three cases of port site recurrence have been reported; but in two of these cases, principles of surgical oncology were not employed. A report described long-term cancer control in 89 patients treated laparoscopically with a variety of techniques for distal ureterectomy, open in 36 cases and endoscopic stapling in 53 cases (Hattori et al, 2005). These data were compared with results seen by the authors with open nephroureterectomy. In this series, patients' survival and metastasis-free rates were 79% and 75% for the open group, 80% and 80% for the combined laparoscopic and open group, and 78% and 72% for the pure laparoscopic group, respectively. In this nonrandomized series, the authors reported no significant difference in the groups (Sagalowsky and Jarrett, 2002) (Table 48–4).

Results. Numerous series have demonstrated that the outcome after nephroureterectomy strongly correlates with tumor stage and grade (see Table 48–4). Nearly all series suggest that nephroureterectomy provides an improved 5-year survival rate compared with simple nephrectomy or endoscopic management, particularly in patients with high-grade or locally advanced (stage T3 or T4, N1 or N2) disease (Batata et al, 1975; Johansson and Wahlquist, 1979; Murphy et al, 1980; McCarron et al, 1983; Zungri et al, 1990). For example, one series reported a survival advantage at 5 years of 84% with radical nephroureterectomy versus 51% with simple nephrectomy, and 74% versus 37%, respectively, for patients with high-stage tumors (Johansson and Wahlquist, 1979). Unfortunately, the retrospective, uncontrolled nature of all of these reports limits the conclusions that may be drawn from them. In summary, however, radical nephroureterectomy is warranted in patients with high-grade invasive disease that is organ confined (T1-2, N0) or locally advanced (T3-4, N0 or N+). Tumor-specific survival rates are high in patients with

organ-confined disease and are guarded to poor in patients with locally advanced disease.

The precise role of adjuvant chemotherapy in the setting of locally advanced disease has not been defined, given the relatively low number of patients at risk and the absence of clinical trials. Despite this lack of definitive information, most patients with disease invasion outside the muscle layer or positive lymph node metastases are currently considered for adjuvant chemotherapy with drug regimens developed to treat urothelial cancers of the bladder.

The usefulness of regional lymphadenectomy in this disease has not been firmly established. Although it is recommended by many investigators, little therapeutic value has been established, and nearly every patient with positive nodal metastases has developed early systemic metastases (Cummings, 1980; Heney et al, 1981; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). However, regional lymphadenectomy adds little to the time or morbidity of the procedure and may have some therapeutic value. In one series, a 5-year survival of 23% was noted when patients with T3 or T4, N1 or N2 disease had all disease resected (Batata and Grabstald, 1976).

Use of Topical Immunotherapy and Chemotherapy

Topical immunotherapy or chemotherapy can be used successfully to reduce recurrence and definitely treat upper tract urothelial transitional cell cancers. Instillation can be accomplished in several ways, including infusion through a percutaneous tube (the author's preference), retrograde reflux from the bladder with a double-J indwelling stent in place or after iatrogenic creation of ureteral reflux, and instillation through a retrograde catheter. In addition, repeated ureteral catheterization for instillation of agents has also been reported. Low pressure in the upper urinary tract and care to minimize infection are critical to help prevent systemic absorption of the agent and sepsis. In all cases, continued topical exposure of the urothelium over time and with low intrapelvic pressure are the goals. Several agents have successfully been employed, including BCG (Smith et al, 1987; Studer, et al, 1989; Eastham and Huffman, 1993; Sharpe et al, 1993; Jarrett et al, 1995), mitomycin C (Eastham and Huffman 1993; Weston et al, 1993; Martinez-Pineiro et al, 1996; Keeley et al, 1997a), doxorubicin (See, 2000), and thiotepa (Elliott et al, 1996; Patel et al, 1996). Most investigators have reported satisfactory results with these drugs, but no series has been large enough to show statistically improved survival or decreased recurrence rate. The most common complication reported is sepsis; however, granulomatous involvement of the kidney and systemic signs of BCG infection have also been reported (Bellman et al, 1994).

The agent most commonly employed for treatment or adjuvant therapy is BCG (Table 48–5). Complete resection or destruction of existing tumors has been employed in most cases, but in some, the agent has been used in the presence of incompletely resected lesions.

Table 48–5. Percutaneous BCG Instillation

Author	No. of Patients	No. of Renal Units	Recurrence (%)	DOD (%)	Mean Follow-up (months)
Thalmann et al (2002)	37	41	49	38	42

Jarrett et al (1995)	30	—	33	—	55

DOD, dead of disease.

Chemotherapy for Advanced Disease

Upper tract transitional cell cancers, like bladder cancers, are relatively chemosensitive, with reasonable response rates reported. Because of the relative low frequency of these tumors, however, few clinical trials have been performed, and much of what is the basis for our treatments comes from the experience with bladder cancer trials. Because single-agent chemotherapy with cisplatin, methotrexate, cyclophosphamide, or gemcitabine has yielded response rates only in the 25% to 35% range, combination therapies have commonly employed MVAC (methotrexate, vinblastine, doxorubicin, cisplatin) or combinations of gemcitabine and taxanes.

KEY POINTS: DIAGNOSIS AND TREATMENT OF UPPER TRACT TUMORS

- CT urography with the administration of contrast material provides more information than does excretory urography.
- Urine cytology for upper tract tumors, although highly sensitive, is of low specificity.
- A combination of radiologic studies, tumor grade, and tumor visualization is most useful in identifying invasive upper tract cancers.
- Nephroureterectomy, by whatever technique, is the gold standard therapy for upper tract cancers, especially for larger, high-grade, and invasive lesions.
- Endoscopic management is most indicated when nephron sparing is an issue and for low-grade, low-stage lesions.

TREATMENT OF METASTATIC DISEASE

The treatment of upper tract urothelial tumors has undergone significant changes. **The relatively low frequency of these lesions and the lack of prospective randomized trials do not permit absolute conclusions about treatment impact on outcomes.** In the past, treatment recommendations were based, at least in part, on practical limitations in follow-up and detection of local disease recurrence. Technologic improvements in imaging and, most important, direct endoscopic visualization of all levels of the urinary tract allow earlier and more accurate initial diagnosis and treatment and improved follow-up. Treatment may be based primarily on the risk the tumor poses and on the efficacy of a specific treatment rather than on other considerations. The specific indications and techniques for each form of treatment (open versus laparoscopic radical nephroureterectomy; open versus retrograde endoscopic versus percutaneous renal-sparing tumor ablation) are addressed later in this chapter. However, the following introductory considerations apply. The least invasive and least ablative treatment necessary for safe control of the tumor is preferred. Most upper tract urothelial tumors are not large or bulky. Thus, laparoscopic surgery is ideal, at least for the renal portion of radical nephroureterectomy when the tumor warrants removal of the entire renal unit (see later). A variety of approaches with various combinations of laparoscopic and open techniques are employed for distal ureterectomy. Low-grade noninvasive upper tract tumors are managed initially by ablative renal-sparing surgery. Retrograde ureteroscopy and ureteropyeloscopy are preferred when tumor size, number, and access allow complete tumor ablation. Percutaneous antegrade tumor ablation is chosen when the anatomy and the tumor do not allow complete ablation through a retrograde approach.

KEY POINT: UPPER TRACT UROTHELIAL TUMORS

- The frequency of urothelial tumors of the upper tract is increasing.

The frequency of urothelial tumors of the upper tract is increasing, even though the tumors represent only a small percentage of all urothelial neoplasms (McCarron et al, 1982; Richie, 1988; Williams, 1991; Herr, 1998; Messing and Catalona, 1998; Munoz and Ellison, 2000). The incidence of ureteral and renal pelvis tumors in the United States from 1985 to 1994 was 0.73 and 1.0 each per 100,000 person-years, respectively, based on the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database (Munoz and Ellison, 2000). The 5-year disease-specific survival was 75% overall and 95%, 88.9%, 62.5%, and 16.5% for in situ, localized, regional, and distant disease, respectively. Several factors account for this increase. Survival of patients with the more prevalent transitional cell carcinoma of the bladder is improved owing to more effective diagnosis and treatment. This produces a length-time bias of longer time at risk for development of upper tract tumors.

The etiology, natural history, pathology, detection, and staging of urothelial tumors are presented in Chapter 75. Only

Percutaneous antegrade tumor ablation is chosen when the anatomy and the tumor do not allow complete ablation through a retrograde approach.

KEY POINT: UPPER TRACT UROTHELIAL TUMORS

- The frequency of urothelial tumors of the upper tract is increasing.

The frequency of urothelial tumors of the upper tract is increasing, even though the tumors represent only a small percentage of all urothelial neoplasms (McCarron et al, 1982; Richie, 1988; Williams, 1991; Herr, 1998; Messing and Catalona, 1998; Munoz and Ellison, 2000). The incidence of ureteral and renal pelvis tumors in the United States from 1985 to 1994 was 0.73 and 1.0 each per 100,000 person-years, respectively, based on the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database (Munoz and Ellison, 2000). The 5-year disease-specific survival was 75% overall and 95%, 88.9%, 62.5%, and 16.5% for in situ, localized, regional, and distant disease, respectively. Several factors account for this increase. Survival of patients with the more prevalent transitional cell carcinoma of the bladder is improved owing to more effective diagnosis and treatment. This produces a length-time bias of longer time at risk for development of upper tract tumors.

The etiology, natural history, pathology, detection, and staging of urothelial tumors are presented in Chapter 75. Only

the features that differentiate upper tract tumors from bladder tumors and that are pertinent to treatment are revisited here. The common symptoms of localized disease (hematuria, dysuria) and of advanced upper tract tumors (weight loss, fatigue, anemia, bone pain) are similar in type and frequency to those of bladder cancer. However, flank pain due to obstruction by tumor or clot is more prevalent in upper tract tumors, having been reported in 10% to 40% of cases (Babaian and Johnson, 1980; McCarron et al, 1983; Richie, 1988; Williams, 1991; Melamed and Reuter, 1993). Flank pain in patients with upper tract tumors does not correlate with either locally advanced tumor stage or worse prognosis, as is the case with bladder cancer.

A filling defect is the most common finding on imaging studies. The impact of hydronephrosis and nonvisualization for renal pelvis tumors versus ureteral tumors as indicators of a higher stage is uncertain. Nonvisualization is reported in 20% of renal pelvis tumors, only 33% of which are invasive (McCarron et al, 1983). Nonvisualization is reported in 37% to 45% of ureteral tumors and carried a 60% risk of invasion in one series (McCarron et al, 1983). In other reports, there is no correlation of nonvisualization and stage (Batata and Grabstald, 1976; Anderstrom et al, 1989). Hydronephrosis with or without an associated filling defect is linked with invasion in 80% of ureteral tumors (McCarron et al, 1983).

The histologic characteristics and biology of upper tract tumors still affect treatment decisions, technologic improvements notwithstanding. The entity of benign papilloma, which responds favorably regardless of the extent of treatment, is well described in older series of upper tract tumors (Bloom et al, 1970; Batata and Grabstald, 1976). The existence of similar low-grade papillomas of low-grade malignant potential in the bladder remains controversial (Cheng et al, 1999; Cheng and Bostwick, 2000; Oyasu, 2000). It is unclear whether the differences between upper tract papillomas and bladder papillomas are biologic or semantic. **Approximately 85% of renal pelvis tumors are papillary;** the remainder are sessile. This distribution is similar to that of bladder tumors. However, the stage of upper tract tumors is T1 or T2 in approximately 50% of papillary and 80% of sessile lesions, respectively (Cummings, 1980; Richie, 1988; Williams, 1991). Thus, 50% to 60% of renal pelvis tumors are invasive, in contrast to most bladder tumors, which are noninvasive; 55% to 75% of ureteral tumors are low grade and low stage, but invasion is still more common than among bladder tumors (Anderstrom et al, 1989; Williams, 1991). Patients with upper tract tumors present most often in the sixth or seventh decade of life and thus are generally older than patients with bladder tumors (Melamed and Reuter, 1993).

Tumors of the renal pelvis are slightly more common than ureteral tumors (Batata and Grabstald, 1976; Richie, 1988; Maulard-Durdux et al, 1996). Ureteral tumors occur in the distal, middle, and proximal segments in 70%, 25%, and 5% of cases, respectively (Babaian and Johnson, 1980; Anderstrom et al, 1989; Williams, 1991; Messing and Catalona, 1998). **After conservative treatment, ipsilateral upper tract tumor recurrence is common in a proximal to distal direction and is seen in 33% to 55% of cases** (Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983). Recurrence proximal to the original lesion is rare.

KEY POINT: UPPER TRACT TUMOR RECURRENCE

- Multiple upper tract recurrences are common, in a proximal to distal direction.

This high rate of ipsilateral recurrence is due in part to a multifocal field change, which is even more pronounced than in bladder cancer. Areas of atypia, dysplasia, or carcinoma in situ are reported in 60% to 95% of specimens after nephroureterectomy for renal pelvis tumor (Johansson et al, 1976; Kakizoe et al, 1980; Heney et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Melamed and Reuter, 1993). Molecular techniques demonstrate that downward seeding of tumor accounts for some recurrences (Harris and Neal, 1992). Tumor multifocality does not lessen survival of patients independent of stage (Messing and Catalona, 1998).

The occurrence of bladder tumors after upper tract tumors, and vice versa, is another expression of the field change, multifocal risk that affects initial treatment decisions. Carcinoma in situ is present in the distal ureter at the time of cystectomy in 7% to 25% of cases (Melamed and Reuter, 1993; Solsona et al, 1997; Herr, 1998); 15% to 50% of all cases of upper tract tumor occur in patients with a history of bladder tumor (Batata and Grabstald, 1976; Babaian and Johnson, 1980). The incidence of upper tract tumor after bladder tumor is 2% to 4% with a mean time to occurrence of 70 months (Shinka et al, 1988; Oldbring et al, 1989; Melamed and Reuter, 1993; Herr et al, 1996). Upper tract tumors are reported in 3% to 9% of patients after cystectomy for bladder cancer in older series (Zincke and Neves, 1984; Mufti et al, 1988).

Particular insight into the contemporary risk for upper tract tumor after treatment of bladder cancer is provided in several large series (Solsona et al, 1997; Herr, 1998; Rabbani et al, 2001; Mullerad et al, 2004; Sved et al, 2004). Herr found that among 307 patients with bladder tumor followed up for a median of 12 years, there was an overall incidence of upper tract tumors of 23%. The cumulative risks for upper tract tumors were 10%, 26%, and 34% at follow-ups of 5 years, 5 to 10 years, and 15 years, respectively. Upper tract tumors occurred in 26% of another subgroup of 87 patients with bladder tumor followed up for more than 15 years. Delayed upper tract tumors were more common in the ureter than in the renal pelvis and appeared at a median follow-up of 56 months. Median time to delayed ureteral versus renal pelvis tumors was 40 months versus 67 months, respectively. Ureteral tumors occurred in 29% of 66 patients who were successfully treated with intravesical bacille Calmette-Guérin (BCG) for carcinoma in situ. In a subset of 105 patients who underwent cystectomy for BCG-refractory carcinoma in situ, ureteral carcinoma in situ was present in the distal, juxtavesical, and intramural portions of the ureter in 35%, 68%, and 81% of cases, respectively. In a retrospective study from the same center, treatment outcome in patients with upper tract tumor was worse in patients with a prior history of bladder cancer (superficial or invasive) independent of upper tumor stage (Mullerad et al, 2004). Similarly, Sved and colleagues (2004) reported upper tract tumors in 2% of patients (5 of 235) observed for a mean of 42 months after radical cystectomy for bladder cancer. Upper tract tumor was diagnosed at

a mean follow-up of 39.6 months, because of hematuria in four cases and on routine intravenous urography in the remaining case. Presence of tumor in the prostatic urethra of the cystectomy specimen was the only initial tumor feature that was associated with a higher risk of subsequent upper tract tumor. This may be a predictor of a higher risk of multifocal tumor in such cases. Outcome was poor with disease-related mortality in four of the cases. In contrast, in a review of 91,245 patients with bladder cancer from the SEER database for 1973 to 1996, upper tract tumor occurred in 657 patients (0.7%) at a median follow-up of 4.1 years (Rabbani et al, 2001). These patients had lower tumor stage and improved disease-specific survival than did patients with primary upper tract tumors.

Solsona and colleagues (1997) reported that carcinoma in situ was present in the distal ureter in 25% of 138 cystectomies performed for bladder carcinoma in situ, compared with only 2.3% and 2.9% among 786 and 179 cases of stage Ta to T1 versus stage T2 disease, respectively. This may indicate that bladder carcinoma in situ carries a higher risk of multifocal disease than do other forms of bladder tumor.

The incidence of bladder tumor after treatment of upper tract tumor is 20% to 75% (Batata and Grabstald, 1976; Kakizoe et al, 1980; Nocks et al, 1982; Huben et al, 1988; Anderstrom et al, 1989; Williams, 1991; Melamed and Reuter, 1993; Kang et al, 2003; Matsui et al, 2005). Bladder tumor after upper tract tumor occurs earlier than the reverse, at a median of 21 months versus 86 months afterward, respectively. Both bladder tumor and contralateral upper tract tumor after initial unilateral upper tract tumor are examples of the multifocal nature of urothelial tumor. In one study, subsequent bladder tumors appeared earlier than did contralateral upper tract tumors (Kang et al, 2003). Renal insufficiency was associated with a higher risk of contralateral upper tract tumor.

The occurrence of bladder tumor after treatment of upper tract tumor may be due to a field effect, distal tumor seeding, or both. Association of a higher bladder tumor incidence after upper tract tumor multiplicity supports a role of distal seeding (Matsui et al, 2005). However, reports of distinct tumor clones by microsatellite analysis support a field effect (Takahashi et al, 2001). The paradoxical finding that the risk of subsequent bladder tumor is inversely related to upper tract tumor size and stage may reflect a higher and earlier risk of death from the primary tumor in these cases.

Two particular forms of upper tract urothelial tumor, those seen in Balkan nephropathy and those seen in association with analgesic abuse, have an even higher tendency to multiple and bilateral recurrences than do sporadic tumors (Markovic, 1972; Petkovic, 1975; Mahoney et al, 1977; Johansson and Wahlquist, 1979; Melamed and Reuter, 1993; Stewart et al, 1999). The typically low-grade nature of the tumors and the frequent renal insufficiency seen in Balkan nephropathy underscore the importance of conservative treatment when possible. The degree of scarring of renal papillae seen in phenacetin abuse correlates in a dose-dependent manner with the risk of high tumor grade and progression. Calcification of renal papillae after analgesic abuse is associated with development of squamous carcinoma of the renal pelvis (Stewart et al, 1999).

The staging of upper tract tumors parallels the staging of bladder tumors as presented in Chapter 75. There is a strong correlation of grade and stage for upper tract tumors (Table 49–1). **The single most important determinant of outcome is tumor stage** (Table 49–2) (Bloom et al, 1970; Grabstald et al, 1971; Batata et al, 1975; Wagle et al, 1975; Babaian and Johnson, 1980; Cummings, 1980; McCarron et al, 1983; Huben et al, 1988; Anderstrom et al, 1989; Guinan et al, 1992b; Terrell et al, 1995; Messing and Catalona, 1998). The evolving understanding of molecular predictors of behavior for upper tract urothelial cancer parallels that for bladder cancer. In a recent publication, decreased p63 immunoreactivity and p53 overexpression in upper tract tumors were significantly associated with advanced tumor stage and poor prognosis (Zigeuner et al, 2004). However, these findings were not independent of stage and grade in multivariate analysis.

KEY POINTS: STAGING OF UPPER TRACT TUMORS

- Staging of upper tract tumors parallels that of bladder cancer.
- Stage is the most important determinant of outcome.

The primary tumor characteristics that suggest invasion, the high incidence of ipsilateral multifocal abnormality, and the risk of recurrence distal to the primary lesion are all offered in support of radical excision of large, proximal, and likely invasive tumors of the upper tract. Conversely, the same risks of multiple recurrence and the fact that tumor stage is the main determinant of outcome support conservative nephron-sparing surgery in many cases.

Upper tract tumors spread in the same ways as bladder tumors do, through lymphatic and hematogenous routes and by direct extension into contiguous structures. Thus, **the common metastatic sites are the lungs, liver, bones, and regional lymph nodes.** Preoperative evaluation for the extent of disease includes chest radiography, abdominal computed tomography, liver function tests, and occasional bone scan. The thin muscle layer of the renal pelvis and ureter may allow earlier penetration of invasive upper tract tumors than is seen in bladder neoplasms (Cummings, 1980; Richie, 1988). However, this is not a valid reason for radical versus conservative treatment if a lesion is either noninvasive or invasive and organ confined (stage T2) (Gittes, 1980). The renal parenchyma may be a barrier, slowing distant spread of stage T3 renal pelvis tumors. In contrast, periureteral tumor extension carries a high risk of early tumor dissemination along the periureteral vascular and lymphatic supply. Improved survival of patients with stage T3 renal pelvis tumors versus ureteral tumors has been reported by several investigators (Batata and Grabstald, 1976; Guinan et al, 1992a; Park et al, 2004). Guinan and colleagues confirmed this observation among 611 patients treated at 97 hospitals and in a collection of 250 cases reported in the literature (Guinan et al, 1992a). The 5-year survival rates for patients with stage T3 tumors of the renal pelvis and ureter were 54% and 24%, respectively. In a multivariate analysis, patients with ureteral tumors had a higher local and distant failure rate than did those with renal pelvis tumors of the same stage and grade (Park et al, 2004). Renal pelvis and upper ureteral tumors spread initially to para-aortic and paracaval nodes, whereas distal ureteral tumors spread to pelvic nodes (Batata et al, 1975; Heney et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Mahadevia et al, 1983; Jitsukawa et al, 1985; Geiger et al, 1986).

OPEN NEPHRON-SPARING SURGERY FOR RENAL PELVIS TUMORS: PYELOTOMY AND TUMOR ABLATION AND PARTIAL NEPHRECTOMY

Indications

Open conservative surgery may be applied in selected cases when nephron sparing for preservation of renal function is required (Gittes, 1966, 1980; Petkovic, 1972a, 1972b; Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Cummings, 1980; Wallace et al, 1981; Tomera et al, 1982; McCarron et al, 1983; Zincke and Neves, 1984; Bazeed et al, 1986; Ziegelbaum et al, 1987; Messing and Catalona, 1998). Tumor in a solitary kidney, synchronous bilateral tumors, and predisposition to form multiple recurrences, as in endemic Balkan nephropathy, are all reasons to consider nephron sparing (Fig. 49–1). Pyeloscopy as an initial diagnostic component to open conservative surgery has been supplanted by retrograde or percutaneous antegrade renal endoscopy (Huffman et al, 1985). Direct endoscopic visualization of the lesion and biopsy with cup forceps or brush establish a definitive diagnosis and tumor grade (Gill et al, 1973). The brush biopsy has renewed value because tissue obtained by small cup biopsy forceps used through narrow-caliber flexible endoscopes is limited. Preoperative determination of the stage of renal pelvis tumors remains difficult. Large size, broad base, and nonpapillary pattern favor tumor invasiveness. These improvements in initial diagnosis and assessment of tumor stage and grade allow more specific treatment, including conservative surgery when it is indicated.

The documented risk of wound implantation by tumor is low after open conservative surgery if simple precautions are followed to minimize spillage (Gittes, 1980; Tomera et al, 1982; McCarron et al, 1983). Modern percutaneous antegrade renal surgery allows resection of virtually any lesion formerly treated by open pyeloscopy, and the risk of tumor spillage is even lower (see following discussion).

Technique

Preoperative arteriography is not routinely obtained. However, it may be helpful before partial nephrectomy of rare hypervascular renal pelvis tumors. The affected segmental renal artery may be embolized or more easily identified at the time of surgery on the basis of the arteriogram.

The patient is placed in either a full flank or a torque position, as shown in Chapter 50. The full flank position provides optimal exposure to the renal pelvis for pyelotomy and excision of a large noninvasive tumor. The torque position allows both anterior and posterior exposure to the renal pedicle for partial nephrectomy. An extrapleural, extraperitoneal flank, or thoracoabdominal incision is made. Removal of a portion of the 11th or 12th rib provides maximal exposure to the kidney and aids in mobilization of the upper pole and in gaining

access to the renal vessels. Removal of a rib is especially helpful in obese patients or in those with a high kidney. An incision off the tip of the 12th rib suffices in thin patients with a low kidney and is accompanied by less potential wound discomfort or morbidity. After the incision is completed, Gerota's fascia is opened posteriorly, and the entire kidney is mobilized. The renal vessels and the ureter are each isolated with a vessel loop.

The wound is packed with dry sponges to isolate the kidney before any intrarenal incisions are made. For pyelotomy and tumor excision, the renal pelvis and the major calyceal infundibula are exposed by dissecting the hilar and renal sinus fat as for an extended pyelolithotomy. A gentle curvilinear incision is made in the renal pelvis, and the tumor is excised; the base is cauterized with electrocautery, laser, or argon beam coagulator. Finally, the pelvis is closed with 4-0 chromic catgut or other absorbable suture.

The techniques of partial nephrectomy for renal pelvis tumors are essentially the same as those described in Chapter 50, with the added proviso of taking care to minimize the risk of tumor spillage. The involved segment of the intrarenal collecting system is clamped before removal of the tumor-bearing portion of the kidney is begun. The collecting system of the renal remnant is closed with absorbable 4-0 suture. Identified individual bleeding points are oversewn with 4-0 vascular Prolene or polydioxanone suture. Additional hemostasis is provided by use of electrocautery and the argon beam coagulator on the raw parenchymal surface. The edges of the renal defect and the adjoining renal capsule are approximated over Surgicel bolsters with 2-0 chromic catgut suture.

A suction drain is placed in the renal bed in all cases. A temporary urinary diversion stent is not used routinely unless difficulty is encountered in closing the collecting system.

Results

The reported overall risk of tumor recurrence in the ipsilateral renal pelvis after initial pyelotomy or partial nephrectomy varies from 7% to 60% (Mazeman, 1976; Murphy et al, 1980, 1981; Wallace et al, 1981; McCarron et al, 1983; Zincke and Neves, 1984; Ziegelbaum et al, 1987; Messing and Catalona, 1998). The risk of recurrence after conservative surgery increases with tumor stage from less than 10% for grade 1 to 28% to 60% for grades 2 and 3. The moderate to high risk of recurrence primarily reflects the inherent multifocal atypia and field change of the renal pelvis (Heney et al, 1981; Nocks et al, 1982; Mahadevia et al, 1983; McCarron et al, 1983). The possibility of incomplete initial treatment of the primary tumor cannot be totally excluded.

Estimates of overall and cancer-specific survival after conservative surgery of renal pelvis tumors are hampered by the lack of prospective, controlled, randomized trials and the small numbers of affected patients. The inherent bias introduced by selection of patients for conservative treatment based on medical comorbidities is another variable. Murphy reported 5-year survival of 75% and 2-year survival of 46% after conservative surgery in patients with grade 1 and grade 2 renal pelvis tumors, respectively (Murphy et al, 1980). McCarron and associates reported rates of cures, cancer-related deaths, and deaths due to unrelated causes of 33% each in nine patients who underwent conservative surgery (McCarron et al, 1983). **Radical nephroureterectomy and dialysis still offer the best chance of cure and survival in patients with a large, invasive, high-grade, organ-confined renal pelvis tumor (T2, N0, M0) in a solitary kidney** (Gittes, 1980; McCarron et al, 1983).

OPEN RADICAL NEPHROURETERECTOMY

Indications

Radical nephroureterectomy with excision of a bladder cuff is recommended for large, high-grade, invasive tumors of the renal pelvis and proximal ureter (Batata and Grabstald, 1976; Skinner, 1978; Babaian and Johnson, 1980; Cummings, 1980; Murphy et al, 1981; Nocks et al, 1982; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). Radical surgery also retains a role in treatment of medium-grade, noninvasive tumors of the renal pelvis and upper ureter when they are large, multifocal, or rapidly recurring despite maximal efforts at conservative surgery.

KEY POINT: INDICATIONS FOR RADICAL NEPHROURETERECTOMY

- The treatment of large, invasive tumors of the renal pelvis and proximal ureter is radical nephroureterectomy with removal of a bladder cuff.

Technique

Choice of Incision

Radical nephroureterectomy may be performed through a variety of approaches. The choice of incision is largely one of the surgeon's preference and is based on the surgeon's experience, the patient's body habitus and medical comorbidities, and the size of the kidney. The operation may be performed through one incision with the patient placed in a flank torque position as shown in Chapter 50 and as described in the section on open nephron-sparing surgery (Fig. 49–2). In male patients, the genitalia are included in the surgical field so that the bladder catheter may be accessed during the procedure. An extrapleural, extraperitoneal, thoracoabdominal incision is begun over the 11th or 12th rib or off the tip of the 12th rib as described earlier. In contrast to the incision for partial nephrectomy, for which adequate exposure to the kidney is the primary concern, the lower ureter and the bladder must also be exposed for nephroureterectomy. Thus, the middle and anterior portions of the skin incision angle down toward the pelvis rather than in a subcostal direction (see Fig. 49–2). The peritoneum may be opened at any time to increase exposure as necessary. The thoracoabdominal approach offers the best exposure to the kidney but may cause a greater degree of postoperative atelectasis than the anterior subcostal approach. This may be an important consideration in patients with chronic lung disease.

The operation may also be performed through a single long midline incision and intraperitoneal exposure. However, exposure to the kidney is limited from this approach, particularly for left-sided tumors.

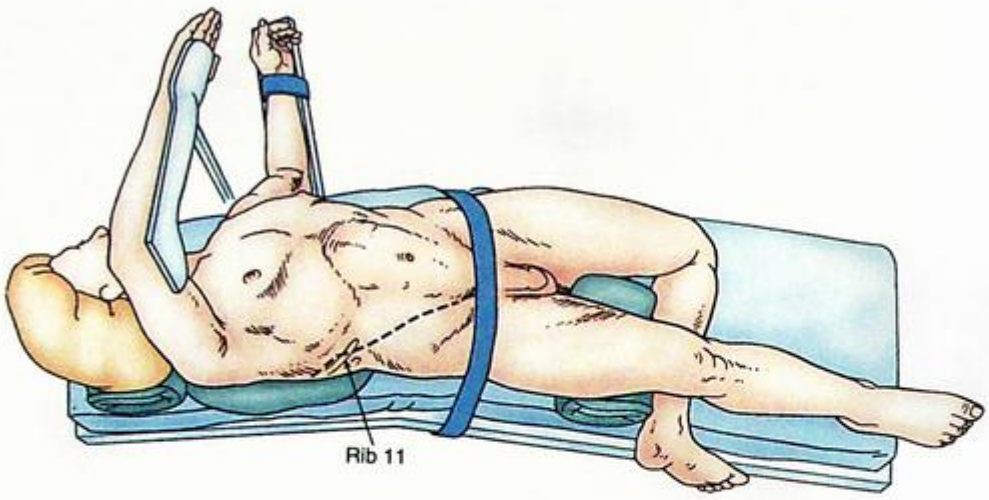

Figure 49–2. Patient in torque flank position for radical nephroureterectomy through a single thoracoabdominal incision. The shoulder girdle is rotated into a full flank position. The pelvic girdle is rolled back nearly to a supine position. All potential pressure points are carefully padded.

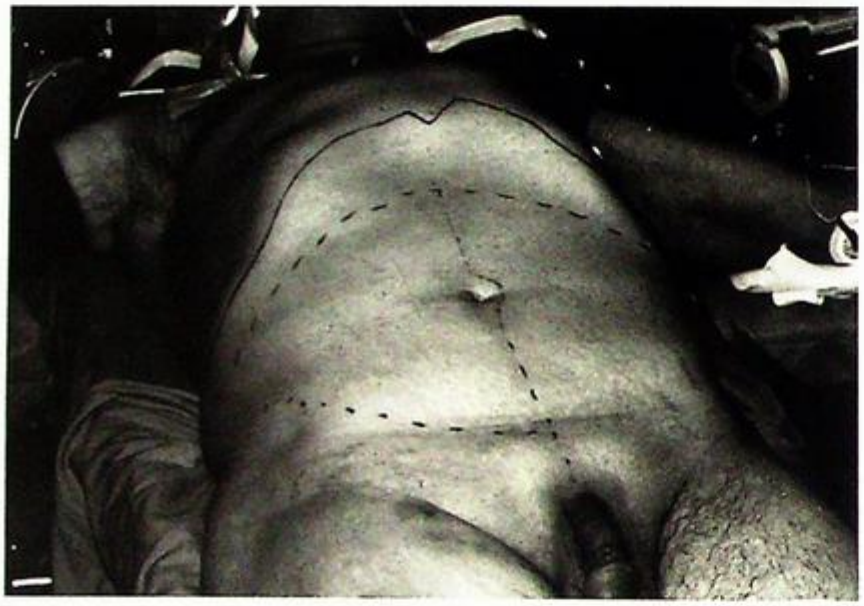

Figure 49–3. Radical nephroureterectomy may be performed through a long midline incision or through a subcostal plus Gibson, lower midline, or Pfannenstiel incision. The patient is supine, and the table is mildly flexed. Placement of a small roll under the edge of the rib cage is helpful. (From Sagalowsky AI: Renal transplantation and autotransplantation. In Marshall F, ed: The Textbook of Operative Urology. Philadelphia, WB Saunders, 1996:320-330.)

Alternatively, the patient may be positioned supine with a small roll placed behind the rib cage on the affected side. The nephroureterectomy is performed through an upper anterior subcostal incision and a lower quadrant Gibson incision as for renal transplantation. A lower midline or Pfannenstiel incision may be substituted (Fig. 49–3). A lower midline incision avoids dividing muscles, is fast, and provides direct exposure to the prevesical space. However, a Gibson incision provides easier exposure to the distal ureter. Nephrectomy may be difficult from an anterior subcostal approach in obese patients.

Radical Nephrectomy

The entire kidney, along with all the perinephric fat and Gerota's fascia, is fully mobilized (Figs. 49–4 and 49–5). The renal vessels are dissected and individually secured and divided in a standard manner. The authors prefer at least one 0 silk tie and 4-0 vascular Prolene suture ligature on an RB needle for each renal artery and renal vein. Combinations of ties plus large hemoclips may be substituted for the suture ligature. The adrenal is a not-infrequent site of metastasis for urothelial tumor. Traditionally, the ipsilateral adrenal gland has been included with the specimen. However, as in the case of renal cell carcinoma, **adrenalectomy adds little to the cure for upper tract tumors.** One may omit adrenalectomy if the gland appears normal on preoperative imaging studies and is grossly normal at the time of surgery and if the disease seems localized within the renal pelvis. However, adrenalectomy is prudent for maximal control if locally advanced disease is discovered.

Distal Ureterectomy

Complete distal ureterectomy with a bladder cuff is necessary with nephroureterectomy and represents a distinct portion of the case, whether an open or laparoscopic approach to the kidney is used. General principles include intact complete ureteral excision with controlled occlusion of the ureteral orifice. **The entire distal ureter, including the intramural portion and the ureteral orifice, is removed.** Failure to completely remove the entire distal ureter and ureteral orifice is associated with a high rate of tumor recurrence. The ureter may be kept in continuity with the kidney to obviate the risk of tumor spillage from the lumen. However, the attached

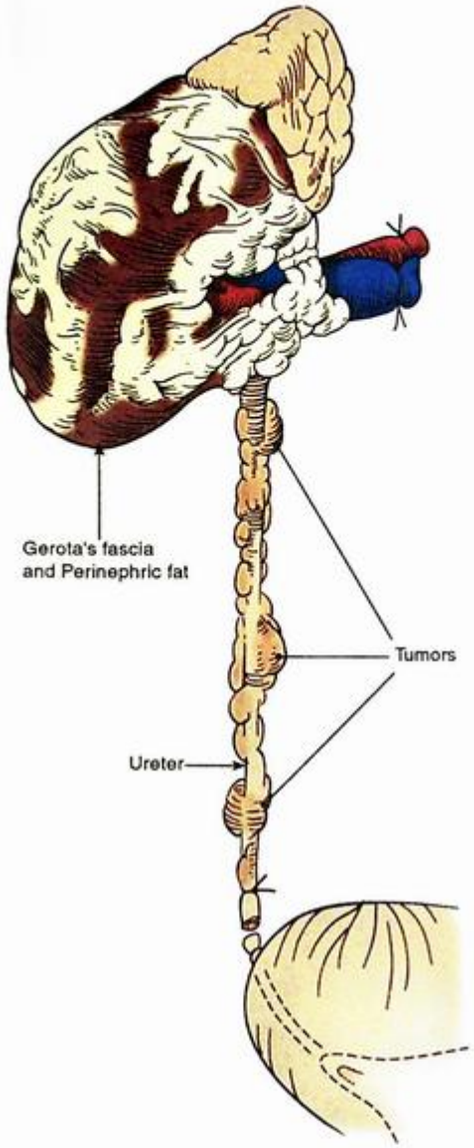

Figure 49–4. Radical nephroureterectomy specimen including the kidney, Gerota's fascia, and perinephric fat, with or without the ipsilateral adrenal gland. Note that the ureter is divided distally in the pelvis between ties for a separate distal ureterectomy.

kidney is cumbersome, and this technique is not necessary as long as the distal ureter is divided between ties or clips at a location that is free of gross abnormality. Following are the options available for management of the distal ureter, whether an open or laparoscopic approach is used. If a laparoscopic approach is chosen, the incision can be placed to facilitate both intact specimen extraction and dissection of the distal ureter. One should keep in mind that transitional cell carcinoma is a tumor that has the potential to seed nonurothelial surfaces, and maintenance of a "closed system" is important, especially with high-grade tumors.

Traditional Open Distal Ureterectomy. This can be done through Gibson, low midline, and Pfannenstiel incisions, depending on the patient's anatomy and the extent of proximal ureteral dissection required. Transvesical, extravesical, and combined approaches have been described. The transvesical approach is the most reliable approach for ensuring complete ureteral excision. An anterior cystotomy may be made and intravesical and extravesical dissection performed as for ureteral neocystostomy (Fig. 49–6); 1 cm of bladder mucosa is included circumferentially around the ureteral orifice. The defect in the bladder wall at the ureteral hiatus is closed in two layers from within the bladder with interrupted 2-0 or 3-0 absorbable suture on the muscle and 4-0 suture on the mucosa. The anterior cystotomy is closed carefully in two layers with running 3-0 absorbable suture. The urethral catheter is maintained for 5 to 7 days; a suprapubic catheter is not routinely used. A flat suction drain is left in the perivesical space.

Complete distal ureterectomy may be performed entirely by extravesical (Fig. 49–7) dissection of the distal ureter and the intramural portion within the bladder wall all the way to the ureteral orifice. The need for a cystotomy is avoided with this approach. The ureter is tented up, and the bladder mucosa is divided between clamps. The defect in the bladder wall is closed in layers as described previously. Care must be taken to ensure a complete dissection of the intramural portion of the ureter and to avoid contralateral injury from excessive traction.

Transurethral Resection of the Ureteral Orifice. This approach, also referred to as the pluck technique, should be reserved for proximal, low-grade tumors (Abercrombie et al, 1988; Palou et al, 2000). The patient is placed in the lithotomy position, and the ureteral orifice and intramural ureter are aggressively resected to the extravesical space (Fig. 49–8). The patient is then positioned for the nephrectomy portion of the procedure, in which dissection must extend down to the perivesical space. The advantage is avoidance of a second incision in performing an open nephroureterectomy. The advantages are less apparent with laparoscopic nephrectomy, in which an incision is necessary for specimen extraction, and this can be used for dissection of the distal ureter. In addition, there is exposure of nonurothelial surfaces, which may predispose to local recurrence, especially with more dysplastic tumor (Jones and Moisey, 1993; Arango et al, 1997).

Intussusception (Stripping) Technique. Several variations of this procedure have been described (McDonald, 1953; Clayman et al, 1983; Roth et al, 1996; Angulo et al, 1998). Basically, a ureteral catheter is placed in the ipsilateral ureter at the beginning of the procedure. The nephrectomy portion of the procedure is carried out, and the ureter is dissected as far distally as possible. The ureter is then ligated and transected with the ureteral catheter secured to the proximal end of the distal ureter (Fig. 49–9). After nephrectomy, the patient is moved to the lithotomy position; the ureter is intussuscepted by traction into the bladder, and a resectoscope is used to excise the bladder cuff and free the ureter from the bladder. Concerns with this technique are presented by Giovansili and associates (2004), who described a failure rate of 18.7% in which there may have been disruption of the ureter and the need for an additional surgical incision.

Transvesical Laparoscopic Ligation and Detachment Technique. This technique most closely mimics the open technique. Before the nephrectomy portion of the procedure, the patient is placed in the low lithotomy position, a ureteral catheter is placed, and two suprapubic 3-mm trocars

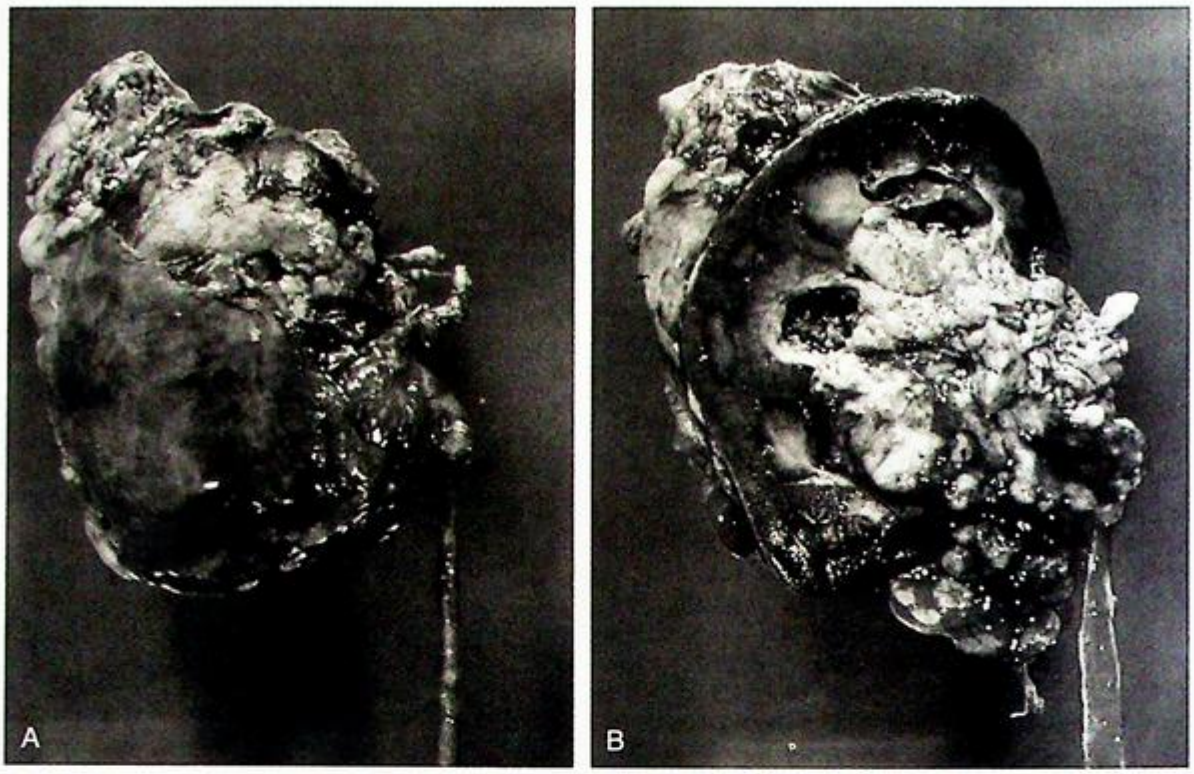

Figure 49–5. **A,** Intact nephroureterectomy specimen for a large renal pelvis tumor. **B,** Bivalved specimen reveals the tumor.

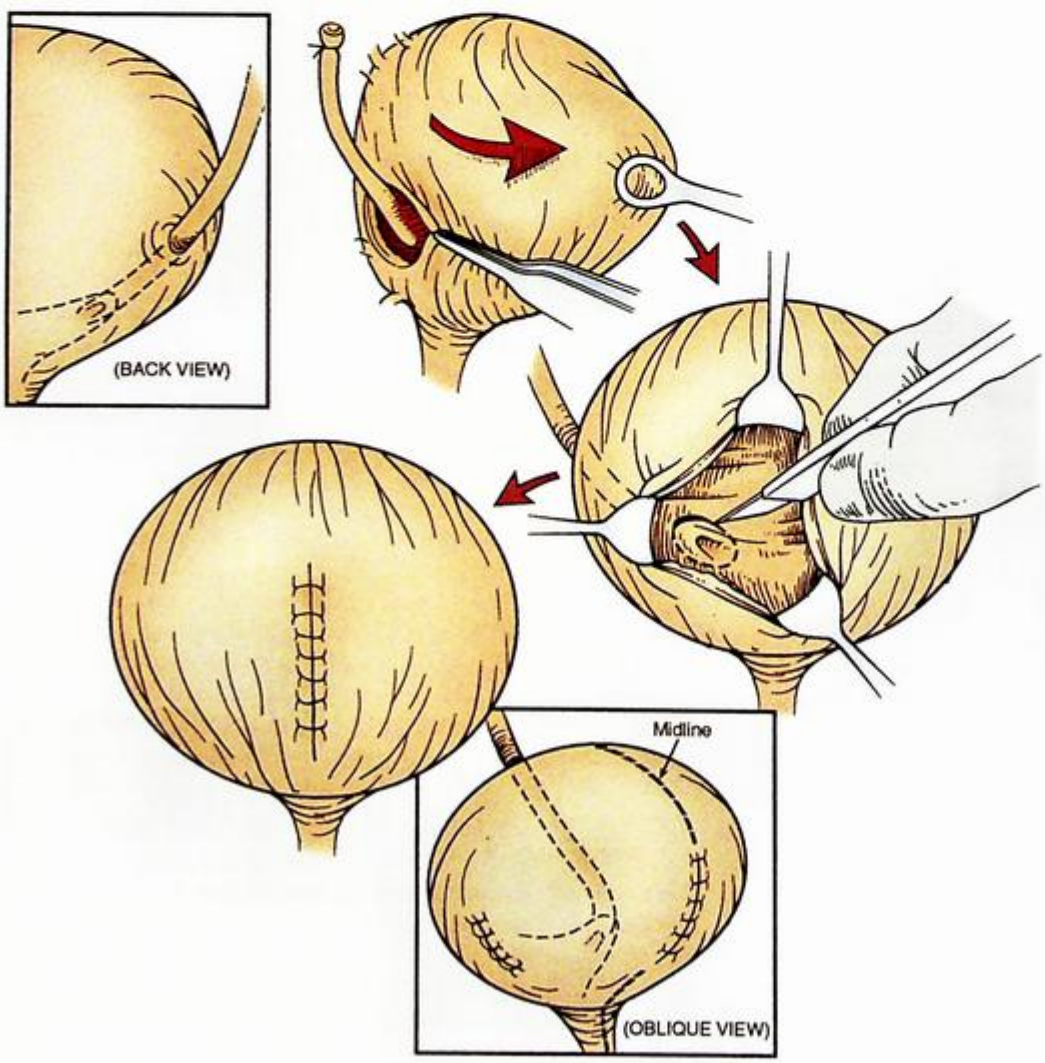

Figure 49–6. Complete distal ureterectomy with bladder cuff is performed by combined extravesical and transvesical dissection.

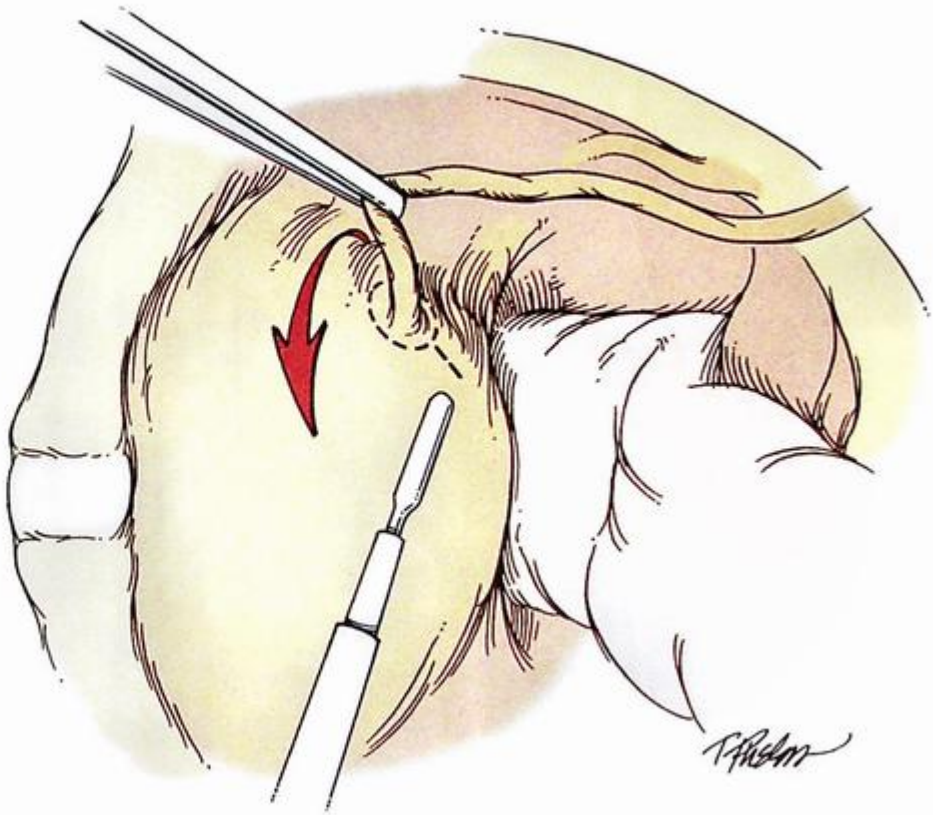

Figure 49–7. Complete distal ureterectomy by extravesical approach. Traction is placed, everting the orifice outside the bladder. Care must be taken to ensure complete removal and to avoid injury to the contralateral ureteral orifice.

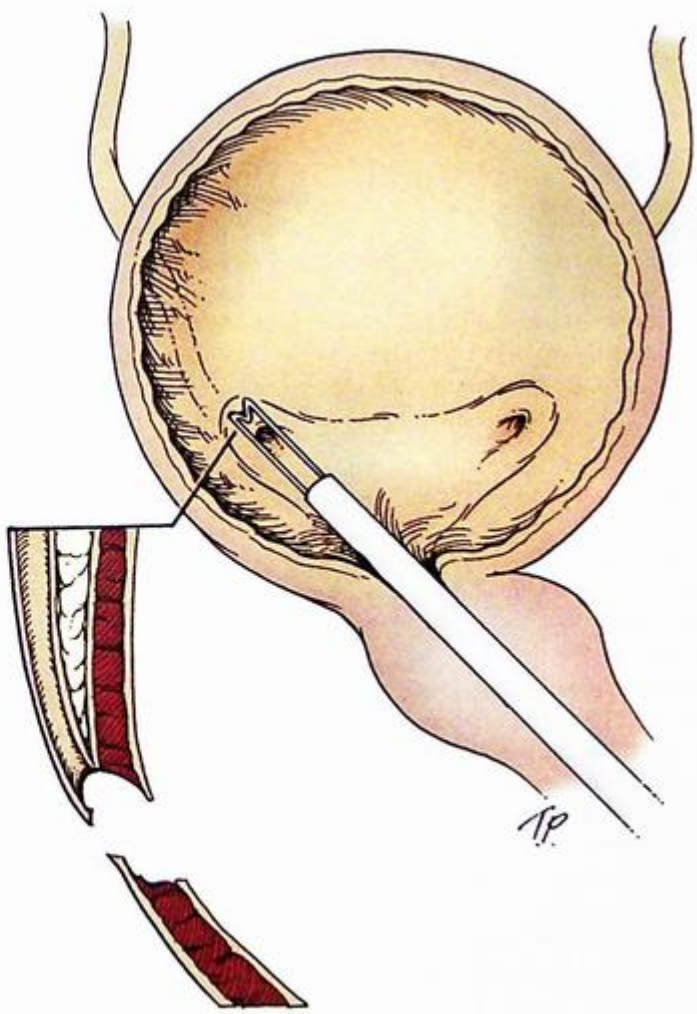

Figure 49–8. The entire orifice and intramural ureter are resected transurethrally until the extravesical fat is seen. This portion is usually done at the beginning but can be done at the end of the procedure.

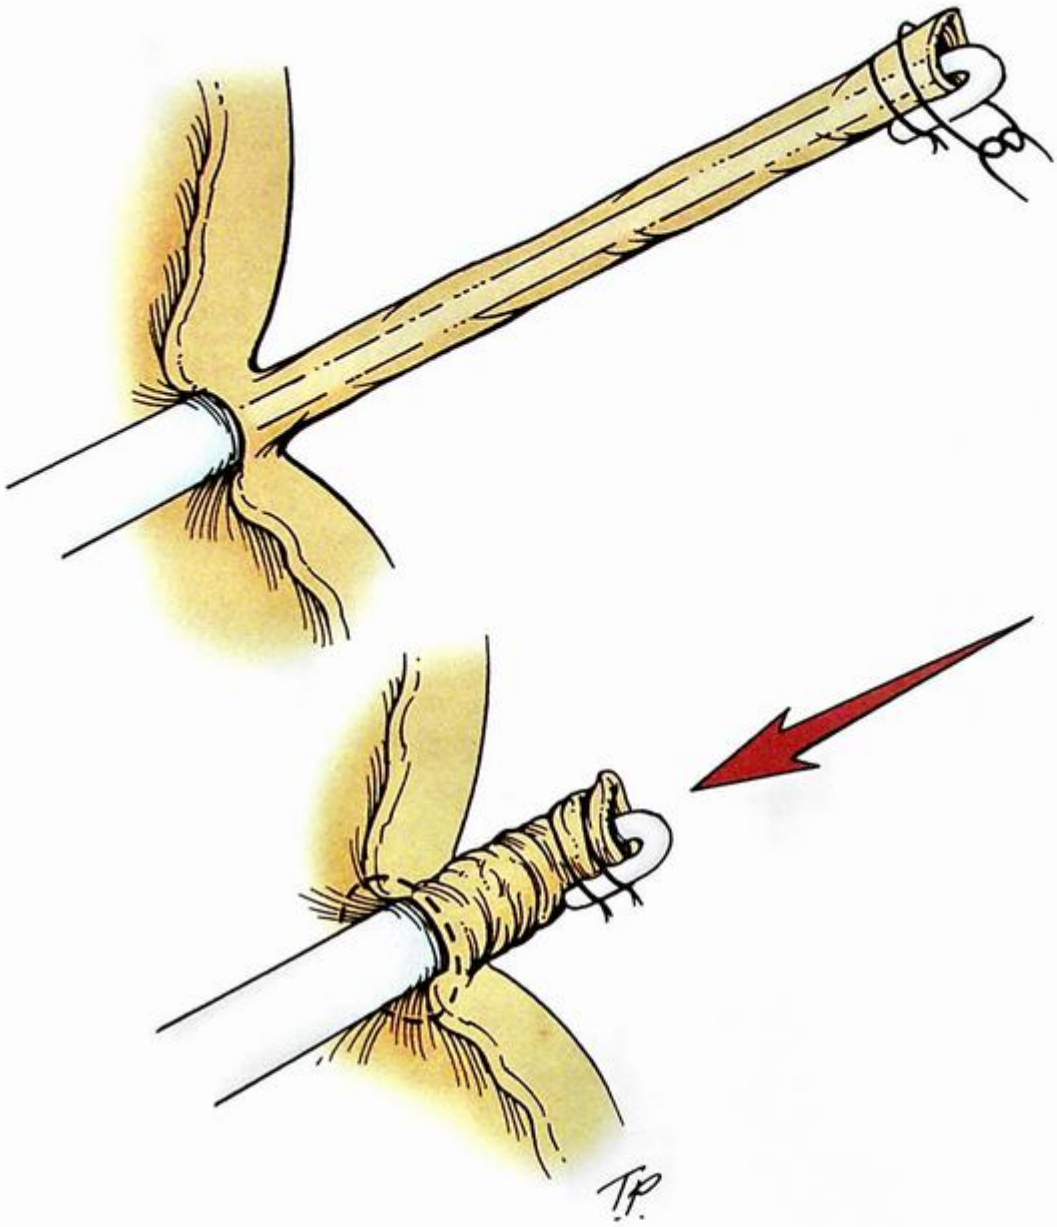

Figure 49–9. With the intussusception technique, a ureteral catheter is placed at the beginning of the case. After nephrectomy, the ureter is divided, and the catheter is secured to the distal portion of the ureter. The patient is moved to the lithotomy position, and the ureter is intussuscepted into the bladder with retrograde traction. A resectoscope is used to excise the attached orifice.

(Fig. 49–10) are placed transvesically. The ureter is tented up, and a loop ligature is placed around the catheter and the orifice, creating a "closed" system. A Collins knife circumscribes the ureteral orifice, and further dissection is facilitated by the grasper, which provides traction until the extravesical space is reached. There has been excellent clinical success reported with this technique (Gill et al, 1999), but it can be technically difficult.

Total Laparoscopic. Flexible cystoscopy is performed before the laparoscopic portion of the case, and a Bugbee electrode is used to cauterize the orifice and intramural ureter completely. Cauterization of the intramural portion of the ureter is important for identification of the distal limits of the dissection during the laparoscopic portion of the procedure. A 20 or 22 French Foley catheter is placed before proceeding to the laparoscopic portion. The nephrectomy and ureteral dissection are carried down to the detrusor muscle. Antegrade traction is placed on the ureter, everting the orifice out of the bladder, and an endovascular stapling device is placed as distally as possible (Fig. 49–11). A flexible cystoscope can be placed at this time if there is any question of the adequacy of the specimen or concern of disturbance of the contralateral ureteral orifice. The endovascular stapling device is then deployed, laying two rows of staples on the bladder and specimen sides. This allows a closed system after division of the ureter.

Lymphadenectomy

Regional lymphadenectomy is included with radical nephroureterectomy. For renal pelvis and proximal or middle ureteral tumors, the ipsilateral renal hilar nodes and the adjacent para-aortic or paracaval nodes are resected. This dissection adds little time or morbidity to the surgery. On occasion, lymphadenectomy is more hazardous in patients with severe atherosclerosis of the aorta or grossly positive and fixed nodes. Node dissection is limited or omitted in these cases.

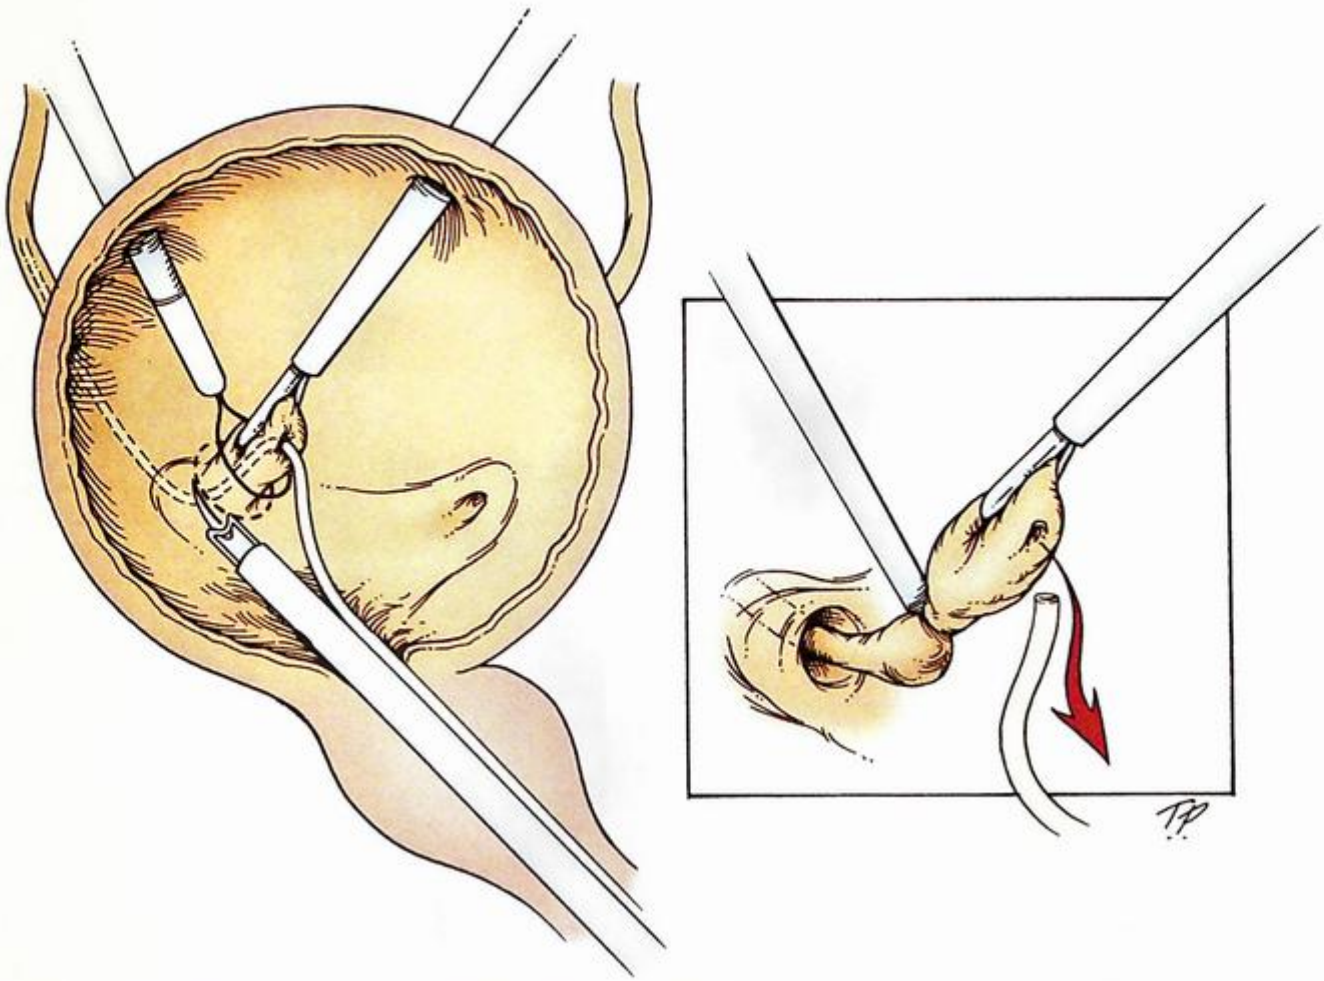

Figure 49–10. A ureteral catheter is placed, and two laparoscopic ports are placed transvesically. The ureteral orifice is tented up; a loop is placed around the orifice to occlude the opening and to place traction on the ureter. A Collins knife then facilitates the dissection to the extravesical space.

KEY POINT: LYMPHADENECTOMY WITH RADICAL NEPHROURETERECTOMY

- Regional lymphadenectomy is included with radical nephroureterectomy.

Results

The outcome strongly correlates with tumor stage and grade as summarized in Table 49–2, compiled from numerous series. The role of complete distal ureterectomy with excision of a bladder cuff in radical nephroureterectomy for upper tract tumors is well established. The risk of tumor recurrence in a remaining ureteral stump is 30% to 75% (Bloom et al, 1970; Strong et al, 1976; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Kakizoe et al, 1980; Mullen and Kovacs, 1980; McCarron et al, 1983). This risk is likely to remain or even to increase as the use of radical nephroureterectomy becomes more selective for patients, mainly those with higher risk tumors. All patients who underwent an extravesical dissection and tenting up of the ureter in the series by Strong and associates retained a portion of the ureter and the ureteral orifice; this demonstrates that the transvesical dissection of the ureter must be thorough to avoid such an error. Complete ureterectomy with a bowel cuff should accompany nephroureterectomy of a renal unit draining into a urinary diversion. Mufti and coworkers (1988) reported a tumor recurrence rate of 37.5% when the ureteroenteric anastomosis was not removed.

The need or benefit of radical nephroureterectomy versus simple nephrectomy or conservative nephron-sparing surgery is less well defined. Radical nephroureterectomy is recommended as providing optimal chance for survival in numerous series (Batata et al, 1975; Johansson and Wahlquist, 1979; Murphy et al, 1980; McCarron et al, 1983; Zungri et al, 1990). Batata and colleagues reported that radical nephroureterectomy provided a 5-year survival rate of 23% among patients with locally advanced disease (stage T3 to T4, N1 to N2). Johansson and Wahlquist reported survival advantage at 5 years for radical versus simple nephrectomy of 84% versus 51%, respectively, and of 74% versus 37%, respectively, for patients with high-stage tumors only. McCarron and associates reported that the subgroup of patients with large, high-grade, but organ-confined disease obtained the most benefit from radical versus conservative surgery. The death rate due

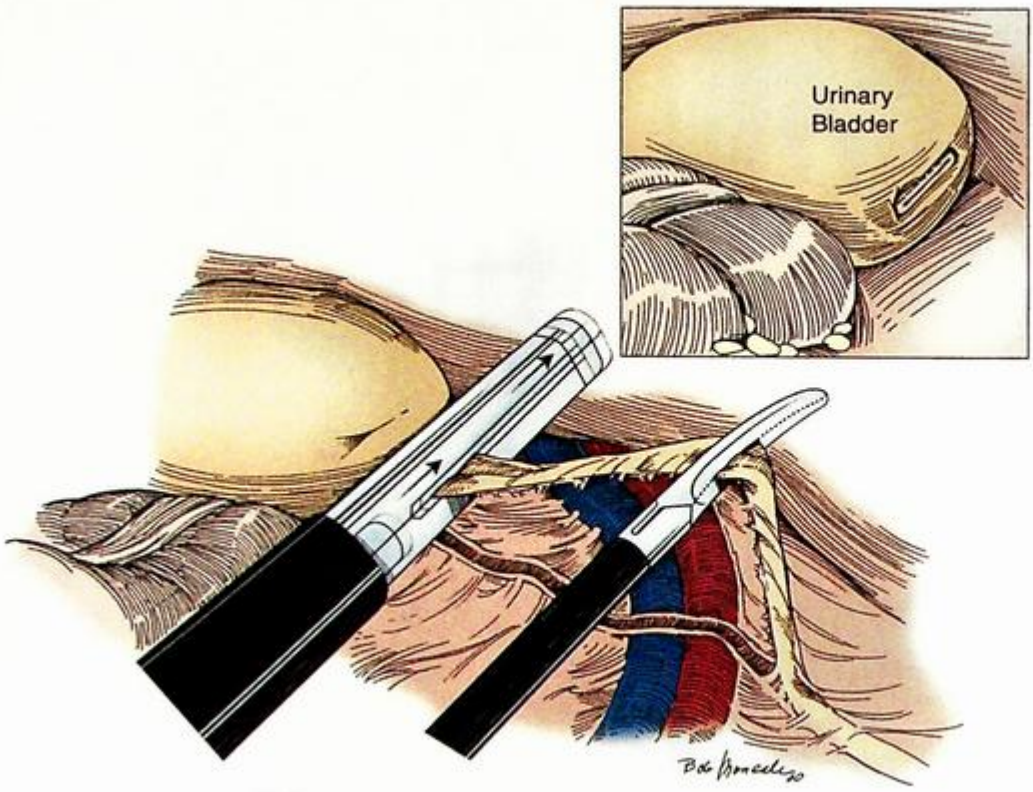

Figure 49–11. The ureter is dissected extravesically to the ureteral orifice. Lateral traction is placed on the ureter, everting the orifice, and the endovascular stapling device is placed at the distal margin, providing simultaneous ligation and division of the distal ureter at the level of the bladder. A cystoscope can be placed to ensure that the entire ureter is removed.

to tumor was 29% versus 89% for the radical and conservative surgery groups, respectively. In the series reported by Murphy, radical surgery conferred a survival advantage over conservative surgery at 5 years of 88% versus 75% for grade 1 tumors and of 90% versus 46% for grade 2 tumors. The retrospective, uncontrolled nature of all these series limits the conclusions that may be drawn. In summary, radical nephroureterectomy is warranted for patients with high-grade invasive disease that is organ confined (stage T1 to T2, N0) or is only locally advanced (stage T3 to T4, N0 to N2, M0). Tumor-free survival rates are high after radical nephroureterectomy for organ-confined disease and are guarded to poor for locally advanced disease. Treatment decisions in patients with compromised renal function must balance the potential beneficial effect of radical surgery on control of the tumor versus the morbidity, mortality, and quality of life risks associated with dialysis.

Regional lymphadenectomy is a recommended accompaniment of radical nephroureterectomy for upper tract tumors in multiple reports (Grabstald et al, 1971; Batata et al, 1975; Batata and Grabstald, 1976; Skinner, 1978; Johansson and Wahlquist, 1979; Babaian and Johnson, 1980; Cummings, 1980; Heney et al, 1981; McCarron et al, 1983; Richie, 1988; Williams, 1991; Messing and Catalona, 1998). However, the authors in nearly every one of these series find little therapeutic value from lymphadenectomy, and almost every patient with node-positive disease develops early distant metastases. **The rationale for continuing regional lymphadenectomy is that it adds little time or morbidity to the surgery, is important for prognosis, and may occasionally have therapeutic value.** In the series by Batata and Grabstald, 5-year survival was seen in 23% of patients with completely resected stage T3 to T4, N1 to N2 disease. Earlier diagnosis in contemporary experience may identify more patients with limited nodal metastases who might benefit from radical surgery. Patients with proven nodal disease are obvious candidates for more careful follow-up and for trials exploring the role of adjuvant therapy.

LAPAROSCOPIC RADICAL NEPHROURETERECTOMY

The indications for laparoscopic nephroureterectomy are the same as those for open nephroureterectomy. Laparoscopic nephroureterectomy can be performed by transperitoneal, retroperitoneal, and hand-assisted approaches. All show a significant decrease in morbidity compared with an open surgical approach for appropriately selected patients. All laparoscopic techniques involve two distinct portions of the procedure, nephrectomy and excision of the distal ureter with intact specimen extraction for accurate staging. Management of the distal ureter is described previously in the chapter. One should bear in mind several factors with laparoscopic nephroureterectomy, including the risk of tumor seeding from both the ureter and the bladder. For these reasons, removal of an intact specimen is desirable. The incision should be strategically placed for both extraction of the specimen and dissection of the distal ureter. Since an incision is necessary regardless of the approach chosen, some techniques for avoidance of a second incision for the distal ureter described previously have less utility.

Technique

Transperitoneal Laparoscopic Nephroureterectomy

Laparoscopic Removal of Kidney Down to Midureter. The patient is placed supine with the ipsilateral hip and shoulder rotated approximately 20 degrees (Fig. 49–12). The patient is secured to the table and can be easily moved from the flank position (nephrectomy portion) to the modified supine position (open portion) by rotating the operative table. The ipsilateral flank and urethra are prepared and draped, and a Foley catheter is placed before insufflation of the abdomen.

Port Insertion and Configuration. The abdomen is insufflated, and three or four trocars are placed as outlined in Figure 49–13, with the first usually being the lateral trocar. Subsequent trocars are placed under direct vision. With this configuration, the camera is kept at the umbilicus for the entire procedure. The upper midline and lateral trocars are used by the surgeon for the dissection of the kidney and the proximal half of the ureter. The lower midline and lateral trocars are used for the dissection of the distal ureter. A 3-mm trocar just below the xiphoid can be helpful in retracting the spleen and liver for left- and right-sided lesions, respectively. The exception is with obese patients, when shifting of the trocars may be necessary to provide optimal visualization (Fig. 49–14).

Mobilization of the Colon. The table is rotated so the patient is in the flank position. The peritoneum is incised along the white line of Toldt from the level of the iliac vessels to the hepatic flexure on the right and to the splenic flexure on the left. The colon is moved medially by releasing the renocolic ligaments while leaving the lateral attachments of Gerota's fascia in place to prevent the kidney from "flopping" medially.

Proximal Ureteronephrectomy. The proximal ureter is identified, just medial to the lower pole of the kidney, and dissected toward the renal pelvis. If an invasive ureteral lesion is suspected, the dissection should include a wide margin of tissue. The renal hilum is identified, and its vessels are carefully exposed with a combination of blunt and sharp dissection. The artery is ligated and divided by use of a gastrointestinal stapling device with a vascular load or

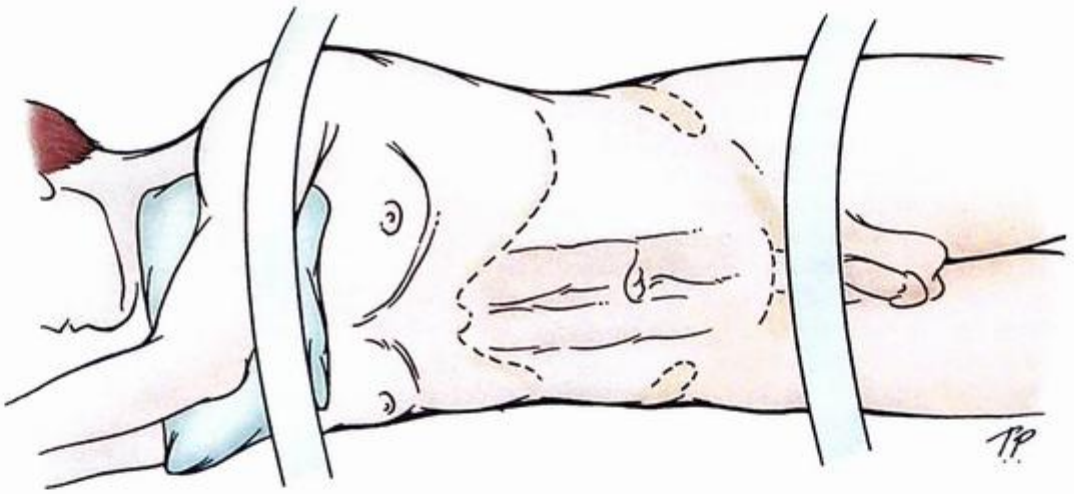

Figure 49–12. The patient is positioned on the table in a modified lateral decubitus position with the ipsilateral flank rotated up 15 degrees. The patient is secured to the table at the chest, waist, and lower extremity. This setup allows the patient to be moved to the full flank or supine position with simple rotation of the operating table. (From Jarrett TW: Laparoscopic nephroureterectomy. In Bishoff JT, Kavoussi LR, eds: Atlas of Laparoscopic Retroperitoneal Surgery. Philadelphia, WB Saunders, 2000:105.)

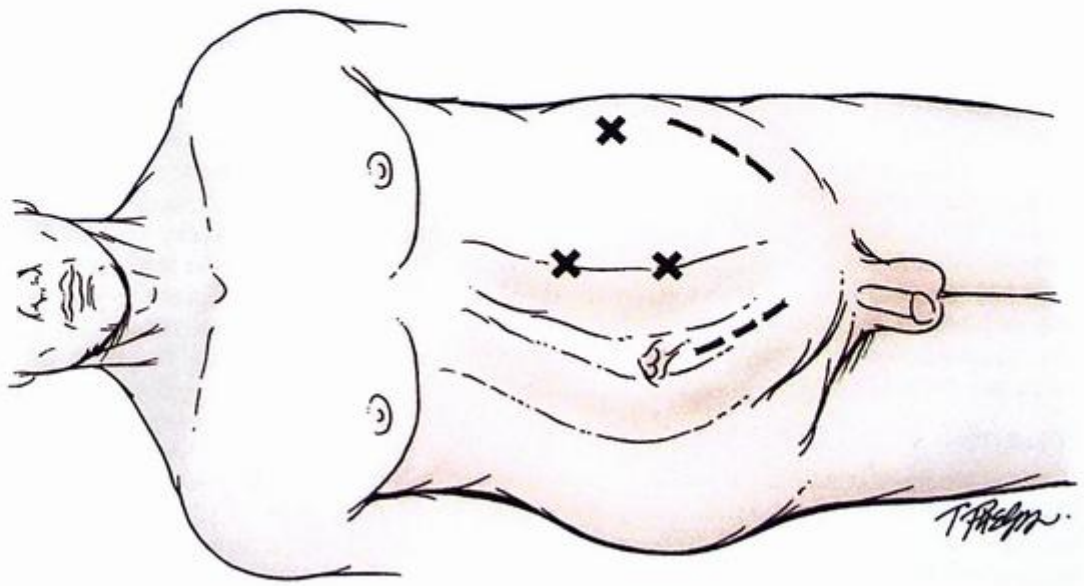

Figure 49–13. Port configuration for laparoscopic-assisted nephroureterectomy. Three ports are generally used for the kidney and upper ureteral dissection. A fourth midline port between the umbilicus and symphysis can be placed, if needed, for further ureteral dissection. The incision is then strategically placed to allow the distal ureteral dissection and specimen removal. The choice of incision largely depends on patient factors and level of dissection reached during the laparoscopic portion of the procedure. A low abdominal (midline or Pfannenstiel) incision is favored if the dissection is below the iliac vessels. A Gibson-type incision will give exposure of the more proximal ureter, if necessary.

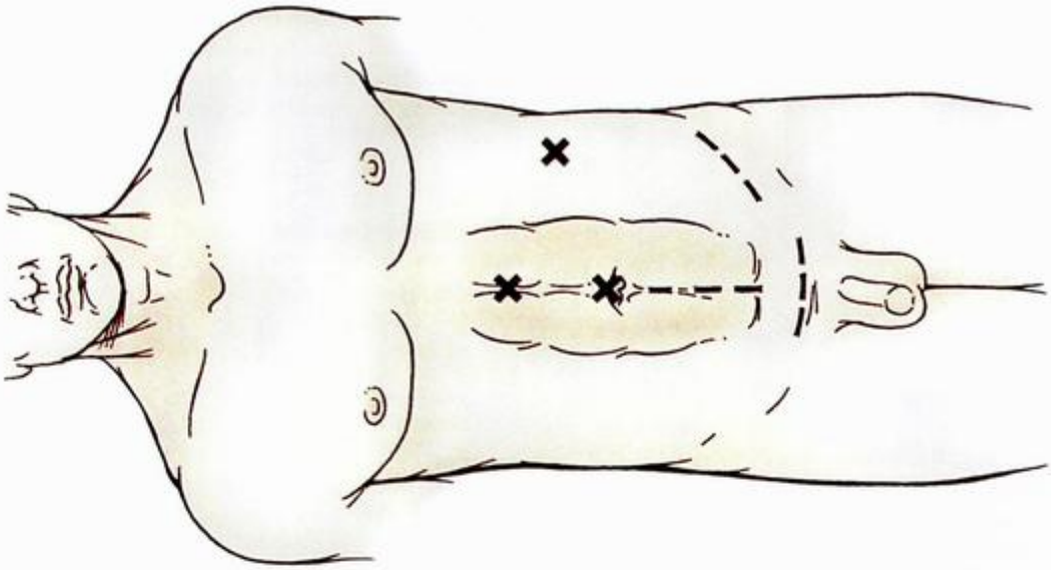

Figure 49–14. For obese patients, the trocars are shifted laterally to accommodate the increased distance from the kidney.

multiple clips. The renal vein is then divided in a similar fashion (Fig. 49–15). With vascular control ensured, the kidney is dissected free, either inside or outside Gerota's fascia, depending on the tumor location and stage. For upper pole lesions thought to invade the parenchyma, the ipsilateral adrenal should be removed.

The ureteral dissection is continued distally, keeping in mind that the ureteral blood supply is generally anteromedially located in the proximal third, medially located in the middle third, and laterally located in the distal third. Dissection of the lower half may require placement of the fourth trocar. In the area of primary disease, surrounding tissue should be left to provide an adequate tumor margin. The ureteral dissection is continued as far as is technically feasible. If the distal limits of the dissection are below the level of the iliac vessels, the remainder of the procedure can easily be completed through a lower abdominal incision. The specimen is placed in the pelvis, and the renal bed is inspected meticulously for bleeding. At this time, the 10-mm port sites are closed before proceeding to the open portion of the case.

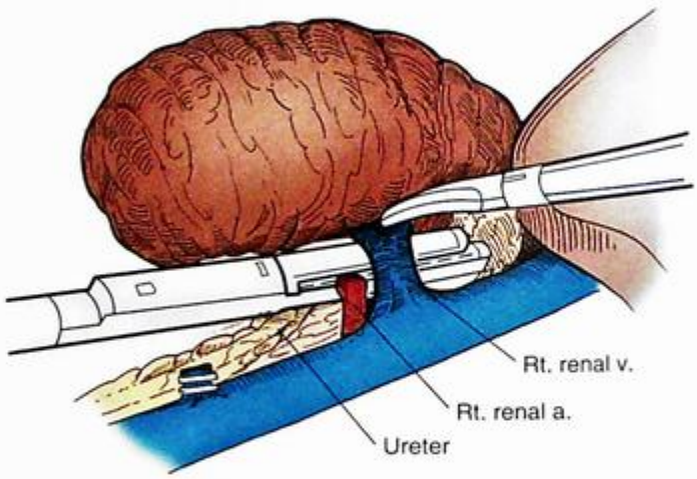

Figure 49–15. The vessels of the renal hilum are carefully dissected, and the endovascular stapling device, with a vascular load, is used to simultaneously ligate and divide the vessels in a controlled environment. (From Jarrett TW: Laparoscopic nephroureterectomy. In Bishoff JT, Kavoussi LR, eds: Atlas of Laparoscopic Retroperitoneal Surgery. Philadelphia, WB Saunders, 2000:112.)

Open Distal Ureterectomy with Excision of Bladder Cuff

The patient is now moved to the supine position, which can usually be done without repreparation, and a low midline Pfannenstiel or Gibson incision is made (see Fig. 49–13). The choice of incision largely depends on the area of disease, the body habitus of the patient, and the most caudal level of ureteral dissection attained during the laparoscopic portion. The Gibson incision is preferable when the distal ureter cannot be freed laparoscopically to the level of the iliac vessels. The open distal ureterectomy is described in the section on open techniques.

Dissection of the Distal Ureter

If one is to consider a total laparoscopic procedure or to minimize the open distal portion, the ureteral dissection needs to continue to the level of the bladder. The patient is placed in the Trendelenburg position to move the bowel contents out of the pelvis. The peritoneal incision is extended from the level of the iliac vessels into the pelvis lateral to the bladder and medial to the medial umbilical ligament (Fig. 49–16). The vas deferens in male patients and the round ligament in female patients is clipped and divided. The ureter can now be traced between the bladder and the medial umbilical ligament down to its origin at the bladder. The bladder cuff may be dissected extravesically, freeing the ureter from the surrounding detrusor muscle.

Results

The first laparoscopic nephroureterectomy was performed in 1991 by Clayman and associates. Since that time, the technical aspects and safety of laparoscopic procedures have been well established. There are multiple published series of

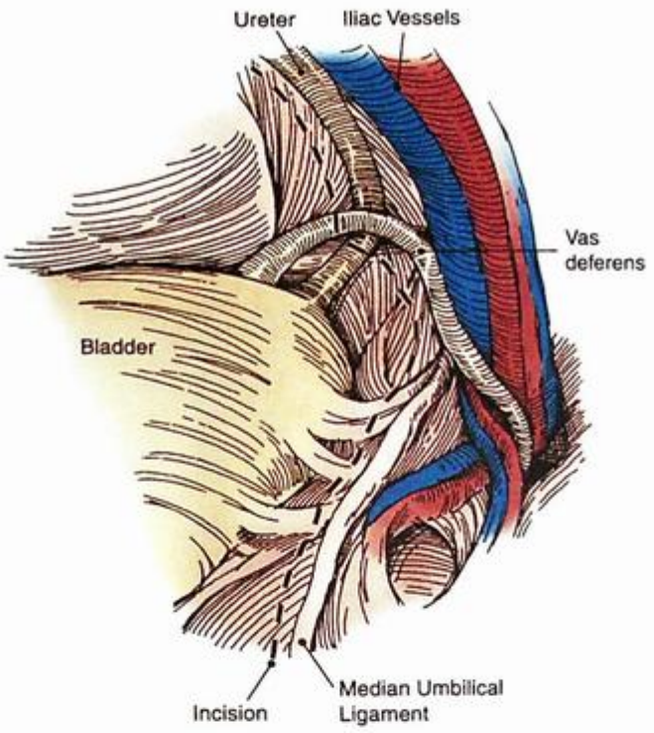

Figure 49–16. The peritoneal incision is continued below the iliac vessels medial to the median umbilical ligament and lateral to the bladder. The vas deferens is divided between clips in the male patient. In the female patient, the round ligament is divided, giving full exposure of the distal ureter to the bladder.

laparoscopic nephroureterectomy (Chung et al, 1996; Keeley and Tolley, 1998; Salomon et al, 1999; Shalhav et al, 2000; Jarrett et al, 2001; Stifleman et al, 2001; Bariol et al, 2004; Hsueh et al, 2004; Matin and Gill, 2005; Wolf et al, 2005). Each varies with regard to approach (transperitoneal versus retroperitoneal), management of the distal ureter by open removal, transurethral resection, and total laparoscopic management. As with other laparoscopic renal procedures, there is no clear-cut benefit of any one approach with regard to morbidity, cosmesis, or return to activity. All, however, show a benefit with regard to morbidity compared with open surgery.

The efficacy of laparoscopic nephroureterectomy is being established for cancer control. With intermediate follow-up, cancer-related outcomes appear comparable to those of the open counterpart. El Fettouh and colleagues (2002), in a multi-institutional study with 116 patients, showed the local and bladder recurrence rates to be 2% and 24%, respectively. The rate of distant metastasis was 9%, and positive margins were seen in 4.5% of cases. This compares favorably with open nephroureterectomy, although longer evaluation is necessary.

Local recurrence and port site seeding are major concerns. There have been five reported instances of port site seeding involving transitional cell carcinoma of the upper urinary tract. Two of these cases were discovered after simple nephrectomy for presumed benign disease in which the principles of surgical oncology were inadvertently not followed (Ahmed et al, 1998; Otani et al, 1999). Three instances were for intended nephroureterectomy for high-grade disease (Ong et al, 2003; Matsui et al, 2004; Barrett, verbal communication, September 1998). Although the potential for seeding exists, it does not appear any higher than that for the open surgical counterpart as long as good surgical principles are followed.

OPEN SEGMENTAL URETERECTOMY

Ureteroureterostomy

Indications

Segmental ureterectomy and ureteroureterostomy are indicated for noninvasive grade 1 and grade 2 tumors of the proximal ureter or midureter that are too large for complete endoscopic ablation and for grade 3 or invasive tumors when nephron sparing for preservation of renal function is a goal.

Technique

The patient is placed in a modified flank position for lesions of the proximal ureter or in a supine position with a roll under the ipsilateral lumbar space for midureteral tumors. An angular extraperitoneal incision from the tip of the 12th rib toward the pelvis provides good exposure to the midureter. The ureter is identified, mobilized, and secured with vessel loops proximally and distally. The approximate location of the lesion is known from preoperative imaging and ureteroscopy. The tumor is palpated, and the ureter is ligated 1 to 2 cm proximal and distal to the tumor (Fig. 49–17*A*). The involved ureteral segment is excised and sent for frozen-section analysis to confirm the diagnosis, grade, and stage and to verify that both ends of the ureter are tumor free. A regional lymphadenectomy is performed. The ureter is repaired by mobilizing both ends to allow a tension-free anastomosis. A defect of up to 4 cm is amenable to ureteroureterostomy in most cases. The entire kidney may be mobilized downward to provide additional length to the proximal ureter when necessary. The periureteral blood supply is preserved as the ureter is mobilized. The ureteral ends are spatulated and anastomosed with interrupted absorbable 4-0 sutures (Fig. 49–17*B* and *C*). A ureteral stent is placed as the anastomosis is in progress, and a closed-suction drain is placed in the retroperitoneal space, near to but not touching the repair (Fig. 49–17*D*).

Distal Ureterectomy and Direct Neocystostomy or Ureteroneocystostomy with a Bladder Psoas Muscle Hitch or a Boari Flap

Indications

Complete distal ureterectomy is recommended for tumors in the distal ureter that cannot be removed completely by endoscopic means (Bloom et al, 1970; Johnson and Babaian, 1979; Babaian and Johnson, 1980; Johnson et al, 1988; Pagano, 1984; Anderstrom et al, 1989; Williams, 1991; Messing and Catalona, 1998). Larger, high-grade, organ-confined, invasive lesions constitute the majority of these tumors.

Technique

The patient is placed in the supine position. It is desirable to include the genitalia in the surgical field so that a bladder catheter may be placed and accessible during the procedure.

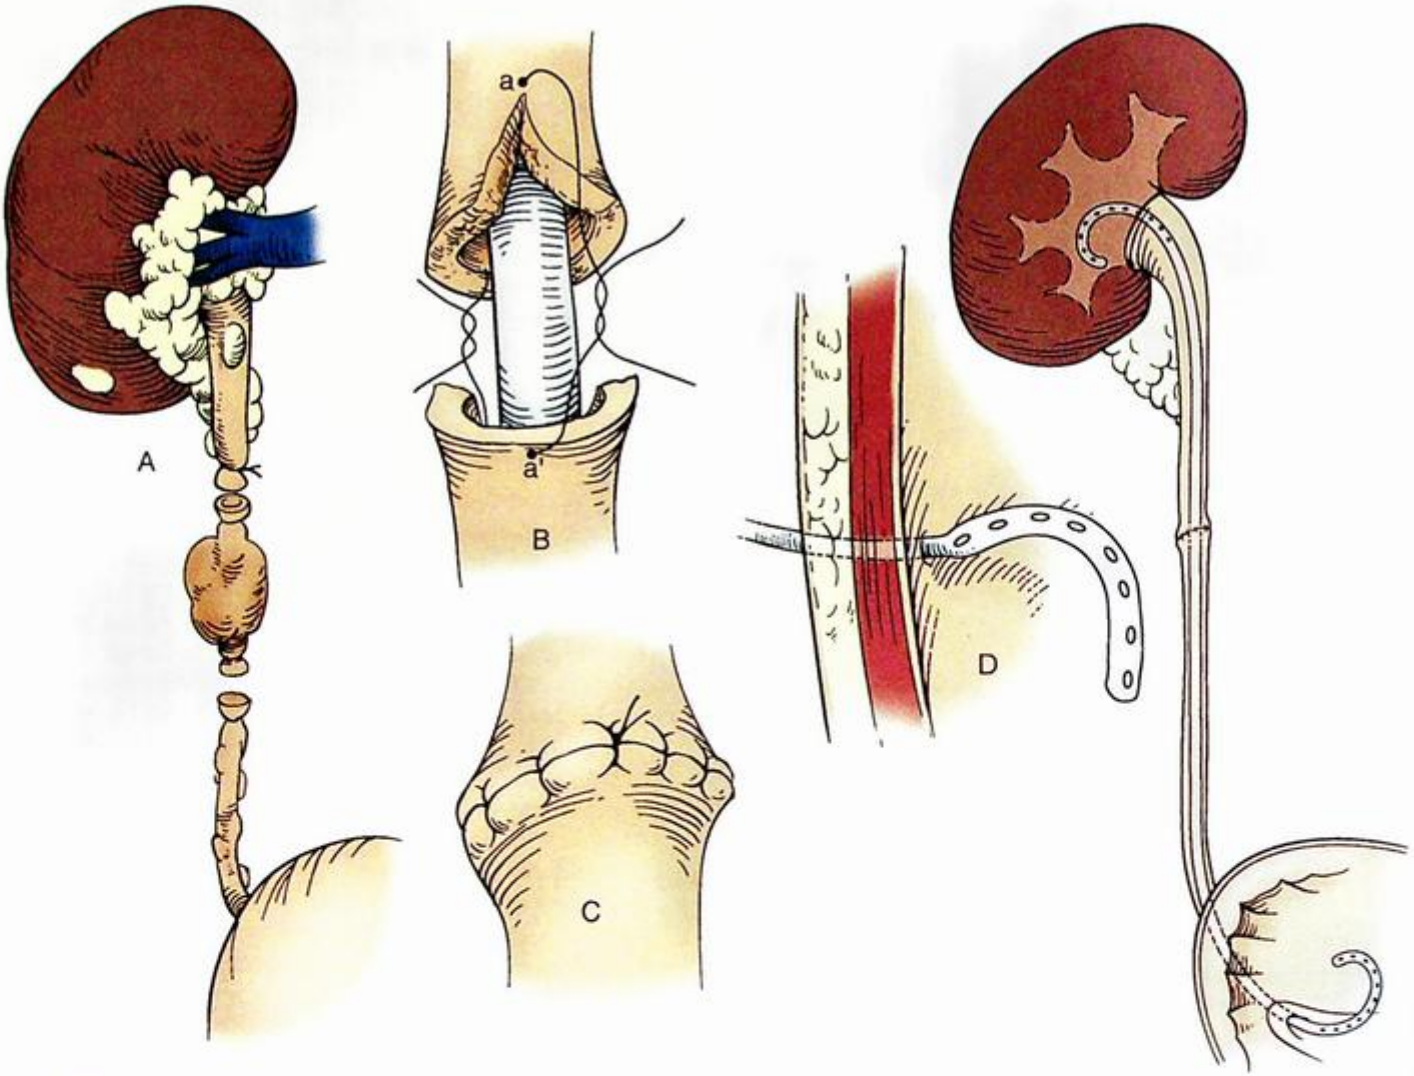

Figure 49–17. **A,** Segmental ureterectomy between ties for a large, invasive tumor of the midureter. **B** and **C,** Ureteroureterostomy of spatulated ends of the ureter. The repair is performed over an internal stent. **D,** Completed repair with closed-suction drain in retroperitoneal space.

A Gibson, Pfannenstiel, or lower midline incision provides good exposure to the distal ureter and bladder for the ureteral excision and the repair. The distal ureterectomy is performed as described in the section on radical nephroureterectomy. Extra care is warranted to avoid spillage of known tumor in the distal ureteral segment.

The choice of a nonrefluxing or refluxing anastomosis is controversial (Pagano, 1984). The nonrefluxing anastomosis may limit infections as well as seeding of the upper tract with tumors from the bladder. The refluxing anastomosis may facilitate follow-up surveillance of the upper tract with imaging studies and ureteroscopy.

Direct ureteroneocystostomy may be possible if only a short segment of the juxtavesical and intramural ureter is removed. Additional techniques are required when the entire distal ureter is removed. The first choice is a bladder psoas muscle hitch. The superior vesical attachments on the opposite side of the bladder are freed. An anterior cystotomy is made, and the bladder is mobilized upward over the iliac vessels to the psoas muscle at the level of the iliac crest (Fig. 49–18*A* and *B*). The bladder is secured to the psoas muscle and tendon with a row of interrupted 2-0 chromic sutures. Entrapment of the genitofemoral nerve is avoided. The ureteral end is spatulated and brought through an opening in the uppermost portion of the bladder. Angulation must be avoided at the ureteral hiatus. A nonrefluxing anastomosis is performed by placing the ureter in a mucosal trough or tunnel if there is sufficient ureteral length (Fig. 49–18*C*). The anastomosis is completed with interrupted 4-0 chromic sutures. A ureteral stent, a urethral catheter, and a closed-suction drain in the perivesical space are placed in all cases (Fig. 49–18*D*). The anterior cystotomy is closed in two layers with 3-0 absorbable suture. Insertion of a suprapubic catheter is optional.

The bladder psoas muscle hitch provides considerable length if the bladder is of normal size and compliance. However, if an even greater gap must be bridged, a Boari flap from the anterior bladder wall combined with a psoas muscle hitch will reach the proximal ureter (Figs. 49–19 and 49–20). If the need for a Boari flap is anticipated, the incisions for the flap should be marked before making the cystotomy and psoas hitch. The spatulated end of the ureter is anastomosed to the cephalad end of the bladder flap as described previously. The

bladder tube is folded and closed in two layers with running 3-0 absorbable suture.

Subtotal Ureterectomy

Indications

Some tumors may require removal of long segments of the ureter by virtue of multifocality and number. However, the tumor grade and stage may not warrant nephroureterectomy. In addition, nephron sparing may be necessary because of compromised function of the contralateral kidney.

Technique

Complete ileal ureteral substitution may be performed as described in Chapter 80. The proximal ileal segment is anastomosed to the renal pelvis, and the distal ileum is connected to the bladder. Ileal interposition may be performed to repair a long midureteral defect when neither ureteroureterostomy nor bladder mobilization is feasible. A suitable length of ileum to bridge the gap is selected. The ileum is narrowed over a 14 French catheter held along the mesenteric edge of the bowel to approximate the diameter of the ureter. Discarding excess bowel from the antimesenteric edge decreases problems with mucus plugging, preserves intestinal blood supply, and allows more efficient peristalsis of urine across the ileal segment. The vermiform appendix has also been used for segmental ureteral substitution (Goldwasser et al, 1994). A preoperative bowel preparation is indicated when possible use of intestine is anticipated.

Finally, total ureterectomy, renal autotransplantation to the iliac fossa, and pyelocystostomy are options when the entire ureter is involved with multiple tumors (Pettersson et al, 1984). However, modern endoscopic techniques provide less invasive means of tumor control with lower morbidity in most cases.

Results

In the past, some authors recommended radical nephroureterectomy for all patients with upper tract urothelial tumors (Skinner, 1978). Others suggested segmental ureterectomy only for patients with low-grade, noninvasive tumors of the distal ureter (Babaian and Johnson, 1980). The cumulative results from the series in Table 49–2 for patients with upper tract tumors of the renal pelvis or ureter reveal that **outcome strongly correlates with tumor stage and grade. Moreover, the results are similar for radical or nephron-sparing surgery.** The outcomes for only ureteral tumors are shown for three series in Table 49–3. Again, overall survival strongly correlates with stage and grade regardless of the extent of surgical treatment. Overall 5-year survival is excellent for patients with grade 1 and grade 2 noninvasive ureteral tumors. Five-year survival remains approximately 50% for patients with stage T2 disease but falls dramatically for stage T3. McCarron and associates (1983) reported 5-year survival

Table 49–3. 5-Year Survival (%) for Patients with Ureteral Tumors

Tumor	Bloom et al, 1970 (n = 102)	Batata and Grabstald, 1976 (n = 77)	McCarron et al, 1983
Grade			
1-2	56-83	50-80	60-87
3-4	16	0-20	15
T stage			
a, 1, cis	62	60-90	64-81
2	50	43	46
3	33	16	22
4	—	—	—
N+	0	0	4
M+	0	0	—

of 64% for patients with stage Ta tumors treated by either segmental ureterectomy or endoscopic tumor ablation. In the same series, 5-year tumor-free survival was 66% and 50% for stage T1 and T2 tumors, respectively, treated with segmental or distal ureterectomy. Anderstrom and colleagues (1989) reported no tumor-related deaths and only one recurrence among 21 patients treated with segmental ureterectomy for low-grade, noninvasive ureteral tumors who were followed up for a median of 83 months.

Booth and associates (1980) reported 5-year survival of 72% versus 31% among 144 patients with ureteral tumors having either superficial or deep ureteral muscle invasion, respectively. This observation has not been duplicated in other series. The concept is of doubtful validity owing to the thin nature of the ureteral wall.

One of the few reports of 5-year cancer-specific survival by stage for patients with ureteral tumors comes from Grabstald and coworkers (1971). Disease-specific survival was 64% and 100% for stage Ta to T1 and stage T2 disease, respectively. All deaths were due to unrelated causes. In contrast, for patients with stage T3 disease, cancer-specific survival was only 7%, and the death rate due to tumor was 87%.

The risk of ipsilateral recurrence after conservative treatment of ureteral tumors is 33% to 55% (Mazeman, 1976; Johnson and Babaian, 1979; Babaian and Johnson, 1980; McCarron et al, 1983; Williams, 1991). Most recurrences are distal to the original lesion, but proximal recurrences are also seen (Strong et al, 1976). The risk for recurrence and the need for follow-up are lifelong (Herr, 1998). Grossman (1978) reported a stage T2 local recurrence in a patient 16 years after segmental ureterectomy and ureteroureterostomy for a grade 1, stage Ta, midureteral tumor. The authors have seen a recurrence of a grade 2, stage Ta tumor in the distal ureter 18 years after segmental ureterectomy of a grade 1, stage Ta tumor of the proximal ureter (Sagalowsky, unpublished data, 1999).

The following are general recommendations for treatment of ureteral tumors in patients with good contralateral renal function. **Segmental ureterectomy is offered for grade 1 to grade 2, stage Ta to stage T1 tumors of the proximal ureter or midureter that are not amenable to complete ablation by endoscopic means because of size or multiplicity. Segmental excision also is offered for grade 1 to grade 2, stage T2 tumors of the proximal ureter or midureter. Distal ureterectomy and neocystostomy are offered for low-grade, low-stage tumors that are not controlled by endoscopic means. Ureteral excision may also be suitable for some high-grade, locally invasive tumors of the distal ureter.**

ENDOSCOPIC TREATMENT

Basic Attributes

Hugh Hampton Young described the first endoscopic evaluation of the upper urinary tract in 1912. Subsequent advances in technology allow us to reach all parts of the urinary tract with minimal morbidity through antegrade and retrograde approaches. Diagnosis and treatment of upper tract transitional cell carcinoma have become possible with these improvements because tumor biopsy and ablation by various energy sources are possible even through the smallest instruments. In addition, miniaturization has made follow-up surveillance of the upper tract more practical with the use of smaller ureteroscopes, which usually do not require previous stenting, or with active dilation of the distal ureter.

Tumors of the upper urinary tract can be approached in a retrograde or antegrade fashion. The approach chosen depends largely on the tumor location and size. In general, a retrograde ureteroscopic approach is used for low-volume ureteral and renal tumors. An antegrade percutaneous approach is preferred for larger tumors of the upper ureter or kidney and for those that cannot be adequately manipulated in a retrograde approach because of location (e.g., lower pole calyx) or previous urinary diversion. In cases with multifocal involvement, combined antegrade and retrograde approaches can be considered (Figs. 49–21 and 49–22).

The basic principles for treatment of transitional cell carcinoma of the upper urinary tract are similar to those for the bladder counterpart (Fig. 49–23). The tumor is sampled and ablated by electrocautery or laser energy sources. A staged procedure should be considered for high-volume disease or disease that is thought to represent high pathologic grade or stage. In such cases, when subsequent nephroureterectomy most likely will be necessary for cure, only biopsy and partial ablation are performed to minimize the risks of perforation or major complications. Endoscopic management is completed only after the pathologic examination shows that the patient is an acceptable candidate for continued minimally invasive endoscopic management. If the pathologic process is unresectable, high grade, or invasive, the patient should proceed immediately to nephroureterectomy, provided he or she is medically fit. Patients who undergo renal-sparing therapy must be committed to a lifetime of follow-up with radiographs and endoscopy.

Ureteroscopy and Ureteropyeloscopy

The ureteroscopic approach to tumors was first described by Goodman in 1984 and is generally favored for ureteral and smaller renal tumors. With the advent of small-diameter rigid and flexible ureteroscopes, tumor location is less of a limiting factor than it used to be. **The advantage of a ureteroscopic approach is lower morbidity than that of the percutaneous and open surgical counterparts, with the maintenance of a closed system. With a closed system, nonurothelial surfaces are not exposed to the possibility of tumor seeding.**

Figure 49–21. Retrograde pyelogram of a patient with a solitary kidney and multifocal low-grade tumors, which required both antegrade and retrograde approaches.

The major disadvantages of a retrograde approach are related to the smaller instruments required. Smaller endoscopes have a smaller field of view and working channel. This limits the size of tumor that can be approached in a retrograde fashion. In addition, some portions of the upper urinary tract, such as the lower pole calyces, cannot be reliably reached with working instruments. Smaller instruments limit the ability to remove large tumors and to obtain deep specimens for reliable staging. Retrograde ureteroscopy is difficult in patients with prior urinary diversion.

KEY POINT: URETEROSCOPY

- Ureteroscopy offers lower morbidity and a closed-system approach to the tumor.

Technique and Instrumentation

A wide variety of ureteroscopic instruments are available, each with its own distinct advantages and disadvantages. In general, rigid ureteroscopes are used primarily for the distal ureter and midureter. Access to the upper ureter and kidney with rigid endoscopy is unreliable, especially in the male patient. Larger, rigid ureteroscopes provide better visualization because of their larger field of view and better irrigation. Smaller rigid ureteroscopes (8 French) generally do not require active dilation of the ureteral orifice (Fig. 49–24*A*).

Newer generation, flexible ureteropyeloscopes are available in sizes smaller than 8 French to allow simple and reliable passage to most portions of the urinary tract (Abdel-Razzak

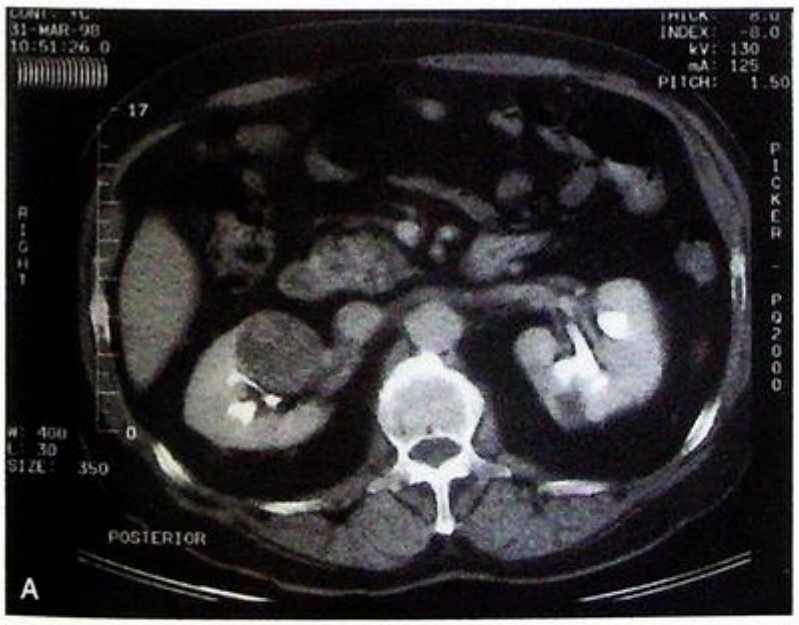

Figure 49–22. Patient with synchronous bilateral tumors. **A,** Right renal cell carcinoma that required radical nephrectomy. **B,** Left proximal ureteral tumor that required combined ureteroscopic and antegrade percutaneous ablation.

and Bagley, 1993; Grasso and Bagley, 1994). These are generally preferred in the upper ureter and kidney, where the rigid ureteroscope cannot be reliably passed. **Flexible ureteroscopes, however, have technical limitations, such as a small working channel, that limit irrigant flow and the diameter of working instruments. Further limitations of flexible ureteroscopy include reduced access to certain areas of the kidney, such as the lower pole, where the infundibulopelvic angle may limit passage of the scope, and prior urinary diversion** (Fig. 49–24*B*).

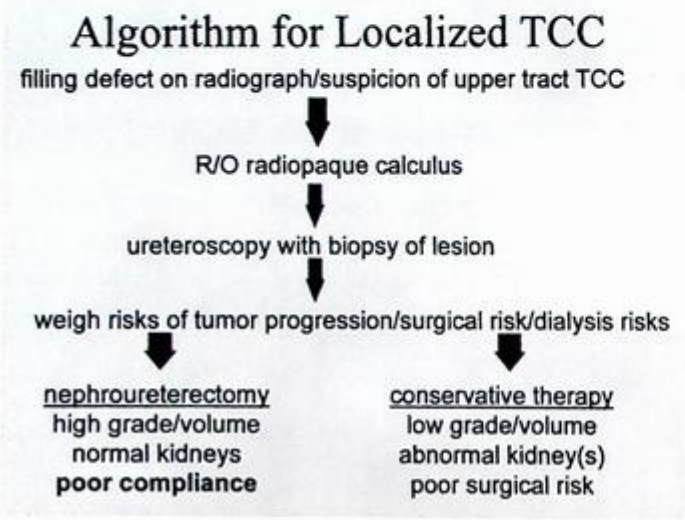

Figure 49–23. Algorithm for endoscopic approach to upper tract transitional cell carcinoma (TCC).

Steps

Endoscopic Evaluation and Collection of Urine Cytology Specimen. Cystoscopy is performed and the bladder inspected for concomitant bladder disease. The ureteral orifice is identified and inspected for lateralizing hematuria. A small-diameter ureteroscope is passed directly (6.9 or 7.5 French) into the ureteral orifice, and the distal ureter is inspected for any trauma from a previously placed guide wire or dilation. A guide wire is then placed through the ureteroscope and up the ureter to the level of the renal pelvis under fluoroscopic guidance. The flexible ureteroscope is used to visualize the remaining urothelium. **When a lesion or suspicious area is seen, a normal saline washing of the area is performed before biopsy or intervention** (Bian et al, 1995). If the ureter does not accept the smaller ureteroscope, active dilation of the ureter is necessary.

Special circumstances include prior urinary diversion and tumor confined to the intramural ureter. With cases of prior urinary diversion, identification of the ureteroenteric anastomosis is difficult and may require antegrade percutaneous passage of a guide wire down the ureter before endoscopy. The wire can be retrieved from the diversion, and the ureteroscope can be passed in a retrograde fashion. The nephrostomy track does not need to be fully dilated in this setting. A second type of case is tumor in the intramural ureter. When a tumor protrudes from the ureteral orifice, complete ureteroscopic ablation of the tumor or aggressive

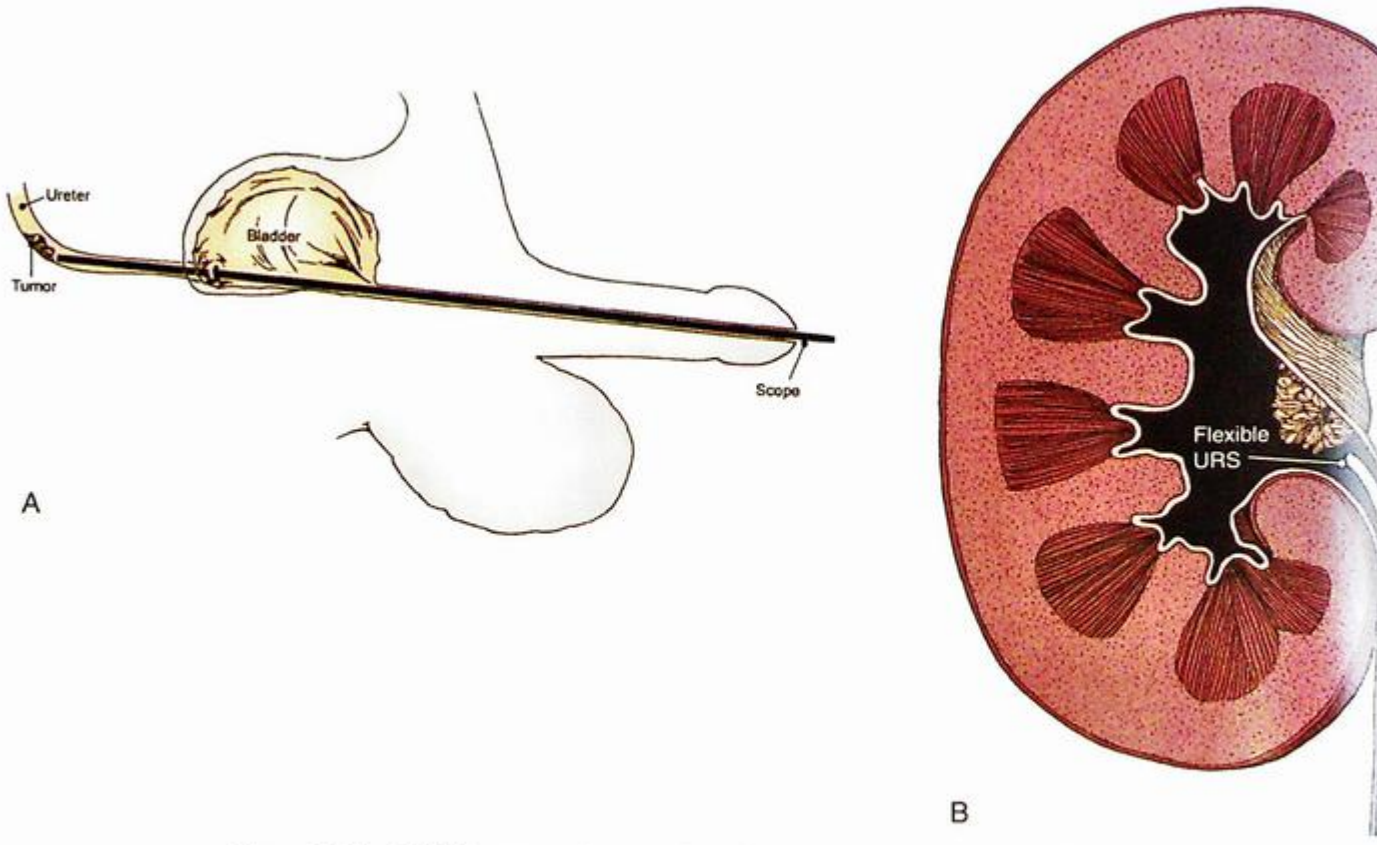

Figure 49–24. **A**, Rigid ureteroscopic approach. **B**, Flexible ureteroscopic approach. URS, ureteroscope.

transurethral resection of the entire most distal ureter can be done with acceptable results (Palou et al, 2000).

Biopsy and Definitive Treatment. Three general approaches can be used for tumor ablation: bulk excision with ablation of the base, resection of the tumor to its base, and diagnostic biopsy followed by ablation with electrocautery or laser energy sources. Regardless of technique used, special attention to biopsy specimens is necessary. Specimens are frequently minute and should be placed in fixative at once and specially labeled for either histologic or cytologic evaluation (Tawfiek et al, 1997).

Ureteroscopic Techniques. The tumor is debulked by use of either grasping forceps or a flat wire basket engaged adjacent to the tumor (Fig. 49–25*A*). Next, the tumor base is treated with either electrocautery or laser energy sources. This technique is especially useful for low-grade papillary tumor on a narrow stalk. The specimen is sent for pathologic evaluation.

A ureteroscopic resectoscope is used to remove the tumor (Fig. 49–25*B*). Only the intraluminal tumor is resected, and no attempt is made to resect deep (beyond the lamina propria). Extra care is necessary in the midureter and upper ureter, where the wall is thin and prone to perforation. Ureteral resectoscopes are approximately 12 French and require more extensive dilation of the ureteral orifice. With larger volume disease of the distal ureter, Jarrett and associates (1995a) described extensive dilation of the ureter followed by resection with a long standard resectoscope. **The tumor is adequately sampled with forceps and sent to the pathology laboratory for diagnostic evaluation. The tumor bulk is then ablated to its base with laser or electrosurgical energy** (Fig. 49–25*C* and *D*). Multiple biopsy specimens are often required when small, flexible, 3 French biopsy forceps are used. Electrocautery delivered through a small Bugbee electrode (2 or 3 French) can be used to fulgurate tumors. However, the variable depth of penetration can make its use in the ureter dangerous, and circumferential fulguration should be avoided because of the high risk of stricture formation. More recently, laser energy with either neodymium:yttrium-aluminum-garnet (Nd:YAG) (Smith et al, 1984; Schmeller and Hofstetter, 1989; Carson, 1991) or holmium:YAG (Bagley and Erhard, 1995; Razvi et al, 1995) sources has been popular. Each has characteristic advantages (Fig. 49–26) and can be delivered through small, flexible fibers (200 or 365 μm) that fit through small, flexible ureteroscopes without significant alteration of irrigant flow or scope deflection.

KEY POINT: BIOPSY AND ABLATION

- The lesion is sampled first for histopathologic staging, if possible; then it is ablated.

The holmium:YAG laser is well suited for use in the ureter. The tissue penetration is less than 0.5 mm, which allows tumor ablation with excellent hemostasis and minimal risk of full-thickness injury to the ureter. Its shallow penetration may, however, make its use cumbersome with larger tumors, especially in the renal pelvis. Settings most commonly used for holmium:YAG are energy of 0.6 to 1 joule with frequency of 10 hertz. The neodymium:YAG laser has a tissue penetration of up to 5 to 6 mm, depending on laser settings and duration of treatment. In contrast to the holmium:YAG laser, which ablates tumor, the Nd:YAG laser works by coagulative necrosis with subsequent sloughing of the necrotic tumor. The safety margin is significantly lower and can limit its use in the ureter, where the ureteral wall is thin. Settings most commonly used for the Nd:YAG laser are 15 watts for 2 seconds for ablation of tumor and 5 to 10 watts for 2 seconds for coagulation.

A ureteral stent is placed for a variable duration to aid with the healing process. Large tumors usually require multiple treatment sessions during several months.

Results

Multiple series have shown the safety and efficacy of ureteroscopic treatment of upper tract transitional cell carcinoma (Elliott et al, 1996; Martinez-Pineiro et al, 1996; Keeley et al, 1997a, 1997b). In a literature review of 205 patients (Tawfiek and Bagley, 1997), the overall recurrence rates for ureteral and renal pelvic lesions were 33% and 31.2%, respectively, and the risk of bladder recurrence was 43%. In the two largest series (Keeley et al, 1997a), there was a single cancer death directly attributed to recurrent upper tract disease. As with any transitional cell carcinoma, the most important prognostic indicator for tumor recurrence was grade. Keeley and associates (1997b) showed a recurrence rate of 26% for grade 1 tumors and 44% for grade 2 tumors, which roughly correlated with previously established recurrence rates for open conservative surgery. More recently, Daneshmand and colleagues (2003) showed the long-term feasibility of ureteroscopic management but a large number of recurrences (3.4 recurrences per patient). This is important in considering patients with a normal contralateral kidney. They must be counseled in the need for lifetime follow-up and possible treatment of ipsilateral recurrence.

Complications were uncommon and usually related to the patient's comorbidities. Complications specific to ureteroscopic therapy included ureteral perforation, which can be managed with indwelling ureteral stent, and ureteral stricture. Stricture formation rate ranged from 5% to 13% (Elliott et al, 1996; Martinez-Pineiro et al, 1996; Keeley et al, 1997a). The complication rates have dropped in more contemporary series, most likely related to smaller endoscopes, improved laser energy sources, and refinements in endoscopic techniques.

Two major concerns of the ureteroscopic approach are the accuracy of ureteroscopic biopsies and the limitations of biopsies, especially with regard to staging (Huffman, 1988). Retrospective reviews of patients who underwent ureteroscopic biopsy followed by nephroureterectomy found the accuracy of ureteroscopic diagnosis to be 89% to 94% and the pathologic grading to match the open surgical technique in 78% to 92% (Keeley et al, 1997a; Guarnizo et al, 2000). From prior studies, we know that there is an excellent correlation between grade of lesion and stage (Chasko et al, 1981; Heney et al, 1981). This holds true for the ureteroscopic approach (Keeley et al, 1997b) because 87% of patients with grade 1 or grade 2 tumors had noninvasive disease (stage Ta or T1), whereas 67% of patients with grade 3 tumors had invasive disease (stage T2 or T3). This information supports the notion that tumor grade is the most important prognostic factor, and although stage cannot be directly assessed, noninvasive disease can be expected in most cases of low-grade tumor.

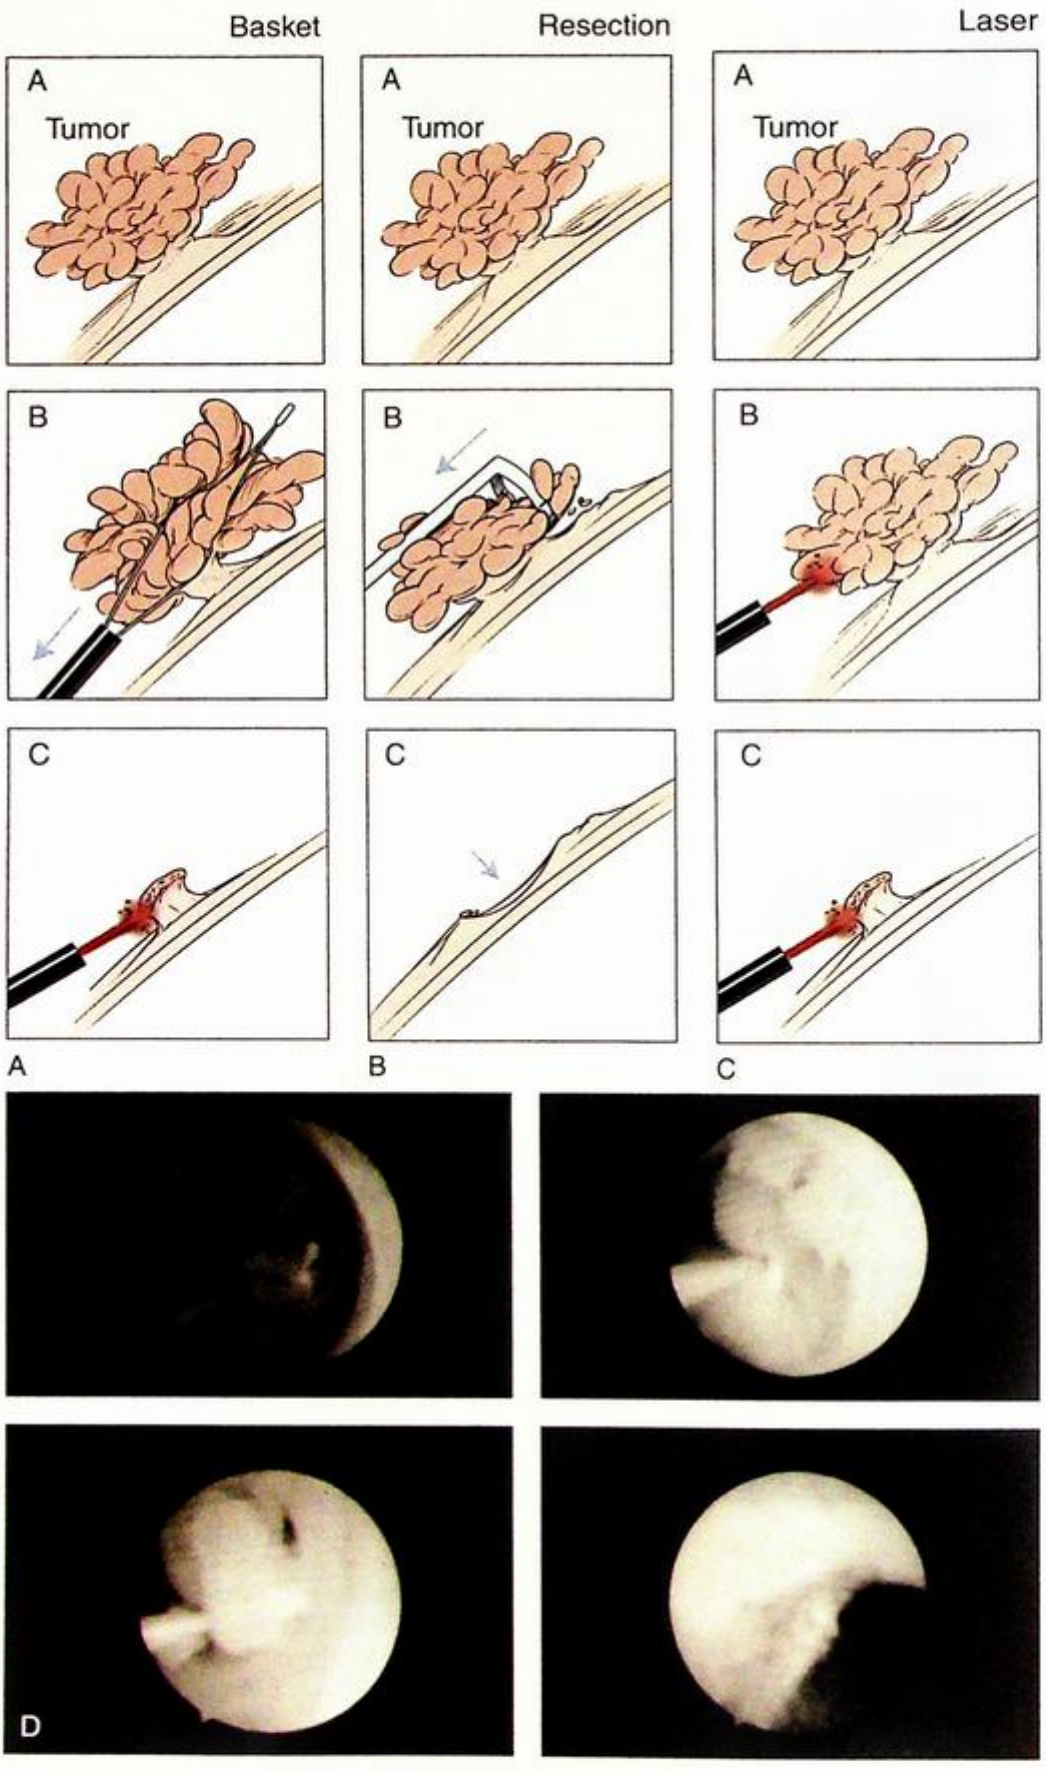

Figure 49–25. Techniques for ureteroscopic treatment of ureteral and renal tumors. **A,** The tumor is identified and removed piecemeal by grasping forceps to its base. **B,** Alternatively, a flat wire basket can be deployed alongside the tumor. The tumor is engaged and removed, with care taken not to avulse the adjacent ureter. With either of these techniques, the base is treated with electrocautery or a laser energy source. **C,** The tumor is identified and removed by a ureteroscopic resectoscope. The technique differs from the technique for bladder tumors in that only intraluminal tumor is resected. No attempt is made to resect deep, as with a bladder tumor. The scope is not arching deep into the tissue. **D,** The tumor is sampled for diagnostic purposes. The bulk of the tumor is then ablated with electrosurgical or laser energy. Laser energy is generally preferred because it has more reliable delivery of energy and depth of penetration. The two most commonly used energy sources are holmium:yttrium-aluminum-garnet and neodymium:yttrium-aluminum-garnet.

Ho:YAG	
	Minimal penetration (<05 mm)
	Efficient ablation of tumor
	Precise cutting
	Settings 0.6-1.2 joules/8-10 Hz
Nd:YAG	
	Deep penetration (5-6mm)
	Excellent hemostasis
	Tumor ablation by coagulative necrosis
	Settings – 20-30 watts

Figure 49–26. Characteristics of holmium:YAG and neodymium:YAG laser energy sources. YAG, yttrium-aluminum-garnet.

A final concern is whether ureteroscopy promotes progression or spread of disease to other urothelial surfaces or metastatic sites. There have been reports of increased tumor appearance in refluxing ureters of patients with bladder tumors (de Torres Mateos et al, 1987) and in the ipsilateral urinary tract and bladder of patients after ureteroscopic treatment. However, Kulp and Bagley (1994) reported on 13 patients who underwent multiple ureteroscopic treatments followed by nephroureterectomy; they found no unusual propagation of transitional cell carcinoma in the specimens. Concerns that ureteroscopy may promote metastatic spread were raised by Lim and associates (1993), who found tumor cells in renal lymphatics after ureteroscopy. However, Hendin and colleagues (1999) reported no increased risk of metastatic disease in a group of patients who underwent ureteroscopy before nephroureterectomy compared with a group undergoing nephroureterectomy alone.

Percutaneous Approach

The percutaneous approach was first described by Tomera and coworkers in 1982 and is generally favored for larger tumors located proximally in the renal pelvis or proximal ureter. **The main advantage of the percutaneous approach is the ability to use larger instruments that can remove a large volume of tumor** in any portion of the renal collecting system. Because deeper biopsy specimens are obtained, tumor staging as well as grading is usually possible. In addition, a percutaneous approach may avoid the limitations of flexible ureteroscopy, especially in complicated calyceal systems or areas difficult to access, such as the lower pole calyx or the upper urinary tract of patients with urinary diversion. With a percutaneous approach, the established nephrostomy track can be maintained for immediate postoperative nephroscopy and administration of topical adjuvant therapy.

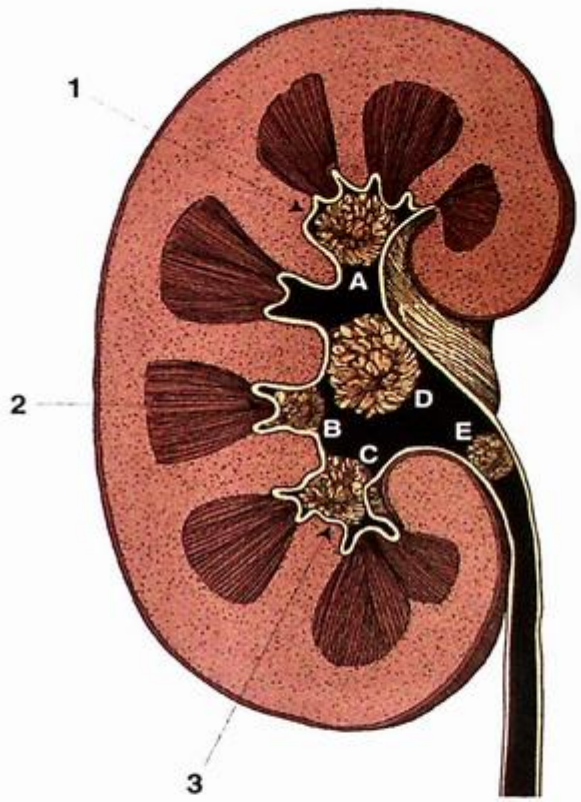

Figure 49–27. Nephrostomy track puncture site. Position of the nephrostomy is imperative for successful percutaneous resection of transitional cell carcinoma of the renal collecting system and upper ureter and requires careful preoperative evaluation of radiographs for tumor location. Tumors in peripheral calyces (A to C) are best approached by direct puncture as far distally in the calyx as possible. Tumors in the renal pelvis (D) and upper ureter (E) are best approached by puncture to an upper (1) or middle (2) calyx, which allows the scope to be maneuvered in the renal pelvis and down the ureter. Tumors in the lower calyx are approached by lower calyx puncture (3).

The main disadvantages are the increased morbidity compared with ureteroscopy and the potential for tumor seeding outside the urinary tract. Establishment of the nephrostomy track has inherent risks, and the procedure usually requires inpatient admission. Distinct risks related to a percutaneous approach are loss of urothelial integrity and exposure of nonurothelial surfaces to tumor cells. This open system provides the possibility of tumor implantation in the nephrostomy track.

Technique and Instrumentation

Establishment of the Nephrostomy Track. Cystoscopy is performed, and an open-ended ureteral catheter is positioned in the pelvis. Contrast material is injected to define the calyceal anatomy, and a percutaneous nephrostomy track is established through the desired calyx (Fig. 49–27). Tumors in peripheral calyces are best approached with direct puncture distal to the tumor (Fig. 49–28). Disease in the renal pelvis and upper ureter is best approached through an upper or middle pole access to allow scope maneuvering through the collecting system and down the ureteropelvic junction. The track is dilated by either sequential (Amplatz) or balloon dilation to accommodate a 30 French sheath. Correct positioning of the nephrostomy track is crucial to the success of the procedure

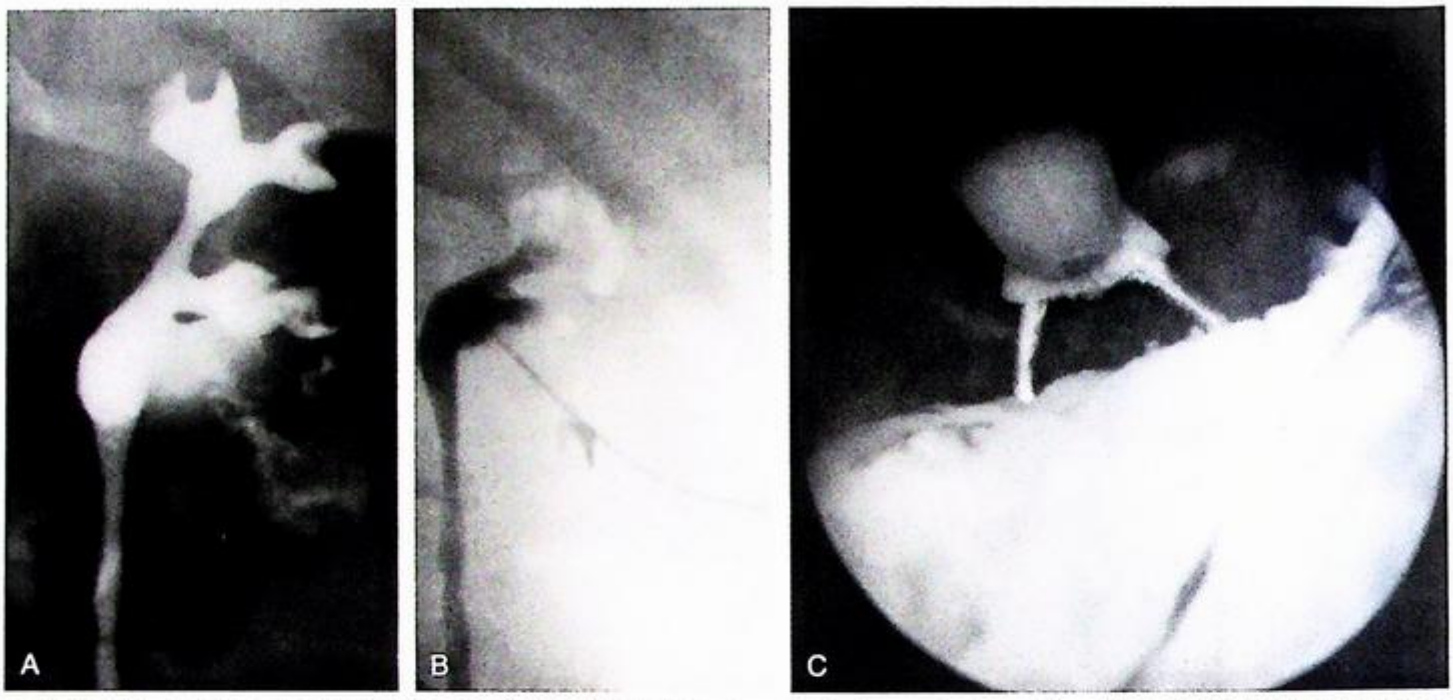

Figure 49–28. **A,** Retrograde pyelogram of a man with transitional cell carcinoma of the lower calyx in a solitary kidney. **B,** Access distal in the calyx allows a clear view of the tumor. **C,** Subsequent resection.

and should be done by the urologist or by the radiologist after direct consultation with the operating surgeon.

A nephroscope is inserted, and the ureteral catheter is grasped, brought out the track, and exchanged for a stiff guide wire, thus providing both antegrade and retrograde control. Complete nephroscopy is performed with rigid and flexible endoscopes when necessary. Any suspicion of upper ureteral involvement warrants antegrade ureteroscopy.

Biopsy and Definitive Therapy. After identification, the tumors are removed by one of the following four techniques (Fig. 49–29). In the first technique, which uses a cold-cup biopsy forceps through a standard nephroscope, the bulk of the tumor is grasped by forceps and removed in piecemeal fashion until the base is reached (Fig. 49–29*A*). A separate biopsy of the base is performed for staging purposes, and the base is cauterized with a Bugbee electrode and cautery. Low-grade papillary lesions on a thin stalk are easily treated in this manner with minimal bleeding.

Alternatively, a cutting loop from a standard resectoscope is used to remove the tumor to its base (Fig. 49–29*B*). Once again, the base should be resected and sent separately for staging purposes. This approach is more effective for larger, broad-based tumors for which simple debulking to a stalk is not possible.

For the third technique, which uses flexible or rigid endoscopes, the tumor is sampled and treated with holmium:YAG or Nd:YAG laser at 25 to 30 watts (Fig. 49–29*C* and *D*). Tissue may also be obtained with a small snare used for gastrointestinal polyps.

Regardless of approach, a nephrostomy tube is left in place. This access can be used for second-look follow-up nephroscopy to ensure complete tumor removal (Fig. 49–30). Nephroureterectomy is indicated if the pathologic examination shows high-grade or invasive disease.

Second-Look Nephroscopy

Follow-up nephroscopy is performed 4 to 14 days later to allow adequate healing. The tumor resection site is identified, and any residual tumor is removed. If no tumor is identified, the base should be sampled and treated by cautery or the Nd:YAG laser (15 to 20 watts and 3-second exposures). The nephrostomy tube can be removed several days later if all tumors have been removed. If the patient is being considered for adjuvant topical therapy, a small, 8 French nephrostomy tube is left to provide access for instillations. Some authors advocate third-look nephroscopy before final nephrostomy tube removal (Jarrett et al, 1995b).

Results

Because of the rarity of the disease, there are only several retrospective series with adequate numbers and follow-up from which to draw reasonable conclusions (Jarrett et al, 1995b; Patel et al, 1996; Clark et al, 1999; Goel et al, 2003; Palou et al, 2004). In a literature review of 84 patients, Okada and colleagues (1997) found an overall recurrence rate of 27%. Tumor grade strongly predicted outcomes; Jarrett and associates showed the recurrence rate for grades 1, 2, and 3 lesions to be 18%, 33%, and 50%, respectively. The only cancer-related mortalities in this series were in patients with high-grade disease. Lee and colleagues (1999) reviewed their 13-year experience with percutaneous management, comparing 50 patients who underwent percutaneous management with 60 patients who underwent nephroureterectomy, and found no significant difference in overall survival. As expected, patients with low-grade disease did well regardless of modality, and patients with high-grade disease did poorly regardless of treatment option.

Most would agree from the literature that percutaneous management is acceptable in patients with low-grade (grade

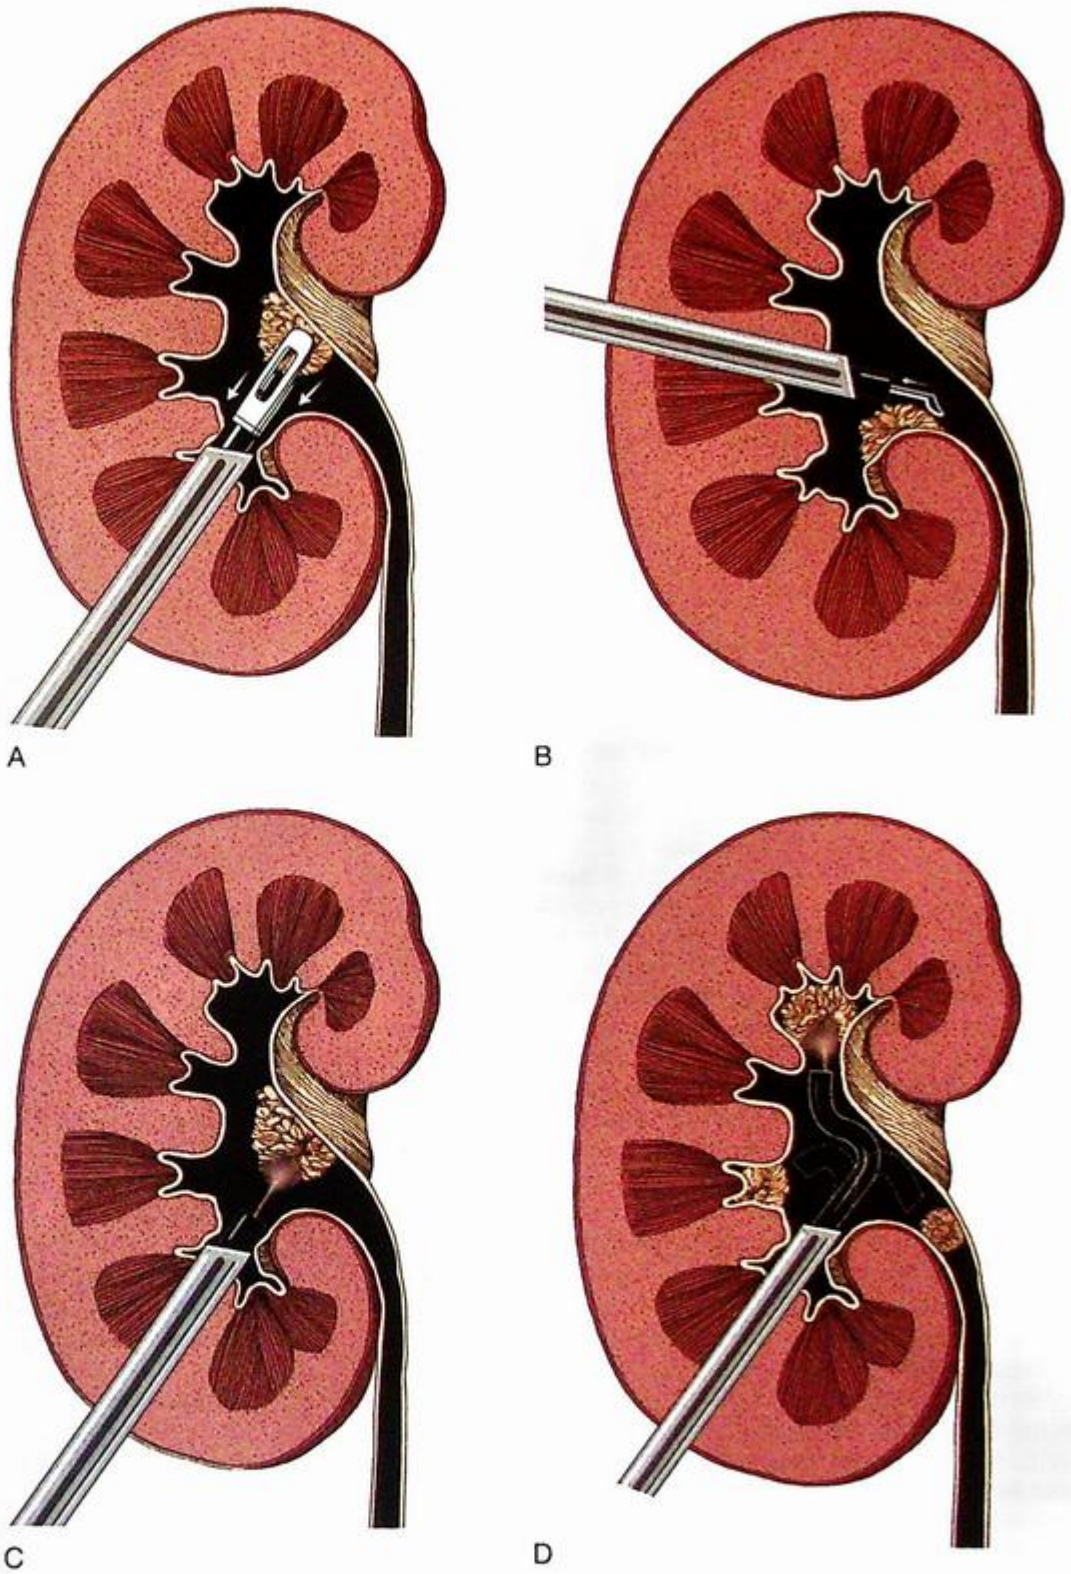

Figure 49–29. Techniques for percutaneous removal of transitional cell carcinoma of the renal collecting system. **A,** The tumor is identified and debulked by forceps to its base. The base is sampled and sent separately for evaluation. This technique works well for papillary tumors on a narrow stalk. Broad-based tumors may cause excessive bleeding and are best approached with resection or laser therapy. **B,** With use of a standard resectoscope, the tumor is identified and resected to its base. Special care should be taken to avoid resection into major renal vasculature. The tumor is identified, sampled for diagnostic purposes, and treated by holmium or neodymium laser sources. This can be done through a standard nephroscope (**C**) or with a flexible cystoscope (**D**).

1) disease regardless of the status of the contralateral kidney, provided the patient is committed to lifelong endoscopic follow-up. Patients with grade 3 disease do poorly regardless of modality chosen but should probably undergo nephroureterectomy to maximize cancer therapy (provided they are medically fit). The largest area of controversy surrounds the use of percutaneous management for patients with grade 2 disease and a normal contralateral kidney. Jabbour and associates (2000) retrospectively evaluated 24 patients and found a disease-specific survival of 95% overall and 100% and 80% for stage Ta and stage T1 lesions, respectively. This study shows an acceptable result with conservative treatment of noninva-

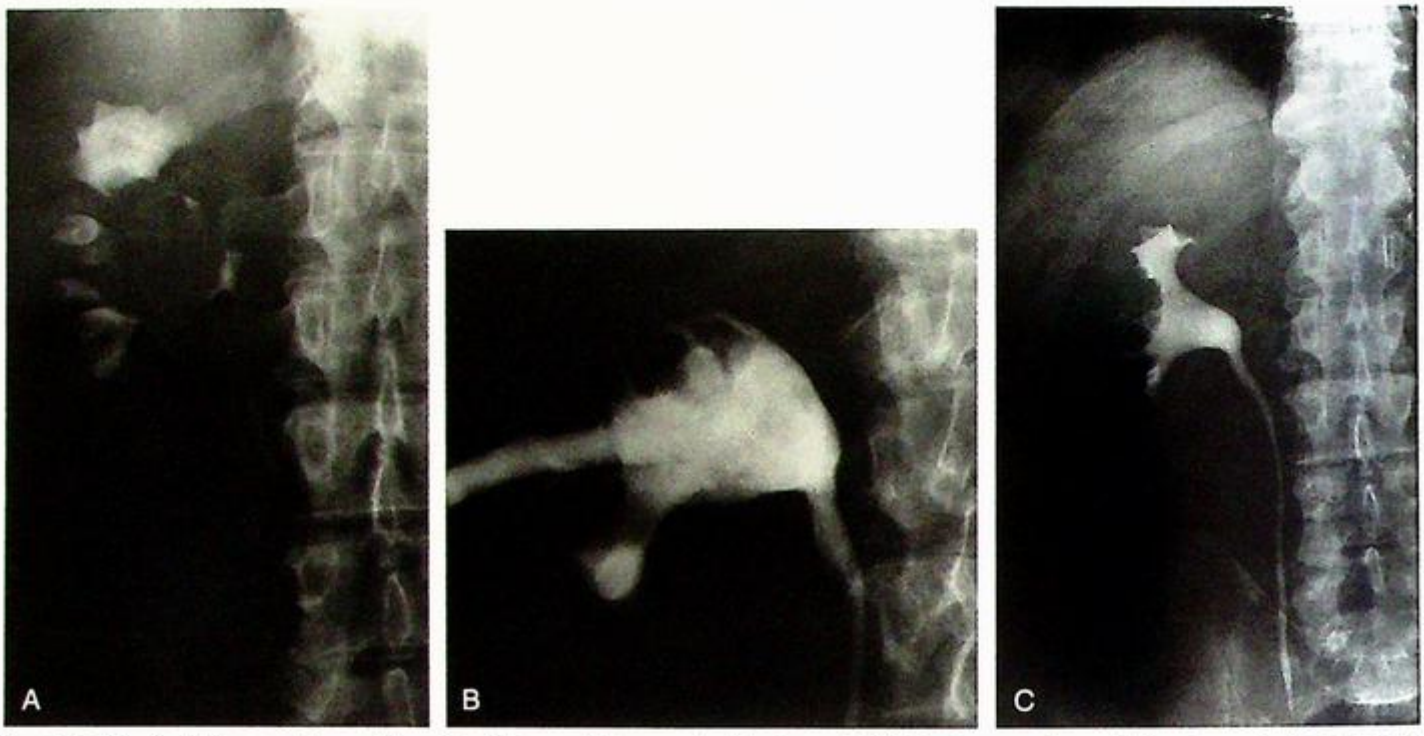

Figure 49–30. **A,** A 65-year-old man with solitary kidney and 5-cm renal pelvis tumor. **B,** Nephrostogram after patient underwent staged resection. **C,** Three-month follow-up retrograde pyelogram after completed resection. The patient showed grade 1 transitional cell carcinoma without invasion to submucosa.

sive grade 2 disease. With more invasive lesions, the potential for disease progression and metastatic disease is significant, and nephroureterectomy should be considered.

Complications from percutaneous management of tumors are similar to those for benign renal processes and include bleeding, perforation of the collecting system, and secondary ureteropelvic junction obstruction. Complications increase in number and severity with higher tumor grade (Jarrett et al, 1995b). This finding is probably due to the more extensive pathologic process and treatments necessary to eradicate the tumor. Unlike ureteroscopic resection, the percutaneous method can stage tumors, and as expected, stage increases with tumor grade.

A major concern of the percutaneous approach is the potential seeding of nonurothelial surfaces with tumor cells. Although there have been multiple reported cases of nephrostomy track infiltration with high-grade tumors (Tomera et al, 1982; Slywotzky and Maya, 1994; Huang et al, 1995; Oefelein and MacLennan, 2003; Treuthardt et al, 2004), there were no reported occurrences in the three largest series (Jarrett et al, 1995b; Patel et al, 1996; Clark et al, 1999). Track seeding is a possibility but appears to be an uncommon event.

ISOLATED UPPER TRACT CYTOLOGIC ABNORMALITY OR URINARY MARKER

On occasion, one is faced with a patient who has an isolated abnormal cytologic finding or other urinary marker from the upper urinary tract. **By definition, the patient should have normal intravenous urography and retrograde pyelography, normal cystoscopy, and normal biopsy findings from the bladder and urethra.** Radical nephroureterectomy was performed in the past for a unilateral cytologic abnormality of the upper tract to eliminate presumed carcinoma in situ. This practice is not recommended (Gittes, 1980; McCarron et al, 1983; Williams, 1991; Messing and Catalona, 1998). Upper tract cytology suffers from the same limitations in specificity as does bladder cytology. Further, properly collected upper tract samples are of limited volume and cell count compared with bladder washings. Any source of inflammation, such as urinary infection or calculus, may produce a false-positive result. A subsequent cytologic abnormality from the contralateral side during follow-up is not rare in cases of true positives from early carcinoma in situ (Murphy et al, 1974; Khan et al, 1979). A variety of urinary markers are being studied to aid in detection of urothelial tumor recurrence. At this time, both urine fluorescence in situ hybridization and urine nuclear matrix protein show particular promise.

Ureteropyeloscopy is indicated in such cases because the yield for direct visualization of small lesions is superior to that of retrograde pyelography. An attempt to perform biopsy and confirm the diagnosis is indicated before treatment is considered. A consistently abnormal finding on upper tract cytology may signify carcinoma in situ. Current treatment options are limited. Instillation of topical immunotherapy or chemotherapy may be performed through ureteral catheters or a small percutaneous nephrostomy. However, the contact time of the agent with the urothelium is minimal. Reports of efficacy are uncontrolled and anecdotal.

Frequent-interval reevaluation with urinalysis, bladder cytology, cystoscopy every 3 months, and retrograde pyelog-

raphy or ureteropyeloscopy every 6 months is indicated for 1 to 2 years. However, one must avoid overtreatment and excessive evaluation and instrumentation of a patient who may have had a single false-positive result.

ADJUVANT THERAPY

After Organ-Sparing Therapy

Any procedure short of nephroureterectomy has a higher local recurrence due to the established risk of ipsilateral recurrence. Several approaches are available to minimize these risks. They fall into two basic categories: instillation of immunotherapeutic or chemotherapeutic agents and brachytherapy of the nephrostomy track.

Instillation Therapy

Instillation therapy can be accomplished in several ways. Accepted techniques include antegrade instillation through a nephrostomy tube (Fig. 49–31) and retrograde instillation directly into a ureteral catheter or by reflux in a patient with an indwelling ureteral stent or iatrogenically created vesicoureteral reflux. Patel and Fuchs (1998) described a convenient technique of outpatient instillation through a ureteral catheter placed suprapubically. Regardless of the technique chosen, administration to the upper urinary tract should be done under low pressure and in the absence of active infection to minimize the risk of bacterial sepsis or systemic absorption of the agent.

Results. The same agents used to treat urothelial carcinoma of the bladder are used to treat tumors of the upper tracts. Many studies have described small, retrospective, uncontrolled series of patients undergoing therapy with thiotepa (Elliott et al, 1996; Patel et al, 1996), **mitomycin** (Eastham and Huffman, 1993; Weston et al, 1993; Martinez-Pineiro et al, 1996; Keeley et al, 1997a), **and BCG** (Smith et al, 1987; Studer et al, 1989; Eastham and Huffman, 1993; Sharpe et al, 1993; Jarrett et al, 1995b; Hayashida, 2004). Although the cumulative experience appears encouraging, no individual study has shown statistical improvement with relation to survival and recurrence rates. Possible reasons for this include (1) insufficient numbers to show clinical significance because of the relative rarity of the disease; (2) tumors of the upper urinary tract, which have a tumor biology different from that of their bladder counterparts; and (3) inadequate delivery system that, unlike in the bladder, does not allow uniform delivery of the agent with adequate dwell time to enable a clinical response. Further, in the report by Hayashida and colleagues (2004) with intrarenal perfusion of BCG, despite initial return of cytology results to normal, 50% of patients (5 of 10) developed disease recurrence after a mean follow-up of 50.9 months, and all of these suffered cancer-specific mortality. There is no doubt that more studies are required to settle this issue. The attempt to decrease multiple recurrences in the upper tract is reasonable in well-selected patients.

The most common complication of instillation therapy is bacterial sepsis. To minimize this problem, patients must be evaluated for active infection before each treatment, and only a low-pressure delivery system should be used. Agent-specific complications of the various therapies include ramification of systemic absorption of the agent. Bellman and colleagues (1994) described upper urinary tract complications of percutaneous BCG instillation. Granulomatous involvement of the kidney in the absence of systemic signs of BCG infection was most commonly seen. Mukamel and associates (1991) saw an inordinate decrease in renal function for patients receiving BCG who had vesicoureteral reflux.

Brachytherapy

Brachytherapy to the nephrostomy track through iridium wire or delivery system was described by Patel and coworkers (1996) and Nurse and colleagues (1989). There were no instances of track recurrences in this series, although the authors acknowledged the rarity of the event. The only major complication attributed to the brachytherapy was cutaneous fistula formation requiring nephroureterectomy.

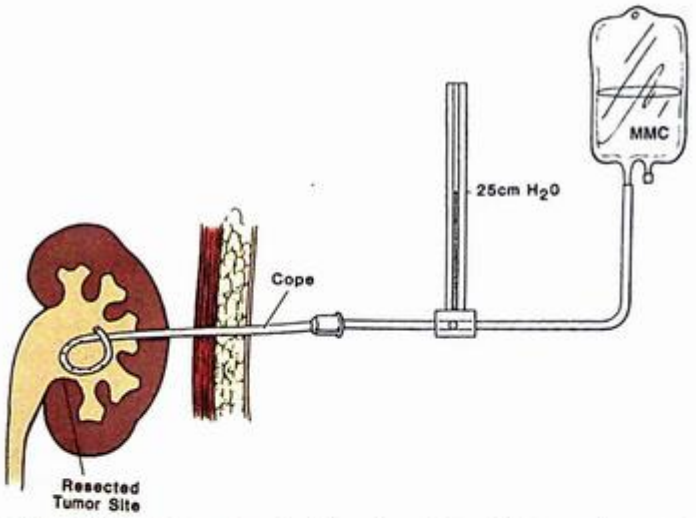

Figure 49–31. Setup for administration of topical immunotherapy or chemotherapy to the upper urinary tract through a previously placed nephrostomy tube. Therapy is instilled by gravity with a mechanism that prevents excessive intrarenal pressures. High pressures have been linked to complications of systemic absorption and bacterial sepsis.

After Complete Excision

Radiation Therapy

The rationale for focal radiation therapy is to decrease the risk of local relapse after radical surgery for locally advanced non–organ-confined disease (stage T3 to T4, N+). Most series concluding that postoperative irradiation is beneficial are small or even anecdotal, uncontrolled, and retrospective (Holtz, 1962; Brady et al, 1968; Leiber and Lupu, 1978). In one series with 41 patients, postoperative radiation therapy decreased local recurrence but had no effect on distant relapse or survival (Brookland and Richter, 1985). Maulard-Durdux and associates (1996) retrospectively reviewed 26 patients who received 46 Gy to the wound bed after radical surgery for upper tract tumors. Tumors were grade 2 in 40% and grade 3 in 60% of cases. Tumor stage was T2, T3, and N+ in 42%, 58%, and 35% of cases, respectively. Five-year survival is shown in Table 49–4. Overall 5-year survival was 49%, with 30% remaining disease free. All patients with local relapse also had distant relapse, leading the authors to conclude that adjuvant radiation therapy is not beneficial.

Table 49–4. 5-Year Survival after Postoperative Adjuvant Radiation Therapy for Upper Tract Urothelial Tumors

Tumor	*5-Year Survival (%)*	
Grade		
2	90	
3	0	$P < .01$
T stage		
2	60	
3	19	
N0	49	$P = .04$
N+	15	

Data from Maulard-Durdux C, Dufour B, Hennequin C, et al: Postoperative radiation therapy in 29 patients with invasive transitional cell carcinoma of the upper urinary tract: No impact on survival? J Urol 1996;155: 115-117.

The largest experience addressing this issue is that reported by Hall and associates (1998). A retrospective review of 252 patients with upper tract tumors who were followed up for a median of 64 months was performed. Radical nephroureterectomy was performed in 77% of cases. Initial tumor stage was T3 in 19% and T4 in 10% of cases; 50% and 52%, respectively, of patients with stage T3 and stage T4 tumors received 40 Gy to the wound bed postoperatively. Disease-specific and overall 5-year survival was 41% and 28%, respectively, for patients with stage T3 disease. Actuarial 5-year disease-specific survival for stage T3 with or without adjuvant radiation therapy was 45% and 40%, respectively. Median survival was 6 months for stage T4 disease. There were no long-term survivors in this group. Local relapse occurred in only 9% of the entire series and was seen only in patients with stage T3 and stage T4 disease. Among the patients who received adjuvant radiation, isolated local relapse without distant metastases occurred in only 10% and 4% of stage T3 and stage T4 cases, respectively. Thus, **radical nephroureterectomy alone provides a high rate of local control. Adjuvant radiation for high-stage disease does not decrease local relapse or protect against a high rate of distant failure.**

Systemic Chemotherapy

The major limitation to long-term survival for patients with locally advanced upper tract tumors is distant relapse with metastatic disease. Both induction (neoadjuvant) and adjuvant systemic therapy with agents used for proven metastatic disease (see following discussion) are reasonable. However, there are no controlled trials that establish the efficacy of either induction or adjuvant chemotherapy in this setting. The small number of cases treated with adjuvant chemotherapy are anecdotal and preclude definitive conclusions of efficacy.

KEY POINT: METASTATIC DISEASE

- Distant relapse with metastatic disease is the main limitation in survival of patients, not local recurrence.

FOLLOW-UP

Issues in Assessing for Recurrence

The propensity of upper tract tumors for multifocal recurrence and metastatic spread with more dysplastic lesions makes follow-up complicated. Postoperative evaluation must routinely include evaluation of the bladder, the ipsilateral (if organ-sparing therapy was chosen) and contralateral urinary tracts, and the extraurinary sites for local and metastatic spread. A follow-up regimen is thus dependent on the time from surgery, the approach chosen (organ sparing versus radical), and the potential for metastatic spread. General recommendations for time intervals are listed in Figure 49–32.

General Procedures

All patients should be assessed at 3-month intervals the first year after they are rendered tumor free by endoscopic or open surgical approaches (Keeley et al, 1997a). This schedule is largely based on work with bladder transitional cell carcinoma that shows that most tumor recurrences after bladder resection develop in the first year (Varkarakis et al, 1974; Loening et al, 1980). The upper urinary tract is more difficult to monitor, and delayed recognition of upper tract tumor recurrence may lead to disease progression and poor results (Mazeman, 1976). Evaluation should include history, physical examination, urinalysis, and office cystoscopy because of the high risk of bladder recurrences in patients treated both conservatively and with nephroureterectomy (Mazeman, 1976). If the patient requires endoscopic evaluation of the upper urinary tract, cystoscopy can be done in conjunction with that procedure.

Urine cytology may be helpful in assessing for upper tract recurrence, especially for high-grade tumors (Murphy et al, 1981). The utility, however, is decreased with less dysplastic tumors (Grace et al, 1967; Sarnacki et al, 1971; Zincke et al, 1976). The same tumor markers under study for bladder transitional cell carcinoma are promising for upper urinary tract transitional cell carcinoma (Brown, 2000). One marker that may be preferentially more involved in upper tract transitional cell carcinoma than in bladder transitional cell carcinoma is the DNA mismatch repair gene *hMSH2* (Leach et al, 2000).

Specific Procedures

Bilateral disease, either synchronous or metachronous, is seen in 1% to 4% of patients (Petkovic, 1975; Babaian and Johnson, 1980; Murphy et al, 1981), and thus imaging of the contralateral kidney is required on a regular basis. Yearly intravenous urography is usually sufficient. However, retrograde pyelography may be necessary if the patient is not a candidate for injection of contrast medium or if intravenous urography is not diagnostic. Computed tomography or sonography is helpful in distinguishing stones from soft tissue densities. Further evaluation of filling defects on imaging studies usually requires ureteroscopic evaluation.

If an organ-sparing approach is chosen, the ipsilateral urinary tract must be assessed as well as the remainder of the urinary tract. The frequency and duration of the follow-up assessments depend largely on the grade and stage of the

- Physical examination, urine cytology (only for high grade lesions) and cystoscopy
  - every 3 months – first year
  - every 6 months thereafter – years 2 –3
  - yearly – thereafter
- Contralateral Imaging (IVU or retrograde pyelography) – yearly
- Ipsilateral Endoscopy (patients undergoing organ-sparing therapy) –
  - every 6 months – first several years
  - yearly – thereafter
- Metastatic Evaluation – necessary in all patients with significant risk of disease progression (i.e., high grade or invasive disease)
  - Physical examination, chest x-ray, comprehensive metabolic panel with liver enzymes
    - Every 3 months – first year
    - Every 6 months – years 2 through 3
    - Yearly – years 4 and 5
    - After 5 years – evaluation of urothelium only
  - Computed tomography or MRI of abdomen and pelvis –
    - Every 6 months – years 1 and 2
    - Yearly – years 3–5
  - Bone scan – only for elevated alkaline phosphatase or symptoms of bone pain

Figure 49–32. Follow-up begins after open surgery or when the patient is rendered tumor free by endoscopic management. The commencement of follow-up may be altered according to the potential for disease progression.

lesion, but they are usually every 6 months for several years and annually thereafter. Radiographic evaluation of the upper tracts alone is not adequate because Keeley and colleagues (1997a) showed that 75% of early tumor recurrences were visible endoscopically and not radiographically. With tumors approached in a percutaneous fashion, immediate follow-up nephroscopy can be performed through the established nephrostomy track.

In the past, the burden of repeated endoscopic evaluation of the upper urinary tracts was a major deterrent to conservative therapy. The use of smaller, 7.5 French flexible ureteroscopes has greatly eased the burden of follow-up because ureteroscopes can be reliably passed up the ureter without the need for dilation of the ureteral orifice or prior stenting. Others have advocated resection of the ureteral orifice to facilitate subsequent surveillance ureteroscopy in the office setting (Kerbl and Clayman, 1993). Even though technology has somewhat facilitated follow-up, both physician and patient must be committed to nephron-sparing treatment.

Metastatic Restaging

Metastatic restaging is required in all patients at significant risk for disease progression to local or distant sites. This group

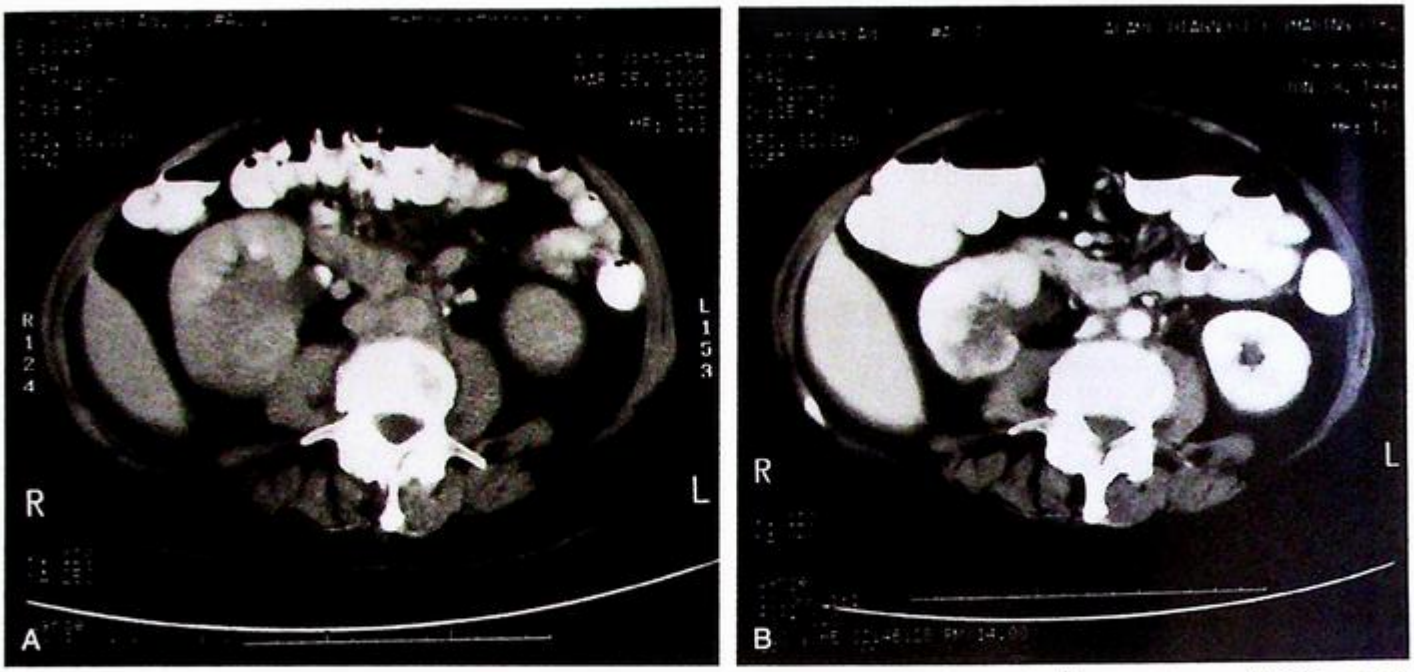

Figure 49–33. Patient with a large, biopsy-proven transitional cell carcinoma of the kidney as well as lung and axillary metastases. **A,** Initial appearance of the renal tumor. **B,** Marked shrinkage of the tumor after four courses of paclitaxel and gemcitabine. The lung and axillary metastases disappeared, and nephroureterectomy was performed. During the next year, the patient developed a brain metastasis. (Courtesy of Dr. Randall Singleton.)

includes those with high-grade or high-stage disease. Metastatic restaging is generally not necessary for low-grade disease when the risks of invasive and subsequent metastatic disease are negligible. Included in metastatic restaging is imaging of the ipsilateral renal bed for recurrence with cross-sectional imaging. Follow-up restaging includes chest radiograph, liver function tests, cross-sectional body imaging, and selective use of bone scan based on an understanding of natural disease history and metastatic pathways (Korman et al, 1996).

TREATMENT OF METASTATIC DISEASE

Outcomes are poor in patients with metastatic urothelial tumors of the upper urinary tract. **The systemic chemotherapy regimens offered for treatment are the same as those used for transitional cell carcinoma of the bladder.** These regimens are discussed in Chapter 77. Only limited data on response rates of advanced upper tract tumors to chemotherapy are available because of the rarity of these lesions. Prospective randomized trials comparing chemotherapeutic regimens for upper tract tumors are not feasible for this reason. Patients with advanced upper tract tumors are excluded from most trials on treatment of advanced bladder cancer. Therefore, one must extrapolate likely chemotherapy response rates for upper tract disease from observations in bladder cancer trials.

The MVAC (methotrexate, vinblastine, doxorubicin, cisplatin) regimen continues to have the highest response rate (Sternberg et al, 1989). However, complete responses are rare, and the duration of response is limited, with overall survival of approximately 12 to 24 months. Toxicity is high and dose limited in some patients. For all these reasons, there is considerable ongoing investigation with newer agents, including paclitaxel, ifosfamide, carboplatin, and gemcitabine, used in various combinations and sequences (Roth et al, 1994; Bajorin et al, 1998; Redman et al, 1998; Vaughn et al, 1998; Kaufman et al, 2000; Lorusso et al, 2000). Many of these show initial overall response rates similar to the response rate to MVAC and lower toxicity. Occasional major responses are seen (Fig. 49–33). However, thus far, complete responses are rare, and neither durability of response nor survival is better than that seen with MVAC. In summary, upper tract urothelial cancer, like bladder cancer, is chemosensitive. It is to be hoped that additional improvements in treatment efficacy and safety are forthcoming, with further experience with new chemotherapeutic regimens. Alternative strategies, such as biologic response modifiers and gene therapy, also should be explored.

KEY POINTS: CHEMOTHERAPY

- The chemotherapy for advanced upper tract transitional cell carcinoma is the same as for bladder cancer.
- Controlled trials limited to upper tract tumors are not practical because of the low prevalence of disease.

HISTORICAL ASPECTS

The first nephrectomies were probably performed serendipitously. Early reports of removal of large ovarian tumors indicate that the surgeon was occasionally surprised to find the kidney included in the surgical specimen. Definitive renal surgery was first performed in 1869 by Gustav Simon, who carried out a planned nephrectomy for treatment of a ureterovaginal fistula. The operation was preceded by extensive experimental investigation of uninephrectomy in dogs to demonstrate that they could survive normally with only one kidney. This application of an experimental model to a clinical problem was the forerunner of the method by which many current surgical procedures were developed.

In 1881, Morris was the first to perform nephrolithotomy in an otherwise healthy kidney, and he later defined the terms *nephrolithiasis, nephrolithotomy, nephrectomy,* and *nephrotomy*. The first partial nephrectomy was performed in 1884 by Wells for removal of a perirenal fibrolipoma. In 1887, Czerny was the first to use partial nephrectomy for excision of a renal neoplasm. Kuster performed the first successful pyeloplasty (a dismembered procedure) in 1891 on the solitary kidney of a 13-year-old boy. In 1892, Fenger applied the Heineke-Mikulicz principle for pyloric stenosis to ureteropelvic junction obstruction. In 1903, Zondek emphasized the importance of thorough knowledge of renal arterial circulation in performing partial nephrectomy.

There was great controversy among early surgeons regarding the relative merits of retroperitoneal versus transperitoneal exposure of the kidney. Kocher and Langham performed an anterior transperitoneal nephrectomy through a midline incision as early as 1878. A transverse abdominal incision was employed in 1913 by Berg, who also mobilized the colon laterally to expose the great vessels and thus secure the renal pedicle with greater safety. Berg was able to remove vena caval tumor thrombi through a cavotomy after control of the veins by vascular clamps. Rehn actually reimplanted the contralateral renal vein after resecting the inferior vena cava (IVC) in 1922. However, the high incidence of peritonitis and other abdominal complications led most urologists to adopt a retroperitoneal flank approach to the kidney during the first half of the 20th century. During the late 1950s, the development of safe abdominal and vascular surgical techniques led to a revival of the anterior approach in patients undergoing renal surgery (Culp and Winterringer, 1955; Poutasse, 1961).

SURGICAL ANATOMY

The kidneys are paired vital organs located on either side of the vertebral column in the lumbar fossa of the retroperitoneal space. Each kidney is surrounded by a layer of perinephric fat, which is in turn covered by a distinct fascial layer termed Gerota's fascia. Posteriorly, both kidneys lie on the psoas major and quadratus lumborum muscles. They are also in relationship with the medial and lateral lumbocostal arches and the tendon of the transverse abdominal muscle. Posteriorly and superiorly, the upper pole of each kidney is in contact with the diaphragm (Fig. 50–1).

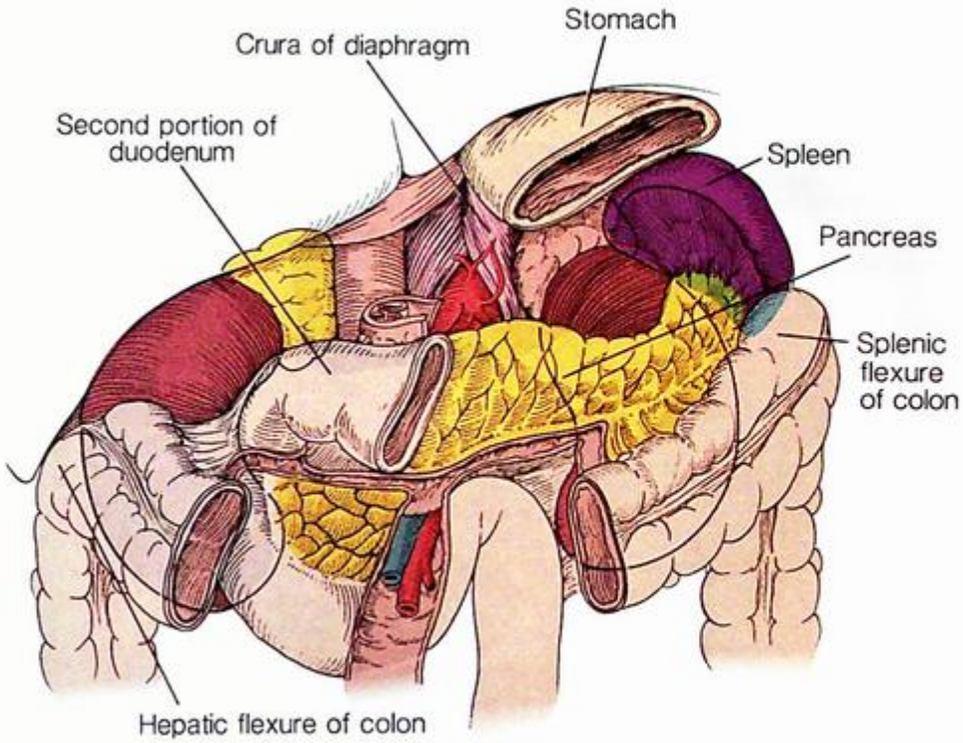

Figure 50–1. The anatomic relationship of the kidneys to surrounding structures. The liver is retracted superiorly.

A small segment of the anterior medial surface of the right kidney is in contact with the right adrenal gland. However, the major anterior relationships of the right kidney are with the liver, which overlies the upper two thirds of the anterior surface, and the hepatic flexure of the colon, which overlies the lower third. The second portion of the duodenum covers the right renal hilum.

A small segment of the anterior medial surface of the left kidney is also covered by the left adrenal gland. The major anterior relationships of the left kidney are with the spleen, the body of the pancreas, the stomach, and the splenic flexure of the colon.

The kidney has four constant vascular segments, which are termed apical, anterior, posterior, and basilar. The anterior segment is the largest and extends beyond the midplane of the kidney onto the posterior surface. A true avascular line exists at the junction of the anterior and posterior segments on the posterior surface of the kidney.

Each vascular segment of the kidney is supplied by one or more major arterial branches (Fig. 50–2). Although the origin of the branches supplying these segments may vary, the anatomic position of the segments is constant. All segmental arteries are end arteries with no collateral circulation; therefore, in performing renal surgery, failure to preserve one of these branches leads to devitalization of functioning renal tissue. Most individuals have a single main artery to each kidney originating from the lateral aspect of the aorta just below the superior mesenteric artery (SMA). Multiple renal arteries occur unilaterally and bilaterally in 23% and 10% of the population, respectively.

The normal renal venous anatomy is depicted in Figure 50–3. The left and right renal veins both terminate in the lateral aspect of the IVC. The left renal vein is longer and has a thicker muscle layer than the right renal vein. These are the gonadal vein inferiorly, the left adrenal vein superiorly, and

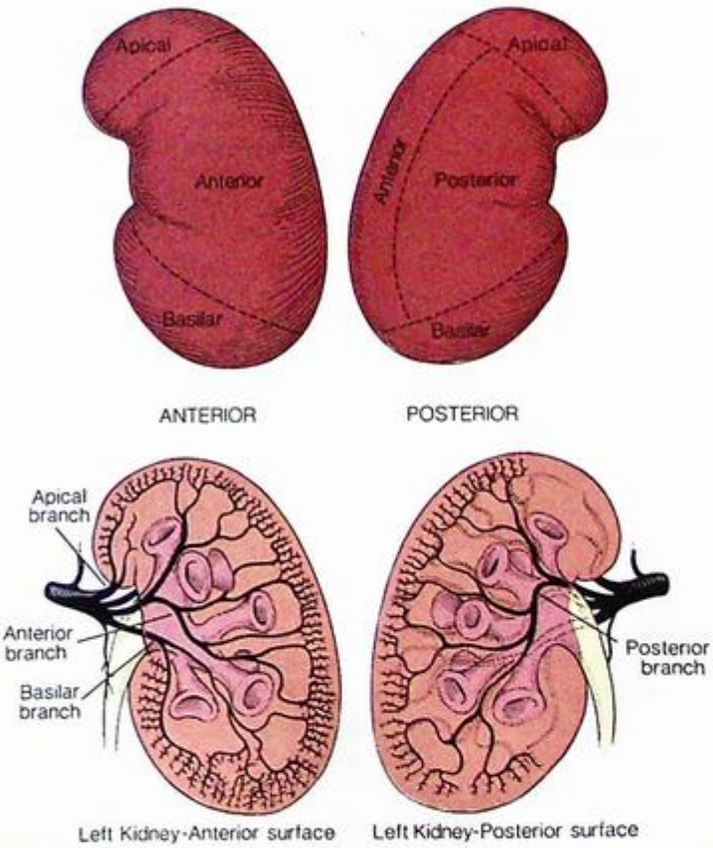

Figure 50–2. The vascular segments of the left kidney, as shown in anterior and posterior projections, and the corresponding segmental arterial supply to each segment.

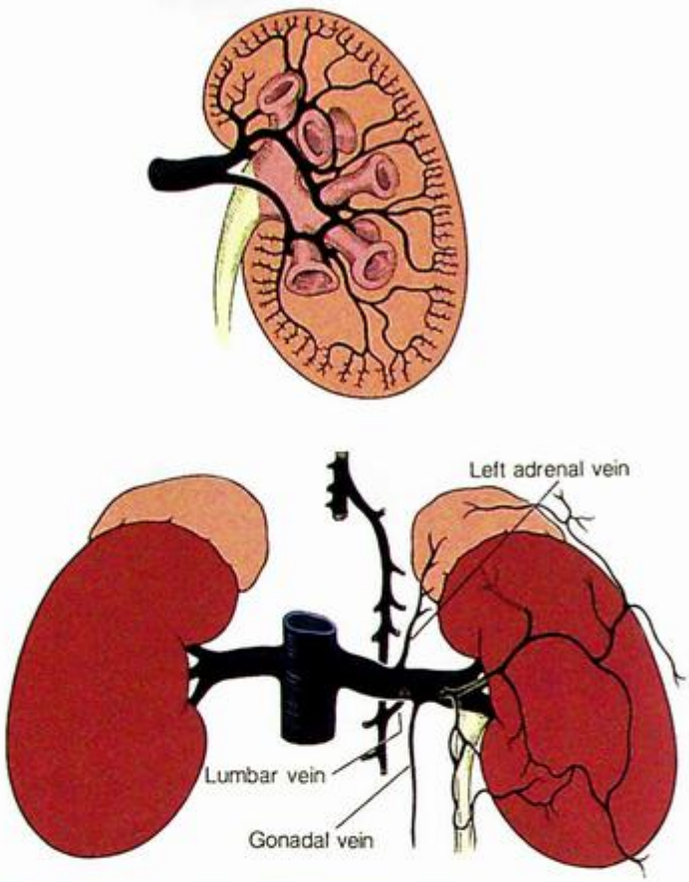

Figure 50–3. The normal renal venous anatomy, including branches of the left renal vein *(bottom)*. The intrarenal venous drainage parallels the segmental arterial supply and is depicted for the left kidney *(top)*.

one or two large lumbar veins posteriorly. There are no significant branches draining into the right renal vein. Multiple renal veins are less common than multiple renal arteries.

The renal venous drainage system differs significantly from the arterial blood supply in that the intrarenal venous branches intercommunicate freely among the various renal segments. Ligation of a branch of the renal vein, therefore, does not result in segmental infarction of the kidney because collateral venous blood supply provides adequate drainage. This is important clinically because it enables one to obtain surgical access to structures in the renal hilum by ligation and division of small adjacent or overlying venous branches.

With regard to the intrarenal collecting system, there are 8 to 10 major calyces that open into the renal pelvis (Fig. 50–4). The apical segment has one major calyx that lies in the midfrontal plane and receives two minor calyces, which are lateral and medial. The basilar segment has a single major calyx in the median plane and receives two minor calyces, which are anterior and posterior. There are three major calyces in the anterior segment that enter the renal pelvis at a 20-degree angle to the midfrontal plane and three major calyces in the posterior segment that enter the renal pelvis at a 75-degree angle to the midfrontal plane.

PREOPERATIVE PREPARATION

A thorough preoperative evaluation is important in patients undergoing renal surgery because of the special positions in

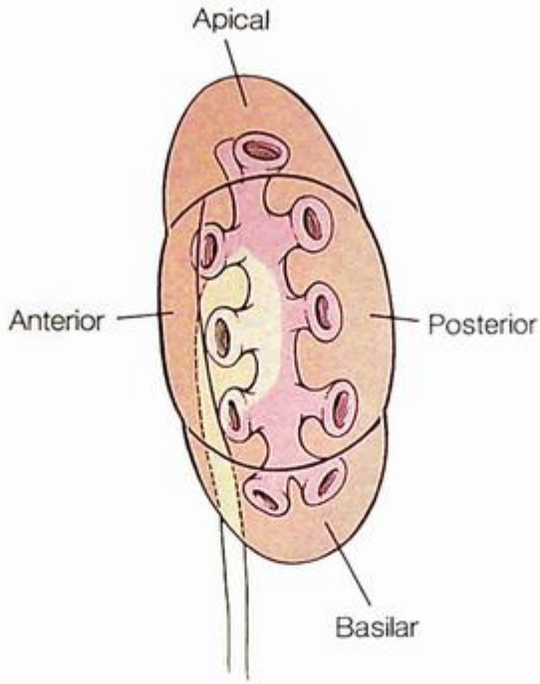

Figure 50–4. The intrarenal collecting system in relation to major vascular segments of the kidney.

which the patient may have to be placed intraoperatively and the systemic disturbances that may occur secondary to renal infections and impairment of renal function.

Cardiorespiratory function is evaluated by eliciting any history of heart disease, chest pain, smoking, or respiratory distress on exertion. An electrocardiogram, chest radiograph, and complete blood count should be obtained for all patients. The flank position with lateral flexion of the spine is known to cause embarrassment of ventilatory capacity, and the venous return may be significantly diminished in this position, resulting in hypotension. Therefore, alternatives to the flank approach should be used whenever possible in patients with a decreased pulmonary reserve. Preoperative pulmonary function studies and blood gas analysis are mandatory in patients thought to have impaired respiratory function. In the event of impairment, use of an anterior surgical approach with the patient in the supine position is preferred.

Regardless of the surgical incision used, respiration may be seriously impaired postoperatively as a result of transection of upper abdominal or flank muscles and, occasionally, removal of a rib. Also, the upper poles of the kidneys encroach on the undersurface of the diaphragm, and the removal of a large upper pole renal mass may interfere temporarily with its function. Preoperative breathing exercises, alleviation of bronchospasm, cessation of smoking, and evaluation of cardiopulmonary function are helpful in improving respiratory function and in preventing postoperative cardiorespiratory problems.

Bleeding tendencies are assessed by examination of platelet function and coagulation factors. Patients should be questioned about excess alcohol intake and ingestion of drugs, such as aspirin, that can influence blood clotting.

A thorough anatomic examination of the urinary tract should be made in all patients undergoing renal surgery.

Available studies include intravenous pyelography, cystoscopy, retrograde pyelography, ureteroscopy, cystourethrography, computed axial tomography, ultrasonography, magnetic resonance imaging, renal arteriography, and renal venography. Three-dimensional volume-rendered computed tomography (CT) is an accurate imaging modality for surgical planning before reconstructive renal surgery (Coll et al, 1999). These tests and their usefulness in evaluating patients for specific renal operations are reviewed in other chapters of this text.

Overall, renal function is evaluated by estimation of the serum creatinine level and either endogenous creatinine clearance or iothalamate glomerular filtration rate. Differential renal function can be assessed noninvasively by computed isotope renography with hippuric acid I 131 or technetium 99. Hippuric acid I 131 is cleared by both glomeruli and tubules and is most useful for measuring unilateral renal dysfunction when overall renal function is normal. Technetium chelated with diethylenetriaminepentaacetic acid is filtered only by the glomeruli and is thus more helpful in assessing differential renal perfusion. Both of these isotopes are excreted in the urine, and in the presence of obstruction, parenchymal concentration is obscured by the high concentration of isotope in the accumulated urine.

Patients with either upper or lower urinary tract infection should receive organism-specific antibiotic therapy preoperatively. With suspected or proven upper tract infection, at least 48 hours of antibiotic therapy is indicated before renal surgery. Severe bacteremia can occur during operation on an infected kidney, with significant resulting morbidity and potential mortality.

Percutaneous embolization of the kidney is occasionally helpful before radical nephrectomy is performed for large renal malignant neoplasms. The major value of this adjunct procedure is for patients with an arterialized vena caval tumor thrombus or a medial extension of tumor that interferes with early ligation of the renal artery. Subsequent transient flank pain is common and often requires analgesic medication for control.

Patients are often concerned about how the removal of a kidney will affect their renal function. After nephrectomy for unilateral renal disease, the opposite kidney undergoes compensatory hypertrophy, and the glomerular filtration rate is ultimately maintained at 75% of the normal value (Aperia et al, 1977; Robitaille et al, 1985). Several long-term studies have shown no increase in hypertension or proteinuria, stable overall renal function, and normal life expectancy after unilateral nephrectomy with a normal contralateral kidney (Kretschmer, 1943; Goldstein, 1956; Anderson et al, 1968). This information should be shared with patients to alleviate their anxiety before surgery.

INTRAOPERATIVE RENAL ISCHEMIA

Temporary occlusion of the renal artery is necessary for a variety of operations, such as partial nephrectomy, renal vascular reconstruction, anatrophic nephrolithotomy, and repair of traumatic renal injury. In such cases, temporary arterial occlusion not only diminishes intraoperative renal bleeding but also improves access to intrarenal structures by causing the kidney to contract and by reducing renal tissue turgor. Performance of these operations requires an understanding of renal responses to warm ischemia and available methods of protecting the kidney when the period of arterial occlusion exceeds that which may be safely tolerated.

Mechanisms of Renal Ischemic Injury

In recent years, there have been significant insights into the pathophysiologic process of renal ischemia. In animal models as well as in humans, postischemic reductions in glomerular filtration rate have been attributed to persistent vasoconstriction, due in part to activation of tubuloglomerular feedback as a result of enhanced delivery of solute to the macula densa. Increased solute delivery to the distal nephron is caused by impaired tight junction integrity resulting in decreased sodium reabsorption due to loss of cell polarity in the proximal tubule with mislocalization of the Na^+,K^+-ATPase (Kwon et al, 1998).

Endothelial injury results in cell swelling and enhanced expression of cell adhesion molecules. This, together with leukocyte activation, leads to enhanced leukocyte–endothelial cell interactions, which can promote injury and swelling of the endothelial cell, physically impede blood flow, contribute to the production of local factors promoting vasoconstriction, and add to effects of vasoconstriction on local blood flow and tubule cell metabolism (Thadhani et al, 1996).

Endothelial injury also leads to changes in the response to vasoactive substances. Arterioles from postischemic kidneys have increased basal tone and reactivity to vasoconstrictive agents and decreased vasodilatory responses compared with arterioles from normal kidneys. Alterations in local levels of vasoconstrictors (angiotensin II, thromboxane A_2, leukotrienes, adenosine, endothelin-1) have been implicated in abnormal vascular tone. Vascular responses may be attributed to enhanced responses to angiotensin II through activation of endothelin B or prostaglandin H_2–thromboxane A_2 receptors. Systemic endothelin-1 levels increase with ischemia, and administration of antiendothelin antibodies or endothelin receptor antagonists has been reported to protect against ischemia-reperfusion injury (Newaz and Oyekan, 2001). Nitric oxide is vasodilatory and decreases endothelin expression and activity in the vascular endothelium, effects that should be protective against ischemic renal injury. With endothelial injury, endothelial nitric oxide synthase is inhibited (Kourembanas et al, 1993). Nevertheless, despite extensive data suggesting that enhanced vasoconstriction is a fundamental contributor to the pathophysiologic process of ischemic acute renal failure, vasodilators have not been found to be clinically useful in prevention or treatment of acute renal failure associated with tubular necrosis in humans.

An important feature of the pathophysiologic mechanism of ischemic injury is related to reductions in medullary blood flow with reduction in oxygen delivery to the tubular structures in this region of the kidney and resultant cellular injury due to imbalance between oxygen delivery and demand. Endothelial activation and injury together with increased leukocyte–endothelial cell interactions and activation of coagulation pathways may have a greater effect on outer medullary ischemia than arteriolar vasoconstriction, as there can be markedly impaired oxygen delivery to the outer medulla despite adequate renal blood flow (Thadhani et al, 1996).

Endothelial cell injury leading to upregulation of adhesion molecules and cell swelling and loss of the patency of the endothelial barrier potentiates interactions with leukocytes and platelets and leads to small vessel–mechanical obstruction. Locally derived cytokines, chemokines, eicosanoids, and reactive oxygen species recruit and activate leukocytes. Activated leukocytes generate reactive oxygen species and eicosanoids, which further the inflammatory response and enhance vascular tone, stimulating further injury.

Infiltration of neutrophils and mononuclear cells is important in reperfusion injury. Tissue injury is ameliorated by prevention of neutrophil accumulation (Suwa et al, 2001). Macrophages and T lymphocytes predominate over neutrophils in the later recovery phase of postischemic injury. Blockade of T-cell CD28-B7 costimulation protects against ischemic injury in rats (Takada et al, 1997). Chemokines are upregulated by inflammatory cytokines such as interleukin-1 and tumor necrosis factor-α. Infusion of a tumor necrosis factor-α–binding protein decreases neutrophil infiltration and is renoprotective. Activation of coagulation pathways also contributes to postischemic injury. An oral inhibitor of platelet-activating factor is protective against ischemic injury in animal models. Attenuation of complement C5 protects against late inflammation and resulting renal dysfunction (Bonventre and Weinberg, 2003).

Renal Tolerance to Warm Ischemia

The extent of renal damage after normothermic arterial occlusion depends on the duration of the ischemic insult. Canine studies have shown that warm ischemic intervals of up to 30 minutes can be sustained with eventual full recovery of renal function (Ward, 1975). **For periods of warm ischemia beyond 30 minutes, there is generally significant, immediate functional loss, and late recovery of renal function is either incomplete or absent. On histologic evaluation, renal ischemia is most damaging to the proximal tubular cells,** which may show varying degrees of necrosis and regeneration, whereas the glomeruli and blood vessels are generally spared.

Human tolerance to warm renal ischemia closely parallels that seen in experimental canine observations, and in general, 30 minutes is the maximum tolerable period of arterial occlusion before permanent damage is sustained. In some clinical situations, this admonition may not apply, and a longer period of ischemia may be safely tolerated. It is acknowledged that the solitary kidney is more resistant to ischemic damage than the paired kidney, although precise limits have not been defined (Askari et al, 1982). Another situation that may enhance renal tolerance to temporary arterial occlusion is the presence of an extensive collateral vascular supply. This is generally observed only in patients with renal arterial occlusive disease (Schefft et al, 1980).

Another determinant of renal ischemic damage is the method employed to achieve vascular control of the kidney. Animal studies have shown that functional impairment is least when the renal artery alone is continuously occluded. Continuous occlusion of the renal artery and vein for an equivalent time interval is more damaging because it prevents retrograde perfusion of the kidney through the renal vein and may also produce venous congestion of the kidney (Neely and Turner, 1959; Leary et al, 1963; Schirmer et al, 1966). Intermittent clamping of the renal artery with short periods of recirculation is also more damaging than continuous arterial occlusion, possibly because of the release and trapping of damaging vasoconstrictor agents within the kidney (Neely and Turner, 1959; Schirmer et al, 1966; Wilson et al, 1971; McLoughlin et al, 1978). Animal studies have further demonstrated that the use of manual renal compression to control intraoperative hemorrhage is more deleterious than simple arterial occlusion (Neely and Turner, 1959).

Prevention of Ischemic Renal Damage

Several general adjunctive measures should be employed in all patients undergoing operations that involve a period of temporary renal arterial occlusion. These include generous preoperative and intraoperative hydration, prevention of hypotension during the period of anesthesia, avoidance of unnecessary manipulation or traction on the renal artery, and intraoperative administration of mannitol. These measures help limit postischemic renal injury by ensuring optimal perfusion with an absence of cortical vasospasm at the time of arterial occlusion, which allows uniform restoration of blood flow throughout the kidney when the renal artery is unclamped. Mannitol is most effective when it is given 5 to 15 minutes before arterial occlusion (Collins et al, 1980), and it is beneficial because it increases renal plasma flow, decreases intrarenal vascular resistance, minimizes intracellular edema, and promotes an osmotic diuresis when renal circulation is restored (Nosowsky and Kaufman, 1963). Systemic or regional heparinization before renal arterial occlusion is not necessary, unless there is existing small vessel or parenchymal renal disease.

When the anticipated period of intraoperative renal ischemia is longer than 30 minutes, additional specific protective measures are indicated to prevent permanent damage to the kidney. Local hypothermia is the most effective and commonly employed method for protecting the kidney from ischemic damage. Lowering renal temperature reduces energy-dependent metabolic activity of the cortical cells, with a resultant decrease in both the consumption of oxygen and the breakdown of adenosine triphosphate (Harvey, 1959; Levy, 1959). The optimum temperature for hypothermic in situ renal preservation is 15°C, based on canine experiments conducted by Ward (1975). In clinical renal surgery, it is difficult to achieve uniform cooling to this level because of the temperature of adjacent tissues and the need to have a portion of the kidney exposed to perform the operation. For practical reasons, a temperature of 20°C to 25°C is easier to maintain and represents a compromise that renders renal surgery technically feasible while still allowing a renal preservative effect. Both animal and human studies have shown that this level of hypothermia provides complete renal protection from arterial occlusion of up to 3 hours (Wickham et al, 1967; Luttrop et al, 1976; Petersen et al, 1977; Wagenknecht et al, 1977; Marberger et al, 1978; Stubbs et al, 1978; Kyriakidis et al, 1979).

In situ renal hypothermia can be achieved with external surface cooling or perfusion of the kidney with a cold solution instilled into the renal artery. These two methods are equally effective; however, the latter is an invasive technique that requires direct entry into the renal artery (Leary et al,

1963; Farcon et al, 1974; Kyriakidis et al, 1979; Abele et al, 1981). Surface cooling of the kidney is a simpler and more widely used method that has been accomplished by a variety of techniques, such as surrounding the kidney with a cold solution (Mitchell, 1959) or applying an external cooling device to the kidney (Cockett, 1961). These methods require complete renal mobilization to achieve effective surface cooling.

Most urologists prefer ice-slush cooling for surface renal hypothermia because of its relative ease and simplicity. The mobilized kidney is surrounded with a rubber sheet on which sterile ice slush is placed to completely immerse the kidney. An important caveat with this method is to keep the entire kidney covered with ice for 10 to 15 minutes immediately after the renal artery is occluded and before the renal operation is commenced. This amount of time is needed to obtain core renal cooling to a temperature (approximately 20°C) that optimizes in situ renal preservation. During performance of the renal operation, invariably, large portions of the kidney are no longer covered with ice slush, and in the absence of adequate prior core renal cooling, rapid rewarming and ischemic renal injury can occur. This technique is effective for in situ renal preservation. Stubbs and associates (1978) described 30 patients with a solitary kidney in whom anatrophic nephrolithotomy was performed with ice-slush surface hypothermia; despite a mean renal artery clamp time of longer than 2 hours and as long as 4 hours in some cases, renal function was completely preserved in all patients.

Another approach to in situ renal preservation that does not involve hypothermia is pretreatment with one or more pharmacologic agents to prevent postischemic renal failure (Novick, 1983).

Whereas agents such as renal-dose dopamine and inosine, captopril, and adenosine triphosphate–magnesium chloride have been proposed to minimize ischemic renal damage, reports have failed to show a consistent renoprotective effect in the setting of transient renal ischemia during solitary partial nephrectomy or in single-kidney animal models. A prospective controlled study from the Cleveland Clinic showed no beneficial effect of perioperative dopamine on renal function after partial nephrectomy in a solitary kidney (O'Hara et al, 2002).

SURGICAL APPROACHES TO THE KIDNEY

Exposure of the kidney during surgery must be adequate to perform the operation and to deal with any possible complications. This is particularly important in renal surgery because the kidney is deeply placed in the upper retroperitoneum with access limited by the lower ribs, liver, and spleen. Injuries to large renal vessels may be difficult to control or to repair through small incisions, particularly in the presence of a large tumor or inflamed perinephric tissues. Poor exposure renders the operation unnecessarily difficult and also leads to excessive retraction, with bruising of the muscles and possible injury to the intercostal nerves, which can increase postoperative pain.

Factors to consider in selecting an appropriate incision for renal surgery include operation to be performed, underlying renal disease, previous operations, concurrent extrarenal disease that requires another operation to be done simultaneously, need for bilateral renal operations, and body habitus. Physical abnormalities in the patient, such as kyphoscoliosis or severe pulmonary disease, may also dictate that certain approaches, such as the standard flank incision, not be used.

The kidney may be approached by four principal routes: an extraperitoneal flank approach, a dorsal lumbotomy, an abdominal incision, and a thoracoabdominal incision. The indications, relative advantages, and technical performance of each approach are reviewed separately.

Flank Approach

This approach provides good access to the renal parenchyma and collecting system (Woodruff, 1955). It is an extraperitoneal approach and involves minimal disturbance to other viscera. Contamination of the peritoneal cavity is avoided, and drainage of the perirenal space is readily established. This approach is particularly useful in the obese patient because most of the panniculus falls forward, making this incision relatively straightforward even in the very large person. **The principal disadvantage of the flank incision is that exposure in the area of the renal pedicle is not as good as with anterior transperitoneal approaches. In addition, the flank incision may prove unsuitable for the patient with scoliosis or cardiorespiratory problems.**

The most commonly used flank approach to the kidney is through the bed of the 11th or 12th rib (Hess, 1939; Hughes, 1949; Bodner and Briskin, 1950). The choice of rib depends on the position of the kidney and on whether the upper or lower pole is the site of disease. With a flank incision, the midportion of the wound and the site of maximal exposure are in the midaxillary line. Access in the posterior part, at the neck of the rib, is limited by the sacrospinal muscle. The appropriate level of the incision is therefore best determined by drawing a horizontal line on the urogram from the hilum of the kidney to the most lateral rib that it intersects (Fig. 50–5).

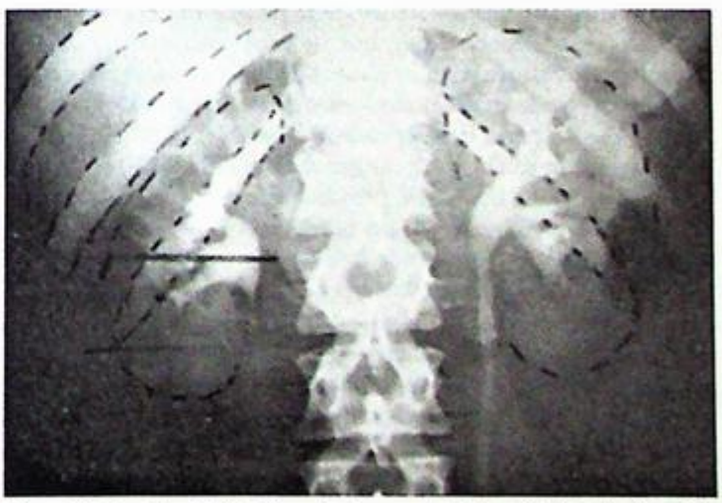

Figure 50–5. The right kidney is traversed at its midpoint by the 12th rib. The ideal incision is chosen by drawing a horizontal line from the hilum to the lateral rib cage.

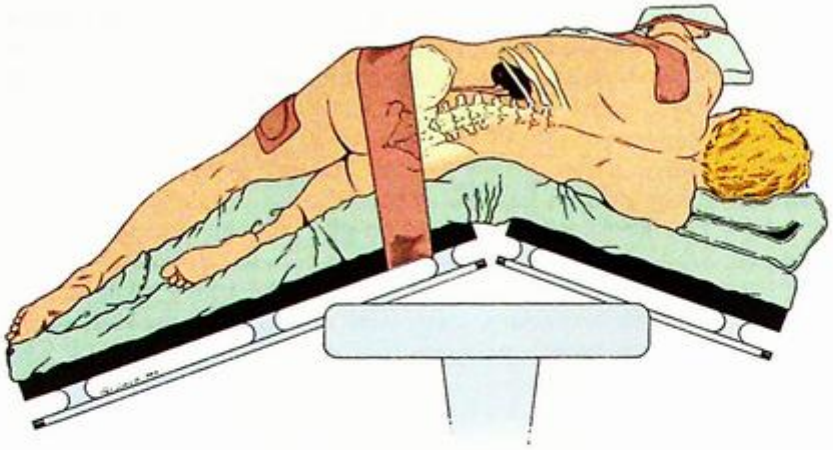

Figure 50–6. Position of the patient for the flank approach. Note the axillary pad. The kidney rest may be elevated if further lateral extension is needed.

When access to the upper renal pole is required, the rib above is selected.

The patient is placed in the lateral position after being anesthetized and having an endotracheal tube inserted. The back should be placed fairly close to the edge of the operating table to ensure unimpeded access by the surgeon, and the patient should be positioned so that the tip of the 12th rib is over the kidney rest. The bottom leg is flexed to 90 degrees with the top leg straight to maintain stability. A pillow is placed between the knees, and a sponge pad is placed under the axilla to prevent compression of the axillary vessels and nerves. The patient is secured in this position with a wide adhesive tape passed over the greater trochanter and attached to the moveable portion of the table (Fig. 50–6). The extended upper arm can be supported on a padded Mayo stand, which is adjusted to the appropriate height to maintain the arm in a horizontal position with the shoulder rotated slightly forward.

Flexion of the table and elevation of the kidney rest should be performed slowly and may be delayed until the surgeon is ready to make the skin incision to minimize the time spent in this position. The flexion increases the space between the costal margin and the iliac crest and puts the flank muscles and skin on tension. Care must be taken with patients who have stiff spines to ensure that their extremities remain in contact with the table because their range of lateral flexion is limited. This position may not be well tolerated by elderly patients or by those with impaired cardiopulmonary function because it results in decreased venous return due to compression of the IVC and the dependent position of the legs. It also limits aeration of the lung on the dependent side. It is important to determine the blood pressure after the patient has been turned on the side and again after the table has been flexed and the kidney rest elevated. The rest may have to be lowered and the table unflexed if hypotension is observed. **Table flexion with elevation of the kidney rest may also cause ischemic damage to a previously operated on contralateral kidney** (Matin and Novick, 2001).

The flank incision is made directly over the appropriate rib, beginning at the lateral border of the sacrospinal muscle (Fig. 50–7). A left-sided 12th rib incision is demonstrated in Figures 50–7 to 50-12. After the external oblique and latissimus dorsi muscles and the slips of the underlying serratus inferior posterior muscles are divided (Fig. 50–8), the periosteum over the rib is incised with a scalpel or by diathermy. The flat periosteal elevator is used to reflect the periosteum off the rib (Fig. 50–9). Mobilization of the periosteum is completed by separating it from the inner aspect of the rib with use of a Doyen periosteal elevator (Fig. 50–10). The proximal end of the rib is then transected as far back as possible with the guillotine

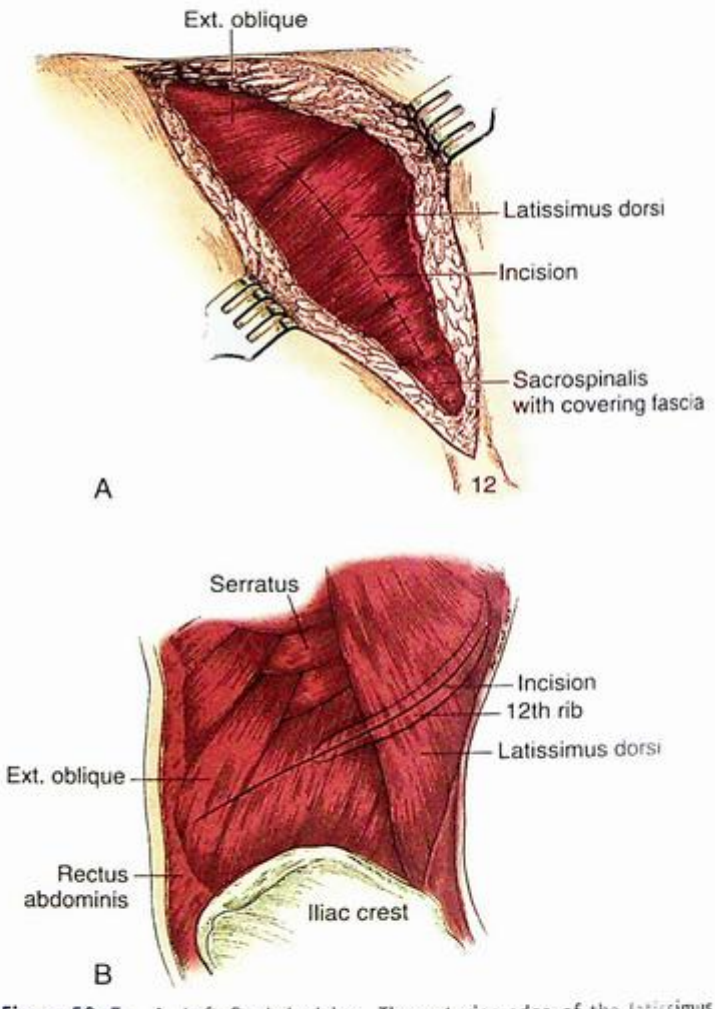

Figure 50–7. **A,** Left flank incision. The anterior edge of the latissimus dorsi muscle overlies the posterior edge of the external oblique muscle. **B,** The relationship of the 12th rib to the overlying muscles.

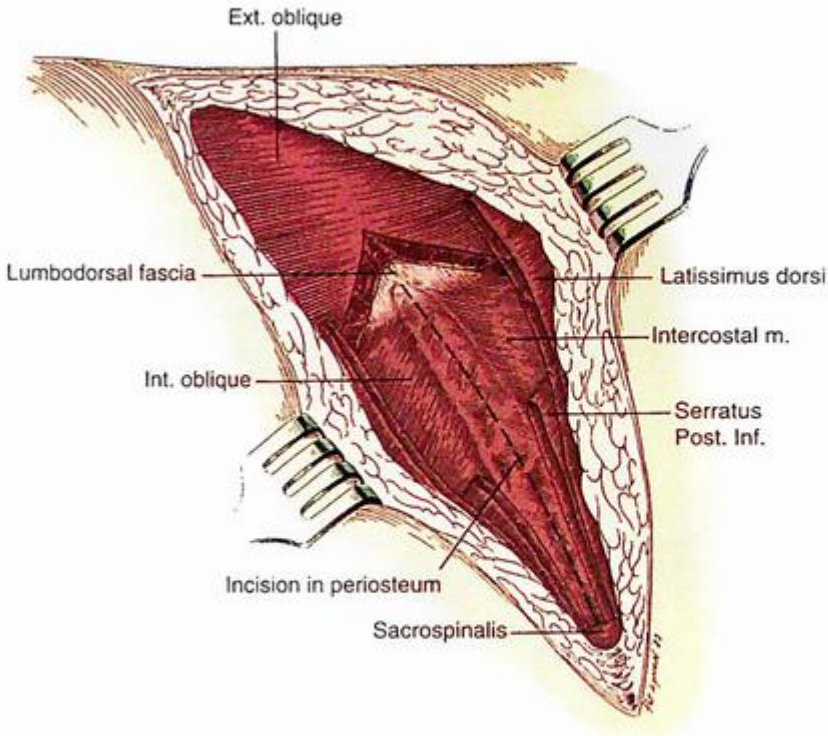

Figure 50–8. The muscles in the posterior part of the wound have been divided to expose the rib for incision of the periosteum.

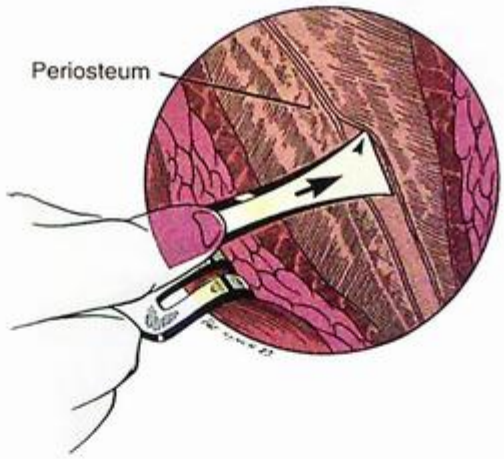

Figure 50–9. The periosteum is reflected off the upper surface of the rib. Note that the periosteal elevator is moved distally or downward on the upper edge of the rib against the direction of the intercostal muscle fibers.

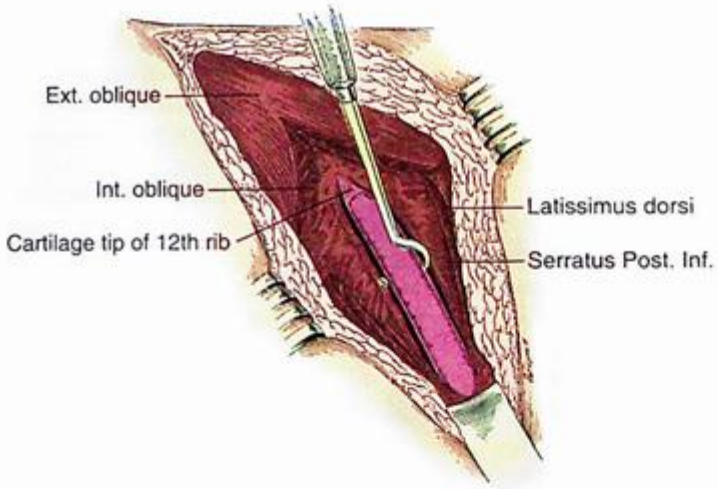

Figure 50–10. The periosteum is dissected off the rib, with use of a Doyen periosteal elevator, before resection of the rib.

rib resector. The retracted muscle mass is allowed to fall back over the sharp cut edge, protecting the operator from injury. The rib is grasped with a Kocher clamp and is separated by sharp dissection from the muscles attached anteriorly to complete its removal.

When the 11th rib is resected, attention must be directed at the pleural reflection, which crosses its lower border at the junction of the anterior and middle thirds and occupies the posterior part of the wound as it lies on the lower fibers of the diaphragm. The pleura may be reflected upward by sharply dividing the fascial attachments to the diaphragm. Alternatively, the lower fibers of the diaphragm can be detached from their insertion into the posterior inner aspect of the 12th rib. This allows the lower diaphragm and pleura to be retracted upward, out of the wound.

An incision is now made through the periosteal bed of the rib to expose Gerota's fascia (Fig. 50–11). The incision is completed anteriorly by incising the lumbar fascia and inserting two fingers into the perinephric space to push the underlying peritoneum forward. The lateral peritoneal reflection is peeled off the undersurface of the anterior abdominal wall and the transversalis fascia by sweeping it forward with the fingers. The external and internal oblique muscles are divided by incising them sharply or with electrocautery while they are tented

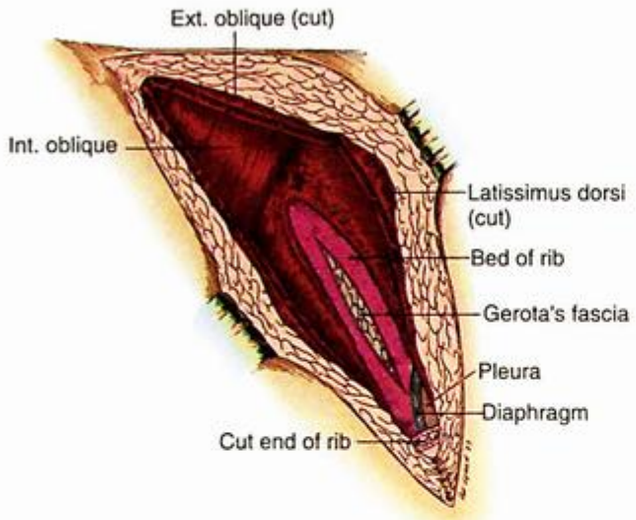

Figure 50–11. The rib has been resected, exposing the diaphragm and pleura in the posterior part of the wound. The slips of the diaphragm inserting into the rib have been divided, allowing the pleura to be displaced upward. An incision is made through the periosteal bed of the wound to expose Gerota's fascia.

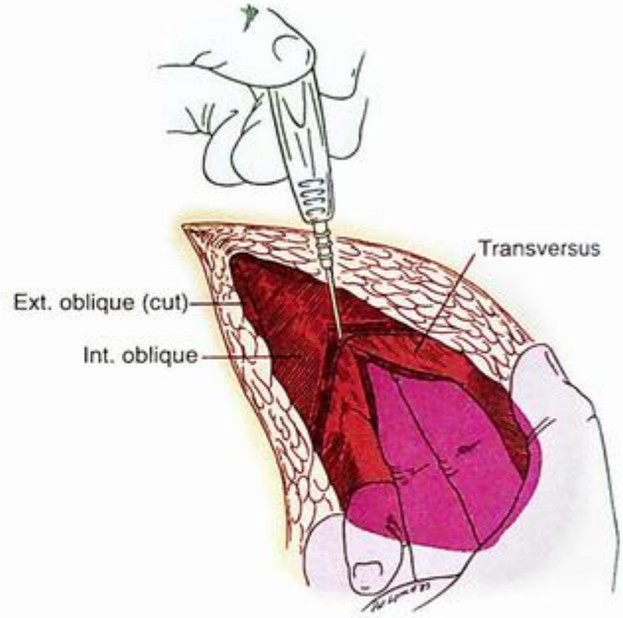

Figure 50–12. Two fingers are inserted into the incision in the posterior part of the transverse muscle to sweep the peritoneal reflection forward and divide the anterior abdominal muscles.

up over the two fingers inserted below the transverse muscle (Fig. 50–12). A little upward pressure controls bleeding from the severed vessels, allowing them to be clamped or cauterized by the assistant. This should expose the intercostal neurovascular bundle as it courses forward and downward between the internal oblique and transverse muscles. The transverse fibers of the transverse muscle may be split by blunt dissection below the nerve, allowing it to fall away with the upper margin of the incision.

A Finochietto retractor is used to maintain the exposure. The blades of the retractor are placed over moistened gauze sponges to avoid breaking a rib. The perinephric space is entered by incising Gerota's fascia posteriorly to avoid injury to the peritoneum. Care should be taken to avoid injury to the iliohypogastric and ilioinguinal nerves as they emerge from behind the lateral border of the psoas muscle and pass down over the anterior surface of the quadratus lumborum in the renal fossa.

The incision is closed by careful approximation of the corresponding muscle and fascial layers. To facilitate this, the kidney rest is lowered, and the table is returned to the horizontal position. Care must be taken to avoid inclusion of any intercostal nerves or branches during closure of the transverse muscle. Injection of 0.5% bupivacaine into the fascial sheath around the intercostal nerves as they emerge from the intervertebral foramina is helpful in diminishing postoperative pain and involuntary splinting of the lower chest. Drains are usually brought out posteriorly through a separate stab incision below the wound.

On occasion, a subcostal flank incision is indicated for surgery on the lower renal pole or upper ureter, insertion of a nephrostomy tube, or drainage of a perinephric abscess. It has the disadvantage of being low in relation to the usual position of the kidney, which makes access to the pedicle and renal pelvis more difficult. Exposure may be hampered by the iliac crest and subcostal nerve. The subcostal incision does not have these disadvantages in children, in whom it provides good access to the kidney because the lower ribs are soft and easily displaced upward.

The subcostal incision is begun at the lateral border of the sacrospinal muscle where it crosses the inferior edge of the 12th rib and is carried forward about a fingerbreadth below the lower border of the last rib onto the anterior abdominal wall. The medial end of the incision is curved slightly downward as it passes the midaxillary line to avoid the subcostal nerve and may be extended as far as the lateral border of the rectus abdominis muscle. The extent of the incision is modified, depending on the location of the kidney and the nature of the disease.

With a subcostal incision, the latissimus dorsi muscle is divided in the posterior part of the wound to expose the posterior edge of the external oblique muscle (Fig. 50–13). The serratus inferior posterior muscles, arising from the lumbar fascia and inserting into the lower four ribs, are divided in the posterior portion of the wound. The external oblique muscle is divided anteriorly. The fused layers of the lumbodorsal fascia are now exposed, giving origin to the internal oblique and transverse muscles. After the internal oblique muscle is divided, the transverse muscle is separated bluntly either above or below the subcostal nerve, depending on the course of the nerve in relation to the incision (Fig. 50–14). Every effort should be made to avoid injury to the intercostal nerves; this may cause persistent postoperative pain or bulging in the flank due to paresis of the denervated muscle. The lumbar fascia and the lateral border of the sacrospinal muscle may need to be incised to improve exposure in the posterior part of the wound. Division of the costotransverse ligament as it passes up to the neck of the 12th rib allows the rib to be retracted upward to further improve the exposure. The closure is as described for a flank incision.

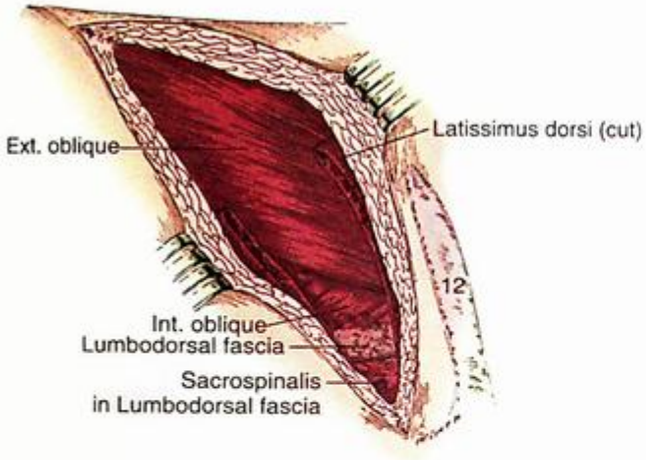

Figure 50–13. Left subcostal incision. The latissimus dorsi muscle has been divided to expose the lumbodorsal fascia and the posterior aspects of the abdominal muscles.

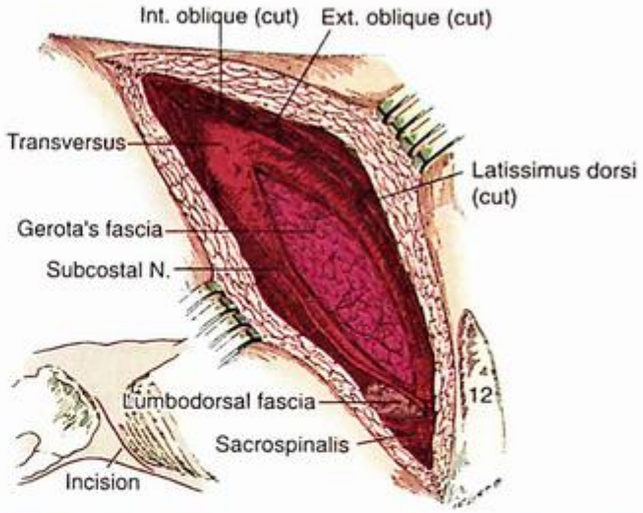

Figure 50–14. The lumbodorsal fascia and transverse muscles have been divided to expose Gerota's fascia. The subcostal nerve and vessels pierce the lumbodorsal fascia posteriorly and course forward on the transverse muscle.

Dorsal Lumbotomy

The dorsal lumbotomy incision is a potentially useful approach for removal of a small kidney, for bilateral nephrectomy in patients with end-stage renal disease, or for open renal biopsy. It has also been used in the past for pyeloplasty, for pyelolithotomy, and for upper ureterolithotomy (Novick, 1980). This approach offers several advantages in performing these operations (Gardiner et al, 1979). Unlike with the standard flank incision, no muscles are transected, and access to the kidney is obtained by simply incising the posterior fascial layers. This approach is more rapid, provides strong wound closure with less postoperative pain, and obviates anterolateral bulging of the abdomen that commonly results from flank incisions. With detachment of the costovertebral ligament, the 12th rib can be retracted widely laterally, rendering resection of the rib unnecessary.

The dorsal lumbotomy approach is also advantageous in patients with prior abdominal or flank operations on the kidney because it permits dissection of fresh tissue planes. **The major disadvantage of dorsal lumbotomy is its limited access to the kidney and renal vessels, which can pose a problem if there are intraoperative complications such as migration of a calculus or injury to major renal vessels with bleeding.**

When bilateral nephrectomy is done, the patient is placed in the prone position with the table flexed to increase the distance between the 12th rib and the iliac crest. In this position, the patient is supported over the sternum and pubis so that there is free excursion of the anterior abdominal wall to prevent embarrassment of respiration and venous return. For unilateral renal operations, the patient may be placed in the lateral position with the table flexed to extend the lumbar region. In this position, a sandbag is placed between the abdomen and the table for support and to help push the kidney posteriorly.

A vertical lumbar incision is made along the lateral margin of the sacrospinal muscle. The incision begins at the upper margin of the 12th rib superiorly and follows a gentle lateral curve to the iliac crest inferiorly (Fig. 50–15*A*). The incision is carried through the lumbodorsal fascia just lateral to the sacrospinal and quadratus lumborum muscles, which are then retracted medially to approach the renal fossa (Fig. 50–15*B*). The transverse fascia is incised to expose the kidney contained within Gerota's fascia (Fig. 50–15C). Exposure of the kidney is thus obtained without transection of any muscle fibers. If additional superior exposure is needed, the costovertebral ligamentous attachment of the 12th rib is divided to allow lateral and superior retraction of the rib (Fig. 50–15*D* and *E*). The kidney can be mobilized and delivered down into the incision, provided the lower third of the kidney is below the 12th rib on preoperative radiographs. However, for high-lying or enlarged kidneys, the dorsal lumbotomy approach is cumbersome, and either a flank or an anterior incision provides better exposure. To close the incision, the retracted muscles are allowed to return to their original position, and the lumbodorsal fascia is reapproximated.

Abdominal Incisions

The principal advantage of the abdominal approach is that exposure in the area of the renal pedicle is excellent. The principal disadvantage is the somewhat longer period of postoperative ileus and the possible long-term complication of intra-abdominal adhesions leading to bowel obstruction. The choice between a vertical and a transverse type of abdominal incision is determined by the patient's anatomy and disease entity. A vertical incision is easier and quicker to perform and repair because it involves division of only the linea alba or the anterior and posterior layers of the rectus sheet rather than several muscle layers. The vertical incision may be used in patients with a narrow subcostal angle and is preferred in patients with renal injury because it allows better access for inspection of the remainder of the abdominal contents for associated injuries. A transverse incision is preferable for patients with a wide subcostal angle and for exploration or removal of renal mass lesions (Chute et al, 1967). This incision provides better access to the lateral and superior portion

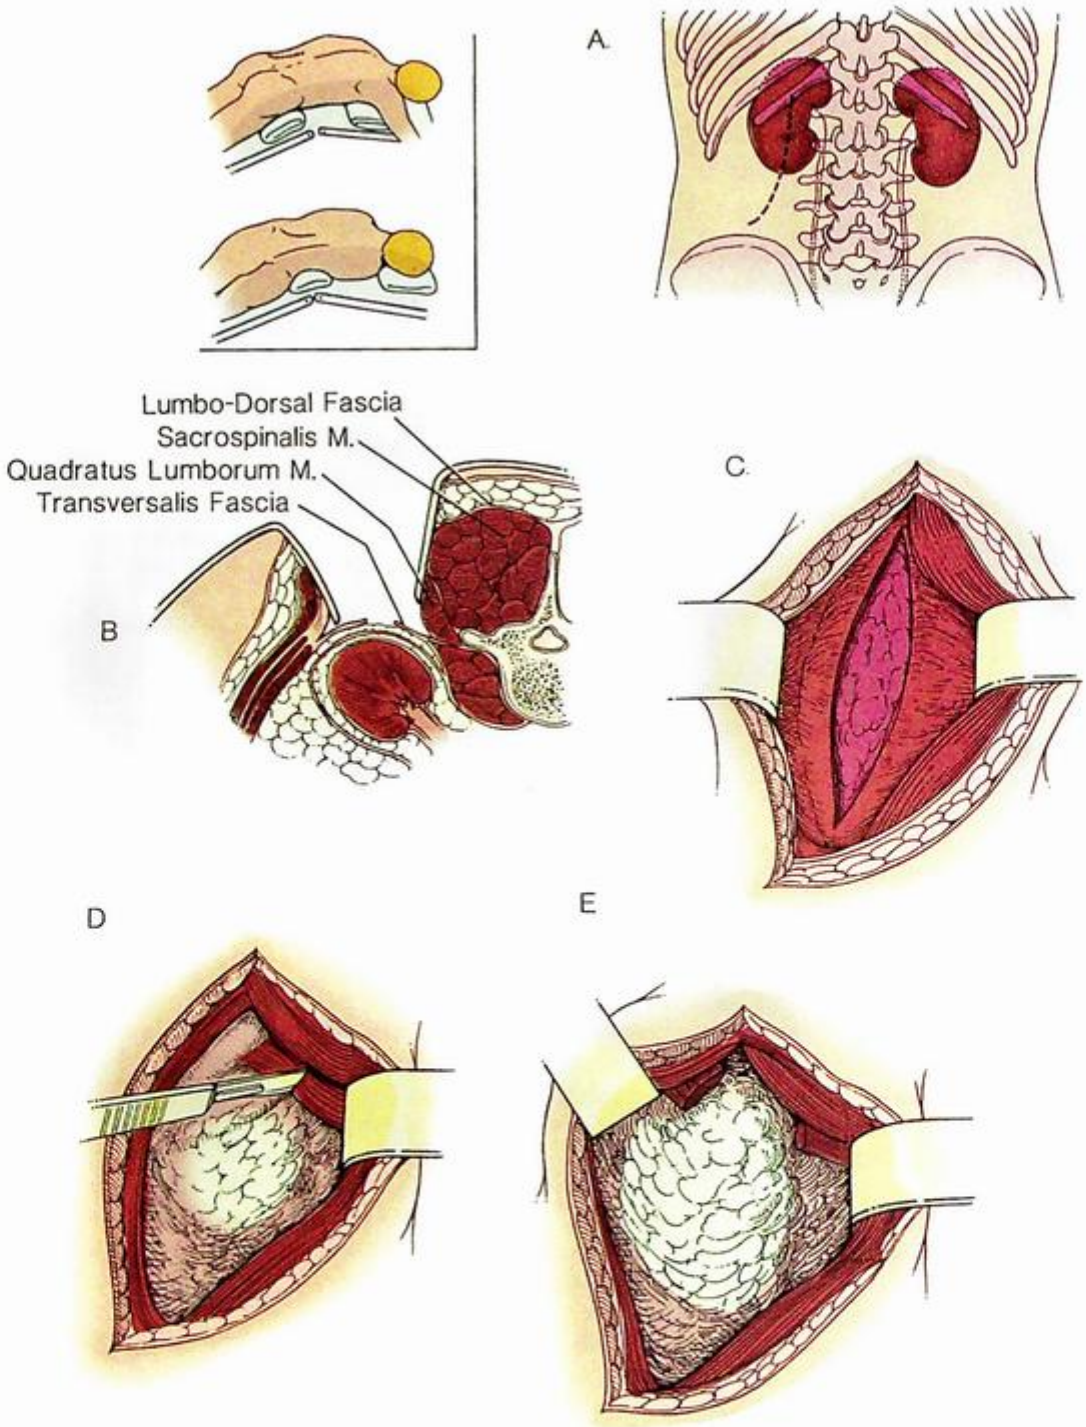

Figure 50–15. The dorsal lumbotomy incision.

of the kidney. A unilateral subcostal incision can be extended across the midline as a chevron incision to provide excellent exposure of both kidneys along with the aorta and the IVC.

When an anterior subcostal incision is employed, the patient is in the supine position with a rolled sheet beneath the upper lumbar spine. The incision begins approximately 1 to 2 fingerbreadths below the costal margin in the anterior axillary line and then extends with a gentle curve across the midline, ending at the midportion of the opposite rectus muscle. The incision is carried through the subcutaneous tissues to the anterior fascia, which is divided in the direction of the incision. In the lateral aspect of the incision, a portion of the latissimus dorsi muscle is divided. The external oblique muscle is divided, exposing the fibers of the internal oblique muscle (Fig. 50–16*A*). The rectus, internal oblique, and transverse abdominal muscles are divided along with the posterior rectus sheath (Fig. 50–16*B* and *C*). The peritoneal cavity is entered in the midline, and the ligamentum teres is divided (Fig. 50–16*D*).

The bilateral subcostal incision is performed as described for the unilateral incision, except that both sides are involved (Fig. 50–17). It extends from one anterior axillary line to the opposite anterior axillary line, with a gentle upward curve as it crosses the midline. This incision provides better exposure

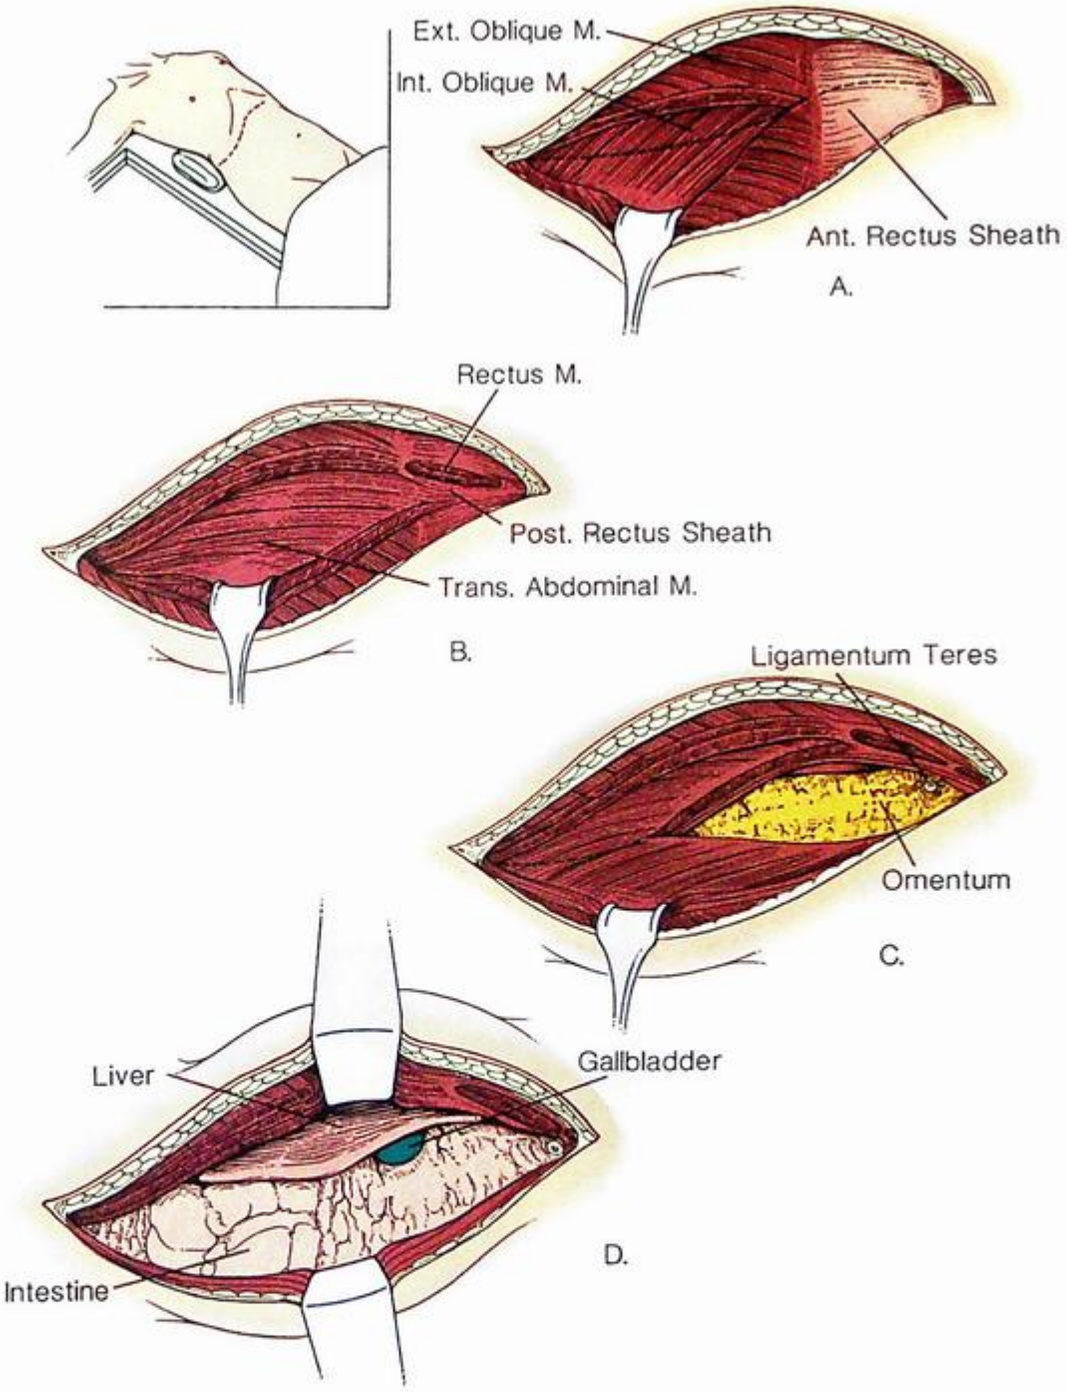

Figure 50–16. Unilateral anterior subcostal transperitoneal incision.

of both kidneys than does a midline incision, particularly in obese patients with a wide subcostal angle. The disadvantage is that it involves extensive transection of the abdominal wall musculature.

An extraperitoneal anterior subcostal approach may be useful to perform open renal biopsy or nephrectomy, particularly when there has been a previous intra-abdominal procedure or when there is a possibility that the patient may require peritoneal dialysis postoperatively (Lyon, 1958). The peritoneal cavity is not entered, thereby minimizing postoperative ileus and the chance of intra-abdominal complications. Reflection of the peritoneum off the anterior abdominal wall may at times be difficult, and access to the renal pedicle may be less satisfactory than with a transperitoneal incision.

The patient is placed in a semioblique position with a rolled sheet beneath the side on which the incision is to be made. The muscle layers are divided as they are for a unilateral subcostal incision, except that the peritoneal cavity is not entered. The peritoneum is mobilized intact from the undersurface of the lateral musculature and rectus sheath and is then retracted medially to expose the retroperitoneal space (Fig. 50–18).

When a midline upper abdominal incision is employed, the patient is placed supine on the operating table with a rolled sheet beneath the upper lumbar spine. The incision extends

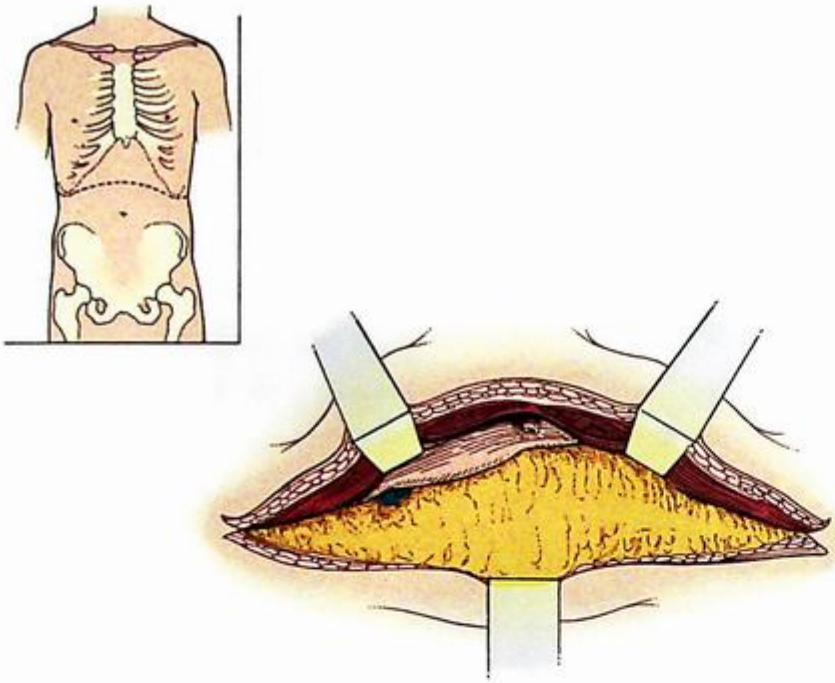

Figure 50–17. Bilateral anterior subcostal transperitoneal incision.

from the xiphoid to the umbilicus and can be extended around the umbilicus on either side if necessary. The incision is carried down through the subcutaneous tissues to the linea alba, which is the midline fusion of the tendinous fibers of the anterior rectus sheath. The linea alba is divided to expose the extraperitoneal fat and peritoneum, which is then entered (Fig. 50–19).

A paramedian incision is another type of vertical abdominal incision that may be preferred because the separate closure of the two layers of the rectus sheath makes the wound more secure. The incision is made about 3 cm lateral to the midline to provide an adequate margin of rectus sheath medially (Fig. 50–20). The anterior sheath is divided and reflected medially off the underlying muscle by sharp division of the tendinous intersections. The free medial edge of the muscle is retracted laterally to allow the posterior rectus sheath and peritoneum to be incised (Fig. 50–21). An extraperitoneal approach to the kidney can also be made through a paramedian incision by carefully reflecting the peritoneum off the posterior rectus sheath after it has been divided (Tessler et al, 1975).

Thoracoabdominal Incision

The thoracoabdominal approach is desirable for performing radical nephrectomy in patients with large tumors involving the upper portion of the kidney (Clarke et al, 1958; Khoury, 1966; Middleton and Presto, 1973; Chute et al, 1949). It is particularly advantageous on the right side, where the liver and its venous drainage into the upper vena cava can limit exposure and impair vascular control as the tumor mass is being removed. There is less need for a thoracoabdominal incision on the left side because the spleen and pancreas can usually be readily elevated away from the tumor mass. The thoracoabdominal incision optimizes exposure of the suprarenal area. Nevertheless, because it involves additional operative time and greater potential pulmonary morbidity, I reserve this approach for patients in whom additional exposure over that provided by an anterior subcostal incision is considered important to achieve complete and safe tumor removal.

The patient is placed in a semioblique position with a rolled sheet placed longitudinally beneath the flank. The lower leg is flexed and the upper one is extended with a pillow beneath the legs. The pelvis assumes a more horizontal position, tilted only about 10 to 15 degrees, which allows free access to the anterior abdominal wall. The incision is begun in the eighth or ninth intercostal space near the angle of the rib and carried across the costal margin to the midpoint of the opposite rectus muscle just above the umbilicus. The incision is carried down to the fascia, which is divided in the direction of the incision (Fig. 50–22*A*). The latissimus dorsi, external oblique, rectus, and intercostal muscles are also divided in the direction of the incision. The costal cartilage between the tips of the adjacent ribs is divided (Fig. 50–22*B*). The pleura in the posterior portion of the incision is opened to obtain complete exposure of the diaphragm (Fig. 50–22*C*).

The diaphragmatic incision is begun at the periphery about 2 cm inside its attachment to the chest wall; the incision is then carried around circumferentially to the posterior aspect of the diaphragm (Fig. 50–22*D*). In doing this, there must be at least 2 or 3 cm of diaphragm left attached to the rib cage to allow later reconstruction. By dividing the diaphragm in a circumferential manner from anterior to posterior, damage to the phrenic nerve is avoided. This also develops a diaphragmatic flap that can be pushed into the chest to provide complete exposure of the liver, which is then simply retracted upward (Fig. 50–22*E*). If further mobilization of the liver is needed, the right triangular ligament and coronary ligament can be incised to mobilize the entire right lobe of the liver upward. This provides excellent additional exposure of the suprarenal vena cava. Medial to the ribs, the internal oblique and transverse abdominal muscles are divided and the peritoneal cavity is entered. The colon and duodenum are mobilized medially, and the liver is

retracted upward to expose the kidney and great vessels (Fig. 50–22*F*).

At the completion of the procedure, the abdominal viscera are replaced in their anatomic position. The diaphragm is repaired with interrupted 2-0 silk mattress sutures with the knots tied on the undersurface. The chest wall is reapproximated by passing 0-0 polyglycolic sutures around the ribs above and below. The sutures should be passed on a tapered needle to avoid cutting any vessels, with care taken to avoid the neurovascular bundle. Before the pleura is closed, a 20 French chest tube is placed in the pleural cavity and brought out through a stab wound below the incision in the posterior axillary line. The transected muscle and fascial layers are reapproximated separately. The chest tube is connected to an underwater drain; it is usually removed 24 to 48 hours postoperatively, provided there is no persistent leakage of air and a chest radiograph shows satisfactory lung expansion.

SIMPLE NEPHRECTOMY

Indications

Simple nephrectomy is indicated in patients with an irreversibly damaged kidney due to symptomatic chronic infection, obstruction, calculus disease, or severe traumatic injury. It is occasionally appropriate to remove a functioning kidney involved with one of these conditions when the patient's age or general condition is too poor to permit a reconstructive operation and provided the opposite kidney is normal. Nephrectomy may also be indicated to treat renovascular hypertension due to noncorrectable renal artery disease or severe unilateral parenchymal damage from nephrosclerosis, pyelonephritis, reflux, or congenital dysplasia.

Simple nephrectomy can be performed through a variety of incisions. **An extraperitoneal flank approach is usually preferable when the kidney is chronically infected, when the patient is obese, or when multiple prior abdominal operations have been performed.** A subcapsular approach is indicated when severe perirenal inflammation or adhesions obscure anatomic relationships between the kidney and the surrounding structures. A transperitoneal approach is preferable in patients who cannot tolerate the flank position, in patients with end-stage renal disease undergoing bilateral nephrectomy for polycystic kidney disease, and in cases of traumatic renal injury in which early access to the pedicle is necessary. The transperitoneal approach is also useful when multiple operations have been performed previously through the flank with resulting dense adhesions around the kidney. Bilateral nephrectomy in patients with small end-stage kidneys can be done through a bilateral simultaneous posterior approach (Novick, 1980).

Flank Approach

Once the perinephric space is entered, access to the kidney is obtained by incising Gerota's fascia on the lateral aspect of the kidney to avoid injury to the overlying peritoneum (Fig. 50–23*A*). The plane of cleavage between the perinephric fat and the renal capsule is usually developed easily. The kidney is mobilized by blunt dissection, and on the left side, the pancreas and duodenum are carefully reflected medially along with the peritoneum. The ureter is identified during mobilization of the lower renal pole. It is preferable to divide the ureter after ligation of the pedicle to avoid congestion of the kidney. The kidney is pulled downward, and the upper pole is dissected free. There is normally a separate compartment in Gerota's fascia for the adrenal gland, which enables it to be readily separated from the upper pole.

The kidney is pulled laterally to identify the renal artery and vein, which are separated from surrounding fatty and lymphatic tissues by blunt dissection (Fig. 50–23*B*). Whenever possible, it is preferable to secure the vessels individually away from the hilum, and the artery should always be ligated first. The renal vein is usually visualized easily and is mobilized by ligating and dividing the gonadal, adrenal, and lumbar branches. The vein can then be retracted to expose the artery, which lies posteriorly. Alternatively, the renal vein can be approached posteriorly by mobilizing the kidney and retracting it up into the wound. The renal artery and vein are individually secured with 2-0 silk ligatures and then divided (Fig. 50–23*C*). The ureter is clamped and divided, and the distal end is ligated with 2-0 chromic catgut to complete the nephrectomy (Fig. 50–23*D*).

Subcapsular Technique

Subcapsular nephrectomy is indicated when severe perirenal inflammation precludes satisfactory dissection between the kidney and the surrounding structures (Kimbrough and Morse, 1953; Kittredge and Fridge, 1958). After the retroperitoneal space has been entered, the renal capsule is identified, and a longitudinal incision is made over the lateral surface of the kidney (Fig. 50–24*A*). Once the capsule has been entered, a plane is developed between the renal parenchyma and the capsule over the entire surface of the kidney down to the level of the hilum (Fig. 50–24*B* and *C*). The renal parenchyma is retracted laterally to expose the major renal vessels as they enter the hilum. Vascular branches are ligated and transected as far laterally as possible to allow satisfactory proximal control of each branch (Fig. 50–24*D*). The upper ureter is then ligated and divided to complete the nephrectomy.

Transperitoneal Approach

In transperitoneal simple nephrectomy, a subcostal incision is made, and the peritoneal cavity is entered. On the left side, the colon, pancreas, and spleen are reflected upward and medially to expose the left renal vein. A self-retaining ring retractor is useful to maintain exposure of the surgical field (Fig. 50–25*A*).

The renal vein and artery are mobilized, ligated, and transected (Fig. 50–25*B*). The artery is occluded first to avoid excessive blood loss into the kidney. The kidney is then mobilized laterally, superiorly, and inferiorly by sharp and blunt dissection. It is best to initiate the dissection laterally to obtain maximum mobilization before approaching the posterior renal hilum, where friable lumbar veins may be present (Fig. 50–25*C*). In cases of severe perirenal fibrosis, it may be necessary to remove some of the posterior psoas fascia together

with the kidney. After complete renal mobilization, the ureter is ligated and divided to complete the nephrectomy.

RADICAL NEPHRECTOMY

Indications and Evaluation

Radical nephrectomy is the treatment of choice for patients with localized renal cell carcinoma (RCC) (Robson et al, 1969; Skinner et al, 1971). The preoperative evaluation of patients with RCC has changed considerably during the past 2 decades owing to the advent of new imaging modalities such as ultrasonography, CT scanning, and magnetic resonance imaging. In many patients, a complete preliminary evaluation can be performed with these noninvasive modalities. Renal arteriography is no longer routinely necessary before radical nephrectomy. All patients should undergo a metastatic evaluation including a chest radiograph, an abdominal CT scan, and occasionally a bone scan; the last is necessary only in patients with bone pain or elevated serum alkaline

phosphatase. Radical nephrectomy is occasionally done in patients with metastatic disease to palliate severe associated local symptoms or to allow entry into a biologic response modifier treatment protocol or concomitant with resection of a solitary metastatic lesion.

Involvement of the IVC with RCC occurs in 4% to 10% of cases and renders the task of complete surgical excision more complicated (Schefft et al, 1978). However, operative removal offers the only hope for cure, and when there are no metastases, an aggressive approach is justified. Five-year survival rates of 40% to 68% have been reported after complete surgical excision (Libertino et al, 1987; Neves and Zincke, 1987; Skinner et al, 1989; Novick et al, 1990). The best results have been achieved when the tumor does not involve the perinephric fat and regional lymph nodes (Cherrie et al, 1982). The cephalad extent of vena caval involvement is not prognostically important, and even with intra-atrial tumor thrombi, extended cancer-free survival is possible after surgical treatment when there is no nodal or distant metastasis (Glazer and Novick, 1996). In planning the appropriate operative approach for tumor removal, it is essential for preoperative radiographic studies to define accurately the distal limits of a vena caval tumor thrombus.

RCC involving the IVC should be suspected in patients who have lower extremity edema, varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or nonfunction of the involved kidney. Magnetic resonance imaging is the preferred diagnostic study for demonstrating both the presence and the distal extent of IVC involvement (Pritchett et al, 1987; Goldfarb et al, 1990). Transesophageal echocardiography (Fig. 50–26) (Treiger et al, 1991; Glazer and Novick, 1997) and transabdominal color Doppler ultrasonography (McGahan et al, 1993) have also proved to be useful diagnostic studies in this regard. Inferior venacavography is reserved for patients in whom a magnetic resonance imaging or ultrasound study is either nondiagnostic or contraindicated. Renal arteriography may be helpful in patients with RCC involving the IVC when distinct arterialization of a tumor thrombus is observed. When this finding is present, preoperative embolization of the kidney often causes shrinkage of the thrombus, which facilitates its intraoperative removal. When adjunctive cardiopulmonary bypass with deep hypothermic circulatory arrest is considered, coronary angiography is also performed preoperatively (Belis et al, 1989; Novick et al, 1990). If significant obstructing coronary lesions are found, these can be repaired simultaneously during cardiopulmonary bypass.

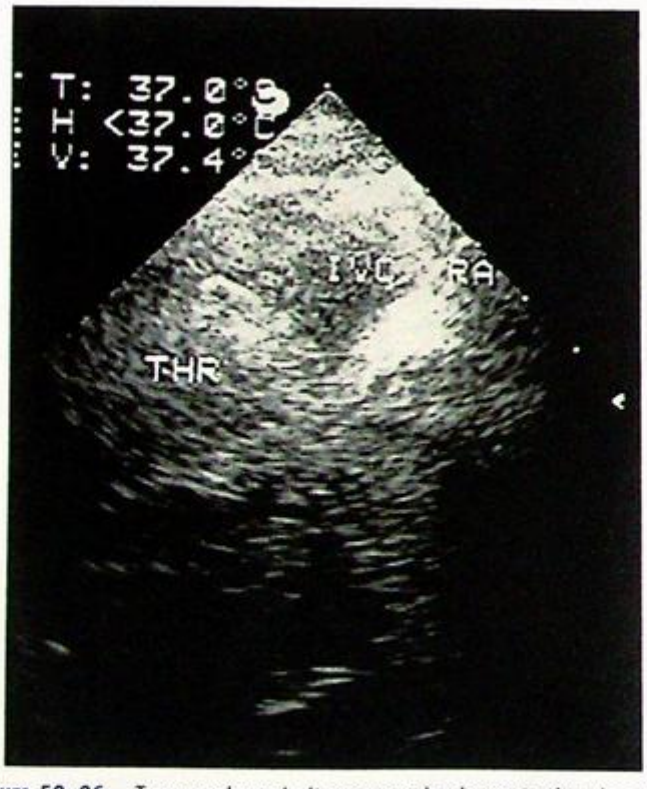

Figure 50–26. Transesophageal ultrasonography demonstrating thrombus (THR) in the intrahepatic inferior vena cava (IVC) proximal to the right atrium (RA).

Standard Technique

Radical nephrectomy encompasses the basic principles of early ligation of the renal artery and vein, removal of the kidney outside Gerota's fascia, removal of the ipsilateral adrenal gland, and performance of a complete regional lymphadenectomy from the crus of the diaphragm to the aortic bifurcation (Robson et al, 1969). **Perhaps the most important aspect of radical nephrectomy is removal of the kidney outside Gerota's fascia because capsular invasion with perinephric fat involvement occurs in 25% of patients. It has been shown that removal of the ipsilateral adrenal gland is not routinely necessary unless the malignant neoplasm either extensively involves the kidney or is located in the upper portion of the kidney** (Sagalowsky et al, 1994). Although lymphadenectomy allows more accurate pathologic staging, its therapeutic value remains controversial. Nevertheless, there may be a subset of patients with micrometastatic lymph node involvement who can benefit from lymphadenectomy (Giuliani et al, 1990). The need for routine performance of a complete lymphadenectomy in all cases is unresolved, and there remains a divergence of clinical practice among urologists with respect to this aspect of radical nephrectomy.

The surgical approach for radical nephrectomy is determined by the size and location of the tumor as well as by the habitus of the patient. The operation is usually performed through a transperitoneal incision to allow abdominal exploration for metastatic disease and early access to the renal vessels with minimal manipulation of the tumor. I prefer **an extended subcostal or bilateral subcostal incision for most patients. A thoracoabdominal incision is used for patients with large upper pole tumors** (Fig. 50–27). I occasionally employ an extraperitoneal flank incision to perform radical nephrectomy in elderly or poor-risk patients with a small tumor.

In radical nephrectomy through a subcostal transperitoneal incision, a thorough exploration for metastatic disease is performed after the abdominal cavity is opened. On the left side, the colon is reflected medially to expose the great vessels. This is facilitated by division of the splenocolic ligaments, which also helps avoid excessive traction on and injury to the spleen.

On the right side, the colon and duodenum are reflected medially to expose the vena cava and aorta (Fig. 50–28).

The operation is initiated with dissection of the renal pedicle. On the right side, the renal vein is short, and care must be taken not to injure the vena cava. The right renal artery may be mobilized either lateral to the vena cava or, with a large medial tumor, between the vena cava and the aorta (Fig. 50–29).

On the left side, the renal vein is quite long as it passes over the aorta. The vein is mobilized completely by ligating and dividing gonadal, adrenal, and lumbar tributaries. The vein can then be retracted to posteriorly expose the artery, which is then mobilized toward the aorta (Fig. 50–30). The renal artery is ligated with 2-0 silk ligatures and divided, and the renal vein is then similarly managed (Fig. 50–31).

The kidney is mobilized outside Gerota's fascia with blunt and sharp dissection as needed. The remaining vascular attachments are secured with nonabsorbable sutures or metal clips. The ureter is then ligated and divided to complete the removal of the kidney and adrenal gland (Fig. 50–32).

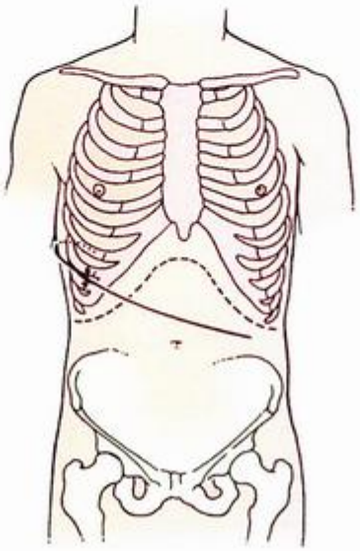

Figure 50–27. Radical nephrectomy is performed through either a bilateral subcostal or a thoracoabdominal incision.

The classic radical nephrectomy procedure includes the performance of a complete regional lymphadenectomy. The lymph nodes can be removed either en bloc with the kidney and adrenal gland or separately after the nephrectomy. Lymph node dissection is begun at the crura of the diaphragm just below the origin of the SMA. There is a readily definable periadventitial plane close to the aorta that can be entered so that the dissection may be carried along the aorta and onto the origin of the major vessels to remove all periaortic lymphatic tissue. Care must be taken to avoid injury to the origins of the celiac artery and SMA superiorly as they arise from the anterior surface of the aorta. The dissection of the periaortic and pericaval lymph nodes is then carried downward en bloc to the origin of the inferior mesenteric artery. The sympathetic ganglia and nerves are removed together with the lymphatic tissue. The cisterna chyli is identified medial to the right crus, and entering lymphatic vessels are secured to prevent the development of chylous ascites.

A thoracoabdominal incision is preferable in performing radical nephrectomy for a large upper pole tumor. This

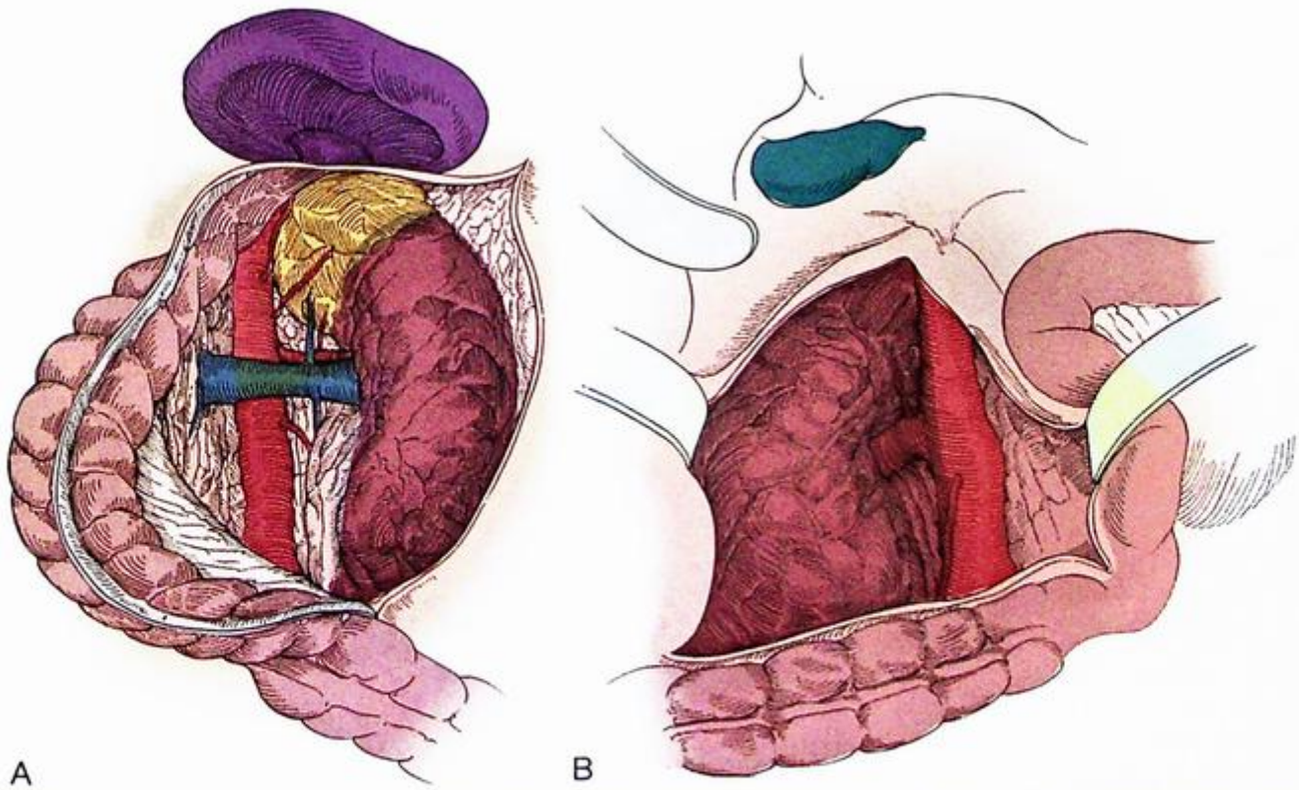

Figure 50–28. After the peritoneal cavity is entered, the colon is reflected medially to expose the left (**A**) or right (**B**) kidney and great vessels. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

approach is demonstrated in Figures 50-33 to 50-35 for a right-sided tumor. Once the liver has been retracted upward into the chest, the hepatic flexure of the colon and the duodenum are reflected medially to expose the anterior surface of the kidney and great vessels (Fig. 50–33). The renal artery is secured with 2-0 silk ligatures and divided, and the renal vein is then similarly managed (Fig. 50–34). The ureter and right gonadal vein are ligated and divided, and the kidney is mobilized outside Gerota's fascia. Downward and lateral traction of the kidney exposes the superior vascular attachments of the tumor and adrenal gland. Exposure of these vessels is also facilitated by medial retraction of the IVC (Fig. 50–35). Care is taken to preserve small hepatic venous branches entering the vena cava at the superior margin of the tumor mass. The tumor mass is then gently separated from the undersurface of the liver to complete the resection.

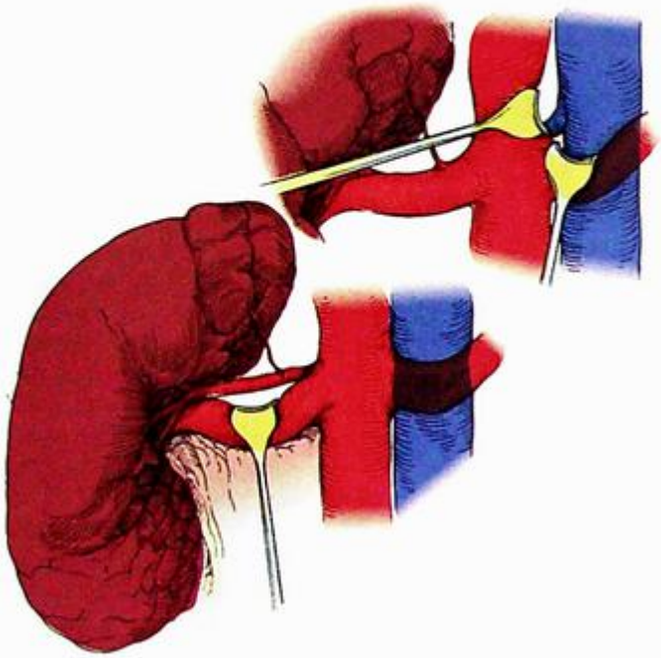

Figure 50–29. The right renal artery may be mobilized either lateral to the vena cava or between the vena cava and the aorta. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

Management of Retroperitoneal Hemorrhage

During performance of radical nephrectomy, intraoperative hemorrhage can occur from the IVC or its tributaries. The urologist should be familiar with methods of preventing or controlling this problem. In most cases, vena caval hemorrhage is caused by the laceration or avulsion of large yet fragile veins entering the vena cava at predictable locations.

Lumbar veins enter the posterolateral aspect of the vena cava at each vertebral level, and undue traction on the cava can result in their avulsion with troublesome bleeding. To prevent this, care should be taken to retract the vena cava gently with curved vein retractors during its dissection; if additional mobilization is necessary, these veins should be dissected free from surrounding structures, ligated, and divided. In ligating venous tributaries entering the vena cava, 3-0 to 4-0 suture material should be used, and the ligatures should not be tied too tightly because this can cause shearing through the

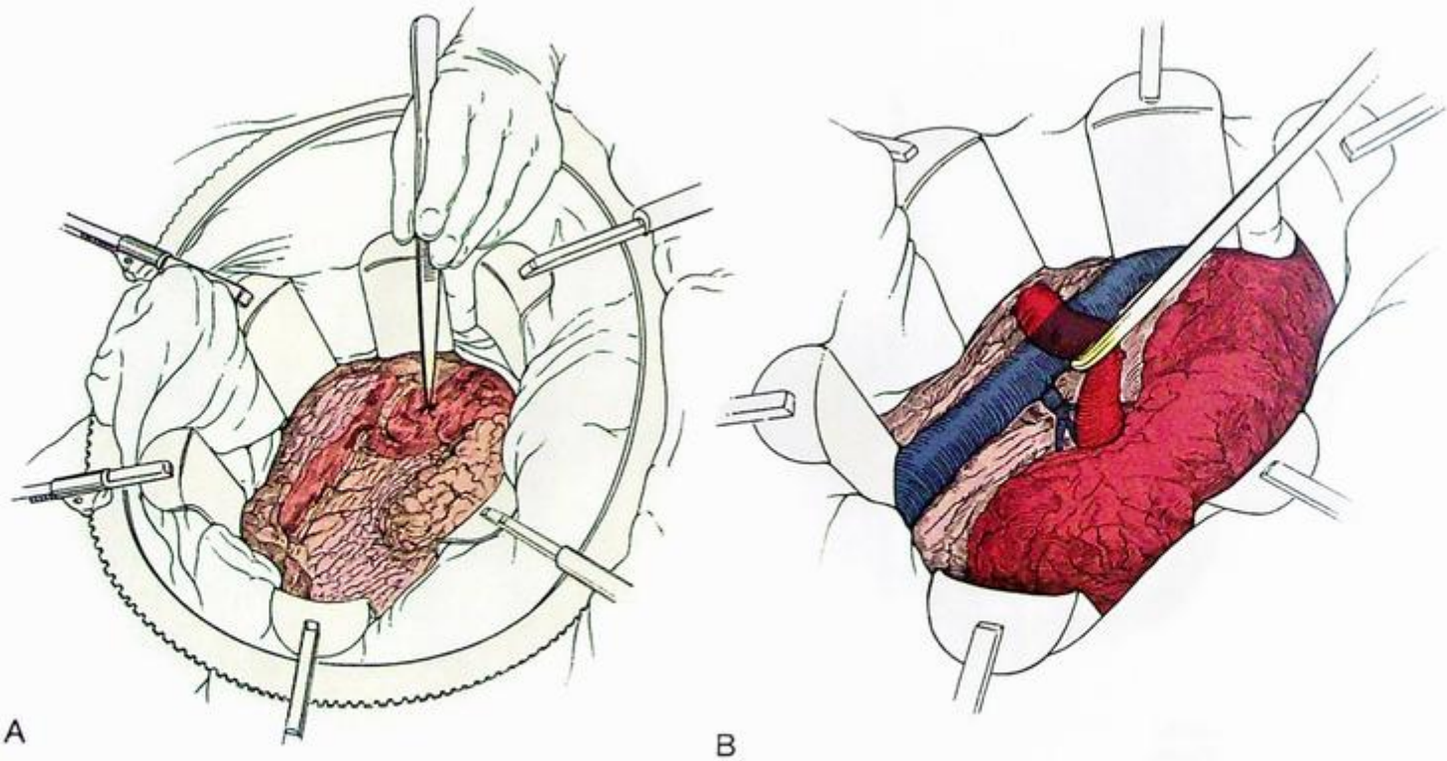

Figure 50–30. **A**, Self-retaining ring retractor is inserted to maintain exposure. **B**, Left renal vein is mobilized by ligation of its major branches to expose the artery posteriorly. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

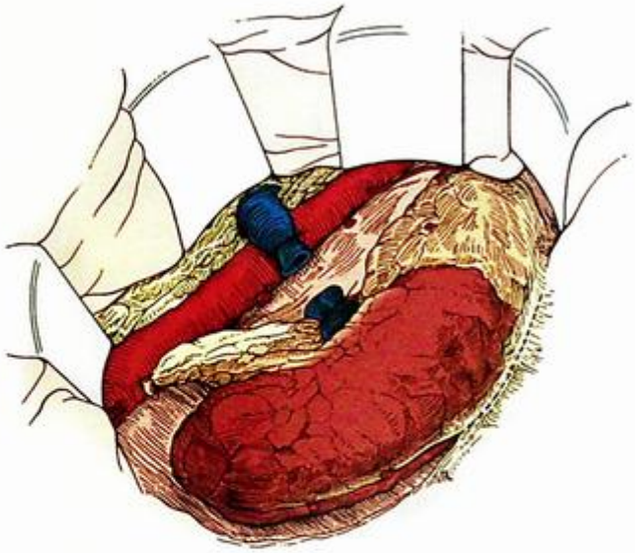

Figure 50–31. After the pedicle is secured and the ureter divided, the kidney is mobilized outside Gerota's fascia. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

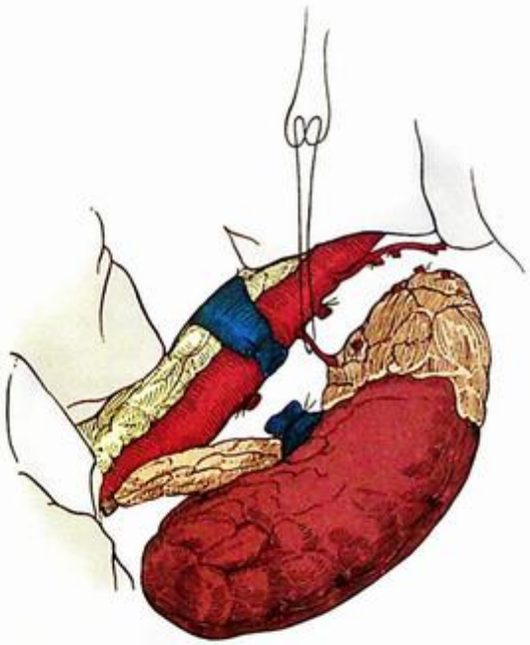

Figure 50–32. Remaining medial vascular attachments are secured and divided to complete the nephrectomy. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

fragile venous wall with further hemorrhage. After the ligature has been applied, it should not be pulled too tightly before the ends of the ligature are cut, again for fear of avulsing the entrance of the vein into the vena cava.

A second predictable bleeding site is the entry of the right gonadal vein into the anterolateral surface of the vena cava. This is an extremely thin-walled vein, and excessive traction or mobilization of the cava at this level can lead to its avulsion, with resulting hemorrhage.

A third predictable site of bleeding lies at the level of the renal veins, where large lumbar veins often course posteriorly from the left renal vein just lateral to the aorta or from the posterior aspect of the vena cava close to the entry of the right renal vein. Injudicious mobilization of the renal veins, without consideration of these fragile and often large-caliber veins, can result in severe hemorrhage that may be difficult to control.

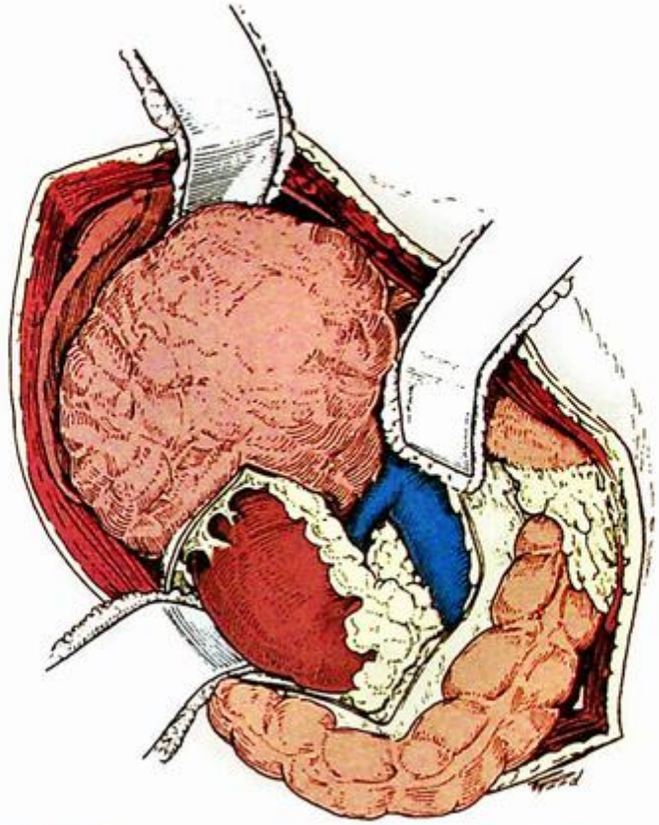

Figure 50–33. Exposure of large right upper pole tumor through a thoracoabdominal incision. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

A fourth predictable site of bleeding is at the level of the right adrenal vein that enters the IVC. This vein is large and friable, frequently lies higher than the surgeon expects, and must be carefully dissected free from surrounding structures to avoid avulsion from the vena cava.

Finally, excessive vena caval hemorrhage can be prevented by careful dissection in proper tissue planes along the vena cava. This may be difficult when tumor involves the vena cava, but a plane can usually be established along the vena caval wall that, if followed, allows safe and relatively bloodless exposure. One should follow the general principle of isolating a relatively normal area of vena cava and working upward or downward from that level to expose the diseased portion.

If inadvertent vena caval laceration or avulsion of entering veins occurs, control of hemorrhage can be accomplished by a variety of techniques. Direct pressure on the site of bleeding gives immediate control until additional exposure can be gained, the field properly illuminated, and additional suckers or retractors brought in if necessary. If the laceration involves the anterior or lateral caval wall and is of considerable length, it can readily be controlled by applying a series of Allis clamps over the edges of the laceration in serial fashion. The edges of the laceration are then oversewn with running 5-0 vascular suture material (Fig. 50–36).

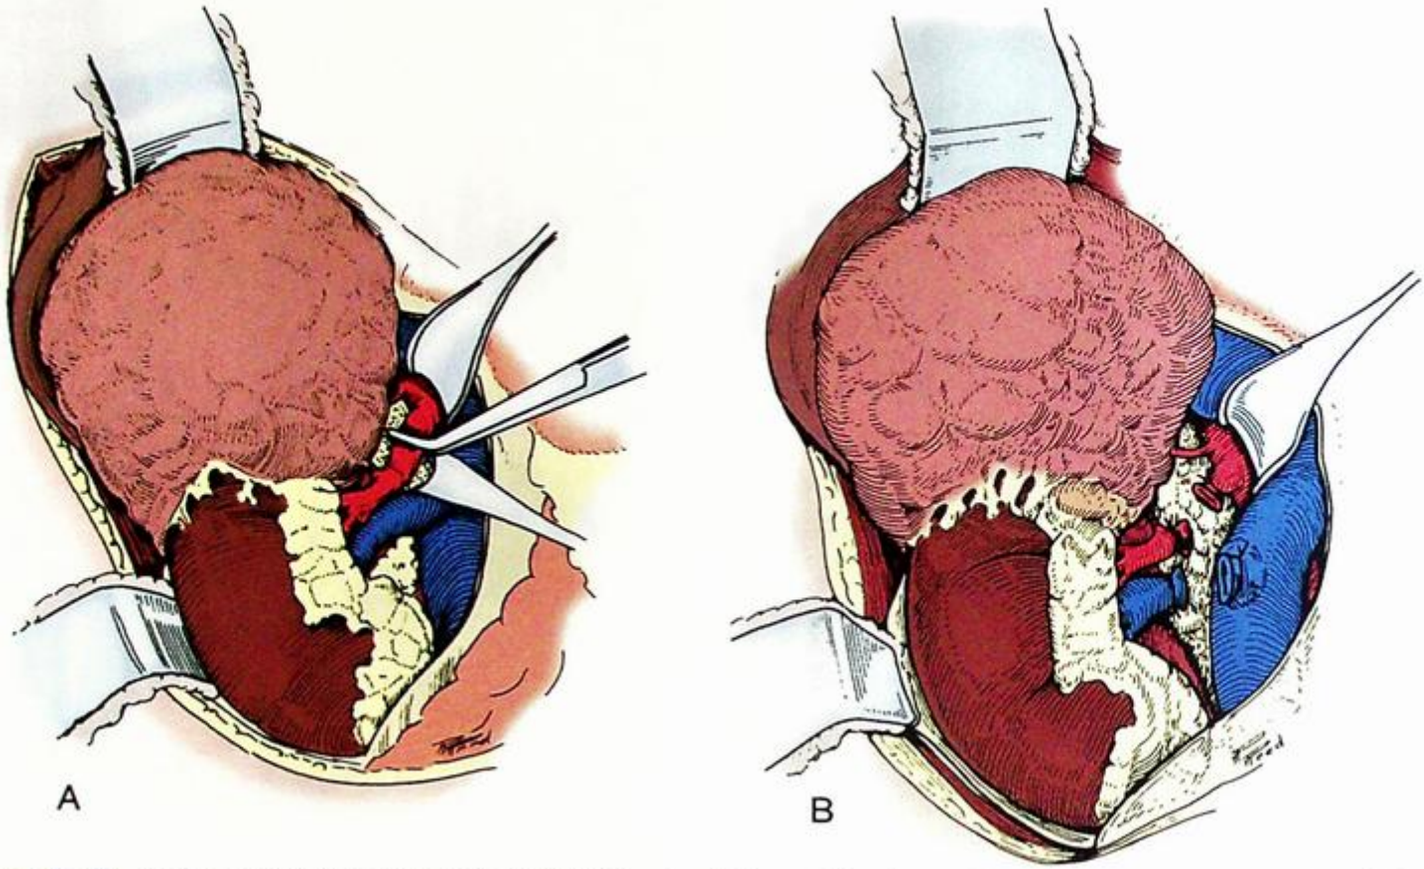

Figure 50–34. The renal artery and vein are secured and divided. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

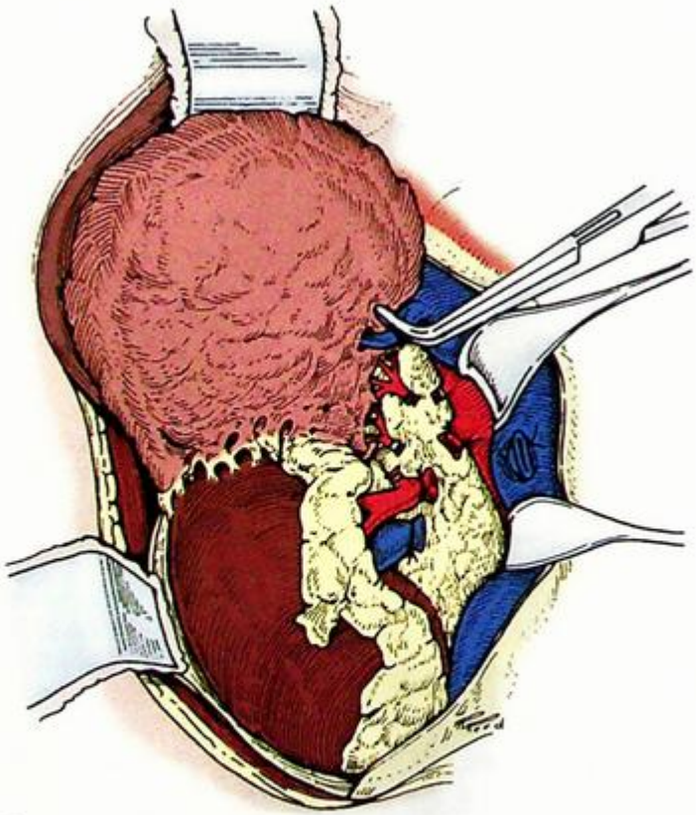

Figure 50–35. The vena cava is retracted medially to expose the remaining superior vascular attachments, which are secured and divided. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

If avulsion of an entering lumbar vein is the cause of bleeding, the vena cava should be rolled medially, with digital compression above and below the site of bleeding, until the posterolateral entry of the avulsed vein is exposed. This is then grasped with one or two Allis clamps, which can be used as tractors to bring the avulsion into better view for oversewing with vascular suture material. Persistent bleeding can occur from the proximal end of an avulsed lumbar vein, which may retract into the psoas muscle and be difficult to secure. This can be controlled in some cases by grasping the end of the vein with a hemostat and then twisting the hemostat to bring the end of the vein into better view for suture ligation (Fig. 50–37). If this is not possible, bleeding can be controlled by inserting a figure-of-eight 2-0 silk suture through the muscle overlying the vein.

Bleeding from large lumbar veins entering the posterior aspect of the left renal vein or the posterior wall of the vena cava near the entry of the right renal vein can be particularly troublesome (Fig. 50–38). Further mobilization of the vena cava and renal veins is often needed while compression is maintained on the bleeding site. It may be necessary to apply a Satinsky side clamp across the entry of the renal vein, as well as a distal bulldog clamp beyond the bleeding point in the renal vein, to control the hemorrhage and allow closure of the venous defect. Mobilization and gentle rotation of the vena cava or the renal veins may also be necessary to gain optimal exposure. In this situation, as well, distal entry of the lumbar vein into the posterior musculature can cause troublesome bleeding and must be controlled as described previously.

Radical Nephrectomy with Infrahepatic Vena Caval Involvement

There are four levels of vena caval involvement in RCC that are characterized according to the distal extent of the tumor thrombus (Fig. 50–39). **A bilateral subcostal transperitoneal incision usually provides excellent exposure for performance of radical nephrectomy and removal of a perirenal or infrahepatic IVC thrombus. For extremely large tumors involving the upper pole of the kidney, a thoracoabdominal incision may alternatively be used.** After the abdomen is entered, the colon is reflected medially, and a self-retaining ring retractor is inserted to maintain exposure of the retroperitoneum (Fig. 50–40*A*). The renal artery and the ureter are ligated and divided, and the entire kidney is mobilized outside Gerota's fascia, leaving the kidney attached by only the renal vein (Fig. 50–40*B* and *C*). During the initial dissection, care is taken to avoid unnecessary manipulation of the renal vein and vena cava.

The vena cava is then completely dissected from surrounding structures above and below the renal vein, and the opposite renal vein is also mobilized. It is essential to obtain exposure and control of the suprarenal vena cava above the level of the tumor thrombus. If necessary, perforating veins to the caudate lobe of the liver are secured and divided to allow separation of the caudate lobe from the vena cava. This maneuver can allow an additional 2 to 3 cm of vena cava to be exposed superiorly. **Mobilization of the liver off of the IVC can further enhance exposure of the intra-abdominal vena cava** (Ciancio et al, 2002). The infrarenal vena cava is then occluded below the thrombus with a Satinsky venous clamp, and the opposite renal vein is gently secured with a small bulldog vascular clamp. Finally, in preparation for tumor thrombectomy, a curved Satinsky clamp is placed around the suprarenal vena cava above the level of the thrombus (Fig. 50–40*D*).

The anterior surface of the renal vein is then incised over the tumor thrombus, and the incision is continued posteriorly with scissors, passing just beneath the thrombus (Fig. 50–40*E*). In most cases, there is no attachment of the thrombus to the wall of the vena cava. After the renal vein has been circumscribed, gentle downward traction is exerted on the kidney to extract the tumor thrombus from the vena cava (Fig. 50–40*F*). After the gross specimen is removed, the suprarenal vena caval clamp may be released temporarily as the anesthetist applies positive pulmonary pressure; this maneuver can ensure that any small remaining fragments of thrombus are flushed free from the vena cava. When the tumor thrombectomy is completed, the cavotomy incision is repaired with a continuous 5-0 vascular suture (Fig. 50–40*G*).

In occasional cases, there is direct caval invasion of the tumor at the level of the entrance of the renal vein and for varying distances. This requires resection of a portion of the vena caval wall. Narrowing of the caval lumen by up to 50% does not adversely affect maintenance of caval patency. If further narrowing appears likely, caval reconstruction can be performed with a free graft of pericardium or polytetrafluoroethylene (Sarkar et al, 1998).

In some patients, more extensive direct growth of tumor into the wall of the vena cava is found at surgery. The prognosis for these patients is generally poor, particularly when hepatic venous tributaries are also involved, and the decision to proceed with radical surgical excision must be carefully considered. Several important principles must be kept in mind when en bloc vena caval resection is undertaken. Resection of the infrarenal portion of the vena cava can usually be done safely because an extensive collateral venous supply has developed in most cases. With right-sided kidney tumors, resection of the suprarenal vena cava is also possible, provided the left renal vein is ligated distal to the gonadal and adrenal tributaries, which then provide collateral venous drainage from the left kidney. With left-sided kidney tumors, the suprarenal vena cava cannot be resected safely owing to the paucity of collateral venous drainage from the right kidney. In such cases, right renal venous drainage can be maintained by preserving a tumor-free strip of vena cava, augmented, if necessary, with a pericardial patch; alternatively, the right kidney can be autotransplanted to the pelvis, or an interposition graft of saphenous vein may be placed from the right renal vein to the splenic, inferior mesenteric, or portal vein (Fig. 50–41).

Radical Nephrectomy with Intrahepatic or Suprahepatic Vena Caval Involvement

In patients with RCC and an intrahepatic or suprahepatic IVC thrombus, the difficulty of surgical excision is significantly increased. In such cases, the operative technique must be modified because it is not possible to obtain subdiaphragmatic control of the vena cava above the tumor thrombus. Several different surgical maneuvers have been used to provide adequate exposure, to prevent severe bleeding, and to achieve complete tumor removal in this setting (Cummings et al, 1979; Novick, 1980; Foster et al, 1988; Skinner et al, 1989; Burt, 1991; Ciancio et al, 2002).

One technique for obtaining vascular control involves temporary occlusion of the suprahepatic intrapericardial portion of the IVC. To reduce hepatic venous congestion and troublesome backbleeding, the porta hepatis and SMA are also temporarily occluded (Skinner et al, 1989). A disadvantage of this approach is that occlusion of these vessels can be safely tolerated for only 20 minutes. This approach is also not applicable in cases of tumor extension into the right atrium. **At the Cleveland Clinic, the preferred approach is to employ cardiopulmonary bypass with deep hypothermic circulatory arrest for most patients with complex supradiaphragmatic tumor thrombi and for all patients with right atrial tumor thrombi** (Marshall and Reitz, 1986). A favorable experience with this approach was reported in 43 patients (Novick et al, 1990), and a subsequent study showed excellent long-term cancer-free survival after its use in patients with right atrial thrombi (Glazer and Novick, 1996). The relevant technical aspects are described subsequently.

A bilateral subcostal incision is used for the abdominal portion of the operation. After resectability is confirmed, a median sternotomy is made (Fig. 50–42). Intraoperative monitoring is accomplished with an arterial line, a multiple-lumen central venous pressure catheter, and a pulmonary artery catheter. Nasopharyngeal and bladder temperatures are monitored. Anesthesia is induced with fentanyl, sufentanil, or

Figure 50–39. thiopental and is maintained with a narcotic inhalation agent (Welch et al, 1989).

The kidney is completely mobilized outside Gerota's fascia with division of the renal artery and ureter, such that the kidney is left attached by only the renal vein. The infrarenal vena cava and contralateral renal vein are also exposed. Extensive dissection and mobilization of the suprarenal vena cava are not necessary with this approach. Adequate exposure is somewhat more difficult to achieve for a left renal tumor. Simultaneous exposure of the vena cava on the right and the tumor on the left is not readily accomplished simply by reflecting the left colon medially. I have dealt with this by transposing the mobilized left kidney anteriorly through a window in the mesentery of the left colon while leaving the renal vein attached. This maneuver yields excellent exposure of the abdominal vena cava with the attached left renal vein and kidney. Precise retroperitoneal hemostasis is essential before proceeding with cardiopulmonary bypass because of the risk of bleeding associated with systemic heparinization.

The heart and great vessels are exposed through the median sternotomy. The patient is heparinized, ascending aortic and right atrial venous cannulas are placed, and cardiopulmonary bypass is initiated (Fig. 50–43). When the heart fibrillates, the aorta is clamped, and crystalloid cardioplegic solution is infused. Under circulatory arrest, deep hypothermia is initiated by reducing arterial inflow blood temperature as low as 10°C. The head and abdomen are packed in ice during the cooling process. After approximately 15 to 30 minutes, a core temperature of 18°C to 20°C is achieved.

At this point, flow through the perfusion machine is stopped, and 95% of the blood volume is drained into the pump with no flow to any organ.

The tumor thrombus can now be removed in an essentially bloodless operative field. An incision is made in the IVC at the entrance of the involved renal vein, and the ostium is circumscribed. When the tumor extends into the right atrium, the atrium is opened at the same time (Fig. 50–44*A*). If possible, the tumor thrombus is removed intact with the kidney.

pneumothorax that is causing respiratory distress requires insertion of a chest tube.

Postoperative atelectasis is common in patients undergoing radical nephrectomy and is probably secondary to the positioning of the patient during the procedure. This is a common cause of fever postoperatively and may be effectively treated with pulmonary physiotherapy, including deep breathing, coughing, and incentive spirometry.

Infection is a common complication encountered in the postoperative period. Superficial wound infections are best managed by removal of skin sutures or staples to allow drainage. Deeper infections must be treated by the establishment of adequate drainage and the administration of appropriate antibiotics when there are systemic manifestations of the infection. If the drainage is persistent and profuse, the possibility of a retained foreign body or a fistulous communication with the intestine should be considered. Accumulations of lymph or serous fluid in the renal fossa or pleura are best managed expectantly, unless they are causing respiratory embarrassment. Such accumulations may become infected or may be complicated by bleeding if they are treated by needle aspiration.

Temporary renal insufficiency may develop postoperatively after ligation of the left renal vein in conjunction with right radical nephrectomy and extension of a vena caval tumor thrombus (Clark, 1961; Pathak, 1971). Renal failure in this setting is probably secondary to venous obstruction and usually resolves as drainage improves with the development of venous collaterals, although temporary hemodialysis may occasionally be needed. It is always preferable, if possible, to preserve left renal venous drainage into the vena cava to diminish the risk of this complication. As previously mentioned, ligation of the right renal vein leads to permanent and complete renal failure.

When a flank incision is used to perform nephrectomy, an incisional hernia or bulge may occur postoperatively. The intracostal nerve lies immediately below the corresponding rib between the internal oblique and the transverse abdominal muscles. At surgery, an effort should be made to spare this nerve by dissecting both proximally and distally, enabling careful padding and retraction of the nerve out of the operative field, because transection may lead to muscle denervation. Postoperatively, muscle denervation with flank bulging must be differentiated from a flank incisional hernia, which is rare. With the hernia, a fascial defect is usually palpable.

PARTIAL NEPHRECTOMY FOR MALIGNANT DISEASE

Interest in partial nephrectomy, or nephron-sparing surgery, for RCC has been stimulated by advances in renal imaging, improved surgical techniques, increasing numbers of incidentally discovered low-stage RCCs, and good long-term survival in patients undergoing this form of treatment. Partial nephrectomy entails complete local resection of a renal tumor while leaving the largest possible amount of normal functioning parenchyma in the involved kidney.

Accepted indications for partial nephrectomy include situations in which radical nephrectomy would render the patient anephric with subsequent immediate need for dialysis. This encompasses patients with bilateral RCC or RCC involving a solitary functioning kidney. The patient may have a solitary functioning kidney because of unilateral renal agenesis, prior removal of the contralateral kidney, or irreversible impairment of contralateral renal function from a benign disorder. Another indication for partial nephrectomy is represented by patients with unilateral RCC and a functioning opposite kidney affected by a condition that might threaten its future function, such as calculus disease, chronic pyelonephritis, renal artery stenosis, ureteral reflux, or systemic diseases such as diabetes and nephrosclerosis (Licht and Novick, 1994).

Studies have clarified the role of partial nephrectomy in patients with localized unilateral RCC and a normal contralateral kidney. These data indicate that **radical nephrectomy and partial nephrectomy provide equally effective curative treatment for patients who present with a single, small (<4 cm), and clearly localized RCC** (Butler et al, 1995; Lerner et al, 1996; Uzzo and Novick, 2001). The long-term renal functional advantage of partial nephrectomy with a normal opposite kidney requires further study. Partial nephrectomy is also occasionally indicated in the management of patients with renal pelvic transitional cell carcinoma or Wilms' tumor when preservation of functioning renal

parenchyma is a clinically relevant consideration (Zincke and Neves, 1984; Ziegelbaum et al, 1987).

The technical success rate with partial nephrectomy for RCC is excellent, and several large studies have reported 5-year cancer-specific survival rates of 87% to 90% in such patients (Morgan and Zincke, 1990; Steinbach et al, 1992; Licht and Novick, 1994). These survival rates are comparable to those obtained after radical nephrectomy, particularly for low-stage RCC. The major disadvantage of partial nephrectomy for RCC is the risk of postoperative local tumor recurrence in the kidney that was operated on, which has been observed in 4% to 6% of patients (Morgan and Zincke, 1990; Steinbach et al, 1992; Licht and Novick, 1994). These local recurrences are most likely a manifestation of undetected microscopic multifocal RCC in the renal remnant. The risk of local tumor recurrence after radical nephrectomy has not been studied, but it is presumably very low.

A study from the Cleveland Clinic reviewed the results of partial nephrectomy for treatment of localized sporadic RCC in 485 patients. The mean postoperative follow-up was 4 years (Hafez et al, 1999). The overall and cancer-specific 5-year patient survival rates in the series were 81% and 92%, respectively. Recurrent RCC developed postoperatively in 44 patients (9%), including 16 (3.2%) with local recurrence in the remnant kidney and 28 (5.8%) with metastatic disease.

In a subsequent study, Fergany and colleagues (2000) reviewed the results of partial nephrectomy in 107 patients with localized sporadic RCC treated before 1988 and observed a minimum of 10 years at the Cleveland Clinic. Tumors were symptomatic in 73 patients (68%), and indications for surgery were imperative in 96 (90%). All patients were observed for at least 10 years or until death. Cancer-specific survival was 88.2% at 5 years and 73% at 10 years, and 26% of the patients died of metastatic disease. Long-term preservation of renal function was achieved in 93% of patients.

In a more recent study from the Cleveland Clinic, Fergany reviewed the long-term results of open partial nephrectomy in 400 patients with RCC in a solitary kidney. Postoperatively, 97% of patients maintained satisfactory renal function without the need for dialysis. Cancer-specific survival was 89% at 5 years and 82% at 10 years (Fergany et al, 2005). These results attest to the long-term biologic and functional efficacy of partial nephrectomy for localized RCC.

Evaluation of patients with RCC for partial nephrectomy should include preoperative testing to rule out locally extensive or metastatic disease. Previously, preoperative renal arteriography was routinely performed to delineate the intrarenal vasculature so that the tumor could be excised with minimal blood loss and damage to adjacent normal parenchyma. Selective renal venography was performed in patients with large or centrally located tumors to evaluate for intrarenal venous thrombosis secondary to malignant disease, which, if present, implies a more advanced local tumor stage and also increases the technical complexity of tumor excision. These invasive studies have been replaced by three-dimensional volume-rendered CT, which can accurately and less invasively depict the renal parenchymal and vascular anatomy in a format familiar to urologic surgeons (Coll et al, 1999). The data integrate essential information from arteriography, venography, excretory urography, and conventional two-dimensional CT into a single imaging modality and obviate the need for more invasive imaging (Fig. 50–46). **Three-dimensional CT scanning is additionally advantageous by accurately demonstrating involvement of the collecting system with a localized renal tumor** (Derweesh et al, 2005).

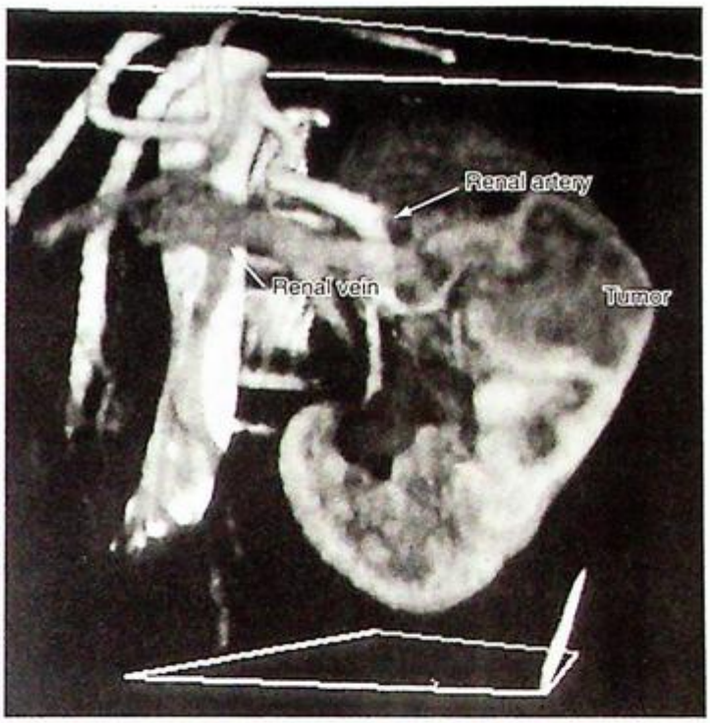

Figure 50–46. Three-dimensional CT scan shows tumor in upper part of left kidney with renal arterial and venous supply.

In patients with bilateral large synchronous RCCs, I usually approach the kidney most amenable to a partial nephrectomy first. Then, approximately 1 month after a technically successful result has been documented, I perform a second partial nephrectomy or a radical nephrectomy on the opposite kidney. Staging surgery in this fashion obviates the need for temporary dialysis if ischemic renal failure occurs after nephron-sparing excision of RCC. In patients with bilateral, small, synchronous RCCs, bilateral simultaneous partial nephrectomies are performed.

It is usually possible to perform partial nephrectomy for a malignant neoplasm in situ by using an operative approach that optimizes exposure of the kidney and by combining meticulous surgical technique with an understanding of the renal vascular anatomy in relation to the tumor. Preoperative hydration and mannitol administration are important adjuncts to ensure optimal renal perfusion at operation. I employ an extraperitoneal flank incision through the bed of the 11th or 12th rib for almost all these operations; I occasionally use a thoracoabdominal incision for very large tumors involving the upper portion of the kidney. These incisions allow the surgeon to operate on the mobilized kidney almost at skin level and provide excellent exposure of the peripheral renal vessels (Fig. 50–47). With an anterior subcostal transperitoneal incision, the kidney is invariably located in the depth of the wound, and the surgical exposure is simply not as good. Extracorporeal surgery is rarely necessary in these patients today.

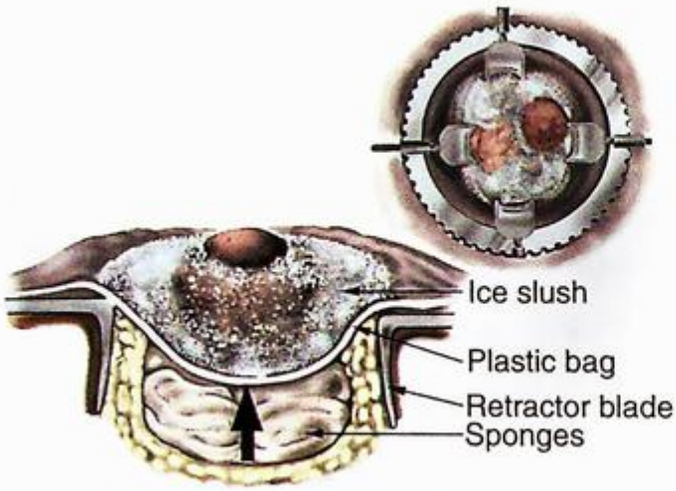

Figure 50–47. Elevation of the mobilized kidney to skin level is demonstrated by placement of sponges under the plastic bag containing the kidney and ice slush.

A report highlighted the potential for renal dysfunction associated with staged bilateral renal exploration through the flank. Specifically, when the second renal operation is performed, flexion with elevation of the kidney rest may cause ischemic damage to the previously operated on contralateral kidney, which has become fixed in place by postoperative scarring. In such cases, the second flank operation should be performed without elevation of the kidney rest. Alternatively, an anterior surgical approach may be elected for the second operation (Matin and Novick, 2001).

When in situ partial nephrectomy is performed for malignant disease, the kidney is mobilized within Gerota's fascia while the perirenal fat around the tumor is left intact. For small, peripheral renal tumors, it is not necessary to control the renal artery. In most other cases, however, partial nephrectomy is most effectively performed after temporary renal arterial occlusion. This measure not only limits intraoperative bleeding but also, by reducing renal tissue turgor, improves access to intrarenal structures. When possible, it is helpful to leave the renal vein patent throughout the operation. This measure decreases intraoperative renal ischemia and, by allowing venous backbleeding, facilitates hemostasis by enabling identification of small, transected renal veins. In patients with centrally located tumors, it is necessary to occlude the renal vein temporarily to minimize intraoperative bleeding from transected major venous branches.

When the renal circulation is temporarily interrupted, in situ renal hypothermia is used to protect against postischemic renal injury. Surface cooling of the kidney with ice slush allows up to 3 hours of safe ischemia without permanent renal injury. An important caveat with this method is to keep the entire kidney covered with ice slush for 10 to 15 minutes immediately after the renal artery is occluded and before the partial nephrectomy is commenced (see Fig. 50–47). This amount of time is needed to obtain core renal cooling to a temperature (approximately 20°C) that optimizes in situ renal preservation. During excision of the tumor, invariably, large portions of the kidney are no longer covered with ice slush, and in the absence of adequate prior renal cooling, rapid rewarming and ischemic renal injury can occur. Cooling by perfusion of the kidney with a cold solution instilled through the renal artery is not recommended because of the theoretical risk of tumor dissemination. **Mannitol is given intravenously 5 to 10 minutes before temporary renal arterial occlusion. Systemic or regional anticoagulation to prevent intrarenal vascular thrombosis is not necessary.** A prospective controlled study from the Cleveland Clinic demonstrated that perioperative dopamine does not help preserve renal function in partial nephrectomy operations (O'Hara et al, 2002).

A variety of surgical techniques are available for performing partial nephrectomy in patients with malignant disease (Novick, 1998). These include simple enucleation, polar segmental nephrectomy, wedge resection, transverse resection, and extracorporeal partial nephrectomy with renal autotransplantation. All these techniques require adherence to basic principles of early vascular control, avoidance of ischemic renal damage, complete tumor excision with free margins, precise closure of the collecting system, careful hemostasis, and closure or coverage of the renal defect with adjacent fat, fascia, peritoneum, or Oxycel. Whichever technique is employed, the tumor is removed with a small surrounding margin of grossly normal renal parenchyma. **Data have shown that as long as a histologic tumor-free margin of resection is present, the width of the resection margin is of no biologic or prognostic significance** (Castilla et al, 2002). Intraoperative ultrasonography is helpful in achieving accurate tumor localization, particularly for intrarenal lesions that are not visible or palpable from the external surface of the kidney (Assimos et al, 1991; Campbell et al, 1996) (Fig. 50–48).

In performing a transverse resection of the upper part of the kidney, care must be taken to avoid injury to the posterior segmental renal arterial branch, which may also occasionally supply the basilar renal segment (Fig. 50–49). Preoperative vascular imaging with three-dimensional CT scanning is integral to the identification and preservation of the posterior segmental artery at surgery to avoid devascularization of a major portion of the healthy remnant kidney. Midrenal resections may also be particularly complicated because the arterial supply comprises branches of anterior and posterior renal artery divisions, and the calyces often enter the same infundibula as those draining the upper and lower poles.

Whatever nephron-sparing technique is used, the parenchyma around the tumor is divided with a combination of sharp and blunt dissection. In many cases, the tumor extends deeply into the kidney, and the collecting system is entered. Often, renal arterial and venous branches supplying the tumor can be identified as the parenchyma is being incised, and these should be directly suture ligated at that time while they are most visible (Fig. 50–50). Similarly, in many cases, direct entry into the collecting system may be avoided by isolation and ligation of major infundibula draining the tumor-bearing renal segment as the incision into the parenchyma is developed (see Fig. 50–50).

After excision of the tumor, the remaining transected blood vessels on the renal surface are secured with figure-of-eight 4-0 chromic sutures. Bleeding at this point is usually minimal, and the operative field can be kept satisfactorily clear by gentle suction during placement of hemostatic sutures. Residual collecting system defects are similarly closed with interrupted or continuous 4-0 chromic sutures. At this point, with the renal artery still clamped but with the renal vein open, the anesthe-

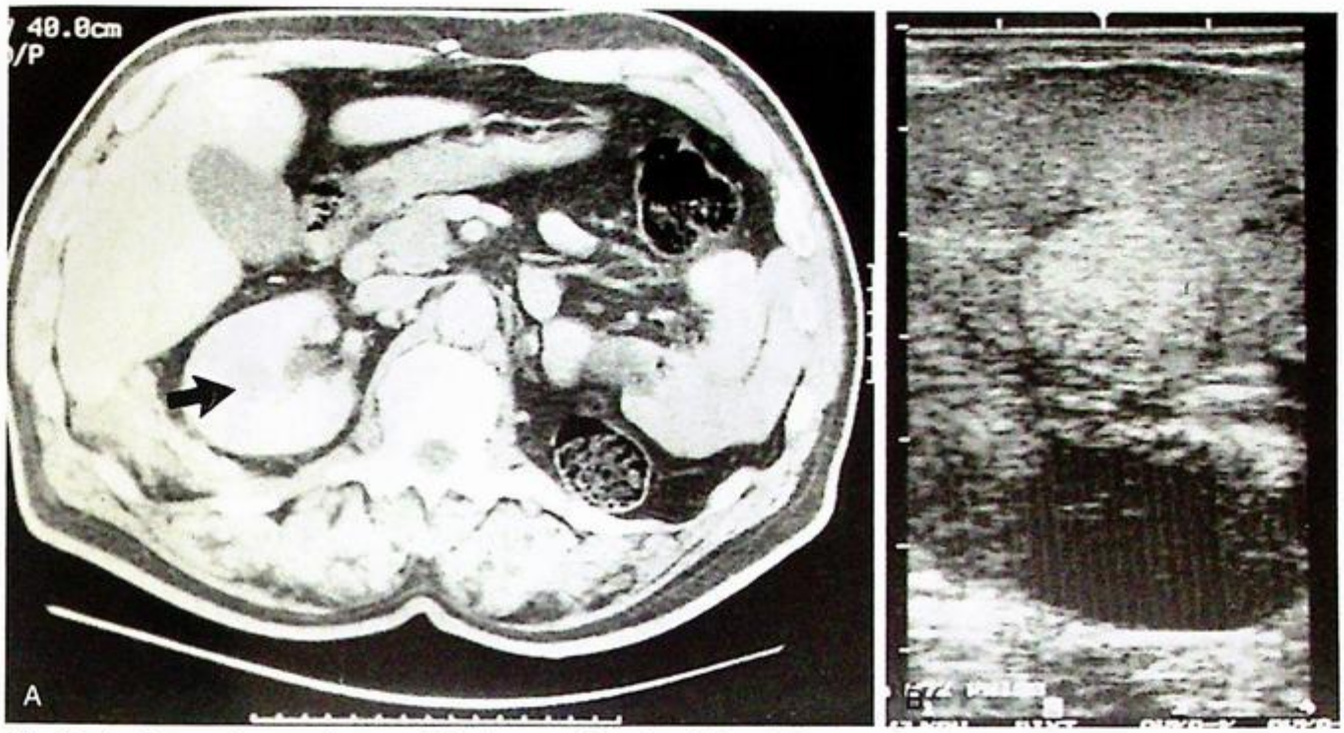

Figure 50–48. **A,** CT scan shows small tumor within the center of a solitary kidney. **B,** Intraoperative ultrasonography demonstrates localization of this intrarenal tumor.

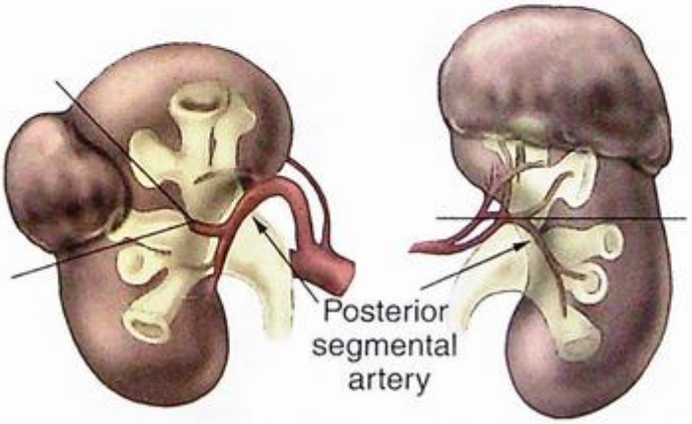

Figure 50–49. Injury to the posterior segmental renal arterial branch must be avoided during upper or midrenal resections.

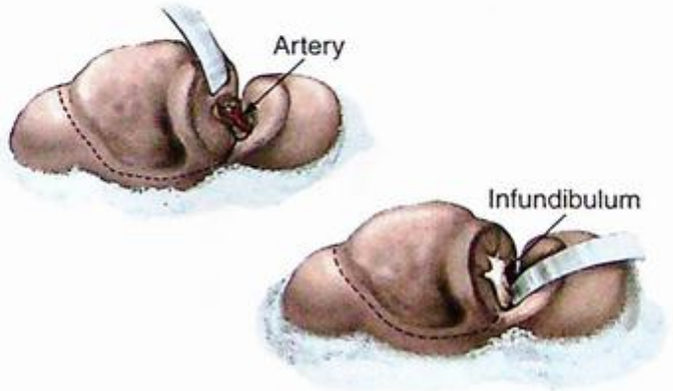

Figure 50–50. As the parenchyma around the tumor is incised, major vessels supplying the tumor are identified and secured. Similarly, infundibula draining the tumor-bearing portion of the kidney are also identified and secured.

siologist is asked to hyperinflate the lungs and thereby raise the central and renal venous pressures. This forces blood out through residual, unsecured, transected veins on the renal surface and thereby facilitates their detection (Fig. 50–51). Once identified, these veins are secured with interrupted figure-of-eight 4-0 chromic sutures. The argon beam coagulator is a useful adjunct for achieving hemostasis on the transected peripheral renal surface.

In most cases, after the renal vasculature and the collecting system are secured, the kidney is closed on itself by approximating the transected cortical margins with simple interrupted 3-0 chromic sutures after placement of a small piece of Oxycel at the base of the defect. This is an important additional hemostatic measure. When it is done, the suture line must be free of tension and the blood vessels supplying the kidney must be free of significant angulation or kinking. After the renal defect is closed, the renal artery is unclamped, and circulation to the kidney is restored. When the remnant kidney resides within a large retroperitoneal fossa, the kidney is fixed to the posterior musculature with interrupted 3-0 chromic sutures to prevent postoperative movement or rotation of the kidney, which may compromise the blood supply (Fig. 50–52). A retroperitoneal drain is always left in place for at least 7 days, and an intraoperative ureteral stent is placed only when major reconstruction of the intrarenal collecting system has been performed.

In patients with RCC or transitional cell carcinoma, partial nephrectomy is contraindicated in the presence of

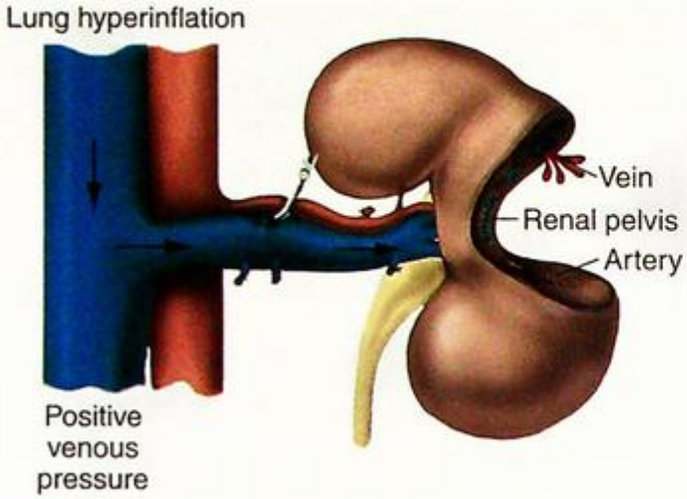

Figure 50–51. Identification of residual unsecured transected vessels (particularly veins) on the renal surface is facilitated by increasing the renal venous pressure through hyperinflation of the lungs.

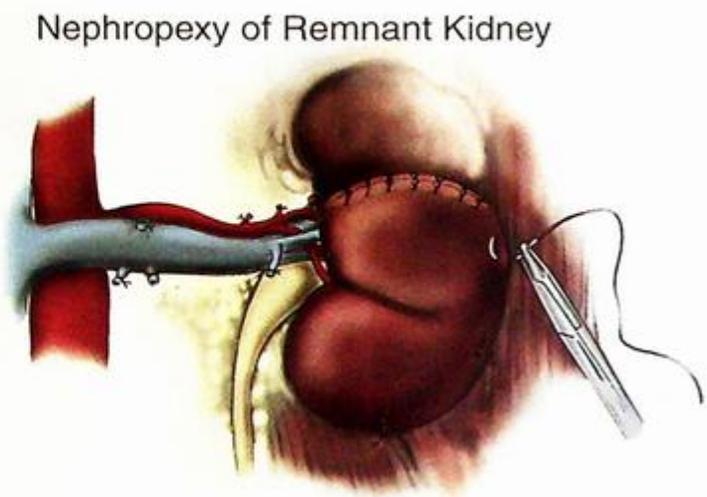

Figure 50–52. Nephropexy of the remnant kidney to the retroperitoneum is achieved with several interrupted sutures.

lymph node metastasis because the prognosis for these patients is poor. Biopsy of enlarged or suspicious-looking lymph nodes should be done before the renal resection is initiated. When partial nephrectomy is performed, after excision of all gross tumor, absence of malignant change in the remaining portion of the kidney should be verified intraoperatively by frozen-section examinations of biopsy specimens obtained at random from the renal margin of excision. Such biopsies do not usually demonstrate residual tumor, but if they do, additional renal tissue must be excised.

Segmental Polar Nephrectomy

In patients with a malignant neoplasm confined to the upper or lower pole of the kidney, partial nephrectomy can be performed by isolation and ligation of the segmental apical or basilar arterial branch while unrepaired perfusion is allowed to the remainder of the kidney from the main renal artery. This procedure is illustrated in Figure 50–53 for a tumor confined to the apical vascular segment. The apical artery is dissected away from the adjacent structures, ligated, and divided. A corresponding venous branch is often present, and it is similarly ligated and divided. An ischemic line of demarcation then generally appears on the surface of the kidney and outlines the segment to be excised. If this area is not obvious, a few milliliters of methylene blue can be directly injected distally into the ligated apical artery to better outline the limits of the involved renal segment. An incision is then made in the renal cortex at the line of demarcation, which should be several millimeters away from the visible edge of the cancer. The parenchyma is divided by sharp and blunt dissection, and the polar segment is removed. In cases of malignant disease, it is not possible to preserve a strip of capsule beyond the parenchymal line of resection for use in closing the renal defect. When the collecting system and vasculature have been repaired, the edges of the kidney are reapproximated as an additional hemostatic measure with simple, interrupted 3-0 chromic sutures inserted through the capsule and a small amount of parenchyma. Before these sutures are tied, perirenal fat or Oxycel can be inserted into the defect for inclusion in the renal closure.

Wedge Resection

Wedge resection is an appropriate technique for removal of peripheral tumors on the surface of the kidney, particularly ones that are larger or not confined to either renal pole. Because these lesions often encompass more than one renal segment and because this technique is generally associated with heavier bleeding, it is best to perform wedge resection with temporary renal arterial occlusion and surface hypothermia.

In a wedge resection, the tumor is removed with a several-millimeter surrounding margin of grossly normal renal parenchyma (Fig. 50–54). The parenchyma is divided by a combination of sharp and blunt dissection. Often, prominent intrarenal vessels are identified as the parenchyma is being incised. These may be directly suture ligated at the time, while they are most visible. After excision of the tumor, the collecting system and vasculature are then repaired as needed. The renal defect can then be closed in one of two ways (see Fig. 50–54). The kidney may be closed on itself by approximating the transected cortical margins with simple interrupted 3-0 chromic sutures after placement of a small piece of Oxycel at the base of the defect. If this is done, there must be no tension on the suture line and no significant angulation or kinking of blood vessels supplying the kidney. Alternatively, a portion of perirenal fat may simply be inserted into the base of the renal defect as a hemostatic measure and sutured to the parenchymal margins with interrupted 4-0 chromic sutures. After closure or coverage of the renal defect, the renal artery is unclamped, and circulation to the kidney is restored.

Major Transverse Resection

A transverse resection is done to remove large tumors that extensively involve the upper or lower portion of the kidney.

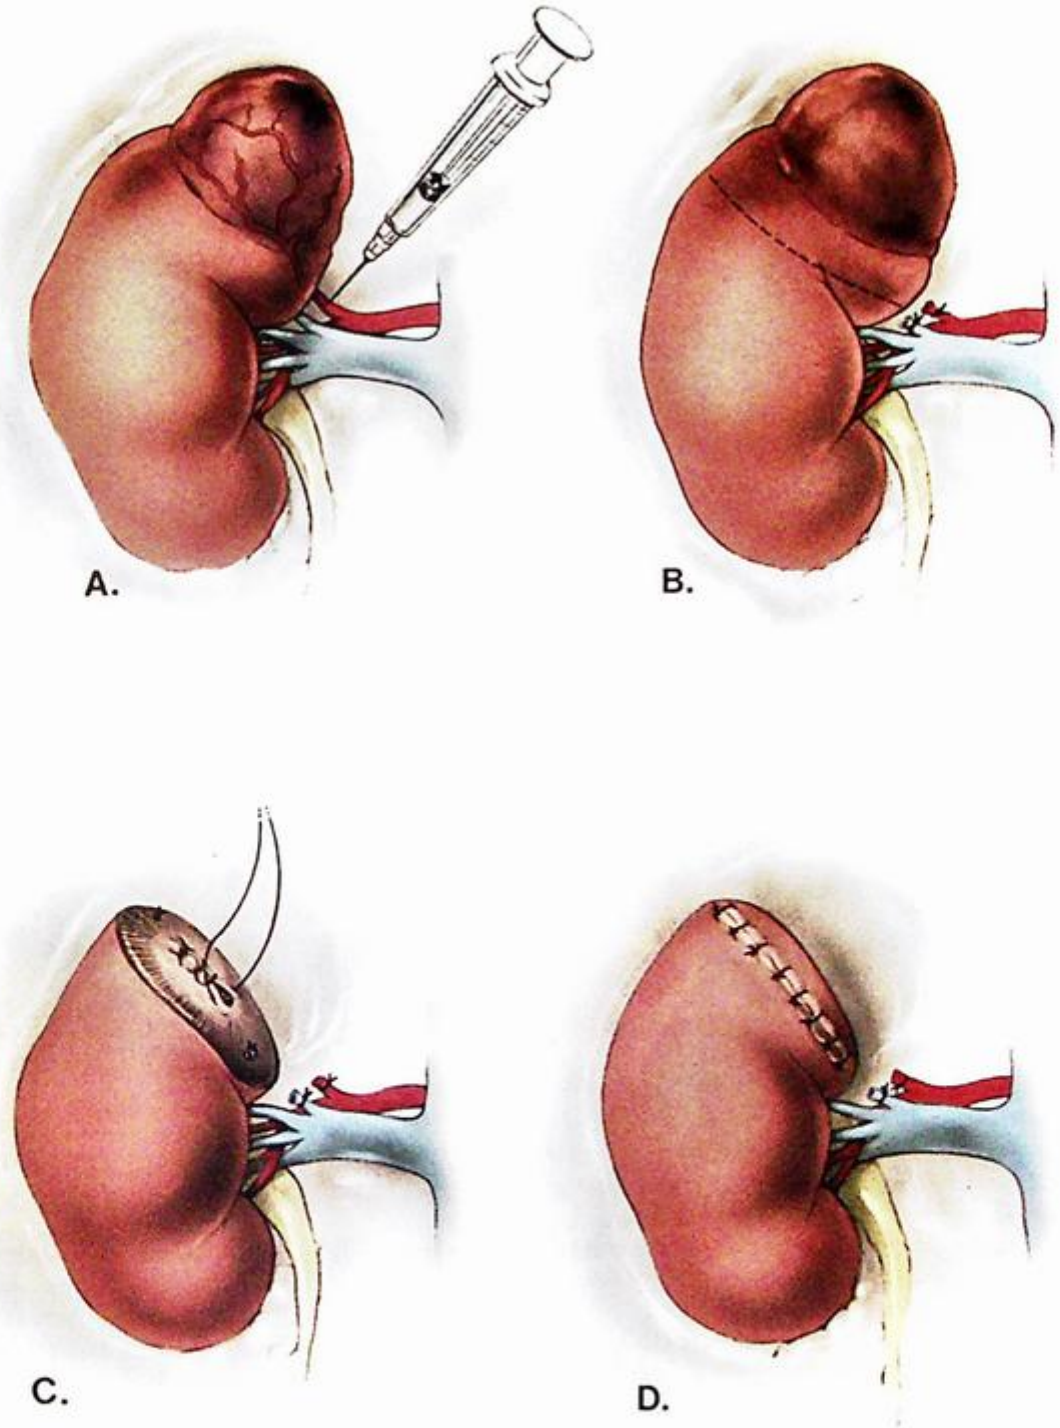

Figure 50–53. Technique of segmental (apical) polar nephrectomy with preliminary ligation of apical arterial and venous branches. (From Novick AC: Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

This technique is performed with surface hypothermia after temporary occlusion of the renal artery. Major branches of the renal artery and vein supplying the tumor-bearing portion of the kidney are identified in the renal hilum, ligated, and divided (Fig. 50–55*A*). If possible, this should be done before the renal artery is temporarily occluded to minimize the overall period of renal ischemia.

After the renal artery is occluded, the parenchyma is divided by blunt and sharp dissection, leaving a several-millimeter margin of grossly normal tissue around the tumor (Fig. 50–55*B*). Transected blood vessels on the renal surface are secured as previously described, and the hilum is inspected carefully for remaining unligated segmental vessels. If possible, the renal defect is sutured together with one of the techniques previously described (Fig. 50–55*C*). If this suture cannot be placed without tension or without distorting the renal vessels, a piece of peritoneum or perirenal fat is sutured in place to cover the defect.

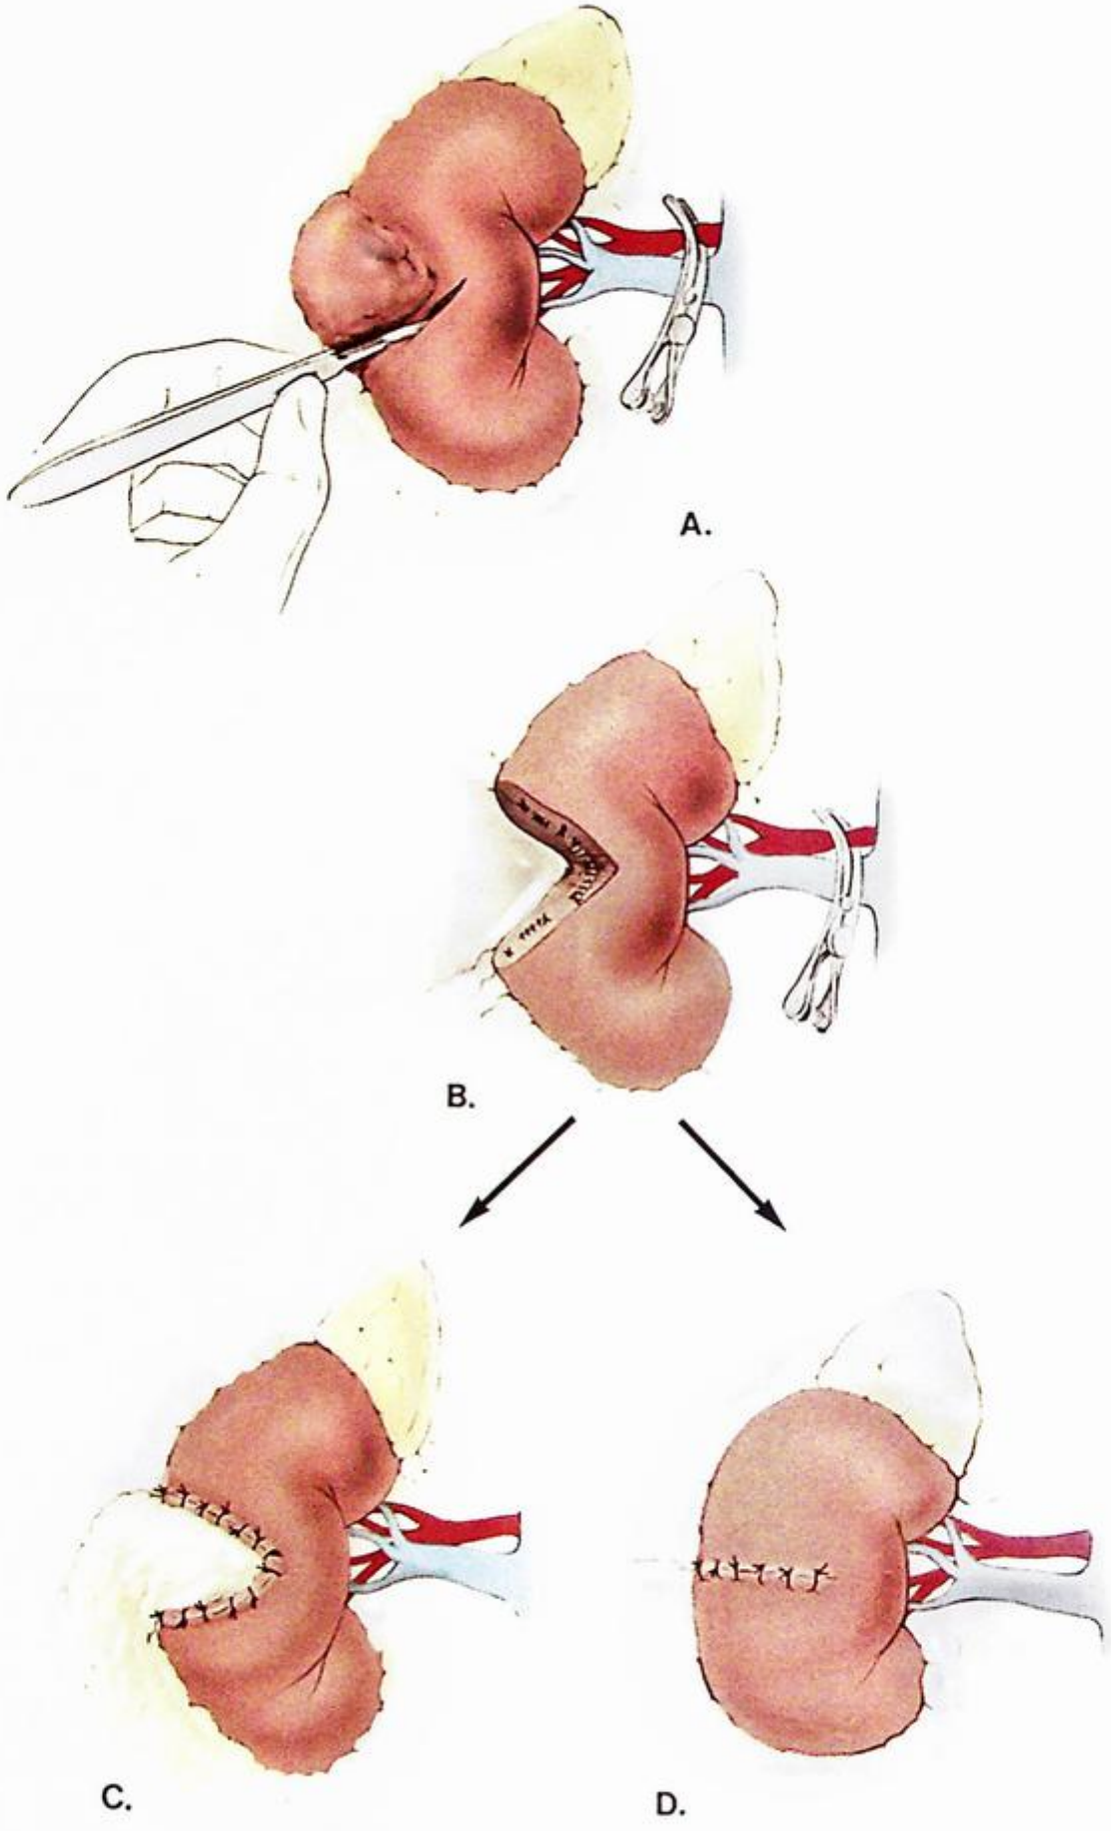

Figure 50–54. Technique of wedge resection for a peripheral tumor on the surface of the kidney. The renal defect may be closed on itself or covered with perirenal fat. (From Novick AC: Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

Partial Nephrectomy for Central Tumors

For patients with central tumors, complete delineation of the renal arterial and venous supply is mandatory for surgical planning. As stated, this information can now be obtained with three-dimensional CT scanning, and invasive vascular imaging studies are no longer necessary (Coll et al, 1999). In patients with central tumors, partial nephrectomy is most effectively performed after temporary occlusion of the renal artery and vein. Renal vein occlusion is important to minimize intraoperative bleeding from transected major venous branches. The renal artery and vein are occluded separately with individual atraumatic vascular clamps.

During the preliminary dissection, the kidney is mobilized within Gerota's fascia while the perirenal fat around the tumor is left intact. There may be relatively little perirenal fat to preserve with central tumors that extend into the renal hilum. The tumor is mobilized and isolated as much as possible by dissecting away adjacent segmental renal vessels that provide critical blood supply to the **non–tumor-bearing part of the kidney that is to be preserved.**

The differences between the renal arterial and venous circulations must be borne in mind and may be used to advantage in these operations. Because all segmental arteries are end-arteries with no collateral circulation, all branches supplying tumor-free parenchyma must be preserved to avoid devitalization of functioning renal tissue. However, the renal venous drainage system is different, in that intrarenal venous branches intercommunicate freely among the various renal segments. Therefore, ligation of a branch of the renal vein does not result in segmental infarction of the kidney because collateral venous blood supply provides adequate drainage. This is important clinically because it enables one to obtain safe surgical access to central tumors in the renal hilum by ligation and division of small adjacent or overlying venous branches. This allows the main renal vein to be completely mobilized and freely retracted in either direction to expose a central tumor with no vascular compromise of uninvolved parenchyma (Fig. 50–56). At this stage, small, segmental arterial branches that directly supply the tumor can also be secured and divided. If the portion of kidney or tumor supplied by a segmental artery is not readily apparent, temporary occlusion of the branch with a miniature vascular clamp can resolve this by enabling direct visualization of the ischemic supplied renal tissue. In dissecting on the posterior renal surface, particular care must be taken to avoid injury to the posterior segmental renal arterial branch, which has a variable

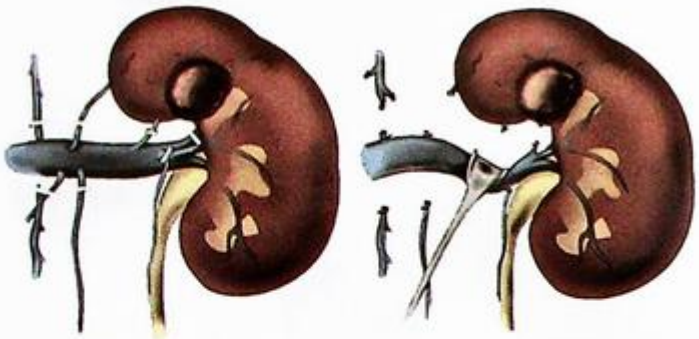

Figure 50–56. Mobilization of the left renal vein to obtain better exposure of a tumor in the renal hilum by ligation and division of small renal venous branches.

location and may also occasionally supply the basilar renal segment; if this is the case, failure to identify and preserve this branch can lead to devascularization of a major portion of the healthy remnant kidney.

The object of the preliminary dissection is to isolate the tumor and to secure as much of its direct blood supply as possible before clamping the main renal artery and vein, so that overall warm renal ischemia time can be minimized. Intraoperative ultrasonography is also performed before temporary renal vascular occlusion for the same reason. The primary value of this adjunctive imaging modality is for localization of intrarenal tumors that are not visible or palpable from the external surface of the kidney. A prospective study demonstrated that intraoperative ultrasonography is of limited value for detecting occult multicentric tumors in the kidney (Campbell et al, 1996).

After temporary occlusion of the renal artery and vein, the mobilized and isolated tumor is resected by incision of the attachment to the renal parenchyma. Small renal arterial and venous branches supplying the tumor can often be identified as the parenchyma is being incised, and these should be directly suture ligated at that time while they are most visible. Whereas a surrounding margin of normal parenchyma should be removed with the tumor, a wide margin of normal renal tissue is often not available for hilar tumors that may, in part, impinge directly on the central collecting system. It is sufficient to remove these tumors with all adjacent renal sinus fat and with a 3- to 4-mm margin of surrounding normal parenchyma where this is available.

In most cases, after the renal vessels and the collecting system are secured, the kidney is closed on itself by approximating the transected cortical margins with interrupted sutures as an additional hemostatic measure. When this is done, the parenchymal suture line must be free of tension and the blood vessels supplying the kidney must be free of significant angulation or kinking. After closure of the renal defect, the renal artery is unclamped, and circulation to the kidney is restored.

Simple Enucleation

Some RCCs are surrounded by a distinct pseudocapsule of fibrous tissue (Vermooten, 1950). The technique of simple enucleation implies circumferential incision of the renal parenchyma around the tumors simply and rapidly at any location, often with no vascular occlusion and with maximal preservation of normal parenchyma.

Initial reports indicated satisfactory short-term clinical results after enucleation, with good survival of patients and low rate of local tumor recurrence (Graham and Glenn, 1979; Jaeger et al, 1985). However, **most studies suggested a higher risk of leaving residual malignant cells in the kidney when enucleation is performed** (Rosenthal et al, 1984; Marshall et al, 1986; Blackley et al, 1988). These reports included several carefully done histopathologic studies that demonstrated frequent microscopic tumor penetration of the pseudocapsule surrounding the neoplasm. These data indicated that it is not always possible to be assured of complete tumor encapsulation before surgery. Local recurrence of tumor in the treated kidney is a grave complication of partial nephrectomy for RCC, and every attempt should be made to prevent it. Therefore, it is my view that a surrounding margin of normal parenchyma should be removed with the tumor whenever possible. This provides an added margin of safety against the development of local tumor recurrence and, in most cases, does not appreciably increase the technical difficulty of the operation. The technique of enucleation is currently employed only in occasional patients with von Hippel–Lindau disease and multiple low-stage encapsulated tumors involving both kidneys (Spencer et al, 1988).

Extracorporeal Partial Nephrectomy and Autotransplantation

Extracorporeal partial nephrectomy for RCC with autotransplantation of the renal remnant was initially described by several surgeons (Calne, 1973; Gittes and McCullough, 1975) as an approach to facilitate successful excision of large complex tumors involving the renal hilum. Reconstruction of kidneys with RCC as well as with renal artery disease may be facilitated by this approach (Campbell et al, 1993). The practical and theoretical advantages of an extracorporeal approach include optimum exposure, bloodless surgical field, ability to perform a more precise operation with maximum conservation of renal parenchyma, and greater protection of the kidney from prolonged ischemia. Disadvantages of extracorporeal surgery include longer operative time with the need for vascular and ureteral anastomoses and increased risk of temporary and permanent renal failure (Campbell et al, 1994); the latter presumably reflects a more severe intraoperative ischemic insult to the kidney. **Whereas some urologic surgeons have found that almost all patients undergoing partial nephrectomy for RCC can be managed satisfactorily in situ** (Novick et al, 1989), others have continued to recommend an extracorporeal approach for selected patients (Morgan and Zincke, 1990).

Extracorporeal partial nephrectomy and renal autotransplantation are generally performed through a single midline incision. The kidney is mobilized and removed outside Gerota's fascia with ligation and division of the renal artery and vein as the last steps in the operation (Fig. 50–57*A*). Immediately after the renal vessels are divided, the removed kidney is flushed with 500 mL of a chilled intracellular electrolyte solution and submerged in a basin of ice-slush saline solution to maintain hypothermia. Under these conditions, if warm renal ischemia has been minimal, the kidney can safely

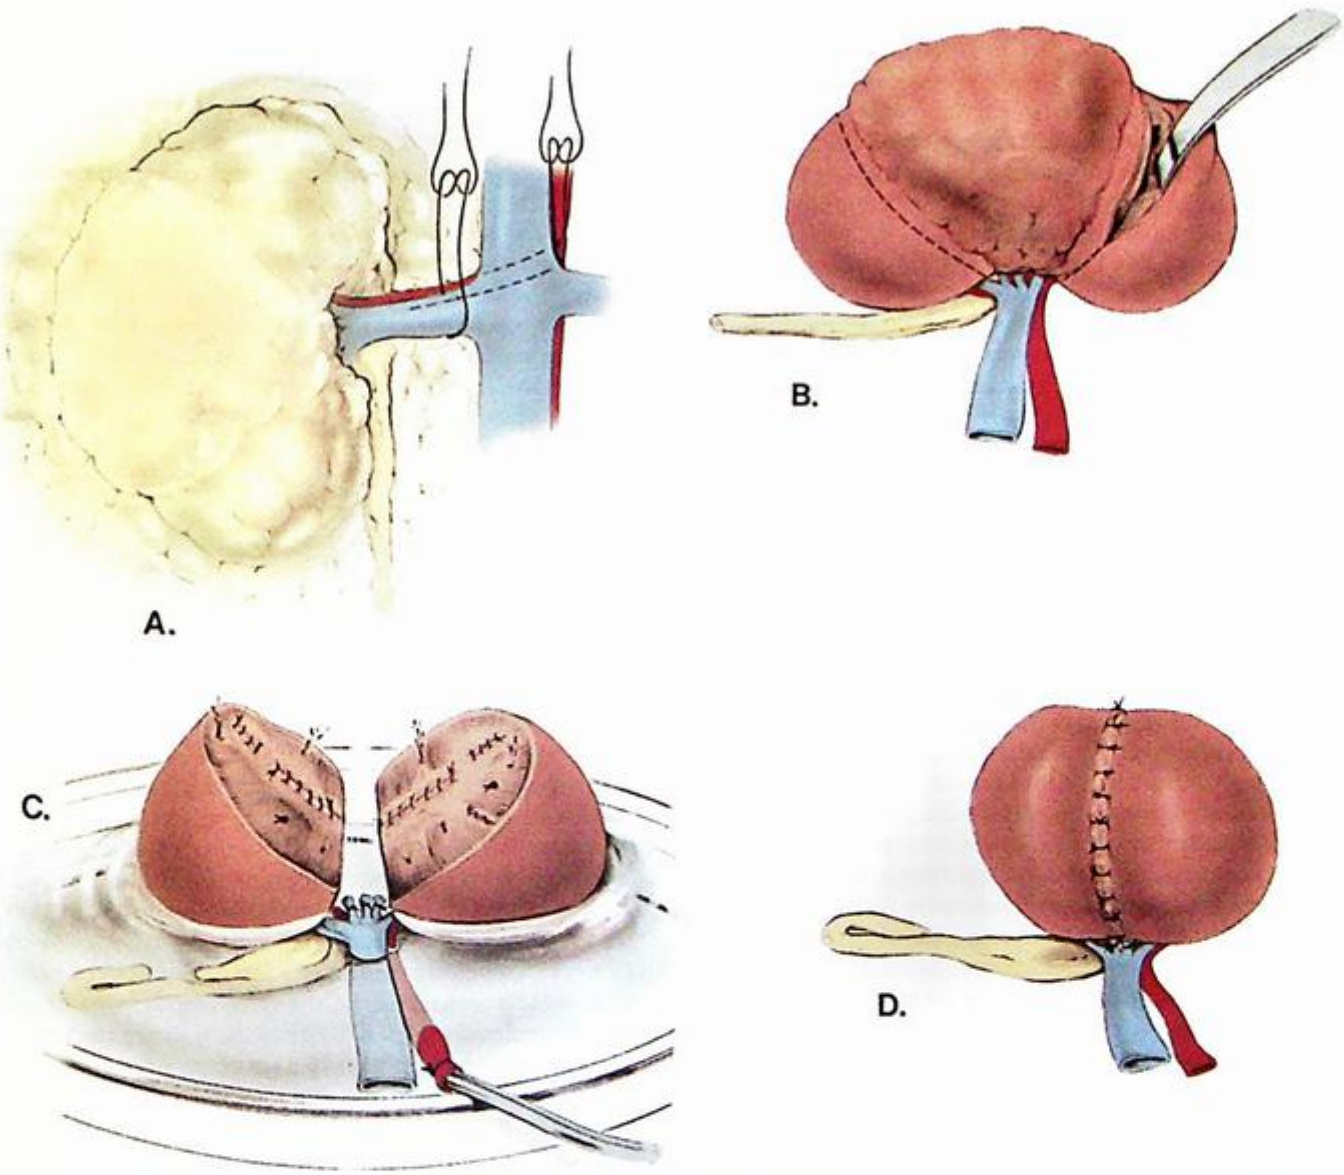

Figure 50–57. Technique of extracorporeal partial nephrectomy for a large central tumor. **A,** The kidney is removed outside Gerota's fascia. **B,** The tumor is excised extracorporeally while the vascular branches to uninvolved parenchyma are preserved. **C,** Pulsatile perfusion or reflushing is used to identify transected blood vessels. **D,** The kidney is closed on itself. (From Novick AC: Partial nephrectomy for renal cell carcinoma. Urol Clin North Am 1987;14:419.)

be preserved outside the body for as much time as needed to perform extracorporeal partial nephrectomy.

If possible, it is best to leave the ureter attached in such cases to preserve its distal collateral vascular supply, particularly with large hilar or lower renal tumors in which complex excision may unavoidably compromise the blood supply to the pelvis, ureter, or both. When this procedure is done, the extracorporeal operation is performed on the abdominal wall. If the ureter is left attached, it must be occluded temporarily to prevent retrograde blood flow to the kidney when it is outside the body. Often, unless the patient is thin, working on the abdominal wall with the ureter attached is cumbersome because of the tethering and restricted movement of the kidney. If these are observed, the ureter should be divided and the kidney placed on a separate workbench. This practice provides better exposure for the extracorporeal operation, and as this is being done, a second surgical team can simultaneously prepare the iliac fossa for autotransplantation. If concern exists about the adequacy of ureteral blood supply, the risk of postoperative urinary extravasation can be diminished by restoration of urinary continuity through direct anastomosis of the renal pelvis to the retained distal ureter.

Extracorporeal partial nephrectomy is performed with the flushed kidney preserved under surface hypothermia (Fig. 50–57*B*). After the tumor has been completely resected, the renal remnant may be reflushed or placed on the pulsatile perfusion unit to facilitate identification and suture ligation of remaining potential bleeding points (Fig. 50–57*C*). The kidney can alternatively be perfused through the renal artery and vein to ensure both arterial and venous hemostasis. Because the flushing solution and perfusate lack clotting ability, there may continue to be some parenchymal oozing, which can safely be ignored. If possible, the defect made by the partial nephrectomy is closed by suturing the kidney on itself to further ensure a watertight repair (Fig. 50–57*D*).

Autotransplantation into the iliac fossa is done by the same vascular technique as for renal allotransplantation. Urinary continuity may be restored with ureteroneocystostomy or pyeloureterostomy, leaving an internal ureteral stent in place. After autotransplantation, a Penrose drain is positioned extraperitoneally in the iliac fossa away from the vascular anastomotic sites.

Complications

Complications of partial nephrectomy include hemorrhage, urinary fistula formation, ureteral obstruction, renal insufficiency, and infection. Significant intraoperative bleeding can occur in patients who are undergoing partial nephrectomy. The need for early control and ready access to the renal artery is emphasized. Postoperative hemorrhage may be self-limited, if it is confined to the retroperitoneum, or it may be associated with gross hematuria. The initial management of postoperative hemorrhage is expectant, with bed rest, serial hemoglobin and hematocrit determinations, frequent monitoring of vital signs, and blood transfusions as needed. Angiography may be helpful in some patients to localize actively bleeding segmental renal arteries, which may be controlled by angioinfarction. Severe intractable hemorrhage may necessitate re-exploration with early control of the renal vessels and ligation of the active bleeding points.

Postoperative urinary flank drainage after a partial nephrectomy is common and usually resolves as the collecting system closes with healing. Persistent drainage suggests the development of a urinary cutaneous fistula. This diagnosis can be confirmed by determination of the creatinine level of the drainage fluid and by intravenous injection of indigo carmine with subsequent appearance of the dye in the drainage fluid. The majority of urinary fistulas resolve spontaneously if there is no obstruction of urinary drainage from the involved renal unit. If the perirenal space is not adequately drained, a urinoma or abscess may develop. An intravenous pyelogram or a retrograde pyelogram should be obtained to rule out obstruction of the involved urinary collecting system. In the event of hydronephrosis or persistent urinary leakage, an internal ureteral stent is placed. If this is not possible, a percutaneous nephrostomy may be inserted. Most urinary fistulas resolve spontaneously with proper conservative management, although it may take several weeks in some cases. A second operation to close the urinary fistula is rarely necessary.

Ureteral obstruction can occur after partial nephrectomy because of postoperative bleeding into the collecting system with resulting clot obstruction of the ureter and pelvis. This obstruction can lead to temporary extravasation of urine from the renal suture line. In most cases, expectant management is appropriate, and the obstruction resolves spontaneously with lysis of the clots. When urinary leakage is excessive, or in the presence of intercurrent urinary infection, placement of an internal ureteral stent can help maintain antegrade ureteral drainage.

Varying degrees of **renal insufficiency** often occur postoperatively when partial nephrectomy is performed in a patient with a solitary kidney. This insufficiency is a consequence of both intraoperative renal ischemia and removal of some normal parenchyma along with the diseased portion of the kidney. Such renal insufficiency is usually mild and resolves spontaneously with proper fluid and electrolyte management. Also, in most cases, the remaining parenchyma undergoes compensatory hypertrophy that serves to further improve renal function. Severe renal insufficiency may require temporary or permanent hemodialysis, and the patient should be aware of this possibility preoperatively.

Postoperative infections are usually self-limited if the operative site is well drained and in the absence of existing untreated urinary infection at the time of surgery. Unusual complications of partial nephrectomy include transient postoperative hypertension and aneurysm or arteriovenous fistula in the remaining portion of the parenchyma (Snodgrass and Robinson, 1964; Rezvani et al, 1973).

A study detailed the incidence and clinical outcome of technical or kidney-related complications occurring after 259 partial nephrectomies for renal tumors at the Cleveland Clinic (Campbell et al, 1994). In the overall series, local or kidney-related complications occurred after 78 operations (30.1%). The incidence of complications was significantly less for operations performed after 1988 and significantly less for incidentally detected versus suspected tumors. The most common complications were urinary fistula formation and acute renal failure. A urinary fistula occurred after 45 of 259 operations (17%). Significant predisposing factors for a urinary fistula included central tumor location, tumor smaller than 4 cm, need for major reconstruction of the collecting system, and ex vivo surgery. Only one urinary fistula required open operative repair; the remainder resolved either spontaneously (n = 30) or with endoscopic management (n = 14).

Acute renal failure occurred after 30 of 115 operations (26%) performed on a solitary kidney. Significant predisposing factors for acute renal failure were tumor larger than 7 cm, parenchymal excision of more than 50%, ischemia time longer than 60 minutes, and ex vivo surgery. **Acute renal failure resolved completely in 25 patients, of whom 9 (8%) required temporary dialysis; 5 patients (4%) required permanent dialysis.**

Overall, only eight complications (3.1%) required repeated open surgery for treatment, whereas all other complications resolved with nonintervention or endourologic management. Surgical complications contributed to an adverse clinical outcome in only seven patients (2.9%). These data indicate that partial nephrectomy can be performed safely with preservation of renal function in most patients with renal tumors.

With increasing experience, the morbidity of open partial nephrectomy continues to diminish. A study from the Cleveland Clinic detailed the outcome of open partial nephrectomy in 100 consecutive patients (Gill et al, 2003). **A postoperative renal or urologic complication occurred in only two patients (one urine leak, one ureteral obstruction), and both of these resolved with appropriate management.**

Postoperative Follow-up

Patients who undergo nephron-sparing surgery for RCC are advised to return for initial follow-up 4 to 6 weeks postoperatively. At that time, a serum creatinine measurement and intravenous pyelogram are obtained to document renal function and anatomy; in patients with impaired overall renal

function, a renal ultrasound study is obtained instead of an intravenous pyelogram.

A study from the Cleveland Clinic analyzed tumor recurrence patterns after partial nephrectomy in 327 patients with sporadic localized RCC (Hafez et al, 1997). The purpose of this study was to develop appropriate guidelines for long-term surveillance after nephron-sparing surgery for RCC. RCC occurred postoperatively in 38 patients (11.6%), including 13 patients (4.0%) who developed local tumor recurrence and 25 patients (7.6%) who developed metastatic disease. The incidence of postoperative local tumor recurrence and metastatic disease, respectively, according to initial pathologic tumor stage was as follows: 0% and 4.4% for stage T1 RCC, 2% and 5.3% for stage T2 RCC, 8.2% and 11.5% for stage T3a RCC, and 10.6% and 14.9% for stage T3b RCC. The peak postoperative intervals for development of local tumor recurrence were 6 to 24 months (in patients with stage T3 RCC) and more than 48 months (in patients with stage T2 RCC).

These data indicate that surveillance for recurrent malignant disease after nephron-sparing surgery for RCC can be tailored according to the initial pathologic tumor stage. All patients should be evaluated with medical history, physical examination, and selected blood studies on a yearly basis. The blood studies should include serum calcium, alkaline phosphatase, blood urea nitrogen, serum creatinine, and electrolyte determinations and liver function tests.

The need for postoperative radiographic surveillance studies varies according to the initial pathologic tumor (pT) stage. Patients who undergo nephron-sparing surgery for pT1 RCC do not require radiographic imaging postoperatively in view of the very low risk for recurrent malignant disease. A yearly chest radiograph is recommended after nephron-sparing surgery for pT2 or pT3 RCC because the lung is the most common site of postoperative metastasis in both groups. Abdominal or retroperitoneal tumor recurrence is uncommon in patients assigned to stage pT2, particularly early after nephron-sparing surgery, and these patients require only occasional follow-up abdominal CT scanning; I recommend that this be done every 2 years for this category. Patients with pT3 RCC have a higher risk for local tumor recurrence, particularly during the first 2 years after nephron-sparing surgery, and they may benefit from more frequent follow-up abdominal CT scanning initially; I recommend that this be done every 6 months for 3 years and every 2 years thereafter. If a local recurrence is found without metastatic disease, either a second partial nephrectomy or a total nephrectomy may be performed (Novick and Straffon, 1987).

Patients with less than one kidney are at higher risk for development of proteinuria, glomerular damage, and impaired renal function as a result of glomerular hyperfiltration (Solomon et al, 1985; Foster et al, 1991). In one study, long-term renal function was evaluated in 14 patients with a solitary kidney who underwent partial nephrectomy for localized malignant disease (Novick et al, 1991). Preoperatively, there was no clinical or histopathologic evidence of primary renal disease. Postoperative renal function remained stable in 12 patients, whereas 2 patients developed end-stage renal failure. A total of nine patients had proteinuria: low grade (<750 mg/day) in four patients and moderate to severe (930 to 6740 mg/day) in five patients. A statistically significant association was found between more proteinuria and a reduced amount of remaining renal tissue as well as a longer follow-up interval. A renal biopsy was done in four patients with moderate to severe proteinuria that, in each case, showed focal segmental or global glomerulosclerosis.

These data suggest that patients with more than 50% reduction in overall renal mass are at the greatest risk for proteinuria, glomerulopathy, and progressive renal failure. Structural or functional renal damage in such cases is usually antedated by the appearance of proteinuria. Therefore, the follow-up of patients after partial nephrectomy in a solitary kidney should include a 24-hour urinary protein determination in addition to the usual renal function and tumor surveillance studies. Patients who have proteinuria (>150 mg/day) may be treated with a low-protein diet and a converting enzyme inhibitor agent, which appear to be beneficial in preventing glomerulopathy caused by reduced renal mass (Meyer et al, 1985; Novick and Schreiber, 1995).

PARTIAL NEPHRECTOMY FOR BENIGN DISEASE

Partial nephrectomy is also indicated in selected patients with localized benign disease of the kidney (Leach and Lieber, 1980). The indications include hydronephrosis with parenchymal atrophy or atrophic pyelonephritis in a duplicated renal segment; calyceal diverticulum complicated by infection, stones, or both; calculus disease with obstruction of the lower pole calyx or segmental parenchyma disease with impaired drainage (Papathanassiadis and Swinney, 1966; Bates et al, 1981); renovascular hypertension due to segmental parenchymal damage or noncorrectable branch renal artery disease (Aoi et al, 1981; Parrott et al, 1984); traumatic renal injury with irreversible damage to a portion of the kidney (Gibson et al, 1982); and removal of a benign renal tumor, such as an angiomyolipoma or oncocytoma (Maatman et al, 1984).

The preoperative considerations are similar to those in patients undergoing partial nephrectomy for malignant disease. In most cases, a vascular imaging study should be performed to delineate the main and segmental renal arterial supplies. The same measures should be taken to minimize intraoperative renal damage from ischemia. The preferred surgical approach is usually through an extraperitoneal flank incision, except in cases of renal trauma, which are best approached anteriorly. The surgical techniques are similar to those described for malignant renal disease.

In performing an apical or basilar partial nephrectomy for benign disease, the segmental apical or basilar arterial branch is secured and the parenchyma is divided at the ischemic line of demarcation, without the need for temporary renal arterial occlusion. More complex transverse or wedge renal resections are best performed with temporary renal arterial occlusion and ice-slush surface hypothermia. When the technique of transverse renal resection is employed for a benign disorder, the renal capsule is excised and reflected off the diseased parenchyma for subsequent use in covering the renal defect (Fig. 50–58). The technical aspects of partial nephrectomy for benign disease are otherwise the same as those described for malignant disease, with adherence to the same basic principles of appropriate vascular control, avoidance of ischemic renal

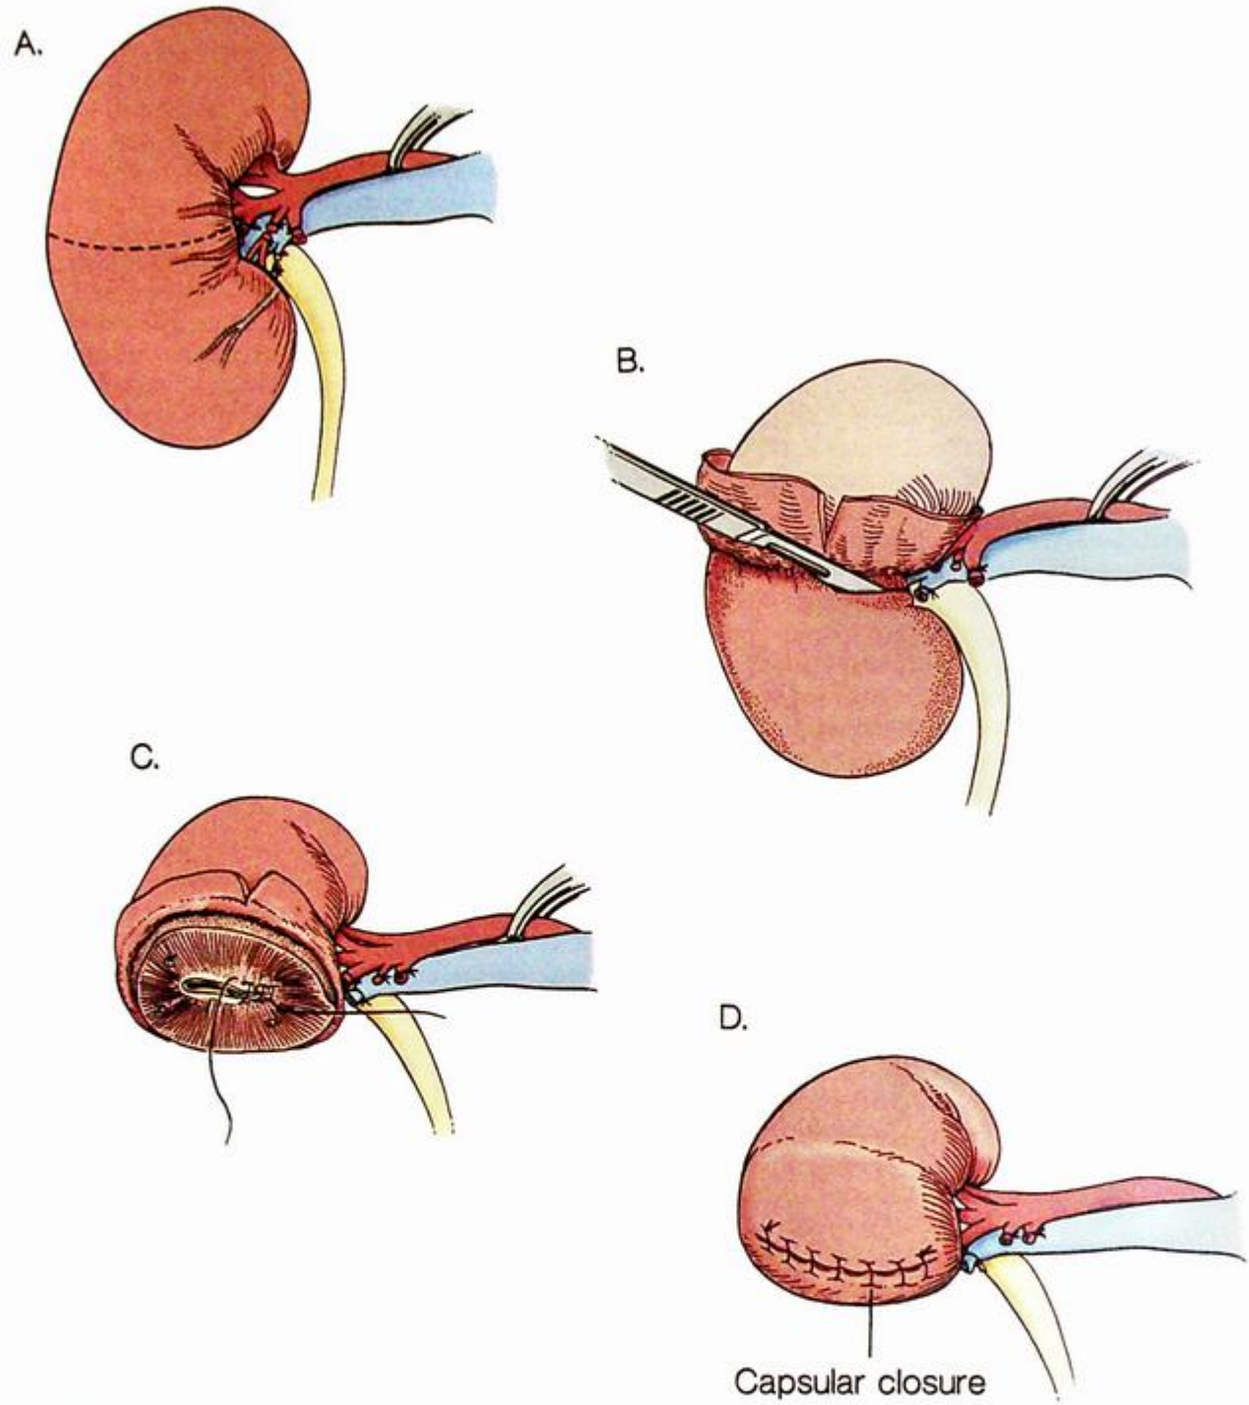

Figure 50–58. Technique of transverse renal resection for a benign disorder. The renal capsule from the diseased parenchyma is preserved and used to cover the transected renal surface.

damage, precise closure of the collecting system, careful hemostasis, and closure or coverage of the renal defect.

Heminephrectomy in Duplicated Collecting Systems

Because the indications for partial nephrectomy in this setting are usually hydronephrosis and parenchymal atrophy of one of the two segments, the demarcation of the tissue to be removed is usually evident. The atrophic parenchyma lining the dilated system can be further delineated by blue pyelotubular backflow if the ureter is ligated and the affected collecting system is distended by blue dye under pressure. In such cases, there is also often a dual arterial supply with distinct segmental branches to the upper and lower halves of the kidney. Segmental arterial and venous branches to the diseased portion of the kidney are ligated and divided. After a strip of renal capsule is preserved, the parenchyma is divided at the observed line of demarcation. There is usually minimal bleeding from the renal surface, and temporary occlusion of the arterial supply to the nondiseased segment is often unnec-

essary. There should be no entry into the collecting system over the transected renal surface, which is then closed or covered as described previously.

RENAL ARTERIAL RECONSTRUCTION

Two main categories of renal artery disease, atherosclerosis and fibrous dysplasia, account for approximately 80% and 20% of all such lesions, respectively. Other unusual causes of renal artery disease include arterial aneurysm, arteriovenous fistula, neurofibromatosis, extrinsic obstruction of the renal artery, middle aortic syndrome, and renal artery thrombosis or embolism. Intervention may be indicated in these disorders to treat associated hypertension, to preserve renal function, or to prevent rupture of an arterial aneurysm.

The role of surgical therapy in the management of these patients has changed for several reasons (Novick and McElroy, 1985). These include the advent of percutaneous transluminal angioplasty (PTA) and stenting as alternative effective forms of treatment for certain patients, the development of new and more effective techniques for surgical revascularization, and an enhanced appreciation of advanced atherosclerotic renal artery disease as a correctable cause of renal failure. Surgical revascularization remains the definitive treatment of choice for patients with branch renal artery disease, with an ostial atherosclerotic lesion, with an arterial aneurysm, or in whom endovascular therapy has been unsuccessful. Surgical revascularization continues to provide excellent long-term results in properly selected patients with renal artery disease (Novick et al, 1987; Steinbach et al, 1997).

A variety of factors must be assessed in determining whether surgical treatment is appropriate for a given patient. These include the causal relationship of renal vascular disease to hypertension, the adequacy of blood pressure control with medical therapy, the natural history of untreated renal vascular disease with attention to the risk for renal function impairment, the medical condition of the patient, and the known results of surgical therapy and other interventions such as PTA or renal artery stents.

Advances in surgical renovascular reconstruction have limited the role of total or partial nephrectomy in the management of patients with renal artery disease. These operations are occasionally indicated in patients with renal infarction, severe arteriolar nephrosclerosis, severe renal atrophy, and noncorrectable renovascular lesions. Nephrectomy may also be indicated in elderly, poor–surgical risk patients with a normal contralateral kidney or after a failed revascularization procedure.

INDICATIONS FOR TREATMENT

Renovascular Hypertension

The coexistence of hypertension and renal artery disease does not always imply a causal relationship between the two. Renal artery disease is far more common than renovascular hypertension. Classically, renovascular hypertension is a retrospective diagnosis rendered when hypertension resolves after intervention to correct a renal artery lesion. The term now commonly refers to renin-mediated hypertension as a result of renal artery disease. Clinical clues to suggest renovascular hypertension include age younger than 30 years or older than 50 years, abrupt onset and short duration of hypertension, presence of extrarenal vascular disease, end-organ damage such as left ventricular hypertrophy or high-grade hypertensive retinopathy, systolic-diastolic abdominal bruit, and deterioration of renal function in response to an angiotensin-converting enzyme inhibitor. In patients who have a moderate clinical suggestion of renovascular hypertension, a number of noninvasive tests have been developed that identify patients with renovascular hypertension and help predict the outcome of intervention treatment.

For patients with renovascular hypertension due to fibrous dysplasia, candidacy for surgical intervention is guided by the specific pathologic process, as determined by angiographic findings, and its associated natural history (Stewart et al, 1970). Medical management of medial fibroplasia is the initial approach because loss of renal function from progressive obstruction is uncommon, and intervention is reserved for those patients with difficult-to-control hypertension. Renal artery disease due to intimal or perimedial fibroplasia is often associated with progressive obstruction, which can result in ischemic renal atrophy. Therefore, early intervention is recommended to improve blood pressure control and to preserve renal function.

The known results of PTA are important in assessing the need for surgery in patients with fibrous dysplasia. **Technical and clinical success rates with PTA for fibrous disease of the main renal artery are 90% to 95% and are no different from results obtainable with surgery** (Novick, 1994a, 1994b). Still, up to 30% of patients may present with branch disease or aneurysm that is not amenable to PTA. Surgery is then reserved for patients with peripheral, complex branch disease or for those whose PTA has failed.

Renal artery aneurysms may require repair if they result in significant hypertension or for prevention of rupture when they are larger than 2 cm and noncalcified (Novick, 1982). This is a particular concern in women of reproductive age because of the predisposition for rupture during pregnancy.

For patients with atherosclerosis and renovascular hypertension, the indications for intervention are more restrictive because of the frequent presence of concomitant extrarenal vascular disease. More vigorous attempts at medical management for this group are warranted. Surgical revascularization is reserved for those patients whose hypertension cannot be satisfactorily controlled with medication or whose renal function becomes threatened by advanced vascular disease. **Whereas PTA is associated with a successful blood pressure result for nonostial atherosclerosis, the long-term success rate with ostial lesions is poor because of a higher incidence of restenosis** (Novick, 1994a, 1994b). The results with endovascular stenting for ostial lesions are better than those with PTA; however, surgical revascularization remains the definitive long-term therapy for these patients (Steinbach et al, 1997).

Ischemic Nephropathy

Epidemiologic studies suggest that atherosclerotic renovascular disease is common in patients with generalized atherosclerosis obliterans regardless of the presence of renovascular

hypertension. **The development of chronic renal insufficiency from atherosclerotic renal artery disease, known as ischemic nephropathy, has become an important clinical issue that is separate and distinct from the problem of renovascular hypertension.** Knowledge of the natural history of atherosclerotic renal artery disease permits identification of patients at risk for ischemic nephropathy (Schreiber et al, 1984).

Those at highest risk are patients with high-grade stenosis (>75%) involving the entire renal mass (bilateral disease or disease in a solitary kidney). Intervention in these patients is for the purpose of preservation of renal function. Many of these patients are older, with diffuse extrarenal vascular disease and ostial renal artery disease. Clinical clues suggesting ischemic nephropathy include azotemia (unexplained or associated with angiotensin-converting enzyme inhibitor treatment), diminished renal size, and vascular disease in other sites (cerebrovascular disease, coronary artery disease, or peripheral vascular disease).

In considering a patient for revascularization, a determination of the potential for renal salvage must be made (Novick, 1996a, 1996b). All testing in this regard is aimed at identifying severe underlying renal parenchymal disease, in which case restoration of renal blood flow would not result in recovery of renal function. Successful revascularization usually results when the affected kidney is larger than 9 cm and demonstrates some evidence of function (usually assessed by isotopic renal scan). Total occlusion of the renal artery is not a contraindication for repair because the viability of the kidney can be maintained by collateral circulation, which is demonstrable by angiography. **Patients with mild to moderate renal dysfunction are acceptable surgical candidates; however, surgical revascularization is generally not worthwhile for patients with advanced azotemia (serum creatinine concentration of more than 4 mg/dL) because of significant underlying renal parenchymal disease. An exception to this rule is the small number of patients with significant renal functional impairment and bilateral total renal artery occlusion when one or both kidneys remain viable on the basis of collateral circulation.** Such kidneys otherwise meet criteria for revascularization (i.e., adequate size and with minimal parenchymal disease). Although such a presentation is uncommon, these patients can have favorable outcomes with surgical revascularization. Finally, in equivocal cases, a renal biopsy is performed at the time of revascularization. Preservation of the majority of glomeruli is the most important element of a favorable biopsy finding. Excessive glomerular hyalinization precludes performance of surgical revascularization. Tubular atrophy, interstitial fibrosis, and arteriolar sclerosis are less important and do not preclude consideration for revascularization.

PREOPERATIVE CONSIDERATIONS

Patients with atherosclerotic renal artery disease who are considered for surgical revascularization should undergo screening and correction of significant associated extrarenal vascular disease, such as coronary and carotid disease. With aggressive treatment of coexisting extrarenal vascular disease before surgical renal revascularization, perioperative morbidity and mortality can be minimized.

Before surgery, all patients require catheter arteriography with iodinated contrast material for accurate anatomic information to be obtained. In selected cases, carbon dioxide angiography can be used, which eliminates the risk for contrast-related nephrotoxicity. In addition to anteroposterior views of the renal artery and aorta, I routinely obtain a lateral aortogram to assess the celiac artery and a view of the lower thoracic aorta. These additional views are obtained in anticipation of the use of extra-anatomic bypass procedures.

Many patients have bilateral disease, especially those with ischemic nephropathy. Because the morbidity of bilateral procedures is greater and disease is frequently asymmetrical, I usually perform unilateral renal revascularization. In cases of renovascular hypertension, the more extensively diseased artery is repaired, and for ischemic nephropathy, the larger kidney is repaired.

All patients undergoing surgical renal revascularization are well hydrated before surgery. Because renovascular hypertension is associated with secondary hyperaldosteronism, potassium supplementation and monitoring of serum potassium levels are needed to guard against hypokalemia. To further ensure optimal renal perfusion and an active diuresis intraoperatively, 12.5 g of mannitol is given intravenously before the operation is commenced; equivalent doses of mannitol are subsequently given before revascularization, immediately after revascularization, and again in the recovery room.

AORTORENAL BYPASS

Although a variety of surgical revascularization techniques are available for treatment of patients with renal artery disease, **aortorenal bypass with a free graft of autogenous saphenous vein or hypogastric artery remains the preferred method in patients with a nondiseased abdominal aorta** (Straffon and Siegel, 1975; Novick et al, 1977a, 1977b; Stoney and Olofsson, 1988). Although an arterial autograft is theoretically advantageous, use of the hypogastric artery as a bypass graft is limited by its short length and frequent involvement with atherosclerosis. Therefore, the autogenous saphenous vein is most often employed, and excellent clinical results continue to be achieved with this type of bypass graft. The gonadal vein should never be used as a renal artery bypass graft. This vein is extremely friable and may either rupture postoperatively or undergo severe dilation. Currently, aortorenal bypass with a synthetic material is indicated only when an autogenous vascular graft is not available, and polytetrafluoroethylene has become the synthetic graft of choice in such cases (Khauli et al, 1984; Cormier et al, 1990).

For an aortorenal bypass on the right side, the kidney is exposed by reflection of the ascending colon medially and Kocher's maneuver on the duodenum (Fig. 50–59). The liver and gallbladder are retracted upward, with care taken to protect the hepatic ligament with its vessels and common bile duct. Exposure of the right renal artery, right renal vein, IVC, and aorta is thereby obtained. The Buckwalter self-retaining ring retractor is inserted to maintain exposure. Gerota's fascia is opened laterally to expose the surface of the kidney so that its color and consistency may be observed.

The aorta is exposed from the level of the left renal vein to the inferior mesenteric artery; overlying lymphatic vessels and lumbar segmental branches are ligated as necessary to gain

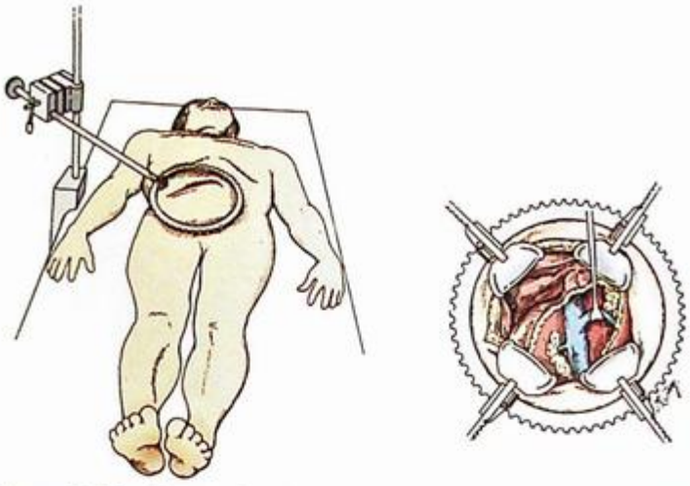

Figure 50–59. Transperitoneal exposure of the right kidney and renal vessels for aortorenal bypass.

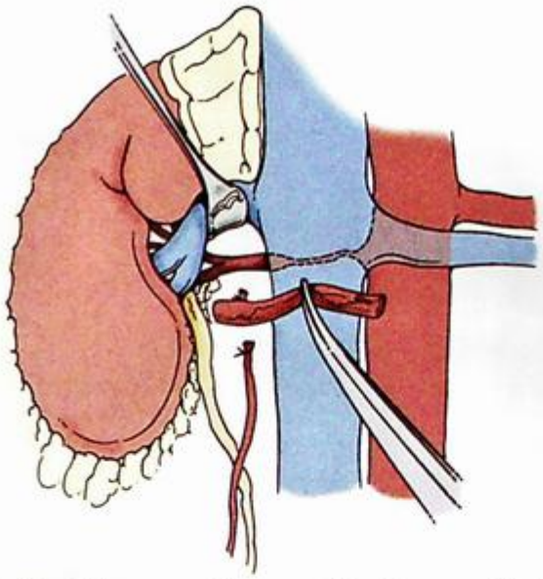

Figure 50–60. The bypass graft is measured for alignment with the aorta and distal renal artery.

exposure. The proximal aspect of the right renal artery is exposed by mobilizing and retracting the vena cava laterally and the left renal vein superiorly, carrying the dissection along the anterolateral aspect of the aortic wall until the renal artery origin is encountered.

The distal two thirds of the main right renal artery are exposed by retracting the mobilized vena cava medially and the right renal vein superiorly. To accomplish this, it is often necessary to secure and divide one or more lumbar veins entering the posterior aspect of the vena cava. There are generally no significant tributaries of the right renal vein. After exposure of the right renal artery, it is then mobilized from its attached and surrounding lymphatics and nerves. Small vessels and lymphatics are secured by light electrocautery or fine suture ligatures.

The bypass graft is placed along the lateral aortic wall to determine the best position for placement of the graft (Fig. 50–60). At this point, the ring retractor blades are relaxed to allow the aorta to return to its normal position and to prevent distortion of an otherwise well-placed graft after the final retraction is released.

On the right side, it is important to bring the graft off the anterolateral aspect of the aortic wall to avoid kinking of the proximal anastomosis as the graft passes in front of the vena cava. If the aortotomy is made too far anteriorly or posteriorly, the graft may kink, with subsequent development of stenosis or thrombosis. On the left side, the graft may be placed directly off the lateral aspect of the aorta.

An end-to-side anastomosis of the bypass graft to the aorta is done first to minimize the time of renal ischemia (Fig. 50–61). A DeBakey clamp is placed to occlude the aorta, with care taken to avoid compression of the mesenteric and contralateral renal arteries. In most cases, the lateral aortic wall is only partially occluded, thereby preserving distal aortic flow and obviating the need for systemic heparinization. In some patients with a small abdominal aorta (e.g., children, young women), better exposure is obtained by placing the DeBakey clamp completely across the aorta; this maneuver totally interrupts aortic blood flow, and in this event, systemic heparinization is initiated before aortic clamping.

An oval aortotomy is made on the anterolateral wall of the aorta. If significant atherosclerosis of the perirenal aorta is present, a local endarterectomy is performed to remove atheromatous plaque from the region of the anastomosis.

The bypass graft is spatulated for a short distance, and if length permits, the apex of the spatulation is generally placed at the caudal end of the aortotomy so that the graft can follow a gentle curve as it emerges from the aorta. If the aortotomy is located a significant distance below the distal renal artery or if the graft is short, as on the side, the apex is reversed cephalad to avoid kinking of the aortorenal bypass graft. Two corner sutures of 6-0 silk are inserted 180 degrees apart to begin the anastomosis.

The anastomosis is performed with interrupted 6-0 arterial sutures, and the anterior wall of the anastomosis is completed first. The aorta is rotated anteriorly to expose the posterior wall of the anastomosis, which is similarly completed with interrupted 6-0 arterial sutures. The graft is occluded beyond its origin with a bulldog clamp, and the aortic clamp is gently released. An arterial leakage is corrected at this time with additional sutures as needed. The bulldog clamp is intermittently released to ensure good blood flow and to flush the graft free of any atherosclerotic fragments. The graft distal to the clamp is then irrigated with heparin solution.

The main renal artery is then mobilized in its entirety, if this has not already been done. The renal artery is ligated proximally, a bulldog clamp is placed distally, and the diseased arterial segment is excised and sent for pathologic examination (Fig. 50–62). Before the distal anastomosis is performed, 10 mL of diluted heparin solution is instilled into the distal renal artery.

The bypass graft is brought anterior to the vena cava to lie in proximity to the distal renal artery. The graft is trimmed as necessary to allow a tension-free end-to-end anastomosis with no redundancy in the length of the graft. The graft and distal renal artery are spatulated to create a wider anastomosis, which minimizes the possibility of subsequent stenosis. The

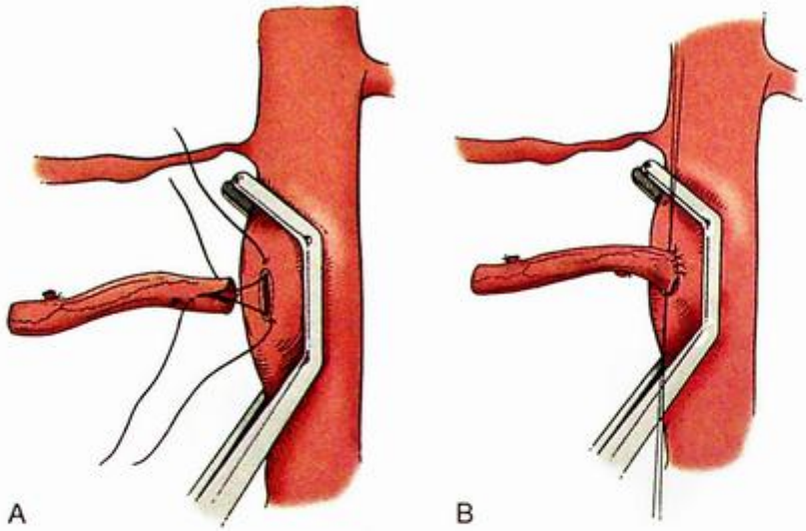

Figure 50–61. **A** and **B**, End-to-side anastomosis of the graft to the aorta is performed.

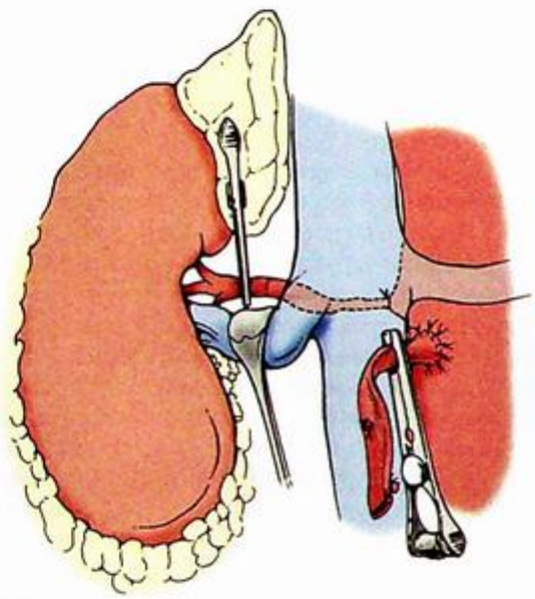

Figure 50–62. After completion of the proximal anastomosis, the distal renal artery is temporarily occluded before its division.

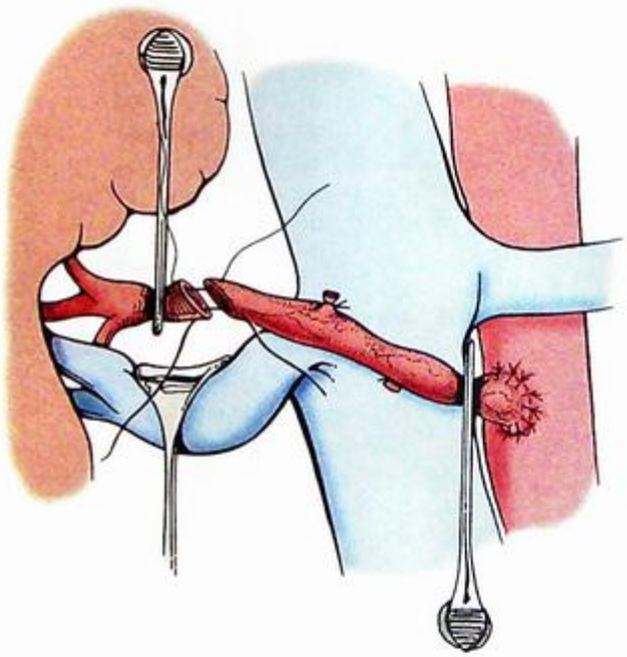

Figure 50–63. Performance of end-to-end anastomosis between the graft and the distal renal artery.

anastomosis is performed with 6-0 arterial sutures. Stay sutures, 180 degrees apart, are placed in the cephalic and caudal margins of the anastomosis. An end-to-end anastomosis of the graft to the renal artery is preferred to an end-to-side technique because it provides better flow rates, is easier to perform, and allows removal of the diseased renal arterial segment for pathologic study. The anastomosis is performed with interrupted 6-0 arterial sutures (Fig. 50–63).

The proximal and distal bulldog clamps are released, and circulation to the kidney is restored. Adequate renal perfusion is verified by palpating the pulse in the distal renal artery and by visually inspecting the renal surface. Arterial anastomotic leakage, if present, is controlled with Oxycel cotton or additional 6-0 interrupted arterial sutures (Fig. 50–64).

Surgical revascularization is more complicated when the disease extends into the branches of the renal artery or when vascular reconstruction is required for a kidney supplied by multiple renal arteries. When disease-free distal arterial branches occur outside the renal hilum, aortorenal bypass operation can usually be done in situ. The size of the involved vessels is not a significant factor; with use of microvascular instruments and optical magnification, vessels as small as 1.5 mm in diameter can be repaired in situ. There are several variations of the standard aortorenal bypass technique that may be used to repair branch renal artery disease. Because the bypass graft must be sufficiently long to reach the renal artery branches, an autogenous saphenous vein graft is the graft of choice in these cases.

In patients with disease involving two or more renal artery branches, I have found that aortorenal bypass with a branched vascular graft offers the most useful and versatile technique for in situ vascular reconstruction (Fig. 50–65) (Streem and Novick, 1982). These end-to-side anastomoses are done with interrupted 7-0 arterial sutures and lead to construction of a

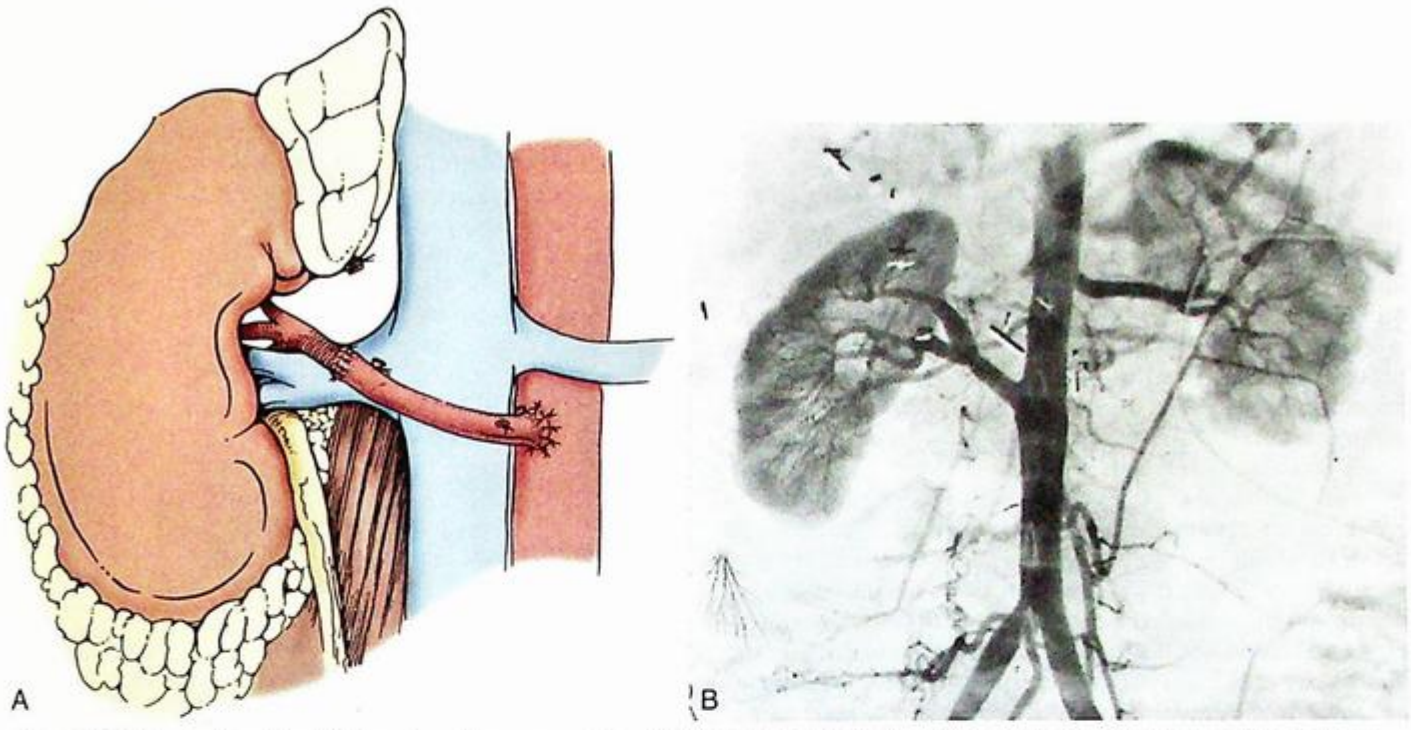

Figure 50–64. A, Completed right aortorenal bypass operation. B, Postoperative abdominal aortogram after successful right aortorenal bypass.

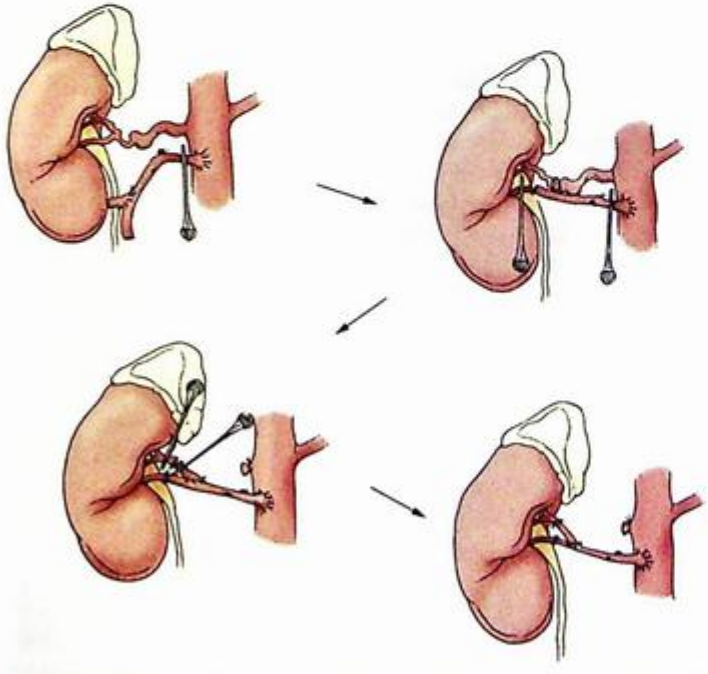

Figure 50–65. Technique of aortorenal bypass with a branched graft of autogenous saphenous vein.

multibranched graft that can be used to replace several diseased renal artery branches. After insertion of the proximal graft into the aorta, direct end-to-end anastomosis of each graft branch to a renal artery branch is done. During performance of each individual branch anastomosis, the remainder of the kidney continues to be perfused, and overall renal ischemia is thus limited to the time required for completion of a single end-to-end anastomosis (approximately 15 to 20 minutes), which is an important advantage.

Renal artery aneurysms have a variable presentation, and vascular involvement may be focal or diffuse (Poutasse, 1976; Novick, 1982). **Saccular aneurysms are the most commonly encountered type of renal artery aneurysm and are often located at the initial bifurcation or trifurcation of the main renal artery.** When the aneurysm is outside the renal hilum, in situ excision may be done. If the renal artery wall at the base of the aneurysm is intact, aneurysmectomy by either primary closure or patch angioplasty with a segment of saphenous vein can be performed (Fig. 50–66). If the entire circumference of the renal artery wall is diseased, aortorenal bypass with a branched autogenous vascular graft is done as described earlier (Ortenberg et al, 1983).

ALTERNATIVE BYPASS TECHNIQUES

In older patients with renal artery disease, involvement of the abdominal aorta with severe atherosclerosis, aneurysmal disease, or dense fibrosis from a prior operation may render an aortorenal bypass or endarterectomy technically difficult and potentially hazardous to perform. Simultaneous aortic replacement and renal revascularization have been associated with operative mortality rates of 5% to 30% (Brewster et al, 1976; Shahian et al, 1980; Dean et al, 1984; Tarazi et al, 1987) compared with rates of 2% to 6% (Novick et al, 1987; Libertino et al, 1992) for renal revascularization without aortic replacement. Dean and associates (1984) analyzed various risk factors to identify patients at greatest risk from a combined aortic and renal operation. The most significant risk factors were myocardial infarction, existing myocardial ischemia or ventricular hypertrophy, serum crea-

tinine level higher than 3 mg/dL, diffuse peripheral vascular disease, and revascularization of both renal arteries at the time of aortic replacement. Although operative mortality was 0% if none of these risk factors were present, it increased to 63% if three or more were present. Therefore, simultaneous aortic replacement and renal revascularization should be considered only in patients with a significant aortic aneurysm or symptomatic aortoiliac occlusive disease. In the absence of a definite indication for aortic replacement, alternative bypass techniques are preferable because they can safely and effectively restore renal arterial blood flow while avoiding the need for a more hazardous operation. These alternative bypass operations include hepatorenal bypass, splenorenal bypass, iliorenal bypass, thoracic aortorenal bypass, and mesenterorenal bypass. The relative indications, surgical technique, and efficacy of these approaches are reviewed here.

In considering the patient's eligibility for alternative visceral–renal arterial bypass operations, the absence of occlusive disease involving the donor artery must be verified by preliminary arteriography. **Candidates for hepatorenal or splenorenal bypass must be evaluated with both anteroposterior and lateral abdominal aortography to ensure that the celiac artery and its branches are unobstructed. Pelvic arteriography is a requisite study in patients considered for an iliorenal bypass. If thoracic aortorenal revascularization is contemplated, lower thoracic aortography must be obtained.**

Surgical revascularization has been performed more often to preserve renal function in patients with ischemic nephropathy from atherosclerotic renal artery disease. Such patients are generally older, with ostial renal artery lesions and diffuse atherosclerosis involving other major abdominal vessels. Significant atherosclerotic occlusive disease involving the celiac and iliac arteries may preclude use of these vessels for renal revascularization. Abdominal aortographic findings were reviewed in 254 patients with atherosclerotic renal artery disease to document the prevalence of associated abdominal aortic and visceral arterial atherosclerosis (Fergany et al, 1995). All patients were evaluated with both anteroposterior and lateral aortography. The renal, celiac, superior mesenteric, and common iliac arteries were evaluated for the presence and severity of stenosis. The incidence of moderate (50% to 75%) or severe (>75%) visceral artery stenosis was determined in patients with varying degrees of renal artery stenosis (Table 50–1).

In the overall group of 254 patients with atherosclerotic renal artery stenosis, the incidence of significant celiac and iliac artery stenosis was 54% and 50%, respectively. Patients with severe renal artery stenosis bilaterally or in a solitary kidney are of greatest interest because they compose the most common candidate group for revascularization to preserve renal function. In this group, the incidence of significant celiac and iliac artery stenosis was 59% and 58%, respectively. Patients with severe unilateral renal artery stenosis also occasionally require revascularization for treatment of poorly controlled hypertension. In this group, the incidence of significant celiac and iliac stenosis was 52% and 30%, respectively (Fig. 50–67). A majority (75% to 81%) of patients in both of these groups had significant abdominal aortic atherosclerosis, which would preclude abdominal aortorenal revascularization. These findings underscore the prevalence of celiac and iliac arterial occlusive disease in these patients; if it is present, it obviates use of these vessels for renal revascularization. The only other published study relevant to this issue is from Valentine and colleagues (1991), who noted celiac artery stenosis in 17 of 50 patients (34%) with more than 50% renal artery stenosis and in 10 of 20 patients (50%) with more than 75% renal artery stenosis.

Splenorenal Bypass

Splenorenal bypass is the preferred vascular reconstructive technique for patients with a troublesome aorta who require left renal revascularization (Khauli et al, 1985; Brewster and Darling, 1979). Transposition of the splenic artery by retroduodenal passage for right renal revascularization has been unsatisfactory and is not recommended. A requisite for performing splenorenal bypass is the demonstration on preoperative aortography, with both anteroposterior and lateral views,

Table 50-1. Incidence of Significant Aortic Disease and Visceral Artery Stenosis in Patients with Renal Artery Stenosis

Renal Artery Status	*Aortic Disease (%)*	*Celiac Stenosis (%)*	*SMA Stenosis (%)*	*Iliac Stenosis (%)*
Unilateral mild or moderate stenosis (N = 45)	89	53	31	48
Unilateral severe stenosis (N = 44)	75	52	20	30
Bilateral mild or moderate stenosis (N = 36)	72	39	25	47
Severe stenosis bilaterally or in a solitary kidney (N = 129)	81	59	29	58

SMA, superior mesenteric artery.

Figure 50–67. Lateral abdominal aortography shows significant stenosis at the origin of the celiac artery. SMA, superior mesenteric artery.

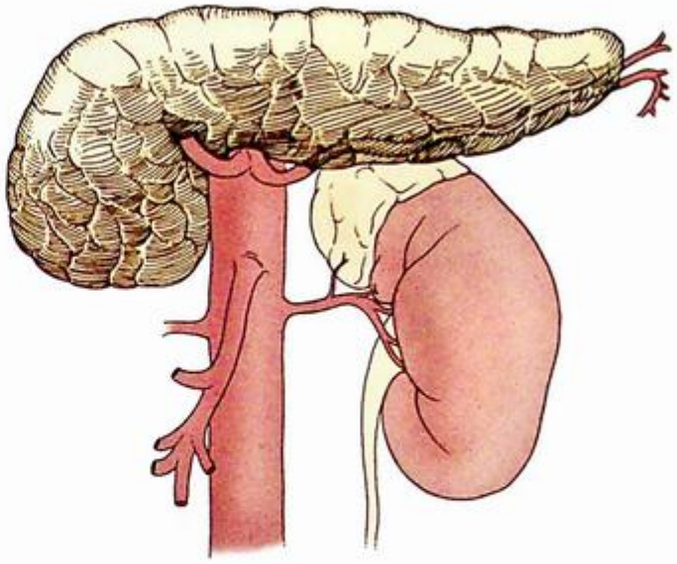

Figure 50–68. The normal anatomic relationships of the celiac, splenic, and left renal arteries.

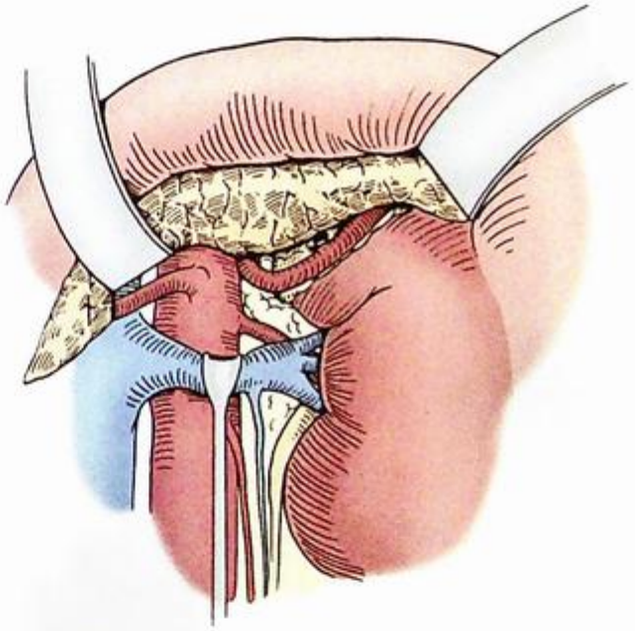

Figure 50–69. The pancreas is gently retracted cephalad to expose the splenic artery. The left renal vein is retracted inferiorly to expose the left renal artery.

of widely patent celiac and splenic arteries. The splenic artery must also be carefully examined intraoperatively for intramural atheromatous disease, which may be minimally occlusive and therefore not apparent on angiography but significant nonetheless. This problem, which is more commonly observed in women than in men, also militates against use of the splenic artery for renal revascularization.

The normal anatomic relationships of the splenic and renal vessels are shown in Figure 50–68. For splenorenal bypass, an extended left subcostal transperitoneal incision is made, and the left colon and duodenum are reflected medially. The plane between Gerota's fascia and the pancreas is developed by blunt dissection, and the pancreas and spleen are gently retracted cephalad. The left renal vein is mobilized and retracted inferiorly to expose the main left renal artery. The pancreas is gently retracted upward to permit access to the splenic vessels (Fig. 50–69). The splenic artery may be palpated posterior and superior to the splenic vein, and that portion lying closest to the distal aspect of the renal artery is chosen for mobilization. Small pancreatic arterial branches are divided and secured with fine silk sutures. The splenic artery may be tortuous and should be mobilized proximally as close to the celiac artery as possible, where the vessel wall is thicker and the luminal diameter larger.

After mobilization, the splenic artery is occluded proximally with a bulldog clamp, ligated distally with a 2-0 silk suture, and transected. It is not necessary to remove the spleen, which receives adequate collateral supply from the short gastric and gastric epiploic vessels to maintain its viability. After transection, the splenic artery is often observed to be in spasm with a considerably reduced luminal size. After irrigation of the lumen with diluted heparin solution, the spasm can be relieved by gentle dilation of the splenic artery with graduated sounds. In general, there is no significant disparity in the caliber of the splenic and renal arteries, and a direct end-to-end anastomosis is performed (Fig. 50–70). I prefer this type of anastomosis because it provides better flow, is easier to perform, and allows removal of the diseased arterial segment for pathologic study (Fig. 50–71). An alternative method for splenorenal bypass involves end-to-side anastomosis of the

splenic artery to the distal disease-free renal artery. I have employed this technique only in the unusual event of significant disparity in the caliber of the splenic and renal arteries.

The advantages of the splenorenal bypass technique are that the operation is done well away from the aorta, that only a single vascular anastomosis is necessary, and that revascularization is accomplished with an autogenous vascular graft. In properly selected patients, splenorenal bypass is an excellent method for vascular reconstruction of the left kidney.

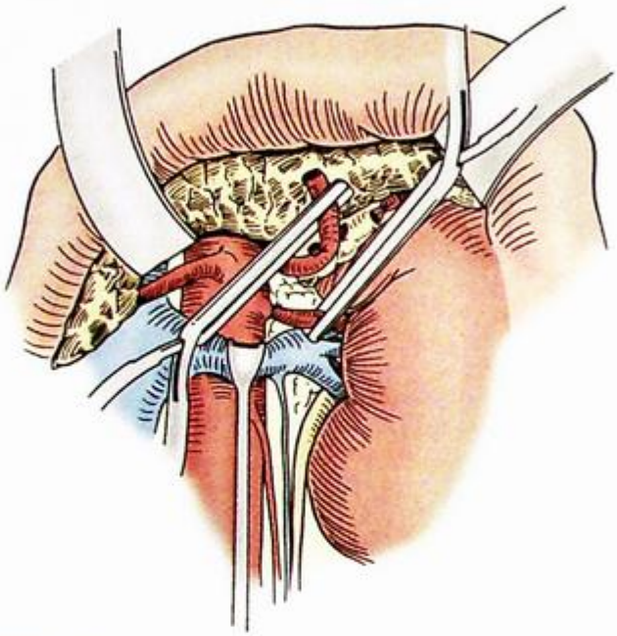

Figure 50–70. The splenic artery has been transected and is temporarily occluded proximally. The left renal artery is being prepared for anastomosis to the splenic artery.

Hepatorenal Bypass

Hepatorenal bypass is the preferred vascular reconstructive technique for patients with a troublesome aorta who require right renal revascularization. The hepatic circulation is ideally suited for a visceral–right renal arterial bypass operation. The liver receives 28% of the cardiac output in resting adults and is unique in having dual circulation from the portal vein and the hepatic artery, which contribute 80% and 20% of hepatic blood flow, respectively. Hepatic oxygenation is equally derived from these two circulations. It has been well demonstrated that hepatic artery flow can be safely interrupted. When this occurs, hepatic function and morphologic appearance are maintained by increased extraction of oxygen from portal venous blood and by rapid development of an extensive collateral arterial flow to the liver (Novick et al, 1979).

The hepatic artery arises from the celiac axis and runs anterior to the portal vein and to the left of the common bile duct. The first major branch is the gastroduodenal artery, and thereafter the hepatic artery divides into its right and left branches. In considering a hepatorenal bypass operation, one of the more clinically significant anatomic variations is origin of the right hepatic artery from the SMA, which occurs in about 12% of patients. The left hepatic artery arises from the gastric artery in approximately 11.5% of patients.

In patients considered for a hepatorenal bypass operation, preoperative aortography with lateral views must demonstrate patent celiac and hepatic arteries. In my experience, the hepatic artery is rarely involved with atherosclerosis—certainly less often than the splenic artery. Hepatorenal bypass should also be undertaken only when preoperative biochemical screening reveals normal liver function. The most common method of performing hepatorenal bypass is with an interposition saphenous vein graft anastomosed end-to-side to the common hepatic artery, just beyond the gastroduodenal origin, and then end-to-end to the right renal artery

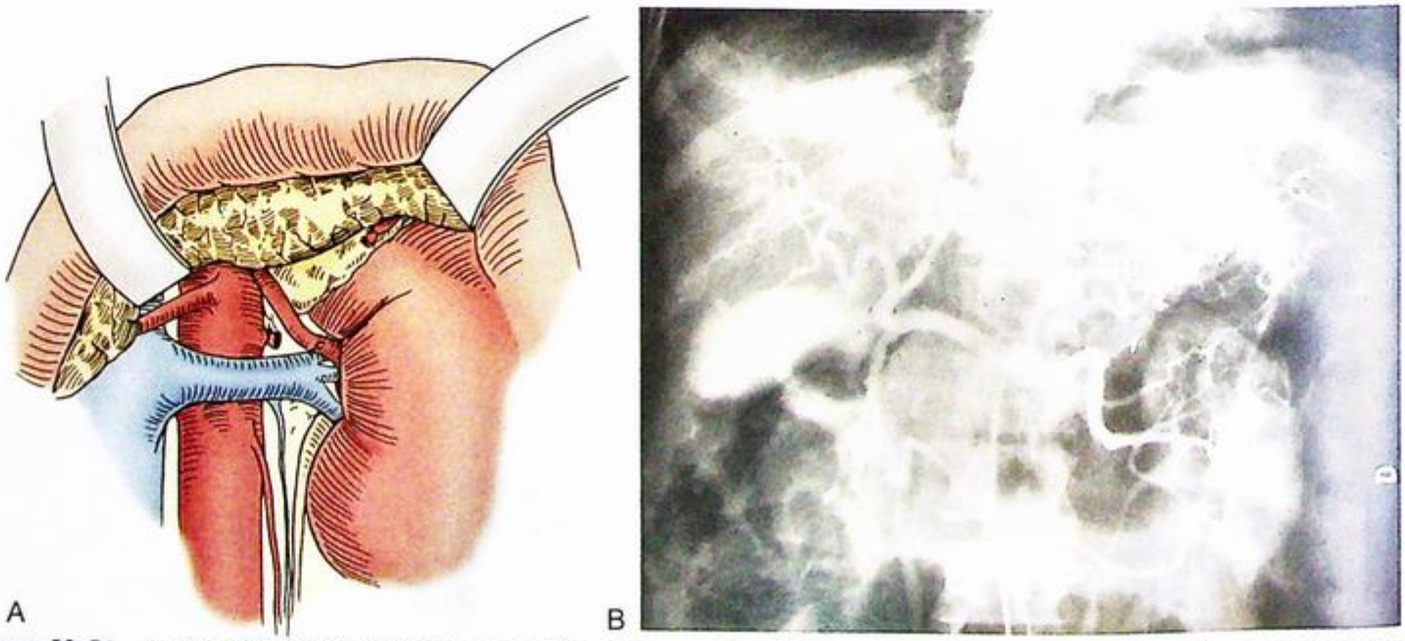

Figure 50–71. **A,** Completed left splenorenal bypass operation. **B,** Postoperative celiac arteriogram shows unobstructed left splenorenal anastomosis.

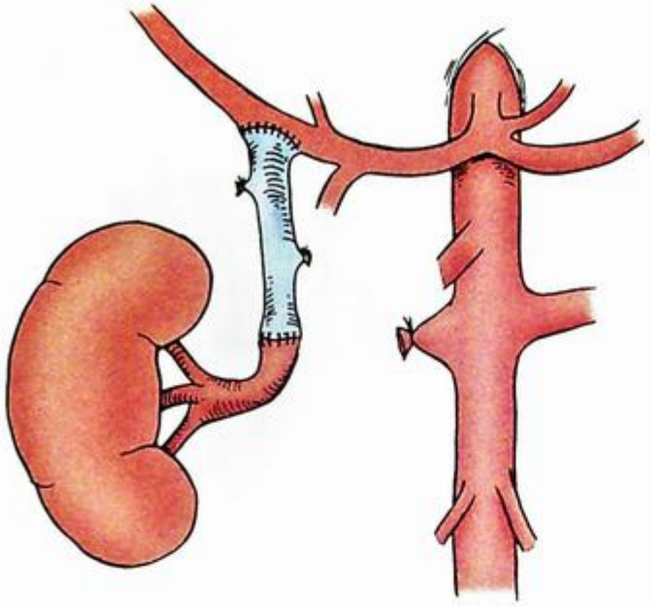

Figure 50–72. The most common method of performing hepatorenal bypass, with an interposition saphenous vein graft anastomosed end-to-side to the common hepatic artery and end-to-end to the right renal artery.

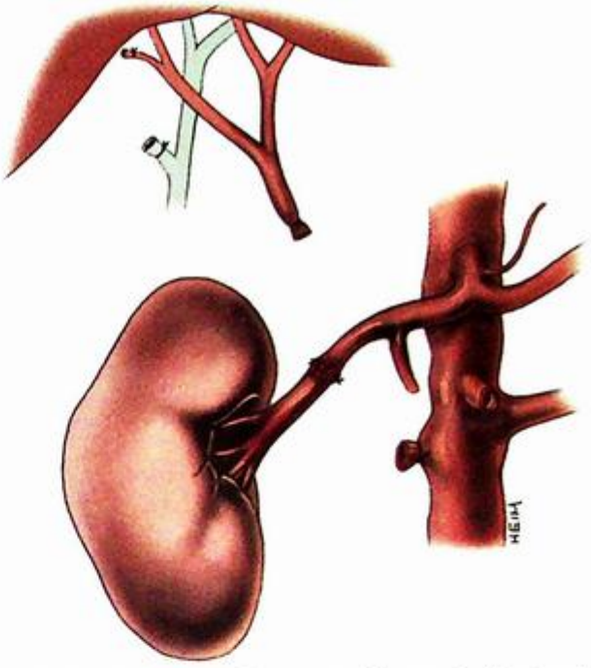

Figure 50–73. Performance of hepatorenal bypass by direct end-to-end anastomosis of the common hepatic artery to the right renal artery.

(Fig. 50–72). This technique preserves distal hepatic arterial flow and thereby reduces the risk of ischemic liver damage.

In some patients, the common hepatic artery cannot be employed in this manner for hepatorenal revascularization, either because it is smaller than the renal artery or because of an anatomic variation in which the right and left hepatic arterial branches have separate origins. In these situations, the available major hepatic arteries are generally of insufficient caliber to maintain adequate blood flow to both the liver and the right kidney. It is then preferable to perform end-to-end anastomosis of the common, right, or left hepatic arteries to the right renal artery (Fig. 50–73) (Novick and McElroy, 1985). In some patients, a direct tension-free anastomosis of these vessels can be done; otherwise, an interposition saphenous vein graft is needed. Despite the resulting total or segmental hepatic dearterialization in these patients, postoperative liver function studies have remained normal. However, **the gallbladder is more susceptible to ischemic damage and may undergo necrosis when its blood supply from the right hepatic artery is interrupted.**

Strategies are available to avoid the complication of gallbladder ischemia in patients undergoing end-to-end hepatorenal revascularization. First, when separate right and left hepatic arteries are present, the left hepatic artery should be used preferentially for anastomosis with the renal artery. Second, if it is necessary to use the common or right hepatic arteries in this manner, an adjunctive cholecystectomy should be performed. A third option is to perform end-to-end anastomosis of the gastroduodenal and renal arteries, with an interposition saphenous vein graft if necessary (Fig. 50–74). However, the origin and course of the gastroduodenal artery must be such that proximal kinking does not occur when this vessel is rotated toward the right kidney. It is also somewhat more difficult to mobilize an adequate length of this artery, and care must be taken to avoid damage to the duodenum or pancreas. This technique is not as widely applicable as other methods of hepatorenal revascularization, but it does offer the advantage of preserving hepatic arterial flow.

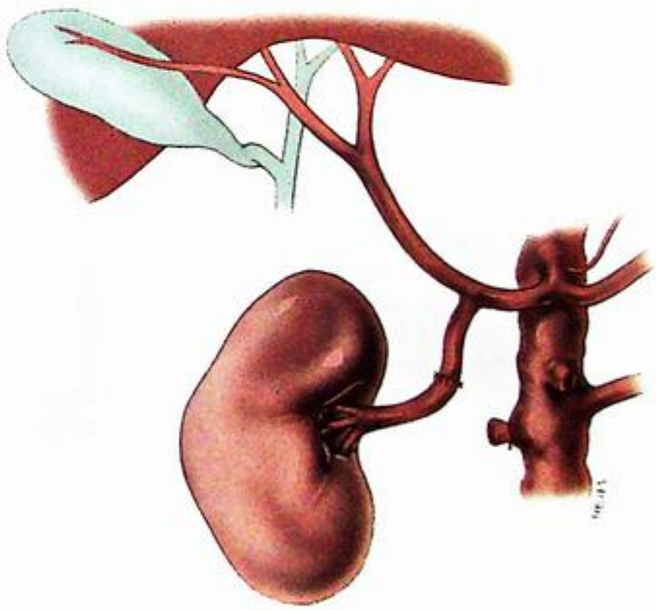

Figure 50–74. Hepatorenal revascularization by end-to-end anastomosis of the gastroduodenal and right renal arteries.

The results of hepatorenal bypass for right renal arterial occlusive disease have been excellent (Fig. 50–75) and indicate that this is a safe and effective operative approach in properly selected patients with a diseased abdominal aorta (Chibaro et al, 1984).

Figure 50–75. Postoperative selective celiac arteriogram after successful right hepatorenal and left splenorenal bypass operations.

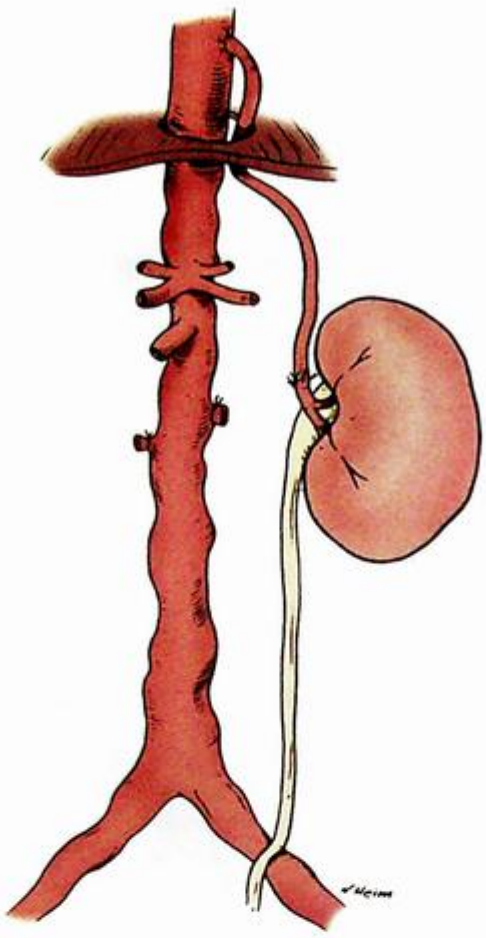

Figure 50–76. Technique of left thoracic aortorenal revascularization.

Thoracic Aortorenal Bypass

Use of the thoracic aorta for renal revascularization is a surgical alternative for patients with significant abdominal aortic atherosclerosis, celiac artery stenosis, and no primary indication for replacement of the abdominal aorta. The subdiaphragmatic supraceliac and descending thoracic aorta are often relatively free of disease in such patients and can be used to achieve renal vascular reconstruction with an interposition saphenous vein graft (Fry and Fry, 1989; Novick, 1994a, 1994b). Preoperative angiographic evaluation should include views of the supraceliac aorta and the thoracic aorta to verify their disease-free status.

For left renal revascularization, I have employed the descending thoracic aorta as a donor site because I believe that it is more readily accessible than the subdiaphragmatic supraceliac aorta (Fig. 50–76). A left thoracoabdominal incision is made below the eighth rib and extended medially across the midline. This incision provides excellent simultaneous exposure of the thoracic aorta and renal artery with no need for extensive abdominal visceral mobilization. The left colon is reflected medially to expose the kidney and renal artery. The descending thoracic aorta is exposed above the diaphragm and partially occluded laterally with a DeBakey clamp. A small aortotomy is made, a reversed saphenous vein graft is anastomosed end-to-side to the aorta, and the aortic clamp is then removed. During performance of the proximal anastomosis, distal aortic flow is preserved and systemic heparinization is therefore not employed. A 2-cm incision is then made in the diaphragm just lateral to the aorta to enlarge the hiatus. The saphenous vein graft is passed alongside the aorta, through the diaphragmatic hiatus, posterior to the pancreas, and into the left retroperitoneum. End-to-end anastomosis of the vein graft and distal left renal artery is performed to complete the operation (Fig. 50–77). On the right side, the subdiaphragmatic supraceliac or lower thoracic aorta is equally accessible through an anterior bilateral subcostal incision. The technique of thoracic aortorenal bypass is otherwise analogous to that described on the left side.

I reported my initial results with thoracic aortorenal bypass in 23 patients with hypertension, abdominal aortic atherosclerosis, and celiac artery stenosis; in 21 patients, renal artery stenosis was present bilaterally or in a solitary kidney (Novick, 1994a, 1994b). There was one operative death due to myocardial infarction. Postoperatively, among the remaining 22 patients, hypertension was cured or improved in 19 (86%), and renal function was stable or improved in 21 (95%).

Thoracic aortorenal revascularization is an attractive approach for several reasons. The thoracic aorta provides an excellent inflow source, and the proximal end-to-side vein graft anastomosis yields an antegrade acute angle that is hemodynamically advantageous. Because the thoracic aorta is only partially occluded during performance of the proximal anastomosis, distal aortic flow is preserved and systemic heparinization is unnecessary. The potential morbidity of aortic cross-clamping, which includes the risk of spinal cord ischemia, is avoided. The period of renal ischemia is also minimal and is limited to the time required for completion of the distal anastomosis, which is 15 to 20 minutes. Revascularization of the kidney is achieved with an autogenous vascular graft, which is the optimal material for renal

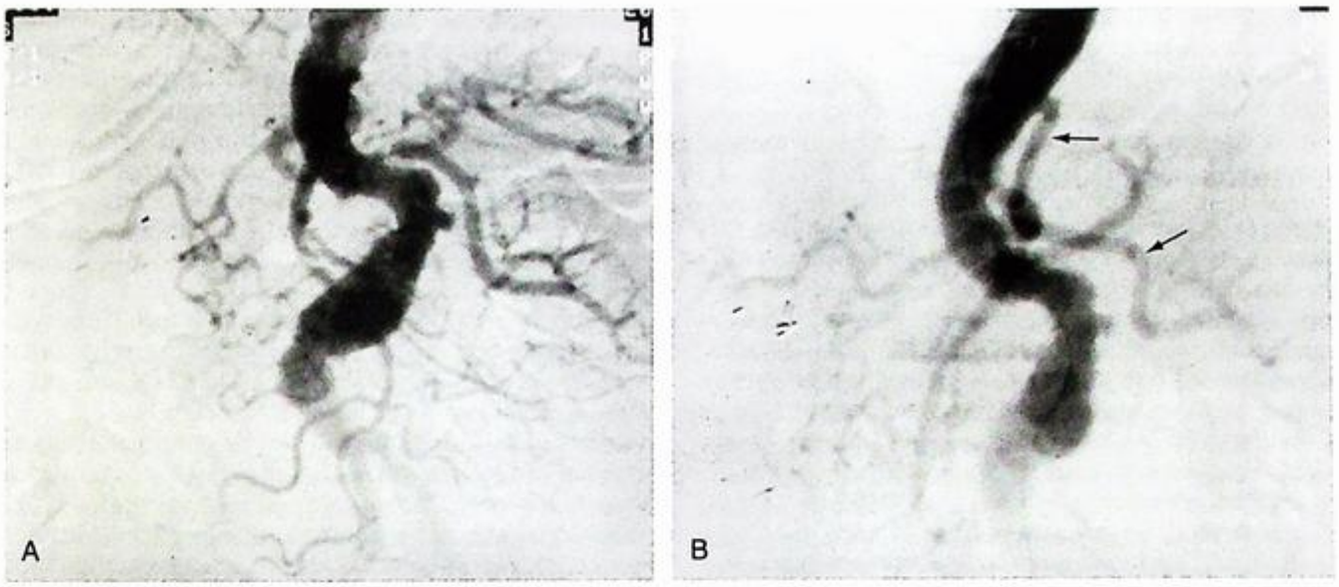

Figure 50–77. A, Preoperative abdominal aortogram shows solitary left kidney with high-grade stenosis. B, Postoperative aortogram shows patent thoracic aortorenal saphenous vein bypass graft.

artery replacement. Finally, use of the invariably healthy thoracic aorta minimizes the risk of peripheral embolization.

Iliorenal Bypass

Iliorenal bypass is an occasionally useful technique for revascularization in patients with severe aortic atherosclerosis, provided there is satisfactory flow through the diseased aorta and absence of significant iliac disease (Novick and Banowsky, 1979). My approach is to consider this operation only when a splenorenal, hepatorenal, or thoracic aortorenal bypass cannot be done. This preference is based on the fact that aortic atherosclerosis may continue to progress in these patients, and if so, this process is most likely to involve the intrarenal aorta. Such a development might then compromise flow to a revascularized kidney whose blood supply is derived exclusively from one of the iliac arteries. The suprarenal aorta and supraceliac aorta are more often spared from progressive atherosclerosis—hence, my preference for bypass procedures originating from these locations.

In general, iliorenal bypass is performed with use of the ipsilateral iliac artery because this simplifies exposure of the operative field (Fig. 50–78). This is a relatively minor consideration, and use of the contralateral common iliac artery is also satisfactory, particularly if it is less diseased than the ipsilateral counterpart. Iliorenal bypass is performed through a midline transperitoneal incision after harvesting of a long saphenous vein graft. The colon is reflected medially to obtain simultaneous exposure of the ipsilateral common iliac and renal arteries. The common iliac artery is occluded proximally and distally with bulldog clamps. An oval arteriotomy is made on the anterolateral aspect of the common iliac artery. The distal clamp is temporarily released to enable 20 mL of diluted heparin solution to be instilled into the distal iliac and femoral arteries. Systemic heparinization is not routinely employed.

The proximal end of the saphenous vein graft is spatulated, and the apex of the spatulation is placed at the cephalic end

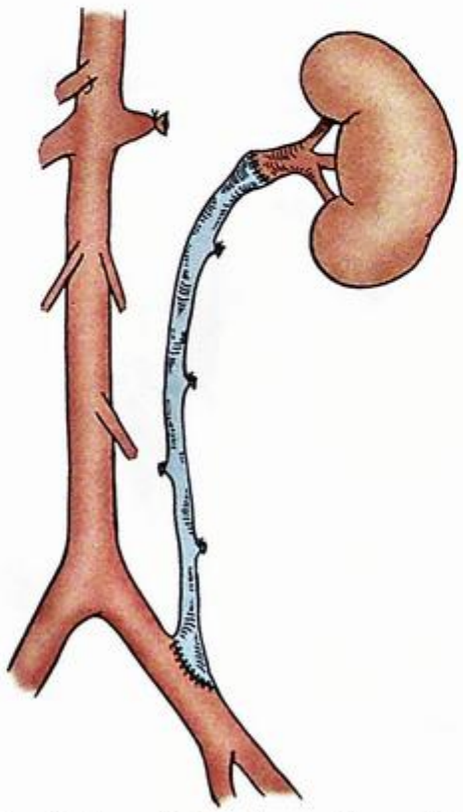

Figure 50–78. Technique of iliorenal bypass with a saphenous vein graft.

of the arteriotomy. Stay sutures are placed in both cephalic and caudal margins of the anastomosis, which is then completed with interrupted 6-0 arterial sutures. A bulldog clamp is placed across the proximal portion of the vein graft, and the iliac clamps are removed, restoring circulation to the lower extremity. The saphenous vein graft follows a direct cephalad course toward the ipsilateral renal artery between the aorta medially and the ureter laterally. An end-to-end anastomosis

of the saphenous vein graft to the distal disease-free renal artery is then performed with interrupted 6-0 arterial sutures. The graft is positioned to allow a tension-free distal anastomosis while avoiding angulation or kinking of the renal artery.

Mesenterorenal Bypass

In unusual cases, aortography reveals an enlarged SMA that may then be employed for visceral arterial bypass to either kidney (Fig. 50–79). I have employed the superior mesenterorenal bypass technique in occasional patients with a troublesome aorta in whom a bypass to the kidney from the celiac or iliac arteries was not possible (Khauli et al, 1985a, 1985b). The finding of an enlarged and widely patent SMA is most often observed in patients with total occlusion of the infrarenal aorta. In such cases, the SMA has a wider caliber than normal because it is supplying collateral vessels to areas ordinarily vascularized from the infrarenal aorta (i.e., large bowel, pelvis, and lower extremities). Use of such an enlarged SMA for performance of a mesenterorenal bypass has been well tolerated, with no compromise of intestinal blood flow. I have not used this approach in patients with normal-sized SMA and cannot comment on its efficacy in this setting.

For mesenterorenal bypass, the abdomen is entered through a midline incision. During revascularization of the left kidney, the descending colon and splenic flexure are reflected medially, and a plane of dissection is developed between the pancreas and Gerota's fascia. Exposure of the suprarenal aorta is obtained by gentle retraction of the pancreas and the first portion of jejunum cephalad; the mesocolon is reflected medially. If necessary, additional exposure may be obtained by mobilization and evisceration of the right colon and small bowel, as is done commonly for retroperitoneal lymphadenectomy. The SMA can be palpated readily at its origin from the aorta approximately 1 to 2 cm above the level of the renal arteries. The vessel lies against the neck of the pancreas as it courses between the neck and the uncinate process. The artery then crosses the third part of the duodenum to enter the large bowel mesentery, where it lies posterior and to the left of the superior mesenteric vein. The SMA is mobilized for a distance of 2 to 3 cm beyond its origin, where it is most accessible and without branches. The left renal artery then is exposed and isolated similarly. A reversed segment of saphenous vein is anastomosed end-to-side to the lateral aspect of the SMA with interrupted 6-0 vascular sutures. After completion of this anastomosis, which generally takes 15 to 20 minutes, blood flow through the SMA is restored immediately, and the saphenous vein graft is occluded temporarily. End-to-end anastomosis of the vein graft to the left renal artery is then done with interrupted 6-0 vascular sutures.

During revascularization of the right kidney, the ascending colon and duodenum are reflected medially to gain exposure of the aorta and right renal artery. The ascending colon and small bowel are then rotated back to their normal position,

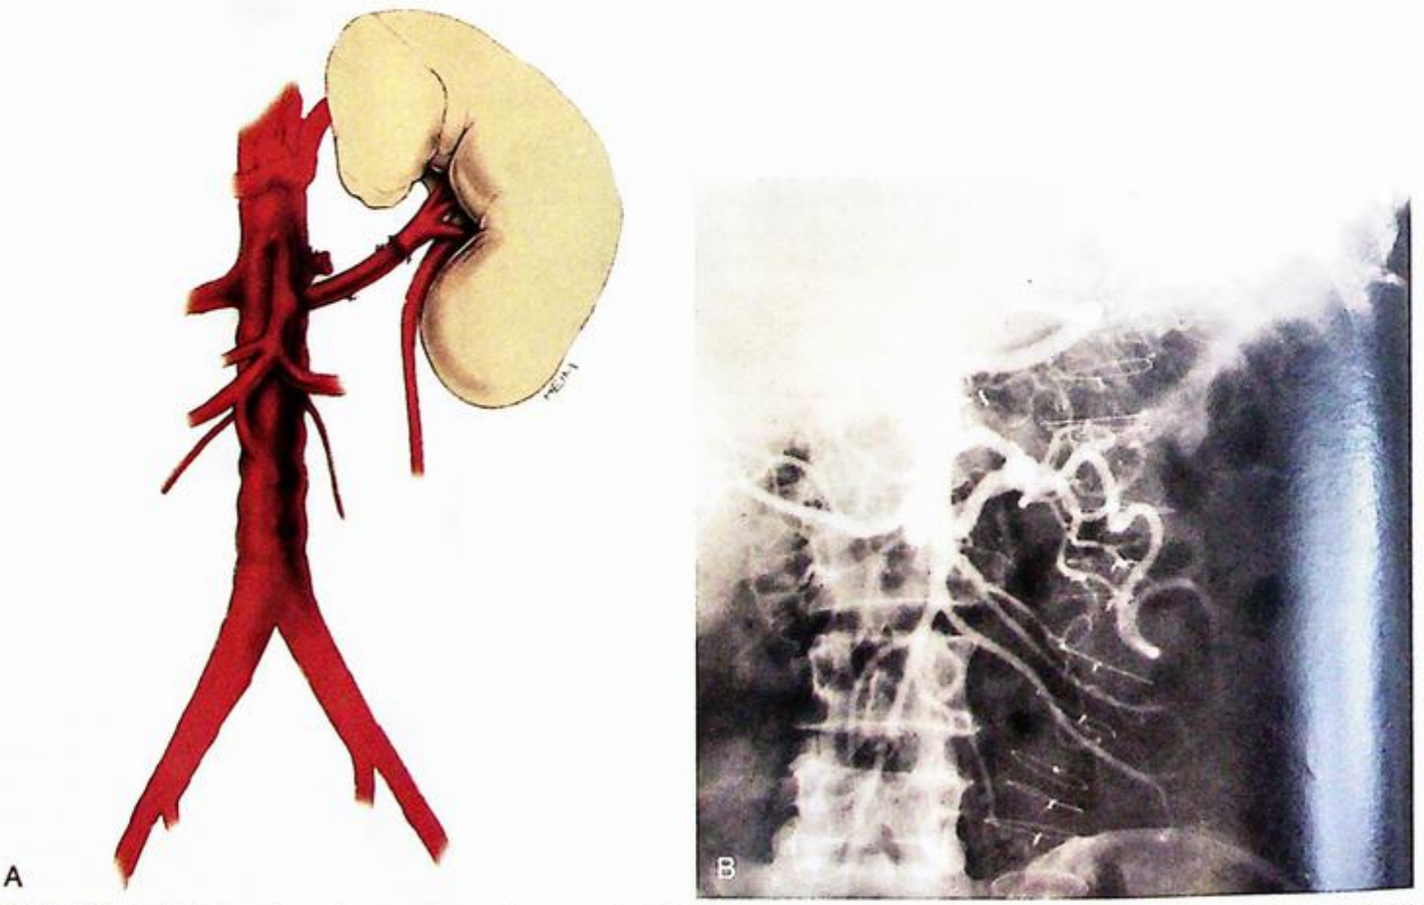

Figure 50–79. **A,** Technique of superior mesenterorenal bypass to the left kidney with a saphenous vein graft. **B,** Aortogram in a patient who underwent left mesenterorenal saphenous vein bypass shows excellent flow to the left kidney.

and the SMA is palpated where it crosses the third portion of the duodenum. The SMA is mobilized and isolated in this location for a distance of 3 to 4 cm. A saphenous vein graft is sutured end-to-side to this portion of the SMA, and the graft is then passed through a tunnel in the root of the small bowel mesentery, after a gentle curve as it crosses the third portion of the duodenum to enter the right retroperitoneum. End-to-end anastomosis of the graft to the right renal artery is performed to complete the operation.

Extracorporeal Microvascular Branch Renal Artery Reconstruction

Vascular disease involving the branches of the renal artery is most often caused by one of the fibrous dysplasias, namely, intimal, medial, or perimedial fibroplasia. Other causes of branch disease include arterial aneurysm, arteriovenous malformation, Takayasu's arteritis, neurofibromatosis, trauma, and, rarely, atherosclerosis. In such cases, the task of renovascular reconstruction is considerably more complicated because it necessitates multiple vascular anastomoses to renal artery branches that may be difficult to expose and are small in caliber. For these reasons, many patients in this category were formerly considered inoperable or candidates for total or partial nephrectomy. However, technical advances have improved this outlook, and successful vascular reconstruction is now possible in most patients. This evolution has primarily been due to the incorporation of microvascular and extracorporeal techniques into the armamentarium of the renovascular surgeon.

Branch renal artery lesions can often be repaired in situ with an aortorenal bypass when distal branches free of disease are present outside the renal hilum (Novick, 1980). Extracorporeal branch arterial repair and autotransplantation are indicated primarily when preoperative arteriography, with oblique views, demonstrates intrarenal extension of renovascular disease (Salvatierra et al, 1978; Novick, 1981a, 1981b; Dubernard et al, 1985; Dean et al, 1986). The advantages of an extracorporeal surgical approach include optimum exposure and illumination, bloodless surgical field, greater protection of the kidney from ischemia, and more facile employment of microvascular techniques and optical magnification. Removal and flushing of the kidney also cause it to contract in size, thereby enabling more peripheral dissection in the renal sinus for mobilization of distal arterial branches. Finally, the completed branch anastomosis can be tested for patency and integrity before autotransplantation.

In evaluating patients for extracorporeal revascularization and autotransplantation, preoperative renal and pelvic arteriography should be performed to define renal arterial anatomy, to ensure disease-free iliac vessels, and to assess the hypogastric artery and its branches for use as a reconstructive graft. Assuming the presence of a viable functioning kidney, the only absolute contraindication to this approach is such severe aortoiliac vascular disease as to preclude renal autotransplantation. It is also best to avoid autotransplantation of kidneys involved by severe renal parenchymal or small vessel disease. Such kidneys generally flush poorly after their removal, often leading to irreversible ischemic damage and nonfunction.

Extracorporeal revascularization and autotransplantation are generally performed through an anterior subcostal transperitoneal incision combined with a separate, lower quadrant, transverse semilunar incision. For nonobese patients, a single midline incision extending from the xiphoid process to the symphysis pubis may be used. The same intraoperative measures are taken as in live donor nephrectomy for allotransplantation to ensure minimal renal ischemia and immediate function after revascularization. These measures include prevention of hypotension during anesthesia, administration of mannitol, minimal surgical manipulation of the kidney, and rapid flushing and cooling of the kidney after its removal. Systemic heparinization before nephrectomy is unnecessary.

Immediately after its removal, the kidney is flushed intra-arterially with 500 mL of a chilled intracellular electrolyte solution and then submerged in a basin of ice-slush saline to maintain hypothermia (Fig. 50–80). The extracorporeal operation is completed under ice-slush surface hypothermia, and if there has been minimal warm renal ischemia, the kidney can be safely preserved in this manner for many more hours than are needed to perform even the most complex renal repair. In performing extracorporeal revascularization, I have found it cumbersome to work on the abdominal wall with the ureter attached. It is preferable to divide the ureter and place the kidney on a separate workbench. This provides better exposure for the extracorporeal operation and allows a second surgical team to prepare the iliac fossa simultaneously. This approach is also justified by the low incidence of complications after ureteroneocystostomy in renal allotransplantation.

Extracorporeal branch arterial reconstruction is performed with microvascular instruments, 7-0 to 9-0 suture material, and optical magnification with loupes (3.5× or 6×) or an operating microscope. The basic instruments required for microvascular surgery include a microneedle holder, microscissors, fine jeweler's forceps, small vessel dilators, microvascular clamps, and a 10-mL syringe with a 27-gauge blunt needle for irrigation.

After removal and flushing of the kidney, and with maintenance of surface hypothermia, the renal artery branches are mobilized distally in the renal sinus beyond the area of

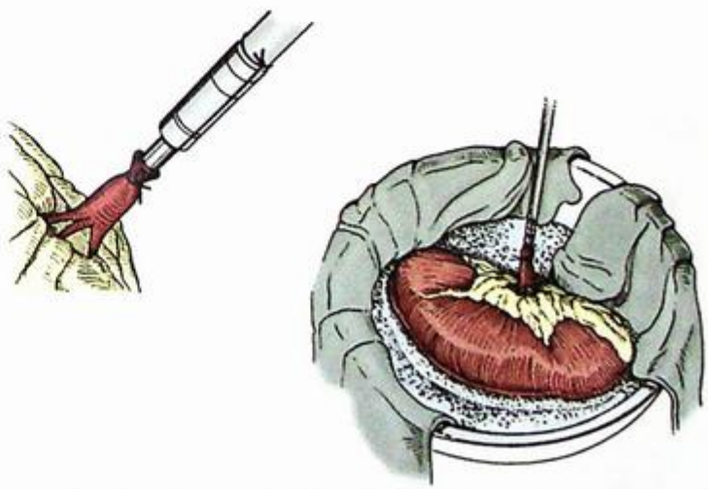

Figure 50–80. The removed kidney is flushed intra-arterially with a cold electrolyte solution and is placed in a basin of ice slush to maintain hypothermia.

vascular disease (Fig. 50–81). During this dissection, care is taken not to interfere with ureteral or renal pelvic blood supply. When the diseased renal artery branches are completely exposed, an appropriate technique for vascular reconstruction is selected.

The optimal method for extracorporeal branch renal artery repair involves the use of a branched autogenous vascular graft (Novick, 1981a, 1981b). This technique permits separate end-to-end microvascular anastomosis of each graft branch to a distal renal artery branch (Fig. 50–82). A hypogastric arterial autograft is the preferred material for vascular reconstruction because this vessel may be obtained intact with several of its branches (Fig. 50–83).

On occasion, the hypogastric artery is not suitable for use as a reconstructive graft because of atherosclerotic degeneration. When this occurs, a long segment of saphenous vein can be harvested, and by sequential end-to-side microvascular anastomoses, a branched graft can be fashioned from this vessel. This branched graft is then used in a similar manner to achieve reconstruction of the diseased renal artery branches (Fig. 50–84).

Branched grafts of the hypogastric artery and saphenous vein may occasionally prove too large in caliber for

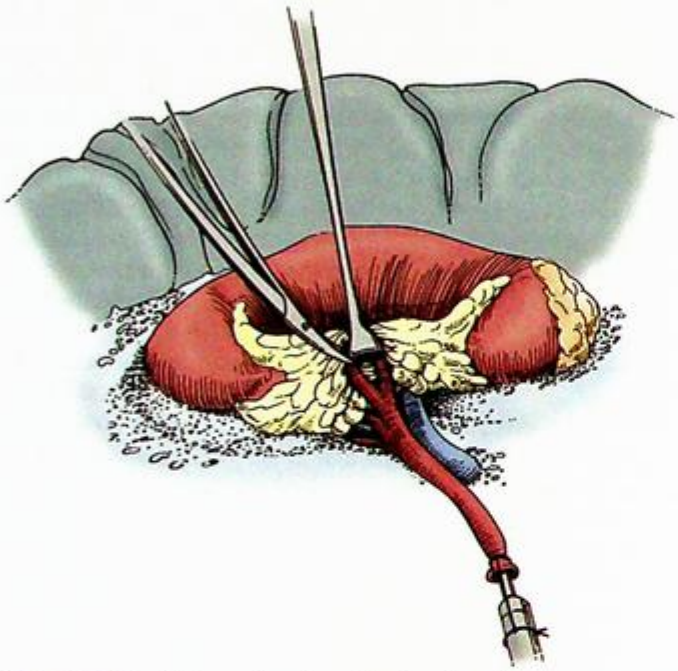

Figure 50–81. Under surface hypothermia, the diseased renal artery branches are mobilized in the renal sinus.

Figure 50–83. Operative photograph of the hypogastric artery removed intact with its branches.

anastomosis to small secondary or tertiary renal arterial branches. In these cases, the inferior epigastric artery provides an excellent alternative free graft for extracorporeal microvascular repair (Novick, 1981a, 1981b). This artery measures 1.5 to 2 mm in diameter, is rarely diseased, and coapts nicely in caliber and thickness to small renal artery branches (Fig. 50–85). The inferior epigastric artery may also be employed as a branched graft, either individually or in conjunction with a segment of saphenous vein (Fig. 50–86).

Although use of a branched autogenous vascular graft provides a simple, versatile, and effective method for branch renal arterial reconstruction, other techniques are occasionally preferable, depending on the extent of vascular disease. In some patients with localized segmental intrarenal branch lesions, there may be other arterial branches that either are uninvolved or have more proximally located vascular disease. Such branches with longer disease-free distal segments may be anastomosed end-to-side, either into a larger arterial branch or into the reconstructive vascular graft (Fig. 50–87).

On occasion, two distal arterial branches of similar diameter and free of disease are found adjacent to one another. When this occurs, the two adjacent branches can be conjoined and then anastomosed end-to-end to a single limb of the branched graft (Fig. 50–88).

Renal artery aneurysms have a variable presentation, and the method of extracorporeal repair is determined by whether

renovascular involvement is focal or diffuse. If the renal artery wall at the base of an aneurysm is intact, aneurysmectomy with patch angioplasty can be performed.

Aneurysms with short focal involvement of renal artery branches may also be simply resected with end-to-side branch reanastomosis or end-to-side reimplantation into an adjacent branch. In other cases, with more extensive vascular disease, aneurysmectomy and revascularization with a branched autogenous graft are indicated (Fig. 50–89).

These extracorporeal vascular techniques are performed with interrupted sutures, except for the conjoined anastomosis, for which a continuous suture is used. In revascularizing multiple arterial branches, one must anticipate the position that the various branches will assume in relation to one another on completion of the repair. Individual branch anastomoses are then done with careful attention to avoid subsequent malrotation, angulation, or tension. In all cases, extracorporeal repair leads to formation of a single main renal artery so that autotransplantation may be performed with one arterial anastomosis and no increase in revascularization time. When extracorporeal revascularization has been completed, the kidney is either reflushed or placed on the hypothermic pulsatile perfusion unit to verify patency and integrity of the repaired branches. Renal autotransplantation into the iliac fossa is then performed, with anastomosis of the renal vessels to the iliac vessels and restoration of urinary continuity by ureteroneocystostomy.

POSTOPERATIVE CARE

Patients undergoing surgical renal revascularization may experience wide fluctuations in blood pressure in the early postoperative period; either hypotensive or hypertensive episodes may predispose to graft thrombosis or bleeding from vascular anastomotic sites, respectively. Therefore, these patients are placed in the intensive care unit for monitoring of central venous pressure, urine output, pulse rate, and serum levels of hemoglobin and creatinine. During this period, diastolic blood pressure is maintained at approximately 90 mm Hg to ensure satisfactory renal perfusion. If hypertensive episodes occur, they are managed with intravenous infusion of sodium nitroprusside. Within the first 24 hours postoperatively, a technetium 99m renal scan is obtained to verify perfusion of the revascularized kidney. If clear evidence of perfusion is not present, arteriography should be done immediately to examine the repaired renal artery.

If the patient's condition is stable, the nasogastric tube, central venous line, arterial line, and urethral catheter are removed 48 hours postoperatively, and intensive care monitoring is discontinued. Most patients are discharged from the hospital 1 week postoperatively. Subsequent follow-up is performed by periodic evaluation of blood pressure and serum creatinine level and technetium 99m renal scanning.

CLINICAL RESULTS

Experiences with alternative bypass techniques for renal revascularization at the Cleveland Clinic from January 1980 to December 1992 were analyzed (Fergany et al, 1995). A total of 175 revascularization operations were performed in 171 patients. In all patients, alternative bypass techniques were employed because of severe abdominal aortic atherosclerosis or previous aortic surgery. The revascularization operations comprised hepatorenal bypass (n = 59), splenorenal bypass (n = 54), iliorenal bypass (n = 37), thoracic aortorenal bypass (n = 23), renal autotransplantation (n = 1), and superior mesenterorenal bypass (n = 1). Surgical renal revascularization was indicated for treatment of poorly controlled hypertension in 13 patients and ischemic nephropathy in 158 patients; all patients in the latter group had severe renal artery stenosis bilaterally or in a solitary kidney.

There were five patient deaths within the first postoperative month for an overall operative mortality rate of 2.9%. Postoperative thrombosis of the repaired renal artery occurred after 7 of 175 revascularization operations (4%). In the 13 patients with severe hypertension, the mean preoperative blood pressure was 176/101 mm Hg, and the mean postoperative blood pressure was 142/78 mm Hg. The mean preoperative and postoperative serum creatinine levels in this group were 1.2 mg/dL and 1 mg/dL, respectively.

In patients with ischemic nephropathy, postoperative renal function was improved in 41%, stable in 44%, and deteriorated in 15%. The best results were obtained in patients with a preoperative serum creatinine level of less than 2 mg/dL; 90% experienced postoperative improvement or stabilization of renal function. Although preservation of renal function was the predominant indication for intervention in the ischemic nephropathy group, all these patients also had hypertension that was controlled with medical therapy. Postoperatively, hypertension was cured in 14%, improved in 63%, and unchanged in 23%. The results of this study affirmed the efficacy of alternative bypass techniques for renal revascularization when the prerequisite conditions for their use were present.

From 1976 to 1991, extracorporeal microvascular reconstruction and autotransplantation were performed in 66 patients with complex branch renal artery disease at the Cleveland Clinic (Novick, 1996a, 1996b). This series included 50 female patients and 16 male patients ranging in age from 4 to

62 years. Renovascular disease was caused by fibrous dysplasia in 42 patients, arterial aneurysm in 13 patients, atherosclerosis in 7 patients, primary dissection in 2 patients, arteriovenous fistula in 1 patient, and arteritis in 1 patient. Eighteen patients presented with branch disease in a solitary kidney, 27 patients had bilateral renovascular disease, and 21 patients had unilateral branch disease with a normal contralateral kidney. Renal revascularization was indicated for treatment of renovascular hypertension in 58 patients, for prevention of rupture of an arterial aneurysm in 7 patients, and for treatment of an asymptomatic arteriovenous fistula in 1 patient.

In the 66 patients who underwent extracorporeal branch reconstruction and autotransplantation (including one bilateral autotransplantation), a total of 187 diseased renal artery branches were repaired (mean, 2.8 branches per operation). The period of cold renal ischemia needed for extracorporeal microvascular repair to be performed ranged from 1 to 3.5 hours. All patients were studied postoperatively with isotope renography and, in many cases, with arteriography as well. Postoperative follow-up in these cases ranged from 1 to 15 years. In 64 patients, branch arterial reconstruction was technically successful, whereas 2 patients suffered postoperative occlusion of the repaired renal artery. Fortunately, in both of these patients, a normal contralateral kidney was present. Currently, all 66 patients are normotensive, including 11 patients who continue to require low-dose antihypertensive medication. The current level of renal function is stable or improved in all patients. These results attest to the efficacy of extracorporeal microvascular reconstruction in enabling revascularization with preservation of renal parenchyma to be achieved in patients with complex branch arterial lesions.

COMPLICATIONS

Operative Mortality

Most patients with nonatherosclerotic lesions, such as fibrous dysplasia or aneurysm, are young and otherwise healthy. Therefore, the risk of operative death in this group is minimal. However, several studies during the 1970s indicated significant operative mortality rates of 6% to 10% in patients with atherosclerotic renal artery disease. These patients compose an older group and often have associated coronary, cerebrovascular, or peripheral vascular disease. In the National Cooperative Study, coronary artery disease was the leading cause of operative mortality after surgical treatment for atherosclerotic renal artery disease (Franklin et al, 1975). Other significant risk factors included magnitude of the operation performed and presence of extracranial cerebrovascular disease.

Several policies have been adopted to reduce operative mortality after surgical revascularization in patients with atherosclerotic renal artery disease. These include preliminary screening and correction of existing coronary or cerebrovascular occlusive disease, avoidance of bilateral simultaneous renal operations, and reliance on methods of revascularization that avoid operation on a severely diseased aorta. The impact of these policies at the Cleveland Clinic was evaluated in a review of surgical revascularization for renal artery disease in 361 patients from 1975 to 1984 (Novick et al, 1987). The cause of renal artery disease was atherosclerosis in 241 patients and fibrous dysplasia or an arterial aneurysm in 120 patients. The operative mortality rate was 21% and 0% in the former and latter groups, respectively. These data indicate that when appropriate measures are taken, the risk of operative mortality after renal revascularization is small even in older patients with generalized atherosclerosis.

Hypertension

Patients undergoing renal revascularization often experience hypertension postoperatively, even with technically satisfactory vascular repair. This hypertension may be due to hypervolemia, vasoconstriction from total body hypothermia, poorly controlled incisional pain, or renal ischemia sustained intraoperatively. Such blood pressure elevation may be severe immediately after surgery and, if not properly controlled, can promote hemorrhage from fresh vascular anastomoses. Therefore, these patients are initially placed in an intensive care unit for monitoring of the central venous pressure, blood pressure, urine output, pulse rate, and serum levels of hemoglobin and creatinine. During this time, diastolic blood pressure is maintained at 90 to 100 mm Hg to ensure satisfactory renal perfusion. I prefer to manage postoperative hypertension with continuous intravenous infusion of sodium nitroprusside for the first 24 to 36 hours. At this time, if hypertension persists, maintenance therapy with oral agents is initiated, and the nitroprusside infusion is gradually discontinued.

Approximately 50% of patients who are ultimately cured of hypertension by renal revascularization experience blood pressure elevation for a time postoperatively. In fact, it is not uncommon for such hypertension to persist for several weeks after surgery before gradually resolving. Of course, when this occurs, patency of the reconstructed renal artery must be confirmed with isotope renography or angiography.

Hemorrhage

Early hemorrhage after renal revascularization is generally a consequence of poor surgical technique. Bleeding from a vascular anastomotic site can occur if it is under tension, if one or both of the anastomosed vessels are diseased, or if the vascular sutures have not been placed sufficiently close together. Eversion of intima through the anastomosis may also predispose to hemorrhage and should be avoided.

Early hemorrhage may also be due to poor surgical hemostasis. This complication is most likely to occur because of unsecured collateral vessels in the renal hilum; because of damage to the left adrenal gland, which is often closely apposed to the left renal artery; or because of inadequately secured lumbar arteries that have been divided during aortic mobilization. When a saphenous vein bypass graft has been used, bleeding can occur from avulsion of a ligature applied to one of the branches of the vein graft; this can be avoided by suture ligation of all such branches.

Factors that predispose to early postoperative hemorrhage include incomplete reversal of systemic heparinization, episode of hypertension, or unrecognized coagulopathy. Mild bleeding that ceases spontaneously in an asymptomatic patient does not require reoperation. Such small hematomas

generally undergo complete reabsorption without sequelae, although extrinsic cicatricial stenosis of the repaired renal artery may occasionally result. With severe or uncontrolled bleeding, immediate reoperation is indicated to evacuate the accumulated blood and secure hemostasis.

In unusual cases, late hemorrhage can occur weeks, months, or even years after renal revascularization. This may be due to infection involving the vascular suture line (Nerstrom and Engell, 1972; Szilagy et al, 1971), rupture of a noninfected false aneurysm at the anastomotic site into the retroperitoneum or gastrointestinal tract (Moore and Hall, 1970), or erosion of a prosthetic bypass graft into the duodenum (Cerny et al, 1972). All present as sudden catastrophic hemorrhage that requires immediate operation. Prosthetic graft erosion can be avoided at the original operation by interposition of peritoneum or omentum between such grafts and the duodenum or by placement of the graft retrocaval on the right side. It is also appropriate to state that prosthetic renal artery bypass grafts should be used only when an autogenous vascular graft is not available.

Renal Artery Thrombosis

Thrombosis of the repaired renal artery is an uncommon complication that occurs in less than 5% of patients undergoing revascularization, generally within the first few days of surgery. Postoperative hypotension, a hypercoagulable state, and hypovolemia are factors that predispose to this problem. Significant intrarenal arteriolar nephrosclerosis causes poor runoff, which can also lead to arterial thrombosis. Nevertheless, arterial thrombosis is usually due to poor technical performance of revascularization, and in this regard, several points deserve emphasis.

All the vessels used for anastomosis should be free of disease that may cause subsequent occlusion. Complete excision of all renal artery disease is necessary. On occasion, a local aortic endarterectomy is performed when an aortorenal bypass is done. All vascular anastomoses must be done precisely to avoid intraluminal intrusion of adventitia and trauma to the intima. Intimal trauma may result from improperly applied surgical forceps or vascular clamps and is known to promote intraluminal platelet aggregation, fibrin deposition, and development of a thrombus. When an endarterectomy is done, the resulting traumatized arterial surface can also predispose to thrombus formation.

If an intimal flap is present in the distal renal artery at revascularization, it must be tacked down with interrupted sutures to avoid intramural dissection and occlusion after restoration of blood flow. End-to-end anastomosis of vessels that are more than 50% disparate in diameter should also be avoided. This invariably leads to bunching of the smaller vessel and unfavorable hemodynamics that can lead eventually to thrombus formation and vascular occlusion.

When a renal artery bypass procedure is performed, the bypass graft must be properly placed to avoid angulation, kinking, or malrotation with the renal artery. Figures 50–90 and 50–91 illustrate the most common errors in the positioning of an aortorenal bypass graft that can lead to thrombosis or stenosis. These same considerations apply to all renal revascularization operations, especially extracorporeal branch repairs. In these repairs, multiple renal arterial branch anastomoses are commonly done, and it is important to anticipate the position that the various branches will assume in relation to one another on completion of the repair and after autotransplantation.

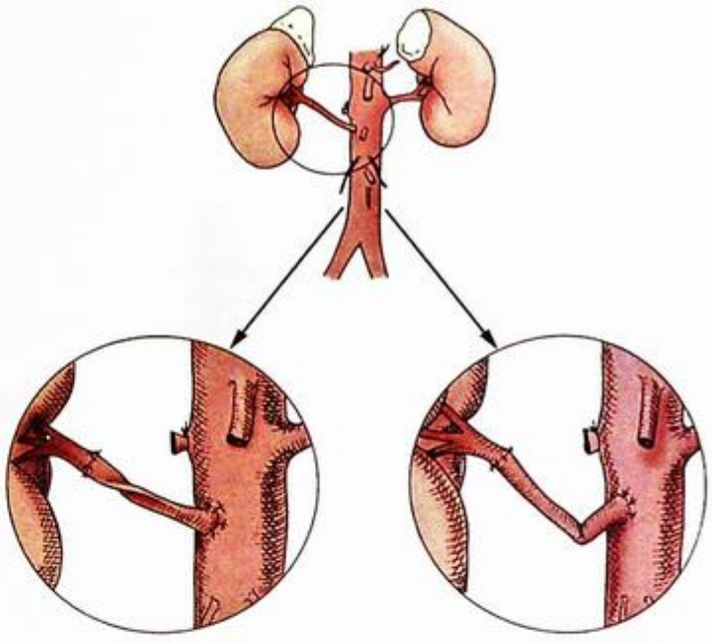

Figure 50–90. Improper placement of an aortorenal bypass graft with longitudinal torsion *(left)* or angulation *(right)* that can lead to postoperative thrombosis or stenosis.

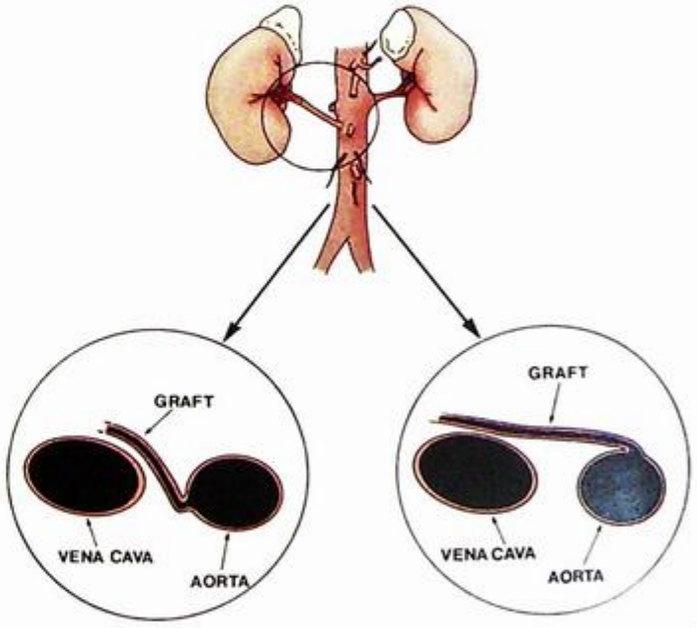

Figure 50–91. In performing aortorenal bypass, it is important for the graft to be brought off the anterolateral aspect of the aorta. If the graft originates too far posteriorly *(left)* or anteriorly *(right)*, it can predispose to postoperative thrombosis or stenosis at the origin of the graft.

Embolization of an atheroma from a traumatized aorta into the kidney and external compression of the repaired artery by retroperitoneal fluid collection are additional causes of postoperative thrombosis. Finally, although thrombosis is typically an early event, occlusion of an aortorenal bypass graft can occur months or years later from progressive aortic atherosclerosis at the origin of the graft.

The diagnosis of renal artery thrombosis must be established almost immediately for salvage of the kidney to be possible. In some cases, subtotally occlusive thrombus and extensive collateral renal arterial supply allow additional time for successful intervention to be undertaken. The most helpful clinical clues to postoperative thrombosis are persistent or sudden hypertension and elevated serum creatinine level. However, both of these findings may initially be present with a patent vascular repair. Therefore, a radiographic renal imaging study should be routinely done within the first 24 hours of surgery; in this regard, I have found isotope renography with technetium to be an excellent noninvasive method. Because I always perform direct end-to-end anastomosis of the bypass graft to the distal renal artery, renal uptake of isotope ensures patency of the vascular repair. This study is less reliable if an end-to-side anastomosis of the bypass graft to the distal renal artery has been done. If isotope renographic findings are equivocal or clinical suspicion for arterial thrombosis remains high, angiography should be done immediately.

The traditional treatment of postoperative renal arterial thrombosis has been emergency surgical re-exploration with thrombectomy or graft revision if the kidney is found to be viable. More commonly, the kidney is no longer viable, and a nephrectomy is done. Percutaneous low-dose intra-arterial infusion of streptokinase may be undertaken as an alternative to surgery (Berni et al, 1983; Cronan and Dorfman, 1983; Dardik et al, 1984). Although successful clot lysis has been reported with this technique, there also appears to be an increased risk of bleeding from hypofibrinogenemia. Percutaneous transcatheter thrombectomy has also been described as treatment of acute renal artery thrombosis or embolism; however, this technique cannot be safely done in the presence of a fresh vascular anastomosis (Millan et al, 1978). Systemic anticoagulation with heparin is not effective as primary therapy for postoperative arterial thrombosis but is a useful adjunctive measure after surgical thrombectomy or intra-arterial streptokinase infusion.

Renal Artery Stenosis

The incidence of stenosis of a surgically reconstructed renal artery is less than 10% with current techniques, and this complication typically occurs weeks, months, or even years after revascularization. Many of the causes are similar to those outlined for postoperative thrombosis, such as faulty suture technique, intimal trauma, incomplete excision of primary vascular disease, wide disparity in vessel size, dissection of a distal intimal flap constructed at surgery, and torsion, angulation, or kinking of the vessels. When an end-to-end vascular anastomosis is performed, the likelihood of subsequent stenosis can be minimized by spatulating the ends of the two vessels to fashion a suture line that is wider than the normal circumference of the renal artery. Tension on the vascular suture line can also cause narrowing in this area and should be avoided. Finally, during procurement of a saphenous vein graft, care should be taken not to overdistend the vein or injudiciously dissect periadventitial tissue, both of which may cause devascularization of the graft that leads to subsequent stenosis.

Other causes of late postoperative renal artery stenosis include diffuse subendothelial fibroplastic proliferation in saphenous vein grafts, neointimal proliferation at the suture line of synthetic grafts, recurrent primary vascular disease, and obstruction from a valve in a segment of saphenous vein (Dean et al, 1974). With the last cause, grafts should always be reversed so that blood flow is directed toward the cephalic end, which allows venous valves to assume a neutral position. However, even when this is done, such valves may undergo fibrotic contracture to produce a weblike stenosis of the vein graft. This occurrence, although rare, suggests that a valveless segment of vein should be used, if possible.

All patients undergoing renal revascularization should be followed up at yearly intervals with blood pressure measurements, determination of renal function, and isotope renography with technetium. Postoperative renal artery stenosis that is more than 70% occlusive is invariably accompanied by an elevation in blood pressure and, not uncommonly, evidence of deteriorating renal function. When either of these conditions is present, or if there is isotope renographic evidence of diminished renal perfusion, angiography should be done. Recurrent arterial stenosis is most often located at a vascular suture line but may present anywhere along the course of the reconstruction renal arterial supply. The therapeutic options are surgical reoperation and PTA-stenting. Because secondary revascularization in such cases is difficult and may lead to nephrectomy, PTA-stenting is a reasonable initial approach to therapy if it is technically feasible.

Renal Artery Aneurysm

Long-term angiographic studies of patients who underwent aortorenal saphenous vein bypass revealed graft dilation in 25% to 52% of patients and frank aneurysm formation in 5% to 8% of patients (Stanley et al, 1973; Dean et al, 1974). These findings have been observed more often in children than in adults. The clinical significance of these abnormal-appearing vein grafts remains uncertain because most of these patients continue to be normotensive with excellent renal function. In some cases, graft dilation has been associated with a distal anastomotic stenosis, suggesting this as a possible inciting factor (Fig. 50–92). However, in other cases, similar dilation has been found with no evidence of stenosis (Fig. 50–93). This problem has only rarely been encountered with autogenous arterial grafts. It may be possible to prevent saphenous vein graft dilation by more careful procurement and storage of the graft in chilled heparinized lactated Ringer irrigation or autologous blood to prevent transmural ischemia. When severe aneurysmal dilation is present, or if graft expansion is associated with recurrent hypertension, reoperation and attempted secondary revascularization are indicated.

Postoperative aneurysm formation has also been associated with use of the spermatic or ovarian veins for renal artery bypass surgery. These veins are extremely friable, cannot withstand the stress of arterial pressure, and undergo severe dilation or frank rupture. Therefore, their use as bypass grafts in arterial reconstruction is absolutely contraindicated.

After renal revascularization, a false aneurysm may develop at a vascular anastomotic site months or years later. Mycotic false aneurysms are caused by deep wound infection involving the vascular suture line (Nerstrom and Engell, 1972). Contrary to a widely held impression, there is no increased risk of infection with vascular silk sutures when they are used for

Figure 50–92. Right renal arteriogram after aortorenal saphenous vein bypass demonstrates dilation of the graft with distal anastomotic stenosis.

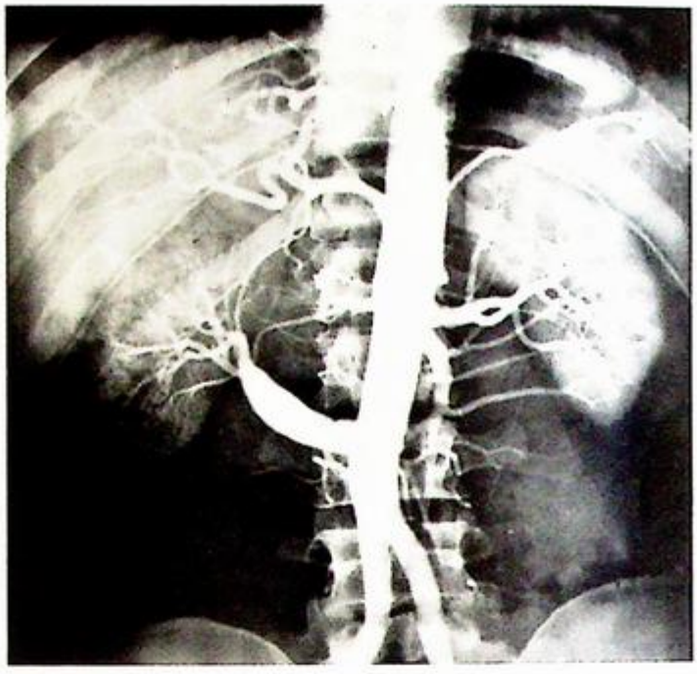

Figure 50–93. Abdominal aortogram after right aortorenal saphenous vein bypass demonstrates aneurysmal dilation of the bypass graft with no evidence of stenosis.

anastomosis of autogenous vessels. Noninfected false aneurysms have most often been associated with synthetic bypass grafts because anastomoses of native vessels with these grafts never acquire significant strength other than that determined by the suture line (Moore and Hall, 1970). For this reason, synthetic graft anastomoses should always be done with a nonresorbable suture, such as polypropylene, rather than with silk, which loses its tensile strength over time. Infected or uninfected false anastomotic aneurysms can rupture spontaneously and should be repaired as soon as the diagnosis is established.

Aortic Complications

During an aortorenal bypass operation, clamping and unclamping of the abdominal aorta is performed. When the aorta is involved with atherosclerosis, this maneuver can cause dislodgment of plaque, resulting in aortic thrombosis or distal embolization. This occurrence can be minimized by selecting the healthiest portion of the abdominal aorta for use in such operations. Intraoperative systemic heparinization also helps prevent this problem. Ultimately, the most effective prevention is to avoid operation on the extensively diseased aorta by use of alternative techniques, such as hepatorenal or splenorenal bypass.

Whenever aortic surgery is undertaken, the peripheral pulses and lower extremities should always be examined before and immediately after revascularization. If there is evidence of compromised peripheral circulation postoperatively, emergency transbrachial abdominal aortography should be done. Immediate surgical thromboembolectomy is indicated to relieve aortic or major peripheral vascular occlusion. Minor discoloration of the toes from cholesterol microemboli can be observed easily when good peripheral pulses are present. This problem generally resolves spontaneously, and digital amputation is rarely necessary.

Clamping and unclamping of the aorta may also produce an intraluminal aortic dissection, especially if a local endarterectomy has been done. This can be prevented by suturing down distal flaps of intima within the aorta when the lumen is exposed. This type of aortic dissection can cause peripheral ischemia or may be entirely asymptomatic, in which case simple observation is sufficient.

Visceral Complications

Visceral–renal arterial bypass operations are indicated in patients with severe aortic disease and may be associated with specific complications. When splenorenal bypass is done, splenic viability is maintained by collateral vascular supply from the short gastric and gastroepiploic arteries. Nevertheless, a retractor-induced splenic laceration may be sustained during mobilization of the splenic artery, which necessitates performance of an incidental splenectomy. In an initial series of splenorenal bypasses, this complication occurred in 5 of 32 cases (16%) (Novick et al, 1977a, 1977b). During mobilization of the splenic artery, the splenic vein, which is thin walled and directly adjacent to the artery, may be inadvertently damaged. Lacerations of the splenic vein are repaired with interrupted 5-0 vascular sutures. Injury to the pancreas, with resulting pancreatitis or pseudocyst formation, is a potential complication of splenorenal bypass that I have not yet encountered.

In hepatorenal bypass, the common hepatic artery and its major branches can be mobilized readily without damage to the portal vein or common bile duct. Hepatorenal bypass is

usually done by end-to-side anastomosis of a saphenous vein graft to the common hepatic artery, which allows preservation of distal hepatic arterial flow (Chibaro et al, 1984). However, in some cases, a direct end-to-end anastomosis of the hepatic and right renal arteries is done, which produces complete hepatic dearterialization (Novick and McElroy, 1985). This is well tolerated by the liver because of the increased extraction of oxygen from portal venous blood and the fairly rapid development of collateral hepatic arterial flow. Thus, although transient abnormalities in liver function parameters may occur, permanent hepatic damage has not yet been observed. However, the gallbladder is more susceptible to ischemic damage and may undergo postoperative necrosis when its blood supply from the right hepatic artery is interrupted. This problem can be avoided by an adjunctive cholecystectomy in patients whose blood flow through the common hepatic artery is totally diverted to the kidney.

A bypass from the SMA to the kidney is occasionally an option in patients with severe aortic atherosclerosis (Khauli et al, 1985a, 1985b). Because the SMA is the only source of blood supply to a large portion of the bowel, this operation may produce postoperative intestinal ischemia. Such ischemia can be avoided by limiting this approach to patients with infrarenal aortic occlusion, in whom a significantly enlarged SMA is invariably present.

Acute Renal Failure

Acute renal failure induced by ischemia is a potential complication of surgical revascularization that, fortunately, can be prevented in most cases. Because all revascularization operations require temporary occlusion of the renal artery, it is important to understand renal responses to warm ischemia. If the period of arterial occlusion exceeds that which may be safely tolerated, specific renal preservation measures are indicated.

In general, 30 minutes is the maximum period of arterial occlusion that the kidney can withstand before permanent damage is sustained (Novick, 1983). In some clinical situations, this time may not apply, and a longer period of ischemia may be safely tolerated. It is acknowledged that the solitary kidney is more resistant to ischemic damage than the paired kidney, although precise limits have not been defined. I reviewed the outcome of renal revascularization in 43 patients with a solitary kidney in whom warm ischemic intervals ranged from 14 to 59 minutes and in whom no specific renal protective measures were employed. In this series, there were no cases of acute renal failure postoperatively, which indicated in many of these patients the ability of the solitary kidney to safely withstand periods of warm ischemia longer than 30 minutes (Askari et al, 1982). Another situation that may enhance renal tolerance to temporary arterial occlusion is the presence of an extensive collateral vascular supply, which is often observed in patients with renal arterial occlusive disease.

When postoperative acute renal failure occurs, it is generally manifested by a fall in urine output and a rise in serum creatinine level. Alternatively, nonoliguric renal insufficiency may be observed. The cornerstone of therapy for such acute renal failure is judicious fluid management to ensure normal extracellular volume and sodium content. In older patients, central venous pressure is not reliable for monitoring fluid replacement, and pulmonary artery wedge pressure provides a more accurate measurement of left ventricular filling pressure. This information allows precise control of the volume and rate of fluid infusion so that maximum cardiac output can be achieved without inducing left ventricular decompensation. The role of diuretic and vasoactive drug therapy for improving renal perfusion after ischemic injury is controversial. Furosemide administration appears to be of value because it is known to increase renal blood flow by stimulating the release of intrarenal alprostadil, a potent dilator of the afferent renal arterioles (Patak et al, 1975).

MISCELLANEOUS RENAL OPERATIONS

Open Renal Biopsy

Open renal biopsy may be necessary to establish a tissue diagnosis in patients with renal disease, to assess the severity of such disease, or to evaluate the potential for salvable renal function in patients with a known correctable disorder who are candidates for a reconstructive operation. Open biopsy is usually preferred to the percutaneous technique in patients with a solitary kidney, coagulopathy, atypical anatomy, or other factors that may increase the risk of a closed biopsy. An open biopsy also provides more tissue for study and minimizes the potential for complications such as arteriovenous fistula, perirenal hematoma, and gross hematuria.

An open renal biopsy may be performed through an extraperitoneal flank or posterior incision. General anesthesia is preferable; however, in a thin, cooperative patient, local anesthesia may be employed. Biopsy of the right kidney is usually done because of its more caudal location.

After the surgical incision is made, Gerota's fascia is opened and the lower pole of the kidney is exposed. An elliptical incision is made in the renal capsule, which is usually 1 to 2 cm long and 0.5 to 1 cm wide (Fig. 50–94*A*). The incision is deepened on either side with a scalpel and beveled so that the final wedge depth includes an adequate segment of cortical tissue, usually 5 to 8 mm deep. Fine Metzenbaum scissors are used to complete the transection of cortex at the bottom of the wedge, and the tissue is gently lifted out with the slightly spread scissor blades rather than a forceps, which might crush the specimen (Fig. 50–94*B*). Suction is avoided during this final maneuver to prevent loss of tissue into the suction tip. This technique of elliptical wedge biopsy is preferred to open needle biopsy because bleeding is more readily controlled and more renal tissue is obtained. The renal incision is closed with absorbable 2-0 or 3-0 sutures placed across the defect and gently tied over Oxycel (Fig. 50–94*C*).

Surgery for Simple Renal Cysts

Simple renal cysts usually present as mass lesions and are often detected during renal imaging studies performed for unrelated reasons. A small number of patients require exploration to distinguish between a cyst and an atypical tumor mass. Large renal cysts causing obstruction may also occasionally require open surgical drainage with unroofing (Stanisic et al, 1977).

The preferred surgical approach for drainage of a renal cyst is through an extraperitoneal posterior, flank, or anterior

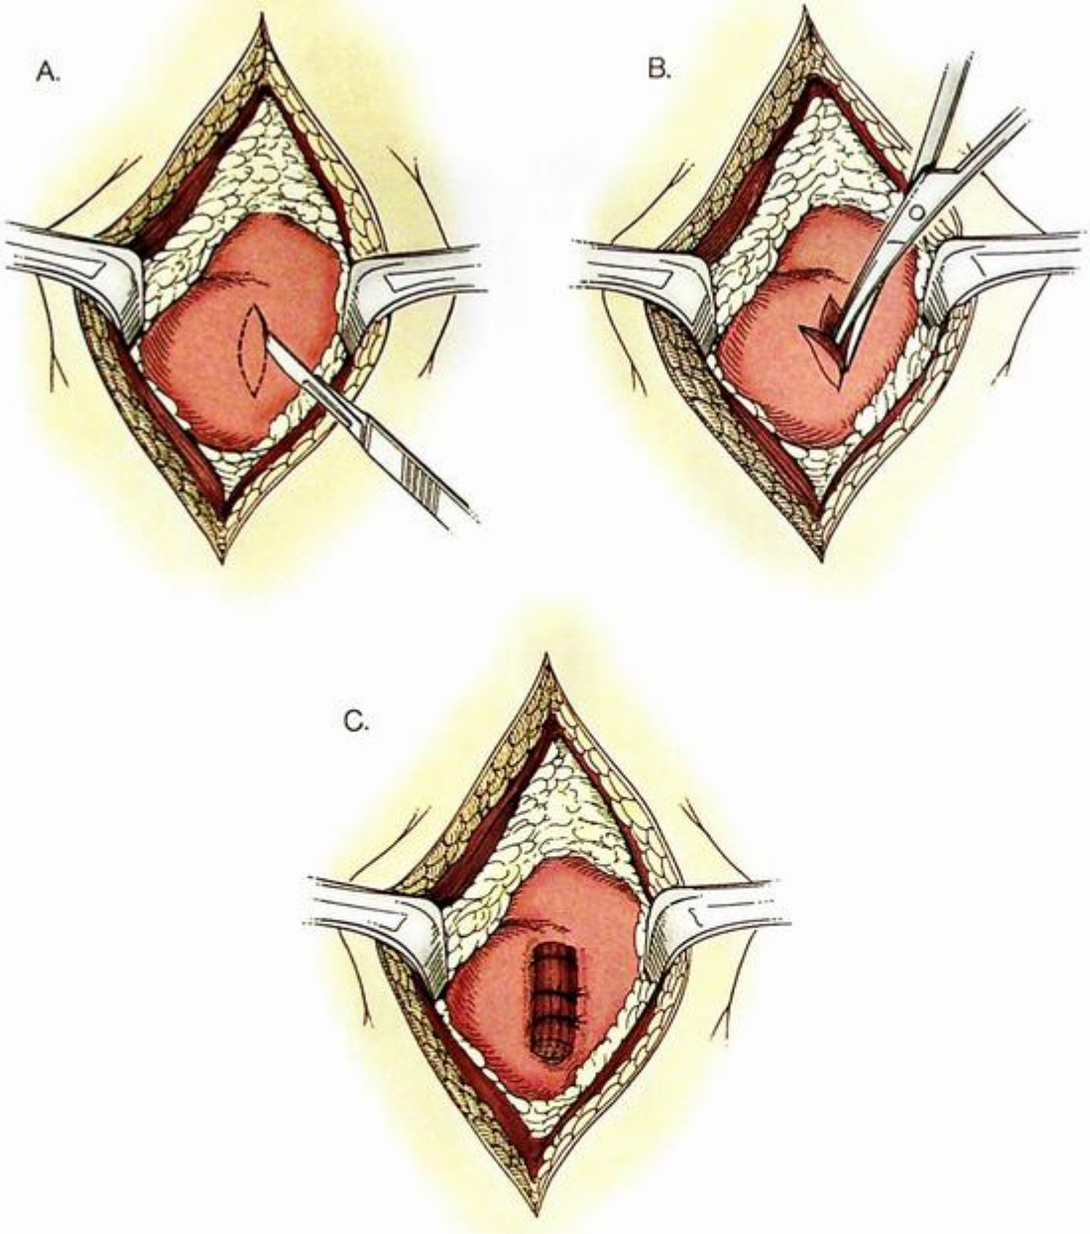

Figure 50–94. Technique of open renal biopsy.

incision, according to the number and location of lesions. Gerota's fascia is opened, and the cystic lesion is exposed by dissection of perirenal fat from the cyst and adjacent parenchyma (Fig. 50–95*A*). The surrounding area is packed off, and cyst fluid is aspirated for diagnostic study. The cyst wall is then entered sharply and resected near its junction with normal parenchyma (Fig. 50–95*B*). The base of the cyst cavity is inspected, and biopsy of any suspicious areas is performed with immediate frozen-section examination. After unroofing, the perimeter of the cyst wall is oversewn with an absorbable 3-0 or 4-0 continuous suture to achieve hemostasis (Fig. 50–95*C*). Alternatively, the edge of the cyst wall may be cauterized and persistent bleeders controlled with interrupted figure-of-eight absorbable sutures. Drainage is not required unless the cyst is infected.

Open Nephrostomy Insertion

Nephrostomy tube drainage is usually achieved by the percutaneous approach, but an open operation is occasionally necessary because of difficult anatomy or a minimally dilated upper urinary tract. Open nephrostomy insertion may also be performed intraoperatively during reconstructive procedures such as pyeloplasty and ureterocalicostomy.

Primary nephrostomy insertion is usually performed through an extraperitoneal flank incision. After the kidney is mobilized, the renal pelvis is exposed and opened. A Willscher nephrostomy tube, as illustrated in Figure 50–96, is particularly simple to place because of a built-in malleable stylet within a smoothly tapered sheath (Noble, 1989). The stylet of the catheter is passed through the pyelotomy and then used to

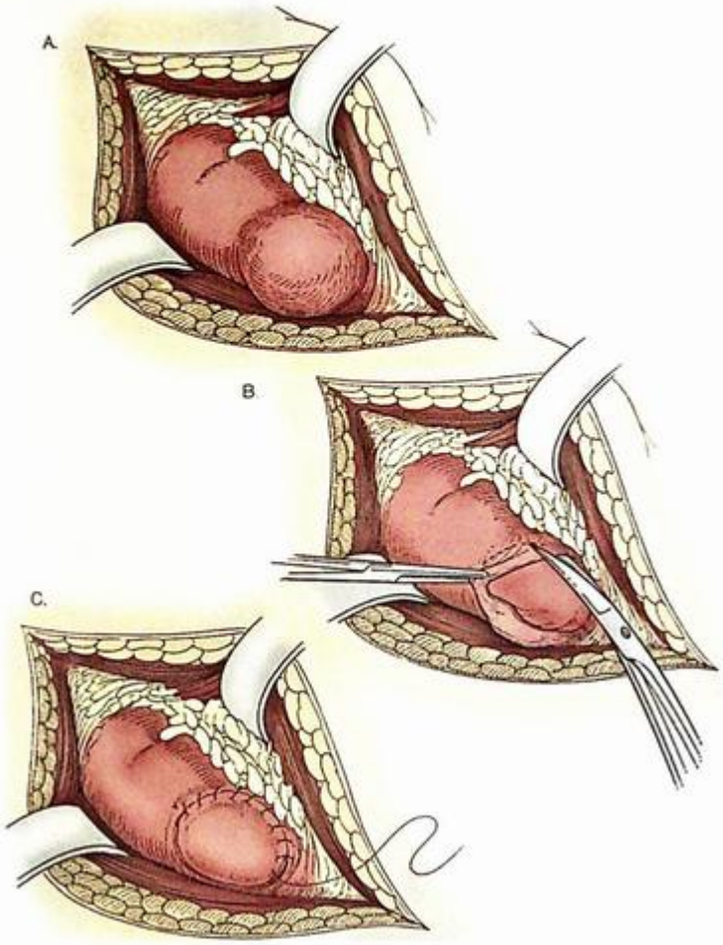

Figure 50–95. Technique of excision of renal cyst.

puncture the cortex from within a calyx (Fig. 50–96*A*). It is important to ensure that the nephrostomy is made near the convex border of the kidney and not in the anterior or posterior surface; this allows better positioning of the tube and minimizes the risk of injury to large intrarenal vessels. Usually, a 22 or 24 French catheter is used. The Willscher tube has a flared portion with wide openings followed by a long tip, which may be used as a splint through the ureteropelvic junction if necessary. The catheter is pulled through the cortex until the flared portion lies in good position within the collecting system, usually in the pelvic calyx or a dependent calyx (Fig. 50–96*B*). The nephrostomy tube is secured to the renal capsule with a 3-0 absorbable purse-string suture. The pyelotomy is closed with 3-0 or 4-0 absorbable suture. The stylet of the nephrostomy tube is passed through the flank muscles, subcutaneous tissue, and skin, with care taken to ensure proper alignment of the tube as it passes from the kidney to the exterior. Heavy 2-0 skin sutures are inserted to secure the tube near the flank wall exit point to prevent inadvertent dislodgment. A Penrose drain is placed near the pyelotomy site and brought out through a separate stab wound in the flank.

Ongoing care of a nephrostomy tube is important to prevent infection and to ensure unobstructed drainage. Periodic urine culture specimens are obtained, and significant intercurrent urinary infection is appropriately treated. If the tube is dislodged within 7 to 10 days of its insertion, it may not be possible to replace it through the track, and a secondary procedure may be necessary. Even with the best of care, encrustations form around the tube and require periodic tube replacement at 6- to 8-week intervals. This is usually readily performed under fluoroscopic guidance once a chronic track has been established.

Surgery for Polycystic Kidney Disease

Bilateral nephrectomy may be necessary in selected patients with end-stage renal failure from polycystic kidney disease who are candidates for renal transplantation. Indications for bilateral nephrectomy in this setting include a history of significant bleeding or renal infection and massively enlarged kidneys that may interfere with placement of an allograft in the pelvis. This operation is best performed through an anterior bilateral subcostal or midline transperitoneal incision.

Unilateral nephrectomy is occasionally required before end-stage renal failure develops or when the polycystic kidney is a site of complications such as infection, severe pain due to bleeding or obstruction, or development of a tumor. Cyst puncture and unroofing of cysts may be helpful when they obstruct the collecting system or cause flank pain (Lue et al, 1966). **Multiple cyst punctures and unroofing of cysts (Rovsing's operation) do not appear to improve renal function or to prevent further deterioration** (Milam et al, 1963). However, this approach can provide long-term pain relief in symptomatic patients (Elzinga et al, 1993).

Isthmusectomy for Horseshoe Kidney

Horseshoe kidney occurs in about 1 in 700 individuals and is frequently associated with other urologic anomalies. The isthmus that joins the kidneys usually lies anterior to the great vessels. Ureteral obstruction with hydronephrosis, stone formation, or infection is the most common problem with this condition and may require surgical treatment (Culp and Winterringer, 1955). In patients with ureteral or ureteropelvic junction obstruction, division of the isthmus alone is insufficient, and appropriate correction of the obstruction is required; in such cases, isthmusectomy may be a useful adjunctive measure to allow repositioning of the kidney and maintenance of an unobstructed upper urinary tract. Abdominal pain in the absence of any demonstrable renal symptoms is rarely due to polar fusion and is not an indication for isthmusectomy.

When surgery is performed on a horseshoe kidney, an anterior subcostal extraperitoneal approach is preferred. This provides good access to the isthmus as well as to the pelvis and ureter, which are rotated anteriorly. Horseshoe kidneys are generally supplied by multiple renal vessels that, in some cases, can enter the isthmus directly. The isthmus may be fibrous but often consists of parenchyma tissue. Isthmusectomy is performed by mobilizing the isthmus from the great vessels, being careful to avoid injury to any anomalous vessels, and placing mattress sutures of 0-0 chromic catgut through the parenchyma about 1 cm on either side of the line of section to control bleeding. The divided ends can be further oversewn with sutures passed through the capsule of the cut edges. Two or three sutures through the divided isthmus and into the fascia overlying the muscles of the posterior abdominal wall are used to fix the lower pole, which is rotated outward to

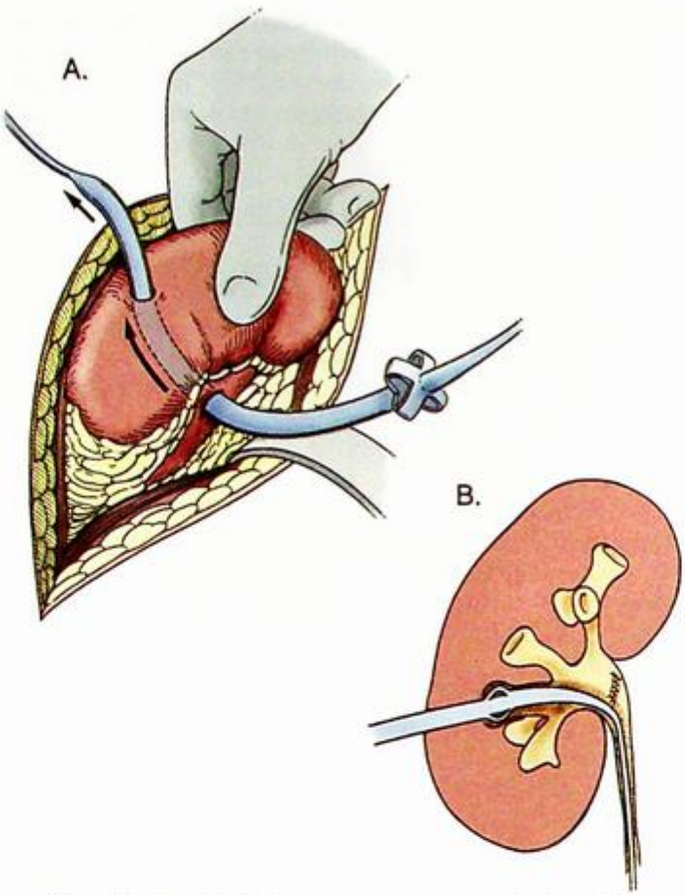

Figure 50–96. Technique of open nephrostomy tube insertion.

allow room for the ureter to lie on the posterior abdominal wall.

Local Excision of Renal Pelvic Tumor

In patients with localized transitional cell carcinoma of the renal pelvis, nephroureterectomy with a bladder cuff is the treatment of choice. A nephron-sparing operation may be indicated in selected patients with low-grade, noninvasive malignant disease present bilaterally or in a solitary kidney to avoid the need for dialytic renal replacement therapy. A variety of conservative surgical approaches are available in such cases, including open pyelotomy with tumor excision and fulguration, partial nephrectomy (Fig. 50–97), and endourologic techniques with or without adjunctive topical chemotherapy (Zincke and Neves, 1984; Huffman et al, 1985; Streem and Pontes, 1986; Smith et al, 1987; Ziegelbaum et al, 1987; Vasavada et al, 1995). The last two approaches are reviewed elsewhere.

Open pyelotomy and tumor excision may be employed in patients with noninvasive transitional cell carcinoma confined to a portion of the renal pelvis. On occasion, small lesions involving an infundibulum may be accessible by this approach. This operation is performed through an extraperitoneal flank incision after mobilization of the entire kidney within Gerota's fascia.

The upper ureter and renal pelvis are mobilized along the posterior renal aspect. Renal pelvic dissection is carried into the renal sinus, which often also exposes one or more infundibula. Small vein or Gil-Vernet retractors are used to maintain this operative exposure (Fig. 50–98*A*). The renal

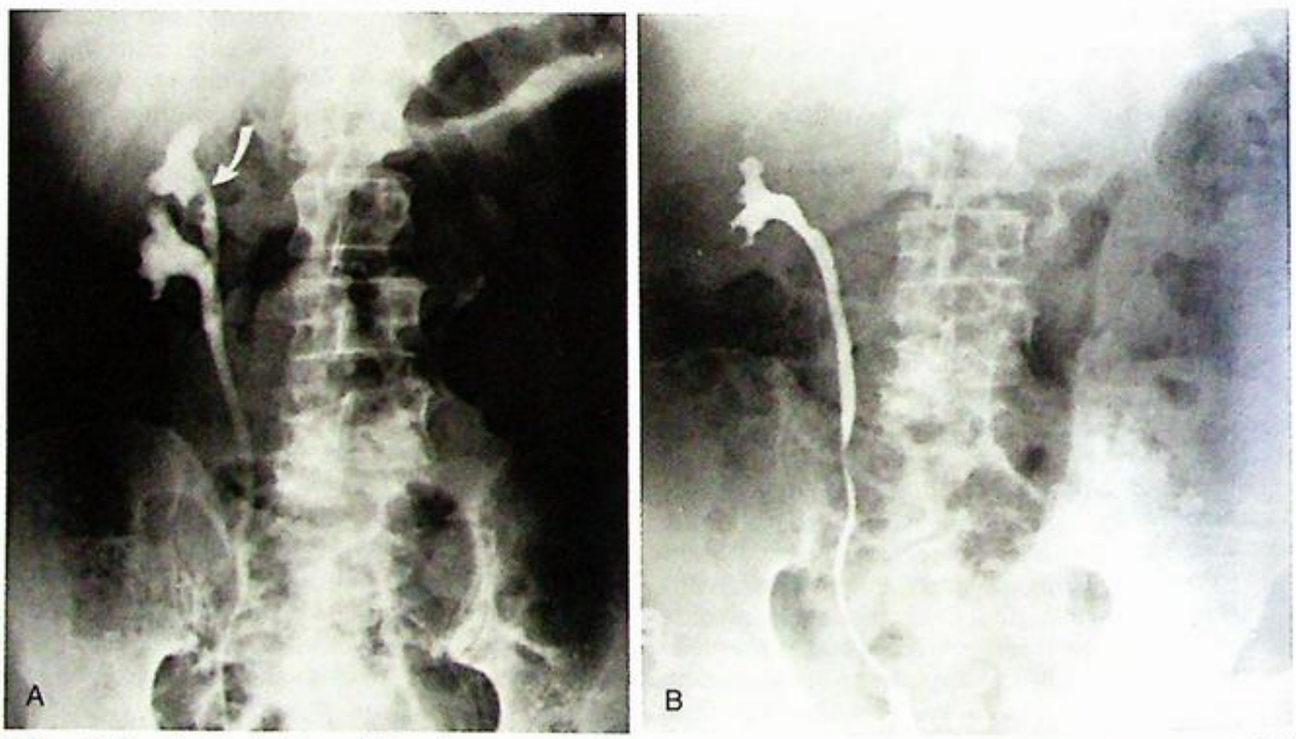

Figure 50–97. A, This patient had undergone left nephroureterectomy for transitional cell carcinoma of the left renal pelvis. Intravenous pyelography suggests a lesion in the upper infundibulum of the remaining right kidney *(arrow)*. This is confirmed at the time of retrograde pyelography. B, Upper pole partial nephrectomy is performed, leaving the pelvis and lower infundibulocalyceal system intact, as demonstrated on this postoperative retrograde pyelogram. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

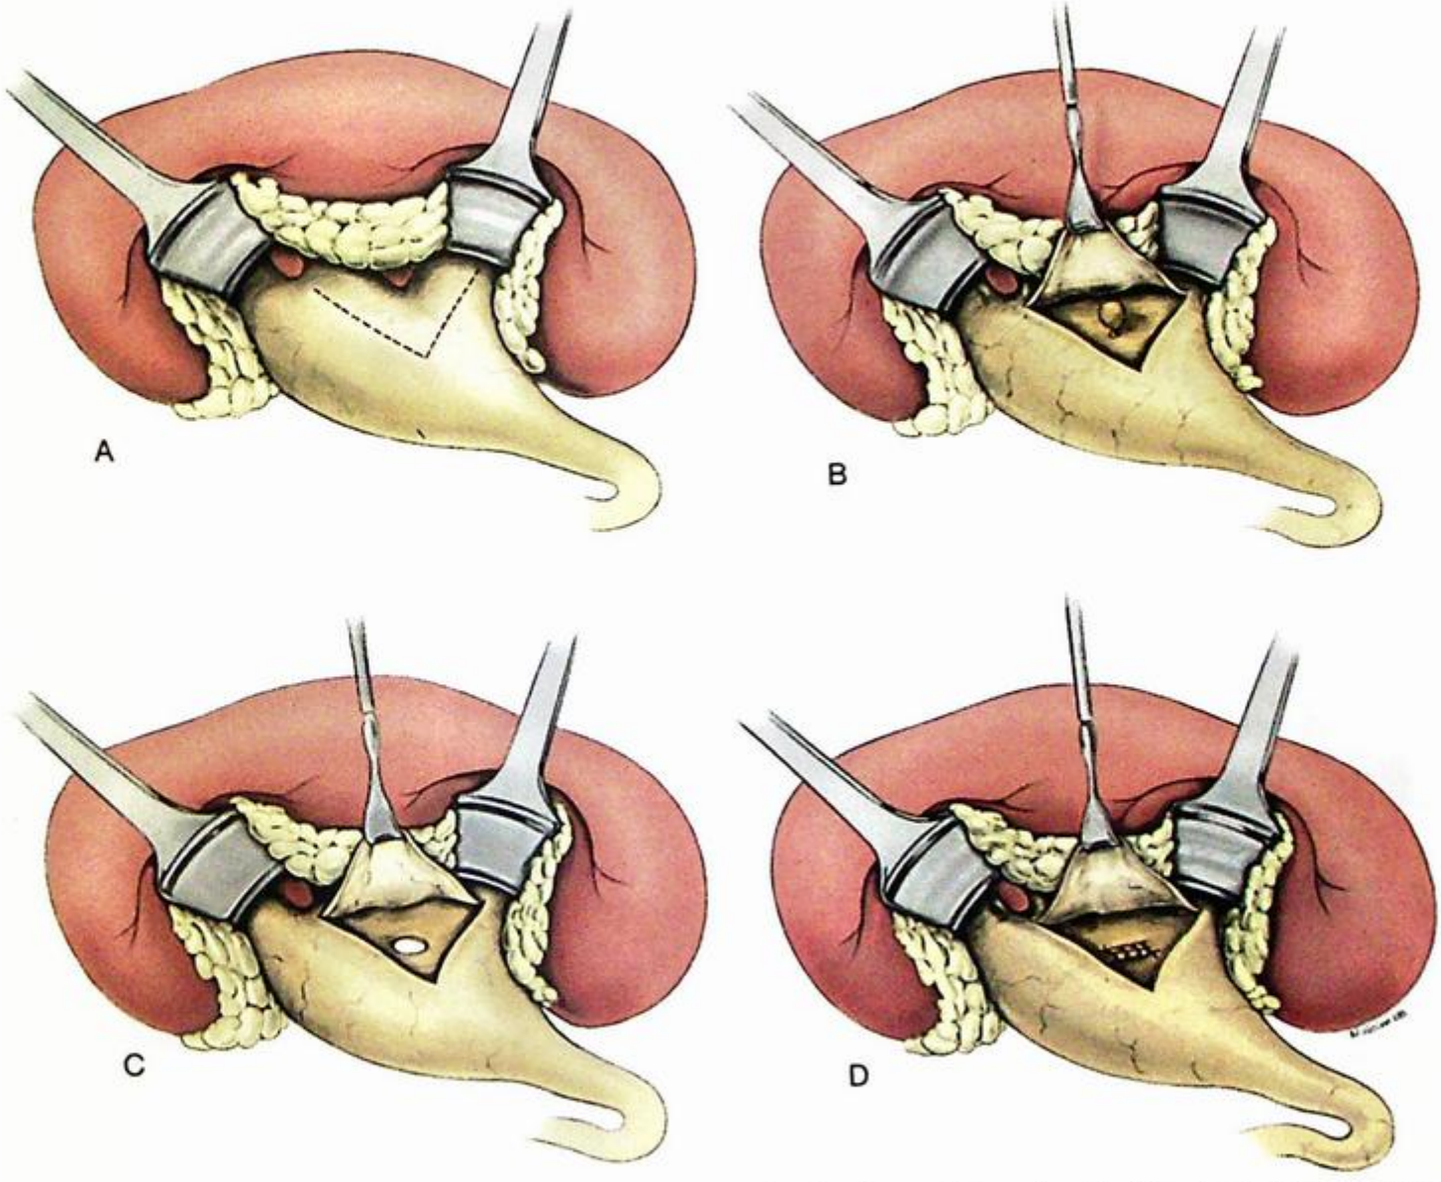

Figure 50–98. Technique of open pyelotomy and tumor excision for transitional cell carcinoma of the renal pelvis. (Reproduced with permission from Novick AC, Streem SB, Pontes E, eds: Stewart's Operative Urology, 2nd ed. Baltimore, Williams & Wilkins, 1989.)

pelvic incision is made to expose the tumor-bearing portion of the renal pelvis (Fig. 50–98*B*). This incision may be extended into an infundibulum if necessary. It is preferable to excise a full-thickness segment of the renal pelvis encompassing the tumor (Fig. 50–98*C*). Frozen sections are prepared to ensure that the resected margins are free of disease. An alternative approach is to sharply excise the tumor at its base while preserving the integrity of the renal pelvic wall and then to fulgurate the base and surrounding area extensively. After excision of all gross tumor, operative pyeloscopy is used to examine the intrarenal collecting system for any remaining lesions. The site of renal pelvic tumor excision is repaired with 4-0 chromic suture (Fig. 50–98*D*), and the pyelotomy incision is then similarly closed. A Penrose drain is placed near the pyelotomy and brought out through a separate stab wound in the flank.

KEY POINTS: SURGERY OF THE KIDNEY

- During reconstructive renal surgery, when renal vascular occlusion is employed for a period of more than 30 minutes, adjunctive surface renal hypothermia is needed to prevent permanent ischemic renal damage.
- Radical nephrectomy with removal of a perirenal or infrahepatic IVC thrombus is best performed through a bilateral subcostal transperitoneal incision.
- Radical nephrectomy with removal of an atrial thrombus is best performed with adjunctive cardiopulmonary bypass and deep hypothermic circulatory arrest.
- Techniques for partial nephrectomy require adherence to basic principles of early vascular control, avoidance of ischemic renal damage, complete tumor excision with free margins, precise closure of the collecting system, careful hemostasis, and closure or coverage of the renal defect.
- The two primary kidney-threatening complications of partial nephrectomy are hemorrhage and ischemic renal failure.
- Patients with atherosclerotic renal artery disease who are considered for surgical revascularization should undergo screening and correction of significant associated extrarenal vascular disease, such as coronary and carotid disease.
- In older patients with renal artery disease, involvement of the abdominal aorta with severe atherosclerosis or aneurysmal disease may render an aortorenal bypass technically difficult and hazardous to perform. In such cases, alternative extra-anatomic bypass techniques, such as hepatorenal or splenorenal bypass, are preferable.
- Extracorporeal revascularization and autotransplantation are indicated for intrarenal branch arterial lesions due to fibrous dysplasia or aneurysmal disease.

SUMMARY

HISTORICAL OVERVIEW

The current practice of laparoscopic renal surgery evolved slowly over a period of almost 200 years. In 1804, Bozzini developed the first reproducible device to illuminate dark cavities previously unseen in the living body. Seventy years later, Nitze and Leiter laid the foundation for the modern urologic endoscope. In parallel, surgeons began toying with the idea of filling the abdominal cavity with air to create a diagnostic space. These technologies fused in 1901 when Jacobius used room air to fill the abdomen of 15 patients and then inserted a laparoscope to assist with the diagnosis of ascites. Progress from a simple diagnostic modality to therapeutic intervention finally occurred in 1983, when Semm removed an appendix laparoscopically (Clayman, 2004).

Only recently has laparoscopy become a practical and acceptable alternative to treat complex urologic surgical diseases. William Schuessler conceived the first urologic laparoscopic procedure: the pelvic lymphadenectomy for patients with prostate cancer (Griffith et al, 1990). Shortly thereafter, in 1990, Clayman and coworkers at Washington University developed a solution to laparoscopic solid organ removal by performing the first laparoscopic nephrectomy. During an operation that lasted more than 7 hours, an elderly patient with a 3-cm solid renal mass underwent laparoscopic radical nephrectomy through five trocar sites. Inside the abdomen, the kidney was placed in an impermeable bag and morcellated into small pieces. The entire radical nephrectomy specimen was extracted through a 12-mm incision (Clayman et al, 1991). This work has paved the way for a variety of both extraperitoneal and reconstructive renal surgical procedures.

The proven benefits of laparoscopic surgery, compared with open surgery, are now recognized in the treatment of renal disease and include decreased requirements for pain medication, shorter hospital stay, improved cosmetic result, and a more rapid return to full activity.

PATIENT EVALUATION AND PREPARATION

Patient preparation for laparoscopic kidney surgery is similar to that for comparable open surgical procedures. **Informed consent should include a discussion of possible complications, including injury to the diaphragm, vascular structures, nerves, bowel, spleen, and pancreas. In addition, the patient should be informed that conversion to open surgery may be necessary to safely complete the planned procedure.**

For the surgeon to assess for operative contraindications, the preoperative evaluation should include a careful history and detailed physical examination. **Laparoscopic renal surgery requires controlled ventilation and, therefore, is restricted in patients who are not candidates for a general**

anesthetic (Monk and Weldon, 1992). Prior abdominal surgery may alter the choice between transperitoneal or retroperitoneal approaches, patient positioning, and the placement site of trocars but is not a contraindication to laparoscopic surgery (Chen et al, 1998; Cadeddu et al, 1999). Severe cardiac or pulmonary disease may place the patient at risk for complications due to the pneumoperitoneum, which can compromise ventilation and limit venous return (Arthure, 1970; Hodgson et al, 1970; Nunn, 1987; Lew et al, 1992). Patients with chronic obstructive pulmonary disease may not be able to compensate for hypercarbia induced by the pneumoperitoneum and may require lower insufflation pressures, use of an alternative insufflant insufflator such as helium, or conversion to open surgery (Monk and Weldon, 1992; Wolf, 1996).

Obesity is not a contraindication to laparoscopic transperitoneal, retroperitoneal, or hand-assisted kidney procedures. However, fatty tissue can make identification of anatomic structures challenging. Moreover, the increased distance to the operative field may require alterations in traditional trocar site selection (Mendoza et al, 1996; Doublet and Belair, 2000; Jacobs et al, 2000). The weight of the pannus may raise the intra-abdominal pressure and limit the working space. Obese patients are at increased risk for complications from open or laparoscopic surgery (Fazeli-Matin et al, 1999) and may have a greater chance of conversion to open surgery. Of note, postoperative pulmonary and wound complications are often lower in obese patients undergoing laparoscopic surgery compared with the open approach (Fugita et al, 2004; Hedican et al, 2004; Kapoor et al, 2004). Rhabdomyolysis is a rare complication of prolonged laparoscopic renal surgery in the obese population as well as extremely muscular individuals (Troppmann et al, 2003).

Laparoscopy during pregnancy should be approached with care and has been reported in cases of adrenal pheochromocytoma and Cushing's syndrome. There are also published cases of laparoscopic radical nephrectomy for renal cell carcinoma diagnosed during pregnancy. No complications were reported in any of these cases, and all pregnancies were carried to term (O'Conner et al, 2004; Sainsbury et al, 2004).

Anticoagulated patients are managed in cooperation with their primary physician. One should have results of blood studies available for patients with bleeding disorders. Platelets and fresh frozen plasma can be given if needed before the procedure. Patients with thrombocytopenia receive platelets 30 minutes before the incision, to increase their platelet count to greater than 50,000/mL. Additional platelet transfusion should not be necessary in the absence of symptomatic bleeding. Uremic patients with prolonged bleeding time may benefit from infusion of desmopressin acetate (0.3 to 0.4 μg/kg) 1 hour before the procedure to improve platelet function.

The patient's medical history dictates the laboratory and imaging studies to be obtained. An electrocardiogram and a chest radiograph may be obtained before surgery. Pulmonary function studies are performed only in those patients with known respiratory disease or those at risk based on the history and physical examination. It is recommended that patients have their blood typed and screened. For complex reconstructive procedures, one may consider crossmatching blood. Bowel preparation varies according to the procedure, likelihood of bowel adhesions, and the physician's preference. For left-sided transperitoneal procedures, we prefer to evacuate the colon the evening before surgery with enemas or laxatives.

Preoperative abdominal axial imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is helpful in defining renal pathology as well as individual anatomy. Areas of perinephric stranding discovered on CT may indicate significant inflammation and adhesions, increasing the chance for conversion to an open procedure (Fig. 51–1). In addition, the contrast medium–enhanced scans provide data on the appearance and function of the contralateral kidney. Differential function can be determined with a diethylenetriaminepentaacetic acid renal scan if needed. Angiography, embolization, or placement of a ureteral stent may be helpful in select patients but is not routine.

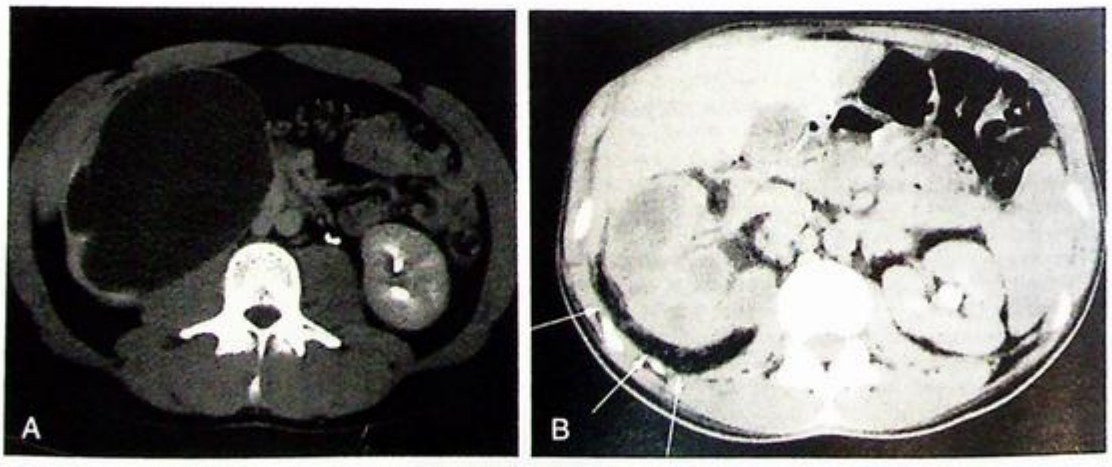

Figure 51–1. Preoperative abdominal CT scans from two different patients before simple nephrectomy for nonfunctioning kidneys. **A,** Minimal perinephric stranding is seen, and an uncomplicated laparoscopic nephrectomy was performed. **B,** *Arrows* show significant perinephric stranding. These represent dense adhesions that required conversion to open surgery to complete the nephrectomy. (From Bishoff JT, Kavoussi LR [eds]: Atlas of Laparoscopic Retroperitoneal Surgery. Philadelphia, WB Saunders, 2000).

SURGICAL APPROACHES

There are three basic laparoscopic approaches for laparoscopic nephrectomy: transperitoneal, retroperitoneal, and hand-assisted.

Transperitoneal Approach

The transperitoneal approach is the traditional method used to perform laparoscopic surgery. It results in small incisions and gives latitude in the location of trocar placement. It also affords an optimal working space and facilitates orientation from readily identifiable anatomic landmarks. Nambirajan and colleagues (2004) performed a prospective randomized study between the transperitoneal and retroperitoneal approaches. They showed no significant operative differences between the two approaches but did report that resumption of oral intake was significantly faster in the transperitoneal group.

Retroperitoneal Approach

The retroperitoneal approach mimics traditional open surgery in that the kidney is approached without entry into the peritoneal cavity. A potential space must be developed to allow adequate visualization of the surgical field. Even though urologists have conventionally approached the kidney through the retroperitoneum, the laparoscopic approach can appear unfamiliar owing to overlying adipose tissue and the limited working space. For the novice, this can cause difficulty with orientation, visualization, instrument manipulation, and organ entrapment.

There are patients in whom retroperitoneal access is preferred over the transperitoneal approach. Patients with a history of multiple abdominal surgical procedures or peritonitis may benefit from this approach. Initial retroperitoneal access can be achieved with subsequent opening of the peritoneum as indicated (Cadeddu et al, 1999). Also, patients with abnormalities on the posterior surface of the kidney (exophytic cyst or mass) may be better served through retroperitoneal access. Consequently, the laparoscopic surgeon should be familiar with both transperitoneal and retroperitoneal approaches.

Hand-Assisted Approach

To facilitate learning of laparoscopic techniques and to increase the availability of less invasive procedures, hand-assisted endoscopic techniques have been introduced. The first hand-assisted laparoscopic nephrectomy (HALN) was reported by Nakada and coworkers in 1997. The hand-assisted devices offer a bridge between laparoscopic and open surgery and may help surgeons without advanced laparoscopic training gain the necessary experience. At the time of this writing, there were three devices available to maintain the pneumoperitoneum during HALN: the Gelport (Applied Medical, Rancho Santa Margarita, CA), the LapDisc (Ethicon Endosurgery, Cincinnati, OH), and the Omniport (Advanced Surgical Concepts, Ireland; distributed in the US by Weck Closure, Raleigh, NC) (Table 51–1) (Rane et al, 2003; Patel and Stifelman, 2004; Wolf et al, 2005). Hand-assisted laparoscopic surgery has the advantage of restoring tactile feedback and use of the hand to assist with dissection, retraction, extraction, and rapid control of bleeding if needed. An incision large enough to allow the surgeon or assistant to insert a hand must be created, and this site can be utilized for organ extraction. Hand-assisted dissection may be helpful in those patients whose pathologic condition makes laparoscopy more difficult, such as infectious processes or prior renal surgery. Multiple series have documented the utility of the hand-assisted technique for most kidney procedures (Keeley et al, 1997; Wolf et al, 1998; Nakada et al, 1997, 1999).

SIMPLE NEPHRECTOMY

Indications and Contraindications

Laparoscopic simple nephrectomy is indicated in the treatment of most benign renal diseases, including renovascular hypertension, symptomatic acquired renal cystic disease

Table 51–1. Characteristics of Commercially Available Devices for Hand-Assisted Laparoscopy

Characteristic	*Gelport*	*Lap Disc*	*Omniport*
Manufacturer	Applied Medical, Rancho Santa Margarita, CA	Ethicon Endo-Surgery, Cincinnati, OH	Advanced Surgical Concepts, Ireland, Distributed in US by Weck Closure, Raleigh, NC
Device diameter	13 cm	12 cm	12 cm
No. of different sizes	2	2	1
No. of components	3 pieces: flexible skirt, rigid base, gel cap	One piece	2 pieces: cuff with retention rings, insufflation device
Advantages	Gel cap maintains pneumoperitoneum with or without instruments and allows instrument to be placed directly though cap device.	Small and simple to work. An iris configuration allows opening to be large enough for hand or tightly placed around a trocar.	Able to maintain pneumoperitoneum even when incision is too long.
Disadvantages	Gas leak if incision is too long	Gas leak if incision is too long	Loss of pneumoperitoneum when hand is removed
Cost per device	$575	$490	$415

Data from Wolf JS: Tips and tricks for hand-assisted surgery. AUA Update Series 2005;24:2; Rane A, Dasgupta P: Prospective experience with a second-generation hand-assisted laparoscopic device and comparison with first-generation devices. in dialysis patients, nephrosclerosis, symptomatic patients with autosomal dominant polycystic kidney disease (ADPKD), chronic pain of renal origin refractory to conservative measures, chronic pyelonephritis, reflux or obstructive nephropathy, and multicystic dysplastic kidney (Fricke et al, 1998).

Prior abdominal surgery may result in the formation of intra-abdominal adhesions and potentially increase injury to bowel during insufflation, trocar placement, or dissection. The initial entry site in these patients should be away from scars and prior surgical fields. Open trocar placement or a retroperitoneal approach may be necessary to minimize access injuries (Hassan, 1971). **Patients with large, dilated loops of bowel from either functional or obstructive ileus should be approached cautiously because the dilated intestinal segments can limit the working space and may be injured during access, dissection, and trocar site closure** (Borten, 1986). Other contraindications include an uncorrected coagulopathy, untreated infection, and hypovolemic shock (Capelouto and Kavoussi, 1993). Although not a contraindication, xanthogranulomatous pyelonephritis and renal tuberculosis (Gupta et al, 1997; Bercowsky et al, 1999) can be associated with dense adhesions and lead to conversion to open surgery. Of note, Lee and associates (2002) reported successful retroperitoneal laparoscopic simple nephrectomy in 30 of 31 patients with nonfunctioning kidneys secondary to tuberculosis.

Patient Positioning

For transperitoneal laparoscopic nephrectomy, the patient is initially positioned supine for intravenous access, the induction of general anesthesia, endotracheal intubation, bladder catheterization, and orogastric tube placement. The patient is then positioned in a modified lateral decubitus position. Approximately 30 degrees of rotation of the chest and abdomen is used. The table can be flexed as needed, an axillary roll is placed, and padding is used to support the buttocks and flank. **The patient is taped in position with multiple strips of wide cloth tape so that the patient's arms, legs, and abdomen remain securely in place while the table is rolled toward the surgeon to assist with gravity retraction of the bowel** (Fig. 51–2).

The equipment in the operating room is configured to maximize the use of operating room space and to allow all members of the surgical team to view the procedure (Fig. 51–3). During the skin preparation and towel placement, the entire flank and abdomen are included in case conversion to an open procedure is required.

Insufflation and Trocar Placement

Once a pneumoperitoneum is established, a 12-mm port is placed lateral to the rectus muscle at the level of the umbilicus. This can be accomplished blindly or with the aid of a visual obturator to allow entry into the abdomen under direct vision. Once the port is in place, the abdomen is then inspected for any injury from Veress needle placement. Also, one should inspect for adhesions in areas where the secondary ports will be placed. Remaining trocars are inserted under direct vision.

The use of local anesthesia to prevent postoperative trocar site pain may be helpful. Khaira and Wolf (2004) performed a double-blind, randomized placebo-controlled trial showing that the infiltration of trocar and hand-assisted sites with 0.5% bupivacaine before incision or port placement decreased postoperative narcotic requirements at all time points compared with placebo injection.

Three to five trocars are utilized to complete the dissection. **A 12-mm trocar is placed lateral to the rectus at the level of the umbilicus; this trocar is used for instrumentation and the passage of staplers to secure and divide hilar vessels. A 10- or 12-mm trocar is placed at the umbilicus for the camera, and a 5-mm port is inserted in the midline between the umbilicus and the xiphoid process.** In obese patients, all trocar sites are moved laterally (Fig. 51–4). A lower midline additional trocar may be needed for retraction or to complete the hilar dissection or assist with organ entrapment (Fig. 51–5). A subxiphoid 3- to 5-mm retractor may be needed to retract the liver for right-sided procedures.

Procedure

Reflection of the Colon

For a left nephrectomy, the white line of Toldt is incised from the level of the iliac vessels inferiorly, extending above the spleen superiorly. The lienocolic ligament should be incised to allow the spleen to fall medially along with the pancreas and

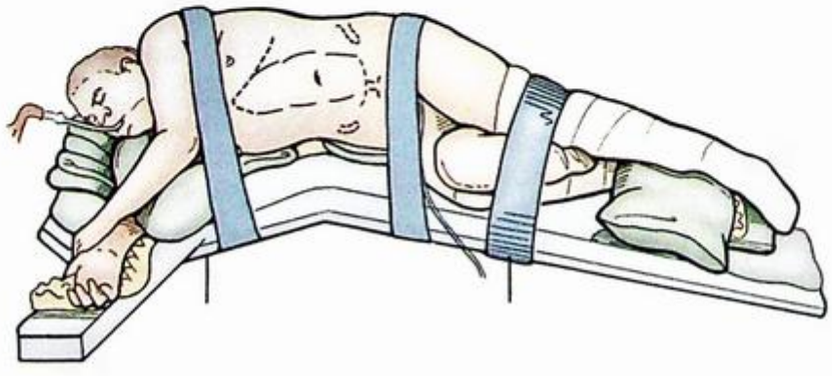

Figure 51–2. The patient is placed in a modified flank position, with the umbilicus over the break in the operating table. This position allows the arms to be placed on the table in a "praying mantis" position or crossed over the chest with two pillows placed between them.

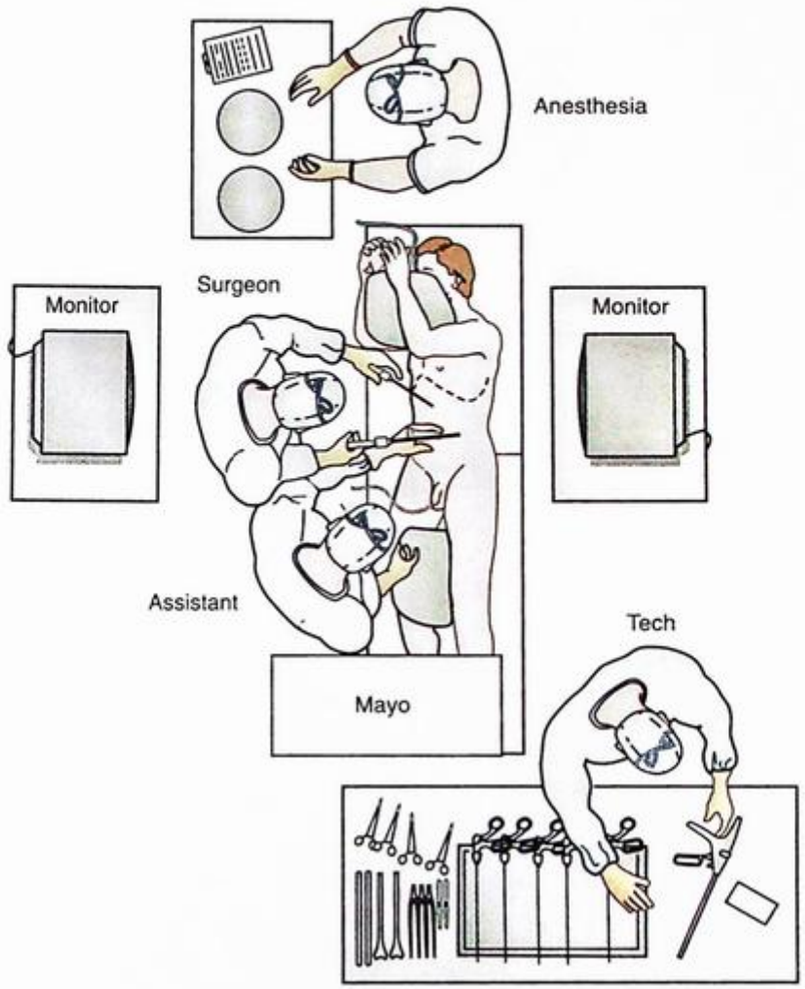

Figure 51–3. The operating room is configured for left nephrectomy. Two monitors allow the assistant to follow the procedure.

the colon (Fig. 51–6). Care must be taken to avoid injuring the diaphragm with this maneuver. Also, the surgeon must be cognizant of the stomach as superior attachments are incised. During a right-sided nephrectomy the hepatic flexure of the colon is usually below the lower pole of the kidney. As such, the peritoneal incision begins at the hepatic flexure and is carried cephalad, above the hepatic flexure, including the right triangular and right anterior coronary ligaments. On both sides, medial traction on the colon reveals colorenal attachments that must be divided to complete mobilization (Fig. 51–7).

Dissection of the Ureter

Once the colon has been freed, the psoas muscle and psoas tendon should be identified. When the psoas muscle is followed medially, the gonadal vessels are usually first encountered. These should be swept laterally and the ureter is usually located just deep to these vessels. The ureter is usually more medial than anticipated. Peristalsis of the ureter can help differentiate from the gonadal vein. **Once identified, the ureter alone on the right side or both the ureter and gonadal vessels together on the left side are elevated and followed proximally to the lower pole and hilum of the kidney. The ureter is not divided at this time because it can be used to help elevate the kidney** (Fig. 51–8).

Identification of the Renal Hilum

Safe dissection of the renal hilum requires two conditions: (1) medial retraction of the colon and bowel by gravity or an additional retractor and (2) lateral retraction of the kidney by lifting it out of the renal fossa. **Lateral retraction of the kidney, with a grasper placed under the lower pole, will place the vessels on tension, allowing for visualization and control of bleeding vessels should a small accessory vessel be avulsed. This is accomplished by gently placing the lateral grasper under the ureter and lower pole of the kidney until the grasper abuts against the abdominal sidewall. It is important to be sure that the grasper is not into the renal parenchyma.** With the ureter and lower pole of the kidney elevated, layer-by-layer anterior dissection is performed with the irrigator aspirator until the renal vein is uncovered. Gonadal, lumbar, and accessory venous branches can then be clipped and divided as encountered (Fig. 51–9).

Securing the Renal Blood Vessels

By clearing off anterior Gerota's fascia and inferior lymphatics, one can identify the renal artery. If the irrigator-aspirator tip is not precise enough for meticulous dissection, a hook electrode can be used to dissect the lymphatic vessels free of the vein and artery. It has been our experience that smokers,

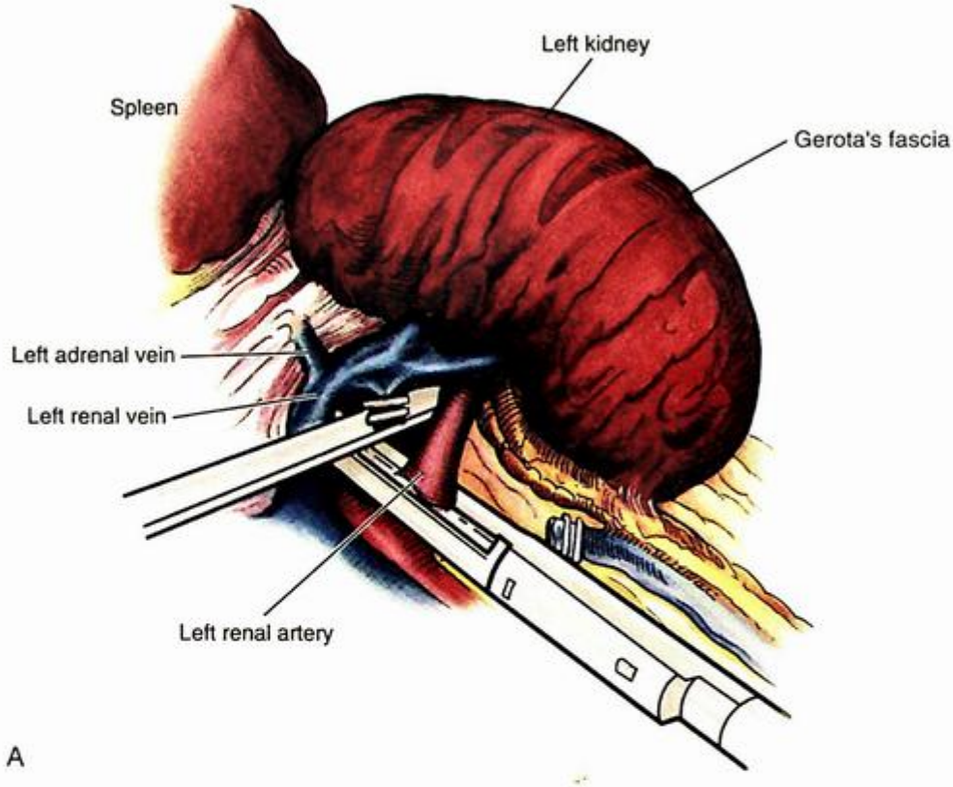
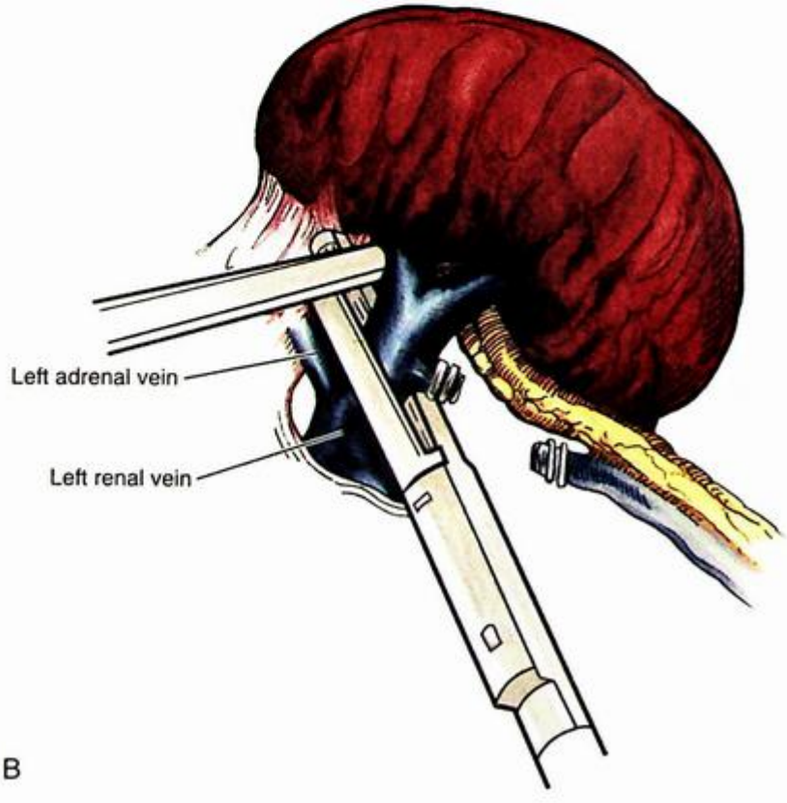
particularly users of marijuana, will have lymphatics that are more tenacious and dense than nonsmokers. **Clips or staples can be used on the artery** (Fig. 51–10). The artery is divided first, followed by the vein. We prefer to use an endovascular gastrointestinal anastomosis (GIA) stapler on both the artery and vein, because three rows of staples will be left on the vessel stump and are unlikely to be dislodged during subsequent dissection. Occasionally, oozing may be seen from the stump when using a GIA stapler. In these cases, a reinforcing clip may be helpful. On the left side, to preserve the adrenal gland, the GIA stapler is fired distally to the take-off of the adrenal vein.



A



B

Figure 51–10. **A,** First, the renal artery is stapled using an endovascular gastrointestinal anastomosis (GIA) stapler. **B,** The renal vein is secured lateral to the adrenal vein with the GIA stapler. If clips are used on the gonadal or adrenal vessels, the surgeon must be careful to exclude them from the jaws of the stapler.

Isolation of the Upper Pole

Once all the hilar vessels have been divided, the dissection continues posteriorly and superiorly to the upper pole. The adrenal gland is preserved in cases of simple nephrectomy by first applying the GIA stapler distal to the takeoff of the adrenal vein. Gerota's fat is then peeled off circumferentially above the upper pole of the kidney (Fig. 51–11). At this point during the dissection, it may be necessary to clip and transect the ureter. This allows the kidney to be rotated anteriorly above the liver (right) or spleen (left) to facilitate incision of the uppermost attachments under direct vision.

In cases of extreme fibrosis, a subcapsular nephrectomy can be performed once the artery and vein have been controlled (Moore et al, 1998). Long, blunt instruments such as the closed stapler or the 10-mm LigaSure Atlas (Valleylab, Tyco Healthcare Group, Boulder, CO) are particularly well suited for reaching and freeing the upper pole and adrenal attachments.

Organ Entrapment

The kidney can be removed intact through an enlarged incision or after morcellation. When morcellation is performed, the specimen should be placed into a sturdy entrapment sac such as the LapSac (Cook Urological, Spencer, IN) (Urban et al, 1993). This minimizes the risk of rupture during mechanical morcellation of the tissue (Walther et al, 1999; Landman et al, 2000). By using ring forceps and a Kocher clamp the kidney and collecting system can be morcellated and removed in small pieces. Alternatively, the kidney can be removed intact through an incision after placement into a sac. The kidney can be worked out of an extended trocar site or Pfannenstiel incision. For trocar sites greater than 5 mm, it is helpful to place the closure sutures before removing the kidney. Once the sutures are placed, trocars can be reinserted for kidney entrapment and removal.

Postoperative Management

The orogastric tube is removed at the conclusion of the procedure. The patient can begin a diet as tolerated. The Foley catheter should be removed once the patient is comfortably ambulating. The patient is discharged when tolerating a regular diet. Unrestricted activity can usually be resumed according to the patient's comfort. If a specimen has been removed through an incision, lifting is limited to 6 weeks.

Results

The postoperative results of the laparoscopic nephrectomy are comparable to that of open surgery with much less pain and shorter convalescence. **Postoperative pain requirements are approximately four times less than with traditional open incisions. Hospital stays have been decreased by 50%, and the time to full convalescence has been reported to be markedly less than with open removal.** In early series, the mean operative times were greater than 300 minutes. However, with advances in techniques, experience, and equipment, current operative times have decreased dramatically (Kerbl et al, 1994a, 1994b; Nicol et al, 1994; Perez et al, 1994; Parra et al, 1995; Baba et al, 1996; Rassweiler et al, 1998a, 1998b; Permpongkosol et al, 2005).

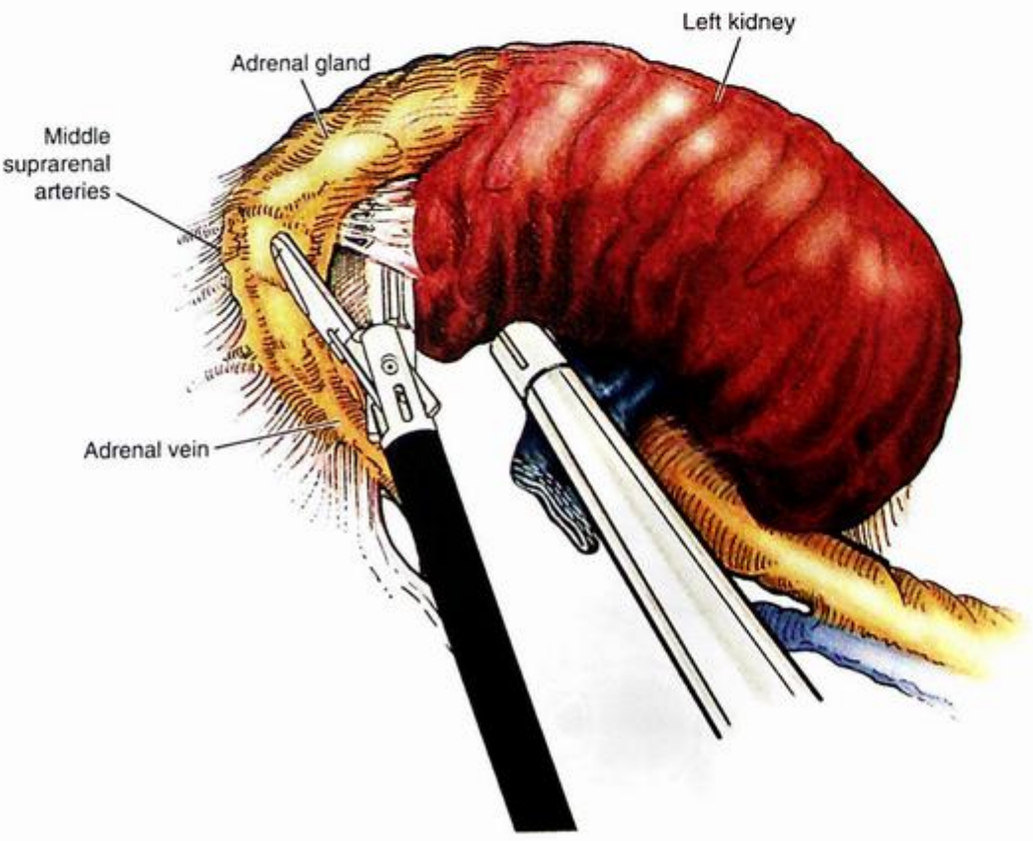


Figure 51–11. The adrenal gland can be preserved during simple nephrectomy or radical nephrectomy as indicated by dissecting it from the superior pole of the kidney.

RENAL BIOPSY

Renal biopsy can play an important role in the assessment of proteinuria or unexplained medical disease of the kidney. Histologic information is often pivotal in making treatment decisions and prognosis (Morel-Maroger, 1982; Gault and Muehrcke, 1983; Manoligod and Pirani, 1985). **Ultrasound-guided percutaneous needle biopsy, under local anesthesia, is the current standard for obtaining renal tissue. Unfortunately, there is a 5% rate of significant hemorrhagic complications, and as many as 5% to 20% of cases yield inadequate tissue for accurate diagnosis** (Wickre and Golper, 1982). In morbidly obese patients it can be difficult or impossible to identify the kidney using ultrasound, prohibiting biopsy. When percutaneous or transjugular biopsy fails or is considered to have risk, patients may benefit from surgical renal biopsy. This allows hemostasis to be achieved under direct vision and provides the pathologist with adequate tissue to make a diagnosis. Laparoscopic renal biopsy offers the advantages of open biopsy with the decreased morbidity of a two-port outpatient procedure and can be performed in the morbidly obese.

Indications

Renal biopsy under direct vision is indicated in three primary categories of patients: failed percutaneous needle or transjugular biopsy, anatomic variations, and a risk of bleeding complication. Factors that may make a patient unsuitable for percutaneous biopsy include morbid obesity, multiple bilateral cysts, a body habitus that makes localization impossible, and a solitary functioning kidney. Renal imaging with CT or ultrasonography is performed to determine any abnormality, such as renal cysts or solitary kidney, that may alter the choice of kidney for biopsy.

Patient Positioning

The patient is placed in the full flank position with the umbilicus over the table break. The table is fully flexed to help increase the distance between the ribs and the iliac crest. Grounding pads for electrocautery and the argon beam coagulator are placed on the exposed upper thigh.

Procedure

Retroperitoneal Access

A 10-mm transverse incision is made in the skin midway between the iliac crest and the tip of the 12th rib in the posterior axillary line. A 0-degree lens and visual obturator (Visiport, AutoSuture, Norwalk CT; or Optiview, Ethicon Endosurgery, Cincinnati, OH) are placed in the incision. Holding the trocar with the laparoscope in the visual obturator perpendicular to the skin and aiming approximately 10 degrees anteriorly, the surgeon enters the retroperitoneum under direct vision. Characteristic retroperitoneal fat helps identify the correct space. **Straying too far anteriorly can result in peritoneal entry or colon injury, whereas veering posteriorly can cause bleeding in the quadratus or psoas muscles.**

Once entry is made into the retroperitoneum, the visual obturator is removed, leaving behind the 10-mm trocar. Carbon dioxide insufflation is begun at a pressure of 20 mm Hg. Blunt dissection, using only the laparoscope, is initially used to create a retroperitoneal working space. Anteriorly, the peritoneum is swept medially, exposing the underside of the transversalis fascia (Fig. 51–12). Once anterior dissection has mobilized the peritoneum medially, a 5-mm port is placed in the anterior axillary line at the same level as the first port (Fig. 51–13).

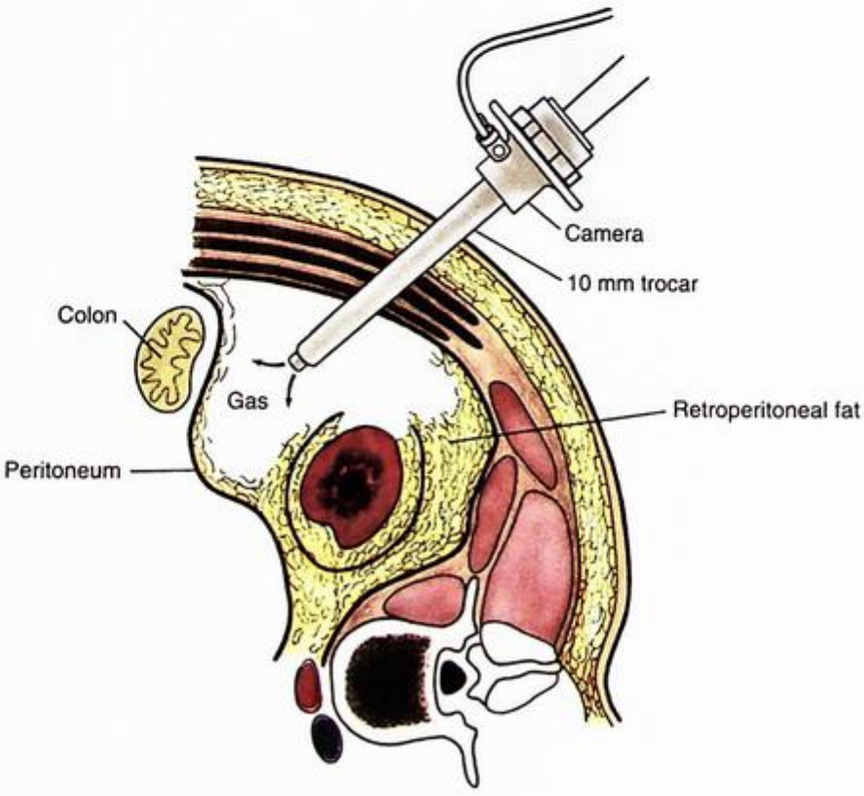

Figure 51–12. Standing behind the patient, the surgeon places the visual obturator in the posterior axillary line. The 0-degree laparoscope is used to bluntly push the peritoneum medially, creating a working space large enough to allow placement of the second trocar.

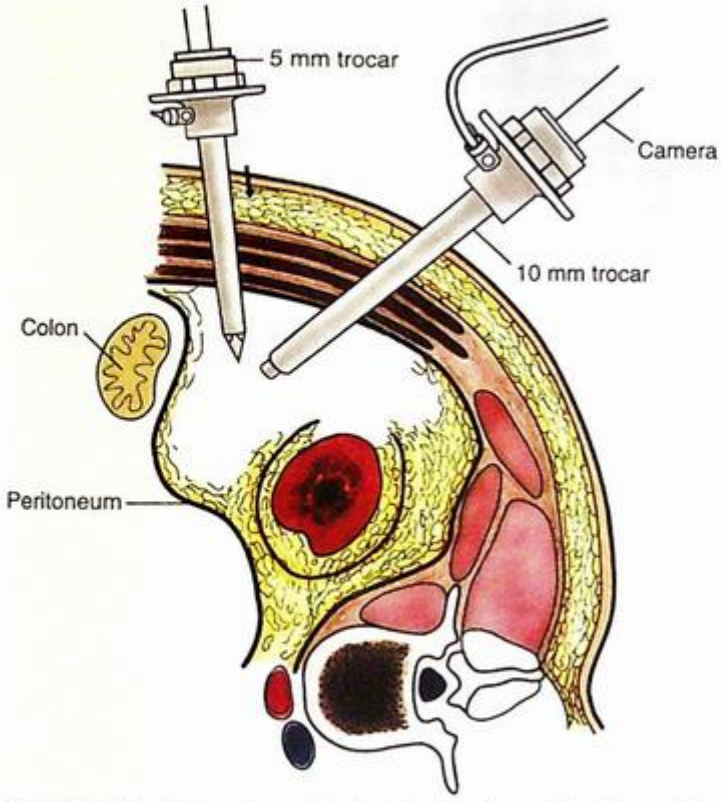

Figure 51–13. A 5-mm trocar is placed under direct vision. The working instruments are passed through this port. The camera can be used to assist with dissection and is frequently cleaned to maintain adequate visualization.

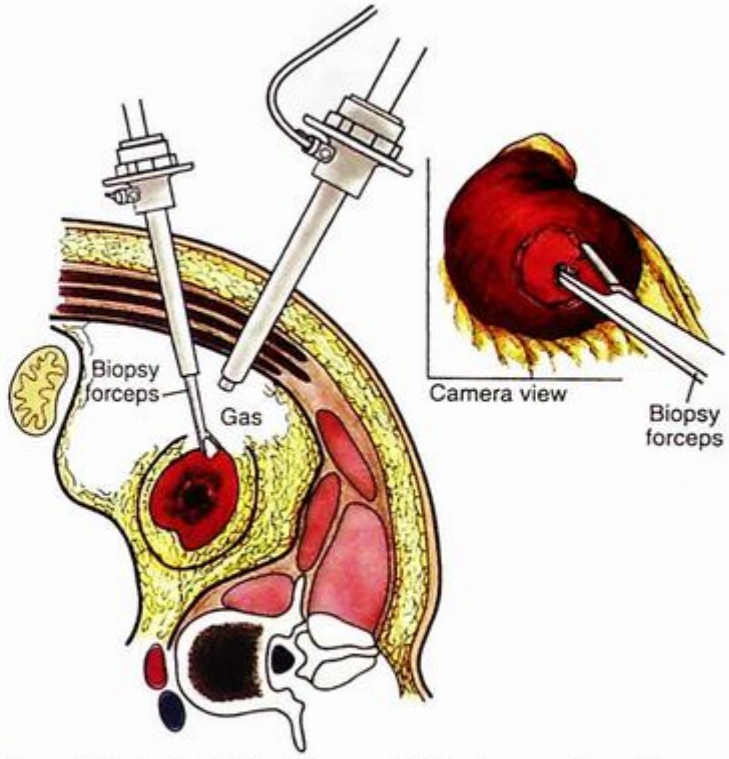

Figure 51–14. Gerota's fascia is opened with the use of the scissors. A 5-mm two-tooth laparoscopic biopsy forceps is used to take two to three samples from the lower pole of the kidney.

Kidney Exposure and Biopsy

The lower pole of the kidney is located, and Gerota's fascia is opened using blunt and sharp dissection. **In anatomically challenging patients such as those who are morbidly obese, preoperative transcutaneous or intraoperative ultrasonography may be valuable in localizing the kidney** (Chen et al, 1997). Once Gerota's fascia is incised, the perirenal fat is swept aside to expose the lower pole. A 5-mm biopsy forceps is used to take several cortical samples (Fig. 51–14). Only a small amount of tissue is needed to obtain adequate sampling of the glomeruli for diagnosis. To prevent errors in tissue processing, the fresh renal biopsy specimen may be placed in formalin but transferred fresh, directly to a nephrologist or pathologist for immediate frozen section confirmation and then processing.

Hemostasis and Closure

Hemostasis is obtained with the argon beam coagulator. During activation of the argon beam, it is important to open an insufflation port, because the flow of argon gas can markedly increase the intra-abdominal pressure. Once adequate hemostasis is achieved, the insufflation pressure is lowered to 5 mm Hg for at least 5 minutes and the entire retroperitoneum is inspected for hemostasis. Persistent bleeding from the biopsy site is treated with repeated argon beam coagulation. Once hemostasis has been confirmed under low pressure, oxidized cellulose is packed into the biopsy site and direct pressure is applied. The skin incisions are irrigated, inspected for hemostasis, and closed with a 4-0 absorbable subcuticular suture.

Postoperative Considerations

The length of hospital stay depends on the patient's health status. Specific attention is given to control of blood pressure. **Care must be taken in patients requiring postoperative resumption of anticoagulation. Usually, patients can resume oral warfarin or subcutaneous injection anticoagulation therapy 24 to 48 hours after surgery. Patients who require intravenous heparin must be observed very closely to ensure that they do not become supratherapeutic and bleed from the biopsy site.** Most nonhospitalized patients can be discharged the same day as the biopsy.

Results

A report of 32 consecutive patients who underwent laparoscopic renal biopsy showed 100% success in obtaining adequate tissue for histopathologic diagnosis (Gimenez et al, 1998). The mean blood loss was 26 mL, the operative time was 1.5 hours, and the hospital stay was 1.7 days. Sixteen patients (50%) were treated as outpatients. Complications included one inadvertent biopsy of the spleen without consequence and one 300-mL hematoma that resolved without a need for intervention. The overall complication rate was 6% (2 of 32) and included a patient who was a Jehovah's Witness and on high-dose corticosteroid therapy who developed a perforated gastric ulcer and died 7 days after surgery.

A multi-institutional study over a period of 9 years and 74 patients undergoing laparoscopic renal biopsy showed that adequate tissue was retrieved from 96% of patients. The mean operating room time was 123 minutes (range: 9 to 261 minutes) and the mean estimated blood loss was 67 mL (range: 5 to 2000 mL) (Shetye et al, 2003).

In another series of 17 patients, a balloon was inserted into the retroperitoneum to create the working space (Gaur et al, 1994). Adequate renal tissue for diagnosis was obtained in each case. The mean operative time was 35 minutes, excluding anesthesia time, with a range of 20 to 45 minutes. Fifteen patients were discharged within 24 hours, and 2 patients remained hospitalized for 4 days. Complications were seen in 11% of the patients (2 of 17), including severe bleeding requiring conversion to an open procedure and 1 patient with marked gross hematuria. **Hemorrhage is the most common major complication associated with laparoscopic renal biopsy. Slow resumption of anticoagulation is important to prevent bleeding from the biopsy site. The cause of a persistent decline in hematocrit or symptoms of hypovolemia should be evaluated by CT.**

RENAL CYSTIC DISEASE

Renal cysts are present in over one third of patients older than 50 years, and few require surgical intervention (Hoenig et al, 1997; Wolf, 1998). Patients with pain, infection, or obstruction may need cyst excision. Moreover, with the advent of CT and ultrasonography, the detection of indeterminate renal masses and complex renal cysts has become a frequent occurrence. Classification schemes have been devised based on CT criteria to help surgeons determine whether further diagnostic or therapeutic maneuvers are necessary (Table 51–2) (Bosniak, 1986). Unfortunately, imaging studies are not always diagnostic, and surgical removal may be needed to exclude the possibility of malignancy.

Approximately 600,000 individuals suffer from autosomal dominant polycystic kidney disease (ADPKD). The clinical course of ADPKD is usually dominated by symptoms of abdominal fullness or pain and may require surgical treatment for symptomatic relief. End-stage ADPKD may occasionally require bilateral or unilateral nephrectomy for the treatment of cyst complications, bleeding, infection, or pain.

Indications

Needle aspiration with or without sclerosis of symptomatic solitary renal cysts is often the first line of therapy and diagnosis. Resolution of symptoms after drainage and then recurrent symptoms with reaccumulation of cyst fluid increases the likelihood that laparoscopic cyst decortication will be successful in eliminating the patient's pain (Rane, 2004). **However, cyst aspiration and sclerosis is not always effective and can pose a risk of fibrosis when peripelvic cysts are treated in this manner** (Wehle and Grabstald, 1986; Hulbert et al, 1988; McDougall, 1998; Santiago et al, 1998). Symptomatic parapelvic renal cysts are usually treated with laparoscopic decortication (Doumas et al, 2004). Renal cysts may also obstruct the collecting system, compress renal parenchyma, or spontaneously hemorrhage, inducing pain and hematuria. In addition, they may become infected and cause obstructive uropathy or hypertension. Complex cysts can be explored laparoscopically and sampled, and definitive treatment can be initiated if renal cell carcinoma is confirmed on frozen section histopathologic examination.

In patients with ADPKD, laparoscopic renal cyst marsupialization, decortication, or unroofing large numbers of cysts has been successful in providing pain relief in up to 83% of patients (Bennett et al, 1987; Rubenstein et al, 1993; Teichman and Hulbert, 1995; Brown et al, 1996; Elashry et al, 1996; Lifson et al, 1998). Some patients with renal cysts may experience pain. Those patients in whom standard medical therapies have failed to treat pain may be candidates for laparoscopic cyst decortication. In addition to pain, patients with hypertension, hematuria, or infections may also benefit from treatment. Bilateral synchronous laparoscopic nephrectomy and hand-assisted nephrectomy have also been reported in ADPKD patients with end-stage renal disease and symptoms from enlarged or infected kidneys (Dunn et al, 2000; Kaouk et al, 2000; Bendavid et al, 2004; Luke and Spodek, 2004).

Surgical approaches for complex renal cysts include exploration with biopsy, enucleation, partial nephrectomy, or radical nephrectomy. Radiographic evaluation utilizing the Bosniak classification can help select those patients who should undergo laparoscopic exploration (Bosniak, 1986) (see Table 51–2). Bosniak class 3 and class 4 cysts have an increased chance of malignancy and may benefit from excision (Cloix et al, 1996; Santiago et al, 1998).

Caution should be used in patients with intraparenchymal cysts. Although intraoperative ultrasonography is helpful for locating deep parenchymal renal cysts, removal of the cysts may be challenging and there is a risk of injuring the collecting system or causing significant bleeding (Polascik and Marshall, 1997). Laparoscopic or percutaneous cryoablation may be helpful in these cases.

Patient Preparation

All patients undergoing laparoscopic cyst biopsy should be informed that if malignancy is detected, more extensive resec-

Table 51–2. Renal Cyst Classification Based on Bosniak Criteria

tion may be performed, including simple enucleation, partial nephrectomy, or radical nephrectomy. If a lesion is clearly peripheral and does not involve the collecting system, a ureteral stent or catheter is not necessary. **If there is any question that a cyst may be in proximity to the collecting system, cystoscopy and placement of an open-ended ureteral catheter can be performed at the time of surgery and used to instill contrast material or methylene blue intraoperatively to evaluate the integrity of the collecting system after cyst excision.**

Patient Positioning

Patient positioning depends on the type of approach (extraperitoneal vs. transperitoneal). If cystoscopy and ureteral catheter placement are required, the patient is first placed in the supine position for flexible cystoscopy or in the dorsal lithotomy position if rigid cystoscopy is used. For patients with cysts located in the anterior portion of the kidney, a transperitoneal approach is preferred. The patient is placed in a 45-degree modified flank position. Posterior lesions may be easier to approach through the retroperitoneum, where the patient is placed in the full flank position.

Procedure

Transperitoneal Approach

Trocar placement and renal exposure are as previously described. For right-sided dissections, caution should be exercised when dissecting the medial attachments, because the duodenum lies in close proximity. For middle pole or medial lesions, it is often necessary to mobilize the duodenum with a Kocher maneuver (Fig. 51–15). This should be done with a combination of sharp and gentle blunt dissection. The use of cautery in this area should be avoided, because an injury to the duodenum can lead to significant morbidity or death. The cyst usually appears as a well-defined blue dome protruding from the surface of the kidney. If there is difficulty in identifying the location of the cyst, intraoperative ultrasonography can be performed. After visual inspection, the cyst is decompressed using a laparoscopic cyst aspiration needle. If suspect, the fluid can be sent for cytopathologic analysis; however, in our experience, this is of limited utility. At this point, the cyst wall is excised at its junction with the parenchyma and sent for pathologic interpretation (Fig. 51–16). If the cyst wall is too large to be easily removed through the 12-mm trocar, it should be placed in a laparoscopic retrieval sac and removed directly through the abdominal wall trocar site. **The edge of the cyst wall where normal parenchyma is encountered should be inspected and biopsies performed using the 5-mm laparoscopic biopsy forceps. If there is no evidence of malignancy, the parenchymal surface of the cyst wall can be fulgurated with electrocautery or the argon beam coagulator. Biopsy or cauterization of the center of the cyst can cause entry into the collecting system.** Surgical cellulose (Surgicel, Johnson & Johnson, Arlington, TX) can be packed into the cyst base. If malignancy is noted, the patient should have a partial or radical nephrectomy, as indicated.

A drain is usually not required; however, if the collecting system has been violated, it should be closed and a drain placed. This is accomplished by passing a hemostat through a small stab incision in a posterior axillary line under direct

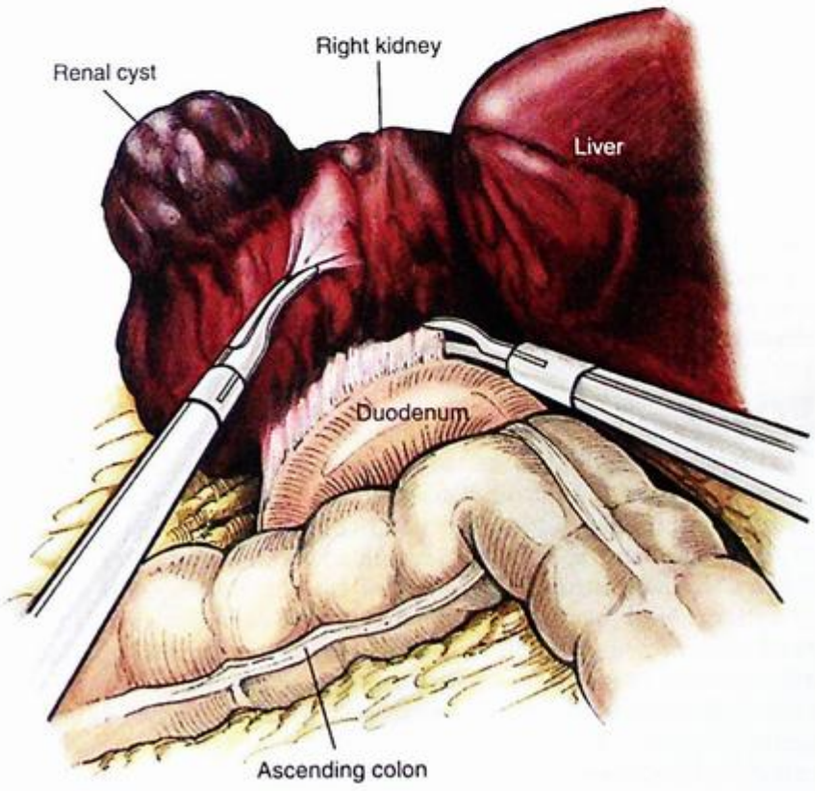

Figure 51–15. On the right side, the colon is reflected and a Kocher maneuver may be performed to completely expose the kidney and the renal hilum.

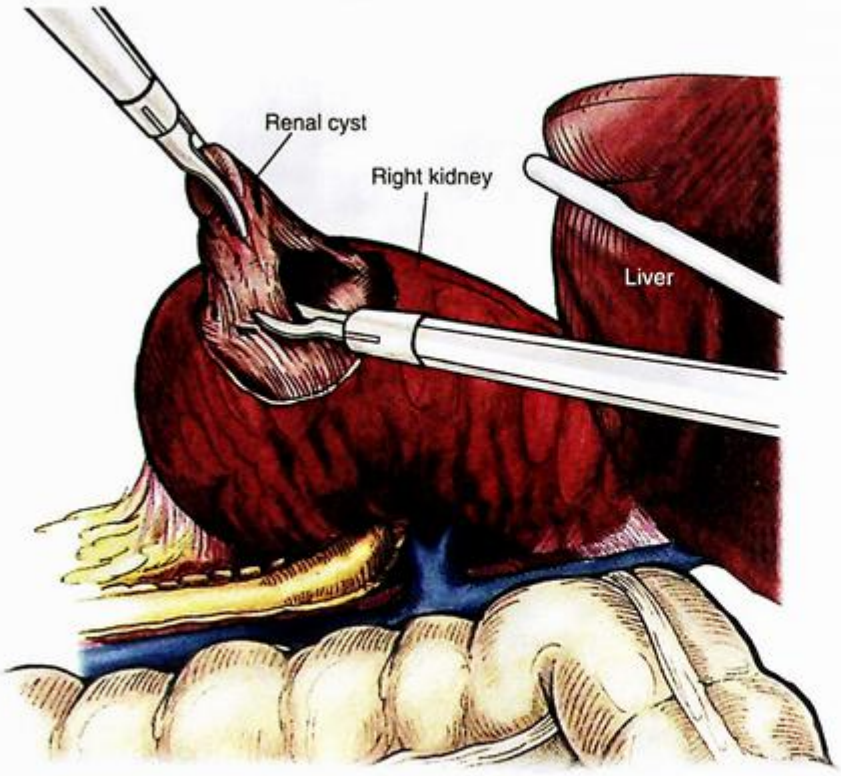

Figure 51–16. The cyst fluid is aspirated with a laparoscopic aspiration needle and sent for cytologic study. After decompression of the cyst, the wall can easily be grasped and manipulated. The cyst is elevated with a grasper and scissors or ultrasonic shears to circumferentially excise the cyst wall. The edge of the cyst is carefully inspected, and biopsies are performed using the 5-mm laparoscopic biopsy forceps as needed.

vision. A round suction drain is placed through a 10-mm trocar site and placed on one of the jaws of the hemostat (Fig. 51–17). The holes of the drain are placed in a dependent position.

Retroperitoneal Approach

The retroperitoneal approach is used for posterior or lower pole lesions. With the patient in a full flank position, a 10-mm trocar is placed in the posterior axillary line, halfway between the iliac crest and the 12th rib. Once the trocar is in place, a pneumoretroperitoneum is established and the anterior abdominal wall is identified with gentle dissection of the retroperitoneal fat. The peritoneum is swept medially by "hugging" the anterior abdominal wall. The second 5-mm port is placed under direct vision in the anterior axillary line as described. A third 5-mm port can be placed superior to the second port below the rib cage. By using the perinephric fat to elevate the kidney, the surgeon readily sees the lower pole and posterior surfaces. The remainder of the procedure is as described for the transperitoneal approach.

Results

The laparoscopic approach to symptomatic renal cystic disease has been found to be effective in decompression and pain control (Hulbert, 1992; Morgan and Rader, 1992; Munch et al, 1992; Roberts et al, 2001). Iannelli and colleagues (2003) showed that, at a mean follow-up of 60 months, 80% to 90% of patients with symptomatic renal cysts will have complete resolution of pain after laparoscopic cyst decortication. In another series of nine patients with solitary symptomatic renal cysts, 100% remained pain free at an average follow-up of 26 months (range: 3 to 63 months) (Lifson et al, 1998). Similar pain-free rates were reported by Rubenstein and associates (1993) in 10 patients. However, in their series, 20% of the patients (2 of 10) were found to have malignancy on cyst wall biopsy, despite a negative cytologic appearance on cyst aspiration, and subsequently underwent radical nephrectomy. Santiago and associates (1998) also found unsuspected renal cell carcinoma in 4 of 35 patients with renal cysts undergoing laparoscopic exploration and cyst decortication. These series underscore the need to treat cystic tissue as though it contained renal cancer cells, by removal of specimens in closed systems (i.e., spoon grasper or entrapment sac).

Autosomal Dominant Polycystic Kidney Disease

In cases of symptomatic ADPKD and adequate renal function, multiple cysts must be marsupialized by aspirating the cyst fluid and unroofing the cyst wall with electrocautery or ultrasonic energy. It is often necessary to unroof 100 or more cysts to adequately relieve pain (Bennett et al, 1987; Elzinga et al, 1992; Elashry et al, 1996). Because of marked distortion of the anatomy, care should be taken to avoid entering the collecting system (Cherullo et al, 1999). Laparoscopic intraoperative ultrasonography can be particularly helpful in evaluating and ablating perihilar cysts, which may be in close proximity to renal vessels.

Patients with symptomatic ADPKD and renal failure are approached as described under "Simple Nephrectomy." Multiple cysts are aspirated to decrease the size of the kidney, allowing access to the renal vessels for ligation and for ease of entrapment for removal or morcellation. Occasionally, the size, even after aspiration of many cysts, is too great to be manipulated into a retrieval device and requires removal through a low midline incision. Because these kidneys are

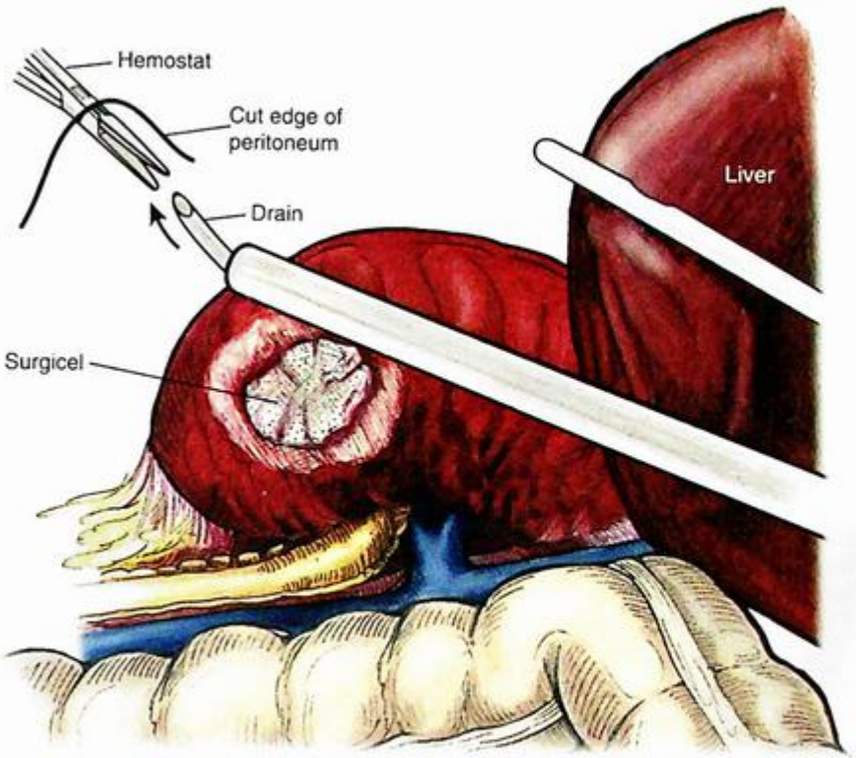

Figure 51–17. If the collecting system has been entered, it is closed and a drain placed. To insert the drain, a hemostat is passed through a small stab incision in the side and advanced into the abdominal cavity under direct vision. A 7-mm drain is placed through a trocar site and advanced toward the open hemostat using the trocar to direct the drain. The colon is brought back over the kidney and attached to the sidewall to "reperitonealize" the kidney and drain.

often too large to fit into an entrapment sac they may be removed by enlarging a midline incision or directly through a hand-assisted port, if used for the dissection (Jenkins et al, 2002).

Postoperative Management

Postoperative management is as with nephrectomy; however, if there is any concern regarding an injury to the collecting system, a double-pigtail stent can be left in place for up to 4 weeks. In the postoperative period, a urinoma should be in the differential diagnosis with any patient who develops a fever (>38.5°C [101.3°F]), persistent ileus, abdominal pain, nausea or vomiting, or an elevated white blood cell count with a left shift. Retroperitoneal hematomas can also occur, and the majority of these patients can be treated conservatively with observation and other supportive measures (including transfusion). Rarely, arteriography may be required to identify and treat a source of active bleeding.

Results

The experience with laparoscopic cyst decortication in cases of symptomatic ADPKD is increasing, and results demonstrate decreased pain and occasionally improvement in hypertension. Lee and coworkers (2003) reported unroofing an average of 220 cysts in 29 patients and found that 81% of patients had greater than 50% improvement in pain up to a mean of 3 years after cyst decortication. Furthermore, no patient showed a significant decrease in renal function and several patients had decreased blood pressure after the procedure. Their results were similar to those from historical open series (Elzinga et al, 1993). Other published series report pain-free rates ranging from 75% to 100% at 6 to 40 months of follow-up (Barry and Lowe, 1992; Chehval et al, 1995; Segura et al, 1995; Teichman et al, 1995; Brown et al, 1996; Elashry et al, 1996; Kaouk et al, 2000; Dunn et al, 2001). Laparoscopic decortication for symptomatic ADPKD is technically feasible and less morbid than open surgery.

Laparoscopic nephrectomy is occasionally indicated in symptomatic ADPKD patients with end-stage renal disease. Several series demonstrate the feasibility of laparoscopic removal with lower morbidity when compared with open removal. However, laparoscopic nephrectomy in the ADPKD patient can be challenging owing to the large size of the kidney causing difficulty in the dissection of the renal hilum. Bendavid and associates (2004) reported their series of 22 laparoscopic nephrectomies in 19 patients with ADPKD. The mean size was 22 cm, and the mean operative time was 255 minutes. They experienced an 8% intraoperative and a 32% postoperative complication rate. Conversion to open surgery was required in 18%. Gill and colleagues (2001) compared a series of 10 bilateral synchronous laparoscopic nephrectomies performed for symptomatic ADPKD to 10 open procedures performed for the same indication. None of the laparoscopic procedures required conversion to open surgery. There was no difference in operating time, specimen weight, or blood loss between the two groups. However, there was a significant difference in the length of the hospital stay (2.4 vs. 8.1 days, $P = .001$) and narcotic use (30 vs. 177 mg, $P = .001$), favoring the laparoscopic approach. Two patients in the laparoscopic group had a retroperitoneal hematoma that did not require surgical intervention.

Because an incision is often needed to remove the large ADPKD specimens, a hand-assisted dissection may be helpful in exposure and manipulation of the kidney specimen. Several series support the use of hand-assisted surgery for bilateral ADPKD nephrectomy. The hand port is placed in the midline

to allow access to both kidneys through one device, and additional trocars are placed as described for hand-assisted nephrectomy in this chapter (Rehman et al, 2001; Jenkins et al, 2002).

NEPHROPEXY

Nephroptosis has been recognized and treated surgically since the 1800s, when nephropexy was described in Berlin by Hahn (Harrison, 1969). In one of the first urology texts, Hugh Hampton Young defined *nephroptosis* as the inferior displacement of the kidney by more than 5 cm, when the patient moves from a supine to an erect position (Young and Davis, 1926). William Mayo diagnosed "floating kidneys" in 20% of random patients, and William Osler (1892) had recorded over 700 cases of nephroptosis. The ptotic kidney has also been blamed for abnormalities and symptoms in other organs, including stomach, bowel, and pancreas. It has been estimated that over 170 innovative procedures have been described to adhere the kidney to the retroperitoneum to prevent descent while standing (Kelly, 1910; Deming, 1930; Moss, 1997).

Unfortunately, in the past nephroptosis was frequently cited as the cause of a variety of symptoms, many unrelated to the kidney, and surgical repair was greatly overutilized. Because repair did not afford patients relief of symptoms, this diagnosis was questioned to the point of extinction. Time has borne out that there are patients in whom positional changes can result in obstruction of the collecting system or blood flow to the kidney. These patients may benefit from laparoscopic surgical repair.

Indications

Nephroptosis is characterized by a significant downward displacement (>5 cm) of the kidney as the patient moves from the supine to the erect position, causing pain in the abdomen or flank. The most severe manifestation causes *Dietl's crisis,* which is heralded by severe colicky flank pain, nausea, chills, tachycardia, oliguria, and transient hematuria or proteinuria (Irwin, 1948). The exact cause of pain is not known but is likely to be from transient renal ischemia or urinary tract obstruction (Moss, 1997). Patients who are symptomatic are generally young, thin females, who complain of pain in the erect position as the primary symptom. Several different means of evaluating the ptotic kidney are available. **The diagnosis can be made using color Doppler imaging in the supine and upright positions where diminished blood flow to the ptotic kidney in the upright position would be detected. Also, erect and supine intravenous urograms or renal scans documenting obstruction are good diagnostic studies for nephroptosis. Descent of the symptomatic kidney by two vertebral bodies and obstruction or diminished flow to the symptomatic side should be documented before surgical repair.**

Procedure

In the transperitoneal approach, a three-port midline configuration is used (see Fig. 51–4). The kidney is fully mobilized by freeing the lower, lateral, posterior attachments (Fig. 51–18). Once cleared, the fascia overlying the quadratus lumborum and psoas muscle is easily exposed. Beginning at the upper pole, three interrupted sutures are placed laparoscopically between the lateral edge of the capsule of the kidney and the fascia overlying the quadratus lumborum or psoas muscle (Fig. 51–19). The subhepatic parietal peritoneum may also be sutured to the anterior portion of the renal capsule to provide additional support for the kidney. Sutures with a preplaced LapraTY clip (Ethicon Endosurgery, Cincinnati, OH) can facilitate this procedure. The suture with a LapraTy clip is used for the initial pass though the quadratus lumborum or psoas muscle and then a second LapraTy is used to secure the suture on the kidney.

A retroperitoneal approach can also be used with success and may be useful in patients with prior abdominal surgery (Chueh et al, 2002; Ichikawa et al, 2003; Matsui et al, 2004). Symptomatic evaluation, along with erect and supine radiographic studies, is performed 12 weeks after surgery to evaluate the efficacy of the repair.

Results

In a series of 26 symptomatic patients with renal ptosis evaluated with Doppler ultrasound and isotope renal scans in the supine and upright positions, Strohmeyer and colleagues (2004) showed improved blood flow and decreased symptoms in 20 of 26 patients and marked improvement in symptoms in the remaining 6 patients treated laparoscopically.

McDougall and associates (2000) reported a series of laparoscopic nephropexy done in 14 women with right flank pain and documented nephroptosis. At a mean follow-up of 3.3 years, patients reported an average of 80% improvement in pain (range: 56% to 100% improvement).

Fornara and coworkers (1997) reported their results from 23 patients (22 women and 1 man) who underwent laparoscopic nephropexy. The mean operative time was 60 minutes, and there were no complications or conversions to an open procedure. Split renal function while erect improved from 38% preoperatively to 47% postoperatively ($P = .03$). At a mean follow-up of 13 months (range: 2 to 37 months), pain intensity had improved in 21 patients. The laparoscopic group was retrospectively compared with a series of 12 patients treated with open nephropexy. Follow-up in the open group at a mean 7.6 years showed 4 patients free of pain, 5 with occasional pain, and 3 without any resolution of symptoms.

PYELOLITHOTOMY AND URETEROLITHOTOMY

The treatment of renal and ureteral stones has gone through dramatic changes with the advent of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy, and ureteroscopic laser lithotripsy. These new techniques have almost eliminated the need for pyelolithotomy to remove renal stones; however, there are some patients who benefit from laparoscopic pyelolithotomy. **Individuals to be considered for this approach include those who have failed ESWL or percutaneous or ureteroscopic procedures, patients with unusual anatomy such as the pelvic kidney, and patients with stones resistant to fragmentation, such as those of cystine composition. In addition, patients with**

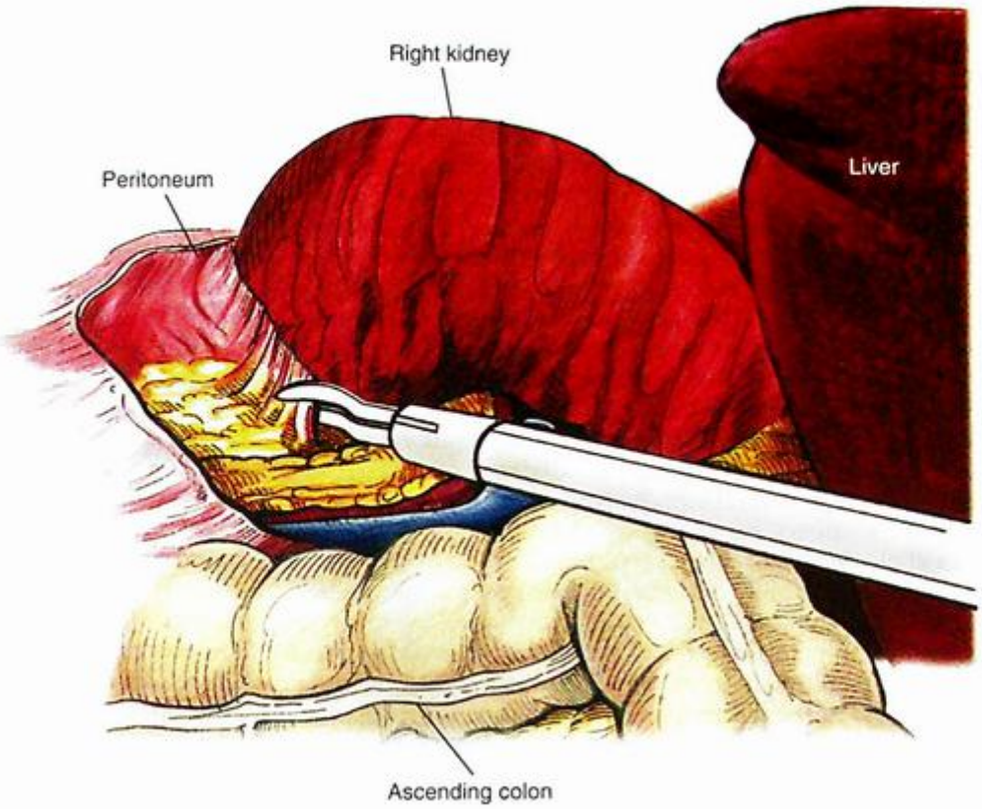

Figure 51–18. The kidney is stripped of overlying Gerota's fascia down to the surface of the renal capsule. All remaining attachments are divided, allowing full mobility for repositioning.

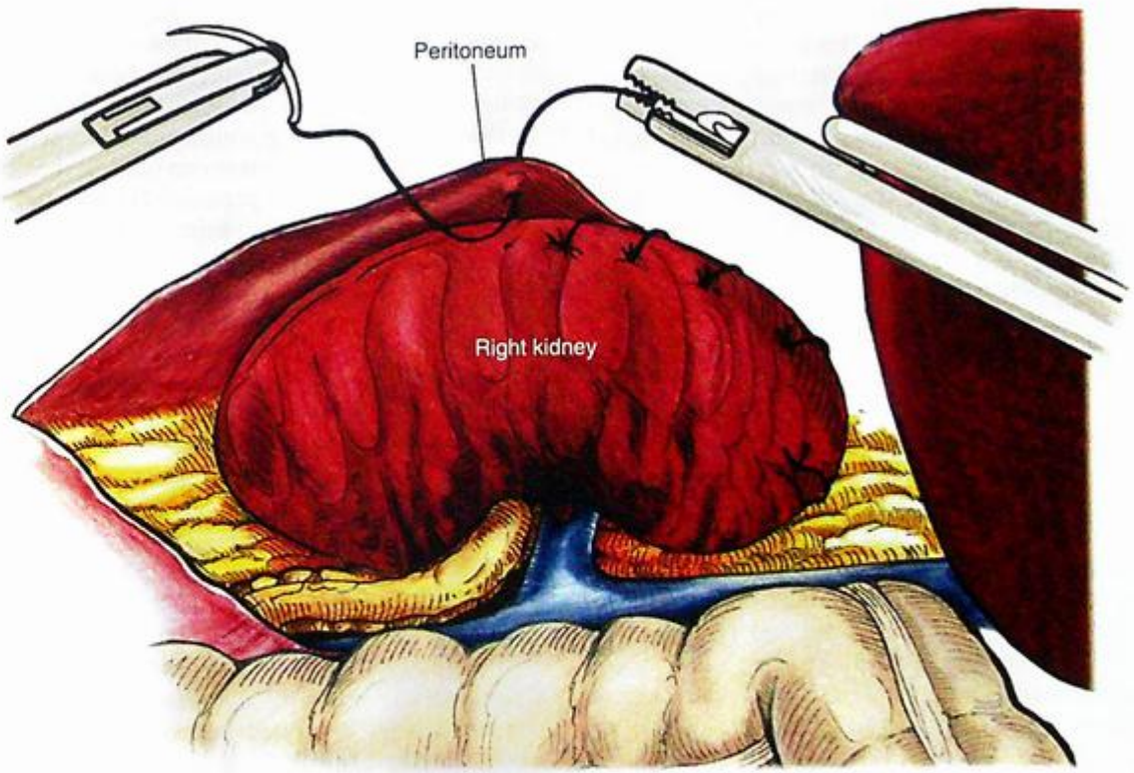

Figure 51–19. Once the kidney is free of lateral and posterior attachments, multiple 2-0 sutures are placed into the capsule and the lateral edge of the fascia overlying the abdominal wall.

ureteropelvic junction obstruction and renal stones undergoing laparoscopic reconstruction can have stones removed during the same procedure using a flexible cystoscope (Ball et al, 2004; Whelan et al, 2004). Successful laparoscopic transperitoneal pyelolithotomy has been reported in ectopic kidneys with stones as large as 4 cm (Chang and Dretler, 1996; Harmon et al, 1996; Hoenig et al, 1997). Laparoscopic anatrophic nephrolithotomy has also been described in several small series with low morbidity and preservation of kidney function (Gaur et al, 2002; Deger et al, 2004).

When stones develop in pelvic or ectopic kidneys, treatment may be challenging. ESWL is acceptable for initial treatment but may not be successful because of the stones' composition or position or the anatomy of the renal collecting system. Percutaneous techniques risk damage to anomalous vasculature with subsequent bleeding. To avoid damage to vessels in ectopic kidneys, several authors have used laparoscopic visualization to direct percutaneous access (Eshghi et al, 1985; Toth et al, 1993; Troxel et al, 2002).

In 1994, Gaur and colleagues reported successfully removing five of eight stones utilizing retroperitoneal laparoscopic pyelolithotomy. In two patients, the kidney was not accessed because of failure in retroperitoneal dilatation techniques. Once access to the kidney was obtained, the stones were successfully removed in five of six cases. In one case, attempts to palpate the stone in the renal pelvis before pyelotomy dislodged the stone into an upper pole calyx requiring open conversion for removal. Others have also described the retroperitoneal approach to kidney stones (Goel and Hemal, 2003).

Ureteral stones can also be approached laparoscopically. In a series of 31 patients with ureteral stones, Hemal and associates (2003) performed ureteral lithotomy with intracorporeal suturing of the ureterotomy with a mean operating room time of 67 minutes and a mean hospital stay of 2.4 days. Gaur and colleagues (2002a, 2002b) performed laparoscopic ureterolithotomy in 93 patients with only eight failed attempts, which were due to difficulty in locating the stone. The mean operating room time was 80 minutes. In many patients the ureter was not closed and subsequent urine leak ensued. When the ureter was closed, urine leak was seen for 3 days, compared with 6 days when the ureter was not closed.

CALYCEAL DIVERTICULECTOMY

The management of calyceal diverticula with stones has always been challenging. The classic management was by open surgery. Partial nephrectomy and open marsupialization with fulguration of the diverticulum and even total nephrectomy have been used in the past (Devine et al, 1969; Williams et al, 1969; Middleton and Pfister, 1974; Timmons et al, 1975; Wulfsohn, 1980; Donnellan et al, 1999). Advances in less invasive equipment and techniques have changed the treatment of these difficult cases. **The ideal means of treating symptomatic calyceal diverticula includes removal of the stones and widening of the infundibulum to prevent urine stasis or ablation of the diverticula cavity.** Percutaneous treatment is most often used for treatment in symptomatic cases (Donnellan et al, 1999). ESWL and ureteroscopy have also been applied, but anatomic factors can result in a lower rate of achieving stone clearance (Jones et al, 1991; Pang et al, 1992; Stream et al, 1992). Recurrence of symptoms and stones can occur if the diverticulum has not been ablated.

Indications

Large peripheral diverticula, those located medially near the renal hilum and those in an anterior location, may be treated using laparoscopic techniques. A laparoscopic approach allows evacuation of the stone fragments, careful inspection, and fulguration of the cavity using argon beam or standard monopolar coagulation. Additionally, perirenal fat or biological agents can be inserted into the cavity to decrease the chance for recurrence.

Procedure

As with the treatment of renal cysts, the location of the diverticulum dictates a transabdominal or retroperitoneal approach. Gerota's fascia is opened and perirenal fat is cleared from the surface of the kidney. **The exact location of the diverticulum in the kidney can be difficult to find. Once Gerota's fat has been removed from the kidney, the diverticulum can usually be identified by the presence of dense adhesions from the surface of the kidney to surrounding fat and a "dimpling" on the surface of the kidney.** Intraoperative fluoroscopy or ultrasonography may be necessary to confirm the correct location of the diverticulum and stones before attempting entry into the renal parenchyma. Once located, the thin parenchyma over the cavity is cauterized and opened. Spoon graspers are useful for removing stones intact. Milk of calcium stones and many small stone fragments can be encountered, despite the appearance of a solitary dense stone on conventional radiographs. Argon beam coagulation or monopolar cautery is used to fulgurate the lining of the cavity to prevent recurrence. Methylene blue can be given intravenously, and careful inspection allows detection of blue urine in the cavity, indicating communication with the collecting system. The collecting system can be closed using laparoscopic suturing techniques and perirenal fat inserted into the cavity. Stenting and drainage are performed as indicated.

Results

Several authors have reported successful laparoscopic treatment of calyceal diverticula. This approach is associated with high stone-free rates and allows definitive management of the diverticulum to decrease the incidence of recurrence (Gluckman et al, 1993; Ruckle and Segura, 1994; Harewood et al, 1996; Wolf, 2000; Miller et al, 2002; Canales and Monga, 2003).

LAPAROSCOPY FOR RENAL MALIGNANCY

The initial use of laparoscopy in the treatment of renal malignancies initially generated controversy based on fear of inadequate cancer control. Early laparoscopic experiences in the surgical and gynecologic literature raised concerns regarding the risk of port site seeding, inadequate surgical margins, and inaccurate staging due to morcellation. Five- and 10-year follow-up studies established the role of laparoscopy in safely

treating urologic cancers. Experience has borne out that laparoscopic removal of urologic cancers provides equivalent cancer control when compared with traditional open approaches.

Trocar or Port Site Recurrence

Port site recurrence after laparoscopic procedures in cancer patients has been described in the general surgery, gynecology, and urology literature. In a broad survey of over 1050 European general surgery programs, port site recurrence occurred in 17% of laparoscopic cholecystectomies for incidental gallbladder carcinoma and in 4.6% of cases of colorectal cancer (Paolucci et al, 1999). Studies have demonstrated that tumor cells may be deposited at the port site during laparoscopy either directly from contaminated instruments or indirectly by way of insufflation gas (Neuhaus et al, 1998; Schaeff et al, 1998; Whelan and Lee, 1999).

In the urologic literature, there have been rare reports of laparoscopic port site seeding of transitional cell carcinoma, adrenal, prostate, and renal cell carcinomas. Bangma and coworkers (1995) reported on the first patient with port site seeding from prostate cancer after laparoscopic pelvic lymph node dissection (LPLND). In contrast, Cadeddu and associates (1996) found no cases of port site seeding after 372 cases of LPLND. A review of a subset of 40 patients with positive pelvic lymph nodes for prostate cancer (at the time of LPLND) revealed no instance of port site seeding up to 3 years after surgery. Furthermore, there was no acceleration in the natural history of the disease after laparoscopic pelvic lymph node procedures (Kavoussi et al, 1993) (Table 51–3).

In the laparoscopic staging and treatment of transitional cell carcinoma, there have been seven reports of port site seeding (Stolla et al, 1994; Anderson and Steven, 1995; Ahmed et al, 1998; Elbahnasy et al, 1998; Altieri et al, 1998; Otani et al, 1999; Ong et al, 2003). In three instances, port site recurrence developed after laparoscopic staging with a biopsy or LPLND of a primary bladder tumor and in one case laparoscopic staging and biopsy of the kidney. In one of three cases related to nephrectomy, seeding developed in a patient with a tuberculous atrophic kidney containing unsuspected transitional cell carcinoma.

To date, there have been four reports of port site seeding after laparoscopic radical nephrectomy for renal cell carcinoma. In a series of 94 laparoscopic radical nephrectomies with specimen morcellation, one patient with T3 N0 M0 (Fuhrman grade IV/IV) disease suffered a solitary recurrence at one trocar site, 25 months after radical nephrectomy (Fentie et al, 2000). In the second case, a patient with a T1 N0 M0 renal cell carcinoma (Furhman grade II) underwent transperitoneal radical laparoscopic nephrectomy with morcellation of the specimen. Five months later, the patient developed disseminated metastatic renal cell carcinoma, carcinomatosis, and recurrence at all the trocar sites (Castilho et al, 2001). Port site recurrence has been reported in one radical HALN. A patient with a 10-cm T2 N0 M0, Fuhrman grade III, renal cell carcinoma was without initial tumor violation and negative surgical margins but had the specimen delivered intact through the hand port without entrapment. Specific delivery through the hand port orifice or wound (with wound protector) was not detailed. At 9 months after nephrectomy, however, a 6 × 5-cm hand port site mass was seen. The patient was treated with wide local excision and immunotherapy (Chen et al, 2003) (Fig. 51–20). Finally, at 39 weeks after left retroperitoneoscopic radical nephrectomy, Iwamura and colleagues (2004) reported the most recent abdominal wall recurrence in a patient with a primary T3a, Fuhrman grade II, clear cell renal cell carcinoma. Importantly, tissue entrapment was not used in this case.

The exact incidence of laparoscopic port site seeding with recurrence after laparoscopic radical nephrectomy is not known. However, wound metastases after open radical nephrectomy for renal cell carcinoma are reported in approximately 0.4% (2 of 518) of cases (Uson, 1982). In open colon surgery for known cancer there is a 1.5% wound recurrence rate reported in the literature (Reilly et al, 1996). In a retrospective multicenter study, with a mean follow-up of 19.2 months (range: 1 to 72 months; 51 with greater than 2 years' follow-up), Cadeddu and coworkers (1998) reported no port site recurrence from laparoscopic nephrectomy for renal cell carcinoma in 157 cases. Comparison of long-term open versus laparoscopic nephrectomy by Portis and others (2002) demonstrates no significant differences in local or distant metastatic recurrence rates, with no wound or port site recurrence.

Several steps should be taken to prevent port site seeding and tumor spillage. First, the basic principles of cancer surgery should be followed. Direct handling of the tissue must be minimized and all attempts made to prevent violation of the tumor. An en-bloc dissection to obtain an adequate surgical margin should be performed. All potentially cancerous tissue should be entrapped in an impermeable sack before extracting though a trocar site or hand-assisted incision. The field should be draped before morcellation or extraction (Urban et al, 1993) (Table 51–4).

Morcellation of specimens for extraction has raised concerns about accurate pathologic staging. CT has been proved

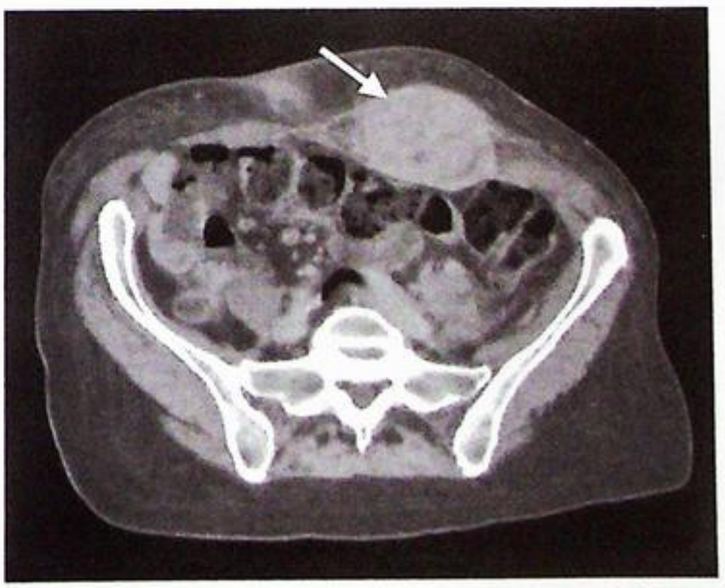

Figure 51–20. A patient with a 10-cm T2 N0 M0 Fuhrman grade III renal cell carcinoma was treated using hand-assisted laparoscopic nephrectomy with intact specimen removal through the hand port. Nine months after surgery he presented with 6 × 5-cm mass that was found to be renal cell carcinoma. (Courtesy of Y. T. Chen.)

Table 51–3. Trocar or Port Site Recurrence (PSR) after Laparoscopic Surgery

Author	Pathology (Primary TNM Stage, Grade)	Primary Laparoscopic Approach	Recurrence Identification/ Month Post-Op	Management
Iwamura et al, 2004	Renal cell carcinoma	Retroperitoneoscopic, extracted intact without entrapment sac or wound protector	CT mass in left flank at 39 mos	Refused further treatment
Chen et al, 2003	Renal cell carcinoma T2N0M0, Fuhrman III/IV)	Hand-assisted, transperitoneal	Clinically palpable with CT confirmation at 9 months	Operative excision, biopsy, and immunotherapy referral
Castilho et al, 2001	Renal cell carcinoma (morcellated specimen, stage not reported, Fuhrman IV/IV)	Transperitoneal	Abdominal masses identified on CT	Interferon-alfa immunotherapy. Patient died 8 months post nephrectomy.
Fentie et al, 2000	Renal cell carcinoma (T3N0M0, Fuhrman IV/IV)	Transperitoneal	Port site discomfort with solid mass CT confirmation at 25 months	Surgical excision, every 3-month clinical and radiographic (CXR, CT) follow-up. No evidence of disease at 35 months post nephrectomy.
Ong et al, 2003	Ureteral transitional cell carcinoma (T1NxMx, "high grade")	Extraperitoneal	Clinically palpable with CT confirmation at 12 months	Operative excision with negative pathologic margins and 18-month follow-up
Otani et al 1999	Transitional cell carcinoma (TNM not reported, "high grade"). TCC invasive into renal parenchyma with one positive hilar lymph node	Extraperitoneal.	Painful mass at trocar site, with CT confirmation at 3 months	Ultrasound biopsy for confirmation. No other management reported.
Ahmed et al, 1998	Transitional cell carcinoma (stage not reported, "high grade"). TCC invasion with small vascular focus of invasion	"Laparoscopic" nephrectomy	Painful umbilical port site 8 months post nephrectomy	Open positive biopsy with CT follow-up demonstrating residual local recurrence at renal fossa, along psoas muscle, and hepatic metastases. Patient referred for chemotherapy. No follow-up was reported.
Andersen et al, 1995	Transitional cell carcinoma T4bNxM0, grade 2	Transperitoneal laparoscopic staging and biopsy	Palpable nodule "shortly after" biopsy	Open exploration with positive biopsy. Tumor involvement of urachus, anterior abdominal wall, and preaortic lymph nodes
Altieri et al, 1998	Transitional cell carcinoma (T2NxM0, grade 2 (at time of LPLND; T3N0M0, grade 3 after open cystectomy and ureterosigmoidoscopy	Transperitoneal	Right lower extremity edema 3 months post cystectomy, with positive CT for right pelvic lymphadenopathy and 3 cm right superior port site mass	Open biopsy positive for TCC. Patient refused chemotherapy and died 3 months later.
Bangma et al, 1995	LPLND for CaP (T3N1M0, grade 2)	Transperitoneal	Clinically palpable at 6 months	Aspiration cytologic confirmation with no other diagnostic or therapeutic maneuvers. Patient died 8 months post lymphadenectomy.
Stolla et al, 1994	LPLND for transitional cell carcinoma (T3N1M0, grade 2)	Transperitoneal	Clinically palpable subcutaneous masses at multiple port sites, with CT confirmation	Observation secondary to previous post-LPLND failure of M-VAC chemotherapy and external-beam irradiation. Hepatic mass identified on CT. Patient died 1 month after PSR recognition.
Matsui et al, 2004	Squamous cell carcinoma of the renal pelvis (T3N0M0)	Retroperitoneoscopic nephroureterectomy	Clinically palpable with CT confirmation at 6 months	Surgical excision with mesh repair of aponeurotic defect. Disease free at 6-month follow-up from excision.
Rassweiler et al, 2003	Metastatic small cell carcinoma to adrenal. (TNM not reported) Nonseminomatous germ cell tumor to the retroperitoneum. (TNM not reported)	Not reported	CT (adrenal lesion)/month not reported	Not reported. Each patient died within 6 months after identification of PSR.
Chen et al, J Urol 2002	Metastatic small cell carcinoma to adrenal (stage IIb small cell carcinoma of lung)	Transperitoneal	Clinically palpable with CT confirmation at 5 months	Palliative external-beam irradiation; patient died 10 10 months post-adrenalectomy.

CT, computed tomography; LPLND, laparoscopic lymph node dissection; CXR, chest radiograph; CaP, carcinoma of the prostate.

to be an effective tool for planning surgery and predicting pathologic findings. The overall accuracy of CT in staging renal cell carcinoma ranges from 72% to 90% (Johnson et al, 1987; London et al, 1989; Parks and Kelley, 1994; Zagoria et al, 1995). Roberts and colleagues (2005) retrospectively reviewed the records of 296 patients treated for renal cell carcinoma with nephrectomy between 1990 and 1999 who had CT or MRI preoperatively. Pathologic results were then compared with preoperative imaging for staging comparison. Of the patients with clinical T1 tumors, 67% had pathologic T1 tumors and 31% had pathologic T3a tumors. Mean tumor size for the pT1 group was 3.9 cm, and it was 3.8 cm for the pT3a patients. Kaplan-Meier analysis showed the 5-year recurrence-free survival to be the same for the pT1 (91%) and pT3a (98%) groups.

In a review of 172 renal tumors treated with open radical nephrectomy, Shalhav and coworkers (1998) correlated the preoperative CT-based clinical stage with the final pathologic tumor stage. They found 1 tumor (0.6%) to be understaged and 7 tumors (4%) overstaged by preoperative CT. They concluded that clinical CT staging of low-stage renal tumors is reliable and tends to overstage rather than understage renal tumors. Currently, if a patient with clinically localized renal cell carcinoma is found to have microscopically advanced disease, there is no effective adjunct therapy. Thus, morcellation does not alter subsequent follow-up, treatment, or survival in pT1 and pT3a patients. The long-term follow-up in laparoscopic series in which kidneys are morcellated compared with open radical nephrectomy shows equivalent cancer-free survival (Barrett et al, 1998; Ono et al, 2000; Chan et al, 2001). When pathologic staging is required, the specimen may be removed intact through a low midline or Pfannenstiel incision. Landman and coworkers (2000) reported on the ability of pathologists to read renal specimens before and after morcellation. They found that morcellation of kidneys after radical nephrectomy did not change the determination of histopathology, grade, or local invasion compared with findings in nonmorcellated specimens.

TRANSPERITONEAL RADICAL NEPHRECTOMY

Radical nephrectomy for patients with clinically localized renal cell carcinoma provides the best opportunity for cure. However, the pain, morbidity, and cosmetic changes associated with an open flank incision can be significant. The laparoscopic approach to renal cell carcinoma has evolved into a safe and effective minimally invasive alternative to open surgery. The disease-free and cancer-specific survival rates for laparoscopic radical nephrectomy are comparable with those of open surgery (Permpongkosol et al, 2005) (Table 51–5).

Table 51–4. Prevention of Port Site Seeding during Laparoscopy for Malignancy

- Avoid resection and excision of tissue in presence of carcinomatosis.
- Isolate ascitic fluid to be sent for cytology from all wounds.
- Minimize direct tumor handling to prevent iatrogenic tumor violation.
- Ensure wide en-bloc dissection of tumor and surrounding tissues.
- Place all tissues within an impermeable laparoscopic sac before morcellation or tissue extraction.
- Re-drape port sites at time of tissue removal.
- Remove all possible contaminated instrumentation from the newly towel-draped operative field.
- Change the surgeons' and technicians' gloves before formal peritoneal closure.

Indications and Contraindications

Laparoscopic radical nephrectomy is indicated in patients with T1 to T3a renal tumors. In addition, laparoscopic radical nephrectomy has been applied to patients with advanced stages of renal cell carcinoma and those with large tumors (Walther et al, 1999; Pautler et al, 2002). Some patients with tumor thrombus extending into the renal vein can also be treated with laparoscopic radical nephrectomy (Desai et al, 2003). Patients with a prior history of ipsilateral renal surgery, perinephric inflammation, or extensive intra-abdominal surgery are still candidates for laparoscopic surgery, based on the experience of the surgeon and an informed patient who understands that it may be necessary to convert to open surgery. Although tumors with a small vein thrombus have been treated laparoscopically, with current limits in technology renal tumors with thrombus extending to the level of the liver represent a challenge to the laparoscopic approach.

Preoperative Evaluation

The preoperative evaluation of the patient with a suspected renal malignancy is the same whether an open or a laparoscopic approach is planned. A complete metastatic evaluation is necessary and includes an abdominal CT and chest radiograph or chest CT. A bone scan is obtained in patients with elevated serum calcium or alkaline phosphatase levels and in those with symptomatic bone pain. If there is a question of renal vein tumor thrombus, then an appropriate study (MRI, venography, sonography, or three-dimensional CT) to preoperatively evaluate the vein is required. Contralateral renal function is assessed before radical nephrectomy by measuring serum creatinine levels and evaluating the kidney appearance on contrast medium–enhanced CT. In equivocal cases, a functional renal scan and 24-hour urinary creatinine clearance studies can be obtained. The presence of renal insufficiency should prompt the surgeon to consider partial nephrectomy.

Positioning and Trocar Placement

Patient positioning and trocar placement are similar to those described for the simple nephrectomy (see Fig. 51–4). Three ports are generally sufficient to complete the procedure, although a fourth trocar may be necessary for organ entrapment or liver or bowel retraction during nephrectomy.

Procedure

Reflection of the Colon

The colon is reflected to provide adequate visualization of the anterior surface of Gerota's fascia. On the right, the duodenum is mobilized medially, using the Kocher maneuver, until the vena cava is clearly visualized.

Table 51–5. Results of Laparoscopic Radical Nephrectomy

Author	Approach	Indication	OR Time	LOH	EBL	Conversion	Complications	Morcellation	Intact	Follow-up	Local Recurrence	Metastatic Disease

*Major complications.
LOH, length of hospitalization; EBL, estimated blood loss.

Dissection of the Ureter

The midureter is located in the retroperitoneal fat medial to the psoas muscle. During proximal mobilization, the gonadal vein is usually first encountered and may be elevated with the ureter. The ureter is located just posterior to the gonadal vein, anterior to the psoas muscle. The psoas tendon is a reliable landmark when searching for the gonadal and ureter (Fig. 51–21). Once located, the ureter is elevated, revealing the psoas muscle and traced proximally to identify the renal hilum.

Mobilization of the Lower Pole

As opposed to a simple nephrectomy, the radical nephrectomy preserves Gerota's fascia so that the renal parenchyma and mass are not visualized during this operation. Once the ureter is mobilized up to the ureteropelvic junction, forceps are inserted beneath Gerota's fascia and lower pole along the psoas fascia. The specimen is lifted superolaterally; and with the use of the suction-irrigator and electrosurgical scissors, the inferior and posterior sidewall attachments are divided. The inferior cone of Gerota's fascia lateral to the ureter is also divided. To facilitate this dissection and assist with lateral specimen retraction during the hilar dissection, the fourth port may be necessary, as outlined earlier. Dissection of the renal hilum requires (1) the kidney to be displaced laterally to render the renal vessels taut and (2) the bowel must be retracted medially by gravity or with assistance from a laparoscopic retractor to fully expose the renal hilum.

Securing the Renal Blood Vessels

During right-sided radical nephrectomies, retraction of the liver to improve visualization of the renal hilum and upper pole is usually necessary and can be accomplished by passing a 3- or 5-mm instrument through a fourth trocar placed below the ribs in the anterior axillary line. Visualization of the renal vein is accomplished by using the tip of the irrigator-aspirator to dissect individual layers of lymphatics and tissue from the lower pole of the kidney to the renal hilum. The renal artery and vein are usually individually dissected and divided. The surgeon places the renal hilum on gentle tension by lifting the lower pole laterally. With the use of the electrosurgical scissors and the suction-irrigator, the hilum is identified by moving cephalad along the medial aspect of the ureter and renal pelvis. From an anterior approach, the renal vein is first identified.

Once the renal vein is dissected, the renal artery can readily be identified and transected with the GIA stapler (Fig. 51–22). On the left side the gonadal, lumbar, and adrenal branches of the renal vein are identified and divided using either bipolar cautery, ultrasonic energy, or clips. The renal vein is ligated and transected with a GIA stapler. **If nylon or metal clips to secure renal branches are used, the surgeon must ensure that these clips are not included in the jaws of the stapler. The clips will prevent anticipated activation of the staples and result in bleeding.** Alternating clips can be used to secure the artery and vein. When using clips, three should be placed proximally to minimize the risk of dislodgement. Extended lymphadenectomy can be readily performed once the vessels are identified and dissected circumferentially. On occasion (i.e., large tumors, bleeding) one may need to transect the renal vein before occluding the artery.

Dissection of the Upper Pole

The decision whether to remove the ipsilateral adrenal with the specimen determines the superior margin of dissection. If

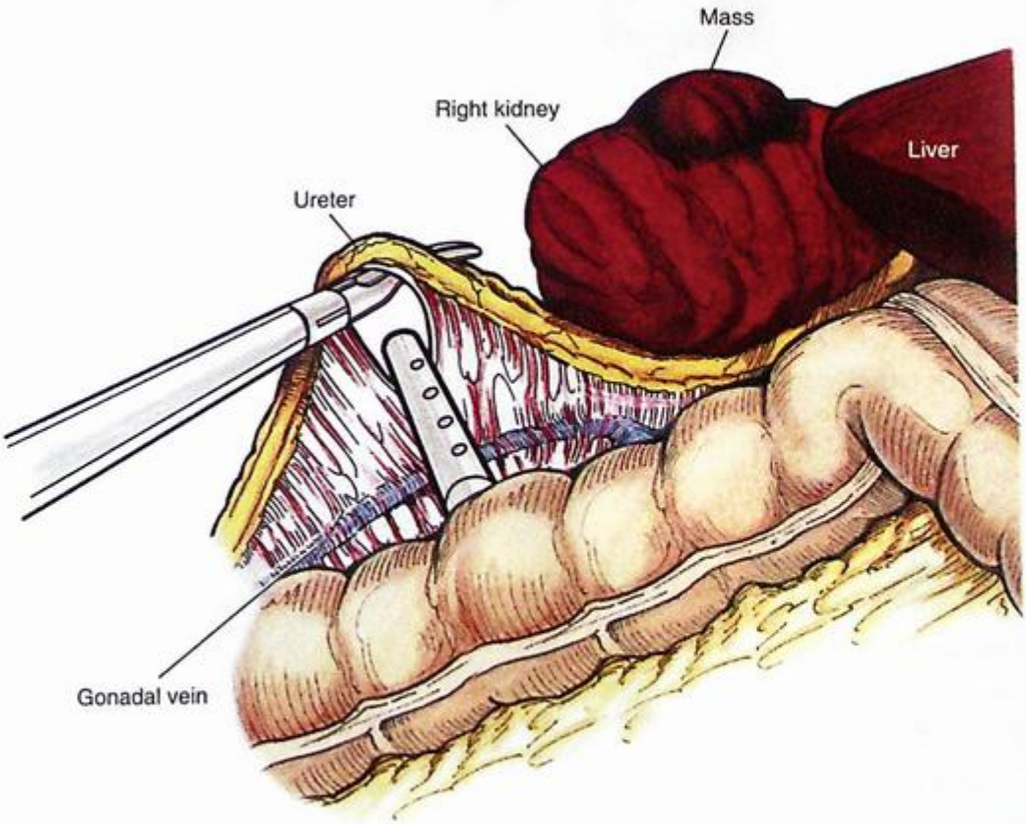

Figure 51–21. The ureter alone or the ureter and gonadal vein together are elevated with a grasper and mobilized cephalad. As the cephalad dissection approaches the renal hilum, the gonadal vein crosses anterior to the ureter. On the right side the angle of insertion from the gonadal to the vena cava can be a source of significant bleeding if torn during elevation.

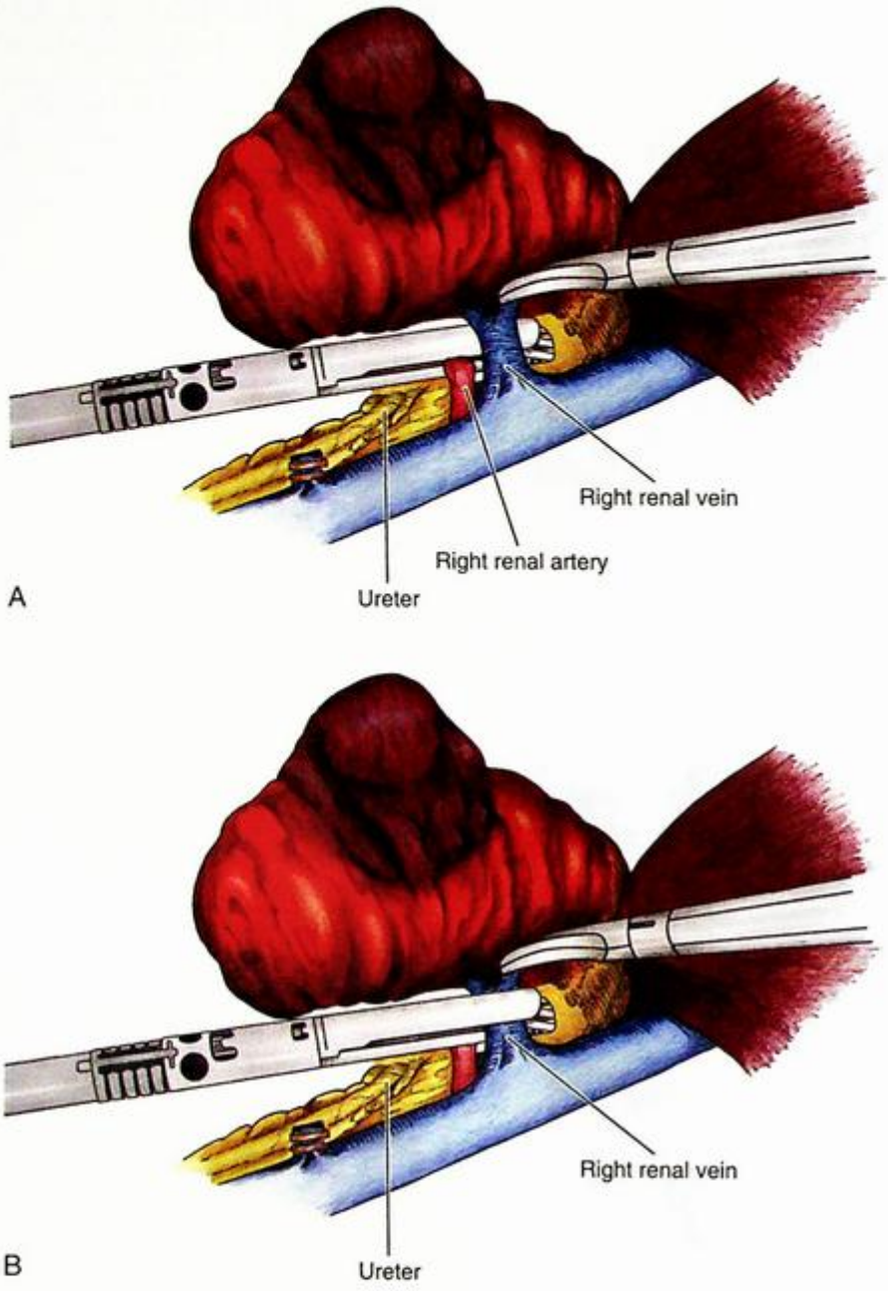

Figure 51–22. **A,** After mobilization of the lower pole and posterior attachments, the renal hilum is exposed. The vein is displaced to expose the artery, and a plane is dissected to allow the introduction of the vascular GIA stapler. **B,** The renal vein is also divided with an endovascular vascular stapler after the artery or arteries have been secured. After passing the tips of the stapler around the renal vein, the vein is positioned in the middle of the jaws of the stapler.

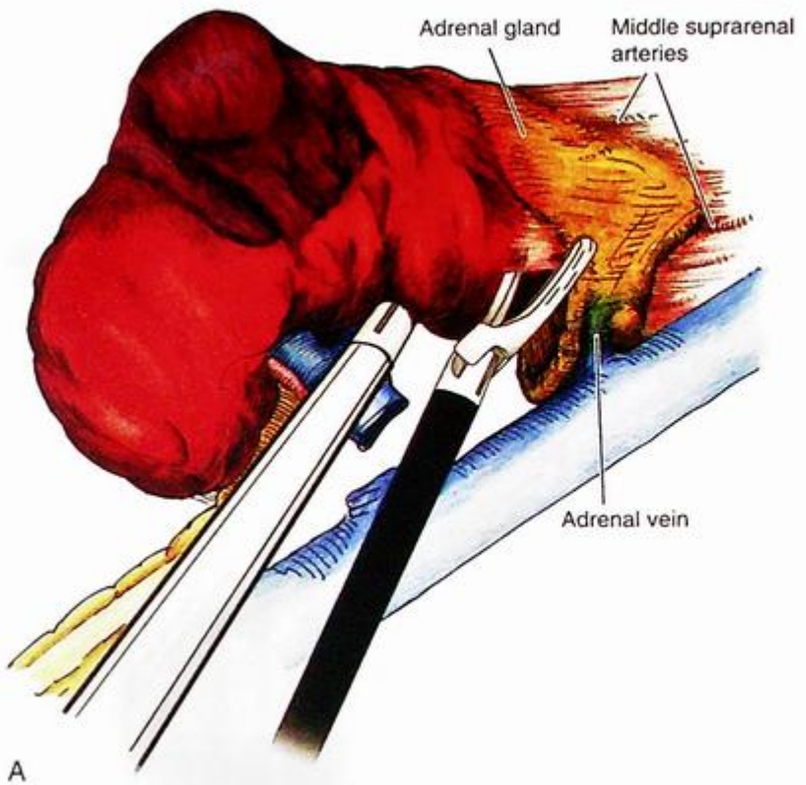
the adrenal gland is not removed, upper and lateral attachments to Gerota's fascia are incised. Care must be taken to avoid injury to the diaphragm at this point. If the adrenal gland is to be removed on the right side with the specimen, control and division of the adrenal vein is imperative. Dissection cephalad along the vena cava identifies the adrenal vein. Once it is divided, the superior, medial, and posterior attachments of the adrenal are mobilized (Fig. 51–23). For left-sided tumors, the GIA is placed proximal to the adrenal vein if the adrenal gland is to be taken with the specimen. If the gland is to be left, the GIA is positioned distal to the adrenal vein.

Specimen Entrapment and Extraction

Intra-abdominal entrapment of the excised specimen is performed to facilitate removal. If it is to be removed intact through an incision, a 15-mm deployable sac is recommended. It consists of a plastic bag attached to a self-opening, flexible metal ring. The primary advantage of a self-opening bag is that the specimen can be easily manipulated into the opening of the bag with a single grasper.

The retrieval device is 15 mm and thus needs to be placed through one of the 10-mm trocar sites after the trocar has been removed (Fig. 51–24). Once the specimen is placed into the sac, the opening is withdrawn through the trocar site. Using electrocautery, the trocar site is enlarged to allow extraction of the specimen, and the specimen and sac are protected by the surgeon's finger positioned through the trocar site alongside the specimen (Fig. 51–25). Alternatively, the kidney can be removed through a Pfannenstiel incision.

If the specimen is to be morcellated, a LapSac (Cook Urological, Inc., Spencer, IN) fabricated from a double layer of plastic and nondistensible nylon should be used. This sac has been shown to be impermeable to bacteria and tumor cells even after its use for morcellation (Urban et al, 1993). The LapSac is prepared by passing a moistened hydrophilic wire alternating through every third hole in the sac. The sac is then



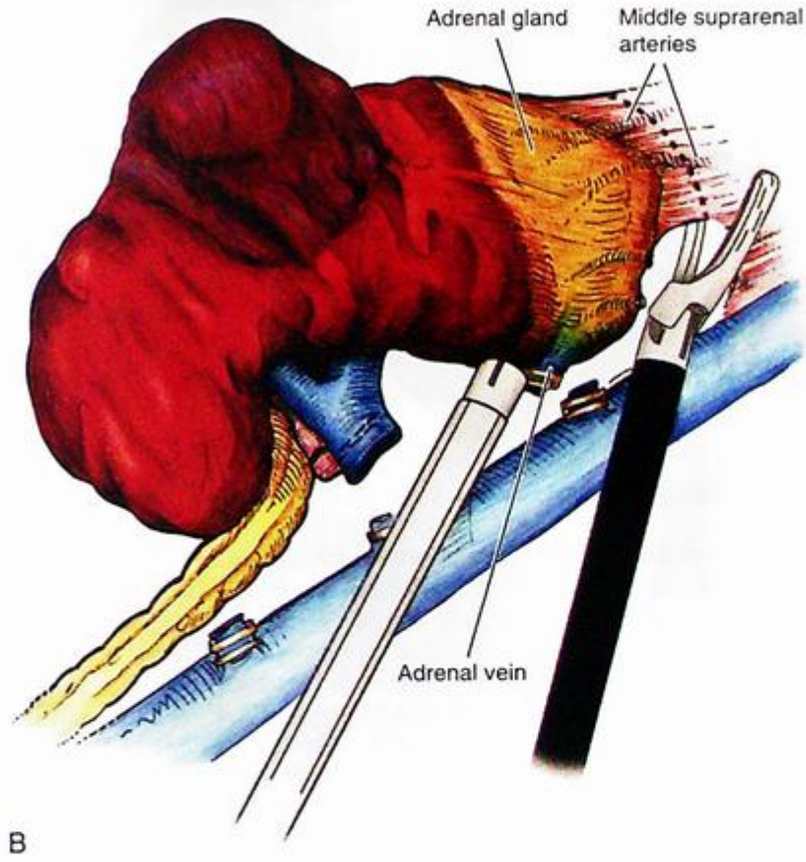


Figure 51–23. **A,** Adrenal-sparing right radical nephrectomy. Bipolar or ultrasonic energy devices are used to release all adrenocolic attachments. Inferior retraction of the specimen facilitates exposure of this surgical plane. **B,** Inclusion of the adrenal gland with right radical nephrectomy can be readily accomplished using ultrasonic or bipolar shears to control the multiple arterial branches to the adrenal gland.

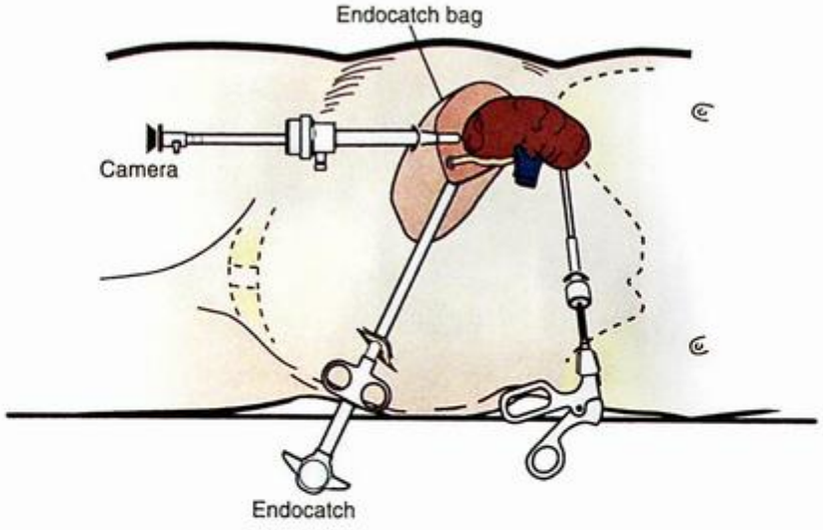

Figure 51–24. Placement of a specimen into an opened Endocatch device placed through an umbilical trocar site. Note that the camera is positioned in the lateral port and the specimen is maneuvered through the upper midline trocar. (From Bishoff JT, Kavoussi LR [eds]: Atlas of Laparoscopic Retroperitoneal Surgery. Philadelphia, WB Saunders, 2000.)

Figure 51–25. For removal of the intact specimen, a 4- to 6-cm incision is made including one of the trocar sites. The surgeon's finger protects the specimen and underlying structures from injury.

rolled from the bottom of the sac toward the top and the roll placed though a 12-mm trocar site with the free ends of the wire protruding from the trocar site. The trocar is then replaced alongside the wires. The sac is unrolled, and the wire will help to hold the mouth of the sac in an open position (Wakabayashi et al, 2003). Once introduced, it is held open with several graspers and the specimen is placed in the entrapment sac (Fig. 51–26). The wire is then withdrawn and the drawstring is grasped, tightened, and withdrawn into the 10-mm umbilical port. The neck of the sac is pulled tightly against the abdomen. Enlarging the trocar site by 1 cm will allow small amounts of tissue to protrude through the mouth of the sac. The morcellation process is performed by grasping only tissue protruding from the mouth of the sac with alternating bites from a ring forceps to break up the parenchyma and a Kocher clamp to pull apart the tenacious collecting system. Deep passes into the sac should be avoided because bowel resting near the edge of the sac can be inadvertently grasped and pulled into the sac and injured. All of the morcellated tissue is carefully collected and sent for histopathologic evaluation. The pneumoperitoneum should be preserved throughout the morcellation process so that the intra-abdominal portion of the sac can be monitored laparoscopically for possible perforation. Surgical towels are placed around the sac, and the entire surgical field is covered to prevent port site contamination with any spillage of the morcellated specimen (Fig. 51–27).

In a series comparing patient outcomes of 33 morcellated specimens and 23 intact kidneys, the patents had no difference in surgical time, postoperative pain, or hospital stay. The only

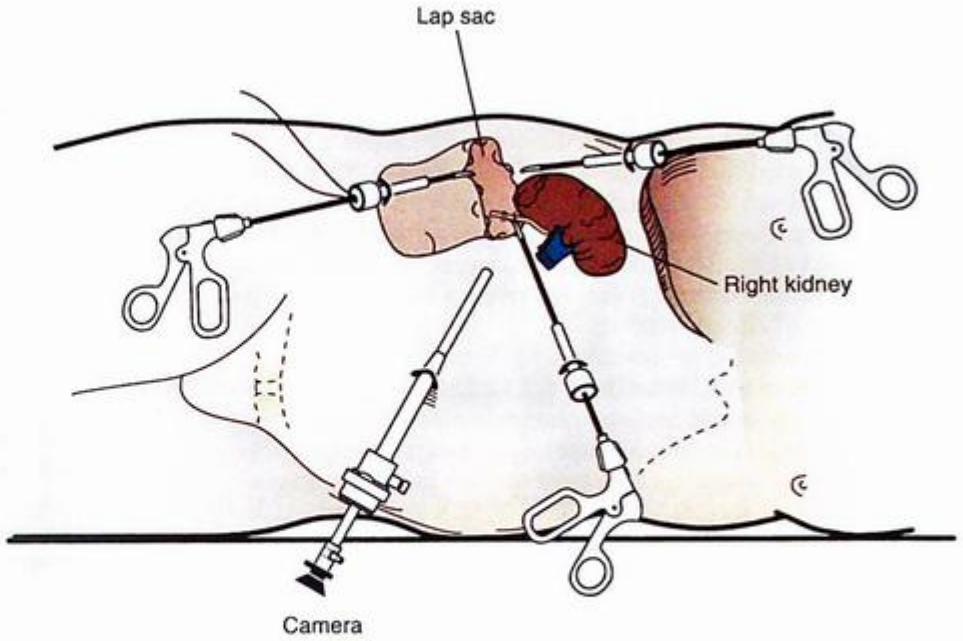

Figure 51–26. In cases in which the kidney is morcellated, the LapSac (Cook Urological, Inc., Spencer, IN) entrapment sac is introduced through the lateral 10-mm trocar site after passing a hydrophilic wire through the opening of the LapSac. After the entrapment sac is released within the abdomen, the 10-mm port is replaced and the sac is unfurled. The wire will facilitate opening the bag and placement of the specimen. A lateral 5- or 3-mm port may be necessary to assist with holding placement of the specimen inside the LapSac. Once the specimen is within the LapSac, the wire is removed, the bag cinched closed, and the opening withdrawn through the 10-mm trocar site.

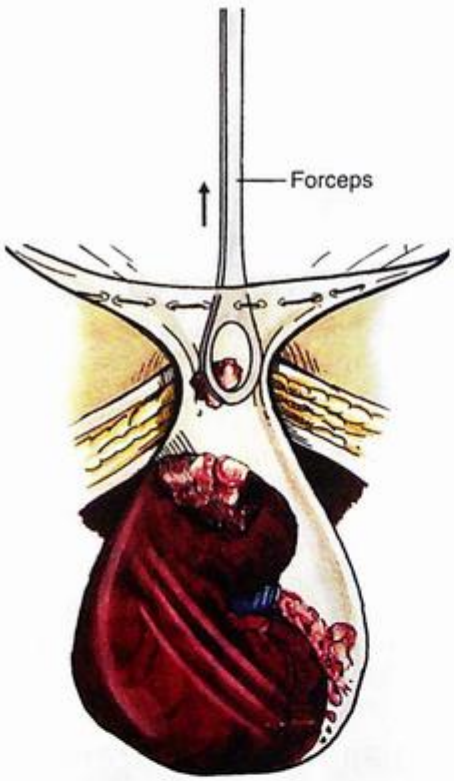

Figure 51–27. The entrapment sac is pulled tightly up against the abdominal wall with two hands pushing part of the specimen to appear through the opening of the LapSac. After the site is carefully draped, manual morcellation with ring forceps or a Kelly clamp can be used, and the entrapment sac is removed once the remaining specimen fragments are small enough to be extracted through the trocar site. Only the tissue visible from the opening is grasped. Blind passes into the bag may injure surrounding bowel segments.

Table 51–6. Laparoscopic Radical Nephrectomy for Renal Cell Carcinoma: Long-Term Cancer-Specific Survival in 248 Patients

Pathologic Stage	*No. of Patients*	*5 Year*	*10 Year*
T1a N0 M0	169	94%	88%
T1b N0 M0	69	90%	NA
T2 N0 M0	10	100%	NA

From Ono Y, Hattori R, Gotoh M, et al: Laparoscopic radical nephrectomy for renal cell carcinoma: The standard of care already? Curr Opin Urol 2005;15:75-78.

significant difference was the length of incision, which was a mean 1.2 cm in the morcellation group and 7 cm in the intact removal group (Hernandez et al, 2003).

Results

Five- and 10-year cancer survival data demonstrate that laparoscopic radical nephrectomy is equivalent to open radical nephrectomy in the treatment of renal cancer. Consequently, laparoscopic radical nephrectomy has become a standard of care for most renal malignancies. Ono and associates (2005) reported their results from 312 patients with histopathologically proved renal cell carcinoma. They found 5- and 10-year cancer-specific survival equal to that seen in open series (Table 51–6). Others have reported similar long-term survival using the laparoscopic approach. Portis and colleagues (2002) reported results from three different centers that started performing laparoscopic nephrectomy in the early 1990s. This report compared the surgical outcomes of laparoscopic and open nephrectomy for renal cancer with a median follow-up of 54 months (range: 0 to 94 months) for the laparoscopic group and 69 months (range: 8 to 114 months) in the open group. Kaplan-Meier analysis showed 5-year recurrence-free

survival of 92% for laparoscopy and 91% for open nephrectomy (P = .583). The 5-year cancer-specific survival was found to be 98% for laparoscopy and 92% for open surgery (P = .124).

In one of the largest published series, Saika and associates (2003) presented their results from 195 patients with pathologic stage T1 renal cell carcinoma treated with laparoscopic radical nephrectomy. At a median follow-up of 40 months (range: 2 to 121 months) they found a 5-year disease-free survival of 91% and overall 5-year survival of 94%. No patient developed port site recurrence.

Similar results were described by Fentie and colleagues (2000) in a series of 57 patients with T1 to T4 renal cell tumors followed for a mean of 33.4 months (range: 14 to 70 months). All patients were treated laparoscopically, and in each case the kidney was morcellated. Three patients developed metastasis. One patient with a pathologic T3 N0 M0, Fuhrman grade III/IV tumor developed a recurrence in the renal fossa and chest metastasis 14 months after surgery. A second patient with a pathologic T2 N0 M0, Fuhrman grade II/IV tumor developed metastasis to the bone 20 months after radical nephrectomy. Finally, a patient with a pathologic T3 N0 M0 Fuhrman grade IV/IV tumor developed a solitary port site recurrence more than 2 years after nephrectomy (Barrett and Fentie, 1999).

Permpongkosol and associates (2005) reported their experience comparing 67 laparoscopic nephrectomies with 54 patients undergoing open removal. All patients were clinical stage cT1 to cT2 N0 M0. There were no differences in patient age, tumor size, and estimated blood loss differences between the two procedures. The patients in the laparoscopic group, however, did consistently have a shorter period of hospitalization. The mean operating time was 193 minutes in the open group, which was faster than in the laparoscopic group (256 minutes). A significant operating time difference between the first 34 and last 33 laparoscopic radical nephrectomies existed, reinforcing the notion of the learning curve. **The calculated disease-free survival rates for laparoscopic and open radical nephrectomy were 95% and 89%, respectively, at 10 years, and the actuarial survival rates for laparoscopic and open radical nephrectomy were 86% and 75%, respectively, at 10 years.** These differences were not statistically significant, and no laparoscopic trocar site implantation was identified. One operative conversion (1.5%) was required in the laparoscopic group. Complications occurred in 10 patients (15%) in the laparoscopic group and 8 (15%) in the open group. Six laparoscopic patients required blood transfusions (8%), compared with 11 in the open group.

Gill and associates (2000) compared a series of 53 laparoscopic radical nephrectomies to 34 open radical nephrectomies. There were no differences in body mass index, age, American Society of Anesthesiologists status, tumor size, specimen weight, or surgical time between the two groups. In the 53 laparoscopic radical nephrectomies for tumors with a mean size of 4.6 cm (range: 2 to 12 cm), the mean specimen weight was 484 g. All specimens were removed intact. Minor complications occurred in eight patients (17%,) and major complications requiring conversion to open surgery occurred in two patients (4%). The laparoscopic approach was found to have less blood loss (P = .001), a shorter hospital stay (P = .001), lower analgesic requirements (P = .001), and shorter convalescence (P = .005) compared with open radical nephrectomy. Complications were seen in 13% of the laparoscopic patients and in 24% of the open surgical candidates. Similar results have been reported by other investigators comparing open and laparoscopic radical nephrectomy (Kerbl et al, 1994; McDougall et al, 1996; Clayman et al, 1997).

RETROPERITONEAL RADICAL NEPHRECTOMY

Access to the kidney through the retroperitoneum requires creation of a working space from a potential space. Clayman and associates (1991) were the first to perform a complete retroperitoneal nephrectomy. Gaur (1992) described a simple technique using readily available and inexpensive equipment to create a balloon for access to the retroperitoneum. The utility of this approach has been shown in many different series for all laparoscopic kidney procedures as well as ureteral and adrenal surgery.

Indications and Contraindications

The indications for laparoscopic retroperitoneal nephrectomy (LRPN) are the same as those for open, laparoscopic, and hand-assisted nephrectomy. In addition, patients with extensive transperitoneal surgery may still maintain well-preserved tissue planes in the retroperitoneum, allowing the surgeon to avoid abdominal adhesions. Additional potential advantages include more direct access to the renal vessels for early control.

Relative contraindications include previous retroperitoneal surgery, large tumors with possible adjacent organ involvement, and infectious disease processes. Because the retroperitoneal space is a potential space that must be created, prior renal surgery may make it difficult to approach using LRPN. Dense adhesions may result from recurrent infections, tuberculosis, xanthogranulomatous pyelonephritis, prior episodes of pyelonephritis, and extracorporeal shock wave lithotripsy. Typically, uncomplicated percutaneous stone procedures do not create extensive scar tissue preventing access to the kidney using LRPN. Evaluation with preoperative CT may reveal adhesions that may be difficult to approach with LRPN. Disadvantages include disorientation due to unfamiliar landmarks being obscured by adipose tissue. The small working space can make trocar placement, instrument movement, and organ manipulation difficult.

Positioning and Trocar Placement

The patient is placed in the full lateral position, similar to open nephrectomy, with the hips flexed and the kidney rest elevated. A 15-mm incision is made off the tip of the 12th rib, which will serve as the middle trocar and is usually used for the camera port (Fig. 51–28). The index finger is inserted through the incision and used for blunt dissection to create a hole from the skin through the muscle into the retroperitoneal space. If the finger is in the correct position, the surgeon should feel the smooth surface of psoas muscle and the lower pole of the kidney covered by Gerota's fascia (Fig. 51–29).

The potential working space can be created with a balloon made from the two fingers of a size 8 or 9 glove secured with

silk suture over a red rubber catheter (Fig. 51–30). Commercial balloons are available and offer the advantage of dilation under direct vision. The empty balloon catheter is inserted into the space and directed under the kidney. It is then filled to 600- to 800-mL capacity with normal saline and removed. Usually an instrument trocar is placed posterior to the initial trocar site by directing the nonbladed trocar onto the tip of an inserted finger. A Blunt Tip Trocar (U.S. Surgical, Norwalk, CT) is used to seal the trocar site and because of its low profile, it will not obstruct the view or working space (Fig. 51–31). The retroperitoneum is insufflated to 15 to 20 mm Hg. The posterior trocar allows use of a dissector or aspirator to push the peritoneum medially allowing adequate space for placement of the anterior secondary trocars. These include a 12-mm trocar to allow placement of an endovascular stapler and a fourth trocar for retraction and elevation of the kidney.

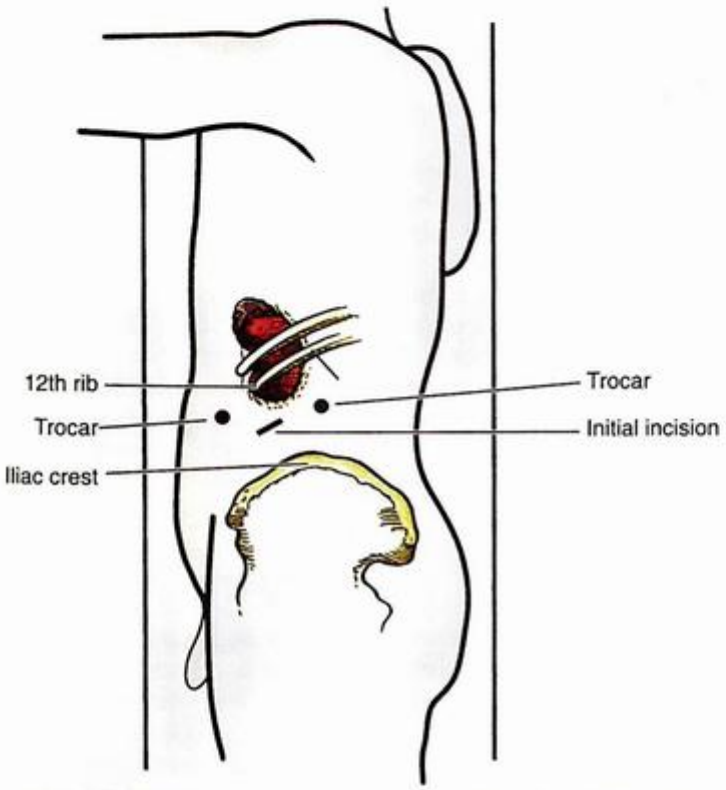

Figure 51–28. With the patient in the full lateral position, the hips flexed, and the kidney rest elevated, a 15-mm incision is made 2 cm below the tip of the 12th rib, between the rib and the anterior superior iliac spine.

Procedure

The first step in the LRPN is to identify the psoas muscle and psoas tendon. From the psoas tendon, medial dissection will reveal the ureter, which is then elevated and followed to the lower pole of the kidney. Because the instruments are being placed perpendicular to the ureter during dissection, the surgeon must be aware of the close proximity of the ureter to the aorta on the left and the vena cava on the right. Elevation of the lower pole of the kidney places the renal vessels on stretch, assisting with dissection. Visualization of the ureter and psoas helps with orientation, which can be especially valuable on the right side where the vena cava is close to the renal hilum.

By dissecting medially, the renal artery is identified. The pulsating artery is dissected with a right-angled dissector and divided with an endovascular stapler or with clips according to the surgeon's preference. On the left side the lumbar vein may be encountered first or intimately involved with the renal artery and can be unwittingly injured during dissection of the artery. Once the artery is divided, the vein is usually readily apparent and, once circumferentially dissected, can be divided with an endovascular stapler. **However when the vein is identified, the surgeon should recheck the orientation of the camera and the relationship of the vein to the ureter and psoas to ensure that the identified structure is the renal vein and not the vena cava. Care must be taken because there are reports of dividing the vena cava during LRPN with the**

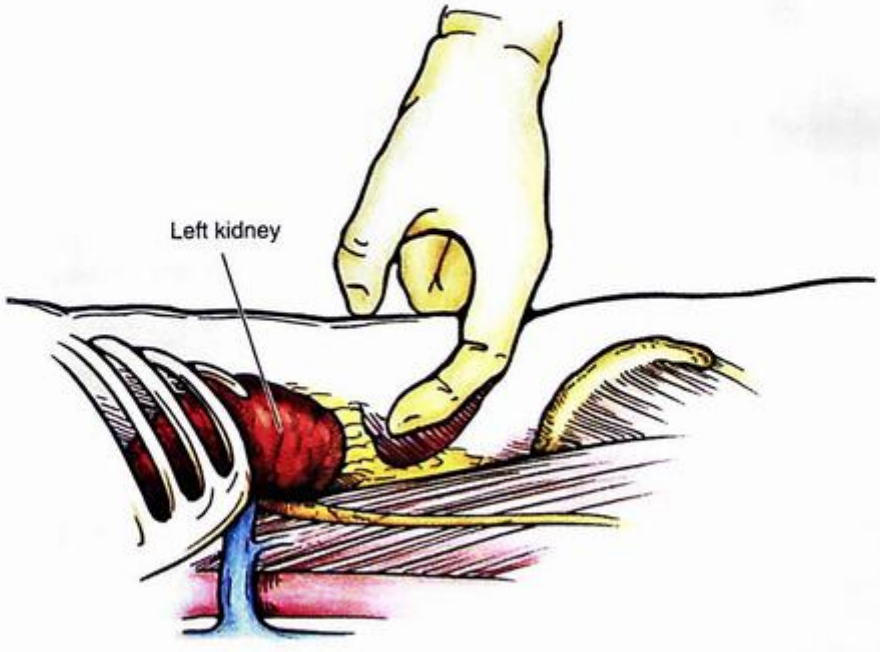

Figure 51–29. The index finger is inserted through the incision and used for blunt dissection to create a hole from the skin through the muscle into the retroperitoneal space. If the finger is in the correct position, the surgeon should feel the smooth surface of psoas muscle and the lower pole of the kidney covered by Gerota's fascia.

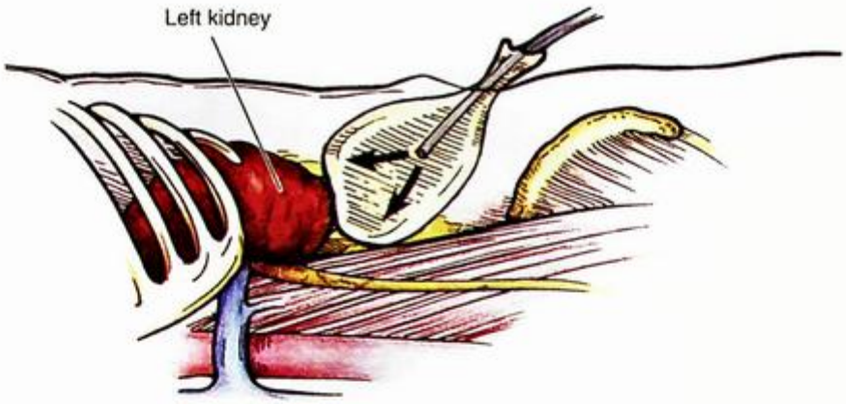

Figure 51–30. To quickly create the working space, we insert an inexpensive Gaur balloon created from the two fingers of a size 8 or 9 glove, secured with silk suture over a simple red rubber catheter. The balloon is then filled with 600 to 800 mL of saline.

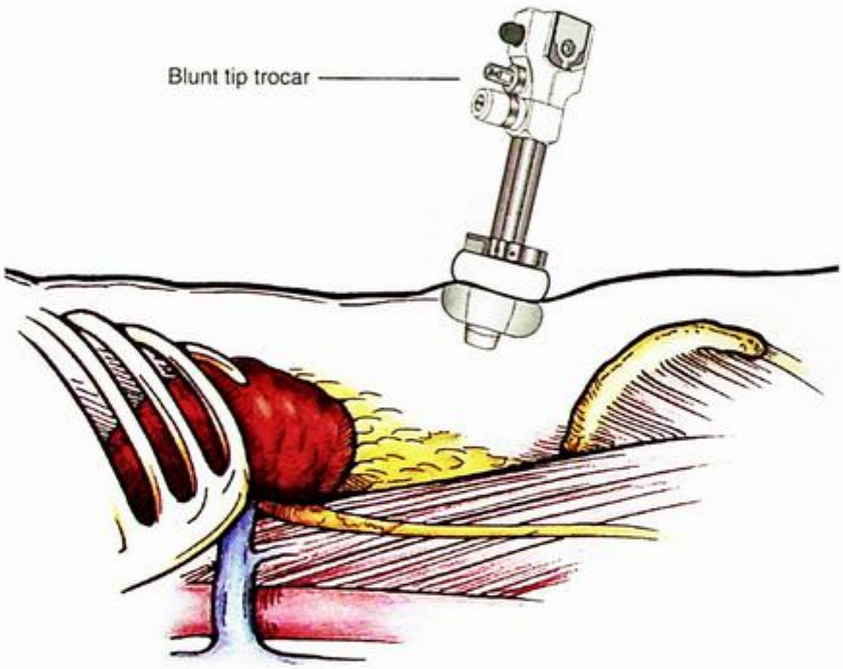

Figure 51–31. A Blunt Tip Trocar (U.S. Surgical, Norwalk, CT) is used to seal the trocar site. Because of its low profile it will not obstruct the view or take up useful space in the retroperitoneum. The balloon/collar configuration eliminates the need for sutures and allows 360-degree rotation.

endovascular stapler (see "Complications of Laparoscopic Renal Surgery" later in this chapter).

Next the lower pole attachments are dissected and the gonadal vessel is divided. The posterior attachments along the length of the kidney are freed, and the kidney is then lowered so that the anterior surface can be dissected. Depending on the indication for nephrectomy the adrenal gland is removed with the specimen or left in place. The retroperitoneal approach offers excellent visualization of the adrenal gland.

Entrapment of the specimen is done with an entrapment bag if removed intact or with a LapSac when morcellated. With intact removal the patient should be warned about the possibility of nerve injury and a resulting flank bulge, even with a small flank incision.

Results

Compared with a transperitoneal approach, a retroperitoneal approach offers similar outcomes in complication rates, pain medication requirements, length of hospital stay, and time to return to normal activity (McDougall et al, 1996). Even with an extraperitoneal operation, injury to intra-abdominal organs can occur, and a hernia can be created during balloon dilatation of the extraperitoneal space.

There are two prospective randomized transperitoneal versus retroperitoneal laparoscopic nephrectomy series reported in the literature. Desai and colleagues (2005) published results on 50 patients randomized to transperitoneal and 52 patients to an LRPN for renal tumors averaging 5 cm in size. They found no difference in blood loss, narcotic requirements, hospital stay, or complications. The retroperitoneal approach had a shorter mean operative time of 150 minutes compared with 207 minutes in the transperitoneal series ($P = .001$).

Nambirajan and associates (2004) randomized 40 patients into two equal groups with a mean tumor size of 4.5 cm. They found no difference between the two approaches for laparoscopic kidney removal when comparing number and size of trocars, pathologic stage, operating room time, blood loss, length of hospital stay, or incidence of complications. Operating room times in the retroperitoneal group were slightly longer than in the transperitoneal group but did not reach statistical significance. Interestingly, Nambirajan and associates report that all patients in the transperitoneal group resumed oral intake by postoperative day 1 but only 75% did so in the

retroperitoneal group. Although the retroperitoneal group had difficulty scores greater than the transperitoneal group, the difference did not reach statistical significance.

HAND-ASSISTED RADICAL NEPHRECTOMY

The first HALN was performed in 1997 by Nakada to remove a nonfunctioning, obstructed kidney. Several clinical reports have demonstrated the utility of the hand-assisted technique for radical nephrectomy, simple nephrectomy, autosomal dominant polycystic kidneys, nephroureterectomy, donor nephrectomy, partial nephrectomy, and pyeloplasty.

Pure laparoscopic nephrectomy requires a different set of surgical skills compared with open surgery. The hand-assisted devices have increased the availability of minimally invasive kidney surgery by offering urologists a technique that helps transfer many open surgery skills to the less invasive approach. The hand-assisted approach has the potential to decrease the learning curve of laparoscopic surgery. It can be useful for cases in which the specimen is going to be extracted intact or when a difficult dissection is anticipated. Some surgeons see the hand-assisted device as a bridge to learn pure laparoscopy when starting out learning laparoscopy, when unable to progress the case using laparoscopic techniques, or to assist in learning new complex procedures (Batker et al, 2001).

The popularity of the hand-assisted technique has also launched an ongoing debate between the hand-assisted surgeons and those who prefer pure laparoscopy, centered on the advantages and disadvantages of these two approaches. Proponents of the hand-assisted technique assert the benefits of tactile sensation for dissection of blood vessels and obscured organs, spatial orientation, as well as the use of the hand for dissection, retraction, and suturing. When bilateral procedures are being performed, a midline hand-assisted port can be of value in working on both kidneys and preventing repositioning of the patient. One of the greatest benefits of the hand-assisted technique may be the ability to control bleeding, which would otherwise result in conversion to open surgery or at least permit conversion to open surgery in a more controlled fashion than may be required during laparoscopic surgery. Disadvantages include the fact that even if the kidney is to be extracted intact, the hand-assisted approach requires a larger incision than that of a complete laparoscopic approach. Moreover, one is limited as to the placement of the hand-assisted incision. In some patients it is difficult to maintain an adequate airtight seal with the hand-assisted device (Rane et al, 2003). Once the incision is made it can be difficult to partially close in order to stop gas escaping from the edge of the insertion site. Chronic loss of the pneumoperitoneum can result in difficulty maintaining adequate visualization during the procedure. Some surgeons who use this technique report forearm compression with tingling, numbness, or pain in the forearm and hand (Wolf et al, 2000). Recent studies have shown that these devices exert between 30 to 100 mm Hg pressure on the hand and arm and vary in the ease of hand insertion and removal (Monga et al, 2004).

Currently, there are three devices marketed for hand-assisted surgery (see Table 51–1). The surgeon must be familiar with the particular characteristics of the chosen hand device to maximize its effectiveness and to prevent loss of pneumoperitoneum during the procedure.

Indications and Contraindications

Indications for HALN are identical to those for laparoscopic nephrectomy. Favorable characteristics for this approach include thin or normal body habitus, left-sided tumors, no prior surgery, and patients with tumors not in the area of the renal hilum. Prior abdominal surgery and obesity are not contraindications to HALN but can make the dissection more difficult. Patients undergoing surgery to remove kidneys destroyed by infectious processes may benefit from the hand-assisted approach to help dissect adhesions. Patients with well-developed abdominal musculature may not allow adequate distention of the abdomen, resulting in a diminished working space and less room for intra-abdominal placement of the surgeon's hand. Relative contraindications include large tumors (>15 cm), history of peritonitis, extensive abdominal surgery, inferior vena cava thrombus, or ipsilateral abdominal wall stoma.

Positioning and Hand Port and Trocar Placement

The patient is placed in a 30-degree lateral decubitus position. Once in position the patient is secured to the table with 3- or 4-inch cloth tape. All pressure points should be carefully checked and padded to prevent nerve or muscle injury. It is helpful to mark the midline before positioning on the table. Once the patient is prepped and draped the incision is made for hand port placement through the skin and fascia into the abdominal cavity. The success of the operation can be compromised if the initial incision for hand port placement is too large because gas will escape, resulting in a small working space.

After the hand port is placed and the hand inserted, the additional nonbladed trocars can quickly be placed using palpation with the intra-abdominal hand and gently inserting the trocars directly onto the finger inside the abdomen. The hand in the abdomen can also be used to identify and avoid adhesions if present. Alternatively, a trocar can be inserted through the hand-assisted port and the abdomen insufflated (Fig. 51–32). With the camera placed through the hand port, the secondary trocars can be placed under direct vision.

Hand port and trocar placement is different for left and right kidney surgery and between right- and left-handed surgeons. In general, the nondominant hand is inserted into the abdomen for dissection and the dominant hand is used to operate the laparoscopic instruments. Incorrect placement of the hand port may prevent ready access to the hilum and interfere with the instruments or the camera (Figs. 51–33 and 51–34).

Procedure

Reflection of the Colon

The colon is reflected after incising the peritoneum along the line of Toldt from the spleen or liver superiorly to the

Text continued on p. 1796.

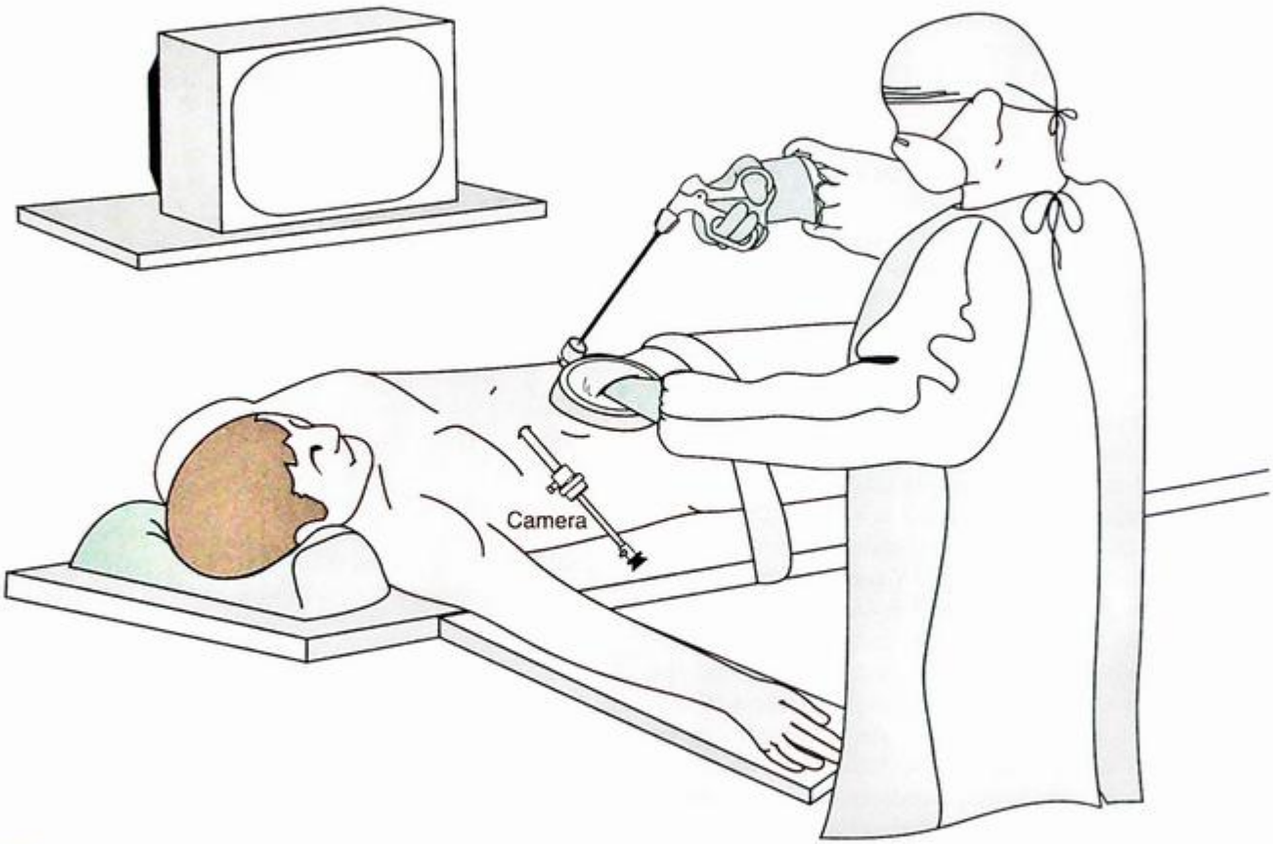

Figure 51–32. A right-handed surgeon working on the left kidney will usually insert the left hand through the working port while using instruments for dissection, cautery, and stapling with the dominant right hand.

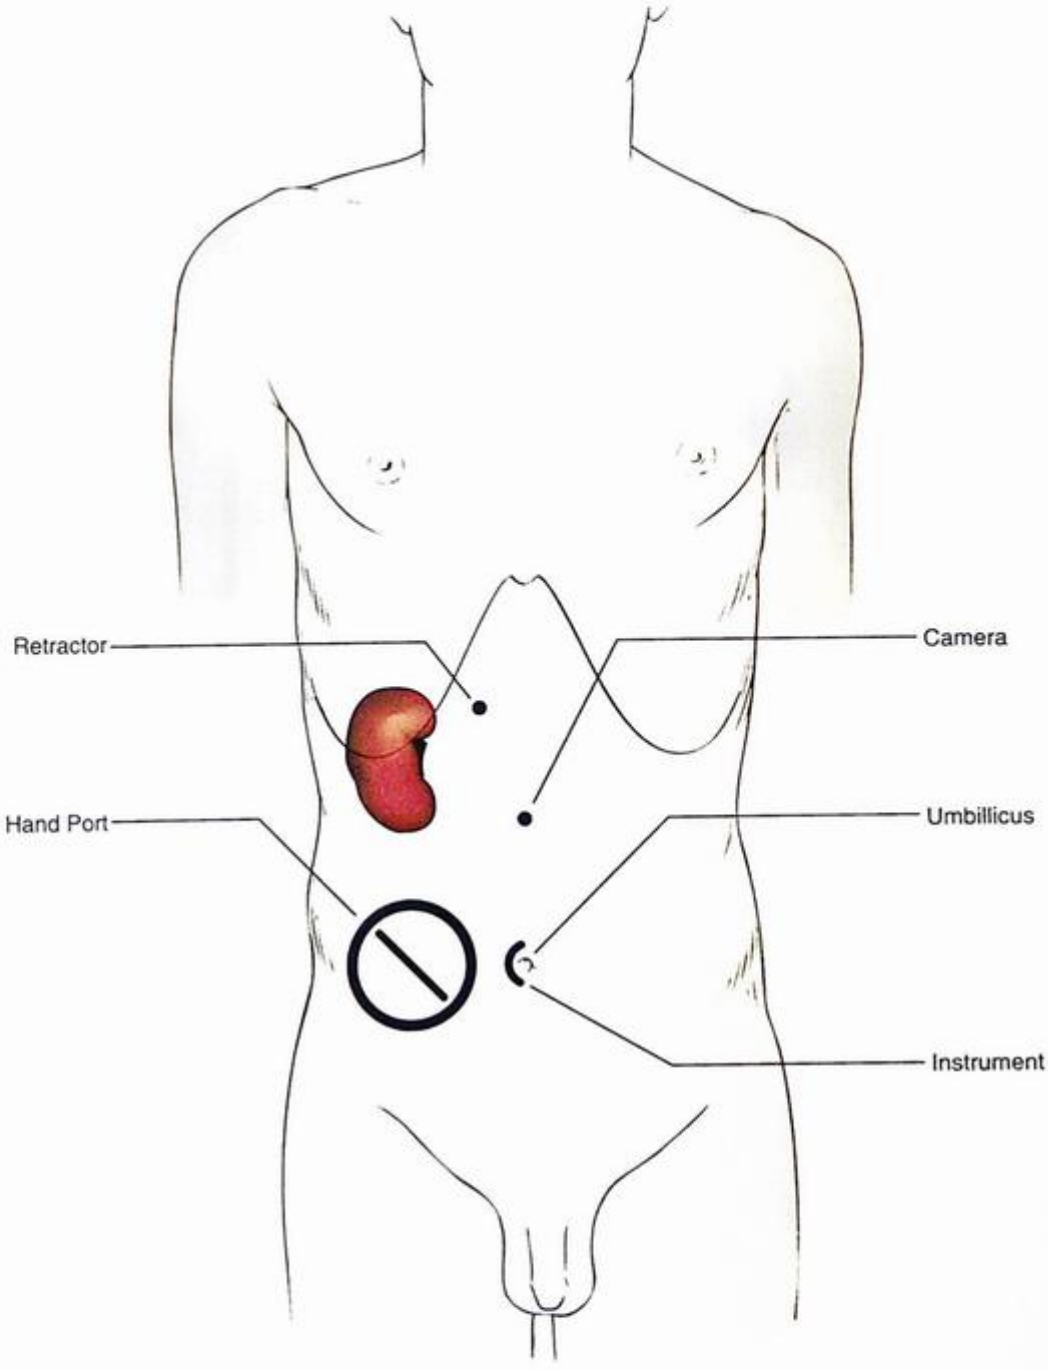

Figure 51–33. A, In a right-handed surgeon operating on a right-sided kidney, the hand-assisted device is placed in the right lower quadrant for insertion of the left hand and dissection is performed with instruments in the right hand placed through an umbilical trocar. The camera is placed several centimeters above the umbilicus in the midline. On the right side, retraction of the liver is usually necessary to allow visualization and dissection of the renal hilum. A liver or bowel retractor can be placed through a subcostal trocar to assist with visualization or irrigation/aspiration. *Continued*

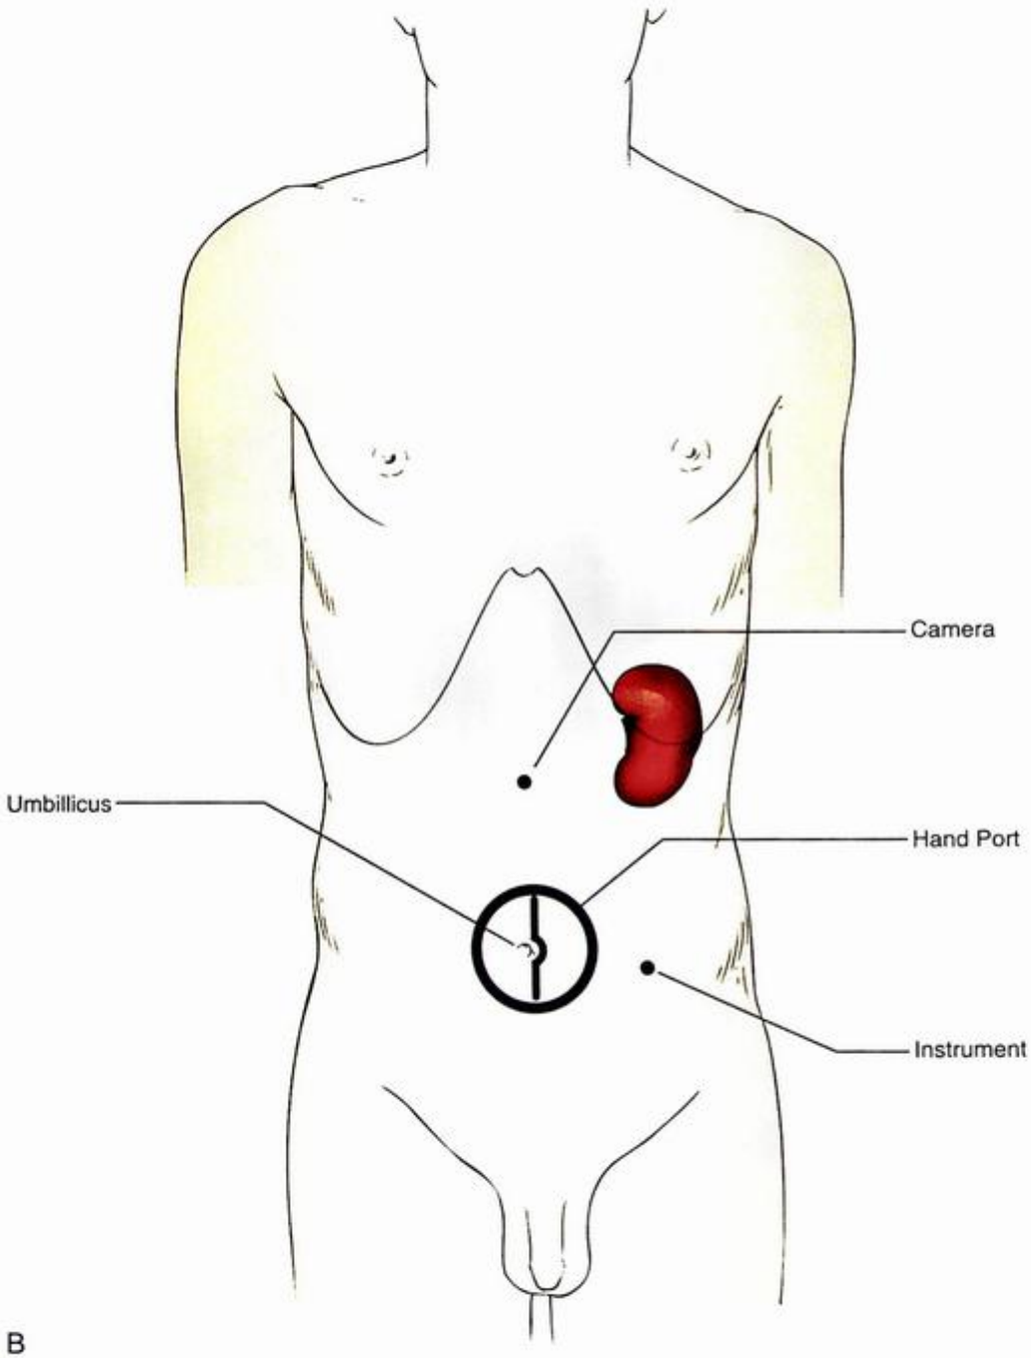

Figure 51–33, cont'd. B, For a right-handed surgeon operating on the left kidney the hand-assisted device and left hand are placed though a periumbilical incision and dissection is performed with the right hand using an instrument placed in the subcostal margin just medial to the nipple. The camera is placed several centimeters lateral to the edge of the actual hand-assisted device (not the edge of the incision). Additional assistance can be delivered through the most lateral trocar site.

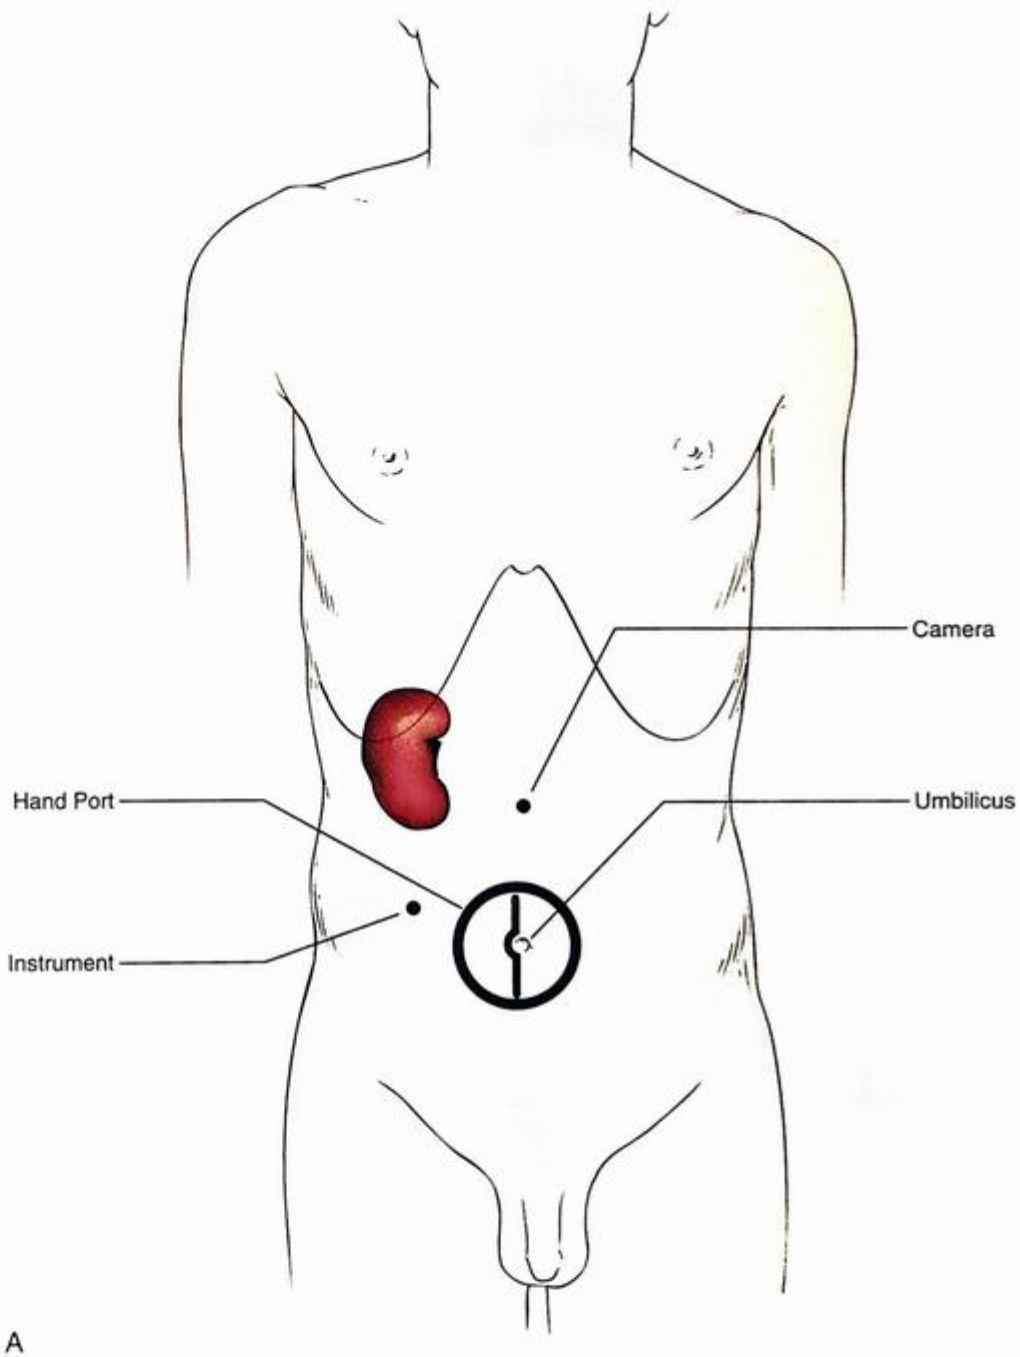

Figure 51–34. **A,** When operating on the right kidney a left-handed surgeon places the hand-assisted port in the periumbilical location for insertion of the right hand. The working port for the left hand is placed lateral to the rectus muscle, in line with or just inferior to the level of the umbilicus. The camera is placed through a lateral trocar in the anterior axillary line. Additional assistance with retraction of the liver can be accomplished through a subcostal trocar. *Continued*

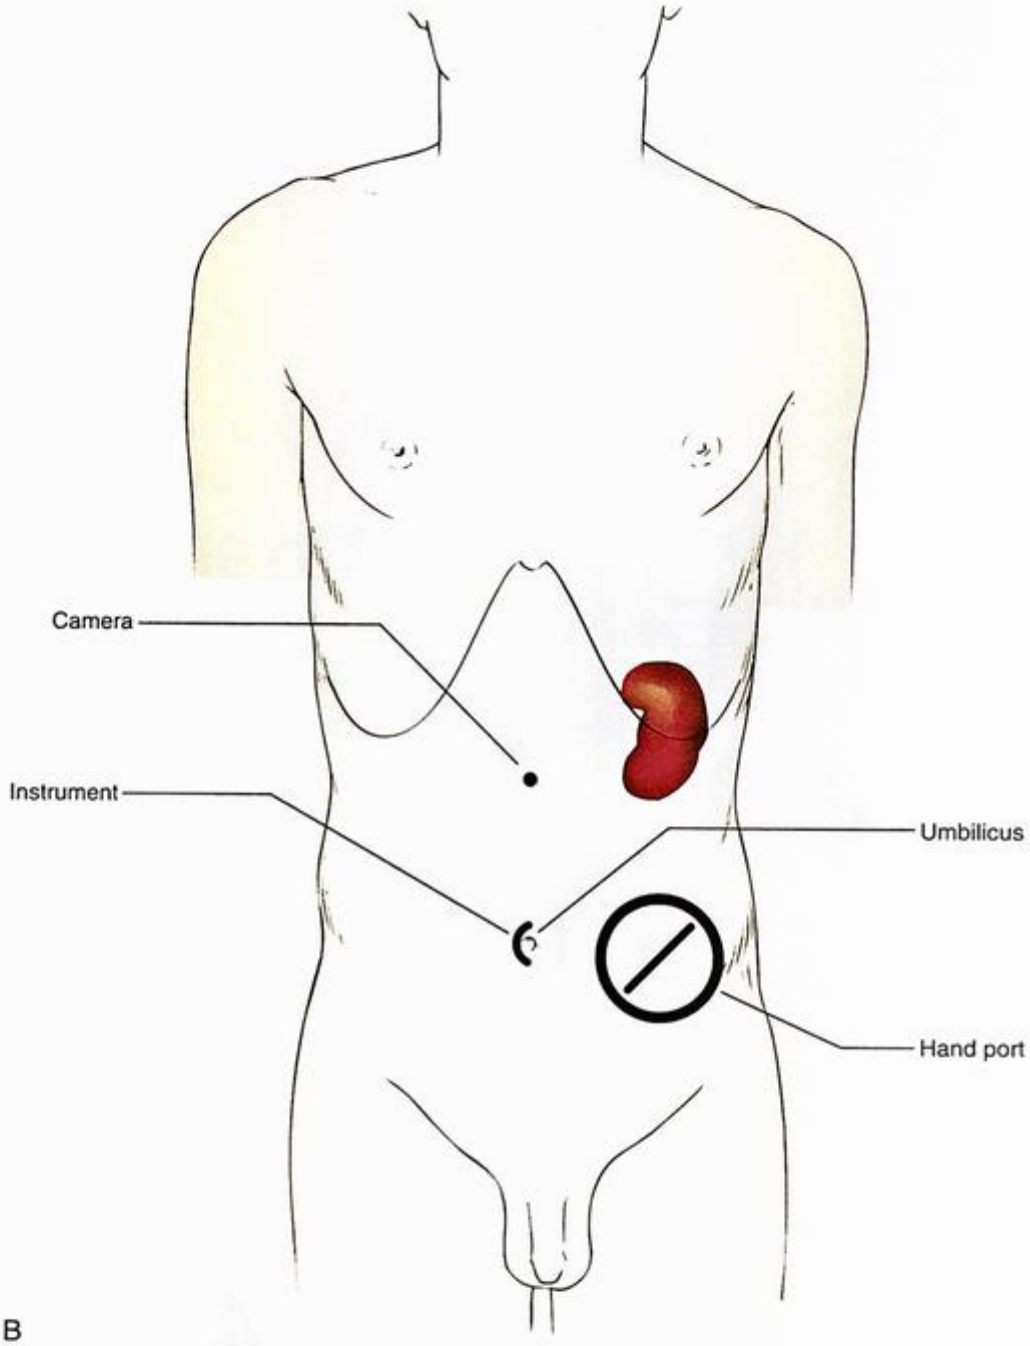

Figure 51–34, cont'd. B, For a left-handed surgeon operating on the left kidney the hand-assisted port is placed in the left lower quadrant for insertion of the right hand. The left hand works with the instrument passed through an umbilical trocar, and the camera is placed midway between the umbilicus and the xiphoid process. Additional assistance with retraction or aspiration can be accomplished through a fourth trocar placed at the subcostal margin.

iliac vessels inferiorly. The nondominant hand is used to retract the colon medially, while the dominant hand uses the irrigator-aspirator to bluntly dissect the correct plane and divide tissue as needed to develop the correct plane between the posterior aspect of the large bowel mesentery and underlying structures. Lateral traction of the kidney by the assistant can help identify correct tissue planes (Fig. 51–35). It is important to enter the correct plane between the large bowel mesentery and Gerota's fascia. If the surgeon wanders too far medially, significant bleeding can occur from mesenteric vessels; and if movement is too far laterally, Gerota's fascia will be violated. Lateral countertraction on the kidney from the assistant will help demonstrate the correct plane of dissection. For left-sided nephrectomy the spleen can be retracted with the inserted hand while sidewall attachments of splenorenal ligaments are divided, allowing the spleen to be retracted medially.

Dissection of the Ureter

Once the colon is reflected the psoas muscle can be identified and the ureter elevated. The gonadal vessel is usually included with the ureteral packet on the left side. On the right, the gonadal vessel is reflected medially. The ureter is followed to the renal hilum. Once the hand palpates the lower pole, the kidney is displaced laterally with the fingers while the thumb pushes the bowel and mesentery medially. Some surgeons divide the ureter after the lower pole of the kidney is identified, because the hand can be used to elevate the kidney for further dissection. In contrast, during transperitoneal laparoscopic surgery the ureter is left intact until the upper pole and

Figure 51–35. The nondominant hand is used to retract the colon medially and to dissect tissue planes, while the dominant hand uses endoscopic scissors to divide colon attachments.

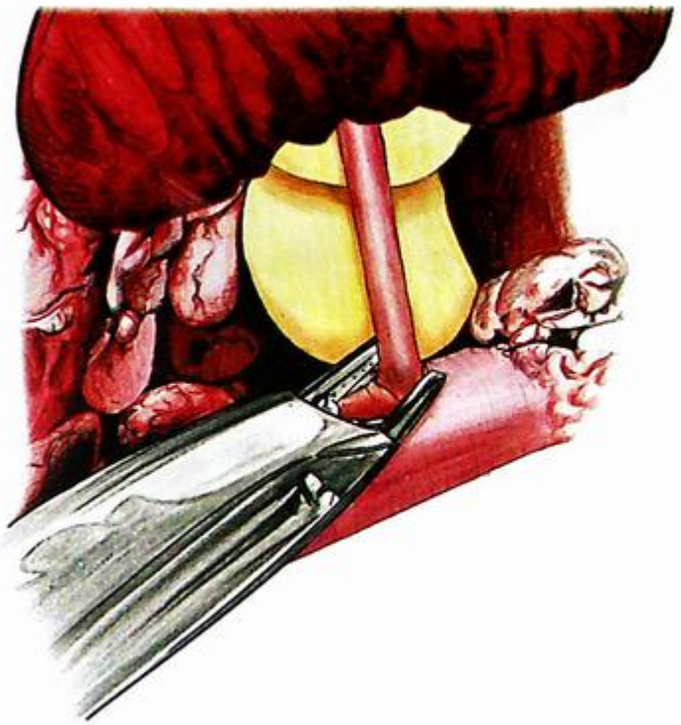

Figure 51–36. With the renal hilum on stretch and the bowel retracted medially to expose the vessels, the fingers can be used to palpate the renal artery and guide a stapler or clip applier to secure and divide the artery.

lateral and posterior attachments are divided and the kidney is completely mobilized.

Dissection: Lateral Attachments and Upper Pole

In the case of hand-assisted laparoscopic radical nephrectomy the surgeon must ensure that Gerota's fascia is not violated but dissected intact from the lateral body sidewall attachments and from the psoas muscle. Retraction and dissection with the hand can allow division of the lateral attachments with harmonic shears or bipolar cautery. If the adrenal gland is to be removed with the specimen, ultrasonic energy or bipolar cautery can be used to divide all medial and superior adrenal attachments, which include the remaining branches from the aorta and inferior phrenic arteries. The hand can be used for retraction and exposure but not usually dissection of the adrenal gland, because this will usually result in bleeding from adrenal vessels or a fragile adrenal gland. If the adrenal gland is to remain in place, then the surgeon's fingers can be used to dissect the plane between the adrenal gland and the kidney. Medial retraction of the kidney can displace the diaphragm and cause perforation of the diaphragm during dissection.

Securing the Renal Blood Vessels

On the left side, the gonadal branch will lead the surgeon to the renal vein. The gonadal vessel can be divided using bipolar cautery or clips. If clips are used, the surgeon must be careful to note the exact location of the clips to prevent inadvertently placing the clip within the jaws of the endovascular stapler, which will result in a misfire. On the left side, a lumbar vein will usually course posterior to the renal vein and be intimately involved with the renal artery. On the right side, the surgeon may divide the gonadal vessel as it enters the vena cava to avoid bleeding. On the left side, the adrenal vein should be identified and spared in the case of simple nephrectomy or divided for radical nephrectomy if appropriate. To dissect the renal hilum, the kidney should be retracted laterally and the bowel retracted medially. This maneuver places the artery and vein on stretch and if injured keeps the vessels elevated so that vascular control can be achieved with clips or staplers. Palpation of the hilum can help with identifying the artery, which can be dissected with the tip of the irrigator-aspirator while the vessels are on stretch and the fingers are directing the tip of the irrigator-aspirator. When the lateral and posterior attachments are divided, the kidney can be retracted medially, exposing the posterior view of the renal hilum. Some surgeons will dissect the vessels from a posterior approach, allowing the fingertips to surround the renal hilum and exposing the renal artery first, followed by the renal vein (Fig. 51–36).

Clips, staples, or a tie can be used on the artery. We prefer to use staples on the renal artery because clips can interfere with stapling of the vein and have been displaced during subsequent dissection of the upper pole and posterior attachments during hand-assisted surgery (Maartense et al, 2003). Once the artery is divided, the renal vein is freed circumferentially and divided with an endovascular stapler (Fig. 51–37).

Aspiration

Placement of the hand-assisted device allows placement of a laparotomy sponge at the start of the case that can be used to assist with retraction and absorption of blood. If the sponge is saturated, the aspirator can be used to remove blood from

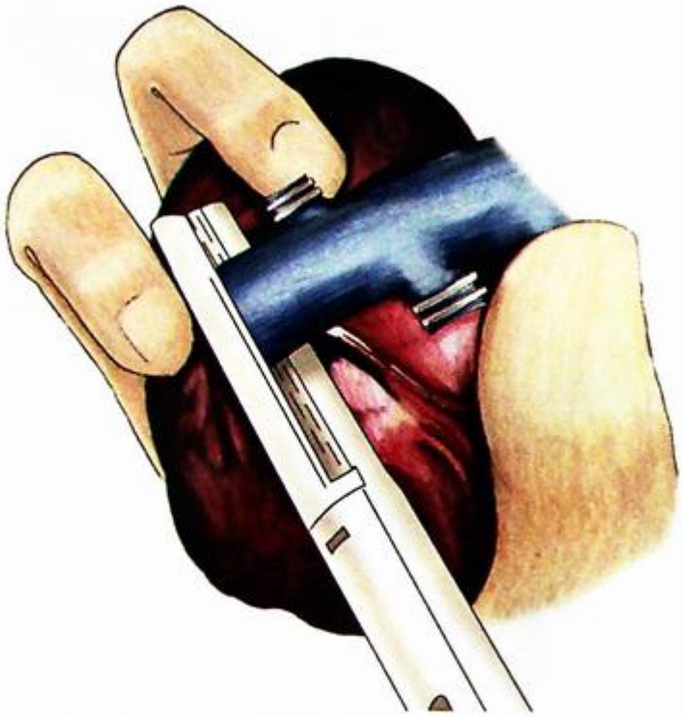

Figure 51–37. Once the artery is divided, the renal vein is freed circumferentially and divided with an endovascular stapler.

the compressed sponge or replace it through the hand port. Because the sponge is often out of the surgeon's view, the surgeon must remember to remove the laparotomy sponge at the end of the case.

Specimen Entrapment and Extraction

The incision for hand placement allows rapid removal of the kidney specimen. Tissue should not be directly pulled across unprotected wound edges. Metastasis of renal cell carcinoma at the site of the hand port has been reported (Chen et al, 2003). An unsuspected renal malignancy may be present even in cases of simple nephrectomy. We recommend that renal specimens be placed in a removal device before being extracted through the hand-assisted site to prevent wound edge contamination.

Port and Trocar Site Closure

The inserted hand can facilitate closure of trocar sites greater than 10 mm with a suture-passing device. Hand-assisted incision sites can be a location for hernia formation and complications. **Several authors have reported problems with wound complications and a 4% hernia incidence, with all hernias presenting at least 3 months after HALN** (Okeke et al, 2002; Wolf, 2005).

Cost Comparison

With increased use of the hand-assisted devices the manufacturers have reduced the cost of the devices to make them more cost-effective. Baldwin and associates (2003) found the overall cost of laparoscopic nephrectomy to be 21% lower than both HALN and open radical nephrectomy. However, Velidedeoglu and coworkers (2002) showed decreased cost with HALN owing to shorter operative times and decreased hospital stay compared with open surgery.

Results

The efficacy, operative times, complication rates, narcotic requirements, length of hospital stay, and convalescence outcomes for simple HALN are comparable to the laparoscopic technique. Nelson and Wolf (2002) compared 22 HALNs to 16 laparoscopic radical nephrectomy procedures and found HALN to be shorter (205 vs. 270 minutes), but the HALN patients had more abdominal pain and more wound complications.

A large number of radical HALN series are reported in the literature, but the vast majority give only a comparison of the overall short-term morbidity and operative outcomes between laparoscopy, HALN, and open surgery. In the treatment of renal cell carcinoma, the laparoscopic radical nephrectomy had a 6-year head start on HALN and, as a result, long-term cancer survival data for radical HALN are not yet available. Several series with short-term follow-up data demonstrate promising results. Stifelman and coworkers (2003) have published a multi-institutional series of 95 radical HALNs in which a comparison was made between patients according to tumor size. Thirty-two patients had tumors greater than 7 cm, and 63 patients had tumors less than 7 cm. At a mean follow-up of 12 months the investigators found no difference between the two groups, comparing positive margins, local recurrence, or metastasis. Patel and Leveillee (2003) reported on a series of 60 radical HALNs for T1 or T2 renal tumors with a mean follow-up of 11 months and showed no recurrence or trocar site seeding.

Several authors have demonstrated the use of hand-assisted surgery in the management of renal cell carcinoma with tumor thrombus extension into the renal vein or vena cava. Sundaram and associates (2002) used hand-assisted laparoscopy in a patient with T3b renal cancer with inferior vena cava thrombus. Using the hand-assisted device they controlled the inferior vena cava with vessel loops, and an endoscopic Satinsky clamp was placed to open the vena cava and remove the tumor thrombus; the defect was then closed with 4-0 vascular polypropylene suture. A similar procedure was reported by Troxel and colleagues (2002) for a level 1 renal vein tumor thrombus.

Summary

Laparoscopic radical nephrectomy has become a standard of care for most renal tumors. This approach has proved itself to be less morbid than open surgery, with contemporary operative times comparable to open operative times. Follow-up data have now established laparoscopic radical nephrectomy as an effective means of treating renal cell carcinoma comparable to open radical nephrectomy. This can be accomplished via a hand-assisted or radical laparoscopic approach. Hand-assisted laparoscopy offers benefit when the renal specimen is going to be removed intact, in treating large tumors, and in learning laparoscopic surgery.

Laparoscopic surgery on the kidney through a retroperitoneal approach has similar outcomes compared with the transperitoneal laparoscopic approach. Although there are distinct advantages to both procedures, a laparoscopic surgeon should be familiar with both approaches to maximize

safety and efficiency of laparoscopic renal surgery for a given surgical condition and the particular patient's prior history.

NEPHRON-SPARING SURGERY

Nephron-sparing surgery (NSS) was initially reserved for patients at high risk for developing renal failure after kidney surgery to treat renal cancer. **Several series have shown open partial nephrectomy to be equivalent to open radical nephrectomy in terms of long-term cancer-free survival with unilateral renal involvement, unifocal disease, and a tumor size less than 4 cm.** Fergnany and coworkers (2000) reported a 10-year cancer-specific survival of 100% in this subset of patients. Lee and associates (2000) reported a series of 79 patients treated with open partial nephrectomy for tumors less than 4 cm compared with 183 patients with the same stage of renal cancers treated with open radical nephrectomy. They found no local recurrence and no significant difference between the two groups in disease-specific, disease-free, or overall survival. **In a matched comparison of 1566 open radical nephrectomies and 164 nephron-sparing procedures, Lau and colleagues** (2000) **reported no overall or cause-specific survival advantage at 5, 10, and 15 years for the radical nephrectomy group. Additionally, they found comparable early complications and similar rates of local recurrence and distant metastasis. The only difference discovered was an increased risk of developing renal insufficiency after open radical nephrectomy** ($P = .002$).

The widespread use of modern imaging techniques has resulted in a 32% decrease in the mean tumor size since the early 1990s. The result is a staged migration, with lower stages being discovered at the time of initial diagnosis (Lee et al, 2000). Thus, many individuals are advocating the use of NSS in patients with small renal tumors.

An extension of laparoscopy in the treatment of small renal lesions has been laparoscopic nephron-sparing surgery (LNSS), which mimics the fundamentals of open surgery. Tissue is removed under direct vision, with the margin status assessed intraoperatively. Direct vision and laparoscopic ultrasonography permit the laparoscopist to identify multifocal tumors, determine an adequate surgical margin, and maintain orientation with respect to the collecting system and renal hilum. If necessary, the collecting system can be resected with the surgical specimen to obtain adequate margins and then repaired. Endoscopic retrieval pouches allow safe removal of the tumor specimen.

Indications and Contraindications

Paramount to the application of LNSS is patient selection. Peripheral, well-circumscribed lesions, with enhancement on preoperative imaging that are less than 4 cm (the latter criterion being seen in up to 40% of all renal tumors) can usually be approached laparoscopically. Intrarenal, endophytic, and centrally located tumors are amenable to larger resections with adequate collecting system closure and hemostasis. Studies evaluating the utility of LNSS include patients with solitary renal units, bilateral tumors, significant renal insufficiency, recurrent or metastatic disease, compromised function of the contralateral kidney, previous renal surgery, obesity, and comorbid disease. Unique patient populations with a predisposition to renal tumors, such as von Hippel–Lindau disease, tuberous sclerosis, and hereditary papillary renal cell carcinoma are optimal candidates for LNSS and ablative techniques. Superior polar lesions with adrenal invasion may be amenable to en-bloc resection (Ramani et al, 2003).

Preoperative Preparation

All patients anticipating LNSS should complete a metastatic evaluation before the procedure. Patients should be prescribed a bowel preparation the day before surgery. Broad-spectrum intravenous antibiotics are administered in the preoperative holding area. Blood is typed and screened. Crossmatching of blood is done, and 2 units of typed, screened, and crossmatched blood is usually reserved for each patient.

Patient Positioning and Operating Room Configuration

After induction of general anesthesia and placement of calf sequential compression devices, the umbilicus is positioned over the operative table break and the patient is placed in a modified lateral decubitus position. The ipsilateral chest and shoulder are placed 30- to 45-degrees off the table using the same position as transperitoneal laparoscopic nephrectomy. Throughout the case, rotating the operative table toward the surgeon facilitates the medial displacement of the colon within the pneumoperitoneum (Schulam et al, 2002). A laparotomy set, including vascular clamps, is open on the instrument table for immediate access if needed.

In select cases, an open-ended 5-Fr catheter is passed cystoscopically up the ipsilateral ureter. This is connected to a syringe of methylene blue solution. Injecting fluid once the collecting system is transected can aid in closure.

Trocar Placement

Veress needle insufflation is performed as previously described. Trocar placement is similar to laparoscopic nephrectomy (see Figs. 51–4 and 51–28).

Procedure

Renal mobilization ensures inspection of the entire capsular surface for possible satellite metastasis. Complete hilar control allows excellent visualization, to ensure negative margins at the posterior aspect of the dissection. Arterial and venous clamping can be achieved with laparoscopic bulldog devices or a Satinsky clamp (Klein Medical, San Antonio, TX). Clamping of the renal vessels (with or without intrarenal or extrarenal cooling) mimics open techniques, facilitates tumor resection, and is associated with less blood loss and shorter operative times (Guillonneau et al, 2003). Intraoperative laparoscopic ultrasound (IOLUS) augments the visual inspection, helping the surgeon gain further understanding of the intrarenal margins of a primary tumor and assessment for possible satellite lesions.

Circumscription and lesion excision is completed with scissors, ultrasonic shears, or an endoscopic scalpel. The scalpel can be fashioned from a No. 15 scalpel blade affixed with Steri-

Strips to a blunt laparoscopic dissector and visually directed through a 5-mm trocar (Fig. 51–38).

Incisional hemostatic devices (i.e., TissueLink, TissueLink Medical, Inc., Dover, NH) may allow the resection of some renal lesions without the need for hilar control (Yoshihiko et al, 1998; Sundaram et al, 2003; Urena et al, 2004) (Fig. 51–39). Surgeons must recognize that with these devices severe bleeding can suddenly occur as the dissection progresses into the kidney with deeper lesions. Consequently, the hilum should be ready for hilar occlusion if bleeding occurs.

Collecting system defects can be visualized and closed with absorbable suture material using intracorporeal suture techniques. Intentional calyceal entry (to obviate positive surgical margins) is effectively repaired in a watertight manner by intracorporeal and extracorporeal laparoscopic suture maneuvers (Desai et al, 2003) (Fig. 51–40). Arterial branches may be clipped or oversewn.

Argon beam coagulation for hemostasis of the parenchymal bed is useful, taking great care to ensure its deployment is directed only at the cut renal parenchymal surface. Some authors also use a fibrin sealant product applied to the parenchymal bed (Ramakumar et al, 2002; User and Nadler, 2003).

A preplaced oxidized cellulose bolster can be used for larger defects to compress the parenchyma and aid in closure. Interrupted, horizontal mattress sutures (0-Polyglactin) on a CTX or SH needle are used for capsular closure. Continued intracorporeal suture techniques are employed, and complete renal defect closure is ensured before removal of the laparoscopic bulldog clamps. Drain placement is at the discretion of the surgeon.

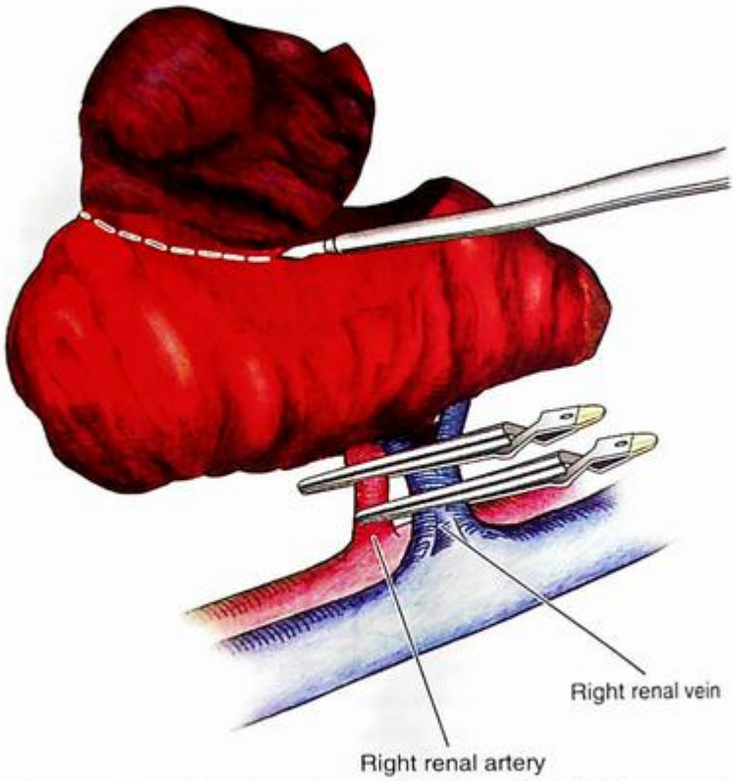

Figure 51–38. After the renal artery and vein are identified, laparoscopic bulldog clips are placed on the artery and vein. An endoscopic scalpel is used to rapidly and precisely excise the renal mass with a large rim of normal parenchyma. The excised mass is placed in an entrapment sac and left in the abdomen during kidney reconstruction.

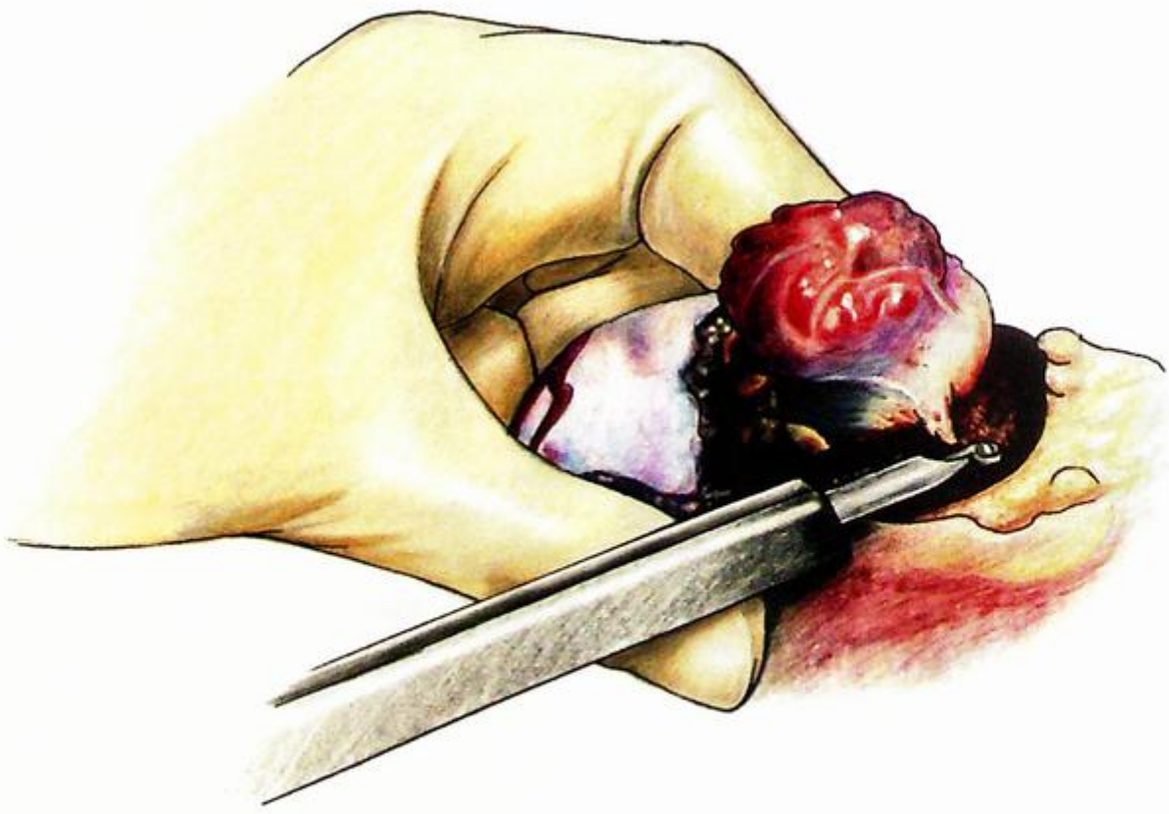

Figure 51–39. Advances in technology, such as monopolar radiofrequency instruments and microwave coagulators, allow some tumors to be excised without the need for renal ischemia.

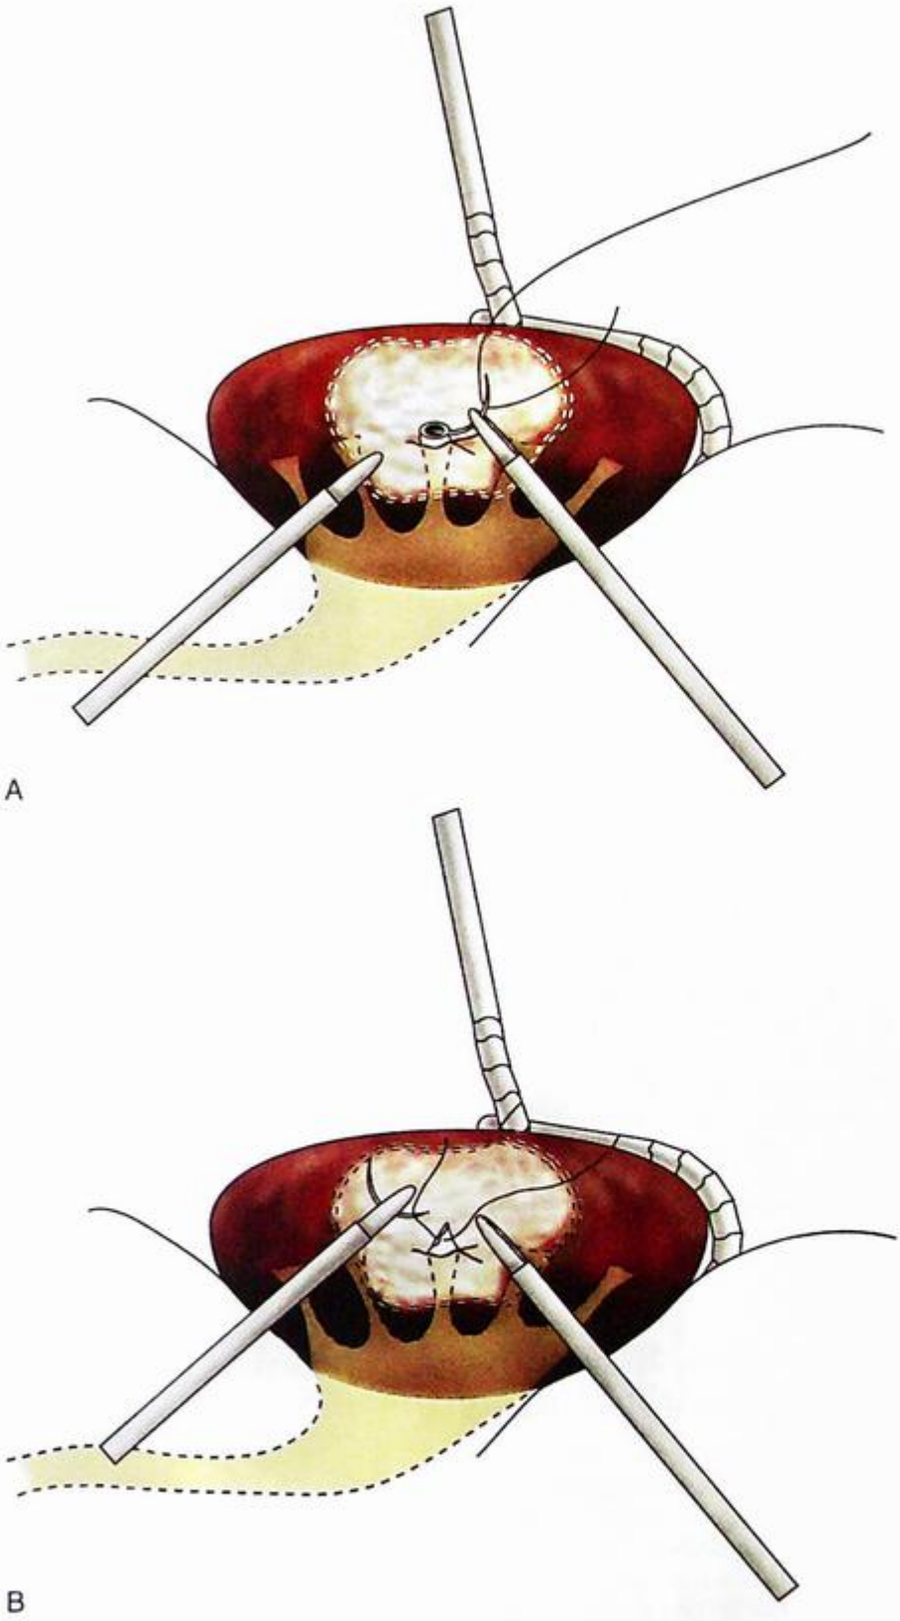

Figure 51–40. **A,** When deep resection is required, the collecting system will often be transected. With occlusion of the renal vessels these defects can easily be identified and closed using absorbable sutures. The cut edge of the collecting system is identified with the tip of the needle and elevated. **B,** An interrupted figure-of-eight suture or running suture is used to completely close the collecting system. The integrity of the repair can be determined by intravenous indigo carmine administration or retrograde instillation if a ureteral catheter was placed at the beginning of the case. Care must be taken not to destroy the suture if argon beam coagulation of the parenchyma surface will be performed.

Oxidized cellulose (Surgicel, Ethicon, Inc., Cincinnati, OH) **is often placed in the defect created after removal of the renal mass. In the early postoperative period this may appear as a gas-containing abscess, owing to air in the gauze spaces, when no real infection is present.** This appearance on CT has been reported as long as 30 days after surgery (Farina Perez et al, 2004).

Renal Cooling and Special Considerations

Renal hypothermia has long been a part of open partial nephrectomy. To date, two primary laparoscopic renal cooling techniques have been reported: intrarenal and extrarenal. Several authors have described unique means of placing ice on

the kidney after occlusion of the renal hilum. Gill and colleagues (2003) reported the initial novel technique of laparoscopic extrarenal cooling using an Endocatch II (U.S. Surgical, Norwalk, CT) bag with drawstring cinched around a clamped hilum. Ice slush was then introduced through an opened isolated inferior portion of the bag through a 12-mm port site with thermocouple-measured nadir renal parenchymal temperature of 5°C. Temperatures less than 20°C during in situ renal preservation have been reported for open partial nephrectomy (Novick, 2002). Wakabayashi and associates (2004) used a cylindrical tube to deliver ice slush directly to the kidney surface, resulting in a temperature of 18.4°C.

Landman and colleagues (2003) have reported intrarenal cooling through the infusion of ice-cold saline through ureteral catheters with cortical and medullary temperatures of 21°C and 27°C, respectively. However, the renal cooling in a recent porcine model with this type of catheter scheme demonstrated mean temperatures of only 26.1°C, which exceeds the temperatures for adequate renal preservation hypothermia, so the exact utility remains in question.

Janetschek and coworkers (2004) reported an aggressive renal hypothermia program in 15 patients undergoing LNSS. Continuous perfusion of the kidney was performed with Ringer's lactate solution at 4°C instilled directly through a needle placed in the clamped renal artery. Their mean ischemic time was 40 minutes (range: 27 to 101 minutes) with no report of decreased renal function.

Retroperitoneal Approach

There are several contemporary adult laparoscopic retroperitoneal partial nephrectomy reports (Gill et al, 1994; Hoznek et al, 1999). To date, the posterior approach appears to grant access to the renal pedicle in the pediatric population, but peritoneal tears in the younger peritoneum appear common.

Most masses approached in this manner are small and exophytic (Tanaka et al, 2000). The limited working space creates a challenge for adequate visualization and for suturing. Murota and colleagues (2002) have used the microwave coagulator to achieve hemostasis in the retroperitoneum for NSS surgery.

Hand-Assisted Laparoscopic Nephron-Sparing Surgery (HAL NSS)

In HAL partial nephrectomy the hand plays an integral part with both placement and removal of the bulldog occlusion clamp or compression of the renal parenchyma for hemostasis during the dissection. In a series of 15 HAL NSS procedures Pruthi and associates (2004) used the inserted hand to compress the kidney during resection of the mass followed by application of argon beam coagulation and then Tisseel (Baxter, Inc, Deerfield, IL) to the fresh resection edge while hand compression was maintained. They reported excellent hemostasis without the need for additional hemostatic measures and without delayed bleeding or formation of a urinoma.

Brown and colleagues (2004) published their results in 30 patients undergoing NSS with HAL and hand compression without vascular occlusion and reported delayed bleeding and urine leakage. Argon beam coagulation and fibrin glue were used for hemostasis. In the postoperative period, 6 patients required transfusion of red blood cells and 6 patients had urinary extravasation with 1 patient requiring a ureteral stent. Patients with centrally located tumors were more likely to have postoperative complications than those with peripheral or polar lesions.

Stifelman and coworkers (2001) have published their results from 11 HAL NSS procedures for tumors with a mean size of 2 cm. No patient required hilar occlusion; however, one patient was converted to a full open procedure to successfully complete the surgery. The mean estimated blood loss was 320 mL. No patient has shown a recurrence of renal cell carcinoma.

In-Situ Ablation and Resection

The use of in-situ laparoscopic applications of ablative technologies (i.e., radiofrequency [RF] ablation and microwave tissue coagulation) before lesion extirpation is advocated by some to facilitate hemostasis (Gettman et al, 2001; Itoh et al, 2002). Jacomides and coworkers (2003) have employed laparoscopic RF ablation followed by tissue excision in a small series of five renal tumors with excellent results and low incidence of bleeding during LNSS. We reported our initial series of 10 patients treated in a similar fashion in tumors with a mean size of 2.1 cm (range: 1.0 to 3.2 cm) and found it to be of assistance in facilitating LNSS for both exophytic and endophytic lesions, while avoiding renal ischemia.

Microwave tissue coagulation (MTC) is being used with increasing frequency as a means for hemostatic extirpation of renal tissue during laparoscopic partial nephrectomy without renal ischemia. The MTC probe is placed sequentially around the area to be removed in a circumferential manner, and the tumor is then excised. Even when the collecting system is involved in the resection, the MTC techniques appear to be effective. Several recent reports on MTC have demonstrated positive margins, delayed bleeding, or formation of a urinoma (Maito et al, 1998; Furuya et al, 2003; Hiroya et al, 2003; Iinuma et al, 2004; Terai et al, 2004).

Results

Multiple series have shown the feasibility and low morbidity of LNSS in the treatment of renal cell carcinoma (Table 51–7). The effect of warm ischemia on renal function is a major concern after LNSS. Bhayani and coworkers (2004) evaluated serum creatinine values in 188 LNSS patients divided into three groups: group I, no warm ischemia (N = 42); group II, warm ischemia less than 30 minutes (N = 49); and group III, warm ischemia greater than 30 minutes (N = 28). At a mean follow-up of 28 months there were no differences in serum creatinine values between the three groups and no progression to renal insufficiency after LNSS. Shekarriz and associates (2004) prospectively evaluated patients with renal tumors treated with LNSS with renal scans performed 1 month before surgery and 3 months after LNSS in 17 patients with mean warm ischemic time of 23 minutes (range: 10 to 40 minutes). They found no significant difference in glomerular filtration rate before or after surgery and no association with clamp time and changes in renal function. Kane and colleagues (2004) found similar results in 27 patients who also had

postoperative renal scans after LNSS with mean warm ischemic time of 43 minutes (range: 25 to 65 minutes). They found no change in serum creatinine values after surgery and no change in differential renal function postoperatively.

Data suggest that LNSS for small solid renal masses can be performed safely utilizing innovative modalities to achieve hemostasis. This technique closely approximates the surgical goals of open NSS.

Allaf and associates (2004) have reported on their series of 48 patients treated with LNSS for T1 renal tumors less than 4 cm in size. The mean tumor size was 2.4 cm (range: 1.0 to 4 cm). This study had follow-up at a mean of 38 months (range: 22 to 84 months) with two recurrences. In a patient with von Hippel–Lindau disease a new tumor was seen at the edge of the initial LNSS site 18 months after surgery and the second was in a patient who demonstrated a new tumor remote from the original surgical site 46 months after his first procedure.

Complications

Complications associated with LNSS are uncommon (Table 51–8). Kim and coworkers (2003) found no difference in the incidence of complications in 35 patients undergoing laparoscopic radical nephrectomy and 79 patients undergoing LNSS. Gill and associates (2003) described their complications in a series of 100 open NSS procedures compared with 100 LNSS procedures. The laparoscopic approach was found to have a longer warm ischemic time: 28 minutes versus 18 minutes ($P < .001$). In the laparoscopic group, intraoperative complications occurred in 5% of patients, compared with 0% in the open group. Positive margins were seen in 3% of the laparoscopic group and 0% of the open series. There was no difference in postoperative complications between the two groups. Transfusion needs are reported in many series, with hemorrhage necessitating open nephrectomy in one (Gill et al, 2002). Tension pneumothorax secondary to use of argon beam coagulation during pediatric laparoscopic partial nephrectomy is also noted in the literature (Shanberg et al, 2002). With experience, these complications are approaching the rates seen with open surgery.

A review of complications after LNSS in 200 patients was reported by Ramani and colleagues (2005). The mean tumor size was 3 cm (range: 1 to 10 cm), and the mean ischemic time was 29 minutes (range: 15 to 58 minutes). Only two patients required conversion to open surgery. Bleeding was one of the most common complications reported. The mean blood loss was 250 mL (range: 25 to 1500 mL). Intraoperative hemorrhage was seen in 4% of cases and postoperative bleeding in 6%, including 8 patients who had hemorrhage after discharge to home. Intraoperative bleeding occurred due to bulldog or vascular clamp malposition or malfunction. Urine extravasation from the kidney resection site was seen in 5% of patients and was treated with stent placement or percutaneous drainage. Fifteen patients had solitary kidneys, and 4 of these patients needed hemodialysis in the postoperative period. Finally, 4 patients required reoperation to treat a complication.

Renal insufficiency

Summary

In its current form, LNSS mimics the gold standard techniques for open partial nephrectomy and current results are encouraging. Capsular inspection, tumor extirpation, and margin status also meet the standards set by open NSS. Intraoperative identification and repair of collecting system defects and hemorrhagic foci ensure early postoperative success.

LAPAROSCOPIC ABLATIVE TECHNIQUES

With an increasing incidence of renal cell carcinoma and stage migration to lower stage at the time of diagnosis, there is continued ongoing pursuit of minimally invasive treatments for renal cancer. Several new methods are being investigated to treat small renal lesions in situ. These techniques have the potential to minimize blood loss, dissection, and complications when compared with extirpative approaches. Moreover, these modalities have the potential to be used in an image-guided percutaneous manner on an outpatient basis, eliminating the need for surgical intervention. Cryotherapy, RF ablation, high-intensity focused ultrasonography, microwave therapy, and high-intensity radiation have all been investigated as tools to ablate renal tumors. The future and ultimate goal of ablative technologies in the treatment of renal carcinoma rests on our ability to develop techniques that ensure complete tumor destruction and are delivered percutaneously, as an outpatient procedure. Not all tumors are accessible percutaneously and may require direct visualization and manipulation through the laparoscopic approach. Cryoablation and RF ablation have received the most attention for clinical applications.

Cryoablation

The indications are similar for all of the ablative technologies and include hereditary renal cell, solitary renal unit, tumors located adjacent to bowel or vital organs, bilateral renal tumors, patients with renal insufficiency, patients with significant comorbid disease, and at the informed patient's request. This technique may be best suited for the treatment of exophytic lesions 3.0 cm or less. Small renal lesions in close proximity to the renal hilum can be difficult to remove using open or laparoscopic extirpative techniques and may be treated with laparoscopic delivery of cryosurgical ablation.

The laparoscopic delivery of renal cryotherapy calls on standard transperitoneal or retroperitoneal techniques to gain access to the kidney. The only variable is the location of the mass. Those tumors located in the posterior aspect of the kidney may be easily visualized and treated through the retroperitoneal approach and those more anteriorly located through a transabdominal technique. Laparoscopic delivery of cryoablation permits visualization of probe placement, and

with the use of intraoperative laparoscopic ultrasonography the progression of the ice ball can be monitored.

Once the kidney is mobilized, Gerota's fascia is opened and the tumor is localized. The perirenal fat overlying the tumor should be dissected off of the lesion, placed in a retrieval bag, and extracted for evaluation of histopathology. Complete mobilization of the kidney will allow the use of intraoperative ultrasound to monitor the size and location of the cryolesion as well as to identify multifocal lesions. Once the lesion has been visualized, an 18-gauge biopsy needle is inserted into the mass and biopsy samples are taken. If frozen section analysis will not change the planned procedure, the samples are sent for permanent pathologic section evaluation.

Initially, researchers used a single freeze-thaw cycle to destroy tumor cells. However, most current clinical series have utilized double freeze-thaw cycles in an attempt at greater tumor destruction (Gill and Novick, 1999; Gill et al, 2000; Johnson et al, 2001). Although there is concern that vascular flow to the kidney may affect the freezing of tissue, renal artery occlusion does not significantly alter the freezing process and provided no practical advantage in an animal model (Campbell et al, 1998).

Because of the destructive nature of the ice ball and the inability to rapidly arrest its progression, the developing edge must be constantly monitored during freezing. Furthermore, direct vision is not a sufficient predictor of tissue destruction, with incomplete ablation noted in 11% of samples taken within the visible margins of the ice ball (Chosy et al, 1998). Real-time ultrasound is the most common monitoring modality for use during laparoscopic application. The evolving renal ice ball is visualized as a hyperechoic, crescentic advancing edge with posterior acoustic shadowing. On the other hand, renal tumors are mildly hyperechoic or of mixed echogenicity and the renal sinus fat is hyperechoic. The ultrasound probe is placed opposite the tumor, allowing precise placement of the cryoprobe up to the deep margin of the tumor. Zegel and colleagues (1998) found that intraoperative ultrasonography accurately delineated tumor size, cryoprobe placement, and depth of freezing. An echogenic interface was generated by the marked differences at the junction of the normal renal parenchyma and frozen tissue.

Potential complications of cryosurgery include urinary fistula formation, post-treatment hemorrhage, and injury to adjacent structures including the collecting system, bowel, and liver (Campbell et al, 1998). Bishoff and coworkers (1999) in a porcine model noted severe adhesions between cryoablated kidney and overlying bowel in non-retroperitonealized kidneys. There was no evidence of bowel injury or fistulas. Gill and Novick (1999) reported the complication of small bowel obstruction when the cryoprobe inadvertently contacted a loop of small bowel during porcine laparoscopic renal cryoablation. Campbell and associates (1998) described an obstructive stricture at the ureteropelvic junction.

Results

Cryotherapy has been one of the most studied ablative techniques, with multiple investigators having demonstrated the ability of temperatures of −20°C to induce tissue necrosis (Chosy et al, 1996; Campbell et al, 1998; Bishoff et al, 1999; Gill and Novick, 1999). In cryoablation, target tissue destruction is achieved through rapid freezing with liquid nitrogen or argon to a central, core temperature of approximately −195°C. Rapid freezing causes crystal formation in the microvasculature, extracellular spaces, and within the cells, eventually resulting in uncoupling of oxidative phosphorylation and rupturing of plasma cell membranes with subsequent solute shifts. Progressive failure of the microvasculature results in endothelial cell damage, edema, and platelet aggregation, with thrombosis and vascular occlusion. Thirteen weeks after ablation, fibrous collagen bundles replace the region of coagulation necrosis.

Chosy and associates (1996) demonstrated that a renal tissue temperature less than −20°C was necessary to create tissue necrosis. Uchida and colleagues (1995) evaluated renal cancer cell lines in culture by phase microscopy 24 hours after subjecting them to 60 minutes of −5°C, −10°C, −20°C, and −30°C. Approximately 95% of renal cancer cells survived after cooling for 60 minutes at temperature about −10°C but only 15% survived at a temperature of −20°C. Schmidlin and colleagues (2001) also found the threshold temperature for complete tissue ablation to be −16.1°C.

Despite the low temperatures achieved at the center of the probe during renal cryoablation, there is rapid warming of surrounding tissue toward the periphery of the ice ball. The margin of cell death beyond the probe is an important consideration in deciding the depth of probe deployment. Campbell and coworkers (1998) demonstrated that a temperature less than −20°C was achieved 3.1 mm behind the leading edge of the ice ball. These types of reports have encouraged surgeons to extend the ice ball to a minimum of 1 cm beyond the edge of the target lesion.

Sharp and associates (2003) demonstrated considerable variability in the actual tissue temperature created in the kidney during cryoablation. A single cryoprobe of 3 or 5 mm, with a central core temperature of −143°C (range: −133°C to −153°C), was used to take measurements at predetermined points moving away from the center of the probe. At only 8 mm from the center of the probe significant variability was found in tissue temperatures, ranging from −60° to −16°C. At a distance of 15 mm from the center of the probe tissue temperatures ranged from −50° to +13.5°C. These data may explain incomplete ablations reported, despite the ice ball extending beyond the margin of the lesion.

Microscopic examination of the ablation site immediately after the procedure demonstrates extensive hemorrhage into the glomerular and tubular urinary spaces. One week after cryosurgery, the lesion reflects four distinct histologic zones from the center: (1) complete necrosis, (2) inflammatory infiltrate, (3) hemorrhage, and (4) fibrosis and regeneration. By 13 weeks, these zones are replaced by fibrous connective tissue with occasional necrotic cellular debris (Bishoff et al, 1999).

Both CT and MRI have been used to assess patients after cryoablation. Gill and Novick (1999) used MRI for follow-up and noted that the primary criterion for successful cryoablation is nonenhancement of lesions after gadolinium administration. All cryolesions are isointense to the adjacent normal parenchyma on T1-weighted images and hypointense on T2-weighted images. On day 1, half the cases may have a hyperintense peripheral rim at the border of the cryolesion and normal kidney. On day 30, the cryolesions demonstrate an increase in signal intensity on both T1- and T2-weighted

images but no enhancement. MRI also demonstrates sequential contraction of the cryolesion (Gill et al, 2000). The disadvantage of radiologic follow-up, however, is that most cryolesions do not resolve completely (Rodriguez et al, 2000; Chan et al, 2001).

Rukstalis and coworkers (2001) performed open renal cryoablation on 29 patients with a median preoperative lesion size of 2.2 cm. Serious adverse events occurred in 5 patients, with only one event directly related to the procedure. One patient experienced a biopsy-proved local recurrence, and 91.3% of patients (median follow-up 16 months) demonstrated a complete radiographic response with only a residual scar or small, nonenhancing cyst.

Cestari and associates (2004) reported on 29 patients with renal cell carcinoma who underwent laparoscopic cryoablation for lesions averaging 2.6 cm (range: 1.0 to 6.0 cm). Close follow-up with MRI at day 1 and then at 1, 3, 6, 12, and 24 months and biopsy of the cryo site was done at 6 months. They found a progressive decrease in size of the renal lesion over time as determined by sequential MRI evaluation, with a mean size of 3.7 cm at 1 month and a mean size of 0.7 cm at 24 months. At a mean overall follow-up of 20.5 months they reported 2 of 29 patients with documented recurrence or inadequate treatment.

Gill and associates (2000) reported their results from a series of 32 patients with a pathologically proved renal cell carcinoma (mean tumor size of 2.3 cm) treated with laparoscopic cryoablation who had a minimum follow-up of 3 years. Two patients had positive biopsy for renal cell carcinoma at 6 months, and 3 patients developed new renal cell carcinoma lesions in the cryoablated kidney. Cancer-free survival was 98%.

Radiofrequency Interstitial Tissue Ablation

RF ablation has been utilized in a number of different clinical applications, including ablation of cardiac dysrhythmias and treatment of lesions arising from the liver, nervous system, and bone (Zlotta et al, 1997; McGovern et al, 1999; Nakada, 1999; Crowley et al, 2001). Urologists have used this technology to treat benign prostatic hypertrophy through a transurethral approach. RF energy can be introduced percutaneously, laparoscopically, or through an open approach under ultrasonographic, fluoroscopic, CT, or MRI guidance. The RF energy returns to the RF generator by way of a grounding pad that completes the electric circuit. The probe carries an alternating current of high-frequency radiowaves that causes the local ions to vibrate, and the resistance in the tissue creates heat to the point of desiccation (thermal coagulation). Microscopic examination reveals intense stromal and epithelial edema with marked hypereosinophilia and pyknosis immediately after RF treatment (Zlotta et al, 1997). This is replaced in a matter of days to weeks by coagulative necrosis with concentric zones of inflammatory infiltrate, hemorrhage, and fibrosis (Crowley et al, 2001).

Precise control of the size of the lesion can be achieved by temperature-based or impedance-based monitoring. Temperature-based systems depend on thermocouples imbedded within the tips of the electrodes. Sufficient amounts of RF energy (10 to 90 W) are applied to raise the tissue temperature to the minimal 60°C required to induce coagulative necrosis (Crowley et al, 2001). However, the observation that temperatures recorded at the limit of ablation have been found to be 20°C to 30°C cooler than temperatures recorded at the thermocouples makes sufficient tissue desiccation uncertain. For this reason, some authors favor an impedance-based system, which applies RF energy through the electric circuit until the tissue becomes sufficiently desiccated to become an insulator. In this manner, the flow of RF energy back to the return pad is blocked. A gradual decrease in tissue impedance suggests that the thermal lesion is continuing to evolve; a rise in impedance (to approximately 200 Ω) suggests that the tissue is desiccated and that further thermal lesion growth is unlikely (Lewin et al, 1998).

Although ultrasonography, fluoroscopy, CT, and MRI have all been used for positioning of the patient and for percutaneous placement of the RF probe, none of these modalities has proved reliable for the intraoperative monitoring of the RF lesion. On ultrasound imaging, there is no immediate change in the echotexture in the area of RF ablation, and color and power Doppler ultrasonography are of no added benefit because of variable and inconsistent findings (Crowley et al, 2001). Moreover, RF treatment can sometimes disturb ultrasound imaging (Zlotta et al, 1997).

Walther and coworkers (2000) explored 14 tumors less than 5 cm in 4 patients with multiple renal lesions and performed RF ablation just before surgical excision. A complete immediate treatment effect was noted in 10 of 11 patients; in the final case, only 35% of the tumor was ablated. Excluding any technical inconsistencies, as with the early results of cryoablation, this early treatment failure needs to be put into the context of long-term, prospective clinical trials.

The definition of success after RF ablation is similar to that for cryoablation in that lack of enhancement on radiographic imaging is currently considered to be successful ablation. Matsumoto and associates (2004) describe contrast medium–enhanced images in a series of 64 patients treated with either percutaneous (34), laparoscopic (28), or open RF ablation. At a median follow-up of 14 months, 62 lesions demonstrated no enhancement on CT. Endophytic tumors developed a low-density, nonenhancing, wedge-shaped defect with fat infiltration between the ablated tissue and normal kidney. Exophytic tumors maintained their shape but had no enhancement on CT. Two patients had pathologic confirmation of recurrence after RF ablation.

Complications

In a multi-institutional review of 139 cryoablation procedures and 133 RF procedures Johnson and associates (2004) reported an 11% complication rate with 1.8% major and 9% minor complications. In this series, 181 procedures were performed percutaneously and 90 performed laparoscopically. Significant complications included hemorrhage, ileus, ureteropelvic junction obstruction, urinoma, conversion to open surgery, and death (from aspiration pneumonia). In the laparoscopic subgroup, complications were seen in 9% of patients; 4% were directly related to the laparoscopic approach, 4% were attributed to the ablation procedure, and there was one iatrogenic case of pneumonia. The most

common complication in the series was pain or paresthesia at the ablation probe insertion site (Johnson et al, 2004).

COMPLICATIONS OF LAPAROSCOPIC RENAL SURGERY

Complications are an unavoidable consequence of surgical practice. Even when the surgery is in the most experienced hands, factors related to the patient, operating room environment, and chaotic forces can lead to an untoward event. Thus, efforts at prevention and the patients' understanding should be maximized. Moreover, if complications occur, the consequences can often be minimized through early recognition and appropriate intervention.

Life-threatening vascular injuries usually occur during dissection of the renal hilum. The acute angle of insertion of the right gonadal vein into the inferior vena cava is a potential site of injury and bleeding during elevation of the gonadal and ureter. Injury to arteries, veins, branches, and accessory vessels can result in bleeding that may require conversion to open surgery. **There are also reports of complete transection of the vena cava during retroperitoneoscopic nephrectomy** (McAllister et al, 2004). As such, one must be certain of anatomic relationships before firing a stapling device. A multiinstitutional review of endovascular stapler complications showed a malfunction rate of 1.7% (10 of 565 cases), with 8 cases involving the renal vein and 2 cases involving the renal artery. Blood loss resulting from the malfunction was between 200 and 1200 mL. Conversion to open surgery for hemostasis was required in 20% of the malfunction cases. The etiology of stapler failure was due directly to the instrument in 3 cases and to preventable causes in 7 cases. Preventable causes included stapling over clips or incomplete transection due to incorrect placement (Chan et al, 2000).

Recently, reports of patient concern over body image alteration after renal surgery have appeared in the literature. These studies show that flank incisions, as traditionally made for open surgery and some hand-assisted cases, result in significantly larger postoperative, surface area and volume changes on the operated side compared with the noninvolved flank. Furthermore, patients reported dissatisfaction with the body changes occurring in up to 60% of flank incisions (Chatterjee et al, 2004; Kobayashi et al, 2004). These types of body image changes have not been reported from laparoscopic or transperitoneal (midline or subcostal) surgical approaches.

Complications can arise during each step of the laparoscopic nephrectomy. Access-related problems such as solid organ injury, bowel injury, abdominal wall hematomas, and epigastric vessel injuries have been reported. **Bleeding complications can be minimized by carefully inspecting the abdomen at the conclusion of surgery. Examination after lowering the intra-abdominal pressure can reveal bleeding veins tamponaded by the pneumoperitoneum. One also needs to carefully inspect the area of surgical dissection and the trocar sites for adequate hemostasis. Common areas of postoperative intra-abdominal bleeding include the adrenal gland, renal hilum, mesentery, gonadal vessels, and ureteral stump.**

Coagulation of the surface of the kidney with the argon beam coagulator will increase the intra-abdominal pressure to dangerously elevated levels if the gas is not allowed to escape or be actively evacuated during coagulation. There is one case report of a tension pneumothorax caused by the argon beam coagulator during laparoscopic partial nephrectomy (Shanberg et al, 2002).

Patients undergoing laparoscopic renal surgery can experience intravascular volume overload, because the laparoscopic approach is associated with far less insensible fluid loss compared with the open procedures. There is also a vascular-mediated oliguria that should not be aggressively treated because diuresis is seen after release of the pneumoperitoneum. Volume overload in patients with diminished cardiac reserve can result in congestive heart failure manifested by oliguria. Poor urine output or hemodynamic instability in the postoperative period should initiate an evaluation to rule out bleeding; if the workup is negative, diuresis can be induced if clinically indicated.

Additionally reported common complications include incision hernia after intact specimen removal, transient thigh numbness, prolonged ileus, pulmonary embolus, pneumonia, brachial nerve injury, and unrecognized bowel injury (Copcoat et al, 1992; Kavoussi et al, 1993; Kerbl et al 1993a, 1993b, 1994; Rassweiler et al, 1993, 1996, 1998; Nicol et al, 1994; Perez et al, 1994; Parra et al, 1995; Keeley and Tolley, 1998; Rozenberg et al, 1999).

Unrecognized bowel injury is a potential complication of any transabdominal or retroperitoneal surgical procedure. **One of the most devastating complications occurring as a result of laparoscopic surgery is unrecognized bowel injury. Because only 10% of the laparoscopic instrument is in the visual field, these injuries can occur out of the surgeon's field of view. The combined incidence of bowel injury in the literature is 1.3 in 1000 cases.** Most injuries (69%) are not recognized at the time of surgery. Small bowel segments account for 58% of injuries, followed by colon (32%) and stomach (7%). Fifty percent of bowel injuries are caused by electrocautery, and 32% occur during Veress needle or trocar insertion. The presentation of bowel injuries in the laparoscopic group differs from that described with open postoperative injury with peritonitis. Patients with unrecognized bowel injury after laparoscopy typically present with persistent and increased trocar site pain at the site closest to the bowel injury. Later, signs and symptoms include nausea, diarrhea, anorexia, low-grade fever, persistent bowel sounds, and a low or normal white blood cell count. The patient's condition can rapidly deteriorate to hemodynamic instability and death if the injury is not quickly recognized and treated (Bishoff et al, 1999). CT is the initial diagnostic modality of choice (Cadeddu et al, 1997), and open exploration is usually required to evacuate bowel spillage and perform the necessary repair (Fig. 51–41).

Insufflation-related complications include subcutaneous emphysema and gas embolism. The laparoscopic surgeon should be aware that the subcutaneous space communicates with the anterior mediastinum. Consequently, leaking trocar sites or incorrectly positioned trocars can allow gas to travel under the skin into the mediastinum, resulting in a pneumomediastinum or pneumothorax (Bruyere et al, 2001; Siu et al, 2003).

Diaphragm injury is uncommon and is usually immediately recognized as peak airway pressures suddenly increase and ventilation of the patient becomes difficult. Immediate

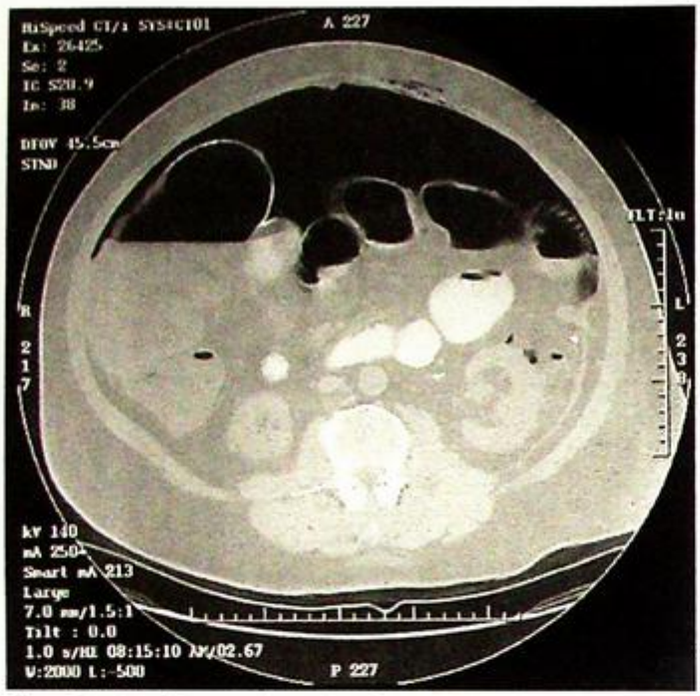

Figure 51–41. CT scan taken 9 days after partial nephrectomy when the patient presented to the clinic for routine follow-up complaining of distention and worsening abdominal pain for the past 3 days, low-grade fever, leukopenia, and pain out of proportion at a single trocar site. CT shows dilated loops of large bowel and significant amounts of free air. Exploration revealed a small perforation in the cecum.

treatment is needed to prevent a tension pneumothorax. This complication usually occurs during dissection of the upper pole of the kidney. It can be successfully treated laparoscopically with placement of a percutaneous meter to relieve the pneumothorax (Del Pizzo et al, 2003).

Complication rates have been reported in several large multi-institutional reviews of laparoscopic simple nephrectomy. In a series of 185 patients, Gill and coworkers (1995) reported an overall complication rate of 12% for benign disease, with 5% of patients requiring conversion to open surgery. In their series, the incidence of complications decreased markedly with increasing experience. **In fact, 70% of the complications occurred during the first 20 cases at each institution. A learning curve of approximately 20 laparoscopic nephrectomy cases is also supported by other reports** (Keeley and Tolley, 1998; Rassweiler et al 1998; Fahlenkamp et al, 1999). Rassweiler and colleagues (1998) published the results of a series of 482 laparoscopic nephrectomies (444 procedures for benign disease) performed by 20 surgeons at 14 different European medical centers. They reported a 6% overall complication rate, with 10% of the cases converted to open surgery. **The majority of patients converted to open surgery had infectious causes of renal abnormality as the leading indication for kidney removal.** Bleeding was the most common cause of open conversion, followed by the surgeon's inability to visualize the renal hilum for dissection. Hemal and associates (1999) presented a series of 126 laparoscopic nephrectomies performed for benign disease. In their series, 12% (15 of 126) of the patients required conversion to an open surgical procedure. The overall incidence of major and minor complications was 17% (22 of 126).

In 1998, Cadeddu and colleagues reported a minor and major complication rate of 9.6% in a series of 157 laparoscopic radical nephrectomies.

In several different contemporary series, comparing open, hand-assisted, and laparoscopic nephrectomy for malignancy the complication rates were 10%, 17%, and 12%, respectively ($P = .133$) (Chan et al, 2001; Shuford et al, 2004).

Varkarakis and associates (2004) compared complication rates between 28 patients younger than 75 years of age and 33 patients older than 75 years of age and found no difference in surgical or longer-term morbidity between these two groups. In patients at high risk for perioperative complications determined by the American Society of Anesthesiologists score greater than or equal to 3, no significant differences were noted in complication rates between HALN and open radical nephrectomy (Baldwin et al, 2003).

Rare or unusual complications include nerve injury, chronic pain syndrome, and orchialgia. Several authors have reported cases of chronic pain syndrome or nerve injury after laparoscopic radical nephrectomy presenting as constant burning discomfort in the ipsilateral flank requiring narcotics and pain clinic consultation for chronic management (Wolf et al, 2000; Oefelein and Bayazit, 2003). In a series of 381 laparoscopic donor nephrectomies, Kim and colleagues (2003) reported ipsilateral orchialgia in 10% of patients. Onset of pain occurred at a mean of 5 days after surgery (range: 6 to 52 months), and at 6 months 50% had complete spontaneous resolution.

SUMMARY

The laparoscopic approach to renal disease has emerged as a standard treatment of renal pathology. In a wide variety of

KEY POINTS: LAPAROSCOPIC SURGERY OF THE KIDNEY

- Laparoscopic radical and partial nephrectomies provide equivalent cancer control compared with open techniques.
- When ablating renal lesions, temperatures less than 20°C are necessary for cell death. Moreover, the leading edge of the ice ball should be 1 cm beyond the tumor.
- Unrecognized laparoscopic bowel injuries usually present as indolent signs compared with injuries sustained after open surgery.
- Patients with a laparoscopic bowel injury are usually afebrile with a normal to low serum white blood cell count, focal abdominal discomfort, and mild ileus.
- Vascular injuries are the most common cause of conversion to open surgery with laparoscopic renal surgery. This is more commonly seen in patients undergoing nephrectomies for chronic inflammatory processes.

applications, patients benefit from decreased morbidity without sacrificing therapeutic outcomes. Results are similar to those obtained with open surgery. Early results with ablative techniques hold promise for eventual nonoperative management of many renal lesions.

CONCLUSION

RATIONALE FOR ENERGY ABLATIVE THERAPY

Modern imaging techniques have resulted in a dramatic change in the clinical landscape of renal tumors, with a significant migration to smaller and lower stage lesions in asymptomatic patients (Chow et al, 1999; Pantuck et al, 2001). Incidentally detected renal cell carcinoma (RCC) has a more favorable prognosis (Hsu et al, 2004), and there is an inverse correlation between tumor size and the odds of having clear cell versus papillary and high-grade versus low-grade RCC (Duchene et al, 2003; Frank et al, 2003). Even with most advanced cross-sectional imaging techniques it remains difficult to differentiate between RCC and some solid benign tumors, especially oncocytoma (Herts, 2003; Walter et al, 2003). Twenty percent to 22% of tumors 4 cm or less in diameter and up to 46% of tumors smaller than 1 cm prove to be benign at histologic examination (Duchene et al, 2003; Frank et al, 2003).

Not surprisingly, the majority of small renal masses grow slowly, with growth rates in diameter of 0.22 to 0.54 cm per year (Volpe et al, 2004; Wehle et al, 2004) having been observed in patients managed by surveillance only. A small number, however, progress rapidly, and at present there is no way these can be identified by imaging. Magnetic resonance imaging (MRI) or computed tomography (CT)–guided fine needle aspiration biopsy correctly defines most benign lesions, but it is usually insufficient for subclassification or grading of RCC (Tuncali et al, 2004). Core biopsies taken with larger caliber needles permit this more reliably but carry an inherent, albeit low, risk of tumor cell seeding and hemorrhage (Wolf, 1998). Even advocates of surveillance strategies consider higher nuclear grade RCC unsuited for a "watchful waiting" approach (Renshaw, 2004). Given the fact that up to 38% of incidentally discovered RCCs smaller than 3 cm in diameter have extracapsular extension (>T3) and up to 28% are Fuhrman grade greater than 3 (Hsu et al, 2004), surgical removal remains the standard therapy.

Nephron-sparing partial nephrectomy has been shown to be as effective as radical nephrectomy in achieving cure for tumors less than 4 cm in diameter (Herr, 1999; Fergany et al, 2000; Lau et al, 2000) regardless of whether they are in a peripheral or central location (Hafez et al, 1998). To reduce access trauma, laparoscopic partial nephrectomy is rapidly gaining acceptance (Janetschek et al, 2000; Gill et al, 2002; Janetschek, et al, 2004). Nevertheless, the learning curve in mastering laparoscopic partial nephrectomy remains substantial, with a reported median surgical time of 3 hours and a median warm renal ischemia time of 27.8 minutes in one of the largest series (Gill et al, 2003). Given the low tendency of the majority of small renal tumors to progress and the fact that the largest increase in their incidence occurred in the seventh to ninth decade age groups (Chow et al, 1999) with inherently high comorbidity, less invasive treatment options appear very attractive.

Less invasive treatment can be achieved by targeted destruction of the tumor with energy-based ablation techniques. These techniques were initially employed to provide an ischemic plane at nephron-sparing partial nephrectomy to reduce bleeding, but destruction of the entire tumor with or without subsequent removal is now the objective. Small renal tumors are good targets as they often have a spherical shape, are unifocal, and are surrounded by homogeneous renal parenchyma and perirenal fat. The entire surface of the kidney is fairly simple to reach either laparoscopically or percutaneously, and real-time monitoring of tissue destruction can be

attempted by intraoperative thermometry, ultrasonography, CT, or MRI. Conversely, high renal perfusion poses real challenges for this approach. Needle puncture of the renal capsule immediately results in bleeding along the tract, with the risk of seeding tumor cells and losing ablative energy. Even more significant are the proximity to large intrarenal vessels, which may drain ablative energy by conduction in a manner that is difficult to control. Attempts at needle chemoablation have proved disappointing in the kidney for this reason, as the chemoablative agent tends to spread in an irregular and unpredictable manner (Rehman et al, 2003). Only ablative techniques that destroy renal tissue in a homogeneous, safe, and rapid manner can adequately destroy renal tumors. At present, this appears possible only by freezing, heating, or radiosurgery.

DEFINING SUCCESSFUL ABLATION

To gain clinical acceptance, the techniques have to achieve oncologically complete destruction of the tumor with less morbidity than with standard surgical procedures. Moreover, these must be of technical complexity that allows widespread adoption. Definitive proof of their efficacy requires long-term data on disease-free survival. Given the slow growth rate of most of the lesions, intermediate evaluation has to be based on experimental data showing dose-dependent tissue destruction in the target area, on intraoperative monitoring of the lesion with subsequent histologic evaluation, and on clinical data on complications and intermediate follow-up.

Complete loss of contrast enhancement on follow-up CT or MRI scans has been considered a sign of complete tissue destruction (Matsumoto et al, 2004). Of note, viable residual tumor has been demonstrated in nonenhancing lesions (Rendon et al, 2002) after radiofrequency (RF) ablation. The lesion should also show progressive shrinking after therapy as proof of remission, although this may take months and is less pronounced after RF ablation (Lee et al, 2003; Lowry and Nakada, 2003; Nakada et al, 2004). The role of biopsies remains controversial. A preoperative needle biopsy establishes the diagnosis and is important for assessing outcome results, but frozen sections of intraoperative needle biopsy specimens are fairly inaccurate and unreliable for clinical decision-making (Dechet et al, 1999, Zagoria et al, 2004). Likewise, perioperative biopsies may be misleading as to the viability of residual structures, and negative results in masses less than 3 cm in diameter should always be viewed with caution (Lechevallier et al, 2000; Raj et al, 2003; Rybicki et al, 2003). Whatever ablative technique is used, patients need close post-procedural follow-up with serial CT or MRI scans performed by a dedicated radiologist every 3 months for 12 to 18 months followed by long-term surveillance either until complete regression or, if a lesion becomes stable, annually to ensure no potential recurrence from a margin (Lowry and Nakada, 2003; Nakada et al, 2004). Failure of the lesion to shrink within 6 months after therapy or any growth mandates renal biopsy regardless of contrast enhancement. In addition, 3.7% of renal cell cancers less than 3 cm in diameter have multifocal satellite lesions (Nissenkorn and Bernheim, 1995), a possible reason for recurrent tumors after any form of nephron-sparing therapy (Jang et al, 2005).

CRYOABLATION

Mode of Action and Experimental Data

Tissue destruction by freezing and thawing has been utilized for a variety of medical indications for over 150 years, but it was not until vacuum-insulated liquid nitrogen or argon-cooled probes were developed that targeted cryoablation of kidney tumors came within clinical reach (Gage, 1998). Through the Joule-Thomson effect (i.e., rapid cooling of the tip of a probe by highly compressed liquid nitrogen or argon expanding though a restricted orifice to the gaseous state), temperatures of −175° C to −190° C can be pinpointed within soft tissues. Cryoprobes 1.5 to 8 mm in diameter are now available. An ice ball is rapidly generated around this core and can be monitored by real-time intraoperative ultrasonography, CT, or MRI. Tissue necrosis is achieved by direct damage on a cellular level and indirect damage from malperfusion during the thawing phase. The former are complex sequelae of intracellular ice formation with mechanical cell destruction and extracellular ice formation with subsequent dehydration injury and solute effects on cellular lipid and protein biophysics (Hoffmann and Bischof, 2002). Even if primarily sublethal, secondary reperfusion injury ultimately results in cell death. Histologically, the ultimate outcome is coagulation necrosis, followed by fibrosis and scarring (Campbell et al, 1998; Chosy et al, 1998).

Renal cryoablation has been shown to produce predictable and reproducible tissue destruction in animal models (Campbell et al, 1998; Chosy et al, 1998; Collier et al, 2004). Its extent depends on the speed of freezing, the number of freeze-thaw cycles, the size as well as area of contact of the cryoprobe, and, most important, on the lowest temperatures reached and the hold time at subzero temperatures (Smith DJ et al, 1999; Finelli et al, 2003). Complete destruction of normal renal parenchyma occurs at temperatures below −19.4° C (Chosy et al, 1998). Cancer cells may need even lower temperatures for reliable cell death (Larson et al, 2000). In experimental settings, these temperatures were reached only 4 to 6 mm inside the edge of the forming ice ball (Campbell et al, 1998; Chosy et al, 1998). Histologic data on cryotherapy-assisted partial nephrectomy of large RCCs confirm this (Bargman et al, 2003). In clinical practice, the ice ball is therefore in general extended 5 to 10 mm beyond the tumor margin. Thus, for reliable treatment of tumors 2.5 cm in diameter, a cryoprobe of 3.4 mm or greater or multiple thinner probes must be used (Gill et al, 2000; Rukstalis et al, 2001). Not all structures are equally cryosensitive. The renal collecting system has been shown to remain intact in spite of being within the ice ball, provided it is not lacerated mechanically (Sung, 2003).

Comparing lesion size and volumes of confluent necrosis, significantly larger lesions were noted with double-freeze cycles than with a single freeze (Woolley et al, 2002). In contrast to previous assumptions, active thawing with helium gas at 15° C to 20° C/min does not infringe on lesion size but reduces procedural time significantly (Gage, 1998; Gill and Novick, 1999). Occlusion of the renal artery during freezing increases the size of the cryolesion only marginally (Campbell et al, 1998; Collier et al, 2004). In clinical practice, real-time monitoring of the advancing ice ball, with an extension 10 mm beyond the tumor margins, has proved a reliable clinical end-

point (Gill et al, 2000). Thermometry with thermocouples at the tumor margin targeting a margin temperature of −40° C and on-line MRI monitoring have been reported to be comparable (Rukstalis et al, 2001; Shingleton and Sewell, 2001). As the freeze process depends on probe contact, puncture cryoablation is the preferred technique today. It can be achieved by open surgical access, laparoscopically, or percutaneously.

Open Surgical and Laparoscopic Cryoablation

After isolated case reports on cryoablation using open access (Delworth et al, 1996), a first report on systematic use of this approach to treat 29 tumors averaging 2.2 cm in diameter in 29 patients was published (Rukstalis et al, 2001). Using intraoperative ultrasound monitoring and targeting thermosensor-controlled margin temperatures of −40° C, double-freeze sequences were performed with one to three cryoprobes. With a median follow-up of 16 months, only one patient had a biopsy-confirmed recurrent tumor. Postoperative morbidity was moderate, with five patients needing some intervention after cryoablation to control bleeding from the ablation site. Cryotherapy-assisted nephron-sparing removal of larger renal masses using a single-freeze ice ball along the tumor margin as a guide for excision has also been utilized to reduce the morbidity of open partial nephrectomy (Bargman et al, 2003).

The laparoscopic approach permits similar exposure and visualization of the kidney with less access trauma. Anterior or medially located tumors are approached transperitoneally, and posterior tumors by retroperitoneal access. A deflectable, laparoscopic ultrasound transducer is used for precise insertion of the cryoprobe and for monitoring the advancing ice ball (Gill et al, 2000). After withdrawing the cryoprobe, hemostasis is ascertained by local compression with bioadhesive bolsters or argon beam coagulation, or both. In the first larger clinical series 32 patients with small peripheral renal tumors were treated. Using a double freeze-thaw cycle, cryoablation time averaged 15.1 minutes and surgical time 2.9 hours. Morbidity was minimal with a mean blood loss of 67 mL, no complication requiring an additional intervention, and an average hospital stay of 1.8 days. Five of 20 patients followed up by sequential MRI had no demonstrable residual lesion after 1 year, and in the other 15 the lesions had decreased in size by an average 66% (Gill et al, 2000). Subsequently, the group presented 3-year follow-up data for the first 56 patients with a mean tumor size of 2.3 cm (range 1 to 4 cm) and biopsy-confirmed renal cancer in 36 patients (Steinberg et al, 2002; Spaliviero et al, 2004). Only two patients had biopsy-confirmed recurrences and subsequently had a radical nephrectomy. Other authors reproduced these results (Table 52–1; Fig. 52–1). Negative biopsies or loss of gadolinium enhancement and shrinkage of the tumor on follow-up MRI or CT or both were achieved in 84 of 91 patients with histologically confirmed renal cell cancer, although some lesions required retreatment. This represents an approximately 8% failure rate, which is higher than that for standard partial nephrectomy, especially given the lack of long-term follow-up. Failure mainly occurs with tumors more than 3 cm in diameter and centrally located tumors (Jang et al, 2005).

Percutaneous Cryoablation

The first attempts at cryoablation of kidney tumors in humans were performed percutaneously but proved unsatisfactory because of technical limitations (Uchida et al, 1995). The development of ultrathin nonmagnetic cryoprobes and open access interventional MRI systems, which permit simultaneous monitoring of the procedure in sagittal and coronal planes with imaging beyond the ice ball, provided technical breakthroughs (Harada et al, 2001). Shingleton and Sewell (2001) used a 2- or 3-mm cryoprobe, 5-mm margins, and triple

freeze-thaw sequences of −80° C to −70° C. To treat larger tumors, the probe was inserted repeatedly to create overlying ice balls. The procedure was performed with general anesthesia or sedation, with a hospital stay less than 24 hours in 95% of patients treated. They updated their experience in 70 patients, including patients with von Hippel–Lindau disease and RCC in a transplanted kidney (Shingleton, 2003). With an average follow-up of 24 months for 59 patients, 9 (15%) patients required retreatment because of incomplete initial tumor ablation. Only one patient required transfusions secondary to a perinephric hematoma and there were no cancer-related deaths. In spite of the encouraging results, the efficacy of percutaneous cryoablation in achieving complete tumor ablation has not been confirmed histologically in clinical series. Moreover, the need for an open access MRI unit or fluoroscopy capable CT scanner for intraoperative monitoring can limit availability. Percutaneous cryoablation with sonographic guidance has been described (Bassignani et al, 2004), but the poor echogenicity of the cryoprobes, difficult monitoring of the situation anterior to the ice ball, and the mobility of the kidney at puncture render this a potentially suboptimal approach.

In conclusion, experimental data document the potential of cryoablation for treating renal tumors. Promising clinical results are emerging that show that this is a minimally invasive and feasible approach for treating peripheral lesions less than 3 cm in diameter. Morbidity is low and mainly consists of probe site pain and paresthesia and minor hemorrhage, with a higher incidence after percutaneous cryoablation (Johnson et al, 2004). Major complications have been reported in about 2% of patients, mainly from hemorrhage and urinary fistula (Johnson et al, 2004).

RADIOFREQUENCY ABLATION

Mode of Action and Experimental Data

Heating above 60° C results in instantaneous and irreversible coagulation necrosis of all biologic tissues, with denaturation of cellular proteins, melting of lipids, and disintegration of cell membranes. Temperatures in this range are reached consistently by delivering alternating electric current with a frequency in the radio segment of the electromagnetic spectrum to the target area through an interstitial needle electrode (Leveen, 1997; Rendon et al, 2001; Rehman et al, 2004). This can be achieved either with bipolar electrodes, where the current flows from an active electrode to a negative electrode built into the delivery needle, or with a monopolar system. With the latter, the patient is grounded with an electrode pad applied to the skin to complete the electric circuit and RF energy is released at the uninsulated monopolar needle tip. RF energy administered to the tissue causes ionic agitation in the cells and, as a result of electrical impedance of the tissue, local heating. The energy then dissipates by conductive heating. Provided the electrical impedance of the tissue remains low, a dynamically expanding sphere of heat-induced tissue damage is created outward from the electrode (Leveen, 1997).

Tissue death depends on the distance from the electrode, RF current intensity, and the duration of its application. If the current is too high or applied too rapidly, desiccation and charring occur, impedance increases sharply, and the heating process comes to a standstill (Djavan et al, 2000). Lesion volume is then smaller than desired and, because of scattered areas of water vaporization, may have an irregular shape. Multiarray electrodes from which up to 10 evenly spaced wire electrodes are deployed into the tissue in an umbrella-like manner at a constant radius from an axial insulated sheath achieve more regular spherical lesions. As tissue impedance adjacent to a particular electrode rises, the current is automatically redistributed to areas of lower impedance, resulting in more homogeneous lesions (Leveen, 1997).

In experimental studies, only multitine RF has been shown to cause complete necrosis consistently. Single-needle RF alone, regardless of whether monopolar or bipolar, always produced lesions with skip areas of viable cells (Rehman et al, 2004). Rapid increase of impedance can be avoided by cooling the electrode with circulating chilled water. The tissues closest to the electrode are not overheated, permitting greater overall energy deposition and subsequently larger lesions (Lorentzen, 1992). Alternatively, hypertonic saline or gel can be perfused into the tissue through a cannulated RF probe. The electrically conductive agent facilitates the delivery of energy from the electrode to surrounding tissue, rendering it a much larger, "virtual" electrode. Impedance remains lower and larger volumes are ablated (Leveillee and Hoey, 2003). Saline diffusion depends on the anatomic structure. In the kidneys of laboratory animals, "wet" RF has consistently been shown to produce larger lesions (Patel et al, 2000; Renshaw, 2004), although, in contrast to cryoablation, not always complete necrosis.

With all thermal ablation techniques the "heat sink" effect of large blood vessels near the target zone may conduct energy away to an extent that complete cell killing is not achieved. In swine kidneys, dry RF ablation usually caused slightly larger and more homogeneous lesions if the renal artery was occluded during ablation, but the difference from lesions obtained in normally perfused kidneys appeared marginal (Corwin et al, 2001; Marcovich et al, 2002) and not worth risking renal infarction peripheral to the thermal lesion (Kariya et al, 2003).

Because of the low intrinsic contrast between normal and ablated tissues and artifacts from gas bubble formation, real-time imaging of the developing thermal lesion with intraoperative ultrasonography, MRI, or CT has proved unreliable (Renshaw, 2004). In general, imaging techniques are used only to place the electrodes (Fig. 52–2), and RF is monitored by measuring temperature or impedance changes, or both, usually with feedback from thermosensors integrated at the end of the RF tines. Provided the treatment protocols recommended by the manufacturer are adhered to, temperature-based and impedance-based RF generators seem equally effective (Gettman et al, 2002a). Temperatures over 70° C throughout the entire target zone are needed for complete ablation. To achieve this consistently, temperatures of 105° C have to be targeted at the tip of each RF tine, and this may even be insufficient with central tumors located in the vicinity of large vessels (Ogan and Cadeddu, 2002a). Infrared thermography with a laparoscopic infrared camera reliably documents renal temperatures above 70° C but only at the surface of the organ (Ogan et al, 2003).

Ultimately, monitoring of the spatial distribution of heating with real-time image-based thermometry is needed. Attempts to achieve this using ultrasonography, MRI thermometry, impedance tomography, or microwave radiometry appear promising but are still experimental (Varghese et al, 2002). Simpler visualization of the expanding RF lesion may be another advantage of wet RF ablation, especially if a temperature-modulated vapor appearing hyperechoic at ultrasonography is used (Johnson et al, 2003).

Laparoscopic Radiofrequency Ablation

RF ablation has been utilized laparoscopically, both for in situ ablation of tumors and to secure hemostasis at partial nephrectomy. In one series (Jacomides et al, 2003), 11 tumors 1.1 to 3.6 cm in diameter, which were located in positions where partial nephrectomy was considered difficult, were ablated. The RF probe was introduced percutaneously and, under laparoscopic control, the tumor was ablated at 105° C, with impedance less than 75 ohm, and the target zone extended at least 1 cm over the tumor diameter. With a mean follow-up of 9.8 months, no lesion showed enhancement on serial CT studies and five lesions disappeared completely. The authors nevertheless recommend excision after RF ablation

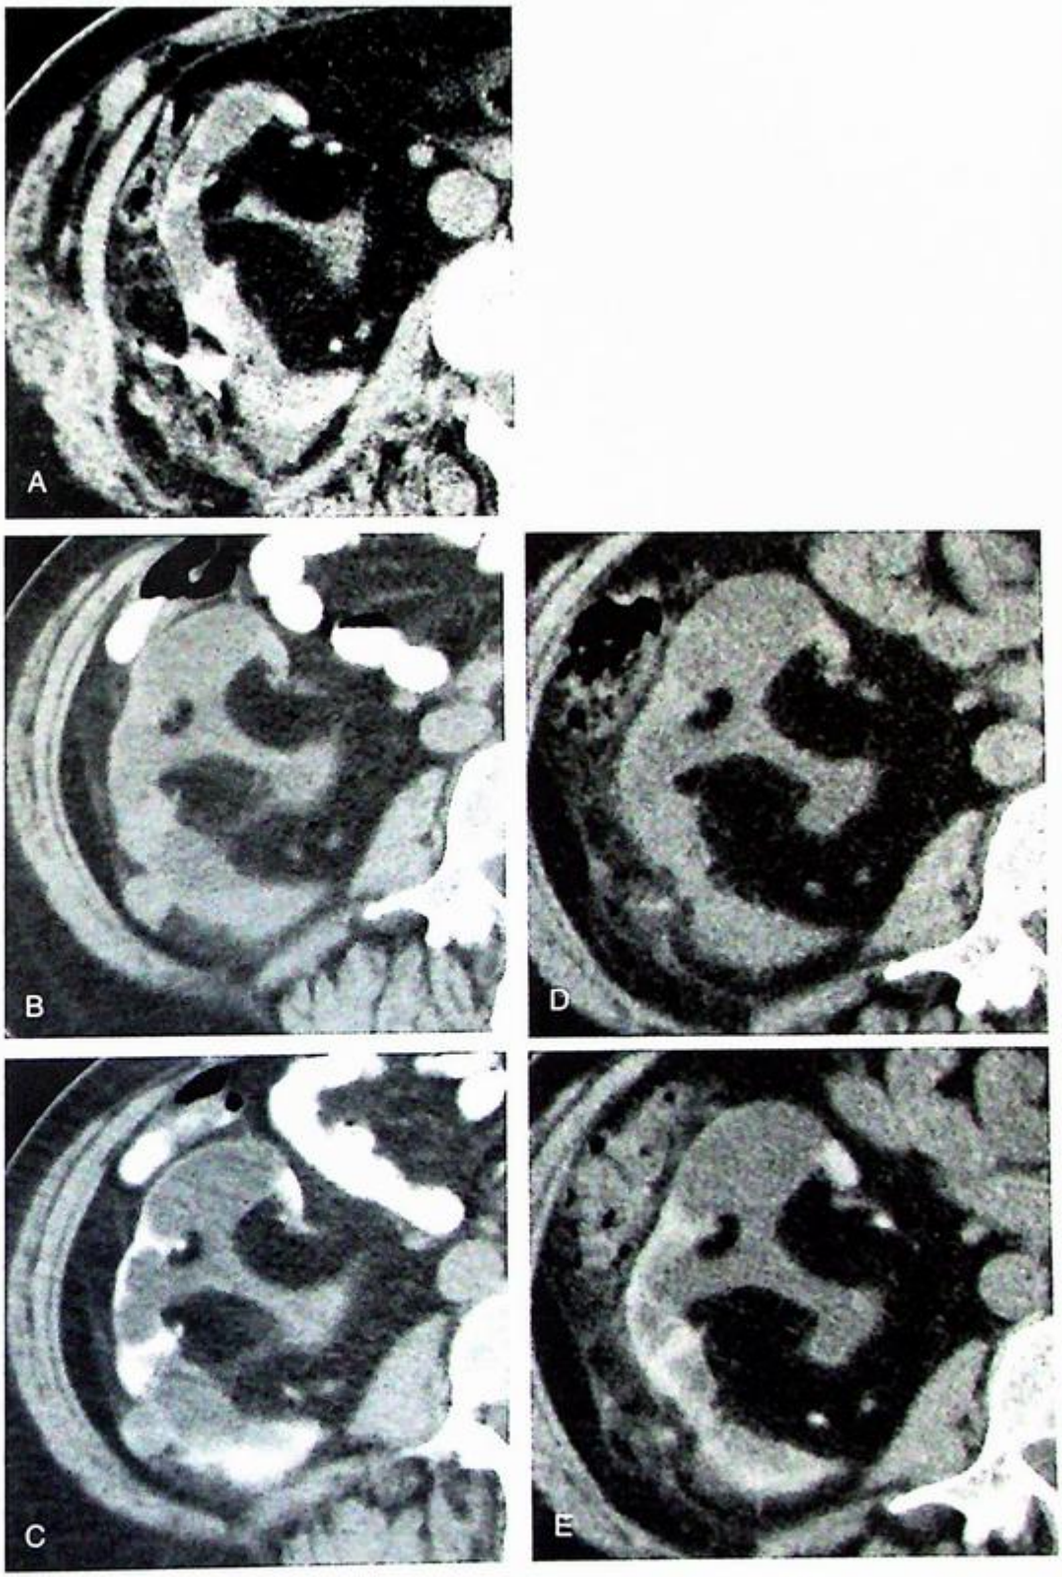

Figure 52–2. Percutaneous radiofrequency (RF) ablation of biopsy-proved papillary cancer in a hydronephrotic kidney after multiple stone episodes: monopolar RF probe in tumor (**A**) and unenhanced and contrast-enhanced computed tomography scans before (**B** and **C**) and 6 months (**D** and **E**) after RF ablation showing complete loss of contrast enhancement and fibrotic shrinking of lesion.

where this is technically simple, and they performed it without complication in six patients. One of these patients had a focal positive margin at histologic evaluation. RF has also been employed for circumferential coagulation around the tumor to be used as a plane of resection at laparoscopic partial nephrectomy (Coleman et al, 2003). Histologic evaluation of the specimen was not impaired. Laparoscopic control does, however, not rule out complications from damage to adjacent structures such as the collecting system (Johnson et al, 2003) or loss of renal function from overzealous tissue ablation (Ogan et al, 2002).

Percutaneous Radiofrequency Ablation

The thinner diameters of RF probes render a percutaneous approach using CT guidance most attractive. Since a first report in 1997 (Zlotta et al, 1997), a number of phase II studies have been published (Table 52–2). Tumor persistence or

recurrence seems to depend mainly on selection of patients. With small exophytic, peripheral tumors radiographic complete remission was achieved in 50 of 51 (98%) masses treated in one series, whereas this was accomplished in only 16 of 22 (72%) masses located centrally, although of comparable size (McGovern et al, 2003). Morbidity is low and in general limited to minor perinephric hematomas, although bile and urine fistulas, pancreatic pseudocysts, and a ureteric stricture have been reported (Johnson et al, 2004; Zagoria et al, 2004).

These enthusiastic reports are dampened by three studies in which renal tumors were removed after "curative" RF therapy (Matlaga et al, 2002; Michaels et al, 2002; Rendon et al, 2002). At histologic examination the majority of tumors still showed areas of viable-appearing tumor cells. Standard histology may be misleading immediately after RF application, and loss of reduced nicotinamide adenine dinucleotide (NADH) activity has been postulated as a definitive sign of cell death (Ogan and Cadeddu, 2002b). Six of 13 (46%) tumors had residual NADH activity after RF ablation (Matlaga et al, 2002; Michaels et al, 2002). These findings question the therapeutic efficacy of RF ablation with the techniques presently used. Clearly, tumor cells are destroyed, but the unreliability of cell kill at least in the border region renders the technique problematic. The use of higher energy generators, multiple treatment cycles, wet RF, and better cooling of the electrodes seem to produce more reliable results (Rehman et al, 2004; Zagoria et al, 2004), but further refinement of the RF delivery systems, better selection of patients, standardization of the technique, and, most important, improved intraoperative monitoring are needed.

MICROWAVE ABLATION

Early experimental studies with microwave thermotherapy and needle-shaped antennas have shown that temperatures around 60° C can be reached and sustained over time in rabbit kidneys, resulting in focal coagulative necrosis (Hradec and Fuchs, 1969; Kigure et al, 1996). Higher temperatures are difficult to achieve in a normally perfused kidney, and hence multiple needle placements and treatments are necessary for ablating larger lesions. A microwave tissue coagulator based on this principle has been developed to facilitate hemostasis

at partial resection of parenchymal organs without ischemia. A needle antenna 10 to 40 mm long is inserted into the parenchyma along the planned plane of resection and a cone-shaped area of coagulative necrosis is produced between the needle and a circle electrode at its base. Parenchymal dissection then follows this plane in a bloodless field. Large clinical series document that the technique permits safe partial nephrectomy for small renal tumors without the need to clamp hilar vessels (Naito et al, 1998; Hirao et al, 2002; Hiroya et al, 2003), but the instruments presently available limit this to open access.

INTERSTITIAL LASER COAGULATION

By inserting bare-tip laser fibers directly into tissue, laser energy can be utilized for focal tissue ablation by a combination of cavitation and thermal processes. Both neodymium:yttrium-aluminum-garnet (Nd:YAG, 1064 nm) lasers and diode lasers (830 to 980 nm) have been utilized experimentally and in selected patients for interstitial application in the kidney (Lofti et al, 1994; De Jode et al, 1999; Williams et al, 2000; Gettman et al, 2002b). Dose-dependent areas of coagulative necrosis were achieved with target temperatures up to 85° C, but small areas staining NADH positive consistently documented viable residual tissue (Gettman et al, 2002b). The use of diffusing laser tips and multiple laser fiber treatments might bring improvements. Moreover, treatment success also crucially depends on precise delivery of the laser fiber to the target zone, with a stabilization system of the probe during energy delivery to compensate for respiratory movement, and on real-time monitoring of the treatment effect.

HIGH-INTENSITY FOCUSED ULTRASOUND

Mode of Action and Experimental Data

As an ultrasound wave propagates through biologic tissues, it is progressively absorbed and energy is converted to heat. If the ultrasound beam is brought to a tight focus at a selected depth within the body, the high energy density produced in this region results in temperatures exceeding the threshold level of protein denaturation. As a consequence, coagulative necrosis occurs. The energy drops sharply outside the focal zone so that surrounding tissues remain unchanged. Utilization of these physical principles open a new prospect in minimally invasive therapy—**targeted tissue ablation from an extracorporeal approach**. Size and location of the ablated region depend on the shape of the piezoceramic element and its focusing system, ultrasound frequency, exposure duration, absorption coefficient of the incident tissues, and in situ intensity achieved (Madersbacher et al, 1995). With higher site intensities (>3500 W/cm^3) cavitation phenomena occur, which are more difficult to control. In a multitude of experimental studies, high-intensity focused ultrasound (HIFU) of malignant tumors has not been shown to cause tumor cell dissemination or an increased rate of metastases (Gelet and Chapelon, 1995).

Some of the first attempts at extracorporeal HIFU of renal tissue used a system of multiple piezoceramic elements arranged on a concave disk that targeted a common focal area. Devised from piezoelectric lithotriptors, they generated site intensities in excess of 10,000 W/cm^3 and hence predominantly cavitation-induced lesions. Although studies on porcine kidneys and limited clinical trials demonstrated renal lesions (Vallancien et al, 1991, 1992), focusing proved to be too unreliable for clinical use.

All systems presently employed for therapeutic HIFU have single transducers, which are focused either by having a concave shape or with acoustic lenses. The former are smaller and have been employed clinically mainly for intracavitary use, such as transrectal HIFU in the prostate (Madersbacher 1995). As the focal lengths are smaller, frequencies in the 3 to 4 MHz range can be used. They produce smaller but better defined lesions. A modified system of this type was developed for laparoscopic use, which in porcine kidneys permitted reproducible partial kidney ablation with no damage to surrounding structures (Paterson et al, 2003). For extracorporeal HIFU ablation, penetration at this frequency is too short, even in small laboratory animals (Adams et al, 1996). In the 1 to 1.5 MHz range penetration increases, and in animal studies significant renal lesions were obtained at this frequency with an extracorporeal approach (Chapelon et al, 1992; Watkin et al, 1997).

Extracorporeal High-Intensity Focused Ultrasound: Clinical Experience

Using a prototype system based on a 1-MHz piezoelement focused at a depth of 10 cm with a parabolic reflector and with an integrated 3.5-MHz ultrasonic transducer for real-time imaging, Köhrmann and colleagues (2002) were able to achieve radiologic regression of two of three tumors treated in a solitary kidney. Another system with exchangeable transducers of 0.8, 1.2, and 1.6 MHz and focal lengths of 100 to 160 mm has been tested extensively in China (Wu et al, 2002). Site intensities of 5000 to 20,000 W/cm^3 are targeted and the bubble formation in the tissue from cavitation effects is used for real-time ultrasound monitoring. To ablate larger volumes, the focal spot is moved continuously over the target zone, that is, "painting" it rather than spacing one individual lesion next to another. In 13 patients with advanced renal cancer, 3 renal tumors treated in this manner were ablated completely and 10 partially without significant complications (Wu, 2003).

In contrast, a report on the use of these two systems for the treatment of 18 kidney tumors that were subsequently removed and examined histologically found incomplete ablation of the tumors in all patients (Marberger et al, 2005). The disappointing results are due mainly to difficult targeting because of the respiratory movements of the kidney, the complexity of acoustic interphases from intervening structures of the abdominal wall and ribs, and the acoustic inhomogeneities within the tumor. These problems could be overcome by individualizing treatment parameters if a reliable method were available for on-line assessment of the treatment effect. As standard thermosensors cannot be used with HIFU because of acoustic interference, at present this is possible only by complex MRI thermometry (Smith NB et al, 1999; Damianou, 2004). In contrast to applications in other organs, HIFU

ablation in the kidney must therefore still be categorized as experimental.

RADIOSURGERY

In contrast to thermal ablation techniques, radiation destroys dividing tumor cells by mitosis-linked death. Because it is temperature independent, loss of efficacy near larger vessels is avoided. High-energy external-beam radiation affects tissues surrounding the target area with wide margins and even with modern planning techniques can therefore not be applied for truly focal tissue ablation in radiosensitive organs. Brachytherapy permits sharply defined ablation but relies on precise placement of radioactive seeds, which is difficult to achieve in highly perfused mobile organs such as the kidney. All these problems are overcome by using stereotactic techniques to apply highly focused radiation. Pioneered in neurosurgery for the treatment of intracranial tumors, two "radiosurgical" methods have so far been evaluated for tissue ablation in the kidney.

In **interstitial photon radiation**, a miniature linear accelerator generates x-ray photons when accelerated electrons collide with a metal target at the tip of a 3.2-mm needle-shaped target tube. The tube is inserted into the target to deliver a spherical field of radiation with an extremely sharp dose fall-off curve with minimal exposure to surrounding tissues. A dose of 15 Gy of local radiation at a radius of 1.3 cm resulted in well-defined lesions of coagulative necrosis averaging 2.5 cm in diameter, regardless of whether they were in a hilar or peripheral location (Chan et al, 2000). Real-time monitoring of the developing lesion is not possible, but serial CT scans showed a loss of enhancement and shrinkage over time similar to that observed with other ablative techniques (Solomon et al, 2001).

A strictly extracorporeal approach using a frameless image-guided radiosurgical device (**cyberknife**) for focal renal ablation appears even more attractive. The system combines a lightweight 6-V linear accelerator mounted on a robotic arm with an image-to-image algorithm for target localization. An adequate conformal radiation dose is delivered by focusing a multitude of radiation beams at the target zone, yet directing the individual beams along different pathways so that the surrounding tissues are not exposed to a harmful dose. With a targeted dose of up to 40 Gy, complete fibrosis of the target zone without any apparent damage to the surrounding structures was achieved in porcine kidneys (Ponsky et al, 2003). With more than 30 units of this type already operating in clinical radiation oncology centers worldwide, further experimental and also first clinical data on the ablation of renal tumors will presumably soon become available.

CONCLUSION

A variety of energy ablative techniques have been shown to achieve focal destruction of renal tissue in experimental settings and, to a more limited extent, of renal tumors clinically. Morbidity appears to be lower than with the standard surgical procedures. The main problem with the approach remains adequate intraoperative monitoring of the developing lesions to administer the energy needed for complete tumor ablation on an individualized basis. At present, cryoablation under laparoscopic control appears to be most consistent in achieving this goal and intermediate clinical data are encouraging. Given the low growth rate of small renal tumors, long-term clinical follow-up data are needed. Patients should be treated within well-controlled studies, with defined treatment parameters and the possibility of precise follow-up. Selection of patients appears crucial. At present, only renal masses smaller than 3 cm in diameter and located peripherally on the convexity of the kidney, in an easily accessible position, can be considered curable. Standard nephron-sparing procedures achieve excellent results in tumors of this size, so that energy ablative techniques appear justified only if a less invasive approach is mandated because the patient has significant comorbidity.

KEY POINTS: ENERGY ABLATION OF RENAL TUMORS

- Small renal tumors can be destroyed by heat or freezing with low morbidity.
- At present, percutaneous or laparoscopic cryoablation and RF ablation are the only techniques with emerging clinical data.
- Reliable results are obtained with peripheral tumors less than 3 cm in diameter.
- Adherence to technical details with defined treatment parameters and precise long-term follow-up with sequential cross-sectional imaging and frequent biopsy are mandatory.
- Long-term results are emerging.
- This is an alternative for patients unsuited for standard therapy.

HISTORICAL BACKGROUND

Understanding of the essential physiologic role of the adrenal glands has evolved from the initial description by Eustachius in *Opuscula Anatomica* in 1563 to the elegant biochemical analysis of adrenal secretory products and the precise radiologic imaging studies currently available. Despite earlier recognition of the presence of the adrenals and their division into cortex and medulla (Cuvier and Baron, 1800-1805), it was not until the precise observations of Addison in 1855 that the essential role of these glands was recognized in patients who died with adrenal destruction secondary to tuberculosis. Soon thereafter, Brown-Séquard (1856) performed bilateral adrenalectomies in animals and predicted that the adrenals were essential for life.

Hyperfunction of the adrenal cortex was not documented until 1912, with a definitive report in 1932 of 11 patients with basophilic adenomas of the pituitary that described the now-classic characteristics of Cushing's syndrome (Cushing, 1912, 1932). It was not until the purification of adrenocortical extracts, however, that adrenalectomized animals could be maintained; the adrenal cortex was then documented as the site of critical and essential steroid production (Hartman et al, 1927). Progressive and sequential advances in the understanding of adrenal steroid production have led to the development of precise diagnostic tests to identify patients with Cushing's syndrome (Orth, 1995), adrenocortical forms of hypertension (Biglieri et al, 1995), congenital adrenal hyperplasia (New et al, 2003; Merke and Bornstein, 2005), adrenal carcinoma (Schulick and Brennan, 1999), and other adrenal disorders.

Fränkel first described a medullary adrenal tumor in 1886. London physiologists demonstrated a pressor substance from the adrenal medulla, which they named *adrenaline* (Oliver and Sharpey-Schafer, 1895). Subsequently, Abel (1897) coined the term *epinephrine*, and Kohn (1902) described the chromaffin system. In 1912, the pathologist Pick formulated the descriptive term *pheochromocytoma*, from the Greek *phaios* (dark or dusty) and *chroma* (color), to describe adrenal medullary tumors with their chromaffin reaction.

The development of precise urine and plasma tests led to the accurate identification of patients with adrenal medullary disorders (Rosano et al, 1991; Stein and Black, 1991). Moreover, it is particularly in the identification and localization of pheochromocytomas that imaging techniques have become highly accurate and essential (Heinz-Peer et al, 1999; Sohaib and Reznek, 2000; Teeger et al, 2003).

The diagnosis of the major adrenal disorders is actually simpler now than in the past because of precise diagnostic assays and radiologic tests. The evaluation of a patient for a potential adrenal disorder can be performed efficiently, usually without hospitalization, by a practicing urologist knowledgeable in adrenal disease. Moreover, the surgical approaches are well within the expertise of the urologist and

are precisely described (Vaughan, 2004). Finally, laparoscopic adrenalectomy is now the surgical procedure of choice for most adrenal tumors (Gagner et al, 1992).

This chapter reviews the relevant adrenal anatomy, pathology, and physiology that serve as the bases for the clinical, biologic, and radiologic diagnoses of the major adrenal disorders. The adrenal disorders of neuroblastoma and congenital adrenal hyperplasia are reviewed in detail elsewhere in this book and are mentioned only briefly here.

ANATOMY, HISTOLOGY, AND EMBRYOLOGY

The adrenal glands are paired retroperitoneal organs that lie within perinephric fat at the anterosuperior and medial aspects of the kidneys. They measure up to 5 cm in length by 3 cm in width and are 1 cm thick. In the healthy, nonstressed adult, the glands weigh about 5 g each. **In contrast, the adrenal weight at birth is large (5 to 10 g) because of the fetal adrenal cortex, which may play a major role in fetal embryogenesis and homeostasis** (Pepe and Albrecht, 1990; Anand et al, 1998). The fetal adrenal cortex regresses rapidly during the first 6 weeks of life (Scott, 1990); adrenal tissue remodeling is due to apoptotic cell death at birth after the fetal adrenal serves as a reservoir of progenitor cells that move centrally to populate the definitive zones of the adult adrenal (Jaffe et al, 1998; Wolkersdorfer and Bornstein, 1998). The presence of pituitary adenylate cyclase–activating peptide receptors in developing chromaffin cells in the human fetal adrenal suggests a role for neuropeptides in adrenal development (Breault et al, 1998), but the adrenal is susceptible to hemorrhage at the time of birth, a condition now readily diagnosed by magnetic resonance imaging (Fig. 53–1).

Sectional imaging has provided a better understanding of the precise appearance of the adrenals. Both glands are flattened anteriorly with a thick central ridge and thinner medial and lateral rami (Markisz and Kazam, 1989). Cortical infoldings, especially seen on sagittal sections, may be confused with small adenomas, especially in primary aldosteronism, in which the lesions are small.

The right adrenal lies above the kidney posterolateral to the inferior vena cava. The anterior surface is in immediate contact with the inferior-posterior surface of the liver. Thus, from an anterior approach, the anterior surface of the adrenal can be exposed extraperitoneally by gently lifting the liver cephalad, the inferior vena cava being medial. The posterior surface of both adrenals is in contact with the posterior diaphragm (Fig. 53–2). Both adrenals lie more posteriorly as they follow the lumbar curve of the spine, thus falling away from the surgeon for the superior dissection.

The left adrenal is in more intimate contact with the kidney, and the main left renal artery often lies deep to the left adrenal vein as it enters the left renal vein. The gland overlies the upper pole of the kidney, with its anterior surface and medial aspect behind the pancreas and splenic artery (see Fig. 53–2). The anterior surface of the left adrenal can be exposed by remaining retroperitoneal and by gently retracting the spleen cephalad within the peritoneum. Division of the splenorenal ligament facilitates this dissection.

The adrenals have a delicate and rich blood supply estimated to be 6 to 7 mL/g per minute, without a dominant single artery. The inferior phrenic artery is the main blood supply, with additional branches from the aorta and the renal artery (Fig. 53–3) (Pick and Anson, 1940; Anson et al, 1947). In addition, there can be an adrenal arterial supply arising from the gonadal arteries in 60% of fetal adrenal vascular dissections (Bianchi and Ferrari, 1991). The small arteries penetrate the gland in a circumferential stellate fashion, leaving both anterior and posterior surfaces avascular. The venous drainage is usually a common vein on the right, exiting the apex of the gland and **entering the posterior surface of the**

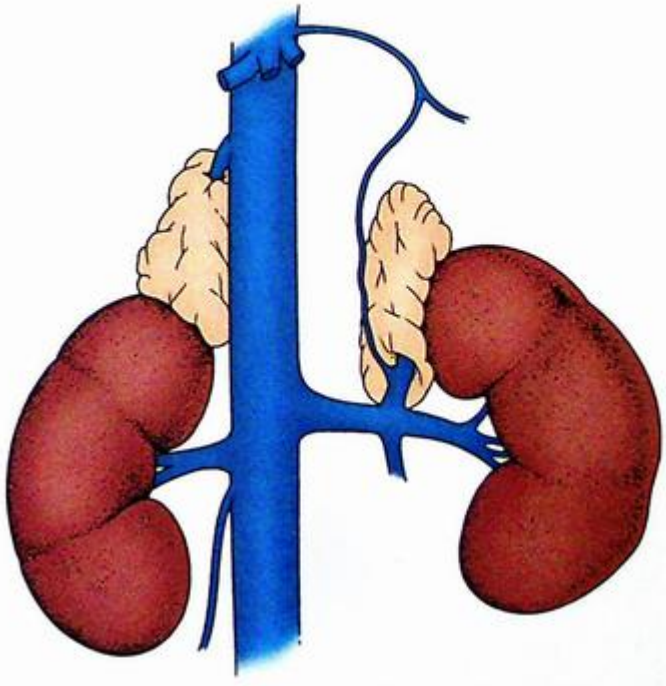

Figure 53–4. Venous drainage of the left and right adrenal glands with particular attention to the intercommunicating vein on the left, which is medial and drains into the phrenic system. (From Vaughan ED Jr, Carey RM, eds: Adrenal Disorders. New York, Thieme Medical, 1989.)

inferior vena cava; this vein is short, fragile, and the most common source of troublesome bleeding during right adrenalectomy (Fig. 53–4). Uncommonly, the right adrenal vein is joined by a hepatic vein that enters the undersurface of the liver. The left vein empties directly into the left renal vein, about 3 cm from the inferior vena cava and often opposite the gonadal vein (Johnstone, 1957). Not well recognized is the left inferior phrenic vein, which typically communicates with the adrenal vein but then courses medially and can be injured during dissection of the medial edge of the gland.

The adrenal cortex develops from mesoderm, and the medulla develops from neuroectoderm. During the fifth week of development, mesothelial cells located between the root of the mesentery and the developing gonad proliferate and invade the mesenchyme. These cells form the fetal cortex, whereas a second migration of cells forms the definitive cortex; an additional cell type is of mesonephric origin (Crowder, 1957). The intimate relationship with the developing gonad, kidney, and adrenal generally explains the finding of ectopic or aberrant adrenal tissue. Heterotopic adrenal tissue is usually associated with the kidney but is also reported

to be associated with the broad ligament, gonadal vessels, spermatic cord, canal of Zuck, uterus, testis, and sites of peritoneal attachment (Culp, 1959; Schechter, 1968). Ectopic adrenocortical tissue was found in 2.7% of groin explorations in male children, with none detected in females (Sullivan et al, 2005).

On microscopic examination, the mature adrenal cortex constitutes 90% of the gland and is divided into three zones: zona glomerulosa, zona fasciculata, and zona reticularis (Fig. 53–5). Zonation is complete by 18 months, although adult configuration is not reached until the age of 10 to 12 years (Moore et al, 1989). The zona glomerulosa is less prominent in humans than in other species and is the site of aldosterone production. The zona fasciculata and zona reticularis form a single functional zone that produces glucocorticoids, androgens, and estrogens.

The adrenal medulla is derived from cells of the neural crest that migrate at the seventh week to form collections that enter the fetal cortex, leaving nodules of neuroblasts scattered throughout the cortex. Neuroblastic cortical nodules regress as the medulla forms, but they can persist and should not be confused with an in situ neuroblastoma. By the 20th week, there is a primitive medulla, but the distinct medulla is not present until atrophy of the fetal cortex.

The medulla is soft and currant jelly–like and can be bluntly dissected free from the cortex for adrenal medullary transplantation (Madrazo et al, 1987). The medulla produces both norepinephrine and epinephrine, with the reaction facilitated in the presence of glucocorticoids. Moreover, there is morphologic evidence for a close interaction of chromaffin cells with cortical cells of the adrenal gland, suggesting a possible paracrine role for neuroregulation of the adrenal cortex (Bornstein et al, 1991). The chromaffin cells are polyhedral, arranged in cords, and richly innervated. Epinephrine-secreting and norepinephrine-secreting cells are distinct (Tannenbaum, 1970).

ADRENAL PHYSIOLOGY

The adrenal can be thought of functionally as two distinct organs, cortex and medulla. Each has its own unique physiology and hormonally active secretory products.

Adrenal Cortex

From a common precursor, the zones of the adrenal cortex produce a series of steroid hormones that have an array of actions, including salt retention, metabolic homeostasis, and

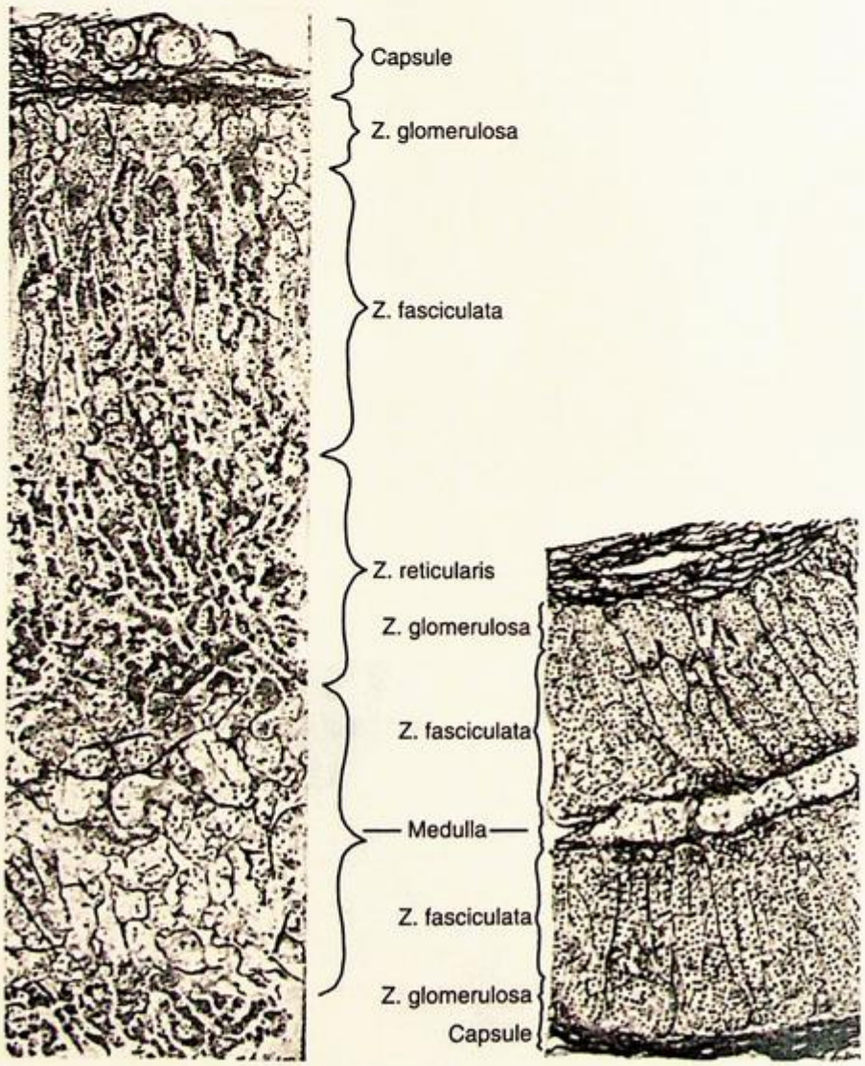

Figure 53–5. Section of an adrenal of a man *(left)* and of a 6-month-old infant *(right)* (Mallory's azan stain, about ×105). (From Fawcett DW: Bloom and Fawcett: A Textbook of Histology, 11th ed. Philadelphia, WB Saunders, 1986. With permission from Dr. Don W. Fawcett.)

adrenarche development. The basic steroid structure of pregnenolone as derived from cholesterol is shown in Figure 53–6. The zona glomerulosa is the only source of the major mineralocorticoid aldosterone, which regulates sodium resorption in the kidney, gut, and salivary and sweat glands (Carey and Sen, 1986). The other zones produce and secrete cortisol, the major glucocorticoid in humans, and the **principal androgens dehydroepiandrosterone (DHEA), DHEA sulfate (DHEAS), and androstenedione.** The pathways for production of these steroids are shown in Figures 53–7 and 53–8. The rate-limiting step for the formation of all these hormones is the production of pregnenolone (see Fig. 53–6) (Lindzey and Korach, 1997).

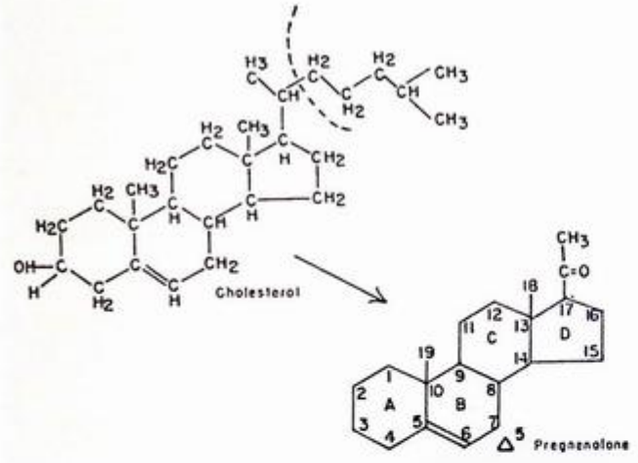

Figure 53–6. Conversion of cholesterol to pregnenolone. The cholesterol formula shows the complete steroid structure; the pregnenolone formula shows the conventional representation of the steroid molecule with the rings designated by letter and the carbon atoms numbered.

As is discussed in detail elsewhere in this text, it is the deficiency of one of the five enzymes necessary to convert cholesterol to cortisol that leads to the family of diseases termed congenital adrenal hyperplasia (New, 2003); the presenting symptom complexes depend on the specific enzyme deficiency, the lack of necessary pituitary feedback, and the resultant adrenal hyperplasia and proximal precursor excess. The excess of one or numerous steroid products gives the characteristic signs and symptoms of Cushing's syndrome, primary hyperaldosteronism (Conn's syndrome), or adrenal carcinoma.

Now that these pathways have been established clearly, it is possible to perturb the system purposely for diagnostic purposes. Thus, the system can be stimulated with adrenocorticotropic hormone (ACTH), also known as corticotropin, to search for adrenal insufficiency; suppressed with dexamethasone, a synthetic glucocorticoid, to identify different types of Cushing's syndrome; or interrupted with a drug such as metyrapone, which inhibits the enzyme 11β-hydroxylase, thus decreasing circulating cortisol and thereby stimulating the hypothalamic-pituitary axis to increase ACTH (Liu et al, 2003).

Regulation of Hormone Release

The regulation of corticosteroid release involves a complex interaction of the hypothalamus, pituitary gland, and adrenal gland. ACTH is a 39–amino acid polypeptide that exerts a major influence on the adrenal cortex (Hoffman, 1974). ACTH is produced from a large protein (290 amino acids) termed pro-opiomelanocortin. Other peptides derived from pro-opiomelanocortin include β-lipotropin, α-melanocyte–stimulating hormone, β-melanocyte–stimulating hormone, β-endorphin, and methionine enkephalin (Fig.

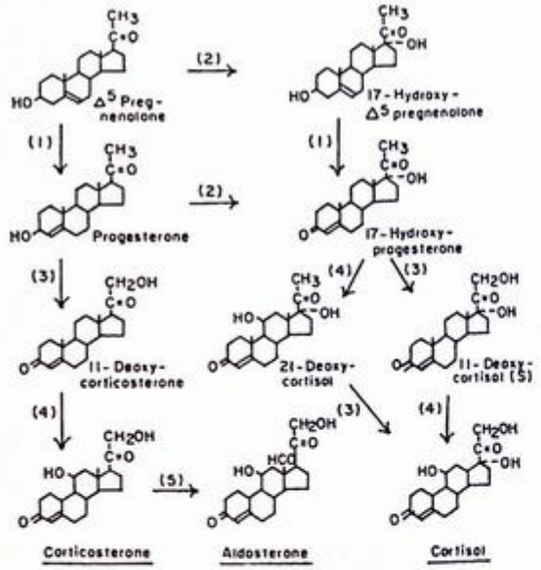

Figure 53–7. Corticosteroid synthesis in the adrenal cortex. Enzyme systems are numbered: 1, β-hydroxysteroid dehydrogenase–β5-oxosteroid isomerase complex; 2, C-17-hydroxylase; 3, C-21-hydroxylase; 4, C-11-hydroxylase; 5, C-18-hydroxylase. The β signifies a double bond, and the attached number shows its position in the nucleus.

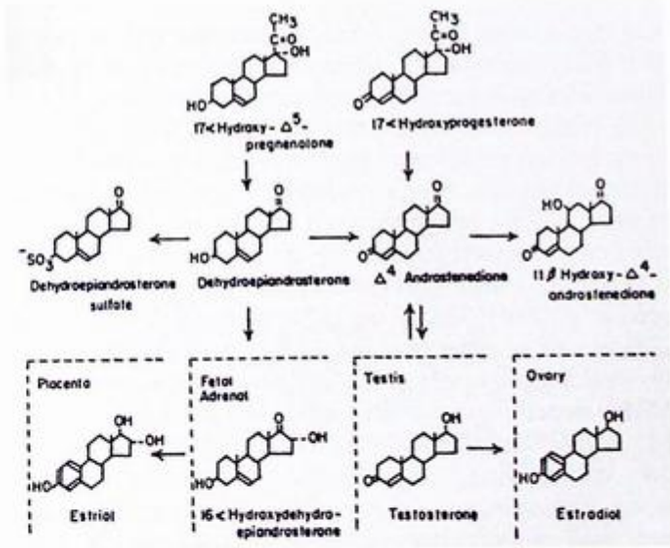

Figure 53–8. Sex hormone synthesis. The upper two panels of the scheme show the synthesis of adrenal androgens. The lower panel shows conversion of androstenedione to testosterone (testis, adrenal cortex, and, to a small degree, liver), 16β-hydroxylation of dehydroepiandrosterone by the fetal adrenal and conversion to estrogen in the placenta, and conversion of androgen to estrogen in the ovary. Note that the initial steps in sex hormone synthesis are the same in all these organs.

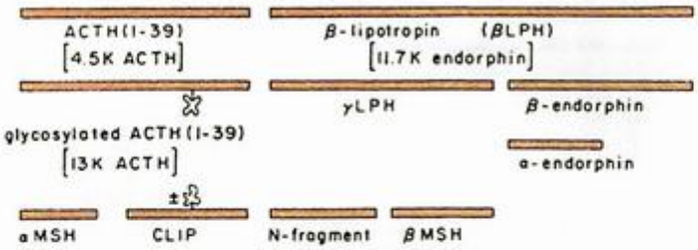

Figure 53–9. Structural relationships of peptides with a parental compound of pro-opiomelanocortin. (Modified from Eipper BA, Mains RE: Structure and biosynthesis of pro-adrenocorticotropin/endorphin and related peptides. Endocr Rev 1980;1:2.)

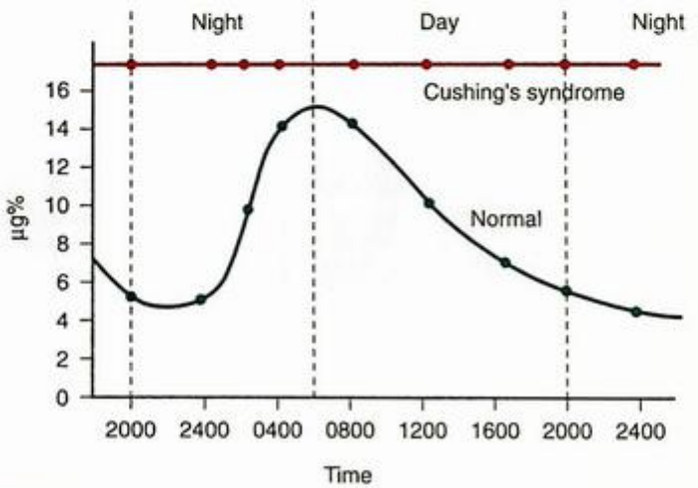

Figure 53–10. Circadian rhythm in cortisol secretion of plasma in a normal subject contrasted with absence of rhythm in a patient with Cushing's syndrome. (From Bergland RM, Harrison TS: Pituitary and adrenal. In Schwartz SI, ed: Principles of Surgery, 3rd ed. New York, McGraw-Hill, 1979:1493.)

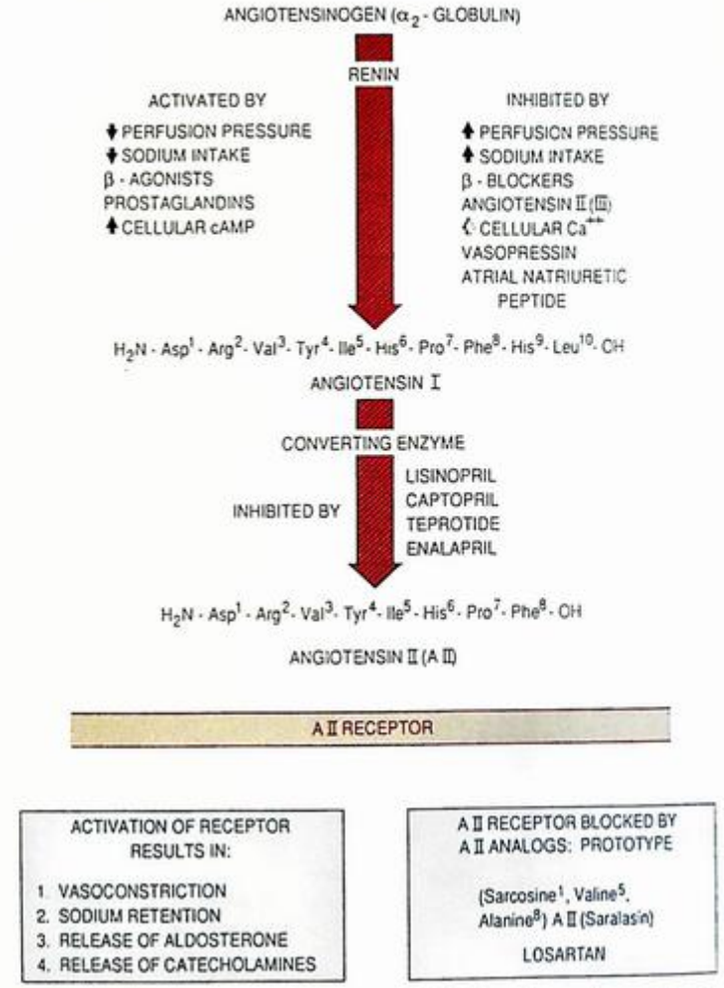

Figure 53–11. Factors activating and inhibiting the renin-angiotensin-aldosterone system.

53–9) (Mains and Eipper, 1980; Tepperman and Tepperman, 1987). ACTH secretion is characterized by an inherent diurnal rhythm leading to parallel changes in cortisol and ACTH (Fig. 53–10) (Orth et al, 1967; Kreiger, 1975). The absence of the normal diurnal variation of plasma cortisol is a critical finding in a patient with Cushing's syndrome. Corticotropin-releasing hormone (CRH) is synthesized in the hypothalamus and carried to the anterior pituitary in the portal blood (Taylor and Fishman, 1988). CRH is a 41–amino acid linear peptide (Speiss et al, 1981; Vale et al, 1981) that stimulates release of ACTH as well as other pro-opiomelanocortin products, probably working through a cyclic adenosine monophosphate (cAMP)–dependent process requiring calcium (Vale et al, 1981). Other stimulators of ACTH include vasopressin, oxytocin, epinephrine, angiotensin II, vasoactive intestinal peptide, serotonin, gastrin-releasing peptide, atrial natriuretic factor, and γ-aminobutyric acid (Antoni, 1986). Finally, ACTH secretion is reciprocally related to the circulating cortisol level.

Adrenal androgen production in the reticular and fascicular zones is also under the influence of ACTH, but other mechanisms are involved. DHEA level rises after administration of ACTH; a later elevation of DHEAS level occurs, presumably because of the slow peripheral conversion (Vaitukaitis et al, 1969). There are clearly situations, however, in which adrenal androgen stimulation is disassociated from ACTH. These include adrenarche, puberty, aging, fasting, and stress (Parker and Odell, 1980).

In contrast to glucocorticoids and adrenal androgens, the **primary physiologic control of aldosterone secretion is angiotensin II** (Laragh et al, 1960; Laragh and Sealey, 1992). ACTH control is secondary. The physiology of the renin-angiotensin-aldosterone system is thoroughly reviewed in Chapters 36. A clear knowledge of the system is mandatory to understand the pathophysiology and to evaluate patients with primary hyperaldosteronism.

The critical sensor of the renin-angiotensin-aldosterone system resides in the juxtaglomerular apparatus within the kidney. Thus, in response to a variety of stimuli but primarily decreased renal perfusion (Fig. 53–11), renin release, angiotensin II formation, and subsequent aldosterone secretion occur, resulting in sodium retention in an attempt to restore renal perfusion (Fig. 53–12). Conversely, if there is sodium retention, renin secretion is suppressed, aldosterone secretion falls, and urinary sodium rises. The inverse relationship found between plasma renin activity or aldosterone

and urinary sodium excretion in normal volunteers is shown in Figure 53–13.

A second, less potent stimulus for aldosterone release is potassium; thus, there is a second cybernetic system for the control of serum potassium involving the renin-angiotensin-aldosterone system (Laragh and Sealey, 1992). Hypokalemia blunts the adrenal's ability to synthesize aldosterone and can result in the lowering of the plasma aldosterone to a normal range in patients with hypokalemia and hyperaldosteronism (Herf et al, 1979).

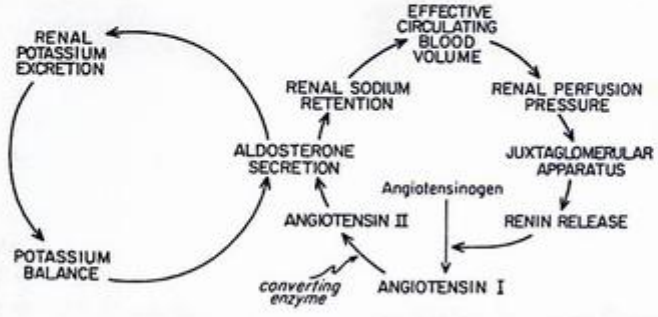

Figure 53–12. Control of aldosterone secretion by means of interrelationships between the potassium and renin-angiotensin feedback loops.

Hormone Actions

All steroid hormones diffuse passively into cells and bind to and activate nuclear steroid receptor proteins. The activated steroid receptor–ligand complexes then bind to specific DNA sequences, termed steroid response elements, which are associated with promoter regions that regulate transcription of genes (Lindzey and Korach, 1997). In the absence of hormone estrogen receptors, androgen receptors and progesterone receptors are primarily localized in the nucleus, whereas glucocorticoid receptors are localized in the cytoplasm.

In addition, glucocorticoids have a non-nuclear pathway that is important in the control of ACTH. The numerous activities of this pathway include inhibition of prostaglandin synthesis, inhibition of calcium flux, inhibition of cAMP protein kinase, and others (Hubbard et al, 1990).

Glucocorticoids are essential for life, even after mineralocorticoid replacement. Glucocorticoids exert their effects on a wide spectrum of cellular metabolism, including accumulation of glycogen in liver and muscle, enhanced gluconeogen-

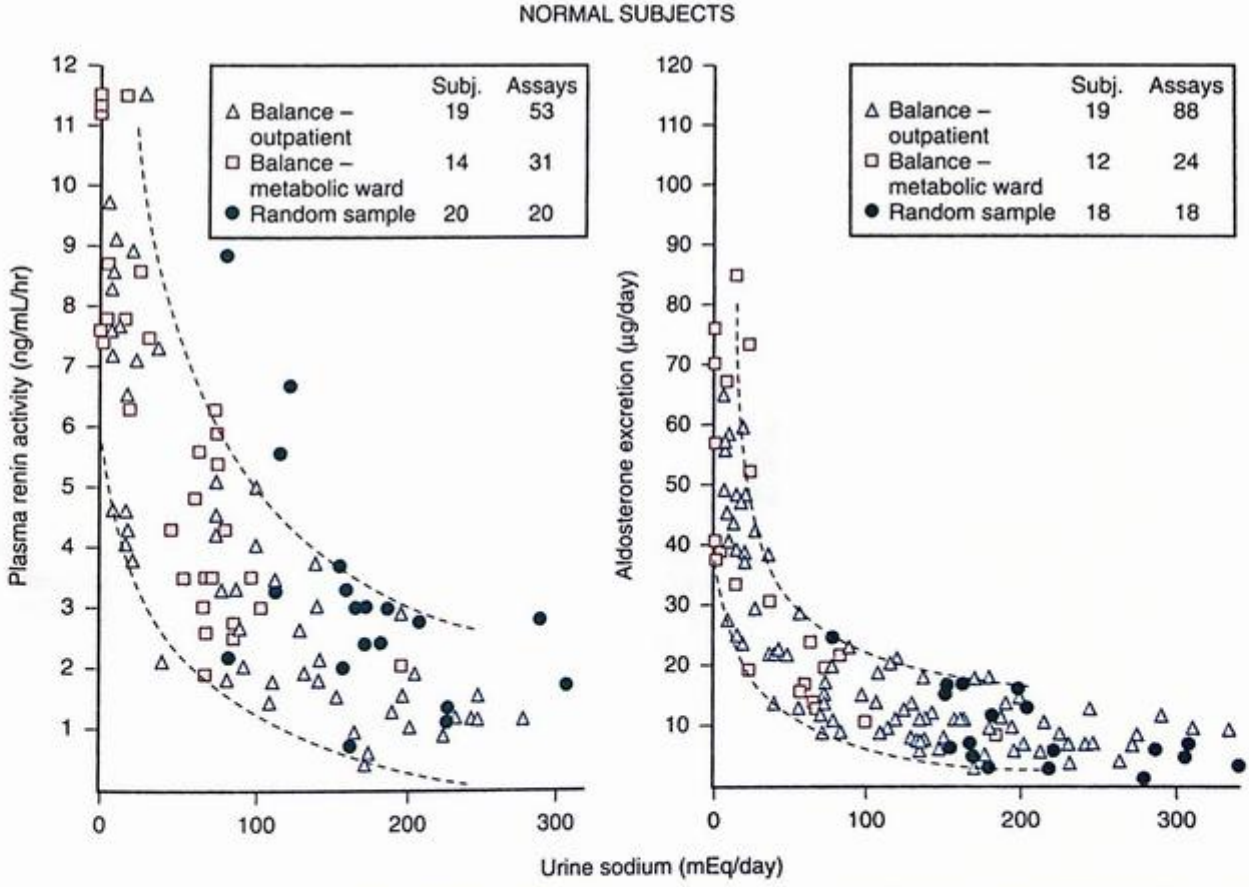

Figure 53–13. Relation of renin activity in plasma samples obtained at noon and the corresponding 24-hour urinary excretion of aldosterone to the concurrent daily rate of sodium excretion. For these normal subjects, the data describe a dynamic hyperbolic relationship between each hormone and sodium excretion. The dynamic fluctuations in renin in response to changes in sodium intake help maintain constant blood pressure in the presence of wide changes in sodium balance. The renin and aldosterone responses work together in the kidney to conserve or to eliminate sodium in response to changes in dietary sodium intake. Subjects who were studied while on random diets outside the hospital or on carefully controlled diets in the hospital exhibited similar relationships—a finding that validates the use of this nomogram in the study of outpatients or subjects not on controlled diets. (From Laragh JH, Baer L, Brunner MR, et al: Angiotensin—the renin-aldosterone system in pathogenesis and management of hypertensive vascular diseases. In Laragh JH, ed: Hypertension Manual. New York, Yorke Medical, 1974:313.)

Table 53–1. Effects and Implications of Glucocorticoids

Effects	*Clinical Implications*
Enhance skeletal and cardiac muscle contraction	Absence results in weakness
Cause protein catabolism	Excess results in wastage and weakness
Inhibit bone formation	Excess decreases bone mass
Inhibit collagen synthesis	Excess causes thin skin and fragile capillaries
Increase vascular contractility and decrease permeability	Absence makes it difficult to maintain blood pressure
Have anti-inflammatory activity	Exogenous steroid is useful in treating inflammatory diseases
Have anti-immune system activity	Exogenous steroids are useful in treating transplantation and various immune diseases
Maintain normal glomerular filtration	Absence reduces glomerular filtration

From Howards SS, Carey RM: The adrenals. In Gillenwater JY, Grayhack JT, Howards SS, Duckett JW, eds: Adult and Pediatric Urology, 2nd ed. Chicago, Year Book, 1991.

esis, impaired peripheral glucose utilization, muscle wasting and myopathy, osteopenia, immune-mediated inflammation, and numerous interactions with other hormones (Table 53–1) (Howards and Carey, 1991; Chrousos, 1995).

Aldosterone accounts for 95% of adrenal mineralocorticoid activity and serves to maintain sodium and potassium balance, as previously stated. The active sites include the kidney, gut, salivary glands, and sweat glands. In all sites, there is the effect of stimulating sodium reabsorption and the increased secretion of potassium and hydrogen through activation of Na^+,K^+-ATPase activity or activation of permease in the luminal membrane (Biglieri et al, 1990).

Adrenal androgens are only weakly active, in contrast to testosterone. They appear to be relevant only in pathologic states, such as congenital adrenal hyperplasia, in which there may be excess production.

Metabolism

The release of these steroids and their metabolism and route of excretion play a critical role in understanding the tests used to diagnose adrenal disorders. In the circulation, 80% of cortisol is bound to corticosterone-binding globulin, 10% to 15% is bound to albumin, and 7% to 10% is free.

Therefore, variations in binding proteins influence the total plasma cortisol value but not the free cortisol, which is metabolically active (Baxter and Tyrrell, 1981). Accurate plasma cortisol assays are now available. Thus, the diurnal variation of plasma cortisol and its response to dexamethasone suppression have evolved as critical tests in the evaluation of patients for possible Cushing's syndrome (Orth, 1995; Liu et al, 2003). Urinary free cortisol is also used as a screening test, although about 3.3% of lean, obese, or chronically ill individuals have elevated values, and values are not well established in children. Difficulties have also been found in establishing upper limits of 17-hydroxysteroid secretion. They are most valuable in evaluation of normal adrenal function, particularly in looking for adrenal insufficiency or congenital adrenal hyperplasia, in which 17-hydroxysteroid levels are low and 11-hydroxylase levels are high.

The precise control of adrenal androgens is not totally understood, although there is some ACTH control. Peripheral conversion of DHEA to DHEAS contributes to the DHEAS level (Liu et al, 2003). DHEA does show some diurnal variation. DHEA is not produced in significant quantities by other tissues except occasionally in polycystic ovarian disease and gonadal androgen-producing tumors (Osborn and Yannone, 1971; Nelson, 1980). Patients with high DHEA levels also have high 17-ketosteroids, whereas those with virilization caused by elevated testosterone do not. Elevated levels of DHEA, androstenedione, or 17-ketosteroids out of proportion to glucocorticoid production call to mind the diagnosis of adrenal carcinoma (Cohn et al, 1986). Of these tests of adrenal androgen function, the plasma DHEAS value is more commonly used today and is more accurate than the androstenedione value. **Elevated serum concentrations of testosterone and DHEA are the hallmarks of adrenal tumors in women who present with hirsutism** and are used to identify the 5% of women with hirsutism who have a significant adrenal pathologic process (Derksen et al, 1994).

Aldosterone, the major sodium-retaining hormone secreted by the zona glomerulosa, is poorly bound to albumin and plasma protein (Laragh and Sealey, 1992) and has a short half-life of 20 to 30 minutes. Plasma aldosterone can be measured by radioimmunoassay. The plasma value has to be related to the sodium status of the patient and should be measured in conjunction with the plasma renin activity. Equally accurate is urinary aldosterone excretion analyzed in a similar fashion (see Fig. 53–13).

Adrenal Medulla

The adrenal medulla is composed of large chromaffin cells, which secrete primarily epinephrine but also norepinephrine and dopamine. The fact that the cells stain brown when they are exposed to chromium salts as the result of oxidation of epinephrine and norepinephrine is the origin of the term *chromaffin cell* (Fig. 53–14). The enzyme phenylethanolamine-*N*-methyltransferase (PNMT), which catalyzes the methylation of norepinephrine to form epinephrine, is almost solely localized to the adrenal medulla (Axelrod, 1962). Thus, if there is excessive production of both norepinephrine and epinephrine, the offending lesion is almost always within the adrenal and not the other sites of chromaffin tissue. Data suggest that high levels of glucocorticoids are necessary to maintain high levels of PNMT and thus epinephrine secretion (Wurtman and Axelrod, 1965). These observations explain the unique location of the adrenal medulla and the central venous drainage system within the adrenal bathing the medullary cells with high levels of glucocorticoids.

Catecholamine synthesis begins with dietary tyrosine and phenylalanine, which are the substrates (Fig. 53–15). Catecholamine synthesis occurs in the adrenal, the central nervous system, and the adrenergic nerve terminals. Activation and suppression of tyrosine hydroxylase activity are the major regulators of catecholamine biosynthesis and may be influenced by the adrenal cortex (Mueller et al, 1970). Norepinephrine is

Figure 53–14. Pheochromocytoma showing chromaffin reaction 1 *(right)*.

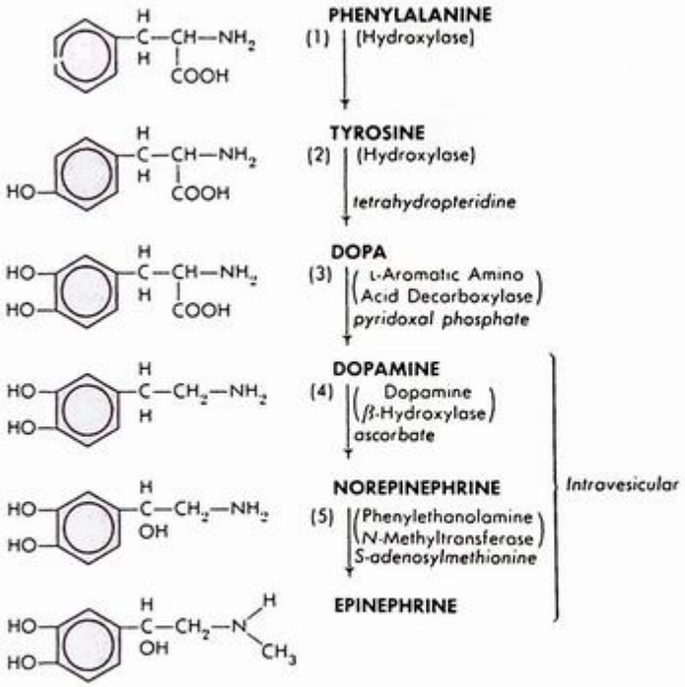

Figure 53–15. Enzymatic pathway for dopamine, norepinephrine, and epinephrine synthesis. Enzymes are in parentheses; cofactors are in italics. (Modified from Goodman AG, Goodman LS, Gilman A, eds: The Pharmacologic Basis of Therapeutics, 6th ed. New York, Macmillan, 1980:72.)

the major catecholamine secreted by sympathetic neurons. Studies of healthy humans indicate that plasma dopamine accounts for 13% of the free catechols; epinephrine, 14%; and norepinephrine, 73% (Manger and Gifford, 1990).

Catecholamines are stored in separate vesicles along with adenosine triphosphate, chromogranins, and the enzyme dopamine β-hydroxylase. Stimulation of the preganglionic sympathetic nerves during stress, pain, cold, heat, asphyxia, hypotension, hypoglycemia, and sodium depletion increases catecholamine release (Lewis, 1975). After stimulation, the contents of the vesicles are released by exocytosis (Winkler and Smith, 1975). In addition, catechols may be released without sympathetic stimulation and possibly without exocytosis—a phenomenon postulated in patients with pheochromocytomas.

Catecholamine Metabolism

Catecholamines are rapidly removed from the circulation with a plasma half-life of less than 20 seconds (Ferrerira and Vane, 1967). The metabolic pathways for catecholamines are shown in Figure 53–16. Neuronal reuptake is of major importance in the removal of norepinephrine from the synaptic gap for re-release and has been termed uptake (Iverson, 1975). Catecholamines are degraded by the action of catechol-*O*-methyltransferase and monoamine oxidase, with either enzyme beginning the degrading process. **The primary metabolite in the urine is vanillylmandelic acid; metanephrine, normetanephrine, and their derivatives contribute to total metabolic products,** which are often measured in evaluation of patients with pheochromocytomas (Bravo and Tagle, 2003).

Catecholamine Actions

Catecholamines exert varied effects by stimulating specific cellular receptors (adrenoreceptors), which are protein-binding sites (Table 53–2). The diversity of effects of circulating catecholamines on various organs acting at specific receptors accounts for the diversity of symptoms exhibited by patients with pheochromocytomas. Moreover, different tumors can produce different proportions of norepinephrine, epinephrine, or dopamine.

Table 53–2. Catecholamine Receptors

The actions of epinephrine and norepinephrine are not totally independent and are dose dependent. Hence, the classification of naturally occurring adrenergic hormones as α-adrenergic or β-adrenergic or as blocking agents, such as an α_1 antagonist, is useful but does not fully characterize

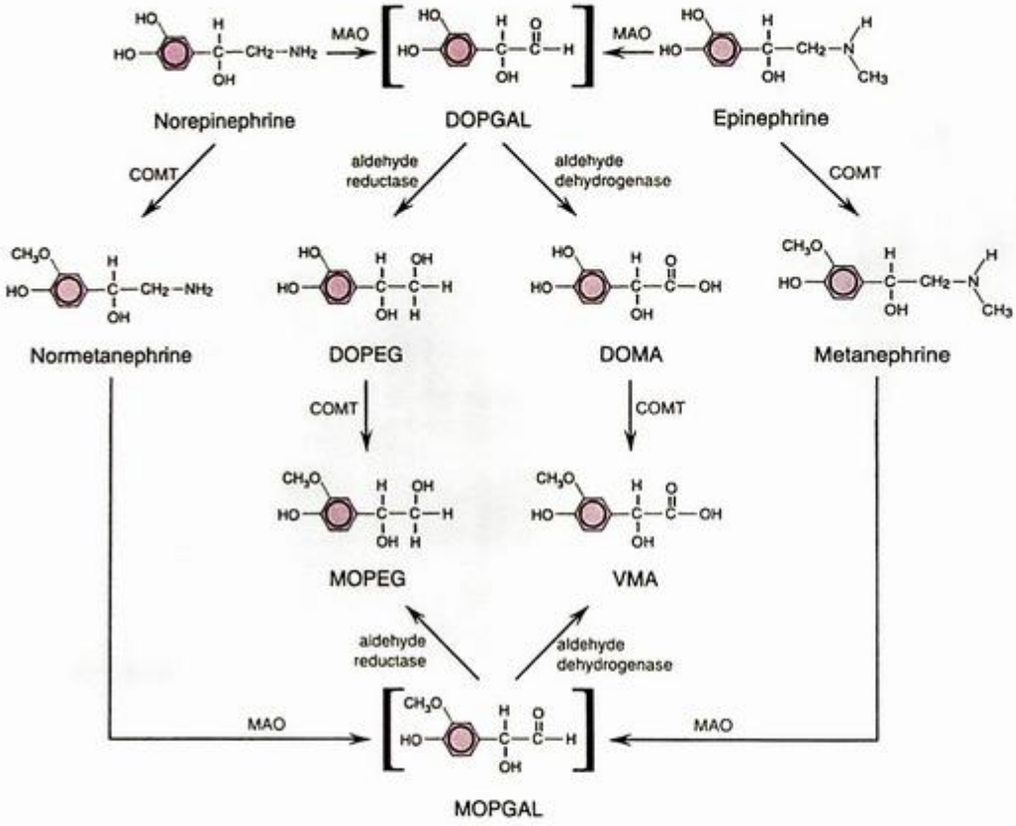

Figure 53–16. Steps in the metabolic disposition of catecholamines. Both norepinephrine and epinephrine are first oxidatively deaminated by monoamine oxidase (MAO) to 3,4-dihydroxyphenylglycoaldehyde (DOPGAL) and then either reduced to 3,4-dihydroxyphenylethylene glycol (DOPEG) or oxidized to 3,4-dihydroxymandelic acid (DOMA). Alternatively, they can be initially methylated by catechol-*O*-methyltransferase (COMT) to normetanephrine and metanephrine, respectively. Most of the products of either type of reaction are then metabolized by the other enzyme to form the major excretory products 3-methoxy-4-hydroxyphenylethylene glycol (MOPEG or MHPG) and 3-methoxy-4-hydroxymandelic acid (VMA). Free MOPEG is largely converted to VMA. The glycol and, to some extent, the *O*-methylated amines and the catecholamines may be conjugated to the corresponding sulfates or glucuronides. (From Hardman JG, Limbird LE, Molinoff PB, et al: Neurotransmission: The autonomic and somatic nervous system. In Lefkowitz RJ, Hoffman BB, Taylor P, eds: Goodman and Gilman's The Pharmacological Basis of Therapeutics, 9th ed. New York, McGraw-Hill, 1996:105.)

the activity of the hormone or antagonist in all clinical settings.

CUSHING'S SYNDROME

Cushing's syndrome describes the symptom complex caused by excess circulating glucocorticoids (Cushing, 1912, 1932; Arnaldi et al, 2003; Findling and Raff, 2005). The term is all-encompassing and includes patients with pituitary hypersecretion of ACTH (corticotropin); **patients with Cushing's disease, who account for 75% to 85% of patients with endogenous Cushing's syndrome;** patients with adrenal adenomas or carcinomas; and patients with ectopic secretion of ACTH or CRH (Carey et al, 1984), or about 20% of those with ACTH-dependent disease (Meador et al, 1962; Scott, 1990) (Tables 53–3 and 53–4).

The entity is rare, occurs most often in young adults, and is more common in females. **An exogenous source of Cushing's syndrome should always be excluded first because therapeutic steroids are the most common cause.** Often, the patient does not even realize he or she is using a steroid-containing preparation, especially creams or lotions (Champion, 1974; Flavin et al, 1983). The manifestations of the disease are legion and are the result of the manifold actions of glucocorticoids (see Table 53–1). There are few diseases in which the clinical appearance of the patient can be as useful in suggesting the diagnosis (Figs. 53–17 and 53–18). Old photographs are helpful in documenting the changes in appearance that have occurred. The more common clinical manifestations of Cushing's syndrome, found in several series of patients, are

Table 53–3. Relative Prevalence of Various Types of Cushing's Syndrome Among 630 Patients Studied at Different Times*

Diagnosis	*Percentage of Patients*
Corticotropin-dependent Cushing's syndrome	
Cushing's disease	68
Ectopic corticotropin syndrome	12
Ectopic corticotropin-releasing hormone syndrome	<1
Corticotropin-dependent Cushing's syndrome	
Adrenal adenoma	10
Adrenal carcinoma	8
Micronodular hyperplasia	<1
Macronodular hyperplasia	<1
Pseudo–Cushing's syndrome	
Major depressive disorder	<1
Alcoholism	<1

*Data are based on a study of 146 consecutive patients seen at Vanderbilt University Medical Center before 1993 and on published reports describing a total of 484 patients. Because these and most other published series were reported by major referral centers, the proportion of patients with unusual diagnoses may be exaggerated compared with that of patients with more common diagnoses. The prevalence of pseudo–Cushing's syndrome depends largely on the individual physician's threshold of clinical suspicion. The proportions of children and adolescents with the different causes of Cushing's syndrome may differ slightly from the proportions of adults; for example, ectopic corticotropin syndrome is less common in children.

From Orth DN: Cushing's syndrome. N Engl J Med 1995;332:791.

described in Table 53–5. The clinical findings do not distinguish patients with Cushing's disease from those with adrenal adenomas or carcinomas. Most patients with ectopic ACTH do not present with the typical features (Bagshaw, 1960) but exhibit cachexia due to underlying tumor as well as hypertension, hypokalemic alkalosis, and skin pigmentation (Bagshaw, 1960; Schambelan et al, 1971). The most common characteristics in children are weight gain and growth retardation (Magiakou et al, 1994). Virilization in the female or feminization in the male should raise the question of adrenal carcinoma, although more patients present with traditional manifestations of glucocorticoid excess (Luton et al, 1990; Ng and Libertino, 2003).

From Scott HW Jr, Orth DN: Hypercortisolism (Cushing's syndrome). In Scott HW, ed: Surgery of the Adrenal Glands. Philadelphia, JB Lippincott, 1990:145.

The goals of management of Cushing's syndrome have been articulated by investigators who have a long-standing interest in this disease: lowering of daily cortisol secretion to normal, eradication of any tumor threatening health, production of no permanent endocrine deficiency, and avoidance of permanent dependence on medications (Orth and Liddle, 1971; Orth, 1995). Obviously, not all of these goals can be met in all

patients; however, they serve as a thoughtful frame of reference. To initiate evaluation, the cause of Cushing's syndrome in a given patient must be established. **Importantly, patients with nonendocrine disorders that mimic the clinical and sometimes biochemical manifestations of Cushing's syndrome must be separated from those patients with true Cushing's syndrome;** these patients have been said to have pseudo–Cushing's syndrome. Abnormally regulated cortical secretion, albeit mild, may exist in as many as 80% of patients with major depression and can occur commonly in patients with chronic alcoholism (Gold et al, 1986; Stewart et al, 1993; Orth, 1995). Finally, although Cushing's syndrome has always been described as rare, about two or three cases per million (Findling and Raff, 2005), it is now recognized that there is an entity termed subclinical Cushing's syndrome. **Remarkably, in early studies of the common "metabolic syndrome," 3% to 5% of patients have been found to have this entity** (Catargi et al, 2003). Moreover, in a study of patients with incidentalomas, 24% had subclinical Cushing's syndrome after careful evaluation, and clinical features of the syndrome improved after adrenalectomy in a selected group of patients (Rossi et al, 2000). Thus, the indications for screening for Cushing's syndrome have expanded (Table 53–6) (Findling and Raff, 2005). In the future, many more patients with this entity may be diagnosed and treated.

Table 53–6. Who Should Be Screened for Cushing's Syndrome?

Signs and Symptoms
Central obesity with
Facial rounding with plethora
Increased supraclavicular and dorsocervical fat
Cutaneous wasting with ecchymoses
Wide violaceous striae (>1 cm)
Proximal myopathy
Increased lanugo hair
Superficial fungal infections
Growth retardation (in children)
Clinical Diagnosis
Metabolic syndrome X
Diabetes mellitus (Hgb A_{1c} > 8%)
Hypertension
Hyperlipidemia
Polycystic ovary syndrome
Hypogonadotropic hypogonadism
Oligomenorrhea, amenorrhea, infertility
Decreased libido and impotence
Osteoporosis (especially rib fracture)
Patients aged < 65 yr
Incidental adrenal mass

Laboratory Diagnosis

A panoply of tests of glucocorticoid function have evolved that are used to establish the presence of Cushing's syndrome and to distinguish between pituitary and adrenal causes as well as ectopic ACTH secretion (Orth, 1995; Liu et al, 2003; Raff and Findling, 2003) (Fig. 53–19). The clinical diagnosis of Cushing's syndrome is confirmed by the demonstration of cortisol hypersecretion. **The determination of 24-hour excretion of cortisol in the urine is the most direct and reliable index of cortisol secretion.** A consensus statement on the diagnosis of Cushing's syndrome (Arnaldi et al, 2003) recommended that urinary cortisol be measured in two or preferably three consecutive 24-hour urine specimens collected on an outpatient basis. If cortisol excretion results are normal in three collections, Cushing's syndrome is unlikely. Multiple collections are necessary because of the possibility of errors in collection and because of variations in hour-to-hour or day-to-day cortisol excretion. As for other 24-hour urine

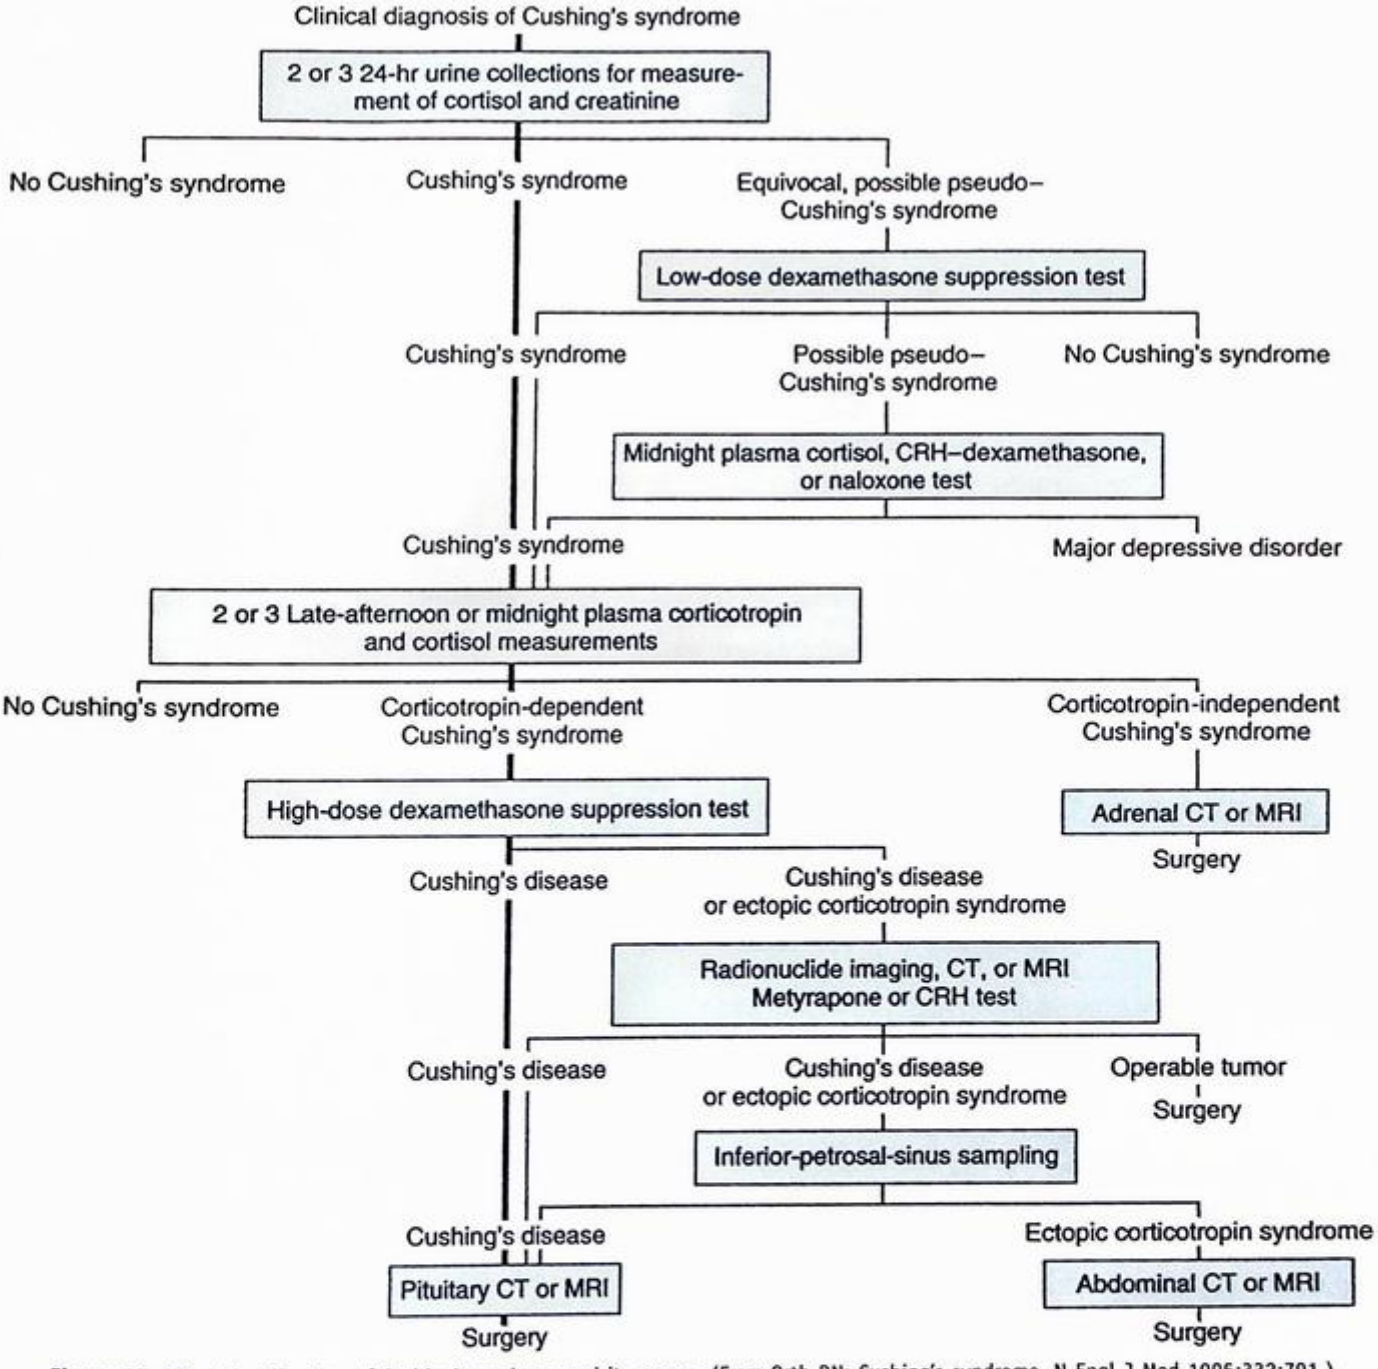

Figure 53–19. Identification of Cushing's syndrome and its causes. (From Orth DN: Cushing's syndrome. N Engl J Med 1995;332:791.)

collections, cortisol excretion should be calculated as a function of creatinine excretion.

In the patient with elevated 24-hour urinary cortisol, we advocate determining the presence or absence of the normal circadian rhythm in plasma cortisol by obtaining ambulatory morning and evening plasma cortisol levels to continue the diagnosis. After ACTH release, healthy subjects show a characteristic rise in plasma cortisol in the morning, with a fall to less than 5 ng/dL in the evening (see Fig. 53–10). Patients with Cushing's syndrome lose the diurnal variation (Besser and Edwards, 1972) or show some variations, but at higher basal levels (Glass et al, 1984).

Commonly, the next test used is the dexamethasone suppression test as developed by Liddle (1960). Pituitary ACTH secretion is regulated with negative feedback inhibition by cortisol. Liddle used the synthetic steroid dexamethasone, 30 times as potent as cortisol, to study the pituitary feedback mechanism in patients with suspected Cushing's syndrome. In normal subjects, 0.5 mg orally every 6 hours for 2 days causes a dramatic fall in 17-hydroxycorticosteroid, urinary free cortisol, or plasma cortisol (<5 ng/dL). A simplification of the test is to administer a single 1-mg oral dose between 11 PM and midnight and to measure the plasma cortisol level between 8 AM and 9 AM (Fig. 53–20) (Paulotos et al, 1965; Sarvin et al, 1968). The test is less reliable, however, than the formal low-dose 2-day test, especially in obese patients. Patients with Cushing's syndrome show resistance to suppression with low-dose dexamethasone. This failure of suppression has been

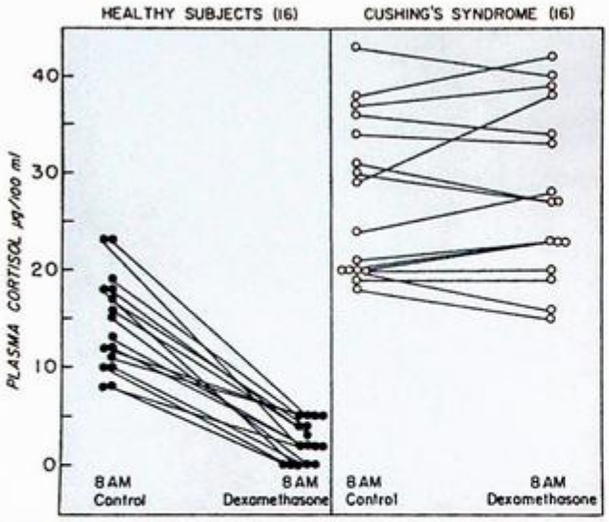

Figure 53–20. The rapid dexamethasone suppression test distinguishes patients with Cushing's syndrome from healthy subjects or other obese subjects. Note the overlap in cortisol levels between the two groups before suppression. The patients with high basal cortisol levels were those with ectopic ACTH production by a nonendocrine tumor as the underlying cause. (From Melby J: Assessment of adrenocortical function. N Engl J Med 1971;285:735.)

found to be characteristic of all patients with Cushing's syndrome studied by Scott and Orth (1990). These low-dose suppression tests are now reserved primarily for patients with equivocal 24-hour urinary cortisol excretion (Orth, 1995) and are especially useful for identifying patients with pseudo–Cushing's syndrome. **A recently described test that is likely to be used more commonly by endocrinologists is the late-night salivary cortisol concentration measurement** (Arnaldi et al, 2003; Findling and Raff, 2005). The test has high sensitivity and specificity and may be combined with the low-dose overnight dexamethasone test.

Alternatively, **the ideal way to determine whether a patient has ACTH-dependent or ACTH-independent hypercortisolism is the concurrent measurement of both plasma ACTH and cortisol** (Raff and Findling, 1989). Despite the fact that the ideal time to measure these hormones is between midnight and 2 AM, when the concentrations are at the lowest, a more practical approach is to measure the test late in the afternoon. Again, Orth (1995) recommends the measurement of the two hormones at least on 2 and preferably 3 separate days. If the plasma cortisol concentration is more than 50 μg/dL and the corticotropin concentration is less than 5 pg/mL, cortical secretion is ACTH independent (the patient has primary adrenal Cushing's syndrome). If the plasma ACTH level is more than 50 pg/mL, the cortical secretion is ACTH dependent (the patient has Cushing's disease or ectopic ACTH or CRH syndrome) (Orth, 1995). In situations in which the two-site immunoradiometric assay test is not available, the high-dose dexamethasone suppression test has always been the standard test to differentiate between pituitary and adrenal Cushing's syndrome. Patients are given high-dose dexamethasone (2 mg every 6 hours for 2 days), and plasma cortisol and urinary free cortisol levels are measured. In patients with pituitary disease, there should be a 50% or greater suppression in cortisol. Patients with adrenal adenomas or carcinomas fail to suppress cortisol secretion. In addition, the tests usually distinguish Cushing's disease, in which there is only relative resistance to glucocorticoid negative feedback, from ectopic ACTH syndrome, in which there is usually complete resistance. A number of different criteria have been established to try to obtain greater sensitivity in correctly identifying patients with Cushing's disease; but in almost all the different studies, patients with ectopic ACTH as well as those with primary adrenal disease have uniformly failed to suppress cortisol (Avgerinos et al, 1994; Miller and Crapo, 1994).

Additional tests in use to differentiate between pituitary Cushing's disease and ectopic ACTH secretion are metyrapone stimulation tests and petrosal venous sinus catheterization. The metyrapone stimulation test was originally used to determine pituitary insufficiency. Metyrapone blocks conversion of 11-desoxycortisol to cortisol, and as the plasma cortisol concentration falls, the pituitary secretes more ACTH, and there is an increase in urinary 17-hydroxycorticosteroid concentration. Patients with Cushing's disease have a normal or supernormal increase in urinary excretion of 17-hydroxycorticosteroids, in contrast to patients with ectopic ACTH-secreting tumors, who have little or no increase in either value because of the suppression of pituitary ACTH (Avgerinos et al, 1994). **Obviously, the most direct way to demonstrate pituitary hypersecretion of ACTH is to measure its level in the petrosal venous sinus and compare the level with the peripheral level.** Sampling can also be done before and after stimulation with CRH. This is an invasive procedure, however, and significant complications have been reported (Oldfield et al, 1991; Miller et al, 1992). Before petrosal sinus catheterization is indicated, thorough studies should be performed to identify occult ACTH-secreting tumors. Many of these tumors can be identified with standard computed tomography (CT) or magnetic resonance imaging (MRI) and, more recently, unique radionuclide imaging for somatostatin receptors, which are present in small cell lung carcinomas and thymic carcinoid tumors (Phlipponneau et al, 1994).

At this point, despite the availability of numerous stimulatory and inhibitory tests (Liu et al, 2003), the dramatic advances in radiologic localizing tests usually make further biochemical studies unnecessary.

Radiographic Localization

The development of computer-aided sectional imaging and MRI has revolutionized adrenal imaging. Accordingly, older tests such as intravenous urography with tomography, ultrasonography, and adrenal arteriography and venography are only rarely used today. In general, CT has become the initial imaging procedure.

In patients with Cushing's disease, additional information can be obtained with CT or MRI of the sella turcica in search of a pituitary adenoma (Fig. 53–21) (Mitty and Yeh, 1982). More recently, both unenhanced and gadolinium-enhanced MRI is used; however, only 50% of microadenomas are detected (Klibanski and Zervas, 1991; Hall et al, 1994).

Patients with hyperplasia can show diffuse thickening and elongation of the adrenal rami (Fig. 53–22) or, unfortunately, prominent glands bilaterally that fall within normal range (Teeger et al, 2003). A second variant, found in 10% to 20% of cases, is nodular cortical hyperplasia characterized by

Figure 53–21. CT scan of a chromophobe adenoma in the sella turcica of a patient with Cushing's syndrome presenting with hyperpigmentation, headaches, and a visual field defect.

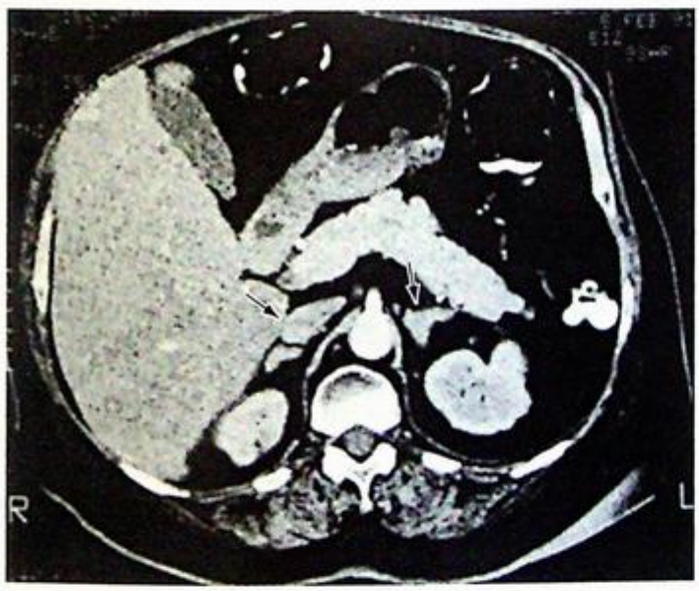

Figure 53–22. CT scan showing bilateral adrenal hyperplasia in a patient with Cushing's disease.

multinodularity of both adrenals (Fig. 53–23). The CT appearance does not distinguish between patients with glucocorticoid excess and patients with idiopathic hyperaldosteronism (pseudo–primary hyperaldosteronism) because of bilateral adrenal hyperplasia. The small size (<2 cm) and multiplicity of the nodules as well as the bilateral distribution are the distinguishing features from Cushing's adenomas. Rarely, patients with macronodular hyperplasia develop autonomous glucocorticoid secretion and may require adrenalectomy.

Adrenal adenomas are usually larger than 2 cm, solitary, and associated with atrophy of the opposite gland. The density is low because of the high concentration of lipid. Sonography and study after the administration of contrast material showing enhancement avoid misdiagnosis of an adrenal cyst

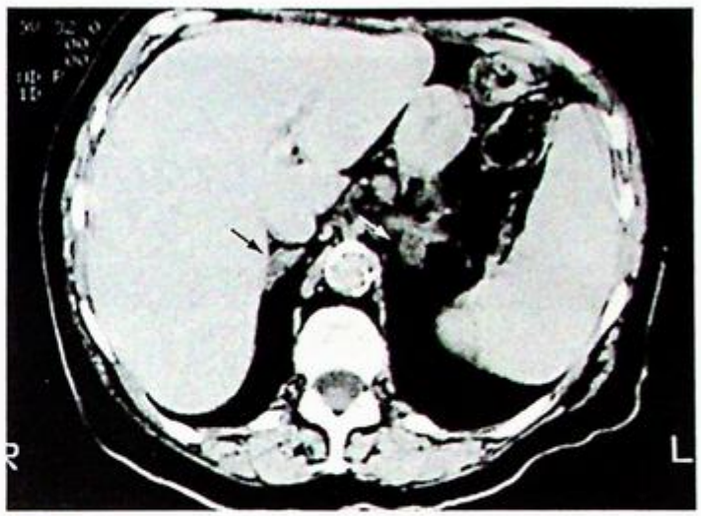

Figure 53–23. CT scan showing a patient with macronodular adrenal hyperplasia.

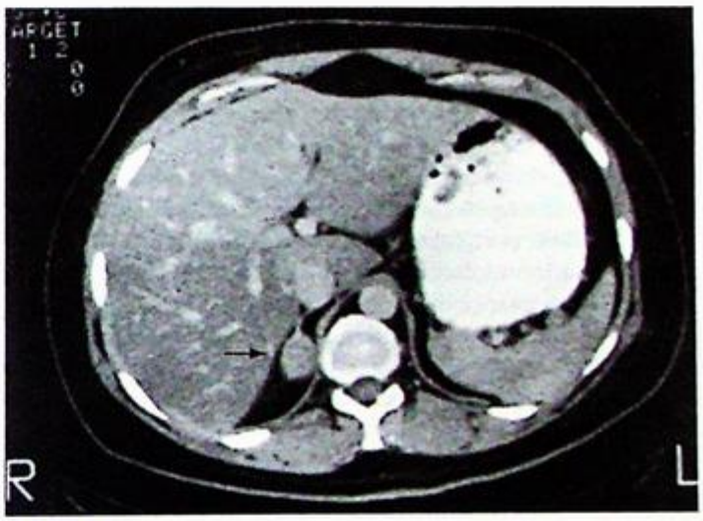

Figure 53–24. CT scan of a patient with right adrenal adenoma.

(Fig. 53–24) (Huebener and Treugut, 1984). However, large benign adenomas (5 cm or larger) often show calcification, heterogenicity, and cystic characteristics on CT and have regions of high signal intensity on T2-weighted MRI (Newhouse et al, 1999). Thus, these large adenomas share the radiologic characteristics of adrenal carcinoma.

Adrenal carcinomas are often indistinguishable from adenomas except for the larger size (>6 cm) (Fig. 53–25) (Belldegrun and deKernion, 1989). **Necrosis and calcification are also more common in association with adrenal carcinoma but are not diagnostic.** Clearly, large, irregular adrenal lesions with invasion represent carcinoma; however, metastatic carcinoma to the adrenal has the same appearance.

MRI is not usually necessary in patients with Cushing's syndrome unless adrenal carcinoma is suspected. In that clinical setting, **the signal intensity may be much higher with carcinoma than that in the spleen, accurately differentiating adenomas from carcinomas** (Bilbey et al, 1995). MRI may also provide useful information about adjacent-organ or vascular invasion.

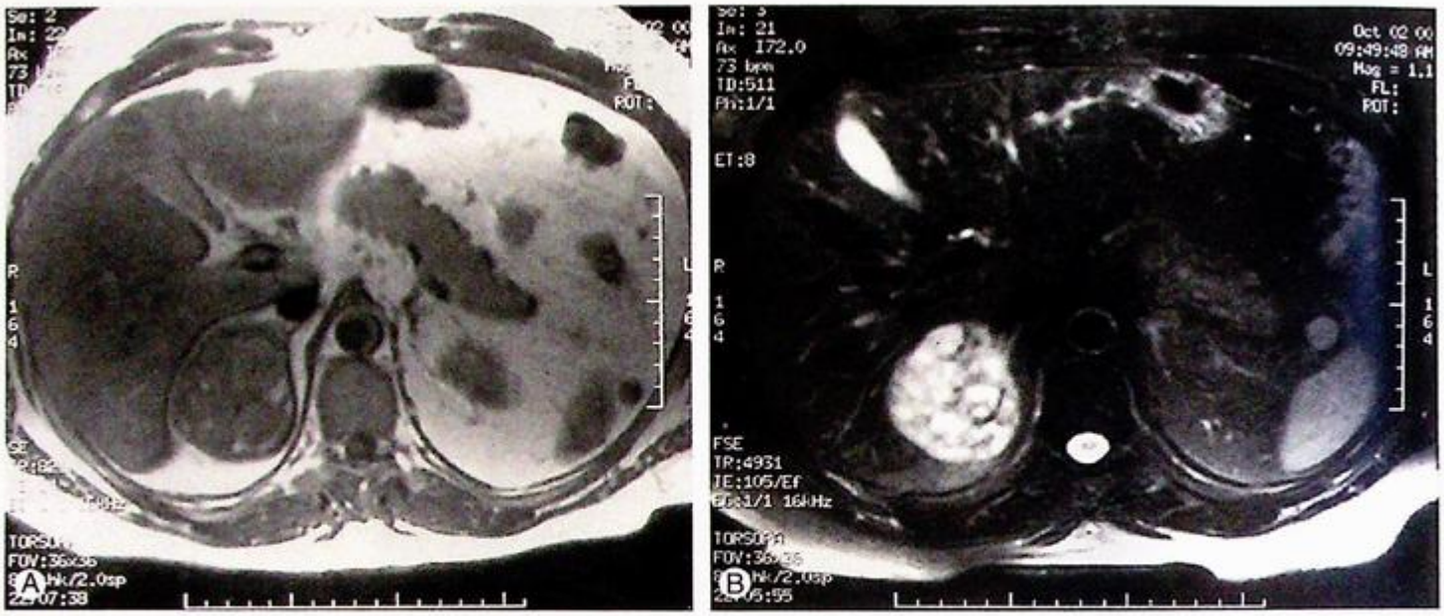

Figure 53–25. Large right adrenal carcinoma showing a heterogeneous pattern (**A**) and bright enhancement on a T2-weighted magnetic resonance image (**B**).

Adrenal cortical scanning with iodinated cholesterol agents is no longer routinely used but can be helpful in differentiating functional adrenal tissue from other retroperitoneal lesions (Kazerooni et al, 1990; Nakajo et al, 1993) and in identifying residual cortical tissues. It is not useful for the identification of adrenal carcinoma (Pasieka et al, 1992). Positron emission tomography has recently been used to image adrenal masses. To date, there is evidence that a variety of agents can discriminate between cortical lesions and either metastatic disease or neural tumors but not between benign and malignant cortical tumors (Hoh et al, 1998; Yun et al, 2001; Zettinig et al, 2004).

Treatment

Cushing's Disease and Ectopic ACTH Syndrome

In recalling the goals of management of Cushing's syndrome as outlined by Liddle, it is obvious that precise diagnosis is critical. Accordingly, in the patient with ectopic ACTH syndrome, treatment is directed to the primary tumor. Reduction of secretion of functional steroids by use of blocking agents can further ameliorate symptoms. Agents include aminoglutethimide, which blocks the conversion of cholesterol to pregnenolone; metyrapone, which blocks the conversion of 11-desoxycortisol to cortisone and ketoconazole; and an antifungal agent that blocks cytochrome P-450–mediated side chain cleavage and hydroxylation at both early and late steps in steroid biosynthesis (Loose et al, 1983; Farwell et al, 1988; Mortimer et al, 1991). Patients given aminoglutethimide must be observed for adrenocortical insufficiency because aldosterone production is also impaired. Metyrapone does not normally result in salt wasting at the usual dose of 250 to 500 mg three times daily because of increased production of desoxycorticosterone, a potent mineralocorticoid (see Figs. 53–7 and 53–8) (Scott and Orth, 1990). Other agents used with some success are ketoconazole (Sonino et al, 1991) and the cortisol receptor blocker mifepristone (Bertagna et al, 1986).

The synthesis of cortisol in 1950 (Wendler et al, 1950) led to the availability of replacement steroids not only for patients with Addison's disease but also for those with bilateral adrenalectomy for Cushing's disease. Thus, bilateral adrenalectomy through a bilateral posterior approach was used in patients with severe Cushing's disease. In general, patients did well with resolution of the disease (Scott et al, 1977, 1990). **However, 10% to 20% of patients subsequently developed pituitary tumors, usually chromophobe adenomas, perhaps caused by the lack of hypothalamic-pituitary feedback and the high levels of ACTH and related compounds** (Nelson et al, 1958; Cohen et al, 1978). This entity, called Nelson's syndrome, may arise many years after bilateral adrenalectomy. Thus, patients must be followed up with determination of ACTH levels and evaluation of the sella turcica (Fig. 53–26). The development of Nelson's syndrome may be prevented by prophylactic pituitary radiotherapy (Jenkins et al, 1995).

The development of pituitary irradiation subsequently limited the use of bilateral adrenalectomy for Cushing's disease beginning in the 1950s (Orth and Liddle, 1971). Long-term follow-up reveals an 83% remission rate after unsuccessful transsphenoidal surgery, which is the initial treatment of choice (Estrada et al, 1997). Irradiation is useful to treat Nelson's syndrome. Heavy particle proton beam therapy may be more effective but also is more likely to induce panhypopituitarism (Burch, 1985).

In 1971, Hardy reported his experience with transsphenoidal hypophyseal microsurgery for removal of pituitary adenomas with preservation of pituitary function. Subsequently, this technique evolved as the single most effective and safest treatment of Cushing's disease. Cure rates are 85% to 95%, results are immediate, complications are low, and recurrences are rare (Ludecke, 1991; Swearingen et al, 1999). Patients often have transient decreases in cortisol levels and may need replacement therapy and monitoring for some months (Fitzgerald et al, 1982). Transient diabetes insipidus may also occur. In adults, irradiation is reserved for patients

Figure 53–26. **A,** Full-face view of a patient with hyperadrenocorticism in 1954, treated by total adrenalectomy at that time. **B,** The same patient 6 months after total adrenalectomy, showing striking improvement. All symptoms and signs of Cushing's syndrome have disappeared. **C,** Deep pigmentation, headache, and failing vision supervened in 1957; emergency craniotomy was necessary after radiation therapy. **D,** Disappearance of pigmentation is shown in the facial view after removal of chromophobe adenoma of pituitary by Dr. Donald Matson. (From Rothenberg RE, ed: Reoperative Surgery. New York, McGraw-Hill, 1969.)

not cured by transsphenoidal surgery (Estrada et al, 1997). Finally, although it is unusual, there may be spontaneous regression of Cushing's disease (Dickstein et al, 1991).

Medical management is also available for specific hormone-secreting pituitary adenomas. Often, medical management is part of a multimodal, integrated therapeutic approach (Shimon and Melmed, 1998).

Cushing's Syndrome during Pregnancy

Adrenal tumors (Harrington et al, 1999) including those producing Cushing's syndrome during pregnancy are rare (Mulder et al, 1990; Guilhaume et al, 1992; Kamiya et al, 1998) because of the menstrual irregularities characteristic of the disease. Of cases reported, 59% have been ACTH independent and 33% ACTH dependent. The others were not classified. During normal pregnancy, plasma cortisol-binding protein and plasma protein bound and unbound cortisone levels rise; however, the normal diurnal variation persists (Liu et al, 2003). The urinary free cortisol level also rises slightly. Moreover, there is some resistance to dexamethasone suppression that progresses with each trimester; however, some suppression remains so that the total absence of suppression

Table 53–7. Adrenocortical Carcinoma: Clinical Features (N = 602)

38%	Nonfunctional
62%	Functional
39.5%	Cushing's syndrome
24%	Cushing's + virilization
20%	Virilization alone*
6%	Feminization

From Ng L, Libertino JM: Adrenocortical carcinoma: Diagnosis, evaluation and treatment. J Urol 2003;169:5-11.

to low-dose dexamethasone is compatible with Cushing's syndrome.

Obviously, imaging studies are contraindicated during pregnancy, especially in the first trimester. **We have used MRI to identify an adenoma in a pregnant patient with Cushing's syndrome** (Fig. 53–27).

Both maternal and fetal morbidity are reduced with treatment. Surgical removal of an adenoma can be successfully achieved during pregnancy, as was done in our patient, especially during the second trimester. Alternatively, some patients have been treated with metyrapone or transsphenoidal adenectomy when indicated (Casson et al, 1987).

Fortunately, because of the low transplacental transfer of adrenal corticosteroids, the fetus is not affected in most cases and does not require steroid replacement after birth. However, the prematurity rate is high.

Adrenal Adenoma

Adrenal adenomas causing Cushing's syndrome are treated by surgical removal, which is discussed in Chapter 54.

ADRENAL CARCINOMA

Adrenal carcinoma is a rare disease and has a poor overall survival of 16% to 37% despite treatment (Novakovic et al, 2004; Ng and Libertino, 2003). The incidence is estimated as 1 case per 1.7 million, accounting for 0.02% of cancers and 0.2% of all cancer deaths (Nader et al, 1983; Plager, 1984; Brennan, 1987). Most adrenal tumors are sporadic and unilateral, but 2% to 6% are bilateral and associated with Li-Fraumeni syndrome, multiple endocrine neoplasia type I, Beckwith-Wiedemann syndrome, and the Carney complex primarily in children (Novakovic et al, 2004).

The etiology is unknown. Chromosomal heterozygosity on chromosomes 11p, 13q, and 17p may play a role (Fogt et al, 1998; Schulick and Brennan, 2003). In addition, *p53* abnormalities have been reported but may represent a late event (McNicol et al, 1997).

A practical subclassification for adrenal carcinomas is according to their ability to produce adrenal hormones. The varieties and distribution of the types identified in a review of the literature are shown in Table 53–7. Most tumors secrete multiple compounds. A review of 62 patients with functional tumors reported that 53% had Cushing's syndrome, 21% only virilization, 10% Cushing's syndrome and virilization, 8% feminization, and 5% hyperaldosteronism (Schulick and Brennan, 2003). In a series by Luton and

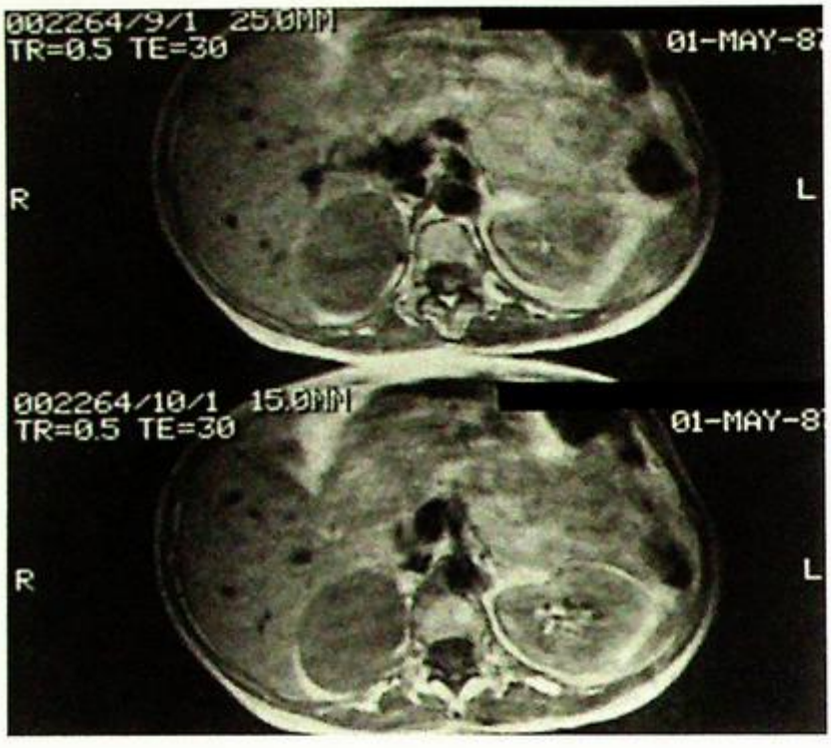

Figure 53–27. Magnetic resonance T1- and T2-weighted images of patient who developed Cushing's syndrome during pregnancy, showing the large right adrenal adenoma. (From Vaughan ED Jr, Carey RM, eds: Adrenal Disorders. New York, Thieme Medical, 1989.)

coworkers (1990), 79% of adrenal tumors were functional, a higher percentage than previously reported, probably because of more sensitive assays. In addition, nonfunctional tumors may become functional, or a tumor may subsequently produce multiple hormones (Grunberg, 1982; Arteaga et al, 1984). Moreover, tumors may produce metabolites that are nonfunctional or in such low amounts as not to cause physiologic changes. Thus, although convenient, a classification of tumors by product is somewhat contrived, and debate exists as to whether "nonfunctioning" tumors carry a worse prognosis for the patient than do functioning tumors (Heinbecker et al, 1957; Lewinsky et al, 1974).

Incidentally Discovered Adrenal Masses

The increased use of abdominal ultrasonography and CT scanning has led to the frequent finding of an unexpected adrenal mass, an "incidentaloma" (Fig. 53–28). Evolving experience with this entity led to a consensus conference on the topic at the National Institute of Health in 2002 (Grumbach et al, 2003). Numerous observations were made. Three fourths of lesions found in patients with cancer are metastatic; in contrast, two thirds of masses in patients without a cancer diagnosis are benign. **Moreover, adrenal cortical carcinoma accounts for 2% of tumors that are smaller than 4 cm, 6% of tumors that are 4.1 to 6.0 cm, and 25% of tumors that are larger than 6.0 cm, confirming earlier studies.** This observation supports the prior observation that **adrenal malignant neoplasms are usually larger than 6 cm. Belldegrun and coworkers** (1986), **reviewing six series, found that 105 of 114 adrenocortical carcinomas were larger than 6 cm** (Heinbecker et al, 1957; Knight et al, 1960; Lewinsky et al, 1974; Sullivan et al, 1978; Bertagna and Orth, 1981).

Figure 53–28. CT scan of patient with a 5-cm nonfunctioning adrenal mass found incidentally.

Accordingly, solid adrenal lesions of more than 6 cm should be considered malignant until proved otherwise by exploration and adrenalectomy. Follow-up of patients with smaller nodules reveals that 5% to 25% increase in size by at least 1 cm during a varied time, the risk of malignancy is 1 of 1000, and up to 20% develop hormonal hyperfunction, especially if the tumor is larger than 3 cm (Rossi et al, 2000; Grumbach et al, 2003).

The problem arises in the management of incidentally found adrenal lesions smaller than 6 cm. Unsuspected adrenal masses have been detected in 0.6% to 1.3% of upper abdominal CT studies (Copeland, 1983; Abecassis et al, 1985; Ross and Aron, 1990). Moreover, the prevalence of benign, clinically silent adrenal adenomas found on autopsy series ranges from less than 1% in patients younger than 30 years to 7% in patients 70 years or older (Grumbach et al, 2003). In contrast,

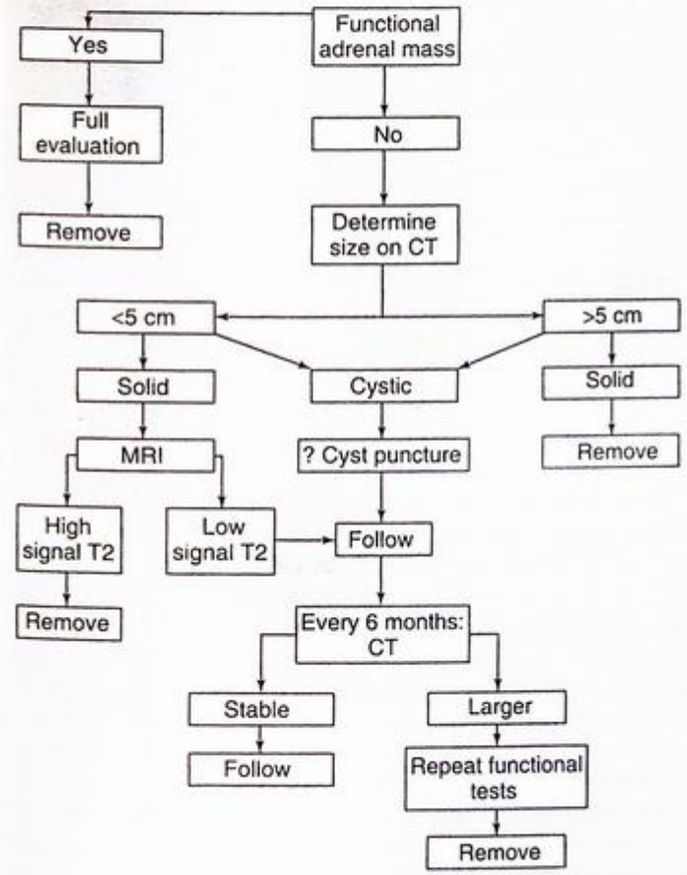
occult nonfunctioning adrenocortical carcinoma is rarely found on autopsy. Accordingly, attention has turned to the appropriate management of the incidentaloma (Ross and Aron, 1990; Rossi et al, 2000; Grumbach et al, 2003).

One approach is shown in Table 53–8. Several points do not engender controversy. First, there is agreement that all patients with solid adrenal masses should undergo biochemical assessment. If biochemical abnormalities are identified, the lesions should be treated appropriately as described elsewhere in this chapter—usually by removal of the offending lesion. The extent of the biochemical evaluation has been reviewed (Ross and Aron, 1990; Grumbach et al, 2003). A selective approach has been outlined, which markedly limits cost without sacrificing diagnostic accuracy. A limited evaluation is recommended, including urine or plasma metanephrine determinations to rule out pheochromocytoma; a 1-mg dexamethasone suppression test to rule out Cushing's syndrome; and in patients with hypertension, serum potassium concentration and plasma renin-to-aldosterone ratio. The test recommendations have expanded since 1990 following the demonstration of more subclinical hormonal abnormalities. Because of the likelihood that nonfunctioning solid lesions larger than 6 cm are malignant, these lesions should be removed. **CT scanning may underestimate the size of an adrenal lesion, and we suggest that exploration be performed when the lesion is larger than 5 cm on CT or MRI** (Cerfolio et al, 1993). Furthermore, lesions clearly proved to be cystic by CT, MRI, or cyst puncture, which is often not necessary, can also be observed. Other approaches include removal of smaller (3 cm) lesions in patients younger than 50 years (Staren and Prinz, 1995) and use of 4-cm criteria for removal (Barzon and Boscaro, 2000). Lesions smaller than 4 cm are rarely malignant, and it is thought that these lesions can be observed with repeated CT at 6- to 12-month intervals (Grumbach et al, 2003). However controversy still arises concerning the management strategy of lesions smaller than 4 cm. Glazer and coworkers (1982) suggested that adrenalectomy be considered for solid lesions larger than 3 to 4 cm. Prinz and associates (1982) also suggested a surgical approach, especially in younger patients. Copeland (1983) challenged the 3- to 4-cm criterion and suggested observation for all patients with nonfunctioning lesions smaller than 6 cm. **These authors estimate that more than 4000 adrenalectomies would have to be done on patients with masses 1.5 cm or larger in diameter to remove one carcinoma.** In a review of 311 incidentally found lesions, 22 were proved to be carcinoma, with tumor sizes from 3.2 cm to 20 cm. Importantly, both localized disease and survival were greater than in a group of 51 patients with clinically apparent adrenal carcinoma (Kasperlik-Zaluska et al, 1998).

Thus, the 4- to 6-cm, solid, nonfunctioning adrenal mass incidentally found remains the major area of controversy. Certainly, on statistical grounds, the majority are benign. An occasional mass, however, is malignant and potentially curable, a situation not frequently encountered in patients with adrenal carcinomas. Fine-needle adrenal biopsy guided by ultrasound and CT is now available and is well tolerated by the patient and associated with minimal complications. The nondiagnostic rate is as high as 28%, but of diagnostic aspirates, the ability to identify the current adrenal lesion accurately is greater than 95% (Nguyen and Akin, 1998). In addition, with polymerase chain reaction and microdissection, loss of heterozygosity of several suppressor genes has been suggested to separate adrenal carcinomas from adenomas (Abati et al, 1999).

An additional useful test is MRI; a high signal intensity ratio on T2 images suggests that the lesion is not a benign adenoma (see Fig. 53–25) (Reinig et al, 1986). There is controversy over the ability of signal characteristics to reliably differentiate benign from malignant masses (Lubat and Weinreb, 1990; Bilbey et al, 1995; Teeger et al, 2003). **A number of entities other than adrenal carcinoma, however, can cause high intensity, including neural tumors, metastatic tumors to the adrenal, and hemorrhage into a variety of adrenal lesions** (Lubat and Weinreb, 1990).

Table 53–8. Evaluation of Incidentally Found Adrenal Mass



Myelolipoma

In the past, this nonfunctioning benign lesion was incidentally found at autopsy. These lesions are generally smaller than 5 cm, unilateral, asymptomatic, and benign, containing hematopoietic and fatty elements (Del Gaudio and Solidoro, 1986; Del Gaudio et al, 1992; Sanders et al, 1995; Han et al, 1997).

The lesion has been recognized with increasing frequency because it has a characteristic appearance on CT scanning and MRI (Casey et al, 1994) that establishes the diagnosis and excludes the need for extensive metabolic evaluation or surgical exploration. The exception may be large lesions (Fig. 53–29), in which confusion with necrotic adrenal carcinoma

Figure 53–29. Myelolipoma, left adrenal.

could occur (Wilhelmus et al, 1981). Rarely, pure adrenal lipomas may occur; these should be removed to exclude the possibility of a retroperitoneal liposarcoma (Milatianakis et al, 2002) or an adrenal leiomyosarcoma (Thamboo et al, 2003).

The cause of the lesion is unknown, but it may be part of a group of entities characterized by deposition of myeloid and adipose tissue (Papavasiliou et al, 1990). Patients are predominantly obese, with a male-to-female ratio of 1.75:1. Pain is the most common presenting symptom. The lesions are rarely calcified or hormonally active. Hormone levels should be obtained, however, because coexisting functional cortical adenoma and myelolipoma have been reported (Hisamatsu et al, 2004).

Adrenal Metastasis

Primary adrenocortical carcinoma is actually less common than metastatic tumor to the adrenal. In a series of 500 autopsy cases, Willis (1952) found adrenal metastasis in 9%. Specifically, the adrenal has been found to be a site of metastasis in more than 50% of patients with melanomas and carcinomas of the breast and lung; in 40% of patients with renal cell carcinomas; and in patients with, in order of frequency, carcinomas of the contralateral adrenal, bladder, colon, esophagus, gallbladder, liver, pancreas, prostate, stomach, and uterus (Bullock and Hirst, 1953).

Now that adrenal imaging with CT and MRI is commonplace, more adrenal lesions are identified earlier in the course of patients with cancer (Thomas et al, 1982). Management is obviously predicated on the underlying malignant neoplasm. The major clinical point is not to confuse a metastatic adrenal lesion with a primary adrenal process. In general, the adrenal lesion is part of the clinical picture of diffuse metastatic disease. Long-term survival after adrenalectomy and aggressive treatment of the primary process, however, has been reported in patients with pulmonary carcinoma and adrenal metastasis (Porte et al, 2001). In addition, it is routine to include the adrenal with a radical nephrectomy in patients with T3-4 renal cell carcinoma, large upper pole lesions, or CT evidence of adrenal invasion (Siemer et al, 2004). Moreover, the finding of an unsuspected adrenal mass should heighten the clinical suspicion of a neoplasm elsewhere. An MR

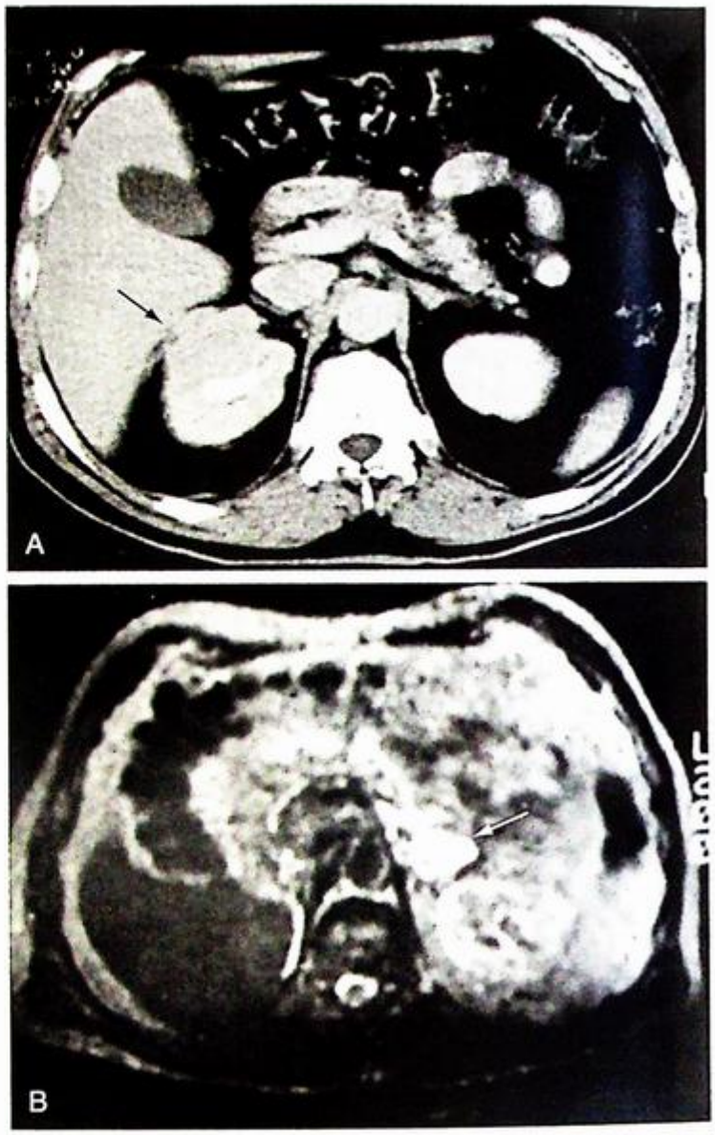


Figure 53–30. A, CT scan showing a left renal cell carcinoma. B, Subsequent right adrenal metastasis with high intensity. The pathologic process was proved by excision.

pattern not characteristic of a benign adenoma raises the index of suspicion for metastatic disease (Fig. 53–30) (Reinig et al, 1986; Bilbey et al, 1995). In this setting, adrenal biopsy is more accurate than it is in distinguishing between adrenal adenomas and carcinoma. In addition, CT-guided radiofrequency ablation has been described to treat metastatic lesions (Mayo-Smith and Dupuy, 2004). Adrenal insufficiency has been reported secondary to both benign adenomas and bilateral adrenal metastases (Sheeler et al, 1983).

Benign Adenoma

The difficulty in discriminating adenoma from carcinoma by pathologic examination is a major problem for pathologists (Amberson and Gray, 1989; Medeiros and Weiss, 1992). Not all large adrenal lesions behave biologically like carcinomas. Some lesions that appear benign on histologic evaluation eventually metastasize. Hence, as discussed previously, surgical removal is recommended for all lesions larger than 5 cm.

Table 53–9. Adrenocortical Carcinoma: Weiss Criteria

High mitotic rate (>5 per 50 high-power field)
Atypical mitoses
Venous invasion
High nuclear grade (Fuhrman 3-4)
Absence of cells with clear cytoplasm (<25% of cells)
A diffuse growth pattern (more than one third of tumor)
Necrosis
Sinusoidal invasion
Capsular invasion

Three or more are needed for diagnosis of carcinoma.

Weiss, 1984.

In an attempt to better determine the prognosis of these lesions and to predict the metastatic potential, Weiss proposed nine histologic criteria (Table 53–9); if more than three are present, the lesion is considered malignant (Weiss, 1984; Aubert et al, 2002).

Klein and coworkers (1985) reported that flow cytometry accurately demonstrated aneuploid stem lines in four cases classified histologically as carcinoma. We also found that all but one patient exhibiting subsequent metastatic disease had aneuploid primary tumors (Fig. 53–31) (Amberson et al, 1987).

Others have also shown that adrenal carcinomas can demonstrate either aneuploid or diploid characteristics; however, there is some evidence that there may be longer disease-free survival in patients with hypodiploid or hyperdiploid carcinomas, in contrast to those with aneuploid patterns (Haak et al, 1993a). Abnormalities in DNA content may not be as useful in children with adrenal cortical tumors (Moore et al, 1993). Also, DNA tetraploidy by fluorescence in situ hybridization is common in adrenal cortical adenomas associated with primary aldosteronism (Shono et al, 2002). Determination of mutations of *p53* (Sameshima et al, 1992; Reincke et al, 1994) may be helpful in predicting prognosis. However, in a comprehensive analysis of 67 primary adrenal and 36 metastatic tumors, multimolecular phenotyping showed molecular complexity and heterogeneity to the extent that any therapy based on this type of analysis would have to be patient specific (Stojadinovic et al, 2002). Interestingly, the use of a modification of the Weiss criteria predicted prognosis, whereas cell cycle proteins and multimolecular phenotypic expression did not.

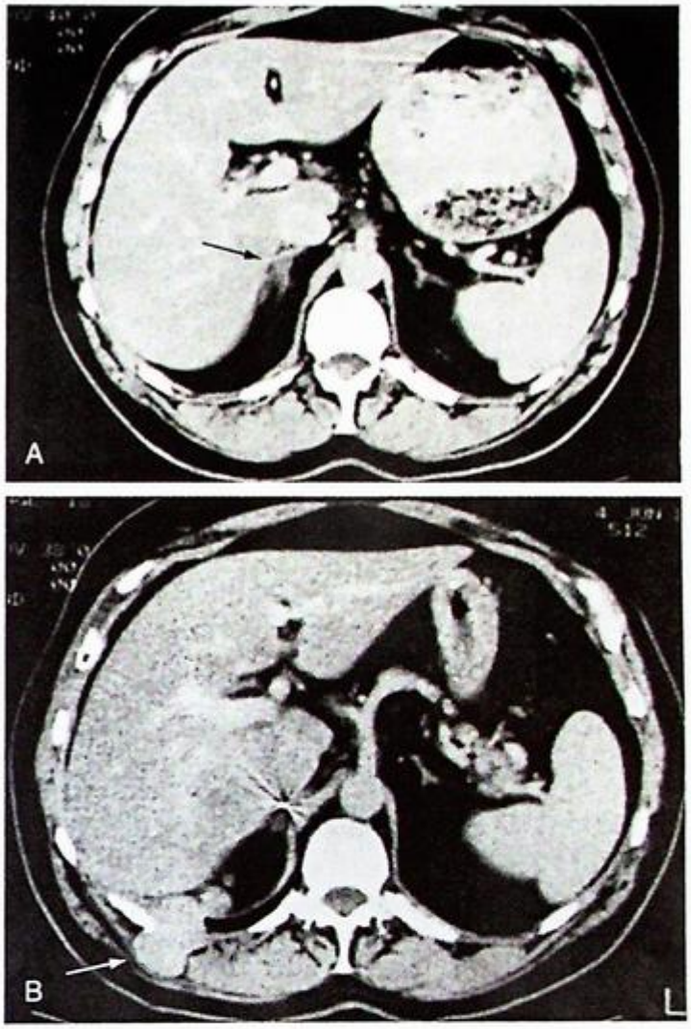

Figure 53–31. Patient with a small, right, aldosterone-producing adenoma (**A**), which was malignant and recurred in the adrenal bed and at the site of the flank incision (**B**). The disease caused the death of the patient.

Functional Tumors

Cushing's Syndrome

Cushing's syndrome has been discussed in detail, adrenal carcinoma being one of the causes of corticosteroid excess. This form of functional tumor is the most common in its pure form or with associated virilization. In a study comparing clinical and laboratory studies of patients with Cushing's syndrome caused by adenoma and carcinoma, Bertagna and Orth (1981) found that virilization without evidence of cortisol excess was indicative of carcinoma, except in children. Other clinical parameters were not helpful except for hirsutism, which is more common in patients with carcinoma. Thin skin, purple striae, thin hair, and temporal hair loss were more common in patients with adenomas. From a metabolic standpoint, 17-ketosteroid (Forbes and Albright, 1951) and DHEAS levels (Yamaji et al, 1984) are often high in patients with carcinomas, usually in conjunction with elevated glucocorticoid production (Luton et al, 1990). Prognosis is poor.

Testosterone-Secreting Adrenal Cortical Tumors

Virilization is the hallmark of Cushing's syndrome secondary to adrenal carcinoma. Virilization in the absence of elevated urinary 17-ketosteroids, however, is uncommon and should raise the possibility of testosterone-secreting ovarian or adrenal lesions (Imperato-McGinley et al, 1981; Del Gaudio and Del Gaudio, 1993). Of the two sites of origin, adrenal cortical tumors that secrete testosterone are exceedingly rare. Most adrenal tumors have been adenomas, but several have been ganglioneuromas with Leydig cell nodules (Aguirre and Sculley, 1983) or Leydig cell adenoma (Trost et al, 1981). Most tumors have been found in women, although they have been reported in men and children. Testosterone secretion can be autonomous, under gonadotropin control (Werk et al, 1973), or under ACTH control (Trost et al, 1981).

In contrast to the other tumors described in this chapter, these tumors are usually smaller than 6 cm, and they behave

in a benign fashion. In a review of 47 documented cases of testosterone-producing neoplasms, however, eight were virilizing carcinomas (Gabrilove et al, 1981; Mattox and Phelan, 1987).

Estrogen-Secreting Adrenal Cortical Tumors

Most feminizing tumors occur in men 25 to 50 years old, and in contradistinction to testosterone-secreting tumors, they are usually larger, often palpable, and highly malignant (Gabrilove et al, 1965). Characteristically, the patients present with gynecomastia. In addition, they may exhibit testicular atrophy, impotence, or decreased libido. In one of our patients, the clinical presentation was infertility and oligospermia.

These tumors secrete androstenedione, which is converted peripherally to estrogens. Other steroids may also be secreted, and the clinical picture may be mixed, with associated cushingoid features.

Of these tumors, 80% are malignant. Half the patients with this disease expire within 18 months of diagnosis. Three-year survival is less than 20%.

The prime therapy is surgical, usually employing a thoracoabdominal approach with wide excision of the tumor, the adjacent organs if necessary, and the regional lymph nodes. Despite wide resection, the patient's prognosis remains poor, and no effective adjunctive therapy has been developed.

Aldosterone-Secreting Adrenal Cortical Carcinoma

Primary hyperaldosteronism is almost always due to a small, benign, solitary adenoma; Conn's syndrome; or bilateral adrenal hyperplasia. The syndrome in its pure form, however, may rarely be caused by adrenal carcinoma (Vaughan and Carey, 1989). In fact, in most cases with evidence of mineralocorticoid excess and hypokalemia due to adrenal carcinoma, there are also signs of abnormalities in glucocorticoid or androgen secretion.

On review of the cases, the striking difference between the tumors found in these patients and in those with Conn's syndrome caused by benign adenoma is the size of the tumor. Benign adenomas are rarely larger than 3 cm. In contrast, all but two reported aldosterone-secreting carcinomas were larger than 3 cm (Vaughan and Carey, 1989). Accordingly, the clinical and biochemical syndrome of hyperaldosteronism and the CT evidence of a large adrenal mass strongly suggest carcinoma. Similar to most other patients with tumors as described, these patients do poorly despite initial resection of the tumor. Adjunctive therapy is ineffective.

Adrenocortical Carcinoma in Children

Adrenocortical carcinoma constitutes only 0.002% of all childhood malignant neoplasms (Young and Miller, 1975) and only 6% of childhood malignant adrenal tumors—the majority being neuroblastomas (Stewart et al, 1974). Despite the finding that survival is better in children—double that in adults—the entity is still highly lethal and refractory to adjunctive therapy, although adequate trials have not been carried out (Kay et al, 1983; Teinturier et al, 1999).

In contrast to tumors in adults, most of these tumors in children are hormonally active, and perhaps earlier detection is the reason for their better survival. The clinical syndromes include Cushing's syndrome, commonly as a result of carcinoma—not adenoma—in children; virilization in girls; and isosexual precocious puberty in boys. Evaluation follows the same lines as those described for adults, with careful examination for steroid precursors and byproducts. These may be of later use as tumor markers after initial tumor removal. In addition to recurrence, late occurrence of other tumors has also been reported (Andler et al, 1978). Adrenocortical carcinoma is also found in excess in children with Beckwith-Wiedemann syndrome, among children with isolated hemihypertrophy, and in association with Li-Fraumeni syndrome. Tumors have been found to show a high frequency of germline *p53* mutations, as are found in Li-Fraumeni syndrome, suggesting a potential relationship (Wagner et al, 1994; Venara et al, 1998).

Management of Adrenocortical Carcinoma

Except for testosterone-secreting tumors, adrenocortical carcinomas are highly malignant, with both local and hematogenous spread and a 5-year survival rate of about 35% (Icard et al, 1992; Schulick and Brennan, 1999). In a series by Richie and Gittes (1980), the most common sites of metastasis were lung, liver, and lymph nodes. A large autopsy study of 132 cases showed metastases to lungs (60%), liver (50%), lymph nodes (48%), bone (24%), and pleura and heart (10%) (Didolkar et al, 1981). In addition, these tumors often extend directly into adjacent structures, especially the kidney, and may involve the inferior vena cava (Long et al, 1993) or splenic vein (Stein et al, 1998). Treatment is surgical removal of the primary tumor, with an attempt to remove the entire lesion even if resection of adjacent organs (e.g., kidney, spleen) and of local lymph nodes en bloc is necessary, and any caval thrombus that is present (Ekici and Ciancio, 2004). In one review, patients with complete resection had a higher 5-year survival rate (38% to 62%) than the overall survival in the series reported (16% to 37%) (Schulick and Brennan, 2003). After surgical removal of functioning adrenal tumors, the patient can be followed up with appropriate hormone levels as markers for tumor recurrence.

Medical Therapy

Despite the current accuracy in anatomic and biochemical definition of adrenal carcinoma, about 40% of patients present with metastatic disease. Unfortunately, many patients with locally resectable disease eventually die of recurrent local or distant disease. The search for effective adjunctive therapy has been frustrating; radiation therapy has not been useful except for palliation (Percarpio and Knowlton, 1976). In addition, conventional chemotherapy, although not widely studied in a systematic fashion, has not been effective, probably because of P-glycoprotein expression (Flynn et al, 1992; Haak et al, 1993b).

The most success has been reported with adrenolytic drugs (1,1-dichloro-2-[*o*-chlorophenyl]-2-[*p*-chlorophenyl]ethane; *o,p'*-DDD) or mitotane (Bergenstal et al, 1960). This DDT derivative was shown by Hutter and Kayhoe (1966) to induce tumor response in 34%; Wooten and King (1993), in a review

of 551 cases reported in the literature, showed tumor response in 35%. The major use has been for patients with metastatic disease, and despite the response rates given, survival time has not been prolonged (Hoffman and Mattox, 1972; Luton et al, 1990) unless high serum levels are obtained (Haak et al, 1994; Khorram-Manesh et al, 1998) or it is given postoperatively in an adjuvant fashion (Vassilopoulou-Sellin et al, 1993). Moreover, the usual treatment regimen is to increase the dosage to 8 to 10 g/day until toxicity occurs. Significant toxicity includes gastrointestinal, neurologic, and dermatologic disorders, most of which regress on cessation of therapy.

During management, adrenal insufficiency can occur, and cortisol and aldosterone levels should be monitored. Because of the high fat solubility of the drug, traces of it can be found several months after the drug has been discontinued, warranting continued steroid monitoring during this period.

The overall response to mitotane has been disappointing, even in combination regimens (Bukowski et al, 1993). Suramin, the antiparasitic agent, also has limited efficacy (Arit et al, 1994). The antifungal drug ketoconazole, which has an adrenolytic effect, has also induced regression in metastatic adrenal carcinoma (Contreras et al, 1985), as have cisplatin and etoposide (Berruti et al, 1998; Bonacci et al, 1998).

Thus, drugs such as mitotane, ketoconazole, metyrapone, and aminoglutethimide may help relieve the devastating symptoms of glucocorticoid or mineralocorticoid excess. Little evidence exists, however, showing that survival is extended in most cases.

Transarterial embolization has been reported to achieve partial remission of symptoms in a patient with metastatic disease (Koh et al, 1991).

ADRENAL ONCOCYTOMA

Oncocytic tumors are rare neoplasms that are histologically composed of epithelial cells with abundant acidophilic granular cytoplasm that can be arranged in alveolar, tubular, or solid patterns (Chang and Harawi, 1992). Oncocytic neoplasms of the adrenal are nonfunctional, usually benign, and often large before being detected (Lin et al, 1998; Baloch and LiVolsi, 1999). Because they cannot be distinguished from adrenal carcinomas, treatment is surgical removal (Kitching et al, 1999). An additional rare benign tumor of the adrenal is an adenomatoid tumor of mesothelial origin (Isotalo et al, 2003).

ADRENAL CYSTS

These are usually unilateral lesions discovered incidentally during imaging procedures or surgery and at autopsy. Calcifications may be found in approximately 15% of cases and need not imply malignancy. Endothelial or lymphangiomatous cysts account for nearly 45% of these lesions and are usually small, measuring 0.1 to 1.5 cm in diameter. Adrenal pseudocysts that lack an epithelial lining are the next most common variety (39%) and most likely represent encapsulated residua of previous adrenal hemorrhages. Pseudocysts may become massive and may cause symptoms because of the compression of adjacent structures (Fig. 53–32). The acute hemorrhage in the case shown was readily distinguished by MRI. Traumatic rupture of adrenal cysts has also been reported (Favorito et al, 2004). Parasitic cysts due to echinococcal disease (7%) and true epithelial cysts (9%) account for the remainder of adrenal cysts (Kazam et al, 1989; Sroujieh et al, 1990). **Most cystic adrenal lesions are found incidentally and can be observed; symptomatic cysts can be percutaneously drained or laparoscopically decorticated** (Yoder and Wolf, 2004).

ADRENAL INSUFFICIENCY

Adrenal insufficiency is rarely encountered in the practice of urology. Because it is potentially fatal if it is not recognized, the salient features of the entity are worthy of review. In addition, delayed adrenal insufficiency can rarely be seen after unilateral adrenalectomy (Kazama et al, 2005).

Addison's disease is rare, the death rate being approximately 0.3 per 100,000; the most common cause in the past was either tuberculosis or adrenal atrophy (Dunlop, 1963; Irvine and Barnes, 1972; Eason et al, 1982). **However, at present in industrialized countries, the most common cause is autoimmune destruction of the adrenal gland** (Lovas and Husebye, 2005). The diagnosis is based on the presence of adrenal autoantibodies, of which 21-hydroxylase is the most important. Addison's disease may be a part of autoimmune polyendocrine syndrome type I and type II, syndromes that may also include primary hypogonadism. Other causes include malignant infiltration (Cedermark et al, 1977), sarcoidosis (Rickards and Barrett, 1954; Irvine and Barnes, 1972), histoplasmosis (Crispel et al, 1956), North American blastomycosis (Fish et al, 1960), South American blastomycosis (Osa et al, 1981), and coccidioidomycosis (Moloney, 1952). The general term *adrenal atrophy* actually refers to a pathologic process of lymphocytic adenitis with fibrosis (Maisey and Stevens, 1969). From a clinical point of view, however, symptoms of adrenal insufficiency usually appear in hospitalized patients in whom a history of the long-term use of exogenous steroids has not been obtained and acute withdrawal from steroids has occurred. Adrenal insufficiency may be an important aspect of the care of a patient with cancer and may be due to replacement of the adrenals with metastases, infiltration with lymphoma, hemorrhagic necrosis in association with anticoagulation or sepsis, and impaired adrenal steroidogenesis in patients receiving aminoglutethimide, ketoconazole, mitotane, or suramin (Ihde et al, 1990).

The symptoms and signs of chronic adrenal insufficiency are nonspecific and may be associated with numerous other diseases (Table 53–10). Similarly, abnormalities determined with routine laboratory tests are also nonspecific. The most common abnormalities are hyponatremia and hyperkalemia, with at least one electrolyte abnormality being found in 99 of 108 patients in one series (Nerup, 1974). The classic triad of hyponatremia, hyperkalemia, and azotemia was present in only 50% to 60% of cases. Hypercalcemia may also be an initial abnormality. Other endocrine disorders, including hyperthyroidism or hypothyroidism (17%), diabetes mellitus (12%), gonadal dysfunction (12%), and hypothyroidism (5%), occur in about 10% to 30% of patients with Addison's disease (May et al, 1989).

The symptoms of acute adrenal insufficiency "crisis," usually caused by withdrawal of exogenous steroids, sepsis, bilateral adrenal hemorrhage, or postadrenalectomy state,

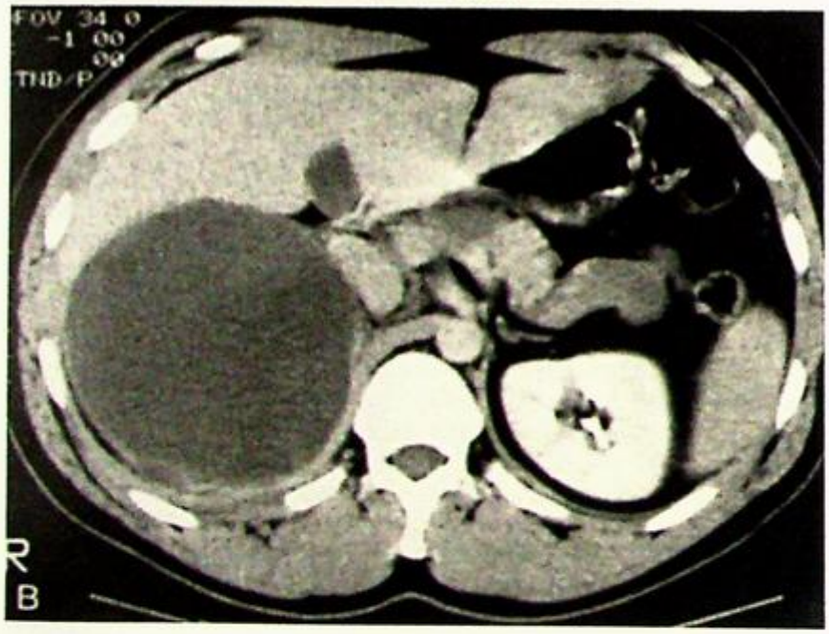

Figure 53–32. **A,** Massive right adrenal cyst. The patient presented with fever, pain, and anemia. **B,** CT scan of cyst. **C,** MRI image of bright hemorrhage into the lumen and cyst proved at exploration.

differ somewhat from those of Addison's disease, particularly fever, which occurs in 70% of patients (see Table 53–10) (Liu et al, 1982). Abdominal pain is also often present and may be due to unilateral or bilateral adrenal hemorrhage, which can be diagnosed by CT (Liu et al, 1982) or MRI (Falke et al, 1987). A useful screening test is an 8 AM measure of serum cortisol level (Dullaart et al, 1999).

However, the critical test to confirm Addison's disease is the demonstration of a failure to increase plasma (Perkoff et al, 1954) or urine corticosteroid level into the normal range with ACTH infusions (Renold et al, 1952; Schlaghecke et al, 1992). A provocative test is particularly important because there are numerous reports of patients with primary adrenal insufficiency having normal-based plasma cortisol or urine 17-hydroxycorticoid levels (May et al, 1989). Plasma ACTH levels may be markedly elevated, but such an assay is not always available. The simplest screening test is the rapid ACTH test, whereby plasma cortisol levels are measured before and 60

Table 53–10. Signs and Symptoms of Chronic Addison's Disease and Acute Adrenal Insufficiency

Prevalence		
Number	*%*	*Symptom*
Addison's Disease		
435/462	94	Weakness, tiredness, fatigue
393/438	90	Weight loss
303/351	86	Anorexia
178/268	66	Nausea, vomiting
100/164	61	Unspecified gastrointestinal complaints
35/127	28	Abdominal pain
44/246	18	Diarrhea
15/94	16	Muscle pain
24/168	14	Salt craving
24/166	14	Orthostatic hypotension, dizziness, or syncope
4/33	12	Lethargy, disorientation
Acute Adrenal Insufficiency		
165/165	100	Severe clinical deterioration
98/140	70	Fever

minutes after 0.25 mg of cosyntropin is given intravenously; cortisol levels should be higher than 18 µg/dL at 60 minutes (Fig. 53–33) (Speckard et al, 1971). Alternatively, 100 µg of human CRH can be used (Schlaghecke et al, 1992). A patient with a relative or an absolute lack of ACTH may respond normally to cosyntropin but not respond properly to surgical stress (Jasani et al, 1968; Kehlet and Binder, 1973). Most of these patients, however, tolerate surgical stress without steroid coverage. If treatment is mandated in a patient with suspected adrenal insufficiency, the ACTH stimulation test can be performed when treatment is with the synthetic steroid dexamethasone (Sheridan and Mattingly, 1975). Other, more definitive but more complex and longer infusion tests also can be used (Liu et al, 2003).

The treatment of acute or chronic adrenal insufficiency is obviously the administration of glucocorticoids. In acute adrenal crisis, stress-level dexamethasone (8 to 12 mg/day) is given, along with replacement saline (Smith and Byrne, 1981) and a simultaneous ACTH stimulation test to confirm the diagnosis (Sheridan and Mattingly, 1975) (Table 53–11).

The treatment of chronic Addison's disease is maintenance therapy—approximately 30 mg of hydrocortisone plus 0.05 to 0.1 µg fluorohydrocortisone per day orally, or a synthetic steroid (Table 53–12).

Replacement therapy after unilateral adrenalectomy is discussed elsewhere. The same guidelines pertain, however, and it is helpful to maintain patients on dexamethasone so that the ACTH test can be used to follow the recovery of the contralateral gland.

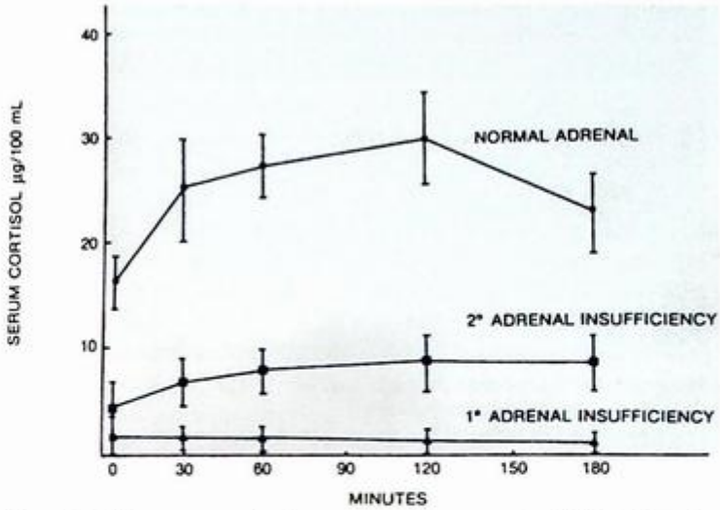

Figure 53–33. Serum cortisol response and response to ACTH infusion in normal persons and in patients with primary and secondary adrenal insufficiency. (From Vaughan ED Jr, Carey RM, eds: Adrenal Disorders. New York, Thieme Medical, 1989.)

Table 53–11. Treatment of Adrenal Crisis

Emergency Treatment

Establish 19-gauge IV line. Obtain stat serum electrolytes, glucose, cortisol, and plasma ACTH. Do not wait for results.

Infuse 2-3 L 0.9% saline solution (154 mmol/L) or 5% dextrose (50 g/L) in 0.9% saline solution as quickly as possible. Monitor for fluid overload by observing central or peripheral venous pressure or listening for pulmonary rales. Reduce infusion rate if indicated.

Inject 4 mg dexamethasone sodium phosphate (Decadron) IV at beginning of IV infusion or give 100 mg hydrocortisone sodium succinate (Solu-Cortef) or hydrocortisone sodium phosphate (Hydrocortone Phosphate) IV and 100 mg every 8 hours thereafter.

Provide supportive measures as needed.

Mineralocorticoids are unnecessary; ACTH is useless.

Subacute Treatment after Stabilization of Patient

Continue IV infusion of 0.9% saline solution at a lower rate for 24-48 hours as needed.

Search for and treat, if possible, precipitating cause of adrenal crisis.

In patient not known to have Addison's disease, and if not already done, perform short ACTH stimulation test to confirm diagnosis of adrenal insufficiency.

Taper glucocorticoid to maintenance dosage over 1-3 days if precipitating or complicating disease permits.

Begin or resume mineralocorticoid replacement with fludrocortisone (Florinef), 0.1 mg orally daily, when saline infusion is stopped.

Selective Adrenal Insufficiency

Selective hypoaldosteronism is rare and is usually due to hyporeninemia or functional hypoaldosteronism caused by tubular insensitivity to normal aldosterone levels (Schambelan et al, 1972; Williams et al, 1983). The urologist occasionally observes this phenomenon in an adult or a child who exhibits unexplained hyperkalemia after relief of chronic obstructive uropathy, especially in association with azotemia (Schambelan et al, 1980; Pelleya et al, 1983; Kozeny et al, 1986).

Table 53–12. Comparison of Half-life and Biologic Activity of Various Natural and Synthetic Steroids

Compound	Biologic Half-life (hr)	Plasma Half-life (hr)	Equivalent Dose (mg)	Relative Sodium-Retaining Activity
Cortisone*	8-12	0.5	25	0.8
Cortisol (hydrocortisone)	8-12	1.5	20	1
Prednisone*	12-36	1	5	0.8

From May ME, Vaughan ED Jr, Carey RM: Adrenocortical insufficiency—clinical aspects. In Vaughan ED Jr, Carey RM, eds: Adrenal Disorders. New York, Thieme Medical, 1989.

Other selective hypoaldosteronism may occur from primary disturbances of the zona glomerulosa, endogenous impairment of angiotensin II production (Findling et al, 1987), or aldosterone receptor deficiency (Armanini et al, 1985). Congenital primary hypoaldosteronism may be sporadic or familial (May et al, 1989).

Selective familial glucocorticoid deficiency has been well described, almost totally in the pediatric literature (May et al, 1989). The clinical presentation is dominated by recurrent hypoglycemia, both fasting and reactive, with subsequent seizures. The children usually have normal findings of electrolytes, which often delays the proper diagnosis.

PRIMARY HYPERALDOSTERONISM

The term *primary hyperaldosteronism* was originally coined by Conn (1955a, 1955b) to describe the clinical syndrome characterized by hypertension, hypokalemia, hypernatremia, alkalosis, and periodic paralysis caused by an aldosterone-secreting adenoma. As diagnostic tests for quantifying the components of the renin-angiotensin-aldosterone system have become available, the syndrome of primary hyperaldosteronism (PAL) is now identified by hypertension, suppressed plasma renin activity (PRA), and high urine and plasma aldosterone levels. However, there remain several unresolved issues related to the diagnosis and management of this disorder. What is the prevalence of primary aldosteronism, and which diagnostic screening tests should be used? Moreover, the term *primary hyperaldosteronism* encompasses a family of adrenal disorders, including variants that cannot be cured by adrenalectomy (Young, 2003; Mulatero et al, 2005; New et al, 2005). Which diagnostic tests are most likely to identify patients with surgically remediable subtypes? The following section provides evidence to support a diagnostic and therapeutic approach to the patient with primary aldosteronism.

Pathophysiology

The normal physiology of the renin-angiotensin-aldosterone system including the stimuli for aldosterone release is reviewed in Chapter 36. When aldosterone is secreted in amounts that are inappropriately high for the state of sodium balance, sodium reabsorption is augmented by the distal nephron (O'Neil, 1990; Rossier, 2003; Verrey et al, 2003; Kahle et al, 2005). Extracellular sodium content is increased and is accompanied by water so that isotonicity is maintained as body volume increases. Sodium accumulation is usually gradual and is dependent on its availability and on the magnitude of aldosterone excess. After a gain of about 1.5 kg of extracellular fluid, however, there is diminished renal sodium reabsorption. This phenomenon, which accounts for the absence of edema in this disorder, is referred to as mineralocorticoid escape; it enables the kidney to overcome the sodium-retaining effects of mineralocorticoid excess and consequently maintains sodium balance (Knowlton and Laragh, 1970; Knepper et al, 2003). Aldosterone-induced increases in glomerular filtration rate and fractional excretion of sodium are required for mineralocorticoid escape, and thus it is a manifestation of the pressure-natriuresis phenomenon (Hall et al, 1984). In addition, atrial natriuretic peptide participates in this response (de Bold et al, 2001). More recently, dynamic regulation of sodium transport by the distal nephron has been shown to contribute importantly to this adaptation to high levels of aldosterone (Meneton et al, 2004). For example, increased excretion of sodium during mineralocorticoid escape is associated with a major decrease in the abundance of the thiazide-sensitive Na^+-Cl^- cotransporter in the distal nephrons (Knepper et al, 2003).

As the understanding of adrenal physiology, biochemistry, histopathology, molecular biology, and genetics has advanced, it has become evident that there are distinct subsets of PAL. Reports from several centers indicate that the majority of patients with PAL can have hypertension and metabolic abnormalities ameliorated by unilateral adrenalectomy (Blumenfeld et al, 1994; Stowasser et al, 2003; Young et al, 2004). **Patients who are most likely to respond favorably to surgery are those in whom aldosterone production is highly autonomous from renin-angiotensin** (Mulatero et al, 2005) (see "Diagnostic Tests"). **Among the features that identify autonomy are**

1. **limited effect on aldosterone production by maneuvers that either increase the angiotensin II level (e.g., angiotensin II infusion or postural stimulation) or**

decrease it (e.g., saline infusion, fludrocortisone administration, angiotensin-converting enzyme inhibition);

2. **increased levels of aldosterone biosynthetic precursors (e.g., ratio of 18-hydroxycorticosterone to cortisol);**
3. **elevated levels of "hybrid" steroids (e.g., urinary cortisol C-18–methyloxygenated metabolites [18-hydroxycortisol and 18-oxocortisol])** (Ulick et al, 1992; Blumenfeld et al, 1994); and
4. **lateralization of aldosterone secretion to one adrenal gland** (Blumenfeld et al, 1994; Espiner et al, 2003; Stowasser and Gordon, 2004; Young et al, 2004).

Identification of patients with these diagnostic features has important implications for determining clinical management and for predicting the response to treatment.

The response of PRA to aldosterone-induced sodium retention and blood pressure elevation is the cornerstone of early diagnosis of PAL (Fig. 53–34). Accordingly, the normal renal juxtaglomerular responses to increased blood pressure (the baroreceptor mechanism) and the increased distal delivery of sodium chloride (the macula densa mechanism) result in suppression of PRA (Laragh and Sealey, 1992; Komlosi et al, 2004; Schweda and Kurtz, 2004). Moreover, PRA remains low even in the presence of sodium depletion or acute furosemide administration (Weinberger et al, 1979). This observation is in marked contrast to the elevated PRA seen in patients with secondary aldosteronism, whereby oversecretion of aldosterone is the consequence of excess production of renin and angiotensin II usually caused by renal arterial or parenchymal disease (Laragh and Sealey, 1992) (see Chapters 35 and 36).

Measurements of urine and plasma aldosterone have provided further insight into abnormalities of aldosterone secretion (Laragh and Sealey, 1992; Gordon et al, 2005). Hence, in contrast with healthy subjects, the oversecretion of aldosterone is not suppressed by sodium loading in primary aldosteronism (Weinberger et al, 1979; Mulatero et al, 2005). Conversely, with ambulation, patients with an aldosterone-producing adenoma (APA) do not exhibit the characteristic rise in aldosterone secretion found in normal subjects (Ganguly et al, 1973; Ganguly, 1998). These observations highlight the autonomous secretion that is present in patients with APA and identify differences in the pathophysiology of APA and other subtypes of primary aldosteronism (Fontes et al, 1991; Ganguly, 1998; Espiner et al, 2003).

In a subset of APAs, aldosterone production is stimulated by the renin-angiotensin-aldosterone system, as determined by angiotensin II infusion and postural stimulation (Tunny et al, 1991). In these cases, angiotensin II infusion no longer stimulates aldosterone release shortly after adrenalectomy, suggesting that the adenoma is the sole source of aldosterone. This variant, referred to as angiotensin II responsive (AII-R) APA, has other unique biochemical and histologic features (Tunny et al, 1991). In contrast to the typical APA, which is angiotensin II unresponsive (AII-U APA) and in which there is overproduction of cortisol C-18–oxygenated metabolites (i.e., 18-oxocortisol, 18-hydroxycortisol), AII-R APA is not associated with increased levels of these hybrid steroids. In addition, plasma cortisol levels are suppressible in AII-U APA but not in AII-R APA. These findings indicate that autonomous overproduction of cortisol occurs from some APAs (Imai et al, 1991). These heterogeneous biochemical responses are consistent with the histologic characteristics: AII-U APAs consist predominantly of fasciculata-like cells, whereas AII-R APAs are primarily composed of glomerulosa-like cells. Tunny and coworkers (1991) found a reciprocal relationship between the increment in plasma aldosterone during angiotensin II infusion and the percentage of fasciculata-type cells in the adenoma and concluded that the aldosterone responsiveness to angiotensin II was related to the predominant tumor cell type.

Biglieri and coworkers (Banks et al, 1984; Irony et al, 1990) and others (Blumenfeld et al, 1994; Young et al, 2004) have characterized a subset of patients with autonomous aldosterone production in whom an adrenal adenoma could not be identified. This variant has been referred to as primary adrenal hyperplasia. The adrenal glands in primary adrenal hyperplasia are hyperplastic, frequently with a dominant nodule. As in AII-R APA, aldosterone production in primary adrenal hyperplasia is autonomous (Fontes et al, 1991). Furthermore, correction of the metabolic abnormalities and hypertension in this subset occurs after unilateral adrenalectomy.

Adrenal carcinoma is an extremely rare cause of PAL (Arteaga et al, 1984; Isles et al, 1987). Of 141 patients with adrenal carcinoma presenting to the Mayo Clinic for surgery, 15 patients were identified with aldosterone-secreting adrenal carcinoma (Kendrick et al, 2002). Isolated aldosterone hypersecretion was present in 10 patients, and mixed hormonal secretion was detected in 5. Mean tumor size and weight were 10.8 cm and 453 g, respectively. Surgical resection was curative in 10 patients (67%), although the perioperative mortality was 20% and the disease recurrence rate was 70%, with a median interval of 17 months. Five-year survival was 52%.

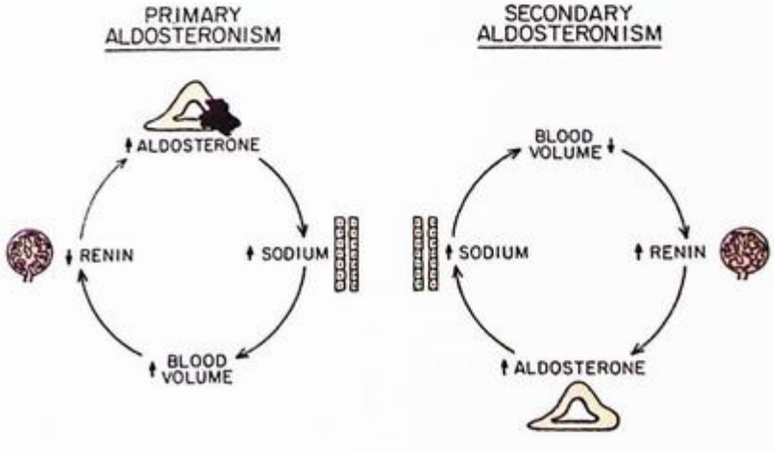

Figure 53–34. Hyperaldosteronism may be seen in association with elevated (secondary) or depressed (primary) levels of plasma renin activity. In primary aldosteronism, an adrenal neoplasm or bilateral hyperplasia is the initiating event. Secondary aldosteronism is most commonly seen in edematous disorders (e.g., cirrhosis, renal failure), in which the elevated renin levels are a physiologic adjustment to a contracted blood volume; it is also present in renal artery stenosis, secondary to the stimulus of elevated levels of renin and angiotensin II.

Patients with aldosterone-secreting adrenal carcinoma had an increased risk of perioperative mortality compared with those with an adrenal carcinoma that did not secrete aldosterone (20% versus 5%), although overall survival was longer in aldosterone-secreting adrenal carcinoma (63 months versus 19 months).

The pathogenesis of idiopathic hyperaldosteronism associated with bilateral adrenal hyperplasia remains uncertain. However, a systemic stimulus other than angiotensin II or ACTH seems to be responsible. Less common disorders associated with bilateral adrenal hyperplasia and hyperaldosteronism have been identified and characterized (see preceding, primary adrenal hyperplasia). Glucocorticoid-remediable aldosteronism (GRA), also termed familial hyperaldosteronism type I (FH-I), is an autosomal dominant disorder in which aldosterone biosynthesis is regulated by ACTH rather than by the renin-angiotensin-aldosterone system (Sutherland et al, 1966; Isles et al, 1987; Lifton et al, 1992; McMahon and Dluhy, 2004; Mulatero et al, 2004a). The exaggerated aldosterone responsiveness to ACTH in GRA can be corrected by glucocorticoid treatment (McMahon and Dluhy, 2004; New et al, 2005). Clinical features include a strong family history of hypertension, early-onset hypertension, and increased risk of intracerebral hemorrhage or aortic dissection. The most common, routine laboratory finding is low PRA; however, other biochemical evidence of aldosterone excess may be absent (e.g., hypokalemia) (Rich et al, 1992; Litchfield et al, 1997). A key diagnostic feature is the overproduction of C-18 cortisol-aldosterone structural hybrids, 18-hydroxycortisol and 18-oxocortisol, which are formed when cortisol is accepted by aldosterone synthase as a substrate for methyloxidation (Ulick and Chan, 1989) (Fig. 53–35). Normally, this enzyme is expressed predominantly in the adrenal glomerulosa zone (White, 1994, 2001). On the basis of these biochemical features and the associated hyperplasia of the zona fasciculata, Ulick and associates proposed that the fascicular zone acquires aldosterone synthase activity, thereby abrogating the normal zonation of adrenal function (Ulick and Chan, 1989; Ulick et al, 1992). This hypothesis was supported by the finding that GRA is caused by a chimeric gene duplication that results from unequal crossing over between the highly homologous 11-hydroxylase (*CYP11B1*) and aldosterone synthase (*CYP11B2*) genes, which are located in proximity on chromosome 8 (Lifton et al, 1992; Dluhy and Lifton, 1999). This chimeric gene represents a fusion of the 5′ ACTH-responsive promoter region of the 11-hydroxylase gene and 3′ coding sequences of the aldosterone synthase gene. It results in ectopic expression of aldosterone synthase activity in the cortisol-producing zona fasciculata that is stimulated by ACTH instead of angiotensin II (Fig. 53–36). Furthermore, because of its aberrant expression in the fascicular zone, the enzymatic product of this chimeric gene uses cortisol as a substrate for C-18 oxidation to the cortisol-aldosterone hybrid steroids. Treatment of this syndrome with low doses of exogenous glucocorticoid inhibits ACTH secretion, suppresses aldosterone production (thereby promoting natriuresis), normalizes PRA, and consequently reduces blood pressure and corrects metabolic abnormalities caused by mineralocorticoid excess.

Although GRA is a rare disorder, several previously undiagnosed patients were discovered when elevated urinary levels of 18-hydroxycortisol and 18-oxocortisol were used to screen the relatives of a proband with GRA (Rich et al, 1992). All affected adults were hypertensive before the age of 20 years and had lower PRA than their unaffected family members.

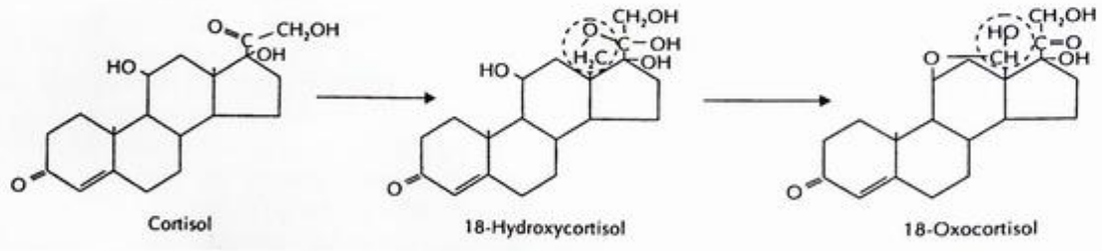

Figure 53–35. Biosynthesis of the C-18 methyloxygenation metabolites of cortisol. (From Blumenfeld JD: Hypertension and adrenal disorders. Curr Opin Nephrol Hypertens 1993;2:274.)

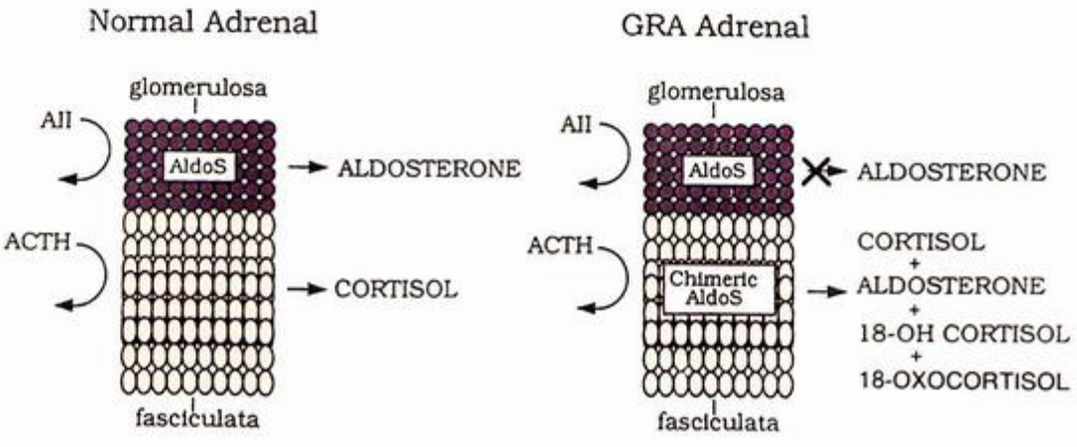

Figure 53–36. Adrenal cortex responsiveness to ACTH and angiotensin II in normal subjects and in glucocorticoid-remediable aldosteronism (GRA). (From Lifton RP, Dluhy RG, Powers M, et al: Hereditary hypertension caused by chimeric gene duplications and ectopic expression of aldosterone synthase. Nat Genet 1992;2:66-74.)

Surprisingly, none of those affected were hypokalemic, and their urinary aldosterone excretion overlapped with the unaffected group. An attenuated aldosterone response to potassium in GRA has been described in association with a sharp diurnal decline in aldosterone in this ACTH-regulated syndrome (Litchfield et al, 1997). It has been proposed that these pathophysiologic responses in GRA cause milder clinical and laboratory manifestations of hyperaldosteronism compared with other forms of primary aldosteronism, thereby producing volume expansion with minimal renal potassium wasting (Litchfield et al, 1997).

Diagnostic tests for GRA include direct genetic analysis to identify the chimeric *CYP11B1/CYP11B2* gene; 24-hour urine collection, demonstrating overproduction of cortisol C-18 oxidation metabolites (i.e., 18-hydroxycortisol, 18-oxocortisol); and dexamethasone suppression test (Dluhy and Lifton, 1999). Although C-18 hybrid steroids are also present in APA, the chimeric *CYP11B1/CYP11B2* gene has not been identified in these tumors (Pilon et al, 1999).

Gordon and colleagues have described another familial form of primary aldosteronism termed FH-II, distinct from GRA (FH-I), in which aldosterone production is not suppressed by glucocorticoid treatment (Stowasser et al, 2001; Gordon et al, 2005). The inheritance pattern of FH-II has not been completely determined, and there is no common histologic presentation encompassing family members with AII-R APA, AII-U APA, and bilateral hypersecretion of aldosterone.

Apparent mineralocorticoid excess type 1 is characterized by hypertension, low PRA, low urinary aldosterone excretion rate, and increased urinary excretion of metabolites of cortisol rather than cortisone (ratio of free cortisol to cortisone and of tetrahydrocortisols to tetrahydrocortisone) (Ulick et al, 1979; Quinkler and Stewart, 2003; New et al, 2005). Normally, the mineralocorticoid receptor in vitro binds cortisol and aldosterone with equal affinity, whereas cortisone binding is less avid (Arriza et al, 1987; Quinkler and Stewart, 2003). Although the serum concentration of cortisol is normally 1000-fold greater than that of aldosterone, cortisol is inactivated by conversion to cortisone (which has a relatively low affinity for the mineralocorticoid receptor) by 11β-hydroxysteroid dehydrogenase at mineralocorticoid-responsive tissues. This allows aldosterone, rather than cortisol, to gain access to the mineralocorticoid receptor. **Thus, it is 11β-hydroxysteroid dehydrogenase rather than the mineralocorticoid receptor that confers tissue specificity for aldosterone.** Hypothalamic-pituitary-adrenal axis responsiveness is normal in apparent mineralocorticoid excess, and the serum cortisol concentration is normal and does not aid in the diagnosis.

Treatment options in apparent mineralocorticoid excess include (1) blockade of either the mineralocorticoid receptor (e.g., spironolactone) or the renal apical sodium channel (amiloride) and (2) suppression of endogenous cortisol production with dexamethasone, which has a low affinity for the mineralocorticoid receptor. In patients with Cushing's syndrome, cortisol can become the active mineralocorticoid, especially in the ectopic ACTH syndrome, in which cortisol secretion is extremely high (Ulick et al, 1992; Stewart, 1999). In this disorder, mechanisms of cortisol inactivation are overwhelmed, allowing it to gain access to the mineralocorticoid receptor.

Licorice ingestion can cause hypertension with features that are similar to apparent mineralocorticoid excess (Stewart et al, 1987; Edwards et al, 1988; Farese et al, 1991; Stewart, 1999). **Glycerrhizic acid and its hydrolytic product (glycyrrhetenic acid) are the active ingredients of licorice that inhibit 11β-hydroxysteroid dehydrogenase and thereby allow cortisol to gain access to the mineralocorticoid receptor.** Aldosterone receptor antagonism normalizes blood pressure, prevents upregulation of vascular endothelin-1, and restores nitric oxide–mediated endothelial dysfunction in an animal model of glycyrrhizic acid–induced hypertension (Quaschning et al, 2001).

Liddle's syndrome is an autosomal dominant condition characterized by low-renin hypertension, hypokalemia, renal potassium wasting, and low levels of aldosterone (Liddle and Coppage, 1963). The genetic defects responsible for this syndrome are deletion mutations in the C terminus of the β/γ subunits of the renal epithelial sodium channel (ENaC) (Shimkets et al, 1994; Schild et al, 1995; Warnock, 1998; O'Shaughnessy and Karet, 2004). These gain of function mutations lead to constitutive activation of ENaC, resulting in electrogenic sodium reabsorption and kaliuresis. Amiloride, which blocks the apical sodium channel, is effective treatment. By contrast, mineralocorticoid receptor blockade (e.g., spironolactone) is ineffective because renin, angiotensin II, and aldosterone levels are all suppressed by the sodium-dependent hypertension.

Epidemiology

PAL has traditionally been considered a rare form of hypertension, affecting 1% to 2% of hypertensive patients, with APA the most prevalent diagnostic subset (Weinberger et al, 1979; Bravo et al, 1983; Blumenfeld et al, 1994). However, results of screening efforts at several large centers, which rely primarily on the ratio of plasma aldosterone to plasma renin activity (see later), suggest that the prevalence of PAL is substantially higher than previously thought. After the aldosterone-to-renin ratio was introduced as a screening strategy, the reported prevalence of PAL increased by 5- to 15-fold at five medical centers, with detection rates of PAL ranging from 3% to 32% of all hypertensive patients (Stowasser et al, 2003; Mulatero et al, 2004b). This screening strategy has also uncovered a higher proportion of PAL patients with milder laboratory abnormalities, accounting for the observation that hypokalemia was found in only 9% to 37% of patients. Moreover, a dramatic change in the prevalence of diagnostic subsets of PAL has been reported. Whereas APA was reported as the cause of PAL in two thirds of patients before screening by the aldosterone-to-renin ratio was introduced (Weinberger et al, 1979; Bravo et al, 1983; Blumenfeld et al, 1994), a marked increase in the proportion of patients with bilateral adrenal hyperplasia has since been reported and the prevalence of patients with APA has decreased to the range of 9% to 50% (Stowasser et al, 2003; Mulatero et al, 2004b; Stowasser and Gordon, 2004; Young et al, 2004). However, use of the aldosterone-to-renin ratio as the cornerstone for PAL screening has been challenged and the validity of this apparent dramatic shift in the epidemiology of PAL questioned (Padfield, 2002; Kaplan, 2004) (see later).

Table 53–13. Age Distribution of 266 Tumors of the Adrenal Cortex in Hyperaldosteronism with Low Plasma Renin

		Age (yr)

Clinical Characteristics

The clinical findings in patients with this syndrome are primarily due to the increased total body sodium content and deficit in total body potassium (Ferriss et al, 1978). Symptoms include nocturia and urinary frequency, reflecting the urine concentrating defect induced by the potassium deficit, although patients may not be aware of these symptoms and thus the history may have to be elicited. In patients with more severe hypokalemia and other manifestations, muscle weakness, frontal headaches, polydipsia, paresthesias, visual disturbances, temporary paralysis, cramps, and tetany may occur. If the patient is normokalemic, these characteristic symptoms are usually mild or absent.

An adenoma is more likely to be detected in younger patients and in women. The age and gender distribution of 266 tumors in patients with hyperaldosteronism is shown in Table 53–13. The weights and sites of adrenal adenomas and adrenal carcinomas are shown in Table 53–14.

Patients with PAL are not edematous because sodium retention in this syndrome is limited by the mineralocorticoid escape phenomenon (Nakada et al, 1989) (see earlier). Patients with an adenoma, however, usually have more extensive manifestations of mineralocorticoid excess than do those with hyperplasia, including more severe hypertension (Ferriss et al, 1978; Blumenfeld et al, 1994). The physical examination findings are not usually distinguishable from essential hypertension, unless hypokalemia is severe. Malignant hypertension occurs rarely.

Hypertension is present in virtually all patients with primary aldosteronism. Moreover, the prevalence of primary aldosteronism is reportedly higher in patients with more severe hypertension. For example, of 609 hypertensive patients evaluated for PAL at primary care centers in Chile, PAL prevalence was 2% in patients with blood pressure of 140-159/90-99 mm Hg, 8% in those with blood pressure of 160-179/100-109 mm Hg, and 13.2% in those with blood pressure above 180/110 mm Hg (Mosso et al, 2003).

At our center, after withdrawal of antihypertensive medication, patients with an adenoma had significantly higher systolic (184 versus 161 mm Hg) and diastolic (112 versus 105 mm Hg) levels than did those with adrenal hyperplasia (Blumenfeld et al, 1994). Systolic blood pressure was 175 mm Hg or higher in 66% with adenoma, compared with only 15% with hyperplasia. Diastolic pressure was 114 mm Hg or higher in 50% of patients with adenoma, compared with only 19% of those in the hyperplasia group. There was a direct relationship ($r = 0.58$) between the urinary aldosterone excretion rate and the mean arterial pressure among the adenoma patients.

Table 53–14. Hyperaldosteronism

Weights of 151 Adrenal Adenomas			Weights of 25 Adrenal Carcinomas	
Weight (g)	*No.*	*%*	*Weight (g)*	*No.*
<2	51	34	<30	1

In contrast to the escape from sodium retention that occurs in this syndrome, aldosterone-mediated renal secretion of potassium is persistent and causes total body potassium deficit, hypokalemia, nephrogenic diabetes insipidus, and related symptoms (Ferriss et al, 1978). In the Cornell study, serum potassium levels were significantly lower in the patients with adenoma (3.0 versus 3.5 mEq/L) (Blumenfeld et al, 1994). Levels below 2.8 mEq/L occurred in 44% of the adenoma group compared with only 6% of the group with hyperplasia. The profound hypokalemia that occurs in patients with an adenoma contributes to its marked metabolic alkalosis. Conversely, 18% of the hyperplasia group had a serum potassium concentration above 3.5 mEq/L compared with only 6% of those with an adenoma. Several previous studies have also reported normal serum potassium levels in

approximately 20% of patients with PAL (Conn et al, 1966; Bravo et al, 1983; Melby, 1984; Takeda et al, 1995; Mosso et al, 2003; Mulatero et al, 2004b; Stowasser and Gordon, 2004), most commonly in patients with adrenal hyperplasia. **Because severe hypokalemia occurs less frequently in patients with restricted dietary sodium intake, the authors do not recommend screening patients for this syndrome unless they are adequately sodium loaded** (see "Diagnostic Tests").

Cardiovascular Disease. Although case reports and other studies with relatively few patients illustrate that cardiovascular complications can occur in patients with PAL, there is little information about the prevalence of these complications (Suzuki et al, 1988; Rossi et al, 1996, 1997, 2002, 2003; Porodko et al, 2002; Rossi, 2005). However, a case-control study identified 124 patients with PAL (APA in 52%) from a rigorously screened population of 5500 patients referred for evaluation of hypertension (Milliez et al, 2005). Compared with the control group of 465 patients with essential hypertension in that study, those with PAL were at significantly greater risk of atrial fibrillation (7.3% versus 0.6%), myocardial infarction (4% versus 0.6%), stroke (12.9% versus 3.4%), and left ventricular hypertrophy (by electrocardiography: 32% versus 14%; by echocardiography: 34% versus 24%) during a mean follow-up period of 13.6 months. Blood pressure was reportedly controlled during follow-up by unilateral adrenalectomy or antihypertensive drug treatment. The risk of complications was not preferentially associated with either diagnostic subtype of PAL. The clinical characteristics, blood pressure (mean, ~175/105 mm Hg), and other risk factors were reportedly well matched, with the exception of a slightly greater serum cholesterol level in the essential hypertension group. The cardiovascular complication rates reported in this study were unusually high, and those results will have to be confirmed in subsequent studies. However, treatment with mineralocorticoid receptor blockade (i.e., spironolactone, eplerenone) in patients with severe heart failure, which is commonly associated with secondary hyperaldosteronism, improves survival and decreases the risk of cardiovascular complications (Pitt et al, 1999, 2003). Although there is a temptation to relate the cardiovascular impact of secondary hyperaldosteronism in heart failure with that of primary aldosteronism, this comparison has significant and obvious limitations. Nevertheless, whether the dramatically high prevalence of cardiovascular complications reported by Milliez and coworkers (2005) can be generalized to all patients with primary aldosteronism will require further investigation.

Diagnostic Tests

The diagnostic tests described here are designed to screen the large hypertensive population for PAL and to identify patients with surgically remediable subtypes of PAL. The absence of a reliable clinical picture of hyperaldosteronism has led to an array of tests suggested to accomplish these goals.

Unprovoked hypokalemia is the hallmark of hyperaldosteronism, but as already discussed, serum potassium levels between 3.5 and 4.0 mEq/L are relatively common in patients subsequently proved to have PAL. Moreover, patients with essential hypertension may exhibit hypokalemia, especially during treatment with thiazide and loop diuretics. Monitoring serum potassium concentration after salt loading increases the likelihood that hypokalemia will be observed, but the entity of normokalemic PAL is well recognized (Weinberger et al, 1979; Blumenfeld et al, 1994; Stowasser et al, 2003).

Plasma Renin Activity

The first breakthrough followed the ability to determine PRA accurately. In 1964, Conn and associates demonstrated the suppression of PRA in patients with PAL (Conn, 1964). Until that time, a major diagnostic dilemma was distinguishing patients with PAL from those with excessive secretion of aldosterone as the consequence of high levels of renin due to primary renal parenchymal or renovascular diseases (secondary hyperaldosteronism). This problem was solved by the accurate measurement of PRA (Streeten et al, 1990; Laragh and Sealey, 1992).

Two methods are now commonly used to measure plasma renin. The PRA enzyme kinetic assay quantifies the amount of angiotensin I generated during incubation of plasma. PRA is expressed as the hourly rate of angiotensin I generation (as nanograms per milliliter per hour). It reflects the net capacity of the blood to generate angiotensin II because angiotensin-converting enzyme is not normally rate limiting unless it is pharmacologically blocked (Sealey et al, 2005). This is the most sensitive method available for quantifying the low levels of renin activity that are characteristic of PAL.

The direct renin assay is an alternative method that is based on a chemiluminescence assay (expressed as microunits per milliliter). Unlike the PRA measurement by the enzyme kinetic assay, the direct renin method does not measure angiotensin I generation and lacks its sensitivity (Sealey et al, 2005).

Although approximately one third of patients with essential hypertension also exhibit low PRA (Brunner et al, 1972), with an increased prevalence of low-renin essential hypertension among black patients (Alderman et al, 2004), these patients are normokalemic and have normal aldosterone responses to changes in posture, sodium depletion, and saline loading.

Aldosterone-to-Renin Ratio

An elevated ratio of plasma aldosterone to PRA is another indicator of autonomous aldosterone secretion that is now widely used as a screening test for PAL (Hiramatsu et al, 1981; Young, 2003; Mulatero et al, 2004b; Stowasser and Gordon, 2004). Dunn and Espiner (1976) first reported the use of the aldosterone-to-renin ratio (ARR) as a screening test for PAL, and Hiramatsu and colleagues (1981) showed that an ARR above 40 (aldosterone [ng/dL] to PRA [ng/mL/hr]) successfully identified untreated patients with APA. Since then, investigators from several centers have used ARR cutoff values ranging from 14 to 50 (Blumenfeld et al, 1994; Mosso et al, 2003; Mulatero et al, 2004b; Young et al, 2004) and consequently have identified PAL in significantly higher proportions of patients with previously diagnosed essential hypertension. However, a precise partition value for the ARR has not been established in the diagnosis of PAL. In the Cornell study, a plasma ARR above 50 was more commonly observed in PAL than in essential hypertension, including patients with low-renin essential hypertension (Blumenfeld et al, 1994). However, there was considerable overlap between

the hyperplasia and adenoma patients, and the magnitude of ARR was not predictive of surgical cure. Therefore, ARR is not a useful index for differentiating these diagnostic subsets or the potential for surgical cure.

Several factors can have an impact on the measurements of plasma renin and aldosterone and thus influence the interpretation of the ARR. **When the PRA is less than 1 ng/mL/hr, which is a characteristic finding in patients with PAL, the ARR is disproportionately affected by small changes in the renin level** (Auchus, 2003). For example, a patient with essential hypertension with a PRA of 0.6 ng/mL/hr and a serum aldosterone level of 8 ng/dL (ARR = 13) would be misdiagnosed with PAL if the PRA was erroneously reported as 0.2 ng/mL/hr (ARR = 40). The risk of a false-positive screening test result and hence the likelihood of an incorrect diagnosis of PAL is amplified because the accuracy of the PRA measurement is limited at these low levels. The large intrapatient and interpatient variations in plasma aldosterone concentration, PRA, and ARR in patients with APA highlight this problem. In fact, only 37% of PAL patients always have the characteristic profile associated with APA (i.e., plasma aldosterone > 15 ng/dL, PRA < 0.5 ng/mL/hr, ARR > 35) (Tanabe et al, 2003).

To minimize the risk that the ARR will result in an incorrect diagnosis, several additional steps should be employed before proceeding with the ARR as a screening test for primary aldosteronism (Stowasser and Gordon, 2004).

1. The patient should be seated when blood samples are obtained.
2. Hypokalemia should be corrected with oral potassium supplementation because potassium depletion attenuates aldosterone secretion and leads to a false-negative ARR.
3. Plasma (or serum) aldosterone concentration (PAC) above 15 ng/dL: Although there is no clearly defined level, a PAC of less than 15 ng/dL is unlikely to occur in patients with PAL (especially those with APA). However, a false-positive ARR can occur with very low PRA encountered in patients with low-renin essential hypertension (e.g., PRA of 0.1 ng/mL/hr, PAC of 6 ng/dL, ARR of 60) (Mulatero et al, 2005).
4. Antihypertensive medications:
   False-negative ARR: Diuretics (amiloride, spironolactone, thiazide and loop diuretics) stimulate renin secretion and should be discontinued 4 weeks before testing to decrease the chance of a false-negative test result. Dihydropyridine calcium channel blockers can inhibit aldosterone secretion and increase renin and should be discontinued at least 2 weeks before testing.
   False-positive ARR: β-Adrenergic receptor blockers, clonidine, and methyldopa suppress PRA and should be discontinued for at least 2 weeks before testing to reduce the chance of a false-positive test result.
5. Captopril test: Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers stimulate renin secretion and should be discontinued 2 weeks before testing to reduce the likelihood of potentially false-negative ARR, particularly in patients with idiopathic hyperaldosteronism or an angiotensin II–responsive adenoma. However, several investigators have reported that acute administration of a single dose of captopril (25 to 50 mg 1 to 2 hours before measurement of plasma renin and aldosterone levels) enhances the accuracy for diagnosis of patients with primary aldosteronism and have recommended its use for screening (Agharazii et al, 2001; Castro et al, 2002; Racine et al, 2002; Rossi E et al, 2002).
   If antihypertensive medication is required, verapamil and α_1-adrenergic receptor blockers do not significantly influence renin or aldosterone secretion and thus are less likely to confound the ARR.
6. If the ARR screening test result is positive (>25 to 50), a salt-loading suppression test is indicated (see later).

Problems with the ARR as a Screening Test for PAL. The ARR has gained broad acceptance and is now widely used to screen patients for primary aldosteronism. However, several methodologic inconsistencies have limited the interpretation of the ARR results (Kaplan, 2004). As discussed before, the elevated ARR is predominantly an indicator of low PRA and is especially vulnerable to variability in this assay that can occur from antihypertensive medication use and volume depletion (Padfield, 2002). Several centers that have reported ARR for the diagnosis of PAL do not use sodium suppression protocols (Kaplan, 2004). Moreover, only limited data exist regarding the sensitivity and specificity of ARR. In one study of patients in whom the adrenal status was clearly defined, an ARR of 32 or higher had a specificity of 61% (Hirohara et al, 2001). Some investigators do not require an absolutely elevated plasma aldosterone level for the interpretation of an elevated ARR (Stowasser et al, 2003). Critics of ARR for PAL screening raise other issues, including the risks of potentially unnecessary invasive testing and treatment (e.g., adrenal vein sampling, adrenalectomy; see later). Moreover, bilateral adrenal hyperplasia predominates in patients with PAL that is detected by an elevated ARR. This diagnostic variant is not surgically remediable and requires treatment with antihypertensive medication, preferably a selective mineralocorticoid receptor antagonist (i.e., spironolactone or eplerenone). Hence, critics question the necessity of these elaborate maneuvers when treatment with a mineralocorticoid receptor antagonist is the most likely outcome. The true sensitivity and specificity, cost-efficacy, and safety can best be defined by properly designed clinical studies. Moreover, any safe screening test that can facilitate the stratification of patients with essential hypertension into more clearly defined pathophysiologic subgroups and improve treatment efficacy is desirable.

Postural Stimulation Test

Stimulation of renin and aldosterone secretion occurs in normal individuals during upright posture (Laragh and Sealey, 1992). **In subsets of PAL associated with autonomous aldosterone production (including angiotensin II–unresponsive adenoma and primary adrenal hyperplasia), however, postural stimulation of aldosterone does not occur** (Ganguly et al, 1973; Fontes et al, 1991; Blumenfeld et al, 1994). The postural stimulation test is conducted by drawing plasma cortisol and aldosterone samples at 8:00 AM with the patient supine after an overnight recumbency and again while the patient is upright after 2 to 4 hours of ambulation. In patients with angiotensin II–unresponsive adenoma and primary adrenal hyperplasia who have highly autonomous

aldosterone production, plasma aldosterone levels *decrease* during this test, reflecting the diurnal fall in ACTH. **Normally, ACTH is a relatively minor stimulus for aldosterone production, but this effect is accentuated in angiotensin II–unresponsive adenoma and primary adrenal hyperplasia because renin-angiotensin levels are highly suppressed** (Schambelan et al, 1976). A false-negative response, which might occur during a stress-related increase in ACTH, can be detected if plasma cortisol levels rise during upright posture. By contrast, in patients with idiopathic hyperaldosteronism or angiotensin II–responsive adenoma, renin and angiotensin II levels increase slightly during upright posture and aldosterone production increases because of the increased sensitivity of the zona glomerulosa to angiotensin II (Tunny et al, 1991). In GRA, aldosterone production falls during the test because of the ACTH dependency of aldosterone biosynthesis. This response may lead to an inaccurate diagnosis.

Sodium Loading

Sodium-loading maneuvers are useful for identifying patients with PAL (Weinberger et al, 1979; Arteaga et al, 1985; Stowasser and Gordon, 2004; Mulatero et al, 2005). Accordingly, during volume expansion in normal individuals or in patients with essential hypertension, PRA levels decrease and consequently aldosterone secretion falls. **In patients with PAL, renin secretion is suppressed before salt loading, and therefore additional volume expansion does not decrease aldosterone levels to the same extent as in normal subjects or patients with essential hypertension.** Several salt-loading protocols have been validated for diagnostic screening (Mulatero et al, 2005):

1. Oral sodium loading for 3 to 5 days (≥200 mEq/day; 5 g of sodium per day). This may be accomplished by instructing the patient to eat a high-salt diet or to supplement the diet with sodium chloride tablets (1 g NaCl = 17 mEq Na). On the last day of the high-salt diet, a 24-hour urine specimen is collected to measure sodium, potassium, and aldosterone concentrations. The test result is positive if the aldosterone level is greater than 14 μg with a concomitant sodium content above 200 mEq. Because sodium loading can cause kaliuresis and exacerbate hypokalemia, potassium chloride supplementation is required.
2. Intravenous saline loading. Plasma aldosterone concentration is measured after the infusion of 2 liters 0.9% NaCl during 4 hours. PAL is ruled out if the plasma aldosterone level is less than 5 ng/dL and is confirmed if the level exceeds 10 ng/dL. Although a plasma aldosterone level in the range of 5 to 10 ng/dL after sodium loading is considered equivocal by some investigators, many consider a level above 5 ng/dL diagnostic of PAL (Mulatero et al, 2005).

   Although this maneuver is useful for identifying patients with PAL, it does not adequately discriminate patients with an APA from those with nonadenomatous adrenal hyperplasia. By contrast, measurement of morning levels of plasma cortisol, aldosterone, and 18-hydroxycorticosterone after intravenous saline loading (1.25 to 2.0 liters during 90 to 120 minutes) reportedly can distinguish these diagnostic subsets. In APA, the ratio of aldosterone to cortisol is greater than 2.2, or the ratio of 18-hydroxycorticosterone to cortisol is greater than 3; whereas for patients with idiopathic hyperaldosteronism, the ratios are lower (Arteaga et al, 1985). With a normal sodium intake, a supine morning 18-hydroxycorticosterone plasma level above 50 ng/dL is characteristic of PAL, and a level of 100 ng/dL or more is diagnostic of aldosteronoma (Biglieri and Schambelan, 1979; Bravo et al, 1983).
3. Fludrocortisone suppression test. Plasma aldosterone and cortisol levels are measured in an upright position at 10 AM after 4 days of administration of fludrocortisone (0.1 mg every 6 hours) and sodium chloride supplementation (30 mEq thrice daily) with a corresponding 24-hour urine sodium excretion rate of 3 mEq/kg/day. This test is diagnostic of PAL if, on day 4, the plasma aldosterone level exceeds 5 ng/dL, provided the concurrent PRA is less than 1 ng/mL/hr, the serum potassium level is normal, and the plasma cortisol level at 10 AM is no higher than at 7 AM (Stowasser et al, 2003; Mulatero et al, 2005).

Cortisol Metabolites

C-18–methyloxygenated metabolites of cortisol, 18-hydroxycortisol and 18-oxocortisol, are increased in PAL when it is caused by adenoma but not by nonadenomatous adrenal hyperplasia (Ulick and Chan, 1989; Ulick et al, 1992). This steroid pattern appears to reflect the loss of normal functional zonation of the adrenal gland (see previously). In the Cornell study, two of the adenoma patients with hybrid steroid levels in hyperplasia range also had a negative postural stimulation test response, and their blood pressures were improved but not cured by surgery (Blumenfeld et al, 1994). These findings are in accord with a previous report that patients with adenomas who increase aldosterone production during upright posture or infusion of exogenous angiotensin II have low levels of these hybrid cortisol metabolites (Gordon et al, 1987).

Lateralizing Tests

Adrenal Vein Sampling

The diagnostic tests provide the biochemical evidence necessary to confirm the diagnosis of PAL. Although the results of these tests may identify surgically remediable variants (e.g., lack of postural stimulation of aldosterone in patients with an APA), they do not locate the tumor and thus fail to guide surgical treatment. Adrenal CT and MRI lack sufficient sensitivity and specificity to identify adrenal tumors less than 1.5 cm in diameter and thus cannot reliably distinguish APA from bilateral adrenal hyperplasia (Espiner et al, 2003; Young et al, 2004). **Thus, scans can appear normal when a small APA is not identified because of limited spatial resolution or when an APA is not detected because of the concomitant benign unilateral or bilateral adrenal nodularity that occurs normally with aging.**

The ability to measure plasma aldosterone concentration from selectively catheterized adrenal veins has added an important dimension to the localization of APA (Melby, 1984; Blumenfeld et al, 1994; Phillips et al, 2000; Rossi et al, 2001; Espiner et al, 2003; Young et al, 2004). Adrenal veins are catheterized by the percutaneous femoral approach, and

blood is obtained from both adrenal veins and from the inferior vena cava below the level of the renal veins. Aldosterone and cortisol levels are measured from both adrenal veins and from the inferior vena cava. **To minimize stress-induced fluctuations in cortisol and aldosterone, continuous infusion of cosyntropin (50 μg/hr) is recommended, beginning 30 minutes before the catheterization and continuing throughout the procedure.** Adrenal vein catheterization is considered to be technically successful if the cortisol level measured from the adrenal vein is significantly higher than that obtained from the inferior vena cava. **The specific adrenal–inferior vena cava ratio cutoff value of 2 or greater for the cortisol concentration identifies a successful adrenal vein cannulation.** Studies have reported ratios ranging from 1.1 to 5 (Phillips et al, 2000; Rossi et al, 2001; Espiner et al, 2003; Young et al, 2004).

Studies have evaluated several criteria for lateralization of aldosterone secretion by adrenal vein sampling in which these levels are normalized for the corresponding adrenal venous cortisol concentrations (Espiner et al, 2003):

1. *Lateralized ratio:* the aldosterone-to-cortisol ratio of the dominant adrenal vein divided by the aldosterone-to-cortisol ratio of the nondominant adrenal vein. **The patient with a lateralized ratio exceeding 5, together with a peripheral venous aldosterone level above 15 ng/dL, reportedly has about 180 times the odds of having an APA compared with the patient having a peripheral venous aldosterone level below 15 ng/dL and a lateralized ratio below 5** (Phillips et al, 2000). Others have reported a lateralized ratio above 4 to have a positive predictive index of 89% (Espiner et al, 2003) and a sensitivity of 96% for the diagnosis of APA (Young et al, 2004). In a large series in which cosyntropin stimulation was not employed during adrenal vein sampling and a low adrenal–inferior vena cava cortisol ratio was used to confirm successful adrenal vein catheterization, a lateralized ratio above 2 reportedly had a sensitivity of 80% for identification of APA (Rossi et al, 2001).
2. *Contralateral ratio:* the aldosterone-to-cortisol ratio of the nondominant adrenal vein divided by the aldosterone-to-cortisol ratio in the matching antecubital vein or inferior vena cava. When this value is less than 1, it indicates suppression of aldosterone secretion by the uninvolved adrenal gland and has been reported to have a high positive predictive value in patients with APA. It has been proposed that a contralateral ratio below 1 is diagnostic of APA and is thus an important consideration when the vein from the affected adrenal gland (i.e., with the adenoma) is not successfully sampled. However, there is considerable disagreement about the importance of this value in separating the diagnosis of APA from bilateral adrenal hyperplasia (Doppman et al, 1992; Espiner et al, 2003; Young et al, 2004).
3. *Ipsilateral ratio:* the aldosterone-to-cortisol ratio in the dominant adrenal vein divided by the aldosterone-to-cortisol ratio in the matching antecubital vein or inferior vena cava. This value does not aid in distinguishing APA from bilateral adrenal hyperplasia (Espiner et al, 2003).

Technical problems that are encountered during adrenal vein sampling include difficulty in catheterization of the short right adrenal vein; trauma, including adrenal hemorrhage that can result in acute adrenal insufficiency; dilution of blood by blood from nonadrenal sources; and episodic changes in aldosterone secretion coincident with changes in cortisol (Weinberger et al, 1979). Most of these problems can be controlled by careful catheter localization, simultaneous plasma cortisol measurements to document appropriate catheter placement, and collection of blood during ACTH administration.

Radionuclide Scintigraphy

[^{131}I]6β-Iodomethyl-19-norcholesterol (NP-59) scintigraphy has the potential to correlate anatomy and function of APA. However, this test is limited by poor tracer uptake by tumors less than 1.5 cm in diameter and by the exposure to and disposal of a radioactive isotope (Young et al, 2004). This test is not routinely used at most centers for the diagnostic evaluation of primary aldosteronism.

The sensitivity and specificity of adrenal imaging techniques may differ substantially among medical centers, depending on the local resources and expertise. Incidental, nonfunctioning adrenal masses are relatively common; they are found in 0.6% of all CT scans of the abdomen, and 2% to 9% of adults have grossly visible adenomas at autopsy. Conversely, a subset of patients with surgically curable PAL have radiographically normal adrenal glands (Radin et al, 1992; Blumenfeld et al, 1994; Young et al, 2004). **Therefore, to minimize confusion during diagnostic evaluation, radiographic imaging procedures should be withheld until after biochemical confirmation of PAL has been accomplished** (Radin et al, 1992).

Diagnostic Strategy

The results of diagnostic screening of patients with this syndrome are often ambiguous, especially when the serum potassium level is in the normal range. Relatively simple tests that can improve the diagnostic accuracy include the following:

1. 24-hour urinary aldosterone excretion rate above 14 μg or higher and PRA less than 1.0 ng/mL/hr, after sodium loading for at least 3 days (urine sodium content > 250 mEq/day) (Bravo et al, 1983);
2. ratio of plasma aldosterone to renin activity above 50, although a lower ratio is used by others with a concurrent serum aldosterone concentration above 15 ng/dL (Blumenfeld et al, 1994; Stowasser et al, 2003; Young et al, 2004; Mulatero et al, 2005);
3. failure to increase PRA after sodium restriction, furosemide-induced diuresis (Weinberger et al, 1979) and;
4. supine plasma 18-hydroxycorticosterone levels above 50 ng/dL or ratio of plasma 18-hydroxycorticosterone to cortisol greater than 3 after saline infusion (Biglieri and Schambelan, 1979; Bravo et al, 1983; Arteaga et al, 1985).

Measurements of aldosterone should be performed only after potassium supplementation because aldosterone secretion is attenuated by the potassium deficit and thus may obfuscate the diagnosis. The presence of hypokalemia and renal potassium wasting (24-hour urine potassium concentration above 40 mEq), together with the characteristics described before, confirms the diagnosis of primary aldosteronism.

The sensitivity and specificity of each of these diagnostic maneuvers can be adversely influenced by concurrent use of antihypertensive medications. For example, β-adrenoceptor antagonists markedly decrease PRA in essential hypertension and may alter the interpretation of these tests (Buhler et al, 1972; Blumenfeld et al, 1999). Hypokalemia, when it is caused by thiazide diuretics, may be difficult to distinguish from PAL, although the PRA is often elevated during diuretic use in patients with essential hypertension (Laragh and Sealey, 1992). Angiotensin-converting enzyme inhibitors and calcium channel antagonists reportedly reduce aldosterone biosynthesis and improve hypokalemia in some patients with PAL (Melby, 1984; Nadler et al, 1985) (see later). Therefore, antihypertensive medications should be discontinued for at least 2 weeks before diagnostic evaluation and potassium supplements provided to hypokalemic patients. Spironolactone should be discontinued for at least 1 month before these biochemical assessments because it has a long duration of action.

Figure 53–37 is a diagnostic algorithm that can be useful for directing treatment when biochemical screening tests are indicative of PAL. Hypertensive patients with a low PRA (<0.65 ng/mL/hr) warrant measurement of plasma aldosterone level, particularly if their blood pressure is difficult to control. Those patients with an ARR above 25 to 50 should

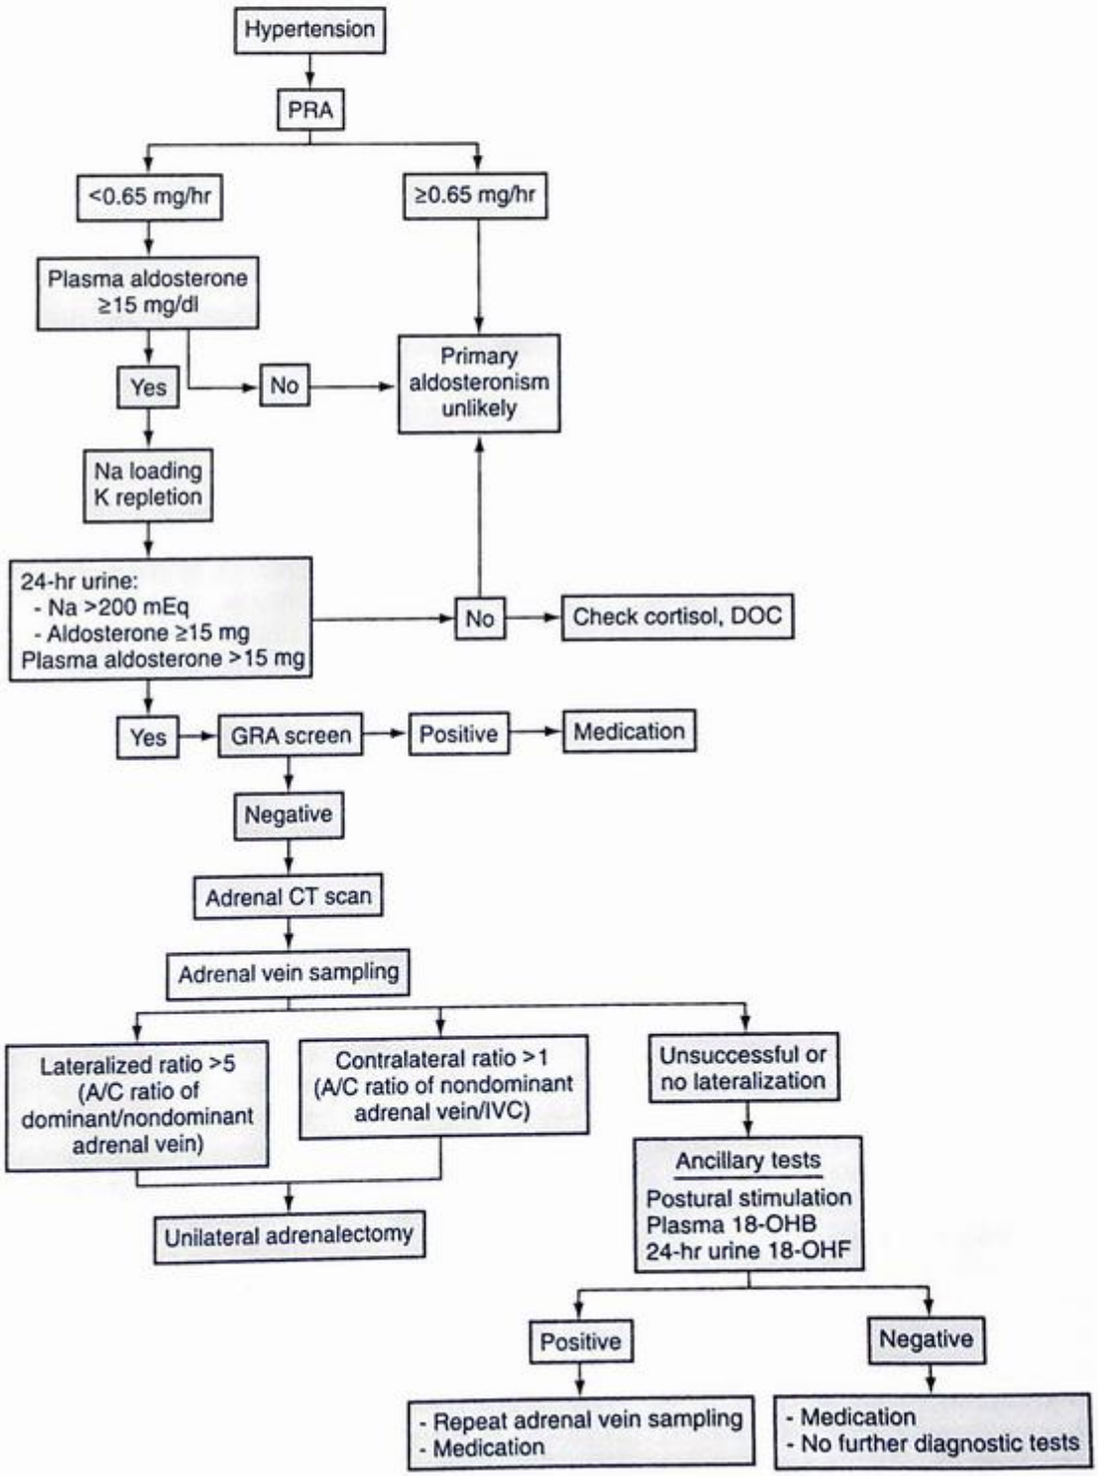

Figure 53–37. Algorithm for the diagnosis and treatment of primary aldosteronism. PRA, plasma renin activity; DOC, deoxycorticosterone; GRA, glucocorticoid-remediable aldosteronism; A/C, ratio of the concentration of plasma aldosteronism to cortisol; IVC, inferior vena cava; 18-OHB, 18-hydroxycorticosterone; 18-OHF, 18-hydroxycortisol.

undergo either an oral or intravenous sodium loading protocol followed by a repeated measurement of either plasma or 24-hour urine aldosterone level. Failure to suppress aldosterone by sodium loading is diagnostic of primary aldosteronism. To exclude GRA, screening for the chimeric gene is indicated, particularly if there is a personal history or family history of early-onset hypertension, stroke, or aortic dissection; if results are negative, adrenal vein sampling is warranted. Adrenal imaging, preferably by CT scan, does not reliably exclude or confirm the diagnosis of APA, but it is reasonable at this point because it can assist the interventional radiologist in identifying anatomic landmarks. A positive lateralized ratio or, perhaps less reliably, a positive contralateral ratio is suggestive of a surgically remediable lesion regardless of the radiographic appearance of the adrenal gland. In those patients with nondiagnostic or unsuccessful adrenal vein sampling results, a positive postural stimulation test result and elevated levels of serum 18-hydroxycorticosterone and 24-hour urine 18-hydroxycortisol are strongly suggestive of a surgically remediable diagnostic subtype. In that case, we often treat the patient medically with a mineralocorticoid receptor antagonist (e.g., spironolactone, eplerenone) for 6 to 12 months and then repeat adrenal vein sampling after withdrawal of this medication for 4 to 6 weeks. **Adrenalectomy should be preceded by several weeks of adequate control of hypertension and correction of hypokalemia and other metabolic abnormalities** (see later).

If the patient fails to lateralize aldosterone secretion during adrenal vein sampling, the postural stimulation test result is negative, and levels of 18-hydroxycorticosterone and 18-hydroxycortisol are normal, adrenalectomy is not indicated and the patient should be treated with a mineralocorticoid receptor antagonist. When a discrete adrenal tumor appears to be present in this situation, unilateral adrenalectomy may be considered, particularly in relatively young (<40 years) patients (Young et al, 2004). However, the risk of persistent hypertension in this situation is not well established but is probably relatively high.

Treatment

Idiopathic Hyperaldosteronism (Bilateral Adrenal Hyperplasia)

The cornerstone of medical therapy in PAL caused by idiopathic hyperaldosteronism is a mineralocorticoid receptor antagonist (i.e., spironolactone, eplerenone). The efficacy of this drug class relates to the reduction in plasma volume in disorders associated with aldosterone excess. Although a favorable blood pressure response to spironolactone has been associated with improved chances of surgical cure, it does not reliably predict outcome (Celen et al, 1996). Side effects of spironolactone include painful gynecomastia, erectile dysfunction, decreased libido, and menstrual irregularities that are caused by nonspecific binding to cellular receptors for progesterone and dihydrotestosterone. In a study of 182 patients with essential hypertension treated with spironolactone, daily doses of 75 to 100 mg/day lowered blood pressure as effectively as 150 to 300 mg/day. Overall, gynecomastia developed in 13% of patients, and its occurrence was dose related—6.9% of patients taking 50 mg/day were symptomatic compared with 52% of those taking a dose of 150 mg/day or more (de Gasparo et al, 1989).

Eplerenone is a steroid-based competitive and highly selective mineralocorticoid receptor antagonist that was recently approved for use in patients with essential hypertension. This drug has 0.1% of the binding affinity to androgen receptors and less than 1% of the binding affinity to progesterone receptors compared with spironolactone (Young, 2003). Although eplerenone is reported to be effective, with a side effect profile similar to that of placebo in patients with essential hypertension (Young, 2003), there are no reported studies comparing it with spironolactone in patients with primary aldosteronism.

Amiloride can also effectively lower blood pressure and correct hypokalemia in patients with gynecomastia or other side effects associated with spironolactone (Griffing et al, 1982). The dihydropyridine calcium channel antagonists can acutely decrease blood pressure and aldosterone secretion in patients with this syndrome (Melby, 1984; Nadler et al, 1985). Other studies of longer duration, however, have failed to demonstrate these beneficial effects when nifedipine was used as monotherapy (Bravo et al, 1985; Bursztyn et al, 1988). Angiotensin-converting enzyme inhibitors have been reported to successfully treat some patients with hyperplasia in whom aldosterone production is not completely autonomous from angiotensin II stimulation (Melby, 1984). Phentolamine does not acutely reduce blood pressure; therefore, a role for α-adrenergic receptor blockade has not been established (Bravo et al, 1985). Nevertheless, long-term treatment with prazosin is effective in low-renin essential hypertension, suggesting that α-adrenergic receptor antagonists may have an ancillary role in the treatment of PAL (Bolli et al, 1980).

Subsets of patients with PAL who demonstrate autonomous aldosterone production should be managed with excision of the adrenal gland containing the adenoma or, in the case of nonadenomatous adrenal hyperplasia, the gland from which aldosterone secretion is predominant. This rationale is based on the observation that both the metabolic abnormalities and the hypertension are alleviated by unilateral adrenalectomy in most of these patients (Fontes et al, 1991). By contrast, patients with idiopathic hyperaldosteronism usually do not have significant improvement in hypertension after unilateral or bilateral adrenalectomy.

Aldosterone-Producing Adenoma

Laparoscopic unilateral adrenalectomy is now the standard of care for patients with an APA. Although more than 90% of patients will have their blood pressure controlled postoperatively, antihypertensive medication is required in 40% to 70% (Blumenfeld et al, 1994; Young, 2003). Factors that have been associated with persistent hypertension after unilateral adrenalectomy include age older than 50 years, duration of hypertension, increased serum creatinine concentration, one first-degree relative with hypertension, and preoperative use of more than two antihypertensive medications (Blumenfeld et al, 1994; Young, 2003). In the Cornell study, preoperative renin system activity was also an important predictor of blood pressure outcome (Blumenfeld et al, 1994). Cured patients had significantly lower pretreatment PRA (0.17 versus 0.50 ng/mL/hr) than did those who were not cured. Further-

more, in cured patients, there was also a correlation between the preoperative urinary aldosterone excretion and the relative decrease in diastolic blood pressure after adrenalectomy ($r = 0.59$). All patients in whom lateralization of aldosterone secretion occurred had hypertension cured or improved by adrenalectomy.

Summary

Establishing the diagnosis of PAL is important because hypertension and metabolic disturbances are potentially curable by unilateral adrenalectomy. Furthermore, hypertension associated with PAL is often severe and can be difficult to control solely with antihypertensive medication. The diagnosis may be obscured, however, because the complete clinical and biochemical expression of mineralocorticoid hypertension may not be present, particularly in those with adrenal hyperplasia who present with a serum potassium level in the normal range. Support for the diagnosis is provided by low PRA, elevated 24-hour urinary aldosterone level and ratio of plasma aldosterone to renin activity, positive postural stimulation test result, and elevated urinary excretion of hybrid steroids (i.e., 18-hydroxycortisol). Adrenal vein sampling has a central role in the diagnostic evaluation of PAL because lateralization of aldosterone secretion indicates the presence of a curable lesion regardless of the radiographic findings.

PHEOCHROMOCYTOMA

Pheochromocytoma is an uncommon entity but one that has fascinated both clinicians and investigators, who have worked together to derive effective means for detection, localization, and management (Bravo and Tagle, 2003; Manger and Gifford, 2002; Lenders et al, 2005). **Although it is the causative factor of hypertension in about 0.1% to 0.6% of the hypertensive population, or 1 or 2 per 100,000 adults per year, detection is mandatory, not only for the potential cure of the hypertension but also to avoid the potentially lethal effects of the unrecognized tumor.**

Clinical manifestations of pheochromocytoma are all due to the physiologic effects of the amines produced by the lesion. Epinephrine and norepinephrine are similar in their metabolic action, although epinephrine is more potent. The symptom complex manifested by the patient depends somewhat on the secretory products, both type and amount, including the more unusual products dopa and dopamine as well as a variety of peptides produced from amine precursor uptake and decarboxylation (APUD)–type cells (Pearse and Polak, 1971; Bolande, 1974). The peptides are ACTH, somatostatin, serotonin, enkephalins, calcitonin, vasoactive intestinal peptide, neuropeptide, lipotropin, β-endorphin, and dynorphin (Robertson et al, 1990). Small tumors generally bind catecholamine poorly. Thus, the severity of symptoms, despite the small size of these tumors, results from direct release of most catecholamines directly into the circulation. Large lesions have high catecholamine content but bind them well and metabolize substantial quantities directly within the tumors. Thus, only relatively small amounts of the vasoactive amines mixed with large amounts of inactive metabolites are secreted.

Signs and Symptoms

Signs and symptoms of patients with pheochromocytoma, all secondary to secretion of the neurohormonal agents epinephrine and norepinephrine, may be extraordinarily variable. In all reported series, hypertension is by far the most consistent sign (Tables 53–15 and 53–16). Of 106 patients described by Van Heerden and colleagues (1982), 84% were hypertensive. As a sign itself, hypertension may have a variety of manifestations. The three common patterns are as follows:

1. Sustained hypertension. Thirty-seven percent of Van Heerden and colleagues' patients manifested sustained hypertension with little fluctuation, much as in patients with essential hypertension. This form is most common in children and in patients with multiple endocrine adenoma (MEA) type II.
2. Paroxysmal hypertension. "Dramatic attacks" of hypertension, usually associated with other signs and symptoms, punctuated the patient's usual asymptomatic, normotensive status. This pattern more readily provokes the suspicion of and workup for the possibility of an underlying pheochromocytoma and was reported to affect 47% of patients. Females are more likely than males to manifest paroxysmal hypertension.
3. Sustained hypertension with superimposed paroxysms. The phenomenon is self-explanatory. Manger and Gifford (1990) reported a 50% incidence of this manifestation. Scott and coworkers (1976, 1990) reported a 66% incidence.

The frequency of attacks among patients is variable, ranging from a few times per year to multiple daily episodes. Their duration may be minutes to hours, usually with rapid onset and slower subsidence. One or more episodes per week occur in 75% of patients. Daily attacks, or more than one attack each day, occur in nearly all other patients. Among patients with pheochromocytoma, half experience symptoms for a duration of less than 15 minutes. In 80% of patients, attacks last less than an hour. With the passage of time after the initial appearance of symptoms, frequency of attacks tends to increase, although severity may or may not change.

Attacks may occur in the absence of recognizable stimuli. A multitude of associated factors, however, have been reported: compression of the tumor elicited by massage; physical exercise, particularly a certain posture or lying in a certain position; and direct trauma. Similar precursors of attacks are wearing tight clothing, straining to defecate or to void, micturition itself, bladder distention, sexual intercourse, laughing, sneezing, coughing, retching, Valsalva's maneuver, and hyperventilation, which cause increased intra-abdominal pressure. Foods that are rich in tyramine (beer, wine, and aged cheese) may elicit attacks. Potentially provocative drugs are tyramine, histamine, epinephrine and norepinephrine, nicotine, glucagon, tetraethylammonium, methacholine, succinylcholine, phenothiazine, ACTH, and β blockers such as propranolol.

Additional signs and symptoms are numerous but not specific. Among these are headaches, sweating, pallor or flushing, palpitations, tachycardia, abdominal or chest pain, and postural hypotension. Also common are weakness, nausea, emesis, and anorexia. Profound psychological changes are frequently observed. The occasional patient in whom the

Table 53–15. Symptoms Reported by 76 Patients (Almost All Adults) with Pheochromocytoma Associated with Paroxysmal or Persistent Hypertension

Symptoms	Percentage Paroxysmal (37 patients)	Percentage Persistent (39 patients)
Symptoms Presumably Due to Excessive Catecholamines or Hypertension		
Headache (severe)	92	72
Excessive sweating (generalized)	65	69
Palpitations ± tachycardia	73	51
Anxiety or nervousness (± fear of impending death, panic)	60	28
Tremulousness	51	26
Pain in chest, abdomen (usually epigastric), lumbar regions, lower abdomen, or groin	48	28
Nausea ± vomiting	43	26
Weakness, fatigue, prostration	38	15
Weight loss (severe)	14	15
Dyspnea	11	18
Warmth ± heat intolerance	13	15
Visual disturbances	3	21
Dizziness or faintness	11	3
Constipation	0	13
Paresthesia or pain in arms	11	0
Bradycardia (noted by patient)	8	3
Grand mal	5	3
Manifestations Due to Complications		
Congestive heart failure ± cardiomyopathy		
Myocardial infarction		
Cerebrovascular accident		
Ischemic enterocolitis ± megacolon		
Azotemia		
Dissecting aneurysm		
Encephalopathy		
Shock		
Hemorrhagic necrosis in a pheochromocytoma		
Manifestations Due to Coexisting Diseases or Syndromes		
Cholelithiasis		
Medullary thyroid carcinoma ± effects of secretions of serotonin, calcitonin, prostaglandin, or ACTH-like substance		
Hyperparathyroidism		
Mucocutaneous neuromas with characteristic facies		
Thickened corneal nerves (seen only with slit lamp)		
Marfanoid habitus		
Alimentary tract ganglioneuromatosis		
Neurofibromatosis and its complications		
Cushing's syndrome (rare)		
von Hippel–Lindau disease (rare)		
Virilism, Addison's disease, acromegaly (extremely rare)		
Symptoms caused by encroachment on adjacent structures or by invasion and pressure effects of metastases		

From Manger WM, Gifford RW Jr: Pheochromocytoma. In Laragh JH, Brenner BM, eds: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.

Table 53–16. Signs Observed in Patients with Pheochromocytoma

Blood pressure changes
± Hypertension ± wide fluctuations (rarely, paroxysmal hypotension or hypertension alternating with hypotension)
Hypertension induced by physical maneuver such as exercise, postural change, or palpation and massage of flank or mass elsewhere
Orthostatic hypotension ± postural tachycardia
Paradoxical blood pressure response to certain antihypertensive drugs; marked pressor response with induction of anesthesia
Other signs of catecholamine excess
Hyperhidrosis
Tachycardia or reflex bradycardia, forceful heartbeat, arrhythmia
Pallor of face and upper part of body (rarely flushing; mottled cyanosis)
Anxious, frightened, troubled appearance
Hypertensive retinopathy
Dilated pupils (rarely exophthalmos, lacrimation, scleral pallor, or injection; pupils may not react to light)
Leanness or underweight
Tremor (± shaking)
Raynaud's phenomenon or livedo reticularis (occasionally puffy, red, cyanotic hands in children); skin of extremities wet, cold, clammy, or pale; gooseflesh; occasionally cyanotic nail beds
Fever
Mass lesion (rarely palpable)
Tumor in abdomen or neck (pheochromocytoma, chemodectoma, thyroid carcinoma, or thyroid swelling that is rare and only during hypertensive paroxysm)
Signs caused by encroachment on adjacent structures or by invasion and pressure effects of metastases
Manifestations related to complications or to coexisting diseases or syndromes

From Manger WM, Gifford RW Jr: Pheochromocytoma. In Laragh JH, Brenner BM, eds: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.

diagnosis has not been recognized has sometimes been referred for psychiatric evaluation of what were thought to have been functional symptoms.

Some patients are symptomatic for years before diagnosis. Others may present with convulsions, cerebrovascular accidents, and coma. Others have died of massive intracranial bleeding. The appearance of sudden, severe hypertension during the induction of anesthesia or during the course of a surgical procedure may herald underlying pheochromocytoma.

Patients may have pheochromocytomas without manifesting hypertension. **About 10% of pheochromocytomas are found in normotensive patients** (Scott et al, 1976). About 5% of all incidentalomas are pheochromocytomas, and about 25% of all pheochromocytomas are found incidentally (Lenders et al, 2005). On occasion, during a severe paroxysmal attack, blood pressure may be unobtainable. Herein, the patient is not hypotensive. Marked peripheral vasoconstriction occurs; therefore, one cannot measure the blood pressure with a sphygmomanometer. Hypertension may also be modest in nature, less serious than other signs and symptoms. Flushing, pallor, and signs of hypermetabolism closely mimic the classic appearance of thyrotoxicosis, leading to surgery of the thyroid gland before recognition of the underlying cause of the disease process.

Many reports exist of pheochromocytoma diagnosed during pregnancy (Schenker and Chowers, 1971; Fudge et al,

1980). Symptoms commonly mimic those of eclampsia, preeclampsia, and toxemia. Headache, visual disturbances, palpitations, diaphoresis, and hypertension (paroxysmal or sustained) are common. According to Fudge and associates (1980), the diagnosis of pheochromocytoma in association with pregnancy has been made before delivery in only one third of patients. All too often, it is only with the stress of labor and delivery, although more commonly during the postpartum period, that resultant fulminant hypertension or shock leads to the diagnosis of an underlying pheochromocytoma (Hume, 1960). Maternal and infant mortality rates exceed 40%. Despite a history of prior successful pregnancy, in the presence of hypertension, the diagnosis of pheochromocytoma should be considered in the pregnant patient with labile or postural hypertension, congestive heart failure, or arrhythmias. Appropriate diagnostic studies must be carried out.

Pheochromocytoma may be the underlying causative agent in patients afflicted by other disease states with conditions that may result from excess catecholamine secretion. Common manifestations are cerebrovascular accident, encephalopathy, retinopathy, congestive heart failure, cardiomyopathy, dissecting aneurysm, acute respiratory distress syndrome, shock, renal failure, azotemia, ischemic enterocolitis, and megacolon. Conversely, numerous entities mimic some of the symptoms and signs of pheochromocytoma (Table 53–17).

One specific entity that has gained more recognition is catecholamine-induced cardiomyopathy (Imperato-McGinley et al, 1987; Vaughan, 1991; Quigg and Om, 1994). Experimentally injected catecholamines can cause foci of myocardial necrosis, with inflammation and fibrosis (Van Vliet et al, 1966; Rosenbaum et al, 1988). These patients may have a reduction in blood pressure because of a global reduction in myocardial pump functions, considered to be due to both a downregulation of β receptors and a decrease in viable myofibrils (Sardesai et al, 1990). Fortunately, the lesion is usually reversible with the combination of α blockade and α-methylparatyrosine (Imperato-McGinley et al, 1987). All patients with pheochromocytoma should have a complete cardiac evaluation with echocardiography and radionuclide scans before corrective surgery.

An appreciable number of pheochromocytomas have been found in association with several disease entities and hereditary syndromes (see Table 53–17). Among these unusual conditions are the association of tumors of the glomus jugulare region with either pheochromocytoma or ectopic paragangliomas (Hamberger et al, 1967; Sato et al, 1974; Blumenfeld et al, 1993; Mena et al, 1993). It is now recognized that both the tumor in the glomus jugulare region and the other adrenal or nonadrenal chromaffin tumors can secrete catecholamines. It is also apparent that these patients can have multiple lesions (Fig. 53–38). Accordingly, the patients have to have sequential procedures with appropriate blockade and determination of catecholamine secretion after each procedure to determine residual activity. Tank and colleagues (1982) estimated that 95% of pheochromocytomas are sporadic in occurrence but that the remaining 5% have a familial pattern; 10% is often reported. Calkins and Howard (1947) published the first report of familial pheochromocytoma. Familial transmission is believed to be through autosomal dominance, with a locus on chromosome 10 (Simpson et al, 1987) found in the subset designated multiple endocrine neoplasia (MEN) type II.

Table 53–17. Differential Diagnosis*

All hypertensives (sustained and paroxysmal)
Anxiety, tension states, psychoneurosis, psychosis
Hyperthyroidism
Paroxysmal tachycardia
Hyperdynamic β-adrenergic circulatory state
Menopause
Vasodilating headache (migraine and cluster headaches)
Coronary insufficiency syndrome
Acute hypertensive encephalopathy
Diabetes mellitus
Renal parenchymal or renal arterial disease with hypertension
Local arterial insufficiency of the brain
Intracranial lesions (with or without increased intracranial pressure)
Autonomic hyperreflexia
Diencephalic seizures and syndrome
Toxemia of pregnancy (or eclampsia with convulsions)
Hypertensive crises associated with monoamine oxidase inhibitors
Carcinoid
Hypoglycemia
Mastocytosis
Familial dysautonomia
Acrodynia
Neuroblastoma; ganglioneuroblastoma; ganglioneuroma
Neurofibromatosis (with or without renal arterial disease)
Adrenocortical carcinoma
Acute infectious disease
Rare causes of paroxysmal hypertension (*adrenal medullary hyperplasia, acute porphyria, lead poisoning,* tabetic crisis, encephalitis, *clonidine withdrawal,* hypovolemia with inappropriate vasoconstriction, pulmonary artery fibrosarcoma, portal hypersensitivity, dysregulation of hypothalamus, *tetanus, Guillain-Barré syndrome, factitious*)
Fortuitous circumstances simulating pheochromocytoma
Conditions sometimes associated with pheochromocytoma
Coexisting disease or syndromes
Cholelithiasis
Medullary thyroid carcinoma
Hyperparathyroidism
Mucosal neuromas
Thickened corneal nerves
Marfanoid habitus
Alimentary tract ganglioneuromatosis
Neurofibromatosis
Cushing's syndrome
von Hippel–Lindau disease
Polycythemia
Virilism, Addison's disease, acromegaly
Complications
Cardiovascular disease†
Cerebrovascular disease
Renovascular disease
Circulatory shock
Renal insufficiency
Hemorrhagic necrosis of pheochromocytoma†
Dissecting aneurysm†
Ischemic enterocolitis with or without intestinal obstruction†

*Conditions in italics may have increased excretion of catecholamines or metabolites (or both).
†Patient may present as having abdominal or cardiovascular catastrophe.
From Manger WM, Gifford RW Jr: Pheochromocytoma. In Laragh JH, Brenner BM, eds: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.

Familial pheochromocytomas may be divided into different types of genetic abnormalities. In 1961, Sipple described the combination of pheochromocytoma and medullary carcinoma of the thyroid (MCT) that came to be known as Sipple's syndrome. In subsequent years, as more cases came to light,

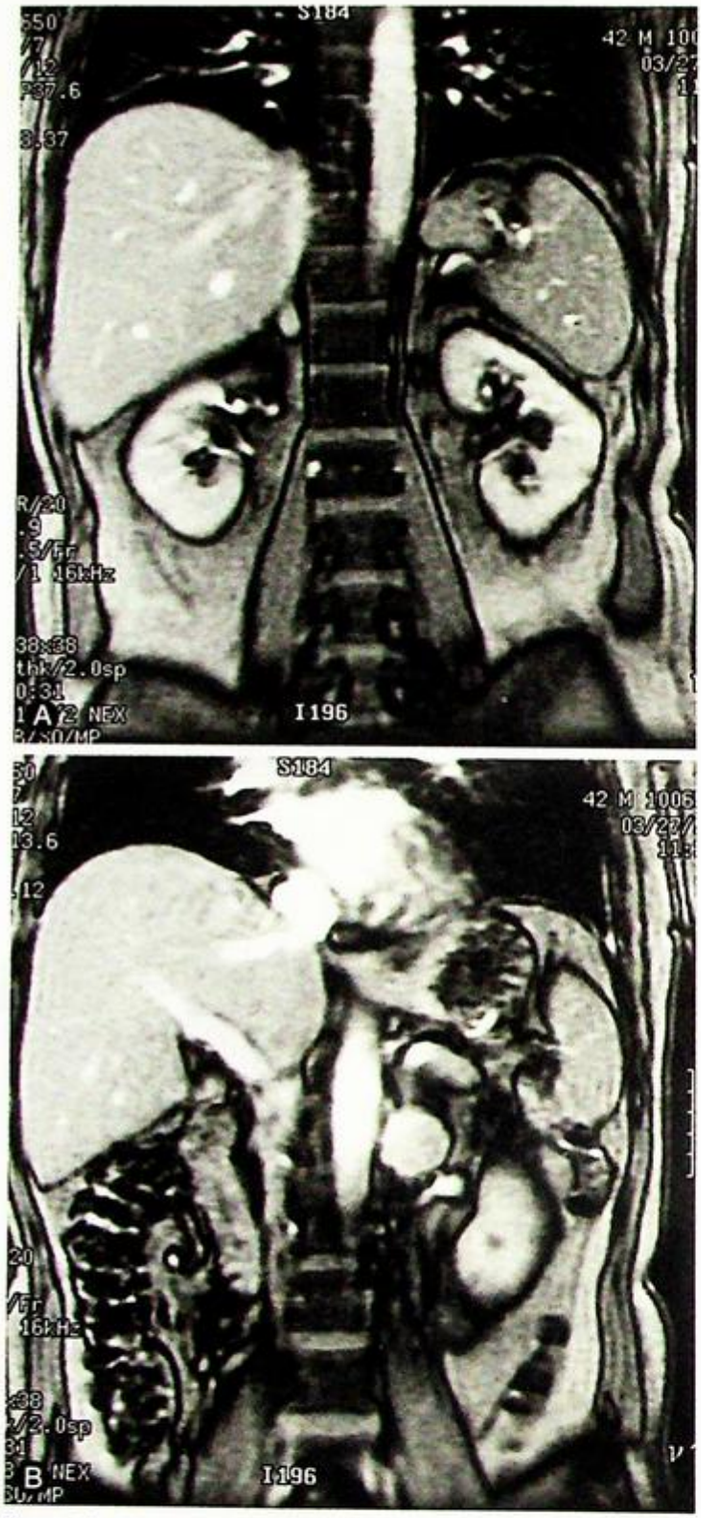

Figure 53–38. MRI scan showing bilateral adrenal pheochromocytomas in a patient with bilateral glomus jugulare tumors. The patient was treated with left adrenalectomy and enucleation of the smaller right pheochromocytoma. **A,** Small right pheochromocytoma. **B,** Larger left pheochromocytoma.

new terminology—MEA or MEN—has been popularized, as has a subclassification system: MEA I, MEA II, and MEA III or MEA IIB (Raue et al, 1985; Larsson and Nordenskjold, 1990). Pheochromocytomas occur in MEA II, a triad including pheochromocytoma, MCT, and parathyroid adenomas. The last may be a secondary phenomenon. The parafollicular cells of MCT elaborate thyrocalcitonin. The resulting decrease in serum calcium concentration leads to parathyroid stimulation with subsequent hyperplasia or development of adenomas. Pheochromocytoma may also be a part of MEN III, which also includes MCT, mucosal neuromas, thickened corneal nerves, alimentary tract ganglioneuromatosis, and frequently a marfanoid habitus (Manger and Gifford, 2002).

Recognition of MEA II and aggressive evaluation of MEA II kindreds are mandatory. Carney and associates (1976) reported 22% mortality from complications of pheochromocytoma in a review of 149 patients with MEA II. MCT has an expected incidence of 50% in MEA II kindreds. The development of DNA technology to identify carriers of the MEN IIA gene (Lips et al, 1994) and the awareness of patients with pheochromocytomas as a component of MEN IIA or von Hippel–Lindau disease have resulted in the recommendation that all patients with pheochromocytoma be screened for these syndromes, as well as family members of patients with these diseases (Lips et al, 1994; Neumann et al, 1995).

Families with von Hippel–Lindau disease and pheochromocytoma are classified as von Hippel–Lindau disease type 2 (Walther et al, 1999). Some of these patients have renal cell carcinoma (type 2A); others do not (type 2B). von Hippel–Lindau disease type 2 is most frequently associated with a missense mutation of the *VHL* gene (Chen et al, 1995). Patients with this entity can be identified at a younger age when the tumors are smaller (Pomares et al, 1998; Walther et al, 1999).

Partial adrenalectomy is indicated because of the high occurrence of bilateral disease (Pavlovich and Walther, 2001; Diner et al, 2005). In addition, in patients with von Hippel–Lindau disease, there may be multiorgan visceral tumors of the adrenal, kidney, and pancreas that can be managed with a single-stage operation (Hwang et al, 2003).

The neuroectodermal dysplasias are a group of related diseases: von Recklinghausen's disease (neurofibromatosis), tuberous sclerosis, Sturge-Weber syndrome, and von Hippel–Lindau disease. All are strongly familial and associated with each other and with pheochromocytoma.

The prevalence of pheochromocytoma in patients with neurofibromatosis is reported as 1% to 2%. Of those patients with pheochromocytoma, 5% have von Recklinghausen's disease. Kalff and associates (1982), having seen 10 patients with pheochromocytoma and neurofibromatosis, reviewed the sample population, selecting patients with both von Recklinghausen's disease and hypertension. They found 17 such patients, 53% of whom had pheochromocytomas.

Pheochromocytoma is distinctly less common than the other neuroectodermal dysplasias (Kalff et al, 1982). The rare association of a somatostatin-rich duodenal carcinoid tumor and pheochromocytoma has also been reported (Wheeler et al, 1986).

The increased incidence of pheochromocytomas in association with neuroectodermal dysplasias and MCT may be explained by the APUD cell system of Pearse. The APUD cells derive from the neural crest of the embryo, sharing common ultrastructural and cytochemical features and elaborating amines by precursor uptake and decarboxylation (Pearse and Polak, 1971; Bolande, 1974). The products of these cells have been previously listed. Immunochemical techniques showing both neuron-specific enolase and chromogranin A in a variety

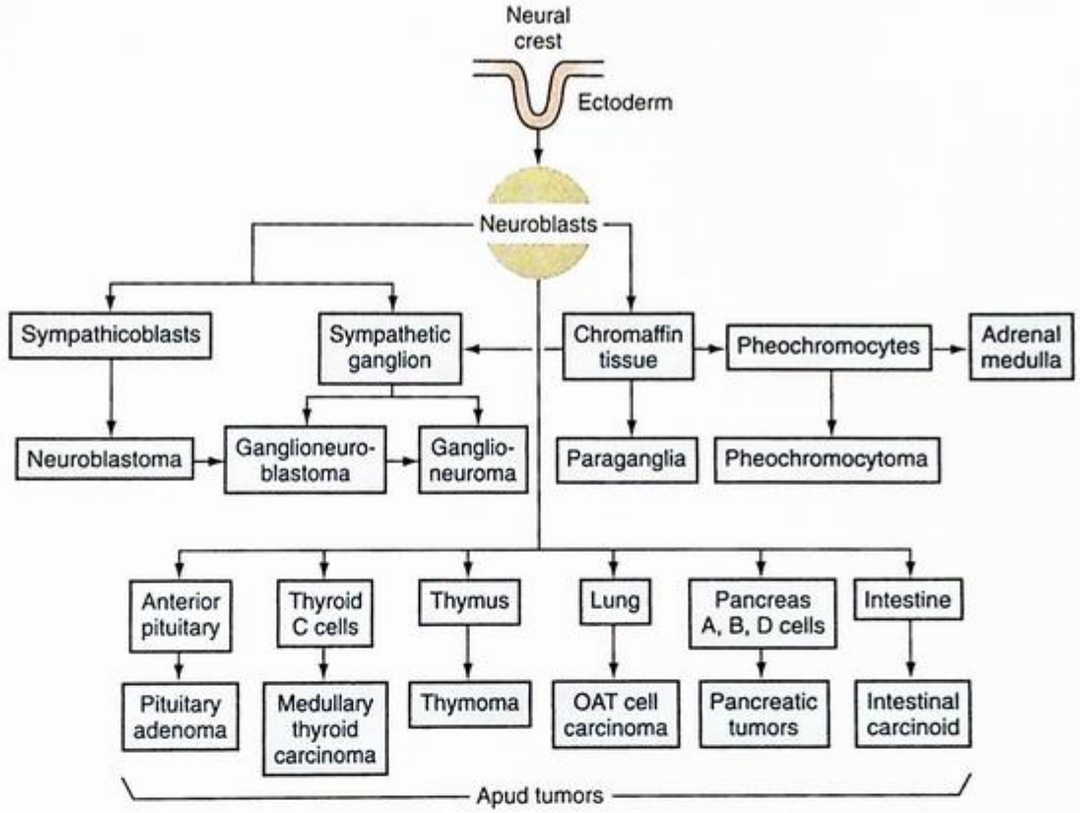

Figure 53–39. Ectodermal origin of amine precursor uptake and decarboxylation tumors. (From Manger WM, Gifford RW Jr: Pheochromocytoma: A clinical review. In Laragh JH, Brenner BM, eds: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.)

of polypeptide hormone–producing tissues support the concept of the APUD system (Fig. 53–39) (Lloyd et al, 1984; O'Connor and Deftos, 1986; Hsiao et al, 1991).Considerable information is now available concerning the chromosomal localization and gene in the hereditary forms of pheochromocytoma (Table 53–18), which are useful in screening of families with these syndromes.

Children

Manifestations of pheochromocytoma in children vary somewhat from those in adults. Headache, nausea or vomiting, weight loss, and visual complaints occur more commonly in children than in adults. Manger and Gifford (1977) reported polydipsia, polyuria, and convulsions—rarely observed in adults—in 25% of children. Puffy, red, and cyanotic appearance of the hands is reported in 11% of children. Of children with pheochromocytomas, 90% have sustained hypertension. Paroxysmal hypertension occurs in less than 10% of children.

In contrast to adults, children manifest a higher incidence of familial pheochromocytomas (10%) and bilaterality (24%). Multiple pheochromocytomas have been reported in children with an incidence of 15% to 32%, and extra-adrenal location of pheochromocytomas has been reported in 15% to 31% of the children (Glenn et al, 1968). Glenn and coworkers (1968) believed that on a histologic basis, there was a higher incidence of malignant pheochromocytomas in children. Stackpole and colleagues' review (1963) found a random distribution of age at diagnosis among boys. In girls, the diagnosis was made in 62% during menarche. Because of the tendency toward multiplicity and thus asynchronous recurrence, close follow-up for recurrent symptoms and hypertension is mandatory in children (Ein et al, 1990).

Table 53–18. Hereditary Forms of Pheochromocytoma

Syndrome	*Gene*	*Chromosome Location*

From Pacak et al, 2001.

MALIGNANT PHEOCHROMOCYTOMA

Approximately 10% to 20% of pheochromocytomas are malignant. In the Cleveland Clinic series, 19% of all cases were malignant, which was more common in tumors larger than 5 cm than in smaller tumors (76% versus 24%) and in extra-adrenal tumors (52% versus 9%) (Bravo and Tagle, 2003). A number of markers including Ki-67, p53, telomerase activity, and expression of angiogenesis factors are being studied to differentiate benign from malignant tumors, but none has achieved clinical usefulness (Novakovic et al, 2004; Lenders et al, 2005). In a separate report in 251 patients with MEN IIA, the prevalence of malignancy was 4.4% (Gagel et al, 1988). Treatment is surgical resection with wide excision and resection of involved adjacent organs; debulking is indicated even when it is not curative to diminish symptoms of catecholamine excess and to facilitate medical management. Chemotherapeutic therapy is limited, although partial responses have been reported in about half the patients treated with a neuroblastoma regimen (Averbuch et al, 1988). An

additional approach that has given a partial response is radioactive metaiodobenzylguanidine (MIBG) for therapy in patients who have abnormal MIBG imaging studies (Rose et al, 2003).

Laboratory Diagnosis

The clinical diagnosis of pheochromocytoma is based on the subjective evaluation of signs and symptoms. Laboratory confirmation of the clinical diagnosis is mandatory and may be divided into two general categories: biochemical diagnosis and radiologic diagnosis (Fig. 53–40).

Confirmation of the diagnosis is obtained by demonstrating elevated levels of catecholamines in the blood or urine, which occur in 95% to 99% of patients with pheochromocytoma. Extremely accurate assays exist (Manger and Gifford, 2002; Bravo and Tagle, 2003; Liu et al, 2003). There are considerable numbers of foods and drugs that can affect urine levels of catecholamines or breakdown products (Table 53–19). Plasma catecholamines are highly responsive to stress, activity, blood loss, and other stimuli.

Because of the severe consequences of the undiagnosed pheochromocytoma, it is recommended that all hypertensive patients be screened. Measurement of urine catecholamines and metanephrines is adequate in most patients.

Rarely, the concentrations of plasma and urine catecholamines and their metabolites are not elevated, especially if the patient is normotensive at the time of study. In this clinical setting, if there is a high index of suspicion, studies with ^{131}I-labeled MIBG scanning (Shapiro et al, 1985), MRI (Newhouse, 1990), or repeated sampling when the patient is hypertensive are indicated. Provocative tests with histamine, glucagon, or phentolamine are rarely used.

In contrast, some patients with essential hypertension and signs or symptoms of pheochromocytoma have slightly elevated plasma catecholamine levels, probably representing a neurogenic component to the hypertension. The clonidine suppression test distinguishes these patients (Bravo et al, 2003). Two to 3 hours after a single 0.3-mg oral dose of clonidine, patients with neurogenic hypertension at rest show a fall in plasma norepinephrine plus epinephrine to a level below 500 pg/mL (Bravo et al, 2003), whereas patients with pheochromocytoma do not.

Radiologic Tests

As for other adrenal tumors, the development of sectional imaging was a major advancement in the diagnosis and localization of pheochromocytoma (Kazam et al, 1989). For adrenal pheochromocytomas, the CT accuracy for detection is more than 90% (Thomas et al, 1980; Abrams et al, 1982), and CT has rapidly replaced angiography, venography, and ultrasonography for extra-adrenal pheochromocytoma, in which the detection is less (about 75%). CT, however, does not aid in differentiating pheochromocytomas from other adrenal lesions or in predicting malignancy.

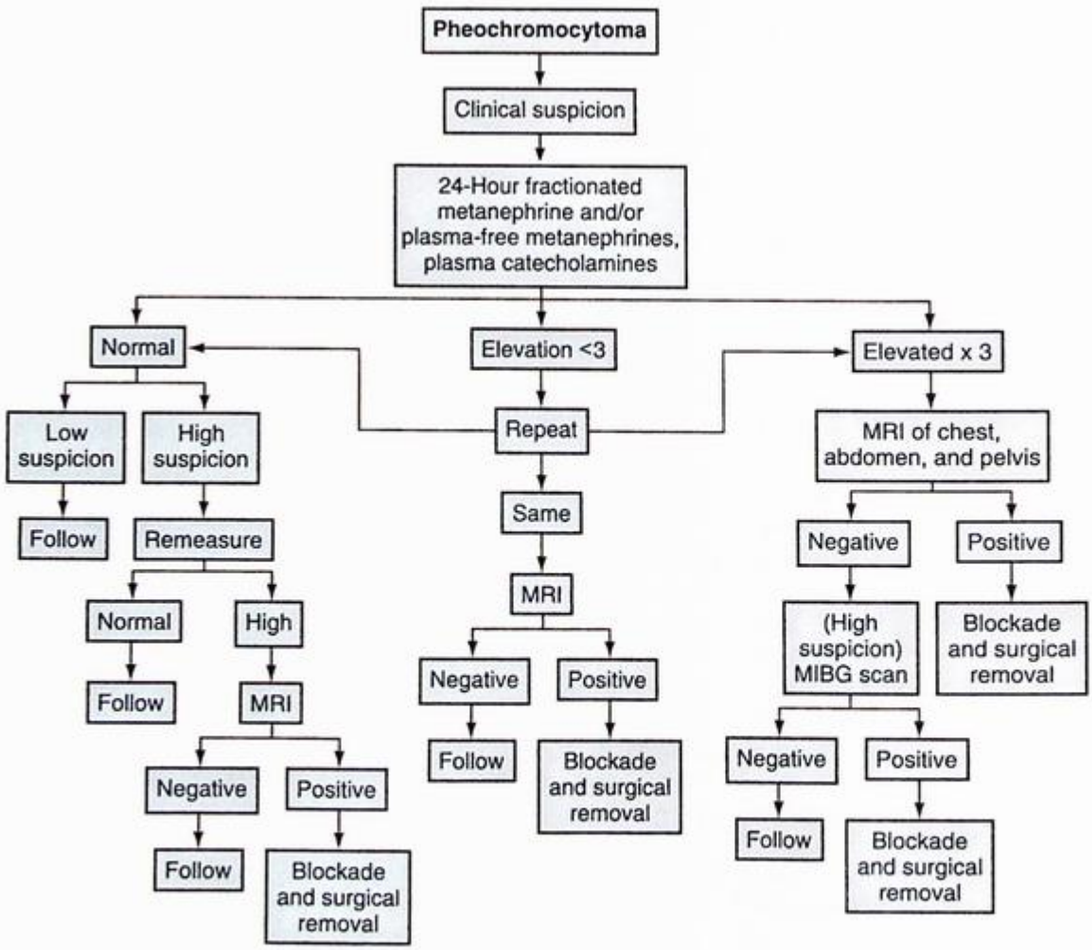

Figure 53–40. Identification of pheochromocytoma. MRI, magnetic resonance imaging; MIBG, metaiodobenzylguanidine.

Table 53–19. Effects of Drugs and Interfering Substances on Concentrations of Urinary Catecholamines and Metabolites*

	Effects

From Manger WM, Gifford RW Jr: Pheochromocytoma. In Laragh JH, Brenner BM, eds: Hypertension: Pathophysiology, Diagnosis, and Management. New York, Raven Press, 1990.

We have been impressed with the multiple uses of MRI in patients with pheochromocytoma. The test appears to be as accurate as CT in identifying lesions while having a characteristically bright, "light bulb" image on T2-weighted study (Fig. 53–41) (Reinig et al, 1986). In addition, sagittal and coronal imaging can give excellent anatomic information about the relationship between the tumor and the surrounding vasculature as well as the draining venous channels (Figs. 53–42 and 53–43). We believe that MRI should be the initial scanning procedure in patients with biochemical findings of pheochromocytoma.

An alternative approach that is also useful at times, particularly in the search for residual or multiple pheochromocytoma, is the MIBG scan that images medullary tissue (Shapiro et al, 1985; Campeau et al, 1991). In an experience with 400 cases, the developers of the technique found sensitivity of 78.4% in primary sporadic tumors, 92.4% in malignant lesions, and 94.3% in familial cases, giving an overall sensitivity of 87.4% with 99% specificity. Thus, the test may be more sensitive than CT in patients with extra-adrenal lesions. The isotope may be picked up by other APUD cell–type tumors. In a smaller series involving children, the MIBG scan findings were abnormal in all cases (Deal et al, 1990). The MIBG scan is highly sensitive and is a useful tool, especially if CT and MRI findings are normal or confusing (Fig. 53–44). Sequential venous sampling has been used successfully to identify small extra-adrenal lesions (Newbould et al, 1991). One warning is that the normal adrenal medulla may be visualized in more than 50% to 70% of patients imaged at 24 to 48 hours after injection (Roelants et al, 1998). Positron emission tomographic scanning with a variety of agents remains controversial at this time because of nonspecificity and limited sensitivity (Lenders et al, 2005).

Preoperative Management

There is unanimity of opinion that surgical extirpation is the only effective treatment of pheochromocytoma. The one accepted exception to this principle is treatment late in pregnancy. The patient should be treated with α-adrenergic blockade by oral administration of phenoxybenzamine until the fetus has reached maturity. At this point, cesarean section with tumor excision should be carried out in one operation, without allowing the patient to undergo the stress of vaginal delivery.

A controversial issue in the management of patients with pheochromocytoma is whether to employ pharmacologic blockade preoperatively, and some with extensive and highly successful experience do not use α-adrenergic blockade (Ulchaker et al, 1999). **We do not believe that this is an issue at present. The evolution of an accurate localization test weakens the argument that α blockade limits the ability to identify the lesion at the time of exploration.**

Moreover, the greater stability of the patient with adequate preoperative preparation greatly facilitates the procedure for both surgeon and anesthesiologist as well as increases the safety to the patient. At our institution, the preoperative medical preparation is of utmost importance to provide an ideal anesthetic and operative environment (Malhotra, 1995). The perioperative course is smoother with adequate preoperative preparation. **Phenoxybenzamine hydrochloride (Dibenzyline), a long-acting α-adrenergic blocker, controls**

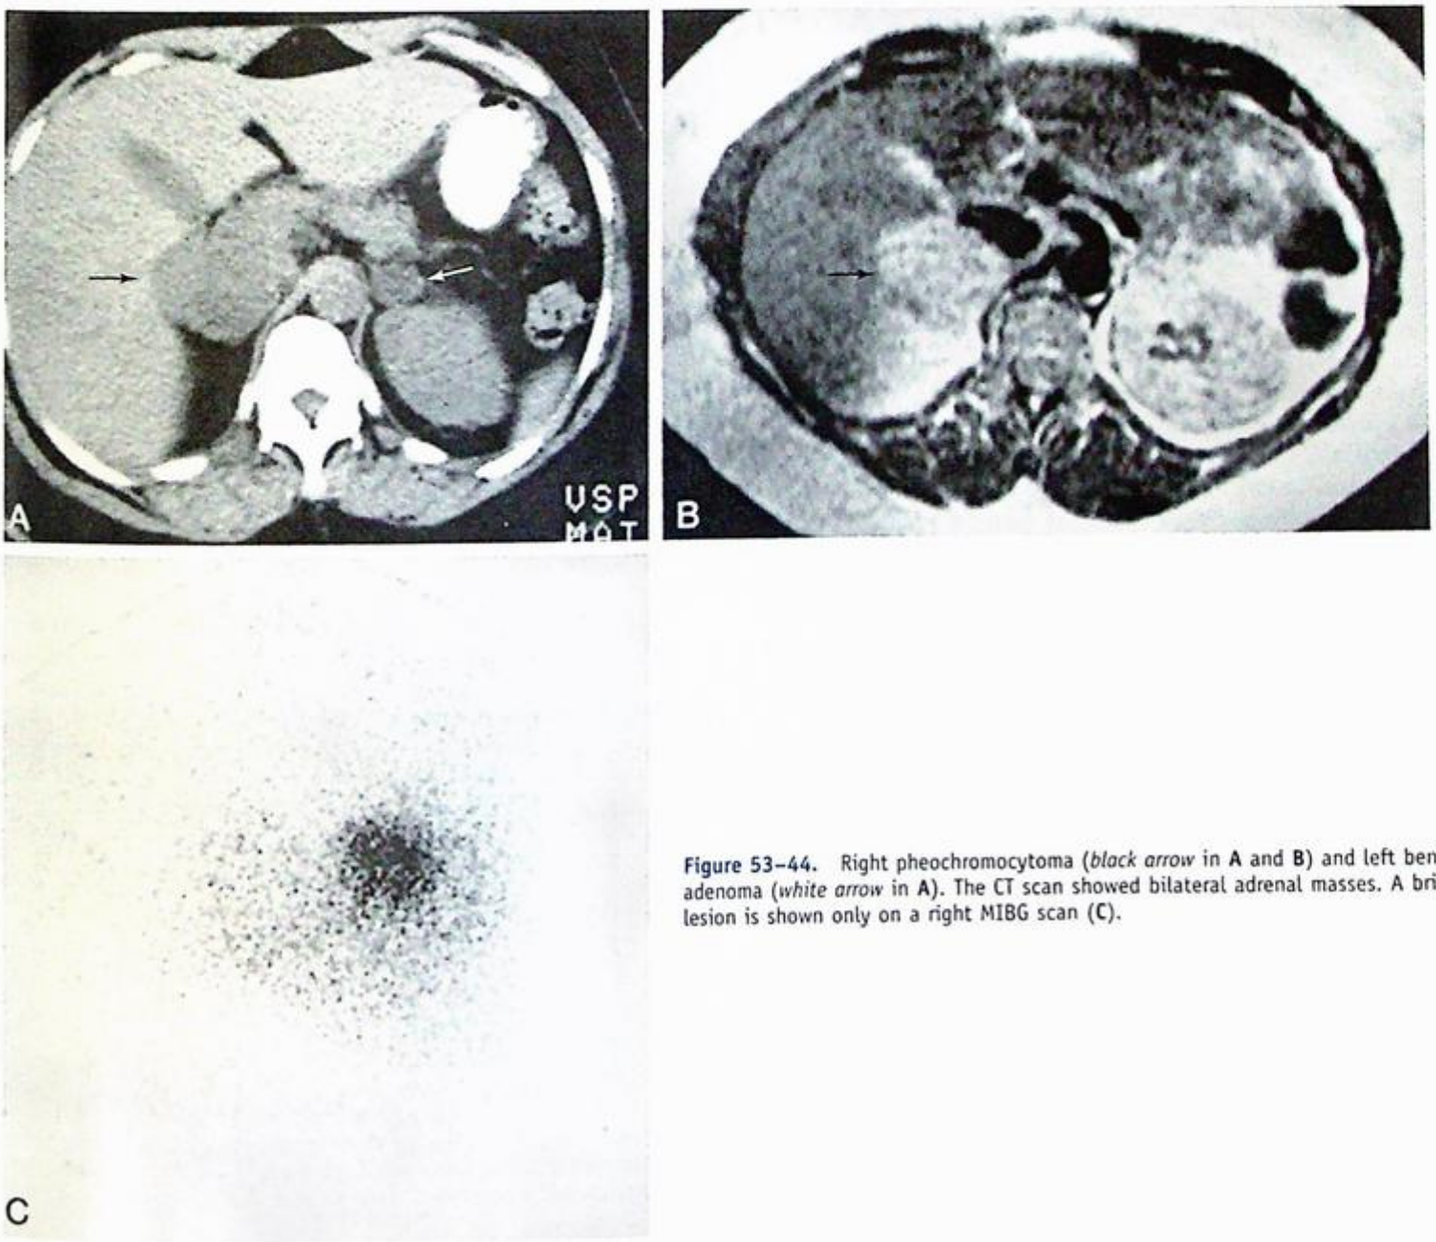

Figure 53–44. Right pheochromocytoma (*black arrow* in **A** and **B**) and left benign adenoma (*white arrow* in **A**). The CT scan showed bilateral adrenal masses. A bright lesion is shown only on a right MIBG scan (**C**).

blood pressure in patients with pheochromocytoma. The initial divided dose of 20 to 30 mg is given orally and is increased by 10 to 20 mg/day until the blood pressure has been stabilized and there is mild postural hypotension. Usually, a dose of 40 to 100 mg/day is required.

β-Adrenergic blockers, such as propranolol, have been added to α blockers to prepare patients for anesthesia and surgery. The β blockers protect against arrhythmias and permit reduction in the amount of α-adrenergic blockers necessary to control blood pressure (Ross et al, 1967). The β blockers have also been given when tachyphylaxis to α blockers occurs. However, they must be used carefully. A β-adrenergic blocker should be administered only when α blockade is established; β blockade alone may cause a marked rise in total peripheral vascular resistance, secondary to unopposed α-adrenergic activity. Accordingly, we do not routinely prepare patients with propranolol. A β-adrenergic blocker is provided only when cardiac arrhythmias are prominent. Propranolol is given orally in doses of 20 to 40 mg three or four times daily.

α-Methylparatyrosine (metyrosine, a tyrosine hydroxylase inhibitor) has been recommended in addition to phenoxybenzamine or propranolol during preparation of the patient for anesthesia and surgery (Sjoerdsma et al, 1965; Engelman et al, 1968). Metyrosine decreases the rate of catecholamine synthesis—the conversion of tyrosine to dihydroxyphenylalanine. Adverse effects include crystalluria, sedation, diarrhea, anxiety, psychic disturbance, and extrapyramidal signs. Experience with α-methylparatyrosine is limited, although its combination with α-adrenergic blockade has been recommended (Perry et al, 1990). We therefore do not use it routinely but reserve the drug for patients who have myocardiopathy, multiple catecholamine-secreting paragangliomas, or resistance to α-adrenergic blockers. α-Methylparatyrosine is given in doses of 0.5 to 1 g orally three or four times daily and is usually started before surgery. The dose is determined by repeated catecholamine evaluations.

Prazosin, a specific postsynaptic α_1-adrenergic blocker, has gained rapid acceptance as an effective antihypertensive agent. The drug has been evaluated in the medical management of patients with pheochromocytoma either alone (Wallace and Gill, 1978) or in combination with a β blocker. We, however, have experience with four patients who were prepared with prazosin alone for surgical removal of adrenal pheochromocytoma. The control of blood pressure was effective preoperatively but was not adequate during surgical removal of the tumor. Marked blood pressure elevations were present in all four patients. In contrast to phenoxybenzamine, which binds irreversibly to α-adrenergic receptors, prazosin blockade is reversible and may be overwhelmed by the surge in catecholamine secretion during intubation and surgical manipulation. We have since abandoned prazosin in preparing patients for anesthesia and surgery (Nicholson et al, 1983).

In addition to the α-blocking and β-blocking agents, it is important that the state of hydration and blood volume be evaluated because many patients have decreased intravascular volume. Crystalloids may be needed to raise the intravascular volume to accommodate the expanded vascular bed produced by α-blocking agents. To avoid this potential problem, patients receive at least 1 liter of 5% glucose in lactated Ringer's irrigation preoperatively. The α-blocking agent and β-blocking agent (if used) should be continued through the day of surgery.

Anesthetic Management

Anesthetic management of the patient undergoing surgical removal of a pheochromocytoma is directed toward control of the cardiovascular system (Robertson et al, 1990; Artusio, 1995). Close monitoring is of utmost importance and includes attention to the electrocardiogram, blood pressure (arterial line for continuous arterial pressure reading), urine output, and central venous pressure. A Swan-Ganz catheter may be employed to measure pulmonary capillary wedge pressure if the patient has left ventricular dysfunction.

Patients should arrive in the operating room in a relaxed state, and therefore some form of preanesthesia medication such as a barbiturate (pentobarbital at a dose of 100 to 300 mg) should be given an hour before the patient's arrival to the operating room. **We recommend general anesthesia with a combined approach—induction with an intravenous agent such as thiopental followed by isoflurane as the inhalation agent of choice.** At the time of induction of anesthesia, there may be a marked vasopressor response, and appropriate α-adrenergic and β-adrenergic blocking agents should be available for intravenous use. Acutely, it is recommended that phentolamine (Regitine), a short-acting α blocker, be used to control blood pressure during the induction of anesthesia. Phentolamine can be given in boluses of 1 to 5 mg or by continuous infusion (50 mg of phentolamine per 500 mL of lactated Ringer's irrigation). Alternatively, sodium nitroprusside may be needed to control severe hypertension, and it should be present in a solution of 50 mg in 250 mL of 5% dextrose and water.

Throughout the procedure, particularly during any manipulations of the tumor, hypertensive episodes as well as arrhythmias may occur. The use of general anesthesia allows the anesthesiologist to follow the progress of the surgery, and as the blood supply of the tumor is diminished, fluids can be increased, and the depth of the anesthesia can be decreased. β-Adrenergic blockers, such as esmolol and propranolol, should be reserved for persistent tachycardias or arrhythmias that persist despite α blockade.

A variety of anesthetic agents and drugs should be avoided in patients with pheochromocytoma (Table 53–20). With use

Table 53–20. Anesthetics and Drugs to Be Avoided in Pheochromocytoma

Inhalation agents	Halothane
Intravenous agents	Propofol

KEY POINTS: ADRENAL DISORDERS

- An exogenous source of Cushing's syndrome should always be excluded first because therapeutic steroids are the most common cause of the syndrome.
- Subclinical Cushing's syndrome represents 3% to 5% of the common metabolic syndrome.
- The determination of 24-hour excretion of cortisol in the urine is the most direct and reliable index of cortisol secretion.
- Most adrenal carcinomas are larger than 5 cm and show a heterogeneous pattern and high signal intensity on MRI.
- The critical requirement for potential cure in patients with adrenal carcinoma is complete surgical removal of the primary tumor.
- Extra-adrenal neural tumors (paragangliomas) are more likely than adrenal pheochromocytoma to be malignant.
- MRI is the most useful radiologic test to confirm the diagnosis of a pheochromocytoma (bright "light bulb" on T2-weighted imaging). It shows the relationship of the tumor with adjacent structures and identifies multiple lesions.
- Solid lesions of the adrenal gland that give a high signal intensity on MRI include pheochromocytoma, other neural tumors, metastatic tumors, primary hyperaldosteronism, and adrenal carcinoma.
- The classic triad for diagnosis of primary hyperaldosteronism is low potassium concentration (after sodium repletion), suppressed plasma renin activity, and high plasma or urine aldosterone level.
- Metastatic tumors to the adrenal from other primary tumors are more common than primary adrenal tumors.

of this approach and adequate preoperative blockade, at times with both α-adrenergic blocking agents and α-methylparatyrosine, hypotension after removal of the tumor now rarely occurs. If the systolic blood pressure falls below 100 mm Hg, however, norepinephrine (4 to 8 mg per 500 mL normal saline) should be started and blood pressure stabilized above 100 mm Hg. The norepinephrine can usually be withdrawn after further fluid resuscitation.

NONSURGICAL ALTERNATIVES

Surgery of the adrenal gland consists of operative procedures to correct endocrine abnormalities or to treat malignant disease. As outlined in Chapter 53, various adrenal disorders can be identified and treated medically. When medical therapy is ineffective or does not exist for a particular adrenal disease, surgery becomes necessary.

Traditional open adrenal surgery has been performed since the late 19th century. Various techniques and anatomic approaches have been described for adrenalectomy, but the essential surgical principles have remained unchanged for a century. The introduction of laparoscopic adrenalectomy has revolutionized adrenal surgery and largely supplanted the open approach. However, we are not yet ready to relegate open adrenal surgery to the history books. There is a diminished but vital role for open adrenal surgery in the management of invasive adrenal carcinoma. Furthermore, all urologic surgeons should be familiar with the open techniques in the event that emergent open surgical conversion is necessary.

The future of adrenal surgery is a study in evolution. New technology, such as robotics and percutaneous ablation, is being developed. These minimally invasive nonsurgical approaches may obviate the skills of the surgeon. Nevertheless, it is important that the urologist be part of the treatment team, either as direct practitioner of the technique or in direct consultation guiding therapy.

HISTORY

The first adrenalectomy was performed by Thornton in 1889 for a large tumor in a 36-year-old woman (Thornton, 1890). At the time, Thornton was unaware of the adrenal origin of the patient's disease and removed the adrenal en bloc with the kidney. Sargent performed the first planned adrenalectomy in 1914 for a large adrenal adenoma. Charles Mayo performed the first flank adrenalectomy for pheochromocytoma in 1927 (Mayo, 1927). As was often the case in these early forays, Mayo was not aware of the exact nature of the pathologic process with which he was dealing and assumed that he was removing an aberrant retroperitoneal nerve.

In 1936, Young described the posterior approach by a "hockey stick" incision to access both adrenal glands simultaneously (Young, 1936). The thoracoabdominal incision for management of large retroperitoneal masses was first described in 1949 by Chute (Chute et al, 1949). Turner-Warwick developed a supracostal transdiaphragmatic variation of Young's posterior approach in 1965 (Turner-Warwick, 1965).

Gagner performed the first laparoscopic adrenalectomy in 1991 (Gagner et al, 1992). He used a transperitoneal approach to gain access to the adrenal gland. Also in 1992, Gaur developed the first device for balloon dilation of the retroperitoneum (Gaur, 1992). Retroperitoneal access has been developed for both flank (Gasman et al, 1998) and posterior (Baba et al, 1997) approaches.

SURGICAL ANATOMY

The adrenal glands are situated in the retroperitoneum within Gerota's fascia. The right adrenal gland tends to lie more cephalad than the left adrenal gland. The anatomic borders of the right adrenal gland are the liver anteriorly, the vena cava medially, the right kidney laterally and inferiorly, and the diaphragm along its superior and posterior aspects. The medial aspect of the right adrenal gland will often be retrocaval, and the right adrenal vein will enter the inferior vena cava in a posterolateral position.

The left adrenal gland is bordered by the aorta medially, the stomach and body of the pancreas anteriorly, the kidney inferiorly, the spleen superiorly, and the diaphragm posteriorly. The left adrenal gland is often more elongated than the right adrenal gland and will lie in a more superomedial position to the kidney. This tends to place the gland closer to the left renal hilum, and these structures must be accounted for during dissection. The anatomic relationships of the adrenal glands are summarized in Figure 54–1.

The arterial blood supply to the adrenal gland can be variable but tends to derive from three major sources on each side. Each adrenal gland receives branches from its ipsilateral inferior phrenic artery (superior adrenal arteries), aorta (middle adrenal arteries), and renal artery (inferior adrenal arteries). The venous drainage is typically simple; a single adrenal vein drains into the vena cava directly on the right and into the left renal vein on the left. Accessory veins (5% to 10%) that drain into the right renal vein, right hepatic vein, or inferior phrenic vein can be present (Fig. 54–2).

Lymphatic drainage from the adrenal glands consists of a lateral aortic lymph node chain extending from the diaphragm to the ipsilateral renal artery.

CLINICAL INDICATIONS AND SELECTION OF PATIENTS

Clinical Indications

The clinical indications for adrenalectomy are summarized in Table 54–1. The pathophysiology, diagnosis, and treatment of these diseases are detailed in Chapter 53.

Exclusion Criteria

Severe coagulopathy and poor cardiopulmonary performance status are absolute contraindications to adrenalectomy by any technique. As far as laparoscopy is concerned, the

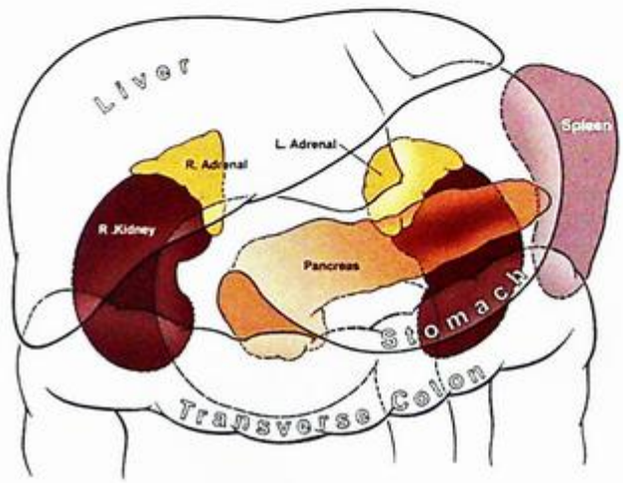

Figure 54–1. Regional anatomy of adrenal glands.

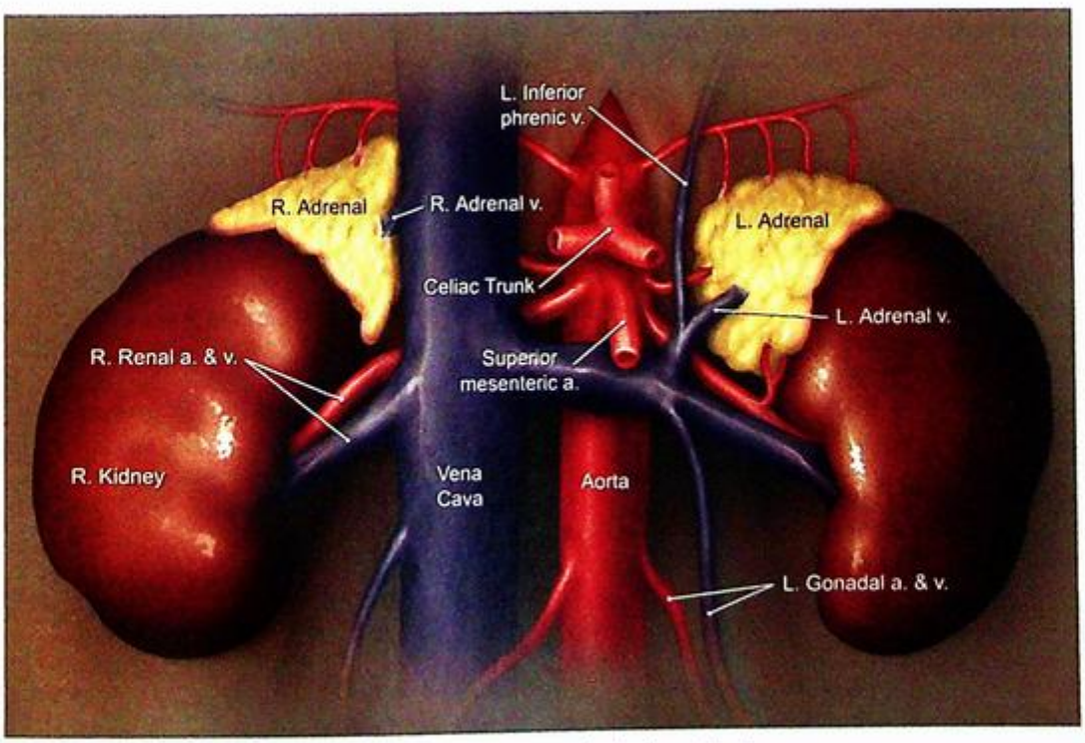

Figure 54–2. Vascular supply of adrenal glands.

Table 54–1. Clinical Indications for Adrenalectomy

Primary aldosteronism (solitary adenoma versus bilateral adrenal hyperplasia)
Cushing's syndrome
Pheochromocytoma
Adrenal adenoma
Myelolipoma
Adrenal cyst
Metastatic tumor
Adrenocortical carcinoma
Neuroblastoma (pediatric)
Incidentally discovered adrenal mass or "incidentaloma"

Table 54–2. Surgical Options (Open Adrenalectomy)

Disease	*Approach*
Primary hyperaldosteronism	Posterior (left or right) Modified posterior (right) 11th rib (left > right) Posterior transthoracic
Cushing's adenoma	11th rib (left or right) Thoracoabdominal (large) Posterior (small)
Cushing's disease (bilateral hyperplasia)	Bilateral posterior Bilateral 11th rib (alternating)
Adrenal carcinoma	Thoracoabdominal 11th rib Transabdominal
Bilateral adrenal ablation	Bilateral posterior
Pheochromocytoma	Transabdominal chevron Thoracoabdominal (large, usually right) 11th rib
Neuroblastoma	Transabdominal 11th rib

From Vaughn ED: Adrenal surgery. In Marshall F, ed: Operative Urology. Philadelphia, WB Saunders, 1996:222.

shrinking number of contraindications attests to the high level of skill exhibited by pioneering laparoscopic surgeons. These relative contraindications include previous open surgery, tumor size, obesity, and adrenal cortical carcinoma.

Indications for Open Surgery

The current indications for open adrenalectomy are few but important. First, **adrenal cortical carcinoma with radiographic evidence of extra-adrenal tumor invasion of adjacent organs may benefit from maximal surgical exposure. Similarly, the extension of adrenal vein tumor thrombus into the inferior vena cava necessitates a more invasive approach.** Finally, in developing countries, the resources for laparoscopic surgery may be lacking, and the open approach will be preferred out of necessity. The choice of open surgical approach is dictated by the surgeon's experience and the pathologic process in question. Table 54–2 summarizes the best surgical approach for a given adrenal disease.

Past Surgical History

Is open surgery indicated when there is a history of previous surgery close to the adrenal gland? The laparoscopic approach can be tailored to deal with past surgical history; a patient with previous transabdominal surgery could have a retroperitoneal laparoscopic procedure (Caddedu et al, 1999), and a history of previous open flank surgery could be addressed by performing a transperitoneal laparoscopic procedure. Furthermore, Gill and colleagues (2001) have reported their experience with a transthoracic laparoscopic approach that may be ideally suited for this situation. The thoracic cavity is entered thorascopically, the diaphragm is divided, and the adrenal gland is approached superiorly.

Size

Tumor size is a relative contraindication to laparoscopic surgery. In the initial experience of many laparoscopists, a cutoff of 5 or 6 cm was chosen because of the increased risk of treating an adrenal cortical carcinoma. Subsequently, ample empirical evidence has accumulated to suggest that specimen size is not necessarily a contraindication to laparoscopic adrenalectomy. MacGillivray and colleagues (2002) noted no difference in operative time, blood loss, complication rate, and hospital stay between 12 patients with large tumors (mean, 8.2 cm; range, 6 to 12 cm) and 36 patients with small tumors (mean, 2.5 cm; range, 0.4 to 5.6 cm).

In contrast, Hobart and coworkers (2000) noted increased operative time (205 minutes versus 158 minutes; $P = .07$), increased blood loss (400 mL versus 113 mL; $P = .009$), higher complication rate (21.4% versus 8.9%; $P = .21$), and higher open conversion rate (14.3% versus 2.2%; $P = .14$) in comparing 14 large tumors (mean, 8 cm) with 45 small tumors (mean, 2.2 cm). However, Hobart did find that operative time, blood loss, hospital stay, narcotic use, and complication rate were lower with laparoscopic adrenalectomy than with traditional open adrenalectomy for large tumors. Although a higher morbidity could be expected with larger tumors, morbidity was still less than with open surgery.

Conversion to open surgery is most often due to infiltrative adrenal cortical carcinoma. In the largest series, conversion occurred electively after initial laparoscopic exploration and not because of hemorrhage or other emergent causes. MacGillivray concluded that **preoperative computed tomographic scanning can identify those infiltrative tumors that are likely to be invasive carcinoma.**

MacGillivray and Henry recommend an upper size limit of 12 cm for laparoscopic adrenalectomy. However, keep in mind that computed tomographic scanning can underestimate specimen size by as much as 16% (Lau et al, 1999).

Obesity

With a worldwide epidemic of obesity, it is an increasingly common occurrence to operate on morbidly obese patients. Rather than obesity's being a relative contraindication, laparoscopy may offer a less morbid alternative for adrenalectomy on obese patients. Comparing results between obese patients (body mass index greater than 30) who underwent laparoscopic adrenal or renal surgery and those who underwent open surgery, Fazeli-Matin and associates (1999) noted that patients who underwent laparoscopic surgery had fewer complications (18% versus 47%; $P = .21$), less blood loss (50 mL versus 300 mL; $P = .03$), less narcotic use ($P = .01$), and shorter hospital stay (<24 hours versus 5.5 days; $P = .01$). However, these surgeries were performed by a veteran laparoscopist, and obesity may remain a relative contraindication for less experienced surgeons.

Adrenal Cortical Carcinoma

Laparoscopic adrenalectomy on adrenal cortical carcinoma can be a daunting task. Adrenal carcinomas tend to be larger (>6 cm). Henry and colleagues (2002) noted that of 150 consecutive laparoscopic adrenalectomies, none of the smaller (<4 cm) tumors (N = 102) was malignant. In contrast, 12.5% of tumors larger than 4 cm (N = 48) were malignant. Using a 6-cm cutoff, Prager and coworkers (2004) noted that 21.2% of tumors larger than 6 cm were malignant versus 1.9% of lesions smaller than 6 cm. Also, the prospect of invasion by infiltrative lesions into surrounding structures can prohibit successful laparoscopic surgery. However, if computed tomography indicates that no local invasion is present and the lesion is not excessively large, laparoscopic adrenalectomy is possible.

Known adrenal vein or vena caval involvement is an absolute contraindication to laparoscopic surgery. However, in one case report, Kim and associates (2004) described an intraoperatively discovered adrenal vein thrombus with a 7-cm adrenal mass. With use of atraumatic vascular clamps, the renal vein was entered, and the intact tumor thrombus was removed en bloc with the adrenalectomy specimen.

Cancer control is dependent on adherence to the same oncologic principles as in open surgery. Wide local excision with periadrenal fat is necessary for good local control to be obtained. Adrenal cortical carcinoma tends to be an aggressive disease, and locoregional recurrence can develop as often as 60% (Vassilopoulou-Sellin and Schultz, 2001). Most reports of postoperative adrenal cortical carcinoma recurrence have been in case reports. Henry and coworkers (2002) published a summary of 12 cases of carcinoma recurrence in the medical literature. In 25% of the cases, the authors admitted to specimen disruption during the case.

PREOPERATIVE MANAGEMENT

It is important to correct any electrolyte abnormalities that may result from an endocrinologically active adrenal tumor. Most notably, aldosteronoma can result in hypokalemia that may require potassium repletion and administration of potassium-sparing diuretic. Hypertension should also be treated before surgery.

With pheochromocytoma, α-adrenergic blockade should be started 2 weeks before surgery. Phenoxybenzamine (10 to 40 mg four times daily; maximum, 300 mg/day) is used, starting gradually with a dose of 10 to 20 mg twice per day. Some patients with tachycardia may benefit from concurrent β blockade. Alternatively, an α_1-selective blocker such as prazosin or doxazosin can be used. Intraoperatively, high blood pressure can be treated with nitroprusside or a short-acting β blocker like esmolol. Volume repletion is important to prevent the postoperative hypotension secondary to loss of tonic vasoconstriction after removal of a pheochromocytoma.

Patients with Cushing's syndrome require correction of electrolyte abnormalities and hyperglycemia before surgery. These patients may benefit from administration of adrenolytic agents such as mitotane or aminoglutethimide.

Potential errors in preoperative preparation are summarized in Table 54–3.

A mechanical bowel preparation can be helpful for open or laparoscopic transperitoneal surgery. Retroperitoneal surgery may not require this bowel preparation. All patients should receive appropriate preoperative antibiotics. A nasogastric or orogastric tube can be placed to decompress the bowel, especially helpful for transperitoneal cases. The placement of a urinary catheter to help measure urine output and to decompress the bladder is essential.

Table 54–3. Errors in Preparation of Patients for Adrenal Surgery

Primary aldosteronism
Potassium repletion
Blood pressure control
Cushing's syndrome
Inhibition of glucocorticoid production when there is severe manifestation with metyrapone
Control of diabetes
Preoperative antibiotics
Operative steroid administration
Incidentalomas
Anesthetic preparation for pheochromocytoma; 5% have normal diagnostic studies

OPEN ADRENALECTOMY

Open adrenalectomy can be performed through either a transperitoneal or retroperitoneal approach. The transperitoneal approaches include midline, subcostal, and thoracoabdominal. The retroperitoneal approaches include flank and posterior lumbodorsal. The advantages of the transperitoneal approaches are better exposure for larger tumors and excellent access to the great vessels and retroperitoneum. The main disadvantages are prolonged ileus and difficult exposure in morbidly obese patients. The retroperitoneal approach results in less ileus and may result in shorter hospital stays. There is a smaller operative field, and access to larger tumors and surrounding involved organs may be difficult. The best surgical approach for a given adrenal disease is indicated in Table 54–2.

Flank Retroperitoneal Approach

Right Side. The patient is placed in flank position with the right side facing up (Fig. 54–3). The bed is placed in maximal flexion, and the kidney rest is deployed to accentuate the space between the costal margin and iliac crest. Palpation is used to identify the course of the 11th rib. The skin and fat overlying the 11th rib are incised, and the fascia and muscle overlying the rib are divided (Fig. 54–4).

Once the anterior surface of the rib is exposed, the anterior periosteum is cauterized and the periosteal elevator is used to scrape it off the anterior rib surface. The edges of the periosteum on the superior and inferior aspects of the rib should now be visible. The periosteal elevator is used to develop a plane between the posterior rib surface and the posterior leaf of the periosteum. The Doyen instrument and surgical cautery are used to strip the periosteum off of the rib from the tip of the rib back toward the paraspinal muscles. With the rib cutter, the 11th rib is excised (Fig. 54–5). A rongeur can be used to remove any sharp remnants on the rib stump. Cautery or bone wax can be used to render the marrow hemostatic.

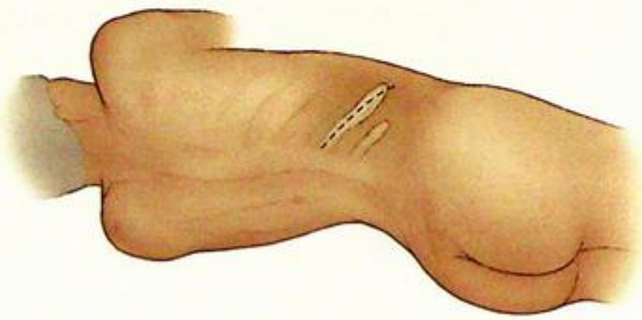

Figure 54–3. Surgical incision over 11th rib for flank adrenalectomy. The patient is in flexion with the kidney rest deployed to maximally expose the right retroperitoneum.

Next, the neurovascular bundle is identified and freed with sharp and blunt dissection to avoid injury during subsequent dissection and closure (Fig. 54–6). The lumbodorsal fascia is entered sharply with Metzenbaum scissors, and blunt dissection is used to dissect the peritoneum off of the transverse fascia anteriorly. The flank muscles and their accompanying fasciae are divided anteriorly—the external oblique, internal oblique, and transverse abdominal. Next, the posterior muscle diaphragmatic attachments are divided with cautery. The pleura is sharply and bluntly dissected off the superior edge of the 12 rib.

The plane between Gerota's fascia and the peritoneum can be started with the cautery or sharp dissection. Once it is identified, this plane can be maximally developed with blunt dissection. The peritoneum needs to be freed from the superior aspect of Gerota's fascia as well. Once the peritoneum is mobilized, on the right side, the vena cava can be visualized, and with cephalad dissection, the adrenal gland and renal vein can be seen as well. Placement of a self-retaining retractor is essential for maximal exposure to be obtained.

Dissection of the adrenal gland typically begins along the medial border of the gland with the vena cava. The overlying peritoneum is divided, and blunt dissection is used to expose the plane between the medial surface of the adrenal gland and the lateral surface of the vena cava. The adrenal vein is often difficult to identify until this plane is developed. The adrenal vein is dissected out with a right-angled instrument like a Mixter forceps. Surgical ties or clips can be placed to ligate the adrenal vein. In our opinion, surgical ties are more reliable

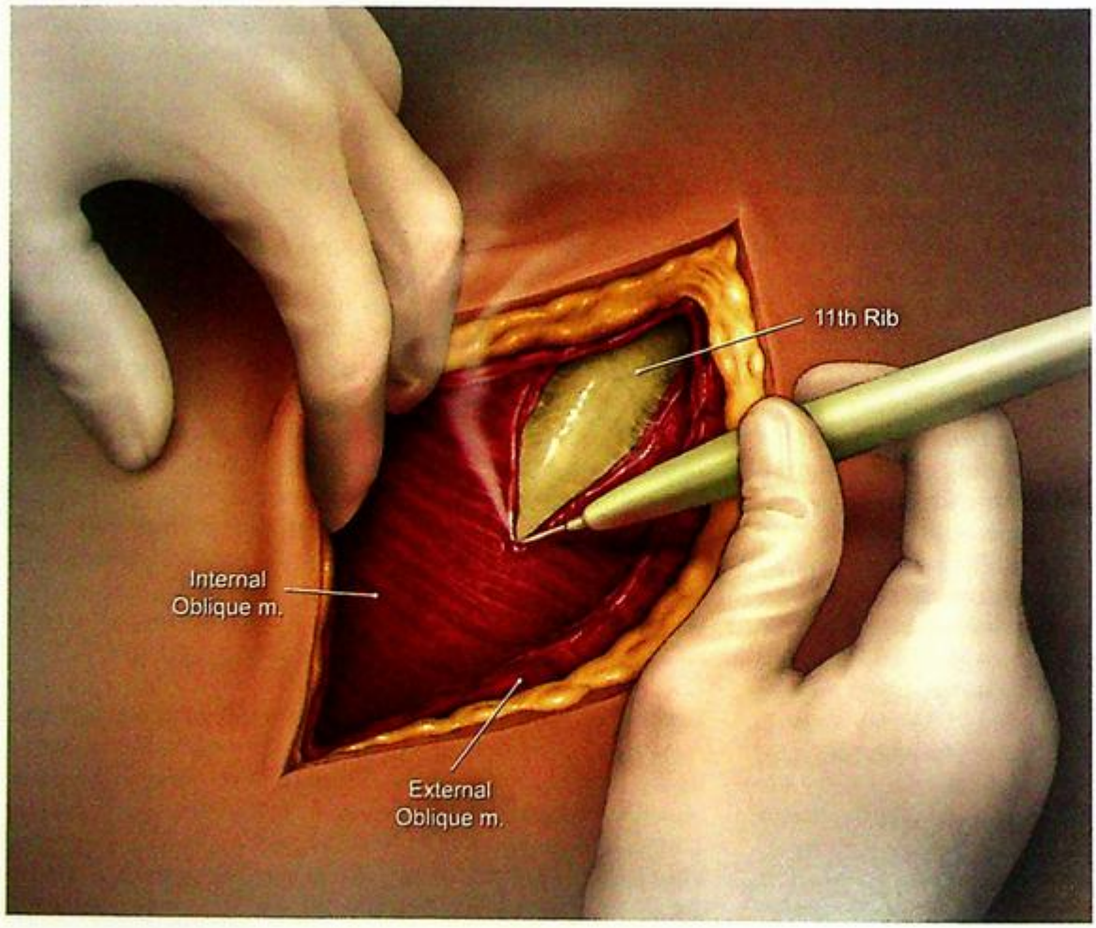

Figure 54–4. Flank approach. Incision of muscle overlying 11th rib.

than standard titanium clips. However, locking surgical clips may be substituted for added security. There are numerous arterial branches to the gland that can be ligated and divided individually. Alternatively, many authors attest to the utility of the harmonic scalpel in hemostatically dividing arterial attachments. Once this is done, the psoas muscle is often visible posteriorly. Superior attachments are divided with the aid of surgical cautery or harmonic scalpel. Downward traction on the kidney assists with this dissection. Inferomedial attachments to the kidney are taken with sharp or cautery hook dissection.

Dissection of the left adrenal gland is similar except that the aorta is visualized, and the adrenal vein originates from the renal vein. Other authors have described supracostal technique with intentional violation of the pleura. This approach may be helpful for larger tumors.

Closure of the incision consists of a two-layer closure with a running No. 1 polydioxanone suture. The deep layer consists of the transverse abdominal muscle and internal oblique muscle and fascia. The outer layer consists of the external oblique muscle and fascia. Skin closure can be completed with surgical staples or absorbable subcuticular suture.

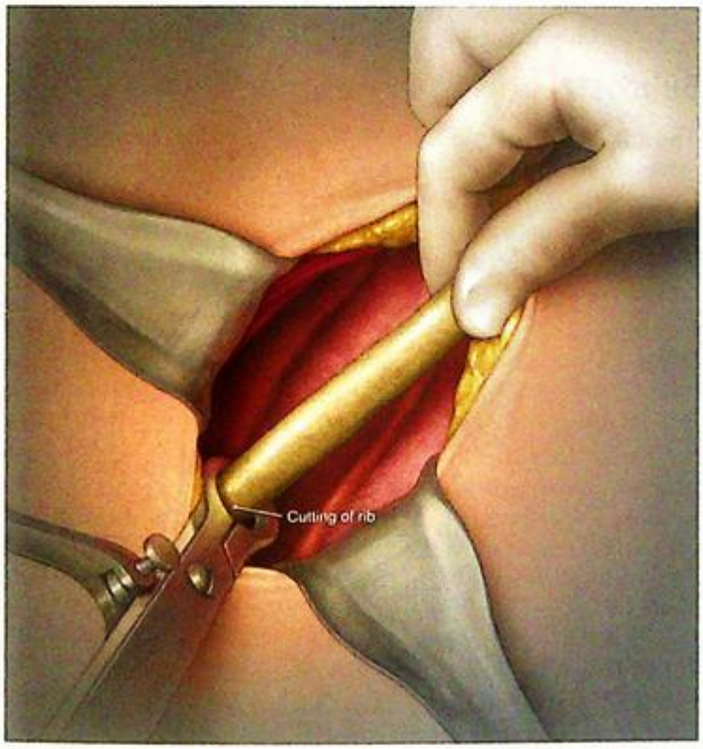

Figure 54–5. Flank approach. Excision of 11th rib.

Lumbodorsal Posterior Approach

The main advantage of this approach is the ability to easily access both adrenal glands for bilateral surgery. The disadvantages include a limited operative field and respiratory limitation. If bleeding is extensive, it can be difficult to control from this position. The posterior approach requires prone positioning of the patient with arms extended cephalad. The procedure has been extensively modified over time—with or without rib resection, transthoracic through the diaphragm, or diaphragm sparing. A rib-resecting, diaphragm-sparing approach is described.

Right Side. An incision is made along the course of the right 11th rib (Fig. 54–7). This is taken down to the periosteum, and the rib resection is performed in a manner similar to that described for flank incision. The diaphragm is dissected off the underlying peritoneum and liver. The peritoneum is then dissected off of Gerota's fascia, which is retracted inferiorly. If a bilateral procedure is undertaken, a Finochietto retractor can be used to assist in bilateral exposure (Fig. 54–8). With division of the final hepatic attachments, the adrenal gland

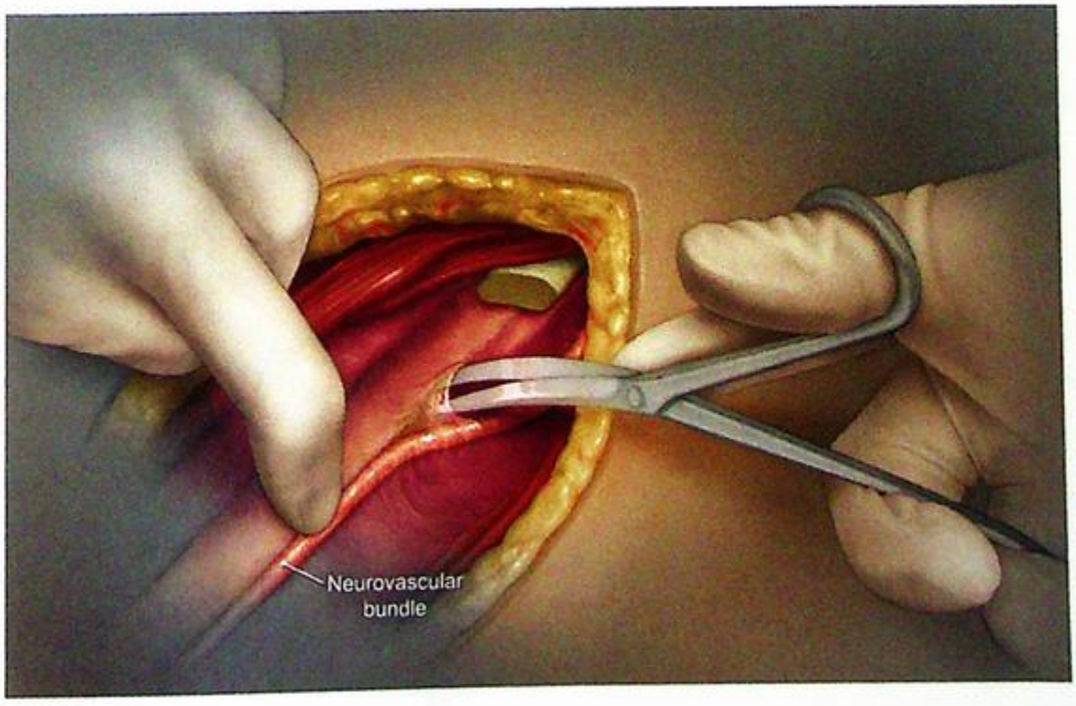

Figure 54–6. Flank approach. Mobilization of the intercostal neurovascular bundle from the 11th rib. This is performed with a combination of blunt dissection with a Kittner dissector and sharp dissection with Metzenbaum scissors.

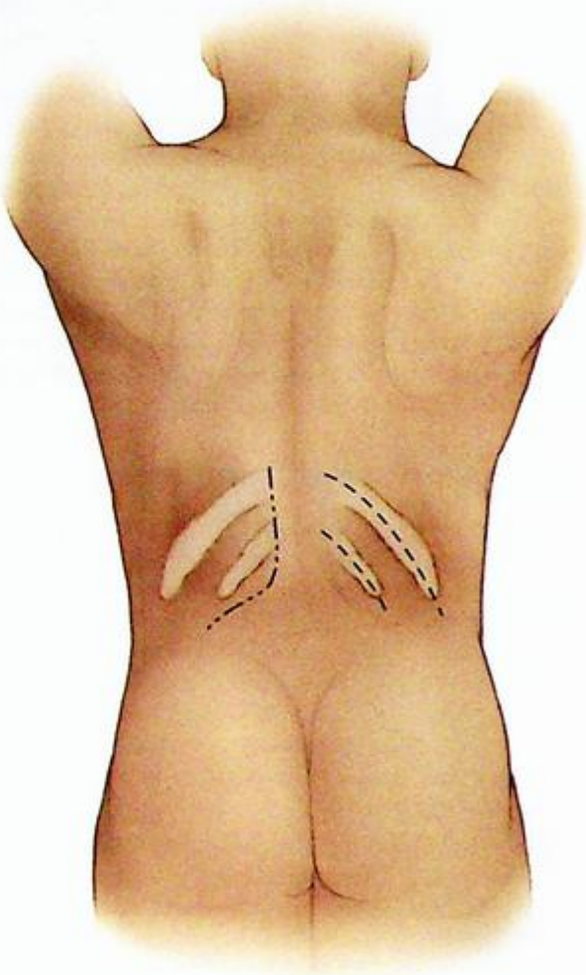

Figure 54–7. Posterior approach—possible incisions for lumbodorsal incisions.

becomes visible. The vena cava often becomes visible at this point, and the right adrenal vein is easily identified at its posterolateral origin. After division of arterial branches to the adrenal that course behind the vena cava and anterior to the paraspinal muscles, the adrenal gland can be mobilized posteriorly away from the paraspinal muscles, exposing the anterior vena cava. Given the small operative field, manual retraction of the kidney to assist dissection is not usually possible. Fortunately, division of the vascular attachments is relatively simple, and direct manipulation of the adrenal gland is possible. **The posterior approach should not be used for large tumors or adrenocortical carcinoma.**

Subcostal Anterior Approach

The anterior approach is useful for larger tumors and can be extended to the contralateral side as a chevron incision for treatment of bilateral lesions (Fig. 54–9). This approach also affords excellent exposure of the great vessels in the event that lymph nodes or venous tumor thrombus needs to be addressed.

Left Side. The patient is placed supine on the surgical table. If it is desired, a body roll can be placed under the back at the level of the costal margin to accentuate the costal margin. A skin incision is made approximately two fingerbreadths below the costal margin. This incision is extended medially to the midline or beyond, depending on the degree of exposure needed. The external oblique, internal oblique, and transverse abdominal muscles and their corresponding fasciae are divided laterally, and the rectus muscle and the rectus sheath are divided medially. The peritoneum is entered sharply, and the falciform ligament is divided after it is clamped and ligated with a large-gauge vascular tie (0 or 1 silk). The line of Toldt is incised, and the left colon is mobilized medially. The splenic

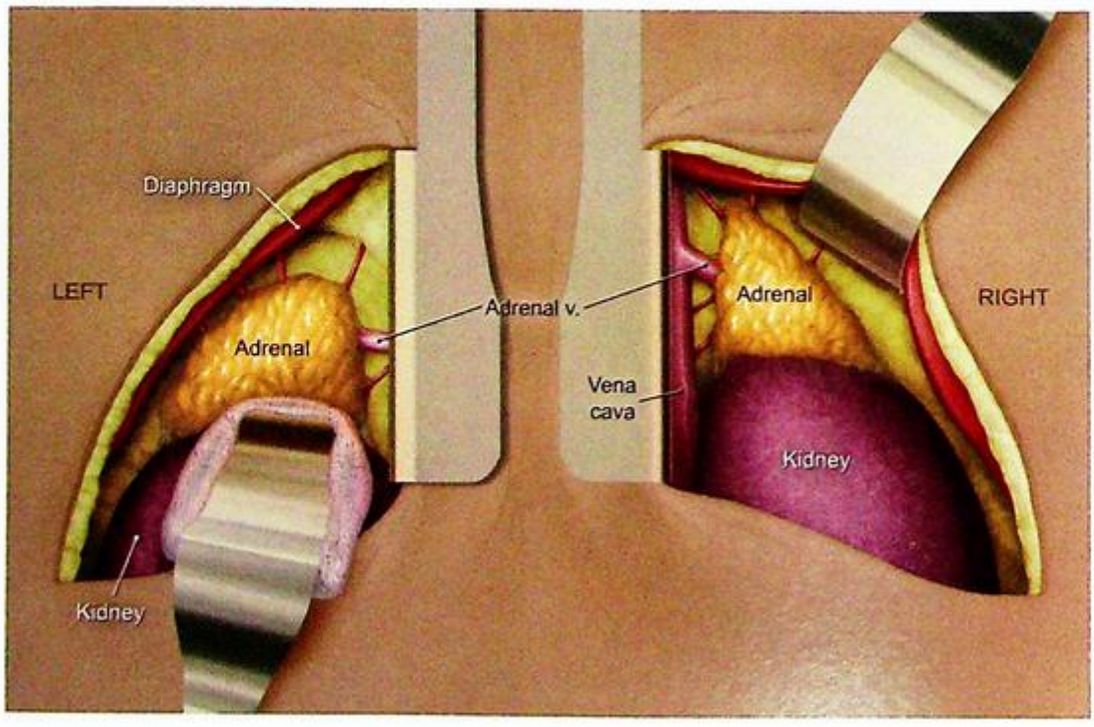

Figure 54–8. Bilateral posterior approach—anatomic relations to the adrenal gland as seen from behind.

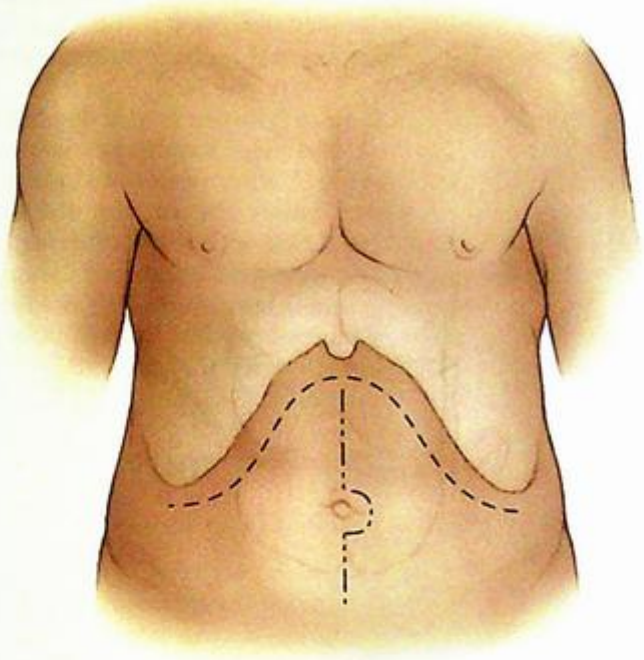

Figure 54–9. Anterior approach. The transperitoneal approach may be attempted through a midline incision or subcostal incision. The subcostal incision can be extended into a full chevron for bilateral adrenalectomy or if a large unilateral tumor is encountered.

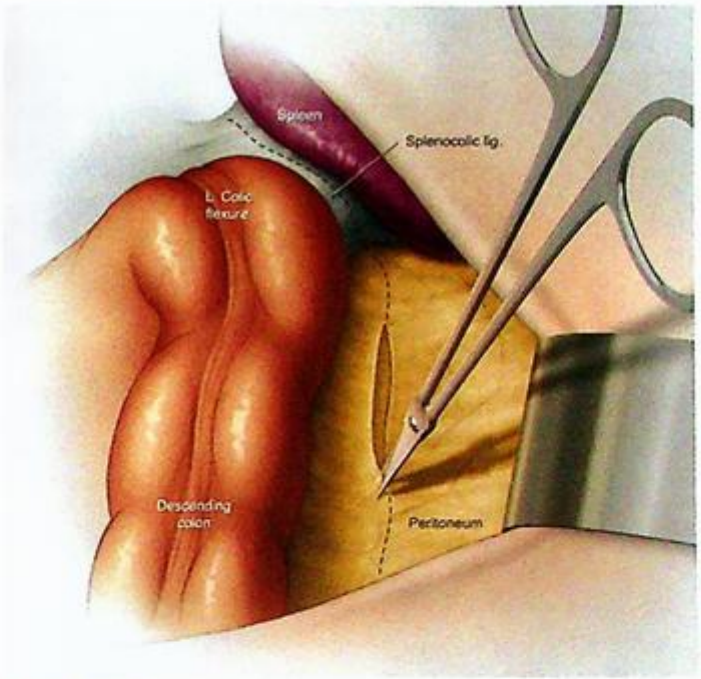

Figure 54–10. Anterior approach. Peritoneum lateral to left colon is incised at the line of Toldt and extended cephalad to the splenocolic ligament and inferiorly.

flexure is taken down by dividing the splenocolic ligament (Fig. 54–10). Division of the lienorenal ligament will allow medial mobilization of the spleen. The tail of the pancreas may come into view at this point. In a thin individual, the adrenal may be visible at this point. The left adrenal vein is identified on dissecting out the left renal vein (Fig. 54–11). After ligation and division of the left adrenal vein, medial attachments to the aorta can be taken with the harmonic scalpel or with careful dissection and ligation of small arterial vessels while gentle lateral traction is placed on the gland. The lateral and inferior attachments to the kidney can be taken by blunt and sharp dissection off of the renal capsule. Care must be taken to avoid hitting upper pole renal vascular attachments. After removal of the left adrenal gland, closure of the incision is performed with a running No. 1 polydioxanone suture in two layers; the deep layer consists of the transverse abdominal muscle, transverse fascia, internal oblique muscle and fascia, and posterior rectus sheath, and the superficial layer consists of the external oblique muscle and fascia and the anterior rectus sheath.

For right-sided tumors, the dissection is similar except for the necessity to dissect the duodenum medially by the Kocher maneuver (Fig. 54–12).

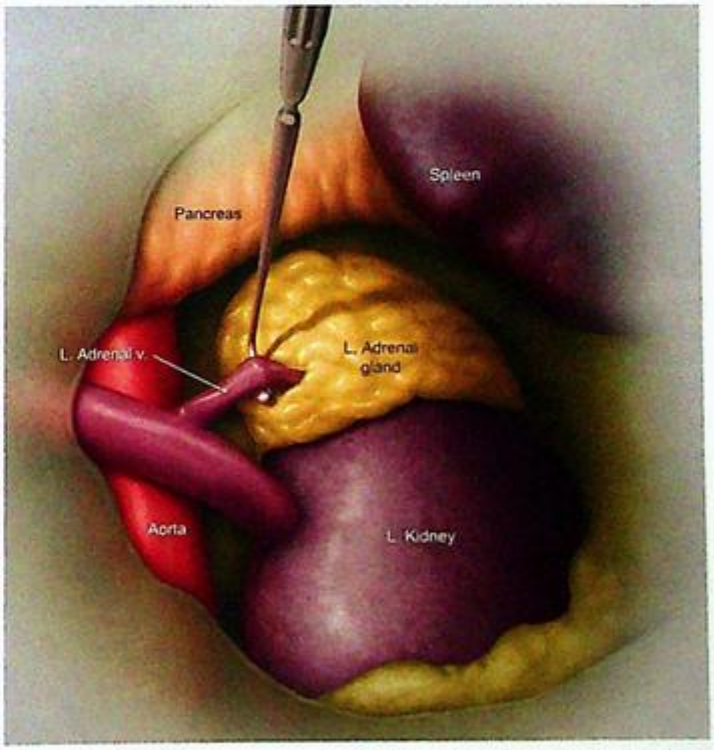

Figure 54–11. Anterior approach. The left adrenal vein is dissected out and ligated.

Thoracoabdominal Approach

This approach is a maximally invasive way to ensure superb surgical exposure of the retroperitoneum, adrenal gland, and great vessels. However, this exposure comes at a price: increased incisional pain, prolonged ileus, pulmonary morbidity, and a chest tube. **The thoracoabdominal approach is reserved for large or invasive adrenal carcinomas.**

Right Side. The patient is placed in an oblique position with the upper torso at a 45-degree angle to the table and the lower body flat on the table. A body roll is used to achieve the 45-degree position, and the right arm is placed in a sling with the arm bent at the elbow (Fig. 54–13). The left arm is secured to an arm board. The incision is made through the eighth or

ninth intercostal space (Fig. 54–14), dividing the intercostal muscles and fasciae. The costal cartilage is divided with the surgical cautery. The incision is carried farther through the anterior and posterior rectus sheaths and the rectus abdominal muscle. The pleura is entered, and the lung is packed away with laparotomy sponges (Fig. 54–15). The diaphragm is divided with the cautery. Do not cut directly to the center of the diaphragm as the phrenic nerve can be damaged. Once the diaphragm is divided, a Finochietto self-retaining retractor is placed to expose the surgical area. The rest of the dissection is similar to that of the previously described techniques. The relationship of the thoracoabdominal incision to the adrenal gland is illustrated in Figures 54–16 and 54–17.

Closure of the incision requires closure of the diaphragm and reapproximation of the ribs. The diaphragm is closed with interrupted figure-of-eight stitches with nonabsorbable suture. A chest tube is placed before the anterior thorax is closed. The anterior thorax is closed with several interrupted 0 chromic sutures on blunt-tip liver needles around the superior border of the eighth rib and inferior border of the ninth rib. A 0 Prolene suture on a tapered needle is placed through the cut costal cartilage to bring the costal margin together. The chest tube is placed to a water seal and suction.

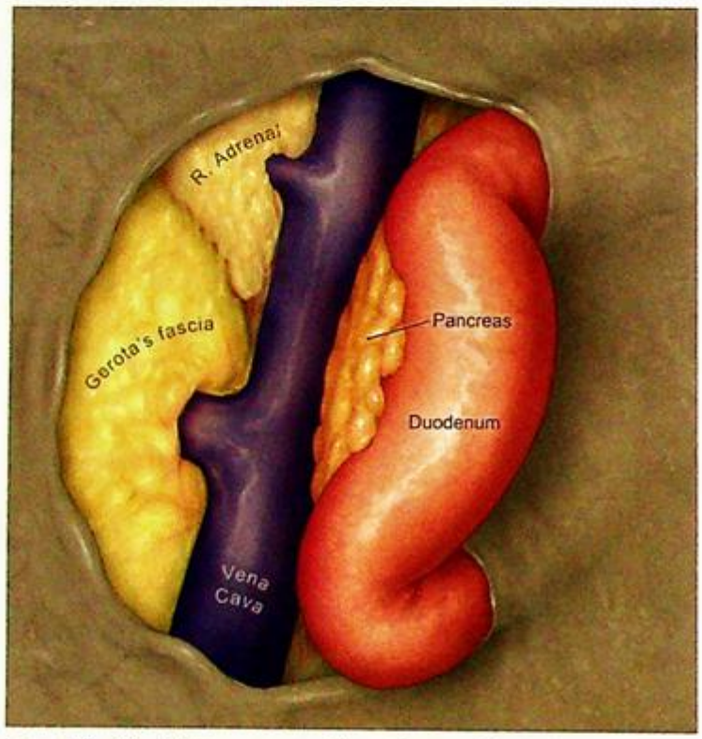

Figure 54–12. Kocher maneuver. The peritoneum is incised, and sharp dissection and blunt dissection are used to mobilize the second stage of the duodenum away from the renal hilum.

LAPAROSCOPIC ADRENALECTOMY
Transperitoneal Approach

Transperitoneal laparoscopic adrenalectomy can be performed through either an anterior supine approach or a lateral approach. In general, the anterior supine approach allows bilateral adrenalectomy without having to reposition the patient. The lateral position is advantageous because greater

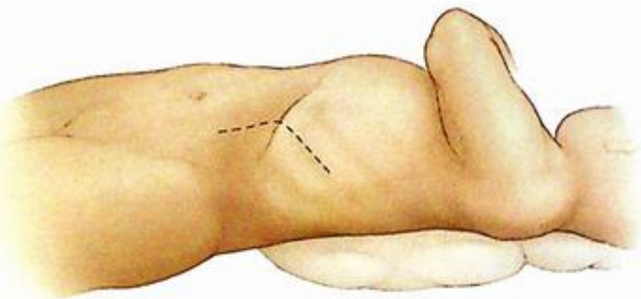

Figure 54–13. Positioning for thoracoabdominal surgery. A body roll elevates the flank on the side of surgery, and the arm and shoulder are rotated away, supported by a sling.

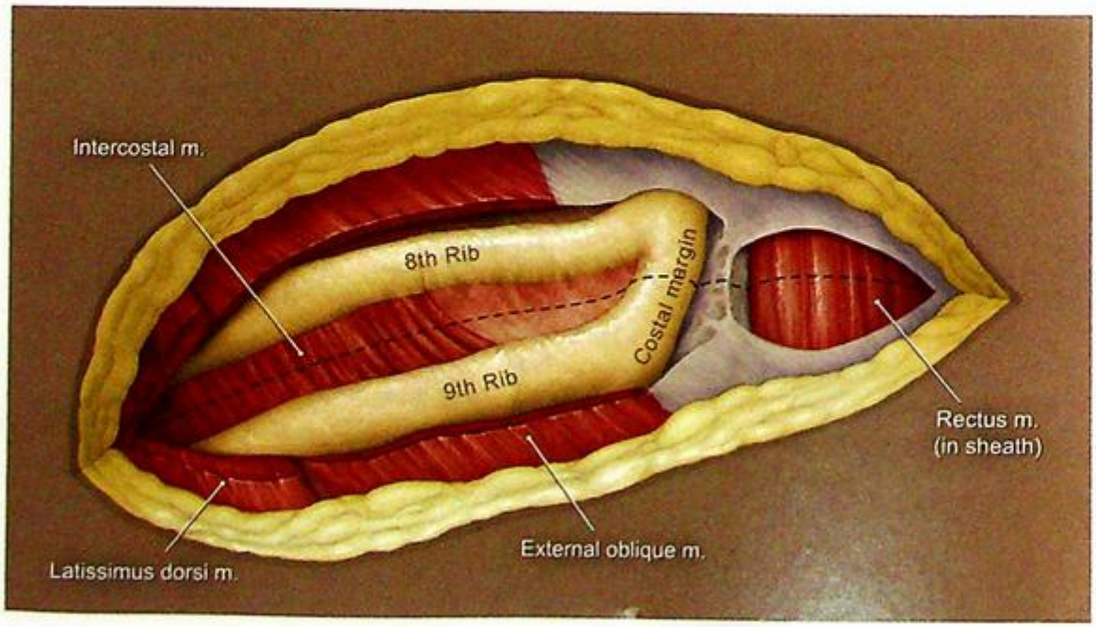

Figure 54–14. Thoracoabdominal approach. Incision at the eighth intercostal space. The costal margin, external intercostal muscle and fascia, and anterior rectus sheath are divided.

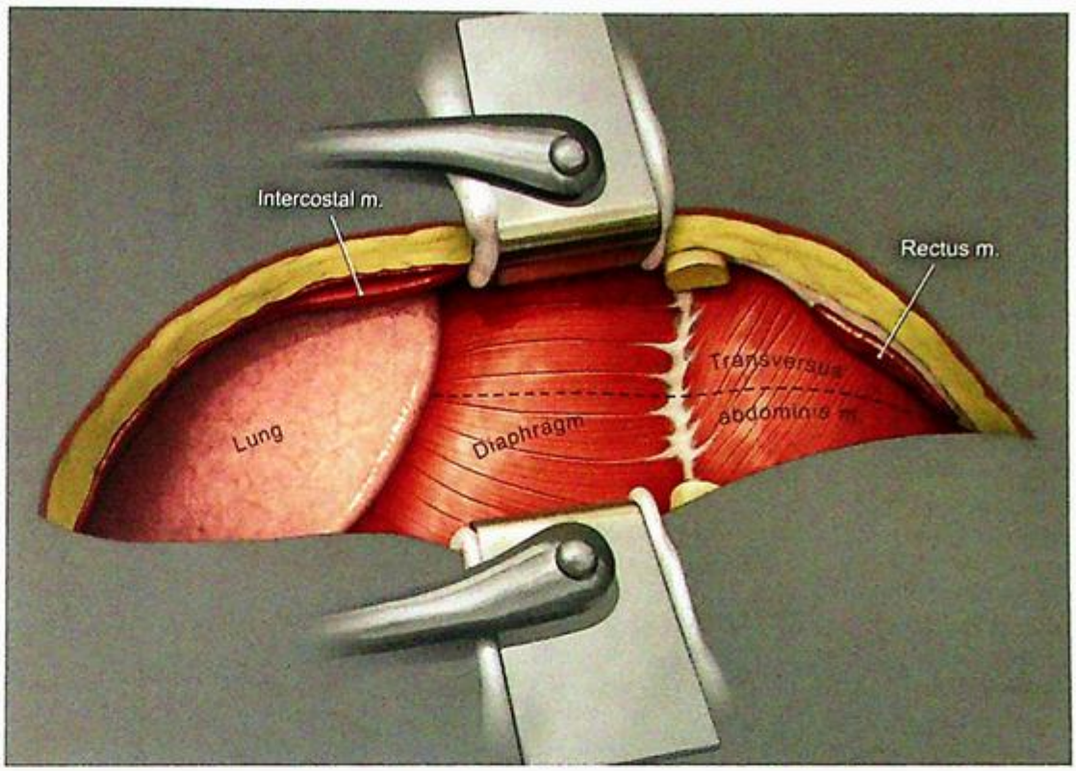

Figure 54–15. Thoracoabdominal approach. The Finochietto retractor is placed to expose the anatomy. The lung visible in this view is packed away with laparotomy sponges.

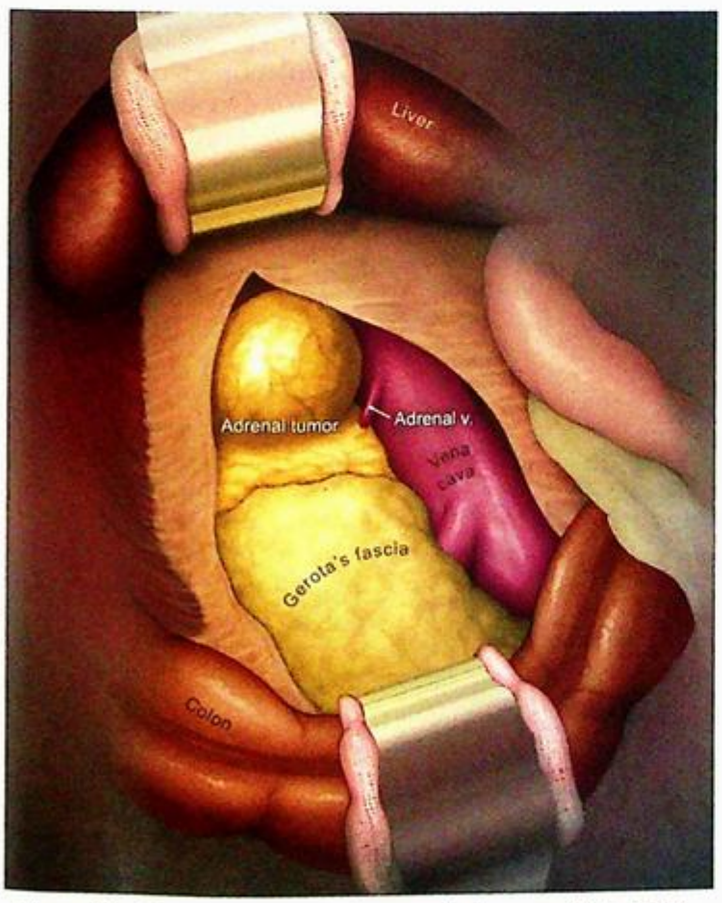

Figure 54–16. Thoracoabdominal approach. Exposure of the adrenal.

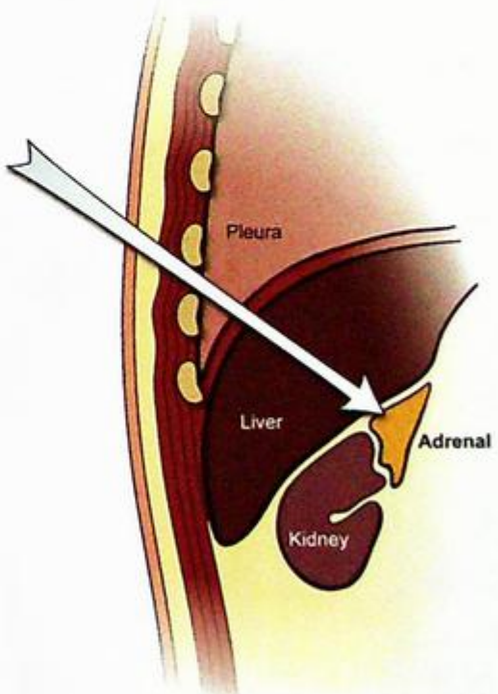

Figure 54–17. Demonstration of the route of surgical dissection during thoracoabdominal incision.

workspace is available secondary to gravity-assisted retraction of the bowel. The flank approach is described in detail.

Left Side. The patient is positioned in a modified flank position. The patient is angled back about 30 to 45 degrees. After insufflation of the abdomen, four trocars are placed along the left costal margin (Fig. 54–18). The line of Toldt is incised and the left colon medially mobilized (Fig. 54–19). The lienorenal and splenocolic ligaments are divided. The lateral and superior attachments of the spleen can be divided to facilitate medial mobilization of the spleen if necessary. In many cases, the spleen may fall away sufficiently by gravity without having to extend the dissection above the spleen. The renal vein and adrenal vein are dissected free (Fig. 54–20). The left adrenal vein is dissected out, ligated, and divided (Fig. 54–21). Surgical clips are used to control the adrenal vein. It is advisable to leave two clips on the body side of the vein and one on the specimen side. Adrenal arterial supply is divided as the adrenal is dissected free (Fig. 54–22). The harmonic scalpel is effective for performing this dissection. The remaining attachments to the kidney are divided bluntly and with the hook cautery (Fig. 54–23). The specimen is placed in an endoscopic sac and extracted (Fig. 54–24).

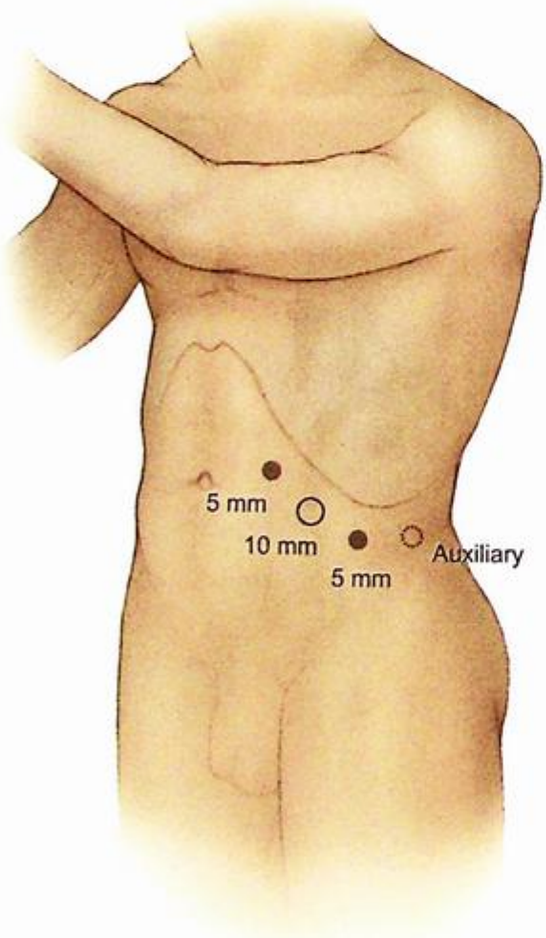

Figure 54–18. Four-trocar configuration for left transperitoneal laparoscopic adrenalectomy.

The operative field is examined with the insufflation pressure turned down to 5 mm Hg. If it is hemostatic, the trocar sites are closed with absorbable suture. A drain usually does not need to be placed.

On the right side, the approach is similar. However, the duodenum must be dissected away by the Kocher maneuver. As on the left side, a four-trocar configuration is used (Fig. 54–25). The most medial trocar is used for liver retraction. A 2-mm trocar can be used with a 2-mm locking grasper to fashion a self-retaining retractor of the liver (Fig. 54–26).

Retroperitoneal Approach

Left Side. The patient is placed in flank position with the left side up. The patient is placed in flexion, and the kidney rest is deployed to accentuate the left flank. A 12-mm incision is made near the tip of the 12th rib under the 11th rib. The underlying muscle and fasciae are divided with cautery until the lumbodorsal fascia is visible or palpable. The lumbodorsal fascia is divided with cautery or Metzenbaum scissors, and blunt finger dissection is used to develop a plane between the posterior Gerota's fascia and the psoas fascia. With this plane developed, a retroperitoneal dissection balloon is placed and inflated. Typically, a laparoscope can be placed down the hollow shaft of the dissection balloon to visually confirm the accurate anatomic placement of the balloon between the kidney and psoas. A balloon-tip trocar is placed into the defect and secured in position. After insufflation of the retroperitoneum, a 5- or 10-mm trocar is placed at the angle of the paraspinal muscle and the origin of the 12th rib. A 5- or 10-mm trocar is placed about two fingerbreadths above the iliac crest near the anterior superior iliac spine (Fig. 54–27).

The renal hilum is usually located fairly rapidly in the retroperitoneal approach by direct visualization of arterial pulsations. The left adrenal vein can be isolated from its origin on the left renal vein (Fig. 54–28). The left adrenal vein is dissected out and ligated with surgical clips and divided (Fig. 54–29). The left adrenal gland is then dissected out as described previously; small arterial branches can be clipped or divided hemostatically with a harmonic scalpel. The specimen is placed in a specimen bag and extracted. The trocar sites are closed with absorbable suture after hemostasis is ensured. The right adrenalectomy is performed in similar fashion; anatomic relations of this approach are illustrated in Figure 54–30.

HAND-ASSISTED SURGERY

The advantage of hand assistance stems from the addition of tactile sensation. This may result in faster dissection and added security in the event of bleeding complications. Also, the learning curve may be shorter with hand assistance. Only case reports exist regarding hand-assisted laparoscopic adrenalectomy. This may be especially advantageous for large adrenal tumors that may require an incision for extraction. Bilateral tumors may also be treated in this fashion.

ROBOTIC SURGERY

Robotic-assisted laparoscopic adrenalectomy has been performed with the da Vinci surgical robotic system.* The robot provides handlike dexterity to laparoscopic surgery. The case reports of a total of five patients were completed successfully without complication, except for one case with a minor capsular tear (Undre et al, 2004).

INTRAOPERATIVE ULTRASONOGRAPHY

It can be difficult at times to locate the adrenal gland, especially if the patient is obese and there is a lot of intra-abdominal fat. Without tactile feedback, unless the lesion is grossly evident, it can be difficult to localize the adrenal gland during surgery. Ultrasonography of the adrenal gland is extremely difficult as an extracorporeal technique. The ability to directly apply the ultrasound probe to the operative area under laparoscopic guidance facilitates identification of the adrenal gland. Furthermore, **intraoperative ultrasonography can help identify the adrenal vein,** especially on the left side.

Brunt and coworkers (1999) used intraoperative ultrasonography in 28 adrenalectomies and had 100% success in identifying the adrenal gland. Lucas and associates (1999) had similar success with 42 adrenalectomies.

Intraoperative ultrasonography is especially helpful in laparoscopic partial adrenalectomy. It can delineate the tumor within the adrenal gland to facilitate adrenal-sparing surgery. Pautler and colleagues (2002) successfully performed laparoscopic partial adrenalectomy on seven patients with ultrasound assistance. There were no complications and no open conversions.

POSTOPERATIVE MANAGEMENT

Electrolyte values are checked the night of surgery and each morning; this is especially important for patients with Conn's or Cushing's syndrome. The urinary catheter can usually be removed on the first postoperative day when the patient is ambulatory. If a nasogastric tube was placed for open surgery, it can be removed with return of bowel sounds. Diet resumption is usually started on the first postoperative day for laparoscopic surgery and when bowel sounds resume for open surgery.

Blood pressure is carefully evaluated for hypertension or hypotension. Unexplained hypotension, confusion, lethargy, nausea, vomiting, or fever could represent addisonian crisis (adrenal insufficiency). **Adrenal insufficiency is most commonly seen after surgery for Cushing's syndrome as a result of contralateral cortisol suppression.** Stress-dose steroid administration may be necessary. Corticosteroid replacement and mineralocorticoid (fludrocortisone) may be required for the long term. Hospital stay may be prolonged by the necessary adjustment of antihypertensive medications and steroids.

OUTPATIENT AND SHORT-STAY LAPAROSCOPIC ADRENALECTOMY

In select patients who underwent uneventful surgery, same-day or less than 24-hour hospital discharge has been attempted. Gill and colleagues (2000) were able to discharge 9 of 27 patients who underwent laparoscopic adrenalectomies within 8 hours of surgery. One patient was readmitted for

*Intuitive Surgical, Mountain View, Calif.

abscess formation. Edwin and coworkers (2001) described 13 patients with aldosteronoma who underwent laparoscopic adrenalectomy. All were discharged within 3 to 6 hours of surgery. None was readmitted. The satisfaction of patients was high for all but one patient who had poorly controlled pain after discharge. Rayan and Hodin (2000) performed 19 laparoscopic adrenalectomies and were able to discharge 47% of patients within 24 hours.

OUTCOMES

Retrospective studies demonstrate a clear advantage to laparoscopic surgery over open surgery in terms of analgesia, hospital stay, blood loss, and complication rate. The laparoscopic surgeries typically had longer operative times than the open surgery did. There are no randomized prospective studies comparing laparoscopic with open adrenalectomy. In a rare non-randomized prospective study, Prager and colleagues (2004) assigned patients to laparoscopic or open surgery on the basis of a cutoff of 6 cm; lesions smaller than 6 cm were removed laparoscopically. As one would expect, operative times, complication rate, and blood loss were higher in the open surgery group. It is difficult to compare these two groups fairly since the patients assigned to open surgery had larger tumors and a higher incidence of malignant disease (1.9% versus 29.1%) than the laparoscopic cohort did.

Comparison of retroperitoneal with transperitoneal laparoscopy tended to favor the retroperitoneal approach. Bonjer and colleagues (1997) showed an advantage in operative time (75 minutes versus 150 minutes; $P = .005$), blood loss (20 mL versus 150 mL; $P = .01$), postoperative analgesia (6 mg versus 20 mg of morphine sulfate; $P = .003$), and hospital stay (4 versus 6 days; $P = .027$) for retroperitoneal over transperitoneal approach. Suzuki and coworkers (2001) also found less blood loss, shorter convalescence, and faster resumption of oral intake with retroperitoneal surgery than with anterior and lateral transperitoneal procedures. Interestingly, the authors initially attempted to perform a prospective randomized study, but patients expressed strong preference for retroperitoneal surgery.

Is laparoscopic adrenalectomy too costly? In the current era of soaring medical costs, the cost-effectiveness of laparoscopic surgery must be proven to justify its use. Initially, the cost of laparoscopic adrenalectomy was much higher than the cost of open surgery. Thompson and colleagues (1997) noted that hospital charges for laparoscopic adrenalectomy were $1000 higher than for open adrenalectomy. With increased use of disposables and with growing surgical experience, the costs are becoming manageable. Hobart and colleagues (1999) have shown that with 2-mm instrumentation, laparoscopic adrenalectomy resulted in 17.9% less cost than open adrenalectomy. The laparoscopic adrenalectomy had an 18.1% increased intraoperative cost but a 63.4% less postoperative cost. In Spain, Ortega and associates (2002) calculated that laparoscopic adrenalectomy was not more expensive in terms of direct surgical cost (€6306 versus €7581; P = NS). However, hospital stay was significantly shorter and cheaper (€742 versus €1191; $P = .004$). Interestingly, the most expensive part of the entire therapeutic process was the preoperative hospitalization for diagnostic workup. In the United States, most diagnostic tests are carried out on an ambulatory outpatient basis, and these costs would be considerably less. Outside of the direct cost of surgery and hospitalization, laparoscopic adrenalectomy is often less expensive than long-term medical therapy for certain adrenal disorders. In Canada, aldosteronoma management with surgery represents a savings of C$31,132 over the lifetime of each patient (Sywak and Pasieka, 2002).

COMPLICATIONS

Operative Complications (Table 54–4)

As expected, adrenal surgery, both open and laparoscopic, can involve injury to adjacent organs. Hemorrhage is a potentially catastrophic complication of adrenal surgery. Bleeding can result from injury to the adrenal vein, inferior vena cava, lumbar vein, or renal vein. These injuries are managed initially by application of direct pressure to the injury. Grasping a small injury with an Allis clamp and closing it with suture or by placement of a vascular clamp for a larger vena cava injury may be curative. For laparoscopic cases, the management is more of a problem. In the early days of laparoscopic adrenalectomy, open conversion was the typical consequence of vascular injury. However, with increasing experience with laparoscopic suturing techniques, these injuries are often managed as in the open surgery.

Nonhemorrhagic vascular injuries can occur as well. An upper pole renal artery branch can be divided inadvertently during dissection. If the branch is small and supplies a minimal portion of the kidney, it can be ignored. More substantial injuries may require a revascularization attempt. If the patient has a large tumor, there can be distortion of the regional anatomy, and inadvertent ligation of the superior mesenteric vein is possible. This is a potentially fatal injury, and one must have a high index of suspicion to restore vascular supply to the bowel as soon as possible.

Table 54–4. Operative Complications of Adrenal Surgery

Hemorrhage

Kidney

From Vaughn ED: Complications of adrenal surgery. In Taneja SS, Smith RB, Ehrlich RM, eds: Complications of Urologic Surgery: Prevention and Management, 3rd ed. Philadelphia, WB Saunders, 2001:366.

The adjacent organs can be injured during dissection of the adrenal gland. The liver can be injured during right adrenalectomy. Liver lacerations can be treated with argon beam coagulation and application of hemostatic agents such as methyl cellulose. More serious injuries may require hemostatic sutures with a blunt-tip liver needle. The spleen can be injured during left adrenalectomy. As with hepatic injury, argon beam coagulation and hemostatic agents can be used to control bleeding. If this is not sufficient, splenorrhaphy can be attempted. If these measures are unsuccessful, splenectomy may be necessary. It is important to remember to give pneumonia vaccination to these patients during postoperative care.

The pancreas can be injured during surgery on either the right or left adrenal gland. If an injury to the tail of the pancreas occurs, distal pancreatectomy may be performed. If the injury is to the pancreatic duct, this may be repaired and surgical drains left. If there is uncertainty of pancreatic injury, leaving closed-suction surgical drains behind is advisable. Postoperative drainage high in triglycerides is indicative of pancreas injury. Management consists of bowel rest with parenteral nutrition. The administration of octreotide can decrease pancreatic secretions while the pancreas heals.

The proximity of the kidney to the adrenal gland can be a problem in cases of large adrenal cortical carcinomas. **It is imperative for all patients undergoing surgery for large adrenal masses to be counseled about the possibility of concurrent en bloc nephrectomy.**

During 11th rib flank adrenalectomy, it is not unusual for pleural injury to be incurred. These injuries can be repaired with a purse-string chromic suture and a red rubber catheter to water seal. Expulsion of air from the pleura followed by cinching of the purse-string usually repairs the defect. Postoperative chest radiography should be routinely performed after flank or thoracoabdominal nephrectomy. If a significant pneumothorax is present, a chest tube should be placed.

With pheochromocytoma, blood pressure fluctuations can be life-threatening. The anesthesiologist typically manages high blood pressure with short-acting β blockade, α blockers, or nitroprusside. Arrhythmias are usually treated with β blockers. When the adrenal vein is ligated, there can be a sudden drop in blood pressure. It is important to inform the anesthesiologist just before the adrenal vein is ligated to avoid any nasty surprises. Fluid repletion and pressors may be necessary to bring the pressure to normal.

Postoperative Complications

Table 54–5 summarizes the postoperative complications that can occur. Disease-specific complications must be accounted for to ensure an uneventful postoperative course.

Patients with primary hyperaldosteronism require close monitoring of potassium levels as they can be either hypokalemic or hyperkalemic. Hyperkalemia, secondary to contralateral adrenal zona glomerulosa suppression, should be managed medically with the typical hyperkalemia regimens. Hypokalemia can persist in the immediate period after adrenalectomy, and this should be corrected with potassium repletion. In patients who had only one adrenal gland to begin with, mineralocorticoid replacement with fludrocortisone is essential.

Table 54–5. Postoperative Complications of Adrenal Surgery

Primary aldosteronism
Hypokalemia: secondary to continued potassium loss immediately postoperative
Hyperkalemia: secondary to failure of contralateral adrenal to secrete aldosterone
Cushing's syndrome
Inadequate steroid replacement leading to hypocorticoidism
Fracture secondary to osteoporosis
Hyperglycemia
Poor wound healing
Increased risk of infections
Pheochromocytoma
Hypotension secondary to α-adrenergic blockade after tumor removal
Generic complications
Hemorrhage
Inferior vena cava
Adrenal arteries
Pneumothorax
Pancreatitis
Pneumonia
Hiccups

From Vaughn ED: Complications of adrenal surgery. In Taneja SS, Smith RB, Ehrlich RM, eds: Complications of Urologic Surgery: Prevention and Management, 3rd ed. Philadelphia, WB Saunders, 2001:368.

Patients with Cushing's syndrome will require steroid replacement after surgery until the contralateral gland recovers function. Measurements of plasma cortisol can be useful in determining when steroid replacement can be tapered. Furthermore, these patients have increased risk of fracture secondary to osteoporosis, hyperglycemia, and poor wound healing.

Patients with pheochromocytoma may have hypotension secondary to α blockade. These patients need to be monitored closely until α blockade wears off, often in the intensive care unit. If α blockade was not used preoperatively, as it is done at the Cleveland Clinic, intensive care stay is unnecessary in most cases.

Laparoscopy Versus Open Adrenalectomy

Brunt (2002) compiled the complication statistics of 50 laparoscopic studies and 48 open studies to evaluate the impact of laparoscopy on adrenalectomy. To limit selection bias, open surgical series with adrenal cortical carcinoma cases were excluded. Laparoscopy resulted in a lower complication rate (10.9% versus 25.2%; $P \leq .0001$) than did open adrenalectomy. Specifically, **pulmonary, wound, and infectious complications were statistically less common with laparoscopic surgery.** There were also fewer injuries to adjacent organs (0.7% versus 2.4%; $P = .05$). Splenic injuries decreased dramatically in incidence (laparoscopic, 0.2%; open, 2.0%). A number of factors account for this decrease, including

division of the splenocolic and lienorenal ligaments under magnification and the assistance of gravity in retracting the spleen rather than manual retraction. With retroperitoneal surgery, the spleen would not even be in the surgical field to be injured. A decrease in cardiac complications was observed, but some of the improvement in complication rate was thought to be attributable to improvements in perioperative management of vasoactive tumors. The most common complication of laparoscopic adrenalectomy is bleeding (4.7%). Bleeding is also the most common reason for open conversion of laparoscopic adrenalectomy (30%). Bleeding results from vascular injury to the adrenal vein, injury to the vena cava, direct injury to the adrenal gland, renal capsular tear, or surgical clip dislocation.

SPECIAL CONSIDERATIONS

Pediatric

There are relatively few cases of laparoscopic adrenalectomy for pediatric patients. The small body habitus of the patients makes surgery more technically challenging. Neuroblastoma is the most common adrenal tumor in this age group, and this tumor tends to be large and infiltrative, complicating laparoscopic extraction.

Nevertheless, laparoscopic surgery has been successfully performed on pediatric patients. The first case was performed on a small asymptomatic neuroblastoma identified by mass screening of children in Japan (Yamamoto et al, 1996). Comparing open with laparoscopic biopsies and excisions, Iwanaka and colleagues (2001) showed that laparoscopy was associated with shorter hospitalization and rapid resumption of diet. Bilateral laparoscopic adrenalectomy can be performed safely as well (Schier et al, 1998).

In financial terms, laparoscopic adrenalectomy is cost-saving when postoperative stay is accounted for (Stanford et al, 2002). Even though laparoscopic adrenalectomy was more expensive as a procedure ($12,941 versus $4,714; $P < .001$), the overall cost difference between the two procedures was statistically insignificant.

Pregnancy

The pregnant patient can present with an endocrinologically active adrenal tumor. Pheochromocytoma must be distinguished from preeclampsia or pregnancy-induced hypertension, a more medically accurate term. The main distinguishing factors are the absence of proteinuria in pheochromocytoma and the fact that pregnancy-induced hypertension tends to occur in the third trimester. When pheochromocytoma is diagnosed late in pregnancy, the pregnancy can be taken to term with medical management and the child delivered by cesarean section. If pheochromocytoma is diagnosed in the first or second trimester, the risk of surgery must be weighed against the risk of the pheochromocytoma to the pregnancy.

Laparoscopic adrenalectomy can be successfully performed on a pregnant patient. Several reports exist of successful surgery. Maneuvers to minimize risk include keeping insufflation pressure below 15 mm Hg, using open Hasson technique to gain access, and monitoring fetal heart rate and maternal arterial blood gases.

Partial Adrenalectomy

The main indications for partial adrenalectomy are solitary adrenal gland, bilateral disease, and patients with familial syndromes. Pheochromocytoma has been treated with partial adrenalectomy, especially in patients with von Hippel–Lindau syndrome (Al-Sobhi et al, 2002; Baghai et al, 2002), familial pheochromocytoma, or multiple endocrine neoplasia type IIA (Brauckhoff et al, 2004, Sackett and Bambach, 2003). Aldosteronomas have been removed laparoscopically (Sasagawa et al, 2000; Jeschke et al, 2003).

Partial adrenalectomy is usually performed with an endoscopic stapler. Dividing the adrenal vein does not affect viability of the adrenal gland, so it can be taken with the mass. However, Sasagawa and colleagues (2000) described a technique using the ultrasonic scalpel. Intraoperative ultrasonography can help identify the mass to facilitate surgery (Pautler et al, 2002).

NONSURGICAL ALTERNATIVES

Radiofrequency Ablation

Radiofrequency ablation has been used successfully to treat adrenal lesions, primarily adrenal metastases (Rohde et al, 2003) or metastases of adrenal cortical carcinoma (Abraham et al, 2003; Wood et al, 2003) and malignant pheochromocytoma. In the largest series to date, Mayo-Smith and Dupuy (2004) described performing 13 procedures on 12 patients without incident. These procedures can be safely and comfortably employed on an outpatient or overnight-stay basis. However, life-threatening hypertension has been reported in one case of adrenal ablation (Chini et al, 2004). The lesion may have been a pheochromocytoma. Unfortunately, no pathologic examination or preoperative workup for vasoactive adrenal masses was performed. Presumably, **catecholamine release can be caused by thermal injury to the adrenal in the absence of pheochromocytoma.** Onik and colleagues (2003) described their experience with two cases of hypertensive crisis in patients undergoing hepatic radiofrequency ablation. Both cases involved radiofrequency ablation of the posterior right lobe of the liver, close to the right adrenal. In one patient in whom catecholamine levels were measured, the values were 10-fold greater than the upper limit of normal.

Cryoablation

The clinical experience with cryoablation is fairly limited (Munver and Sosa, 2004). Canine experiments have confirmed that cryotherapy can be delivered to the adrenal gland effectively (Schulsinger et al, 1999). Furthermore, the ability to observe the ice ball under ultrasound examination in a live dynamic fashion allows it to be applied in a controlled, reproducible fashion.

KEY POINTS: SURGERY OF THE ADRENAL GLANDS

- Laparoscopic adrenalectomy is the current standard of care for adrenal lesions with the exception of invasive adrenocortical carcinoma or adrenocortical carcinoma with caval thrombus.
- Preoperative computed tomography can help distinguish invasive from noninvasive adrenocortical carcinoma.
- Percutaneous ablative technologies are an increasingly attractive alternative to surgery for small incidental masses.
- If you suspect pheochromocytoma, avoid percutaneous ablation because of the risk for catecholamine release.
- Open adrenal surgery is reserved for lesions not amenable to minimally invasive techniques (i.e., invasive, large carcinomas, or carcinoma with caval involvement).
- When operating on patients for large invasive adrenocortical carcinoma, be sure to obtain consent for possible en bloc resection of adjacent organs.

treatment of, 2118-2119, 2122
voiding dysfunction in, 2037-2038
Detumescence. *See* Penile detumescence.
Developmental milestones, in children, 3210, 3211t

Dexamethasone
for hormone-refractory prostate cancer, palliative, 3113
for painful bladder syndrome/interstitial cystitis, 364
prenatal treatment with, for congenital adrenal hyperplasia, 3819
Dexamethasone suppression test, for Cushing's syndrome, 1833-1834, 1834f
Dextranomer hyaluronic copolymer, for endoscopic correction of reflux, 4364t, 4365
Dextranomer microspheres, injection of, for incontinence, 2286
DHH gene, in 46,XY complete gonadal dysgenesis, 3813
DHIC (detrusor hyperactivity with impaired contractility), in elderly, 2310
Diabetes insipidus, nephrogenic, in children, 3229
Diabetes mellitus
after renal transplantation, 1298, 1324
erectile dysfunction and, 746-747, 747t
PDE-5 inhibitors for, 775
in chronic renal failure, 1358-1359
urinary tract infections and, 236
voiding dysfunction in, 2012t, 2033-2035
Diacylglycerol, in ureteral smooth muscle contraction, 1901-1902
Diagnostic algorithms, for male infertility, 619-623, 620t
absent or low-volume ejaculate and, 619, 620f, 620t, 621
asthenospermia and, 622-623, 622f
azoospermia and, 621-622, 621f
normal seminal parameters and, 623
oligospermia and, 622
seminal parameter defects and, 623
teratospermia and, 623
Diagnostic markers, for painful bladder syndrome/interstitial cystitis, 353-354
Dialysis. *See* Hemodialysis; Peritoneal dialysis.
Dialysis membranes, classification of, 1339
Dialysis Outcomes and practice Patterns (DOPPS) study, 1354-1355
Diapedesis, 493
DIAPERS mnemonic, for incontinence, 2306, 2307t
Diaphragm
injury to, laparoscopic renal surgery causing, 1807-1808
pelvic, 2191-2192, 2191f, 2192f
urogenital, 68-69, 69f, 2192-2194, 2193f
Diaphragmatic hernia, as contraindication to laparoscopy, 175
Diarrhea
antibiotic bowel preparation causing, 2539
chronic
after augmentation cystoplasty, 3680
hypocitraturic lithiasis and, 1404
management of, 1422-1423
hemolytic-uremic syndrome associated with, 3227-3228
Diathesis
bleeding, ureteroscopic management of, 1520-1521
gouty, 1405, 1405f
treatment of, 1424
Diazepam, for prostatitis, clinical trial data on, 322
Dicyclomine, for overactive bladder/detrusor overactivity, 2093t, 2102
Diet
benign prostatic hyperplasia and, 2745
prostate cancer and, epidemiologic studies of, 2862
Dietary bran, for nephrolithiasis, 1419
Dietary calcium, in nephrolithiasis, 1414-1415
Dietary factors, in prevention of bladder cancer, 2443-2444
Dietary fat, prostate cancer and, epidemiologic studies of, 2862-2872
Dietary hyperoxaluria, 1378, 1403
Dietary maneuvers, for incontinence, 2129
Dietary restrictions
for chronic renal failure, 1350
for nephrolithiasis, 1412-1413
for painful bladder syndrome/interstitial cystitis, 358-359, 359t
of protein, after partial nephrectomy, 1613-1614
Diethylcarbamazine, for filariasis, prophylactic, 458
Diethylstilbestrol, in utero exposure to, 611
Dietl's crisis, in nephrotosis, 1776
Differential display technology, in diagnosis of oncology, 548-549
Diffuse mesangial sclerosis, congenital nephrosis with, 3328-3329
characteristics of, 3314t
Digital rectal examination, 93-94
for benign prostatic hyperplasia, 2767
for prostate cancer, 2922-2923
routine use of, 2913
tumor staging with, 2929-2930
of prostate, 313-314
Digital video recorders, in laparoscopic surgery, 190
Digoxin
erectile dysfunction caused by, 745
for priapism, 846t
Dihydrotestosterone. *See also* Testosterone.
circulation of, 3084, 3085t
conversion of testosterone to, 767
daily application of, before hypospadias repair, 3711
fetal secretion of, 3804
for erectile dysfunction, 772
for late-onset hypogonadism, 858
in benign prostatic hyperplasia, 2729
in epididymis, 603-604
in prostate, 2678-2679, 2684, 2686t, 2687f
influence of, 2863-2864
levels of, 2728-2729, 2729f
in testicular descent, 3766-3767
Dihydroxyadenine calculi, 1387
Dilatation
balloon. *See* Balloon dilatation.
manual, in laparoscopic surgery, 182
of fetal bladder, 3574
of nephrolithotomy tract, 1491-1494, 1492f-1494f
of nephrostomy tract, 1541-1544
guide wire entry in, 1541-1542
novel methods in, 1543-1544
types of dilators in, 1542-1543, 1542f, 1543f
of ureters, 1511t, 1512, 1512f. *See also* Megaureter(s).
urethral. *See* Urethral dilatation.
Diltiazem, for incontinence, in elderly, 2317t
Dimercaptosuccinic acid, scanning with, in pediatric renal injury, 3932
Dimethyl sulfoxide
for overactive bladder/detrusor overactivity, 2106
for painful bladder syndrome/interstitial cystitis, 362t, 363
Diode laser, in treatment of benign prostatic hyperplasia, 2821
Dip slide test, for urine culture, 240, 240f
Diphallia, 3757
Diphenoxybenzamine, for prostatitis, 321
Dipstick testing
for hematuria, 98
for ketones, 104
in urinalysis, 97
Direct surface plating, for urine culture, 240
Disc kidney, 3284f, 3285-3286
Discomfort, post-biopsy, 2892
Dismembered pyeloplasty, for ureteropelvic junction obstruction, 1242-1243, 1243f, 1244f
in children, 3370, 3372f, 3373
laparoscopic, tubularized flap technique of, 1253
Dissecting aneurysm, of renal artery, 1187, 1188f
Dissection, anterior, for continence preservation after orthotopic diversion
in female patient, 2623
in male patient, 2622-2623
Distal procedure, in hypospadias repair, 3722-3725
advancement techniques for, 3722, 3723f
flap techniques for, 3725, 3726f-3727f
other techniques for, 3725
tubularization techniques for, 3722-3723, 3724f, 3725
Distigmine, to facilitate bladder emptying, 2115
Diuresis
effect of, on ureteral function, 1909
physiologic postnatal, 3156
postobstructive
clinical management of, 1214
experimental modulation of, 1214
mechanisms of, 1213-1214
Diuretic scintigraphy, 141f-142f, 142-143
Diuretics. *See also* Thiazides.
erectile dysfunction caused by, 743, 744t
for calcium oxalate nephrolithiasis, 1421t
for hypercalciuria, 1419
for nocturnal enuresis, 2114
loop, for acute renal failure, 1336
renal cell carcinoma associated with, 1584
Diverticulectomy
bladder
complications of, 2371
intravesical and extravesical approach to, 2369, 2371, 2372f
laparoscopic, 2511-2512, 2511f
transvesical approach to, 2369, 2369f-2371f
laparoscopic, 1778
urethral, in females, 2385-2389
complications of, 2388, 2388t, 2389f
excision and reconstruction in, 2385-2386, 2385t
indications for, 2385, 2386f
postoperative care in, 2388
preoperative preparation in, 2386
symptoms persistence after, 2388-2389
technique in, 2386-2388, 2387f
Diverticulum(a)
bladder. *See* Bladder diverticulum(a).
calyceal, 3354. *See also* Renal calyx (calyces), diverticula of.
paraureteral, in children, 3579-3580, 3579f
urachal, 3577f, 3579

Electrohydraulic (spark gap) generator, for shockwave lithotripsy, 1465, 1465f, 1466t, 1470t
Electrohydraulic lithotripsy, 1458-1460, 1459f, 1513-1514
advantages and disadvantages of, 1459-1460
technique of, 1460
Electrolyte(s)
abnormalities of, conduit urinary diversion causing, 2570-2573, 2571f, 2571t
management of
in neonate, 3156, 3157f
postoperative, in renal transplant recipient, 1312-1313
Electromagnetic generator
for shockwave lithotripsy, 1465, 1467t, 1468, 1468f
imaging and financial aspects of, 1470t-1471t
Electromagnetic therapy, for incontinence, 2136
Electromyography
corpus cavernosum, in erectile dysfunction, 767
equipment for, 1989-1990
in urodynamic studies, 2002
of urethral sphincter, 3626-3627, 3628f
sphincter, 2068
Electronic dip stick flowmeter, 1989
Electronic spread, of current, 1897
Electrosurgical devices, bipolar, in laparoscopy, 192
Elephantitis
penile, 457
scrotal, 456, 456f, 457
Onchocerca volvulus causing, 455
treatment of, 458
El-Ghorab shunt, for priapism, 847f, 848
Elimination syndrome, dysfunctional, of childhood, 3611, 3613
ELISA (enzyme-linked immunosorbent assay)
for antisperm antibodies, 624t
for HIV infection, 393
Elsberg syndrome, 2033
Embolization
arterial, for nonischemic priapism, 848
of pseudoaneurysm, 1546-1547, 1547f
percutaneous, in varicocele repair, 662-663
Embolus (embolism)
carbon dioxide, pediatric laparoscopy and, 3917
gas, with pneumoperitoneum, 205
pulmonary, due to radical retropubic prostatectomy, 2973
renal artery, 1190, 1190t
cholesterol, 1166
Embryonal carcinoma, testicular, 895
incidence, pathology, and presentation of, 897t
Embryonal rhabdomyosarcoma, 3879
Emissary vein(s), 723, 723f

Emphysema
insufflation-related, laparoscopic renal surgery causing, 1807
subcutaneous, with pneumoperitoneum, 205-206
Encephalomyelitis, acute disseminated, voiding dysfunction in, 2036
Encephalopathy, Wernicke's, voiding dysfunction in, 2042
Endemic bladder calculi, 2663-2664
Endocarditis. *See* Bacterial endocarditis.
in pediatric genitourinary procedures, 3242t
Endocrine signals, in prostate, 2690, 2690f
Endocrine system
effect of
on male infertility, 635-638
on prostate growth, 2684-2689
in testicular descent, 3766-3768
Endocrine/paraendocrine mechanisms, in renin-angiotensin-aldosterone system, 1162
Endogenous inhibitors, of angiogenesis, 544
Endometriosis
definition of, 1220
painful bladder syndrome/interstitial cystitis and, 351
ureteral obstruction due to, 1220-1221
within urethral diverticula, 2389
Endometrium, biopsy of, in evaluation of fertility, 612
Endopelvic fascia, 2194-2195
incision of, in radical retropubic prostatectomy, 2960-2961, 2961f
Endopyelotomy
antegrade, for ureteropelvic junction obstruction
complications of, 1236-1237
in children, 3374-3375, 3375f
indications for and contraindications to, 1233, 1233f
patient preparation in, 1233
postoperative care following, 1234, 1236
results of, 1236
simultaneous nephrolithotomy with, 1234
technique of, 1233-1234, 1235f, 1236f
cautery wire balloon, for ureteropelvic junction obstruction
complications of, 1238-1239
indications for and contraindications to, 1237, 1237f
postoperative care following, 1237
results of, 1237-1238
technique of, 1237, 1238f
in children
access for, 3913
incision for, 3913
indications for, 3912-3913
results of, 3913
ureteroscopic, for ureteropelvic junction obstruction
complications of, 1241
indications for and contraindications to, 1239
results of, 1241
success of, 1522
technique of, 1239, 1240f, 1241
Endoscope(s), pediatric application of, 3908t
Endoscopic lithotripsy, for bladder calculi, 2669-2670
Endoscopic resection, of urothelial tumors, 1647-1648
percutaneous approach to, 1648
results of, 1648, 1648t
Endoscopy
antegrade, of urothelial tumors, 1645
antibiotic prophylaxis for
of lower urinary tract, 252
of upper urinary tract, 253
in bladder cancer, non–muscle-invasive
office-based, 2454
therapeutic, 2450-2454
in incontinent patient, 2069-2070
in laparoscopy, 177
in prostatitis, 316
in surgical approach, to seminal vesicles, 1125
in vesicoureteral reflux, 4362-4366
emerging role of, 4348
follow-up of, 4363-4364
materials for, 4364-4365, 4364t
reflux recurrence after, 4365-4366
STING technique of, 4362-4363, 4363f
of bladder diverticula, 2365, 2366f
of cloacal anomalies, 3852
of ureterocele, 3406
of ureteropelvic junction obstruction, in children, 3374-3375, 3375f
of urethral strictures, 2660
of urogenital sinus anomalies, 3851, 3852f
of urothelial tumors, 1672-1680
basic attributes of, 1672, 1673f, 1674f
biopsy and definitive treatment in, 1675, 1676f, 1677f
collection of urine in, 1674-1675
percutaneous approach to, 1677-1680
biopsy and definitive treatment in, 1678, 1679f, 1680f
establishment of nephrostomy tract in, 1677-1678, 1677f, 1678f
results of, 1679-1680
second-look nephroscopy in, 1679
results of, 1675, 1677
steps in, 1674-1675, 1676f, 1677f
technique and instrumentation in, 1673-1674, 1674f
ureteral injury due to, in children, 3937
Endothelial barrier, traversing, 493-494
Endothelial cell(s)
adhesion molecule expression on, 493
T cell interaction with, 493, 493f
vascular, 477
Endothelial growth factor, in urothelial tumors, 2425
Endothelin(s), 2711
effect of, on ureteral function, 1920
in male sexual function, 728
in renal hemodynamics, 1134
uropharmacology of, 1956
Endothelin-1, 537-538, 2711
in hormone-refractory prostate cancer, 3116
Endothelium, of corpus cavernosum, erectile dysfunction and, 742
Endothelium-dependent vasodilation, impaired, in erectile dysfunction, 741-742
Endoureterotomy, for ureteral stricture, 1257-1259
antegrade approach to, 1258
cautery wire balloon incision in, 1257-1258
combined approaches to, 1259
retrograde approach to, 1257, 1257f
Endourologic procedures
for ureteroenteric anastomotic stricture, 1269
for ureteropelvic junction obstruction, 1232-1241
complications of, 1236-1237, 1238-1239, 1241
indications for and contraindications to, 1232, 1233f, 1237, 1237f, 1239
Endourologic procedures *(Continued)*
patient preparation in, 1232
postoperative care following, 1234, 1236, 1237
results of, 1236, 1237-1238, 1241
technique of, 1232-1234, 1235f, 1236f, 1237, 1238f, 1239, 1240f, 1241
in children, 3907-3914
prior to laparoscopy, 176
Endovascular stenting. *See* Stent (stenting).
End-stage renal disease

in HIV patients, 396
for *Chlamydia trachomatis* infection, 378
for mollicute infections, 384
neomycin with, in antibiotic bowel preparation, 2538t
Erythroplasia of Queyrat, 426-427, 427f, 964. *See also* Penile cancer.
Erythropoiesis, 1135-1136
regulation of, 1136
Erythropoietin, renal production of, 1136
Escherichia coli
epithelial cell receptivity of, 231-234, 233f, 234f
in acute pyelonephritis, 268
in prostatitis, 306
Escherichia coli (Continued)
in renal abscess, 3246
in urinary tract infections, 228, 229-230, 229f, 230f
pediatric, 3234
Estradiol
and female sexual function, 875
daily production of, in males, 2686t, 2688
Estramustine phosphate, for hormone-refractory prostate cancer, 3105t, 3106, 3108
multidrug regimens with, 3107t
Estrogen(s)
assessment of, in females, 872, 872f
deficiency of
genital tissue atrophy associated with, 879-880
menopausal, 879, 879f
effects of, on prostate, 2679-2680, 2686t, 2687f, 2688
excess, male infertility and, 637
fetal secretion of, 3804-3805
for incontinence, 2107-2108
in elderly, 2318
for sexual dysfunction
in perimenopausal and postmenopausal women, 878-880
in premenopausal women, 875-876
for stress incontinence, 2075, 2112-2113
for vaginal atrophy, 880
in benign prostatic hyperplasia, 2731
in prostate growth, 2679-2680
estrogen-androgen synergism in, 2693
in testicular descent, 3768
preoperative, for vaginal surgery, in postmenopausal women, 2215-2216
prostate cancer and, epidemiologic studies of, 2861
synergism of, on androgen-induced prostate growth, 2693
uropharmacology of, 1956
Estrogen receptor modulators, selective, for prostate cancer, chemopreventive, 2871
Estrogen-secreting adrenal tumor, 1842
Ethambutol, for genitourinary tuberculosis, 444, 445t
Ethnicity
pediatric urinary tract infection and, 3237-3238
renal stones associated with, 1363-1364
Ethylene vinyl alcohol injections, for incontinence, 2274-2275
efficacy of, 2282
Ethylsuccinate, for *Chlamydia trachomatis* infection, 378
Etoposide
for hormone-refractory prostate cancer, 3105t
high-dose, for nonseminomatous germ cell tumors, 923
Euchromatin, 2712
Euro-Collins solution, for kidney transplant preservation, 1306-1307
European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-C30), 150-151
Excision, of renal pelvis tumor, local, 1756, 1756f, 1757f, 1758
Excision strategies
conservative, for penile cancer, 994, 995f, 996
for hydrocelectomy, 1105, 1105f, 1106f
for urethral stricture, reanastomosis with, 1062, 1063f, 1064f
limited, for penile cancer, circumcision and, 973

Excitation, vanilloid-induced, 1959
Excitation-contraction coupling
  in bladder smooth muscle, 1928-1929, 1928t, 1929f
  in ureteral smooth muscle, 1899-1900
Excretory urography. *See* Urography, excretory.
Exenteration, anterior, urethrectomy with, in female radical cystectomy, 2496-2498, 2497f-2499f
Exercise(s)
  incontinence associated with, 2190
  pelvic floor, for erectile dysfunction, 770
Exercise-induced hematuria, 100
Exstrophy
  bladder. *See* Bladder exstrophy.
  cloacal. *See* Cloacal exstrophy.

Foam cells, in glomerulus, 1344
Foley catheter, 162, 162f
for percutaneous nephrostomy, 1559-1560
in urethral diverticula repair, 2387f, 2388
Foley Y-V plasty technique, for ureteropelvic junction obstruction, 1243-1245, 1245f
in children, 3370, 3370f
Follicle-stimulating hormone (FSH)
deficiency of, in male, 636
for male infertility, 636
in evaluation of fertility, 612
in evaluation of infertility, 618-619, 618t
in male reproductive axis, 577, 578f
increased levels of, following varicocele repair, 664
role of, in spermatogenesis, 596
secretion of, 578
Sertoli cell stimulation by, 579-580
Folliculitis, of male genitalia, 421, 422f
Foods
avoidance of, ICA recommendations for, in painful bladder syndrome/interstitial cystitis, 359t
oxalate-rich, 1378, 1403t
Force-length relations, of ureteral smooth muscle, 1902-1903, 1902f, 1903f
Force-velocity relations, of ureteral smooth muscle, 1903, 1903f
Forearm flap. *See also* Flap(s).
in penile reconstruction, 1092-1093
disadvantages of, 1093
modifications of, 1093, 1094f, 1095f
Forebrain, involved in sexual function, 726t
Foreign body(ies), bladder calculi related to, 2666, 2667f
Foreskin, neonatal bacterial colonization of, 3238
Fosfomycin, for pediatric urinary tract infections, 3248t
Fossa navicularis, urethral, 1029, 1030f
Four-corner bladder neck suspension, for vaginal wall prolapse, 2219-2221, 2220t, 2221f
Fournier's gangrene, 301-302
genital skin loss due to, 2654
in AIDS patients, 397
of male genitalia, 421, 421f
Fowler syndrome, voiding dysfunction in, 2040
Fowler-Stephens orchidopexy, 3781
for prune-belly syndrome, 3492-3493
laparoscopic, 3786
Fowler-Stephens test, 3781
Fractional excretion of sodium
gestational age and, 3150
in infant and child, 3154
in preterm and term neonates, 3151, 3153f
Fracture(s)
pelvic
associated with posterior urethral injury, in children, 3940
urethral disruption related to, 2659
penile, 2649-2650, 2650f
straddle, of pubic rami, 2658, 2658f
Frank technique, in creation of neovagina, modification of, 3835
Free graft. *See also* Graft(s).
in hypospadias repair, 3716
neourethral formation and, 3734, 3736-3738, 3738f
reoperative, 3741
Freeze-thaw cycle, in cryotherapy, 3036-3037
Freezing process, in cryotherapy. *See also* Cryotherapy.
monitoring of, 3041, 3044
tissue response to, 3035-3036, 3035f
Frenulae, sexual pain disorders involving, 883
Frequency, 84
causes of, 370t
definition of, 331, 2079
in elderly, 2311
measurement of, 2084
nocturnal, 84
Fructose, in prostatic secretions, 2716
FSH. *See* Follicle-stimulating hormone (FSH).
Fuhrman's classification, of renal cell carcinoma, 1591, 1591t
Fulguration, of urothelial tumors, 1647-1648
Fumagillin, as inhibitor of angiogenesis, 543
Fungal bezoar(s)
Aspergillus, 465f
Candida, 460, 460f, 463, 463f
in children, 3265
percutaneous treatment of, 1556
Fungal infection(s), of genitourinary tract, 459-469. *See also specific infection, e.g.,* Candidiasis.
pediatric, 3265
Funguria, 299-301
clinical presentation of, 299
diagnosis of, 299
in pediatric urinary tract infections, 3265
management of, 299-301, 300f
Funiculoepididymitis, 456-457
Furunculosis, of male genitalia, 422, 422f
Fusiform aneurysm, of renal artery, 1187, 1188f
Fusion anomaly(ies). *See also specific anomaly.*
of female genitalia
lateral, 3839, 3839f, 3840f
vertical, 3832-3839, 3833f-3839f

G

G protein, muscarinic receptor-coupling to, 2092
G protein–coupled ligand, cancer and, 537-538
G protein–coupled receptor(s), 539
G_1S checkpoint, in cell cycle, 521-524
cip/cik function and, 523-524
cyclin-dependent kinase complexes and, 523-524
INK4 function and, 523
retinoblastoma protein and, 524
TP53 in urologic malignancies and, 522-523
TP53 regulator of, 521-522, 522f
G_2M checkpoint, in cell cycle, 525, 525f
Gabapentin, effect of, on detrusor overactivity, 2108
Gallium nitrate, for bladder cancer, metastatic, 2478
Gamma-aminobutyric acid
in male sexual function, 730
uropharmacology of, 1962, 1965, 2120-2121
Gamma-glutamyl transpeptidase, in testicular tumors, 907
Ganglioneuroma, 3871, 3871f
Gangliosides, in suppression of tumor immunity, 497
Gangrene
Fournier's. *See* Fournier's gangrene.
necrotizing, genital skin loss due to, 2654, 2655f
Gap junctions
in penile function, 742
in ureteral function, 1897
Gardnerella vaginalis, in painful bladder syndrome/interstitial cystitis, 339
Gartner's duct, abnormalities of, vs. urethral diverticula, 2383, 2383f
Gartner's duct cyst, 3843, 3843f
Gas embolism
insufflation-related, laparoscopic renal surgery causing, 1807
with pneumoperitoneum, 205
Gasless technique, for pneumoperitoneum, 181
Gastric artery, 2533, 2534f
Gastric contents, aspiration of, in laparoscopy, 211
Gastric pouches, for continent urinary diversion, 2604-2606
postoperative care of, 2606
procedure in, 2604-2606, 2604f, 2605f
Gastrocystoplasty, in children
antrum technique of, 3678
body technique of, 3678-3679, 3678f
Gastroepiploic artery, 2533, 2534f
Gastrointestinal tract. *See also specific part.*
anomalies of
in cloacal exstrophy, 3540
in prune-belly syndrome, 3485t, 3487

Gastrointestinal tract *(Continued)*

communicating, 3788-3789
differential diagnosis of, 3787
in children, 3203
in filariasis, 456f, 457
in infants, 3204
of spermatic cord, 3789
Hydrocelectomy
complications of, 1106
excisional technique of, 1105, 1105f, 1106f
inguinal approach to, 1105
plication technique of, 1105-1106, 1106f
sclerotherapy in, 1106
scrotal approach to, 1105-1106, 1105f, 1106f
Hydrocephalus, normal pressure, voiding dysfunction in, 2017
Hydrochlorothiazide, for renal hypercalciuria, 1419, 1421t
Hydrocolpos, imperforate hymen with, 3194
Hydrocortisone, for congenital adrenal hyperplasia, in children and adolescents, 3820
Hydrodistention, for painful bladder syndrome/interstitial cystitis, 365-366
Hydrogen, renal reabsorption of, in cortical collecting tubules, 1145
Hydrogen ion, transport of, ureteral obstruction and, 1202
Hydrometrocolpos, 3848
Hydronephrosis, 1195
after aortic bypass graft surgery, 1223
after renal transplantation, 1320, 1321f
Down syndrome and, 3184
fetal
bilateral, postnatal evaluation and management of, 3190-3191, 3190t
evaluation of, 3204
ultrasound appearance of, 3176-3177, 3177f, 3179f
unilateral, postnatal evaluation and management of, 3191-3193, 3192f
upper pole, 3182
in infants, evaluation of, 3198
in multicystic dysplastic kidney, 3334, 3335f
in pelvic organ prolapse, prevalence of, 2204
in pregnancy, 1219-1220
in urinary tract infections, 276
intraoperative ureteral manipulation causing, 1283
pathophysiology of, 3185-3186
prenatal diagnosis of, vs. multicystic dysplastic kidney, 3183
schistosomal, 450
upper pole, with ureterocele, 3398, 3399, 3399f, 3400f
with ectopic ureter, 3389, 3390f
Hydronephrosis *(Continued)*
with posterior urethral valves
fetal sonography of, 3590f
management of, 3596
with single-system ectopic ureters, 3396, 3396f
with ureteral duplication, 3414
Hydroureter, fetal, ultrasound appearance of, 3177, 3179f
α-Hydroxy acids, polymers of, for tissue engineering, 556
Hydroxy-3-methylglutaryl coenzyme A, for chronic renal failure, 1350
11β-Hydroxylase deficiency, in congenital adrenal hyperplasia, 3819
17α-Hydroxylase deficiency, 3822
21-Hydroxylase steroid deficiency, in congenital adrenal hyperplasia, 3816-3819, 3817f, 3818f
3β-Hydroxysteroid deficiency, 3821-3822
3β-Hydroxysteroid dehydrogenase deficiency in congenital adrenal hyperplasia, 3819
type 2, 3767
17β-Hydroxysteroid dehydrogenase deficiency, type 3, 3767
17β-Hydroxysteroid oxidoreductase deficiency, 3822-3823
5-Hydroxytryptamine receptor sensitivity, in premature ejaculation, 785
Hydroxyzine, for painful bladder syndrome/interstitial cystitis, 360, 360t
Hylagel Uro injection, for incontinence, 2286
Hymen
examination of, in adolescents, 3209
imperforate, 3843-3844, 3844f
with hydrocolpos, 3194
Hymenal skin tags, 3843, 3843f, 3844f
Hyperaldosteronism, primary, 1846-1857
adrenal surgery for, 1871t
postoperative complications of, 1886t
clinical characteristics of, 1850-1851, 1850t
diagnostic strategy for, 1854-1856, 1855f
diagnostic test(s) for, 1851-1853
aldosterone-to-renin ratio, 1851-1852
cortisol metabolites, 1853
lateralizing, 1853-1854
plasma renin activity, 1851
postural stimulation, 1852-1853
sodium loading, 1853
epidemiology of, 1849-1850
pathophysiology of, 1846-1849, 1847f, 1848f
treatment of, 1856-1857
Hypercalcemia
glucocorticoid-induced, 1376-1377
in medullary sponge kidney, 3349
in renal cell carcinoma, 1597-1598, 1597t
malignancy-associated, 1376, 1376t
penile cancer associated with, 969
sarcoid and granulomatous diseases associated with, 1376
Hypercalciuria
absorptive, 1374-1375, 1401-1402
management of, 1416-1419
drug guidelines in, 1418
calcium stone formation associated with, 1374-1377, 1376t, 1401-1402
definition of, 1374
differential diagnosis of, 1402t
idiopathic, 1374, 1402, 1402t
in children, 3222-3223, 3222t
treatment of, 3223
renal, 1375, 1402
management of, 1419-1420, 1421t
resorptive, 1375-1377, 1402

Hypercarbia, laparoscopy and, 210-211, 3917
Hyperchloremia, conduit urinary diversion causing, 2571-2572, 2571t
Hypercholesterolemia, erectile dysfunction associated with, statins for, 769
Hypercontinence, in females undergoing orthotopic reconstruction, 2621
Hypercortisolism, ACTH-dependent vs. ACTH-independent, 1834
Hyperglycemia, in acute renal failure, 1338
Hyperkalemia, 1150-1151, 1151t
  in acute renal failure, 1338
Hyperlipidemia, erectile dysfunction associated with, 741, 768
Hypermethylation, of DNA, 514-515
Hypermobility, in retropubic suspension surgery, contribution of, 2170
Hypernatremia
  clinical approach to, 1149, 1150f
  treatment of, 1149
Hypernephroid tumors, 1567
Hypernephroma, 1567
Hyperoxaluria, 1377-1379, 1403
  definition of, 1377
  dietary, 1378, 1403
  enteric, 1378, 1378f, 1403
    management of, 1422
  idiopathic, 1378-1379
  in children, 3223
  primary, 1377-1378, 1377f, 1403
Hyperparathyroidism, primary, parathyroidectomy for, 1420
Hyperprolactinemia
  erectile dysfunction associated with, 740
  male infertility associated with, 637
Hyperreflexia
  autonomic, voiding dysfunction with, 2012t, 2026-2027
  of detrusor muscle, 1981, 1981t
Hypertension
  after renal bypass surgery, 1749
  after renal injury, 1282
    in children, 3935
  age at onset of, 1167
  anesthesia-related, in laparoscopy, 211
  benign prostatic hyperplasia with, 2745
    α-adrenergic blockers for, 2786
  definition of, 1157
  erectile dysfunction associated with, 741
  family history of, 1167
  in autosomal dominant polycystic kidney disease, 3320-3321
  in chronic renal failure, 1351
  in multicystic dysplastic kidney, 3337, 3339
  in neonate, 3196
  in pheochromocytoma, 1857-1858, 1858t
  in primary hyperaldosteronism, 1850
  in renal cell carcinoma, 1597t, 1598
  in ureteral obstruction, management of, 1211-1212, 1212t
  licorice ingestion causing, 1849
  malignant, 1167
  nonsurgical, after renal transplantation, 1324
  pyelonephritic, pediatric urinary tract infection and, 3259-3260
  renovascular. *See* Renovascular hypertension.
  vesicoureteral reflux causing, 4340
Hyperthermia
  chemotherapy and, for invasive bladder cancer, 2476
  microwave, for prostatitis, 324
Hyperthyroidism
  erectile dysfunction associated with, 740
  male infertility associated with, 637-638
  voiding dysfunction in, 2041
Hypertrichosis, 3210, 3211f
Hyperuricosuria, 1379, 1385, 1402
  in children, 3223
  management of, 1420
Hypnotics, causing geriatric incontinence, 2308, 2308t
Hypoactive sexual desire disorder, 727, 859
Hypocitraturia, 1379, 1403-1404, 1404f, 1404t
  idiopathic, 1404
  thiazide-induced, 1404
    management of, 1423
Hypoestrogenism, role of, in labial adhesions, 3841
Hypogastric artery. *See* Iliac artery, internal (hypogastric).
Hypogastric plexus
  inferior, 15, 17, 17f
  superior, 15, 17, 17f
Hypogastric vein. *See* Iliac vein, internal (hypogastric).
Hypogonadism
  erectile dysfunction in, 740
  hypogonadotropic
    anabolic steroid-induced, 611
    gene mutation in, 3767
    in Kallmann syndrome, 635
    isolated, 635-636
    micropenis in, 3752-3753
  late-onset
    biochemical diagnosis of, 854-856, 855t, 856f
    clinical diagnosis of, 853-854, 853t, 854f, 854t
    clinical manifestations of, 851t
    definition of, 850

with diffuse mesangial sclerosis, 3328-3329
characteristics of, 3314t
Nephrostography (antegrade urography), 118
Nephrostomy, percutaneous
catheters in, 1541
complication(s) of
bowel perforation as, 1548
fluid absorption as, 1547
hemorrhage as, 1544-1547, 1545f-1547f
liver injury as, 1548
pleural cavity injury as, 1547-1548
renal pelvic injury as, 1547
sepsis as, 1548
splenic injury as, 1548
CT-guided, 1532-1533
drainage procedures in, 1549, 1557-1562
balloon retention catheters for, 1559-1560
choice of appropriate, 1562, 1562t
circle loop, 1560, 1561f
Councill catheters for, 1558f, 1559-1560
Foley catheters for, 1559-1560
for calyceal diverticula, 1552-1554, 1553f
for emphysematous pyelonephritis, 1550-1551
for fibroepithelial polyps, 1556-1557
for fungal bezoars, 1556
for infundibular stenosis, 1554-1556, 1555f
for pyonephrosis, 1550-1551
for ureteroenteric anastomotic strictures, 1557
innovations of, 1563
Malecot tubes for, 1558
of renal cysts, 1551-1552
of uninfected obstruction, 1549-1550
pigtail catheters for, 1558-1559, 1558f, 1559f
re-entry tubes for, 1559f, 1560
fluoroscopic approach to, 1531-1532, 1531f, 1531t
future directions of, 1562-1563
guide wires in, 1541
imaging for, 1530-1534
innovations in, 1562-1563
indications for, 1526-1527
MRI-guided, 1532-1533
patient positioning for, 1536-1537, 1536f
pertinent renal anatomy for, 1527-1529, 1527f-1530f
preoperative preparation for, 1536
retrograde-assisted, 1534-1535, 1534f, 1535f

Nephrostomy, percutaneous *(Continued)*
sealants and hemostatic agents in, 1561
site selection for, 1537-1541
anomalous kidneys and, 1540-1541, 1540f
intercostal approach in, 1539-1540, 1539f, 1540f
subcostal approach in, 1537-1539, 1537f, 1538f
stone removal through, 1433
technical aspects of, 1535-1541
tract dilation in, 1541-1544
dilators in, 1542-1544, 1542f, 1543f
guide wire entry in, 1541-1542
tubeless, 1561
ultrasound-guided, 1530-1531, 1531f
Nephrostomy tract
dilation of, 1541-1544, 1542f, 1543f
establishment of, 1677-1678, 1677f, 1678f
Nephrostomy tube
after percutaneous nephrolithotomy, 1495-1496, 1496f
choice of, 1562, 1562t
insertion of, 1754-1755, 1756
large bore vs. small bore, 1560-1561
re-entry, 1559f, 1560
Nephrotic syndrome, in children, 3225
congenital, 3226
Nephrotosis
definition of, 1776
Dietl's crisis in, 1776
Nephrotoxic agents, acute renal failure related to, 1329t, 1330
Nephrotoxicity, cisplatin-induced, 924
Nephroureterectomy
laparoscopic, 1650, 1650t
in children, 3921-3922
radical, 1649-1650
laparoscopic, 1664-1667
results of, 1666-1667
transperitoneal, 1665-1666, 1665f, 1666f
lymphadenectomy with, 1662
open, 1657-1664
choice of incision in, 1657-1658, 1658f
indications for, 1657
results of, 1663-1664
technique of, 1657-1662, 1659f-1664f
results of, 1650-1651, 1650t
Nernst equation, 1892

of electrical stimulation, for storage and emptying disorders, 2148-2150, 2149f-2151f
of motor unit action potentials, 2003-2004, 2004f
Neurospinal dysraphism. *See also specific dysraphism.*
in children, 3628-3648
in cloacal exstrophy, 3538-3539, 3539f
voiding dysfunction in, 2029-2030
Neurostimulation, intraoperative, during retroperitoneal lymph node dissection, 945
Neurotoxicity, cisplatin-induced, 924
Neurotransmitters, in male sexual function, 728-730
central, 729-730
interaction between nerves and, 729
peripheral, 728-729
Neurovascular bundles
in radical cystectomy, preservation of, 2487-2488, 2488f, 2489f
in radical retropubic prostatectomy, 2967-2968, 2967f
high anterior release of, 2965, 2965f
identification and preservation of, 2966-2967, 2967f
wide excision of, 2968, 2968f
in robotic-assisted laparoscopic radical prostatectomy
antegrade preservation of, 2993, 2994f, 2995f
interfascial dissection of, 2992, 2993f
retrograde preservation of, 2993
Neutrophils, in injury cascade, 1332
NEVA device, for nocturnal penile tumescence testing, 764
Nevus(i), of male genitalia, 433, 434f
NFκB activation, angiotensin II in, 1204
NFκB regulation, of apoptosis, 490
Nicotinic agonists, effect of, in ureteral function, 1904
Nifedipine
for autonomic hyperreflexia, 2027
for incontinence, in elderly, 2317t
for painful bladder syndrome/interstitial cystitis, 360t, 361
Nilutamide, androgen blockade with, 3085t, 3087
Nimesulide, for prostatitis, clinical trial data on, 322
Nipple(s), supernumerary, in children, 3207
Nipple "rosebud" stoma, 2552, 2552f
Nipple valves
for continent urinary diversion, in children, 3693-3694, 3694f
in ureterointestinal anastomosis, 2562, 2562f
reinforced, of ileum, for antireflux surgery, 3662

Nitric oxide
and renal development, 3159
in male sexual function, 728-729, 730, 734-735
in obstructive renal fibrosis, 3170
in renal hemodynamics, 1135
in smooth muscle relaxation, 1954
in ureteral smooth muscle contraction, 1901, 1901f
uropharmacology of, 1953-1954, 1957
Nitric oxide donors, for voiding dysfunction, 2119-2120
Nitric oxide synthase, in ureteral smooth muscle contraction, 1901, 1901f
Nitrite tests
for pediatric urinary tract infection, 3244, 3244t
in urinalysis, 104-105
Nitrofurantoin
for cystitis, 256t, 257
for urinary tract infections, 245, 245t, 246t, 247t, 248
in children, 3248t
prophylactic, 3251, 3426
low-dose prophylactic, for recurrent urinary tract infections, 262t, 263-264
Nitrous oxide, for pneumoperitoneum, in laparoscopic surgery, 199
NK cell(s). *See* Natural killer cell(s).
NK receptors, 1954-1955
NK_1 antagonists, 1954
NKX3-1 gene, 536
in prostate cancer, 2865-2866
NMP 48 (50.8 kD) protein, in prostate cancer, 2909
NMP22 protein, in urothelial tumors, 1644
N-*myc* oncogene, amplification of, in neuroblastoma, 3874, 3875
Nocturia, 84, 2047
causes of, 2312t
definition of, 2079
in children, 3621-3624
bladder-brain dialogue in, 3624
etiology of, 3621
evaluation of, 3204
role of bladder dysfunction in, 3621-3622, 3623f
sleep arousal disturbance in, 3622, 3624
in elderly, 2311-2312
measurement of, 2084
treatment of, pharmacotherapy in, 2113-2114
Nocturnal penile tumescence, monitoring of, 763-764, 764f
Nodule(s)
painless, in germ cell tumors, 903
postoperative spindle cell, of bladder, 2418
Nonadrenergic noncholinergic mechanism, of bladder emptying, 1975
Nonautologous materials, for endoscopic correction of reflux, 4364-4365, 4364t
Noncompliance, in renal transplant recipients, 1299
Noncutaneous lesions, of penis, benign, 959-960
Nonepithelial tumor(s), of bladder, 2445-2446
angiosarcoma as, 2445
hemangioma as, 2445
leiomyosarcoma as, 2445
lymphoma as, 2445
neurofibroma as, 2445
pheochromocytoma as, 2445
rhabdomyosarcoma as, 2446
Nonfebrile infections, of urinary tract, in children, 3203
Non-Hodgkin's lymphoma, in AIDS patients, 399
Nonhormonal therapy, for sexual health problems, in females, 881-883
Noninfectious ulcers, of male genitalia, 417-419, 417t, 418f, 419f
Nonischemic priapism, 841, 843. *See also* Priapism.
cavernosal blood gas determinants in, 845
natural history of, 841
treatment of, 848
Non–muscle-invasive bladder cancer, 2447-2467. *See also* Bladder cancer, non–muscle-invasive.
Non-nociceptive pain, characteristic features of, 346, 346t
Non–nucleoside reverse transcriptase inhibitors, for HIV infection, 401
Nonrenal cystic lesions, prenatal diagnosis of, vs. multicystic dysplastic kidney, 3183
Nonseminomatous germ cell tumor(s), 895-896. *See also specific tumor.*
high-stage

vaginal pessaries in, 2137-2138, 2138f, 2139f
vaginal support prosthesis in, 2137, 2137f
vaginal surgery for, 2212-2215
complications of, 2214-2215
intraoperative, 2214
postoperative, 2214
preoperative and intraoperative management in, 2212
technique(s) of, 2212-2214
Gittes bladder neck suspension, 2212-2213
modified Pereyra, 2212
Raz bladder neck suspension, 2213-2214, 2213f
Raz vaginal wall sling, 2214
Stamey needle bladder neck suspension, 2212
vs. urgency incontinence, 2083
Stress relaxation, of ureter, 1902-1903, 1903f
Stress testing, 2313
Stress urethral pressure profilometry, 2007
Striated muscle
fiber types in, 1936-1937
vs. smooth muscle, 1928t
Strickler technique, of ureterocolonic anastomosis, 2556-2557, 2556f
Stricture. *See at anatomic site.*
String, in penile strangulation injury, 2652
Stroke
after renal transplantation, 1324
brain stem, voiding dysfunction after, 2016
voiding dysfunction after, 2012t, 2014-2016
Stromal cell(s)
epithelial cell interactions with, 2693-2694, 2706, 2707f
in benign prostatic hyperplasia, 2731
of bladder wall, 1931-1932
nonfibrillar matrix of, 1932
of prostate, 2683-2684, 2730
Stromal tumor(s), testicular, 927-928
in children, 3904-3905
Strontium 89, clinical experience with, therapy, 3029
Struma lipomatodes aberrata renis, of tumors, 1567
Struvite calculi, 1407-1408, 1407f, 1408f
in children, 3223
urea-splitting bacteria causing, 261
Studer ileal bladder substitute, for orthotopic urinary diversion, 2635, 2636f
Sturge-Weber syndrome, pheochromocytoma associated with, 1861
SU11248, for renal cell carcinoma, 1630, 1630t
Subarachnoid block, for bladder denervation, 2289
Subcostal incisions, in adrenal surgery, 1874, 1875f
Subcostal nerve, 18, 18f
Subcutaneous fascia, of abdominal wall, anterior, 38, 40, 40f, 41f
Subcutaneous (dartos) flap. *See also* Flap(s).
in hypospadias repair, 3716, 3716f
Subcutaneous (cavernous) hemangioma, of male genitalia, 3760
Subinguinal ligation, for varicocele, 3797
Substance P
in pain transmission, 1959
renal nerve activity responses to, 1906
Substitution cystoplasty, for painful bladder syndrome/interstitial cystitis, 367
Sulfisoxazole, prophylactic, for pediatric urinary tract infections, 3250t
Superfocusing mechanism, of stone fragmentation, 1476
Supernumerary kidney(s)
associated anomalies with, 3277
diagnosis of, 3278
embryology of, 3277
features of, 3277, 3277f, 3278f
incidence of, 3276-3277
symptoms of, 3277-3278
Supernumerary nipple(s), in children, 3207
Supernumerary ureter(s), 3417
Support devices, for bladder filling/storage disorders, 2291-2292
Supracostal puncture, for percutaneous nephrolithotomy, 1490, 1490f, 1490t, 1491f
Suprapubic cystostomy, for urethral injury, 2659
Suprapubic pain, patient history of, 82-92
Supraspinal pathways, in penile erection, 725-728, 726t, 727t
Supratrigonal cystectomy, for painful bladder syndrome/interstitial cystitis, 366-367
Suramin, for hormone-refractory prostate cancer, multidrug regimens with, 3107t
Surgery. *See also specific procedure.*
antibiotic prophylaxis for, 253, 253t
for genitourinary tuberculosis, 444-447
reconstructive, 446-447
for neuroblastoma, 3875-3877
in high-risk disease, 3876-3877
in low-risk disease, 3875-3876, 3876f
for painful bladder syndrome/interstitial cystitis, 366-368
for Peyronie's disease, 829-831, 831f-836f, 833, 836
candidates for, 828-829
for prostatitis, 325
minimally invasive, 324
for schistosomiasis, 454
for sexual health problems, in females, 887-889, 887f, 888f
for stress incontinence
in females, 2076-2077
in males, 2077
laparoscopic. *See* Laparoscopic *entries.*
organ-preserving, for testicular tumors, 908-909
previous, patient history of, 88
reconstructive. *See* Reconstructive surgery; *specific procedure.*
Surgical compression, for bladder filling/storage disorders, 2293-2294
Surgical templates, in retroperitoneal lymph node dissection, 915, 915f, 916f, 940-941, 940f, 941f
Surgical wounds, classification of, 253t
Surveillance studies
after nonseminomatous germ cell tumor therapy, for stage I and stage IIA disease, 916-918, 917t
after seminoma therapy, for stage I disease, 911-912, 911t
Survival pathways, in hormone-refractory prostate cancer, 3115-3116
Survivin, in bladder cancer, 2435-2436
Susceptibility gene(s), in prostate cancer, 2858, 2858t
Suspensory ligament, of clitoris, 67

Suture (suturing)
in hypospadias repair, 3719
in laparoscopy, 193-194
material for, in retropubic suspension surgery, 2174
sling, determination of tension in, 2244
traction, 3372f, 3377, 3378f
Sutured anastomosis, 2540-2542, 2540f-2542f
ileocolonic
end-to-end, 2542, 2542f
end-to-side, 2541-2542, 2541f, 2542f
single-layer, 2541, 2541f
two-layer, 2540-2541, 2540f
Sweeteners, artificial, bladder cancer associated with, 2415
Switch therapy, for pediatric urinary tract infection, 3249
Sympathectomy, for painful bladder syndrome/interstitial cystitis, 366
Sympathetic nervous system
degeneration of, in transurethral microwave therapy, 2815
increased activity of, in painful bladder syndrome/interstitial cystitis, 346-347, 346t
of lower urinary tract, pathways in, 1938
role of, in ureteral function, 1905-1906
Sympathetic skin response, in erectile dysfunction, 766-767
Sympatholytic agents, affecting lower urinary tract function, 3628t
Sympathomimetic agents
affecting lower urinary tract function, 3628t
for priapism, 845-846, 846t
Syndrome of inappropriate ADH secretion, 1147
disorders associated with, 1149t
Synthetic grafts. *See also* Graft(s).
in vaginal prolapse surgery, 2216, 2216t
Synthetic materials, injection of, for incontinence, 2274-2275, 2275f
Syphilis
chancre with, 420f
diagnosis of, 375-377, 375f, 376f
in HIV patients, 395
latent, 375
rates of, 372
secondary, 375-376, 376f
tertiary, 376
treatment of, 377
Syringomyelia, voiding dysfunction in, 2036
Systemic inflammatory response syndrome, 287
biologic effects of, 288
clinical presentation of, 288
Systemic lupus erythematosus
painful bladder syndrome/interstitial cystitis and, 336
renal manifestation of, in children, 3227
voiding dysfunction in, 2037
Systemic sclerosis (scleroderma), voiding dysfunction in, 2042
Systemic therapy, for cutaneous diseases, of external genitalia, 406

T

T cell(s), 476-477
activation of, 480-481, 480f
NFAT in, 483
signal 1 in, 480
signal 2 in, 481
signal 3 in, 481
signaling events in, 482-483, 482f
upregulated adhesion molecule expression in, 492-494, 493t
T cell(s) *(Continued)*
antigen-specific
activation of, 484-488
clonal expansion in, 485, 485f
cytokine production in, 486-487, 486f, 486t
cytolysis of target cells in, 487-488, 487f
development of memory cells in, 488
phenotypic changes in, 488
CD4+. *See* CD4+ T cell(s).
CD8+. *See* CD8+ T cell(s).
clonal anergy of, 491
endothelial cell interaction with, 493, 493f
in painful bladder syndrome/interstitial cystitis, 341
induction of apoptosis of, mechanism of tumor escape in, 498-499
memory, 488
naive, trafficking of, 492
peripheral deletion of, 491
regulatory, 491-492
in lymphocyte tolerance, 491-492
role of, in tumor immunology, 495
tumor antigens recognized by, 496t
T pouch ileal neobladder, for orthotopic urinary diversion, 2638, 2639f-2640f, 2640
Tabes dorsalis, voiding dysfunction with, 2030
Tachykinin(s), 1954-1955, 1954t
effect of, on ureteral function, 1906
Tachykinin receptors, 1954-1955, 1954t
Tacrolimus
as immunosuppressant, 1316, 1316f, 1316t
drug interactions with, 1317, 1317t
Tadalafil
adverse effects of, 776-777
clinical response of, 776
efficacy of, 775
for erectile dysfunction, 773-775
onset of action of, 776
patient satisfaction with, 776
starting dose of, 777
structure of, 774f
vasodilator effects of, 778
vs. sildenafil and vardenafil, 774t
Tail stents, 1517
Takayasu's arteritis, in children, 1184
Tamm-Horsfall protein, 100, 3219, 3234, 3260
as calcium oxalate crystal inhibitor, 1367, 1370
in renal casts, 107
renal excretion of, loop of Henle in, 1144
Tamoxifen
for male infertility, 646
for Peyronie's disease, 827
for retroperitoneal fibrosis, 1217
Tamsulosin
for benign prostatic hyperplasia, 2783-2784
dosage of, 2778t, 2784
efficacy of, 2784t
for prostatitis, 321, 327t
uropharmacology of, 2119
vs. other α-adrenergic blockers, 2787
Tanagho technique, of bladder outlet reconstruction, 2294
Tanner classification, of sex maturity stages, in boys, 3745, 3746t
Tape erosion, intravesical, 2262-2263, 2262t
Tapering procedure, for megaureter, 4379, 4379f
Target cells, cytolysis of, 487-488, 487f
Target populations
prostate cancer screening in, 2867-2868, 2868t
renal cell carcinoma screening in, 1599, 1599t
Targeted agents, for metastatic renal cell carcinoma, 1629-1631, 1630f, 1630t
TATA box, 2703
Taxanes
for bladder cancer, non–muscle-invasive, 2459-2460
for locally advanced prostate cancer, before radical prostatectomy, 3060-3061
Taxol. *See* Paclitaxel.
Taxotere. *See* Docetaxel.
T-cell receptor
in immune response, 479-480
signaling events transmitted via, 482-483, 482f
Tea consumption, bladder cancer associated with, 2415
TEBS. *See* Transurethral electrical stimulation (TEBS).
Technetium-99m-mercaptoacetyltriglycine (Tc-99m-MAG3) scintigraphy, of kidneys, 140f-142f, 142, 1335
Technical process, in quality of health care, 148
TEF3 protein, overexpression of, in renal cell carcinoma, 1583
Telomerase, 533, 534f, 2713
in bladder cancer, 2435, 2465
in renal cell carcinoma, 1590
in urothelial tumors, 1644
prostate cancer and, 2866
Telomerase reverse transcriptase, 2713
Telomerase RNA component, 2713
Telophase, in mitosis, 2712
Temperature, in transurethral microwave therapy, 2814-2815
Templates, brachytherapy-like, for cryotherapy, 3038, 3038f
Tendon reflexes, depression of, after sacral spinal cord injury, 2024
Tenesmus, 2204
Tenets of treatment, in cryptorchidism, 3775
TENS (transcutaneous electrical nerve stimulation), for painful bladder syndrome/interstitial cystitis, 364-365
Tension pneumothorax, laparoscopic renal surgery causing, 1808
Tension-free vaginal tape procedure. *See* Vaginal tape procedure, tension-free.
Teratoma(s), testicular, 895
in children, 3901
immature, 3903
mature, 3902-3903
incidence, pathology, and presentation of, 898t
resection of, 951-952
Teratospermia, evaluation of, 623
Terazosin
for autonomic hyperreflexia, 2027
for benign prostatic hyperplasia, 2779-2780, 2779f, 2780t, 2781f
dosage of, 2778t, 2780
efficacy of, 2779t
for prostatitis, 321, 327t
uropharmacology of, 2119
vs. other α-adrenergic blockers, 2787
Terbutaline, for overactive bladder/detrusor overactivity, 2093t, 2103-2104
Terfenadine, for Peyronie's disease, 827
Testicular adnexa tumor(s), 931-934, 932t
adenomatoid, 931-933, 932t
cystadenoma as, 933
epithelial, 931
mesothelioma as, 932
paratesticular, 932t, 933-934
leiomyosarcoma as, 934
management of, 933-934
rhabdomyosarcoma as, 933

Testicular appendage torsion, in acute scrotum, 3792
Testicular artery, 74, 75f, 581, 582-583, 583f
injury to, varicocelectomy and, 665
Testicular cancer, 93, 893-934
adenocarcinoma in, 929, 932t
cryptorchidism associated with, 3772-3773
germ cell tumors in, 893-925. *See also* Germ cell tumor(s), testicular.
gonadoblastoma as, 926t, 928-929. *See also* Gonadoblastoma(s).
in AIDS patients, 399-400
leukemic infiltration in, 930-931
lymphoma in, 930, 932t
mesenchymal origin of, 929
metastatic, 931
sex cord–mesenchymal tumors in, 925-928, 926t
surgery for, 936-957. *See also specific procedure.*
teratoma as, 895. *See also* Teratoma(s).
Testicular cystic dysplasia, in children, 3905
Testicular dysfunction, pathology of, 3794-3795
Testicular failure, primary, micropenis due to, 3753
Testicular hormone replacement, 569, 569f
Testicular microlithiasis, in children, 3905
Testicular pain
patient history of, 83
post-hernia repair, 1108
Testicular regression, embryonic, 3814-3815
Testicular torsion, 93
cryptorchidism and, 3773
infertility with, 641
intermittent, orchidopexy for, 1107
Testicular tumor(s)
adenomatoid, 930
adrenal rest tumors as, 929-930
carcinoids as, 930
epidermoid cysts as, 929
in children, 3900-3905. *See also specific tumor.*
classification of, 3900t
diagnosis of, 3902
etiology of, 3900-3901
evaluation of, 3199
genetics of, 3900
pathology of, 3901-3902
staging of, 3902, 3903t
malignant. *See* Testicular cancer; *specific neoplasm.*
surgery for, 936-957. *See also specific procedure.*
Testicular vein, 74, 75f, 583-584, 583f
thrombophlebitis of, ureteral obstruction due to, 1223
tortuosity and dilation of. *See* Varicocele.
Testis(es), 73-74, 74f, 75f, 77
absent (vanishing), 3765
laparoscopic assessment of, 3783-3784
androgen production by, 2685-2686, 2686t, 2687f
atrophy of, 621-622
mumps-associated, germ cell tumors due to, 901
biopsy of, 633-634, 633f
complications of, 658
indications for, 655
open, 655-657, 656f, 657f
sperm retrieval through, 701
percutaneous, 657, 657f
blood barrier of, 589-591, 590f, 591f
blood supply to, 1099t
cancer of. *See* Testicular cancer; *specific neoplasm.*

in children
after open, laparoscopic, and endoscopic procedures, 3937
operative management of, 3937-3938
in laparoscopy, 214-215
management of, 1286-1291, 1286f
algorithm in, 1290f-1291f
for external ureteral trauma, 1286, 1286f, 1287f
for lower ureteral trauma, 1288
for mid-ureteral trauma, 1288
for upper ureteral trauma, 1287, 1287f
surgical
delayed recognition in, 1289
immediate recognition in, 1288-1289
perforation as. *See* Ureter(s), perforation of.
posterior urethral valves causing, 3586
ureteroscopic, management of, 1289, 1291
vesicovaginal fistula repair causing, 2336
Ureteral neocystostomy, in endoscopic cross-trigonal reimplantation, 4367
Ureteral obstruction. *See also* Hydronephrosis; Ureteropelvic junction obstruction.
after partial nephrectomy, 1730
antegrade pyelography in, 1210
assessment of
general, 1910-1913, 1910f-1913f
physiologic methodologies in, 1913-1914, 1914f
bilateral
atrial natriuretic peptide in, 1201
hemodynamic changes with, 1198, 1199f
hypertension with, 1211-1212, 1212t
potassium transport and, 1202
sodium transport in, 1201-1202
tubular function changes in, 1200
urinary concentrating ability after, 1200-1201
diagnosis of, 1208-1211
antegrade pyelography in, 1210
computed tomography in, 1211
excretory urography in, 1209-1210
magnetic resonance imaging in, 1211
nuclear renography in, 1210-1211
retrograde pyelography in, 1210
ultrasonography in, 1209
Whitaker test in, 1210
effect of
on anion and cation transport, 1202-1203
on peptide and protein excretion, 1203
extrinsic cause(s) of, 1215-1225
abdominal aortic aneurysm as, 1221, 1222f
benign pelvic anomalies as, 1220-1221
circumcaval ureter as, 1223-1225, 1224f, 1225f, 1226f
endometriosis as, 1220-1221
iliac artery aneurysm as, 1222-1223, 1222f
ovarian lesions as, 1221
ovarian remnants as, 1221
pelvic lipomatosis as, 1218-1219, 1218f, 1219f
pregnancy as, 1219-1220, 1220t
puerperal ovarian vein thrombophlebitis as, 1223
retroperitoneal fibrosis as, 1215-1218, 1215t, 1216f, 1217f
testicular vein thrombophlebitis as, 1223
tubo-ovarian abscess as, 1220
Ureteral obstruction *(Continued)*
uterine lesions as, 1221
vascular, 1221-1225
vascular graft placement as, 1223
fetal, 1913
hydrogen ion transport and, 1202
management of, 1208-1214
diagnostic imaging in, 1208-1211
hypertension in, 1211-1212, 1212t
pain, 1213
postobstructive diuresis in, 1213-1214
renal drainage in, 1212
surgical intervention in, 1212-1213
partial, 1198-1200
pathologic changes in, 1207-1208, 1208f, 1209f
perfusion studies of, 1913-1914, 1914f
renal recovery after, 1207
resection causing, 2483
tissue inhibitors of metalloproteinase in, 1204
tumor necrosis factor-α in, 1204
unilateral
functional response to, 3160
hemodynamic changes with, 1196-1198, 1197f
in neonate, 3161
potassium transport and, 1202
sodium transport in, 1201-1202
transforming growth factor-β in, 1204
tubular function changes in, 1200
urinary acidification deficit in, 1202
Ureteral stent
after ureteroscopic stone manipulation, in children, 3908
for contusions, 1286-1287
for reimplanted ureters, in exstrophy patient, 3526
for ureteral obstruction, 1212
for ureteral stricture, 1255
placement of, before shockwave lithotripsy, 1501-1502
Ureteral stricture, 1255-1267, 1503, 3409-3410
balloon dilatation for
antegrade approach to, 1256
results of, 1256-1257
retrograde approach to, 1255-1256, 1257f
diagnostic studies of, 1255
endoureterotomy for, 1257-1259
antegrade approach to, 1258
cautery wire balloon incision in, 1257-1258
combined approaches to, 1259
retrograde approach to, 1257, 1257f
etiology of, 1255, 1255t
from stone impaction, 1503
in tuberculosis, surgical management of, 446
intervention for
indications for, 1255
options for, 1255-1259
surgical repair of, 1259-1267, 1259t
autotransplantation in, 1267
Boari flap in, 1262, 1264, 1264f
laparoscopic, 1264
ileal ureteral substitution in, 1266, 1267f
laparoscopic, 1266-1267
intubated ureterotomy in, 1264
psoas hitch in, 1261, 1262f, 1263f
laparoscopic, 1261
renal descensus in, 1264
transureteroureterostomy in, 1264-1266
ureteroneocystostomy in, 1261
laparoscopic, 1261
ureteroureterostomy in, 1259-1261, 1260f
laparoscopic, 1261

Ureteral stricture *(Continued)*
ureteral stent placement for, 1255
ureteroscopic management of, 1521-1522
ureteroscopy causing, 1524
Ureteral valves, 3410-3411, 3410f, 3411f
Ureterectomy
distal, 1658-1662
intussusception technique of, 1659, 1662f
laparoscopic ligation and detachment technique of, 1662, 1663f
total laparoscopic, 1662, 1664f
traditional open, 1659, 1660f, 1661f
transurethral ureteral orifice resection in, 1659, 1661f
with bladder cuff excision, 1666
open segmental, 1667-1672
subtotal, 1671-1672, 1672t
ureteroneocystostomy with Boari flap in
indications for, 1667
technique of, 1667-1668, 1669f-1671f, 1671
ureteroureterostomy in, 1667, 1668f
segmental, 1649
results of, 1649, 1649t
Ureteric bud, 3384-3387, 3385f-3387f
dichotomous branching of, 3126, 3127f, 3129-3130
division of, 3124-3125, 3125f
interaction of metanephric mesenchyme with, 3125, 3125f
outgrowth of, toward metanephric mesenchyme, 3127, 3129, 3129f
Ureteritis, tuberculous, 438
Ureterocalycostomy, for ureteropelvic junction obstruction, 1247-1249, 1248f, 1253
Ureterocele, 3312, 3397-3412
classification of, 3384
diagnosis of, 3397-3401
ectopic
dilated, 3399
prolapse of, 3194
embryology of, 3397
intravenous pyelography of, 3399-3400, 3399f
intravesical, 3384, 3385f
definition of, 3384
single-system, 3384, 3385f
prenatal diagnosis of, 3181-3182, 3182f
prolapsed, 3398, 3398f, 3409, 3845, 3845f
simple, definition of, 3383
single-system, 3408-3409, 3409f
sphincteric, 3383, 3384f
definition of, 3383
terminology for, 3383-3384
treatment of, 3402-3404, 3406-3408
cystoscopic incision in, 3407-3408, 3407f, 3408f
endoscopic, 3406
excision in, 3404, 3405f, 3406
ultrasonography of, 3398-3399, 3399f
voiding cystourethrography of, 3400-3401, 3401f, 3402f
Ureteroenteric fistula, 2353
Ureteroenteric stricture, anastomotic
etiology of, 1267-1268
evaluation of, 1268
incidence of, 1267
percutaneous treatment of, 1557
radical cystectomy and, 2472
surgical management of, 1269-1270
indications for, 1268-1269
Ureterography, of ureteral injury, 1276
Ureterointestinal anastomosis, 2554-2563
antireflux valves in, 2561-2562, 2561f, 2562f
complications of, 2556t, 2562-2563
ureterocolonic
complications of, 2556t
Cordonnier and Nesbit technique of, 2557
Leadbetter and Clarke technique of, 2555-2556, 2556f
Pagano technique of, 2557, 2557f
Strickler technique of, 2556-2557, 2556f
transcolonic Goodwin technique of, 2556, 2556f
Ureterolithotomy, laparoscopic, 1776, 1778
for ureteral calculi, 1455
Ureterolysis, for retroperitoneal fibrosis, 1217-1218, 1272-1273, 1273f
laparoscopic, 1273
Ureteroneocystostomy
antireflux, in renal transplantation, 1310, 1313f-1314f
for lower ureteral injuries, 1288
for ureteral stricture, 1261
laparoscopic, 1261
laparoscopic
extravesical, 2506, 2507f
intravesical, 2506, 2508f
results of, 2506-2507
with psoas hitch or Boari flap
indications for, 1667
technique of, 1667-1668, 1669f-1671f, 1671
Ureteronephrectomy, proximal, laparoscopic, 1665-1666, 1666f
Ureteropelvic junction
disruption of, trauma-induced, 1283, 1283f
in children, 3936
kinking at, 3361, 3361f
physiology of, 1907, 1908f
Ureteropelvic junction obstruction, 1227-1253
acquired, 1228
cautery wire balloon endopyelotomy for
complications of, 1238-1239
indications for and contraindications to, 1237, 1237f
postoperative care following, 1237
results of, 1237-1238
technique of, 1237, 1238f
congenital, 1227. *See also* Urinary tract obstruction, congenital.
progressive renal dysfunction in, 3164, 3164f
diagnosis of, 1228-1231
computed tomography in, 1229, 1230f
radiographic studies in, 1228, 1229f, 1230f
radionuclide renography in, 1229-1230, 1231f
ultrasonography in, 1228-1229
etiology of, aberrant vessels in, 1228
in children, 3359-3382
associated anomalies in, 3362, 3363f
biochemical parameters in, 3369-3370
diagnosis of, 3363-3370
etiology of, 3359-3362
evidence of, 3359
extrinsic narrowing contributing to, 3361, 3361f
intrinsic narrowing contributing to, 3360, 3360f, 3361f
lower pole, 3361-3362, 3362f
magnetic resonance imaging of, 3367-3368, 3368f, 3369f
presentation of, 3362-3363, 3364f
pressure flow studies of, 3368-3369
radionuclide renography of, 3365-3367, 3366f-3367f
Ureteropelvic junction obstruction *(Continued)*
secondary, 3361, 3362f
surgical repair of, 3370-3380, 3370f-3372f
Davis intubated ureterotomy in, 3370, 3371f
dismembered pyeloplasty in, 3370, 3372f, 3373
Anderson-Hynes modified, 3373-3374, 3373f, 3374f
endoscopic approaches to, 3374-3375, 3375f
flank approach to, 3374
Foley Y-V plasty in, 3370, 3370f
laparoscopic pyeloplasty in, 3375-3376, 3376f
minimally invasive techniques in, 3374-3376
outcome of, 3380, 3380t, 3381f
posterior lumbotomy in, 3374
retroperitoneal access in, 3376-3378
laparoscopic retroperitoneal pyeloplasty in, 3377-3378, 3378f, 3379f
lateral approach to, 3376-3377, 3376f, 3377f
prone posterior approach to, 3377
transperitoneal approach to, 3377, 3378f
special situations in, 3378, 3380
spiral flap technique in, 3370, 3371f
traction sutures in, 3372f, 3377, 3378f
vertical flap technique in, 3370, 3372f
ultrasonography, 3364-3365
in multicystic dysplastic kidney, 3335
intervention in
endourologic, 1232-1241
indications for, 1231-1232
laparoscopic, 1249-1253
open operative, 1241-1249
options for, 1232-1253
intubated ureterotomy for, 1245, 1247, 1247f
laparoscopic calicovesicostomy for, 1253
laparoscopic dismembered tubularized flap pyeloplasty for, 1253
laparoscopic pyeloplasty for, 1249-1252
anterior extraperitoneal approach to, 1250
complications of, 1252, 1252f
indications for and contraindications to, 1249-1250
postoperative care following, 1250, 1252
results of, 1252
robotic-assisted approach to, 1250
transperitoneal approach to, 1250, 1251f
with concomitant pyelolithotomy, 1253
laparoscopic ureterocalicostomy for, 1253
pathogenesis of, 1227-1228
percutaneous antegrade endopyelotomy for, 1233-1237
complications of, 1236-1237
indications for and contraindications to, 1233, 1233f
patient preparation in, 1233
postoperative care following, 1234, 1236
results of, 1236
simultaneous nephrolithotomy with, 1234
technique of, 1233-1234, 1235f, 1236f
prenatal diagnosis of, 3180
presentation of, 1228
pyeloplasty for
Culp-DeWeerd spiral flap technique of, 1245, 1246f
dismembered, 1242-1243, 1243f, 1244f
flap procedures in, 1243-1245, 1245f

Ureteropelvic junction obstruction *(Continued)*
Foley YV-plasty technique of, 1243-1245, 1245f
historical aspects of, 1242
laparoscopic, 1249-1253, 1251f, 1252f
Scardino-Prince vertical flap technique of, 1245, 1246f
surgical principles of, 1241-1242
salvage procedures for, 1249
secondary, 1232
stone formation in, 1389-1390
surgical management of, 1442
ureterocalycostomy for, 1247-1249, 1248f
ureteroscopic endopyelotomy for
complications of, 1241
indications for and contraindications to, 1239
results of, 1241
technique of, 1239, 1240f, 1241
ureteroscopic management of, 1522
vesicoureteral reflux and, 3361, 3362, 3362f, 4341, 4342f
Ureteroplasty, in children, 3687-3688, 3688f
Ureteropyeloscopy, 1672-1677
results of, 1675, 1677
steps in, 1674-1675, 1676f, 1677f
technique and instrumentation in, 1673-1674, 1674f
Ureteroscope(s)
damage caused by, 1524-1525
flexible, 1433, 1509, 1511t
characteristics of, 1509t
insertion of, 1516, 1516t
rigid, 1433
insertion of, 1516
semirigid, 1433, 1508-1509, 1511t
Ureteroscopic endopyelotomy. *See* Endopyelotomy, ureteroscopic.
Ureteroscopy, 1672-1677
anesthesia for, 1501
antibiotic prophylaxis for, 253
complications of, 1284, 1523t, 1524
in children, 1520, 3907-3909
access in, 3908

Vitamin(s), in prevention of bladder cancer, 2442
Vitamin A
in prevention of bladder cancer, 2442, 2467
role of, in prostatic function, 2705
Vitamin B_6, in prevention of bladder cancer, 2442, 2467
Vitamin B_{12} deficiency
after augmentation cystoplasty, 3680
due to conduit urinary diversion, 2575
Vitamin D
active form of, in calcium absorption, 1371-1372
activity of, 1137
effect of, on calcium homeostasis, 1136, 1136f
for metastatic prostate cancer, 3114
in prostate cancer, epidemiologic studies of, 2861-2862
regulation of, 1136-1137
role of, in prostatic function, 2705
Vitamin D analogues, for hormone-refractory prostate cancer, 3116
Vitamin D receptors
in hypercalciuria, 1374
in prostate cancer, epidemiologic studies of, 2861-2862
Vitamin E
for painful bladder syndrome/interstitial cystitis, 360t, 361
for Peyronie's disease, 827
for prostate cancer, chemopreventive, 2870-2871
in prevention of bladder cancer, 2442
Vitamin E with selenium, for prostate cancer, chemopreventive, 2871
Vitiligo, of male genitalia, 433, 435
Void, urge to, vs. urgency, 2082
Voided volume, 3606-3607
Voiding. *See also* Micturition.
absence of, in neonate, 3196
active phase of, 3657
detrusor pressure at, 3607, 3607f
dysfunctional, 3612. *See also* Voiding dysfunction.
during active bladder phase, 3659
fractionated, 3612
frequency of, 3606, 3606f
